1996 Polanyi Award Lecture
Proton reactions in clusters[1]

Raymond Kapral, Styliani Consta, and Daniel Laria

Abstract: Reactions in mesoscopic, molecular clusters may proceed by mechanisms and with rates that differ from those in bulk solvents. Two examples of reactions in large, liquid-state, molecular clusters are described to illustrate the distinctive features of these reactions: acid dissociation and proton transfer in aprotic, polar solvents. Both of these reactions involve proton dynamics so methods for dealing with mixed quantum–classical systems must be utilized to investigate the reaction dynamics. Surface versus bulk solvation effects play an important role in determining the reaction mechanisms as do the strong cluster fluctuations. Mechanisms for proton transfer within clusters that have no bulk analogs will be described.

Key words: proton reactions, mesoscopic clusters.

Résumé : Les mécanismes de réactions qui se produisent dans des agrégats moléculaires mésoscopiques peuvent être différents de ceux observés dans les masses de solvants. Pour illustrer les caractéristiques particulières de ces réactions, on décrit deux exemples de réactions effectuées dans de grands agrégats moléculaires, à l'état liquide : la dissociation acide et le transfert de proton dans des solvants polaires aprotiques. Ces deux réactions impliquent la dynamique des protons; pour étudier la dynamique de ces réactions, on doit donc utiliser les méthodes qui s'appliquent aux systèmes de quantum–classique mixtes. Par rapport aux effets de solvatation, les effets de surface jouent un rôle plus important dans la détermination des mécanismes de réaction; il en est de même pour les fortes variations dans les agrégats. On décrira les mécanismes de transfert de proton dans les agrégats qui n'ont aucune ressemblance avec ceux impliqués dans les masses de solvant.

Mots clés : réactions de proton, agrégats mésoscopiques.

1. Introduction

Clusters composed of tens to hundreds of molecules are sufficiently large that their chemistry differs from that of few-molecule clusters, yet they are so small that they cannot be classified as macroscopic objects. Important features that enter the description of chemical properties and dynamics are the cluster density and shape fluctuations and the strong effects that surface forces have on the position and orientation of molecules in the cluster. A number of different aspects of cluster reactions have been studied (see, for example, ref. 1) but here we examine reaction dynamics in mesoscopic, liquid-state clusters.

Since these clusters provide environments that differ significantly from either small molecular aggregates or bulk liquids, it is of interest to inquire if reaction rates or mechanisms have distinctive features in such media. By means of two examples, acid ionization and proton transfer, we shall show that this is indeed the case. The mechanisms of both reactions are known to be influenced by the solvent in which they take place; in fact, the solvent is responsible for the very existence of reactant and product states. In addition, the two examples involve protons so one must consider the quantum character of the proton in any description of the reaction dynamics.

In Sect. 2 we examine acid ionization processes in aprotic, polar, molecular solvents. In particular, we consider the ionization of HCl in acetonitrile and dimethyl sulfoxide, two solvents with similar dipole moments but very different solvation properties (2). We determine whether solvent-separated ion pairs can exist in clusters and examine the influence of surface forces on the solvation structure. Section 3 considers proton transfer in a proton–ion complex consisting of two ions and a proton. This complex is a constituent of a polar molecular cluster and again the focus is on how the cluster environment can alter the mechanism and rate of the transfer reaction (3, 4). The conclusions are presented in Sect. 4.

2. Ionization of acids in clusters

The equilibria of ions dissolved in polar solvents present some interesting features that have consequences for the mechanisms of reactions. Consider an acid HA dissolved in

a polar solvent S. We may schematically represent the ionization process as

[1] $HA \longrightarrow H^+||A^- \longrightarrow H^+(S) + A^-(S)$

The configuration $H^+ \,||\, A^-$ denotes a solvent-separated ion pair (SSIP), a metastable configuration corresponding to a local minimum in the free energy as a function of the separation between the H^+ and A^- ions (5). In this section we shall investigate this process for HCl in acetonitrile (ACN) and dimethyl sulfoxide (DMSO) clusters and bulk. In particular we shall describe the computation of the free energy for this quantum ionization process and determine if a local minimum does indeed exist so that a SSIP species may be identified (2).

A. Potential of mean force

The equilibrium structure is determined by the potential of mean force, $W(r)$, as a function of the separation between the H^+ and Cl^- ions. This quantity may be determined from a knowledge of the probability density, $P(r')$, for finding a particular numerical value r' of the separation r according to the formula

[2] $$W(r') \sim -kT \ln P(r') = -kT \ln \langle \delta(r - r') \rangle$$

where $\langle \cdots \rangle$ signifies an equilibrium ensemble average and $\delta(r)$ is the Dirac delta function. The mean force is related to the mean potential by

[3] $$F(r') = -\frac{dW(r')}{dr'}$$

From eq. [2] we see that in order to compute $W(r)$ one must consider a fixed value of the separation $r = r'$ and average over an equilibrium distribution of all other degrees of freedom. This calculation was carried out using the constrained-reaction-coordinate-dynamics (CRCD) ensemble (6, 7) by applying a holonomic constraint to the equations of motion that fixes the separation at a prescribed value (8).

B. Quantum description of the proton

Since the proton is a quantum mechanical particle and the chloride ion and solvent are classical particles to a good approximation, a scheme must be devised for the computation of the potential of mean force that takes this feature into account. If only static properties are of interest this is easily accomplished by using a Feynman path integral representation of the proton (9). In this scheme the similarity between the Boltzmann factor $\exp(-\beta\hat{H})$ and the quantum mechanical propagator $\exp(-i\hat{H}t/\hbar)$ is utilized with the identification of $\beta \rightarrow it/\hbar$ as the imaginary time where β^{-1} is Boltzmann's constant times the temperature. If the imaginary time is discretized into P segments, where P is determined by the de Broglie wavelength of the particle, the quantum proton is represented as a classical ring polymer composed of P monomers (9, 10). In this representation the effective potential of the system, solvent plus chloride ion and proton, is given by

[4] $$V_{\text{eff}} = V_{\text{cl}}(\boldsymbol{R}^N) + \frac{Pm_{\text{p}}}{2(\beta\hbar)^2} \sum_{i=1}^{P} (\boldsymbol{r}_i - \boldsymbol{r}_{i+1})^2 + \frac{1}{P} V_{\text{p}}(\boldsymbol{r}^P, \boldsymbol{R}^N)$$

where m_{p} is the proton mass. Here $V_{\text{cl}}(\boldsymbol{R}^N)$ is the potential energy for all the classical particles and $V_{\text{p}}(\boldsymbol{r}^P, \boldsymbol{R}^N)$ is the interaction energy between the proton monomers and the classical particles. A value $P = 20$ suffices for an accurate description of the proton.

If one assigns a fictitious mass m^* to the proton monomers and adds a kinetic energy term to the effective potential energy a Hamiltonian may be constructed for this system:

[5] $$H = \sum_{i=1}^{P} \frac{1}{2} m^* \dot{\boldsymbol{r}}_i^2 + \sum_{j=1}^{N} \frac{1}{2} M_j \dot{\boldsymbol{R}}_j^2 + V_{\text{eff}}$$

where the second term on the right hand side is the usual kinetic energy term for the classical particles. This Hamiltonian may be used to generate the dynamics of the classical particles and proton monomers. While this dynamics is fictitious due to the introduction of the proton monomer kinetic energy, the equilibrium properties are independent of the kinetic energy and thus the trajectories may be used to compute equilibrium averages making use of the usual replacement of ensemble averages by time averages over the system trajectory.

The proton position was taken to be the centroid of the proton polymer (11)

[6] $$\boldsymbol{r}_{\text{c}} = \frac{1}{P} \sum_{i=1}^{P} \boldsymbol{r}_i$$

The mean force on the ion pair separated by a distance $r = |\boldsymbol{R}_{\text{Cl}} - \boldsymbol{r}_{\text{c}}|$ was calculated from the formula (12)

[7] $$F(r) = \left\langle \sum_{i=1}^{P} \boldsymbol{F}_i \cdot \hat{\boldsymbol{r}} \right\rangle_r + \frac{2}{\beta r}$$

where $\boldsymbol{F}_i$ is the force exerted by the Cl^- and the solvent particles upon the ith proton monomer, $\hat{\boldsymbol{r}} = \boldsymbol{r}/|\boldsymbol{r}|$ and $\langle \ldots . \rangle_r$ signifies a time average computed using the constrained reaction coordinate dynamics ensemble (6). The situation is shown schematically in Fig. 1. The mean potential $W(r)$ was computed from an integration of the mean force:

[8] $$W(r) = W(r_0) + \int_{r_0}^{r} dr' \, F(r')$$

C. Ionization in ACN and DMSO clusters

The potential of mean force is shown in Fig. 2 for bulk phase ACN and DMSO as well as for a cluster containing 30 DMSO solvent molecules. These results for bulk solvent show that SSIPs are found in DMSO but not in ACN. The free energy barrier for passage from the SSIP configuration at $r_{\text{s}} = 7.5$ Å to the bound ion pair is $\Delta W_{\text{DMSO}} = W_{\text{DMSO}}(r_{\text{max}}) - W_{\text{DMSO}}(r_{\text{s}}) = 5.4$ kcal/mol, where r_{max} is the position of the maximum between the bound ion pair configuration and the SSIP. In contrast, ACN has only a very shallow minimum whose magnitude is within the statistical uncertainty of our results.

The cluster free energy shows that SSIPs are also found in

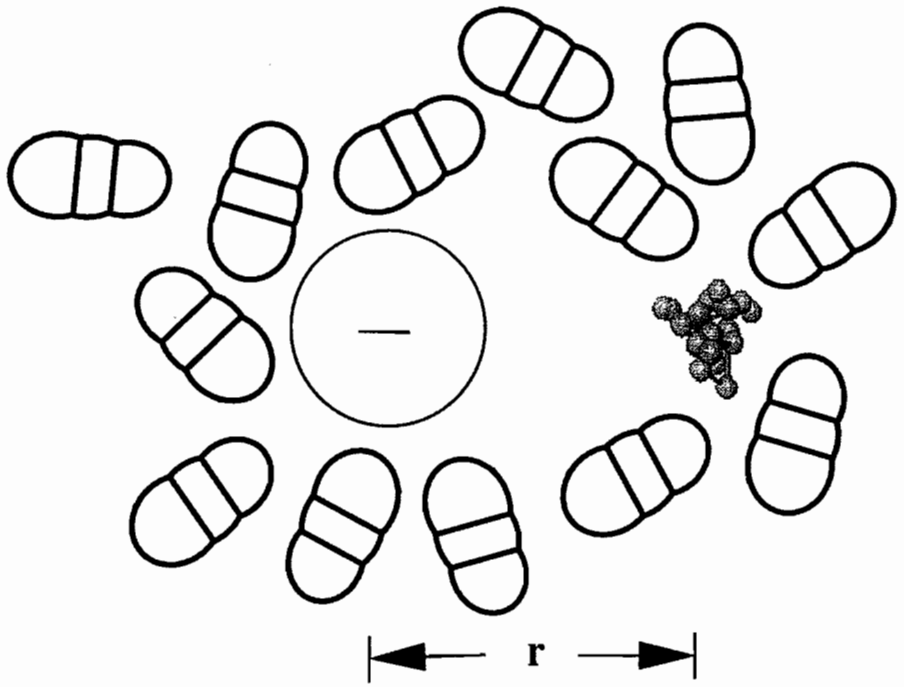
Fig. 1. Schematic diagram showing the constrained separation r between the Cl^- ion and the proton centroid. In the molecular dynamics simulation r is constrained but all other coordinates (apart from those fixed by bond constraints) are allowed to evolve according to the equations of motion.



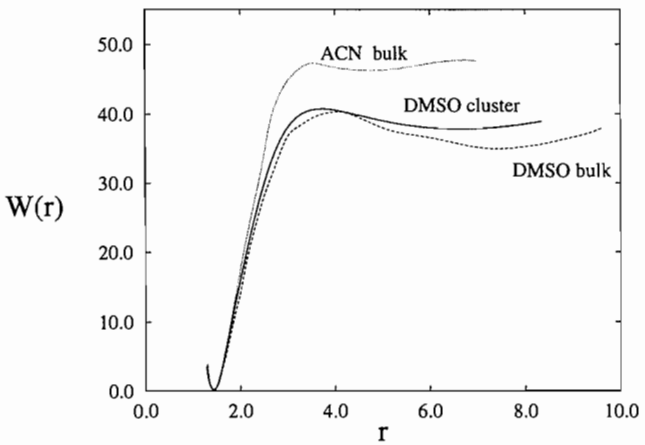


Fig. 2. Potential of mean force $W(r)$ in kcal/mol for bulk ACN, bulk DMSO, and a $N = 30$ DMSO cluster.

four nearest solvent molecules around the proton. Examina- the $N = 30$ DMSO cluster with a free energy barrier between the SSIP and bound ion pair states of $\Delta W_{DMSO}(n = 30) = 1.8$ kcal/mol. The solvation structure in the bulk and cluster phases is subtly different for both solvents. In either solvent case there is similar coordination and orientation of roughly tion of the solvation structure reveals qualitatively similar configurations at r values in the vicinity of the metastable minimum. In the ACN cluster, which is not shown in Fig. 2, the free energy presents no SSIP minimum.

In spite of the qualitative similarities in the solvation structure there are differences that are responsible for both the widely different ionization constants in these two solvents and the existence of SSIPs in DMSO. For example, the solvent structure in the transition region between bound ion pair and SSIP configurations is different in the two solvents. The dipolar density shows that the ACN molecules have a considerable degree of orientational variability so that when the molecular dipole moment is projected onto the z-axis of the ion pair the projection can take either sign. However, the dipolar density of DMSO shows no such effect, implying that the DMSO molecules are much more rigidly ordered in the first solvation shell. Consequently, it appears that, in ACN, fluctuations are sufficiently large to promote dipolar orientations that favor passage from SSIP to bound ion pair states. In DMSO a much more structured three-dimensional solvent network exists that hinders molecular rotations and leads to a larger free energy barrier.

The cluster environment has an important influence on the ionization process. For ion pair separations as large as that for the SSIP state, the cluster potential of mean force closely corresponds to that of the bulk, even for clusters with as few as $n = 14$ solvent molecules. If the separation between the H^+ and Cl^- ions is large, the finite size of the cluster gives rise to changes in the mean potential as reflected in the "rubber band"-like solvent configurations (cf. Fig. 3) that lead to attractive forces between the ions that cannot exist in the bulk.

3. Proton transfer in clusters

The transfer of a proton between two ions in a proton–ion

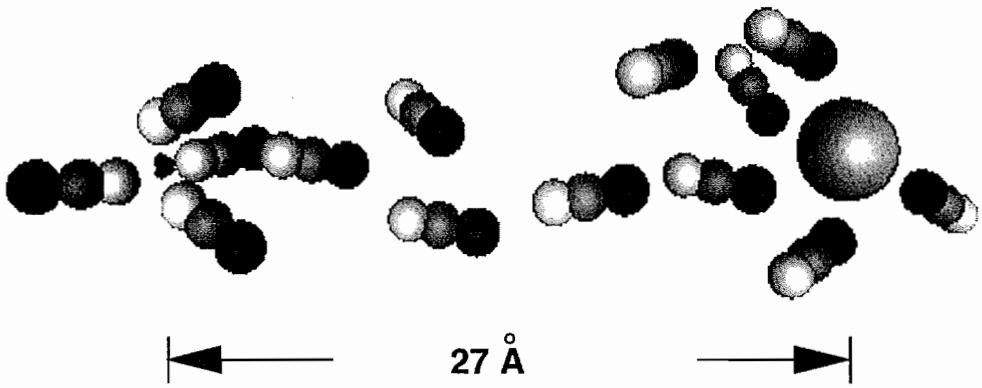

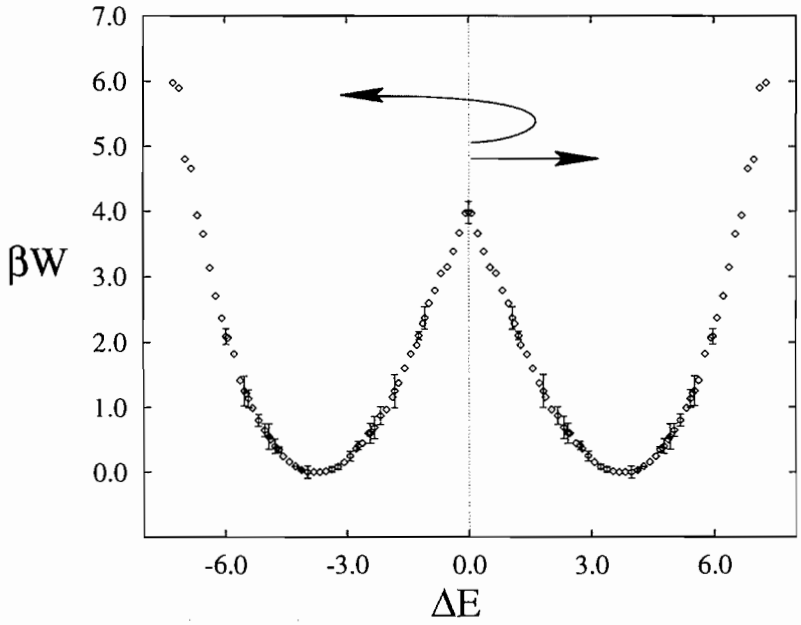

Fig. 4. Potential of mean force and a schematic representation of direct and recrossing trajectories.

complex within a molecular cluster will now be considered (3). The two ions may be taken to represent ion sites in an intramolecular proton transfer or free ions in an intermolecular proton transfer. Since the internuclear separation is fixed, we neglect contributions of the internal modes of the proton–ion complex to the proton transfer reaction. The proton transfer reaction may be written as

[9] $\mathrm{A} - \mathrm{H} \cdots \mathrm{A}^- \rightleftharpoons \mathrm{A}^- \cdots \mathrm{H} - \mathrm{A}$

The solvent molecules comprising the cluster are rigid diatomic molecules with molecular dipole moment $\mu = 5.0$ D (3). We consider liquid-state clusters with $N = 20$ and 67 molecules.

A. Adiabatic dynamics

If the ground state protonic energy level is well separated from the excited states for all solvent configurations the dynamics of the quantum proton in the classical solvent may be treated in the Born–Oppenheimer approximation (for bulk-phase studies, see ref. 13). The Schrödinger equation for the proton in the fixed field of the classical particles is

[10] $$\hat{H}_\mathrm{p}(\nabla_u, u; \boldsymbol{R}^N)\Psi_n(u; \{\boldsymbol{R}\}) = \left[-\frac{\hbar^2}{2m_\mathrm{p}}\nabla_u{}^2 + V_\mathrm{p}(u, \boldsymbol{R}^N)\right]\Psi_n(u; \boldsymbol{R}^N) = \epsilon_n(\boldsymbol{R}^N)\Psi_n(u; \boldsymbol{R}^N)$$

Here $\hat{H}_\mathrm{p}$ is the total proton Hamiltonian, $2\pi\hbar$ is Planck's constant, and n labels the protonic state. The potential energy V_p is the sum of the intrinsic, V_int, and Coulomb, V_c, potentials.

The intrinsic potential has essentially no barrier so that we model proton transfer in a strongly hydrogen-bonded system (see, for instance, ref. 14). Solvent effects are especially large in such a circumstance and in the present model are responsible for the existence of reactant and product species. The free energy along the reaction coordinate is shown in Fig. 4 and indicates the formation of reactant and product states

as a result of solvent interactions. The time evolution of the classical particles is given by Newton's equations of motion

$$[11] \quad m_i\ddot{\boldsymbol{R}}_i = -\nabla_{\boldsymbol{R}_i} V_s(\boldsymbol{R}^N) - \nabla_{\boldsymbol{R}_i}\langle\Psi_0(\boldsymbol{R}^N)|\hat{H}_p(\boldsymbol{R}^N)|\Psi_0(\boldsymbol{R}^N)\rangle$$

where the first term on the right hand side is the force due to all classical particles and the second term is the Hellmann–Feynman force. The Schrödinger equation was solved at each molecular dynamics time step by expanding the wave function in a Gaussian basis and solving the resulting non-orthogonal eigenvalue problem (3).

B. Reaction coordinate

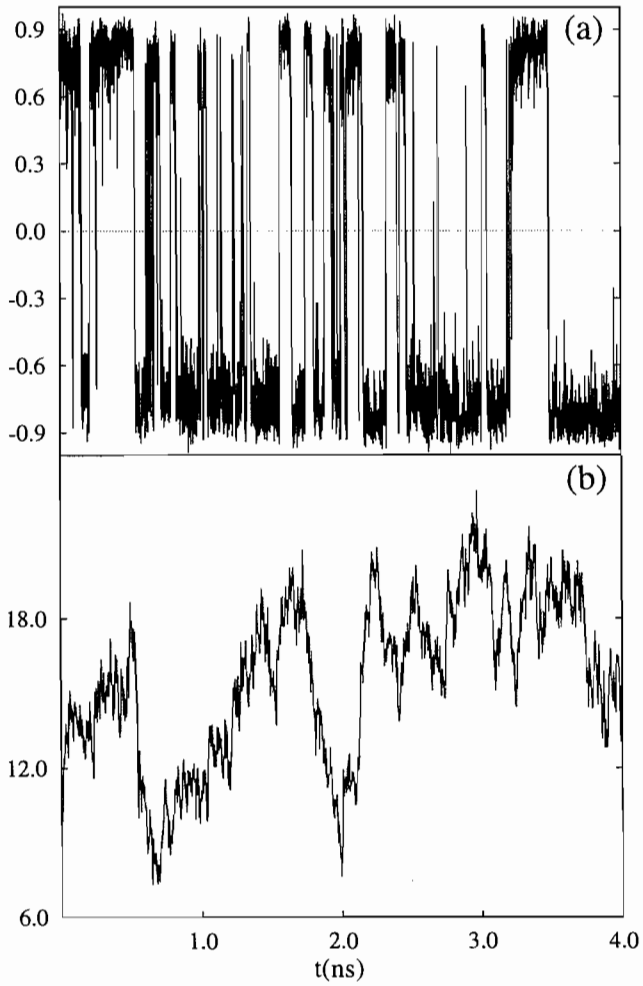
Two reaction coordinates were used to monitor the progress of the reaction. The first is the expectation value of the proton position in the adiabatic ground state,

$$[12] \quad \xi(\boldsymbol{R}^N) = \bar{z}_p(\boldsymbol{R}^N) = \langle\Psi_0(\boldsymbol{R}^N) \mid u \mid \Psi_0(\boldsymbol{R}^N)\rangle$$

While this reaction coordinate monitors the position of the proton one should note that it is a function of the solvent configuration through the dependence of the adiabatic wave function on $\boldsymbol{R}^N$. The second reaction coordinate monitors the progress of the reaction through the solvent polarization (15),

$$[13] \quad \xi(\boldsymbol{R}^N) = \Delta E(\boldsymbol{R}^N) = \sum_{i,a} z_a e\left(\frac{1}{|\boldsymbol{R}_i^a - \boldsymbol{s}|} - \frac{1}{|\boldsymbol{R}_i^a - \boldsymbol{s}'|}\right)$$

where $\boldsymbol{s}$ and $\boldsymbol{s}'$ are two points in the vicinities of the reactant and product configurations. Using this reaction coordinate one views the reaction as being driven by the solvent polarization fluctuations. The transition state corresponds to a symmetrically solvated proton–ion complex in which $\Delta E = 0$ (cf. Fig. 4). In fact, there is a third possibility for the choice of reaction coordinate, the centroid of the polymer chain representing the proton in the Feynman path integral representation, as in the acid dissociation problem considered in the previous section. We have considered this reaction coordinate for cluster proton transfer reactions (4) but here we focus on the first two choices. Both choices of reaction coordinate, $\bar{z}_p(\boldsymbol{R}^N)$ and $\Delta E(\boldsymbol{R}^N)$, provide equivalent descriptions of the transfer process.



C. Reaction mechanism and rate In the bulk phase the proton transfer reaction is driven by solvent polarization fluctuations due primarily to solvent reorientation. We now consider how the transfer occurs in mesoscopic molecular clusters where surface forces and strong solvent orientational and translational fluctuations play an important role. The mechanism of such transfer events depends on the cluster size, even within the mesoscopic domain. As an example we consider one case, a cluster with $N = 67$ solvent molecules, to illustrate some features of the cluster mechanism. This cluster size is large enough to support two solvent shells around the proton–ion complex.

Reactions occur both in the interior of the cluster and on its surface. This can be seen from a comparison of the time series of the reaction coordinate (here $\bar{z}_p(\boldsymbol{R}^N)$) and the distance, $d = |\boldsymbol{d}|$, between the center of mass (CM) of the proton–ion complex and the center of mass of the solvent molecules in the cluster

$$[14] \quad \boldsymbol{d} = N^{-1}\sum_{i=1}^{N} \boldsymbol{R}_i^{CM} - \boldsymbol{R}_{CM} = N^{-1}\sum_{i=1}^{N} \boldsymbol{d}_i$$

where $\boldsymbol{d}_i$ is the vector from the center of mass of the complex to that of the ith solvent molecule, $\boldsymbol{d}_i = \frac{1}{2}(\boldsymbol{R}_{i,1} + \boldsymbol{R}_{i,2}) - \boldsymbol{R}_{CM} = \boldsymbol{R}_i^{CM} - \boldsymbol{R}_{CM}$. This quantity provides a rough measure of the position of the complex within the cluster. One sees in panel (*a*) of Fig. 5 a large number of flips between the reactant and product states of the complex. In the course of this reaction the complex resides for long portions of time on the surface of the cluster but also makes excursions to the interior of the cluster. There is some evidence from this figure that proton transfers are more rapid when the complex is within the cluster. This is not surprising in view of the fact that in this circumstance it is more likely to find symmetric solvent configurations that correspond to the transition state configurations through which the transfer process occurs. In fact, in smaller clusters ($N = 20$) proton transfer occurs only within the interior of the cluster on the several nanosecond time scale on which the simulations were carried out (3).

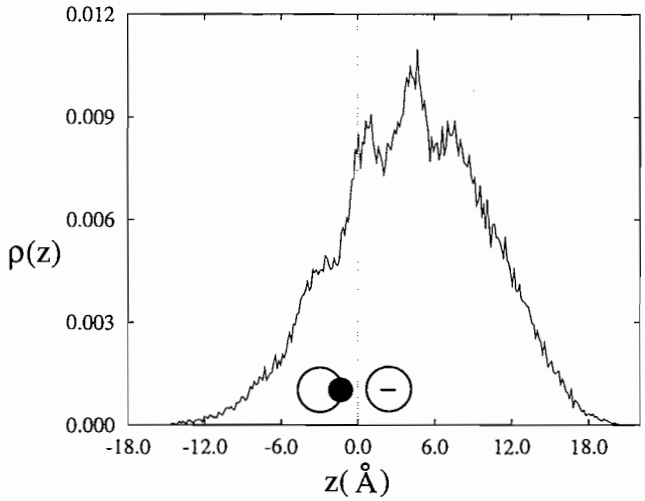


Fig. 5. (*a*) The reaction coordinate $\bar{z}_p(\boldsymbol{R}^N)$ versus time for a cluster with 67 solvent molecules. (*b*) The distance d versus time for the same trajectory.

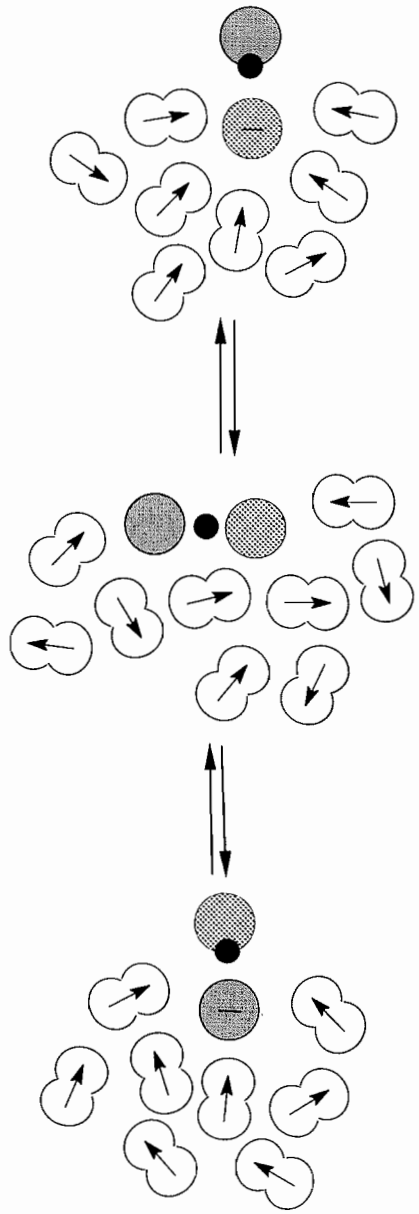
Fig. 6. Probability density of the solvent molecule center of mass projected on the proton–ion complex internuclear axis.



In the somewhat larger clusters, where there are on average approximately two solvent shells, the distinction between bulk and surface manifests itself more clearly. The surface reaction is controlled by the specific solvation structure associated with the proton–ion complex (3, 4). For the complex A—H ··· A^-, the solvent–solvent interactions are stronger than the solvent–(A—H) interactions, while the solvent–A^- interactions are very strong. These considerations suggest that the A^- end of the complex will tend to be strongly solvated within the cluster while the (A—H) end will tend to reside on the surface. In addition to energetic factors, entropic factors favor configurations where the complex resides close to the surface of the cluster. This is indeed the case as can be seen from Fig. 6, which shows the probability density for finding the center of mass of a solvent molecule projected on the z-axis along the interionic bond in the proton–ion complex. This probability density was computed directly from the molecular dynamics trajectory by sampling configurations only when the proton was in the reactant (or product) configuration. The high and asymmetric probability density confirms that the exposed ion is strongly solvated and that the cluster accommodates to the state of the proton–ion complex. Thus, the tendency is for the complex to float on the surface of the cluster like a fishing bob on the surface of a lake: the A^- end is in the cluster and the (A—H) end is out. The reaction occurs as a result of the orientational and positional fluctuations of the complex and solvent. These fluctuations can lead to an orientational change of the complex relative to the surface so that the complex lies parallel to the surface. Also, solvent fluctuations can lead to configurations where the solvation is more nearly symmetrical without deep excursions of the complex to the interior of the cluster. These situations will favor a proton transfer. Once the transfer takes place the original solvation structure is no longer favorable and the proton–ion complex "bob" flips and adopts a configuration with the opposite ion strongly solvated within the cluster. This situation is depicted schematically in Fig. 7.

The rate constant of the reaction was computed using the reactive flux correlation expression (7, 16)

$$[15] \quad k(t) = \frac{\langle \Delta\dot{E}(0)\delta(\Delta E(0))\theta[\Delta E(t)]\rangle}{\langle\theta[\Delta E(t)]\rangle} = k^{\mathrm{TST}}\kappa(t)$$

Fig. 7. Schematic picture showing the dominant solvation structures of the proton–ion complex in the reactant and product configurations and the process responsible for the proton transfer.

where the angular brackets represent a canonical ensemble average, and $\theta(\Delta E(t))$ is the Heaviside function. Here we have used the solvent polarization coordinate $\Delta E(\boldsymbol{R}^N)$ to monitor the progress of the reaction. The ensemble averages were computed in the CRCD ensemble. The breakup of $k(t)$ into a transition state theory rate constant, k^{TST}, and a time-dependent transmission coefficient, $\kappa(t)$, is a convenient way to view the reaction dynamics. Figure 4 shows the free energy along the reaction coordinate and a schematic representation of trajectories starting at the free energy barrier that go directly to products and contribute to the TST rate constant, and recrossing trajectories that lower the TST rate and lead to a κ value that is less than unity. Provided there is a large time scale separation between the reactive and other processes, the full rate constant k can be determined as $k(t^*)$

© 1997 NRC Canada

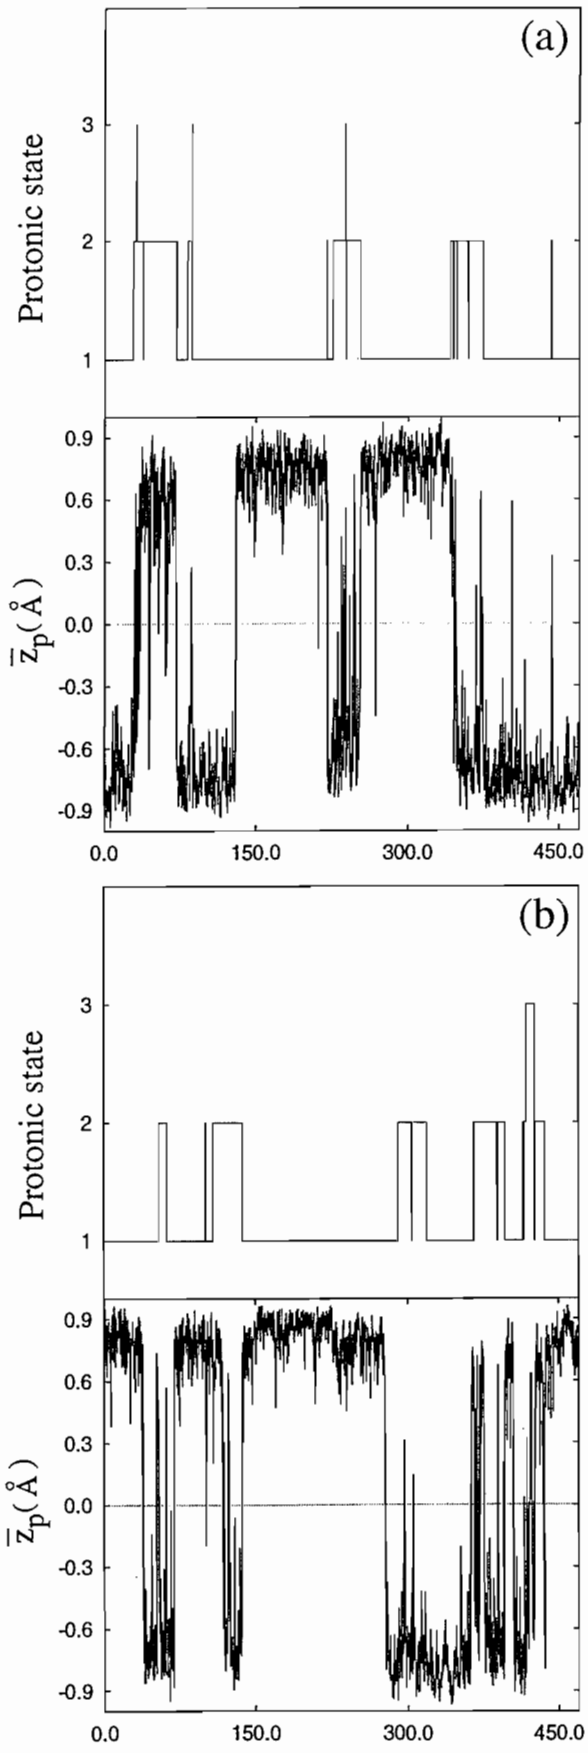
where t^* is a time of order $t_{mic} \ll t^* \ll t_{chem}$ with t_{mic} a microscopic time and t_{chem} the chemical relaxation time (7, 16, 17).

