To a solution of $LiAlH_4$ (51.2 mg, 1.5 equiv.) in dry THF (10 mL) at 0°C, under an atmosphere of argon, was added dropwise a solution of lactone **26** (302.1 mg, 0.85 mmol) in dry THF (15 mL). The temperature was next raised to 50°C, this being maintained for an additional 1.5 h. After cooling to r.t., the solution was neutralized with saturated $NH_4Cl_{(aq)}$ and extracted with $CHCl_3$ (3 × 10 mL). The organic solubles were combined, dried (Na_2SO_4), evaporated to dryness in vacuo, and the resulting residue purified by chromatography on silica gel, eluted sequentially with hexanes:EtOAc 2:1 (v/v) and EtOAc, to give the diastereoisomeric triol **27** (258 mg, 89%) mixture, which was not resolved further. IR ($CHCl_3$) ν_{max}: 3310 (br, OH), 1640 (C=C), 1606, 1593, 1510, 1455 (C=C, C=CAr), 1261, 1219 (C-O) cm^{-1}; ^1H NMR δ: 7.35–7.20 (m, 5H, Bn), 6.90–6.80 and 6.80–6.70 (m, 3H, C*H*Ar), 5.90–5.50 (m, 1H, =C*H*), 5.20–5.00 (m, 2H, =CH_2), 5.07 (s, 1H) and 5.06 (s, 1H, CH_2-Ph), 5.00–4.70 (m, 1H, C*H*OH), 3.81 (s, 3H, OCH_3), 3.80–3.30 (m, 4H, CH_2OH), 2.60–2.20 (m, 1H, C*H*-CHOH), 2.10–1.60 (m, 1H, =CH-C*H*); ^{13}C NMR δ: 149.29, 149.20 (C-4), 146.99, 146.90 (C-3), 138.52, 138.40 (*C*H=), 136.86, 136.05 (C-1, *C*q/Bn), 128.32, 127.67, 127.15 (*C*H/Bn), 118.40, 117.95 (C-6), 117.24, 116.30 (*C*H$_2$=), 113.59, 113.46 (C-5), 109.87, 109.49 (C-2), 74.55, 72.16 (*C*HOH), 70.82 (*C*H$_2$-Ph), 63.06, 62.50, 59.96, 59.53 (2 × *C*H$_2$OH), 55.77 (O*C*H$_3$), 50.06, 48.07 (=CH-*C*H), 44.87, 43.05 (*C*H-CHOH); MS *m/e* (relative %): 340 ($M^+ - H_2O^+$, 19), 322 (100), 291 (19), 275 (34), 231 (85), 201 (81), 167 (87), 149 (79), 128 (81); HRMS, calcd. for $C_{21}H_{26}O_5$: 340.1675 ($M - H_2O^+$); found: 340.1686.

Tetrahydrofuran 28

To a solution of the diastereoisomeric triol mixture **27** (189 mg, 0.55 mmol) in dry CH_2Cl_2 (5 mL) was added TMSBr (140 μL, 2 equiv.). The resulting solution was then stirred at r.t. for 15 min, neutralized with saturated $NaHCO_{3(aq)}$ (0.5 mL), dried (Na_2SO_4), with the organic solvent evaporated in vacuo and the residue subjected to silica gel column chromatography, eluted with hexanes:EtOAc 2:1 (v/v), to give tetrahydrofuran **28** (159.3 mg, 89%). IR ($CHCl_3$) ν_{max}: 3300 (br, OH), 1640 (C=C), 1606, 1594, 1515, 1465 (C=CAr), 1263, 1225 (C-O) cm^{-1}; ^1H NMR δ: 7.45–7.30 (m, 5H, Bn), 6.93 (d, 1H, J = 1.7, C*H*Ar), 6.84–6.78 (m, 1H, C*H*Ar), 5.97–5.90 (m, 1H, =C*H*), 5.22–5.14 (m, 2H, =CH_2), 5.16 (s, 2H, CH_2-Ph), 4.70 (d, 1H, J = 7.3, ArC*H*O), 4.23 and 3.83 (dd, 2H, J = 6.7, 8.6, CH_2OC), 3.90 (s, 3H, OCH_3), 3.75–3.69 (m, 1H) and 3.64–3.60 (m, 1H, CH_2OH), 3.15–3.05 (m, 1H, =CH-C*H*), 2.40–2.30 (m, 1H, C*H*-CH$_2$OH); ^{13}C NMR δ: 149.63 (C-4), 147.49 (C-3), 137.07 (*C*q/Bn), 135.57 (*C*H=), 135.38 (C-1), 128.44, 127.73, 127.19 (*C*H/Bn), 118.10 (C-6), 117.32 (*C*H$_2$=), 113.72 (C-5), 109.47 (C-2), 82.41 (C-7), 72.61 (C-9′), 70.94 (*C*H$_2$-Ph), 60.76 (C-9), 55.90 (O*C*H$_3$), 53.41 (C-8), 45.62 (C-8′); MS *m/e* (relative %): 322 ($M - H_2O^+$, 100), 293 (10), 268 (5), 231 (95), 201 (73), 171 (55), 149 (63), 123 (Ar_1^+, 65); HRMS, calcd. for $C_{21}H_{24}O_4$ ($M - H_2O^+$): 322.1569; found: 322.1558.

Triol 29

To a solution of tetrahydrofuran **28** (144 mg, 0.45 mmol) in THF (3 mL) was added OsO_4 (2.5% equiv., 108 μL of a 2.5% soln. in *t*-BuOH) and *N*-methylmorpholine-*N*-oxide (NMO) (1.4 equiv., 124 μL of a 60% soln. in H_2O). The suspension was stirred for 2 days at r.t., following which it was extracted with $CHCl_3$ (3 × 10 mL). The organic solubles were combined, dried (Na_2SO_4), the solvent removed in vacuo, and the resulting residue chromatographed on silica gel, eluted with hexanes:EtOAc 2:1 (v/v), to give the triol **29** (132.1 mg, 79%). IR ($CHCl_3$) ν_{max}: 3390 (br, OH), 1607, 1594, 1515, 1455 (C=CAr), 1263, 1217 (C-O) cm^{-1}; ^1H NMR δ: 7.40–7.20 (m, 5H, Bn), 6.90–6.70 (m, 3H, C*H*Ar), 5.14 (s, 2H, CH_2-Ph), 4.79 (d, J = 6.4) and 4.51 (d, J = 3.8, 1H, OC*H*-Ar), 4.10–3.90 (m, 1H, C*H*OH-CH$_2$OH), 3.90–3.30 (m, 6H, CH_2OH and CH_2O), 3.83 (s, 3H, OCH_3), 2.60–2.30 (m, 1H, C*H*CHOH), 2.60–2.35 and 2.30–2.20 (m, 1H, C*H*CH$_2$OH); ^{13}C NMR δ: 149.51 (C-4), 147.47 (C-3), 136.84 (*C*q/Bn), 135.07, 134.98 (C-1), 128.38, 127.73, 127.20 (*C*H/Bn), 117.96, 117.81 (C-6), 113.62 (C-5), 109.41 (C-2), 82.81, 82.11 (C-7), 70.87 (*C*H$_2$-Ph), 70.46, 70.35 (*C*HOH), 68.93, 68.25 (C-7′) 65.71, 65.39 (*C*H$_2$OH), 60.67, 59.53 (C-9), 55.91 (O*C*H$_3$), 51.15, 50.74 (C-8), 43.86, 42.54 (C-8′); MS *m/e* (relative %): 374 (M^+, 83), 356 (80), 338 (50), 295 (50), 283 (20), 265 (90), 175 (78), 151 (Ar_1CO^+, 80), 123 (Ar_1^+, 100), 107 (90); HRMS, calcd. for $C_{21}H_{26}O_6$: 374.1726; found: 374.1741.

Furanofuran-1-ol 24

To a solution of triol **29** (125.1 mg, 0.334 mmol) in MeOH (3 mL) at 0°C was added dropwise a solution of $NaIO_4$ (85.7 mg, 1.2 equiv.) in MeOH–H_2O (6.5 mL, 10:3) over 10 min. The

temperature was raised to r.t., with the mixture allowed to stir for an additional 12 h, and then filtered. The resulting filtrate was extracted with $CHCl_3$ (3 × 10 mL) with the organic layers combined and dried (Na_2SO_4), and the solution evaporated to dryness in vacuo. The residue was subjected to chromatography on silica gel, eluted with hexanes:EtOAc 2:1 (v/v), to give the furanofuranol **24** (101.8 mg, 89%). IR ($CHCl_3$) ν_{max}: 3410 (br, OH), 1594, 1515, 1455 (C═CAr) cm^{-1}; ^1H NMR δ: 7.45–7.20 (m, 5H, Bn), 6.95 (d, 1H, $J_{2,6}$ = 1.7, H-2), 6.75–6.65 (m, 2H, H-5, H-6), 5.16 (s, 2H, CH_2-Ph), 5.35 (s, 1H, H-7′), 4.38 (d, 1H, $J_{7,8}$ = 7.1, H-7), 4.39 (dd, 1H, $J_{9ax,9eq}$ = 7, $J_{8,9ax}$ = 8.9, H-9ax), 4.25-4.10 (m, 1H, H-9′ax), 3.95–3.85 (m, 1H, H-9′eq), 3.56 (dd, 1H, $J_{9ax,9eq}$ = 7, $J_{8,9eq}$ = 9.1, H-9 eq), 3.91 (s, 3H, OCH_3), 3.76 (br s, 1H, O*H*), 3.11–2.87 (m, 2H, H-8, H-8′), ^{13}C NMR δ: 149.78 (C-3), 147.82 (C-4), 136.99 (*C*q/Bn), 133.51 (C-1), 128.47, 127.78, 127.20 (*C*H/Bn), 118.47 (C-6), 113.69 (C-5), 109.61 (C-2), 102.02 (C-7′), 85.79 (C-7), 71.21 (C-9), 70.93 (*C*H_2Ph), 69.13 (C-9′), 55.95 (OCH_3), 53.51 (C-8′), 52.52 (C-8); MS *m/e* (relative %): 342 (M^+, 20), 251 (10), 223 (10), 193 (5), 151 (Ar_1CO^+, 6), 137 ($Ar_1CH_2^+$, 5), 123 (Ar_1^+, 5), 91 (100); HRMS, calcd. for $C_{20}H_{22}O_5$: 342.1467; found: 342.1475.

Furolactone 30

To a solution of **24** (34.41 mg, 0.1 mmol) in dry CH_2Cl_2 (5 mL) was added pyridinium dichromate (PDC) (4 equiv., 151.4 mg), AcOH (1 equiv., 5.76 μL), and 4Å molecular sieves (150 mg). Following stirring for 6 h at r.t., the suspension was filtered through a short-path silica gel plug and the filtrate removed in vacuo to give a residue that was then subjected to silica gel column chromatography, eluted with hexanes:EtOAc 2:1 (v/v), to give **30** (26.7 mg, 78%); mp 114–115°C; IR ($CHCl_3$) ν_{max}: 1772 (C═O), 1594, 1516, 1456 (C═CAr), 1244 (C-O) cm^{-1}; ^1H NMR δ: 7.45–7.25 (m, 5H, Bn), 6.93 (d, 1H, *J* = 1.8, H-2), 6.87 (d, 1H, $J_{5,6}$ = 8.2, H-5), 6.79 (dd, 1H, $J_{2,6}$ = 1.8, $J_{5,6}$ = 8.2, H-6), 5.17 (s, 2H, Ar-CH_2), 4.62 (d, 1H, $J_{7,8}$ = 6.7, H-7), 4.50 (dd, 1H, $J_{9eq,8}$ = 9.8, $J_{9eq,9ax}$ = 6.8, H-9 eq), 4.40–4.30 (m, 2H, H-9ax and H-9′ax), 4.20 (dd, 1H, $J_{8',9'eq}$ = 9.2, $J_{9'eq,9'ax}$ = 3.8, H-9′ eq), 3.92 (s, 3H, OCH_3), 3.45 (ddd, 1H, $J_{8',9'ax}$ = 9.2, $J_{8',8}$ = 9.2, $J_{8',9'eq}$ = 3.8, H-8′), 3.15–3.10 (m, 1H, H-8); ^{13}C NMR δ: 178.13 (C-7′), 149.94 (C-4), 148.17 (C-5), 136.81 (*C*q/Bn), 131.81 (C-1), 128.49, 127.82, 127.13 (*C*H/Bn), 118.29 (C-6), 113.70 (C-5), 109.43 (C-2), 85.89 (C-7), 70.89 (*C*H_2Ph), 69.93 and 69.77 (C-9 and C-9′), 55.98 (OCH_3), 48.03 (C-8′), 45.92 (C-8); MS *m/e* (relative %): 340 (M^+, 100), 250 (20), 221 (45), 149 (48); HRMS, calcd. for $C_{20}H_{20}O_5$: 340.1311; found: 340.1319.

(±)-Salicifoliol 31

To a solution of **30** (26.7 mg, 0.078 mmol) in EtOAc (5 mL) was added Pd/C 10% (15 mg). The suspension was then stirred under an H_2 atmosphere, as described for epi-(+)-sesamolinol **15**, with salicifoliol **31** purified by silica gel column chromatography, eluted with hexanes:EtOAc (2:1 → 1:1 (v/v)), to give **31** (17.66 mg, 90%); mp 101–102°C (lit. (39) mp 102–103°C); IR ($CHCl_3$) ν_{max}: 3417 (br, OH), 1768 (C═O), 1605, 1519, 1466 (C═CAr), 1241 (C-O) cm^{-1}; UV λ_{max}: 234, 278 nm; ^1H NMR δ: 6.93 (d, 1H, *J* = 6.9, H-5), 6.89 (d, 1H, *J* = 1.6, H-2), 6.80 (dd, 1H, $J_{2,6}$ = 1.6, $J_{5,6}$ = 8, H-6), 5.74 (s, 1H, OH), 4.61 (d, 1H, $J_{7,8}$ = 6.9, H-7), 4.51 (dd, 1H, $J_{9eq,8}$ = 9.8, $J_{9eq,9ax}$ = 6.8, H-9ax), 4.40–4.30 (m, 1H, H-9eq and H-9′ax), 4.19 (dd, 1H, $J_{8',9'eq}$ = 9.2, $J_{9'eq,9'ax}$ = 3.8, H-9′ eq), 3.90 (s, 3H, OCH_3), 3.43 (ddd, $J_{8',9'eq}$ = 9.2, $J_{8',8}$ = 9.2, $J_{8',9'ax}$ = 3.8, 1H, H-8′), 3.18–3.08 (m, 1H, H-8); ^{13}C NMR δ: 178.32 (C-7′), 146.98 (C-3), 145.88 (C-4), 130.63 (C-1), 119.15 (C-6), 114.47 (C-5), 105.51 (C-2), 86.13 (C-7), 70.01 and 69.91 (C-9/C-9′), 56.02 (OCH_3), 48.21 (H-8), 45.99 (H-8′); MS *m/e* (relative %): 250 (M^+, 100), 233 (10), 219 (15), 205 ($Ar_1C_5H_6O^+$, 10), 165 (50), 152 (Ar_1CHO^+, 90), 151 (Ar_1CO^+, 100), 137 ($Ar_1CH_2^+$, 95), 123 (Ar_1^+, 50), 109 (75); HRMS, calcd. for $C_{14}H_{14}O_5$: 250.0841; found: 250.0843.

Furofuran 32

To a solution of lactol **24** (101.1 mg, 0.3 mmol) in dry THF (30 mL), PPh_3 (79 mg, 0.3 mmol), and 4-benzyloxy-3-methoxyphenol **22** (65.4 mg, 0.3 mmol) was added diethylazodicarboxylate (DEAD) (47.5 μL, 1 equiv.), and the mixture was allowed to stir at r.t. for an additional 24 h. The solvent was then removed in vacuo and the residue subjected to silica gel column chromatography, eluted with hexanes:EtOAc (3:1 → 2:1 (v/v)), to give the furofuran lignan **32** (147.9 mg, 89%). IR ($CHCl_3$) ν_{max}: 1597, 1510, 1455 (C═CAr) cm^{-1}; ^1H NMR δ: 7.43–7.25 (m, 10H, Bn), 6.95 (d, 1H, $J_{2,6}$ = 1.5 , H-2), 6.85–6.70 (m, 2H, C*H*Ar), 6.70 (d, 1H, $J_{2',6'}$ = 2.7, H-2′), 6.60 (dd, 1H, *J* = 2.7, H-6′), 5.59 (d, 1H, *J* = 5.6, H-7′), 5.13 (s, 2H, CH_2Ph), 5.08 (s, 2H, CH_2Ph), 4.78 (d, 1H, $J_{7',8'}$ = 6.9, H-7), 4.38 (dd, 1H, $J_{9'ax,8'}$ = 9.1, $J_{9'eq,9'ax}$ = 4.7, H-9′ax), 4.20–4.00 (m, 2H, H-9′eq and H-9ax), 3.95 (dd, $J_{8,9eq}$ = 9.1, $J_{9eq,9ax}$ = 4.7, H-9eq), 3.89 (s, 3H, OCH_3), 3.86 (s, 3H, OCH_3), 3.35-3.20 (m, 1H, H-8′), 3.04 (m, 1H, H-8); ^{13}C NMR δ: 151.95 (C-1′), 150.53 (C-3′), 149.72 (C-3), 147.63 (C-4), 143.27 (C-4′), 137.31 (*C*q/Bn), 137.02 (*C*q/Bn), 133.92 (C-1), 128.47, 128.42, 127.71, 127.70, 127.35, 127.20 (*C*H/Bn), 118.17 (C-6), 115.53 (C-5), 113.80 (C-5′), 109.63 (C-6′), 107.06 (C-2), 102.63 (C-7′), 102.47 (C-2′), 85.21 (C-7), 71.82 (*C*H_2Ph), 70.96 (*C*H_2Ph), 69.38 (C-9), 67.04 (C-9′), 55.93 (OCH_3), 55.92 (OCH_3), 52.78 (C-8), 51.15 (C-8′); MS *m/e* (relative %): 554 (M^+, 5), 464 (3), 445 (2), 429 (2), 325 (10), 295 (30), 243 (50), 230 (100), 139 (75); HRMS, calcd. for $C_{34}H_{34}O_7$: 554.2304; found: 554.2318.

(±)-Epi-pinoresinolin 13

To a solution of the protected furolignan **32** (69.7 mg, 0.125 mmol) in EtOAc (5 mL) was added Pd/C 10% (20 mg). The solution was then stirred for 3 h under an H_2 atmosphere, as for epi-sesamolinol **15**, to give epi-pinoresinolin **13** (39.4 mg, 84%). IR ($CHCl_3$) ν_{max}: 3410 (br, OH), 1613, 1511, 1452 (C═CAr) cm^{-1}; ^1H and ^{13}C NMR spectra (see Table 1); MS *m/e* (relative %): 374 (M^+, 35), 275 (22), 235 (90), 205 ($Ar_1C_5H_6O^+$, 95), 137 ($Ar_1CH_2^+$, 100); HRMS, calcd. for $C_{20}H_{22}O_7$: 374.1366; found: 374.1387.

Furofuran 34

The furanofuranol **24** (17.7 mg, 0.05 mmol) was treated with sesamol **33** (7.01 mg, 0.05 mmol) as described above to give **34** (20.3 mg, 85%). Diversity in crystal production by some bird's nest fungi (Nidulariaceae) in culture

Tracy C. Shinners and Jalpa P. Tewari

Abstract: Hyphae of many species of bird's nest fungi (Nidulariaceae) were examined for the presence of crystals. Scanning electron microscopy revealed crystals typical of calcium oxalate associated with hyphae. Crystal depositions included complete hyphal encrustation, organized druses, randomly arranged groups, single crystals, and relatively "clean" hyphae. The majority of crystals could be morphologically classified as styloid, raphide, or bipyramidal type. Energy-dispersive X-ray microanalyses confirmed that all crystal types were rich in calcium, and X-ray diffraction identified both the dihydrate (weddellite) and monohydrate (whewellite) forms of calcium oxalate. Morphological variation of crystals was species and medium specific, with generally more crystals being produced on relatively calcium-rich V8 juice agar than on PDA. No association was found between crystal types and geographic and habitat distribution of species.

Key words: wood rotting fungus, decomposition, calcium oxalate.

Résumé : On a examiné les hyphes de plusieurs espèces de champignons (Nidulariacae) de nids d'oiseau afin d'évaluer la présence de cristaux. La microscopie électronique à balayage a révélé la présence de cristaux typiques d'oxalate de calcium associés aux hyphes. Les dépôts de cristaux comportent des incrustations complètes des hyphes, des maclages organisés, des groupes arrangés au hasard, des cristaux uniques et des hyphes relativement « propres ». D'un point de vue morphologique, la majorité des cristaux peut être classifiée sous les types styloïde, raphide ou bipyramidal. Les microanalyses de rayons X à dispersion d'énergie ont confirmé que tous les types de cristaux sont riches en calcium; la diffraction des rayons X a permis d'identifier les formes dihydratée (weddellite) et monohydratée (whewellite) de l'oxalate de calcium. Les variations morphologiques des cristaux sont spécifiques aux espèces et aux milieux; il y a généralement une plus grande production de cristaux sur le jus V-8, relativement riche en calcium, que sur le « PDA ». On n'a pas observé d'association entre les types de cristaux et la distribution géographique ou de l'habitat des espèces.

Mots clés : champignon du pourissement du bois, décomposition, oxalate de calcium.

[Traduit par la rédaction]

Introduction

The Nidulariaceae are an interesting group of fungi that have attracted much attention due to their beauty, morphology, and unique dispersal mechanisms. From a functional perspective, these fungi are ecologically important as white-wood rotters involved in the decomposition of numerous substrates worldwide. Some are coprophilous, but many are commonly found growing and fruiting on plant residues, twigs, or some type of plant fibre (Table 1) (1). These fungi are aggressive colonizers due to the formation of mycelial cords or rhizomorphs that invade the substrate and travel through the soil. In addition to these physical attributes, the Nidulariaceae are a chemically active group that produce many enzymes (2), an antibiotic complex (3–5), and other specific metabolites (6–8).

Based on these biochemical and plant residue-colonizing capabilities, research has been initiated to evaluate the potential role of some bird's nest fungi in accelerating biodegradation of crop residues, such as that of canola. Crop stubble serves as a habitat for microbes, and hence plays an important role in the epidemiology of many stubble-borne diseases. Research in this area may lead to the development of a microbial inoculant (biological control agent) to accelerate stubble decomposition, and hence reduce disease incidence.

Recently, calcium oxalate crystals have been found to be associated with hyphae of *Cyathus olla* and *C. striatus* (Nidulariaceae) (9). This crystal production is an indicator of oxalic acid biosynthesis and secretion by these fungi. During decomposition, oxalic acid secretion leads to the sequestration of calcium, mostly from the cell walls of the substrate, which subsequently combines with oxalic acid to form insoluble calcium oxalate crystals (10–12). Crystal-forming fungi are important ecosystem inhabitants as they are involved in calcium recycling, nutrient availability for plant growth, and soil genesis (13, 14). To date, other members of the Nidulariaceae have not been studied for crystal development.

Crystals have been described on the hyphae of many members of Basidiomycotina under a given set of conditions (10, 13, 15, 16). However, it is not known if crystal morphology

Received December 19, 1996.

This paper is dedicated to Professor William A. Ayer whose research has significantly contributed to understanding the chemical activities of this group of fungi.

Table 1. Geographic location and common substrates of some members of the Nidulariaceae.

Species	Location	Common substrate
Crucibulum laeve	Europe North America South America Japan Australia/ New Zealand (temperate zone species)	Stems, twigs, old nut shells, wood fruits, woodchips, manure Primarily lignicolous
Cyathus africanus	Tanzania	Unknown
Cyathus berkeleyanus	Widespread in tropics	Bamboo pots
Cyathus bulleri	Tropics	Unknown
Cyathus canna	Exclusively tropical (Jamaica, Costa Rica, Barbados, Mexico, Mauritius)	Unknown
Cyathus earlei	Tropical/sub-tropical (Cuba, Puerto Rico, Mexico, Hawaii)	Unknown
Cyathus julietae	Jamaica	Unknown
Cyathus olla	Europe North America South America South Africa Australia Not found in warm, moist tropics	Old wood, dead herbaceous plant stems Plant fibres/artifacts
Cyathus pallidus	American tropics West Indies Mexico South America China	Small chips and twigs Compost/mulch
Cyathus pygmaeus	United States	Old dead stems of shrubby plants of arid area Manure
Cyathus stercoreus	Worldwide	Coprophilous Manured soils
Cyathus striatus	Widespread in temperate areas	Small twigs, woody leaf mould Cereal residue Plant fibre/ artifacts
Nidula niveo-tomentosa	Western North America South America Japan New Zealand Jamaica	Associated with bracken fern

would vary if the conditions were changed. Cultures of these fungi are usually mycelial and fruiting can only be achieved in some cases under special conditions often requiring extended periods of time. It would be advantageous to develop diagnostic criteria for species identification using hyphal morphology.

Hyphae of many species of Nidulariaceae were examined in this investigation with the objective of answering the following questions: (*a*) Do the various species produce different types of crystals? (*b*) Is crystal morphology affected by growth media? (*c*) Do species from various geographical areas and habitats differ in crystal production?

Materials and methods

Fungal cultures were obtained from the University of Alberta Microfungus Collection, Edmonton, and the Canadian Collection of Fungal Cultures, Agriculture and Agri-Food Canada, Ottawa (Table 2). All cultures were subcultured on to V8 agar (V8 juice (Campbell Soup Co.) 200 mL, Difco Bacto-Agar 20 g, $CaCO_3$ 3 g, distilled H_2O to 1 litre) and Difco potato-dextrose agar (PDA) and maintained at room temperature (approx. 22°C) in the dark.

Agar blocks of both V8 and PDA media were excised approximately 1 cm from the original inoculation plug from

3-week-old cultures of *Nidula niveo-tomentosa, Crucibulum laeve, Cyathus olla, C. earlei, C. pygmaeus, C. canna, C. africanus, C. pallidus, C. julietae, C. stercoreus, C. striatus, C. berkeleyanus,* and *C. bulleri.* Each block was placed on a microscope coverslip (7 mm diameter) and secured with double-sided tape. All samples were vapor-fixed with 1% osmium tetroxide in water for 1 h, then air-dried for several days in a fume hood. Samples were mounted onto scanning electron microscope (SEM) stubs and secured with Marivac colloidal carbon paint. The specimens were sputter-coated with approx. 1 nm layer of gold and examined in a Jeol JSM 6301 FXV SEM operated at 5 kV. Energy-dispersive X-ray microanalyses were conducted using a Link eXL energy-dispersive X-ray system with a light element detector. All samples were examined in triplicate.

Crystals for X-ray diffraction analysis were collected by preparing a 10 mL hyphal suspension prepared from the agar plate. The suspension was filtered through four layers of cheesecloth and the filtrate spun at 1750*g* for 10 min at 20°C in a Sorvall GLC-1 table-top centrifuge. The supernatant was discarded and the pellet was resuspended in 5 mL of distilled water. Droplets of the solution were dried down on a quartz plate and examined using a Rigaku-Geigerflex vertical goniometer system with a graphite monochromator. The crystals were exposed to cobalt radiation ($CoK_{\alpha\ 1+2}$ = 1.79026Å) and compared to American Society for Materials (ASTM) X-ray standard file cards for weddellite (17-541) and whewellite (20-231).

Results

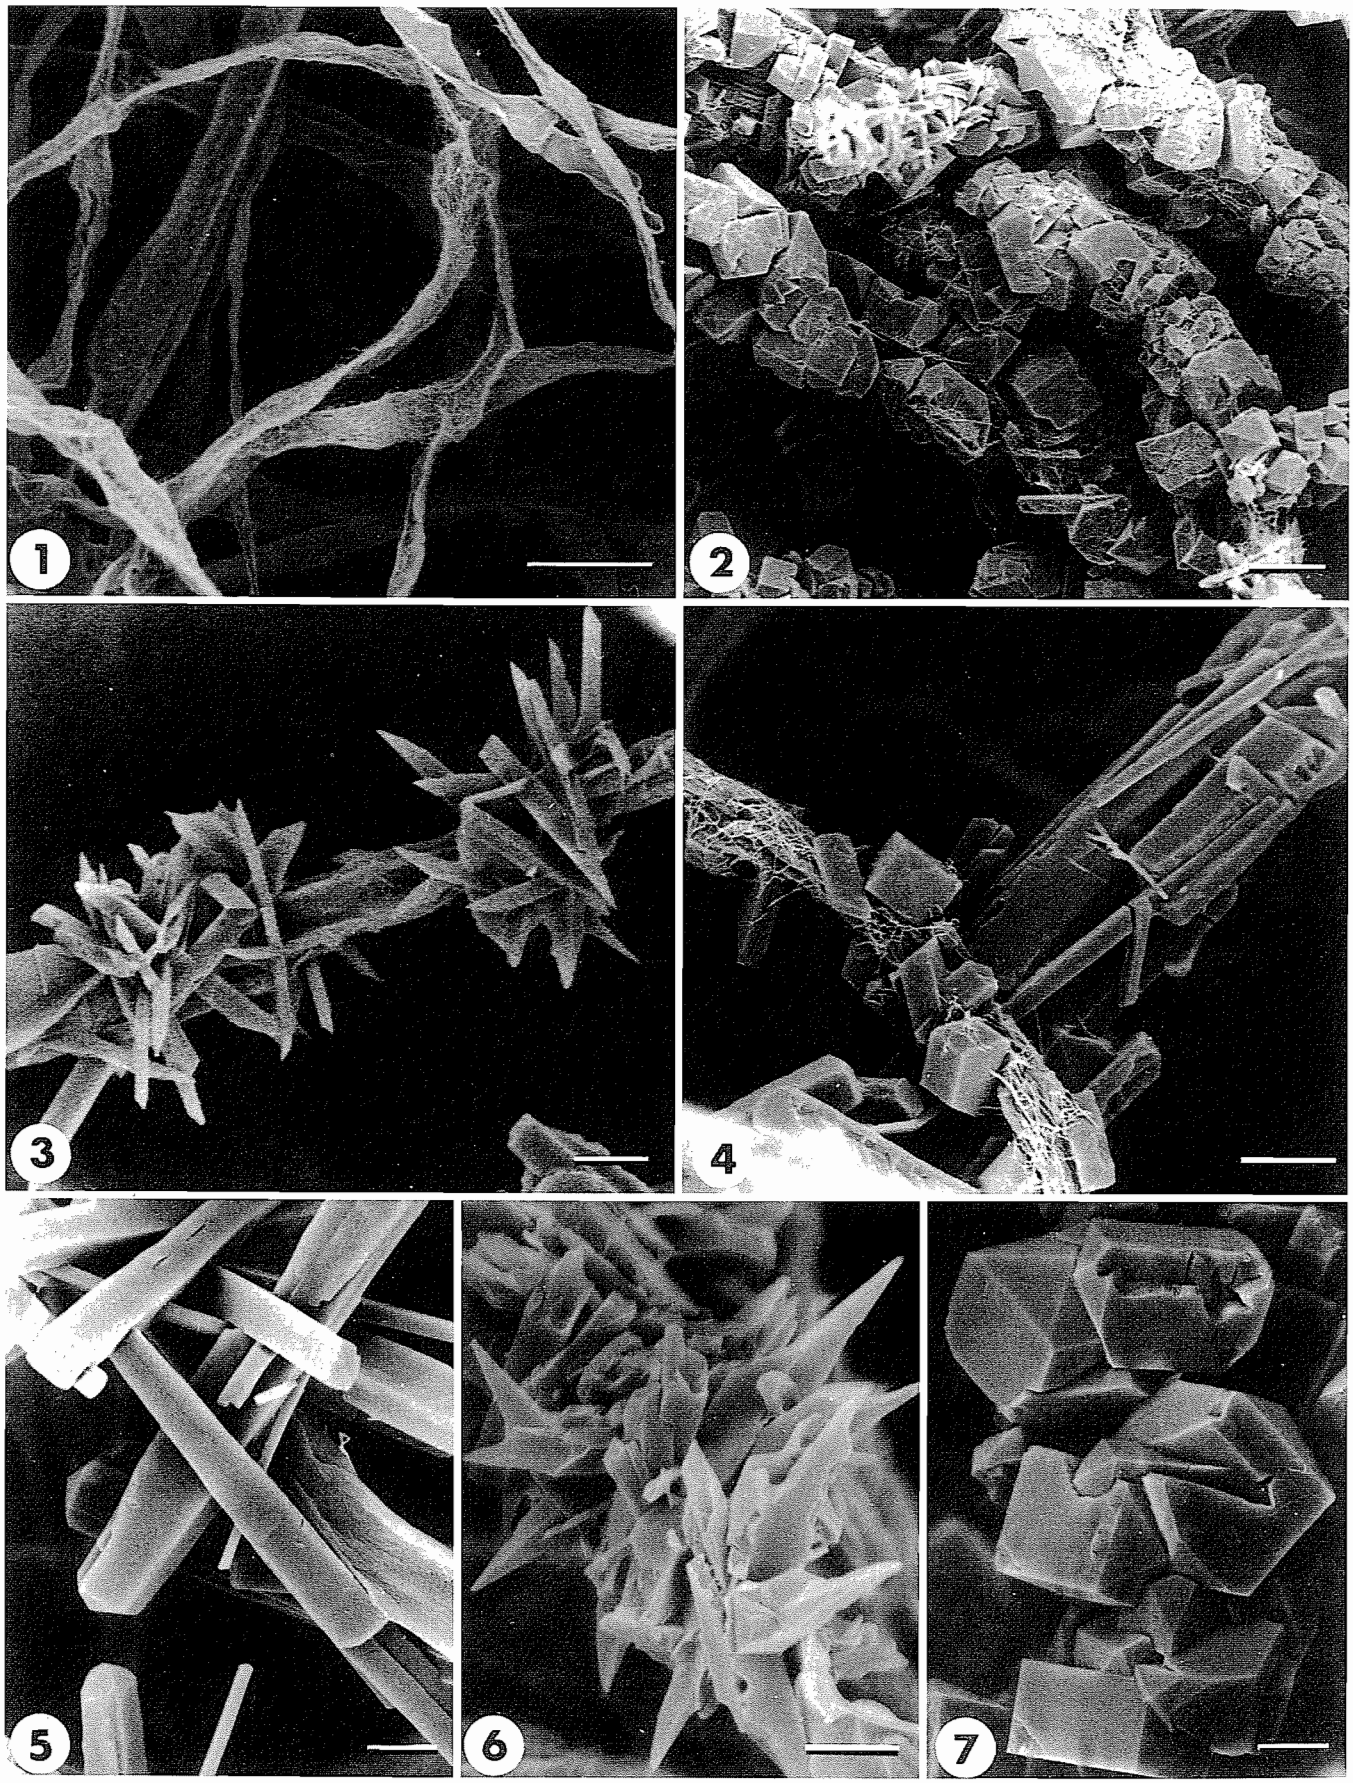
In total, 13 species of bird's nest fungi were examined. From this group, 10 were shown to produce crystals rich in calcium. Detailed crystal morphology for each species is presented in Table 3. Crystals were not observed in *C. pygmaeus, N. niveo-tomentosa*, and *C. laeve.* Hyphae of these species appeared "clean" (Fig. 1). In contrast to this, hyphae of *C. earlei, C. stercoreus,* and *C. africanus* (Fig. 2) growing on V8 media were heavily encrusted with variably shaped crystals, typical of both the monohydrate (whewellite) and dihydrate (weddellite) forms of calcium oxalate (17). Encrustation in these species was extremely heavy, rendering hyphae unidentifiable. On PDA, crystals were evident on these species but were considerably sparse compared with hyphae on V8 agar.

Cyathus olla, C. striatus, C. berkeleyanus, C. julietae, C. bulleri, and *C. pallidus* all produced crystals of various morphologies when grown on V8 media. From this group, only *C. olla* and *C. striatus* produced crystals on PDA. *Cyathus canna* was an exception, producing styloids and variably shaped crystals on PDA and none when grown on V8 agar.

Crystals were observed in druses (spherical aggregates) (Fig. 3) or randomly attached to hyphae singly or in groups. Druses produced by *C. olla* and *C. berkeleyanus* on V8 agar were all raphide crystals, but other crystal clusters seen on these species, as well as on many others, contained many different crystal types (Fig. 4).

Crystal types observed during this study were typically styloid- (Fig. 5) and raphide-shaped (monohydrate forms of calcium oxalate) (Fig. 6), or bipyramidal crystals, typical of the dihydrate form (Fig. 7). Styloids and raphides are elongated crystals that are easily distinguished from one another. Both ends of a styloid crystal form a prism, whereas raphide crystals form a tapered, spearlike end (17). Dihydrate forms such as bipyramidal types have a fourfold axis, a plane of symmetry perpendicular to it, and a center of symmetry with no symmetrical planes parallel to the crystal axis (17).

Energy-dispersive X-ray microanalyses of all crystal types produced spectra high in calcium (Fig. 8). Osmium and gold peaks resulted from the fixative and gold coating, respectively. Potassium and chlorine peaks are attributed to components from the V8 juice-based medium. X-ray diffraction results confirmed the presence of both the monohydrate (whewellite) and dihydrate (weddellite) forms of calcium oxalate (Fig. 9). Based on these spectral data, documented calcium oxalate crystal morphology (17), and previous identification of calcium oxalate crystals associated with *C. olla* and *C. striatus* (9), the crystals observed in this study were identified as calcium oxalate. In addition to crystals, many exudate droplets were present on the hyphae of a number of species. Identification of components of this exudate was not performed during this study.



Discussion

Crystal production and morphology may be influenced by many factors including oxalic acid secretion, calcium availability, hydration state, and other environmental factors (11, 17). Diversity among species of Nidulariaceae with respect to crystal production appears to be attributed to species-specific variation since factors such as calcium availability and environmental conditions were consistent throughout this experiment. In many plants, calcium oxalate crystal shape and location are species and tissue specific (18). There are many similar reports for fungi (19); however, with respect to the Nidulariaceae, many more isolates must be examined to confirm these observations.

Crystal production was greatest on the V8 medium (approximately 3.0072 g Ca/ L), which had a greater concentration and availability of calcium than PDA (approximately 30.85–38.85 mg Ca/ L). Calculations of calcium content are based on

media formulation, information, and mineral analyses provided by Campbell's Soup Company, Difco Laboratories, and potato mineral content information (20). The approximate calcium content of PDA does not reflect the actual value since PDA is made from potato infusion. For this preparation, the solid phase, which contains most of the calcium (plant cell walls), is removed. Therefore, the actual value will be significantly lower than the estimate. From this information, it can be assumed that calcium was a limiting factor to crystal production on the PDA medium for most species. It is not clear why *C. canna* produced crystals on PDA and none on the V8 medium. This species may require a starch-rich medium for

induction of crystals, but this stipulation has to be validated further.

Morphological variation of crystals is a function of hydration state and was species and medium specific. There was no association between crystal types and geographic and habitat distribution of species. *Cyathus stercoreus* is coprophilous whereas all the other species used in this investigation were from woody substrata. These two groups did not differ in crystal morphologies.

Crystal-producing ability of the fungi observed in culture can be extrapolated to natural environments and the ecological niche these fungi inhabit. Many bird's nest fungi are involved in the decomposition of plant residues. Oxalic acid secretion and subsequent sequestration of calcium weakens cell wall stability, and improves access for enzymes involved in decomposition (10, 11). Horner et al. (13) have suggested that crystal-forming fungi are ecologically important for calcium recycling, nutrient availability, and soil genesis. From this study, it can be concluded that many species of the Nidulariaceae play a role in these environmental/ ecological processes. Crystals were not observed in all species examined in this experiment; however, the importance of these species cannot be minimized by these results. Crystal production by these fungi may be induced by natural or environmental factors not provided in this experiment.

Acknowledgments

This research was supported through a research grant (OGP 0491) from the Natural Sciences and Engineering Research Council of Canada (NSERC) to J.P.T. T.C.S. was supported through a postgraduate scholarship, also from NSERC. George Braybrook, Christina Barker, and Diane Caird helped in scanning electron microscopy, energy-dispersive X-ray microanalyses, and X-ray diffraction analyses, respectively.

Thermolysis and photolysis of two steroidal hydroxamic acid methanesulfonates

Oliver E. Edwards, Gunnar Grue-Sørensen, and Barbara A. Blackwell

Abstract: Thermolysis or photolysis of *N*-methanesulfonyloxy-4-aza-5α-cholestan-3-one gave derivatives of 4-azacholestan-3-one, 4-aza-A-nor-B-homocholestan-3-one, 3-aza-A-norcholestane, bis (4-aza-3-oxocholest-5-en-6-yl) methane, and bis(3-aza-A-norcholestan-3-yl) urea. The corresponding 5β-methanesulfonate gave the 5β (coprostane) analogues. Evidence for the mechanism of formation of these products, including a Favorski-like ring contraction and amide oxidation by methanesulfonic acid, is presented. Detailed ^{1}H and ^{13}C assignments are made for many of the products, and ultraviolet absorption for seven steroidal enamides is tabled. Long-range homo- and heteronuclear NMR connectivities were used to confirm the structure of three dimeric compounds and to assign the configuration of the methoxy function of 4-aza-5-methoxy-A-nor-β-homocholestan-3-one to be 5α.

Key words: steroidal enamides, 3-aza-A-norcholestanes, 4-aza-A-nor-B-homocholestanes, aza-Favorskii ring contraction.

Résumé : La thermolyse ou la photolyse de la *N*-méthanesulfonyloxy-4-aza-5α-cholestan-3-one fournit des dérivés de la 4-azacholestan-3-one, de la 4-aza-A-nor-B-homocholestan-3-one, du 3-aza-A-norcholestane, du bis(4-aza-3-oxocholest-5-én-6-yl)méthane et de la bis(3-aza-A-norcholestan-3-yl)urée. Le 5β-méthanesulfonate conduit aux analogues 5β (coprostane). On présente des données relatives au mécanisme de formation de ces produits, y compris une contraction de cycle de type Favorski et une oxydation d'amide par l'aide méthanesulfonique. On a effectué des attributions détaillées des spectres RMN du ^{1}H et du ^{13}C de plusieurs produits et on présente un tableau incorporant les absorptions ultraviolettes de sept énamides stéroïdaux. On a utilisé les connectivités RMN homo- et hétéronucléaires à longue distance pour confirmer les structures de trois composés dimères et pour conclure que la configuration de la fonction méthoxy de la 4-aza-5-méthoxy-A-nor-β-homocholestan-3-one est 5α.

Mots clés : énamides stéroïdaux, 3-aza-A-norcholestanes, 4-aza-A-nor-B-homocholestanes, contraction de cycle d'aza-Favorski.

[Traduit par la rédaction]

Introduction

Considerable interest has been shown in the potential of *N*-acyl imines (**1**) and related carbinolamides (**2**) as biochemical intermediates (1*a*), as possible biological alkylating agents with chemotherapeutic activity (1*b–d*), and as reagents for organic synthesis (1*e*). Three aliphatic *N*-acyl imines have been isolated in our laboratories (1*c*, 2) and showed moderate stability. Thus we were encouraged to attempt preparation of 4-azacholest-4-en-3-one (**3**) and related steroidal *N*-acyl imines.

Received January 15, 1997.

This paper is dedicated to Professor William A. Ayer on the occasion of his 65th birthday.

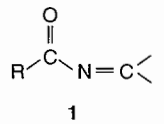
Attempts to prepare 5α-azido-A-norcholestan-3-one **4** failed,[2] foiling attempts to prepare **3** by the photochemical route discovered in our laboratories (1*c*).

Thermolysis of keto acid **5** (R = H) in ammonia (3*a*) or exposure of the corresponding keto amide or enol lactone to ammonia gave enamide **17** or the corresponding carbinolamide (3*b*). Base-catalysed elimination of HCl from the *N*-chloro lactam **6** also gave **17** as major product[3] (see also recent work on photolysis of **6** by Back and Brunner (1*d*)). Thus it was evident that isomerization of **3** to **17** was facile.

This paper details attempts to observe or obtain **3** by rupture of the relatively weak N—O bond of hydroxamic acid methanesulfonates **13** and **14**. Since this work was initiated, Hoffman et al. (4) have shown that thermolysis of hydroxamic acid triflates gives transient *N*-acyl immonium salts.



Results

The desired methanesulfonates were prepared from keto acid **5** (R = H) as shown in Scheme 1. After the cyanoborohydride reduction of oximino acid **7** the cyclization to the hydroxamic

acids **9** and **10** was spontaneous. The methyl ethers **11** and **12** were prepared for comparison with subsequent products. The properties and configurations as determined by the ^{1}H NMR signals for the 5-hydrogens agreed well with those reported by Edward and Morand (5) for samples prepared in other ways.

Finally, the methanesulfonates **13** and **14** were prepared using methanesulfonyl chloride in pyridine. Heating of **7** in vacuo gave the enamide *N*-hydroxycholest-5-en-3-one **8**.

Thermolysis of both mesylates **13** and **14** in dry tetramethylurea at 185°C under argon produced at least seven products (TLC), three of which were purified and characterized. The minor one (ca. 6%) was the hitherto unknown enamide 4-aza-A-nor-B-homocholest-5-en-3-one **15**. This had ν_{max} 1690 cm^{-1} (five-membered lactam), no NH, and two vinyl hydrogens. Its ultraviolet absorption (Table 1) indicated an enamide character. This, its chemistry, and the ^{13}C NMR spectrum (see Table 3) left no doubt that it had structure **15**.

A major product (52–57%) was 4-azacholest-5-en-3-one **17**, a known compound.[2] Another was the unexpected coupling product bis(4-aza-3-oxocholest-5-en-6-yl)-methane **16** (7–19%). This was a polar enamide (see Table 1) with NH absorption (ν_{max} 3390 cm^{-1}; δ 7.45). Its EI mass spectrum showed only very weak peaks above *m/z* 427, so it appeared to be a monomer. However a 2D NMR spectrum showed that an apparent one-hydrogen signal at δ 2.6 ppm was actually due to a methylene group, thus suggesting that it was linking two steroid units. The fact that none of the hydrogen or carbon signals were doubled indicated high symmetry. Since the general spectra were similar to those of **17** but the vinyl hydrogen was missing, the structure appeared to be **16**. Partial synthesis from **17** (see below) confirmed this.

To test if the methanesulfonic acid produced in the thermolysis was catalysing the isomerization of preformed **3**, powdered calcium carbonate was added to the reaction mixture before thermolysis. The results were erratic, but the yield of **17** increased at the expense of **16**, reaching as high as 84%. No *N*-acyl imine **3** was detected using ^{13}C NMR.

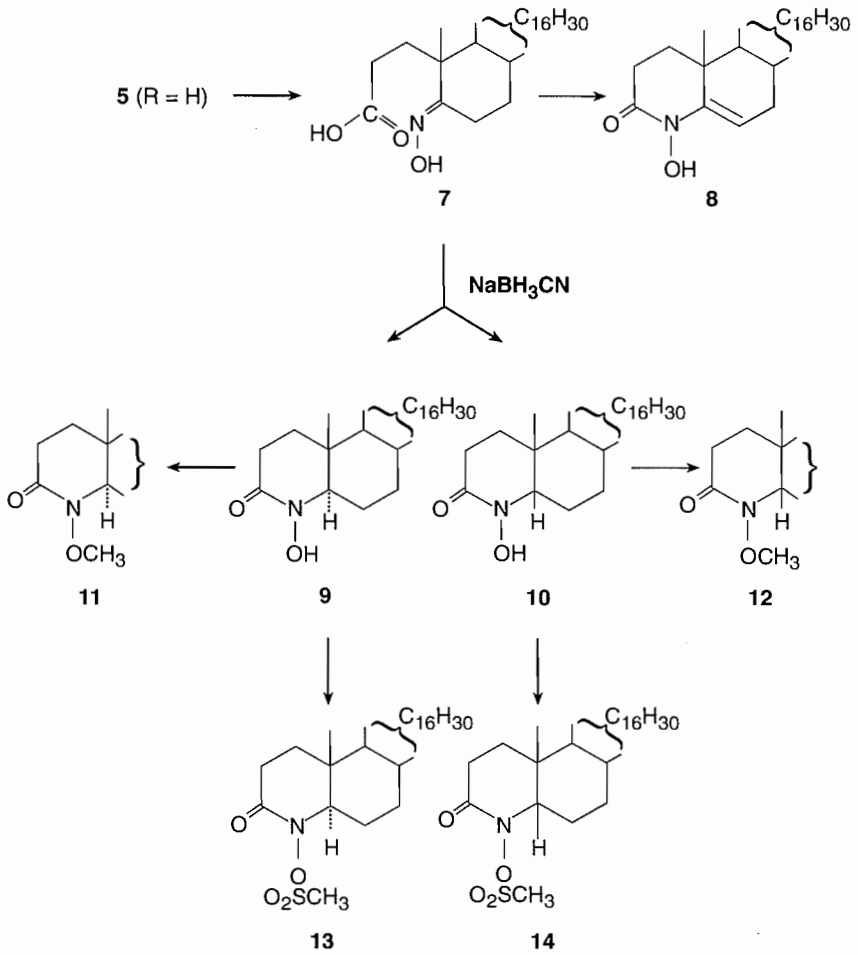
To reduce the effect of the methanesulfonic acid even further, the thermolysis was conducted in dry collidine. Yields of **17** of 73% (5α) and 80% (5β) were realized. No products derived from the A-nor base **24** were detected from **14** and no **3** was observed despite gentle work-up (expected ^{13}C NMR signals near 180 ppm and ν_{max} near 1700 cm^{-1}).

Thermolysis of **13** and **14** in dry methanol at 180°C in sealed tubes under argon again gave **15** and **17**, as well as **5** (R = CH_3), which undoubtedly arose by acid-catalysed methanolysis of **17** followed by hydrolysis during work-up. Indeed, treatment of **17** with acidic methanol did give **5** (R = CH_3). Additional products of the thermolysis were the methyl carbamates **18** and **19** (eqs. [1] and [2]). Since **19** formed excellent crystals it was submitted for X-ray crystallography. We are grateful to Prof. C. Bensimon for the structure and stereochemistry shown in formula **19**. The analogous spectra of **18** left no doubt as to its identity (Tables 2 and 3).

Photolysis of **13** and **14** in dry methanol gave enamide **17**, the carbamates **18** and **19**, respectively, and a new common product, the carbinolamide ether **20** clearly related to **15**. Indeed the two could be interconverted (see eq. [15]). Apparently pure samples of **20** slowly converted to a crystalline mixture containing **15** and **20** plus methanol, according to NMR results. Approximately 5% of the two lactams **21** and **22** (eqs. [3] and [4]) were formed from **13** and **14**, respectively.

In the hope of obtaining the bases corresponding to carbamates **18** and **19**, the mesylates **13** and **14** were photolyzed in aqueous tetrahydrofuran (eqs. [5] and [6]). The bases **23** and **24** were formed, and were characterized as their hydrochlorides and *N*-acetyl derivatives **27** and **28**. The yield of lactams **21** and **22** increased to 11%.

Photolysis of **13** and **14** in dichloromethane gave spectroscopic evidence for reactive intermediates with ν_{max} 1743 cm^{-1} (see Mechanism section). Depending on work-up conditions the products shown in eqs. [7]–[10] were formed. The reactive intermediates appeared to be the source of the carbamates **18** and **19**, the ureas **25** and **26**, and, as a consequence of traces of water (aqueous work-up), the bases **23** and **24**. The latter were subsequently acetylated, giving **27** and **28**.



In a last attempt to intercept the *N*-acylimine **3**, a small molar excess of triethylamine was added to a dichloromethane solution of **14** before photolysis. Again a transient species with ν_{max} 1743 cm^{-1} was formed. Treatment of the product with methanol, then acetic anhydride, gave a mixture of

5β-carbamate **19**, enamide **15**, and *N*-acetyl derivative **28**. No evidence for the presence of **3** or the related 5-methoxy or 5-acetoxy lactams **34** was found.

Since methoxy lactam **20** was moderately stable, attempts were made to prepare the 5-acetoxy-4-aza-A-nor-B-homo-cholest-3-one. However, the exposure of enamide **15** to an acetic acid – acetic anhydride mixture in the presence of *p*-toluenesulfonic acid at room temperature or at 68°C gave no isolable acetoxy compound.

Enamides **8**, **15**, **16**, and **17** deteriorated in air, especially in

solution. The melting points obtained in evacuated capillaries were higher and sharper than those taken in air.

Partial synthesis of enamide **16** was readily achieved by reaction of enamide **17** with formaldehyde using p-toluenesulfonic acid as catalyst. It was also possible to prepare 6-ethoxymethyl-4-azacholest-5-en-3-one **31** and react this with **17** to give the dimer **16** (eq. [11]).

Hydrogenation of **15** gave the parent lactam **32** (4-aza-A-nor-B-homocholestane-3-one).

Mechanism

The thermolysis of **13** and **14** in tetramethylurea or methanol is readily understood in ionic terms involving ion pair **A**

(Scheme 3). The high yield of **17** in collidine and the effect of calcium carbonate in the other solvents is consistent with a base-catalysed elimination involving the 5-hydrogen, leading to **3** as a metastable intermediate. This must rapidly rearrange to the more thermodynamically stable **17**.

However, since no *N*-methoxy compounds **11** or **12** were formed in methanol we conclude that free nitrenium ions **A** were not involved and that processes (a), (b), or (c) were synchronous with N—O bond rupture.

The formation of the A-nor amine derivatives could follow the ionic pathway (a) through ion pair **B**. However, an alternate ionic process involving an α-lactam could proceed as illustrated in eq. [12], although spectroscopic evidence for a reactive intermediate (ν_{max} 1743 cm^{-1}) in photolysis of **13** and

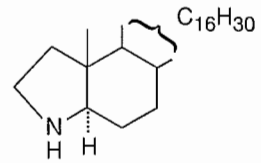
14 in dichloromethane favors **C**[4] since an α-lactam would have absorption near 1850 cm^{-1} (7). Secondly, α-lactam formation as in eq. [12] and subsequent reaction would involve a 2-hydrogen. But thermolysis or photolysis of the mesylates in methanol-*d* gave no more than minor deuterium exchange on C-2 for **18** and **19**. Thirdly, photolysis or thermolysis of **13** and **14** in methanol (acidic) or photolysis in dichloromethane followed by treatment with acidic methanol gave none of the 2-methoxy-4-azacholest-3-one expected for an α-lactam intermediate (*7b*) and no acid **29** or its derivatives were observed[5] under more basic conditions.

Finally, had proton elimination as in eq. [12] been the source of the A-nor derivatives, a base such as collidine for thermolysis, or triethylamine for photolysis in dichloromethane, should have increased the yield of these. Actually the A-nor derivatives could not be detected in thermolysis in collidine and the yields in the photolysis did not change.

We conclude that the mechanisms in Scheme 3 are essentially correct. The formation of the A-nor derivatives is a new type of ring contraction. Since the reaction is closely analogous to the Favorskii-type ring contraction observed in deamination of α-amino ketones when cyclopropanone formation was impossible (8), it can be called an aza-Favorskii reaction.

The high energy available in the photolyses (ca. 250 nm) means that a homolytic fission of the N—O bond as a first step (eq. [13]) is possible. Cadogan and Rowley have produced evidence for such fission for hydroxamic acid toluenesulfonates (9). The only direct evidence for nitrogen-centered radicals in our work is the isolation of lactams **21** and **22** (eqs. [3] and [4]). As expected, the yields of these were highest in the best hydrogen atom donor tetrahydrofuran, lower in methanol, and near zero for dichloromethane.[6] Since most of our

[4] Attempts to make a simple analogue of C failed.



[5] The base-promoted opening of *N-tert*-butyl phenylaziridinones are cases of C—C bond cleavage of α-lactams (*7c*).

[6] The high yield of parent lactams in the photolysis of *N*-chlorolactams (*1d*) contrasts with our experience with the mesylates.

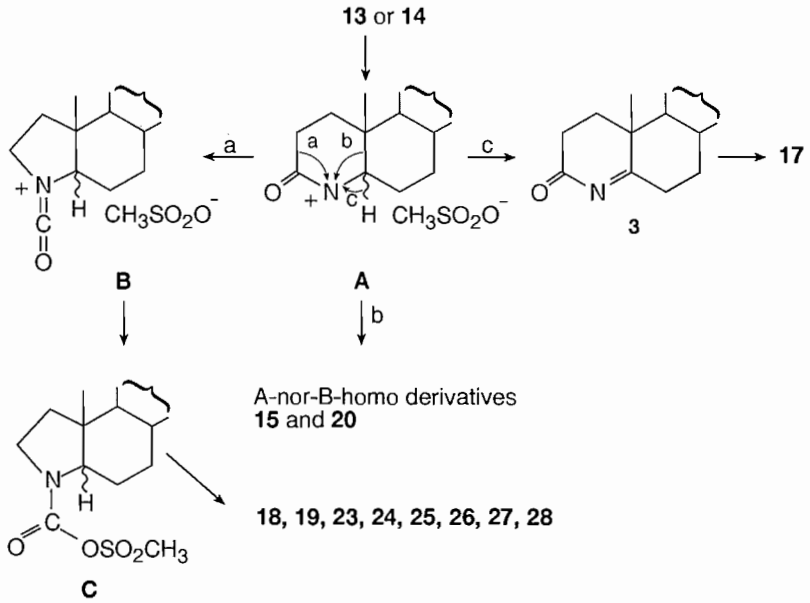
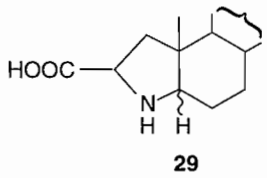
products seem to be of ionic origin, electron transfer to ion pair **A** would have to occur as a major step (eq. [13]). For similar electron transfer, see ref. 10*a* (see, however, ref. 10*b*).



The rearrangement of the proposed *N*-acyl nitrenium ion **A** to the A-nor-B-homo derivatives **15** and **20** (path b, Scheme 3) is plausible. It gave a modest yield of **15** (maximum observed 30% in aqueous tetrahydrofuran). Recently a preparation of 2-alkylated steroids with this skeleton was developed by Back et al. (11).



A most surprising result in the photolyses in tetramethyl urea was the formation of the methylene-bridged dimer **16**. When TMU containing methanesulfonic acid was heated at 180°C neither formaldehyde nor trimethyl urea could be detected among the products. However, the formaldehyde required to form the methylene bridge must have arisen from a methyl group of the TMU (eq. [14]). Heating **17** with tetramethyl urea under argon at 180°C gave no **16**, but if methanesulfonic acid was included a 50% yield of **16** was obtained. Thus the methanesulfonic acid formed from the mesylates is the oxidant. The occurrence of products containing both methylamido and steroid units was evident from ^{1}H NMR spectra, but none were characterized. These must arise from reaction

[16]

of carbinolamides such as **30** with enamides such as **17**. The acid-catalysed formation of **16** from **17** and formaldehyde or from **17** and the ethoxymethylene compound **31** (eq. [11]) shows the electron-donating potential of enamides. The addition of methanol to enamide **15** undoubtedly involves the same phenomenon: i.e., protonation on C-6 to give the immonium salt, then methanol attack on C-5 (eq. [15]). Attempts to convert **17** to the immonium salt **33** and then to neutralize this using weak base to obtain **3** failed. Acid-catalysed addition of methanol or acetic acid to **17** to give the 5-methoxy or 5-acetoxy compounds **34** (R = OCH_3 or $OCOCH_3$) also failed, probably due to the steric crowding at C-5.

Spectra

Table 1 lists the characteristic ultraviolet absorption spectra of the known steroidal enamides. Detailed NMR spectral assignments for the C-1 to C-19 nuclei of many of the compounds discussed are presented in Tables 2A, 2B, and 3. These constitute either full chemical shift assignments of known compounds or those of the new compounds to determine their structures. Other NMR data to confirm known structures are reported in the Experimental. The assignments reported in Table 2A result from a combination of homo- and heteronuclear correlation experiments so that, even if the multiplets themselves cannot be resolved in the overlapped portion of the proton spectrum (0.8–1.8 ppm), the centres of AB systems can be determined. Selected proton chemical shift assignments for other compounds are reported in Table 2B where more detailed information was not available (i.e., no 2D experiments were performed). The ^{13}C chemical shift assignments were determined from direct and long-range (HMBC) $^{1}H/^{13}C$ correlation experiments for critical or new structures (i.e., **12**, **15**, **16**, **18**, **24**, **26**, and **32**), while assignments for others were made by comparison of related spectra (e.g., **27** and **33** compared to **18** and **25**, **28** and **24** compared to **19** and **26**, etc.). Tables 2 and 3 show that the chemical shifts of positions C-11

to C-17 are relatively constant for all compounds, but that positions C-8 and C-9 are strongly influenced by the nature of the B ring (six- or seven-membered, presence of a 5,6 double bond, etc.).

There is some ambiguity regarding the assignment of resonances due to C-14 and C-17. Although similar in chemical shift, these may be distinguished as long as the corresponding proton resonances are resolved. Thus for compounds **12**, **15**, **16**, **18**, **25**, and **26** these resonances may be distinguished by correlation to their respective protons and the proton coupling of H-14 to H-15 or that of H-17 to H-16 and H-20 as seen in the COSY spectrum. However, for compounds such as **19**, **20**, and **32**, where H-14 and H-17 are coincident, the identity of the carbon resonances is not confirmed.

For simplicity, the chemical shift assignments for the C_8H_{17} side chain for all compounds are summarized in Table 4. These figures represent an average of all compounds characterized. Variability between compounds was very slight, amounting to only ± 0.1 ppm for ^{13}C and ± 0.02 ppm for ^{1}H. This indicates that the overall molecular configuration for all compounds studied was very similar, in spite of changes in the A and B rings.

Interesting differences show up between the spectra of the members of the 5α and 5β series of compounds, especially for the A-nor series. Comparison of the ^{13}C chemical shifts of the 5α A-nor compounds (**18**, **23**, **27**, and **25**) with the 5β analogues (**19**, **24**, **28**, and **26**) shows that C-5, C-7, and C-9 are shifted upfield by ca. 3, 3–4, and 8 ppm, respectively, in the 5β compared to the 5α compounds. C-6, however, is unaffected, while the methyl function C-19 is shifted downfield by 5 ppm in the β series. A similar comparison of the spectra of the 6,6-nucleus analogues (**11**, **21** (5H-α) and **12**, **22** (5H-β) yields the same qualitative effects although shift differences are larger for C-9 and C-19 (11 ppm upfield and 8 ppm downfield, respectively). The shift of the C-5 resonance is the same (ca. 3 ppm upfield). Both C-6 and C-7 are relatively unaffected in these compounds by the orientation of the H-5 proton. Concomitant but much smaller shift effects are seen in the proton spectra for all of these compounds. The effects observed in the ^{13}C spectra may be due to a marked increase in the strain of ring A (according to Dreiding models) in the 5α, as compared to the 5β, configurations. There is no evidence for such strain in the 6,6 series. However, for the 5β compounds **12** and **22**, the H-9 and C-9 are in the shielding cone of the amide. In all cases, the 5α proton is distinguished from the 5β proton by the presence of a large *trans* diaxial coupling (ca. 12 Hz) to one of the hydrogens at position 6.

The dimeric compounds **16**, **25**, and **26** yield deceptively simple NMR spectra, in that identical ^{1}H and ^{13}C shifts are observed for both steroid nuclei in these structures. In the absence of clear mass spectrometric evidence (see above), the only clue to the presence of a dimer rather than a monomer for these compounds is the appearance of a carbonyl resonance of reduced intensity in the ^{13}C spectra of **25** and **26** (at 165.4 and 163.3 ppm, respectively) and of an extra methylene carbon (again reduced in intensity) at 31.5 ppm in the spectrum of **16**, which in turn was correlated to a broad singlet at 2.59 ppm in the proton spectrum. The location of this methylene bridge at position C-6 was confirmed by the HMBC experiment, which showed coupling of the methylene singlet at 2.56 ppm in the proton spectrum to C-6 at 109.3 ppm in the carbon spectrum. Weaker couplings were also observed between this proton signal and C-5 and C-7 at 135.5 and 34.8 ppm, respectively. Similarly, couplings were observed between the H-5 protons at 3.0 and 3.5 ppm and H-2 protons at 3.4 and 3.1 ppm in the spectra of **25** and **26** to the carbonyl carbons at 165.4 and 163.3 ppm, respectively, thus supporting other spectroscopic and chemical evidence for the urea structures.

Two explanations are possible for the simplicity of the NMR spectra: either that rotation about the bonds of the bridging function is sufficiently fast on the NMR time scale to average out any effects or that the barrier to rotation is high and only one rotamer exists — one that has a plane of symmetry. The former explanation is preferred in the case of compound **16**, since free rotation about the bridging methylene function would be expected. In the case of the ureas **25** and **26**, the overlap of the two nitrogen lone pairs with the carbonyl function predicts that there is less double bond character than in an ordinary amide and therefore the barrier to rotation should also be relatively low. This is consistent with the fact that tetramethyl urea gives a single signal for both ^{1}H and ^{13}C at room temperature while for the classical example of dimethyl formamide, where the barrier to rotation is quite high, there is doubling of signals (12).

Other motional effects are observed when the spectra of the A-nor series of compounds are compared. In the ^{13}C spectra of the carbamates **18** and **19**, the resonances due to C-2, C-6, and C-10 of the A ring are broadened and reduced in intensity. The C-5 resonance is also affected but to a lesser extent. In the proton spectrum of **19**, the resonance due to H-6α is only barely visible and shifted to 2.6 ppm and the resonances of H-5 and H-2 are also broadened. These effects are also seen in the spectra of **18**. The broadening of these particular resonances was also observed for the *N*-acetyl derivatives **27** and **28** but is not so pronounced, less so for the ureas **25** and **26**, and absent for the salts **23** and **24**. In all cases the effect is more pronounced in the 5β compounds than the 5α. This behavior may be accounted for by the presence of two rotamers with restricted rotation on the NMR time scale. This restricted motion would be maximum in the carbamates, less for the *N*-acetyl compounds, and least for the ureas and the salts. This is supported by the infrared spectra, in which the carbamate frequencies are high (ca. 1695 cm^{-1}) with little overlap while the frequencies for the ureas are low (1626 cm^{-1}). Therefore, the energy required to stretch the C=O bond is lowest in the ureas, where the amount of the double-bond character is the least. The restricted rotation is greater in the 5β compounds since the nonbonded interactions are also maximized.

Long-range couplings, both homonuclear ($^1H/^1H$) and heteronuclear ($^1H/^{13}C$), that occurred through the nitrogen atom in ring A were observed in several cases in COSY and HMBC spectra. These long-range *J* values are likely enhanced by the partial C=N double-bond character of the amide system. In particular, long-range couplings were observed in the spectra of compounds **32** and **20** that permit the determination of configuration of C-5 in the latter. In the COSY spectrum of **32**, a homoallylic coupling ($^5J_{HH}$) was observed between H-2β at 2.25 ppm and H-5β at 2.95 ppm. Homoallylic coupling is often observed in aromatic systems where the π orbitals of the double bond system are parallel and overlap with the CH bond (13). This would favour a conformation in which the 5β hydrogen is axial. In the spectra of compound **20**, no allylic coupling was observed but NOE measurements show a positive effect both between H-2 at 2.30 ppm and H-5 at 5.44 and H-5 and CH_3-19 at 1.35 ppm. Thus the methoxy function has an α configuration and the conformation of ring β is such that the 5β proton is axial and proximate to the CH_3-19. This conformation minimizes the nonbonded interaction of the 5α methoxy group with the carbonyl function.

The correct assignment of the C-2 proton of the A-nor compounds was critical to the determination of mechanism for the aza-Favorskii reaction (see mechanism section). Integration of the H-2 signals at ca. 3.4 ppm from samples of **18** and **19** formed from methanol-*d* showed that less than 5% exchange of these hydrogens had occurred. As expected (see eq. [15]), both enamides **15** and **17** produced in these reactions showed partial exchange of the C-6 hydrogens (at 5.25 ppm and 4.24 ppm, respectively), while no reduction in the intensity of the H-2 signals at ca. 2.4 ppm was observed.

Summary

Attempts to prepare *N*-acyl imine **3** failed, but it was implicated as a transient intermediate in reactions of hydroxamic acid methanesulfonates **13** and **14**. A new aza-Favorskii reaction was observed, leading to a new route to 3-aza-A-nor steroids. A new preparation of 4-aza-A-nor-B-homocholestane derivatives and a high-yielding synthesis of the enamide 4-azacholest-5-ene-3-one (**17**) were described. Both homolytic and heterolytic reactions were implicated in the photochemistry of the methanesulfonates.

Experimental

Infrared spectra were for dichloromethane solutions, unless otherwise indicated, on a Perkin–Elmer model 683 grating spectrometer, and ultraviolet spectra were taken for 95% ethanol solutions unless otherwise indicated. Routine ^1H NMR spectra were taken on a Varian Gemini instrument at 200 MHz and ^{13}C spectra at 50 MHz. High-resolution ^1H and ^{13}C NMR spectra were recorded in deuterochloroform ($CDCl_3$) at 500.13 and 125.18 MHz, respectively, on a Bruker AM500 NMR spectrometer operating at 303 K. A 5 mm normal geometry $^{13}C/^1H$ probe was used (90° ^{13}C = 18 μs, 90° ^1H = 7 μs). Chemical shifts were referenced to $CDCl_3$ at 77.0 ppm (^{13}C) and 7.24 ppm (^1H) and are reported relative to TMS. The resonance assignments for known compounds were elaborated and for new compounds were determined using a combination of $^1H/^1H$ correlation (COSY, TOCSY), DEPT, ID NOE, and $^1H/^{13}C$ correlation (HETCOR, HMBC) experiments using standard Bruker pulse sequences.

All preparative thin-layer chromatography was done on 20 × 20 cm glass plates with fluorescent indicator and column chromatography on 100–200 mesh silica gel or Woelm neutral alumina. Melting points were corrected using standards. Tetramethyl urea and 2,4,6-collidine were distilled from calcium hydride, tetrahydrofuran from lithium aluminum hydride, methanol from magnesium methoxide, and dichloromethane from phosphorus pentoxide. Yields were calculated based on unrecovered starting material.

Unless otherwise noted, the NMR spectral assignments, both ^1H and ^{13}C, of the following compounds are documented in Tables 2 and 3.

3,5-Seco-A-nor-5-oxocholestan-3-oic acid 5 (R = H)

A modified procedure of Singh and Paul (14) was used to prepare **5** (R = H).

To a stirred solution of 13 g of 4-cholesten-3-one in 600 mL of *tert*-butyl alcohol was added 7 g of potassium carbonate in 150 mL of water, then 45 g of sodium periodate in 350 mL of water, followed by 100 mg of potassium permanganate in 10 mL of water. A cold water bath was used to keep the temperature below 38°C. After 3 h the solid (mostly inorganic) was removed by filtration. Solid sodium hydrogen sulfite was added to the filtrate until only a pale yellow color persisted. The two phases were separated. The aqueous phase was extracted with dichloromethane. The phase rich in *tert*-butyl alcohol was evaporated to a volume of 150 mL. This was made strongly acid using dilute sulfuric acid, then extracted with dichloromethane. The combined dichloromethane extracts were washed with water, dried, and concentrated. Addition of hexane resulted in crystallization of 7.7 g of desired acid with mp as high as 145°C. On recrystallization from methanol this gave 6.9 g (50%), mp 147–152°C (lit. (13) mp 154–154.5°C). A purified specimen had mp 151–153°C, ν_{max}: 1703 cm^{-1}, and ^1H NMR signals at δ 1.13 (3H), 0.93, 0.89, 0.85 (methyl resonances), and 0.73 (3H).

Methyl 3,5-seco-A-nor-5-oxocholestan-3-oate 5 (R = CH_3)

This ester, prepared by action of diazomethane on a methanol solution of **5** (R = H), remained amorphous. It has ν_{max} 1732 and 1700 cm^{-1} and gave ^1H NMR signals at δ 3.66 (3H), 1.12 (3H), 0.93, 0.89, 0.85 (methyl resonances), and 0.73 (3H). ^{13}C NMR: 214.7, 174.3, 56.0, 55.7, 51.5, 50.3, 47.8, 42.5, 39.4, 38.1, 36.1, 35.9, 35.7, 31.3, 29.5, 29.1, 28.0, 24.4, 24.2, 23.8, 22.5, 21.4, 20.5, 18.6, and 12.0 ppm.

3,5-Seco-A-nor-5-oximinocholestan-3-oic acid 7

Acid **5** (2.0 g) and hydroxylamine hydrochloride (2.5 g) were dissolved in 30 mL of ethanol, then 2.0 g of anhydrous sodium acetate was added. The mixture was heated under reflux for 3 h, cooled, then filtered from inorganic salts. The filtrate was evaporated to dryness. The residue was dissolved in 100 mL of dichloromethane. This solution was washed with 1 M sulfuric acid, then water, dried over sodium sulfate, then concentrated (care; the oxime may crystallize at any stage). Three crops of crystals totalling 1.8 g (87%), mp 181°C, were collected. These were purified on 55 g of "flash" silica gel using 5% methanol in chloroform (a red zone just precedes the main eluate, probably an iron chelate) raising the mp to 183–185°C.

For personal use only.

This gave ν_{max}: 3580, 3260, and 1703 cm^{-1} and ^1H NMR signals at δ 3.35 (1H, br d), 1.09, 0.88, 0.85, and 0.69 (sharp methyl signals).

***N*-Hydroxy-4-aza-cholestane-3-ones (hydroxamic acids)**

The oximino seco acid **7** (2.35 g) was dissolved in 45 mL of hot acetic acid. The solution was cooled to room temperature, then 1.1 g of sodium cyanoborohydride was added in portions with stirring during 7 min. Hydrogen was steadily evolved. After 0.5 h a further 250 mg of cyanoborohydride was added. After warming gently to dissolve all solids, the mixture was stirred for 1 h. The acetic acid was then removed on a rotating evaporator under 1 Torr (133.3 Pa), leaving a froth. This was dissolved in dichloromethane and the solution washed with water (emulsion). The dichloromethane layer gave 2.5 g of colorless froth. This was separated on 100 g of flash silica gel using chloroform. The lower melting isomer (5β) eluted first, followed by a sharp orange band (a small amount of iron chelate) and then the higher melting isomer (5α). Both isomers crystallized from ethyl acetate. The yield of **9** (5α) was 402 mg (18%) and of **10** (5β), 608 mg (27%).

***N*-Hydroxy-4-aza-5α-cholestane-3-one 9**

The higher melting isomer after recrystallization from ethyl acetate formed shimmering needles with mp 195°C (lit. (5) mp 185–187°C). It had ν_{max}: 3390, 3250, and 1625 cm^{-1} and gave ^1H NMR signals at δ 8.5 (OH), 3.33 (1H dd, J = 11.6, 3.3 Hz), 2.52 (2H m), 2.25 (1H, m), 0.97, 0.92, 0.88, 0.85, and 0.67 (sharp methyl signals). ^{13}C NMR: 165.6, 68.0, 56.1, 55.9, 51.4, 42.7, 39.6, 39.5, 37.5, 36.1, 35.7, 34.4, 32.6, 29.3, 28.2, 28.0, 27.8, 24.0, 23.8, 23.1, 22.8, 22.5, 21.0, 18.6, 12.5, and 12.1 ppm. Anal. calcd. for $C_{26}H_{45}NO_2$: C 77.36, H 11.24, N 3.47; found: C 77.23, H 11.37, N 3.49.

***N*-Methanesulfonyloxy-4-aza-5α-cholestan-3-one 13**

A solution of 402 mg of hydroxamic acid **9** and 0.3 mL of methanesulfonyl chloride in 2 mL dry pyridine was left at room temperature for 16 h. A crystalline solid separated. The mixture was cooled with ice, then 1 mL of water was added. After 50 min much of the pyridine and water was removed under reduced pressure. The residue was distributed between dichloromethane and dilute sulfuric acid. The dichloromethane yielded 466 mg of light brown gum, which crystallized from ethyl acetate. The product was purified by passage of a dichloromethane solution through a column of 6 g of neutral alumina, activity 1, giving 350 mg of **13**. This crystallized from ethyl acetate as fine needles, mp 158–159°C. It had ν_{max}: 1692, 1373, and 1183 cm^{-1} and gave ^1H NMR signals at δ 3.45 (1H dd, J = 13, 4 Hz), 2.62 (2H m), 1.06, 0.91, 0.88, 0.85, and 0.67 (sharp methyl signals). ^{13}C NMR: 169.5, 71.9, 56.2, 55.8, 51.7, 42.6, 40.3, 39.7, 39.5, 39.2, 36.1, 35.7, 34.4, 33.3, 30.5, 29.3, 28.2, 28.0, 24.5, 24.0, 23.8, 22.8, 22.6, 21.2, 18.7, 12.5, 12.1. Anal. calcd. for $C_{27}H_{47}NO_4S$: C 67.25, H 9.77, N 2.91; found: C 67.40, H 9.89, N 3.08.

***N*-Hydroxy-4-aza-5β-cholestan-3-one 10**

This crystallized from ethyl acetate, mp 125–126°C (lit. (5) mp 122–124°C), recrystallizing and melting at 131°C if heating was very slow. It had ν_{max}: 3670, 3390, 3240, and 1014 cm^{-1} and gave ^1H NMR signals at δ 8.65 (OH), 3.51 (1H s), 2.40 (3H m), 1.04 (3H s), 0.91, 0.88, 0.85 (sharp methyl signals), 0.67 (3H s). ^{13}C NMR: 164.9, 66.0, 56.2, 55.8, 42.6, 41.0, 39.9, 39.5, 36.4, 36.1, 35.8, 35.0, 31.3, 28.2, 28.0, 26.8, 25.7, 24.1, 23.9, 23.1, 22.8, 22.6, 21.4, 21.1, 18.7, 12.0 ppm. Anal. calcd. for $C_{26}H_{45}NO_2$: C 77.36, H 11.24, N 3.47; found: C: 77.18, H 11.40, N 3.53.

***N*-Methanesulfonyloxy-4-aza-5β-cholestan-3-one 14**

The 126°C hydroxamic acid **5** (218 mg) was treated with methanesulfonyl chloride in pyridine as for the 192°C isomer. The product was purified by passage through a column of 4 g of neutral alumina, activity 1. Hexane eluted 31 mg of mesylate containing a small amount of higher R_f impurities (TLC). A 30% ethyl acetate in hexane mixture eluted 211 mg of pure mesylate. This did not crystallize readily, but finally separated from hexane as fine needles, mp 87–88°C. Methanol proved to be the solvent of choice for recrystallization. The crystals had ν_{max}: 1678, 1372, and 1182 cm^{-1} and gave ^1H NMR signals at δ 3.80 (1H, br s), 3.45 (3 H, s), 2.5 (2H, m), 1.07, 0.91, 0.88, 0.85, and 0.67 (sharp methyl signals). ^{13}C NMR: 167.9, 71.2, 56.2, 55.8, 42.6, 40.8, 40.7, 39.8, 39.5, 37.8, 36.1, 35.8, 35.0, 31.2, 29.2, 28.2, 28.0, 25.5, 24.1, 23.8, 23.6, 22.8, 22.6, 21.5, 20.9, 18.7, 12.0. Its CI mass spectrum gave *m/z*: 482(81), 388(100), 387(44), and 386(75); calcd. for $C_{27}H_{47}NO_4S$: 481.

***N*-Methoxy-4-aza-5α-cholestan-3-one 11**

A solution of sodium methoxide in 3 mL of dry methanol was prepared using 104 mg of sodium hydride. To this was added 95 mg of hydroxamic acid **9** and 90 μL of methyl iodide in 5 mL of methanol. After 2 h refluxing a further 80 μL of methyl iodide was added, then the refluxing continued for an extra 2 h. The mixture was evaporated under reduced pressure, water was added, and then the product was extracted into dichloromethane. The 70 mg of **11** recovered from the dichloromethane was recrystallized from hexane. It had mp 146°C and ν_{max} 1668 cm^{-1}.

***N*-Methoxy-4-aza-5β-cholestan-3-one 12**

This was prepared from hydroxamic acid **10** as described for **11**. It crystallized from aqueous methanol as thin plates with mp 115°C (Lit. (5) mp 115°C). It had ν_{max} 1655 cm^{-1}.

***N*-Hydroxy-4-azacholest-5-en-3-one 8**

Oximino acid **7** in an evacuated (0.2 Torr) flask was placed in a bath at 185°C for 20 min. The melt bubbled vigorously. After cooling, the product was dissolved in dichloromethane. After addition of ethyl acetate the bulk of the dichloromethane was evaporated. A gel formed that was slowly transformed into balls of extremely fine needles, mp 196–198°C, in an evacuated capillary (immersed at 180°C). Chromatography over silica gel with chloroform eluant gave an orange zone followed by **8**. Its mp remained the same. It had ν_{max}: 3660, 3380, 3230, and 1617 cm^{-1} and λ_{max} 238.5 nm (Table 1).

Thermolysis of 13

(a) In tetramethyl urea

The 5α mesylate **13** (77 mg) in 2 mL of dry tetramethylurea (TMU) was heated in a bath at 180°C under argon for 5 h. The solvent was then removed at 100°C under 0.5 Torr pressure. A dichloromethane solution of the residue was washed with aqueous sodium carbonate. The 65 mg recovered from the

For personal use only.

dichloromethane crystallized in part from an ethyl acetate – hexane mixture giving 30 mg of enamide **17**. The mother liquor was separated on a 1 mm SiO_2 plate using 80% ethyl acetate – 20% hexane. Of the seven zones visible under UV light, three were characterized as enamide **15** (R_f 0.5, 3 mg, 5%), enamide **17** (R_f 0.33, 4 mg), and dimeric enamide **16** (R_f 0.14, 8 mg, 7%). The total yield of enamide **17** was 34 mg (57%). The yield of **17** and products related to it with the 4-azacholest-5-ene skeleton was 71% (calculated as monomer).

(b) In TMU with $CaCO_3$

For details see the comparable experiment with **14**: 71 mg of **13** and 158 mg of $CaCO_3$ in 2 mL of dry TMU under argon were stirred at 180°C for 3 h. Mesylate (3 mg) was recovered. Crystalline **17** (42 mg, 77%) was obtained, along with small amounts of **15** and **16**.

(c) In collidine

A solution of 5α-mesylate **13** in 0.8 mL of dry 2,4,6-collidine under argon was placed in a bath at 145°C. The temperature was raised to 175°C (1 h), then maintained at that temperature for 2.5 h. The bulk of the collidine was removed under 0.5 Torr pressure, and then the residue was dissolved in dichloromethane. This solution was washed with 1 N sulfuric acid, then with aqueous sodium carbonate. The 65 mg of brown residue recovered from the dichloromethane crystallized from ethyl acetate – hexane mixture, giving 40 mg of enamide **17**. Separation of the contents of the mother liquor as for (*c*) gave 8 mg of **17**; total yield 48 mg (73%).

Thermolysis of 5β-mesylate 14

(a) In tetramethylurea (TMU)

A flask containing 180 mg of mesylate **14** and 4 mL of dry TMU was flushed with argon, then heated in a bath at 180°C for 3 h. The solvent was removed under 0.5 Torr pressure, the residue dissolved in dichloromethane, then this was washed with saturated aqueous sodium bicarbonate. The aqueous layer was evaporated, finally at 60°C under 0.5 Torr pressure, leaving 179 mg of gum. This crystallized in part from 1:1 ethyl acetate/hexane giving 38 mg of **17**. Again the solvents were removed, finally at 120°C, 0.5 Torr. A ^{13}C NMR spectrum of the residue showed the presence of **17** (140.0, 103.4 ppm), **15** (135.3, 109.6 ppm), and **16** (125.1, 116.3 ppm) with carbonyl carbons at 169.7 and 169.6 ppm. No signal corresponding to an *N*-acyl imine was present.

The residue (121 mg) was separated on a 1 mm plate of C-18 coated silica gel using 30% benzene – 70% acetonitrile. The products, in order of decreasing R_f, were **15** (9 mg, 7%), unchanged mesylate (25 mg), unknown (9 mg), **17** (15 mg), and dimer **16** (47 mg, 19%). The total yield of crystalline **17** was 50 mg (41%) but the yield of products with the 4-azacholest-5-ene skeleton was 79%.

(b) In TMU with $CaCO_3$

A solution of 161 mg of **14** in 4 mL of dry TMU and 373 mg of powdered $CaCO_3$ in a flask fitted with a sintered glass funnel was flushed with argon, then heated at 180°C for 3.5 h. The cooled suspension was diluted with dichloromethane, then filtered under pressure. The solid was washed twice with dichloromethane. The filtrate was evaporated, finally at 75°C, 0.5 Torr pressure. The residue crystallized in part from dichloromethane–hexane, giving 88 mg of **17**. The products recovered from the filtrate were separated on a 1 Torr SiO_2 plate using 1:1 ethyl acetate/hexane giving, in order of decreasing R_f, recovered mesylate, 9 mg; enamide **15**, 6 mg (5%), enamide **17**, 7 mg; and enamide **16**, 12 mg (5%). The total yield of crystalline **17** was 95 mg (78%). A zone just ahead of **16** contained 9 mg of a mixture giving two main N-CH_3 or N-CH_2 signals near δ 3.0 and the steroid CH signals, i.e., these were coupling products of **17** with products such as **30**. None of these was characterized further. The use of higher ratios of $CaCO_3$ produced yields of **17** as high as 88%. A ^{13}C NMR spectrum of the total chloroform-soluble product before plating showed only low-field signals due to **17**.

(c) In 2,4,6-collidine

This was carried out as for the 5α-mesylate **13**. The yield of **17** was 80%, averaged over three runs.

(d) In methanol with $CaCO_3$

A mixture of 90 mg of **14**, 273 mg of $CaCO_3$ powder, and 5 mL of dry methanol was sealed in a tube under argon. This was heated at 190 ± 5°C for 3 h. The cooled suspension was filtered and the solid washed with methanol. The filtrate was evaporated in vacuo, finally at 60°C, 0.5 Torr pressure. The residue was suspended in dichloromethane, then filtered, giving 11 mg of insoluble solid. The filtrate yielded 74 mg of gum. The ^1H NMR and ^{13}C NMR of this residue showed only the main products described below. These were separated on a 1 mm SiO_2 plate using 1:1 ethyl acetate/hexane. The products identified were, in order of decreasing R_f, methyl keto ester **5** (R = CH_3), 12 mg (16%); carbamate **19**, 12 mg (15%); enamide **15**, 22 mg (30%); methoxy lactam **20**, 5 mg (6%); enamide **17**, 9 mg (16%).

(e) In methanol-d *with $CaCO_3$*

A solution of 116 mg of **14** in 4 mL of methanol-*d* and 244 mg of $CaCO_3$ was heated as for (*d*) but at 175°C for 4 h. The yields were **5** (R = CH_3), 9 mg (9%); **19**, 24 mg (18%); **15**, 48 mg (38%); **17**, 11 mg (12%).

The ^1H NMR spectrum of carbamate **19** showed less than 5% exchange of the hydrogens on C-2. Both enamides **15** and **17** showed approximately 50% exchange of the 6-hydrogens for deuterium (see the NMR section).

Irradiation of 13

(a) In methanol

A solution of 189 mg of 5α mesylate **13** (warming) in 55 mL of dry methanol was irradiated for 5.5 h using 254 nm Rayonet lamps (cold finger at 15°C). The bulk of the methanol was removed on a rotating evaporator, the residue was dissolved in dichloromethane, and then this solution was washed with 5% sodium carbonate. The organic layer yielded a gum that was separated on two 1 mm plates using 30% hexane – 70% ethyl acetate. The products identified were methyl keto ester **5** (R = CH_3, 4%); carbamate **18**, 57 mg (35%); methoxy lactam **20**, 42 mg (25%); enamide **17**, 12 mg (8%); and lactam **21**, 8 mg (5%).

(b) In methanol-d

A solution of 103 mg of **13** in 42 mL of methanol-*d* was irra-

For personal use only.

diated as for (*a*) with the cold finger at 23°C. The main products and yields were the same as for the photolysis in methanol. Enamide **17** had partial exchange of the vinyl hydrogen (H-6) (see NMR section)

(c) In aqueous tetrahydrofuran

A solution of 114 mg of **13** in 50 mL of tetrahydrofuran and 5 mL of water was flushed with argon. This was irradiated for 4.5 h with the cold finger at 5°C, with mixing at half-hour intervals. The solvent was evaporated on a rotating evaporator, then the product was distributed between 5% sodium carbonate and chloroform. The mixture recovered from the chloroform was dissolved in methanol, then this was titrated to pH 2 with hydrochloric acid in methanol. The solvent was evaporated to dryness and the residue suspended in ethyl acetate. This was filtered, giving 56 mg of solid (mainly **23** hydrochloride). The products in the filtrate were separated on a 0.5 mm plate using 10% ethanol in chloroform. The products identified were: **15**, 27 mg (30%); **17**, 3 mg (5%); **21**, 10 mg (11%); and **23** hydrochloride, 5 mg. The total yield of pure **23** hydrochloride was 34%.

(d) In dichloromethane

13 (103 mg) in 50 mL of dry dichloromethane was irradiated for 4 h with the cold finger at −5°C. The solvent was evaporated (bath at 40°C), then 2 mL of dry dichloromethane was added. This solution had ν_{max}: 1750 (str), 1696 (med), 1625 (wk), and 1215 (str) cm^{-1}. Methanol (2 mL) was added, then the mixture was heated for 10 min, distilling off the dichloromethane. The methanol was removed in a rotating evaporator, dichloromethane was added, then this was shaken with sodium carbonate solution. The organic layers yielded 94 mg of neutral and basic products. Acetic anhydride (1 mL) was added. After 20 h at room temperature the anhydride was removed in vacuo, the residues were heated with methanol, and then the mixture was evaporated again. A dichloromethane solution of the residue was washed with sodium carbonate solution, dried, and then the solvent was distilled, giving 86 mg of gum. This was separated on a 1 mm plate using 10% hexane – 80% ethyl acetate giving, in order of decreasing R_f, carbamate **19**, 21 mg (24%); unknown, 4 mg; unknown, 6 mg; *N*-acetyl derivative **27**, 10 mg (12%); unknown (origin), 11 mg. The estimated yield of products having the A-nor skeleton **23** was 36%.

(e) In moist dichloromethane

A dichloromethane solution (70 mL) of **13** (243 mg) was irradiated (cold finger at 15°C, stirring at intervals) for 5 h. The solution was washed with aqueous sodium carbonate, dried, and evaporated. The residue in 1 mL of acetic anhydride and 1 mL of pyridine was heated to give a clear solution. After 18 h at room temperature the mixture was worked up as in (*d*), giving 228 mg of product. This was separated on three 1 mm plates as for (*d*,) giving in order of decreasing R_f: urea **25**, 30 mg (9%); unchanged **13**, 28 mg; enamide **15**, 29 mg (16%); unknown, 12 mg; an unknown, 10 mg; and *N*-acetyl derivative **27**, 50 mg (29%). The yield of products with the A-nor skeleton **23** was 29% + (2 × 9%) = 47%.

Irradiation of 14

(a) In methanol

Mesylate **14** (188 mg) in 45 mL of dry methanol was irradiated under argon with the cold finger at 10°C for 4.5 h, with mixing at 1 h intervals. The methanol was evaporated and the residue dissolved in dichloromethane, then this solution was washed with aqueous sodium bicarbonate. The 165 mg of colorless oil was separated on two 1 mm plates using 30% hexane – 70% ethyl acetate. Recovered mesylate **14** (17 mg) was followed in order of decreasing R_f by carbamate **19**, 56 mg (38%); methoxy lactam **20**, 47 mg (32%); and enamide **17**, 14 mg (10%).

(b) In methanol-d

A solution of **14** (122 mg) in 30 mL of methanol-*d* was irradiated (cold finger at 23°C) for 4 h. Work-up and separation as for (*a*) gave 14 mg of unchanged **14**; carbamate **19**, 35 mg (32%); enamide **15**, 4 mg (5%); methoxy lactam **20**, 11 mg (12%); and **17**, 9 mg (10%). ^{1}H NMR spectra of **15** and **17** showed partial exchange of H-6 for deuterium. Carbamate **19** showed less than 5% exchange of the 2-hydrogens (see NMR section).

(c) In aqueous tetrahydrofuran

A solution of 212 mg of **14** in 100 mL of tetrahydrofuran and 10 mL of water was irradiated in two equal portions as for **13**. In the work-up, ether was used to precipitate the hydrochloride (50 mg). The filtrate was evaporated and the residue separated on two 1 Torr plates using 15% hexane – 75% ethyl acetate. The products characterized in order of decreasing R_f were enamide **15**, 48 mg (28%); enamide **17**, 11 mg (6%); and lactam **22**, 19 mg (11%). The low R_f zone was extracted with hot methanol in chloroform. After evaporation of the solvent the extract was treated with 1:1 acetic anhydride/pyridine, giving *N*-acetyl derivative **28**, 9 mg (5%). The total yield of products related to A-nor base **24** was 33%.

(d) In dichloromethane

1. Dry, methanol work-up: Following irradiation of 102 mg of **14** as for **13** but at 15°C, 10 mL of methanol was added. After 0.5 h the solvents were evaporated under reduced pressure. The residue was dissolved in dichloromethane, then the solution was washed with aqueous sodium carbonate. The dried solution was evaporated. The residue was suspended in chloroform, filtered from a small amount of inorganic solid, and then separated on a 1 mm plate using 30% hexane – 70% ethyl acetate. The products characterized were carbamate **19**, 15 mg (19%); recovered **14**, 10 mg; and enamide **15**, 9 mg (12%). The low R_f zone was treated as in (*c*) yielding **28**, 8 mg (10%).

2. Dry dichloromethane (55 mL) containing 118 mg of **14** was irradiated for 4 h with the cold finger at 5°C. Moisture was probably introduced during stirring. The solution was shaken with aqueous sodium carbonate, dried, and distilled. The residue was acetylated using acetic anhydride and pyridine (20 h). The product after removal of the reagents under 1 Torr pressure was dissolved in dichloromethane. This solution was washed with 1 N sulfuric acid, then with 5% sodium carbonate. The dried solution gave 100 mg of gum, which was separated on a 1 mm plate using 2% methanol in chloroform. The products identified were urea **26**, 10 mg (6%); recovered mesylate, 11 mg; enamide **16**, 15 mg (17%); and *N*-acetyl derivative **28**, 16 mg (19%).

(e) In dichloromethane with triethylamine

Mesylate **14** (58 mg) and triethylamine (20 mg) in 50 mL of

For personal use only.

dry dichloromethane were irradiated under argon with the cold finger at 20°C for 3 h. The solvent was evaporated on a rotating evaporator in a bath at 40°C, then the residue put under 0.5 Torr pressure at 40°C. The residue had ν_{max}: 1743, 1686, 1614, and 1037 cm^{-1}. Its ^{13}C NMR spectrum (500 MHz) had the olefinic and carbonyl peaks of **15** as dominant, but also minor ones of unknown origin at 175.5, 162.9, 146.3, 144.8, and 136.6. A signal at 89.05, corresponding to a carbon carrying two hetero atoms, is also unassigned.

The product recovered from the $CDCl_3$ was heated briefly in methanol, then left in solution for 2 h at room temperature. After removal of the methanol the infrared spectrum was retaken. The 1743 cm^{-1} band was completely gone but the 1686 and 1614 cm^{-1} peaks remained. A dilute dichloromethane solution was shaken with aqueous sodium carbonate. The organic layer gave 55 mg of brown gum. This was acetylated using acetic anhydride. The neutral products were then separated on a 1 Torr plate using 30% hexane – 70% ethyl acetate. The major components were carbamate **19**, 13 mg (28%); recovered **14**, 4 mg; enamide **15**, 6 mg (14%); and *N*-acetyl derivative **28**, 6 mg (13%).

*Enamide **15***: This crystallized from ethyl acetate – hexane as fine needles, mp 134°C. For its UV spectrum, see Table 1. It gave ν_{max}: 1690 and 1180 cm. Its EI mass spectrum had peaks at *m/z* 385.3345 (M^+), 370, 272, 173, and 137 (base peak); calcd. for $C_{26}H_{43}NO$: 385.3344. Its CI mass spectrum had peaks at *m/z* 386 ($M^+ + 1$) and 370 ($M^+ - CH_3$).

*Bis(4-aza-3-oxocholest-5-en-6-yl)-methane **16***: This remained amorphous. Its UV absorption is listed in Table 1. It had ν_{max}: 3390 and 1667 cm.

*4-Azacholest-5-en-3-one **17***: This crystallized from dichloromethane – ethyl acetate as short needles, mp 253°C (immersed at 243°C), 258–260°C (immersed at 230°C in an evacuated capillary (lit. (3*a*) mp 256°C). Its ultraviolet spectrum is listed in Table 1. It had ν_{max}: 3380, 3185, 1681 (med), and 1661 (str) cm^{-1}.

N-*Methoxycarbonyl 3-aza-A-nor-5α-cholestane **18***: This formed fine needles from methanol, mp 128–129°C. It had ν_{max}: 1695 and 1124 cm^{-1}. The mass spectrum in CI mode showed a strong $M^+ + 1$ ion at *m/z* 418 and in EI mode an M^+ ion at *m/z* 417.

N-*methoxycarbonyl-3-aza-A-nor-5β-cholestane **19***: This crystallized from aqueous methanol as hexagonal plates with mp 88°C. It had ν_{max}: 1691, 1135, and 1105 cm^{-1}. Its CI mass spectrum had peaks at *m/z* 418 ($M^+ + 1$), 402 ($M^+ + 1$) $- CH_4$), and 386 ($M^+ + 1 - CH_3OH$). Its structure was determined by X-ray crystallography (unpublished work by Professor C. Bensimon, University of Ottawa).

*4-Aza-5-methoxy-A-nor-B-homocholestan-3-one **20***: This crystallized as rods from cold hexane, mp 82–83°C. It had ν_{max}: 1682 and 1089 cm^{-1}. Its CI mass spectrum gave *m/z* 387 ($M - 31 + H^+$).

*4-Aza-5α-cholestan-3-one **21***: This crystallized from methanol as short needles, mp 250–252°C (lit. (5) mp 252°C) and had ν_{max}: 3380, 3190, and 1659 cm^{-1}.

*4-Aza-5β-cholestan-3-one **22***: This crystallized from ethyl acetate, mp 189–190°C, which disagrees with the literature value of 151–155°C (5) (dimorphic ?). It had ν_{max}: 3380 and 1658 cm^{-1}.

*3-Aza-5α-A-norcholestane hydrochloride (**23** hydrochloride)*: The hydrochloride of **23** crystallized as fine needles from dichloromethane – ethyl acetate, mp 262°C (dec.) when heating was started at 245°C.

*3-Aza-5β-A-norcholestane hydrochloride (**24** hydrochloride)*: The hydrochloride of **24** crystallized from methanol – ethyl acetate as small plates or needles, mp 258°C (dec.) when heated from 245°C.

*Urea **25***: After purification using a preparative plate and 1:1 dichloromethane/hexane (R_f 0.3) and crystallization from methanol – ethyl acetate, **25** formed fine needles, mp 236–242°C. It had ν_{max} 1627 cm^{-1}.

*Urea **26***: The 5β urea **26** crystallized from dichloromethane – methanol or ethyl acetate, mp 250–252°C. It had ν_{max} 1626 cm^{-1}.

N-*Acetyl-3-aza-5α-A-norcholestane **27***: This was hard to free from a trace of UV – visible contaminant. Recrystallization from methanol gave **27** as fine needles, mp 122–123°C. It had ν_{max} 1642 cm^{-1}.

N-*Acetyl-3-aza-5β-A-norcholestane **28***: Preparative TLC (2% ethanol in chloroform (R_f 0.2), then 80% ethyl acetate – 20% hexane) failed to remove a trace of UV-active impurity. Recrystallization from hexane, then aqueous methanol, gave **28** as flat needles, mp 94°C. It gave ν_{max} 1641 cm^{-1}.

*A-Nor-β-homo-4-azacholestan-3-one **32***
A suspension of 26 mg of 10% Pd on charcoal in 4 mL of 95% ethanol was saturated with hydrogen, then 36 mg of enamide **15** was added. Uptake of 2.5 mL (1.1 mol) of hydrogen was rapid. The filtrate from removal of the catalyst was evaporated. The residue was suspended in hexane, then filtered from a trace of insoluble product. A concentrated hexane solution gave twisted hair-like crystals of **32**, mp 117–118°C. This had ν_{max} 1665 cm^{-1}.

*Action of methanesulfonic acid on **17** in TMU*
A solution of 125 mg of **17** and 98 mg of methanesulfonic acid in 5 mL of tetramethylurea was heated in a bath at 180°C under argon for 3 h. The solvent was removed under 1 Torr pressure in a bath at 60°C, the residue was dissolved in dichloromethane, and this was washed with aqueous sodium carbonate. The dried dichloromethane solution yielded 129 mg of gum after evaporation and heating at 100°C under 0.1 Torr pressure. This crystallized from a hexane–dichloromethane mixture, giving 53 mg of recovered enamide **17**. The mother liquor was evaporated and the residue separated on a 1 Torr silica gel plate using 80% ethyl acetate – 20% hexane mixture. The products in order of decreasing R_f were enamide **17**

© 1997 NRC Canada

(12 mg; total recovered 62 mg), unknown (14 mg), and enamide **16** (30 mg). The yield of **16** was 50% based on unrecovered **17**.

4-Aza-6-ethoxymethylcholest-5-en-3-one 31

A solution of paraformaldehyde (59 mg), *p*-toluenesulfonic acid hydrate (8 mg), and *p*-toluenesulfonic anhydride (14 mg) in 3 mL of dry chloroform and 0.3 mL of absolute ethanol was prepared. After addition of 48 mg of enamide **17** the mixture was heated in a bath at 60°C for 24 h. A crop of crystals was removed by filtration, then the filtrate was evaporated to small volume. The residue was dissolved in chloroform, and the solution was shaken with aqueous sodium carbonate, dried, and distilled, leaving 63 mg of product. This was separated on a 1 mm plate using 5% ethanol in chloroform. The main ultraviolet–visible zone yielded 34 mg of crude **31**, which crystallized from ethyl acetate – hexane to give 26 mg, mp 143°C (47%). Recrystallization of this from hexane gave **31** with mp 146–148°C after sintering at 143°C (heating started at 135°C). It had ν_{max}: 3310 and 1659 cm^{-1}. For λ_{max} see Table 1.

Coupling of 6-ethoxymethyl enamide 31 and enamide 17

A mixture of 16 mg of 4-aza-6-ethoxymethylcholest-5-en-3-one **31**, 4.7 mg of *p*-toluenesulfonic acid hydrate, 7.7 mg of *p*-toluenesulfonic anhydride, and 14 mg of enamide **17** in 3 mL of dry ethanol-free chloroform was left in a bath at 65°C under argon for 4 h. The cooled solution was extracted with aqueous sodium bicarbonate, dried, and distilled. The residue was separated on a 1 mm SiO_2 plate using 5% methanol in ethyl acetate. The main UV – visible zone yielded 26 mg (91%) of product, identified as the dimeric enamide **16** by ^1H and ^{13}C NMR.

Enamide 15 and acetic acid

A solution of **15** (21 mg) in 1 mL of acetic acid and 17 mg of acetic anhydride containing 9 mg of toluenesulfonic acid hydrate was left at room temperature for 2 days. After addition of 21 mg of sodium bicarbonate and 0.05 mL of water the mixture was stirred for 1 h. It was then evaporated to small volume on a rotating evaporator (bath at 55°C), finally under 0.5 Torr pressure. The residue was extracted with dichloromethane, filtered, then the filtrate evaporated, finally under 0.5 Torr. The residue gave an ^1H NMR spectrum identical to that of **15**.

Action of acids on enamide 17

(*a*) Dry hydrogen chloride was bubbled into a solution of 65 mg of **17** in 4 mL of dry ethanol-free chloroform at 0°C for 5 h. The residue from evaporation of the solvent crystallized from ethyl acetate giving 55 mg (84%) of unchanged **17**. The mother liquor contained a mixture of products (TLC) giving ^{13}C NMR signals at 132.5, 130.9, and 128.8 ppm.

(*b*) A solution of 138 mg of **17** and 89 mg of *p*-toluenesulfonic acid hydrate in 10 mL of dry methanol (heat) was left overnight, then refluxed for 6 h. The residue after evaporation of the solvent (rotating evaporator) was dissolved in dichloromethane. After washing with aqueous sodium carbonate and drying (Na_2SO_4), this was evaporated, yielding 140 mg of semi-crystalline solid. This was suspended in methanol and filtered, giving 46 mg of unchanged **17**. The contents of the filtrate were separated on a 1 mm SiO_2 plate using 5% methanol in chloroform. The highest R_f component (53 mg) proved, by IR and ^1H NMR to be **5** (R = CH_3). Other than another 13 mg of **17**, the other minor products were not identified.

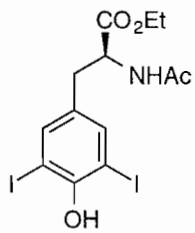
Synthesis of thyroxine: biomimetic studies

Natalie V. Bell, W. Russell Bowman, Paul F. Coe, Andrew T. Turner, and Del Whybrow

Abstract: The biomimetic oxidative coupling of the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) to yield the ethyl ester of *N*-acetylthyroxine (**2**) has been investigated. A putative mechanism involving phenolic coupling to yield an intermediate aryloxydienone (**7**) followed by an E2 elimination for loss of the side chain has been proposed. Oxidative couplings with analogous 4-substituted 3,5-diiodophenols indicate that a number of mechanisms are possible; these include quinone methide intermediates and S_N2 substitutions in the intermediate aryloxydienones. Rearomatization of the intermediate aryloxydienones is a strong driving force for the loss of the side chains. The results indicate that 3,5-diiodo-4-aryloxydienones are good leaving groups in E2 and S_N2 mechanisms. The synthetic method provides a facile synthesis of thyroxine analogues from readily available 4-substituted 3,5-diiodophenols.

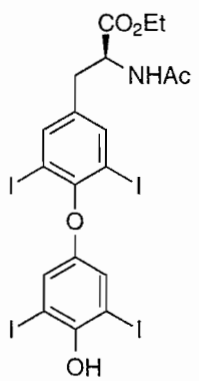
Key words: diiodotyrosine, phenolic coupling, phenoxyl radicals, thyroxine.

Résumé : On a étudié le couplage oxydant biomimétique de l'ester éthylique de la *N*-acétyl-3,5-diiodotyrosine (**1**) qui conduit à l'ester éthylique de la *N*-acétylthyroxine (**2**). On propose un mécanisme impliquant un couplage phénolique conduisant à un intermédiaire aryloxydiénone (**7**), suivi d'une élimination E2 impliquant la perte de la chaîne latérale. Des couplages oxydants avec des 3,5-diiodophénols substitués d'une façon analogue en position 4 indiquent qu'un certain nombre de mécanismes possibles incluent des intermédiaires quinométhanes et des substitutions S_N2 dans les aryloxydiénones intermédiaires. La réaromatisation des aryloxydiénones intermédiaires fournit une importante force motrice pour la perte des chaînes latérales. Les résultats indiquent que les 3,5-diiodo-4-aryloxydiénones sont de bons groupes partants dans les mécanismes E2 et S_N2. La méthode de synthèse permet de préparer facilement des analogues de la thyroxine à partir de 3,5-diiodophénols substitués en position 4 facilement disponibles.



Mots clés : diiodotyrosine, couplage phénolique, radicaux phényloxyles, thyroxine.

[Traduit par la rédaction]



Introduction

Oxidative coupling of phenols is well researched (1), has been known for more than a century, and was first invoked in biosynthesis over 50 years ago. The biomimetic synthesis and biosynthesis of the hormone thyroxine from 3,5-diiodotyrosine provides one of the most interesting and unusual examples of oxidative coupling of phenols. The two diiodotyrosine units make up part of the thyroglobulin protein responsible for thyroxine biosynthesis in the thyroid gland and the coupling is catalyzed by the enzyme, thyroid peroxidase. The coupling of two molecules of 3,5-diiodotyrosine to form thyroxine was first proposed as early as 1927 (2) and biomimetic studies were first carried out in 1942 (3). Study of the biosynthesis continues to produce interesting results in the elucidation of the mechanism (4).

One of the industrial syntheses of thyroxine involves a step in which the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) is subjected to phenolic coupling to yield the ethyl ester of *N*-acetylthyroxine (**2**) in good yield. While the reaction conditions are obviously different from those in the biological system the crucial coupling step can be regarded as biomimetic. For instance, the phenolate anion is oxidized to phenoxyl radicals, followed by coupling and elimination of one the tyrosine side chains. In this paper we report our studies to elucidate the

[d]Acetic acid was used in place of aqueous ethanol as the solvent.

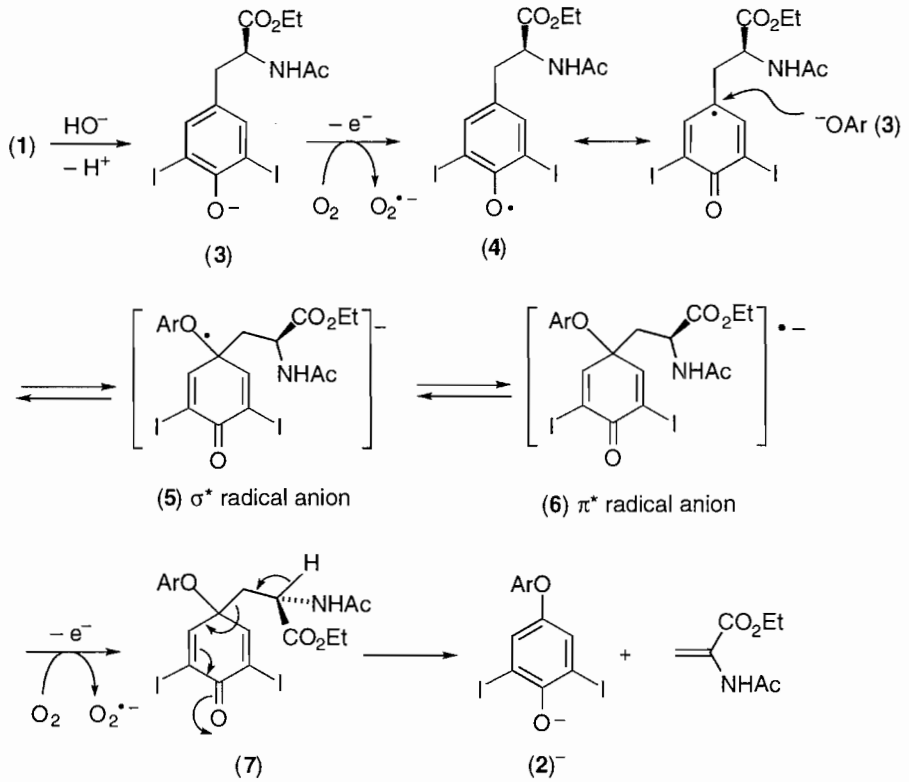
mechanism of this coupling/elimination step and to determine the generality of this unusual reaction. A competing non-radical reaction takes place at low pH to yield C—C *ortho-ortho* coupling to give the corresponding dityrosines and will be reported in a future publication. Electrochemical studies of the oxidation of diiodophenols and their phenolates will also be reported in a future publication.

There is growing evidence to suggest that an α,β-dehydroalanine unit is left in the protein chain after elimination of the side chain, which is subsequently hydrolyzed (4–6). An E2 mechanism to explain the loss of side chain has been proposed since 1944 (7) but none of the studies have clearly proven the identity of the eliminated fragment (2–12). This mechanism has replaced an early and well-studied proposal (8–12), which suggested that the side chain was oxidized prior to coupling to the corresponding α-ketoacid, 3,5-diiodo-4-hydroxyphenylpyruvic acid. A number of biological processes, including transamination catalysed by transaminases with the coenzyme pyridoxal phosphate, readily convert α-amino acids to α-ketoacids (8). This proposal was supported by biomimetic reactions with 3,5-diiodo-4-hydroxyphenylpyruvic acid and 3,5-diiodotyrosine, which gave small yields of thyroxine (9–12). No clear mechanism was proposed for loss of the pyruvate side chain.

Oxidative coupling of the ethyl ester of *N*-acetyl-3,5-diiodotyrosine

The reaction conditions employed in the industrial synthesis involve oxidation of the phenolate anion of the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) in aqueous ethanol solution at ca. 60–65°C and under pressure for 20 h. The oxidant is molecular oxygen. The solution contains catalytic amounts of manganese(II) sulfate and the pH is controlled to 9.2–9.4 by using sodium hydroxide. The reactions were carried out under various conditions to determine the parameters of the reaction and the results are shown in Table 1. The effects of time, temperature, and pressure are as expected (experiments 1–3). Longer reactions gave higher yields. Oxygen was shown to be essential (experiments 4 and 5) with no reaction taking place under an atmosphere of nitrogen.

The effect of the Mn(II) was also tested in concurrent reactions (experiments 6 and 7). The difference in yields between reactions carried out with or without Mn(II) is relatively small and therefore its effect is possibly secondary. Mn(II) is oxidized by oxygen to Mn(III), which could act as an oxidant. However, the use of $Mn(IV)O_2$ or $Mn(III)(OAc)_3$ in place of $Mn(II)SO_4$ in the absence of oxygen (nitrogen atmosphere) gave only unaltered **1**, indicating that Mn(III) is not the primary oxidant in the reaction and is not able to replace oxygen as the oxidant (experiments 8–10). The use of Mn(III) as an oxidant of enols from β-dicarbonyl compounds in radical reactions has been extensively studied in recent years (13) and the diiodophenols could be regarded as suitable substrates for $Mn(III)(OAc)_3$ oxidations. Oxidation of **1** with $Mn(III)(OAc)_3$ in acetic acid also failed to yield any of the thyroxine derivative **2**. Studies of possible oxidation of the amino acid side chain by Mn(III)/Mn(II) were carried out using the ethyl ester of *N*-acetylphenylalanine and also proved negative.



Superoxide is almost certainly formed and could be predicted to attack the starting diiodophenol or intermediate phenoxyl radicals but no evidence of such products was observed. Superoxide has been reported to rapidly add to tyrosine and tyrosinyl radicals (14). All reactions were particularly clean and only contained starting diiodophenol and coupled product.

We propose the mechanism shown in Scheme 1. Our results provide further evidence that oxygen oxidizes the phenolate anion (**3**) to the phenoxyl radical (**4**), which rapidly reacts with further phenolate anion to yield an intermediate radical anion (**5**). Dimerization of the phenoxyl radical (**4**) to yield the dienone (**7**) as suggested in earlier studies (1) for phenolic oxidation is unlikely. The phenoxyl radical is present in low concentration whereas the anion is present in high concentration and, therefore, the rate of reaction between phenoxyl (**4**) and phenolate (**3**) will be much faster than the rate of reaction between two molecules of the phenoxyl radical (**4**). The intermediate radical anion (**5**) will initially hold the unpaired electron in an unstable C—O σ* molecular orbital (MO). Rapid reorganization of MOs will give the more stable π* intermediate (**6**). Loss of the electron to molecular oxygen will be extremely rapid but reversible.

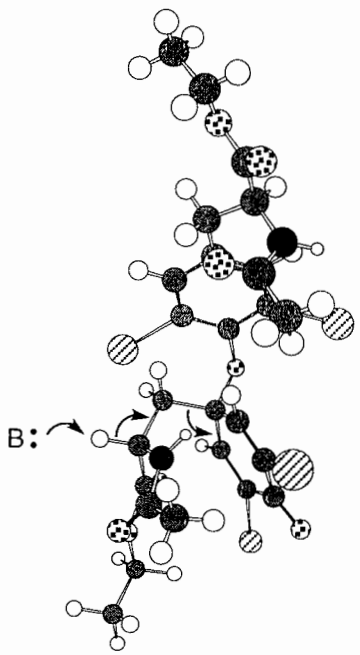
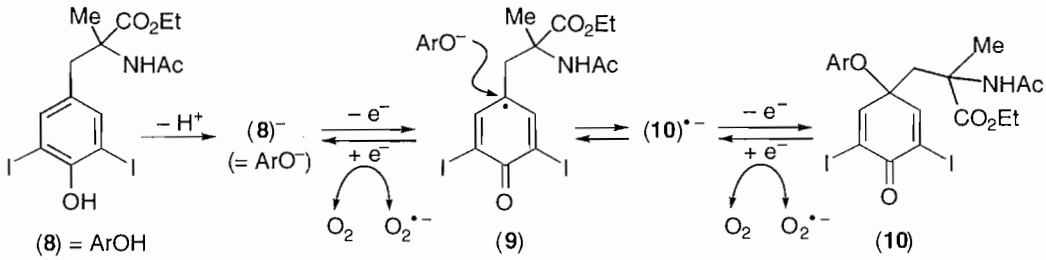


Scheme 1. Putative mechanism for phenolic coupling of the ethyl ester of *N*-acetyltyrosine (**1**).

E2 elimination is the best explanation for loss of the side chain and has been proposed by several research groups (4–7, 15). The elimination must be fast, otherwise the dienone would accumulate in the reaction. E2 elimination with a dienone as a leaving group coupled with rearomatization as a driving force has been known for some time in the biosynthesis of alkaloids that proceed via phenolic coupling. A useful example has been reported in the biosynthesis of erythrina alkaloids (16). Elementary molecular modelling of the intermediate aryloxydienone (**7**) using Chem3D and MM2 packages showed a localized energy minimum with the acetamidoester α-hydrogen lining up at exactly 180° to the dienone leaving group (Fig. 1). This is the correct conformation required for E2 elimination. The predicted product of E2 elimination is ethyl 2-acetamidopropenoate. Another potential product is the ethyl ester of *N*-acetylserine formed by addition of hydroxide to the β-position of the α,β-unsaturated ester. Both were synthesized and used as standards in all the analyses of coupling reactions. Disappointingly, no signs of these products were observed by ^{1}H NMR spectroscopy or TLC and HPLC analysis of product mixtures. However, both were found to be unstable under the vigorous conditions of the reactions, which could explain their absence. Further study is required to ascertain the product of elimination of the side chain.

This unusual reaction and the uncommon presence of iodine in nature deserves some comment. Interestingly, the most active thyroxine hormone species is the triiodo analogue, 3,5,3′-triiodo-L-thyronine. Therefore, for maximum hormone activity, one of the iodine atoms is lost. We propose that the

Fig. 1. E2 elimination in intermediate dienone (**7**). MM2 model.



iodine atoms serve a number of functions. Firstly, they are required to encourage the elimination of the side chain by making the dienone a better leaving group. Secondly, the pK_a of 3,5-diiodotyrosine is 6.35 which is ca. 100 times more acidic than 3-iodotyrosine (pK_a = 8.7). Therefore, 3,5-diiodo-

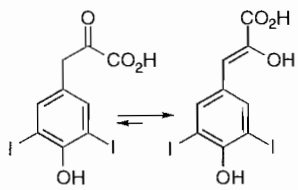
Scheme 2. Reversible coupling with E2 elimination blocked.

tyrosine is ionized at physiological pH. Phenols are most easily oxidized when ionized as the phenolate anion and would not be oxidized by oxygen in the non-ionized phenol form.



The large size of the iodine atoms may also play a role in sterically directing the coupling to give *para* regioselectivity. Molecular modelling (MM2) indicates that coupling between the oxygen centre of the phenolate and the radical, localized on the *ortho* position of the phenoxyl radical, is sterically hindered. In the attacking phenolate anion, the oxygen centre is sterically hindered by the very large *ortho*-iodine atoms. Both *ortho* positions of the phenoxyl radical also have large iodine substituents that are planar with the ring. The methylene group in the *para* position is much smaller and rotation allows the α-acetamidoester group to swing out of the way. Therefore, this lower steric hindrance may facilitate faster attack by the phenoxide at the *para* position rather than at the *ortho* position. However, this regioselectivity may also be explained by the fact that the electron density in phenoxyl radicals is higher at the *para* position than in the *ortho* position.

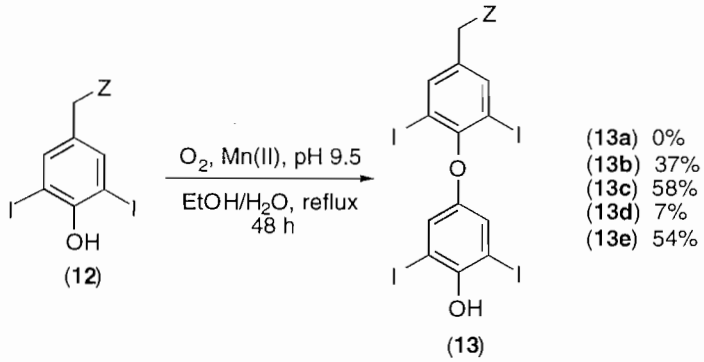
Attempted oxidative coupling of ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)-2-methylpropanoate (8)

Isolation of the intermediate aryloxydienone (**7**) would provide strong evidence for the mechanism proposed in Scheme 1. We reasoned that if the α-position of the acetamidoester was substituted by a methyl group instead of a hydrogen, E2 elimination would be blocked and allow isolation of an aryloxydienone intermediate, e.g., **10** in Scheme 2. With this aim in mind, the α-methyl derivative of the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**), ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)-2-methylpropanoate (**8**), was synthesized. The α-methyl analogue **8** was oxidized using the standard conditions under atmospheric pressure for 48 and 96 h. Only unaltered **8** was recovered, in quantitative yield. The α-methyl group is not able to affect the reactivity of the oxidation of the phenolate or the coupling process relative to the phenolate of **1**, only the elimination is blocked. Therefore, to explain the apparent lack of reaction, we propose that all the steps are reversible. Thus, if elimination is blocked, the intermediate aryloxydienone **10** is reduced and reverts to starting phenolate via the radical anion **10**$^{\bullet-}$] and the phenoxyl radical (**9**) (Scheme 2). The reversibility of phenolic coupling has been clearly demonstrated for some of the reactions of 2,4,6-tri(*tert*-butyl)phenol (15). In this coupling E2 elimination from the intermediate aryloxydienone is very slow. In the presence of reductants the dienone reverts to phenolates.

Oxidative coupling between (3,5-diiodo-4-hydroxyphenyl)pyruvic acid (11) and the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (1)

Early proposals (8–12) suggested that the side chain of 3,5-diiodotyrosine was oxidized to the corresponding α-ketoacid, (3,5-diiodo-4-hydroxyphenyl)pyruvic acid (**11**), prior to coupling. To test this hypothesis, equimolar amounts of **1** and **11** were reacted under similar conditions under pressure at 60–70°C and at room temperature. Thyroxine **2** was obtained in 11 and 7% yields, respectively (yield based on **1**), and unaltered **1** was recovered (89, 93%, respectively). A large amount of decomposition products resulting from **11**, which included

(**11**)



3,5-diiodo-4-hydroxybenzaldehyde, were observed. Reaction between 3,4-diiodotyrosine and **11** at room temperature and pressure in ethanol–water with sodium hydroxide, pH 7–8.5, and oxygen has been reported (11, 15) to give low yields of thyroxine (5–15%). Reaction between **1** and **11** at room temperature and pressure gave similar yields (**2**, 6 and 2%). The ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) does not undergo coupling under these conditions. Considerable attempts were made to improve yields but without success. Our results also confirmed that 3,5-diiodo-4-hydroxyphenylpyruvic acid breaks down rapidly at higher pH to yield 3,5-diiodo-4-hydroxybenzaldehyde and other decomposition products (11, 15).

Studies were also carried out to show that 3,5-diiodo-4-hydroxybenzaldehyde and 3,5-diiodo-4-hydroxybenzoic acid, potential breakdown products from (3,5-diiodo-4-hydroxyphenyl)pyruvic acid **11**, were not involved in the synthesis of **2**. A 2:3 molar ratio of **1** and 3,5-diiodo-4-hydroxybenzaldehyde, and **1** and 3,5-diiodo-4-hydroxybenzoic acid, were reacted under similar conditions under pressure at 60–70°C to yield thyroxine **2** (20 and 18%, respectively) and unaltered **1** (80, 82%) and quantitative recovery of 3,5-diiodo-4-hydroxybenzaldehyde and 3,5-diiodo-4-hydroxybenzoic acid. The yields of **2** (see Table 1) are unaltered by the addition of 3,5-diiodo-4-hydroxybenzaldehyde and 3,5-diiodo-4-hydroxybenzoic acid, indicating that they play no role in the coupling.

Scheme 3. Oxidative coupling of 2,6-diiodo-4-substituted phenols.

(**a**), Z = CH_2CO_2Et; (**b**), Z = CH_2NHAc, (**c**), Z = H; (**d**), Z = CH_2CH_3; (**e**), Z = CO_2Et

Scheme 4. Putative S_N2 mechanism for side-chain loss.

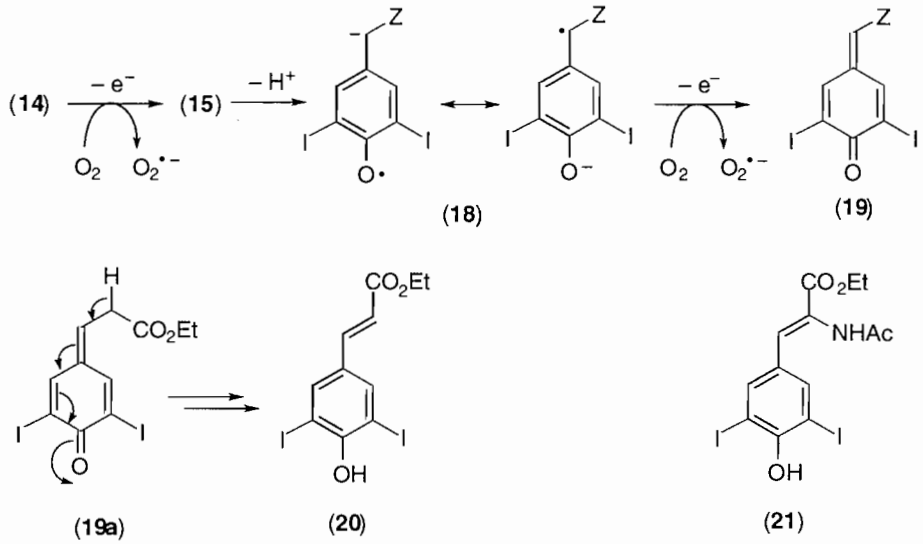
The possibility of side-chain oxidation prior to phenolic coupling to yield 3,5-diiodo-4-hydroxyphenylpyruvic acid was investigated using the methyl ester of *N*-acetylphenylalanine as a model without the complication of the phenolic group. A number of oxidative conditions similar to those in the coupling of the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) were used, including potassium ferricyanide and hydroxide, $Mn[(III)OAc]_3$ or $Mn(III)(acac)_3$ in methanol or acetic acid and under nitrogen or oxygen, and $Mn(II)(OAc)_2 \cdot 2H_2O$ and $Mn(II)SO_4$ in ethanol–water under an atmosphere of oxygen at normal pressure and under 5 bar pressure at 60–65°C for 20 h (1 bar = 100 kPa). While the substrate is not necessarily comparable, the reactions indicate that the side chain is not readily oxidized under the general conditions of the reaction.

In summary, these results indicate that prior oxidation of the side chain is not a route for the oxidative coupling of **1** even though the corresponding pyruvate (**11**) does facilitate a small amount of coupling at room temperature.

Oxidative coupling of 2,6-diiodo-4-substituted phenols

To further investigate the mechanism, the oxidative coupling of a range of 2,6-diiodo-4-substituted phenols (**12a**–**12e**) was investigated (Scheme 3). The same procedure as for the oxidative coupling of the ethyl ester of *N*-acetyl-3,5-diiodotyrosine under atmospheric pressure was used. Yields were not optimized. Analogues **12a** and **12b** were investigated because they have one group removed compared to the tyrosine (**1**). The ester **12a** was predicted to behave like **1** because it has an acidic α-H for E2 elimination whereas **12b** does not and differences in mechanism were expected. However, the tyramine analogue **12b** gave a good yield of the thyroxine analogue **13b** (37%) whereas **12a** yielded ethyl 3-(3,5-diiodo-4-hydroxyphenyl)propenoate (**15**) (53%) and no traces of the corresponding thyroxine analogue **13a**. 2,6-Diiodophenols **12c**, **12d**, and **12e** also gave corresponding thyroxine analogues, **13c** (58%), **13d** (7%), and **13e** (54%). All the reactions were faster than the tyrosine (**1**) reaction, indicating alternative mechanisms with faster rates of reaction.

Ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)propenoate (**21**), 3,5-diiodo-4-hydroxybenzaldehyde, and 3,5-diiodo-4-hydroxybenzoic acid do not undergo coupling under the same reaction conditions and are recovered unaltered.



The E2 mechanism shown in Scheme 1 cannot be used to explain the formation of the thyroxine derivatives **13c**–**13e** because the 2,6-diiodophenols **12c**, **12d**, and **12e** do not have a hydrogen β to the aryloxydienone leaving group. The β-hydrogen is required for an E2 elimination for removal of the side chain from the intermediate aryloxydienone. We propose that an S_N2 mechanism is operative (Scheme 4). If the aryloxydienone is a good leaving group in an E2 elimination for the aryloxydienone **7**, then it should also be able to act as a leaving group in S_N2 substitutions. S_N2 substitution is not normally favoured on a "neopentyl" type carbon because of steric hindrance. However, in the "neopentyl" system the bulky group is orthogonal to the incoming nucleophile and leaving group, whereas in this mechanism the bulky group is the leaving group and is at 180° to the nucleophile; therefore steric hindrance is not a major problem.

The S_N2 mechanism (Scheme 4) is also a good explanation for the mechanism of formation of the thyroxine derivative **13b**. The hydrogen α to the acetamido group is not acidic and therefore an E2 elimination, although possible, is not

Scheme 5. Quinone methide mechanism.

favoured. However, the S_N2 mechanism for the elimination of the side chains from aryloxydienones **7** and **10**, resulting from the tyrosines **1** and **8**, would be unfavourable. The sterically bulky groups α to the carbon center under S_N2 attack would severely hinder S_N2 attack by nucleophiles. The α-"neopentyl" group in the dienone intermediate **10** would make S_N2 substitution very unfavourable. Both S_N2 and E2 mechanisms are unfavourable for the reaction of **8**, which helps to explain the lack of reactivity. The formation of ethyl 3-(3,5-diiodo-4-hydroxyphenyl)propenoate **20** from **12a** has to be explained by a faster competing reaction than coupling followed by S_N2 or E2 mechanisms. A possible mechanism is removal of the acidic proton α to the ester to yield an anion. This would allow oxidation with addition of oxygen to yield an intermediate α-peroxyl ester. E2 elimination would be favoured and yield to the conjugated alkene present in **20**.

An alternative explanation for the formation of ethyl 3-(3,5-diiodo-4-hydroxyphenyl)propenoate **15** from **12a** may be the intermediacy of a quinone methide (**19a**) (Scheme 5). Loss of a proton from the intermediate phenoxyl **15** to form a quinone methide radical anion (**18**) is likely to be fast if planarity can be readily achieved. Loss of a proton from radicals is generally favoured because of enhanced acidity (17), e.g., hydroquinone, pK_a = 9.9, 4-hydoxyphenoxyl, pK_a = 4.1. The benzylic hydrogen in **15a** is more acidic than phenoxyls **15b**–**15d** due to the β-effect of the ester group. Loss of an electron from the radical anion **18** to yield the quinone methide **19** will be extremely fast in the presence of oxygen. Similarly, the rearomatization of the quinone methide **19a** to yield **20** will be fast. Deprotonation in the quinone methides **19b** and **19d** is unlikely and does not take place.

The formation of this unusual unsaturated product (**20**) begs the question why the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) does not also proceed by this route to ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)propenoate (**21**). If the proposal that prior side chain oxidation (8–12) was important, either via phenolic oxidation or α-amino acid oxidation, then a likely product would be the side-chain unsaturated intermediate **21**. This proposal requires side-chain oxidation, followed by phenolic oxidation of the new intermediate, and then coupling to **1**. The phenolate of **1** would be more nucleophilic than the phenolate of **21** and hence be predicted to react faster in the coupling reaction.

When **21** was reacted under the standard coupling conditions under pressure, the only isolable product was 3,5-diiodo-4-hydroxybenzaldehyde, which is stable under the conditions. This hydrolytic cleavage is explained by hydroxide addition to the β-position of the α,β-unsaturated ester followed by a retro-aldol reaction (11, 15). When **21** was oxidized under the same conditions with the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) in the same reaction (**21**:**1**, 3:2), only the normal amount (11%) of the thyroxine **2** was observed along with a small amount of 3,5-diiodo-4-hydroxybenzaldehyde (10%). These results suggest that **21** is not an intermediate and breaks down under the conditions of the reaction.

While formation of the α,β-unsaturated ester **21** (see mechanism in Scheme 5) from the phenoxyl radical **4** by loss of a proton requires planarity for quinone methide formation, models indicate that the steric bulk of the α-acetamidoester would make this unfavourable, thereby raising the energy of the transition state (TS). Hence the bimolecular coupling reaction is more favourable than quinone methide formation. Ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)-2-methylpropanoate (**8**) would similarly not be able to form a quinone methide intermediate.

The mechanism for coupling and side-chain loss for 2,6-diiodophenols **12b**, **12c**, **12d**, and **12e** to the corresponding thyroxine analogues is difficult to explain by a quinone methide mechanism. The quinone methides **19b**–**19e**, if formed, would react rapidly with nucleophiles such as phenolate anions or hydroxide and no signs of such products were observed. The reactions were very clean with only starting phenols and thyroxine analogues being observed or isolated. Hydroxide addition would yield benzyl alcohol analogues, which would rapidly form new quinone methides and lose a proton to yield the keto analogues. Ethyl 2-(3,5-diiodo-4-hydroxyphenyl)acetate **12e** should readily form a quinone methide because the benzylic hydrogen in phenoxyl **15e** will

© 1997 NRC Canada

be very acidic. A possible explanation is that allylic strain inhibits planarity and makes the rate of quinone methide formation slower than the rate of coupling. These explanations are preliminary and may not fully explain the range of mechanisms observed.

In conclusion, we have further elucidated the mechanism of the biomimetic formation of thyroxine analogues. Furthermore, extensive studies need to be undertaken to fully determine the mechanisms, and, in particular, isolation of the "lost" side chain remains a challenge. The facile oxidative coupling provides a useful synthetic protocol for the formation of thyroxine analogues.

Experimental

IR spectra were run as neat samples using a Nicolet 205 FT-IR spectrometer. Elemental analyses were carried out using a Perkin Elmer 2400 CHN elemental analyser. Mass spectra were run on a Kratos MS80 spectrometer or on a VG Analytical ZAB-E spectrometer by the EPSRC Mass Spectrometry Service at the University of Wales, Swansea, Wales. All mass spectra are electron impact (EI) spectra unless otherwise stated. ^{1}H NMR spectra were run at 250 MHz and ^{13}C NMR spectra were run 62.9 MHz using a Bruker AC 250 and (or) DPX400 spectrometer and are quoted at 250 and 62.9 MHz, respectively, unless otherwise stated. $CDCl_3$ was used as the NMR solvent with TMS as internal standard. Light petroleum refers to the bp 40–60°C fraction. Solvents were purified by standard methods. Analytical thin-layer chromatography was carried out using aluminium-backed plates coated with Merck Kieselgel 60 GF_{254} and compounds were visualized by UV light, iodine vapour, or by staining with potassium permanganate dip followed by heating. Flash chromatography was carried out using silica gel as absorbent and light petroleum (bp 40–60°C) and dichloromethane mixtures as eluant unless otherwise stated. HPLC was carried using a Pye Unicam PU4015 pump and Pye Unicam PU4025 UV detector fitted with a Zorbax SB-C8 4.6 mm × 15 cm column.

The ethyl ester of *N*-acetyl-3,5-diiodotyrosine was obtained from Knoll Pharmaceuticals and 3,5-diiodo-4-hydroxybenzoic acid was purchased commercially.

2,6-Diiodo-4-methylphenol (12c). General procedure for the iodination of phenols

A solution of iodine (4.713 g, 18.55 mmol) and potassium iodide (12.521 g, 75.42 mmol) in water (75 mL) was added to a two-phase mixture of *p*-cresol (1.023 g, 9.25 mmol) in dichloromethane (75 mL) and potassium carbonate (1.412 g, 10.08 mmol) in water (100 mL). The reaction was stirred for 14 h, acidified using hydrochloric acid (2 M), and the product was extracted into dichloromethane. The organic extracts were washed with dilute hydrochloric acid, sodium thiosulfate solution, dried, and evaporated to dryness. Flash column chromatography yielded 2,6-diiodo-4-methylphenol (**12c**) as colourless crystals (2.332 g, 70%), mp 55–58°C (lit. (18) mp 62°C). IR (Nujol) cm^{-1}: 3575, 1545, 1250, 852. ^{1}H NMR δ: 2.25 (s, 3H), 5.60 (s, 1H), 7.57 (s, 2H). ^{13}C NMR δ: 19.52, 82.12, 152.08, 139.52, 133.79.

Ethyl 2-acetamidopropenoate

The ethyl ester of *N*-acetylserine (105 mg, 0.60 mmol) was dissolved in acetonitrile (60 mL). To this solution was added 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (0.135 g, 7.06 mmol) and copper(I) chloride (17 mg, 0.17 mmol), and the reaction was stirred at 40°C for 24 h and evaporated to dryness. The residual oil was taken up in ethyl acetate and the solution washed with sodium hydrogen carbonate solution and water, dried, and evaporated to dryness. Flash column chromatography yielded ethyl 2-acetamidopropenoate as a colourless oil (73 mg, 78%). IR (neat) cm^{-1}: 3365, 3024, 1695, 1630, 1039. ^1H NMR δ: 1.34 (t, J = 7.1 Hz, 3H), 2.12 (s, 3H), 4.29 (q, J = 7.1 Hz, 2H), 5.88 (s, 1H), 6.58 (s, 1H), 7.74 (s, 1H, NH). ^{13}C NMR (100.62 MHz) δ: 13.23, 23.82, 61.37, 107.51, 130.20, 163.30, 167.95. MS (EI) *m/z* (M^+, 157.0739. $C_7H_{11}NO_3$ requires 157.0739), 157 (61, M^+), 115 (100, M^+ − Ac), 71 (98).

Oxidative coupling reactions with the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (1)

The reactions were carried out under a number of different reaction conditions, which included 5 bar and atmospheric pressure. Oxygen gas was replaced by nitrogen as required.

Oxidative coupling under pressure

The ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) (0.75 g, 1.5 mmol) was dissolved in ethanol (90 mL) and water (75 mL). Mn(II) sulfate (18 mg, 0.075 mmol) was added and the pH adjusted to 9.5 using aqueous sodium hydroxide solution (2.0 M). When the pH had stabilized at 9.5 for 10 min the solution was charged to a glass pressure vessel surrounded by a jacket containing oil for heating. The reaction was heated to 60–65°C and pressurized to 5 bar with oxygen, kept under these conditions for 18–24 h (normally 20 h), then cooled, and the pressure released. The final reaction pH was measured and the reaction solution evaporated to dryness. The solid residue was taken up in ethyl acetate and hydrochloric acid (0.01 M). The layers were separated and the aqueous layer was washed with ethyl acetate. The organic extracts were washed twice with hydrochloric acid (0.01 M), dried, and evaporated to dryness to give a mixture of the ethyl esters of *N*-acetyl-3,5-diiodotyrosine and *N*-acetylthyroxine. The combined yields of the ethyl esters of *N*-acetyl-3,5-diiodotyrosine (**1**) and *N*-acetylthyroxine (**2**) were high (>90%) with minor impurities. The ethyl ester of *N*-acetylthyroxine was characterized by comparison with authentic material in a number of experiments after purification using flash column chromatography; mp 206–211°C. IR (Nujol) cm^{-1}: 3401, 3277, 1708, 1636, 1545, 1180, 911. ^1H NMR ($CDCl_3$: d_6-DMSO, 20:1) δ: 1.21 (t, J = 7.1 Hz, 3H), 1.89 (s, 3H), 2.90 (ddd, J = 6.0, 8.5, 15.0, Hz, 2H, ArCH_2), 4.14 (m, 2H), 4.56 (dt, J = 7.5, 8.5 Hz, 1H, α-H), 7.06 (s, 2H), 7.76 (s, 2H), 8.29 (d, J = 7.5 Hz, 1H, NH), 9.08 (s, 1H). ^{13}C NMR (100.62 MHz) δ: 14.35, 23.18, 36.57, 53.20, 62.00, 81.51, 90.56, 126.01, 137.73, 141.22, 149.48, 150.12, 152.57, 169.58, 171.08.

Oxidative coupling of the ethyl ester of N*-acetyl-3,5-diiodotyrosine (1) under atmospheric pressure*

The reaction was carried out and worked up as above except that the reaction was refluxed for 48 h under an atmosphere of oxygen, which was bubbled through the reaction solution. The pH was checked regularly and kept close to 9.5 by the addition of aqueous sodium hydroxide solution (0.5 M) when necessary. In the crude product mixture the combined yields of the ethyl esters of *N*-acetyl-3,5-diiodotyrosine (**1**) and *N*-acetylthyroxine (**2**) were essentially quantitative with no impurities.

Analysis of the extent of reaction

Standards of the pure starting materials and the ethyl ester of *N*-acetylthyroxine (**2**) in acetonitrile:water (9:1) were analysed by HPLC to obtain peak areas at known concentrations. The mobile phase was acetonitrile:water:orthophosphoric acid (520:480:0.5 mL) and compounds were detected by UV light at 225 nm. Samples of the reaction mixtures were dissolved in the sample solution (acetonitrile:water, 9:1) and analysed. From the peak areas the ratios of compounds, and hence relative yield of the ethyl ester of *N*-acetylthyroxine (**2**) could be calculated. The product mixtures were also analysed by ^1H NMR spectroscopy, which confirmed the HPLC results.

(3,5-Diiodo-4-hydroxyphenyl)pyruvic acid (11)

A mixture of hippuric acid (0.359 g, 2.17 mmol), 3,5-diiodo-4-hydroxybenzaldehyde (0.733 g, 1.96 mmol), and sodium acetate (8.432 g, 102.82 mmol) was dissolved in acetic anhydride (150 mL) and refluxed for 2 h. The reaction was cooled, filtered, and washed with water to remove the sodium acetate. The crystals were recrystallized from toluene to give 4-(4-acetoxy-3,5-diiodobenzal)-2-phenyl-5-oxazolone as yellow crystals (0.410 g, 56%), mp 227–232°C (lit. (19) mp 242–242.5°C). IR (Nujol) cm^{-1}: 3050, 1805, 1765, 1660, 1590, 1465, 1360. ^1H NMR δ: 2.38 (s, 3H), 6.96 (s, 1H), 7.57 (m, 3H), 8.59 (s, 2H), 8.10 (dd, J = 1.6, 8.4 Hz, 2H). ^{13}C NMR δ: 21.24, 90.49, 124.93, 126.43, 128.55, 129.00, 133.81, 134.76, 134.90, 142.63, 153.08, 164.83, 166.76, 167.07. Anal. calcd. for $C_{18}H_{11}I_2NO_4$: C 38.67, H 1.98, N 2.51; found: C 38.59, H 1.90, N 2.57.

4-(4-Acetoxy-3,5-diiodobenzal)-2-phenyl-5-oxazolone (0.223 g, 0.42 mmol) was dissolved in glacial acetic acid (160 mL) and hydrochloric acid (6 M, 40 mL). The reaction was refluxed for 5 h, cooled, and placed in an ice bath. The crystals were filtered, washed with water, and dried to give the enol of 3,5-diiodo-4-hydroxyphenylpyruvic acid as a white powder (0.135 g, 78%), mp 222–228°C (lit. (10) mp 215–220°C). IR (Nujol) cm^{-1}: 3525, 3050, 1720, 1675, 1550, 1460, 1260. ^1H NMR (CD_3OD) δ: 6.27 (s, 1H), 8.16 (s, 2H). ^{13}C NMR (CD_3OD) δ: 85.33, 108.76, 133.24, 142.10, 142.73, 143.05, 168.34. MS (EI) *m/z*: 432 (M^+), 306 (M^+ − I).

Oxidative coupling reactions between the ethyl *N*-acetyl-3,5-diiodotyrosine (1) and (3,5-diiodo-4-hydroxyphenyl)pyruvic acid (11)

The ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) (2 mmol) was dissolved in ethanol (50 mL) and phosphate buffer (0.003 M, pH 7.5, 20 mL) or borate buffer (0.1 M, pH 8.3). The pH was adjusted to pH 7.5–8.5 using sodium hydroxide solution (1 M) and oxygen was vigorously bubbled through the solution. The pH was kept between 7.6 and 8.3 throughout the reaction. (3,5-Diiodo-4-hydroxyphenyl)pyruvic acid (**11**) (2 mmol) was added in small portions every 5–10 min over 1 h. The pH was checked regularly during addition and, when necessary, sodium hydroxide solution (1 M) was added to keep the pH between 7.6 and 7.8. After the addition was complete,

For personal use only.

oxygen was bubbled through the solution until the dichloromethane had evaporated and then was stopped. The reaction was left stirring in air for a further 18 h. Hydrochloric acid (4 M) was used to acidify the reaction and the aqueous layer was extracted with ethyl acetate. The organic fractions were washed with saturated ammonium chloride solution, dried, and evaporated to dryness. The products and remaining starting material were characterized by TLC and ^{1}H NMR spectroscopy and the relative yields were calculated from ^{1}H NMR spectroscopy with *p*-dimethoxybenzene as internal standard.

Ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)propenoate (21)

4-(4-Acetoxy-3,5-diiodobenzal)-2-methyl-5-oxazolone was prepared using the same method as used for the synthesis of 4-(4-acetoxy-3,5-diiodobenzal)-2-phenyl-5-oxazolone in the preparation of (3,5-diiodo-4-hydroxyphenyl)pyruvic acid (**11**) except that *N*-acetyl glycine (1.932 g, 16.53 mmol) was used in place of hippuric acid. 4-(4-Acetoxy-3,5-diiodobenzal)-2-methyl-5-oxazolone was isolated as yellow crystals (57%). ^{1}H NMR δ: 2.43 (s, 3H), 2.44 (s, 3H), 6.90 (s, 1H), 8.52 (s, 2H). ^{13}C NMR δ: 16.18, 21.763, 91.11, 126.69, 134.60, 134.72, 142.86, 153.47, 167.33, 167.42, 167.99.

4-(4-Acetoxy-3,5-diiodobenzal)-2-methyl-5-oxazolone (0.305 g, 0.61 mmol) was dissolved in anhydrous ethanol (150 mL) under a nitrogen atmosphere. Sodium hydride (0.034 g, 1.41 mmol) was added and the reaction stirred for 3 h. Water was then added and the reaction evaporated to dryness. The residue was dissolved in ethyl acetate and dilute hydrochloric acid and separated. The organic extracts were washed with water, dried, and evaporated to dryness. Flash column chromatography gave ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)propenoate (**21**) as colourless crystals (0.297 g, 97%), mp 190–194°C. ^{1}H NMR (d_6-acetone) δ: 1.28 (t, J = 7.1 Hz, 3H), 2.09 (s, 3H), 4.21 (q, J = 7.1 Hz, 2H), 7.14 (s, 1H), 8.05 (s, 2H), 8.73 (s, 1H). ^{13}C NMR (d_6-acetone) δ: 14.49, 22.83, 61.77, 83.99, 127.44, 128.89, 131.29, 141.82, 156.64, 165.60, 169.49. MS (EI) *m/z*: 500 (M^+), 459 (M^+ − Ac), 385. Anal. calcd. for $C_{13}H_{13}I_2NO_4$: C 31.16, H 2.61, N 2.79; found: C 31.04, H 2.48, N 2.87.

Ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)-2-methylpropanoate (8)

N-*Acetyl*-O-(tert-*butyldimethylsilyl)-3,5-diiodotyrosine*

The ethyl ester of *N*-acetyltyrosine (2.066 g, 4.10 mmol) was dissolved in dichloromethane (120 mL) under an atmosphere of nitrogen. Imidazole (0.323 g, 4.74 mmol) was added and the reaction was stirred and cooled to 0°C. *tert*-Butyldimethylsilyl chloride (0.617 g, 4.11 mmol) was added and the reaction was stirred for 72 h and allowed to warm to room temperature. The reaction was washed with water, dilute aqueous sodium hydroxide solution, and water, dried, and evaporated to dryness. Flash column chromatography yielded the ethyl ester of *N*-acetyl-*O*-(*tert*-butyldimethylsilyl)tyrosine as a pale yellow solid (1.72 g, 68%), mp 58–61°C. IR (Nujol) cm^{-1}: 3405, 2930, 2120, 1733, 1652, 1548, 1252, 1117, 885. ^{1}H NMR δ: 0.44 (s, 6H), 1.04 (s, 9H), 1.25 (t, J = 7.1 Hz, 3H), 2.00 (s, 3H), 2.94–2.91 (m, 2H, $ArCH_2$), 4.22–4.12 (m, 2H), 4.75–4.70 (m, 1H, α-H), 6.23 (d, J = 7.6 Hz, 1H, NH), 7.52 (s, 2H). ^{13}C NMR (100.62 MHz) δ: 0.00, 14.26, 18.58, 23.08, 26.52, 35.83, 53.19, 61.79, 88.32, 132.85, 141.11, 154.34, 169.71, 171.29. MS (CI) *m/z* (M^+, 616.9954. $C_{19}H_{29}I_2NO_4Si$ requires 616.9954), 618 (44, M^+), 492 (33, M^+ − I), 451 (43, M^+ − I, Ac), 364 (100, M^+ − 2 I).

*Ethyl 2-acetamido-3-[4-(*tert*-butyldimethylsilyloxy)-3,5-diiodophenyl)]-2-methylpropanoate*

Diisopropylamine (2.260 g, 22.43 mmol) was stirred in THF (4 mL) and cooled to −78°C. Butyllithium (1.436 g, 22.43 mmol) was added and the reaction stirred for 30 min. A solution of the ethyl ester of *N*-acetyl-*O*-(*tert*-butyldimethylsilyl)tyrosine (4.621 g, 7.48 mmol) in THF (20 mL) was added slowly and the reaction allowed to warm to −30°C, cooled to −78°C, and stirred for a further 10 min. Methyl iodide (2.818 g, 19.98 mmol) was added, and the reaction was stirred for 30 min and warmed to room temperature. The reaction was quenched by the addition of a few drops of saturated ammonium chloride solution and allowed to stir 5 min, further saturated ammonium chloride solution (50 mL) and diethyl ether (40 mL) were added, and the layers separated. The aqueous layer was extracted with diethyl ether. The organic extracts were washed with water, dried, and evaporated to dryness to yield ethyl 2-acetamido-3-[4-(*tert*-butyldimethylsilyloxy)-3,5-diiodophenyl]-2-methylpropanoate as a white solid (4.186 g, 88%), mp 135–137°C. IR (Nujol) cm^{-1}: 3405, 2930, 2102, 1733, 1652, 1548, 1252, 1117, 885. ^{1}H NMR δ: 0.46 (s, 6H), 1.06 (s, 9H), 1.35 (t, J = 7.1 Hz, 3H), 1.65 (s, 3H), 2.00 (s, 3H), 3.00 (d, J = 13.5 Hz, 1H), 3.51 (d, J = 13.6 Hz, 1H), 4.24 (q, J = 6.9 Hz, 2H), 6.18 (s, 1H), 7.46 (s, 2H). ^{13}C NMR (100.62 MHz) δ: 0.00, 14.23, 18.89, 23.35, 24.01, 26.47, 38.29, 61.34, 62.16, 88.27, 133.45, 141.52, 154.09, 169.67, 173.56. MS (CI) *m/z* (M^+, 631.0110. $C_{20}H_{31}I_2NO_4Si$ requires 631.0110), 632 (100, MH^+), 506 (25, M^+ − I), 465 (22, M^+ − I, Ac), 378 (66, M^+ − 2 I). Anal. calcd. for $C_{20}H_{31}I_2NO_4Si$: C 38.05, H 4.95, N 2.12; found: C 37.75, H 4.84, N 2.36.

Ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)-2-methylpropanoate

Ethyl 2-acetamido-3-[4-(*tert*-butyldimethylsilyl)-3,5-diiodo-4-hydroxyphenyl)]-2-methylpropanoate (4.186 g, 6.63 mmol) was dissolved in THF and tetrabutylammonium fluoride (0.190 g, 6.63 mmol) was added as a solution in THF. The solution was stirred for 2 h, a small amount of water added, and the reaction evaporated to dryness. The resulting solid was separated between dichloromethane and dilute hydrochloric acid and the aqueous layer extracted with dichloromethane. The organic extracts were washed with dilute hydrochloric acid, dried, and evaporated to dryness. Flash column chromatography yielded ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)-2-methylpropanoate as pale yellow crystals (3.263 g, 95 %), mp 66–68°C. IR (Nujol) cm^{-1}: 3381, 2982, 1737, 1657, 1544, 1181, 883. ^{1}H NMR δ: 1.36 (t, J = 7.0 Hz, 3H), 1.65 (s, 3H), 2.00 (s, 3H), 3.03 (d, J = 13.7 Hz, 1H), 3.55 (d, J = 13.7 Hz, 1H), 4.25 (q, J = 7.1 Hz, 2H), 5.69 (s, 1H), 6.18 (s, 1H), 7.37 (s, 2H). ^{13}C NMR (100.62 MHz) δ: 14.68, 23.77, 24.46, 38.86, 61.86, 62.64, 82.30, 133.26, 140.82, 152.93, 170.14, 174.00. MS (CI) *m/z* (M^+, 516.9246. $C_{14}H_{17}I_2NO_4$ requires 516.9253), 518 (22, MH^+), 392 (32, M^+ − I), 266 (100, M^+ − 2I).

Oxidative coupling of diiodophenols 12a–12e

The procedure for oxidative coupling of the ethyl ester of *N*-acetyl-3,5-diiodotyrosine (**1**) under atmospheric pressure was used for the following diiodophenols except that reaction times were 48 h. Yields were not optimized.

*Ethyl 3-(3,5-diiodo-4-hydroxyphenyl)propenoate (**20**)*

Ethyl 3-(3,5-diiodo-4-hydroxyphenyl)propionate (**12a**) (1.456 g). Flash column chromatography (dichloromethane:ethyl acetate, 9:1) yielded ethyl 3-(3,5-diiodo-4-hydroxyphenyl)propenoate (**20**) as colourless crystals (0.769 g, 53%), mp 104–106°C. IR (Nujol) cm^{-1}: 3460, 1687, 1624, 1577, 1199, 1114, 856. ^1H NMR δ: 1.32 (t, J = 7.1 Hz, 3H), 4.25 (q, J = 7.1 Hz, 2H), 5.94 (s, 1H, OH), 6.29 (d, J = 15.9 Hz, 1H, ArC*H*), 7.45 (d, J = 15.9 Hz, 1H, C*H*CO_2Et), 7.85 (s, 2H). ^{13}C NMR (100.62 MHz) δ: 14.68, 61.03, 82.94, 118.79, 131.48, 139.17, 141.12, 155.35, 166.86. MS (CI) *m/z* (M^+, 443.8719. $C_{11}H_{10}I_2O_3$ requires 443.8719), 445 (5, MH^+), 336 (16), 319 (17), 193 (100).

*4-(2-Acetylaminoethyl)-2,6-diiodo-1-(3,5-diiodo-4-hydroxyphenoxyl)benzene (**13b**)*

N-Acetyl-3,5-diiodotyramine (**12b**) (1.034 g). Trituration of the crude product with ethyl acetate yielded 4-(2-acetylaminoethyl)-2,6-diiodo-1-(3,5-diiodo-4-hydroxyphenoxyl)benzene (**13b**) as colourless crystals (0.327 g, 37%), mp 233–235°C. IR (Nujol) cm^{-1}: 3358, 1637, 1534, 1186. ^1H NMR (400 MHz, d_6-acetone) δ: 7.84 (s, 2H), 7.20 (s, 2H), 7.18 (s, 1H, NH or OH), 3.46–3.41 (m, 2H, CH_2N), 2.80 (t, J = 7.0 Hz, 2H, ArCH_2), 1.84 (s, 3H). ^{13}C NMR (100.62 MHz, d_6-acetone) δ: 21.93, 32.71 (CH_2N), 38.83, 86.99, 191.01, 24.54, 139.63, 140.86, 149.62, 150.34, 150.49, 168.59. MS (CI) *m/z* (M^+, 774.7056. $C_{16}H_{13}I_4NO_3$ requires 774.7075), 776 (30, MH^+), 647 (6, $M^+ - I$), 432 (10).

*2,6-Diiodo-1-(3,5-diiodo-4-hydroxyphenoxyl)-4-methylbenzene (**13c**)*

2,6-Diiodo-4-methylphenol (**12c**) (1.338 g). Flash column chromatography yielded 2,6-diiodo-1-(3,5-diiodo-4-hydroxyphenoxyl)-4-methylbenzene (**13c**) as colourless crystals (0.756 g, 58%), mp 176–178°C. IR (Nujol) cm^{-1}: 3476, 3058, 1586, 1435, 1183, 853. ^1H NMR δ: 2.31 (s, 3H), 5.46 (s, 1H, OH), 7.12 (s, 2H), 7.66 (s, 2H). ^{13}C NMR δ: 20.27, 81.97 (*C*-I), 50.73, 90.82, 126.34, 139.78, 141.35, 149.67, 151.57. MS (CI) *m/z* (M^+, 703.6703. $C_{13}H_8I_4O_2$ requires 703.6694), 703 (21, M^+), 578 (10, $M^+ - I$), 450 (15, $M^+ - 2I$), 324 (4, $M^+ - 3$ I).

*2,6-Diiodo-1-(3,5-diiodo-4-hydroxyphenoxyl)-4-propylbenzene (**13d**)*

2,6-Diiodo-4-propylphenol (**12d**) (1.123 g). Flash column chromatography yielded 2,6-diiodo-1-(3,5-diiodo-4-hydroxyphenoxyl)-4-propylbenzene (**13d**) as a colourless oil (0.074 g, 7%). IR (neat) cm^{-1}: 3486, 2960, 2930, 1585, 1422, 1183, 851. ^1H NMR (400 MHz) δ: 0.90 (t, J = 7.3 Hz, 3H), 1.61–1.51 (m, 2H), 2.46 (t, J = 7.3 Hz, 2H), 5.38 (s, 1H, OH), 7.04 (s, 2H), 7.58 (s, 2H). ^{13}C NMR (100.62 MHz) δ: 14.14, 24.60, 36.78, 81.91 (*C*-I), 90.85, 126.35, 140.64, 144.55, 149.66, 150.73, 151.65. MS (CI) *m/z* (M^+, 731.7016. $C_{15}H_{12}I_4O_2$ requires 731.7016), 732 (7, M^+), 606 (4, $M^+ - I$), 478 (2, $M^+ - 2I$).

*2,6-Diiodo-1-(3,5-diiodo-4-hydroxyphenoxyl)-4-(ethoxycarbonylmethyl)benzene (**13e**)*

Ethyl 2-(3,5-diiodo-4-hydroxyphenyl)acetate (**12e**) (1.761 g). Flash column chromatography (dichloromethane:ethyl acetate, 9:1) yielded 2,6-diiodo-1-(3,5-diiodo-4-hydroxyphenoxyl)-4-(ethoxycarbonylmethyl)benzene (**13e**) as colourless crystals (0.853 g, 54%), mp 72–75°C. IR (Nujol) cm^{-1}: 3471, 3065, 1726, 1585, 1423, 1182, 850. ^1H NMR δ: 1.29 (t, J = 7.1 Hz, 3H), 3.57 (s, 2H), 4.20 (q, J = 7.1 Hz, 2H), 5.47 (s, 1H, OH), 7.11 (s, 2H), 7.81 (s, 2H). ^{13}C NMR (100.62 MHz) δ: 13.92, 39.08, 61.17, 81.32 (*C*-I), 90.11, 125.70, 134.98, 140.97, 149.14, 150.13, 153.52, 170.05. MS (CI) *m/z* (M^+, 775.6914. $C_{16}H_{12}I_4O_4$ requires 775.6917), 793 (100, MNH_4^+), 776 (6, M^+), 668 (61, $MNH_4^+ - I$).

*Ethyl 2-acetamido-3-(3,5-diiodo-4-hydroxyphenyl)-2-methylpropanoate (**8**)*

The starting material was recovered in quantitative yield under the same conditions as all the other phenolic oxidations.

Synthesis of the fatty acid of pramanicin

Christopher Cow, David Valentini, and Paul Harrison

Abstract: The natural product tetradec-2-enoic acid-4,5-epoxide (**2**), which is also a component of the antibiotic pramanicin (**1**), was prepared in racemic form by a glycoluril-template directed approach. Two sequential additions of acetate units to decanoic acid are effected by intramolecular condensations on the template, mimicking the proposed biosynthetic pathway to **1**. Cleavage of the grown *trans,trans*-tetradeca-2,4-dienoyl chain from the template and epoxidation yields **2**. The reaction sequence illustrates the applicability of this biomimetic approach to total synthesis of natural products.

Key words: pramanicin, biomimetic, glycoluril, template.

Résumé : On a préparé la forme racémique de l'acide 4,5-époxy tétradéc-2-énoïque (**2**), un produit naturel qui est également un constituant de l'antibiotique pramanicine (**1**), en utilisant l'approche directe à l'aide d'un modèle glycolurile. On a effectué deux additions séquentielles d'unités acétates sur l'acide décanoïque par condensations intramoléculaires sur le composé modèle, imitant ainsi la voie biosynthétique proposée pour le composé **1**. Le clivage de la chaîne *trans-trans*-tétradéca-2,4-diénoyle en formation à partir du composé modèle et son époxydation subséquente conduisent au composé **2**. La séquence des réactions illustre la validité de cette approche biomimétique lors de la synthèse totale des produits naturels.

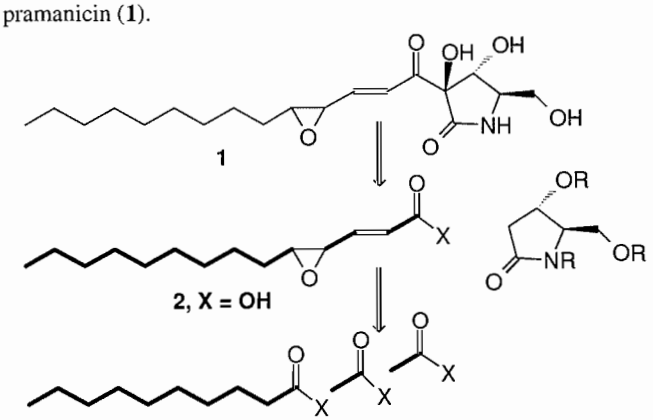
Mots clés : pramanicine, biomimétique, glycolurile, modèle.

[Traduit par la rédaction]

Introduction

Pramanicin (**1**) and the related fatty acid **2** (Scheme 1) are co-occurring natural products isolated recently by Schwartz et al. from an unidentified fungus in grass (1). The antibiotic activity of **1** against the fungal pathogen *Cryptococcus neoformans* (1), the causative agent of meningitis in AIDS patients, makes it an interesting target for synthesis. Such a synthesis should allow for the determination of the absolute stereochemistry of the epoxide, as well as for the preparation of analogues for structure–activity correlations.

The glycoluril **3** is being developed in our group as a template to effect intramolecular crossed-Claisen-like condensations between two acyl units (2, 3) in a manner that mimics some of the features of polyketide and fatty acid biosynthesis (4). To utilize this approach in the synthesis of **1**, the fatty acid **2** was chosen as a key intermediate, since a Claisen-like condensation between **2** and an appropriately substituted and protected pyrrolidinone would generate the carbon skeleton of **1** (Scheme 1). Further, **2** could be derived from a series of Claisen-type condensations between acyl units, followed by functional group manipulations. Although the biosynthetic pathway to **1** and **2** has not been investigated, it is probable that this retrosynthetic analysis corresponds to the sequence of events in the biosynthesis of **1**.



Received October 30, 1996.

This paper is dedicated to Professor William A. Ayer on the occasion of his 65th birthday.

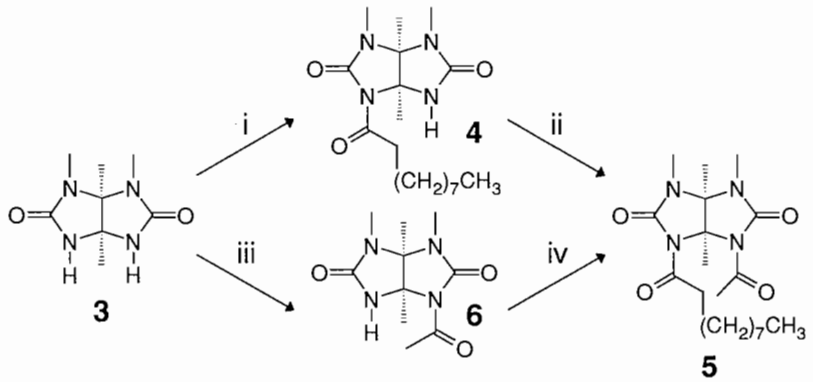
Scheme 1. Retrosynthetic, and probable biogenetic, analysis of pramanicin (**1**).

Herein, we describe the application of this methodology to the synthesis of **2** from decanoic acid. Although **2** could in principle be constructed by sequential "head-to-tail" condensations of seven acetate units, we chose to assemble the target from decanoyl chloride, which is the last readily available acid derivative in the proposed synthetic sequence.

Results



Treatment of glycoluril **3** (5) with *n*-BuLi, then decanoyl chloride, afforded the decanoyl derivative **4** (Scheme 2). As with other acylations of glycoluril **3** (2, 3), only a small amount of didecanoylglycoluril was formed in this reaction; presumably, the steric hindrance provided by the first acyl moiety prevents acylation at the second, free, NH site. Further acylation can be accomplished, however, by treating **4** with *n*-BuLi, then acetyl chloride, to give the decanoyl acetyl derivative **5**. This reaction, which proceeded rather poorly, was not optimized since the yield of **5** was considerably improved by acetylation of

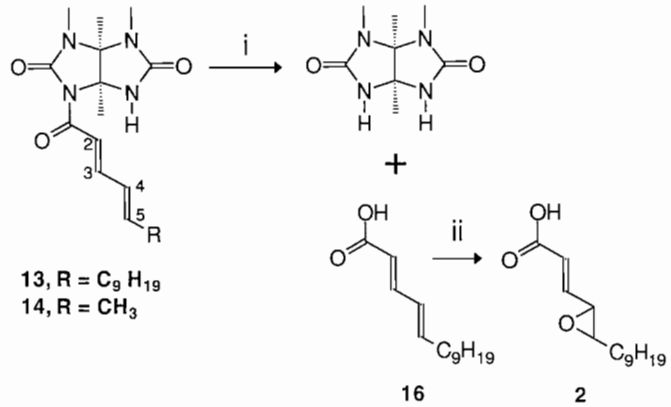
Scheme 2.



Reagents: (i) *n*-BuLi, THF, reflux, 2 h, then $C_9H_{19}COCl$, r.t., 1 h, 65%; (ii) *n*-BuLi, THF, r.t., 10 min, then CH_3COCl, 1 h, 38%; (iii) $(CH_3CO)_2O$, neat, reflux, 16 h, 78%; (iv) *n*-BuLi, THF, reflux, 2 h, then $C_9H_{19}COCl$, r.t., 1 h, 75%.

Scheme 3.

Reagents: (i) *t*-AmOLi, THF, 0°C, 20 min, then $NaHSO_4$(aq); for **7**: 65%, for **11**: 50%; (ii) $NaBH_4$, MeOH, 0°C, 10 min, then AcOH; for **8**: 79%, for **12**: 24%; (iii) $(CF_3CO)_2O$, 1 h, then excess Et_3N, reflux 20 min; for **9**: 76%, for **13**: 94%; (iv) *n*-BuLi, THF, r.t., 10 min, then CH_3COCl, 1 h, 61%, Cycle 1 to Cycle 2. R = C_9H_{19} for Cycle 1, R = $C_9H_{19}CH{=}CH$ for Cycle 2.

Scheme 4.

Reagents: (i) *t*-BuOK (6 equiv.), H_2O (2 equiv.), Et_2O, r.t., 3 h, 68%; (ii) Oxone, H_2O, PhH, Me_2CO, 18-crown-6, 0°C, pH 7.5, 3 h, 35%.

glycoluril **3** first, to give **6** (2, 3), followed by treatment with *n*-BuLi and decanoyl chloride.

The Claisen-like condensation between the acetyl and decanoyl groups of **5** was effected with lithium *tert*-amylate in THF at 0°C (Scheme 3). As in our previous studies (2, 3), the condensation proceeded rapidly under mild conditions to give **7** as the sole detectable product. Compound **7** was reduced to the β-hydroxydodecanoylglycoluril **8**, from which elimination of water proceeded smoothly to give the unsaturated derivative **9**, which was >99% *trans* by NMR. The sequence of reactions was now repeated: acetylation of **9** gave **10**, and intramolecular Claisen-like condensation afforded ketone **11**. Reduction of **11** yielded alcohol **12**, and elimination of water gave exclusively the *trans,trans* isomer of tetradeca-2,4-dienoylglycoluril (**13**).

It now remained to convert **13** to **2**. It was unclear, however, whether to remove the acyl moiety from the glycoluril template prior to or after the epoxidation of the 4,5 double bond, and we therefore investigated both possible routes using *trans,trans*-hexa-2,4-dienoylglycoluril **14** (3) as a model substrate. Treatment of **14** with *m*CPBA furnished the desired epoxide **15** in good yield and with high selectivity for the 4,5 over the 2,3 double bond. However, when **15** was treated with a variety of reagents that were expected to effect cleavage of the acyl–glycoluril bond (LiOH, LiOMe, LiOBn, or KO*t*Bu–H_2O), in all cases these reactions failed to yield the desired products. In contrast, when either **13** or **14** was treated with potassium *tert*-butoxide–water according to the procedure of

Gassman et al. (6), the free acids were obtained in good yields (Scheme 4). Subsequent epoxidation of tetradeca-2,4-dienoic acid **16** (7, 8) using oxone (9) required the use of a biphasic mixture of benzene, 18-crown-6, aqueous buffered phosphate, and acetone in order to solubilize the components. This reaction is again highly selective for the 4,5 double bond, affording racemic epoxide **2**, which was spectroscopically identical to the natural product.

Discussion

This sequence of reactions presumably corresponds to the events occurring on the putative polyketide synthase that is responsible for formation of **2** in vivo. After assembly of the decanoyl chain from five acetate units in the conventional manner of fatty acid biosynthesis, the condensing subunit of the enzyme is loaded with the decanoyl moiety, and a malonyl group, which acts as an acetyl enolate equivalent, is then covalently attached. Decarboxylative condensation on the enzyme surface generates a new C—C bond; likewise, covalent attachment of an acetyl group to decanoyl glycoluril **4**, followed by intramolecular Claisen-like condensation, generates a 12-carbon chain. Further, both the β-ketoacyl enzyme and the corresponding glycoluril **7** undergo reductions to β-hydroxyacyl groups, and subsequent eliminations of water. The resulting enoyl derivatives can be reacylated and the sequence repeated, resulting in the iterative growth of long chains on both the enzyme and the mimic. Finally, cleavage of the newly synthesized acyl chain regenerates the glycoluril template or the enzyme, which can in either case be recycled.

Since this methodology parallels the enzymatic events, it should prove useful for the synthesis of natural products, as well as putative precursors for the investigation of biosynthetic pathways. This sequence represents the first application of this methodology to the synthesis of a natural product that is not readily available, and illustrates the potential of the approach for the synthesis of a variety of fatty acid and polyketide natural products, or analogues thereof. The approach provides a useful method for effecting Claisen condensations on α,β-unsaturated acyl groups; no detectable conjugate addition was observed in these cases, presumably due to the orientational effects of the glycoluril template. The preparation of the pyrrolidinone moiety and condensation with **2** to give pramanicin will be described in due course.

Experimental

General

All reactions were performed in flame-dried glassware, under a positive pressure of dry nitrogen, unless otherwise noted. Air- and moisture-sensitive compounds were transferred by syringe. Melting points are uncorrected. Proton and carbon-13 NMR spectra were obtained on a Bruker AC-200 spectrometer. The reference for NMR chemical shifts was TMS. Data are given as chemical shift (integral, multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet), coupling constant(s) (Hz), assignment). Fourier transform infrared (FTIR) spectra were recorded on a Bio-Rad SPC 3200 spectrophotometer. Mass spectra were recorded on a VG analytical ZAB-E machine using electron impact (EIMS). High-resolution mass spectra were also recorded on the same spectrometer. Flash column chromatography was performed with Kieselgel 60 (230–400 mesh ASTM) according to the method of Still et al. (10). THF was freshly distilled under nitrogen protection from potassium–benzophenone. *n*-Butyllithium (*n*-BuLi) was titrated using 2,5-dimethoxybenzyl alcohol in THF (11). Water was obtained from a Millipore purification device.

Preparation of 1-decanoyl-3,4,7,8-tetramethylglycoluril (4)

To a suspension of glycoluril **3** (1 g, 5.1 mmol) in THF (60 mL) at reflux was added *n*-BuLi (3.45 mL of a 1.6 M solution in hexane, 5.5 mmol). The mixture was cooled to room temperature and decanoyl chloride (1.3 mL, 1.2 g, 6.3 mmol) was added. After stirring for 1 h, solid ammonium bicarbonate (2 g) was added. The mixture was filtered, and the residue was washed with chloroform (2 × 30 mL). The filtrate was evaporated, and the product was purified by flash column chromatography in EtOAc to give 1.17 g (3.3 mmol, 65%) of **4** as white crystals. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 6.09 (1H, br s, N*H*), 2.98 (3H, s, NCH_3), 2.84 (3H, s, NCH_3), 2.81 (2H, m, O=C-CH_2), 1.65 (3H, s, CH_3), 1.56 (2H, pent, J = 7.3 Hz, O=C-CH_2CH_2), 1.52 (3H, s, CH_3), 1.24 (12 H, br s, CH_2), 0.83 (3H, t, J = 6.6 Hz, CH_2CH_3); ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 174.28 (*C*=O), 157.20 (NN*C*=O), 152.94 (NN*C*=O), 78.53 (*C*NN), 77.63 (*C*NN), 36.36, 31.78, 29.33, 29.18 (2C), 29.07, 27.00, 26.34, 24.23, 22.58, 19.60, 15.67, 14.02; EIMS *m/z*: 352 $[M]^+$, 253, 240 (base), 199, 156, 141, 125; HRMS (EI) calcd. for $C_{18}H_{32}N_4O_3$: 352.2474; found: 352.2482.

1-Decanoyl-6-acetyl-3,4,7,8-tetramethylglycoluril (5)

Method 1

A solution of decanoylglycoluril **4** (500 mg, 1.4 mmol) in THF (30 mL) at 0°C was treated with *n*-BuLi (0.88 mL of a 1.6 M solution in hexane, 1.4 mmol). The mixture was stirred for 10 min, then acetyl chloride (0.12 mL, 0.13 g, 1.7 mmol) was added and stirring continued for 1 h, during which time the mixture warmed slowly to room temperature. Aqueous $NaHSO_4$ (5 mL, 1 M) was added, and the mixture was extracted with chloroform (3 × 30 mL). The chloroform layers were combined, washed with water, dried over Na_2SO_4, and concentrated. Flash column chromatography of the residue in EtOAc gave white crystals of **5** (214 mg, 38%) and unreacted **4** (159 mg, 32%).

Method 2

A solution of acetylglycoluril **6** (524 mg, 2.2 mmol) in THF (50 mL) was treated with *n*-BuLi (1.5 mL of a 1.6 M solution in hexane, 2.4 mmol) at 0°C for 30 min. Decanoyl chloride (0.54 mL, 0.50 g, 2.6 mmol) was added and the solution was stirred for 1 h, during which time the mixture warmed slowly to room temperature. Aqueous $NaHSO_4$ (5 mL, 1 M) was added, and the mixture was extracted with chloroform (3 × 30 mL). The chloroform layers were combined, washed with water, dried over Na_2SO_4, and concentrated. Flash column chromatography of the residue in EtOAc gave product **5** (517 mg, 62%) and unreacted **6** (34 mg, 6%). IR (KBr pellet): 2921, 2853 (C-H str.), 1684-1749 (br C=O str.), 1332, 1092, 759, 607; ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 2.92 (6H, s, NCH_3), 2.81 (2H, m, O=CCH_2), 2.44 (3H, s, O=CCH_3), 1.90 (3H, s, CH_3), 1.56 (4H, m, O=CCH_2CH_2 and O=$CH_2CH_2CH_2$),

1.45 (3H, s, CH_3), 1.22 (10 H, br m, CH_2), 0.83 (3H, t, J = 7 Hz, CH_2CH_3); ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 173.73 (*C*=O), 170.50 (*C*=O), 153.06 (2 NN*C*=O), 80.48 (*C*NN), 77.63 (*C*NN), 37.61, 31.80, 29.37–29.05 (5 C overlapping), 26.70, 26.14, 24.31, 22.60, 19.06, 14.51, 14.04; EIMS *m/z*: 394 $[M]^+$, 353, 295, 282, 253, 241 (base), 199, 168, 141, 125.

1-(3′-Oxododecanoyl)-3,4,7,8-tetramethylglycoluril (7)

Acetyl decanoyl glycoluril **5** (4.7 g, 12 mmol) was dissolved in THF (200 mL). Separately, *n*-BuLi (9.4 mL of a 1.6 M solution in hexane, 15 mmol) was added to *tert*-amyl alcohol (2.6 mL, 24 mmol) in THF (10 mL) at 0°C, and the mixture was stirred for 10 min. The amylate solution was cannulated into the glycoluril solution at 0°C, and the mixture was stirred for 2 h at 0°C. Aqueous $NaHSO_4$ (20 mL, 1 M) was added, and the mixture was extracted into chloroform. The chloroform layers were combined, washed with water, dried over Na_2SO_4, and concentrated. Flash column chromatography of the residue in EtOAc gave **7** (3.0 g, 65%) as white crystals and unreacted **5** (0.92 g, 17%). IR (KBr pellet): 3337 (N-H str.), 2925, 2854 (C-H str.), 1724 (br C=O str.), 1411, 1111, 760; ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 6.05 (1H, s, N*H*), 4.29 (1H, d, J = 16.3 Hz, O=C-CH_aH-C=O), 3.52 (1H, d, J = 16.3 Hz, O=C-CHH_b-C=O), 2.93 (3H, s, NCH_3), 2.83 (3H, s, NCH_3), 2.48 (2H, m, O=CCH_2CH$_2$), 1.71 (3H, s, CH_3), 1.65 (2H, m, O=CCH$_2$CH_2),1.53 (3H, s, CH_3), 1.22 (12 H, br m, CH_2), 0.84 (3H, t, J = 6.0 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 203.66 (*C*=O), 167.42 (*C*=O), 157.14 (*C*=O), 152.73 (*C*=O), 76.71, 76.60, 51.48, 42.06, 31.80, 29.34 (2C), 29.20, 28.99, 27.06, 26.40, 23.28, 22.60, 19.23, 15.68, 14.04; EIMS *m/z*: 394 $[M]^+$ 352, 295, 282, 253, 240, 199, 183, 138, 125 (base); HRMS (EI) calcd. for $C_{20}H_{34}N_4O_4$: 394.2851; found: 394.2589.

1-(3′-Hydroxydodecanoyl)-3,4,7,8-tetramethylglycoluril (8)

Oxododecanoyl glycoluril **7** (45 mg, 0.11 mmol) was dissolved in MeOH (7 mL) at 0°C. $NaBH_4$ (5 mg, 0.16 mmol) was added and the mixture was stirred for 10 min. Glacial acetic acid (1 mL) was added, then solvents were removed on the rotary evaporator. Flash column chromatography of the residue in EtOAc gave **8** (36 mg, 79%) as a white crystalline solid. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 6.04 (1H, br m, N*H*), 4.00 (1H, m, C*H*OH), 3.21 (1H, dd, J = 17.0, 2.6 Hz, O=C-CH_aH$_b$), 2.98 (3H, s, NCH$_3$), 2.84 (3H, s, NCH$_3$), 2.84 (1H, m, O=CCH_bH$_a$), 1.67 (3H, s, CH_3), 1.60 (3H, s, CH_3), 1.44 (2H, m, HOCHCH_2), 1.23 (15 H, br s, CH_2 and O*H*), 0.85 (3H, t, J = 6.0 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 167.42 (*C*=O), 157.14 (*C*=O), 152.73 (*C*=O), 77.63, 76.50, 67.95, 43.34, 31.86, 29.55–29.28 (6C), 27.13, 26.41, 22.60, 19.23, 15.68, 14.04; EIMS *m/z*: 396 $[M]^+$ 378, 269, 240, 199, 156, 138, 125 (base).

1-(*trans*-Dodec-2′-enoyl)-3,4,7,8-tetramethylglycoluril (9)

Compound **8** (720 mg, 1.8 mmol) was dissolved in CH_2Cl_2 (10 mL), then trifluoroacetic anhydride (0.77 mL, 5.4 mmol) was added and the mixture was stirred for 1 h. Triethylamine (0.33 mL, 3.6 mmol) in CH_2Cl_2 (5 mL) was added dropwise. After 10 min, further Et_3N (2 mL) was added and the mixture was heated at reflux for 20 min. Evaporation and flash column chromatography of the residue in EtOAc gave **9** (520 mg, 76%) as a white crystalline solid. IR (KBr pellet): 3337 (N-H str.) 2925, 2854 (C-H str.), 1702–1736 (br C=O str.), 1630 (C=C str.), 1468, 1089, 761; ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 7.28 (1H, dd, J = 15.3, 3.2 Hz, O=CC*H*=CH), 7.09 (1H, dt, J = 15.3, 6.6 Hz, O=C-CH=C*H*), 6.09 (1H, s, N*H*), 3.04 (3H, s, NCH_3), 2.89 (3H, s, NCH_3), 2.27 (2H, dt, J = 6.9, 6.9 Hz, O=CCH=CHCH_2), 1.74 (3H, s, CH_3), 1.59 (3H, s, CH_3), 1.49 (2H, m, CH=CHCH$_2$-CH_2), 1.29 (12H, br s, CH_2), 0.90 (3H, t, J = 6.7 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 165.90 (*C*=O), 157.25 (*C*=O), 153.02 (*C*=O), 150.60 (*C*=O), 121.74, 78.54, 76.68, 32.60, 31.80, 29.40–29.17 (4C), 28.07, 27.06, 26.33, 22.60, 19.70, 15.71, 14.05; EIMS *m/z*: 378 $[M]^+$, 251, 199, 125 (base). HRMS (EI) calcd. for $C_{20}H_{34}N_4O_3$: 378.2632; found: 378.2618.

1-(*trans*-Dodec-2-enoyl)-6-acetyl-3,4,7,8-tetramethylglycoluril (10)

Dodecenoylglycoluril **9** (416 mg, 1.1 mmol) was dissolved in THF (10 mL). *n*-BuLi (0.73 mL of a 1.6 M solution in hexane, 1.1 mmol) was added at 0°C, the mixture was stirred (10 min), and acetyl chloride (86 μL, 1.2 mmol) was added. After 1 h, aqueous $NaHSO_4$ (1 mL, 1 M) was added, and the mixture was extracted with chloroform (3 × 10 mL). The chloroform layers were combined, washed with water (2 × 10 mL), dried over Na_2SO_4, and concentrated. Flash column chromatography in EtOAc afforded **10** as a white solid (282 mg, 61%) and recovered **9** (98 mg, 24%). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 6.8–7.1 (2H, m, C*H*=C*H*), 2.90 (3H, s, NCH_3), 2.89 (3H, s, NCH_3), 2.39 (3H, s, O=CCH_3), 2.14 (2H, dt, J = 6.9, 6.9 Hz, O=CCH=CHCH_2), 1.89 (3H, s, CH_3), 1.44 (3H, s, CH_3), 1.44 (2H, m, CH=CHCH$_2$CH_2), 1.17 (12H, br s, CH_2), 0.79 (3H, t, J = 6.7 Hz, CH_3); EIMS *m/z*: 420 $[M]^+$, 336, 293, 282, 241, 225, 199, 168, 125 (base).

1-(3′-Oxo-*trans*-tetradec-4′-enoyl)-3,4,7,8-tetramethylglycoluril (11)

Acetyl dodecenoyl glycoluril **10** (395 mg, 0.94 mmol) was dissolved in THF (20 mL). Separately, *n*-BuLi (0.69 mL of a 1.6 M solution in hexane, 1.1 mmol) was added to *tert*-amyl alcohol (0.21 mL, 2.2 mmol) in 5 mL THF and the mixture was stirred for 10 min at 0°C. The *tert*-amylate solution was cannulated into the glycoluril solution, and the mixture was stirred at 0°C for 2 h. Aqueous $NaHSO_4$ (2 mL, 1 M) was added and the mixture was extracted into chloroform (3 × 20 mL). The chloroform layers were combined, washed with water, dried over Na_2SO_4, and concentrated. Flash column chromatography of the residue in EtOAc gave **11** (197 mg, 50%) as a white crystalline solid, and recovered **10** (140 mg, 35%). IR (KBr pellet): 3237 (N-H str.), 2914, 2851 (C-H str.), 1690–1722 (br C=O str.), 1466, 1412, 1090, 759; ^{1}H NMR ($CDCl_3$, 200 MHz), keto form, δ: 7.03 (1H, m, O=C-C*H*=CH), 6.26 (1H, s, N*H*), 6.05 (1H, d, J = 15.8 Hz, O=CCH=C*H*), 4.46 (1H, d, J = 16.2 Hz, O=C-C*H*H-C=O), 3.69 (1H, d, J = 16.2 Hz, O=C-CH*H*-C=O), 2.97 (3H, s, NCH_3), 2.82 (3H, s, NCH_3), 2.17 (2H, m, O=CCH=CHCH_2), 1.72 (3H, s, CH_3), 1.52 (3H, s, CH_3), 1.42 (2H, br m, CH=CHCH$_2$CH_2), 1.22 (12H, br m, CH_2), 0.84 (3H, t, CH_3); enol form, δ: 13.17 (1H, s, O*H*), 6.72 (1H, m, HOC-C*H*=CH), 6.47 (1H, s, O=C-C*H*=COH), 6.20 (1H s, N*H*), 5.84 (1H, dd, J = 12.3, 1.6 Hz, HOC-CH=C*H*), 2.92 (3H, s, NCH_3), 2.82 (3H, s, NCH_3), 2.17 (2H, m, O=C-

CH=CH-CH_2), 1.69 (3H, s, CH_3), 1.52 (3H, s, CH_3), 1.42 (2H, br m, CH=CH-CH$_2$-CH_2), 1.22 (12H, br m, CH_2), 0.84 (3H, t, J = 7.0 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 193.23, 172.67, 171.29, 170.01, 167.76, 165.84, 157.34, 152.70, 151.19, 150.60, 149.30, 129.36, 125.01, 121.70, 120.81, 90.90, 78.69, 78.52, 76.70, 76.35, 48.93, 32.57, 32.45, 32.18, 31.78, 29.39, 29.30, 29.20, 28.31, 28.02, 27.84, 27.04, 26.37, 22.58, 19.97, 19.67, 19.23, 15.67, 14.02; EIMS *m/z*: 420 $[M]^+$ 378, 240, 141, 125 (base); HRMS (EI) calcd. for $C_{22}H_{36}N_4O_4$: 420.2737; found: 420.2732.

1-(3′-Hydroxy-*trans*-tetradec-4′-enoyl)-3,4,7,8-tetramethylglycoluril (12)

Oxotetradecenoyl glycoluril **11** (84 mg, 0.20 mmol) was dissolved in MeOH at 0°C. $NaBH_4$ (11.3 mg, 0.30 mmol) was added and the mixture was stirred for 10 min. Excess glacial acetic acid (0.5 mL) was added, and solvents were removed on the rotary evaporator. Flash column chromatography of the residue in EtOAc gave **17** (20 mg, 24%). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 6.04 (1H, s, N*H*), 5.70 (1H, td, J = 6.5, 15.5 Hz, HOCH-CH=C*H*), 5.47 (1H, dd, J = 15.5, 5.0 Hz, HOCH-C*H*=CH), 4.51 (1H, m, C*H*OH), 3.23 (1H, m, OCCH_aH$_b$), 3.01 (1H, m, O=CCH$_b$H$_a$), 2.98 (3H, s, NCH_3), 2.84 (3H, s, NCH_3), 1.96 (2H, m, CH=CH-CH_2), 1.70 (3H, s, CH_3), 1.54 (3H, s, CH_3), 1.23 (15H, br s, CH_2 and O*H*), 0.85 (3H, t, J = 6.7 Hz, CH_3); EIMS *m/z*: 422 $[M]^+$ 406, 348, 295, 282, 240, 206, 199, 125 (base); HRMS (EI) calcd. for $C_{22}H_{38}N_4O_4$: 422.2893; found: 422.2889.

1-(*trans*, *trans*-Tetradeca-2′,4′-dienoyl)-3,4,7,8-tetramethylglycoluril (13)

Alcohol **12** (5.5 mg, 0.013 mmol) was dissolved in CH_2Cl_2 (2 mL), and trifluoroacetic anhydride (5.5 μL, 0.039 mmol) was added. The mixture was stirred for 1 h, then Et_3N (1.8 μL, 0.026 mmol) dissolved in CH_2Cl_2 (1 mL) was added dropwise. After 10 min, an additional 0.5 mL Et_3N was added and the mixture was heated at reflux for 20 min. Evaporation followed by flash column chromatography of the residue in EtOAc afforded **13** (4.9 mg, 94%) as a white crystalline solid. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 7.40 (1H, dd, J = 15.3, 9.2 Hz, O=CCH=C*H*), 7.22 (1H, d, J = 15.2 Hz, O=C-C*H*), 6.20 (2H, m, C*H*=C*H*CH$_2$), 6.09 (1H, s, N*H*), 3.02 (3H, s, NCH_3), 2.86 (3H, s, NCH_3), 2.17 (2H, q, J = 6.6 Hz, CH=CHCH_2), 1.71 (3H, s, CH_3), 1.56 (3H, s, CH_3), 1.37 (2H, br m, CH=CHCH$_2$CH_2), 1.26 (12H, br m, CH_2), 0.87 (3H, t, J = 6.8 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 166.22 (CH*C*=O), 157.29 (*C*=O), 153.02 (*C*=O), 145.90 (*C*=C), 145.78 (C=*C*), 128.97 (*C*=C), 119.73 (C=*C*), 78.53, 33.00, 31.81, 29.44, 29.36, 29.22, 29.10, 28.60, 27.04, 26.36, 22.59, 19.76, 16.94, 15.71, 14.02; EIMS *m/z*: 404 $[M]^+$, 277, 236, 220, 206, 199, 153, 125 (base), 94, 84, 56, 49; HRMS (EI) calcd. for $C_{22}H_{36}N_4O_3$: 404.2789; found: 404.2795.

trans, *trans*-Tetradeca-2,4-dienoic acid (16)

The tetradecadienoyl adduct **13** (22.7 mg, 0.056 mmol) was added to a slurry of H_2O (2.1 μL, 0.11 mmol) and *t*-BuOK (38 mg, 0.33 mmol) in ether (10 mL). The mixture was stirred at room temperature overnight, then 5% HCl (1 mL) was added and the mixture was extracted with chloroform (3 × 10 mL). The combined extracts were washed with water (10 mL) and brine (10 mL), then dried over Na_2SO_4 and filtered. Concentration of the filtrate gave the title acid as a solid white powder (8.9 mg, 71%). IR (KBr pellet): 3423 (O-H str.), 2924, 2854 (C-H str.), 1686 (C=O str.), 1638 (C=C str.), 1617 (C=C str.), 1466, 1307, 1007, 698; ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 7.34 (1H, m, C*H*=CH), 6.20 (2H, m, 2 C*H*=CH), 5.78 (1H, d, J = 15.22 Hz, O=CC*H*=CH), 2.18 (2H, m, CH=CHCH_2), 1.42 (2H, m, CH=CHCH$_2$-CH_2), 1.26 (12 H, m, CH_2), 0.88 (3H, t, J = 6.12 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 171.36 (C=O), 147.49 (C=C), 146.23 (C=C), 128.22 (C=C), 117.94 (C=C), 33.05, 31.87, 29.50, 29.41, 29.28, 29.18, 28.64, 22.66, 14.07; EIMS *m/z*: 225 $[MH]^+$, 224 $[M]^+$, 216, 195, 181, 164, 153, 142, 125, 109, 97, 84, 49, 45 (base), 43; HRMS (EI) calcd. for $C_{14}H_{25}O_2$ (MH^+): 225.1856; found: 225.1864.

trans, *trans*-Tetradec-2-enoic acid 4,5-epoxide (2)

Tetradeca-2,4-dienoic acid (**16**) (100 mg, 0.45 mmol) was added to a well-stirred biphasic mixture of benzene (30 mL) and phosphate buffer (15 mL, pH 7.5, 0.5 M) containing acetone (2 mL) and 18-crown-6 (100 mg, 0.38 mmol) as the phase transfer catalyst. A freshly prepared solution of potassium peroxomonosulfate (Oxone) (0.04 M, 20 mL) with $EDTANa_2$ (4×10^{-4} M) was added dropwise over 30 min. at 6–8°C. During addition, the pH was maintained at 7.5 by addition of 0.5 N KOH. The mixture was stirred for 3 h at room temperature, then extracted with benzene (3 × 30 mL) and dried over $MgSO_4$. The combined extracts were concentrated, then purified by flash column chromatography using 30% EtOAc in hexanes as eluant. Evaporation gave a white powder (35%, 37.5 mg) mp 81–81.5°C; IR (KBr pellet): 3420 (O-H str.), 2916, 2851 (C-H str.), 1730 (C=O str.), 1696 (C=C str.), 1308, 857 (epoxide); ^{1}H NMR (CD_3OD, 200 MHz) δ: 6.62 (1H, dd, ^3J = 7.2, 15.7 Hz, O=C-CH=C*H*), 6.11 (1H, d, ^3J = 15.6 Hz, O=C-C*H*=CH), 3.21 (1H, dd, ^3J = 1.6, 7.0 Hz, CH=CH-C*H*-O), 2.90 (1H, dt, ^3J = 5.9, 2.0 Hz, CH=CH-CH-O-C*H*), 1.58 (2H, m, O-CH-CH_2), 1.44 (2H, m, O-CH-CH$_2$-CH_2), 1.29 (12 H, br s, CH$_2$), 0.89 (3H, t, ^3J = 6.7 Hz, CH_3); ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 169.89 (C=O), 147.34 (C=C), 122.56 (C=C), 61.72 (C-O-C), 56.13 (C-O-C), 31.90, 31.86, 29.46, 29.33, 29.26, 25.78, 25.65, 22.65, 14.06 (CH_3); EIMS *m/z*: 241 $[MH]^+$ (v. weak), 240 $[M]^+$ (v. weak), 195, 84 (base).

Abstract: We have prepared the new $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(4\text{-pic})_6](PF_6)_2$ complex and followed the kinetics of exchange of the 4-picoline ligands, *trans* to the oxo bridge, with dimethyl sulfoxide (DMSO-d_6) by ^{1}H NMR at 30, 40, 50, and 60°C. The ^{1}H NMR spectra of this complex in DMSO gradually change in the acetyl methyl region as solvent substitution of the 4-picoline *trans* to the oxo bridge takes place. This substitution is in accordance with the lability of the ligands *trans* to the Ru^{III}-O-Ru^{III} bridge in this kind of complex. The kinetic data fit in a series of double reversible reactions, pseudo first order in the forward direction and second order in the reverse direction, with $\Delta H^{\ddagger}$ = 115, 105, 116, and 106 kJ mol^{-1} and $\Delta S^{\ddagger}$ = 35.7, 17.2, 38.8, and 16.9 J K^{-1} mol^{-1} associated with k_1, k_{-1}, k_2, and k_{-2} rate constants, respectively.

$$\mathbf{A} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathbf{B} + \text{4-pic} \qquad \mathbf{B} \underset{k_{-1}}{\overset{k_2}{\rightleftarrows}} \mathbf{C} + \text{4-pic}$$

A, **B** and **C** stand for the nonexchanged, monoexchanged, and diexchanged complexes, respectively. The large $\Delta H^{\ddagger}$ and positive $\Delta S^{\ddagger}$ values agree with the dissociative nature of the mechanism in both forward and reverse reactions. The differences in ^{1}H and ^{13}C NMR chemical shifts of the three complexes are explained in terms of the effect of the ligand exchange on the N—Ru bond lengths and the geometry of the dimetal core. It is evident from our data that the exchange on one metallic site modifies the reactivity at the other site in this kind of dinuclear complex.

Key words: diruthenium complex, variable temperature NMR, ligand exchange kinetics.

Résumé : On a préparé le nouveau complexe $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(4\text{-pic})_6](PF_6)_2$ et on a suivi la cinétique de l'échange des coordinats 4-picoline, *trans* par rapport au pont oxo, avec le diméthylsulfoxyde (DMSO-d_6) par RMN du ^{1}H à 30, 40, 50 et 60°C. Au fur et à mesure que le solvant remplace la 4-picoline *trans* par rapport au pont oxo, le spectre de RMN du ^{1}H de ce complexe dans le DMSO se modifie graduellement dans la région du méthyle de l'acétyle. Cette substitution se fait à cause de la labilité des coordinats *trans* par rapport au pont Ru(III)-O-Ru(III) dans ce genre de complexe. Les données cinétiques s'accordent bien avec une série de doubles réactions réversibles, de pseudo-premier ordre pour la réaction vers l'avant et du deuxième ordre pour la direction inverse, avec $\Delta H^{\ddagger}$ = 115, 105, 116 et 106 kJ mol^{-1} et $\Delta S^{\ddagger}$ = 35,7, 17,2, 38,8, et 16,9 J K^{-1} mol^{-1} associés respectivement avec les constantes de vitesse k_1, k_{-1}, k_2, k_{-2}.

$$\mathbf{A} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathbf{B} + \text{4-pic} \qquad \mathbf{B} \underset{k_{-1}}{\overset{k_2}{\rightleftarrows}} \mathbf{C} + \text{4-pic}$$

A, **B** et **C** représentent respectivement les complexes non échangés, monoéchangés et diéchangés. Les valeurs élevées du $\Delta H^{\ddagger}$ et positives $\Delta S^{\ddagger}$ sont en accord avec la nature dissociative du mécanisme tant dans les réactions vers l'avant qu'à l'inverse. Les différences de déplacements chimiques dans les spectres RMN du ^{1}H et du ^{13}C des trois complexes peuvent être expliquées en

Introduction

The recent discovery of a tribridged (μ-oxo)bis(μ-carboxylato)diiron core as the active site of non-heme iron enzymes, such as methane monooxygenase (MMO) (1), has brought new perspectives to the study and preparation of several interesting artificial low molecular weight transition-metal dinuclear complexes, principally of iron and ruthenium. In spite of the promising results obtained with (μ-oxo)bis(μ-carboxylato)diruthenium complexes, for example, the conversion of cyclohexane into cyclohexanol (2), the solution chemistry of these complexes has rarely been studied as a model for homogeneous catalytic processes. Furthermore, since the chemistry of the terminal ligands is important in understanding the catalytic role of these dinuclear complexes (3), the preparation and study of model ruthenium complexes with exchangeable ligands at terminal positions should contribute to a better understanding of the mechanism of action of these catalysts.

Wilkinson and co-workers were the first to propose ruthenium complexes of the type $Ru_2O(O_2CR)_4(PPh_3)_2$ (4). In recent years, it has been shown that this core can also be stabilized by the presence of other facial ligands, such as pyridine (5), tridentate triazacyclononane (6), tris(1-pyrazolyl)methane (7), (2-pyridylethyl)(2-pyridylmethyl)methylamine (8), or even by two or three different terminal ligands (9, 10). Sasaki et al. have shown that the pyridine ligands *trans* to the oxygen bridge in the $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(py)_6]^{2+}$ complex are exchanged by deuterated pyridine (5).

We have prepared a new $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(4\text{-pic})_6]^{2+}$ complex as its PF_6^- salt in order to study its chemistry in solution, and especially the exchange reaction of the 4-picoline ligands *trans* to the oxygen bridge with dimethyl sulfoxide (DMSO). We present herein a complete kinetic study derived from NMR spectroscopy of the complexes to elucidate the mechanism of this exchange reaction.

Our results also show that the ligands *trans* to the Ru^{III}-O-Ru^{III} bridge are preferentially labile, and their exchange is composed of two reversible reactions.

We have for the first time been able to determine the rate constants and activation parameters for ligand exchange on a (μ-oxo)bis(μ-carboxylato)dimetal complex by NMR spectroscopy. To the best of our knowledge, this is the first time that all the activation parameters for all of the steps in a series of double reversible reactions have been determined for a ligand substitution process on a transition metal complex.

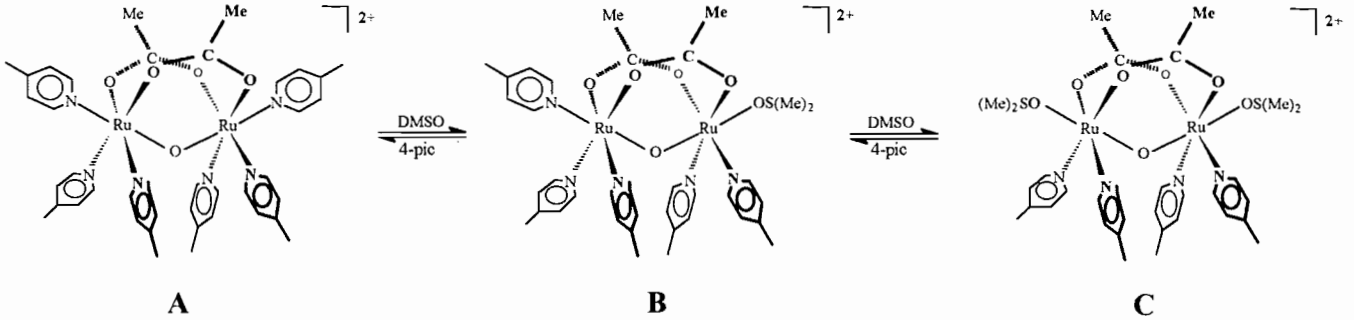
A complete ^1H and ^{13}C NMR assignment for the three complexes involved in the exchange process is presented and these data are used to speculate on the structural modifications of the complexes throughout the reactions.

Experimental section

General

Acetonitrile was distilled over P_2O_5, 4-picoline was distilled over KOH. Double-distilled acetone and ether were used throughout all the work. All other reagents and solvents used were reagent grade quality and used as supplied. The instruments used in the characterization of the complex were a Perkin–Elmer 2400 elementary analysis apparatus, a HP 8452A ultraviolet–visible spectrophotometer, and a Varian Unity-300 NMR spectrometer. All NMR chemical shifts were measured using TMS as internal reference and DMSO-d_6 99.9 at.% D (Aldrich) as solvent.

Preparation of the complex



The $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(4\text{-pic})_6(PF_6)_2$ complex was prepared according to the procedure described by Sasaki et al. (5). To a solution of $RuCl_3 \cdot nH_2O$ (0.5 g) in acetic acid (40 mL) – water (60 mL) – ethanol (20 mL), preheated for 10 min at 70°C, was added the ligand 4-picoline (3.5 mL). The mixture was refluxed for 1 h at 90°C. The crude product was dissolved in acetonitrile and filtered through an acidic alumina column. After addition of a few drops of 4-picoline, the filtrate was kept at 80°C for 15 min and the solvent removed under reduced pressure. The complex was recrystallized from acetone, by diffusion of gaseous ether, to produce blue crystals of the pure product in 65% overall yield. UV–VIS (CH_3CN) λ_{max}/nm (log ε): 210 (4.6), 242 (4.4), 288 (4.2), 322 (4.3) and 582 (4.0). ^1H NMR (300 MHz, CD_3CN) δ: 1.48 (s, 6H, CH_3 acetate), 2.44 (s, 12H, CH_3 4-pic *cis* to μ-O), 2.85 (s, 6H, CH_3 4-pic *trans* to μ-O), 7.02 (d, 8H, H-3 and H-5 4-pic *cis* to μ-O), 7.35 (d, 8H, H-2 and H-6 4-pic *cis* to μ-O), 8.04 (d, 4H, H-3 and H-5 4-pic *trans* to μ-O), 9.17 (d, 4H, H-2 and H-6 4-pic *trans* to μ-O). ^{13}C NMR (75 MHz, CD_3CN) δ: 18.5 (CH_3 4-pic *cis* to μ-O), 19.2 (CH_3 4-pic *trans* to μ-O), 21.4 (CH_3 acetate), 124.0 (C-3 and C-5 4-pic *cis* to μ-O), 126.6 (C-3 and C-5 4-pic *trans* to μ-O), 151.1 (C-4 4-pic *cis* to μ-O), 151.4 (C-2 and C-6 4-pic *cis* to μ-O), 153.4 (C-4 4-pic *trans* to μ-O), 155.5 (C-2 and C-6 4-pic *trans* to μ-O), 194.0 (CO_2 acetate). Anal. calcd. for $[C_{40}H_{48}N_6O_5Ru_2P_2F_{12}]$: C 40.55, H 4.08, N 7.09%; found: C 40.42, H 4.06, N 6.89%.

NMR kinetic study of the 4-picoline–DMSO exchange reaction

All the ^1H NMR spectra were obtained using 20 mg samples of the complex dissolved in 0.50 mL of 99.9% DMSO-d_6 in 5 mm NMR tubes. The spectra were recorded using a spectral width of 5000 Hz (transmitter offset 500) and 16 transients of 37 440 data points. A series of spectra was recorded at 30, 40,

Scheme 1.

50, and 60°C, with temperature control of ± 0.1°C for different samples. For the experiments carried out at 30°C, the samples were kept in a temperature-controlled oven between measurements. For the other higher temperatures, the samples were kept inside the spectrometer and the interval between measurements was controlled using its preacquisition delay, which was fixed as 120, 30, and 10 min for 40, 50, and 60°C, respectively. The course of the reaction was followed by measuring the integrated area of the singlets at δ 1.55, 1.59, and 1.62, which correspond to the acetate methyl signals of the nonexchanged (**A**), the monoexchanged (**B**), and the diexchanged (**C**) complexes, respectively. The integration interval (in ppm) for each signal was rigorously kept the same for all experiments at a given temperature.

Kinetic modeling

The concentration of each species is defined as [X] which is equal to $[\mathbf{A}]_{total} \cdot I_X/(I_A + I_B + I_C)$, where X = **A**, **B**, or **C**, $[\mathbf{A}]_{total}$ is the summed concentration of the complexes, and I_X is the integrated intensity of the methyl groups of the acetate bridges of the complex under consideration. The concentration vs time curves obtained experimentally were compared with the curves simulated using numerical integration according to the reaction scheme proposed in eqs. [1] and [2] (see ahead). The differential equation system corresponding to the chemical equations was solved by the Euler–Cauchy method using a spreadsheet (11). The integration step was selected by reducing its size until the results did not change with further decrease of the integration step. The numerical integration results for some experiments were checked using Lengyel's Turbo Pascal program, which solves autonomous ordinary differential equation systems using a semi-implicit Runge-Kutta method (12). Exactly the same results were obtained with both methods.

Results and discussion

Syntheses

The complex $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(4\text{-pic})_6(PF_6)_2$ was obtained in high yield from $RuCl_3 \cdot nH_2O$ using the procedure described by Sasaki et al. (5). The $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2$ core is the most likely precursor of the isolated dinuclear complex. Purification by column chromatography followed by recrystallization from acetone afforded a crystalline complex, which was fully characterized by spectroscopic methods. The evidence for a binuclear ruthenium complex containing a (μ-oxo)bis(μ-carboxilato)diruthenium(III) core was the strong absorption at 582 nm in the electronic spectra obtained in acetonitrile. This absorption is attributed to a charge-transfer band involving the Ru^{III}-$d\pi$ and μ-oxo-$p\pi$ orbitals, which is characteristic of this kind of compound (7). The structure of the complex was confirmed by ^{1}H NMR in deuterated acetonitrile. The two 4-picoline ligands *trans* to the Ru-O-Ru bridge appear at different chemical shifts from those of the other four facial ligands.

Exchange of the 4-picolines with DMSO-d_6

The ^{1}H NMR spectrum of the complex at 20°C in DMSO-d_6 shows a well-resolved singlet at δ 1.55, which integrates for six hydrogens corresponding to the two methyl groups of the acetate bridges. The intensity of this singlet at δ 1.55 decreases with time, as the sample is heated, giving rise first to one singlet at δ 1.59 and then to another singlet at δ 1.62 (see Fig. 1). The appearance of these signals at δ 1.59 and δ 1.62 is attributed to the exchange of the labile *trans* 4-picoline ligands with DMSO-d_6. The lability of N-heterocyclic bonded ligands *trans* to the oxygen bridge is known to occur in binuclear Ru clusters (5), and has been observed in trinuclear Ru clusters (13). The signal at δ 1.59 was assigned to the hydrogens of the two equivalent methyl groups in the acetate bridges after the exchange of only one 4-picoline ligand *trans* to the oxo bridge with DMSO-d_6. The singlet at δ 1.62 corresponds to the same methyl hydrogens after the exchange of the two labile 4-picoline ligands with DMSO-d_6.

The ligand exchange is also supported by the gradual decrease of the signals at δ 9.30, 8.22, and 2.90, which correspond to the *ortho* (H2, H6), *meta* (H3, H5), and the methyl hydrogens of the 4-picolines *trans* to the oxygen bridge, respectively. The gradual and almost complete disappearance of these signals is accompanied by a simultaneous appearance of the signals at δ 8.42, 7.21, and 2.31, corresponding to the respective hydrogens of the free 4-picoline. The integration of these signals, shown in Fig. 2, supports these assignments.

Thus, the integration of the NMR singlets at δ 1.55, 1.59, and 1.62, corresponding to the methyl groups of the acetate bridges of the nonexchanged (**A**), the monoexchanged (**B**), and the diexchanged (**C**) complexes, respectively, was used to monitor the concentration of these three species [**A**], [**B**], and [**C**] during the course of the exchange reaction at different temperatures, as illustrated in Fig. 3 for the experiment at 60°C.

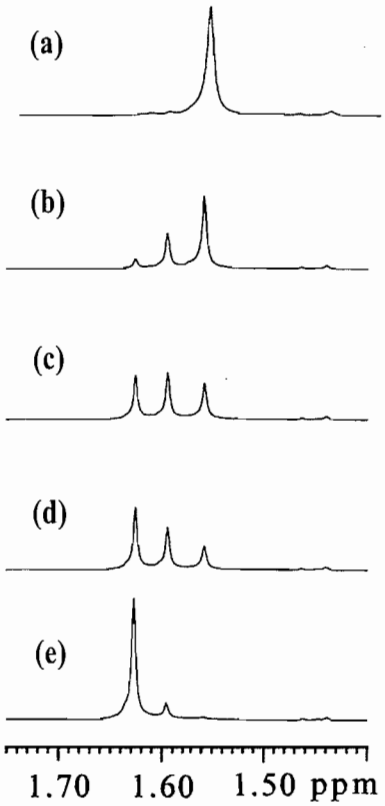

Figure 3 shows that the concentration of the nonexchanged

Fig. 1. Time dependence of the ^{1}H NMR spectrum of $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(4\text{-pic})_6(PF_6)_2$ in DMSO-d_6 for the acetate methyl region: (*a*) 30 min after dissolution at 20°C, (*b*) 14 min after dissolution at 60°C, (*c*) 37 min at 60°C, (*d*) 70 min at 60°C, (*e*) 140 min at 60°C.

species (**A**) decreases as the concentration of the diexchanged species (**C**) increases until it reaches equilibrium. The concentration of the monoexchanged species (**B**) shows a different behavior. It initially increases to a maximum, and then decreases gradually to a final equilibrium concentration. The same trend is found when the exchange reaction is carried out at 30, 40, and 50°C.

We took advantage of this information to conduct the spectroscopic characterization of the three complexes. The same sample was utilized to obtain the ^{1}H and ^{13}C NMR spectra of the three complexes and the conversion of one species into another was accomplished by temperature manipulation of this sample. Thus, the characterization of the nonexchanged species (**A**) was possible by recording the spectra of a freshly prepared sample of the complex at 20°C. At this temperature no significant exchange is detected by NMR within 3 h, and the recorded NMR spectra could unequivocally be assigned to complex **A**. The sample was then heated to 60°C for 30 min in order to achieve a maximum concentration of the monoexchanged species (**B**). The NMR spectra, recorded after cooling the sample to 20°C, show the presence of all three complexes (**A**, **B**, and **C**) in approximately the same concentration. The assignment of the resonances due to complex **B** was done by subtracting the signals due to complex **A** and complex **C** from the spectra. The spectra corresponding to complex **C** were recorded using the sample treated at 60°C for 3 h and then cooled to 20°C. The recorded ^{1}H and ^{13}C NMR spectra show the presence of complex **C** as the major compound, complex **B** as the minor compound, and traces of complex **A**. The signals due to complexes **A** and **B** did not interfere in the analysis of the spectra, which provided an unambiguous assignment of complex **C**. Table 1 summarizes these assignments. The resonance of the bonded DMSO-d_6 is observed at δ 37.42 in the ^{13}C NMR spectra of **C** (the chemical shift of the central line of free DMSO-d_6 is δ 39.45), which represents additional evidence for the participation of DMSO-d_6 in the exchange reaction.

The data shown in Table 1 along with X-ray diffraction data of a similar diruthenium complex (5), $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(py)_6]^{2+}$, enable us to explore several interesting aspects of this exchange reaction. For example, Sasaki has shown in his study that the Ru—N bond distance *trans* to the oxygen bridge (average 2.185 Å) is larger than that of the *cis* Ru—N bond (average 2.087 Å). We observed that the chemical shifts of all the atoms of the *trans* ligands in complex **A** are deshielded when compared with the atoms of the *cis* ligands. Clearly, when the Ru—N bond is shorter the chemical shifts are smaller. This may be partly due to an increase in electronic density as a consequence of the shortening of the Ru—N bond. On the other hand, analysis of the data in Table 1 indicates that the exchange of the *trans* 4-picoline with DMSO decreases the chemical shifts of C2, C6, and C4 of the *cis* 4-picolines located at the same face of the complex where the exchange took place. Since the atoms affected are the ones in the *ortho* and *para* positions of the 4-picoline, this effect must be due to a change in the electronic density at the nitrogen atom. Possibly the exchange of one 4-picoline for DMSO decreases the steric hindrance between the ligands, allowing the vicinal 4-picolines to bond more tightly to the ruthenium atom. It is even more important to observe that the chemical shifts of the 4-picoline *trans* to the Ru-O-Ru bridge at the face opposite to where the exchange took place are affected. It has usually been accepted that the metallic centers in this kind of complex are chemically independent from one another (13*a*, 14) but from our results in Table 1 it is clear that this is not the case. In fact, the substitution of one of the *trans* 4-picolines by DMSO decreases the chemical shifts of C2, C6, and C4 of the other *trans* 4-picoline remaining in the complex. This suggests that the exchange shortens the bond between the remaining *trans* 4-picoline and ruthenium. According to this, the second forward substitution reaction should be slower than the first one. On the other hand, the chemical shifts of the *cis* 4-picoline ligands at one face of the complex are practically unaffected by the exchange of the *trans* ligand at the other face. This seems to indicate that the effects of changes at one face are transmitted to the other face through the oxygen bridge. The observation that the chemical shift of the sp^2 carbon of the acetate bridges changes from δ 194.50 in **A** to δ 190.88 in **B** and δ 187.97 in **C** may be related to changes in the geometry of the complex as the bulkier 4-picoline ligands are gradually substituted by DMSO. To a lesser extent, the same kind of effect is shown by the ^{13}C NMR of acetate bridge methyl groups.

Kinetics of the exchange reaction

The change in the concentration of the different species involved in the exchange reaction shown in Fig. 3 can be

[a]*cis* and *trans* refer to the position of the ligand in relation to the Ru-O-Ru bridge, except for free 4-picoline. The numbers 2,6 are the *ortho* CH; 3,5 are the *meta* CH; and 4 is *para* C of the 4-picolines. An asterisk indicates 4-picoline vicinal to the exchanged DMSO-d_6 in **B**.

explained considering the kinetic schemes proposed in eqs. [1] and [2].

$$[1]\quad \mathbf{A} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathbf{B} + \mathrm{L}$$

$$[2]\quad \mathbf{B} \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} \mathbf{C} + \mathrm{L}$$

Where k_1 and k_2 are pseudo-first-order rate constants, which include the DMSO concentration, k_{-1} and k_{-2} are second-order rate constants, and L stands for the 4-picoline ligand.

Evidence for the participation of 4-picoline in the rate law comes from the non-zero areas of ^{1}H NMR signals at δ 1.55 and 1.59 at equilibrium, corresponding to non-zero equilibrium concentrations for **A** and **B**, respectively. When the experiments were carried out in the presence of an initial amount of free 4-picoline, higher equilibrium concentrations of **A** and lower equilibrium concentrations of **C** were found, and the rate of formation of these species changed. These

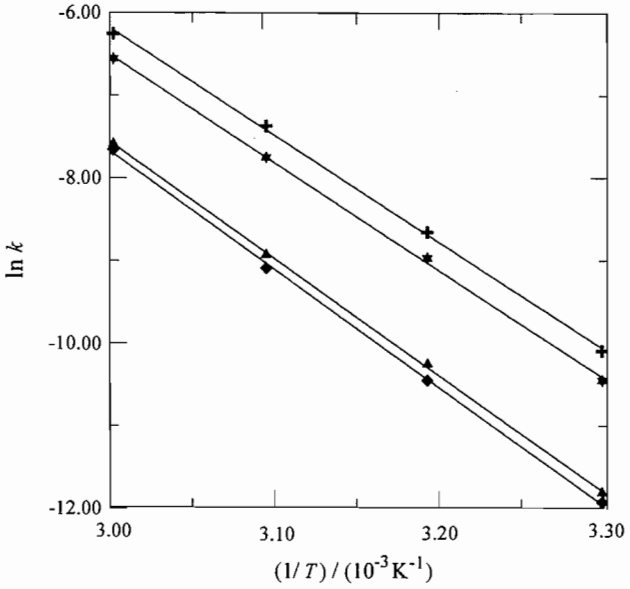
results indicate that the concentration of free 4-picoline affects the rate of formation of **B** and **C** and, consequently, the equilibrium concentration of **A**, **B**, and **C**. This result was the driving force to include the concentration of free 4-picoline in the mechanistic consideration for the reverse reactions. Attempts to use other kinetic mechanistic schemes, for example, a series of two reversible first-order reactions, did not provide good agreement with the experimental data. When only first-order reactions were considered, it was not possible to explain the dependence on the concentration of free 4-picoline in the equilibrium. Moreover, it is clear that as the 4-picoline ligand is exchanged with DMSO the concentration of free 4-picoline increases and it slows the whole process by accelerating the reverse reactions.

Equations [1] and [2] were used as a model to find the rate constant combinations that provide the best fit to the experimental data obtained for the exchange reaction at all four different temperatures. The results are listed in Table 2 and Fig. 3, which present one typical fit of the model given by eqs. [1] and [2] to the experimental data at 60°C. In Fig. 3 we see very good agreement between the calculated (solid line) and the experimental (symbols) data. Similar agreement is observed when the data at 30, 40, and 50°C are considered.

The Arrhenius plots of the rate constants obtained are shown in Fig. 4, and a very good linear behavior is indicated by their correlation coefficients, R^2, which are equal to or greater than 0.9992.