Computations show that for the 67-molecule cluster the free energy barrier is $\Delta W = 4.47\ kT(T = 260K)$ leading to a TST rate constant of $k^{TST} = 0.04\ ps^{-1}$, and the transmission coefficient is found to be $\kappa = 0.4$ giving $k = 0.016\ ps^{-1}$ (3).

D. Non-adiabatic dynamics

Adiabatic dynamics is most likely to break down in the vicinity of the transition state configuration where the configuration of solvent molecules in the cluster provides a nearly symmetrical solvation structure around the proton–ion complex. In this configuration the two lowest adiabatic states may be separated by energies that are a fraction of a kT unit. Since this is the region that influences the reaction dynamics, it is of interest to examine the extent to which the reaction rate is modified if account is taken of the excited protonic states.

In Tully's surface-hopping, stochastic model (18) an ensemble of trajectories is evolved on the adiabatic surfaces with hops between the adiabatic states determined from a master equation. The time-dependent quantum wave function of the proton $\Phi(u, \boldsymbol{R}^N, t)$ is expanded in terms of the adiabatic states as



$$[16] \quad \Phi(u, \boldsymbol{R}^N, t) = \sum_n c_n(t)\Psi_n(u; \boldsymbol{R}^N)$$

The Schrödinger equation for the expansion coefficients is solved along with Newton's equations of motion to determine the time evolution of the system. The probability of a hop from state k at time t to state j in the time interval between t and $t+\Delta$ is given by $g_{kj} = (b_{jk}(t+\Delta)\Delta)/a_{kk}(t+\Delta)$ if $g_{kj} \geq 0$ and zero otherwise. Here $a_{kj} = c_k c_j^*$ and $b_{jk} = -2$ Re $(a_{jk}^* \dot{\boldsymbol{R}} \cdot \boldsymbol{d}_{kj})$ where $\boldsymbol{d}_{kj}$ is the non-adiabatic coupling vector

$$[17] \quad \boldsymbol{d}_{kj}(\boldsymbol{R}^N) = \langle \Psi_k(\boldsymbol{R}^N) | \nabla_{\boldsymbol{R}^N} | \Psi_j(\boldsymbol{R}^N) \rangle$$

In non-adiabatic dynamics we use $\bar{z}_p^n = \langle \Psi_n | u | \Psi_n \rangle$ as the reaction coordinate. In Fig. 8 (*a* and *b*) for a 67-molecule cluster we see that transitions of the proton from the ground state to the excited states frequently occur in the transition state region. From a series of non-adiabatic trajectories it was estimated that (*a*) the number of proton transfers while the proton is in an excited state is comparable to that when the proton is in the ground state (note that the proton spends 88% of the time in the ground state) and (*b*) the number of recrossings of the transition state is much higher when the proton is in an excited state compared to that when the proton is in the ground state. These observations are consistent with the fact that the excited state proton charge density is more expanded along the interionic axis than the ground state charge density. Therefore, the Hellman–Feynman forces determined by the excited state densities lead to solvent configurations that favour the transition state. The rate of the reaction computed from the direct observation of reactive transitions was found to be $k = 0.017\ ps^{-1}$ (1/59.0 ps). Recall that the value using adiabatic dynamics was $k = 1/62.5$ ps. The similarity of the adiabatic and non-adiabatic rate constants may arise from a cancellation of effects. The proton excited state charge density may favor transition state configurations where proton transfer is likely but it also appears to favor increased tran-

sition surface recrossings that lower the rate. These effects deserve further detailed study.

4. Conclusions

The two examples described above have served to illustrate only a few aspects of the unique chemistry that is possible on the mesoscale domain in liquid-state molecular clusters. The principal factors that come into play determining the reaction rates and mechanisms are the specific solvation effects and strong fluctuations for such clusters. The rather large surface-to-volume ratio makes surface forces very important and these surface forces can influence the solvation of species within the cluster. They may determine whether a species resides within the cluster or on its surface, as was the case for the proton–ion complex we studied. This in turn will have implications for the mechanism of a reaction. The precise nature of these surface-specific solvation effects will of course depend on the nature of the solvent and reactants: for example, whether they are charged or polar and the relative magnitudes of solvent–solvent versus solvent–solute forces. Effects of this kind have been seen in studies of S_N2 reactions in water clusters (19).

The liquid-state clusters we examined are dynamic objects with strong particle and shape fluctuations. The extent to which these cluster environments can be modeled by simple stochastic theories is an open problem but, clearly, models of the reactive dynamics that neglect these fluctuations are likey to miss important aspects of the reaction mechanism.

We have focused on liquid-state clusters. The general aspects of such cluster reactions could have implications for the reactive processes occurring in the atmosphere. Normally one is concerned with reactive dynamics in much larger liquid clusters where macroscopic concepts have greater validity. However, large clusters grow from small ones and one must consider the dynamics on these smaller scales, which is still "terra incognito" and deserves further exploration. Of course, clusters in the same size domain but in other physical states, such as solid clusters and mixed clusters, are also interesting environments in which to examine fundamental questions of condensed-phase reaction dynamics.

The mechanism of oxidation of 3-mercaptopropionic acid

Paula Forlano, José A. Olabe, Jorge F. Magallanes, and Miguel A. Blesa

Abstract: The mechanism of the oxidation of 3-mercaptopropionic acid (3-MPA) by hydrogen peroxide was studied in the acidic pH range. The nucleophilic attack by sulphur on the peroxide bond controls the rate. Extrapolation of the pH dependency suggests that the rate of attack by the deprotonated dianion is highest. Traces of Fe(III), at levels below 10^{-7} mol dm^{-3}, do not catalyze efficiently the process through one-electron mechanisms; at higher concentrations, or on the surface of iron(III) oxides, this type of catalysis becomes important. The electrochemical oxidation of 3-MPA was also studied, using differential pulse polarography and cyclic voltammetry techniques. The mechanism is of the EC_2E type, the second electron transfer step corresponding to the oxidation of the disulphide RS-SR. The rate constant for the dimerization of the RS$^{\bullet}$ radicals was 1.8×10^3 mol^{-1} dm^3 s^{-1}; the slowness of this step agrees with the mechanisms observed in the course of one-electron oxidations by metal ions.

Key words: electrochemistry, kinetics, 3-mercaptopropionic acid, autooxidation.

Résumé : Opérant dans la plage acide des pH, on a étudié le mécanisme d'oxydation de l'acide 3-mercaptopropanoïque («3-MPA») par le peroxyde d'hydrogène. La vitesse de la réaction est fixée par l'attaque nucléophile du soufre sur la liaison peroxyde. Une extrapolation de la dépendance sur le pH suggère que l'attaque par le dianion déprotoné est celle qui se fait avec la vitesse la plus grande. Le fer(III), à l'état de traces, à des niveaux inférieurs à 10^{-7} mol dm^{-3}, ne catalyse pas le processus d'une façon efficace par le biais de mécanismes à un électron; à des concentrations plus élevées, ou sur la surface d'oxydes de fer(III), ce type de catalyse devient important. On a aussi examiné l'oxydation électrochimique du «3-MPA» en faisant appel à des techniques de polarographie différentielle pulsée et de voltampérométrie cyclique. Le mécanisme de cette réaction est du type EC_2E, l'étape du deuxième transfert d'électron correspondant à l'oxydation du disulfure RS-SR. La constante de vitesse de dimérisation des radicaux RS$^{\bullet}$ est égale à $1,8 \times 10^3$ mol^{-1} dm^3 s^{-1}; la lenteur de cette étape est en accord avec les mécanismes observés lors des oxydations à un électron en présence d'ions métalliques.

Mots clés : électrochimie, cinétique, acide 3-mercaptopropanoïque, autooxydation.

[Traduit par la rédaction]

Introduction

The oxidation of mercaptocarboxylic acids is a reaction of importance in biological systems, and has therefore been studied by several authors (1–7). The oxidation of other organic compounds, such as thiourea or thiols, has also been the subject of extensive research (8–11). It seems clear that no single mechanism is involved in all cases, although the disulphide is generally the main "initial" product. The formation of disulphide may be mediated by sulphenic acids R-SOH originating in the attack of hydrogen peroxide on the deprotonated R-S$^-$ moiety, or by R-S$^{\bullet}$ free radicals formed by attack of OH$^{\bullet}$ on R-S-(H$^+$), the OH$^{\bullet}$ radical having been formed by radiolysis, or by chemical means from H_2O_2 (metal ion catalysis).

The present note reports a study of the oxidation of 3-mercaptopropionic acid both by hydrogen peroxide and in an electrochemical cell. In the former case, the influence of added Fe(III) was cursorily explored to define the limits of relevance of direct attack and radical, Fenton-like mechanisms. The intervention of these latter mechanisms was also explored in heterogeneous media, i.e., under conditions of iron oxide catalyzed H_2O_2 decomposition.

Experimental

All reagents were analytical grade; tridistilled water was used to prepare the solutions, the last two distillations being made in a quartz apparatus. Hydrogen peroxide free of stabilizers was used as solutions freshly prepared and titrated against a $KMnO_4$ standard solution. Fe(III) stock solution was prepared by oxidation with H_2O_2 of a Fe(II) solution obtained by dissolving the metal in $HClO_4$ and titrated potentiometrically against standard $K_2Cr_2O_7$.

The ionic strength was kept constant at 4×10^{-3} M using $HClO_4$ and $NaClO_4$ solutions. This ionic strength was high enough to ensure appropriate behavior of the differential pulse polarography (dpp) waves in the experiments described below. The reversibility of 3-MPA oxidation was checked, and the width at half-peak height ($W_{1/2}$) of dpp was found to agree with the theoretical values of the Heijne and Van der Linden (12) treatment, over the whole 3-MPA concentration range explored ($4 \times 10^{-5} - 4 \times 10^{-4}$ M).

Oxidation by hydrogen peroxide

The kinetics of the oxidation of 3-MPA by H_2O_2 was studied in the pH range 2.4–6. The decrease of the 3-MPA peak height during oxidation was followed by measuring the height of the dpp wave. The concentration was obtained from the linear calibration plot (peak height vs. concentration) previously determined for each pH value. Solutions of 10^{-4} M 3-MPA were prepared and the pH adjusted with $HClO_4$. The solution was placed in the thermostatted (25°C) cell of a PAR 174A polarographic analyzer, with a dropping or hanging drop Hg electrode, a Pt wire auxiliary electrode, and the reference electrode. All potentials were measured against a Ag/AgCl, KCl saturated reference electrode. Differential pulse polarograms (dpp) were obtained at $t = 0$ and sequentially after the addition of the adequate amount of hydrogen peroxide; all experiments were conducted under conditions of excess H_2O_2. The 3-MPA oxidation wave is found in the range between −0.35 and 0.40 V, with $E_{1/2} = -0.15$ V. At concentrations higher than 7×10^{-4} mol dm^{-3}, a new wave appears at more positive potentials, due to multilayer formation on the adsorbed monolayer (13). The reaction is slow enough to permit the sequential determination of 3-MPA. Occasionally, hydrogen peroxide was determined using its reduction wave in the range −0.35 to −1.85 V ($E_{1/2} = -0.96$ V) (14).

To assess the possible operation of metal ion catalysis, measurements were also carried out in the presence of EDTA, or in the presence of added iron(III) perchlorate, in the concentration range 10^{-8}–10^{-6} mol dm^{-3}.

Electrochemical oxidation

The mechanism of the electrochemical oxidation was explored by using polarographic and cyclic voltammetric (CV) techniques at pH = 2.4. The dependence of $E_{1/2}$ on the 3-MPA concentration and the $W_{1/2}$ of differential pulse polarography was measured. Experiments were also carried out at different drop times.

A complementary set of CV experiments were done at sweep rates between 10 and 200 mV s^{-1} and various 3-MPA concentrations. In the range $3 \times 10^{-4} - 5 \times 10^{-3}$ mol dm^{-3} of 3-MPA, no multilayer effect is observed.

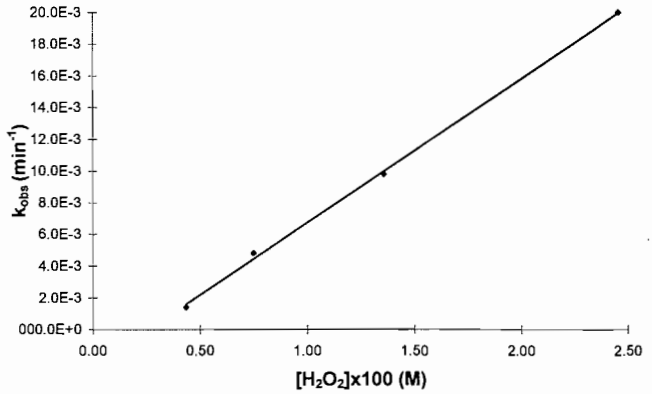
Results and discussion

Oxidation by hydrogen peroxide

At constant pH and $[H_2O_2]$, plots of $\ln([MPA]/[MPA]_o)$ vs. time yield straight lines from which pseudo-first-order rate constants can be obtained. Figure 1 shows the plot of the pseudo-first-order constants at pH = 2.4 as a function of $[H_2O_2]$, which demonstrates that the kinetic law is

$$[1] \quad R = k[MPA][H_2O_2]$$

Fig. 1. Dependence of the pseudo-first-order rate constants upon $[H_2O_2]$ at pH = 2.4 and 298 K, ionic strength 4×10^{-3} M.



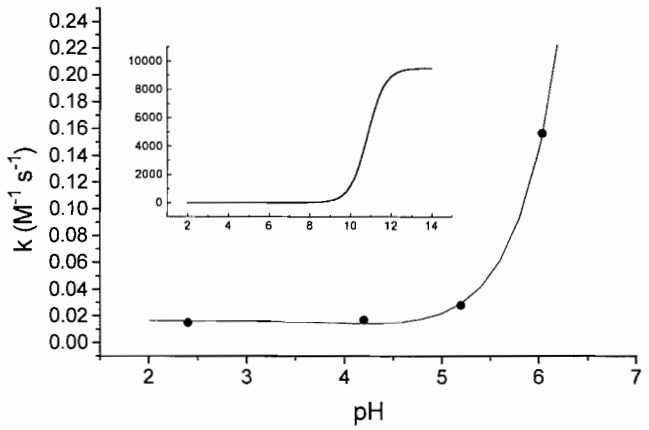


Fig. 2. pH dependence of the second-order rate constant for the reaction of 3-MPA upon H_2O_2 at 298 K, ionic strength 4×10^{-3} M: (•) experimental points; (—) eq. [2]. Inset: pH dependence of the empirical rate constant k (eq. [1]) according to eq. [2].

where [MPA] represents the total (analytical) concentration of 3-mercaptopropionic acid.

The straight line in Fig. 1 extrapolates to an apparent negative rate for $[H_2O_2] = 0$; this behavior is most probably an experimental artifact associated with some decomposition of hydrogen peroxide.

Figure 2 shows the pH dependency of k, together with the curve drawn assuming that the general eq. [2] can be used to describe the pH effects in terms of the contribution of three parallel pathways to eq. [1], each path corresponding to the reaction with hydrogen peroxide of each of the three protolysis species of 3-MPA. The values $pK_{a1} = 4.34$ and $pK_{a2} = 10.84$ (taken from ref. 15) were used to calculate the concentration of each species at each pH.

$$[2] \quad k = (k_1[H_2X] + k_2[HX^-] + k_3[X^{2-}])/[MPA]$$

where X^{2-} represents the dianion of 3-MPA.

The data were collected in a pH range well below pK_{a2} and the steep rise in rate at the highest pH explored can be accounted for only if it is assumed that the reactivity is essentially governed by the dianion. From our data, it is not possible to derive a value for k_2; only an upper limit can be given. The

second-order rate constants that yield the best fit shown in Fig. 2 are (in mol^{-1} dm^3 s^{-1}) $k_1 = 1.6 \times 10^{-2}$; $k_2 = 10^{-2}$; $k_3 = 9.5 \times 10^3$.

This kinetic law is compatible with a rate-determining direct attack by sulphur on hydrogen peroxide, the rate being highest for the deprotonated sulphur of the dianion:

[3] $$^{-}R\text{-}S^{-} + HO\text{-}OH \rightarrow [^{-}R - S - \underset{OH}{OH^{-}}]^{\#} \rightarrow {}^{-}R\text{-}SOH + OH^{-}$$

This mechanism involves a nucleophilic attack on hydrogen peroxide. The ensuing population of the LUMO of H_2O_2 (mainly antibonding about the peroxide bond) results in O—O bond breaking. The simplest stoichiometry of the reaction results from the further fast reaction of the sulphenic derivative RSOH with RSH:

[4] $$RSOH + RSH \rightarrow RS\text{-}SR + H_2O$$

but other products may also form in the presence of excess oxidant (7, 16).

Barton et al. (3) have studied the analogous reactions of cysteine and cysteamine, and report second-order rate constants of 12.4 and 10 mol^{-1} dm^3 s^{-1} for the corresponding zwitterionic species, $^{+}H_3N\text{-}R\text{-}S^{-}$. These two values are strikingly similar, taking into account that cysteine bears a net negative charge due to the ionized carboxylate group. It is also reported that the corresponding anions $H_2N\text{-}R\text{-}S^{-}$ react more slowly. Of particular interest is the comparison of cysteine (2-amino-3-mercaptopropionic acid) and 3-MPA. The dianion $^{-}O_2CCH_2CH_2S^{-}$ is more basic than $^{-}O_2CCH(NH_2)CH_2S^{-}$ (the corresponding pK_a values of the conjugate acids are 10.84 and 8.53, respectively). The former dianion is also more reactive towards H_2O_2, and 3-MPA reacts faster at any given pH value (correspondingly, the pH range spanned in our study is lower than that explored by Barton et al. (3)). The presence of the amino group in the 2-position is seen to affect profoundly the basicity of the $R\text{-}S^{-}$ group. The decrease in basicity is related to the very large decrease in the rate of attack on the peroxide bond. In agreement, in a separate study, we have found that the rates of coordination through sulphur to $[Ru^{III}(edta)H_2O]^{-}$ by various R-SH ligands correlate with the pK_a values of the -SH group.[3] Also in agreement, we have shown previously that the rate of reductive attack on iron(III) oxides by 3-MPA is much larger than that of cysteine (17). An important consequence is that the amino group gives some protection to cysteine against hydrogen peroxide attack at physiological pH.

Protonation of the leaving OH group of hydrogen peroxide at low pH catalyzes the attack of thiourea on H_2O_2 (8); a related phenomenon has been involved in the reaction of the cysteine zwitterion, even though the bulk pH in this case precludes equilibrium protonation of H_2O_2. Acid catalysis is totally ruled out under our experimental conditions. The very small effect of the carboxylate group, as documented by the comparison of cysteine and cysteamine, still remains unexplained.

[3] V. Povse and J.A. Olabe. Work in progress.

The influence of Fe(III)

It is well known that Fe(III) oxidizes mercaptocarboxylic acids to disulphides, through an inner-sphere reaction (4). This reaction takes place both with dissolved Fe(III) salts and with suspended iron(III) oxides (17) (in this case, the anaerobic oxidation of 3-MPA by Fe(III) takes place along with oxide dissolution). In the heterogeneous case, addition of excess hydrogen peroxide shifts the stoichiometry of the reaction to the catalyzed oxidation of 3-MPA, with negligible dissolution.

The coupling of the internal redox decomposition of Fe(III)-mercaptocarboxylate complexes and the reoxidation of Fe(II) by hydrogen peroxide may lead to the catalytic oxidation of mercaptocarboxylic acids:

[5] $$Fe(III)\text{-}{}^{-}S\text{-}R \rightarrow Fe(II) + {}^{\cdot}SR$$

[6] $$Fe(II) + H_2O_2 \rightarrow Fe(III) + OH^{-} + OH^{\cdot}$$

[7] $$Fe(III) + {}^{-}S\text{-}R \rightarrow Fe(III)\text{-}{}^{-}S\text{-}R$$

The reaction scheme is completed with the fast scavenging of $OH^{\cdot}$ by HSR.

The possible contribution of free radicals due to Fenton-type reactions of hydrogen peroxide with metal ion impurities was explored in a series of experiments with added EDTA and added Fe(III). In the presence of EDTA, the measured rates were identical to those discussed above. Added Fe(III), on the other hand, led to erratic rate changes; for example, a fivefold rate enhancement was observed when [Fe(III)] = 10^{-7} mol dm^{-3}. Although the rate generally increased upon addition of Fe(III), no clear relationship could be observed between the rates and [Fe(III)]. Although this reaction pathway may become important under adequate experimental conditions, at pH 2.4 the stability of the complex and rates of internal redox decomposition are low enough to make the rate of the catalyzed reaction (at [Fe(III)] below 10^{-7} mol dm^{-3}) slow in comparison with the direct bimolecular reaction. The rate values reported above are therefore not affected by contributions of this type.

Electrochemical oxidation

As early as 1940 Kolthoff, Barnum, and Lingane (18, 19, and refs. therein) studied the polarographic anodic oxidation of cysteine. They found that the reaction is not reversible, even in 0.1 M $HClO_4$. At higher pH (> 2) abnormal waves are obtained because of the strong adsorption on the mercury electrode. At low concentration (0.002 M) the reaction is diffusion controlled, but at higher concentration the film formation controls the current. After considering several possible mechanisms, including the EC_2 (EDIM), these authors conclude that the reaction mechanism is simply

$$RSH + Hg \rightleftarrows HgSR + H^{+} + e^{-}$$

The dimerization stage of $RS^{\cdot}$ radicals to yield the disulphide is therefore inhibited by the stability of adsorbed Hg(I) salt. Birke and Mazorra report that $Hg(SR)_2$ layers may be formed in the oxidation of several thiols. Our results in the oxidation of 3-mercaptopropionic acid at pH 2.4 bear some similarities, but there is clear evidence for an EC_2E (EDIME) mechanism, in which the disulphide RS-SR is involved, as discussed below.

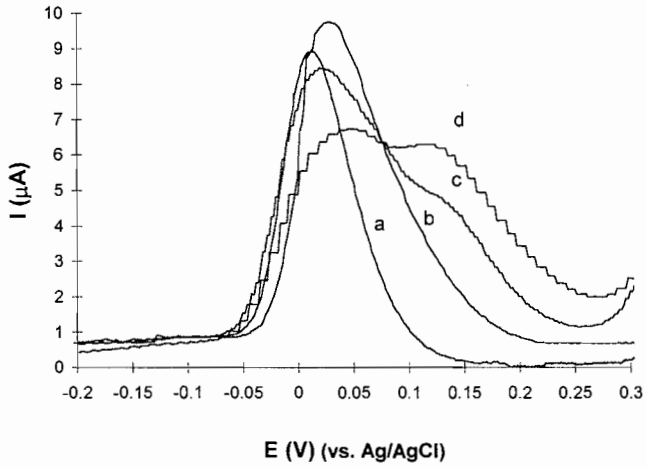
Fig. 3. The dpp traces of the oxidation of 3-MPA at pH = 2.4 for various drop times. (*a*): 0.5 s, (*b*): 1 s, (*c*): 2 s, (*d*): 5 s.



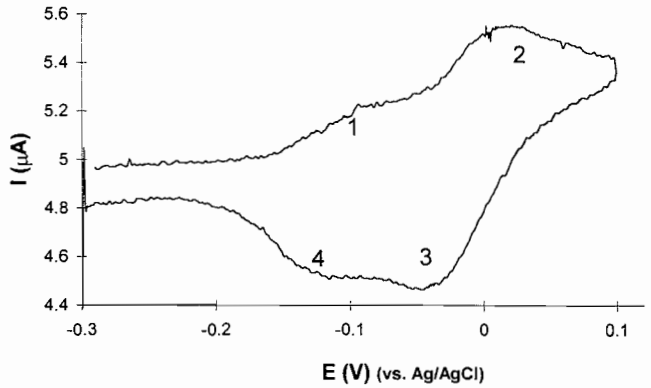


Fig. 4. Voltammogram of 3-MPA at pH 2.4, scan rate 100 mV s^{-1}. Peaks 1 and 2 correspond to reaction steps [9] and [11], respectively (see text).

The dpp of 3-MPA in 4×10^{-3} mol dm^{-3} $HClO_4$ shows a value of $W_{1/2}$ = 80.5 mV, appreciably lower than the theoretical value for reversible one-electron transfer, 92.8 mV (12). This observation suggests that more than one electron is transferred in the overall reaction.

When the 3-MPA concentration is increased, the maximum of the dpp oxidation wave E_p shifts to more negative potentials. As $E_p = E_{1/2} + \Delta E/2$ (where ΔE is the modulation potential) the shift in E_p with concentration is identical with the shift in $E_{1/2}$, and the observed behavior is indicative of an EC-type mechanism (20), at variance with the mechanism postulated by Kolthoff and Barnum for cysteine. The plot of $E_{1/2}$ vs. ln [MPA] is linear, the slope being 13.3 mV/decade. This value is identical within the error limits with the theoretical slope for an EC_2 (EDIM) mechanism involving one-electron transfer and surface reaction of adsorbed species, $RT/2nF$ = 12.85 mV at 25°C (20). For an EDIM mechanism involving a "volume" reaction (no adsorption), Mairanovskii (20) and Koutecky and Hanus (22) found that this slope is $RT/3nF$ = 8.5 mV.

Figure 3 shows a set of dpp traces at different drop times. At short drop times, a single wave is observed; when the drop time increases, a second wave at more positive potentials emerges progressively. For a modulation potential of 25 mV and drop time 1 s, the difference between the potentials of both waves is 28 mV; separate experiments with pure disulphide demonstrated that the dpp oxidation wave of this compound reaches the maximum at a potential positively shifted from the value for 3-MPA by 22.2 mV. In view of the different experimental conditions (no adsorbed reactant, no overlapped waves), the agreement is reasonably good, and it may be concluded that the second wave observed in Fig. 3 is due to the oxidation of RS-SR. This process may be observed only when the drop time is long enough to permit dimer formation, and an EC_2E mechanism is thus suggested, involving a second electron transfer stage that produces reversibly an otherwise undefined oxidation product. No experimental evidence on the nature of this product is available. Several experimental characteristics of the disulphide oxidation indicate a one-electron reaction. In CV experiments (Fig. 4, peaks 2 and 3), the ΔE_{peak} (anodic − cathodic) is 63 mV; also, the peak position does not shift with the sweep rate. Finally, in dpp, $W_{1/2}$ = 94 mV indicates a reversible one-electron transfer. This mechanism also accounts for the small difference between the theoretical and the calculated slope in the $E_{1/2}$ vs. ln [MPA] plots:

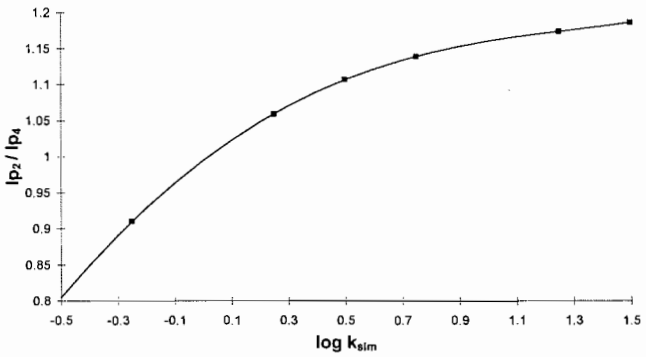
[9] $RSH \rightleftarrows RSH^{\bullet+} + e^-$

[10] $2\,RSH^{\bullet+} \rightarrow RS\text{-}SR + 2\,H^+$

[11] $RS\text{-}SR \rightleftarrows$ oxidation products + e^-

The voltammograms of 3-MPA show four peaks, corresponding to the two electron transfers, the intensity and position of which are dependent on sweep rate. Figure 4 shows an example; although the definition of some peaks was poor (for instance peaks 1 and 4 in Fig. 4), it was possible to draw clear conclusions from the analysis of the whole set of voltammograms. In particular, the ratio of the heights of peaks 2 and 4 is strongly dependent on the sweep rate: I_{p2}/I_{p4} decreases when the sweep rate increases, as expected for the above mechanism. From the values of I_{p2}/I_{p4} for various 3-MPA concentrations, measured at two sweep rate values, v = 50 and 100 mV s^{-1}, the value of the radical dimerization (eq. [10]) rate constant k_{dim} may be calculated. The calculations must be done by simulation of the I_{p2}/I_{p4} ratio as a function of the dimensionless rate constant k_{sim}, defined by eqs. [12] and [13]:

[12] $k_{sim} = k_{dim}([MPA]/a)$



where:

[13] $a = nFv/RT$

An explicit digital simulation, based on the exponential expanded space grid method developed by S.W. Feldberg (23) was used. Details of this program applied to a similar mechanism are explained in ref. 24. Due to the overlapping of $I_{p1}|I_{p2}$ and $I_{p3}|I_{p4}$, the ratio would be difficult to measure using the basic analytical theories of voltammetry. However, because the separation between $E_{1/2}$ for reactions [9] and [11] is measured experimentally, the digital simulation of the system leads to a set of partially overlapped waves, similar to those

© 1997 NRC Canada

Fig. 5. Simulated I_{p2}/I_{p4} ratio as a function of log k_{sim} (see text for further details).

obtained in practice. The simulated and experimental I_{p2}/I_{p4} ratios behave similarly.

Figure 5 shows the simulated function $I_{p2}/I_{p4} = f(\log k_{sim})$; interpolation of the experimental I_{p2}/I_{p4} values yields values of k_{sim} from which k_{dim} may be obtained, using eq. [12]. The dependence of k_{sim} on the concentration at constant sweep rates is indeed linear, and from the slopes at v = 50 and 100 mV s^{-1}, the derived values of k_{dim} are $1.7(\pm 0.2) \times 10^3$ and $1.97(\pm 0.04) \times 10^3$ mol dm^{-3} s^{-1}.

As a further check, simulated voltammograms were computed using these k_{dim} values; a reasonable coincidence between simulated and experimental traces was obtained. Also, the relative heights of the dpp waves at different drop times can be calculated using k_{dim} to estimate the concentration of 3-MPA on the electrode surface. For drop times of 2 and 5 s, the height ratio is calculated to be 0.74, as compared with an experimental ratio of 0.83. The lack of data at other drop times precludes further elaboration of this point.

The slowness of radical dimerization poses a certain limitation to the operation of one-electron chemical oxidation of 3-MPA, because the reverse regeneration of the dianion may become important. In fact, in the course of oxidation by one-electron metallic oxidants such as Fe(III), the activated complex composition normally reflects the need to bring together two oxidants, thus allowing the formation of the disulphide in a more efficient way (17). In view of the large atom transfer rate constant between the dianion of 3-MPA and hydrogen peroxide, it is not surprising that the radical pathway does not contribute significantly to the reaction mechanism.

Abstract: Humic substances (HS) were extracted from the sediments of four Sudbury area lakes, namely, Tilton, Clearwater, Silver, and Ramsey Lakes, with the aid of 0.1 M $Na_4P_2O_7$ and 0.5 M NaOH solutions . The HS (humic and fulvic acids) were purified and characterized using the methods of elemental analysis, visible spectroscopy (E_4/E_6 ratio), FTIR, and solid-state ^{13}C CPMAS NMR. A substantial amount of information with regard to the composition and chemical nature of lake sediment HS was obtained. The results obtained for the Sudbury area lake sediments were compared with one another and with HS from other sources, such as soils. The elemental composition, atomic ratios, E_4/E_6 ratios, and FTIR and NMR features of the samples from the above lakes were found to be nearly identical, suggesting that HS formed in the Sudbury area have similar chemical properties. Compared with soil HS, the Sudbury lake sediments HS have undergone a low degree of aromatic condensation and are considerably more aliphatic in nature.

Key words: humic substances, characterization, lake sediments, extraction, ^{13}C NMR.

Résumé : Des substances humiques (SH) ont été extraites des sédiments de quatre lacs de la région de Sudbury : les lacs Tilton, Clearwater, Silver et Ramsey, au moyen de solutions de $Na_4P_2O_7$ 0.1 M et de NaOH 0.5 M. Les SH (acides humiques et fulviques) ont été purifiées et caractérisées à l'aide des méthodes d'analyse élémentaire, de la spectroscopie visible (rapport E_4/E_6), FTIR et état solide RMN ^{13}C CPMAS. Une quantité substantielle d'information a été obtenue sur la composition et la nature chimique de SH des sédiments lacustres. Les résultats obtenus pour les sédiments lacustres de la région de Sudbury ont pu être comparés entre eux et avec des SH provenant d'autres sources tels les sols. La composition élémentaire, les rapports atomiques, les rapports E_4/E_6, les caractéristiques FTIR et RMN des échantillons des lacs étudiés se sont montrés presqu'identiques ce qui suggère que les SH formées dans la région de Sudbury ont des propriétés chimiques semblables. En comparaison avec les SH des sols, les SH des sédiments lacustres de Sudbury ont subi un moindre degré de condensation aromatique et sont considérablement plus aliphatiques en nature.

Mots clés : substances humiques, caractérisation, sédiments lacustres, extraction, RMN ^{13}C.

Introduction

Organic matter (OM) constitutes a minor but important fraction of lake sediment. It is made up of a complex mixture of lipids, carbohydrates, proteins, and other biochemicals originating from the tissues of living benthic micro-organisms and the detritus of organisms formerly living in the lake and its watershed. Humic substances (HS) are formed from these biochemical starting materials and represent the major constituent of the organic materials found in lake sediments (1). HS play a vital role in terrestrial and aquatic ecosystems; consequently they have long been a subject of scientific interest.

Operational definition of HS

HS can be classified as humic acid, fulvic acid or humin depending on their solubility in alkali and acid. More specifically, *humic acid* (HA) is defined as the fraction of the HS that is soluble in dilute alkali but is coagulated by acidification of the alkaline extract (below pH 2); *fulvic acid* (FA) is the fraction of the HS that remains in solution when the alkaline extract is acidified, that is, the fraction that is soluble in both dilute alkali and dilute acid; *humin* is the fraction of the HS that cannot be extracted from the soil by dilute base or acid. These definitions have survived the test of time because of their practical utility. Solubility is an effective criterion for the classification of substances because of its dependence on important chemical characteristics, such as the number of acidic functional groups present, molecular weight, aromaticity, etc. (2). The definitions described above have been accepted by most scientists and specialists investigating humic materials (3). It is important to note that other classification schemes for natural organic matter exist. These schemes are based on the biochemical classification and the physical form of the natural organic matter (4).

Roles

HS, being an important source of organic matter in all terrestrial and aquatic environments, participate in a variety of biochemical and geochemical processes and serve as a major reservoir of organic carbon in soils and oceans for the global carbon cycle. HS can be nutrients on which plants, benthic animals, and microbes live and grow. As well, HS play an

For personal use only.

important role in the cycles of nutrient elements such as nitrogen and phosphorus (3). One of the most striking characteristics of HS is their ability to interact with metal ions (5–8), oxides, hydroxides, and minerals (9), to form water-soluble and water-insoluble complexes of widely differing chemical and biological stabilities. Through the formation of water-soluble complexes, humic materials can dissolve, mobilize, and transport metals and organics in soil and water, while the formation of water-insoluble complexes brings about their accumulation in certain soil horizons and in sediments (3). In addition, organic compounds with appropriate functional groups can bind to HS through the formation of hydrogen bonds. Such interactions affect the environmental behaviour of these materials, including the rate of chemical degradation, photolysis, volatilization, migration, and biological uptake of the organic compound (3). For instance, the presence of high concentrations of humic materials in water increases the solubility of toxic pollutants such as DDT (10, 11) and aromatic hydrocarbons in water (12). Finally, HS can produce degradation products that are harmful to the environment. For example, the degradation of HS found in chlorinated municipal drinking water can lead to the formation of haloforms which are a health hazard even at low concentration (2, 13, 14).

Organic matter in lakes and lake sediments originates both from aquatic organisms living in the lake (autochthonous) and from organic matter that is washed into the lake from surrounding soils and streams (allochthonous). Therefore, the amount and composition of the organic matter in lake sediments are dependent on various factors such as the trophic level, climate, drainage into the lake, and chemical, biological, and geological characteristics of the surrounding environments. HS are clearly the major constituent of organic matter in lake sediments and thus should play a central role in the geochemical cycling of carbon compounds in lakes, lake sediments, and sedimentary rocks (15). It should be pointed out that because HS are a complex mixture of organic matter it has not been possible to elucidate their exact composition and structure. Hence, as more detailed information on the structure and composition of HS becomes available it will be possible to comment on their nature, origin, and geochemical roles.

Characterization

The most common techniques used to obtain structural and compositional information on HS include elemental analysis, visible, infrared, and ^{13}C NMR spectroscopies, and degradation methods. The elemental composition (C,H,N,O,S,P) of HS, determined with the aid of an elemental analyzer, can establish the nature and origin of these compounds. The elemental composition of a substance is often expressed in terms of atomic ratios because errors due to ash content are then factored out. The ratios of H/C, O/C, and N/C have been used (16): (*i*) to identify different types of HS, (*ii*) to monitor the structural changes of humates in soils and sediments, and, (*iii*) to elucidate structural formulae for humates. For instance, the O/C ratio is believed to be an indicator of the carbohydrate content of a humic substance and can be used to compare HS from different origins.

Visible spectroscopy is a simple but important method used to characterize HS. The ratio of optical densities or absorbances of dilute aqueous HA and FA solutions at 465 and 665 nm is widely used for the characterization of these materials. This ratio, usually referred to as E_4/E_6, is independent of the concentrations of humic materials, but varies for humic materials of different soil types (17, 18). Schnitzer (18) suggests that the absorption of light by aqueous HA and FA solutions in the visible region of the electromagnetic spectrum is dependent upon (*i*) the total carbon content of the material, (*ii*) the number of aromatic residues versus the number of aliphatic residues, and (*iii*) the molecular weight of the HS. Attempts have been made to extract structural information by relating the E_4/E_6 ratio for HS to such characteristics as viscosity, carbon content, oxygen content, and total acidity (19).

Infrared (IR) spectroscopy has been widely used for the characterization of HS (18, 20–23). Since HS comprise complex mixtures, each type of functional group present in the HS exists in a variety of different chemical environments. As a result, the spectra usually consist of relatively few bands, which are very broad. However, the development of high-performance FTIR has resulted in improved transmission spectra of HS obtained from various sources (22–24).

Recently, ^{13}C nuclear magnetic resonance (NMR) spectroscopy has become a powerful tool in elucidating the structure of HS. The nondestructive technique makes use of the signals recorded from the small proportion of ^{13}C in naturally occurring substances. It has several inherent advantages over conventional ^{1}H NMR spectroscopy in that it provides direct information on the carbon skeleton of organic substances. In addition, the large chemical shifts associated with ^{13}C nuclei allow signals of carbon atoms with only slightly different magnetic environments to be resolved. Furthermore, a comparison of the peak areas of the signals found in the aromatic and aliphatic regions of the ^{13}C NMR spectra of HS is indicative of the degree of aromaticity vs. aliphaticity of the HS (25–28). Macromolecular substances can also be studied by determining the structure of the molecular fragments that make up the long molecular chain. The degradation methods used to fragment macromolecular substances include chemical oxidation with alkaline permanganate (29) or alkaline cupric oxide (30, 31) and thermal degradation. Recently, the thermal degradation products of HS have been analyzed by coupling of a pyrolysis unit to a gas chromatograph, which is in turn coupled to a mass spectrometer (32–37).

It should be pointed out that the methods most frequently used to characterize HS, namely elemental analysis, IR, NMR, etc., provide general information with respect to the origin of the organic matter, the degree of humification, the nature of the functional groups present in the organic matter, and the degree of aromaticity associated with the organic matter. Thermal and chemical degradation techniques, on the other hand, provide information concerning the building blocks that make up the HS. Unfortunately, information on how the fragments were assembled in the original material is not given by the degradation techniques.

In this study, we present the results of the chemical and structural characterization of HA and FA isolated from the sediment of four Sudbury Lakes using elemental analysis, FTIR, and solid-state ^{13}C NMR. The chemical characteristics of the HS originating from the different lake sediments are compared in order to study the influence of water pH, contaminants, surrounding vegetation, etc. on the HS. We also compare the chemical characteristics of the lake sediment HS with those from other environments such as

soil, lake water, etc., in order to establish the differences and similarities.

Methodology

Sampling sites and sample collection

Sediment samples were collected from four different lakes located in the Sudbury region, namely, Tilton, Clearwater, Silver, and Ramsey. The four lakes chosen in this area differ in pH, levels of metal contamination, surrounding vegetation, and in the amount of dissolved organic matter in the water. Three sampling points were selected for each lake and surficial sediments were collected by using a sediment grab. The sediments obtained from the three points were mixed to give one sample. The sediments were stored in plastic containers and taken to the laboratory. After being air-dried at room temperature for 7 days, the sediment samples were ground and sieved through a 2 mm sieve. The sediment samples were stored in sealed plastic bottles for further analysis.

Sequential extraction of organic matter

(i) Hexane extraction

Sediment (25.0 g) in a single thickness Whatman extraction thimble (43 × 123 mm) was extracted in a Soxhlet apparatus for 48 h with 300 mL of spectroscopic grade *n*-hexane (Caledon). The hexane extract was filtered and reduced in volume with the aid of a rotary evaporator. The residue was transferred to a preweighed 4 mL vial and reduced to dryness under a gentle stream of N_2.

(ii) Chloroform extraction

The residual sediment in the extraction thimble was subsequently extracted with 300 mL of spectrograde chloroform (Caledon) for 48 h using the method described above. The filtered extract was concentrated with the aid of a rotary evaporator and transferred to a preweighed 4 mL vial. A gentle stream of N_2 was used to evaporate the remaining chloroform. As before, the weight of the residue was determined.

(iii) $Na_4P_2O_7$ extraction

The residual dried sediment in the extraction thimble was transferred to a 250 mL polyethylene centrifuge bottle containing 250 mL of a 0.1 M $Na_4P_2O_7$ solution (pH ≃ 10.5). The bottle was flushed with N_2 to displace air, sealed tightly, and shaken on a reciprocal shaker at room temperature for 24 h. The $Na_4P_2O_7$ extract was separated from the insoluble sediment by centrifugation at 10 400 *g* for 10 min followed by vacuum filtration using a Millipore filter system (0.45 μm pore).

(iv) NaOH extraction

Next, 250 mL of a 0.5 M NaOH solution was added to the centrifuge bottle containing the residual sediment. The contents of the bottle were shaken under N_2 for 24 h. The NaOH extract was centrifuged at 10 400 *g* and filtered. Both the $Na_4P_2O_7$ extract (from step *iii*) and the NaOH extract (from step *iv*) were used in the following separation of FA and HA, respectively.

Separation and purification of HA and FA

Both the $Na_4P_2O_7$ and the NaOH extracts were adjusted to pH 1.0 with 6 N HCl. The solutions were allowed to stand at room temperature for 24 h. The supernatant (FA fraction) was separated from the coagulate (HA fraction) by centrifugation at 10 400 *g* for 10 min followed by vacuum filtration. The FA fraction was adjusted to pH 8.0 with a 5 N NaOH solution and was allowed to stand for 4 h. It was next centrifuged at 10 400 *g* for 10 min and filtered. The clear solution was reduced to 20 mL on a rotary evaporator and dialyzed in a dialysis bag tubing (100 mm, Spectra/Por, Spectrum Medical Industries, Houston, Texas) with a molecular weight cutoff point of 3500 amu to allow removal of Na^+ and Cl^-. The dialysis procedure was repeated until a negative chloride test was obtained (ca. 72 h). The dialysed FA solution was subjected to freeze-drying and the dried FA was stored in a vacuum desiccator ready for further characterization.

The HA fraction was dissolved in 20 mL of a 0.1 M KOH solution under a N_2 atmosphere. Potassium chloride (0.3 g) was added to make the system 0.3 M in K^+. The inorganic colloid in the solution precipitated more easily at this ionic strength. After standing for 4 h, the solution was centrifuged at 10 400 *g* for 10 min. The supernatant was decanted to another centrifuge bottle and the remaining solid residue was discarded. The clear HA supernatant was acidified to pH 1.0 with 6 M HCl and the HA allowed to coagulate. The solid was separated from the liquid phase by centrifugation at 10 400 *g* for 10 min. The liquid was discarded and the solid was subsequently shaken on a reciprocal shaker for 24 h at room temperature with 250 mL of a HCl–HF solution (0.5% v/v of each acid). The HA was separated from the liquid phase by centrifugation at 10 400 *g* for 10 min. The solid (HA) remaining after decantation was treated with an additional 250 mL of the HCl–HF mixture. The solution was shaken for 24 h at which point the HA was separated from the liquid phase by centrifugation as described above. The solid (HA) was next washed with distilled H_2O. The residual water was removed from the HA with the aid of a freeze dryer. The dried HA was stored in a vacuum desiccator pending further characterization.

Characterization of sediment, HA, and FA samples

Determination of C, H, and N

Carbon, hydrogen, and nitrogen present in samples of lake sediments and in the HA and FA extracted from the sediment were determined on a Perkin–Elmer 2400 CHN elemental analyzer. The coefficients of variability for three replicate reference analyses were 0.20% for C, 2.2% for H, and 0.19% for N. The %O was calculated by difference, i.e., %O = 100 − %C − %H − %N, and can therefore include trace fractions of S or P.

Moisture and ash content

Weighed sediment, FA, or HA samples were placed in dry, preweighed porcelain crucibles. The crucibles and their contents were dried in an oven at 105°C for 4 h. After being allowed to cool in a desiccator the crucibles were reweighed. The process was repeated until a constant weight was obtained. The % moisture was calculated using eq. [1]:

$$[1] \quad \%\ \text{moisture} = \frac{w_0 - w_{105}}{w_0} \times 100$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

where w_0 is the initial weight of the sample and w_{105} is the weight of the sample after being heated at 105°C. Similarly, to determine the ash content, weighed samples of the sediment, FA, or HA in dry preweighed crucibles were placed in a muffle furnace at 750°C for 4 h. The weight of the remaining residue (w_{750}) and eq. [2] were used to determine the % ash content of the sample:

$$[2] \quad \% \text{ ash} = \frac{w_{105} - w_{750}}{w_{105}} \times 100$$

E_4/E_6 ratios:
The E_4/E_6 ratios, defined as the ratio of absorbance found at 465 and 665 nm, respectively, were determined for a series of FA and HA samples. More specifically, the absorbance of a 0.04% (w/v) solution of FA or HA in 0.05 M $NaHCO_3$ was measured at 465 nm and 665 nm on a Beckman DU-65 spectrophotometer. A 0.05 M $NaHCO_3$ solution was used as the reference solution.

IR analysis
The Fourier-transform infrared (FTIR) spectra of the *n*-hexane and chloroform extracts were recorded on smears between NaCl plates. The FTIR spectra of FA and HA were run in the form of potassium bromide pellets. Potassium bromide pellets were made from a mixture of 0.5 mg of a FA or HA sample and 200 mg of KBr which had been dried at 200°C for 12 h. The FTIR spectra of the KBr pellets were recorded on a Bomen Michelson-100 FTIR spectrophotometer between 4000 and 650 cm^{-1}. A pellet consisting of only KBr was used as the reference material.

NMR analysis
The solid state CPMAS ^{13}C NMR spectra were recorded at the laboratory of the U.S. Geological Survey, Denver, Colorado. The following parameters were used to record the ^{13}C NMR spectra of the various HA and FA samples: spectrometer frequency: 50.30 MHz; 90 degree pulse width: 4.5 μs; contact time : 1.00 ms. Determination of optimum contact and relaxation time was done prior to ^{13}C NMR analysis being performed. Spectra were interpreted in the manner described by Malcolm (28). Each NMR spectrum was divided into five regions based on the type of the carbon nucleus. The relative quantities of C in each region were calculated according to the method described by Novak and Smeck (38). Briefly, the areas under the peaks found in a particular region of the spectrum were estimated by dropping verticals to the baseline. The error associated with estimating the area of well-defined peaks in ^{13}C NMR spectra is approximately ±5% (26). The aliphaticity and aromaticity of humic and fulvic acids were determined using the following formulae (3), eqs. [3] and [4]:

$$[3] \quad \% \text{ aliphaticity} = \frac{\text{peak area for C signals from 0–110 ppm}}{\text{peak area for C signals from 0–160 ppm}} \times 100$$

$$[4] \quad \% \text{ aromaticity} = \frac{\text{peak area for C signals from 110–160 ppm}}{\text{peak area for C signals from 0–160 ppm}} \times 100$$

Results and Discussion

Sediments

Some characteristics of the lakes studied are listed in Table 1. It is interesting to note that both the colour index and the dissolved organic matter (DOC) reflect the same trend as found with the pH, i.e., the values for colour index and DOC increase in the order Silver, Clearwater, Tilton, and Ramsey. The conductivity measurements and the chloride ion concentration are high for Silver and Ramsey and relatively low for Tilton and Clearwater. The high chloride content of the lakes could be due to road salting (39) as Silver and Ramsey Lake are very close to the city and are therefore more susceptible to the effects of human activity. Finally, the area surrounding Tilton and Clearwater Lake is highly vegetated compared to that of Ramsey and Silver Lake.

Total organic matter (TOM) refers to the total amount of organic substances present in the sediments. TOM was calculated for the four lakes using eq. [5].

$$[5] \quad \text{TOM (\%)} = 100 - \text{moisture (\%)} - \text{ash (\%)}$$

The moisture, ash, and TOM contents of the four lake sediments are shown in Table 2. The moisture content of the sediments was found to range from 0.22 to 2.78%. The ash content, which corresponds to noncombustible material, was found to range from 74.08 to 96.78%. The TOM in these sediments ranged from 3.03 to 23.05%. The sediments collected from Silver Lake were found to contain the highest percentage of TOM. The primary source of organic matter for lake sediments is the debris of plants that have lived in the waters and on the land surrounding the lake (1). The TOM content of lake sediment therefore depends on the degree of vegetation sur-

O% = 100 − C(%) − H(%) − N(%).

rounding the lake and the abundance of plants in the lake and watershed. The fact that the sediments taken from Silver Lake have a relatively high TOM content suggests a high contribution from plants in the water and (or) on the land surrounding the lake. This is somewhat surprising because the current level of vegetation surrounding the lake is sparse. The low pH of Silver Lake water could, however, contribute to the precipitation of HS, which as stated earlier is the primary source of organic matter (OM) found in sediments. This would have the effect of increasing the content of TOM in the sediment, and cause the lake water to be relatively low in DOC, as was in fact observed. However, it should be noted that the pH alone cannot be used to explain the high TOM content of Silver Lake sediments. Further investigation will be needed to explain the high content of TOM in the lake sediment as little information is known about the history of the activities that could have affected Silver Lake sediment when vegetation was probably more abundant. The TOM appears to be correlated with the moisture content. For instance, the sediment collected from Silver Lake has the highest TOM content as well as the highest moisture content. This phenomenon could be related to the structural composition of the OM. It is a well-known fact that HS contain many polar groups such as -OH, -COOH, etc. (4). These groups have a strong affinity for water owing to the formation of hydrogen bonds. As a result it is more difficult to air-dry the sediments, which are richer in organic matter. Finally, it follows that the % ash is inversely proportional to the % moisture and % TOM.

The elemental composition of the sediments was obtained through analysis of C, H, and N in the sediment samples. The percentage of O in the TOM was calculated by difference. The amount of C, H, and N (expressed in g/100 g of sediment) found in the four lake sediments as well as the elemental composition of the TOM of sediments is presented in Table 3. The C content of the sediments was found to range from 1.24 to 11.08 g/100 g. The H content was found to range from 0.25 to 2.14 g/100 g while the range of the N content was 0.10–0.92 g/100 g. Ishiwatari (15) reported the average values of organic C and N in lake sediments as 4.42 g/100 g and 0.44 g/100 g, respectively. The values of the C and N content of the sediment collected from Tilton, Clearwater, and Ramsey lakes are lower than the average values, while the Silver Lake sediment has much higher values of C and N content. The high values are consistent with the high TOM content of the Silver Lake sediment. Although the elemental content of the Silver Lake sediment is significantly different from that of the other lake sediments, the elemental compositions of the TOM in all the lake sediments are similar. With regard to the elemental composition of TOM in the different lake sediments, C was found to range from 41.3 to 48.1%, H was found to range from 8.3 to 9.3%, N ranged from 3.2 to 4.0%, and O ranged from 38.6 to 47.1%. The fact that the elemental composition of the TOM varies very slightly suggests that the organic matter in the sediments collected from the four lakes may have a similar composition and structure.

The N/C ratios of the lake sediments were calculated and can be found in the last column of Table 3. They range from 0.065 to 0.071. The N/C ratios of organic matter are considered to be an indicator of the source of TOM in lake sediments. It has been reported that N/C ratios are dependant on whether cellulose is present in the plants contributing organic matter to lake sediments (1). Nonvascular aquatic plants have high N/C ratios, typically between 0.1 and 0.25, whereas vascular land plants, which contain cellulose, have N/C ratios of 0.05 and lower. Lakes for which the contribution of organic matter from vascular land plants is small show higher N/C ratios in their sediments (values between 0.11 and 0.16) than do lakes receiving important amounts of vascular plant debris (values between 0.072 and 0.077) (1). The fact that low N/C ratios were found in the organic matter of the four lake sediments suggests that land plants are the major contributor to the organic matter. In addition, the similarity in N/C ratios indicates that the sources of the organic matter are similar for the different lakes (40).

Extracted HA and FA

In the sequential extraction method used in this study, the extractants included organic solvents (*n*-hexane and chloroform), as well as $Na_4P_2O_7$ and NaOH. The organic solvents were used to extract alkanes, fatty acids, long-chain alcohols, and wax esters. With the exception of Silver Lake, OM extracted by hexane and chloroform represented less than 2% of TOM. Values of the OM extracted from the soil samples by the same two organic solvents were reported as ranging from 0.04 to 0.06% (41). FTIR spectra of each chloroform and hexane extract were recorded to obtain information on the compounds extracted. A summary of the FTIR bands observed is presented in Table 4. There is not much difference between

Table 4. FTIR bands of *n*-hexane and chloroform extracted OM of the lake sediments.

		FTIR bands (cm^{-1})						
Lakes	Extractants	~2920	~2850	~1730	~1460	1370~1240	1165~1100	~730
Tilton	*n*-Hexane	+++	+++	+	++	+	±	+
	Chloroform	+++	+++	++	+	±	±	+
Clearwater	*n*-Hexane	+++	+++	+	++	+	±	+
	Chloroform	+++	+++	++	+	±	±	++
Silver	*n*-Hexane	+++	+++	+	++	+	±	+
	Chloroform	+++	+++	++	+	±	±	+
Ramsey	*n*-Hexane	+++	+++	+	++	+	±	+
	Chloroform	+++	+++	++	+	+	+	++

Note: +++ = very strong signal; ++ = strong signal; + = weak signal; ± = very weak signal.

the FTIR spectra of the material extracted from the lake sediments by *n*-hexane and chloroform. More important, the OM extracted from the four different lake sediments does not seem to differ significantly. The most prominent IR absorption bands are at ~2920 cm^{-1} (asymmetric C–H stretch of CH_2) and ~2850 cm^{-1} (symmetric C–H stretch of CH_2). Some strong absorptions are also found at ~1730 cm^{-1} (C=O stretch of CO_2H), ~1460 cm^{-1} (CH_3 bending), and 730 cm^{-1} ($(CH_2)_n$ bending of paraffins). In addition, there are minor bands at ~1370 cm^{-1} (CH_3 bending), ~1270 cm^{-1} (C–OH stretch), and ~1130 cm^{-1} (C–C or C–OH stretch), all indicative of the presence of paraffins and fatty acids. The intensity of the bands at ~1730 cm^{-1} and 1460 cm^{-1} differs slightly when comparing the OM obtained from the *n*-hexane extraction and that obtained from the chloroform extractions. The band at 1730 cm^{-1} is more intense than at 1460 cm^{-1} in the chloroform-extracted material suggesting that the concentration of fatty acids is greater. These results are similar to those reported in the literature (41), suggesting that the *n*-hexane extracts more specifically alkanes and fatty acids while the chloroform removes mainly fatty acids, long-chain alcohols, and wax esters from the soil samples. These are believed to be compounds that are trapped in the complex matrix that makes up HS. The fact that more material was extracted by chloroform from the Silver Lake sediment suggests that the sediment contained more fatty acids, long-chain alcohols, and wax esters than the other lake sediments studied.

The two extraction reagents most often used in the studies of HS are $Na_4P_2O_7$ and NaOH. HS extracted by the two reagents have been known to be slightly different. More specifically, the molecular weight of the HS extracted from soils by $Na_4P_2O_7$ is smaller. The HS are also more aromatic in nature than those extracted by NaOH (42). The use of both reagents ensures that a maximum amount of HS is extracted from the lake sediments. The extraction procedure generated the following four samples for each sediment sample: 1. FA–$Na_4P_2O_7$ (the FA extracted using $Na_4P_2O_7$); 2. HA–$Na_4P_2O_7$ (the HA extracted using $Na_4P_2O_7$); 3. FA–NaOH (the FA extracted using NaOH); 4. HA–NaOH (the HA extracted using NaOH).

The amount of FA–$Na_4P_2O_7$ from a 25 g sediment sample ranges from 40.5 to 309.9 mg while the amount of FA–NaOH ranges from 59.8 to 237.6 mg. The total amount of FA extracted constitutes 0.4–2.19% of the sample weight and 9.27–13.02% of the TOM. The amount of HA–$Na_4P_2O_7$ from a 25 g sediment sample ranges from 23.5 to 639.7 mg and HA–NaOH ranges from 40.6 to 875.7 mg. HA makes up 0.26–6.04% of the sample weight and 8.27–25.90% of the TOM. Small amounts of FA and HA are found in the sediment samples collected from Tilton, Clearwater, and Ramsey lakes while relatively large amounts of FA and HA are observed in the Silver Lake sediments. These findings correlate well with the sediments. A comparison of these results with that reported (42) for the HA content of soils (2.08–18.8% by weight) indicates that lake sediments are relatively deficient in HA. Although there is a large difference in the amounts of FA and HA recovered from the four lake sediments (ranging from 0.40 to 2.19% for FA and from 0.26 to 6.04% for HA), the percentage of FA and HA in the TOM of the lake sediments is similar (ranging from 9.27 to 13.02% for FA and 8.27 to 25.9% for HA). The results in this study also agree with the observations (15) that FA make up 6–23% and HA 8–24% of the OM found in lake sediments. Our results show that the sediments are richer in HA than FA. This is because FA have higher solubility in lake water than HA. The highest HA content was found in the Silver Lake sediments, possibly due to the relatively low pH of the lake water (pH = 4.0).

Elemental composition of HA and FA

Once the FA and HA were separated from the lake sediments, they were analyzed for carbon, hydrogen, nitrogen, and oxygen content. The carbon, hydrogen, nitrogen, and oxygen composition of the FA and HA extracted from the four lake sediments is presented in Table 5. The percentage of carbon in the FA–$Na_4P_2O_7$ ranges from 37.47 to 46.15. The hydrogen ranges from 6.40 to 6.93%, the nitrogen ranges from 2.48 to 3.89%, and the oxygen ranges from 43.44 to 53.60%. The FA extracted from the Silver Lake sediments with $Na_4P_2O_7$ is lower in carbon, lower in nitrogen, and higher in oxygen when compared to that of the other sediments. The percentage of carbon in FA–NaOH ranges from 45.1 to 48.01. The hydrogen ranges from 6.59 to 6.94%, the nitrogen ranges from 4.95 to 5.76%, and the oxygen ranges from 40.36 to 42.75%. The elemental composition of FA extracted from all four sediments by NaOH is similar. It should be noted that in comparing the FA extracted from the lake sediment by NaOH with that obtained by using $Na_4P_2O_7$ the NaOH extracts contain higher carbon (except for Tilton), hydrogen, and nitrogen but lower

Table 6. A comparison of elemental composition of FA and HA from different lake sediments.

Element	Reported values[a] (%)	Values determined in this study (%)
Fulvic acids		
Carbon	44.98 ± 3.90	44.94 ± 3.39
Hydrogen	5.12 ± 1.24	6.65 ± 0.20
Nitrogen	7.63 ± 0.56	4.31 ± 1.07
Oxygen	42.27 ± 4.69	44.11 ± 4.34
Humic acids		
Carbon	52.05 ± 3.61	52.36 ± 1.87
Hydrogen	5.67 ± 0.65	5.26 ± 0.60
Nitrogen	5.63 ± 1.08	4.77 ± 0.36
Oxygen	36.55 ± 4.27	37.32 ± 2.54

[a]The values reported by Ishiwatari (15).

oxygen. In the HA–$Na_4P_2O_7$, the carbon ranges from 48.78 to 53.41%, the hydrogen ranges from 4.52 to 5.16%, the nitrogen ranges from 4.26 to 4.70%, and oxygen ranges from 37.03 to 41.80%. The carbon in the HA–NaOH ranges from 52.69 to 54.67%, the hydrogen ranges from 5.83 to 6.27%, the nitrogen ranges from 4.85 to 5.23%, and the oxygen ranges from 34.27 to 36.29%. In each extract, there are small variations of the elemental composition of HA among the lake sediments. But, as was the case for FA, the HA resulting from extraction by NaOH contains higher carbon, hydrogen, and nitrogen but lower oxygen than the $Na_4P_2O_7$ extracts. These results suggest that the NaOH and $Na_4P_2O_7$ extracted OM from the lake sediments differs in composition.

Average values of the elemental composition of FA and HA reported (15) for different lake sediments of Japan are summarized in Table 6 where they are compared to the values calculated from our data for the NaOH and $Na_4P_2O_7$ extracted materials (Table 5). The values of the elemental composition of the HA determined in this study are close to the average values reported (15). The FA found in the Sudbury area lake sediments appear to be slightly higher in hydrogen content and lower in nitrogen content.

When comparing the FA and HA one notices that the carbon content of fulvic acid is lower than that of humic acid while oxygen displays the opposite trend (Table 5). The nitrogen content of HA–$Na_4P_2O_7$ is slightly higher than that of FA–$Na_4P_2O_7$ but there is no such trend found in the NaOH extracts. The results also show that the hydrogen content for FA appears to be higher than that for HA (Table 5).

Elemental ratios of HA and FA

The elemental ratios most often used in the study of HS are H/C, N/C, and O/C. By using the H, C, N, and O elemental analysis data, H/C, N/C, and O/C ratios of fulvic and humic acids extracted from the four lake sediments were calculated (Table 7). The H/C ratio varies from 1.66 to 2.06 in the FA–$Na_4P_2O_7$ and from 1.66 to 1.84 in the FA–NaOH. The H/C ratio varies from 1.05 to 1.35 in the HA–$Na_4P_2O_7$ and from 1.30 to 1.43 in the HA–NaOH. Higher H/C ratios were found in the FA than in the HA. In addition, for the HA, the H/C ratios of the NaOH extracts appear to be slightly higher than that of the $Na_4P_2O_7$ extracts. The N/C ratio varies from 0.057 to 0.074 in the FA–$Na_4P_2O_7$ and from 0.089 to 0.105 in the FA–NaOH. The ranges of the N/C ratio are 0.070 to 0.078 in the HA–$Na_4P_2O_7$ and 0.076 to 0.085 in the HA–NaOH. The HA extracted by both NaOH and $Na_4P_2O_7$ produces N/C ratios that are within experimental error of one other. The FA extracted by $Na_4P_2O_7$ have lower N/C ratios than those observed for the NaOH extracted FA. The O/C ratio varies from 0.708 to 1.07 in the FA–$Na_4P_2O_7$ and from 0.630 to 0.710 in the FA–NaOH. The ratio varies from 0.520 to 0.643

	0.5 M NaOH	1.30 ± 0.02	0.083 ± 0.001	0.486 ± 0.001

in the HA–$Na_4P_2O_7$ and from 0.470 to 0.516 in the HA–NaOH. Higher O/C ratios were found in the FA than in the HA and the ratios of the $Na_4P_2O_7$ extracts appear to be higher than those of the NaOH extracts for both the FA and HA.