The data shown in Table 2 enable us to explore other interesting aspects of this chemistry. First, even though k_1 and k_2 are very similar, k_1 is consistently larger than k_2, indicating that the substitution of one *trans* 4-picoline by DMSO slightly hinders the substitution of the other one. This is in agreement with the proposed shortening of the N—Ru bond for the *trans* 4-picoline in complex **B**, suggested by the X-ray data and by our NMR results discussed earlier. In perfect accord with these results is the observation that k_{-1} is always larger than k_{-2}, showing that the substitution of one DMSO for 4-picoline in **C** increases the lability of the DMSO ligand left in the complex. This implies that there is a significant difference between the *trans* effect of 4-picoline and DMSO that is transmitted through the Ru^{III}-O-Ru^{III} bridge. In other words, the exchange

Fig. 3. Experimental (symbols) and calculated (solid lines) concentration vs. time dependence of the complexes formed in the reaction between $Ru_2(\mu O)(\mu\text{-}O_2CCH_3)_2(4\text{-pic})_6(PF_6)_2$ and DMSO-d_6 at 60°C: (Δ) $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(4\text{-pic})_6]^{2+}$, **A**; (○) $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(DMSO\text{-}d_6)(4\text{-pic})_5]^{2+}$, **B**; (□) $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(DMSO\text{-}d_6)_2(4\text{-pic})_4]^{2+}$, **C**.



of one *trans*-4-picoline for DMSO in **A** makes more difficult the exchange of the other *trans*-4-picoline, because the *trans* effect of the DMSO is weaker than the 4-picoline *trans* effect, and therefore k_1 is greater than k_2. In the reverse reaction the exchange of one DMSO for 4-picoline in **C** facilitates the exchange of the remaining DMSO, because the *trans* effect of 4-picoline is stronger than the DMSO *trans* effect, and therefore k_{-2} is smaller than k_{-1}. This interpretation contradicts the existing view of independent substitution at each site of trinuclear complexes such as Ru, Mo, and W (13*a*, 14).

Second, it is interesting to note that the forward first-order rate constants k_1 and k_2 are lower than the reverse second-order rate constants k_{-1} and k_{-2}, which makes the equilibrium constant K smaller than unity. This is consistent with the expected lower affinity of DMSO for ruthenium as compared with that of 4-picoline, which is due to the stronger basic char-

Fig. 4. Arrhenius plots for k_1 (▲), k_{-1} (+), k_2 (◆), and k_{-2} (★) (see eqs. [1] and [2] for model).

acter of nitrogen in relation to oxygen. It has been shown that DMSO binds through its oxygen in some mono- and trinuclear Ru(III) complexes (15).

Another statistical approach to be considered for the analysis of these data is the *per metal ion* rate constants, k_1^M and k_{-2}^M values which are half of the respective k_1 and k_{-2}, values listed in Table 2. When k_1^M values are calculated from the k_1 values listed in Table 1 at all temperatures, we obtain k_1^M values lower than the k_2 values. Contrary to what was postulated using the NMR results, the lower k_1^M values calculated suggest that the DMSO ligand exerts a stronger *trans* effect than the 4-picoline ligand in the forward reaction. Also, a comparison of the k_{-2}^M and k_{-1} values leads to a weaker *trans* effect for the reverse reaction. This implies that either the *trans* effect through the Ru^{III}-O-Ru^{III} bridge is not statistically significant or that this kind of statistical treatment does not apply in this case. The same kind of result was found in a kinetic study on diplatinum(III) complexes (16).

In spite of the possibility of having no significance in this case, the k^M values were used to compare the rate of ligand exchange found for these 4-picoline complexes (**A** and **B**) with rates for other ruthenium complexes (Table 3). We observe that the values are lower for the former (entries 4 and 5). This is expected because of the more labile interaction of DMSO with ruthenium compared to that of 4-picoline. The high k_1^M values observed for the exchange of water with isonicotinamide in trinuclear ruthenium complexes (entries 8 and 9) support this observation.

The rate constant k_1 that we obtained at 50°C is 1.33×10^{-4} s^{-1}, which is almost the same value found by Sasaki et al. for the pyridine exchange reaction in the complex $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(py)_6]^{2+}$ ($k = 2.2 \times 10^{-4}$ s^{-1}) (5). Since the two exchange reactions mentioned involve very different entering ligands, the similarity between these two complexes indicates that the rate constant k_1 is probably independent of the nature of the ligand entering the coordination sphere of the metal. In

Table 3. Rate constants and activation parameters for some selected ligand exchange reactions on ruthenium complexes at 25°C.

Entry	Complex	System	$k^{M\,a}$ (s^{-1})(25°C)	$\Delta H^{\ddagger}$ (kJ mol^{-1})	$\Delta S^{\ddagger}$ (J mol^{-1} K^{-1})	Reference

this case the ligand substitution mechanism must be of the dissociative type. Another similarity of our results with Sasaki's pyridine exchange reaction is the absence of *cis*-oxo bridge ligand substitution, as we concluded from our NMR data for the temperature range of 30–60°C (5).

The activation parameters (Table 2) were calculated from the rate constants using transition state theory and 45°C as the average temperature (19). From Table 1 we see that the $\Delta H^{\ddagger}$ values associated with k_1 and k_2 are greater than those associated with k_{-1} and k_{-2}. This is in agreement with the expected stronger bond between Ru and N than between Ru and O, based on the greater basicity of 4-picoline compared to DMSO. The positive $\Delta S^{\ddagger}$ values associated with k_1 are similar to those associated with k_2. The values of $\Delta S^{\ddagger}$ associated with k_{-1} and k_{-2} are also positive and about half the values for the forward reactions. It is generally accepted that positive $\Delta S^{\ddagger}$ and large $\Delta H^{\ddagger}$ values indicate that the ligand substitution is dominated by a dissociative process (20). This, together with the similarity of the rate constants k_1 at 50°C found in our experiments and reported by Sasaki for the pyridine complex (which suggest that the mechanism of exchange is not dependent on the nature of the entering ligand), led us to consider, for the present study, the dissociative mechanism shown below.

$$[3]\quad \mathbf{A} \underset{k_{-a}}{\overset{k_a}{\rightleftarrows}} I_1 + L$$

$$[4]\quad I_1 + S \underset{k_{-b}}{\overset{k_b}{\rightleftarrows}} \mathbf{B}$$

$$[5]\quad \mathbf{B} \underset{k_{-c}}{\overset{k_c}{\rightleftarrows}} I_2 + L$$

$$[6]\quad I_2 + S \underset{k_{-d}}{\overset{k_d}{\rightleftarrows}} \mathbf{C}$$

where L = 4-picoline, S = DMSO-d_6, I_1 is the intermediate lacking one ligand, i.e., with one Ru atom pentacoordinate, and I_2 is another intermediate containing one DMSO-d_6 ligand *trans* to the oxygen bridge bonded to one hexacoordinate ruthenium and with the other ruthenium pentacoordinate.

In this mechanism I_1 and I_2 are reactive intermediates. The second-order nature of the reverse reactions can be explained based on the competition between I_1 (or I_2 for the solvent (DMSO-d_6)) and 4-picoline. As the 4-picoline concentration increases during the reaction, more intermediates are able to react with it and show second-order behavior (first order on 4-picoline).

Although no experiments were carried out with different DMSO concentrations to verify whether they affect the velocity of the forward reaction, it is reasonable to suppose that forward reactions are pseudo first order with [DMSO] included in the rate constants k_1 and k_2. Dividing k_1 and k_2 by [DMSO-d_6] will render two new second-order rate constants k_1' and k_2' with $\Delta S^{\ddagger}$ = 13.7 ± 4.2 and 16.8 ± 6.7 J K^{-1} mol^{-1}, respectively. In this way, all four $\Delta S^{\ddagger}$ (for k_1', k_{-1}, k_2', and k_{-2}) become very close to each other, in agreement with the dissociative mechanism proposed in eqs. [3]–[6]. As expected, the values obtained for $\Delta H^{\ddagger}$ associated with k_1' and k_2' did not suffer any significant change compared to those related to k_1 and k_2.

The activation parameters, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, associated with the k_1^{M} values are comparable to the values found in the literature (13, 17, 18). From Table 3 it can be seen that the values of $\Delta H^{\ddagger}$ for complexes **A** and **B** (entries 4 and 5) are in good agreement with those for trinuclear Ru complexes (entries 6–9). It should be noted that some of these literature values were obtained assuming different kinetic models, usually direct but not reversible reactions. The $\Delta S^{\ddagger}$ values for complexes **A** and **B** are positive, similar to those reported for the trinuclear complexes. We note that our results for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are closer to those for trinuclear than for mononuclear ruthenium complexes. This may be related to the presence of the $Ru_n(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_m$ ($n > 1$) core in the di- and trinuclear complexes. In addition, some mononuclear ruthenium complexes (entries 1 and 3) react by an associative mechanism in ligand exchange reactions as determined by the authors (suggested by their negative $\Delta S^{\ddagger}$ and $\Delta V^{\ddagger}$) (17, 18). The associative mechanism is probably not possible for di- and trinuclear complexes because of steric hindrance. On the other hand, it seems that the dissociative mechanism is favored by steric hindrance and increased lability of the ligand–ruthenium bonds *trans* to the oxo bridge present in the multinuclear ruthenium complexes.

The sequence of four dissociative reversible reactions, eqs. [3] and [4] (or eqs. [5] and [6]), cannot be taken as a final proposition. Other possibilities, such as the formation of outer-sphere complexes, cannot be excluded at this time.

Conclusions

The substitution of 4-picoline by DMSO-d_6 in a $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(4\text{-pic})_6]^{2+}$ complex was followed by ^{1}H NMR at four different temperatures. The ^{1}H NMR data present clear evidence for the lability of the ligands *trans* to the Ru^{III}-O-Ru^{III} bridge when compared to the ligands at other positions.

The kinetics of exchange could also be followed by ^{13}C NMR. The ^{13}C NMR studies allowed the assignment of all carbons in the three complexes involved in the process of exchange. The effect, of the substitution of one 4-picoline by DMSO, on the chemical shifts of the *cis* ligands at the face where the reaction took place, and on the *trans* ligand at the other face, indicates that the Ru—N bonds are shortened after the exchange.

The kinetic results are better explained in terms of a complex mechanism involving a series of two reversible reactions. Pseudo-first-order reactions were considered for the forward direction and second-order reactions for the reverse.

The activation parameters ($\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$) for each of the two forward substitution steps are very similar. The large $\Delta H^{\ddagger}$ and positive $\Delta S^{\ddagger}$ values suggest a dissociative mechanism for the process in which the rate-controlling step is the breaking of the Ru—N bond.

For the reverse reactions the activation parameters again show identical and large $\Delta H^{\ddagger}$ values and identical and positive $\Delta S^{\ddagger}$ values, also suggesting a dissociative mechanism. The $\Delta H^{\ddagger}$ values for reverse reaction steps are lower than those for the forward steps and correspond to the Ru—O (oxygen from DMSO) bond breaking.

The supposition that the two forward pseudo-first-order rate

© 1997 NRC Canada

constants include the solvent concentration (DMSO) allowed us to calculate the second-order forward rate constants, which have positive $\Delta S^{\ddagger}$ values very similar to those for the second-order reverse rate constants. This supposition, which seems valid, gives additional support to the conclusion that all four steps (two forward and two reverse) are dominated by a dissociative mechanism controlled by bond-breaking steps.

Analysis of the NMR chemical shifts of the three complexes involved in the exchange process, together with the kinetic data, shows that the two metallic sites in these complexes are chemically dependent on one another.

Activated cyclooctenones are effective dienophiles[1]

Hsing-Jang Liu, Dan-Xiong Wang, Jeung Bea Kim, Eric N.C. Browne, and Yu Wang

Abstract: The first Diels–Alder addition of a diene to a cyclooctenone dienophile has been observed. Three activated cyclooctenone dienophiles **1**, **2**, and **3** are studied with a variety of simple and functionalized dienes. Diels–Alder adducts are produced in excellent yields under very mild Lewis acid catalyzed conditions. The usual orientation rules are followed and, as predicted, the products are formed for the most part exclusively by ester-*endo* addition. The stereoselectivity is influenced by the substitution pattern of the diene in some cases. The factors influencing the stereochemical selectivity of the addition are discussed in some detail.

Key words: 2-carbalkoxy-2-cyclooctenones, Diels–Alder reaction, six–eight fused ring system.

Résumé : On a observé la première addition de Diels–Alder d'un diène sur une cycloocténone comme diénophile. On a étudié trois diénophiles, des cycloocténones activées **1**, **2** et **3**, avec divers dienes simples et fonctionalisées. On a obtenu les adduits de Diels–Alder avec d'excellents rendements dans des conditions très douces avec des catalyseurs de Lewis. On a suivi les règles usuelles d'orientation et comme prévu, les produits obtenus sont presqu'exclusivement les résultats d'une addition *endo* d'esters. La stéréosélectivité, dans quelques cas, est influencée par le schéma de distribution des dienes. On discute des facteurs qui influencent la sélectivité stéréochimique de l'addition.

Mots clés : 2-carbalkoxy-2-cycloocténones, réaction de Diels–Alder, système à six–huit noyaux condensés.

[Traduit par la rédaction]

Introduction

Our group has continued to expand on our long-standing program of investigation into the Diels–Alder chemistry of cycloalkenone dienophiles.[5] Encouraged by recent successes in applying our discoveries of methodology in this field to the synthesis of structurally challenging and important natural products such as (+)-qinghaoshu (2), (−)-qinghaoshu IV (3), and two diterpenoids of the *cis*-clerodane family (4), we have turned our attention to the more challenging larger ring cycloalkenones as a tool for rapid assembly of less accessible polycyclic ring systems. We recently reported (1) our work on the scarcely precedented Diels–Alder addition to cycloheptenones in which the tactic of activating reactivity by the use of a 2-carbalkoxy substituent aided additions to a variety of substituted derivatives. There are no reports in the literature of intermolecular Diels–Alder additions to 2-cyclooctenones. Yet there is an increasing number of examples in the literature of complex natural products possessing the six–eight fused ring system that could result from such an addition.[6]

This provides a strong challenge for the development of this unprecedented approach and its application to synthesis. We are pleased now to report for the first time on the facile, selective, and highly efficient additions of 1,3-dienes to activated cyclooctenones.

Results and discussion

We examined three activated cyclooctenones **1**, **2**, and **3**, which were selected for their simplicity yet still would serve as probes to the regio- and stereoselectivity of the additions. As outlined in Scheme 1, the unsaturated enone ester **1** was prepared from cycloheptanone via boron trifluoride catalyzed ring expansion with ethyl diazoacetate (9), which gave a 74% yield of keto ester **4** and its enol tautomer **5** in ca. 1.6:1 ratio. This was followed by a phenylselenenylation – oxidative elimination process (10) to furnish **1** in 85% yield.

Two complementary approaches to the substituted enone ester system of **2** and **3**, summarized in Schemes 2 and 3, were

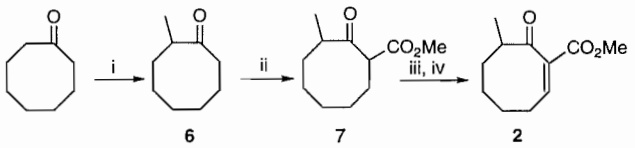
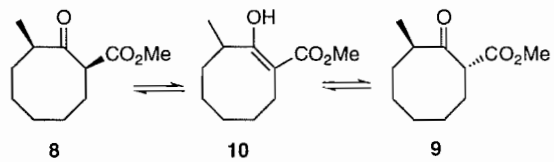


Scheme 1. The preparation of enone ester **1**.

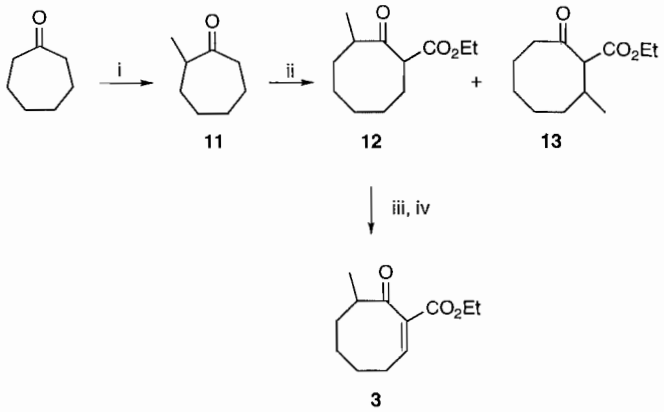


(i) N_2CHCO_2Et, $BF_3{\bullet}OEt_2$, ether, r.t., 24 h, 74%; (ii) PhSeCl, Py, CH_2Cl_2, 0°C, 1 h; (iii) H_2O_2, CH_2Cl_2, 0°C, 40 min, 85% (two steps).

Scheme 2. The preparation of enone ester **2**.

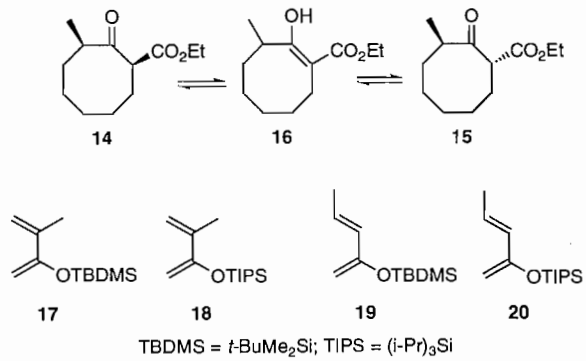
(i) LDA, THF, -78°C, 30 min; then CH_3I, r.t., 40 h, 89%; (ii) NaH, $(CH_3O)_2CO$, DME, reflux, 19 h, 85%; (iii) NaH, PhSeCl, THF, 0°C, 15 min; (iv) H_2O_2, CH_2Cl_2, 0°C → r.t., 40 min, 86% (two steps).

followed. α-Methylation of cyclooctanone with lithium diisopropylamide and methyl iodide (11) gave ketone **6** in 89% yield. Carbomethoxylation of **6** with dimethyl carbonate and sodium hydride (12) gave exclusively keto ester **7** in 85% yield as a mixture of two epimeric keto forms **8** and **9** and the enol tautomer **10** (4:2:3 ratio). The cross-conjugated double bond was introduced by phenylselenenylation and oxidative elimination (10) to give **2** in 86% overall yield.



Alternatively, α-methylation of cycloheptanone by the same method used above gave ketone **11** in 70% yield. The keto ester **12** was obtained in this case by ring expansion with ethyl diazoacetate and boron trifluoride etherate (9), giving the product in 56% yield along with a significant quantity (38% yield) of the separable by-product **13**.[7] The keto ester **12** was also obtained as a mixture of epimeric ketones **14** and **15** and the enol tautomer **16** in a ratio of about 3:1:1. The same selenenylation – oxidative elimination approach used previously converted **12** to **3** in 85% yield. A bromination–dehydrobromination approach (13), used in our laboratory in other systems, was unsuccessful as treatment of **12** with *N*-bromosuccinimide gave a complex mixture of products.

The 2-silyloxy-substituted dienes **17**–**20** used in our study



[7] The ethyl diazoacetate – boron trifluoride ring expansion has been used frequently in our laboratories and is usually much more selective than in this case.

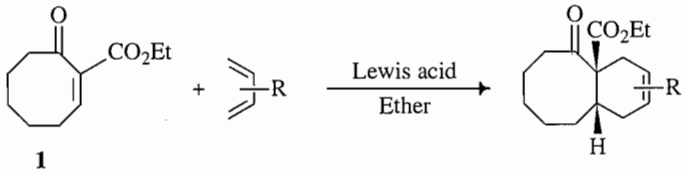
Scheme 3. The preparation of enone ester **3**.

(i) LDA, THF, -78°C, 30 min; then CH_3I, r.t., 10 h, 70 %; (ii) N_2CHCO_2Et, $BF_3{\bullet}OEt_2$, ether, r.t., 24 h, 94% (**12** : **13** = 1.5 : 1); (iii) NaH, PhSeCl, THF, 0°C, 30 min; (iv) H_2O_2, CH_2Cl_2, 0°C → r.t., 40 min, 85% (two steps).

were not commercially available and were prepared by the general method of Ireland and Thompson (14) using *tert*-butyldimethylsilyl chloride and triisopropylsilyl chloride to trap the enolates generated from *trans*-3-penten-2-one and 3-methyl-3-buten-2-one with lithium diisopropylamide.

TBDMS = *t*-$BuMe_2Si$; TIPS = $(i\text{-}Pr)_3Si$

Diels–Alder reactions



The general procedures for the Diels–Alder cycloaddition were straightforward. For those catalyzed by ferric chloride, stannic chloride, or boron trifluoride etherate, the Lewis acid was simply added to an ether solution of the diene and dienophile. For zinc chloride catalyzed reaction, the Lewis acid was first flame fused and then dissolved in ether. The dienophile was then added as a solution in ether and, after stirring for 30 min to allow for complex formation, the diene was introduced. After complete consumption of the dienophile, the reaction was quenched by addition of aqueous sodium bicarbonate and worked up. The additions to unsubstituted enone ester **1** are summarized in Table 1. At −20°C, both ferric chloride and stannic chloride gave adduct **21** in high yield. Ferric chloride gave a particularly fast conversion to product. Boron trifluoride etherate and zinc chloride gave slow conversions even at higher temperature (0°C). As expected, the uncatalyzed reaction gave virtually no adduct at room temperature. Having thus determined effective conditions and catalysts for this system, we investigated a selected group of examples with simple dienes to give adducts **22** through **27**. The yields were uniformly high. The addition took place as expected with com-

Scheme 4. The conformational equilibrium of cyclooctenones.

plete *ortho*-rule and *para*-rule selectivity and with moderate to good preference for the same ester-*endo* addition as in other systems.[5]

Initial investigations of additions to enone ester **3** are summarized in Table 2. Again ferric chloride and stannic chloride were superior and powerful catalysts. But in this sequence boron trifluoride was completely ineffective. The dienophile was recovered quantitatively. Zinc chloride did in fact produce product **28** in good yield although with a much slower rate than the first two catalysts mentioned. Thus the broader studies on Diels–Alder reactions of **2** and **3** were concentrated on examples with stannic chloride and ferric chloride. The results of these investigations are summarized in Table 3. These reactions too followed the expected regiochemical rules (15). Even for addition of the 2,3-disubstituted diene **18** the expected regio-directing dominance of the electron-donating silyloxy substituent led to complete selection in favor of the adduct **34** with none of the isomeric adduct observed. All of the adducts were formed by preferential ester-*endo* addition except for that with cyclopentadiene, which was at best only slightly selective. A significant proportion of the keto-*endo* adduct **43** was formed. This particular loss of selectivity for cyclopentadiene is not exhibited in other systems we have studied and is not readily explained. The ester-*endo* attack observed for the majority of adducts is expected on the basis of minimum steric interaction between the diene and dienophile in the transition state.

The face selectivity of the additions to the dienophiles with two different diastereotopic faces was less consistent. When the C-2 position of the diene was substituted, addition to **2** and **3** proceeded with preferential addition to the apparently less hindered face (opposite to the methyl substituent). This was expected even though reversed selectivity in favor of the apparently more hindered face had previously been observed for additions to the congener **44** (1). But where the diene had no C-2 substituent, the diene appeared to add to **3** preferentially from the more hindered methyl-substituted face. As noted for additions to **44**, the rationale for this unexpected selectivity is unclear.[8] Several of the additions (Entries 2, 5, and 8) also produced one inseparable minor isomer whose stereochemistry could not be completely assigned. It was therefore impossible to determine if these minor isomers were derived from keto-*endo* addition, which would indicate diminished preference for the established ester-*endo* orientation of addition, giving products epimeric at C-12, or from diminished face selectivity resulting in products that are epimeric at C-3.

We considered the conformational effects of the eight-membered ring on the orientations of the Diels–Alder additions. Using the report of Arshinova (16) and considering the effect of planar fragments (ketone carbonyl and double bond) as constraints on the flexibility of the ring system, we have proposed two conformations around the enone-ester system that are illustrated in Scheme 4. The conformations **A1** and **A2** would clearly present a face opposite to the methyl substituent for relatively unhindered cycloaddition to the enone. Conformations **B1** and **B2** are clearly less suited to additions at the enone double bond since the methyl substituent is pseudo-axial on one face while the remainder of the eight-membered ring occupies the other face of the system. And yet addition to the methyl-substituted face was observed. Further study and a broadened selection of examples may provide a better understanding of the complex stereochemical and conformational relationships that are expressed in this system.

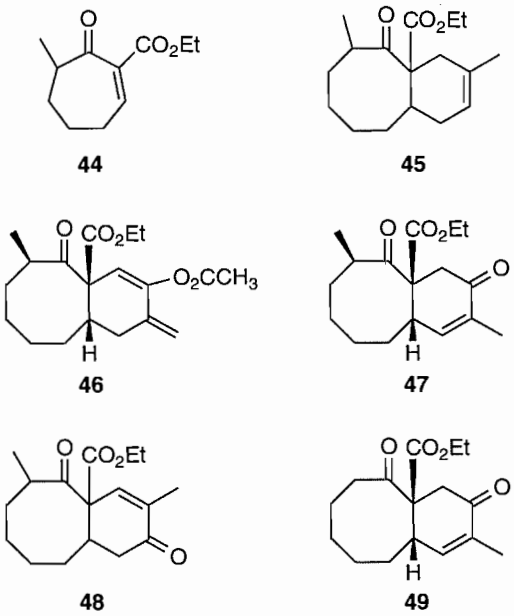
Structural assignments

While the establishment of product structures has by now become fairly routine in our studies of cycloalkenone dienophiles, there are a few elements that warrant particular attention and are discussed below. For the most part, however, the structures were clearly evident on first-order examination of the spectroscopic data.

The stereochemistry of adduct **28** was confirmed by NOE experiments in which irradiation of the C-3 methyl substituent gave enhancement of the signals for the ester methyl (11%) and methylene (1%) protons and for the C-8 ring-junction proton (5%). Irradiation of the C-3 proton gave enhancement of the allylic methyls at C-10 and C-11 (1% each) and one of the C-12 protons (7%). These two results indicated that the methyl substituent was on the same face of the ring as the carbethoxy group. Similar NOE studies were run for other compounds in the series and the results of those experiments are summarized in Table 4.

Proof of the *para*-addition orientation for adduct **29** was made by an INEPT-NMR experiment and by chemical transformation. In the INEPT experiment, when the vinyl proton of **29** at δ 5.30 was irradiated the signal of the quaternary ring junction carbon at C-1 (δ 63.3 in the ^{13}C NMR APT spectrum) was observed in the corresponding INEPT ^{13}C NMR spectrum. If the adduct had the *anti-para* addition structure **45**, this irradiation should cause display of the signal for the tertiary ring junction carbon at C-8.

Chemical derivatization of **29** was achieved by photooxidation (17) to give two products **46** and **47**. In the ^{1}H NMR spectrum of the enone derivative **47** the vinyl proton was observed at δ 6.60 as a quartet of doublets (J = 1, 5.5 Hz) due to coupling with the enone methyl substituent and most importantly with the ring junction proton. In the corresponding derivative **48** of the *anti-para* product **45**, the 5.5 Hz coupling to the ring junction would be absent and the enone proton would appear only as a finely split quartet.



[8] It could be that the C-2 substituted diene reacts in an almost stepwise manner under pseudo-charge control, which has a different steric demand from the C-2 unsubstituted diene that should react in a more concerted manner. We thank the referee for this suggestion.

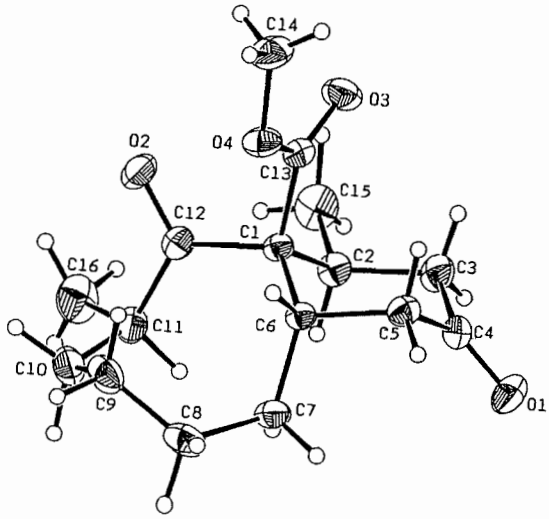
The regiochemistry of adduct **21** was confirmed in a similar manner. Photooxidation of this compound gave enone **49** as the sole product, which showed, in the ^{1}H NMR spectrum, a quartet of doublets (J = 1, 6 Hz) at δ 6.68 for the vinylic proton.



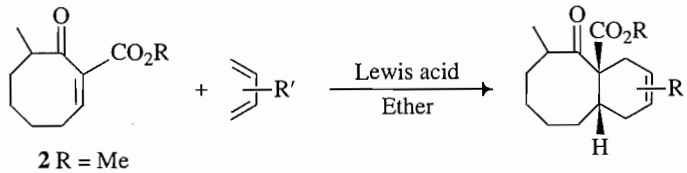
Adducts of **2** and **3** with diene **17** were found to be highly unstable and could not be isolated or characterized. Decomposition occurred in an NMR sample tube in deuteriobenzene within 20 min to give a complex mixture. Even at –22°C extensive decomposition was seen within 24 h. The other functionalized dienes **18**, **19**, and **20** gave stable adducts that could be purified. Nevertheless, addition of **20** to **2** gave primarily the deprotected derivative **37** and only a trace of protected enol ether **38** in which the double bond had migrated. TLC analyses showed that the silyl protecting group was eliminated in the cycloaddition reaction mixture. The structure of **37** was verified by X-ray crystallographic analysis.[9] The X-ray structure is shown in Scheme 5. The regiochemistry of compound **38** was confirmed by ^{1}H NMR decoupling experiments.

Conclusion

The Lewis acid catalyzed Diels–Alder addition of activated cyclooctenones proceeds under mild conditions in high yield and with moderate to high and predictable stereochemistry to give adducts with great potential for synthetic use. Adducts are in use in our laboratory as key intermediates in the synthesis of several natural products and further details on this work will be reported in a future publication.

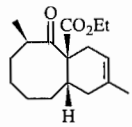
Scheme 5. The three-dimensional X-ray crystallographical structure of compound **37**.

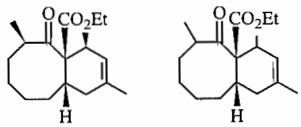
Experimental

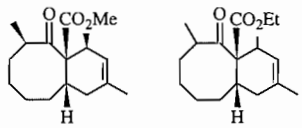


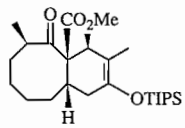
General

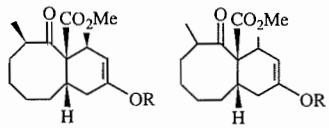
Melting points were recorded on a Kofler hot stage apparatus and are not corrected. Combustion elemental analyses were performed by the microanalytical laboratory of this department. Fourier transform infrared (FT-IR) spectra were recorded on a Nicolet 7199 or Nicolet MX-1 FT-IR spectrophotometer. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Bruker WH-200, Bruker WH-300, Bruker WH-400, or UNITY-500 using deuteriochloroform ($CDCl_3$) as solvent unless otherwise stated. The chemical shift of the deuterated solvent peak (for $CDCl_3$: δ = 7.25 ppm, for C_6D_6: δ = 7.15 ppm) was used as an internal reference. Coupling constants are reported to ±0.5 Hz. Chemical shift measurements are reported in delta (δ) units. The following abbreviations are used: s = singlet, d= doublet, t = triplet, q = quartet, m = multiplet and br = broad. Carbon-13 nuclear magnetic resonance (^{13}C NMR) spectra were recorded on a Bruker WH-300 (75 MHz) NMR spectrometer as solutions in deuteriochloroform ($CDCl_3$) as the internal standard, setting the central peak at 77.00 ppm. Carbon-13 multiplicities were derived from Carr–Purcell–Meiboom–Gill spin echo J-modulated experiments (APT or Attached Proton Test) (18). Methyl and methine groups are shown as singlets antiphase (a) with respect to the deuteriochloroform signal, whereas methylene groups, quaternary carbons, and carbonyl groups appear in phase (p) with it. Nuclear Overhauser enhancement (NOE) experiments were determined in the difference mode in which a control (undecoupled) spectrum was computer subtracted from the irradiated spectrum after Fourier transformation. Positive enhancements are defined as signals possessing an antiphase with respect to the irradiated signal. Samples for NOE measurements were deoxygenated with argon for 10 min prior to use. Two-dimensional (2D) homonuclear correlation spectrum (COSY) and proton spin decoupling experiments were performed on the Bruker WH-300 MHz NMR machine

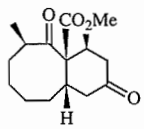


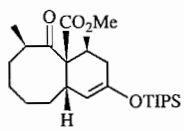


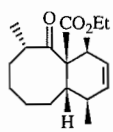












[9] X-ray crystallographic data for **37**, comprising tables of bond distances and angles, atomic parameters, and anisotropic temperature factors, have been deposited and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. With the exception of the anisotropic temperature factors, these data have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

using the standard proton parameters. High-resolution electron impact mass spectra (HRMS) were recorded using an A.E.I. model MS-50 mass spectrometer. Chemical ionization mass spectra (CIMS) were recorded on an A.E.I. MS-12 mass spectrometer, using ammonia as the reagent gas. Spectral data are reported as *m/z* values. Bulb-to-bulb distillation was performed using a Kugelrohr distillation apparatus. Concentrations of solvent systems used in column chromatography are given by volumes.

Unless otherwise stated, all materials used were commercially available. All compounds made were racemic. With the exception of photooxidation, all reactions were carried out under a positive pressure of argon. Solvents were distilled under argon from appropriate drying agents before use. Tetrahydrofuran (THF), diethyl ether, toluene, and 1,2-dimethoxyethane (DME) were freshly distilled from solutions of sodium benzophenone ketyl. Diisopropylamine was distilled from sodium hydroxide or potassium hydroxide. Pyridine, benzene, dichloromethane, and triethylamine (TEA) were distilled from calcium hydride. Reactions requiring anhydrous conditions were performed using oven- or flame-dried glassware, assembled, and allowed to cool while being purged with argon. Argon was passed through a column of 4 Å molecular sieves, with a self-indicating silica gel (coarse grained) as the indicator. Flash chromatography was used routinely for purification and separation of product mixtures, using silica gel (Merck) of 230–400 mesh. All solvents were distilled prior to use for chromatography. Skellysolve B (Skelly B) refers to Skelly Oil Company light petroleum, bp 62–70°C. Analytical thin-layer chromatography (TLC) was carried out on aluminum sheets precoated (0.2 mm layer thickness) with silica gel 60 F_{254} (E. Merck, Darmstadt). Ultraviolet-active materials were detected by visualization under a UV lamp (254 or 350 nm). For TLC, the visualization of the chromatograms was completed by dipping in an ethanol solution of vanillin (5%, w/v) and sulfuric acid (5%, v/v), followed by careful charring on a hot plate.

2-Carbethoxycyclooctanone (4)

To a solution of cycloheptanone (1.12 g, 10 mmol) in ether (15 mL) cooled to 0°C was added boron trifluoride etherate (1.85 mL, 15 mmol). A solution of ethyl diazoacetate (1.71 g, 1.57 mL, 15 mmol) in ether (2 mL) was then added dropwise over 10 min. After 24 h at room temperature, the reaction mixture was cooled to 0°C, and a saturated aqueous solution of sodium bicarbonate was added to the mixture until the pH was raised to 7. The aqueous layer was extracted with ether (3 × 10 mL) and the organic layers were combined, washed twice with water (10 mL each), and once with saturated aqueous sodium chloride solution (10 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The crude product was subjected to flash chromatography on silica gel. Elution with 5% ethyl acetate in Skelly B gave 2-carbethoxycyclooctanone (**4**) (19) (1.47 g, 74% yield). Compound **4** existed as a mixture of ketone and enol in a ratio of 1:1.56. IR ($CHCl_3$ cast): 1747 (C=O, ester, keto form), 1708 (C=O, ketone), 1644 (C=O, ester, enol form), 1613 (enol C=C) cm^{-1}; ^1H NMR (300 MHz in $CDCl_3$) δ: 12.57 (s, 0.39H, O**H**, enol form), 4.20 (q, 0.78H, J = 7.5 Hz, O**C**$\mathbf{H}_2$, enol form), 4.13 (q, 1.22H, J = 7.5 Hz, O**C**$\mathbf{H}_2$ keto form), 3.55 (dd, 0.61H, J = 5, 10.5 Hz, O=CC**H**CO_2Et), 1.28 (t, 1.17H, J = 7.5 Hz, $OCH_2C\mathbf{H}_3$, enol form), 1.22 (t, 1.83 H, J = 7.5 Hz, $OCH_2C\mathbf{H}_3$ keto form); ^{13}C NMR (APT, 75 MHz in $CDCl_3$) for the keto form δ: 212.2 (p), 176.0 (p), 61.1 (p), 57.0 (a), 41.6 (p), 28.9 (p), 27.0 (p), 26.5 (p), 25.2 (p), 24.5 (p), 14.0 (a), for the enol form δ: 172.9 (p), 170.1 (p), 99.2 (p), 60.1 (p), 32.2 (p), 29.9 (p), 28.7 (p), 26.0 (p), 25.5 (p), 23.8 (p), 14.3 (a); HRMS, *m/z* (M^+) calcd. for $C_{11}H_{18}O_3$: 198.12560; found: 198.12535.

2-Carbethoxy-2-cyclooctenone (1)

At 0°C, to a solution of pyridine (0.27 mL, 3.40 mmol) and phenylselenenyl chloride (651 mg, 3.40 mmol) in dichloromethane (20 mL) was added a dichloromethane solution (5 mL) of 2-carbethoxycyclooctanone (**4**) (562 mg, 2.83 mmol) over 30 min. The mixture was stirred at 0°C for 30 min and then poured into ice-cold 2 N aqueous HCl (10 mL). The organic layer was then separated and cooled to 0°C. Aqueous hydrogen peroxide (30%, 1 mL) was added dropwise till the yellow color of the solution discharged. The mixture was stirred for 30 min and then diluted with water (10 mL). The organic layer was separated, and the aqueous layer extracted with ether (3 × 10 mL). The organic layers were combined, washed with saturated aqueous sodium bicarbonate (10 mL), water (10 mL), and saturated aqueous solution of sodium chloride (10 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The crude product was subjected to flash chromatography. Elution with 10% ethyl acetate in Skelly B gave enone **1** (20) (473 mg, 85% yield). IR ($CHCl_3$ cast): 1720 (C=O, ester), 1695 (C=O, ketone), 1640 (C=C) cm^{-1}; ^1H NMR (300 MHz in $CDCl_3$) δ: 7.20 (t, 1H, J = 4.5 Hz, =C**H**), 4.18 (m, 2H, O**C**$\mathbf{H}_2$), 2.55 (m, 2H, O=CC**H**$_2$), 2.38 (m, 1H, =CHC**H**H), 1.25 (t, 3H, J = 7.5 Hz, $OCH_2C\mathbf{H}_3$); ^{13}C NMR (APT, 75 MHz in $CDCl_3$) δ: 208.9 (p), 164.4 (p), 146.4 (a), 131.7 (p), 61.1 (p), 44.53 (p), 30.1 (p), 29.2 (p), 22.1 (p), 21.7 (p), 14.1 (a); HRMS, *m/z* (M^+) calcd. for $C_{11}H_{16}O_3$: 196.10994; found: 196.10952. Anal. calcd. for $C_{11}H_{16}O_3$: C 67.32%, H 8.22%; found: C 67.59%, H 8.17%.

2-Methylcyclooctanone (6)

Diisopropylamine (2.62 mL, 0.02 mol) was dissolved in 12.5 mL of THF and cooled to 0°C while stirring. A solution of *n*-butyllithium (1.6 M in THF, 12.5 mL) was added dropwise over 20 min and the mixture was cooled to −78°C. A solution of cyclooctanone (1.26 g, 0.01 mol) in 5 mL of THF was added dropwise over 30 min. The solution was stirred at −78°C for 30 min followed by rapid addition of methyl iodide (1.24 mL, 0.02 mol). After 5 min, the reaction mixture was allowed to warm to room temperature and was stirred for 40 h. The reaction mixture was quenched with 25 mL of water and the aqueous layer was extracted three times with ether (10 mL each). The organic layers were combined, washed twice with water (10 mL each) and once with saturated aqueous sodium chloride solution (10 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The crude was subjected to flash chromatography on silica gel, eluting with 2.5% ethyl acetate in Skelly B, to give 2-methylcyclooctanone (**6**) (21, 22) (0.86 g, 89% yield based on consumed starting material) along with 30% recovery of the starting material. IR ($CHCl_3$ cast): 1701 (C=O), 1376 (CH_3) cm^{-1}; ^1H NMR (300 MHz in $CDCl_3$) δ: 2.55 (m, 1H, C**H**CH_3), 2.35 (m, 2H, C$\mathbf{H}_2$C=O), 1.00 (d, 3H, J = 7 Hz, C$\mathbf{H}_3$); ^{13}C NMR (APT, 75 MHz in $CDCl_3$) δ: 220.3 (p), 45.3 (a), 40.4 (p), 33.2 (p), 26.4 (p), 26.0

(p), 25.2 (p), 24.1 (p), 6.9 (a); HRMS, *m/z* (M^+) calcd. for $C_9H_{16}O$: 140.12012; found: 140.11977.

2-Methylcycloheptanone (11)

The title compound (23) was prepared from cycloheptanone (5.0 g, 44.6 mmol) in 70% yield using the same procedure as described above.

2-Carbomethoxy-8-methylcyclooctanone (7)

To a suspension of sodium hydride (8.57 g, 0.214 mol, 60% in oil) in 60 mL of DME was added predried dimethyl carbonate (32.17 g, 0.357 mol). The mixture was heated to reflux with stirring. A solution of 2-methylcyclooctanone (**6**) (10 g, 0.0714 mol) in 20 mL of DME was added dropwise and the reaction mixture was refluxed for 19 h, then cooled to 0°C. A 10% aqueous solution of acetic acid was added with stirring until the pH was acidic. The mixture was separated and the aqueous layer was extracted three times with ether (30 mL each). The organic layers were combined, washed with water (30 mL), saturated aqueous solution of sodium bicarbonate (30 mL), water (30 mL), and saturated aqueous solution of sodium chloride (30 mL), dried over magnesium sulfate, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 2.5% ethyl acetate in Skelly B, gave the ß-keto ester **7** (12.0 g, 85% yield) as a colorless oil. This compound was a mixture of two keto forms and an enol form (4:2:3 ratio). IR ($CHCl_3$, cast): 1749 (C═O, ester), 1707 (C═O, ketone), 1640 (C═O, ester, enol form), 1609 (C═C, enol form), 1365 (CH_3) cm^{-1}; ^1H NMR (300 MHz in $CDCl_3$) δ: 13.47 (d, 0.33H, J = 1.5 Hz, **OH**, enol form), 3.46 (dd, 0.22H, J = 5, 10.5 Hz, OCC**H**CO_2Me, minor keto form), 3.29 (dd, 0.45H, J = 3, 15.5 Hz, OCC**H**CO_2Me, major keto form), 3.36 (s, 1.35H, O**C**H_3, ester, major keto form), 3.31 (s, 0.66H, O**C**H_3, ester, minor keto form), 3.25 (s, 0.99H, O**C**H_3, ester, enol form), 1.55 (d, 1.35H, J = 7 Hz, **C**H_3, major keto form), 1.06 (d, 0.99H, J = 7 Hz, **C**H_3, enol form), 1.01 (d, 0.66H, J = 7 Hz, **C**H_3, minor keto form); ^{13}C NMR (75 MHz in $CDCl_3$) for the major keto form, δ: 213.1 (p), 178.5 (p), 56.2 (a), 51.1 (a), 45.2 (a), 37.9 (p), 31.3 (p), 28.2 (p), 26.1 (p), 24.5 (p), 19.1 (a). The following minor ^{13}C NMR signals were observed for the other two isomers: 212.4 (p), 173.8 (p), 170.5 (p), 170.3 (p), 99.6 (p), 54.9 (a), 51.6 (a), 51.5 (a), 46.3 (p), 34.8 (p), 34.4 (a), 31.4 (p), 30.1 (p), 27.4 (p), 26.2 (p), 25.6 (p), 25.0 (p), 24.4 (p), 17.0 (a), 13.9 (a); HRMS, *m/z* (M^+) calcd. for $C_{11}H_{18}O_3$: 198.12560; found: 198.12635. Anal. calcd. for $C_{11}H_{18}O_3$: C 66.64%, H 9.15%; found: C 66.90%, H 9.15%.

2-Carbethoxy-8-methylcyclooctanone (12) and 2-carbethoxy-3-methylcyclooctanone (13)

To a solution of 2-methylcycloheptanone (**11**) (2.56 g, 0.02 mol) in 50 mL of dry ether cooled to 0°C was added boron trifluoride etherate (3.94 mL, 0.032 mol). A solution of ethyl diazoacetate (3.31 mL, 0.032 mol) in 5 mL of dry ether was then added dropwise over 10 min followed by warming to room temperature. After 24 h, the reaction mixture was cooled to 0°C and a saturated aqueous solution of sodium bicarbonate was added to the mixture until the pH was raised to 7. The aqueous layer was extracted three times with ether (10 mL each) and the organic layers were combined, washed twice with water (10 mL each) and once with saturated aqueous sodium chloride solution (10 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The crude product was subjected to flash chromatography on silica gel. Elution with 5% ethyl acetate in Skelly B gave first 2-carbethoxy-8-methylcyclooctanone (**12**) (2.4 g, 56% yield) and then 2-carbethoxy-3-methylcyclooctanone (**13**) (1.6 g, 38% yield). Compound **12** was a mixture of two keto forms and an enol form (3:1:1 ratio). IR ($CHCl_3$ cast): 1747 (C═O, ester), 1708 (C═O, ketone), 1638 (C═O, ester, enol form), 1610 (C═C, enol form) cm^{-1}; ^1H NMR (300 MHz in $CDCl_3$) δ: 12.89 (d, 0.22H, J = 1.5 Hz, **OH**, enol form), 4.19 (q, 0.44H, J = 7 Hz, O**C**H_2, enol form), 4.15–4.05 (m, 1.56H, O**C**H_2, two keto forms), 3.85 (dd, 0.2H, J = 4, 11 Hz, COC**H**CO_2Et, minor keto form), 3.50 (dd, 0.58H, J = 3.5, 12 Hz, COC**H**CO_2Et, major keto form), 1.95 (t, 0.6H, J = 7 Hz, $OCH_2C\mathbf{H}_3$, minor keto form), 1.28 (t, 0.66H, J = 7 Hz, $OCH_2C\mathbf{H}_3$, enol form), 1.21 (t, 1.74H, J = 7 Hz, $OCH_2C\mathbf{H}_3$, major keto form), 1.12 (d, 0.66H, J = 7 Hz, **C**H_3, enol form), 1.11 (d, 1.74H, J = 7 Hz, **C**H_3, major keto form), 0.95 (d, 0.6H, J = 7 Hz, **C**H_3, minor keto form); ^{13}C NMR (75 MHz in $CDCl_3$) for the major keto form, δ: 215.0 (p), 170.24 (p) 61.1 (p), 56.4 (a), 45.1 (a), 35.0 (p), 28.5 (p), 25.9 (p), 25.6 (p), 24.2 (p), 19.0 (a), 14.0 (a). The following minor ^{13}C NMR signals were observed for the other two isomers: 213.7 (p), 177.9 (p), 170.15 (p), 99.6 (p), 60.9 (p), 60.1 (p), 55.0 (a), 46.4 (a), 37.7 (p), 34.1 (a), 31.3 (p), 30.9 (p), 30.2 (p), 27.2 (p), 26.0 (p), 24.7 (p), 24.5 (p), 24.4 (p), 16.7 (a), 14.3 (a), 13.7 (a); HRMS, *m/z* (M^+) calcd. for $C_{12}H_{20}O_3$: 212.14125; found: 212.14087. Compound **13** existed completely in the keto form: IR ($CHCl_3$, cast): 1745 (C═O, ester), 1705 (C═O, ketone), 1385 (CH_3) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 4.10 (m, 2H, O**C**H_2), 3.30 (d, 1H, J = 11 Hz, COC**H**CO_2Et), 2.75–2.56 (m, 1H, C**H**HC═O), 2.54–2.23 (m, 1H, CH**H**C═O), 1.20 (t, 3H, J = 7 Hz, $OCH_2C\mathbf{H}_3$), 0.95 (d, 3H, J = 7 Hz, **C**H_3); ^{13}C NMR (APT, 75 MHz, $CDCl_3$) δ: 211.0 (p), 169.4 (p), 64.7 (a), 61.1 (p), 42.0 (p), 34.7 (a), 34.5 (p), 27.3 (p), 25.6 (p), 23.6 (p), 20.7 (a), 14.1 (a); HRMS, *m/z* (M^+) calcd. for $C_{12}H_{20}O_3$: 212.14125; found: 212.14058.

2-Carbomethoxy-8-methyl-2-cyclooctenone (2)

Sodium hydride (1.02 g, 60% in oil, 25.3 mmol) was suspended in 10 mL of THF with stirring and cooled to 0°C. A solution of 2-carbomethoxy-8-methylcyclooctanone (**7**) (1.0 g, 5.05 mmol) in 5 mL of THF was added dropwise to the suspension over 15 min. When formation of the sodium enolate was complete and hydrogen gas evolution had ceased, a thick suspension developed. Stirring and cooling were continued for 20 min. Then a solution of phenylselenenyl chloride (4.86 g, 25.3 mmol) in 10 mL of THF was added. The reaction mixture was stirred at 0°C for another 15 min, then poured into a solution of ether and aqueous saturated sodium bicarbonate. The aqueous layer was extracted three times with ether (10 mL each). All the organic layers were combined, washed with water twice (10 mL each) and saturated aqueous sodium chloride solution once (10 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The crude product was dissolved in 20 mL of dichloromethane. The solution was stirred at 0°C and aqueous hydrogen peroxide (30%, 2 mL) was added dropwise to the solution. When oxidation was complete, as indicated by the discharge of the yellow color of the solution, the reaction mixture was warmed to room temperature with vigorous stirring for 20 min and then cooled again to 0°C. After 15 min, the suspension of benzeneselenenic acid

For personal use only.

was filtered off. The filtrate was washed once with 10 mL of saturated aqueous solution of sodium bicarbonate, twice with water (10 mL each), and once with saturated aqueous solution of sodium chloride (10 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The crude product was subjected to flash chromatography on silica gel. Elution with 10% ethyl acetate in Skelly B gave 2-carbomethoxy-8-methyl-2-cyclooctenone (**2**) (0.86 g, 86% yield) as a colorless oil. IR ($CHCl_3$ cast): 1723 (C=O, ester), 1695 (C=O, ketone), 1640 (C=C), 1379 (α-CH_3), 1365 (OCH_3) cm^{-1}; ^1H NMR (300 MHz in $CDCl_3$) δ: 7.18 (t, 1H, J = 4.5 Hz, =C**H**), 3.68 (s, 3H, O**C**$\mathbf{H}_3$), 2.60 (m, 1H, C**H**CH_3), 2.34 (m, 2H, =CHC$\mathbf{H}_2$), 1.10 (d, 3H, J = 7 Hz, C$\mathbf{H}_3$); ^{13}C NMR (APT, 75 MHz in $CDCl_3$) δ: 211.0 (p), 165.0 (p), 147.0 (a), 131.4 (p), 52.2 (a), 47.5 (a), 30.2 (p), 29.7 (p), 26.0 (p), 21.5 (p), 15.3 (a); HRMS, *m/z* (M^+) calcd. for $C_{11}H_{16}O_3$: 196.10984; found: 196.11022. Anal. calcd. for $C_{11}H_{16}O_3$: C 67.32%, H 8.22%; found: C 67.23%, H 8.31%.

2-Carbethoxy-8-methyl-2-cyclooctenone (3)

This compound was prepared from keto ester **12** (500 mg, 2.36 mmol) in 85% yield using the phenylselenenylation – oxidative elimination process described above. IR ($CHCl_3$ cast): 1720 (C=O, ester), 1696 (C=O, ketone), 1639 (C=C), 1378 (α-CH_3), 1369 (CH_3, ester) cm^{-1}; ^1H NMR (300 MHz in $CDCl_3$) δ: 7.18 (t, 1H, J = 4.5 Hz, =C**H**), 4.27 (m, 2H, O$\mathbf{CH}_2$), 2.60 (m, 1H, C**H**CH_3), 2.35 (m, 2H, $\mathbf{CH}_2$CH=), 1.23 (t, 3H, J = 7 Hz, $OCH_2\mathbf{CH}_3$), 1.14 (d, 3H, J = 7 Hz, C$\mathbf{H}_3$); ^{13}C NMR (APT, 75 MHz in $CDCl_3$) δ: 211.0 (p), 164.6 (p), 146.0 (a), 131.9 (p), 61.1 (p), 47.7 (a), 30.2 (p), 29.9 (p), 26.1 (p), 21.6 (p), 15.6 (a), 14.1 (a); HRMS, *m/z* (M^+) calcd. for $C_{12}H_{18}O_3$: 210.12560; found: 21.12554. Anal. calcd. for $C_{12}H_{18}O_3$: C 68.55%, H 8.63%; found: C 68.45%, H 8.50%.

General procedure for the preparation of trialkylsilyloxy substituted 1,3-butadienes 17–20

Diisopropylamine (0.25 mL, 1.8 mmol) was dissolved in 5 mL of THF and cooled to 0°C with stirring. A solution of *n*-butyllithium (1.6 M in THF, 1.2 mL, 1.9 mmol) was added dropwise over 20 min. The resulting lithium diisopropylamide solution was then cooled to −78°C followed by dropwise addition of a solution of the corresponding substituted methyl vinyl ketone (100 mg, 1.2 mmol) in 5 mL of THF over 30 min. The solution was stirred at −78°C for 30 min followed by rapid addition of the corresponding trialkylsilyl chloride (1.8 mmol). The reaction mixture was allowed to warm to room temperature after 15 min and stirred at room temperature for 40 h. The reaction mixture was quenched with 10 mL of water and the aqueous layer was extracted three times with Skelly B (10 mL each). The organic solutions were combined, washed twice with water (10 mL each) and once with saturated aqueous sodium chloride solution (10 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The crude yellow oil was purified by bulb-to-bulb distillation to give the product.

2-tert-*Butyldimethylsilyloxy-3-methyl-1,3-butadiene (**17**)*

This compound was prepared in an improved yield of 92% yield from 3-methyl-3-buten-2-one using *tert*-butyldimethylsilyl chloride as the trapping reagent according to the reported procedure (14, 24).

*2-Triisopropylsilyloxy-3-methyl-1,3-butadiene (**18**)*

The title compound was prepared from 3-methyl-3-buten-2-one using triisopropylsilyl chloride as the trapping reagent. Bulb-to-bulb distillation of the crude product at 80°C/0.2 Torr (1 Torr = 133.3 Pa) gave the desired diene **18** in 70% yield. IR (hexane cast): 1590 (C=C-O), 1384 (CH_3), 1023, 819 (Si-O-C) cm^{-1}; ^1H NMR (300 MHz in C_6D_6) δ: 5.70 (ddd, 1H, J = 0.5, 0.5, 2.5 Hz, C**H**H=C(CH_3)), 5.00 (s, br, CH**H**=C(CH_3)), 4.45 (s, 1H, C**H**H=C(OTIPS)), 4.35 (s, 1H, CH**H**=C-(OTIPS)), 1.75 (s, 3H, C$\mathbf{H}_3$C=), 1.13–1.11 (m, 21H, C**H**, C$\mathbf{H}_3$ on TIPS); ^{13}C NMR (75 MHz in C_6D_6) δ: 157.2 (p), 140.2 (p), 113.9 (p), 91.7 (p), 19.9 (a), 18.3 (6C, a), 13.2 (3C, a); HRMS, *m/z* (M^+) calcd. for $C_{14}H_{28}OSi$: 240.19095; found: 240.18995.

trans-*2*-tert-*Butyldimethylsilyloxy-1,3-pentadiene (**19**)*

Diene **19** was prepared from *trans*-3-penten-2-one using *tert*-butyldimethylsilyl chloride as the trapping reagent. Bulb-to-bulb distillation of the crude product and collecting the fraction at 70°C/0.5 Torr gave the diene in 85% yield. IR (neat film): 1657 and 1641 (C=C, conjugated), 1593 (C=C-O), 1023, 826 (Si-O-C) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 6.17 (qd, 1H, J = 7, 14 Hz, CH_3C**H**=CH), 5.88 (qd, 1H, J = 2, 14 Hz, CH_3CH=C**H**), 4.29 (s, 1H, =CH**H**), 4.22 (s, 1H, =C**H**H), 1.58 (dd, 3H, J = 2, 7 Hz, C$\mathbf{H}_3$CH=), 0.99 (s, br, 9H, $(\mathbf{CH}_3)_3$C), 0.15 (s, br, 6H, 2 C$\mathbf{H}_3$); ^{13}C NMR (APT, 75 MHz, C_6D_6) δ: 155.4 (p), 129.8 (a), 126.0 (a), 93.4 (p), 25.8 (3C, a), 18.3 (p), 17.3 (a), −4.7 (2C, a); HRMS, *m/z* (M^+) calcd. for $C_{14}H_{28}OSi$: 240.19095; found: 240.18995.

trans-*2-Triisopropylsilyloxy-1,3-pentadiene (**20**)*

The title compound was prepared from 3-penten-2-one using triisopropylsilyl chloride as the trapping reagent. The crude product was purified by bulb-to-bulb distillation. Diene **20** was collected at 40°C/0.5 Torr in 90% yield. ^1H NMR (300 MHz, C_6D_6) δ: 6.25 (qd, 1H, J = 7, 14 Hz, CH_3C**H**=CH), 5.88 (qd, 1H, J = 2, 14 Hz, CH_3CH=C**H**), 4.29 (s, br, 1H, **H**HC=), 4.19 (s, br, 1H, H**H**C=), 1.60 (dd, 3H, J = 2, 7 Hz, =CHC$\mathbf{H}_3$), 1.13 (m, 3H, 3 SiC**H**$(CH_3)_2$), 1.02 (d, 18H, J = 6.5 Hz, 3 CH($\mathbf{CH}_3)_2$); ^{13}C NMR (300 MHz, C_6D_6) δ: 155.8 (p), 130.0 (a), 126.1 (a), 92.8 (p), 18.3 (a), 17.9 (6C, a), 12.6 (3C, a); HRMS, *m/z* (M^+) calcd. for $C_{14}H_{28}OSi$: 240.19095; found: 240.18994.

General procedure for $FeCl_3$, $SnCl_4$, and $BF_3 \cdot OEt_2$ catalyzed Diels–Alder reactions

To an ethereal solution (3 mL) of enone (0.24 mmol) was added the diene (2.4 mmol). Lewis acid (0.24 mmol) was then added and the resulting solution was stirred. The progress of the reaction was monitored by TLC. Upon completion, a saturated aqueous sodium bicarbonate solution was added. The ether layer was separated and the aqueous layer was extracted three times with ether (10 mL each). The combined ether solutions were washed with water (10 mL) and saturated aqueous sodium chloride solution (10 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The residue was purified by flash chromatography (ethyl acetate – Skelly B) to give the desired adduct(s). Yield, time, and temperature of each reaction are shown in Tables 1, 2, and 3. When more than one product was obtained, products are presented in order of elution from flash chromatography.

General procedure for $ZnCl_2$ catalyzed Diels–Alder reactions

Zinc chloride (0.48 mmol) was fused in a reaction flask under an argon atmosphere and dissolved in dry ether (3 mL). A solution of enone (0.24 mmol) in dry ether (1 mL) was added. After stirring at room temperature for 30 min, diene (2.4 mmol) was then added. The resulting mixture was stirred at room temperature. The reaction was monitored with TLC and upon completion was quenched with saturated aqueous sodium bicarbonate solution. The ether layer was separated and the aqueous layer was extracted three times with ether (10 mL each). The combined ether solutions were washed with saturated aqueous sodium chloride solution (10 mL), dried over anhydrous magnesium sulfate, filtered, and concentrated. The residue was purified by flash chromatography (ethyl acetate – Skelly B) to give the desired adduct(s). Yields and reaction conditions are shown in Tables 1, 2, and 3.

(1S, 8S*)-1-Carbethoxy-10-methylbicyclo[6.4.0]dodec-10-en-2-one (**21**)*: IR ($CHCl_3$ cast): 1738 (C=O, ester), 1705 (C=O, ketone) cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) δ: 5.18 (m, 1H, =C**H**), 4.10 (m, 2H, OC$\mathbf{H}_2$), 3.15 (m, 1H, C**H**, C-8), 3.11 (dm, 1H, J = 12 Hz, CH**H**C=O), 2.80 (ddd, 1H, J = 1.5, 5.5, 18.5 Hz, C**H**H, C-12), 2.54 (dm, 1H, J = 18 Hz, C**H**H, C-9), 2.16 (dddd, 1H, J = 2, 4, 7, 18.5 Hz, CH**H**, C-12), 2.08 (ddd, 1H, J = 3.5, 5, 12 Hz, C**H**HC=O), 1.58 (s, br, 3H, =CC$\mathbf{H}_3$), 1.18 (t, 3H, J = 7 Hz, $OCH_2C\mathbf{H}_3$); ^{13}C (APT, 75 MHz, $CDCl_3$) δ: 212.3 (p), 170.6 (p), 131.6 (p), 118.5 (a), 63.34 (p), 61.5 (p), 37.2 (p), 36.4 (p), 32.8 (a), 32.6 (p), 29.8 (p), 26.2 (p), 25.09 (p), 24.2 (p), 23.4 (a), 14.0 (a); HRMS, *m/z* (M^+) calcd. for $C_{16}H_{24}O_3$: 264.17255; found: 264.17239.

General procedure for the $SnCl_4$ catalyzed Diels–Alder reaction of trialkylsilyloxy substituted dienes 17–20

Stannic chloride (0.24 mmol) was added to an ether solution (3 mL) of enone **2** (0.24 mmol) at −78°C and stirred for a period of time to allow for the formation of the complex of stannic chloride and the dienophile **2**. Then an ether solution (1 mL) of diene (0.48 mmol for dienes **18** and **20**, 2.4 mmol for dienes **17** and **19**) was added and the reaction was monitored by TLC. Upon completion of the reaction, saturated aqueous sodium bicarbonate solution was added. The ether layer was separated and the aqueous layer was extracted three times with ether (10 mL each). The combined ether solutions were washed with water (10 mL) and saturated aqueous sodium chloride solution (10 mL), dried over anhydrous magnesium

(1R, 3R*, 8S*)-11-Acetoxy-1-carbethoxy-3-methyl-10-methylenebicyclo[6.4.0]dodec-11-en-2-one (**46**) and (1S*, 3R*, 8S*)-1-carbethoxy-3,10-dimethylbicyclo-[6.4.0]dodec-9-ene-2,11-dione (**47**)*

A gentle stream of oxygen was bubbled through a solution of the Diels–Alder adduct **29** (50 mg, 0.18 mmol), acetic anhydride (0.025 mL, 0.27 mmol), pyridine (0.021 mL, 0.27 mmol), 5,10,15,20-tetraphenyl-21*H*, 23*H*-porphine (5 mg), and 4-dimethylaminopyridine (catalytic amount) in 40 mL of carbon tetrachloride for 20 min. The bubbling was continued while the solution was irradiated with two 200-W tungsten light bulbs for 35 h. After turning off the light, bubbling was continued for another 19 h. The solution was diluted with 20 mL of ether and then washed with saturated aqueous sodium bicarbonate (15 mL), aqueous 1 M HCl (15 mL), and saturated aqueous sodium chloride solution (10 mL). The organic layer was separated, dried over anhydrous magnesium sulfate, filtered, and concentrated to give the crude product. This crude product was subjected to flash chromatography. Elution with 5% ethyl acetate in Skelly-B gave first the compound **46** (16.3 mg, 31% yield) and then compound **47** (7 mg, 13% yield). For compound **46**: IR (CH_2Cl_2, cast): 1767 (C=O, acetate), 1761 (C=O, ketone), 1744 (C=O, ester), 1682 (C=C, endocyclic), 1678 (C=C, exocyclic) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 5.70 (s, 1H, =C**H**), 5.10 (m, 1H, =CH**H**), 4.95 (s, 1H, =C**H**H), 4.18 (m, 2H, OC**H**$_2$), 3.12 (m, 1H, C**H**CH$_3$), 2.80 (dddd, 1H, *J* = 2, 2, 4, 15 Hz, C**H**HC=CH$_2$), 2.70 (m, 1H, C**H**, ring junction), 2.30 (s, 3H, COC**H**$_3$), 2.20 (dd, 1H, *J* = 3, 15 Hz, CH**H**C=CH$_2$), 1.20 (t, 3H, *J* = 7 Hz, OCH$_2$C**H**$_3$), 0.90 (d, 3H, *J* = 7 Hz, C**H**$_3$); ^{13}C NMR (APT, 75 MHz, $CDCl_3$) δ: 215.5 (p), 170.4 (p), 169.0 (p), 147.0 (p), 134.7 (p), 114.0 (a), 111.6 (p), 65.5 (p), 61.5 (p), 42.2 (a), 41.3 (a), 38.1 (p), 34.4 (p), 29.8 (p), 29.5 (p), 28.7 (p), 24.9 (p), 20.8 (a), 19.1 (a); HRMS, *m/z* (M^+) calcd. for $C_{19}H_{26}O_5$: 334.17801; found: 334.17771. For compound **47**: IR ($CHCl_3$, cast): 1738 (C=O, ester), 1698 (C=O, ketone), 1682 (C=O, enone) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 6.60 (dq, 1H, *J* = 1, 5.5 Hz, =C**H**), 4.15 (m, 2H, OC**H**$_2$), 3.40 (m, 1H, C**H**CH=), 3.15 (m, 1H, C**H**CH$_3$), 3.05 (s, br, 2H, C**H**$_2$CO), 1.72 (d, 3H, *J* = 1 Hz, =CC**H**$_3$), 1.19 (t, 3H, *J* = 7 Hz, OCH$_2$C**H**$_3$), 1.09 (d, 3H, *J* = 7 Hz, C**H**$_3$); ^{13}C NMR (APT 75 MHz, $CDCl_3$) δ: 213.0 (p), 195.2 (p), 171.1 (p), 148.1 (a), 133.3 (p), 64.5 (p), 61.9 (p), 42.2 (a), 41.6 (a), 38.3 (p), 35.5 (p), 27.9 (p), 26.5 (p), 26.1 (p), 19.5 (a), 15.5 (a), 14.0 (a); HRMS, *m/z* (M^+) calcd. for $C_{17}H_{24}O_4$: 292.16745; found: 292.16791.

(1S, 8S*)-1-Carbethoxy-10-methylbicyclo[6.4.0]dodec-9-ene-2,11-dione (**49**)*

This compound was prepared from adduct **21** in 31% yield using the photooxidation process described above. IR ($CHCl_3$ cast): 1733 (C=O, ester), 1708 (C=O, ketone), 1680 (C=O, conjugated ketone) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 6.68 (dd, 1H, *J* = 1, 6 Hz, =C**H**), 4.13 (m, 2H, OC**H**$_2$), 3.70 (m, 1H, C**H**, ring junction), 3.13 (dd, 1H, *J* = 1, 18 Hz, CH**H**C=O, C-12), 3.04 (ddd, 1H, *J* = 4, 12, 13 Hz, C**H**HC=O, C-3), 2.69 (d, 1H, *J* = 18 Hz, C**H**HC=O, C-12), 2.21 (ddd, 1H, *J* = 4, 5.5, 13 Hz, CH**H**C=O, C-3), 1.57 (s, 3H, =CC**H**$_3$), 1.17 (t, 3H, *J* = 7 Hz, OCH$_2$C**H**$_3$); ^{13}C NMR (APT, 75 MHz $CDCl_3$) δ: 208.4 (p), 196.5 (p), 170.4 (p), 147.0 (a), 134.7 (p), 65.9 (p), 62.3 (p), 38.8 (a), 37.3 (p), 30.2 (p), 29.8 (p), 28.0 (p), 26.1 (p), 25.0 (p), 15.5 (a), 13.9 (a); HRMS, *m/z* (M^+) calcd. for $C_{16}H_{22}O_4$: 278.15179; found: 278.15197.

Acknowledgments

The contribution of Miss J. Yip of this laboratory is gratefully acknowledged for the preparation of diene **17**. We are also grateful to the Natural Sciences and Engineering Research Council of Canada and the National Science Council of the Republic of China for financial support.

Preparation and bioactivity of pyrazole derivatives as potential cross-linking agent

H. Katayama and T. Oshiyama

Abstract: A series of pyrazole derivatives with two and three alkylating sites were prepared and their cytotoxicity against cancer cells as well as antitumor activity against L1210 was investigated. The best result of cytotoxicity was obtained with the trichloride **5** and the best antitumor activity (ILS 33%) with the dibromide **3**. These results can provide valuable information for further study of the more effective antitumor agent.

Key words: pyrazole, synthesis, cytotoxicity, antitumor activity, polyalkylator.

Résumé : On a préparé une série de dérivés du pyrazole avec deux et trois sites d'alkylation et on a étudié leur cytotoxicité contre les cellules cancéreuses aussi bien que leur activité antitumorale vis à vis du L1210. On a obtenu les meilleurs résultats de cytotoxicité avec le trichlorure **5** et la meilleure activité antitumorale (ILS 33%) avec le dibromure **3**. Ces résultats peuvent fournir une information valable pour une étude plus poussée de l'agent antitumoral le plus efficace.

Mots clés : pyrazole, synthèse, cytotoxicité, activité antitumorale, polyalkylateur.

Introduction

Among alkylating agents with antitumor activities, the agents that are able to cross-link DNA are believed to be much more effective than singly alkylating agents (e.g., nitrogen mustard) (1). The degree of DNA cross-linking was correlated with the rate of cell death and it was suggested that the cross-linking of DNA represents the molecular basis for the inhibition of DNA replication and consequent cell death (e.g., mitomycin C) (2). The cross-linking distance is quite important for clinically effective anticancer agents and the distance of four carbons was reported to be quite important for effective clinical treatment as demonstrated in an activated form of mitomycin C (MMC), pyrrolizidine alkaloid, and busulphan (Chart 1) (3). The DNA cross-linking action of the mitomycins remains unique among the known naturally occurring antibiotics (2). This action was confirmed with simplified molecular models such as 2,3-bis(acetoxymethyl)-1-methylpyrrole (BAMP). Similar simplification of the pyrrolizidine alkaloid was also accomplished with the synthesis of dehydroretronecine diacetate (DHRA). These compounds were able to cross-link the DNA with some sequence selectivity (Chart 1, cross-linking sites are marked with full circle) (4). We had planned to introduce the cross-linking distance of these compounds into the skeleton of pyrazolo[1,5-*a*]indole, which has been attracting our interest from the chemical and bioactive standpoint (5), and elaborated the target compounds **A** and **B**. Compound **A** can be regarded as an 3-azamitosene. We are also interested in compound **C**, because it is formed by cleaving the C4—C4a bond of **B** and may provide useful information for evaluating the bioactivities of compound **B**. The nonplanarity of the 1-phenyl group in **C** is also important in this evaluation, because the twist angle between the 1-phenyl and pyrazole rings was estimated to be around 50° (6), but these two rings are planar in **B**. In this article we would like to report the preparation and bioactivity of compound **C**.

Results and discussion

Compounds **1–5** were synthesized according to the scheme summarized in Chart 2. Starting compound **6** was prepared by coupling benzaldehyde phenylhydrazone and ethyl acetoacetate at 120°C for 3.5 h in an open flask (7*a*). Introduction of bromide at the 5-methyl group was carried out by radical bromination with *N*-bromosuccimide (NBS) (8), and the bromide **7** was hydrolyzed with $NaHCO_3$ in aqueous tetrahydrofuran (THF) at refluxing temperature to give hydroxyester **8**. Addition of tetra-*n*-butylammonium salt was essential for this selective reaction. This reaction is analogous with the esterification of carboxylate with alkyl halide catalyzed with phase transfer catalyst (9). Reduction of hydroxyester **8** with lithium aluminum hydride (LAH) in ether yielded diol **9** in 51% yield. Transformation of the diol to the dicarbamate was carried out by the reported method (10). Thus diol **9** was esterified with phenyl chloroformate, and the bis-phenyl carbonate **10** so obtained was treated with ammonia to give the bis-carbamate **1** in good yield. When diol **9** was mesylated with methanesulfonyl chloride and triethylamine in dichloromethane, dimesylate was not obtained but the stable dichloride **2** was formed as a single product. This type of substitution readily takes place when the mesylate is treated with nucleophiles (e.g.,

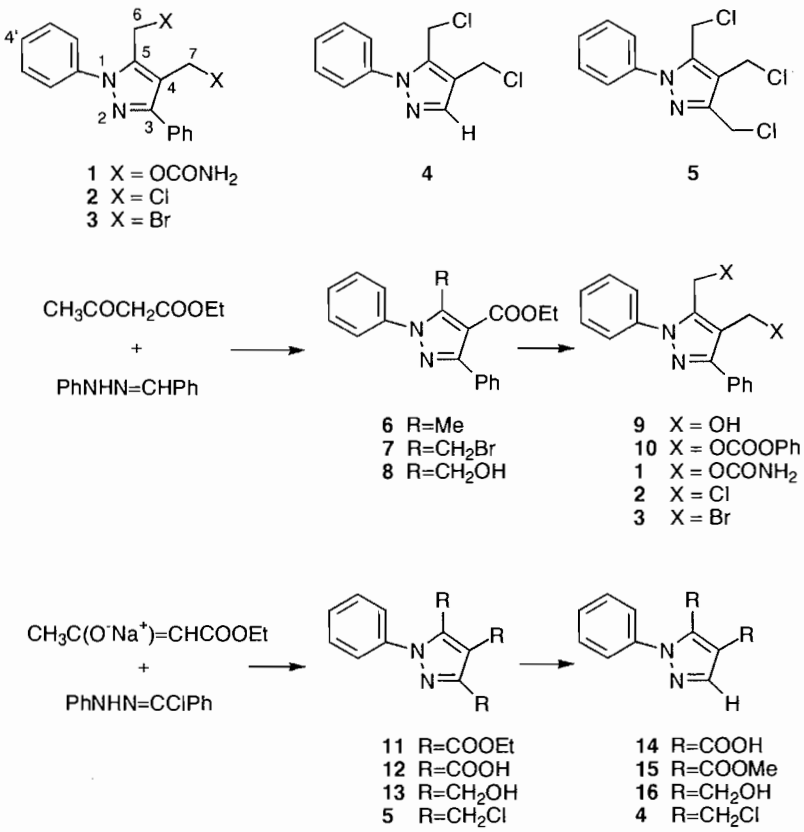
Chart 1.

LiCl) in polar aprotic solvent (11), and this method is useful even at non-activated positions such as the C-11 of mitomycins (12). In the ^{13}C NMR of **2**, the difference in the chemical shifts of the C-7 (Δ 18.1 ppm) between diol **9** and dichloride **2** was about the same as that of the benzylic site (Δ 18.1 ppm) between benzyl alcohol and benzyl chloride (13). This similarity suggests that the chemical reactivity of **2** is comparable with that of benzyl chloride. As a compound that is more reactive than dichloride **2**, the dibromide **3** was prepared from the dialcohol **9** by refluxing in 48% HBr solution.

In preliminary cytotoxic tests a better level of activity was detected with chloride **2** than with carbamate **1**, so only chlorides were synthesized for the following pyrazole derivatives. Dichloride **4** was required to investigate the effect of the 2-substituent and trichloride **5** to explore the effect of an additional alkylating site on bioactivities. Compound **5** is unique in having three alkylating sites within the same molecule, all in a 1,4 relationship. Few alkylating agents with more than three alkylating sites in the molecule, e.g., polyaziridinyl compounds (14), have been investigated. Compounds **4** and **5** were prepared from triester **11**, which was obtained by the coupling reaction of hydrazonylchloride with the sodium salt of the β-ketoester as shown in Chart 2 (15). Since the formation of anhydride may takes place readily between two carboxyl groups and the removal of the 3-carboxyl group at 120°C was reported with 1-*p*-nitrophenylpyrazole-3,4,5-tricarboxylic acid (15), the triester **11** was converted to the triacid **12** (16) and **12** was reacted with acetic anhydride at the boiling point (138–140°C) for 7 h. During the reaction a stream of argon was introduced to the reaction vessel and CO_2 generation was monitored by bubbling the argon stream into an aqueous solution of barium hydroxide. The reaction was halted when no generation of CO_2 was detected (7 h). The crude reaction product of **14** obtained by the removal of acetic anhydride was dissolved in methanol and methylated by refluxing with sulfuric acid. The diester **15** (16) thus obtained was reduced with LAH to give the diol **16**. In the ^1H NMR spectrum of **16** a characteristic singlet signal for the 3-H (δ 7.62) was observed, which supports the removal of the 3-carboxyl group. The transformation of diol **16** to dichloride **4** was effected with MsCl, *s*-collidine, and LiCl in DMF (11). Triol **13** was prepared by the reduction of the triester **11** with LAH and was transformed to the trichloride **5** by a reaction similar to that used in the preparation of **4**. Special care was taken to isolate the diols **9** and **16** and the triol **13** after LAH reduction. Aqueous work-up of the LAH reduction product caused difficulties in the isolation of these alcohols and resulted in poor yields. Thus the work-up procedure using NaF and a controlled amount of water (17) was adopted and only moderate yields of these alcohols were obtained. An alternative procedure reported for isolating intractable aminodiol by using triethanolamine (18) was not effective in our case. Reduction of **11** with $NaBH_4$ in *t*-BuOH–MeOH (19) was used to avoid this work-up problem but was also not effective in reducing the ester group.



Cytotoxicity was measured by the microculture tetrazolium assay (20). Results for pyrazole derivatives **1–5** against cancer cells are summarized in Table 1. The activities of these compounds are relatively weak compared with the reference compound, MMC. The dichloride **2** was found to be more active than the dicarbamate **1**. The low activity of **1** may be a result of the poor reactivity of carbamate as a leaving group. But the

Chart 2.

dibromide **3**, which is chemically more reactive than the dichloride **2**, did not show a higher activity than **2**. The activity of **3** was found to be as low as that of the carbamate **1**. The small difference in activity between the two dichlorides, **2** and **4**, indicates that the contribution of the 2-phenyl group to the cytotoxic activity may be poor. Selectivity of activity against cancer cells was small. Since the trichloride **5** showed the highest activity against cancer cells, the number of alkylating sites may play an important role in the cytotoxicity. The activity of the trichloride **5** against uterus cervical cancer cells (HeLa) was noteworthy, since the increase of the alkylating sites from two to three increased the activity of the trichloride **5** 36 times more than that of the dichloride **2**. The activity of **5** against HeLa cell was found to be 2.8 times stronger than that of MMC.

Antitumor activities of the selected pyrazole derivatives **1–3** and **5** against murine leukemia L1210 are cited in Table 2 and the effect is expressed by ILS (increase of life span in %). The carbamate **1** did not show antitumor activity but it showed toxicity in mice. ILS of the dichloride **2** was proportional to the dose and 25.6% of ILS was obtained when a dose of 200 mg/kg was applied. At the same dose, the dibromide **3** showed a slightly better ILS value of 33.3%, which is thought to be effective. Although these ILS were relatively low compared with mitomycin C (74.4%), this dose dependence suggests that the intrinsic toxic property of the skeleton **C** is small. Contrary to the encouraging effects of **2** and **3**, the ILS of trichloride **5** was disappointingly small (4.8%) at maximum dose (12.5 mg/kg). In **5**, toxic effects became more significant than the desired activity at higher dose. The high chemical reactivity could be the reason for the toxic effect of **5**. Since the electron density at N-1 can control the reactivity of the alkylating sites, it may be possible to explore the desirable properties of the more effective antitumor agent by introducing a proper substituent at the N-1 position. Finally, the trichloride **5** attracted the attention of NCI in its in vitro screening test against 60 cancer cell lines but the potency in the test against prostate cell strains was disappointing. In conclusion, we have prepared a series of 1-phenylpyrazole derivatives with two and three alkylating sites and evaluated their cytotoxicities against cancer cells and antitumor activities against murine leukemia L1210. The best result of cytotoxicity was obtained with the trichloride **5** and the best in vivo result (ILS 33%) was obtained with the dibromide **3**. These results could provide valuable information for the further study of a series of **B** compounds.

Experimental

All melting points (mp) were determined with a Yanaco micro melting point apparatus without correction. Spectra were measured with the following spectrometers: IR (KBr pellet unless otherwise stated), Perkin–Elmer FT-IR 1720; ^{1}H and ^{13}C NMR, JEOL JNM-FT 200 and JNM-ALPHA 400 in $CDCl_3$ (unless otherwise mentioned) at ambient temperature (25–27°C) with tetramethylsilane as an internal standard; MS and high-resolution MS (HRMS), Hitachi RMU-7MG; UV and visible spectra (VIS), Shimadzu UV-200.

Anal. calcd. for $C_{19}H_{17}BrN_2O_2$ (mw 385.25): C 59.24, H 4.45, N 7.27%; found: C 59.33, H 4.46, N 7.25.

Ethyl 5-hydroxymethyl-1,3-diphenylpyrazole-4-carboxylate 8

Bromide **7** (3.00 g, 7.8 mmol) and tetra-*n*-butylammonium bromide (0.75 g, 2.3 mmol; 29 mol%) were dissolved in tetrahydrofuran (THF, 30 mL). To this solution was added saturated aqueous $NaHCO_3$ solution (30 mL) and the mixture was refluxed until the total disappearance of **7** was observed on TLC (27 h). The solution was evaporated and the residue was diluted with water. Following extraction with CH_2Cl_2 (60 mL × 3), usual work-up of the extracts gave the crude product. Purification with flash column chromatography (SiO_2, petroleum ether – ethyl acetate 4:1) yielded the alcohol **8** (2.51 g, 41.0%), mp 80.5–81.5°C (petroleum ether – ethyl acetate 10:1). IR: 3451, 1707, 1598, 1538, 1501, 1216, 1185, 775, 769, 764, 759, 697 cm^{-1}. ^1H NMR δ: 1.20 (3H, t, J = 7.1, OCH_2CH_3), 4.14 (1H, t, J = 7.3, OH), 4.27 (2H, q, J = 7.1, OCH_2Me), 4.77 (2H, d, J = 7.1, 6-*H*; singlet by D_2O addition), 7.36–7.43 (3H, m, Ar-*H*), 7.45–7.61 (5H, m, Ar-*H*), 7.63–7.68 (2H, m, Ar-*H*). ^{13}C NMR δ: 13.9 (C-*9*), 55.3 (C-*6*), 60.9 (C-*8*), 111.7 (C-*4*), 125.6 (2 × C), 127.6 (2 × C), 128.5, 129.0, 129.4 (2 × C), 129.6 (2 × C), 132.7, 138.2 (C-*3*), 147.7 (C-*5*), 153.5,

165.1 (C-7). MS *m/e* (relative %): 323 (M^+ + 1, 7), 322 (M^+, 45), 276 (36), 275 (100), 247 (4), 104 (7), 77 (55), 43 (78). Anal. calcd. for $C_{19}H_{18}N_2O_3$ (mw 322.36): C 70.79, H 5.63, N 8.69%; found: C 70.84, H 5.63, N 8.66.

4,5-Dihydroxymethyl-1,3-diphenylpyrazole 9

A solution of hydroxyester **8** (0.285 g, 0.88 mmol) in anhydrous ether (60 mL) was added gradually to a solution of lithium aluminum hydride (0.8 g, 21.1 mmol) in dry ether (10 mL) for 1 h. The reaction mixture was stirred overnight. After cooling with an ice-bath, the reaction was successively quenched with NaF (2.5 g, 59.5 mmol) and water (5 mL). The resulting solution was stirred vigorously at room temperature until the inorganic precipitates became totally white. The inorganics were removed by filtration and washed well with ether (50 mL). The filtrate and washings were combined, dried with anhydrous $MgSO_4$ overnight, and evaporated. Chromatographic purification of the crude product gave the diol **9** (0.127 g, 51.3%), mp 167.0–168.0°C (from EtOH). IR: 3379, 3338, 3181, 3060, 1596, 1559, 1503, 1117, 1008, 993, 775, 715 cm^{-1}; ^1H NMR δ: 4.53 (2H, d, *J* = 5.0, 7-H; singlet by irradiation at δ 5.00), 4.54 (2H, d, *J* = 5.2, 6-H; singlet when irradiated at δ 5.44), 5.00 (1H, t, *J* = 5.0, O*H*), 5.44 (1H, t, *J* = 5.2, O*H*), 7.86–7.93 (2H, m, Ar-*H*), 7.74–7.80 (2H, m, Ar-*H*), 7.34–7.60 (6H, m, Ar-*H*). ^{13}C NMR δ: 51.7 (C-*7*), 52.7 (C-*6*), 119.1 (C-*4*), 123.8 (2 × C), 127.4, 127.5 (2 × C), 127.7, 128.4 (2 × C), 129.1 (2 × C), 133.1, 139.4 (C-*3*), 142.0 (C-*5*), 150.3. MS *m/e* (relative %): 281 (M^+ + 1, 14), 280 (M^+, 100), 262 (35), 261 (57), 233 (49), 130 (31), 104 (26), 77 (86). Anal. calcd. for $C_{17}H_{16}N_2O_2$ (mw 280.33): C 72.84, H 5.75, N 9.99%; found: C 72.90, H 5.89, N 9,99.

4,5-Diphenoxycarbonyloxymethyl-1,3-diphenylpyrazole 10

Phenyl chloroformate (2.98 mL, 23.8 mmol) was introduced into a solution of the dialcohol **9** (2.20 g, 7.8 mmol) in dry pyridine (15 mL) that was precooled in an ice-bath. The resulting solution was stirred at room temperature for 46 h. The solution was diluted with water (100 mL), and precipitates were collected. Recrystallization of the crude product from acetone–hexane (1:5) gave **10** (3.797 g, 93.0%), mp 138.5–139.0°C. IR: 1765, 1598, 1501, 1471, 1376, 1257, 1204, 779, 706 cm^{-1}. ^1H NMR δ: 5.45 (4H, s, 6-H_2 + 7-*H*), 7.07–7.58 (16H, m, Ar-*H*), 7.64 (2H, m, Ar-*H*), 7.83 (2H, m, Ar-*H*). ^{13}C NMR δ: 58.5 (C-*7*), 60.5 (C-*6*), 114.6 (C-*4*), 121.0 (2 × C), 121.1 (2 × C), 125.5 (2 × C), 126.0, 126.1, 128.3 (2 × C), 128.6, 128.8 (2 × C), 128.9, 129.4 (4 × C), 132.1, 137.7 (C-*3*), 138.9 (C-*5*), 151.1, 151.2, 152.7, 153.2 (C-*8*), 153.6 (C-*9*). MS *m/e* (relative %): 520 (M^+, <1), 384 (28), 383 (100), 339 (12), 246 (26), 245 (30), 94 (21), 43 (55). Anal. calcd. for $C_{31}H_{24}N_2O_6$: C 71.53, H 4.65, N 5.38%; found: C 71.74, H 4.65, N 5.49.

4,5-Diaminocarbonyloxymethyl-1,3-diphenylpyrazole 1

A solution of **10** (2.00 g, 3.84 mmol) in dry CH_2Cl_2 (100 mL) was cooled to −78°C by Dry Ice – acetone, and dry ammonia was introduced under a stream of nitrogen to this solution to collect about 200 mL of ammonia. The cooling bath was removed and the flask equipped with the Dry Ice condenser was left at room temperature for 5 h. Ammonia was evaporated during this period and the crystals isolated in the residual solution were collected. Usual work-up of the filtrate yielded the second crop of the crystals. The combined crystals were recrystallized from ethanol to give **1** (1.34 g, 95.0%), mp 226.0–227.0°C. IR: 3437, 3339, 3279, 3215, 1703, 1692, 1613, 1504, 1422, 1344, 1339, 1063, 1009, 779, 697, 571 cm^{-1}. ^1H NMR δ: 5.07 (2H, s, 6-*H*), 5.10 (2H, s, 7-*H*), 6.60–6.66 (4H, br s, 2 × NH_2), 7.42–7.65 (8H, m, Ar-*H*), 7.74–7.79 (2H, m, Ar-*H*). ^{13}C NMR δ: 53.8 (C-*6*), 55.1 (C-*7*), 115.2 (C-*4*), 124.8 (2 × C), 127.5 (2 × C), 128.1, 128.3, 128.5 (2 × C), 129.2 (2 × C), 132.3, 138.8 (C-*3*), 138.9 (C-*5*), 150.9, 155.7 (*C*O), 156.4 (*C*O). MS *m/e* (relative %): 366 (M^+, 6), 305 (13), 262 (100), 233 (19), 142 (7), 130 (16), 77 (46), 57 (36), 43 (80). Anal. calcd. for $C_{19}H_{18}N_4O_4$: C 62.29, H 4.95, N 15.29%; found: C 62.09, H 4.89, N 15.32.

4,5-Dichloromethyl-1,3-diphenylpyrazole 2

Methanesulfonyl chloride (0.63 mL, 8.0 mmol) was dropped for 5 min into a solution of the dialcohol **9** (0.84 g, 3.0 mmol) and triethylamine (1.26 mL, 9.1 mmol) in dry CH_2Cl_2 (30 mL) that was cooled in an ice-bath, and the reaction mixture was stirred at room temperature until the solution showed a single spot on TLC (22 h). The solution was washed successively with water, aqueous 10% HCl solution, aqueous $NaHCO_3$-saturated solution, and a saturated brine. The crude product obtained was recrystallized from ether–pentane to give the dichloride **2** (0.51 g, 39%), mp 119.0–120.0°C. IR: 3068, 2968, 1596, 1559, 1503, 1471, 1373, 1284, 1193, 1110, 1075, 1028, 917, 876, 766, 756, 695, 664, 514 cm^{-1}. ^1H NMR δ: 4.69 (2H, s, CH_2Cl), 4.77 (2H, s, CH_2Cl), 7.41–7.58 (6H, m, Ar-*H*), 7.61–7.67 (2H, m, Ar-*H*), 7.75–7.82 (2H, m, Ar-*H*); ^{13}C NMR δ: 33.6 (C-*7*), 36.3 (C-*6*), 116.2 (C-*4*), 125.2 (2 × C), 128.1 (2 × C), 128.5, 128.8 (2 × C), 128.9, 129.5 (2 × C), 131.9, 138.6 (C-*3*), 138.7 (C-*5*), 151.6. MS *m/e* (relative %): 320 (M^+ + 4, 4), 318 (M^++ 2, 26), 316 (M^+, 39), 283 (36), 282 (20), 281 (100), 245 (18), 142 (11), 115 (6), 77 (16). Anal. calcd. for $C_{17}H_{14}N_2Cl_2$: C 64.67, H 4.45, N 8.63%; found: C 64.37, H 4.74, N 8.83.

4,5-Dibromomethyl-1,3-diphenylpyrazole 3

A solution of **9** (500 mg, 1.78 mmol) in aqueous 48% HBr solution (5 mL) was refluxed for 0.5 h. The solution was diluted with water, basified to pH 7–8 with Na_2CO_3, and extracted with ether. The extract was washed with water and aqueous 50% NaBr solution and, following the usual work-up, gave the crude product (0.73 g). Chromatographic purification (silica gel, CH_2Cl_2–hexane 1:1) yielded pure **3** (0.473 g, 65.3%), mp 94.5–95.5°C (hexane–ether 5:2). IR: 1597, 1550, 1503, 1457, 1375, 1212, 1198, 916, 779, 761, 699, 685, 590 cm^{-1}. ^1H NMR δ: 4.58 (2H, s, CH_2Br), 4.69 (2H, s, CH_2Br), 7.42–7.60 (6H, m, Ar-*H*), 7.65–7.69 (2H, m, Ar-*H*), 7.79–7.83 (2H, m, Ar-*H*). ^{13}C NMR δ: 19.3 (C-*7*), 23.5 (C-*6*), 116.3 (C-*4*), 125.1 (2 × C), 128.1 (2 × C), 128.6, 128.8 (2 × C), 128.9, 129.5 (2 × C), 131.9, 138.5 (C-*3*), 138.8 (C-*5*), 151.5. MS *m/e* (relative %): 327 (91), 325 (90), 246 (100), 245 (95), 142 (27), 123 (20), 115 (19), 77 (54), 51 (20). Anal. calcd. for $C_{17}H_{14}Br_2N_2$: C 50.28, H 3.47, N 6.90%; found: C 50.39, H 3.54, N 6.83.

4,5-Bis (hydroxymethyl)-1-phenylpyrazole 16

The triester **11** (2.00 g, 5.55 mmol) was dissolved in the KOH solution prepared from KOH (12.46 g) and aqueous ethanol

For personal use only.

(water-EtOH 1:1, 200 mL), and the resulting solution was refluxed for 4 h. After evaporation the residual solution was acidified with 35% HCl solution and the isolated crystals were collected to give the triacid **12** (1.32 g, 86.1%), mp 228.0–229.0°C (Lit. (14) mp 213.0–214.0°C). IR: 3442 (br), 1718, 1598, 1498, 1429, 1384, 1320, 1132, 1017, 770 cm^{-1}. ^1H NMR δ: 7.46–7.53 (5H, m, Ar-*H*). ^{13}C NMR δ: 118.1, 126.3 (2 × C), 128.6 (2 × C), 129.0, 137.5 (C-*4*), 141.0 (C-*5*), 144.0 (C-*3*), 158.4 (C-*7*), 160.9 (C-*5*), 167.6 (C-*6*).

The triacid **12** (2.00 g, 7.24 mmol) was added to acetic anhydride (50 mL), and the solution was refluxed for 7 h under a stream of argon. Reaction was halted when the stream of argon was introduced to the barium hydroxide solution and no generation of CO_2 was detected. Solvent was removed and the residue containing diacid **14** was dissolved in methanol (50 mL) containing sulfuric acid (3 mL). The solution was refluxed for 5 h, and evaporated. Basification with aqueous 1 M sodium carbonate solution and extraction with ethyl acetate gave, after the usual work-up, 1.41 g of **15** (14).

A solution of the diester **15** (0.30 g, 1.2 mmol) in dry THF (100 mL) was slowly added to a solution of LAH (0.175 g, 4.6 mmol) in dry THF (200 mL) for 30 min. The solution was refluxed for 2.5 h, and the reaction was quenched by the addition of NaF (0.773 g, 18.4 mmol) and water (1 mL). After stirring the solution for 2 h, the inorganic precipitates were removed and the filtrate was evaporated to give the oily dialcohol **16** (0.157 g, 66.8%). IR: 3338, 1599, 1505, 1392, 1017, 757, 692 cm^{-1}. ^1H NMR δ: 4.47 (2H, d, *J* = 5.4, 7-*H*), 4.48 (2H, d, *J* = 5.4, 6-*H*), 4.84 (1H, t, *J* = 5.4, 7-O*H*), 5.35 (1H, t, *J* = 5.4, 6-O*H*), 7.36–7.44 (1H, m, Ar-*H*), 7.48–7.55 (2H, m, Ar-*H*), 7.62 (1H, s, 3-*H*), 7.65–7.69 (2H, m, Ar-*H*). ^{13}C NMR δ: 51.7 (C-*7*), 53.6 (C-*6*), 122.4 (s, C-*4*), 123.7 (d, 2 × C), 127.2 (d), 129.0 (d, 2 × C), 139.2 (s, C-*5*), 139.5 (s + d, *ipso*-C + C-*3*). MS *m/e* (relative %): 204 (M^+, 44), 188 (50), 187 (39), 186 (45), 185 (53), 171 (21), 159 (40).

4,5-Bis (dichloromethyl)-1-phenylpyrazole 4

Under an argon atmosphere, methanesulfonyl chloride (1.13 mL, 8.1 mmol) was gradually dropped into a solution of the dialcohol **16** (0.75 g, 3.7 mmol), *s*-collidine (1.07 mL, 8.8 mmol), and LiCl (0.31 g, 7.6 mmol) in dry dimethylformamide (DMF, 35 mL) at 0°C. The solution was stirred at the same temperature for 1 h, then left at room temperature overnight. Dilution with ice-water and extraction with ether–pentane yielded the crude product (1.17 g), which was crystallized from isopropyl ether – ethyl acetate to give **4** (0.20 g, 22.6%), mp 90.0–91.5°C. IR: 1598, 1570, 1407, 1288, 1260, 1206, 1131, 1070, 987, 911, 868, 772 cm^{-1}. ^1H NMR δ: 4.62 (2H, s, 7-*H*), 4.67 (2H, s, 6-*H*), 7.45–7.60 (5H, m, Ar-*H*), 7.71 (1H, s, 3-*H*). ^{13}C NMR δ: 33.3 (C-*7*), 35.7 (C-*6*), 119.0, 125.1 (2 × C), 128.9, 129.5 (Ar-*H*), 137.0 (C-*4*), 138.7 (C-*5*), 140.4 (C-*3*). MS *m/e* (relative %): 242 (M^+ + 2, 12), 240 (M^+, 19), 207 (35), 206 (14), 205 (100), 170 (11), 169 (20), 142 (11), 115 (7), 77 (23). Anal. calcd. for $C_{11}H_{10}N_2Cl_2$: C 54.79, H 4.18, N 11.62, Cl 29.41%; found: C 54.96, H 4.19, N 11.56.

1-Phenyl-3,4,5-tris (hydroxymethyl)pyrazole 13

A solution of the triester **11** (5.40 g, 15 mmol) in dry THF (400 mL) was slowly dropped into a solution of LAH (2.28 g, 60 mmol) in dry THF (600 mL) at room temperature for 6 h, and the resulting solution was stirred overnight. Under vigorous stirring, NaF (10.08 g, 240 mmol) and water (15 mL) were added and the stirring was resumed until the inorganic precipitates became totally white. The inorganics were removed by filtration and washed with THF. The filtrate and washings were combined and evaporated. The oily product (3.02 g) was purified by column chromatography (silica gel 90 g, CH_2Cl_2 containing 10% methanol) to give 1.02 g (29.1%) of the trialcohol **13**, mp 102.0–103.0°C (ethyl acetate – isopropyl ether). IR: 3310, 3274, 1506, 1402, 1082, 1031, 1003, 830, 769, 701 cm^{-1}. ^1H NMR δ: 4.46 (2H, d, *J* = 5.1, 7-*H*; singlet by D_2O addition), 4.53 (4H, d, *J* = 5.3, 6-*H* and 8-*H*; singlet after addition of D_2O), 4.76 (1H, t, *J* = 5.4, O*H*), 5.05 (1H, t, *J* = 5.6, O*H*), 5.40 (1H, t, *J* = 5.4, O*H*), 7.41 (1H, d, *J* = 7.1, Ar-*H*), 7.52 (2H, t, *J* = 7.4, Ar-*H*), 7.67 (2H, d, *J* = 7.1, Ar-*H*). ^{13}C NMR δ: 51.8 (C-*7*), 52.8 (C-*6*), 56.1 (C-*8*), 120.0, 123.9 (2 × C), 127.3, 129.2 (2 × C), 139.5 (C-*4*), 140.7 (C-*5*), 151.4 (C-*3*). MS *m/e* (relative %): 234 (M^+, 59%), 216 (61), 198 (100), 187 (36), 169 (22), 157 (20), 142 (19), 130 (23), 117 (13), 104 (16), 77 (78), 51 (22). Anal. calcd. for $C_{12}H_{14}H_2O_3$ (mw 234.25): C 61.53, H 6.02, N 11.96%; found: C 61.34, H 6.01, N 12.00.

1-Phenyl-3,4,5-tris (chloromethyl)pyrazole 5

Under an argon atmosphere at ice-cooling temperature, methanesulfonyl chloride (0.924 mL, 6.6 mmol) was gradually dropped into a solution of trialcohol **13** (468 mg, 2.0 mmol), *s*-collidine (0.876 mL, 6.6 mmol), and LiCl (254 mg, 6.0 mmol) in dry DMF (30 mL) for 1 h, and the resulting solution was stirred overnight. The reaction was quenched with addition of ice-water (5 mL), and the solution was extracted with ether–pentane (1:1). The combined extracts were washed once with aqueous Cu $(NO_3)_2$ solution, and the usual work-up was followed. Crystallization of the crude product (436 mg, 75%) from ether–petroleum ether yielded the trichloride **5**, mp 53.0–54.0°C. IR: 3066, 1603, 1578, 1509, 1463, 1402, 1280, 1265, 1230, 1053, 1024, 813, 780, 770, 752 cm^{-1}. ^1H NMR δ: 4.60 (2H, s, 7-*H*), 4.74 (2H, s, 8-*H*), 4.76 (2H, s, 6-*H*), 7.47–7.58 (5H, m, Ar-*H*). ^{13}C NMR δ: 33.1 (C-*7*), 34.5 (C-*8*), 36.9 (C-*6*), 117.3, 125.1 (2 × C), 129.1 (2 × C), 129.5 (2 × C), 138.1 (C-*4*), 138.5 (C-*5*), 148.1 (C-*3*). MS *m/e* (relative %): 292 (M^+ + 4, 6), 290 (M^+ + 2, 18), 288 (M^+, 20), 255 (66), 253 (100), 217 (19), 183 (12), 77 (14), 51 (5). Anal. calcd. for $C_{12}H_{11}C_{l3}N_2$ (mw 289.59): C 49.77, H 3.83, N 9.67; found: C 50.07, H 3.78, N 9.74.

Cytotoxic activities

Cytotoxicity was measured by the microculture tetrazolium assay as described (20). Cancer cell lines of uterus cervical (HeLa), human lung (PC-1), gastric (KATOIII), colon (LoVo), breast (MCF-7), and murine leukemia cell (L1210) were maintained in RPM1 1640 (Nissui Pharmaceutical Co. Ltd., Tokyo) supplemented with 10% fetal bovine serum (Hyclone Laboratories, Inc., Utah, U.S.A.). Growth inhibition experiments were carried out in 96-well (flat bottom) microplates, and the amount of viable cells at the end of the incubation was determined using the MTT assay. Thus, tumor cells (L1210, 5×10^3 cells/well; HeLa, 2×10^3 cells/well, and other cells, 3×10^3 cells/well) were incubated in RPM1-1640 supplemented with 10% fetal calf serum. Drugs were dissolved in DMSO (2 mg/mL), diluted with cultural media (20 μg/mL), and introduced to the cell culture with gradual dilution. The

© 1997 NRC Canada

cells were exposed to drugs for 3 days at 37°C in air containing 5% carbon dioxide.

MTT (10 μL, 5 mg/mL in phosphate-buffered saline) was added to each culture well. The plates were incubated for an additional 4 h, and the medium was removed. The formazan product was dissolved in DMSO (150 μL/well) and the absorbance was measured at 540 nm using a Microplate Reader (Molecular Devices Corporation, California, U.S.A.). Each data point on the growth curves was an average of three wells. The 50% growth inhibitory concentration (IC_{50}) was calculated by the probit method.

Antitumor activity

The assays for L1210 leukemia in mice were performed as specified in the standard NCI protocols (21). L1210 Cells (1×10^5) were inoculated interperitoneally (i.p.) into BDF1 mice (male, 6 weeks old) on day 0 and mice divided into several groups (5 mice per group) on day 1. Test compounds were suspended in 0.5% CMC and given i.p. on days 1. Survival was monitored daily and the increase in life span (ILS) was calculated using the following formula: ILS (%) = [(mean survival time of treated group)/(mean survival time of control group) − 1] × 100.

Isolation and structure of spongilipid from the Republic of Singapore marine porifera *Spongia cf. hispida*[1]

George R. Pettit, Timothy J. Bond, Delbert L. Herald, Martin Penny, Dennis L. Doubek, Michael D. Williams, Robin K. Pettit, and John N.A. Hooper

Abstract: Cell growth inhibitory (P388 lymphocytic leukemia) fractions from the purple marine sponge *Spongia cf. hispida* were employed to uncover a new biologically active monogalactosyl monoglyceride designated spongilipid (**5a**). The structure and absolute configuration of spongilipid was established by X-ray crystallography. Spongilipid specifically inhibited growth of the fecal opportunist *Enterococcus faecalis*.

Key words: marine sponge, *Spongia hispida*, spongilipid.

Résumé : On a fait appel à des fractions inhibant la croissance de cellules (leucémie lymphocytique P388) extraites de l'éponge marine pourpre (*Spongia cf. hispida*) pour mettre à jour un nouveau monoglycéride monogalactosylé biologiquement actif appelé spongilipide (**5a**). On a déterminé la structure et la configuration absolue du spongilipide par diffraction des rayons X. Le spongilipide inhibe spécifiquement la croissance de l'opportuniste fécal *Enterococus faecalis*.

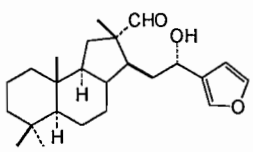
Mots clés : éponge marine, *Spongia hispida*, spongilipide.

[Traduit par la rédaction]

Introduction

In 1989, we extended our broad geographic survey (2, 3) of marine animals as new sources of structurally unique antineoplastic substances (4–11) to Republic of Singapore ocean areas. During that expedition, a purple (darkens on exposure to air) colored reef sponge subsequently identified as *Spongia sp.* was collected and found to afford methanol extracts with cancer cell line (murine P388 lymphocytic leukemia) inhibitory activity.

Marine sponges in the genus *Spongia* previously yielded a variety of terpenoids (9–12). Australian specimens of *Spongia hispida* have been found to contain the sesterterpenoids hyrtiosal (**1**) (12, 13), isocalafurans A (**2**) and B (13), the sesterterpene/quinone 5-epi-isospongiaquinone (**3**) (14), and the Mediterranean *Spongia virgultosa* furan (**4**) (15). Hyrtiosal (**1**) was found to show moderate cell growth inhibitory activity against the KB cell line and 5-epi-isospongiaquinone (**3**) displayed antibiotic activity against *Staphyloccus aureus* and a *Micrococcus sp.* No biological data have been reported for terpene **2**. We herein summarize the isolation (P388 bioassay directed), structure elucidation, and preliminary biological activity for the monogalactosyl monoacylglyceride (MGMG) designated spongilipid (**5a**) from *Spongia cf. hispida* collected in the Republic of Singapore.



Received March 26, 1997.

This paper is dedicated to Professor William A. Ayer on the occasion of his 65th birthday.

Scheme 1.

Results

The methanol–water used as preservative during shipment was concentrated to a water fraction and partitioned with methylene chloride. Further partitioning between methanol–water (9:1 → 3:2) and hexane followed by methylene chloride yielded a gummy brown methylene chloride fraction (49 g) that inhibited growth of the P388 (ED_{50} 4.5 µg/mL) murine leukemia cell line. Initial gel-permeation chromatographic separation on a column of Sephadex LH-20 in methanol was followed by another LH-20 chromatography of the resulting active fraction with 3:2 methylene chloride – methanol as eluent, affording a concentration of activity. Further separation was achieved by employment of column partition chromatography on Sephadex LH-20 with 3:1:1 hexane–toluene–methanol as the mobile phase. Slow evaporation of the solvent mixture from one fraction yielded two crops of fine colorless needlelike crystals of a new substance designated spongilipid (**5a**) (Scheme 1). Under standard P388 techniques, the activities of spongilipid ranged from about 2 to >100 µg/mL, presumably owing to difficulties caused by severe solubility problems and suspension formation in the cell media. Further approaches to resolve this problem are ongoing. However, we were able to show unequivocally that this MGMG (**5a**) exhibited antimicrobial activity.

By FAB high-resolution mass spectrometry, spongilipid (**5a**) was found to have molecular formula $C_{25}H_{48}O_9$ (*m/z* 515.3202 for $C_{25}H_{48}O_9Na$ — 1.1 ppm) and two double bond equivalents. The IR spectrum indicated the presence of hydroxyl, ester, and ether groups (3356, 1737, and 1467 cm^{-1}). The ^1H NMR (C_5D_5N) spectrum showed a broad peak at δ5.48 (OH), complex overlapping signals at δ5.00–4.00 ppm, a triplet at δ2.33, multiplets at δ1.63 and 1.27, and a triplet at δ0.87. The multiplet at δ1.24 integrated to at least 24 protons and the triplet at δ0.87 indicated a long-chain aliphatic unit terminating in a methyl group. In the mass spectrum, loss of *m/e* 239 was attributed to the mass fragment $[C_{16}H_{31}O]^+$, thus indicating a C_{16} saturated aliphatic ester (palmitoyl group).

Conversion of alcohol **5a** to acetate **5b** and measurement of the ^1H NMR chemical shifts in benzene-d_6 indicated the presence of five acetate groups and caused spreading of the previously overlapping peaks in the δ5.00–4.00 region to *ca* δ5.80–3.20 ppm. Acetylation allowed the assignment of a signal at δ4.20 ppm to that of an anomeric hydrogen of the sugar. Because of the large coupling constant (J = 9.7 Hz) observed, which is indicative of an axial–axial vicinal relationship, a β-linkage was deemed to be present. The five signals at δ5.33(m), δ4.35(dd), δ4.17(dd), δ3.84(dd), and δ3.54(dd) indicated a glycerol unit. The shift sequence suggested a 1,3 linkage via a C-1 ether and a C-3 ester. An APT NMR experiment for carbon hybridization combined with COSY, HMQC, and HMBC deductions required for determining the connectivities led to overall structure **5b** (and by inference **5a**). The structure of this spongilipid was unequivocally confirmed and the absolute stereochemistry assigned by X-ray analysis.

Figure 1 shows the absolute structure and conformation of spongilipid **5a**. The sugar moiety assumes the preferred $^4C_1$ conformation for a β-D-galactopyranoside with the glycerol ester occupying an equatorial position on the anomeric carbon. A rather striking feature exhibited by this structure is the perfectly linear orientation and nearly perpendicular direction assumed by the long fatty acid side chain with respect to the sugar ring. This phenomenon is fairly typical of that observed in the crystal structures of lipids (16) and emphasizes the amphiphilic nature of these compounds. No apparent twist or turn is discernable in the long side chain of spongilipid, and the molecule thus occupies a much larger volume of space than that which might be anticipated if the side chain were to wrap or curl back toward the sugar moiety. Stabilization for this arrangement of atoms can be seen by examination of the cell packing diagram, shown in Fig. 2. Sheets of the long fatty acid side chains are formed by alignment of alternating molecules of the spongilipid in the unit cell such that the interior of the cell is composed of adjacent and parallel side chains, whereas the ends of the cell are occupied by layers of sugar molecules. The alternating layers of sugar moieties are, in turn, stabilized via H-bonding between the O6′ galactose atom of one layer and the O4′ oxygen of the adjacent galactose layer (O6′ ··· O4′ distance, 2.90 Å). As a consequence, the interior of the cell is very hydrophobic, while the ends of the cell are quite hydrophilic. Finally, it should be noted that the *S* configuration at C2 of the glycerol unit is identical to that of an ether type glycolipid recently isolated from another marine sponge (17). According to the standard nomenclature for lipids, the absolute structure of spongilipid can thus be designated as 1-palmitoyl-3-β-D-galactosyl-*sn*-glycerol (**5a**).

As part of an extended biological evaluation, the antimicrobial activity of spongilipid was assessed. Spongilipid was active against *Enterococcus faecalis*, an opportunist of current

clinical concern due to its innate and acquired resistance to many antibiotics. This Gram-positive bacterium is a normal flora of the large intestine, but can cause urinary tract infections, endocarditis, and abdominal abscesses. The enterococci are also an emerging cause of nosocomial bacteremia. This can be explained in part by a recent study, which showed that the frequency of multiple antibiotic resistant *E. faecalis* blood culture isolates increased significantly during the period 1988–1995 (18).

Other monogalactosyl monoacylglycerides (MGMG) and monogalactosyl diacylglycerides (MGDG) have been isolated from higher plants and bacteria (19–23) and are the predominant lipid components of chloroplast membranes. More recently, microalgae (24) have also yielded related biologically active MGMG, MGDG, and digalactosyl diacylglycerides (DGDG), which have been shown to possess cell growth inhibitory (25) and antimicrobial activities (26). Interestingly, compounds related to structure **5a** have been synthesized using a β-galactosidase to introduce the β-anomeric configuration (27). Because of the hydrophilic galactose unit and lipophilic side chain, glycerol derivatives such as spongilipid are presumed to be important in cellular differentiation mechanisms and in other important aspects of cell chemistry (28–30). The role of spongilipid in Porifera biology and implications for cancer cell growth inhibition and antibiotic development warrant further investigation.

Experimental

General methods

Prior to use, all solvents for chromatographic procedures were redistilled. The Sephadex® LH-20 (25–100 μg) employed for gel permeation and partition chromatography was obtained from Pharmacia Fine Chemicals AB, Uppsala, Sweden. The silica gel GF Uniplates for TLC were from Analtech Inc., Newark, Del. TLC analyses utilized 9:1 CH_2Cl_2–CH_3OH as eluent and the plates were developed with anisaldehyde spray reagent or by exposure to iodine vapor. The IR spectrum was obtained with a Mattson Instruments Galaxy 20/20 FT-IR spectrometer. The ^1H and ^{13}C NMR spectra were recorded using a Varian Unity 500 spectrometer. Melting points are uncorrected. X-ray data collection was performed on an Enraf–Nonius CAD4 diffractionater.

Animal collection

The sponge was collected off the south side of the Terumbu Pempang Jaut reef by SCUBA in 1989 at a depth of 7–10 m. *Spongia cf. hispida* Lamarck, 1814 (class Demospongiae, order Dictyoceratida, family Spongiidae) corresponds to an irregular branching specimen with an exterior purple color, which darkens upon exposure to air, and an interior color of beige. The sample gave a dark green original extract. Voucher samples are maintained at the Cancer Research Institute, Arizona State University, and the Queensland Museum, South Brisbane, Queensland, Australia.

Animal extraction and partitioning

The preserving methanol–water solution (~450 L) was removed from the sponge (~500 kg wet weight) and concentrated to 120 L. The resulting fraction was partitioned with methylene chloride (4 × 60 L). The methylene chloride extract (608 g, P388 ED_{50} 38 μg/mL) was redissolved in methanol–water (9:1) and partitioned with hexane (4 × 20 L each). Water was added to dilute to 3:2 methanol–water and the solution was partitioned (4×) with 20 L of methylene chloride. The methylene chloride fraction (49 g, P388 ED_{50} 4.5 μg/mL) was used for isolation of spongilipid as outlined in Scheme 1.

Isolation of spongilipid (5a)

The 49 g active fraction (Scheme 1) was subjected to three steps of column chromatography on Sephadex® LH-20 with sequential (see Scheme 1) columns eluted with CH_3OH, CH_2Cl_2–CH_3OH (3:2), and *n*-hexane–toluene–CH_3OH (3:1:1) to afford two fractions that, upon standing, gave spongilipid (**5a**) as a crystalline solid (0.55 g): mp 119–121°C; $[\alpha]_D$ 0.0 (*c* 0.3, pyridine); IR (NaCl thin film) ν_{max} (cm^{-1}): 3356(m), 2916(s), 2850(m), 1737(s), 1467(m), 1066(m); NMR, δ^1H (500 MHz, C_5D_5N): 5.48 (4H, br s), 4.90 (1H, d, J = 8 Hz), 4.57 (2H, m), 4.50 (2H, m), 4.45 (2H, d, J = 6 Hz), 4.41 (1H, dd, J = 10.25, 6 Hz), 4.17 (1H, dd, J = 9.5, 3.5 Hz), 4.09 (2H, m), 2.33 (2H, t, J = 7.5 Hz), 1.63 (2H, q, J = 7 Hz), 1.27 (26H, m), 0.87 (3H, t, J = 7 Hz); $\delta^{13}C$ (C_6D_5N): 173.67, 105.95, 77.14, 75.38, 72.61, 72.28, 70.30, 69.06, 66.64, 62.37, 34.35, 32.13, 29.98, (δ29–30 ppm not discrete peaks, overlap), 29.93, 29.78, 29.61, 29.41, 25.28, 22.95, 14.28; FABHRMS *m/z*: 515.3202 for $C_{25}H_{48}O_9Na$ (−1.1 ppm from the calcd. *m/z*).

Acetylation of spongilipid (5b)

To alcohol **5a** (35 mg) in dry pyridine (5 mL) was added freshly distilled acetic anhydride (1 mL) under argon, with stirring at room temperature. After 24 h the reaction mixture was poured into ice water (10 mL) and extracted with ethyl acetate (3 × 10 mL). The combined organic extract was washed sequentially with saturated copper sulfate solution (10 mL) and water (2 × 10 mL), dried over sodium sulfate, and the solvent was removed in vacuo to yield peracetate **5b** as a clear gum (52 mg, 96%); δ^1H (500 MHz, C_6D_6): 5.59 (1H, dd, J = 10.5, 7.5 Hz, H-2′), 5.46 (1H, d, J = 3.5 Hz, H-4′), 5.33 (1H, m, H-2), 5.14 (1H, dd, J = 14, 4 Hz, H-3′), 4.35 (1H, dd, J = 9.5, 4 Hz, H-3a), 4.20 (1H, dd, J = 9.7, 2.5 Hz, H-1′), 4.17 (2H, dd, J = 12.5, 7 Hz, H-6′), 4.13 (1H, d, J = 8.5 Hz, H-3b), 3.84 (1H, dd, J = 13.5, 7 Hz, H-1a), 3.54 (1H, dd, J = 13.5, 6.5 Hz, H-1b), 3.38 (1H, m, H-5′), 2.11 (2H, t, J = 9.5 Hz, H-5), 1.85 (3H, s, OAc), 1.72 (3H, s, OAc), 1.71 (3H, s, OAc), 1.68 (3H, s, OAc), 1.55 (3H, s, OAc), 1.30 (22–26 H, m, CH_2's), 0.9 (3H, t, J = 6.5 Hz, terminal CH_3); $\delta^{13}C$ (C_6D_6): 172.77, 170.06, 169.79, 169.65, 169.58, 168.99, 101.79, 71.23, 71.06, 70.36, 69.00, 67.71, 67.31, 62.53, 61.34, 34.09, 32.29, 30.13 (δ29–31 ppm not discrete peaks, overlap), 30.09, 30.05, 29.88, 29.78, 29.65, 29.40, 25.16, 23.07, 20.49, 20.42, 20.18, 20.13, 19.84, 14.32; FABHRMS *m/z*: 709.3963 ($C_{35}H_{58}O_{14}Li$).

X-ray structure determination of spongilipid (5a)

Very long, slender, colorless needles were obtained by the slow evaporation of a hexane:toluene:methanol solution of the compound obtained via partition chromatography. The thickest crystal specimen was chosen and cleaved to the approximate dimensions of 0.12 × 0.30 × 0.32 mm, then mounted on the tip of a glass fiber. Refined lattice parameters were obtained by least-squares fitting of 25 carefully measured independent reflections in the 35–40° θ range. Data collection was performed at 299 ± 1 K for a monoclinic system. All

reflections corresponding to a complete quadrant, with $2\theta \leq 130°$, were measured using the ω–2θ scan technique. Friedel reflections were also recorded, whenever possible, after each reflection. Subsequent statistical analysis of the complete reflection data set using the XPREP program,[3] coupled with density measurements, indicated the space group was $P2_1$, the asymmetric unit of the cell containing a single molecule of compound **5a**.

Crystal data

$C_{25}H_{48}O_9$, monoclinic space group $P2_1$, with $a = 5.519(1)$, $b = 8.977(1)$, $c = 27.328(5)$ Å, $\beta = 93.48(2)°$, $V = 1351.4(4)$ Å^3, λ (Cu Kα) = 1.54184 Å, $\rho_c = 1.211$ g cm^{-3}, $\rho_o = 1.181$ g cm^{-3} for $Z = 2$ and F.W. = 390.05, $F(000) = 380$. After Lorentz and polarization corrections, merging of equivalent reflections, and rejection of systematic absences, 4472 unique reflections (R(int) = 0.1220) remained, of which 4217 were considered observed ($I_o > 2\sigma(I_o)$) and were used in the subsequent structure determination and refinement. Linear and anisotropic decay corrections were applied to the intensity data as well as an empirical absorption correction (based on a series of ψ-scans) (31). Structure determination was readily accomplished with the direct-methods program SIR92 (32). All non-hydrogen atom coordinates were located in a routine run using default values in that program. The remaining hydrogen atoms, calculated at optimum positions for **5a** using the program SHELXL-93 (33), were assigned thermal parameters equal to 1.5, the U_{iso} value of the atom to which they were attached, and then both coordinates and thermal values were forced to ride that atom during final cycles of refinement. All non-hydrogen atoms were refined anisotropically in a full-matrix least-squares refinement process with the SHELXL-93 software package. The final standard residual R value for the model shown in Fig. 1[4] was 0.0769 for observed data (4217 reflections) and 0.0802 for all data (4472 reflections). The corresponding Sheldrick R values were wR_2 of 0.1951 and 0.2077, respectively. A final difference Fourier map showed minimal residual electron density; the largest difference peak and hole being 0.330 and −0.494 e/Å^3, respectively. All final bond distances and angles were within acceptable limits.[5]

The structure and absolute stereochemistry of spongilipid (**5a**) is presented in Fig. 1. Refinement of the enantiomer depicted in Fig. 1, in conjunction with the Flack absolute structure parameter χ (34), resulted in a value of −0.08 (e.s.d. 0.25). On the other hand, refinement of the opposite enantiomer of **5a** resulted in a Flack parameter value of 1.07 (e.s.d. 0.26). Nearly identical R values were observed for the refinement of the opposite enantiomer, e.g., $R = 0.0769$, $wR_2 = 0.2081$. Although these results were certainly not conclusive in enabling assignment of the absolute stereochemistry, the relation of the relative stereochemistry of the molecule to the absolute stereochemistry known for the D-galactose sugar moiety contained in spongilipid established the absolute stereochemistry with certainty. As a consequence, the absolute stereochemistry for the six stereogenic centers of the **5a** could be assigned as follows (using the X-ray numbering system): 2*S*, 1′*R*, 2′*R*, 3′*S*, 4′*R*, 5′*R*.

Antimicrobial susceptibility evaluation

Antimicrobial disk susceptibility tests were performed according to the method established by the National Committee for Clinical Laboratory Standards (35). Mueller–Hinton agar was used for susceptibility testing of *Staphylococcus aureus* (ATCC no. 29213), *Enterococcus faecalis* (ATCC no. 29212), and *Escherichia coli* (ATCC no. 25922); Gonococcal Typing agar was used for *Neisseria gonorrhoeae* (ATCC no. 49226); and YM agar for *Candida albicans* (ATCC no. 90028) and *Cryptococcus neoformans* (ATCC no. 90112). Immediately prior to susceptibility assays, spongilipid (**5a**) was reconstituted in sterile DMSO and twofold dilutions were applied to sterile 6-mm disks. Zones of inhibition were read at 16 h for *S. aureus, E. faecalis, E. coli*, and *N. gonorrhoeae* and at 42 h for *M. luteus*, *C. albicans*, and *C. neoformans*. MIC determinations were performed in duplicate. The MIC of spongilipid for *Enterococcus faecalis* was 25–50 μg/disk. At 100 μg/disk, spongilipid had no activity against the other bacteria and fungi tested.

Acknowledgments

The research reported here was supported by Outstanding Investigator Grant CA-443440-1A1-09 awarded by the Division of Cancer Treatment, the U.S. National Cancer Institute, DHHS, The Arizona Disease Control Research Commission, the Fannie E. Rippel Foundation, and the Robert B. Dalton Endowment Fund. We also wish to thank Drs. Fiona Hogan, Michael R. Boyd, and Jean M. Schmidt for other assistance, as well as the Republic of Singapore (Professors T. J. Lam, Chou Loke Ming, and Khoo Hong Woo, Zoology Department, National University of Singapore), Larry Tackett, Denise Nielsen Tackett, and Deanna Hansen.

A spectral displacement study of the binding constants of cyclodextrin–hydrocarbon and –fluorocarbon surfactant inclusion complexes

Lee D. Wilson, Stephanie R. Siddall, and Ronald E. Verrall

Abstract: The spectral displacement technique with phenolphthalein as the chromophore has been used to obtain 1:1 equilibrium binding constants (K_2) for a homologous series of hydrocarbon (hc) ($C_nH_{2n+1}COONa$, n = 5–13) and fluorocarbon (fc) anionic surfactants ($C_nF_{2n+1}COONa$, n = 3–8) with β-cyclodextrin (β-CD). The magnitude of K_2 increases as the alkyl chain length increases in each homologous series. K_2 values in the ranges of 10^2–10^5 M^{-1} and 10^1–10^4 M^{-1} were obtained for the β-CD–fc and for the β-CD–hc surfactant complexes, respectively. The different binding affinity of β-CD with hc and fc surfactants is discussed in terms of such physicochemical properties of the guest species as hydrophobicity, geometrical size, conformational effects, molecular polarizability, and solvation of the head group.

Key words: spectral displacement, phenolphthalein, cyclodextrin, surfactant, binding constant.

Résumé : On a fait appel à la technique du déplacement spectral avec la phénolphtaléine comme chromophore pour déterminer les constantes d'association (K_2) de la β-cyclodextrine avec une série d'agents de surface hydrocarbonés (hc) ($C_nH_{2n+1}COONa$, n = 5–13) et fluorocarbonés (fc) ($C_nF_{2n+1}COONa$, n = 3–8). Dans chacune de ces deux séries, l'amplitude des constantes K_2 augmente avec une augmentation de la longueur de la chaîne alkyle. On a obtenu des valeurs de K_2 de 10^2–10^5 M^{-1} et de 10^1–10^4 M^{-1} respectivement pour les complexes de β-CD – agents de surface fc et β-CD – agents de surface hc. On discute des diverses affinités d'association des β-CD avec les agents de surface hc et fc en fonction des propriétés physicochimiques des espèces incluses, telles que l'hydrophobicité, la taille géométrique, les effets conformationnels, la polarisabilité moléculaire et la solvatation des groupes formant la tête.

Mots clés : déplacement spectral, phénolphtaléine, cyclodextrine, agent de surface, constante d'association.

Introduction

Cyclodextrins (CDs) show remarkable complexation behaviour with a wide variety of inorganic and organic inclusates (1, 2). The inclusion properties of CDs in aqueous media have attracted considerable attention due to their potential application as controlled-release agents (3). For example, pharmaceutical drugs are generally hydrophobic in nature and of a size that is suitable for their encapsulation by CDs. Of necessity, a rational design of improved drug delivery systems requires a correlation of physicochemical properties and binding affinity between the host and guest molecules. Thus there is a need to carry out systematic studies of a wide variety of CD–inclusate systems and to determine, as accurately as possible, the magnitude of the binding constants and their correlation with the physicochemical nature of the host–guest system. Of further interest is the need to better understand the fundamental nature of these relatively strong binding constants in terms of the weak intermolecular forces that are the basis for the existence of such complexes.

A number of different instrumental methods have been used to study CD–inclusate complexes. Among the most widely used of these techniques are NMR (4), sound velocity (5), conductivity (6), surface tension (7), emf (8), and UV–VIS spectrophotometry (9). The latter two methods involve direct measurement of bound or free inclusate concentrations whereas the other methods involve measurement of a total solution property, essentially a weighted average of two or more states, that is a measure of complex formation. Discrepancies in the literature between binding constants derived from different physical measurements have been attributed to the relative accuracies of the measured variables. Techniques that measure the concentration of free or bound species are expected to yield a more accurate estimate of the binding constant (10).

The spectral displacement technique (11–16), with phenolphthalein (phth) as the chromophoric species, can be used to determine the binding constants of optically transparent compounds to CD. The determination of these binding constants involves measuring the change in absorbance of phth in the presence of CD and a competing non-chromophoric surfactant

Scheme 1. Competing equilibria involved in the indirect spectral displacement technique, which utilizes phenolphthalein (phth) as a probe molecule.

(S). Scheme 1 illustrates the two competitive equilibria involved in the spectral displacement technique. K_1 and K_2 are the 1:1 binding constants for the CD–phth and CD–S complexes, respectively, as defined in ref. 11.

[1] K_1 = [CD–phth]/[CD] [phth]

[2] K_2 = [CD–S]/[CD] [S]

This technique provides a relatively accurate determination of K_2 since the absorbance changes are generally large and directly related to the amount of unbound inclusate. On the other hand, non-spectroscopic techniques are susceptible to larger error when K_2 is large (>10^4 M^{-1}) since the fraction of unbound species is low and the total solution property does not accurately reflect contributions from species of low concentration.

This paper presents the results of a determination of the binding constants between β-CD and a series of homologous hydrocarbon (hc) ($C_nH_{2n+1}COONa$, n = 5–13) and fluorocarbon (fc) ($C_nF_{2n+1}COONa$, n = 3–8) anionic surfactants at room temperature using the spectral displacement technique with phenolphthalein as the indirect chromophoric probe (11).

Experimental

Absorption measurements in the visible region were obtained using a fixed wavelength spectrophotometer (Milton Roy Spectronic 20) operating at 550 nm and at room temperature (295 ± 0.5 K). A double-beam spectrophotometer (Varian CARY 2315) was used to measure absorption vs. wavelength, when required. All solutions were prepared by volume in a 0.1 M Na_2CO_3 buffer adjusted to pH 10.5. The concentration of phth (C_{phth}) was 2×10^{-5} M in all experiments. For the determination of K_2, the concentration of β-CD (C_{CD}) was fixed at 3×10^{-4} M and the concentration of surfactant (C_S) was varied to exceed the 1:1 mole ratio of CD–S. The concentration of S was always kept below the critical micelle concentration (CMC) and values of the property for the surfactants used in this study are listed in Tables 1 and 2. A stock solution of phth in ethanol was made and aliquots were utilized to prepare ethanol–water (0.04%; v/v) solutions of phth in buffer. All aqueous solutions were freshly prepared and run within 1.5 h to ensure that any small absorbance change arising from instability of phth at pH 10.5 did not contribute to an experimental artifact.

β-CD (Aldrich) was used as received and the water content was determined from a Karl Fischer titration. It was accounted for in the determination of C_{CD}. All hydrocarbon surfactants ($C_nH_{2n+1}COONa$, n = 5–13) (Sigma, 99%) were used as received. All fluorocarbon surfactants ($C_nF_{2n+1}COONa$, n = 3–8) were prepared from the corresponding acids (Fluorochem, 99%) by titration with an equimolar quantity of NaOH (BDH, 99%). The sodium salts were recrystallized several times from methanol–chloroform mixtures. Phenolphthalein (Aldrich) was recrystallized from an ethanol–water mixture but no difference was observed between the molar absorptivities of the purified and unrecrystallized material.

A previously described (11) nonlinear least-squares (NLLS) fitting procedure was used to determine the 1:1 binding constants, K_1 and K_2, for the chromophore and the surfactant, respectively. The method is based on application of the Beer–Lambert law with the assumption that the molar absorptivity of the CD–phth complex is zero (13).

Results and discussion

The molar absorptivity of phth (ε_{phth}) was studied as a function of pH and water–ethanol composition. The magnitude of ε_{phth} was found to increase with increasing pH but remained constant as a function of ethanol content in the range 0.025–5% v/v. The latter result indicates that phth is fully dissolved at the conditions employed in this study. A low ethanol composition (0.04% v/v) was chosen in order to minimize competitive binding of ethanol with CD and to avoid any solvent effects (17–19) while a pH of 10.5 was used to optimize the optical density and to minimize the possibility of deprotonation of the hydroxyl groups of β-CD ($pK_a \cong 12$) (1). All absorption measurements were carried out at 550 nm since no

change in the shape of the VIS absorption band of phth in the presence of CD was observed at this wavelength.

To obtain the best estimates of the 1:1 binding constant (K_2), two essential conditions must be met when using the spectral displacement technique: (*i*) competing ligands must not absorb in the wavelength region of interest or interact with the chromophore and (*ii*) ligands must bind exclusively in a 1:1 stoichiometry. With respect to the first condition, any contribution from micelle–phth interactions was eliminated by carrying out all measurements below the CMC of the surfactants (20). Nevertheless, in a few instances a very small decrease in the absorbance of phth did occur and it is believed to be due to the formation of small clusters of surfactant around phth. An appropriate correction was applied to absorbance data in these cases. Condition (*ii*) is likely met in this study as it has been shown (7, 21) that surfactants possessing alkyl chain lengths (n_c) $\geq$ 16 carbon atoms are required to form 2:1 CD–surfactant complexes. The surfactants examined in this study were restricted to $n_c \leq 14$. Also, from a consideration of mass balance, the range of values of C_S used in this study, when compared to C_{CD}, do not favor the formation of 2:1 complexes. A further condition that should be met is that the competing ligand must fully displace the chromophore and bind as a well-defined CD–ligand inclusion complex. For example, the formation of a ternary (CD–phth–ligand) complex would not fully displace the chromophore and this could affect the magnitude of K_2 (20). However, the monotonic variations in the magnitude of K_2 as a function of the hydrocarbon chain lengths studied in each series seem to militate against this possibility. Finally, a practical requirement is to have $K_1 \geq K_2$ such that phth is displaced over a suitable range of C_S in order to obtain adequate absorbance changes (11). This condition is satisfied for most of the surfactants studied in this work.

Figure 1 illustrates a typical plot of absorbance vs. C_{CD} at a fixed concentration of phth. The line through the experimental data represents the calculated absorbance values obtained by using the NLLS fitting procedure. The rapid falloff of absorbance with increasing C_{CD} represents the formation of the CD–phth complex since the molar absorptivity of the latter is assumed to be zero. Benesi–Hildebrand (22) plots were not utilized to determine values of K_1 since the assumption that $[CD]_{total} >> [CD\text{–phth}]$ is not valid in the present study. As well, such classical double-reciprocal plots (1/Abs against $1/C_{CD}$) improperly weight the data, particularly at lower values of absorbance, i.e., low C_{CD} (11, 21). This is why a NLLS fitting procedure was employed to obtain values of K_1 and K_2 (11). A value of $K_1 = (2.5 \pm 0.3) \times 10^4$ M^{-1} was determined from several independent measurements and is in good agreement with literature values (12–14, 16). However, the value of K_1 reported here is slightly higher than that of Selvidge and Eftink (11). Since a lower concentration of ethanol was used in the present study, this difference may be due to a solvent effect.

Figure 2 shows a representative plot of absorbance vs. C_S for a weak binding CD–S system (β-CD–$C_5H_{11}COONa$). The absorbance exhibits a smooth monotonic increase with increasing C_S corresponding to the displacement of phth from the CD cavity upon inclusion of the surfactant. Table 1 lists the values of K_2 obtained for the β-CD–hc systems. The error in K_2 is based on the standard deviation in K_1 and the error associated with the absorbance measurements. The magnitude of K_2 ranges from 10^1 to 10^4 M^{-1} and increases with increasing hydrocarbon chain length.

Fig. 1. Absorbance (Abs; λ = 550 nm) vs. concentration of β-CD (C_{CD}) in 0.1 M Na_2CO_3 at pH 10.5, [phth] = 2×10^{-5} M and T = 295 K.

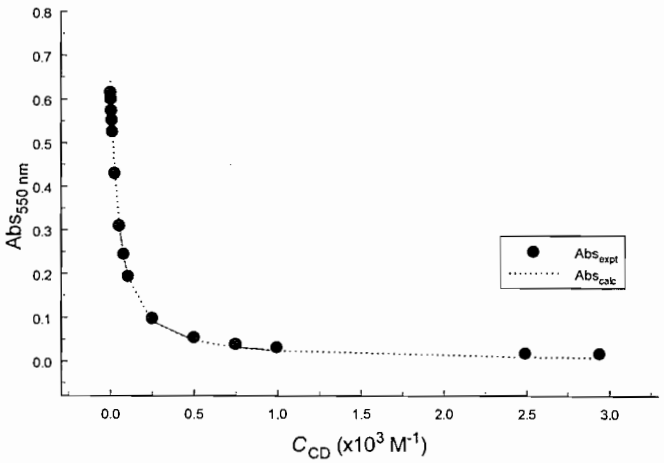

Fig. 2. Absorbance (Abs; λ = 550 nm) vs. concentration of sodium hexanoate (C_S) in 0.1 M Na_2CO_3 at pH 10.5, [β-CD] = 3×10^{-4} M, [Phth] = 2×10^{-5} M, and T = 295 K.

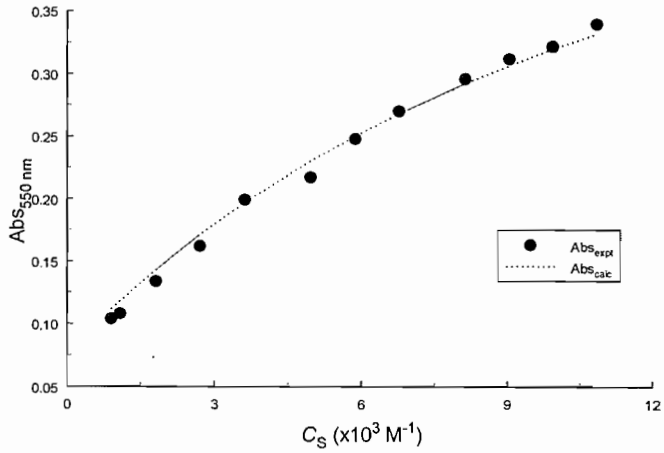

Figure 3 represents a typical plot of absorbance vs. C_S for a strongly bound CD–S system (β-CD–$C_{11}H_{23}COONa$). The absorbance changes sharply as a function of C_S and the shape of the curve becomes increasingly sigmoidal because the displacement of phth by surfactant occurs over a narrower range of C_S than in the case of the system shown in Fig. 2. Values of K_2 were also obtained for β-CD–$C_{12}H_{25}SO_4Na$(SDS) and β-CD–$C_8H_{17}SO_3Na$(SOS) systems in order to compare with known literature values under similar conditions. As seen from Table 1, there is good agreement with previously reported values ($K_2 = 1.8 \times 10^4$ M^{-1} (β-CD–SDS) and $K_2 = 9.0 \times 10^2$ M^{-1} (β-CD–SOS)) (14, 16). It is to be noted that these values of K_2 are similar in magnitude to those obtained for alkyl carboxylates of comparable chain length (see Table 1). These results support previous conclusions that host–guest alkyl chain interactions may play a more important role than

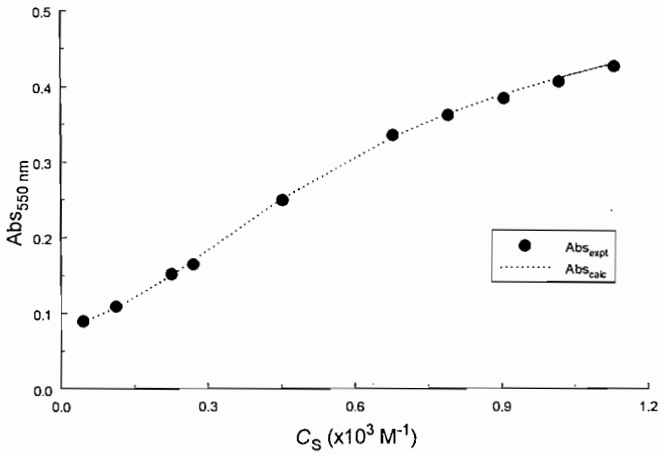
Fig. 3. Absorbance (Abs; λ = 550 nm) vs. concentration of sodium dodecanoate (C_S) in 0.1 M Na_2CO_3 at pH 10.5, [β-CD] = 3×10^{-4} M, [Phth] = 2×10^{-5} M, and T = 295 K.



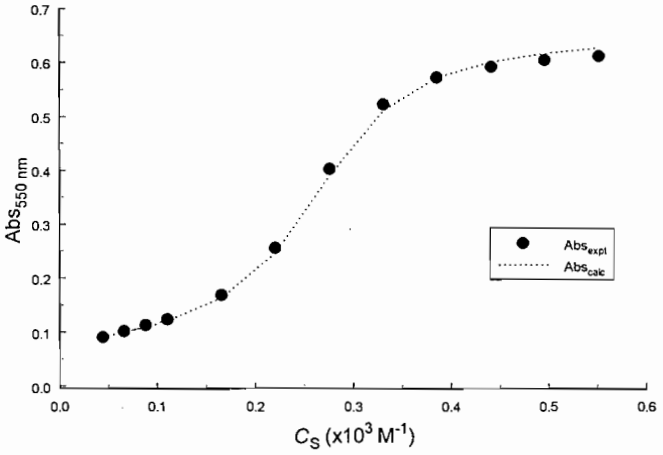


Fig. 4. Absorbance (Abs; λ = 550 nm) vs. concentration of sodium perfluorononanoate (C_S) in 0.1 M Na_2CO_3 at pH 10.5, [β-CD] = 3×10^{-4} M, [Phth] = 2×10^{-5} M, and T = 295 K.

host–guest head group interactions in the binding of surfactants to cyclodextrins.

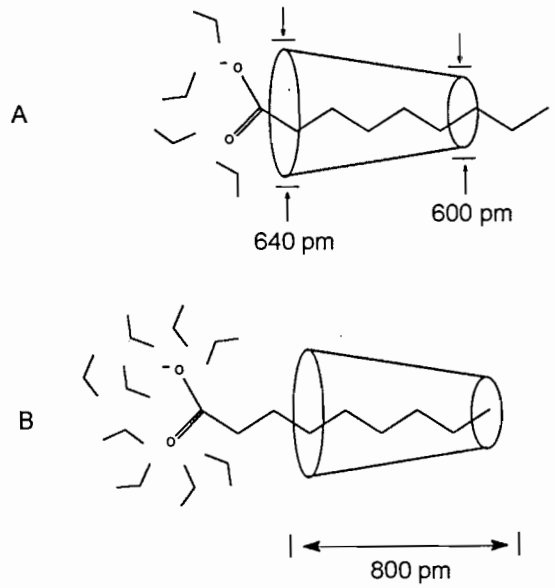
Figure 4 is a typical plot of absorbance against C_S for a strongly bound CD–S system (β-CD–C_8F_{17}COONa). This curve exhibits a sigmoidal appearance that is more pronounced than that for a strongly bound hc surfactant (cf. Fig. 3). Table 2 lists the values of K_2 for the β-CD–fc surfactant systems investigated. The magnitude of K_2 ranges from 10^2 to 10^5 M^{-1} and increases with increasing hydrocarbon chain length (n_c). Furthermore, the values of K_2 are systematically greater for fc than for hc surfactants possessing similar n_c. Schuette and Warner observed a similar trend in their study of the complexation of low molecular weight hc and fc alcohols with β-CD (18).

Cooperative binding phenomena are often associated with sigmoidal-shaped binding isotherms, as seen in Figs. 3 and 4 (23). Thus it appears that cooperativity becomes more important for CD–S complexes as the hydrocarbon chain length increases for both the fc and hc surfactants. A comment about the cooperativity observed for the 1:1 CD–S complexes is warranted as it does not seem reasonable to attribute it to traditional allosteric arguments.

Lemieux has shown that water plays a critical role in regulating various aspects of molecular recognition, for example, the association of carbohydrates to the surfaces of proteins (24). The importance of the solvent in CD–inclusate binding phenomena has been outlined previously (2). Solvent-mediated cooperative binding processes can be readily appreciated by considering the contributions, shown by the different terms in eq. [3], made by the solvent to the overall Gibbs energy change of complexation (ΔG^0) between a host and guest species

$$[3] \quad \Delta G^0 = \Delta G^0_{H/S} + \Delta G^0_{G/S} + \Delta G^0_{H/G/S} + \Delta G^0_{S/S}$$

where G, H, and S are guest, host, and solvent, respectively. Equation [3] indicates that extensive coupling and, hence, cooperative binding between host and guest can occur due to resolvation of these species during complex formation. Hydration phenomena of this type are consistent with the hydrophobic effect. Such solvent-mediated cooperative binding phenomena should exhibit a dependence on the concentration and size of the apolar guest due to the destruction of hydrophobic hydration during complex formation. Independent support for solvent-based cooperative binding phenomena has been alluded to in a previous study where the binding constant was found to be dependent on the activity of the water (25). Chervenak and Toone argued that solvent reorganization encompasses 25–100% of the enthalpy contribution of ligand binding to macromolecules (26). Thus it would appear that solvent-based cooperativity is a more tenable argument for the molecular origins of the cooperative binding observed here, and further studies are being carried out to clarify this conjecture.



A number of physicochemical properties of the guest species may contribute to the different binding affinities of hc and fc surfactants to β-CD. They are hydrophobicity, geometrical size and conformation, molecular polarizability, and head group solvation. First, the greater hydrophobicity of an fc compared to an hc, as evidenced by lower CMC values and higher surface activities, may contribute to a higher binding affinity of fc surfactants to β-CD (27, 28). Secondly, the size differences between hc and fc alkyl chains are apparent from a comparison of the van der Waals radii for H (145 pm) and F (160 pm) and from the van der Waals volumes of the groups, CF_3 (21.3), CF_2 (15.3), CH_3 (13.7), and CH_2 (10.2), where the volumes are expressed in cm^3 mol^{-1} (29). Because the magnitude of the attractive and repulsive intermolecular potentials ($U_{ij}(R) \approx 1/R^n$) are related to the distance (R) between binding sites, molecular size is an important factor in determining the magnitude of K_2. As well, the contribution of different conformational isomers of the surfactant chain is a factor that affects the apparent size of the guest. Fluorocarbon chains generally exist in an all-*trans* conformation due to a relatively higher *gauche–trans* energy difference (263 J/mol) (30) resulting from unfavorable steric effects between adjacent perfluorinated methylene groups. The lower *gauche–trans* energy difference (170 J/mol) (30) for hc chains results in a higher population of *gauche* conformers relative to fc chains. Consequently, conformational effects as well as van der Waals radii are factors that influence the size of the guest. As the size of

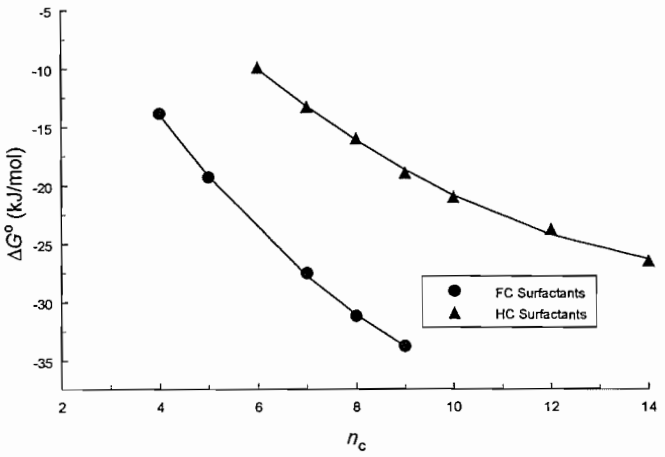
Scheme 2. Influence of head group solvation on inclusion geometry of β-CD–surfactant complexes: (*A*) β-CD–fc surfactant complex and (*B*) β-CD–hc surfactant complex. (∧) represents a water molecule.

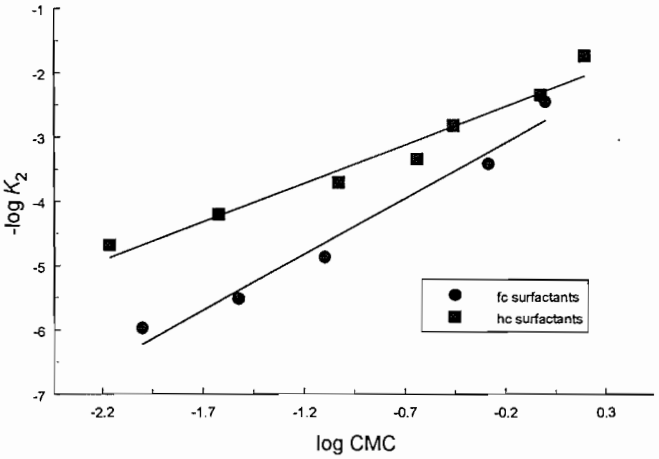


guest increases, more points of interaction may exist between host and guest and thereby affect the binding affinity. The importance of the size of aliphatic guest molecules has been discussed previously (31).

Thirdly, the importance of the polarizability property has been inferred from studies of mixed micelles consisting of fc and hc surfactants where the mixing behaviour is often non-ideal and phase separation is observed at certain concentrations (32). Furthermore, the relative strength of intermolecular interactions has been found to follow the order: fc–fc > hc–hc > fc–hc, based on NMR studies of mixed hc and fc anionic micelles (33). These observations are readily understood in terms of the relative molecular polarizabilities (α) of hc and fc groups, namely, $\alpha(CH_3) > \alpha(CH_2) > \alpha(CF_3) > \alpha(CF_2)$ (34). CDs are microheterogeneous assemblies consisting of C, H, and O atoms that can provide numerous potential atom–atom (O–F, O–H, H–H, H–F) interaction sites for an fc or an hc surfactant. It is expected that dispersive interactions should dominate within the apolar CD interior, whereas dipolar interactions should take place in the hydrophilic annular region of β-CD. The similar polarizabilities (34, 35) of O and F should result in more favorable dispersion interactions between them than between O and H or H and F. Indirect experimental support for this argument derives from the fact that molecular oxygen has a higher solubility in fc than in hc solvents. There are 28 oxygen atoms in the CD interior that may complex with an fc chain. In comparison, there are 14 H atoms in the CD interior that may complex with an hc chain. The hydroxyl group protons are neglected due to their participation in intramolecular H-bonding. Consequently, one might expect that the binding affinity of β-CD to an fc chain will be greater than to an hc chain due to the number and type of available interaction sites.

Fourthly, the importance of the head group solvation can be understood in terms of the dipolar interactions between the

Fig. 5. ΔG^0 vs. alkyl chain length (n_c) for the binding of hc and fc surfactants to β-CD.



hydroxyl groups of the CD annulus and the carboxylate head group. The inclusion geometry and stoichiometry is dependent on the length of the surfactant chain (21); however, there are subtle differences in the way hc and fc surfactants appear to bind with β-CD. The effects of these differences can be understood from consideration of Scheme 2. Previous ^{19}F NMR studies (36) indicated that the carboxylate head group of fc surfactants interacts strongly with the hydroxyl groups in the annulus region of CD. The occurrence of multipoint (head group and alkyl chain) interactions in β-CD–surfactant complexes may result in greater binding affinity than in complexes where the latter effect is absent (see Scheme 2). The latter scenario could apply to hc surfactants where the highly hydrated head group is sterically restricted from interacting with β-CD and consequently lowers the binding affinity. Significant differences in the relative basicities and hydration of the hc and fc carboxylate anions are anticipated since pK_a (hydrogenated fatty acids) > pK_a (perfluorinated fatty acids) (37). Studies of emf (38, 39) indicate also that sodium ion binding to the β-CD–$C_7F_{15}COO^-$ complex is greater than for the β-CD–$C_9H_{19}COO^-$ complex. These results further support the contention that the carboxylate head group is more hydrated in β-CD–hc than in β-CD–fc complexes. It is important to recognize that β-CD does not form an inclusion complex with the Na^+ ion and, therefore, has no effect on the value of K_2 (38, 39).

Figure 5 shows a plot of ΔG^0 against n_c for binding of both fc and hc surfactants with β-CD. ΔG^0 exhibits a monotonic decrease (more negative) with increasing value of n_c for both surfactant series, with the decrease being more negative for the fc series. This result can be attributed to the physicochemical properties discussed above but it is of interest to compare the changes in ΔG^0 per methylene group determined in this work with values obtained from consideration of incremental free energies, $\Delta\Delta G^0(H_2O \rightarrow$ hc–water), for the transfer of a CF_2 or CH_2 group from water to an hc–water interface. Mukerjee reported $\Delta\Delta G^0(H_2O \rightarrow$ hc–water) = −5.1 kJ/mol (CF_2) and −3.4 kJ/mol (CH_2) (32). These incremental values are in reasonable agreement but slightly greater than the incremental free energies of complexation (−4.4 kJ/mol (CF_2) and −2.7 kJ/mol (CH_2)) obtained from the slopes of the curves in Fig. 5.

© 1997 NRC Canada

Fig. 6. $-\text{Log } K_2$ vs. log CMC for hc and fc surfactants.

However, the hexane–water interface is a crude approximation of the microenviroment of the CD interior and the interfacial region. What is clear from the present results is that the less negative values of $\Delta\Delta G^0$ per methylene moiety are closer to values expected for the transfer of a methylene group from the bulk phase to a micelle ($\Delta\Delta G^0(CH_2) = -2.7$ to -3.0 kJ/mol) (32) where a change in the hydration of the head group may also make a contribution. Nevertheless, the relative difference in the magnitude of $\Delta\Delta G^0$ between fc and hc methylene groups obtained from the slopes in Fig. 5 is consistent with the data of Mukerjee.

The nonlinear dependence of ΔG^0 on n_c for hc and fc chains can be attributed to the degree of inclusion of the surfactant chain within the CD cavity. As the alkyl chain exceeds the depth of the CD cavity, ΔG^0 decreases less due to fewer alkyl groups interacting with the CD interior. Park and Song (40) have suggested that the β-CD interior can accommodate no more than approximately eight CH_2 groups if allowance is made for chain coiling. Because of the all-*trans* conformation of the fc chain, it is likely that fewer CF_2 than CH_2 groups can be included in the CD interior and the fc series will show greater nonlinearity than the hc series, as seen in Fig. 5. While it can also be argued that the nonlinear dependence of ΔG^0 on n_c may be due to the contribution of higher order binding phenomena, the experimental range of C_S chosen in this work was done with the view to minimize, as much as possible, the formation of such complexes. Furthermore, the goodness of fit of the experimental data to a 1:1 binding model does not warrant the consideration of higher order binding phenomena.

The hydrophobic effect has been implicated in various CD–inclusate complexation phenomena (41). Since hydrophobicity can be related to the CMC, there should be a correlation between K_2 and the CMC. A plot of $-\log K_2$ vs. log CMC is shown in Fig. 6. The relationship is approximately linear for both surfactant systems and the slope is greater for the fc surfactants, consistent with their greater hydrophobicity. Fig. 6 provides additional evidence that the hydrophobic effect is a significant contributor to the different binding affinities of hc and fc surfactants to β-CD. The approximately linear relation shown in Fig. 6 offers a useful semiempirical method for estimating a value of K_2, by interpolation, for a complex within a homologous series of inclusates when K_2 values are known for only a few members of the series.

Conclusion

The spectral displacement technique has been used to obtain accurate estimates of the 1:1 binding constants (K_2) for a series of hc surfactants, ($C_nH_{2n+1}COONa$, n = 5–13) and fc surfactants ($C_nF_{2n+1}COONa$, n = 3–8) with β-CD. The values of K_2 for the hc surfactants are in the range 10^1–10^4 M^{-1} and the values of K_2 for the fc surfactants are in the range 10^2–10^5 M^{-1}. The values of K_2 for the fc surfactants are systematically greater than those for the hc surfactants. The stronger binding affinity of fc surfactants compared to that of hc surfactants can be attributed to differences in hydrophobicity, conformational effects, size, polarizability, and solvation of the surfactant head group. The contribution of the hydrophobic effect in these complexation phenomena is supported by the near-linear relation observed between $-\log K_2$ and log CMC as well as the dependence of K_2 on the alkyl chain length.

The spectral displacement technique using phenolphthalein appears to be a good method of obtaining accurate estimates of K_2 for anionic surfactants with strong binding affinities to β-CD. Thermodynamic studies of CD–surfactant systems are in progress to better understand various aspects of the hydrophobic and cooperative solvent effects observed in these systems.

The electronic absorption spectra of some *N*-sulfinylanilines. A molecular orbital treatment

R. Abu-Eittah, H. Moustafa, and A.M. Al-Omar

Abstract: The electronic absorption spectra of *N*-sulfinylaniline and some of its derivatives were investigated using different solvents. The spectral behavior of the molecules indicated their planarity and that the NSO group is a strong electron acceptor. All the observed bands correspond to delocalized $\pi \rightarrow \pi^*$ transitions; $n \rightarrow \pi^*$ transition were not observed as discrete bands. Ab initio molecular orbital calculations were performed using four different basis sets. The results showed that the NSO group is nonlinear, the molecules studied are planar, and the *syn* conformer is more stable than the *anti* conformer.

Key words: *N*-sulfinylanilines, spectra and theoretical treatment.

Résumé : On a étudié, dans différents solvants, les spectres d'absorption électronique de la *N*-sulfinylaniline et de certains de ses dérivés. Le comportement spectral des molécules indique qu'elles sont planes et que le groupe NSO est un puissant accepteur d'électrons. Toutes les bandes observées correspondent à des transitions délocalisées $\pi \rightarrow \pi^*$, on n'a pas observé de bandes discrètes correspondant à des transitions $n \rightarrow \pi^*$. On a effectué des calculs d'orbitales moléculaires ab initio en utilisant quatre ensembles de base différents. Les résultats indiquent que le groupe NSO est non linéaire, que les molécules étudiées sont planes et que le conformère *syn* est plus stable que le conformère *anti*.

Mots clés : *N*-sulfinylanilines, spectres et théorie.

[Traduit par la rédaction]

Introduction

Although discovered in 1890–1893, the aryl(ArNSO) (1, 2), alkyl (RNSO) (2, 3), and thionylamines have not been extensively investigated and their electronic spectra are hardly discussed in the literature. *N*-Sulfinylaniline (Ph.N:S:O) is considered to be an interesting potential donor–acceptor system (4). The spectra of fluorinated *N*-sulfinylanilines showed that the -NSO group is a strong electron acceptor (5). The interaction of fluorinated *N*-sulfinylanilines with low-energy electrons leads to the formation of resonant states of the negative molecular ions (6). The infrared and Raman spectra of several substituted *N*-sulfinylanilines showed that no coupling exists between ν(N-S) and ν(S-O) (7–9). Butt et al. (7) showed that the NSO group has little resonance interaction with the benzene ring in the ground state but is capable of resonance donation or acceptance depending on the electron demand of the substituents. Microwave (10, 11) spectra indicated that the molecule is planar. Infrared spectra at low temperature showed two very close components of the NSO group that may be attributed to the existence of two rotational isomers (12).

The NMR spectra of R-C_6H_4NSO (R = *o*, *m*-Me) have shown that the NSO group is nonlinear and its free rotation around the C—N bond is restricted to some extent because of charge delocalization (13). No significant shift or splitting was observed upon cooling from 40 to −60°C, a result that indicates that the molecules have only one conformation (14). Substitution of hydrogen atoms by methyl groups in C_6H_5NSO causes the expected shifts in the NMR spectra. The spectra showed free rotation, even at −60°C, of the aryl ring around the C—N axis. If one *ortho* position of the phenyl ring is occupied by a methyl group the free rotation is hindered. This idea was supported by Waclawek et al. (15) who studied the rotation of the NSO group about the N—C_{ar} bond by dipole moment measurements.

The electronic dipole moment measurements and ^{1}H NMR spectra of a series of *N*-sulfinylanilines have shown that these compounds adopt preferentially a *cis* or *syn* structure with respect to the central -N=S- bond (16); the same result was obtained for alkylsulfinylanilines (17). However, infrared spectroscopic methods as well as dielectric constant measurements have shown that the NSO group, on various aliphatic and aromatic molecules, exists in a stable *anti* conformation and acts as a weak π-electron acceptor (18).

UV spectral studies (19) indicated that the N—S bond can be regarded as a 4-electron bond that is in resonance with the neighboring π-electron system. The X-ray spectra (20) of 4-RC_6H_4NSO (R = H, Me, MeO) indicated the participation of the sulfur 3*d* orbital in bonding.

In this work the electronic absorption spectra of some *N*-sulfinylanilines have been investigated and the results interpreted with respect to the properties of sulfinyl and the attached groups. Gaussian analysis was adapted to the observed spectra to resolve the overlapping bands. A MATHCAD (21) program was used and the best analysis is that which results in a minimum residue between the analyzed spectrum and the experimental one. Molecular orbital calculations with

geometry optimization were performed on the ground states of the molecules studied, using ab initio procedures through the GAMESS (22) program. Excited states were treated theoretically using the AM1 (23) procedure.

Experimental

Compounds

The compounds studied were prepared and purified by standard procedures cited in the literature (2, 14). The refractive indices for the prepared compounds {X-C_6H_4NSO} are given:

Compounds, X =	Refractive index (this work)	Refractive index (Ref. 19)
H[a]	1.6248(25°C)	1.6259(20°C)
m-CH_3	1.6250(25°C)	1.6132(20°C)
p-CH_3	1.6170(25°C)	1.6241(20°C)
p-OCH_3	1.6480(25°C)	1.6300(20°C)

Solvents

Polar and nonpolar solvents were obtained form Merck, AR-grade, and were used without further purification.

Apparatus

Spectra were scanned on a Perkin Elmer Lambda 4B spectrophotometer using 1.0 cm fused silica cells. The machine records linearly in percent transmittance over the range 190–900 nm.

Results and discussion

I Electronic absorption spectra

I.1 N-*Sulfinylaniline*

The electronic absorption spectrum of *N*-sulfinylaniline consists of two intense and well-separated bands. The long-wavelength band is rather broad, extends from 360 to 250 nm, and is easily resolved (Fig. 1) by Gaussian analysis to three overlapping bands with λ_{max} at 330, 317, and 281 nm. Band intensity varies from $\varepsilon \cong 800$ to 3200 L mol^{-1} cm^{-1}, which indicates that these bands correspond to allowed $\pi \rightarrow \pi^*$ transitions and none of them corresponds to an $n \rightarrow \pi^*$ transition. The spectrum reflects the planarity of the molecule. If the molecule were nonplanar its spectrum would have been the additive spectra of benzene and NSO chromophores. Molecular orbital calculations gave two distinct bands for NSO^-, at 397 and 300 nm, but only the 379 nm band is observed (24).

The variation of λ_{max} with solvent polarity is apparent for the lowest energy transition (Table 1), a result that indicates a contribution of the charge transfer (CT) configuration to the excited states of the molecule.

I.2 p-*Methyl*-N-*sulfinylaniline*

Substitution by a methyl group in the *para* position will enhance the electron donor and acceptor properties in the molecule. The spectrum shows two well-defined separated bands. The long-wavelength band is broad, 360–260 nm, and easily resolved to three overlapping bands corresponding to three transitions with band maxima at 339, 321, and 272 nm (Fig. 2). A red shift of λ_{max} with the polarity of solvent, from 339 nm in heptane to 344 nm in ethanol, is observed (Table 1). The spectra of the molecule have been scanned in different solvents and Gaussian analysis of the bands shows that all the components are strong enough to exclude any $n \rightarrow \pi^*$ transition.

I.3 m-*Methyl*-N-*sulfinylaniline*

The spectrum of this molecule in heptane as a solvent is given in Fig. 3. A comparison of band maxima of the lowest-energy transition shows that for *N*-sulfinylaniline and *p*-methyl and *m*-methyl derivatives the values are 330, 339, and 335 nm, respectively. The perturbation effect of methyl substitution is detected.

I.4 p-*Methoxy*-N-*sulfinylaniline*

The electronic spectrum shows two main bands (Fig. 4), a broad one in the 400–260 nm region and another relatively sharp one with λ_{max} around 246 nm. The long-wavelength

		245	6094	0.14

broad band has been analyzed to four bands with λ_{max} (heptane as solvent) at 367, 354, 326, and 282 nm, (Fig. 4). All obtained bands are sufficiently intense and correspond to $\pi \rightarrow \pi^*$ transitions. A comparison of the values of λ_{max} of the most intense bands of *p*-methoxy-*N*-sulfinylaniline, *N*-sulfinylaniline, *p*-methyl- and *m*-methyl-*N*-sulfinylaniline in heptane as a solvent gives 354, 317, 321, 317 nm, respectively. A significant red shift is observed with *p*-methoxy substitution that, again, confirms the electron-accepting properties of the NSO group.

II Molecular orbital calculations

II.1 N-*Sulfinylaniline*

II.1.a Ground state of N-*sulfinylaniline:* The equilibrium geometry of the molecule in the ground state was predicted by ab initio calculations using the GAMESS program package (version 1995). Several basis sets, namely, STO-3G**, STO-6G**, 3-21G**, and 6-21G**, which are stored in the program, were considered initially to determine the

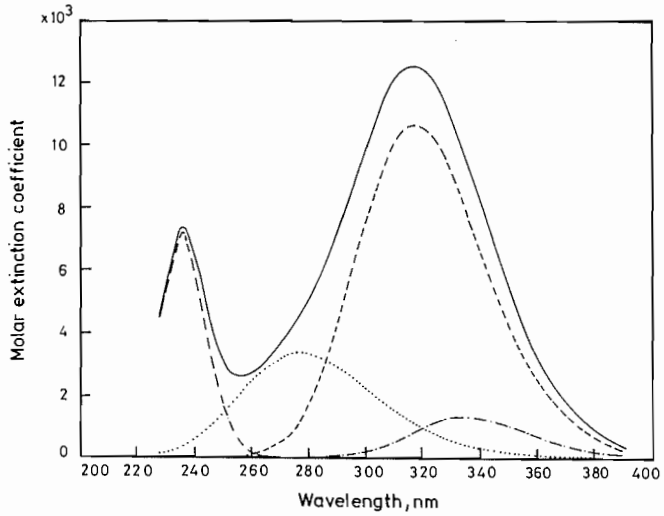
Fig. 3. The electronic spectrum of *m*-methyl-*N*-sulfinylaniline using heptane as a solvent.



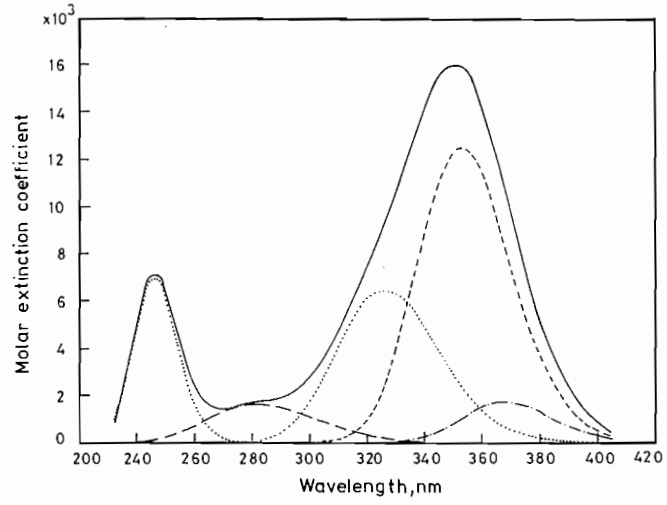


Fig. 4. The electronic spectrum of *p*-methoxy-*N*-sulfinylaniline using heptane as a solvent.

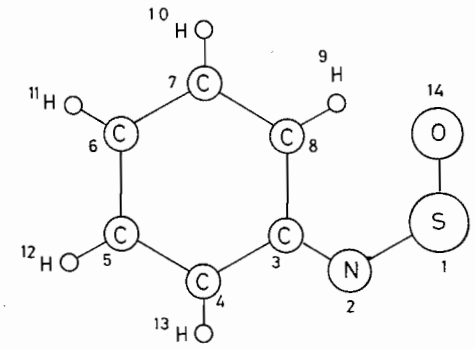
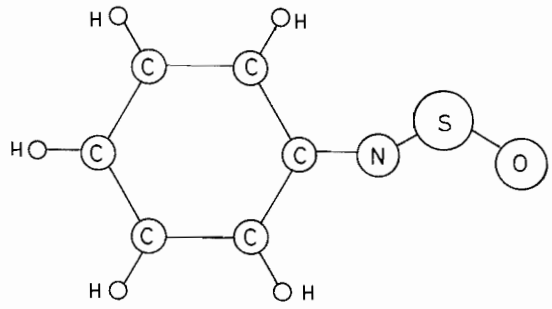


equilibrium geometry of the molecule. In this work explicit MO calculations using the SCF-HF method were performed on both the *syn* (*cis*), I, and the *anti* (*trans*), II, conformers (Fig. 5). The calculated parameters for the optimized geometries, Tables 2 and 3, were used in further calculations. All the basis sets used include *d*-functions for heavy atoms and *p*-functions for the H-atom.

Experimental results indicate that *N*-sulfinylaniline exists in the planar *syn* conformer (8) and molecular orbital calculations performed in this work confirm this result. The *syn* conformer is of lower total energy than the *anti* conformer, with a *syn* ⇒ *anti* conversion energy varying from 6.9 kcal mol^{-1} (STO-6G**) to 10.7 kcal mol^{-1} (6-21G**).



For the *syn* conformer Tables 2 and 3 show that the lowest total energy, −756.453 24 au, is obtained with the split-valence basis set 6-21G**, which was used to calculate all the structural parameters of the molecule. The experimental C—N

ANTI-N-SULFINYLANILINE

bond length, Table 2, in CH_3NSO is 1.421 ± 0.005 Å (25); that expected in C_6H_5NSO would be shortened as a result of a partial contribution of resonance structures representing possible delocalization involving the phenyl group. The same reasoning applies to the expected shortening of the N—S and S—O bonds in *N*-sulfinylaniline compared to HNSO or CH_3NSO.

The values of bond angles (Table 2) NSO, CNS, and NC_3C_4 are nicely reproduced by both basis sets 3-21G** and 6-21G**. For the NSO angle a value of 119.01° compares well with a value of 117 ± 2° (25) found for the same angle in CH_3NSO, 120.4° (26) in HNSO, and 123° in C_6H_5NSO (10). In the mean time the bond angle CNS is calculated by the 6-21G** basis set to be 133.6°, which is in good order compared with experimental values 126 ± 2° (25) in CH_3NSO and 130° adjusted to reproduce the rotation spectra of *N*-sulfinylaniline (10).

The difference is bonding between N, S and S, O in *N*-sulfinylaniline is clearly reflected in the calculated values of Mulliken overlap population between the respective atoms using split-valence basis sets. The overlap population between C_{ar}—N, 0.526 (Table 3), is an indication of an essential single bond whereas a value of 1.023–1.058 between the atoms N and S and a value of 0.907–0.938 between the atoms S and O indicate the existence of double bonds but of different degrees. The aromatic double bond character in the benzene ring of *N*-sulfinylaniline gives an overlap population of 0.925–0.927 (Table 3), using split-valence basis sets.

The calculated charge densities are accurate and lead to accurate values of dipole moments. The calculated dipole

Table 4. A comparison between the first ionization potential and ab initio eigenvalues of *syn*-, *anti*-C_6H_5NSO, *syn*- and *anti*-*p*-CH_3-C_6H_4NSO using 6-21G** basis sets.

Compound	MO	Eigenvalue, eV	I. P., eV (28)
C_6H_5NSO	ψ_{36}	−8.825 (−8.839)[a]	9.12
	ψ_{35}	−9.578 (−9.766)	9.65
	ψ_{34}	−11.920 (−11.203)	10.62
	ψ_{33}	−12.264 (−12.274)	11.09
p-CH_3-C_6H_4NSO	ψ_{40}	−8.546 (−8.468)	8.84
	ψ_{39}	−9.548 (−9.744)	0.53
	ψ_{38}	−11.836 (−11.099)	10.60
	ψ_{37}	−11.950 (−11.948)	11.09

[a]Values for *anti* conformer.

moments of *N*-sulfinylaniline are 1.999 D (using 3-21G**) and 1.994 D (using 6-21G**), which agree nicely with the experimental one, 2.07 D (27). The same behavior is observed with *p*-methyl-*N*-sulfinylanine; calculations using the split-valence basis set 6-21G** lead to accurate values of charge density, which in turn give 2.429 D for the dipole moment, corresponding nicely to the experimental value (2.40 D) (27).

He(I) and He(II) photoelectron spectra of some *N*-sulfinylanilines have been reported (28). A comparison between experimental values of the ionization potentials of C_6H_5NSO with the results of ab initio calculations is given in Table 4. The correspondence is quite adequate. The first, lowest, ionization potential for C_6H_5NSO, 9.12 eV, corresponds nicely to the energy of the HOMO (ψ_{36}). This MO is a combination of a $\pi(e_{1g})$ orbital of benzene and a π(N═S) bonding orbital.

The second ionization potential, at 9.65 eV, is assigned to the energy of the molecular orbital ψ_{35}; this orbital is a π-MO and is almost completely localized on the *ortho* and *meta* carbon atoms of the benzene ring of *N*-sulfinylaniline. However, an ionization energy of 9.65 eV is significantly higher than the corresponding value in benzene, indicating a substantial charge flow to the NSO moiety.

The third ionization potential, 10.62 eV, corresponding to the eigenvalue (11.92) of the MO ψ_{34}, this MO is a delocalized σ-MO with a large contribution of N, O, and S atoms. The overlap between the NSO group and the benzene ring, in ψ_{34}, is nil. The overlap between AOs of C-atoms in benzene ring is also nil in ψ_{34} (antibonding MO) and this explains the high eigenvalue of ψ_{34}. The third ionization from a π orbital is harder to identify in the photoelectron spectrum of C_6H_5NSO and, applying the same rule for the three π-orbitals, a value of 11.31 eV was derived for it (28).

II.1.b Excited states of N-*sulfinylaniline:* An appropriate semi-empirical method that reproduces the spectroscopic properties of the molecules is the AM1 method stored in a MOPAC6 (29) program package. The MOs were computed and the CI matrix was solved where electronic transitions were considered between the highest three occupied and the lowest two unoccupied MOs. In the AM1 procedure both α and β spins are considered for the transferred electron.

The electronic transitions and the corresponding assignments of *N*-sulfinylaniline are given in Table 5. For the *syn* conformer, four electronic transitions are calculated and

Table 5. Electronic transition and the corresponding assignments of *N*-sulfinylaniline.

Transition energy, eV		
Calcd.	Exp.	Assignment
***syn* Conformer**		
3.47	—	$n \rightarrow \pi_1^*$: localized on NSO
3.60	3.70	$\pi_2 \rightarrow \pi_1^*$: CT $C_6H_5 \rightarrow$ NSO
3.84	3.91	$\pi_2 \rightarrow \pi_2^*$, $\pi_1 \rightarrow \pi_1^*$: delocalized
4.80	4.42	$\pi_2 \rightarrow \pi_2^*$, $\pi_1 \rightarrow \pi_1^*$: delocalized
5.52	5.43	$\pi_1 \rightarrow \pi_2^*$: localized on C_6H_5
***anti* Conformer**		
3.69		$\pi_2 \rightarrow \pi_1^*$: CT $C_6H_5 \rightarrow$ NSO
3.94		$\pi_2 \rightarrow \pi_2^*$, $\pi_1 \rightarrow \pi_1^*$: delocalized
4.90		$\pi_2 \rightarrow \pi_2^*$, $\pi_1 \rightarrow \pi_1^*$: delocalized
5.53		$\pi_1 \rightarrow \pi_2^*$: localized on C_6H_5

The MOs, ϕ_{21}, ϕ_{22}, and ϕ_{23} are identified as n, π_1, π_2 MOs whereas the MOs ϕ_{24} and ϕ_{25} are identified as π_1^* and π_2^* MOs.

observed in the UV–VIS region. The calculated energy for the lowest transition is 3.47 eV and corresponds to an $n \rightarrow \pi_1^*$ transition, localized over the NSO group. This transition is not observed in the spectrum, Fig. 1, and is obscured by the stronger $\pi_2 \rightarrow \pi_1^*$ transition.

II.2 p-*Methyl*-N-*sulfinylaniline*

Molecular orbital calculations were performed on this molecule following the same steps, and all the basis sets, used with *N*-sulfinylaniline. The calculated results indicate that bond lengths, Table 2, were generally elongated in the *anti* conformer compared to the *syn* conformer; the bond lengths and bond angles calculated for the *syn* conformer are nearer to the experimental values (25). The *syn* conformer is more stable than the *anti* conformer with all the basis sets used, Table 3. The dipole moment calculated for the *syn* conformer, using split-valence basis sets, is 2.429 D, in excellent agreement with the experimental value, 2.40 D (27).

The photoelectron spectrum (28) of the molecule shows an overlap of most of the bands. Table 4 compares the eigenvalues of the highest four occupied MOs of the *syn* and *anti* conformers using the 6-21G** basis sets and the ionization potentials that were measured experimentally.

Excited states were investigated by solving the CI matrix using the AM1 procedure. The CI matrix built from interaction terms between the highest three occupied MOs, ψ_{24}–ψ_{26}, and the lowest two unoccupied MOs, ψ_{27}–ψ_{28}, was solved. It is found that ψ_{24} is a $\sigma(n)$ MO localized over the NSO group where ψ_{25} is a π-MO, localized over the tolyl ring. The MO ψ_{26} is a delocalized π-MO whereas ψ_{27} is a π^*-MO delocalized over the NSO group and ψ_{28} is a π^*-MO localized on the tolyl ring. The calculated $n \rightarrow \pi_1^*$ transition energy, 3.44 eV (Table 6), has no experimental correspondence. The broad band in the spectrum, 275–370 nm (Fig. 2), is resolved into bands with energies 3.65 and 3.86 eV and these corresponding nicely to the calculated transition energies at 3.49 and 3.87 eV, respectively. The highest-energy transition, 5.53 eV, corresponds to a $\pi_1 \rightarrow \pi_2^*$ transition localized over the tolyl ring

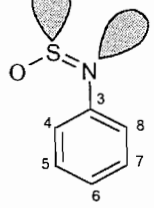
Table 6. Electronic transition of *syn-p*-methyl- and -*m*-methyl-*N*-sulfinylanilines and the corresponding assignments.



Transition energy, eV		
Calcd.	Exp.	Assignment
***syn-p*-Methyl-*N*-sulfinylaniline**		
3.44	—	$n \rightarrow \pi_1^*$: localized on NSO
3.49	3.65	$\pi_2 \rightarrow \pi_1^*$: CT p-CH_3-$C_6H_4 \rightarrow$ NSO
3.87	3.86	$\pi_1 \rightarrow \pi_1^*$, $\pi_1 \rightarrow \pi_2^*$: delocalized
4.68	4.56	$\pi_2 \rightarrow \pi_2^*$, $\pi_1 \rightarrow \pi_1^*$: delocalized
5.53	5.28	$\pi_1 \rightarrow \pi_2^*$: localized on p-CH_3-C_6H_4
***syn-m*-Methyl-*N*-sulfinylaniline**		
3.43	—	$n \rightarrow \pi_1^*$: localized on NSO
3.54	3.70	$\pi_2 \rightarrow \pi_1^*$: CT m-CH_3-$C_6H_4 \rightarrow$ NSO
3.83	3.90	$\pi_1 \rightarrow \pi_1^*$, $\pi_2 \rightarrow \pi_2^*$: delocalized
4.68	4.48	$\pi_2 \rightarrow \pi_2^*$, $\pi_1 \rightarrow \pi_1^*$: delocalized
5.52	5.27	$\pi_1 \rightarrow \pi_2^*$: localized on m-CH_3-C_6H_4

The MOs ϕ_{24}, ϕ_{25}, and ϕ_{26} are identified as n, π_1, π_2 MOs whereas the MOs ϕ_{27} and ϕ_{28} are identified as π_1^* and π_2^* MOs.

and nicely corresponds to the experimentally observed band with energy 5.28 eV.

II.3 m-*Methyl*-N-*sulfinylaniline*

The optimized equilibrium geometry parameters using the split-valence basis sets, 3-21G** and 6-21G**, are given for the *syn* and *anti* conformers in Table 2. Results show only a slight difference in the bond lengths N—S and S—O, which suggests the existence of the same type of bonding between N and S and between S and O atoms. The values of bond angles NSO and NC_3C_4 indicate sp^2 hybridization on the central atom. The enlargement of angle θSNC_3 must be related to the lone pair – lone pair repulsion.

Excited states of the *syn* conformer of *m*-methyl-*N*-sulfinylaniline were obtained as with the *syn-p*-methyl-*N*-sulfinylaniline. Configuration interaction was allowed between the highest three occupied MOs, ψ_{24}–ψ_{26}, and the lowest two unoccupied MOs, ψ_{27}–ψ_{28}. The AM1 calculations showed that ψ_{24} is a $\sigma(n)$ MO localized over the NSO group, MO ψ_{25} is a π-MO localized over the tolyl group, ψ_{26} is a π delocalized MO, whereas ψ_{27} is a π^*-MO localized over the NSO group and ψ_{28} is a π^*-MO localized over the tolyl group.

Four $\pi \rightarrow \pi^*$ electronic transitions in addition to a low-energy $n \rightarrow \pi^*$ transition are calculated for this molecule in the accessible UV region, Table 6. The $n \rightarrow \pi_1^*$ transition is not observed and is obscured by the stronger, $\pi_2 \rightarrow \pi_1^*$, transition. The correspondence between calculated and experimentally observed transition energies is satisfactory, 3.54 eV versus 3.70, 3.83 versus 3.90, 4.68 versus 4.48, and 5.52 versus 5.27 eV.

Table 7. Electronic transition and the corresponding assignments of *syn-p*-methoxy-*N*-sulfinylanilines.

Transition energy, eV		
Calcd.	Exp.	Assignment
3.34	3.38	$\pi_2 \rightarrow \pi_1^*$: CT p-CH_3O-$C_6H_4 \rightarrow$ NSO
3.40	3.50	$\pi_1 \rightarrow \pi_1^*$, $\pi_2 \rightarrow \pi_2^*$: delocalized
3.44		$n \rightarrow \pi_1^*$: localized on NSO
3.96	3.80	$\pi_1 \rightarrow \pi_1^*$, $\pi_2 \rightarrow \pi_2^*$: delocalized
4.62	4.40	$\pi_1 \rightarrow \pi_1^*$, $\pi_2 \rightarrow \pi_2^*$: delocalized
5.50	5.04	$\pi_1 \rightarrow \pi_2^*$: localized on p-CH_3O-C_6H_4

The MOs ϕ_{27}, ϕ_{28}, and ϕ_{29} are identified as n, π_1, π_2 MOs whereas the MOs ϕ_{30} and ϕ_{31} are identified as π_1^* and π_2^* MOs.

II.4 p-*Methoxy*-N-*sulfinylaniline*

The total energy calculated for the *syn* conformer was always less than that for the *anti* conformer, Table 3. There is a slight elongation of the N—S bond (Table 2) relative to the S—O bond, which is a result of the resonance effect of the *p*-methoxy group.

The AM1 procedure was used to perform MO calculations on the excited states of the *syn* conformer of this molecule. The results showed that the highest occupied MOs ψ_{27}, ψ_{28}, and ψ_{29} are $\sigma(n)$ MO localized on the NSO group, π-MO localized over the p-$OCH_3C_6H_4$ group, and π-MO delocalized over the whole molecule, respectively. The LUMOs, ψ_{30} and ψ_{31} are π^*-MO localized over the NSO group and π^*-MO localized over the p-$OCH_3C_6H_4$ chromophore, respectively. The lowest-energy electronic transition is a $\pi_2 \rightarrow \pi_1^*$ charge transfer transition from the p-$OCH_3C_6H_4$ group to the NSO moiety, Table 7. The $n \rightarrow \pi_1^*$ transition, calculated theoretically with an energy of 3.44 eV, is localized on the NSO group and is submerged under the stronger $\pi_1 \rightarrow \pi_1^*$ transition. Three $\pi \rightarrow \pi^*$ electronic transitions are predicted theoretically and observed experimentally for the molecule; these are delocalized over the whole molecule except for the highest energy transition, which is localized over the p-$CH_3OC_6H_4$ group. The correspondence between calculated and observed transition energies is rather satisfactory, 3.34 versus 3.38, 3.40 versus 3.50, 3.96 versus 3.80, 4.62 versus 4.40, and 5.50 versus 5.04 eV.

Conclusions

The electronic absorption spectra of the *N*-sulfinylanilines studied reflect the planarity of the molecules. The observed spectra were not the additive spectra of the NSO group and the benzene ring. The overlap of the low-energy electronic transitions is a common feature of the observed spectra and no discrete band was observed for any $n \rightarrow \pi^*$ transition. Solvent effect on band maxima is not pronounced, a result that indicates the small contribution of the charge transfer configuration to the wave function of the excited states. The NSO group acts as an electron acceptor, especially in the presence of a

© 1997 NRC Canada

complementary group, methyl or methoxy, which enhances the electron-donor or electron-acceptor properties of the NSO group. Charge transfer transitions become more clear than they are in the parent molecule (C_6H_5NSO).

MO calculations at the levels used indicated the planarity of the molecules studied and that the NSO group is nonlinear. The *syn* conformer is more stable, of lower energy, and the height of the barrier of rotation is 6.9–10.7 kcal mol^{-1}. The calculated dipole moment agrees satisfactorily with the experimental one when using split-valence basis sets. The calculated structural parameters, bond lengths, and bond angles agree nicely with the experimental ones. Also, the calculated energies of the occupied MOs agree with the experimental ionization potentials.

The difference in bonding between the N—S and S—O atoms is reflected in the calculate values of Mulliken overlap population. The results indicated an essential single bond between C_{ar} and N and double bonds between N and S as well as between S and O atoms but with different extents.

Molecular orbital calculations showed the existence of an $n \rightarrow \pi^*$ transition localized on the NSO group. However, this transition is not observed experimentally and is obscured by the neighboring strong $\pi \rightarrow \pi^*$ transition.

5-Hydroxypentane-2,3-dione and 3-amino-1-hydroxypropan-2-one, putative precursors of vitamin B_6

Eckardt Wolf, Isaac A. Kennedy, Klaus Himmeldirk, and Ian D. Spenser

Abstract: New syntheses are described of 5-hydroxypentane-2,3-dione (**7**) (i.e., laurencione (**7** ⇄ **8**)) and of 3-amino-1-hydroxypropan-2-one (3-amino-1-hydroxyacetone) (**5**) hydrochloride, putative precursors of the C_5 unit, C-2′,2,3,4,4′, and of the C_3N unit, N-1,C-6,5,5′, respectively, of pyridoxine (**6**).

Key words: 3-amino-1-hydroxyacetone, 3-amino-1-hydroxypropanone, 5-hydroxypentane-2,3-dione, laurencione, vitamin B_6.

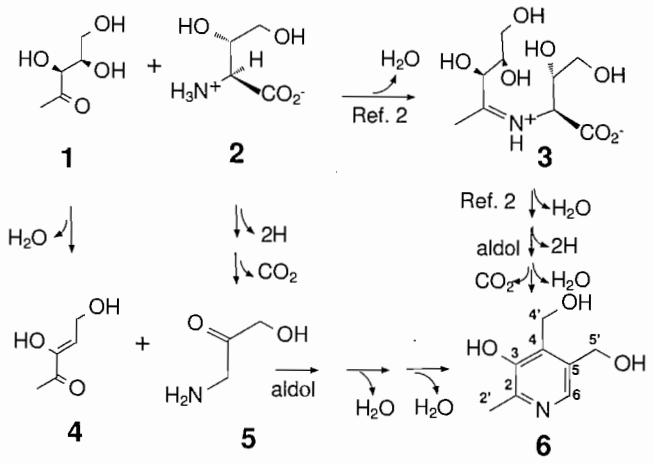
Résumé : On décrit de nouvelles synthèses de la 5-hydroxypentane-2,3-dione (**7**) (c'est-à-dire de la laurencione (**7** ⇄ **8**)) et du chlorhydrate de la 3-amino-1-hydroxypropan-2-one (3-amino-1-hydroxyacétone) (**5**), des précurseurs potentiels respectivement de l'unité en C_5, C-2′,2,3,4,4′, et de l'unité C_3N, N-1,C-6,5,5′, de la pyridoxine (**6**).

Mots clés : 3-amino-1-hydroxypropane-2-one, 3-amino-1-hydroxyacétone, 5-hydroxypentane-2,3-dione, laurencione, vitamine B_6.

[Traduit par la rédaction]

Introduction

Two precursors, one a modified pentose, 1-deoxy-D-xylulose (**1**), the other a non-protein amino acid, 4-hydroxy-L-threonine (**2**), account for the origin of the entire C_8N skeleton of vitamin B_6 (pyridoxol, pyridoxine) (**6**) (1). A hypothetical seven-step reaction sequence was advanced to account for the chemical mechanism of the formation of the pyridoxine skeleton from these two substrates (2). The first step in this sequence was postulated to be the union of the two precursors to form a Schiff base (**3**), which was then primed to generate the bond destined to become C-4—C-5 of pyridoxol, by intramolecular aldol condensation in a multistep reaction sequence. The fragment destined to become C-2′,2,3,4,4′ of pyridoxol, derived from 1-deoxy-D-xylulose (**1**), was modified by dehydration, and the fragment destined to yield N-1,C-6,5,5′, derived from 4-hydroxy-L-threonine (**2**), underwent dehydrogenation and decarboxylation.



It is equally plausible, however, that the corresponding modifications of the two substrates take place ahead of Schiff base formation, so that the immediate precursors that undergo condensation to form the pyridoxine skeleton are the enol (**4**) of 5-hydroxypentane-2,3-dione (**7**), generated by dehydration of 1-deoxy-D-xylulose (**1**), rather than 1-deoxy-D-xylulose itself, and 3-amino-1-hydroxypropan-2-one (**5**), generated by dehydrogenation and decarboxylation of 4-hydroxy-L-threonine (**2**), rather than the intact amino acid (Scheme 1).

Scheme 1. Alternative routes for the derivation of pyridoxol (**6**) from 1-deoxy-D-xylulose (**1**) plus 4-hydroxy-L-threonine (**2**).

In an effort to throw further light on the mechanism of formation of pyridoxol, we have prepared synthetic samples of **5** and **7**, the two compounds that incorporate these structural modifications.

5-Hydroxypentane-2,3-dione (**7**), in an equilibrium mixture with the isomeric furanose (**8**), i.e., laurencione (**7** ⇄ **8**) (3), was prepared in five steps from the commercially available pent-3-yn-1-ol (**18**) in an overall yield of 81%. Furthermore, a bond-labeled sample, [2,3-$^{13}C_2$]-5-hydroxypentane-2,3-dione (**7***) (or rather [2,3-$^{13}C_2$]laurencione (**7*** ⇄ **8***)) was prepared from [$^{13}C_2$]acetylene (**15***) in seven steps in an overall yield of 31% (cf. Scheme **4**). Earlier syntheses of laurencione (**7** ⇄ **8**) had given the product in overall yields of 21% (in six steps, starting from γ-butyrolactone), 19% (in eight steps from 2-acetylbutyrolactone) and 17% (in five steps from 1,1-dichloroacetone), respectively (4).

3-Amino-1-hydroxypropan-2-one (3-amino-1-hydroxyacetone) (**5**) hydrochloride, the compound derivable from 4-hydroxy-L-threonine (**2**) by dehydrogenation and decarboxylation, was synthesized in four steps from DL-3-aminopropane-1,2-diol (**23**) in an overall yield of 42% (cf. Scheme 5).

A discussion of the rationale for the selection of the two compounds as putative pyridoxine precursors, and of their synthesis follows.

Results and discussion

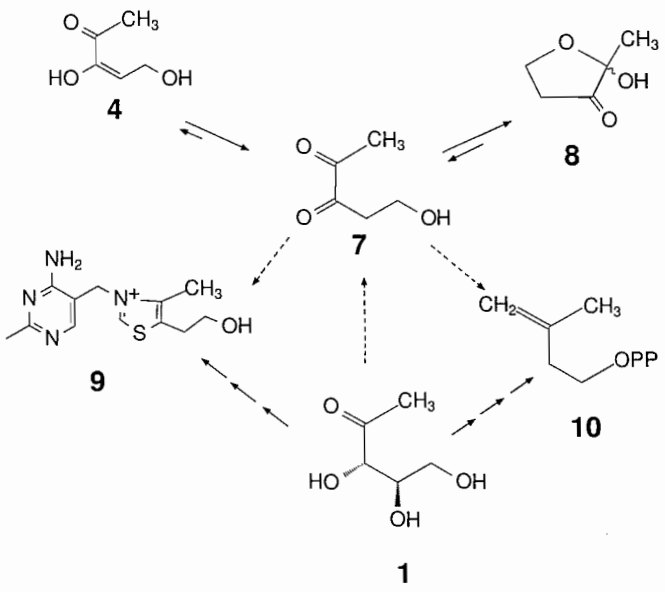
Rationale for the choice of 5-hydroxypentane-2,3-dione (7) and 3-amino-1-hydroxypropan-2-one (5) as putative pyridoxine precursors

In *Escherichia coli* only two genes, *pdxA* and *pdxJ*, and therefore only two enzyme-catalyzed steps, are implicated in the generation of pyridoxol (**6**) from 1-deoxy-D-xylulose (**1**) plus 4-hydroxy-L-threonine (**2**) (5).

In considering a possible mechanism of this process it is a reasonable assumption that each one of the two substrates is involved in one of these enzymic steps. If these steps occurred before the two substrates interacted, then the products of the two reactions would be intermediates in the formation of pyridoxol (**6**) from **1** plus **2**. Formally, the creation of the pyridoxol skeleton ($C_8H_{11}NO_3$) (**6**) from **1** ($C_5H_{10}O_4$) plus **2** ($C_4H_9NO_4$) requires a decarboxylation ($-CO_2$), the elimination of three molecules of water ($-3\ H_2O$), and a dehydrogenation ($-2H$). If these processes corresponded to the actual mechanistic steps, then two of them must be enzyme catalyzed.

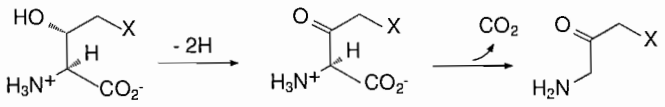
In the formation of pyridoxol from the two acyclic substrates, **1** plus **2**, a new C—N bond and a new C—C bond must be formed. Formation of the new C—N bond, between the keto group, C-2, of **1** and the amino group of **2**, poses no problems. However, since the new C—C bond must be formed by interaction of C-4 of **1** with C-3 of **2**, both of which are secondary carbinols, activation at these sites is required, so that bond formation between them can take place.

One way of achieving activation of C-4 of **1** is by dehydration, to yield the enol (**4**), i.e., a tautomer of the diketone (**7**). This diketone, 5-hydroxypentane-2,3-dione, has recently been found in nature (3), existing as an equilibrium mixture with its furanose isomer (**8**). The mixture **7** ⇄ **8** is referred to as laurencione. The 5-phosphate ester of hydroxypentane-2,3-dione (**7**) had earlier been postulated (6) as the precursor of the C_5 chain, C-4′,4,5,6,7, of the thiazole unit of thiamin (**9**). 1-Deoxy-D-xylulose (**1**), the compound from which 5-hydroxypentane-2,3-dione (**7**) may be derived by dehydration, has been shown to be incorporated into the C_5 chain, C-4′,4,5,6,7, of the thiazole unit of thiamin (7–10) and concurrently also into C-2′,2,3,4,4′ of pyridoxol (10). Furthermore, 1-deoxy-D-xylulose (**1**) has been identified as an intermediate of the nonmevalonic acid route to isoprenoids (e.g., **10**) in *E. coli* (11) and 5-hydroxypentane-2,3-dione (**7**) was again invoked as an intermediate (12).



Thus, 5-hydroxypentane-2,3-dione (**7**) appeared to be a prime candidate in the choice of possible intermediates on the route from 1-deoxy-D-xylulose (**1**) into the C_5 unit, C-2′,2,3,4,4′, of pyridoxol (**6**).

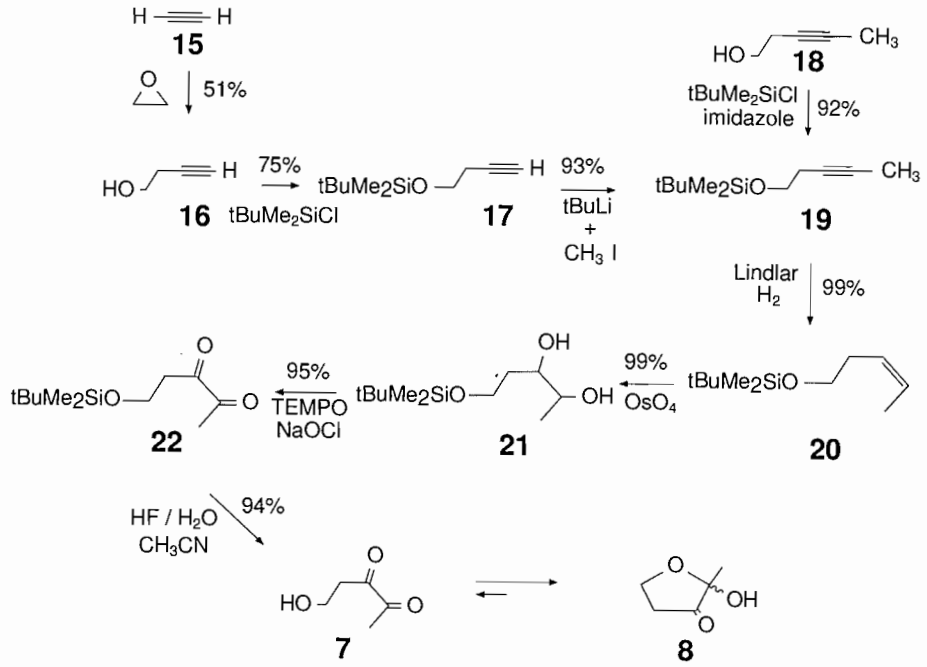
In selecting the reaction that might serve to activate the carbinol carbon, C-3, of the other substrate, 4-hydroxy-L-threonine (**2**), for bond formation, we considered dehydrogenation, a process that is formally required in the conversion of the two substrates, **1** plus **2**, into pyridoxol (**6**) (Scheme 1). The product of dehydrogenation at C-3 of 4-hydroxy-L-threonine would be L-2-amino-4-hydroxy-3-oxobutanoic acid (**11**). This compound has not been described. The corresponding dehydrogenation product of threonine (**12**), L-2-amino-3-oxobutanoic acid (**13**), has been prepared (13, 14): It was found that this compound lacks stability, with a half life of ca. 10 min at physiological pH, undergoing spontaneous decarboxylation to yield 1-aminopropan-2-one (**14**) (Scheme 3). It is most likely that the corresponding dehydrogenation of 4-hydroxy-L-threonine (**2**) to the oxoamino acid (**11**) is accompanied by an analogous spontaneous decarboxylation, leading to 3-amino-1-hydroxypropan-2-one (**5**). Such a reaction sequence on the route to pyridoxol would then account not only for the required, presumably enzyme-catalyzed, dehydrogenation, but also for the required, but presumably spontaneous, decarboxylation.



3-Amino-1-hydroxypropan-2-one (**5**) thus appeared to be a promising choice as a possible intermediate on the route from 4-hydroxy-L-threonine (**2**) into the C_3N unit, N-1,C-6,5,5′, of pyridoxol (**6**).

To date we have not been able to obtain evidence that either of the two compounds serves as precursor of pyridoxol in *Escherichia coli*. The reason for this lack of success may be

Scheme 2. 5-Hydroxypentane-2,3-dione (**7**) as a possible intermediate on the routes from 1-deoxy-D-xylulose (**1**) into thiamin (**9**) and into isoprenoids (e.g., **10**).



Scheme 3. The oxidative decarboxylation of threonine (**12**).

Scheme 4. Synthesis of laurencione (**7** ⇄ **8**).

that the actual substrates for the enzymic reaction are the 5-phosphate ester of **7** and the 1-phosphate ester of **5**, rather than the non-phosphorylated species.

A discussion of the synthesis of the two putative intermediates of pyridoxol biosynthesis, **5** and **7**, follows.

Synthesis of 5-hydroxypentane-2,3-dione (7) (i.e., laurencione (7 ⇄ 8)) (Scheme 4)

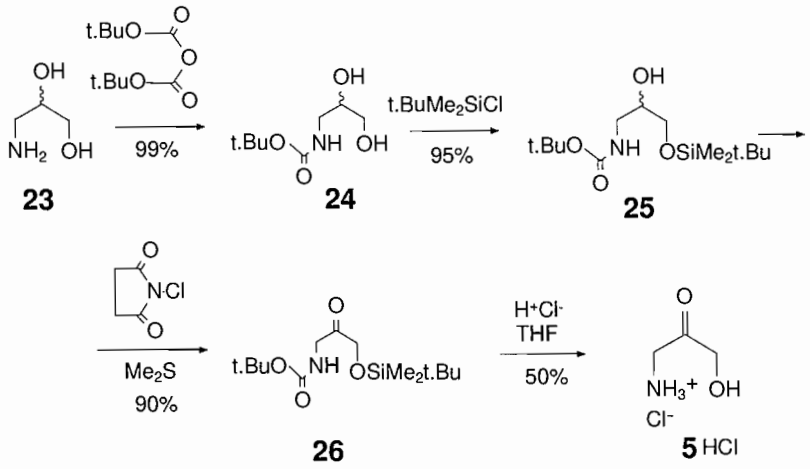
Recent syntheses of laurencione (4) start from γ-butyrolactone, from 2-acetylbutyrolactone or from 1,1-dichloroacetone. These syntheses are not readily adaptable to the preparation of the [2,3-$^{13}C_2$]-labeled sample of 5-hydroxypentane-2,3-dione that we required. Our synthesis starts with [$^{13}C_2$]acetylene, one of the few bond-labeled compounds that are commercially available (Cambridge Isotope Laboratories).

[$^{13}C_2$]Acetylene (**15***) was converted into [3,4-$^{13}C_2$]but-3-yn-1-ol (**16***) by generating the mono lithium salt, which was reacted with ethylene oxide.[2] Reaction with *tert*-butyldimethylsilyl chloride in the presence of imidazole then protected the alcohol group. The resulting silyl ether (**17***) was treated with *tert*-butyllithium, followed by methyl iodide, to yield the silyl ether (**19***) of [3,4-$^{13}C_2$]pent-3-yn-1-ol. The corresponding unlabeled compound (**19**) is accessible by *tert*-butyldimethylsilyl chloride – imidazole treatment of pent-3-yn-1-ol (**18**), which is commercially available. Lindlar hydrogenation of the triple bond of **19*** gave [2,3-$^{13}C_2$]-(*Z*)-5-*tert*-butyldimethylsilyloxypent-2-ene (**20***), which was converted to the corresponding *cis*-diol (**21***) by means of osmium tetroxide. TEMPO oxidation (16) of the diol gave the corresponding dione (**22***), i.e., the silyl ether of the desired product. Removal of the silyl ether group by means of fluoride gave [2,3-$^{13}C_2$]-5-hydroxypentane-2,3-dione (**7***), together with the corresponding cyclic isomer, [2,3-$^{13}C_2$]-(2*RS*)-2-hydroxy-2-methyl-3-oxotetrahydrofuran (**8***), that is, [2,3-$^{13}C_2$]-laurencione. The overall yield in the seven-step synthesis of [2,3-$^{13}C_2$]laurencione (**7*** ⇄ **8***) from [$^{13}C_2$]acetylene (**15***) was 31%. The five-step synthetic route to unlabeled laurencione (**7** ⇄ **8**) from pent-3-yn-1-ol (**18**) gave the product in 81% yield and thus represents a significant improvement on the earlier syntheses (4). The composition of the equilibrium mixture **7** ⇄ **8** of laurencione, as determined by ^{13}C NMR spectroscopy, depends on the solvent. In $CDCl_3$ the ratio, **7** to **8**, was found (3) to be 17:83, whereas in C_6D_6 the **7** to **8** ratio was 40:60. Laurencione is unstable at room temperature, due to oligomerization. It can be stored in benzene (frozen) at ca. 0°C or in aqueous solution at 4°C. From aqueous solution it can be recovered by extraction into chloroform followed by evaporation of the solvent.

Synthesis of 3-amino-1-hydroxypropan-2-one (5) hydrochloride (Scheme 5)

Surprisingly, neither Beilstein nor the Dictionary of Organic Compounds contains an entry for this simple three-carbon compound. Certainly, the compound is not described in the recent chemical literature. A very determined search did uncover a preparation of the compound by a three-step synthesis, in indifferent yield, from *N*-acetonylphthalimide, in connection with an early synthetic approach to ergothioneine (17).

3-Amino-1-hydroxypropan-2-one (**5**) hydrochloride was prepared starting from (±)-3-aminopropane-1,2-diol (**23**), a compound that is available commercially.



Conversion of (±)-3-aminopropane-1,2-diol (**23**) into the desired product requires preferential oxidation of the secondary alcohol group. To achieve this the primary alcohol and the amino group of the starting material had to be protected.

[2] The preparation of unlabeled but-3-yn-1-ol by this method is described by Verkruijsse and Brandsma (15*a*); see also ref. 15*b*.

Scheme 5. Synthesis of 3-amino-1-hydroxypropan-2-one (**5**).

Scheme 6. Dimers of 3-amino-1-hydroxypropan-2-one (**5**).

Protection of the amino group in the presence of the two alcohol functions was implemented by means of di-*tert*-butyl dicarbonate (18), to yield (±)-*N*-*tert*-butyloxycarbonyl-3-aminopropane-1,2-diol (**24**). The primary alcohol group of the latter was protected selectively by means of Corey silylation in the presence of 4-dimethylaminopyridine (19). The resulting doubly protected product (**25**) was then oxidized with *N*-chlorosuccinimide in the presence of dimethyl sulfide (20) to yield the protected aminoketone (**26**), which was deprotected by acid hydrolysis. 3-Amino-1-hydroxyacetone (**5**) hydrochloride was obtained as slightly yellow crystals that darkened on standing.

Slow recrystallization from ethanol-*tert*-butyl methyl ether gave the product as long, slightly yellow needles. X-ray crystallography of a 0.02 mm thick single crystal of the crystalline product shows it to be pure 3-amino-1-hydroxyacetone (**5**) hydrochloride.

However, the ^{1}H NMR spectrum in D_2O of every sample of the product **5** showed, in addition to the COCH_2O (δ 4.35 ppm) and the COCH_2N (δ 4.03 ppm) singlet signals of equal intensity, two additional singlets, each ca. one fifth as intense as the other two, at δ 3.54 and 3.06 ppm, indicating the presence of another component, with which **5** was in equilibrium in aqueous solution. The structure of the minor component was deduced from the ^{13}C NMR spectrum. In addition to the three major signals at δ 204.6 (*C*O), 65.7 (*C*H_2O), 44.9 (*C*H_2N), the spectrum showed a less intense signal at δ 92.7 (ketal). Furthermore, the two *C*H_2 signals show satellites of lower intensity: three satellites (δ 66.2, 65.6, 65.3 ppm) straddle the *C*H_2O signal, two (δ 45.3, 44.2 ppm) appear at the *C*H_2N signal.

We conclude that in aqueous solution the aminoketone exists in equilibrium with the two stereoisomers of a dimer, *trans*- and *cis*-2,5-dihydroxy-2,5-aminomethyl-1,4-dioxane dihydrochloride (**27** and **28**). Since these ring compounds are fluxional, the ^{1}H NMR spectrum does not show evidence of diastereotopic protons. When the D_2O solution of the sample is kept for 3 weeks at room temperature, the COCH_2N signals (δ 4.03 and 3.04 ppm) in the ^{1}H NMR spectrum have almost completely disappeared, indicating deuterium exchange. In addition, weak signals in the aromatic region of the spectrum are observable. These become prominent when the sample is exposed to air for several weeks at elevated temperature. This suggests formation of another dimer (**29**), which eventually oxidizes to the pyrazine (**30**). We did not attempt to isolate samples of the decomposition products.

Experimental

Synthesis of 5-hydroxypentane-2,3-dione (7), in equilibrium with (2*RS*)-2-hydroxy-2-methyl-3-oxotetrahydrofuran [(2*RS*)-2-hydroxy-2-methyl-dihydrofuran-3(2*H*)-one] (8) (i.e., laurencione (7 ⇄ 8)) (Scheme 4)

5-tert-Butyldimethylsilyloxypent-2-yne (19)

Pent-3-yn-1-ol (**18**) (3.21 g, 38.1 mmol) was dissolved in dry *N,N*-dimethylformamide (100 mL). Imidazole (5.71 g, 83.9 mmol) was added, followed by *tert*-butyldimethylsilyl chloride (6.36 g, 42.2 mmol) in small portions. The mixture was stirred overnight at room temperature, was then poured into petroleum ether (150 mL), and the solution was extracted with water (750 mL), aqueous HCl (ca. 5%, 2 × 100 mL), and water. The organic phase was dried ($MgSO_4$) and the solvent distilled off. The residue was distilled at reduced pressure

(bp 80–85°C at 10 Torr (1 Torr = 133.3 Pa)) to yield the silyl ether (**19**) (7.00 g, 92.5%). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.66 (t, $^3J_{H,H}$ = 7.0 Hz, 2H), 2.31 (tq, $^3J_{H,H}$ = 7.0 Hz, $^5J_{H,H}$ = 2.5 Hz, 2H), 1.74 (t, $^5J_{H,H}$ = 2.5 Hz, 3H), 0.87 (s, 9H), 0.04 (s, 6H).

^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 76.6, 76.1, 62.3, 25.8, 23.1, 18.3, 3.4, −5.3. MS (CI) *m/z*: 199 (100%, m + H$^+$).

*(Z)-5-*tert*-Butyldimethylsilyloxypent-2-ene (**20**)*

Alkyne **19** (3.97 g, 20 mmol) and quinoline (1 mL) were dissolved in ethyl acetate (100 mL). Lindlar catalyst (450 mg, Aldrich) was added and the mixture hydrogenated at ca. 1 atm (101.3 kPa) until uptake of hydrogen ceased. The catalyst was filtered off and washed with ethyl acetate, and the filtrate was extracted with HCl (ca. 5%, 2 × 50 mL) and brine. The organic layer was dried over K_2CO_3, and the solvent was evaporated, to yield the alkene (**20**) (4.00 g, 99%). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 5.33–5.56 (m, 2H), 3.59 (t, $^3J_{H,H}$ = 7.0 Hz, 2H), 2.26 (t, $^3J_{H,H}$ = 7.0 Hz, 2H), 1.60 (d, $^3J_{H,H}$ = 6.5 Hz, 3H), 0.88 (s, 9H), 0.04 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 126.6, 125.7, 62.8, 30.8, 25.9, 18.4, 12.9, −5.3. MS (CI) *m/z*: 201 (80%, m + H$^+$), 135 (100%).

*(3R4S,3S4R)-1-*O*-*tert*-Butyldimethylsilylpentane-1,3,4-triol (**21**)*

Alkene **20** (2.77 g, 13.8 mmol) was dissolved in *tert*-butanol (28 mL) and tetrahydrofuran (12 mL). Water (4 mL) and 4-methylmorpholine-*N*-oxide (NMO) (2.10 g) was added. Air was displaced by passing a stream of nitrogen through the mixture. An aqueous solution of osmium tetroxide (4%, 1 mL) was added and the mixture stirred 5 h at room temperature. An aqueous solution of sodium bisulfite (150 mg in 5 mL water) was added, followed by Florisil R (5.0 g). The mixture was stirred 10 min and then filtered through silica gel, which was then washed with ethyl acetate. Evaporation of the filtrate in vacuo yielded the colourless oily product (**21**) (3.20 g, 99%). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.78–3.91 (m, 4H), 2.11 (s (br), 2H), 1.60–1.72 (m, 2H), 1.16 (d, $^3J_{H,H}$ = 6.0 Hz, 3H), 0.89 (s, 9H), 0.07 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 75.7, 70.0, 62.2, 32.5, 25.8, 18.0, 17.7, −5.7. MS (CI) *m/z*: 235 (100%, m + H$^+$).

*5-*tert*-Butyldimethylsilyloxypentane-2,3-dione (**22**)*

Compound **21** (938 mg, 4 mmol) was dissolved in methylene chloride (60 mL). 2,2,6,6-Tetramethyl-1-piperidinyloxy (TEMPO, 30 mg), water (4 mL), and KBr (240 mg) were added and the mixture was cooled in an ice bath. Ice-cold aqueous solutions of saturated $NaHCO_3$ (48 mL) and of NaOCl (Cl_2 content ca. 4%, 48 mL) were added and the mixture, cooled in an ice bath, was stirred 10 min. The layers were separated, the aqueous layer was extracted with methylene chloride (50 mL), and the combined organic phases were dried ($MgSO_4$). The mixture was filtered through silica gel, which was then washed with methylene chloride until the washings emerged colourless. Concentration in vacuo gave the pure product **22** as a yellow liquid (892 mg, 95%). UV–VIS: λ_{max} = 422 nm, $\varepsilon_0 = 1.63 \times 10^6$. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.91 (t, $^3J_{H,H}$ = 6.2 Hz, 2H), 2.91 (t, $^3J_{H,H}$ = 6.1 Hz, 2H), 2.29 (s, 3H), 0.83 (s, 9H), 0.02 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 197.8, 196.7, 59.8, 38.5, 25.1, 22.9, 17.5, −6.2. MS (CI) *m/z*: 231 (100%, m + H$^+$).

*5-Hydroxypentane-2,3-dione (**7**), in equilibrium with (2*RS*)-2-hydroxy-2-methyl-3-oxotetrahydrofuran (**8**)*

Freshly distilled (Kugelrohr, bp 120°C at 0.7 Torr) diketone **22** (230 mg, 1 mmol) was dissolved in acetonitrile (10 mL). The solution was cooled in an ice bath and aqueous hydrofluoric acid (49% w/v, 0.6 mL) was added with stirring. The ice bath was removed after 15 min and stirring continued for 45 min. The mixture was poured into chloroform (30 mL), sodium bicarbonate (1.5 g) followed by saturated aqueous bicarbonate solution (1 mL) was added, and the mixture was stirred until evolution of CO_2 had ceased (ca. 10 min). Solid $MgSO_4$ (ca. 5 g) was added to remove water and the mixture was filtered after standing overnight. Evaporation of the solvent in vacuo gave the product as a yellow oily liquid (108 mg, 94%). Fast distillation in vacuo (Kugelrohr, 130°C, 0.5 Torr) gave pure product (92 mg, 80%) consisting of 5-hydroxypentane-2,3-dione (**7**) (17%), in equilibrium with (2*RS*)-2-hydroxy-2-methyl-3-oxotetrahydrofuran (**8**) (83%), as determined on the basis of an NMR spectrum in $CDCl_3$. In C_6D_6 the ratio of **7** to **8** was 40:60.

***7** (cf. ref. 3)*: ^{1}H NMR (200 MHz, $CDCl_3$) δ: ~4.2 (OH, overlapping OCH_2 of **8**), 3.84 (t, $^3J_{H,H}$ = 5.5 Hz, 2H), 2.91 (t, $^3J_{H,H}$ = 5.5 Hz, 2H), 2.24 (s, 3H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 198.4, 197.1, 56.9, 38.2, 23.3.

***8** (cf. ref. 3)*: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 4.00–4.27 (m, ca. 3H; OCH_2 of **8**, overlapped by OH of **7** and **8**), 2.37–2.55 (m, 2H), 1.29 (s, 3H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 210.2, 96.3, 61.6, 33.4, 20.9.

***7** + **8** (cf. ref. 3)*: MS (CI, NH_3) *m/z*: 116 (100%, m − OH + NH_3^+).

Synthesis of [2,3-$^{13}C_2$]-5-hydroxypentane-2,3-dione (7*), in equilibrium with [2,3-$^{13}C_2$]-(2*RS*)-2-hydroxy-2-methyl-3-oxotetrahydrofuran ([2,3-$^{13}C_2$]-(2*RS*)-2-hydroxy-2-methyldihydrofuran-3(2*H*)-one) (8*) (*i.e.*, [$^{13}C_2$]laurencione (7* ⇄ 8*))

*[2,3-$^{13}C_2$]-5-*tert*-Butyldimethylsilyloxypent-2-yne (**19***) from [1,2-$^{13}C_2$]acetylene (**15***)*

*[3,4-$^{13}C_2$]But-3-yn-1-ol (**16***) (cf. ref. 15)*

[$^{13}C_2$]Acetylene (**15***) (0.5 L, ca. 22 mmol) was condensed from the breakseal flask in which it was supplied (Cambridge Isotope Laboratories) into an evacuated 250 mL reaction flask, immersed in a liquid nitrogen bath. After complete transfer (ca. 1 h) the breakseal flask was disconnected and the reaction vessel was flushed with dry nitrogen while still maintained at ca. −180°C. Dry NH_3 (ca. 50 mL) was condensed into the system and $LiNH_2$ (0.55 g, 22.8 mmol) was then added. The liquid nitrogen bath was replaced by an ethanol – solid CO_2 bath that had been precooled to ca. −50°C, and the mixture was refluxed (Dry Ice condenser) for 2 h. Ethylene oxide (ca. 1.5 mL, 30 mmol) was then condensed into the system and the mixture was refluxed for 40 h. NH_3 was evaporated and water (30 mL) and saturated NH_4Cl solution (10 mL) were then added. The aqueous phase was continuously extracted with diethyl ether (2 days); the ether was then evaporated at atmospheric pressure to yield the crude product (823 mg) as a

IR; ν (cm^{-1}): 3279, 2947, 2889, 1048 (ν_{max}). ^1H NMR (200 MHz, $CDCl_3$) δ: 3.71 (dt(q), $^3J_{H,H} = {}^3J_{C,H} = 6.1$, 2H), 2.36–2.44 (m, 2H), 2.22 (br s), 1H), 2.01 (ddt, $^4J_{H,H} = 2.6$ Hz, $^1J_{C,H} = 244.2$ Hz, $^2J_{C,H} = 54.2$ Hz, 1H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 81.3 (enriched)(d, $^1J_{C,C} = 171$ Hz), 69.7 (enriched)(d, $^1J_{C,C} = 171$ Hz), 60.8, 22.7 (dd, $^1J_{C,C} = 65.4$ Hz, $^2J_{C,C} = 14$ Hz). MS (EI) *m/z*: 73 (5%, m + H^+), 71 (15%), 55 (30%), 45 (100%).

*[1,2-$^{13}C_2$]-4-*tert*-Butyldimethylsilyloxybut-1-yne (**17***)*
[3,4-$^{13}C_2$]But-3-yn-1-ol (**16***) (1.25 g, 17.3 mmol) was dissolved in dry dimethylformamide (40 mL). Imidazole (2.50 g, 36.7 mmol) was added, followed by *tert*-butyldimethylsilyl chloride (3.00 g, 19.9 mmol). The mixture was stirred overnight and was then poured into petroleum ether (40–60°C) (50 mL). The mixture was extracted with water (400 mL), dilute HCl (5% v/v, 2 × 25 mL), and water (50 mL). The petroleum ether solution was then dried (anhydrous $MgSO_4$), the solvent distilled off, and the residue distilled in vacuo. [1,2-$^{13}C_2$]-4-*tert*-Butyldimethylsilyloxybut-1-yne (**17***) (2.65 g, purity 92% by NMR, yield 75%) was obtained from the fraction, bp 65–70°C at 10 Torr. IR (film) ν (cm^{-1}): 2956, 2932, 2859, 1111, 839 (ν_{max}). ^1H NMR (200 MHz, $CDCl_3$) δ: 3.72 (dt, $^3J_{H,H} = 7.1$ Hz, $^3J_{C,H} = 4.3$, 2H), 2.30–2.45 (m, 2H), 1.93 (ddt, $^4J_{H,H} = 2.6$ Hz, $^1J_{C,H} = 244.4$ Hz, $^2J_{C,H} = 53.4$ Hz, 1H), 0.88 (s, 9H), 0.05 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 81.7 (enriched)(d, $^1J_{C,C} = 172$ Hz), 69.0 (enriched) (d, $^1J_{C,C} = 172$ Hz), 61.8, 25.9, 22.8 (dd, $^1J_{C,C} = 64$ Hz, $^2J_{C,C} = 10$ Hz), 18.3, −5.3. MS (CI) *m/z*: 187 (100%, m + H^+), 132 (60%).