From Table 7, the elemental ratios for the FA and HA can be summarized as follows: for **FA:** H/C: 1.66–2.06; N/C: 0.057–0.11; O/C: 0.63–1.07; for **HA:** H/C: 1.05–1.43; N/C: 0.070–0.085; O/C: 0.47–0.64. Using the average elemental ratios, the empirical formulae for the FA and HA extracted from lake sediments are: **FA:** C:H:O:N = 12:22:9:1 and **HA:** C:H:O:N = 12:16:6:1. The elements present in FA and HA decrease in the order: H > C > O > N.

Larger amounts of H and O found in the FA with respect to HA suggest that FA molecules contain a greater number of carbohydrate and carboxylic acid groups. This has been further confirmed by the ^{13}C NMR spectra of the FA and HA (see further in the text). In addition, for the HA, the NaOH extracted material has a higher H/C ratio and a lower O/C ratio than the $Na_4P_2O_7$ extracted material. This appears to suggest that the material extracted by the 0.5 M NaOH solution could be more aliphatic in nature than that extracted by the 0.1 M $Na_4P_2O_7$ solution. Using ^{13}C NMR, it has been reported (42) that HA extracted by 0.1 M $Na_4P_2O_7$ solution are more aromatic than those removed from the same soils by 0.5 M NaOH solution. The ^{13}C spectra in our study also indicate the same results.

A comparison of elemental ratios of FA and HA from different sources was made and the results are shown in Table 8. Ishiwatari (15) summarized the average values of elemental ratios for FA from sediments of Japanese lakes. The FA in the present study have a slightly higher H/C (1.66–2.06) and O/C ratio (0.63–1.07) while the N/C ratio (0.057–0.11) is lower than the average values published by Ishiwatari. Organic material with a relatively high O-alkyl and carboxylic acid composition would result in high H/C and O/C ratios. Therefore, the FA isolated from the Sudbury area lake sediments would seem to contain a higher proportion of O-alkyl and carboxylic acid functionalities than those studied thus far based on the H/C and O/C ratios. The values for the HA in the present study (H/C = 1.05–1.43, N/C = 0.070–0.085, and O/C = 0.47–0.64) are essentially in the same range as those previously reported for lake sediments (15).

The data in Table 8 show that there are significant differences among the values of the elemental ratios for FA and HA derived from lake sediments and other sources such as soil, river water, and groundwater. It can been seen that FA and HA extracted from lake sediments produce relatively high H/C, O/C, and N/C ratios compared to those for FA and HA extracted from soil, river, and groundwater. High N/C ratios suggest that lake sediment FA and HA are closely related to their precursory materials (e.g., the N/C ratios for phytoplankton range from 0.11 to 0.16 (1)) and have a relatively low degree of humification (15). High H/C and O/C ratios reflect high carbohydrate content and the high aliphatic character of lake sediment FA and HA. These trends have also been observed in the analysis of the ^{13}C NMR spectra in this study.

E_4/E_6 ratios of HA and FA

The E_4/E_6 ratio refers to the ratio of the absorbances of dilute aqueous FA or HA solution at 465 and 665 nm. The ratio is inversely related to the molecular weight or particle size of FA or HA (42) as larger molecules have higher absorbances at long wavelengths than at the shorter ones. As shown in Table 9, the E_4/E_6 ratio of the FA–$Na_4P_2O_7$ ranges from 11.11 to 12.40 and the E_4/E_6 ratio of the FA–NaOH ranges from 8.81 to 11.03, while the E_4/E_6 ratio of the HA–$Na_4P_2O_7$ ranges from 5.59 to 5.88 and the E_4/E_6 ratio of the HA–NaOH ranges from 4.23 to 4.66. There are two trends observed from the E_4/E_6

values. Firstly, the E_4/E_6 ratios of FA are higher than those of HA, suggesting that the molecular weight of FA is lower than those of HA. These are similar to the E_4/E_6 ratios of HA (3.95 ± 0.16) and FA (10.66 ± 0.49) reported for fulvic acid extracted from Lake Huron sediment (43). Secondly, the E_4/E_6 ratios of the $Na_4P_2O_7$ extracted FA and HA are higher than those of the NaOH extracted material. This suggests that the NaOH extracted material has a higher molecular weight than the $Na_4P_2O_7$ extracted material. Piccolo and Mirabella (44) also found that 0.1 M NaOH extracted OM from soil with higher molecular weight than did a 0.1 M $Na_4P_2O_7$ solution.

In addition, E_4/E_6 ratios, being a function of molecular weight or particle size, are expected to be related to the elemental composition of the molecules. Plots were drawn of the E_4/E_6 ratio versus %C, %H, %N, %O, H/C, N/C, and O/C, respectively, and the resulting correlation coefficients are presented in Table 10. The negative correlation coefficient indicates that the E_4/E_6 ratio decreases as %C increases. HA have higher %C and lower E_4/E_6 ratios while FA have a lower %C and higher E_4/E_6 ratios. As the %H increases, the E_4/E_6 ratios also increase. HA have lower E_4/E_6 ratios and lower %H while FA have higher E_4/E_6 ratios and higher %H. There is no obvious trend between the E_4/E_6 ratio and %N. The r value seems to indicate that the lower molecular weight material (high E_4/E_6 ratios) has a variable amount of N (~2.5–6%) while the N in higher molecular weight material has a narrower range (4.2–5.2%). The data in Table 10 suggest that the larger molecular weight materials (low E_4/E_6 ratios) have a relatively low %O (~34–42%) while the smaller molecular weight materials have a relatively high %O (~40–54%). E_4/E_6 ratios appear to increase as H/C and O/C ratios increase. HA have lower E_4/E_6 H/C and O/C ratios than FA. No relationship was observed between the E_4/E_6 ratios and N/C ratios. However, as in the case of the E_4/E_6 versus %N plot, the N/C ratio of the FA (high E_4/E_6) is highly variable (0.057–0.105) while HA have a much narrower range of N/C ratios (0.07–0.085). In summary, for lake sediment FA and HA, a low E_4/E_6 ratio is associated with a molecule that has a high carbon content, but is relatively low in hydrogen and oxygen. A high E_4/E_6 ratio, in contrast, indicates that the molecule has a low carbon content, but is relatively high in hydrogen and oxygen. These are consistent with the observations made for soil FA and HA (42), the

correlation coefficients for E_4/E_6 ratios with %C and %O were −0.73 and 0.82, respectively.

FTIR spectroscopy of HA and FA

Fourier-transform infra red spectroscopy (FTIR) is a very useful method for determining the functional groups present in HS. In this study, FTIR spectra of FA and HA samples extracted from Sudbury area lakes were recorded in the form of KBr pellets. A summary of the major bands found in the FTIR spectra is presented in Table 11. The FTIR spectra of the FA and HA are relatively simple. There are no apparent structural differences between the FA and HA extracted from the four lake sediments according to the infrared analysis. McCarthy and Rice (24) comment that the most striking feature of the infrared spectra of HS is the overall simplicity of the spectra and the similarity suggests that the chemical structures of these compounds are closely related. When compared to the infrared spectra of a commercial humic acid and a peat fulvic acid (not shown), it is immediately obvious that their spectra resemble closely those recorded in the present study. Although there are relatively few bands, which are generally very broad and nondescript, some structural information regarding the lake sediment FA and HA can be extracted from the spectra. It should be noted, however, that infrared spectroscopy is not sensitive enough to uncover minor structural differences that may exist between HS. The FTIR spectra of FA exhibit the following features: a broad band around 3300–3400 cm^{-1} (OH stretching vibration, or H_2O, contribution from aliphatic OH stretching vibration, and possibly NH stretching vibration), a small shoulder around 2935 cm^{-1} (asymmetric CH stretching vibration of $-CH_2-$), a well-pronounced peak at 1625 cm^{-1} (aromatic C=C stretching vibration and (or) asymmetric $-COO^-$ stretching vibration), a peak at around 1400 cm^{-1} (-CH bending vibration of $-CH_2$ and $-CH_3$), a small peak at 1220 cm^{-1} (-C–O stretching vibration and OH bending vibration of -COOH), a major peak at around 1080 cm^{-1} (-C–OH stretching vibration of polysaccharides) and an absorption band at around 800 cm^{-1} (=C–H out-of-plane bending vibration, characteristic of aromatics or alkene).

The FTIR spectra of HA exhibit basically the same features as those of FA except for a shoulder at ca. 2860 cm^{-1} (aliphatic CH stretching vibration), a band at 1720 cm^{-1} (-C=O stretch of -COOH), and a peak at ca. 1530 cm^{-1} (aromatic C=C stretching vibration). These FTIR spectra indicate that FA and HA extracted from the lake sediments are composed of aromatic groups (bands at around 1620 cm^{-1} and 900 cm^{-1}), aliphatic groups (bands in the 2860–2930 cm^{-1} region and at around 1422 cm^{-1}), carboxylic groups (bands at around 1720 cm^{-1} and 1220 cm^{-1}), and polysaccharide-like components (bands at 1040 cm^{-1}). The band at 1040 cm^{-1} is more intense for the FA samples, than that found for the HA samples, indicating that the FA contains more polysaccharide components. This has been confirmed by the solid-state ^{13}C NMR analysis carried out in the present study. The bands observed at ca. 1720 cm^{-1} (due to C=O stretching vibration of COOH) in the spectra of HA appear to reflect the relatively high acidity of the HA. This finding is consistent with the results of the PY–GC–MS analysis (37), as many components of fatty acids were found in the pyrolysis products of HA. It is worth noting that the band at 1625 cm^{-1} is of similar intensity in both FA and HA spectra, indicating that the aromatic character of FA and HA is similar. This observation was confirmed by the

analysis of the ^{13}C spectra of the FA and HA samples. This is interesting as IR and ^{13}C NMR data of soil HS (38) indicated that the aromatic character of FA was less than that of HA.

Solid-state CPMAS ^{13}C NMR spectroscopy of HA and FA

Solid samples of FA and HA were subjected to cross polarization magic-angle spinning (CPMAS) ^{13}C NMR analysis. As described earlier, each ^{13}C NMR spectrum was divided into five chemical shift regions, corresponding to aliphatic C (0–50 ppm), O-substituted alkyl C (50–110 ppm), aromatic C (110–160 ppm), carboxylic acid C (160–190 ppm), and carbonyl C (190–240 ppm), respectively. Relative quantities of each type of C found in the five regions were determined by planimetry and are expressed as a percentage of the total organic carbon content. Spectral identification was facilitated by using the chemical shift data for FA and HA reported by Malcolm (28). The distribution of C in the five regions of the spectra is presented in Table 12. The spectra have five well-resolved and three poorly resolved peaks. The well-resolved peaks are in the regions of 15–40 ppm (methyl, methylene, and methine groups), 50–60 ppm (methoxy groups), 60–90 ppm (C–O groups), 115–145 ppm (aromatic carbons), and 160–190 ppm (carboxyl and ester groups). The poorly resolved peaks occur between 95 and 108 ppm (anomeric carbons), 145 and 160 ppm (phenolic carbons), and 190 and 215 ppm, (carbonyl groups). The most intense peak in the HA spectra is found at around 35 ppm, which corresponds to the aliphatic C region (0–50 ppm) (28). The percentage of C in this region varies from 28.1 to 44.0 for the $Na_4P_2O_7$ extracted material and from 43.7 to 45.4 for the NaOH extracted material (Table 12). This suggests that the structure of HA from the lake sediments is primarily aliphatic in nature. Furthermore, the higher percentage of C in the aliphatic region for the NaOH extracts than that for the $Na_4P_2O_7$ extracts indicates that the organic material extracted by the 0.5 M NaOH solution possesses more aliphatic groups than that extracted by the 0.1 M $Na_4P_2O_7$ solution. In the O-alkyl region (50–110 ppm), two well-resolved peaks at 54 and 76 ppm as well as a small peak at 104 ppm were evident in the spectra of all the HA samples. The peak at 54 ppm has been attributed to methoxy groups associated with lignin and lignin-like products (28, 45, 46). The peak at 76 ppm is thought to correspond to ring carbons of polysaccharides (28, 47), whereas the signal at 104 ppm has been assigned to anomeric carbons in polysaccharides (28). The intensity of the signals found in the 50–110 ppm region of the spectra suggests that HA from the lake sediments contain a substantial amount of carbohydrate-like matter. More specifically, the percentage of the O-alkyl carbons with respect to the total organic carbon varies from 24.0 to 30.8% for both extracts (Table 12). This is the second highest percentage of carbon in the five regions considered. Hence, the groups with O-alkyl carbons (which might include carbohydrate O-methylene and methine, and aromatic O-methyl and methylene) constitute the second major structural component of HA. In the aromatic C region (110–160 ppm), a well-resolved peak at 130 ppm has been attributed to aromatic structures substituted with alkyl groups. A minor peak, indicative of phenolic groups, also occurs at 153–154 ppm in all the spectra recorded for the samples of HA. The fact that peaks in the aromatic C region are less intense than those in the aliphatic and O-alkyl regions indicates that aromatic structure is not the major component of lake sediment HA. The percentage of aromatic carbon relative to the total organic carbon varies from 8.9 to 24.2% (Table 12), which is a relatively low percentage. It should be noted that significantly more aromatic carbon containing material (21.1–24.2%) is extracted from the sediments of Tilton, Silver, and Ramsey lakes by the 0.1 M $Na_4P_2O_7$ solution than by the 0.5 M NaOH solution (9.2–11.2%). In the region between 160 and 190 ppm, all lake sediment HA spectra exhibit a prominent peak between 173 and 174 ppm, which

[a]Reported by Novak and Smeck (38).
[b]Reported by Boerchke et al. (48).
[c]This study.

is characteristic of the carboxyl, amido, and ester functionalities. The percentage of carbon in this region varies from 10.8 to 15.6 for both extracts (Table 12). Minor peaks in the carbonyl region (190–230 ppm) are evident in the spectra of the four HA samples. The similarities between the ^{13}C NMR spectra of the HA extracted from the four lake sediment samples show that their structures are virtually identical. In comparing the % carbon in the five regions of the HA spectra one finds that: %aliphatic C > %O-alkyl C > %aromatic C > %carboxylic C > %carbonyl C.

In addition, HA from Clearwater Lake has a relatively low aromatic C content. The aromaticity and aliphaticity of HA, calculated using the formulae provided by Schnitzer (3), vary from 10.7 to 29.2% and from 83.3 to 70.8%, respectively (Table 12). It should be noted that the aromaticity for material extracted with 0.1 M $Na_4P_2O_7$ is higher than that for material extracted with 0.5 M NaOH. Schnitzer and Schuppli (42) also found in their study of the soil HA that the $Na_4P_2O_7$ extracted OM was more aromatic in nature.

Solid-state CPMAS ^{13}C NMR spectra of FA extracted from Silver Lake and Ramsey Lake were recorded. The percentages of carbon in the five regions of the spectra are shown in Table 12. The spectra of FA extracted from those two lake sediments by both $Na_4P_2O_7$ and NaOH are similar. The FA spectra differ significantly from those obtained for HA extracted from the same lake sediments. The most intense signal occurs at 176 ppm (in the carboxylic C region) rather than at 31 ppm (in the aliphatic region) as was observed in the HA spectra. In contrast to HA, the signal at 76 ppm (in the O-alkyl region) of the FA spectra is also higher than the 31 ppm peak. Table 12 shows that the percentage of the O-alkyl C and the carboxylic C in the FA extracted from the sediments of Silver and Ramsey lakes varies from 31.0 to 37.1% and from 17.0 to 21.2%, respectively, which are higher than those determined for HA. On the other hand, the percentage of the aliphatic C in the FA varies from 21.6 to 34.1%, which is lower than that calculated for HA. This suggests that there are more O-alkyl groups, which are attributed to carbohydrate-like compounds, and more carboxylic groups in the structure of the FA than in the structure of the HA. It is also worth noting from Table 12 that the aromatic C content of the FA (8.6–22.3%) is close to that of HA (9.2–24.2%). The aromaticity of the FA obtained from the sediments of Silver Lake (27.3% for 0.1 M $Na_4P_2O_7$ and 24.0% for 0.5 M NaOH) is even slightly higher than that calculated for the HA extracted from the sediments of the same lake (26.1% for 0.1 M $Na_4P_2O_7$ and 11.3% for 0.5 M NaOH).

A comparison of the distribution of C in HA and FA from soils (38), lake waters (48), and lake sediments (this study) can be found in Table 13. The relative amount of aromatic carbon in the structure of HA is dependent upon the origin. The percentage of aromatic C in the lake sediment HA (9.1–17%) and lake waters (20.6–21.9%) is much lower than in the soil HA (30–42%). Thus, the highest contribution of C in the structure of the lake HA is in the aliphatic (0–50 ppm) rather than in the aromatic region (110–160 ppm). This suggests that the aromaticity of soil HA is higher than that of lake HA. Boerschke et al. (48) reported the aromaticity of HA from Ramsey Lake water to be 25%, which is slightly higher than those aromaticity of the sediment HA (21%). Lake sediment FA have a slightly higher amount of O-alkyl carbons and a lower amount of carboxylic carbons than those found for soil FA. Fulvic acid from lake water appears to contain a relatively high number of aliphatic carbon groups in its structure. The structural implications of the information obtained from the different techniques are summarized in Table 14.

Conclusions

In this study, organic matter was extracted from the sediment of four Sudbury area lakes, with the aid of *n*-hexane, chloroform, 0.1 M $Na_4P_2O_7$, and 0.5 M NaOH solutions. The different FA and HA fractions were characterized using a number of different analytical methods. In general, the HS from the different lake sediments were shown to have similar chemical composition and structure. Such similarities suggest that the factors that play major roles in the formation and preservation of HS, such as the nature of the sediments, climatic and botanical environments, etc., are quite similar in the lakes tested and

that the pH of lakewater does not significantly affect the HS composition. A careful analysis of the data showed that the HS from the lake sediments have low aromaticity and relatively high carbohydrate content compared to the soil HS. The data on the composition and structure of the organic matter obtained from this study should provide useful information for the investigation of the interaction of organic matter in the lakes with trace metals, pollutants, etc.

The results of this study are summarized as follows:

1. The TOM in the four Sudbury area lakes range from 3 to 23% with Silver Lake being the highest. This could be related to the intense acidification of the lake watershed.
2. A very small portion of organic matter in the sediments was extracted by *n*-hexane and chloroform. Similar FTIR spectra were found for both the *n*-hexane and chloroform extracts. The spectra indicate that the material extracted from the lake sediments by the two organic solvents are a mixture of alkanes, fatty acids, long-chain alcohols, and wax esters.
3. The HS of lake sediments were found to contain a greater proportion of HA than FA. This could be due to the higher solubility of the smaller molecular weight FA in lakewater.
4. Elemental analysis showed that higher H/C and O/C ratios were found for FA than for HA, suggesting that the FA molecules contain more carbohydrate and carboxylic-like groups. The NaOH extracted material had a higher H/C ratio than the $Na_4P_2O_7$ extracted material, indicating that the material extracted by the 0.5 M NaOH solution is more aliphatic in nature than that extracted by the 0.1 M $Na_4P_2O_7$ solution.
5. E_4/E_6 ratios indicate that the molecular weight of HA is higher than that of FA and the 0.1 M $Na_4P_2O_7$ solution extracted smaller molecular weight material from the lake sediments than did the 0.5 M NaOH solution.
6. No apparent structural differences between the FA and HA extracted from the four lake sediments were detected by FTIR spectroscopy. The spectra indicate that both FA and HA possess aromatic, aliphatic, O-alkyl, and carboxylic functional groups.
7. The ^{13}C NMR spectra of FA and HA extracted from the lake sediments confirm that there are aliphatic, O-alkyl, aromatic, carboxylic, and carbonyl carbon nuclei in the FA and HA. The higher alkyl C and carboxylic C content found in the FA with respect to HA suggests that FA contain more carbohydrate and carboxylic groups than HA. Analysis of the spectra also showed that FA and HA extracted from the lake sediments are highly aliphatic. The aromaticity of lake HA is lower than that of soil HS. The ^{13}C NMR spectra of the $Na_4P_2O_7$ and NaOH extracts show that the aromatic C content found in the $Na_4P_2O_7$ extracts is higher than that found in the NaOH extracts, confirming that the $Na_4P_2O_7$ extracted material is more aromatic in nature than the NaOH extracted material.

Annulated derivatives of 2,2′-biimidazole, 2-(2′-imidazolyl)benzimidazole, and 2,2′-bibenzimidazole

James R. Ames, Melissa A. Houghtaling, Deborah L. Terrian, and Timothy P. Mitchell

Abstract: Preparation of bisannulated salts of 2,2′-biimidazole, 2-(2′-imidazolyl)benzimidazole, 2,2′-bibenzimidazole, and annulated salts of 1,1′-dimethyl-2,2′-biimidazole, 1,1′-dimethyl-2-(2′-imidazolyl)benzimidazole, and 1,1′-dimethyl-2,2′-bibenzimidazole is accomplished by direct alkylation of the parent azaheterocycle with excess 1,*n*-dihaloalkane. Discussions of the product conformations use electronic absorption spectra and NMR. The redox potentials of these salts are measured in DMF and CH_3CN, and become increasingly more negative and less reversible as the systems become less planar.

Key words: electrochemistry, bridged azabiaryl salts.

Résumé : On a fait appel à une alkylation directe des azahétérocycles parents à l'aide d'un excès de 1,*n*-dihalogénoalcane pour effectuer la préparation des sels à deux anneaux des 2,2′-biimidazole, 2-(2′-imidazolyl)benzimidazole, 2,2′-bibenzimidazole et des sels à un anneau des 1,1′-diméthyl-2,2′-biimidazole, 1,1′-diméthyl-2-(2′-imidazolyl)benzimidazole et 1,1′-diméthyl-2,2′-bibenzimidazole. On discute des conformations des produits en fonction des spectres d'absorption électronique et de la RMN. On a mesuré les potentiels rédox de ces sels dans le DMF et dans le CH_3CN; lorsque les systèmes adoptent des conformations de moins en moins planaires, ils deviennent de plus en plus négatifs et moins réversibles.

Mots clés : électrochimie, sels azabiaryles pontés.

[Traduit par la rédaction]

Introduction

The organic chemist has long been intrigued by biaryl molecules, the prototype being 1,1′-biphenyl, and the π-interaction between the two covalently bound rings. Researchers have used ultraviolet spectroscopy and ^1H NMR to examine the twisted nature of bridged biphenyls (1, 2).

The biphenyl work was soon extended to the diaza analogue, 2,2′-bipyridine. Homer and Tomlinson studied the electronic spectrum and reduction potential as a function of the length of the *N,N′* bridges quaternizing the nitrogens in 2,2′-bipyridine (3). They found that conjugation between the rings was affected by the length of the quaternizing chain.

Bridged diquaternary salts of 2,2′-biimidazole, **1**, and 2,2′-bibenzimidazole, **2**, have also been studied with respect to their redox and electronic properties (4–6). These 1,4-diaza systems differ significantly from that of 2,2′-bipyridine. For example, the chelation angle has been estimanted to be about 20° less for 2,2′-biimidazole than for 2,2′-bipyridine, causing a larger *N,N′* distance. Therefore, bridging between these sites should be affected, and the dihedral angle between the rings resulting from bridging should be reduced. In fact, molecular mechanics calculations on bridged 2,2′-biimidazoles have given dihedral angles of up to 20° less than the corresponding 3,3′-bridged-2,2′-bipyridines (4). The increased *N,N′* distance in the 2,2′-biimidazole molecule has prevented the synthesis of the *N,N′*-bis(dimethylene)-bridged salt (4). Furthermore, the doubly bridged 2,2′-biimidazolium and 2,2′-bibenzimidazolium salts are of interest because of their redox behavior — a neutral, tetraazaethylene derivative can be formed after two-electron reduction. These species are of great interest because they are aza analogues of tetrathiafulvene, an important donor in conducting charge transfer salts.

Thummel has demonstrated the importance of the effect of annulation on aromaticity in other heteroaromatics. His group has prepared mono- and bisannulated derivatives of 2,2′-bipyridine (7, 8), 2,2′-biquinoline (9), 2,2′-bi-1,8-naphthyridine (10), 2,2′-biimidazole (4), 2,2′-bithiazole (11), and 2,2′-bibenzimidazole (6).

As an extension of the 2,2′-biimidazolium (4) and 2,2′-bibenzimidazolium (5, 6) studies, the preparation, and spectral and redox properties of more than 20 mono- and bisannulated diquaternary salts of **1**, **2**, 2-(2′-imidazolyl)benzimidazole, **3**, 1,1′-dimethyl-2,2′-biimidazole, **4**, 1,1′-dimethyl-2,2′-bibenzimidazole, **5**, and 1,1′-dimethyl-2-(2′-imidazolyl)benzimidazole, **6**, is now reported. It is hoped that these studies will allow the prediction of the reduction potential for the unknown salt **7** (bis-dimethylene bridged). Table 1 indicates the structures of the diquaternary salts.

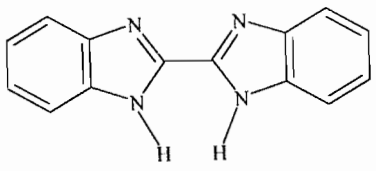
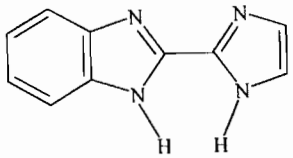
Results and discussion



A. Synthesis

Diquaternary salts in this study are prepared by one of two methods (see experimental section). Treatment of the parent azaheterocycle with an excess of 1,*n*-dibromoalkane in refluxing solvent generates the symmetrically bridged bisannulated salts and the monoannulated salts. For example, preparation of compound **7***b* involves the direct treatment of 2,2′-biimidazole with an excess of 1,3-dibromopropane. The yields of these reactions are typically 40–80%. However, the yield of compound **9***a* was only 10%. The corresponding 2,2′-biimidazolium salt is unknown (4) and Hunig et al. (5) have reported a 40% yield of **8***a*. The more facile bridging in the 2-(2′-imidazolyl)benzimidazole and the 2,2′-bibenzimidazole systems is likely due to the increased N1-C2-N3 bond angle resulting from the benzo-ring fusion.



Preparation of the unsymmetrically bridged salts **7***a*, **9***b*, **9***c*, and **9***e* is accomplished by first treating either **1** or **3** with a slight excess of 1-bromo-*n*-chloroalkane to give the bridged species. This is followed by reaction with 1,*n*-dihaloalkane to give the salt.

B. Spectroscopic properties

Spectroscopic properties and molecular modeling may be used to gain information about the dihedral angle between the rings of bridged azabiaryl compounds. Early work correlated the dihedral angle with the ultraviolet absorption maxima (3). Proton NMR spectra have also been related to the dihedral angle. Vogtle and Brombach (12) studied differences in the chemical shift of H_3 and H_5 of 2,2′-bipyridines, while Font and co-workers (13) and Thummel et al. (4, 7–9, 11, 14) analyzed the conformational mobility of biaryl systems by the coupling constants and the multiplicity of the bridge protons.

Several trends become apparent from the absorbance data given in Tables 2 and 3. First, as the *N,N′* bridges increase, there is a clear hypsochromic shift. In the case of the 1,1′-dimethyl salts the shift is consistently about 20 nm per CH_2 unit. The intensity of these absorptions is less consistent but shows a general trend wherein absorptions for the more planar systems are generally more intense. Both the shifts to higher energy and to lower intensity correspond with decreasing planarity (3).

The absorption maximum value is greatly influenced by the presence of an ethylene bridge. For example, the absorption maximum is 359 nm for **8***a* and **8***d*, near 335 nm for **8***e*, **9***a*, **9***d*, and **9***e*, and 300 nm for **7***a* and **7***d*. The differences in absorption maxima as a result of the parent nucleus, cf., **7***b*, **8***b*, and **9***d*, is expected.

Finally, incorporation of a second bridge imposes added rigidity to the salt. That is, increasing the bridge size from two to three carbon units appears not to greatly alter the dihedral angle as evidenced by the small change in absorption maxima, cf., **8***a* and **8***b*, or **9***a* and **9***d*. The greatest amount of molecular distortion is indicated for the bis(tetramethylene) bridged systems **7***c*, **8***c*, and **9***f*. The change is less for **9***e*; apparently, the trimethylene bridge affects the conformation to some degree. The results from the UV observations reflect a diminished π-delocalization resulting from the concurrent decrease in conjugative interaction between the two aromatic rings as the tethers increase, as expected for twisting about an essentially single bond in a conjugated system.

[a]Potentials are given for 0.5 mM solutions with 0.1 M tetraethylammonium perchlorate, recorded at a scan rate of 100 mV/s. The difference between cathodic and anodic peak potentials (mV) is given in parentheses; ir indicates irreversible, and for these systems the potential given is the peak of the cathodic wave.

[b]The value is −1.39 V (ir) in CH_3CN with tetrabutylammonium perchlorate as electrolyte.

[c]Reference 5 questioned the reversibility of the reduction.

the ^1H NMR. In the ethano-bridged salts, the methylene protons in trifluoroacetic acid-*d* appear as singlets in the δ 5.1–5.4 range, indicating that for these quasi-planar systems bridge protons are equivalent. Differences in shielding of the different π-systems is evident. For example, bridge protons in salt **8***b* give a triplet at 5.23 (8H) and a quintet at 3.25 ppm (4H), while salt **9***d* gives triplets at 4.88 and 4.77 (4H each), with a quintet at 2.77 ppm (4H). The two triplets are due to the unsymmetrical shielding effects of the two rings. These results suggest that the structures are conformationally mobile at room temperature on the NMR time scale; the added methylene unit allows for added flexibility. Thummel has reported on

Fig. 1. 360 MHz ^{1}H NMR spectrum of the upfield region of 1:1′,3:3′-bis(tetramethylene)-2-(2′-imidazolyl)-benzimidazolium dibromide (DMSO-d_6), **9***f*.

the fluxional nature of trimethylene bridged salts of 2,2′-biimidazole (4), 2,2′-bibenzimidazole (6), and bithiazole (11) at room temperature. Conversely, a tetramethylene bridge introduces rigidity on the NMR time scale. Salt **8***c* provides an AA′BB′ pattern centered at 8.21 (8H), two doublet of doublets at 5.16 (4H) and 4.58 (4H), a multiplet at 2.33 (4H), and a quintet at 1.97 (4H). At 360 MHz, salt **9***f* gives well-separated resonances for the bridge protons (Fig. 1). Examination of models shows that some of the geminal α-protons lie more in the plane of the adjacent aromatic ring, accounting for the downfield shift in these salts.

In direct contrast to the bis-bridged salts **8***b* and **9***d*, magnetic nonequivalence for the α-methyl protons is indicated by broad, relatively unresolved peaks in the aliphatic region for the trimethylene bridged salts **7***e*, **8***e*, and **9***h*. Spotswood and Tanzer found evidence for conformational rigidity in di-, tri-, and tetramethylene bridged 3,3′-dimethyl-2,2′-bipyridines, which they attributed to the steric repulsions between the methyl groups (15). Salts **7***f*, **8***f*, and **9***i* all give four poorly resolved peaks for the bridge protons. In addition, there is a shift of about 0.1 ppm upfield per methylene addition for the methyl resonances in the mono-bridged salts. Models indicate that, as the bridges lengthen, the methyl groups point more toward the shielding region of the adjacent ring. Apparently, there is a significant amount of steric repulsion between the methyl groups even with the larger chelation angles present in these salts.

In the ^{13}C NMR, an interesting trend is observed for the C-2 resonance, which shifts steadily to higher field as the length of the N,N′ bridge is increased. The mono-annulated salts will be

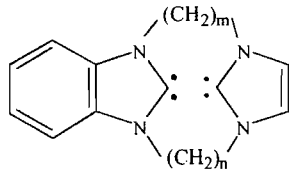
discussed first. The resonances change from 128.5 ppm (**7***d*) to 125.6 (**7***f*); 132.4, 128.3 (**9***g*) to 130.1, 125.7 (**9***i*); and 134.5 (**8***d*) to 130.3 (**8***f*). A similar trend is observed for the bisannulated salts where $n \geq 3$. For example, 129.0 ppm (**7***b*) to 125.8 (**7***c*); 133.6 (**8***b*) to 130.7 (**8***c*); and 133.8, 128.9 (**9***d*) to 130.6, 126.2 (**9***f*). Interestingly, the values for **8***a* (131.2 ppm) and **9***a* (131.8, 128.3) are between those for the corresponding $n = 3$ and $n = 4$ salts. This is possibly due to the strain on the molecule imposed by such short *N,N′* bridges. The general implication of the C-2 results is that positive charge density at this carbon is decreasing as the delocalization becomes inhibited by nonplanarity.

C. Redox properties



The ability of diquaternary salts of azabiaryl systems to undergo two one-electron reductions has been extensively studied (3–5, 7, 11, 16). Electron uptake depends on the electrophilicity of the material being reduced and the stability of the generated species (3, 17).

The salts in this study are capable of undergoing the same type of redox chemistry, as illustrated in **9** →**11** →**12**. For the intermediate radical cations (**11**) to be the most stable, delocalization over the entire aromatic framework should be possible.

The reduction potentials for all salts, determined in dimethylformamide and acetonitrile, are reported in Tables 2

9 **11** **12**

13

and 3. Representative voltammograms are presented in Figs. 2 and 3. The slight differences between the reduction values for **7***a–c* in this study and a previous one (see Table 2 and ref. 4) are due to differences in the conditions under which they were collected. The reduction properties for salt **7***c* become identical if our electrolyte system is changed to the previously reported system in CH_3CN.

The first obvious trend is the shift to more negative potentials as the bridges lengthen. Furthermore, with the exception of **7***d–f* and the most highly strained salts, the reductions (in CH_3CN) also become more irreversible. The least planar systems, e.g., **7***c*, **9***f*, and **9***i*, all show a single irreversible wave.

Secondly, as with the NMR data, a larger dihedral angle for the 1,1′-dimethyl salts is implied by comparing the reduction potentials of these salts to the corresponding bisannulated salts. The reduction potentials of salts **7***d*, **8***d*, and **9***g* are nearly identical to the bisannulated salts with one more methylene unit in the *N,N′* bridge, i.e., **7***b*, **8***b*, and **9***d*, respectively.

The irreversible nature of many of the reductions in this study implies that the species formed upon reduction undergoes some other process faster than it can be oxidized back to the original salt. The typical processes that might interfere with reoxidation include a conformational change, a subsequent chemical reaction, or adsorption of the reduced species onto the electrode surface. The formation of species such as **11** and **12** may involve a conformational change as a discrete step that occurs after electron transfer. Normally the energy barrier for this process is low enough that it does not interfere with the reversibility of the electron transfer. However, for systems such as **7***c*, **8***c*, and **9***e*, we know from the NMR studies that the barrier has become large enough that its importance cannot be ignored. Furthermore, an appreciable barrier is evident in the methyl-containing salts that accounts for the decreased reversibility of the reductions in the mono-bridged salts. The nature of the reductions of salts **8***a* and **9***a* may be explained by the strain put on the systems by the short bridges. Perhaps reduction is accompanied by a chemical change. Thummel has recently discussed possible *bis*-carbene formation (similar to **13**) for bisbenzimidazole, **8***b* and *c* (18), and bisimidazole, **7***c* and $R_{1\text{-}4} = CH_3$, (19). The bridges may impose steric and conformational effects restraining dimerization. Furthermore, it has been noted that radical cations formed from reduction of bridged 2-(2′-pyridyl)quinolinium salts (20) and bridged 2,2′-bithiazolium salts (11) could not always be completely oxidized (chemically or electrochemically) back to the parent.

Finally, it is noteworthy that the reduction potentials for salts **9***d*, and **9***f–i* are nearly intermediate between those of the corresponding structures, which predict potentials of −0.91 V

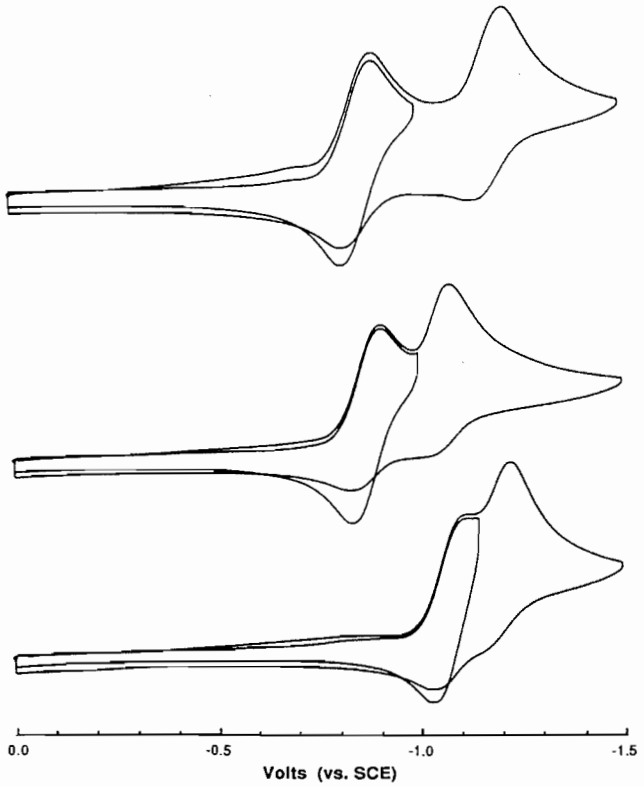
Fig. 2. Cyclic voltammograms of 0.5 mM solutions of salts **9***b* (top), **9***d* (middle), and **9***f* (bottom) in dimethylformamide at a scan rate of 100 mV/s.



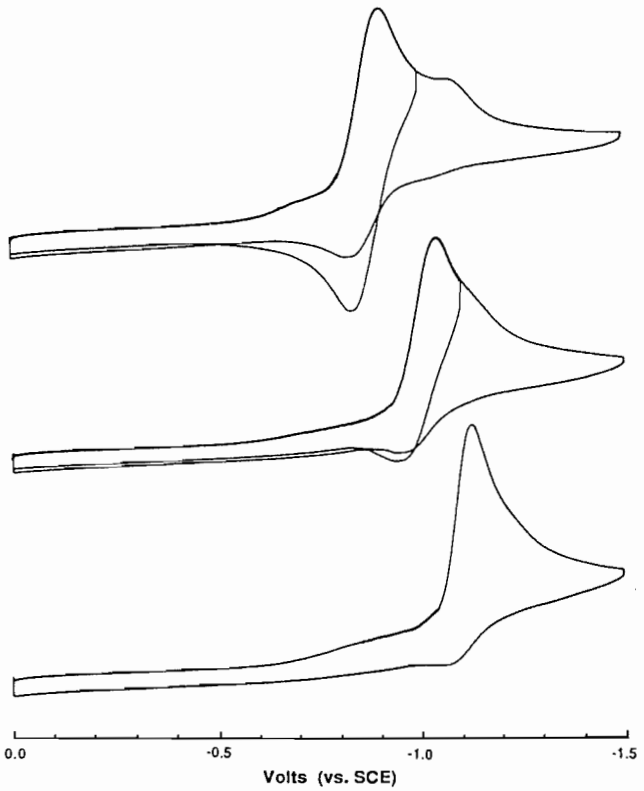


Fig. 3. Cyclic voltammograms of 0.5 mM solutions of salts **9***g* (top), **9***h* (middle) and **9***i* (bottom) in CH_3CN of a scan rate of 100 mV/s.

for **9***d*, −1.12 V for **9***f*, −0.90 V for **9***g*, −1.04 V for **9***h*, and −1.14 V for **9***i*. Therefore, the incorporation of the fused electron-attracting benzo substituent in these compounds has an additive effect of about 0.3 V, which is similar to the value found when comparing methylene-bridged 2,2′-bipyridinium and 2-(2′-pyridyl)quinolinium salts (20). Subtracting 0.3 V from the reduction value for **9***a* leads to a predicted reduction potential of about −1.1 V for the hypothetical salt **7** (bis-dimethylene bridged). Further support for this value comes from the examination of the differences in reduction potentials for salts **8** and **9**, when the bridge size decreases from three to two. There is, on average, about a 70 mV change in the positive direction as the methylene bridges contract. Decreasing the value for **7***b* by the same amount would lead to the predicted reduction potential.

Experimental

2,2′-Biimidazole, **1**, 2,2′-bibenzimidazole, **2** (5, 21), 2-(2′-imidazolyl)benzimidazole, **3** (22), 1,1′-dimethyl-2,2′-biimidazole, **4** (23), 1,1′-dimethyl-2,2′-bibenzimidazole, **6** (24), and **8***a*, **8***b* (5), **8***d* (24), and **7***a* (4) were prepared according to literature procedures. Salts **7***b*, **7***c*, and **8***c* were synthesized by modifications to the literature (4, 6) methods. Ultraviolet spectra were obtained, in EtOH, on a Milton Roy Spectronic 3000 spectrophotometer. All solvents were reagent grade, and all melting points are uncorrected. Details of the electrochemical experiments are given elsewhere (25, 26). Half-wave potentials were calculated as the average of the cathodic and anodic peak potentials (27). Microanalyses were performed by Desert Analytics, Tucson, Ariz. Nuclear magnetic resonance spectra were generally recorded on a JEOL FX-90Q spectrometer: ^1H (90 MHz) (CF_3CO_2D or DMSO-d_6); ^{13}C (20 MHz) (D_2O with dioxane as reference). The 360 MHz NMR spectra were collected by Spectral Data Services, Inc., Champaign, Ill.

1,1′-Dimethyl-2-(2′-imidazolyl)benzimidazole (6)

To a refluxing solution of 3 g (0.016 mol) of 2-(2′-imidazolyl)benzimidazole, 45 mL of absolute ethanol, and 20 mL of 20% NaOH, 7.7 g (0.081 mol) of dimethyl sulfate was added dropwise. The solution was refluxed for 14 h. After cooling, filtering, and neutralizing with HCl, it was evaporated to dryness. The resulting solid was then dissolved in 35 mL of water and extracted with 150 mL of chloroform. The chloroform extracts were washed with 8% NaOH to remove any monomethylated product. The $CHCl_3$ layer was dried over anhydrous sodium sulfate and evaporated to dryness. The resulting thick yellow liquid, which solidified on standing, was chromatographed (alumina) with $CHCl_3$. Evaporation of the solvent gave 1.6 g (47%) of a yellow solid. ^1H NMR (CF_3CO_2D) δ: 7.99 (s, 6H), 4.29 (s, 3H), 4.24 (s, 3H). ^{13}C NMR (22.5 MHz, $CHCl_3$-*d*) δ: 32.1, 35.7, 109.7, 119.7, 122.4, 123.2, 123.8, 128.5, 135.9, 138.1, 142.4.

1,1′-Dimethyl-3,3′-(dimethylene)-2,2′-biimidazolium dibromide (7*d*)

1,1′-Dimethylbiimidazole (0.15 g, 0.92 mmol) was refluxed in 8.8 g (0.047 mol) of 1,2-dibromoethane for 24 h to yield 0.30 g

For personal use only.

(94%) of crude product. The product was recrystallized from EtOH (95%); mp 288°C. ^{1}H NMR (CF_3CO_2D) δ: 7.83 (AA′BB′, 4H), 5.07 (s, 4H), 4.47 (s, 6H). ^{13}C NMR (D_2O, dioxane) δ: 39.2, 45.4, 124.8, 127.5, 128.5. Anal. calcd. for $C_{10}H_{14}N_4Br_2$: C 34.31, H 4.03, N 16.00; found: C 34.17, H 3.98, N 15.91.

1,1′-Dimethyl-3,3′-(trimethylene)-2,2′-biimidazolium dibromide (*7e*)

1,1′-Dimethyl-2,2′-biimidazole (0.21 g, 1.3 mmol) and 12.1 g (60 mmol) of 1,3-dibromopropane were refluxed in 5 mL of 2-methoxyethanol for 18 h. The solution was cooled and 10 mL of ether was added to afford 0.20 g (43%) of the product. Recrystallization from ethanol (95%) – ether gave a material with mp 241°C (dec.). ^{1}H NMR (CF_3CO_2D) δ: 7.99 (AA′BB′, 4H), 4.78 (bm, 4H), 4.36 (s, 6H), 2.95 (m, 2H). ^{13}C NMR (D_2O, dioxane) δ: 29.8, 37.5, 46.3, 126.8, 127.5. Anal. calcd. for $C_{22}H_{16}N_4Br_2 \cdot H_2O$: C 35.41, H 4.86, N 15.02; found: C 35.20, H 4.59, N 14.92.

1,1′-Dimethyl-3,3′-(tetramethylene)-2,2′-biimidazolium diiodide (*7f*)

1,1′-Dimethyl-2,2′-biimidazole (0.24 g, 1.45 mmol) and 4.13 g (1.33 mmol) of 1,4-diiodobutane were heated at 125°C in 1 mL of 2-methoxyethanol for 4 h. The solution was cooled and 10 mL of ether was added to afford 0.41 g (59%) of the product. Recrystallization from ethanol gave a material with mp 252°C (dec.). ^{1}H NMR (CF_3CO_2D) δ: 8.00 (s, 4H), 4.79 (m, 2H), 4.45 (m, 2H), 4.28 (s, 6H), 2.29 (bm, 4H). ^{13}C NMR (D_2O, dioxane) δ: 27.1, 36.9, 50.4, 125.6, 127.0, 128.4. Anal. calcd. for $C_{12}H_{18}N_4I_2$: C 30.53, H 3.84, N 11.87; found: C 30.71, H 3.80, N 11.96.

1,1′-Dimethyl-3,3′-(dimethylene)-2,2′-bibenzimidazolium Dibromide (*8d*)

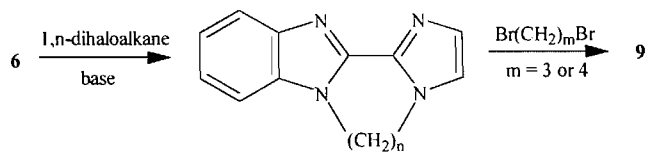
The method of Rochling was used to prepare this material, mp 280°C (lit. (14) mp 275–277°C). ^{1}H NMR (CF_3CO_2D) δ: 8.02 (s, 8H), 5.44 (s, 4H), 4.74 (s, 6H). ^{13}C NMR (D_2O, dioxane) δ: 36.4, 42.6, 113.6, 114.1, 130.0, 130.1, 131.3, 133.9, 134.5.

1,1′-Dimethyl-3,3′-(trimethylene)-2,2′-bibenzimidazolium Dibromide (*8e*)

1,1′-Dimethyl-2,2′-bibenzimidazole (0.68 g, 2.6 mmol) and 6.25 g (30.9 mmol) of 1,3-dibromopropane was refluxed in 1.5 mL of 2-methoxyethanol for 20 h. After cooling, 10 mL of ethyl ether was added and the solution was filtered and washed with ice-cold ethanol. Recrystallization from ethanol (95%) yielded 0.41 g (34%) of an off-white material; mp 266–270°C (dec.). ^{1}H NMR (CF_3CO_2D) δ: 8.04 (s, 8H), 5.16 (m, 2H), 4.88 (m, 2H), 4.61 (s, 6H), 3.14 (m, 2H); (DMSO-d_6) δ: 8.46 (m, 4H), 8.03 (m, 4H), 5.43 (m, 2H), 4.69 (m, 2H), 3.34 (s, H_2O), 2.84 (m, 2H). ^{13}C NMR (D_2O, dioxane) δ: 29.5, 35.0, 43.1, 113.4, 114.1, 129.8, 129.9, 132.0, 132.4, 133.6. Anal. calcd. for $C_{19}H_{20}N_4Br_2 \cdot \frac{1}{2}H_2O$: C 48.22, H 4.47, N 11.84; found: C 47.96; H 4.51, N 11.78.

1,1′-Dimethyl-3,3′-(tetramethylene)-2,2′-bibenzimidazolium dibromide (*8f*)

A procedure similar to that for **8***e* was used. Recrystallization from ethanol (95%) yielded 0.26 g (40%) of an off-white material; mp 217–221°C (dec.). ^{1}H NMR (CF_3CO_2D) δ: 8.08 (s, 8H), 5.51–5.00 (bm, 2H), 4.94–4.60 (bm, 2H), 4.53 (s, 6H), 2.48 (bm, 4H); (DMSO-d_6) δ: 8.43 (m, 4H), 8.03 (m, 4H), 5.22 (m, 2H), 4.55 (m, 2H), 3.48 (s, H_2O), 2.25 (m, 2H), 2.01 (m, 2H). ^{13}C NMR (D_2O, dioxane) δ: 25.7, 34.2, 47.1, 113.7, 114.2, 129.9, 130.3, 132.5, 133.8. Anal. calcd. for $C_{20}H_{22}N_4Br_2 \cdot \frac{1}{2}H_2O$: C 49.29, H 4.76, N 11.49; found: C 49.32; H 4.91, N 11.32.



1,1′:3,3′-Bis(dimethylene)-2-(2′-imidazolyl)-benzimidazolium dibromide (*9a*)

Method A

2-(2′-Imidazolyl)benzimidazole (0.5 g, 2.7 mmol), 1.0 g (7.8 mmol) of *N,N′*-diisopropylethylamine, and 21.98 g (0.117 mol) of 1,2-dibromoethane were heated at reflux in 12 mL of 2-methoxyethanol for 48 h. After cooling, the cream solid 0.11 g (10%) was filtered and recrystallized from EtOH (95%) – MeOH (1:1); mp 330°C (dec.). ^{1}H NMR (CF_3CO_2D) δ: 7.92 (s, 6H), 5.39 (s, 4H); (200 MHz, DMSO-d_6) δ: 8.29 (s, 2H), 7.83–8.26 (AA′BB′ centered at 8.04, 4H), 5.06–5.19 (m, 8H), 3.33 (s, H_2O). ^{13}C NMR (D_2O, dioxane) δ: 44.4, 46.6, 114.3, 126.0, 128.3, 129.1, 131.8, 132.3. Anal. calcd. for $C_{14}H_{14}N_4Br_2$: C 42.24, H 3.54, N 14.07; found: C 41.91; H 3.57, N 13.75.

Method B

10*a* (0.05 g, 0.24 mmol) was refluxed with stirring in 3 mL (34 mmol) of 1,2-dibromoethane for 4 h. After cooling, filtration, and recrystallization from EtOH (95%) – MeOH, the material (52%) had identical properties as that prepared by Method A.

10
a = 2
b = 3

1,1′-(Dimethylene)-3,3′-(trimethylene)-2-(2′-imidazolyl)-benzimidazolium dibromide (*9b*)

Method A

A mixture of 0.05 g (0.24 mmol) of **10***a* and 2 mL (20 mmol) of 1,3-dibromopropane was heated at 167°C for 4 h. After cooling, filtering, and recrystallization from EtOH (95%) – MeOH (1:1), the product yield was 0.05 g (51.0%). The melting point of the purified product was 361°C (dec.). ^{1}H NMR (360 MHz, DMSO-d_6) δ: 8.32 (m, 2H), 8.29–7.82 (AA′BB′ centered at 8.05, 4H), 5.08 (m, 2H), 4.96 (m, 4H), 4.82 (m, 2H), 3.33 (s, H_2O), 2.61 (quintet, 2H). ^{13}C NMR (D_2O, dioxane) δ: 36.2, 39.6, 42.5, 45.7, 113.4, 113.9, 126.0, 128.3, 128.8, 129.4, 129.6, 130.9, 132.4, 133.3. Anal. calcd. for $C_{15}H_{16}N_4Br_2 \cdot H_2O$: C 41.88, H 4.21, N 13.03; found: C 42.13, H 3.94, N 12.75.

Method B

Similarly 0.035 g (0.16 mmol) of **10***b* and 3 mL (34 mmol) of 1,2-dibromoethane were stirred at reflux for 4 h. The product, 0.057 g (88%), had a melting point of 360°C after recrystallization from EtOH (95%) – MeOH (1:1).

For personal use only.

1,1′-(Dimethylene)-3,3′-(tetramethylene)-2-(2′-imidazolyl)benzimidazolium dibromide (9*c*)

Via the procedure described above for **9***b*, 0.05 g (0.24 mmol) of **10***a* and 3 mL (25 mmol) of 1,4-dibromobutane were used to obtain 0.06 g (59.4%) of product. After recrystallization from ethanol (95%), the melting point was 285–287°C. ^{1}H NMR (200 MHz, DMSO-d_6) δ: 8.35 (s, 2H), 8.29–7.86 (AA′BB′, centered at 8.08, 4H), 4.82–5.08 (m, 8H), 3.32 (s, H_2O), 2.29 (m, 4H). ^{13}C NMR (D_2O, dioxane) δ: 29.6, 34.7, 37.9, 42.7, 46.7, 113.2, 113.9, 127.6, 128.3, 129.3, 129.5, 132.0, 132.2, 133.2. Anal. calcd. for $C_{16}H_{18}N_4Br_2 \cdot H_2O$: C 43.26, H 4.53, N 12.61; found: C 42.90, H 4.58, N 12.31.

1,1′:3,3′-Bis(trimethylene)-2-(2′-imidazolyl)-benzimidazolium dibromide (9*d*)

Method A

Via the procedure described for **9***a*, 0.5 g (2.7 mmol) of 2-(2′-imidazolyl)benzimidazole, 1.0 g of *N,N*′-diisopropylethylamine, and 23.7 g (0.18 mol) of 1,3-dibromopropane gave a cream product in 90% yield. The material was recrystallized from EtOH (95%) – MeOH; mp 334–335°C. ^{1}H NMR (360 MHz, DMSO-d_6) δ: 8.33 (s, 2H), 8.31–7.87 (AA′BB′ centered at 8.10, 4H), 4.88 (t, 4H), 4.77 (t, 4H), 3.32 (s, H_2O), 2.77 (quintet, 4H). ^{13}C NMR (D_2O, dioxane) δ: 26.0, 47.1, 50.1, 113.5, 127.6, 128.9, 129.4, 132.5, 133.8. Anal. calcd. for $C_{16}H_{18}N_4Br_2 \cdot H_2O$: C 43.26, H 4.53, N 12.61; found: C 43.06, H 4.26, N 12.43.

Method B

A mixture 0.05 g (0.22 mmol) of **10***b* and 2 mL (20 mmol) of 1,3-dibromopropane was heated at 167°C for 4 h. After cooling and filtering, 0.08 g (84.2%) of product was obtained and recrystallized from EtOH (95%) to give an identical melting point with that prepared by Method A.

1,1′-(Trimethylene)-3,3′-(tetramethylene)-2-(2′-imidazolyl)benzimidazolium dibromide (9*e*)

Via the procedure described for **9***d*, 0.05 g (0.22 mmol) of **10***b* and 3 mL (25 mmol) of 1,4-dibromobutane were used to obtain 0.05 g (51.0%) of product. After recrystallization from 2-propanol, the melting point was 265°C. ^{1}H NMR (60 MHz, DMSO-d_6) δ: 8.6–8.3 (m, 4H), 8.2–7.7 (m, 2H), 4.85 (m, 8H), 3.63 (s, H_2O), 2.95 (m, 2H), 2.25 (m, 4H). ^{13}C NMR (D_2O, dioxane) δ: 25.7, 27.0, 34.1, 37.3, 47.0, 50.7, 113.6, 114.1, 125.8, 127.7, 128.9, 129.7, 130.1, 132.2, 133.6. Anal. calcd. for $C_{17}H_{20}N_4Br_2 \cdot 2H_2O$: C 42.87, H 5.07, N 11.76; found: C 42.94, H 4.92, N 11.64.

1,1′:3,3′-Bis(tetramethylene)-2-(2′-imidazolyl)-benzimidazolium dibromide (9*f*)

Compound **3** (0.5 g, 2.7 mmol), 1.0 g of *N,N*′-diisopropylethylamine, and 25.3 g (0.12 mol) of 1,4-dibromobutane were heated under reflux in 15 mL of 2-methoxyethanol for 48 h. Filtration yielded 85% of an off-white product that was recrystallized from EtOH (95%) – MeOH (mp 283°C (dec.)). ^{1}H NMR (360 MHz, DMSO-d_6) δ: 8.47 (s, 2H), 8.41–7.91 (AA′BB′ centered at 8.15, 4H), 5.12 (dd, 2H), 4.76 (dd, 2H), 4.38 (m, 4H), 3.33 (s, H_2O), 1.90 (m, 4H). ^{13}C NMR (D_2O, dioxane) δ: 29.6, 30.6, 42.9, 46.9, 47.6, 50.9, 113.2, 113.6, 127.5, 127.7, 129.3, 129.4, 132.2, 132.3, 132.6. Anal. calcd. for $C_{18}H_{22}N_4Br_2 \cdot H_2O$: C 44.09, H 5.35, N 11.42; found: C 43.74, H 5.39, N 11.31.

1,1′-Dimethyl-3,3′-(dimethylene)-2-(2′-imidazolyl)-benzimidazolium dibromide (9*g*)

A similar procedure to that for **8***e* was used. Recrystallization from ethanol (95%) yielded 0.37 g (56%) of a light yellow material; mp 322–325°C (dec.). ^{1}H NMR (CF_3CO_2D) δ: 7.96 (m, 6H), 5.25 (s, 4H), 4.63 (s, 3H), 4.58 (s, 3H). ^{13}C NMR (D_2O, dioxane) δ: 36.1, 39.6, 42.4, 45.6, 113.3, 113.8, 125.9, 128.3, 128.8, 129.4, 129.5, 130.9, 132.4, 133.3. Anal. calcd. for $C_{14}H_{16}N_4Br_2$: C 42.02, H 4.03, N 14.00; found: C 42.12, H 4.03, N 14.04.

1,1′-Dimethyl-3,3′-(trimethylene)-2-(2′-imidazolyl)-benzimidazolium dibromide (9*h*)

A similar procedure to that for **8***e* was used. Recrystallization from ethanol (95%) yielded 0.48 g (48%) of an off-white material; mp 220°C (dec.). ^{1}H NMR (CF_3CO_2D) δ: 8.00 (m, 6H), 5.18–4.71 (bm, 4H), 4.53 (s, 3H), 4.46 (s, 3H), 3.07 (m, 2H). ^{13}C NMR (D_2O, dioxane) δ: 29.6, 34.7, 37.9, 42.7, 46.7, 113.2, 113.9, 127.6, 128.3, 129.3, 129.5, 132.0, 132.2, 133.2. Anal. calcd. for $C_{15}H_{18}N_4Br_2 \cdot H_2O$: C 41.69, H 4.66, N 12.96; found: C 41.37, H 4.31, N 12.83.

1,1′-Dimethyl-3,3′-(tetramethylene)-2-(2′-imidazolyl)-benzimidazolium diiodide (9*i*)

A procedure similar to that for **7***f* yielded 0.42 g (55%) of product from 0.31 g (1.45 mmol) of 1,1′-dimethyl-2,2′-biimidazole and 4.53 (1.46 mmol) of 1,4-diiodobutane. Recrystallization from ethanol (95%) gave a material with mp 257°C (dec.). ^{1}H NMR (CF_3CO_2D) δ: 8.00 (m, 6H), 5.05 (m, 2H), 4.65 (m, 2H), 4.46 (s, 3H), 4.36 (s, 3H), 2.35 (bm, 4H). ^{13}C NMR (D_2O, dioxane) δ: 25.7, 26.9, 34.1, 37.3, 46.9, 50.6, 113.5, 114.1, 125.7, 127.6, 128.9, 129.6, 130.1, 132.2, 133.6. Anal. calcd. for $C_{16}H_{20}N_4I_2 \cdot H_2O$: C 36.80, H 3.86, N 10.73; found: C 37.08, H 3.90, N 10.74.

1,1′-Dimethylene-2-(2′-imidazolyl)benzimidazole (10*a*)

To a well stirred solution of 1.0 g (5.4 mmol) of **3** and 13 mL of DMF, 1.0 mL of 35% NaOH was added. After stirring for 2 h, 1.5 g (10.5 mmol) of 1-bromo-2-chloroethane was slowly added to the reaction mixture, which was then stirred overnight. The reaction mixture was vacuum filtered and the solid was washed with ethanol. The filtrate was evaporated to dryness under vacuum and the residue was washed with hot acetonitrile. The acetonitrile was evaporated and the residue recrystallized from EtOH to yield 0.11 g (9.7%) of creamy yellow crystals, mp 255–257°C. ^{1}H NMR (200 MHz, DMSO-d_6) δ: 7.1–7.7 (m, 6H), 4.59 (s, 4H). Anal. calcd. for $C_{12}H_{10}N_4$: C 68.55, H 4.79, N 26.65; found: C 68.42, H 4.74, N 26.81.

1,1′-Trimethylene-2-(2′-imidazolyl)benzimidazole (10*b*)

Compound **3** (1.0 g, 5.4 mmol) and 0.59 g (11 mmol) of $NaOCH_3$ were refluxed in 50 mL of absolute EtOH, with a drying tube, for 1 h with stirring followed by the dropwise addition of 1-bromo-3-chloropropane (10.5 mmol). After an additional 20 h of refluxing, the mixture was cooled, filtered, and the filtercake was extracted with EtOH. The ethanol filtrate was evaporated to dryness and extracted with boiling

© 1997 NRC Canada

CH_3CN. The acetonitrile was evaporated to dryness to yield a residue of 0.20 g (17%), which was recrystallized from EtOH–H_2O; mp 187–200°C. ^1H NMR (200 MHz, DMSO-d_6) δ: 7.1–7.7 (m, 6H), 4.35–4.46 (m, 6H), 2.47 (quintet, 2H). Anal. calcd. for $C_{13}H_{12}N_4$: C 69.62, H 5.39, N 24.98; found: C 69.22, H 5.25, N 25.20.

Acknowledgments

This project was supported in part by grants from the Faculty Research Grant/Fellowship Program and the Faculty Development Fund of the University of Michigan–Flint. We thank Robert M. Smith, Bobbi Beckers, Vicki H. Larsen, Christopher Houston, and Timothy Lauer for experimental assistance.

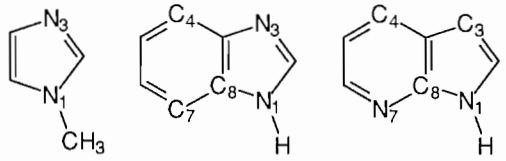
Abstract: *trans*-$[ReO_2(BzimH)_4]I$ is generated by reacting $ReO_2I(PPh_3)_2$ with excess BzimH in methanol, but free ligand is difficult to eliminate from the product. Pure samples of the *trans*-$[ReO_2(BzimH)_4]BPh_4$ salt and of the protonated oxo-hydroxo form $[ReO(OH)(BzimH)_4](BF_4)_2$ are isolated. Recrystallization of the dioxo complex in acetone–ether yields a pink solid. Red crystals suitable for X-ray diffraction are obtained by recrystallization of this solid in ethanol. The crystallographic study reveals a hemiprotonated $[ReO_2(BzimH)_4][ReO(OH)(BzimH)_4](ReO_4)_3$ phase (*Acam*, $a = 10.794$, $b = 21.520$, $c = 27.196$ Å, $R = 0.049$). The O═Re═O fragments are parallel to one another along the unit cell *c* axis, forming layers of dimeric units consisting of one dioxo and one oxo-hydroxo species connected by a very short O—H···O hydrogen bond of 2.44 Å. The ReO_4^- anions form hydrogen bonds with ligand N-H groups. The complexes are characterized by solution (^1H and ^{13}C) and solid-state (^{13}C CP-MAS) NMR, UV–VIS, and IR spectroscopies. ^1H NMR reveals that the benzimidazole protons in close proximity to the rhenium–oxo multiple bond or adjacent benzimidazole ligands are very sensitive to nonbonded magnetic effects.



Key words: rhenium, oxo complexes, benzimidazole, X-ray diffraction.

Résumé : Le complexe *trans*-$[ReO_2(BzimH)_4]I$ est obtenu par réaction de $ReO_2I(PPh_3)_2$ avec un excès de BzimH dans le méthanol, mais le ligand libre est difficile à éliminer du produit. Des échantillons purs du sel *trans*-$[ReO_2(BzimH)_4]BPh_4$ et de la forme protonée oxo-hydroxo $[ReO(OH)(BzimH)_4](BF_4)_2$ ont été isolés. La recrystallization du complexe dioxo dans un mélange acetone–éther conduit à un solide rose. Des cristaux rouges sont isolés par recristallisation de cet échantillon dans l'éthanol et leur étude par diffraction des rayons X révèle une phase mixte stoechiométrique $[ReO_2(BzimH)_4][ReO(OH)(BzimH)_4](ReO_4)_3$ (*Acam*, $a = 10{,}794$, $b = 21{,}520$, $c = 27{,}196$ Å, $R = 0{,}049$). Les fragments O═Re═O sont orientés parallèlement les uns aux autres selon l'axe *c* de la maille, où ils forment des couches de motifs dimères comprenant un cation dioxo et un cation oxo-hydroxo reliés par une liaison hydrogène O—H···O très courte de 2,44 Å. Les anions ReO_4^- forment des liaisons hydrogène avec les groupes N-H des ligands. Les composés préparés sont caractérisés par spectroscopies RMN en solution (^1H et ^{13}C) et à l'état solide (^{13}C CP-MAS), UV–visible et infrarouge. La RMN ^1H indique que les protons du benzimidazole se trouvant à proximité du lien multiple rhenium–oxo ou des ligands benzimidazole voisins sont très sensibles aux effets magnétiques à travers l'espace.

Mots clés : rhénium, complexes oxo, benzimidazole, diffraction des rayons X.

Introduction

Rhenium(V) oxo complexes with imidazoles and related nitrogen heterocyclic ligands are currently being investigated in this laboratory. These compounds are of interest not only for their particular optical properties (1), but also because various compounds containing Re═O and Re≡N groups are being considered for potential applications of radioactive Re isotopes in radiopharmacy (2). In general, $[ReO_2L_4]^+$ is readily generated by reacting excess ligand with $ReO_2I(PPh_3)_2$ or $ReOCl_3(PPh_3)_2$, but stability problems are often encountered with the compounds once isolated. Complexes of pyridines and imidazoles as chloride salts tend to decompose slowly (3, 4). Although stable complexes of imidazoles were obtained as iodides and tetraphenylborates (5), we recently found that controlled decomposition of the 1-methylimidazole (**1**, 1-MeIm) complex *trans*-$[ReO_2(1\text{-MeIm})_4]^+$ in low pH aqueous solution generates an unusual oxo-bridged trinuclear complex (6). In less acidic media, when air is not excluded, oxidation occurs at some point, generating ReO_4^- ions. The latter process undoubtedly produces H^+, since some protonated $[ReO(OH)L_4]^{2+}$ complex is formed, as observed in the non-stoichiometric 1,2-dimethylimidazole $[ReO_2(1,2\text{-}Me_2Im)_4]^+$/$[ReO(OH)(1,2\text{-}Me_2Im)_4]^{2+}$ phase (3).