*[2,3-$^{13}C_2$]-5-*tert*-Butyldimethylsilyloxypent-2-yne (**19***)*
[1,2-$^{13}C_2$]-4-*tert*-Butyldimethylsilyloxybut-1-yne (**17***) (1.78 g, 8.8 mmol) was dissolved in dry tetrahydrofuran (100 mL). The mixture was cooled to −20°C, a solution of *tert*-butyllithium (5.5 mL, 1.7 M in pentane) was added over a period of 5 min, and the mixture was allowed to stand for 1 h. Methyl iodide (1.0 mL, 16 mmol) was added, the cooling bath was removed after 30 min and stirring was continued for another 30 min. The mixture was poured into petroleum ether (40–60°C, 150 mL), followed by extraction with half-concentrated NaCl solution (2 × 150 mL). The organic phase was dried (anhydrous $MgSO_4$) and the solvent distilled off. The residual liquid was distilled in vacuo (Kugelrohr, 85°C, 10 Torr), yielding [2,3-$^{13}C_2$]-5-*tert*-butyldimethylsilyloxypent-2-yne (**19***) (1.80 g, 93%). IR (film); ν (cm^{-1}): 2956, 2930, 2858, 1103, 837 (ν_{max}). ^1H NMR (200 MHz, $CDCl_3$) δ: 3.76 (dt, $^3J_{H,H} = 7.4$ Hz, $^3J_{C,H} = {}^4J_{C,H} = 1.8$ Hz, 2H), 2.24–2.39 (m, 2H), 1.74 (q, $^4J_{H,H} = 2.5$ Hz, $^2J_{C,H} = 2.5$ Hz, 3H), 0.88 (s, 9H), 0.05 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 78.1 (enriched)(d, $^1J_{C,C} = 176$ Hz), 74.6 (enriched)(d, $^1J_{C,C} = 176$ Hz), 62.3, 25.9 (dd, $^1J_{C,C} = 45$ Hz, $^2J_{C,C} = 34$ Hz), 23.0 (dd, $^1J_{C,C} = 45$ Hz, $^2J_{C,C} = 34$ Hz), 18.3, 3.4, −5.3. MS (CI, NH_3) *m/z*: 218 (20%, m + NH_4^+), 201 (100%, m+H^+), 132 (20%).

The experimental procedure for the conversion of [2,3-$^{13}C_2$]-5-*tert*-butyldimethylsilyloxypent-2-yne (**19***) into [2,3-$^{13}C_2$]-(*Z*)-5-*tert*-butyldimethylsilyloxypent-2-ene (**20***) and thence, via **21*** and **22***, into bond-labeled laurencione (**7*** ⇄ **8***), was similar to that described above for the preparation of the corresponding unenriched compounds. Spectral data for the enriched compounds are given below.

*[2,3-$^{13}C_2$]-(Z)-5-*tert*-Butyldimethylsilyloxypent-2-ene (**20***)*: IR (film), ν (cm^{-1}): 3004, 2956, 2931, 2859, 1255, 1089, 837 (ν_{max}). ^1H NMR (200 MHz, $CDCl_3$) δ: 6.06–4.83 (m, 2H), 3.59 (dt, $^3J_{H,H} = 7.1$ Hz, $^3J_{C,H} = 3.4$ Hz, 2H), 2.20–2.39 (m, 2H), 1.60 (ddd, $^3J_{H,H} = 5.0$ Hz, $^2J_{C,H} = 6.8$ Hz, $^4J_{H,H} = 0.9$ Hz, 3H), 0.86 (s, 9H), 0.04 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 126.9 (enriched)(d, $^1J_{C,C} = 70$ Hz), 125.2 (enriched)(d, $^1J_{C,C} = 70$ Hz), 62.8 (d, $^2J_{C,C} = 3$ Hz), 30.8 (dd, $^1J_{C,C} = 33$ Hz, $^2J_{C,C} = 10$ Hz), 26.0 18.4, 12.9 (dd, $^1J_{C,C} = 32$ Hz, $^2J_{C,C} = 10$ Hz), −5.2. MS (CI), *m/z*: 203 (100%, m + H^+), 162 (20%), 130 (60%).

*[2,3-$^{13}C_2$]-(2R3S,2S3R)-5-*O*-tert-Butyldimethylsilylpentane-2,3,5-triol (**21***)*: IR (film), ν (cm^{-1}): 3385, 2956 (ν_{max}), 2931, 2859, 1256, 1090, 836. ^1H NMR (200 MHz, $CDCl_3$) δ: 4.16–3.33 (m, 2H), 3.77–3.96 (m, 2H), 2.54 (br s), OH, 2H), 1.58–1.78 (m, 2H), 1.15 (dt, $^3J_{H,H} = 6.4$ Hz, $^3J_{C,H} = {}^2J_{C,H} = 2.1$ Hz, 3H), 0.88 (s, 9H), 0.07 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 75.7 (enriched)(d_{AB}, $^1J_{C,C} = 43$ Hz), 70.0 (enriched)(d_{AB}, $^1J_{C,C} = 42$ Hz), 62.5, 31.8 (d, $^1J_{C,C} = 37$ Hz), 25.8, 18.0, 17.7 (d, $^1J_{C,C} = 39$ Hz), −5.7. MS (CI), *m/z*: 237 (100%, m + H^+), 140 (30%).

*[2,3-$^{13}C_2$]-5-*tert*-Butyldimethylsilyloxypentane-2,3-dione (**22***)*: IR (film), ν (cm^{-1}): 2957, 2932, 2887, 2859, 1677 (ν_{max}). ^1H NMR (200 MHz, $CDCl_3$) δ: 3.40 (dt, $^3J_{H,H} = 6.1$ Hz, $^3J_{C,H} = 4.0$ Hz, 2H), 2.91 (q, $^3J_{H,H} = 6.1$ Hz, $^2J_{C,H} = 6.1$ Hz, 2H), 2.30 (d, $^2J_{C,H} = 5.5$ Hz, 3H), 0.83 (s, 9H), 0.01 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 198.7 (enriched)(d_{AB}, $^1J_{C,C} = 46$ Hz), 197.2 (enriched)(d_{AB}, $^1J_{C,C} = 46$ Hz), 58.4, 39.4 (dd, $^1J_{C,C} = 39$ Hz, $^2J_{C,C} = 15$ Hz), 25.8, 22.4 (d, $^1J_{C,C} = 35$ Hz), 18.2, −5.7. MS (CI, NH_3), *m/z*: 250 (100%, m + NH_4^+), 233 (100% m + H^+).

[2,3-$^{13}C_2$]-5-Hydroxypentane-2,3-dione (7*), in equilibrium with [2,3-$^{13}C_2$]-(2*RS*)-2-hydroxy-2-methyldihydrofuran-3(2*H*)-one ([2,3-$^{13}C_2$]-(2*RS*)-2-hydroxy-2-methyl-3-oxotetrahydrofuran) (8*)

7*: ^1H NMR (200 MHz, C_6D_6) δ: 3.69 (q, $^3J_{H,H} = 7.8$ Hz, 2H), 2.55–2.64 (m, 2H), 1.85 (d, $^2J_{C,H} = 4.2$ Hz, 3H). ^{13}C NMR (50.3 MHz, C_6D_6) δ: 196.2 (enriched)(d_{AB}, $^1J_{C,C} = 46$ Hz), 195.2 (enriched)(d_{AB}, $^1J_{C,C} = 46$ Hz), 55.2, 35.2 (dd, $^1J_{C,C} = 31$ Hz, $^2J_{C,C} = 22$ Hz), 21.9 (dd, $^1J_{C,C} = 33$ Hz, $^2J_{C,C} = 24$ Hz).

8*: ^1H NMR (200 MHz, C_6D_6) δ: 3.43–3.60 (m, 2H), 1.70–1.90 (m, 2H), 1.27 (dd, $^2J_{C,H} = 5.0$ Hz, $^3J_{C,H} = 2.8$ Hz, 3H). ^{13}C NMR (50.3 MHz, C_6D_6) δ: 206.0 (enriched)(d, $^1J_{C,C} = 51$ Hz), 98.3 (enriched)(d, $^1J_{C,C} = 51$ Hz), 60.7, 32.1 (dd, $^1J_{C,C} = 39$ Hz, $^2J_{C,C} = 13$ Hz), 15.8 (d, $^1J_{C,C} = 47$ Hz).

7* + 8*: IR (film), ν (cm^{-1}): 3939, 2990, 2900, 1725 (ν_{max}), 1678, 1075. MS (CI, NH_3), *m/z*: 118 (100%, m − OH + NH_3^+).

Synthesis of 3-amino-1-hydroxypropan-2-one (3-amino-1-hydroxyacetone) (5) hydrochloride from (±)-3-aminopropane-1,2-diol (23) (Scheme 5)

*(±)-*N*-tert-Butyloxycarbonyl-3-aminopropane-1,2-diol (**24**)*
Di-*tert*-butyl dicarbonate (18) (25 g, 114.6 mmol), dissolved

For personal use only.

in CH_2Cl_2 (25 mL), was added slowly to a stirred solution of (±)-3-aminopropane-1,2-diol (**23**) (8.7 g, 95.5 mmol) in CH_2Cl_2–MeOH (20 mL, 1:5) and triethylamine (1.3 mL, 9.6 mmol). The reaction, which was followed by TLC, was complete in 2 h. Evaporation of the solvents gave the product **24** (18 g, 99%) as a colourless solid that was used without further purification; mp 55–58°C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 5.12 (br s, 1H), 3.18–3.76 (m, 5H), 1.39 (s, 9H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 157.4, 80.0, 71.3, 63.6, 42.8, 27.9.

N-tert-*Butyloxycarbonyl-3-amino-1*-tert-*butyldimethylsilyloxy-2-propanol (25)*

N-tert-Butyloxycarbonyl-3-amino-1,2-propanediol (**24**) (18 g, 94.2 mmol) was dissolved in CH_2Cl_2 (150 mL) and *tert*-butyldimethylsilyl chloride (11 g, 103.7 mmol) and triethylamine (15.7 mL, 113 mmol) were added with stirring, followed by 4-dimethylaminopyridine (19) (0.46 g, 3.7 mmol), and stirring was continued overnight. Water (20 mL) was then added to quench the reaction. The layers were separated, the aqueous layer was washed with CH_2Cl_2 (3 × 10 mL), and the combined organic fraction was washed with water (3 × 10 mL) and brine and dried with anhydrous $MgSO_4$. Concentration of the solution gave a light yellow oil that was distilled at reduced pressure to give the product (**25**) (27.3 g, 95%) as a colourless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 5.26 (br s, 1H), 2.80–3.71 (m, 5H), 1.41 (s, 9H), 0.86 (s, 9H), 0.04 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 156.7, 79.4, 71.2, 64.8, 43.3, 28.3, 25.8, 18.2, −5.5. MS (EI), *m/z*: 306 (m + H^+), 250, 232, 206, 148.

N-tert-*Butyloxycarbonyl-3-amino-1*-tert-*butyldimethylsilyloxy-2-propanone (26)*

A suspension of *N*-chlorosuccinimide (16 g, 120.5 mmol) in CH_2Cl_2 (100 mL) was cooled to 0°C, dimethyl sulfide (12.2 mL, 166 mmol) (20) was added, and the mixture was cooled further to −20°C (CCl_4 – Dry Ice). *N-tert*-Butyloxycarbonyl-3-amino-1-*tert*-butyldimethylsilyloxy-2-propanol (**25**) (24.5 g, 80.3 mmol) in CH_2Cl_2 (20 mL) was added and the mixture was stirred at −20°C for 2 h. Triethylamine (16.8 mL, 120.5 mmol) was then added, the cooling mixture was removed, and stirring continued for 1 h. The reaction mixture was then diluted with ether (100 mL), washed with 1 M HCl, water, and brine, and dried with anhydrous $MgSO_4$. The solution was concentrated and the oily residue was chromatographed (5% diethyl ether – hexanes) on silica gel (200–400 mesh). The product **26** (21.9 g, 90%) was obtained as a colourless oil. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 4.19 (s, 4H), 1.39 (s, 9H), 0.86 (s, 9H), 0.04 (s, 6H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 206.7, 115.6, 79.6, 68.2, 48.0, 28.2, 25.7, 18.1, −5.7. MS (EI), *m/z*: 246 (m − *t*.Bu^+), 230, 190, 129. MS (CI, NH_3), *m/z*: 321 (100%, m + NH_4^+).

3-Amino-1-hydroxyacetone (3-amino-1-hydroxypropan-2-one) (5) hydrochloride

N-tert-Butyloxycarbonyl-3-amino-1-*tert*-butyldimethylsilyloxy-2-propanone (**26**) (11.2 g, 37 mmol) was dissolved in a mixture containing aqueous 20% HCl and THF (50 mL, 2:5) and stirred for 24 h. Removal of the solvent gave a brownish crystalline solid that was recrystallized from EtOH-*tert*-butyl methyl ether to afford the product **5** (2.3 g) as light yellow needles; m.p. 134–136°C (lit. (8) mp 136–137°C). ^{1}H NMR (200 MHz, D_2O) δ: 4.35 (s, 2H, CH_2O), 4.03 (s, 2H, $CH_2NH_3^+$), 3.54 (s, CH_2O of dimer, intensity ca. 20% of 4.35 ppm signal), 3.06 (s, CH_2N of dimer, intensity ca. 20% of 4.05 ppm signal). ^{13}C NMR (50.3 MHz, D_2O), major signals δ: 204.6, 65.7, 44.9; minor signals δ: 92.7, 66.2, 65.6, 65.3, 45.3, 44.5. MS (CI, NH_3), *m/z*: 107 (5%, m (of free base) + NH_4^+), 90 (100%, m + H^+).

Acknowledgments

Research grants from the Natural Sciences and Engineering Research Council of Canada and from the National Institute of General Medical Sciences, U.S. Public Health Service, are gratefully acknowledged. We thank Dr. James F. Britten for confirming the structure of the synthetic sample of **5** HCl by X-ray crystallography.

Transition metal azolates from metallocenes. Part 1: Dimetallic and trimetallic cyclopentadienyl nickel pyrazolates, synthesis and structural studies

Steven J. Rettig, Alan Storr, David A. Summers, Robert C. Thompson, and James Trotter

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.146.161.215 on 09/08/12
For personal use only.

Abstract: The reactions of nickelocene with pyrazoles in benzene solution have resulted in the isolation of either dimeric compounds, $[CpNi(\mu\text{-}pz')]_2$, (room temperature conditions) or trimetallic complexes, $[CpNi(\mu\text{-}pz'')_2]_2Ni$, (elevated temperature conditions). Both dimeric and trimetallic species were obtained as red crystalline materials and X-ray structural investigations are reported for representative samples of each type. Structural features are interpreted and compared with similar, previously reported, nickel pyrazolate structures. Crystals of $[CpNi(3,5\text{-diMepz})]_2$ ($C_{20}H_{24}N_4Ni_2$), **1**, are orthorhombic, a = 15.204(1), b = 17.967(2), c = 6.9786(9) Å, Z = 4, space group *Ama*2; those of $[CpNi(4\text{-}NO_2\text{-}3,5\text{-diMepz})]_2$ ($C_{20}H_{22}N_6Ni_2O_2$), **5**, are orthorhombic, a = 17.145(3), b = 17.738(1), c = 7.006(1) Å, Z = 4, space group $P2_12_12_1$; those of $[CpNi(3,5\text{-}F_6\text{diMepz})]_2$ ($C_{20}H_{12}F_{12}N_4Ni_2$), **6**, are orthorhombic, a = 18.7134(8), b = 15.619(2), c = 7.7263(9) Å, Z = 4, space group *Pnma*; those of $[CpNi(3,5\text{-diMepz})_2]_2Ni$ ($C_{30}H_{38}N_8Ni_3$), **7**, are triclinic, a = 10.078(2), b = 16.134(2), c = 9.992(1) Å, α = 91.586(10)°, β = 111.050(9)°, γ = 86.95(1)°, Z = 2, space group $P\bar{1}$; and those of $[CpNi(4\text{-Cl-}3,5\text{-diMepz})_2]_2Ni$ ($C_{30}H_{34}Cl_4N_8Ni_3$), **10**, are monoclinic, a = 10.2201(7), b = 16.174(1), c = 10.7207(9) Å, β = 108.193(5)°, Z = 2, space group $P2_1/a$. The structures were solved by direct (dimetallic species) or Patterson (trimetallic complexes) methods and were refined by full-matrix least-squares procedures to R = 0.035, 0.032, 0.058, 0.032, and 0.033 (R_w = 0.021, 0.026, 0.053, 0.028, and 0.032) for 1157, 1894, 1642, 4499, and 2113 reflections with $I \geq 3\sigma(F^2)$, respectively.

Key words: crystal structures, nickel, nickelocene, pyrazolates, cyclopentadienyl.

Résumé : Les réactions du nickelocène avec les pyrazoles en solution dans le benzène conduisent à la formation de composés de nature dimère, $[CpNi(\mu\text{-}pz')]_2$ (réactions à la température ambiante), ou à des complexes trimétalliques, $[CpNi(\mu\text{-}pz'')_2]_2Ni$ (réactions à température élevée). Les espèces tant dimériques que trimétalliques ont été obtenues sous la forme de matériaux cristallins rouges; on a effectué des déterminations de structure par diffraction des rayons X sur des échantillons représentatifs de chacun des types. On a interprété les caractéristiques structurales et on les compare avec celles rapportées antérieurement pour des structures semblables de pyrazolate de nickel. Les cristaux de $[CpNi(3,5\text{-diMepz})]_2$ ($C_{20}H_{24}N_4Ni_2$), **1**, sont orthorhombiques, groupe d'espace *Ama*2, avec a = 15,204(1), b = 17,967(2) et c = 6,9786(9) Å et Z = 4; ceux du $[CpNi(4\text{-}NO_2\text{-}3,5\text{-diMepz})]_2$ ($C_{20}H_{22}N_6Ni_2O_2$), **5**, sont orthorhombiques, groupe d'espace $P2_12_12_1$, avec a = 17,145(3), b = 17,738(1) et c = 7,006(1) Å, Z = 4; ceux de $[CpNi(3,5\text{-}F_6\text{diMepz})]_2$ ($C_{20}H_{12}F_{12}N_4Ni_2$), **6**, sont orthorhombiques, groupe d'espace *Pnma*, avec a = 18,7134(8), b = 15,619(2) et c = 7,7263(9) Å, Z = 4; ceux de $[CpNi(3,5\text{-diMepz})_2]_2Ni$ ($C_{30}H_{38}N_8Ni_3$), **7**, sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 10,078(2), b = 16,134(2) et c = 9,992(1) Å, α = 91,586(10)°, β =111,050(9)° et γ = 86,95(1)° et Z = 2 et ceux de $[CpNi(4\text{-Cl-}3,5\text{-diMepz})_2]_2Ni$ ($C_{30}H_{34}Cl_4N_8Ni_3$), **10**, sont monocliniques, groupe d'espace $P2_1/a$, avec a = 10,2201(7), b = 16,174(1) et c = 10,7207(9) Å, β = 108,193(5)° et Z = 2. Les structures ont été résolues par des méthodes directes (espèces bimétalliques) ou de Patterson (complexes trimétalliques) et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs respectives de R de 0,035, 0,032, 0,058, 0,032 et 0,033 (R_w de 0,021, 0,026, 0,053, 0,028 et 0,032) pour 1157, 1894, 1642, 4499 et 2113 réflexions avec $I \geq 3\sigma(F^2)$.

Mots clés : structures cristallines, nickel, nickelocène, pyrazolates, cyclopentadiényle.

Introduction

In 1977, Blake et al. reported reactions of bis(η-cyclopentadienyl)nickel, nickelocene, with several pyrazoles. In this report the authors describe the isolation of (*i*) polymeric (or, at least, highly oligomeric) nickel complexes incorporating pyrazole and 3-methylpyrazole and (*ii*) dimeric nickel complexes containing doubly bridging 3,5-dialkylpyrazolate ligands and end-capping η-C_5H_5 groups (1). Steric arguments were used in an attempt to explain the lack of polymerization in the reactions involving the 3,5-disubstituted pyrazole. No structures were confirmed by X-ray diffraction studies in this earlier work. Our long-standing interest in transition metal azolate polymers and oligomers (2–6) has prompted further investigations on this system, particularly on the products of reactions involving 3,5-disubstituted pyrazoles. Specifically, we report studies of the reactions of nickelocene with 4-X-3,5-dimethylpyrazole (X = H, Cl, Br, CH_3, and NO_2) and with 3,5-bis(perfluoromethyl)pyrazole that, depending on conditions, have led not only to the isolation of dimeric complexes (analogous to those reported by Blake et al.) but also trimetallic and polymeric materials. This report focuses on the synthesis of the dimeric and trimetallic complexes and their characterization, including the structure determination of five of these by single crystal X-ray diffraction studies. Studies on the polymeric materials are still in progress and will be reported in a future communication.[2]

Experimental

Nickelocene was prepared by the method of R.B. King (7). Pyrazoles were used as supplied (Aldrich) or prepared as described previously (3*a*, 6, 8). Solvents used were reagent grade and were dried and distilled under an atmosphere of dry dinitrogen before use.

Synthesis of $[CpNi(\mu\text{-}pz')]_2$ dimers

where μ-pz′ = 3,5-dimethylpyrazolate, 3,5-diMepz **1**
= 4-chloro-3,5-dimethylpyrazolate, 4-Cl-3,5-diMepz **2**
= 4-bromo-3,5-dimethylpyrazolate, 4-Br-3,5-diMepz **3**
= 3,4,5-trimethylpyrazolate, 3,4,5-triMepz **4**
= 4-nitro-3,5-dimethylpyrazolate, 4-NO_2-3,5-diMepz **5**
= 3,5-bis(trifluoromethyl)pyrazolate, 3,5-F_6diMepz **6**

Nickelocene (1.9 g, 0.010 mol) and the appropriate pyrazole were mixed in equimolar amounts and dissolved in ~150 mL of dry, oxygen-free benzene under a dinitrogen atmosphere. The resulting solution was stirred at room temperature over a period of ~12 h with the initial green colour changing to red within 30 min. The benzene solvent was then removed under vacuum and any remaining reactants were removed by sublimation. This resulted in the isolation of the products as red solid materials in yields of 45–55%. Recrystallization of these products was achieved by dissolving the solids in benzene, followed by slow evaporation of the solvent. Elemental analytical results and ^1H nmr data on recrystallized samples are given in Table 1.

[a]δ (C_6H_6) = 7.20 ppm.
NA = not applicable.

Synthesis of trimetallic $[CpNi(\mu\text{-pz}'')_2]_2Ni$ compounds

where μ-pz″ = 3,5-dimethylpyrazolate, 3,5-diMepz **7**
= 4-bromo-3,5-dimethylpyrazolate, 4-Br-3,5-diMepz **8**
= 3,4,5-trimethylpyrazolate, 3,4,5-triMepz **9**
= 4-chloro-3,5-dimethylpyrazolate, 4-Cl-3,5-diMepz **10**

Nickelocene (0.5 g, 2.7 mmol) and an approximately 10-fold excess of the appropriate pyrazole (~30 mmol) were mixed and dissolved in dry and oxygen-free benzene solvent. The initially green solution was heated at 60–70 °C under a dinitrogen atmosphere. After a very short period of time the solution had turned red and after about 3 h a red precipitate began to deposit in the reaction vessel. After ~18 h the solution was allowed to cool and the red crystalline product was isolated by filtration in yields of 30–35%. The product was subsequently washed with small amounts of the dry benzene to remove any residual ligand. Analytical results and ^{1}H nmr data are given in Table 2.

X-ray crystallographic analyses of $[CpNi(3,5\text{-diMepz})]_2$, **1**, $[CpNi(4\text{-}NO_2\text{-}3,5\text{-diMepz})]_2$, **5**, $[CpNi(3,5\text{-}F_6\text{diMepz})]_2$, **6**, $[CpNi(3,5\text{-diMepz})_2]_2Ni$, **7**, and $[CpNi(4\text{-Cl-}3,5\text{-diMepz})_2]_2Ni$, **10**

Crystallographic data appear in Table 3. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 35.0°–41.5° for **1**, 23.5°–30.9° for **5**, 88.6°–109.5° for **6**, 30.6°–34.0° for **7**, and 46.0°–66.0° for **10**. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, decayed linearly by 2.5% for **5**, by 2.4% for **6**, and showed only small random fluctuations for the three other complexes. The data were processed,[3] corrected for Lorentz and polarization effects, decay (**5** and **6**), and absorption (based on azimuthal scans).

The structures were solved by direct (dimeric complexes) or Patterson (trimetallic complexes) methods. The structure analysis of **1** was initiated in the centrosymmetric space group *Cmcm* but was disordered, prompting a change to the lower symmetry space group *Ama*2. Molecules **1** and **6** have crystallographic mirror symmetry. The asymmetric unit of **7** consists of two crystallographically independent half-molecules, each complete molecule being located at a center of symmetry. Molecule **10** is also located at a centre of symmetry. All nonhydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in calculated positions (methyl orientations based on difference map peak positions) with C—H = 0.98 Å and $B_H = 1.2\ B_{\text{bonded atom}}$. Corrections for secondary extinction were applied (Zachariasen type, isotropic, Gaussian) for four of the complexes, the final values of the extinction coefficients being $4.60(9) \times 10^{-7}$ for **1**, $2.39(10) \times 10^{-6}$ for **6**, $4.7(2) \times 10^{-7}$ for **7**, and $1.04(8) \times 10^{-6}$ for **10**. No secondary extinction correction was necessary for **5**. In some instances, the cyclopentadienyl ring thermal motion suggests possible disordering. In no case was it possible to refine disordered models. This high thermal motion is probably due to significant libration about the metal–centroid vector, common in sterically unhindered complexes of this type. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (9). The absolute configuration of **5** (for the particular crystal used for data collection) was determined by a parallel refinement of the mirror image, which resulted in significantly higher residuals, the R and R_w factor ratios being 1.18 and 1.24, respectively. Selected bond lengths and selected bond angles appear in Tables 4 and 5, respectively. Final atomic coordinates and equivalent isotropic thermal parameters, complete listings of bond lengths and angles, hydrogen atom

parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes are included as supplementary material.[4]

Physical measurements

The ^{1}H nmr spectra were recorded in C_6D_6 solution using a Bruker AC-200E nmr spectrometer. Magnetic susceptibilities were measured using a Quantum Design (MPMS) SQUID magnetometer. The sample holder and procedures involving the use of the equipment were described previously (2*g*). Magnetic susceptibilities were corrected for the background signal of the sample holder and for diamagnetic susceptibilities of all atoms (10). Susceptibility versus temperature behaviour (2–300 K) was measured at 1.0 T.

Results and discussion

On the basis of their earlier studies Blake et al. suggested that, due to steric restraints, reactions of nickelocene with 3,5-dialkyl-substituted pyrazoles would yield only dimeric complexes of formation $[CpNi(\mu\text{-pz}')]_2$. In the present work we have found that reactions of nickelocene with 3,5-dimethylpyrazoles under mild conditions yield not only dimeric complexes of formulation $[CpNi(\mu\text{-pz}')]_2$ (obtained in benzene solution at room temperature) but also trimetallic species of formulation $[CpNi(\mu\text{-pz}'')_2]_2Ni$ at slightly elevated temperatures. Indeed, reactions at even higher temperatures yield paramagnetic polymeric materials of composition $[Ni(\mu\text{-pz}'')_2]_x$.[2] Both the dimeric and trimetallic complexes can be isolated as crystalline materials and five have been subjected to X-ray crystallographic study in the present work.

Dimeric $[CpNi(\mu\text{-pz}')]_2$ complexes

The analytical data for these complexes are given in Table 1. The ^{1}H nmr results are consistent with a symmetrical structure with equivalent μ-pz′ and Cp groups, the latter exhibiting but one sharp singlet signal indicative of free rotation about the Ni–Cp centroid axis. A planar six-membered Ni-(N-N)$_2$-Ni central ring system with end-capping, freely rotating Cp groups could explain these ^{1}H nmr results, but molecular modeling studies show such an arrangement would lead to severe steric interaction between the methyl substituents on the μ-pz′ rings and the Cp groups. A boat conformation for the Ni-(N-N)$_2$-Ni ring reduces these steric interactions considerably and maintains planarity about the nitrogen atoms of the μ-pz′ rings, thereby retaining the resonance delocalization energy of the system. We have determined the X-ray crystal structures of three of the dimeric complexes and all of them display the predicted boat-like conformation for the Ni-(N-N)$_2$-Ni ring system.

A noteworthy feature in the ^{1}H nmr results is the effect of substituting CF_3 for CH_3 groups on the bridging pyrazolates. This substitution leads to a marked shift in the signals for both the 4-H proton on the pyrazolate rings and the Cp ring protons. The latter signal moves to a higher field position at δ 3.37 whereas the former signal shifts to a lower field position as δ 6.67. Similar shifts in the 4-H proton signal have been reported by Dias et al. for a number of HB(3,5-F_6diMepz)$_3$ containing complexes (11, 12).

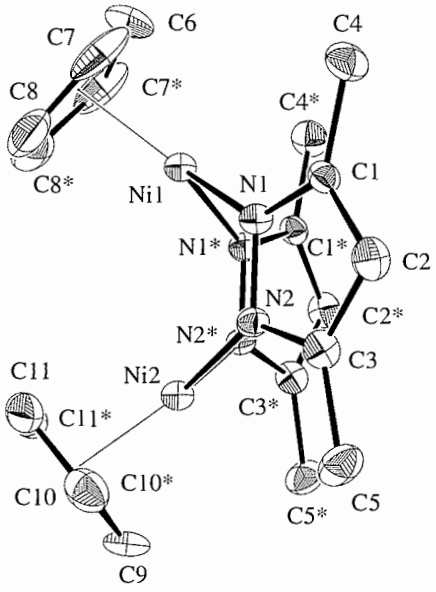

Fig. 1. The molecular structure of $[CpNi(3,5\text{-diMepz})]_2$, **1**, with atom numbering scheme and 33% probability thermal ellipsoids for all non-hydrogen atoms.

The molecular structures of **1**, **5**, and **6** are shown in Figs. 1–3. The internal bond angles and bond lengths in the cyclopentadienyl and pyrazolate ligands are normal for all three complexes. Examination of the nickel(II) coordination spheres of **1** and **5** reveal no significant differences in bond parameters (Tables 4 and 5) and hence no measurable structural effect, on substitution of the hydrogen in the 4-position of the pyrazolate ring by the nitro group. Larger structural effects might be expected with the substitution of the methyl substituents in the 3,5-positions by the significantly more electron-withdrawing and larger trifluoromethyl groups. Comparisons of the average Ni—N bond lengths in the two complexes (1.891(20) for **1** versus 1.926(8) for **6**) indicates a slight lengthening in the complex with the electron-withdrawing substituents. This is accompanied by a small increase in the Ni-N-C bond angles and decrease in the Ni-N-N bond angles in **6** compared to **1** (Tables 4 and 5), a consequence perhaps of increased steric repulsion between the CF_3 groups and the cyclopentadienyl ligands in **6**. This also appears to result in a slightly shorter nonbonded Ni···Ni distance in **6** than in **1** (see below).

It is interesting to compare the nonbonded Ni···Ni separations in these complexes with previously reported values for similar doubly pyrazolate-bridged dinickel systems (13, 14). These values are listed in Table 6. In the three structures reported here the Ni···Ni separations vary very little, with only a slight reduction in the distance observed on substituting CH_3

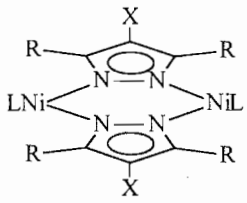
groups by the CF_3 groups on the bridging μ-pz′ moieties. All three of these dimeric compounds are formally 18-electron Ni complexes in contrast to the η^3-allyl and linear nitrosyl complexes listed in the table. These latter complexes are both 16-electron Ni systems and display widely different Ni···Ni separations. The η^3-allyl complex value at 3.00 Å arises from a

Fig. 4. The molecular structure of one of the two independent molecules of $[CpNi(3,5\text{-}diMepz)_2]_2Ni$, **7**, with atom numbering scheme and 33% probability thermal ellipsoids for all non-hydrogen atoms.

severely puckered Ni-$(N\text{-}N)_2$-Ni ring and suggests a possible metal–metal bonding interaction. In contrast, the very long Ni···Ni separation (3.673 Å) in the nitrosyl derivative results from the planar Ni-$(N\text{-}N)_2$-Ni six-membered ring. This arrangement is not disadvantaged sterically since the NO group, unlike the η^3-allyl group, is sterically nondemanding. In addition, it has been suggested that the planar arrangement in the nitrosyl complex may arise from favorable π-bonding between the pyrazolate π-system and the filled *d*-orbitals on the Ni atoms (14).

Trimetallic $[CpNi(\mu\text{-}pz'')_2]_2Ni$ complexes



The analytical data for these complexes are given in Table 2. The ^1H nmr data for the complexes in C_6D_6 solution are again consistent with the solid state structures described below. In solution, the two end-capping Cp rings are equivalent and freely rotating about the Ni–Cp axis, giving rise to one sharp singlet at δ 5.6. The 3-Me and 5-Me groups on the μ-pz″ ligands are nonequivalent in these structures and give rise to two closely separated singlets at ~ δ 2.1–2.2. The 4-X substituents, where applicable, give signals that are easily located in the ^1H nmr spectra on the basis of both anticipated intensities and predicted chemical shifts.

The molecular structures of **7** and **10** are shown in Figs. 4 and 5 and, as expected, display the boat conformation for the Ni-$(N\text{-}N)_2$-Ni ring systems. These are favoured over a planar conformation on two counts, to relieve steric interactions between the Cp rings and adjacent Me substituents on the μ-pz″ ligands, and also to relieve steric interaction between the Me substituents of the μ-pz″ rings that are adjacent to the

central Ni atom. As observed for the dimeric complexes, the internal bond lengths and angles of the ligands in **7** and **10** are normal. Moreover, bond parameters associated with the nickel coordination sphere are not significantly different in the two complexes, showing, again, that substitution of the hydrogen in the 4-position by a more electron-withdrawing substituent (Cl) has no measurable structural consequence. The Ni···Ni nonbonded distance is slightly greater in **10** than in **7** and this is accompanied by marginally greater Ni-N-N and smaller Ni-N-C bond angles in the former complex (Table 5). There seem no obvious intramolecular steric interactions that could cause these small differences, suggesting that intermolecular packing forces are responsible. In Table 7 we have listed the Ni···Ni nonbonded distances observed in **7** and **10** together with those for related trinickel complexes (13–15). In these systems the values of the Ni···Ni nonbonded distances span a much smaller range of values than in the dimetallic systems discussed above. Even the $[(ON)Ni(\mu\text{-}pz'')_2]_2Ni$ complex displays only a slightly longer Ni···Ni distance than the other complexes listed. The result is not unexpected since a totally planar structure, which might lead to a longer nonbonded nickel–nickel distance (as observed for the dimeric nitrosyl derivative (14)), is not favoured since this would lead to severe steric interactions around the central Ni atom (see above).

The observation of nmr spectra for all complexes is consistent with spin-paired d^8 Ni(II) configurations. To verify this we examined the magnetic susceptibilities at temperatures from 2 to 300 K of two representative dimeric compounds (R = CH_3, X = H and R = CH_3, X = NO_2) and two trimetallic compounds, (R = CH_3, X = H and R = CH_3, X = Cl). All four compounds gave evidence for weak paramagnetism. In the high-temperature region the magnetization could not be measured accurately as it was of the order of that obtained as a background signal for the sample container. The susceptibilities measured below 50 K showed an increase in magnitude with decreasing temperature as expected for paramagnetism. The magnitude of the measured susceptibilities was small, typically of the order of 3% or less than expected for $S = 1$ high-spin nickel(II). These results support the conclusion that the compounds involve diamagnetic spin-paired nickel(II) centers with small amounts of high-spin nickel(II) impurity. In the dimeric systems, Blake et al. (1) concluded that the ligand environment of Ni(II) in the complexes resulted in a low-spin d^8 configuration. Our results confirm this. Moreover, Blake et al. (1) observed weak paramagnetism in their complexes that they ascribe to either the presence of small amounts of paramagnetic pseudotetrahedral monomers or the presence of a thermally accessible excited $S = 1$ state in the dimers. Our results eliminate the second possibility since the observation

of an increase in susceptibility with decreasing temperature is not consistent with it. In the trimetallic systems the outer Ni(II) ions have the same environment as the Ni(II) ions in the dimeric systems, whereas the central Ni(II) ion is in a regular square planar environment. It is not surprising therefore that the trimetallic species also display diamagnetic behaviour.

Chemoselective intramolecular annulation of 3-alkylindolines into dihydro or tetrahydrofuro[2,3-*b*]indoles

Oscar R. Suárez-Castillo, Manuel García-Velgara, Martha S. Morales-Ríos, and Pedro Joseph-Nathan

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.146.161.215 on 09/08/12
For personal use only.

Abstract: 3-Alkyl-2-hydroxyindolines, conveniently prepared from 2-hydroxyindolenines and a Grignard reagent, cyclize in the aprotic solvent tetrahydrofuran to afford tetrahydro-3-cyano-2-oxofuro[2,3-*b*]indoles, while in the protic solvent methanol the chemoselectivity changed to give dihydro-2-amino-3-carbomethoxyfuro[2,3-*b*]indoles. The steric effect of the alkyl group on the reactivity of 3-alkyl-2-hydroxyindolines is discussed for both processes. The ring transformation of tetrahydro-3-cyano-2-oxofuro[2,3-*b*]indoles into dihydro-2-amino-3-carbomethoxyfuro[2,3-*b*]indoles via γ-lactone imines is also discussed.

Key words: furo[2,3-*b*]indoles, α-cyano-γ-lactones, chemoselectivity, ring transformation, β-enamino esters.

Résumé : Les 3-alkyl-2-hydroxyindolines convenablement préparées à partir des 2-hydroxyindolénines et un réactif de Grignard, se cyclisent dans un solvant aprotique, le tétrahydrofuranne, pour donner les tétrahydro-3-cyano-oxofuro[2,3-*b*]-indoles tandis que dans un solvant protique, le méthanol, la chimiosélectivité change pour donner les dihydro-2-amino-3-carbométhoxyfuro[2,3-*b*]indoles. On discute de l'effet stérique du groupe alkyle sur la réactivité des 3-alkyl-2-hydroxyindolines dans les deux réactions étudiées. On discute également de la transformation du cycle des tétrahydro-3-cyano-oxofuro[2,3-*b*]-indoles en dihydro-2-amino-3-carbométhoxyfuro[2,3-*b*]indoles via les imines de γ-lactones.

Mots clés : furo[2,3-*b*]indole, α-cyano-γ-lactones, chimiosélectivité, transformation de cycle, β-énamino-esters.

[Traduit par la rédaction]

Introduction

The reaction of nitriles with alcohols is a standard procedure for preparing imino esters (1). These compounds are important not only because they are versatile intermediates in organic transformations, but also because they or their ketene amino-hemiketal tautomers have been used in the synthesis of nitrogen heterocycles (2). In particular, the alkoxide-catalyzed rearrangement of α-cyano-γ-lactones has attracted significant attention because the β-enamino esters formed represent an access to heterocyclic systems of potential biological interest (3). We recently reported (4) that the conjugate addition of Grignard reagents to the 2-hydroxyindolenine **1** resulted in the formation of 3-alkyl-2-hydroxyindolines **2***a–c* (R = Me, Et, i-Pr) together with the corresponding *cis*-fused tetrahydro-3-cyano-2-oxofuro[2,3-*b*]indoles **3***b–d* (R = Et, i-Pr, *t*-Bu). We also found that, regardless of the existence of two potential paths for intramolecular cyclization, compounds **2***b* and **2***c* cyclized selectively and efficiently to the corresponding tetrahydro-3-cyano-2-oxofuro[2,3-*b*]indoles **3***b* and **3***c* by treatment with triethylamine in anhydrous THF at room temperature. Clearly, under these reaction conditions, intramolecular attack at the nitrile group is not competitive with the lactonization process. Thus, we set out to explore the reaction conditions under which the γ-lactone imines **4** or their tautomeric β-enamino esters **5** could be selectively formed.

Herein, we wish to describe the chemoselective formation of dihydro-2-amino-3-carbomethoxyfuro[2,3-*b*]indoles **5***a–c* from 3-alkyl-2-hydroxyindolines **2***a–c*, as well as the ring transformations of **3***a–d* into **5***a–d* via γ-lactone imines **4***a–d* (Scheme 1). The influence of steric effects as well as that of the base and the temperature has been tested. These reactions provide a useful mild method for the construction of the furo[2,3-*b*]indole ring system, a skeleton frame found in several biologically active natural and synthetic compounds (5).

Results and discussion

Before studying the chemoselective transformation of 3-alkyl-2-hydroxyindolines **2***a–c* into dihydro-2-amino-3-carbomethoxyfuroindoles **5***a–c* we felt the need to refocus our attention on the selective lactonization of **2***a*, since in our previous work we found that diastereomerically pure (2*R**, 3*S**, 8*S**)-3-alkyl-2-hydroxyindolines **2***b* and **2***c* cyclized smoothly to the tetrahydro-3-cyano-2-oxofuroindoles **3***b* and **3***c* in the aprotic solvent THF containing triethylamine (4*a*). In contrast, under these conditions, the less hindered (2*R**, 3*S**, 8*S**)-2-hydroxy-3-methylindoline **2***a* was recovered as an epimeric mixture (ca. 1:1) (4*b*), resulting from a ring–chain tautomerization at the C2 hemiaminalic stereogenic center (6). We now have found that a successful lactonization of **2***a* to afford **3***a* can be achieved by employing the more polar solvent DMSO,

and NaCN (25 mol%) as the catalyst (7). Under these conditions, the cyclization of the 2-hydroxy-3-methylindoline **2***a* is completed within 0.5 h at 100°C in 70% yield (Table 1, entry 1). Higher temperatures are ineffective at improving the yield, resulting instead in the formation of decomposition products. The *cis*-fused tetrahydro-3-cyano-2-oxofuroindole **3***a* was obtained in a diastereomerical ratio of 4:1 as determined by ^{1}H NMR spectroscopy (in DMSO-d_6) of the crude reaction product. This result can be rationalized in terms of a partial epimerization at the acidic C3 stereogenic center, as evidenced by fast deuterium exchange with D_2O. A steric hindrance between the methyl and the nitrile groups should favor an *anti* C3/C3a relationship. The *cis*-ring junction of **3***a* was evidenced by an NOE experiment, in which an enhancement of the H8a signal was observed when the angular methyl was irradiated.

Although nitrile carbon atoms are weak electrophilic sites when compared with ester carbonyl carbons, the intramolecular cyclization of 3-alkyl-2-hydroxyindolines **2** might proceed with chemoselectivity in protic solvents to give the desired dihydro-2-amino-3-carbomethoxyfuroindoles **5**, via formation of a γ-lactone imine **4** (8). Thus, the reaction course of **2***a* with the protic solvent methanol was monitored by TLC as a function of the disappearance of the starting material over time (Table 1). The reaction of **2***a* with $NaHCO_3$ (1:1 w/w) at 25°C in methanol furnished compound **5***a* after 2 h in 82% yield, accompanied by trace amounts of **3***a* (<3%, entry 2). When the reaction of **2***a* in methanol was performed under reflux for 0.5 h, a mixture of **3***a* and **5***a* was obtained in slightly lower yield (77%, entry 3), and with poorer chemoselectivity (4:5, from ^{1}H NMR). A more effective procedure involved reaction of **2***a* in refluxing methanol with MeONa (entry 4). In this case, the intramolecular reaction proceeded cleanly at the nitrile group and almost no products derived from attack at the carbonyl ester group were produced. In a similar fashion, the change of solvent from THF to methanol reversed the chemoselectivity of the cyclization in substrates **2***b* and **2***c*, leading to the almost exclusive formation of the dihydro-2-amino-3-carbomethoxyfuroindoles **5***b* and **5***c* in excellent yields (Table 1, entries 5–8). The above experimental results indicate that the nature of the solvent, the base, and reaction temperature exert a dramatic influence on the chemoselectivity regardless of the size of the alkyl group at C3. We noticed that increasing the steric requirement in the substrate by the bulkiness of the alkyl group (R) resulted in a decreased reactivity in the order i-Pr < Et < Me (Table 1, entries 4, 6, and 8). This trend, showing that a larger R group on C3a decreases the reactivity, can be attributed to steric interactions between the R group and the bulky carbonyl ester group in conformer **B**, which governs the for-

mation of dihydro-2-amino-3-carbomethoxyfuroindoles **5***a–c* (Scheme 2). In other words, as the size of R increases, the steric destabilization in conformer **B** also increases. In contraposition, the formation of tetrahydro-3-cyano-2-oxofuroindoles **3***a–c*, which gave a reversed trend regarding the size of the R group (**5***a*), could be rationalized considering that conformer **A** becomes more populated as the size of the R group increases.

We next turned our attention to the possibility of forming dihydro-2-amino-3-carbomethoxyfuroindoles **5***a–d* by ring transformation of tetrahydro-3-cyano-2-oxofuroindoles **3***a–d*. This ring transformation is favored by the presence of the neighboring electron-withdrawing nitrile group, which may strongly activate the carbonyl ring group for addition reactions of nucleophiles such as methoxide (9), thus affording in a first step the bielectrophilic ring-opening α-nitrile esters **2***a–d*. In agreement with our expectation, **3***a* reacted cleanly under reflux with sodium methoxide – methanol, furnishing the desired dihydro-2-amino-3-carbomethoxyfuroindole **5***a* in 90% yield (Table 2, entry 1). The homologous tetrahydro-3-cyano-2-oxofuroindoles **3***b–c* exhibited analogous behavior, affording the dihydro-2-amino-3-carbomethoxyfuroindoles **5***b–c* in excellent yields. However, as can be seen in Table 2, a dramatic decrease in reactivity was observed as the bulkiness of the alkyl group was increased. Thus, on changing the methyl group at C3 for an isopropyl group, the reaction time increased from 9 to 77 h (entries 1 and 3), as determined by TLC. Moreover, the reaction of **3***d* was extremely slow (entry 4), since only a 25% conversion was observed after 17 days under reflux, as determined from the ^{1}H NMR spectrum of the crude reaction mixture, wherein no side-reaction products were detected. The extremely low

reactivity of **3***d* as compared with **3***a* may be ascribed to the bulkier *tert*-butyl group, which introduces a severe steric hindrance unfavorable for ring opening in the first step (**3** → **2**). In fact, comparison of the reaction times given in

Tables 1 (entries 4, 6, 8) and 2 suggests that the ring-opening step (**3** → **2**) is slower than the intramolecular ring closure (**2** → **4**), irrespective of the bulkiness of the alkyl group at C3.

The sequence involving the intramolecular cyclization of **2** to either **3** or **5** and the ring transformation of **3** into **5**, depicted in Scheme 1, involves the γ-lactone imines **4** as common intermediates (8). From a mechanistic point of view it is clear that lactones **3** are first transformed, in a base-catalyzed ring-opening reaction, to γ-alkoxy esters, which after attack at the cyano carbon atom afford the rearranged γ-imino lactones **4**. In the next step, a tautomerization allows the conversion of the intermediate γ-imino lactones **4** into the β-enamino esters **5**. Under the reaction conditions, neither the 3-alkyl-2-hydroxyindolines **2***a–d* nor the γ-imino lactones **4***a–d* could be isolated or detected in the ^{1}H NMR spectra of the crude material. Thus, the rearranged products **5** were driven by the reversibility between **2** and **3** (see Scheme 1). Implicit in the observed chemoselectivity is that the β-enamino esters **5** are the thermodynamic products.

The versatile 3-alkyl-2-hydroxyindolines **2** can serve as an entry point into either *cis*-fused tetrahydro-3-cyano-2-oxofuroindoles **3** or dihydro-2-amino-3-carbomethoxyfuroindoles **5**. The fact that the 1,3-prototropic rearrangement appears to be an irreversible process under these conditions allowed us to prepare compounds **5***a–c* uncontaminated by either **2***a–c* or **3***a–c*. The IR, ^{1}H and ^{13}C NMR, as well as the EIMS and HRMS, are in agreement with the given structures (see Experimental). ^{1}H NMR assignments were made on the basis of chemical shift and multiplicity and were confirmed, where necessary, by homonuclear decoupling and ^{13}C–^{1}H correlation experiments. The ^{1}H NMR spectra of **5***a–d* show in the aromatic region two triplets, one of which couples to a broad signal (H7, $^3J_{6,7}$ = 7.5 ± 0.2 Hz) and is thus due to H6, leaving the other one for H5 ($^4J_{5,7}$ = 1.0 ± 0.1 Hz). Also, a doublet is identified as the H4 signal by its NOE with the alkyl group at C3a (R = Me, *t*-Bu). In addition, the signal of H8a appears as a singlet and the remaining broad signal is due to the NH_2 group (D_2O exchangeable). The *cis*-ring junction was supported by NOE experiments. In particular, irradiation of the *tert*-butyl singlet (δ = 1.04 ppm) in **5***d* resulted in a strong enhancement (37%) of the H8a signal (δ = 6.34 ppm), demonstrating that the alkyl group and H8a are located in the same half-space. In addition, the C4 hydrogen (δ = 7.79 ppm) in **5***d* also showed a significant NOE (21%) on saturation of the *tert*-butyl singlet.

Summary

Intramolecular carbon–oxygen bond formation was achieved using 3-hydroxyindolines **2**, from which either products **3** or **5** can be obtained with total chemoselectivity in good to excellent yields by the proper choice of base and solvent. Formation of dihydro-2-amino-3-carbomethoxyfuroindoles **5** is also possible via ring transformation of tetrahydro-3-cyano-2-oxofuroindoles **3**. The success of these processes relies on the irreversibility of the 1,3-prototropic rearrangement of the intermediate γ-lactone imines **4**. The steric hindrance of the alkyl group on C3 has an important effect on the reaction times. These new transformations provide access to the dihydrofuro[2,3-*b*]indole ring system.

Experimental

Starting 3-alkyl-2-hydroxyindolines **2***a–c* and tetrahydro-3-cyano-2-oxofuro[2,3-*b*]indoles **3***b–d* were prepared from the corresponding 2-hydroxyindolenine **1** according to a previously published procedure (4). Melting points were determined on a Fisher–Johns apparatus and are uncorrected. UV spectra were obtained on a Perkin Elmer Lambda 12 spectrophotometer. IR spectra were obtained using a Perkin Elmer 727B spectrophotometer; only diagnostic peaks are reported. ^{1}H and ^{13}C NMR spectra were recorded on a Varian XL 300GS spectrometer working at 300 and 75.4 MHz, respectively, and chemical shifts are reported in ppm downfield from TMS. Multiplicities are indicated by one or more of the following: s (singlet), d (doublet), t (triplet), q (quartet), h (heptet), m (multiplet), br (broad); the list of coupling constants (*J*) corresponds to the order of the multiplicity assignment. NOE measurements were made with difference spectra (10). Analytical TLC was performed on silica gel 60 F_{254} coated aluminum sheets and visualized with UV light (254 nm). Electron impact mass spectra (EIMS) were recorded on a Hewlett Packard 5989A spectrometer. High-resolution (HR) and fast atom bombardment mass spectra (FABMS) were measured on a Jeol JMS-SX 102A spectrometer. Microanalytical determinations were performed by the MHW Laboratories, Phoenix, Ariz.

cis-(±)-Methyl 2,3,3a,8a-tetrahydro-3-cyano-3a-methyl-2-oxo-8*H*-furo[2,3-*b*]indole-8-carboxylate (3*a*)

To a solution of **2***a* (150 mg, 0.49 mol) in DMSO (1.5 mL) and H_2O (0.2 mL) was added NaCN (6 mg, 25 mol%). The resulting mixture was stirred at 100°C for 0.5 h and then concentrated in vacuo to a syrup. The residue was dissolved in EtOAc (40 mL), washed with brine, dried over anhydrous Na_2SO_4, and concentrated in vacuo. The crude product was purified by crystallization from EtOAc–*n*-hexane to afford **3***a* (94 mg, 70%) as white crystals: mp 211–212°C; IR (KBr) ν_{max}: 2253 (CN), 1794 (C=O γ- lactone), 1741 (C=O carbamate) cm^{-1}; **3***a anti* (from 4:1 *anti/syn* mixture) ^{1}H NMR (DMSO-d_6) δ: 7.75 (1H, br s, H7), 7.59 (1H, d, *J* = 7.4 Hz, H4), 7.43 (1H, td, *J* = 7.4, 1.0 Hz, H6), 7.23 (1H, td, *J* = 7.4, 1.0 Hz, H5), 6.44 (1H, s, H8a), 5.21 (1H, s, H3, D_2O exchangeable), 3.87 (3H, s, OCH_3), 1.57 (3H, s, CH_3);^{13}C NMR (DMSO-d_6) δ: 166.8 (s, CO), 152.0 (s, NCO), 139.2 (s, C7a), 130.3 (s, C3b), 130.1 (d, C6), 125.0 (d, C4), 124.1 (d, C5), 114.9 (d, C7), 114.0 (s, CN), 96.1 (d, C8a), 53.5 (q, OCH_3), 50.3 (s, C3a), 42.8 (d, C3), 23.1 (q, CH_3); **3***a syn* (from 4:1 *anti/syn* mixture) ^{1}H NMR (DMSO-d_6) δ: 7.75 (1H, br s, H7), 7.52 (1H, d, *J* = 7.4 Hz, H4), 7.37 (1H, td, *J* = 7.4, 1.0 Hz, H6), 7.17 (1H, td, *J* = 7.4, 1.0 Hz, H5), 6.54 (1H, s, H8a), 5.07 (1H, s, H3, D_2O exchangeable), 3.87 (3H, s, OCH_3), 1.63 (3H, s, CH_3); ^{13}C NMR (DMSO-d_6) δ: 166.8 (s, CO), 152.0 (s, NCO), 139.5 (s, C7a), 130.3 (s, C3b), 129.0 (d, C6), 125.0 (d, C4), 124.3 (d, C5), 115.5 (d, C7), 114.0 (s, CN), 96.8 (d, C8a), 53.4 (q, OCH_3), 49.3 (s, C3a), 42.3 (d, C3), 23.8 (q, CH_3); EIMS *m/z* (relative intensity): 272 (M^+, 68), 169 (100). General procedure for the preparation of *cis*-(±)-dimethyl 3a,8a-dihydro-3a-alkyl-2-amino-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylates (5*a–c*)

Method A

To a solution of 0.03 mmol of **2***a–c* in 3 mL of anhydrous methanol was added two drops of 0.5% sodium methoxide. The reaction mixture was refluxed until TLC analysis (4% EtOAc in CH_2Cl_2) showed complete loss of starting material (see Table 1 entries 4, 6, and 8). The solvent was evaporated in vacuo. The residue was dissolved in EtOAc (30 mL), washed with brine, dried over anhydrous Na_2SO_4, and concentrated in vacuo. The solid residue was purified by crystallization from $CHCl_3$–*n*-hexane to afford **5***a–c* in excellent yields.

Method B

To a solution of 0.35 mmol of **3***a–c* in 5 mL of anhydrous methanol was added two drops of 0.5% sodium methoxide. The reaction mixture was refluxed until TLC analysis (4% EtOAc in CH_2Cl_2) showed complete loss of starting material (see Table 2, entries 1–3). The solvent was evaporated in vacuo. After general work-up, the residue was purified by crystallization from $CHCl_3$–*n*-hexane to afford **5***a–c* in good yields.

cis-*(±)-Dimethyl 3a,8a-dihydro-2-amino-3a-methyl-8*H-*furo[2,3-*b*]indole-3,8-dicarboxylate (5*a*)*

Compound **5***a* was obtained as a white solid in 95% yield using method A and in 90% yield using method B; mp 202–203°C; R_f 0.30 (CH_2Cl_2/EtOAc 96:4); UV (MeOH) λ (log ε): 201 (4.52), 231 (4.12), 269 (4.02); IR ($CHCl_3$) ν_{max}: 3550 and 3358 (NH_2), 1720 (C=O carbamate), 1680 (C=O ester) cm^{-1}; ^1H NMR (DMSO-d_6) δ: 7.62 (1H, br s, H7), 7.52 (1H, d, J = 7.5 Hz, H4), 7.18 (1H, td, J = 7.5, 1.4 Hz, H6), 7.10 (2H, br s, NH_2, D_2O exchangeable), 7.00 (1H, td, J = 7.5, 1.0 Hz, H5), 6.22 (1H, s, H8a), 3.80 (3H, s, OCH_3 carbamate), 3.60 (3H, s, OCH_3 ester), 1.58 (3H, s, CH_3); ^{13}C NMR (DMSO-d_6) δ: 166.2, 152.9, 139.2, 138.0, 127.8, 124.1, 123.8, 114.2, 99.7, 79.5, 53.3, 53.0, 49.9, 24.2; EIMS *m/z* (relative intensity): 304 (M^+, 31), 255 (100); HRMS (FAB) calcd. for $C_{15}H_{16}N_2O_5$ (M^+): 304.1059; found: 304.1069. Anal. calcd. for $C_{15}H_{16}N_2O_5$: C 59.21, H 5.30, N 9.21; found: C 58.98, H 5.36, N 9.11.

cis-*(±)-Dimethyl 3a,8a-dihydro-2-amino-3a-ethyl-8*H-*furo[2,3-*b*]indole-3,8-dicarboxylate (5*b*)*

Compound **5***b* was obtained as a white solid in 93% yield using method A and in 90% yield using method B; mp 121–123°C; R_f 0.34 (CH_2Cl_2/EtOAc 96:4); UV (MeOH) λ (log ε): 200 (4.72), 234 (4.38), 270 (4.28); IR ($CHCl_3$) ν_{max}: 3500 and 3380 (NH_2), 1720 (C=O carbamate), 1680 (C=O ester) cm^{-1}; ^1H NMR (DMSO-d_6) δ: 7.65 (1H, br s, H7), 7.51 (1H, d, J = 7.4 Hz, H4), 7.20 (1H, t, J = 7.4 Hz, H6), 7.14 (2H, br s, NH_2, D_2O exchangeable), 7.01 (1H, t, J = 7.4 Hz, H5), 6.27 (1H, s, H8a), 3.82 (3H, s, OCH_3 carbamate), 3.61 (3H, s, OCH_3 ester), 2.13 and 1.87 (2H, ABX_3, 2m, CH_2), 0.71 (3H, ABX_3, t, CH_3); ^{13}C NMR (DMSO-d_6) δ: 166.5, 165.8, 152.5, 139.5, 136.9, 127.5, 123.9, 123.5, 113.9, 96.9, 76.9, 57.4, 53.0, 49.5, 27.8, 8.8; EIMS *m/z*: 318 (M^+, 35), 269 (100); HRMS (FAB) calcd. for $C_{16}H_{18}N_2O_5$ (M^+): 318.1216; found: 318.1231.

cis-*(±)-Dimethyl 3a,8a-dihydro-2-amino-3a-iso-propyl-8*H-*furo[2,3-*b*]indole-3,8-dicarboxylate (5*c*)*

Compound **5***c* was obtained as a white solid in 95% yield using both methods A and B; mp 95–97°C; R_f 0.34 (CH_2Cl_2/EtOAc 96:4); UV (MeOH) λ (log ε): 200 (4.66), 234 (4.29), 270 (4.19); IR ($CHCl_3$) ν_{max}: 3510 and 3380 (NH_2), 1730 (C=O carbamate), 1680 (C=O ester) cm^{-1}; ^1H NMR (DMSO-d_6) δ: 7.63 (1H, br s, H7), 7.51 (1H, d, J = 7.5 Hz, H4), 7.20 (1H, td, J = 7.5, 1.2 Hz, H6), 7.15 (2H, br s, NH_2, D_2O exchangeable), 7.01 (1H, td, J = 7.5, 0.9 Hz, H5), 6.27 (1H, s, H8a), 3.83 (3H, s, OCH_3 carbamate), 3.60 (3H, s, OCH_3 ester), 2.80 (1H, h, CH i-Pr), 0.91 and 0.50 (6H, 2d, J = 7.0 Hz, $2CH_3$ i-Pr); ^{13}C NMR (DMSO-d_6) δ: 166.2, 165.7, 152.4, 139.5, 136.7, 127.6, 123.6, 123.5, 113.8, 93.8, 77.4, 61.4, 53.1, 49.6, 30.1, 17.5, 16.4; EIMS *m/z* (relative intensity): 332 (M^+, 33), 283 (100); HRMS (FAB) calcd. for $C_{17}H_{20}N_2O_5$ (M^+): 332.1372; found: 332.1381. Anal. calcd. for $C_{17}H_{20}N_2O_5$: C 61.44, H 6.07, N 8.43; found: C 61.19, H 6.59, N 8.49.

***cis*-(±)-Dimethyl 3a,8a-dihydro-2-amino-3a-*tert*-butyl-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylate (5*d*)**

To a solution of **3***d* (100 mg, 0.32 mmol) in 5 mL of anhydrous methanol was added two drops of 0.5% sodium methoxide in methanol. The reaction mixture was refluxed for 17 days and then concentrated in vacuo to a syrup. ^1H NMR analysis of the crude residue showed a 3:1 mixture of **3***d* and **5***d*. After general work-up, compounds **3***d* and **5***d* were separated on a silica gel column, 230–400 mesh, eluted with ether/*n*-hexane 3:2 to give 72 mg (71%) of unreacted **3***d* and 28 mg (25%) of **5***d* as a white solid; mp 194–196°C; R_f 0.42 (CH_2Cl_2/EtOAc 96:4); UV (MeOH) λ (log ε): 202 (4.74), 238 (4.42), 270 (4.28); IR ($CHCl_3$) ν_{max}: 3510 and 3380 (NH_2), 1730 (C=O carbamate), 1680 (C=O ester) cm^{-1}; ^1H NMR (DMSO-d_6) δ: 7.77 (1H, d, J = 7.7 Hz, H4), 7.67 (1H, br d, J = 7.7 Hz, H7), 7.23 (2H, br s, NH_2, D_2O exchangeable), 7.20 (1H, td, J = 7.7, 1.2 Hz, H6), 7.00 (1H, td, J = 7.7, 1.1 Hz, H5), 6.27 (1H, s, H8a), 3.83 (3H, s, OCH_3 carbamate), 3.55 (3H, s, OCH_3 ester), 0.96 (9H, s, $3CH_3$ *t*-Bu); ^{13}C NMR (DMSO-d_6) δ: 167.4, 166.1, 152.4, 140.2, 133.6, 127.4, 126.9, 122.6, 113.8, 96.1, 77.2, 63.9, 53.2, 49.4, 36.8, 26.4; EIMS *m/z* (relative intensity): 346 (M^+, 22), 273 (100); HRMS (FAB) calcd. for $C_{18}H_{22}N_2O_5$ (M^+): 346.1529; found: 346.1544. Anal. calcd. for $C_{18}H_{22}N_2O_5$: C 62.42, H 6.40, N 8.09; found: C 62.31, H 6.27, N 8.23.

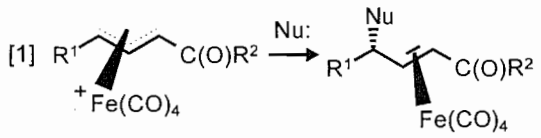
Formation of quaternary centres via iron allyl cations. Rapid entry into spirocyclic ring systems

M. Anne Charlton and James R. Green

Abstract: Ester-substituted allyltetracarbonyliron cations react with cycloalkylidene-type silyl enol ethers, silyl ketene acetals, and β-keto-esters to give 1,6-dicarbonyl compounds containing a newly formed quaternary centre. Selected condensation products are converted by enolate chemistry into spirocyclic [4.4], [4.5], and [4.6] systems. Acyloin and other reductive cyclization reactions are employed to convert the condensation products into spirocyclic [4.5], [5.5], and [5.6] systems.

Key words: allyliron complexes, umpolung synthesis, 1,6-dicarbonyls, spirocycle synthesis.



Résumé : Les cations allyltétracarbonylfer substitués par des fonctions esters réagissent avec des éthers énoliques silylés, des acétals de silylcétènes et des β-céto-esters de type cycloalkylidène; ils conduisent à des composés 1,6-dicarbonylés contenant un centre quaternaire nouvellement formé. Des produits de condensation choisis peuvent être transformés, par le biais de la chimie des énolates, en systèmes spirocycliques [4.4], [4.5] et [4.6]. On a fait appel à des réactions aux acyloïnes et à d'autres types de réactions de cyclisation réductrice pour transformer les produits de condensation en systèmes spirocycliques [4.5], [5.5] et [5.6].

Mots clés : complexes d'allylfer, réactions par inversion de polarité, 1,6-dicarbonyles, synthèse de spirocycles.

[Traduit par la rédaction].

Introduction

Homologous (1,5)-Michael reactions, or γ-carbonyl cation equivalents, are forms of umpolung synthesis that have received increased recent attention (1–6). We are actively engaged in the development of transition metal mediated versions of these homologous (1,5)-Michael reactions (2). In particular, we (3) and others (4) have found that ester- and ketone-substituted tetracarbonyliron allyl cations are effective as these umpolung synthons, as their electrophilic reactions occur exclusively at the allyl terminus remote from the carbonyl function (eq. [1]). Iron allyl cations substituted by phenyl sulphones (4) and lactams (5) behave in a closely analogous fashion. In addition, a reliable retention of configuration has been demonstrated for the formation and attack of these cations in enantiomerically enriched acyclic substrates (4). For cyclic substrates, electrophilic attack occurs on the face opposite the iron tetracarbonyl unit (5), regardless of the relative orientation of the leaving group. A wide variety of nucleophilic species react successfully with these cations, including silyl enol ethers, silyl ketene acetals, *N*-stannyl enamines, allylsilanes and stannanes, electron-rich arenes, amines, β-dicarbonyl compounds, and zinc cyanocuprates. γ-Carbonyl-*N*-acyliminium cation complexes have been shown to react with an even wider range of nucleophiles (6).

We are interested in applying these carbonyl-substituted iron allyl cations to the synthesis of spirocyclic compounds (7).[2] This requires the reaction of the γ-carbonyl cation complexes with nucleophiles of type **1**; few examples of the formation of quaternary carbon centres (and none for cycloalkylidene-type nucleophiles) have been demonstrated with iron allyl cations (4). If these nucleophiles can be readily introduced, then the condensation products (**2**) would be well set up for a general synthesis of spirocyclic [4.*n*] or [5.*n*] systems. As the centre α to the carbonyl of the original nucleophile is tetrasubstituted, enolization at that site is not possible, so that enolate chemistry of the 1,6-dicarbonyls is expected to give [4.*n*] systems in a predictable fashion by Dieckmann or aldol reactions. Alternatively, the disposition of ester functions suggests that acyloin or other reductive coupling reactions will give access to [5.*n*] spirocycles. This report describes our efforts to this end.

Received November 13, 1996.

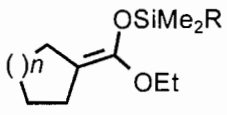
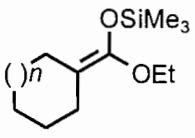
Results and discussion



Formation of quaternary centres

Nucleophiles (**3–9**), containing five-, six-, and seven-membered cycloalkylidene groups, were chosen for reaction with the iron allyl cations, based on ready availability of the precursor carbonyl compounds. Silyl ketene acetals were prepared by standard deprotonation of the appropriate ester with lithium diisopropyl amide (LDA) and subsequent silylation with *tert*-butyldimethylsilyl chloride (TBDMSCl) (**3–6**) (8) or Me_3SiCl (**4a**, **6a**). Silyl ketene acetal **6** was more hydrolytically unstable than **3–5**, as the crude reaction products revealed a significant amount of ester stemming from hydrolysis of **6** during work-up. As a consequence, **6** was used in this impure form. β-Keto-ester **8** was expected to have a sufficient concentration of enol in solution such that activation as a silyl enol ether would be unnecessary (3). Finally, the trimethylsilyl enol ethers were prepared from the corresponding ketone or aldehyde either by Me_3SiI generated in the presence of Et_3N (**7**) (9) or by straightforward deprotonation (LDA) and silylation (**9**).



The γ-acetoxy enoates chosen as precursors to the iron allyl complexes in the condensation reactions were **10** (10) and **11**. These substrates readily form η^2-complexes **12** and **13** by stirring with $Fe_2(CO)_9$ in Et_2O. Subsequent ionization of the acetoxy function with Lewis acids, most successfully BF_3-etherate, is known to give solutions containing tetracarbonyliron allyl cations **14** and **15** (2). The cations were generated in the presence of nucleophiles **3–9**, and the CH_2Cl_2 solutions gradually warmed from −78°C to room temperature. The final isolated products (**16–26**) were obtained by treating the crude reaction product mixtures with Me_3NO, in order to liberate the alkenoate product from the $Fe(CO)_4$ unit.

Analysis of the product mixtures demonstrated that **3–8** and **14** and **15** did undergo addition reactions (Table 1). In all cases, the sole product of reaction was that of condensation of **14** or **15** at the position γ with respect to the ester function, to give 1,6-dicarbonyl compounds **16–26**. The regiochemistry of attack was clear from the spectroscopic characteristics of the addition products. Compound **16**, for example, gave an ^1H NMR spectrum displaying resonances for the vinyl hydrogens at δ 5.76 (d, J = 15.5 Hz) and δ 6.84 (dt), and a ^{13}C NMR spectrum containing vinyl carbon resonances at δ 124.0 and δ 144.1. These are indicative of an (*E*)-α,β-unsaturated ester with substitution at the γ-position. Recovered γ-acetoxyenoate was also observed in several of the cases, at the expense of condensation product. This stems from BF_3 induced decomplexation of η^2-complexes **12** and **13** and (or) desilyation of the silyl enol ether or silyl ketene acetal occurring at a rate competitive with the condensation.

Table 1. Nucleophilic attack on iron allyl cations.

Substrate	Nucleophile	Product	Yield[a]
10	**3**	**16**	72

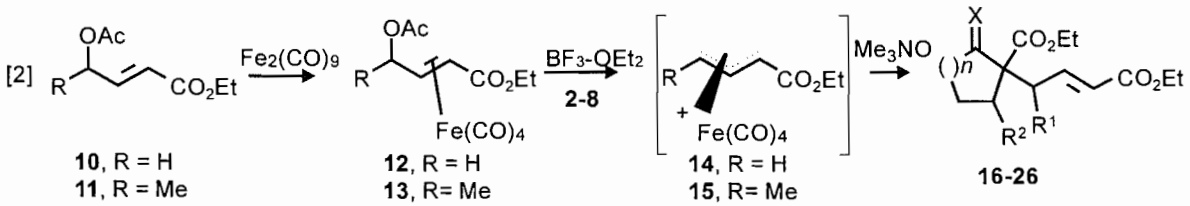
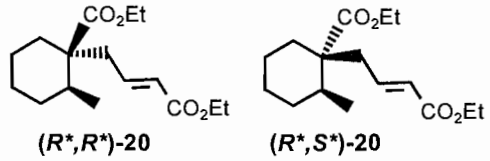
10	**5**	**18**	66
11	**5**	**19**	62
10	**4**	**20**	46[b] (39)
10	**4a**	**20**	52[c] (23)
10	**6**	**21**	37 (44)
10	**6a**	**21**	42 (40)
10	**7**	**22**	74
11	**7**	**23**	68
10	**8**	**24**	43 (41)
11	**8**	**25**	41[d] (35)
10	**9**	**26**	59 (35)

[a]Numbers in parenthese refer to yield of recovered starting **10** or **11** based on integration of the ^1H NMR spectra of the crude reaction products.
[b]Diastereomer ratio, 80:20.
[c]Diastereomer ratio, 70:30.
[d]Diastereomer ratio, 67:33.

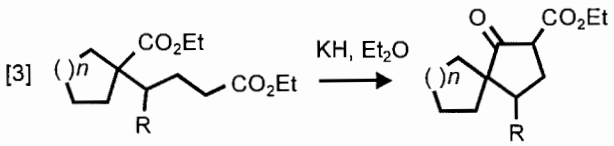


Products **20** and **25** were isolated as diastereomeric mixtures of products. Whereas there was very modest selectivity in the formation of **25** (67:33), compound **20** was obtained as a 80:20 mixture of diastereomers. The major diastereomer was assigned as (*R*,R**)-**20** (*syn*-**20**), the product resulting from attack on the face of **3** opposite the methyl group. The assignment was based on the precedented alkylation of the enolate of methyl 2-methylcyclohexanecarboxylate (11), and the reported attack of an allyliron cation on a C-6 silylated cyclohexanone enolate (4), both of which occur on the enolate face opposite to the additional substituent.



Yields were in general fair to good for the silyl ketene acetals, with the unactivated β-keto-esters giving condensation products in more modest yields. The yields of products **20** (46%) and **21** (37%) were anomalously low, and the corresponding reactions using trimethysilyl ketene acetals **4a** and **6a**, respectively, were investigated. In the event, silyl ketene acetal **4a** reacted with **12** to give **21** in slightly improved yields, at the expense of diastereoselection (52%, 70:30 *R*,R**:*R*,S**). The use of **6a** with **12** similarly gave a slight improvement in the yield of **21** (42%).

Spirocycle formation



With the creation of the quaternary centres accomplished,

© 1997 NRC Canada

attention was turned to the manipulation of the 1,6-dicarbonyls into spirocyclic compounds. Dieckmann reactions were initially attempted on the condensation products (**16–26**) themselves. As the deprotonation of (*E*)-alkenoates and alkenamides has been shown to give (*Z*)-dienolate intermediates (12), it was expected that the dienolates derived from **16–26** would have a geometry suitable for cyclization. This proved not to be the case, as all attempts at Dieckmann cyclizations on **16** under a variety of conditions led only to complex mixtures of products. To circumvent this problem, the alkene functions of **16–18** and **21** were reduced by catalytic hydrogenation to give dicarbonyl compounds **16a–18a** and **21a**. Under such conditions, the ketone function of keto-ester **26** was reduced competitively with the alkene unit to give alcohol **26b**; this was simply reoxidized to keto-ester **26a** with PDC. Treatment of these dicarbonyl compounds with KH in Et_2O induced ready cyclization, to give [4.*n*] spirocycles **27–30** in fair to good yields (eq. [3], Table 2) (13).[3] Since **16a–18a** and **21a** contain five-, six-, and seven-membered ring systems, spirocyclic [4.4], [4.5], and [4.6] ring systems could be obtained in this manner. Under identical conditions, keto-ester **25a** underwent both intramolecular aldol condensation chemistry and saponification to give predominantly the acid **31**; higher yields on **31** were realized when the crude reaction product was subjected to complete saponification.

n	R	
2	H	**27**
2	Me	**28**
1	Me	**29**
3	H	**30**

The acyloin condensation chemistry of selected 1,6-dicarbonyl compounds was also explored. Like the Dieckmann cyclizations, reduction of the alkene unit of **16** (to **16a**) was necessary before tractable product mixtures were obtained. After experimentation with a variety of conditions, success was achieved on **16a** using a sodium–potassium alloy in conjunction with Me_3SiCl (13), giving bis(trimethylsilylated) enediol **32** in good yield. The analogous condensations on **18a**, **20a**, and **21a** similarly gave **33–35**, containing spirocyclic [4.5], [5.5], and [5.6] ring systems (eq. [4], Table 3). As desilylation of **32** gave regiochemical mixtures of α-hydroxyketones (15), characterization was performed on the silylated enediols themselves. These silylated enediols possessed moderate stability on silica gel, and significant material losses occurred if they were subjected to repeated chromatography. In the cyclization of **20a** to give **34**, the 70:30 ratio of diastereomers was preserved; this, in conjunction with the expected behaviour of the quaternary centre, leads us to assign (*R**,*R**)-**34** (*anti*-**34**) as the major diastereomer.

Due to an interest in the application of this methodology to synthesis of sesquiterpenes such as acorenone, we wished to investigate an alternative reductive coupling reaction that would afford a spirobicyclic-2-alkanone, and consequently we explored the feasibility of the preparation of **36** from aldehyde ester **22**. Although the coupling of aldehydes and esters by a variant of the McMurry reaction has been reported (16), we were unable to effect such a coupling on **22a**. As an alternative route, the aldehyde **22** was reduced to ester-alcohol **22b**, and subsequently converted to neopentyl iodide **37** (17). Treatment of this iodide with *t*-BuLi (18) afforded bicyclic ketone **36**, albeit in low yield (20%). Better results were obtained by using sodium metal in the presence of Me_3SiCl (19); this procedure gave **36** in 45% yield.

In summary, it has been demonstrated that the iron allyl cations derived from γ-acetoxyalkenonates react with

cycloalkylidene-type silyl ketene acetal, silyl enol ethers, and β-keto-ester enols to form 1,6-dicarbonyl compounds containing quaternary centres in fair to good yields. The condensation products may be manipulated rapidly to give a variety of [4.*n*] and [5.*n*] spirocyclic ring systems (*n* = 4,5,6). The application of this methodology to synthesis will be reported in due course.

Experimental section

General data

Melting points are uncorrected. Boiling points refer to bulb-to-bulb distillation. ^{1}H NMR and ^{13}C NMR spectra were recorded in $CDCl_3$ at 300 and 75 MHz, respectively; coupling constants (*J*) are expressed in hertz (Hz). High-resolution mass spectra were recorded at the Department of Chemistry and Biochemistry Mass Spectrometry Facility, University of Windsor. Elemental analyses were performed by M-H-W Laboratories, Phoenix, Ariz.

BuLi was obtained from Aldrich Chemical Co., Ltd. The titre was determined using 2,5-dimethoxybenzyl alcohol as standard (20). Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl immediately prior to use. Dichloromethane was distilled from CaH_2 immediately prior to use. Column chromatography on silica gel (Merck, 0.04–0.063 mm) was performed according to the protocol of Still et al. (21).

General procedure for the preparation of silyl ketene acetals

*1-(*tert*-Butyldimethylsiloxy)-1-ethoxymethylenecyclohexane (3)*

To diisopropylamine (2.95 mL, 21.0 mmol) was added dry THF (15 mL) and the mixture was cooled to −78°C in a Dry Ice – acetone bath. *n*-BuLi (11 mL, 1.91 M, 21.0 mmol) was added and the mixture was allowed to stir for 5 min. The cooling bath was removed and the mixture was allowed to stir for an additional 5 min. The reaction was again immersed in a Dry Ice – acetone bath and ethyl cyclohexanecarboxylate (2.967 g, 19.0 mmol) was added. The mixture was allowed to warm to 0°C at which time HMPA (1.5 mL) was added and the mixture was allowed to stir for 15 min. A solution of *tert*-butyldimethylsilyl chloride (TBDMSCl, 3.165 g, 21.0 mmol) in THF (10 mL) was added and the mixture was allowed to warm to room temperature, at which time it was quenched with cold water and subjected to a conventional work-up to afford the crude product. The product was purified by bulb-to-bulb distillation to yield **3** (4.217 g, 84%): bp 80°C (0.50 Torr; 1 Torr = 133.3 Pa); IR (neat, KBr): 2929, 2856, 1697 cm^{-1}; ^{1}H NMR δ: 3.74 (q, 2H, *J* = 7.1), 2.10–1.65 (m, 10H), 1.19 (t, 3H, *J* = 7.1), 0.92 (s, 9H), 0.11 (s, 6H); ^{13}C NMR δ: 146.2, 100.6, 65.2, 27.8, 27.3, 27.2, 27.1, 26.9, 25.8, 18.2, 14.8, −4.6; MS *m/e*: 270 (M^+); HRMS calcd. for $C_{15}H_{30}O_2Si$ *m/e* (M^+): 270.2015; found: 270.2018.

*(*tert*-Butyldimethylsiloxy)ethoxymethylenecyclopentane (5)*

Subjecting ethyl cyclopentanecarboxylate (2.953 g, 23.1 mmol) to the general procedure, followed by bulb-to-bulb dis-

tillation, produced **5** (2.063 g, 79%): bp 95°C (3.0 Torr); IR (neat, KBr): 2955, 2859, 1711 cm^{-1}; ^1H NMR δ: 3.78 (q, 2H, J = 7.1), 1.21 (t, 3H, J = 7.1) 2.18–1.54 (m, 8H), 0.92 (s, 9H), 0.12 (s, 6H); ^{13}C NMR δ: 146.3, 102.3, 64.5, 28.4, 27.8, 27.1, 26.9, 25.7, 18.0, 15.1, −4.5; MS *m/e*: 256 (M^+); HRMS calcd. for $C_{14}H_{28}O_2Si$ *m/e* (M^+): 256.1859; found: 256.1864.

*2-Methyl-1-[(trimethylsiloxy)ethoxymethylene]cyclohexane (**4a**)*

To a −78°C solution of LDA (3.0 mmol) in THF (10 mL) was added a solution of ethyl 2-methylcyclohexane-1-carboxylate (0.4620 g, 2.71 mmol) in THF (5 mL). After stirring at −78°C for 1 h, Me_3SiCl (0.5 mL) was added, and the solution was allowed to warm to room temperature. The volatiles were removed under reduced pressure, and the resulting residue was distilled under reduced pressure to afford **3a** (0.5972 g, approx. 85%) which contained a small amount (approx. 6%) of the starting ester; bp 55–57°C (0.30 Torr); IR (neat, KBr): 2961, 2925, 2851, 1688 cm^{-1}; ^1H NMR δ: 3.70–3.85 (m, 2H), 2.74 (m, 1H), 2.40 (m, 1H), 1.85 (m, 1H), 1.72 (m, 1H), 1.35–1.60 (m, 5H), 1.21 (t, 3H, J = 7.1), 1.03 (d, 3H, J = 7.2), 0.21 (s, 9H); peaks from the minor isomer could be observed at 1.25 (t, 3H, J = 7.1), 1.05 (d, 3H, J = 7.1), 0.20 (s, 9H); ^{13}C NMR δ: 145.4, 104.1, 64.8, 33.0, 28.5, 28.2, 27.9, 22.7, 22.3, 21.0, 17.9, 14.7, 0.0; peaks from the minor isomer could be observed at 103.9, 64.2, 33.2, 28.3, 27.5, 22.7, 20.9, −0.1.

*1-(Trimethylsiloxy)ethoxymethylenecycloheptane (**6a**)*

To a −78°C solution of LDA (3.0 mmol) in THF (7 mL) was added a solution of ethyl 2-methylcyclohexane-1-carboxylate (0.2684 g, 1.58 mmol) in THF (3 mL). After stirring at −78°C for 1 h, Me_3SiCl (0.5 mL) was added, and the solution was allowed to warm to room temperature. The volatiles were removed under reduced pressure, and the resulting residue was distilled under reduced pressure to afford **6a** (0.3451 g, approx. 86%), which contained a small amount (ca. 5%) of the starting ester: bp 65–66°C (0.48 Torr); IR (neat, KBr): 2923, 2852, 1684 cm^{-1}; ^1H NMR δ: 3.77 (q, 2H, J = 7.1), 2.20 (m, 2H), 2.14 (m, 2H) 1.40–1.65 (m, 6H), 1.23 (t, 3H, J = 7.1), 0.22 (s, 9H); ^{13}C NMR δ: 148.1, 101.6, 64.5, 29.9, 29.7, 29.2, 28.9, 28.7, 28.0, 14.9, 0.1.

*(Trimethylsiloxy)methylenecyclohexane (**7**)*

Cyclohexanecarboxaldehyde (0.660 g, 6.00 mmol) and triethylamine (0.84 mL, 6.0 mmol) were added to a three-neck flask equipped with a reflux condenser and a pressure-equalizing addition funnel. Me_3SiCl (0.76 mL, 6.0 mmol) was added dropwise and, after completion, the reaction was heated to 35°C and allowed to stir for 10 min. NaI (0.90 g, 6.0 mmol) in CH_3CN (25 mL) was added through the addition funnel. The reaction was then heated to 70°C for 2 h and poured into cold water. A conventional work-up was performed, followed by bulb-to-bulb distillation to afford **7** (0.651 g, 60%), bp 39–41°C (0.4 Torr); IR (neat, KBr): 2957, 2926, 2853, 1679 cm^{-1}; ^1H NMR δ: 5.97 (s, 1H), 2.17 (m, 2H), 1.94 (m, 2H), 1.40–1.60 (m, 6H), 0.17 (s, 9H); ^{13}C NMR δ: 130.1, 122.5, 30.6, 28.4, 27.0, 25.3, −0.5; MS *m/e*: 184 (M^+); HRMS calcd. for $C_{10}H_{20}OSi$ *m/e* (M^+): 184.1283; found: 184.1287.

*Phenyl(trimethylsiloxy)methylenecyclopentane (**9**)*

To a −78°C solution of LDA (22.3 mmol) in THF (20 mL) was added cyclopentyl phenyl ketone (3.42 mL, 20.3 mmol). The solution was stirred for 1 h, and Me_3SiCl (2.83 mL, 22.3 mmol) was added. The cooling bath was removed and the solution was allowed to warm to room temperature. The reaction mixture was poured into ice-cold water. A conventional work-up gave a residue that was distilled under reduced pressure to afford **9** (4.633 g, 93%) as a colourless oil: bp 92–94°C (0.80 Torr); IR (KBr): 3057, 3026, 2956, 2869, 1682 cm^{-1}; ^1H NMR δ: 7.42 (m, 2H), 7.15–7.35 (m, 3H), 2.42 (m, 4H), 1.67 (m, 4H), 0.06 (s, 9H); ^{13}C NMR δ: 140.8, 139.5, 127.7, 127.6, 126.7, 125.9, 31.1, 30.3, 27.6, 25.8, 0.6; MS *m/e*: 246 (M^+); HRMS calcd. for $C_{15}H_{22}OSi$ *m/e* (M^+): 246.1440; found: 246.1433.

*Ethyl (*E*)-4-acetoxy-2-pentenoate (**11**)*

Ethyl (*E*)-4-hydroxy-pentenoate (22) (3.62 g, 25.2 mmol) and acetic anhydride (15 mL) were mixed in a two-neck flask and cooled in ice. Pyridine (2 mL) was added and the resultant mixture was allowed to stir overnight. A conventional work-up was performed and the crude product was purified by bulb-to-bulb distillation to yield ethyl (*E*)-4-acetoxy-2-pentenoate (3.20 g, 68%): bp 100°C (1.0 Torr); IR (neat, KBr): 1740, 1725, 1662 cm^{-1}; ^1H NMR δ: 6.84 (dd, 1H, J = 15.6, 5.0), 5.93 (d, 1H, J = 15.6), 5.46 (m, 1H), 4.18 (q, 2H, J = 7.1), 2.06 (s, 3H), 1.34 (d, 3H, J = 6.7), 1.27 (t, 3H, J = 7.1); ^{13}C NMR δ: 169.7, 165.8, 146.0, 120.8, 68.6, 60.3, 20.8, 19.4, 14.0; MS *m/e*: 127 ($M^+ - CH_3C(O)O$); HRMS calcd. for $C_9H_{14}O_4$ *m/e* ($M^+ - C_2H_3O_2$): 127.0754; found: 127.0759.

General procedure for the iron allyl cation addition reaction

*Ethyl (*E*)-4-(1-ethoxycarbonylcyclohexyl)-2-butenoate (**16**)*

A mixture of $Fe_2(CO)_9$ (1.94 g, 5.34 mmol) and ethyl 4-acetoxy-2-butenoate (**10**) (0.657 g, 3.82 mmol) in dry Et_2O (20 mL) was stirred under a CO atmosphere at room temperature for 5 h. The reaction product was then filtered through Celite® and concentrated under reduced pressure to yield a dark brown oil. The oil was redissolved in dry CH_2Cl_2 (20 mL) and the mixture was cooled to −78°C. Compound **3** (1.140 g, 4.20 mmol) was added, followed by BF_3-Et_2O (0.52 mL, 4.2 mmol). The reaction mixture was stirred for 12 h during which time it was allowed to warm to room temperature. The mixture was opened to the air and $NaHCO_3$ (10 drops) was added, followed by $Me_3NO{\cdot}2H_2O$ and acetone (20 mL). After stirring for 8 h, 3 M HCl was added and a conventional work-up was performed. The crude product was subjected to bulb-to-bulb distillation followed by flash chromatography (10:1 petroleum ether:Et_2O) to yield **16** (0.730 g, 72% yield): bp 93°C (0.70 Torr); IR (neat, KBr): 1723, 1657 cm^{-1}; ^1H NMR δ: 6.84 (dt, 1H, J = 15.5, 7.8), 5.76 (d, 1H, J = 15.5), 4.17 (q, 2H, J = 7.0), 4.14 (q, 2H, J = 7.0), 2.34 (d, 2H, J = 7.8), 2.06–1.52 (m, 10H), 1.27 (t, 3H, J = 7.0), 1.25 (t, 3H, J = 7.0); ^{13}C NMR δ: 175.6, 166.1, 144.0, 123.9, 60.3, 60.2, 47.0, 42.4, 33.8, 25.6, 22.9, 14.2; MS *m/e*: 268 (M^+); HRMS calcd. for $C_{15}H_{24}O_4$ *m/e* (M^+): 268.1675; found: 268.1663.

*Ethyl (*E*)-4-(1-ethoxycarbonylcyclohexyl)-4-methyl-2-butenoate (**17**)*

Ethyl 4-acetoxy-2-pentenoate (**11**) (0.511 g, 2.74 mmol) was subjected to the general procedure. The crude product was

For personal use only.

subjected to bulb-to-bulb distillation, followed by flash chromatography (10:1 petroleum ether:Et_2O), to yield **17** (0.508 g, 66%): bp 88°C (0.60 Torr); IR (neat, KBr): 1721, 1652 cm^{-1}; ^1H NMR δ: 6.87 (dd, 1H, J = 15.6, 8.2), 5.76 (d, 1H, J = 15.6), 4.17 (q, 2H, J = 7.1), 4.15 (m, 2H), 2.38 (m, 1H), 2.08 (m, 2H), 1.45–1.70 (m, 3H), 1.27 (t, 3H, J = 7.1), 1.26 (t, 3H, J = 7.1), 1.00–1.40 (m, 5H), 0.98 (d, 3H, J = 8.2); ^{13}C NMR δ: 175.0, 166.5, 150.2, 122.0, 60.3, 50.3, 45.4, 32.6, 31.2, 25.8, 23.6, 23.4, 14.8, 14.4; MS *m/e*: 282 (M^+); HRMS calcd. for $C_{16}H_{26}O_4$ *m/e* (M^+): 282.1831; found: 282.1827.

Ethyl (E)*-4-(1-ethoxycarbonylcyclopentyl)-2-butenoate* (***18***)
Ethyl-4-acetoxy-2-butenoate (**10**) (0.653 g, 3.79 mmol) was subjected to the general procedure, using **5** (1.070 g, 4.172 mmol) in place of **3**. Bulb-to-bulb distillation of the crude reaction product, followed by flash chromatography (10:1, petroleum ether:Et_2O), provided **18** (0.632 g, 66%) as a colourless liquid: bp 90°C (0.35 Torr); IR (neat, KBr): 1723, 1651 cm^{-1}; ^1H NMR δ: 6.78 (dt, 1H, J = 7.7, J = 15.5), 5.75 (d, 1H, J = 15.5), 4.13 (q, 2H, J = 7.1), 4.08 (q, 2H, J = 7.1), 2.47 (d, 2H, J = 7.7), 2.10–1.23 (m, 8H), 1.20 (t, 3H, J = 7.1), 1.17 (t, 3H, J = 7.1); ^{13}C NMR δ: 176.7, 166.2, 145.1, 123.6, 60.5, 60.1, 53.0, 40.9, 35.9 (two resonances, incidental overlap), 25.0, 14.1; MS *m/e*: 254 (M^+); HRMS calcd. for $C_{14}H_{22}O_4$ *m/e* (M^+): 254.1518; found: 254.1512.

Ethyl (E)*-4-(1-ethoxycarbonylcyclopentyl)-4-methyl-2-butenoate* (***19***)
Ethyl 4-acetoxy-2-pentenoate (**11**) (0.581 g, 3.12 mmol) was subjected to the general procedure, using **5** (0.880 g, 3.44 mmol) in place of **3**. Bulb-to-bulb distillation, and subsequent flash chromatography (2:1 petroleum ether:Et_2O), gave **19** (0.519 g, 62%): bp 90°C (0.35 Torr); IR (neat, KBr): 1723, 1651 cm^{-1}; ^1H NMR δ: 6.95 (dd, 1H, J = 15.6, 8.6), 5.80 (d, 1H, J = 15.6), 4.19 (q, 2H, J = 7.1), 4.14 (m, 2H), 2.68 (m, 1H), 2.13 (m, 2H) 1.40–1.75 (m, 6H), 1.29 (t, 3H, J = 7.1), 1.26 (t, 3H, J = 7.1), 1.03 (d, 3H, J = 6.8); ^{13}C NMR δ: 176.4, 166.5, 150.6, 121.7, 60.5, 60.2, 57.6, 43.3, 34.5, 32.8, 25.1, 25.0, 15.9, 14.2; MS *m/e*: 268 (M^+); HRMS calcd. for $C_{15}H_{24}O_4$ *m/e* (M^+): 268.1675; found: 268.1665.

Ethyl (E)*-4-(1-ethoxycarbonyl-2-methylcyclohexyl)-2-butenoate* (***20***)
Compound **10** (0.1086 g, 0.631 mmol) was subjected to the general procedure, using **4a** (0.1910 g) in place of **3**. Purification of the crude reaction product by preparative TLC (10:1 petroleum ether:Et_2O) afforded **20** (0.0926 g, 52%) as a colourless liquid: bp 93°C (0.70 Torr); IR (neat, KBr): 1725, 1654 cm^{-1}; ^1H NMR δ, major diastereomer (*R**,*R**-**20**): 6.85 (dt, 1H, J = 15.5, 7.7), 5.83 (d, 1H, J = 15.5), 4.17 (q, 2H, J = 7.1), 4.15 (q, 2H, J = 7.1), 2.62 (dd, 1H, J = 14.1, 7.2), 2.51 (dd, 1H, J = 14.2, 8.3), 1.90–1.21 (m, 9H), 1.28 (t, 3H, J = 7.1), 1.26 (t, 3H, J = 7.1), 0.95 (d, 3H, J = 6.9); peaks from the minor diastereomer (*R**,*S**-**20**) could be observed at 6.93 (dd, 1H, J = 15.2, 6.9), 5.83 (d, 1H, J = 15.2), 2.30 (dd, 1H, J = 14.3, 8.8), 2.08 (m, 1H), 0.84 (d, 3H, J = 6.9); ^{13}C NMR δ: 175.2, 166.1, 144.7, 124.0, 60.1, 60.0, 49.3, 39.2, 37.3, 29.6, 29.5, 22.9, 21.9, 16.4, 14.2; peaks from the minor diastereomer could be observed at 176.1, 166.2, 145.8, 123.5, 60.3, 49.8, 36.0, 32.7, 30.8, 30.0, 23.8, 21.2, 16.0; MS *m/e*: 282 (M^+); HRMS calcd. for $C_{16}H_{26}O_4$ *m/e* (M^+): 282.1831; found: 282.1833.

Ethyl (E)*-4-(1-ethoxycarbonylcycloheptyl)-2-butenoate* (***21***)
Compound **10** (0.1182 g, 0.686 mmol) was subjected to the general procedure, using **6a** (0.2080 g) in place of **3**. Purification by preparative TLC (10:1 petroleum ether:Et_2O) afforded **21** (0.0780 g) as a colourless liquid: bp 100–105°C (0.50 Torr); IR (neat, KBr): 1724, 1654 cm^{-1}; ^1H NMR δ: 6.83 (dq, 1H, J = 15.4, 7.7), 5.80 (d, 1H, J = 15.4), 4.17 (q, 2H, J = 7.0), 4.15 (q, 2H, J = 7.0), 2.40 (d, 2H, J = 7.7), 1.95–2.20 (m, 2H), 1.4–1.65 (m, 10H), 1.28 (t, 3H, J = 7.0), 1.25 (t, 3H, J = 7.0); ^{13}C NMR δ: 176.7, 166.2, 144.7, 124.0, 60.5, 60.2, 49.7, 43.0, 36.2, 29.9, 23.5, 14.2 (2 resonances, incidental overlap); MS *m/e*: 282 (M^+); HRMS calcd. for $C_{16}H_{26}O_4$ *m/e* (M^+): 282.1831; found: 282.1830.

Ethyl (E)*-4-[1-(oxomethyl)cyclohexyl]-2-butenoate* (***22***)
Ethyl 4-acetoxy-2-butenoate (**3**) (0.193 g, 1.12 mmol) was subjected to the general procedure, using **7** (0.220 g, 1.23 mmol) in place of **3**. The crude product was purified by bulb-to-bulb distillation, followed by flash chromatography (2:1 petroleum ether:Et_2O), to afford **22** (0.186 g, 74%): bp 100°C (1.1 Torr); IR (neat, KBr): 1722, 1654 cm^{-1}; ^1H NMR δ: 9.48 (s, 1H), 6.80 (dt, 1H, J = 15.5, 7.8), 5.83 (d, 1H, J = 15.5), 4.18 (q, 2H, J = 7.2), 2.32 (d, 2H, J = 7.8), 1.88 (m, 2H), 1.20–1.80 (m, 8H), 1.28 (t, 3H, J = 7.2); ^{13}C NMR δ: 205.8, 165.9, 143.0, 124.7, 60.3, 49.7, 38.4, 30.7, 25.4, 22.2, 14.2; MS *m/e*: 224 (M^+); HRMS calcd. for $C_{13}H_{20}O_3$ *m/e* (M^+): 224.1412; found: 224.1405.

Ethyl (E)*-4-[1-(oxomethyl)cyclohexyl]-4-methyl-2-butenoate* (***23***)
Ethyl 4-acetoxy-2-pentenoate (**11**) (0.782 g, 4.20 mmol) was subjected to the general procedure using **7** (0.840 g, 4.62 mmol) in place of **3**. Purification by bulb-to-bulb distillation, followed by flash chromatography (2:1 petroleum ether:Et_2O), afforded **23** (0.620 g, 68%): bp 95°C (0.50 Torr); IR (neat, KBr): 1721, 1652 cm^{-1}; ^1H NMR δ: 9.49 (s, 1H), 6.86 (dd, 1H, J = 15.6, 9.4), 5.75 (d, 1H, J = 15.6), 4.18 (q, 2H, J = 7.1), 2.38 (m, 1H), 1.99 (m, 2H), 1.50–1.70 (m, 3H), 1.28 (t, 3H, J = 7.1), 1.05–1.40 (m, 5H), 0.99 (d, 3H, J = 6.6); ^{13}C NMR δ: 206.8, 166.2, 148.7, 122.7, 60.4, 52.2, 42.8, 30.0, 28.1, 25.5, 22.9, 22.6, 14.2, 14.1; MS *m/e*: 238 (M^+); HRMS calcd. for $C_{14}H_{22}O_3$ *m/e* (M^+): 238.1569; found: 238.1572.

Ethyl (E)*-4-(1-ethoxycarbonyl-2-oxocyclopentyl)-2-butenoate* (***24***)
Compound **3** (1.326 g, 7.70 mmol) was subjected to the general procedure, using **8** (1.330 g, 8.55 mmol) in place of compound **3**. Purification of the crude reaction product by bulb-to-bulb distillation, followed by flash chromatography (5:3 petroleum ether:ethyl acetate), gave **24** (0.893 g, 43%): bp 95°C (0.80 Torr); IR (neat, KBr): 1749, 1722, 1654 cm^{-1}; ^1H NMR δ: 6.78 (dt, 1H, J = 15.5, J = 7.6), 5.83 (d, 1H, J = 15.5), 4.12 (apparent q, J = 7.1, 4H), 2.82 (m, 1H), 1.85–2.70 (m, 7H), 1.25 (t, 3H, J = 7.1), 1.22 (t, 3H, J = 7.1); ^{13}C NMR δ: 213.9, 170.5, 166.0, 143.1, 125.2, 61.6, 60.5, 59.5, 37.9, 36.0, 32.5, 19.6, 14.3, 14.1; MS *m/e*: 268 (M^+); HRMS calcd. for $C_{14}H_{20}O_5$ *m/e* (M^+): 268.1311; found: 268.1302. Anal. calcd. for $C_{14}H_{20}O_5$: C 62.65, H 7.52; found: C 62.60, H 7.91.

Ethyl (E)*-4-(1-ethoxycarbonyl-2-oxocyclopentyl)-4-methyl-2-butenoate* (***25***)
Compound **11** (0.528 g, 2.84 mmol) was subjected to the

For personal use only.

general procedure, using **8** (2.22 g, 14.2 mmol) in place of **3**. The crude reaction product was subjected to bulb-to-bulb distillation, followed by flash chromatography (5:3 petroleum ether:ethyl acetate), to provide compound **25** as a mixture of diastereomers (2:1) (0.330 g, 41%): bp 95°C (0.80 Torr); IR (neat, KBr): 1754, 1722, 1652 cm^{-1}; ^1H NMR δ, major diastereomer: 6.78 (dd, 1H, J = 15.5, 8.0), 5.80 (d, 1H, J = 15.5), 4.14 (q, 2H, J = 7.1), 4.10 (m, 2H), 3.23 (m, 1H), 2.30–2.50 (m, 2H), 1.70–2.35 (m, 4H), 1.24 (t, 3H, J = 7.1), 1.21 (t, 3H, J = 7.1), 0.97 (d, 3H, J = 6.6); peaks from the minor diastereomer could be observed at 6.72 (dd, 1H, J = 15.5, 7.8), 5.78 (d, 1H, J = 15.5), 1.04 (d, 3H, J = 6.6); ^{13}C NMR δ, major diastereomer: 213.6, 169.6, 166.3, 148.7, 122.6, 63.9, 61.9, 60.4, 39.9, 38.9, 28.6, 19.7, 14.8, 14.3, 14.1; peaks from the minor diastereomer could be observed at 213.4, 169.3, 166.3, 148.0, 123.4, 64.6, 39.8, 28.7, 15.0; MS *m/e*: 282 (M^+); HRMS calcd. for $C_{15}H_{22}O_5$ *m/e* (M^+): 282.1467; found: 282.1471. Anal. calcd. for $C_{15}H_{22}O_5$: C 63.79, H 7.86; found: C 63.43, H 7.83.

*Ethyl 4-(1-phenylcarbonylcyclopentyl)-2-butenoate (**26**)*
Ethyl 4-acetoxy-2-butenoate (**10**) (0.146 g, 0.848 mmol) was subjected to the general procedure using **9** (0.263 g, 1.06 mmol) in place of **3**. Purification by preparative TLC (10:1 petroleum ether:Et_2O), followed by bulb-to-bulb distillation, gave **26** as a colourless oil (0.144 g, 59%): bp 125–130°C (0.2 Torr); IR: 1717, 1655 cm^{-1}; ^1H NMR δ: 7.81 (d, 2H, J = 8.4), 7.49 (m, 1H), 7.41 (m, 2H), 6.71 (dt, 1H, J = 15.5, 7.6), 5.65 (dt, 1H, J = 15.5, 1.3), 4.13 (q, 2H, J = 7.1), 2.72 (dd, 2H, J = 7.6, 1.3), 2.36 (m, 2H), 1.60–1.85 (m, 6H), 1.24 (t, 3H, J = 7.1); ^{13}C NMR δ: 204.8, 166.0, 144.2, 136.6, 131.8, 128.6, 128.2, 124.0, 60.2, 58.3, 42.2, 36.0, 25.5, 14.4; MS *m/e*: 286 (M^+); HRMS calcd. for $C_{18}H_{22}O_3$ *m/e* (M^+): 286.1569; found: 286.1561.

General procedure for hydrogenations

*Ethyl (*E*)-4-(1-ethoxycarbonylcyclohexyl)butanoate (**16a**)*
Compound **16** (0.0858 g, 0.337 mmol) was added to ethanol (15 mL). Raney® nickel was added and the mixture was allowed to stir under a hydrogen atmosphere at room temperature for 8 h. The Raney® nickel was then removed by filtration through Celite® and the filtrate was concentrated under reduced pressure. The crude product was subjected to a bulb-to-bulb distillation to yield **16a** (0.0858 g, 99%): bp 95°C (0.90 Torr) (lit. (13) bp 135–36°C (1.3 Torr)); IR (neat, KBr): 1728 cm^{-1}; ^1H NMR δ: 4.14 (q, 2H, J = 7.1), 4.11 (q, 2H, J = 7.1), 2.23 (t, 2H, J = 6.6), 2.04 (m, 2H), 1.10–1.40 (m, 12H), 1.25 (t, 3H, J = 7.1), 1.24 (t, 3H, J = 7.1); ^{13}C NMR δ: 176.6, 173.4, 60.3, 60.1, 46.7, 39.8, 34.7, 34.1, 26.0, 23.2, 19.8, 14.4, 14.3; MS *m/e*: 270 (M^+).

*Ethyl 4-(1-ethoxycarbonylcyclohexyl)-4-methylbutanoate (**17a**)*
Subjecting compound **17** (0.0725 g, 0.257 mmol) to the general hydrogenation procedure afforded **17a** (0.0707 g, 97%) following bulb-to-bulb distillation: bp 97°C (0.50 Torr); IR (neat, KBr): 1735, 1725 cm^{-1}; ^1H NMR δ: 4.14 (q, 2H, J = 7.2), 4.10 (q, 2H, J = 7.1), 2.35 (m, 1H), 1.80–2.25 (m, 4H), 1.10–1.70 (m, 10H), 1.25 (t, 3H, J = 7.2), 1.23 (t, 3H, J = 7.1), 0.84 (d, 3H, J = 6.8); ^{13}C NMR δ: 175.8, 173.7, 60.3, 59.9, 50.7, 41.0, 33.1, 31.5, 31.2, 26.8, 25.9, 23.63, 23.57, 14.3, 14.2, 13.8; MS *m/e*: 284 (M^+).

*Ethyl (*E*)-4-(1-ethoxycarbonylcyclopentyl)butanoate (**18a**)*
Subjecting compound **18** (0.0949 g, 0.373 mmol) to the general hydrogenation procedure provided **18a** (0.0927 g, 97%) after bulb-to-bulb distillation: bp 95°C (0.80 Torr); IR (neat, KBr): 1738, 1726 cm^{-1}; ^1H NMR δ: 4.10 (q, 2H, J = 7.0), 4.09 (q, 2H, J = 7.2), 2.24 (t, 2H, J = 7.1), 2.09 (m, 2H), 1.70–1.40 (m, 10H), 1.19 (t, 6H, J = 7.1); ^{13}C NMR δ: 177.6, 173.4, 60.3, 60.3, 53.9, 38.6, 36.1, 34.7, 25.0, 21.5, 14.3; MS *m/e*: 256 (M^+).

*Ethyl 4-(1-ethoxycarbonyl-2-methylcyclohexyl)butanoate (**20a**)*
Subjecting compound **20** (0.0926 g, 0.328 mmol) to the general hydrogenation procedure afforded **20a** (0.0918 g, 98%) after bulb-to-bulb distillation; bp 85°C (0.3 Torr); IR (neat, KBr): 1735 cm^{-1}; ^1H NMR δ, major diastereomer: 4.10 (q, 2H, J = 7.1), 4.09 (q, 2H, J = 7.1), 2.24 (m, 2H), 1.30–1.90 (m, 10H), 1.23 (t, 3H, J = 7.1), 1.22 (t, 3H, J = 7.1), 0.92 (t, 6H, J = 6.6); peaks from the minor diastereomer could be observed at 0.81 (d, 3H, J = 7.1); ^{13}C NMR δ, major diastereomer: 176.7, 173.5, 60.3, 59.9, 49.2, 37.4, 35.7, 35.0, 34.8, 29.6, 27.9, 22.5, 22.1, 20.0, 16.5, 14.4; peaks from the minor diastereomer could be observed at 49.6, 30.4, 30.3, 29.8, 23.2, 22.2, 19.8, 15.6; MS *m/e*: 284 (M^+).

*Ethyl 4-(1-ethoxycarbonylcycloheptyl)butanoate (**21a**)*
Subjecting **21** (0.1063 g, 0.376 mmol) to the general hydrogenation procedure afforded **21a** (0.1023 g, 96%) after bulb-to-bulb distillation: bp 100–105°C (0.44 Torr); IR (neat, KBr): 1737, 1731 cm^{-1}; ^1H NMR δ: 4.12 (q, 2H, J = 7.1), 4.11 (q, 2H, J = 7.1), 2.24 (m, 2H), 2.07 (m, 2H), 1.4–1.6 (m, 14H), 1.24 (apparent t, 6H, J = 7.1); ^{13}C NMR δ: 177.6, 173.3, 60.2, 60.1, 49.4, 40.1, 36.1, 34.7, 29.9, 23.5, 20.3, 14.24, 14.21; MS *m/e*: 284 (M^+).

*Ethyl 4-[1-(hydroxymethyl)cyclohexyl]butanoate (**22b**)*
Subjecting **22** (0.1412 g, 0.330 mmol) to the general hydrogenation procedure afforded **22b** (0.1396 g, 97%) after bulb-to-bulb distillation: bp 100°C (1.0 Torr); IR (neat, KBr): 3447 (br), 1735 cm^{-1}; ^1H NMR δ: 4.13 (q, 2H, J = 7.1), 3.43 (s, 2H), 2.30 (t, 2H, 6.9), 2.10 (br, 1H), 1.20–1.60 (m, 14H), 1.26 (t, 3H, J = 7.1); ^{13}C NMR δ: 174.3, 68.4, 60.5, 37.2, 34.6, 33.8, 32.6, 26.5, 21.6, 18.2, 14.3; MS *m/e*: 228 (M^+).

*Ethyl 4-[(1-iodomethylcyclohexyl)butanoate (**37**)*
Compound **22b** (0.112 g, 0.491 mmol) was added to a flask containing triphenylphosphine (0.390 g, 1.49 mmol), imidazole (0.100 g, 1.49 mmol), and iodine (0.250 g, 0.99 mmol). Toluene (25 mL) was added and the mixture was allowed to reflux for 4 h. At this time the mixture was allowed to cool to room temperature, sodium bicarbonate was added, and stirring was allowed to continue for 5 min. Iodine was then added until the toluene layer remained orange. A saturated aqueous sodium thiosulphate was added to remove the excess iodine, at which time a conventional work-up was done, extracting with toluene. The crude product was purified by flash chromatography (20:1 petroleum ether:Et_2O) to afford **37** (0.145 g, 87%): bp 100°C (0.48 Torr); IR (neat, KBr): 2927, 2855, 1735

For personal use only.

cm^{-1}; ^{1}H NMR δ: 4.14 (q, 2H, J = 7.1), 3.24 (s, 2H), 2.30 (t, 2H, J = 6.9), 1.30–1.55 (m, 14 H), 1.27 (t, 3H, J = 7.1); ^{13}C NMR δ: 173.6, 60.3, 37.2, 35.0, 34.9, 34.7, 26.0, 21.8, 18.2, 14.3; MS *m/e*: 338 (M$^+$); HRMS calcd. for $C_{13}H_{23}IO_2$ *m/e* (M$^+$): 338.0743; found: 338.0732.

*Ethyl 4-[1-(phenyloxomethyl)cyclopentyl]butanoate (**26a**)*
Compound **26** (0.0887 g, 0.310 mmol) was subjected to the general hydrogenation procedure. The crude reaction product (containing **26b**) was dissolved in CH_2Cl_2 (10 mL), and neutral alumina (ca. 0.5 g) and PDC (0.2 g) were added. After stirring for 4 h, an additional amount of PDC (0.2 g) was added. After stirring for a further 8 h, the reaction mixture was filtered through neutral alumina, and the filtrate was subject to a conventional work-up. Thin-layer chromatography (10:1 petroleum ether:Et_2O) afforded **26a** (0.0781 g, 88%) as a colourless oil: bp 125–130°C (0.2 Torr); IR (neat, KBr): 1735, 1671 cm^{-1}; ^{1}H NMR δ: 7.86 (dd, 2H, J = 8.5, 1.7), 7.47 (m, 1H), 7.39 (m, 2H), 4.01 (q, 2H, J = 7.1), 2.25–2.45 (m, 2H), 2.14 (t, 2H, J = 7.2), 1.80–1.95 (m, 2H), 1.50–1.77 (m, 6H), 1.35–1.50 (m, 2H), 1.16 (t, 3H, J = 7.1); ^{13}C NMR δ: 205.3, 173.0, 136.6, 131.7, 128.7, 128.1, 60.1, 58.9, 39.9, 36.2, 34.5, 25.5, 21.1, 14.1; MS *m/e*: 288 (M$^+$).

General procedure for Dieckmann condensations

*2-Ethoxycarbonyl-1-oxospiro[4.5]decane (**27**)*
KH (0.060 g, 1.6 mmol) was washed three times with dry Et_2O, with the supernatant Et_2O being removed by syringe each time. Dry Et_2O (20 mL) was added, followed by **16a** (0.355 g, 1.31 mmol). The mixture was allowed to stir overnight, at which time 3 M HCl was added. The mixture was stirred for an additional 5 min, after which an aqueous work-up was performed. The crude product was purified by bulb-to-bulb distillation to afford compound **27** (0.247 g, 84%); bp 85°C (0.20 Torr) (lit. (13) bp 100–101°C (0.1 Torr)); ^{1}H NMR δ: 4.17 (q, 2H, J = 7.1), 3.19 (t, 1H, J = 9.0), 2.21–1.49 (m, 14H), 1.26 (t, 3H, J = 7.1); ^{13}C NMR δ: 215.7, 169.7, 61.2, 57.1, 54.8, 50.3, 33.2, 32.2, 31.3, 25.5, 23.4, 22.1, 21.9, 14.1; MS *m/e*: 224 (M$^+$); HRMS calcd. for $C_{13}H_{20}O_3$ *m/e* (M$^+$): 224.1412; found: 224.1410.

*2-Ethoxycarbonyl-1-oxo-4-methylspiro[4.5]decane (**28**)*
Subjecting compound **19a** (0.048 g, 0.17 mmol) to the general procedure, followed by bulb-to-bulb distillation and preparative TLC (5:1 petroleum ether:ethyl acetate), afforded **28** (0.020 g, 53%): bp 90°C (0.68 Torr); IR (neat, KBr): 2931, 2857, 1748, 1723, 1654, 1450, 1254, 1177, 800 cm^{-1}; ^{1}H NMR δ, major diastereomer: 4.16 (q, 2H, J = 7.1), 3.26 (t, 1H, J = 9.2), 2.48 (m, 1H), 2.32 (m, 1H), 1.16–2.10 (m, 11H), 1.26 (t, 3H, J = 7.1), 0.93 (d, 3H, J = 7.1); peaks from the minor diastereomer could be observed at 4.18 (q, 2H, J = 7.3), 3.19 (t, 1H, J = 9.4), 2.23 (m, 1H), 1.02 (d, 3H, J = 6.8); ^{13}C NMR (diastereomeric mixture) δ: 215.1, 214.8, 169.9, 61.2, 53.8, 53.4, 52.2, 51.1, 39.6, 36.2, 32.1, 31.7, 30.8, 27.3, 25.8, 25.6, 25.3, 21.9, 21.6, 20.9, 15.9, 14.6, 14.1; MS *m/e*: 238 (M$^+$); HRMS calcd. for $C_{14}H_{22}O_3$ *m/e* (M$^+$): 238.1569; found: 238.1570. Resolution-enhanced ^{13}C NMR experiments resolved the 61.2 ppm resonance into 61.21 and 61.26 ppm resonances.

*2-Ethoxycarbonyl-1-oxospiro[4.4]nonane (**29**)*
Subjecting compound **18a** (0.178 g, 0.695 mmol) to the general procedure, followed by bulb-to-bulb distillation, produced compound **29** (0.101 g, 69%): bp 83°C (0.29 Torr); IR (neat, KBr): 1749, 1723 cm^{-1}; ^{1}H NMR δ: 4.16 (q, 2H, J = 7.1), 3.18 (t, 1H, J = 8.9), 2.20–1.44 (m, 12H), 1.25 (t, 3H, J = 7.1); ^{13}C NMR δ: 216.1, 169.8, 61.2, 56.9, 54.3, 37.1, 36.3, 36.1, 25.9, 25.7, 24.2, 14.1; MS *m/e*: 210 (M$^+$); HRMS calcd. for $C_{12}H_{18}O_3$ *m/e* (M$^+$): 210.1256; found: 210.1248.

*2-Ethoxycarbonyl-1-oxospiro[4.6]undecane (**30**)*
Subjecting **21a** (0.0481 g, 0.169 mmol) to the general procedure, followed by preparative TLC (5:1 petroleum ether:Et_2O), afforded **30** (0.0268 g, 67%): bp 85–90°C (1.2 Torr); IR (neat, KBr): 1749, 1724 cm^{-1}; ^{1}H NMR δ: 4.19 (m, 2H), 3.24 (apparent t, 1H, J = 9.0), 2.00–2.40 (m, 3H), 1.35–1.85 (m, 13H), 1.28 (apparent t, 3H, J = 7.1); ^{13}C NMR δ: 215.9, 169.8, 61.2, 54.3, 52.6, 36.1, 35.1, 34.5, 29.7, 23.8, 23.4, 23.2, 14.1; MS *m/e*: 238 (M$^+$); HRMS calcd. for $C_{14}H_{22}O_3$ *m/e* (M$^+$): 238.1569; found: 238.1564.

*1-Phenylspiro[4.4]non-1-ene-2-carboxylic acid (**31**)*
Subjecting **26a** (0.0691 g, 0.240 mmol) to the general reaction procedure afforded the crude product. This material was redissolved in 1:1 MeOH:H_2O (5 mL), and KOH (0.1 g) was added. After stirring 8 h, 10% NaOH (10 mL) was added, and the mixture extracted with Et_2O. The aqueous layer was acidified with 3 M HCl, and subsequently extracted three times with Et_2O. The combined Et_2O layers from the acidic solution extractions were dried over $MgSO_4$, filtered, and concentrated under reduced pressure. Preparative TLC (1:1 petroleum ether:Et_2O) afforded **31** (0.0435 g, 75%) as white crystals: mp 160–161°C (hexanes); IR (KBr): 3000 (v br), 1683, 1660 cm^{-1}; ^{1}H NMR δ: 7.20–7.40 (m, 3H), 7.03 (dd, 2H, J = 7.4, 1.3), 2.66 (apparent t, 2H, J = 7.2), 1.86 (apparent t, 2H, J = 7.2), 1.35–1.75 (m, 8H). The resonance of the carboxylic acid OH proton was insufficiently sharp to be detected; ^{13}C NMR δ: 170.1, 163.5, 136.3, 129.5, 128.0, 127.6, 127.1, 61.4, 37.4, 35.8, 30.6, 23.9; MS *m/e*: 242 (M$^+$); HRMS calcd. for $C_{16}H_{18}O_2$ *m/e* (M$^+$): 242.1307; found: 242.1312.

General procedure for acyloin condensation

*Bis(1,2-trimethylsiloxy)spiro[5.5]undec-1-ene (**32**)*
Sodium metal (0.010 g, 0.43 mmol) and potassium metal (0.030 g, 0.68 mmol) were placed in a two-neck flask under argon and washed three times with dry Et_2O. The metal alloy was formed by heating the flask with a heat gun under constant stirring. After formation, the alloy was allowed to cool and Et_2O (40 mL) was added. A solution of compound **16** (0.090 g, 0.33 mmol) and Me_3SiCl (0.150 g, 1.37 mmol) in Et_2O (1 mL) was added over 40 min using a syringe pump. The solution turned a purple colour during this time. The mixture was allowed to stir overnight, at which time it was filtered through Celite® under nitrogen. The solvent was removed under reduced pressure; flash chromatography on the residue (50:1 petroleum ether:Et_2O) gave **32** as a colourless liquid (0.092 g, 85%): IR (neat, KBr): 2929, 2860, 1676, 1292, 1250, 1207, 843, 758 cm^{-1}; ^{1}H NMR δ: 2.10 (m, 2H), 0.85–1.80 (m, 14H), 0.17 (s, 18H); ^{13}C NMR δ: 139.4, 131.8, 38.2, 33.7, 31.0, 30.2, 26.1, 21.8, 18.9, 1.4, 1.1; MS *m/e*: 326 (M$^+$); HRMS calcd. for $C_{17}H_{34}O_2Si_2$ *m/e* (M$^+$): 326.2097; found: 326.2109.

Bis(6,7-trimethylsiloxy)spiro[4.5]dec-6-ene (33)
Compound **18a** (0.0893 g, 0.348 mmol) was subjected to the general reaction procedure. Preparative TLC (100% petroleum ether) produced spirocycle **33** (0.0667 g, 67%): IR (neat, KBr): 2954, 2863, 1677, 1444, 1250, 842, 757 cm^{-1}; ^1H NMR δ: 2.11 (apparent t, 2H, J = 6.2), 1.80 (m, 2H), 1.20–1.65 (m, 10H), 0.17 (s, 9H), 0.15 (s, 9H); ^{13}C NMR δ: 137.4, 131.3, 46.6, 37.2, 36.8, 30.1, 25.6, 20.5, 1.5, 1.2; MS *m/e*: 312 (M^+); HRMS calcd. for $C_{16}H_{32}O_2Si_2$ *m/e* (M^+): 312.1941; found: 312.1941.

Bis(1,2-trimethylsiloxy)-7-methylspiro[5.5]undec-1-ene (34)
Compound **20a** (0.0918 g, 0.323 mmol) was subjected to the general reaction procedure. Flash chromatography (50:1 petroleum ether:Et_2O) afforded **34** as a mixture of diastereomers (70:30) (0.0660 g, 60%). The major diastereomer could be separated by preparative TLC (100% petroleum ether): IR (neat, KBr): 2955, 2930, 2862, 1668 cm^{-1}; ^1H NMR δ, major diastereomer (*R**, *R**-**34**): 2.13 (apparent t, 2H, J = 6.4), 0.80–2.05 (m, 13H), 0.98 (d, 3H, J = 6.7), 0.20 and 0.18 (2 s, 9H) 0.08 (s, 9H); peaks from the minor diastereomer could be observed at 2.49 (apparent dd, 2H, J = 7.6, 15.1), 0.80–2.20 (m, 13H), 0.74 (d, 3H, J = 6.7), 0.27 (s, 9H), 0.18 (s, 9H); ^{13}C NMR δ, major diastereomer: 139.8, 131.7, 40.4, 37.5, 35.2, 33.9, 30.3, 30.0, 22.3, 22.0, 18.5, 17.1, 1.72; peaks from the minor diastereomer could be observed at 138.4, 132.5, 42.0, 35.8, 33.7, 30.4, 30.0, 18.8, 17.3, 1.35; MS *m/e*: 340 (M^+); HRMS calcd. for $C_{18}H_{36}O_2Si_2$ *m/e* (M^+): 340.2254; found: 340.2261.

Bis(1,2-trimethylsiloxy)spiro[6.5]dodec-1-ene (35)
Compound **21a** (0.1023 g, 0.360 mmol) was subjected to the general reaction procedure. Flash chromatography (50:1 petroleum ether:Et_2O) of the crude product afforded spirocycle **35** (0.0857 g, 70%); IR (neat, KBr): 2923, 2851, 1674 cm^{-1}; ^1H NMR δ: 2.10 (apparent t, 2H, J = 6.2), 1.79 (dd, 2H, J = 14.1, 9.5) 1.23–1.70 (m, 14H), 0.20 (s, 9H), 0.19 (s, 9H); ^{13}C NMR δ: 141.2, 130.2, 40.7, 38.5, 35.5, 30.9, 30.3, 24.2, 19.1, 1.5, 1.2; MS *m/e*: 340 (M^+); HRMS calcd. for $C_{18}H_{36}O_2Si_2$ *m/e* (M^+): 340.2254; found: 340.2266.

Spiro[5.5]undecan-2-one (36)
Sodium metal (0.025 g) was heated in toluene at reflux (10 mL) with vigourous stirring. Stirring was continued as the solution was allowed to cool to room temperature. The toluene was removed by syringe, and the finely divided sodium suspended in Et_2O (20 mL). Me_3SiCl (0.5 mL) was added. Iodide **37** (0.0868 g, 0.257 mmol) was added as a solution in Et_2O over a period of 10 min. After stirring 12 h, the mixture was filtered through Celite®. Ethanol (95%, 10 mL) was added to the filtrate, and the solution stirred for 2 h. After concentration under reduced pressure, preparative TLC (5:1 petroleum ether:Et_2O) gave **36** (0.0190, 45%), whose spectral data were identical with the literature report (23).

Material on deposit

The ^{13}C NMR spectra of **11**, **16–23**, **26–35**, and **37** (20 pages) have been deposited as supplementary material.[4]

Abstract: Laser flash photolysis (193 nm) of 1,1-dimethyl-(1-sila)cyclobut-2-ene in hexane solution leads to the formation of a transient species ($\tau \sim 1.5$ μs at 23°C) assigned to 1,1-dimethyl-1,3-(1-sila)butadiene on the basis of its UV absorption spectrum ($\lambda_{max} = 312$ nm), and reactivity toward methanol ($k_{MeOH} = (3.6 \pm 0.1) \times 10^9$ M^{-1} s^{-1}; $k_H/k_D = 1.3 \pm 0.1$), ethanol ($k_{EtOH} = (2.41 \pm 0.06) \times 10^9$ M^{-1} s^{-1}), *tert*-butanol ($k_{BuOH} = (1.8 \pm 0.1) \times 10^9$ M^{-1} s^{-1}; $k_H/k_D = 1.5 \pm 0.1$), and oxygen ($k_{O_2} = (3.0 \pm 0.9) \times 10^8$ M^{-1} s^{-1}). Experiments using isooctane and acetonitrile as solvent are also described. In acetonitrile, the lifetime of the silene is shortened considerably compared to hydrocarbon solvents, presumably due to quenching by adventitious water. In isooctane, under conditions of low excitation intensity, the siladiene decays with clean pseudo-first-order kinetics and a maximum lifetime of ~ 5 μs at 23°C. The decay rate constant varies only slightly with temperature over the 20–60°C range, leading to Arrhenius activation parameters of $E_a = 0.5 \pm 0.2$ kcal/mol and $\log A = 5.7 \pm 0.2$. While steady state irradiation experiments suggest that in the absence of silene traps the predominant fate of the silabutadiene is thermal ring closure to regenerate the precursor, it is concluded that the rate constants and activation parameters for decay of the siladiene measured by flash photolysis represent a composite of those due to thermal electrocyclic ring closure (with $E_a > \sim 3$ kcal/mol) and reaction with adventitious quenchers (probably water, with $E_a < 0$). The measured Arrhenius parameters for reaction of the siladiene with methanol in isooctane ($E_a = -2.6 \pm 0.3$ kcal/mol and $\log A = 7.6 \pm 0.3$) are consistent with this proposal. The potential and limitations of the use of 193-nm laser excitation for flash photolysis studies in solution are discussed.

Key words: far-UV, silene, flash photolysis, kinetics, electrocyclic.

Résumé : Une photolyse éclair à 193 nm du 1,1-diméthyl-(1-sila)cyclobut-2-ène en solution dans l'hexane conduit à la formation d'une espèce transitoire ($\tau \sim 1,5$ μs, à 23°C) qui serait du 1,1-diméthyl-1,3-(1-sila)butadiène si l'on se base sur son spectre d'absorption UV ($\lambda_{max} = 312$ nm) et sa réactivité vis-à-vis du méthanol ($k_{MeOH} = (3,6 \pm 0,1) \times 10^9$ M^{-1} s^{-1}; $k_H/k_D = 1,3 \pm 0,1$), de l'éthanol ($k_{EtOH} = (2,41 \pm 0,06) \times 10^9$ M^{-1} s^{-1}), du *tert*-butanol ($k_{BuOH} = (1,8 \pm 0,1) \times 10^9$ M^{-1} s^{-1}; $k_H/k_D = 1,5 \pm 0,1$) et de l'oxygène ($k_{O_2} = (3,0 \pm 0,9) \times 10^8$ M^{-1} s^{-1}). On décrit aussi des expériences impliquant de l'isooctane et de l'acétonitrile comme solvants. Dans l'acétonitrile, le temps de vie du silène est beaucoup plus court que dans les solvants hydrocarbonés, probablement à cause d'une désactivation par de l'eau qui s'y trouve par inadvertance. Dans l'isooctane, dans des conditions de faible intensité d'excitation, le siladiène se désagrège selon une cinétique propre de pseudo-premier ordre et un temps de vie maximal d'environ 5 μs, à 23°C. Dans la plage de température allant de 20 à 60°C, la constante de la vitesse de désactivation ne varie que faiblement avec la température; ce qui conduit aux paramètres d'activation d'Arrhenius $E_a = 0,5 \pm 0,2$ kcal/mol et $\log A = 5,7 \pm 0,2$. Même si des expériences d'irradiation en état stationnaire suggèrent que, en l'absence de pièges pour les silènes, le silabutadiène conduit principalement à une cyclisation thermique régénérant le précurseur, on conclut que les constantes de vitesse et les paramètres d'activation pour la décroissance du siladiène mesurés par la photolyse éclair correspondent à une situation mixte entre la cyclisation électrocyclique thermique (avec une E_a supérieure à environ 3 kcal/mol) et la réaction avec des molécules désactivantes présentes par inadvertance (probablement de l'eau, avec une $E_a < 0$). Les paramètres d'Arrhenius mesurés pour la réaction du siladiène avec le méthanol dans l'isooctane ($E_a = -2,6 \pm 0,3$ kcal/mol et $\log A = 7,6 \pm 0,3$) sont en accord avec cette hypothèse. On discute des possibilités et des limites de l'utilisation de l'excitation laser à 293 nm pour les études de photolyse éclair en solution.

Mots clés : UV lointain, silène, photolyse éclair, cinétique, électrocyclique.

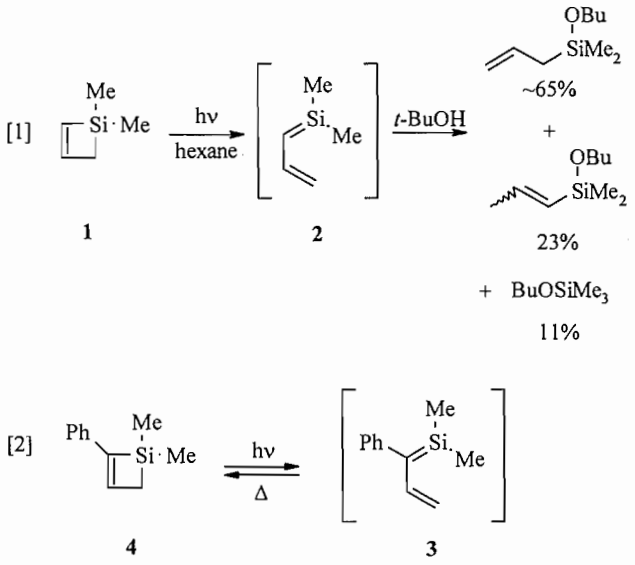
Introduction



The chemistry of the silicon–carbon double bond has been an area of active interest over the past few decades. While a large number of stable (or at least, persistent) derivatives containing this functionality are known, *silenes* are more frequently encountered as reactive intermediates in various thermal and photochemical reactions of organosilicon compounds (1–4). Most commonly, their intermediacy is inferred from the results of trapping experiments, employing water, alcohols, or alkoxysilanes to trap the silene as the [1,2]-addition product. Numerous bimolecular pericyclic processes are also well known, such as ene-, [2+2]-, and [4+2]-cycloadditions with alkenes, dienes, and carbonyl compounds, and [2+2]-dimerization. Unimolecular pericyclic reactions have been much less extensively investigated.

Nanosecond laser flash photolysis techniques have proven to be extremely useful for the generation and direct detection of reactive silenes in solution (5–8) and, through determination of the effects of solvent, substituent, and temperature effects on absolute reaction rate constants, have allowed study of the mechanisms of several classic silene trapping reactions (9–15). To date, we have employed two general methodologies for the generation of transient silenes for these studies, photoinduced [1,3]-silyl migrations of aryl- (8, 11, 12, 15, 16), alkynyl- (17), and vinyldisilanes,[2] and photoinduced [2+2]-cycloreversion of arylsilacyclobutanes (10, 13, 14). The UV absorption spectra of these silene precursors extend to at least 260 nm in every case, which allows study of a wide variety of transient silenes using conventional pulsed UV lasers (KrF excimer (248 nm) or Nd/YAG (266 nm)) as excitation sources.

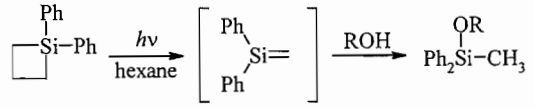
Time-resolved studies of silenes that are most conveniently derived from photolysis of precursors absorbing below ~240 nm have been largely confined to the gas phase, where 193 nm (ArF excimer) laser excitation can be employed (18, 19). In fact, this is true of *all* chemical reaction intermediates derived from precursors absorbing only in the far-UV. The principal reason for this is obvious — most organic solvents absorb significantly at such short wavelengths, either because of their intrinsic absorption characteristics or the presence of absorbing impurities in the commercially available materials. Water is the only solvent that might be identified as readily suitable for such studies and, indeed, the only reports of the use of the ArF laser for solution phase laser flash photolysis studies (to our knowledge) have been carried out in aqueous solution (20, 21). Furthermore, the selection of potential transient quenchers suitable for use with 193 nm excitation is rather limited, since accurate determination of bimolecular rate constants by flash photolysis can only be carried out when the quencher does not absorb significantly at the excitation wavelength (over the concentration range necessary to detect the reaction kinetically). These limitations notwithstanding, our experience with the use of far-UV excitation sources for solution phase *steady state* photochemical studies (22) suggested that, in fact, it might very well be possible — even practical — to employ the ArF laser as an excitation source for flash photolysis experiments in nonaqueous solvents.

[2] W.J. Leigh, C.J. Bradaric, G.W. Slugett, P.C. Venneri, R.T. Conlin, M.S.K. Dhurjati, and M.B. Ezhova. Unpublished results.

In this paper, we report the results of a nanosecond laser flash photolysis study of the chemistry of 1,1-dimethyl-1,3-(1-sila)butadiene (**2**) in hydrocarbon and acetonitrile solutions, using the 193 nm irradiation of 1,1-dimethyl-(1-sila)cyclobut-2-ene (**1**) to generate the silene under conditions where it can be detected directly. The photochemistry of **1** in solution has been reported previously (23), as has its gas phase thermolysis (24, 25). Under both sets of conditions, the formation of **2** as the major product has been demonstrated on the basis of chemical trapping experiments (e.g., eq. [1]). In this paper, we report absolute rate constants for the reaction of **2** with alcohols and oxygen in hexane and acetonitrile solution. An additional goal of this work was to determine rate constants and activation parameters for the thermal electrocyclic ring closure of **2** (which regenerates **1**) in solution at near ambient temperatures, to compare with previously reported data for the corresponding process in 1,1-dimethyl-2-phenyl-1,3-(1-sila)-butadiene (**3**; eq. [2]) (7).

Results and discussion

The laser flash photolysis experiments described below employed an ArF excimer laser (193 nm, ~15 ns, ~20 mJ, 1 Hz), a conventional front-face-excitation optical/detection system with nanosecond time resolution (26), and a 3 × 7 mm Suprasil quartz flow cell. Our system requires use of a single mirror to direct the excitation beam at the front face of the sample cell; for 193 nm experiments, the conventional Suprasil mirror that is used for longer wavelength excitation is replaced with a dichroic mirror manufactured specifically for 193 nm light. With a total travel distance of ~2 m through air, the intensity of the beam at the sample was reduced to about 50% of its value at the laser optic. The beam intensity was further reduced as required by use of stainless steel wire meshes as neutral density filters.



Various commercial solvents were examined for their potential suitability for 193-nm experiments. The main requirements are a low static absorbance at the laser wavelength (<0.1 through the path length of the sample cell is satisfactory), and the absence of absorbing transients in the 230–600 nm spectral range when the "pure" solvent is subjected to

For personal use only.

193-nm laser excitation. HPLC-grade hexane and isooctane ($A_{193}^{3\text{-mm}} \sim 0.1$ in both cases) both proved to yield satisfactory results after a single distillation. Acetonitrile was somewhat more problematic; 193-nm laser flash photolysis of an HPLC-grade sample ($A_{193}^{3\text{-mm}} \sim 0.2$) led to the formation of an unidentified transient species that absorbs more or less continuously over the 235–500 nm range and exhibits a lifetime of ~200 ns. Several distillations of the solvent from phosphorus pentoxide substantially reduced both the static absorbance at 193-nm ($A_{193}^{3\text{-mm}} \sim 0.06$) and the production of the transient absorption. The P_2O_5-distilled solvent contains small (ca. 10^{-2} M) amounts of water or other hydroxylic impurities (vide infra). However, further treatment of the solvent by passage through activated alumina (which reduces the water concentration to ca. 10^{-4} M (14)) reintroduced unacceptable levels of absorbing impurities.

A few initial experiments were carried out to establish the general reliability of far-UV laser flash photolysis data, by examining a couple of systems that were previously studied using a (248 nm) KrF excimer laser as the excitation source. For example, far-UV flash photolysis of a continuously deoxygenated hexane solution of 1,1-diphenylsilacyclobutane (**5**; 3.4×10^{-5} M) led to the formation of a transient whose decay characteristics, lifetime, and UV spectrum correspond very closely to those reported previously for 1,1-diphenylsilene (**6**; $\tau > 5$ μs; $\lambda_{max} = 325$ nm; see eq. [3]). The silene was quenched by methanol with a rate constant of $k_q = (2.8 \pm 0.1) \times 10^9$ M^{-1} s^{-1}, in excellent agreement with the value reported previously with 248 nm excitation and solutions of ~100-fold higher precursor concentrations (14). Similarly, a rate constant of $k_q = (1.3 \pm 0.5) \times 10^6$ M^{-1} s^{-1} was determined for methanol quenching of 1,1-dimethyl-3,3-bis(trimethylsilyl)-1-silaallene (**8**), produced by 193-nm excitation of a deoxygenated hexane solution of (trimethylsilylethynyl)pentamethyldisilane (**7**; 6.3×10^{-5} M; see eq. [4]). The transient absorption spectrum and quenching rate constant observed in this case are also in excellent agreement with those measured using 248-nm excitation (17).

[3] 

5 **6**

[4] 

7 **8**

Excitation of a deoxygenated hexane solution of **1** (8×10^{-4} M, $A_{193} \sim 0.6$) under similar conditions afforded readily detectable transient absorptions that decayed with mixed first- and second-order kinetics on the microsecond time scale ($\tau \sim 1.5$ μs). Reduction in the intensity of the excitation source with neutral density filters resulted in a change to clean pseudo-first-order decay kinetics and lengthening of the lifetime of the transient to a maximum of ca. 5 μs. The UV absorption spectrum of the transient, recorded in point-by-point fashion 0.23–0.55 μs after the pulse, is shown in Fig. 1 along with a typical decay trace. Similar results were obtained using distilled isooctane as the solvent.

The lifetime of the transient is shortened upon addition of methanol ($\varepsilon_{193} = (39 \pm 1)$ $M^{-1}cm^{-1}$), ethanol ($\varepsilon_{193} = (39 \pm 1)$ $M^{-1}cm^{-1}$), *tert*-butanol ($\varepsilon_{193} = (114 \pm 6)$, $M^{-1}cm^{-1}$) or oxygen[3] to the solution of **1**. Bimolecular rate constants for quenching of the transient by these compounds were obtained, as usual, from the slopes of plots of the rate constant for transient decay (k_{decay}) versus quencher concentration according to eq. [5]. These were linear in every case; Fig. 2 shows representative plots for quenching by methanol and methanol-*O*-*d*. Table 1 summarizes the results of these experiments. We assign the structure of the transient observed in these experiments to 1,1-dimethyl-1,3-(1-sila)butadiene (**2**), based on its reactivity toward alcohols and oxygen,[3] and comparison of its UV absorption spectrum ($\lambda_{max} = 312$ nm) to those of other transient silenes that have been reported — in particular, to that of 1,1-dimethyl-2-phenyl-1,3-(1-sila)butadiene (**3**) ($\lambda_{max} = 338$ nm in cyclohexane), which was reported by Conlin et al. (7). The spectrum of **2** consists of a single, rather sharp, absorption band, which may indicate that the conformational distribution of the molecule lies largely in favour of a single conformer, most likely the s-*trans* (23).

[5] $k_{decay} = k_d^0 + k_q[Q]$

A solution of **1** (0.001 M) and *tert*-butanol (0.005 M) in hexane was deoxygenated and irradiated with the ArF laser (5 Hz repetition rate) in a 10×10 mm Suprasil cuvette with vigorous stirring. GC–MS analysis of the solution after ~3% conversion of **1** verified the formation of the major product reported by Steinmetz et al., from experiments carried out with a Zn resonance lamp (214 nm) (23). This experiment indicates that the photolysis of **1** with the ArF laser proceeds in the same manner as that with the 214-nm lamp, and supports our assignment of the transient species observed in time-resolved experiments to silene **2**.

Far-UV flash photolysis of a deoxygenated 8×10^{-4} M solution of **1** in P_2O_5-treated acetonitrile afforded a transient with a similar absorption spectrum to that recorded for **2** in hexane solution, though it is considerably shorter-lived ($\tau = (120 \pm 8)$ ns). Judging from the magnitude of the rate constant for quenching of **2** by methanol in hexane, the short lifetime of the silene in P_2O_5-treated acetonitrile can most likely be attributed

[3] **Note added in proof:** Saturation of hydrocarbon solutions of **1** with oxygen results in only small reductions in the initial strength of the transient absorbance due to **2** at 312 nm. However, new transient absorptions centered at ~250 nm are also produced, probably through reaction of (directly) excited oxygen with the solvent (30). While the decay rate constant at 250 nm does not appear to depend on the presence of 1, it is clear that oxygen is not generally appropriate for use as a transient quencher in 193 nm experiments.

Fig. 1. Transient UV absorption spectrum from far-UV (193 nm) laser flash photolysis of 1,1-dimethylsilacyclobut-2-ene (**1**; 8×10^{-4} M) in deoxygenated hexane solution at 23°C. The spectrum was recorded in point-by-point fashion, 0.1–0.3 μs after the laser pulse. The insert shows a typical decay trace, recorded at a monitoring wavelength of 312 nm.

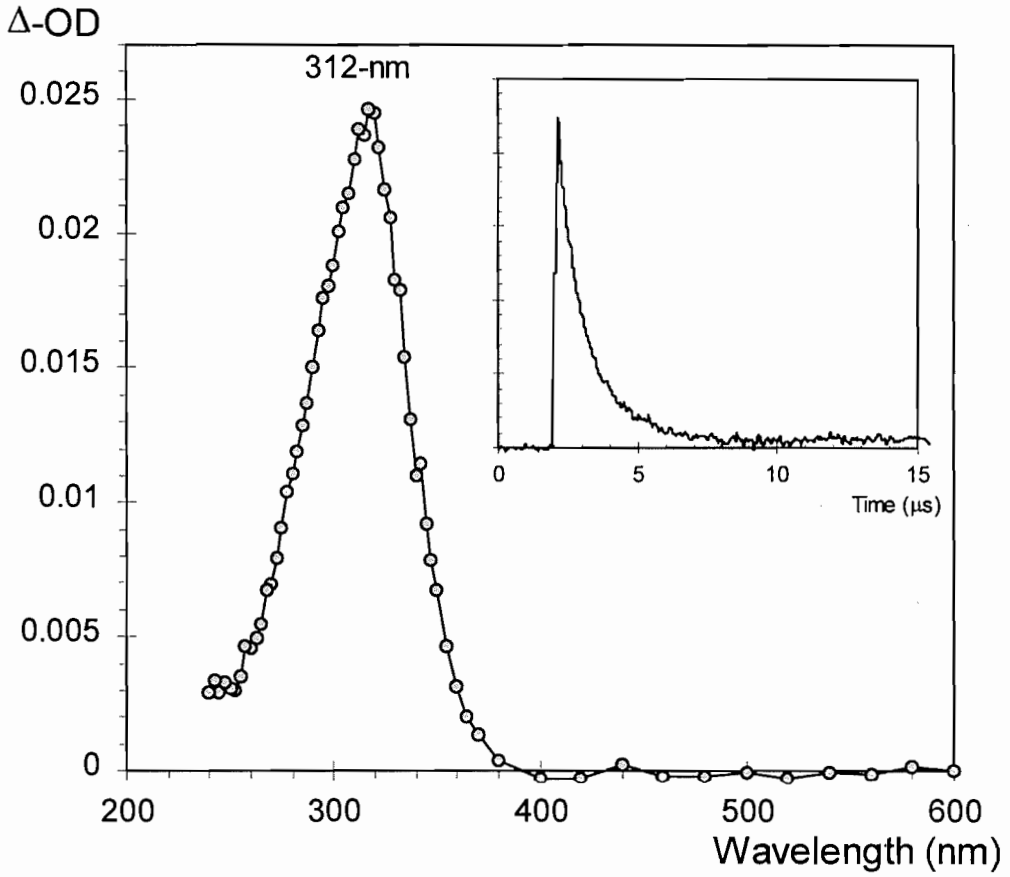

Table 1. Absolute rate constants for quenching of 1,1-dimethyl-1,3-(1-sila)butadiene (**2**) in deoxygenated hexane solution at 23.0 ± 0.2°C.[a]

Quencher	MeOH	MeOD	EtOH	*t*-BuOH	*t*-BuOD	O_2
$k_q/10^9$ M^{-1} s^{-1}	3.6 ± 0.1	2.8 ± 0.2	2.41 ± 0.06	1.8 ± 0.1	1.24 ± 0.04	0.30 ± 0.12

[a]From analysis of k_{decay} vs. concentration data according to eq. [5]. Errors are quoted as twice the standard deviation obtained from linear least-squares analysis of these data.

to the presence of small amounts of water or phosphoric acid (27). Because of the short lifetime of the silene in this solvent, determination of bimolecular quenching rate constants could not be carried out with the same level of precision as those determined for hexane solution. Nevertheless, values of k_q = (2.4 ± 0.4) × 10^9 and (2.8 ± 0.5) × 10^9 M^{-1} s^{-1} for methanol and *tert*-butanol, respectively, were estimated from data recorded over a limited range of alcohol concentrations.

A deoxygenated 0.05 M pentane solution of **1** was irradiated (214 nm) in a merry-go-round apparatus along with a similar solution containing 0.15 M *tert*-butanol, with periodic monitoring of the two solutions by gas chromatography. Over the time period necessary for ~20% consumption of **1** in the solution containing *tert*-butanol, there was no detectable destruction of **1** in the absence of the silene trap. This experiment indicates that the predominant fate of siladiene **2** in the absence of silene traps is thermal electrocyclic ring closure to regenerate the silacyclobutene (**1**).

Decay rate constants for **2** were measured as a function of temperature in deoxygenated isooctane solution, using neutral density filters to reduce the laser intensity sufficiently to produce clean pseudo-first-order transient decays, and a lifetime at 23°C of ~5 μs. Interestingly, the decay rate constant varies only slightly with temperature over the 20–60°C range. The Arrhenius plot for the data obtained in isooctane solution is shown in Fig. 3; least-squares analysis of the data affords activation parameters of E_a = 0.5 ± 0.2 kcal/mol and log A = 5.7 ± 0.2. These values are too small for a thermal electrocyclic ring closure of an acyclic diene system, assuming that the reaction proceeds from the s-*cis* conformer and that the s-*trans*

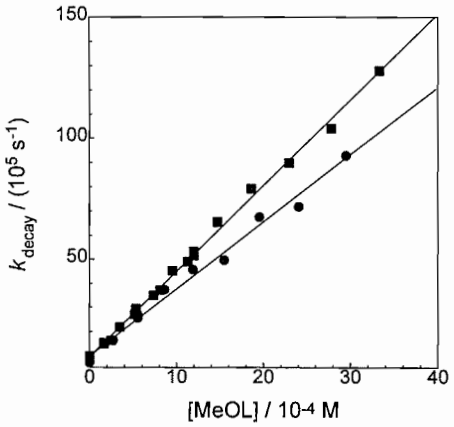
Fig. 2. Plots of k_{decay} versus alcohol concentration for quenching of 1,1-dimethyl-1,3-(1–sila)butadiene (**2**) by methanol (■) and methanol-*O*-*d* (●) in deoxygenated hexane solution at 23°C.



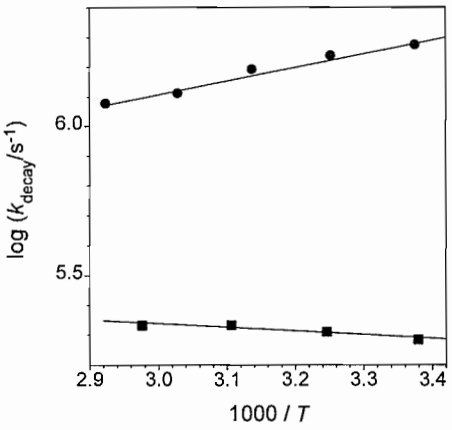


Fig. 3. Arrhenius plots for the pseudo-first-order decay of **2** in deoxygenated isooctane solution (■) and in deoxygenated isooctane containing 6×10^{-4} M methanol (●) over the 20–60°C temperature range, measured by far-UV laser flash photolysis.

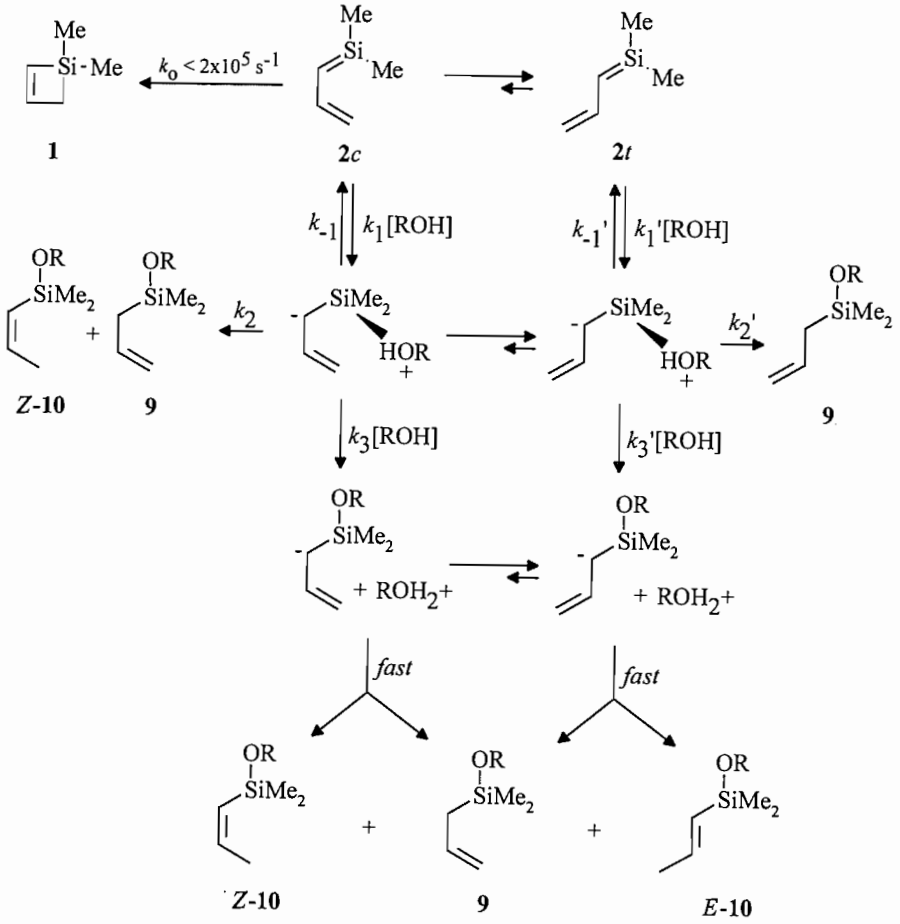
conformer is the thermodynamically favoured one in solution; in such cases, the minimum obtainable value for the activation energy for ring closure will be the difference in enthalpy between the nonreactive s-*trans* and the reactive s-*cis* conformers. AM1 calculations on the individual conformers of **1** predict the s-*trans* conformer to be ~3 kcal/mol more stable than the s-*cis*, a result that is consistent with the results of ab initio calculations on the s-*cis* and s-*trans* conformers of 1,3-(1-sila)butadiene (23).

It is most likely that the pseudo-first-order rate constant for the decay of **2** in isooctane solution is at least partially controlled by impurity quenching, the most probable culprit being water. Assuming a quenching rate constant of $k_q \sim 2 \times 10^9$ M^{-1} s^{-1}, then a concentration of only 10^{-4} M water would be required to produce the observed lifetime of ~5 μs. It should be noted that the presence of such small concentrations of reactive impurities would *not* lead to appreciable consumption of **1** in steady state photolysis experiments, since the bulk concentration of **1** that was employed in these experiments was relatively high (0.05 M).

If this explanation is correct, then the unexpectedly low activation parameters for siladiene decay could result from the combination of a positive activation energy for ring closure with a *negative* activation energy for reaction with water. That the latter is reasonable can be inferred from the reported activation parameters for reaction of 1,1-diphenylsilene (**6**) with alcohols (13), which likely proceeds by an identical mechanism to that of the reaction with water (8). The negative E_a for alcohol addition to **6** has been explained in terms of a two-step mechanism involving reversible, exothermic formation of a silene–alcohol complex followed by rate-limiting proton transfer from oxygen to carbon (13).

This possible explanation was verified indirectly by measuring rate constants for decay of siladiene **2** in deoxygenated isooctane containing 6×10^{-4} M methanol as a function of temperature, the results of which are included in Fig. 3. Under these conditions, the concentration of the alcohol is such that at least 90% of the observed pseudo-first-order decay rate constant is due to bimolecular reaction. The activation energy for the reaction of **2** with methanol is indeed negative; an Arrhenius plot of the bimolecular quenching rate constants (calculated from the k_{decay} values) afford the activation parameters $E_a = -2.6 \pm 0.3$ kcal/mol and $\log A = 7.6 \pm 0.3$.



We conclude that the rapidity with which **2** reacts with trace amounts of hydroxylic impurities precludes a reliable determination of the rate constant for unimolecular reaction of the siladiene in solution, although our data indicate that it is significantly smaller than 2×10^5 s^{-1} at near-ambient temperatures. It is relevant to note that a similar rate constant was reported for the decay of the phenyl-substituted analogue (**3**; see eq. [2]) at ambient temperature and attributed to that of electrocyclic ring closure (7). Clearly, the reported Arrhenius parameters for ring closure of **3**, which were estimated from the single rate constant, are not likely to be meaningful.

The reaction of silenes with alcohols is thought to proceed by a mechanism initiated by reversible nucleophilic attack at silicon to yield a zwitterion (or σ-complex), which collapses to product by competing intra- and intermolecular proton transfer, the latter involving a second molecule of alcohol (8, 11, 13, 14, 28). Arrhenius data and kinetic isotope effect studies for the reaction of methanol and *tert*-butanol with 1,1-diphenylsilene indicate that the first step is exothermic and the intramolecular proton-transfer step, though slower than return of the zwitterion to starting materials, proceeds with a low enough activation enthalpy that the overall reaction exhibits a negative activation energy (13). The kinetic and Arrhenius data reported here for the reaction of siladiene **2** with methanol and *tert*-butanol are entirely consistent with this mechanism.

Intermolecular proton transfer from the zwitterion to a second molecule of alcohol competes with the intramolecular process at high alcohol concentrations, and can lead to concentration-dependent product distributions in appropriate cases (11, 14, 28). The intervention of this pathway in the reaction of **2** with *tert*-butanol was deduced by Steinmetz et al., from a careful study of the variation in product distribution with alcohol concentration (23). A detailed mechanism, illustrating the evolution of the various products of reaction of **2** with *tert*-butanol, is shown in Scheme 1. In terms of product

Scheme 1.

formation, the most important aspect of this mechanism is the fact that adduct *E*-**10** can *only* be formed by a pathway involving two or more molecules of alcohol. Indeed, the yield of *E*-**10** was found to increase quite significantly with increasing *tert*-butanol concentration (23). This result is also consistent with s-*trans* **2** being the favoured conformer in solution, as is suggested by theoretical calculations as well as the UV spectrum reported in the present work.

Conclusions

Despite the limited selection of solvents and quenchers that can be employed with 193-nm excitation, the far-UV nanosecond laser flash photolysis technique is clearly of considerable potential utility. It provides a method for studying the chemistry of a number of small, fundamentally important, reactive intermediates in solution, in cases where the most desirable precursor is devoid of absorption in the spectral range accessible with longer wavelength pulsed lasers, or where its absorption spectrum overlaps substantially with that of the reactive intermediate of interest. In the latter cases, the use of 193 nm excitation allows one to employ solutions of substantially lower concentration than are required for longer wavelength excitation, so that the 200–300 nm spectral range is not screened by the precursor, and transient decay pathways involving reaction with the precursor can be minimized. The ability to employ very low precursor concentrations is also advantageous in cases where it is difficult to obtain the compound in large enough quantities for study by conventional laser flash photolysis techniques. In cases where "kinetic identification" of a transient is required, it must exhibit substantial (i.e., $k_q \geq 10^8\ M^{-1}\ s^{-1}$) reactivity toward water, aliphatic alcohols, silanes, or other reagents that exhibit low absorptivity at the excitation wavelength. A number of reactive intermediates in organic and organosilicon chemistry satisfy this requirement, and are under investigation in our laboratory.

Experimental

^{1}H NMR spectra were recorded on a Bruker AC200 spectrometer in chloroform-*d* solution. Low-resolution mass spectra were recorded on a Hewlett–Packard 5890II gas chromatograph equipped with an HP-5971A mass selective detector and a DB5 fused silica capillary column (30 m × 0.25 mm; Chromatographic Specialties, Inc.). Ultraviolet absorption spectra were recorded on a Perkin Elmer Lambda 9 spectrometer interfaced to a Pentium™ microcomputer. Gas chromatographic (GC) analyses were carried out using a Hewlett–Packard 5890II+ gas chromatograph equipped with a conventional heated injector, a flame ionization detector, a Hewlett–Packard 3396A integrator, and a DB-1 megabore capillary column (15 m × 0.53 mm; Chromatographic Specialties, Inc).

Semi-preparative gas chromatographic separations were carried out using a Varian 3300 gas chromatograph equipped with a thermal conductivity detector and one of the following two columns (Supelco, Inc.): (a) 20% TCEP on 80/100 Chromosorb PNAW (10 ft × 4-mm i.d. glass); (b) 3.8% UCW982 on 80/100 Supelcoport (24 ft × 0.25 in. stainless steel).

Hexane (BDH Omnisolv) and 2,2,4-trimethylpentane (isooctane; BDH Omnisolv) exhibited absorbances of <0.2 at 193 nm in a 3-mm cell, and were distilled once before use. Acetonitrile (Aldrich HPLC) exhibited an absorbance at 193 nm of 0.2 in a 3-mm cell after a single distillation. Purification by reflux over phosphorus pentoxide for several hours followed by distillation (repeating the procedure six times, or until no discolouration of the solvent occurred during the initial reflux period) reduced the absorbance at 193 nm to 0.06 in a 3-mm cell. Methanol, methanol-*O-d*, ethanol, *tert*-butanol, and *tert*-butanol-*O-d* were of the highest purity available and were used as received from Aldrich Chemical Co.

1,1-Dimethyl-(1-sila)cyclobut-2-ene (**1**) was prepared by flash vacuum pyrolysis of dimethyldiallylsilane according to the published method (23, 29). The compound was isolated and obtained in >99% purity (as estimated by capillary GC analysis) after sequential semi-preparative gas chromatography on columns (a) and (b). The spectral and analytical data for the compound were in excellent agreement with those reported previously (23, 29).

Analytical-scale photolyses were carried out using a zinc resonance lamp (214 nm; Philips 93106E), with solutions contained in Suprasil quartz cuvettes (10 mm × 10 mm) and mounted in a merry-go-round apparatus, or the ArF laser (5 Hz repetition rate), with solutions contained in similar cuvettes and clamped ~2 m from the light source. In the latter case, the solutions were stirred during irradiation with a small magnetic stirrer. In all cases, the solutions were deoxygenated prior to photolysis with a stream of dry argon, and sealed with rubber septums. In each case, the course of the photolysis was monitored periodically by GC and (or) GC–MS analysis.

Nanosecond laser flash photolysis experiments employed the pulses (193 nm; ca. 15 ns; 20 mJ) from a Lumonics 510 excimer laser filled with F_2–Ar–He mixtures, and a microcomputer-controlled detection system (26). The laser beam was focussed on the front face of the sample compartment using a single 193-nm dichroic mirror and a Suprasil lens. The total travel distance of the excitation beam is ca. 2 m, which results in a loss of ~50% in power between the source and the sample compartment; the intensity of the beam was reduced to <2 mJ at the cell using a series of stainless steel wire meshes as neutral density filters. The system incorporates a brass sample holder whose temperature is controlled to within 0.1°C by a VWR 1166 constant temperature circulating bath. Solutions were prepared at concentrations such that the absorbance at the excitation wavelength (193 nm) was ca. 0.7 (~8×10^{-4} M), and were flowed continuously through a 3 × 7 mm Suprasil flow cell connected to a calibrated 100 mL reservoir. Nitrogen or nitrogen–oxygen mixtures were bubbled continuously through the reservoir throughout the experiments; the composition of the gas was controlled using a Matheson 7351–600 gas proportioner. Solution temperatures were measured with a Teflon-coated copper–constantan thermocouple that was inserted directly into the flow cell. Quenchers were added directly to the reservoir by microlitre syringe as aliquots of standard solutions. Rate constants were calculated by linear least-squares analysis of decay rate – concentration data (six or more points) which spanned at least one order of magnitude in the transient decay rate. Errors are quoted as twice the standard deviation obtained from the least-squares analysis in each case.

A novel approach to carbohydrate clusters: the regioselective synthesis of non-glycosidically linked oligosaccharides[1]

Hassan Namazi and T. Bruce Grindley

Abstract: Dialkylstannylene acetals derived from a number of different carbohydrates having both *cis*- and *trans*-1,2-diols free were reacted with diacyl chlorides and disulfonyl chlorides in the presence of tertiary amines at room temperature to give symmetrical non-glycosidically linked disaccharides with excellent regioselectivity and in excellent yield. The regioselectivity obtained was the same as that previously found in acylation reactions of the same substrates. In one case, a symmetric non-glycosidically linked trisaccharide was also obtained in excellent yield. For methyl 4,6-*O*-benzylidene-α-D-glucopyranoside, a 16-membered ring macrocyclic tetralactone was obtained in 50% yield by altering the reaction stoichiometry and performing the reaction at 80°C.

Key words: carbohydrates, clusters, non-glycosidically linked oligosaccharides, disaccharides, trisaccharides.

Résumé : La réaction des acétals de dialkylstannylène, obtenus à partir de différents carbohydrates ayant à la fois des 1,2-diols *cis* et *trans* libres, avec le chlorure de sulfonyle en présence d'amines tertiaires à la température ambiante, donne, avec une excellente régiosélectivité et d'excellents rendements, des disaccharides symétriques dont la liaison n'est pas glycosidique. La régiosélectivité obtenue est la même que celle trouvée antérieurement lors des réactions d'acylation avec les mêmes substrats. On a, dans un cas avec un excellent rendement, obtenu un trisaccharide symétrique dont les liaisons ne sont pas glycosidiques. Avec le méthyl 4,6-*O*-benzylidène-α-D-glucopyranoside, on a obtenu une tétralactone macrocyclique à 16 chaînons avec un rendement de 50% en modifiant la stochiométrie de la réaction et en opérant à 80°C.

Mots clés : carbohydrates, aggrégats, oligosaccharides dont les liaisons ne sont pas glycosidiques, disaccharides, trisaccharides.

[Traduit par la rédaction]

Introduction

Although carbohydrate–protein binding plays an important role in biological recognition, the binding constants of proteins for individual carbohydrate molecules are small. Proteins achieve sufficient binding strength to carbohydrates on the surface of antibodies, viruses, bacteria, etc., by clustering the carbohydrate recognition domains of the proteins and also by recognizing clusters of carbohydrate molecules on the surfaces of these entities (2). To develop therapeutic agents that mimic this binding, it will be necessary either to prepare clusters of carbohydrates or to make compounds that attach to the carbohydrate recognition sites on the protein but bind more strongly. Previously described approaches to this problem include synthesis of small native carbohydrate clusters (3), preparation of carbohydrate dendrimers (4, 5), and preparation of carbohydrate mimics (6, 7). Here, we describe a versatile and efficient method for creating carbohydrate clusters. This method creates clusters without having to form glycosidic bonds, often the most difficult step in carbohydrate synthesis and one that is an integral part of the previous carbohydrate-based approaches.

Results and discussion

Dialkylstannylene acetals serve as convenient intermediates for obtaining highly regioselective substitution of diols and polyols (8, 9). We demonstrate here that use of difunctional or trifunctional electrophiles can result in the efficient formation of non-glycosidically linked disaccharides or trisaccharides. For instance, reaction of the dibutylstannylene acetal of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**) with a variety of diacyl chlorides in the presence of triethylamine (TEA) results in non-glycosidically linked disaccharides in a highly regioselective manner and in excellent yield as shown in Fig. 1. These reactions are essentially complete in 5 min at room temperature.

In theory, there are three possible products that contain two monosaccharide segments and one segment arising from a diacyl chloride molecule, namely, the 2,2′-, 2,3′-, and 3,3′-diesters. Methyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-glucopyranoside is known to produce 2-*O*-acylated products with very good regioselectivity on reaction with one equivalent of acyl chloride (8, 9), leading to the expectation that the majority of products should have this regiochemistry. Confirmation of this expectation was obtained unambiguously

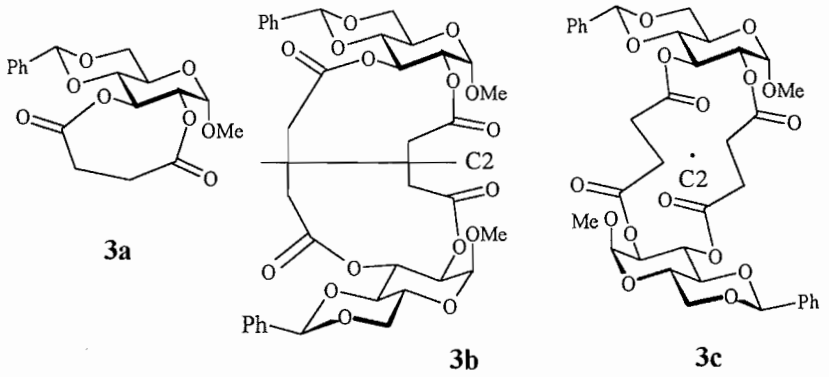
from the ^{1}H NMR spectra of the major products in each case. Those of the symmetric disaccharides contained signals assigned to carbohydrate and assigned to linker that integrated in the ratio of two to one. The signals of all carbohydrate protons were assigned by combinations of first-order analysis, and COSY and HETCOR experiments. It was immediately obvious that the spectra of the major products only contained one type of monosaccharide unit; thus, the products were symmetric, eliminating the 2,3′-diester structure. The location of the acyl linker was determined unambiguously from the identity of the secondary proton that was most deshielded by the presence of the attached acyl group. In addition, in the ^{1}H NMR spectra of carefully dried samples of **2a**, **2b**, and **2c** in dry chloroform-*d*, the signal of the hydroxyl proton appeared as a doublet, coupled to H-3. The fact that the single hydroxyl proton in these compounds is coupled to H-3 was established both by the size of the coupling constants and by COSY experiments. With the largest diacyl dichloride, a second product (**2d**) was obtained in 12% yield. This product was shown to be the 2,3′-diester by means of the lack of symmetry in its ^{1}H and ^{13}C NMR spectra.

These compounds are named here using the new IUPAC–IUBMB rules for carbohydrate nomenclature that redefine how carbohydrates are named as substituents (10*a*); thus, compound **2a** is bis(methyl 4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranosid-2-yl) butanedioate.

Reactions of electrophiles with dialkylstannylene acetals performed in the absence of added nucleophiles often give different regiochemistry (11, 12) or, particularly with *trans*-diols, better regioselectivity than those performed in the presence of base (13), and initial experiments were performed under these conditions. Under these conditions, it was observed that the reactions required about 1 h to be complete at room temperature, much longer than in the presence of added triethylamine. More importantly, a second product (**3**) was obtained in yields of between 5 and 20%. The structure of this product, a cyclic diester dimer that is also a macrocyclic lactone, is shown in Fig. 2.



The structure of **3** was established from its molecular weight, and its NMR spectra. In the ^{1}H NMR spectrum, the signals of both H-2 and H-3 were deshielded by about 1 ppm with respect to their positions in the spectrum of the starting material, appearing at 4.80 and 5.50 ppm, respectively. This information indicated that both O-2 and O-3 were esterified. Integration of the ^{1}H NMR spectrum indicated that the ratio of succinyl units to monosaccharide units was 1:1. By changing the stoichiometry to 1:1, and by running the reaction at a higher temperature and under more dilute conditions, it was possible to raise the yield of this minor product (**3**) to 50%.

Monomeric and oligomeric structures were possible for **3** (see Fig. 3). No peaks at the monomer molecular weight (*m*/*z* 364) were present in the mass spectra of **3** recorded under a wide range of conditions (EI, electrospray, APCI) but a peak

Fig. 3. The structures of possible monomeric (**3a**) and dimeric (**3b** and **3c**) products containing methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**) and succinate in a 1:1 stoichiometry.

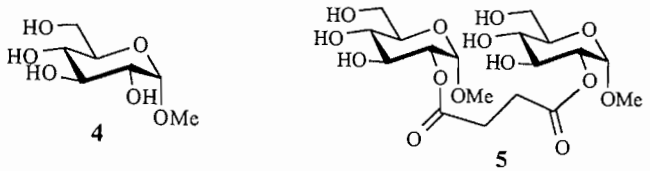
did occur at M^+ for the dimer (*m/z* 728) along with others between the dimer M^+ and 364 (*m/z* 411 and 368). This molecular ion peak had the correct exact mass. No peaks were observed at masses above *m/z* 730, confirming that the structure was not a higher oligomer. Two dimeric structures are possible, one in which the succinyl groups are linked through the same oxygen atoms on the two monosaccharides (O-2 to O-2′, and O-3 to O-3′) (**3b**), another, in which different oxygen atoms are linked (O-2 to O-3′, and O-3 to O-2′) (**3c**). Both potential dimers have C_2 symmetry, as indicated in Fig. 3. For **3b**, the C_2 axis relates the two CH_2 groups in each succinyl group but does not relate the two succinyl chains. For **3c**, the C_2 axis relates the two succinyl chains to each other but does not relate the CH_2 groups inside each succinyl chain. Since the two hydrogens in each CH_2 group are diastereotopic, the ^1H NMR spectrum of **3b** should contain two different AA′BB′ patterns, whereas that of **3c** should contain one ABCD pattern, which would also be observed for the monomer (**3a**). The complex region of the 400.14 MHz ^1H NMR spectrum of **3** assigned to the succinyl hydrogens was observed to contain two overlapping AA′BB′ patterns, and this was proven by simulation using the program LAME8 (14) (see Fig. 4). Thus, of the three possible structures considered for **3**, only dimeric structure **3b** fits the NMR data. Higher oligomers having both the correct symmetry and even numbers of glucose units would also give two AA′BB′ patterns but can be ruled out by the mass spectral data. The structure of the product suggests that **2a** or a mono- or di-chlorodibutyltin ether of **2a** is an intermediate in its formation, rather than a diesterified monosaccharide.



Compound **3b** was particularly difficult to name. The name used, (bis(methyl 4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranosyl-2,3-diyl 2,2′:3,3′-butanedioate), contains modifiers of the principle functional group that are not included in the most recent rules (10*a*). However, these modifiers, which come from the previous rules (10*b*), are necessary to distinguish **3b** from **3a**.

Non-glycosidically linked disaccharides were also formed easily using aromatic acyl dichlorides. Compound **1** reacted with 0.43 equivalent of terephthaloyl chloride and phthaloyl dichloride in the presence of triethylamine to give the 2,2′ diester-linked disaccharides **2e** and **2f** in 95 and 81% yields, respectively (see Fig. 5 for structures) .

The ^1H and ^{13}C NMR spectra of **2e** displayed unusual concentration- and temperature-dependent features in chloroform-*d* (see Fig. 6). All non-aromatic signals in the 400.14 MHz ^1H NMR spectrum of a 0.016 M solution at room temperature were broadened. However, lowering the concentration to 0.008 M caused all signals to become sharp. This unusual effect must be caused by self-association and the precise nature of the association is currently under investigation. Effects like this were not observed for any of the other compounds studied.

In the same way, use of polyfunctional electrophiles leads to non-glycosidically linked oligosaccharides regioselectively in good yield. Reaction of **1** with 1,3,5-benzenetricarbonyl trichloride gave the corresponding non-glycosidically linked trisaccharide (**2g**) in excellent yield as shown in Fig. 7.

Formation of a non-glycosidically linked disaccharide from methyl α-D-glucopyranoside (**4**) had to be performed under conditions different than those above because of its lack of solubility in nonpolar solvents. Refluxing **4** with 1 equivalent of dibutyltin oxide in methanol gave a dibutylstannylene acetal derivative that was carefully dried, then reacted with succinyl chloride in dioxane to give a good yield (72%) of the symmetric 2,2′-linked disaccharide (**5**) plus a small amount (5%) of a syrupy product that was tentatively identified as a monomethyl ester, presumably arising from the residual methanol.

Another *trans*-diol was investigated, benzyl 4,6-*O*-benzylidene β-D-galactopyranoside (**6**). It also gave an excellent yield (78%) of a symmetric non-glycosidically linked disaccharide (**7**), joined through O-3, the site at which electrophiles are known to react with the dibutylstannylene acetal of **6**.

Similar reactions were conducted with the dibutylstannylene acetals derived from two *cis*-diols. Dibutylstannylene acetals derived from *cis*-diols on pyranose rings normally give highly regioselective reactions with electro-

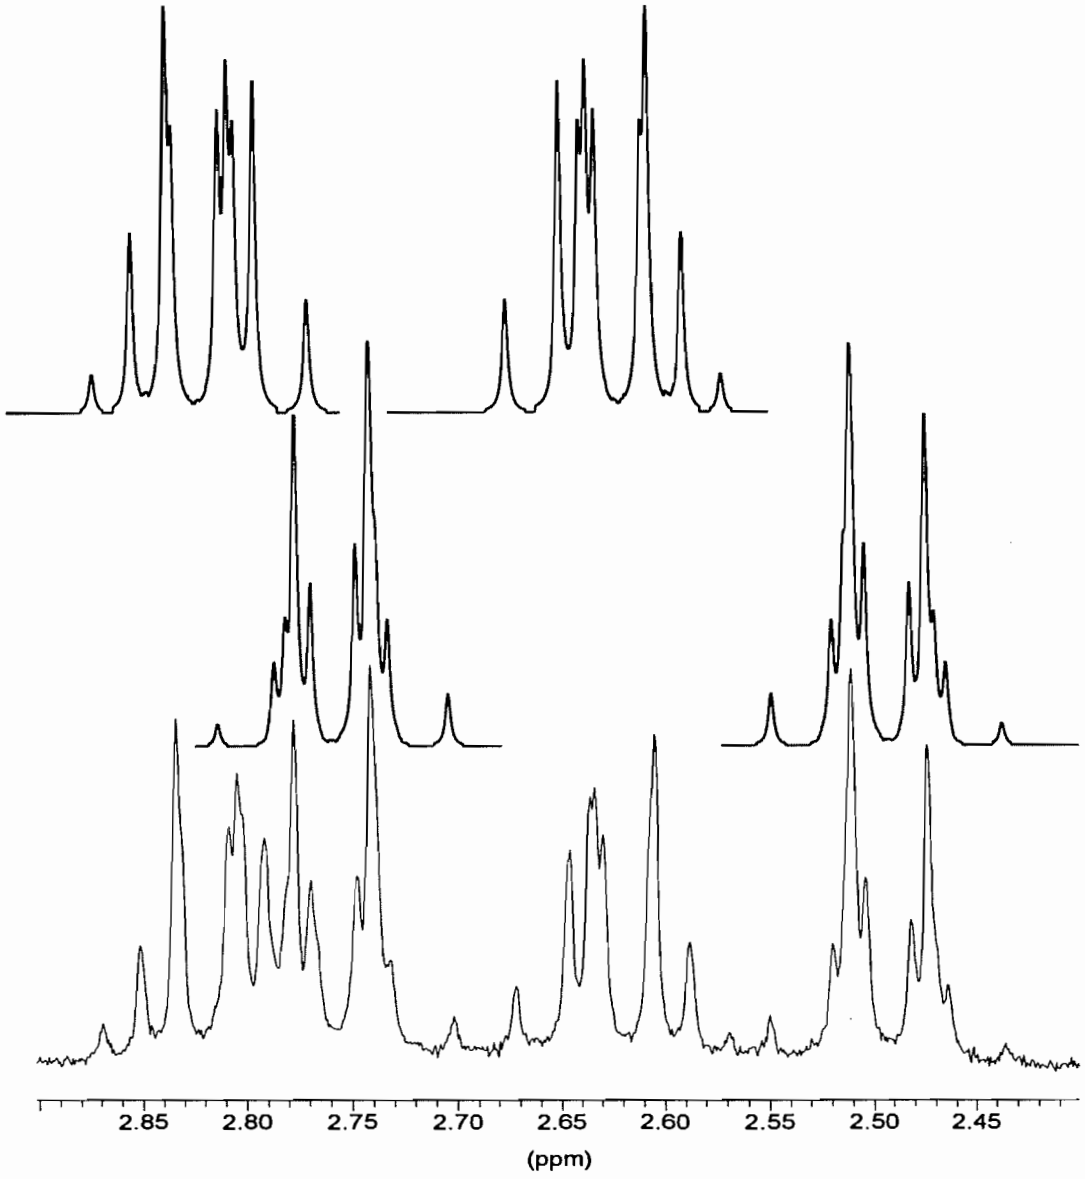
Fig. 4. The region of the 400.14 MHz NMR spectrum of **3** (see Fig. 3 for possible structures) containing the signals of the two CH_2CH_2 groups: bottom, experimental spectrum; middle, LAME8 simulation of one AA′BB′ pattern; top, LAME8 simulation of the other AA′BB′ pattern. The iterative simulations were performed using the transitions from resolution-enhanced spectra. The simulations shown have a slightly narrower line width than the experimental spectrum to emphasize the extra peaks observed in the resolution-enhanced spectra.



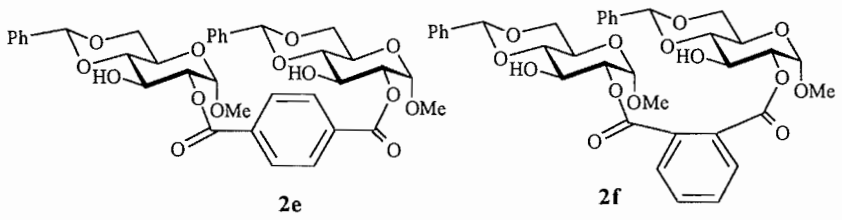


Fig. 5. Structures of products obtained from reactions of the dibutylstannylene acetal of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**) with aromatic diacyl chlorides.

philes, favouring reaction on equatorial oxygen atoms over the axial oxygen atoms (8, 9) although exceptions have been observed, particularly with mannopyranose derivatives (11), and when the *cis*-diol is flanked by two axial substituents (15). These trends were followed here; methyl 4,6-*O*-benzylidene-α-D-allopyranoside (**8**) was converted to a symmetric non-glycosidically linked disaccharide (**9**) in a highly regioselective manner and in excellent yield (97%) but methyl 4,6-*O*-benzyl-

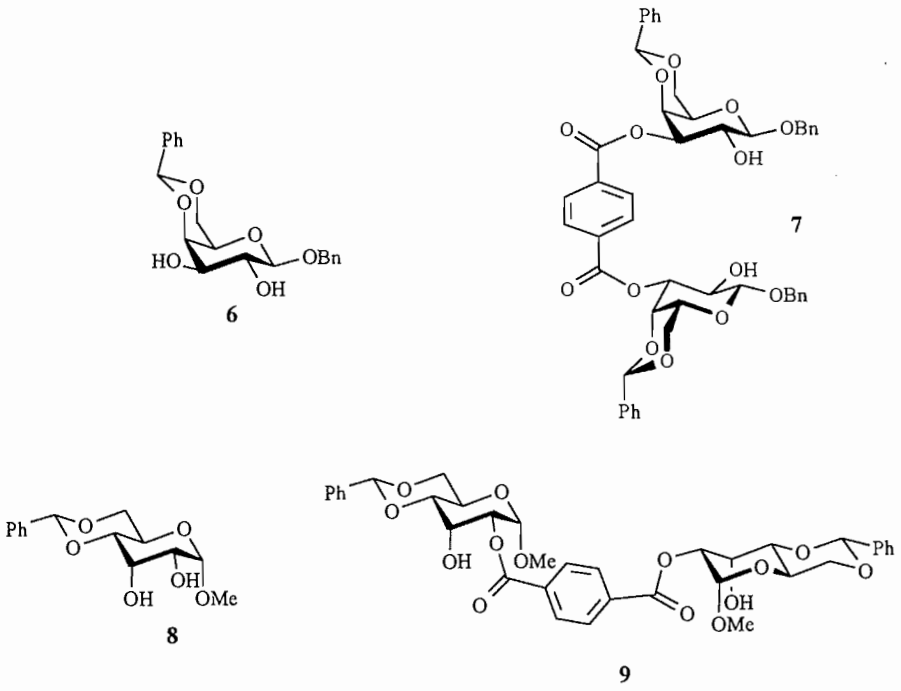

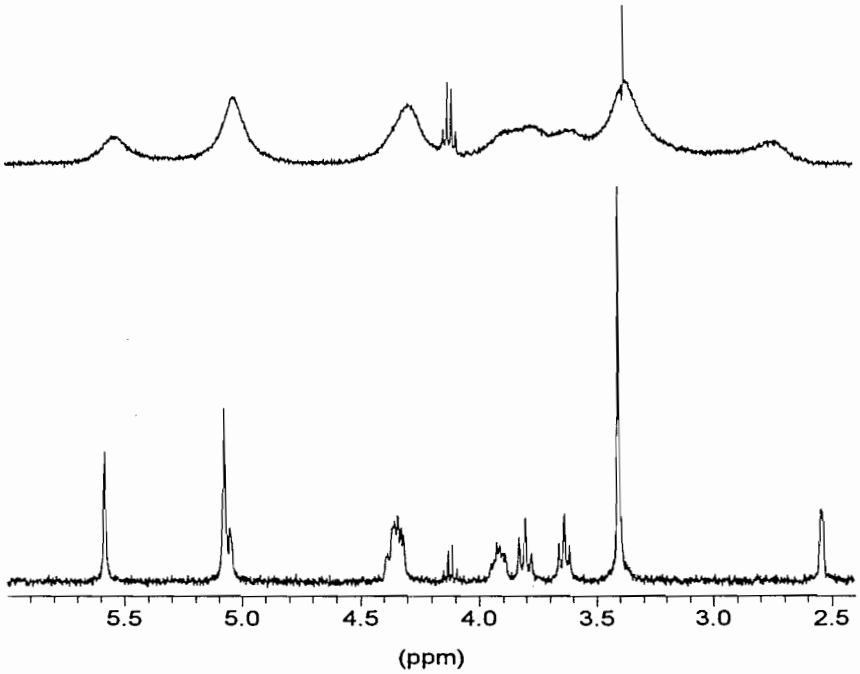

Fig. 6. The 400.14 MHz ^{1}H NMR spectra of bis(methyl 4,6-*O*-benzylidene-α-D-glucopyranoside) 2,2′-terephthalate (**2e**, see Fig. 5 for structure) in chloroform-*d* at two different concentrations: top, 0.016 M; bottom, 0.008 M. For assignments, see the experimental section.

idene-α-D-mannopyranoside (**10**) gave mixtures that varied with the reaction conditions as discussed below.

The reactions of the dibutylstannylene acetal of methyl 4,6-*O*-benzylidene-α-D-mannopyranoside (**10**) with adipoyl chloride under several different conditions are shown in Fig. 8. The structures of these products were established as above. In the reaction performed without added base, TLC evidence suggested that the initial product, the 2,2′-linked dimer (**11a**), rearranged as the reaction progressed. Similar rearrangements were observed in the benzoylation of the dialkylstannylene acetals of primary/secondary diols (16). Under these conditions, where acylation is slowest, the non-glycosidically linked disaccharides were obtained as a close to statistical distribution of 2,2′, 2,3′, and 3,3′ diesters. A monomer (**12**) was

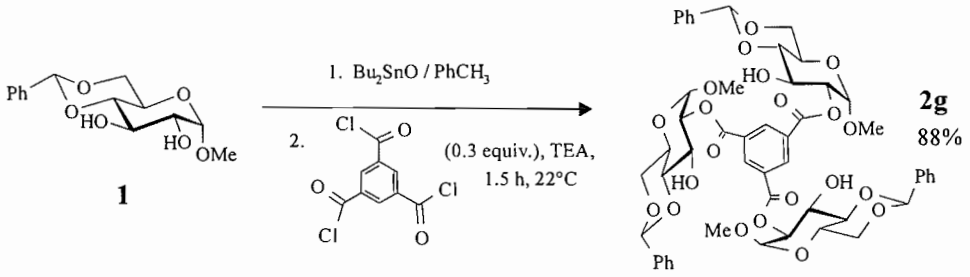
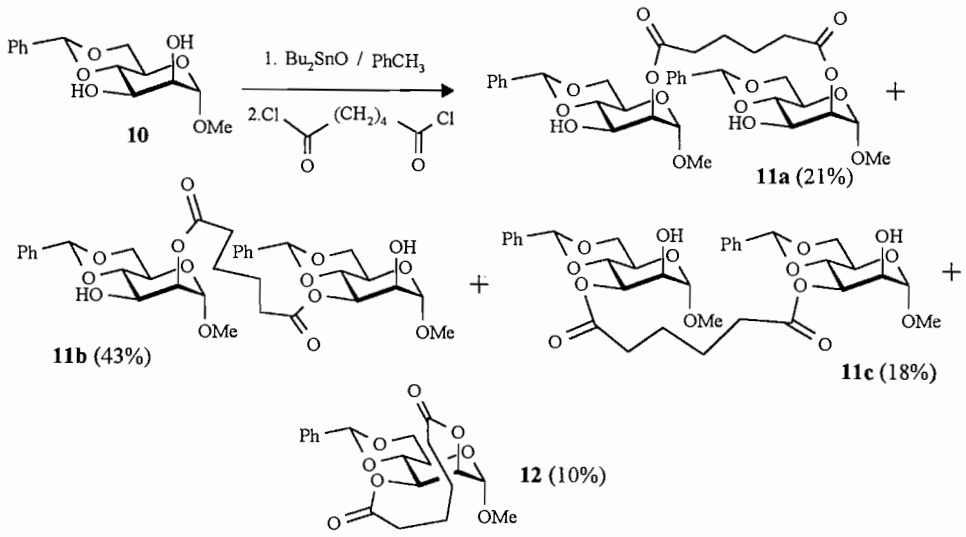
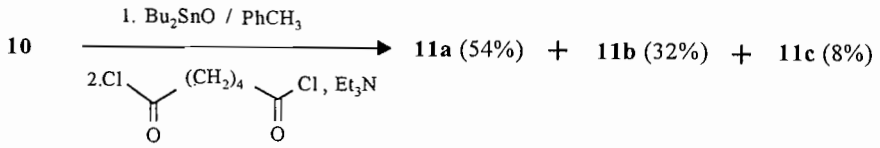
Fig. 7. The reaction of the dibutylstannylene acetal of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**) with 1,3,5-benzenetricarbonyl trichloride.







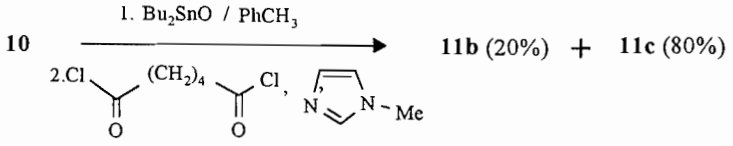


Fig. 8. The reactions of methyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-mannopyranoside with adipoyl chloride under various conditions.

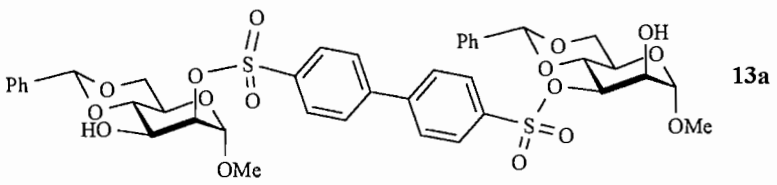
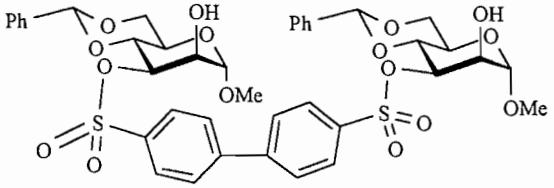


also obtained under these conditions in 10% yield. It was clearly demonstrated to be a monomer, rather than a doubly linked dimer with the same stoichiometry of adipoyl to sugar, by the presence of a M^+ peak (16%) in its EI mass spectrum. Apparently, the succinoyl linkage is too short to form an internal cyclic diester with the dibutylstannylene acetal derived from a *trans*-diol whereas an adipoyl linkage can assume the requisite geometry to give this type of diester with that from a *cis*-diol.

The best yield of a symmetrical non-glycosidically linked disaccharide, the 3,3′-linked compound (**11c**), was obtained from the *O*-dibutylstannylene acetal of **10** using *N*-methylimidazole as an added nucleophile, consistent with the observations of Holzapfel et al. on the benzoylation of the same compound (11). Interestingly, the best yield of the 2,2′-non-glycosidically linked disaccharide (**11a**) was obtained from **10** using triethylamine as an added nucleophile but conditions were never found that yielded a single product from this starting material.



Reactions were also performed on the 2,3-*O*-dibutylstan-

nylene acetal of **10** with 4,4′-biphenyldisulfonyl dichloride. It had been found previously that sulfonates do not rearrange during reactions with dialkylstannylene acetals (16). The major product (93% yield) obtained in this reaction, performed in the presence of *N*-methylimidazole, was the 3,3′-non-glycosidically linked disaccharide (**13b**). Compound **13a** has the same regiochemistry as that of the major product obtained in the benzoylation of the dibutylstannylene acetal of **3** performed in the presence of added base (11). It should be noted that the structure of this compound was erroneously reported as the 2,2′-dimer in the preliminary communication (1). A small amount of the non-symmetrically substituted disaccharide (**13a**) was also obtained (5%).

Repetitive application of reactions of this type could result in the rapid formation of large clusters. Valverde et al. have recently shown that carbohydrates having single free hydroxyl groups can be reacted with anhydrides and the product acids converted to acid chlorides, which then can be reacted with stannylene acetals of other sugars to produce nonsymmetric non-glycosidically linked disaccharides with some of the same linkers as employed here (17). Hanessian et al. had earlier made an ester-linked pentaerythritol-centered cluster by first reacting benzyl 2,3,4-tri-*O*-benzyl-α-D-glucopyranoside with succinic anhydride, then esterifying 4 equivalents of the resulting carboxylic acid with pentaerythritol and DCC (18). Combination of the two-step nonselective method used by these two groups with our regioselective one-step approach will make a wide range of clusters available. The availability of a wide variety of possible linkers potentially allows adjustment of the distance between biologically active carbohydrate units to match that required for efficient binding. Investigations of some of these possibilities are in progress.

Conclusions

Symmetrical non-glycosidically linked disaccharides can be prepared with excellent regioselectivity and in excellent yield by reaction of dialkylstannylene acetals with diacyl chlorides and disulfonyl chlorides in the presence of tertiary amines at room temperature. The regioselectivity obtained is the same as previously observed for reaction of acyl chlorides with diols. Formation of diesters is a minor competing reaction that can be minimized by making the initial esterification as fast as possible through addition of added nucleophiles or bases and by controlling the stoichiometry by keeping the diacyl chloride concentration somewhat less than one-half that of the dialkylstannylene acetal. Diester formation is enhanced by using a 1:1 stoichiometry, raising the temperature, and conducting the reaction in the absence of added nucleophiles. Examples of diesters that are cyclic monomers and macrocyclic dimers were observed. Which is obtained depends on the structure of the carbohydrate (*cis*- or *trans*-diol) and on that of the diacyl chloride.

Experimental

General methods

Melting points were determined using a Fisher–Johns melting point apparatus and were uncorrected. Optical rotations were measured with a Perkin–Elmer 141 polarimeter. Thin-layer chromatography (TLC) was performed on Silica Gel aluminium sheets (60 PF-254, Merck, or Al Sil G/UV, Whatman) cut to be approximately 7 cm long, using solvent mixtures measured on a v/v basis. After chromatography was performed, components were located by examination under UV light and by spraying with 2% ceric sulfate in 12 M sulfuric acid and heating on a hot plate until colouration took place. Elemental analyses were performed by Canadian Microanalytical Service Ltd., Vancouver, B.C. Purification or separation of compounds was carried out with "dry column" flash chromatography on silica gel 60 (avg. particle size 2–5μm, Aldrich). Unless otherwise noted, ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC-250F spectrometer operating at 250.13 and 62.9 MHz, respectively, at ambient temperature on solutions in chloroform-*d*. One ^{1}H NMR spectrum was recorded with a Bruker AMX-400 NMR spectrometer at 400.14 MHz. Chemical shifts are expressed in ppm and referenced to internal Me_4Si (0.03%) or to the central line of the solvent: chloroform-*d* (δ_C = 77.0), dimethyl sulfoxide-d_6 (δ_H = 2.49 and δ_C = 39.7), benzene-d_6 (δ_H = 7.15 and δ_C = 128.0). Assignments and magnitudes of coupling constants were obtained for ^{1}H NMR spectra by first-order analyses and confirmed by COSY experiments. In some cases, HETCOR experiments also aided in assignment. The appearance of signals is indicated using the designations b, s, d, t, q, p, and m for broad, singlet, doublet, triplet, quartet, pentet, and multiplet, respectively. ^{13}C NMR spectral assignments were confirmed by JMD and HETCOR experiments. Accurate mass measure-

ments were made on Fisons VG ZAB-EQ (FAB) or Dupont-CEC 21-110 (EI) double focussing mass spectrometers at an accuracy of 3 ppm by voltage scanning using PEG Na and PFK reference ions, respectively. APCI or electrospray mass spectra were recorded on a Fisons VG Quattro mass spectrometer. All solvents used in experiments and also in column chromatography were dried and purified by standard methods and distilled before use. Methyl α-D-glucopyranoside, methyl α-D-mannopyranoside, and linker reagents were purchased from Aldrich.

General method for preparation of dibutylstannylene acetals

Unless otherwise stated, the specified monosaccharide 1,2-diol (1 mmol) and dibutyltin oxide (1.1 mmol) were refluxed for 12 h in toluene (20 mL) with continuous azeotropic removal of water. The reaction solution was concentrated to 12 mL and the residue was used directly without further purification for the synthesis of the oligosaccharide with the specified spacer reagent.

Standard work-up

Water (2 mL) was added to the reaction mixture in toluene and the mixture was stirred for 1 h at room temperature, then diluted with chloroform (15 mL). The organic layer was washed with a dilute solution of hydrochloric acid (0.1 M, 5 mL), with water (2 × 15 mL), and with a saturated solution of sodium bicarbonate (15 mL), unless otherwise mentioned, then dried over magnesium sulfate and concentrated.

*Bis(methyl 4,6-O-benzylidene-2-deoxy-α-D-glucopyranosid-2-yl) butanedioate (**2a**)*

Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**1**) (19) (0.423 g, 1.5 mmol) was reacted with dibutyltin oxide (0.441g, 1.65 mmol) as in the general method to give the dibutylstannylene acetal. The stirred solution was cooled to room temperature and triethylamine (230 μL, 1.65 mmol) was added. After 0.5 h, a solution of freshly distilled succinyl chloride (72 μL, 0.652 mmol) in toluene (1 mL) was added slowly. The colour of the solution gradually changed to dark brown. Standard work-up after 30 min was followed by purification of the residue by dry column flash chromatography using a solvent gradient from cyclohexane to cyclohexane/ethyl acetate 1:5 as eluent. The product, a solid, was recrystallized from ethyl acetate and cyclohexane to give fine colourless needles of the title compound (**2a**); mp 117–118°C, R_F = 0.25 (ethyl acetate: hexane; 1:1), yield 0.383 g (91%); $[\alpha]_D^{24}$ +76.7 (*c* 1.25, chloroform); ^{1}H NMR δ: 2.72 (s, 4H, 2 × CH_2), 3.38 (s, 6H, 2 × OMe), 3.52 (t, 2H, $J_{4,5} = J_{3,4}$ = 8.9 Hz, 2 × H-4), 3.72 (t, 2H, $J_{5,6a} = J_{6a,6e}$ = 10.1 Hz, 2 × H-6_{ax}), 3.82 (td, 2H, $J_{5,6a} = J_{4,5}$ = 9.6 Hz, $J_{5,6e}$ = 4.2 Hz, 2 × H-5), 4.15 (t, 2H, $J_{2,3} = J_{3,4}$ = 9.2 Hz, 2 × H-3), 4.26 (X of ABX pattern, 2H, 2 × H-6_{eq}), 4.79 (dd, 2H, $J_{2,3}$ = 9.5 Hz, $J_{1,2}$ = 4.0 Hz, 2 × H-2), 4.90 (d, 2H, $J_{1,2}$ = 3.7 Hz, 2 × H-1), 5.51 (s, 2H, 2 × PhCH), 7.26–7.58 (m, 10H, 2 × ArH); ^{13}C NMR δ: 29.2 (2C, 2 × CH_2), 55.3 (2C, 2 × OMe), 62.0 (2C, 2 × C-5), 68.4 (2C, 2 × C-3), 68.7 (2C, 2 × C-6), 73.9 (2C, 2 × C-2), 81.1 (2C, 2 × C-4), 97.4 (2C, 2 × C-1), 101.9 (2C, 2 × PhCH), 126.2, 128.1, 129.2 (6C, 2 × Ar-C), 136.9 (2C, 2 × Ar-C_{ipso}), 172.0 (2C, 2 × COO). Anal. calcd. for $C_{32}H_{38}O_{14}$: C 59.44, H 5.92; found: C 59.12, H 5.95.

*Bis(methyl 4,6-O-benzylidene-2-deoxy-α-D-glucopyranosid-2-yl) hexanedioate (**2b**)*

Compound **1** (0.564 g, 2 mmol) was reacted with dibutyltin oxide (0.523 g, 2.1 mmol) as in the standard method. The solution was concentrated to 15 mL and triethylamine (297 μL, 2.1 mmol) was added to the stirred room temperature solution. After 30 min, the solution was cooled to 0°C and freshly distilled adipoyl chloride (98 μL, 0.67 mmol) was added dropwise. The cooling bath was removed 30 min later, then the reaction was stopped after a further 20 min and worked up in the standard fashion. Dry column flash chromatography (gradient from cyclohexane to ethyl acetate) gave the title compound (**2b**) as a solid: R_F = 0.23 (ethyl acetate/hexanes 1:1); yield 0.380 g (84%); mp 165–166°C; $[\alpha]_D^{22}$ +102 (*c* 1.08, chloroform); ^{1}H NMR δ: 1.71 (b m, 4H, 2 × $CH_2CH_2CH_2$), 2.43 (b m, 2 × CH_2CO), 2.94 (d, 2H, $J_{3,OH\text{-}3}$ = 3.1 Hz, 2 × OH-3), 3.37 (s, 6H, 2 × OMe), 3.53 (t, 2H, $J_{4,5} = J_{3,4}$ = 9.2 Hz, 2 × H-4), 3.74 (t, 2H, $J_{5,6ax} = J_{6eq,6ax}$ = 9.8 Hz, 2 × H-6_{ax}), 3.82 (td, 2H, $J_{5,6eq}$ = 4.3 Hz, $J_{4,5} = J_{5,6ax}$ = 9.8 Hz, 2 × H-5), 4.15 (dt, 2H, $J_{2,3} = J_{3,4}$ = 9.5 Hz, 2 × H-3), 4.27 (X of ABX pattern, 2H, 2 × H_{6eq}), 4.81 (dd, 2H, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.8 Hz, 2 × H-2), 4.93 (d, 2H, 2 × H-1), 5.53 (s, 2H, 2 × PhCH), 7.32–7.52 (m, 10H, 2 × Ar-H); ^{13}C NMR δ: 24.0 (2 × $CH_2CH_2CH_2$), 33.6 (2 × CH_2CO), 55.3 (2 × OMe), 62.0 (2 × C-5), 68.5 (2 × C-3), 68.8 (2 × C-6), 73.5 (2 × C-2), 81.3 (2 × C-4), 97.5 (2 × C-1), 101.9 (2 × PhCH), 126.3, 128.3, 129.2 (Ar-C), 136.9 (2 × Ar-C_{ipso}), 173.1 (2 × COO). Anal. calcd. for $C_{34}H_{42}O_{14}$: C 60.53, H 6.27; found: C 60.76, H 6.34.

*Bis(methyl 4,6-O-benzylidene-2-deoxy-α-D-glucopyranosid-2-yl) dodecanedioate (**2c**)*

Treatment of compound **1** (0.564 g, 2 mmol) with dibutyltin oxide (0.523 g, 2.1 mmol) as in the standard method gave the dibutylstannylene acetal. The reaction mixture was concentrated to 15 mL and triethylamine (297 μL, 2.1 mmol) was added. After 0.5 h, the solution was cooled to 0°C and freshly distilled dodecanedioyl chloride (175 μL, 0.7 mmol) was added dropwise to the magnetically stirred solution. The cooling bath was removed after 30 min and 1 h later the reaction was quenched by adding water. Standard work-up yielded a syrupy residue that was fractionated by means of dry column flash chromatography using ethyl acetate/cyclohexane 2:1 as eluent. The first fraction was the title compound (**10**), a solid, R_F = 0.76 (ethyl acetate/cyclohexane, 2:1); yield 0.415 g (78%); mp 123–124°C; $[\alpha]_D^{23}$ +256 (*c* 0.29, chloroform); ^{1}H NMR δ: 1.28 (b, 12H, 6 × CH_2), 1.65 (b p, *J* = 7 Hz, 4H, 2 × CH_2CH_2CO), 2.40 (t, 4H, *J* = 7.3 Hz, 2 × CH_2CO), 2.50 (d, 2H, $J_{3,OH\text{-}3}$ = 3.1 Hz, 2 × OH-3), 3.39 (s, 6H, 2 × OMe), 3.55 (t, 2H, $J_{3,4} = J_{4,5}$ = 9 Hz, 2 × H-4), 3.75 (t, 2H, $J_{5,6ax} = J_{6ax,6eq}$ = 9.8 Hz, 2 × H-6_{ax}), 3.84 (td, 2H, $J_{5,6e}$ = 4.2 Hz, $J_{4,5} = J_{5,6a}$ = 9.7 Hz, 2 × H-5), 4.17 (td, 2H, $J_{2,3} = J_{3,4}$ = 9.3 Hz, $J_{3,OH}$ = 2.8 Hz, 2 × H-3), 4.29 (dd, 2H, 2 × H-6_{eq}), 4.80 (dd, 2H, 2 × H-2), 4.97 (d, 2H, $J_{1,2}$ = 4.0 Hz, 2 × H-1), 5.54 (s, 2H, 2 × PhCH), 7.36–7.42 (m, 6H, Ar-H), 7.46–7.51 (m, 4H, Ar-H); ^{13}C NMR δ: 24.8 (2 × CH_2CH_2CO, 28.9, 29.1, 29.3 (6 × CH_2), 34.4 (2 × CH_2CO), 55.4 (2 × OMe), 61.9 (2 × C-5), 68.6 (2 × C-3), 65.8 (2 × C-6), 73.4 (2 × C-2), 81.3 (2 × C-4), 97.5 (2 × C-1), 102.0 (2 × PhCH), 126.3, 128.3, 129.3 (Ar-C), 136.9 (2 × Ar-C_{ipso}), 173.5 (2 × COO). Anal. calcd. for $C_{40}H_{54}O_{14}$: C 63.31, H 7.17; found: C 62.94, H 6.81.

Further elution gave (methyl 4,6-*O*-benzylidene-2-

deoxy-α-D-glucopyranosid-2-yl) (methyl 4,6-*O*-benzylidene-3-deoxy-α-D-glucopyranosid-3-yl) dodecanedioate (**2d**), a solid, recrystallized from ethyl acetate – cyclohexane, mp 134–135°C; R_F = 0.57 (ethyl acetate:cyclohexane, 2:1); yield 0.065 g (12%); $[\alpha]_D^{23}$ +171 (*c* 0.39, chloroform); ^{1}H NMR δ: 1.17–1.33 (m, 12H, 6 × CH_2), 1.56–1.70 (m, 5H, 2 × CH_2CH_2CO), 2.32(d, 1H, $J_{2',OH\text{-}2'}$ = 11.6 Hz, OH-2′), 2.36, 2.40 (2 t, 4H, *J* = 7.5 Hz, 2 × CH_2CO), 2.60 (br d, 1H, $J_{3,OH\text{-}3}$ = 2.2 Hz, OH-3), 3.39 (s, 3H, OMe), 3.45 (s, 3H, OMe′), 3.56 (t, 1H, $J_{3,4} = J_{4,5}$ = 9.3 Hz, H-4), 3.71 (t, 1H, $J_{3',4'} = J_{4',5'}$ = 9.5 Hz, H-4′), 3.65 (ddd, 1H, $J_{1',2'}$ = 3.8 Hz, $J_{2',3'}$ = 9.8 Hz, $J_{2',OH\text{-}2'}$ = 11.6 Hz, H-2′), 3.74 (t, 1H, $J_{5',6'ax} = J_{6'eq,6'ax}$ = 10.1 Hz, H-6′$_{ax}$), 3.76 (t, 1H, $J_{5,6ax} = J_{6eq,6ax}$ = 9.8 Hz, H-6$_{ax}$), 3.84, 3.86 (2 td, 2H, $J_{5,6e}$ = 3.4 Hz, $J_{4,5} = J_{5,6a}$ = 10.0 Hz, H-5 and H-5′), 4.17 (td, 1H, $J_{2,3} = J_{3,4}$ = 9.5 Hz, $J_{3,OH\text{-}3}$ = 2.2 Hz, H-3), 4.30 (dd, 2H, $J_{6eq,6ax} = J_{6'eq,6'ax}$ = 9.5 Hz, $J_{5,6eq} = J_{5',6'eq}$ = 4.0 Hz, H-6$_{eq}$ and H-6′$_{eq}$), 4.78 (d, 1H, $J_{1',2'}$ = 3.8 Hz, H-1′), 4.81 (dd, 1H, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.8 Hz, H-2), 4.95 (d, 1H, $J_{1,2}$ = 4.0 Hz, H-1), 5.33 (t, 1H, $J_{2',3'} = J_{3',4'}$ = 9.6 Hz, H-3′), 5.49 (s, 1H, PhCH′), 5.55 (s, 1H, PhCH), 7.33–7.52 (m, 10H, Ar-H and Ar′-H); ^{13}C NMR δ: 24.8, 25.0 (2 × CH_2CH_2CO), 28.8, 28.9, 29.1, 29.2, 29.3 (5 × CH_2), 34.0, 34.3 (2 × CH_2CO), 55.4, 55.5 (2 × OMe), 61.9 (C-5), 62.6 (C-5′), 68.6 (C-3), 68.8 (C-6 and C-6′), 71.8 (C-2′), 72.0 (C-3′), 73.3 (C-2), 78.6 (C-4′), 81.3 (C-4), 97.5 (C-1), 100.1 (C-1′), 101.4, 101.9 (2 × CHPh), 126.1, 126.3, 128.1, 128.3, 129.0, 129.2 (Ar-C), 136.91, 136.94 (Ar-C_{ipso}), 173.5, 173.9 (COO); Anal. calcd. for $C_{10}H_{54}O_{14}$: C 63.31, H 7.17; found: C 63.05, H 7.12.

*Bis(methyl 4,6-O-benzylidene-2-deoxy-α-D-glucopyranosid-2,3-diyl 2,2′:3,3′-butanedioate) (**3**)*

Compound **1** (0.423 g, 1.5 mmol) was reacted with dibutyltin oxide (0.373 g, 1.5 mmol) in toluene (20 mL) as in the general method. Toluene (350 mL) was added and the resulting solution was heated to 80°C. Succinyl chloride (1.5 mmol, 164 μL) in toluene (5 mL) was added dropwise to the solution stirred at that temperature. The reaction was stopped after 10 h and worked up as in the standard method. The solid residue were separated by means of dry column flash chromatography using a gradient from cyclohexane to ethyl acetate as eluent. The first fraction was present in very small amounts and was not identified. The second fraction was the title compound (**3**), a solid, which was recrystallized from ethyl acetate and cyclohexane; mp 209–210°C; yield 0.275 g (50%); R_F = 0.5 (ethyl acetate: hexane; 1:1); $[\alpha]_D^{23}$ +52.2 (*c* 0.465, chloroform); ^{1}H NMR (400.14 MHz) δ: 2.493, 2.757 (AA′XX′ pattern, 4H, $J_{AX} = J_{A'X'}$ = −17.3 Hz, $J_{AX'} = J_{A'X}$ = 2.4 Hz, $J_{AA'}$ = 10.6 Hz, $J_{XX=}$ = 8.1 Hz, one CH_2CH_2 unit, RMS error for LAME8 simulation 0.18 Hz), 2.620, 2.817 (AA′BB′ pattern, 4H, $J_{AB} = J_{A'B'}$ = −17.0 Hz, $J_{AB'} = J_{A'B}$ = 6.4 Hz, $J_{AA'} = J_{BB'}$ = 7.3 Hz, the 2nd CH_2CH_2 unit, RMS error for LAME8 simulation 0.14 Hz), 3.40 (s, 3H, OMe), 3.71 (t, 1H, $J_{3,4} = J_{4,5}$ = 9.6 Hz, H-4), 3.75 (t, 1H, $J_{5,6ax} = J_{6ax,6eq}$ = 10.1 Hz, H-6$_{ax}$), 3.91 (td, 1H, H-5), 4.30 (dd, 1H, $J_{6eq,6ax}$ = 9.8 Hz, $J_{5,6eq}$ = 4.3 Hz, H-6$_{eq}$), 4.80 (dd, 1H, $J_{2,3}$ = 9.8 Hz, $J_{1,2}$ = 3.7 Hz, H-2), 5.00 (d, 1H, H-1), 5.50 (t, 1H, $J_{2,3} = J_{3,4}$ = 9.6 Hz, H-3), 5.51 (s, 1H, PhCH), 7.24–7.55 (m, 5H, Ar-H); ^{13}C NMR δ: 28.9, 29.3 (2 CH_2), 55.4 (OMe), 62.2 (C-5), 68.8 (C-6), 69.9 (C-3), 72.8 (C-2), 78.6 (C-4), 97.5 (C-1), 101.7 (PhCH), 126.2, 128.2, 129.2 (Ar-C), 136.9 (Ar-C_{ipso}), 170.7, 171.5 (CO); mass spectrum (EI) (scan from *m/z* 800 to *m/z* 150) *m/z*: M^+ (11%), $M^+ - 1$ (2.7%), 579 (1.7%), 465 (2.9%), 410 (1.7%), 386 (4.2), 368 (2.5%), 247 (100%). HRMS (EI), calcd. for $C_{36}H_{40}O_{16}$: 728.2316; found: 728.2310. Anal. calcd. for $C_{36}H_{40}O_{16}\cdot H_2O$: C 58.56, H 5.58; found: C 58.68, H 5.60.

The third fraction was compound **2a**, yield 0.443 g (46%).

*Bis(methyl 4,6-O-benzylidene-2-deoxy-α-D-glucopyranosid-2-yl) terephthalate (**2e**)*

Compound **1** (0.282 g, 1 mmol) was reacted with dibutyltin oxide (0.2738 g, 1.1 mmol) as in the general method. To the dibutylstannylene acetal solution was added triethylamine (156 μL, 1.1 mmol) and the resulting solution was stirred for 0.5 h. Terephthaloyl chloride (79 mg, 0.43 mmol) was added slowly to the mixture and stirring was continued for 1 h, then standard work-up was performed. The residue was purified by flash dry column chromatography (cyclohexane – ethyl acetate, gradient elution), which gave the title compound (**2e**) as a solid, R_F = 0.54 (ethyl acetate/cyclohexane, 1:1), yield 0.283 g (95%), which was recrystallized from ethyl acetate and cyclohexane to give needle-like crystals: mp 139–140°C; $[\alpha]_D^{25}$ +129 (*c* 0.73, chloroform); ^{1}H NMR δ: 2.26 (d, 2H, $J_{3,3\text{-}OH}$ = 2.8 Hz, 2 × OH-3), 3.41 (s, 6H, 2 × OMe), 3.64 (t , 2H, $J_{3,4} = J_{4,5}$ = 9.2 Hz, 2 × H-4), 3.81 (t, 2H, $J_{5,6ax} = J_{6ax,6eq}$ = 10.1 Hz, 2 × H-6$_{ax}$), 3.92 (td, 2H, $J_{5,6eq}$ = 4.3 Hz, $J_{4,5} = J_{5,6ax}$ = 9.7 Hz, 2 × H-5), 4.34 (dd, 2H, $J_{5,6eq}$ = 4.3 Hz, $J_{6eq,6ax}$ = 9.8 Hz, H-6$_{eq}$), 4.37 (b dt, 2 × H-3), 5.04–5.09 (m, 4H, 2 × H-1 and 2 H-2), 5.59 (s, 2H, 2 × PhCH), 7.36–7.42 (m, 6H, 2 × Ar-H), 7.48–7.54 (m, 4H, 2 × Ar-H), 8.17 (s, 4H, Ar′-H); ^{13}C NMR ($CDCl_3$, 62.9 MHz), δ: 55.5 (2C, 2 × OMe), 62.0 (2C, 2 × C-5), 68.8 (2C, 2 × C-3), 68.9 (2C, 2 × C-6), 74.4 (2C, 2 × C-2), 81.5 (2C, 2 × C-4), 97.6 (2C, 2 × C-1), 102.1 (2C, 2 × PhCH), 126.3, 128.4, 129.0 (2 × Ar-C), 129.4 (2 × Ar′-C), 133.7 (2 × Ar′-C_{ipso}), 136.9 (2 × Ar-C_{ipso}), 165.3 (2C, 2 × COO).

*Bis(methyl 4,6-O-benzylidene-2-deoxy-α-D-glucopyranosid-2-yl) phthalate (**2f**)*

Compound **1** (0.564 g, 2 mmol) was reacted with dibutyltin oxide (0.523 g, 2.1 mmol) under standard conditions to give a solution of the dibutylstannylene acetal. The solution was concentrated to 15 mL and cooled to room temperature, triethylamine (297 μL, 2.1 mmol) was added, and the solution was stirred for 30 min. The solution was cooled to 0°C and freshly distilled phthaloyl dichloride (97 μL, 0.67 mmol) was added dropwise. The reaction mixture was stirred 30 min at 0°C, then another 30 min at room temperature. Work-up using the standard method gave a solid residue that was separated by dry column flash chromatography (hexane, ethyl acetate as gradient). The first fraction, yield (0.014 g, 4.4%) was not identified.

The second fraction was the title compound (**2f**), a solid: R_F = 0.51 (ethyl acetate/cyclohexane, 1:1); yield 0.378 g (81%). It was recrystallized from chloroform and hexane; mp 124–125°C, $[\alpha]_D^{22}$ +82.4 (*c* 0.418, chloroform); ^{1}H NMR δ: 3.32 (bd, 2H, $J_{3,OH\text{-}3}$ = 2.4 Hz, 2 × OH-3), 3.38 (s, 6H, 2 × OMe), 3.58 (t, 2H, $J_{4,5} = J_{3,4}$ = 9.2 Hz, 2 × H-4), 3.74 (t, 2H, $J_{5,6ax} = J_{6eq,6ax}$ = 9.8 Hz, 2 × H-6$_{ax}$), 3.84 (td, 2H, $J_{4,5} = J_{5,6ax}$ = 9.6 Hz, $J_{5,6eq}$ = 4.3 Hz, 2 × H-5), 4.23 (td, 2H, $J_{3,OH\text{-}3}$ = 1.8 Hz, $J_{2,3} = J_{3,4}$ = 9.2 Hz, 2 × H-3), 4.28 (dd, 2H, $J_{5,6eq}$ = 3.7 Hz, $J_{6eq,6ax}$ = 9.2 Hz, 2 × H-6$_{eq}$), 5.01 (m, 4H, 2 × H-2 and 2 × H-1), 5.52 (s, 2H, 2 × PhCH), 7.33–7.42 (m, 6H, Ar-H), 7.47–7.59 (m, 6H, ArH + 2 Phth ArH), 7.78–7.82 (m, 2H, F-Phth Ar-H); ^{13}C

*Tris(methyl 4,6-O-benzylidene-2-deoxy-α-D-glucopyranosid-2-yl) (1,3,5-benzenetricarboxylate)(**2g**)*

Compound **1** (0.564 g, 2 mmol) was treated with dibutyltin oxide (0.523 g, 2.1 mmol) in toluene (30 mL) as in the standard method. The resulting solution was concentrated to 15 mL, cooled to room temperature, and triethylamine (296 μL, 2.1 mmol) was added. The reaction mixture was stirred for 0.5 h, then cooled to 0°C. 1,3,5-Benzenetricarbonyl trichloride (0.159 g, 0.6 mmol) was added slowly to the cooled mixture. The cooling bath was removed after 30 min and the solution was stirred a further 1 h. Standard work-up gave a solid that was purified by means of dry flash column chromatography (cyclohexane, ethyl acetate) to give the title compound (**2g**), R_F = 0.8 (ethyl acetate: hexane, 3:2), as a colourless solid; mp 172–173°C; yield 0.531 g (88%); $[\alpha]_D^{24}$ + 123 (*c* 1.63, chloroform); ^{1}H NMR δ: 3.28 (s, 9H, 3 × OMe), 3.64 (t, 3H, $J_{3,4}$ = $J_{4,5}$ = 9.2 Hz, 3 × H-4), 3.75 (t, 3H, $J_{5,6ax}$ = $J_{6ax,6eq}$ = 9.6 Hz, 3 × H-6_{ax}), 3.86 (td, 3H, $J_{4,5}$ = $J_{5,6ax}$ = 9.6 Hz, $J_{5,6eq}$ = 4.2 Hz, 3 × H-5), 4.02 (b s, 3H, 3 × OH-3), 4.27 (X of ABX pattern, 3H, 3 × H-6_{eq}), 4.35 (t, 3H, $J_{2,3}$ = $J_{4,5}$ = 9.3 Hz, 3 × H-3), 4.99 (dd, 3H, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.2 Hz, 3 × H-2), 5.04 (d, 3H, $J_{1,2}$ = 4.0 Hz, 3 × H-1), 5.54 (s, 3H, 3 × PhCH), 7.28–7.35 (m, 9H, Ar-H), 7.46–7.52 (m, 6H, Ar-H), 8.74 (s, 3H, Ar′-H); ^{13}C NMR δ: 55.2 (3C, 3 × OMe), 62.0 (3C, 3 × C-5), 68.4 (3C, 3 × C-3), 68.7 (3C, 3 × C-6), 75.0 (3C, 3 × C-2), 81.2 (3C, 3 × C-4), 97.3 (3C, 3 × C-1), 102.0 (3C, 3 × PhCH), 126.3, 128.3, 129.2 (2 × Ar-C), 130.3 (3 × Ar′-C_{ipso}), 135.4 (2 × Ar-C_{ipso}), 137.0 (3 × Ar′-C), 164.4 (3C, 3 × COO). *Bis(methyl 2-deoxy-α-D-glucopyranosid-2-yl) butanedioate (**5**)*

The milky solution resulting from refluxing methyl α-D-glucopyranoside (**4**) (0.583 g, 3 mmol) and dibutyltin oxide (0.747 g, 3 mmol) in freshly dried methanol (30 mL) became a clear homogenous solution after about 1 h and was refluxed for an additional 1.5 h. The solution was concentrated, then kept under vacuum (0.1 Torr; 1 Torr = 133.3 Pa) for an additional 1 h. This residue was dissolved in dry dioxane (15 mL), cooled to 0°C, and a solution of freshly distilled succinyl chloride (144 μL, 1.304 mmol) in dioxane (2 mL) was added dropwise. After 30 min, the cooling bath was removed, and the solution was stirred a further 8 h. The solution was concentrated and the syrupy residue was separated by dry column flash chromatography using a solvent gradient from ethyl acetate to ethanol. The first fraction was methyl (methyl 2-deoxy-α-D-glucopyranosid-2-yl) butanedioate as a syrup, R_F = 0.66 (ethyl acetate/methanol 1:2); yield 0.022 g (5.4%); $[\alpha]_D^{24}$ +131 (*c* 0.61, chloroform) ; ^{1}H NMR δ: 2.7 (m, 4H, 2 × CH_2), 3.38 (s, 3H, OMe), 3.55–3.75 (b m, 2H, H-4 and H-5), 3.70 (s, 3H, COO*Me*), 3.86 (b s, 2H, H-6 and H-6′), 3.96 (t, 1H, $J_{2,3}$ = $J_{3,4}$ = 8.9 Hz, H-3), 4.77 (dd, 1H, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.8 Hz, H-2), 4.86 (d, 1H, H-1); ^{13}C NMR δ: 29.0, 29.2 (2 CH_2), 52.1 (COO*Me*), 55.2 (glycoside OMe), 61.7 (C-6), 70.2 (C-5), 70.9 (C-4), 71.6 (C-3), 73.5 (C-2), 97.1 (C-1), 172.3, 173.3 (COO).