1 **2** **3**

With the goal of identifying factors affecting these processes, our work on imidazoles was extended to rigid and ster-

ically more demanding ligands. In a previous study (7), the reactivity 7-azaindole (**3**, Haza) was investigated. Coordination was found to take place via the pyridine ring (N7) and the crystal structure of $[ReO_2(Haza)_4]Cl$ showed an all-upright conformation stabilized by N1—H···oxo intramolecular hydrogen bonding (**4**).

4

The present work deals with benzimidazole (**2**, BzimH), a ligand with a similar steric demand, which was expected to lead to conformational differences, since the hydrogen-bonding five-membred ring of azaindole is replaced by a hydrophobic benzene ring in benzimidazole. As anticipated, a compound similar to $[ReO_2(Haza)_4]^+$ could be obtained, but it showed an unusually high preference to form a *stoichiometric* $[ReO_2L_4]^+/[ReO(OH)L_4]^{2+}$ phase. The preparation and protonation of *trans*-$[ReO_2(BzimH)_4]^+$ are described in the present paper.

Experimental

Reactants and methods

Reactants and solvents (reagent grade) from Aldrich, except for HI (Anachemia), HBF_4, and $NaBF_4$ (Johnson-Matthey), were used as received. $ReO_2I(PPh_3)_2$ was prepared from $KReO_4$ according to literature (8, 9). IR spectra were recorded as CsI pellets on a 1750 Perkin–Elmer Fourier-transform spectrophotometer. Routine solution ^1H and ^{13}C NMR spectra were run on either a Varian VXR-300 or a Bruker AMX-300 spectrometer. Solid-state ^{13}C CP-MAS spectra were obtained at 75.43 MHz on the Varian instrument. The (^1H–^1H) COSY spectra were recorded on a Bruker ARX-400 spectrometer. Chemical shifts are expressed in ppm relative to TMS. The residual CD_3OD signal was used as internal reference for solution spectra (^1H, δ 3.30; ^{13}C, δ 49.0 ppm). The aromatic signal of hexamethylbenzene (δ = 132.1 ppm) was used as an external reference for the solid-state ^{13}C NMR experiments. Electronic spectra were recorded on a UV–VIS/NIR Varian/Cary-5E spectrophotometer.

Preparative work

$[ReO_2(BzimH)_4]I$

Samples free of uncoordinated BzimH could not be obtained, since attempts to remove excess BzimH inevitably yielded a partially protonated material. A typical run is described here.

Under argon, methanol is added to $ReO_2I(PPh_3)_2$ (2.15 g; 2.27 mmol) and benzimidazole (1.65 g; 15.3 mmol), and the mixture is stirred at room temperature. All the solid dissolves and a brown solution is obtained within minutes. The mixture is allowed to react for 60–70 min, after which time toluene (80 mL) is added and the solution is evaporated under reduced pressure until all the complex has come out of solution as a sticky brick-red material. Toluene is decanted and acetone (20 mL) is added. A brownish-red suspension is obtained in which about half of the original material has dissolved. The mixture is filtered and a first crop (0.58 g) of solid is isolated and washed with ether. Its composition roughly corresponds to $[ReO_2(BzimH)_4]I{\cdot}2BzimH$ as determined from ^1H NMR. Whether it is a mixture of $[ReO_2(BzimH)_4]I$ and BzimH, or a stoichiometric phase containing uncoordinated lattice BzimH molecules was not checked. To the filtrate, excess ether is added until no more precipitate forms. The peach solid is filtered and washed with ether (yield: 1.43 g). On the basis of elemental analysis, the sample contains ~30% of protonated complex whose charge is balanced by ReO_4^- counterions. IR (cm^{-1}): 792 (s), ν_{as}(O═Re═O); ~920 (w), $\nu_{as}(ReO_4^-)$/ν(Re═O) of O═Re-OH. ^{13}C CP-MAS (ppm): ~142 (sh, C2), 140.6 (C9), 133.1 (C8), 123.8 (C5/C6), 117.6 (C4), 113.5 (C7). Anal. calcd. for $C_{28}H_{27.3}N_8O_2I(ReO_4)_{0.3}{\cdot}0.5\ (CH_3)_2CO$: C 38.43, H 2.98, N 12.15; found: C 38.26, H 2.88, N 12.13.

UV–VIS and solution NMR data were obtained after adding 0.5 equivalent of CH_3ONa to the half-protonated compound described below, to make sure that any $[ReO(OH)(BzimH)_4]^{2+}$ species is converted back to $[ReO_2(BzimH)_4]^+$. UV–VIS (CH_3OH): 472 nm (ε = 681 M^{-1} cm^{-1}), ~570 nm (sh) (ε = ~139 M^{-1} cm^{-1}). ^1H NMR (CD_3OD) (ppm): 8.27 (s, H2), 7.63 (d, H4), 7.57 (d, H7), 7.29 (t, H6), 7.02 (t, H5), ($^3J_{45}$ = $^3J_{67}$ = 8.3 Hz, $^3J_{56}$ = ~8 Hz). ^{13}C NMR (CD_3OD) (ppm): 146.2 (C2), 141.9 (C9), 134.2 (C8), 125.7 (C6), 124.8 (C5), 119.0 (C4), 113.9 (C7).

$[ReO_2(BzimH)_4]/[ReO(OH)(BzimH)_4](I)_3{\cdot}2H_2O$

The dioxo species is generated as above with 60 min reaction time, up to obtention of the oily residue, which is precipitated in this case by addition of ether. To recrystallize the sample from acetone, large quantities of solvent are required and subsequent addition of excess ether affords a fine pink solid. The suspension is allowed to crystallize overnight and the resulting pink sample is filtered and washed with ether. Elemental analysis reveals a hemiprotonated complex containing two crystallization water molecules. Yield based on $ReO_2I(PPh_3)_2$: 0.55 g, 59%. IR (cm^{-1}): 795 (m), ν_{as} (O═Re═O); 920 (m, br), ν(Re═O). UV–VIS (CH_3OH): 472 nm (ε = 592 M^{-1} cm^{-1}). ^1H NMR (CD_3OD) (ppm): 8.27 (s, H2), 7.58 (d, br, superimposed H4/H7), 7.30 (t, H6), 7.03 (t, H5), ($^3J_{45}$ = $^3J_{67}$ = 8.7 Hz, $^3J_{56}$ = ~8 Hz). ^{13}C NMR (CD_3OD) not significantly different from above, because the ^{13}C spectra of all forms reported here are quite similar and because the protonated form may be partly dissociated. ^{13}C CP-MAS (ppm): ~142 (C2), 140.8 (C9), 132.7 (C8), 123.5 (C5/C6), 117.9 (C4), 114.1 (C7). Anal. calcd. for $C_{56}H_{53}N_{16}O_6I_3Re_2$: C 37.38, H 2.97, N 12.46; found: C 37.32, H 2.91, N 12.16.

Slow recrystallization of the pink sample in ethanol gave red crystals of the stoichiometric mixed phase $[ReO_2(BzimH)_4][ReO(OH)(BzimH)_4](ReO_4)_3$, which were used for X-ray work (see below). IR (cm^{-1}): 792 (m), ν_{as} (O═Re═O); 918 (s)/925 (sh), $\nu_{as}(ReO_4^-)$/ν(Re═O) of O═Re-OH.

$[ReO_2(BzimH)_4]BPh_4$

The reaction is effected with a 1:6 $ReO_2I(PPh_3)_2$:benzimidazole ratio in methanol at room temperature for 1 h. To the orange-brown solution, $NaBPh_4$ (2 equiv.) in methanol is added dropwise. The resulting solution is stirred for a few minutes and evaporated to dryness. Dissolution in methanol and partial evaporation of the solvent affords an orange solution and a beige residue (PPh_3 and excess $NaBPh_4$), which is removed by filtration. The orange solution is evaporated and the dioxo complex is isolated as a sticky brown residue. Addition of ether gives a brick-brown solid, which is filtered and washed with ether. Yield: 0.35 g; 60%. IR (cm^{-1}): 792 (s), ν_{as} (O═Re═O). ^1H NMR (CD_3OD) (ppm): 8.25 (s, H2), 7.65 (d, H4), 7.54 (d, H7), ~7.3 (H6, interference with BPh_4^-), 7.02 (t, H5), ($^3J_{45} = {}^3J_{67} = 8.4$ Hz, $^3J_{56} = \sim 7.5$ Hz), ~7.3 (m, BPh_4^-), 6.94 (t, 7.4 Hz, BPh_4^-), 6.79 (t, 7.3 Hz, BPh_4^-). ^{13}C CP-MAS (ppm): ~142 (C2), 140.3 (C9/BPh_4^-), 133.1 (C8/BPh_4^-), ~128 (sh) (BPh_4^-), 124.1 (C5/C6), 118.2 (C4), 116.9 (C7).

$[ReO(OH)(BzimH)_4](BF_4)_2 \cdot 0.5\ (CH_3)_2CO$

One drop of concentrated HBF_4 is added to $[ReO_2(BzimH)_4]I$ (0.362 g, 0.443 mmol) dissolved in a minimum volume (2–3 mL) of methanol. To the purple solution, $NaBF_4$ (0.194 g, 1.76 mmol) in methanol is added with stirring. Addition of ether to the solution initiates the precipitation of a lavender powder, which is filtered. The sample contains excess $NaBF_4$ and is purified by stirring in aqueous HBF_4 (pH ~1) for a few minutes. The lavender compound is filtered and washed with ether after recrystallization in acetone–ether to remove water. Yield: 0.22 g, 56%. IR (cm^{-1}): 931, ν (Re═O). UV–VIS (CH_3OH): 535 nm ($\varepsilon = 526\ M^{-1}\ cm^{-1}$). ^1H NMR (CD_3OD) (ppm): 8.20 (s, H2), 7.65 (t, H7), 7.38 (d, H4), 7.37 (t, H6), 7.10 (t, H5), ($^3J_{45} = {}^3J_{67} = 8.3$ Hz, $^3J_{56} = \sim 7.5$ Hz). ^{13}C CP-MAS (ppm): ~140 (C9), ~133 (C8), 123.8 (C6), 122.6 (C5), 115.8 (C4), 113.5 (C7), C2 not observed. Anal. calcd. for $C_{29.5}H_{28}B_2F_8N_8O_{2.5}Re$: C 39.24, H 3.12, N 12.42; found: C 39.33, H 2.69, N 12.50.

Crystallographic measurement and structure resolution

Experimental data collection details are collected in Table 1. X-ray work was carried out on an Enraf–Nonius CAD-4 diffractometer (graphite-monochromatized CuKα radiation). The reduced cell was determined from a rotation picture and checked with axial photographs. An *A*-centred orthorhombic cell was indicated from the Niggli matrix and *mmm* Laue symmetry was verified on a limited set of data. The orthorhombic cell was refined with 25 reflections ($22.5° < \theta < 25°$). Systematic absences (*hkl k+l* odd; *0kl k,l* odd; *h0l h,l* odd) indicated *Aba*2 (no. 41) or *Acam* (no. 64) as possible space groups. Intensities were collected in the entire sphere and averaged to one octant (*hkl*) at this stage. These data were corrected for the effects of Lorentz, polarization, and absorption (Gaussian integration).

The crystal structure was solved in the *Acam* space group, which is an alternate definition of *Cmca* (16-fold general equipoint of *Acam*: x,y,z; $x+1/2,-y+1/2,-z$; $-x+1/2,y+1/2,-z$; $-x,-y,z$; $-x,-y,-z$; $-x+1/2,y+1/2,z$; $x+1/2,-y+1/2,z$; $x,y,-z$, and corresponding sites translated by 0,1/2,1/2). The stoichiometry is unambiguously determined from the crystal structure. The rhenium atoms were located from the Patterson map and all non-hydrogen atoms from difference Fourier maps. The $ReO_2(BzimH)_4$ unit is found to lie on a crystallographic twofold axis (Re1, O1, and O2 on equipoint *8d*) and contains two independent benzimidazole ligands in general positions. ReO_4^- ions are present on two different sites. One of them occupies a mirror plane: Re3, O301, and O302 on equipoint *8f*, O303 in general position. For the second ReO_4^- anion, the Re2 atom is also found on equipoint *8f*, equally disordered over two sites near, but not exactly on, equipoint *4b* (*2/m* symmetry). In addition, this anion shows orientational disorder about the twofold axis, so that each oxygen atom (general position) has an occupancy of 0.25. Therefore, the unit cell contains 1.5 ReO_4^- ion per $ReO_2(BzimH)_4$ unit, indicating that only half of these units are $[ReO_2(BzimH)_4]^+$, the other half having been protonated to $[ReO(OH)(BzimH)_4]^{2+}$. A packing pattern reveals that two such units are facing each other across the origin with an O···O separation of 2.44 Å indicative of O═Re-O-H···O═Re═O hydrogen bonding. All $ReO_2(BzimH)_4$ units being symmetry equivalent, "O═Re-O-H···O═Re═O" and "O═Re═O···H-O-Re═O" pairings are equally probable, so that each pair of hydrogen-bonded ions is involved in twofold disorder. However, this does not introduce appreciable disorder in most of the atomic positions.

[a] $U_{eq} = (1/3)\Sigma_i\Sigma_j U_{ij} a^*_i a^*_j \boldsymbol{a}_i \cdot \boldsymbol{a}_j$.
[b] Occupancy factor: Re2, 0.5; O201–O204, 0.25.
[c] Refined isotropically with constrained $U_{iso} = [U_{eq}(O201)+U_{eq}(O202)+U_{eq}(O204)]/3$.

Both perrhenate ions were described with an idealized tetrahedral geometry. The Re—O distances were constrained to be equal, but allowed to refine with a common bond length. To maintain tetrahedral geometry, a similar constraint was applied to the O—O distances. Hydrogen atoms of benzimidazole were calculated at idealized positions (N—H = 0.87 Å, C—H = 0.94 Å) using a riding model. The isotropic displacement factors were adjusted to a value 20% higher than that of the bonded atom. All non-hydrogen atoms were refined anisotropically, except for the oxo ligands, for which only isotropic refinement was suitable, since their positions in O═Re═O and H-O-Re═O groups apparently differ appreciably. The disordered perrhenate oxygens were refined isotropically. O203 was assigned a fixed isotropic thermal parameter, because of its proximity to the symmetry-generated Re2 atom. The position of the "half-proton" involved in the Re-O-H···O hydrogen bond was not determined with certainty: the ΔF map showed a residual at the origin and this proton was arbitrarily fixed at this position (U_{iso} fixed at 0.05 $Å^2$). The final ΔF map contains a residual of 3.8 e $Å^{-3}$ near the disordered Re2 atom, a few more of |1.4–0.9| e $Å^{-3}$ near Re or disordered O atoms, whereas the general background is below ±0.8 e $Å^{-3}$. Refined coordinates are listed in Table 2.[2] All calculations were done using NRCVAX (10), SHELXS-86 (11), and SHELXL-93 (12).

The structure was also interpreted in terms of the corresponding non-centric *Aba2* space group (no. 41) after averag-

[2] The supplementary material includes distances and angles in the ligand and perrhenate anions, hydrogen atom coordinates, anisotropic displacement factors, and distances to the weighted least-squares planes. The complete set of data (6 pages) can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada ON K1A 0S2. The lists of coordinates and of distances and angles have also been deposited with the Cambridge Crystallographic Data Centre. The can be obtained from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K. A table of observed and calculated structure factors (13 pages) can be obtained from the corresponding author.

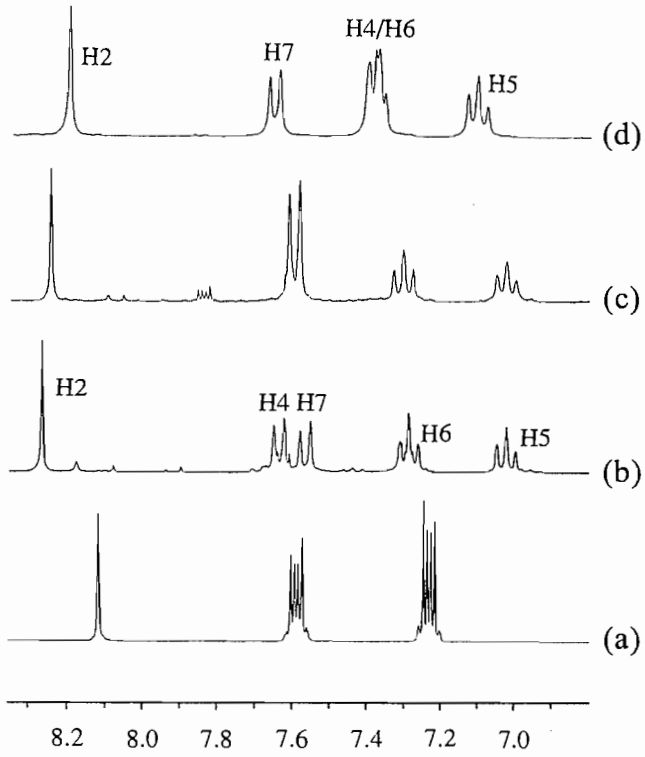
ing the data set to octants *hkl* and *hkl̄*: refinement was very unstable, disorder on the ReO_4^- ions was not removed, and the *R* factor was not improved. Other space groups in which one set of glide planes is removed were also considered. Replacing either glide plane by a mirror would generate superimposed non-coincident images of the benzimidazole ligands: since no disorder or abnormal thermal motion was noted in this part of the structure for the *Acam* model, these possibilities were discarded. The two remaining groups, namely $A2_1am$ (no. 36) and *Ac2m* (no. 39), in which the glide planes are replaced by two-fold axes, were tested. Again, refinement was extremely unstable and the ReO_4^- ions remained disordered. Thus, the *Acam* solution was retained.

Results



trans-$[ReO_2(BzimH)_4]I$ is formed by reacting BzimH with $ReO_2I(PPh_3)_2$ as described for imidazoles (5), but pure samples of this iodide salt cannot be isolated: reacting a stoichiometric amount or slight excess of ligand gives incomplete conversion, whereas large excess leaves large amounts of unreacted BzimH difficult to separate. The typical case described in the experimental section yields a sample containing two BzimH molecules per complex. When attempting to purify the sample by recrystallization in acetone–ether, the solution quickly turns pink and yields a protonated material, whose elemental analysis reveals an exactly hemiprotonated form of the complex. Recrystallization of this pink compound in ethanol gives red crystals, whose structure determined by X-ray diffraction shows a stoichiometric mixed phase $[ReO_2(BzimH)_4]^+/[ReO(OH)(BzimH)_4]^{2+}$ with perrhenate counterions. $[ReO_2(BzimH)_4]^+$ can be isolated as the BPh_4^- salt and the fully protonated complex as $[ReO(OH)(BzimH)_4](BF_4)_2$.

Infrared spectroscopy

The dominant spectral feature is the rhenium–oxygen stretching band. The asymmetric O═Re═O stretch in $[ReO_2(BzimH)_4]I$ is observed at 795 cm^{-1}, which compares well with related imidazole and other nitrogen–ligand systems (765–825 cm^{-1}) (5). In the hemiprotonated sample obtained after recrystallization from acetone, partial protonation of the oxo ligand is apparent, since the ν_{as}(O═Re═O) band loses intensity, while a new band arising from the protonated oxo group is found near 920 cm^{-1}. In the completely protonated compound, the ν(Re═O) frequency is located at 931 cm^{-1}. This mode has been observed in the 955–973 cm^{-1} range for related oxo-hydroxo and oxo-methoxo systems (5, 13–15).

The IR spectrum of benzimidazole undergoes several modifications upon coordination. The tentative assignments used here are based on the literature spectrum of the free ligand (16). Besides the disappearance of combination bands at 1700–2000 cm^{-1}, coordination introduces noticeable effects in various spectral regions. Near 1600 cm^{-1}, the benzimidazole C═C stretching band at 1588 cm^{-1} moves to 1602 cm^{-1} and loses intensity. The most obvious changes occur in the 1400–1500 cm^{-1} region, where benzimidazole shows ν(C═C) bands at 1410, 1459, and 1478 cm^{-1}. In the coordinated ligand, the lowest frequency mode is split in two components at 1425/1440 cm^{-1}, the vibration at 1459 cm^{-1} loses much intensity, whereas the most intense vibration in this region is found at 1510 cm^{-1}. Complexation also results in reduced intensity for other vibration modes, such as ν(C-N) at 1350 and 1370 cm^{-1}, δ(C-H) at 1135 and 1205 cm^{-1}, ν(C═C) at 1276 cm^{-1}, and γ(C-H) at 885 cm^{-1}.

NMR spectroscopy

The ^1H NMR spectrum of free benzimidazole in D_2O has been previously reported (17), but assignments differ from those adopted here for CD_3OD solution, which are made by comparison with 1-methylbenzimidazole (18, 19). Only three C-H signals are found because of fast tautomeric exchange of the N-H proton between the two N sites (Fig. 1*a*). H2 appears as a singlet at 8.12 ppm. We attribute the multiplet centred at 7.59 ppm to H4/H7 and the multiplet at 7.23 ppm to H5/H6 ($^3J_{45} = {}^3J_{67} = 8.1$, $^3J_{56} = 6.9$, $^4J_{46} = {}^4J_{57} = 1.1$ Hz) (see **2** for ring numbering). The coupling constants for this AA′XX′ spectrum were calculated as described by Sohár (20), assuming $^5J_{47} = 0$. The following data have been reported for 1-methylbenzimidazole in acetone–water: 8.19 (H2), 7.75 (H4), 7.58 (H7), 7.32 (H5), and 7.36 (H6) with the same coupling constants (19). Our interpretation is consistent with these results, since the chemical shifts for H5/H6 and H4/H7 are close to the mean values for the corresponding protons in 1-methylbenzimidazole (19).

Monodentate coordination of benzimidazole to the metal centre removes tautomerism. Hence, five distinct signals appear in the ^1H NMR spectrum of $[ReO_2(BzimH)_4]^+$ (Fig. 1*b*): two pseudo-triplets (H5 and H6) at high field, one singlet (H2) at low field, and two intermediate doublets (H4 and H7). From signal multiplicity, H4 and H7 can be unambiguously

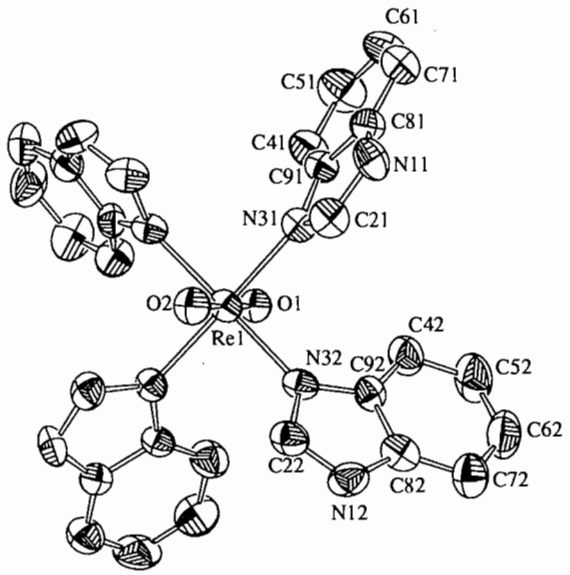
Fig. 2. ORTEP drawing of the $ReO_2(BzimH)_4$ unit showing the numbering scheme. The Re–O bonds lie along a crystallographic twofold axis. Ellipsoids are drawn at a 50% probability level. Hydrogens are omitted.



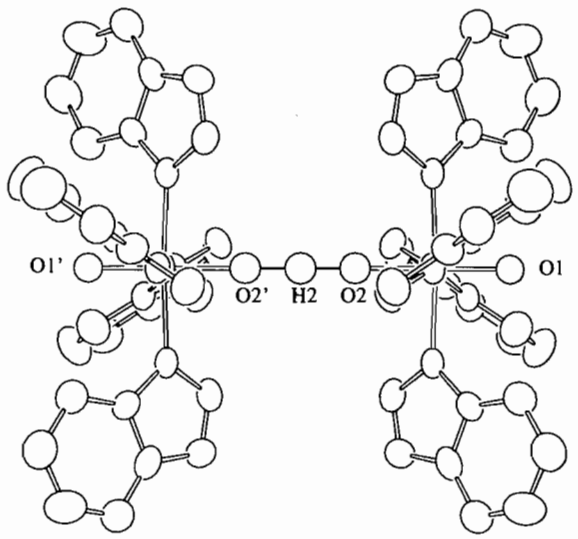


Fig. 3. Representation of the dimeric hemiprotonated $[ReO_2(BzimH)_4]^+/[ReO(OH)(BzimH)_4]^{2+}$ ion pair showing the short O2–O2′ contact along *c* and the orientation of the benzimidazole ligand relative to the Re–O bonds. The O-Re-O unit lies on a crystallographic twofold axis and the O—H···O proton was fixed at the origin (2/*m* site symmetry).

differentiated from H5 and H6. Identification of the next neighbour(s) of each proton is made from a ^1H–^1H COSY experiment. Final assignment is based on the safe assumption that H7 occurs upfield from H4: this trend is followed by free 1-methylated benzimidazoles (18, 19, 21), as well as Ni (22), Co (21), and Ru complexes (23). This is consistent with the relative insensitivity of H7 to its environment, as expected from its being remote from the coordination centre. Alessio et al. (23) have recently described a detailed NMR study on conformationally rigid Ru complexes with 1,5,6-trimethylbenzimidazole and found that, regardless of the conformation, the chemical shift of H7 remains in a narrow range. This gives further support to our assignments, since the doublet assigned to H7 (7.54–7.65 ppm) is much less affected by the protonation state than the other (7.38–7.63 ppm) assigned to H4 (Fig. 1*b*–*d*). The signals in the complexes being broader than in the free ligand, the ^4J couplings (~1 Hz) were rarely resolved. The observed ^3J coupling constants (7–9 Hz) are similar to those of free benzimidazole.

The spectra obtained with $[ReO_2(BzimH)_4][ReO(OH)(BzimH)_4](I)_3$ and $[ReO(OH)(BzimH)_4](BF_4)_2$ are given in Fig. 1(*c*, *d*). In the former case, a single set of averaged signals is observed as expected for a fast exchange between the two forms. Since protonation of the oxo group increases the positive charge at the Re centre, all signals should be shifted downfield. This is indeed what happens when 1-methylbenzimidazole is N3-methylated to generate the N1,N3-dimethylbenzimidazolium cation (24). For the Re complex, downfield shifts of ~0.08 are actually observed on H5, H6, and H7, but H2 and H4 move *upfield* by 0.07 and 0.25 ppm, respectively. The opposite displacement observed for the inner protons H2 and H4 indicates particular sensitivity to the environment in the complex, probably originating from anisotropic effects. With the ligand orientation observed in the crystal structure (Figs. 2 and 3), anisotropy from the Re═O multiple bond is likely felt by H2 and H4. At the same time, these protons can be influenced by the anisotropy of the adjacent benzimidazole ligands and, considering the recent detailed analysis of Alessio et al. (23) on Ru complexes with 1,5,6-trimethylbenzimidazole, this effect is very sensitive to conformation. Protonation is known to introduce significant structural modifications in the coordination sphere: bond orders change in the $[O{=}Re{=}O]^+$ unit and the four Re—N bonds are displaced 4°–5° away from the $[O{=}Re\text{-}OH]^{2+}$ multiple bond (see Crystal structure below). Unpredictable changes in the orientation of the benzimidazole ligands can also take place. In related imidazole systems (5), protonation has been found to shift H2 downfield by ~0.2 ppm, which is opposite to what is observed here for this proton. The much higher upfield shift on H4 could be explained by its greater distance from the Re—N bond: a small rotation about the Re—N bond produces large displacements for this remote proton, thereby changing considerably its position relative to the groups responsible for anisotropy.

Our ^{13}C NMR data for free benzimidazole in CD_3OD (141.5 (C2), 137.9 (C8/C9), 122.9 (C5/C6), 115.4 ppm (C4/C7)) compare well with those previously reported in D_2O (25). A solid-state spectrum was recorded in order to remove averaging due to fast tautomeric N–H exchange and obtain distinct chemical shifts for C4/C7 and C5/C6: 142.6 (C2), 141.0 (C9), 135.8 (C8), 132.4 (C6), 121.7 (C5), 118.8 (C4), 113.4 (C7) ppm. ^{13}C NMR data, both in solution and in the solid state, for the various complexes were assigned by comparison with related nickel complexes (22). Shifts between the coordinated ligand and its free solid-state spectrum are small. Only C2, which is adjacent to the coordination site, appears to be appreciably shifted (+3.4 ppm) upon coordination to the rhenium centre.

Crystal structure of $[ReO_2(BzimH)_4]$-$[ReO(OH)(BzimH)_4][ReO_4]_3$

Crystallographic work unambiguously establishes the presence of a hemiprotonated phase. The unit cell contains 1.5 ReO_4^- ions per Re complex, which requires an extra positive charge for each pair of $[ReO_2(BzimH)_4]^+$ species. Furthermore, the short O···O distance between two centrosymmetrically related units necessitates an O—H···O bond in this region. However, the $[ReO_2(BzimH)_4]^+$ and $[ReO(OH)(BzimH)_4]^{2+}$ ions occupy symmetry-equivalent crystallographic sites, with the consequence that the geometry represented in Fig. 2 and the bond lengths and angles in Table 3 are averages over these two species.

Overall geometry and individual parameters involving the BzimH ligands are not expected to differ appreciably in the two forms. The Re—N bonds (2.11 Å) are similar to those found in imidazole compounds (5, 13). Coordination takes place approximately along the expected lone-pair direction, as indicated by the small difference between the C2-N3-Re and C9-N3-Re angles (~125° and 130°, respectively). The O1-Re-O2 angle is 180°, as required by symmetry. Two distinct rhenium–oxo distances are present in the structure. The longer Re1—O2 distance (1.805(11) Å) on the side of the O—H···O interaction is intermediate between the Re=O distance in $[ReO_2L_4]^+$ (1.765 Å) (5) and the Re—OH distances (~1.90 Å) in $[ReO(OH)(1,2\text{-}Me_2Im)_4]^{2+}$ (5) and $[ReO(OH)(CN)_4]^{2-}$ (26), as expected for disorder. The "outside" Re=O distance of 1.682(10) Å is close to the value found for $[ReO(OH)(O_1cyclam)]^{2+}$ (O_1cyclam = 1,4,8,11-tetraazacyclodecan-2-one) (1.685(8) Å) (27). The four heterocycles are similarly oriented with the phenyl groups away from the O—H···O region. Rotations about the Re—N bonds bring the plane of the rings at 32.4(9)° (ring 1) and 36.3(9)° (ring 2) from the O-Re-O direction. The Re—N bonds are slightly displaced towards the O—H···O region, producing an "umbrella" deformation with O1-Re1-N angles of 91.9(2)°. Again, this is intermediate between the ~90° angles observed in dioxo compounds and the ~94° angles introduced by the steric constrains of the higher multiplicity Re1=O1 bond in oxo-hydroxo species (5, 26, 27). The geometry of the BzimH ligands is normal (supplementary material).

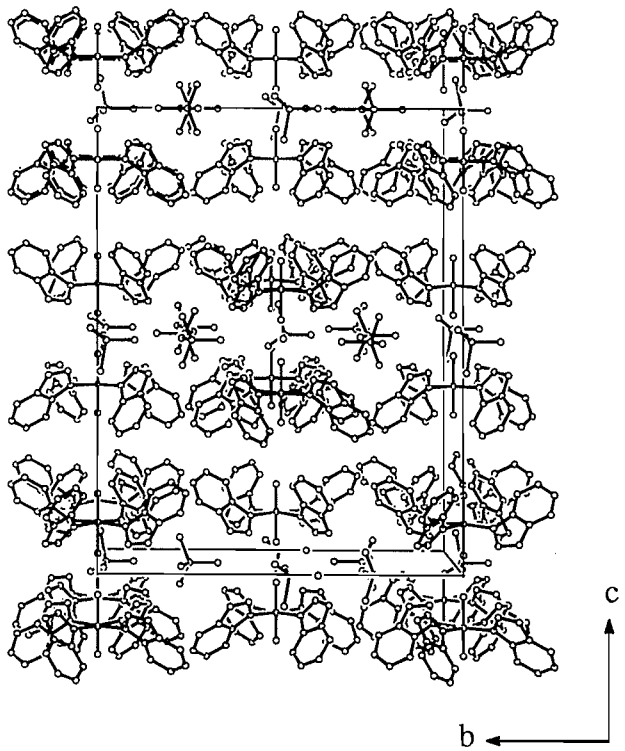
Extensive hydrogen bonding takes place in the crystal. The most interesting is the strong O—H···O bond between centrosymmetrically related complex cations, leading to dimeric units (Fig. 3). The protonated oxo ligand O2 is close (2.44(2) Å) to its symmetry generated position O2′ (Table 3), but this O···O separation is not unprecedented, the lower limit for an intermolecular O···O interaction in the solid state being considered to be ~2.40 Å (28). Hydrogen bonds in the 2.40–2.50 Å range are nevertheless considered to be very short.

The position of the proton could not be reliably determined in the crystallographic study. It was fixed on the origin, since no electron density was found elsewhere in the ΔF map on or near the c axis. Nevertheless, this position is quite consistent with various correlations made for O—H···O hydrogen bonds between O—H, H···O′, and O···O′ distances and O-H···O′ angles (28). According to Olovsson and Jönsson (28), the shorter the O···O′ distance, the more linear the interaction and the more equal the O—H and H···O′ distances are expected to get. The model proposed here with the proton at the origin follows these trends, with an O-H-O′ angle of 180°, a short O···O′ separation (2.44(2) Å) and equal O—H and H—O′ distances of 1.22 Å.

The view of the unit cell represented in Fig. 4 clearly shows the arrangement of anions and cations in the crystal: layers of ReO_4^- ions are intercalated between two layers of $[ReO_2(BzimH)_4]^+/[ReO(OH)(BzimH)_4]^{2+}$ ions, in the region containing the connecting O—H···O bonds, where they form hydrogen bonds with ligand N-H groups. The linear O-Re-O groups are all oriented parallel to the c axis. The phenyl rings of all BzimH ligands are pointing away from this hydrophilic region, towards the surfaces of these three-decker sheets, thereby providing hydrophobic van der Waals contacts between the sheets.

Distances and angles related to the N—H···O(perrhenate) hydrogen bonds are reported in Table 3. Interactions are present between N11 and O302 (2.960(15) Å) and between N12 and O303 (2.962(14) Å), two oxygens belonging to the undisordered ReO_4^- ion. The N···O separations are in the normal range (2.6–3.2 Å) (29) and the N-H···O angles (165.5(5)° and 141.9(4)°, respectively) are favourable. Extra N—H···O bonds exist between N12 and O202 (3.05(5) Å), and between N12 and O202′ (3.11(6) Å). The fact that these interactions are much weaker accounts for the disorder observed for perrhenate ion Re2.

Discussion



Under mild conditions, excess benzimidazole reacts well with $ReO_2I(PPh_3)_2$, forming *trans*-$[ReO_2(BzimH)_4]I$, but under stoichiometric conditions (4:1 ligand:Re ratio), the reaction does not proceed to completion even after 24 h. With excess ligand, conversion into $[ReO_2(BzimH)_4]^+$ is nearly quantita-

Fig. 4. View of the unit cell down the *a* axis, showing alternating layers of hydrogen-bonded cation pairs and perrhenate ions. Hydrogens are omitted and atoms are represented with spheres of arbitrary size for clarity.

tive, but removal of excess free ligand proved to be problematic, since some protonation usually occurs during recrystallization. Protonation is easily detected by the reddish-brown dioxo complexes taking a pink coloration even when protonation is only partial. In the IR spectrum, the ν(Re=O) mode of $[ReO(OH)(BzimH)_4]^{2+}$ appears at 931 cm^{-1}, whereas the ν_{as}(O=Re=O) mode of $[ReO_2(BzimH)_4]^+$ at 795 cm^{-1}, which is the most intense vibration in the spectrum of a non-protonated sample, loses intensity. From concentrated acetone solutions, nearly ligand-free *trans*-$[ReO_2(BzimH)_4]I$ can be isolated, but partial protonation is nevertheless present. From very dilute solutions in acetone, an unusual exactly hemiprotonated iodide salt $[ReO_2(BzimH)_4][ReO(OH)(BzimH)_4](I)_3$ is isolated. Slow recrystallization from alcohols results in ligand loss and partial decomposition, and the hemiprotonated material precipitates as the perrhenate salt. Nonprotonated ligand-free $[ReO_2(BzimH)_4]^+$ could be obtained as the tetraphenylborate salt.

More robust reaction conditions do not help. Refluxing mixtures of $ReO_2I(PPh_3)_2$ and benzimidazole (stoichiometric amounts or excess) yields a dark reddish-brown material. From IR spectroscopy, this sample is believed to be a mixture of products, including the dioxo complex (ν_{as}(O=Re=O) at 795 cm^{-1}) and an oxo-bridged dimer (medium bands at 965 and 700 cm^{-1} for ν(Re=O) and ν_{as}(Re-O-Re), respectively) (30).

Both the dioxo and the oxo-hydroxo complexes are unstable in methanol, free protonated ligand being present in aged (several minutes) NMR solutions. The instability towards oxidation observed here in alcohol solutions is not uncommon for *trans*-dioxo compounds of Re(V) (27, 31). Mixed $[O=Re=O]^+/[O=Re\text{-}OH]^{2+}$ phases have been reported and structurally characterized for 1,2-dimethylimidazole (3). Partial protonation could also be responsible for unexplained colour changes in *trans*-$[TcO_2L_4]^+$ complexes (32, 33). Pink solids were isolated from initially orange solutions when acetone was used to recrystallize $[TcO_2L_4]Cl$ imidazole complexes (32). These reports possibly involve partly protonated mixed phases of the type described in this paper, since a very small amount of protonation could lead to colour variations. The crystal structure of these Tc complexes shows no obvious signs of protonation, with normal Tc=O bonds (1.71(2) Å), although the relatively large uncertainties and the symmetry equivalence of the two oxo ligands could mask a small bond length variation due to a partly protonated Tc=O bond. The oxygen atoms in *trans*-dioxo systems are nucleophilic and are good hydrogen bond acceptors from water or other protic crystallization solvents. Traces of protonation would imply a slight excess of Cl^- counterions, but the extra electron density could go unnoticed if the anion lies approximately on the same site as a solvent molecule.

In contrast with the $[ReO_2(1,2\text{-}Me_2Im)_4]^+/[ReO(OH)(1,2\text{-}Me_2Im)_4]^{2+}$ phases, which are only partially protonated and non-stoichiometric (3), the mixed phase isolated here with benzimidazole is exactly hemiprotonated. In both cases, hydrogen bonding has a determining effect. In the 1,2-Me_2Im materials, a lattice water molecule lying on a crystallographic 3-fold axis is surrounded by three complex cations and it plays the double role of hydrogen-bond donor and acceptor: most water molecules act as hydrogen-bond donor to two Re=O groups and as acceptor for one Re-OH group. The high symmetry of the cubic unit cell provides each Re=O or Re-OH group with a suitable hydrogen-bonding partner. However, water is disordered over two close positions, so that it can move away from the third group when it is Re=O instead of Re-OH. As a consequence, the crystal lattice can accommodate a certain range of $[ReO_2(1,2\text{-}Me_2Im)_4]^+/[ReO(OH)(1,2\text{-}Me_2Im)_4]^{2+}$ composition and non-stoichiometric phases are obtained.

In the present case, although hydrogen bonding also plays a crucial role, the bulky benzimidazole ligands also control the structure to a large extent. In the first place, all benzimidazole side-rings adopt head-to-head orientations, hence providing enough space on the other side for the Re-OH group of one cation and the Re=O group of another one to approach each other and form the O—H···O bond. Secondly, the Re-O-H···O=Re segments should not deviate much from linearity since repulsions would develop between the benzimidazoles in the two cations. Thirdly, these restrictions at the dimer level generate sheets with a hydrophilic interior, where extra N—H···perrhenate hydrogen bonds are formed, and hydrophobic surfaces where inter-sheet contacts are taking place. It is difficult to decide which of these three factors plays the most important role in determining the structure, but this type of structure could not exist if it did not contain exactly the same amount of $[ReO_2(BzimH)_4]^+$ and $[ReO(OH)(BzimH)_4]^{2+}$, since two Re=O groups or two Re-OH groups could not face each other at the very short O···O distance observed. However, the same structural pattern could be retained in the iodide

salt $[ReO_2(BzimH)_4][ReO(OH)(BzimH)_4](I)_3$ prepared here, where the ReO_4^- ions would be replaced by I^- ions with the same charge and a similar size.

Another interesting structural aspect is revealed from a comparison with the related $[ReO_2(Haza)_4]Cl$ compound (7). In both complexes, the cations all have mutually parallel and linearly stacked O-Re-O segments. The azaindole complexes adopt a "windmill" conformation with all ligands parallel to the O═Re═O axis to favour intramolecular N—H···oxo hydrogen bonding. In the benzimidazole compound, the rings are tilted about 35° away from the axis, leading to a "propeller" conformation. This results in the 7-azaindole complex crystallizing as *chains* of cations, while the crystal structure of the benzimidazole complex shows *layers* of dimeric units.

Although the "all head-to-head" conformer discussed in this communication is no doubt the major conformer, the presence of weak secondary signals was sometimes detected in the NMR spectra of non-recrystallized samples. Whether these signals should be attributed to "head-to-tail" $[ReO_2L_4]^+$ conformers or chemically different species is not known. From the X-ray diffraction study, it is reasonable to think that the structure should promote preferential crystallization of the "all head-to-head" conformer, leading to a "conformationally pure" sample.

^{1}H NMR shows that oxo protonation produces unexpected effects on the H2 and H4 protons close to the coordination sphere, the effect being particularly large for H4. Such effects may become efficient ways of studying conformation in these systems, but a detailed discussion must await a better understanding of Re═O multiple bond anisotropy.

Acknowledgments

We wish to thank M. Simard and F. Bélanger-Gariépy for help in collecting the X-ray data, R. Mayer for running the CP-MAS spectra, and S. Bilodeau who did the COSY experiments. The financial support of the Natural Sciences and Engineering Research Council of Canada and the Fonds FCAR du Ministère de l'Éducation du Québec is gratefully acknowledged.

Abstract: The main component of the solid originally believed to be a peroxosilicate with pulp-brightening properties has been shown to be $Na_2O_2 \cdot 8H_2O$. The solid crystallizes in the monoclinic space group *C2/c*, with an empirical formula H_8O_5Na, and with a = 14.335(3), b = 6.461(1), c = 11.432(2) Å, β = 118.28(3)°, and Z = 8. The centrosymmetric structure consists of a peroxide anion with an O—O distance of 1.499(2) Å. Each of these oxygen atoms is at the apex of an approximate square-based pyramid, the base of which consists of four oxygen atoms of water molecules. The bases of the two pyramids are staggered when viewed down the peroxide bond. Each sodium is at the centre of an approximate octahedron of water molecules, four of which bridge other sodium atoms and two bridge to the peroxide anions. One hydrogen atom of each of these two water molecules is terminal and the other two are hydrogen bonded to peroxide oxygen atoms. The compound reacts very rapidly with CO_2 in moist air to form Na_2CO_3, but in drier conditions, formation of the carbonate can take many days and proceeds via a percarbonate, believed to be Na_2CO_4. This has been identified by infrared spectroscopy and X-ray powder diffraction and can persist for long periods in dry air.

Key words: sodium peroxide hydrate, sodium percarbonate, pulp brightening, X-ray diffraction, infrared.

Résumé : On démontre que le produit principal d'un solide, auquel on avait originalement attribué la structure d'un peroxosilicate ayant des propriétés de blanchiment de la pulpe, est formé de $Na_2O_2 \cdot 8H_2O$. Le solide, de formule empirique de H_8O_5Na, cristallise dans le groupe d'espace monoclinique *C2/c*, avec a = 14,335(3), b = 6,461(1), et c = 11,432(2) Å, β = 118,28(3)°, et Z = 8. La structure centrosymétrique comporte un anion peroxyde dans lequel la longueur de la liaison O—O est égale à 1,499(2) Å. Chacun de ces atomes d'oxygène se trouve au sommet d'une pyramide à base approximativement carrée dont la base est formée de quatre atomes d'oxygène des molécules d'eau. Lorsqu'on les regarde le long de la liaison du peroxyde, les bases des deux pyramides sont décalées. Chaque atome de sodium se trouve approximativement au centre d'un octaèdre de molécules d'eau, dont quatre forment des ponts avec d'autres atomes de sodium et deux forment des ponts avec des anions peroxydes. L'un des atomes d'hydrogène de chacune de ces molécules d'eau est terminal et les deux autres forment des liaisons hydrogènes avec les atomes d'oxygène du peroxyde. Le composé réagit rapidement avec le CO_2, dans l'air humide, pour conduire à la formation de Na_2CO_3; toutefois, dans des conditions plus sèches, la formation du carbonate nécessite plusieurs jours et elle implique un intermédiaire percarbonate que l'on croit être le Na_2CO_4. Celui-ci a été identifié par spectroscopie infrarouge et par diffraction de poudre des rayons X et il peut exister pour de longues périodes dans de l'air sec.

Mots clés : hydrate de peroxyde de sodium; percarbonate de sodium; blanchiment de la pulpe; diffraction des rayons X; infrarouge.

[Traduit par la rédaction]

Introduction

The work described here arose during research aimed at improving the procedures for the lignin-preserving brightening of mechanical wood pulps. (Bleaching more often refers to the production of pure cellulose by delignification with reagents such as Cl_2, ClO_2, O_2, etc. in Kraft pulps; for a general reference, see Smook (1)). The most widely used brightening reagent is an alkaline solution of hydrogen peroxide and its successful use in mills requires the presence of a variety of additional reagents (2) whose primary goals are to stabilize the peroxide and minimize its autodecomposition and its decomposition catalyzed by transition metal ions in the wood (2, 3). The most common additives include sodium silicate, magnesium ions, and the sodium salt of diethylenetriaminepentaacetic acid. Because of the enormous amounts of mechanical pulps being produced, and since hydrogen peroxide is the most expensive chemical used in such mills, it is of consider-

able economic importance to understand the chemistry involved in these processes so that peroxide losses can be minimized. For example, there has been much discussion and speculation on the specific role(s) of the silicate (4). It has been shown (3) that a major (but not total (5)) function is the deactivation of metal cations involved in catalyzing peroxide decomposition. In addition, it has long been suspected that peroxosilicates are involved (3), and there are several reports describing the solid obtained when solutions of hydrogen peroxide and sodium silicate solutions are mixed at high pH values as $Na_2SiO_3 \cdot xH_2O_2$ (6), sodium persilicate (7), and sodium peroxysilicate (3, 8, 9). The solid has brightening properties (7, 8), but no evidence has been presented to support any of the above formulations. This paper describes the structure of the only crystalline compound, $Na_2O_2 \cdot 8H_2O$, present in the solid and its reactions with CO_2.

Results and discussion

The presence of silicon in the very unstable solid obtained in bulk from solutions containing silicate, hydrogen peroxide, and sodium hydroxide, and generally referred to as a peroxosilicate, has been confirmed by strong signals in the ^{29}Si nmr spectra, by ir spectroscopy, and by energy-dispersive X-ray microanalysis. Since this solid shows brightening properties (7, 8), and is of unknown composition, it was of importance to establish its composition. We have shown previously (4) that, compared to pure silicate, there are minor changes in the ^{29}Si nmr spectra of solutions from which the solid crystallizes and that these are probably due to the formation of labile complexes of dissolved silicates and radical H_2O_2 decomposition products. No evidence for the existence of peroxide coordinated to silicate was found in such solutions.

Well-formed crystals were obtained from a variety of solutions (especially at very high pH) containing NaOH, SiO_2, and H_2O_2, prepared in connection with the ^{29}Si nmr studies (4). These crystals are colourless, transparent plates that become opaque very rapidly when removed from the mother liquor in air. Decomposition is slightly less rapid under nitrogen at room temperature, but to preserve a crystal for data collection, it was necessary to transfer crystals rapidly, under nitrogen, to sealed Lindemann capillaries for storage at liquid nitrogen temperatures.

Results from the structural determination (see below) show that the compound is $Na_2O_2 \cdot 8H_2O$, which was made previously (10) either by reacting sodium peroxide with water or, more conveniently (11), from mixtures of hydrogen peroxide and sodium hydroxide. It is reported as a white powder that reacts readily with carbon dioxide and water vapour. The stabilization of this compound for industrial use has formed the subject of patents (12).

Views of the structure, showing the arrangement of the water molecules about each Na atom and about each peroxide ion, are shown in Figs. 1 and 2, with selected bond lengths and angles recorded in Table 1. From Fig. 1, it can be seen that each Na (Nab for example) is surrounded by O atoms from six water molecules. Four of these (O2b, O2c, O4a, and O4) are from water molecules that essentially act as bridges to other Na atoms. Two (O1b and O3b) serve to bridge Nab to O5b and O5e, the oxygen atoms of peroxide anions. Na—O distances are in the range 2.376(12)–2.508(12) Å, and the O-Na-O angles approximate to 90° so that each Na ion is in the centre of an approximate octahedron.

Effects of hydrogen bonding can be seen by considering the distances labelled ***a***, ***b***, and ***c*** in Fig. 2 and tabulated below.

	a	*b*	*c*	*d*
O1	0.787(25)	1.032(31)	1.555(1)	2.582(1)
O2	0.768(25)	0.847(25)	1.897(1)	2.742(1)
O3	0.791(22)	0.855(27)	1.788(1)	2.622(1)
O4	0.795(25)	0.865(25)	1.802(1)	2.665(2)

Distance ***b*** is greater than distance ***a*** for all lattice waters. This fact is consistent with the H atom oriented towards the peroxide being hydrogen bonded to the peroxide O atom, whereas the second H atom is terminal, with little or no hydrogen bonding as distances range from 1.958 to 2.581 Å. It is apparent from Fig. 2 and from a comparison of ***d***, the peroxide O to

water O distance, with the sum of ***b*** and ***c*** that the hydrogen bond is approximately linear (angles range from 164.4° to 176.2°).

The environment of the anions can also be seen in Fig. 1 and, more clearly, in Fig. 2. Each O atom of the O_2^{2-} is approximately 0.5 Å above a plane formed by four O atoms from neighbouring water molecules. When viewed down the O—O bond, the eight O atoms are in a staggered configuration. Distances from a peroxide O to its closest four water O atoms are 2.582(2)–2.742(1) Å, with angles of the type O(5f)-O(5g)-O(2c) ranging between 100° and 110°. The O—O distance of 1.499(2) Å is comparable to that found in the related $SrO_2 \cdot 8H_2O$ and in fact the two structures are quite similar (10, 13). In previous work, the space group of $Na_2O_2 \cdot 8H_2O$ was reported as either *Cc* or *C2/c*, with a unit cell of $a = 13.5$, $b = 6.5$, $c = 11.5$ Å, $\beta = 100.5$ and $Z = 4$ (14).

The solid obtained by literature methods (7, 8) in high yields from mixtures of NaOH, Na_2SiO_3, and H_2O_2 is very sticky because of the high NaOH content. After washing with small amounts of ethanol and H_2O_2, small well-formed crystals are clearly visible in the bulk solid, suggesting that the original precipitate is a mixture. The powder diffraction patterns of several samples at various stages of washing are the same as that of the pure octahydrate (see experimental section). The observed pattern agrees very closely with that calculated from the single crystal data and is only slightly different from that on file (15) in the ICDD data bank. Data from ir, nmr, and energy-dispersive X-ray spectrometry suggest that the amorphous, silicon-containing contaminant is sodium silicate, which is more soluble in water (16) or H_2O_2 than is $Na_2O_2 \cdot 8H_2O$ and explains why the pure octahydrate is the only solid remaining after washing.

There is a clear phase change when the pure octahydrate is pumped under vacuum for 5 h, and the powder pattern of the new phase corresponds to that reported for the dihydrate (15), obtained when the octahydrate is allowed to stand over desiccants (11).

Because decomposition of the peroxide begins as soon as the solid is exposed to atmosphere, samples for ir measurements were handled under dry nitrogen. The ir spectrum (Fig. 3) consists of a series of broad absorptions due to the lattice water and peaks in the 500–1000 cm^{-1} region. The peak at 985 cm^{-1} is possibly due to νO—O, which is typically (17) found in this region. There are additional peaks in the 500–850 cm^{-1} region but, significantly, no peaks between 1000 and 1600 cm^{-1}, and therefore the sample is carbonate free at this point (18).

The rate of decomposition and the product formed greatly depend on the amount of moisture present in the atmosphere. Exposure to moist air (relative humidity ~80%) results in the rapid (within minutes) appearance of the very intense signal at ~1450 cm^{-1} due to CO_3^{2-} (18). Transformation is complete in a few hours. This accounts for the previously published spectra (19) of both $Na_2O_2 \cdot 8H_2O$ and $Na_2O_2 \cdot 8D_2O$, which are dominated by absorptions due to water (~3000 cm^{-1}) and to sodium carbonate at ~1450 cm^{-1} (very strong), ~880, and ~700 (very weak) cm^{-1} (18). In fact there is little evidence of any peroxide remaining in the samples used to record these spectra, which were also used to argue that the structure of $Na_2O_2 \cdot 8H_2O$ does not consist of units of $2NaOH \cdot H_2O_2 \cdot 6H_2O$.

However, in drier air (relative humidity ~20%), dehydration is accompanied by the appearance, within minutes, of new signals that continue to grow in intensity over several hours. The changes after 20 h are shown in Fig. 3. There is little peroxide remaining, almost all the water has been lost, and a small amount of CO_3^{2-} is present. The three peaks due to the latter continue to increase with time, but many days are required for complete conversion to CO_3^{2-}. The remaining peaks in the spectrum in Fig. 3 are most likely due to a surprisingly stable, colourless sodium percarbonate.

A detailed analysis of ir and Raman spectra of various percarbonates suggests that the spectra of most species are best interpreted on the basis of the centrosymmetric $(C_2O_6)^{2-}$ anion (20). The ir spectra of $Na_2C_2O_6 \cdot nH_2O$ ($n = 0$–1) and three coloured (orange and blue) forms of $K_2C_2O_6$, prepared by reactions between CO_2, KOH, and H_2O_2, have been analyzed (20). In addition, ("yellowish") $Na_2C_2O_6$ has been reported from $Na_2O_2 \cdot 8H_2O$ and CO_2 (21). Percarbonates formulated as

For personal use only.

CO_4^{2-} are less well known. Attempts to prove the existence of Li_2CO_4 by X-ray powder diffraction methods were unsuccessful and it was concluded that the compound does not exist at room temperature (22). It was later obtained from LiOH–H_2O_2–CO_2 mixtures and characterized by elemental analysis and ir spectroscopy (20); its (unpublished) powder pattern does not contain lines due to Li_2CO_3, LiOH, LiO_2H, or Li_2O_2 (20). There is a report of CO_4^{2-} coordinated to Pt (23).

The ir spectrum of the colourless percarbonate shown in Fig. 3 closely resembles that of $Li_2CO_4 \cdot H_2O$. The one difference is that the very strong 1350 cm^{-1} peak in the Li compound, assigned to the C--O stretching vibration (20), appears as a doublet at 1371 and 1339 cm^{-1} in Fig. 3. These may be the symmetric and antisymmetric modes. The spectrum is quite different from that of $Na_2C_2O_6$ (20). The X-ray powder pattern of this sample (see experimental section) shows it to be mostly the percarbonate, contaminated by approximately 5% Na_2CO_3, with no detectable amount of $Na_2O_2 \cdot 8H_2O$. The pattern is also quite different from that reported for $Na_2C_2O_6$ (21) and is therefore probably due to Na_2CO_4.

There is a variety of adducts of H_2O_2 and Na_2CO_3 (20, 24) and it appears to be common practice in the literature (see, for example, ref. 25) to refer to these, particularly the important bleaching agent $Na_2CO_3 \cdot 1.5H_2O_2$, as percarbonates. The crystal structure of the latter (24, 26) shows that it contains H_2O_2 molecules hydrogen bonded to CO_3^{2-}, and is therefore not a percarbonate. Its powder pattern and ir spectrum (20) are quite different from the compound prepared in this work.

Relationship to pulp brightening

All the evidence now points to the fact that the bulk solid obtained from NaOH, H_2O_2, and Na_2SiO_3 mixtures, previously described as sodium peroxysilicate (3, 8, 9) with pulp-brightening properties (7, 8), is in fact a mixture of $Na_2O_2 \cdot 8H_2O$ and amorphous Na_2SiO_3. The pulp-brightening properties of such solids are due to the title compound. The presence of other known crystalline species, such as $Na_2O_2 \cdot xH_2O_2 \cdot yH_2O$ ($x = 2$, $y = 4$ and $x = 4$, $y = 0$) (27), $Na_2(HO_2)_2 \cdot H_2O_2$ (10), and $Na_2SiO_3 \cdot xH_2O_2 \cdot yH_2O$ (particularly with $x = 3$, $y = 0$ (7) and $x = 2$, $y = 1$ (28)) can be also ruled out from powder pattern data. The compound containing the hydroperoxide anion would be particularly important since this anion is believed to be the major active pulp-brightening agent (1). Isolation of peroxide adducts of silicate require that silicate–peroxide solutions be taken to dryness under vacuum (6, 28). In addition, they are very water soluble when first formed and therefore would likely not precipitate under the conditions studied in this work.

Experimental

Physical measurements and syntheses

Infrared spectra as both Nujol mulls and KBr discs were recorded on a Bruker IFS 66 FTIR spectrophotometer. Scanning electron microscopy (SEM) spectra were collected from a Hitachi 570 energy-dispersive X-ray microanalysis instrument equipped with a Tracor Northern 5502 energy-dispersive X-ray spectrometer. X-ray powder data were recorded on a 114.83 mm diameter Debye–Scherrer camera using Ni-filtered Cu-K_α radiation from a Phillips PW 1010 generator. Samples were contained in sealed Lindemann capillaries.

The title compound was made by the literature method (11), and also obtained from mixtures of NaOH, Na_2SiO_3, and H_2O_2 (7, 8) by careful washing with H_2O_2. Optimum conditions for the growth of single crystals suitable for structural determination occur when solutions contain 3.0 mol dm^{-3} SiO_2, 2.0 mol dm^{-3} H_2O_2, and 6.5–7.0 mol dm^{-3} NaOH, crystallization being complete after 48 h; ir (KBr): 3625, 3533, 3446, 3305 (w on broad background, νOH), 2920 (w,vb), 1918 (w,b), 1672 (m, δHOH), 985 (s, νO–O), 833 (sh), 717 (m), 627 (m), 537 (m) cm^{-1}. When exposed to air new peaks due to CO_4^{2-} occur at 1664 (vs, νC═O), 1645 (sh, δHOH?), 1369, 1342 (d,s), 1016 (m), 877 (m), 818 (m), 724 (m) cm^{-1}. In addition, peaks due to CO_3^{2-} occur at 1450 (vs,b), 878 (m) and 724 (w) cm^{-1}.

The first 25 lines in the powder pattern of Na_2CO_4, *d*-spacing in Å (relative intensities): 5.10(2), 4.88(2), 4.30(1), 3.7395), 3.65(2), 3.42(2), 3.29(5), 3.08(20), 2.99(10), 2.915(20), 2.800(2), 2.750(5), 2.700(100), 2.610(2), 2.530(80) br, 2.37(5), 2.300(100), 2.275(5), 2.205(5).

X-ray crystallography

A small crystal was mounted in a sealed Lindemann capillary under nitrogen, and immediately placed in liquid nitrogen.

Data were collected on an Enraf–Nonius CAD4 diffractometer using graphite-monchromatized Mo-K_α radiation at 173 K; 1343 independent reflections were measured in the range $-20 \le h \le 17, 0 \le k \le 9, 0 \le l \le 6$ with a 2θ (max) = 59.96°. Of these, 1064 had $F_o > 4\sigma(F_o)$ and were used for further computation of *wR*2. The Enraf–Nonius peak search, centering, and indexing program was used to determine the initial choice for crystal class and space group. Unit cell parameters were obtained by least-squares analysis of 25 low-angle reflections. The stability of the crystal was measured by periodically monitoring three standard reflections; no systematic intensity variations were observed. Intensity data were corrected for Lorentz and polarization factors. NRCVAX programs (29; PC version of the system) were used for scaling and data reduction. Atomic scattering factors were taken from tabulated values (30).

Crystal data were as follows: H_8O_5Na, $F_w = 111.05$, monoclinic, *C*2/*c*; $a = 14.335(3)$, $b = 6.461(1)$, $c = 11.432(2)$ Å, $\beta = 118.28(3)°$, $V = 932.44$ Å^3, $Z = 8$, $D_c = 1.582$ g cm^{-3}, $F(000) = 472.0$, $\lambda = 0.71073$ Å, μ(Mo-K_α) = 0.24 mm^{-1}, $T = 173$ K.

The structure was solved by a combination of direct methods and difference Fourier cycles. The Na and the O atoms were refined anisotropically and H atoms were refined isotropically. Coordinates of all atoms were refined. Full-matrix least-squares refinement on F^2, for 1064 data ($F_o > 4\sigma(F_o)$), 0 restraints, and 87 parameters resulted in a gof on $F^2 = 1.129$, $R1 = 0.0313$, and $wR2 = 0.0760$.[2] The largest peaks in the final difference Fourier were 0.243 and −0.223 e/Å^3. Positional thermal parameters are shown in Table 2.[3]

[2] $R1 = \sigma||F_o|-|F_c||/\sigma|F_o|$ and $wR2 = [\sigma[w(F_o^2-F_c^2)^2]/\sigma[w(F_o^2)^2]]^{0.5}$.

The complexation of glucose and other monosaccharides with cyclodextrins[1]

Frank Hacket, Jose-Miguel Coteron, Hans-Jörg Schneider, and Vladimir P. Kazachenko

Abstract: Equilibrium constants of complexes between β-cyclodextrin and glucose, galactose, or mannose have been determined by fluorometric competition titrations in water to be as low as $K = 1–0.5\ M^{-1}$, in sharp contrast to recently published values for glucose around $K = 400\ M^{-1}$. The pentoses ribose, xylose, and arabinose show association constants between 6.3 and $1.5\ M^{-1}$, in agreement with published values. Preliminary computer-aided molecular modelling studies suggest that the small values observed for the hexoses are not due to steric hindrance of an intracavity inclusion but to a smaller number of intermolecular hydrogen bonds and to some strain as a result of cyclodextrin deformation. Calorimetric measurements of the glucose–β-cyclodextrin complex show, again in contradiction with the literature, an **endo**thermic reaction, or a free enthalpy value close to zero.

Key words: cyclodextrin complexes, sugar complexation, glucose complexation, calorimetry, computer-aided molecular modelling.

Résumé : Faisant appel à des titrages fluorométriques compétitifs et opérant dans l'eau, on a déterminé que les constantes d'équilibre des complexes formés entre la β-cyclodextrine et le glucose, le galactose ou le mannose peuvent avoir des valeurs aussi faibles que $K = 1$ ou $0{,}5\ M^{-1}$; ces valeurs sont en opposition avec les valeurs de $K = 400\ M^{-1}$ rapportées récemment pour le glucose. Les constantes d'association des pentoses, comme le ribose, le xylose et l'arabinose, se situent entre 6,3 et $1{,}5\ M^{-1}$. Des études préliminaires de modelage moléculaire assisté par ordinateur suggèrent que les faibles valeurs observées avec les hexoses ne sont pas le résultat d'un empêchement stérique à une inclusion intracavité, mais à la présence de moins de liaisons hydrogènes intermoléculaires et à une tension résultant d'une déformation de la cyclodextrine. Des mesures calorimétriques du complexe glucose–β-cyclodextrine indiquent, encore une fois en contradiction avec ce qui a été rapporté dans la littérature, que la réaction est **endo**thermique ou que son enthalpie libre est très proche de zéro.

Mots clés : complexes de la cyclodextrine, complexation des sucres, complexation du glucose, calorimétrie, modelage moléculaire assisté par ordinateur.

[Traduit par la rédaction]

Introduction

Several authors have recently investigated interactions of cyclodextrins with sugars, with, however, quite conflicting results (2–4). Although the interactions between the hydrophilic guest molecules with cycloamyloses in water must be expected to be small, the most recent publication by Hirsch et al. (2) claims for the complex between D-glucose and β-cyclodextrin an association constant of $450\ M^{-1}$, based on measurements with a glucose-sensitive electrode, or of $380\ M^{-1}$, on competition with methyl orange as optical indicator. This is in sharp contrast to earlier data from Aoyama et al. (3) and de Namor et al. (4), who reported that binding of cyclodextrins with aldohexoses, and in particular with glucose, is barely measurable. We have shown (5) that efficient binding of saccharides in cyclodextrins requires the presence of additional groups on the cycloamylose ring. As not only the most recent paper (2) reports binding that by far exceeds any predictions and earlier measurements, but also the others (3, 4) contain some discrepancies, or K values of "0" (3), we have remeasured some association constants with a competition assay using the fluorescence dye 8-anilinonaphthalen-1-sulfonate ANS, and carried out some calorimetric measurements. To provide firmer grounds for the inclusion modes discussed in the earlier papers (2–4) we also performed some preliminary computer-aided molecular modelling studies on cyclodextrin complexes with glucose and ribose.

Fig. 1. Example of a linear least-squares fit to eq. [1] for a titration of β-CD, ANS, and D-ribose.

Competition titrations (Table 1) with ANS were carried out at 298°C by adding a stock solution of the monosacchcaride (1.0 M) to a solution of β-CD (1.5×10^{-2} M) and ANS (1×10^{-4} M) in buffer solution at pH = 7.0 (Na_2HPO_4 + NaOH), measuring a fluorescence decrease from, for example, 1500 to 800 relative units. The instrument used was a Hitachi fluorescence spectrophotometer F-2000. The association constant K for ANS + β-CD (measured in a fluorescence titration by adding a stock solution of β-CD (1.5×10^{-2} M) to a solution of 1×10^{-4} M ANS) was 110 M^{-1} (±7%), in accord with published values (6). With TNS instead of ANS, we obtained an association constant with ß-CD of $K = 2.5 \times 10^3$ M^{-1} (corresponding to a free energy of association of ΔG = 19.4 kJ/mol). (With TNS, longer exposure times in the fluorimeter lead to changes of the emission intensity.)