The second fraction was the title compound (**5**), R_F = 0.52 (ethyl acetate/ethanol, 2:7), a solid, mp 38–40°C; yield 0.441 g (72%); $[\alpha]_D^{23}$ + 105 (*c* 2.97, chloroform); ^{1}H NMR (D_2O) δ: 2.52 (s, 4H, 2 × CH_2), 3.13 (s, 6H, 2 × OMe), 3.24 (t, 2H, $J_{3,4}$ = $J_{4,5}$ = 9.5 Hz, 2 × H-4), 3.36–3.44 (m, 2H, 2 × H-5), 3.34–3.64 (m, 6H, 2 × H-3, 2 × H-6, and 2 × H-6′), 4.50 (dd, 2H, $J_{2,3}$ = 10.1 Hz, 2 × H-2), 4.68 (d, 2H, $J_{1,2}$ = 3.5 Hz, 2 × H-1); ^{13}C NMR (D_2O) δ: 31.3 (4C, 4 × CH_2), 57.5 (2C, 2 × OMe), 63.1 (2C, 2 × C-6), 72.1 (2C, 2 × C-4), 73.4 (2C, 2 × C-3), 74.2 (2C, 2 × C-5), 75.9 (2C, 2 × C-2), 99.1 (2C, 2 × C-1), 176.5 (2C, 2 × COO). Anal. calcd. for $C_{18}H_{30}O_{14}\cdot H_2O$: C 44.26, H 6.60; found: C 43.83, H 6.43.

*Bis(benzyl 4,6-O-benzylidene-3-deoxy-β-D-galactopyranosid-3-yl) terephthalate (**7**)*

The solution from the reaction of benzyl 4,6-*O*-benzylidene-β-D-galactopyranoside (**6**) (20) (0.197 g, 0.55 mmol) with dibutyltin oxide (0.192 g, 0.77 mmol) as in the standard method was concentrated to 10 mL, triethylamine (109 μL, 0.77 mmol) was added, and the resulting solution was stirred at room temperature for 0.5 h. Terephthaloyl chloride (65 mg, 0.32 mmol) was added and the mixture was was stirred until TLC (ethyl acetate:cyclohexane, 1:1) indicated that starting material was consumed (2 h). Standard work-up gave a syrupy residue that was purified using dry column flash chromatography with a solvent gradient from cyclohexane to ethyl acetate. The title compound (**7**), R_F = 0.41, a solid, was recrystallized from ethyl acetate – cyclohexane to give fine crystals: mp 223–224°C; yield 0.210 g (78%); $[\alpha]_D^{25}$ +69.9 (*c* 0.925, chloroform); ^{1}H NMR δ: 1.61 (s, 2H, H_2O), 2.52 (d, 2H, $J_{2,OH\text{-}2}$ = 1.8 Hz, 2 × OH-2), 3.56 (b s, 2H, H-5), 4.10 (dd, 2H, $J_{5,6ax}$ = 1.4 Hz, $J_{6ax,6eq}$ = 12.5 Hz, 2 × H-6_{ax}), 4.23 (ddd, 2H, $J_{1,2}$ = 7.9 Hz, $J_{2,3}$ = 10.4 Hz, 2 × H-2), 4.39 (b d, 2H, 2 × H-6_{eq}), 4.48 (b d, 2H, $J_{3,4}$ = 4.3 Hz, 2 × H-4), 4.51 (d, 2H, 2 × H-1), 4.65 (d, 2H, *J* = 11.6 Hz, $\frac{1}{2}$ $PhCH_2$), 5.01 (d, 2H, $\frac{1}{2}$ $PhCH_2$), 5.13 (dd, 2H, $J_{2,3}$ = 10.4 Hz, $J_{3,4}$ = 3.7 Hz, 2 × H-3), 5.51 (s, 2H, 2 × PhCH), 7.31–7.36 (m, 20H, Ar-H), 8.09 (s, 4H, tereph Ar-H); ^{13}C NMR δ: 66.6 (2 × C-5), 68.7 (2 × C-2), 69.0 (2 × C-6), 71.0 (2 × $PhCH_2$), 73.5 (2 × C-4), 74.4 (2 × C-3), 100.7 (2 × PhCH), 101.8 (2 × C-1), 126.1, 128.08, 128.11, 128.2, 128.5, 128.9, 129.9 (Ar-C), 133.7, 136.9, 137.5 (Ar-C_{ipso}), 165.5 (2 × COO). Anal. calcd. for $C_{48}H_{46}O_{14}.H_2O$: C 66.66, H 5.59; found: C 66.22, H 5.22.

*Bis(methyl 4,6-O-benzylidene-2-deoxy-α-D-allopyranosid-2-yl) terephthalate (**9**)*

Methyl 4,6-*O*-benzylidene-α-D-allopyranoside (**8**) (21) (0.113 g, 0.4 mmol) was reacted with dibutyltin oxide (0.110 g, 0.44 mmol) as in the standard method to give a solution that was concentrated to 6 mL and cooled to room temperature. Triethylamine (63 μL, 0.44 mmol) was added and the resulting solution was stirred at ambient temperature for 0.5 h. Then terephthaloyl chloride (41 mg, 0.2 mmol) was added and stirring was continued a further 20 min. Standard work-up gave a solid residue that was purified by means of dry column flash chromatography using cyclohexane – ethyl acetate gradient elution. The title compound (**9**) was obtained as a solid, then recrystallized from ethyl acetate and cyclohex-

Reaction of methyl 4,6-O-benzylidene-2-deoxy-α-D-mannopyranoside with adipoyl chloride

(a) Without added base: The stirred solution resulting from the reaction of methyl 4,6-*O*-benzylidene-α-D-mannopyranoside (**10**) (22) (0.282 g, 1 mmol) and dibutyltin oxide (0.274 g, 1.1 mmol) as in the general method was cooled to room temperature. A solution of freshly distilled adipoyl chloride (61 μL, 0.415 mmol) in toluene (2 mL) was added dropwise and stirring was continued for 45 min. Standard work-up gave a syrupy residue that was separated by means of dry column flash chromatography (eluent gradient: hexane to ethyl acetate). The first fraction from the column was methyl 4,6-*O*-benzylidene-2,3-deoxy-α-D-mannopyranosid-2,3-diyl hexanedioate (**12**), a solid; R_F = 0.8 (ethyl acetate: hexane, 2:1); yield 0.016 g (9.8%). It was recrystallized from ethyl acetate and hexane to give fine needles: mp 194–196°C; $[\alpha]_D^{23}$ −19.6 (*c* 0.32, chloroform); ^{1}H NMR δ: 1.90–1.98 (m, 2H, CH_2), 2.18–2.36 (m, 2H, CH_2), 2.37–2.52 (m, 4H, 2 × CH_2CO), 3.42 (s, 3H, OMe), 3.86 (t, 1H, $J_{5,6ax} = J_{6ax,6eq}$ = 9.8 Hz, H-6_{ax}), 3.98 (td, 2H, $J_{4,5} = J_{5,6ax}$ = 9.5 Hz, $J_{5,6eq}$ = 4.3 Hz, H-5), 4.08 (t, 2H, $J_{3,4} = J_{4,5}$ = 9.3 Hz, H-4), 4.33 (dd, 1H, $J_{5,6eq}$ = 4.6 Hz, $J_{6eq,6ax}$ = 9.6 Hz, H_{6eq}), 4.77 (d, 1H, $J_{1,2}$ = 1.2 Hz, H-1), 5.08 (dd, 1H, $J_{2,3}$ = 4.4 Hz, $J_{3,4}$ = 9.2 Hz, H-3), 5.56 (dd, 1H, $J_{1,2}$ = 1.2 Hz, $J_{2,3}$ = 4.3 Hz, H-2), 5.62 (s, 1H, PhCH), 7.35–7.46 (m, 5H, Ar-H), ^{13}C NMR δ: 26.5, 26.9 (CH_2), 35.1, 35.9 (CH_2CO), 55.1 (OMe), 62.1 (C-5), 68.9 (C-6), 69.8 (C-2), 70.1 (C-3), 76.5 (C-4), 99.7 (C-1), 102.2 (PhCH), 126.2, 128.3, 129.3 (Ar-C), 137.0 (Ar-C_{ipso}), 172.2, 173.8 (COO); EI MS for $C_{20}H_{24}O_8$: M^+ (16%), M − 30 (5%), 243 (34%), 55 (100%), no peaks at masses greater than 393. HRMS (EI), calcd. for $C_{20}H_{24}O_{14}$: 392.1471; found: 392.1460.

The second fraction was a solid, bis(methyl 4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranosid-2-yl) hexanedioate (**11a**), mp 87–88°C; R_F = 0.65 (ethyl acetate: hexane, 2:1); yield 0.058 g (21%); $[\alpha]_D^{24}$ +11.2 (*c* 2.02, chloroform); ^{1}H NMR δ: 1.73–1.83 (m, 4H, 2 × CH_2), 2.45–2.51 (m, 4H, 2 × CH_2CO), 2.72 (b s, 2H, OH-3), 3.39 (s, 6H, 2 × OMe), 3.80–3.92 (m, 6H, 2 H-4, 2 × H-5 and 2 × H-6_{ax}), 4.15 (dd, 2H, $J_{2,3}$ = 3.7 Hz, $J_{3,4}$ = 9.5 Hz, 2 × H-3), 4.25–4.28 (m, 2H, 2 × H-6_{eq}), 4.67 (d, $J_{1,2}$ = 1.5 Hz, 2 × H-1), 5.21 (dd, 2H, $J_{1,2}$ = 1.5 Hz, $J_{2,3}$ = 3.7 Hz, 2 × H-2), 5.59 (s, 2H, 2 × PhCH), 7.33–7.51 (m, 10H, 2 × Ar-H); ^{13}C NMR δ: 24.1 (2 × CH_2), 33.8 (2 × CH_2CO), 55.2 (2 × OMe), 63.2 (2 × C-5), 67.1 (2 × C-3), 68.7 (2 × C-6), 71.8 (2 × C-2), 79.0 (2 × C-4), 99.6 (2 × C-1), 102.2 (2 × PhCH), 129.2, 128.3, 129.2 (Ar-C), 137.1 (2 × Ar-C_{ipso}), 172.9 (2 × COO). Anal. calcd. for $C_{34}H_{42}O_{14}$: C 60.53, H 6.27; found: C 59.94, H 5.94.

The third fraction, also a solid, was (methyl 4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranosid-2-yl) (methyl 4,6-*O*-benzylidene-3-deoxy-α-D-mannopyranosid-3-yl) hexanedioate (**11b**), R_F = 0.38 (ethyl acetate/hexane 2:1); mp 87–88°C; yield 0.120 g (43%); $[\alpha]_D^{24}$ +19.7 (*c* 1.11, chloroform); ^{1}H NMR δ: 1.71–1.78 (m, 4H, 2 × CH_2), 2.40–2.48 (m, 4H, 2 × CH_2CO), 2.63 (d, 1H, $J_{3',OH\text{-}2'}$ = 4.3 Hz, OH-2′), 3.01 (d, 1H, $J_{2,OH\text{-}3}$ = 4.3 Hz, OH-3), 3.37, 3.38 (s, 2 × 3H, 2 OMe), 3.79–3.90 (m, 4H, H-5, H-5′, H-6_{ax}, and H-$6'_{ax}$), 4.05–4.15 (m, 4H, H-2′, H-3, H-4, and H-4′), 4.24–4.29 (m, 2H, H-6_{eq} and H-$6'_{eq}$), 4.66 (d, 1H, $J_{1,2}$ = 1.8 Hz, H-1), 4.71 (d, 1H, $J_{1',2'}$ = 1.2 Hz, H-1′), 5.22 (dd, 1H, $J_{1,2}$ = 1.8 Hz, $J_{2,3}$ = 3.7 Hz, H-2), 5.31 (dd, 1H, $J_{2',3'}$ = 3.7 Hz, $J_{3',4'}$ = 9.8 Hz, H-3′), 5.52, 5.60 (2s, 2H, 2 PhCH), 7.31–7.53 (m, 10H, PhCH and PhCH0); ^{13}C NMR δ: 23.7, 24.2 (2 CH_2), 33.5, 33.7 (2 CH_2CO), 55.0, 55.2 (OMe), 63.2, 63.8 (C-5 and C-5′), 67.1 (C-3), 68.7, 68.8 (C-6 and C-6′), 69.5 (C-2), 70.6 (C-3′), 71.9 (C-2), 76.0 (C-4′), 78.9 (C-4), 99.5 (C-1), 101.6 (C-1′), 101.8, 102.1 (PhCH), 126.16, 126.23, 128.2, 128.3, 129.0, 129.2 (Ar-C), 137.1, 137.2 (Ar-C_{ipso}), 172.2, 173.2 (COO). Anal. calcd. for $C_{34}H_{42}O_{14}$: C 60.53, H 6.27; found: C 60.16, H 6.36.

The fourth fraction was bis(methyl 4,6-*O*-benzylidene-3-deoxy-α-D-mannopyranosid-3-yl) hexanedioate (**11c**), a solid, mp 90–91°C; R_F = 0.16 (ethyl acetate/hexane, 2:1); yield 0.051 g (18%); $[\alpha]_D^{24}$ +32.0 (*c* 2.07, chloroform); ^{1}H NMR δ: 1.61–1.70 (b m, 4H, 2 × CH_2), 2.33–2.42 (b m, 4H, 2 × CH_2CO), 2.95 (d, $J_{2,OH\text{-}2}$ = 4.3 Hz, 2 × OH-2), 3.41 (s, 6H, 2 × OMe), 3.85 (t, 2H, $J_{5,6ax} = J_{6eq,6ax}$ = 10.4 Hz, 2 × H-6_{ax}), 3.93 (td, 2H, 4.11 (t, 2H, $J_{3,4} = J_{4,5}$ = 9.8 Hz, 2 × H-4), 4.14 (b m, 2H, 2 × H-2), 4.28 (dd, 2H, $J_{5,6ea}$ = 3.66 Hz, $J_{6eq,6ax}$ = 9.16 Hz, 2 × H-6_{eq}), 4.75 (d, 2H, $J_{1,2}$ = 1.8 Hz, 2 × H-1), 5.35 (dd, 2H, $J_{2,3}$ = 3.1 Hz, $J_{3,4}$ = 10.4 Hz, 2 × H-3), 5.52 (s, 2H, 2 × PhCH), 7.29–7.50 (m, 10H, 2 × Ar-H); ^{13}C NMR δ: 23.7 (2C, 2 × CH_2), 33.6 (2C, 2 × CH_2'), 55.0 (2C, 2 × OMe), 63.7 (2C, 2 × C-5), 68.8 (2C, 2 × C-6), 69.6 (2C, 2 × C-2), 70.8 (2C, 2 × C-3), 76.1 (2C, 2 × C-4), 101.6 (2C, 2 × C-1), 101.9 (2C, 2 × PhCH), 126.2, 128.2, 129.1 (Ar-C), 137.2 (2 × Ar-C_{ipso}), 172.7 (2C, 2 × COO). Despite repeated rechromatography, this compound was always obtained contaminated by a small amount of a dibutyltin-containing impurity, as apparent from small signals ascribed to a butyl group in its ^{1}H NMR spectra (not listed).

(b) In the presence of triethylamine: To the solution resulting from treatment of compound **10** (0.564 g, 2 mmol) with dibutyltin oxide (0.795 g, 2.2 mmol) in toluene (20 mL) as the general method was added triethylamine (0.307 mL, 2.2 mmol) and the product was stirred for 20 min at 25°C, then cooled to 0°C. A solution of adipoyl chloride (0121 mL, 0.83 mmol) in toluene (3 mL) was added dropwise. After 30 min, cooling was removed and the reaction mixture was stirred for 2 h. Standard work-up yielded a solid residue that was separated as previously to give compound **11a**, yield 0.305 g (54%); compound **11b**, yield 0.182 g (32%); and compound **11c**, yield 0.043 g (8%).

(c) In the presence of diisopropylethylamine (DIPEA): To the room temperature solution arising from the reaction of com-

pound **10** (0.141 g, 0.5 mmol) and dibutyltin oxide in toluene (15 mL) as in the general method was added freshly distilled diisopropylethylamine (0.96 mL, 0.55 mmol) and stirring was continued for 20 min. The reaction mixture was cooled to 0°C and a solution of adipoyl chloride (0.034 mL, 0.23 mmol) in toluene (2 mL) was added dropwise. The resulting solution was stirred at room temperature until TLC showed no further change in reaction (1.5 h). Standard work-up yielded a colourless solid residue that was analysed by ^{1}H NMR spectroscopy. Integration indicated that the products formed were compounds **11a** (20%), **11b** (42%), and **11c** (38%).

(d) In the presence of N-*methylimidazole (NMI)*: To the solution arising from treatment of compound **4** (1 mmol, 0.282 g) with dibutyltin oxide (0.274 g, 1.1 mmol) as in the general method was added *N*-methylimidazole (0.876 mL, 10 mmol) and stirring was continued for 20 min before the solution was cooled to 0°C. A solution of adipoyl chloride (61 μL, 0.415 mmol) in toluene (2 mL) was added dropwise to the cooled mixture, which was then stirred at room temperature for 1.5 h. Standard work-up gave a syrupy residue shown by TLC to contain only two products, **11b** and **11c**. ^{1}H NMR integration indicated that the ratio of compounds **11b** to **11c** was 1:4.

*Bis(methyl 4,6-O-benzylidene-3-deoxy-α-D-mannopyranosid-3-yl) (4,4′-biphenyldisulfonate) (**13b**)*

The solution resulting from treatment of compound **10** (0.564 g, 2 mmol) with dibutyltin oxide (0.523 g, 2.1 mmol) as in the general method was concentrated to 15 mL and cooled to the room temperature. *N*-Methylimidazole (796 μL, 10 mmol) was added and the solution was stirred for 20 min at room temperature, then cooled to 0°C. When a solution of 4,4′-biphenyldisulfonyl chloride (0.2985 g, 0.85 mmol) in toluene (2 mL) was added dropwise, the colour of the mixture turned yellowish immediately. The mixture was stirred at room temperature until TLC showed the starting material was consumed (14 h). Standard work-up yielded a solid residue that was separated by dry column flash chromatography using a gradient of hexane to ethyl acetate as eluent. The first fraction was (methyl 4,6-*O*-benzylidene-2-deoxy-α-D-mannopyranosid-2-yl) (methyl 4,6-*O*-benzylidene-3-deoxy-α-D-mannopyranosid-3-yl) (4,4′-biphenyldisulfonate) (**13a**), R_F = 0.72 (benzene/ethyl acetate, 1:1), a solid; mp 97–99°C; yield 0.034 g (5%); $[\alpha]_D^{23}$ +6.8 (*c* 2.26, chloroform); ^{1}H NMR δ: 2.42 (d, 1H, $J_{3,OH\text{-}3}$ = 4.6 Hz, OH-3), 3.04 (d, 1H, $J_{2',OH\text{-}2'}$ = 4.0 Hz, OH-2′), 3.38, 3.41 (2 s, 6H, 2 × OMe), 3.76–3.91 (m, 5H, H-5, H-5′, H-6$_{ax}$, H-6′$_{ax}$, and H-4), 4.08 (t,1H, $J_{3',4'} = J_{4',5'}$ = 9.3 Hz, H-4′), 4.15–4.32 (m, 3H, H-3, H-6$_{eq}$, H-6′$_{eq}$), 4.35 (m, 1H, H-2′), 4.76 (d, 1H, $J_{1',2'}$ = 1.5 Hz, H-1′), 4.82 (dd, 1H, $J_{2',3'}$ = 3.5, $J_{3',4'}$ = 10.1 Hz, H-3′), 4.84 (dd, 1H, $J_{1,2}$ = 1.5 Hz, $J_{2,3}$ = 3.7 Hz, H-2), 4.93 (d, 1H, $J_{1,2}$ = 1.5 Hz, H-1), 5.37 (s, 1H, PhCH′), 5.55 (s, 1H, PhCH), 7.13–7.19 (m, 5H, Ar-H), 7.33–7.37 (m, 5H, Ar-H), 7.43–7.47 (m, 2H, Ar), 7.59 (XX′ part of AA′XX′ pattern, 2H, ArH′ *meta* to SO_2), 7.89 (AA′ part of AA′XX′ pattern, 2H, J_o = 6.7 Hz, ArH *ortho* to SO_2), 8.08 (AA′ part of AA′XX′ pattern, 2H, J_o = 6.7 Hz, ArH′ *ortho* to SO_2); ^{13}C NMR δ: 55.1, 55.4 (OMe), 63.3, 63.7 (C-5, C-5′), 66.8 (C-3), 68.6, 69.3 (C-6, C-6′), 70.6 (C-2′), 75.5 (C-4′), 78.4 (C-4), 78.9 (C-2), 79.3 (C-3′), 99.6 (C-1), 101.4 (C-1′), 101.9 (PhCH′), 102.2 (PhCH), 126.1, 126.2, 127.6, 128.0, 128.3, 128.9, 129.0, 129.3 (Ar-C, Ar′-C, and Ar″-C), 135.8, 135.9, 136.8 (Ar-C_{ipso}), 140.0, 144.5 (Ar′-C_{ipso}).

The second fraction was the title compound **13b**, R_F = 0.55 (benzene/ethyl acetate, 1:1), a colourless solid; mp 141–143°C; yield 0.667 g (93%); $[\alpha]_D^{23}$ +23.3 (*c* 1.83, chloroform); ^{1}H NMR δ: 3.40 (s, 6H, 2 OMe), 3.48 (b s, 2H, 2 OH-2), 3.70–3.86 (m, 4H, H-5 and H-6$_{ax}$), 4.08–4.25 (m, 4H, H-4 and H-6$_{eq}$), 4.39 (bs, 2H, 2 × H-2), 4.81 (d, 2H, $J_{1,2}$ = 1.8 Hz, H-1), 4.84 (dd, $J_{2,3}$ = 3.1 Hz, $J_{3,4}$ = 10.1 Hz, H-3), 5.42 (s, 2H, PhCH), 7.08–7.27 (m, 14H, Ar-H and Ar-H′), 7.92 (d, 4H, $J_{ortho\text{-}Ar'\text{-}H}$ = 8.6 Hz, ArH *ortho* to SO_2); ^{13}C NMR δ: 55.1 (2 × OMe), 63.7 (2 × C-5), 68.5 (2 × C-6), 70.4 (2 × C-2), 75.4 (2 × C-3), 79.2 (2 × C-4), 101.5 (2 × C-1), 101.8 (2 × CHPh), 126.1, 127.2, 127.9, 128.7, 129.0 (Ar-C), 135.6 (2 × Ar′-C_{ipso}), 136.8 (2 × Ar-C_{ipso}), 143.8 (2 × Ar′-C_{ipso}). HRMS (ES) calcd. for M + H$^+$, $C_{40}H_{43}O_{16}S_2$: 843.1992; found: 843.2009.

Theoretical study on the insertion reaction of CH($X^2\Pi$) with CH_4

Zhi-Xiang Wang, Ming-Bao Huang, and Ruo-Zhuang Liu

Abstract: The CH + CH_4 reaction has been studied by means of ab initio molecular orbital calculations incorporating electron correlation with Møller–Plesset perturbation theory up to second and fourth orders with the 6-31G(*d*,*p*) and 6-311++G(2*d*,*p*) basis sets. An energetically feasible insertion reaction path has been found in the potential energy surface that confirms the experimental proposal for the mechanism of the CH + CH_4 reaction. The feature of the mechanism for the CH + CH_4 insertion reaction is found to be different from the feature of the mechanisms for the CH + NH_3, CH + H_2O, and CH + HF insertion reactions, but somewhat similar to that for the CH_2 + CH_4 insertion reaction. Energetic results for the CH + CH_4 reactions are in agreement with experiment.

Key words: CH radical, methane, reaction mechanism.

Résumé : On a étudié la réaction CH + CH_4 en faisant appel aux calculs d'orbitales moléculaires ab initio incorporant une corrélation d'électrons, avec la théorie de la pertubation de Møller–Plesset, jusqu'à des ordres 2 et 4 avec les ensembles de base 6-31G(*d*,*p*) et 6-311++G(2*d*,*p*). On a trouvé une réaction d'insertion énergétiquement possible à la surface d'énergie potentielle, qui confirme le mécanisme expérimental proposé pour la réaction CH + CH_4. On a trouvé que le mécanisme de la réaction d'insertion CH + CH_4 est différent des mécanismes d'insertion de CH + NH_3, CH + H_2O et CH + HF, mais il est quelque peu similaire à celui de la réaction d'insertion CH_2 + CH_4. Les résultats énergétiques de la réaction CH + CH_4 sont en accord avec les valeurs expérimentales.

Mots clés : radical CH, méthane, mécanisme réactionnel.

Introduction

Methylidyne, known to be one of the most reactive of all free radicals, is important in combustion and planetary atmospheric chemistry. The CH reactions with numerous small molecules have been studied by kinetic experiments (1). However, only a few theoretical studies (2–7) on the CH reactions have been reported, and those studies all show unexpected situations and complexities in the reaction paths.

We have been interested in the reactions of CH($X^2\Pi$) with the XH_n molecules (X = C, N, O, and F with n = 4, 3, 2, and 1, respectively). Experimental studies (8–10) have suggested that the insertion reaction path is the dominant channel for these CH reactions (no reported experimental study on the CH + HF reaction) because of the weak endothermicity of the abstraction reaction. The insertion mechanisms of the CH reactions with NH_3, H_2O, and HF were confirmed by our recent theoretical study (6). In the calculated reaction path of the energetically favorable insertion channel for each of the three reactions there exists an intermediate complex prior to the transition state that has a lower energy than the reactants. The MO interaction analyses imply that these intermediate complexes are stabilized due to the donation of the lone pair on the X-atom (X = N, O, and F) to the empty carbon p-orbital of the CH radical.

The CH reaction with CH_4, as a prototype of CH reactions with saturated hydrocarbons, is supposed to be more important than the above-mentioned three reactions. In 1983, Berman and Lin (8) carried out kinetic studies on the CH reaction with CH_4, and on the basis of their experimental results the following reaction mechanisms could be proposed:

where the reaction step (a) was proposed to proceed through CH inserting into a C—H bond of CH_4 to produce the ethyl radical, which contains 94.5 kcal/mol internal energy. In 1993, we investigated the mechanism of the CH + CH_4 reaction by ab initio calculations (4). Addition, insertion, and abstraction–addition reaction paths were examined by, in total, five meth-

ods of approach. However, the reaction path calculations were performed at the HF level, and the results indicated that the assumed insertion path did not seem to exist and the most favorable channel was the abstraction–addition reaction path (with a considerable energy barrier), which was not in line with that proposed by experiment (1, 8).

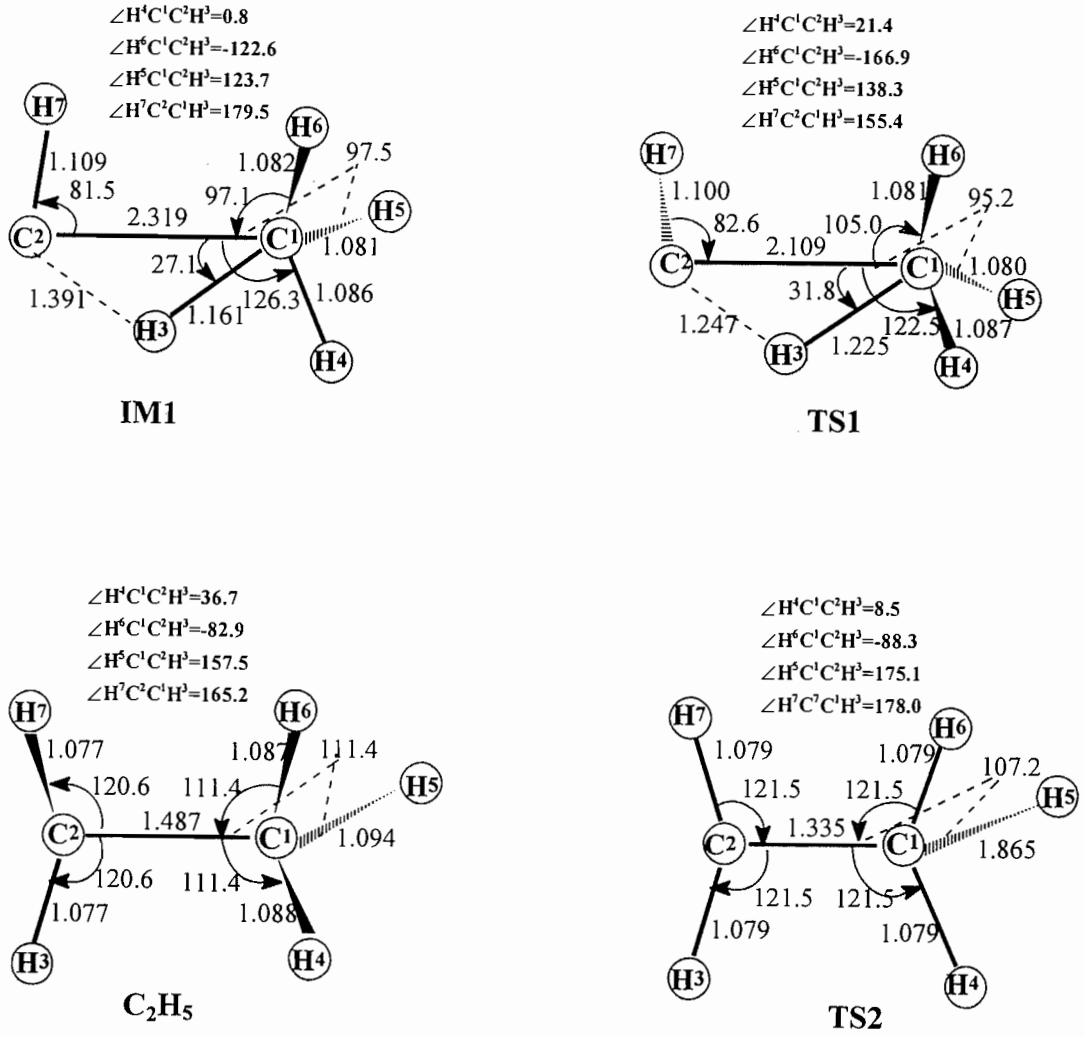
We have reinvestigated the mechanism of the CH + CH_4 reaction by ab initio calculations at high levels, and this time we found the feasible insertion reaction path in the potential energy surface. In the present paper, we report our new theoretical results for the CH + CH_4 reaction and discuss the insertion mechanisms of the CH + CH_4 reaction and some related reactions.

Computational details

Ab initio molecular orbital calculations incorporating electron correlation with unrestricted Møller–Plesset perturbation theory (11) up to second order (UMP2) and up to fourth order (UMP4) were carried out with the Gaussian 92 (12) suite of programs, and the 6-31G(*d,p*) (13, 14) and 6-311++G(2*d,p*) (15, 16) basis sets were used. The reaction path calculations were carried out at the UMP2/6-31G(*d,p*) level, and these calculations include: (*i*) geometry optimization calculations for scanning all the stationary points along the paths; (*ii*) frequency analysis calculations for characterizing the stationary points as minima (intermediate complexes) or saddle points (transition states); and (*iii*) intrinsic reaction coordinate (IRC) (17) calculations from the transition states for tracing the reaction paths (minimum energy paths). No symmetry constraints were imposed on the reaction system. The UMP4/6-311++G(2*d,p*) single-point calculations were performed at the UMP2/6-31G(*d,p*) geometries of the intermediate complexes, transition states, reactants, and products.

Results and discussion

The potential energy curve shown in Fig. 1 represents the UMP2/6-31G(*d,p*) reaction paths of the CH reaction with CH_4. The part of the potential energy curve to the left of C_2H_5 represents the insertion reaction step (a) of eq. [1]. Along the path, the reaction system proceeds from the reactants, first via a very shallow energy minimum and then a very low energy barrier, to the insertion product C_2H_5. The intermediate complex corresponding to the minimum and the transition state corresponding to the barrier are denoted as IM1 and TS1, respectively.



The two branches, starting at C_2H_5, of the potential energy curve shown in Fig. 1 describe the two subsequent (separate) reaction steps (b) and (c) in eq. [1], leading to the two sets of the final products, CH_2 (X^3B_1)+ CH_3 and C_2H_4 + H, respectively. In the calculated path for reaction step (c), there exists a transition state denoted as TS2.

In Fig. 1, the UMP2/6-31G(*d,p*) energies of IMn, TSn, and the products relative to the reactants are given. The energetic results for the CH + CH_4 reactions obtained in the present study are all collected in Table 1, and they include: (*i*) total energies, relative energies, and relative energies with zero-

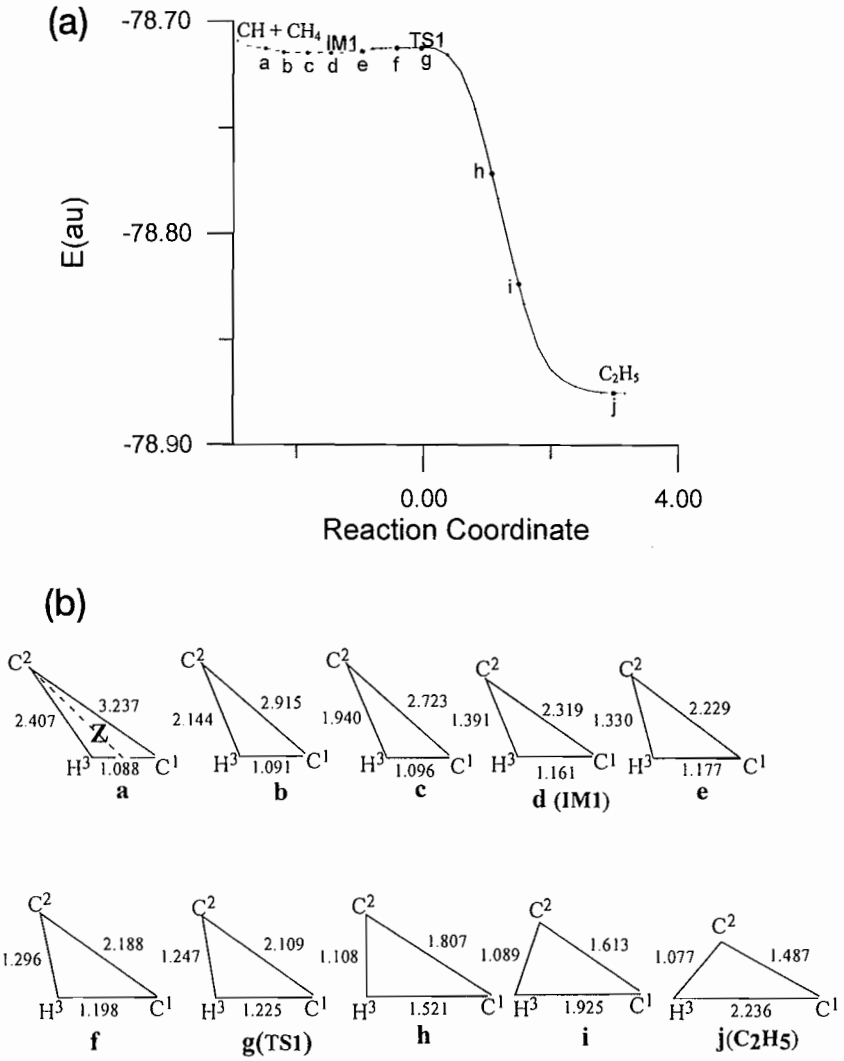
Fig. 2. UMP2/6-31G(*d,p*) optimized structures of the intermediate complexes (IM1 and C_2H_5) and transition states (TS1 and TS2) for the $CH(X^2\Pi)$ reaction with CH_4. Bond lengths are given in Å and angles in degrees.

point energy corrections based on our UMP2/6-31G(*d,p*) calculations; and (*ii*) total energies and relative energies with (UMP2/6-31G(*d,p*)) zero-point energy corrections based on our UMP4/6-311++G(2*d,p*)//UMP2/6-31G(*d,p*) calculations. The UMP2/6-31G(*d,p*) optimized geometries for IM1, TS1, TS2, and C_2H_5 are given in Fig. 2. The spin contaminations in the wave functions calculated at all the stationary points, except TS2 (see below) in reaction step (c), along the potential energy curve shown in Fig. 1 are small ($\langle S^2\rangle < 0.77$).

1. Insertion reaction leading to the ethyl radical



To confirm the fact that the part of the potential energy curve to the left of C_2H_5 shown in Fig. 1 describes the process of methylidyne insertion into CH_4, we examined the geometry evolution of the system. The UMP2/6-31G(*d,p*) IRC minimum energy path curve for reaction step (a) is given in Fig. 3(*a*) (the part to the left of IM1 was calculated by using the main reaction coordinate Z — the distance between the C-atom (denoted as C^2) of CH and the center of the attacked C—H (denoted as C^1—H^3) bond of CH_4. Ten geometries along this curve were examined and they are denoted in sequence as **a**, **b**, **c**, **d**(IM1), **e**, **f**, **g**(TS1), **h**, **i**, and **j**(C_2H_5), respectively. The main parts, the triangles $C^2H^3C^1$, of these geometries are given in sequence in Fig. 3(*b*). It is shown in Fig. 3(*b*) that, as the reaction proceeds (from **a** to **j**), the C^1—H^3 distance becomes longer and the C^2—C^1 and C^2—H^3 distances become shorter, finally leading to the breaking of the C^1—H^3 bond and simultaneous formation of the C^2—C^1 and C^2—H^3 bonds. The spin contaminations in the wave functions calculated at the 10 geometries are small ($\langle S^2\rangle < 0.77$). The geometry evolution definitely indicates that our calculated reaction path for step (*a*) of the CH + CH_4 reaction describes the insertion mechanism.

The energetic results for the CH + CH_4 → C_2H_5 insertion reaction are given in Table 1. The UMP2/6-31G(*d,p*) energies of IM1 and TS1 relative to the reactants are predicted to be −0.7 kcal/mol and −0.3 kcal/mol, respectively, and their relative energies corrected for zero-point energies (ZPEs) are small positive values. The UMP4/6-311++G(2*d,p*) //UMP2/6-31G(*d,p*) relative energies corrected for the UMP2/6-31G(*d,p*) ZPEs are considered to be the most sophisticated energetic results in the present study. At this level, the relative energies of IM1 and TS1 are predicted to be −3.3 kcal/mol

Fig. 3. (*a*) UMP2/6-31G(*d,p*) IRC minimum energy path curve for the CH + $CH_4 \rightarrow C_2H_5$ insertion reaction (the part left of IM1 was calculated by using the main reaction coordinate *Z* — the distance between the C-atom of CH and the center of the attacked C—H bond of CH_4). (*b*) Structures of $\Delta C^2H^3C^1$ abstracted from the 10 UMP2/6-31G(*d,p*) geometries (**a** – **j**) of the CH + CH_4 ($HC^2 + H^3C^1H_3$) system corresponding to the 10 points (**a–j**) along the UMP2/6-31G(*d,p*) path curve for the CH + CH_4 insertion reaction shown in (*a*). Distances are given in Å.

and −0.2 kcal/mol, respectively, which implies that the CH + $CH_4 \rightarrow C_2H_5$ insertion reaction is energetically feasible; the relative energy of C_2H_5 is predicted to be −87.2 kcal/mol, which is comparable with the available experimental value of −94.5 kcal/mol (1, 8) for the heat of the CH + $CH_4 \rightarrow C_2H_5$ reaction.

The UMP2/6-31G(*d,p*) optimized structures of IM1, TS1, and C_2H_5 are given in Fig. 2. The structure of IM1 seems to have a symmetry plane, but the structure of TS1 has no symmetry at all. The structure of C_2H_5 is actually identical with the UMP2/6-31G(*d,p*) geometry of the eclipsed conformer (the most stable conformer) of C_2H_5 reported by Suter and Ha (18), and our UMP2/6-31G(*d,p*) total energy value is also identical with theirs.

In our previous theoretical (UHFSCF) study (4) for the CH + CH_4 reaction, we examined the insertion path by taking the *Z*-parameter (see above) as the main reaction coordinate. We found that, when the *Z*-value decreased to 1.6 Å, the C—C distance and the attacked C—H bond distance suddenly became very long. The geometry evolution implied an abstraction process (CH + $CH_4 \rightarrow CH_2 + CH_3$), and we failed to find the insertion path. The main reason for the previous failure was probably that the reaction path calculations were carried out at only the HF level. Considering that the UMP2/6-31G(*d,p*) geometry of TS1 has no symmetry, we would suspect that another reason for the failure was the imposition of an artificial symmetry plane on the reaction system in the previous path calculations (4).

2. A comparison between different insertion mechanisms

As mentioned in the introduction, experimental studies (8–10) have already suggested insertion mechanisms for the CH + CH_4, CH + NH_3, and CH + H_2O reactions (no reported experimental study on the CH + HF reaction). In our previous theoretical study (6), the insertion reaction paths were found to be the favorable channels for the CH + NH_3, CH + H_2O, and

CH + HF reactions, and the skeletons of the potential energy curves describing the three insertion reactions indicate the same process: reactant → intermediate complex → transition state → insertion product. At the UMP2/6-31G(*d*,*p*) level, these intermediate complexes were predicted to be 31.4, 14.3, and 7.2 kcal/mol (the binding energies) more stable than their respective reactants. The skeleton of the potential energy curve for the CH + CH_4 insertion reaction (see Fig. 3(*a*) and Fig. 1) somehow seems to indicate the same process. However, the insertion mechanism for the CH + CH_4 reaction is considerd to have a completely different feature from those for the CH + NH_3, CH + H_2O, and CH + HF reactions, based on the analyses given below. The intermediate complexes, appearing in the insertion paths of the CH + NH_3, CH + H_2O, and CH + HF reactions, are donor–acceptor complexes stabilized because of the donation of the lone pair on the N, O, and F atoms to the empty carbon *p*-orbital of the CH radical (6). The decreasing order in binding energy for the three intermediate complexes is rationalized by the increasing order in electronegativity for the N, O, and F atoms (6). Since there is no lone pair on CH_4, no such donor–acceptor intermediate complex can be formed in the CH + CH_4 reaction. If IM1 were a donor–acceptor complex, its binding energy would be larger than that of the donor–acceptor complex for the CH + NH_3 insertion. The UMP2/6-31G(*d*,*p*) binding energy of IM1 toward CH + CH_4 is a very small value (0.7 kcal/mol). We would suppose that, at higher levels of calculation, IM1 and TS1 would disappear in the CH + CH_4 insertion path (we failed to find them in our preliminary UMP2/6-311G(*d*,*p*) optimization calculations).

The insertion reaction of CH_2 into CH_4 was theoretically studied by Gordon and Gano (19). The potential energy curve (see Fig. 2 of ref. 19) shows that at the early stage the energy of the system changes very slowly and it decreases rapidly after the transition state (the barrier disappears upon the introduction of correlation corrections). The geometry evolution of the CH_2 + CH_4 system (see Fig. 4 of ref. 19) shows that at the beginning of the insertion reaction the (H_2)C-H-C(H_3) angle is much larger than 90° (the "abstraction-like" initial approach) and it decreases monotonically. We note that the potential energy curve shown in Fig. 3(*a*), if the shallow minimum and low barrier are neglected, has the same general feature as that for the CH_2 + CH_4 insertion reaction and that the C^2-H^3-C^1 angle in the triangles shown in Fig. 3(*b*) varies, as the CH + CH_4 insertion reaction proceeds, in the same manner as the (H_2)C-H-C(H_3) angle of the CH_2 + CH_4 system. These facts imply that the mechanism for the CH + CH_4 insertion reaction has a feature similar to that for the CH_2 + CH_4 insertion reaction. It is also noted that, at the beginning of the CH + NH_3 insertion reaction, the C-H-N angle is very small while the C-N-H angle is very large (see Fig. 3 of ref. 6). For the insertion mechanism of the CH_2 + CH_4 reaction there has been a plausible MO interaction analysis that involves the empty *p*-orbital and lone pair on the methylene carbon (20, 21). It is realized that there are similar orbitals on the methylidyne carbon.

3. Subsequent reaction steps

Reaction steps (b) and (c) in eq. [1] are both dissociation processes of C_2H_5. In the UMP2/6-31G(*d*,*p*) calculations for the reaction paths of steps (b) and (c), the C^2—C^1 and C^1—H^5 distances (see the structure of C_2H_5 in Fig. 2) were taken as the main reaction coordinates, respectively.

The UMP2/6-31G(*d*,*p*) calculations for reaction step (b) indicate that the products ($CH_2(X^3B_1)$ + CH_3) are 103.3 kcal/mol higher in energy than the reactant (C_2H_5) and there is no transition state along the reaction path (see Fig. 1). At the UMP4/6-311++G(2*d*,*p*)//UMP2/6-31G(*d*,*p*) + ZPE(UMP2/6-31G(*d*,*p*)) level, the energy of the products relative to that of the original reactants (CH + CH_4) is predicted to be a very small value of −0.2 kcal/mol (see Table 1). The experimental value for the heat of the reaction CH + CH_4 → CH_2 + CH_3 is also a small value (2.6 kcal/mol) (1, 8).

The UMP2/6-31G(*d*,*p*) calculations for reaction step (c) indicate that the products (C_2H_4 + H) are 37.9 kcal/mol higher in energy than the reactant (C_2H_5) and the transition state TS2 is 48.8 and 10.9 kcal/mol higher in energy than C_2H_5 and C_2H_4 + H, respectively (see Fig. 1). At the UMP4/6-311++G(2*d*,*p*)//UMP2/6-31G(*d*,*p*) + ZPE(UMP2/6-31G(*d*,*p*) level, the energy of the products relative to that of the original reactants is predicted to be −59.0 kcal/mol (see Table 1), which is identical to the experimental value (1, 8) for the heat of the reaction CH + CH_4 → C_2H_4 + H. At the same level, the barrier in reaction step (c) is predicted to be 43.2 kcal/mol. The spin contaminations in the wave functions of TS2 are quite large ($\langle S^2\rangle \cong 0.95$), and the predicted barrier height for reaction step (c) may not be so accurate. Much higher levels of calculation are required for this reaction step (22).

Summary

For the CH($X^2\prod$) reaction with CH_4, an energetically feasible insertion reaction path has been found in the potential energy surface, which confirms the experimental proposal (1, 8) for the mechanism of this reaction. The feature of the mechanism for the CH + CH_4 insertion reaction is found to be different from the feature of the mechanisms for the CH + NH_3, CH + H_2O, and CH + HF insertion reactions, but similar to that for the CH_2 + CH_4 insertion reaction. Energetic results for the CH + CH_4 reactions (step (a), step (a) + step (b), and step (a) + step (c)) are in agreement with experiment.

Abstract: The aqueous reactions of hydroxylamine and *N*-methylhydroxylamine with vanadate have been studied. Ligand, vanadium, and proton stoichiometries of the products have been obtained as have their formation constants. At lower ligand concentrations the predominant complex contains a single hydroxamido ligand and this has been assigned a five-coordinate, tetrahedral-like structure where the hydroxamido group is coordinated in a side-on fashion. Four bishydroxamido products were observed. These four complexes consisted of two distinct groups of two isomeric complexes each and have been assigned six-coordinate (tetrahedral-like) and seven-coordinate (trigonal bipyramidal-like) geometries. For the *N*-methylhydroxamido ligand, 10 bisligand products in 2 groups of 5 isomers each were observed. The additional products over the hydroxylamine situation arise from the relative orientations of the ligand methyl groups. For both ligands, the monoligand products carried a single negative charge and did not have a pK_a within the range of about 6–10. The bisligand products did not carry a charge under neutral conditions. The tetrahedral bisligand products could be protonated under acidic conditions ($pK_a \sim 6.6$) but could not be deprotonated. In contrast, the trigonal bipyramidal products were not protonated under acidic conditions but could give up a proton under basic conditions ($pK_a \sim 7.4$) to form anionic complexes. The relative orientations of the ligands and also the number of methyl groups and their relative orientations in the complex have a significant influence on the ^{51}V chemical shifts. One additional complex was observed to form and was assigned to an ester-like product formed by reaction at the hydroxyl group.

Key words: vanadate, complexes, hydroxylamine, methylhydroxylamine, peroxovanadate.

Résumé : On a étudié les réactions des solutions aqueuses d'hydroxylamine et de *N*-méthylhydroxylamine avec le vanadate. On a déterminé les stoechiométries ainsi que les constantes de formations du coordinat, du vanadium et du proton avec les produits. Aux concentrations faibles de coordinats, le complexe principal ne comprend qu'un seul coordinat hydroxamido et on lui a attribué une structure pentacoordinée, en forme de tétraèdre, dans laquelle le groupe hydroxamido est coordiné de façon à être sur le côté. On a observé quatre produits bishydroxamido. Ces quatre complexes comportent deux groupes distincts de deux complexes isomères chacun et on a leur a attribué des géométries hexacoordinées (de formes tétraédriques) et heptacoordinées (de formes bipyramides trigonales). Pour le coordinat *N*-méthylhydroxamido, on a observé 10 produits à biscoordination qui peuvent être divisés en 2 groupes comportant chacun 5 isomères. Les produits additionnels, par rapport à la situation avec l'hydroxylamine, proviennent des orientations relatives des groupes méthyles des coordinats. Pour les deux types de coordinats, les produits ne comportant qu'un coordinat portent une seule charge négative et présentent pas de pK_a dans la région de 6 à 10. Dans les conditions neutres, les produits à deux coordinats ne portent pas de charge. Les produits tétraédriques à deux coordinats peuvent être protonés dans des conditions acides (pK_a d'environ 6,6), mais il est impossible de les déprotoner. Par ailleurs, il est impossible de protoner les produits dicoordinés de forme bipyramide trigonale dans des conditions acides; toutefois, en milieu alcalin (pK_a d'environ 7,4), il est possible de leur enlever un proton pour former des complexes anioniques. Les orientations relatives des coordinats ainsi que le nombre et les orientations relatives des groupes méthyles influencent fortement les déplacements chimiques du ^{51}V. On a observé qu'il se forme un complexe additionnel et on lui a attribué une structure semblable à celle d'un ester qui se formerait par réaction du groupe hydroxyle.

Mots clés : vanadate, complexes, hydroxylamine, méthylhydroxylamine, peroxovanadate.

[Traduit par la rédaction]

Introduction

The past 10 years have seen a tremendous increase in our understanding of the aqueous chemistry of vanadium oxo-anions. This effort has focussed mainly on the V(IV) and V(V) oxidation states and, to a large extent, was driven by the desire to understand the biological and biochemical influences exerted by vanadium, particularly by its influence on the function of many phosphate-metabolizing enzymes (1–4), its function in vanadium-dependent haloperoxidases (5–8) and nitrogenases (9, 10), and by its insulin-mimetic properties (11–13).

The biochemical role of vanadate (V(V)) as an oxidant (14, 15) has been less well studied, while that of peroxovanadates has been largely restricted to its possible function in vanadium haloperoxidases (5, 8, 16–18). It is known, however, that oxovanadium(V) peroxides function as insulin-mimetic materials

in live animals (11–13). In this case, it is by no means clear what the actual active material is.

Peroxovanadates have a strong influence on the function of numerous phosphatases and kinases (13, 19, 20). Although the mechanism of action is not known for most enzymes, recent work has provided evidence that the strong inhibition of protein tyrosine phosphatases occurs because of oxidation of the active site cysteines, certainly for the case of PTP-1B (21). A number of studies, over the past few years, have delineated peroxovanadate chemistry over the physiological pH range through studies of the complexation interactions with metabolic materials (22–24) and also of the oxidative reactions that peroxovanadate undergoes (6, 15, 22, 25, 26). These oxidative processes may well represent the underlying source of the insulin-mimetic properties of many peroxovanadium complexes.

Because of the importance of peroxovanadate in haloperoxidases, in influencing the function of phosphate-metabolizing enzymes, in potential insulin-mimetic applications, and because they are interesting compounds in their own right, we have extended our studies of peroxovanadates to include the closely related oxovanadium complexes with hydroxylamine. This ligand is isoelectronic with hydrogen peroxide but, because of the asymmetry resulting from replacement of OH by NH_2, it allows aspects of the chemistry of the vanadate complexes to be studied that would not otherwise be accessible. Furthermore, a naturally occurring hydroxylamine–vanadium(IV) complex, amavadin, which is readily oxidized to an amavadin V(V) complex, is known (27–29). The ligand in amavadin is highly substituted and multidentate. As a consequence, this study with a much simpler ligand is relevant to amavadin only to the extent that it provides information on possible modes of binding of hydroxamido ligands.

Initial studies of the interactions between vanadate and hydroxylamine were complicated by the instability of hydroxylamine, particularly at elevated pH. Consequently, our attention was directed towards the chemically less complicated *N*,*N*-dimethylhydroxylamine system. Using this ligand, it was possible to obtain details of the aqueous equilibria and to also obtain proton stoichiometry for the various reactions. A crystalline product was also obtained and its characterization by X-ray diffraction followed by NMR dissolution studies allowed structural assignments to the solution products to be made (30). Proton NMR studies also revealed a rapid internal isomerization of a type that, because of the higher symmetry, would not be observable with a similar hydrogen peroxide complex (30). With this information, together with that obtained from the studies of *N*-methylhydroxylamine–vanadate equilibria of this work, we have now been able to provide a detailed analysis of the aqueous hydroxylamine–vanadate system.

Experimental section

Materials

All reagents used in this study were reagent grade materials. Hydroxylamine hydrochloride and HEPES (*N*-(2-hydroxyethyl)piperazine-*N*′-2-ethanesulphonic acid) buffer were obtained from Sigma Chemical Co. Vanadium(V) oxide (99.99%) and methylhydroxylamine hydrochloride were obtained from Aldrich Chemical Co. All chemicals were used as supplied.

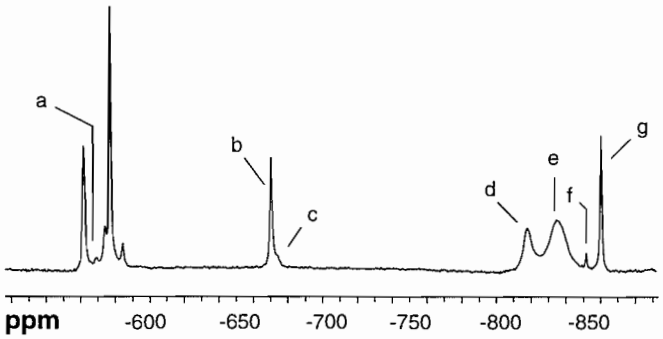
Solutions

A stock solution of sodium vanadate of strength 0.100 M was prepared by adding 0.5 mol equivalents of vanadium pentoxide to a 1.00 M solution of NaOH and stirring until the solution became colourless. This solution was diluted with distilled water to attain the desired concentration. Stock solutions of 1.0 M HEPES, 2.0 M KCl, 0.100 M hydroxylamine hydrochloride, and 0.100 M methylhydroxylamine hydrochloride were prepared by dissolving the requisite amount of the materials in distilled water. All solutions for NMR studies were kept at 1.0 M ionic strength by adding an appropriate volume of KCl solution. Solutions for the NMR studies were prepared by combining appropriate quantities of the stock solutions for the final desired concentration of vanadate, ligand, buffer, and KCl and diluting to near the final volume. The pH of the KCl solution was adjusted prior to use by NaOH or HCl, as required, so that the resultant pH of the solutions after mixing lies in the range 6.3–6.5. This procedure avoided the formation of decavanadate in solution. The pH levels of the solutions were finally adjusted to their desired value with dilute NaOH solution and the final volumes attained by the addition of distilled water. For ligand concentration studies the conditions of the experiments were maintained as follows: 3.00 mM vanadate, 1.0 M KCl, 20 mM HEPES, and 1–7 mM hydroxylamine or 1.5–5.5 mM methylhydroxylamine. The compositions of the solutions used for the pH variation studies, for both hydroxylamine and methylhydroxylamine, were 3.00 mM vanadate, 20 mM HEPES, 1.0 M KCl, and 5.00 mM hydroxylamine or 3.00 mM methylhydroxylamine ligand. Studies in the acidic pH range were carried out in the presence of excess ligand concentration and the conditions of the experiments were 3.00 mM vanadate, 20 mM hydroxylamine or methylhydroxylamine, 20 mM HEPES, and 1.0 M KCl.

All pH measurements were made with a pH-meter calibrated with freshly opened pH 4 and 7 standards.

An experiment was also conducted to check the stability of alkaline hydroxylamine in aqueous medium. A time-dependent pH measurement of aqueous hydroxylamine in alkaline medium showed a continuous change of pH with time.

Spectroscopy



^{51}V spectra were recorded on a Bruker AMX-400 NMR spectrometer operating at 105.2 MHz at ambient temperature. Vanadium chemical shifts are relative to external reference $VOCl_3$ assigned to 0 ppm. A polynomial baseline correction was applied to all spectra before integrals were obtained. NMR spectral parameters were as follows: pulse widths, 60°; spectral widths, 80 kHz; acquisition times, 0.05 s; line broadening, 40 Hz; frequency domain size, 16 K data points.

Analysis

Time course studies were carried out to verify that decomposition of hydroxylamine during the course of the NMR experiments was negligible. For the equilibria analysis, the concentrations as provided from the NMR spectra were used. The process of data reduction and analysis, as outlined in the text, was followed. All errors in parameters are reported at the 95% (3σ) level.

Fig. 1. ^{51}V NMR spectrum showing the formation of various complexes of vanadate with hydroxylamine. The unlabelled signals derive from vanadate and its oligomers. Conditions of the experiment: 3.0 mM total vanadate; 5.3 mM total hydroxylamine; 1.0 M KCl; 20 mM HEPES buffer; pH 6.9.

Results

Hydroxylamine

To better understand the equilibria established in the presence of vanadate, a separate experiment was done to check the stability of aqueous hydroxylamine in basic medium. Continuous monitoring of the pH revealed that there was a change in pH as a function of time. This change was reasonably slow under neutral conditions but the rate of change increased with a more basic medium. This inconstancy of pH is probably due to the decomposition of hydroxylamine ligand in alkaline medium to form ammonia, nirogen, and water although other products such as hyponitrous acid can be formed (31). A consequence of this reaction was that equilibrium studies were reasonably easily carried out at neutral pH but pH-variation studies of the equilibria were more difficult.

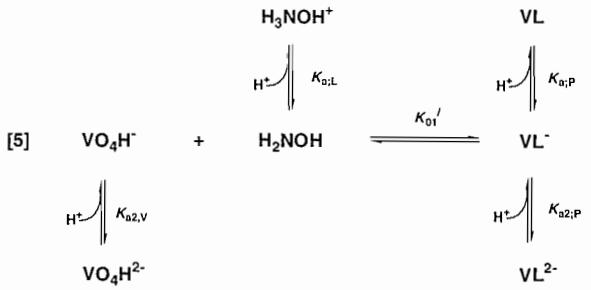
In spite of these problems, it was possible to characterize the system and it is felt that reasonably good parameters were obtained from the pH studies. This work was aided substantially by concurrent equilibration studies of methylhydroxylamine and from studies of dimethylhydroxylamine with vanadate (30). These last two systems did not present the problems encountered with the hydroxylamine studies and provided confidence that the results were being correctly interpreted.

Hydroxylamine in the presence of vanadate gives rise to two main sets of ^{51}V NMR signals. As shown in Fig. 1, these signals occur near -670 and -820 ppm. These chemical shifts are within the range commonly encountered for peroxovanadium complexes (23, 32–34) and suggest a similar side-on coordination. Within the -820 ppm set of signals, there are two subsets, those giving rise to rather broad vanadium signals (signals d,e) and those giving comparatively sharp signals (signals f,g). A close examination of the -670 ppm region revealed the presence of a minor component (signal c) compared to the major product (signal b). An additional product signal (-571 ppm, signal a) was also observed.

The stoichiometries of the products were readily determined by vanadium and ligand concentration studies at neutral pH. Initial studies suggested that all products contained a single vanadium and one and two ligands, respectively, for the -670 and -820 ppm products. The equilibrium reactions can then be written as eqs. [1] through [3]

$$[1] \quad V + L \overset{K_{01}}{\rightleftharpoons} VL \qquad [V][L]K_{01} = [VL]$$

$$[2] \quad VL + L \overset{K_{12}}{\rightleftharpoons} VL_2 \qquad [VL][L]K_{12} = [VL_2]$$



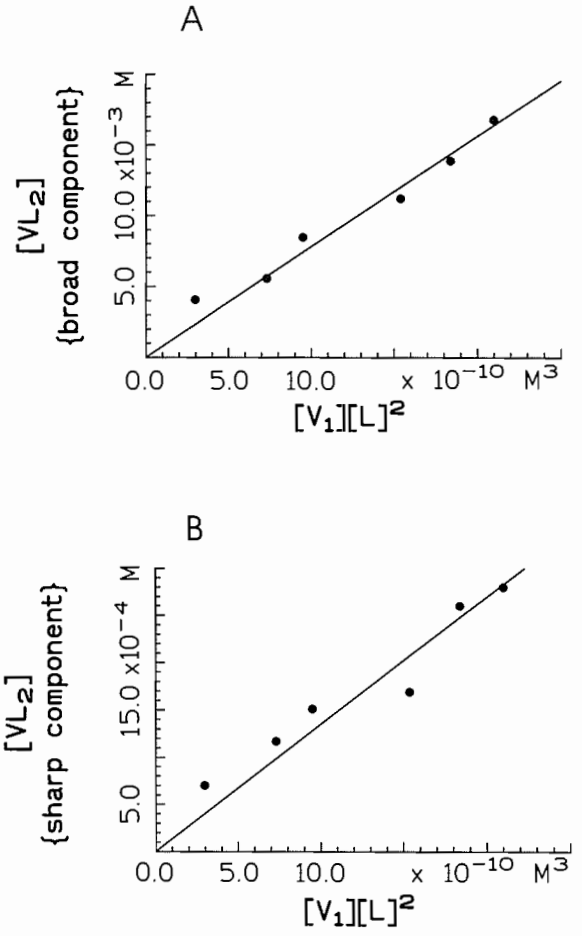
$$[3] \quad V + 2L \overset{K_{02}}{\rightleftharpoons} VL_2 \qquad [V][L]^2K_{02} = [VL_2]$$

where V refers to vanadate and L to hydroxylamine and VL and VL_2 to products. It was evident from the initial studies that product formation constants were so large that it was necessary to utilize the conservation equation, eq. [4], in order to specify the free ligand concentration as a function of the total amount of ligand (cL_t) and the product concentrations.

$$[4] \quad cL_t = [L] + [VL] + 2[VL_2]$$

Each of the graphs from the concentration studies for the -670 (eq. [1]) and -820 ppm (eq. [2]) products was linear. For the latter set of signals, the graph was broken into a plot for the broad, Fig. 2A, and sharp, Fig. 2B, signals although the product ratio is constant at fixed pH. The overall values, inclusive of minor and major products, obtained for the equilibrium constants of eqs. [1]–[3] were $K_{01} = (5.4 \pm 0.3) \times 10^2\ M^{-1}$) and $K_{02} = (9.1 \pm 0.7) \times 10^5\ M^{-2}$ ($K_{02} = K_{01}K_{12}$). The contribution of the individual products, within each group of products, to the overall formation constant is given simply by their relative concentrations, which are provided in Table 2.

Variation of the pH had a significant influence on the vanadium spectrum as shown in Fig. 3. Detailed analysis of the pH variation results requires consideration both of the pK_a's of the reactants and of the products. This is described by eq. [5] for the monoligand product.



Since pH, $pK_{a2;V}$ (8.30) (35), $pK_{a;L}$ (6.02) (36), and the various concentrations are known, then, from the NMR spectra, all quantities required for the analysis of the results, according to eq. [5], are available. Figure 4 shows the result of plotting the equilibrium data according to the assumption that the monoligand product has no pK_a. The linear relationship obtained is in agreement with this assumption and a $K_{01}' = (8.1 \pm 0.8) \times 10^2\ M^{-1}$ was obtained. For this particular investigation, concentration studies were also carried out for various pH values and the individual sets of results analyzed according to eq. [1]. These pH-dependent formation constants, K_{01}, can then be written in terms of the pH-independent constants, K_{01}', of eq. [5] and the hydrogen ion concentrations. The relationship between K_{01} and K_{01}' is given by eq. [6], where it is assumed that the product can lose a proton. An analogous equation can readily be written for the alternative situation.

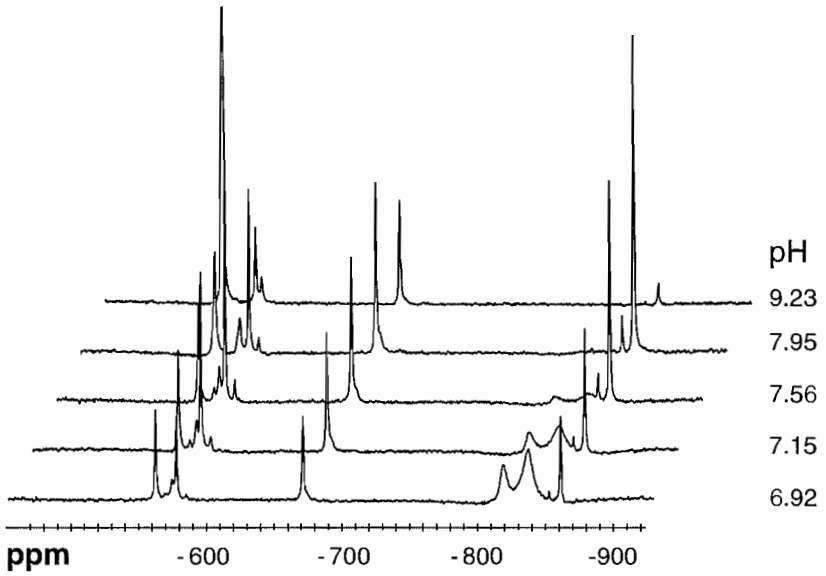
Fig. 2. Graphical display of the formation of vanadate/hydroxylamine products plotted according to eq. [2]. Good linear relationships were obtained. The graph establishes the VL_2 stoichiometry of the −860 ppm (A) and −820 ppm (B) products. Conditions of the experiments were: pH 7.05; 1.0 M KCl; 20 mM HEPES; 3.0 mM total vanadate; variable hydroxylamine total concentration, 1–7.0 mM.

$$[6] \quad (1 + K_{a2;V}/[H^+])\,(1 + [H^+]/K_{a;L}])K_{01} = K_{01}'(1 + K_{a;P}/[H^+])$$

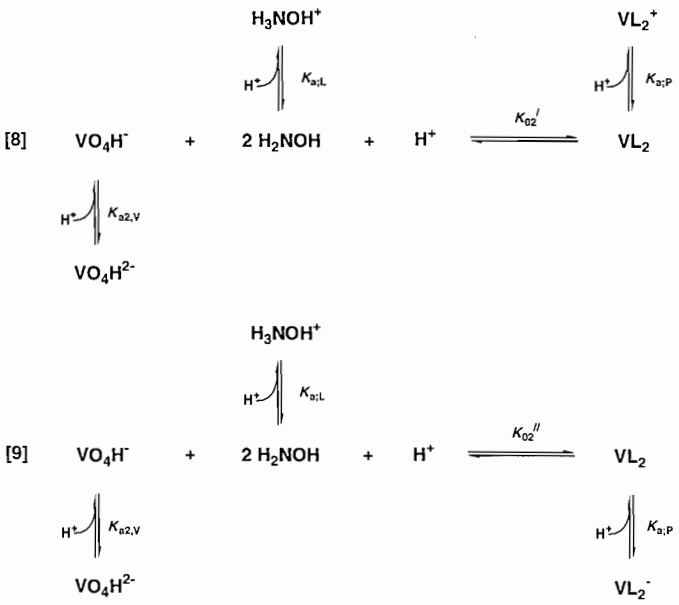
When the term on the left of eq. [6] was plotted against $1/[H^+]$, a line with an intercept but no slope was obtained. The intercept gave a value for K_{01}' of $(7.5 \pm 0.6) \times 10^2$ M^{-1}, in good agreement with the above value for K_{01}'. The zero slope is expected if there is no change in protonation state throughout the pH range of the study (pH 6.7 through 8.8). With this value for K_{01}' and by neglecting the term in $K_{a;P}$, which has no measurable influence, eq. [6] can be used to calculate K_{01}, the pH-dependent formation constant, for any pH within the range of this study. It is possible that the monoligand product does have a pK_a outside the range of pH values that would influence this study.

The pH study made it possible to show that there is a fundamental chemical difference between the products giving rise to the broad and sharp NMR signals of the bisligand products. The influence that pH has on the relative populations of the two types of products is evident from Fig. 3. The products giving rise to the two broad signals (d and e, Fig. 1) were favoured by low pH while the products providing the two sharp signals (f and g, Fig. 1) were favoured by increasing pH. There was, however, no appreciable change in relative intensity of the NMR signals within the two groups. Furthermore, the broad signals showed a systematic change in chemical shift with change in pH while the sharp signals did not move. Since both sets of products contain one vanadium and two ligands, these observations are in keeping with different proton requirements for the two sets of products.

Since the two components of the bisligand products behave differently with the change in hydrogen ion concentration, they were treated separately in the detailed analysis of the pH variation study. To gather more information concerning the protonation states of the broad signal components, spectra were recorded from pH 8 to 3. A fivefold excess ligand concentration was maintained in order to attain a condition where no, or very little, decavanadate is formed in solution at low pH. The intensity of the sharp signal components of the bisligand product decreased with lower pH and finally was not observed below pH 5. In contrast to the sharp component, the intensity of the broad components increased with the rise in acidity and, also, the signals became progressively sharper and the chemical shifts changed. In addition, there was a relative change in chemical shifts of the two signals. This behavior clearly indicated that the chemical environment around the vanadium center of the complexes giving rise to the broad signals was being influenced. A plot of pH versus chemical shift of the products d and e (Fig. 1) was consistent with a change in protonation state of the complexes. In both plots an inflection point was observed. If the pH-dependent chemical shift derives from protonation/deprotonation of the products, then the chemical shift can be related to pK_a directly, according to eq. [7],



$$[7] \quad pH = pK_a + \log [(\delta_L - \delta_O)/(\delta_O - \delta_H)]$$



where δ_L is the limiting chemical shift at low pH, δ_H is the limiting chemical shift at high pH and δ_O is the observed chemical shift. A plot of pH versus the logarithm term gave a straight line having an intercept equal to the pK_a of the products in both cases. The pK_a values determined for the products d and e were 5.92 ± 0.12 and 6.60 ± 0.14, respectively. It is possible, but not very probable, that a change in coordination to a less hydrated product accompanies the protonation step but this cannot be determined from these studies. The ^{51}V chemical shifts corresponding to product d were −823 ppm for VL_2 and −801 ppm for VL_2^+. The corresponding shifts for product e were −848 and −815 ppm, respectively.

It is possible that the source of the chemical shift change is not a protonation/deprotonation of the complexes. It was necessary to confirm this from a detailed analysis of the pH dependence of product formation. This is also required in order to establish the proton stoichiometry and charge state of the products. Considering both protonation and deprotonation reactions, eqs. [8] and [9] can be derived. These equations anticipate the finding that the products do not carry a charge under neutral conditions.

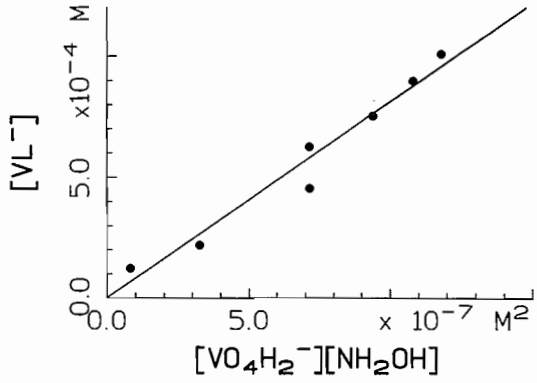
Fig. 3. ^{51}V NMR spectra showing the change in relative intensities of the resonances of various vanadate hydroxylamine products as a function of pH. Conditions of the experiments: 3.0 mM total vanadate; 5.0 mM total hydroxylamine; 1.0 M KCl; 20 mM HEPES buffer; variable pH, pH 6.9–9.2.



An intercept form of these equations, eqs. [10] and [11], can be derived from eqs. [8] and [9], respectively, where cVL_2, cV_1, and cL correspond to total concentrations of product (VL_2), of monomeric vanadate (V_1), and of free ligand (L).

$$[10]\quad K_{02}' + K_{02}'[H^+]/K_{a;P} = cVL_2/[H^+]\{cV_1/(1 + K_{a2;V}/[H^+])\}\{cL/(1 + [H^+]/K_{a;L})\}^2$$

$$[11]\quad K_{02}'' + K_{02}''K_{a;P}/[H^+] = cVL_2/[H^+]\{cV_1/(1 + K_{a2;V}/[H^+])\}\{cL/(1 + [H^+]/K_{a;L})\}^2$$

A plot of the term on the right-hand side of eq. [10] versus H^+ ion concentration yielded a linear relationship. The intercept of this line gave the pH-independent formation constant,

Fig. 4. Graphical representation of the formation of monoligand product as a function of pH. The graph is plotted according to eq. [5]. Experimental conditions: variable pH, pH 6.5–9.0; 3 mM total vanadate; 3.0 mM hydroxylamine; 1.0 M KCl; 20 mM HEPES buffer.

$K_{02}' = (9 \pm 3) \times 10^{12}\ M^{-3}$. The slope of the graph gave $K_{02}'K_{a;P}$, from which $K_{a;P} = (2.3 \pm 0.4) \times 10^{-7}$ was obtained, or $pK_{a;P} = 6.6$. This is an average value for the products giving rise to the two broad signals but is in good agreement with the values obtained from the variation of chemical shifts with change in pH. An average value was measured because the individual product signals were not well resolved over the entire pH range of the study. It is evident that neither of these products (d, e; Fig. 1) carry a charge under neutral conditions but are protonated and thus cationic under slightly acidic conditions. The equilibrium constants from this study are summarized in Table 1.

The overall pH-independent formation constant K_{02}'' for the sharp signal components of the bisligand products (f, g; Fig. 1) was obtained by plotting the appropriate parameters of eq. [11]. The value obtained for K_{02}'' was $(5 \pm 2) \times 10^{12}\ M^{-3}$. The $pK_{a;P}$ values for the two sharp components, within the

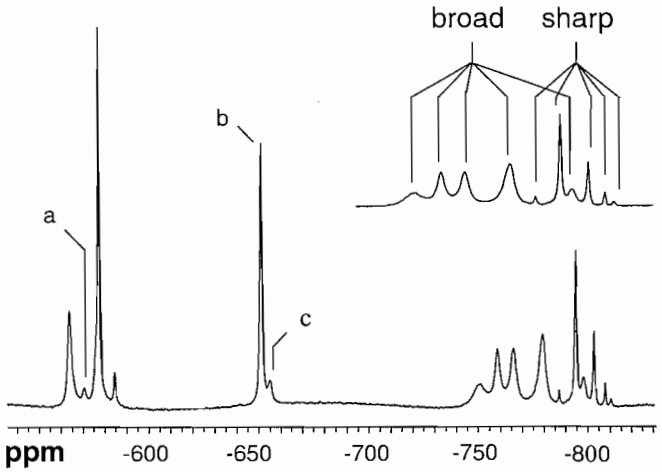
[a]sh and br refer to broad and sharp NMR signal components, respectively.
[b]The pH-dependent equilibrium constants were determined at pH 7.05 and 7.50, respectively, for the hydroxamido and *N*-methylhydroxamido complexes and are overall values for the indicated number of products. For instance, *N*-methylhydroxylamine gives rise to five products with sharp signals near −795 ppm. The value quoted is for the sum. Errors in the equilibrium constants are reported at the 3σ level. See Table 2 for all signal positions and relative intensities.
[c]The position of these signals is pH dependent.

error of the experiments, were the same ($pK_{a;P}$ = 7.4). The results are summarized in Table 1. It is interesting to note that, although these products have a pK_a, their ^{51}V chemical shifts are not pH dependent.

The pH-independent formation constants, K_{02}' and K_{02}'', for the broad and sharp component can be related to the pH-dependent formation constant, K_{02}, for the individual products, according to the following equations:

$$[12] \quad (1 + K_{a2;V}/[H^+])(1 + [H^+]/K_{a;L})^2 K_{02} = K_{02}'[H^+](1 + [H^+]/K_{a;P})$$



$$[13] \quad (1 + K_{a2;V}/[H^+])(1 + [H^+]/K_{a;L})^2 K_{02} = K_{02}''[H^+](1 + K_{a;P}/[H^+])$$

The calculated K_{02} values from eqs. [12] and [13] were consistent with the formation constants determined at specific pH values. With the appropriate juggling of pK_a values and relative intensities of the individual signals at pH 6.70 (Table 2), any concentration for any pH can be calculated using eqs. [12] and [13] together with eq. [3].

N-Methylhydroxylamine

The reactions of *N*-methylhydroxylamine with vanadate, not surprisingly, were very similar to the reactions with hydroxylamine. The complications arising from instability of the ligand at elevated pH were not encountered and, in this respect, it was easier to characterize the system. Complications did, however, arise because the ^{51}V NMR spectra were more complex. The complexity was a consequence of the occurrence of signals for each of the isomers formed as a result of the various relative orientations of the methyl groups of the ligand. A typical spectrum is displayed in Fig. 5.

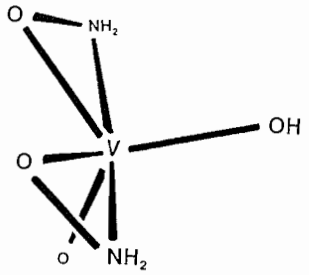


Fig. 5. ^{51}V NMR spectrum demonstrating the reaction of vanadate with methylhydroxylamine to yield various products. The inset spectrum shows the signals corresponding to the bisligand products. The experimental conditions were: 3.1 mM total vanadate; 4.1 mM total methylhydroxylamine; 1.0 M KCl; 20 mM HEPES buffer; pH 6.6.

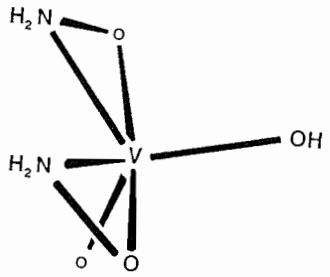

Analysis of the concentration and pH variation studies proceeded as for hydroxylamine and the various equilibrium constants are provided in Table 1. As for hydroxylamine, the monoligand product did not have pK_a while both types of bisligand products did. It was not possible to obtain pK_a values for all the broad signal products from the influence of pH on their chemical shifts. However, one signal was assignable over the pH range and a pK_a value of 5.7 ± 0.2 obtained. This agrees favourably with the value of 6.1 ± 0.2 obtained overall

III

for the broad signal products from concentration studies under various pH conditions (Table 1), and compares with $pK_a = 7.8 \pm 0.1$ overall for the sharp signals. Here, as for the hydroxylamine system, there was little indication that there was significant variation of pK_a values within the set of products giving rise to the sharp signals.

Discussion

Both hydroxylamine and *N*-methylhydroxylamine undergo condensation reactions with vanadate to form four types of complexes. The least preferred products provide ^{51}V signals (−571 ppm) near those of vanadate and its oligomers. The formation constants for these materials are several orders of magnitude larger than those typically found for products formed from alkyl alcohols (37, 38) but comparable to those from phosphate (39). These products are formed equally well whether the ligand is $HONH_2$, $HONHCH_3$, or $HON(CH_3)_2$. This suggests that the reaction is not occurring at the nitrogen. As a consequence, it is proposed that these are ester-like compounds where monodentate complexation occurs at the hydroxyl group. Although similar peroxovanadium complexes have not been reported, it seems likely that corresponding complexes are formed. Such an "end-on" coordination may be important in the function of haloperoxidases.

Under moderate ligand concentrations, the predominant products are mono- and bisligand complexes. The two types of bisligand compounds are chemically quite distinct. Under neutral conditions, neither product carries a charge. However, the broad signal components can be protonated at lower pH to form cationic complexes. It cannot be ascertained from this work whether a change in coordination accompanies the protonation step but it is possible. Apparently these products do not release a proton at higher pH and, consequently, with increase in pH, they are rapidly lost from solution. The situation is opposite for the sharp signal components. They release a proton at higher pH but, because they do not accept protons, are lost from the solution as the acidity is increased. The NMR signals for these compounds occur within the same chemical shift range as those for peroxovanadates and this suggests that they are similarly coordinated. For the case of the broad signal component of the bisligand products of *N*,*N*-dimethylhydroxylamine, X-ray crystal structure analysis and NMR dissolution studies have been used to assign a six-coordinate (tetrahedral if the bonds to the hydroxylamine are formally considered to be unidentate) structure (30). Since the spectral patterns for the ligands of this study are similar to those for the dimethylhydroxylamine case and they have the same stoichiometry and a similar protonation pattern, a corresponding tetrahedral-like coordination is assigned to the products giving the broad signals (d, e; Fig. 1) of this study.

The chemical differences between the bisligand products giving rise to the sharp NMR signals (f, g; Fig. 1) and those giving rise to the broad signals clearly shows that these two products must have a different coordination. There is some evidence that the sharp signal components correspond to a pentagonal bipyramidal (trigonal bipyramidal for formal unidentate assumption) coordination. This coordination is found in the crystalline glycylglycine complex of bis(hydroxamido)vanadate (40, 41) and the NMR spectra of this complex provide a sharp signal that overlaps the chemical shift range of the sharp signals of the precursor bisligand complex (41). A somewhat similar structure is also found in a tris(hydroxylamine)–vanadate complex where the side-on coordination arises for only two of the three ligands, the third ligand being complexed only through the oxygen (42).

Scheme 1 shows the coordination proposed for the products giving rise to the broad signal products. A similar set of three

[c]Values arranged vertically in parentheses correspond to the relative concentrations within each set of products.

Scheme 2.

rotational isomers is possible for the seven coordinate products, only one of which is displayed in Scheme 2. It is known for the dimethylhydroxylamine ligand that the isomers of the six-coordinate complex undergo a rapid exchange process (30). The arrangement in which the two oxygens are *cis* to each other is the predominant one observed in crystal structure studies. This suggests that this arrangement is the thermodynamically favoured one. For hydroxylamine and dimethylhydroxylamine, the ratio of products for the broad components is about 1:2 and is about 1:8 for the sharp components. A somewhat similar ratio (1:3) of glycylglycinato complexes is also found in the glycylglycine–hydroxylamine–vanadate system (41). On this basis, the *cis* arrangement in which the oxygens are close together is assigned to the major isomer (Scheme 1, I), the second *cis* arrangement in which the nitrogens are close together (Scheme 1, II) to the second isomer, and the *trans* arrangement (Scheme 1, III) to the least preferred isomer. It seems clear that a fundamental characteristic of both bisperoxo and bishydroxamido ligand complexes is that the liganding atoms of both ligands lie in a common plane. This arrangement and the isomer selectivity may be closely related and a consequence of an underlying physical property of this type of complex.

The information obtained from this study also allows a structural assignment to be made for the coordination of the monohydroxamido complexes. Two signals for monoligand products are observed for *N,N*-dimethylhydroxamido, *N*-methylhydroxamido, and hydroxamido complexes. They are found in an approximate 1:10 ratio for all three systems. For the monoligand situation, (except for methylhydroxylamine complexes) neither of the coordinations discussed for the bisligand compounds can give rise to more than one vanadium NMR signal. Therefore, the two signals observed correspond to distinct coordination geometries. Since, under neutral conditions, the major bisligand product is six-coordinate (tetrahedral-like if the hydroxylamine is formally considered unidentate), then it seems possible that the major monohydroxamido complex is five-coordinate and also tetrahedral-like. If the complex were trigonal bipyramidal, then, for the *N*-methylhydroxylamine ligand, two signals of roughly comparable intensities, corresponding to the two possible methyl group orientations similar to that observed for the bisligand complexes, would be expected and only one signal is observed (Fig. 5). Only one such signal is expected for a tetrahedral coordination. This suggests the coordination of the major monoligand product is tetrahedral but the possibility of rapid isomerization cannot be ruled out for this complex even though it is slow in the other complexes. Tetrahedral-like coordination would, however, explain why the monoligand complexes do not have a pK_a in the range 6–9. Products of such a structure would probably have a second pK_a somewhat closer to the third pK_a of the vanadate anion (about 12) as opposed to a much lower pK_a for a seven-coordinate structure. For instance, monoperoxovanadate, for which a trigonal bipyramidal coordination has been proposed on the basis of ^{17}O NMR studies (33), has a second pK_a of 6.2 (34). Furthermore, the complex giving rise to the sharp signal components of bis(hydroxamido)vanadate and the bisperoxovanadate complex have similar seven-coordinate geometries and similar pK_a's; pK_{a1} = 7.4 and pK_{a2} = 7.2, respectively.

The ^{51}V chemical shifts observed for the various bishydroxamido complexes are provided in Table 2. It is somewhat surprising that the vanadium chemical shifts are as sensitive to replacement of an NH by an NCH_3 as to a change in coordination from six to seven (tetrahedral to trigonal bipyramidal), ~30 ppm. Even the *cis*/*trans* isomerization can lead to about a 20 ppm change in chemical shifts. The average change in chemical shifts is about 50 ppm for replacement of NH by NCH_3 in the bisligand complexes but drops to about half this value for the monoligand products. This suggests that the

influence of the methyl groups is cumulative and corresponds to +20–+25 ppm per methyl group per ligand.

It is evident from this work that, despite the similarity of hydrogen peroxide and hydroxylamine, there are some significant differences in their complexation reactions with vanadate. The monoligand six-coordinate tetrahedral-like complexes have not been reported for peroxovanadium complexes although triperoxovanadate is known to have a tetrahedral coordination (43). Tetrahedral coordination in peroxovanadium complexes might well be more ubiquitous than presently anticipated. Since changes in coordination number have a rather small influence on chemical shifts compared to the influences attributable to side-on coordination, use of vanadium chemical shifts to characterize coordination geometry in these complexes could be highly misleading.

Diphenylmethane and diphenyl ether — experimental conformations and torsional surfaces calculated with AM1, MNDO, PM3, and density functional theory (Becke3LYP)

Thomas Straßner

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.146.161.215 on 09/08/12
For personal use only.

Abstract: The complete energy surfaces of the torsion around the central C—O or C—CH_2 bonds in diphenyl ether (DPE) and diphenylmethane (DPM) are calculated with semiempirical methods (AM1, MNDO, PM3) and density functional theory (Becke3LYP/3-21G). Stationary points are optimized at the Becke3LYP/6-31G(d) level of theory. The geometry of a very recently published X-ray structure of 4,4′-bis[*N*-(2,4,6-trimethyl)benzenesulfonamide]diphenylmethane (**1**), as well as the solid state structures of many other diphenyl ethers and diphenylmethanes, is found in the low-energy regions of the AM1 surfaces of the parent compounds.

Key words: Conformational analysis, diphenyl ether, diphenylmethane, quantum chemistry (AM1, MNDO, PM3), density functional theory (Becke3LYP).

Résumé : On a calculé les surfaces complètes d'énergie pour la torsion autour des liaisons centrales C—O et C—CH_2 du diphényléther (DPE) et du diphénylméthane (DPM) en faisant appel à des méthodes semiempiriques (AM1, «MNDO», PM3) et à la théorie de la densité fonctionnelle (Becke3LYP-21G). On a optimisé les points stationnaires au niveau Becke3LYP/6-31G(d) de la théorie. On a trouvé que la géométrie du 4,4′-bis[*N*-(2,4,6-triméthyl)benzènesulfonamide]diphénylméthane (**1**), déterminée par diffraction des rayons X et rapportée très récemment, ainsi que les structures à l'état solide de plusieurs autres diphényléthers et diphénylméthanes se trouvent toutes dans des régions de faibles énergies de srufaces AM1 des composés fondamentaux.

Mots clés : analyse conformationnelle, diphényléther, diphénylméthane, chimie quantique (AM1, «MNDO», PM3), théorie de la densité fonctionnelle (Becke3LYP).

[Traduit par la rédaction]

Introduction

The geometry at the central atom of diphenylmethane and diphenyl ether has been under discussion for many years and several attempts have been made to explain and predict the torsional angles by calculational procedures. However, all these previous studies used assumptions o froze coordinates, due to the resources needed for the calculation of an energy surface without constraints. The present article is a complete study of the torsional energy hypersurfaces of diphenylmethane (DPM) and diphenyl ether (DPE). The results of semiempirical and density functional theory calculations are discussed and compared with experimental data.

The geometries of compounds of the type aryl-X-aryl with different groups X (X = O, X = CH_2, X = SO_2, e.g., diphenyl ether (DPE) and diphenylmethane (DPM)) have been discussed now for several years (1–9). One of the reasons for this interest is the occurrence of the structural unit "aryl-X-aryl" in many important natural compounds like the thyroid hormone T_3 (10), in antibiotics like vancomycin (11) or bouvardin (12), as well as in aminopeptidase inhibitors like OF4949-III (13). Additionally, the aryl-X-aryl unit seems to account for the characteristics of polymeric materials with very special properties like PEK, PEEK, PES, and PEES,[3] where initial calculations of different conformations of such polymer chains have been published (2, 7).

Many authors have discussed the geometry of aryl-X-aryl structures on the basis of different calculational methods (EH (1), INDO (3), STO-3G (4), 3-21G (5), C-INDO (6), MNDO (7), MM2 (8), AM1 (9), and CNDO/2 (14)). However, all studies were either restricted to selected points on the torsional hypersurface or use symmetry constraints. The ab initio calculations (4, 5) are reported with small basis sets, assuming C_2 symmetry and (or) a frozen C-X-C angle. The C-INDO calcu-

[3] PEK = poly(aryl ether ketone); PEEK = poly(aryl ether ether ketone); PES = poly(ether sulfone); PEES = poly(ether ether sulfone).

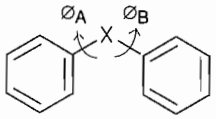
lations (6) are based on assumptions about the hybridization of the central atom X. MNDO results were obtained with frozen bond lengths and bond angles. It seems to be questionable whether calculations with such restrictions will give valuable results. Very recently a paper was published using high-level ab initio methods (RHF/6-31G(d)) with full geometry optimization (15).

The most thorough way to check the torsional energy surface of diphenyl-X compounds is certainly ab initio calculations with high-level basis sets including electron correlation. On the other hand, the calculation of a whole ab initio surface requires a great deal of computational time and hardware. Is it necessary, for these systems, to spend a lot of computer time or are the semiempirical calculations sufficient? One of the advantages of density functional theory is the partial inclusion of correlation, also with smaller basis sets such as 3-21G; another is its more reasonable requirement of system resources. Furthermore, DFT has proven useful in cases where semiempirical calculations are known to fail (16). Therefore, the Becke3LYP/3-21G basis set was used to check the semiempirical calculations. Semiempirical methods are often used in industry due to their cost efficiency and because they have produced reliable results. For example, AM1 is capable of reproducing the ab initio results of the torsion in amides and ureas after introduction of a correction term (17). Therefore the surface was calculated using semiempirical methods and the Becke3LYP/3-21G level. The local minima and transition states were reoptimized at the Becke3LYP/6-31G(d) level. The results of the calculations have been compared to published experimental data and recently published ab initio calculations on the HF/6-31G(d) level (15).



Methods

AM1, MNDO, and PM3 were used in the form of the computing package VAMP 4.50[4] (18) (running on a CONVEX C220 and an SGI-Indigo) using the EF-optimizer (19). All structures were calculated using the keyword PRECISE. The C-C-X-C torsions are calculated by reaction coordinates from 0° to 180° in 5° steps, optimizing all other coordinates. The density functional theory (DFT) (20) calculations were performed using the GAUSSIAN-94 set of codes (21). The surface is calculated by reaction coordinates from 0° to 180° in 15° steps. DFT takes into account electron correlation by a correlation functional (20). The introduction of gradient-corrected (non-local) functionals has significantly improved the theoretical predictions (22, 23). DFT includes dynamic and nondynamic electron correlation to some extent and appears to be the best choice for both efficiency and accuracy. The economy of DFT methods makes them a promising alternative approach to ab initio methods. The well-approved Hartree–Fock hybrid model Becke3LYP (23) implemented in Gaussian-94 was used throughout this study.

The split valence DZ basis sets 3-21G and 6-31G(d) were employed in the DFT calculations. The geometries and energies of stationary points were checked with force calculations to ensure that they were stationary points. Transition states can be distinguished from other stationary points by the fact that the Hessian matrix has a sole negative value for these states.

[4] The program package VAMP 4.50 (*V*ectorized *AMP*AC) by T. Clark is used for semiempirical calculations at the Universities Erlangen and Dresden, Germany.

Scheme 1. Definition of angles $\varnothing_A$, $\varnothing_B$.

Results

Structures and X-ray data

Structure **1** was recently published in Acta Crystallographica (24); important geometrical data are mentioned in Table 7. The angles $\varnothing_A$, $\varnothing_B$ are defined in Scheme 1.

The various conformations of aryl-X-aryl compounds are defined by the ring twist angles $\varnothing_A$, $\varnothing_B$, i.e., the dihedral angles between the angle C-X-C and the plane of the aromatic rings A and B, respectively (25*m*). The two torsional angles $\varnothing_A$ and $\varnothing_B$ lead to different conformational classes with C_s (**D**), C_2 (**E**), and, of course, C_1 (**F**) symmetry. Three additional conformations of high symmetry (**A**, **B**, and **C**), can be constructed where $\varnothing_A$ and (or) $\varnothing_B$ have values of 0° or 90°. The structures are shown in Scheme 2.

In agreement with previous publications, we will name the conformations shown in Scheme 2 as "all-planar" (**A**), as "perpendicular" (**B**), as "skewed" (**C**), and as "butterfly" forms (**D**, **E**, and **F**). Form **A** is expected to be very unstable due to the short H—H bond distance of the *ortho*-hydrogen atoms. Predictions cannot be made for the other structures. Of course, π-conjugation with the lone pair of the ether oxygen (DPE) and the steric demand of the CH_2 group (DPM) will influence the stability of the conformations.

Many X-ray structures of *para*-substituted aryl-X-aryl compounds are known from the Cambridge data base (25, 26). They have been useful for the evaluation of the calculated energy surfaces. The recently published X-ray structure of 4,4′-bis[*N*-(2,4,6-trimethyl)benzenesulfonamide]diphenylmethane shows angles of 54° and 57° degrees (**1**) relative to the central carbon atom, which is not unusual for this class of compounds (see Fig. 1). The geometry of **1** is comparable to some already published X-ray structures (25*m*) (see below).

Semiempirical energy surfaces of diphenylmethane and diphenyl ether

From comparison of the different diphenylmethane surfaces, it is obvious that the minimum of the AM1 surface is large and nearly flat. This is shown in Fig. 2, a three-dimensional plot of the AM1 surface of diphenylmethane.

The energy surfaces in $\varnothing_A$ and $\varnothing_B$, calculated with AM1, MNDO, and PM3 are given in Figs. 3–8. The distance between the lines of the energy contour maps in Figs. 3–8 is 0.1 kcal/mol. Marked points correspond to the data in Table 1 (diphenylmethane) and Table 2 (diphenyl ether).

The energy difference between points 1 and 2 in Fig. 3 is only 0.01 kcal/mol. The program used calculates that point 2 has no imaginary frequencies and is a local minimum. This might be a result of the numerical instabilities of the minimizer, which does not work properly for such very flat

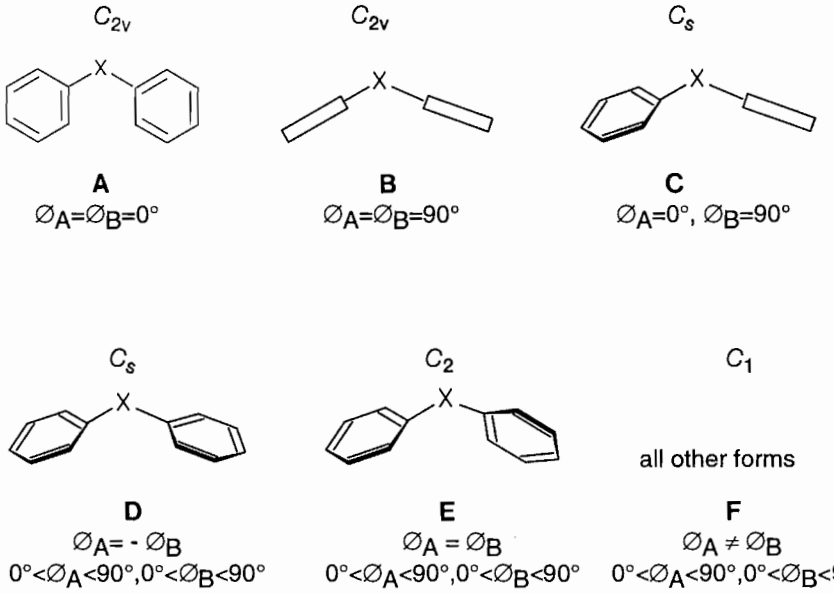
Scheme 2. Possible conformations with different symmetry of aryl-X-aryl compounds.



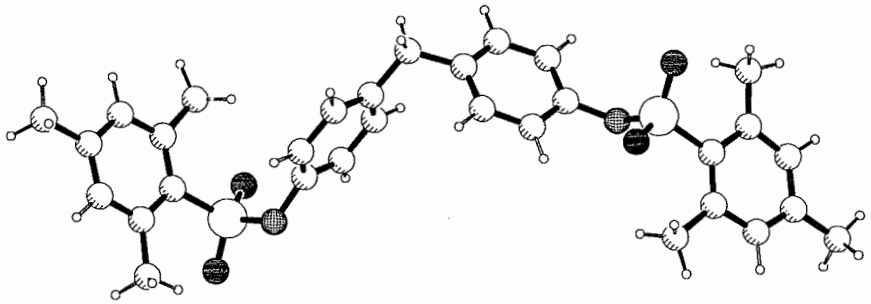


Fig. 1. 3D view of the X-ray structure of compound **1**.

1

$\varnothing_A=54°$, $\varnothing_B=57°$

surfaces (see Table 1). PM3 also calculates the C_{2v} structure to be a local minimum, but all other structures of type **B** (C_{2v} symmetry) are transition states (Tables 1 and 2). The diphenyl ether surfaces have minima at angles of about 36° ± 3°, the shape of the low-energy region obviously favouring C_2-symmetrical geometries.

Diphenylmethane

The different diphenylmethane surfaces are represented in Figs. 2–5, with results of frequency calculations for extrema in these surfaces given in Table 1.

Diphenyl ether

The results of all three Hamiltonians are similar for diphenylmethane. They differ in the degree of curvature of the minimum, but all three show a very large region of almost equal energy. The largest and flatest minimum region is calculated by AM1. In the case of diphenyl ether the results differ. While AM1 and PM3 calculate a minimum for $\varnothing_A/\varnothing_B$ of about 30°/30°, the MNDO minimum is about 50°/50°. All three Hamiltonians calculate the transition state at 90°/90°, between both minima, to be about 1 kcal/mol higher in energy. To decide which semiempirical method (AM1, MNDO, or PM3) better describes the conformation of diphenylmethane and diphenyl ether, the surfaces are compared with experimental and density functional theory data.

Energy surfaces of diphenylmethane and diphenyl ether calculated by density functional theory

The results of the DFT calculations agree very well with the semiempirical results. They, as well as published ab initio calculations (15), favour the C_2 conformation for the parent compounds.

The hypersurfaces shown in Figs. 9 and 10 are very similar

Fig. 2. Three-dimensional representation of the energy surface of diphenylmethane, calculated with AM1. The vertical axis is the heat of formation in kcal/mol. $\varnothing_A$, $\varnothing_B$ are given between 0° and 180° on the axis of the two-dimensional surface.

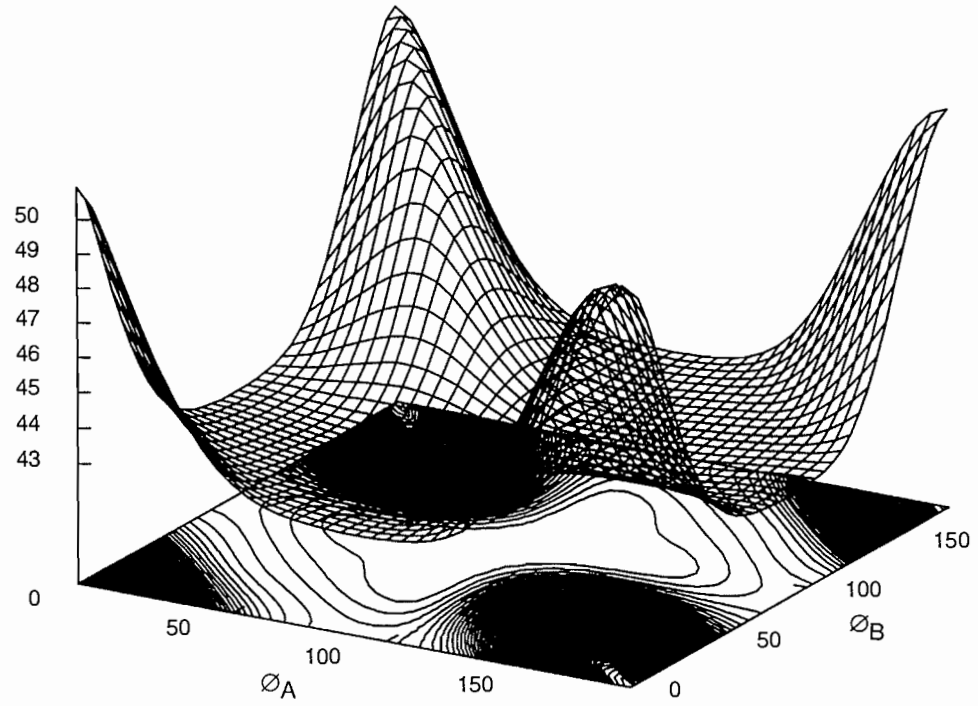

Fig. 3. Two-dimensional energy surface of diphenylmethane, calculated with AM1 from 0° to 180° (see Scheme 1 for the definition of $\varnothing_A$, $\varnothing_B$).

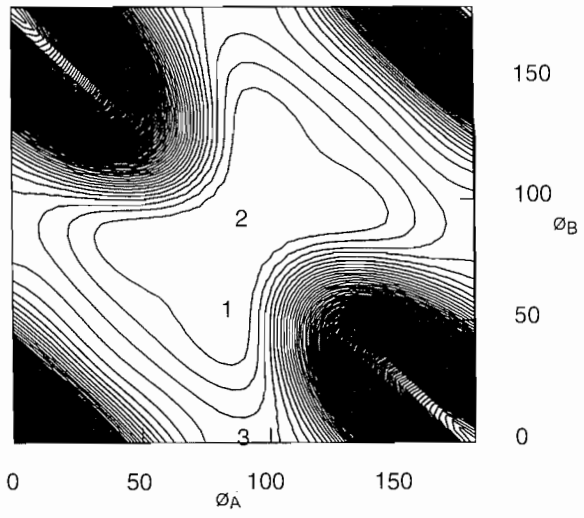

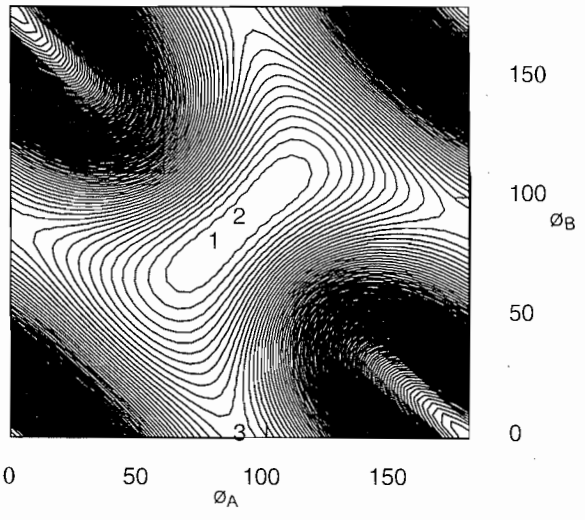

Fig. 4. Two-dimensional energy surface of diphenylmethane, calculated with MNDO from 0° to 180° (see Scheme 1 for the definition of $\varnothing_A$, $\varnothing_B$).

to the surfaces calculated by AM1, except for the lower smoothness of the density functional surfaces, which are calculated using a 15° grid. The energy difference between two lines is 0.25 kcal/mol, compared to 0.1 kcal/mol for the semiempirical surfaces. This does not influence the minimum, which is exactly the same when plotted with 0.1 kcal/mol, but, for the sake of simplicity, the higher energy difference was chosen.

In the case of diphenylmethane, the DFT and AM1 surfaces are almost identical. Both show a large, flat minimum between 30° and 95° degree with a C_2-symmetrical minimum structure at 57° (B3LYP/6-31G(d)). This is in perfect agreement with recent Hartree–Fock ab initio calculations (15), which calculate the minimum to be at 58.3° for RHF/6-31G(d) and at 58.5° for the MP2/6-31G(d) optimized geometry.

The minimum of the diphenyl ether surface is slightly narrower with AM1 than in the case of DFT. Becke3LYP calculates a minimum region for $\varnothing_A$ between 25° and 50°, while

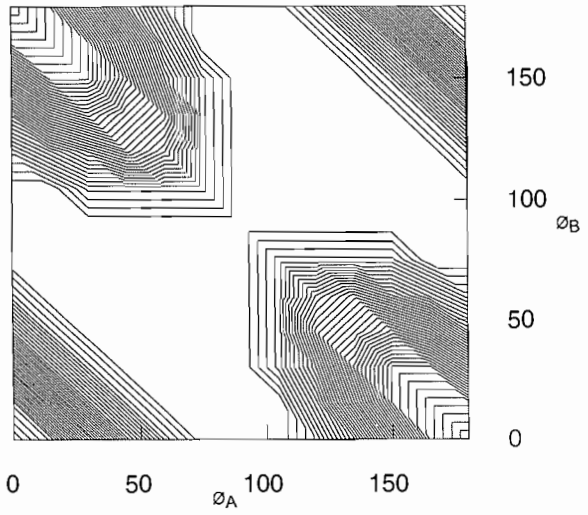
Fig. 9. Two-dimensional energy surface of diphenylmethane, calculated with Becke3LYP/3-21G from 0° to 180° (see Scheme 1 for the definition of of $\varnothing_A$, $\varnothing_B$). The energy difference between the lines is 0.25 kcal/mol.



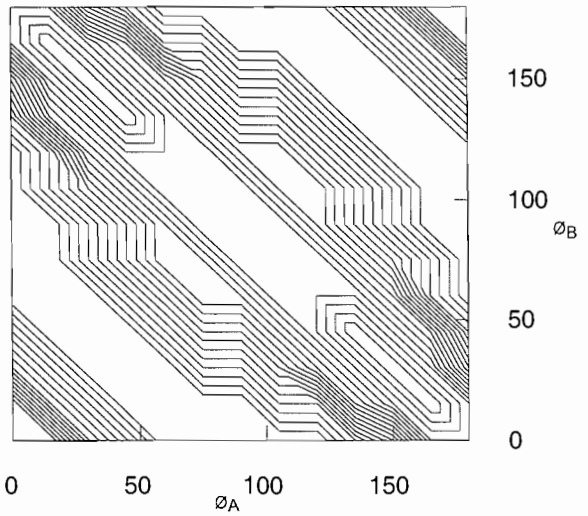


Fig. 10. Two-dimensional energy surface of diphenyl ether, calculated with Becke3LYP/3-21G from 0° to 180° (see Scheme 1 for the definition of of $\varnothing_A$, $\varnothing_B$). The energy difference between the lines is 0.25 kcal/mol.

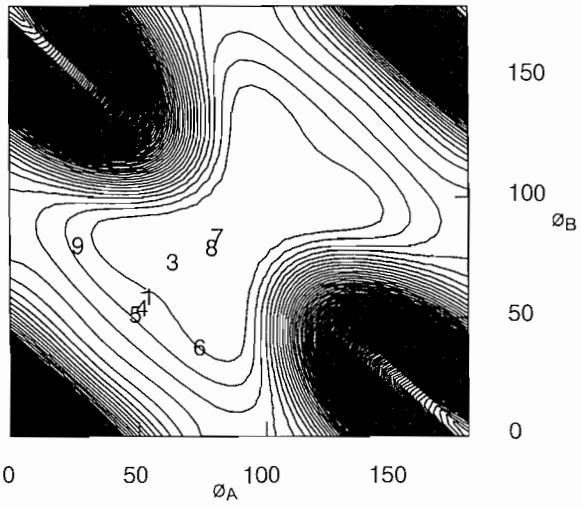

AM1 calculates it to be between 25° and 45°. The overall shape is again identical for the surfaces calculated by AM1 and Becke3LYP. The calculated minima at 35° (AM1) and 40° (B3LYP/6-31G(d)) are in agreement with RHF/6-31G(d) (44.1°) and MP2/6-31G(d) (39.4°) (15). But how do experimental results correlate with theory?

Comparison between experimental and theoretical data

As mentioned before (25, 26), there are many X-ray structures available for *para*-substituted aryl-X-aryl compounds. They fit very well, as can be seen from Tables 7 and 8. To include different substitution patterns, data for the molecules shown in Figs. 12 and 14 were used for the comparison of theory to experiment. Figs. 11 and 13 show the comparison between

Fig. 11. AM1 energy hypersurface of diphenylmethane; marked points represent the molecules shown in Fig. 12.

selected experimental (X-ray structures) and calculated data (AM1).

Molecules **2**–**8** shown in Fig. 12 are used to evaluate the energy surface of diphenylmethane. Their X-ray data have been published (25*m*).

Table 7 shows selected data of those compounds shown in Fig. 12. The dihedral angles are given in degrees (25*m*).

Diphenyl ether

As can be seen from Figs. 11 and 13, the experimental values from X-ray structures are in agreement with our theoretical calculations. All diphenylmethane X-ray structures are within 0.1 kcal/mol of the calculated minimum. In the case of diphenyl ether, the crosses are more widespread, but they still are within 0.7 kcal/mol of the calculated minimum.

Discussion of the energy surfaces

Structures of type **D** are on a line from the upper left corner of the surface down to the bottom right, which means from (0°/180°) to (180°/0°). Type **E**, in contrast, are on the line from (0°/0°) to (180°/180°). In general, structures with C_s symmetry (**D**) are higher in energy than those with C_2 symmetry (**E**). This is in agreement with high-level ab initio and density functional theory calculations. The C_s symmetrical structures (**C**) are transition states between the C_2-symmetrical minima and their mirror images.

The energy surfaces of DPE (Figs. 6–8), calculated with all three Hamiltonians, show a similar overall shape. The global minimum is a C_2 structure with approximately 35°/35°; the transition to its enantiomer is best achieved over the transition state marked as number 3 in Fig. 6, which has the type **C** structure (C_s symmetry) with very low activation barriers (AM1: 0.4 kcal/mol; MNDO: 0.29 kcal/mol; PM3: 0.13 kcal/mol). The second possible transition over the C_{2v}-symmetrical structure at 90°/90° requires slightly higher activation energies (AM1: 1.9 kcal/mol; MNDO: 1.1 kcal/mol; PM3: 1.2 kcal/mol). The energy barriers are not quite accurate compared to the density functional and ab initio calculations. The

barrier for the transition over the C_s-symmetrical structure is in the same range (0.65 kcal/mol for B3LYP/6-31G(d) and 0.30 kcal/mol for MP2/6-31G(d)) (15), but the transition via the C_{2v}-symmetrical structure is underestimated by about 2.5 kcal/mol compared to 4.22 kcal/mol for B3LYP/6-31G(d) and 3.59 kcal/mol for MP2/6-31G(d)) (15). However, the transition will follow the path of lower energy over the C_s-symmetrical structure, where the AM1 value is between the values calculated by ab initio and density functional theory.

Obviously, AM1 gives the highest barriers for this weakly conjugated system, a picture that is known from rotations at amide and urea bonds (16, 17). All available X-ray data are consistent with the calculations, as is obvious from Fig. 13, where the crosses are grouped together (up to a maximum deviation of 0.7 kcal/mol) close to the absolute minimum. This is surprising considering the large differences in structures **9**–**22**, but proves the usefulness of the semiempirical calculations for these compounds.

The shape of the diphenylmethane surfaces looks different at first sight when calculated with AM1, MNDO, and PM3.

However, all three Hamiltonians yield only one minimum centered around the 90°/90° structure. The valley is more narrow with MNDO and PM3 than with AM1; only one transition state at 90°/0° is to be considered for all methods. The activation barriers (AM1: 0.3 kcal/mol; MNDO: 1.4 kcal/mol; PM3: 0.9 kcal/mol) are contrary to the diphenyl ether picture. The reason is that obvious sterical demands determine the transition state. Again, the experimental structures are embedded most comfortably in the AM1 surface (Fig. 11). They are within a deviation of 0.1 kcal/mol from the global minimum. For diphenylmethane the calculated energy difference compared to density functional theory and high-level ab initio

[a]$\varnothing_A$, $\varnothing_B$ are defined in literature as the dihedral angles C_2-C_1-X-C_1'.

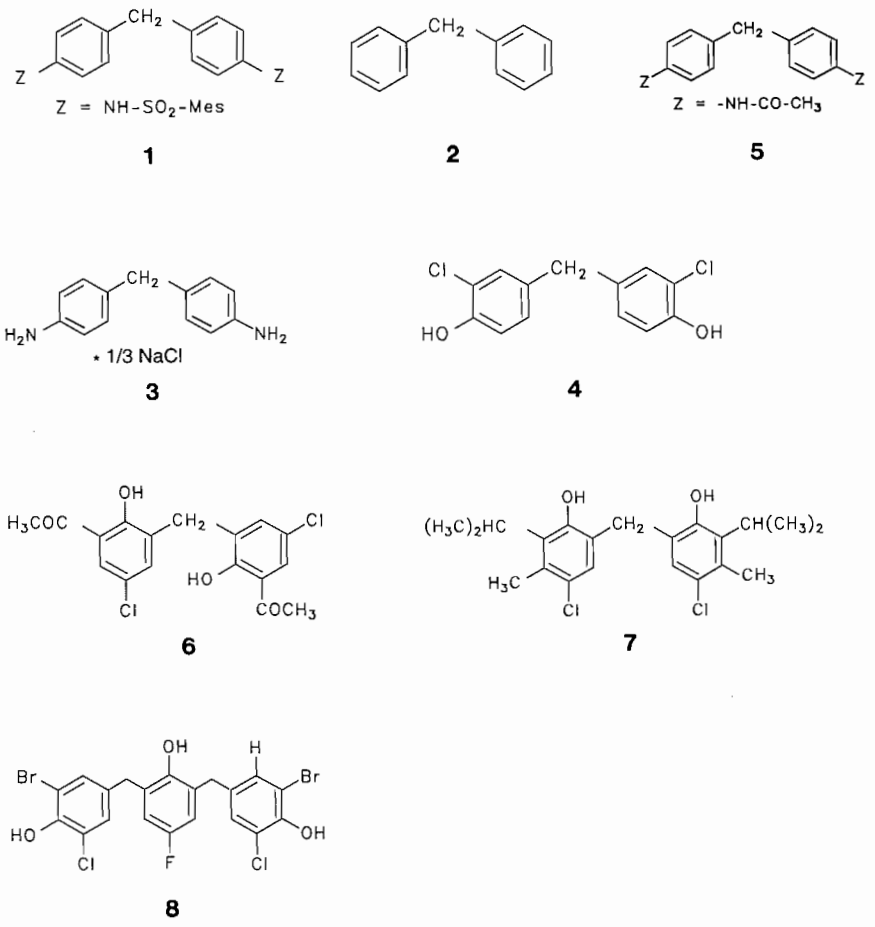
calculations is not as large as in the diphenyl ether case (C_s symmetry: 0.6 kcal/mol for B3LYP/6-31G(d), 0.49 kcal/mol for MP2/6-31G(d)) (15); C_{2v} symmetry: 0.65 kcal/mol for B3LYP/6-31G(d), 0.51 kcal/mol for MP2/6-31G(d)) (15)).



The symmetry of the surfaces reflects the symmetry of aryl-X-aryl compounds and is proof of the complete relaxation of all internal degrees of freedom except $\varnothing_A$ and $\varnothing_B$.

The differences between the results of semiempirical and density functional theory calculations are small. The minimizer problem of the C_{2v} structure of diphenylmethane, which was calculated to be a minimum by AM1 and PM3, is solved using DFT; it is a transition state with DFT as would be expected. Also, the influence of the basis set used is small. Tables 5 and 6 show the results of symmetry-imposed calculations with Becke3LYP/3-21G and Becke3LYP/6-31G(d). All extrema have the same number of imaginary frequencies

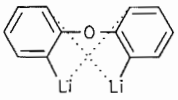
and differ only little in the calculated $\varnothing_A$ and $\varnothing_B$ values. Also, the energy differences between the different symmetries are small. The energy differences are compiled in Tables 5 and 6.



The shape of the surfaces is very similar and experimental data are reproduced very well by both methods. To evaluate properties of potential polymers it is absolutely necessary to get information about the molecular conformation of the monomers. But, as shown in this study, semiempirical methods also allow us to calculate oligomers with reasonable accuracy. In general, AM1 can calculate at least eight times as many atoms as density functional theory on the same computer and the results are qualitatively the same. Therefore semiempirical calculations seem to be very useful for all problems related to the phenyl rotation and especially AM1 is capable of calculating the molecular geometries of larger polymer units. Considering polymers in which conformational effects have a large influence on the potential usefulness of the blend, it might be necessary to calculate larger oligomers for a better prediction. This seems possible given the results of this study, which dealt with the main polymer structural units.

Electrochemical reduction of nickel(II) dithiocarboxylates at the mercury electrode

A. Safavi and L. Fotouhi

Abstract: The reduction mechanisms of a series of nickel(II) dithiocarboxylate complexes have been investigated in dimethyl sulphoxide at the mercury electrode. Various electrochemical techniques, including polarography, cyclic voltammetry, chronoamperometry, and controlled potential coulometry, were employed. The reduction of the complexes of the acid derivatives of 2-aminocyclopentene-1-dithiocarboxylate (ACD) proceeds initially by an ECE mechanism (electron transfer – chemical reaction – electron transfer) followed by a one-electron irreversible process. The nature of the complete electrode reaction suggests a metal-centered reduction. The nickel complexes of the ester derivatives of ACD underwent a one-electron reduction that was subject to a follow-up catalytic reaction (EC′ mechanism) and the original complex is regenerated through this regeneration reaction.

Key words: reduction, nickel(II) dithiocarboxylate, mercury electrode.

Résumé : On a étudié les mécanismes de la réduction d'une série de complexes de dithiocarboxylate de nickel(II) dans le diméthylsulfoxyde au niveau d'une électrode à mercure. On a utilisé divers techniques électrochimiques, incluant la polarographie, la voltampérométrie cyclique, la chronoampérométrie, et la coulométrie à potentiel contrôle. La réduction des complexes formés à partir des dérivés de l'acide 2-aminocyclopentène-1-dithiocarboxylate (ACD) se fait au début selon un mécanisme ECE (transfert d'électrons – réaction chimique – transfert d'électrons) suivi d'un processus irréversible à un électron. La nature de la réaction complète à l'électrode suggère une réduction centrée sur le métal. Les complexes de nickel des esters du composé ACD subissent une réduction à un électron suivie d'une réaction catalysée (mécanisme EC′) et le complexe original est regénéré par cette réaction de régénération.

Mots clés : réduction, dithiocarboxylate de nickel(II), électrode à mercure.

Introduction

A number of articles and several reviews (1–3) deal with complexes of platinum metals with mono- and polyfunctional S-containing ligands. Dithiocarboxylic acids and their complexes are of interest because of their antifungal activity (4) and because they are used as models of sulfur–metal proteins (5–7). It has been reported that 2-aminocyclopentene-1-dithiocarboxylate (ACD) and some of its derivatives form intense coloured complexes with various bi- and trivalent metal ions (8–11). Complexes of Cu(II), Ni(II), and Zn(II) with methyl-2-amino-1-cyclopentene dithiocarboxylate (6) and *N*-alkyl methyl-2-aminocyclopentene dithiocarboxylate (7) have been prepared and characterized using NMR, ESR, electronic absorption, and electrochemical spectroscopy. To understand the role of metals in processes of vital importance and to evaluate the stability of the oxidation number of the central atom and the reactivity of ligands in these complexes, their redox properties must be known. Yet these are limited (12, 13) or practically lacking, as for Ni(II) complexes of dithiocarboxylic acids.

While the work on dithiocarboxylate complexes is very limited, many workers have pioneered the redox behaviour of their analogue, dithiocarbamates, and have found that dithiocarbamate complexes of the first-row transition metals on platinum electrodes (14–19) participate in simple, generally reversible, one-electron reduction reactions, where the orbitals involved in electron transfer are essentially ligand in character. However, it was shown later that at mercury electrodes, the electrochemistry of dithiocarbamate complexes is more complex than at platinum electrodes (14).

As part of a continuing study into the electrochemistry of the transition metal dithiocarboxylates, this paper describes a detailed electrochemical study on the reduction of nickel(II) complexes with 2-aminocyclopentene-1-dithiocarboxylate (ACD) and some of its acid and ester derivatives. Since the compounds were completely insoluble in water and most organic solvents, dimethyl sulphoxide (DMSO) was chosen as the solvent. The complexes are moderately soluble in this solvent. Previous investigations on free dithiocarboxylate anions showed an anodic wave at ~ -0.68 V relative to SCE (12), while a reduction wave at -1.65 V relative to the same electrode was obtained from dithiocarboxylic acids (13).

Experimental

Instrumentation

Electrochemical measurements were performed in DMSO containing 0.5 M potassium perchlorate as supporting electrolyte using a Princeton Applied Research Corp. (PAR) electrochemical system, model 170. A three-electrode system was employed for all measurements. The working electrode was either a dropping mercury electrode (for polarographic measurements) or a hanging mercury drop electrode (H.M.D.E.). A platinum auxiliary electrode was used for all measurements while the reference electrode was a saturated calomel electrode (SCE).

Electrochemical measurements were made in solvent initially degassed with solvent-saturated argon.

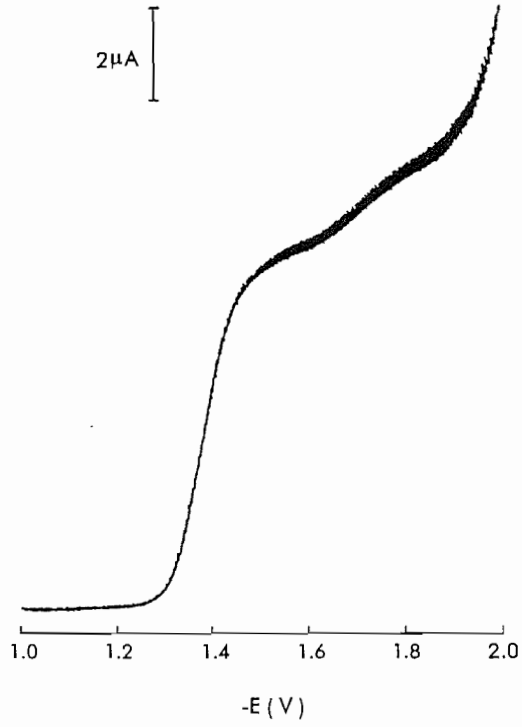
Unless otherwise stated, all measurements were made under the following conditions: temperature, 25 ± 1°C; concentration of NiL_2, 2.0 mM; polarographic drop time, 1.0 s.

Cyclic voltammograms were recorded using a Metrohm hanging mercury drop electrode.

Controlled-potential electrolysis experiments were performed using a mercury pool electrode. The experiments were monitored both electrochemically and spectrophotometrically. Electronic spectra were recorded with a Philips 8750 ratio recording UV–visible spectrophotometer.

Materials

ACD and its derivatives were prepared according to the procedure described by Takeshima et al. (20) and Bordas et al. (21). Yellow crystalline powders of each compound were isolated and identified by comparison of their melting points and IR and NMR spectra with those of authentic samples.



The Ni(II) complexes of ACD and its derivatives were prepared as described previously (9). Compound purity was established by elementary analysis.

Dimethyl sulphoxide (Fluka) was stored over type 4A molecular sieves. The potassium perchlorate used (Fluka) was recrystallized from triply distilled water and was oven-dried for several days.

Results and discussion

The ligands that were studied can be categorized into two groups: (*i*) the acid derivatives of ACD, which differ from each other by the substitution on nitrogen (L_I–L_{IV}), and (*ii*) the ester derivatives of ACD (L_V, L_{VI}), in which the hydrogen on the dithiocarboxylic acid group is substituted with an alkyl group. In this study, compounds L_I–L_{IV} are referred to as the acid derivatives of ACD, while L_V and L_{VI} are referred to as the ester derivatives (Scheme 1).

Fig. 1. The polarogram of $Ni(L_I)_2$ (3.3 mM) in 0.5 M $KClO_4$ in DMSO; drop time 5 s.

The electroanalytical behaviour of the nickel complexes of the acid derivatives is discussed first. When the acid derivatives are treated with Ni(II) solutions according to the procedure described previously (9), it has been claimed (9) that metal–ligand bond formation through the -SH site caused the -SH proton to be released from the molecule.

Nickel complexes of all the acid derivatives (L_I–L_{IV}) were prepared. However, complexes of L_{III} and L_{IV} were practically insoluble in aqueous and all the nonaqueous solvents tried, and thus it was not possible to investigate their electrochemical characteristics and the study was limited to complexes of L_I and L_{II}.

Nickel complexes of the ester derivatives (L_V, L_{VI}) were also prepared according to an established procedure (22). The complexes had limited solubility in DMSO, but their concentration was sufficient to investigate their electrochemistry.

Electrochemistry of the nickel complexes with the acid derivatives

Reduction at a dropping mercury electrode produced two dc polarographic reduction waves in the case of both acid derivatives (23). The second wave was not well defined and was later found to be a kinetic reduction (23) wave (Fig. 1, Table 1), the magnitude of which was governed by the rate of a chemical reaction (24). However, most of the interest lies in the first reduction wave, which will be considered in more detail.

The first wave, the less negative wave, was diffusion controlled in all cases. The diffusion current showed a linear dependence on the square root of the mercury column height and concentration within the range 0–3.5 mM, while the half-wave potentials were independent of concentration. Plots of

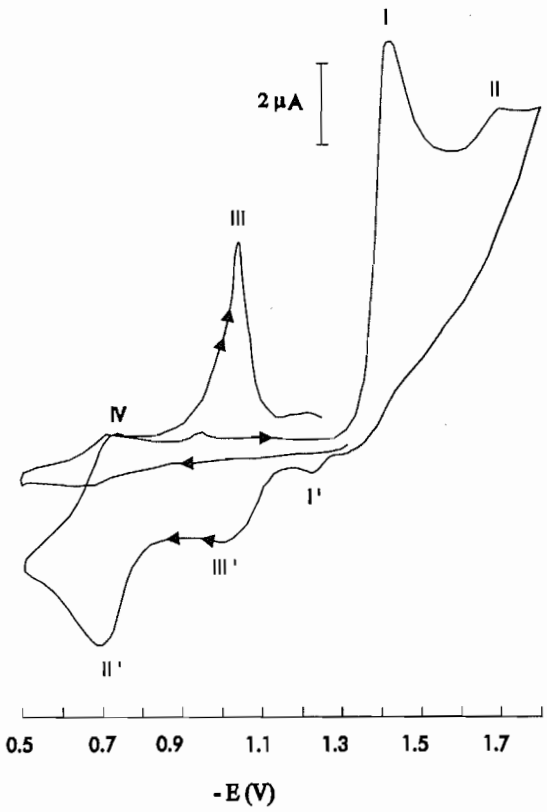
Table 1. Potentials ($E_{1/2}$) of the complexes (vs. SCE).

	Wave I		Wave II	
Compound	$E_{1/2}$ (V)	$E_{1/4} - E_{3/4}$ (mV)	$E_{1/2}$ (V)	$E_{1/4} - E_{3/4}$ (mV)
$Ni(L_I)_2$	−1.38	67	−1.72	80
$Ni(L_{II})_2$	−1.42	78	−1.80	85
$Ni(L_V)_2$	−1.65	65	—	—
$Ni(L_{VI})_2$	−1.35	60	—	—

Fig. 2. Cyclic voltammogram of $Ni(L_I)_2$ (3.0 mM) at H.M.D.E. (*a*) before and after holding for 15 s at −1.45 V (dotted line shows cyclic voltammogram of L_I^-); (*b*) from −0.5 to −1.8 V, 0.5 M $KClO_4$ in DMSO and scan rate 0.05 V s^{-1}.



E vs. log $(i_d - i)/i$ were all linear ($r = 0.998$) with a slope of 67 and 80 mV for nickel complexes of L_I and L_{II}, respectively, indicative of a one-electron, quasi-reversible reduction in each case.

The second (more negative) wave for each of the complexes of acid derivatives is drawn out and arises from an irreversible one-electron reduction process. The associated $E_{1/4} - E_{3/4}$ values are large (Table 1). The height of the second wave is proportional to concentration in the range of 0–3.0 mM and is independent of mercury column height (h), thus showing a kinetic character. It is expected therefore that the magnitude of the current in this wave is governed by the kinetics of a chemical reaction (24).

Cyclic voltammetry was used to study the mechanism of reduction of the nickel complexes. Under cyclic voltammetric conditions, two reduction peaks and three anodic peaks were obtained with both complexes of nickel(II) with the acid derivatives. Taking $Ni(L_I)_2$ as an example, the following observations were made. When the switching potential was selected at −1.45 V, where only the first reduction peak was observed (Fig. 2*a*), only two anodic peaks, I′ and II′ (at −1.18 and −0.67 V, respectively) were observed. The height of the anodic peak II′ was increased after holding the potential at the switching potential for 15 s. When the current was recorded at −1.80 V (down to the second cathodic peak), another anodic

Fig. 3. The initial anodic scan of $Ni(L_I)_2$ (3.3 mM) from −1.3 V to −0.5 V (at H.M.D.E.) and reversing scan up to −1.8 V; scan rate 0.05 V s^{-1}.

peak III′ (−1.08 V) also appeared (Fig. 2*b*). As can be seen in Fig. 2*a* (dotted line, cyclic voltammogram of ammonium salt of the acid L_I, L_I^-), the anodic peak at −0.67 V (peak II′) is due to the mercury complex of L_I^- (12). L_I^- is supposed to be released via a coupled chemical reaction in the first cathodic peak. The initial anodic scan of $Ni(L_I)_2$ from −1.3 to −0.5 V and the reverse scan to −1.8 V are shown in Fig. 3. As can be seen, after reversing the scan at −1.8 V and the appearance of the two cathodic peaks ($E_{pc,I} = -1.4$ V and $E_{pc,II} = -1.75$ V), three anodic peaks appeared. These observations further prove that the three anodic peaks are related to the products of the two cathodic peaks at −1.4 and −1.75 V. Figure 3 also shows that multiscan cyclic voltammograms recorded in the absence of free ligand display waves in the anodic sweep and second cathodic sweep (peaks IV/II′) and the peak potentials correspond closely to those for the system (12):

[1] $Hg + L_I^- \rightleftharpoons Hg(L_I) + e^-$

The mercury(I) complex formed in this process later undergoes disproportionation to the mercury(II) complex (12).

The above observations indicate that the ligand should be released during the reduction step, presumably via a chemical reaction.

A cathodic peak (sharp peak) after the second scan reversal (peak III) was also observed. It is difficult to determine exactly to which process peak III/III′ is due, as this is obvi-

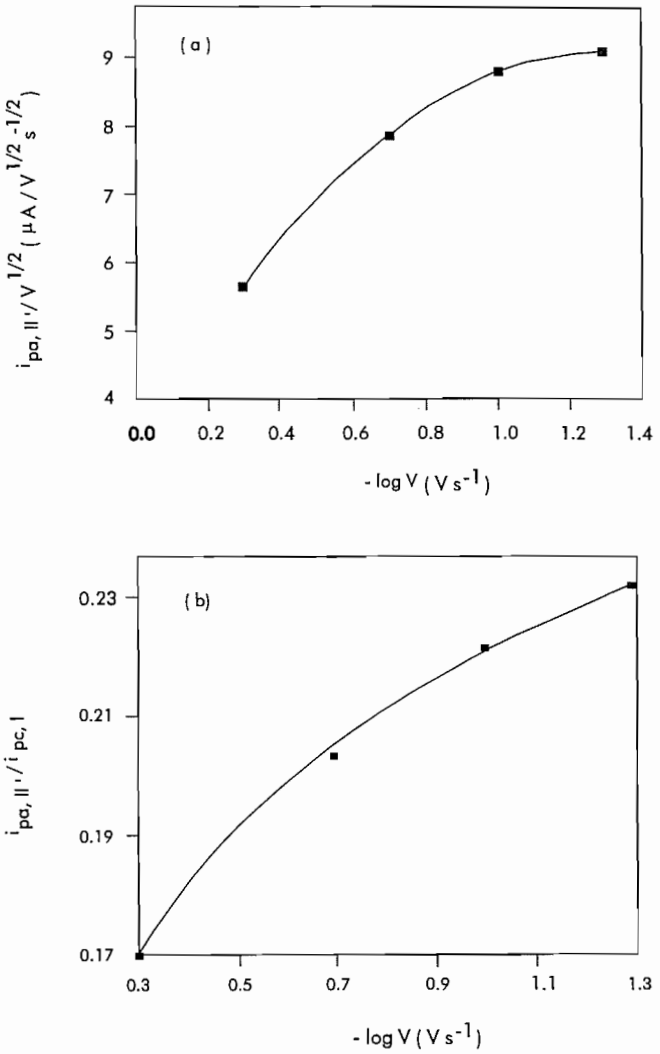
ously a very complicated reduction mechanism, with a number of processes occurring in solution after the reduction. It does appear to be formed as a consequence of the second reduction wave, peak II. The $E_{pc/2} - E_{pc}$ value for the first cathodic peak was changed from 55 to 60 mV by changing the scan rate from 0.02 to 0.2 mV s^{-1}. At slow scan rates, the cyclic voltammetric peak current function, represented by $i_{pc}/v^{1/2}$, is much higher than that expected for a reversible, one-electron, diffusion-controlled reduction. At high scan rates, the peak current function approaches the expected value of 0.446 and in fact is about 20% lower at 500 mV s^{-1}, probably as a result of the quasi-reversible nature of the electrode reaction. Although some of the above CV results, together with those derived from the analysis of dc wave (I), are consistent with a simple quasi-reversible electron transfer process, other results show that a more complex process prevails in this step and that, in fact, the assignment of an ECE mechanism to peak (I) is more appropriate. Analysis of the cyclic voltammetric parameters at various scan rates shows that at fast scan rates, where the influence of the coupled chemical reaction is slight, the CV half-wave peak widths ($E_{pc/2} - E_{pc}$) indicate a nearly reversible one-electron transfer process, while at slow scan rates deviation from this behaviour is observed. The calculated ratios of $i_{pa,II}/i_{pc,I}$ and $i_{pa,II}/v^{1/2}$ were decreased by increasing the scan rate (Fig. 4), which can be another reason for the presence of a coupled chemical reaction in the first cathodic peak.

For further elucidation of the mechanism, a chronoamperometric experiment was performed at an H.M.D.E., which demonstrated clearly that the reduction of $Ni(L_I)_2$ involves increasing departure from diffusion control with increasing electrolysis time. This result is illustrated by the variations in the main wave parameters shown in Fig. 5. At short electrolysis times, the slope of the chronoamperometric i against $t^{-1/2}$ plot is typical of a one-electron reduction for each complex, but approaches a slope representative of a two-electron reduction at longer electrolysis times.

Controlled potential coulometric analysis of the complexes, at a potential of -1.6 V, gave n values of 1.90 ± 0.2, with a change in colour from purple to orange (Fig. 6). The polarogram of the electrolysis product formed at this step showed an anodic wave due to the presence of free ligand (L^-_I), which appears because of the formation of a mercury complex (12).



As mentioned previously, analysis of the dependence of E on $\log(i_d - i)/i$ showed a linear relationship (with $r = 0.996$) with a slope that is indicative of a one-electron process. If the assumption of a direct two-electron reduction step is accurate, the plot of E vs. $\log(i_d - i)/i$ should be linear with a slope of 29 mV. The experimentally determined slopes are much greater than this for the two nickel complexes, 67 and 80 mV for nickel complexes of L_I and L_{II}, respectively. Also, the $E_{1/4} - E_{3/4}$ values are close to the expected value for a one-electron process, while coulometry shows a two-electron transfer for this reduction step. Thus, all of the above observations are consistent with two one-electron processes with a chemical process interposed between them, as below.

[2] $A + n_1 e \longrightarrow B \qquad E_1^\circ$

[3] $B \xrightarrow{k} C$

[4] $C + n_2 e \longrightarrow D \qquad E_2^\circ$

Fig. 4. Variation of cyclic voltammetric parameters with voltage scan rate in the reduction of $Ni(L_I)_2$ in dimethyl sulphoxide: (*a*) cathodic peak current function, represented by $i_{p,c}/v^{1/2}$, against log v; (*b*) anodic to cathodic peak current ratio against log v.

where species C is more easily reduced than A, and $n_1 = n_2 = 1$ (24), where $E_2^\circ >> E_1^\circ$.

At long electrolysis times, or at sweep rates slow in comparison to the rate of the chemical reaction, the reduction current is the sum of $A + n_1e \rightarrow B$ and $C + n_2e \rightarrow D$. At high sweep rates or at short electrolysis times, only the simple diffusion-controlled reaction, $A + n_1e \rightarrow B$, is observed. At slow scan rates, B reacts chemically before it can be oxidized in the reverse anodic sweep and hence the anodic to cathodic peak current ratio decreases with decreasing scan rate.

Nicholson and Shain (25) introduced the theory of stationary electrode voltammetry for both single and cyclic triangular wave experiments to systems in which the preceding, following, or catalytic reactions are coupled with reversible or irreversible charge transfer processes. In the reduction wave of $Ni(L_I)_2$ at -1.4 V (ECE mechanism) and at high sweep rates, where the influence of the coupled chemical reaction is slight, the first charge transfer process seems to be reversible. Therefore, by recording the cyclic voltammogram of $Ni(L_I)_2$ at high

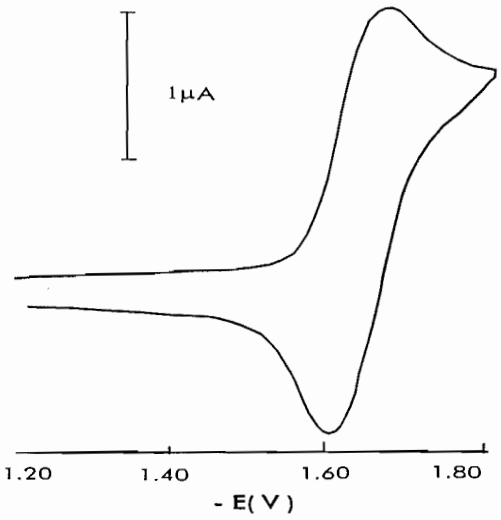
scan rates, such as 500 mV s^{-1}, the rate constant of the coupled chemical reaction (25) was calculated as 0.290 s^{-1}. The increase of the anodic peak due to the reaction of L^-_I with mercury upon holding the switching potential for 15 s can be good evidence that ligand loss is taking place through this coupled chemical reaction.



Thus, a possible mechanism for the first reduction wave of nickel complexes of the acid derivative ligands can be written as below:

[5] $Ni(L_I)_2 + e^- \longrightarrow [Ni(L_I)_2]^-$ (E)

[6] $[Ni(L_I)_2]^- \longrightarrow NiL_I + L_I^-$ (C)

[7] $NiL_I + e^- \longrightarrow [NiL_I]^-$ (E)

Fig. 7. Cyclic voltammogram of $Ni(L_v)_2$ (3.0 mM) at H.M.D.E.; scan rate 0.1 V s^{-1}; 0.5 M $KClO_4$ in DMSO.

For an ECE mechanism as above, where the second electron transfer is regarded as easier than the first one, the interference of the disproportionation reaction (24) in the overall kinetics must, however, be considered.

[8] $[Ni(L_I)_2]^- + NiL_I \longrightarrow [NiL_I]^- + Ni(L_I)_2$

This disproportionation step indeed favours the right-hand side since NiL_I is assumed to be more reducible than $Ni(L_I)_2$.

The analysis of the second wave at about −1.75 and −1.80 V, for $Ni(L_I)_2$ and $Ni(L_{II})_2$, respectively, showed that this wave has a drawn-out nature and a kinetic character, because its height was proportional to concentration in the range 0–3 mM and it was independent of mercury column height (*h*). The kinetic character of the wave suggests that the rate of electron transfer process in this step is controlled by the rate of a chemical reaction. The slopes of the plot of E vs. $\log(i_d - i)/i$ are 95 and 100 mV for Ni complexes of L_I and L_{II}, respectively, and the $E_{1/4} - E_{3/4}$ values (Table 1) show, together with the controlled potential coulometric data at −1.8 V ($n = 1.0 \pm 0.1$), that the process is an irreversible one-electron transfer process. The instability of the product formed in this step is emphasized by the irreversibility of its associated wave, which indicates that significant structural changes follow as a consequence.

Electrochemistry of the nickel complexes with the ester derivatives

The behaviour of the Ni(II) complexes with the ester derivative ligands (L_V and L_{VI}) differed from that of the nickel complexes of the acid derivatives. In these cases, only one reversible one-electron reduction wave was observed at −1.65 and −1.35 V for complexes of L_V and L_{VI}, respectively. Figure 7 shows the cyclic voltammogram of $Ni(L_v)_2$.

The polarographic slopes were consistent with a one-electron electrochemically reversible process, and CV measurements of peak separation (Table 2) confirmed this.

At CV scan rates between 0.02 and 0.20 V s^{-1}, the i_{pa}/i_{pc} ratio indicated a stable Ni(I) complex in the cyclic voltammet-

ric time scale. The above observation suggests a simple one-electron reversible process. However, the reactions were more appropriately studied by long-term, large-scale electrolytic procedures. Inspection of the current–time curve for this electrolysis showed that, whereas the reduction of $Ni(L_I)_2$ and $Ni(L_{II})_2$ was 90% complete in about 1 h, a decrease of about 10% in electrolysis current required approximately 4 h for $Ni(L_V)_2$ and $Ni(L_{VI})_2$, electrolysis conditions being nominally identical (Fig. 8). Our coulometric measurements indicated that in this 4.0 h period, the equivalent of approximately 6 electrons per molecule was consumed. Polarograms obtained periodically throughout the electrolysis showed no waves except that due to the starting material (never was there an indication of an anodic current from the presence of the free ligand, as in the case of $Ni(L_I)_2$ and $Ni(L_{II})_2$, and the plateau currents for those waves remained practically constant as the electrolysis proceeded). This indicated that the steady-state concentration of the Ni(I) product was zero and that follow-up reaction(s) are coupled to the electron transfer step (a dark colour could be seen to develop at the electrode surface, but it rapidly dissipated in the bulk of solution). The electrolysis was also monitored spectrally in the uv–vis range with the in situ electrolysis cell. In several experiments during electrolysis, only spectroscopic characteristics of the Ni(II) complex starting material were observed.

Electrochemical and electronic absorption data on nickel complexes of L_V and L_{VI} were thus consistent with the following equation, in which the Ni(I) product is subject to the follow-up reaction, resulting in regeneration of the Ni(II) complex. This reaction occurs through reaction of the Ni(I)

$$[9]\quad Ni(L_V)_2 + e^- \longrightarrow [Ni(L_V)_2]^- \xrightarrow{[Z]}$$

species with some component of the electrolyte solution, likely the solvent itself, although the effect of undetected solvent impurities cannot be ruled out (24). It is likely that the oxidant, Z is present in excess of the nickel complex by several orders of magnitude and this is the reason for obtaining a high steady-state electrolysis current.

The above study clearly demonstrates the effect of ligand substitution and site of donation (6, 9, 22) on the electrochemical behaviour of the complex, even if the electron transfer process is metal based. Since the nature of the complete electrode reaction suggests a metal-centered reduction for both the acid and ester derivatives complexes, completely different mechanisms must prevail. For the Ni(II) complexes of the acid derivatives, where bonding occurs through amino nitrogen and deprotonated thiosulphur (9), the reduction proceeds via an ECE mechanism with $n = 1$ for each electron transfer process and the chemical reaction involves a dissociation to produce a nickel species more easily reduced than the Ni(II) ACD complex. However, for the Ni(II) complexes of the ester derivatives, where chelation occurs through thioketonate sulphur and amino nitrogen groups (6, 26), reduction occurs via an EC′ mechanism with $n = 1$ for the electron transfer step. Different reduction mechanisms are also suggested (14) for different Ni(II) dithiocarbamates based on the structural difference between their ligands. So, while some Ni(II) dithio-

© 1997 NRC Canada

carbamate complexes are reduced via an ECE mechanism, some others show an ECCE reduction mechanism of the type where the product of the first chemical reaction reacts further to produce a nickel species more difficult to reduce than Ni(II) dithiocarbamates.

In this work, the nature of the electrode reaction suggests a metal-centered reduction, in which the orbitals involved in the electron transfer process are essentially metallic in character. This is in agreement with the nature of the reduction process of nickel(II) dithiocarbamates at the mercury electrode (14).

cis-2,3-Di-*tert*-butylcyclopropanones

T.S. Sorensen and F. Sun

Abstract: The preparation of the strained *cis*-2,3-di-*tert*-butylcyclopropanone **2** from the acyclic compound, α,α′-dibromodineopentyl ketone **1**, using a previously reported methodology, is dramatic evidence of both the existence of oxyallyl intermediates in the mechanism of this reaction, and of the integrity with which oxyallyls ring-close to cyclopropanones by a disrotatory route. Because of the bulky *cis* substituents, cyclopropanone **2** exhibits a number of unusual spectroscopic features (as compared to the *trans* isomer **5**). With the aid of ab initio calculations on **2** and **5**, it can be shown that the C2—C3 bond in **2** interacts with the carbonyl π-orbitals, thus causing the carbonyl oxygen to bend 12° out of the plane; this interaction is absent in **5** and the latter has a planar carbonyl group. As with other cyclopropanones, **2** can be photochemically decarbonylated. This process itself appears to be stereospecific even though highly strained alkenes are produced. Cyclopropanone **2** is thermally rearranged to the *trans* isomer **5** and the kinetics for this are reported; our favoured mechanism involves oxyallyl intermediates. Other reactions of **2** also appear to proceed through these oxyallyl species; for example, alcohols initially add to **2** to give α-alkoxy enols, solutions of **2** enter into very facile diene cycloadditions, and the dimerization of neat **2** also appears to involve these oxyallyl species.

Key words: cyclopropanones, oxyallyl, stereomutation, stereospecific decarbonylation, nonplanar carbonyl.

Résumé : On a préparé la *cis*-2,3-di-*tert*-butylcyclopropanone (**2**) tendue à partir de l'α,α′-dibromodinéopentylcétone acyclique, **1**, en faisant appel à la méthodologie développée antérieurement. Cette synthèse est une preuve évidente à la fois de l'existence d'intermédiaires oxyallyles dans le mécanisme de cette réaction et de l'intégrité avec laquelle les oxyallyles se cyclisent en cyclopropanones par une voie disrotatoire. À cause de l'encombrement des substituants *cis*, la cyclopropanone **2** présente un certain nombre de caractéristiques spectroscopiques inhabituelles (par comparaison avec son isomère *trans*, **5**). En appliquant des calculs ab initio aux composés **2** et **5**, on peut montrer que la liaison C2—C3 du composé **2** interagit avec les orbitales π du carbonyle provoquant ainsi un déplacement de 12° de l'oxygène du carbonyle hors du plan; cette interaction est absente dans le composé **5** et ce dernier possède donc un groupe carbonyle planaire. Comme c'est le cas avec d'autres cyclopropanones, le composé **2** peut être décarbonylé photochimiquement. Ce processus semble être stéréospécifique, même s'il conduit à des alcènes fortement tendus. La cyclopropanone **2** se réarrange thermiquement en isomère *trans*, **5**, et on a mesuré la cinétique de cette réaction; le mécanisme que nous favorisons implique des intermédiaires oxyallyles. Il semble que d'autres réactions du composé **2** se produisent aussi par le biais de ces espèces oxyallyles; par exemple, les espèces oxyallyles semblent être aussi impliquées dans l'addition initiale des alcools à **2** pour donner des α-alkoxyénols, dans les réactions très faciles de cycloadditions diéniques des solutions de **2** ainsi que dans la dimérisation de **2** à l'état pur.

Mots clés : cyclopropanones, oxyallyle, stéréomutation, décarbonylation stéréospécific, carbonyle non planaire.

[Traduit par la rédaction]

Introduction

The reaction of the metallate salt, $PPN^+Cr(CO)_4NO^-$ with α,α′-dibromo ketones has recently been explored as a low-temperature route to cyclopropanones (1–3). The reaction is extremely rapid, even at −100°C, and is postulated to involve the intermediates **B** and **C** (eq. [1]).

The existence of the bromo enolate **B** can be shown by trapping experiments with $(CH_3)_3SiCl$ (1), and the oxyallyl species **C** is inferred from the similarity of this overall reaction to the early steps of the Favorski rearrangement, and by using a cyclopentyl ring system, whereby dimers of the oxyallyl can be characterized in this special case (4).

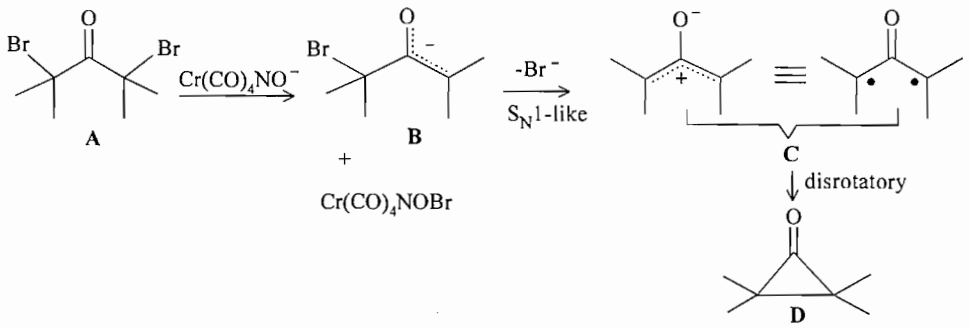
Another approach to clarifying the existence of **B** and **C** in eq. [1] is to use stereochemical markers, and we have recently communicated (2) the result that α,α′-dibromodineopentyl ketone **1** produces only *cis*-2,3-di-*tert*-butylcyclopropanone **2**, the thermodynamically much less stable of the two possible stereoisomeric cyclopropanones.



In this paper we expand on the earlier results and explore more fully the unusual chemical and physical properties of **2**.

Results and discussion

There are two possible diastereomers of **1**, the meso isomer **1a** and the racemic form **1b**. When dineopentyl ketone is brominated, only a single crystalline diastereomer is isolated in high yield (5). The CHBr ^1H NMR peak for this isomer is found at δ 4.40 (1.18 for the *t*Bu peak) and there is not much evidence for a second isomer in the small amount of mother liquor material. However, when **2** was brominated small additional peaks were observed in the crude reaction mixture, δ 4.50 and 1.20, approximately 5–8% of those for the major isomer. This minor isomer has a considerably shorter GLC retention time

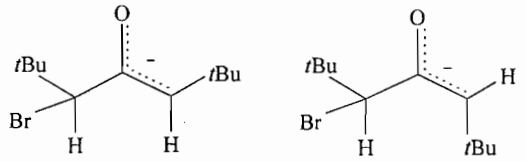
For personal use only.



[1] 

than the major one and it could be isolated free of the latter by preparative GC.

Both dibromo diastereomers were separately reacted with $Cr(CO)_4NO^-$ at −78°C in CD_2Cl_2 solution to give **2** (NMR monitoring) in each case.

This single product result can be nicely rationalized from the eq. [1] mechanism. The bromo enolate formed from either **1a** or **1b** has two possible geometric forms, **B1** and **B2**, assuming a planar enol functionality. From MM2 or AM1 semiempirical calculations, the most stable conformers of **1a** and **1b** both have the C—Br bonds approximately perpendicular to

the plane of the carbonyl group, and the *t*Bu groups in both cases have a steric alignment that will lead to the bromo enolate **B1**, i.e., if "Br^+" loss takes place so that the newly forming enolate *p*-orbital is in conjugation with the carbonyl group. Semiempirical calculations (AM1) also predict that **B1** is about 4 kcal/mol more stable than **B2**.

The loss of Br^- in **B1** perpendicular to the enolate plane will lead to oxyallyl **C1** with both *t*Bu groups in the *syn* position relative to oxygen.

It is unlikely that either the C—Br reduction or the loss of Br^- is reversible, but the above analysis predicts that the kinetic products are also the thermodynamically stable ones up to, and including, the oxyallyl intermediate.

Finally, the ring closure of the oxyallyl **C1** is observed to be strongly pericyclic in nature and the least stable cyclopropanone is ultimately produced.

The above analysis also predicts that the diastereomers of **3** should form the cyclopropanone **4**, as is indeed the case.

cis-2,3-Di-*tert*-butylcyclopropanone **2** can be isolated using a sub-ambient temperature work-up, subliming as white crystals, mp ca. −22°C, onto a surface cooled by Dry Ice at about −10°C/0.01 Torr (1 Torr = 133.3 Pa). At room temperature this ketone is an unstable liquid (see later). In contrast, cyclopropanone **4** could only be examined as an in situ solution since it rapidly rearranges at −30°C, producing the α,β-unsaturated ketone **6**, a known compound (6).

As an aside, it is now known that cyclopropanone thermal stability is associated with having only tertiary alkyl substituents or hydrogen (2, 3), accounting for the stability of the previously reported *trans*-2,3-di-*tert*-butylcyclopropanone **5** (7), 2,2-di-*tert*-butylcyclopropanone (6), and trialkylsilyl-substituted cyclopropanones (8, 9), but not **4**.

The preparation of *cis*-2,3-di-*tert*-butyl-2,3-dimethylcyclopropanone by our procedure failed because the starting ketone could not be dibrominated.

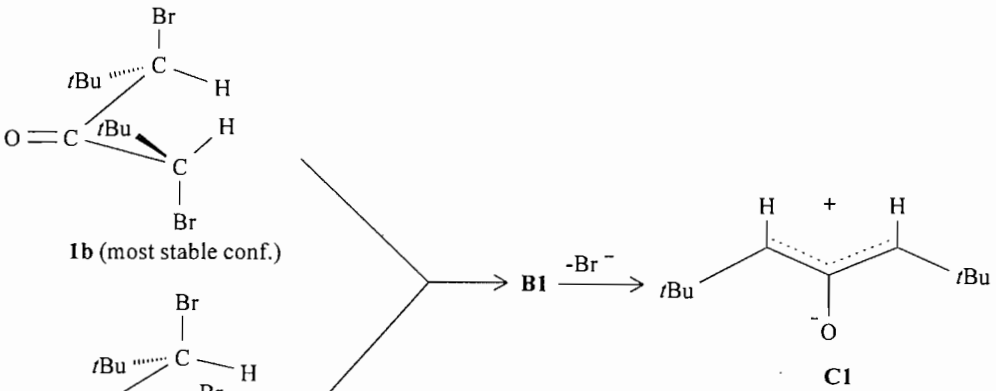
Spectroscopic studies on 2, 4, and 5

As expected, the *cis* ketone **2** has only two ^1H NMR peaks, at δ 3.04 (2H) and 1.10 (18H) in $CDCl_3$. The spectra were also measured in several other solvents. The *trans* ketone **5** has a considerably higher field position for the CH hydrogens (7), δ 1.67. Cyclopropanone **4** has the CH peak at 2.66. The ^{13}C NMR spectrum of **2** ($CDCl_3$) shows the CH carbons at δ 47.1 (vs. 30.8 in **5**).

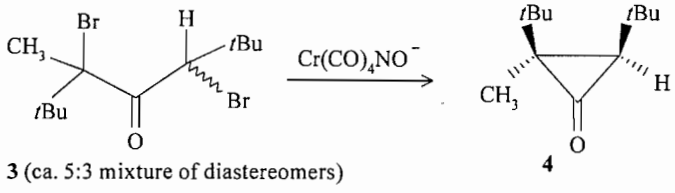
In **4**, the corresponding carbons are found at δ 50.5 (C_q) and 51.9 (CH). The ^{17}O NMR spectra of **2** and **5** were measured in this study because we expected (next section) to see a somewhat higher field shift in **2**, as was indeed the case, δ 487 in **2** vs. 530 in **5**.

The IR spectrum of **2** has a split C=O stretch at 1792 and 1819 cm^{-1}, with the former about twice the intensity of the latter. Coincidentally, the *trans* isomer **5** has (7) a single C=O stretch at 1819 cm^{-1}. This is a significant difference and in the next section we discuss in more detail a probable origin for this result. No IR data were measured for **4** because of its instability.

The $n\rightarrow\pi^*$ UV absorption for **2** is found at 329 nm, compared to a reported (7) 354 nm for **5**, both results for hydrocarbon solvents. This difference of 25 nm can also be rationalized from a detailed analysis of the computed structure for **2**.



Ab initio calculations of 2 and 5. Onset in 2 of a unique delocalization of C2—C3 electron density into the C=O π* orbital. Correlation with spectroscopic data



High-level ab initio calculations (B3LYP-6-31G**) were carried out on cyclopropanones **2** and **5**. Key bond lengths, angles, and dihedrals for the optimized structures are shown in Fig. 1. Although both isomers have severe bond angle distor-

tions, the calculated bond distances are more normal in **5**, particularly the C2—C3 bond at 1.579 Å vs. 1.640 in the *cis* structure **2**. The calculated geometry of **5** is in good agreement with data from an X-ray structure of a closely related *trans*-dialkylcyclopropanone[2] (compound **7**, C2—C3 = 1.584 Å). No X-ray data have yet been obtained for *cis* dialkylcyclopropanones but there are several other benchmarks by which one can judge the quality of the calculations:

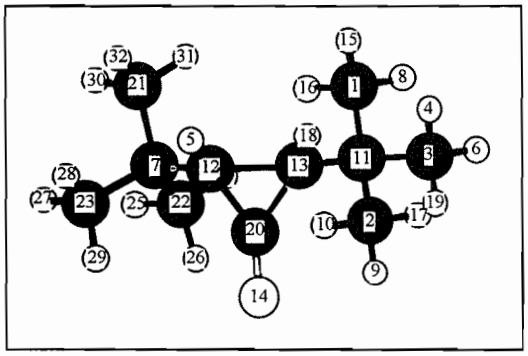
7

1. ^{1}H, ^{13}C, and ^{17}O NMR calculated shifts for **2** and **5** successfully mirror the experimental results (^{1}H, H2–H3 for **2** and **5**, respectively, calculated as δ 2.74 and 1.49; ^{13}C, C2–C3, δ 44.5 and 31.7; ^{17}O, 479 and 514).

2. Calculated C=O stretching frequencies for **2** and **5** are 1805.6 and 1826.2 cm^{-1}, successfully predicting a lower frequency value for **2**.

Besides the C2—C3 bond distance differences calculated for **2** and **5**, there is also a marked difference in the planarity of the >C=O group. In the calculated structure for **5**, and in the X-ray structure for **7**, the carbonyl group is essentially planar, whereas the *cis* isomer calculations give a markedly nonplanar >C=O, in which the oxygen atom is bent towards the *t*Bu face of the molecule (12° from the plane of the three carbons).

This distortion can be linked to an interaction between the C2—C3 bond and the π* orbital of the carbonyl. Because of the short C1—C2(C3) bonds in **2**, and the presence of a three-membered ring, the distance from the carbonyl carbon to the midpoint of the C2—C3 bond (calculated as the line of shortest distance) is only 1.18 Å. This short distance is normally of no great significance because the C2—C3 bond is orthogonal to the π* orbital in a planar cyclopropanone such as **5**, but in the isomer **2** the bulky tBu groups increase the *t*Bu-C2-C3 bond angle on one face compared to the H-C2-C3 angle of the other face (see Fig. 1), the computed angles being 135°–136° vs. 104°–105°. This imbalance has the effect of creating greater electron density on the *t*Bu "face" of the cyclopropanone so that the previously discussed orthogonality is no longer strictly in force and a favourable interaction with the empty π* orbital is possible. Only one lobe of the carbonyl carbon *p*-orbital interacts with this electron density, and a better orbital overlap can obviously be obtained if the carbonyl group tips toward this electron density. This slight C2—C3 bond asymmetry can be seen in an orbital plot of the HOMO-1 orbital (Fig. 2), which mainly comprises the C2—C3 σ bond. A small p_z orbital contribution on the carbonyl oxygen (seen in the Fig. 2 projection) shows that an interaction with the carbonyl π–π* orbitals is present.



This electron delocalization from the C2—C3 bond into the π* orbital can be correlated with the following experimental and theoretical results:

1. a longer C2—C3 bond in **2** (vs. **5**) because of reduced electron density in the bond (clearly steric factors also apply).

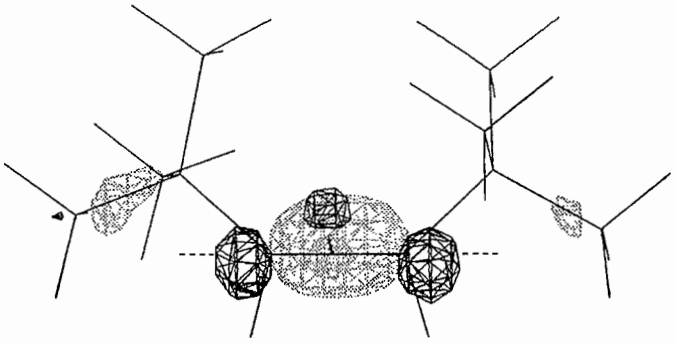
2. in the "three-orbital interaction" picture (10), the "new" π* C═O orbital is somewhat raised in energy compared to the "no interaction" case. This can account for the smaller λ_{max} for the $n\rightarrow\pi^*$ UV absorption of **2** when compared to the *trans* isomer value (both values are unusually high wavelength, and we stress only the comparison here). It also accounts for the higher field shift in the ^{17}O NMR spectrum in **2**, since paramagnetic ^{17}O shifts are also related to the size of $n\rightarrow\pi^*$ transition energies.

3. electron donation into the π* carbonyl reduces the >C═O bond order and one predicts a lower stretching frequency in **2**, as is found.

We have no quantitative measure of how much energy stabilization is provided by the C2—C3 bond electron delocalization but we feel that the latter has more effect on spectroscopic properties than energies. An interesting comparison is the energy difference between **2** and **5**, compared to *cis*- and *trans*-1,2-di-*tert*-butylethene, 7.21 kcal/mol (calcd.) vs. 9.37 (expt.) (11). Given the quite different bond lengths in these sets, it does not appear that cyclopropanone **2** is appreciably stabilized.

Reactions of 2

Photochemistry



The photochemical decarbonylation of cyclopropanone itself (12, 13) and of several substituted derivatives has been reported, including the use of this procedure to create a strained alkene (14). As far as we are aware, *trans* cyclopropanone **5** is the only previous system where the alkene product could exhibit stereochemical differentiation and, in this case, only the *trans* alkene **8** is produced (7). Since this is the thermodynamic product as well, the observation in the present work that the *cis* cyclopropanone **2** produces the *cis* alkene **9**,

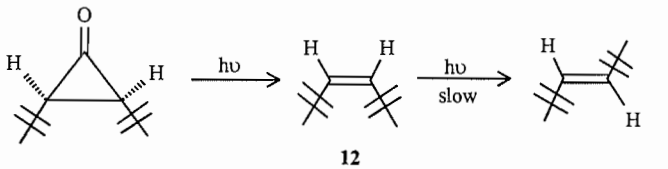
Fig. 2. Plot of the HOMO-1 orbital (the "non-bonding" combination) from the B3LYP/6-31G** calculation of cyclopropanone **2**. The view through the planar cyclopropane ring has the C2—C3 bond in front (C1 is hidden) and one can see that this orbital is not totally symmetrical with respect to a line connecting C2 and C3 (slightly larger on the *tert*-butyl side of **2**, and vice versa for the back lobes). The tipped carbonyl oxygen bond can be seen and the small out-of-phase *p*-orbital contribution of the oxygen to this HOMO-1 orbital can also be seen.



and that **4** produces the *cis* propene **10**, is a much more unambiguous demonstration that stereochemistry is retained in this decarbonylation.

In the actual results, a small amount of *trans* alkene (ca. 5% with both **2** and **4**) is present at the end of the photolysis of the cyclopropanones, but it can be shown that the *cis* alkene is itself photochemically labile (*cis* → *trans* alkene) under our conditions. If one compares the two photochemical rates with the ratio of *cis*:*trans* alkene present immediately after cyclopropanone disappearance, and extrapolates back to zero time, one sees a good correspondence, leading us to conclude that the cyclopropanone decarbonylation is stereospecific. Cyclopropanone **2** is obviously a stringent test of this stereospecificity since the *cis* alkene is 9.37 kcal/mol less stable than the *trans* isomer (11).

In unpublished work,[2] we also prepared the *cis* alkene **12** from the corresponding cyclopropanone, this alkene being even more strained than **9**. In this case the *cis* alkene → *trans* alkene photochemical reaction is relatively faster, leading to ca. 25% of the *trans* alkene at the end of the cyclopropanone photolysis, but the two alkenes can be easily separated by preparative GC.

The photochemical decarbonylation of **4** at −78°C illustrates the advantage of having a low-temperature preparation and work-up procedure since, as described earlier, this particular cyclopropanone rapidly rearranges to the α,β-unsaturated ketone **6** at −30°C.

This photochemical reaction is also useful as a structure proof tool. The stereochemistry assigned to **4** follows logically from the prior preparation of **2**, but we have no *trans* isomer of **4** for comparison purposes. However, the alkene produced from **4** clearly has the *cis*-di-*t*Bu structure **10** since the latter is photochemically isomerized to a more stable alkene that must then have the *t*Bu groups *trans*, i.e., **11**. Also, the H---CH_3 coupling of 1.2 Hz in **11** vs. unresolved coupling in **10** is consistent with this assignment.

cis- *to* trans-*2,3-Di*-tert-*butylcyclopropanone rearrangement* $2 \rightarrow 5$

Under the conditions of the in situ NMR tube reactions used initially to observe **2**, this compound was stable up to about 20°C. Starting at about 0°C, one of the reaction by-products, $Cr(CO)_4NOBr$, decarbonylates (remove NMR tube cap!). Although the resulting inorganic products are of unknown structure, it is possible that they have some Lewis acid properties that may be promoting the *cis*-**2** → *trans*-**5** conversion.

As evidence, when an alternative low-temperature work-up and isolation procedure is adopted, the resulting pure **2**, in various inert solvents at 20°C, only slowly rearranges over a period of days. Under GLC analysis it is possible to obtain a reasonable size peak for **2** (together with **5**) when on-column injection conditions are used, but with split-mode injections one sees mainly the peak for **5**. The shape of the *cis*-**2** peak indicates that no appreciable on-column rearrangement is occurring.

The rate of the thermal uncatalyzed rearrangement of **2** to **5** was measured at 80°C in toluene-d_8 solvent contained in a PTFE-lined 5 mm NMR tube, using ^{1}H NMR to monitor concentrations. Initially the analysis was based on the respective areas of the CH peak in the two isomers, assuming that the combined area was constant. However, the overall conversion is not totally clean and so the rate of the *trans*-**2** formation (first order) was measured directly using the residual ^{1}H peak of the toluene methyl group as a standard area, $k = (1.5 \pm 0.3) \times 10^{-4}$ s^{-1}, $\Delta G^{\ddagger} = 27.1 \pm 0.1$ kcal/mol.

There are several possible mechanisms for the $2 \rightarrow 5$ rearrangement. Cleavage of the C1—C2 bond and reclosure after bond rotation is one possibility. The *trans*-**5** can be thermally decarbonylated at 150°C (7), and this process presumably involves an initial C1—C2 bond cleavage. In the more strained **2**, such a bond cleavage could conceivably be even more favorable, but there is no evidence for any appreciable decarbonylation of **2** along with rearrangement into **5**. This possible mechanism is related to the more general case of stereomutation in cyclopropanes, the subject of much study (15).

Another possible mechanism involves bond rotation in the oxyallyl valence bond partner of **2**. From NMR line-broadening studies on the closely related *cis*-di-*tert*-amylcyclopropanone (2), we have estimated that the oxyallyl **C1** is about 11.3 kcal/mol higher free energy than the cyclopropanone. It is also known from the work of Greene and co-workers (16) that the *trans*-**5** − oxyallyl **C2** free energy difference is about 28 kcal/mol (in both cases we assume that $\Delta G \sim \Delta G^{\ddagger}$ (2, 17)).

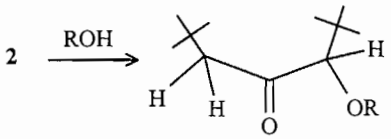
From our theoretical results discussed earlier, we calculate ΔG = 8.96 kcal/mol for the free energy difference between **2** and **5**. Putting these numbers together leads to the free energy diagram shown in Fig. 3. By difference, the two oxyallyls **C1** and **C2** are predicted to differ in energy by 7.7 kcal/mol, very similar to an AM1 semiempirical calculated difference (this work) of 7.6 kcal/mol. The origin of this energy difference is mainly steric so the AM1 method used here should give a reasonable estimate of this. If the *cis*-**2** → *trans*-**5** isomerization followed the route **2** ⇄ **C1** ⇄ **C2** ⇄ **5**, our observed free energy of activation would be above the **C2** oxyallyl free energy value, so this could clearly be a feasible route on energetic grounds. This route predicts a bond rotation barrier in **C1** of ca. 16 kcal/mol. There is almost nothing reported in the literature about rotation barriers in oxyallyls.

Finally, a conrotatory opening of **2** to directly give **C2** is also a possible rearrangement mechanism. If this mechanism were operative, there would be a 27 kcal/mol vs. 11.3 kcal/mol difference in conrotatory vs. disrotatory ring opening (almost a trillionfold rate difference at 25°C). If this mechanism is not operative, the inferred integrity of the disrotatory opening is even larger.

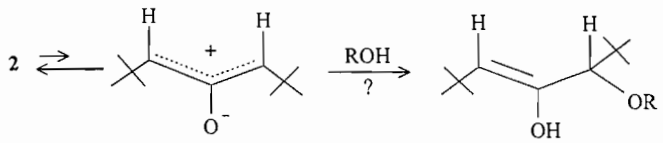
One cannot a priori rule out any of these mechanisms, but the absence of appreciable thermal decarbonylation in **2** leads one to favor the latter two postulates. These are, in any case, only subtly different.



Although clearly not a possible reaction mechanism under our toluene-d_8 solvent conditions, a base-catalyzed enolate mechanism for the rearrangement of **2** to **5** is suggested from the literature results of Greene and co-workers (7). These authors prepared the *trans*-**5** by reacting α-bromodineopentyl ketone with *t*BuO⁻–*t*BuOH (Favorski reaction conditions). The question is, why was the *trans* isomer formed in this reaction? An oxyallyl mechanism cannot directly apply since we have just shown that this mechanism leads to the *cis* isomer **2**. An internal S_N2 displacement[3] (still shown this way in a well-known text (18)) is problematic from a steric viewpoint (19), and would also not explain why this internal displacement did not happen in our work.

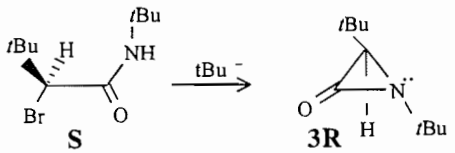
The most appealing explanation is that the route used by Greene does initially yield the *cis* cyclopropanone **2**. Although it is expected to be very reactive at the C2—C3 bond under these alcohol–alkoxide conditions, a deprotonation to the enolate could be competitive with these other reactions, and reprotonation to the *trans*-**5** would of course be overwhelmingly preferred. Greene and co-workers were able to indirectly show that H–D exchange can take place with **5** in *t*BuO⁻–*t*BuOD; recovered **5** was not obtained but the Favorski product from **5** had extra deuterium atom substitution. Based on our calculated $\Delta\Delta G$ difference between **2** and **5** of 8.96 kcal/mol, and the fact that the enolate is common to both ketones, one can calculate that **2** is 6.5 pK_a units more acidic than **5**. The hydrogens in **2** are also more sterically accessible than those in **5** and so it would not be surprising if **2** formed the enolate several million times faster than **5**, and that this reaction could therefore be quite competitive with other possible reactions of **2**.

Reaction with alcohols and water



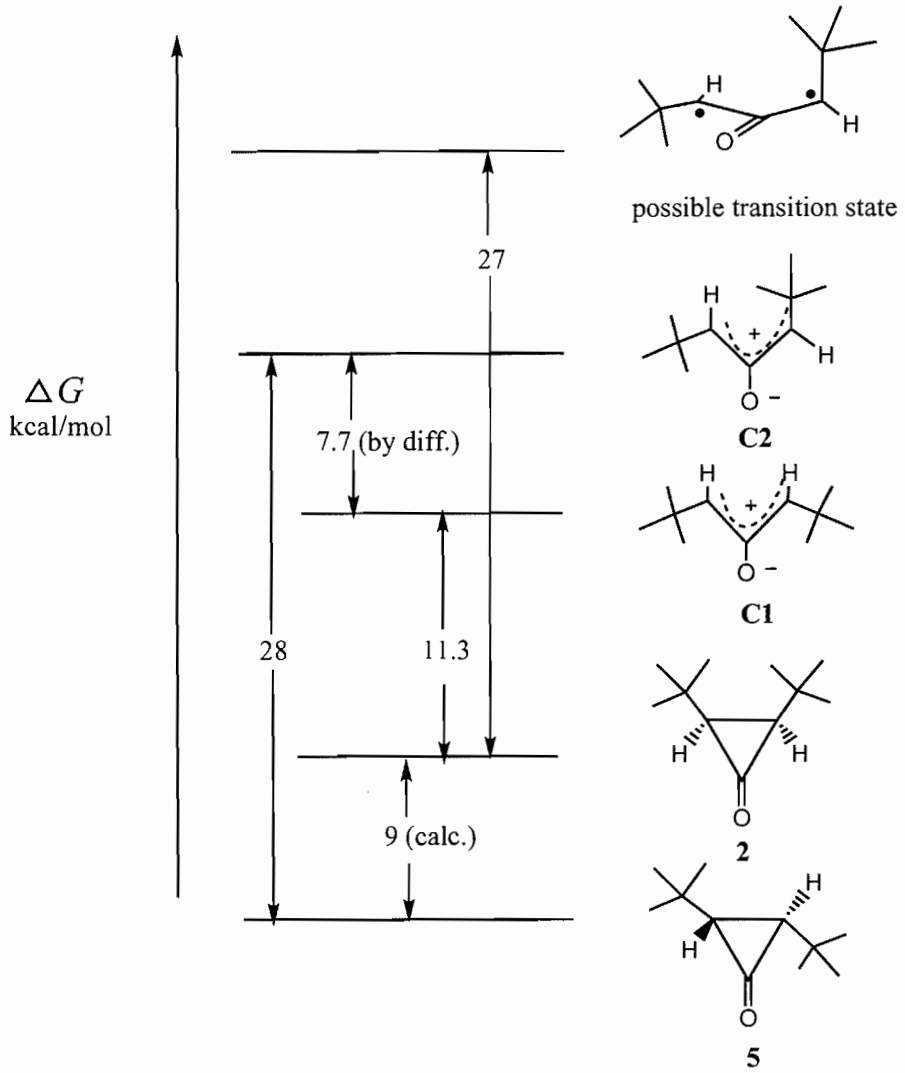
When **2** is reacted with methanol, 2-propanol, or benzyl alcohol (sub-ambient to ambient temperatures), the α-alkoxy ketones **13** are produced on work-up. In contrast, the *trans* isomer **5** is reported (7) to give cyclopropanone hemi-ketals under these conditions but, on heating these, the same α-alkoxy ketones are formed.

13 (R=CH_3, iPr or Bz)



However, when **2** was treated with methanol or 2-propanol and the solution was examined by ^{1}H NMR, all starting ketone had reacted but only a small amount of α-alkoxy ketone **13** was present. The major product had two diagnostic low-field signals (at δ 4.76 and 4.11 in the methanol case, mutually coupled with $J \sim 1.5$ Hz). These peaks can be assigned to the enol of the α-methoxy ketone, structure **14**. Not surprisingly, this enol readily converts to the corresponding ketone on work-up. 2-Propanol likewise forms the enol under these same conditions.

The initial formation of an enol opens the possibility that the reactive species in this reaction may be the oxyallyl **C1**, although other mechanisms are also feasible.



C1 **14** (R=CH_3, iPr)

[3] An internal S_N2-type mechanism is presumably operative in the preparation of 3-*R*-aziridinone (20) from the *S*-amide in the presence of *t*BuO⁻, but nitrogen has two lone pairs in the amide salt intermediate, one of which is in a suitable position to carry out the internal displacement.

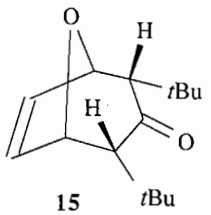
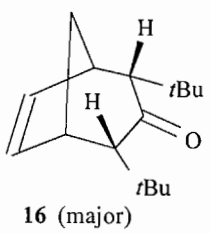
Fig. 3. Relative free energies of cyclopropanones **2** and **5**, and their corresponding oxyallyl valence-bond partners **C1** and **C2**. These data are derived from a combination of experimental and computational data.



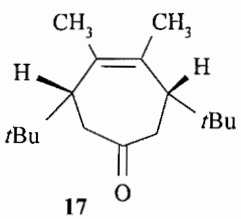
Water readily reacts with **2** to give the α-hydroxy ketone **13** (R = H).

Cycloaddition reactions



A sizeable literature, beginning with the early work of the Turro group (21), exists on 3+4 cycloaddition reactions involving characterized cyclopropanones. There is a much larger body of work involving in situ generated "oxyallyl" species for use in these same cycloaddition reactions; in most cases these can be better described as oxyallyl cations because of complexation of the oxygen (22, 23). In our work we find that **2**, despite the bulky *t*Bu groups, is very reactive with some dienes. Furan, cyclopentadiene, and 2,3-dimethyl-1,3-butadiene form adducts with **2** at (or below) room temperature.

This reactivity can be attributed to the oxyallyl **C1**, which is in equilibrium with **2** (see previous discussion). In contrast, the *trans* isomer **5** is in equilibrium (Fig. 3) with miniscule amounts of the **C2** oxyallyl, and this latter species is also sterically hindered. Not surprisingly, there have been no reports of cycloadditions involving **5**.



As expected from the oxyallyl **C1** structure, the *t*Bu groups have a *cis* orientation in the adducts **15**-**17**.

Cyclopropanone **2** is not stable in the condensed phase at 20°C (or even at −20°C on storage). Two major dimers are formed, and the structure of one of these differs from that of previously isolated cyclopropanone dimers. Based on the NMR spectrum, including a number of 2D techniques, the structure **18** was assigned. This compound is structurally related to dimers previously obtained from a cyclopentyl ring oxyallyl dimerization, but in the present case it may be more reasonable to postulate an addition of the oxyallyl **C1** to the C2—C3 bond of **2**. The other dimer may have structure **19**, which would arise from oxyallyl **C1** addition to the cyclopropanone carbonyl, a mode previously seen in the dimerization of 2,2-dimethylcyclopropanone (24).

18

19

Concluding discussion

The formation of *cis*-di-*tert*-butylcyclopropanone **2** from the acyclic precursor **1** provides a complete verification of the predicted mechanism shown in eq. [1]. Föhlisch et al. (25) previously used a related analysis to rationalize the formation of *cis*-2,3-dimethylcyclopropanone hemiacetal from the reaction of 2-chloro-3-pentanone in methoxide–methanol (Favorski conditions).

A detailed comparison of the bonding and spectroscopic properties in the *cis* and *trans* isomers **2** and **5** reveals the onset of a new type of σ-bond delocalization in the *cis*-**2**, e.g., a nonplanar carbonyl group is computed. This delocalization can potentially be found in any facially asymmetric cyclopropanone and further experiments are ongoing.

Cyclopropanone **2** is also shown to undergo stereospecific photochemical decarbonylation, a stringent test for this specificity given the steric strain in the *cis* alkene product. The overall sequence starting from dineopentyl ketone to give *cis*-1,2-di-*tert*-butylethene **9** can be made nearly stereospecific in a preparative sense, marred only by a competing photochemical isomerization of the *cis* to the *trans* alkene (ca. 5%).

Finally, **2** reacts with alcohols and in cycloaddition reactions as if the valence bond oxyallyl isomer **C1** were the reactive species. In the case of the reaction of alcohols with **2**, the initial adduct is an enol.

Experimental

Mass spectral and capillary GC measurements were carried out on a Hewlett–Packard model 5890 gas chromatograph equipped with a 5971 mass selective detector. Both split and direct on-column injections were used employing a 12 m × 0.2 mm i.d. OV-101 column. Preparative GC was done on an HP 5890A chromatograph employing a thermal conductivity detector and an 8 ft. × 4 mm i.d. column (3% OV-1, WHP-80/100). High-resolution mass spectra were obtained on a Kratos MS-80. NMR spectroscopy ($CDCl_3$ solution) was carried out on Bruker ACE-200, AMX-300, and AM-400 instruments (J in Hz, d = doublet, t = triplet). For $^{13}C\{^1H\}$ NMR, multiplicities were determined from DEPT 90 and 135 spectra. Two-dimensional spectra employed standard pulse sequences. For ^{17}O studies, the labelled dibromo ketone **1** was prepared by adding 15 μL of 20% $H_2{}^{17}O$ and excess Br_2 to a CCl_4 solution of the starting ketone (110 mg) and the closed mixture sonicated. External $H_2{}^{17}O$ was used as a reference for the ^{17}O NMR studies and the isolated dibromide **1** had δ 564. Infrared spectra were determined on a Mattson model 4030 interferometer.

Computational methods

The hybrid density functional (26) level B3LYP/6-31G** was used to calculate the optimized structures for **2** and **5**, employing the Gaussian 94 system of programs (27). NMR calculations employed the GIAO method, and the vibrational frequencies were scaled by a 0.95 factor. Energies and free energies were corrected for ZPVE contributions. Orbital plots were obtained by first importing the raw data into the Spartan program.[4] This latter program was also used for the AM1 and MM2 calculations.

Dibromo ketones

The solid diastereomer of **1** was prepared as described (5). The second diastereomer of **1** was obtained as a minor product (ca. 5–8%) of the direct bromination of **2**. A small sample (ca. 100 μg) was isolated by preparative GC and is apparently a liquid, ^1H NMR (400 MHz): 4.50 (2H), 1.20 (18H). The GC–MS pattern for this isomer is virtually identical to that of the major isomer.

3,5-Dibromo-2,2,3,6,6-pentamethylheptan-4-one ***3***

2,2,6,6-Tetramethylheptan-4-one, 1.24 g, 7.3 mmol, was added to LDA in THF (1.1 equiv.) at −78°C, warmed to −20°C, cooled to −78°C, followed by CH_3I (1.5 equiv.) addition and gradual warming to 20°C. After work-up the crude ketone (28) was directly brominated (sealed tube, excess Br_2 in CCl_4, 80°C, 24 h). Distillation of the residue gave two fractions: first, bp up to 52°C/10 Torr and second, >52°C/10 Torr. The second fraction was a nearly pure mixture of two diastereomers of the title compound (ca. 3:5 ratio of short retention: long retention isomers by GC analysis). ^1H NMR (400 MHz): 5.22 (major) and 4.91 (minor), 2.12 (minor) and 1.88 (major), 1.21–1.25 (overlapping *t*Bu peaks). Partial ^{13}C NMR (100 MHz): 83.3 (major) and 80.6 (minor), 59.7 (major) and 58.4 (minor).

cis-*2,3-Di*-tert-*butylcyclopropanone* ***2***

Dibromo ketone **1** (0.17 g, 0.52 mmol) in 1 mL of dry methylene chloride was added dropwise by syringe into a stirred solution of $PPN^+Cr(CO)_4NO^-$ (0.40 g, 0.54 mmol) (29) in 1 mL of dry methylene chloride. The latter solution was contained in a small Schlenk tube protected with a septum, was prepared under an N_2 atmosphere and was cooled to −78°C. After 20 min, 15 mL of dry, but not deoxygenated, pentane was slowly added by syringe, keeping the resulting mixture at −78°C. This mixture was stirred for a further 10 min, let stand for 30 min, and the supernatant transferred by double-ended

For personal use only.

needle to a clean Schlenk tube also equipped with a septum. The solvent was evaporated at ca. −40 to −50°C under vacuum (ca. 0.01 Torr) to leave a waxy solid. This residue was redissolved in 5 mL of pentane (at ca. −50°C), the solution let stand for 10 min and then filtered by quickly drawing the cold solution into a syringe, replacing the needle with one fitted with a Spartan 3 filter, and then reintroducing the filtered solution into a clean Schlenk tube. The solvent was evaporated as above to leave a solid residue. The septum was removed and a fitted sublimation cold finger was attached, a vacuum of 0.01 Torr was applied, Dry Ice – acetone was added to the cold finger, and the cooling bath temperature was slowly raised to about −20°C and then quickly to 0°C where the material sublimed onto the cold finger surface as white needles. The solid was washed off the cold finger with 3 mL of cold pentane and the solvent removed as above to yield 0.090 g (ca. quantitative) of the title ketone. The ^{1}H NMR spectrum indicates that the material is very nearly pure. ^{1}H NMR (400 MHz): 3.04 (2H), 1.01 (18 H). ^{13}C NMR (100 MHz, −40°C): 212.3 (C═O), 47.1 (CH), 31.2 (C), 29.9 (CH_3). ^{17}O NMR (40.7 MHz) 487. IR: 1818.5 and 1791.5 cm^{-1}, the latter about twice the intensity of the former. An IR spectrum is particularly useful for detecting the presence of $Cr(CO)_4NOBr$, which has a very strong band at 2067 cm^{-1}. The IR spectrum of **2** isolated by the above procedure is essentially free of this peak.

cis-*2,3-Di*-tert-*butyl-2-methylcyclopropanone* ***4***

This compound was not isolated in pure form because solutions of this ketone rearrange to **6** at −30°C. It was possible to conduct a partial purification of **4** by following the procedure described for isolating **2**. After decanting a pentane–CD_2Cl_2 solution of **4** from residual solid, the solvent was removed by vacuum distillation at < −50°C and the residue then taken up in fresh solvent. ^{1}H NMR experiments showed that the material still consisted mainly of **4**. ^{1}H NMR (400 MHz, CD_2Cl_2, −80°C): 2.66 (1H), 1.49 (3H), 0.97 (9H), 0.92 (9H). ^{13}C NMR (100 MHz, CD_2Cl_2, −80°C): 217.0 (C═O), 51.9 (CH, this value in $(CD_3)_2CO$ since it is obscured by solvent peaks in CD_2Cl_2), 50.5 (C), 32.2 (C), 31.3 (C), 29.9 (CH_3 of *t*Bu), 27.7 (CH_3 of *t*Bu), 23.0 (CH_3).

Photolysis experiments

A Westinghouse 275-W Sunlamp was used as a light source. To monitor the reaction progress, the photolysis of **2** was carried out in deuterated solvents in 5 mm NMR tubes. Acetone-d_6 and $CDCl_3$ were both used. Normally the NMR tube was photolyzed while immersed in ice water. Both quartz and Pyrex NMR tubes were used and gave similar results. Low-wavelength filtering was also tried, aqueous $SnCl_2$–HCl at 0°C and acetone – Dry Ice at −78°C. The latter conditions gave a *cis/trans* alkene ratio of better than 95:5 at the point where **2** had just been consumed. The photolysis kinetics were determined by NMR monitoring vs. time, using a rigid positioning of the NMR tube and light source. Cyclopropanone **4** is unstable above −30°C and was photolyzed at −78°C in acetone-d_6. The alkene products were isolated by preparative GC; **8** (11), **9** (11), **10** (30), and **11** (30) have all been reported previously.

Kinetics of the 2 → 5 rearrangement

Initial studies in $CDCl_3$ (^{1}H NMR detection) showed measurable rearrangement rates at 50°C and these were also quite clean reactions. However, we decided to use toluene-d_8 (degassed by N_2 purging) as solvent in order to be assured that no acid catalysis was possible. These rates were slower and could be conveniently carried out at 80°C ($t_{1/2}$ ca. 1.5 h); however, the reaction was not quantitative, and in addition to the product **5** peak, there were small peaks at 0.74, 0.87, and 0.94 ppm, combined area ca. 15%, presumably due to *t*Bu groups in by-products. The fact that these by-products were not produced in the lower temperature $CDCl_3$ solution reaction suggests that other minor thermal pathways are present and that these are more important at higher temperatures, or that toluene is partly reactive. Kinetic experiments were performed in 5 mm NMR tubes. Experiments with a PTFE insert did not change the results (no surface catalysis by the glass). Since competing reactions were diverting some of the **2** concentration, it was not possible to use the **2** + **5** ^{1}H NMR areas as a constant, and we therefore used the residual ^{1}H methyl signal of the toluene as a convenient integration standard to measure the increase per time in the concentration of **5**. The NMR tube was kept at 80.0 ± 0.1°C for a series of time intervals (about 10), the tube solution being quenched each time in cold water and the ^{1}H NMR spectrum quickly measured at ambient temperature. The rate of increase of the *trans*-**5** CH peak was used in the first-order kinetic plot. Experiments were also conducted with widely varying concentrations of initial **2** to confirm the first-order kinetics.

Alcohol and water adducts 13 and 14

When a large excess of methanol was added to a $CDCl_3$ solution of **2**, a new compound immediately formed, as shown by ^{1}H NMR. ^{1}H NMR (200 MHz): 4.77 (d, 1.5, 1H), 4.12 (d, 1.5, 1H), 3.27 (3H), 1.12 (9H), 0.88 (9H). These peaks can be assigned to the enol **14** (R = CH_3). On standing, or by evaporating the solvents and redissolving the residue in $CDCl_3$, these peaks are replaced by ones at 3.35 (3H), 3.11 (1H), 2.48 and 2.37 (AB doublets, 17.5, 1H each), 1.04 (9H), 0.95 (9H). ^{13}C NMR (50 MHz): 95.8, 59.4, 52.0, 35.0, 30.5, 29.7, 26.5. These peaks are assignable to **13** (R = CH_3), previously reported by Greene and co-workers (7). There are minor **13** (R = CH_3) peaks in the initial spectra of **14** (R = CH_3).

Similar results were seen using 2-propanol. Addition of the latter (excess) to a $CDCl_3$ solution of **2** at −10°C led to a new set of NMR peaks; ^{1}H NMR (200 MHz): 5.00 (d, 1.3, 1H), 3.56 (heptet, 6.5, 1H), 0.88 (9H), and 1.12 (9H). One peak is presumed to be buried under the 2-propanol methine heptet and the isopropyl methyl peaks are obscured by the 2-propanol methyl peaks. These peaks remain constant over 4 h at −10°C and can be assigned to the enol **14** (R = iPr). After evaporating the solvents and redissolving the residue in $CDCl_3$, a new set of peaks are observed. ^{1}H NMR (200 MHz): 3.44 (heptet, 6, 1H), 3.26 (1H), 2.52 and 2.44 (AB doublets, 18.7, 1H each), 1.18 (d, 6, 3H), 1.15 (d, 6, 3H), 1.04 (9H), 0.94 (9H). ^{13}C NMR (100 MHz): 214.5, 91.2, 72.1, 51.7, 34.7, 30.3, 29.7, 26.7, 23.0, 21.3. These peaks can be assigned to **13** (R = iPr).

When benzyl alcohol was added to a $CDCl_3$ solution of **2** and left for 3 days at −10°C, a spectrum assignable to **13** (R = benzyl) was obtained. ^{1}H NMR (400 MHz): 7.3–7.4 (complex), 4.575 and 4.380 (both d, 11.5, 1H each), 3.35 (1H), 2.52 and 2.40 (AB doublets, 18.5, 1H each), 1.035 (9H), 0.98 (9H).

© 1997 NRC Canada

^{13}C NMR (100 MHz): 213, 138.9 (C), 128.4 (CH), 127.7 (CH), 93.2 (CH), 73.4 (CH_2), 52.2 (CH_2), 35.1 (C), 30.5 (C), 29.7 (CH_3), 26.7 (CH_3). GC–MS: 177 (15), 99 (15), 91 (100), 57 (50).

Cyclopropanone **2** solutions react rapidly with water to give a compound with an NMR spectrum very similar to **13** (R = CH_3, iPr, or benzyl), ^{1}H NMR (400 MHz): 3.85 (d, 7.5, 1H), 3.16 (d, 7.5, 1H), 2.53 (d, 14.5, 1H), 2.31 (d, 14.5, 1H), 1.04 (9H), 0.98 (9H). ^{13}C NMR (100 MHz): 200.1, 84.4, 54.5, 35.8, 32.0, 29.7, 26.4. These spectral data can be assigned to compound **13** (R = H), with the peak at 3.85 being the hydroxyl hydrogen.

Diene adducts 15, 16, and 17

A large excess of the diene was added to a solution of **2** (0.05–0.5 mmol scale). Two methods were used: (1) pure **2** in $CDCl_3$ solvent, and (2) the diene was added to the initial CH_2Cl_2 (or CD_2Cl_2) solution of **2** (see preparation of **2**) at −78°C, the pentane diluent was added, and, after decanting, the solution was stored at −10°C overnight. Evaporation of the solvent and excess diene gave good yields of the residual adducts (**15** and **16** are solids), which were characterized by NMR and GC–MS methods.

endo-*2,4-Di*-tert-*butyl-8-oxabicyclo[3.2.1]oct-6-en-3-one* ***15***: ^{1}H NMR (200 MHz): 6.28 (2H), 5.07 (d, 4, 2H), 2.60 (d, 4, 2H), 1.05 (18H). ^{13}C NMR (50 MHz): 205.8 (CO), 132.9 (CH), 80.7 (CH), 66.6 (CH), 31.2 (C), 29.0 (CH_3). GC–MS: 236 (M^+), 180 (35), 179 (45), 123 (30), 95 (35), 83 (100). HRMS, calcd. for $C_{15}H_{24}O_2$: 236.1776; found: 236.1770.

endo-*2,4-Di*-tert-*butylbicyclo[3.2.1]oct-6-en-3-one* ***16***: ^{1}H NMR (400 MHz): 6.00 (2H), 3.04 (d, 5, 2H), 2.31 (d, 1, 2H), 2.14 (pent, 5, 10, 1H), 1.82 (d, 10, 1H), 1.01 (18H). ^{13}C NMR (100 MHz): 135.0 (CH), 66.8 (CH), 49.2 (CH_2), 43.6 (CH), 32.8 (C), 28.9 (CH_3). GC–MS: 234 (40, M^+), 219 (50), 163 (45), 91 (60), 83 (65), 75 (90), 77 (100).

Minor *exo* isomer, partial ^{1}H NMR (400 MHz): 6.14 (2H), 2.81 (d, 5, 2H), 1.03 (9H). Partial ^{13}C NMR (100 MHz): 138.7 (CH), 64.5 (CH), 40.5 (CH), 28.2 (CH_3). The GC–MS fragmentation was nearly identical to that of **16**.

cis-*2,7-Di*-tert-*butyl-4,5-dimethylcyclohept-4-enone* ***17***: ^{1}H NMR (400 MHz): 1.9–2.15 (ABC × 2, 6H), 1.78 (d, 0.6, 6H), 1.00 (18H). ^{13}C NMR (100 MHz): 217.5 (CO), 131.2 (C), 64.2 (CH), 35.8 (CH_2), 33.0 (C), 27.6 (CH_3), 20.8 (CH_3). GC–MS: 250 (M^+), 193 (20), 99 (40), 57 (100), 41 (50). HRMS; calcd. for $C_{17}H_{30}O$: 250.2289; found: 250.2297.

Cyclopropanone **2** on storage at ca. −20°C for several weeks is gradually destroyed. Two prominent GC–MS peaks, which correspond to dimers of **2**, are observed from the residual material, although many minor peaks are also present and considerable insoluble material is formed. These dimers can be separated by TLC or preparative GC.

Short-retention dimer ***19***: ^{1}H NMR (400 MHz): 4.40 (1H), 4.08 (1H), 1.16 (9H), 1.10 (9H), 1.07 (9H), 0.965 (9H), 0.96 (2H). Partial ^{13}C NMR (100 MHz): 147.7 (C), 110.1 (CH), 100.1 (C), 87.0 (CH), 39.7, 35.3, 31.6, 30.6, 31.5 (CH_3 × 6), 30.7 (CH_3 × 3), 25.5 (CH_3 × 3). GC–MS, *m/z*: 336 (M^+), 280, 279 (80), 151 (75), 111 (100).

Long-retention dimer ***18***: ^{1}H NMR (400 MHz), 4.39 (1H), 3.90 (1H), 2.55 (1H), 2.28 (1H), 1.16 (9H), 1.145 (9H), 1.04 (9H), 0.94 (9H). COSYDFQ: small coupling between 2.55 and 2.28 peaks, NOESY: interactions between 1.16–4.40, 1.145–3.90, 1.04–2.55 and 2.28, 0.94–2.55 and 2.28, 4.39–2.55. GC–MS, *m/z*: 336 (M^+), 321, 265, 223, 195, 167 (95), 57 (100). HRMS, calcd. for $C_{22}H_{40}O_2$: 336.302830; found: 336.3009.

Theoretical study on naphthylphenylacetylenes for second-order nonlinear optical applications

B.V.V.S.N. Prabhakara Rao, S.C. Mathur, D.C. Dube, D.P. Tewari, and M. Banerjee

Abstract: The ground state dipole moments (μ_g), excited state dipole moments (μ_e), linear polarizabilities (α), first hyperpolarizabilities (β), and absorption maxima ($\hbar\omega_{eg}$) of a new series of 6,4′-disubstituted 2-naphthylphenylacetylenes have been calculated using the finite field – MNDO (Modified Neglect of Diatomic Overlap) technique and studied for second-order nonlinear optical (NLO) applications. Among all the molecules studied here, the strongest and the weakest electron donor/acceptor pairs [$N(CH_3)_2/NO_2$] and [CH_3/CN] exhibit the largest and the smallest β_μ (projection of β on the axis of the μ) of 46.3×10^{-30} esu and 10.2×10^{-30} esu, respectively. The coefficients of the power law that describes the dependence of α and β on the number of conjugated bonds (n) were calculated for $[NH_2/NO_2]_{n=1-5}$ and $[NH_2/CN]_{n=1-5}$ molecules. For β, exponents of 0.36 and 0.31 were obtained for $[NH_2/NO_2]_{n=1-5}$ and $[NH_2/CN]_{n=1-5}$ molecules, respectively, and for α, an exponent of 0.37 was obtained for both series of molecules. A comparison is made between naphthylphenylacetylenes and diphenylacetylenes on the basis of their hyperpolarizabilities.

Key words: nonlinear optics, organic molecules, hyperpolarizabilities.

Résumé : Utilisant une technique modifiée de négligence du recouvrement diatomique («MNDO») finie en fonction du champ, on a calculé les moments dipolaires de l'état fondamental (μ_g) et de l'état excité (μ_e) ainsi que les polarisabilités linéaires (α), les premières hyperpolarisabilités (β) et les maxima d'absorption ($\hbar\omega_{eg}$) d'une nouvelle série de 2-naphthylphénylacétylènes disubstitués en 6,4′ et on les a étudiés pour des applications optiques non linéaires (ONL) du deuxième ordre. Parmi les molécules examinées dans cette étude, les paires de donneur/accepteur d'électron les plus fortes et les plus faibles [$N(CH_3)_2/NO_2$] et [CH_3/CN] présentent respectivement les plus fortes et les plus faibles valeurs de β_μ (projection de β sur l'axe de μ), soit $46{,}3 \times 10^{-30}$ et $10{,}2 \times 10^{-30}$ esu. Utilisant les molécules $[NH_2/NO_2]_{n=1-5}$ et $[NH_2/CN]_{n=1-5}$, on a calculé les coefficients de la loi de puissance qui décrivent la relation de α et β avec le nombre de liaisons conjuguées (n). Pour β, on a obtenu des exposants de 0,36 et de 0,31 respectivement pour les molécules $[NH_2/NO_2]_{n=1-5}$ et $[NH_2/CN]_{n=1-5}$ alors que, pour α, on a obtenu un coefficient de 0,37 pour chacune de ces séries de molécules. En se basant sur leurs hyperpolarisabilités, on a effectué une comparaison entre les naphtylphényacétylènes et les diphénylacétylènes.

Mots clés : optique non linéaire, molécules organiques, hyperpolarisabilités.

[Traduit par la rédaction]

Introduction

Designing novel organic materials for second-order NLO applications such as frequency conversion and optical signal processing has generated immense interest due to their fast and high nonlinearities, high damage thresholds, and unlimited flexibility in chemical modifications (1–3). The macroscopic properties (frequency doubling or second harmonic generation) of the organic materials can be estimated from the microscopic properties (second-order polarizability) of individual molecules, with noncentrosymmetry as a prerequisite condition. Molecular design (4–8) has proven to be a very useful tool in determining the microscopic properties, in reproducing the experimental trends, and in understanding the NLO properties of new materials.

The most promising candidates for first hyperpolarizabilities (β) are molecules with strong electron donors/acceptors ([D/A]) on opposite ends that exhibit intramolecular charge transfer (ICT) interactions in the extended conjugated framework (9–14). Derivatives of 4-nitroaniline and *N,N*-dimethyl-4-nitroaniline are typical examples.

Adequate experimental and theoretical data are available on diphenylacetylenes (15–19) (Fig. 1*a*), which has led to good understanding of their NLO properties, whereas the available literature on naphthylphenylacetylenes (Fig. 1*b*) is very limited. Wong and Nicoud have recently reported (20) two new

Fig. 1. (*a*) Molecular structure of the diphenylacetylenes; (*b*) molecular structure of the 6,4′ disubstituted 2-naphthylphenylacetylenes. **D**: electron donors; **A**: electron acceptors; and (*c*) orientation of the dimethylamino donor group ($N(CH_3)_2$).

classes of organic molecules (6,4′-disubstituted-2-naphthylphenylacetylenes and racemic 6,6′-bis(phenylethynyl)-1,1′-binaphthyls) for NLO applications.

That the main interest turns on naphthylphenylacetylenes is due to the following: (*i*) The limited experimental results (20) on these molecules showed a red shift in their absorption maxima when compared to diphenylacetylenes. This shows that there is an effective conjugation between the naphthalene moiety and the rest of the unsaturated system. Hence, one can anticipate a good charge transfer from donor to the acceptor through the conjugated bridge. (*ii*) There is an increase in conjugation length in these molecules when compared to diphenylacetylenes. These two factors will result in increasing β in naphthylphenylacetylenes. Moreover, the preliminary theoretical (AM1/FF) results (20) showed that β_μ for 6-methoxy-4′-nitronaphthylphenylacetylene is 29×10^{-30} esu, which is substantially greater than that of 4-methoxy-4′-nitrodiphenylacetylene ($\beta_\mu = 15 \times 10^{-30}$ esu).

Hence, in the present work, 6,4′-disubstituted 2-naphthylphenylacetylenes (Fig. 1*b*) have been studied for NLO applications by selective addition of different donor/acceptor groups. The electron [D/A] groups considered for the present studies are the following:

Donors(D) : $N(CH_3)_2$, NH_2, OCH_3, OH, CH_3
Acceptors(A) : NO_2, COOH, CHO, CN

Further, the studies have been extended to observe the effect of an increase in conjugation length (*n*) on μ, α, and β. The calculated hyperpolarizabilities of naphthylphenylacetylenes and diphenylacetylenes have been compared and the results discussed.

Method of calculations

The calculations of μ, α, β, and $\hbar\omega_{eg}$ were made with the MOPAC 5.0 (21) program using the MNDO (Modified Neglect of Diatomic Overlap) Hamiltonian and a finite-field approach (21–23). In this finite-field approach, the dipole moment, μ, of a molecule in the presence of a homogeneous electric field, E_i, can be expanded in a Taylor series in terms of the electric field

$$[1] \quad \mu_i = \mu_{i0} + \Sigma\, \alpha_{ij} E_j + 1/2\, \Sigma\, \beta_{ijk}\, E_j\, E_k + \ldots\ldots$$

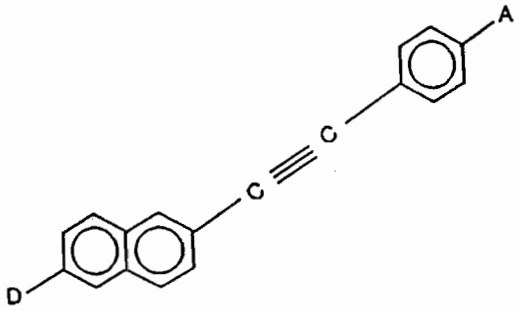
where μ_{i0} is the *i*th component of the permanent dipole moment μ_0, and the tensors α_{ij} and β_{ijk} stand for the polarizability and first hyperpolarizability. The tensors α_{ij} and β_{ijk} are obtained by numerical differentiation of the dipole moment with respect to the electric field components in the limit of zero field (23).

The reliability of the model can be justified since it has been applied to a variety of molecules (19, 23–27) and the results are reasonably accurate. A number of authors have applied the finite field – MNDO technique to calculating linear polarizabilities and hyperpolarizabilities of small molecules (25), substituted benzenes (23), π-electron polycyclic hydrocarbons (24, 26), substituted stilbenes (27), and diphenylacetylenes (19). The details of the justification of model reliability are described elsewhere (28).

However, concerning the accuracy of the theoretical values, the ultimate verification of results will be given by experiment only. The aim of this work is to compare a series of related molecules and to establish reliable trends rather than attempting to predict their absolute hyperpolarizabilities; hence the approach adopted here remains meaningful.

The key words used in the MOPAC package (21) for calculating excited state dipole moment (μ_e) and absorption maxima ($\hbar\omega_{eg}$) are MNDO 1SCF MECI SINGLET ROOT = 2 C.I. = 4. Configuration interaction calculations are performed using the 36 lowest configurations derived from all excitations from the 4 highest occupied orbitals to the 4 lowest unoccupied orbitals. The absorption maxima are evaluated from the difference in energies between ground state (S_o) and first excited singlet state (S_1).

Since β is sensitive to the geometrical structure (24, 29) of the molecules, the geometry optimization has been done for all the molecules by keeping planar conformations. The present calculations were carried out at the field strength of 10^8 V/m for achieving self-consistency in the calculations.



Throughout this paper, the dipole moments (μ_g and μ_e) are expressed in debye (D) units and absorption maxima ($\hbar\omega_{eg}$) are expressed in eV. The average linear polarizabilities are expressed in cubic angstroms ($Å^3$) and can be defined by the expression:

$$[2] \quad \langle\alpha\rangle = \frac{1}{3}(\alpha_{xx} + \alpha_{yy} + \alpha_{zz})$$

[a] μ_g and $\Delta\mu$ values are in D, the $\hbar\omega_{eg}$ (absorption maxima) values are in eV, the α values are in Å^3, and the β_μ values are in 10^{-30} esu.
[b] The experimental values were taken from ref. 20.

The first hyerpolarizabilities β_μ can be expressed as[2]

$$[3] \quad \beta_\mu = \frac{\beta.\mu}{\|\mu\|} = \frac{3/5\sum \beta_i\mu_i}{(\sum\mu_i^2)^{1/2}}$$

where component β_i is given by

$$[4] \quad \beta_i = \beta_{iii}\ 1/3 \sum (\beta_{jii} + 2\beta_{ij})$$

(with one atomic unit of $\beta = 8.63879 \times 10^{-33}$ esu)

Results and discussion

It is well known that the first hyperpolarizability (β) of organic molecules can be enhanced by increasing both [D/A] strengths and conjugation path length (30). The present series of molecules are obtained by replacing one of the benzene rings in diphenylacetylenes with naphthalene (Fig. 1*a*) and the position of the donor and acceptor are as shown in Fig. 1*b*.

The calculated ground state dipole moments (μ_g), differences between the excited state and ground state dipole moments ($\Delta\mu$), absorption maxima ($\hbar\omega_{eg}$), average linear polarizabilities (<α>), and first hyperpolarizabilities β_μ (calculated from eq. [3]) are presented in Table 1.

Dipole moment and linear polarizabilities

The substitution of different [D/A] pairs in the parent molecule [H/H] has shown a significant increase in the calculated μ. The [NH_2/NO_2] molecule possesses the largest dipole moment of 9.0 D and the molecule [CH_3/COOH] has shown the smallest dipole moment of 2.9 D. The μ values for the strongest donor, $N(CH_3)_2$, are slightly lower than those for the donor NH_2 for all acceptor (NO_2, COOH, CHO, and CN) combinations. This error obtained in the μ calculations may be interpreted as follows. All the molecules considered for the present studies were planar constrained, but in case of mole-

[2] In the EFISH experiment, the β component is measured along μ_g (the ground state dipole moment) of the molecule. Hence it is necessary to calculate the projection of β_{Vec} ($\sqrt{\beta_x^2+\beta_y^2+\beta_z^2}$) onto the axis of the μ_g, i.e., β_μ.

cules with the $N(CH_3)_2$ donor group, the torsional angles for H_1-C-N-$C_{aromatic}$, H_2-C-N-$C_{aromatic}$, and H_3-C-N-$C_{aromatic}$ (Fig. 1*c*) were fixed with −60°, +60°, and 180°, and these angles were obtained from AM1 optimized geometries. This orientation at the MNDO level of approximation might have resulted in an error in the μ values.

As the acceptor strength decreases from COOH to CN, the calculated μ increases for almost all the donors. This indicates that the intramolecular charge transfer (ICT), which influences the μ, in the ground state is stronger for the CN group than for CHO and COOH acceptor groups. A similar observation for disubstituted benzenes and styrenes has been reported for the MNDO-PM3 parametrization (15) and for experimental results (16, 17).

In the case of <α> (average polarizabilities), the values vary from 28.5 to 38.3 Å^3. The [D/A] pair [$N(CH_3)_2/NO_2$] exhibits the largest <α> of 38.3 Å^3. As expected, there is no appreciable variation in the calculated values of <α> with changing [D/A] strengths. This suggests that the linear polarizability (α) is purely a function of electron density and does not depend on polarity or charge transfer (31, 32).

First hyperpolarizabilities

Based on the present theoretical calculations of β, the following observations may be noted:

(*i*) The substitution of different [D/A] groups, which drastically enhanced the value of β_μ (0.12×10^{-30} esu) of the parent molecule ([H/H]).

(*ii*) The hyperpolarizabilities increase with increasing [D/A] strength and the molecule [$N(CH_3)_2/NO_2$] exhibits the largest β_μ (46.3×10^{-30} esu) followed by [NH_2/NO_2] with $\beta_\mu = 39.2 \times 10^{-30}$ esu, and the molecule [CH_3/CN] exhibiting the smallest β_μ (10.2×10^{-30} esu). A possible reason for exhibiting high β_μ values in $N(CH_3)_2$ and NH_2 donor combination molecules as compared to other donor combination molecules may be explained as follows. The connecting atom in all the donors except dimethylamino and amino is sp^3 hybridized and the tetrahedral geometry does not allow efficient overlap between the lone pair containing donor orbitals and the π-orbitals of the naphthalene ring. This causes maximum intramolecular charge transfer from donor to acceptor in $N(CH_3)_2$ and NH_2 donor molecules (33).

(*iii*) The present series of molecules possess nearly equal average linear polarizabilities, whereas β_μ varies by almost a factor of 5 from [$N(CH_3)_2/NO_2$] to [CH_3/CN].

From the present β calculations, the following ranking of efficiency of donor groups of the naphthylphenylacetylene series can be established:

$N(CH_3)_2 > NH_2 > OCH_3 > OH > CH_3$

This order is comparable to the ranking in strength of the same donor groups for *para*-disubstituted benzene derivatives, push–pull nitrotolans, nitrostilbenes, and hydrazone derivatives (19, 29, 34). In the case of acceptor groups, the nitro group is an effective acceptor due to its proper hybridization having an effective overlap with the *p*-orbitals of the benzene ring. A weak acceptor like the CN group is found to be comparable to the other COOH and CHO acceptor groups and a similar trend has also been observed in the case of carotenoids (35). Among the acceptor groups, the following ranking of efficiency can be established:

$NO_2 > COOH > CHO \geq CN$

Moreover, the hyperpolarizabilities of naphthylphenylacetylenes obtained from the present calculations are superior to two well known classic donor–acceptor systems, e.g., 4-nitroaniline and *N,N*-dimethyl-4-nitroaniline (36), even in the case of a weak donor (CH_3) group. This suggests a strong interaction between donor and acceptor groups in the present series of molecules. Further, the present β_μ values follow the hypsochromic experimental trends when electron attracting cyano group is inserted at nitro group as in [OCH_3/NO_2], [OCH_3/CN] and [OH/NO_2], [OH/CN] (shown in Table 1).

Relationship between electronic properties and first hyperpolarizability

According to the quantum mechanical two-level model (37, 38), the expression for second-order polarizability (β) is given by

$$[5] \quad \beta = \frac{3}{2} \frac{(\mu_{eg})^2 \Delta\mu}{(\hbar\omega_{eg})^2}$$

where μ_{eg} is the transition dipole moment. From the above expression, β can be enhanced by increasing $\Delta\mu$ and μ_{eg} and by decreasing $\hbar\omega_{eg}$. The above requirements can be achieved by changing [D/A] strengths and by increasing conjugation length.

The calculated $\Delta\mu$ and $\hbar\omega_{eg}$ values are presented in Table 1 and a relationship is established between β_μ, $\Delta\mu$, and $\hbar\omega_{eg}$. Indeed, understanding these relationships is very useful for the design of appropriate materials for nonlinear optics.

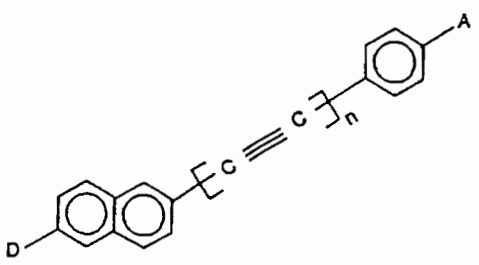
A good degree of linear relationship is obtained between β_μ and $\Delta\mu$ with a reasonable correlation coefficient ($r = 0.87$). The correlation factor obtained between β_μ and $(1/\hbar\omega_{eg})^2$ is 0.97. The correlation ($r = 0.86$) obtained between β_μ and $\Delta\mu/(\hbar\omega_{eg})^2$ strongly confirms that only $\hbar\omega_{eg}$ dominates the magnitude of β_μ in these molecules.

Effect of conjugation length

In principle, an increase in conjugation length (*n*) between an electronic donor and electronic acceptor causes an enhancement in second-order nonlinear response. A logarithmic relationship between *n* and β is usually assumed in both experimental (39, 40) and theoretical (41) studies, where the power law expression (eq. [6]) defines the exponential factor *k* and *C* is a constant:

$$[6] \quad \beta_\mu = Cn^k$$

The exponential factor (*k*) represents the efficiency of an increase in β with an increase in size of the molecule. Further, as the conjugation path length increases, there is a red shift in the absorption maxima ($\hbar\omega_{eg}$) and from the two-level model (eq. [5]) one can infer an increase in β.



The present calculations have been carried out to explore the effect of increasing the conjugation length from $n = 1$ to $n = 5$ (triple bonds) on μ, <α>, and β for [NH_2/NO_2] and [NH_2/CN] molecules. The results are presented in Table 2.

In both molecules ([NH_2/NO_2] and [NH_2/CN]), the same trend is observed between conjugation length (*n*) and the calculated μ, α, and β. As can be noted from Table 2, there is no appreciable change in the calculated μ in passing from $n = 1$ to 5 triple bonds. However, α and β increase moderately with *n*.

Table 2. Effect of conjugation length on the calculated μ (D), <α> (Å^3), and β_μ (10^{-30} esu) values for the [NH_2/NO_2] and [NH_2/CN] molecules.

	D	A	μ	<α>	β_μ
1	NH_2	NO_2	9.0	35.0	39.2
2	NH_2	NO_2	9.3	41.5	45.4
3	NH_2	NO_2	9.5	48.6	51.5
4	NH_2	NO_2	9.8	56.6	62.9
5	NH_2	NO_2	9.9	64.6	69.6
1	NH_2	CN	6.2	34.3	29.0
2	NH_2	CN	6.5	40.9	34.1
3	NH_2	CN	6.6	47.9	40.3
4	NH_2	CN	6.7	55.7	44.5
5	NH_2	CN	6.8	63.8	47.0

Fig. 2. Plot of hyperpolarizability versus the number of triple bonds (*n*) for (*a*) [NH_2/NO_2] and (*b*) [NH_2/CN] molecules.

The *n* dependence of the calculated β (Fig. 2) is $k = 0.36$ and 0.31 for $[NH_2/NO_2]_{n=1-5}$ and $[NH_2/CN]_{n=1-5}$ molecules, respectively. The β dependence on *n* is small and suggests that charge transfer via the conjugated system is ineffective for increasing β. In case of α, the power coefficient (*k*) is 0.37 for both series ($[NH_2/NO_2]_n$ and $[NH_2/CN]_n$) of molecules and suggests that α is independent of the strength of the donor or acceptor groups.

Table 3. Comparison between naphthylphenylacetylenes and diphenylacetylenes.[a]

[D/A]	μ_g (D)	$\Delta\mu$ (D)	$\hbar\omega_{eg}$ (eV)	<α> (Å^3)	β_μ (10^{-30} esu)
[NH_2/NO_2]	9.0 (9.0)	21.7 (23.8)	3.53 (3.86)	35.0 (27.6)	39.2 (35.4)
[NH_2/CN]	6.2 (6.3)	16.0 (18.5)	3.60 (3.98)	34.3 (26.9)	29.0 (24.8)
[OH/NO_2]	6.8 (6.7)	20.9 (19.1)	3.67 (3.65)	33.6 (26.1)	27.2 (21.6)
[OH/CN]	4.1 (4.1)	11.9 (11.5)	3.79 (3.76)	33.2 (25.7)	16.0 (13.3)
[CH_3/NO_2]	6.8 (6.6)	22.2 (15.7)	3.72 (4.10)	34.0 (26.5)	21.0 (15.1)
[CH_3/CN]	4.0 (3.9)	13.0 (8.3)	3.83 (3.84)	33.6 (26.1)	10.2 (7.8)

[a]The values for diphenylacetylenes are given in parentheses.

Comparison between diphenylacetylenes and naphthylphenylacetylenes

The results obtained from the present calculations for diphenylacetylenes and naphthylphenylacetylenes have been compared. It can be seen from Table 3 that the calculated β_μ values of naphthylphenylacetylenes are larger than those for diphenylacetylenes in all [D/A] molecules; however, the increment may not be appreciable. The reason for this small increment may be interpreted as follows. Although there is an increase in the effective conjugation path length between the donor and acceptor of the present series of molecules as compared to diphenylacetylenes, as far as charge transfer is concerned, the naphthalene ring may not be as efficient as the phenyl ring (42).

The present results on naphthylphenylacetylene clearly show a red shift in the absorption maxima as compared to their diphenylacetylene analogues. These trends are consistent with the experimental results (20). In general, a red shift indicates a better charge asymmetry in the π-conjugated systems and leads to higher second-order polarizabilities. A simple electron-in-a-box model also indicates that the excitations of naphthalene are more red shifted than those of benzene. Hence from the two-level model one can expect that the naphthalene would indeed exhibit more nonlinearity than benzene.

The introduction of a naphthalene moiety in the backbone of a classical [D/A] diphenylacetylene molecule leads to a nonlinear shape of the molecule. Hence this may enhance the probability of forming a noncentrosymmetric structure in the case of naphthylphenylacetylenes, an essential condition for achieving second-order nonlinearity (43, 44).

Conclusions

We have calculated the dipole moments and hyper (linear) polarizabilities of a new series of naphthylphenylacetylene molecules. The results obtained clearly indicate that the hyperpolarizability is a function of [D/A] strengths,

© 1997 NRC Canada

effectiveness, and path length of conjugation in these molecules.

We obtained the coefficients of the power law (k) for β as follows: 0.36 and 0.31 for [NH_2/NO_2] and [NH_2/CN] molecules, respectively, and for α, 0.37 for both series of molecules. The result confirms that the efficiency of enhancing β (or α) with n is rather low. The present calculations show that replacement of a benzene by a naphthalene ring in diphenylacetylenes has a small effect in enhancing the hyperpolarizabilities of naphthylphenylacetylenes.

Acknowledgments

We express our gratitude to Professor Mark A. Ratner, Department of Chemistry, Northwestern University, Illinois, U.S.A. and Dr. Isabelle Ledoux, CNET, Bagneux, France, for their many useful suggestions. Fruitful discussions with Professor A.S.N. Murthy, Department of Chemistry, IIT, Delhi, are gratefully acknowledged. We also thank the Computer Services Center, IIT, Delhi, for providing facilities.

Lanthanide catalysts for the hetero Diels–Alder reaction: effect of ligand structure and acidity

Claude Spino, Laurel L. Clouston, and David J. Berg

Abstract: A series of yttrium, ytterbium, and lanthanum hexa- or heptacoordinate complexes were prepared and their catalytic activities tested in the hetero Diels–Alder reaction between crotonaldehyde and ethyl vinyl ether. It was found that a pK_a below 7 of the ligand was necessary but not sufficient for catalytic activity. It was determined that the ligand should possess a perfluoromethyl-β-diketonate functionality. Other factors such as bite angle and hinging motion may also play a determining role.

Key words: lanthanide, catalyst, hetero Diels–Alder, yttrium, ytterbium, lanthanum.

Résumé : L'activité catalytique d'une série de complexes d'yttrium, d'ytterbium et de lanthanum fait à partir de ligands hexa ou heptadentates a été mesurée pour la réaction d'hétéro Diels–Alder entre la crotonaldéhyde et l'éthyl vinyl éther. Nous en avons conclus qu'un pK_a inférieur à 7 du ligand est nécessaire mais pas suffisant pour engendré une activité catalytique. Nous avons déterminé que le ligand doit posséder la fonctionalité perfluorométhyl β-dicétone. D'autres facteurs tel que l'angle de mordage et une action de type charnière des ligands peuvent aussi jouer un rôle déterminant.

Mots clés : lanthanide, catalyseur, Diels–Alder hétéro, yttrium, ytterbium, lanthanum.

The hetero Diels–Alder cycloaddition has proven extremely useful in the synthesis of a multitude of heterocycles (1). The cycloaddition of α,β-unsaturated aldehydes with electron-rich dienes such as vinyl ethers is in the forefront of hetero Diels–Alder reactions due to the importance and prevalence of the dihydropyran and tetrahydropyran (2) substructures contained in such natural compounds as sugars and polyether antibiotics (3, 4). Lanthanide(III) complexes have demonstrated clear effectiveness and mildness in catalyzing this and other reactions (1, 5). The prototypical case of crotonaldehyde reacting with ethyl vinyl ether under $Yb(fod)_3$ catalysis serves to demonstrate this point with an isolated yield greater than 95% of a single *endo* cycloadduct at room temperature (6). In comparison, the thermal reaction of crotonaldehyde and ethyl vinyl ether proceeds at 175°C in sealed tube conditions to give 87% of cycloadducts (7) whereas under high pressure conditions (15 kbar (1 bar = 100 kPa), 75°C, 24 h) one obtains 89% of the *endo* product (8). Also, stronger Lewis acids give reduced yields of product, presumably because of product decomposition (vide infra). We have ourselves observed the high tolerance of lanthanide catalysts for sensitive functional groups such as acetals, silyl ethers, and esters (9).

So far, though, the asymmetric catalysis of the hetero [4+2]-cycloaddition has met with only limited success (10), especially in the case of lanthanide catalysts (1, 10, 6*b*, 11). In the latter case, the lability of the chiral ligands may be partly to blame. As part of a project directed at the preparation of efficient chiral lanthanide catalysts, we initiated a study of the ligand effect on the catalytic activity of ytterbium, lanthanum, and yttrium complexes. The focus of the study was to determine if ligands other than perfluoro-β-diketones could confer catalytic activity on the lanthanide complexes so as to ease the preparation of effective chiral ligands. Also, to address the ligand lability issue, complexes with multidentate ligand systems were investigated. The study not only provided helpful and incisive information on necessary structural features of the ligand for catalytic activity, it also provided novel, air-stable, and effective yttrium and ytterbium catalysts for the hetero Diels–Alder reaction (12). The well-defined and characterized tripodal structures of these catalysts will provide a solid model from which to design and develop highly effective chiral catalysts. Their stability in air is a good indication of low ligand lability.

Figure 1 provides a list of the structural formula of the different ligands prepared or purchased. Compounds **1a–d**, **3a,b**, **7b**, and **7c** were purchased (available from Aldrich). Compound **2** is commercially available but was purchased as its ytterbium complex (Aldrich). Ligand **1e** was prepared as per Morris and Koob (13). Ligands **4a** (14), **4b**, and **5** (14) were prepared by refluxing tris(aminoethyl)amine and **1a**, **1b**, or **3b**, respectively, in benzene with azeotropic removal of water.

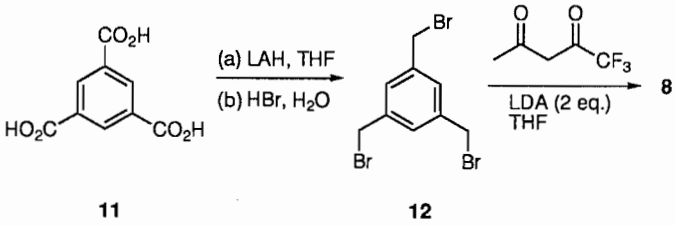

Fig. 1. Ligands tested as their lanthanide complexes.

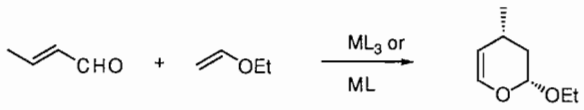
Scheme 1.

Scheme 2.

Their purification was done by sublimation under reduced pressure. Compound **6** was prepared in four steps as described in the literature (15). Ligand **7a** was prepared by monobromination of 1,3,5-tri-*tert*-butylbenzene (16) followed by lithium–halogen exchange with *tert*-butyllithium in THF and quenching with gaseous carbon dioxide (Scheme 1) (17). Finally, ligand **8** was prepared by the reaction sequence shown in Scheme 2. Starting from 1,3,5-benzenetricarboxylic acid **11** using a one-pot procedure where the aluminium salts resulting from the reduction with LAH are directly treated with aqueous hydrobromic acid, we obtained an 80% yield of **12** (18). The dianion of 1,1,1-trifluoroacetylacetone was generated using slight modifications of a standard procedure (19). Though its reactivity was lower than that of non-fluorinated β-diketones, effective alkylation in THF at room temperature with tribromomesitylene **12** could be achieved. The tripodal ligand **8** was thus obtained in 40% yield after recrystallization and sublimation at 140°C / 10^{-2} Torr (1 Torr = 133.3 Pa).



Except for the ytterbium complex of **2**, which was purchased (Aldrich), all other complexes were made by adding the ligand to a toluene solution of the lanthanide tris(bis(trimethylsilyl)amide) at 0°C (20). The complexes precipitated out from solution and were collected and sublimed whenever possible. When the reaction was carried out in THF or other coordinating solvents, the solution was first concentrated under reduced pressure to remove the solvent. Ytterbium complexes of **4a** (21), **5** (21), **6** (15) and the yttrium complex of **4b** were monomeric and characterized by single-crystal X-ray analysis.[2] The yttrium complexes **17a**, **17b**, and **19**·THF were shown to be monomeric by proton NMR spectroscopy. All other complexes were characterized by NMR (in the case of yttrium) and (or) by mass spectrometry and could be

[2] X-ray crystal data and tables of atomic coordinates, isotropic thermal equivalents, bond lengths and angles, torsion angles, and anisotropic displacement factors have been deposited and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. oligomeric. β-Diketonate complexes of a variety of metals, including the lanthanides, are well known and mentioned throughout the literature (22–25). However, few β-diketonate lanthanide complexes have been rigorously characterized. The ytterbium complexes of **1d** (6), **4a** (21), **5** (21), and **6** (15) are known, while those of the remaining ligands are new. The yttrium complexes of all ligands except **1a** are new.

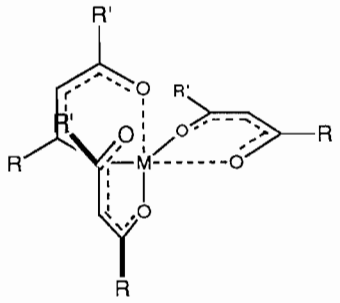
Starting from the observation that lanthanide complexes derived from β-diketone-type ligands are effective catalysts for the hetero Diels–Alder reaction, we initially believed that ligands such as **4a** and **5** would be well suited for our purpose, because they are heptadentate in nature, easily prepared (14), and easily altered for the eventuality of chiral design. Such tripodal ligands form stable complexes with lanthanides (21). In fact, the rationale for using these heptadentate ligands was to confer extra stability to the complex, in effect "locking" the ligand in place. Monomeric, tripodal structures would provide a solid base from which to design and develop highly effective chiral catalysts with well-defined coordination sites.

Catalytic activities were tested on the hetero Diels–Alder cycloaddition of crotonaldehyde **13** and ethyl vinyl ether **14**, the latter serving as solvent, with 2 mol% of catalyst (Table 1). Each reaction was monitored by GC at specific time intervals. As expected, the product isolated was regiochemically and diastereomerically pure (racemic) and was derived from the *endo* approach of the dienophile as verified by proton NMR (6). We were surprised to find that neither the yttrium nor the ytterbium complexes of **4a** and **5** displayed significant catalytic behaviour toward the cycloaddition reaction of crotonaldehyde and ethyl vinyl ether (Table 1, entries 9 and 11). Careful examination of the literature revealed that in fact only perfluoro-β-diketone-type ligands are known to be involved in the successful catalysis of the hetero Diels–Alder reaction by lanthanide complexes. We thus reasoned that lanthanide complexes of ligand **4b**, the 1,1,1-trifluoro analog of **4a**, should indeed catalyse the desired reaction. To our surprise, the yield of cycloadduct obtained with the yttrium and lanthanum complexes remained negligible even after several days (entry 10). Several factors could be responsible for this lack of activity and we suspected that either the imine nitrogens or the coordinating amine nitrogen could electronically saturate the metal thereby lowering its Lewis acidity.

The degree of Lewis acidity at the metal had to be established and therefore we began studying the effect of pK_a of the ligand on the catalytic activity of the resulting lanthanide complex. Although a direct correlation between the pK_a of the ligand and the Lewis acidity of the corresponding complex is only speculative, it is likely that a rough correlation exists among ligands of similar structure. We attempted to determine the Lewis acidity of some complexes by the method of Childs et al. using crotonaldehyde as the complexing agent (26). However, the low solubility of the catalysts in non-coordinating solvents precluded meaningful results.

$Yb(fod)_3$ is known to be a mild and effective catalyst for the hetero Diels–Alder reaction and it provided a reference point against which all other reactions were compared (6). The complexes having acac-type ligands with pK_a's lower than approximately 6.3 were effective as catalysts (Table 1, entries 2–4, and 6) (27). Other ligands with higher pK_a were less effective or ineffective in the time period studied (entries 1, 5, 7–15). Interestingly, there was no difference between the yttrium, ytterbium, and lanthanum complexes (entries 9–11, 13, 14, and 16). Yttrium and ytterbium have similar van der Waals radii and Lewis acidity but lanthanum is substantially larger and is a weaker Lewis acid. The high catalytic activity of the ytterbium complex of **2** suggests that steric bulk around the metal is not an important factor (entry 6). Complexes of ligands **3** gave modest catalytic activity in line with pK_a values (entries 7 and 8) and the complex of silanol **6** gave no activity at all (entry 12). A catalytic run was also performed with the yttrium complex of ligand **1a** in trifluoroethanol as solvent with no success. It therefore seems unlikely that the fluorines are playing a role other than simply lowering the pK_a of the diketone ligand.



Confident that the Lewis acidity of the metal could be tuned by adjusting the pK_a of the ligand, we surmised that complexes of carboxylic acids would be efficient catalysts because of their low pK_a. We had in mind to eventually use linked amino acids to make chiral tripodal complexes of ytterbium and yttrium, thereby obtaining easy access to chiral catalysts. Before embarking on the synthesis of an elaborate ligand we decided to test the catalytic activity of the lanthanide complexes of acids **7**. The results were unequivocal: no catalysis whatsoever was observed (entries 13 and 14). All of the acids **7** have a pK_a below that of trifluoroacac **1b**. The Yb and Y complexes **17b** (Fig. 2) were tested to verify that the bulky *tert*-butyl groups in **17a** were not sterically blocking the active site; they were also inactive. Not surprisingly, the Y complex made with phenol **7c** did not lead to a better result (entry 15). Finally, the commercially available yttrium tris(hexanoate) was also screened and found to be inactive.

These results are reminders that the mechanism of catalysis

may involve more than just a simple chelation of the Lewis acid to the aldehyde with concurrent lowering of the oxadiene LUMO (28). We considered solubility as a possible explanation for the lack of activity of complexes **17**. However, they are more soluble than many active catalysts in ethereal solvents. The geometry, bulk, and bite angle of the ligand may of course affect the effective Lewis acidity of the metal independently of its pK_a. As stated earlier, a direct measurement of the Lewis acidity of the metal is possible by the method of Childs et al. (26), though Laszlo and Teston pointed out that NMR measurements of Lewis acidities of metals fail to accurately predict the chemical activity of Lewis acids as catalysts (28*a*). In any case, the generally low solubility of these complexes in non-coordinating solvents prevented meaningful measurements by the NMR method. Unfortunately the semiempirical MNDO calculations by the method of Laszlo could not be carried out on lanthanides because the parameters do not yet exist (28*a*). Nevertheless, the difference of catalytic activity between complexes **17** and **16** could not be due to ligand pK_a, steric bulk, or solubility. We considered three alternative explanations, namely, that the catalytic activity may be due to trace impurities emanating from the experimental preparation of the catalysts, or that the effective Lewis acidity of complexes **17** may be lower than that of complexes **16b–d** because of ligand geometry or oligomer formation, or last, that the displacement or, possibly, hinging of one of the ligands may be necessary to free a coordination site for catalysis (hinging specifically refers to partial dissociation of one arm, i.e., bidentate to monodentate for that arm). A hinging motion would be more favorable, from a geometric standpoint, in β-diketone-type ligands than in carboxylic acids.

Whatever the explanation, we concluded that an effective catalyst should possess the unaltered perfluoromethyl-β-diketone functionality on the ligand. Such units could be linked by the end methyl group via a number of linkers, thereby leaving the γ-perfluoro-β-diketone unit intact. 1,3,5-Tribromomesitylene **12** caught our attention as being a useful linker because of its relative ease of preparation and high reactivity toward alkylation. The yttrium and ytterbium complexes of **8** were prepared by mixing the ligand with a solution of yttrium or ytterbium tris(bis(trimethylsilyl)amide) in toluene as described earlier. In each case, an instantaneous reaction occurred with concomitant precipitation of the complex, which was washed several times with toluene. Unfortunately, we could not grow crystals of adequate quality to perform a single-crystal X-ray crystallographic analysis on either of the complexes and neither were soluble in non-coordinating solvents. To secure the structure of the yttrium complex **19**

[a]Method A = ethyl vinyl ether as solvent, 2 mol% catalyst, 25°C; Method B = method A + dioxane (0.5 equiv.) (similar results if **19** is prepared in a coordinating solvent); Method C = method A + deliberately exposed to air for 7 days.
[b]Disappearance of starting materials analysed by gas chromatography.
[c]Isolated yield after distillation.

(Fig. 2, M = Y), we prepared it in THF and isolated the powdery material by reduced pressure evaporation of the solvent. Although no X-ray quality crystals could be grown, the proton NMR analysis of the complex in benzene-d_6 was unequivocal and established the coordination of a molecule of THF (12). Mass spectral data and exact mass measurement on this compound were satisfactory. The structure of the ytterbium complex **19** (M = Yb) was inferred only from mass spectral data and by analogy to its yttrium analogue.

Catalytic activities of these new ligands were tested on the hetero Diels–Alder cycloaddition of crotonaldehyde and ethyl vinyl ether as described earlier (Table 2). In each example involving ytterbium or yttrium catalysts the isolated yields of the respective dihydropyran product **15** were excellent, testimony to their mildness (entries 1–3). In contrast, zinc chloride and BF_3-etherate gave 46% and 12% isolated yield, respectively, of **15** (entries 4 and 5). The yttrium catalyst **19** was superior to all others, including the commonly used $Yb(fod)_3$ (6), having the fastest conversion rate and giving a good isolated yield of **15** (entry 1). If dioxane was utilized as an internal standard for quantitative work, the reaction rate between **13** and **14** dropped (entries 6 and 7), indicating a competition for the active site between the coordinating solvent and crotonaldehyde. We found that when the complexes **19** were prepared in, or came in contact with, coordinating solvents, the reaction rate also dropped, presumably due to the incorporation of a coordinating solvent molecule. This coordinating solvent molecule may compete with crotonaldehyde for the active site or simply reduce the Lewis acidity of the complex. This outcome convinced us that in the case of complexes of **4** and **5** the coordinating amine nitrogen is playing the same role, only more efficiently, and no or very low conversion rates are observed. More importantly though, both catalysts **19** remained active even after several days of exposure to the ambient air (entries 8 and 9), even though the complexes may have picked up water molecules from exposure to air. Moreover, a 3-month-old sample of yttrium complex **19** stored in an opened vial still retained complete catalytic activity and the complex can be stirred in water (it is insoluble in water), extracted with THF, recovered, and used as a catalyst. The activity of the complex, even after exposure to air, is probably due to significantly reduced ligand lability. Multidentate ligands are known to exhibit this phenomenon. In contrast, all other catalysts including $Yb(fod)_3$ had to be kept in a rigorously dry atmosphere to remain active (entry 10).

In conclusion, we have prepared the first lanthanide complexes possessing a hexadentate ligand that are active catalysts. Their high stability, even in air, is not only desirable in terms of handling but is also very promising as a base from which to develop chiral catalysts showing high asymmetric induction. Our results clearly demonstrate that the ligand around the lanthanide should possess the unaltered perfluoromethyl-β-diketone functionality. It would seem that the role of the fluorines is to bring the pK_a of the β-diketone below a minimal level for catalysis and that, possibly, their hinging motion allows access to the catalytic site.

Experimental section

All solvents were distilled from sodium–benzophenone with the exception of di- and tetrachloromethane and dimethyl sulfoxide, which were distilled from calcium hydride. All reactions were performed under an atmosphere of argon unless otherwise stated. Flash column chromatography was done using Merck 60 silica gel. NMR spectra were taken in $CDCl_3$ at 250 or 360 MHz, and IR spectra were recorded in $CHCl_3$. ^{13}C NMR signal multiplicities were determined by DEPT experiments. Gas chromatography was performed on a DB-1 capillary column with FID detector. 2,4-Pentanedione (**1a**), 1,1,1-trifluoroacetylacetone (**1b**), and 1,1,1,5,5,5-hexafluoroacetylacetone (**1c**), were purchased and subsequently purified by distillation. Salicylaldehyde (**3a**), hydroxyacetophenone (**3b**), 2,4,6-trimethylbenzoic acid (**7a**), and 2,6-di-*tert*-butylphenol (**7c**) were purchased and purified by sublimation under vacuum. 1,1,1-Trichloroacetylacetone (**1e**) was synthesized as outlined in ref. 13. Tris(3-aza-4-methyl-6-oxohept-3-

en-1-yl)amine (**4a**), tris(3-aza-4-(2-hydroxyphenyl)-3-penten-1-yl)amine (**5**), and each of their respective yttrium and ytterbium complexes were synthesized and purified as outlined by Orvig and co-workers (14, 21). (*N,N*-Dimethyl-3-aminoprop-1-yl)di-*tert*-butylsilanol (**6**) and its tris-yttrium salt were prepared and isolated as outlined in Shao et al. (15). The yttrium complex of **7c** was prepared and isolated as outlined in Lappert et al. (29). The ytterbium complexes of **1d** and **2** were purchased from Aldrich.

Tris(3-aza-4-methyl-6-oxo-7,7,7-trifluorohept-3-en-1-yl)amine (4b)

In a 25 mL round-bottom flask equipped with a stirbar and a Dean Stark trap, 0.1 g (0.68 mmol) of tris(aminoethyl)amine was dissolved in 10 mL of dry benzene. Then 4.0 mL (5.1 g, 33.0 mmol) of 1,1,1-trifluoroacetylacetone was added via syringe and the reaction mixture was refluxed for 16 h. The resulting solution was concentrated under reduced pressure to obtain a sticky, golden powder. Purification by repeated triturations with Et_2O gave an isolated yield of 0.38 g (85%) of the desired tripodal ligand. ^{1}H NMR (300 MHz, C_6D_6) δ: 11.11 (br s, 3H), 5.24 (s, 3H), 3.48 (q, 6H, J = 7 Hz), 2.84 (t, 6H, J = 7 Hz), 2.06 (s, 3H). ^{13}C NMR (90 MHz, C_6D_6) δ: 175.45 (q, 2C, J_{CF} = 31 Hz), 170.02 (q), 117.63 (q, J_{CF} = 281 Hz), 89.73 (d), 54.36 (t), 42.41 (t), 19.38 (q). ^{19}F NMR (338 MHz, $CDCl_3$) δ: −76.84 (s). HRMS, calcd. for $C_{21}H_{27}F_9N_4O_3$: 152.1201; found: 152.1205.

2,4,6-Tri-*tert*-butylbenzoic acid (7a)

An oven-dried Schlenk tube was charged with 1.4 g (6.3 mmol) of 1-bromo-2,4,6-tri-*tert*-butylbenzene (16) in 125 mL of dry hexanes. Then 3.7 mL (6.3 mmol) of 1.7 M *t*-BuLi in pentanes was added and the resulting mixture was left to stir at −78°C for 1 h. Then, carbon dioxide was bubbled through the solution for 4 h. The mixture was quenched with 3 N aqueous HCl until the water layer was approximately at pH 1. The two phases were separated and the aqueous phase was extracted with ether. The combined organic portions were dried over $MgSO_4$, filtered, and concentrated under reduced pressure. Washing the product repeatedly with hexanes yielded 0.4 g (35%) of the desired product (16). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 7.40 (s, 2H), 1.57 (s, 18H), 1.34 (s, 9H). ^{13}C NMR (63 MHz, $CDCl_3$) δ: 179.24 (s), 150.69 (s), 146.39 (s), 127.46 (s), 122.16 (d), 35.06 (s), 32.22 (s), 31.56 (q), 31.26 (q).

1,3,5-Tribromomesitylene (12)

In an oven-dried 1 L round-bottom flask equipped with a stirbar, was added 2.0 g (74 mmol) of lithium aluminum hydride in 200 mL of dry THF. Then, 5.0 g (23.8 mmol) of 1,3,5-benzenetricarboxylic acid in 200 mL of dry THF was added dropwise into the stirring slurry over 2 h under an atmosphere of N_2 while cooling with an ice bath. The resulting slurry was heated to reflux for 16 h using a condenser equipped with a drying tube. Enough water was then added to destroy excess reagent and the resulting salts were dried under high vacuum. To this vessel was added 150 mL of a 48% HBr solution and 250 mL of benzene. The mixture was heated to reflux for 16 h. The organic layer was separated and the aqueous portion was extracted with Et_2O; the organic layers were combined, dried over $MgSO_4$, and concentrated under reduced pressure. Recrystallization from hot cyclohexanes yielded 6.9 g (80%) of the desired product (18). ^{1}H NMR (360 MHz, $CDCl_3$) δ: 7.33 (s, 3H), 4.43 (s, 6H). ^{13}C NMR (90 MHz, $CDCl_3$) δ: 139.03 (s), 129.56 (d), 32.18 (t).

1,3,5-Tris(3,5-dioxo-6,6,6-trifluorohexan-1-yl)benzene (8)

A solution of 2.0 mL (2.6 g, 16.8 mmol) of 1,1,1-trifluoroacetylacetone in 20 mL of dry THF in an oven-dried Schlenk tube equipped with a stirbar was cooled to −78°C. In a separate oven-dried Schlenk tube was prepared an LDA solution in 10 mL of dry THF using 2.6 mL (2.0 g, 20.2 mmol) of dry diisopropylamine and 12.6 mL (20.2 mmol) of 1.6 M *n*-butyllithium in hexanes. After cooling to −78°C the trifluoroacetylacetone solution was transferred by cannula to the LDA solution while maintaining the temperature at −78°C. In a third oven-dried Schlenk tube was prepared a second LDA solution in 20 mL of dry THF using 2.0 mL (1.5 g, 15.2 mmol) of dry diisopropylamine and 9.5 mL (15.2 mmol) of 1.6 M *n*-butyllithium in hexanes. After cooling to −78°C this LDA solution was transferred into the previous one, while maintaining the temperature at −78°C. The mixture was stirred for 20 min and a solution of 1 g (2.8 mmol) of 1,3,5-tribromomesitylene in 20 mL of dry THF was added via cannula into the the dianion solution at −78°C. The reaction was stirred for 4 h while slowly warming to room temperature. The work-up consisted in adding a 3 M aqueous HCl solution, separating the layers, and, after ensuring that the water layer was acidic, extracting exhaustively with dichloromethane. The combined organic fractions were dried over magnesium sulfate, filtered, and concentrated under reduced pressure. Recrystallizing the resulting golden oil using a dry THF–hexanes mixed solvent system gave pale yellow crystals that could be further purified by sublimation at 140°C/10^{-2} Torr, yielding 0.63 g (40%) of the desired benzene-capped tripodal ligand **8**. ^{1}H NMR (250 MHz, C_6D_6) δ: 6.86 (s, 3H), 5.85 (s, 3H), 3.45 (t, 6H, J = 7 Hz), 2.87 (t, 6H, J = 7 Hz). ^{13}C NMR (63 MHz, C_6D_6) δ: 196.24 (q), 174.69 (q, $^2J_{CF}$ = 36 Hz), 140.57 (q), 126.51 (d), 117.01 (q, $^1J_{CF}$ = 282 Hz), 96.18 (d), 40.17 (t), 31.00 (t). ^{19}F NMR (338 MHz, C_6D_6) δ: −76.76 (s). HRMS, calcd. for $C_{24}H_{21}F_9O_6$: 576.1194; found: 576.1194.

Metal complexes

General procedure for the preparation of Y and Yb complexes of all ligands

Preparation was carried out in a similar manner for all complexes. β-Diketonates have been extensively investigated (22–25) and were previously prepared in high yields using this anhydrous method (23*a*). Hence various metal derivatives of **1a** (23), **1b** (23, 24), **1c** (23, 25), and **1e** (23) had been previously prepared and were used for comparison. In a Schlenk tube equipped with a stirbar, under an inert atmosphere, the ligand was dissolved in dry THF. In a separate oven-dried Schlenk tube equipped with a stirbar, under an inert atmosphere, $Y(N(SiMe_3)_2)_3$ (20) was dissolved in dry THF and transferred via cannula into the ligand solution while stirring. Stirring was continued for 20 min before removing the solvents and the resulting $Y(N(SiMe_3)_2)_3$ under reduced pressure, thereby isolating the desired product as a powder. The insoluble powders were repeatedly washed with toluene and hexanes to give free-flowing powders. The same procedure was used

with $Yb(N(SiMe_3)_2)_3$ and $La(N(SiMe_3)_2)_3$ for those complexes.

*Yttrium and ytterbium tris(acetylacetone) (**16a**)*: Prepared using the general procedure above. The reaction of 1.38 g (2.1 mmol) $Yb(N(SiMe_3)_2)_3$ with 0.65 mL (6.3 mmol) of dry acetylacetone yielded 0.51 g (52%) of the desired material. LRMS: 471 (M^+) with the expected isotopic pattern for ytterbium. Similar quantities, yields, and characterization for the yttrium complex.

*Yttrium and ytterbium tris(1,1,1-trifluoroacetylacetone) (**16b**)*: Prepared using the general procedure above. The reaction of 1.38 g (2.1 mmol) $Yb(N(SiMe_3)_2)_3$ with 0.77 mL (6.3 mmol) of dry trifluoroacetylacetone yielded 0.65 g (50%) of the desired material, purified by sublimation at 90°C at 10^{-4} Torr. LRMS: 633 (M^+) with the expected isotopic pattern for ytterbium. Similar quantities, yields, and characterization for the yttrium complex.

*Ytterbium tris(1,1,1,5,5,5-hexafluoroacetylacetone) (**16c**)*: Prepared using the general procedure above. The reaction of 1.38 g (2.1 mmol) $Yb(N(SiMe_3)_2)_3$ with 0.90 mL (6.3 mmol) hexafluoroacetylacetone yielded 0.83 g (50%) of the desired material, purified by sublimation at 120°C at 10^{-2} Torr. LRMS: 795 (M^+) with the expected isotopic pattern for ytterbium.

*Yttrium tris(1,1,1-trichloroacetylacetone) (**16e**)*: Prepared using the general procedure above. The reaction of 0.71 g (1.3 mmol) of $Y(N(SiMe_3)_2)_3$ with 0.76 g (3.9 mmol) of dry trichloroacetylacetone yielded 0.42 g (49%) of orange powder.

*Ytterbium tris(salicylaldehyde) (Yb of **3b**)*: Prepared using the general procedure above. The reaction of 1.38 g (2.1 mmol) $Yb(N(SiMe_3)_2)_3$ with 0.76 g (6.3 mmol) of dry salicylaldehyde yielded 0.58 g (51%) of pale yellow powder.

*Ytterbium tris(hydroxyacetophenone) (Yb of **3b**)*: Prepared using the general procedure above. The reaction of 1.38 g (2.1 mmol) $Yb(N(SiMe_3)_2)_3$ with 0.75 mL (6.3 mmol) of dry 2-hydroxyacetophenone yielded 0.58 g (48%) of yellow powder.

*Yttrium tris(2,4,6-tri-*tert*-butylbenzoate) (**17a**)*: Prepared as described in the general procedure above using 600 mg (2.1 mmol) of ligand **7a** in 5 mL of dry THF and 0.39 g (0.69 mmol) of $Y(N(SiMe_3)_2)_3$ in 5 mL of dry THF. A white soluble powder was isolated in 75% yield and purified by washing repeatedly with hexanes, giving a 73% overall yield. ^{1}H NMR (360 MHz, C_6D_6) δ: 7.42 (s, 6H), 1.46 (s, 54H), 1.31. (s, 27H). ^{13}C NMR (90 MHz, C_6D_6) δ: 179.94 (s), 150.68 (s), 146.33 (s), 127.53 (d), 122.16 (s), 37.63 (s), 35.05 (s), 32.22 (q), 31.26 (q).

*Yttrium and ytterbium tris(2,4,6-trimethylbenzoate) (**17b**)*: Prepared as described in the general procedure above using 0.38 g (0.67 mmol) $Y(N(SiMe_3)_2)_3$ with 0.33 g (2.0 mmol) of ligand **7b**. A white powder was isolated in 54% yield after repeated washing with hexanes. ^{1}H NMR (360 MHz, C_6D_6) δ: 7.23 (s, 6H), 2.43 (s, 18H), 2.24 (s, 9H). ^{13}C NMR (90 MHz, C_6D_6) δ: 177.74 (s), 149.32 (s), 144.42 (s), 126.92 (d), 121.20 (s), 35.55 (q), 33.43 (q). Similar quantities and yields for the ytterbium complex.

*Yttrium tris(3-aza-4-methyl-6-oxo-7,7,7-trifluorohept-3-en-1-yl)amine (**18b**)*: Prepared following the procedure for Y–**4a** complex described by Berg, Rettig, and Orvig (21) using 0.2 g (0.35 mmol) of $Y(N(SiMe_3)_2)_3$ with 0.195 g (0.35 mmol) of ligand **4b** in 20 mL of dry THF, affording a quantitative yield (0.22 g) of creamy white powder. This could be recrystallized from warm toluene upon standing, yielding colourless brick-like crystals in modest quantities. X-ray (see footnote 2), ^{1}H NMR (360 MHz, C_6D_6) δ: 5.46 (s, 3H), 2.68 (br m, 6H), 1.32 (br m, 6H), 1.29 (s, 9H). ^{13}C NMR (90 MHz, C_6D_6) δ: 173.47 (s), 161.89 (q, $^2J_{CF}$ = 29 Hz), 120.92 (q, $^1J_{CF}$ = 269 Hz), 98.77 (d), 52.68 (t), 46.72 (t), 21.96 (q). ^{19}F NMR (338 MHz, C_6D_6) δ: −74.76.

*Yttrium and ytterbium 1,3,5-tris(3,5-dioxo-6,6,6-trifluorohexan-1-yl)benzene (**19**)*: Prepared as described in the general procedure above using 76 mg (0.13 mmol) of ligand **8** in 5 mL of dry THF and 75 mg (0.13 mmol) of $Y(N(SiMe_3)_2)_3$ in 5 mL of dry THF to afford a pale yellow powder in quantitative yield. ^{1}H NMR (250 MHz, C_6D_6) δ: 6.41 (s, 3H), 5.83 (s, 3H), 3.75 (br t, THF), 2.43 (t, 6H, J = 7 Hz), 2.06 (t, 6H, J = 7 Hz), 1.27 (m, THF). ^{13}C NMR (63 MHz, C_6D_6) δ: 201.14 (s), 169.95 (q, $^2J_{CF}$ = 32 Hz), 138.55 (s), 128.02 (q), 127.87 (d), 97.35 (d), 69.17 (t, THF), 42.21 (t), 33.20 (t), 25.42 (t, THF). ^{19}F NMR (338 MHz, C_6D_6) δ: −75.66 (s). HRMS, calcd. for $C_{24}H_{18}F_9O_6Y$: 662.0018; found: 662.0000. Similar quantities and yields for the ytterbium complex.

Catalytic test run

Into an oven-dried Schlenk tube equipped with a stirbar was loaded 30.5 mg (2 mol%) of the catalyst metal complex. Then 5.0 mL of freshly distilled ethyl vinyl ether was added via syringe into the tightly capped vessel. The reaction mixture was stirred while adding 0.2 mL of distilled *trans*-crotonaldehyde via a syringe. Every 4 h an aliquot of solution was acquired, diluted in 0.5 mL of diethyl ether, and injected (0.5 μL) into a Fisons E980 gas chromotagraph to detect product formation. A 100 μL (1.2 mmol) dioxane standard can be used in the reaction mixture to better quantify results. However, dioxane slows the reaction rate somewhat as stated above. Upon reaction completion the mixture was quenched with 1 N aquous HCl and stirred for 30 min. Extraction of the organic layer with ether and removal of solvent from the combined organic fractions under reduced pressure gave a crude product that can be further purified (8*a*) by column chromatography using a 4:1 pentanes:ether eluant or by distillation (if crotonaldehyde is no longer present in crude product). NMR spectral data of the adduct were in accord with literature values (6).

Abstract: The scope of the photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction has been extended to include cyanide anion as the nucleophile. Highest yields of adducts were obtained when the alkene or diene has an oxidation potential less than ca. 1.5 V (SCE). No adducts were obtained from 2-methylpropene (**9**), oxidation potential 2.6 V. Oxidation of cyanide anion, by the radical cation of the alkene or diene, can compete with the combination. With the alkenes, 2,3-dimethyl-2-butene (**2**) and 2-methyl-2-butene (**10**), both nitriles and isonitriles were obtained; isonitriles were not detected from the reactions involving the dienes, 2-methyl-1,3-butadiene (**11**), 2,3-dimethyl-1,3-butadiene (**12**), 4-methyl-1,3-pentadiene (**13**), 2,4-dimethyl-1,3-pentadiene (**14**), and 2,5-dimethyl-2,4-hexadiene (**6**). The specificity, nitrile versus isonitrile, is explained in terms of the Hard-Soft-Acid-Base (HSAB) principle. The photo-NOCAS reaction also occurs with the allene, 2,4-dimethyl-2,3-pentadiene (**15**), cyanide combining at the central carbon. Factors influencing the regiochemistry of the combination step, Markovnikov versus *anti*-Markovnikov, have been defined. Cyanide anion adds preferentially to the less alkyl-substituted, less sterically hindered, end of an unsymmetric alkene or conjugated diene radical cation, forming the more heavily alkyl-substituted radical intermediate. High-level *ab initio* molecular orbital calculations (MP2/6-31G*//HF/6-31G*) have been used to determine the effect of alkyl substitution on the stability of the intermediates, β-cyano and β-isocyano alkyl radicals, and products, alkyl cyanides and isocyanides. The more heavily alkyl-substituted radical is not necessarily the more stable. The product ratio (Markovnikov versus *anti*-Markovnikov) must be kinetically controlled.

Key words: photochemistry, radical ions, electron transfer, nitriles, isonitriles.

Résumé : On a élargi le domaine d'application de la réaction photochimique de combinaison nucléophile–oléfine avec substitution aromatique («photo-NOCAS») de façon à inclure l'ion cyanure comme nucléophile. Les meilleurs rendements d'adduits sont obtenus lorsque le potentiel d'oxydation de l'alcène ou du diène est inférieur à environ 1,5 V («SCE»). On n'a pas obtenu d'adduits avec les 2-méthylpropène (**9**) dont le potentiel d'oxydation est de 2,6 V. L'oxydation de l'anion cyanure, par le cation radical de l'alcène ou du diène, est en compétition avec la combinaison. Avec les alcènes, 2,3-diméthylbut-2-ène (**2**) et 2-méthylbut-2-ène (**10**), on a obtenu les nitriles ainsi que les isonitriles; on n'a toutefois pas détecté d'isonitriles lors des réactions impliquant les diènes, 2-méthylpenta-1,3-diène (**11**), 2,3-diméthylbuta-1,3-diène (**12**), 4-méthylpenta-1,3-diène (**13**), 2,4-diméthylpenta-1,3-diène (**14**) et 2,5-diméthylhexa-2,4-diène (**6**). On explique la spécificité, nitrile versus isonitrile, en fonction du principe des acides et des bases durs et mous («HSAB»). La réaction de «photo-NOCAS» se produit aussi avec l'allène et le 2,4-diméthylpenta-2,3-diène (**15**); le cyanure s'attache au carbone central. On a défini que les facteurs qui influencent la régiochimie de l'étape de combinaison sont Markovnikov versus *anti*-Markovnikov. L'anion cyanure s'additionne préférentiellement à l'extrémité d'un ion radical d'alcène non symétrique ou de diène conjugué qui est la moins substituée, la moins stériquement encombrée, par des groupes alkyles; cette addition conduit à la formation du radical intermédiaire le plus substitué par des groupes alkyles. On a fait appel à des calculs d'orbitales moléculaires ab initio à niveau élevé (MP2/6-31G*// HF/6-31G*) pour déterminer l'effet de la substitution par des groupes alkyles sur la stabilité des intermédiaires, les radicaux β-cyanoalkyles et les β-isocyanoalkyles, et des produits, les cyanures et les isocyanures. Les radicaux les plus substitués ne sont pas nécessairement les plus stables. Le rapport des produits (Markovnikov versus *anti*-Markovnikov) doit donc être sous contrôle cinétique.

Mots clés : photochimie, ions radicaux, transfert d'électron, nitriles, isonitriles.

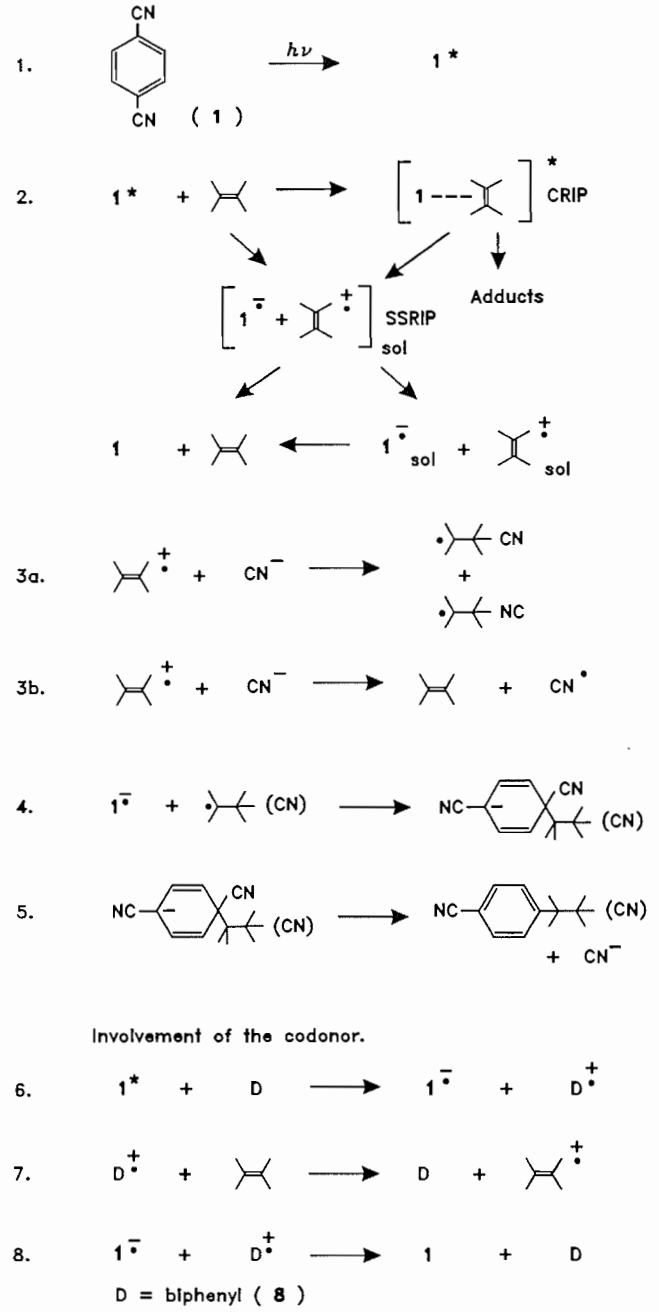
Introduction

The scope and limitations of the photochemically induced nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction, which combines a nucleophile and an alkene or diene radical cation, substituting on an aromatic radical anion, have been defined when an alcohol (methanol) serves as nucleophile (1). A main objective of this study was to extend the scope of this reaction with cyanide anion as the nucleophile (Scheme 1).



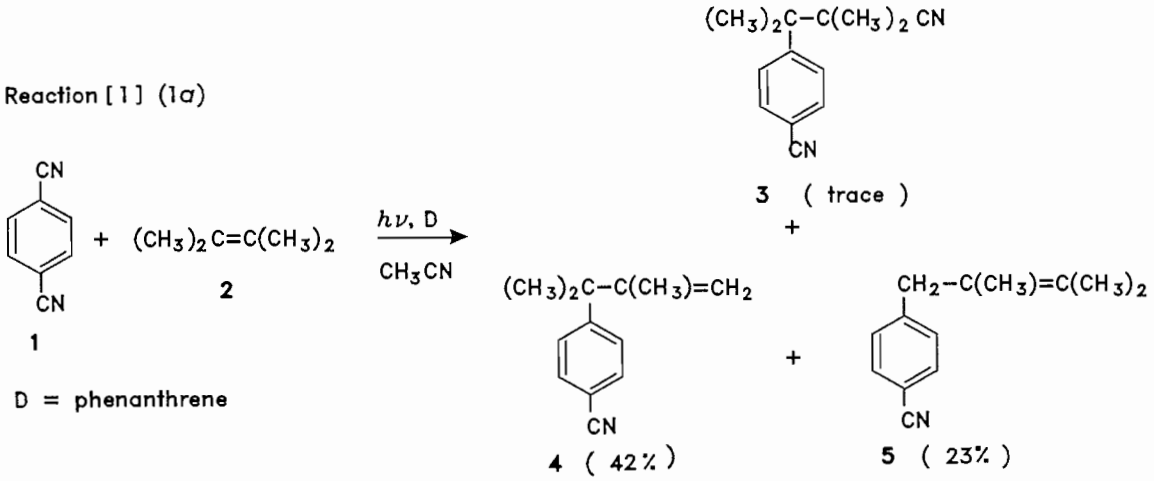
Some previous results were encouraging (1*a*–*c*). Irradiation of an acetonitrile solution (no methanol) of 1,4-dicyanobenzene (**1**) and 2,3-dimethyl-2-butene (**2**) gave primarily the expected 1:1 substitution products, 2,3-dimethyl-3-(4-cyanophenyl)-1-butene (**4**) and 2,3-dimethyl-1-(4-cyanophenyl)-2-butene (**5**), resulting from deprotonation of the alkene radical cation ($\mathbf{2}^{+\cdot}$) followed by coupling of the resulting allylic radical with the radical anion of 1,4-dicyanobenzene ($\mathbf{1}^{-\cdot}$). A minor product from this reaction was the photo-NOCAS adduct, 3-(4-cyanophenyl)-2,3-dimethylbutanenitrile (**3**), formed in "trace" amounts, which had incorporated cyanide anion (reaction [1]) (1*a*). The only source of cyanide anion in this reaction mixture was that generated during the aromatic substitution–rearomatization step (Scheme 1, step 5). This was the only previous report of incorporation of cyanide anion during a photo-NOCAS reaction involving an alkyl-substituted alkene.

One example of the photo-NOCAS reaction, involving cyanide anion combining with the radical cation of a conjugated diene has been reported (1*b*). Competitive formation of the nitrile was initially observed during the photo-NOCAS reaction of 2,5-dimethyl-2,4-hexadiene (**6**) and 1,4-dicyanobenzene (**1**) in acetonitrile–methanol (3:1). Subsequent irradiation of an acetonitrile solution of 2,5-dimethyl-2,4-hexadiene (**6**) and potassium cyanide, with 1,4-dicyanobenzene (**1**) serving as the electron acceptor, gave a good yield (80%) of the photo-NOCAS adduct, (*E*)-5-(4-cyanophenyl)-2,2,5-trimethyl-3-hexenenitrile (**7**) (reaction [2] (1*b*)).

With aryl-substituted alkenes, the products of addition of hydrogen cyanide were obtained (1*c*). For example, irradiation of an acetonitrile – 2,2,2-trifluoroethanol solution of 1,1-diphenylethylene and potassium cyanide, with 1-cyanonaphthalene or methyl 4-cyanobenzoate serving as the electron acceptor, gave the cyanation product, 3,3-diphenylpropanenitrile (reaction [3] (1*c*)). Cyanide anion serves as the nucleophile, adding to the 1,1-diphenylethylene radical cation. In this case, as with other aryl-substituted alkenes, the resulting benzylic radical intermediate is reduced to the carbanion by the radical anion of the initial electron acceptor, followed by protonation.

There is direct physical evidence for the reaction of cyanide anion with the radical cation of aryl alkenes and conjugated dienes. Flash photolysis studies have shown cyanide anion reacts (adds?) with the radical cation of aryl-substituted alkenes and conjugated dienes with rate constants approaching the diffusion-controlled limit (3). The relative rates of the reaction of substituted styrene radical cations with methanol and with cyanide anion reflect the well-established difference in nucleophilicity of these nucleophiles; the nucleophilicity, n (CH_3I), value for cyanide anion is 6.7 (methanol, $n = 0.0$ by definition (4)).

Scheme 1.



We report here results from the irradiation of acetonitrile, potassium cyanide, and solutions of several alkenes and dienes, using 1,4-dicyanobenzene (**1**) as the electron acceptor and with biphenyl (**8**) serving as a codonor. The alkenes and dienes chosen for study include: 2-methylpropene (**9**), 2-methyl-2-butene (**10**), 2,3-dimethyl-2-butene (**2**), 2,5-dimethyl-2,4-hexadiene (**6**), 2-methyl-1,3-butadiene (**11**), 2,3-dimethyl-1,3-butadiene (**12**), 4-methyl-1,3-pentadiene (**13**), 2,4-dimethyl-1,3-pentadiene (**14**), and the allene, 2,4-dimethyl-2,3-pentadiene (**15**).

Another objective of this study involved the identification of the factor(s) that influence the regiochemistry of the bonding of the nucleophile to the alkene or diene radical cation.

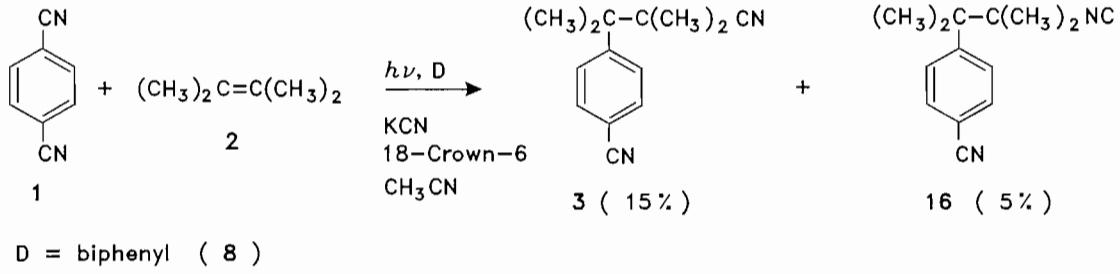
Previous work, with methanol serving as the nucleophile, has led to the following hypothesis: the nucleophile (methanol) adds to that end of the alkene or diene radical cation which leads ultimately to formation of the more stable radical intermediate — the more stable radical intermediate is not necessarily that with the most heavily alkyl substituted radical moiety. The initial intermediate, formed upon addition of methanol, is the distonic radical cation, capable of bridging and equilibration. Of course, there is no distonic radical cation intermediate formed upon addition of a negatively charged nucleophile. High-level ab initio molecular orbital calculations (MP2/6-31G*//HF/6-31G* (5, 6)) have been used to determine the relative stability of the alternative radical intermediates formed upon addition of cyanide anion to the alkene or diene radical cation. These results will be compared with those for the analogous intermediates formed upon addition of methanol (1*i*).

Results

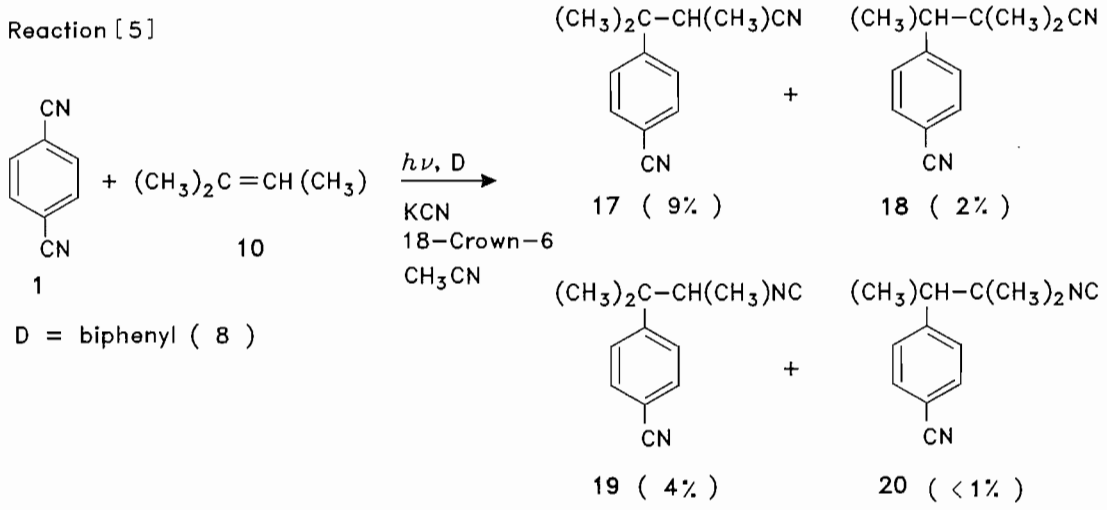
The reaction conditions used for the addition of cyanide anion are similar to those reported for the reactions involving methanol as the nucleophile (1). Acetonitrile solutions of the alkene or diene, 1,4-dicyanobenzene (**1**), biphenyl (**8**) serving as a



© 1997 NRC Canada

codonor, and potassium cyanide, were irradiated with a medium-pressure mercury vapour lamp through Pyrex. The solubility of the potassium cyanide in the acetonitrile was increased by the addition of 18-crown-6 ether (1,4,7,10,13,16-hexaoxacyclooctadecane). Progress of the reaction was followed by capillary column gas chromatography with a flame ionization detector (gc/fid). The first indication of the structure of the product(s) was gleaned from the mass spectrum obtained from a gas chromatograph equipped with a mass selective detector (gc/ms). The ratios of products were determined by integration of the peak areas in the gc/fid. The relative yields of isolated products were generally in agreement with these ratios. The yields were based upon the amount of 1,4-dicyanobenzene (**1**) consumed; the alkene or diene was generally present in excess.

Previous results had shown the photo-NOCAS adduct, **3**, was a minor product, formed along with the 1:1 adducts, **4** and **5**, upon irradiation of an acetonitrile solution of 1,4-dicyanobenzene (**1**) and 2,3-dimethyl-2-butene (**2**) (reaction [1] (1*a*)). When an acetonitrile solution of **1**, **2**, biphenyl (**8**), and potassium cyanide was irradiated, **3** became a major product (15%). The isonitrile (**16**) was also formed (5%), along with the 1:1 adducts (**4** and **5**) (reaction [4]).



In marked contrast, no 1:1:1 adduct was detected (gc/ms) when 2-methylpropene (**9**) was subjected to these reaction conditions. However, irradiation of an acetonitrile solution of 2-methyl-2-butene (**10**), **1**, **8**, and potassium cyanide, did give the photo-NOCAS adducts, nitriles (**17**, **18**) and isonitriles (**19**, **20**), albeit in low yield (reaction [5]). The ratio of the isonitriles, **19** (*anti*-Markovnikov) : **20** (Markovnikov), determined from the integrated peak areas (gc/fid), was large (> 30:1).

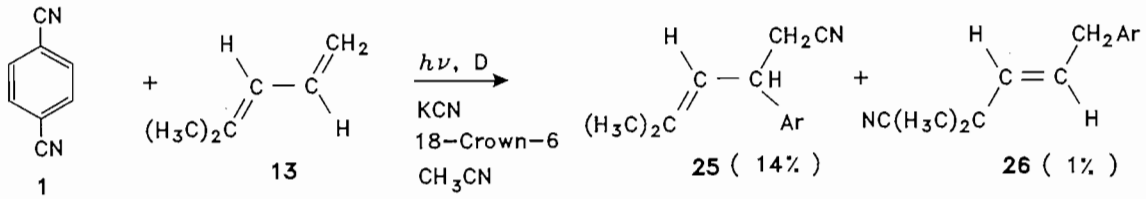
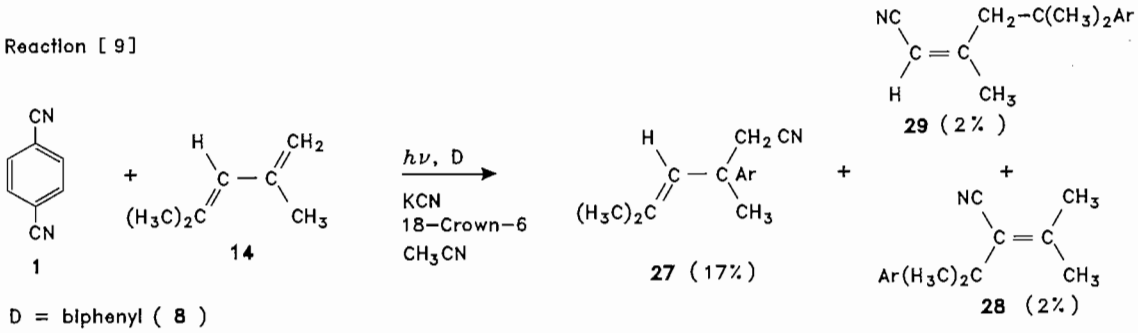
An acetonitrile solution of 2-methyl-1,3-butadiene (**11**), 1,4-dicyanobenzene (**1**), biphenyl (**8**), and potassium cyanide was irradiated; 3-(4-cyanophenyl)-3-methyl-4-pentenenitrile (**21**, 2%) and 3-(4-cyanophenyl)-4-methyl-4-pentenenitrile (**22**, 1%) were isolated in low yield (reaction [6]). Both of these adducts result from 1,2-addition to the diene; no 1,4-addition product was detected.



When an acetonitrile solution of 2,3-dimethyl-1,3-butadiene (**12**), **1**, **8**, and potassium cyanide was irradiated, 3-(4-cyanophenyl)-3,4-dimethyl-4-pentenenitrile (**23**, 7%) and (*E*)-5-(4-cyanophenyl)-3,4-dimethyl-2-pentenenitrile (**24**, 2%) were obtained (reaction [7]). Adduct **23** is a 1,2-addition product. No 1,4-addition product (i.e., neither (*E*)- nor (*Z*)-5-(4-cyanophenyl)-3,4-dimethyl-3-pentenenitrile) was detected; however, **24** may result from isomerization (tautomerization) of this 1,4-adduct.

Reaction [7]



D = biphenyl (**8**)
Ar = 4–cyanophenyl

Reaction [8]

D = biphenyl (**8**)
Ar = 4–cyanophenyl

Reaction [9]

D = biphenyl (**8**)
Ar = 4–cyanophenyl

Two photo-NOCAS adducts were formed upon irradiation of a solution of 4-methyl-1,3-pentadiene (**13**), **1**, **8**, and potassium cyanide in acetonitrile (reaction [8]). The major adduct, 3-(4-cyanophenyl)-5-methyl-4-hexenenitrile (**25**, 14%), was the 1,2-addition product resulting from initial attack of the cyanide anion at the less substituted terminal end of the diene radical cation. A 1,4-addition product, (*E*)-5-(4-cyanophenyl)-2,2-dimethyl-3-pentenenitrile (**26**, 1%), resulting from initial attack of the cyanide anion at the more substituted terminal end of the diene radical cation, was the minor adduct.

When an acetonitrile solution of 2,4-dimethyl-1,3-pentadiene (**14**), **1**, **8**, and potassium cyanide was irradiated, three isomeric 1:1:1 adducts were formed: 3-(4-cyanophenyl)-3,5-dimethyl-4-hexenenitrile (**27**, 17%), 4-(4-cyanophenyl)-2,4-dimethyl-2-pentene-3-nitrile (**28**, 2%), and (*Z*)-5-(4-cyanophenyl)-3,5-dimethyl-2-hexenenitrile (**29**, 2%) (reac-

© 1997 NRC Canada

tion [9]). The major product, **27**, is the expected photo-NOCAS adduct resulting from 1,2-addition to the less substituted terminal end of the diene radical cation. Compound **29**, like compound **24**, may result from isomerization (tautomerization) of initially formed 1,4-addition product(s).

The other minor product, **28**, may result from a photo-NOCAS reaction involving the tautomeric diene, the allene 2,4-dimethyl-2,3-pentadiene (**15**), present as an impurity in the starting diene. To test this possibility a similar solution, starting with **15**, was irradiated under identical conditions; the photo-NOCAS adduct, **28**, was obtained in reasonable yield (22%) (reaction [10]).

Reaction [10]

D = biphenyl (8)
Ar = 4–cyanophenyl

Structural assignments

Structural assignments of the products were based primarily upon detailed analysis of ^1H and ^{13}C nmr, mass, and infrared spectra. For two of the products, 4-(4-cyanophenyl)-2,4-dimethyl-2-pentene-3-nitrile (**28**) and (*Z*)-5-(4-cyanophenyl)-3,5-dimethyl-2-hexenenitrile (**29**), structures were firmly established by X-ray crystallography on a single crystal.[3]

Irradiation of an acetonitrile solution of 1,4-dicyanobenzene (**1**), 2,3-dimethyl-2-butene (**2**), biphenyl (**8**), and potassium cyanide gave the nitrile, 3-(4-cyanophenyl)-2,3-dimethylbutanenitrile (**3**), and the isonitrile, 3-(4-cyanophenyl)-2,3-dimethyl-2-isocyanobutane (**16**) (reaction [4]).

The structure of **3** has been established previously (*1a*). The ^1H and ^{13}C nmr, and the infrared spectra provide convincing evidence for the structure of the isonitrile, **16**. The infrared spectrum shows peaks at both the aromatic nitrile (2229 cm^{-1}) and the aliphatic isonitrile (2131 cm^{-1}) carbon–nitrogen triple-bond stretching frequencies. The ^1H and ^{13}C nmr spectra show the expected patterns; particularly informative is coupling of the signal, in the ^1H nmr spectrum, assigned to the hydrogens vicinal to the isonitrile (1.34 ppm), due to the ^{14}N nuclear spin. In the ^{13}C nmr spectrum, signals due to the isonitrile carbon (155.95 ppm) and the carbon directly bonded to the isonitrile (63.78 ppm) also show distinctive coupling due to the ^{14}N nucleus.

Major photo-NOCAS adducts resulting from the irradiation of an acetonitrile solution of 2-methyl-2-butene (**10**), 1,4-dicyanobenzene (**1**), biphenyl (**8**), and potassium cyanide were the nitriles **17** and **18** (reaction [5]). The first indication of the regiochemistry of these isomers was from the mass spectrum (gc/ms), which showed a dominant fragment of 144 *m/z* ($C_{10}H_{10}N$) for **17**, due to the arylpropyl fragment, and of 130 *m/z* (C_9H_8N) for **18**, due to the arylethyl fragment. The aliphatic region of the ^1H nmr spectrum of **17** shows a doublet (1.10 ppm) corresponding to a methyl group adjacent to a methine group. The proton of the methine group bonded to the nitrile produces a quartet at lower field (2.97 ppm). The typical AA′XX′ pattern in the aromatic region of the ^1H nmr is indicative of the 4-cyanophenyl group. In the ^{13}C nmr spectrum, the cyano-substituted methine group shows up as a doublet (37.61 ppm) and the aryl-substituted carbon appears as a singlet (40.27 ppm).

The ^1H and ^{13}C nmr spectra for compound **18** show characteristic patterns similar to those of **17**. In the aliphatic region of the ^1H nmr spectrum a doublet (1.50 ppm) corresponds to the methyl group adjacent to a methine group. The proton of the methine group, bonded to the aryl group, produces a quartet at lower field (2.77 ppm). In the ^{13}C nmr spectrum, the cyano-substituted carbon appears as a singlet (37.06 ppm) and the benzylic carbon as a doublet (48.15 ppm). The major adduct (**17**:**18**, 4.5:1) results from initial bonding of the cyanide anion to the radical cation, $\mathbf{10}^{+\cdot}$, at the less substituted alkene carbon, giving the more heavily alkyl-substituted radical intermediate, i.e., *anti*-Markovnikov addition.

The isonitriles, **19** and **20**, are minor products from reaction [5]. The ^1H and ^{13}C nmr and the infrared spectra provide convincing evidence for the structures of **19** and **20**. The first indication for the structure of these isonitriles, **19** and **20**, came from the infrared spectra, which again show peaks at both the aromatic nitrile and aliphatic isonitrile carbon–nitrogen triple-bond stretching frequencies. The ^1H and ^{13}C nmr spectra show the expected patterns, including significant coupling of the geminal and vicinal hydrogens, due to the ^{14}N nuclear spin, in the ^1H nmr of **19** and to the vicinal hydrogens in the ^1H nmr of **20**. In the ^{13}C nmr spectrum, the isonitrile carbon, as well the carbon directly bonded to the isonitrile, shows distinctive coupling to the ^{14}N nucleus.

The products resulting from irradiation of an acetonitrile solution of 2-methyl-1,3-butadiene (**11**), **1**, **8**, and potassium cyanide, were 3-(4-cyanophenyl)-3-methyl-4-pentenenitrile

[3] Crystallographic data for **28** and **29** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Details of data collection, structural analysis and refinement, and tables of interatomic distances and bond angles have also been deposited with the Cambridge Crystallographic Data Centre and may be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

(**21**) and 3-(4-cyanophenyl)-4-methyl-4-pentenenitrile (**22**) (reaction [6]). The ^{1}H and ^{13}C nmr spectra provide good evidence for the structures of **21** and **22** as photo-NOCAS 1,2-adducts. Compound **21** results from attack of cyanide anion at the more heavily substituted end of the diene radical cation (C-1), generating the more heavily substituted allylic radical. Coupling of this allylic radical at the more heavily substituted carbon, with the anion radical, $\mathbf{1}^{-\bullet}$, at the *ipso* position, generates the terminal alkene. Evidence for this regiochemistry is the two doublets and a multiplet (5.19, 5.34, and 6.02 ppm) in the vinyl proton region of the ^{1}H nmr spectrum. This spectrum also exhibits a singlet (1.61 ppm) due to the methyl group and a lower-field singlet (2.77 ppm) for the cyanomethylene group.

In the ^{13}C nmr spectrum of compound **21**, there is a triplet (29.82 ppm) indicative of a methylene carbon substituted by a cyano group. There is a lower-field singlet (43.58 ppm) that is consistent with an aryl-substituted quaternary carbon. There are also two low-field singlets (117.18 and 118.44 ppm) consistent with two distinctive cyano groups. The ^{13}C nmr spectrum also exhibits a triplet (115.34 ppm) for the terminal vinyl methylene and a doublet for the vinyl methine (141.93 ppm), additional evidence for the mono-substituted alkene.

Compound **22** was identified as 3-(4-cyanophenyl)-4-methyl-4-pentenenitrile, which would result from initial attack of cyanide anion at the less substituted end of the diene radical cation. The presence of the disubstituted alkene is supported by two apparent singlets in the vinyl proton region (4.99 and 5.11 ppm) assigned to the geminal protons. The ^{1}H nmr spectrum also exhibits a singlet (1.61 ppm) indicative of the methyl group and an ABX pattern (2.72, 2.85, and 3.66 ppm) for the protons of the methylene group, next to a cyano group, and of the benzylic, allylic methine group.

The ^{13}C nmr spectrum of compound **22** exhibits a triplet (22.43 ppm) that is indicative of the methylene group substituted by the cyano group. There is a lower-field doublet (48.55 ppm) that is consistent with an aryl-substituted methine group. And there are two singlets (117.83 and 118.95 ppm) supporting two cyano groups. The ^{13}C nmr spectrum also exhibits a triplet (113.21 ppm) for the terminal vinyl methylene and a singlet (143.18 or 145.06 ppm) due to the quaternary vinyl carbon, further supporting the existence of the disubstituted alkene.

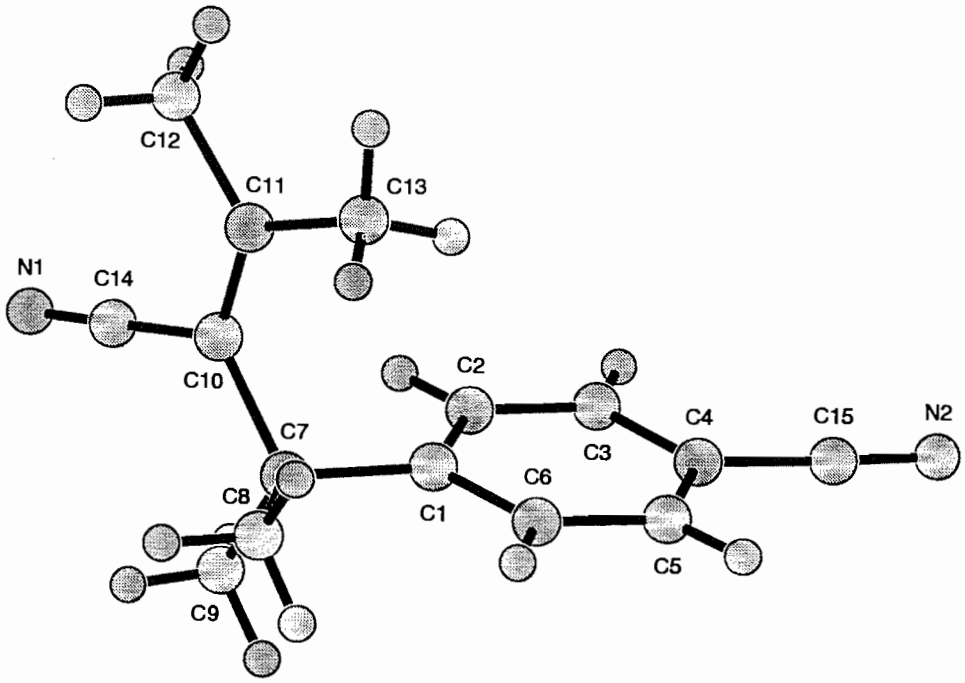
When an acetonitrile solution of 2,3-dimethyl-1,3-butadiene (**12**), **1**, **8**, and potassium cyanide was irradiated, 1:1:1 adducts **23** and **24** were produced (reaction [7]). Compound **23** was identified as 3-(4-cyanophenyl)-3,4-dimethyl-4-pentenenitrile, a 1,2-addition product. The ^{1}H and ^{13}C nmr spectra were similar to those of **21**; however, there are only two singlets in the vinyl region of the ^{1}H nmr spectrum (5.07 and 5.15 ppm), indicative of a terminal, disubstituted alkene. In the ^{13}C nmr spectrum, there are signals due to a vinyl quaternary carbon (147.00 or 148.84 ppm) and a vinyl methylene (113.06 ppm).

Compound **24** was identified as (*E*)-5-(4-cyanophenyl)-3,4-dimethyl-2-pentenenitrile, which may result from isomerization (tautomerization) of the initially formed 1,4-adduct, 5-(4-cyanophenyl)-3,4-dimethyl-3-pentenenitrile. The ^{1}H and ^{13}C nmr spectra of **24** both support the assigned structure. The ^{1}H nmr spectrum shows a doublet (1.08 ppm) that represents a methyl group bonded to a methine group, a singlet (2.06 ppm) due to the methyl group bonded to a vinyl carbon, and multiplets of an ABC second-order pattern (2.62, 2.69, and 2.82 ppm) for the protons of the benzylic methylene group and the allylic methine group. One olefinic proton appears as a singlet (5.05 ppm) and the typical AA′XX′ pattern in the aromatic region of the ^{1}H nmr spectrum is indicative of the 4-cyanophenyl group.

The *E*-configuration was assigned on the basis of the observed nuclear Overhauser effect (nOe). When the signal due to the allylic methyl group was irradiated a small nOe was observed in the signal of the methine and methylene hydrogens (ABC second-order pattern) and of the *ortho*-aryl H's. Irradiation of the signal due to the vinyl hydrogen caused a large nOe on the signals due to the methine and methylene hydrogens (ABC second-order pattern) and the *ortho*- and *meta*-aryl hydrogens.

In the ^{13}C nmr spectrum, there are distinctive carbon shifts, further supporting the structure proposed for compound **24**. The signal at 95.89 ppm is distinctive for an alkene methine group, cyano substituted (7). The quaternary alkene carbon β to the cyano group absorbs at 167.39 ppm. There are also two low-field singlets (116.84 and 118.74 ppm) supporting two different cyano groups. These chemical shifts were reproduced using the Advanced Chemical Development's ^{13}C nmr spectra simulation program; the calculated values are in good agreement with the observed chemical shifts.[4]

When an acetonitrile solution of 4-methyl-1,3-pentadiene (**13**), **1**, **8**, and potassium cyanide was irradiated, two photo-NOCAS adducts, **25** and **26**, were obtained (reaction [8]). Compound **25** was identified as the *anti*-Markovnikov 1,2-addition product, 3-(4-cyanophenyl)-5-methyl-4-hexenenitrile. This regioisomer is the result of initial bonding of cyanide anion at the less substituted end of the diene radical cation, $\mathbf{13}^{+\bullet}$, generating the more heavily alkyl-substituted allylic radical intermediate. The presence of the trisubstituted alkene is supported by a doublet (5.35 ppm, J = 9.3 Hz) in the vinyl proton region of the ^{1}H nmr spectrum, which represents coupling to the allylic methine proton. The ^{1}H nmr spectrum also exhibits two singlets (1.69 and 1.77 ppm), indicative of the two nonequivalent methyl groups bonded to the alkene, and an ABX multiplet (2.66, 2.70, and 3.97 ppm) for the protons of the methylene group next to a cyano group and that of the benzylic, allylic methine group.



The ^{13}C nmr spectrum of compound **25** exhibits a triplet (24.90 ppm) indicative of the methylene group substituted by the cyano group. There is a lower-field doublet (40.56 ppm) that is consistent with an aryl-substituted methine carbon. There are two low-field singlets (117.92 and 118.64 ppm) consistent with two cyano groups. The ^{13}C nmr spectrum also exhibits a doublet (123.08 ppm), for the vinyl methine group, and a singlet (136.94 ppm), for the quaternary vinyl carbon, further supporting the presence of the trisubstituted alkene.

Compound **26** was identified as the 1,4-addition product, (*E*)-5-(4-cyanophenyl)-2,2-dimethyl-3-pentenenitrile, resulting from attack of the cyanide anion at the more heavily substituted terminal end of the diene. The first indication of the

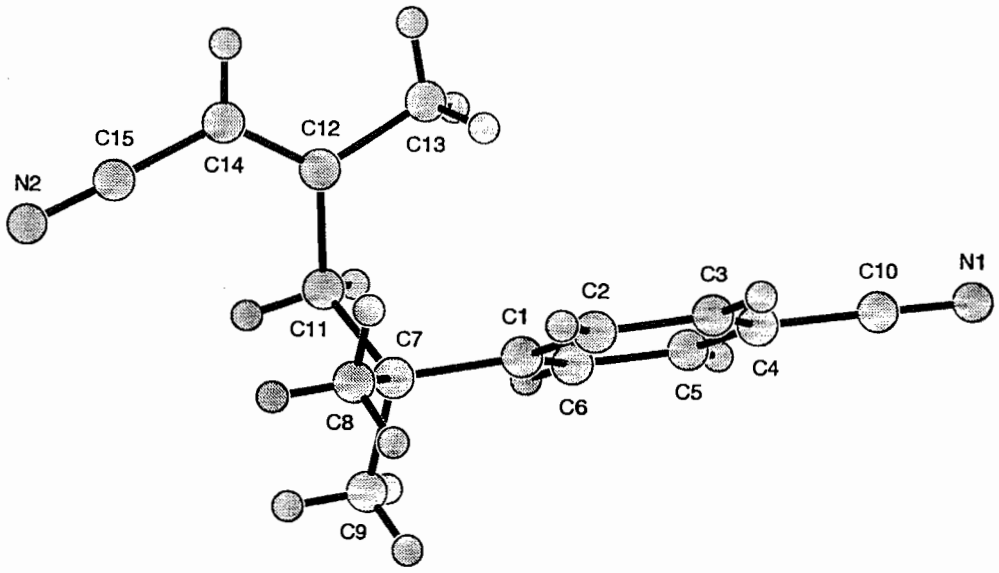
For personal use only.

regiochemistry of this isomer was obtained from the mass spectrum (gc/ms), which shows a dominant fragment of 142 *m/z* ($C_{10}H_8N$) due to loss of the cyanopropyl fragment. There is a singlet (1.41 ppm) in the aliphatic region of the ^{1}H nmr spectrum, representing the two chemically equivalent methyl groups, a lower-field doublet (2.47 ppm) indicating the presence of an aryl-substituted allylic methylene group, and an AA′XX′ pattern in the aromatic region indicative of the 4-cyanophenyl group. A doublet of triplets and a doublet (6.40 and 6.55 ppm, respectively) appear in the vinyl region, each with a coupling constant (15.9 Hz) typical of a *trans* configuration. The infrared spectrum shows a peak at the C-H bending frequency (973 cm^{-1}) further supporting the *trans* configuration for this alkene. In the ^{13}C nmr spectrum of **26**, there is a singlet (32.65 ppm) due to the quaternary carbon substituted by a cyano group and a triplet (44.32 ppm) for the methylene carbon substituted by the aryl group.

Irradiation of an acetonitrile solution of 2,4-dimethyl-1,3-pentadiene (**14**), **1**, **8**, and potassium cyanide gave three 1:1:1 adducts: **27**, **28**, and **29** (reaction [9]). Compound **27** was identified as the *anti*-Markovnikov 1,2-addition product, 3-(4-cyanophenyl)-3,5-dimethyl-4-hexenenitrile. Initial attack of cyanide anion at the less substituted end of the diene radical cation, $\mathbf{14}^{+\bullet}$, gives the more heavily alkyl-substituted allylic radical intermediate. The presence of the trisubstituted alkene is supported by a broad singlet in the vinyl proton region (5.54 ppm) of the ^{1}H nmr spectrum. The ^{1}H nmr spectrum also exhibits three singlets (1.14, 1.64, and 1.76 ppm) indicative of the two nonequivalent methyl groups bonded to the alkene and the allylic methyl group. Also in the ^{1}H nmr spectrum, an AB apparent singlet was observed (2.68 ppm) for the diastereotopic protons of the methylene group bearing the cyano group.



The ^{13}C nmr spectrum of compound **27** exhibits a triplet (33.44 ppm) indicative of the methylene group substituted by the cyano group. There is a lower-field singlet (41.90 ppm) that is consistent with an aryl-substituted quaternary carbon. There are also two singlets (117.63 and 118.71 ppm) supporting two cyano groups. The ^{13}C nmr spectrum also exhibits a doublet (129.15 ppm) for the vinyl methine group and the quaternary vinyl carbon shows up as a singlet (137.27 ppm), further indicating the trisubstituted alkene.

Compound **28**, 4-(4-cyanophenyl)-2,4-dimethyl-2-pentene-3-nitrile, was identified as a possible product of the allene, 2,4-dimethyl-2,3-pentadiene (**15**), which could be an impurity in the starting diene. The ^{1}H nmr spectrum exhibits three singlets (1.31, 1.58, and 2.11 ppm), indicative of the four methyl groups; the singlet at 1.58 ppm represents the pair of magnetically equivalent methyl groups. The ^{13}C nmr spectrum of compound **28** exhibits a singlet (41.08 ppm) that indicates a quaternary carbon substituted by the 4-cyanophenyl group. There are also three singlets (118.26, 118.32, and 118.71 ppm) supporting two types of cyano groups and the quaternary vinyl carbon, cyano substituted. The ^{13}C nmr spectrum also exhibits a singlet (154.57 or 155.69 ppm) representing a quaternary vinyl carbon, alkyl substituted. The overall structure of **28** was firmly established by X-ray analysis of a single crystal (Fig. 1).[3]

Compound **29** was identified as (**Z**)-5-(4-cyanophenyl)-3,5-dimethyl-2-hexenenitrile, which, we believe, results from the tautomerization of the initially formed 1,4-addition product, 5-(4-cyanophenyl)-3,5-dimethyl-3-hexenenitrile. The ^{1}H and ^{13}C nmr spectra are consistent with this structure for compound **29**. The ^{1}H nmr spectrum shows two high-field singlets (1.39 and 1.46 ppm) indicative of the three methyl groups; the singlet at 1.46 ppm is due to the two magnetically equivalent methyl groups. There is a low-field singlet (2.79 ppm) due to the allylic methylene group and a singlet (5.17 ppm) for the vinyl proton. In the ^{13}C nmr spectrum, a doublet (99.24 ppm) is distinctive for the alkene methine group, cyano substituted

Fig. 2. X-ray crystal structure of (*Z*)-5-(4-cyanophenyl)-3,5-dimethyl-2-hexenenitrile (**29**).

(7). The alkene carbon β to the cyano group shows up at low field (162.15 ppm). There are two singlets (117.21 and 118.79 ppm) supporting two types of cyano groups. The *Z*-configuration, as well as the overall structure of **29**, was firmly established by X-ray analysis on a single crystal (Fig. 2).[3]

Discussion

There is a dramatic increase in yield of the photo-NOCAS adduct(s), incorporating cyanide anion, through the series of alkenes: 2-methylpropene (**9**) (0%) < 2-methyl-2-butene (**10**) < 2,3-dimethyl-2-butene (**2**) (20%), and through the series of conjugated dienes: 2-methyl-1,3-butadiene (**11**) (3%) < 2,3-dimethyl-1,3-butadiene (**12**) < 4-methyl-1,3-pentadiene (**13**) < 2,4-dimethyl-1,3-pentadiene (**14**) < 2,5-dimethyl-2,4-hexadiene (**6**) (80%!). Increasing alkyl substitution on the alkene or diene correlates with increased yields of photo-NOCAS adduct(s) incorporating cyanide anion. This trend was not evident in the analogous reactions involving alcohol (methanol) as the nucleophile. The observed dependence in yield of photo-NOCAS adduct(s), through these series, can be attributed to the concomitant decrease in the oxidation potential of the alkene and diene associated with increasing alkyl substitution (Table 1).

The determination of the oxidation potential of cyanide anion, by electrochemical methods, is complicated by ion-pair formation, solvent interaction, adsorption on the electrode, etc. (9, 10). Under some conditions, oxidation begins at an electrode potential as low as +0.6 V (SCE) (9); however, the best estimate of the half-wave potential ($E_{½}^{ox}$, $CN^{-}/CN^{\cdot}$) is +1.65 V (SCE, DMF) (9*d*). Therefore, nucleophilic attack of cyanide anion on the radical cation of an alkene or diene that has an oxidation potential greater than ca. +1.5 V will be accompanied by electron transfer; oxidation of the cyanide anion to the cyano radical by the alkene or diene radical cation will compete with the combination. Similar results have been reported for the anodic cyanation of aromatic compounds where the highest yields of mono-cyanation products were obtained on aromatic substrates with oxidation potentials less than +1.3 V (SCE) (9*a*,*b* and 10*a*,*b*).

Table 1. Oxidation potentials of alkenes and dienes.

Alkene/diene	$E_{1/2}^{Ox}$ (V,SCE)	Reference

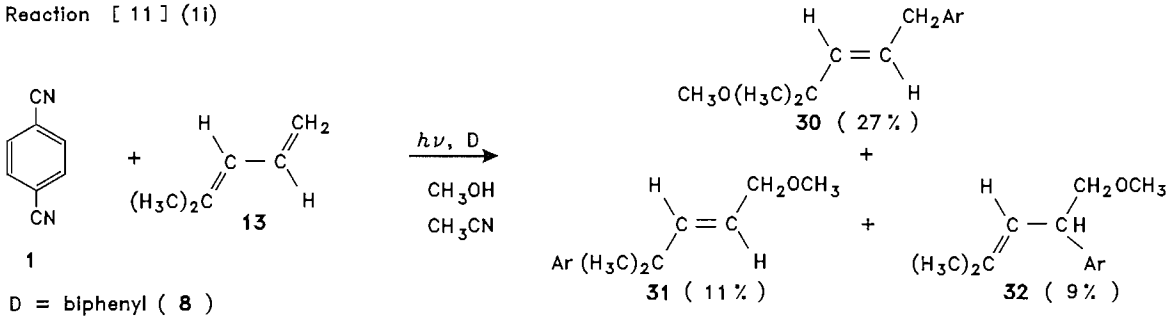
1,1-Diphenylethylene	1.82	2*a*

[a]The anodic wave was irreversible; the half-wave potential was taken as 0.028 V before the peak potential (8).

The ultimate fate of the cyano radical is not known. Certainly the cyano radical is very reactive; it reacts at essentially the diffusion-controlled rate with alkanes and alkenes, with itself, with cyanide anion, and with acetonitrile (11).



Since the first examples of the photo-NOCAS reaction, the regiochemistry of the initial bonding step has been termed *anti*-Markovnikov; that is, the nucleophile (methanol) adds to that end of the radical cation which is less heavily substituted, less sterically hindered, to give the more heavily substituted (more stable?) radical intermediate (1). The (superficial) analogy with the mechanism for free-radical addition to alkenes and dienes is obvious (12).

Usually the more heavily alkyl-substituted radical is also the more stable; however, there are exceptions. Compare the product ratios, Markovnikov *vs.* *anti*-Markovnikov, for the cyanide and methanol addition to the radical cation of 4-

methyl-1,3-pentadiene ($\mathbf{13}^{+\cdot}$) (reactions [8] and [11] (1*i*)). The major photo-NOCAS adduct isolated from reaction [8] is **25** (14%), the *anti*-Markovnikov adduct; the Markovnikov adduct, **26**, is a minor (1%) product. Relevant isodesmic reactions, [8*a*] and [8*b*], are in agreement; both high-level ab initio molecular orbital calculations (MP2/6-31G*//HF/6-31G*) and heats of formation based upon the empirically derived Benson's rules indicate that the more heavily substituted allylic radical, $\mathbf{25a}^{\cdot}$, is the more stable. The cyanide anion bonds preferentially to the less substituted, less sterically hindered, end of the radical cation, $\mathbf{13}^{+\cdot}$ which yields the more stable radical intermediate.

The major photo-NOCAS adduct from reaction [11] is **30**, the Markovnikov adduct. The product ratio, **30** (Markovnikov):**31** + **32** (*anti*-Markovnikov), is 1.4:1. Both ab initio molecular orbital calculations and empirically derived heats of

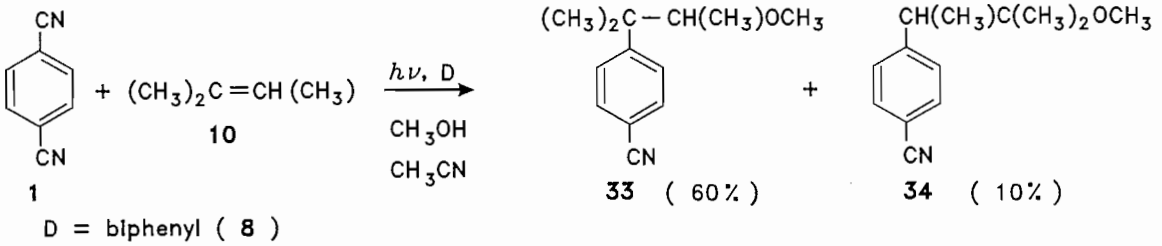
7	0.186	−0.029	



formation indicate that, in this case, the more heavily substituted allylic radical, **31a**$^{\cdot}$, is **not** the more stable (isodesmic reactions [11*a*] and [11*b*] (1*i*)). The effect of alkyl substitution on the carbon bearing the ether-oxygen obviously has a greater influence on the stability of this intermediate than does alkyl substitution on the allylic radical moiety. Of course, the total structure of the intermediate must be considered, not just the radical moiety. Upon addition of this neutral nucleophile, methanol, the initially formed distonic radical cation allows equilibration of the intermediates; steric factors, which generally influence the rate of addition, are less important.

There are previous reports of nucleophilic addition to the radical cation of an allene (13). Formation of 4-(4-cyanophenyl)-2,4-dimethyl-2-pentene-3-nitrile (**28**) indicates cyanide anion addition to the central carbon of the radical cation of 2,4-dimethyl-2,3-pentadiene (**15**$^{+\cdot}$) (reaction [10]). Nucleophilic attack at the central carbon of this radical cation is as expected; the molecular orbital calculations (MP2/6-31G*//HF/6-31G*) indicate the positive charge density is greater at the central carbon than at the terminal carbons (Table 2). In marked contrast, the spin density is greater at the termini than at the central carbon. Nucleophilic attack at the less sterically hindered central carbon also yields (ultimately) the stabilized allylic radical. The lack of isonitrile from this reaction is indicative that this allene radical cation is reacting as a "soft" electrophile; this is consistent with the delocalized charge. The calculated structure for the radical cation, **15**$^{+\cdot}$, is in good agreement with the experimentally determined structure and with lower level molecular orbital calculations (14).

The two photo-NOCAS reactions involving 2-methyl-2-butene (**10**), reactions [5] and [12] (1*b*), allow the comparison of the regiochemistry of the combination with cyanide anion, yielding both nitriles, **17** and **18**, and isonitriles, **19** and **20**, and, with methanol, yielding the ethers, **33** and **34**. The ratios of isomeric adducts (*anti*-Markovnikov:Markovnikov) are, for the nitriles, 4:1, for the isonitriles, >30:1, and, for the ethers, 6:1 (1*e*)). Relevant isodesmic reactions are summarized in Table 3.

For the nitriles, the two possible intermediates are directly compared in reaction [a]. The difference in total energy calculated by the ab initio molecular orbital method (MP2/6-31G*// HF/6-31G*) is still in agreement with the observed product

[a]Ab initio molecular orbital calculations (MP2/6-31G*//HF/6-31G*) (*5*, *6*).
[b]Empirically derived heats of formation, Benson's empirical rules (*15*).
[c]Experimentally determined heats of formation (*16*).

ratio; the *tertiary*-alkyl radical is more stable than the *secondary*-alkyl radical. The isodesmic reactions [b] and [e] are consistent. The ab initio calculations indicate that the nitrile with greater alkyl substitution on the carbon bearing the cyano group is slightly more stable (reaction [c]); as a result, the difference in stability between the *tertiary*- and *secondary*-alkyl radicals (reaction [d]) dominates.

For the isonitriles, the small difference in total energy of the two possible intermediates calculated by the ab initio molecular orbital method is now inconsistent with the observed product ratio (**19**:**20**, >30:1). In fact, in this case, the isodesmic reactions [a] and [b] indicate a preference for formation of the Markovnikov addition product (**20**). The isodesmic reaction [e] shows only a slight preference for the *tertiary*-alkyl radical. The isodesmic reaction [c] provides the explanation; increased alkyl substitution on the carbon bearing the isonitrile group is now significantly stabilizing, comparable to the effect of increased alkyl substitution on the alkyl radical.

For the ethers, the difference in total energy of the two possible β-alkoxyalkyl radicals (isodesmic reactions [a], [b], and [e]), calculated by the ab initio molecular orbital method is in good agreement with the observed product ratio; the *tertiary*-β-alkoxyalkyl radical is more stable than the *secondary*-β-alkoxyalkyl radical. The *tertiary* ether, methyl 2-methyl-2-butyl ether, is more stable than the *secondary* ether, methyl 3-methyl-2-butyl ether (isodesmic reaction [c]); however, the difference in stability between the *tertiary* and *secondary* alkyl radicals is even greater (isodesmic reaction [d]). Consequentially, the combined isodesmic reaction [e] is exothermic, consistent with the observed product ratio (1*e*,*i*).

These differences in the effect of alkyl substitution on the stability of the β-cyano, β-isocyano, and β-methoxy, alkyl radicals must be due to the difference in electron demand (the inductive effect) of the cyano, isocyano, and methoxy groups. The calculated (MP2/6-31G*//HF/6-31G*) charge and spin density distributions from Mulliken and natural population

[a]Values in parentheses are from natural charge and spin population analysis (*6d*).

analysis, for the radical intermediates involved in reactions [5], [8], and [12] are shown in Table 4. Summing the total charge on the substituent indicates the isocyano and methoxy groups are significantly more negative than the cyano group. This order is also evident from the charge on the β-carbon atoms. The carbon atoms directly bonded to the nitrogen of the isocyano group and to the ether oxygen are significantly more positively charged than the corresponding carbon bonded to the carbon of the cyano group. β-Substitution by a cyano, isocyano, or methoxy group has little effect on the spin density distribution of these radicals.

The calculations give an indication of the importance of bridging of the radical with these β-substituents (17). Starting with initially bridged β-cyano and β-isocyano radical structures, the calculations converge to relatively high-energy bridged radicals. Frequency calculations confirm that these bridged radicals are indeed minima. These bridged structures are significantly less stable than conformers that are not bridged, for the nitrile, 96 kJ mol^{-1}, and for the isonitrile 169 kJ mol^{-1}, above the global minimum. Starting with an initially bridged β-methoxy radical, constrained to equal carbon–oxygen bond lengths, the calculations did not converge. The calculations converge to the unbridged structure (**33a**$^{\bullet}$) upon removing the structural constraint.

These calculations also provide a direct comparison of the effect of alkyl substitution on the relative stability of the nitriles, the isonitriles, and the ethers, illustrated with the isodesmic reactions summarized in Table 3 [c] and [f]. The

ΔH (kJ mol^{-1}) +105.3 (calcd.)[a]	

stabilizing effect of alkyl substitution on the carbon bearing the cyano group is relatively small; 2,2-dimethylpropanenitrile is 8.4 kJ mol^{-1} more stable than 3-methylbutanenitrile (*tertiary* vs. *primary*, reaction [f]) while 2,2-dimethylbutanenitrile is only 3.5 kJ mol^{-1} more stable than 2,3-dimethylbutanenitrile (*tertiary* vs. *secondary*, reaction [c]). The influence of alkyl substitution is greatest on the isonitrile; 2-isocyano-2-methylpropane is 21.6 kJ mol^{-1} more stable than 1-isocyano-2-methylpropane (*tertiary* vs. *primary*, reaction [f]) while 2-isocyano-2-methylbutane is 9.5 kJ mol^{-1} more stable than 2-isocyano-3-methylbutane (*tertiary* vs. *secondary*, reaction [c]). *tert*-Butyl methyl ether is also significantly (15.3 kJ mol^{-1}) more stable than isobutyl methyl ether (*tertiary* vs. *primary*, reaction [f]) and methyl 2-(2-methylbutyl) ether is more stable (5.0 kJ mol^{-1}) than methyl 2-(3-methylbutyl) ether (*tertiary* vs. *secondary*, reaction [c]) (1*i*).

It is also reassuring to note (Table 5) that there is good agreement between the differences in the calculated (ab initio) total energy and previously reported experimentally determined heats of isomerization for the alkyl isonitriles to nitriles (18).

Summary and conclusions

Cyanide anion can be an effective nucleophile in the photo-NOCAS reaction; yields of the nitrile can be high. Highest yields are obtained when the alkene or diene has an oxidation potential less than 1.5 V (SCE). When the oxidation potential of the alkene or diene is greater than 1.5 V, electron transfer from the cyanide anion to the alkene or diene radical cation competes with the combination.

With alkenes, both nitriles and isonitriles are obtained. Isonitriles were not observed from the dienes. The explanation is based upon the Hard-Soft-Acid-Base (HSAB) principle. The harder alkene radical cation adds to both the hard nitrogen and the soft carbon ends of the ambident cyanide anion. The relatively soft diene radical cation adds preferentially to the soft carbon end of this nucleophile.

The regiochemistry of the adduct, Markovnikov versus *anti*-Markovnikov, is determined during the initial bonding of the cyanide anion with the alkene or diene radical cation. Cyanide anion adds preferentially to the less sterically hindered end of the radical cation, which, on the way to nitrile, yields the more stable β-cyano alkyl radical intermediates. However, bonding of the cyanide anion at the nitrogen, on the way to isonitrile, gives the less stable β-isocyano alkyl radical intermediate.

The difference in regiochemistry of the photo-NOCAS reactions involving methanol and cyanide anion reflects the fact that the initially formed intermediate, upon the addition of methanol to the alkene or diene radical cation, is a distonic radical cation with the possibility of bridging and concomitant equilibration. The addition of cyanide anion to an alkene or diene radical cation leads directly to the β-cyano- or isocyanoalkyl radical, which are not bridged, and with no possibility for equilibration. Therefore, the addition of cyanide anion must be kinetically controlled, the reaction is significantly exothermic, the transition state is early; as with radical addition to alkenes and dienes, steric effects dominate.

The radical cation of allenes can also combine with cyanide anion in the photo-NOCAS reaction. The radical cation **15**$^{+\cdot}$ couples with the cyanide anion at the central carbon of the allene and only at the carbon of this ambident anion, as a soft-electrophile.

Experimental

General information

The ^{1}H and ^{13}C nmr spectra were obtained from a Bruker 250 MSL or a Bruker 400 MSL spectrometer. Spectra were recorded in parts per million (ppm) and frequencies are relative to tetramethylsilane. Infrared spectra (ir) were recorded on a Nicolet 205 or 510 FTIR and are reported in wave numbers (cm^{-1}). Elemental analyses were performed by the Canadian Microanalytical Service Ltd., B.C. Exact Mass determinations were obtained using a CEC 21-110 mass spectrometer. Melting points were determined using a Cybron Corporation Thermolyne apparatus with a digital thermocouple and are corrected. Product yields and progress of the reactions were determined using a Hewlett–Packard (HP) 5890 gas chromatograph with a DB-1701 fused silica WCOT column (30 m × 0.25 mm, 0.25-μm film thickness) and a calibrated flame ionization detector (gc/fid) and are based upon 1,4-dicyanobenzene (**1**) as the limiting reagent. An HP 3392A integrator was interfaced with the gc/fid to obtain peak areas. An HP 5890 gas chromatograph with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33-μm film thickness) interfaced with an HP 5970 mass selective detector (gc/ms) was also used for product analyses. Mass spectra are reported as *m/z* (relative intensity). Separation of product mixtures was generally carried out using preparative medium-pressure liquid chromatography (mplc) (1*d*). The mplc consists of a 2.5 cm × 1 m column packed with thin-layer chromatography (tlc) grade silica gel (without binder) (Rose Scientific Ltd., Cat. 81632) at a pressure of 19 psi using helium (1 psi = 6.9 kPa). Connected to the mplc was a uv spectrophotometer – fraction collector that collects ca. 10-mL fractions. Dry column flash chromatography (dc/fc) was also used (19). The column was packed with thin-layer chromatography grade silica gel (without binder) (Rose Scientific Ltd., Cat. 81632). Fraction sizes were ca. 5 mL.

Materials

Acetonitrile (Fisher ACS grade) was distilled twice, first from sodium hydride and then from phosphorus pentoxide. It was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), fractionally distilled (under nitrogen), and stored over molecular sieves (3 Å) (20). Methanol was distilled and then stored over

molecular sieves (4 Å). 1,4-Dicyanobenzene (**1**) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by recrystallization from 95% ethanol. Tetraethylammonium perchlorate (TEAP) (Aldrich) was recrystallized three times from water and then dried in a vacuum oven for 15 h, 70°C, 0.25 Torr (1 Torr = 133.3 Pa). 2,3-Dimethyl-2-butene, 98% (**2**), 2-methyl-2-butene, 99+% (**10**), 2-methyl-1,3-butadiene, 99% (**11**), 2,3-dimethyl-1,3-butadiene, 98% (**12**), 2,4-dimethyl-1,3-pentadiene, 98+% (**14**), 2,4-dimethyl-2,3-pentadiene, 97% (**15**), and 18-crown-6, 99% were obtained from the Aldrich Chemical Co. 2-Methylpropene (**9**) was obtained from Matheson and was of a minimum 99.0% purity. 4-Methyl-1,3-pentadiene, ≥98% (**13**) was obtained from Fluka Chemika-BioChemika. Biphenyl (**8**) (Eastman Kodak Co.) was recrystallized from methanol. Potassium cyanide was obtained from BDH, Inc.

Irradiations

Irradiations were generally carried out on acetonitrile solutions of the alkene or diene, 1,4-dicyanobenzene (**1**), biphenyl (**8**), potassium cyanide, and 18-crown-6 ether. Solutions were irradiated in either 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes, which were degassed by nitrogen ebullition. These samples were irradiated at 10°C using a CGE 1-kW medium-pressure mercury vapour lamp contained in a water-cooled Pyrex immersion well.

Cyclic voltammetric measurements

Cyclic voltammetry was used to obtain the oxidation potential of the alkenes/ dienes. The apparatus has been described (21). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (SCE), which was connected to the solution (TEAP 0.1 M, acetonitrile) through a Luggin capillary. The alkene/ diene concentration was ca. 0.005 M in acetonitrile. Since the anodic wave was irreversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (8).

Formation of the cyanide anion, 2,3-dimethyl-2-butene (2), 1,4-dicyanobenzene (1) photo-NOCAS adducts 3 and 16: reaction [4]

A solution of 2,3-dimethyl-2-butene (**2**) (0.9 mL, 0.6 g, 0.0076 mol), 1,4-dicyanobenzene (**1**) (0.6 g, 0.0047 mol), biphenyl (**8**) (0.4 g, 0.0026 mol), potassium cyanide (0.3 g, 0.0046 mol), and 18-crown-6 (0.3 g, 0.0011 mol) in acetonitrile (40 mL) was degassed by nitrogen ebullition and irradiated for 43 h using a 1-kW lamp at 10°C. The solvent was removed to yield a crude photolysate. The crude photolysate was partially separated by repetitive chromatography (mplc) using a linear solvent gradient (hexanes – 10% diethyl ether, 90% hexanes). Two 1:1:1 adducts were detected (gc/ms) and were eluted (mplc) in the order **16** followed by **3**. Purification of **16** required preparative thin-layer chromatography on silica gel, eluting repeatedly with 5% diethyl ether, 95% hexanes.

*3-(4-Cyanophenyl)-2,3-dimethylbutanenitrile (**3**)*

The yield of **3** was 15%. The gc/ms of this compound was identical to that reported (1*a*).

*3-(4-Cyanophenyl)-2,3-dimethyl-2-isocyanobutane (**16**)*

The yield of **16** was 5%; infrared (Nicolet 205) ν: 2989(s), 2951(m), 2923(s), 2852(m), 2229(s), 2131(s), 1682(m), 1607(m), 1507(m), 1461(m), 1404(m), 1384(m), 1150(m), 1093(m), 1019(m), 843(m); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.34 (st, 6H, $^3J_{1-N}$ = 1.8 Hz, 2 CH_3's (1-H)), 1.52 (s, 6H, 2 CH_3's), 7.58 (d, 2H, $^3J_{2'-3'}$ = 8.5 Hz, $^3J_{5'-6'}$ = 8.5 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.64 (d, 2H, $^3J_{2'-3'}$ = 8.5 Hz, $^3J_{5'-6'}$ = 8.5 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 24.07 (q), 26.14 (q), 43.92 (s, quaternary carbon, aryl-substituted), 63.78 (st, quaternary carbon, isocyano substituted), 111.10 (s, quaternary aryl carbon, cyano substituted), 118.87 (s, CN), 129.13 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.67 (d, aromatic CH adjacent to cyano-substituted carbon), 149.40 (s, quaternary aryl carbon, alkyl substituted), 155.95 (st, R-N≡C); ms *m/z*: 51(7), 69(69), 76(5), 77(8), 89(10), 101(6), 102(6), 103(5), 104(17), 116(88), 117(10), 128(8), 130(7), 142(5), 144(100), 145(12), 170(6), 212(4). Exact Mass calcd. for $C_{14}H_{16}N_2$: 212.1313; found: 212.1326.

Irradiation of an acetonitrile solution of potassium cyanide, 2-methylpropene (9), 1,4-dicyanobenzene (1), and biphenyl (8)

A solution of 2-methylpropene (**9**) (0.054 g, 9.6×10^{-4} mol), 1,4-dicyanobenzene (**1**) (0.062 g, 4.8×10^{-4} mol), biphenyl (**8**) (0.040 g, 2.6×10^{-4} mol), potassium cyanide (0.030 g, 4.6×10^{-4} mol), and 18-crown-6 (0.025 g, 9.5×10^{-5} mol) in acetonitrile (4 mL) was degassed by nitrogen ebullition and irradiated for 16 h using a 1-kW lamp at 10°C. No photo-NOCAS products were detected (gc/ms, selective ion monitoring).

Formation of the cyanide anion, 2-methyl-2-butene (10), 1,4-dicyanobenzene (1) photo-NOCAS adducts 17, 18, 19, and 20: reaction [5]

A solution of 2-methyl-2-butene (**10**) (4.1 mL, 2.7 g, 0.038 mol), 1,4-dicyanobenzene (**1**) (2.5 g, 0.020 mol), biphenyl (**8**) (1.6 g, 0.010 mol), potassium cyanide (1.2 g, 0.018 mol), and 18-crown-6 (1.1 g, 0.0042 mol) in acetonitrile (160 mL) was degassed by nitrogen ebullition and irradiated for 24 h using a 1-kW lamp at 10°C. The solvent was removed to yield a crude photolysate. The crude photolysate was separated by repetitive chromatography (mplc) using a linear solvent gradient (hexanes – 10% diethyl ether, 90% hexanes). Four 1:1:1 adducts were detected (gc/ms) and these products were eluted (mplc) in the order **20**, **19**, **18** followed by **17**. Purification of **20** required preparative thin-layer chromatography on silica gel, eluting repeatedly with 5% diethyl ether, 95% hexanes.

*3-(4-Cyanophenyl)-2,3-dimethylbutanenitrile (**17**)*

The yield of **17** was 9%: the melting point was 70–71°C; infrared (Nicolet 205) ν: 2979(s), 2947(m), 2885(w), 2228(s), 1608(m), 1507(m), 1468(m), 1459(m), 1454(m), 1406(m), 1383(m), 1087(m), 1018(w), 915(m), 840(s), 734(s); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.10 (d, 3H, $^3J_{1-2}$ = 7.3 Hz, CH_3 (1-H)), 1.52 (s, 6H, 2 CH_3's), 2.97 (q, 1H, $^3J_{1-2}$ = 7.3 Hz, H of methine group (2-H)), 7.52 (d, 2H, $^3J_{2'-3'}$ = 8.9 Hz, $^3J_{5'-6'}$ = 8.9 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.66 (d, 2H, $^3J_{2'-3'}$ = 8.9 Hz, $^3J_{5'-6'}$ = 8.9 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 13.69 (q), 23.78 (q), 27.29 (q), 37.61 (d, CH, cyano substituted), 40.27 (s, quaternary carbon, aryl substi-

Formation of the cyanide anion, 2,3-dimethyl-1,3-butadiene (12), 1,4-dicyanobenzene (1) photo-NOCAS adducts 23 and 24: reaction [7]

A solution of 2,3-dimethyl-1,3-butadiene (**12**) (6.0 mL, 4.4 g, 0.053 mol), 1,4-dicyanobenzene (**1**) (3.1 g, 0.024 mol), biphenyl (**8**) (2.0 g, 0.013 mol), potassium cyanide (2.0 g, 0.031 mol), and 18-crown-6 (1.2 g, 0.0047 mol) in acetonitrile (200 mL) was degassed by nitrogen ebullition and irradiated for 7 days using a 1-kW lamp at 10°C. The solvent was removed to yield a crude photolysate. The crude photolysate was separated by repetitive chromatography (mplc) using a linear solvent gradient (hexanes – 10% diethyl ether, 90% hexanes). Two 1:1:1 adducts were detected (gc/ms) and these products eluted (mplc) in the order **23** followed by **24**.

3-(4-Cyanophenyl)-3,4-dimethyl-4-pentenenitrile (23)

The yield of **23** was 7%; infrared (Nicolet 205) ν: 3092(w), 2976(s), 2952(m), 2926(m), 2887(w), 2229(s), 1642(m), 1607(s), 1505(s), 1451(m), 1431(m), 1406(m), 1382(m), 1072(w), 1019(w), 909(s), 842(s), 734(s); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.55 (s, 3H, CH_3), 1.66 (s, 3H, CH_3), 2.84 (AB apparent singlet, 2H, CH_2CN), 5.07 (s, 1H, terminal vinyl H), 5.15 (s, 1H, terminal vinyl H), 7.43 (d, 2H, $^3J_{2'-3'}$ = 8.5 Hz, $^3J_{5'-6'}$ = 8.5 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.66 (d, 2H, $^3J_{2'-3'}$ = 8.5 Hz, $^3J_{5'-6'}$ = 8.5 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 19.98 (q), 24.79 (q), 29.83 (t, CH_2, cyano substituted), 46.35 (s, quaternary carbon, aryl substituted), 111.25 (s, quaternary aryl carbon, cyano substituted), 113.06 (t, alkene CH_2), 117.49 (s, CN), 118.52 (s, CN), 127.11 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.54 (d, aromatic CH adjacent to cyano-substituted carbon), 147.00 (s), 148.84 (s); ms *m/z*: 51(24), 75(18), 77(19), 115(26), 116(39), 127(22), 128(29), 140(23), 142(71), 143(35), 153(24), 154(35), 155(21), 167(21), 168(33), 169(69), 170(100). ated for 48 h using a 1-kW lamp at 10°C. The solvent was removed to yield a crude photolysate. The crude photolysate was separated by repetitive chromatography (dc/fc) using a linear solvent gradient (hexanes – 20% diethyl ether, 80% hexanes). One 1:1:1 adduct, 4-(4-cyanophenyl)-2,4-dimethyl-2-pentene-3-nitrile (**28**), was detected (gc/ms); the yield was 22%. The retention time and gc/ms of this compound were identical to the product obtained from **14** (reaction [9]).

Asymmetric synthesis of lignans using oxazolidinones as chiral auxiliaries

James L. Charlton and Gaik-Lean Chee

Abstract: A simple procedure for the asymmetric synthesis of lignans via chiral β-benzyl-γ-butyrolactones has been developed. The key benzylbutyrolactone intermediates were efficiently synthesized using a six-step procedure, starting from 3,4-(methylenedioxy)cinnamic acid. The key step in this sequence was a highly diastereoselective alkylation of an *N*-acyloxazolidinone enolate. The resulting β-benzyl-γ-butyrolactones were subsequently transformed into the benzylidene lignans gossypifan and savinin (hibalactone) via aldol condensation–dehydration reactions, and into the dibenzylbutyrolactone lignan 4′-demethylyatein, through alkylation. Oxidation of 4′-demethylyatein with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) afforded *cis*- and *trans*-benzylidenebenzylbutyrolactones, whereas oxidation with DDQ/TFA gave 4′-demethyldeoxyisopodophyllotoxin.

Key words: lignans, synthesis, asymmetric, biosynthesis, oxidation, benzylbutyrolactones.

Résumé : On a mis au point une méthode de synthèse simple des lignanes impliquant des β-benzyl-γ-butyrolactones chirales. On a synthétisé les intermédiaires benzylbutyrolactones clés d'une façon efficace en faisant appel à une procédure en six étapes, à partir de l'acide 3,4-(méthylènedioxy)cinnamique. L'étape clé de cette séquence est une alkylation hautement diastéréosélective d'un énolate *N*-acyloxazolidinone. Les β-benzyl-γ-butyrolactones qui en découlent sont ultérieurement transformées en benzylidènes des lignanes gossypifane et savinine (hibalactone) par le biais de réactions de condensation aldolique et de déshydratation et en lignane dibenzylbutyrolactone 4′-déméthylyatéine par alkylation. L'oxydation de la 4′-déméthylyatéine par la 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) conduit aux benzylidènebenzylbutyrolactones *cis* et *trans* alors que l'oxydation à l'aide de DDQ/TFA fournit de la 4′-démethyldéoxyisopodophyllotoxyine.

Mots clés : synthèse de lignanes, asymétrique, biosynthèse, oxydation, benzylbutyrolactones.

Introduction

Many lignan natural products have interesting biological properties (1) and developing synthetic methods for this large class of compounds has been a challenge to synthetic chemists.[2] Many of the methods for the asymmetric synthesis of chiral lignans have involved the intermediacy of enantiomerically pure β-benzyl-γ-butyrolactones **1**. These have been used in the synthesis of dibenzylbutyrolactones **2**, benzylidenebenzylbutyrolactones **3**, aryltetralins **4**, and dibenzocyclooctadienes **5** (Scheme 1). In comparison to other general methods for lignan synthesis, using butyrolactones **1** as intermediates offers more structural variability than can be achieved otherwise.

Several synthetic approaches for the preparation of optically active butyrolactones having general structure **1** have been published. The first asymmetric synthesis of a butyrolactone of type **1b** (R = 3,4-methylenedioxy) was reported by Tomioka and Koga (3). In a lengthy procedure they diastereoselectively alkylated a chiral γ-substituted γ-butyrolactone followed by removal of the γ group. Posner et al. synthesized chiral benzylbutyrolactones by diastereoselective conjugate addition to an enantiomerically pure α-sulfinyl-γ-butenolide (4). Similar to the first example, the procedure is lengthy and the overall yield is relatively low. Yoda et al. carried out a conjugate addition on a chiral unsaturated lactam in the preparation of a butyrolactone of type **1b** (R = 3,4-methylenedioxy) (5). Once again, the yields for most steps were only moderate. An elegant catalytic asymmetric hydrogenation reaction was

Scheme 2.

employed by Morimoto et al. to prepare **1a** and **1b** (R = 3,4-methylenedioxy and 3,4-dimethoxy) (6). Unfortunately, the chiral hydrogenation catalyst used by these authors is relatively unavailable. More recently, Honda et al. employed enantioselective deprotonation of a 3-benzylcyclobutanone in the synthesis of a lactone of type **1b** (R = 3,4-methylenedioxy) (7). Although only a few steps were involved in the synthesis, the enantioselectivity of the key reaction was moderate, affording **1b** in only 80% optical purity. Doyle et al. reported a novel and efficient synthesis of lactones **1a** and **1b** (R = H, 3-methoxy and 3,4-methylenedioxy) via an enantioselective intramolecular C-H insertion reaction of an alkyl diazoacetate (8). Chiral oxoimidazolidine carboxylate dirhodium catalysts were applied in the key reaction to afford a chiral benzylbutyrolactone in up to 94% ee, but neither the catalyst nor the chiral ligand that was used is commercially available. Two recent asymmetric syntheses of optically pure β-benzyl-γ-butyrolactones of structure **1a** (R = 3,4-dimethoxy and 4-methoxy) utilized an enzymatic transesterification of a prochiral diol (9). Although the process was highly enantioselective, relatively large amounts of the enzyme (lipase PS from *Pseudomonas fluorescens*) were needed.

Although the above reported methods have provided elegant routes to the preparation of lignan intermediates **1a** and **1b**, many problems still exist. These include laborious methods, poor overall yields, unsatisfactory enantiomeric purity, and (or) expensive reagents. A simple and efficient approach for the asymmetric synthesis of butyrolactones **1** is still required.

Substituted oxazolidinone heterocycles[3] are effective chiral auxiliaries giving excellent asymmetric induction in reactions such as alkylations, hydrogenations, and Diels–Alder reactions. Enolates derived from *N*-acyloxazolidinones can be alkylated with α-bromoacetate to afford diastereomerically pure substituted succinate derivatives (11). After the removal of the oxazolidinone chiral auxiliary, the chiral half acid can be reduced and lactonized to afford the β-substituted butyrolactone in high optical purity (Scheme 2) (11*a*).

We have adopted this simple and versatile method for the asymmetric synthesis of β-benzyl-γ-butyrolactones **11a** and **11b** (see Scheme 3). These were subsequently transformed into the lignans gossypifan (**14a**), savinin (hibalactone) (**14b**), and 4′-demethylyatein (**16**) (these are the first reported syntheses for gossypifan and 4′-demethylyatein) (Schemes 4 and 5).

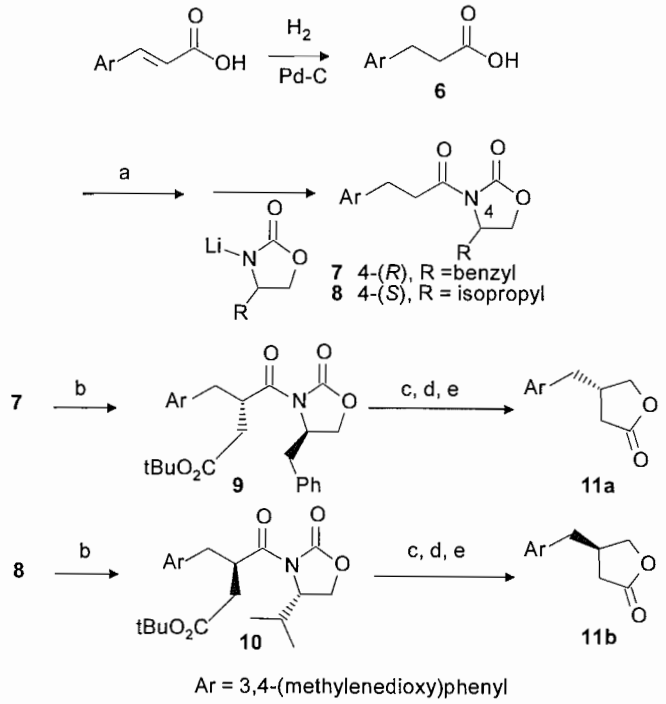
4′-Demethylyatein (**16**) is considered to be a biosynthetic precursor to aryltetralin lignans having the podophyllotoxin pattern of substitution (see **23** in Scheme 7) (12). It has been proposed that oxidation to a quinone methide **20** is followed by cyclization to 4′-demethyldeoxypodophyllotoxin (the 1,2-*cis* isomer of **23**). Kende et al. were able to mimic the biosynthetic pathway and oxidatively cyclize a similar diarylbutane (13); however, attempts to cyclize 4′-demethylyatein itself have been unsuccessful (14*a*).[4] We have restudied the oxidation of this biologically important precursor using DDQ as oxidant. An aryltetralin lignan was successfully prepared and a better understanding of the biosynthesis of lignans was achieved.

Results and discussion

The enantiomerically pure (*S*)- and (*R*)-β-3,4-(methylenedioxy)benzyl-γ-butyrolactones (**11a** and **11b**) were efficiently synthesized in six steps from 3,4-(methylenedioxy)cinnamic acid, as shown in Scheme 3, in an overall yield of >45%. Dihydrocinnamic acid **6** was obtained in excellent yield from hydrogenation of commercially available 3,4-(methylenedioxy)cinnamic acid. Using a modified literature procedure (11), commercially available (4*R*)-benzyl and (4*S*)-isopropyl-2-oxazolidinone were *N*-acylated with dihydrocinnamic acid **6** to give N-acyloxazolidinones **7** and **8** in 88% and 84% yield, respectively. The *N*-acyloxazolidinones **7** and **8** were diastereoselectively alkylated with *tert*-butyl bromoacetate to afford one major diastereomer in each case (**9** and **10**, ca. 80% yield), having >95% diastereomeric excess as shown by the ^{1}H NMR spectrum. Although the absolute configuration could not be determined at this stage it was expected to be that shown in Scheme 3. The oxazolidinone chiral auxiliary was removed with LiOH–H_2O_2 without affecting the *tert*-butyl ester. The crude acid was reduced to an alcohol using BH_3·THF, then lactonized with TFA to afford the benzylbutyrolactone **11** in about 70% yield from the *N*-acyloxazolidinone. The benzylbutyrolactones **11a** and **11b** have optical activities and other spectroscopic characteristics consistent with the previously reported values (15). Based on their optical activity, the enantiomeric excesses of these lactones were >95%. The chiral auxiliaries, (4*S*)-isopropyl- and (4*R*)-benzyl-2-oxazolidinone, were readily recovered from the lactonized product by chromatography. Compared to previously reported methods, the present approach to the synthesis of β-benzyl-γ-butyrolactones is more efficient. It is simple, gives high asymmetric induction, and uses commercially available reagents.

Having obtained the enantiomerically pure butyrolactones **11a** and **11b**, their conversion to optically pure lignans was undertaken. The benzylidene lignans gossypifan (**14a**) and savinin (hibalactone) (**14b**) were synthesized from **11a** and **11b** following a modified literature procedure (16) as illustrated in Scheme 4. The β-benzyl-γ-butyrolactones **11a** and **11b** were each deprotonated with *N*-sodiohexamethyldisilazane (NaHMDS), and then treated with 3,4-dimethoxybenzaldehyde (for **11a**) and 3,4-(methylenedioxy)benzaldehyde (for **11b**) to afford aldol products **12a** and **12b**, which were acetylated in situ by adding a mixture of Ac_2O–DMAP–Et_3N to the reaction mixtures. The crude acetylated products **13a** and **13b** were then treated with DBU in refluxing toluene to produce the *trans*-benzylidene lignans gossypifan (**14a**) and savinin (**14b**) respectively, in >90% overall yield (from **11**). Gossypifan (**14a**) is a naturally occurring lignan recently isolated from a plant (*Jatropha gossypifolia*) and possesses medicinal and

[3] The use of oxazolidinones as chiral auxiliaries was recently reviewed in textbooks (refs. 10*a*–10*c*) and by Evans et al. (10*d*).



[4] The cyclization of yatein itself to aryltetralin and arylnaphthalene lignans has been more successful: see refs. 14*b*–14*d*.

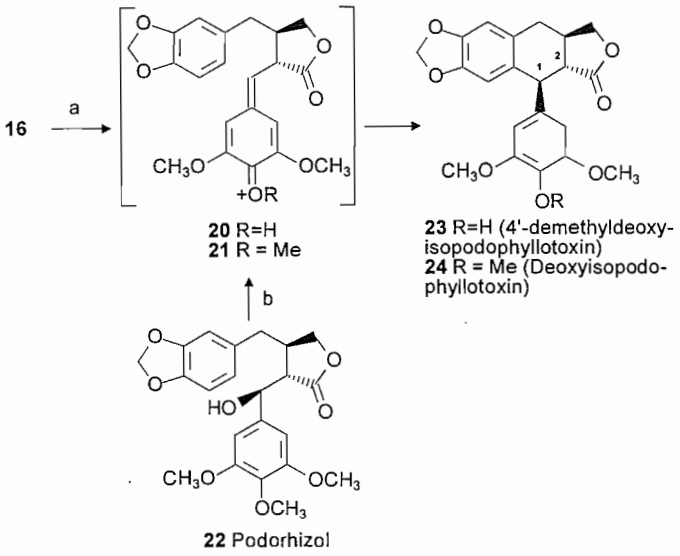
pesticidal properties (17). The synthetic material, **14a**, had both rotation and other spectroscopic properties consistent with those reported for the natural product (17). This is the first reported synthesis of this compound. Savinin (also known as hibalactone (18*a*)) (**14b**), which is an insecticide synergist, also had properties consistent with those previously reported (18*b*, 18*c*). It should be noted that savinin has been previously prepared from **11b** by Honda et al. in four steps and 37% yield (7). The method of Tanaka et al. (16) that was used in the current work has the advantage that it is a one-pot procedure that gives savinin in 90% yield.

In addition to savinin, butyrolactone **11b** was also converted to 4′-demethylyatein (**16**), a naturally occurring dibenzylbutyrolactone lignan that has been regarded as a biosynthetic precursor to 4′-demethylpodophyllotoxin derivatives (12). The anion of butyrolactone **11b** was reacted with benzyl bromide **15**, which was, in turn, prepared from syringic acid by benzylation, reduction, and bromination (19). Careful control of the reaction temperature during benzylation of **11b** was necessary to prevent formation of the dibenzylated product. HMPA, often used for this type of benzylation, was not required for this reaction. The resulting crude 4′-benzylated yatein was hydrogenated to afford 4′-demethylyatein in an overall yield of 62% from **11b** (see Scheme 5). The synthetic 4′-demethylyatein had spectroscopic properties identical to those reported previously (20).



Previous attempts to oxidize racemic 4′-demethylyatein using metallic oxidants such as vanadium oxytrifluoride and thallium trifluoroacetate in order to induce cyclization to an aryltetralin lignan were totally unsuccessful (14*a*). On the other hand, Pelter et al. have reported a successful oxidative cyclization of a monophenolic lignan, which is structurally related to 4′-demethylyatein, using phenyliodonium bis(trifluoroacetate) (PIFA) as oxidant (21). The reaction afforded a mixture of dibenzocyclooctadiene diastereomers in good yield. In view of their success with the nonmetallic oxidant PIFA we decided to study the oxidation reaction of 4′-demethylyatein using DDQ. Oxidation of 4′-demethylyatein with DDQ in THF at room temperature resulted in the formation of a mixture of two compounds, *cis*- and *trans*-benzylidenelactones, **18** and **19**, in 95% total yield. The ratio of the *cis* to the *trans* isomer was about 1.3:1, as determined by ^{1}H NMR spectroscopy. The proposed elimination mechanism is shown in Scheme 6. Quinone methide **17** is considered to be the reactive intermediate. Elimination of a proton from **17** (from conformations **17a** and **17b**) could lead to **18** and **19**. It has previously been proposed that benzylidene lignans such as **18** and **19** (general structure **3**) may be formed biosynthetically via oxidation of dibenzylbutyrolactones **2** (12*a*). The oxidation result obtained for 4′-demethylyatein appears to confirm this possibility. After standing exposed to the air at room temperature for 2 weeks, *cis*-benzylidenelactone **18** isomerized completely to the *trans* isomer **19**. The isomerization process could also be achieved in 2 h by refluxing the *cis* and *trans* isomeric mixture with iodine in benzene, with UV irradiation. The isomerization process indicates the instability

Scheme 7.

Key: (a) DDQ, TFA.; (b) TFA.

of the *cis* isomer and may explain the lack of reports of isolation of *cis*-benzylidenelactone lignans from plants.

If quinone methide **17** were formed during oxidation of **16**, addition of acid might alter the course of the subsequent reactions of the quinone methide. Treating 4′-demethylyatein (**16**) with DDQ in the presence of TFA (see Scheme 7) resulted in the formation of 4′-demethyldeoxyisopodophyllotoxin (**23**), a naturally occurring all-*trans* aryltetralin lignan, in about 65% yield after preparative TLC and recrystallization. The concentration and the ratio of substrate to reagent were found to be very critical to the cyclization process. Protonated quinone methide **20** is proposed as the intermediate in the cyclization reaction. Friedel–Crafts substitution on the other aryl group leads to compound **23**. Notably, **23** has an all-*trans* geometry, in contrast to the podophyllotoxin type of stereochemistry (1,2-*cis*) often found in aryltetralin lignans formed biosynthetically.

An all-*trans* stereochemistry is also found in the product (see **24** in Scheme 7) obtained from the acid-catalysed cyclization of podorhizol (**22**) and structural analogues (12*a*). These reactions presumably involve the intermediate delocalized benzylic cation **21**, which is similar to **20** (Scheme 7).

To the best of our knowledge, the oxidative conversion of a monophenolic dibenzylbutyrolactone lignan to either an aryltetralin lignan or benzylidenebenzylbutyrolactone is unprecedented. Despite the fact that these reactions have been proposed biosynthetically they have not previously been demonstrated in the laboratory. Combining our current results with the earlier observations of Pelter et al. (21), it now seems reasonable to conclude that benzylidenebenzylbutyrolactone, aryltetralin, and dibenzocyclooctadiene lignans with 4′-hydroxyl groups (**3**, **4**, and **5** in Scheme 1) could all arise biosynthetically from a common 4′-hydroxydibenzylbutyrolactone precursor. The successful cyclization reaction of 4′-demethylyatein with DDQ–TFA has also provided a new method for the synthesis of aryltetralin lignans. Further investigations of structurally related compounds with other oxidants are in progress and will be reported in the near future.

Conclusion

A versatile asymmetric synthesis of β-benzyl-γ-butyrolactones, key intermediates in the synthesis of lignans, has been achieved using a six-step procedure, in an overall yield of >45% from 3,4-(methylenedioxy)cinnamic acid. The method afforded the β-benzyl-γ-butyrolactones in >95% optical purity. These intermediates were used in the synthesis of the benzylidene lignans gossypifan and savinin, and the dibenzylbutyrolactone lignan 4′-demethylyatein, in good to excellent yield. The DDQ oxidation of the latter product provides an alternative route for the preparation of aryltetralin lignans, and affords further substantiation of the proposed mechanism for the biosynthesis of lignans.

Experimental

General methods

The general experimental procedures and instrumentation have been described in a previous publication (22).

3,4-(Methylenedioxy)dihydrocinnamic acid (6)

3,4-(Methylenedioxy)cinnamic acid (1.86 g, 9.69 mmol) was dissolved in DMF (ca. 25 mL) and stirred with Pd–C (0.2 g) under H_2 (1 atm; 101.3 kPa) for 24 h. The suspension was filtered through Celite®, rinsing with water and EtOAc. The organic solution was separated, and the aqueous solution extracted with EtOAc (3 × 15 mL). The organic solutions were combined, washed with water (5 × 20 mL) to remove residual DMF, dried ($MgSO_4$), and concentrated under vacuum to afford a colorless crystalline solid (1.88 g, 100%): mp 82–84°C; IR (CH_2Cl_2): 3085 (COOH), 1711 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.64 (2H, t, J = 7.5), 2.88 (2H, t, J = 7.5), 5.92 (2H, s), 6.63–6.74 (3H, m); ^{13}C NMR ($CDCl_3$) δ: 30.3 (CH_2), 35.9 (CH_2), 100.8 (CH_2), 108.3 (CH), 108.7 (CH), 121.1 (CH), 133.9 (C), 146.0 (C), 147.6 (C), 179.1 (C); mass

spectrum *m/z* (relative intensity): 194 (M^+, 32), 176 (3), 149 (7), 135 (100); HRMS calcd. for $C_{10}H_{10}O_4$: 194.0579; found: 194.0570.

General procedure for the preparation of *N*-acyloxazolidinones 7 and 8

A modified literature procedure was used (11*b*). To a solution of 3,4-(methylenedioxy)dihydrocinnamic acid (**6**, 0.50 g, 2.53 mmol) in THF (6 mL) under N_2 at −70°C was successively added, dropwise, Et_3N (0.41 mL, 2.9 mmol) and pivaloyl chloride (0.32 mL, 2.6 mmol). The mixture was gradually warmed to 0°C, stirred for an hour, and then recooled to −70°C. *n*-BuLi (1.1 mL, 2.45 M in hexane, 2.6 mmol) was added dropwise to a solution of the (4*R*)-benzyl or (4*S*)-isopropyl-2-oxazolidinone (2.53 mmol) in THF (15 mL) under N_2 at −70°C. The resulting lithium salt was added dropwise to the above dihydrocinnamic acid mixture via a double-tipped needle at −70°C over a period of 15 min. The resulting mixture was stirred for an hour, and then warmed gradually to 0°C. After stirring at 0°C for 35 min, saturated aqueous NH_4Cl (2 mL) was added. The solution was concentrated under vacuum to remove most of the THF. Water (10 mL) was added and the solution was extracted with EtOAc (4 × 10 mL), dried ($MgSO_4$), and evaporated.

N-Acyloxazolidinone 7

Reacting dihydrocinnamic acid **6** and (4*R*)-benzyl-2-oxazolidinone as described above gave an oil (0.89 g) that slowly crystallized. Recrystallization from EtOAc–hexanes gave colorless crystals (0.78 g, 88%): mp 68–70°C; $[\alpha]_D^{20}$ −48 (*c* 0.30, $CHCl_3$): IR (CH_2Cl_2): 1783 and 1702 (C═O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.76 (1H, dd, *J* = 9.5, 13.4), 2.91–2.96 (2H, m), 3.13–3.32 (3H, m), 4.15–4.19 (2H, m), 4.66 (1H, m), 5.91 (2H, s), 6.71–6.76 (3H, m), 7.17 (2H, dd, *J* = 8.0, 1.67), 7.25–7.32 (3H, m); ^{13}C NMR ($CDCl_3$) δ: 30.0 (CH_2), 37.4 (CH_2), 37.8 (CH_2), 55.1 (CH), 66.2 (CH_2), 100.8 (CH_2), 108.2 (CH), 109.0 (CH), 121.3 (CH), 127.3 (CH), 128.9 (2 × CH), 129.4 (2 × CH), 134.2 (C), 135.2 (C), 145.9 (C), 147.6 (C), 153.4 (C), 172.3 (C); mass spectrum *m/z* (relative intensity): 353 (M^+, 40.5), 309 (4), 219 (5), 176 (34), 148 (82), 135 (100); HRMS calcd. for $C_{20}H_{19}O_5N$: 353.1263; found: 353.1263.

N-Acyloxazolidinone 8

Reacting dihydrocinnamic acid **6** and (4*S*)-isopropyl-2-oxazolidinone as described above gave an oil. This was chromatographed with 20% EtOAc–hexanes to afford a light yellow oil (0.65 g, 84%): $[\alpha]_D^{20}$ +61 (*c* 0.98, $CHCl_3$); IR (CH_2Cl_2): 1786 and 1708 (C═O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.84 (3H, d, *J* = 7.0), 0.90 (3H, d, *J* = 7.0), 2.35 (1H, dseptet, *J* = 3.9, 7.0), 2.90 (2H, m), 3.10–3.33 (2H, m), 4.22 (2H, m), 4.42 (1H, m), 5.91 (2H, s), 6.68–6.74 (3H, m); ^{13}C NMR ($CDCl_3$) δ: 14.6 (CH_3), 17.9 (CH_3), 28.4 (CH), 30.2 (CH_2), 37.4 (CH_2), 58.4 (CH), 63.4 (CH_2), 100.8 (CH_2), 108.2 (CH), 109.0 (CH), 121.3 (CH), 134.2 (C), 145.9 (C), 147.6 (C), 154.0 (C), 172.3 (C); mass spectrum *m/z* (relative intensity): 305 (M^+, 9), 180 (13), 179 (25), 178 (17), 176 (13), 149 (13), 148 (29), 135 (27); HRMS calcd. for $C_{16}H_{19}O_5N$: 305.1263; found: 305.1269.

General procedure for alkylation of *N*-acyloxazolidinones 7 and 8 with *tert*-butyl bromoacetate

This procedure is a modification of one found in the literature (11*b*). NaHMDS (2.10 mL, 1.0 M in THF, 2.10 mmol) was added dropwise to a solution of the *N*-acyloxazolidinone (2.0 mmol) in THF (15 mL) under N_2 at −73°C, over a period of 10 min. After stirring at −73°C for an hour, *tert*-butyl bromoacetate (0.92 mL, 6.30 mmol) was added dropwise. The mixture was stirred for 2 h before being quenched with saturated aqueous NH_4Cl (4 mL). It was concentrated under vacuum to remove most of the THF, and then diluted with EtOAc (15 mL) and water (10 mL). The organic layer was separated and the aqueous layer extracted with EtOAc (3 × 10 mL). The organic solutions were combined, washed with saturated aqueous NH_4Cl (15 mL), 5% aqueous $NaHCO_3$ (15 mL), and brine (15 mL), dried ($MgSO_4$), and concentrated to afford a liquid that crystallized when triturated with hexane. The hexane washings were concentrated and chromatographed using hexanes–2-propanol (15:1) to give more product. The colorless solid was combined and recrystallized (see below).

Alkylated product 9

N-Acyloxazolidinone **7** (0.706 g, 2.0 mmol) was alkylated as above to give a colorless solid that was further recrystallized from MeOH (0.72 g, 77%): mp 138–139°C; $[\alpha]_D^{20}$ −98.5 (*c* 0.135, $CHCl_3$); IR (CH_2Cl_2): 1782, 1722, 1700 (C═O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.40 (9H, s), 2.36 (1H, dd, *J* = 4.1, 16.9), 2.51 (1H, dd, *J* = 9.3, 13.2), 2.75 (1H, dd, *J* = 9.9, 13.4), 2.80 (1H, dd, *J* = 10.9, 17.0), 2.97 (1H, dd, *J* = 5.7, 13.2), 3.32 (1H, dd, *J* = 3.2, 13.6), 4.03–4.15 (2H, m), 4.39 (1H, m), 4.60 (1H, m), 5.91 (2H, s), 6.67–6.79 (3H, m), 7.25–7.36 (5H, m); ^{13}C NMR ($CDCl_3$) δ: 28.1 (3 × CH_3), 36.5 (CH_2), 37.6 (CH_2), 37.8 (CH_2), 41.6 (CH), 55.5 (CH), 66.0 (CH_2), 80.8 (C), 100.9 (CH_2), 108.1 (CH), 109.6 (CH), 122.2 (CH), 127.2 (CH), 128.9 (2 × CH), 129.5 (2 × CH), 131.7 (C), 135.6 (C), 146.3 (C), 147.6 (C), 153.0 (C), 171.2 (C), 175.2 (C); mass spectrum *m/z* (relative intensity): 467 (M^+, 1), 411 (5), 234 (25), 192 (16), 135 (100), 92 (90); HRMS calcd. for $C_{26}H_{29}O_7N$: 467.1944; found: 467.1924.

Alkylated product 10

N-Acyloxazolidinone **8** (0.610 g, 2.0 mmol) was alkylated as above to give a colorless solid that was further recrystallized from EtOAc–hexanes (0.67 g, 80%): mp 123–124°C; $[\alpha]_D^{20}$ +92 (*c* 0.37, $CHCl_3$); IR (CH_2Cl_2): 1779 and 1723 (C═O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.90 (3H, d, *J* = 6.8), 0.93 (3H, d, *J* = 6.8), 1.39 (9H, s), 2.32 (1H, dd, *J* = 4.3, 16.8), 2.34 (1H, m), 2.47 (1H, dd, *J* = 9.3, 13.2), 2.74 (1H, dd, *J* = 10.5, 16.8), 2.94 (1H, dd, *J* = 5.8, 13.2), 4.15 (2H, m), 4.36 (2H, m), 5.96 (2H, s), 6.67 (1H, dd, *J* = 1.5, 7.9), 6.72 (1H, d, *J* = 7.9), 6.78 (1H, d, *J* = 1.5); ^{13}C NMR ($CDCl_3$) δ: 14.7 (CH_3), 18.0 (CH_3), 28.0 (3 × CH_3), 28.3 (CH), 36.6 (CH_2), 37.6 (CH_2), 41.5 (CH), 58.8 (CH), 63.2 (CH_2), 80.6 (C), 100.8 (CH_2), 108.1 (CH), 109.6 (CH), 122.2 (CH), 131.9 (C), 146.2 (C), 147.6 (C), 153.5 (C), 171.1 (C), 175.1 (C); mass spectrum *m/z* (relative intensity): 419 (M^+, 3), 363 (36), 346 (9), 304 (8), 303 (6), 234 (17), 206 (19), 175 (20), 149 (14), 135 (100); HRMS calcd. for $C_{22}H_{29}O_7N$: 419.1944; found: 419.1951.

General procedure for the preparation of benzylbutyrolactones 11a and 11b

A modification of a literature procedure was used (11*a*). The alkylated product (**9** or **10**, 1.40 mmol) was dissolved in THF (20 mL), and water was added (7.0 mL). The solution was

For personal use only.

cooled to ice temperature, followed by addition of H_2O_2 (0.66 mL, 30% in H_2O, 5.8 mmol) and $LiOH \cdot H_2O$ powder (0.12 g, 2.8 mmol). The resulting mixture was stirred at 0–5°C for 1.5 h, then at room temperature (rt) for 3 h. After recooling to 0°C, saturated aqueous $NaHSO_3$ (2 mL), cold water (50 mL), and 2% HCl (2 mL) were added. The solution was carefully kept at 0°C during the additions to prevent hydrolysis of the *tert*-butyl ester. The resulting mixture was extracted with EtOAc (4 × 25 mL). The organic solutions were combined, washed with water (20 mL) and brine (20 mL), dried ($MgSO_4$), and evaporated to give a liquid that was used in the following reaction without further purification. The crude liquid was redissolved in THF (25 mL) and cooled to 0°C. $BH_3 \cdot THF$ (1.68 mL, 1.0 M in THF, 1.68 mmol) was added dropwise to the acid solution over a period of 10 min. The resulting mixture was stirred at 0°C for 1 h, then at rt for 4 h. It was recooled to 0°C, MeOH (0.5 mL) added dropwise to destroy excess $BH_3 \cdot THF$, followed by cold water (10 mL) and 2% HCl (5 mL). The mixture was concentrated under vacuum to remove most of the THF. The remaining solution was extracted with EtOAc (3 × 15 mL). The combined EtOAc solution was washed with water (20 mL) and brine (20 mL), dried ($MgSO_4$), and concentrated to afford a light brown liquid. The crude product was redissolved in CH_2Cl_2 (4 mL), cooled to 0°C, and TFA (4 mL) was added dropwise. The mixture was stirred for 1 h at ice temperature and for 3 h at rt, followed by concentration under vacuum with several coevaporations with benzene to remove all of the TFA. The resulting brown liquid was chromatographed with 20–33% EtOAc–hexanes.

(*S*)-(−)-Benzylbutyrolactone 11a

Alkylated product **9** (0.65 g, 1.4 mmol) was hydrolysed, reduced, and lactonized as described in the above general procedure to give, after chromatography, a light yellow liquid (0.215 g, 70% from **9**): $[\alpha]_D^{20}$ −4.8 (*c* 0.50, $CHCl_3$) (lit. (15) $[\alpha]_D^{20}$ −4.78 (*c* 1.14, $CHCl_3$)); NMR spectral data were consistent with those published previously (15).

(*R*)-(+)-Benzylbutyrolactone 11b

Alkylated product **10** (0.586 g, 1.4 mmol) was treated as above to afford a light yellow liquid (0.202 g, 66% from **10**): $[\alpha]_D^{20}$ +4.8 (*c* 0.665, $CHCl_3$) (lit. (15) $[\alpha]_D^{20}$ +4.87 (*c* 0.87, $CHCl_3$)); spectroscopic data were identical to those obtained from **11a**.

General procedure for preparation of benzylidenebenzylbutyrolactones 14a and 14b

A modified literature procedure was employed (16). To a solution of benzylbutyrolactone **11a** or **11b** (61 mg, 0.28 mmol) in THF (1 mL) under N_2 at −70°C was added NaHMDS (0.33 mL, 1.0 M in THF, 0.33 mmol) over a period of 5 min. The solution was stirred at −70°C for 15 min, then at −20°C (CCl_4 – Dry Ice) for 15 min to ensure complete deprotonation. The color of the solution changed from light yellow to intense bright yellow. The mixture was recooled to −70°C and a solution of a benzaldehyde (3,4-dimethoxybenzaldehyde for **11a**; 3,4-(methylenedioxy)benzaldehyde for **11b**) (0.28 mmol) in THF (1 mL) was added dropwise. After stirring at −70°C for 1.3 h, a mixture of Ac_2O (78 μL, 0.83 mmol), Et_3N (0.16 mL, 1.14 mmol), and DMAP (6 mg, 0.049 mmol) in THF (1 mL) was added dropwise to the reaction mixture. The resulting thick mixture was warmed to rt and stirred for 1.5 h before water (1 mL) was added. The solution was concentrated to remove most of the THF, diluted with water (5 mL) and 2% HCl (2 mL), and then extracted with CH_2Cl_2 (3 × 10 mL). The combined CH_2Cl_2 phases were washed with 2% HCl (3 × 5 mL), 5% aqueous $NaHCO_3$ (2 × 5 mL), and brine (10 mL), dried ($MgSO_4$), and concentrated under vacuum to give a foamy residue. The crude product was redissolved in toluene (3 mL), DBU (90 μL, 0.61 mmol) was added, and the solution was heated to 80°C. After 1.5 h the mixture was diluted with EtOAc (10 mL), washed successively with 2% HCl (2 × 5 mL), water (2 × 10 mL), and brine (15 mL), dried ($MgSO_4$), and evaporated to afford a yellow residue that crystallized on standing under vacuum.

Gossypifan (14a)

(*S*)-(−)-benzylbutyrolactone **11a** (0.61 g, 0.28 mmol) was hydroxyalkylated with 3,4-dimethoxybenzaldehyde (46 mg, 0.28 mmol), acetylated, and treated with DBU as described above. The crude product was chromatographed with EtOAc–hexanes (1:2) to afford a light yellow solid (95 mg, 92%): mp 143–146°C (lit. (17) mp 145–146°C); $[\alpha]_D^{20}$ 79.1 (*c* 0.110, $CHCl_3$) (lit. (17) $[\alpha]_D^{20}$ 82.4 (*c* 0.875, $CHCl_3$)). NMR spectral data were consistent with those published previously (17).

Savinin (14b)

(*R*)-(+)-Benzylbutyrolactone **11b** (0.61 g, 0.28 mmol) was hydroxyalkylated with 3,4-(methylenedioxy)benzaldehyde (42 mg, 0.28 mmol), acetylated, and treated with DBU as described above. The yellow residue crystallized upon standing under vacuum and was recrystallized from ethanol–chloroform to afford colorless crystals (89 mg, 90%): mp 139–142°C (lit. (18*b*), from benzene and ethanol, mp 146.4–148.4°C); $[\alpha]_D^{20}$ −82.9 (*c* 0.135, $CHCl_3$) (lit. (18*c*) $[\alpha]_D^{20}$ −82 (*c* 2.5, $CHCl_3$); lit. (18d) $[\alpha]_D^{20}$ −88 (*c* 1.0, $CHCl_3$)). NMR spectral data were consistent with those published previously (7).

Benzyl ester of *p*-*O*-benzyl syringic acid

A mixture of syringic acid (3.12 g, 15.7 mmol), benzyl bromide (5.6 mL, 47 mmol), and dry K_2CO_3 (11 g, 78 mmol) in acetone (80 mL) was refluxed under N_2 for 24 h. The resulting suspension was cooled to rt, concentrated under vacuum, diluted with water (100 mL), and extracted with CH_2Cl_2 (4 × 20 mL). The organic solution was dried ($MgSO_4$), concentrated, and chromatographed with hexanes and 6% EtOAc–hexanes to remove benzyl bromide. The product was eluted with EtOAc and concentrated to leave a colorless solid (5.70 g, 95%): mp 64–65°C; IR (CH_2Cl_2): 1714 (C═O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.85 (6H, s), 5.08 (2H, s), 5.35 (2H, s), 7.27–7.48 (12H, m); ^{13}C NMR ($CDCl_3$) δ: 56.2 (2 × CH_3), 66.8 (CH_2), 74.9 (CH_2), 107.0 (2 × CH), 125.2 (C), 127.9 (CH), 128.1$_3$ (2 × CH), 128.1$_6$ (2 × CH), 128.2 (CH), 128.4 (2 × CH), 128.6 (2 × CH) 136.1 (C), 137.3 (C), 141.1 (C), 153.2 (2 × C), 166.1 (C); mass spectrum *m/z* (relative intensity): 378 (M^+, 4), 287 (6), 181 (6), 149 (7), 105 (11), 91 (100); HRMS calcd. for $C_{23}H_{22}O_5$: 378.1467; found: 378.1463.

p-*O*-Benzyl syringyl bromide (15)

To a solution of the benzyl ester of *p*-*O*-benzyl syringic acid (0.919 g, 2.43 mmol) in THF (10 mL) under N_2 at ice temperature was carefully added $LiEt_3BH$ (7.0 mL, 0.8 M in THF,

For personal use only.

5.6 mmol). The resulting mixture was stirred for 2 h and then 10% HCl (15 mL) was slowly added. The solution was concentrated under vacuum, diluted with water (10 mL), and extracted with CH_2Cl_2 (3 × 20 mL). The organic layer was washed successively with 5% HCl (3 × 20 mL), 5% aqueous $NaHCO_3$ (2 × 20 mL), and brine (20 mL). It was then dried ($MgSO_4$) and concentrated to afford an oil. The crude product (0.893 g) was redissolved in anhydrous ether (10 mL), followed by addition of pyridine (0.6 mL) and PBr_3 (0.55 mL, 5.79 mmol). The resulting colorless suspension was stirred for 2.5 h before filtering through Celite®. The filtrate was diluted with CH_2Cl_2 (10 mL), washed with 3% HCl (3 × 20 mL), water (2 × 20 mL), and brine (25 mL), then dried ($MgSO_4$), concentrated, and chromatographed (6–15% EtOAc–hexanes) to give a colorless liquid (0.53 g, 65%) that slowly solidified on standing: mp 53–55°C (lit. (19*b*) mp 40–42°C); IR (CH_2Cl_2): 1593, 1503, 1461, 1336, 1130 (vs) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.82 (6H, s), 4.45 (2H, s), 4.99 (2H, s), 6.60 (2H, s), 7.25–7.35 (3H, m), 7.48 (2H, dd, J = 8.1, 1.7); ^{13}C NMR ($CDCl_3$) δ: 34.3 (CH_2), 56.1 (2 × CH_3), 75.0 (CH_2), 106.2 (2 × CH), 127.8 (CH), 128.1 (2 × CH), 128.4 (2 × CH), 133.2 (C), 137.1 (C), 137.7 (C), 153.5 (2 × C); mass spectrum *m/z* (relative intensity): 338 ($M^+(^{81}Br)$, 0.1), 336 ($M^+(^{79}Br)$, 0.1), 148 (22), 136 (12), 91 (100); HRMS calcd. for $C_{16}H_{17}O_3{}^{79}Br$: 336.0361; found: 336.0333.

4′-Demethylyatein (16)

(*R*)-(+)-Benzylbutyrolactone **11b** (86 mg, 0.39 mmol) in THF (1.5 mL) under N_2 was cooled to −72°C. NaHMDS (0.45 mL, 1.0 M in THF, 0.45 mmol) was then added dropwise over a period of 10 min. The mixture was stirred at that temperature for 15 min, then at −20°C (CCl_4 – Dry Ice) for 25 min. It was recooled to −72°C and a solution of syringyl bromide **15** (0.135 g, 0.40 mmol) in THF (2 mL) was added. After stirring at −72°C for 5 h, the reaction mixture was quenched with 5% aqueous NH_4Cl (1 mL). The mixture was concentrated, diluted with 2% HCl (10 mL), and extracted with CH_2Cl_2 (3 × 7 mL). The organic fractions were combined, washed with water (10 mL) and brine (10 mL), dried ($MgSO_4$), and concentrated to afford an oil (0.20 g). The crude product was redissolved in EtOAc and stirred with Pd–C (40 mg) under H_2 overnight. The suspension was filtered through Celite® and the filtrate was concentrated and chromatographed (50% EtOAc–hexanes) to afford an oil (93 mg, 62%): $[\alpha]_D^{20}$ −25.8 (*c* 0.225, CH_2Cl_2): (lit. (20) $[\alpha]_D^{20}$ −25 (*c* 0.32, CH_2Cl_2)). NMR spectral data were consistent with those published previously (20).

***trans*-Benzylidene, 19**

To 4′-demethylyatein (**16**, 20 mg, 0.052 mmol) in THF (1 mL) was added dropwise a solution of DDQ (14 mg, 0.062 mmol) in THF under N_2. A temporary blue color appeared after each addition of the DDQ solution. The resulting mixture was stirred for 12 h and worked up by adding saturated aqueous $NaHSO_3$ (1 mL) and 2% HCl (2 mL), and extracting with EtOAc (3 × 5 mL). The organic solutions were combined, washed with 5% aqueous $NaHCO_3$ (5 × 5 mL), water (10 mL), and brine (10 mL), dried ($MgSO_4$), and concentrated to afford a light yellow oil (22 mg). The crude product contained two compounds, the *cis*- and *trans*-benzylidenes **18** and **19**, respectively, in a 1.3:1 ratio as determined by ^1H NMR spectroscopy. After standing exposed to the air at rt for about 2 weeks, the crude product was found to contain only the *trans* isomer **19**, as indicated by the ^1H NMR spectrum. This product resisted crystallization. It was purified by chromatography (EtOAc–hexanes 1:2 ratio) to afford an oil that slowly solidified (18 mg, total 95% from 4′-demethylyatein). The isomerization process observed above was also achieved by refluxing a crude product mixture of **18** and **19** (2 mg) in benzene (1.5 mL) in the presence of I_2 (1 mg), for 1.5 h, with UV irradiation for the first 10 min of reflux. The light pink solution was worked up by adding saturated aqueous $NaHSO_3$ (0.5 mL) and extracting with EtOAc (3 × 5 mL). The extract was dried ($MgSO_4$) and evaporated to give a light yellow residue (1.7 mg, 85%) that contained only *trans* isomer **19**, as shown by the ^1H NMR spectrum: mp 130–132°C; $[\alpha]_D^{20}$ −54 (*c* 0.31, $CHCl_3$); IR (CH_2Cl_2): 3529 (OH), 1748 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.65 (1H, dd, J = 10.0, 14.5), 3.04 (1H, dd, J = 4.6, 14.5), 3.84 (1H, m), 3.92 (6H, s), 4.23–4.32 (2H, m), 5.92 (2H, AB, Δδ = 2.4, J = 1.4), 6.61 (2H, m), 6.71 (1H, d, J = 7.9), 6.81 (2H, s), 7.50 (1H, d, J = 1.8); ^{13}C NMR ($CDCl_3$) δ: 37.6 (CH_2), 39.6 (CH), 56.4 (2 × CH_3), 69.6 (CH_2), 101.1 (CH_2), 107.2 (2 × CH), 108.4 (CH), 109.0 (CH), 121.8 (CH), 125.4 (C), 125.5 (C), 131.3 (C), 136.9 (C), 137.9 (CH), 146.6 (C), 147.2 (2 × C), 148.0 (C), 172.5 (C); mass spectrum *m/z* (relative intensity): 384 (M^+, 11), 249 (90), 189 (14), 135 (100); HRMS calcd. for $C_{21}H_{20}O_7$: 384.1209; found: 384.1222.

4′-Demethyldeoxyisopodophyllotoxin (23)

To 4′-demethylyatein (**16**, 35 mg, 0.091 mmol) in THF (3 mL) at 4°C was added TFA (24 μL, 0.31 mmol), followed by a solution of DDQ (42 mg, 0.185 mmol) in THF (1 mL). The solution became green for more than 1.5 h. It was stirred at ice temperature for 1.5 h, then at rt overnight. The color of the solution became deep red after stirring overnight. The reaction mixture was diluted with saturated aqueous $NaHSO_3$ (1 mL), concentrated to remove most of the THF, and diluted again with 5% aqueous $NaHCO_3$ (5 mL). The resulting bright yellow solution was extracted with CH_2Cl_2 (4 × 5 mL). The combined CH_2Cl_2 extracts were washed with 5% aqueous $NaHCO_3$ (5 × 5 mL) and water (10 mL), dried ($MgSO_4$), and concentrated to afford a light yellow solid (35 mg) that was sparingly soluble in EtOAc, Et_2O, and MeOH, but more soluble in CH_2Cl_2 and $CHCl_3$. Recrystallization of the crude solid from CH_2Cl_2 gave fine colorless needles (25 mg, 71%). The recrystallized product, analysed by ^1H NMR, was shown to be contaminated with an unknown component (ca. 5%) that could not be eliminated even after multiple recrystallizations from CH_2Cl_2. This by-product was removed by preparative TLC using a solvent mixture of $CHCl_3$–MeOH–AcOH (25:1:1) to yield a colorless solid (22 mg, 65% from 4′-demethylyatein); mp 282–285°C (lit. (15*a*) mp 285–287°C); $[\alpha]_D^{20}$ −77 (*c* 0.26, $CHCl_3$) (lit. (15*a*) $[\alpha]_D^{20}$ −81)). NMR spectral data were consistent with those published previously (15*a*).

Copies of ^1H and ^{13}C NMR spectra of all compounds have been deposited as supplementary material.[5]

Speciation of trimethyltin(IV): hydrolysis, complexation equilibria, and structures of trimethyltin(IV) ion in aqueous solution

Akio Takahashi, Takayuki Natsume, Nobuyoshi Koshino, Shigenobu Funahashi, Yasuhiro Inada, and Hideo D. Takagi

Abstract: The hydrolysis constants of trimethyl- and triethyltin(IV) ions and the stability constants for the complexation of trimethyltin(IV) with trimethylamine, *N*-substituted glycines (*N,N*-dimethylglycine and *N,N,N*-trimethylglycine), and aminopolycarboxylate ions (*N*-methyliminodiacetate, nitrilotriacetate, and ethylenediamine-*N,N'*-diacetate) were determined by the potentiometric method at 25°C and $I = 0.1$ mol dm^{-3} ((H, Na)ClO_4 and (H, Na)NO_3). The structural parameters of $Me_3Sn(OH_2)_2$, $Et_3Sn(OH_2)_2$, and $Me_3Sn(OH_2)(OH)$ in solution were determined by the EXAFS method. The coordination structures of trimethyltin(IV) complexes with *N*-substituted glycines, trimethylamine, and aminopolycarboxylate ions are discussed on the basis of the electronic interaction between the donor atom and Sn(IV).

Key words: organotin(IV), EXAFS, structure, potentiometry.

Résumé : Utilisant la méthode potentiométrique à 25°C et $I = 0,1$ mol dm^3 ((H, NA)ClO_4 et (H, Na)NO_3), on a déterminé les constantes d'hydrolyse des ions triéthyl- et triéthylétain(IV) et les constantes de stabilité pour la complexation du triméthylétain(IV) avec la triméthylamine, les glycines *N*-substituées (*N,N*-diméthylglycine et *N,N,N*-triméthylglycine) et avec les ions aminopolycarboxylates (*N*-méthyliminodiacétate, nitrilotriacétate et éthylènediamine-*N,N'*-diacétate). Les paramètres structuraux des composés $Me_3Sn(OH_2)_2$, $Et_3Sn(OH_2)_2$, et $Me_3Sn(OH_2)(OH)$ ont été déterminés en solution par la méthode EXAFS. On discute des structures de coordination des complexes de triméthylétain(IV) avec les glycines *N*-substituées, la triméthylamine et les ions aminopolycarboxylates, en terme d'une interaction électronique entre l'atome donneur et Sn(IV).

Mots clés : organoétain(IV), EXAFS, structure, potentiométrie.

[Traduit par la rédaction]

Introduction

In recent years, interest in organotin chemistry has increased dramatically as a result of the wide range of industrial applications of organotin compounds (1). Various organotin(IV) compounds are widely used in the environment as antifoulants, agrochemicals, etc. Organotin compounds have the advantage of being very selective, and it had been believed that neither they nor their degradation products were particularly toxic to the higher animals, including humans. However, recent analysis has revealed that organotin compounds are toxic, even for the higher animals, due to their ability to bind to certain proteins such as haemoglobin, cysteine, and histidine residues (2–4). The toxicity of alkyltin(IV) compounds decreases in the order of $R_3SnX > R_4Sn \sim R_2SnX_2 > RSnX_3$ (R = alkyl group and X = halide ion). From the environmental point of view, the speciation of organotin(IV) compounds in water is important for a better understanding of their reactivities and recovery.

There are several studies concerning the stability constants and structures of dialkyl- and trialkyltin(IV) with various organic and inorganic ligands (5–10). However, most of the structural information reported has been for organotin compounds examined in the solid state, and no structural parameters for trimethyltin(IV) complexes with relatively weak donors in solution have been obtained, as such species cannot be successfully isolated as crystals (7, 10).

The main objective of this study is to analyze the coordination structures of the trimethyltin(IV) species in solution, by combining the EXAFS method (Extended X-ray Absorption Fine Structure) and the orthodox potentiometric method. The EXAFS method was utilized for the analyses of the structures of hydrolyzed species in solution. The coordination structures of various trimethyltin(IV) complexes with organic ligands were determined from the stability constants and the pK_a values of the complexes. For this purpose, trimethylamine and *N,N,N*-trimethylglycine were chosen as ligands to distinguish the stability and hydrolysis constants for the two structurally different trimethyltin(IV) complexes: the nitrogen-coordinated trimethylamine complex and the oxygen-coordinated *N,N,N*-trimethylglycinatotrimethyltin(IV) complex. The hydrolysis of trimethyl- and triethyltin(IV) ions and the complex formation reactions of trimethyltin(IV) with trimethyl-

[a] C_{Sn}^0 denotes the initial concentration of trimethyltin(IV).

amine, *N,N,N*-trimethylglycine, *N,N*-dimethylglycine, *N*-methyliminodiacetate, nitrilotriacetate, and ethylenediamine-*N,N'*-diacetate ligands were examined potentiometrically in aqueous perchlorate and nitrate media. The coordination geometry of these species is discussed on the basis of the electronic interaction between the donor atom and Sn(IV).

Experimental

Reagents

Trimethyltin(IV) chloride and triethyltin(IV) chloride obtained from Strem were purified by a method similar to that described elsewhere (9, 10). Several trimethyl- and triethyltin(IV) complexes were prepared for the purpose of the EXAFS measurements. Trimethyl- and triethyltin(IV) hydroxide were synthesized by the reaction of trimethyl- or triethyltin(IV) chloride (Strem 98%) with 7 mol dm^{-3} sodium hydroxide. The white powder was filtered and dried in a vacuum. The crude compounds were then purified by sublimation. Bis(2,4-pentanedionato)dimethyltin(IV) was synthesized by the literature method (11) (calcd. for $C_{12}H_{22}SnO_2$: C 41.54, H 5.81%; found: C 40.67, H 5.58%). The sample was sufficiently pure for the EXAFS measurements (>97%).

Doubly distilled water was used throughout the experiment. Nitrilotriacetic acid, *N*-methyliminodiacetic acid, and ethylenediamine-*N,N'*-diacetic acid were obtained from Dojindo Co. Ltd. The glycine derivatives (*N,N*-dimethylglycine and *N,N,N*-trimethylglycine) were obtained from Nakarai Tesque Co. Ltd. Trimethylamine was obtained from Wako Pure Chemicals Inc., and the concentration of the stock solution was determined by titration. All the ligands, other than trimethylamine, used for the potentiometric measurements were recrystallized from doubly distilled water and dried in a vacuum prior to use. The concentrations of the stock solutions of sodium nitrate and sodium perchlorate were determined gravimetrically.

Electromotive force measurements

The potentiometric measurements were carried out using a Metrohm E 654 pH meter with a hand-piston burette, a glass electrode, and a calomel electrode. The electrolyte, KCl, in the original electrode was replaced by NaCl for use in the perchlorate media. The electrode couple was standardized by titrating either a standard perchloric acid or a nitric acid solution with a standard sodium hydroxide solution. Determination of the equivalence point by Gran's method allowed us to determine the standard potential $E°$ and the ionic product of water (12–15). The temperature of the sample solutions was maintained at 25.0 ± 0.1°C by circulating thermostatically controlled water through the jacket of the titration vessel. The ionic strength, I, was adjusted to 0.10 mol dm^{-3} with either sodium perchlorate or sodium nitrate. All potentiometric measurements were carried out for several different total concentrations of trimethyl- or triethyltin(IV) ion under nitrogen atmosphere. The experimental conditions used for the potentiometric titrations are listed in Tables 1*A*–1*C*. Each

experiment was repeated at least twice to confirm reproducibility.

EXAFS measurements and analyses

EXAFS spectra were measured around the Sn K-edge (E_0) at the BL6B station of the Photon Factory of the National Laboratory for High Energy Physics. The monochromatized X-ray was obtained by a Si(111) double crystal. The intensity of the incident X-ray was measured by an ionization chamber filled with nitrogen gas, while the intensity of the transmitted X-ray was measured by an ionization chamber filled with a nitrogen/argon (85:15) mixture.

The outline of the EXAFS analysis is as follows. The background absorption was estimated by fitting the Victoreen formula to the data in the pre-edge region (16), and the smooth K-shell absorption (μ_0) was approximated by the cubic spine function. The values of the extracted absorbance were normalized by μ_0 and then converted to the EXAFS oscillation, $\chi(k)$. The photoelectron wave vector, k, is equal to $[8m(E - E_0 - \Delta E_0)]^{1/2}\pi/h$, where E, E_0, ΔE_0, and m denote the energy of the incident X-ray, the threshold energy of the K-shell electron, shift of the energy for the individual sample, and the mass of the electron, respectively. The Fourier filtered $k^3\chi(k)$ values were analyzed by the least-squares method over the range of

$2 < k/10^{-2}\ pm^{-1} < 12$, on the basis of the following model function for the EXAFS oscillation (17–22).

$$[1]\quad \chi_{calcd}(k) = \sum(n_j k R_j^2)\exp(-2\sigma_j^2 k^2 - 2R_j/\lambda)F_j(\pi,k) \times \sin[2kR_j - \alpha_j(k)]$$

where $F_j(\pi,k)$ is the backscattering amplitude from each scatterer j at a distance R_j from the X-ray absorbing atom, and $\alpha_j(k)$ is the total scattering phase shift experienced by the photoelectron. Reported values were used for the backscattering amplitude and the total scattering phase shift (23). In Table 2 are listed the experimental conditions of the tin(IV) samples used for the EXAFS measurements.

Results

Hydrolysis of trimethyl- and triethyltin(IV) and complex formation of trimethyltin(IV)

Trialkyltin(IV) ion hydrolyzes to form a series of hydroxo species. The hydrolysis of trimethyl- and triethyltin(IV) ions in aqueous solution can be expressed by the following equation.

$$[2]\quad pR_3Sn^+ + qH_2O \overset{\beta pq}{\rightleftharpoons} (R_3Sn)_p(OH)_q^{(p-q)+} + qH^+$$

where βpq is the overall stability constant defined as $[(R_3Sn)_p(OH)_q^{(p-q)+}][H^+]^q/[R_3Sn^+]^p$ (R = Me or Et). The stability constants were evaluated using the computer program SUPERQUAD (24). By using the data measured under the experimetal conditions in Tables 1*A*–1*C*, the calculations were carried out for various values of p and q. The stability constants for the (p, q) = (1, 1), (1, 2), and (2, 1) species are listed in Table 3, and the species distribution diagrams are shown in Figs. 1(*A*) and (*B*). The (2, 1) species may be a dimeric species bridged by the hydroxide ion. Other species corresponding to $p, q > 2$ were rejected by the SUPERQUAD criteria.

The protonation constants for the free ligands were determined by the SUPERQUAD program based on the experimental results obtained by the potentiometric titration. The experimental conditions for the potentiometric measurements are also listed in Table 1*A*, and the protonation constants defined by the following equation are listed in Table 4.

$$[3]\quad qH^+ + rL^{n-} \overset{\beta qr}{\rightleftharpoons} H_qL^{(q-rn)+}$$

where βqr is defined as $[H_qL^{(q-rn)+}]/[H^+]^q[L^{n-}]^r$, and n is the ionic charge of the free ligand, L. The protonation constants for the aminopolycarboxylate ligands were reported in a previous article (25).

EXAFS oscillations $k^3(k)$ for the species examined in this study are shown in Fig. 2. The X-ray energy at half-height of the absorption edge of the spectrum was used as E_0. Values of ΔE_0 and the mean free path of a photoelectron, λ, were evaluated by using the EXAFS data for bis(2,4-pentanedionato)dimethyltin(IV) by fixing the scatterer number n as 6 (equivalent to 4 positions in the equatorial plane and the 2 axial positions) on the basis of the crystal structure of this compound (11). The values of ΔE_0 and λ obtained for the bis(2,4-pentandionato)dimethyltin(IV) complex were used for the structural analyses of the other trimethyl- and triethyltin(IV) species. In Table 6 are listed the interatomic distance R, the Debye–Waller factor σ, and the scatterer numbers n for the trimethyl- and triethyltin(IV) species estimated by the EXAFS analyses.

Discussion

Earlier structural studies by means of X-ray, neutron, and electron diffraction studies (7*b*) and Mossbauer spectroscopy (7*c*) revealed that the five-coordinate tin structure is trigonal bipyramidal, and many polymeric compounds of trigonal bipyramidal structure have been found. It has been suggested that strong donors, which can make σ-bonding comparable to the alkyl group, bring about a distribution of the *s* character of the preexisting Sn—C bonds (10, 26). Crystallographic analysis revealed that the five-coordinate triphenyltin(IV) compound has slightly distorted trigonal bipyramidal structure, with the three phenyl groups in the equatorial plane (27). As the oxygen and nitrogen donor atoms of the substituted glycines and aminopolycaboxylate ligands analyzed in this study are moderate donors, it is plausible that the trimethyltin(IV) skeleton is kept triangular in the equatorial plane even by the coordination of these ligands. However, the coordination of OH^- (hydrolyzed species) may cause a significant deformation of the $Me_3Sn(IV)$ skeleton because of the relatively strong σ-donicity of this ligand.

According to the results of the EXAFS analyses (Table 6), the Sn—OH bond length is very short (207 pm) for $Me_3Sn(OH)(OH_2)$, while the Sn—OH_2 bond length is significantly elongated (280 pm) compared with the original bond length of Sn(IV)—OH_2 in the $Me_3Sn(OH_2)_2^+$ ion (243 pm). It has been suggested that OH^- forms a strong σ-bond with

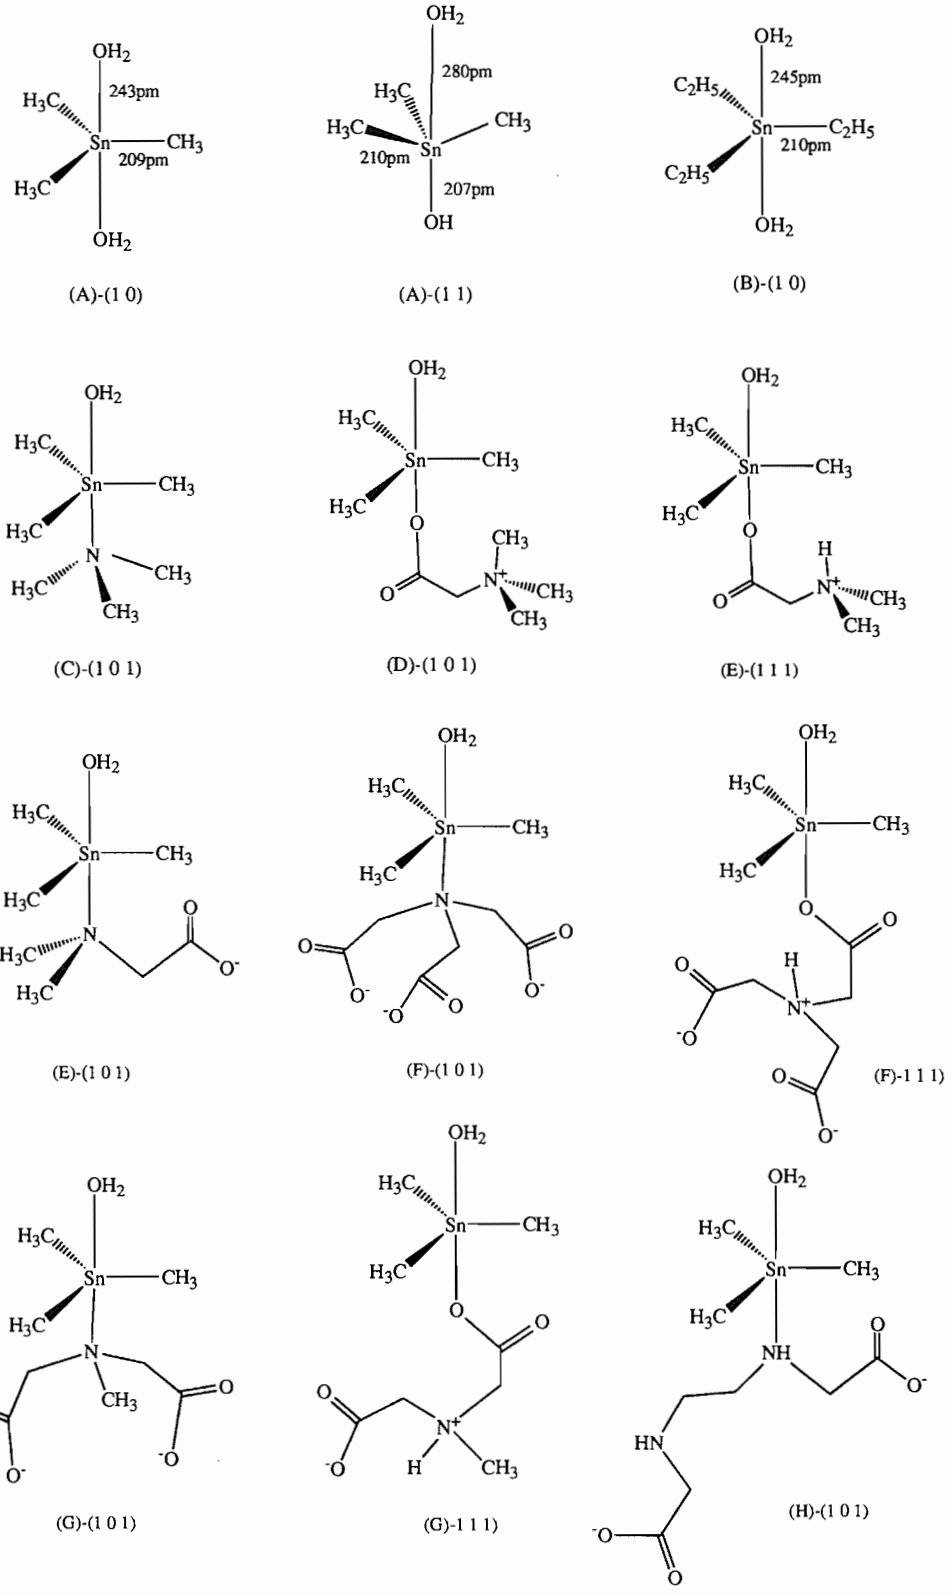
[b]Fixed value.

Sn(IV) (10, 26). Therefore, it is expected that the formation of Sn—OH bond distributes the *s* character of three Sn—C bonds towards the Sn—OH bond (10, 26), and the resulting sp^3 hybridization causes the deformation of the original trigonal bipyramidal structure to the pseudo-tetrahedral structure as shown in Fig. 3(*A*)-(1,1). As a result, the Sn—OH bond strength may be largely enhanced by the release of a proton from one of the coordinated water molecules. As the water molecule is attracted to the tin(IV) center by the ion–dipole interaction (26), the bond length between Sn(IV) and H_2O at the *trans* position of OH^- should be largely elongated because of the significant increase of the electron density on the central Sn(IV) atom. However, the elongation of the Sn(IV)—OH_2 bond caused by the coordination of trimethylamine, *N*-substituted glycines, and aminopolycarboxylate ligands may not be so large as that caused by the coordination of OH^-.



The previously reported values of the hydrolysis constants for trimethyl- and triethyltin(IV) ions were determined under different conditions from those used in this study ($\beta_{11} = -6.26$ at $I = 0.30$ mol dm^{-3} in perchlorate media) (10, 28). However, it is possible to compare the hydrolysis constants of trimethyl- and triethyltin(IV) species obtained in this study. The hydrolysis constants, β_{11}, of trimethyltin(IV) ion in perchlorate and nitrate solutions are slightly different, which suggests a difference in the medium effect between these two solutions. The difference between the hydrolysis constants for the triethyltin(IV) ion ($\log \beta_{11} = -6.42$) and the trimethyltin(IV) ion ($\log \beta_{11} = -6.35$) in perchlorate medium reflects the smaller electron density of the $Me_3Sn(IV)$ center caused by the less inductive effect of the methyl group in the equatorial plane, compared with the corresponding $Et_3Sn(IV)$ center.

The protonation constant for trimethylglycine was previouly measured by the NMR method (29). Considering the difference in the experimental conditions, the agreement is fair ($\log \beta_{11} = 1.87$ by the NMR method). The β_{11} value for *N,N*-dimethylglycine was consistent with the literature value (30).

As the β_{11} value for trimethylamine is identical to that of *N,N*-dimethylglycine, similar values of the stability constants are expected for the formation of the (1,0,1) species with trimethylamine and *N,N*-dimethylglycine in case the coordination of *N,N*-dimethylglycine to trimethyltin(IV) takes place through the nitrogen donor atom. The value of $\log \beta_{101}$ for the formation of *N,N,N*-trimethylglycinatotrimethyltin(IV) was 1.82, which is comparable to the reported $\log \beta_{101}$ value for the formation of the acetato complex (10) in which the coordination of acetate ion takes place through the carboxyl oxygen atom. The value of $\log \beta_{101}$ for the formation of *N,N*-dimethylglycinatotrimethyltin(IV) was 6.65, which is very different from the value obtained for the formation of the *N,N,N*-trimethylglycinatotrimethyltin(IV) species. This difference in the $\log \beta_{101}$ values indicates that the coordination of *N,N*-dimethylglycine to trimethyltin(IV) takes place through the nitrogen donor atom rather than the oxygen atom. The pK_a value for the hydrolysis of the *N,N,N*-trimethylglycinatotrimethyltin(IV) complex was calculated as 5.76 ($pK_a = \log \beta_{101} - \log \beta_{1-11}$). The corresponding pK_a values for the hydrolysis of the *N,N*-dimethylglycinato and trimethylamine complexes of trimethyltin(IV) were calculated as 9.84 and 9.86, respectively. The similarity of the pK_a values for hydrolysis of the trimethylamine complex and the *N,N*-dimethylglycinato complex also indicates that the coordination of *N,N*-dimethylglycine to the trimethyltin(IV) center occurs through the nitrogen atom, as the electron densities of the central tin(IV) should be similar for these two complexes. Rather high pK_a values for the hydrolysis of the *N,N*-dimethylglycinato and trimethylamine complexes reflect the stronger interaction between Sn(IV) and the coordinated nitrogen atom compared with the interaction between Sn(IV) and the carboxyl oxygen

© 1997 NRC Canada

donor atom. The pK_a value of the hydroxotrimethyltin(IV) was calculated as 11.55 ($pK_a = \log \beta_{11} - \log \beta_{12}$), which reflects the strong σ-interaction between the OH^- and Me_3Sn(IV) (10, 26): the strong σ-interaction between Sn(IV) and OH^- induces more symmetrical sp^3 hybidization at the tin(IV) center and the interaction between tin(IV) and the water molecule at the *trans* position of OH^- became significantly weak.

The (2,0,1) species in the reaction of trimethyltin(IV) and *N,N*-dimethylglycine is considered to be the dimeric trimethyltin(IV) species bridged by *N,N*-dimethylglycine through both of the N and O donor atoms. It has been reported that the pK_a values are 3.33 and 2.12 for protonation of the carboxyl oxygen of ethylenediamine-*N,N'*-diacetate and pyridine-2,6-dicarboxylate coordinated to dimethyltin(IV), re-spectively (25). Therefore, the (1,1,1) species found for the reaction of trimethyltin(IV) and *N,N*-dimethylglycine is probably the *N*-protonated *N,N*-dimethylglycine complex in which the coordination of *N,N*-dimethylglycine takes place through the oxygen atom, by considering the relatively large pK_a value ($\log \beta_{111} - \log \beta_{101} = 6.19$) for the formation of the (1,1,1) species.

The aminopolycarboxylate ions examined in this study are, therefore, supposed to coordinate to trimethyltin(IV) ion primarily through the nitrogen donor atom. The $\log \beta_{101}$ values for the formation of aminopolycarboxylatotrimethyltin(IV) are 4.81, 4.78, and 5.63 for the *N*-methyliminodiacetate, ethylenediamine-*N,N'*-diacetate, and nitrilotriacetate ligands, respectively. These values indicate that the coordination of these ligands to trimethyltin(IV) takes place through the nitrogen donor atom rather than through the carboxyl oxygen atom, from the analogy of the $\log \beta_{101}$ values for the formation of *N,N*-dimethylglycinato and trimethylamine complexes. The pK_a value ($pK_a = \log \beta_{101} - \log \beta_{1-11}$) for the hydrolysis of the trimethyltin(IV) complex with *N*-methyliminodiacetate is calculated as 9.25, which is also similar to the value obtained for the hydrolysis of the trimethylamine complex. In the (1,1,1) species found for the complex formation of trimethyltin(IV) with nitrilotriacetate and ethylenediamine-*N,N'*-diacetate, it is considered that the coordination takes place through the carboxyl oxygen atom of the *N*-protonated species, from the similarity of the pK_a values ($pK_a = \log \beta_{111} - \log \beta_{101}$) for the *N,N*-dimethylglycine complex (pK_a = 6.19, 6.48, and 6.92 for the *N,N*-dimethylglycine, nitrilotriacetato, and ethylenediamine-*N,N'*-diacetato complexes, respectively). Such structural changes from the (1,0,1) to (1,1,1) species are possible, considering the relatively weak ion–dipole interactions between these ligands and Me_3Sn(IV) (10, 26).

In conclusion, the trimethyltin(IV) ion primarily prefers coordination with strong σ-donors to achieve sp^3 hybridization. As for moderate donors such as *N*-substituted glycines and aminopolycarboxylate ions, Sn(IV) tends to form coordination bonds through the nitrogen rather than the oxygen atom. However, at lower pH, where the protonation of amine nitrogen is favorable, coordination through the carboxyl oxygen atom takes place. The $\log \beta_{qr}$ values for glycine are 2.34 and 11.94 at 25.0°C (I = 0.1 mol dm^{-3} KCl) for (q, r) = (1, 1) and (2, 1) species, respectively (30). Hynes and O'Dowd reported that they could not observe any complexation of trimethyltin(IV) with glycine at I = 0.3 mol dm^{-3} ($NaClO_4$) (10). As the $\log \beta_{21}$ value for *N,N*-dimethylglycine (11.96) is comparable to that for glycine, it is probable that the existence of (1, 0, 1) species was rejected in their study by the SUPERQUAD criteria, as the titration range was too narrow (pH < 6.5). Plausible structures of the species discussed above are summarized in Fig. 3(*C*)–(*H*). These results may provide basic knowledge for the application of these ligand systems against environmental pollution with organotin(IV) compounds.

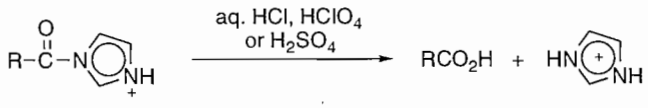
Abstract: The mechanism of the hydrolysis of acetylimidazole in aqueous perchloric, sulfuric, and hydrochloric acid mixtures has been determined. Benzoylimidazole was also studied in the latter two acids. The method of analyzing the available data, pseudo-first-order reaction rate constants as a function of acid concentration and, in one case, temperature, is the excess acidity method, here applied to the same reaction in the three different acid media, allowing their comparison. The reaction is not acid catalyzed; the rates decrease with increasing acidity. The substrate reacts in the form that is monoprotonated on the imidazole ring; it is 100% protonated at acidities much lower than those used here. Acetylimidazole is shown to become diprotonated at high acidity ($pK_{SH_2^{2+}} = -6.7$), protonating on the carbonyl oxygen, but the diprotonated form is not reactive. The hydrolysis involves the reversible addition of one water molecule to the substrate to give a tetrahedral intermediate; at low acidities the decomposition of this hydrate is the rate-determining step, but as the acidity increases and the water activity decreases its formation becomes rate limiting. Hydroxide catalysis was also observed in dilute perchloric acid, but this is swamped by nucleophilic catalysis by the acid anion in HCl and H_2SO_4.

Key words: acylimidazoles, excess acidity, hydrolysis, protonation, tetrahedral intermediate.

Résumé : On a déterminé le mécanisme d'hydrolyse de l'acétylimidazole dans l'acide perchlorique aqueux, l'acide sulfurique aqueux et l'acide chlorhydrique aqueux. On a utilisé la méthode d'excès d'acidité pour analyser les données disponibles, les constantes de vitesse de la réaction de pseudo-premier ordre en fonction de la concentration d'acide et, dans un cas, la température; dans ce travail, on a appliqué la méthode à la même réaction dans trois milieux acides différents et ceci permet de les comparer. La réaction n'est pas catalysée par les acides; les vitesses diminuent avec une augmentation de l'acidité. Le substrat réagit sous la forme monoprotonée du noyau imidazole; il est 100% protoné à des acidités beaucoup plus faible que celles utilisées dans ce travail. À acidités élevées, on a montré que l'acétylimidazole devient diprotoné ($pK_{SH_2^{2+}} = -6,7$), par protonation sur l'oxygène du carbonyle; toutefois, la forme diprotonée n'est pas réactive. L'hydrolyse implique l'addition réversible d'une molécule d'eau sur le substrat conduisant à un intermédiaire tétraédrique. Aux acidités faibles, l'étape cinétiquement limitante est la décomposition de cet hydrate; toutefois, lorsque l'acidité augmente et que l'activité de l'eau diminue, sa formation devient cinétiquement limitante. Dans l'acide perchlorique dilué, on a aussi observé une catalyse par l'hydroxyde; toutefois, dans les acides chlorhydrique et sulfurique, elle est submergée par la catalyse nucléophile de l'anion acide.



Mots clés : acylimidazoles, acidité en excès, hydrolyse, protonation, intermédiaire tétraédrique.

[Traduit par la rédaction]

Introduction

The hydrolysis of acylimidazoles in aqueous buffer media is fairly well understood (1), but the mechanism of the reaction in aqueous mineral acid (2, 3) and other nonideal solutions (2) has never been adequately described. Benzoylimidazole was originally used as a model for *N*-protonated benzamide in a study of the mechanism of amide hydrolysis (3), and it is true that the rate–acidity profiles for the hydrolyses of benzamide and benzoylimidazole are quite different. In this paper the excess acidity method (4, 5) will be used to analyze reaction rate data obtained as a function of medium composition for acetylimidazole and benzoylimidazole.

Substrates

R = CH_3, Ph

The excess acidity method has been widely used to determine the mechanisms of reactions in aqueous sulfuric acid, among the more recent studies being hydrations of fluoroalkyl-substituted vinyl ethers (6), cyclizations of substituted imidazolines (7), methyl azophenyl ether cleavages (8), and

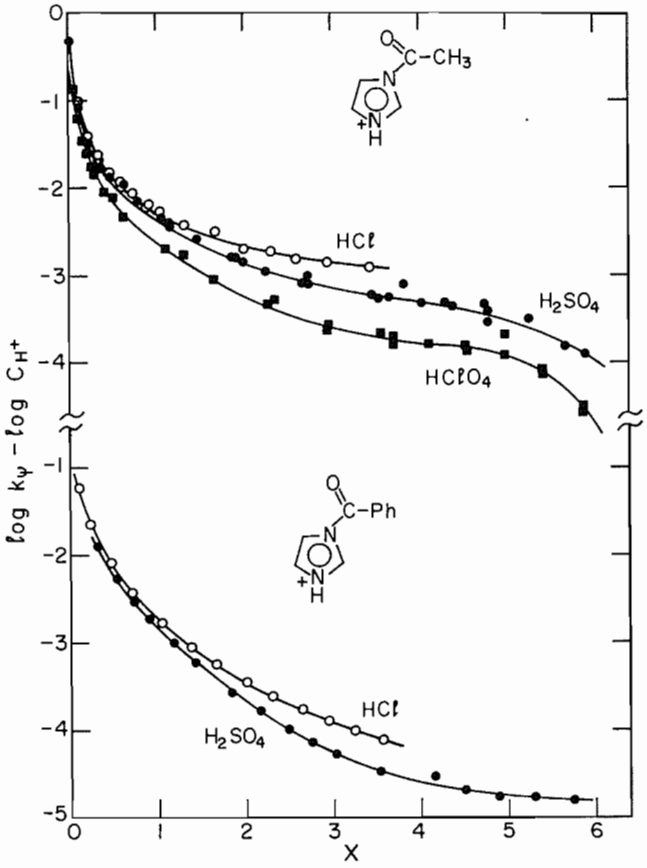
aromatic hydrogen exchange processes (9). It has also been used extensively for delineating the mechanisms of reactions in aqueous perchloric acid media, among them being alkene (10), alkyne (11), and ketene (12) hydrations, vinyl ether hydrolyses (13), thioacetal hydrolyses (14), and the hydrolyses of isothiocyanates (15), acid anhydrides (16), and acyl fluorides (17). Most recently it has been used to study the various decomposition mechanisms of several *N*-nitro amides and sulfonamides in aqueous sulfuric acid (18), to show that the mechanism of decomposition of aliphatic *N*-nitroamines in H_2SO_4 is an S_N2 displacement by water or bisulfate ion at the alkyl group (19), and to show that the parent molecule, nitramide (NH_2NO_2), decomposes in an acid-catalyzed process in relatively strong acid media, but that the decomposition mechanism involves neutral water molecules without acid catalysis in more dilute acid (20).

In two of these studies (18, 20), reactions that were not acid catalyzed were involved, and in one of them hydroxide catalysis was visible in dilute H_2SO_4 (18). One of the reasons for undertaking the work in this paper was to further study processes of this type. Also, although reactions in aqueous H_2SO_4 and $HClO_4$ have received a lot of attention, reactions in aqueous HCl have not. Since data for the hydrolysis of acetylimidazole were available in all three acid media (2), and data for the hydrolysis of benzoylimidazole in two of them (2, 3), a comparison of the same reaction in different acid solutions could be performed, to see whether the excess acidity analysis gives the same answers in different media. Values of pK_{BH^+} determined using the equilibrium version of the excess acidity analysis (21) are similar but not identical in different acid systems (21, 22).



Results

Marburg and Jencks studied the hydrolyses of acetyl- and benzoyl-imidazole in many different aqueous media (2). Rate constants are not given in the paper, but fortunately the original concentration vs. time data are still available,[3] and these were curve-fitted to an exponential first-order rate equation (23) to obtain pseudo-first-order rate constants k_ψ as a function of acid concentration. Rate constants for the hydrolysis of benzoylimidazole as a function of sulfuric acid concentration and temperature are given by Smith and Yates (3). Excess acidities X, which are activity coefficient ratios of the form $\log(f_{B^*}f_{H^+}/f_{B^*H^+})$ for a standard base B* (21), were obtained from published sources (21, 22), which also give $\log C_{H^+}$ values for H_2SO_4; for HCl and $HClO_4$ these are simply the log acid molarities. These were adjusted to the reaction temperature as before if it was not 25°C (24). Water activities in H_2SO_4 at any temperature, a_{H_2O}, were calculated from available thermodynamic data (25), and 25°C values for HCl (26) and $HClO_4$ (27) were interpolated from published values.

The excess acidity kinetic method works by examining plots of $\log k_\psi - \log C_{H^+}$ against X, the excess acidity (21); for acid-catalyzed processes these are linear with positive slopes for A1 and A-S_E2 mechanisms, and curve downwards for A2 reactions (4, 5). Such plots for the experimental data used in this work are given in Fig. 1. It is at once apparent that these are not acid-catalyzed reactions, the rate constants decreasing

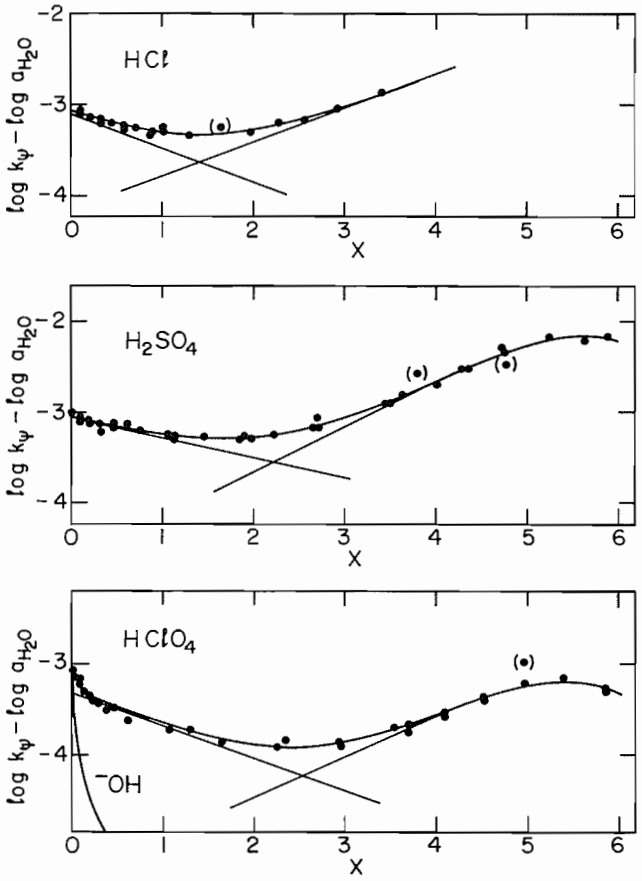
Fig. 1. Conventional excess acidity plot, $\log k_\psi - \log C_{H^+}$ vs. the excess acidity X, for the hydrolyses of the acylimidazoles in different aqueous acid systems at 25°C.

continuously with acidity. By trial and error, it was found that in most cases the data could be fitted as two successive straight lines in plots of $\log k_\psi - \log a_{H_2O}$ against X. Plots of the 25°C data on this basis are given in Fig. 2 for acetylimidazole and in Fig. 3 for benzoylimidazole; to obtain the fitted lines a computer program, which fits experimental data to any equation(s) supplied, was used (23). The associated slopes, intercepts, statistical data, etc. from the computer fit for Figs. 2 and 3 are given in Tables 1 and 2 for the two substrates. For acetylimidazole in perchloric acid a hydroxide-catalyzed process was also apparent in dilute acid; the $X = 0$ intercept of this was -4.30 ± 0.11. For acetylimidazole in H_2SO_4 and $HClO_4$ the downturn at high acidity could be used to calculate $pK_{SH_2^{2+}}$ values, and these are given in Table 1.



Discussion

The mechanism that applies to these reactions is given in Scheme 1, based on the original suggestion of Marburg and Jencks (2). The imidazole substrates are fully protonated at acidities much lower than those involved in this work, pK_a = 3.6 (28), and so at all acidities the substrate is the ring-protonated imidazolium species SH^+. This is assumed to add water reversibly to the hydrate or tetrahedral intermediate SHy^+ (K_{Hy}); thinking of the imidazolium ring as a strongly electron-withdrawing substituent on a carbonyl compound leads to the conclusion that hydration should be facile, much

as is chloral hydrate formation from CCl_3CHO (29). (Unfortunately it is not possible to estimate K_{Hy} from the correlation line for other carbonyl compounds (30) because a σ* value for the protonated imidazole substituent, needed for the correlation (30), does not appear to be known.) Either the formation

Fig. 3. Plots of log k_ψ − log a_{H_2O} vs. the excess acidity X for benzoylimidazole in aqueous sulfuric and hydrochloric acids at 25°C, showing the contributions of the different rate-determining steps at different acidities.

of this hydrate (k_1) or its cleavage (k_2) can be rate determining; the former should be the case at high acidity (low water activity) and the latter at low acidity. Imidazolium cation and carboxylic acid product formation as shown should render the reaction essentially irreversible. At high acidities the substrate SH^+ may protonate again on the carbonyl group to give diprotonated SH_2^{2+}.

Deriving excess acidity rate equations based on this scheme is not particularly difficult. At low acidity, where the k_2 step is rate determining, absolute rate theory requires

[1] $k_\psi C_{SH^+} = k_2 a_{SHy^+}/f_\ddagger$

Using the definitions $K_{Hy} = k_1/k_{-1} = a_{SHy^+}/a_{SH^+}a_{H_2O}$ and $a_{SH^+} = C_{SH^+}f_{SH^+}$, eq. [1] becomes eq. [2]:

[2] $k_\psi C_{SH^+} = (k_1k_2/k_{-1})a_{H_2O}C_{SH^+}(f_{SH^+}/f_\ddagger)$

which on taking logs and rearranging gives eq. [3]:

[3] $\log k_\psi - \log a_{H_2O} = \log(k_1k_2/k_{-1}) + m_2X$

if we assume linearity in X: $\log(f_{SH^+}/f_\ddagger) = m_2X$. (Linearity for equations like this has been found previously, for instance in amide and lactam hydrolyses (31).)

At high acidity, where the k_1 step is rate determining, we can write eq. [4]:

[4] $k_\psi(C_{SH^+} + C_{SH_2^{2+}}) = k_1 a_{SH^+}a_{H_2O}/f_\ddagger = k_1 C_{SH^+}a_{H_2O}(f_{SH^+}/f_\ddagger)$

Now the substrate concentration has to be written as the sum

[a]$\Delta H^{\ddagger}$ = 11.52 ± 0.72 kcal mol^{-1}; $\Delta S^{\ddagger}$ = −35.0 ± 2.4 cal mol^{-1} K^{-1}.
[b]$\Delta H^{\ddagger}$ = 16.98 ± 0.57 kcal mol^{-1}; $\Delta S^{\ddagger}$ = −27.4 ± 1.9 cal mol^{-1} K^{-1}.
[c]Root-mean-square deviation between the experimental points and the fitted lines in Fig. 3; in log k units.

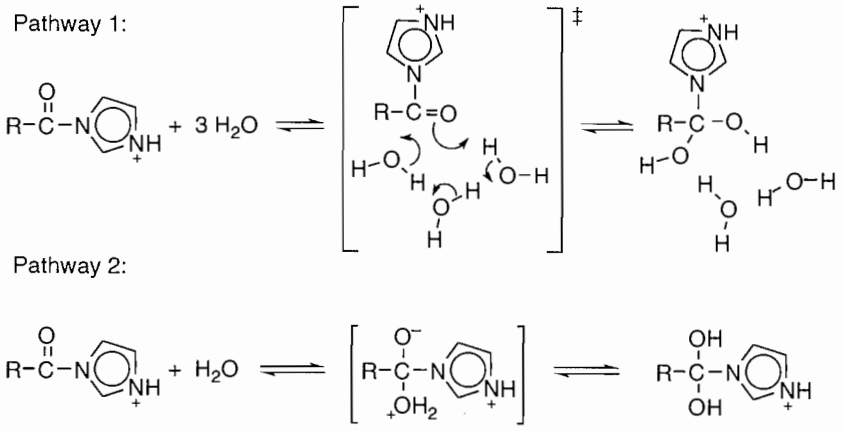
of SH^+ and SH_2^{2+}, because at high acidity we would expect the protonation of the carbonyl group to become important. Rearranging and taking logs gives eq. [5], if we assume that $\log(f_{SH^+}/f_{\ddagger}) = m_1X$.

$$[5] \quad \log k_{\psi} - \log(C_{SH^+}/(C_{SH^+} + C_{SH_2^{2+}})) - \log a_{H_2O} = \log k_1 + m_1X$$

The protonation correction term can be obtained by dividing by C_{SH^+}, which enables it to be expressed in terms of the ionization ratio $I = C_{SH_2^{2+}}/C_{SH^+}$ as in eq. [6]:

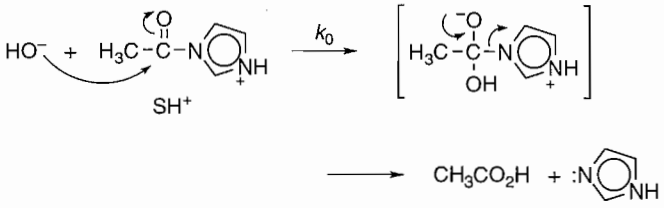
$$[6] \quad (C_{SH^+}/(C_{SH^+} + C_{SH_2^{2+}})) = 1/(1 + I)$$

and this can be obtained from the excess acidity equilibrium equation, $\log I = pK_{SH_2^{2+}} + 0.6X + \log C_{H^+}$ (21). (It is known that the m^* value of 0.6 applies to carbonyl group protonations (21).)



Equations [3] and [5] are the ones that give the lines in Figs. 2 and 3. In the topmost part of Fig. 2 (HCl) the theoretical curve is calculated with four coefficients, two slopes and two intercepts; for clarity the lines for the individual rate-determining steps are given in addition to the overall fitted curve. The middle curve (H_2SO_4) is calculated on the basis of five coefficients, the additional one being $pK_{SH_2^{2+}}$, calculated as above. The bottom plot ($HClO_4$) is also based on these five coefficients, with an additional one for the hydroxide mechanism, discussed below. In Fig. 3 the HCl plot is based on four coefficients, but the H_2SO_4 plot is based on six, with the data at additional temperatures being used to obtain $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ from the intercepts as before (18).

As can be seen from Figs. 2 and 3, the linearity assumption used in deriving eqs. [3] and [5] works very well. The slope values obtained are in Tables 1 and 2; there is not much that can be said about them as there are few studies to which they can be compared. The m_1 slopes for the k_1 processes compare favorably with the 0.56 ± 0.02 found for nitramide reacting in a similar way (20), and with the 0.3–0.7 found for some water additions to *N*-nitrobenzamides (18), which implies that the mechanisms of these processes are similar. The m_2 slopes for the tetrahedral intermediate breakup are all negative, but what this means, if anything, will have to wait until similar parameters for other substrates and reactions are obtained.



Two pathways can be visualized for the addition of water to SH^+, both of which result in rate equations involving one water molecule. Pathway 1 in Scheme 2 involves three water molecules in a proton switch, as proposed before for acid-catalyzed amide hydrolysis (31), and for the neutral hydrolyses of nitramide (20) and some *N*-nitro amides (18) in dilute acid. Pathway 2 is the conventional mechanism given in most textbooks (e.g., ref. 29). Both pathways will constrain several water molecules; the involvement of more than one in pathway 2 has been proposed before, based on a proton inventory analysis (32). Both are compatible with the entropy of activa-

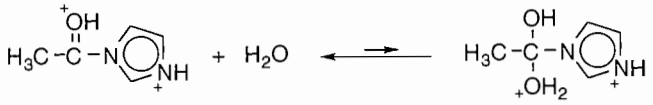


Scheme 2.

Scheme 3.

Scheme 4.

tion for the k_1 step in Table 2; however, pathway 1 involves no charge transfer at all, and is preferred on that basis.

The magnitudes of the intercept rate constants in Tables 1 and 2 seem reasonable; the breakup of the intermediate is slower than its formation in the standard state (water). The intercepts for the two rate-determining steps can be used to compare the rates of decomposition of the intermediate; values of $\log(k_2/k_{-1})$ given in the tables show that it goes on to product 10–100 times faster than it reverts to starting material. This implies that the hydrate should accumulate in solution in pure water; apparently this has never been tested experimentally.

The $pK_{SH_2^{2+}}$ values found for the second protonation at the carbonyl group of acetylimidazole are given in Table 1; they average to −6.7. This is much less basic than the values found for normal aliphatic (≈ −0.5) and aromatic (≈ −1.5) amides (33), which is only to be expected because of the positive charge already present in the molecule. Presumably the second protonation of benzoylimidazole is at least one pK unit more difficult, as there is no evidence of curvature at the higher acidities in Fig. 3. The technique used here shows that it is quite possible to obtain these values from kinetic data with a fair degree of accuracy, if they cannot be obtained directly.

Hydroxide addition to SH^+ would be highly favorable (Scheme 3); imidazole is a much better leaving group from the tetrahedral intermediate than is HO^-. An excess acidity rate equation for this can be based on eq. [7]:

$$[7] \quad k_\psi C_{SH^+} = k_0 a_{SH^+} a_{HO^-}/f_\ddagger$$

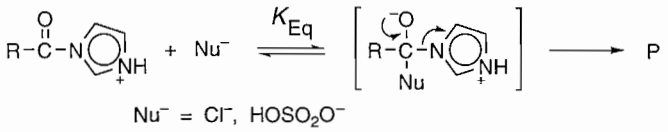
We have the definition $K_w = a_{H^+}a_{HO^-}/a_{H_2O}$ (one water molecule because the solvent is conventionally omitted from definitions of K_a and K_{BH^+}, so for consistency it is omitted from K_w also); substituting this, $a_{H^+} = C_{H^+}f_{H^+}$, and $a_{SH^+} = C_{SH^+}f_{SH^+}$ into eq. [7] gives eq. [8]:

$$[8] \quad k_\psi C_{SH^+} = (k_0 K_w) C_{SH^+}(a_{H_2O}/C_{H^+})(f_{SH^+}/f_\ddagger f_{H^+})$$

Rearranging, taking logs, and ignoring the activity coefficient ratio term gives eq. [9]:

$$[9] \quad \log k_\psi - \log a_{H_2O} + \log C_{H^+} = \log(k_0 K_w)$$

This is the equation that gives the HO^- curve in the lower part of Fig. 2. The activity coefficient term is omitted because the acidity region to which the equation refers is very close to ideality; actual testing in the one other case in which this behavior has been found (18) gave a slope value against X of zero. The intercept of this curve is −4.3, which means that k_0 is $10^{9.7}$, corresponding to diffusion control, which seems exactly what would be expected.



It was found that the diprotonated form is unreactive, hydrolysis only from the monoprotonated substrate being observed. This might seem surprising, but an examination of the tetrahedral intermediate formed when water adds, Scheme 4, reveals why this should be. There are two possible leaving groups here, neutral water and neutral imidazole, and of the two neutral water is far better. Thus the intermediate reverts to starting material very quickly, or more likely never forms in the first place as the $\Delta G^\ddagger$ is too unfavorable; SH_2^{2+} is resonance stabilized (to the carbonyl carbon), whereas the hydrate is not, ensuring an unfavorable equilibrium constant for its formation. Thus, when diprotonation starts to occur, the substrate SH^+ is simply being stored in an unreactive form, and this causes the reaction to slow down abruptly at high acidity (see Fig. 1).

The agreement between the results obtained in the three different aqueous mineral acid media can probably be best categorized as good but not great. However, it is apparent that the

Scheme 5.

excess acidity method *does* give the same answer in different acids. The further from the standard state, the worse the agreement; thus the log (k_1k_2/k_{-1}) values in the tables are much closer to one another than are the log k_1 values. In view of what is known of the agreement between pK_{BH^+} values measured in different acid media (21, 22), this is about what would have been expected. The $pK_{SH_2^{2+}}$ values agree quite well, and the slopes m_1 and m_2 fairly well, with the exception of the k_1 process for benzoylimidazole; perhaps this is due to the lack of rate constants at higher acidity for the reaction in HCl.

The really interesting observation in Fig. 2 is the difference between aqueous $HClO_4$ and the other two acids. In the former the log (k_1k_2/k_{-1}) process is slow enough that the hydroxide-catalyzed reaction is revealed, but this is swamped (presumably) by the faster log (k_1k_2/k_{-1}) process in aqueous HCl and aqueous H_2SO_4. The best guess as to what is going on here is that Cl^- and HSO_4^- can add to SH^+, as in Scheme 5, but ClO_4^- cannot, being non-nucleophilic. The resulting acid chloride and mixed anhydride will hydrolyze to the same carboxylic acid and protonated imidazole reaction products as given by the reaction with water in Scheme 1. Presumably this addition will be highly reversible; however, the mere existence of this extra reaction pathway is enough to accelerate the reaction in HCl and H_2SO_4. Perhaps this could be called nucleophilic catalysis by the acid anion.[4]

Marburg and Jencks (2) studied acetylimidazole hydrolysis in many aqueous salt solutions, as well as in the acid media discussed here, and the rate – salt concentration profiles for these solutions resemble the rate–acidity profiles. This means that derivation of an activity coefficient ratio term like X for salt or salt–acid media could prove useful in determining the mechanisms of reactions taking place in them. An equilibrium process that has large changes in K_{eq} with salt concentration, preferably over a wide concentration range, should enable a quantity like the excess acidity to be defined for salt solutions.

[4] One of the referees has commented that if this mechanism were important the reaction rate should increase as the acid concentration increases. It is not quite that simple, however; increasing C_{Nu^-} will certainly drive the Scheme 5 equilibrium further to the right, but the hydrolyses of the resulting acid chloride and anhydride products are not acid catalyzed in this acidity region, the observed rates actually decreasing with acidity according to Satchell's latest results (16, 17), and their actual hydrolysis rate constants may well be lower than those found in this work, as well (16, 17). Thus a decreasing rate constant with increasing acidity is in fact consistent with the contribution of the Scheme 5 pathway. It should be possible to separate out the rate constants due to the different processes, on the assumption that the same mechanism has the same rate parameters in the different acid media, but this is not thought to be justified experimentally at this time.

Acknowledgments

I would like to thank Professor W.P. Jencks for sending me the unpublished concentration vs. time data used here. Valuable discussions with Professor A.J. Kresge and his group are acknowledged, and I would like to thank Professor Kresge for reading the manuscript.

Near-infrared spectra of $Ba(NO_2)_2 \cdot X_2O$ (X = H,D) at 10 K. A local-mode approach

Ian M. Walker and Paul J. McCarthy

Abstract: The fundamental and overtone vibrational spectra of $Ba(NO_2)_2 \cdot X_2O$ (X = H,D) have been interpreted using the local-mode model. The calculated parameters are consistent with the structure, which has one strong hydrogen bond and one weak bifurcated hydrogen bond. Evidence for Fermi resonance between stretch and bend features having similar energies is discussed. Evidence for the breakdown of the simple Morse oscillator model, which was quite successful for O—H···Cl hydrogen bonds, is also presented.

Key words: overtone, spectra, near-infrared, hydrates, local-mode model.

Résumé : Faisant appel au modèle du mode local, on a interprété les spectres vibrationnels fondamentaux et harmoniques du $Ba(NO_2)_2 \cdot X_2O$ (X = H,D). Les paramètres calculés sont en accord avec la structure impliquant une liaison hydrogène forte et une faible liaison hydrogène bifurquée. On discute des données suggérant l'existence d'une résonance de Fermi entre les caractéristiques d'élongation et de déformation d'énergies semblables. On présente aussi des résultats suggérant que le modèle d'oscillateur simple de Morse, qui a été très utile pour les liaisons hydrogènes O—H···Cl, ne s'applique pas ici.

Mots clés : harmonique, spectre, proche infrarouge, hydrates, modèle du mode local.

Introduction

We have, in a series of papers, used local-mode theory to analyze the vibrational overtone and combination bands of water (1–5) and of the NH_2 group in the guanidinium ion (6) in crystals. The purpose of these studies is to try to correlate the local-mode parameters with the length and strength of the hydrogen bonds formed by O—H and N—H bonds. For such studies barium nitrite monohydrate, $Ba(NO_2)_2 \cdot H_2O$, is a suitable material. It can be recrystallized to yield large, well-formed crystals, and polarized crystal spectra in the near-infrared (NIR) region can readily be recorded.

Crystal structure

The X-ray crystal structure of $Ba(NO_2)_2 \cdot H_2O$ at 298 K has been reported (7, 8). In addition, an extensive neutron diffraction study at 298, 102, and 20 K has appeared (9). These studies show that the material has a hexagonal unit cell, which at 20 K has the parameters a = 7.0524 Å, c = 17.6372 Å, Z = 6, and that the crystal belongs either to space group $P6_5$ (C_6^3, no. 170) or to the enantiomorphous $P6_1$ (C_6^2, no. 169). Since $Ba(NO_2)_2 \cdot H_2O$ is expected to crystallize in a statistical mixture of enantiomorphs, the experimental results might be reported for either space group. Thomas and Gomes (10) have shown that the crystal they studied is optically dextrorotatory in the visible region of the spectrum and so belongs to the latter space group. The structures in the neutron diffraction study were, however, refined on the basis of the former space group. For our study the difference is immaterial.

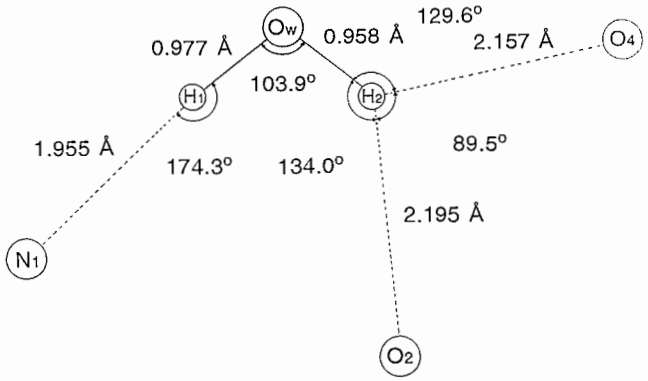

Fig. 1. The water molecule in $Ba(NO_2)_2 \cdot H_2O$ showing the hydrogen bonds to atoms on three nearby nitrite ions. The angles around H(2) do not sum to 360°, since H(2), O(w), O(2), and O(4) do not lie exactly in a plane. Atom designations are from ref. 9.

All the waters in the crystal are equivalent, and they form two different hydrogen bonds (see Fig. 1). The nearly linear O—H(1)···N(1) forms the stronger hydrogen bond, while O—H(2) forms a weaker bifurcated hydrogen bond to oxygens on two different nitrite groups. Kvick et al. (9) have noted that the HOH angle (103.9°) and the shorter O—H distance (0.958 Å) agree well with the values reported for gaseous water, 104.52° and 0.9572 Å (11). The other O—H bond is substantially longer, and this indicates a weakening of the

O—H bond due to strong hydrogen-bond formation with N(1). The nitrite ions in the crystal are of two independent types, and the Ba^{2+} ion is coordinated with one nitrogen and nine oxygen atoms at an average distance of 2.881 Å at 20 K (9).

Spectra

The fundamental vibrational spectrum of this substance has been studied in considerable detail (12–17). Eriksson et al. (17) noted that as the crystal is cooled from 298 to 102 and then to 20 K the energy of most IR absorptions increases. (In the following, ν, δ, and ρ are stretching, bending, and librational vibrations, respectively.) As for the two ν(OH) or ν(OD) bands, the higher energy band increases a small amount in energy, while the band at lower energy decreases in energy to a greater extent. This was also noted earlier by Brink and Falk (13). The O—H···N hydrogen bond presumably gets stronger as the temperature is lowered. This is not unexpected, since molecular motion decreases with lowered temperature.

The large asymmetry of the water molecule in this compound was noted in the IR spectrum before it was confirmed by diffraction studies. It was early pointed out by Schiffer (18) that the two ν(OH) correspond to the stretches of the individual OH bonds rather than to symmetric and unsymmetric combinations of the two stretches. Brink and Falk (13) note that this is confirmed by the fact that the stretching fundamentals of H_2O and D_2O have values almost the same as those found in HOD. Eriksson et al. (17) noted that this is a "well-known consequence of an asymmetric bonding situation in the water molecule." This means that the local-mode model should apply very well in this case.

Brink and Falk (13) further noted that in this compound the separation of the two ν(OH) or ν(OD) in the two forms of HOD decreases with increasing temperature. This they ascribe to increased molecular motion, especially librational motion, in the crystals, which would tend to equalize the weak and strong hydrogen bonds.

The IR spectra of HOD in $Ba(NO_2)_2 \cdot 2HOD$ show two δ(HOD) bands. Since stronger hydrogen bonding augments the energy of the bending vibration, the band at 1481 cm^{-1} is assigned to δ(N···H-O-D···O), while that at 1442 cm^{-1} has H and D reversed; the data are for 102 K (17).

The polarized crystal spectra of $Ba(NO_2)_2 \cdot H_2O$ in the 1300–2700 nm region were recorded at room temperature by Wood (19). Our low-temperature study has revealed additional features; this enables us to make a more complete treatment of this system from a local-mode point of view.

Local-mode theory

The local-mode theory for water on general sites has been outlined elsewhere (2, 3). Its application here is very similar to the case of $CsMnCl_3 \cdot 2H_2O$, in which all waters are identical but form two different hydrogen bonds to adjacent chlorines (4). The vibrational basis functions for the O—H bonds are written as products of Morse oscillator eigenfunctions, each of which is described by a local-mode quantum number, v_i. The basis ket for a water molecule is accordingly written as $|v_1 v_2>$. After subtracting the energy of the ground $|00>$ state, the diagonal elements of the secular determinant can be calculated from the relation:

$$[1] \quad <v_i v_j|H|v_i v_j> = \omega_1 v_1 + \omega_2 v_2 + X_1 v_1(v_1 + 1) + X_2 v_2(v_2 + 1)$$

Here ω_1 and ω_2 are the harmonic frequencies and X_1 and X_2 the anharmonicity parameters of the O—H (O—D) bonds. Coupling between stretching modes in H_2O and D_2O is taken into account by the inclusion of off-diagonal elements of the form:

$$[2] \quad <v_i + 1, v_j - 1|H|v_i, v_j> = \lambda[(v_i + 1)v_j]^{1/2}$$

λ represents the coupling between the two O—H or O—D oscillators. From eq. [2] it is clear that only coupling between states with the same value of $(v_1 + v_2)$ need be considered. An initial parameter set is chosen and the vibrational energies are calculated by diagonalization of the appropriate matrices (2). An iterative process changes all parameters simultaneously so as to minimize the sum of the squares of the differences between calculated and observed energies. The procedure stops when successive iterations differ by less than a preset amount. The standard deviations were estimated by the method outlined by Cowan (20).

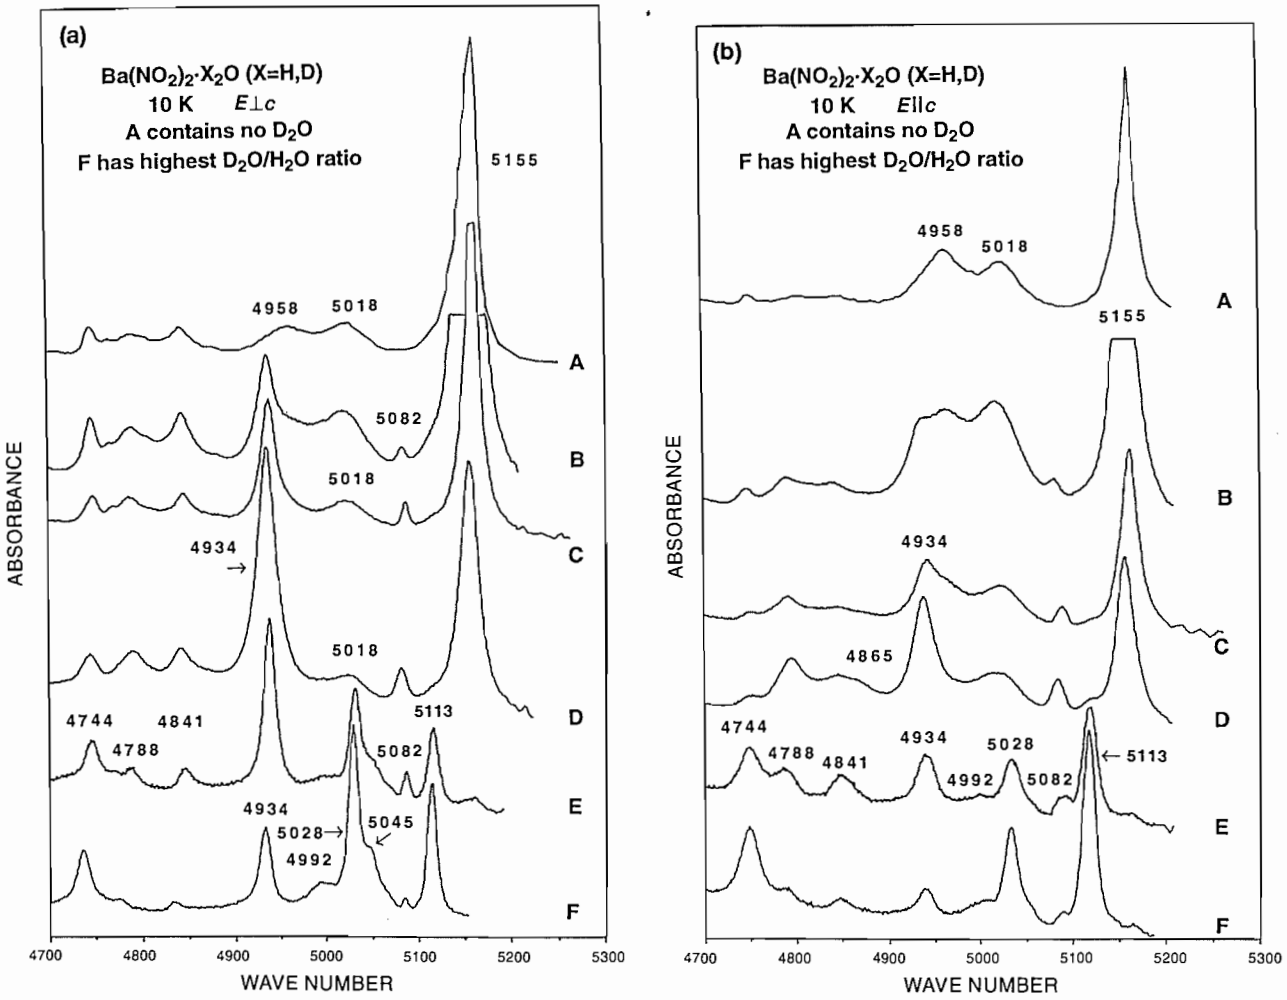
Experimental

Well-formed hexagonal prisms were obtained by slow evaporation of $Ba(NO_2)_2 \cdot H_2O$ from aqueous solution. Crystals with various H/D ratios were prepared by evaporating solutions of barium nitrite in mixtures of H_2O and D_2O in a desiccator over concentrated H_2SO_4. Spectra were recorded at 10 K on a Varian 2300 spectrophotometer with the sample cooled in a Displex cryogenic refrigerator. A pair of Glan–Thompson prisms provided polarized light. Spectra were recorded with the electric vector (E) of the light parallel and perpendicular to the crystal c axis.

Results and discussion

The spectra of crystals with various H/D ratios are shown together for easier comparison. Figure 2 presents the 4700–5300 cm^{-1} region, while Fig. 3 shows the 5900–7100 cm^{-1} region. Figure 4 contains the spectra of the 3ν region of the protiated crystal only, since we were not able to observe any distinctive bands in the appropriate region in deuterated crystals. Other spectral regions are not shown, but will be commented on briefly.

For some band energies there may be a difference of a few wave numbers between polarizations or within a single polarization as the D/H ratio changes. The precision of our measurements is also of this order of magnitude. Therefore, unless there is an unambiguous difference between polarizations or between spectra with various D/H ratios, we have used the average values for the band energies. In fact, for the most part, absorption energies in the two polarizations appear to be identical within experimental error.



The observed vibrational energies of $Ba(NO_2)_2 \cdot H_2O$ and its deutero analogs are listed in Table 1 together with the band assignments. Along with these are the calculated energies and the parameters that yielded this best fit.

Spectra of $Ba(NO_2)_2 \cdot H_2O$

Our room-temperature spectra of $Ba(NO_2)_2 \cdot H_2O$ match those reported by Wood (19). When the crystal is cooled to 10 K, however, a great deal of detail is seen in all of the bands. The sums of fundamentals allow one to assign a group of band components of comparable intensity to a generic combination

© 1997 NRC Canada

Fig. 2. Spectra of $Ba(NO_2)_2 \cdot X_2O$ (X = H,D) at 10 K in the range 4700–5300 cm^{-1}; (*a*) $E \perp c$, (*b*) $E \parallel c$.

of the fundamentals. For example, the rather strong features between 3900 and 4150 cm^{-1} are due to $\nu + \rho$ of water in the crystal (19). The series of weak bands in the 4500–4900 cm^{-1} region are due to coupling of the stretches of water with those of the nitrite groups. The $\nu+2\rho$ bands of H_2O are calculated also to appear between 4350 and 4860 cm^{-1}. Finally, a group of very weak bands between 7200 and 7500 cm^{-1} are probably due to $2\nu + \rho$ of water.

For most of the bands such a generic assignment is all that is feasible, since no model is available that would allow the calculation of the energies of the individual band components. For some regions, however, such as those of the stretch overtones and the stretch–bend combinations of water, assignments of individual bands can be made with reasonable certitude, and we will concentrate on these.

In Figure 2 (trace A) the bands at 5018 and 5155 cm^{-1} are the $\nu + \delta$ combinations of H_2O. In the spectra of a thick crystal, weak bands lie 470, 587, and 746 cm^{-1} above the 5018 cm^{-1} band. Since the average values at 102 K for the three librations of water are 471, 579, and 724 cm^{-1} (17), these three bands can be assigned to $\nu + \delta + \rho$ combinations. It is interesting to note that the observed progressions in the librational modes are associated principally with $\nu + \delta$ of the **stronger** hydrogen bond. The other moderately strong band at 4958 cm^{-1} might be the 3δ band of H_2O, which is calculated to appear in this region. It seems inordinately strong for a ternary combination; the origin of its intensity will be discussed below.

Figure 3 (trace A) shows the stretch overtone region of water. The band at 6842 cm^{-1}, assigned to the |11> state of H_2O, is noticeably polarized $\perp c$. (See the discussion of the HOD spectrum below.) The strong band at 6820 cm^{-1} is |02> of the weakly hydrogen-bonded OH; it persists in the most highly deuterated samples. The |20> of the strongly hydrogen-bonded OH appears at considerably lower energy, 6287 cm^{-1}. The $\nu + 2\delta$ bands of water are also calculated to appear at about 6661 and 6830 cm^{-1} (17). Although the latter are ternary bands, they could gain intensity by Fermi resonance with the 2ν bands (see below). Accordingly, the strong band at 6787 cm^{-1} is assigned as one of these $\nu + 2\delta$ bands. The other is not clearly observed, but may be one of the weak bands between 6600 and 6700 cm^{-1}. This assignment is strengthened by the fact that in both polarizations the spectrum of this region is repeated at higher energy. Bands are found at 7924, 8434, and 8465 cm^{-1}. They are about 3% as intense as the 2ν features and they lie about 1624 cm^{-1} above the 2ν bands. Since δ = 1662 cm^{-1} at 102 K (17), the bands at higher energy can be assigned

to $2\nu + \delta$ of water. A band at 6787 + 1624 cm^{-1} is notably missing from this group. It would be the quaternary band, $\nu + 3\delta$, and is accordingly too weak to be observed.

Of particular interest is the complex feature on the high-energy side of the 6287 cm^{-1} band, the first overtone of O—H in the O—H···N hydrogen bond. It represents simultaneous excitation of H-bond acceptor vibrations with the |20> mode. The band contains broad maxima that appear to be short progressions in 50–60 and 100 cm^{-1}. They could represent the H-bond wag and stretch modes. Sandorfy made such an assignment in his study of the HCl – dimethyl ether system (21). The |02> and |11> bands should show similar structure. And in fact the overall |02> plus |11> band group is slightly broadened on its high-energy side and shows several weak, resolved features. The lowest band in the $2\nu + \delta$ complex (7924 cm^{-1}) also has associated structure in both polarizations. This band is stronger in the $E \| c$ spectrum, just as is the 6287 cm^{-1} band. We have also noted similar diffuse structure on the high-energy side of bands in the spectra of $CsMnCl_3 \cdot 2H_2O$ (4), $Cs_2MnCl_4 \cdot 2H_2O$ (5), and guanidinium salts (6).

Figure 4 shows the spectra of the 3ν region of the protiated crystal. The crystal was the thickest we could grow (1.7 mm) and the strongest band is about 2% as strong as the strongest band in the 2ν region. The |30> state was not included in the fitting routine described above, since no band was found near the expected value, 8868 cm^{-1} (Table 1). The band at 9065 cm^{-1} can, however, most likely be assigned to this strongly hydrogen-bonded |30> state, even though it lies so high in energy. It is possible to evaluate deviations from the simple model used in this paper due to the formation of such strong hydrogen bonds. The problem has been treated in depth by Foldes and Sandorfy (22), who showed that additional terms are needed in the Hamiltonian in order to account for the position of the second overtone in hydrogen-bonded alcohols. If the two terms

$$Y_i [v_i^3 + (3/2)\, v_i^2 + (3/4)\, v_i] \qquad (i = 1, 2)$$

are added to eq. [1], then it can be shown that

$$[3] \quad 2Y_1 = E(|10>) + E(|30>)/3 - E(|20>)$$

with a similar expression for Y_2. Using the data for oscillator 1 (Table 1), we estimate that $Y_1 = 35$ cm^{-1}, which is comparable to the value calculated for isopropanol (22). It is of interest that the signs of X and Y are opposite in this crystal, just as they are in associated alcohols. In contrast, for oscillator 2, $Y_2 = -2$ cm^{-1}. This indicates that this weakly hydrogen-bonded oscillator is very similar to a gas-phase Morse OH oscillator.

Spectra of $Ba(NO_2)_2 \cdot HOD$

The most interesting feature of the spectra of this species is the pair of bands at 5915 and 5969 cm^{-1} (see Fig. 3). They are assigned to combinations ν(OH) + ν(OD) in the two HOD molecules. Their energies match nicely the sums of the fundamentals at 102 K, namely, 5918 and 5967 cm^{-1} (17). The appearance of two bands in this region is consistent with the difference in hydrogen-bond strength for the two OH(OD) oscillators. Both components are almost completely polarized $\perp c$. The bisector of the HOD angle lies almost in the plane $\perp c$. If the resultant of the OH and OD vectors is taken to lie along this bisector, then the dipole strength of this resultant is calculated to be 97% polarized $\perp c$.

It is noteworthy that the two stretch combination bands differ in intensity. The band at lower energy (5915 cm^{-1}) has about half the area of the other band (5969 cm^{-1}). The 5915 cm^{-1} band contains the strong O—H···N(1) hydrogen bond and weak O—D bifurcated hydrogen bond, while the 5969 cm^{-1} band contains the opposite configuration. Barium chloride dihydrate contains two crystallographically distinct water

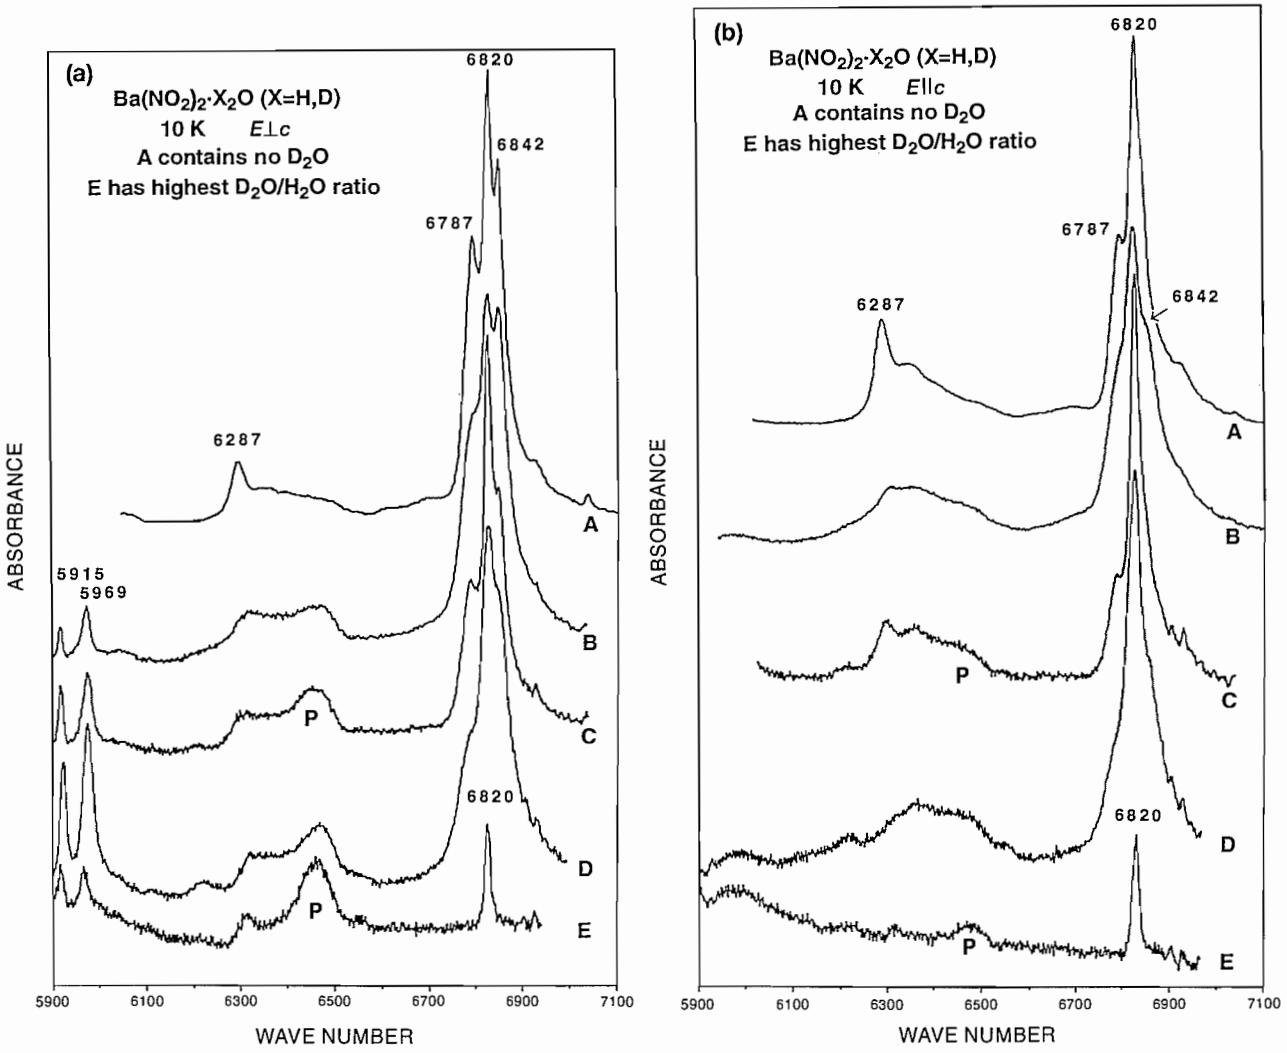
Fig. 3. Spectra of $Ba(NO_2)_2 \cdot X_2O$ (X = H,D) at 10 K in the range 5900–7100 cm^{-1}; (*a*) $E \perp c$, (*b*) $E \parallel c$. The bands marked P are due to the polarizers.



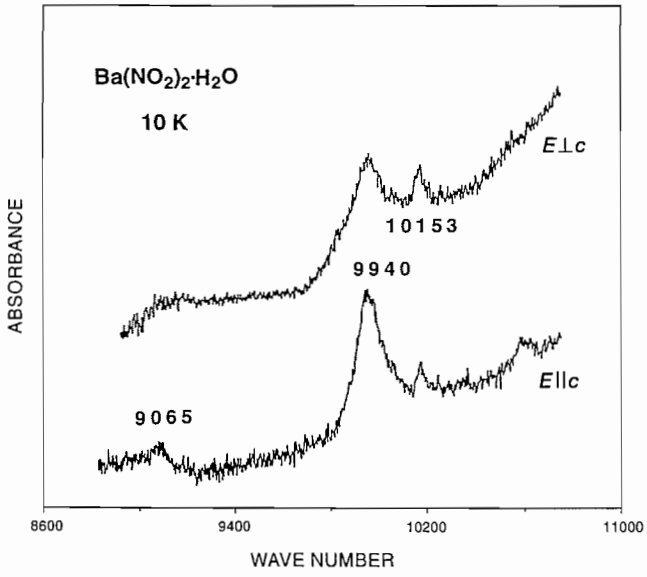


Fig. 4. Spectra of $Ba(NO_2)_2 \cdot H_2O$ at 10 K in the range 8600 – 11 000 cm^{-1}.

molecules, and the spectra of $BaCl_2 \cdot 2HOD$ show four $\nu(OH) + \nu(OD)$ combination bands (2, 3). In this case the band at highest energy is considerably less intense than the other three. This weakest band is due to the sum of a strong O—H hydrogen bond and a weak O—D bifurcated hydrogen bond in the water on site 2. It is interesting that the same trend is found in both crystals. We have no explanation of this at present. In the other compounds for which we have done deuterated studies, either the bands are roughly the same in area ($Cs_2MnCl_4 \cdot 2H_2O$ (5)) or only a single band is observed ($CsMnCl_3 \cdot 2H_2O$ (4)).

The $\nu(OD) + \delta(HOD)$ bands are calculated to appear at 3904 and 4072 cm^{-1}. Bands that intensify and then weaken on addition of H_2O are found at 3900 and 4062 cm^{-1} (not shown) and can therefore be assigned to these combinations. The pair of bands at 4788 and 4934 cm^{-1} behave similarly (see Fig. 2), and so are assigned to $\nu(OH) + \delta(HOD)$. They are calculated to be at 4808 and 4947 cm^{-1}. This confirms the assignment of the $\delta(HOD)$ features. Because of its behavior on the addition of H_2O, the band at 5082 cm^{-1} can be assigned as an absorption of HOD. It is likely the overtone of the weakly bonded OD oscillator.

Spectra of $Ba(NO_2)_2 \cdot D_2O$

In the spectra of a highly deuterated crystal a very strong band lies at 3795 cm^{-1} ($E \perp c$) (not shown). It is probably one of the $\nu + \delta$ bands of D_2O, which are calculated to appear at 3669 and 3805 cm^{-1}. The same spectra (see Fig. 2) show a weak band at 4992 cm^{-1} that can be assigned to one of the $\nu + 2\delta$ combinations of D_2O; the sums of the fundamentals at 102 K are 4875 and 5011 cm^{-1} (17). The bands at 4744, 5028, and 5113 cm^{-1} lose intensity rapidly on the addition of H_2O, and so have been assigned as the 2ν bands of D_2O. The band at 4744 cm^{-1} appears also to contain an absorption of H_2O. A few other band positions are noted in the figures, but at present we have no assignment for these bands.

Fermi resonance

To explore some of the fine details of the H_2O spectra, we have analyzed a more complete data set that includes the bend and bend–stretch combination features. The Hamiltonian of eqs. [1] and [2] was augmented by inclusion of Fermi resonance matrix elements (23) between stretch states and bend overtones and stretch–bend combinations of like energies. Inclusion of Fermi resonance can explain certain anomalies in the spectra without materially affecting the best-fit values of the local-mode parameters of Table 1.

First, in the IR spectrum the energy of the OH stretch of the strong hydrogen bond ($|10\rangle$) is anomalously high. If Fermi resonance were not present, this band should lie near 3327 cm^{-1}, as it does in the HOD spectrum. This suggests that the $|10\rangle$ state interacts with 2δ in H_2O, calculated to be at 3322 cm^{-1}. The interaction raises the value of the former state to 3336 cm^{-1}, while the energy of the latter is lowered to 3295 cm^{-1}. The other stretch is affected much less. Setting the Fermi resonance parameter to about 25 cm^{-1} accounts for this anomaly.

Second, the enhanced intensity of the $|01\rangle + 2\delta$ band at 6787 cm^{-1} can also be explained by Fermi resonance. Our calculations show that the same small parameter (about 25 cm^{-1}) causes strong mixing of this $\nu + 2\delta$ state with the adjacent $|02\rangle$ state of H_2O. The $|10\rangle + 2\delta$ band is very weak and is not observed. Calculations show that there is almost no mixing of this combination with the $|20\rangle$ state. This can be attributed to the rather large difference in their energies.

Finally, the 3δ band is abnormally strong. This can be ascribed to strong mixing of the 3δ state with the combination state $|10\rangle + \delta$, which lies nearby. This is confirmed by our calculations.

Conclusions

Our analysis of the data in Table 1 permits us to draw the following conclusions.

1. Although the two hydrogen bonds differ considerably in strength, this is not mirrored in the magnitude of ω. The two values differ only slightly and are about 5% lower than ω for gaseous H_2O (3876.2 cm^{-1}) (24) or D_2O (2818.8 cm^{-1}) (25). This was also found for several other systems that we have studied. Accordingly, the magnitude of ω is **not** a good indicator of the strength of the hydrogen bond formed by an O—H or O—D bond.

2. The values of X for the weaker hydrogen bond (−96 cm^{-1} (OH), −48 cm^{-1}(OD)) are somewhat more negative than the values for the corresponding oscillators in gaseous H_2O (−84.4 cm^{-1}) (24) or D_2O (−45.4 cm^{-1}) (25), while those for the stronger hydrogen bond (−187 cm^{-1}(OH), −89 cm^{-1}(OD)) are about twice as large as those for gaseous H_2O and D_2O. Therefore, in this study as well as earlier reports, we find that the value of X is a considerably better indicator of hydrogen-bond strength. While the data we have been able to amass do not provide a highly correlated relationship between X and hydrogen-bond length, the general trend is that the shorter (and therefore stronger) the hydrogen bond formed, the more negative the value of X. This matches what is reported in the literature for water in condensed phases and for numerous hydrogen-bonded alcohol multimers (22, 26). Berglund et al. (16) calculated the values of X(OH) for $Ba(NO_2)_2 \cdot H_2O$ by a simple method that uses the four stretch fundamentals of HOD and DOH. The values they obtained, −220 and −223 cm^{-1}, are quite unrealistic, however, given the extreme difference in hydrogen-bond environment of the two O—H bonds.

3. On hydrogen-bond formation, the value of λ in H_2O is considerably reduced from the value in gas-phase water. This is in accord with our earlier studies on $CsMnCl_3 \cdot 2H_2O$ (4) and $M_2MnCl_4 \cdot 2H_2O$ (M = Rb, Cs) (5). The value of λ is larger for D_2O than for H_2O, but it too is reduced upon hydrogen-bond formation. The reduction is not so marked, however, as in the case of H_2O. This is also consistent with our earlier studies.

4. The ratios ω(OD)/ω(OH) and X(OD)/X(OH) are 0.713 and 0.477 for the strong OH···N hydrogen bond and 0.726 and 0.502 for the weak bifurcated OH···O hydrogen bond. The second set is closer to the theoretical ratios (0.728 and 0.529) because such an oscillator most closely resembles a Morse oscillator. In the more strongly hydrogen bonded-case, the presence of the Y-term, which depends on the third power of the vibrational quantum number, is expected to cause substantial deviations from Morse behaviour (22).

Abstract: The cuprous iodide catalyzed reaction of 2-methyl-2-[1-(3-benzoyl-4-phenylpyridinium)]acetic acid methyl ester bromide (**5**), prepared by reaction of 3-benzoylpyridine (**4**) with racemic methyl 2-bromopropionate, with phenylmagnesium chloride at −23°C afforded the 2-methyl-2-[1-(3-benzoyl-4-phenyl-1,4-dihydropyridyl)acetic acid methyl ester (**6**, 74%), which was a mixture of four diastereomers. Recrystallization of this diastereomeric mixture from diethyl ether afforded a solid product (**6a-solid**, 30%, 4*R**,2*R** and 4*S**,2*S**) and an oil product (**6b-oil**, 39%, 4*R**,2*S** and 4*S**,2*R**), each consisting of a mixture of two diastereomers that differ in relative configuration (*R** or *S**) at the 1,4-dihydropyridine C-4 position and the -*CH*(Me)CO_2Me moiety. Addition of the Grignard reagent from either of the two diastereotopically different faces of the planar pyridinium salt (**5**) gives rise to two diastereomeric products **6a-solid** and **6b-oil** in which the C-4 phenyl substituent is pseudo-axial to the boat-shaped 1,4-dihydropyridine ring. Alkaline hydrolysis, or ammonolysis, of the acetic acid methyl ester (**6**) afforded the respective acetic acid (**7**), or acetamide (**8**), derivative.

Key words: 1,4-dihydropyridines, diastereomers.

Résumé : On a préparé l'ester bromométhylique de l'acide 2-méthyl-2-[1-(3-benzoyl-4-phénylpyridinium)]acétique (**5**), en faisant réagir la 3-benzoylpyridine (**4**) avec le 2-bromopropionate de méthyle racémique. Le composé (**5**) en présence de iodure cuivreux comme catalyseur réagit avec le chlorure de phénylmagnésium à −23°C pour donner l'ester méthylique de l'acide 2-méthyl-2-[1-(3-benzoyl-4-phényl-1,4-dihydropyridyl)acétique (**6**, 74%) qui est un mélange de quatre diastéréoisomères. La recristallisation de ce mélange de diastéréoisomères dans l'éther donne un produit solide (**6a-solide**, 30%, 4*R**,2*R** et 4*S**,2*S**) et un produit huileux (**6b-huile**, 39%, 4*R**,2*S** et 4*S**,2*R**), ces deux produits étant un mélange de deux diastéréoisomères, qui diffèrent par la configuration relative (*R** ou *S**) au niveau du carbone en position 4 de la 1,4-dihydropyridine et au niveau de l'unité -*CH*(Me)CO_2Me. L'addition du réactif de Grignard sur l'une ou l'autre des faces, diastéréotypiquement différentes, du sel de pyridinium plan (**5**) donne deux produits diastéréoisomères **6a-solide** et **6b-huile** dans lesquels le substituant phényle en C-4 est pseudo-axial par rapport à la forme bateau du cycle 1,4-dihydropyridine. L'hydrolyse alcaline, ou l'ammonolyse, de l'acétate de méthyle (**6**) donne l'acide acétique (**7**) ou le dérivé acétamide (**8**) correspondant.

Mots clés : 1,4-dihydropyridines, diastéréoisomères.

Introduction

A number of benzoylaryl or heteroaryl acetic acids (nonsteroidal anti-inflammatory drugs, NSAIDs) such as ketoprofen (**1**), tolmetin (**2**), and indomethacin (**3**) exhibit useful analgesic and anti-inflammatory activity (1). Unfortunately, NSAIDs that block arachidonate metabolism by acting as cyclooxygenase (COX) inhibitors are limited by toxicity and only provide temporary relief of pain and inflammation symptoms without any effect on the underlying disease process. New classes of anti-arthritic drugs, that act by novel mechanisms, are required to separate the potent anti-inflammatory effects from adverse effects associated with NSAID use, and to treat the disease process rather than simply relieving the symptoms associated with inflammation.

The 1,4-dihydropyridyl ring system in 2-methyl-2-[1-(3-benzoyl-4-phenyl-1,4-dihydropyridyl)]acetic acid analogs (**6–8**) has conformational and steric characteristics that are distinctly different from those present in the traditional benzoylaryl or heteroaryl acetic acids (NSAIDs, **1–3**). The 1,4-dihydropyridyl ring system is more puckered than the planar aryl(heteroaryl) ring system due to distortion at the 1,4-dihydropyridyl N-1 and C-4 positions. It has been reported, based on ab initio STO-3G calculations for 4-phenyl-3,5-dicarboxy-1,4-dihydropyridine, that a boat conformation is favored over a planar conformation, that ring distortion is greater at C-4 than at N-1, and that a pseudo-axial orientation

of the C-4 phenyl substituent is unequivocally favored (2, 3). Similar theoretical calculations also showed that 1,4-dihydronicotinamide (4) and Hantzsch 1,4-dihydropyridine calcium channel antagonists (5) exist in a boat conformation. These conformational differences, together with steric and physicochemical effects due to 1,4-dihydropyridyl N-1, C-3, and C-4 substituents, are expected to change the global size of the molecule, tissue biodistribution, and potential mechanism of action. We now report the synthesis and some structural features for a small group of 2-methyl-2-[1-(3-benzoyl-4-phenyl-1,4-dihydropyridyl)]acetic acid analogs (**6**–**8**).

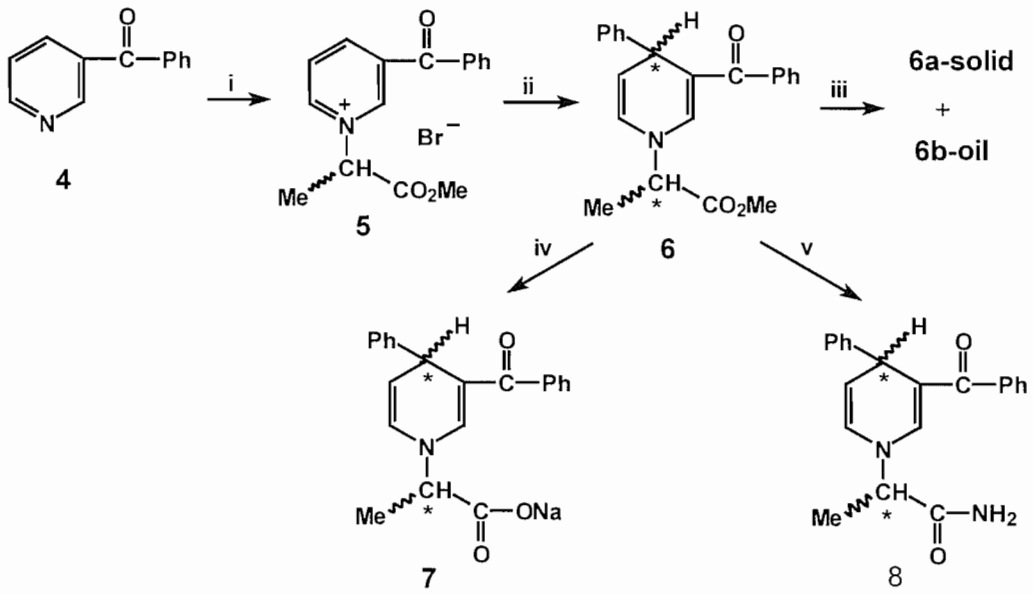
Chemistry

Reaction of 3-benzoylpyridine (**4**) with racemic methyl 2-bromopropionate at reflux in acetone afforded the 2-methyl-2-[1-(3-benzoyl-4-phenylpyridinium)]acetic acid methyl ester bromide (**5**, 73%). The regiospecific copper-catalyzed reaction (6) of phenylmagnesium chloride with the pyridinium salt (**5**) yielded the 2-methyl-2-[1-(3-benzoyl-4-phenyl-1,4-dihydropyridyl)]acetic acid methyl ester (**6**, 74%) as a mixture of four diastereomers. No product resulting from reaction of the benzoyl substituent of the pyridinium salt (**5**) with the Grignard reagent was observed. This is consistent with a report that pyridinium salts are so reactive toward Grignard reagents in the presence of cuprous iodide that addition at C-4 of the pyridinium ring occurs selectively even in the presence of other reactive substituents, such as ketones, at C-3 (7). The position of other reactive groups is not important since they would not compete even at positions other than C-3. The 1,4-dihydropyridyl compound **6** is very stable to aromatization due to the electron-withdrawing effect of the 3-benzoyl group, which is conjugated with the enamine moiety (8).

2-Methyl-2-[1-(3-benzoyl-4-phenyl-1,4-dihydropyridyl)]-acetic acid methyl ester (**6**), which contains two asymmetric carbons at the dihydropyridine C-4 and α-methylacetate methine positions, could have four possible diastereomers (*SS*, *SR*, *RS*, *RR*). The ^{1}H NMR spectrum for **6** exhibited dual resonances for the 1,4-dihydropyridyl ring and ester O*Me* protons, whereas the ^{13}C NMR spectrum showed dual resonances for the dihydropyridine C-2, C-3, C-5, C-6, and ester -CH*Me* carbons. A variable-temperature ^{1}H NMR study, using DMSO as solvent, showed that no coalescence of dual resonances occurred up to a temperature of 333 K. Recrystallization of product **6** from diethyl ether afforded a solid product (**6a-solid**, 30%), and an oil product (**6b-oil**, 39%) that remained in the mother liquor. The ^{1}H NMR and ^{13}C NMR spectra for **6a-solid** and **6b-oil** did not exhibit dual resonances. The ^{1}H NMR coupling constants ($J_{4,5}$ = 4.8, $J_{5,6}$ = 7.8 Hz) were identical for **6a-solid** and **6b-oil**. ^{1}H NMR nuclear Overhauser enhancement (nOe) studies indicated that the magnitudes of the nOe effect between the 1,4-dihydropyridyl (DHP) H-4 and its neighboring protons were very similar for **6a-solid** and **6b-oil**, which suggests that the conformation of the DHP ring is similar in both compounds. Addition of the chiral shift reagent (+)-Eu(hfc)$_3$ to **6a-solid** or **6b-oil** separated the *Me*CH doublet into two doublets, and the *Me*O singlet into two singlets, respectively (see data in experimental section). This latter study suggests that **6a-solid** (4*R**,2*R** and 4*S**,2*S**) and **6b-oil** (4*R**,2*S** and 4*S**,2*R**) each consist of a mixture of two diastereomers, which differ in relative configuration (*R** or *S**) at the DHP C-4 position and the methine carbon of the -*CH*(Me)CO$_2$Me moiety. Addition of the Grignard reagent from either of the two diastereotopically different faces of the planar pyridinium salt **5** would give rise to the two diastereomeric products **6a-solid** and **6b-oil** in which the C-4 phenyl substituent is pseudo-axial to the boat-shaped 1,4-dihydropyridine ring.

Hydrolysis of the methyl ester (**6**, mixture of four diastereomers) with aqueous sodium hydroxide at 25°C for 1 h afforded the sodium acetate analog **7** (mixture of four diastereomers) in 95% yield. Ammonolysis of the methyl acetate ester (**6**, mixture of four diastereomers) yielded the acetamide derivative (**8**, mixture of four diastereomers) in 67% yield.

The pharmacological evaluation of compounds **6**–**8** as analgesic and anti-inflammatory agents is in progress and will the subject of a future report.



Experimental

Melting points were determined using a Thomas–Hoover capilliary apparatus and are uncorrected. Nuclear magnetic resonance spectra (^{1}H NMR, ^{13}C NMR) were recorded on a Bruker AM-300 spectrometer. The assignment of ^{1}H NMR exchangeable protons (O*H*, N*H*) was confirmed by the addition of D_2O. ^{13}C NMR spectra were acquired using the *J* modulated spin echo technique where methyl and methine carbon resonances appear as positive peaks, and methylene and quaternary carbon resonances appear as negative peaks. Infrared (IR) spectra were acquired using a Nicolet 5DX-FT spectrometer. Exact Mass measurements (HRMS) were obtained using an AEI MS-50 mass spectrometer (electron impact). Column chromatography was performed using Merck 7734 (100–200 mesh) silica gel. Preparative thin-layer chromatography (PTLC) was carried out using Camag Kieselgel DF-5 plates, 1 mm in thickness, activated at 120°C overnight prior to use.

Tetrahydrofuran (THF) was dried over sodium benzophenone and distilled just prior to use. Phenylmagnesium chloride and tris[3-heptafluoropropylhydroxymethylene)-(+)-camphorato]-europium(III) [(+)-Eu(hfc)$_3$] were purchased from the Aldrich Chemical Co.

2-Methyl-2-[1-(3-benzoyl-4-phenyl-1,4-dihydropyridyl)]acetic acid methyl ester diastereomers (6)

A solution of 3-benzoylpyridine (**4**, 2.0 g, 10.9 mmol) and racemic methyl 2-bromopropionate (2.6 g, 16.4 mmol) in anhydrous acetone (20 mL) was heated at reflux for 8 h. After cooling to 25°C, the solid was filtered and dried to give the pyridinium bromide salt (**5**, 2.8 g, 73%), which was used immediately in the subsequent reaction. A mixture of **5** (1.64 g, 4.7 mmol) and cuprous iodide (89 mg, 0.47 mmol) in dry THF (25 mL) was stirred under a nitrogen atmosphere for 5 min at −23°C (Dry Ice – CCl_4 bath), a solution of PhMgCl (6.1 mmol) in THF (3.1 mL of a 2 M solution) was added dropwise, and the reaction mixture was maintained at −23°C for 30 min prior to warming to 25°C. The reaction mixture was stirred for a further 1.5 h before quenching by addition of saturated aqueous NH_4Cl (5 mL). Removal of the solvent in vacuo gave a residue that was extracted with EtOAc (25 mL), and the EtOAc extract was washed successively with solutions of 30% NH_4OH:saturated NH_4Cl (3:1, v/v; 3 × 15 mL) and then water (3 × 15 mL). The organic phase was dried ($MgSO_4$), and the solvent was removed in vacuo to yield a brown oil that was purified by elution from a silica gel column using EtOAc–hexane (1:2, v/v) as eluent to afford a mixture of four diastereomers of **6** (1.21 g, 74%) as a yellow oil. Recrystallization of this mixture of diastereomers **6** (1.11 g) from diethyl ether afforded a white solid (**6a-solid**, 0.45 g), mp 134–135°C. Removal of the solvent from the mother liquor yielded a pale yellow oil (**6b-oil**, 0.58 g).

6a-solid: Yield, 30.1%; IR (KBr) ν: 1745 (CO_2), 1671 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 7.15–7.50 (m, 10H, phenyl hydrogens), 6.95 (d, $J_{2,6}$ = 1.5 Hz, 1H, H-2), 6.02 (dd, $J_{5,6}$ = 7.8, $J_{2,6}$ = 1.5 Hz, 1H, H-6), 5.14 (dd, $J_{5,6}$ = 7.8, $J_{4,5}$ = 4.8 Hz, 1H, H-5), 4.87 (d, $J_{4,5}$ = 4.8 Hz, 1H, H-4), 4.00 (q, $J_{CH,Me}$ = 7.2 Hz, 1H, C*H*Me), 3.80 (s, 3H, O*Me*), 1.52 (d, $J_{CH,Me}$ = 7.2 Hz, 3H, CH*Me*); ^{13}C NMR ($CDCl_3$) δ: 194.55 (Ph*C*O), 171.28 (*C*O_2), 147.19 (phenyl C-1), 143.26 (C-2), 139.93 (benzoyl C-1), 130.20 (benzoyl C-4), 137.92–128.41 (other phenyl and benzoyl carbons), 126.16 (phenyl C-4), 124.49 (C-6), 113.99 (C-3), 110.53 (C-5), 60.42 (*C*HMe), 52.60 (O*C*H_3), 38.06 (C-4), 16.39 (CH*C*H_3). try. Addition of (+)-Eu(hfc)$_3$ (40 μL) to **6a-solid** separated the *Me*CH doublet at δ 1.52 into two doublets at δ 1.74 and 1.78, and the *Me*O singlet at δ 3.80 into two singlets at δ 3.97 and 4.0, respectively. A similar addition of (+)-Eu(hfc)$_3$ (40 μL) to **6b-oil** separated the *Me*CH doublet at δ 1.52 into two doublets at δ:1.74 and 1.76, and the *Me*O singlet at δ 3.79 into two singlets at δ 3.96 and 3.98, respectively.

2-Methyl-2-[1-(3-benzoyl-4-phenyl-1,4-dihydropyridyl)]acetic acid sodium diastereomers (7)

A solution of aqueous sodium hydroxide (4.2 mL of 0.56 N, 2.49 mmol) was added slowly with stirring to a solution of **6** (mixture of four diastereomers, 0.91 g, 2.62 mmol) in 95% EtOH:water (26:4, v/v) (30 mL) and the reaction was allowed to proceed at 25°C for 1 h. Removal of the solvent in vacuo gave a solid residue that was washed with dry diethyl ether (3 × 25 mL), and the pale yellow solid **7** (mixture of four diastereomers) was dried in vacuo at 25°C (0.85 g, 95%); mp 95–147°C; ^{1}H NMR (DMSO-d_6) δ: 7.09–7.46 (m, 11H, phenyl hydrogens, H-2), 6.11 (dd, $J_{5,6}$ = 7.6, $J_{4,5}$ = 3.2 Hz, 1H, H-6), 4.88–4.95 (m, 1H, H-5), 4.63–4.68 (m, 1H, H-4), 3.64–3.72 (m, 1H, C*H*Me), 1.22–1.27 (m, 3H, CH*Me*). The product **7** was characterized as the methyl ester **6**, which was prepared using the following procedure: An aliquot of product **7** (3 mg) was dissolved in methanol (2 mL), the pH of the solution was adjusted to 3 using HCl gas, and a solution of excess diazomethane in methanol was added at 25°C with stirring. When the evolution of nitrogen gas had ceased, the solvent was removed in vacuo to afford the methyl ester product **6**, in near quantitative yield, that was identical (^{1}H NMR) to the original product **6** described previously.

2-Methyl-2-[1-(3-benzoyl-4-phenyl-1,4-dihydropyridyl)]acetamide diastereomers (8)

A saturated solution of ammonia in MeOH (10 mL) was added to a solution of **6** (mixture of four diastereomers, 2.7 mmol) in MeOH (20 mL), the reaction flask was sealed with a rubber septum, and the reaction was allowed to proceed at 25°C for 48 h with stirring. Removal of the solvent in vacuo yielded a solid that was purified by preparative TLC using EtOAc–hexane (3:1, v/v) as development solvent. Extraction of the product band using EtOAc and removal of the solvent in vacuo gave **8** (mixture of four diastereomers) in 67% yield: mp 105–107°C; IR (KBr) ν: 3361 and 3301 (NH_2), 1730 (CONH), 1676 (CO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.22–7.40 (m, 10H, phenyl hydrogens), 7.02 and 7.04 (two d, $J_{2,6}$ = 1.5 Hz, 1H total, H-2), 6.14 and 5.75 (two s, 1H each, NH_2), 6.02 (dd, $J_{5,6}$ = 7.8, $J_{2,6}$ = 1.5 Hz, 1H, H-6), 5.18 (dd, $J_{5,6}$ = 7.8, $J_{4,5}$ = 4.8 Hz, 1H, H-6), 4.90 (d, $J_{4,5}$ = 4.8 Hz, 1H, H-4), 3.90 (q, J = 7.2 Hz, 1H, C*H*Me), 1.42 and 1.46 (two d, $J_{CH,Me}$ = 7.2 Hz, 3H total, CH*Me*). Exact Mass calcd. for $C_{21}H_{20}N_2O_2$: 332.1525; found (HRMS): 322.1526.

Calorimetric investigations of $Al^{3+}(aq)$, $Al(OH)_4^-(aq)$, and aluminum–citrate complexes at 298.15 K

Ching-hsien Wu, Celina Dobrogowska, Xin Zhang, and Loren G. Hepler

Abstract: We have combined results of earlier measurements leading to equilibrium constants for formation and reaction of aluminum–citrate complexes in aqueous solution at 298.15 K with results of our calorimetric measurements at this same temperature to obtain ΔH values for reactions of $Al^{3+}(aq)$ with citrate ions. Results of some of these calorimetric measurements also lead to a value of ΔH for the reaction $Al^{3+}(aq) + 4\ OH^-(aq) = Al(OH)_4^-(aq)$.

Key words: aluminum hydroxide, $Al(OH)_4^-(aq)$, thermodynamics; aluminum–citrate complexes, thermodynamics; citrate–aluminum complexes, thermodynamics; aluminum (3+, aq), thermodynamics.

Résumé : On a combiné les résultats de mesures effectuées antérieurement, conduisant à des constantes d'équilibre pour la formation et la réaction de complexes de citrate–aluminium en solutions aqueuses à 298,15 K, avec les résultats de nos mesures calorimétriques à la même température afin d'en déduire les valeurs de ΔH pour les réactions du $Al^{3+}(aq)$ avec les ions citrates. Les résultats de quelques-unes de ces mesures calorimétriques conduisent aussi à une valeur de ΔH pour la réaction : $Al^{3+}(aq) + 4\ OH^-(aq) = Al(OH)_4^-(aq)$.

Mots clés : thermodynamique, hydroxyde d'aluminium, $Al(OH)_4^-(aq)$, complexes de citrate–aluminium, aluminium(3+, aq).

[Traduit par la rédaction]

Introduction

Martin (1–4) has reviewed the biochemistry of aluminum, including some emphasis on the complexing of $Al^{3+}(aq)$ by citrate ions, which is important in the chemistry of blood and in the transport of aluminum through membranes. One of the purposes of this research has been to investigate the stoichiometry of reaction of one of the proposed aluminum–citrate complexes and also to obtain a ΔH value that can be used to calculate a corresponding ΔS° value.

There have been several equilibrium and calorimetric investigations intended to lead to the thermodynamic properties of $Al^{3+}(aq)$ and $Al(OH)_4^-(aq)$, which are of fundamental importance in the aqueous chemistry and geochemistry of aluminum. As reviewed by Hemingway and Robie (5), there are substantial differences between their recommended "best" values and those that have been reported elsewhere, such as in the useful tabulations from the US Bureau of Standards (6, 7). Another purpose of this research has been to obtain a value of ΔH for the reaction

[1] $Al^{3+}(aq) + 4\ OH^-(aq) = Al(OH)_4^-(aq)$

that can be used as part of a longer term effort to establish more reliable thermodynamic properties of $Al^{3+}(aq)$ and $Al(OH)_4^-(aq)$.

Experimental

Our calorimeter consisted of a glass Dewar vessel (360 cm^3) suspended in a brass can that was immersed in a constant temperature bath maintained at (25.00 ± 0.02)°C and held constant to ±0.001°C during each measurement. A small glass ampoule containing a solid or solution to be added to the solution in the calorimeter could be attached to the end of the stirrer and broken at an appropriate time to initiate the calorimetric reaction. The calorimeter was also fitted with a small-bore injection tube attached to a Metrohm automatic buret so that we could do titration calorimetry as in the research described here. Temperature changes in the calorimeter were measured with a thermistor (YSI 44005) combined with a resistance bridge (Guildline 9975). The calorimeter was calibrated electrically for each measurement. We have checked the accuracy of this calorimeter by way of test measurements of the enthalpy of solution of KCl, the enthalpy of solution of 4-aminopyridine in excess perchloric acid, the enthalpy of solution of THAM(cr) in excess hydrochloric acid, and the enthalpy of neutralization of THAM(aq) by hydrochloric acid. Results of all of these test measurements were in good agreement with the 'best' results from the literature (7–13).

Measurements of pH were carried out with an Accumet pH meter from Fisher Scientific and a combination glass-

reference electrode from Orion. Standard buffer solutions from Fisher were used for calibration.

Preparations and standardizations of solutions described below were all done by mass, which leads to compositions of solutions being described in terms of molalities, m (moles solute/kg of water).

Aluminum chloride hexahydrate, $AlCl_3 \cdot 6H_2O$, an ACS-certified reagent, was from Fisher Scientific. Two reagent grade (99% minimum assay) samples of sodium citrate dihydrate, $Na_3C_6H_5O_7 \cdot 2H_2O$, were from Matheson Coleman and Bell Manufacturing.

Carbonate-free sodium hydroxide solution was standardized by titration against potassium acid phthalate. Hydrochloric acid solution was then standardized by titration against the previously standardized sodium hydroxide solution.

A stock solution of aluminum chloride was prepared by dissolving aluminum chloride hexahydrate in dilute hydrochloric acid and was then standardized gravimetrically (14).

Our first calorimetric measurements were carried out to test earlier suggestions about stoichiometry of certain reactions and to establish conditions (amounts of NaOH needed) for subsequent measurements. The aluminum–citrate solutions placed in the calorimeter had initial pH = 7.00 and the stoichiometric compositions were Σ[Al] = 0.04303 m and Σ[citrate] = 0.1604 m. The experimental procedure involved relatively small incremental additions of NaOH solution to the aluminum–citrate solution in the calorimeter, with the enthalpy change associated with each addition being measured. This procedure of incremental addition of NaOH solution was continued for two additions after no more enthalpy of reaction was detectable.

To prepare solutions for our principal calorimetric measurements, we added known amounts of standardized hydrochloric acid to two aluminum–citrate solutions (prepared as described above) to obtain solutions having measured pH = 2.36. Stoichiometric compositions of these solutions were Σ[Al] = 7.769×10^{-3} m and Σ[citrate] = 7.985×10^{-3} m. Calorimetric measurements (duplicate runs) involved measuring the enthalpy change associated with adding an increment of standardized NaOH solution to the aluminum–citrate solution (pH = 2.36) in the calorimeter to obtain a solution having pH = 6.83. Next, without taking the calorimeter apart, we measured the enthalpy change associated with adding another increment of NaOH solution, leading to a final solution with pH = 11.8. The amounts of NaOH solution needed to achieve these changes in pH were established before doing the calorimetry by way of earlier titrations outside the calorimeter.

It should be noted that after each addition of NaOH (whether in small incremental additions or in bulk) to the aluminum–citrate solution in the calorimetric measurements, there appeared a slow drift of temperature and small pH changes after an instant, major change of temperature and pH of the solution. This observation is consistent with Ohman's finding (15) that in addition to the major aluminum–citrate species in the solution, there are other time-dependent, metastable species reaching a state of equilibrium. Since the equilibria of metastable species are much slower processes, this part of heats has been considered as a part of the temperature-drift correction in the treatment of data.

Table 1. Equilibrium constants and ΔH^0 values for ionization of aqueous citric acid and water at 298.15 K.

Reaction equation	pK^a	ΔH^0/kJ mol^{-1}

Results and calculations

Analysis of the results of our calorimetric results requires auxiliary information as follows.

Bates and Pinching (16) have reported pK values for all three ionizations of aqueous citric acid at 5° intervals over the range 0–50°C. Although there are good reasons for assigning large uncertainties to many ΔH^0 values derived from the temperature dependence of equilibrium constants, the pK values from Bates and Pinching are sufficiently accurate that their derived ΔH^0 values are also quite accurate. We have used results from Bates and Pinching, as summarized in Table 1.

Analysis of results of our calorimetric measurements has also required use of the accurately known (17) enthalpy of ionization of water, as given in Table 1.

Martin (2) has reviewed reported equilibria and corresponding equilibrium constants for the aluminum–citrate system, with his choices of most probable equilibria and equilibrium constants being largely based on the results that have been reported by Motekaitis and Martell (18). The conclusions based on Martin's analysis that are important for us are the following, where we follow usual practice in representing citric acid by H_3L. The principal aluminum species in our solutions at pH = 2.4 is $Al^{3+}(aq)$, the principal species at pH = 6.8 is traditionally represented by $(AlLH_{-1})^-(aq)$, and the principal species at pH > 9 is $Al(OH)_4^-(aq)$. We return later to explanation of what is meant by $(AlLH_{-1})^-$. Equations to represent the equilibria and corresponding equilibrium constants (from Martin) that are important for our solutions having pH = 6.8 are the following:

[2] $Al^{3+}(aq) + L^{3-}(aq) = AlL(aq)$ $\quad K_2 = 1.0 \times 10^8$

[3] $AlL(aq) = (AlLH_{-1})^-(aq) + H^+(aq)$ $\quad K_3 = 4.0 \times 10^{-4}$

Because the species represented by $(AlLH_{-1})^-$ is the principal aluminum–containing species at pH = 6.8, we combine eqs. [2] and [3] to obtain

[4] $Al^{3+}(aq) + L^{3-}(aq) = (AlLH_{-1})^-(aq) + H^+(aq)$ $\quad K_4 = 4.0 \times 10^4$

Before going on to use our calorimetric results for evaluation of ΔH_4, we consider the composition of the species represented by $(AlLH_{-1})^-$. The experimental results obtained by Motekaitis and Martell (18) showed that an important species is obtained by removal of H^+ from the electrically neutral species that is represented by AlL, but their results could not

© 1997 NRC Canada

provide structural information about AlL nor specify which hydrogen atom was lost as H^+. It was therefore reasonable to avoid this uncertainty by representing the negatively charged species as above, where H_{-1} indicates that one hydrogen has been removed. More recently, Martin (2) summarized evidence leading to the suggestion that the structure of the electrically neutral complex represented by AlL involves an Al^{3+} ion bound to the two end COO^- groups and the middle CO^- derived from citric acid. According to this picture, it might be best to represent citric acid by H_3LOH, which leads us to rewrite eq. [4] as follows:

[4*] $Al^{3+}(aq) + HOL^{3-}(aq) = AlLO^-(aq) + H^+(aq)$ $\quad K_4 = K_{4*}$

Although Martin (2) has summarized reasonable evidence (not proof) for the representation summarized above, there is another possible representation. It is well known that the aqueous aluminum ion "hydrolyzes" as often represented by

[5] $Al^{3+}(aq) + H_2O = AlOH^{2+}(aq) + H^+(aq)$

or, more realistically, by

[6] $Al^{3+}(H_2O)_n = [Al(OH)(H_2O)_{n-1}]^{2+} + H^+(aq)$

It is known that $\log K_5 = \log K_6 \approx -5$. We do not know of any report of a value of pK_4 for citric acid, but our electrochemical measurements (pH titration at high pH) show that pK_4 is at least as large as 14. It is therefore possible that the species represented by AlL involves bonding of Al^{3+} to three COO^- groups (in accord with the "ordinary" ionization of citric acid) and that the loss of H^+ from AlL is from a molecule of water bound to the aluminum ion. This picture leads to writing eq. [4] as

[4#] $Al(H_2O)^{3+}(aq) + L^{3-}(aq) = Al(OH)L^-(aq) + H^+(aq)$

in which we have included only one of the unknown number of molecules of water that are associated with aluminum in solution.

The equilibrium constant and the ΔH for the reaction being discussed do not depend on whether we choose to represent the reaction by eq. [4], [4*], or [4#]. This kind of choice cannot be made on the basis of thermodynamics. On the other hand, as will be shown, our calorimetric results do support the evidence from Motekaitis and Martell (18) that there is an aluminum–citrate species of the charge type specified in eq. [4], [4*], or [4#].

Two separate calorimetric measurements were made to obtain the enthalpy change associated with adding a known amount of sodium hydroxide solution to a known amount of solution of aluminum chloride, sodium citrate, and hydrochloric acid having pH = 2.36 to obtain a final solution having pH = 6.83. 'Correction' of the measured enthalpy change for reaction of $OH^-(aq)$ with $H^+(aq)$ and citric acid (using information in Table 1) and division by the number of moles of aluminum led to $\Delta H_4 = 42.6$ and 40.5 kJ mol^{-1} and thence to an average $\Delta H_4 = 41.6$ kJ mol^{-1}.

We combine this $\Delta H_4 = 41.6$ kJ mol^{-1} (ignoring the difference between ΔH and ΔH^o) with $\Delta G_4{}^0 = -26.3$ kJ mol^{-1} (calculated as $\Delta G^0 = -RT \ln K$) to obtain $\Delta S_4{}^0 = 228$ J K^{-1} mol^{-1}. Useful tests of the reality of chemical representation are often provided by comparing a ΔS^0 value obtained as above with whatever estimate of $\Delta S_4{}^0$ can be made on the basis of reliably known ΔS^0 values for more or less similar reactions. In this case, all that we can predict reliably is that the $\Delta S_4{}^0$ value is expected to be large and positive because the reaction represented by eq. [4] involves two highly charged species (+3 and −3) reacting to yield two less highly charged species (+1 and −1). This qualitative prediction of a large positive value is in accord with our $\Delta S_4{}^0 = 228$ J K^{-1} mol^{-1}.

As explained in the experimental section, our calorimetric procedure involved adding enough NaOH solution to the aluminum–citrate solution in the calorimeter to obtain a solution with pH = 6.83. The results of two separate calorimetric measurements of this kind have led to the $\Delta H_4 = 41.6$ kJ mol^{-1} cited above. Next, without taking the calorimeter apart or removing any solution, we added more NaOH solution to each of these solutions with pH = 6.83 to obtain final solutions with pH = 11.8. Equations to represent this latter reaction in the calorimeter are the following:

[5] $(AlLH_{-1})^-(aq) + 3\ OH^-(aq) + H_2O = Al(OH)_4{}^-(aq) + L^{3-}(aq)$

[5*] $AlLO^-(aq) + 3\ OH^-(aq) + H_2O = Al(OH)_4{}^-(aq) + HOL^{3-}(aq)$

[5#] $Al(OH)L^-(aq) + 3\ OH^-(aq) = Al(OH)_4{}^-(aq) + L^{3-}(aq)$

Because each of these equations is merely a different way of representing the same reaction, we have only one enthalpy of reaction, which we label ΔH_5. Our two independent measurements led to $\Delta H_5 = -28.8$ and -29.5 kJ mol^{-1}. We use the average $\Delta H_5 = -29.2$ kJ mol^{-1} for further calculations.

Reaction equations [5], [5*], and [5#] all indicate that only three $OH^-(aq)$ are required to form $Al(OH)_4{}^-(aq)$ from the aluminum–citrate complex that has charge −1. This (possibly surprising) indication that is based on appropriate balancing of reaction equations has been confirmed directly by the calorimetric measurements (small incremental titrations, as described in the seventh paragraph of the Experimental section), which showed clearly that the reaction to form $Al(OH)_4{}^-(aq)$ was complete after only three moles of hydroxide had been added for every mole of aluminum in the solution. The calorimetric results therefore provide support for the conclusion of Motekaitis and Martell (18) that the principal species at pH = 6.8 is the aluminum–citrate complex that was originally represented by $(AlLH_{-1})^-$, which can also be represented by $AlLO^-$ or by $Al(OH)L^-$.

The sum of the reactions represented by eqs. [4] and [5] with $H^+(aq) + OH^-(aq) = H_2O$ gives the reaction of $Al^{3+}(aq)$ with 4 $OH^-(aq)$ to form $Al(OH)_4{}^-(aq)$ as in eq. [1]. Similarly, we may add eq. {[4*] + [5*]} or {[4#] + [5#]} with $H^+(aq) + OH^-(aq) = H_2O$ to obtain eq. [1] for formation of $Al(OH)_4{}^-(aq)$ from $Al^{3+}(aq)$. It follows that

[7] $\Delta H_1 = \Delta H_4 + \Delta H_5 - \Delta H_w$

in which ΔH_w represents the enthalpy of ionization of water (Table 1). In this fashion we obtain $\Delta H_1 = 41.6 - 29.2 - 55.8 = -43.4$ kJ mol^{-1}.

In Table 2 we list some standard enthalpies of formation ($\Delta_f H^0$) of $Al^{3+}(aq)$ and $Al(OH)_4{}^-(aq)$ as taken from several

Table 2. Standard enthalpies of formation ($\Delta_f H^0$) of $Al^{3+}(aq)$ and $Al(OH)_4^-(aq)$ at 298.15 K.

$\Delta_f H^0$ of $Al^{3+}(aq)$/kJ mol^{-1}	$\Delta_f H^0$ of $Al(OH)_4^-(aq)$/kJ mol^{-1}
−524.7[a]	−1486.3[b]
−531[c]	−1502.6[d]
−538.25[e]	−1496.1[f]
	−1502.8[g]
	−1503.65[h]

[a]Reference 6.
[b]Reference 6 lists $\Delta_f H^0$ = −218.6 kcal mol^{-1} for $AlO_2^-(aq)$, which is equivalent to −1486.3 kJ mol^{-1} for $Al(OH)_4^-(aq)$.
[c]Reference 7.
[d]Reference 7 lists $\Delta_f H^0$ = −930.9 kJ mol^{-1} for $AlO_2^-(aq)$, which is equivalent to −1502.6 kJ mol^{-1} for $Al(OH)_4^-(aq)$.
[e]Reference 21.

[g]Reference 20.
[h]Reference 22.

sources. Combination of these values with $\Delta_f H^0 = -229.994$ kJ mol^{-1} for $OH^-(aq)$ from ref. 7 leads to calculated values of ΔH_1 that range from −35 to −58 kJ mol^{-1}, whereas we have found $\Delta H_1 = -43.4$ kJ mol^{-1}, with uncertainty that we estimate (considering enthalpies of dilution that we have ignored and the probable uncertainties in our calorimetric results) to be ±2 kJ mol^{-1}. If we use the recent values reported by Chen that $\Delta_f H^0 = -538.25$ kJ mol^{-1} for $Al^{3+}(aq)$ (21) and $\Delta_f H^0 = -1503.65$ kJ mol^{-1} for $Al(OH)_4^-(aq)$ (22), and combine them with $\Delta_f H^0 = -229.994$ kJ mol^{-1} for $OH^-(aq)$ from ref. 7, ΔH_1 would be −45.4 kJ mol^{-1}. This value is in good agreement with our $\Delta H_1 = -43.4$ kJ mol^{-1}, given the uncertainty inherent to our indirect and unconventional method. Pinning down the "best" $\Delta_f H^0$ values for $Al^{3+}(aq)$ and $Al(OH)_4^-(aq)$ requires complicated considerations of our value for ΔH_1 along with the thermodynamic properties of $Al(OH)_3$(gibbsite) and several other compounds of aluminum, which must be a subject for further research.

Rate constants for the reaction of the hydrogen atom with aliphatic ketones in water[1]

Stephen P. Mezyk, Annett Lossack, and David M. Bartels

Abstract: Arrhenius parameters for the reaction of hydrogen atoms with 3-methyl-2-butanone, 3-pentanone, cyclopentanone, 4-methyl-2-pentanone, and 2-butanone in aqueous solution have been directly calculated from electron paramagnetic resonance free induction decay (FID) attenuation measurements. For these compounds, absolute scavenging rate constants at 25.0°C of $(8.84 \pm 0.26) \times 10^7$, $(4.20 \pm 0.15) \times 10^7$, $(4.91 \pm 0.28) \times 10^7$, $(3.25 \pm 0.27) \times 10^7$, and $(2.20 \pm 0.32) \times 10^7$ dm^3 mol^{-1} s^{-1}, with corresponding activation energies of 17.43 ± 0.29, 20.69 ± 0.31, 18.73 ± 0.36, 22.24 ± 0.80, and 22.30 ± 1.04 kJ mol^{-1} were determined, respectively. Competition kinetic measurements based on total H_2 yields have established that for all of these ketones the dominant hydrogen atom reaction path is by $^{\cdot}$H atom abstraction. The new activation energy for 2-butanone is much lower than the previously reported value of 40.1 ± 0.7 kJ mol^{-1} with this difference attributed to interfering reactions from the added bromide previously used as a hydroxyl radical scavenger.

Key words: Arrhenius, kinetics, hydrogen atom, aqueous, ketones.

Résumé : En se basant sur des mesures d'atténuation de la décroissance de l'induction libre («FID») en résonance paramagnétique électronique, on a calculé directement les paramètres d'Arrhenius pour les réactions des atomes d'hydrogène avec les 3-méthylbutan-2-one, pentan-3-one, 4-méthylpentan-2-one et butan-2-one en solution aqueuse. Pour ces composés, on a déterminé que les constantes absolues de vitesse de piégeage, à 25°C, sont respectivement : $(8{,}84 \pm 0{,}26) \times 10^7$, $(4{,}20 \pm 0{,}15) \times 10^7$, $(4{,}91 \pm 0{,}28) \times 10^7$, $(3{,}25 \pm 0{,}27) \times 10^7$ et $(2{,}20 \pm 0{,}32) \times 10^7$ dm^3 mol^{-1} s^{-1}; ceci correspond à des énergies d'activation de 17,43 ± 0,29, 20,69 ± 0,31, 18,73 ± 0,36, 22,24 ± 0,80 et 22,30 ± 1,04 kJ mol^{-1} respectivement. Des mesures cinétiques en compétition basées sur les rendements globaux de H_2 ont permis d'établir que, pour chacune de ces cétones, la voie principale de réaction de l'atome d'hydrogène implique un enlèvement d'atome d'hydrogène. La nouvelle énergie d'activation pour la butan-2-one est beaucoup plus faible que la valeur de 40,1 ± 0,7 kJ mol^{-1} mesurée antérieurement; on attribue cette différence à des réactions d'interférence de la part du brome ajouté comme piège à radical dans le travail antérieur.

Mots clés : Arrhenius, cinétique, atome d'hydrogène, aqueux, cétones.

[Traduit par la rédaction]

Introduction

In a recent study (1), Arrhenius parameters for hydrogen atom reaction with acetone and 2-butanone in aqueous solution were determined. This work was part of a continuing investigation into the mechanisms of volatile iodine-species formation following a severe loss-of-coolant nuclear accident, a scenario of major concern to the nuclear reactor industry because radioactive iodine is one of the most hazardous fission products that could be released to the environment (2). Although the initial release of radioactive iodine into a containment building should be in the nonvolatile iodide form (3, 4), the presence of high radiation fields and elevated temperatures enhances the formation of volatile species such as low molecular weight iodoalkanes (5).

It has been demonstrated that one of the major sources of organics within containment arises from the leaching of paint solvents from the walls inside the building (6). This can give aqueous organic concentrations in the millimolar range. To understand iodoalkane formation under such conditions, a systematic program (7) utilizing steady-state radiolysis of the prototypical organic paint solvent 2-butanone in aqueous solution was undertaken. This and other related work (8) has shown that a large number of product species are produced, and a complete understanding of the process can only be obtained by detailed computer modeling. Such modeling is dependent on having rate constant data for the aqueous radiolysis species reaction with 2-butanone and its subsequent degradation products.

As few hydrogen atom rate constants for these reactions were available in the literature (9, 10), rates were determined for $^{\cdot}$H atom reaction with 2-butanone, propanal, acetone, and

butyraldehyde as a function of temperature (1). The reactions with the ketones 2-butanone and acetone were characterized by activation energies of 40.1 and 30.7 kJ mol^{-1}, respectively. From previous direct measurements of the H_2 yield produced in the steady-state irradiation of acidic acetone solutions (11), it was shown that the hydrogen atom reaction pathways

[1] $^{\cdot}H + CH_3COCH_3 \rightarrow H_2 + {}^{\cdot}CH_2COCH_3$

[2] $^{\cdot}H + CH_3COCH_3 \rightarrow CH_3CO{}^{\cdot}HCH_3$

have a branching ratio of 2.0:1. For 2-butanone it was shown that the hydrogen atom reaction is almost quantitative abstraction (1).

The higher activation energy for hydrogen atom reaction with 2-butanone was very surprising, especially since the reaction is also much faster than with acetone. Hydrogen atom abstraction from 2-butanone is expected to occur at the methylene group, and based on the order of the gas phase activation energies for $^{\cdot}H$ atom abstraction from these two compounds (12), and on the fact that the methylene group C—H bond is weaker and the secondary carbon radical has greater stability (13), one expects a lower activation energy than for acetone.

To explain this experimental result, the higher activation energy for 2-butanone was attributed to a specific effect of solvation that provided a large degree of entropic compensation for the higher energy abstraction process. Two possible concerted reactions were postulated: either that abstraction at the methylene group stimulated the hydration of the carbonyl bond, which has been shown to give a positive entropy change for reaction with substituted acetones (14), or that reaction with 2-butanone occurred by abstraction from the terminal methyl group that was aided by a simultaneous keto–enol conversion involving a water molecule within the solvation shell to transform the terminal methyl groups into allylic positions, with much weaker C—H bonds (12, 15). Subsequent to publication of ref. 1, direct time-resolved EPR observation of the product showed it to be the expected radical at the methylene carbon.[4]

To obtain further insight into this reaction, and to establish whether 2-butanone can be used as a prototypical ketone for applied modeling studies, further hydrogen atom reaction experiments have been performed using the ketones 3-methyl-2-butanone (methyl isopropyl ketone), 3-pentanone (diethyl ketone), cyclopentanone, and 4-methyl-2-pentanone (methyl isobutyl ketone) in aqueous solution. These compounds were chosen to characterize the influence of position and number of methylene groups on the activation energy. Because of its great specificity, direct EPR detection of the decay of the $^{\cdot}H$ atom following electron pulse radiolysis was again used in this study (16, 17); the pulsed EPR-based free induction decay (FID) attenuation method (18–23) is particularly advantageous for these measurements because of the simple pseudo-first-order kinetics obtained.

Experimental

The experimental procedure for determining $^{\cdot}H$ atom reaction rate constants using this technique has been described in detail in several previous publications (18–21), and thus only a short description will be given here. Hydrogen atoms were generated in aqueous solution using 3 MeV electrons from a Van de Graaff accelerator. A microwave probe pulse was applied to the sample immediately after irradiation, and the resulting free induction decay of the $^{\cdot}H$ atom low-field EPR transition was recorded on a digital oscilloscope. Typically, 500–2000 pulses were averaged to measure each FID trace, at a repetition rate of 120 Hz.

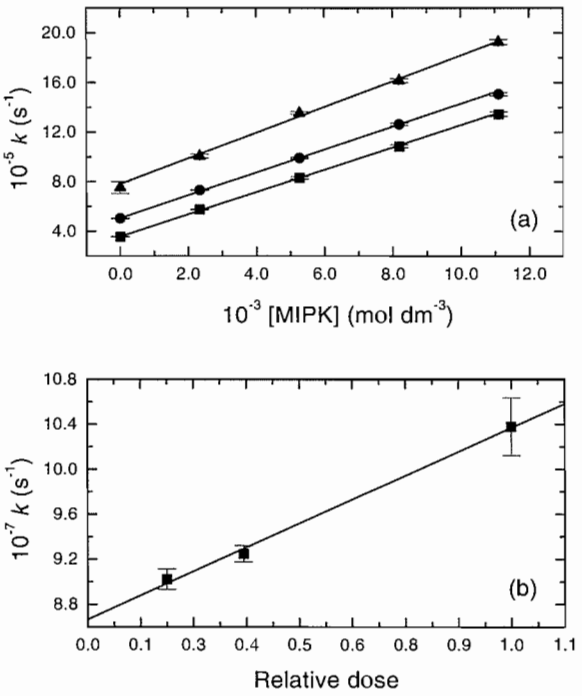
All measurements were performed in acidic solution, to increase the initial yield of hydrogen atoms. Stock acid solutions (pH 1.0 and 2.0) were prepared by addition of $HClO_4$ (Mallinkrodt, A. R. Grade, 69.05%) to Millipore filtered water. Actual acid concentrations were determined by standardization of the concentrated acid against 1.029 N HCl (Aldrich, Volumetric Standard). A total aqueous sample of ~190 mL was recirculated through a flat cell within an EPR cavity, at a rate sufficient to ensure that each cell volume was replaced between pulses (the actual volume irradiated in each pulse was less than 0.1 mL).

Scavenging experiments were performed by the successive injection of known volumes of the ketone to the initial known volume of solution that had been fully deoxygenated by bubbling with argon. All of the ketones used in this study were from Aldrich, of the highest purity available, and used as received. Accuracy of the concentrations is estimated at better than 3%.

In the previous ketone experiments using this technique (1), it was observed that the measured scavenging rate constants were slightly dependent on the radiation dose used. This phenomenon was also found in the present study, as shown in Fig. 1*a* for hydrogen atom reaction with 3-methyl-2-butanone at 24.0°C. The general expression of the effective damping rate of the FID in these experiments is given by (18–21)

$$[3] \quad \frac{1}{T_2(\text{eff})} = \frac{1}{T_2^0} + k_s[S] + \Sigma k_{ex}^i[R_i]$$

where $k_s[S]$ is the $^{\cdot}H$ atom scavenging rate and $\Sigma k_{ex}^i[R_i]$ represents the spin-dephasing contribution of the second-order spin exchange and recombination reactions between $^{\cdot}H$ atoms and other free radicals. The latter term in eq. [3] is responsible for the shift in the intercept seen in Fig. 1*a*, as the total free radical concentration $\Sigma[R_i]$ increases. The scavenging reaction converts the hydrogen atoms into other free radicals, and the corresponding change in k_{ex}^i during the 5 μs experimental time period is responsible for the small change in the slopes. The systematic error due to this second-order chemistry can be avoided either by working with a very small $^{\cdot}H$ atom concentration, or by extrapolation to a "zero dose" limit.



The technique used in this study was extrapolation to zero dose. The actual rate constants for hydrogen atom reaction with 3-methyl-2-butanone at this temperature, obtained from the second-order slopes of the data shown in Fig. 1*a*, were $(9.02 \pm 0.09) \times 10^7$, $(9.25 \pm 0.07) \times 10^7$, and $(1.04 \pm 0.03) \times 10^8$ dm^3 mol^{-1} s^{-1} for the 12, 25, and 55 ns pulse widths, respectively. These pulses corresponded to relative doses of 3.0, 5.9, and 16.0, where an absolute dose of approximately 3.0 krad/pulse was estimated for the 25 ns width. The relative values were simply the measurements of the average beam current on a shutter positioned before the irradiation cell, and

Fig. 1. (*a*) Dose dependence of the hydrogen atom scavenging rate constants for methyl isopropyl ketone (MIPK) at pH 2.0 and 24.0°C. Solid lines correspond to fitted values of $(9.02 \pm 0.09) \times 10^7$ (■), $(9.25 \pm 0.07) \times 10^7$ (●), and $(1.04 \pm 0.03) \times 10^8$ (▲) dm^3 mol^{-1} s^{-1} for Van de Graaff pulse widths of 12, 25, and 55 ns, respectively. (*b*) Rate constant extrapolation to "zero dose" for methyl isopropyl ketone at pH 2.0 and 24.0°C, to give a limiting value of $k = (8.67 \pm 0.06) \times 10^7$ dm^3 mol^{-1} s^{-1}. Error bars correspond to one standard deviation obtained from weighted linear fit to scavenging plots.

were assumed to be proportional to the actual dose given to the sample. The beam current was monitored frequently to allow for any slight drift.

The extrapolation of these dose-dependent rate constants to zero dose is shown in Fig. 1*b*. A very good linear relationship is obtained, with a limiting, zero-dose, rate constant of $(8.67 \pm 0.06) \times 10^7$ dm^3 mol^{-1} s^{-1}. This behavior was consistent for all of the systems of this study.

For some of the highest temperatures investigated, where ketone concentrations were smallest, scavenging rate constants were obtained only using the 25 ns pulse. Values measured using the 12 ns pulse width under these conditions were extremely noisy and not reproducible, while those measured using the 55 ns pulse showed effects attributable to substrate depletion. For these single dose points the measured value with the 25 ns pulse was "corrected" to zero dose by multiplying by the average ratio of the extrapolated and 25 ns measured rate constants determined at lower temperatures. Larger error bars were included on these points, to allow for the inherent lack of precision in this extrapolation method.

Total hydrogen yield measurements were also performed for these ketones to determine the fractions of addition and abstraction for hydrogen atom reaction with these compounds. Stock solutions of 0.10 mol dm^{-3} $HClO_4$ containing 0.10 mol dm^{-3} methanol were saturated with argon before injecting sufficient ketone to allow equal reaction between the two organics calculated from their relative rate constants of hydrogen atom reaction at 28°C (see later). These samples were irradiated using a 10 MeV e-beam from an I-10/1 electron accelerator, with dosimetry performed using Far West Technologies radiochromic dye film.[5] The H_2 gas analyses were performed using a VG Instruments MM 8-80 magnetic sector mass spectrometer.

Results and discussion

Reaction with methyl isopropyl ketone

To obtain further insight into the possible mechanisms for hydrogen atom reaction with methyl ethyl ketone it was decided to investigate reactions with geometrically similar compounds. One of the simplest analogues of methyl ethyl ketone is methyl isopropyl ketone. The hydrogen atom reaction with this compound is expected to be abstraction of the tertiary hydrogen

[4] $^{\cdot}H + CH_3COCH(CH_3)_2 \rightarrow H_2 + CH_3COC^{\cdot}(CH_3)_2$

producing a carbon-centered radical adjacent to the carbonyl group.

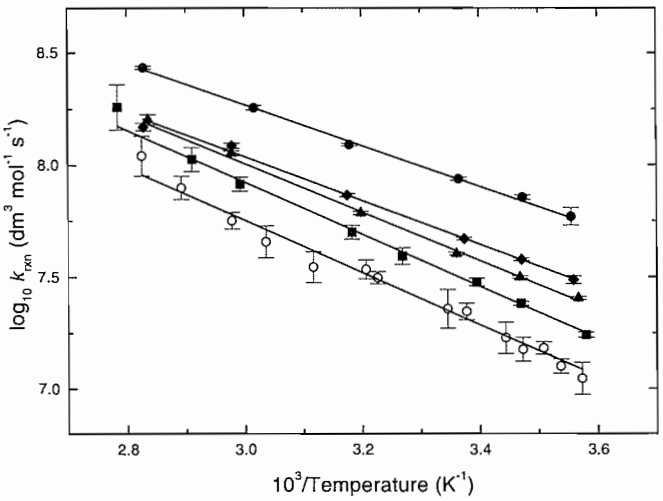
From the kinetic data shown in Fig. 1, the extrapolated reaction rate constant for methyl isopropyl ketone at 24.0°C is $k_4 = (8.67 \pm 0.06) \times 10^7$ dm^3 mol^{-1} s^{-1}, about a factor of two higher than the hydrogen atom reaction with methyl ethyl ketone, $k = (3.82 \pm 0.32) \times 10^7$ dm^3 mol^{-1} s^{-1} at 25.0°C (1). Over the temperature range 8.1–80.4°C the rate constant was found to be well described by the equation

[5] $\log_{10} k_4 = (11.00 \pm 0.05) - [(17\,430 \pm 290)/2.303\,RT]$

(units of dm^3 mol^{-1} s^{-1} and K for k_4 and T, respectively), which corresponds to an activation energy of 17.43 ± 0.29 kJ mol^{-1}. This number is over a factor of two smaller than originally measured for methyl ethyl ketone (40.1 ± 0.7 kJ mol^{-1}), a difference much greater than can be attributed to the additional stability of the tertiary carbon radical product for the larger ketone. The pre-exponential factor of 1.00×10^{11} dm^3 mol^{-1} s^{-1} is also much lower than originally obtained for methyl ethyl ketone (4.4×10^{14} dm^3 mol^{-1} s^{-1}). All of the individual rate constants measured for methyl isopropyl ketone are listed in Table 1, and shown in comparison to the measured data for acetone and methyl ethyl ketone in Fig. 2.

Reaction with diethyl ketone

As the reaction of aqueous hydrogen atoms with methyl isopropyl ketone gave very different Arrhenius parameters from methyl ethyl ketone, it was decided to investigate the hydrogen atom reaction with a ketone containing intact methylene groups, using the compound diethyl ketone. The reaction anticipated here should be analogous to the methyl ethyl ketone reaction,



[6] $^{\cdot}H + CH_3CH_2COCH_2CH_3 \rightarrow H_2 + CH_3CH_2CO^{\cdot}CHCH_3$

[5] Far West Technology, Inc., Goleta, CA 93117, U.S.A.

Fig. 2. Arrhenius plot for methyl isopropyl ketone (●), diethyl ketone (▲), cyclopentanone (◆), and methyl isobutyl ketone (■) in comparison to the revised values for methyl ethyl ketone (○). Solid lines are fitted values of equations as given in text.

with symmetry, as well as gas phase reaction data (12), suggesting that similar Arrhenius parameters should be obtained. The EPR measurements for this compound at 24.4°C gave an extrapolated rate constant of $k_6 = (4.01 \pm 0.05) \times 10^7$ dm^3 mol^{-1} s^{-1}, which is almost identical to our original value for methyl ethyl ketone at this temperature. However, when these measurements were repeated over the range 7.1–79.4°C the overall temperature dependence was found to be well described by the equation

[7] $\log_{10} k_6 = (11.24 \pm 0.06) - [(20\,690 \pm 310)/2.303\,RT]$

(the rate constants are given in Table 1 and shown in Fig. 2). The activation energy of 20.69 ± 0.31 kJ mol^{-1} is much lower than previously obtained for methyl ethyl ketone.

Reaction with cyclopentanone

Analogous hydrogen atom reaction measurements were also undertaken with cyclopentanone

[8] $^{\cdot}H + c\text{-}(CH_2)_4CO \rightarrow H_2 + c(CH_2)_3{}^{\cdot}CHCO$

which only has methylene groups adjacent to the carbonyl bond. The extrapolated rate constant at 23.2°C was determined as $k_8 = (4.68 \pm 0.07) \times 10^7$ dm^3 mol^{-1} s^{-1} and, over the range 7.8–80.5°C, the temperature-dependent rate constants were found to be well predicted by the equation

[9] $\log_{10} k_8 = (10.97 \pm 0.06) - [(18\,730 \pm 360)/2.303\,RT]$

with individual rate constants again given in Table 1 and shown in Fig. 2. Both the activation energy of 18.73 ± 0.36 kJ mol^{-1} and the pre-exponential factor are in very good agreement with the values obtained for methyl isopropyl ketone, similar to those for diethyl ketone, and again much lower than the values originally measured for methyl ethyl ketone.

Table 1. Summary of zero-dose-extrapolated, temperature-dependent rate constants for hydrogen atom reaction with methyl isopropyl ketone, diethyl ketone, cyclopentanone, methyl isobutyl ketone, and methyl ethyl ketone in aqueous solution.

Reaction with methyl isobutyl ketone

The smaller Arrhenius parameter values obtained for the first three ketones in this study suggested that the presence of the α-methyl group in methyl ethyl ketone has an important role in the overall reaction mechanism. The fourth ketone investigated in this study was methyl isobutyl ketone, which incorporates the full geometry of methyl ethyl ketone,

[10] $^{\cdot}H + CH_3COCH_2CH(CH_3)_2 \rightarrow$ products

For this ketone hydrogen abstraction could occur both at the secondary and tertiary carbon hydrogens, the former pathway

For personal use only.

being identical to the reaction with methyl ethyl ketone. Measurements performed over the temperature range 6.2–86.0°C were again found to have excellent Arrhenius behavior, and to be fitted by the equation

[11] $\log_{10} k_{10} = (11.41 \pm 0.14) - [(22\,240 \pm 800)/2.303\,RT]$

(see individual rate constant data in Fig. 2 and Table 1). This corresponds to a room temperature (22°C) value of $k_{10} = (2.98 \pm 0.25) \times 10^7$ dm^3 mol^{-1} s^{-1}, again similar to the value measured for methyl ethyl ketone. The activation energy of 22.24 ± 0.80 kJ mol^{-1} is again much lower than originally found for methyl ethyl ketone, but consistent with the other ketone measurements of this study.

Yield measurements

The ·H atom reaction with all four of the ketones measured in this study showed essentially the same Arrhenius parameters, with minor differences attributable to the slight variations in stability in the different carbon-centered radicals formed. None of these systems gave Arrhenius values close to those originally measured for methyl ethyl ketone, suggesting that the ·H atom reaction mechanism with this latter ketone is very different. One can also eliminate differences due to the direct reaction with the enol form of all of these ketones, as they all have extremely small (ca. 10^{-8}) enol fractions in aqueous solution (24). Likewise, reaction with an impurity can also be rejected.

To confirm the hydrogen atom abstraction mechanism, total H_2 gas yield measurements were also performed for these compounds. The technique used for these measurements was e-beam irradiation and mass spectrometry analysis. Preliminary tests showed that the temperature of the irradiated 100 mL aqueous samples was raised to 28°C by passage through the e-beam. Ketones were added to the methanol–acid solutions in sufficient concentration to allow the ·H atoms produced, both directly and by the reaction of the hydrated electrons with H^+, to react with the methanol and ketone in a 1.0:1.0 ratio at this temperature (1, 25). Acetone and methyl ethyl ketone were also included in these experiments to ensure the validity of the technique.

The H_2 yield from only the methanol–acid blank was found to be $G = 4.01 \pm 0.09$ (no. of molecules/100 eV). This yield corresponds to quantitative abstraction; subtracting the fundamental molecular yield of H_2 ($G = 0.41$ (26)) from this value gives $G(\cdot H) = 3.60 \pm 0.09$, which represents the yield of ·H atoms directly produced ($G \sim 0.6$) from the direct radiolysis of water and the initial yield of hydrated electrons in the presence of a high concentration of intra-spur scavenger such as 0.10 mol dm^{-3} methanol (27).

Quantitative H_2 yields for all the ketone systems were calculated relative to this methanol–acid value. Acetone was found to have $G(H_2) = 3.02 \pm 0.11$, which corresponds to an abstraction efficiency of 67.8 ± 3.7%, in excellent agreement with previous determinations of 67% (11, 28). *All* of the other ketones showed quantitative H_2 production.

Reaction with methyl ethyl ketone

As no convincing argument could be found to explain a higher activation energy for methyl ethyl ketone relative to the other ketones of this study it was decided to repeat this compound in this work. These experiments were performed as for all of the other ketones investigated in this study. For the expected reaction

[12] $\cdot H + CH_3COCH_2CH_3 \rightarrow H_2 + CH_3CO\cdot CHCH_3$

the initial measurement at 22.9°C gave a zero-dose-extrapolated value of $k_{12} = (2.22 \pm 0.20) \times 10^7$ dm^3 mol^{-1} s^{-1}, about 40% slower than previously measured at this temperature, $k = (3.82 \pm 0.32) \times 10^7$ dm^3 mol^{-1} s^{-1}. By repeating these measurements over the temperature range 6.7–80.8°C, the individual rate constants given in Table 1 and shown in Fig. 2 were obtained, and were found to be well described by the equation

[13] $\log k_{12} = (11.25 \pm 0.18) - [(22\,300 \pm 1000)/2.303\,RT]$

The activation energy, 22.3 ± 1.0 kJ mol^{-1}, and pre-exponential factor are in very good agreement with the values measured for the other ketones of this study, and much lower than previously determined.

While the newfound agreement between methyl ethyl ketone and the other ketones is gratifying, an explanation for our previous, high, Arrhenius parameters is also necessary. Given that the same bottle of methyl ethyl ketone was used in both experiments, this was not the source of the discrepancy. A close examination of original data books showed that the only difference between the two experiments was in the hydroxyl radical scavenger used; for the current experiments 0.02 mol dm^{-3} methanol was added to the system whereas previously the same concentration of bromide ion was used (9).

The reason for the original high activation energy has not been confirmed, but is believed to be due to the chemistry of bromide in an irradiation field. While the added bromide was an efficient and nonvolatile hydroxyl radical scavenger, its subsequent chemistry might produce Br_2 in solution, via reactions such as

[14] $\cdot OH + Br^- \rightarrow BrOH^{\cdot -}$

[15] $BrOH^{\cdot -} \rightarrow Br\cdot + OH^-$

[16] $Br\cdot + Br^- \rightleftharpoons Br_2^{\cdot -}$

[17] $2\,Br_2^{\cdot -} \rightleftharpoons Br_3^- + Br^-$

[18] $Br_3^- \rightleftharpoons Br^- + Br_2$

The presence of Br_2 and methyl ethyl ketone in acidic solution could allow an acid-catalyzed thermal bromination reaction to occur in the solution reservoir (13),

[19] $Br_2 + CH_3COCH_2CH_3 \xrightarrow{H^+} CH_3COCHBrCH_3 + HBr$

Reaction of the ·H atom with this brominated compound

[20] $\cdot H + CH_3COCHBrCH_3 \rightarrow HBr + CH_3CO\cdot CHCH_3$

would give an artificial increase in the scavenging rate constants measured previously. In fact, because hydrogen atom reaction with brominated compounds is nearly diffusion

For personal use only.

controlled (9), essentially *all* subsequent ·H atom reaction might occur by reaction with this compound, not with methyl ethyl ketone. The activation energy of 40 kJ mol^{-1} previously measured would therefore correspond to the thermal reaction producing this species in the reservoir between the successive injections of the ketone. Given the routine nature of this experiment the time between injections was nearly constant and this background chemistry was missed.

A search of the literature failed to discover any experimental measurements for the thermal activation energy of the bromination process for 2-butanone under acidic conditions. One previous study (29), which looked at thermal iodonation of 2-butanone at 25.0 and 33.4°C (the 25°C rate constant for iodonation and bromination being very similar (29) in neutral solution) reported a 40% increase in the measured rate over this (admittedly small) temperature range. Assuming that solvent differences are not important (the higher temperature measurement was performed in D_2O, the lower in H_2O) then this difference corresponds to an activation energy of ca. 40 kJ mol^{-1}, consistent with our original determination.

In our previous study (1) bromide was only used in the methyl ethyl ketone and butyraldehyde measurements, and so the Arrhenius parameters reported for acetone and propanal are considered correct. The measured activation energy for butyraldehyde is very similar to that determined for propanal, and therefore it is believed that the bromide interference observed for methyl ethyl ketone is not important in the butyraldehyde experiments.

Conclusion

The temperature-dependent FID rate constant measurements of hydrogen atom reactions with methyl isopropyl ketone, diethyl ketone, cyclopentanone, and methyl isobutyl ketone in aqueous solution were found to be given by the equations

[5] $\log_{10} k_4 = (11.00 \pm 0.05) - [(17\,430 \pm 290)/2.303\,RT]$

[7] $\log_{10} k_6 = (11.24 \pm 0.06) - [(20\,690 \pm 310)/2.303\,RT]$

[9] $\log_{10} k_8 = (10.97 \pm 0.06) - [(18\,730 \pm 360)/2.303\,RT]$

[11] $\log_{10} k_{10} = (11.41 \pm 0.14) - [(22\,240 \pm 800)/2.303\,RT]$

respectively. The similarity of the activation energies and pre-exponential factors of these four ketones suggests that the model of hydrogen atom reaction is the same for all four compounds and, based on the results of H_2 yield measurements, is attributed to essentially quantitative ·H atom abstraction from these compounds. Further corroboration of this mechanism is given by the magnitude of the pre-exponential factors ($\log A$ = 11.0–11.4), these values being in the range expected for simple hydrogen atom abstraction. Upon remeasurement of the Arrhenius parameters for methyl ethyl ketone, a consistent temperature behavior described by

[13] $\log k_{12} = (11.25 \pm 0.18) - [(22\,300 \pm 1000)/2.303\,RT]$

was obtained. The original higher values are attributed to interfering background chemistry resulting from the added bromide used as a hydroxyl radical scavenger in ref. 1.

Acknowledgments

The authors would like to thank Dr. David Werst for his assistance in operating and maintaining the Van de Graaff accelerator. We would also like to thank Mr. R. MacFarlane and Mr. H.G. Delaney for performing the H_2 yield measurements and Drs. D.C. Walker and E. Roduner for helpful discussions throughout the course of this study.

Abstract: Phenylalanine is the simplest among the four natural amino acid residues that have aromatic side chains. The ab initio conformational analysis performed at the RHF/3-21G level on a phenylalanine-containing diamide model system (*N*-Formyl-L-Phe-NH_2) revealed 19 different structures. Single-point energy calculations were performed using RHF/6-31+G* and DFT(B3LYP)/6-311++G** levels for all conformers. The inverse (γ_L) and the normal (γ_D) gamma turn, the extended (β_L), the left-handed helical (α_D [$\phi \approx +60°$, $\psi \approx +60°$]), and the inverse polyproline II (ε_D [$\phi \approx 60°$, $\psi \approx 180°$]) backbone conformers each have three (g^+, *a*, and g^-) side-chain (χ_1) rotamers. The δ_L [$\phi \approx 240°$, $\psi \approx 60°$] and the δ_D [$\phi \approx 180°$, $\psi \approx -60°$] type main-chain conformers have only two side-chain orientations, respectively. No minima have been found for the conformational building unit of the right-handed helical (α_L [$\phi \approx -60°$, $\psi \approx -60°$]) and for the polyproline II (ε_L [$\phi \approx -60°$, $\psi \approx 180°$]) structures. The present ab initio conformational analysis for For-L-Phe-NH_2 is a unique example in which a systematic and complete conformational set was established for a diamide system with an aromatic side chain. Analytic vibrational frequency calculations were established for all stationary points found as minima on the potential energy surface. These data may be used in the future as reference conformers in more detailed vibrational and (or) chemical shielding calculations or during the structural analysis of peptides and proteins by X-ray or NMR techniques.

Key words: ab initio peptide conformers, all RHF/3-21G structures of For-L-Phe-NH_2, backbone – side-chain interaction in phenylalanine-containing peptide models.

Résumé : La phénylalanine est le plus simple des quatre acides aminés naturels comportant un noyau aromatique dans la chaîne latérale. Des calculs d'analyse conformationnelle effectués au niveau RHF/3-21G sur une phénylalanine comportant le système modèle diamide (*N*-formyl-L-Phe-NH_2) ont révélé l'existence de 19 structures différentes. On a effectué des calculs d'énergie en un seul point, aux niveaux RHF/6-31G+G* et DFT(B3LYP)/6-311++G**, pour chacun des conformères. Les squelettes des conformères à hélice gamme normale (γ_D) et inverse (γ_L), étendus (β_L), l'hélice *gauche* (α_D [$\phi \approx +60°$, $\psi \approx +60°$]) et la polyproline II (ε_D [$\phi \approx +60°$, $\psi \approx +180°$]) comportent tous les trois (g^+, *a* et g^-) rotamères dans la chaîne latérale (χ_1). Les conformères dont la chaîne principale est du type δ_L [$\phi \approx 240°$, $\psi \approx 60°$]) et δ_D [$\phi \approx 180°$, $\psi \approx -60°$]) ne comportent respectivement que deux orientations de la chaîne latérale. On n'a pas observé de minima pour les structures des unités conformationnelles de l'hélice droite (α_L [$\phi \approx -60°$, $\psi \approx -60°$]) et de la polyproline II (ε_L [$\phi \approx -60°$, $\psi \approx 180°$]). L'analyse conformationnelle ab initio de la For-L-Phe-NH_2 rapportée ici est un exemple unique dans laquelle on a déterminé un ensemble conformationnel systématique et complet d'un système diamide portant une chaîne latérale aromatique. On a effectué des calculs analytiques de fréquence de vibration pour tous les points stationnaires trouvés comme minima sur la surface d'énergie potentielle. Il sera possible d'utiliser ces données dans le futur comme conformères de référence dans des calculs plus détaillés de

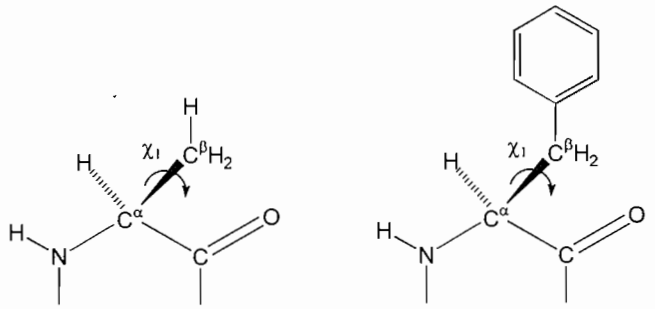
Introduction

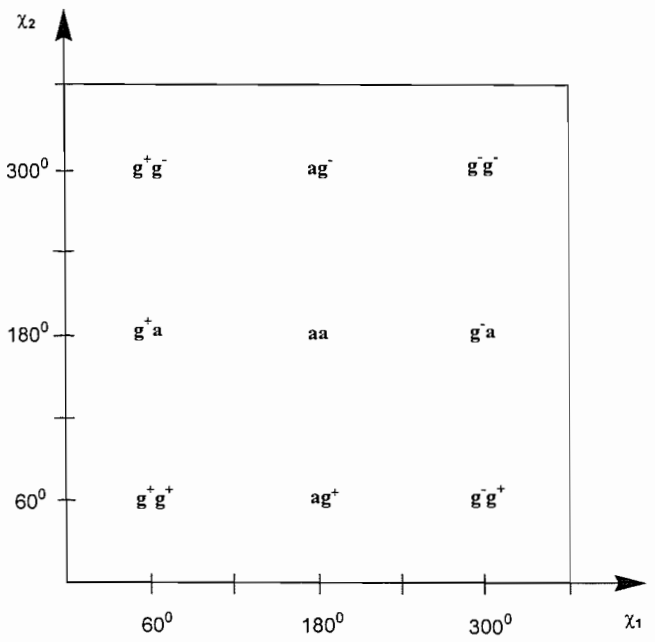
General considerations

Ab initio investigation of aromatic–aromatic and polar–aromatic interactions (1) has recently emerged as an important tool in biochemical, pharmaceutical, and medical research. In the core region of proteins, interresidual interaction between amino acids containing an aromatic side chain (Phe, Tyr, Trp) is common (2–4). Formation of hydrophobic contacts in amphipatical helical networks (5) and the binding of aromatic substrates into receptors (6) or to the binding pocket of enzymes (7) are well known. Numerous examples can be found in the literature where the crucial role of a phenylalanine residue has been observed. Some well-known problems, such as that of cholecystokinin (CCK) (8*a*), have been around for almost 30 years, while other more recent ones, such as the binding site of the CD4 receptor for human immunodeficiency virus gp120 (8*b*, *c*) focus attention on the importance of aromatic–amide or aromatic–aromatic interaction. CD4 is a fascinating structural example, where the aromatic side chain is not buried inside the molecule but is exposed on the surface of the protein. According to Burley and Petsko (9) the aromatic–aromatic interaction between aromatic side chains may be effective from 4.5 to 7 Å. However, analysis of the most probable side-chain distances between Phe-Phe residues has quoted values in the range 3.5–4.2 Å (10).



Based on the chemical nature of the side chains, L-amino acids may be classified as forming apolar and polar residues. Based on the pK_a values of the side chain, polar side chains may further be divided into acidic and bases subclasses. On the other hand, at least one representative element of each of these side-chain groups has aromatic character. Histidine is a weak base ($pK_a \approx 6$), tyrosine is a weak acid ($pK_a \approx 10$), while tryptophane and phenylalanine are apolar; however, all have a side chain with aromatic character.

Side-chain conformations



The purpose of the present paper is to explore the side-chain and backbone conformational subspaces of the conformational energy hyperspace, spanned by four torsional angles. Such an exploration will determine not only the location and relative stabilities of all conformers but it will also reveal the coupling between side-chain orientation and backbone structures.

Phenylalanine is the simplest side chain among the aromatic amino acid residues that can constitutionally be derived from alanine with the formal replacement of a β proton (H^{β}) with a phenyl (Phe = C_6H_5) group. While in alanine all three β protons (H^{β}_A, H^{β}_B, and H^{β}_C) can be considered as equivalent (and therefore energetically degenerate), in phenylalanine the β carbon is a prochiral center. Thus, an unambiguous description requires the inclusion of the two independent side-chain torsional angle variables: χ_1 and χ_2 (Scheme 1).

Scheme 1.

Scheme 2.

For amino acid residues that have both carbon atoms C^{β} and C^{γ} with an sp^3 character, a maximum of nine different side-chain conformers are expected (Scheme 2).

It has been demonstrated recently by using ab initio computations (11), that for selected amino acid residues having an sp^3 type C^{β} and an sp^3 type X^{γ} atom (e.g., X^{γ} = oxygen (ser, Thr) and X^{γ} = sulphur (Cys)) the expected nine minima can indeed be found. In contrast, in amino acid residues that have aromatic side chains the C^{γ} atom is of an sp^2 rather than an sp^3 type. In the latter constitution χ_2 may have fewer, or more than, three orientations and therefore such a molecule will not

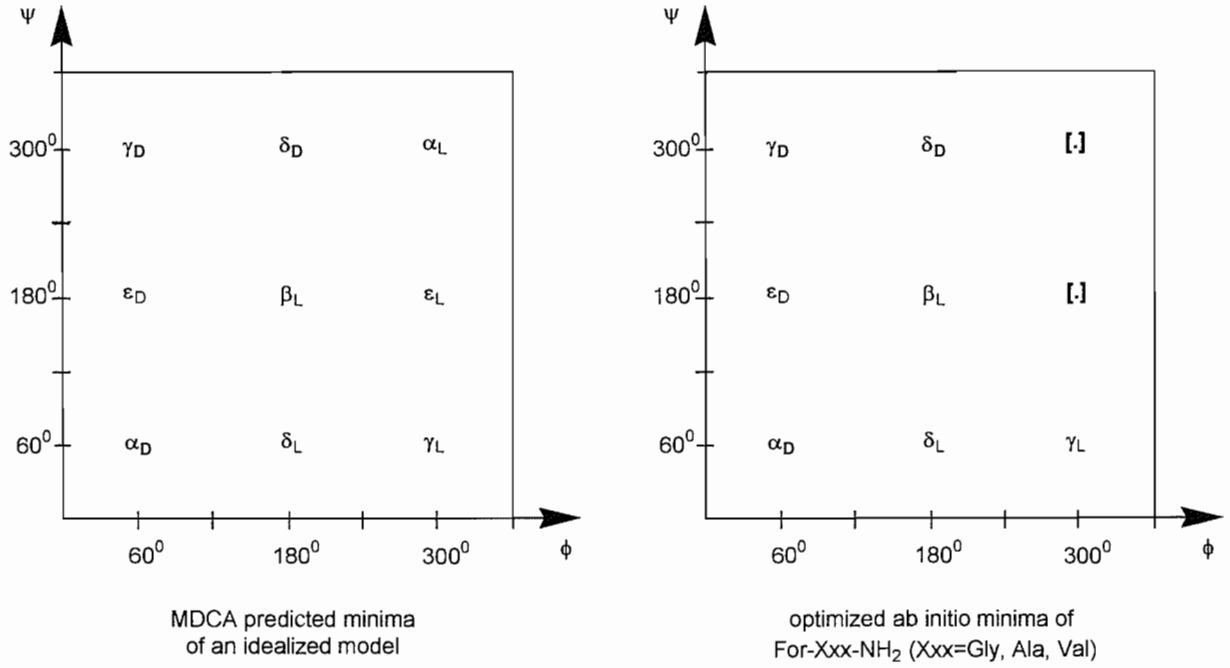
Scheme 3.



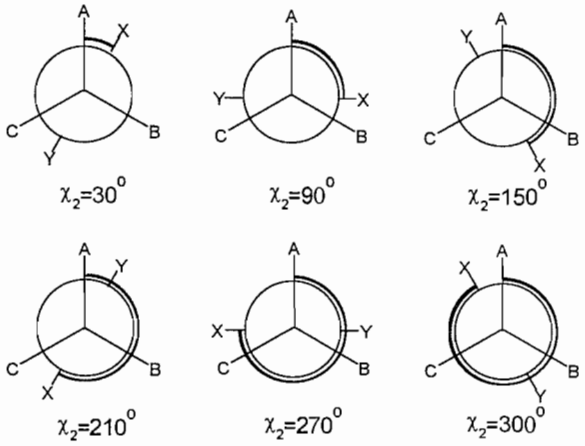


Fig. 1. Rotation about a C(sp^2)—C(sp^3) covalent bond with all six distinguishable minima [30°, 90°, 150°, 210°, 270°, and 330°]. If X = Y then the torsional potential shows sixfold degeneracy. (It is convenient to take A = C^{α} and B = C = H in the case of For-L-Phe-NH_2.)

show a side-chain conformation pattern similar to that of Scheme 2. Since in this case the two substituents attached to the sp^2 type C^{γ} atoms are constitutionally distinguishable (X ≠ Y), therefore, along χ_2 we may have as many as six different minima: [30°, 90°, 150°, 210°, 270°, and 330°] (Fig. 1). If the two substituents attached to the sp^2 C^{γ} atom are indistinguishable (X = Y) then three conformers remain. Thus, if X = Y, then $\chi_2[30°] = \chi_2[210°]$, $\chi_2[90°] = \chi_2[270°]$, and $\chi_2[150°] = \chi_2[330°]$ (Fig. 1). The latter situation is expected to occur in aspartate and in phenylalanine. For aspartate (Asp^-) both X and Y stand for oxygen, while in phenylalanine both X and Y are methyne (-CH-) groups. However, in any system that behaves as non-ideal, certain minima may be annihilated.

Backbone conformations

Multidimensional Conformational Analysis (12) (MDCA) predicts the existence of nine (13) legitimate backbone conformations denoted as α_L, α_D, β_L, γ_L, γ_D, δ_L, δ_D, ε_L, and ε_D, on the 2D-Ramachandran (14) map, $E = E(\phi, \psi)$, of a single amino acid diamide (HCONH-CHR-$CONH_2$) (Scheme 3).

Schäfer et al. (15) first noted that no minimum exists for CH_3CO-L-Ala-$NHCH_3$ in the neighborhood of the [$\phi \approx 300°$, $\psi \approx 300°$] conformational region, where the conformational building unit of the right-handed helix-like structure is expected. This region of the $E = E(\phi, \psi)$ potential energy surface is also called α_L (11, 13, 16, 17). Recent attempts confirmed that for diamide systems composed of apolar side chains (Ala, Val) no α_L-type minimum is present (11, 13, 15–17). Moreover, an additional minimum, the so-called ε_L [$\phi \approx 300°$, $\psi \approx 180°$] structure, which is the conformational building unit of the polyproline II structure, has so far not been observed during ab initio calculations of simple amino acid diamides (11, 13, 16, 17).

Backbone–backbone (18) and side-chain–backbone (19) interactions may stabilize the α_L conformation, as well as a special hydration effect (20), which exists in an intermolecular hydrogen-bonded complex. However, it is still a major challenge to understand the intrinsic relationship between the side-chain constitution and the expected ε_L backbone conformation. The ab initio conformers of For-L-Phe-NH_2 reported here could be used as reference conformers in further vibrational and (or) chemical shielding calculations, in structural analysis of peptides and proteins by X-ray or NMR techniques, as well as in understanding the fundamental problem of protein structure prediction based on primary sequence (21).

Computational details

Conformers of For-L-Phe-NH_2 were located at the restricted Hartree–Fock (RHF) level of theory (22) employing the stan-

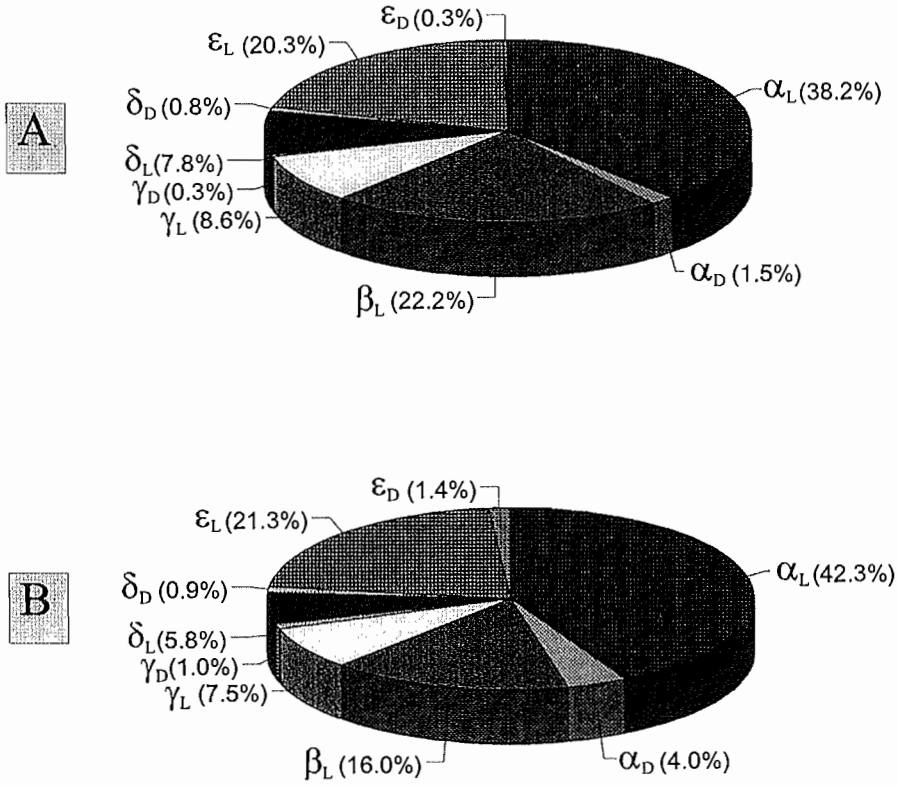
dard 3-21G basis set (23). Minimization of all structures was performed by using a modified GDIIS (24) optimization algorithm with natural internal coordinates (25). RHF energies and gradients were calculated by the program package TX90.[4] Vibrational frequencies were obtained with the program TURBOMOLE taking advantage of its analytic second-derivatives facility. The maximum residual forces at the end of the geometry optimizations were always less than 10^{-6} au. The computed total energy values are summarized in Table 1, together with additional selected geometrical parameters. The relative energies of the fully optimized conformers are taken with respect to the global minimum; $E(\gamma_L[g^+])$ = −640.745 238 hartree. Single-point energies of the 19 conformers were also computed at the Hartree–Fock (RHF/6-31+G*) and density functional (B3LYP/6311++G**) levels of theory (Table 1*A*). The latter level of theory has been employed as in recent studies (26, 27). This level proved to yield accurate relative energies for several conformers of glycine (26) and alanine (27).



To limit the number of possible structures, preliminary

force field calculations investigated the space requirement of the phenyl group at different $[\chi_1, \chi_2]$ orientations. Setting χ_2 equal to 30°, 90°, and 150° and χ_1 to the most probable 60°, 180°, and 300° values, we analyzed the interatomic distances between the *ortho* hydrogens and the backbone atoms (H^α, N^α, and carbonyl C). Comprehensive analysis of these side-chain structures revealed that one or more of the above interatomic distances turned out to be shorter than 1.9 Å, which should be

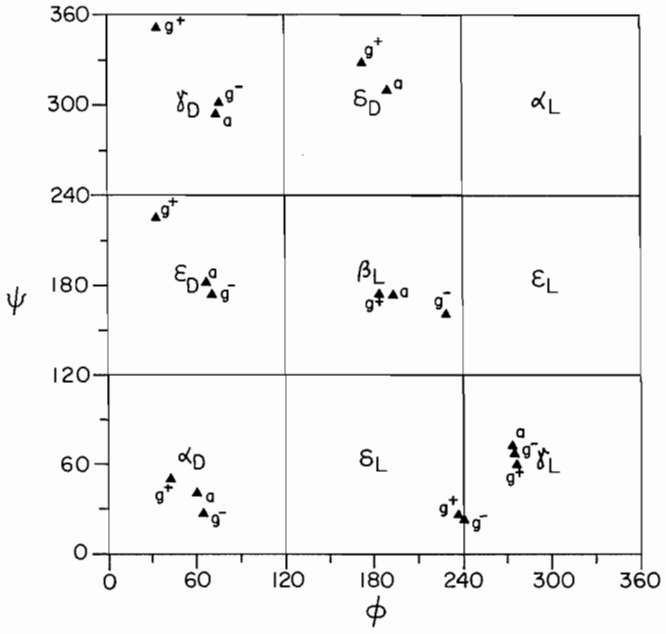
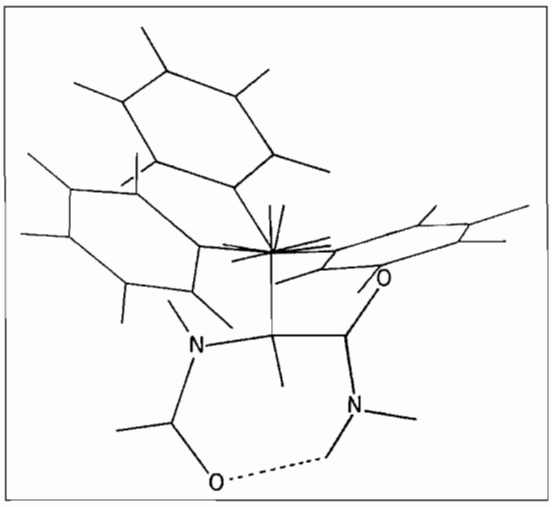
Fig. 3. Location of the 19 RHF/3-21G relaxed structures For-L-Phe-NH_2 on a "ϕ, ψ" map. Backbone conformations (γ_D, β_L, etc.) are labelled according to the appropriate catchment region (α_L, α_D, β_L, etc.) plus their χ_1 conformers (g^+, a, or g^-). For the clarity of the catchment regions, both ϕ and ψ values are plotted using a 0°–360° scale. Note that for γ_D, ε_D, α_D, β_L, and γ_L backbone conformers three, and for δ_D and δ_L only two, χ_1 rotamers were found.





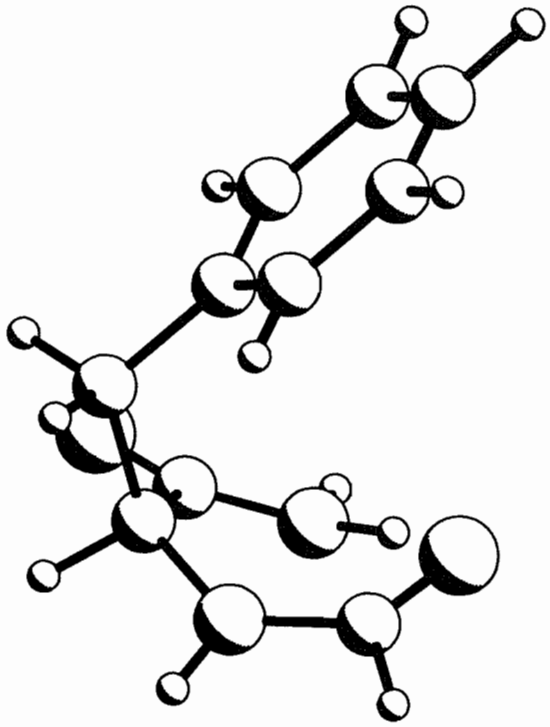


Fig. 4. Superimposed conformers of the three (g^+, a, and g^-) inverse gamma turn (γ_L) structures of For-L-Phe-NH_2.

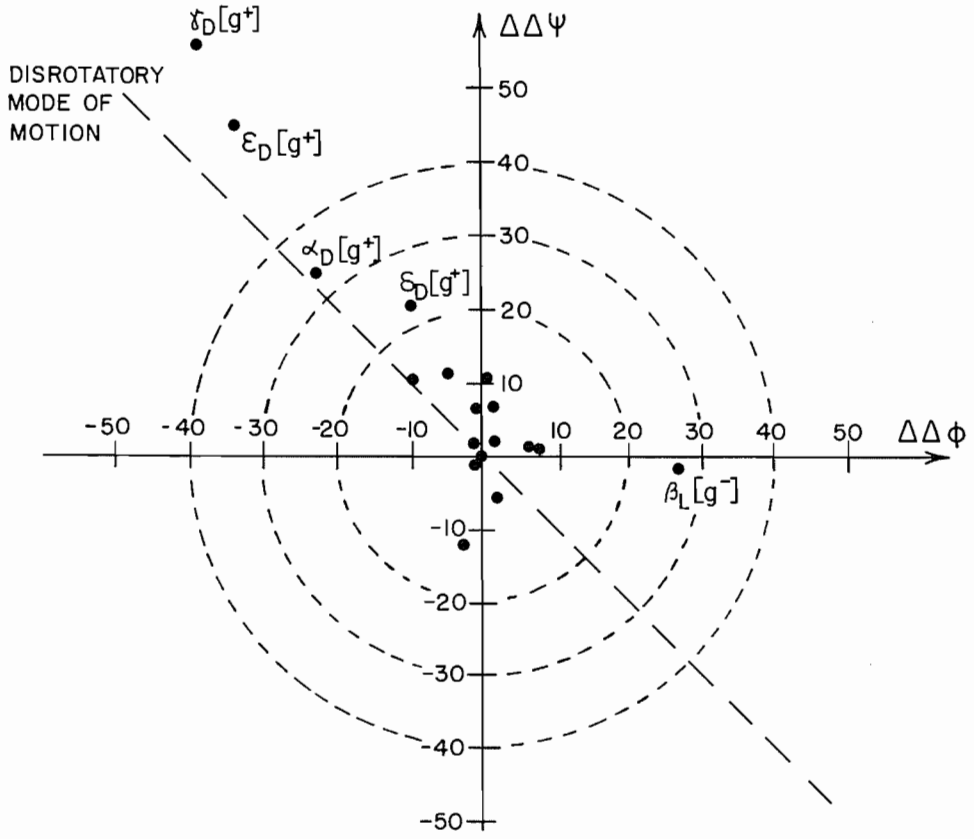
considered unnatural. Therefore, two out of the three possible χ_2 orientations, $\chi_2 = 30°$ and $\chi_2 = 150°$, can be ignored. Keeping only the single minimum of $\chi_2 = 90°$, the conformational analysis of For-Phe-NH_2 would incorporate three different side-chain orientations, $\chi_1 \approx 60°$ [$\chi_2 \approx 90°$], $\chi_1 \approx 180°$ [$\chi_2 \approx 90°$], and $\chi_1 \approx 300°$ [$\chi_2 \approx 90°$], for each of the different backbone conformers. In three of these conformers the plane of the phenyl group is nearly perpendicular to the projection of the

Fig. 5. The $\gamma_D(g^+)$ structure of For-L-Phe-NH_2 (HF/DZP) ($\phi = 53.26°$, $\psi = -14.85°$, $\chi_1 = 68.87°$, $\chi_2 = 82.38°$; $E_{total} = -644.283\,6515$ hartree).

C^α—C^β bond. This is in agreement with the results of a conformational study carried out on ethyl benzene (Ph-CH_2-CH_3), where the carbon atom of the terminal -CH_3 group corresponds to the α carbon of the amino acid residue (28) (the benzyl group [Ph-CH_2-] is the actual side chain of the phenylalanine residue (28)). In the case of ethyl benzene the rotation of the Ph group has its global minimum at $\chi_2 = 90°$ and there is a very shallow local minimum, $\Delta E = 1.83$ kcal/mol higher on the energy scale, corresponding to $\chi_1 = 0°$.



Results and discussion

Data-base analysis

In selected non-homologous proteins (29), we compared the relative frequencies of the nine different backbone conformers (α_L, α_D, β_L, ε_L, γ_L, γ_D, δ_L, δ_D, and ε_D) associated with a phenylalanine residue and with all 20 naturally occurring amino acid residues. All proteins included in this study had a a high-resolution X-ray structure taken from the January 1994 issue of the Protein Data Bank (PDB) (30, 31). From a total of 54 824 residues in 267 proteins, 2229 phenylalanine residues were counted. In all these, we compared the relative [ϕ, ψ] distribution of Phe with all 20 natural amino acid residues around the nine conformation clusters. The observed differences in relative frequencies slightly exceeded 7% for the β_L- and five percentage for the α_L-type backbone conformations (Fig. 2 *A*, *B*). The 7% increase in β_L is in favor of the Phe residues, while for the same amino acid residue there is a 5% drop in the α_L conformer. The frequency fluctuation of the other seven (α_D, ε_L, γ_L, γ_D, δ_L, δ_D, and ε_D) backbone conformations remains under 2.5%. Since phenylalanine shows an "average" conforma-

Fig. 6. Distribution of the computed For-L-Phe-NH_2 conformations on a double difference ($\Delta\Delta\phi$ and $\Delta\Delta\psi$) Ramachandran map.

tional character, which may be typical for aromatic amino acid, the present conformational results may be extrapolated with confidence for tyrosine and phenylalanine.

Conformational analysis

During the ab initio calculations, For-L-Phe-NH_2 has shown conformational features similar to those observed in glycine- (13, 16), alanine- (13, 16, 32, 33), and valine- (16, 17) containing diamide model compounds. All these diamide model systems (with the exception of Gly) have an apolar side chain. One striking conformational feature of all the above model compounds is that they do not have a minimum energy structure similar to the conformational building unit of the right-handed helical structure [$\phi \approx 300° \pm 30°$, $\psi \approx 330° \pm 30°$] (designated α_L) or to that of the polyproline II structure [$\phi \approx 300° \pm 30°$, $\psi \approx +220° \pm 30°$] (labelled as ε_L). The other seven (α_D, β_L, γ_L, γ_D, δ_L, δ_D, and ε_D) MDCA predicted backbone structures (13) were found within the quantum chemical calculations employed (Table 1). The location of the 19 ab initio For-L-Phe-NH_2 relaxed structures shows a clear separation on a "ϕ, ψ" map around seven distinguishable cluster centers. The γ_D, ε_D, α_D, β_L, and γ_L backbone conformers have three, while the δ_D and δ_L have two, different χ_1 rotamers (18 out of the 19 different structures have χ_2 around 90° in the range of 64.6° and 111.5°; thus $\chi_2 \approx 90 \pm 25°$. Note that the $\varepsilon_D(g^+)$ is an exception where χ_2 is shifted into the vicinity of 180° (Table 1).)

The inverse gamma turn (γ_L) is the only backbone conformer where all three χ_1 rotamers (g^+, *a*, and g^-) have rather similar [ϕ, ψ] values (Fig. 3). This indicates the lack of specific backbone–side-chain feedback. The intrinsic seven-membered intramolecular hydrogen bond between backbone NH and C=O units (Fig. 4) may explain this rigidity. Consequently, in the [$\phi = -84.3 \pm 1.3°$, $\psi = 66.5 \pm 6.7°$] region of the Ramachandran plot, where this hydrogen bond pattern is possible, it seems to be strong enough to "lock" the backbone conformation in all three (g^+, *a*, and g^-) side-chain conformers. Therefore, the γ_L backbone conformation is particularly useful to establish the magnitude of stabilization of the CH_2-C_6H_5 group on the backbone (34).

The "normal" gamma turn (γ_D) structure, the backbone conformational mirror image of the γ_L conformer, has a similar intramolecular hydrogen bond pattern. However, one out of the three γ_D type structures of For-L-Phe-NH_2, the $\gamma_D(g^+)$, shows a clear backbone conformational shift (Fig. 3). Due to the *gauche*$^+$ side-chain orientation, the [ϕ, ψ] values have shifted [$\Delta\psi \approx -40°$, $\Delta\psi \approx +60°$] from the expected region although the seven-membered hydrogen bond is preserved. Fearing the limitations of the RHF/3-21G basis set, this conformer was recalculated and geometry optimized using RHF/DZP level of theory. Although the more elaborate calculation resulted in ϕ, ψ torsional angles closer to the expected values [$\phi = 53.3°$, $\psi = 345.1°$] (Fig. 5) the moderate ϕ [$\Delta\phi \approx -25°$] and the large ψ [$\Delta\psi \approx +55°$] shift would need some explanation. One of these could be an aromatic–amide type interaction due to the spatial closeness of these two groups in the present conformers, which was quoted for cyclic peptide models in the literature (35–37).

[a]Shifts presented in this table are based on the data of Table 1.
[b]Torsional angle shifts (ϕ, ψ) are relative to those of For-L-Ala-NH_2.
[c]Relative to the $\Delta\phi$ and $\Delta\psi$ values of the $\gamma_L[g^+]$ conformer of For-L-Phe-NH_2.
[d]$\Delta\Delta E$ = ΔE(For-L-Phe-NH_2) − ΔE(For-L-Ala-NH_2). Values are in kcal/mol.

Similarly to the γ_D conformer, the g^+ side-chain orientation also has a remarkable impact in the ε_D and α_D backbone orientations. (Note that in all these conformers the ϕ has g^+ orientation.) In the $\varepsilon_D(g^+)$ and $\alpha_D(g^+)$ structures the [ϕ, ψ] values deviate once again from the other two ε_D and α_D backbone conformers (Fig. 6). Comparison of the energies (ΔE) of all three conformers (α_D, ε_D, and γ_D) at all three basis set types (3-21G, 631+G*, and 6311++G**) (Table 1*B*) reveals their high energy, relative to all the others.

While the *anti* and the *gauche*$^+$ side-chain conformers of the "extended" backbone structures, β_L(s), have very similar [ϕ, ψ] values, the *gauche*$^-$ orientation induces a significant backbone structural shift. It appears obvious that in the above four backbone conformers (γ_D, ε_D, α_D, and β_L) one among the three side-chain orientations (g^+ or g^-) has important backbone-structure-modifying effects. In these cases the aromatic group induces a considerable side-chain–backbone effect that shifts the [ϕ, ψ] values to the edge of the "catchment" region. In two additional backbone conformers, δ_D and δ_L, the side-chain-induced backbone-modifying effect is increased to such an extent that one of the three possible χ_1 orientations (g^+, a, g^-), namely the $\delta_D(g^-)$ for the δ_D(s) and $\delta_L(a)$ for the δ_L(s), are missing. In summary, due to the aromatic ring – backbone amide interactin in the $\gamma_D(g^+)$, $\varepsilon_D(g^+)$, $\alpha_D(g^+)$, and $\beta_L(g^-)$ structures, the [ϕ, ψ] values are strongly modified (Fig. 6), while in $\delta_L(a)$ and $\delta_D(g^-)$ the backbone conformation is transferred into one of the neighboring conformers. It should be emphasized again that when the backbone conformation of the input structure was of an α_L or ε_L type at any χ_1 value ($\alpha_L(g^+)$, $\alpha_L(a)$, and $\alpha_L(g^-)$ or $\varepsilon_L(g^+)$, $\varepsilon_L(a)$, and $\varepsilon_L(g^-)$), the ab initio computation resulted in a conformer that falls into another backbone conformation cluster.

The conformational shifts ($\Delta\phi$, $\Delta\psi$) of For-L-Phe-NH_2 with respect to For-L-Ala-NH_2 are summarized in Table 2. The relative conformational shifts ($\Delta\Delta\phi$, $\Delta\Delta\psi$) with respect to the $\Delta\phi$, $\Delta\psi$ values of the $\gamma_L[g^+]$ conformer of For-L-Phe-NH_2 are also collected in Table 2. The last column of this table summarizes the shift in relative energies.

When calculating these quantities the following equations were used:

$$\Delta\phi_x = \phi_x(\text{For-L-Phe-NH}_2) - \phi_x(\text{For-L-Ala-NH}_2)$$

$$\Delta\psi_x = \psi_x(\text{For-L-Phe-NH}_2) - \psi_x(\text{For-L-Ala-NH}_2)$$

$$\Delta\Delta\phi_x = \Delta\phi_x - \Delta\phi_{\gamma L(g^+)}$$

$$\Delta\Delta\psi_x = \Delta\psi_x - \Delta\psi_{\gamma L(g^+)}$$

$$\Delta E_x(\text{For-L-Phe-NH}_2) = E_x - E_{\gamma L(g^+)}$$

$$\Delta E_x(\text{For-L-Ala-NH}_2) = E_x - E_{\gamma L}$$

$$\Delta\Delta E_x = \Delta E_x(\text{For-L-Phe-NH}_2) - \Delta E_x(\text{For-L-Ala-NH}_2)$$

A number of interesting facts should be emphasized.

1. The $\Delta\Delta E$ values are all positive, with two exceptions:

[a]Indicates whether the C═O oxygen is involved in hydrogen bond (HB).
[b]Unscaled frequencies obtained at the RHF/3-21G level of theory.
[c]Scale factors chosen in the spirit of SQM methodology (36, 37) for the C═O stretching and NH_2 scissoring vibrations.

$\Delta\Delta E(\delta_L[g^+]) = -0.85$ kcal/mol and $\Delta\Delta E(\alpha_D[g^-]) = -2.05$ kcal/mol. This implies that in the $\delta_L(g^+)$ and $\alpha_D(g^-)$ conformers the Ph group of R = -CH_2-Ph, *indeed* acts as a stabilizing substituent with respect to the -H of the R = -CH_2-H of alanine. In all the other 17 cases the $\Delta\Delta E$ values are positive.

2. The trend in $\Delta\Delta\phi$ and $\Delta\Delta\psi$ values (Table 2, Fig. 6) is such that it may be classified as conrotatory (i.e., the signs of $\Delta\Delta\phi$ and $\Delta\Delta\psi$ are usually opposite to one another).

3. The five "ghost" conformers, $\gamma_D(g^+)$, $\varepsilon_D(g^+)$, $\alpha_D(g^+)$, $\delta_D(g^+)$, and $\beta_L(g^-)$, noticed in Fig. 3, occupy extended positions in Fig. 6. Perhaps these two extreme sites represent a different type of interaction. In the $\gamma_D(g^+)$, $\alpha_D(g^+)$, $\delta_D(g^+)$, and $\beta_L(g^-)$ conformers the Ph group has $\chi_2 \approx 90°$ but in the $\varepsilon_D[g^+]$ conformer the Ph group is twisted ($\chi_2 \approx 180°$).

4. One may speculate that the $\Delta\Delta E$ values associated with these five conformers

$\Delta\Delta E\ \{\gamma([g^+)\} = 8.19$ kcal/mol

$\Delta\Delta E\ \{\varepsilon_D(g^+)\} = 9.45$ kcal/mol

© 1997 NRC Canada

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.146.161.215 on 09/08/12
For personal use only.

$\Delta\Delta E$ {$\alpha_D(g^+)$} = 5.21 kcal/mol

$\Delta\Delta E$ {$\delta_D(g^+)$} = 8.54 kcal/mol

$\Delta\Delta E$ {$\beta_L(g^-)$} = 5.86 kcal/mol

would be higher without a stabilizing interaction. The fact that their $|\Delta\Delta\phi|$ and $|\Delta\Delta\psi|$ values are significant indicates that there should be a stabilizing (e.g., charge transfer) interaction.

It is clear, when one compares the average deviations presented in Table 3 with the individual deviations, Table 2, that some of the differences have been averaged out.

Vibrational analysis of selected conformers

Table 4 summarizes computed fundamental vibrational frequencies, infrared intensities, and vibrational total energy distributions of the C═O stretching region of selected conformers. As shown by data compiled in Table 4, there are three normal modes expected in the C═O stretching region of the spectrum. As expected, the C═O stretching not involved in hydrogen bonds usually comes at the highest wave number. In conformers where the other C═O bond is involved in an intramolecular H-bond, the respective normal modes show strong mixing between the C═O stretching and the NH_2 scissoring motions.

Conclusions

Based on a preliminary force field study indicating that the phenyl ring is typically perpendicular to the C^α—C^β bond, MDCA predicted 27 different structures for the phenylalanine-containing diamide system (For-L-Phe-NH_2). Among these, 19 fully optimized structures were determined at the RHF/3-21G level of theory, while the other 8 relaxed to one of the 19 structures. Except for the inverse gamma turn (γ_L) conformers of this model system, a serious side-chain–backbone effect is operative in all other conformers. Such side-chain–backbone interactions markedly shift the [ϕ, ψ] values of the γ_D-, ε_D-, α_D-, and β_L-type structures in one out of the three side-chain conformations. The same effect is thought to be responsible for the "elimination" of the $\delta_L(a)$ and $\delta_D(g^-)$ structures. The aromatic side chain may have such an impact on some of the backbone structures that none of the three α_L nor any of the ε_L conformers have been found computationally. As observed previously for the hydroxymethyl-type side chain in the For-L-Ser-NH_2 molecule, the side-chain–backbone interaction may have a serious impact on the possible orientation of the two amide bonds influencing the ϕ and ψ values. The conformational analyses of For-L-Phe-NH_2 provide a unique example in which it was possible to monitor an apolar aromatic side-chain-induced backbone-modifying effect at the ab initio level of theory.

3-Phosphorylated 1,5-hexadienes as precursors for vinylic or 3-silanylvinylic phosphonates

Michael F. Probst, Agnes M. Modro, and Tomasz A. Modro

Abstract: 3-(Diethylphosphono) substituted 1,5-hexadienes are prepared by the α-regioselective allylation of allylic phosphonates. The products can be converted into vinylic phosphonates via two types of reactions. The first involves Cope rearrangement yielding the terminal vinylphosphonates of the 1,5-hexadiene system. The second involves γ-silanylation leading to the formation of the 1-silanyl-3-phosphono derivatives of the 2,5-hexadiene skeleton.

Key words: allylic and vinylic phosphonates, nucleophilicity of allylphosphonate carbanions, electrophilic silanylation, Cope rearrangement of alkenylphosphonates.

Résumé : On a préparé les 3-(diéthylphosphono)-1,5-hexadiènes par allylation α-régiosélective des phosphonates allyliques. Les produits peuvent être transformés en phosphonates vinyliques en utilisant deux types de réactions. Le premier type implique une transposition de Cope conduisant aux phosphonates vinyliques avec le vinyle en position terminale du système 1,5-hexadiène. Le second type implique une γ-silanylation conduisant à la formation de dérivés 1-silanyl-3-phosphono du squelette 2,5-hexadiène.

Mots clés : phosphonates allyliques et vinyliques, nucléophilicité des carbanions allylphosphonate, silanylation électophile, transposition de Cope des alcénylphosphonates.

[Traduit par la rédaction]

Introduction

Synthetic usefulness of allylphosphonates (1) and allylsilanes (2) is well recognised. Although the corresponding vinyl silanes also found wide application in synthesis (ref. 2, chap. 3), relatively little is known about the synthetic use of vinylphosphonates. It has been shown recently that the latter systems can be used as substrates for the preparation of a variety of chain-substituted allylphosphonates (also valuable synthetic reagents) via the conjugate addition of organocuprates, followed by electrophilic quenching (3). Introduction of two heteroatom-containing functionalities, PO_3Et_2 and SiR_3, into the 1,3-positions of the propenyl backbone opens a possibility of a combination of the abovementioned reactive systems within a single molecular framework, and should offer new synthetic options. In the first paper of this series (4) we showed that 3-silanylprop-1-enylphosphonates **1** can be easily prepared by silylation of the corresponding allylphosphonates, and that **1** could be converted to the isomeric 3-silanylallylic phosphonates **2** via the 1,3-sigmatropic shift (eq. [1]). In this paper we report some chemistry of the 3-phosphorylated 1,5-hexadiene system leading to the formation of new vinylic and 3-silanylvinylic phosphonates.

Results and discussion

The regioselectivity of the silylation of lithiated allylic phosphonates depends on the substitution of the propenyl skeleton. While diethyl prop-2-enylphosphonate **3a** undergoes silylation exclusively at the γ-carbon (5), its 3-methyl derivative **3b** was reported to give exclusively the α-silylated product **4a** (6). We have now found that the isomeric 2-methylallylphosphonate **3c** retains the exclusive γ-selectivity, yielding the corresponding 3-silanylprop-1-enylphosphonate **1b** (eq. [2]). As in the case of the unsubstituted substrate (4), only the *E* stereoisomer of **1c** was formed. Among many factors that contribute to the α vs. γ selectivity in nucleophilic reactivity of carbanions derived from the 1-heteroatom-substituted propenyl system, steric effects of the carbanion and of the electrophile are frequently suggested as playing an important role (7). The results given in eq. [2] do not confirm that conclusion; it would be difficult to accept that the difference in the steric hindrance for the substitution and C_α and C_γ in **3b** justifies the rigorous selectivity leading to the exclusive formation of **4a**. We believe that the regioselectivity of the silylation is determined rather by the combination of the effect of the substituents R, R′ on the charge distribution within the allylic carbanion, by the *stability* of the product, as measured by the number of the carbon atoms attached to the olefinic bond, and by the number of the allylic hydrogens available for the hyperconjugative stabilization of that bond (8). In all cases given in eq. [2] the formation of the observed isomer results in the increase of carbon substitution and of the number of allylic hydrogens, while the location of the phosphoryl group with respect to the olefinic bond seems to be of lesser importance. A weak (if any) stabilizing effect of the PO_3Et_2 substituent on

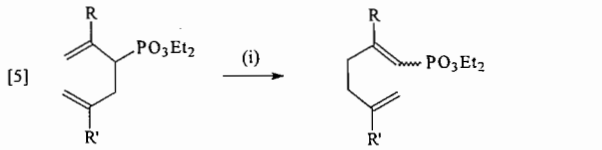
an adjacent olefinic bond has been demonstrated before (5) and in the present work by the thermal isomerization **1** → **2** (eq. [1], second step). We have now found that the isomerization can also be achieved via prototropic equilibrium (eq. [3]) leading to the silicon-substituted, rather than the phosphonyl-substituted alkene.

[3] 

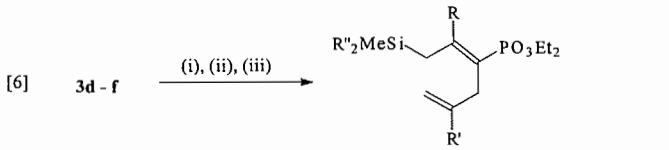


(i) BuLi or tBuLi or LDA
(ii) aq NH_4Cl

In electrophilic alkylation, as opposed to the silylation, allylic phosphonates **3a** and **3c** behaved as exclusive α-carbon nucleophiles; allylation of those substrates led to new allylphosphonates of the 1,5-hexadiene series (eq. [4]). Formation of the α-allylated products **3d–f** violates the rule of

[4] 

(i) BuLi
(ii) $CH_2=C(R')CH_2Br$



"carbon substitution and hyperconjugative hydrogens" (8), suggesting that **3d–f** represent the kinetic products of the alkylation, and not necessarily the more stable isomers. Indeed, when phosphonates **3d–f** were heated as neat liquids at 210°C, they underwent complete isomerisation via the Cope rearrangement to the corresponding vinylphosphonates **5** (eq. [5]). In each case, in addition to the location of one olefinic bond in

[5] 

(i) 210°C

the α,β-position with respect to the PO_3Et_2 group, the total number of the allylic hydrogens available for hyperconjugation with the olefinic bonds of the diene increased by one.

In addition to their conversion into the terminal vinylic phosphonates **5**, allylic phosphonates **3d–f** were also used as precursors of the vinylic phosphonates branched at the α-carbon and substituted at the terminal carbon with the silanyl group (eq. [6]). The silylation occurs exclusively at the γ-position, and the large (ca. 19 ppm) value of the $^3J_{CP}$ coupling

vinylphosphonates of the 1,4-hexadiene series is currently studied in our laboratory.

Experimental section

Solvents and commercially available substrates were purified by conventional methods immediately before use. All reactions were carried out in an atmosphere of dry nitrogen. NMR spectra were recorded as solutions in $CDCl_3$ on a Bruker AC 300 spectrometer. Chemical shifts are given in ppm relative to $SiMe_4$ (^1H, ^{13}C) as an internal standard, and 85% H_3PO_4 (^{31}P) as an external standard. Proton-coupled ^{13}C NMR spectra are given. Mass spectra were recorded on a Varian MAT-212 double-focusing direct-inlet spectrometer and a GC-coupled spectrometer at an ionization potential of 70 eV. For column chromatography, Merck Kieselgel 60 (0.063–0.200 mm) was used. Chlorotrimethylsilane and chlorodiphenylmethylsilane were purchased from Aldrich and were redistilled before use.

Diethyl prop-2-enylphosphonate **3a** was prepared as described before (4). Diethyl 2-methylprop-2-enylphosphonate **3c** was prepared from triethyl phosphite and 3-bromo-2-methylpropene (79%): bp 62°C at 0.1 Torr (1 Torr = 133.3 Pa); δ_P: 27.7 (lit. (10) δ_P: 26.5); δ_H: 1.26 (6H, t, J_{HH} 7.08), 1.83 (3H, dd, J_{HH} 1.08, 1.09), 2.53 (2H, d, J_{HP} 22.38), 4.05 (4H, quint, J_{HH}, J_{HP} 7.17), 4.85 (2H, m); δ_C: 15.8 (dq, J_{CP} 6.1, J_{CH} 127.0), 22.9 (dq, J_{CP} 11.7, J_{CH} 126.0), 34.8 (dt, J_{CP} 137.4, J_{CH} 131.0), 61.2 (dt, J_{CP} 6.6, J_{CH} 147.2), 115.4 (dt, J_{CP} 12.5, J_{CH} 131.0), 135.6 (d, J_{CP} 10.9); MS, *m/z*: 192 (M^+, 47%), 177 (21), 163 (10), 137 (100), 108 (33), 92 (24), 55 (80).

Silanylation of allylic phosphonates. General procedure

n-Butyllithium (1.6 M solution in hexane, 1.2 mol-equiv.) or *tert*-butyllithium (1.7 M solution in pentane, 1.1 mol-equiv.) or lithium diisopropylamide (10% suspension in pentane, 1.3 mol-equiv.) was cooled to −78°C. A solution of allylphosphonate (ca. 10 mmol, 1.0 mol-equiv.) in THF was added dropwise at −78°C and the solution was stirred at that temperature for 90 min. The silanylating reagent (1.2 mol-equiv.) was added slowly to the solution, the mixture was stirred at −78°C for an additional 45 min, allowed to warm up to room temperature, and stirred for 16 h. After quenching with 10% aqueous NH_4Cl, the product was extracted with ether, the ether solution was dried ($MgSO_4$), evaporated under reduced pressure, and the crude product was purified by distillation or bulb-to-bulb distillation.

Isomerization of 3-silanylprop-1-enylphosphonates. General procedure

A. Thermal

A sample of the vinylic phosphonate (ca. 10 mmol) was sealed in a glass tube and the tube was heated in an oil bath at 140°C for 6 h. The tube was opened and the product was purified by bulb-to-bulb distillation.

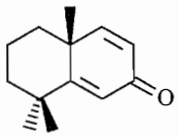
The chemistry of thujone. XX.[1] New enantioselective syntheses of Ambrox and *epi*-Ambrox

James P. Kutney and Carles Cirera

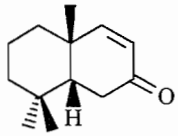
Abstract: The development of a new synthetic approach to (−)-Ambrox® (**37**) and *epi*-Ambrox® (**29**) using thujone (**1**) as a chiral synthon, is presented. Thujone (**1**), a readily available starting material obtained from Western red cedar, can be efficiently converted to β-cyperone (**2**) and the latter is then chemically elaborated to the key intermediate, the enone **6**. A carbonyl transposition of **6** to enone **9** also allows a formal synthesis of (−)-Polywood® (**18**).

Key words: thujone, β-cyperone, (−)-Ambrox®, *epi*-Ambrox®, synthesis.



Résumé : On présente une nouvelle approche à la synthèse du (−)-Ambrox® (**37**) et de l'*epi*-Ambrox® (**29**) utilisant la thujone (**1**) comme synthon chiral. La thujone (**1**), un produit facilement disponible à partir des cèdres rouges de l'ouest, peut être transformé d'une façon efficace en β-cypérone (**2**) qui peut, par la suite, être converti en énone **6**, un intermédiaire clé. Une transposition du carbonyle de l'énone **6** en énone **9** permet de réaliser aussi une synthèse formelle du (−)-Polywood® (**18**).

Mots clés : thujone, β-cypérone, (−)-Ambrox®, *épi*-Ambrox®, synthèse.



[Traduit par la rédaction]

The ambergris fragrances are well established as an important family of perfumes. Extensive reviews, which detail studies correlating their structure with smell, synthetic efforts, etc., are available (2–4). In particular, the classic members, (−)-Ambrox® (**37**) and (+)-iso-Ambrox® (**38**), form the basis of commercial products, for example, Fixateur 404 (trade name of Firmenich), which has been marketed in the perfumery industry for more than 30 years. In a previous study (5), we presented one of our synthetic approaches to these compounds from the readily available chiral synthon thujone (**1**). We now wish to detail our most recent studies, which afford alternative and novel enantioselective syntheses to (−)-Ambrox® (**37**) and (−)-*epi*-Ambrox® (**29**) from thujone.

In developing a possible route to the above, our consideration turned to the conjugated enone **6** (Scheme 1) available from β-cyperone (**2**), via a previously published procedure (6–8). To functionalize decalone **6** in a manner that would allow eventual synthesis of Ambrox® (**37**), it was evident that a two-carbon unit had to be attached at position C9. Based on unsuccessful attempts to achieve 1,4-addition products with **7** and only very moderate yields with the *cis*-decalone **8**, an alternative ketone transposition process (**6** → **9**, Scheme 2) appeared as an attractive alternative route. Based on the relatively inefficient published procedures (9–11), the route summarized in Scheme 2 was selected.

7

8

For this purpose, it was important to maintain the double bond functionality during the transposition steps, in order to ensure the regioselective alkylation at position C9, since competing alkylation is expected at C7 when both C7 and C9 positions are accessible for alkylation (12–14). As noted in the conversion of **6** to **10**, an oxidation at C8 is essential. For this purpose, the reaction involving α-hydroxylation of α,β-unsaturated ketones, by means of manganese(III) acetate originally described by Williams and Hunter (15), and subsequently improved by Watt and coworkers (16–18), was selected. When the reported conditions were applied to **6**, only low to moderate yields (35–60%) of the acetoxylated product were obtained even though special care was taken in drying the manganese(III) acetate. Since manganese(III) acetate is commercially available in its hydrated form, the reported drying method (phosphorus pentoxide and high vacuum for several days) proved to be insufficient for our purpose. Indeed, when azeotropic removal of water was carried out, the lower yields obtained by Watt (16, 17), could be improved and a mixture of the desired acetoxyketones **10/11** (R = Ac) were consistently obtained in 86% yield (Scheme 3). The mechanism proposed is consistent with that presented earlier (18).

α-Acetoxylation of enone **6** resulted in an inseparable mixture of isomers **10/11** in a 4:1 ratio. Assignment of the structures was done from the analysis of the C8 proton signal in the ^{1}H NMR spectrum. The proton at position C8 of the major

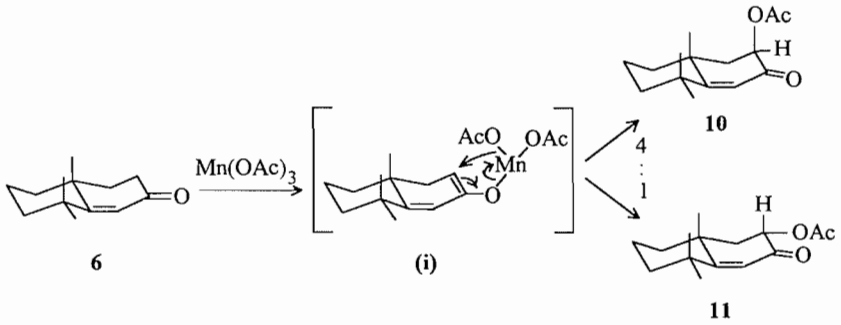

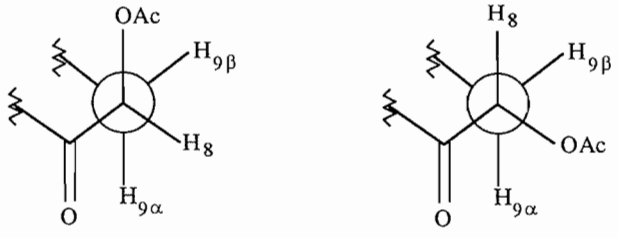

Fig. 1. The spatial relationship of the C8 and C9 protons in isomers **10/11**.

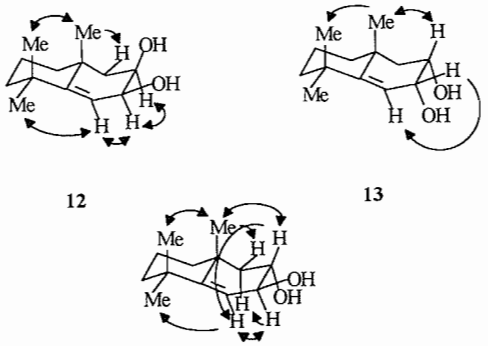
isomer displayed a triplet at δ 5.25 ppm (J = 4 Hz), which is in accordance with an equatorial position at C8 since it resides at an equal distance from the C9-αH and C9-βH (Fig. 1). On the other hand, the minor isomer, with its acetoxyl group in the α orientation, displayed a doublet of doublets at δ 5.60 ppm (J = 12, 4 Hz) for the axial C8 proton, being anti-periplanar to the C9-αH, and displaying therefore a large coupling constant (J = 12 Hz) when coupled with this hydrogen, and a small coupling constant (J = 4 Hz) when coupled with C9-βH, which corresponds to an angle of 60°.



The mixture of isomers **10/11** was reduced with LAH, yielding a mixture of four isomeric diols **12/13/14/15** in a ratio of 50:1:3:18, as observed after isolation of the pure diols. The diols **12–15** were separated by column chromatography for characterization purposes. Assignment of the different configurations for diols **12–14** was done by ^{1}H NMR and NOE difference experiments (Fig. 2). It was expected that the two major isomers should possess the hydroxyl group at position C7 in the β orientation, since the reducing agent was expected to approach the carbonyl function predominantly from the less hindered side (α face). The remaining diol **15** was then assigned as the 7α,8β isomer.

The following dehydration step was experimentally rather "delicate." A selective dehydration of the hydroxyl at position C7 was required in order to furnish the desired ketone **9**. The expected different reactivity of the two hydroxyl groups was a key factor for the success of the sequence. Discrimination of

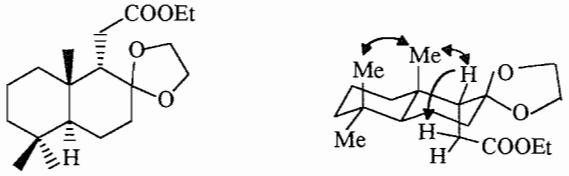
12 **13**

14

the hydroxyl groups under acidic conditions was indeed achieved and the hydroxyl at C7 underwent selective dehydration and conversion to the desired product **9** (Scheme 4). The elimination of the hydroxyl group at C8 would simply regenerate the initial enone **6** but this was not observed. The final step, in which the migration of the double bond occurs, was expected to take place easily under acidic conditions, fortunately towards the desired *trans*-decalone system.

By using 1.2 equivalents of *p*-toluenesulfonic acid and 0.1 M concentration of diols **12–15** in anhydrous THF, 64% of the *trans*-enone **9**, 25% of the nonconjugated enone (**16**), and less than 2% of the *cis*-enone (**17**) were isolated. These results suggested that the transformation of **12–15** to the mixture of **9**, **16**, **17** is kinetically controlled since published studies (ref. 19, footnote 9) have determined that the proportions at thermodynamic equilibrium are **9** (26%), **16** (6%), and **17** (69%). In a separate experiment, when enone **16** was submitted to the same conditions, a 65% yield of the *trans*-decalone (**9**), and 31% of the nonconjugated enone (**16**) was obtained, while no *cis*-decalone was isolated.



The overall yield in the three steps for the conversion, **12–15** to **9**, was 64% when the isolated nonconjugated enone (**16**) was recycled. A notable advantage of this novel sequence is that these three operations can be done without isolation of the intermediates, so that an effective route to **9** was now available. For preparative purposes, the sequence, **6** → **10/11** → **12–15** → **9**, can be conducted *without* isolation of the pure components in the various stages and in an overall yield of 64%.

Compound **9** displayed a peak at *m/z* 192 in the mass spectrum, corresponding to the molecular ion. Its ^{1}H and ^{13}C NMR spectra agreed with the published data (20), although an authentic sample was unavailable for direct comparison. Similarly, the data for the *cis*-decalone (**17**) and the nonconjugated enone (**16**) were also in agreement with the published data (20).

Enone **9** as well as **16** have been prepared as racemic intermediates, by a completely different route, by Snowden et al. (19) in their synthesis of (±)-Polywood® (**18**) and its unsaturated analogs. On this basis, a formal synthesis of (−)-Polywood® (**18**) and its chiral unsaturated analogs has been completed starting from thujone (**1**) (Scheme 5).

With the desired enone **9** on hand, introduction of a two-carbon unit at C9 was considered. Generation of the enolate by reacting **9** with lithium diisopropylamide at −78°C and subsequent reaction with ethyl iodoacetate afforded the desired intermediate **19** in 73% yield. The α orientation of the side chain in **19** was established from an analysis of the NMR data (see Experimental). It should be noted that a minor by-product (8% yield) was isolated and, on the basis of spectroscopic data (see Experimental), was assigned the structure **27**.

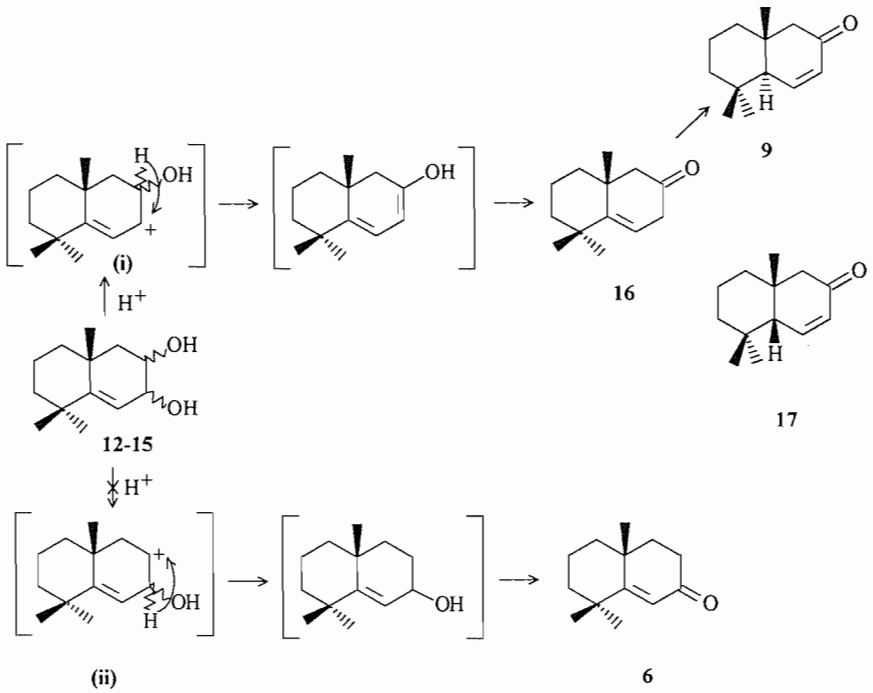
Fig. 3. A summary of proton interactions as determined from a NOE difference experiment with ketal **21**.

21

Catalytic hydrogenation of the double bond in **19** was achieved in quantitative yield by using catalytic amounts of 10% palladium on charcoal in ethanol at 40 psi of hydrogen (1 psi = 6.9 kPa). Under these conditions, the double bond in compound **19** was selectively hydrogenated in 20 min without reducing the carbonyl group.

Elaboration of the ester side chain in **20** to the required primary alcohol **22** (Scheme 6) via classical LAH reduction required prior protection of the ketone function. Preliminary experiments under acid-catalyzed ketalization conditions suggested a facile epimerization of the α-oriented side chain in **19** to the thermodynamic β-oriented position (see **28**, Scheme 6). On this basis, a series of reactions, under carefully controlled conditions and utilizing triflic acid (20) and TMS-triflate (21, 22) as catalysts, were undertaken. With the former catalyst, ketal **21** could be obtained in reasonable yield (67%) when the ketone **20** (1.0 mmol in anhydrous THF) was reacted with triflic acid (0.2 mmol) and 1,2-bis(TMSO)–ethane (1.9 mmol) at 0°C (14 h). Similar results were obtained with TMS-triflate and further details are provided in the experimental section. Detailed NOE experiments (Fig. 3 and Experimental) established that no epimerization of the axially oriented side chain had occurred during the ketalization reaction. The isomeric ketal **28** was obtained as a minor product (8%).

Having found a suitable protection method for the ketone functionality, we turned our attention to the synthetic steps required to obtain diol **26**. Reduction of the ester in **21**, protection of the alcohol, deprotection of the ketone, Grignard reaction, and finally deprotection of the primary alcohol, were the synthetic steps envisaged in order to obtain diol **26**.



Ketal ester **21** was reduced with an excess of LAH in diethyl ether in 10 min at room temperature, affording the alcohol **22** in essentially quantitative yield.

Protection of the primary alcohol was required before further transformation could be done since removal of the ketal function under mild acidic conditions afforded only low recovery of the desired keto alcohol, indicating that decomposition took place to a considerable extent. In addition, attempted purification of the expected keto alcohol showed that this compound was unstable and a complex mixture of compounds was obtained. For this purpose, the benzyl group appeared ideal since it is expected to be stable under acidic conditions and could be subsequently removed by catalytic hydrogenolysis. Reaction of **22** with benzyl chloride in

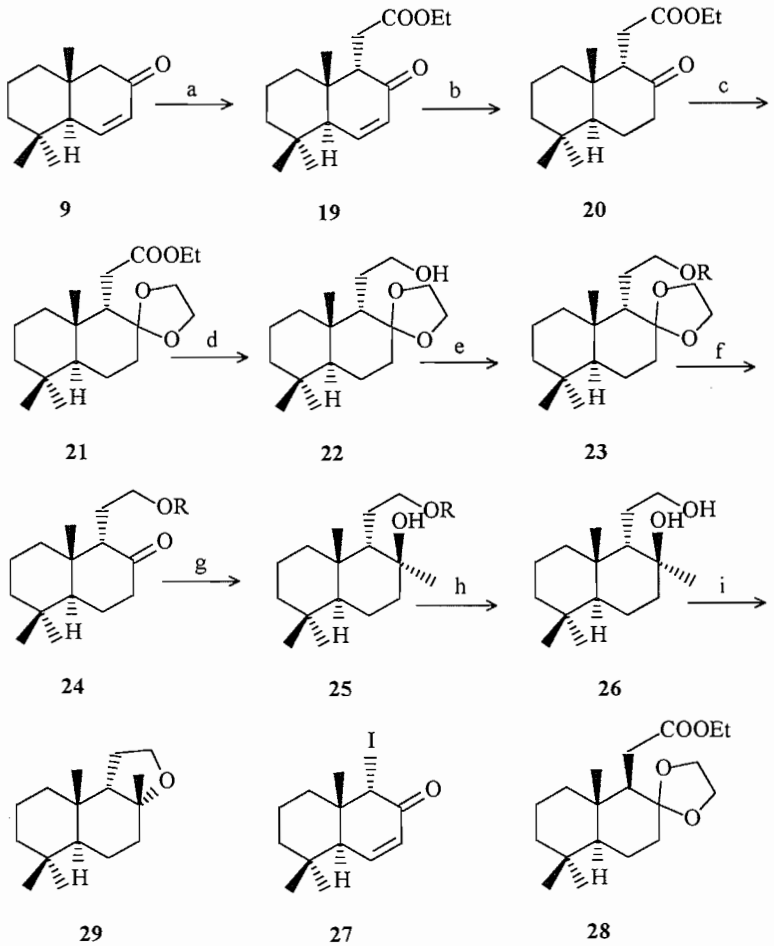
Scheme 4. Proposed mechanism for the dehydration of diols **12–15**.

Scheme 5. Formal synthesis of (−)-Polywood® (**18**) from thujone (**1**).

ethanol heated at reflux for 12 h in the presence of sodium hydride, potassium carbonate, and catalytic amounts of sodium iodide furnished the desired product in 68% yield (87% based on starting material recovered). A method reported by Provelenghiou and co-workers (23), used in the protection of hydroxyl groups in carbohydrates and claimed to be simple, rapid, and quantitative, was also evaluated. Removal of the weakly acidic alcoholic proton in compound **22** was done with sodium hydride, followed by addition of excess of benzyl bromide and 0.1 equivalent of tetrabutylammonium iodide followed by reflux, afforded an essentially quantitative yield of **23** (R = $CH_2C_6H_5$).

Regeneration of the carbonyl function to afford **24** (R = $CH_2C_6H_5$) was readily achieved (1 M HCl at room temperature). In summary, for preparative purposes, the three-step conversion, **21** → → **24**, could be achieved in a "one-pot" operation and in an overall yield of 87%.

With the ketone **24** (R = $CH_2C_6H_5$) available, the conversion to the tertiary alcohol **25** was now considered. Conventional Grignard reaction conditions (methylmagnesium iodide in refluxing ether) afforded **25** (R = $CH_2C_6H_5$) in low yield (20%). However, reaction of **24** (R = $CH_2C_6H_5$) with the methyl cerium(III) reagent, generated by reaction of methyllithium with anhydrous cerium(III) chloride (24–26), afforded **25** in essentially quantitative yield.



Removal of the benzyl group was achieved by catalytic hydrogenolysis (palladium in charcoal) to provide **26** in excellent yield (97%).

The final step in the synthetic route involved acid-catalyzed cyclization of **26** to (−)-*epi*-Ambrox® (**29**). Of the various approaches available from the literature (27–31), the method chosen involved *p*-toluenesulfonic acid as catalyst. When a nitromethane solution of **26** was treated with this catalyst at 80°C, the desired natural product **29** (32, 33) was obtained in 83% yield. For preparative purposes, (−)-*epi*-Ambrox® (**29**) has been prepared from the ketone **24** (R = $CH_2C_6H_5$) in 80%

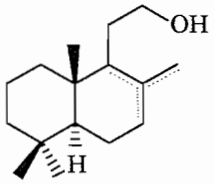


Scheme 6. Synthesis of (−)-*epi*-Ambrox® (**29**) from enone **9**.

(a) LDA; ICH_2CO_2Et; (b) H_2/Pd–C; (c) 1,2-bis(TMSO)ethane; TMS triflate; (d) LAH; (e) $PhCH_2Br$, *n*-Bu_4NI; (f) HCl, acetone; (g) MeLi, $CeCl_3$; (h) H_2/Pd–C; (i) *p*-TsOH, CH_3NO_2

overall yield without isolation of intermediates (see Method B, experimental section).

In addition to **29**, in the cyclization of **26**, a mixture of olefinic alcohols, tentatively assigned the general structure **30**, was also obtained (11%). This mixture could not be purified further by column chromatography and studies to clarify this mixture were not pursued.

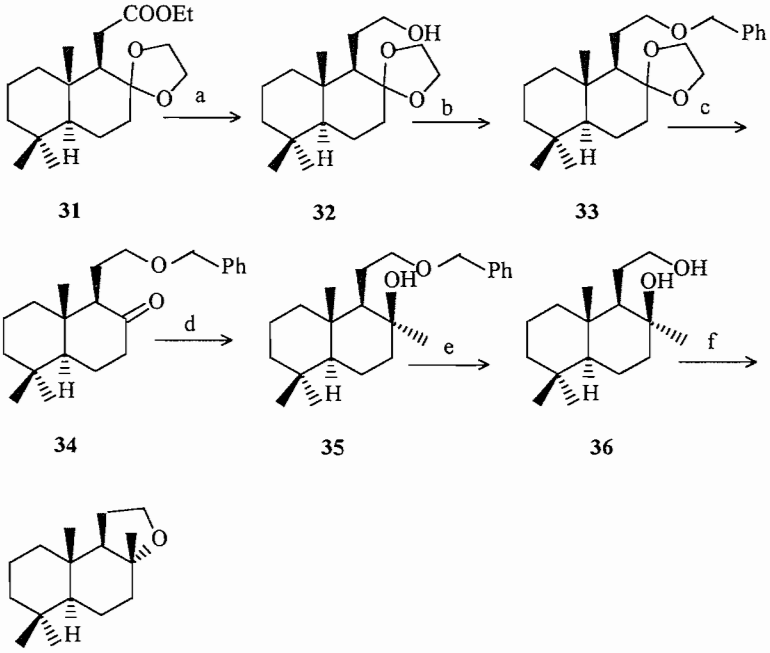
30

In conclusion, the above five-step synthetic route from enone **6** (previously prepared from thujone) to **29** allows synthesis of the latter in 33% overall yield.

A similar sequence to the one reported for (−)-*epi*-Ambrox® (**29**) has been followed for the synthesis of (−)-Ambrox® (**37**). In this case, the secondary product **31** from the ketalization reaction under protic conditions (and the main product when thermodynamic equilibration conditions were applied), was used to develop a parallel sequence towards (−)-Ambrox® (**37**) (Scheme 7). The starting material **31** contains the desired equatorial side chain required for Ambrox® (**37**). Reduction of ketal **31** with LAH afforded alcohol **32** in 92% yield.

Benzylation of the hydroxyl group was performed as for compound **22**, yielding compound **33** in 92% yield.

Removal of the ketal group in **33** was performed as indicated for compound **23** although in this case longer reaction times were required when the same conditions were employed.



Ketone **34** was also obtained by isomerization of the axial side chain in compound **24** (R = $CH_2C_6H_5$) under equilibrating conditions (sodium methoxide in THF–MeOH, 22 h reflux). Under these conditions, an equilibrium mixture containing a 9:1 ration of **34**:**24** (R = $CH_2C_6H_5$), respectively, was observed.

Methylation of the carbonyl function in **34** was performed

as for compound **24** (R = $CH_2C_6H_5$) using the organocerium reagent chemistry described earlier. Although in this case, having the side chain in an equatorial position may well facilitate the attack by a classical (and less reactive) Grignard reagent, as utilized by Buchi and Wuest (30), to achieve the desired stereochemistry at C8.

Hydrogenolysis of the benzyl group using palladium on charcoal, afforded diol **36**.

The cyclization of **36** was performed as for compound **26**. It was recognized that in this case the cyclization step, under acidic conditions, could generate the thermodynamically more stable *cis*-fused tetrahydrofuran ring, giving iso-Ambrox® (**38**) instead. It has been established that Ambrox® (**37**), with a *trans*-fused tetrahydrofuran ring, isomerizes to iso-Ambrox® (**38**) when treated with acid (34), demonstrating that the latter is the thermodynamically preferred isomer (35).

Equatorial approach to the tertiary carbocation at C8 should be preferred over the axial approach due to steric hindrance from the angular methyl group (30, 31). Therefore, Ambrox® (**37**) is preferentially produced through a lower energy transition state. However, iso-Ambrox® (**38**), resulting from the β-face attack, becomes the major product under prolonged reaction times under the same conditions. Investigation of the optimum conditions to effect such a cyclization by Buchi and Wuest (30) showed that treatment of diol **36** with a catalytic amount of *p*-toluenesulfonic acid in nitromethane at 80°C minimizes the formation of **38** in favour of Ambrox® (**37**).

In our case, under the same conditions, no formation of **38** was observed. The melting point and specific rotation $[\alpha]_D^{25}$ of the (−)-Ambrox® (**37**) obtained were measured to be 76–77°C and −24.1 (c = 1.00, $CHCl_3$), respectively. They agree well with the reported values (mp 77–77.5°C and −24.7 (c = 1.00, $CHCl_3$) (36). As in the previous study, a mixture of alcohols, tentatively assigned the general structure **30**, was also isolated (21% yield).

In summary, a novel route to (−)-Ambrox® (**37**) and (−)-*epi*-Ambrox® (**29**) has been developed from the thujone-derived enone **6**. Since a number of conversions can be achieved without isolation of intermediates, the overall yield from **6** to **29** is 33% while the synthetic route to **37** is 27%.

It should be noted that a very recent report by Tanimoto and Oritani (37) provides a completely different route to enantiomerically pure Ambrox from farnesyl acetate. The key reaction in this study involves a lipase-catalyzed kinetic resolution of (±)-drimane-8,11-diol. An extensive list of previous syntheses of Ambrox is also provided in this publication (37).

Experimental

General

Solvents used for chromatographic separations were glass-distilled prior to use. The term "petroleum ether" refers to a commercially available hydrocarbon mixture boiling in the 35–60°C range. All anhydrous solvents were prepared according to standard procedures. *n*-Butyllithium and methyllithium solutions were standardized by titration against diphenylacetic acid in anhydrous THF. Thujone was distilled from Western red cedar leaf oil generously donated by Intrinsic Research and Development Incorporated. All reactions were performed under a positive pressure of argon.

Reactions were monitored by analytical TLC and (or) gas chromatography. Analytical TLC was performed using Merck precoated silica gel 60 F_{254} aluminum-backed TLC plates. Visualization of the samples was realized with UV light and

For personal use only.

(or) by spraying with a 10% solution of ammonium molybdate in 10% sulfuric acid followed by heating at 180°C until blue spots developed. Gas chromatography analyses were performed on a Hewlett–Packard 5890A gas chromatograph fitted with a fused silica capillary column coated with cyanopropylphenyl silicone gum (DB 1701) (J & W Scientific: 15 m × 0.262 mm) connected to a Hewlett–Packard 3388A integrator and flame ionization detector (carrier gas: helium; injection temperature: 250°C).

Ozone was generated in a Welsbach model T-23 laboratory ozonator.

Purification of all reaction products was carried out, unless otherwise stated, by flash chromatography using silica gel (Sigma, 10–40 μm), with nitrogen gas pressure to obtain a suitable flow.

Bulb-to-bulb distillation was performed using a Kugelrohr distillation apparatus (the air bath temperature at which distillation occurred is given in parentheses).

All melting points were recorded on a Reichert melting point apparatus and are uncorrected. Optical rotations were recorded on a Perkin–Elmer 141 automatic polarimeter using quartz cells of 10 cm path length, in chloroform solution unless otherwise stated. The concentration (g/100 mL) is given in parentheses.

UV spectra were recorded on a Perkin–Elmer Lambda 4B UV/VIS spectrophotometer using quartz cells of 1 cm path length. IR spectra were recorded on a Perkin–Elmer 710B infrared spectrophotometer. Fourier transform IR spectra were recorded on either Perkin–Elmer 1710 or Bomen Michelson 100 Fourier transform infrared spectrophotometers.

^{1}H NMR spectra were recorded in $CDCl_3$ at 400 MHz on a Bruker WH 400 spectrometer, unless otherwise noted. Chemical shifts were recorded in ppm relative to TMS (internal standard). ^{13}C NMR spectra were recorded on a Bruker AE-200 spectrometer and chemical shifts are reported in ppm relative to TMS.

Low-resolution mass spectra were recorded on Kratos MS 50 and MS 80 mass spectrometers. High-resolution mass spectra were recorded on a Kratos MS 50 mass spectrometer. Chemical ionization mass spectra were recorded on a Delsi–Nermag R10–10C mass spectrometer using ammonia as carrier gas.

Elemental analyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia, Vancouver.

All compounds are named in accordance with Chemical Abstracts Rules. The skeletal numbering system employed in the Discussion section, as well as proton and carbon designations to interpret the NMR spectra, follows the normal conventions of terpenoid and steroid literature. This allows an easier comparison between the compounds under discussion with related natural products.

4,4a,5,6,7,8-Hexahydro-3-acetyloxy-4aβ,8,8-trimethylnaphthalen-2(3*H*)-one (10/11)

To a solution of enone **6** (5.10 g, 26 mmol) in anhydrous benzene (280 mL), manganese triacetate dihydrate (20.40 g, 76 mmol) was added. The brown suspension was heated at reflux for 1 h with azeotropic removal of water. After cooling to room temperature, additional manganese triacetate dihydrate (20.40 g, 76 mmol) was added and the mixture was heated at reflux for 20 h. The reaction was then cooled to room temperature, diluted with ethyl acetate (500 mL), and washed with 1 M HCl (200 mL), saturated sodium bicarbonate solution (200 mL), and brine (200 mL). The organic fraction was dried, filtered, and concentrated in vacuo to yield 9.03 g of a yellow oil. Chromatographic purification of the oil using diethyl ether/hexanes 3:7 as eluent gave 5.71 g (86%) of a white solid. GC analysis (200°C) of this product showed a 4:1 mixture of isomers (**10/11**, R = Ac). Recrystallization from ethyl acetate gave colourless needles with the same isomeric ratio, mp 114–115°C; IR ($CHCl_3$) of the mixture ν_{max}: 3051, 2917, 1718, 1660, 1596 cm^{-1}; UV (methanol) λ_{max} (log ε): 240 (3.99); ^{1}H NMR of the mixture, signals corresponding to the major isomer, β acetate) δ: 1.18 (3H, s), 1.25 (3H, s), 1.40 (3H, s), 2.12 (3H, s), 5.25 (1H, t, J = 4 Hz, C8-H), 6.07 (1H, s, C6-H); (signals corresponding to the minor isomer, α acetate) δ: 1.17 (3H, s), 1.24 (3H, s), 1.39 (3H, s), 2.11 (3H, s), 5.60 (1H, t, J = 12, 4 Hz, C8-H), 5.98 (1H, s, C6-H); ^{13}C NMR (signals corresponding to the minor isomer) δ: 17.79, 20.92, 25.83, 29.28 (×2), 36.93, 38.01, 40.22, 40.83, 46.74, 71.00, 121.99, 170.31, 177.68, 194.85; MS *m/z*: 250 (M$^+$, 2.9), 208 (4.1), 193 (1.6), 164 (100); HRMS calcd. for $C_{15}H_{22}O_3$: 250.1570; found: 250.1568. Anal. calcd. for $C_{15}H_{22}O_3$: C 7.98, H 8.85; found: C 72.19, H 8.82.

2,3,4,4a,5,6,7,8-Octahydro-2β,3β-dihydroxy-4aβ,8,8-trimethylnaphthalene (12), 2,3,4,4a,5,6,7,8-octahydro-2α,3α-dihydroxy-4aβ,8,8-trimethylnaphthalene (13), 2,3,4,4a,5,6,7,8-octahydro-2α,3β-dihydroxy-4aβ,8,8-trimethylnaphthalene (15), and 2,3,4,4a,5,6,7,8-octahydro-2β,3α-dihydroxy-4aβ,8,8-trimethylnaphthalene (14)

To a solution of **10/11** (1.44 g, 5.76 mmol) (4:1 isomeric mixture) in anhydrous THF (80 mL) was added lithium aluminum hydride (LAH) (726 mg, 19.1 mmol). After stirring at room temperature for 10 min, the reaction was quenched by adding 1 M HCl (100 mL) slowly to the suspension and then extracted with diethyl ether (400 mL). The combined organic layers were washed with water (100 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo, to yield 1.45 g of the crude products **12–15**. Chromatographic purification using EtOAc/petroleum ether (3:2) as eluent afforded 7β,8β diol **12** (770.8 mg, 63.7%) as well as 7α,8α diol **13** (15.4 mg, 1.3%). Further elution afforded 7α,8β diol **15** (46.2 mg, 3.8%) and 7β,8α diol **14** (277.5 mg, 23%).

*7β,8β-Diol **12***: mp 103–104°C (EtOAc); $[\alpha]_D^{25}$ +41.8 (c = 1.00); IR (KBr) ν_{max}: 3349, 3012, 2927, 1627 cm^{-1}; ^{1}H NMR δ: 1.09 (3H, s, C4-αCH_3), 1.16 (3H, s, C4-βCH_3), 1.35 (3H, s, C10-CH_3), 1.10–1.60 (5H, m), 1.51 (1H, dd, J = 14, 3 Hz, C9-H), 1.85 (2H, dd, J = 13, 8 Hz), 2.08 (2H, br s, O-H), 3.93 (1H, ddd, J = 7, 4, 3 Hz, C8-H), 4.21 (1H, dd, J = 4, 4 Hz, C7-H), 5.45 (1H, d, J = 4 Hz, C6-H); ^{13}C NMR δ: 18.59, 28.28, 29.22, 32.67, 35.51, 36.57, 42.09, 42.16, 45.30, 67.08, 68.58, 118.85, 154.15; MS *m/z*: 210 (M$^+$, 21.2), 192 (33.6), 177 (21.1), 166 (17.5), 151 (36.1), 135 (100); HRMS calcd. for $C_{13}H_{22}O_2$: 210.1620; found: 210.1615. Anal. calcd. for $C_{13}H_{22}O_2$: C 74.25, H 10.53; found: C 74.36, H 10.60.

^{1}H NMR decoupling experiment: irradiation of the signal resonating at δ 3.93 ppm simplified the doublet of doublets resonating at δ 4.21 ppm to a doublet with a coupling constant

^{1}H NMR decoupling experiment: irradiation of the signal at δ 3.85 ppm collapsed the doublet of doublets at δ 4.08 ppm to a doublet with a coupling constant value of 2.5 Hz and simplified the multiplet resonating at δ 1.50 ppm. Irradiation of the doublet of doublets resonating at δ 4.08 ppm collapsed the signal resonating at δ 5.35 ppm to a singlet, and simplified the signal at δ 3.85 ppm to a doublet of doublets with coupling constant values of 4 and 12 Hz.

^{1}H NMR NOE difference experiment: irradiation of the singlet resonating at δ 1.28 ppm led to enhancement of the signals resonating at δ 1.11, 1.50, 1.80, and 3.85 ppm; irradiation of the signal resonating at δ 1.80 ppm led to enhancement of the singlets resonating at δ 1.11 and 1.28 ppm; irradiation of the signal resonating at δ 3.85 ppm led to enhancement of the signals resonating at δ 1.28 and 5.35 ppm; irradiation of the doublet of doublets resonating at δ 4.08 ppm led to enhancement of the signals resonating at δ 1.50 and 5.35 ppm; irradiation of the doublet resonating at δ 5.35 ppm. led to enhancement of the signals resonating at δ 1.08 and 4.08 ppm.

4aα,5,6,7,8,8a-Hexahydro-5,5,8aβ-trimethylnaphthalen-2(1*H*)-one (9), 3,5,6,7,8,8a-hexahydro-5,5,8aβ-trimethylnaphthalen-2(1*H*)-one (16), and 4aβ,5,6,7,8,8a-hexahydro-5,5,8aβ-trimethylnaphthalen-2(1*H*)-one (17)

Method A

To a solution of isomeric diols **12–15** (1.35 g, 6.4 mmol) in glacial acetic acid (80 mL), concentrated sulfuric acid (395 μL) was added. The reaction mixture was heated at reflux for 2 h, cooled to room temperature, and diluted with water (300 mL). The aqueous layer was extracted with diethyl ether (400 mL). The combined organic layers were washed with saturated sodium bicarbonate solution (200 mL), water (200 mL), dried, filtered, and concentrated in vacuo. Chromatographic purification of the residue, using EtOAc/petroleum ether 5:95 as eluent, gave ketone **16** (60.9 mg, 5%) as a colourless oil, enone **17** (50.5 mg, 4%) as a light yellow oil, and enone **9** (72.5 mg, 6%) as a colourless oil that solidified upon standing. The spectroscopic data are in agreement with published values (19).

Method B

A mixture of 7β,8β-diol **12** (1.09 g, 5.2 mmol) and *p*-toluenesulfonic acid (1.19 g, 6.2 mmol) in anhydrous THF (50 mL) was heated at reflux for 24 h. After cooling to room temperature, the solvent was removed in vacuo and the residue was

For personal use only.

chromatographed on silica gel using EtOAc/cyclohexane 1:9 as eluent, affording ketone **16** (250.5 mg, 25%) as a colourless oil. Further elution afforded enone **17** (18.0 mg, 2%) as a light yellow oil and enone **9** (643.0 mg, 64%) as a colourless oil that solidified on standing.

Method C

To a solution of 7β,8α-diol **14** (25.0 mg, 0.12 mmol) in anhydrous THF (5 mL), *p*-toluenesulfonic acid (27.0 mg, 0.14 mmol) was added. The mixture was heated at reflux for 24 h. After cooling the reaction to room temperature, the solvent was removed in vacuo and the residue was purified by column chromatography on silica gel using EtOAc/cyclohexane 1:9 as eluent, affording ketone **16** (3.0 mg, 13%) and enone **9** (15 mg, 66%).

Method D

To a solution of enone **6** (2.30 g, 12.0 mmol) in anhydrous benzene (130 mL) was added manganese triacetate dihydrate (9.00 g, 33.5 mmol). The brown suspension was heated at reflux for 1 h with azeotropic removal of water. After cooling to room temperature, additional manganese triacetate dihydrate (9.00 g, 33.5 mmol) was added and the mixture was heated at reflux for a further 20 h. The reaction was cooled to room temperature, diluted with ethyl acetate (200 mL), and sequentially washed with 1 M HCl (75 mL), saturated sodium bicarbonate solution (75 mL), and brine (75 mL). The organic layer was dried, filtered, and concentrated in vacuo. The residue was dissolved in anhydrous THF (160 mL) and LAH (1.60 g, 42 mmol) was added. After stirring for 10 min at room temperature, the suspension was slowly poured into 1 M HCl (200 mL) and extracted with diethyl ether (600 mL). The combined organic layers were washed with water (100 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo to yield a crude mixture of isomeric diols **12–15** (3.12 g) as a white solid. This solid was dissolved in anhydrous THF (115 mL). *p*-Toluenesulfonic acid (2.70 g, 14.2 mmol) was added and the mixture was heated at reflux for 24 h. After cooling to room temperature, the reaction was diluted with diethyl ether (500 mL), washed with saturated sodium bicarbonate solution (200 mL) and with water (200 mL), then dried, filtered, and concentrated in vacuo to yield 2.35 g of residue. Chromatographic purification of the crude using EtOAc/cyclohexane 1:9 as eluent gave ketone **16** (342 mg, 15%), enone **17** (40.5 mg, 2%), and enone **9** (1.12 g, 49%).

Method E

A solution of ketone **16** (230.7 mg, 1.2 mmol) and *p*-toluenesulfonic acid (286.8 mg, 1.5 mmol) in anhydrous THF (18 mL) was heated at reflux for 24 h. After cooling the reaction mixture to room temperature, the solution was concentrated in vacuo, and the residue was chromatographed on silica gel using EtOAc/cyclohexane 1:9 as eluent, yielding unreacted ketone **16** (72.0 mg, 31%), enone **17** (3.0 mg, 1%), and enone **9** (149.3 mg, 65%).

4aα,5,6,7,8,8a-Hexahydro-5,5,8aβ-trimethyl-2,oxo-lα-naphthalene acetic acid ethyl ester (19), and 4aα,5,6,7,8,8a-hexahydro-1α-iodo-5,5,8aβ-trimethylnaphthalen-2(1*H*)-one (27)

A solution of diisopropylamine (1.47 mL, 10.5 mmol) in anhydrous THF (12 mL) was cooled to −78°C and *n*-butyllithium (7.33 mL, 9.17 mmol) was added. The solution was allowed to warm up to −15°C for 30 min, then cooled to −78°C, and a solution of enone **9** (1.26 g, 6.56 mmol) in anhydrous THF (50 mL) was added dropwise. The reaction was warmed to 0°C for 30 min, then cooled to −78°C, and freshly distilled ethyl iodoacetate (2.32 mL, 19.65 mmol) was added. The reaction mixture was stirred at −78°C for 1 h and then warmed to 0°C for another hour, poured into a saturated ammonium chloride solution (200 mL), and extracted with diethyl ether (400 mL). The organic extracts were washed with water (200 mL), dried, filtered, and concentrated in vacuo to yield 2.12 g of residue as a yellow oil. Chromatographic purification of the residue, using EtOAc/hexanes 1:9 as eluent, gave unreacted starting material **9** (230 mg, 18%), enone **27** (185 mg, 9%) as a white solid, and enone **19** (1.33 g, 73%) as a yellowish oil.

Enone 27: mp 109–110°C (EtOAc); $[\alpha]_D^{25}$ −164.6 (c = 1.00); IR (KBr) ν_{max}: 3006, 2927, 1675, 1610 cm^{-1}; UV (methanol) ν_{max} (log ε): 245 (3.6); ^1H NMR δ: 0.95 (3H, s, C4-βCH$_3$), 1.11 (3H, s, C4-αCH$_3$), 1.16 (3H, s, C10-CH$_3$), 1.19–1.70 (6H, m), 2.16 (1H, dd, J = 3, 2 Hz, C5-H), 4.26 (1H, d, J = 1.4 Hz, C9-H), 6.12 (1H, ddd, J = 10, 3, 1.4 Hz, C7-H), 6.89 (1H, dd, J = 10, 2 Hz, C6-H); ^{13}C NMR δ: 15.34, 18.54, 22.40, 32.22, 32.45, 39.14, 40.74, 41.68, 50.79, 51.59, 127.23, 149.94, 193.08; MS *m/z*: 318 (M^+, 1.1), 191 (66.7), 147 (39.9), 135 (37.3), 121 (100); HRMS calcd. for $C_{13}H_{19}OI$: 318.0479; found: 318.0481. 3,4,4aα,5,6,7,8,8a-Octahydro-5,5,8aβ-trimethyl-2-oxo-1α-naphthalene acetic acid ethyl ester (20)

A hydrogenation vessel containing a suspension of enone **19** (2.106 g, 7.6 mmol) and 10% palladium on charcoal (210 mg) in EtOAc (100 mL) was purged three times with hydrogen at a pressure of 15 psi. The vessel was then pressurized to 40 psi with hydrogen and shaken for 20 min at room temperature. A sample taken for analytical TLC (EtOAc/hexanes 1:4) indicated the reaction was complete. The mixture was filtered through Celite 545, and the flask and Celite were washed with EtOAc (175 mL). The solution was concentrated in vacuo to yield 2.50 g of crude product. Chromatographic purification using EtOAc/hexanes 1:4 as eluent gave keto ester **20** (2.11 g, 100 %) as a colourless oil. $[\alpha]_D^{25}$ −34.8 (c = 1.00); IR (neat) ν_{max}: 2943, 1732 cm^{-1}; ^1H NMR δ: 0.87 (3H, s), 0.98 (3H, s), 0.99 (3H, s), 1.24 (3H, t, J = 8 Hz, CH_3-CH_2), 1.10–1.70 (8H, m), 1.95 (1H, m), 2.30–2.75 (5H, m), 4.11 (2H, q, J = 8 Hz, CH_3-CH_2) ; ^{13}C NMR δ: 14.08, 18.52, 21.55, 22.01, 23.33, 33.30 (×2), 33.44, 36.37, 38.54, 40.08, 42.15, 44.94, 60.38, 60.86, 171.72, 213.04; MS *m/z*: 280 (M^+, 1.4), 262 (3.6), 247 (6.3), 232 (30.1), 109 (100); HRMS calcd. for $C_{17}H_{28}O_3$: 280.2038; found: 280.2044. 1,2,3,4,4aα,5,6,7,8,8a-Decahydro-5,5,8aβ-trimethyl-2,2-ethylenediozy-1α-naphthalene acetic acid ethyl ester (21), and 1,2,3,4,4aα,5,6,7,8,8a-decahydro-5,5,8aβ-trimethyl-2,2-ethylenedioxy-1β-naphthalene acetic acid ethyl ester (28)

Method A

A solution of keto ester **20** (133.2 mg, 0.5 mmol), *p*-toluenesulfonic acid (3.8 mg, 2×10^{-2} mmol), and ethylene glycol (0.159 mL, 2.8 mmol) in anhydrous benzene (7 mL) was heated at reflux with azeotropic removal of water. The reaction was monitored by GC and showed 90% conversion after 6 h. The reaction mixture was then cooled to room temperature, diluted with benzene (20 mL), washed with saturated sodium bicarbonate solution (10 mL) and with water (10 mL), then dried, filtered, and concentrated in vacuo. The resulting oil was purified by column chromatography using EtOAc/hexanes 1:4 as eluent. The silica gel was treated with a mixture of EtOAc/hexanes/Et_3N in a ratio of 1: 4: 4×10^{-2}, prior to use. Purification yielded ketal **21** (71.4 mg, 46%) as a colourless oil that solidified upon standing, ketal **28** (46.3 mg, 29%) as a colourless oil, and starting keto ester **20** (13 mg, 10%).

A longer reflux (19 h) proved to increase the ratio of ketal **28** (61% by GC), lowering the ratio of ketal **21** to 11% (by GC).

*Ketal **21***: mp 42°C; $[\alpha]_D^{25}$ −7.7 (c = 1.00); IR ($CHCl_3$) ν_{max}: 2946, 1735 cm^{-1}; ^1H NMR δ: 0.82 (3H, s, C4-βCH$_3$), 0.87 (3H, s, C4-αCH$_3$), 0.90–1.18 (2H, m), 1.19 (3H, s, C10-CH$_3$), 1.27 (3H, t, J = 7 Hz, CH_3-CH_2), 1.30–1.40 (2H, m), 1.50–1.70 (7H, m), 2.08 (1H, ddd, J = 5, 5, 2 Hz, C9-H), 2.47 (2H, dd, J = 5, 3.6 Hz, C11-2H), 3.80 (2H, dt, J = 6.5, 3 Hz), 3.98 (2H, m), 4.14 (2H, dq, J = 7, 1 Hz, CH_3-CH_2); ^{13}C NMR δ: 14.20, 18.51, 20.13, 21.74, 22.23, 32.69, 33.03, 33.42, 33.59, 37.01, 38.08, 42.22, 46.59, 50.30, 60.25, 63.34, 64.46, 111.04, 174.21; MS *m/z*: 324 (M^+, 29), 309 (6.4), 279 (18.8), 99 (100); HRMS calcd. for $C_{19}H_{32}O_4$: 324.2302; found: 324.2293. Method B

To a solution of trimethylsilyl triflate (30 μL, 0.15 mmol) in anhydrous methylene chloride (1 mL) at −78°C was added 1,2-bis(trimethylsilyloxy)ethane (0.42 mL, 1.7 mmol). A solution of keto ester **20** (434.6 mg, 1.55 mmol) in anhydrous methylene chloride (5 mL) was added to the reaction and the mixture was warmed to 0°C and stirred for 2 h; the reaction was monitored by GC. (Strict anhydrous conditions were required; traces of moisture were found to lower the yield of ketal **21** to 44%, increasing the presence of ketal **28** up to 30%.) The reaction was quenched with dry pyridine (0.35 mL), poured into saturated sodium bicarbonate solution (10 mL), and extracted with diethyl ether (50 mL). The combined organic layers were washed with 10% copper sulfate solution (30 mL) and water, dried, filtered, and concentrated in vacuo. Bulb-to-bulb distillation of the crude product gave 482 mg of a colourless oil (bp 118°C at 9 Torr (1 Torr = 133.3 Pa)). GC analysis of the oil showed a 93:5:2 mixture of products, the minor compounds being ketal **28** and starting keto ester **20**, respectively, and the major one being ketal **21**. The mixture was not further purified.

Method C

A solution of triflic acid (17.4 μL, 0.2 mmol) in anhydrous THF (2.4 mL) was cooled to −78°C, and 1,2-bis(trimethylsilyloxy)ethane (0.48 mL, 1.9 mmol) was added to the solution with temperature maintained at −78°C. A solution of

keto ester **20** (276.1 mg, 1.0 mmol) in anhydrous THF (12.2 mL) was added and the reaction mixture was stirred at 0°C. After 14 h, GC analysis showed a mixture of **21**, **28**, and **20** in an 8:1:1 ratio. The reaction was quenched with dry pyridine (150 μL), poured into saturated sodium bicarbonate solution (10 mL), and extracted with diethyl ether (50 mL). The combined organic layers were washed with 10% copper sulfate solution (20 mL) and with water (20 mL), then dried, filtered, and concentrated in vacuo. The residue was purified by chromatography on silica gel treated with EtOAc/hexanes/Et_3N in a 1:4:4 × 10^{-2} ratio prior to use, and eluted with EtOAc/hexanes 1:4, affording ketal **21** (214.4 mg, 67%), ketal **28** (27.1 mg, 8%), and starting keto ester **20** (27.0 mg, 10%).

1,2,3,4,4aα,5,6,7,8,8α-Decahydro-2,2-ethylenedioxy-1α-(2′-hydroxyethylen)-5,5,8aβ-trimethylnaphthalene (22)

To a solution of ketal **21** (621.9 mg, 1.9 mmol) in anhydrous diethyl ether (50 mL) was added LAH (218 mg, 5.7 mmol). The suspension was stirred at room temperature. After 10 min, analytical TLC (EtOAc/hexanes 1:1) showed reaction completion. Water (10 mL) was slowly added to the reaction mixture and stirred for 5 min, then 15% sodium hydroxide solution (10 mL) was added and stirred for 5 min more. The mixture was then filtered and the filtrate was washed with diethyl ether (50 mL). The aqueous layer was extracted with diethyl ether (60 mL). The combined organic layers were washed with water (60 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo. The residue was chromatographed on silica gel, treated with EtOAc/hexanes/Et_3N in a 1:1:2 × 10^{-2} ratio prior to use, and eluted with EtOAc/hexanes 1:1, affording hydroxy ketal **22** (537.8 mg, 100%) as a colourless oil. $[\alpha]_D^{25}$ −7.5 (c = 1.00); IR (neat) $-\nu_{max}$: 3300, 2947 cm^{-1}; ^1H NMR δ: 0.83 (3H, s), 0.88 (3H, s), 1.00–1.15 (2H, m), 1.17 (3H, s), 1.25 (1H, m), 1.35–1.71 (10H, m), 1.82 (1H, m, C11-H_A), 2.02 (1H, m, C11-H_B), 3.49 (1H, m, C12-H_A), 3.68 (1H, m, C12-H_B), 3.85 (2H, m), 3.98 (2H, m); ^{13}C NMR δ: 16.46, 20.13, 21.52, 22.71, 30.95, 32.88, 32.96, 33.36, 36.09, 38.90, 42.31, 46.29, 52.72, 63.09, 64.46, 64.63, 112.32; MS *m/z*: 282 ($M^{+\cdot}$ 2.4), 267 (03), 252 (0.2), 99 (100); HRMS calcd. for $C_{17}H_{30}O_3$: 282.2195; found: 282.2195. ^1H NMR decoupling experiment: irradiation of the signal resonating at δ 3.49 ppm affected the multiplets resonating at δ 1.82, 2.02, and 3.68 ppm; irradiation of the signal resonating at δ 3.68 ppm affected the multiplets resonating at δ 1.82, 2.02, and 3.49 ppm.

1,2,3,4,4aα,5,6,7,8,8a-Decahydro-2,2-ethylenedioxy-1α-(2′-*O*-benzyl ethyl)-5,5,8aβ-trimethylnaphthalene (23)

Method A

Sodium hydride, 60% dispersion in paraffin oil (9.2 mg, 0.23 mmol), was weighed and then washed three times with anhydrous THF (9 mL), under argon atmosphere. Anhydrous THF (3 mL) was added. A solution of hydroxy ketal **22** (58.7 mg, 0.21 mmol) in anhydrous THF (10 mL) was added dropwise with good stirring. Sodium iodide (3.3 mg, 0.02 mmol) and potassium carbonate (55 mg, 0.40 mmol) were added to the suspension, then benzyl chloride (25.3 μL, 0.22 mmol) was added. The reaction mixture was heated at reflux for 12 h. After cooling the reaction to room temperature, water (5 mL) was added slowly. The aqueous layer was extracted with diethyl ether (15 mL). The combined organic layers were washed with water (5 mL), dried, filtered, and concentrated in vacuo. The residue was chromatographed on silica gel treated with EtOAc/hexanes/Et_3N 1:9:1 × 10^{-2} ratio prior to use, and eluted with EtOAc/hexanes 1:9, affording hydroxybenzyl ketal **23** (52.8 mg, 68%) as a colourless oil and starting hydroxy ketal **22** (12.8 mg).

*Hydroxybenzyl ketal **23***: $[\alpha]_D^{25}$ +0.95 (c = 1.00); IR (neat) ν_{max}: 2946 cm^{-1}; ^1H NMR δ: 0.82 (3H, s), 0.87 (3H, s), 1.06 (3H, m), 1.15 (3H, s), 1.35–1.80 (11H, m), 3.44 (2H, m), 3.80 (2H, m), 3.92 (2H, m), 4.52 (2H, d, J = 3 Hz, CH_2-Ph), 7.25 (1H, m), 7.32 (4H, m); ^{13}C NMR δ: 16.46, 20.13, 21.53, 22.67, 27.94, 32.87, 33.23, 33.36, 36.38, 38.66, 42.21, 46.19, 51.11, 63.25, 64.36, 71.98, 72.59, 112.15, 127.37, 127.59 (×2), 128.26 (×2), 138.75; MS *m/z*: 372 (M^+, 25.7), 357 (2.1), 281 (42.1), 99 (100); HRMS calcd. for $C_{24}H_{36}O_3$: 372.2666; found: 372.2665. Method B

Sodium hydride, 80% dispersion in paraffin oil (169 mg, 5.63 mmol), was weighed, and then washed three times with anhydrous THF (15 mL), under argon atmosphere. Anhydrous THF (24 mL) was added. A solution of hydroxy ketal **22** (529.5 mg, 1.88 mmol) in anhydrous THF (35 mL) was added dropwise with good stirring. Benzyl bromide (0.67 mL, 5.63 mmol) and tetrabutylammonium iodide (67.6 mg, 0.18 mmol) were added to the suspension. The reaction mixture was refluxed for 22 h, and monitored by analytical TLC (EtOAc/hexanes 1:4). After reaction completion, the mixture was cooled to room temperature and water (10 mL) was added slowly. The aqueous layer was extracted with diethyl ether (30 mL). The combined organic layers were washed with water (30 mL), dried, filtered, and concentrated in vacuo. The residue was chromatographed on silica gel treated with EtOAc/hexanes/Et_3N 1:9:1 × 10^{-2} ratio prior to use, and eluted with EtOAc/hexanes 1:9, affording hydroxybenzyl ketal **23** (684.7 mg, 98%) as a colourless oil.

3,4,4aα,5,6,7,8,8a-Octahydro-1α(2′-*O*-benzyl ethyl)-5,5,8aβ-trimethylnaphthalen-2(1*H*)-one (24)

Method A

To a solution of hydroxybenzyl ketal **23** (683 mg, 1.83 mmol) in acetone (20 mL), 1 M HCl (5.5 mL) was added. The reaction mixture was stirred at room temperature. After 1 h, analytical TLC (EtOAc/hexanes 1:4) showed reaction completion. Saturated sodium bicarbonate solution (20 mL) was added and the solution was extracted with diethyl ether (80 mL). The combined organic layers were washed with water (30 mL), dried, filtered, and concentrated in vacuo. Chromatographic purification of the crude product using EtOAc/hexanes 1:4 as eluent gave hydroxybenzyl ketone **24** (584 mg, 97%) as a colourless oil. $[\alpha]_D^{25}$ −27.6 (c = 1.00); IR (neat) ν_{max}: 2947, 1708 cm^{-1}; ^1H NMR δ: 0.86 (3H, s), 0.94 (3H, s), 0.95 (3H, s), 1.05–1.25 (2H, m), 1.40–1.70 (6H, m), 1.80–1.95 (3H, m), 2.02 (1H, m), 2.27 (1H, m), 2.54 (1H, m), 3.30 (1H, m), 3.42 (1H, m), 4.42 (2H, s), 7.32 (5H, m). ^{13}C NMR δ: 18.61, 21.78, 22.07, 23.48, 27.73, 33.29, 33.46,

Anal. calcd. for $C_{22}H_{32}O_2$: C 80.45, H 9.81; found: C 80.40, H 9.79.

Method B

To a solution of ketal **21** (3.95 g, 12.2 mmol) in anhydrous diethyl ether (120 mL), LAH (1.39 g, 36.6 mmol) was added and the solution was stirred at room temperature for 10 min. Water (50 mL) was added slowly and stirred for 5 min, then 15% sodium hydroxide solution (30 mL) was added and stirred for 5 min more. The mixture was filtered and the filtrate was washed with diethyl ether (150 mL). The aqueous layer was extracted with diethyl ether (200 mL). The combined organic layers were washed with water (150 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo to yield 3.60 g of crude hydroxy ketal **22**. This was dissolved in anhydrous THF (100 mL) and added to a solution of sodium hydride (80% dispersion in paraffin oil) (1.10 g, 36.6 mmol) in anhydrous THF (22 mL). Benzyl bromide (4.35 mL, 36.6 mmol) and tetrabutylammonium iodide (439 mg, 1.2 mmol) were added to the suspension. The reaction mixture was heated at reflux for 22 h. After cooling to room temperature, water (70 mL) was added slowly. The aqueous layer was extracted with diethyl ether (250 mL). The combined organic layers were washed with water (100 mL), dried, filtered, and concentrated in vacuo. The residue was dissolved in acetone (122 mL) and 1 M HCl (37 mL) was added. The reaction was stirred at room temperature for 1 h. Saturated sodium bicarbonate solution (130 mL) was added and the solution was extracted with diethyl ether (500 mL). The combined organic layers were washed with water (200 mL), dried, filtered, and concentrated in vacuo. Chromatographic purification of the residue using EtOAc/hexanes 1:4 as eluent afforded hydroxybenzyl ketone **24** (3.50 g, 87% from **21** over three steps) as a colourless oil.

1,2,3,4,4aα,5,6,7,8,8a-Decahydro-1α-(2′-*O*-benzyl ethyl)-2α,5,5,8aβ-tetramethylnaphthalen-2β-ol (25)

Method A

To a solution of hydroxybenzyl ketone **24** (44.5 mg, 0.13 mmol) in anhydrous diethyl ether (10 mL) was added methylmagnesium iodide (70 μL, 0.21 mmol). The mixture was refluxed for 5 h, then cooled to room temperature and saturated ammonium chloride solution (6 mL) added. The aqueous layer was extracted with diethyl ether (30 mL). The combined organic layers were washed with water (20 mL), dried, filtered, and concentrated in vacuo. Chromatographic purification of the residue, eluting with EtOAc/hexanes 1:6, afforded starting ketone **24** (32.0 mg, 72%) as well as alcohol **25** (6.9 mg, 15%) as a white solid; mp 85–86°C (EtOAc); $[\alpha]_D^{25}$ −12.1 (c = 1.00); IR (KBr) ν_{max}: 3397, 2946 cm^{-1}; ^1H NMR δ: 0.83 (3H, s), 0.86 (3H, s), 1.02 (2H, m), 1.14 (2H, m), 1.25 (3H, s), 1.27 (3H, s), 1.35–1.60 (9H, m), 1.70 (1H, m), 1.87 (1H, m, C11-H), 3.40 (2H, dd, J = 8, 8 Hz, C12-2H), 4.52 (2H, s, CH_2-Ph), 7.26 (1H, m), 7.36 (4H, m); ^{13}C NMR δ: 18.33, 18.76, 21.38, 24.65, 29.44, 31.15, 32.89, 33.30, 36.18, 36.97, 38.71, 42.20, 46.63, 55.38, 72.12, 72.96, 75.08, 127.54, 127.58 (×2), 128.37 (×2), 138.50; MS *m/z*: 344 (M^+, 0.5), 329 (0.7), 253 (2.3), 91 (100); HRMS calcd. for $C_{23}H_{36}O_2$: 344.2715; found: 344.2706. Anal. calcd. for $C_{23}H_{36}O_2$: C 80.19, H 10.52; found: C 80.00, H 10.45.

^1H NMR decoupling experiment: irradiation of the doublet of doublets resonating at δ 3.40 ppm affected the signals resonating at δ 1.40 and 1.86 ppm.

Method B

Cerium chloride heptahydrate (652.0 mg, 1.75 mmol) was dried at 140°C for 2 h under high vacuum, then cooled to room temperature. Anhydrous THF (11 mL) was added and the suspension was stirred for 1 h at room temperature, then cooled to −78°C; methyllithium (1.25 mol, 1.75 mmol) was added and stirred for 1 h (at −78°C). Hydroxybenzyl ketone **24** (441.4 mg, 1.34 mmol) in anhydrous THF (14 mL) was added to the suspension. After the addition was completed, the syringe was rinsed into the reaction with anhydrous THF (2 mL). Analytical TLC (EtOAc/hexanes 1:6) showed reaction completion after 10 min. The reaction was quenched with saturated ammonium chloride solution (20 mL) at −78°C. The mixture was allowed to warm to room temperature, and the aqueous layer was extracted with EtOAc (100 mL). The combined organic layers were dried, filtered, and concentrated in vacuo. Chromatographic purification of the crude product, eluting with EtOAc/hexanes 1:6, gave alcohol **25** (458.5 mg, 100%) as a white solid.

1,2,3,4,4aα,5,6,7,8,8a-Decahydro-1α-(2′-hydroxyethyl)-2α,5,5,8aβ-tetramethylnaphthalen-2β-ol (26)

A suspension of alcohol **25** (114.4 mg, 0.33 mmol) and 10% palladium on charcoal (117.2 mg) in absolute EtOH (20 mL), was purged three times with hydrogen at a pressure of 15 psi in a hydrogenation vessel. The pressure was increased to 20 psi of hydrogen and the vessel was shaken for 10 min at room temperature. A sample taken for analytical TLC (EtOAc/hexanes 1:1) showed reaction completion. The suspension was filtered through Celite 545. The flask and Celite were washed with EtOH (60 mL). Concentration in vacuo afforded diol **26** (95.5 mg) as a white solid; mp 145.5–146°C (EtOAc); $[\alpha]_D^{25}$ −22.7 (c = 1.00). IR (KBr) ν_{max}: 3315, 2947 cm^{-1}; ^1H NMR δ: 0.84 (3H, s), 0.85 (1H, m, C9-H), 0.88 (3H, s), 0.98–1.20 (4H, m), 1.27 (3H, s), 1.29 (3H, s), 1.30–1.75 (10H, m), 1.84 (1H, m, C11-H), 3.57 (2H, dd, J = 8, 8 Hz, C12-2H); ^{13}C NMR δ: 18.31, 18.72, 21.35, 24.65, 31.15, 32.48, 32.88, 33.28, 36.28, 36.97, 38.65, 42.22, 46.71, 55.15, 64.50, 75.03; MS *m/z*: 254 (M^+, 4.9), 239 (27.1), 236 (50.9), 221 (100); HRMS calcd. for $C_{16}H_{30}O_2$: 254.2246; found: 254.2242. Anal. calcd. for $C_{16}H_{30}O_2$: C 75.55, H 11.88; found: C 75.50, H 11.79.

^1H NMR decoupling experiment: irradiation of the signal resonating at δ 3.57 ppm simplified the multiplet resonating at δ 1.34 ppm to a doublet of doublets with coupling constant values of 3 and 13 Hz, and simplified the multiplet resonating at δ 1.84 ppm to a doublet of doublets with coupling constant values of 4 and 13 Hz.

1,2,3β,3a,4,5,5aα,6,7,8,9,9a-Dodecahydro-3aβ,6,6,9aβ-tetramethylnaphtho[2,1-*b*]furan, (−)-*epi*-Ambrox® (29)

Method A

p-Toluenesulfonic acid (33 mg, 0.17 mmol) was added to a suspension of diol **26** (337 mg, 1.33 mmol) in nitromethane

(30 mL). The reaction mixture was heated to 80°C (oil bath temperature) for 30 min; after cooling to room temperature, it was diluted with diethyl ether (50 mL) and washed with saturated sodium bicarbonate solution (25 mL). The organic layer was dried, filtered, and concentrated in vacuo. Chromatographic purification of the crude product, eluting with EtOAc/hexanes 1:4 mixture, yielded (−)-*epi*-Ambrox® (**29**) (261 mg, 83%) as a colourless oil that solidified upon standing. The spectroscopic and other data were in agreement with the published data (36). The primary alcohol **30** was also obtained (33.8 mg, 11%).

Method B

Cerium chloride heptahydrate (1.45 g, 3.90 mmol) was dried at 140°C for 2 h under high vacuum, then cooled to room temperature. Anhydrous THF (16 mL) was added and the suspension was stirred for 1 h at room temperature, then cooled to −78°C. Methyllithium (2.9 mL, 3.90 mmol) was added and stirred for 1 h at −78°C. Hydroxybenzyl ketone **24** (640 mg, 1.95 mmol) in anhydrous THF (20 mL) was added dropwise to the suspension. After 10 min, analytical TLC (EtOAc/hexanes 1:6) showed reaction completion. Saturated ammonium chloride solution (30 mL) was added. The mixture was allowed to warm to room temperature, and the aqueous layer was extracted with EtOAc (150 mL). The combined organic layers were dried, filtered, and concentrated in vacuo. The residue was dissolved in absolute ethanol (20 mL) in a hydrogenation vessel. 10% Palladium on charcoal (670 mg) was added and the vessel was purged 3 times with hydrogen at 15 psi, then shaken for 10 min at hydrogen pressure of 20 psi, at room temperature. The suspension was filtered through Celite 545 using a water aspirator. The flask and Celite were washed with ethanol (60 mL). Concentration in vacuo yielded 565 mg of an oil. Nitromethane (44 mL) was added to the crude product, then *p*-toluenesulfonic acid (49 mg, 0.26 mmol) was added, and the mixture was heated to 80°C (oil bath temperature) for 30 min. After cooling to room temperature, the reaction mixture was diluted with diethyl ether (100 mL). The organic layer was washed with saturated sodium bicarbonate solution (50 mL), dried, filtered, and concentrated in vacuo. Chromatographic purification of the residue, eluting with EtOAc/hexanes: 1:4, yielded (−)-*epi*-Ambrox® (**29**) (371 mg, 80% from **24**, three steps) as a colourless oil that solidified in vacuo, and 50 mg (11%) mixture of primary alcohols (**30**).

1,2,3,4,4aα,5,6,7,8,8a-Decahydro-2,2-ethylenedioxy-1β-(2′-hydroxyethylen)-5,5,8aβ-trimethylnaphthalene (32)

To a solution of ketal **31** (428 mg, 1.32 mmol) in anhydrous diethyl ether (40 mL), LAH (150 mg, 3.95 mmol) was added. The suspension was stirred at room temperature. After 10 min, analytical TLC (EtOAc/hexanes 1:1) showed reaction completion. Water (5 mL) was added and stirrred for 5 min, then 15% sodium hydroxide solution (5 mL) was added and stirred for 5 min more. The mixture was filtered and the filtrate was washed with diethyl ether (50 mL). The aqueous layer was extracted with diethyl ether (50 mL). The combined organic layers were washed with water (50 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo. The remaining oil was chromatographed on silica gel treated with EtOAc/hexanes/Et_3N in a $1:1:2 \times 10^{-2}$ ratio, prior to use, and eluted with EtOAc/hexanes 1:1 to yield hydroxy ketal **32** (342.7 mg, 92%) as a white solid, mp 69–70°C (EtOAc); $[\alpha]_D^{25}$ +9.3 (c = 1.00, EtOH); IR (KBr) ν_{max}: 3228, 2916 cm^{-1}; ^1H NMR (acetone-d_6) δ: 0.84 (3H, s), 0.90 (6H, s), 0.90–1.00 (4H, m), 1.15–1.65 (8H, m), 1.73 (1H, m), 1.94 (1H, ddd, J = 12, 4, 4 Hz), 2.82 (1H, br s, O-H), 3.50 (2H, m), 3.80 (1H, dd, J = 8, 8 Hz), 3.90 (1H, m), 4.00 (2H, m); ^{13}C NMR (acetone-d_6) δ: 15.02, 19.17, 20.56, 22.04, 28.04, 33.81, 33.91, 36.60, 39.74, 39.82, 42.73, 55.02, 55.98, 63.94, 64.40, 65.73, 111.68; MS *m/z*: 282 (M^+, 0.1), 264 (0.5), 249 (1.1), 220 (15.6), 205 (100); HRMS calcd. for $C_{17}H_{30}O_3$: 282.2195; found: 282.2189. Anal. calcd. for $C_{17}H_{30}O_3$: C 72.31, H 10.70; found: C 72.52, H 10.85.

1,2,3,4,4aα,5,6,7,8,8a-Decahydro-2,2-ethylenedioxy-1β(2′-*O*-benzyl ethyl)-5,5,8aβ-trimethylnaphthalene (33)

Sodium hydride, 80% dispersion in paraffin oil (108.8 mg, 3.62 mmol) was weighed and washed three times with anhydrous THF (15 mL), under argon atmosphere. Anhydrous THF (15 mL) was added. A solution of hydroxy ketal **32** (340 mg, 1.20 mmol) in anhydrous THF (23 mL) was added dropwise with good stirring. Benzyl bromide (0.43 mL, 3.62 mmol) and tetrabutylammonium iodide (43.5 mg, 0.12 mmol) were added to the suspension. The reaction mixture was heated at reflux. After 22 h, TLC (EtOAc/hexanes 1:4) showed reaction completion. The reaction was cooled to room temperature and water (7 mL) was added slowly. The aqueous layer was extracted with diethyl ether (25 mL). The combined organic layers were washed with water (25 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo. The residue was chromatographed on silica gel treated with EtOAc/hexanes/Et_3N $1:9:1 \times 10^{-2}$, prior to use, and eluted with EtOAc/hexanes 1:9, affording hydroxy benzyl ketal **33** (412.2 mg, 92%) as a white solid, mp 85–86°C (EtOAc); $[\alpha]_D^{25}$ +22.9 (c = 1.00); IR (KBr) ν_{max}: 2910 cm^{-1}; ^1H NMR δ: 0.82 (3H, s), 0.88 (3H, s), 0.90 (3H, s), 0.90–0.96 (2H, m), 1.15 (1H, ddd, J = 13, 13, 5 Hz), 1.25–1.80 (10H, m), 1.90 (1H, ddd, J = 10, 3, 3 Hz), 3.40 (1H, m, C12-H_A), 3.60 (1H, m, C12-H_B), 3.75 (1H, dd, J = 4, 4 Hz), 3.86 (1H, ddd, J = 7, 7, 5 Hz), 3.96 (1H, ddd, J = 7, 7, 7 Hz), 4.03 (1H, m), 4.50 (2H, d, J = 3 Hz, CH_2-Ph), 7.27 (1H, m), 7.34 (4H, m); ^{13}C NMR δ: 14.43, 18.50, 19.80, 21.68, 24.01, 33.22, 33.58, 36.09, 39.02, 39.17, 41.98, 53.84, 55.23, 63.28, 65.09, 72.39, 72.62, 111.35, 127.31, 127.54 (×2), 128.24 (×2), 138.90; MS *m/z*: 372 (M^+, 1.2), 357 (0.3), 281 (5.3), 205 (13.9), 99 (100); HRMS calcd. for $C_{24}H_{36}O_3$: 372.2664; found: 372.2656. Method B

To a solution of hydroxybenzyl ketone **24** (546.0 mg, 1.66 mmol) in THF/MeOH 1:1 (20 mL) was added sodium methoxide (270.0 mg, 5.0 mmol) and the solution was heated at reflux for 22 h. After cooling to room temperature, saturated ammonium chloride solution (15 mL) was added and the mixture was extracted with diethyl ether (150 mL). The combined organic layers were washed with water (75 mL), dried, filtered, and concentrated in vacuo. Chromatographic purification of the residue, eluting with EtOAc/hexanes 1:4, afforded hydroxybenzyl ketone **34** (487.6 mg, 89%) as a colourless oil and starting ketone **24** (52.3 mg, 10%).

1,2,3,4,4aα,5,6,7,8,8a-Decahydro-1β-(2′-*O*-benzyl ethyl)-2α,5,5,8aβ-tetramethylnaphthalen-2β-ol (35)

Cerium chloride heptahydrate (720.0 mg, 1.93 mmol) was dried at 140°C under high vacuum for a period of 2 h, then cooled to room temperature. Anhydrous THF (12 mL) was added, and the suspension was stirred at room temperature for 1 h, then cooled to −78°C, and methyllithium (1.38 mL, 1.93 mmol) was added. The mixture was stirred at −78°C for 1 h. A solution of hydroxybenzyl ketone **34** (487.6 mg, 1.49 mmol) in anhydrous THF (15 mL) was added dropwise to the suspension, with maintenance of the temperature. After 10 min, a sample taken for analytical TLC (EtOAc/hexanes 1:4) showed reaction completion. Saturated ammonium chloride solution (15 mL) was added to the reaction mixture, and the temperature was allowed to rise to 25°C. The aqueous layer was extracted with EtOAc (80 mL). The combined organic layers were washed with water (40 mL), dried, filtered, and concentrated in vacuo. Chromatographic purification of the residue with EtOAc/hexanes 1:4 afforded hydroxybenzyl alcohol **35** (502.8 mg, 98%) as a white solid, mp 88.5–89°C (EtOAc/hexane); $[\alpha]_D^{25}$ +10.8 (c = 1.00); IR (KBr) ν_{max}: 3479, 2910 cm^{-1}; ^{1}H NMR δ: 0.83 (3H, s), 0.86 (3H, s), 0.70–0.90 (2H, m), 0.97 (3H, s), 1.10 (3H, s), 1.20–1.80 (13H, m), 3.44 (2H, m), 4.50 (2H, s), 7.27 (1H, m), 7.33 (4H, m); ^{13}C NMR δ: 15.07, 18.13, 18.30, 21.64, 25.28, 30.68, 33.25, 33.42, 38.63, 39.22, 41.98, 42.18, 54.91, 55.89, 72.42, 72.73, 72.89, 127.43, 127.48 (×2), 128.31 (×2), 138.63; CI MS *m/z*: 345 (M^+, +1), 326 (0.2), 311 (0.2), 267 (0.2), 235 (10.3), 218 (34.2), 91 (100). Anal. calcd. for $C_{23}H_{36}O_2$: C 80.19, H 10.52; found: C 80.40, H 10.58.

1,2,3,4,4aα,5,6,7,8,8a-Decahydro-1β-(2′-hydroxyethyl)-2α,5,5,8aβ-tetramethylnaphthalen-2β-ol (36)

A suspension of hydroxybenzyl alcohol **35** (502.8 mg, 1.46 mmol) and 10% palladium on charcoal (500.6 mg) in absolute ethanol (15 mL) was purged three times with hydrogen at 15 psi. The hydrogen pressure was then increased to 20 psi and the vessel was shaken for 10 min. A sample taken for analytical TLC (EtOAc/hexanes 1:1) showed reaction completion. The suspension was then filtered through Celite 545. The vessel and the Celite were washed with ethanol (50 mL). Concentration in vacuo and chromatographic purification of the residue, using diethyl ether/hexanes 5:1 as eluent, afforded diol **36** (370.0 gm, 100%) as a white solid, mp 168–170°C (EtOAc); $[\alpha]_D^{25}$ +15.7 (c = 1.00, ethanol); IR (KBr) $\nu_{max:}$ 3358, 3322, 2925 cm^{-1}; ^{1}H NMR δ: 0.83 (3H, s), 0.87 (3H, s), 0.80–0.90 (2H, m), 0.98 (3H, s), 1.14 (3H, s), 1.30–1.80 (14H, m), 3.56–3.68 (2H, m, C12-2H); ^{13}C NMR δ: 15.13, 18.13, 18.30, 21.64, 28.66, 30.68, 33.27, 33.42, 38.52, 39.33, 41.96, 42.25, 54.65, 55.88, 64.94, 72.91; MS *m/z*: 254 (M^+, 1.2), 236 (6.7), 221 (11.2), 43 (100); HRMS calcd. for $C_{16}H_{30}O_2$: 254.2247; found: 254.2254. Anal. calcd. for $C_{16}H_{30}O_2$: C 75.55, H 11.88; found: C 75.58, H 11.80.

1,2,3β,3a,4,5,5aα,6,7,8,9,9a-Dodecahydro-3aβ,6,6,9aβ-tetramethylnaphtho[2,1-*b*]furan, (−)-Ambrox® (37)

To a suspension of diol **36** (370 mg, 1.46 mmol) in nitromethane (29 mL) was added *p*-toluenesulfonic acid (11.6 mg, 6×10^{-2} mmol). The reaction mixture was heated to 80°C (oil bath temperature) for 30 min with good stirring. It was then cooled to room temperature and diluted with diethyl ether (60 mL). The organic layer was washed with saturated sodium bicarbonate solution (40 mL), dried, and concentrated in vacuo. Chromatographic purification of the residue, eluting with EtOAc/hexanes 1:4, gave pure (−)-Ambrox® (**37**) (261.4 mg, 76%). The spectroscopic and other data were in agreement with the published data (36).

β-Cyclodextrin effects on photo-Claisen rearrangement of allyl phenyl ether

Ana M. Sanchez, Alicia V. Veglia, and Rita H. de Rossi

Abstract: The photo rearrangement of allyl phenyl ether (**1**) in water and in solutions containing β-cyclodextrin (β-CD) leads to the *para* (**2**) and *ortho* (**3**) allyl phenols and phenol (**4**) as principal products. The substrate associates with β-CD forming a **1**:CD complex with a $K_{1\text{-CD}} = (4.6 \pm 0.6) \times 10^2\ M^{-1}$. When the photolysis is carried out in presence of oxygen there is a decrease in the total yields of products, but the inhibition is less marked in the presence of β-CD. The product quantum yields (Φ) for the complexed substrate are different for the free substrate, being higher for the *ortho* product, almost the same for the *para* product, and lower for phenol. The *ortho* selectivity was confirmed in the photolysis of the solid complex; these results are in agreement with those reported by this laboratory for the photo-Fries rearrangement of acetanilide and phenyl acetate.

Key words: cyclodextrin, photo-Claisen rearrangement, selectivity.

Résumé : Le photoréarrangement de l'oxyde d'allyle et de phényle (**1**), dans l'eau et dans des solutions contenant de la β-cyclodextrine (β-CD), conduit à la formation de *para* (**2**) et d'*ortho* (**3**) allylphénol et de phénol (**4**) comme produits principaux. Le substrat s'associe avec la β-CD conduisant à la formation d'un complexe **1** : CD avec un $K_{1\text{-CD}} = (4{,}6 \pm 0{,}6) \times 10^2\ M^{-1}$. Lorsqu'on effectue la photolyse en présence d'oxygène, les rendements globaux en produits augmentent, mais l'inhibition est moins marquée en présence de β-CD. Les rendements quantiques en produit (Φ) pour le substrat complexé sont différents de ceux du substrat libre; Φ est plus élevé pour le produit *ortho*, pratiquement le même pour le produit *para* et plus faible pour le phénol. La sélectivité pour le produit *ortho* a été confirmée lors de la photolyse du complexe solide; ces résultats sont en accord avec ceux rapportés par ce laboratoire pour le réarrangement de photo-Fries de l'acétanilide et l'acétate de phényle.

Mots clés : cyclodextrine, réarrangement de photo-Claisen, sélectivité.

[Traduit par la rédaction]

Introduction

During the last 10 years we have been concerned with the study of several aspects of the chemistry of cyclodextrins (CD), which are doughnut-shaped molecules formed by six, seven, or eight glucose units (α, β, and γ) and are able to form inclusion complexes with a great variety of compounds (1). This property of CD is responsible for certain changes in the reactivity and selectivity of organic reactions, of which we have reported some examples (2, 3).

Results from this laboratory concerning the selectivity induced by CD in organic reactions indicated *ortho* selectivity in the case of the photo-Fries rearrangement of acetanilide (4) and phenyl acetate (5), this effect being produced by sterically blocking certain potential sites of reaction in the complexed substrate. In the reactions of phenyl alkyl esters with different alkyl chain length (6), the *ortho* selectivity depends on the hydrophobicity of the alkyl chain competing with the aromatic group for the apolar cavity of CD.

We have undertaken the study of the photo-Claisen rearrangement of allyl phenyl ether (**1**) in water solutions in the presence of β-cyclodextrin (β-CD) in order to determine the effect of inclusion complex formation on the quantum yields for the *ortho* and *para* rearrangement products and phenol.

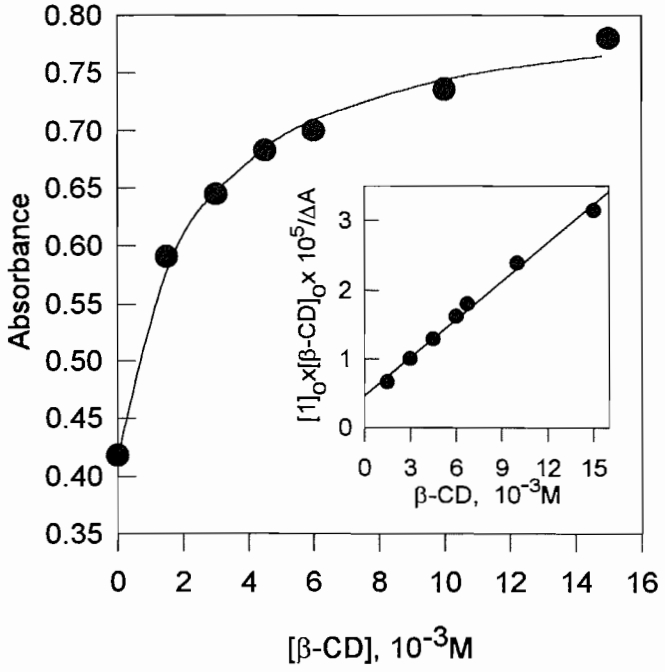
Results

Inclusion complex formation

The addition of β-CD to a water solution of the substrate **1** (0.76 mM) produced a bathochromic shift (2 nm) in the absorption maximum of **1** centered at 268.8 nm and an increase of absorbance, indicating the formation of a complex. The change in absorbance (ΔA) of the difference spectrum between the solution without β-CD and the solution with the higher concentration of β-CD employed was measured in order to choose the wavelength showing maximum ΔA value (λ = 277.9 nm). From the absorbance values measured at this wavelength at various β-CD concentrations (0–15 mM), Fig. 1, we obtained the equilibrium constant for the 1:1 association, $K_{1\text{-CD}} = (4.6 \pm 0.6) \times 10^2\ M^{-1}$, by nonlinear regression analysis of eq. [1] (7). This value is similar to those obtained for phenyl alkanoates (5, 6). Rearrangement of eq. [1] yields eq. [2].

$$[1] \quad A = A_0 + \{(\Delta A_{max} K_{1\text{-CD}}[\beta\text{-CD}])/(1 + K_{1\text{-CD}}[\beta\text{-CD}])\}$$

$$[2] \quad ([\mathbf{1}] \times [\beta\text{-CD}]_0)/\Delta A = (1/K_{1\text{-CD}}\Delta\varepsilon) + ([\beta\text{-CD}]_0/\Delta\varepsilon)$$



A plot of the left-hand side of eq. [2] vs. [β-CD] (7, 8) is

Fig. 1. Absorbance of solutions of **1** (0.76 mM) at different concentrations of β-CD. The curve is the fit using eq. [1]. *Inset:* Plot of the data and regression line according to eq. [2].

linear (correlation coefficient = 0.993) (Fig. 1, inset) and from the ratio of the slope and the intercept a value of $K_{1\text{-CD}} = (4.0 \pm 0.7) \times 10^2\ M^{-1}$ is calculated, in good agreement with the value obtained by nonlinear regression. Linearity of the plot according to eq. [2] confirms the stoichiometric ratio 1:1 (9).

The lack of an isosbestic point in the spectrum may indicate that complexes of higher stoichiometry are formed or that the spectra of the species are dependent on the reaction medium (7). Since similar results were obtained with other substrates (3, 5, 6), we think that the major complexes have 1:1 stoichiometry.

Photolysis

The photolysis of **1** in water solution and in solution containing β-CD leads to *p*-allylphenol (**2**), *o*-allylphenol (**3**), and phenol (**4**) as major products (eq. [3]). The formation of some minor quantities of *m*-allylphenol and cyclic products in protic solvents have been reported (10). Since compounds **2** and **3** decompose under these conditions, it is difficult to determine the contribution of the minor products to the total products yield; however, as can be seen in Table 2, we have a good material balance, which indicates that the formation of other products besides **2**–**4** must be very small.

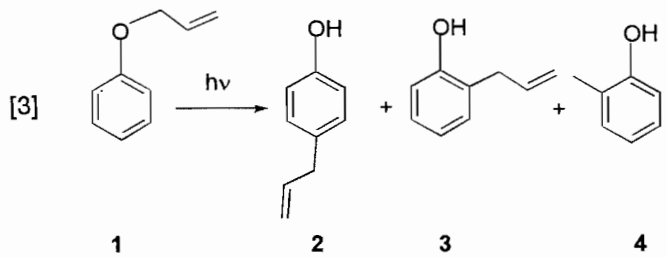

Table 1. UV–visible characteristics of substrate and products[a]

Compound	λ_{max}, nm	ε, $cm^{-1}\ M^{-1}$
Allylphenyl ether[b]	268.8	1036
o-Allyl phenol[c]	271.4	1796
p-Allyl phenol[d]	273.0	1429
Phenol[e]	269.6	1427

[a] T = 25°C; water as solvent. The error in ε is less than 3%.
[b] [Allylphenyl ether] = $(4.5–17.8) \times 10^{-5}$ M.
[c] [*o*-Allylphenol] = $(8.7–34.5) \times 10^{-5}$ M.
[d] [*p*-Allylphenol] = $(3.7–16.5) \times 10^{-5}$ M
[e] [Phenol] = (4-10) x 10^{-5} M.

Table 2. Effect of oxygen and β-cyclodextrin on the photolysis of allyphenyl ether in aqueous solution.[a]

	Yield,[b] %				
Condition	**1**[b,c]	**2**[d]	**3**[d]	**4**[c]	[3]/[2]
N_2	63.1	15.6	22.1	2.3	1.4 ± 0.1
N_2/β-CD	38.7	21.9	40.2	2.1	1.8 ± 0.1
O_2	88.7	6.56	3.99	0.90	1.6 ± 0.1
O_2/β-CD	82.0	11.5	7.33	0.70	1.6 ± 0.1

[a] T = 25°C; water as solvent; $[1]_0$ = 1.5 mM. Irradiation time = 4 h.
[b] Absolute yields based on the initial substrate concentration.
[c] The error in the determinations is less than 3%.
[d] Values corrected by the decomposition percentage determined at the same reaction conditions. The error in **2** and **3** is estimated as less than 5 and 3%, respectively.

We determined the product distribution by high-pressure liquid chromatography (HPLC) (see details in experimental section) because the UV–visible (UV) spectra of substrates and products are very similar (Table 1) making quantification by spectrophotometry impossible.

The results of the photolysis experiments are summarized in Table 2, where it can be seen that the yield of products decreases when oxygen is present (aerated solutions), from 37% in nitrogen to 11% in oxygen without β-CD and from 61% in nitrogen to 18% in oxygen in the presence of β-CD.[2] The **3**/**2** ratio is the same in both cases within the experimental error. It should be noticed that the overall yield increases in the presence of β-CD.

Quantum yield determinations

The addition of β-CD results in an increase in the quantum yield (Φ) of **3** (≈36%), but the change in the quantum yield of

[2] The value of the total yield of products calculated from the difference between the initial and the remaining substrate is considered to be more accurate than that calculated from the sum of the concentrations of **2** + **3** + **4** because this involves the accumulation of errors due to the measurements of three concentrations.

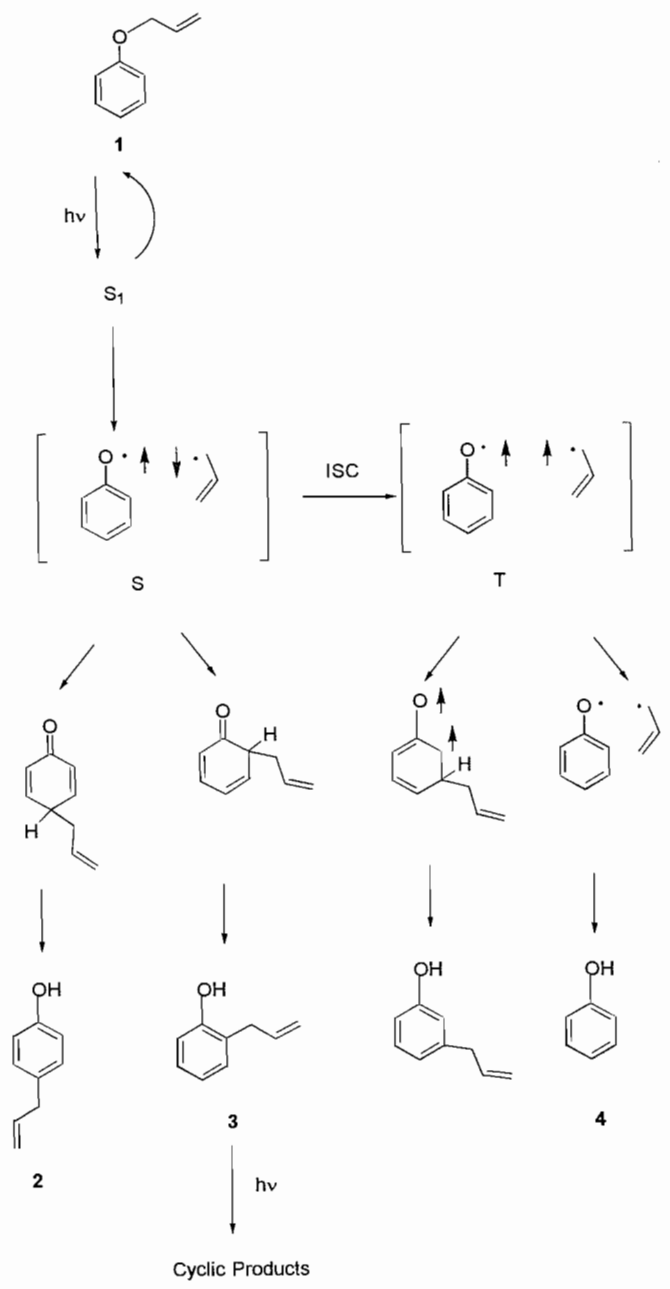
2 is barely outside the experimental error. In these experiments we observed an important decrease in the quantum yield of **4**. These results are summarized in Table 3. The **3/2** ratio increases with β-CD from 2.2 to 3.2.

Cyclodextrin complex photolysis

The solid **1**-CD complex, prepared as in previous papers (5, 6, 11), was irradiated during 4 h with a continuous flow of nitrogen. About 80.5% of substrate was recovered and the only product formed was **3** (18.2%). This result is similar to those obtained upon irradiation of solid complexes of *meta*-alkoxyphenylallyl ethers with α- and β-cyclodextrin (12) and indicates a more restricted environment for the substrate inside the cavity.

Discussion

The photo-Claisen rearrangement has received very scant attention, due mainly to the extensive polymerization products observed upon photolysis. The photochemical rearrangement of **1** has been studied in protic and nonprotic solvents (10, 13) but there have not been detailed studies in aqueous solutions. Some results about the reaction of *meta*-alkoxyphenylallyl ethers complexed with α- and β-CD have been published (12).



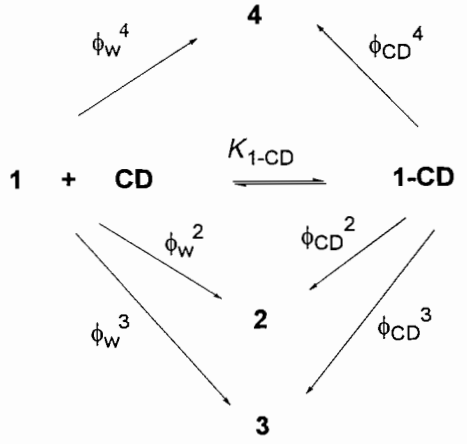
The composition of the photo products depends largely on the nature of the solvent (10). In protic solvents the principal products are 2- and 4-allylphenol and 3-allylphenol is formed in very small amounts (0.02%) (10). However, in aromatic hydrocarbons or cyclohexane, 3-allylphenol, as well as cyclic products, is obtained in significant amount (10).

The general mechanism proposed for the reaction is shown in Scheme 1 (10, 14).

The primary photochemical process produces a pair of radicals from the singlet excited state by homolytic rupture in the solvent cage. This radical pair leads to the *ortho* and *para* rearrangement products or, by intersystem crossing, it produces the triplet radical pair. The triplet radical pair leads to the *meta*-substituted compound and to phenol by escape of the radicals from the solvent cage (10). Cyclic products arise from photocyclization of *ortho* allylphenol, mainly in hydrocarbon solvents (10, 15).

In the presence of cyclodextrin at the maximum concentration used, 87% of the substrate is complexed; therefore the photochemical reaction must be taking place in both environments.[3] The kinetic scheme can be represented as in Scheme 2, where Φ_w^i and Φ_{CD}^i are the quantum yield for each product (i = **2**–**4**) in water and in β-CD, respectively.

Scheme 1.



The observed quantum yield for each product, Φ_{exp}, may be described by eq. [4],

[3] We assume that the photochemical and photophysical primary processes are not appreciably altered by association with CD. We think that the possibility of diffusion outside the cyclodextrin cavity is unlikely because singlet-state lifetimes are in the order of 10^{-9} s, whereas the diffusion rate of organic species outside the cavity of CD is in the range of 10^4–10^6 s^{-1} (see, for instance, ref. 16). On the other hand, escape of the radical pair from the cyclodextrin cavity and recombination in the bulk solution should lead to the same product ratio as in the absence of β-CD.

© 1997 NRC Canada

Scheme 2.

[4] $\Phi_{exp}^{\ i} = \Phi_w^{\ i}(1 - f) + \Phi_{CD}^{\ i}(\varepsilon_{CD}/\varepsilon_W)f$

where $f = K_{1\text{-}CD}[\beta\text{-CD}]/(1 + K_{1\text{-}CD}[\beta\text{-CD}])$ is the fraction of complexed substrate (**1–CD**) and $(\varepsilon_{CD}/\varepsilon_W)$ is a correction factor for the differences in light absorption by **1–CD** and **1.** The value of $\varepsilon_{CD}/\varepsilon_W = 1.2$ was determined from the absorbance at 254.0 nm of solutions with known initial concentration of **1** and β-CD, using the equilibrium concentration determined from $K_{1\text{-}CD}$. The $\Phi_{CD}^{\ i}$ values (Table 3) were calculated from eq. [4] using the measured value of $\Phi_w^{\ i}$ and the value of $K_{1\text{-}CD}$ (see above) determined independently.

The *ortho* selectivity in the presence of β-CD is consistent with the results for the Fries rearrangements of acetanilide (4) and phenyl acetate (5) that involve a similar mechanism, namely, a homolytic radical rupture and posterior recombination in the solvent cage. The change in the quantum yield for the *para* product is also similar. The decrease in phenol found in this work contrasts with the increase observed for this product in the Fries rearrangement of phenyl alkanoates (5, 6). This difference may be attributed to the distinct mechanism of formation of phenol, which in the case of the Fries rearrangement comes from the escape of radicals from the singlet radical pair whereas in the Claisen rearrangement it comes from the triplet radical pair. The results may indicate that in the complexed substrate the transformation of singlet to triplet radical pair is inhibited. Another possibility is that the rate of singlet–triplet interconversion is the same but the rate of recombination of the singlet radical pair increases.

The overall quantum yield for formation of **2** + **3** increases in the presence of β-CD despite the fact that it is known that the photo rearrangement of allyl phenyl ether is favored by polar solvents (10). Since the cavity of β-CD is less polar than water, the increase in quantum yield may indicate that the inclusion in the cavity protects the reactive excited state from quenching (17). The increase in *ortho* reactivity may be due to the geometry of the complex, which may place the migrating group in the appropriate position for reaction. The penetration of **1** into the β-CD cavity probably occurs, as usual, through the wider side (18); in this case the *ortho* position is relatively exposed to water and with little steric constraint.

Experimental section

Reagents

Water was obtained from a Millipore apparatus. Compounds **1** and **3** (Aldrich) and **4** (Merck, analytical grade) were commercial reagents and were used as received. Compound **2** was synthesized as indicated in the literature (19) from phenol (Carlo Erba); other compounds used were allyl chloride (BDH), ZnCl (Merck), and chloroform (Eclaire). The purity of compounds **1–4** was checked by HPLC. β-Cyclodextrin (Roquette)[4] was used as received. Its purity was controlled by UV spectrophotometry. Methanol was HPLC grade (Sintorgan).

Apparatus

The spectrophotometric determinations were carried out in a Shimadzu UV 260. A Varian Vista 5500 liquid chromatograph equipped with a Varian 2550 UV–vis detector and a Varian 4290 integrator was used for the HPLC analysis. The analytic column was a Micro Pack 15 cm × 4 mm MCH-5-n-cap.

Photolysis method

The reactions were carried out in a quartz reactor for 4 h. Solutions of **1** (1.5 mM) with or without CD were irradiated at 254 nm with an immersion-type low-pressure mercury lamp of 6 W with either bubbling nitrogen or nothing. The solid complex **1–CD** was irradiated in the same reactor but in a horizontal position at the same height of the filament lamp. In all cases the reactor was covered with aluminum foil. To check the photostability of the products, solutions containing **2** or **3** (0.2 mM) in water and in water with β-CD were irradiated under the same experimental conditions for the same period of time, taking the UV spectrum of samples every 30 min. The decrease in absorption was undetectable in 30 min but it amounted to ~40% for **2** and ~10% for **3** after 4 h irradiation. The values reported are the corrected ones. The correction was done by increasing the amount of the measured compound by the percentage of the observed decomposition product in a sample of the product irradiated during the same period of time.

Quantum yield determinations

Aqueous solutions of allyl phenyl ether (1.5 mM) with or without 15 mM of β-CD contained in square quartz cuvettes were placed in a merry-go-around apparatus. They were irradiated with a low-pressure mercury lamp (254 nm, 6 W); the lamp was covered every 10 min to stop irradiation and the yield of products was determined as indicated below. The irradiation was stopped at 30 min (3% conversion). The concentrations of **2–4** were plotted vs. time, and the slopes were used to calculate the quantum yields. These values and those of [**3**]/[**2**] ratios are reported in Table 3. The quantum yields were determined by using a solution of acetanilide in water as actinometer as previously reported (4, 5). Control experiments using **2** and **3** instead of the substrate showed that the products are stable under these conditions.

Analytical methods

Attempts to quantify the photolysis products by UV spectrophotometry were unsuccessful because of the similarity of the spectra of compounds **1**–**4**. Analysis of the products by HPLC was carried out at room temperature, using methanol/water/acetic acid (70/30/1) as solvent, with a flux program from 0.3 mL/min (time = 0) up 1 mL/min (time = 12 min); 4-hydroxypropiophenone (st) was used as internal standard. The UV detector was fixed at 269 nm. The quantification factors (qf) are defined as $Area_i \times mg_{st}/mg_i \times Area_{st}$. $Area_i$ and $Area_{st}$ are the areas of the compound analyzed and the standard, respectively, and mg_i and mg_{st} are the corresponding milligrams. The qf and retention times (rt, min) are: (qf, rt) 0.016, 22.05 for **1**; 0.010, 18.42 for **2**, 0.032, 12.97 for **3**; 0.126, 7.17 for **4**; and the rt is 15.77 for st. The concentrations reported are averages of at least three determinations; the differences between them are 2–3%.

Orientational order of 1,3-dichloro-2-ethenylbenzene in liquid-crystal solvents

J.C.T. Rendell, D.S. Zimmerman, A.J. van der Est, and E.E. Burnell

Abstract: The order parameter matrices of a molecule that has no symmetry, 1,3-dichloro-2-ethenylbenzene, dissolved in two different nematic liquid-crystal solvents are analyzed in terms of various models for the intermolecular mean-field potential. In a mixture of liquid crystals for which the interaction between the molecular quadrupole moment tensor and the average electric field gradient of the nematic solvent has been minimized, the orientational order is best described by models for the short-range anisotropic potential. The most successful potentials are written in terms of anisotropic interactions between the solute surface and the liquid-crystal mean field. This represents a strong test of such models because they simultaneously fit the five independent orientational parameters obtained from the same solute, thus removing the problems associated with comparing results among different solutes in either the same or a different sample tube.

Key words: liquid crystals, intermolecular forces, order parameters, anisotropic.

Résumé : Les matrices des paramètres d'ordre d'une molécule qui ne possède pas de symétrie, le 1,3-dichloro-2-éthénylbenzène, dissous dans deux solvants de cristaux liquides nématiques différents, sont analysées en termes de divers modèles pour le potentiel de champ moyen intermoléculaire. Dans un mélange de cristaux liquides pour lequel l'interaction entre le tenseur du moment quadripolaire moléculaire et le gradient moyen du champ électrique du solvant nématique ont été minimisés, la meilleure façon de décrire l'ordre d'orientation implique des modèles pour le potentiel anisotropique à courte distance. Les potentiels les meilleurs sont décrits en termes d'interactions anisotropiques entre la surface du soluté et le champ moyen du cristal liquide. Ceci représente un bon test pour de tels modèles parce qu'ils permettent d'ajuster simultanément les cinq paramètres d'orientation indépendants obtenus pour un même soluté, éliminant ainsi les problèmes associés à une comparaison de résultats de divers solutés dans un même ou dans différents tubes à échantillonage.

Mots clés : cristaux liquides, forces intermoléculaires, paramètres d'ordre, anisotropique.

1. Introduction

A detailed understanding of the mechanisms responsible for orientational ordering in liquid crystalline systems is crucial to the comprehension of this important class of compounds. In recent years we have shown that a considerable contribution comes from the interaction between the average electric field gradient (efg) present in liquid-crystal systems and the anisotropy in the molecular quadrupole moment of an individual molecule (1–7). The molecule can be either a small solute or a liquid-crystal molecule itself. Since the anisotropies in the electric field gradients can be of opposite sign in different nematic liquid crystals, we have been able to produce mixtures where the average electric field gradient as measured at the deuteron in the solute dideuterium is zero (6, 8–10). In such zero efg mixtures the anisotropic interactions involving the molecular quadrupole moment mechanism are assumed to be unimportant. These zero efg mixtures provide an excellent medium for the study of the remaining anisotropic interactions in these nematic phases (2, 11–15).

Most studies in zero efg mixtures have involved solutes with sufficiently high symmetry that three or fewer independent elements of the order parameter matrix are needed to describe the average solute orientation. An exception is provided by the single and multiple quantum NMR spectra of the solute 1,3-dichloro-2-ethenylbenzene (DCEB, Fig. 1), which have been analyzed to obtain the five independent elements of the order parameter matrix of this molecule dissolved in the zero efg mixture 55 wt.% 1132–EBBA[6] (16). A further problem that was treated in this analysis involves the averaging of the dipolar couplings over the internal rotation of the vinyl group. It was shown that for this molecule the NMR data are consistent with a deep minimum in the potential

Fig. 1. The molecule – fixed axis system used for 1,3-dichloro-2-ethenylbenzene, DCEB.

surface for the four symmetry-related structures described by $\phi_{min} = 45.4°$. However, there is a correlation among ϕ_{min}, S_{xz}, and the depth of the potential surface. For realistic values of the potential, all order parameters (except S_{xz}) are equal within 5% to those for a simple model involving rapid interconversion among four rigid symmetry-related sites. A 5% uncertainty is less than that associated with the mean-field models that are used for comparisons with NMR data of average orientations of solutes in nematic solvents. Hence, for the purposes of the present study it is sufficient to use order parameters under the rigid molecule assumption. The results of analysis of the NMR spectra, assuming rapid interconversion among the four rigid symmetry-related sites, are summarized in Table 1, and the experimental details are given in ref. 16.

In this paper we shall examine the experimental order parameters of Table 1 in terms of various models that have been proposed to describe orientational ordering. Because in this case there are five independent parameters associated with a single molecule, the data in Table 1 provide an excellent opportunity to test models; all five parameters must arise from precisely the same intermolecular interaction, and thus an acceptable model will be one that can predict all five numbers with a minimum of adjustable parameters. We shall examine models that attempt to account for short-range intermolecular interactions in terms of molecular size and shape anisotropy. We shall not attempt to include in our analysis models that are based on the potential of mean torque. Such models have been successfully applied to the analysis of liquid crystals and of flexible hydrocarbons as solutes in liquid crystals (17–20). We feel that to include properly the double bond and chlorine atoms would introduce too many adjustable parameters.

2. A comparison of shape-ordering models

If we know the potential energy of the molecule as a function of orientation, the order matrix of the solute is found classically (21) to be

$$[1] \qquad S_{ab} = \frac{\int(3\cos\theta_a\cos\theta_b - \delta_{ab})\exp(-U(\Omega)/kT)\mathrm{d}\Omega}{2\int\exp(-U(\Omega)/kT)\mathrm{d}\Omega}$$

The difficulty lies in determining U. As has already been mentioned, for small molecules U may encompass several contributions. One is an interaction between the molecular quadrupole moment and the anisotropy in a mean electric field gradient in the liquid-crystal solvent. In the mixture 55 wt.% 1132–EBBA used in this paper this interaction is negligible, as demonstrated by experiments using molecular hydrogen (6, 8) and methane (22). We shall assume that the dominant interaction in this mixture involves short-range anisotropic forces. The test of this assumption will be the quality of the fits obtained using models for these short-range interactions.

2.1. Estimate of shape anisotropy from inertial properties of the solute

Years ago Anderson noted that the order parameters and the principal moments of inertia for a series of 27 substituted benzenes showed a reasonable correlation (23) and these findings have been corroborated by other workers (24). Samulski followed up on these ideas and proposed two methods for the prediction of the order matrix from the inertia tensor of the solute (25, 26). These methods have been employed with success in explaining the ordering of flexible solutes such as *n*-octane in nematic solvents. To do this Samulski used the principal moments of inertia to define the semiaxes of the inertia ellipsoid (27) in the manner

$$[2] \qquad A_\alpha = \left[(I_{\beta\beta} + I_{\gamma\gamma} - I_{\alpha\alpha})\frac{5}{2m}\right]^{1/2}$$

The first method, which is purely phenomenological, defines order parameters that are proportional to the dimensions of this ellipsoid as

$$[3] \qquad S_{zz} \propto 1 - \frac{(A_x + A_y)}{2A_z}$$

$$[4] \qquad S_{xx} \propto -\frac{1}{2} + \frac{A_x}{2A_z}$$

$$[5] \qquad S_{yy} \propto -\frac{1}{2} + \frac{A_y}{2A_z}$$

where the semiaxes are chosen such that $A_x \leq A_y \leq A_z$. Definitions [3]–[5] imply one positive (S_{zz}) and two negative order parameters. This is at odds with the experimental results for DCEB (and other prolate solutes) where one principal value of the order matrix is negative and two are positive. Simply reversing the signs of [3]–[5] would rectify the problem, and would in fact lead to an excellent fit for the order parameters of DCEB obtained in the EBBA sample (28). However, there is no physical justification for such a sign reversal. In addition, EBBA is known to have a non-zero mean electric field gradient, and the interaction between this gradient and the quadrupole moment of DCEB should contribute toward the orientational order. Thus the excellent fit for EBBA, obtained with the arbitrary sign reversal, would appear to be accidental. While it is possible to generate different models that are based on the inertial ellipsoid, this is not likely a useful pursuit. The values of the semiaxes of this ellipsoid (which are in the ratio 1.0 : 0.75 : 0.11) are all rather

Table 1. Experimental order parameters from ref. 16 along with those recalculated from best-fit model parameters. The molecular structure used for calculations in this paper is taken from ref. 16. The k_i from ref. 15 are those from the fit to 46 solutes in 55 wt.% 1132–EBBA at 301.4 K. The k_i refer to the parameters k, k_s, k, k, and k_z for the C, I, CI, CZ, and AR models. For CI, CZ, and AR the second parameter ($k_j/k_i = k_s/k$, ξ, or k_{xy}/k_z) is fixed to the value from ref. 15. Least-squares error estimates are given in parentheses. The liquid crystal solvents are *N*-(4-ethoxybenzylidene)-4′-*n*-butylaniline (EBBA) and the commercial mixture Merck ZLI 1132 (1132).

dissimilar because they are dominated by the heavy chlorine atoms. A theory involving these values will invariably yield principal order parameters that are all considerably different. In contrast, the experimental results obtained for DCEB in the zero efg mixture (Table 1) show that the two positive order parameters are almost equal. Therefore, we conclude that models based on the inertial moments are not capable of explaining these results. In cases where inertial properties are successful in describing orientational order, it is because they are providing a reasonable estimate of molecular size and shape.

The second and later method employed by Samulski is based on an excluded volume model, introduced by Straley (29), in which the molecules are approximated by parallelepipeds; the linear dimensions of length, breadth, and width are estimated from the three semiaxes of the inertia ellipsoid defined by eq. [2] (30). There are problems associated with application of this model to solutes in nematic solvents. First, the model is developed in terms of the volume excluded by two identical particles, and the equations do not apply for the volume excluded by dissimilar particles such as two different liquid crystals of a mixture or of a solute and a liquid crystal. If we follow the prescription in the literature (20, 30–32), we predict positive order parameters for the symmetry axes of both prolate and oblate objects. This is consistent with a collection of oblates forming a discotic phase but is not consistent with the negative order parameter anticipated, and observed, for such oblate objects as solutes in a nematic phase. In addition, the second-rank part of the interaction tensor defined in ref. 29 is not traceless; this leads to incorrect Boltzmann factors for the molecular orientational distribution, and hence to incorrect estimates of orientational order parameters. Thus we shall not use this particular excluded volume model for comparison purposes in this paper. Instead, a more reasonable possibility is that the orientation is related to solute size and shape, and that it has little to do with inertial properties. In the next section, we shall discuss models that attempt to account for the size and shape (and therefore the volume) of solutes in a more precise fashion.

2.2. Ordering due to solute size and shape

For molecules much larger than dihydrogen and methane, repulsive interactions dependent upon the size and shape of the solute molecule can be expected to play a dominant role in the orientation mechanism. The effect of molecular size and shape on the interaction potential U has been modeled in several different ways. A simple approach assumes that the interaction along a molecular axis is proportional to the van der Waals dimensions along that axis; this model has been applied with success to a series of aromatic molecules (13). In the case of DCEB it predicts that S_{xx} is of order $0.7 \times S_{yy}$, whereas the experimental numbers in Table 1 have $S_{xx} > S_{yy}$. However, the values predicted with this simple model are closer to the experimental values for the zero electric field gradient mixture 55 wt.% 1132–EBBA than are those for the PMI models discussed above.

In ref. 15 five models that take molecular size and shape into account in a more detailed way are reviewed and fitted to order parameters of 46 solutes of varying symmetry measured in the zero electric field gradient mixture 55 wt.% 1132–EBBA. One model considers the liquid crystal to be an elastic tube surrounding the solute. The Z axis of the tube is coincident with the director of the liquid crystal. The walls of the tube are rigid, so the circumference of the tube surrounding the solute may be found by looking down the axis of the tube at the projection of the solute in the XY plane. As the solute reorients it will, depending on its size, shape, and orientation, deform the walls of the tube. This model considers the tube to resist deformation with a Hooke's Law force,

$$[6] \qquad F(\Omega) = -kC(\Omega)$$

i.e., the restoring force is directly proportional to the circumferential displacement of the walls of the tube. Here, k is the Hooke's Law force constant and $C(\Omega)$ is the circumference of the XY projection of the molecule held in some orientation Ω. The potential energy of the molecule in this orientation is then

$$[7] \qquad U(\Omega) = \frac{1}{2}\, kC^2(\Omega)$$

This potential, which will be referred to as model C (for circumference), is used in numerical integration of eq. [1] over all possible orientations to predict the values of the various elements of the order matrix.

Another one-parameter model assumes that the solute experiences an anisotropic surface potential. The magnitude of this potential varies with $\sin\theta$, where θ is the angle between the solute surface normal and the director Z direction, and is given by

$$[8] \qquad U(\Omega) = -\frac{1}{2}\, k_s \int_{Z_{min}}^{Z_{max}} C_Z(\Omega)\mathrm{d}Z$$

$C_Z(\Omega)$ is the molecular circumference at position Z. This potential will be referred to as model I (for integral).

Three two-parameter models were also considered. The first one developed adds to eq. [7] a term that depends on the length of the solute projected onto the Z axis:

$$[9] \qquad U(\Omega) = \frac{1}{2}\, k[1 - \xi Z_P(\Omega)/C(\Omega)]C^2(\Omega)$$

Equation [9], which will be referred to as the CZ model, involves terms that vary as C^2 and $C \times Z$. If we think of the solute as occupying a cylindrical cavity, these terms are the area of the top, bottom, and sides of the cavity. In fact it was the success of this "anisotropic surface potential" that led to the evolution of two models that attempt to account for anisotropic surface interactions more precisely. One is eq. [8], and the other is that proposed by Ferrarini et al. (14). An additional attempt to account for surface interactions led to the AR (for area) model, eq. [10], where the molecule is assumed to fit tightly into a cavity with top and bottom area $A_{xy}(\Omega)$ and side area $D(\Omega)Z_P(\Omega)$:

$$[10] \qquad U(\Omega) = 2k_{xy}A_{xy}(\Omega) - k_z D(\Omega)Z_P(\Omega)$$

The most successful two-parameter model, referred to as CI, attempts to account for the physical ideas expressed in both

For personal use only.

eqs. [7] and [8] by combining them:

$$[11] \qquad U(\Omega) = \frac{1}{2} kC^2(\Omega) - \frac{1}{2} k_s \int_{Z_{min}}^{Z_{max}} C_Z(\Omega) dZ$$

It evolved from the simpler CZ model.

The five potentials of eqs. [7]–[11] have proved useful in explaining the orientation of a variety of symmetrical solutes in several liquid crystals (10, 15, 33, 34). In fits to the order parameters of 46 solutes, the I model is the most successful one-parameter model, and the CI the most successful two-parameter model. However, the AR model is also a very successful two-parameter model.

For the solution of 20 mol% DCEB in 55 wt.% 1132–EBBA, where the electric field gradient – molecular quadrupole moment orientation mechanism is removed, a prediction using the C model of the five independent elements of the order matrix based upon an estimated geometry of the molecule yielded a starting point for the analysis of the NMR spectrum that was startlingly close to the final solution (16, 28). From these predictions using the C model one is already tempted to judge it a qualified success for even such unsymmetrical solutes such as DCEB.

For each of the models, one of the constants k_i has been adjusted in a least-squares fit to the experimental values of $S_{\alpha\beta}$. For the CI, CZ, and AR models the ratios k_s/k, ξ, and k_{xy}/k_z have been fixed to the values obtained in the fit to 46 solutes in the 55 wt.% 1132–EBBA mixture (15). For all of the models used, the geometry of DCEB was kept fixed to the rigid structure established in ref. 16. Values predicted by the fits to eqs. [7]–[11] for the order matrices of DCEB in the 55 wt.% 1132–EBBA mixtures and in EBBA are reported in Table 1, where the quality of the fits is indicated by the rms difference between predicted and experimental order parameters.

The fits to the order parameters obtained from the spectrum in EBBA are poor for all models. In all cases the asymmetry $(S_{xx} - S_{yy})/S_{zz}$ is poorly predicted. The results do not improve much if both parameters of the two-parameter models are allowed to vary. The poor fits for EBBA are expected because no attempt has been made to account for the mean electric field gradient – molecular quadrupole moment interaction that is anticipated to be important in this liquid crystal.

For the three zero-efg 55 wt.% 1132–EBBA samples, the best results are obtained with the same models that provided the best fits to the 46 solutes in the same mixture (15). The one-parameter I model gives particularly impressive results, and only the I model predicts the correct sign of the asymmetry $(S_{xx} - S_{yy})/S_{zz}$. The CI model also gives excellent fits. All models predict the correct signs of the off-diagonal $S_{\alpha\beta}$ observed in the mixture.

All the models considered in Table 1 give better fits than do the simpler approaches, which assume either that the order parameter matrix is related to the inertial tensor (see previous section), or that the interaction along a molecular axis is proportional to the van der Waals dimensions along that axis (13). We note that the best models are those that take the particulars of the molecular size and shape into account in the most detailed fashion. For example, the I model and the anisotropic surface model of Ferrarini et al. (14) both account for the three-dimensional shape of the solute at each orientation, whereas the projections involved in the C, CZ, and AR models offer a less precise description of the actual molecular shape. As long as precisely the same method is used to define the solute surface, quite similar predictions are obtained with both the I and Ferrarini models.[7]

Also included in Table 1 are the k_i parameters obtained in the fits to 46 solutes (15). Because these values are for results obtained using dilute solutions, they should be compared to the numbers obtained for the dilute 2 mol% DCEB in 55 wt.% 1132–EBBA mixture. In ref. 15 the C and I models were found to require k_i values that varied depending on solute size. The variation tended to be in opposite directions, and this same trend is noted in Table 1. The opposing effects of the C and I calculations are compensated for by adding the two contributions to generate the CI potential. For the CI model, the number obtained for the 2 mol% DCEB in 55 wt.% 1132–EBBA solution is in exact agreement with the number obtained for the 46 solutes in ref. 15. The success of this model is consistent with ref. 15 where CI was found to be the most successful potential in fitting a series of solutes, and with ref. 35 where CI provided the best "fit" to Monte Carlo simulations that employ only hard-body interactions between solute and solvent hard ellipsoids.

3. Conclusion

In this paper we have studied a molecule that has no symmetry, and thus requires five independent second-rank orientational parameters to specify its partial orientation in a nematic phase. Results from liquid crystals in which the average electric field gradient is zero are best rationalized by models for anisotropic short-range interactions, and especially those that involve an anisotropic surface potential. This represents a strong test of such models because they simultaneously fit the five independent orientational parameters obtained from the same solute, thus removing the problems associated with comparing results among different solutes in either the same or a different sample tube.

The results presented in Table 1 demonstrate that the models described above, and especially the one-parameter I and the two-parameter CI models, provide an excellent description of the short-range anisotropic interactions. These are the models that take the particulars of the molecular size and shape into account in the most detailed fashion. All of the models considered in Table 1 give better fits than do the simpler approaches, which assume that the order parameter matrix is related either to the inertial tensor or to van der Waals lengths along molecular axes (13).

The success of the CI model in predicting order parameters *both* of solutes in zero efg mixtures *and* of Monte Carlo simulations that involve only hard-body interactions is important from two points of view. First, it demonstrates that short-range interactions that depend on molecular size and shape are dominant in the zero efg mixtures. Secondly, the CI model provides an excellent way of modeling these interactions. While one can think of this model as being purely phenomenological, there is an interesting physical interpretation to its two contributions. The first term of eq. [11] is associated with an elastic distortion of the liquid crystal, and

[7] A. Ferrarini. Private communication.

© 1997 NRC Canada

the second with an anisotropic interaction between the solute surface and the liquid-crystal mean field.

While it may be risky to base general conclusions upon the analysis of only one system with no symmetry, the success of the models, and especially the one-parameter anisotropic surface potential I model of eq. [8], and of the two-parameter CI model of eq. [11], for orientation based upon the size and shape of a molecule such as 1,3-dichloro-2-ethenylbenzene is quite remarkable.

1996 Merck Frosst Award Lecture Synthetic adventures along a Rocky Mountain road[1]

Brian A. Keay, Shawn P. Maddaford, Walter A. Cristofoli, Neil G. Andersen, Marco S. Passafaro, Noel S. Wilson, and James A. Nieman

Abstract: This paper describes the chemistry presented during the Merck Frosst Centre for Therapeutic Research Lecture Award given at the 79th Chemistry in Canada Conference held in St. John's, Newfoundland in June 1996. The first section describes the synthesis of (+)-xestoquinone using an asymmetric palladium-catalyzed polyene cyclization as the key step that creates the C and D rings and the stereogenic centre (68% ee) in one step. Extensions of the work involving an in situ Suzuki reaction are presented. The synthesis of C_2-symmetric biaryls and the synthesis of a recently isolated binaphthyl natural product is described using this new method. A new one-pot desilylation–oxidation procedure of silyl ethers is described in detail for the preparation of aldehydes and ketones directly without the need for the isolation of the alcohol intermediate. Finally, a highly diastereoselective (>97%) Diels–Alder reaction is presented using (+)-*cis,cis*-spiro[4.4]nonane-1,6-diol as a new chiral auxiliary. One of the alcohols is attached to a pivalate, the other to an acrylate, and the Diels–Alder reaction with cyclopentadiene provides only one adduct (by ^{1}H NMR and HPLC) with the *endo* stereochemistry.

Key words: (+)-xestoquinone, asymmetric palladium-catalyzed polyene cyclization, in situ Suzuki reaction, desilylation–oxidation reaction, spirodiols, chiral auxiliaries.

Résumé : Cette publication décrit la chimie présentée lors de la remise du prix du Centre Merck–Frosst pour la recherche thérapeutique, lors de la 79ème Conférence de chimie au Canada, tenue à St-Jean, Terreneuve, en juin 1996. La première section décrit la synthèse de la (+)-xestiquinone impliquant, comme étape clé, une cyclisation de polyène catalysée par du palladium asymétrique conduisant, en une étape, à la création des cycles C et D et du centre stéréogène (68% ee). On présente des extensions de ce travail impliquant une réaction de Suzuki in situ. Faisant appel à cette méthode, on a réalisé la synthèse de biaryles de symétrie C_2 et d'un produit naturel de la série des binaphtyles qui a été isolé récemment. On décrit en détail une procédure unipot de désilylation–oxydation des éthers silylés permettant de préparer directement des aldéhydes et des cétones sans avoir à isoler l'alcool intermédiaire. Enfin, on présente une réaction de Diels–Alder fortement diastéréosélective (>97%) faisant appel au (+)-*cis,cis*-spiro[4,4]nonane-1,6-diol comme nouvel auxiliaire chiral. On a attaché l'un des groupes hydroxyles à un pivalate et l'autre à un acrylate, et la réaction de Diels–Alder avec le cyclopentadiène ne fournit qu'un seul adduit (RMN du ^{1}H et CLHP) dont la stéréochimie est *endo*.

Mots clés : (+)-xestoquinone, cyclisation de polyène catalysée par du palladium asymétrique, réaction de Suzuki in situ, réaction de désilylation–oxydation, spirodiols, auxiliaires chiraux.

Introduction

The title of the talk was chosen for two reasons. First, it was important to incorporate the fact that most of the work in this presentation was performed in Calgary. This was done by incorporating "Rocky Mountain" into the title since Calgary is very close (~90 km) to the Rocky Mountains. Second, if one word is removed from the title, its context changes dramatically. Removing the word "Mountain" provides the title, "Synthetic Adventures Along a Rocky Road." This title is a reminder that ideas, and what are believed to be the best thought-out plans, do not always proceed[3] in a smooth and orderly manner. Many unforeseen obstacles are encountered during the course of academic research. It is the perseverance, hard work, and dedication of excellent graduate students and post-doctoral Fellows that result in solutions to unforeseen problems and oftentimes lead to new discoveries. It is to past[4]

Received January 15, 1997.

[3] It has been my experience that most of the ideas proposed to date have developed problems at some point along the way. Investigations almost *never* proceed as planned. Many new discoveries and some very interesting chemistry have been found as a result of these obstacles, and some of the chemistry that has developed from these pitfalls is presented in this paper.

and present members[5] of my group that I dedicate this talk, since I would not be presenting this work if not for the excellent chemistry discovered and performed by these people. For this I thank them.

The paper will be divided into four parts. First, the synthesis of (+)-xestoquinone will be discussed, in which an asymmetric palladium-catalyzed polyene cyclization was used to create rings C and D and the stereogenic centre in one step. Second, extensions of our modified in situ Suzuki reaction in which the Shapiro and Suzuki reactions are combined into a one-pot procedure will be illustrated and a new method for the preparation of C_2-symmetric biaryls is described along with the synthesis of a C_2-symmetric binaphthalene natural product. Third, a new one-pot procedure that combines a desilylation–oxidation sequence using catalytic quantities of $PdCl_2$ will be presented in detail. Finally, the use of (+)- and (−)-*cis,cis*-spiro[4.4]nonane-1,6-diol as new chiral auxiliaries for the Diels–Alder reaction, in which one of the alcohols is substituted with a pivalate and the other with an acrylate, will be described.

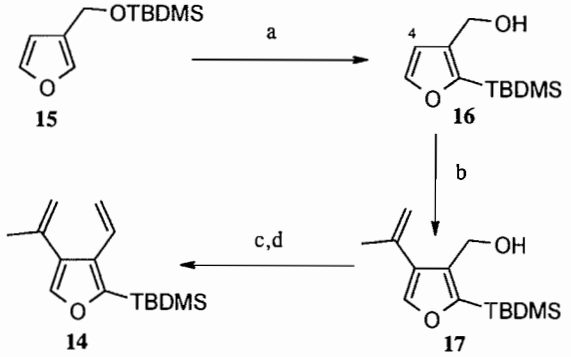
Synthesis of (+)-xestoquinone

Xestoquinone **1** (1) and halenaquinone **2** (2) were isolated from Pacific sponges and shown to possess a unique pentacyclic carbon framework (Scheme 1). Both **1** and **2** (especially **2**) are irreversible inhibitors of oncogenic protein tyrosine kinase $pp60^{v\text{-}src}$ and the human epidermal growth factor kinase (EGF) (3). Xestoquinone also has a positive inotropic effect on cardiac muscle that leads to it being a potent cardiotonic agent (4). Four of the rings common to both **1** and **2** are found in the Viridin class of natural products **3**-**6** (5) as illustrated in Scheme 1. We envisioned that if a short asymmetric route to tetracycle **7** could be developed, then the approach could be applicable towards the preparation of natural products **1**-**6**. We also chose (+)-xestoquinone as our initial target as it contained the least number of functional groups and had not been synthesized asymmetrically, although Harada reported the diastereoselective synthesis of **1** starting with optically pure Wieland–Miescher ketone (6).[6]

Space limitations do not permit the description of the many unsuccessful approaches towards the synthesis of **1** (11). The retrosynthesis that was finally successful is illustrated in Scheme 2 (12). Functional group interconversion of **1** provides **8**, which after a retro-palladium-catalyzed polyene cyclization gives **9**. Disconnection between the furan ring and ketone in **9** provides tetrasubstituted naphthoyl chloride **10** and lithio-furan **13**. The advantages of this approach are (*i*) that rings C and D are introduced in a single step with concurrent formation of the single stereogenic centre; (*ii*) that the polyene cyclization can be performed in the presence of a chiral ligand such as (+)-BINAP so that the synthesis is asymmetric; and (*iii*) that the synthesis is convergent, requiring the preparation and coupling of naphthalene **10** and furan **13**. Other asymmetric polyene cyclizations sequences (13) and Heck reactions (14) have been reported; however, the former has not been applied to the enantioselective synthesis of a natural product (12).

Naphthoyl chloride **10** was prepared from the known ester **11** (15) in two steps by hydrolysis of ester **11** (K_2CO_3, refluxing methanol, 95%) followed by treatment of acid **12** with oxalyl chloride in methylene chloride containing a drop of DMF (>99%) (Scheme 2).

Furan **14** was prepared using some chemistry we discovered in 1988 (16). Furan rings tend to lithiate at the C-2 position and (or) at the C-5 position if the C-2 position is substituted. Thus, the preparation of 3,4-disubstituted furan rings is difficult. We reported that 2-silylated-3-hydroxymethylfuran



[5] I did not present work done by the following current members of my group: Dr. Ian R. Hunt and Bryon E. Carpenter.

[6] Kanematstu et al. have reported a formal synthesis of (±)-**1** (7). Harada et al. (8), Shibasaki and co-workers (9) have reported syntheses of **2** and Rodrigo and co-workers (10) have reported the synthesis of **1** and **2**.

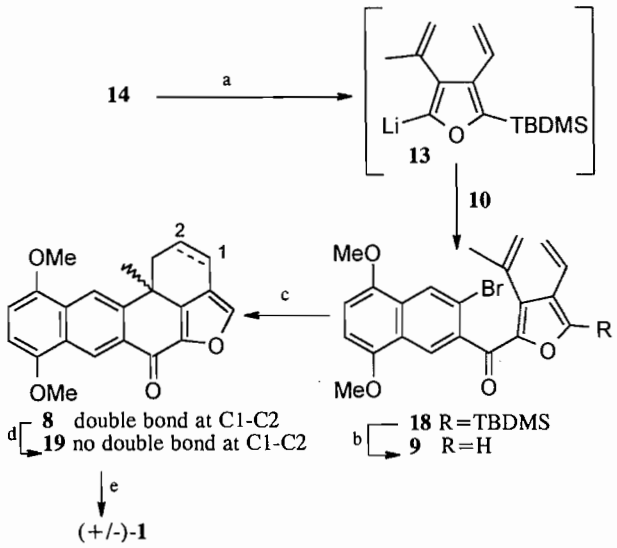
Scheme 3.

Reagents: (a) *n*-BuLi, THF, HMPA, 0°C–rt, 12 h (87%); (b) 2.2 equiv. *n*-BuLi, DME, 0°C; then $B(O^iPr)_3$, 1 h, 0°C; then $Pd(PPh_3)_4$, Na_2CO_3, 2-bromop[ene, reflux, 13 h (95%); (c) PDC, CH_2Cl_2, rt (85%); (d) Ph_3PCH_2, THF, 1 h, reflux (95%).

when treated with 2.2 equiv. of *n*-BuLi results in exclusive lithiation at the C-4 position (16). We used this chemistry to prepare furan **14** (Scheme 3). Treatment of **15** with 1.1 equiv. of *n*-BuLi in THF containing 1 equiv. of HMPA resulted in the formation of furan **16** (87%) via an intramolecular 1,4 O → C silyl migration (17).



We investigated using the Stille (18) and Suzuki (19) reactions to introduce the 2-propenyl group through a palladium coupling with the corresponding C-4 stannane and boronic acid, respectively; however, the Stille coupling gave very poor yields (20) and the C-4 boronic acid species of **16** could not be isolated by quenching the C-4 anion with trimethylborate (21). An in situ variant of the Suzuki reaction was developed (12, 21, 22) in which the C-4 anion of **16** was quenched with triisopropylborate and, after 1 h, immediately treated with $Pd(PPh_3)_4$ (3 mol%), 2 M Na_2CO_3, and 2-bromopropene at reflux for 13 h. Furan **17** was obtained in 95% yield. The required trisubstituted furan **14** was prepared by PDC oxidation of **17** (85%) followed by a standard Wittig reaction (95%).

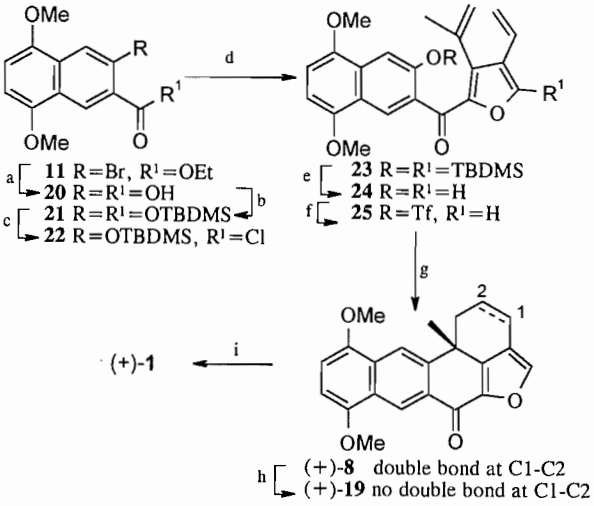
Furan **14** was lithiated at C-5 by treatment with 1.5 equiv. of *n*-BuLi in the presence of 1.2 equiv. HMPA (THF, −78°C) to form **13**, which was immediately reacted with freshly distilled naphthoyl chloride **10**. Furan **18** was isolated in 79% yield (Scheme 4). Compound **18** is the precursor for a palladium-catalyzed polyene cyclization. Although we attempted to perform the cyclization reaction on **18**, a mixture of products was always obtained. Removal of the silyl group prior to attempting the polyene cyclization alleviated the formation of complex mixtures (vide infra) (12, 13*a*). The silyl group in **18** was removed with *n*-Bu_4NF (THF, 0°C), providing **9** in 95% yield.

We initially decided to prepare (±)-xestoquinone **1** in order to demonstrate the viability of the synthetic strategy. Refluxing a mixture of **9** with $Pd(PPh_3)_4$ or $Pd_2(dba)_3$ (10 mol%) in NMP containing Et_3N provided pentacycle **8** in 82% yield. Compound **8** was converted into (±)-xestoquinone **1** by catalytic hydrogenation (H_2, Pd/C, 1 atm (101.3 kPa), 4 h, 99%) to form **19** followed by a ceric ammonium nitrate oxidation (CH_3CN/H_2O, 0°C, 5 min) according to the procedure reported by Harada et al. (6) (Scheme 4).

With a successful route towards (±)-xestoquinone in hand, we turned our attention to attempting an asymmetric

Scheme 4.

Reagents: (a) *n*-BuLi (1.5 equiv.), HMPA (1.5 equiv.), THF, 0°C; then add **10** (79%); (b) *n*-Bu_4NF, THF, 0°C (95%); (c) $Pd(PPh_3)_4$, NMP, Et_3N, (82%); (d) H_2 (1 atm), 5% Pd/C, EtOH, rt (99%); (e) CAN, CH_3CN, H_2O, 5 min.



palladium-catalyzed polyene cyclization. Treatment of **9** with a variety of chiral palladium catalysts provided **8** with very poor enantiomeric excesses (ee's) ($Pd((R)\text{-BINAP})_2/Et_3N$ (5% ee), $Pd((R)\text{-BINAP})_2$/PMP (13% ee), or $Pd((2R,3R)\text{-chiraphos})_2$/PMP (7% ee)) that could not be improved by the addition of silver salts (23). In hopes of increasing the %ee of the polyene cyclization we investigated the use of a triflate instead of a bromine atom in **9**, since it has been reported that triflates provide much higher ee's than bromides or iodides in the Heck reaction due to the increased liability of the Pd—OTf bond when compared to Pd—Br and Pd—I bonds (14*b*).

The bromine atom in **11** (Scheme 5) was changed into a hydroxy group and subsequently converted into a naphthyl triflate prior to the polyene cyclization. Halogen–metal exchange of the bromine atom in **11** with *n*-BuLi (−95°C, THF) followed by the immediate addition of trimethylborate and a basic H_2O_2 work-up provided acid **20** (87%). Bis-silylation of **20** with TBDMSOTf (2 equiv.) gave **21** (79%), which was converted into naphthoyl chloride **22** by treatment with oxalyl chloride in refluxing hexanes containing a drop of DMF (99%). Acid chloride **22** was added slowly to a solution of anion **13**, which was generated by treatment of **14** with *s*-BuLi (THF, −78°C) to provide ketone **23** after work-up (42% from **20**). Removal of both silyl groups with *n*-Bu_4NF (THF, 0°C) provided **24**, which when treated with NaH in DMF followed by the addition of $PhNTf_2$ gave triflate **25**.

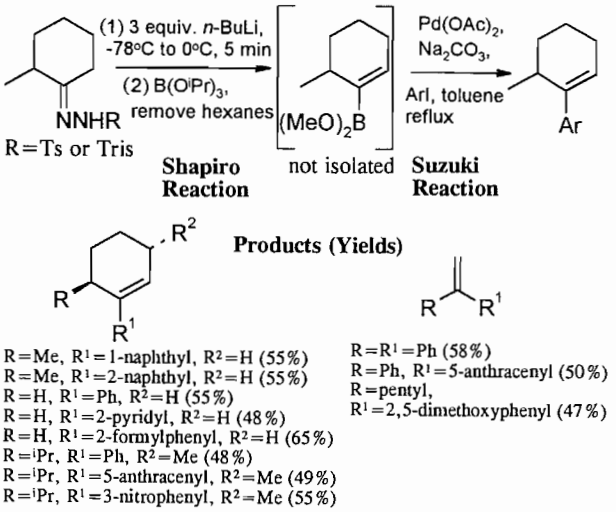
Triflate **25** was used immediately in the asymmetric polyene cyclization, since it was found to be very sensitive to air and moisture. Treatment of **25** using $Pd((S)\text{-BINAP})_2$ gave pentacycle (+)-**8** with 68% ee (82% from **24**). Compound (+)-**8** was also shown to have the correct absolute stereochemistry required for the preparation of (+)-**1** (12). Finally, (+)-xestoquinone (**1**) (68% ee) was synthesized by catalytic hydrogenation of (+)-**8** to provide (+)-**19** (100%) followed by a ceric

© 1997 NRC Canada

Scheme 5.

Reagents: (a) *n*-BuLi, THF, −95°C; then $(MeO)_3B$; then add H_2O_2, NaOH; then 10% HCl (87%); (b) TBDMSOTf, Et_3N (79%); (c) oxalyl chloride, 1 drop of DMF, hexanes (99%); (d) **13** generated from *s*-BuLi/THF (42% from **20**); (e) *n*-Bu_4NF, THF, 0°C (95%); (f) NaH, DMF, rt, $PhNTf_2$ and used immediately; (g) $Pd_2(dba)_3$(2.5 mol%), *S*-BINAP (10 mol%), PMP, toluene, reflux, 22 h (82% from **24**; 68% ee); (h) H_2 (1 atm), 5% Pd/C, EtOH, rt (95%); (i) CAN, CH_3CN, H_2O, 5 min.

ammonium nitrate oxidation (Scheme 5). The ^1H NMR and CD spectra of synthetic (+)-xestoquinone were identical with those provided to us by Prof. Harada (6).



Thus, we have developed a short convergent asymmetric route to (+)-xestoquinone, which represents the first synthesis of a natural product incorporating an asymmetric palladium-catalyzed polyene cyclization. Work is continuing on: (*i*) improving the %ee of the polyene cyclization, (*ii*) developing a rationale to explain the observed absolute stereochemistry of the cyclization; and (*iii*) applying this reaction towards the synthesis of other natural products (i.e., **2**-**6**, Scheme 1).

Further extensions of the in situ Suzuki reaction

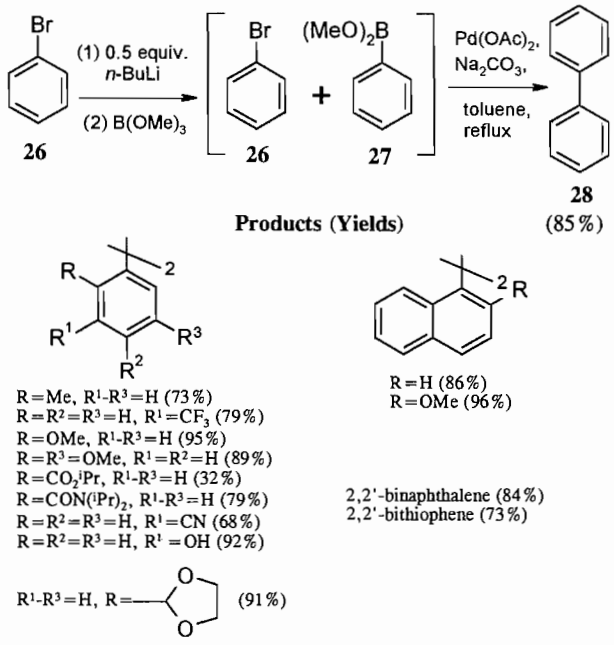
As mentioned above, compound **17** was prepared by developing an in situ variation of the Suzuki reaction (21, 22). We have recently expanded the scope and limitations of this reaction by showing that: (*i*) the Shapiro (24) and Suzuki (19) reactions can be combined into a one-pot reaction sequence (25); and (*ii*) C_2-symmetric biaryls can be prepared in one step starting with a haloarene (26). These new applications are summarized below.

It is well known that when tosyl- or trisylhydrazones are treated with excess *n*-BuLi (>3 equiv.), a vinyl anion develops that can be trapped with a variety of electrophiles (Scheme 6) (24). We investigated whether the anion could be trapped with trimethylborate and subsequently used in a Suzuki reaction without the need for isolation of the vinyl boronic acid. Although we were successful in combining the reactions in one pot, unfortunately a change of solvent was required for the Suzuki reaction. The Shapiro reaction was performed in a mixture of hexanes and TMEDA but the Suzuki reaction would not proceed unless the hexanes were removed and replaced with toluene. Similarly, the Shapiro reaction did not proceed in

Scheme 6.

toluene. Nevertheless, the reaction can be performed in one pot and appears to be quite general. Thus, the anion that forms from the Shapiro reaction is quenched with $B(OMe)_3$, and after 1 h the hexanes are removed in vacuo. The addition of toluene, Na_2CO_3, $Pd(OAc)_2$ (5 mol%), PPh_3 (10 mol%), the aryl or vinyl iodide (or bromide), and reflux of the resulting mixture affords the desired products in yields ranging from 47 to 65% (Scheme 6) (25). It was determined that the yields are limited by the Shapiro reaction since isolation of the vinyl boronic acids and subsequent treatment under Suzuki conditions provided the coupled products in excellent yield. We are currently applying this combined reaction sequence towards the preparation of monoterpenylmagnolol (27).

The second extension of the in situ Suzuki reaction involves the formation of C_2-symmetric biaryls starting only from the arylhalide. In 1994, we reported on the scope and limitations of the in situ Suzuki reaction (22) and showed that iodobenzene could be completely halogen–metal exchanged with *t*-BuLi and the resulting anion quenched with $B(OMe)_3$. A second aryl- or vinylhalide was added along with a palladium catalyst, which after refluxing afforded the coupled product in good to excellent yields. In this procedure, the two aryl components could be different. However, if a C_2-symmetric biaryl was required, we reasoned that the above procedure could be modified slightly so that the second equivalent of arylhalide would not have to be added to the solution after the $B(OMe)_3$ was added (26). The modification was to initially add only 0.5 equiv. of *n*-BuLi so that only 50% of the arylhalide would undergo a halogen–metal exchange. The addition of $(MeO)_3B$ would quench the resulting anion and leave a 50/50 mixture of arylboronate and arylhalide (Scheme 7, **26** and **27**), that should undergo a Suzuki coupling if a palladium catalyst is introduced into the flask. This modification was realized when bromobenzene **26**, when treated as above, provided biphenyl **28** in 85% yield when toluene, $Pd(PPh_3)_4$, and $Ba(OH)_2$ were added to the solution and subsequently refluxed (Scheme 7) (26). The procedure is quite general and a variety of C_2-symmetric biaryl compounds have been prepared in moderate to good yields (Scheme 7).



This method has also been used to prepare 4,4′-

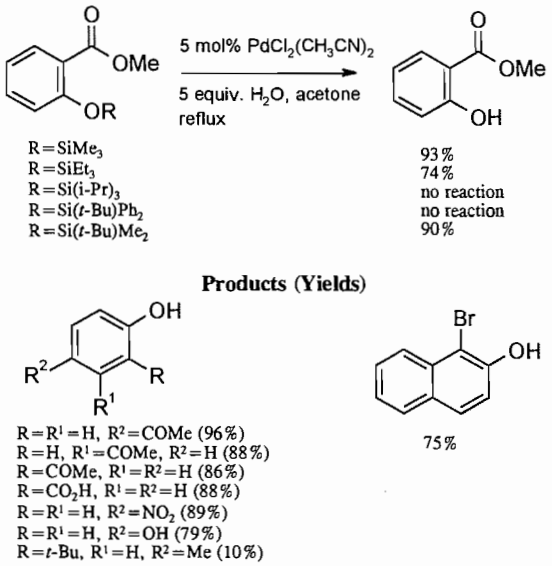
Scheme 8.



Reagents: (a) 1 equiv. NaH, DMF, 5 equiv. MeI (95%); (b) NaH, CCl_4, 1 equiv. Br_2 (60%); (c) NaH, DMF, BnBr (100%); (d) 0.5 equiv. *n*-BuLi, THF, −78°C; then $B(OMe)_3$, rt, 12 h; then toluene, EtOH, H_2O, Na_2CO_3, $Pd(PPh_3)_4$, reflux, 12 h (72%); (e) H_2, Pd/C, $EtOH/CH_2Cl_2$ (100%).

dihydroxy-5,5′-dimethoxy-1,1′-binaphthalene **34**, which has been isolated from the fungus (Ascomycetes) *Daldinia concentrica* (28). Our synthesis began with 1,8-naphthalenediol **29**, which was prepared from 1,8-naphthosultone (29). Diol **29** was converted into **34** in five steps with an overall yield of 41% (Scheme 8). Monomethylation of **29** produced **30**, which underwent a regioselective bromination *para* to the hydroxyl group, giving **31**. Unfortunately, the synthesis was extended by two steps because the hydroxy group in **31** had to be protected. Halogen–metal exchange of **31** by treatment with *n*-butyllithium provided an excellent yield of 8-methoxy-1-naphthol (30). Protection of the free hydroxyl group with a benzyl group alleviated this problem. Binaphthalene **34** was prepared by an in situ palladium coupling of **32** (to give **33**) followed by removal of the benzyl protecting groups by hydrogenolysis.

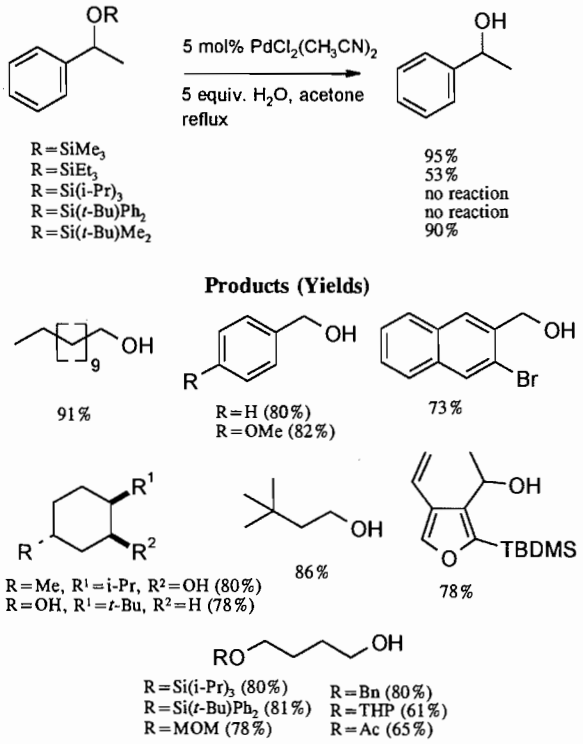
We have shown that the in situ variant of the Suzuki reaction is a general viable process for the preparation of a variety of compounds. It was used in the preparation of furan **14**, which was a key intermediate in the syntheses of (+)-xestoquinone **1** and binaphthalene **34**. Further extensions of this reaction are currently underway.

Scheme 9.

Development of a one-pot desilylation-oxidation of silyl ethers using catalytic amounts of $PdCl_2$

During some work on the palladium-catalyzed polyene cyclization towards xestoquinone, we noticed that a phenol protected as its *tert*-butyldimethylsilyl ether was cleaved in the presence of $Pd(OAc)_2$. Since we could not find any reports on the removal of phenolic silyl ethers with palladium catalysts, we investigated this reaction further (31–35).

A variety of phenolic *tert*-butyldimethylsilyl ethers were cleaved to their respective phenols by treatment with 1–5 mol% $PdCl_2(CH_3CN)_2$ in refluxing reagent grade acetone containing 5 equiv. of water (Scheme 9) (36).[7] Products were formed in yields ranging from 10 to 96%. Both the water and palladium catalyst were necessary for a successful reaction. Hindered silyl ethers were removed very slowly (see the last example) and a variety of functional groups were tolerated during this reaction (halides, esters, nitriles, nitro, aldehydes, and ketones). The reaction was not limited to the *tert*-butyldimethylsilyl ether; trimethyl- and triethylsilyl ethers were desilylated, while triisopropyl- and *tert*-butyldiphenylsilyl ethers were inert under these reaction conditions. Since phenolic silyl ethers were removed with catalytic amounts of $PdCl_2$ we looked at whether aliphatic silyl ethers could be desilylated under similar reaction conditions.



Treatment of a variety of aliphatic *tert*-butyldimethylsilyl ethers with 5 mol% $PdCl_2(CH_3CN)_2$ in acetone containing

[7] We have recently shown that trimethyl-, triethyl-, *tert*-butyldimethyl-, triisopropyl-, and *tert*-butyldiphenyl-silyl phenolic ethers can be removed by refluxing the silyl ether in ethanol containing 1.1 equiv. of K_2CO_3. Aliphatic silyl ethers were not removed under these reaction conditions. See ref. 37 for further details.

Scheme 10.

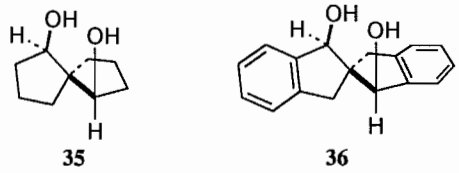
Scheme 11.

5 equiv. of water provided desilylated materials in yields ranging from 73 to 91% (Scheme 10) (38).[8] The reaction conditions also desilylated trimethylsilyl ethers; however, triisopropyl- and *tert*-butyldiphenyl-silyl ethers did not react under these conditions. Triethylsilyl ethers were somewhat capricious and approximately 50% desilylation was all that could be obtained under the best of conditions. The *tert*-butyldimethylsilyl group could also be removed selectively in the presence of triisopropylsilyl, *tert*-butyldiphenylsilyl, methoxymethyl, benzyl, tetrahydropyranyl, and acetate protecting groups (Scheme 10). The reaction is quite general and a number of functional groups were tolerated. In addition, a Si—O bond could be selectively cleaved in the presence of a Si—C bond (see the furan example).

Tamaru et al. reported in 1979 that alcohols could be oxidized to aldehydes and ketones with catalytic amounts of palladium acetate and a stoichiometric amount of 2-bromomesitylene in dry DMF (40). Since desilylations are possible using $PdCl_2(CH_3CN)_2$, we investigated whether the desilylation and oxidation reactions could be combined into a one-pot sequence using catalytic amounts of a palladium catalyst (38). We have successfully combined the two reactions into a one-pot sequence using a 1:1 mixture of acetone:DMF as the solvent with 5 mol% $PdCl_2(CH_3CN)_2$. The mixed solvent system is essential for the success of the combined reactions since the desilylation reaction would not proceed in wet (or dry) DMF and the oxidation would not proceed in wet (or dry) acetone. At this time we do not understand why the mixed solvent system works while the individual solvents do not work on opposite reactions, but we are still investigating this intriguing observation.

The reaction is performed by mixing the silyl ether with the palladium catalyst in an acetone–DMF mixture containing 5 equivalents of water. The mixture is heated to reflux and, once TLC or GC indicates the silyl group has been removed, 2-bromomesitylene (oxidizing agent), PPh_3 (10 mol%), and K_2CO_3 are added and refluxed until the reaction is complete. Aldehydes and ketones are formed in yields ranging from 69 to 90% depending on the substrate (Scheme 11). Aldehydes are not overoxidized to the carboxylic acid, and even benzaldehyde was isolated in 75% yield. The reaction is not general and we have found three limitations so far: (*i*) aryl bromides and iodides are dehalogenated during the procedure. Thus, 3-bromo-2-(*tert*-butyldimethylsilyl)oxymethyl-naphthalene provided a 79% yield of 2-naphthaldehyde; (*ii*) *O*-(*tert*-butyldimethylsilyl)cinnaminol provided cinnamaldehyde in only 10% yield. Allylic alcohols appear to require stoichiometric amounts of the palladium species; finally (*iii*) a THP and acetate protecting group were not tolerated very well during this one-pot sequence (Scheme 11). Nevertheless, many examples provided aldehydes and ketones in good to excellent yield and we highly recommend this procedure over the two-step process that is normally used.

cis,cis-Spiro[4.4]nonane-1,6-diol: new chiral auxiliaries for the Diels–Alder reaction



For the past 4 years we have been investigating the synthesis and use of C_2-symmetric spirodiols as auxiliaries in various organic transformations (41–44). To date, we have concentrated our efforts on the preparation of *cis,cis*-spiro-[4.4]nonane-1,6-diol **35** and *cis,cis*-2,2′-spirobiindane-1,1′-diol **36** (Scheme 12). At the time we started our investigation,

[8] Lipshutz et al. reported the desilylation of a *tert*-butyldimethylsilyl ether as a side reaction when an acetal was being cleaved using $PdCl_2$. See ref. 39.

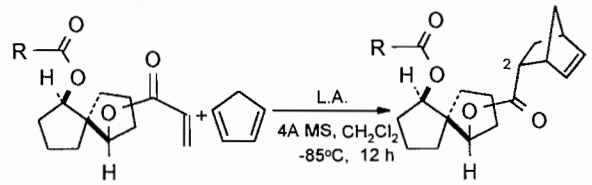
Scheme 12.

there were no reports on the use of **35** and **36** as chiral auxiliaries; however, in 1992 Kumar and co-workers reported that **36** could be used with lithium aluminium hydride for the asymmetric reduction of aromatic ketones (45). Attempts to repeat these results by us, and later by Seebach's group (46), failed to reproduce the results reported by Kumar. We therefore carried on with our investigation. The synthesis and resolution of (±)-**35** (41) and (±)-**36** (43) and the confirmation of the absolute stereochemistry of **35** using a combination of an X-ray crystal structure, VCD spectra, and ab initio calculations have been reported (42) and will not be presented in this article. Instead, the application of (+)- and (−)-**35** as chiral auxiliaries in the Diels–Alder reaction will be discussed in detail. While other diols have been used as chiral auxiliaries in the Diels–Alder reaction (47), to our knowledge this is the first time **35** has been used as such (48).

Although we have used (+)-**35** as a Lewis acid bound chiral auxiliary in the Diels–Alder reaction (Ti) (49), cyclopropanation reaction (Zn) (50), Grignard addition to aryl ketones (Mg) (51), and hydrocyanation reaction (Ti) (52), the enantiomeric excesses (ee's) of the products were never any better than those reported with other diols (48). We then looked at using **35** as a substrate-bound chiral auxiliary. When **35** was used as the alcohol component to prepare acetals and ketals from aldehydes and ketones and used in a variety of diastereotopic reactions (i.e., *ortho*-lithiation of arylacetals and condensation of the anion with aldehydes (53), diastereoselective Ullmann (54) and Suzuki couplings (19, 22) with *ortho*-bromoarylacetals, and cyclopropanation of unsaturated acetals (55)), the diastereomeric excesses (de's) were similar to those reported with other diols (48). The best result obtained with **35** was in the Diels–Alder reaction when a dienophile was attached to one alcohol and a blocking group to the other.



Initially we focused our attention on determining which Lewis acid would provide the highest yield and greatest amount of *endo* isomer in the Diels–Alder reaction between an acrylate and cyclopentadiene. The blocking group chosen was the 2-naphthoate group as Maitra and Mathivanan have reported success with this group when attached to a steroidal backbone (47*d* and *e*). Some selected results are illustrated in Table 1 (entries 1–6). The best result was when **37** (R = 2-Np) was treated at −85°C with 2 equiv. of boron trichloride containing freshly distilled cyclopentadiene. Adduct **38** (R = 2-Np) was formed in 100% yield with 96% *endo* stereochemistry and had a de of 75%.

A variety of blocking groups were used to replace the 2-naphthyl group and the Diels–Alder reaction was attempted using BCl_3. Changing the blocking group to a 1-naphthyl group did not noticeably change the results, but an increase in the de from 75% to 88% was observed when a phenyl group was used in **37**. Replacing the phenyl group with an electron-deficient (R = *p*-NO_2Ph) and electron-rich (R = MeOPh) aromatic ring did not noticeably change the %de, indicating stereoelectronic factors were not really important in this reaction. The steric size of the blocking group was increased by adding a diphenylbenzoate group to **37**, which resulted in a slight increase in the de to 90%. Following along the lines of increasing the steric bulk, a pivalate was attached to **37**. When the cyclopentadiene was precooled to −85°C prior to its addition to a mixture of **37** (R = CMe_3) and BCl_3, only one *endo* isomer was detected by HPLC and ^{1}H NMR spectroscopy.

This result is remarkable when one considers all the possible conformations that **37** can adopt prior to the Diels–Alder reaction. Either one conformation is preferentially formed with **37** (R = CMe_3) in the presence of 2 equiv. of BCl_3, thereby exposing only one face of the dienophile, or more than one conformation exists; but within each, the same face of the dienophile is exposed so that only one *endo* isomer is formed. Whatever the case, the result indicates that the spirononane **35** is a useful auxiliary in the Diels–Alder reaction.

The absolute stereochemistry of the bicyclo component of **38** was determined by treatment of **38** with I_2–KI in CH_2Cl_2 to form tricyclolactone **40** and alcohol **39**. Comparison of the sign of optical rotation of synthetic **40** with that reported in the literature (47*e*, 56) showed that when (+)-**35** was used to form

Table 1. Results for the Diels–Alder reaction of **37**.

R	Equiv. of Lewis acid	Lewis acid	*endo*[a,b] (%)	%de[b] (%ee)	**38**[b] (%)
2-Np	—	—	84	7	100[c]
2-Np	1.1	$TiCl_4$	97	54	6
2-Np	1.1	$SnCl_4$	95	80	15

Scheme 13.

Scheme 14.

37 (and subsequently **38**), lactone (−)-**40** was obtained (Scheme 13). This indicated that the absolute stereochemistry at C-2 in the bicyclo[2.2.1]system of **38** (Table 1) was *R* when 1*R*,5*R*,6*R*-(+)-**35** was used as the chiral auxiliary.

A drawback of using **37** (R=CMe_3) is that both components are attached to spirodiol **35** through an ester functional group. This makes it somewhat difficult to remove the bicyclo adduct without cleaving the pivalate group as well. Although an iodolactonization provides lactone **40** and alcohol **39**, which can be recycled, lactone **40** must be treated further to regenerate the bicyclo acid. To alleviate this problem we investigated whether placing two acrylate groups on diol **35** would lead to a high de of the required bicyclo adduct. Hopefully, each acrylate would be bulky enough and adopt a conformation that would preferentially block the same face on the other acrylate. This would lead to the Diels–Alder reaction at each acrylate giving the same bicyclo adduct. Treatment of **41** with cyclopentadiene in the presence of BCl_3 at −85°C provided only two (**42b** and **42c**) of three possible diastereomers (Scheme 14) with a de of 76%. This was initially disappointing until we removed the bicyclo adducts from **42b** and **42c** by iodolactonization and found the %ee of the resulting mixture of was actually 89% (measured by optical rotation). The %ee was higher than the %de since three bicyclo *endo* isomers with the *S* configuration (at C-2) were formed per bicyclo *R* isomer (at C-2) in **42b** and **42c**, thereby providing **40** with an 89% ee [(88 + 88 + 12 − 12)/(88 + 88 + 12 + 12)] after iodolactonization of the mixture of diastereomers (Scheme 14).

This is as far as we have taken this project to date. Work is continuing to: (*i*) improve the diastereoselectivity of this latter reaction; (*ii*) understand better reasons for the observed absolute stereochemistry; and (*iii*) to increase the scope of the Diels–Alder reaction with **35** by using a variety of dienophiles, dienes, and blocking groups.

Synthesis of thaxtomin C

Russell R. King

Abstract: *N*-Methyl-L-4-nitrotryptophan methyl ester (**2**) and *t*-Boc-L-phenylalanine (**3**) were condensed to form the dipeptide **4**, which was then cyclized to give 12-*N*-methylcyclo-(L-4-nitrotryptophyl-L-phenylalanyl) (**1**), a.k.a. thaxtomin C, the principle phytotoxin associated with *Streptomyces ipomoeae*.

Key words: *Streptomyces ipomoeae*, phytotoxin, thaxtomin C.

Résumé : On a condensé l'ester méthylique du *N*-méthyl-L-4-nitrotryptophan (**2**) et la *t*-Boc-L-phénylalanine (**3**) pour conduire au dipeptide **4** qui a alors été cyclisé pour donner le 12-*N*-méthylcyclo-(L-4-nitrotryptophényl-L-phénylalanyl) (**1**), aussi connu sous le nom de thaxtomine C, la principale phytotoxine associée au *Streptomyces ipomoeae*.

Mots clés : *Streptomyces ipomoeae*, phytotoxine, thaxtomine C.

[Traduit par la rédaction]

Introduction

The bacterium *Streptomyces ipomoeae* (Person and Martin) Waksman and Henrici is the causal agent of an economically important disease of sweet potato, *Ipomoeae batatas* (L.) ham. Infection is characterized by substantial yield reductions and disfigured lesions on the fleshy storage roots (1). Our recent investigations examining the host–parasite relationship of pathogenic *S. ipomoeae* isolates have identified the presence of a phytotoxin, 12-*N*-methylcyclo-(L-4-nitrotryptophyl-L-phenylalanine) a.k.a. thaxtomin C (**1**), which is associated with infection (2). As *S. ipomoeae* isolates could not be enticed to generate the phytotoxin when grown on any of the usual culture media, synthesis to provide convenient access to reasonable quantities for further host-interaction studies was required. Herein we describe a synthesis of the phytotoxin in acceptable yields utilizing standard procedures for the diketopiperazine ring-formation step.

Results and discussion

Thaxtomin C can be envisaged as being derived biosynthetically from the combination (diketopiperazine ring formation) of two amino acids: tryptophan and phenylalanine, with the required nitration and *N*-methylation steps occurring at some point along the way. In line with this approach a synthetically prepared sample of *N*-methyl-L-4-nitrotryptophan methyl ester (**2**) (3) was condensed with *t*-Boc-L-phenylalanine (**3**) (Scheme 1) to give the dipeptide methyl ester (**4**), the formate salt of which was cyclized by standard procedures (4). This gave 12-*N*-methylcyclo-(L-4-nitrotryptophyl-L-phenylalanyl) (**1**), a.k.a. thaxtomin C, in moderate yield (36%) after purification by precipitation. Since no diastereoisomers were detected (TLC, NMR), it was presumed that no racemization had occurred during the process. Unequivocal evidence for confirmation of the integrity of the synthetic sample was then obtained by comparing it with an authentic sample of thaxtomin C (UV, IR, MS, NMR, TLC, and biological activity (2)).

We have previously demonstrated (5) that the minimum structural criterion necessary for induction of scab by the thaxtomins is the presence of the 4-nitroindol-3-yl and phenylalanine groups linked in an L,L configured cyclodipeptide; i.e., elimination of the nitro group, replacement of the phenyl side chain, movement of the 4-nitro group to the 5, 6, or 7 positions, or conversion to a D,L configuration resulted in a complete loss of bioactivity.

Experimental section

Melting points were determined on a Kofler hot-stage microscope and are uncorrected. IR spectra were determined by using a Perkin–Elmer 467 grating infrared spectrophotometer. UV spectra were recorded in absolute ethanol using a Varian Cary 219 spectrophotometer. NMR spectra were recorded for solutions in deuterated chloroform on a Varian Unity 400 operating at 400 MHz for ^{1}H and at 100 MHz for ^{13}C. Chemical shifts were measured downfield from the signal of internal tetramethylsilane. MS were obtained on a Finnigan MAT 312 mass spectrometer. TLC was performed on 0.25 mm Merck silica gel 60 F_{254} plates and 0.2 mm Whatman $KC_{18}F$ plates.

Preparation of 12-*N*-methylcyclo-(L-4-nitrotryptophyl-L-phenylalanyl) (1)

t-Boc-L-Phenylalanine (**3**, 80 mg, 0.3 mmol) was dissolved in methylene chloride (20 mL) at 0°C and *N*-methyl-L-4-nitrotryptophan methyl ester (**2**, 83 mg, 0.3 mmol) was added. After addition of *N*-ethyl-*N'*-(3-dimethylaminopropyl) carbodiimide hydrochloride (58 mg, 0.3 mmol), the solution was stirred at 0°C overnight. The reaction mixture was then washed with water, citric acid (1 N), and sodium bicarbonate, and the solution was evaporated to dryness. The *t*-Boc-dipeptide (**4**, 86 mg) was eluted from a silica gel column ($CHCl_3$:MeOH, 9:1), dissolved in formic acid (10 mL, 98%),

Benzenoid hydrocarbon aromaticity in terms of charge density descriptors

S.T. Howard and T.M. Krygowski

Abstract: Hartree–Fock/6-31G** calculations on the benzenoid hydrocarbons benzene, naphthalene, phenanthrene, anthracene, pyrene, tetracene, triphenylene, chrysene, perylene, and coronene are used to investigate the link between aromaticity and the electron distribution. Topological charge density analysis is used, concentrating on the electron distribution ρ (and its Hessian) at bond and ring critical points. With regard to the bond critical point data, it is shown that ρ_c, $\nabla^2\rho_c$, and the bond "ellipticity" ε are closely correlated with the bond lengths so, as aromaticity indicators, they have little to add over and above existing indices based on structure. However, the same properties evaluated at the ring critical points in the total density, and also at the equivalent stationary points in the π and σ densities, correlate closely with two different aromaticity indices (one based on structure, the other on magnetic properties), the curvature of ρ perpendicular to the ring plane giving (marginally) the best results. Hence a ring critical point (RCP) index is proposed as a way of quantifying aromaticity, based directly on the electron distribution.

Key words: quantum chemistry, electron density, aromaticity, aromaticity index, HOMA, NICS.

Résumé : On a utilisé des calculs Hartree–Fock/6-31G** sur les hydrocarbures benzénoïdes benzène, naphtalène, phénanthrène, anthracène, pyréne, tétracène, triphénylène, chrysène, péryléne et coronène pour étudier la corrélation entre l'aromaticité et la distribution électronique. On utilise une analyse topologique de la densité de charge qui se concentre sur la distribution électronique ρ (et son hessoise) à des points critiques des liaisons et des cycles. En ce qui a trait aux données relatives aux points critiques des liaisons, on a démontré que ρ_c, $\nabla^2\rho_c$ et l'« ellipticité » ε des liaisons sont intrinsèquement liés aux longueurs des liaisons; comme indicateurs de l'aromaticité, ils n'ont pas beaucoup de chose à ajouter aux indices existants basés sur la structure. Toutefois, les mêmes propriétés évaluées aux points critiques des noyaux dans la densité totale ainsi que les points stationnaires équivalents dans les densités π et σ présentent une excellente corrélation avec deux indices différents d'aromaticité (l'un basé sur la structure et l'autre sur les propriétés magnétiques) alors que la courbure de ρ perpendiculaire au plan du noyau conduit à des résultats marginalement meilleurs. Pour quantifier l'aromaticité, on propose donc un indice de point critique du noyau qui est basé directement sur la distribution électronique.

Mots clés : chimie quantique, densité électronique, aromaticité, indice d'aromaticité, «HOMA», «NICS».

[Traduit par la rédaction]

Introduction

The definition of aromaticity has long been a topic of vivid discussion. Since the term was first coined, it has been defined in a dichotomic way, e.g., structural (1) or behaviouristic (2). The Hückel $4n + 2$ rule (3) has served to associate these two ways of defining "aromatic character," by linking the π-electron structure and ring shape with an increase in energetic stability. Most chemists have subsequently abided by the definition summarized by Jackman and Elvidge (4). In brief, this defines aromaticity as a consequence of π-electron delocalization in cyclic systems, which may be characterized by: (*i*) averaging of bond lengths; (*ii*) increased stability (by an amount of energy called the resonance energy); and (*iii*) the presence of certain magnetic properties (shown inter alias by proton NMR spectra). Thus, more generally, aromaticity is "the set of properties associated with cyclic conjugation" (5).

The most extensively studied property has been stabilization energy; hence various definitions of resonance energy have been developed using calorimetric measurements (6) or theoretical ideas (7–10). However, there have been a multitude of other approaches, including: graph-topological (11–13); geometrical structure (bond lengths, bond length/order alternation) (14–21); magnetic properties (diamagnetic susceptibilities, chemical shifts) (22–26); and HOMO–LUMO gap criteria (27, 28). Recently it has been shown that these various measures of aromaticity need not be unequivocally the same (26, 29).

Central to all these ideas about aromaticity is the concept of a conjugated π-electron framework, that is to say, aromatic systems should have a characteristic distribution of electrons. It is therefore a little surprising that not much attention has been paid to the relationship between the topological characteristics of the charge distribution and aromatic character. Instead, theoretical chemists have historically concentrated on Molecular Orbital (MO)-based descriptions of aromaticity — this is implicit when we talk about σ- and π-electron frame-

works. Alternative descriptions based on physical, observable properties are surely preferable. This approach is epitomized by the work of Bader and co-workers over the last 25 years or so (30), and it has illuminated many aspects of chemistry.

In this topological approach, the charge distribution ρ is characterized by its stationary points or "critical points" (CPs) in the scalar fields ρ and $\nabla^2\rho$. We shall be concerned with two of the four CP types that occur in ρ: so-called bond CPs (BCPs) and ring CPs (RCPs). BCPs are located at the minumum along the line of maximal charge density between nuclei: in benzenoid C—C bonds this is always close to the geometric bond centre. (In heteronuclear bonds the position of the critical point is linked to the relative electronegativities of the atoms (31, 32).) RCPs occur close to the geometric centroid in benzenoid hydrocarbon rings, at the position of minimal charge density in the ring plane.

The Hessian of ρ (matrix of partial second derivatives with respect to $\{x, y, z\}$) fully specifies its curvature. The trace of the Hessian, $\nabla^2\rho$, measures the charge concentration or depletion at a point (negative values of $\nabla^2\rho$ mean that charge is locally concentrated, positive values correspond to charge depletion). The ratio of the two negative eigenvalues of the Hessian matrix at a BCP may be used to quantify double bond character (33). More precisely, the ellipticity ϵ is defined as $\varepsilon = \lambda_1/\lambda_2 - 1$, where the λ's are the two Hessian eigenvalues corresponding to directions perpendicular to the bond, and $|\lambda_1| > |\lambda_2|$. At RCPs, two eigenvalues of the Hessian are positive and (in benzenoid hydrocarbons) approximately equal, while the remaining (negative) eigenvalue (λ_3) measures the curvature of ρ perpendicular to the ring plane.

In benzenoid hydrocarbons, each molecular orbital may be classified as σ or π without any ambiguity, unlike the partitioning of the total energy into σ and π contributions, which remains a subject of dispute (34–37). Consequently, the total electron density ρ may be subdivided into corresponding contributions: $\rho = \rho_\sigma + \rho_\pi$. The topological analysis presented above can equally well be applied to these separated ρ_σ and ρ_π densities, and we will present results for the σ, π, and total electron densities. The RCPs and BCPs in the total density ρ occur in the ring plane or nodal plane of the π-electron structure, so at these points $\rho = \rho_\sigma$ and $\rho_\pi = 0$. However, the *curvature* of the electron distribution in this

Fig. 1. The 10 benzenoid hydrocarbons considered in this work, together with the atom labelling scheme.

nodal plane is strongly dependent on both σ and π electrons. We will be concerned especially with the curvature perpendicular to the ring plane (λ_3), which has a positive contribution from π electrons (since these are concentrated above and below the plane) and a negative contribution from σ electrons (concentrated in the plane). The remaining two perpendicular curvatures lie in the ring plane, and therefore again only have non-zero contributions from σ electrons (i.e., $\nabla^2\rho_\pi = \lambda_{3,\pi}$ in this plane).

In this work, we determine the topological properties ρ, $\nabla^2\rho$, and the eigenvalues of the Hessian of ρ at both bond and ring critical points in 10 benzenoid hydrocarbons. To establish whether these quantities may be used as indices of aromatic character, we must somehow correlate these data with an established index of aromatic character, preferably one that can be derived from the same data. We have chosen to concen-

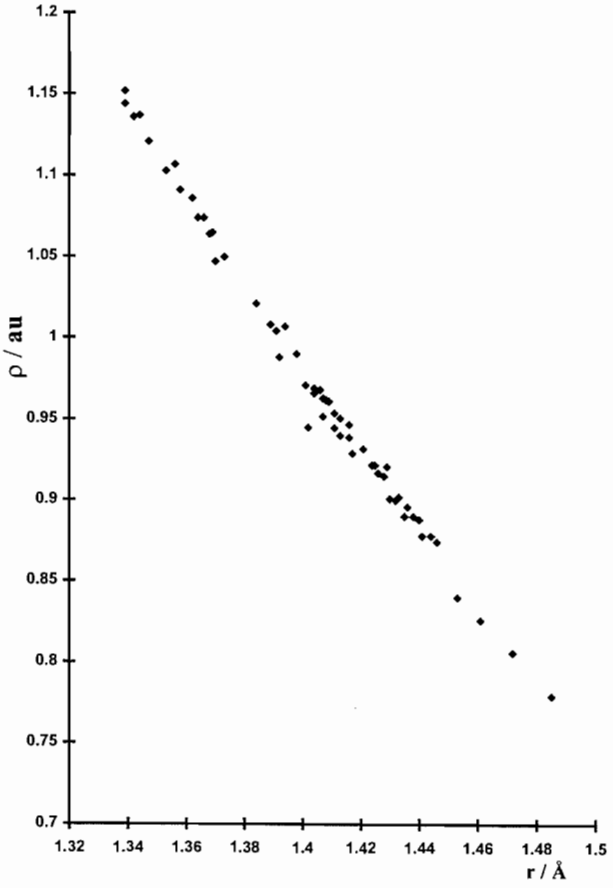
Fig. 2. Relationship between bond length and ρ_c at the 58 bond critical points (correlation coefficient $r = -0.998$).



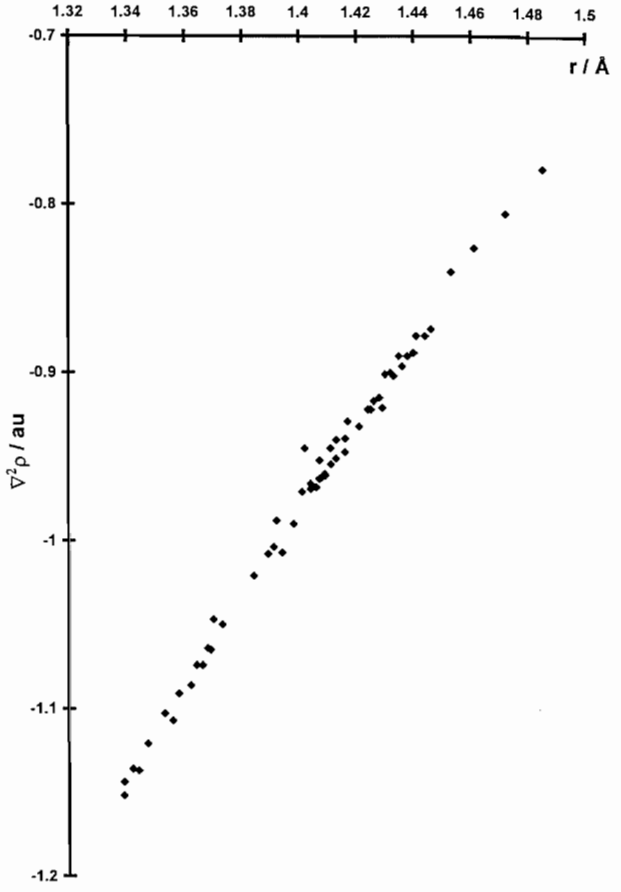


Fig. 3. Relationship between bond length and $\nabla^2\rho_c$ at the 58 bond critical points (correlation coefficient $r = +0.997$).

trate on the so-called HOMA index (harmonic oscillator model of aromaticity) (15), since it is simple to compute (it needs only the bond lengths in a ring $\{r_i\}$) and has found wide application (as reviewed in ref. 16). We will also demonstrate a relationship between this index and an established independent index NICS (based on magnetic susceptibility).

In the case of benzenoid hydrocarbons, the HOMA index for a particular ring is found from a simple sum over the six bonds making up the ring

$$[1] \quad \text{HOMA} = 1 - \left[\sum_{i=1}^{6} 257.7\,(r_i - 1.388)^2\right]/6$$

The constant 257.7 is chosen on the basis of C—C bond lengths and bond stretching force constants, i.e., in general HOMA can take into account heteroatoms by choosing appropriate values of constant for each bond. In this way, the energy to distort the structure from some idealized set of bond lengths is taken into account — it is an energy-weighted sum. The value of 1.388 Å is an optimized C—C bond length for compressing single/expanding double bonds assuming a harmonic potential with a single-bond force constant equal to half the double-bond force constant. The HF/6-31G** optimized value of the C—C bond length in benzene is very close to this (1.386 Å), so benzene gives a HOMA value that is very close to unity (0.999). Thus the index defined in eq. [1], using the set of bond lengths $\{r_i\}$ derived from ab initio optimization, effectively measures the mean deviation of the ring structure from that of benzene.

Computational details

The Hartree–Fock calculations were carried out with GAMESS (38) running on DEC Alpha RISC workstations. The topological analysis of ρ utilized the program SADDLE (39). The 6-31G** basis set (40) was used in geometry optimizations, and the charge distributions were computed and analyzed at the same level. All molecules were constrained to be planar and, furthermore, were optimized within the following point group symmetries: phenanthrene (C_{2v}); chrysene (C_{2h}); naphthalene, anthracene, tetracene, pyrene, perylene (D_{2h}); benzene, coronene (D_{6h}); triphenylene (C_{3h}).

Results and discussion

Table 1 summarizes some energetic data for the 10 hydrocarbons, optimized at the HF/6-31G** level. Anthracene is found to be more stable by $\approx$29 kJ mol^{-1} than its isomorphous partner phenanthrene, and similarly chrysene is marginally more stable than its isomers tetracene and triphenylene. We also report the HOMO–LUMO gaps for the canonical orbitals,

[d]Correlation coefficient with the aromaticity index NICS.

since these may be considered as one measure of (overall) aromaticity (27, 28). For example, benzene has the largest HOMO–LUMO gap and is predicted to be the most aromatic compound, in agreement with all indices of aromaticity. These data are some of the most comprehensive so far reported for benzenoid hydrocarbons, at a consistent ab initio level of theory.

The 10 compounds studied provide a total of 58 unique C—C bonds and 18 unique six-membered rings (tables of bond lengths and critical point analyses are available as supplementary data).[2] The molecules are illustrated, together with the atom labelling scheme, in Fig. 1.

First, we explore whether useful analogous aromaticity indices like HOMA could be constructed on the basis of charge density descriptors like $\{\rho_c, \nabla^2\rho_c, \varepsilon\}$ at the bond CPs. The rationale for this is simple. Indices such as HOMA and (to give another example) the so-called bond-alternation coefficient (BAC) (20):

$$[2] \quad \mathrm{BAC} = 1 - 3.46\left[\sum_{i=1,3}(d_i - d_{i+1})^2\right]$$

[2] These tables can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

have already proved to be very useful measures of aromatic character. Yet definitions of aromaticity are invariably linked to the cyclic delocalization of *electrons*. Although the nuclear framework responds to changes in the electron distribution, some subtle changes in ρ may hardly affect the structure. So indices based directly on the charge distribution could potentially provide more sensitive measures of aromaticity.

With this aim in mind, we consider the interrelationships between parameters from the ab initio optimizations alone, particularly the relationships between bond length and $\{\rho_c, \nabla^2\rho_c, \varepsilon\}$ at bond CPs. These are illustrated in Figs. 2–4. Clearly there are extremely strong linear relationships between all three electron density descriptors and the ring bond lengths. Even ε, which shows the most scatter, correlates with *r* at the level of 0.978. This makes it clear that the bond length can be considered as a controlling parameter (especially for ρ) in benzenoid hydrocarbons, in that it is completely representative of the charge density at the bond CPs. This simple observation has a far-reaching consequence: so far as benzenoid hydrocarbons are concerned, bond charge density descriptors provide very little extra information beyond that in the (Born–Oppenheimer) equilibrium structure. It also explains the past successes of indices based only on structure such as HOMA and BAC, in describing aromatic character.

Table 2*a* reports the ring topological descriptors for both σ and π electrons, evaluated for the σ-density framework (these

[d]Correlation coefficients, described in the legend of Table 2(*a*).

occur at the same points as the RCPs in total density ρ). Sample correlation coefficients for each parameter with the HOMA and NICS indices (taken from ref. 41 in the latter case) are also reported. Table 2*b* contains the same information, but evaluated at a set of stationary points in ρ_π. These points lie above the ring centres at perpendicular distances $d \approx 0.8$ Å (exact values for d are given in Table 2*b* for each ring), unlike the RCPs that lie in the ring planes. Lastly, Table 3 summarizes the HOMA indices derived from our HF/6-31G** optimized structures and the NICS values for the same species computed by Schleyer et al. (41).

However, we first consider the relationship between the HOMA index and RCP indicators $\{\rho_c, \nabla^2\rho_c, \varepsilon\}$, based on the *total* electron density (Figs. 5–7). Evidently, good linear correlations exist between HOMA and all three total electron density descriptors. The correlation found between the indices HOMA and NICS (−0.896, see Fig. 8) demonstrates that these total density descriptors must also correlate with the latter index.

Now we turn to how the HOMA index correlates separately with the σ and π electron density descriptors. Looking at the sample correlation coefficients reported in Tables 2*a* and *b* it is evident that, whether these properties are measured in the ring plane (σ-electron framework) or above the plane (π-electron framework), the correlations of the various descriptors with HOMA and NICS rival those found with the total density. The one exception uncorrelated with HOMA is the value of $\nabla^2\rho_\sigma$, i.e., the concentration of σ-charge density evaluated either at the (in-plane) RCP or at the stationary point in ρ_{pi}. In fact we can be more specific than this, since $\nabla^2\rho_\sigma = \lambda_{\sigma,1} + \lambda_{\sigma,2} + \lambda_{\sigma,3}$, and a good correlation exists between HOMA and $\lambda_{\sigma,3}$ (the curvature perpendicular to the ring plane); evidently it is the sum $\lambda_{\sigma,1} + \lambda_{\sigma,2}$ (the in-plane curvatures) that is independent of aromatic character. This seems to be an important point — both σ and π electrons contribute to aromatic character, in the sense that their values at stationary points in these distributions correlate with two independent aromaticity indices. But the contribution of σ electrons to aromatic character is anisotropic: only the component of σ orbitals in the direction of the π system makes a contribution. In the case of the scalar parameter ρ_σ, the correlations with HOMA and NICS are clearly significant.

The fact that both σ and π electron density measures correlate with aromaticity indices can be rationalized simply: the total charge density consists of only these two symmetry components, so changes in one of them directly affects the other (i.e., $\{\lambda_\sigma, \lambda_\pi\}$ and $\{\rho_\sigma, \rho_\pi\}$ must be mutually correlated). So all things considered, it seems not to be important whether the total, σ, or π density is examined, or which set of points is chosen: the density and (or) its various curvatures correlate very well with two *independent* measures of aromatic character.

Conclusions

Three important conclusions arise from this study. Firstly, it appears that all three of the charge density descriptors ρ_c, $\nabla^2\rho_c$, and ε at the bond critical points in benzenoid hydrocarbons are

linearly related to the bond length. The best relationship occurs for the charge density ρ_c. It is therefore unlikely that indices of aromatic character could be constructed as functions of bond critical point density properties, which would give new information not derivable from the ground state (Born–Oppenheimer) equilibrium structures.

Secondly, the same charge density descriptors evaluated at the ring critical points are linearly related to the HOMA aromaticity index. We cannot explain this correlation in any trivial way. For example: on a simple level, it could be suspected that these electron density descriptors would correlate with the mean area of the ring. But the HOMA index is more sophisticated than this, since it takes account of the *difference* in size of a given ring from that of a reference structure (benzene in this case), i.e., HOMA (ring) $\approx |$area (ring) − area (benzene)$|$. So these results provide further evidence (were it needed) that aromaticity is more than just a concept, and it may be quantified by a number of schemes that should broadly agree, at least in families of structurally related systems. The HOMA index applied here is one of a family of indices based on geometrical structure that has been applied extensively in the analysis of the benzene ring in various chemical and topological environments (16). These results suggest a new set of "RCP" (Ring Critical Point) indices of aromaticity, based directly on the electron distribution. For benzenoid hydrocarbons at least, it seems that the most appropriate RCP charge density descriptor for describing aromaticity is the (negative) Hessian eigen-

value λ_3. The HF/6-31G** values calculated for the 18 unique rings in this work may be used to calibrate an RCP scale of aromaticity, provided that the same technique and basis set is always applied.

Thirdly, it appears that the σ and π density topological descriptors correlate almost equally well with two fundamentally different and independent aromaticity indices. The same descriptors based on the *total* electron density actually correlate slightly better. Choosing another set of points for evaluating the electron density descriptors, such as a set of equivalent stationary points in the π-electron framework, does not change this conclusion.

Given the intense interest in defining aromatic character, this is hardly likely to be the last word on this topic nor the last (or "best") proposed indicator of it. However, it appears to offer some new insight into the phenomenon — in particular, it is not necessary to invoke either unphysical "σ/π" separations of the charge distribution or total energy or hypothetical Kekule-type reference structures in order to arrive at useful working definitions of aromaticity. We feel there is much more to be gained from definitions of benzenoid aromaticity based on observables, e.g., bond length equalization, sizeable ring currents, and *the presence of a characteristic distribution of electrons, conveniently summarized at the ring critical point.*

Indices that can assign individual aromaticities to each ring in a large molecule are perhaps more useful than an overall index for a whole compound (such as the HOMO–LUMO gap criterion of Zhou and Parr). It seems reasonable to suppose that the RCP index (like the HOMA index) can be extended to describe the aromatic character of non-six-membered rings or rings containing heteroatoms, although this remains to be demonstrated.

Electrochemical reduction of the unsaturated cyclic trinuclear $Pd_3(dppm)_3CO^{2+}$ cluster (dppm = $((C_6H_5)_2P)_2CH_2$)

Isabelle Gauthron, Yves Mugnier, Karine Hierso, and Pierre D. Harvey

Abstract: $Pd_3(dppm)_3CO^{2+}$ exhibits a two-electron reduction process at ~−0.5 V vs. SCE in 0.2 M Bu_4NPF_6 solutions of organic solvents such as dry acetonitrile, *N,N*-dimethylformamide (DMF), tetrahydrofuran (THF), and dichloromethane to reversibly produce the zero valent $Pd_3(dppm)_3CO$, which exhibits a ν(CO) band in the 1761–1766 cm^{-1} range in the IR spectra. The mechanistic aspects of this multistep two-electron process are discussed experimentally on the basis of r.d.e. (rotating disk electrode) voltammetry, cyclic voltammetry, and electrolysis results. Geometry optimizations using DFT (Density Functional Theory) predict that the Pd—Pd and C═O bond lengths are 3.008 and 1.182 Å, respectively, which compare favorably with the experimental data for other zero valent polynuclear complexes.

Key words: palladium, cluster, reduction, electrochemistry, density functional theory.

Résumé : En solution dans des solvants organiques, tels que l'acétonitrile, le *N,N*-diméthylformamide (DMF), le tétrahydrofurane et le dichlorométhane secs, contenant 0,2 M de Bu_4NPF_6, le $Pd_3(dppm)_3CO^{2+}$ donne lieu à un processus de réduction à deux électrons à ~0,5 V vs. SCE conduisant à la formation réversible de $Pd_3(dppm)_3CO$ zérovalent dont le spectre IR présente une bande ν(CO) autour de 1761 à 1766 cm^{-1}. On discute des aspects mécanistiques de ce processus à deux électrons en plusieurs étapes en se basant sur des données expérimentales de voltampérométrie à électrode à disque tournant, de voltampérométrie cyclique et d'électrolyse. Des optimisations sur la base de la théorie de densité fonctionnelle permettent de prédire des longueurs de 3,008 et 1,182 Å respectivement pour les liaisons Pd—Pd et C═O; ces prédictions se comparent favorablement avec les données expérimentales obtenues avec d'autres complexes zérovalents polynucléaires.

Mots clés : palladium, agrégats, réduction, électrochimie, théorie de la densité fonctionnelle.

[Traduit par la rédaction]

Introduction

The $Pd_3(dppm)_3CO^{2+}$ cluster (dppm = $((C_6H_5)_2P)_2CH_2$) was reported by Puddephatt and co-workers over 10 years ago (1, 2). The preparation consists of a reaction between $Pd(O_2CF_3)_2$, dppm, and CO in an acetone–CF_3CO_2H–H_2O mixture. Recently, the formation mechanism of this cluster has been studied in detail (1, 3, 4). Although this cluster and the $Pt_3(dppm)_3CO^{2+}$ analogue exhibit a particularly rich addition and oxidative addition reactivity towards small molecules (4), the chemical reduction has never been successful (2). We now wish to report the electrochemical behaviour of $Pd_3(dppm)_3CO^{2+}$ in aprotic media. It will be shown that for the first time the zero valent neutral $Pd_3(dppm)_3CO$ cluster can be prepared under electrolysis conditions. Only a few electrochemical studies of mono- and binuclear palladium complexes containing chelating diphosphine ligands have been reported in the literature (5–7). Density functional theory has been used to predict the structures of one intermediate and the final product.

Experimental

Materials

The $Pd_3(dppm)_3CO^{2+}$ cluster as $CF_3CO_2^-$ (**1**) and PF_6^- (**1′**) salts has been prepared according to literature procedures (1, 2).

IR measurements

All IR measurements were performed on a Nicolet 205 spectrophotometer. The electrolysis solutions were transferred into an airtight IR cell via canular techniques. No attempt to isolate the palladium species was made.

Electrochemistry

All manipulations were performed by using standard Schlenk techniques in an atmosphere of dry oxygen, free nitrogen, or argon. Tetrahydrofuran was distilled under argon from sodium and benzophenone. CH_2Cl_2 and acetonitrile (ACN) were purified by simply passing the solvent through a column packed with alumina previously dried at 120°C; it was deoxygenated by argon bubbling immediately before use. These salts were dried and degassed before use. In cyclic voltammetry experi-

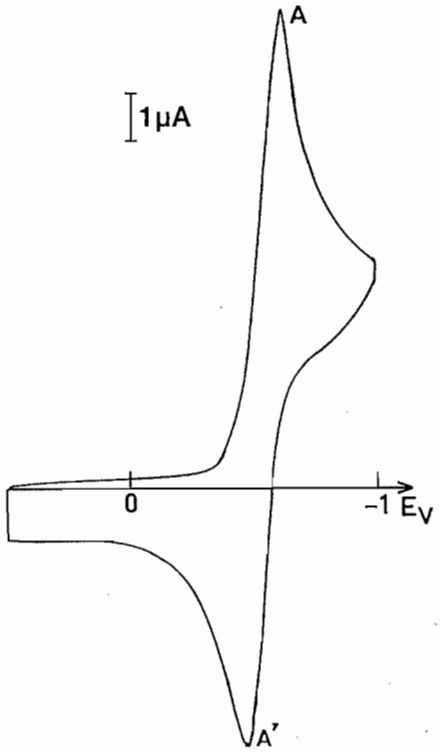
ments the concentration of $Pd_3(dppm)_3CO^{2+}$ was nearly 10^{-3} M. Voltammetry analysis was carried out in a standard three-electrode cell with a Tacussel UAP4 unit cell. The reference electrode was a saturated calomel electrode separated from the solution by a sintered glass disk. The auxiliary electrode was a platinum wire. For all voltammetric measurements the working electrode was a vitreous carbon electrode. The controlled potential electrolysis was performed with an Amel 552 potentiostat coupled to an Amel 721 electronic integrator. High-scale electrolysis was performed in a cell with three compartments being separated with fritted glasses of medium porosity. A carbon gauze was used as the cathode, a platinum plate was used as the anode, and a saturated calomel electrode was used as the reference electrode. The electrolyte was either tetrahydrofuran or methylene chloride 0.2 M in tetrabutylammonium hexafluorophosphate. For thin-layer cyclic voltammetry, the vitreous carbon electrode was lowered until it came into contact with the flat floor of the electrolytic cell so that only a thin layer of solution existed between them.

Computational details

The reported density functional calculations were all carried out utilizing the program called Amsterdam Density Functional, which was developed by Baerends et al. (8, 9) and vectorized by Raveneck (10). The numerical integration procedure applied for the calculations was developed by te Velde and co-workers (11). The geometry optimization procedure was based on the method developed by Versluis and Ziegler (12). The electronic configurations of the molecular systems were described by an uncontracted double-ζ basis set (13) on palladium for 4*s*, 4*p*, and 5*s*, and triple-ζ for 5*d*. Double-ζ STO basis sets (14) were used for phosphorus (3*s*, 3*p*), oxygen (2*s*, 2*p*), carbon (2*s*, 2*p*), nitrogen (2*s*, 2*p*), and hydrogen (1*s*), augmented with a single 4*d* polarization function for P, a single 3*d* function for O and C, and a 2*p* function for H. No polarization function was used for palladium. The $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3d^{10}$ configuration on palladium, the $1s^2\ 2s^2$ configuration on phosphorus, and the $1s^2$ configurations on oxygen and carbon were treated by the frozen-core approximation (9). A set of auxiliary (15) *s*, *p*, *d*, *f*, and *g* STO functions, centered on all nuclei, was used in order to fit the molecular density and present Coulomb and exchange potentials accurately in each SCF cycle. Energy differences were calculated by including the local exchange–correlation potential by Vosko et al. (16). No nonlocal exchange and correlation corrections were made for the geometry optimizations.

Results and discussion



1. Electrochemistry

We have studied the electrochemical reduction of dicationic cluster $Pd_3(dppm)_3CO^{2+}$ in such different solvents as THF, ACN, DMF, and CH_2Cl_2.

1. (a) Electrochemical behaviour of $Pd_3(dppm)_3CO^{2+}$ in THF

An electrochemical process *A*/*A*′ (*A* = −0.62 V, *A*′ = −0.46 V vs. SCE) is observed in the cyclic voltammogram using THF containing 0.2 M Bu_4NPF_6 for $[Pd_3(dppm)_3CO](CF_3CO_2)_2$ **1** (Fig. 1). Upon bulk electrolysis performed at −0.80 V vs. SCE, coulometric measurements indicate that two electrons (n_{exp} = 2.01 F mol^{-1}) are consumed until the current drops to zero. The resulting solution exhibits the same *A*/*A*′ peaks system. These results are consistent with a mechanism described by eq. [1]:

Fig. 1. Cyclic voltammogram of $[Pd_3(dppm)_3CO](CF_3CO_2)_2$ **1** in THF containing 0.2 M Bu_4NPF_6: starting potential = +0.5 V, sweep rate = 0.02 V s^{-1}.

[1] $Pd_3(dppm)_3CO^{2+} + 2e^- \leftrightarrows Pd_3(dppm)_3CO$
1 **2**

The oxidation–reduction electrolysis is quantitative without any evidence of loss of the starting $Pd_3(dppm)_3CO^{2+}$ material, since the two-electron oxidation of **2** gives quantitatively the starting complex. According to the morphology of the cyclic voltammograms exhibiting only a single *A*/*A*′ peaks system, we suggest that the intermediate monocationic $Pd_3(dppm)_3CO^+$ must be reduced at a lower negative potential than $Pd_3(dppm)_3CO^{2+}$ itself. Recently Pierce and Geiger showed that increases in cyclic voltammetry sweep rates change the redox couple for a dicationic ruthenium complex (17). In this case, a single wave associated with a two-electron process could be changed into two waves each associated with a one-electron transfer simply by changing the sweep rates (17). For $Pd_3(dppm)_3CO^{2+}$, no change is observed with sweep rates of 0.01 V s^{-1} to 0.5 V s^{-1}.

The cyclic voltammogram of $[Pd_3(dppm)_3CO](PF_6)_2$ **1′** in the same experimental conditions (THF – 0.2 M Bu_4NPF_6) exhibits two systems A_1/A'_1 and A_2/A'_2 (A_1 = −0.38 V, A'_1 = −0.20 V, A_2 = −0.65 V, A'_2 = −0.46 V vs. SCE at 0.2 V s^{-1}) (Fig. 2). After a two-electron reduction (n_{exp} = 1.88 F mol^{-1}), the rotating disk electrode (r.d.e.) voltammogram shows two waves A'_1 and A'_2 that correspond to the oxidation of $Pd_3(dppm)_3CO$. The mechanism is described by reactions [2] and [3]:

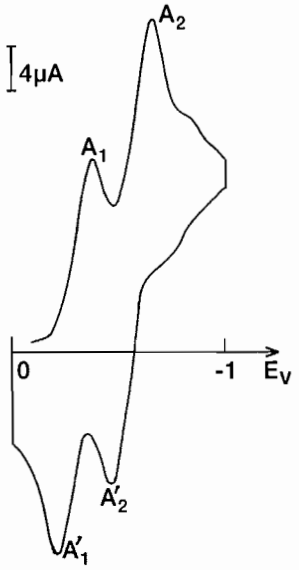
Fig. 2. Cyclic voltammogram of $[Pd_3(dppm)_3CO](PF_6)_2$ **1** in THF containing 0.2 M Bu_4NPF_6: starting potential = 9 V, sweep rate = 0.2 V s^{-1}.



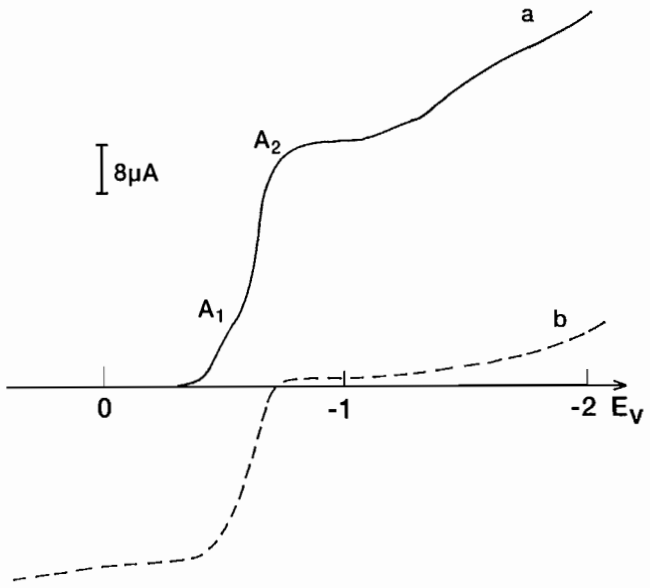


Fig. 3. The r.d.e. voltammograms of $[Pd_3(dppm)_3CO](CF_3CO_2)_2$ **1** in acetonitrile containing 0.2 M Bu_4NPF_6: (*a*) before electrolysis; (*b*) after a two-electron reduction at −1.2 V vs. SCE.

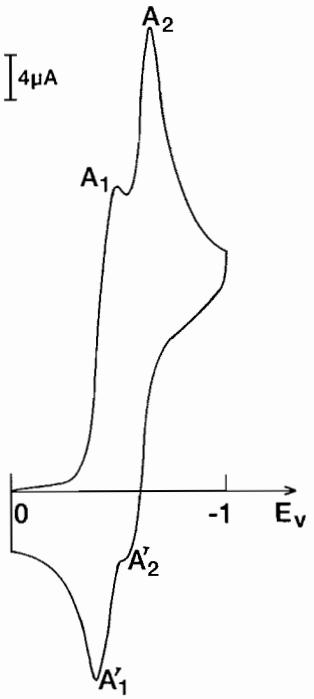
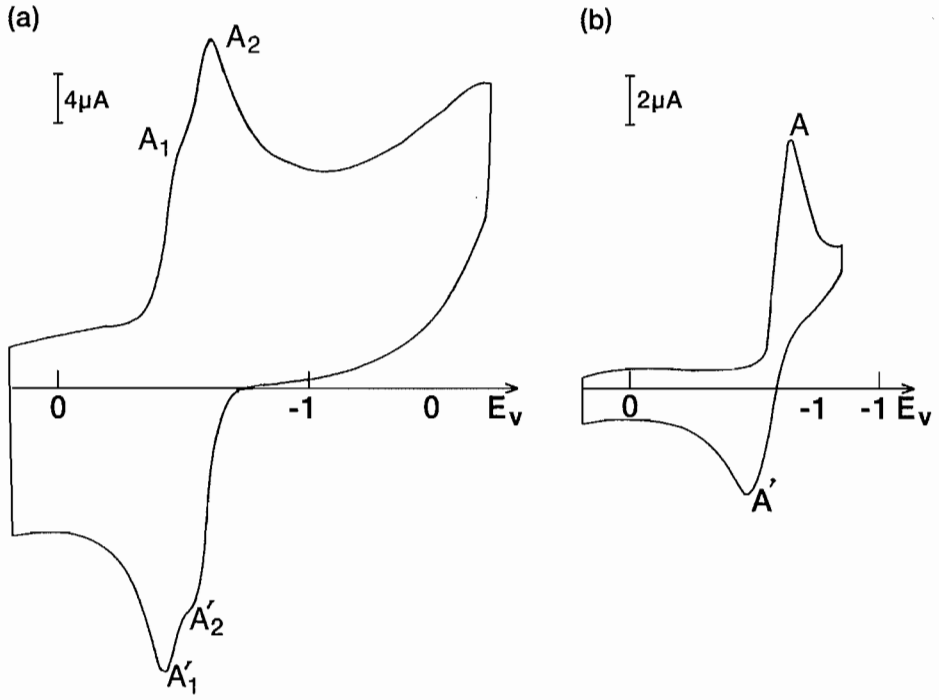
[2] $Pd_3(dppm)_3CO^{2+} + e^- \leftrightarrows Pd_3(dppm)_3CO^+$ (system A_1/A'_1)



[3] $Pd_3(dppm)_3CO^+ + e^- \leftrightarrows Pd_3(dppm)_3CO$ (system A_2/A'_2)

Under these conditions, even by using Schlenk techniques, this neutral cluster proved to be too unstable for IR spectroscopy studies (a ν(CO) band at 1686 cm^{-1} appears that corresponds to the decomposition product).

1.(b) Electrochemical behaviour of $Pd_3(dppm)_3CO^{2+}$ in ACN



The r.d.e. voltammogram of $[Pd_3(dppm)_3CO](CF_3CO_2)_2$ **1** in 0.2 M Bu_4NPF_6 – acetonitrile solution exhibits two reduction electrochemical processes at −0.50 and −0.65 V vs. SCE and are marked by A_1 and A_2, respectively (Fig. 3*a*). By cyclic voltammetry using a vitreous carbon disk electrode, the corresponding peaks A_1 and A_2 are indeed observed. The anodic sweep at a starting potential of −1.50 V vs. SCE exhibits two return peaks (−0.40 V A'_1 and −0.55 V A'_2) (Fig. 4). The electrolysis at −1.2 V on a carbon gauze electrode at room temperature leads to a complete drop of current after a two-electron consumption per mole of cluster (n_{exp} = 2.05 F mol^{-1}). During this electrolysis, the red solution turns brown, and the r.d.e. voltammogram of the resulting solution exhibits two well-defined oxidation waves (A'_1, A'_2) (Fig. 3*b*). Similarly the cyclic voltammogram exhibits the same A_1/A'_1 and A_2/A'_2 peaks systems. These results indicate that the overall electrochemical processes follow reaction [1]. The monitoring of this electrolysis by IR spectroscopy indicates a large decrease in the ν(CO) band intensity located at 1835 cm^{-1}. In this experiment no new IR band is observed and the strong 1695 cm^{-1} ν(CO) band (CF_3CO^{2-}) remains unchanged. No evidence for free CO is found. We believe that ν(CO) of the new species is hidden under the strong 1695 cm^{-1} band (see below). The reduced species appears to be partially soluble in acetonitrile and, even stored under Ar(g), the product exhibits an evolution during which a decrease in intensity of the A'_1 and A'_2 oxidation peaks system is observed. At room temperature, the species produced exhibits limited stability, and no NMR spectroscopic study has been possible. To determine the ν(CO) band in IR spectroscopy, we have examined the electrochemical behaviour of $[Pd_3(dppm)_3CO](PF_6)_2$ **1′**. After a two-electron reduction (n_{exp} = 2.05 F mol^{-1}), the IR spectroscopy of the electrolyzed solution exhibits a ν(CO) band at

Fig. 4. Cyclic voltammogram of $[Pd_3(dppm)_3CO](CF_3CO_2)_2$ **1** in acetonitrile containing 0.2 M Bu_4NPF_6: starting potential = +0.5 V, sweep rate = 0.2 V s^{-1}.

© 1997 NRC Canada

Fig. 5. Cyclic voltammograms of $[Pd_3(dppm)_3CO](CF_3CO_2)_2$ **1** in (*a*) dimethylformamide containing 0.2 M Bu_4NPF_6: starting potential = +0.2 V, sweep rate = 0.2 V s^{-1} , and (*b*) dimethylformamide containing 0.2 M LiCl: starting potential = +0.2 V, sweep rate = 0.02 V s^{-1}.

1761 cm^{-1} that is readily attributed to the formation of $Pd_3(dppm)_3CO$.

[4] $Pd_3(dppm)_3CO^{2+} + 2e^- \leftrightarrows Pd_3(dppm)_3CO$
(ν_{CO} = 1835 cm^{-1}) (ν_{CO} = 1761 cm^{-1})

1.(c) Electrochemical behaviour of $Pd_3(dppm)_3CO^{2+}$ in CH_2Cl_2

Using CH_2Cl_2 as a solvent, the $Pd_3(dppm)_3CO^{2+}$ electrochemical behaviour is similar to that described for acetonitrile where two systems A_1/A'_1 and A_2/A'_2 are observed by cyclic voltammetry (sweep rate (v) range = 0.01–0.5 V s^{-1}). The constant ratio $i_p/v^{1/2}$ (i_p = peak current) indicates that the electrochemical processes are diffusion controlled. A reduction electrolysis performed at −0.9 V vs. SCE consumes two electrons (n_{exp} = 1.98 F mol^{-1}), and the anodic sweep in the cyclic voltammograms exhibits the typical A'_1 and A_2' oxidation peaks associated with the formation of the neutral $Pd_3(dppm)_3CO$. The mechanism is described by reactions [2] and [3].

The monitoring of the bulk electrolysis of $[Pd_3(dppm)_3CO](PF_6)_2$ **1′** (in CH_2Cl_2) by IR spectroscopy indicates that the 1835 cm^{-1} band disappears while a band located at 1766 cm^{-1} appears that is also assigned to the formation of $Pd_3(dppm)_3CO$.

[5] $Pd_3(dppm)_3CO^{2+} + 2e^- \leftrightarrows Pd_3(dppm)_3CO$
(ν_{CO} = 1835 cm^{-1}) (ν_{CO} = 1766 cm^{-1})

The comparison between 1835 and 1766 cm^{-1} (dication vs. neutral) indicates a decrease in C═O bond strength and, therefore, a C═O lengthening (assuming that both species are triply bridged μ^3-CO). The diatomic approximation (ν = $(2\pi c)^{-1}(F/\mu)^{1/2}$; c = speed of light, F = force constant, μ = reduced mass) predicts that F(CO) are 13.63 and 12.62 m dyn $Å^{-1}$ for the dicationic and neutral clusters, respectively. Morrison and Turner have recently reported an empirical equation relating the force constant of a complexed CO group (F(CO)) and the CO distance (r(CO)) (18):

[6] $r(CO) = 1.674 - 0.184 \ln F(CO)$

that allows the estimation of r(CO) calculated with a standard deviation of ±0.005 Å. For the dicationic and neutral species, eq. [6] predicts that the calculated r(CO) values are 1.193 and 1.208 Å, respectively. r(CO) evaluated crystallographically is ~1.165 Å for $Pd_3(dppm)_3CO^{2+}$ (19). Taking into account that the Pd_3 center is ignored in the F(CO) estimation, this comparison is reasonable. The calculated bond length increase is 0.015 Å and is associated with an increase in back donation going from Pd_3^{2+} to Pd_3^0. Interestingly the average r(CO) value for the zero valent related $Pd_6(\mu^2\text{-CO})_6(dppm)_3$ cluster is ~1.20 Å (20) according to X-ray results. The favorable comparison between this 1.208 Å for the neutral $Pd_3(dppm)_3CO$ complex further supports the IR assignment.

1.(d) Electrochemical behaviour of $Pd_3(dppm)_3CO^{2+}$ in DMF

Using dimethylformamide as a solvent, the electrochemical behaviour depends upon the nature of the electrolytic salts. While the A_1/A_1' and A_2/A_2' peaks systems are present with Bu_4NPF_6, only an A/A' peaks system is observed with LiCl (also with a 0.2 M concentration; figs. 5*a* and *b*, respectively). In the presence of 0.2 M LiCl, $Pd_3(dppm)_3CO^{2+}$ is reduced at higher negative potential than in DMF–LiCl-free solutions.

[a]From ref. 25. The values in parentheses are the difference between the average value tabulated here and the maximum and minimum values experimentally observed.

This shift is due to the formation of the monocationic species $Pd_3(dppm)_3(CO)(Cl)^+$ as demonstrated by Puddephatt and co-workers (21):

Scheme 1.

The electrolysis performed at −1.1 V vs. SCE using DMF–Bu_4NPF_6 also consumes two electrons (n_{exp} = 2.04 F mol^{-1}), where a quasi-complete disappearance of the 1833 cm^{-1} IR peak band is observed as expected. Upon a two-electron reoxidation (n_{exp} = 1.7 F mol^{-1}) at 0 V vs. SCE, the dicationic cluster is regenerated quantitatively.

1.(e) Concluding remarks

In all cases, the two-electron reduction of $Pd_3(dppm)_3CO^{2+}$ gives the neutral cluster $Pd_3(dppm)_3CO$ characterized by IR spectroscopy (ν(CO) = 1761 cm^{-1} in ACN, 1766 cm^{-1} in CH_2Cl_2) and by its electrochemical behaviour. In some cases, a single two-electron reversible system *A*/*A′* is observed, while two one-electron systems A_1/A'_1 and A_2/A'_2 appear in other cases (see Table 1 for details). Further $Pd_3(dppm)_3CO^{2+}$ is more easily reduced in CH_2Cl_2 than in DMF. We propose that host–guest interaction (22, 23) be at the origin of this phenomenon (host = cluster; guest = solvent molecule). Indeed, one of us recently demonstrated evidence for the host–guest chemistry in the $Pd_3(dppm)_3CO^{2+}$ ground (18) and lowest energy triplet excited states ($^3A_2$) (24) with various neutral substrates. Since we could not isolate the neutral product in the pure state for structural characterization, the geometry was optimized by the theoretical calculations below.

2. Theoretical calculations

Based upon recent EHMO computations that indicate that the

For personal use only.

LUMO in $Pd_3(PH_3)_6CO^{2+}$ (model compound for $Pd_3(dppm)_3CO^{2+}$) (25) is formally Pd···Pd antibonding, Pd—Pd bond cleavages are anticipated upon the two-electron reduction of $Pd_3(dppm)_3CO^{2+}$. This proposal is supported by the zero valent $Pd_2(dppm)_3$ X-ray structure where no formal Pd—Pd bond is observed ($r(Pd_2)$ = 2.956 Å) (26). Furthermore, the two-electron reduction of $Pd_3(dppm)_3CO^{2+}$ in the presence of an excess of dppm does not lead to the formation of other zero valent Pd complexes.

The structural features of the model compounds $Pd_3(PH_3)_6CO^n$ where $n = 0, +1, +2$ are addressed theoretically using DFT via geometry optimizations. In a recent study, the geometry of the model compound $Pd_3(PH_3)_6CO^{2+}$ has already been optimized by one of us (27) and compared to that of $Pd_3(dppm)_3CO^{2+}$. These data are reported in Table 2. In the $Pd_3(PH_3)_6CO^n$ cases ($n = 0, +1, +2$), the computations were performed using both the C_{3v} symmetry and the "no symmetry" restrictions. Both sets of calculations always gave the same results. The comparison between the experimental data reported for $Pd_3(dppm)_3CO^{2+}$ (X-ray crystallography) and the computed values for $Pd_3(PH_3)_6CO^{2+}$ is excellent with much less than 1% difference.

Upon a one-electron reduction of the dicationic cluster, the computed Pd—Pd (+0.24 Å) and Pd—P (+0.025 Å) bond lengths exhibit the largest increases, which are associated with the antibonding nature of the LUMO and also with the weak anti-bonding behaviour of the Pd—P bonds (25). An $r(Pd_2)$ value of 2.73 Å is one of the longest Pd—Pd bonds (here calculated) for polynuclear complexes (28) and is consistent with a lower bond order (BO) description: $0 < BO < 1$. Upon a second one-electron reduction the Pd—Pd bond length increases dramatically up to ~3 Å, which indicates complete homolytic Pd—Pd bond cleavages. The $r(Pd_2)$ value (3.088 Å) is close to that of $Pd_2(dppm)_3$ ($r(Pd_2)$ = 2.956 Å) (26). Further, the computed C═O bond length has indeed increased as experimentally observed (up to 1.182 Å from 1.170 Å in the dication). The back-donation effect responsible for this bond lengthening is also observed from the slight decrease in computed Pd—C bond lengths (2.080 → 2.062 Å, for $n = +2, +1$, and 0, respectively). The computed C═O bond length change (+0.012 Å) is practically the same as that estimated from IR findings described above (+0.015 Å). The computed r(CO) value for the neutral species (1.182 Å) also compares favorably to that of the zero valent $Pd_6(\mu^2\text{-}CO)_6(dppm)_3$ cluster (1.20 Å) (20).

Final remarks

The two-electron reduction of $Pd_3(dppm)_3CO^{2+}$ leads to $Pd_3(dppm)_3CO$, which has been characterized by IR spectroscopy. This neutral cluster is relatively stable within hours under electrolysis condition but not sufficiently for ^{31}P NMR characterization.

Intramolecular redox cyclization upon oxidation of a sulfur(II)-containing diazene: X-ray structures of $PhS(O)NC(Ar)NNC(Ar)=NSO_2Ph$ (Ar = 4-$CH_3C_6H_4$) and $MeSO_2N(4\text{-}CH_3C_6H_4)CN=NC(C_6H_4CH_3\text{-}4)NSO_2Me$

Vadapalli Chandrasekhar, Tristram Chivers, Laura Ellis, Ian Krouse, Masood Parvez, and Ignacio Vargas-Baca

Abstract: The reaction of *Z,E,Z*-PhSN=C(Ar)N=NC(Ar)=NSPh (Ar = 4-$CH_3C_6H_4$) (**1a**) with MCPBA results in ring closure via an intramolecular redox process to give the 1,2,3,5-thiatriazole $PhS(O)NC(Ar)NNC(Ar)=NSO_2Ph$ (**4**). An X-ray structural determination revealed that **4** contains a planar five-membered CNS(VI)NN ring with *d*(N—N) = 1.402(6) Å. The reaction of $ArCN_2(SiMe_3)_3$ (Ar = 4-$CH_3C_6H_4$) with one equivalent of $MeSO_2Cl$, followed by two equivalents of PhSeCl, produces the sulfonyl-containing diazene $MeSO_2N=C(Ar)N=N(Ar)C=NSO_2Me$ (**11**), which was shown by X-ray crystallography to adopt a *Z,E,Z* geometry. By contrast, the reaction of $ArCN_2(SiMe_3)_3$ with one equivalent of ArS(O)Cl, followed by two equivalents of PhSeCl, yielded the sulfur(II)-containing diazene *Z,E,Z*-ArSN=C(Ar)N=NC(Ar)=NSAr (Ar = 4-$CH_3C_6H_4$) (**1b**).

Key words: thiatriazoles, sulfonyl diazenes, intramolecular redox cyclization.

Résumé : La réaction du *Z,E,Z*-PhSN=C(Ar)N=NC(Ar)=NSPh (Ar = 4-$CH_3C_6H_4$) (**1a**) avec l'acide *m*-chloroperbenzoïque (AMCPB) conduit à une fermeture de cycle par le biais d'un processus rédox intramoléculaire qui conduit au 1,2,3,5-thiatriazole, $PhS(O)NC(Ar)NNC(Ar)=NSO_2Ph$ (**4**). Une détermination de structure par diffraction des rayons X révèle que le composé **4** comporte un noyau CNS(VI)NN planaire à cinq chaînons dans lequel *d*(N—N) = 1,402(6) Å. La réaction de $ArCN_2(SiMe_3)_3$ (Ar = 4-$CH_3C_6H_4$) avec un équivalent de $MeSO_2Cl$, suivie par deux équivalents de PhSeCl, conduit à un diazène contenant des sulfonyles, $MeSO_2N=C(Ar)N=N(Ar)C=NSO_2Me$ (**11**), qui, d'après la diffraction des rayons X, adopte une géométrie *Z,E,Z*. Par opposition, la réaction du $ArCN_2(SiMe_3)_3$ avec un équivalent de ArS(O)Cl, suivie par deux équivalents de PhSeCl, conduit à un diazène contenant du soufre(II), le *Z,E,Z*-ArSN=C(Ar)N=NC(Ar)=NSAr (Ar = 4-$CH_3C_6H_4$) (**1b**).

Mots clés : thiatriazoles, diazènes de sulfonyle, cyclisation rédox intramoléculaire.

[Traduit par la rédaction]

Introduction

Intramolecular interactions can have a profound influence on the structure and properties of chalcogen–nitrogen compounds. For example, diazenes of the type **1** (1, 2) and the bicyclic imine **2** (3) are deep purple compounds with planar structures imposed by S···N interactions of ca. 2.7 Å. In the sulfur(II)-containing diazenes **1** this interaction stabilizes *Z,E,Z* relative to *E,E,E* isomers (2). It involves donation from a chalcogen lone pair into the π^*(N=N) orbital and the intense visible absorption band at 535–550 nm can be attributed to the π-HOMO $\rightarrow$ π-LUMO transition (2). The interannular interaction in **2** also has a remarkable effect on the relative reactivities of the sulfur(II) centres. Treatment of **2** with an excess of MCPBA produces the trioxide **3** in which the S(II) centre involved in that interaction is unaffected by the oxidation process (3*c*).

To determine the influence of oxidizing the two sulfur(II) centres on the S···N interaction in **1**, we have investigated the synthesis of the sulfinyl (S(IV)) and sulfonyl (S(VI)) analogues of **1** by two different routes. The first method was the oxidation of **1a** with MCPBA. The second approach involved the treatment of sulfinyl- or sulfonyl-substituted benzamidinates 4-$CH_3C_6H_4CN[S(O)_nR][N(SiMe_3)_2]$ (R = 4-$CH_3C_6H_4$, *n* = 1; R = Me, *n* = 2) with two equivalents of PhSeCl.

Experimental section

Reagents and general procedures

All reactions and the manipulation of reagents and products were carried out under an atmosphere of dry nitrogen gas. The reagents *p*-tolunitrile, *p*-tolyl disulfide, PhSeCl, and $ClSiMe_3$ (all from Aldrich) were used as received. Celite 545 and sea sand (Fisher) were oven-dried (110°C) before use. $LiN(SiMe_3)_2$ (Aldrich) was dissolved in hexanes and 1.1 equiv. of diethyl ether was added to give a precipitate of $LiN(SiMe_3)_2 \cdot OEt_2$, which was washed twice with hexanes. Sulfuryl chloride (SO_2Cl_2) and $MeSO_2Cl$ (Aldrich) were distilled at ca. 0.01 Torr (1 Torr = 133.3 Pa) over predried molecular sieves (300°C for 3 h) prior to use. A commercial sample of *m*-chloroperbenzoic acid (MCPBA) was purified by the literature procedure (4). The reagents 4-$CH_3C_6H_4CN_2(SiMe_3)_3$ (5), *p*-toluenesulfinyl chloride (6), and PhSNC(Ar)N=N(Ar)-CNSPh (Ar = 4-$CH_3C_6H_4$) (**1a**) (2) were prepared by the published methods. All solvents were dried and distilled immediately prior to use: toluene, tetrahydrofuran, hexane, diethyl ether (Na-benzophenone); dichloromethane, acetonitrile (P_4O_{10} followed by CaH_2); and carbon tetrachloride (P_4O_{10}).

Instrumentation

Infrared spectra (4000–400 cm^{-1}) were recorded as Nujol mulls (KBr windows) on a Mattson Instruments 4030 FT-IR spectrophotometer. UV-visible spectra were obtained by using a Cary 219 spectrophotometer. ^1H and ^{13}C NMR spectra were measured on a Bruker ACE 200 spectrometer, or a Bruker AM 400 spectrometer in the case of variable-temperature experiments. Chemical shifts are reported in ppm relative to Me_4Si (0 ppm) in $CDCl_3$. Mass spectra were obtained by using a Kratos MS80RFA instrument (EI/70 eV). Elemental analyses were provided by the Analytical Services Division, Department of Chemistry, The University of Calgary.

Preparation of PhS(O)NC(Ar)NNC(Ar)=NSO_2Ph (Ar = 4-$CH_3C_6H_4$) (4)[2]

A solution of MCPBA (0.445 g, 2.58 mmol) in diethyl ether (25 mL) was added with stirring to a purple solution of PhSN(4-$CH_3C_6H_4$)CN=NC(4-$CH_3C_6H_4$)NSPh (**1a**) (0.413 g, 0.859 mmol) in diethyl ether (25 mL) at 23°C. After 2 h the deep purple colour of the solution had faded with the formation of a pale yellow precipitate, that, after recrystallization from CH_2Cl_2–diethyl ether, was separated by filtration and identified as **4** (0.345 g, 0.652 mmol, 76%); mp 141–143°C (dec.). ^1H NMR spectrum in $CDCl_3$, δ: 2.40 (s, 3H, $CH_3C_6H_4$), 2.45 (s, 3H, $CH_3C_6H_4$), 7.2–7.9 (m, 18H, C_6H_5 and C_6H_4). ^{13}C {^1H} NMR spectrum in $CDCl_3$, δ: 21.8 ($CH_3C_6H_4$), 22.0 ($CH_3C_6H_4$), 126.3, 126.7, 127.3, 127.7, 128.7, 128.8, 129.3, 129.9, 130.2, 130.5, 132.6, 134.9, 135.2, 141.7, 141.9, 143.2 (C_6H_4 and C_6H_5), 157.6 ($CH_3C_6H_4C$), 161.2 ($CH_3C_6H_4C$). Anal. calcd. for $C_{28}H_{24}N_4O_3S_2$: C 63.62, H 4.58, N 10.61; found: C 63.69, H 4.64, N 10.60.

Preparation of bis(*C*-*p*-tolyl, *N*-methanesulfonyl-formidinyl)-*trans*-diazene $MeSO_2N(4\text{-}CH_3C_6H_4)CN{=}NC(C_6H_4CH_3\text{-}4)NSO_2Me$ (11)

A solution of benzeneselenenyl chloride (0.65 g, 3.34 mmol) in CH_2Cl_2 (30 mL) was added to a CH_2Cl_2 solution of 4-$CH_3C_6H_4C(NSO_2Me)[N(SiMe_3)_2]$ (**12**) at 23°C, prepared in situ from equimolar amounts (1.71 mmol) of $MeSO_2Cl$ and 4-$CH_3C_6H_4CN_2(SiMe_3)_3$ in CH_2Cl_2. After 2 h the solvent and volatile products were removed from the orange solution to give a dark red residue, which was extracted with hexanes (2 × 30 mL) to give Ph_2Se_2 (0.49 g, 92%). The orange product was recrystallized from diethyl ether to give **11** (0.214 g, 60%), mp 170–171°C. ^1H NMR (δ, $CDCl_3$): 7.94 and 7.32 (m, 4H, $CH_3C_6H_4$), 3.29 (s, 3H, CH_3SO_2), 2.45 (s, 3H, $CH_3C_6H_4$). ^{13}C NMR (δ, $CDCl_3$): 198.2 (*C*N=), 146.3, 131.0, 129.6, 125.4 ($CH_3C_6H_4$), 43.2 (CH_3SO_2), 21.9 ($CH_3C_6H_4$). Anal. calcd. for $C_{18}H_{20}N_4O_4S_2$: C 51.41, H 4.79, N 13.32; found: C 50.78, H 5.54, N 12.20.

In a separate experiment ^1H and ^{13}C NMR spectra were obtained for **12**. ^1H NMR (in $CDCl_3$), δ: 0.11 (s, 18H, $Si(CH_3)_3$), 1.97 (s, 3H, $CH_3C_6H_4$), 2.66 (s, 3H, CH_3SO_2), 7.67–6.86 (AB quartet, 4H, C_6H_4). ^{13}C {^1H} NMR (in $CDCl_3$), δ: 3.1 ($Si(CH_3)_3$), 21.7 ($CH_3C_6H_4$), 43.5 (CH_3SO_2), 129.2 and 130.9 (C_6H_4).

Preparation of N,N-bis(trimethylsilyl), *N'*-(*p*-toluenesulfinyl)-*p*-toluamidine 4-$CH_3C_6H_4C[NS(O)C_6H_4CH_3\text{-}4][N(SiMe_3)_2]$ (13)

A solution of 4-$CH_3C_6H_4S(O)Cl$ (0.60 g, 3.43 mmol) in CH_2Cl_2 (25 mL) was added to 4-$CH_3C_6H_4CN_2(SiMe_3)_3$ (1.20 g, 3.42 mmol) in CH_2Cl_2 (25 mL) at −78°C. After 1 h at 23°C, solvent and volatile products were removed under vacuum to give **13** (1.22 g, 2.93 mmol, 86%) as extremely moisture-sensitive colourless crystals, mp 90–95°C. The ^1H NMR spectrum suggested that **13** is a mixture of isomers (see Results and discussion).

Preparation of 4-$CH_3C_6H_4C[(NHS(O)C_6H_4CH_3\text{-}4)](NH)$ (14)

A solution of *p*-toluenesulfinyl chloride (0.667 g, 3.82 mmol) in dichloromethane (25 mL) was added to a solution of 4-$CH_3C_6H_4C(NSiMe_3)[N(SiMe_3)_2]$ (1.34 g, 3.82 mmol) in dichloromethane (25 mL). After 15 min a mixture of water (0.07 mL) and methanol (5 mL) was added by

[2] 2-Hydro-1-phenyl-2-(*C*-*p*-tolyl,*N*-phenylsulfonyl-formidinyl)-4-*p*-tolyl-1,2,3,5-thiatriazole-1-oxide.

syringe. Solvent was removed under vacuum to give 4-$CH_3C_6H_4C[(NHS(O)C_6H_4CH_3$-4)](NH) as a beige solid (0.95 g, 91%). A pure sample was obtained by recrystallization from methanol. IR, ν(SO): 1068 cm^{-1}. EI-MS, *m/z*: 272 (M^+). Anal. calcd. for $C_{15}H_{16}N_2OS$: C 66.15, H 5.92, N 10.29; found: C 65.79, H 5.92, N 10.21.

Reaction of 4-$CH_3C_6H_4CN_2[S(O)C_6H_4CH_3$-4](SiMe$_3$)$_2$ (13) with PhSeCl

A solution of benzeneselenenyl chloride (1.43 g, 7.47 mmol) in CH_2Cl_2 (25 mL) was added dropwise (10 min) to a CH_2Cl_2 solution of **13** (3.74 mmol) at −78°C prepared in situ as described above. After 1 h at 23°C the solvent and volatile products were removed under vacuum to give a purple solid, which was extracted with hexanes (2 × 30 mL) to give Ph_2Se_2 (1.07 g, 3.43 mmol). The residual purple product was identified as ArSN(Ar)CN=NC(Ar)NSAr (Ar = 4-$CH_3C_6H_4$) (**1b**) (0.89 g, 1.75 mmol, 94%) by comparison of the UV and ^{1}H NMR spectra with those of an authentic sample (2).

X-ray analysis

A colourless plate of **4** was obtained by recrystallization from a dichloromethane – diethyl ether solution. Yellow needles of **11** were produced by the slow evaporation of a dichloromethane solution. X-ray structures were determined by using a Rigaku AFC6S diffractometer. Experimental details are summarized in Table 1.[3] The structure of **4** was solved by direct methods (7) and expanded using Fourier techniques (8). The structure of **11** was solved by the heavy-atom method (9). In both cases the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at geometrically idealized positions but not refined. Scattering factors were those of Cromer and Waber (10), and allowance was made for anomalous dispersion (11). All calculations were performed using *teXsan* (12).

Results and discussion

Preparation and X-ray structure of PhS(O)NC(Ar)NNC(Ar)=NSO$_2$Ph (4)

The reaction of **1a** with an excess of MCPBA in diethyl ether unexpectedly produces **4** as a slightly moisture-sensitive pale yellow precipitate in 76% yield after ca. 2 h at 23°C. The reac-

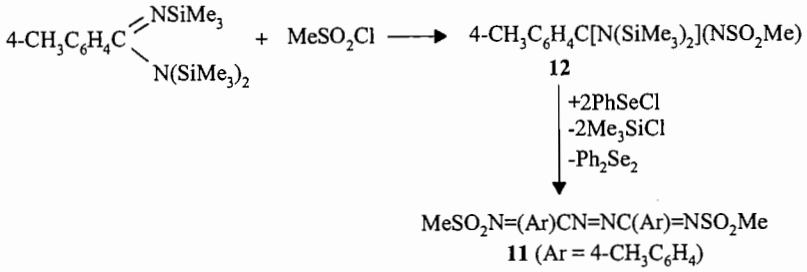
tion is instantaneous at 50°C. Both the ^1H and ^{13}C NMR spectra of **4** show two equally intense resonances for the 4-$CH_3C_6H_4$ groups. In addition, the ^{13}C NMR spectrum exhibits resonances at δ 157.6 and 161.2 for the carbon atoms attached to *p*-tolyl groups, suggesting that the product contains inequivalent sulfur centres. The formation of a product with the sulfur atoms in different oxidation states, e.g., sulfinyl and sulfonyl, is consistent with the NMR data. However, an X-ray structural determination (see Fig. 1) revealed that **4** consists of a five-membered CNSNN (thiatriazole) ring in which the sulfur atom S(1) has been oxidized to S(VI) and the -N=N- double bond of the diazene **1a** has been reduced to an =N—N= single bond (1.402(6) Å, cf. 1.29(1) Å in **1b**). The second sulfur atom S(2) has also been oxidized to S(VI). Pertinent bond lengths and bond angles are summarized in Table 2. The SN (1.545(5) and 1.712(5) Å) and CN (1.289(7) and 1.402(7) Å) bond distances are consistent with localized single and double bonds in the heterocyclic ring of **4**, but the geometry at the three-coordinate nitrogen atom N(1) is essentially planar (Σ 359.7°). In contrast to the related S(IV) system, 2,5-dihydro-2,4-

Scheme 1. Proposed mechanism for the formation of the thiatriazole **4** by the oxidation of the diazene **1a** by MCPBA. (*i*) MCPBA, Et_2O, −78°C, (*ii*) cyclization, (*iii*) excess MCPBA, Et_2O, 23°C.

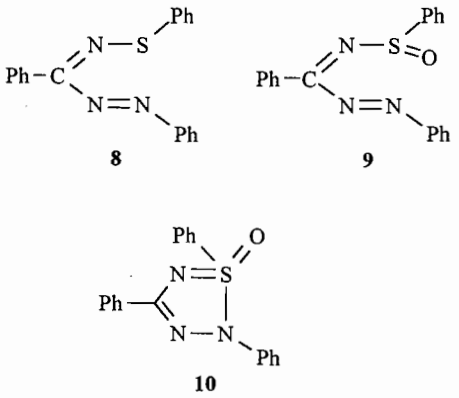
diphenyl-1,2,3,5-thiatriazole 1-oxide (**5**), in which the sulfur atom is displaced by 0.49 Å from the NCNN least-squares plane (13), the five-membered ring in **4** is essentially planar with maximum deviations from the least-squares planes through all five atoms of 0.043(5) and 0.050(5) Å for N(3) and N(1), respectively.

As indicated in Scheme 1, the formation of **4** probably occurs via the oxidation of **1a** to the sulfoxide **6**, followed immediately by ring closure to give **7**, and then sequential oxidation of the second S(II) centre to a sulfone. Steps (ii) and (iii) apparently occur very rapidly, since only **4** and unreacted **1a** were isolated when the oxidation of **1a** with MCPBA was carried out in 1:1 or 1:2 molar ratios.

The reactivity of **1a** upon oxidation with MCPBA provides an interesting contrast to the inertness of the sulfur(II) centre involved in the interannular S···N contact in **2** (3*c*). We also note that the related sulfur(II)-containing diazene PhSN=C(Ph)N=NPh (**8**) yields the corresponding sulfoxide **9** upon oxidation with H_2O_2 (14). Neither **8**, or **9** were structurally characterized. The intense colour of **8**, which forms "almost black" crystals (14), suggests a structural resemblance to diazenes of the type **1**, i.e., an intramolecular S···N interaction. In the light of the present work, the cyclic structure **10** should also be considered for **9**.



Preparation and X-ray structure of $MeSO_2N(4\text{-}CH_3C_6H_4)CN{=}NC(C_6H_4CH_3\text{-}4)NSO_2Me$ (11)



Since the direct oxidation of the sulfur(II)-containing diazene **1a** did not produce the desired sulfonyl or sulfinyl analogues,

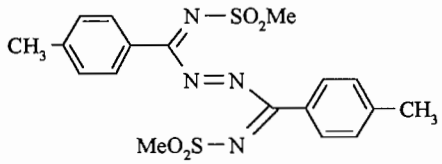

Scheme 2. Synthetic route to sulfonyl-containing diazenes.

an alternative approach that has been applied successfully to the synthesis of diazenes of the type **1** (2) was investigated. As indicated in Scheme 2, this involved the preparation of the sulfonyl-substituted benzamidinate **12**, followed by treatment with two equivalents of PhSeCl.

The reaction of $4\text{-}CH_3C_6H_4CN_2(SiMe_3)_3$ with methanesulfonyl chloride produces the monosubstituted product, $4\text{-}CH_3C_6H_4C(NSO_2Me)[N(SiMe_3)_2]$, as an extremely moisture-sensitive pale yellow oil, which was characterized by ^1H and ^{13}C NMR spectra. For the synthesis of **11**, the reagent **12** was generated in situ prior to the addition of two equivalents of PhSeCl. The sulfonyl-containing diazene **11** was obtained as orange needles in ca. 60% yield, after extraction of the by-product Ph_2Se_2. The ^1H and ^{13}C NMR spectra of **11** show resonances for equivalent $MeSO_2$ and $4\text{-}CH_3C_6H_4$ groups with the appropriate relative intensities (see Experimental section). The IR spectrum of **11** exhibits strong bands at 1377 and 1307 cm^{-1} attributed to $\nu_{asym}(SO_2)$ and $\nu_{sym}(SO_2)$, respectively (cf. R_2SO_2) (15).

11

In view of the three double bonds (C=N, N=N, and N=C) in **11**, several geometric isomers are possible. Density functional theory calculations for the corresponding sulfur(II)-containing diazenes indicate that *Z,E,Z* isomers are stabilized by intramolecular S···N interactions (2). However, an *E,E,E* isomer is obtained when the aryl substituent attached to carbon has an *ortho* substituent (Br or CF_3) (2). Interestingly, an X-ray structural determination of **11** revealed a *Z,E,Z* geometry (see Fig. 2), although there is no significant intramolecular interaction between the sulfonyl (SO_2) group and the diazene (N=N) functionality. Pertinent bond lengths and bond angles are summarized in Table 3. In contrast to the essentially planar geometry of diazenes of the

Fig. 2. Molecular structure of $MeSO_2N{=}C(4\text{-}CH_3C_6H_4)N{=}N(4\text{-}CH_3C_6H_4)C{=}NSO_2Me$ (**11**) with atomic numberings. Asterisks indicate symmetry-related atoms.

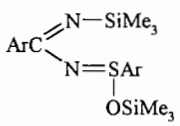
type **1** (2), the backbone of **11** is markedly twisted. The torsion angle N(1)*-N(1)-C(1)-N(2) is 63(1)°, so that the S(1)—N(1)* distance is 3.08 Å, only slightly less than the sum of the van der Waals radii for S and N (3.35 Å) (16). Although the sequence of atoms S(1)-N(2)-C(1)-N(1) is perfectly planar, the S(1)—N(1) separation is 3.16 Å. The lack of a significant intramolecular S···N interaction is also borne out by the relatively short N(1)—N(1)* distance of 1.20(1) Å. By contrast, the N—N distances in S(II)- or Se(II)-containing diazenes fall within the range 1.26–1.29 Å, as a result of donation from a chalcogen lone pair into the N=N (π^*) orbital (1, 2). In the case of **11** there is no lone pair available on sulfur for this interaction. The C—N distances of 1.260(9) and 1.466(9) Å in **11** indicate essentially localized π-bonding within the diazene chain. The S—N bond length of 1.652(6) Å is comparable to the value of 1.647(5) Å found for the corresponding S—N bond in **4**. The mean S(VI)—N single bond distance for comparable compounds is 1.642 Å (17).

Preparation of 4-$CH_3C_6H_4C[NS(O)C_6H_4CH_3$-4][$N(SiMe_3)_2$]



An attempt to extend the approach depicted in Scheme 2 to the synthesis of a sulfinyl-containing diazene produced an unexpected result. The reaction of 4-$CH_3C_6H_4CN_2(SiMe_3)_3$ with *p*-toluene sulfinyl chloride in CH_2Cl_2 proceeds in a straightforward manner to give 4-$CH_3C_6H_4C[NS(O)C_6H_4CH_3$-4]-[$N(SiMe_3)_2$] (**13**) as extremely moisture-sensitive colorless crystals in 86% yield. The EI-MS of **13** displays a parent ion at m/z = 416 amu ($C_{21}H_{32}N_2OSSi_2^+$). The IR spectrum exhibits a strong band at 1045 cm^{-1}, attributable to ν (SO) (15). However, the broad melting point range (90–95°C) suggests that **13** is not a single compound. Consistently, the ^{1}H NMR spectra of **13** indicate that this product consists of a mixture of structural isomers (Ar = 4-$CH_3C_6H_4$), e.g., **13a–c**. At 0°C three sets of resonances are observed at δ 7.2–7.9 (C_6H_4), 2.40–2.46 (CH_3), and 0.17–0.40 [$Si(CH_3)_3$], with the appropriate relative intensities (4:3:9). Each of these resonances consists of several components, which are still apparent when the spectrum is recorded at −78°C. The ^{1}H NMR spectrum could not be assigned to the individual isomers **13a**, **13b**, and **13c** (Ar = $C_6H_4CH_3$-4), owing to the overlap of several resonances. Further evidence for the composition of **13** was obtained by conversion to the hydrolysis product 4-$CH_3C_6H_4C(NH)[(NHS(O)C_6H_4CH_3$-4)] (**14**).

13a

13b

13c

The sulfinyl derivative **13** was generated in situ for the reaction with two equivalents of PhSeCl. Surprisingly, this reaction produces the known sulfenyl-containing diazene **1b** in 94% yield, in addition to Ph_2Se_2 and Me_3SiCl. The fate of the sulfinyl oxygen atom in the reagent **13** is puzzling. The formation of $(Me_3Si)_2O$ in the reactions of trisilylated benzamidines with oxygen-containing reagents such as FeOCl (18) has been suggested. However, the formation of the diazene **1b** at different temperatures was monitored by ^{1}H NMR spectroscopy, and only one trimethylsilyl-containing product, i.e., Me_3SiCl, was detected. An oxygen transfer from sulfur to selenium could also account for the formation of **1b**, but Ph_2Se_2 was isolated in 92% yield. No $(PhSe)_2O$ was detected.

Conclusions

The oxidation of a sulfenyl-containing diazene with MCPBA resulted in a novel intramolecular redox cyclization to give a thiatriazole rather than the corresponding sulfinyl- or sulfonyl-containing diazene. A sulfonyl-containing diazene was obtained from a trisilylated benzamidine via a two-step (substitution–elimination) process, but in the case of the sulfinyl derivative this approach resulted in reduction to give the corresponding sulfenyl-containing diazene.

Characterization of low-barrier hydrogen bonds. 3. Hydrogen maleate. An ab initio and DFT investigation

Michael A. McAllister

Abstract: High-level ab initio molecular orbital and density functional theory calculations predict the existence of a very short-strong hydrogen bond in the monoanion of maleic acid (hydrogen maleate). At all levels of theory (HF, MP2, BLYP, and B3LYP) except B3PW91 the potential energy surface is predicted to contain two minima, and hence resembles a double well. The barrier to proton transfer via a symmetrical transition state is calculated to be very small at all levels of theory. In all cases the calculated zero point vibrational energy available to the system is larger than the calculated barrier for proton transfer, thus the resulting hydrogen bond formed in hydrogen maleate is predicted to be symmetrical. Using the B3PW91 functional and the 6-31+G(d,p) basis set results in a single-well potential and a symmetrically positioned hydrogen. All correlated methods predict the gas phase hydrogen bond energy to be approximately 27 kcal/mol. Effects due to solvents were estimated using solvent cavity methods. Approximating the solvent as a dielectric continuum reduces the calculated hydrogen bond energy by roughly 6 kcal/mol at all levels of theory.

Key words: low-barrier hydrogen bonds, short-strong hydrogen bonds, hydrogen maleate, ab initio, density functional theory.

Résumé : Des calculs théoriques, ab initio à niveau élevé, d'orbitales moléculaires et de la théorie de la densité fonctionnelle permettent de prédire l'existence d'une liaison hydrogène très courte et forte dans la monoanion de l'acide maléique (maléate d'hydrogène). À tous les niveaux de la théorie (HF, MP2, BLYP et B3LYP), excepté B3PW91, on prédit que la surface d'énergie potentielle comporte deux minima et que, en conséquence, elle ressemble à un double puits. À tous les niveaux de la théorie, on a évalué que la barrière au transfert de proton par la biais d'un état de transition symétrique est très faible. Dans tous les cas, il a été calculé que l'énergie vibrationnelle pour le point zéro disponible pour le système est plus importante que la barrière calculée pour le transfert de proton; on prédit donc que la liaison hydrogène qui se forme dans le maléate d'hydrogène est symétrique. Des calculs utilisant la fonction B3PPW91 ou l'ensemble de base 6-31+G(d,p) conduisent à un potentiel à un seul puits et à un hydrogène en position symétrique. Toutes les méthodes soumises à la corrélation permettent de prédire que l'énergie de la liaison hydrogène en phase gazeuse est d'environ 27 kcal/mol. On a évalué les effets dus aux solvants en utilisant les méthodes de la cavité de solvant. Si l'on fait l'hypothèse que le solvant provoque un effet diélectrique continue, la valeur calculée de l'énergie de la liaison hydrogène est réduite par environ 6 kcal/mol, à tous les niveaux de la théorie.

Mots clés : liaisons hydrogènes à faible barrière, liaisons hydrogènes courtes et fortes, maléate d'hydrogène, ab initio, théorie de la densité fonctionnelle.

Introduction

There has been a great deal of interest in "short-strong" or "low-barrier" hydrogen bonds (LBHBs) in recent years (1–16). Most of this interest has stemmed from the suggestion by Cleland, Kreevoy, Gerlt, and Gassman that the formation of a single short-strong, or low-barrier, hydrogen bond during an enzyme catalytic event can provide enough stabilization energy to account for the resulting rate enhancements typically seen in enzymatic reactions (4–6). Briefly, their proposal involves a mechanism whereby an enzyme-bound intermediate, or transition state, is stabilized by the formation of a single LBHB. They hypothesize that such a bond, if formed, could provide 15–20 kcal/mol of stabilization energy to the enzyme complex. This would then be enough to rationalize the rate accelerations observed during most enzyme-catalyzed reactions. This hypothesis has certainly not been without criticism. The most ardent opponents of the low-barrier hydrogen bond facilitated enzyme mechanism have been Guthrie and Kluger (7), Warshel et al. (8), Scheiner (9), and Perrin and Thoburn (10), although there have certainly been others (2, 3, 12).

Experimental evidence for the formation of LBHBs in the gas and solid phases is considerable. Excellent reviews by Hibbert and Emsley (13) detail the conditions necessary for the formation of such bonds, and a recent paper by Gilli et al. (14) extends these studies to the solid state. All of the available experimental and theoretical evidence to date suggests that the formation of LBHBs is dependent on several conditions being

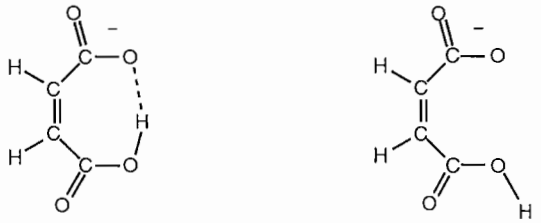
met: (*i*) the proton donor and proton acceptor must have identical, or nearly identical, pK_a values; (*ii*) the proton donor must be a fairly strong acid; (*iii*) almost all LBHBs are charged systems; (*iv*) absence of a hydrogen bonding, or polar, solvent. Most opponents of the LBHB facilitated enzyme mechanism use this last criterion to sermonize their point. That is, if a LBHB cannot exist in solution, surely it cannot exist in an enzyme active site. Of course, that argument assumes that bulk solution and enzyme active sites are similar. That may or may not be true.

Recent solution phase studies by Schwartz and Drueckhammer (3) have shown quite convincingly that LBHBs do not form to an appreciable extent in polar or protic solvents. They studied the maleic acid monoanion (hydrogen maleate) system **1** in considerable detail. By measuring the necessary equilibria they were able to determine that the difference in energy between the *cis* **1a** and *trans* **1b** forms of hydrogen maleate was of the order of 0–5.5 kcal/mol, depending on the actual solvent employed. Clearly, this is nowhere near the 15–20 kcal/mol necessary for the LBHB facilitated enzyme mechanism.

1a **1b**

However, those measurements must be biased towards isomer **1b**, since the *trans* double bond orientation is necessarily more stable than the *cis* linkage. Thus, in an equilibrium like the one above, there are two competing effects; one is the stabilizing effect of the formation of a strong hydrogen bond in **1a**, but the other is the destabilizing effect of forming a *cis* double bond. Thus, the measured "hydrogen bond strength" of 5.5 kcal/mol must be a *lower* limit for this system.

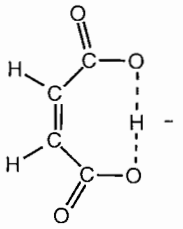
Another intriguing aspect of this particular system is whether or not the hydrogen bond formed is symmetric. Perrin has published the results of some very interesting studies in this area (10). His studies all suggest that the hydrogen bond, once formed, is quite asymmetric. He concludes that, for the most part, it is the inherent asymmetry of the solvent systems that actually cause the hydrogen bond to become asymmetrically placed, and that, in the absence of a solvent, these systems should form symmetrical hydrogen bonds.



We recently became very interested in theoretical studies of LBHBs. Through high-level calculations we hope to be able to study systems like hydrogen maleate in sufficient detail to understand its behaviour in both the gas phase and in solution. In this study we present the results of high-level ab initio and density functional calculations toward this end.

Methodology

Ab initio and density functional calculations were carried out using the Gaussian 94 suite of programs (17). Calculations were carried out at several levels of theory (18), specifically: Hartree–Fock (HF), Moller–Plesset many-body perturbation truncated at the second order (MP2), and using density functionals (DFT) (19). The density functionals that were chosen for this study were BLYP, B3LYP, and B3PW91. BLYP is a gradient-corrected nonlocal functional incorporating the 1988 Becke exchange functional (20) and the correlation functional of Lee, Yang, and Parr (LYP) (21). B3LYP is a hybrid functional made up of Becke's exchange functional, the LYP correlation functional, and a Hartree–Fock exchange term (22). The B3PW91 functional is similar to the B3LYP functional but uses the 1991 correlation functional of Perdew and Wang (23) instead of the LYP functional. The standard 6-31+G(d,p) basis set was used for all calculations.



All structures were fully optimized. The most stable conformations of structures **1** and **3** were those with C_s symmetry, necessary due to the planarity of these systems. Full analytical second derivatives of the energy with respect to nuclear displacements were performed to determine vibrational frequencies and to ascertain the nature of each stationary point.

The hydrogen bond energy in hydrogen maleate was estimated as the difference in energy between isomers **1** and **2**:

1 **2**

To determine the barrier for proton transfer in this system it was necessary to consider structure **3**, where the proton is symmetrically situated between both carboxyl groups:

3

Solvent effects were investigated via use of the self-consistent isodensity polarizable continuum method (SCI–PCM) as developed by Tomasi and co-workers (24) and implemented in Gaussian 94. In this method the solute "cavity" is defined as an isosurface of the total electron density. The surface potential is then calculated via numerical differentiation, and its interaction with the solvent potential, defined by the dielectric constant chosen, is determined self-consistently. This method has been shown to give fairly reliable relative solvation free energies for a wide variety of organic solutes (25, 26).

Results and discussion

Energetics

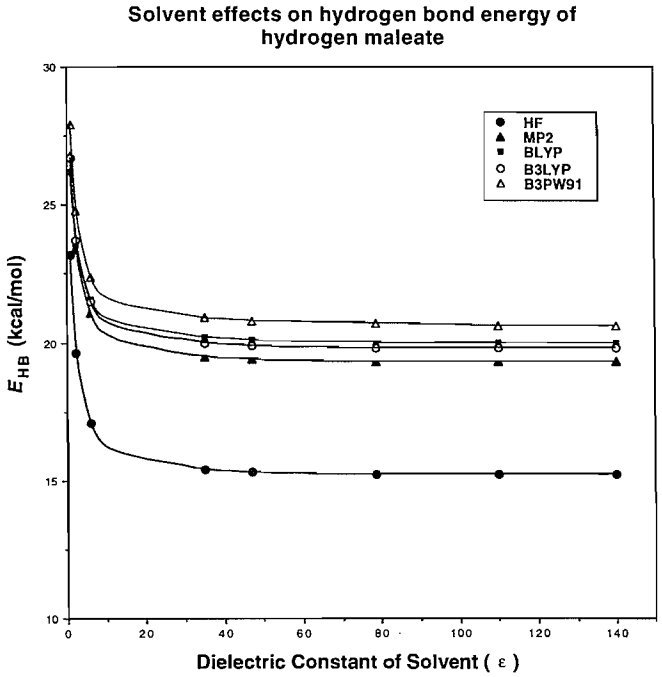

Table 1 shows the calculated hydrogen bond strength (E_{HB}) in hydrogen maleate. At the HF level E_{HB} is 23.2 kcal/mol. When electron correlated levels of theory are used E_{HB} increases to approximately 27 kcal/mol, depending on the exact method used. At the HF, MP2, BLYP, and B3LYP levels of theory structures **1** and **3** are both legitimate critical points on the calculated potential energy surface. At the B3PW91 level of DFT theory only structure **3** exists.

The very large interaction (E_{HB}) energies predicted for the hydrogen maleate system in the gas phase are consistent with the results of studies on other strongly hydrogen-bonded complexes (16). It is clear that in the gas phase such strong interactions can exist.

The calculated barrier for proton transfer is extremely small at all levels of theory studied. In fact, at the correlated levels it is so small as to be insignificant to one decimal place in kcal/mol. Accounting for the effects of zero point vibrational energy in these systems results in negative barriers of activation for proton transfer in all cases. Thus, on the true adiabatic potential energy surface the proton is predicted to be free to travel along the proton transfer coordinate without barrier. Presumably this would result in the observation of a symmetrically hydrogen-bonded hydrogen maleate in any experiment where the environment is also symmetric, such as is possible in crystal lattices and apolar aprotic solutions (10). This is also in agreement with a recent quantum dynamics study (27) of the low-barrier hydrogen bond formed between water and hydroxide ion, which concluded that the proton in such a system is most likely to be centrosymmetrically located, due to a combination of classical and quantum effects.

Table 2 contains results of our extensive solvent study using the SCIPCM solvent cavity reaction field approximation. Each optimized geometry for **1**, **2**, and **3** from a specific level of theory (HF, MP2, BLYP, B3LYP, B3PW91) was used to recalculate the total SCRF energy, incorporating the given dielectric constant of the medium (ε). This led to a new set of relative energies, as shown in Table 2. The difference in energy between the calculated energies of **1** and **2** corresponds to the hydrogen bond energy. Table 2 clearly shows that as the

Fig. 1. Calculated hydrogen bond energy (E_{HB}) (kcal/mol) in hydrogen maleate as a function of the dielectric constant of the medium (ε) for HF, MP2, BLYP, B3LYP, and B3PW91 levels of theory with the 6-31+G(d,p) basis set.

dielectric constant of the medium is increased the calculated hydrogen bond energy decreases very rapidly and then levels off. Figure 1 shows this relationship graphically for all five levels of theory employed here.

Table 2 and Fig. 1 reveal the importance of solvent, or cavity, polarity on the calculated hydrogen bond strength in hydrogen maleate. In each case there is a very rapid decrease in E_{HB} as one goes from the gas phase (ε = 1.0) to even very nonpolar solvents like benzene (ε = 2.3) and chloroform (ε = 6.0). Once the dielectric constant hits values approximating methanol (ε = 35.0), DMSO (ε = 47.0), and water (ε = 78.5), there is a significant leveling-off effect. That is, making the solvent cavity more polar than methanol has very little, if any, effect on the calculated hydrogen bond energy. Calculations on "super-polar" media were performed using ε values of 110.0 and 140.0 to ascertain what effect a hyperpolarized environment might have on a low-barrier hydrogen bond. The observed leveling-off trend continued throughout this region so that the calculated E_{HB} at ε = 140.0 was within 0.3 kcal/mol of the value calculated at ε = 35.0. This would suggest that solvent polarity effects hit a maximum corresponding to the dielectric constant of methanol. Of course, this does not suggest that all solvent effects are predicted to be the same in methanol as in water. It merely predicts that *polarity*-induced effects should be about the same in those two solvents — at least as applied to the study of low-barrier hydrogen bonds. The major shortcoming behind self-consistent reaction field (i.e., SCIPCM) calculations is that they do not, in any way, account for specific or explicit interactions of the solvent with the solute. All observed effects are strictly based on solvent–solute polarity differences. Nonetheless, SCRF calculations

[b]MP2/6-31+G(d,p)//MP2/6-31+G(d,p).

do provide invaluable information about the relative effects of solvents with differing polarities on calculated hydrogen bond energies.

As Table 2 and Fig. 1 clearly show, the calculated E_{HB} for hydrogen maleate decreases by approximately 6 kcal/mol (depending on the exact level of theory chosen) on going from the gas phase to reasonably polar solvents, like methanol and water. Still, the remaining hydrogen bond is calculated to be worth approximately 20 kcal/mol! This is certainly much higher than the experimental value of 2.0 kcal/mol observed in methanol (3). This would suggest that specific interactions between solvent and hydrogen maleate must play a very important role in decreasing the strength of E_{HB} in solvents like methanol and water. This has significant implications for the purported importance of low-barrier hydrogen bonds in enzyme catalysis. These calculations would suggest that a polar environment alone is not enough to disrupt a LBHB. We are currently undertaking related studies of this system to better understand the specific role of solvent molecules in determining the hydrogen bond strength in hydrogen maleate. As one of the referees pointed out, if there are very strong (LBHB?) specific interactions of a solvent molecule with both conformers of hydrogen maleate (**1a**, **1b**) then one might expect only a very small preference for **1a** versus **1b**.

Geometries

Table 3 shows calculated hydrogen bond distances (O—H) and heteroatom–heteroatom (O—O) distances for the atoms involved in the LBHB of hydrogen maleate. Results for all five levels of theory using the 6-31+G(d,p) basis set are presented there. These results clearly show the effects of electron correlation. At the HF level of theory the hydrogen bond distance is 1.49 Å; whereas at the correlated levels of theory that distance shrinks to approximately 1.29 Å. The correlated methods all predict a very nearly delocalized proton in the hydrogen bond. Even though the surface is still technically a double well, with two distinct minima corresponding to when the proton is closer to oxygen 1 versus when it is closer to oxygen 2, it is a very shallow potential. This is certainly reflected in the calculated hydrogen-bonding distances.

The potential energy surface calculated by the B3PW91 functional, on the other hand, is single welled. That is, the only stable minima on this surface is that due to the symmetrically H-bonded structure **3**.

Full geometries for structures **1**, **2**, and **3** are provided in Tables 4–6 for the five levels of theory employed. It is very encouraging that the fully optimized structures from MP2, BLYP, and B3LYP are so similar. This suggests that BLYP and B3LYP may be viable alternatives to MP2 calculations on the larger LBHB containing systems we wish to study in

the future. Specifically, the study of enzyme active sites will likely never be possible with MP2 methods; however, recent advances in DFT methodology suggest that very large-scale calculations of this type may be possible in the near future. Before this study, there were no investigations of how DFT methods perform on systems involving short-strong hydrogen bonds. This study suggests that the BLYP and B3LYP functionals give results in excellent agreement with MP2 cal-

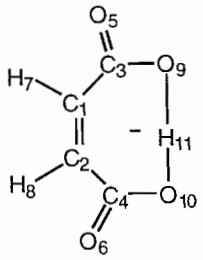
culations, while the B3PW91 functional gives slightly different results. Obviously, from only one study it would be too harsh to conclude that the B3PW91 functional is inappropriate for further use. However, the present study reveals that MP2, BLYP, and B3LYP all give very similar results, both energetically (quantitatively) and geometrically (qualitatively), while the B3PW91 functional gives qualitatively different results. The conclusion would thus be that further studies of similar systems, with comparison to known experimental results wherever possible, are needed before a final determination can be made as to the usefulness of B3PW91 functionals for the study of short, strong, or low-barrier hydrogen bonds.



Conclusions

High-level ab initio molecular orbital and density functional theory calculations predict the existence of a very short-strong hydrogen bond in the monoanion of maleic acid (hydrogen maleate). At all levels of theory (HF, MP2, BLYP, and B3LYP) except B3PW91 the potential energy surface is predicted to contain two minima, and hence to resemble a double well. The barrier to proton transfer via a symmetrical transition state is calculated to be very small at all levels of theory. In all cases the calculated zero point vibrational energy available to the system is larger than the calculated barrier for proton transfer, thus the resulting hydrogen bond formed in hydrogen maleate is predicted to be symmetrical. All correlated methods predict the gas phase hydrogen bond energy to be approximately 27 kcal/mol. This is clearly an upper limit to the true hydrogen bond energy of this system, since we have not taken into account the *cis/trans* isomerization of the hydrogen maleate system. The gas phase hydrogen bond distance in hydrogen maleate is very short, in accordance with the observed strong hydrogen bond. Solvent effects, approximated using self-consistent reaction field theory with the SCIPCM procedure, were found to weaken the calculated hydrogen bond in hydrogen maleate by roughly 6 kcal/mol. This suggests that, even in a highly polar, possibly charged, environment (perhaps like an enzyme active site), low-barrier hydrogen bonds could still exist, even though they may not exist in solutions due to specific solvent–solute interactions. The density functionals BLYP and B3LYP were found to give results in excellent agreement with MP2 calculations. B3PW91 gave quantitatively very similar, but qualitatively different results. It is thus concluded that the BLYP and B3LYP functionals are excellent candidates for

Abstract: The one-pot reaction of equimolar amounts of salicylaldehyde, diphenylborinic acid anhydride, and a tertiary amine in the presence of an alkanol (R′OH) led to the addition of R′OH to the aldehyde group and the formation of an *O,O*-acetal moiety within the chelate anion with the charge balanced by an ammonium cation arising from the tertiary amine. Exchanging the diphenylborinic acid in the three-component reaction system for phenylboronic acid did not give the analogous adduct or chelate but one additional mole equivalent of phenylboronic acid (anhydride) was incorporated, leading to a polycyclic anion containing pyroboronate and acetal boronate functions with an associated ammonium cation. Crystals of 1-methylpiperidinium 4-ethoxy-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalenate, **6***d*, are monoclinic, a = 9.522(1), b = 17.703(1), c = 14.974(1) Å, β = 98.275(10)°, Z = 4, space group $P2_1/n$, and those of 1-methylpiperidinium 6,10-epoxy-4-methoxy-6,8-diphenyl-5,7,9-trioxa-8-bora-6-borata-5,6,7,8,9,10-hexahydrobenzocyclooctenate, **10***e*, are monoclinic, a = 7.968(1), b = 19.3707(4), c = 15.9400(5) Å, β = 100.186(5)°, Z = 4, space group $P2_1/n$. The structures were solved by direct methods and refined by full-matrix least-squares procedures to R = 0.050 and 0.033 (R_w = 0.040 and 0.032) for 2815 and 3529 reflections with $I \geq 3\sigma(F^2)$, respectively. Compounds **6***d* and **10***e* are both representative of new classes of organoboron chelates.

Key words: salicylaldehyde semiacetal diphenylboron chelate, salicylaldehyde bisboronate, organoboron compound, crystal structure.

Résumé : La réaction unipot de quantités équimolaires de salicylaldéhyde, d'anhydride de l'acide diphénylborinique et d'une amine tertiaire en présence d'un alcanol (R′OH) conduit à une addition du R′OH sur le groupe aldéhydique et à la formation d'une portion *O,O*-acétal dans un anion chélate dont la charge est compensée par un cation ammonium dérivé de l'amine tertiaire. Remplaçant l'acide diphénylborinique du système réactionnel à trois composants par de l'acide phénylboronique ne conduit pas à la formation de l'adduit/chélate analogue, mais l'équivalent d'une mole additionnelle d'acide phénylboronique (anhydride) est incorporée et conduit à un anion polycyclique contenant les fonctions pyroboronate et acétalboronate avec un cation ammonium associé. Les cristaux du 4-éthoxy-2,2-diphényl-1,3-dioxa-2-borata-1,2,3,4-tétrahydronaphtalénate de 1-méthylpipéridinium, **6***d*, sont monocliniques, groupe d'espace $P2_1/n$, a = 9,522(1), b = 17,703(1) et c = 14,974(1) Å, β = 98,275(10)° et Z = 4 alors que ceux du 6,10-époxy-4-méthoxy-6,8-diphényl-5,7,9-trioxa-8-bora-6-borata-5,6,7,8,9,10-hexahydrobenzocycloocténate de 1-méthylpipéridinium, **10***e*, sont monocliniques, groupe d'espace $P2_1/n$, a = 7,968(1), b = 19,3707(4) et c = 15,9400(5) Å, β = 100,186(5)° et Z = 4. Les structures ont été résolues par les méthodes directes et affinées par les méthodes des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,050 et 0,033 (R_w = 0,040 et 0,032) pour 2815 et 3529 réflexions $I \geq 3\sigma(F^2)$ respectivement.

Mots clés : chélate du diphénylbore et du semiacétal du salicylaldéhyde, bisboronate du salicylaldéhyde, composé organoboré, structure cristalline.

Introduction

The interaction of salicylaldehyde, amines, and chelate-forming boron compounds is of considerable interest in the study of intermediate steps in catalytic reactions or as enzyme models (1, 2). Considering the partial structural relationships to pyridoxal, pyridoxal-dependent enzyme reactions (3–5) are of particular relevance. In the course of our investigations of boron chelate compounds we synthesized and structurally characterized the zwitterionic diphenylboron chelate **3** (R_3N = quinuclidine) that could be generally obtained from the reaction of salicylaldehyde (**1**, X = H), the tertiary amine, and diphenylborinic acid (anhydride) in water-free aprotic solvents, or from the preformed boron chelate **2** by addition of the amine (6) (Scheme 1). However, carrying out the reaction in ethanol or other alcohols (R′OH) results in crystalline compounds whose elemental analyses show the incorporation of an additional molecule of R′OH into **3**, regardless of the applied tertiary amine. By simple infrared and ^{1}H nmr spectroscopic means it was not possible to distinguish between a ring-opened addition product like **4**, a solvent-type adduct like **5** (retaining the *B,N*-betaine structure of the chelate **3**), or the trialkylammonium salt **6** with an *O,O*-acetal moiety within the chelate anion. For an unambiguous determination of molecular structure by X-ray crystallographic analysis, we synthesized various compounds for the selection of an example providing suitable crystals.

The study was later extended by using phenylboronic acid instead of diphenylborinic acid in the same three-component system. This could possibly lead to similar complexes such as **7**, possessing a B(OH)Ph instead of the BPh_2 moiety in **3**, or perhaps to the corresponding R′OH adducts or condensates when alkanols are used as solvents. Surprisingly, the resulting crystalline compounds did not have the expected compositions. Elemental analyses as well as ^{1}H and ^{11}B nmr spectra instead indicated a condensation of **7** with a second molecule of phenylboronic acid. The distinction between the alternative molecular structures **8**–**10** was again not possible by simple spectroscopic methods. A series of compounds derived from variously substituted salicylaldehydes was synthesized in order to produce a representative example yielding crystals suitable for X-ray structure analysis.

Experimental

Quinuclidinium 4-ethoxy-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalenate, 6*a*

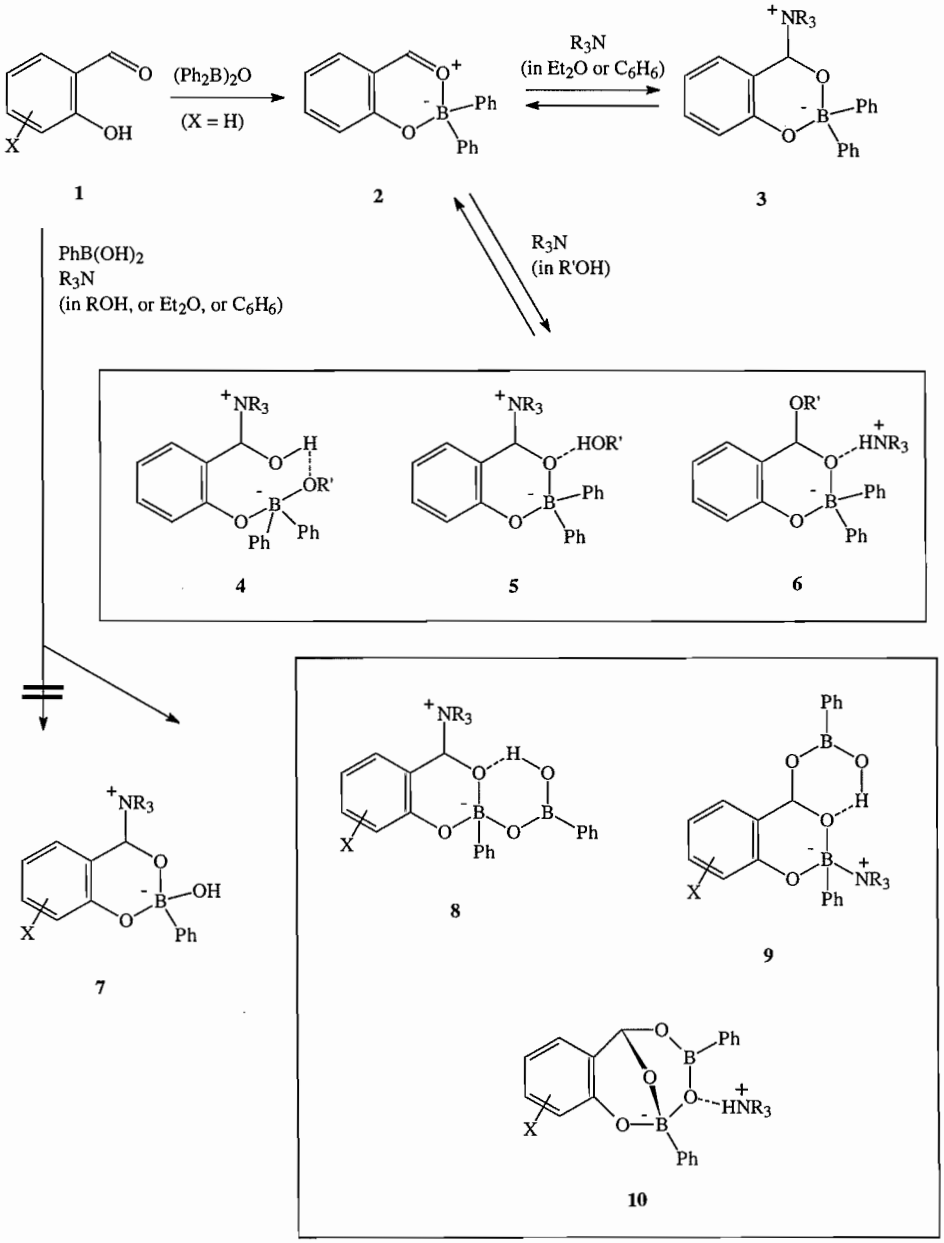
2 (0.29 g, 1.0 mmol) (7) and quinuclidine (0.11 g, 1.0 mmol) are refluxed in 10 mL of ethanol for 5 min. Upon cooling, crystallization yields 0.39 g (88%) of the colorless compound; mp 116–117°C. Infrared (KBr): 1604 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.06 (t, J = 7 Hz, CH_3), 1.53–1.83, and 2.96–3.30 (m and m, $N(C_2H_4)_3CH$), 3.43 (q, J = 7 Hz, OCH_2), 5.50 (s, O-CH-O), 6.80–7.73 (m, 14 aromatic H); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.10–3.06 (m, CH_3, $N(C_2H_4)_3CH$), 3.53–4.23 (m, OCH_2), 5.36 (s, 80% of 1H, O-CH-O), 6.16 (s, broad, exchangeable, NH), 6.50–7.90 (m, 14 aromatic H), 9.83 (s, 20% of 1H, CH═O). Anal. calcd. for $C_{28}H_{34}BNO_3$: C 75.85, H 7.73, B 2.44, N 3.16; found: C 75.93, H 7.86, B 2.55, N 2.99. The product gives a blue-colored solution upon addition of diphenylcarbazone in ethanol, indicating the presence of the chelated diphenylborenium (Ph_2B^+) ion (8).

An identical product is obtained by the three-component one-pot reaction of salicylaldehyde (**1**, X = H), oxybis(diphenylborane) (0.5 mol equivalent), and quinuclidine in ethanol, and also by recrystallization of **3** (R_3N = quinuclidine) (6) from ethanol.

1,4-Diazabicyclo[2.2.2]octanium 4-ethoxy-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalenate, 6*b*

2 (0.29 g, 1.0 mmol) and 1,4-diazabicyclo[2.2.2]octane (0.11 g, 1.0 mmol) are reacted as described for **6***a*. Yield: 0.39 g (88%) of the colorless compound; mp 128°C (EtOH). Infrared (KBr): 1605 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.06 (t, J = 7 Hz, CH_3), 2.90 (s, $N(C_2H_4)_3N$), 3.45 (q, J = 7 Hz, OCH_2), 5.85 (s, O-CH-O), 6.73–7.76 (m, 14 aromatic H); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.26 (t, J = 7 Hz, CH_3), 2.75 (s, $N(C_2H_4)_3N$), 3.90 (q, J = 7 Hz, OCH_2), 6.86–7.80 (m, 14 aromatic H), 9.86 (s, 90% of 1H, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 2.9 ($W_{1/2} \approx$ 200 Hz); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 4.0 ($W_{1/2}$ = 340 Hz) and 45.1 ($W_{1/2}$ = 340 Hz), ratio of peak areas: 1:1. Anal. calcd. for $C_{27}H_{33}BN_2O_3$: C 72.98, H 7.49, B 2.43, N 6.30; found: C 73.00, H 7.68, B 2.46, N 6.15. **6***b* gives a blue-colored solution upon addition of diphenylcarbazone as described for **6***a*.

1-Methylpyrrolidinium 4-ethoxy-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalenate, 6*c*



2 (0.29 g, 1.0 mmol) and 1-methylpyrrolidine (0.09 g, 1.0 mmol) are reacted as described for **6***a*. Yield: 0.32 g (77%) of slightly yellow crystals; mp 188°C (EtOH). Infrared (KBr): 1602 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.06 and 1.17 (t and t, J = 7 Hz, ratio of peak areas: 8:2, C-CH_3), 1.46–1.83 (m, $C(CH_2)_2C$), 2.48 (s, N-CH_3), 2.66–3.06 (m, CH_2NCH_2), 3.45 and 3.90 (q and q, J = 7 Hz, ratio of peak areas: 8:2, OCH_2), 5.52 (s, 80% of 1H, O-CH-O), 6.26 (s, broad, exchangeable, NH), 6.40–7.76 (m, 14 aromatic H), 10.30 (s, 20% of 1H, CH═O), 11.03 (s, partially exchangeable, 20% of 1H, phenolic OH); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.28 (t, J = 7 Hz, C-CH_3), 1.20–1.66 (m, $C(CH_2)_2C$), 2.12 (s, N-CH_3), 2.16–2.50 (m, CH_2NCH_2), 3.63–4.13 (m, OCH_2), 5.60 (s, 50% of 1H, O-CH-O), 6.40–7.83 (m, 14 aromatic H), 8.30 (s, broad, exchangeable, NH), 9.82 (s, 50% of 1H, CH═O); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 3.7 ($W_{1/2}$ = 170 Hz) and 44.9 ($W_{1/2}$ = 260 Hz), ratio of peak areas: 3:2. Anal. calcd. for $C_{26}H_{32}BNO_3$: C 74.82, H 7.73, B 2.59, N 3.36; found: C 74.78, H 8.18, B 2.68, N 3.23. **6***c* gives a blue-colored solution upon addition of diphenylcarbazone as described for **6***a*.

1-Methylpiperidinium 4-ethoxy-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalenate, 6*d*

2 (0.29 g, 1.0 mmol) and 1-methylpiperidine (0.10 g, 1.0 mmol) are reacted as described for **6***a*. Yield: 0.34 g (79%) of yellowish crystals; mp 102–103°C (EtOH). Infrared (KBr): 1605 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 0.96–1.23 (m, C-CH_3), 1.30–1.73 (m, $C(CH_2)_3C$), 2.48 (s, N-CH_3), 2.60–2.86 (m, CH_2NCH_2), 3.33–3.96 (m, OCH_2), 5.43 (s, broad, exchangeable, NH), 5.50 (s, 80% of 1H, O-CH-O), 6.33–7.76 (m, 14 aromatic H), 10.25 (s, 20% of 1H,

CH═O), 11.00 (s, 20% of 1H, OH ?); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.06–1.56 (m, CH_3, $C(CH_2)_3C$), 1.93–2.26 (m, CH_2NCH_2), 2.05 (s, N-CH_3), 3.76–4.16 (m, OCH_2), 5.62 (s, 50% of 1H, O-CH-O), 6.40–8.20 (m, 14 aromatic H), 8.78 (s, broad, exchangeable, NH), 9.82 (s, 50% of 1H, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 4.5 ($W_{1/2}$ = 385 Hz); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 4.3 ($W_{1/2}$ = 215 Hz) and 45.3 ($W_{1/2}$ = 300 Hz), ratio of peak areas: 3:2. Anal. calcd. for $C_{27}H_{34}BNO_3$: C 75.17, H 7.94, B 2.51, N 3.25; found: C 75.19, H 7.94, B 2.81, N 3.16. **6***d* gives a blue-colored solution upon addition of diphenylcarbazone as described for **6***a*. Crystals suitable for X-ray analysis were obtained by very slow crystallization from ethanol.

1-Methylpiperidinium 4-methoxy-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalenate, 6*e*

2 (0.29 g, 1.0 mmol) and 1-methylpiperidine (0.10 g, 1.0 mmol) are reacted in 10 mL of methanol in a procedure similar to that described for **6***a*. Yield: 0.30 g (72%) of colorless crystals; mp 98°C (MeOH). Infrared (KBr): 1608 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.23–1.73 (m, $C(CH_2)_3C$), 2.50 (s, N-CH_3), 2.63–2.90 (m, CH_2NCH_2), 3.20 (s, 60% of 3H, OCH_3), 3.40 (s, 40% of 3H, OCH_3), 5.26 (s, broad, exchangeable, NH), 5.46 (s, 60% of 1H, O-CH-O), 6.30–7.78 (m, 14 aromatic H), 10.30 (s, 40% of 1H, CH═O), 11.03 (s, partially exchangeable, 40% of 1H, phenolic OH); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.13–1.80 (m, $C(CH_2)_3C$), 1.96–2.26 (m, CH_2NCH_2), 2.10 (s, N-CH_3), 3.70 (s, broad, OCH_3), 5.56 (s, 50% of 1H, O-CH-O), 6.46–7.90 (m, 14 aromatic H), 8.95 (s, broad, exchangeable, NH), 9.83 (s, 50% of 1H, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 4.4 ($W_{1/2}$ = 385 Hz); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 3.9 ($W_{1/2}$ = 255 Hz) and 45.5 ($W_{1/2}$ = 300 Hz), ratio of peak areas: 3:2. Anal. calcd. for $C_{26}H_{32}BNO_3$: C 74.82, H 7.73, B 2.59, N 3.36; found: C 74.78, H 7.72, B 2.62, N 3.26. **6***e* gives a blue color reaction with diphenylcarbazone as described for **6***a*.

1-Methylpiperidinium 2,2-diphenyl-4-propoxy-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalenate, 6*f*

2 (0.29 g, 1.0 mmol) and 1-methylpiperidine (0.10 g, 1.0 mmol) are reacted in 10 mL of propanol in a procedure similar to that described for **6***a*. Yield: 0.32 g (72%) of yellowish crystals; mp 92°C (PrOH). Infrared (KBr): 1604 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 0.76–1.06 (m, C-CH_3), 1.20–1.73 (m, $OCCH_2$, $C(CH_2)_3C$), 2.46 (s, N-CH_3), 2.60–2.86 (m, CH_2NCH_2), 3.30–3.96 (m, OCH_2C), 5.50 (s, 70% of 1H, O-CH-O), 6.30–7.76 (m, 14 aromatic H), 11.03 (s, 30% of 1H, CH═O); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 0.96 (t, J = 7 Hz, C-CH_3), 1.16–1.83 (m, $OCCH_2$, $C(CH_2)_3C$), 1.96–2.33 (m, CH_2NCH_2), 2.13 (s, N-CH_3), 3.90 (t, J = 7 Hz, OCH_2C), 5.36 (s, 50% of 1H, O-CH-O), 6.46–7.93 (m, 14 aromatic H), 8.96 (s, broad, exchangeable, NH), 9.80 (s, 50% of 1H, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 4.2 ($W_{1/2}$ = 342 Hz); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 4.1 ($W_{1/2}$ = 300 Hz) and 45.3 ($W_{1/2}$ = 342 Hz), ratio of peak areas: 3:2. Anal. calcd. for $C_{28}H_{36}BNO_3$: C 75.51, H 8.15, B 2.43, N 3.14; found: C 75.05, H 8.20, B 2.92, N 3.00. **6***f* gives a blue color reaction with diphenylcarbazone as described for **6***a*.

1-Methylpiperidinium 4-isopropoxy-2,2-diphenyl-1,3-dioxa-2-borata-1,2,3,4-tetrahydronaphthalenate, 6*g*

2 (0.29 g, 1.0 mmol) and 1-methylpiperidine (0.10 g, 1.0 mmol) are reacted in 10 mL of 2-propanol in a procedure similar to that described for **6***a*. Yield: 0.38 g (85%) of yellowish crystals; mp 95°C (2-PrOH). Infrared (KBr): 1604 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.06 (d, J = 6 Hz, $(CH_3)_2C$), 1.33–1.73 (m, $C(CH_2)_3C$), 2.52 (s, N-CH_3), 2.63–2.90 (m, CH_2NCH_2), 3.66–4.26 (m, O-$CH(C)_2$), 5.56 (s, 60% of 1H, O-CH-O), 6.30–7.80 (m, 14 aromatic H and 1H, exchangeable, NH), 11.03 (s, 40% of 1H, CH═O); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.23 (d, J = 6 Hz, $(CH_3)_2C$), 1.30–1.73 (m, $C(CH_2)_3C$), 2.20 (s, N-CH_3), 2.23–2.40 (m, CH_2NCH_2), 4.06–4.50 (m, O-$CH(C)_2$), 5.70 (s, 20% of 1H, O-CH-O), 6.83–7.90 (m, 14 aromatic H and 1H, exchangeable, NH), 9.83 (s, 80% of 1H, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 4.6 ($W_{1/2}$ = 385 Hz); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 4.2 ($W_{1/2}$ = 300 Hz) and 45.1 ($W_{1/2}$ = 300 Hz), ratio of peak areas: 2:1. **6***g* gives a blue color reaction with diphenylcarbazone as described for **6***a*.

Quinuclidinium 6,10-epoxy-6,8-diphenyl-5,7,9-trioxa-8-bora-6-borata-5,6,7,8,9,10-hexahydrobenzocyclooctenate, 10*a*

Salicylaldehyde (0.61 g, 5.0 mmol) and phenylboronic acid (1.22 g, 10.0 mmol) are dissolved in 20 mL of ethanol. After the addition of quinuclidine (0.56 g, 5.0 mmol) to the stirred solution crystallization starts spontaneously after a few seconds or is provoked by refluxing for a short time. The colorless substance is recrystallized from absolute ethanol. Yield: 1.82 g (83%); mp 145°C (EtOH). Infrared (KBr): 1604 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.50–1.83 (m, $C(CH_2)_3C$), 1.93 (sept, J = 3 Hz, $HC(C)_3$), 2.90–3.23 (m, $N(CH_2)_3$), 5.96 (s, 80% of 1H, O-CH-O), 6.63 (s, broad, exchangeable, NH), 6.43–7.83 (m, 14 aromatic H), 10.22 (s, 20% of 1H, CH═O); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.43–1.73 (m, $C(CH_2)_3C$), 1.85 (sept, J = 3 Hz, $HC(C)_3$), 2.86–3.16 (m, $N(CH_2)_3$), 6.50 (s, 10% of 1H, O-CH-O), 6.83–7.10 (m, 2 aromatic H), 7.20–7.60 (m, 8 aromatic H), 7.90–8.13 (m, 4 aromatic H), 8.96 (s, broad, exchangeable, NH), 9.86 (s, 90% of 1H, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 2.9 ($W_{1/2}$ = 342 Hz) and 28.3 ($W_{1/2} \approx$ 600 Hz), ratio of peak areas: 1:1. Anal. calcd. for $C_{26}H_{29}B_2NO_4$: C 70.79, H 6.63, B 4.90, N 3.18; found: C 70.59, H 6.72, B 4.83, N 2.99.

The identical compound is obtained by using only 5.0 mmol of phenylboronic acid (in an equimolar three-component reaction) in proportionate yields (40–45%). Using solvents such as methanol, benzene, or diethyl ether in place of ethanol has no effect on the result of the reaction.

1,4-Diazabicyclo[2.2.2]octanium 6,10-epoxy-6,8-diphenyl-5,7,9-trioxa-8-bora-6-borata-5,6,7,8,9,10-hexahydrobenzocyclooctenate, 10*b*

Salicylaldehyde (0.61 g, 5.0 mmol), phenylboronic acid (1.22 g, 10.0 mmol), and 1,4-diazabicyclo[2.2.2]octane (0.56 g, 5.0 mmol) are reacted as described for **10***a*. Yield: 1.70 g (77%) of colorless crystals; mp 110°C (EtOH). Infrared (KBr): 1605 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 2.90 (s, $N(C_2H_4)_3$), 5.86 (s, exchangeable,

NH), 6.06 (s, 70% of 1H, O-CH-O), 6.60–8.10 (m, 14 aromatic H), 10.40 (s, 30% of 1H, CH═O); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 2.90 (s, $N(C_2H_4)_3$), 6.83–8.13 (m, 14 aromatic H), 9.83 (s, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 2.9 ($W_{1/2}$ = 342 Hz) and 28.3 ($W_{1/2} \approx$ 500 Hz), ratio of peak areas: 1:1. Anal. calcd. for $C_{25}H_{28}B_2N_2O_4$: C 67.92, H 6.38, B 4.89, N 6.34; found: C 67.88, H 6.47, B 4.80, N 6.34.

1-Methylpiperidinium 6,10-epoxy-6,8-diphenyl-5,7,9-trioxa-8-bora-6-borata-5,6,7,8,9,10-hexahydrobenzocyclooctenate, 10*c*

Salicylaldehyde (0.61 g, 5.0 mmol), phenylboronic acid (1.22 g, 10.0 mmol), and 1-methylpiperidine (0.50 g, 5.0 mmol) are reacted as described for **10***a*. Yield: 1.80 g (84%) of colorless crystals; mp 128°C (EtOH). Infrared (KBr): 1607 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.26–1.76 (m, $C(CH_2)_3C$), 2.53 (s, CH_3), 2.66–2.93 (m, CH_2NCH_2), 5.80 (s, broad, exchangeable, NH), 5.98 (s, 80% of 1H, O-CH-O), 6.46–7.90 (m, 14 aromatic H), 10.26 (s, 20% of 1H, CH═O); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.20–1.76 (m, $C(CH_2)_3C$), 2.40 (s, CH_3), 2.53–2.83 (m, CH_2NCH_2), 6.10 (s, 10% of 1H, O-CH-O), 6.83–8.16 (m, 14 aromatic H), 9.60 (s, exchangeable, NH), 9.88 (s, 90% of 1H, CH═O); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 3.1 ($W_{1/2}$ = 342 Hz) and 21.8 ($W_{1/2}$ = 600 Hz), ratio of peak areas: 1:10. Anal. calcd. for $C_{25}H_{29}B_2NO_4$: C 69.97, H 6.81, B 5.04, N 3.26; found: C 69.89, H 6.96, B 5.16, N 3.22.

Triethylammonium 6,10-epoxy-6,8-diphenyl-5,7,9-trioxa-8-bora-6-borata-5,6,7,8,9,10-hexahydrobenzocyclooctenate, 10*d*

Salicylaldehyde (0.61 g, 5.0 mmol), phenylboronic acid (1.22 g, 10.0 mmol), and triethylamine (0.51 g, 5.0 mmol) are reacted as described for **10***a*. Yield: 1.50 g (70%) of colorless crystals; mp 125°C (EtOH). Infrared (KBr): 1609 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.10 (t, J = 8 Hz, 3 CH_3), 2.92 (q, J = 8 Hz, $N(CH_2)_3$), 5.06 (s, broad, exchangeable, NH), 5.96 (s, 80% of 1H, O-CH-O), 6.43–7.86 (m, 14 aromatic H), 10.25 (s, 20% of 1H, CH═O); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 0.90 (t, J = 8 Hz, 3 CH_3), 2.46 (t, J = 8 Hz, $N(CH_2)_3$), 6.03 (s, 50% of 1H, O-CH-O), 6.63–8.03 (m, 14 aromatic H), 8.85 (s, broad, exchangeable, NH), 9.90 (s, 50% of 1H, CH═O); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 3.4 ($W_{1/2}$ = 428 Hz) and 28.7 ($W_{1/2} \approx$ 700 Hz), ratio of peak areas: 1:1. Anal. calcd. for $C_{25}H_{31}B_2NO_4$: C 69.65, H 7.25, B 5.01, N 3.25; found: C 69.65, H 7.46, B 5.12, N 3.18.

1-Methylpiperidinium 6,10-epoxy-4-methoxy-6,8-diphenyl-5,7,9-trioxa-8-bora-6-borata-5,6,7,8,9,10-hexahydrobenzocyclooctenate, 10*e*

2-Hydroxy-3-methoxybenzaldehyde (0.76 g, 5.0 mmol), phenylboronic acid (1.22 g, 10.0 mmol), and 1-methylpiperidine (0.50 g, 5.0 mmol) are reacted as described for **10***a*. Yield: 1.90 g (83%) of pale yellow crystals; mp 146°C (EtOH). Infrared (KBr): 1601 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.23–1.80 (m, $C(CH_2)_3C$), 2.62 (s, NCH_3), 2.83–3.06 (m, CH_2NCH_2), 3.70 (s, 80% of 3H, OCH_3), 3.83 (s, 20% of 3H, OCH_3), 6.00 (s, 80% of 1H, O-CH-O), 6.43–7.93 (m, 13 aromatic H and 1 NH, exchangeable), 10.32 (s, 20% of 1H, CH═O); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.20–1.73 (m, $C(CH_2)_3C$), 2.40 (s, NCH_3), 2.46–2.80 (m, CH_2NCH_2), 3.73 (s, 25% of 3H, OCH_3), 3.90 (s, 75% of 3H, OCH_3), 6.13 (s, 25% of 1H, O-CH-O), 6.73–8.16 (m, 13 aromatic H), 8.70 (s, exchangeable, NH), 9.93 (s, 75% of 1H, CH═O); ^{1}H nmr (90 MHz, pyridine-d_5–TMS), δ (ppm): 1.26–1.70 (m, $C(CH_2)_3C$), 2.18 (s, NCH_3), 2.20–2.36 (m, CH_2NCH_2), 6.76–7.70 (m, 9 aromatic H), 8.16–8.46 (m, 4 aromatic H), 10.30 (s, broad, exchangeable, NH), 10.70 (s, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 2.9 ($W_{1/2}$ = 342 Hz) and 28.5 ($W_{1/2} \approx$ 700 Hz), ratio of peak areas: 1:1; ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 3.0 ($W_{1/2} \approx$ 700 Hz) and 21.2 ($W_{1/2} \approx$ 600 Hz). Anal. calcd. for $C_{26}H_{31}B_2NO_5$: C 68.01, H 6.81, B 4.71, N 3.05; found: C 67.91, H 6.96, B 4.36, N 3.04.

Crystals suitable for X-ray analysis were obtained by very slow cooling of an ethyl acetate solution of **10***e*.

1-Methylpiperidinium 2-chloro-6,10-epoxy-6,8-diphenyl-5,7,9-trioxa-8-bora-6-borata-5,6,7,8,9,10-hexahydrobenzocyclooctenate, 10*f*

5-Chloro-3-methoxybenzaldehyde (0.78 g, 5.0 mmol), phenylboronic acid (1.22 g, 10.0 mmol), and 1-methylpiperidine (0.50 g, 5.0 mmol) are reacted as described for **10***a*. Yield: 1.52 g (66%) of pale yellow crystals; mp 146°C (EtOH). Infrared (KBr): 1601 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.26–1.80 (m, $C(CH_2)_3C$), 2.60 (s, CH_3), 2.80–3.03 (m, CH_2NCH_2), 5.60 (s, broad, exchangeable, NH), 5.99 (s, 90% of 1H, O-CH-O), 6.62 (d, 1 aromatic H), 6.69–7.86 (m, 12 aromatic H), 10.25 (s, 10% of 1H, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 3.1 ($W_{1/2}$ = 300 Hz) and 30.3 ($W_{1/2}$ = 640 Hz), ratio of peak areas: 5:1. Anal. calcd. for $C_{25}H_{28}B_2ClNO_4$: C 64.77, H 6.09, B 4.66, Cl 7.65, N 3.02; found: C 64.36, H 6.08, B 4.77, Cl 7.67, N 2.90.

1-Methylpiperidinium 6,10-epoxy-2-nitro-6,8-diphenyl-5,7,9-trioxa-8-bora-6-borata-5,6,7,8,9,10-hexahydrobenzocyclooctenate, 10*g*

2-Hydroxy-5-nitrobenzaldehyde (0.84 g, 5.0 mmol), phenylboronic acid (1.22 g, 10.0 mmol), and 1-methylpiperidine (0.50 g, 5.0 mmol) are reacted as described for **10***a*. Yield: 1.40 g (59%) of pale yellow crystals; mp 170°C (EtOH). Infrared (KBr): 1608 (C═C) cm^{-1}; ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.30–1.83 (m, $C(CH_2)_3C$), 2.70 (s, CH_3), 4.76 (s, broad, partially exchangeable, NH), 6.21 (s, 90% of 1H, O-CH-O), 6.80 (d, 1 aromatic H), 7.10–8.20 (m, 12 aromatic H), 10.23 (s, 10% of 1H, CH═O); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 3.5 ($W_{1/2}$ = 428 Hz) and 27.9 ($W_{1/2} \approx$ 700 Hz), ratio of peak areas: 5:1. Anal. calcd. for $C_{25}H_{28}B_2N_2O_6$: C 63.33, H 5.95, B 4.56, N 5.91; found: C 63.29, H 6.04, B 4.58, N 5.82.

X-ray crystallographic analyses of 6*d* and 10*e*

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 82.7–93.1° for **6***d* and 88.2–95.9° for **10***e*. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, decayed linearly by 3.7% for **6***d* and showed only small

[a]Temperature 294 K, Rigaku AFC6S diffractometer, Cu K_α radiation (λ = 1.54178 Å), graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan:background time ratio 2:1), $\sigma^2(F^2) = [S^2(C + 4B)]/Lp^2$ (S = scan rate, C = scan count, B = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1$ for **6***d* and $w = 4F_o^2/\sigma^2(F_o^2)$ for **10***e*, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o| - |F_c|)^2/(m-n)]^{1/2}$. Values given for *R*, R_w, and gof are based on those reflections with $I \geq 3\sigma(F^2)$.

random fluctuations for **10***e*. The data were processed,[3] corrected for Lorentz and polarization effects, decay (**6***d*), and absorption (based on azimuthal scans).

The structures were both solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. For **6***d* the N-H hydrogen atom was refined with an isotropic thermal parameter and the carbon-bound hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and B_H = 1.2 $B_{bonded\ atom}$, and for **10***e* all hydrogen atoms were refined with isotropic thermal parameters. Corrections for secondary extinction were applied (Zachariasen type, isotropic, Gaussian), the final values of the extinction coefficients being $6.66(13) \times 10^{-6}$ for **6***d* and $2.26(5) \times 10^{-6}$ for **10***e*. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (9). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and intra-annular torsion angles appear in Tables 2–5, respectively. Hydrogen atom parameters, anisotropic thermal parameters, and torsion angles, intermolecular contacts, and least-squares planes are included as supplementary material.[4]

Results and discussion

Compound 6

The reaction of **2** with a tertiary amine, or the one-pot reaction of equimolar amounts of salicylaldehyde, diphenylborinic acid anhydride, and a tertiary amine in the presence of an alkanol (R′OH), led to compounds with elemental analyses of "**3**+R′OH." The spectroscopic data cannot distinguish between the alternative structures **4**–**6** but the intermolecular salt structure **6** is established by the X-ray analysis of **6***d*, verifying the addition of R′OH to the aldehyde group and the formation of an *O*,*O*-acetal moiety within the chelate anion (at least in the solid state). The tertiary amine appears as a trialkylammonium cation hydrogen bonded to the organoborate anion in the crystal lattice.

In the ^{1}H nmr spectra of **6***a*–*g* partial solvolysis can be observed to different extents in the two chosen solvents, DMSO-d_6 and $CDCl_3$. In DMSO-d_6 between 60 and 100% of the acetalic O-CH-O grouping is retained, whereas in $CDCl_3$ an average of 50% of the acetal structure remains. Only compound **6***a* shows mostly (80%) acetal structure in $CDCl_3$, presumably due to the somewhat higher basicity of the incorporated quinuclidine relative to the other tertiary amines used (10). The partial elimination of R′OH from **6** leads to the free aldehyde group, similar to the observed elimination of the tertiary amine from **3** (6). Correspondingly, the ^{11}B nmr spectra of **6** in DMSO-d_6 mainly display a 100% signal for tetracoordinated (sp^3) boron between δ(Et_2OBF_3) values of 2.9 and 4.6 ppm, whereas in $CDCl_3$ only about 60% of the signal is found between 3.7 and 4.3 ppm (corresponding to tetracoordinated boron) while the remaining 40% appears between 44.9 and 45.5 ppm (trivalent (sp^2) boron) indicating esterified or free diphenylborinic acid (Ph_2B-O-R) (11). Considering the portion of intact acetal function in the ^{1}H nmr spectra of **6***d*–*g*, prepared with different alkanols, it seems that the isopropanol

derivative (**6***g*) is the most responsive to solvolysis,[5] probably due to the sterically facilitated elimination of the bulkier alkanol group.

As expected, the solid state infrared spectra (KBr pellets) of **6** do not display any C═O stretching absorption in the region

[5] The degree of solvolysis is solvent dependent and does not seem to proceed uniformly in the different solvents. The behavior also varies for different derivatives of **6**. In most cases a signal for the methine CH═O proton of the restored aromatic aldehyde is found in the ^{1}H nmr spectra. In DMSO-d_6 solution this signal is sometimes accompanied by a signal arising from an associated OH proton, possibly from the released phenol group of the salicylaldehyde. The presence of free diphenylborinic acid (Ph_2BOH), however, cannot be ruled out.

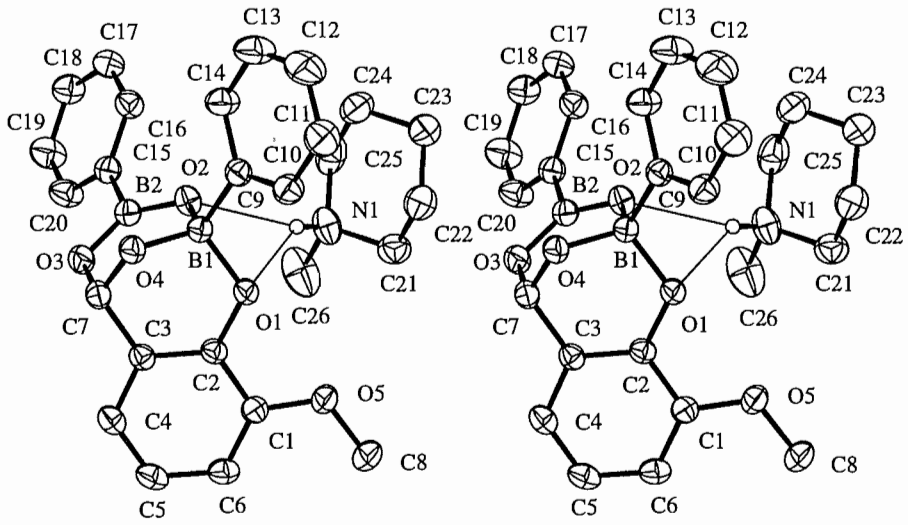
Fig. 1. Stereoview of ***6d***; 20% probability thermal ellipsoids are shown for the non-hydrogen atoms.



of aldehyde carbonyl vibrations, indicative of the conversion of the aldehyde group in **1** or **2** into the *O,O*-acetal function of **6**. This also provides additional proof that the chelate anion of **6** is stable in the crystalline state.

To the best of our knowledge, ***6d*** is the first structurally characterized diphenylboron chelate of a salicylaldehyde semiacetal. The structure of ***6d*** consists of cation–anion pairs (Fig. 1), associated by a N—H···O hydrogen bond (N(1)—H(1) = 1.01(3) Å, H(1)···O(2) = 1.81(3) Å, N(1)···O(2) = 2.808(3) Å, N(1)-H(1)···O(2) = 170(3)°). The slightly bent geometry of the N(1)—H(1)···O(2) hydrogen bond may be the result of a weak N—H···π(phenyl) interaction. Atom H(1) is displaced 2.48 Å from the mean plane of the C(1–6) phenyl ring and the H(1)···C(2) distance is 3.23(3) Å. The ion pairs are separated from one another by normal van der Waals distances. The general geometry of the chelate ring is reminiscent of the ring system in compound **3** (6). The carbonyl C=O double bond of the salicylaldehyde diphenylboron chelate **2**, which has a C—O bond distance of 1.261(4) Å (12), is lengthened by 0.15 Å in the ethanol adduct ***6d*** to 1.415(3) Å. The lengthening in this case is even greater than that observed for the quinuclidine adduct **3** (R_3N = quinuclidine) (6), which retains some of the double bond character of its C—O bond (1.362(4) Å) with an estimated π-bond order of 0.3 (from plots of bond lengths vs. π-bond order (13)). Compound ***6d*** shows a nearly complete loss of the double bond character of

Fig. 2. Stereoview of **10***e*; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms. Carbon-bound hydrogen atoms are omitted for clarity.

the C(7)—O(2) bond. An additional factor in the lengthening of the C(7)—O(2) bond in **6***d* may be the involvement of one oxygen electron pair in the O(2)···H(1)—N(1) hydrogen bond to the tertiary amine.

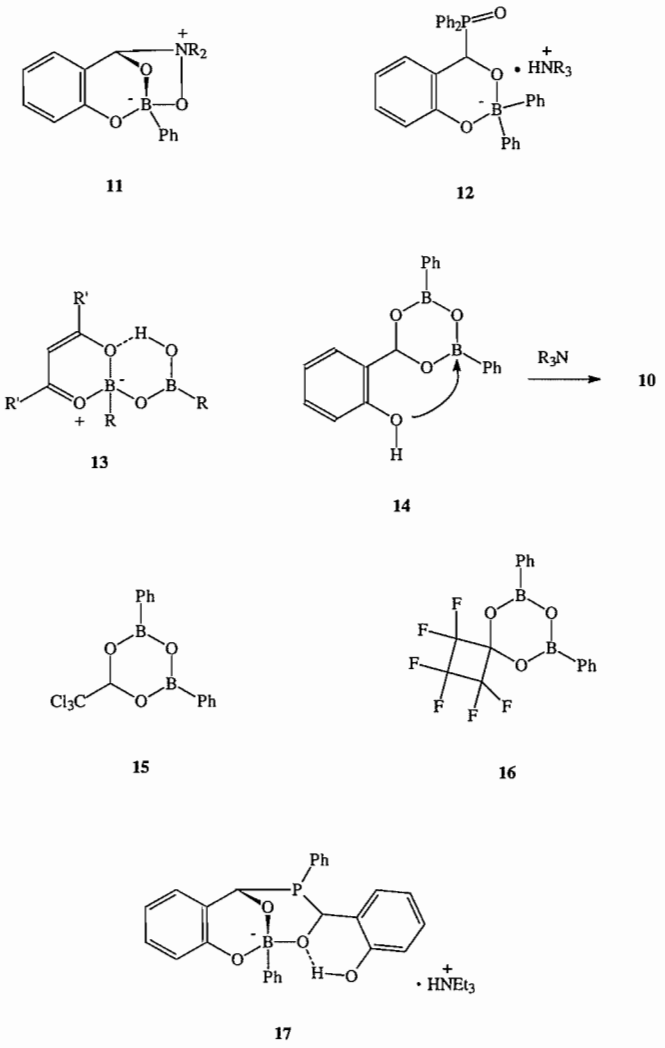
The six-membered boron chelate ring in **6***d* displays a distorted "O(2)-envelope" conformation (see Table 5), the fused benzene ring being coplanar with the approximately planar B(1)-O(1)-C(1)-C(2)-C(7) ring segment. In contrast to the quinuclidine adduct **3**, with a (pseudo-) axial orientation of the added tertiary amine (6), the ethoxy group in **6***d* is in a (pseudo-) equatorial position. As in **2** (12) and in **3** (6) the (pseudo-) axial *B*-phenyl group in the molecule **6***d* has a somewhat longer B—C(phenyl) bond distance than the equatorial *B*-phenyl substituent (**2**: 1.610(5) Å (ax), 1.603(5) Å (eq); **3**: 1.623(5) Å (ax), 1.613(5) Å (eq); **6***d*: 1.620(4) Å (ax), 1.605(4) Å (eq)). This is a general trend in complexes of this type (ref. 6, and refs. therein).

The tetrahedral arrangement about the boron atom includes a nearly strain-free O-B-O angle of 108.6(2)°, similar to the corresponding angle of 108.0(3)° in **3** (R_3N = quinuclidine) (6). There is a chiral centre at C(7), the *R* enantiomer being depicted in Fig. 1. The centrosymmetric crystal structure contains equal numbers of *R* and *S* enantiomers. The hydrogen-bonded *N*-methpiperidinium cation has a normal chair conformation (see Table 5) with the methyl group in an equatorial position and the hydrogen atom in an axial position.

The relatively short C—C distance between the carbonyl C atom and the aryl carbon atom in **2** (1.413(5) Å) (12) is lengthened in **6***d* to 1.495(3) Å between C(2) and C(7) because of the loss of resonance between the benzene ring and the carbonyl double bond. Similar lengthening of the C(carbonyl)—C(aryl) bond can be seen in the molecule of **3** (R_3N = quinuclidine, C—C = 1.504(5) Å) (6), and also in another salicylaldehyde derivative **11** (1.494(2) Å) that represents an intramolecular adduct of a nitrogen base to a salicylaldehyde boron chelate (14). The ammonium salt structure of the ethanol adduct **6***d* corroborates structural postulations made for the diphenylphosphine oxide adducts **12** (15).

Compound 10

The exchange of diphenylborinic acid for phenylboronic acid in the three-component reaction system did not lead to an adduct or chelate **7** by analogy to compound **3** (6) nor to the postulated structure **7** (R_3N = H_2N-CH(C_4H_9)COOH) of an amino acid adduct to the phenylboronate complex (2). Instead the analytical data suggested a composition "**7** + PhBO." This means the incorporation of one additional mole equivalent of phenylboronic acid (anhydride), and could be the result of pyroboronate formation to give **8** as a direct derivative from **7**. A similar hydrogen bond-stabilized anhydride structure **13** has been formulated for the boronates of 1,3-diketones (16). However, an isomeric amine adduct **9** with incorporation of the second boronic acid molecule at the acetal function could not be overlooked. The structure **10**, combining the pyroboronate and the acetal boronate functions in a polycyclic anion with an associated ammonium cation, also had to be considered. Indeed, the latter molecular structure **10** is established by an X-ray analysis of **10***e* (Fig. 2), which gave the most suitable single crystals.



The acetal pyroboronate partial structure in **10** can be thought of as stabilized by ring-closing intramolecular complex formation of the monocyclic salicylaldehyde derivative **14** in the presence of a proton-accepting amine (Scheme 2). Stable six-membered condensates of a carbonyl compound and two molecules of phenylboronic acid were otherwise obtained only from aldehydes or ketones with strong electron-withdrawing substituents, as reported for **15** (17) or **16** (18). The compounds **10** are obtained in approximately the same yields, no matter whether one or two mole equivalents of phenylboronic acid are applied in the reaction. It seems that the formation of the bridged anion of **10** is favored and the relatively poor solubility of the salts **10** leads to spontaneous crystallization, withdrawing the product from an equilibrium reaction. In the solutions prepared for nmr spectra, a solvent-dependent instability is obvious. In DMSO-d_6 the ratio of the intact acetalic group to the solvolytic free-set aldehyde group ranges from 9:1 to 2:1, based on integration of the O-CH-O

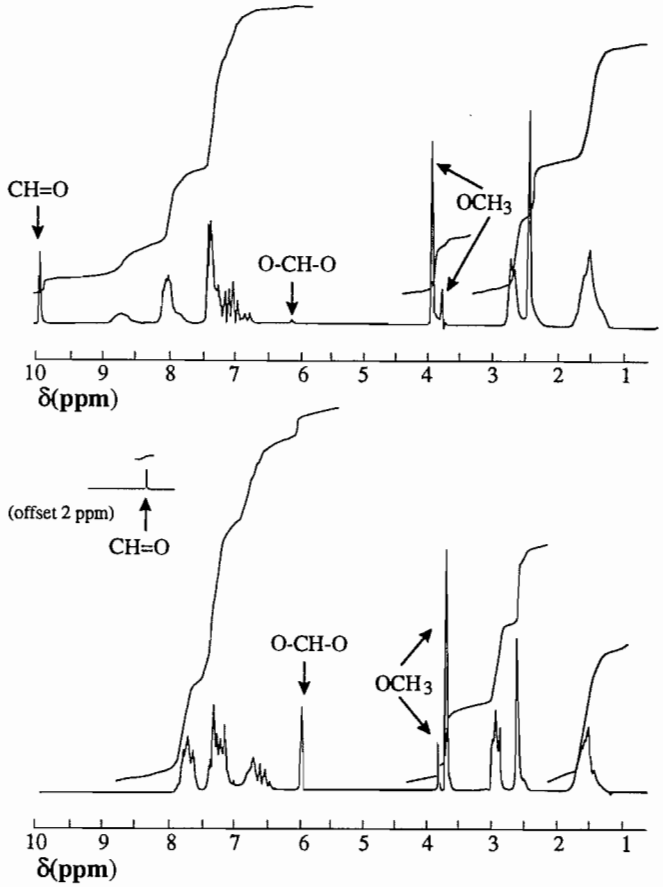

Scheme 2.

and CH═O signals in the ^{1}H nmr spectra. The ^{11}B nmr spectra in DMSO-d_6 show an expected 1:1 ratio of tetracoordinate (sp^3) boron to trivalent (sp^2) boron nuclei or, in some instances, a predominant tetracoordinate boron species. In the $CDCl_3$ solutions of **10** the proportions are essentially reversed, in the ^{1}H as well as in the ^{11}B nmr spectra. This is clearly demonstrated by the ^{1}H nmr spectra of **10***e* (characterized by X-ray analysis) in DMSO-d_6 and $CDCl_3$ shown in Fig. 3. The correspondence of the ratios of the aldehyde or acetal methine proton signals with those of the *ortho*-methoxy group of the aldehyde or acetal moiety is striking. The nature and structures of the various possible solvolysis products and the pathways of interaction with the solvents, however, is not clear at this point.

The overall geometry of **10***e* is characterized by two main (folded-leaf) planes, defined by the atoms [O(2), O(3), C(15)] and [O(1), C(2), C(3), C(7)] with a dihedral angle of 64.9°, parted by an oxygen bridge O(4) into two six-membered rings with O(4)-envelope ("sofa") conformations (see Table 5). The bond angle at the oxygen bridge (110.5(1)°) shows a lesser degree of strain than observed for the oxygen-bridged compound **11** (B-O-C = 102.1(1)°) where the oxygen bridge produces six- and five-membered heterocycles (14).

Fig. 3. The ^{1}H nmr spectra of **10***e* in $CDCl_3$ (top) and in DMSO-d_6 (bottom).

The planar boronate function at B(2) involves two short O—B bonds (1.371(2) and 1.352(2) Å), demonstrating the partial π-bond character that results from the *pp*(π) back donation from the two oxygen atoms to the boron atom. The O(2)—B(2) distance is shorter by 0.02 Å because of the more distinct double bond character typical for bonds within B(sp^3)-O-B(sp^2) anhydridic systems. The involvement of O(2) in the hydrogen bond to N(1) does not significantly decrease the partial double bond character of the O(2)—B(1) bond. The B(2)—C(15) bond length of 1.564(2) Å is similar to those observed for other phenylboronates with trigonal (sp^2) boron atoms. The B(1)—C(9) distance of 1.606(2) Å, similarly, corresponds to a normal B(sp^3)—C(phenyl) bond. The slightly distorted tetrahedron about B(1) is completed by longer O—B bonds in the range 1.462(2)–1.504(2) Å. Despite a supposed interaction between the trigonal planar boron atom B(2) and the aromatic system of the *B*-phenyl ring, the 32.6° angle between normals to the mean planes of the *B*-phenyl ring and the planar O-B-O boronate ring segment of the BOBOCO heterocycle represents a considerable deviation from coplanarity.

The difference between the two acetalic C—O bond lengths corresponds to different adjacent boron connections: the longer C(7)—O(3) bond (1.451(2) Å) involves the boronic ester group and resembles the C—O distances in acylals (19), whereas the shorter C(7)—O(4) bond (1.395(2) Å) is part of the anionic tetrahedral boronate moiety and is like the C—O bonds in acetal systems (19). Correspondingly, the O(3)—

© 1997 NRC Canada

B(2) bond is shorter than the O(4)—B(1) bond. The sum of bond lengths for the two C(7)-O-B ring segments, however, remains fairly consistent (C(7)-O(3)-B(2): 2.822 Å, C(7)-O(4)-B(1): 2.857 Å).

The structure of **10***e* consists of cation–anion pairs (Fig. 2), associated by a weak three-centre ("bifurcated") N-H(···O)$_2$ hydrogen bond system involving O(1) and O(2). The hydrogen bond geometry is as follows: N(1)—H(18) = 0.88(2) Å, H(18)···O(2) = 2.24(2) Å, N(1)···O(2) = 2.994(2) Å, N(1)-H(18)···O(2) = 144(2)°, H(18)···O(1) = 2.32(2) Å, N(1)···O(1) = 3.089(2) Å, N(1)-H(18)···O(1) = 146(2)°. Both N···O distances in this system are at the long end of the reported range of N—H···O distances (20). The acute O(1)···H(18)···O(2) angle of 63(2)° is a consequence of the fact that O(1) and O(2) are separated by only one atom (both are bonded to B(1)). Another factor contributing to the overall weakness of this bifurcated hydrogen-bonding system is a nonideal angle of approach by the N-H vector to both oxygen atoms. In the case of sp^3-hybridized O(1) the C(2)-O(1)···H(18) and B(1)-O(1)···H(18) angles (ideally 109.5°) are 120(2)° and 85(2)°, respectively, and for sp^2-hybridized O(2) the B(1)-O(2)···H(18) and B(2)-O(2)···H(18) angles (ideally 120°) are 88(2)° and 134(2)°, respectively. Furthermore, H(18) is displaced 1.42 Å from the B(1)O(2)B(2) plane suggesting that the interaction with O(2) has a significant π-component. The associated ion-pair units are linked by weak C—H···O interactions: C(8)—H(5)···O(4)($-1/2 + x$, $1/2 - y$, $-1/2 + z$), C(8)—H(5) = 0.96(2) Å, H(5)···O(4) = 2.44(2) Å, C(8)···O(4) = 3.393(2) Å, C(8)-H(5)···O(4) = 175(2)°. The anion of **10***e* possesses two chiral centres at B(1) and C(7), the *R,R* enantiomer being depicted in Fig. 2. The crystal lattice contains equal numbers of *R,R* and *S,S* enantiomers.

Compound **10***e*, to the best of our knowledge, is the first example of a salicylaldehyde bisboronate to be structurally characterized. In contrast to the intramolecular compensation of charge in the *N,B*-betainic hydroxylamine derivative **11** (14), the incorporation of phenylboronic acid into the salicylaldehyde–boronate complex leads to the benzocyclooctene ring system and results in the overall negative charge. Another heterocyclic benzocyclooctene compound **17**, derived from salicylaldehyde, phenylboronic acid, and a phosphorus component, has been crystallized as a tertiary ammonium salt and structurally characterized (21).

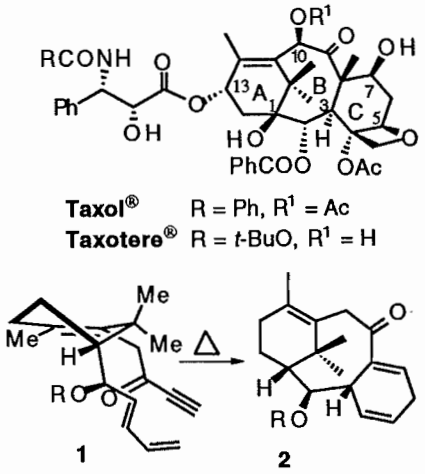
Ring A building blocks for taxoids and taxamycins

Michael W. Tjepkema, Peter D. Wilson, Hélène Audrain, and Alex G. Fallis

Abstract: The syntheses of a series of oxygenated cyclohexene ring A synthons **20**, **22–27**, **34**, **36**, and **37** that possess suitable functionality for further elaboration for taxoid synthesis are described. These compounds have been prepared from β-ionone by a series of oxidative and addition reactions or alternatively by Lewis acid catalyzed Diels–Alder cycloadditions with the oxygen-containing trimethyl substituted dienes **31** and **33**.

Key words: taxoid, paclitaxel, dienes, Diels–Alder, β-ionone.

Résumé : On décrit les synthèses d'une série de synthons (**20**, **22–27**, **34**, **36** et **37**) du cycle A, à cyclohexène oxygéné, qui possèdent des fonctions appropriées pour des élaborations ultérieurs dans la synthèse de taxoïdes. On a préparé ces produits à partir de la β-ionone par une série de réactions d'oxydation et d'addition ou, d'une façon alternative, par des cycloadditions de Diels–Alder catalysées par les acides de Lewis avec les dienes triméthylés **31** et **33** contenant de l'oxygène.



Mots clés : taxoïde, paclitaxel, dienes, Diels–Alder, β-ionone.

[Traduit par la rédaction]

Introduction

The proven clinical utility of the potent antitumor agents paclitaxel (Taxol®) (1) and docetaxel (Taxotere®) for the treatment of ovarian and breast cancer has established the taxoids as an important new class of chemotherapeutic agents. These compounds belong to a new group of antitumor drugs that interfere with the normal microtubule–tubulin cascade prior to cell division (2). This novel mode of action, plus the significant synthetic challenge presented by the sterically congested multicyclic structure has stimulated worldwide interest in these molecules (3). Recently, three groups have reported total syntheses of Taxol® (4–6). In spite of this success, many factors remain to be investigated and over the next decade it is likely that simpler analogues with a better therapeutic profile will be synthesized and become useful pharmaceutical products. They will thus follow the path from natural products to medicine established earlier for penicillins, tetracyclines, etc. This path depends upon an improved knowledge of structure–activity relationships, the further development of efficient synthetic and (or) semi-synthetic routes to the functionalized tricyclo[9.3.1.$0^{3,8}$]pentadecene nucleus, and the development and synthesis of medicinally interesting analogues that possess a better therapeutic profile than paclitaxel itself. The semi-synthetic analogue docetaxel has established that this is possible (7).

Scheme 1. Previous studies.

We have been developing an intramolecular Diels–Alder strategy that proceeds in the left to right direction (ring A to ABC) (8). Ring A cyclohexene building blocks are used as anchors to facilitate an intramolecular Diels–Alder reaction to construct the B and C rings simultaneously. Model studies using this convergent approach led to the functionalized tricyclo[9.3.1.$0^{3,8}$]pentadecene skeleton. The C_2 epimer controls the adduct stereochemistry in accord with other studies concerning the π-facial selectivity of related cycloadditions (9). This is represented by the successful preparation of the adduct **2** from **1** (Scheme 1).

Synthetic strategy

As our research has progressed the field has advanced rapidly and a better understanding of the factors that must be considered in any synthetic approach to the taxoids has emerged. In

Received February 26, 1997.

This paper is dedicated to Professor W.A. Ayer on the occasion of his 65th birthday. Presented with respect and gratitude for his contributions to chemical education and organic chemistry.

Scheme 3. Ring A building blocks.

particular, it has proven difficult to manipulate many of the required oxygen-containing centres in the intact nucleus. Consequently, it is preferable to carry several of the required functional groups from an early stage. In a retrosynthetic sense, removal of the ring D oxetane followed by a double disconnection between C_6—C_7 and C_3—C_8 in ring C (retro-Diels–Alder) in an intermediate such as **E** suggests a precursor related to the tetraene **D** (Scheme 2). In principle this intermediate could contain the majority of the paclitaxel (Taxol®) oxygen substituents, although in practice the use of less substituted systems may be more prudent. Construction of **D** may be envisaged in a direct manner from further disconnections between C_2—C_3 or C_3—C_4 and C_9—C_{10}. In total this leads to a highly convergent approach to the taxane nucleus from a suitably functionalized ring A building block in the form of a masked dialdehyde synthon related to **A** followed by attachment of the lower diene and upper dienophile units **B** and **C**, respectively. An intramolecular Diels–Alder cycloaddition should then afford the carbocyclic nucleus. Based on the success of our model system we wish to report the extension of these ideas through the synthesis of more highly functionalized ring A building blocks by more efficient routes than our original sequence (10). Suitable substituted cyclohexene ring A synthons are represented by the structures **3**–**6** (Scheme 3). These arise retrosynthetically from cleavage of the C_1—C_2 and C_9—C_{10} bonds or, alternatively, the C_2—C_3 and C_9—C_{10} bonds. These structures may be compared with the idealized compound **A**. The interconversions and cycloadditions described afford direct routes to a diverse family of ring A building blocks. These have formed the basis of our initial studies for the synthesis of taxoids and the related bicyclic taxoid-enediyne mimics the taxamycins (11).

Results and discussion

β-Ionone functionalization

Initially, an attractive target for further functionalization was the enol ether β-diketone represented by **15** (Scheme 4). This planar ketone lacks chirality but direct conversion into the desired optically active compounds may be envisaged via the asymmetric addition of a silyl cyanide in the presence of a titanium catalyst as a hydroxy aldehyde equivalent (12). To investigate this possibility the side-chain double bond of β-ionone (**8**) was cleaved selectively with ozone (13) followed by dimethyl sulfide work-up. (Scheme 4) The resulting aldehyde was treated directly with oxalic acid and ethylene glycol to afford the acetal **9** in 45% yield. Various allylic oxidation reagents failed to provide ketone **11**, and the acetal displayed a tendency to hydrolyze readily. Thus a bromination, solvolysis, oxidation protocol was developed. The reaction of **9** with *N*-bromosuccinimide (NBS) in the presence of the radical initiator 2,2′-azobis(isobutyronitrile) (AIBN) afforded the allylic bromide. Direct treatment with potassium carbonate – water – dimethyl sulfoxide afforded the alcohol, which was oxidized under Swern conditions to provide the desired enone **11** (94%). The triisopropylsilyl enol ether **12** was prepared by exposure to potassium hexamethyldisilazide and quenching with triisopropylsilyl chloride (TIPSCl) (86%). Unfortunately, conditions could not be found to effect allylic oxidation and generate the masked β-diketone **15** directly. The fragility of the ethylidene acetal, plus the multistep oxidation sequence required, prompted a change in our approach.

The ozonolysis of **8** was repeated and the intermediate aldehyde was treated with 2,2-dimethyl-1,3-propanediol in refluxing benzene to afford the acetal **7** (64%). Allylic oxidation was accomplished efficiently by a two-step, one-pot sequence. Initial treatment of **7** under buffered conditions with selenium dioxide in refluxing toluene afforded a keto-alcohol mixture that was oxidized directly with pyridinium dichromate (PDC) in dichloromethane containing magnesium sulfate to provide the unsaturated ketone **10** (62%) Direct introduction of the double bond to provide the dienone **13** (85%) with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) failed. Thus the dienone was prepared by selenoxide elimination. Treatment of the ketone **10** with lithium diisopropylamide (LDA) and phenylselenylbromide gave the selenide, which was oxidized with Oxone® in methanol to provide the diene **13** (65%). Of several oxidants examined, Oxone® was the only one that afforded reasonable yields of the diene.

Various nucleophiles (MeS^-, CN^-) could be added in a conjugate manner to the dienone **13** but the size of the nucleophile plus the balance between its nucleophilicity and leaving group ability was critical. For example, lithium thiophenoxide was

Reaction conditions:
(*a*) O_3, CH_2Cl_2, −78°C; Me_2S; oxalic acid, $HOCH_2CH_2OH$, C_6H_6, 80°C, 45%; (*b*) NBS, AIBN, CCl_4, 78%; KOH, DMSO, H_2O, 50°C, 29%; $(COCl_2)_2$, DMSO, CH_2Cl_2, Et_3N, −78 to 21°C, 94%; (*c*) $KN(TMS)_2$, THF, −78°C; TIPSCI, HMPA, 86%; (*d*) O_3, CH_2Cl_2, −78°C; Me_2S; oxalic acid, $HOCH_2CMe_2CH_2OH$, C_6H_6, 80°C, 64%; (*e*) SeO_2, KH_2PO_4, toluene, 110°C; PDC, $MgSO_4$, CH_2Cl_2, 62%; (*f*) LDA, THF, −78°C, PhSeBr; Oxone,® $NaHCO_3$, MeOH, 56%; (*g*) LiSMe, MeOH, 0°C, 87%; (*h*) THF, CH_2=CHMgBr, CuI, TMSCI, −78°C, 69%; (*i*) NCS, CCl_4, 78°C, 97%; (*j*) TlPSOTf, CH_2Cl_2, collidine, 21°C, 95%; (*k*) $NaBH_4$, MeOH, $CeCl_3 \cdot 7H_2O$, 0°C, 96%; (*l*) O_3, CH_2Cl_2, −78°C, Me_2S, 56%; (*m*) TBSTf, collidine, CH_2Cl_2, 21°C, 72%; (*n*) TPSCl, imidazole, DMAP, CH_2Cl_2, 21°C, 96%; (*o*) O_3, CH_2Cl_2, −78°C, Me_2S, 99%; (*p*) O_3, CH_2Cl_2, −78°C, Me_2S, 97%; (*q*) TBSOTf, collidine, CH_2Cl_2, 21°C; O_3, CH_2Cl_2, −78°C; Me_2S, 17%; (*r*) TMSCN, KCN, 18-crown-6, 21°C, 94%.

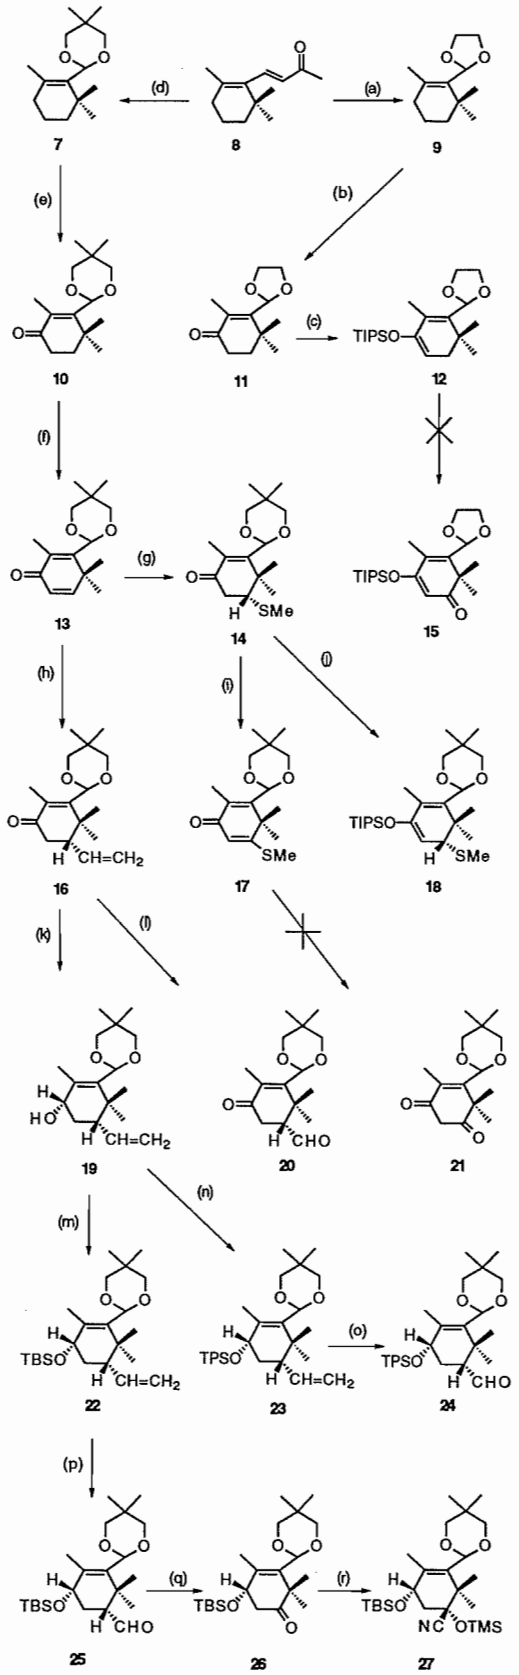

Fig. 1. Preferential direction of nucleophilic attack.

inert while lithium thiomethoxide afforded an 87% yield of ketone **14**. Treatment of this keto-sulfide with *N*-chlorosuccinimide (NCS) in refluxing carbon tetrachloride afforded the thio-enol ether **17** in 97% yield. Thus the reaction did not stop after the initial chlorination, but elimination occurred rapidly to give the unsaturated material. In principle it should be straightforward to convert this compound to the diketone **21.** However, exposure to mercuric chloride in the presence of calcium carbonate in aqueous acetonitrile at temperatures from 21 to 100°C failed to generate any of the diketone. A final attempt was made to prepare a compound related to **21** by conversion of ketone **14** to the enol ether **18** by exposure to collidine and triisopropylsilyl trifluoromethanesulfonate (95%). In this case also, attempted oxidation to the sulfoxide with dimethyldioxirane at 0°C followed by Pummerer rearrangement failed to provide the acetal enol-ether ketone related to structure **15**, and instead gave the dienone **13**, which presumably arose from sulfoxide elimination instead.

The desired oxygenated cyclohexenes have therefore been synthesized by the following route. The addition of the cuprate derived from vinyl magnesium bromide, cuprous iodide, and trimethylsilyl chloride (TMSCl) to the dienone **13** proceeded smoothly to afford the vinyl ketone **16** in 69% yield. Carbonyl reduction with sodium borohydride in the presence of cerium trichloride generated the C_{13} alcohol **19** as a single diastereomer in which attack occurred preferentially *anti* to the vinyl substituent (Fig. 1, **28**). Protection of the hydroxyl function in **19** as a silyl ether with collidine and *tert*-butyldimethylsilyl trifluoromethanesulfonate (TBSTf) afforded ether **22**. Alternatively treatment of **19** with 4–dimethylaminopyridine, triethylamine, and *tert*-butyldiphenylchlorosilane (TPSCl) afforded the vinyl ether **23** (96%). Selective ozonolysis of the vinyl group in ketone **16** provided direct access to the keto-aldehyde **20** (56%). In a parallel manner ozonolysis of **22** gave the aldehyde **25** in 96% yield. Similarly ozonolysis of **23**

Scheme 4. Ring A functionalization.

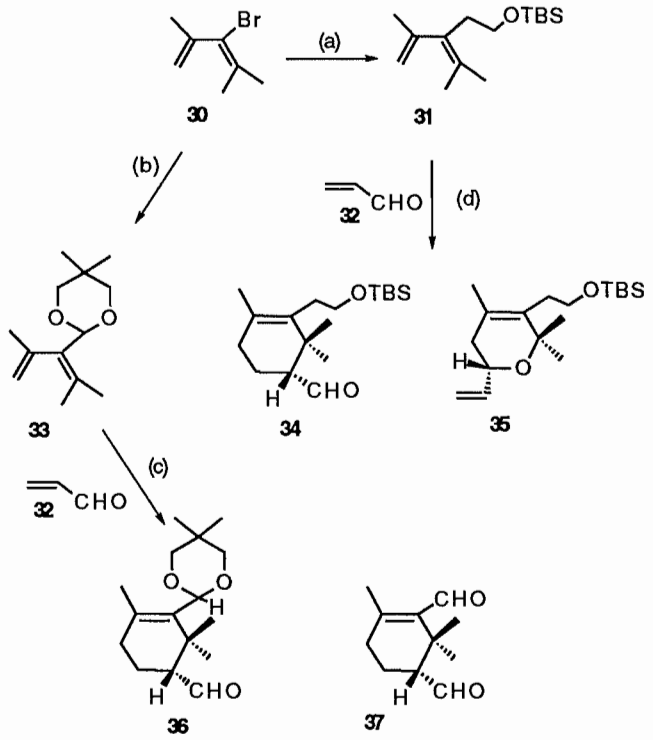
afforded **24**. These aldehydes correspond to the building block **4a**. The aldehyde group in **25** was converted to its *tert*-butyldimethylsilyl enol ether and treated directly with ozone to provide the ketone **26** containing a C_1 carbonyl (Taxol® numbering) corresponding to the building block **3a**. Subsequent addition of trimethylsilylcyanide (TMSCN) to **26** afforded the bis-silyl ether nitrile **27** in which the two ether substituents possessed a *syn* relationship. This stereochemistry is a consequence of the addition *anti* to the C_{13} ether as illustrated in **29** (Fig. 1). This compound is a masked form of the compound **5a** in which the oxygen substituents have the opposite relative orientation to the C_{13} and C_2 oxygens in paclitaxel (Taxol®). However, for our Diels–Alder approach to the tricyclic nucleus, this relative stereochemistry appeared to be required to avoid a 1,3 interaction between this C_{13} group and the diene side chain (8). While this research was in progress Stork and co-workers (14) have developed a different preparation of epimeric C_{13} ring A alcohol intermediates, and Kuwajima and co-workers (15) utilized a related silyl enol ether from an aldehyde related to **25** to prepare chiral C_1 hydroxyaldehyde systems. Many other routes to ring A synthons have also been reported (16) including some that employ an intramolecular Diels–Alder reaction to construct the required cyclohexene ring (17).



Cycloaddition route

Our earlier studies (8) and the results above demonstrated that the C_{13} oxygen could be introduced by allylic oxidation. Consequently for certain investigations it was desirable to have ring A synthons available that lacked this oxygenation pattern and could be synthesized rapidly. A cycloaddition approach was thus very attractive. The desired trimethyldienes **31** and **33** (Scheme 5) were synthesized from the bromodiene **30**. This compound was prepared in 90% yield in two steps from 2,3-dimethylbutene via rapid pyrolysis of the corresponding 1,1-dibromo-2,2,3,3-tetramethylcyclopropane (18). Treatment of **30** with *tert*-butyllithium to effect halogen metal exchange, followed by nucleophilic addition of the organolithium reagent to ethylene oxide, afforded the primary alcohol, which was protected directly as the *tert*-butyldimethylsilyl ether **31**. Alternatively, condensation of the organolithium reagent derived from **30** with dimethylformamide (DMF) provided the anticipated vinyl aldehyde, which upon treatment with 2,2-dimethyl-1,3-propanediol and oxalic acid afforded the diene acetal **33** in 84% overall yield.

Cycloaddition in various combinations generated the requisite ring A synthons. Diels–Alder cycloaddition of diene **33** with acrolein (**32**) at −78°C in the presence of boron trifluoride etherate ($BF_3{\cdot}Et_2O$) provided the adduct **36** in 60% yield accompanied by 15% of the dialdehyde **37**. In a similar fashion, cyclization of diene **31** also proceeded smoothly with acrolein at −78°C to afford the adduct **34** (67%, i.e., **6**, Scheme 3). In this instance the hetero Diels–Alder adduct **35** was also formed (27%). This product, although not unexpected, does not appear to have been observed by others in these systems.

In conclusion, commencing with β-ionone, sequential modification of the cyclohexene nucleus has provided access to several highly functionalized ring A building blocks. Alternatively, less oxygenated synthons may be constructed rapidly by appropriate [4 + 2] cycloadditions. These building blocks have been utilized for the synthesis of more advanced intermediates for taxoids and for the preparation of diverse taxamycin systems of various ring sizes.[2]

Scheme 5. Cycloaddition route to ring A.

Reaction conditions:
(*a*) *t*-BuLi, ethylene oxide, −78 to 21°C, 78%; TBSCl, imidazole, CH_2Cl_2, 62%; (*b*) *t*-BuLi, DMF, −78 to 21°C, $HOCH_2CMe_2CH_2OH$, oxalic acid, C_6H_6, 80°C, 84%; (*c*) $BF_3{\cdot}Et_2O$, CH_2Cl_2, −78°C, 60%; (*d*) $BF_3{\cdot}Et_2O$, CH_2Cl_2, −78°C, 67%.

Experimental

For general methods see ref. 8.

2,6,6-Trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (7)

Ozone was passed through a stirred solution of β-ionone **8** (20.0 g, 104 mmol) in dichloromethane (250 mL) at −78°C until the starting material was consumed (TLC). Dimethyl sulfide (7 mL) was then added and the reaction mixture was allowed to warm slowly to ambient temperature (21°C) over 12 h. The reaction mixture was then concentrated to afford the crude enal. 2,2-Dimethyl-1,3-propanediol (44 g, 0.42 mol) and oxalic acid dihydrate (0.5 g) were added to a stirred solution of the crude enal in benzene (150 mL) and the resultant mixture was heated at reflux in a Dean–Stark water separator for 10 h. The reaction mixture was then cooled to ambient temperature and treated with a saturated aqueous solution

of sodium bicarbonate (100 mL) and diluted with ether (500 mL). The organic phase was separated, washed with water (5 × 50 mL), brine (2 × 25 mL), dried, and concentrated. Chromatography (hexanes) afforded the acetal **7** (15.8 g, 64%) as a light yellow oil that was crystallized from hexane to afford a white solid; mp 38–40.5°C; IR ($CHCl_3$): 3011, 2935, 1658, 1464, 1220, 1090 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.73 (s, 3H), 1.03 (s, 6H), 1.27 (s, 3H), 1.38–1.43 (m, 2H), 1.51–1.58 (m, 2H), 1.94–2.00 (m, 2H), 1.96 (s, 3H), 3.47–3.69 (m, 4H), 4.86 (s, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 19.1, 20.7, 22.0, 23.9, 28.1, 30.0, 33.6, 39.5, 78.3, 101.8, 134.3, 135.2; HRMS (EI) calcd. for $C_{15}H_{26}O_2$: 238.1934; found: 238.1918.

2,6,6-Trimethylcyclohexene-1-carboxaldehyde ethylidene acetal (9)

Ozone was passed through a stirred solution of β-ionone **8** (10.0 mL, 49.1 mmol) in dichloromethane (125 mL) at −78°C until the starting material was consumed (TLC). Dimethyl sulfide (20 mL) was then added and the reaction mixture was allowed to warm slowly to ambient temperature over 12 h. The reaction mixture was then concentrated to afford the crude enal. Ethylene glycol (30 mL) and oxalic acid dihydrate (100 mg) were added to a stirred solution of the crude enal in benzene (150 mL) and the resultant mixture was heated at reflux in a Dean–Stark water separator for 22 h. The reaction mixture was then cooled to ambient temperature, treated with a saturated aqueous solution of sodium bicarbonate (20 mL), and diluted with ether (100 mL). The organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (25 mL), then with brine (2 × 50 mL), dried, and concentrated. The residual oil was distilled (Kugelrohr, oven temperature ~130°C, 20 Torr (1 Torr = 133.3 Pa) to afford the acetal **9** (4.3 g, 45%) as a pale yellow oil; IR ($CHCl_3$): 2940, 1450, 1230, 1035 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.06 (s, 6H), 1.37–1.49 (m, 2H), 1.52–1.55 (m, 2H), 1.74 (s, 3H), 1.93–2.02 (m, 2H), 3.82–4.06 (m, 4H), 5.31 (s, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ:19.1, 23.9, 28.2, 34.1, 35.1, 40.1, 64.4, 102.3, 132.2, 137.3; HRMS (EI) calcd. for $C_{12}H_{20}O_2$: 196.1464; found: 196.1462.

3-Oxo-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (10)

Potassium dihydrogen phosphate (8.59 g, 63.1 mmol) and selenium dioxide (4.95 g, 47.0 mmol) were added to a stirred solution of the acetal **7** (4.80 g, 20.0 mmol) in toluene (280 mL). The resultant mixture was heated at reflux until the starting material was consumed (~2 h, TLC and GC) and then cooled to ambient temperature. The reaction mixture was then treated with a saturated aqueous solution of sodium bicarbonate (100 mL) and diluted with ether (250 mL). The organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (50 mL), then with brine (50 mL), dried, and concentrated to afford a mixture of the ketone **10** and the corresponding allylic alcohol as a viscous black oil. Magnesium sulfate (1.75 g, 14.6 mmol) and pyridinium dichromate (7.52 g, 20.0 mmol) were added sequentially to a solution of the above mixture of products in dichloromethane (50 mL). The resultant mixture was stirred at ambient temperature for 3.5 h and then filtered through a pad of Florisil® with ether. The filtrate was concentrated and then chromatographed (10% ethyl acetate in hexanes) to afford the ketone **10** (3.1 g, 62%) as a pale yellow oil that crystallized on standing; mp 67.5–69.5°C; IR ($CHCl_3$): 2946, 1673, 1466, 1086, 1017 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.75 (s, 3H), 1.23 (s, 9H), 1.28 (s, 3H), 1.79 (apparent t, 2H), 2.45 (apparent t, 2H), 3.50 (apparent d, J = 11.1 Hz, 2H), 3.72 (apparent d, J = 11.1 Hz, 2H), 5.07 (s, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 11.9, 22.0, 23.8, 26.4, 30.2, 34.0, 35.0, 37.8, 78.1, 101.5, 133.8, 155.3, 199.8; HRMS (EI) calcd. for $C_{15}H_{24}O_3$: 252.1726; found: 252.1742.

3-Oxo-2,6,6-trimethylcyclohexene-1-carboxaldehyde ethylidene acetal (11)

Anhydrous potassium carbonate (2.0 g), *N*-bromosuccinimide (5.5 g, 31 mmol), and 2,2′-azobis(isobutyronitrile) (AIBN) (100 mg, 0.6 mmol) were added sequentially to a stirred solution of the acetal **9** (5.5 g, 28 mmol) in carbon tetrachloride (50 mL) and the resultant mixture was heated at reflux. During the first 30 min additional AIBN (4 × 50 mg, 1.2 mmol) was added at intervals of 5–10 min. Heating was continued for a total of 2 h. The reaction mixture was then cooled to ambient temperature and potassium carbonate (2.0 g) was added. The resultant mixture was filtered through a small plug of magnesium sulfate onto potassium carbonate (2.0 g). The filtrate was concentrated and the residue dissolved in water (5 mL) and dimethyl sulfoxide (20 mL). This mixture was heated at 50°C for 48 h and then cooled to ambient temperature. Ether (300 mL) was added, the organic phase separated, and the aqueous phase was extracted further with ether (5 × 100 mL). The combined organic extracts were washed with water (5 × 40 mL), then with brine (2 × 40 mL), dried, and concentrated to afford the corresponding crude allylic alcohol as an oil. This crude product was used in subsequent experiments. Chromatography (30% ethyl acetate in hexanes containing 0.3% v/v triethylamine) of the crude product (300 mg) afforded an analytically pure sample of the allylic alcohol (92 mg, 29%) as a colourless oil. IR (neat): 3409, 2920, 1449, 1226, 1050 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.40 (s, 3H), 1.10 (s, 3H), 1.30–1.40 (m, 1H), 1.48–1.95 (m, 3H), 1.86 (s, 3H), 3.82–3.97 (m, 3H), 4.02–4.10 (m, 2H), 5.30 (s, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 16.6, 27.0, 27.9, 28.3, 34.2, 35.4, 64.5, 64.6, 70.6, 102.0, 136.0, 137.7; HRMS (EI) calcd. for $C_{12}H_{20}O_3$: 212.1413; found: 212.1389. Oxalyl chloride (1.90 mL, 22 mmol) was added to a stirred solution of dimethyl sulfoxide (1.70 mL, 24 mmol) in dichloromethane (200 mL) at −78°C. The resultant mixture was stirred at −78°C for 15 min and then a solution of the above crude allylic alcohol (4.2 g, ~6 mmol) in dichloromethane (25 mL) was added. After an additional 15 min triethylamine (13 mL, 93 mmol) was added. After a further 30 min the reaction mixture was allowed to warm to ambient temperature and then a saturated aqueous solution of sodium bicarbonate (50 mL) and ether (400 mL) were added. The organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (50 mL), then with brine (2 × 50 mL), dried, and concentrated. Chromatography (15% ethyl acetate in petroleum ether containing 0.3% v/v triethylamine) afforded the ketone **11** (1.1 g, 87%) as a colourless oil. IR ($CHCl_3$): 2940, 1673, 1460, 1228, 1027 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.22 (s, 6H), 1.29 (apparent t, 2H), 1.32 (s, 3H), 2.46 (apparent t, 2H), 3.86–4.12 (m, 4H), 5.45 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 11.2,

26.4, 34.1, 38.2, 64.8, 101.8, 135.3, 154.7, 199.6; HRMS (EI) calcd. for $C_{12}H_{18}O_3$: 210.1256; found: 210.1256.

3-Triisopropylsilyloxy-2,6,6-trimethyl-1,3-cyclohexadiene-1-carboxaldehyde ethylidene acetal (12)

Potassium hexamethyldisilazide (3.3 mL, 0.5 M in toluene, 1.7 mmol) and HMPA (200 μL, 1.15 mmol) were added sequentially to a stirred solution of the ketone **11** (273 mg, 1.29 mmol) in THF (80 mL) at −78°C. The resultant mixture was stirred for 15 minutes and then triisopropylsilylchloride (357 μL, 1.67 mmol) was added and the reaction was allowed to warm to 0°C. A saturated aqueous solution of sodium bicarbonate (20 mL) was then added and the THF was removed in vacuo. The resultant aqueous residue was extracted with ether (200 mL) and the extract was washed with a saturated aqueous solution of sodium bicarbonate (25 mL), then with brine (2 × 25 mL), dried, and concentrated. Chromatography (5% ethyl acetate in hexanes) afforded the silyl enolether **12** (407 mg, 86%) as a colourless oil. IR (neat): 2947, 2867, 1655, 1465, 1221, 1069 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.02–1.22 (m, 28H), 1.85 (s, 3H), 2.00 (apparent d, J = 4.7 Hz, 1H), 3.82–4.08 (m, 4H), 4.81 (apparent t, J = 4.7 Hz, 1H), 5.59 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 12.7, 13.0, 18.1, 26.2, 33.4, 39.4, 69.4, 100.7, 102.8, 134.1, 134.3, 149.0; HRMS (EI) calcd. for $C_{21}H_{38}O_3Si$: 366.2592; found: 366.2590.

3-Oxo-2,6,6-trimethyl-1,4-cyclohexadiene-1-carboxaldehyde neopentylidene acetal (13)

n-Butyllithium (19.5 mL, 2.5 M in hexanes, 49 mmol) was added to a stirred solution of *N,N*-diisopropylamine (7.0 mL, 50 mmol) in THF (100 mL) at 0°C. The resultant mixture was stirred at 0°C for 30 min. and then cooled to −78°C. A solution of the ketone **10** (10.1 g, 40.0 mmol) in THF (50 mL) was then added and, after a further 15 min, a solution of phenylselenyl bromide (11.3 g, 47.9 mmol) in THF (50 mL) was added. The resultant mixture was allowed to warm to ambient temperature and a saturated aqueous solution of sodium bicarbonate (150 mL) was added. The THF was removed in vacuo and the aqueous residue was then dissolved in methanol (300 mL) and stirred at 0°C. Oxone® (61.5 g, 100 mmol) was added and the resultant mixture was stirred at ambient temperature for 12 h. The methanol was then removed in vacuo and the resultant aqueous residue was diluted with water (100 mL) and extracted with ether (3 × 300 mL). The combined organic extracts were dried and concentrated. Chromatography (3:1 to 1:2, petroleum ether/ether) afforded the ketone **10** (3.42 g, 34%) and the dienone **13** (5.64 g, 56%, 85% based on recovered starting material) as a white solid; mp 84–86°C; IR ($CHCl_3$): 2950, 1662, 1633, 1169, 1088 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.76 (s, 3H), 1.30 (s, 9H), 2.13 (s, 3H), 3.49–3.77 (m, 4H), 5.17 (s, 1H), 6.14 (d, J = 9.9 Hz, 1H), 6.67 (d, J = 9.9 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 11.8, 22.1, 23.9, 25.3, 30.3, 39.2, 78.3, 101.5, 125.1, 135.0, 153.0, 157.5, 187.2; HRMS (EI) calcd. for $C_{15}H_{22}O_3$: 250.1570; found: 250.1564. Anal. calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 71.79, H 8.78.

(5*R)-Methylthio-3-oxo-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (14)**

A solution of lithium methylthiolate (~24 mmol) (prepared by adding methyllithium (17.2 mL, 1.4 M in ether, 24.1 mmol) to a stirred solution of methyl disulfide (6.00 mL, 66.6 mmol) in THF (100 mL) at 0°C) was added to a stirred solution of the dienone **13** (400 mg, 1.60 mmol) and 12-crown-4 (48 μL, 0.30 mmol) in THF (20 mL) at 0°C . Methanol (1.0 mL, 25 mmol) was then added and the resultant mixture was stirred at ambient temperature for 12 h. A saturated aqueous solution of ammonium chloride (50 mL) was then added and the THF was removed in vacuo. The resultant aqueous residue was extracted with ether (200 mL) and the organic extract was washed with brine (2 × 25 mL), dried, and concentrated. Chromatography (10% ethyl acetate in hexanes) afforded the thioether **14** (414 mg, 87%) as a colourless oil that solidified on standing; mp 76.5–78.5°C; IR ($CHCl_3$): 3019, 1672, 1469, 1321, 1217, 1082 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.73 (s, 3H), 1.20 (s, 3H), 1.25 (s, 3H), 1.41 (s, 3H), 2.00 (s, 3H), 2.07 (s, 3H), 2.59–2.83 (m, 3H), 3.44–3.50 (m, 2H), 3.67–3.73 (m, 2H), 5.07 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 11.9, 15.5, 20.9, 22.1, 23.9, 25.4, 30.3, 40.4, 40.7, 54.0, 78.2, 101.6, 134.0, 155.0, 198.2; HRMS (EI) calcd. for $C_{16}H_{26}O_3S$: 298.1610; found: 298.1605. Anal. calcd. for $C_{16}H_{26}O_3S$: C 64.39, H 8.78; found: C 64.25, H 8.47.

3-Oxo-(5*S)-vinyl-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (16)**

Vinylmagnesium bromide (69.0 mL, 1 M in THF, 69.0 mmol) was added to a stirred suspension of copper(I) iodide (6.50 g, 34.1 mmol) in THF (200 ml) at −20°C. The resultant mixture was stirred for 10 min and then cooled to −78°C. A solution of the dienone **13** (5.71 g, 22.8 mmol) and trimethylsilylchloride (11.5 mL, 90.6 mmol) in THF (50 mL) was then added via a cannula. The reaction mixture was then allowed to warm to ambient temperature over 1 h and was recooled to 0°C. A saturated aqueous solution of ammonium chloride (100 mL) was then added, the resultant mixture was filtered through a pad of Celite, and the filter cake was washed with ether (200 mL). The aqueous phase of the filtrate was extracted further with ether (3 × 100 mL) and the combined organic extracts were dried and concentrated. Chromatography (4:1 to 3:1, petroleum ether/ether) afforded the vinyl ketone **16** (4.37 g, 69%) as a white solid; mp 85.5–87°C; IR ($CHCl_3$): 3018, 2964, 1671, 1468, 1218, 1085 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.75 (s, 3H), 1.09 (s, 3H), 1.23 (s, 3H), 1.28 (s, 3H), 2.04 (s, 3H), 2.45 (m, 2H), 2.46 (m, 1H), 3.47–3.75 (m, 4H), 4.99–5.34 (m, 2H), 5.10 (s, 1H), 5.68–5.86 (m, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 11.9, 20.5, 22.1, 23.9, 25.4, 30.3, 38.1, 39.4, 49.2, 101.6, 117.2, 133.8, 137.3, 155.3, 199.3; HRMS (EI) calcd. for $C_{17}H_{26}O_3$: 278.1882; found: 278.1870. Anal. calcd. for $C_{17}H_{26}O_3$: C 73.35, H 9.41; found: C 73.34, H 9.26.

5-Methylthio-3-oxo-2,6,6-trimethyl-1,4-cyclohexadiene-1-carboxaldehyde neopentylidene acetal (17)

N-Chlorosuccinimide (129 mg, 0.97 mmol) was added to a stirred solution of the thioether **14** (204 mg, 0.685 mmol) in carbon tetrachloride (50 mL) at ambient temperature. The resultant mixture was heated at reflux for 3.5 h and then cooled to ambient temperature. The reaction mixture was then filtered through a small pad of magnesium sulfate and concentrated. Chromatography (60% ether in hexanes) afforded the thio enolether **17** (196 mg, 97%) as a colourless oil that solidified on standing; mp 89–91.5°C; IR ($CHCl_3$): 3016, 2961, 1647, 1620, 1348, 1216, 1170 cm^{-1}; ^1H NMR (200 MHz,

For personal use only.

$CDCl_3$) δ: 0.77 (s, 3H), 1.31 (s, 3H), 1.41 (s, 6H), 2.20 (s, 3H), 2.32 (s, 3H), 3.50–3.79 (m, 4H), 5.15 (s, 1H), 6.06 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 11.9, 14.3, 22.1, 24.0, 27.0, 30.3, 42.9, 78.5, 101.6, 118.2, 134.3, 153.3, 171.7, 183.6; HRMS (EI) calcd. for $C_{16}H_{24}O_3S$: 296.1447; found: 296.1442.

(5*R**)-Methylthio-3-triisopropylsilyloxy-2,6,6-trimethyl-1,3-cyclohexadiene-1-carboxaldehyde neopentylidene acetal (18)

Collidine (67 μL, 0.51 mmol) and triisopropylsilyltrifluoromethanesulfonate (90 μL, 0.33 mmol) were added sequentially to a stirred solution of the thioether **14** (50 mg, 0.17 mmol) in dichloromethane (5 mL) at 0°C. After 5 min a saturated aqueous solution of sodium bicarbonate (5 mL) and ether (50 mL) were added and the phases were separated. The organic phase was washed with a saturated aqueous solution of sodium bicarbonate (5 mL), brine (2 × 10 mL), dried, and concentrated. Chromatography (10% ethyl acetate in hexanes) afforded the silyl enolether **18** (72 mg, 95%) as a colourless oil. IR (neat): 2947, 2867, 1649, 1596, 1465, 1238, 1090 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.72 (s, 3H), 1.05–1.15 (m, 21H), 1.20 (s, 3H), 1.25 (s, 3H), 1.43 (s, 3H), 1.93 (s, 3H), 1.94 (s, 3H), 3.00 (d, J = 6.4 Hz, 1H), 3.41–3.72 (m, 4H), 4.89 (d, J = 6.4 Hz, 1H), 5.17 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 12.7, 12.8, 13.4, 18.1, 22.2, 23.9, 24.4, 28.2, 30.2, 38.1, 54.9, 78.3, 100.9, 102.2, 131.3, 135.8, 150.0; HRMS (EI) calcd. for $C_{24}H_{43}O_3Si$ ($M^+ - CH_3S$): 407.2983; found: 407.2949.

(3*S**)-Hydroxy-(5*S**)-vinyl-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (19)

Cerium trichloride heptahydrate (353 mg, 0.95 mmol) was added to a stirred solution of the ketone **16** (252 mg, 0.91 mmol) in methanol (10 mL) at ambient temperature. After 10 min the reaction mixture was cooled to 0°C and sodium borohydride (76 mg, 2.0 mmol) was then added in one portion. The reaction was monitored (TLC) and, once complete, a saturated aqueous solution of ammonium chloride (2 mL) was added. The methanol was removed in vacuo and the resultant aqueous residue was extracted with ether (4 × 25 mL). The combined organic extracts were dried and concentrated to afford, as a single diastereomer, the alcohol **19** (245 mg, 96%) as a white solid; mp 42–44°C; IR ($CHCl_3$): 3402, 2955, 1639, 1464, 1387, 1089 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.73 (s, 3H), 0.93 (s, 3H), 1.05 (s, 3H), 1.28 (s, 3H), 1.41–1.63 (m, 1H), 1.89–2.14 (m, 2H), 2.09 (s, 3H), 3.45–3.73 (m, 4H), 4.04–4.12 (apparent br t, 2H), 4.86 (s, 1H), 4.96–5.07 (m, 2H), 5.69–5.87 (m, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 15.7, 21.5, 22.0, 23.9, 25.7, 30.0, 34.2, 37.4, 47.7, 71.1, 78.3, 115.8, 137.1, 137.3, 139.0; HRMS (HI) calcd. for $C_{17}H_{28}O_3$: 280.2039; found: 280.2038.

(3*S**)-*tert*-Butyldimethylsilyloxy-(5*S**)-vinyl-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (22)

Collidine (2.0 mL, 15 mmol) and *tert*-butyldimethylsilyltrifluoromethanesulfonate (2.2 mL, 9.6 mmol) were added sequentially to a stirred solution of the alcohol **19** (2.25 g, 8.04 mmol) in dichloromethane (50 mL) at 0°C. The resultant mixture was stirred for 5 min and then a saturated aqueous solution of sodium bicarbonate (100 mL) and ether (350 mL) were added. The organic phase was separated and washed with a saturated aqueous solution of sodium bicarbonate (50 mL), brine (50 mL), dried, and concentrated. Chromatography (5% ethyl acetate in hexanes) afforded the alcohol **19** (0.57 g, 25%) and the silylether **22** (2.29 g, 72%) as a white solid; mp 100–101°C; IR ($CHCl_3$): 2952, 2857, 1639, 1468, 1215, 1083 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.03 (s, 3H), 0.05 (s, 3H), 0.73 (s, 3H), 0.87 (s, 9H), 0.92 (s, 3H), 1.04 (s, 3H), 1.27 (s, 3H), 1.56–1.72 (m, 3H), 2.01 (s, 3H), 3.49–3.73 (m, 4H), 4.06–4.15 (m, 1H), 4.85 (s, 1H), 4.94–5.05 (m, 2H), 5.68–5.86 (m, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: −4.9, −4.1, 16.4, 18.1, 21.7, 22.1, 24.1, 25.9, 30.1, 34.7, 37.4, 48.1, 71.9, 78.4, 78.5, 102.2, 115.6, 136.2, 138.4, 139.5; HRMS (EI) calcd. for $C_{23}H_{42}O_3Si$: 394.2905; found: 394.2887. Anal. calcd. for $C_{23}H_{42}O_3Si$: C 70.00, H 10.73, found: C 70.04, H 10.73.

(3*S**)-*tert*-Butyldiphenylsilyloxy-(5*S**)-vinyl-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (23)

Imidazole (1.60 g, 23.5 mmol), *tert*-butyldiphenylsilylchloride (4.20 g, 15.3 mmol), and *N,N*-dimethyl-4-aminopyridine (0.93 g, 7.6 mmol) were added sequentially to a stirred solution of the alcohol **19** (2.13 g, 7.59 mmol) in dichloromethane (20 mL) at 0°C. The reaction mixture was stirred for 16 h at ambient temperature and then a saturated aqueous solution of ammonium chloride (50 mL) was added. The aqueous phase was separated and extracted further with dichloromethane (3 × 50 mL). The combined organic extracts were dried and concentrated. Chromatography (9:1, petroleum ether/ether) afforded the silylether **23** (3.98 g, 100%) as a white solid; mp 119–122°C; IR ($CHCl_3$): 3017, 2954, 2859, 1639, 1426, 1216 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.74 (s, 3H), 0.92 (s, 3H), 0.98 (s, 3H), 1.05 (s, 9H), 1.26 (s, 3H), 1.57–1.85 (m, 3H), 2.07 (s, 3H), 3.44–3.78 (m, 4H), 4.11–4.19 (m, 1H), 4.73–4.96 (m, 2H), 4.85 (s, 1H), 5.59–5.77 (m, 1H), 7.30–7.46 (m, 6H), 7.51–7.76 (m, 4H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 16.6, 19.2, 21.6, 21.9, 23.8, 25.4, 26.9, 29.9, 33.9, 37.0, 47.4, 72.9, 78.1, 78.3, 101.9, 115.2, 127.0, 127.3, 129.1, 129.3, 133.3, 134.4, 135.9, 136.0, 138.2, 138.9; HRMS (EI) calcd. for $C_{33}H_{46}O_3Si$: 518.3218; found: 518.3199. Anal. calcd. for $C_{33}H_{46}O_3Si$: C 76.40, H 8.94; found: C 76.44, H 8.88.

(5*R**)-Carboxaldehyde-3-oxo-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (20)

Ozone was passed through a stirred solution of the vinyl ketone **16** (107 mg, 0.39 mmol) in dichloromethane (10 mL) at −78°C until the starting material was consumed (TLC). Dimethyl sulfide (2 mL) was then added and the reaction mixture was allowed to warm to ambient temperature over 12 h. The reaction mixture was maintained at this temperature for a further 40 h and then concentrated. Chromatography (15% ethyl acetate in petroleum ether) afforded the ketoaldehyde **20** (60 mg, 56%) as a pale yellow solid; mp 67–69°C; IR ($CHCl_3$): 2958, 2720, 1720, 1676, 1223, 1086 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.76 (s, 3H), 1.27 (s, 3H), 1.34 (s, 3H), 1.51 (s, 3H), 1.99 (s, 3H), 2.53–2.78 (m, 3H), 3.46–3.75 (m, 4H), 5.12 (s, 1H), 9.87 (d, J = 1.6 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 11.8, 21.9, 22.1, 23.9, 26.5, 30.3, 33.7, 37.6, 56.5, 78.2, 101.3, 134.4, 153.4, 197.4, 202.2; HRMS (EI) calcd. for $C_{16}H_{24}O_4$: 280.1675; found: 280.1672.

(3*S)-*tert*-Butyldimethylsilyloxy-(5*R**)-carboxaldehyde-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (25)**

Ozone was passed through a stirred solution of the alkene **22** (2.28 g, 5.79 mmol) in dichloromethane (100 mL) at −78°C until the starting material was consumed (TLC). Dimethyl sulfide (10 mL) was then added and the reaction mixture was allowed to warm to ambient temperature over 12 h. The reaction mixture was then heated (~40°C) for 24 h and then concentrated to afford the aldehyde **25** (2.22 g, 97%) as a light yellow viscous oil. IR ($CHCl_3$): 2957, 2858, 1709, 1467, 1216, 1086 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.07 (s, 3H), 0.10 (s, 3H), 0.74 (s, 3H), 0.88 (s, 9H), 1.15 (s, 3H), 1.70–1.80 (m, 1H), 2.02 (s, 3H), 2.08–2.13 (m, 1H), 2.20–2.29 (m, 1H) 2.28 (s, 3H), 2.29 (s, 3H), 3.47–3.77 (m, 4H), 4.07 (apparent t, 1H), 4.91 (s, 1H), 9.83 (d, J = 3.1 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 205.0 (CO); HRMS (EI) calcd. for $C_{22}H_{40}O_4Si$: 396.2697; found: 396.2705.

(3*S)-*tert*-Butyldiphenylsilyloxy-(5*R**)-carboxaldehyde-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (24)**

Ozone was passed through a stirred solution of the alkene **23** (3.91 g, 7.49 mmol) in dichloromethane (150 mL) at −78°C until the starting material was consumed (TLC). Dimethyl sulfide (5 mL) was then added and the reaction mixture was allowed to warm to ambient temperature over 16 h. The resultant mixture was concentrated to afford the crude aldehyde **24** (4.1 g, 99%) as a colourless oil that was used directly in subsequent experiments. IR ($CHCl_3$): 3018, 2955, 2858, 2754, 1718, 1675, 1216 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.75 (s, 3H), 1.05 (s, 9H), 1.14 (s, 3H), 1.19 (s, 3H), 1.27 (s, 3H), 1.80–1.98 (m, 3H), 1.98 (s, 3H), 3.44–3.77 (m, 4H), 4.07 (apparent t, 1H), 4.87 (s, 1H), 7.31–7.46 (m, 6H), 7.64–7.74 (m, 4H), 9.63 (d, J = 3.1 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 17.1, 19.4, 22.1, 23.0, 24.0, 26.7, 27.0, 29.3, 30.1, 36.3, 55.7, 71.9, 78.4, 78.5, 101.5, 127.4, 127.5, 127.6, 127.8, 129.6, 129.7, 133.2, 136.0, 136.1, 138.5, 204.4; HRMS (EI) calcd. for $C_{32}H_{44}O_4Si$: 520.3010; found: 520.3028.

(3*S)-*tert*-Butyldimethylsilyloxy-5-oxo-2,6,6-trimethyl-cyclohexene-1-carboxaldehyde neopentylidene acetal (26)**

Collidine (580 μL, 4.39 mmol) and *tert*-butyldimethylsilyltrifluoromethanesulfonate (500 μL, 2.18 mmol) were added sequentially to a stirred solution of the aldehyde **25** (206 mg, 0.52 mmol) in dichloromethane (5 mL) at ambient temperature. The resultant mixture was stirred for 8 h and then a saturated aqueous solution of sodium bicarbonate (5 mL) and ether (100 mL) were added. The organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (10 mL), then with brine (2 × 10 mL), dried, and concentrated to afford the corresponding silyl enolether. ^1H NMR (200 MHz, $CDCl_3$) δ: 0.05 (s, 6H), 0.71 (s, 3H), 0.84 (s, 9H), 1.10 (s, 3H), 1.15 (s, 3H), 1.24 (s, 3H), 1.82–1.90 (m, 2H), 2.02 (s, 3H), 3.38–3.72 (m, 4H), 4.07 (d, J = 5 Hz), 4.74 (s, 1H), 5.40 (s, 1H). Ozone was passed through a stirred solution of the above silyl enolether in dichloromethane (10 mL) at −78°C until the starting material was consumed (TLC). Dimethyl sulfide (2 mL) was then added and the reaction mixture was allowed to warm to ambient temperature over 12 h. On concentration of the reaction mixture, chromatography (5% to 20% ethyl acetate in petroleum ether) afforded the ketone **26** (33 mg, 17%) as a white solid; mp 88–90.5°C; IR ($CHCl_3$): 2958, 1718, 1468, 1216, 1083 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.048 (s, 6H), 0.74 (s, 3H), 0.84 (s, 9H), 1.20 (s, 3H), 1.24 (s, 3H), 1.28 (s, 3H), 2.10 (s, 3H), 2.57 (dd, J = 13.4, 6.0 Hz, 1H), 2.74 (dd, J = 13.4, 4.6 Hz, 1H), 3.45–3.74 (m, 4H), 4.25 (apparent t, 1H), 4.90 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: −4.8, −4.6, 17.7, 17.9, 22.2, 23.8, 24.0, 24.6, 25.7, 30.2, 45.7, 47.1, 72.1, 78.5, 101.7, 134.7, 137.4, 212.2; HRMS (EI) calcd. for $C_{17}H_{29}O_4Si$ (M^+ − *t*-Bu): 325.1836; found: 325.1806. Anal. calcd. for $C_{21}H_{38}O_4Si$: C 65.92, H 10.01; found: C 66.09, H 9.87.

3(*S)-*tert*-Butyldimethylsilyloxy-(5*S**)-cyano-5-trimethylsilyloxy-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (27)**

Trimethylsilyl cyanide (500 μL, 3.75 mmol) was added to a stirred mixture of the ketone **26** (23 mg, 0.06 mmol), 18-crown-6 (5 mg, 0.02 mmol), and potassium cyanide (1 mg, 0.02 mmol) at ambient temperature. The resultant mixture was stirred for 3 h and then the excess trimethylsilylcyanide was removed in vacuo. A saturated aqueous solution of sodium bicarbonate (5 mL) and ether (100 mL) were then added. The organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (5 mL), then with brine (2 × 10 mL), dried, and concentrated to afford the cyanohydrin **27** (27 mg, 94%) as a colourless oil. ^1H NMR (200 MHz, $CDCl_3$) δ: 0.22 (s, 6H), 0.72 (s, 3H), 0.87 (s, 9H), 1.08 (s, 3H), 1.25 (s, 3H), 1.33 (s, 3H), 1.95 (s, 3H), 1.95–2.00 (m, 1H), 2.18–2.29 (m, 1H), 3.38–3.72 (m, 4H), 4.30–4.40 (m, 1H), 4.90 (s, 1H); HRMS (EI) calcd. for $C_{25}H_{47}O_4NSi$: 481.3046; found: 481.3030.

3-(2-*tert*-Butyldimethylsilyloxyethyl)-2,4-dimethyl-1,3-pentadiene (31)

A solution of *tert*-butyllithium (46 mL, 1.58 M in pentane, 73 mmol) was added to a stirred solution of 3-bromo-2,4-dimethyl-1,3-pentadiene **30** (18) (5.77 g, 33.0 mmol) in THF (100 mL) at −78°C. After 15 min ethylene oxide (13 mL, 0.3 mol) was added via a cannula. The reaction mixture was then stirred for 1 h at −78°C, for 1 h at 0°C, and then for 30 min at ambient temperature. Water (100 mL) was then added and the aqueous phase was extracted with ether (3 × 100 mL). The combined organic extracts were washed with brine (2 × 100 mL), dried, and concentrated. Chromatography (25% ether in petroleum ether) afforded the corresponding alcohol (3.60 g, 78%) as a colourless liquid. IR (neat): 3330, 2920, 1632, 1444, 1039 cm^{-1}; ^1H NMR (500 MHz, C_6D_6) δ: 1.68 (m, 9H), 1.80 (br m, 1H), 2.33 (t, J = 7.0 Hz, 2H), 2.33 (t, J = 7.0 Hz, 2H), 3.56 (t, J = 7.1 Hz, 2H), 4.60 (m, 1H), 4.91 (m, 1H); ^{13}C NMR (125 MHz, C_6D_6) δ: 19.8, 21.8, 22.6, 34.7, 61.2, 113.5, 128.3, 133.4, 146.8; HRMS (EI) calcd. for $C_9H_{16}O$: 140.1202; found: 140.1199. Anal. calcd. for $C_9H_{16}O$: C 77.09, H 11.50; found: C 76.98, H 11.72.

Imidazole (3.24 g, 47.6 mmol) and *tert*-butyldimethylsilylchloride (5.50 g, 36.5 mmol) were added sequentially to a stirred solution of the above alcohol (3.60 g, 25.7 mmol) in dichloromethane (100 mL) at ambient temperature. The resultant mixture was stirred for 20 min and then a saturated aqueous solution of sodium bicarbonate (30 mL) was added.

For personal use only.

The phases were separated and the aqueous phase was extracted further with dichloromethane (3 × 30 mL). The combined organic extracts were washed with brine (30 mL), dried, and concentrated. Chromatography (petroleum ether) afforded the diene **31** (5.20 g, 80%, 62% overall) as a colourless liquid. IR (neat): 2918, 1631, 1457, 1253, 1096, 841 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.03 (s, 6H), 0.87 (s, 9H), 1.64 (s, 3H), 1.67 (s, 3H), 1.74 (s, 3H), 2.32 (t, J = 8.1 Hz, 2H), 3.54 (dd, J = 8.1 Hz, 2H), 4.51 (br d, J = 2.7 Hz, 1H), 4.89 (m, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: −5.2, 18.3, 19.8, 21.7, 22.6, 26.0, 34.8, 61.8, 113.1, 127.2, 132.8, 146.6; HRMS (EI) calcd. for $C_{11}H_{21}OSi$ (M^+ − *t*-Bu): 197.1363; found: 197.1347.

2,4-Dimethyl-1,3-pentadiene-3-carboxaldehyde neopentylidene acetal (33)

A solution of *tert*-butyllithium (49 mL, 1.7 M in pentane, 83 mmol) was added to a stirred solution of 3-bromo-2,4-dimethyl-1,3-pentadiene **30** (6.60 g, 37.7 mmol) in THF (100 mL) at −78°C. The resultant mixture was stirred for 30 min and then *N,N*-dimethylformamide (8.7 mL, 113 mmol) was added. The reaction mixture was allowed to warm to ambient temperature over a period of 1 h and then a saturated aqueous solution of ammonium chloride (40 mL) and ether (200 mL) were added. The organic phase was separated and washed with a saturated aqueous solution of ammonium chloride (2 × 40 mL), dried, and concentrated. 2,2-Dimethyl-1,3-propanediol (12.0 g, 115 mmol) and oxalic acid dihydrate (1.0 g) were added to a stirred solution of the above crude aldehyde in benzene (100 mL) and the resultant mixture was heated at reflux in a Dean–Stark water separator for 16 h. The reaction mixture was then cooled to ambient temperature and was treated with a saturated aqueous solution of sodium bicarbonate (40 mL) and diluted with ether (100 mL). The organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (2 × 40 mL), dried, and concentrated. The residual oil was distilled (Kugelrohr, oven temperature ~125°C, 1 Torr) to afford the diene **33** (6.62 g, 84%) as a colourless oil. IR (neat): 2908, 1635, 1457, 1098, 924 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) δ: 0.70 (s, 3H), 1.19 (s, 3H), 1.71 (s, 3H), 1.77 (s, 3H), 1.88 (dd, J = 1.4, 1.0 Hz, 3H), 3.46 (m, 2H), 3.65 (m, 2H), 4.64 (m, 1H), 5.04 (m, 1H), 5.15 (s, 1H); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 19.8, 21.9, 22.2, 23.3, 23.9, 30.1, 77.7, 100.9, 114.8, 132.9, 134.8, 143.6; HRMS (EI) calcd. for $C_{13}H_{22}O_2$: 210.1621; found: 210.1632.

1-(2-*tert*-Butyldimethylsilyloxyethyl)-(5*R**)-carboxaldehyde-2,6,6-trimethylcyclohexene (34) and 3-(2-*tert*-butyldimethylsilyloxyethyl)-2,2,4-trimethyl-(6*S**)-vinyl-5,6-dihydro-2*H*-pyran (35)

Boron trifluoride diethyl etherate (1.70 mL, 13.8 mmol) was added to a stirred solution of the diene **31** (3.20 g, 12.6 mmol) and acrolein **32** (5.0 mL, 75 mmol) in dichloromethane (50 mL) at −78°C. The resultant mixture was stirred for 1 h and then a saturated aqueous solution of sodium bicarbonate (50 mL) was added and the reaction mixture was allowed to warm to ambient temperature. Ether (200 mL) was then added and the organic phase separated, washed with a saturated aqueous solution of sodium bicarbonate (2 × 50 mL), dried, and concentrated. Chromatography (10:1, petroleum ether/ether) afforded the aldehyde **34** (2.63 g, 67%) as a colourless oil and the dihydropyran **35** (1.0 g, 27%) as a colourless oil. Aldehyde **34**: IR (neat): 2944, 2858, 2726, 2353, 1722, 1467, 1253, 1089, 842 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.05 (s, 6H), 0.88 (s, 9H), 1.03 (s, 3H), 1.18 (s, 3H), 1.64 (s, 3H), 1.82–1.69 (m, 2H), 1.99–1.96 (m, 2H), 2.14 (dt, J = 10.0, 3.4 Hz, 1H), 2.30 (br t, J = 8.0 Hz, 2H), 3.55 (t, J = 8.0 Hz, 2H), 9.81 (d, J = 3.1 Hz, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: −5.2, 18.4, 19.7, 20.2, 23.5, 26.0, 27.7, 30.6, 32.1, 36.9, 57.6, 62.8, 129.4, 132.7, 206.4; HRMS (EI) calcd. for $C_{14}H_{25}O_2Si$ (M^+ − *t*-Bu): 253.1625; found: 253.1604. Anal. calcd. for $C_{18}H_{34}O_2Si$: C 69.62, H 11.04; found: C 69.01, H 11.22. Dihydropyran **35**: IR (neat): 2920, 1467, 1361, 1255, 1092, 841 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) δ: 0.05 (s, 6H), 0.88 (s, 9H), 1.27 (s, 6H), 1.66 (s, 3H), 1.78 (dd, J = 16.6, 3.2 Hz, 1H), 2.08 (ddd, J = 16.6, 10.9, 1.1 Hz, 1H), 2.23 (t, J = 8.5 Hz, 2H), 3.55 (m, 2H), 4.09 (m, 1H), 5.09 (dt, J = 10.4, 1.4 Hz, 1H), 5.22 (dt, J = 17.4, 1.4 Hz, 1H), 5.86 (ddd, J = 17.4, 10.4, 5.6 Hz, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: −5.2, 18.4, 19.6, 25.0, 26.0, 28.5, 32.9, 37.2, 62.4, 68.9, 76.0, 115.1, 126.5, 132.2, 139.4; HRMS (EI) calcd. for $C_{17}H_{31}O_2Si$ (M^+ − Me): 295.2095; found: 295.2073.

(5*R**)-Carboxaldehyde-2,6,6-trimethylcyclohexene-1-carboxaldehyde neopentylidene acetal (36) and 2,6,6-trimethylcyclohexene-1,5(*RS*)-dicarboxaldehyde (37)

Boron trifluoride diethyl etherate (3.60 mL, 29.3 mmol) was added to a stirred solution of the diene **33** (5.60 g, 26.6 mmol) and acrolein **32** (9.0 mL, 135 mmol) in dichloromethane (100 mL) at −78°C. After 20 min a saturated aqueous solution of sodium bicarbonate (150 mL) was added and the resultant mixture was allowed to warm to ambient temperature. Ether (200 mL) was then added and the organic phase was separated, washed with a saturated aqueous solution of sodium bicarbonate (2 × 25 mL), dried, and concentrated. Chromatography (5:1 to 1:1, petroleum ether/ether) afforded the aldehyde **36** (4.23 g, 60%) as white crystalline solid and the dialdehyde **37** (0.711 g, 25%) as a colourless oil. Aldehyde **36**: mp 63–66°C; IR (neat): 2914, 2868, 2833, 1719, 1465, 1090, 981 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 0.73 (s, 3H), 1.10 (s, 3H), 1.26 (s, 3H), 1.27 (s, 3H), 1.58–1.78 (m, 2H), 1.97 (s, 3H), 2.03–2.20 (m, 3H), 3.47 (d, J = 11.2 Hz, 2H), 3.70 (d, J = 11.2 Hz, 2H), 4.88 (s, 1H), 9.83 (d, J = 2.9 Hz, 1H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 19.4, 20.7, 22.1, 23.4, 24.0, 27.2, 30.2, 31.7, 36.1, 57.5, 78.5, 78.6, 101.4, 134.0, 135.6, 205.9; HRMS calcd. for $C_{16}H_{26}O_3$ (EI): 266.1883; found: 266.1874. Calculation of barriers to rotation in PEEK and some of its substituted derivatives[1]

S. Brownstein and J. Roovers

Abstract: Barriers to rotation have been calculated by molecular mechanics, using the force field MM+, for a fragment of PEEK and its methyl, ethyl, isopropyl, *tert*-butyl and di-*tert*-butyl, substituted derivatives. The barrier for the nearer C—O bond increases from 2.0 kcal/mol in KEEK to 16 kcal/mol in dibutyl substituted KEEK as the bulkiness of the substituent increases. The rotation barrier of the further C—O bond is not affected by the substituent.

Key words: rotation barriers, PEEK, molecular mechanics.

Résumé : Faisant appel à la mécanique moléculaire et au champ de forces MM+, on a calculé les barriéres à la rotation d'un fragment de «PEEK» et de ses dérivés méthyle, éthyle, isopropyle, *tert*-butyle et di-*tert*-butyle. Lorsque l'encombrement stérique du substituant augmente, la barrière de la liaison C—O la plus proche passe de 2,0 kcal/mol dans le «KEEK» à 16,0 kcal/mol dans le «KEEK» portant deux substituants butyles. La barrière à la rotation de la liaison C—O la plus éloignée n'est pas affectée par le substituant.

Mots clés : barriéres à la rotation, «PEEK», méchanique moléculaire.

Introduction

The effect of substituents on the performance of glassy polymeric membranes in gas permeation and gas separation is under intense study (1, 2). We mention the systematic studies of Paul and Koros and co-workers on the effects of substituents in polysulfones (3), polycarbonates (4), and polyphenylene oxide (5). Poly(aryl ether ketones), PEEK, are potential materials for high-temperature gas separation membranes because of their high thermal, chemical, and radiation stability (6). However, to optimize the gas permeation properties, substituents may have to be introduced into the parent polymers (7). The gas diffusion process is thought to be promoted by small local sub-T_g motions of the polymer chain and its substituents. These motions occur within a polymeric matrix with a disordered packing, which itself depends on the type of the polymer chain and of the substituents. For these reasons sub-T_g dynamic mechanical properties and the free volume of the polymer and its modified analogues are related to experimental gas permeation results (8).

In addition, one can simulate the energetics of simple motions of polymer chain fragments. There have been several studies of the barriers to rotation about the ether and carbonyl bonds in molecules relevant to small sections of poly(phenyl ether ether ketone) (PEEK) (9–11). Although fairly sophisticated calculations, e.g., 3-21G (9), CNDO/2 (11), and STO-3G (12), have been used in these studies, they have not considered the effect of substituents on the phenyl rings of the polymer. There have also been X-ray studies on PEEK and some model compounds to determine bond lengths, bond angles, and torsion angles (13–15). It seems worthwhile to calculate, by relatively simple methods, barriers to rotation about the ether bonds in longer fragment chains to compare with the calculations already reported with more elaborate methods and also to perform similar calculations with substituted phenyl rings. Since only a fragment of the polymer is being modeled, the name KEEK, or a variation thereof, is used for the various fragments.

Fig. 1. The connectivity and atom numbering of the polymer fragment used in the calculations.

Geometrical considerations and calculation procedures

The fragment of the PEEK chain used for the calculations is shown in Fig. 1 along with the numbering employed. Hydrogen atoms are not included in the figure for purposes of clarity but their presence was included in the calculations. The calculations were done using the force field MM+ in the computational package of HYPERCHEM 4.0.[3] The force field MM+ is a

variation of MM2 (16). Calculations were performed on a 486 personal computer operating at 33 MHz. Bond lengths and bond angles obtained in this study are compared with the values reported in other references and all are listed in Table 1.

Energies were calculated for the most stable conformations with the only restraint being the torsion angle about either the 15–16 or 11–15 carbon–oxygen bonds, since these are considered to be the most affected by substituents on carbon 17. It is found that if these calculations are performed while uniformly increasing or decreasing the restrained torsion angle, a true minimum energy conformation might be missed. Therefore the restrained angles are chosen in a somewhat arbitrary order to insure that energies for the real minima are always found. The barriers to rotation are taken as the difference in energy between the highest and lowest calculated minimum energies. The actual barriers will be somewhat higher than those

reported since the program did not permit restraining the torsion angles to the values that would correspond exactly to the highest energies.

Sample results for the 11–15 bond of KEEK and the 15–16 bond of DBKEEK are shown in Figs. 2 and 3. The value of 0° represents the two end bonds in the same plane adopting a *cis* position, and 180° is when they adopt the *trans* position.

Results and conclusions

The energy barriers to rotation about the carbon–oxygen bond on the ether linkage side of the polymer chain (O_{15}—C_{16}) and on the carbonyl side of the chain (C_{11}—O_{15}) are listed in Table 2, along with pertinent data from previous calculations. It can be seen that the results of the present calculations using a larger fragment and a simpler force field agree satisfactorily with previous results on diphenyl ether where more elaborate calculation methods were employed and smaller fragments were used in the calculations. Therefore we may conclude that satisfactory results can be obtained for polymer fragments of reasonable size using the simpler method and a less powerful computer, as in this study, to calculate conformations and energetics. It is also apparent that, within the limits of accuracy of the calculations, lengthening the fragment upon which calculations are made does not have any effect upon the barriers calculated for the central bonds. Of course it must be remembered that these calculations are for isolated fragments and do not include any interactions between individual chains in the bulk polymer.

It is also evident that a substituent in position 17 primarily affects the rotation barrier about the 15–16 bond with negligible disturbance of the 11–15 bond. This is in agreement with chemical intuition, which suggests that distant effects will be negligible. The addition of a bulky substituent in the 20 position does not appear to alter the barrier about the 15–16 bond, showing that there is no buttressing effect, as expected, since it is on the opposite side of the benzene ring. This is reasonable given the structure of the lowest energy conformation of DBKEEK, which is shown in Fig. 4. It should be noted that there is departure from strict planarity for this molecule because of the large steric effects of the two *tert*-butyl groups. Minor changes are not further discussed since they may be within the accuracy limits of the calculations.

In addition, these calculations suggest that the *tert*-butyl groups in DBKEEK encourage the polymer to adopt a particular extended chain conformation. Adjacent molecules could pack with the *tert*-butyl groups offset to give the high crystallinity that is observed (17)[4] in the di-*tert*-butyl PEEK homopolymer.

Isotope effects on the reaction of proton transfer to benzene anions in ethanol

Ricard Gelabert, Miquel Moreno, and José M. Lluch

Abstract: A theoretical study on the reaction of proton transfer from ethanol to benzene anions was performed at the ab initio level. It was found that in the gas phase the reaction proceeds without potential energy barrier with respect to reactants held at infinite distance, even though a potential energy barrier exists when measured from the prebarrier complex formed by the reactant molecules. When restrictions on orientation of the reactant molecules in the solid phase are taken into account, the potential energy barrier found exceeds 40 kcal/mol. A theoretical estimate of the kinetic isotope effect due to the tunneling effect, κ_H/κ_D, of 9.0×10^3 is found, in good agreement with available experimental data.

Key words: isotope effects, proton transfer, tunneling.

Résumé : Opérant au niveau ab initio, on a effectué une étude théorique de la réaction de transfert de proton de l'éthanol à des anions du benzène. On a trouvé que, en phase gazeuse, la réaction se produit sans barrière d'énergie potentielle par rapport aux réactifs à distance infinie, même s'il existe une barrière d'énergie potentielle lorsqu'on la mesure à partir du complexe précédant la barrière. Lorsqu'on tient compte des restrictions sur l'orientation des molécules de réactif à l'état solide, on observe que la barrière d'énergie potentielle est supérieure à 40 kcal/mol. L'évaluation théorique de l'effet isotopique cinétique dû à l'effet tunnel, κ_H/κ_D, conduit à une valeur de $9{,}0 \times 10^3$ en bon accord avec les données expérimentales disponibles.

Mots clés : effets isotopiques, transfert de proton, effet tunnel.

1. Introduction

Quantum mechanical phenomena, such as tunneling, are important in molecules and chemical reactions that involve significant motion of light atoms (1). Proton transfer reactions in particular are among the processes that exhibit a large tunneling effect (2–6). Chemical processes involving tunneling can be identified by several telltale factors such as surprisingly small activation energies due to the flattening of Arrhenius plots in the low-temperature end, and very large kinetic isotope effects (KIEs) when substituting transferring hydrogen atoms with deuterium (k_H/k_D) (1). These pieces of evidence become more obvious at lower temperatures.

When temperature is very low, reaction via tunneling is likely to become much more important than reaction through classical means, due to the fact that the chemical system under study is unlikely to have sufficient energy to cross over the potential energy barrier. In addition, at very low temperatures most reactant systems are found in condensed phases, either solid or liquid. These phase changes will have foreseeable effects on the rate constant of such processes, mostly due to the constraints enforced on the motion of the reactant molecules of the system, preventing these from adopting the optimal conformation for the reaction. Under such conditions, the contribution of tunneling to the overall rate constant is likely to become much more important, to the point that at certain temperatures the whole process could take place via a pure tunneling mechanism.

Miyazaki et al. studied the reaction of proton transfer from ethanol to a benzene anion produced by electron pulse radiolysis of an ethanol–benzene (5% mol) mixture at 77 K (7):

[1] $C_6H_6^- + CH_3CH_2OH \longrightarrow C_6H_7^{\cdot} + CH_3CH_2O^-$

This reaction has some points of interest. To begin with, reactions between neutral species and ions are known to generally occur with little or no activation energy in the gas phase (8). However, given that this reaction was studied at 77 K, it seemed likely that this could change, once in the solid phase. Additionally, tunneling could have an important role to play in this reaction at very low temperatures.

Experiments were carried out at 77 K and lower temperatures. It was seen that at temperatures around 20 K only benzene anions were formed after electron capture. When the experiment was carried out at 77 K it was discovered that reaction [1] had an activation energy of only 0.2 kcal/mol. Furthermore, it was found that when C_2H_5OH was used, reaction [1] took place in less than 1 μs, whereas it took between 100 μs and 30 min when C_2D_5OD was used instead. Accordingly, the kinetic isotope effect involved was estimated to be greater than 100 (7).

Both the magnitude of the kinetic isotope effect and the small value of the activation energy seem to indicate that an

important tunneling effect is involved in this reaction at 77 K. Miyazaki et al. tried to estimate theoretically the height of the potential energy barrier by means of the following equation for the rate constant at a given temperature (7):

$$[2] \quad k = \frac{A}{RT} \int_0^\infty G(\omega)\, e^{-\frac{\omega}{RT}}\, d\omega$$

where $G(\omega)$ is the permeability of the potential energy barrier for a particle of energy ω, and A is the frequency factor. When the dimensionality of the problem is reduced to just 1 dimension and the shape of the potential energy barrier is assumed to be parabolic or Eckart-type, analytic expressions exist for $G(\omega)$. Even though the local structure around a benzene molecule in an ethanol–benzene mixture at 77 K is not known, Miyazaki et al. estimated the jump distance of the proton from ethanol to benzene anion to be approximately 0.85 Å (7), assuming that the structure would be similar to that of crystalline ethanol. In this way the width of the energy barrier could be estimated.

By using eq. [2] it can be seen that, in order to theoretically reproduce a primary kinetic isotope effect of 100, a potential energy barrier of at least 4.5 kcal/mol should exist when an Eckart energy profile is used, and probably greater than that, given that 100 is just the lower limit for the KIE in this reaction at 77 K.

Our purpose in this paper has been to perform ab initio calculations in order to theoretically analyze the kinetics of reaction [1] in the gas phase. In a second stage, steps will be taken to estimate and justify the barrier height of the proton transfer in the solid phase, which should be large enough to account for the large KIE found experimentally.

2. Calculational details

Ab initio calculations were carried out with the GAUSSIAN 94 series of programs (9). The system under study has an odd number of electrons and hence the unrestricted Hartree–Fock formalism (UHF) was used throughout the calculations. The basis set chosen for these calculations had to be flexible enough to describe anionic species, and therefore diffuse functions had to be considered. Geometry optimizations were carried out with the 3-21+G split valence basis set (10), and the energies obtained in this way were recalculated with the higher 6-31+G basis set (10*b*, 11). Both basis sets include diffuse functions on heavy atoms in order to provide ampler space allowance for the additional electron in the system. Overall, the number of basis functions for the complete system was 141. No symmetry constraints, either local or global, were enforced at any point of the calculations. Due to severe convergence problems in the electronic wave function, the quadratic convergence algorithm, as implemented in GAUSSIAN 94, had to be used by default (12).

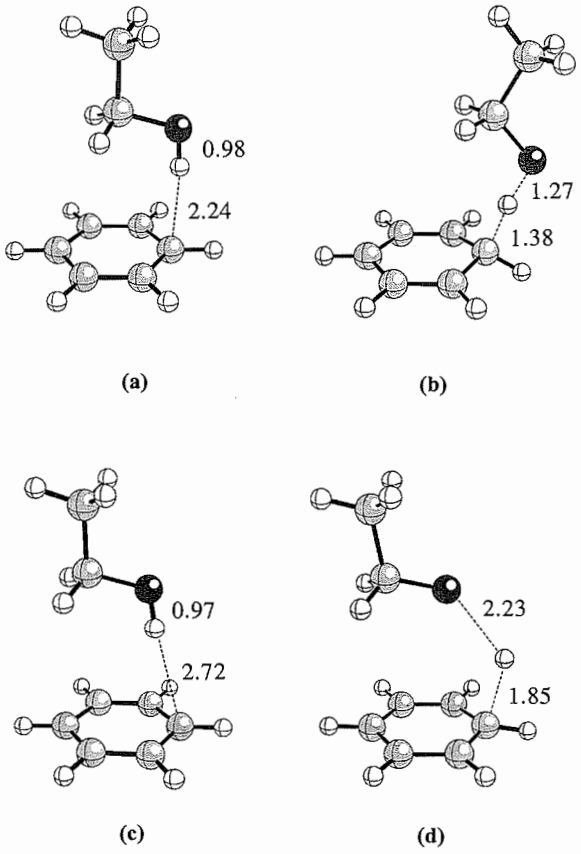
Schlegel's gradient optimization algorithm was used to perform geometry optimizations (13). When necessary, analytical second derivatives of the electronic energy were evaluated to characterize stationary points of the potential energy surface.

An important part of this chemical problem had much to do with the fact that the system was at 77 K, that is, in the solid phase. Steps were taken in order to simulate this fact in the calculations. The main difference when comparing solid and gas phases is that in the solid state the molecules are held fixed in a rigid crystalline matrix, and consequently they are not able to freely adopt the most favorable orientation for reacting. In other words, both reactants are initially neutral, but upon electron capture by benzene they are able to reach the best conformation in the gas phase to produce the reaction. Conversely, in the solid state the system is also initially neutral but, after electron capture, being part of the crystalline structure, it cannot achieve the optimal structure for ethanol + benzene anions. Hence, in order to take this particularity into account, calculations referring to the solid state were carried out fixing the relative distance and orientation of the ethanol molecule and the benzene anion to the optimum values of the ethanol molecule + benzene molecule in the gas phase (both taken as neutral species). After that, to simulate the proton transfer process once the electron has been captured by the benzene molecule, all geometry optimizations were carried out allowing internal relaxation of the internal structures of both molecules *but* holding them fixed in their previous relative positions, so that they cannot approach, rotate, or in any other way modify their relative situation in space. Additional information will be provided in the discussion section of this paper.

3. Results and discussion

The first point to be addressed is, logically, to determine the potential energy barrier height and geometries of reactants and transition state structures for reaction [1] in the gas phase. It was found that the reactants formed a stable "prebarrier complex," stabilized by 10.1 kcal/mol with respect to reactants separated at infinite distance at the 6-31+G//3-21+G level of calculation. From now on all energies will be given as corresponding to this same level of calculation. The transition state structure for the proton transfer was also sought. Both stationary points are depicted in Figs. 1*a* and *b*.

The transition state structure in Fig. 1*b* involved an intrinsic potential energy barrier of 9.6 kcal/mol. However, this structure is still 0.47 kcal/mol below the potential energy of the reactants held at infinite distance. Even though these values lack thermodynamical corrections, it can be seen that, as was expected for ion–molecule reactions in gas phase (8), the reaction will proceed with no potential energy barrier relative to reactants held at infinite distance. In any case, it is expected that the overall process may still have a positive free energy barrier due to entropic effects, according to Variational Transition State Theory (14).



Potential energy barriers are caused by the deformations that reactants must undergo to turn into products. There are semiquantitative methods that allow separation of the factors that contribute to a given energy barrier. In this paper we have used a partitive method based on a scheme first proposed by Morokuma and co-workers to quantify how much of the potential energy barrier is due to geometrical distortion (15, 16). Within this procedure, the contribution to the energy barrier coming from geometrical distortions of the reactants is evaluated as the difference in potential energy between the reactant molecule in its equilibrium conformation and the same molecule in the transition state structure geometry. This last energy is obtained in a calculation of the transition state structure in which all atoms not belonging to the reactant molecule under study have their nuclear charges changed to

Fig. 1. Reaction [1] in the gas phase: (*a*) prebarrier complex; (*b*) transition state structure. Simulation of reaction [1] in the solid phase, in which the relative position of both reactant molecules has been fixed to the optimum values of the ethanol molecule + benzene molecule in the gas phase (both taken as neutral species); (*c*) reactants; (*d*) transition state structure. Distances are given in Å.

zero, and their corresponding electrons have been eliminated from the system. In this way the energies of distortion of a given reactant molecule can be determined.

The reactant molecule that is most distorted upon reaching the transition state structure is the ethanol molecule, which experiences geometrical distortions amounting to 34.3 kcal/mol of the whole destabilization, this being 39.4 kcal/mol. This fact can be better understood if the nature of the geometrical distortions involved on going from reactants to transition state structure is considered. Concretely, the main geometrical distortion experienced by the system is the elongation of the oxygen–hydrogen distance. This geometrical parameter has a value of 0.98 Å in the free ethanol molecule at this level of calculation, whereas in the transition state structure the same distance measures 1.27 Å, which yields a total elongation of 0.29 Å. On the other hand, the benzene anion fragment, which a priori should undergo a severe geometrical distortion (one of the C—H bonds must go out of plane to make enough room for the incoming proton), only provokes an increase in energy of 5.1 kcal/mol. The stabilization energy can be obtained as the difference between the energy barrier and the sum of distortion energies:

$$[3] \quad \Delta V_{\text{stabilization}} = \Delta V_{\text{barrier}} - \sum \Delta V_{\text{distortion}}$$

Obviously, $\Delta V_{\text{stabilization}}$ is negative in sign. In this case, the energy of stabilization is −39.8 kcal/mol.

One of the goals of this paper has been to quantify the differences between solid phase and gas phase for the model reaction. To this end, some effort must be devoted to reproducing the experimental settings in the calculations. The procedure outlined in Sect. 2 has been adopted. Experiments begin with a crystal of frozen ethanol–benzene mixture at 77 K. After electron capture, and depending on temperature and isotopic substitutions carried out, the rate of reaction [1] becomes faster or slower. However, at 77 K the system is in the solid phase and in these conditions the reactant molecules can be considered fixed in a given relative orientation, while frozen in the positions they occupy in the crystal. What we have done to somehow reproduce this situation was to maintain the relative orientation and distances of the reactant system at the minimum values of these parameters found in the gas phase when both reactants are neutral, that is, before benzene anions are formed. It was assumed, then, that the crystal's structure does not significantly differ locally from the one found in the gas phase. This same assumption was adopted by Miyazaki et al. in the original paper, because the structure of a crystal corresponding to an ethanol–benzene mixture is not known experimentally (7). In all that follows, these restrictions on relative distances and orientation have been enforced, allowing the structures to relax internally. In this way, the "constrained" minimum and transition state were obtained, as is depicted in Figs. 1*c* and *d*.

Foreseeably, the potential energy barrier that will be obtained upon lengthening the O—H bond, while forcing the general orientation of the reactant molecules to remain as it was in the equilibrium situation of the neutral system, will be larger than the one found in the gas phase, relative to the prebarrier complex. Concretely, the potential energy barrier found was 39.2 kcal/mol, taking as origin of energies the structure of the neutral minimum in which an additional electron has been added to the system but without allowing the structure of the minimum to relax, or 44.3 kcal/mol above the structure of the anion if only internal relaxation was allowed. The barrier, in either case, is both *very* high and broad, and much higher than the 4.5 kcal/mol estimated by Miyazaki et al. as a lower minimum.

In addition, a different set of calculations was performed here, taking into account that Miyazaki et al. estimated the total distance moved by the proton being transferred as approximately 0.85 Å, based on the crystallographic data of pure ethanol. In our case, the rough distance the proton moved was substantially greater (about twice that value). To check the effects that a smaller distance between the ethanol molecule and the benzene anion would have on the barrier, we performed a different set of calculations in which the distance that the proton should move during the transference was about 1.0 Å. We observed that if both reactant molecules were forced to remain that close, then the proton transfer would occur without barrier.

Interesting information can be learned by analyzing the spin densities along the points of this constrained reaction coordinate and comparing them with those for the reaction in the gas phase. In the gas phase transition state structure, the spin density on the transferring atom has a value of 0.06 au, which would correspond to a proton (a hydrogen atom

© 1997 NRC Canada

deprived of electrons). In the transition state of the solid phase reaction, however, this spin density has a value of 0.84 au, much closer to the value one should expect for a free hydrogen atom (that is, 1.0 au). This difference in the nature of the transition state of both reactions, however, was not unexpected. Examining the O—H and H—C distances in both transition state structures, it can be seen that the solid phase distances ($R_{O—H}$ = 2.23 Å, $R_{C—H}$ = 1.85 Å) are much longer than those for the gas phase ($R_{O—H}$ = 1.27 Å, $R_{C—H}$ = 1.38 Å).

What effects would such a barrier have on the kinetic isotope effect for reaction [1] in the solid phase? To answer this, an expression for the value of the KIE is needed. Within transition state theory (TST), the KIE for the substitution of hydrogen by deuterium can be evaluated in the following way (14):

$$[4]\quad \mathrm{KIE} = \frac{\kappa_H(T)}{\kappa_D(T)} \times \frac{k_H(T)}{k_D(T)}$$

where $k_H(T)(k_D(T))$ is the kinetic rate constant within TST with classical motion along the reaction coordinate, and $\kappa_H(T)(\kappa_D(T))$ is the semiclassical transmission coefficient, which is the ratio of the thermally averaged quantum transmission probability through the potential energy barrier to the thermally averaged classical transmission probability across the same barrier (14):

$$[5]\quad \kappa_i(T) = \frac{\int_0^\infty P_i(E)\, e^{-\frac{E}{k_B T}}\, dE}{\int_{V^\ddagger}^\infty e^{-\frac{E}{k_B T}}\, dE}$$

$$= \frac{1}{k_B T}\, e^{\frac{V^\ddagger}{k_B T}} \int_0^\infty P_i(E)\, e^{-\frac{E}{k_B T}}\, dE$$

In eq. [5], $V^\ddagger$ is the height of the potential energy barrier for the reaction under study, and $P_i(E)$ is the quantum transmission probability of the potential energy barrier for the reactant system that transfers isotope i with total energy E. Bearing in mind that $V^\ddagger$ does not depend on the isotopic substitutions made on the system, eq. [4] becomes:

$$[6]\quad \mathrm{KIE} = \frac{\int_0^\infty P_H(E)\, e^{-\frac{E}{k_B T}}\, dE}{\int_0^\infty P_D(E)\, e^{-\frac{E}{k_B T}}\, dE} \times \frac{k_H(T)}{k_D(T)}$$

The ratio $k_H(T)/k_D(T)$ accounts for the thermodynamic and zero-point energy differences between the system that transfers hydrogen and the one that transfers deuterium, in the transition state and in the minimum. Even though differences exist at this level, these are due mainly to differences in zero-point vibrational energy, which are not likely to produce a KIE as great as the one reported experimentally (greater than 100) (1). However, the first term of eq. [6] is the ratio between the quantum permeabilities of the barrier for two identical reactions that differ only in the nature of the hydrogen isotope being transferred (14). This is the part that accounts for tunneling in the reaction under study. Within the WKB formalism, $P_i(E)$ can be expressed as (14, 17):

$$[7]\quad P_i(E) = \begin{cases} 0 & E < V_0 \\ \dfrac{1}{1 + e^{2\theta(E)}} & V_0 \le E \le V^\ddagger \\ 1 - P_i(2V^\ddagger - E) & V^\ddagger \le E \le 2V^\ddagger - V_0 \\ 1 & 2V^\ddagger - V_0 \le E \end{cases}$$

where V_0 is the highest of the energies of either reactants and products, and $\theta(E)$ is given by:

$$[8]\quad \theta(E) = \frac{1}{\hbar} \int_s \sqrt{2[V(s) - E]}\, ds$$

where s, in mass-weighted Cartesian coordinates, denotes the path along which tunneling is assumed to occur. As can be seen, $P_i(E)$ depends on both the height and the width of the barrier, becoming exponentially lower when the barrier increases its height or width. Even though the height of the potential energy barrier is invariant with the isotopic substitution, the width is not, for it is evaluated in mass-weighted Cartesian coordinates. In this way it can be seen that the same potential energy profile becomes much longer when deuterium is the transferring atom.

Finally, we have tried to estimate the ratio $\kappa_H(T)/\kappa_D(T)$. To calculate it, a tunneling path must be assumed. In our case, we have assumed a tunneling path consisting of a linear interpolation in mass-weighted Cartesian coordinates from the internally relaxed structure of the reactants to the transition state structure of the solid phase, followed by another linear interpolation in mass-weighted Cartesian coordinates from the transition state structure in the solid phase to the structure of the products, also internally relaxed. These interpolations were made in such a way that neither linear nor angular momenta were generated (18). Once this was done, the estimated value of $\kappa_H(T)/\kappa_D(T)$ at 77 K was found to be 9.0×10^3, very high and in good accord with experimental reports of KIEs for this reaction in the solid phase.

4. Conclusions

In this paper we have analyzed, from a theoretical point of view, the reaction of ethanol with benzene anions in the gas phase and in the solid phase.

In the gas phase no potential energy barrier with respect to reactants held at infinite distance has been found for the proton transfer reaction under study. However, we found that the reactants form a stable prebarrier complex stabilized by 10.1 kcal/mol with respect to reactants held at infinite distance. With respect to this prebarrier complex, an intrinsic barrier of 9.6 kcal/mol exists.

When the solid phase was simulated by forcing the relative orientation of both reactants to remain as we found them to be in the neutral, gas phase complex, a very high and broad potential energy barrier was found. This is partly due to the fact that the structure is not allowed to relax, and partly due to the fact that in this case the starting point (reactant's mini-

© 1997 NRC Canada

mum) for the reaction does not correspond to that of the reactants held at infinite distance. Be this as it may, in this case the transferring atom is forced to jump a much longer distance. In effect, it seems that in the solid phase the reaction under study changes and what is being transferred at the transition state is a hydrogen atom instead of a proton.

Given the potential energy barrier height in the solid phase calculations, reaction [1] should proceed through a tunneling mechanism at low temperatures. This being the case, one should expect huge values of the kinetic isotope effect (KIE) when substituting hydrogen with deuterium. In our calculations, an estimate of this KIE was obtained by using the semiclassical expression of the transmission coefficient, yielding a final value of 9.0×10^3 at 77 K. This value only applies to KIEs due to tunneling, so that it would be even greater once thermodynamic and zero-point energy differences were included. This value is in good accord with the range of experimental KIEs reported by Miyazaki et al. (7) for this reaction in the solid phase at 77 K.

Even though the values we have found are not quantitatively valid, they manage to explain the experimentally reported facts and justify qualitatively the differences between the reaction in the gas phase and in the solid phase.

Stereoselective hydrogenation of lignin degradation model compounds

Thomas Q. Hu, Brian R. James, Steven J. Rettig, and Chung-Li Lee

Abstract: Di-μ-chloro-bis(η^4-1,5-hexadiene)dirhodium(I) in a two-phase hexane–aqueous medium catalyzes the diastereoselective H_2-hydrogenation of lignin degradation model compounds 4-propylphenol, 2-methoxy-4-propylphenol, and 2,6-dimethoxy-4-propylphenol. The all-*cis* diastereomer is obtained selectively when the phenolic hydroxy group is protected as a methyl ether or when a model compound possessing two methoxy substituents adjacent to the phenolic hydroxy group is used. The relative stereochemistries of the hydrogenated products are established by X-ray crystal structure analysis and (or) ^{1}H NMR.

Key words: catalytic hydrogenation, diastereomer, lignin degradation model compounds, stereoselective, X-ray crystal structure.

Résumé : Dans un milieu aqueux à deux phases avec de l'hexane, le di-μ-chlorobis(η^4-hexa-1,5-diène)dirhodium(I) catalyse l'hydrogénation diastéréosélective des composés modèles de la dégradation de la lignine, 4-propylphénol, 2-méthoxy-4-propylphénol et 2,6-diméthoxy 4-propylphénol. On obtient sélectivement le diastéréomère complètement *cis* lorsque le groupe hydroxyle phénolique est protégé sous la forme d'éther méthylique ou lorsqu'on utilise un composé modèle possédant deux substituants méthoxy dans les positions adjacentes du groupe hydroxyle phénolique. On a déterminé les stéréochimies relatives des produits d'hydrogénation par le biais de la diffraction des rayons X et (ou) de la RMN du ^{1}H.

Introduction

Lignin, a plant constituent, is the second most abundant biopolymer on earth. The biosphere is estimated to contain 3×10^{11} metric tons of lignin with an annual biosynthesis rate of approximately 2×10^{10} tons (1, 2). Every year more than 50 million tons of lignin are produced as the by-products from the chemical pulping of wood at pulp mills worldwide (3). The lignin so obtained has been used mainly as a low-grade fuel for the pulping process (4). Despite extensive research on the conversion of lignin into valuable fine chemicals over the past 20 years or so, only a few systems have been successfully developed and commercialized. One of these commercialized fine chemicals is vanillin, a common flavoring additive in foods and drinks (5).

The major impediments to the exploitation of lignin as a source of fine chemicals are the difficulties involved in separating a mixture of lignin degradation products and the low commercial values of the isolated products. Degradation of lignin obtained from the chemical pulping of wood via neutral or alkaline hydrogenolysis gives 4-substituted-phenols (**1**), 2-methoxy-4-substituted-phenols (**2**) and 2,6-dimethoxy-4-substituted-phenols (**3**) (Scheme 1) in various yields (6–9).

Scheme 1. Products from the degradation of lignin via hydrogenolysis (R = $CH_2CH_2CH_3$, $CH_2CH_2CH_2OH$, CH_2CH_2COOH, CH_2CH_3, CH_2CH_2OH, CH_2COOH, CH_3, COOH, H) (6).

1 **2** **3**

Since the late 1960s sporadic attempts have been made to convert these aromatic compounds into cyclohexanol derivatives via catalytic hydrogenation (10–12). Typically, the reaction was carried out either at high temperature (>200°C) under high pressure (>1000 psi H_2 (1 psi = 6.9 kPa)) (10) or in the presence of strong acid or base (11, 12). Under such reaction conditions, the hydrogenation of the aromatic rings was accompanied by hydrogenolysis of the substituent side chains, giving a multitude of products (10–12). In addition, the hydrogenation was not stereoselective, further complicating the problems of product isolation and development.

In this paper we present the ^{1}H NMR spectroscopic and X-ray crystallographic evidence for the stereoselective hydrogenation of a number of lignin degradation model compounds catalyzed by di-μ-chloro-bis(η^4-1,5-hexadiene)dirhodium(I), $[(1,5\text{-}C_6H_{10})RhCl]_2$. This catalyst was previously used by others for the hydrogenation of carbonyl and simple aromatic

compounds in a two-phase hexane–aqueous medium at room temperature under 1 atm H_2 (101.3 kPa) (13, 14). The extremely mild reaction conditions prompted us to evaluate its potential in the stereoselective (*cis* vs. *trans* diastereomer) hydrogenation of lignin degradation model compounds. We have reported preliminary work on the catalytic hydrogenation of such model compounds using this Rh system; the aim of this work was to inhibit light-induced yellowing of lignin-rich mechanical wood pulp and paper (15).

Results and discussion

Propylphenol (**4**), 2-methoxy-4-propylphenol (**5**), and 2,6-dimethoxy-4-propylphenol (**6**) were selected as the model substrates (16). The catalytic hydrogenation reactions of these three model compounds are summarized in eqs. [1]–[3] (Pr = *n*-propyl).

Hydrogenation of **4** (50 h at ambient conditions in a two-phase medium with Bu_4NHSO_4 as a phase-transfer agent) afforded 4-propylcyclohexanone (**4a**), *cis*-4-propylcyclohexanol (**4b**), and *trans*-4-propylcyclohexanol (**4c**) in a 1:6:2 ratio with an 89% isolated yield. With a longer reaction time, **4a** was further hydrogenated to **4b** and **4c**. The diastereoselectivity of the hydrogenation was 3:1 in favor of **4b** (Table 1). The presence of a methoxy substituent adjacent to the phenolic hydroxyl group increases the diastereoselectivity of the reaction: hydrogenation of **5** afforded predominantly *cis*-2-methoxy-*cis*-4-propylcyclohexanol (**5a**) and *cis*-2-methoxy-*trans*-4-propylcyclohexanol (**5b**) in a 6:1 ratio, while the hydrogenation of **6** gave exclusively the all-*cis* diastereomer (**6a**) (100% diastereoselectivity) (Table 1). Hydrogenation of **6** was carried out under 200 psi H_2 because the reaction was extremely slow under 1 atm H_2.

The relative stereochemistries of **4b** and **4c** were established by ^{1}H NMR. **4b** has a multiplet signal (m) centered at δ 3.94 ascribable to the equatorial methine proton adjacent to the OH group in the *cis* diastereomer, while **4c** has a signal centered at

Table 1. Diastereoselectivity of the hydrogenation of lignin degradation model compounds.

δ 3.53 (m) ascribable to the axial methine proton adjacent to the OH group in the *trans* diastereomer (Fig. 1) (17).

The relative stereochemistry of **6a** was established by X-ray crystal structure analysis, the ORTEP diagram being given in Figure 2. The atomic coordinates and equivalent isotropic thermal parameters for the C and O atoms are given in Table 2. The two OMe substituents are both *cis* to the OH group, with the torsion angles involving the OMe and the OH oxygens (O(1)-C(1)-C(2)-O(2) and O(1)-C(1)-C(6)-O(3)) being close to *gauche* (61.0° and −57.1°, respectively), while the torsion angles involving the hydrogens at the OMe carbon atoms and the OH oxygen (O(1)-C(1)-C(2)-H(3) and O(1)-C(1)-C(6)-H(9)) are close to *trans* (175° and −176°, respectively). The Pr substituent is *cis* to both OMe groups and thus *cis* to the OH group; H(6) and H(3) are mutually *cis*, and are both *trans* to

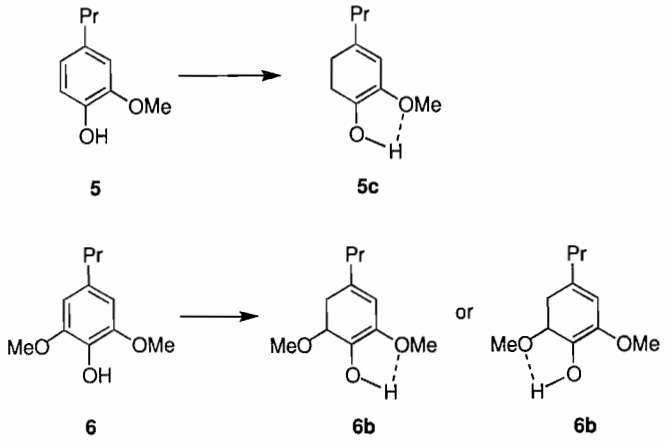
the CH_2 hydrogen H(4) (the torsion angles H(4)-C(3)-C(4)-H(6) and H(3)-C(2)-C(3)-H(4) are 176° and −179°, respectively). The bond lengths and angles are in the usual ranges.

The ^{1}H NMR data of **6a** were then used to establish the relative stereochemistries of **5a** and **5b**. The equatorial methine proton in **6a** has an ^{1}H NMR signal at δ 4.31 while the two axial methine protons adjacent to the OMe groups have signals (m) centered at δ 3.13 (Fig. 3). Based on these assignments for **6a**, the major diastereomer **5a** is thus drawn as shown in Fig. 3, with its assigned ^{1}H NMR signals; the slightly lower δ 4.09 value for the equatorial proton in **5a** compared to that of **6a** (δ 4.31) is due to the presence of only one OMe group β to the proton. A similar effect is also seen in **4b** where there is no OMe group and the equatorial methine proton adjacent to the OH group is seen at δ ~3.94. The minor diastereomer **5b** has two one-proton signals at δ 3.45–3.57 and at δ 3.49–3.56. This is possible only when the methine protons adjacent to the OH and the OMe groups are in the axial and equatorial position, respectively (Fig. 3).

The formation of a predominant or an exclusive *cis* diastereomer must be due to a "continuous" substrate coordination mechanism involved in the hydrogenation, similar to the situation found by others using Co(I)–phosphite complexes for the catalytic hydrogenation of arenes (18) (i.e., the arene substrate remains coordinated throughout successive hydrogen transfer from the metal to give addition of hydrogen on one side of the substrate via η^6-, η^4-, η^3-, and η^2-hydrocarbon moieties). The formation of a small amount of *trans* diastereomer in the hydrogenation of **4** and **5** likely arises from the enol–keto tautomerization of the hydrogenation intermediates. Hydrogenation of the first C=C double bond of the aromatic ring of **4** at the less sterically hindered position will give enol **4d**, which can either hydrogenate directly to the *cis* diastereomer **4b** via the "continuous" substrate coordination mechanism or tautomerize to **4e** and then hydrogenate to **4b** and **4c** through **4a** (Scheme 2). The isolation of **4a** and its further hydrogenation to **4b** and **4c** are consistent with such an enol–keto tautomerization.



Hydrogenation of the first C=C double bond of the aromatic ring of **5** at the least sterically hindered position will give enol **5c**, which is likely stabilized by the OMe substituent via the formation of an intramolecular H-bond (Scheme 3). The opportunities for H-bonding are increased and, hence, the enol is more likely stabilized when a second OMe substituent is present adjacent to the OH group, as in the hydrogenation of **6** (Scheme 3). This increasing enol stabilization could account for the increasing *cis* diastereoselectivity for the hydrogenation of substrates **4**, **5**, and **6**, respectively.

Additional evidence for the contribution of such an enol–keto tautomerization to the formation of the *trans* diastereomer was obtained when we carried out the hydrogenation of 1,2-dimethoxy-4-propylbenzene (**7**). Only *cis,cis*-1,2-dimethoxy-*cis*-4-propylcyclohexane (**7a**) was isolated (eq. [4]). The relative stereochemistry of **7a** was established in a way similar to that used to define the stereochemistries of **5a**

and **5b**. The stereoselective hydrogenation of a similar but simpler compound, *p*-methylanisole, to *cis*-4-methylcyclohexyl methyl ether has been reported by others (14).

The active Rh catalyst is probably present in a colloidal form: as the hydrogenation proceeds, metal particles accumulate and these are not active for subsequent hydrogenation reactions. The presence of the aqueous buffer and Bu_4NHSO_4 (a phase-transfer reagent) (14) is essential for effective catalysis.

Experimental section

General procedures

All the hydrogenation reactions were monitored by TLC and (or) GC. Analytical TLC was performed on aluminum-backed, precoated silica gel plates (E. Merck, type 5554), which were "visualized" by UV fluorescence or by heating after spraying with a mixture of MeOH, HOAc, H_2SO_4, and anisaldehyde (90:10:5:1 by volume). GC analysis was carried out on a Hewlett Packard model 5890 GC with an FID detector and a Carbowax column. Flash column chromatography (19) was performed using Silica Gel 60, 230–400 mesh ASTM (E. Merck). Infrared spectra were recorded on a Bomem Michelson 100 FT-IR spectrophotometer using internal calibration; liquid samples were placed between two 3-mm NaCl plates, and solid samples were dissolved in $CHCl_3$. ^1H NMR spectra were recorded on Bruker WH-400 or Varian XL-300 spectrometers; chemical shifts (δ) were measured in $CDCl_3$ using TMS as the internal standard. LRMS and HRMS spectra were determined on a Kratos-AEI model MS 50 spectrometer operating at 70 eV.

Materials

Propylphenol (**4**) was obtained from Aldrich and purified by vacuum distillation (20). 2-Methoxy-4-propylphenol (**5**), 2,6-dimethoxy-4-propylphenol (**6**), and 1,2-dimethoxy-4-propylbenzene (**7**) were prepared as described below. $RhCl_3 \cdot 3H_2O$ was obtained from Johnson Matthey Ltd; $[(1,5\text{-}C_6H_{10})RhCl]_2$ was prepared by treatment of $RhCl_3 \cdot 3H_2O$ with 1,5-hexadiene in aqueous EtOH according to the literature (21). All other reagents and solvents were obtained from Aldrich and used without further purification.

Preparation of 2-methoxy-4-propylphenol (5) (ref. 22)

To 2.07 g (12.6 mmol) of eugenol (4-allyl-2-methoxyphenol) in 40 mL of EtOH was added 268 mg of 5% Pd on charcoal (0.126 mmol in Pd). The solution was deaerated using the freeze–pump–thaw technique. H_2 at 1 atm was bubbled through the stirred solution overnight at room temperature. The Pd catalyst was filtered off and EtOH was removed under reduced pressure. Et_2O (40 mL) was introduced to the residue and the solution was washed with saturated NaCl (2 × 20 mL), and dried over $MgSO_4$ for 30 min. Removal of the drying agent by filtration and removal of the solvent under reduced pressure gave the crude products, which were then purified by vacuum distillation to give 2.08 g (94%) of 2-methoxy-4-propylphenol (**5**): IR ν_{max}: 3476, 2958, 2930, 2867, 1608, 1514, 1459, 1430, 1367, 1268, 1234, 1151, 1123, 1034, 931, 846, 816, 795, 777, 736; ^1H NMR (300 MHz) δ: 0.93 (t, 3H), 1.53–1.70 (m, 2H), 2.51 (t, 2H), 3.89 (s, 3H), 5.44 (s, 1H), 6.63–6.89 (m, 3H); mass spectrum (EI), *m/z*: 166 (M^+: 30.7); HRMS calcd.: 166.0994; found: 166.0994.

Preparation of 2,6-dimethoxy-4-propylphenol (6)

The procedure was as described for **5**. 4-Allyl-2,6-dimethoxyphenol (9.50 g, 48.9 mmol) was hydrogenated with 1.03 g of 5% Pd/C in 100 mL of EtOH to give 8.53 g (89%) of **6**: IR ν_{max}: 3477, 2944, 2869, 2841, 1610, 1514, 1458, 1427, 1344, 1321, 1279, 1239, 1214, 1150, 1111, 1035, 967, 915, 824, 801, 770, 738; ^1H NMR (300 MHz) δ: 0.94 (t, 3H), 1.56–1.70 (m, 2H), 2.51 (t, 2H), 3.88 (s, 6H), 5.37 (s, 1H), 6.40 (s, 2H); mass spectrum (EI), *m/z*: 196 (M^+: 30.1); HRMS calcd.: 196.1099; found: 196.1096.

Preparation of 1,2-dimethoxy-4-propylbenzene (7)

The procedure was as described for **5**. 4-Allyl-1,2-dimethoxybenzene (8.99 g, 50.5 mmol) was hydrogenated with 1.07 g of 5% Pd/C in 100 mL of EtOH to give 9.01 g (99%) of **7**: IR ν_{max}: 2996, 2956, 2932, 2868, 2834, 1606, 1589, 1513, 1458, 1415, 1377, 1333, 1262, 1236, 1188, 1156, 1140, 1030, 938, 846, 806, 762; ^1H NMR (300 MHz) δ: 0.93 (t, 3H), 1.58–1.69 (m, 2H), 2.53 (t, 2H), 3.88 (s, 3H), 3.89 (s, 3H), 6.68–6.87 (m, 3H); mass spectrum (EI), *m/z*: 180 (M^+: 24.7); HRMS calcd.: 180.1150; found: 180.1145.

Catalytic hydrogenation of 4-propylphenol (4) (ref. 14)

To 28 mg (0.063 mmol) of $[(1,5\text{-}C_6H_{10})RhCl]_2$ in 10 mL of hexane were added **4** (857 mg, 6.30 mmol) dissolved in 5 mL of hexane, Bu_4NHSO_4 (135 mg, 0.40 mmol), and 5 mL of an aqueous buffer of pH 7.5 (boric acid, citric acid, and sodium phosphate) (23). The solution was deaerated using the freeze–pump–thaw technique. H_2 was then bubbled through the stirred solution at room temperature under atmospheric pressure. Upon the completion of the reaction (~50 h), the metal particles that accumulated as the reaction proceeded were removed by suction filtration. The filtrate was diluted with

25 mL of Et_2O. The organic layer was separated, washed twice with saturated NaCl (2 × 20 mL), and dried over $MgSO_4$ for 30 min. Removal of the drying agent by filtration and removal of the solvent under reduced pressure gave the crude products, which were then separated by flash column chromatography (silica gel) using a mixture of hexanes and ethyl acetate (9:1 by volume) as the eluent to give 88 mg (10%) of 4-propylcyclohexanone (**4a**): IR ν_{max}: 2940, 2865, 1716, 1454, 1377, 1329, 1241, 1172, 1123, 1071, 943, 882, 816, 743; ^{1}H NMR (300 MHz) δ: 0.72–1.02 (m, 3H), 1.15–1.52 (m, 5H), 1.53–1.80 (m, 2H), 1.96–2.12 (m, 2H), 2.25–2.42 (m, 4H); mass spectrum (EI), *m/z*: 140 (M^+: 38.3); HRMS calcd.: 140.1201; found: 140.1197; 528 mg (59%) of *cis*-4-propylcyclohexanol (**4b**): IR ν_{max}: 3360, 2931, 2864, 1453, 1371, 1334, 1253, 1209, 1141, 1064, 1049, 1033, 1021, 961, 927, 908, 885, 865, 819, 734; ^{1}H NMR (400 MHz) δ: 0.87 (t, 3H), 1.14–1.42 (m, 7H), 1.43–1.62 (m, 5H), 1.63–1.72 (m, 2H), 3.90–3.98 (m, 1H); mass spectrum (EI), *m/z*: 142 (M^+: 2.7); HRMS calcd.: 142.1358; found: 142.1350; and 179 mg (20%) of *trans*-4-propylcyclohexanol (**4c**): IR ν_{max}: 3343, 2933, 2860, 1456, 1370, 1246, 1204, 1146, 1096, 1054, 1010, 951, 906, 836, 734; ^{1}H NMR (400 MHz) δ: 0.86 (t, 3H), 1.10–1.33 (m, 9H), 1.47 (s, br, 1H), 1.70–1.78 (m, 2H), 1.90–2.00 (m, 2H), 3.48–3.57 (m, 1H); mass spectrum (EI), *m/z*: 142 (M^+: 0.5); HRMS calcd.: 142.1358; found: 142.1366.

Catalytic hydrogenation of 2-methoxy-4-propylphenol (5)

The hydrogenation procedure was as described for **4**. **5** (1.046 g, 6.30 mmol) was hydrogenated to give 748 mg (69%) of *cis*-2-methoxy-*cis*-4-propylcyclohexanol (**5a**): IR ν_{max}: 3468, 2933, 2867, 1459, 1440, 1378, 1328, 1267, 1225, 1194, 1158, 1137, 1110, 1089, 1020, 981, 942, 884, 868, 824, 784, 739; ^{1}H NMR (400 MHz) δ: 0.88 (t, 3H), 1.18–1.45 (m, 9H), 1.70–1.80 (m, 1H), 1.85 (s, br, 1H), 1.94–2.12 (m, 1H), 3.11–3.19 (m, 1H), 3.39 (s, 3H), 4.09 (m, 1H); mass spectrum (EI), *m/z*: 172 (M^+: 13.6); HRMS calcd.: 172.1464; found: 172.1464; and 119 mg (11%) of *cis*-2-methoxy-*trans*-4-propylcyclohexanol (**5b**): IR ν_{max}: 3425, 2956, 2928, 2870, 1459, 1374, 1260, 1211, 1180, 1097, 1058, 969, 806; ^{1}H NMR (400 MHz) δ: 0.89 (t, 3H), 1.12–1.38 (m, 6H), 1.42–1.62 (m, 2H), 1.68–1.77 (m, 2H), 1.80 (s, br, 1H), 2.02–2.12 (m, 1H), 3.38 (s, 3H), 3.45–3.57 (m, 1H), 3.49–3.56 (m, 1H); mass spectrum (EI), *m/z*: 172 (M^+: 8.0); HRMS calcd.: 172.1464; found: 172.1459.

Catalytic hydrogenation of 2,6-dimethoxy-4-propylphenol (6)

To 28 mg (0.063 mmol) of $[(1,5\text{-}C_6H_{10})RhCl]_2$ in 10 mL of hexane in a 25-mL glass liner were added **6** (1.235 g, 6.30 mmol) dissolved in 5 mL of hexane, Bu_4NHSO_4 (135 mg, 0.40 mmol), and 5 mL of the aqueous, pH 7.5 buffer. The solution was deaerated. The glass liner was inserted into a 60-mL laboratory stainless steel autoclave that had been flushed with N_2. The autoclave was sealed and pressurized with H_2 to 200 psi, and the reaction was allowed to proceed at room temperature under magnetic stirring. After 6 h, excess H_2 was carefully released. The metal particles were removed by suction filtration, and the filtrate was diluted with 25 mL of Et_2O. The organic layer was separated, washed twice with saturated NaCl (2 × 20 mL), and dried over $MgSO_4$ for 30 min. Removal of the drying agent by filtration and removal of the solvent under reduced pressure gave the crude product, which was purified by flash column chromatography (silica gel) using a mixture of hexanes and ethyl acetate (12:1 by volume) as the eluent and by recrystallization from EtOH to give 1.044 g (82%) of *cis,cis*-2,6-dimethoxy-4-cis-propylcyclohexanol (**6a**) as colorless crystals: IR ν_{max}: 3580, 3472, 2990, 2933, 2860, 2827, 1459, 1379, 1300, 1099, 994, 956, 900, 861; ^{1}H NMR (400 MHz) δ: 0.90 (t, 3H), 1.25–1.40 (m, 6H), 1.70–1.78 (m, 4H), 3.09–3.17 (m, 2H), 3.40 (s, 6H), 4.31 (s, br, 1H); mass spectrum (EI), *m/z*: 202 (M^+: 0.3); HRMS calcd.: 202.1569; found: 202.1560.

X-ray crystallographic analysis of 6a

A colorless plate crystal of **6a** having approximately dimensions of 0.15 × 0.30 × 0.35 mm was mounted in a glass capillary. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (75.10° < 2θ < 91.09°) measured on a Rigaku AFC6S diffractometer with graphite monochromated Cu-Kα radiation (λ(CuKα) = 1.54178 Å). Crystal data at 21°C are: $C_{11}H_{22}O_3$; FW = 202.29; a = 29.277(1) Å; b = 4.982(1) Å; c = 18.403(1) Å; β = 117.776(4)°; V = 2375.0(4) Å^3; Z = 8, ρ_{calc} = 1.131 g/cm^3; $F(000)$ = 896; μ (MoKα) = 6.47 cm^{-1}. Absent reflection: hkl ($h + k \neq 2n$), $h0l$ ($l \neq 2n$), space group = $C2/c$ (no. 15).

The data were collected at a temperature of 21 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 155.0°. Omega scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.25° with a take-off angle of 6.0°. Scans of (1.00 + 0.20 tan θ)° were made at a speed of 16.0°/min (in ω). The weak reflections (I < 40.0σ(I)) were rescanned (maximum of 8 rescans) and the counts were accumulated to ensure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The diameter of the incident beam collimator was 0.5 mm and the crystal to detector distance was 285 mm. Of the 2781 reflections that were collected, 2725 were unique (R_{int} = 0.028); equivalent reflections were merged. The intensities of three representative reflections were measured after every 200 reflections. No decay correction was applied. The linear absorption coefficient, μ, for Cu-Kα radiation is 6.5 cm^{-1}. An empirical absorption correction based on azimuthal scans of several reflections was applied, which resulted in transmission factors ranging from 0.73 to 1.00. The data were corrected for Lorentz and polarization effects. A correction for secondary extinction was applied (coefficient = 9.1(3) × 10^{-6}).

The structure was solved by direct methods (24) and expanded using Fourier techniques (25). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined isotropically. The final cycle of full-matrix least-squares refinement was based on 1537 observed reflections (I > 3.00 σ(I)) and 216 variable parameters and converged (largest parameter shift was 0.005 times its esd) with unweighted and weighted agreement factors of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.036$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2} = 0.041$. The standard deviation of an observation of unit weight was 2.55. The weighting scheme was based on counting statistics. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, sin θ/λ, and various classes of indices showed no unusual trends. The maximum and minimum peaks on the

© 1997 NRC Canada

final difference Fourier map corresponded to 0.13 and −0.11 e/Å^3, respectively. Neutral atom scattering factors were taken from Cromer and Waber (26). Anomalous dispersion effects were included in F_{calc} (27); the values for $\Delta f'$ and $\Delta f''$ and the mass attenuation coefficients were taken from the literature (28, 29). All calculations were performed using the *teXsan* crystallographic software package of Molecular Structure Co.[2] A listing of bond lengths, bond angles, hydrogen atom parameters, anisotropic thermal parameters, torsion angles, and intermolecular contacts are included as supplementary materials (Tables S1–S6).[3] Measured and calculated structure factor amplitudes are available from the authors.

Catalytic hydrogenation of 1,2-dimethoxy-4-propylbenzene (7)

The hydrogenation procedure was as given for **4**. **7** (1.135 g, 6.30 mmol) was hydrogenated to give 927 mg (79%) of *cis,cis,cis*-1,2-dimethoxy-4-propylcyclohexane (**7a**): IR ν_{max}: 2930, 2871, 2825, 1456, 1377, 1307, 1192, 1163, 1114, 1096, 983, 946, 851, 786, 739; ^{1}H NMR (400 MHz) δ: 0.89 (t, 3H), 1.11–1.44 (m, 9H), 1.72–1.81 (m, 1H), 2.01–2.10 (m, 1H), 3.10–3.18 (m, 1H), 3.37 (s, br, 6H), 3.63 (s, br, 1H); mass spectrum (EI), *m/z*: 186 (M^+: 9.7); HRMS calcd.: 186.1620; found: 186.1614.

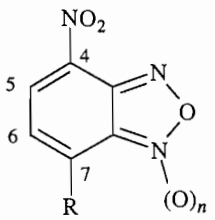
Évaluation de l'effet électroattracteur du motif 4-nitrobenzofurazanyle : ionisation de 7-anilino 4-nitrobenzofurazanes

Jean-Claude Hallé, Malika Mokhtari, Pascale Soulié et Marie-José Pouet

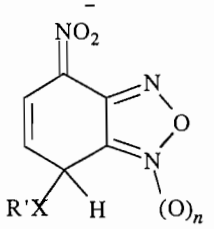
Résumé : L'acidité NH/N⁻ d'une série de 7-(4′-X anilino) 4-nitrobenzofurazanes (**4H**) (X = NO_2, CN, CO_2Me, F, H, Me, OMe) a été déterminée par spectrophotométrie UV–visible dans un milieu H_2O–Me_2SO de fraction molaire N_{Me_2SO} = 0,509. Les pK_a mesurés s'inscrivent dans un domaine assez restreint : 6,40 (X = NO_2)/7,98 (X = OMe), et montrent que **4H** est environ 3 fois plus acide que la 2,4,6-trinitrodiphénylamine identiquement substituée. Ces résultats, complétés par l'analyse des effets du substituant X sur les δ_{H_i} et δ_{C_i}, et l'examen des paramètres de déprotonation $\Delta\delta$ (particulièrement importants pour H_6, C_4, C_6 et C_7) atteste d'un très fort pouvoir électroattracteur du motif 4-nitrobenzofurazanyle. En outre, la mise en évidence d'excellentes corrélations entre les déplacements chimiques ($\delta_{^1H}$ et $\delta_{^{13}C}$) de **4H** et **4**⁻ et les pK_a, a permis de contrôler, et même de préciser, certaines attributions (δ_{C7} et δ_{C9}).



Mots clés : 7-anilino 4-nitrobenzofurazanes, acidités, paramètres de déprotonation (RMN ^1H et ^{13}C, milieux eau–diméthylsulfoxyde.

Abstract: The ionization of a series of 7-(4′-X anilino) 4-nitrobenzofurazans (**4H**) (X = NO_2, CN, CO_2Me, F, H, Me, OMe) to give the conjugate amide anions **4**⁻ has been studied by ^1H and ^{13}C NMR in Me_2SO-d_6. Concomitantly, their acidity (pK_a) has been measured spectrophotometrically in a H_2O–Me_2SO mixture with a molar fraction N_{Me_2SO} = 0,509. Although the measured pK_a values for the whole series of compounds **4H** lie in a relatively narrow range (6.40, X = NO_2 / 7.98, X = OMe), they reveal that each derivative is about 3 times more acidic than the similarly X-substituted 2,4,6-trinitrodiphenylamines. These results, together with an analysis of substituent effects on the proton and carbon chemical shifts (δ_{H_i} et δ_{C_i}) and the related deprotonation parameters ($\Delta\delta$), which are specially significant for H_6, C_4, C_6, and C_7, emphasize the very strong electron-withdrawing character of the 4-nitrobenzofurazanyl moiety. In addition, the observation of nice linear correlations of the type $\delta_{H_i(C_i)} = f(pK_{ai})$ has enabled us to control and sometimes to firmly assign the various chemical shifts.

Key words: 7-anilino 4-nitrobenzofurazans, acidities, ^1H and ^{13}C NMR deprotonation shifts, water – dimethyl sulfoxide mixtures.



Introduction

L'intérêt porté au 4-nitrobenzo-2-oxa-1,3-diazole **1***a* (R = H, *n* = 0), plus communément nommé 4-nitrobenzofurazane, et à ses dérivés N-oxydés, notamment **1***b* (R = H, *n* = 1, 4-nitrobenzofuroxane), remonte à 1968, lorsque Ghosh et Whitehouse ont découvert les activités antileucémiques potentielles de ces hétérocycles, inhibiteurs de la synthèse des acides nucléiques dans les lymphocytes (1–5). C'est le caractère électrophile très important de **1***a* et de **1***b* qui, en bloquant les fonctions thiol et amine des protéines par formation des adduits σ **2**, a été rendu responsable de cette intéressante inhibition (1, 4, 5).

1

a *n* = 0, R = H
b *n* = 1, R = H
c *n* = 0, R = NHR_1 OU NR_1R_2
d *n* = 0, R = Cl
e *n* = 0, R = F

2

X = S
X = NH

Au cours de l'exploration des potentialités biologiques et médicales variées inhérentes à ces hétérocycles (compilées dans une excellente revue (5)), Ghosh et Whitehouse ont également mis en évidence les propriétés fortement fluorescentes des dérivés 7-alkylaminés du 4-nitrobenzofurazane (**1***c*).

Ce comportement a conduit à l'utilisation du 7-chloro

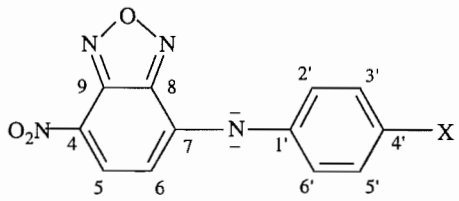
4-nitrobenzofurazane **1***d*, et de son homologue fluoré **1***e*, pour l'analyse fluorimétrique des amines primaires (aminoacides notamment) et secondaires, ainsi que pour leur détection chromatographique (5–14). Ces deux composés sont maintenant très utilisés, notamment le dérivé chloré (noté NBD-Cl) (6).

Dans la mesure où la fluorescence de ces dérivés est étroitement liée à la conjugaison entre le substituant 4-nitro et le groupement fixé en position 7, et que cette émission lumineuse (comme d'ailleurs l'absorption) est très sensible à la nature du milieu et à son pH (5, 14, 15), il est surprenant qu'aucune étude systématique n'ait été entreprise pour chiffrer le caractère électroattracteur du motif NBD. Les seules données actuellement disponibles concernent les déterminations de l'acidité du 4-hydroxy 7-nitrobenzofurazane (NBD-OH) dans l'eau ($pK_a \leq 1{,}8$) (16) et divers solvants organiques (17) : MeOH ($pK_a = 5{,}5$), DMF ($pK_a = 3{,}2$) et Me_2SO ($pK_a = 2{,}6$). Quelques pK_a de dérivés monoalkylés du NBD (**1***c*) ont également été rapportés : $pK_a \approx 10$ (18).

Par ailleurs, le marquage de nombreux lipides au NBD a permis, par l'examen de la fluorescence (très sensible au pH) des modèles obtenus, une meilleure connaissance de l'organisation des membranes biologiques (14, 19). Bien qu'un pK_a d'environ 11,5 ait été avancé pour la sonde NBD des phospholipides ainsi marqués, les auteurs n'ont malheureusement pu conclure si l'équilibre réversible associé correspond à la simple déprotonation de la fonction 7-aminée, ou plutôt à la formation de l'adduit σ-hydroxylé **3***a* (14, 19). La formation de

3



a (R' = H, R = NHR")

b (R' = Me, R = F, Cl ou Br)

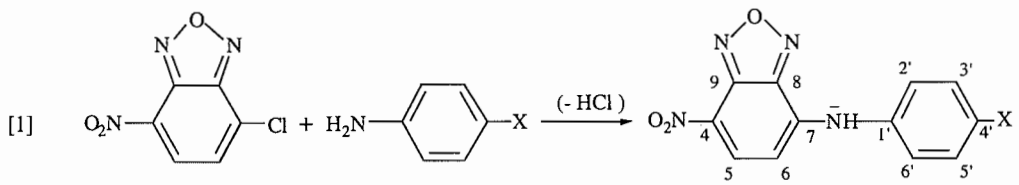
tels adduits σ de type **3**, étudiée en détail dans l'eau et dans le méthanol (20), complique l'étude de la déprotonation de toute fonction acide située sur la position-7 du motif NBD (14, 20, 21). En fait la formation de complexes de type **3** est à l'origine du peu d'informations quantitatives concernant le caractère électrophile du motif NBD.

Le travail présenté a pour but de chiffrer l'aptitude électroattractrice du motif NBD et de la comparer à celle du groupement picryle (2,4,6-trinitrophényle) qui reste une référence en la matière (20, 22). Pour atteindre cet objectif nous avons examiné une série de 7-anilino 4-nitrobenzofurazanes **4H**, diversement substitués en *para* du cycle phényle. Ces composés présentent l'avantage d'être facilement accessibles par simple réaction de substitution nucléophile aromatique (S_NAr) entre le NBD-Cl commercial **1***d* et l'aniline substituée correspondante (23) (eq. [1]).

Après avoir analysé l'influence du substituant X sur l'acidité (NH/N$^-$) de **4H** dans un milieu eau–diméthylsulfoxyde de composition convenable, nous démontrons par analyse RMN ^1H et ^{13}C des molécules **4H** et de leurs anions **4**$^-$ la très grande aptitude du motif 4-nitrobenzofurazanyle (NBD) à délocaliser les électrons.

4 $^-$

Résultats



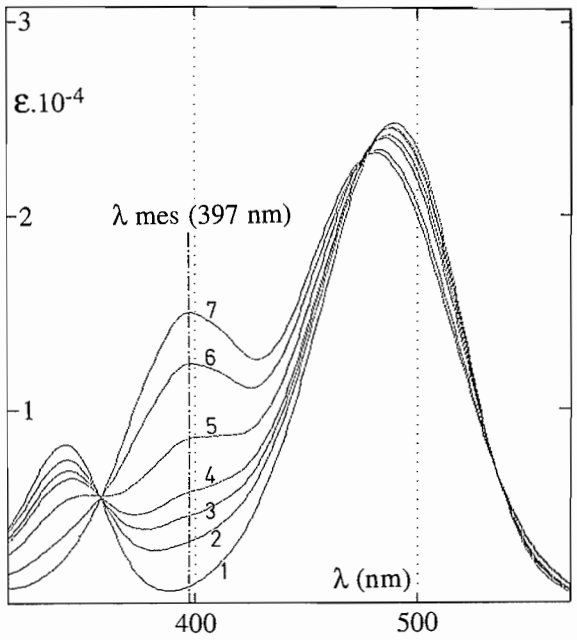
I. Détermination des constantes d'acidité de 4H

En raison d'une très faible solubilité des molécules **4H** en solution aqueuse, les constantes d'acidité K_a^{4H} afférentes à leur ionisation selon l'équation [2] ont été mesurées spectrophotométriquement dans un milieu H_2O–Me_2SO 20/80 (v/v),(0,491/0,509 en fraction molaire), noté S. Pour un couple **4H/4**$^-$ donné, la conversion de la forme acide en forme basique a été étudiée dans divers tampons de pH appropriés

$$[2]\quad \mathbf{4H} + S \underset{}{\overset{K_a^{4H}}{\rightleftharpoons}} \mathbf{4}^- + HS^+$$

$$[3]\quad pK_a^{4H} = pH - \log\frac{\varepsilon - \varepsilon_{4H}}{\varepsilon_{4^-} - \varepsilon} - \log f_{4^-}$$

(figure 1), et le pK_a correspondant calculé selon l'équation [3] où ε_{4H}, ε_{4^-} et ε représentent respectivement les coefficients d'absorption molaire de la molécule pure, de l'anion pur et du mélange des deux formes à l'équilibre au pH de mesure. Pour tous les systèmes étudiés, les niveaux de basicité atteints dans divers tampons CAPS se sont avérés suffisants pour déterminer ε_{4^-}. Ceci a permis d'éviter le recours à des solutions de soude diluées où la formation compétitive des adduits σ de type **3** aurait compliqué les déterminations. L'obtention de faisceaux isosbestiques (cf. figure 1) conforte l'existence d'un seul processus d'ionisation. La réversibilité de la déprotonation de **4H** en **4**$^-$ a d'ailleurs été vérifiée, non seulement par spectroscopie UV–visible dans le mélange eau–Me_2SO



1*d* **4H**

X=NO_2,CN,CO_2Me,F,H,Me,OMe.

© 1997 NRC Canada

Figure 1. Ionisation du 7-anilino 4-nitrobenzofurazane (**4H**, X = H) dans le milieu H_2O–Me_2SO contenant 50,9% de Me_2SO en fraction molaire; t = 25°C; Points isosbestiques : λ = 358 nm (ε = 5440), λ = 477 nm (ε = 22 900); λ_{mesure} = 397 nm. (1) pH = 3,02 (HCl), ε_{4H}^{397} = 840; (2) pH = 6,90, ε^{397} = 3175; (3) pH = 7,15, ε^{397} = 4520; (4) pH = 7,38, ε^{397} = 5730; (5) pH = 7,72, ε^{397} = 8460; (6) pH = 8,17, ε^{397} = 12 120; (7) pH = 10,53, ε_4^{397} = 14 910.

(20/80) utilisé, mais aussi par RMN dans le Me_2SO-d_6. Dans les deux cas la reprotonation de $\mathbf{4}^-$ par un acide fort ($MeSO_3H$) se traduit par la régénération des paramètres spectroscopiques de **4H**. Les structures de **4H** et $\mathbf{4}^-$ ont été confirmées par RMN (vide infra).

Toutes les solutions tamponnées ont été préparées de telle sorte que la force ionique I soit égale à 0,01 mol L^{-1}. Ceci a permis le calcul du coefficient d'activité de $\mathbf{4}^-$ par l'expression simplifiée de Debye–Hückel (24) : $\log f_{4^-} = -A\sqrt{I}$ avec A = 0,5 pour le mélange H_2O–Me_2SO (20/80) retenu (25).

Il convient de noter que les six tampons utilisés pour couvrir la gamme de pH (5,7–10,5), nécessaire au suivi de l'ionisation de l'ensemble des composés **4H** étudiés, sont des tampons biologiques dont les pK_a n'étaient connus qu'à 20°C dans ce milieu (26). Ces tampons ont donc été recalibrés à 25°C suivant une méthode potentiométrique décrite dans la partie expérimentale.

Le tableau 1 rassemble les pK_a de **4H** ainsi déterminés.

II. Études RMN ^{1}H et ^{13}C des 7-anilino 4-nitrobenzofurazanes 4H et de leurs anions 4^-

La numérotation retenue pour **4H** et $\mathbf{4}^-$ est indiquée dans l'équation [1].

II. 1. Analyse des spectres ^{1}H

Pour les molécules **4H**, chaque spectre ^{1}H présente un système AX assorti d'un système AA′XX′ (NO_2, CO_2Me, OMe) qui dégénère en système AA′BB′ pour les substituants CN, F et Me. L'analyse de ces systèmes a été faite au premier ordre et les attributions tiennent compte des intégrations relatives et des effets connus (blindage ou déblindage) des différents substituants (28). Par addition progressive de base, on aboutit aux paramètres de l'anion $\mathbf{4}^-$ dont les protons sont tous blindés par rapport à ceux de **4H**. Le tableau 2 regroupe les paramètres spectroscopiques ^{1}H de **4H** et $\mathbf{4}^-$.

II. 2. Analyse des spectres ^{13}C

Les molécules **4H** et leurs anions $\mathbf{4}^-$ comportent six carbones quaternaires dont l'un d'eux, C_4, va nous servir de sonde puisque, de par sa conjugaison avec le site ionisable, les variations de ses déplacements chimiques dues, d'une part, à la nature du substituant X et, d'autre part, à la déprotonation de la fonction NH, doivent être le reflet des densités de charge et de leurs variations au cours de l'ionisation.

L'identification des carbones a été réalisée en utilisant les méthodes classiques (mesure des constantes de couplage et irradiations sélectives des H à faible puissance) mais aussi par des corrélations ^{1}H/^{13}C optimisées pour les couplages ^1J et ^3J. Le tableau 3 (documentation complémentaire)[2] donne un exemple des paramètres δ^{13}C et $J_{^{13}CH}$ relevés sur les spectres non découplés du 7-(paraméthoxy anilino) 4-nitrobenzofurazane et de son anion et la figure 2 (documentation complémentaire)[2] illustre la corrélation ^{1}H/^{13}C obtenue pour ce même substrat. Dans la mesure où les couplages $^3J_{^{13}CH}$ sont supérieurs aux couplages $^2J_{^{13}CH}$ dans les cycles aromatiques (29), les attributions ne soulèvent aucune ambiguïté à l'exception de celles des deux carbones quaternaires C_7 et C_9 qui sont tous deux uniquement couplés avec H_5 (tableau 3 et figure 2). Dans ce cas les attributions ont été faites sur la base des corrélations $\delta_{^{13}C}/pK_a^{4H}$ (cft. Disussion). Le tableau 4 rassemble les $\delta_{^{13}C}$ relatifs aux molécules **4H** et de leurs anions $\mathbf{4}^-$.

Discussion

I. Mesures d'acidité

Il ressort du tableau 1 que les valeurs de $pK_a^{4H,X}$ mesurées varient de 6,40 pour le composé le plus acide (X = NO_2) à 7,98 pour le composé le moins acide (X = OMe). Ces pK_a correspondent à des acidités relativement importantes pour des équilibres de type NH/N^-. En effet, si l'on se réfère à l'acidité de la *p*-nitroaniline ($ArNH_2/ArNH^-$) dont le pK_a est voisin de 19 dans le milieu étudié (30), c'est par un facteur 4×10^{12} que le motif 4-nitrobenzofurazanyle exalte la déprotonation de la fonction amine. On constate également que l'acidité du 7-anilino 4-nitrobenzofurazane (X = H, pK_a = 7,68) est, dans ce milieu, 3,3 fois plus grande que celle de la 2,4,6-trinitrodiphénylamine (pK_a = 8,20) (30). Ainsi, vis-à-vis de notre modèle ($ArNH/ArN^-$), le *pouvoir électroattracteur du groupement NBD s'avère supérieur à celui du groupement picryle.*

La forte délocalisation des électrons vers le motif NBD de ces molécules a nécessairement lieu au détriment du cycle phényle *para*-substitué. Cette idée est confirmée par un traitement selon Hammett (équation [4]) des pK_a^{4H} obtenus :

$$[4] \quad pK_a^{4H,H} - pK_a^{4H,X} = \rho^S \cdot \sigma_X$$

2. Cette documentation complémentaire (tableau 3 et figure 2) peut être achetée de : Dépot des données non publiées, Service de fourniture de documents, ICIST, Conseil national de recherches Canada, Ottawa, Canada K1A 0S2.

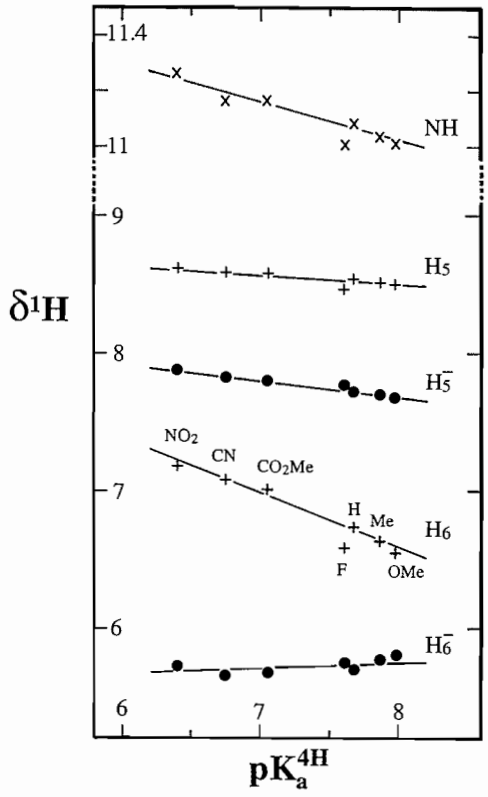
Figure 3. Corrélation entre δ_{1H} des molécules **4H** et de leurs anions **4**$^-$ (Me_2SO-d_6) avec les pK_a (H_2O–Me_2SO contenant 50,9% de Me_2SO en fraction molaire).



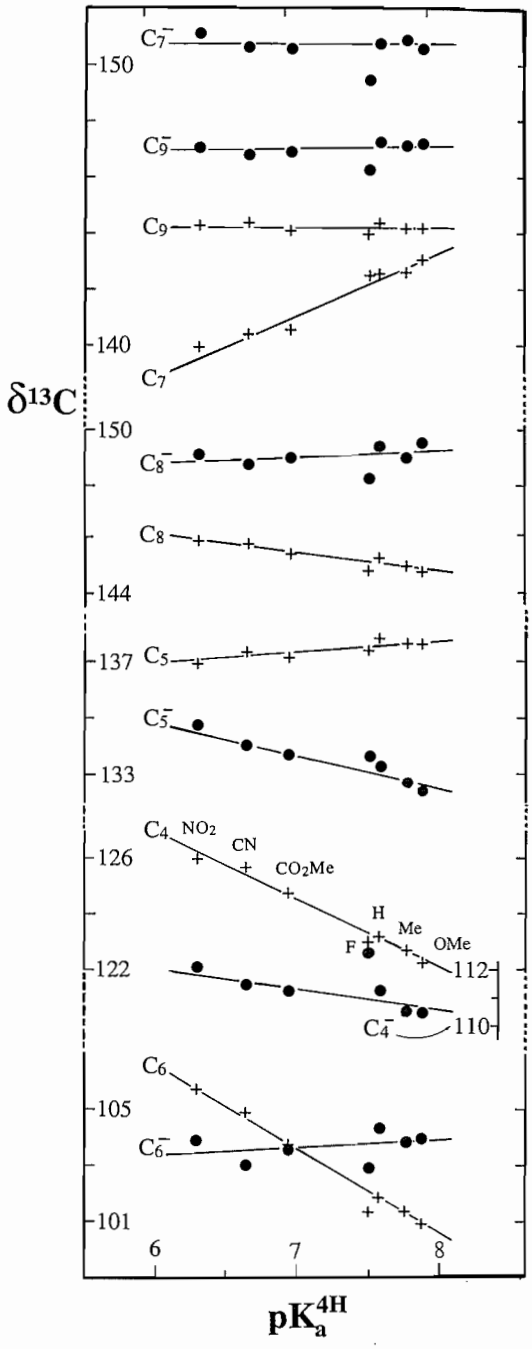


Figure 4. Corrélation entre δ_{13C} des molécules **4H** et de leurs anions **4**$^-$ (Me_2SO-d_6) avec les pK_a (H_2O–Me_2SO contenant 50,9% de Me_2SO en fraction molaire).

La constante de réaction ρ^S déduite de l'excellente corrélation linéaire observée, en utilisant les constantes σ_{p-} pour les substituants à effet mésomère attracteur, est en effet très faible (ρ^S = 1,0; cf. tableau 1), ce qui implique bien l'existence d'une faible conjugaison entre le groupe NH ionisable et le substituant X. Cette constante de réaction est 3,5 fois plus petite que celle afférente à l'ionisation des phénols où les effets de conjugaison entre le site ionisable et le substituant *para* sont très importants (ρ^S = 3,52 dans ce même milieu S eau–Me_2SO) (31, 32). Elle est aussi très inférieure à celle qui gouverne la déprotonation des acides benzoïques *para*-substitués dans ce même milieu (ρ^S = 1,85) (32). La faible valeur de ρ^S pour l'équilibre **4H**/**4**$^-$ témoigne donc bien du *peu d'influence du substituant X sur l'aptitude des composés 4H* à se déprotoner.

L'analyse des δ_{1H} et δ_{13C} des molécules **4H** et des anions **4**$^-$ va nous conduire à la même conclusion.

II. Analyse des δ^1H et δ^{13}C des molécules 4H et des anions 4$^-$

II. 1. Influence du substituant X

Comme le montrent les figures 3 et 4, d'excellentes corrélations linéaires régissent l'influence du substituant X sur les déplacements chimiques des divers protons et carbones du motif NBD des molécules **4H** et des anions conjugués **4**$^-$. Seules les valeurs de δ_H et δ_C afférentes au dérivé fluoré, s'éloignent parfois sensiblement des corrélations. À cet égard, il est connu que la constante σ_p de F, atome très accepteur de liaison hydrogène, est très sensible à la nature du solvant (33). Il se peut donc que le passage du Me_2SO utilisé pour les mesures RMN, au milieu H_2O–Me_2SO (20/80) utilisé pour les mesures d'acidité, soit à l'origine des écarts observés.

L'existence de corrélations linéaires δ vs. pK_a est intéressante à plusieurs titres. En premier lieu, elles constituent un contrôle a posteriori des attributions proposées pour les δ_{1H} et δ_{13C} dans les tableaux 2 et 4. En particulier, ces corrélations lèvent toute ambiguïté concernant les attributions des déplacements chimiques des carbones 7 et 9 de **4H** et **4**$^-$ (vide supra). En effet, outre le regroupement des δ relatifs à C_7 et des δ rela-

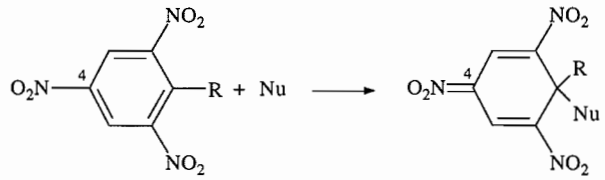
For personal use only.

tifs à C_9 que ces corrélations permettent, il est logique d'attribuer à C_7 la droite de corrélation sensible à la *para* X-substitution (δ variant de 140 (X = NO_2) à 143 (X = OMe)) et à C_9 celle de pente nulle (δ ≈ 144 ppm).



Il est connu que la déprotonation du phénol s'accompagne d'un déblindage très important (13 ppm) du carbone hydroxylé (réf. 29, p. 257). Par analogie, nous avons attribué au carbone 7 des anions **4**$^-$ (C_7^-, fig. 4) la droite de corrélation située à 150,7 ppm, ce qui correspond à un déblindage variant de 10,7 ppm (X = NO_2) à 7,7 ppm (X = OMe), pour le carbone 7 du motif NBD de **4H**. Quant au carbone 9, le déblindage observé est moins important et peu sensible au substituant X ($\delta_{C_7^-} - \delta_{C_7} = 2{,}6 \pm 0{,}3$ ppm). Il convient également de noter que ces attributions conduisent à des constantes de couplage $^3J_{^{13}C_7H_5}$ homogènes entre elles (≈ 9,2/**4H**; ≈ 10/**4**$^-$) et supérieures aux constantes de couplage $^3J_{^{13}C_9H_5}$ (≈ 8/**4H**; ≈ 7,4/**4**$^-$).

En ce qui concerne l'influence de la déprotonation sur les autres carbones du motif benzofurazanyle, on remarque le fort blindage subi par le carbone **4** : $\Delta\delta_{C_4} \approx -13$. Ce résultat est à rapprocher du blindage observé pour le carbone 4 du motif picryle, que ce soit lors de la déprotonation en position benzylique de picryl-acétophénones **5** : $\Delta\delta_{C_4} = -18$ (34), ou bien au cours de la formation des nombreux σ-adduits **6** (eq. [5]) (35–42) par exemple : $\Delta\delta_{C_4} = -24$, R = Nu = OMe (37).

5

[5]

6

Ce déplacement vers les champs forts est en faveur d'une forte délocalisation de la charge négative, générée par la déprotonation de **4H**, par le motif 4-nitrobenzofurazanyle. Notons également que dans les anions **4**$^-$ l'influence du substituant X sur les déplacements chimiques des six carbones du motif NBD reste toujours très faible puisqu'elle ne dépasse jamais 2 ppm (C_4^- et C_5^-) et est le plus souvent nulle (cf. fig. 4). Ceci atteste de la conjugaison quasiment inexistante entre les deux cycles de **4**$^-$.

En ce qui concerne la résonance du proton aminé des molécules **4H**, on constate qu'elle est située à champs très faibles comparée à celle du NH_2 des anilines identiquement substituées (43) et que, contrairement à ces anilines où δ_{NH_2} varie de 2,13 ppm (Me_2SO-d_6) quand on passe du substituant *para* méthoxy (δ_{NH_2} = 4,5) au substituant *para* nitro (δ_{NH_2} = 6,63) (43), elle est ici peu sensible à l'influence du substituant : $11{,}01 < \delta_{NH} < 11{,}27$; cf. tableau 2. D'autre part, le fait que le NH du 7-anilino 4-nitrobenzofurazane (δ_{NH} = 11,08, Me_2SO-d_6) résonne à champ plus faible que le NH de la 2,4,6-trinitrodiphénylamine (δ_{NH} = 10,24, Me_2SO-d_6) (44) est une preuve supplémentaire que le motif NBD est plus électroattracteur que le groupement picryle.

II. 2. Influence de la para-*X anilino substitution*

Si l'on se réfère au 4-nitrobenzofurazane **1***a* dont les déplacements chimiques dans Me_2SO-d_6 sont les suivants : 8,70 (H_5), 7,88 (H_6), 8,60 (H_7), 136,4 (C_4), 131,9 (C_5), 131,5 (C_6), 124,5 (C_7) (45),[3] on constate que l'introduction du groupement *para*-X anilino en position-7 n'engendre qu'un très faible blindage du proton H_5 (0,1 à 0,25 ppm, cf. tableau 2). En revanche, le blindage produit sur H_6 est beaucoup plus conséquent et varie notablement avec X puisque de 1,34 ppm dans le cas de la *para*-méthoxy anilino substitution (X = OMe), il passe à 0,70 ppm, minimum observé dans le cas de la *para*-nitro anilino substitution (X = NO_2). Ce résultat, qui atteste de l'apport électronique important des groupements anilino introduits, s'explique par la contribution plus (X = OMe) ou moins (X = NO_2) importante de la forme mésomère c des molécules **4H** : cf. schéma 1.

Ces observations se trouvent confirmées par l'examen des δ ^{13}C. En effet, la *para*-X anilino substitution blinde notablement le carbone 4 et encore plus le carbone 6 ($\Delta\delta_{C4} = -13{,}1$, $\Delta\delta_{C6} = -29{,}6$ pour X = H) ce qui confirme, non seulement l'importante contribution de la forme mésomère **4H** (c) mais aussi celle de la forme mésomère **4H** (b) du schéma 1.[4]

Partie expérimentale

Préparation des 7-anilino 4-nitrobenzofurazanes 4H

La condensation des anilines *para*-substituées (produits Aldrich) sur le NBD-Cl (Fluka) a été réalisée en utilisant le protocole décrit par Ghosh (23). Si pour les anilines les plus nucléophiles (X = OMe, Me, H), la condensation se fait dans l'éthanol (23), le recours à un solvant dipolaire aprotique, tel que le diméthylsulfoxyde, connu pour faciliter les réactions S_NAr (22), a été nécessaire pour condenser les autres anilines. La moins basique notamment (X = NO_2, pK_a = 1,00) (31) exige un long chauffage à reflux dans Me_2SO pour réaliser la substitution du chlore de NBD-Cl avec un rendement convenable. Le tableau 5 regroupe les conditions utilisées ainsi que les caractéristiques physiques des composés **4H** préparés.

Préparation et standardisation des solutions tampons

La préparation des solutions tampons (produits Aldrich, Janssen ou Sigma, recristallisés dans des mélanges eau–éthanol) ainsi que la purification du Me_2SO (Chimiphar) a déjà été décrite (26). Pour chacun des six composés retenus (cft. tableau 6), dont la forme acide est zwittérionique ($TH^{\pm}$), nous avons standardisé trois solutions tampons présentant les rapports d'ionisation $C_{T^-}/C_{TH^{\pm}}$ égaux à 1/3, 1 et 3 en mesurant leur pH à partir de la chaîne électrolytique déjà décrite

3. J.-C. Hallé et M.-J. Pouet, résultats non publiés.
4. Comme l'a suggéré un référé, on notera toutefois qu'il ne peut être exclu que le blindage observé ne soit pas en partie lié à des effets stériques. Dans ce cas, la conjugaison entre les deux cycles pourrait être légèrement réduite par une rotation du cycle X-substitué autour de la liaison N-$C_{1'}$.

(25, 26), où l'électrode à hydrogène est indicatrice de l'activité du proton solvaté (25, 26, 46) : $a_{HS^+} = 10^{-pH}$. Le tableau 6 rassemble les valeurs de pH obtenues. Elles conduisent à des valeurs de $pK_a^{TH^\pm}$ (= pH − log ($C_{T^-}/C_{TH^\pm}$) + 0,05) sensiblement inférieures à celles préalablement mesurées dans des conditions légèrement différentes (26) (cf. tableau 6).

Mesures spectroscopiques

L'ionisation des molécules **4H** a été suivie sur un spectrophotomètre UVIKON 930. Les enregistrements RMN ont été réalisés sur des spectromètres Bruker AM 250 ou AC 300. Malgré le solvant utilisé, Me_2SO-d_6, la solubilité de certains substrats est restée faible (≈ 0,08 M) ce qui en RMN ^{13}C a impliqué de longues accumulations. Les anions $\mathbf{4}^-$ ont été préparés dans le tube RMN par ajout à **4H** d'un équivalent ou plus de triéthylamine (pK_a = 9,0 dans Me_2SO) (47) et leur formation quantitative contrôlée en vérifiant qu'un ajout supplémentaire de Et_3N ou d'un peu de base forte (*t*BuOK par exemple) est sans incidence sur les δ.

Tableau 6. Valeurs des pH obtenus pour les solutions tamponnées $TH^\pm/T^-$ et des $pK_a^{TH^\pm}$ correspondants : milieu eau–Me_2SO contenant 50,9% de Me_2SO en fraction molaire; *t* = 25°C.

		MES[d]	MOPS[d]	BES[d]	HEPES[d]	TES[d]	CAPS[d]

Sedimentation of fine colloidal particles adsorbed onto a long polymer chain

Waldemar Nowicki and Grażyna Nowicka

Abstract: A system containing aggregates composed of several fine colloidal particles attached to a single very long polymer molecule is considered. It is shown that the sedimentation equilibrium of the system depends on the extent of restriction over the Brownian motions of particles. On the basis of analysis of sedimentation equilibrium, a simple stability model for such systems is developed. The model elucidates the deterioration of the ability of ultralarge polymers to flocculate fine suspensions.

Key words: high polymers, fine colloidal particles, sedimentation, diffusion, flocculation, stabilization of suspensions.

Résumé : On a examiné un système contenant des agrégats formés de plusieurs particules colloïdales fines attachées à une seule molécule de polymère très longue. On démontre que l'équilibre de sédimentation du système dépend du degré de restriction sur les mouvements browniens des particules. En se basant sur l'analyse de l'équilibre de sédimentation, on a développé un modèle de stabilité simple pour de tels systèmes. Le modèle permet d'élucider la détérioration de l'habilité des polymères extrêmement longs à faire floculer des suspensions fines.

Mots clés : hauts polymères, particules colloïdales fines, sédimentation, diffusion, floculation, stabilisation de suspensions.

[Traduit par la rédaction]

1. Introduction

It has been observed experimentally that when the size of polymer coils exceeds that of particles, aggregates composed of many particles attached to a single macromolecule are formed (1–6). One can expect that the formation of aggregates should affect the stability of the suspension. However, when the sedimentation of aggregates is insignificant, then no effect of polymer addition on the suspension stability is macroscopically observed. Therefore, discussion of the stability of the system of aggregates composed of colloidal particles attached to a long-chain macromolecule seems to be more suitable in terms of sedimentation behavior than aggregation kinetics.

The sedimentation can be described by two parameters: the sedimentation velocity and a factor describing sedimentation equilibrium. These parameters are determined by the density and size of colloidal particles and can be affected by an aggregation process as well as by interparticle interaction and the excluded volume effect (7). In the case of complex random aggregates, their elastic and plastic properties may also affect the sedimentation phenomenon (8). Thus, the intra-aggregate movements of particles attached to a macromolecule should also be taken into account in analysis of the sedimentation behavior of the system.

The stability of suspensions containing particles and their aggregates whose formation does not involve polymers was discussed on the basis of a population balance model for aggregates of different types, their diffusion, and settling behavior (9). The stability of suspensions of fine particles after introduction of supersized linear nonionic polymers undergoing adsorption onto particles was also studied in terms of sedimentation phenomena (10, 11). A number of models describing the flocculation and adsorption phenomena in such systems have been developed. Analysis of the system at equilibrium showed that the degree of polymer-induced flocculation is determined by the size of polymer coils in the solution, the particle radius, and the maximum number of particles that can be bound to a single macromolecule (10). Distribution of particles among molecules was studied by a direct simulation of diffusion and binding of particles to polymer molecules (11), the modelling of reversible and irreversible adsorption of macromolecules onto particles (12), and on the basis of dynamic analysis in which the transient behavior of particle adsorption to a polymer molecule and the particle–particle interactions are taken into account (13). In the above models, destabilization of the colloidal system was assumed to occur when aggregates reached a critical number n_f of particles per macromolecule (10, 11). However, in these models a refined analysis of the sedimentation rate and (or) the sedimentation equilibrium in systems containing polymer molecules carrying different numbers of attached particles was not performed.

In this work we replace the study of the influence of an arbitrarily chosen parameter n_f on the colloid stability by a more accurate analysis of the sedimentation process. We performed a two-stage analysis of the influence of aggregate properties on the colloidal system stability. At first, we defined the parameters describing the colloid stability in terms of sedimentation and examined the dependence between the structure of aggregates and the values of these parameters. Then, we discussed the random Brownian motions of fine colloidal particles attached to a very long polymer chain and studied the influence of such polymer–particle aggregate properties on the stability criteria.

2. Model

The model is designed for a system containing identical fine colloidal particles and identical very long polymer chains in a good solvent. In the system, the aggregation process takes place due to adsorption of the polymer segments onto the surface of the particles. We assumed that the process of aggregate formation was complete. The colloidal suspension was assumed to be dilute, so that the aggregates could be considered as separate species.

2.1. Sedimentation velocity and sedimentation equilibrium

In the gravitational field, a colloidal suspension is a heterogeneous fluid characterized by a dependence of the number of particles $n(z)$ on the altitude z. In a monodisperse and sufficiently dilute colloidal system, where interactions among particles can be neglected, $n(z)$ is proportional to the Boltzmann factor, i.e., it is given by the barometric law (14):

$$[1] \quad n(z) = n_0 \exp\left(-\frac{z}{\xi}\right)$$

where n_0 is the number of particles at the zero altitude and ζ is the gravitational length:

$$[2] \quad \xi = \frac{RT}{Mg} = \frac{k_B T}{m_{eff}\, g} = \frac{k_B T}{V(\rho_p - \rho_s)g}$$

M, m_{eff} are the macromolecular mass and the effective colloidal particle mass (corrected by Archimedes law), R, k_B are gas and Boltzmann constants, ρ_p, ρ_s are densities of particles and dispersion medium (for $\rho_p > \rho_s$ one can observe the sedimentation process, otherwise the creaming process), respectively, V is the particle volume, T is the temperature, and g denotes acceleration due to gravity.

Let us assume that the velocity of a colloidal particle falling down in the gravitational field has reached a stable value. In this case:

$$[3] \quad m_{eff}\, g = f\frac{z_g}{t}$$

where z_g is the distance that the particle covers during time t due to gravity, and f is the friction factor. The mean-square displacement covered by the particle in its random Brownian walk in the vertical direction $\langle z^2 \rangle$ is given by the Einstein equation (15):

$$[4] \quad \langle z^2 \rangle = 2Dt$$

where D is the diffusion coefficient of the colloidal particle or the aggregate.

Combining eqs. [2]–[4] (and taking into account that $Df = k_B T$) we find:

$$[5] \quad \xi = \frac{\langle z^2 \rangle}{2z_g} = \frac{Df}{m_{eff}\, g}$$

The probability p that n particles can be found at the level z is given on the basis of eq. [1] by

$$[6] \quad p(z,z+dz) = \frac{n(z,z+dz)}{n_T} = \frac{n_0}{n_T}\exp\left(-\frac{z}{\xi}\right)dz$$

where n_T denotes the total number of particles in the system.

Since the sum of the numbers of particles on all levels of the vessel of height z_H should be equal to n_T, we have

$$[7] \quad n_0 \int_{z=0}^{z=z_H} \exp\left(-\frac{z}{\xi}\right)dz = n_T$$

Finally, we obtain the probability distribution:

$$[8] \quad p = \frac{1/\xi}{1 - \exp(-z_H/\xi)}\exp\left(-\frac{z}{\xi}\right)$$

For the sedimentation equilibrium attained in the centrifugal field, parameter g in eq. [2] is replaced by $\omega^2 z$, where ω is an angular velocity. Equation [8] then takes the form:

$$[9] \quad p = \frac{1}{\sum_{k=0}^{\infty} \frac{1}{(\xi^c)^k} \frac{z_B^{2k+1} - (z_B - z_H)^{2k+1}}{(2k+1)k!}} \exp\left(\frac{(z_B - z)^2}{\xi^c}\right)$$

where k is an integer, z_B denotes the radial position of the bottom of the centrifugal vessel, and

$$[10] \quad \xi^c = \frac{2g}{\omega^2}\xi$$

It is noteworthy that the distributions defined by eqs. [8] and [9] depend on only one parameter. This parameter, the gravitational length ζ (or ξ^c), determines behavior of particles and (or) aggregates of different types, which are suspended in liquid in either the gravitational or centrifugal field. This parameter can be influenced by various aggregate properties; unfortunately, the parameter cannot provide information about any of these properties separately.

The gravitational length ξ characterizes the colloidal system at the sedimentation equilibrium. Thereafter, the value of this parameter is considered a criterion of the suspension stability. However, a full description of the sedimentation process should also include the rate of the equilibrium attainment. The rate is determined by the sedimentation coefficient s, defined by eq. [11]:

$$[11] \quad s \equiv \frac{v}{a}$$

where v is sedimentation velocity and a is acceleration due to the force causing the sedimentation. Below, we consider the values of ξ and s parameters of colloidal systems in which aggregation occurred, taking into account different types of aggregates that could be formed.

1. A suspension composed of particle–polymer aggregates, consisting of one colloidal particle of radius r covered by an adsorbed polymer layer of a thickness δ and of density ρ_l.

© 1997 NRC Canada

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 91.121.58.235 on 09/08/12
For personal use only.

The gravitational length ξ_{agg} for the suspension composed of such aggregates can be described as

$$[12] \quad \xi_{agg} = \frac{k_B T}{m_{eff}\, g} = \frac{k_B T}{\frac{4}{3}\pi g \left(r^3(\rho_p - \rho_s) + ((r+\delta)^3 - r^3)(\rho_l - \rho_s)\right)}$$

Taking into account that usually $\rho_l \cong \rho_s$ (16) it is found that

$$[13] \quad \xi_{agg} = \xi$$

which means that the same sedimentation equilibrium is attained for the suspension of polymer-covered particles and for the suspension of bare particles.

On the other hand, the sedimentation coefficient of the suspension of polymer-covered particles depends, as has recently been shown by Siffert and Li (16), on the thickness of the polymer layer. If one assumes $\rho_l \cong \rho_s$ and the absence of free, nonadsorbed polymer in the dispersion medium, the sedimentation coefficient of the suspension of polymer-covered particles, s_{agg}, is equal to

$$[14] \quad s_{agg} = \frac{r}{r+\delta} s$$

2. A suspension consisting of compact aggregates built of N primary particles.

Such aggregates can be formed in the process of coagulation. If one assumes, for the sake of simplicity, that the aggregation of particles leads to coalescence, the gravitational length and sedimentation coefficient of the suspension are given by

$$[15] \quad \xi_{agg} = \frac{\xi}{N}$$

and

$$[16] \quad s_{agg} = s\sqrt[3]{N^2}$$

3. A suspension of rigid, spherical aggregates built of a very large polymer molecule (or molecules) and of N primary particles.

According to eq. [5], the gravitational length is equal to

$$[17] \quad \xi_{agg} = \frac{k_B T}{\frac{4}{3}\pi g(r^3 N(\rho_p - \rho_l) + r_{agg}^3(\rho_l - \rho_s))}$$

where r_{agg} denotes the aggregate radius. Taking into account that $\rho_l \cong \rho_s$, one can easily find that

$$[18] \quad \xi_{agg} = \frac{\xi}{N}$$

and that the sedimentation equilibrium is independent of the aggregate radius.

In this case the sedimentation coefficient is given by

$$[19] \quad s_{agg} = \frac{r}{r_{agg}} Ns$$

4. A suspension consisting of aggregates composed of N primary particles attached to a flexible linear very large polymer molecule.

For the suspension under consideration (according to eq. [5]) we have

$$[20] \quad \xi_{agg} = \frac{\langle z_{agg}^2 \rangle}{2\, z_{g_{agg}}} = \frac{D_{agg}\, f_{agg}}{m_{agg}\, g}$$

where parameters with subscript "agg" refer to polymer-bound particles.

A colloidal particle, which belongs to a suspended aggregate, covers a distance that is a superposition of two displacements: a downward movement due to gravity and a random Brownian walk. The downward movements of all particles attached to a macromolecule are mutually independent. On the contrary, the particle displacement due to the Brownian walk, $(\langle z_{agg}^2 \rangle)^{1/2}$, is restricted by the length of the polymer chain and the displacements of other particles. However, if one assumes that the aggregate is built of an infinitely long expanded polymer molecule, particle motions are mutually independent ($\langle z_{agg}^2 \rangle = \langle z^2 \rangle$), and the sedimentation equilibrium of the system composed of such aggregates is the same as for the system of primary particles, provided that the diffusion coefficient and the friction factor of a particle in an infinite aggregate do not differ from those of the primary particles.

In the case of an aggregate formed by a finite but very long chain, in which particles are far away from each other and their friction factors are the same as for primary particles, one can assume that the only parameter determining the particle motion is the space available for the random walk. The shortening of a polymer chain results in a depression of self-diffusion of colloidal particles and hence in a decrease of the diffusion coefficient of the particle attached to the chain, D_{ap}. Thus, eq. [20] can be simplified to

$$[21] \quad \xi_{agg} = \frac{\langle z_{agg}^2 \rangle}{2 z_g} = \frac{D_{ap} f}{m_{eff}\, g}$$

Because for an infinitely long polymer chain the sedimentation velocity v takes the same value for the suspension of primary particles and that of aggregates, the sedimentation coefficient reads

$$[22] \quad s_{agg} = s$$

provided that the intra-aggregate viscosity is the same as the viscosity of the dispersion medium.

2.2. Diffusion of attached particles

Let us assume that the aggregate consists of identical colloidal

For personal use only.

particles connected by a weightless thread instead of a physical polymer chain. Individual motions of particles in such an aggregate are mutually independent, unless the distance between two neighbouring particles exceeds the length of the thread fragment between them. For the sake of simplicity, let us assume that no particle can be placed any further from the mass centre of the aggregate than r_{agg} (considered here as the aggregate radius). Moreover, the model is simplified by considering a one-dimensional description in which the only spatial coordinate z, parallel to the vessel axis, is taken into account. The Brownian motion of a particle in the aggregate can be evaluated in the way described below.

The single-body probability density for the particle position z at time t_S is given by the Gaussian distribution with the expected value equal to 0 (15):

$$[23] \quad \varphi(z) = \frac{1}{\sigma_{fp}\sqrt{2\pi}} \exp\left(-\frac{1}{2}\left(\frac{z}{\sigma_{fp}}\right)^2\right)$$

The deviation of the particle position from the mean value at time t is analogous to the *root-mean-square* (rms) displacement of a single colloidal particle given by the Einstein equation (eq. [4]) (15). Choosing the standard time t_S at which the deviation of the distribution is equal to the standard deviation σ_{fp} of the normal distribution of free colloidal particles, and according to the Einstein equation [4], the probability density (eq. [23]) can be expressed:

$$[24] \quad \varphi(z) = \frac{1}{\sqrt{4\pi D_{fp} t_S}} \exp\left(-\frac{z^2}{4D_{fp}t_S}\right)$$

where D_{fp} denotes the diffusion coefficient of primary particle.

The position of a particle attached to a macromolecule is restricted to the space occupied by the whole aggregate. Let us assume that the probability distribution of the position of the particle can be expressed by a normal distribution [24] truncated to the interval $(-r_{agg}, r_{agg})$ (the particle volume was assumed to be negligible):

$$[25] \quad \varphi(z)dz = \begin{cases} \dfrac{1}{\sigma_{fp}\sqrt{2\pi}} Y \exp\left(-\dfrac{z^2}{2\sigma_{fp}^2}\right) dz & \text{for } -r_{agg} < z < r_{agg} \\ 0 & \text{for } z \le -r_{agg} \text{ or } z \ge r_{agg} \end{cases}$$

where Y is the normalization constant.

The calculation of the normalization constant leads to:

$$[26] \quad \varphi(z) = \begin{cases} \dfrac{1}{\sigma_{fp}\sqrt{2\pi}} \dfrac{1}{\operatorname{erf}\left(\dfrac{r_{agg}}{\sqrt{2}\sigma_{fp}}\right)} \exp\left(-\dfrac{z^2}{2\sigma_{fp}^2}\right) & \text{for } -r_{agg} < z < r_{agg} \\ 0 & \text{for } z \le -r_{agg} \text{ or } z \ge r_{agg} \end{cases}$$

The standard deviation σ_{rap} of the distribution [26] is given by eq. [27] (17):

$$[27] \quad \frac{\sigma_{rap}}{\sigma_{fp}} = \left(\frac{\left[\operatorname{erf}\left(\dfrac{r_{agg}}{\sqrt{2}\sigma_{fp}}\right) - \sqrt{\dfrac{2}{\pi}} \exp\left(-\left(\dfrac{r_{agg}}{\sqrt{2}\sigma_{fp}}\right)^2\right)\dfrac{r_{agg}}{\sigma_{fp}}\right]}{\operatorname{erf}\left(\dfrac{r_{agg}}{\sqrt{2}\sigma_{fp}}\right)}\right)^{1/2}$$

The dependence of the relative standard deviation σ_{rap}/σ_{fp} of the position of a particle attached to a chain on the relative aggregate radius R_{agg} ($R_{agg} = r_{agg}/\sigma_{fp}$) is shown in Fig. 1. The standard deviation σ_{rap} takes the maximum value (equal to the standard deviation of free particle) when r_{agg} tends to infinity. Assuming the same standard time t_S (at which the deviation is equal to the standard deviation), the diffusion coefficient of a particle attached to a chain in the coordinate system with the beginning at the aggregate centre, D_{rap}, can be evaluated as follows:

$$[28] \quad \frac{D_{rap}}{D_{fp}} = \frac{\left[\operatorname{erf}\left(\dfrac{R_{agg}}{\sqrt{2}}\right) - \sqrt{\dfrac{2}{\pi}} \exp\left(-\left(\dfrac{R_{agg}}{\sqrt{2}}\right)^2\right) R_{agg}\right]}{\operatorname{erf}\left(\dfrac{R_{agg}}{\sqrt{2}}\right)}$$

It is worth noticing that R_{agg} is a function of the Brownian displacement of the particle at time t_S, so this parameter depends also on temperature. The aggregate radius r_{agg} also depends on temperature since the temperature influences the expansion factor of polymer coil.

The total diffusion coefficient of a particle attached to a polymer molecule, D_{ap}, can be treated as a superposition of two components: the diffusion coefficient of single particle, D_{rap}, and the diffusion coefficient of mass centre of all other particles attached to the chain, D_{mc}. Since the mean-square sum of displacements of a single particle z_{rap} and of the centre of mass z_{mc}, $\langle(z_{rap} + z_{mc})^2\rangle$, is equal to $\langle z_{rap}^2\rangle + \langle z_{mc}^2\rangle$ (as the value of $z_{rap}z_{mc}$ is zero), the total diffusion coefficient D_{ap} is the sum of D_{rap} and D_{mc}. In estimating the D_{mc} component for a very large aggregate, it can be assumed that the diffusion coefficient of the aggregate mass centre is equal to the mean diffusion coefficient of an attached particle divided by N (as the standard deviation of the mean value is equal to the mean standard deviation divided by $\sqrt{N}$ (17)). Assuming the mean diffusion coefficient as equal to D_{fp}, we obtain the approximation of D_{ap} given by eq. [29]:

$$[29] \quad D_{ap} = D_{rap} + \frac{D_{fp} - D_{rap}}{N}$$

Another approximation of D_{ap} can be obtained if the D_{mc} value is calculated as the diffusion coefficient of the sphere that is formed by the coalescence of primary particles of a

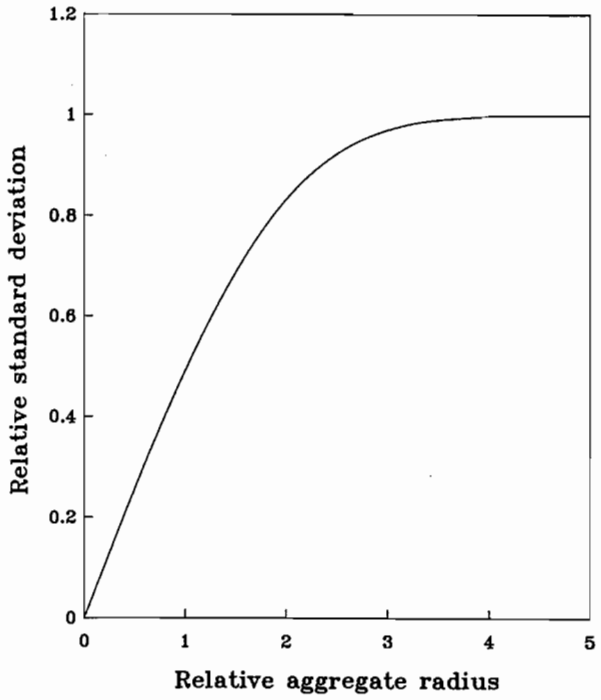
Fig. 1. Dependence of the relative standard deviation of the position of a particle attached to polymer chain, σ_{rap}/σ_{fp}, on the relative aggregate radius R_{agg}.



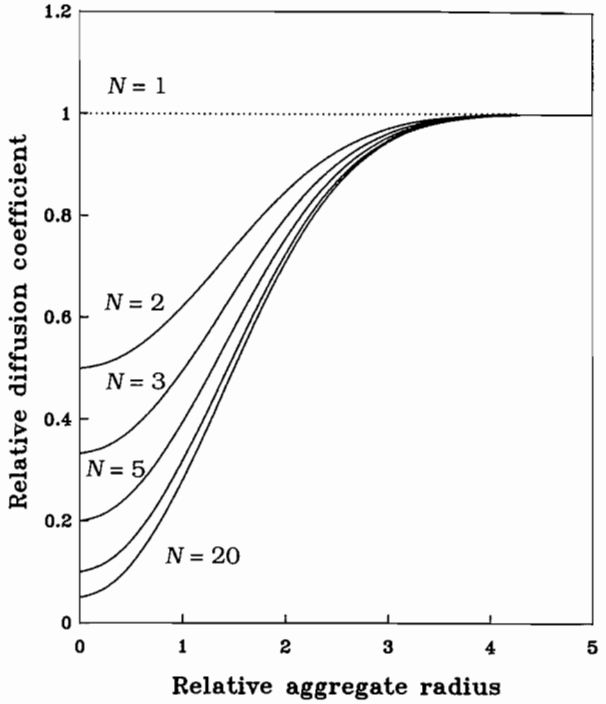


Fig. 2. D_{ap}/D_{fp} versus R_{agg} plots calculated for different N values.

relative radius R ($R = r/\sigma_{fp}$, $R_{agg} = R\sqrt[3]{N}$, $f_{agg} = f\sqrt[3]{N}$, and the diffusion coefficient of the aggregate centre for all attached particles is equal to $D_{fp}/\sqrt[3]{N}$):

$$[30] \quad D_{ap} = D_{rap} + \frac{D_{fp} - D_{rap}}{\sqrt[3]{N}}$$

Thus, eq. [29] is a better estimation of the dependence of D_{ap} on R_{agg} in the case of large and loose aggregates whereas approximation [30] is better in the case of rigid and compact aggregates.

The dependence of the relative diffusion coefficient on a single particle attached to a macromolecule D_{ap}/D_{fp} and the relative aggregate radius is shown in Fig. 2. The diffusion coefficient takes the maximum value (equal to the diffusion coefficient of free primary particles) when R_{agg} tends to infinity. When R_{agg} tends to zero, the diffusion coefficient takes a value characteristic of a rigid aggregate.

One can expect the intra-aggregate viscosity η_{agg} to be greater than the viscosity of the dispersion medium η_0. If the intra-aggregate viscosity is taken into account, the total diffusion coefficient of an attached particle takes the form:

$$[31] \quad D_{ap}(\eta) = D_{rap}(\eta_0/\eta_{agg}) + \frac{D_{fp} - D_{rap}(\eta_0/\eta_{agg})}{N}$$

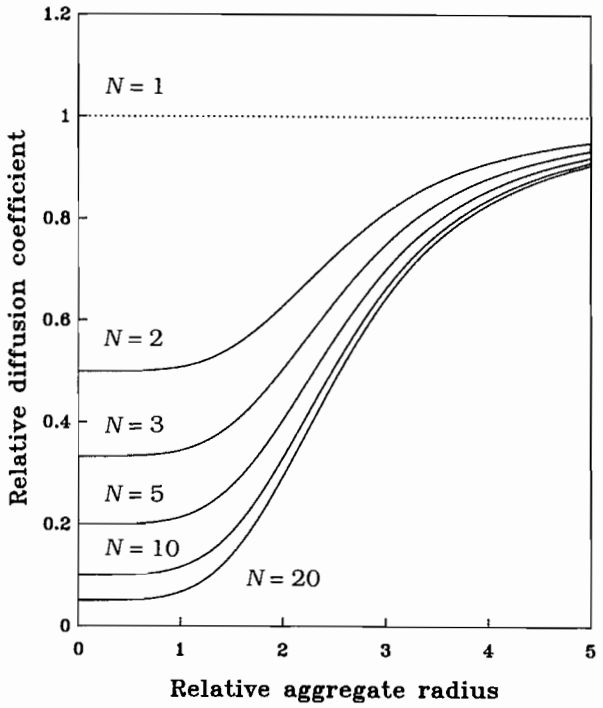
The intra-aggregate viscosity η_{agg} can be estimated experimentally according to the Taylor equation (18):

$$[32] \quad \eta_{agg} = \frac{(\Phi_2 + 1)\eta_0 - \eta}{-\left(\frac{5}{2}\Phi_2 + 1\right)\eta_0 + \eta}\eta_0$$

where η is the viscosity of the system and Φ_2 is the volume fraction occupied by polymer chains.

The size of polymer coils in the solution is mainly determined by the polymer molecular weight (MW) and the quality of the solvent. In view of a comparison between systems containing a polymer of the same MW but of different coil size, we assumed a simple linear dependence of the viscosity on the polymer segment concentration. The intra-aggregate viscosity can be approximated now by eq. [33]:

$$[33] \quad \eta_{agg} = \frac{\eta_{intr}}{R_{agg}^3} + \eta_0$$



where η_{intr} is the parameter characteristic of the polymer.

Figure 3 illustrates relations between ratio $D_{ap}(\eta)/D_{fp}$ and the parameter R_{agg} for different N values. The dependencies were calculated assuming that intra-aggregate viscosity can be evaluated from eq. [33]. From a comparison of Figs. 2 and 3 one can state that the higher the intra-aggregate viscosity, the smaller the increase in the diffusion coefficient of an attached particle that accompanies the increase in R_{agg}.

Fig. 3. $D_{ap}(\eta)/D_{fp}$ versus R_{agg} dependencies calculated for different N values ($\eta_{intr} = 10$ assumed).

3.3. A relation between the colloid stability and the diffusion of particles attached to polymer chains

As we have shown above, the stability of the colloidal system can be described by the gravitational length ξ which can be calculated from eqs. [21], [28], and [31]. However, it is difficult to measure ξ directly. Therefore, let us introduce a new parameter, the stability coefficient S, which can be easily obtained from experiment:

$$[34] \quad S = \frac{n}{n_T}$$

where n_T denotes the number of particles in a unit volume of a colloidal system of uniform particle distribution and n is the mean number of particles in the unit volume of the upper half of the vessel after the completion of the sedimentation process and after the particles have achieved a uniform distribution. The definition of S is based on the typical experimental procedure.

With the equilibrium of the system in the gravitational field and for n calculated from eq. [8], the dependence between S and ξ, represented by eq. [35], is obtained:

$$[35] \quad S = \frac{n}{n_T} = \int_{z=z_H/2}^{z=z_H} \frac{2/\xi}{1 - \exp\left(-\frac{h}{\xi}\right)} \exp\left(-\frac{z}{\xi}\right) dz$$

The profiles of distribution of colloidal particles versus the distance from the bottom of the vessel, as well as the values of stability coefficients for different ξ are shown in Fig. 4. Large ξ values indicate that the distribution of particles at the sedimentation equilibrium does not differ significantly from the uniform particle distribution, and hence they correspond to relatively stable suspensions. Small ξ values correspond to unstable suspensions in which particles gather at the bottom of the vessel.

According to eqs. [21], [28], [31], and [35], the stability coefficient S is a function of N and R_{agg} parameters. Figure 5 shows S versus R_{agg} dependencies calculated for suspensions of aggregates of different N. In these calculations we assumed that the suspensions are monodisperse, i.e., composed of identical aggregates. As can be seen in Fig. 5, the smaller the number of particles attached to a polymer molecule and the greater the relative aggregate radius, the more stable is the suspension. The model parameter R_{agg} (eq. [28]) is a measure of the extent of restriction of Brownian motions of particles. Physically, this restriction depends on the relative sizes of polymer coils and particles. In other words, the model predicts that very large polymers in a good solvent are not effective flocculants for fine suspensions.

The process of polymeric flocculation of suspensions is very complex. It consists of many steps such as formation of primary aggregates, rearrangement of their structure, formation of macroscopic "flocs," sedimentation, formation of the sediment structure, et cetera. An outcome depends on a number of factors that can influence the equilibrium and (or) kinetics of the steps. These factors can interfere, which makes the description of the process very difficult. Therefore, the model presented does not pretend to explain all details of flocculation of fine suspensions by very large polymers. It emphasizes only the effect of quasi-free Brownian motions of particles attached to a very long polymer chain on the sedimentation equilibrium. In systems where this effect plays an important role in the whole flocculation process, the model can be used in a discussion of the stability of the colloidal suspension.

Experiments on the effect of chain polymers of different MW on the stability of fine suspensions are reported in the literature and their results seem to confirm the predictions of the model. Otsubo and Watanabe (19) studied the flocculation of suspension of 10 nm silica particles with the aid of polyacrylamides of different MW, and they observed that with increasing MW the ability of polymer to flocculate the suspension first increased, then reached a maximum, and finally decreased at MW over $(2–5) \times 10^6$. Also, Furusawa et al. (20), studying the flocculation of the tungstic acid sol by polyacrylamide, found an optimum polymer MW ($(3–6) \times 10^6$) for the flocculation efficiency. We believe that whereas the increase in the flocculation efficiency with increasing polymer MW can be explained using the classical theory of bridging flocculation (21), the deterioration of the flocculation ability at MW over a few millions can result from increased quasi-free Brownian motions of particles when they are attached to a very long polymer chain.

Also, results of our studies on the effect of very high MW polyacrylamides on the stability of silver iodide hydrosol at various electrolyte concentrations (22) seem to agree, although somewhat indirectly, with the model predictions. We found that the polymer-induced destabilization efficiency (defined as $F = 1 - n/n_T = 1 - S$, provided that the coagulation due to an electrolyte can be neglected) increased with the ionic strength of the medium. In the system examined, in which the adsorption of few particles onto a single macromolecule could

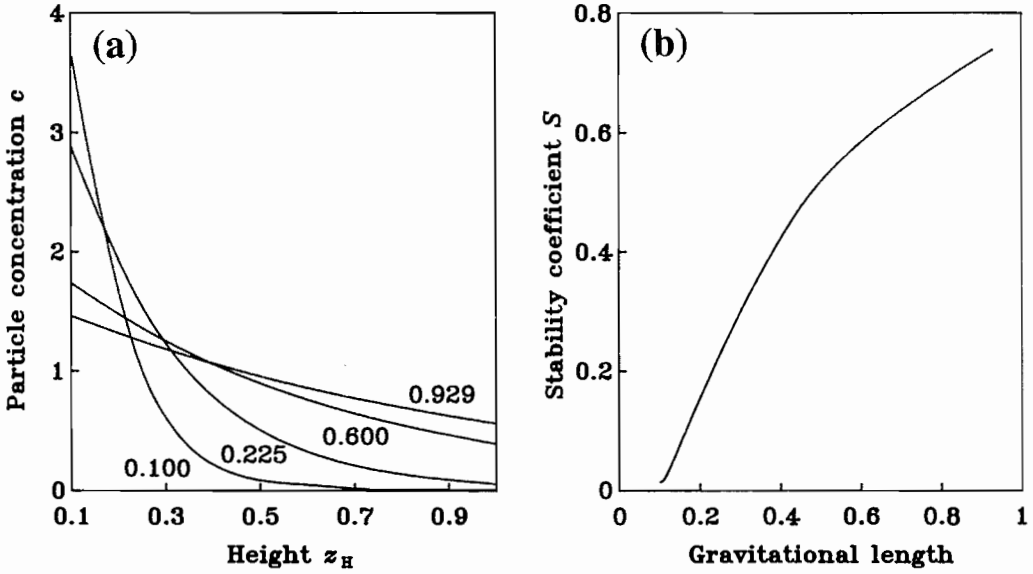

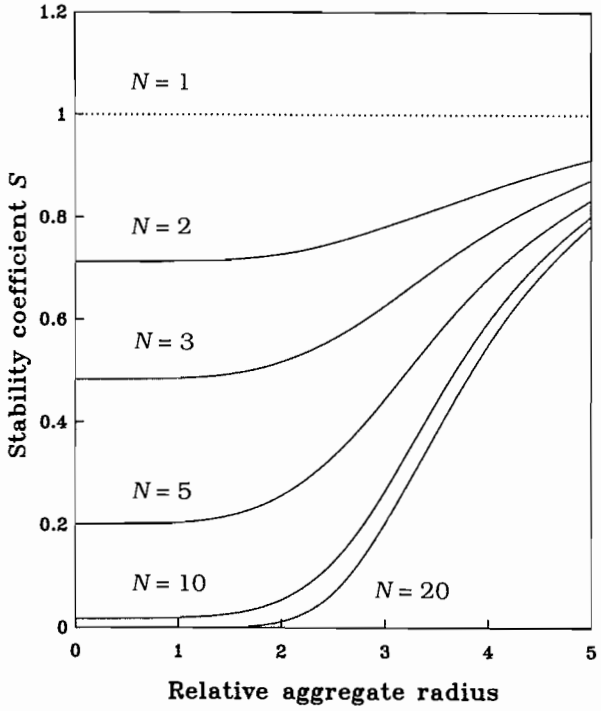

Fig. 5. *S* versus R_{agg} relationships calculated for different *N* values (the monodisperse aggregate system assumed).

be assumed (12), the increase in the ionic strength simultaneously caused two effects facilitating destabilization. It brought about a decrease in the polymer coil dimension as a result of the deterioration of solvent quality and, at the same time, a reduction of the distance of closest approach between particles (12). However, we found that the increase in electrolyte concentration had a much stronger effect on the dimensions of the polyacrylamide coil than on the effective radius of the AgI particles (obtained by adding the distances of effective interparticle repulsion, calculated from DLVO theory, to the mean AgI particle radius determined electron microscopically) (12, 23). Thus, one can conclude that the restriction of the space available for quasi-free motions of AgI particles attached to a polyacrylamide molecule was an important factor, if not the main one, that promoted the destabilization process.

5. Concluding remarks

A simple model describing the stability of a colloidal system containing aggregates composed of ultralarge polymer chains and fine colloidal particles is presented. The model describes monodisperse and diluted colloidal systems. The model is based on the following ideas: (*i*) a single polymer molecule may bind a number of colloidal particles; (*ii*) the Brownian mobility of an attached particle is restricted by the polymer chain length and by the number of particles attached to a polymer molecule; (*iii*) a change in the Brownian mobility of particles attached to the polymer chain influences the sedimentation equilibrium of the colloidal system. The model predicts that (*a*) the longer the polymer chain (i.e., the larger the MW), the lower the flocculation effectiveness of the polymer, and (*b*) the more particles that are attached to a single polymer molecule, the less stable the colloidal system. The former effect is contrary to the commonly known influence of polymer MW on flocculation efficiency. Therefore we wish to emphasize that the model presented deals only with systems containing macromolecules and particles of considerably different sizes. Thus, the model results can be employed to elucidate the deterioration of the ability of ultralarge polymers to flocculate fine suspensions. They do not allow, however, a generalization of the relationship obtained between the stability coefficient and the macromolecule size for the whole range of polymer MW.

Reactions of alkoxyaryloxycarbenes with tethered triple bonds: a new synthesis of substituted benzofurans

Karim Kassam, Paul C. Venneri, and John Warkentin

Abstract: Cyclic 3-alkoxy-3-aryloxyvinylcarbenes can be generated by a highly *exo*-selective intramolecular cyclization of a dioxycarbene onto a tethered triple bond. Like their dialkoxy counterparts, the 3-alkoxy-3-aryloxyvinylcarbene intermediates are capable of interesting reactions. In contrast to 3,3-dialkoxyvinylcarbenes, which undergo a formal [3+2] cycloaddition with highly electron-deficient olefins such as benzylidenemalononitrile, 3-alkoxy-3-aryloxyvinylcarbenes undergo a highly diastereoselective [1+2] cycloaddition with benzylidenemalononitrile to give cyclopropylketene acetals. At high temperatures, those cyclopropylketene acetals undergo a clean vinylcyclopropane rearrangement in which the stereochemical integrity of the cyclopropane is retained.

Key words: carbene, alkoxyaryloxy, [1+2] cycloaddition, ketene acetal, vinylcyclopropane rearrangement, oxadiazoline.

Résumé : Il est possible de générer des 3-alkoxy-3-aryloxyvinylcarbènes cycliques par le biais d'une cyclisation intramoléculaire *exo*-sélective d'un dioxycarbène sur une triple liaison fixée. À l'instar de leurs analogues dialkoxy, les intermédiaires 3-alkoxy-3-aryloxyvinylcarbènes peuvent donner lieu à des réactions intéressantes. Par opposition aux 3,3-dialkoxyvinylcarbènes, qui subissent une cycloaddition formelle [3+2] avec les oléfines hautement déficientes en électrons tel que le benzylidènemalononitrile, les 3-alkoxy-3-aryloxyvinylcarbènes réagissent avec le benzylidènemalononitrile pour donner une cycloaddition [1+2] hautement diastéréosélective conduisant à ces acétals de cyclopropylcétènes. À températures élevées, ces acétals de cyclopropylcétènes subissent un réarrangement propre de vinylcyclopropane dans lequel l'intégrité stéréochimique du cyclopropane est maintenue.

Mots clés : alkoxyaryloxycarbène, cycloaddition [1+2], acétal de cétène, réarrangement de vinylcyclopropane, oxadiazoline.

[Traduit par la rédaction]

Introduction

Ring-forming reactions through reactive intermediates such as anions, cations, radicals, carbenes, and ylides have long held a prominent place in organic synthesis. In an extensive study, Boger et al. demonstrated that 3,3-dialkoxyvinylcarbenes such as **1**, which are reversibly generated by the thermal (≈80°C) ring opening of the corresponding cyclopropenone acetals (**2**), are interesting and synthetically useful reactive intermediates (1). These vinylcarbenes undergo a variety of reactions that depend highly upon the nature of the reacting partner. In one reaction pathway, the vinylcarbenes can react with olefins in a [1+2] cycloaddition (1*c*), a process that is also common to other carbenes. For example, thermal generation of **1** from **2** in the presence of an olefin such as methylacrylate or acrylonitrile, with one electron-withdrawing substituent, leads to the participation of the vinylcarbene (**1**) in a [1+2] cycloaddition reaction with the olefin to give the corresponding cyclopropylketene acetal (**3**) (Scheme 1). This reaction proceeds with a pronounced *endo* effect to give primarily the *cis* cycloadduct (1*h*). Due to the labile nature of the ketene acetal moiety, **3** were intentionally hydrolyzed (1*h*) with aqueous acid prior to chromatography to give the corresponding *cis*-cyclopropane esters (**4**).

In contrast to the above reaction, generation of 3,3-dialkoxyvinylcarbenes such as **1** in the presence of a highly electron-deficient olefin such as benzylidenemalononitrile or dimethyl benzylidenemalonate, each possessing two geminal electron-withdrawing groups (EWG), leads to overall [3+2] cycloaddition between the vinylcarbene and the olefin (Scheme 1) (1*b*, *g*). In this case, the vinylcarbene (**1**) behaves as a 1,3-dipole to give a substituted cyclopentenone acetal (**5**). This reaction, which is unique to this particular class of vinylcarbenes (2), represents one of a few all-carbon, overall [3+2] cycloadditions (3) and may provide a valuable complement to the Diels–Alder reaction.[2] The mechanism for the *Boger cycloaddition* is believed to involve a single electron transfer

[2] Such vinylcarbenes are not 4π systems (not vinyl anions) and cannot undergo concerted [$_{\pi}4_{s}$ + $_{\pi}2_{s}$] cycloadditions with 2π systems (1*a*). For that reason we use the words "formal" or "overall" to denote the [3+2] outcome of the reaction rather than the mechanism.

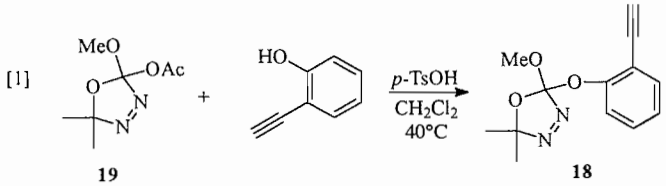
Scheme 1.

from the electron-rich vinylcarbene to the electron-deficient olefin, followed by subsequent radical-cation – radical-anion collapse (1*a*). This proposed mechanism nicely accounts for the fact that only highly electron-deficient olefins, which are good electron acceptors, undergo the overall [3+2] cycloaddition with 3,3-dioxyvinylcarbenes, whereas mildly electron-deficient olefins react via the [1+2] cycloaddition pathway.

Ab initio calculations with electron correlation (at the MP2/6-31^{++}G(d)//6G-31^{++}G(d) level) on 3,3-dihydroxyvinylmethylene revealed that the *anti* π-delocalized closed-shell singlet (**6**) is the most stable state of this vinylcarbene (1*a*). This result is consistent with the observed dual reactivity of 3,3-dialkoxyvinylcarbenes as three carbon 1,1- and 1,3-dipole equivalents.

6

Following the investigation by Boger and Brotherton, Nakamura and co-workers reported the preparation and subsequent thermal reactions of a variety of substituted cyclopropenone acetals (4). In this study a number of substituents, of different electronic character, were investigated. It was found that anion-stabilizing substituents (such as ester or phenylthio) dramatically control the regioselectivity of the cyclopropenone acetal ring opening to give exclusively the more stable vinylcarbene **8**. Like their unsubstituted counterparts, the substituted vinylcarbenes (**8**) also effectively participate in overall [3+2] cycloadditions with highly electron-deficient olefins (Scheme 2). Moreover, ester- or phenylthio-substituted cyclopropenone acetals undergo thermal ring opening at temperatures well below 25°C. With careful preparation of the substituted cyclopropenone acetals (**7**), followed by immediate addition of a suitable electron-deficient olefin, a mild and regioselective construction of highly substituted cyclopentenone acetals (**9**) is available. The low temperature sufficient for the thermal ring opening of these cyclopropenone acetals (**7**) is also a disadvantage because, in contrast to **2**, the cyclopropenone acetals cannot be stored for future application.



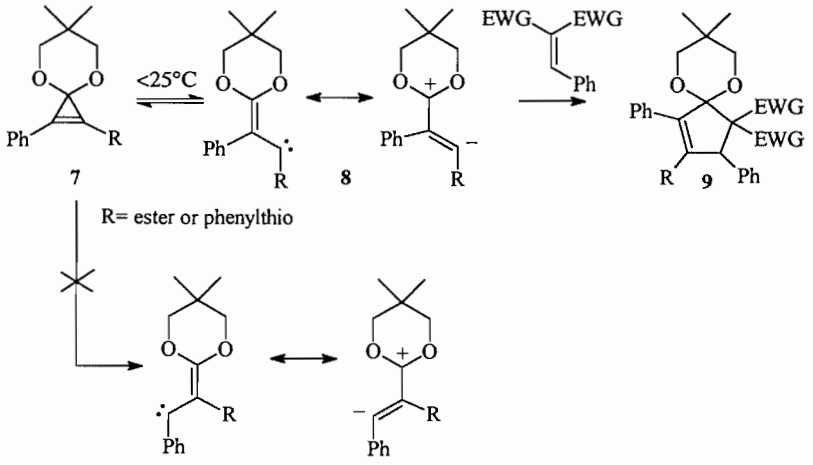
Recently, we have demonstrated that cyclic 3,3-dialkoxyvinylcarbenes (**10** or **11**) can be generated efficiently by the intramolecular cyclization of dialkoxycarbene **12** onto a tethered alkyne moiety (Scheme 3) (5). This reaction could proceed either via a cyclopropenone acetal intermediate (**13**) or via direct intramolecular attack of the dialkoxycarbene onto one of the two alkyne carbon atoms. It was found that the nature of the alkynyl substituent (R) controls the regioselectivity of the vinylcarbene formation. For example, when R = H or CH_3 and n = 1, an endocyclic 3,3-dialkoxyvinylcarbene (**10**) is generated, as inferred from trapping of the intermediate vinylcarbene with an alcohol to give ketene acetal **14**. Conversely, when R = E (ester) and n = 1 or n = 2, an exocyclic vinylcarbene (**11**) is generated exclusively. Vinylcarbene **11** can be trapped by an alcohol to give the corresponding ketene acetal (**15**), or it can participate in a formal [3+2] cycloaddition with benzylidenemalononitrile. The latter reaction has significant synthetic potential as it leads to the rapid and selective construction of a highly functionalized bicyclic ring system (**16**).

The requisite dialkoxycarbenes possessing a tethered triple bond (**12**) can be generated conveniently by the thermal decomposition of the corresponding oxadiazolines (**17**) (5, 6). Such oxadiazolines can undergo thermal decomposition (110°C) by the loss of N_2 and acetone to generate dialkoxycarbenes cleanly. The fact that oxadiazolines are easily prepared (7) and are stable at room temperature makes them convenient dioxycarbene precursors for synthetic applications.

Herein we report a study of aryloxymethoxy analogues of **17**. These systems are strikingly different from those studied previously, in terms of the regioselectivity of the vinylcarbene formation as well as the reactions of the vinylcarbene intermediate.

Results and discussion

Aryloxymethoxy-substituted oxadiazoline **18** was of interest in order to investigate whether the carbene resulting from thermolysis would undergo an intramolecular cyclization onto the tethered alkyne moiety and, if so, whether the resulting vinylcarbene would be formed regioselectively as observed for **12** with R = H or CH_3. It could be prepared by an acid-catalyzed exchange reaction between the acetoxymethoxy oxadiazoline **19** (7) and *ortho*-hydroxyphenylacetylene (8) in CH_2Cl_2 (eq. [1]). The geometry of the initially formed aryloxymethoxycarbene **20**, Scheme 4, is considerably different from that of **12** (R = H), Scheme 3, in that the tether now consists of five atoms (from oxygen to the terminal alkyne carbon atom) that are coplanar. In addition, the electronic properties of both the carbene and the alkyne are presumably different from those of **12** (R = H) due to the aromatic ring.



19 **18**

Thermolysis (refluxing toluene) of oxadiazoline **18** in the presence of *tert*-butyl alcohol at a low concentration (to minimize capture of the first-formed carbene) gave one major product with the mass of the carbene plus the alcohol. This composition was inferred from the GC–MS trace of the crude

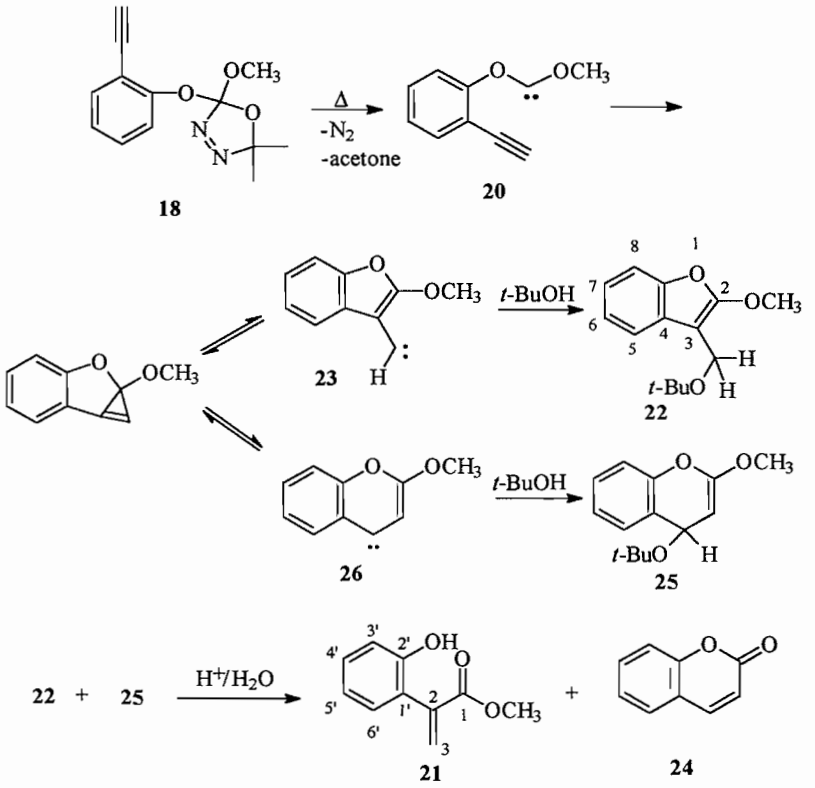
Scheme 3.

thermolysis product. Attempted purification of this product by chromatography or by distillation led to decomposition. This sensitivity was not surprising given that the expected product is a ketene acetal, a class of compounds that are prone to hydrolysis or polymerization (9). Consequently, the crude thermolysis product was intentionally hydrolyzed (*p*-TsOH–H_2O) to give a stable compound that could easily be purified by chromatography. The major product obtained from hydrolysis was isolated in 40% yield and was shown to have structure **21** on the basis of spectral data. Formation of **21** is attributed to hydrolysis of **22**, which is derived from an O-H insertion reaction of the exocyclic vinylcarbene **23** with the alcohol. The presence of **22** was confirmed from the spectroscopic data of the crude thermolysis mixture. Therefore, in contrast to **12** (R = H), which cyclizes to give an endocyclic vinylcarbene (**10**) exclusively, the cyclization of **20** seems to give primarily the exocyclic vinylcarbene (**23**). Analysis of the ^{1}H NMR spectra and GC–MS trace of the crude hydrolysis mixture also showed evidence for the formation of coumarin (**24**), which is likely obtained from hydrolysis of **25**. The formation of **25** can be attributed to trapping of the endocyclic vinylcarbene **26** with *tert*-butyl alcohol. The ratio, **21**:**24**, was estimated to be approximately 5:1 by ^{1}H NMR spectroscopy, indicating a moderately high preference for the formation of **23**.

The preferential formation of an exocyclic vinylcarbene (**23**) upon thermolysis of oxadiazoline **18** raised the possibility of capturing **23** in a formal [3+2] cycloaddition with a highly electron-deficient olefin such as benzylidenemalononitrile. This cycloaddition would lead to a novel functionalized tricyclic benzofuran ring system **27** (Scheme 5).

Thermolysis of oxadiazoline **18** in the presence of benzylidenemalononitrile in low concentration led to the formation of one major product in 67% yield. This product had the mass (by EI mass spectrometry) expected for **27**. Surprisingly, only a single diastereomer was obtained. The ^{1}H NMR and ^{13}C NMR spectra of this product, on the other hand, were not consistent with structure **27**. Most significantly, in the ^{1}H NMR spectrum, two doublets corresponding to two methine protons were too far upfield to be consistent with structure **27** and, in addition, the ^{13}C NMR spectrum included a signal at high field (δ: 14.4 ppm), which could not be assigned to a carbon of **27**. The product was eventually shown to have structure **28**, based on comparison of its ^{1}H and ^{13}C NMR spectra with those of a close analogue (**30**, vide infra), the structure of which was secured by single crystal X-ray diffraction.



The formation of **28** is highly unusual, given that reactions of a 3,3-dioxyvinylcarbene with benzylidenemalononitrile, or related olefins, have been shown to give cyclopentene

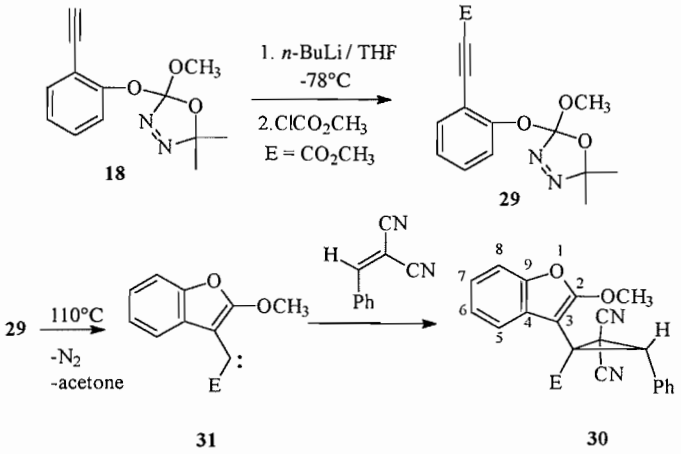
Scheme 4.

Scheme 5.

products in every previous case studied (1, 4, 5). There has not been any evidence in support of formation of a [1+2] cycloadduct. Of additional interest is the fact that **28** was formed with *trans* stereoselectivity on the cyclopropane ring.



An ester-substituted analog of **18** was prepared in order to investigate whether the ester group may have played a role in facilitating the overall [3+2] cycloaddition of **12** (R = E) with benzylidenemalononitrile. Oxadiazoline **29** was prepared from **18** by deprotonation of the alkyne moiety with *n*-butyllithium, to form the corresponding acetylide, followed by treatment of the acetylide with methyl chloroformate (Scheme 6).

Thermolysis of **29** in the presence of benzylidenemalononitrile in low concentration led to the formation of one major product (**30**) with NMR spectra closely resembling those of **28** (Scheme 6). This product was isolated in 37% yield and its structure was determined by single crystal X-ray diffraction.[3]

[3] A manuscript containing details of the molecular and crystal structures will be submitted to Acta Crystallogr. Sect. C.

© 1997 NRC Canada

Scheme 6.

The formation of **30** can be attributed to a [1+2] cycloaddition of the intermediate 3,3-dioxyvinylcarbene (**31**) and, as in the case of **27**, only one stereoisomer, with the benzofuran and the phenyl groups *trans*, was obtained.

The stereochemistry observed for both **28** and **30** can be rationalized simply on the basis of steric effects. The transition state for the [1+2] cycloaddition, which has the benzofuran moiety of the vinylcarbene *syn* with respect to the phenyl group of the olefin, suffers greater steric hindrance than that in which the two groups are *anti*.

The surprising [1+2] cycloaddition of both vinylcarbenes **23** and **31**, in the face of precedents for exclusive overall [3+2] cycloadditions by analogues (Introduction), can also be rationalized. Presumably both **23** and **31** have less 1,3-dipole character[4] than dialkoxy counterparts and are therefore more likely to behave as typical localized carbenes. The reduced 1,3-dipole character could stem from two possible sources. First, π-donation into the formally vacant carbene *p*-orbital is reduced because of the inherently poorer electron-donating ability of an aryloxy substituent than of an alkoxy substituent. Second, benzofuran is a 10 π-electron aromatic ring system, and both **23** and **31** presumably have reduced contributions from 1,3-dipolar contributors in order to maintain most of the aromaticity (Scheme 7).

As a result of the poorer π-electron delocalization of carbenes **23** and **31**, a single electron transfer from the carbene to the olefin, which, according to Boger and Brotherton-Pleiss, is required for an overall [3+2] cycloaddition (1*a*), would result in a radical cation that is less stabilized than the corresponding radical cation from systems such as **11** (Scheme 7). Consequently, the reason why **23** and **31** undergo a [1+2] cycloaddition, instead of a formal [3+2] cycloaddition, with benzylidenemalononitrile probably lies in the higher oxidation potentials of these carbenes. Nevertheless, the fact that vinylcarbenes **23** and **31** undergo facile reaction with the highly electron-deficient olefin implies that these carbenes still have nucleophilic character.

Thermolysis of **18** or **29** in the presence of dimethyl acetylenedicarboxylate (DMAD) at a low concentration produced a complex mixture of products that were not identified. This clearly indicates the dramatically different nature of vinylcarbenes **23** and **31** in comparison to vinylcarbenes **11** (n = 1 or 2), which undergo a relatively clean, formal [3+2] cycloaddition with DMAD (5*a*).

Vinylcyclopropane rearrangement of adducts 28 and 30

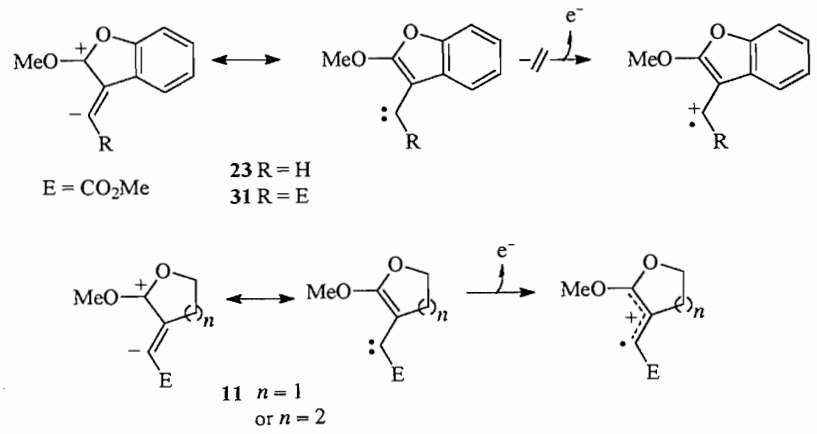
The vinylcyclopropane rearrangement in simple unsubstituted systems has been studied extensively (10). This transformation has also been exploited in a number of synthetic applications for the construction of substituted cyclopentenes (11).

In theory, cycloadducts **28** and **30** can undergo a vinylcyclopropane rearrangement, to afford the ring system that was initially expected from overall [3+2] cycloaddition of vinylcarbenes **23** or **31** to benzylidenemalononitrile. However, Boger and Brotherton-Pleiss had shown that cyclopropyl ketene acetals such as **3** (Introduction), which are closely related to **28** and **30**, do not undergo vinylcyclopropane rearrangement even at temperatures as high as 200°C (1*a*). Nevertheless, adducts **28** and **30** might be more likely than **3** to undergo the vinylcyclopropane rearrangement because of the presence of the two geminal electron-withdrawing cyano groups on the cyclopropane ring, which would be expected to stabilize a possible zwitterionic or biradical intermediate. Added interest in the rearrangement was derived from the potential for diastereoselectivity, **28** and **30** being diastereomerically pure.

Heating a degassed[5] sample in toluene indeed converted **30** to the expected product (**32**) of a vinylcyclopropane rearrangement, as inferred from the spectroscopic data and later confirmed by single crystal X-ray diffraction.[3] The reaction proceeded cleanly but very slowly; even after 4 days at 150°C, the conversion was only about 50%.

Of particular interest was the fact that a single diastereomer was obtained, indicating that the vinylcyclopropane rearrangement proceeded with very high diastereoselectivity. Specifically, the closure of a possible dipolar or diradical intermediate in this rearrangement proceeds with π-facial selectivity (Scheme 8) or, alternatively, the rearrangement is concerted, as in the case reported recently by Gajewski et al. (12). In favour of a diradical process, either as the mechanism of formation of **32** or as a minor side reaction, was the observation that bibenzyl (from toluene solvent) could be detected by GC–MS. In any case, this two-step approach involving an initial [1+2] cycloaddition to give a cyclopropylketene acetal, followed by a vinylcyclopropane rearrangement, results in the diastereoselective formation of an interesting ring system (**32**).

Cyclopropylketene acetal **28** was also shown to undergo a vinylcyclopropane rearrangement, albeit more slowly, under similar conditions. After four days at 150°C, the conversion was about 33% complete. The rearrangement in this case also proceeded diastereoselectively to provide **27**. A minor coproduct, detectable by GC–MS, was bibenzyl, presumably from



[4] Alternatively, one can write "are less easily oxidized," to emphasize the proposed radical cation mechanism (1*a*).

[5] An undegassed sample afforded a product containing an extra atom of oxygen (HRMS). Although it was a solid, attempts to grow a crystal satisfactory for single crystal X-ray diffraction failed. The NMR spectroscopic data were inconclusive and further work on that potentially interesting product is required.