The data were evaluated by a linear least-squares fit to eq. [1] (ref. 7); Fig. 1 shows an example of the fitting.

[1] $S_t/P = (K_I/K_{11})\ Q + 1$

where $P = L_t - 1/QK_I - I_t/Q + 1$
$Q = (e - e_{IL}) / (e_I - e)$
S = [Monosaccharide], S_t = [Monosaccharide]total
L = βCD, L_t = [βCD]total
I = ANS, I_t = [ANS]total
K_I = [IL]/[I] [L], K_{11} = [SL]/[S] [L]
e = measured fluorescence intensity
e_I = fluorescence intensity of ANS without βCD
e_{IL} = fluorescence intensity of the complex ANS–βCD

K is in M^{-1}; S, P and L in M; other parameters are dimensionless.

Heats of complexation of cyclodextrins with α-D-glucose in fresh doubly distilled water at 298 K were measured with a LKB-2107 microcalorimetry system. Aqueous solutions of cyclodextrins (2 mL) in the calorimetric vessel were titrated with the α-D-glucose–water solutions contained in a 1 mL gastight motor-driven Hamilton syringe (for concentrations see below). Dilution heats of glucose were automatically taken into account by differential calorimetry, adding parallel glucose solutions to pure water. Dilution heats of cyclodextrins were negligible, as checked by a separate experiment.

The following total concentrations of the reagents were used in calorimetric titrations (we could not reach the concentration 0.08–0.10 mol/L reported in the literature (4) for α-CD in water).

Cyclodextrin	[Cyclodextrin] (mmol/L)	[Glucose] mmol/L
α-CD	25.2–28.3	14.9–92.5
	67.8–73.2	107.0–231.4
β-CD	25.8–29.4	7.5–92.5
	17.2–19.4	7.5–46.7

The reliability of the calorimetric equipment was checked by measuring in duplicate and by measuring stability constants and enthalpies of a well-known reaction. Thus. for the 1:1 complexation of 18-crown-6 with KNO_2 in H_2O at 298 K, values of log K 1.98(0.01) and ΔH −25.8(0.2) kJ/mol were obtained, in close agreement with published calorimetric data (log K 2.03, ΔH −26.0 kJ/mol) (8).

The calorimetric data were analyzed using the multipurpose computer program CHEM-EQUI as described elsewhere (9). For the complexation of cyclodextrins (CD) with α-D-glucose (G) fitting was satisfactory for a simple 1:1 (CD+G ⇌ CD–G) complexation model.

Molecular modelling was carried out with QUANTA/CHARMm (version 4.0) from MSI on a SGI workstation, with a constant dielectric value of ε = 3 D; minimizations were done by the steepest descent method followed by the Adapted Newton Raphson technique. Several start geometries were generated by manual docking of the sugar within the cyclodextrins.

Discussion

The discrepancies documented in Tables 1 and 2 provide an illustration of the serious problems involved in measurements of very weak complexes. The association constants K obtained from the fluorescence titrations are believed to be fraught with less error in view of the relatively large signal intensity changes. It should be noticed that the cyclodextrins and the sugars are ideal candidates for fluorescence titrations in view of their inactivity in luminescence. However, the necessity to use concentrations around 1 M of the excess compound (sugar) for complexes with K around 1 M^{-1} may well lead to problems arising from the varying self-association and from changes in bulk properies of the medium. Nevertheless, we have been able to replace for the hexose complexes the "zero" K values published until now (3) by discrete numbers, showing that indeed the glucose, galactose, and mannose are complexed close to or a little below 50% at standard conditions (1 M solution of either host or guest, or both). The larger association constants obtained for the pentoses agree with the earlier reported values (3) (Table 1), within the experimental error.

The problems arising from weak complexes become much more serious with calorimetric determinations as here the measurement signal is a function of the then usually low reaction heat, and therefore susceptible to even greater error. The measurements by Danil de Namor et al. (4) were carried out with very sensitive microcalorimetric equipment and showed for the measured systems remarkably high reproducibilities and low errors. It is noteworthy, however, that their measurements were restricted to complexes with association constants above 15 M^{-1}. In view of the weak complex with glucose, we tried to measure with as high concentrations as possible, using the observation that the β-CD solubility was enhanced in the presence of glucose. Our calorimetric analysis with glucose and ß-CD was hampered by considerable error, yet demonstrates unequivocally that the formation of the glucose complex is either **endo**thermic, or has values of ΔH close to zero, in agreement with the spectroscopic measurements, and in sharp contrast to other published values (2).

With respect to the binding of different monosaccharides little more can be said other than that a better defined and useful cyclodextrin–glucose complex requires chemical modification of the cycloamylose before one can come even near the claimed (2) association constants around 400 M^{-1}. Several arguments have been put forward (3, 4) for the slightly better binding of pentoses, based on the assumption of intracavity inclusion of the sugars. While we have been able to prove intracavity inclusion for aminocyclodextrins and ribosephosphate by intermolecular NOEs (*5b*), this method is totally unsuited for the extremely weak complexes studied here, which are characterized by a multitude of rapidly exchanging conformers. One cannot even exclude the possibility that the sugars are associated *outside* the cavity, as this has been demonstrated recently by intermolecular NOEs between protons outside the CD host cavity and those of cyclohexanecarboxylate.[3]

Our molecular mechanics calculations at least demonstrate that a larger pyranose with a CH_2OH side chain can also be accommodated within the β-CD cavity (Fig. 2). Although we have not scanned systematically all possible conformations in view of the almost countless orientations,[4] the unknown role of water, and the absence of experimental constraints, it is noteworthy that a complex with the glucose outside the cavity (**OC**) yields a **smaller** calculated association energy than the intracavity complex **IC**. The gas-phase calculations yield for the intracavity complex **IC** an enthalpy 13 kJ/mol below the **OC** complex; **OC** shows four intermolecular hydrogen bonds, **IC** only one, which replaces the intramolecular glucose–hydrogen bond. The simulations suggest deformation of the CD ring. In the **OC** complex, however, the deformations seem to be larger than in the case of **IC**. Thus, at distances between the different glycosidic oxygens of 1–4 glucose, parts of the CD ring change by 0.45–0.89 Å for the **OC** case, and by 0.05–0.19 Å in the **IC** case. The concomitant strain built up during intracavity inclusion is calculated to be as large as 15 kJ/mol, and must be compensated for by large dispersion interactions, which can only materialize within the cavity.

Acid-catalyzed hydrolysis of 4-diazo-isothiochroman-3-one. Comparison with the acyclic analog and the corresponding oxygen system

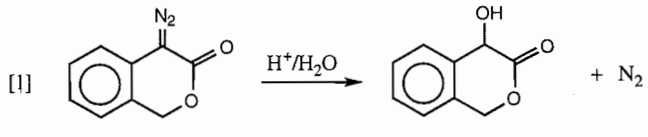
E.A. Jefferson, A.J. Kresge, and S.W. Paine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

Abstract: The acid-catalyzed hydrolysis of the cyclic diazothiolactone, 4-diazoisochroman-3-one (**3**) was found to occur with the hydronium-ion isotope effect, $k_{H^+}/k_{D^+} = 2.04$ and to give the ring-contracted product, 1,3-dihydrobenzo[*c*]thiophene-1-carboxylic acid (**4**). This shows that protonation of the diazo carbon atom occurs in the rate-determining step and that the reaction also involves migration of the thio group. The hydronium-ion catalytic coefficient for this reaction, $k_{H^+} = 4.04 \times 10^{-3}$ M^{-1} s^{-1}, is 45 times less than that for hydrolysis of its acyclic thio ester analog, *S*-methyl phenyldiazothioacetate (**5**). Semiempirical AM1 molecular orbital calculations support the idea that this difference in reactivity is the result of increased delocalization of negative charge into the aromatic ring in the case of the cyclic substrate, which reduces the negative charge on the diazo carbon atom and makes it less susceptible to protonation.

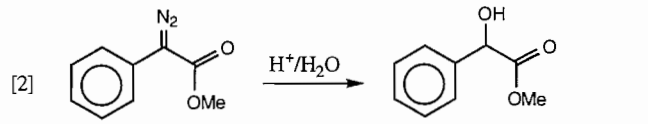
Key words: hydrolysis, diazoalkanes, charge delocalization, AM1 calculations, thio group migration.

Résumé : On a observé que l'hydrolyse acidocatalysée de la diazothiolactone, 4-diazoisochroman-3-one (**3**), se produit avec un effet isotopique de l'ion hydronium, $k_{H^+}/k_{D^+} = 2{,}04$, et conduit à un produit résultant d'une contraction de cycle, l'acide 1,3-dihydrobenzo[*c*]thiophène-1-carboxylique (**4**). Ces résultats démontrent que, dans l'étape qui détermine la vitesse de la réaction, il se produit une protonation de l'atome de carbone du diazo et que la réaction implique aussi la migration du groupe thio. Le coefficient catalytique de l'ion hydronium pour cette réaction, $k_{H^+} = 4{,}04 \times 10^{-3}$ M^{-1} s^{-1}, est 45 fois moins important que celui observé lors de l'hydrolyse du thioester acyclique analogue, le phényldiazoacétate de *S*-méthyle (**5**). Des calculs d'orbitales moléculaires semiempiriques AM1 supportent l'hypothèse d'après laquelle cette différence de réactivité résulte du fait que, dans le cas du substrat cyclique, il se produit une augmentation de la délocalisation de la charge négative par le noyau aromatique qui réduit la charge négative sur l'atome de carbone du groupe diazo et qui le rend moins susceptible à la protonation.



Mots clés : hydrolyse, diazoalcanes, délocalisation le la charge, calculs AM1, migration du groupe thio.

[Traduit par la rédaction]



Introduction

We recently reported (1) that the acid-catalyzed hydrolysis of 4-diazoisochroman-3-one, **1**, eq. [1], occurs almost two orders of magnitude more slowly than that of its acyclic analog, methylphenyldiazoacetate, **2**, eq. [2], and we were able, with the aid of semiempirical molecular orbital AM1 calculations, to attribute this difference in reactivity to enforced near-coplanarity of the diazo and phenyl groups in the cyclic substrate as opposed to a staggered arrangement of these groups in the acyclic system.

We have now extended that work to the corresponding thiolactone, 4-diazoisothiochroman-3-one, **3**, whose hydrolytic reactivity we find to be similarly decreased below that of its acyclic analog, *S*-methyl phenyldiazothioacetate, **5** (2). These sulfur systems, however, are unlike their oxygen counterparts, where, as shown in eqs. [1] and [2], hydrolysis involves simple replacement of the diazo group by hydroxyl. In the sulfur analogs, hydrolysis is accompanied by thio group migration to give the ring-contracted product, 1,3-dihydrobenzo-

Experimental section

Materials

4-Diazoisothiochroman-3-one was prepared from isothiochroman-3-one (3)[2] by a diazo transfer reaction using *p*-acetamidobenzenesulfonyl azide as the diazo transfer reagent and triethylamine as the base (4). The product, mp 49–50°C, was obtained in 51% yield. Its spectral properties are as follows: ^{1}H NMR (200 MHz, $CDCl_3$); δ/ppm: 7.40–7.01 (m, 4H, Ar), 4.19 (s, 2H, CH_2); ^{13}C NMR (50 MHz, $CDCl_3$), δ/ppm: 186.96 (C=O), 128.29 (Ar), 127.77 (Ar), 125.80 (Ar), 125.32 (Ar), 121.05 (Ar), 72.83 (C=N_2), 32.70 (CH_2); HRMS, M^+ for $C_9H_6N_2OS$, *m/e*: 190.0201 (calcd.); 190.0197 (found).

All other materials were best available commercial grades.

Kinetics

Rates of hydrolysis of 4-diazoisothiochroman-3-one were determined spectrophotometrically by monitoring the decrease in absorbance of this diazo compound at λ = 325 nm. Measurements were made at substrate concentrations of ca. 10^{-5} M using a Cary model 2200 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.05°C. The rate data fit the first-order rate law well, and observed first-order rate constants were calculated by least-squares fitting of an exponential function.

Molecular Orbital Calculations

Semiempirical AM1 (5) molecular orbital calculations were performed using the program MOPAC 93 (6) in conjunction with a Hewlett Packard 755 computer. The geometries of the singlet ground state for all molecules studied were fully optimized, and energy minima were identified as having all positive eigenvalues and all positive vibrational frequencies.

[2] ^{1}H NMR (200 MHz, $CDCl_3$), δ/ppm: 7.34–7.19 (m, 5H, Ar), 4.22 (s, 2H, CH_2S), 3.80 (s, 2H, CH_2CO).

Results

The acid-catalyzed hydrolysis of 4-diazoisothiochroman-3-one was found to give 1,3-dihydrobenzo[*c*]thiophene-1-carboxylic acid (**4**) as the sole reaction product. This was established by allowing a 10^{-4} M solution of the substrate in 0.1 M aqueous perchloric acid to stand in the dark for 48 h and then extracting the reaction mixture with ethyl acetate. Removal of the extraction solvent gave a residue whose ^{1}H NMR spectrum was identical with that of an authentic sample of the acid, prepared by hydration of the corresponding ketene, **7**, eq. [5],

[5] 

7

itself obtained by photo-Wolff rearrangement of 4-diazoisothiochroman-3-one.[3] This spectrum also showed the absence of any other substance.

Rates of hydrolysis of 4-diazoisothiochroman-3-one were measured in H_2O and D_2O solutions of perchloric acid over a range of acid concentrations. The data are summarized in Table 1. Observed first-order rate constants proved to be accurately proportional to acid concentration, and linear least-squares analysis gave the hydronium ion catalytic coefficients, $k_{H^+} = 4.04 \times 10^{-3}$ M^{-1} s^{-1} and $k_{D^+} = 1.98 \times 10^{-3}$ M^{-1} s^{-1}, whose ratio provides the kinetic isotope effect $k_{H^+}/k_{D^+} = 2.04$.

Semiempirical AM1 molecular orbital calculations were performed to obtain minimum energy structures for 4-diazoisothiochroman-3-one and *S*-methyl phenyldiazothioacetate. Two minimum energy structures were found for the latter, cor-

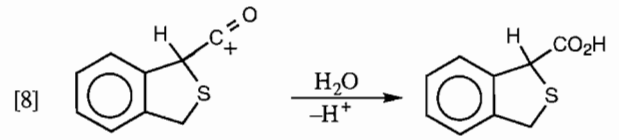
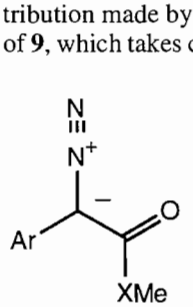
responding to s-*cis* and s-*trans* conformations about the bond connecting the diazoalkane and carbonyl groups, with the s-*cis* isomer being the more stable by 2.5 kcal mol^{-1}. Some selected results of the calculations for this isomer and the cyclic substrate are given in Table 2.



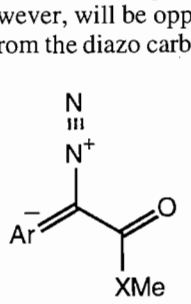
Discussion

The present work shows that the hydrolysis of 4-diazoisothiochroman-3-one is an acid-catalyzed reaction with a substantial hydronium-ion kinetic isotope effect in the normal direction: $k_{H^+}/k_{D^+} = 2.04$. This is classic evidence for rate-determining proton transfer to carbon (8), and it implies that the site of protonation by the acid catalyst in this reaction is the diazo carbon atom, eq. [6]. Another potential site for protonation is the carbonyl oxygen atom, and such a mechanism has been found to operate in the hydrolysis of some diazocarbonyl compounds (9). Proton transfer to oxygen, however, is generally fast and reversible, and that should give an inverse isotope effect, $k_{H^+}/k_{D^+} < 1$, contrary to present observation. Protonation on carbon could also be fast and reversible rather than rate determining, and there is evidence that such a mechanism operates in some cases as well (10, 11), but that too would give an inverse isotope effect. It seems clear, therefore, that the present reaction occurs by rate-determining proton transfer to the diazo carbon atom.



[6] 

In the hydrolysis of diazocompounds, proton transfer to carbon is usually followed by displacement of nitrogen by a water molecule. In the present case, however, because the sole reaction product is the ring-contracted 1,3-dibenzo[*c*]thiophene-1-carboxylic acid (eq. [3]), displacement by water must be being replaced by thio group migration. Such thio group migration had been observed before, in the hydrolysis of the acyclic analog of the present reaction (eq. [4]) (2). It was argued then that migration could be concerted with proton transfer, but it was also pointed out that such a concerted mechanism would require a rather contorted transition state in which proton transfer, migration, and leaving group departure all were occurring at the same time; a stepwise mechanism with migration taking place after proton transfer might therefore be more plausible. Such a stepwise mechanism would convert the diazonium ion formed by proton transfer, as shown in eq. [6], into an acylium ion, eq. [7], which could then be hydrated to give the final reaction product, eq. [8].



[7] 

[8] 

Comparison of the hydronium-ion catalytic coefficient for hydrolysis of 4-diazoisothiochroman-3-one determined here with that found before for the acyclic analog, *S*-methyl phenyldiazothioacetate, eq. [4] (2), shows the cyclic compound to be 45 times less reactive. This is similar to the 57-fold reduction observed before in a comparison of the rates of hydrolyses of cyclic and acyclic substrates in the corresponding oxygen series, eqs. [1] and [2] (1). It was suggested then that this rate reduction is produced by a change in the balance of contributions provided by the various resonance forms that make up the structure of these diazo compounds. The rate of reaction might be expected to increase in proportion to the importance of resonance form **8**, which puts negative charge on the carbon atom that is protonated in the rate-determining step. The contribution made by this form, however, will be opposed by that of **9**, which takes charge away from the diazo carbon atom and puts it into the aromatic group. Such charge delocalization into the aromatic group will be most efficient when the *p*-orbital of the sp^2 hybridized diazo carbon atom is parallel to the *p*-orbitals of the aromatic ring and the dihedral angle between the diazo and aromatic groups is zero. This is more likely to be the case in the cyclic substrate, whose small heterocyclic ring

8

enforces near coplanarity of the diazo and aromatic groups, than in the acyclic substrate, where steric interference between the side chain and aromatic hydrogens at the *ortho* positions encourages twisting about the diazo carbon – aromatic bond.

This argument is supported here, as it was in the oxygen series, by AM1 calculations. As the results summarized in Table 2 show, the dihedral angle between diazo and aromatic groups is considerably less for the cyclic than for the acyclic substrate, and the increased charge delocalization that this produces is reflected in a less negative charge on the diazo carbon and a more negative (less positive) charge in the aromatic group for the cyclic substrate.

Substituent effects on basicity in Group 15 compounds: an analysis based on proton affinities, charge distributions, and dipole polarizabilities

S.T. Howard, J.P. Foreman, and P.G. Edwards

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

Abstract: Ab initio calculations on a series of trisubstituted amines, phosphines, and arsines are presented at the MP2/6-311G(d,p) level. Specifically, the species studied are XH_3, XF_3, and $X(Me)_3$, where X = N, P, or As. The influence of the substituents on the proton affinity is analyzed in terms of the charge distribution, its topology, some one-electron properties (dipole moments, electric field gradients), and dipole polarizabilities. An atoms-in-molecules decomposition of the charge distribution, energetics, and polarizabilities also proves informative. There seems to be no straightforward way of rationalizing the basicities of these compounds on the basis of electrostatic properties (i.e., properties of the charge distribution in the unprotonated bases). However, substituent effects on basicities can be correlated with response properties, such as the molecular (and atoms-in-molecules) polarizability tensors, and the amount of charge that a substituent group or atom donates on protonation.

Key words: quantum chemistry, proton affinity, electron density, lone pairs, polarizability, basicity, dipole moment, electric field gradient.

Résumé : On a effectué des calculs ab initio, au niveau MP2/6-311G(d,p), sur une série d'amines, des phosphines et d'arsines trisubstituées. D'une façon spécifique, les espèces étudiées sont : XH_3, XF_3 et $X(Me)_3$ dans lesquelles X = N, P ou As. On a analysé l'influence des substituants sur l'affinité protonique en fonction de la distribution de la charge, de sa topologie, de quelques-unes de ses propriétés impliquant un électron (moments dipolaires, gradients des champs électriques) et des polarisabilités dipolaires. Une décomposition de la distribution de charge, des énergies et des polarisabilités, effectuée en fonction de la théorie des atomes dans les molécules, s'est aussi avérée utile pour fournir de l'information. Il ne semble pas y avoir de façons simples de rationaliser les basicités de ces composés sur la base des propriétés électrostatiques (c'est-à-dire des propriétés de la distribution de charge dans les bases qui ne sont pas protonées). Toutefois, on peut établir une corrélation entre les effets des substituants sur les basicités et les propriétés de réponse, telles que les tenseurs de polarisabilité moléculaire (et des atomes dans les molécules) et la quantité de charge donnée par un atome ou un groupe substituant lors de sa protonation.

Mots clés : chimie quantique, affinité protonique, densité électronique, paires libres, polarisabilité, basicité, moments dipolaires, gradient du champ électrique.

[Traduit par la rédaction]

Introduction

The concept of basicity is a cornerstone of chemistry. It has traditionally been defined in a dichotomous way: as the ability of an atom to furnish an electron pair (the Lewis definition), or as a scale based on acid–base equilibrium constants (Brønsted–Lowry definition). If these two definitions are really describing the same phenomena, then it ought to be possible to link the lone pair electron distributions in a series of related monofunctional bases, and their corresponding (thermodynamic) basicities. Some recent theoretical attempts to do just this in simple amine (1) and phosphine (2) bases have met with only limited success. Other theoretical approaches for rationalizing substituent effects on basicity utilize response functions, such as softness and hardness (3). The remaining parameter often used in predicting basicity trends, electronegativity (χ), is also effectively a response function, since Nagle has shown that atomic dipole polarizabilities (α's) and χ's are closely correlated (4).

In this work we present high-level calculations on a series of simple amines, phosphines, and arsines, looking at both electrostatic and response properties, in order to see which (if any) act as indicators for the proton affinity (PA). We also apply Bader's Atoms-In-Molecules (AIM) decomposition of the charge distribution (5) to the ground state charge distribution of the free bases, and to the α tensors (6–8). In this way it is possible to focus on the properties of the central

basic atom. This work additionally addresses the following questions:

(*i*) are the conclusions of our earlier Hartree–Fock (HF) level study on substituent effects in phosphines (2) (hereafter Paper I) still valid when correlated charge distributions are considered?

(*ii*) do similar effects operate in amines and arsines?

(*iii*) is the "chemistry" of Group 15 compounds (e.g., enthalpy changes in subsequent chemical interactions) actually reflected in the basic atom charge distribution, especially in the lone pair region?

The last point is of particular relevance to experimental, diffraction-based studies of charge distributions (9, 10), where it is widely supposed that measuring the charge distribution of a compound must give us detailed information about its chemistry.

We note that most of the amine and phosphine PAs reported here were previously known from both experiment and quantum chemical calculations, but the results for substituted arsines appear to be new. Moreover, these results are presented at a consistent (correlated) level, and include a number of properties such as polarizabilities and electric field gradients (EFGs) that are hitherto unreported.

Computational details

The geometries of NH_3, PH_3, AsH_3, NF_3, PF_3, AsF_3, NMe_3, PMe_3, $AsMe_3$, and their protonated cations were optimized at the HF level with the standard 6-31G(d,p) basis set, and subsequently using 2nd order Møller–Plesset (frozen core) perturbation theory (MP2) with the standard 6-311G(d,p) basis sets on C, H, F, N, and P. Arsenic 6-31G(d,p) and 6-311G(d,p) basis sets were taken from refs. 11 and 12, respectively. The calculations were performed using GAUSSIAN 94/DFT (13) running on a Convex C3860 supercomputer at the University of London Computing Centre. C_{3v} symmetry was assumed throughout, except for the (tetrahedral) XH^{4+} cations. Harmonic frequency calculations performed on all species at the RHF/6-31G(d,p) level verified that all optimized structures were true minima (MP2 optimized structures, starting from the HF results, were assumed to be minima). Changes in zero point energy (ZPE) on protonation are included in the computed PAs, using HF/6-31G(d,p) level frequencies scaled by a factor of 0.9 (14). Basis set superposition error was estimated using the counterpoise method (15). Molecular dipole polarizabilities were computed using the MP2/coupled perturbed Hartree–Fock technique as implemented in GAUSSIAN 94. Finite-field single-point calculations with an electric field of 0.001 au were also carried out at this level, in order to determine AIM α's based on the method of Bader et al. and Howard (6–8). EFGs at the nitrogen, phosphorus, and arsenic nuclei in the various compounds were computed at the MP2 level, and will be reported in a traceless tensor form.

The critical point (CP) analyses of $\nabla^2\rho$ were carried out using Laidig's program BUFFALO, part of the AIMPAC suite of programs (16). The program PROAIMV, also part of AIMPAC, was used to compute integrated atomic properties (energies, charges, dipoles, and α's).

Results and discussion

Structures and proton affinities (Table 1)

In both phosphines and arsines, protonation decreases the X—R bond length with the largest shortening observed in the fluoro compounds. In amines the length of the X—R bond varies on protonation according to the type of substituent present. In all compounds the R-X-R angle increases on protonation (due to loss of bond pair – lone pair repulsions), with much larger changes being observed in phosphines and arsines.

The last column of Table 1 contains a number of experimentally determined gas phase PAs. It should be noted that these experimental values are measured at 300 K (except for the NH_3 value, which is a 0 K extrapolated PA), and some are subject to substantial uncertainties. Despite this, there is generally good agreement between the theoretical and experimental values, where the latter are available.

PAs relative to XH_3 are enhanced by methyl substitution and diminished by fluorine substitution in all compounds. The reductions of PA caused by fluorination are almost twice as large as the enhancements caused by methylation. Methylation of phosphine and arsine causes significantly larger enhancements in PA than for ammonia. Fluorination causes the opposite behaviour — the largest reduction in PA is ob-

served for ammonia. These observations make sense in terms of simple ideas about hardness and softness, i.e., combination of the "hardest" acid and base (fluorine and nitrogen) causes the largest decrease in basicity; combination of the "softest" acid and base (methyl and phosphorus/arsenic) gives rise to the largest increase in basicity. The expected trend in PA down the group

$$NH_3 > PH_3 > AsH_3$$

is observed. Trends that are less predictable include

$$PF_3 > NF_3 > AsF_3$$

and

$$NMe_3 \approx PMe_3 > AsMe_3$$

(the equivalence of PMe_3 and NMe_3 PAs has been noted before by Ikuta and Kebarle (17)). The observed enhancements in basicity of methylated amines and phosphines have been discussed at length in the literature, and are neatly summarized by Ikuta and Kebarle. Qualitative concepts of polarizability and especially "group polarizability" are often invoked (quite plausibly), although we are unaware of a quantitative analysis of these effects in terms of actual α tensors. It will be shown that dipole polarizabilities may provide a basis for explaining the substituent effects on the PAs.

Charges and dipole moments (Tables 2 and 3)

In phosphine and arsine, the molecular dipole moment is enhanced by methylation. On fluorination, the dipole moment reverses polarity, which is reflected in the large changes in

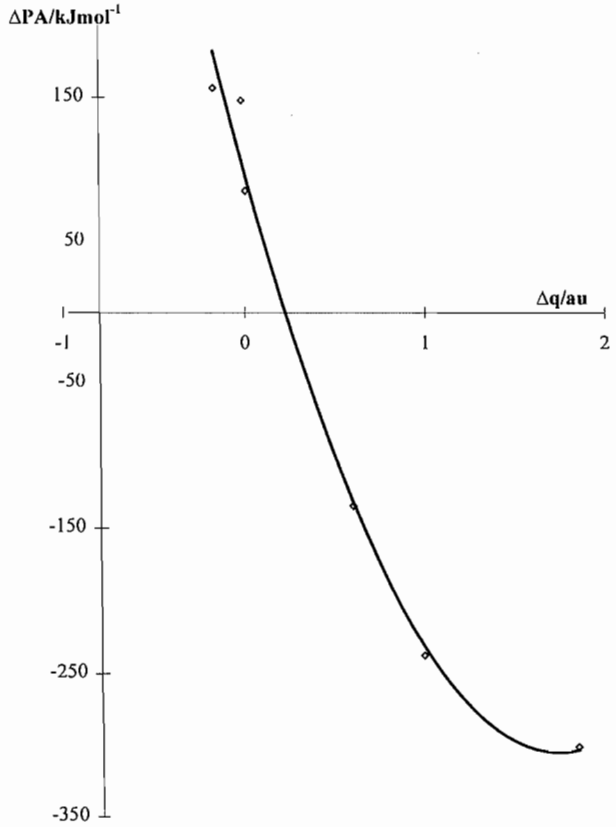
For personal use only.

magnitude (and in sign) of phosphorus and arsenic atomic charges. So, the dipole moment does show an approximate relationship with PA in these compounds.

The dipole moment of ammonia, however, is diminished on methylation, and all but disappears on fluorination. Staley and Beauchamp (18) have argued that this is due to rehybridization of the nitrogen atom on substitution, such that the lone pair "shrinks" (acquiring more *s*-type character). As can be seen in Table 3 the dipole moment of the nitrogen atom, which effectively measures how much electronic charge is located in the lone pair, is in fact larger in NMe_3 than in NH_3. The molecular dipole moment P_z can be expressed as a sum over the individual atomic charges q_i and dipoles $p_{z,i}$



$$[1] \quad P_z = \sum_i p_{z,i} + q_i \cdot z_i$$

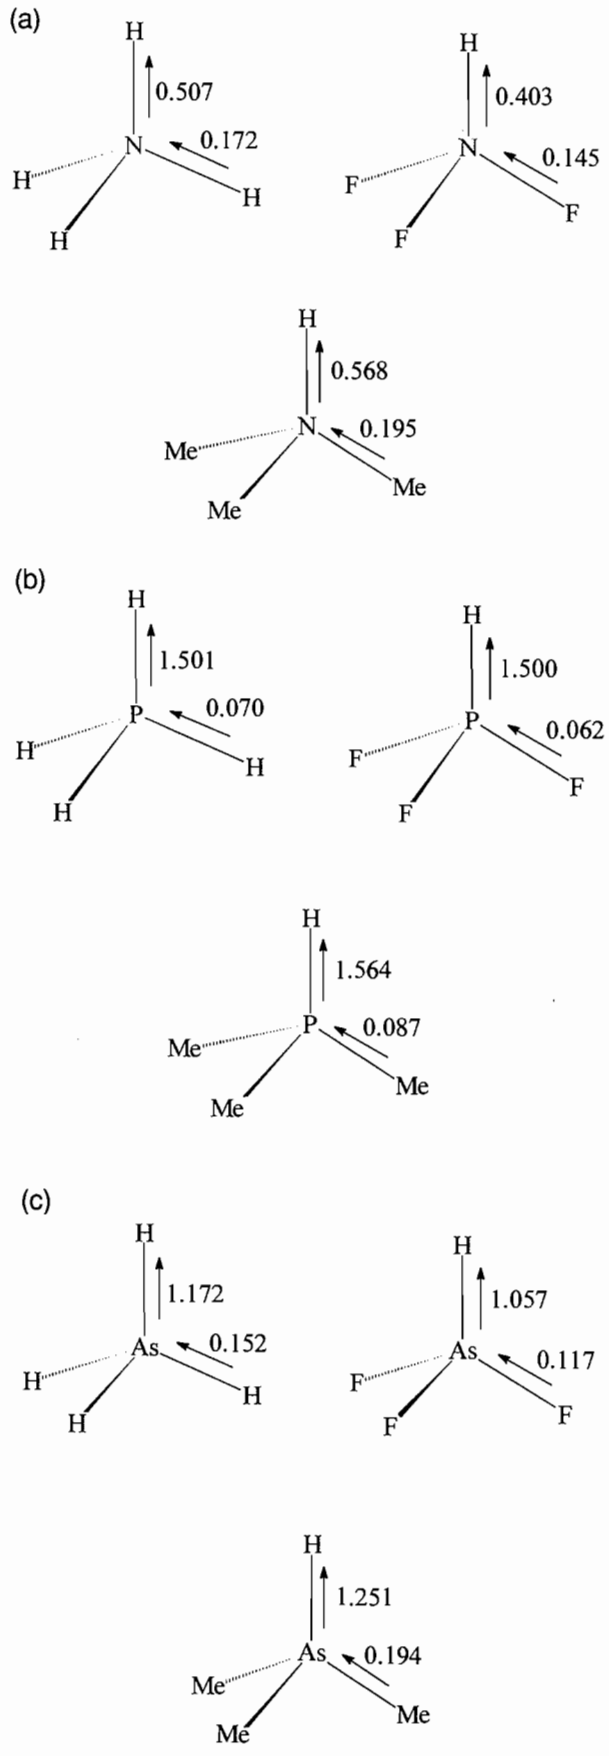
In NH_3 the contribution of the atomic dipoles to the total moment is very small (+0.15 D) compared to the charge terms (−1.89 D). In NMe_3 the atomic dipole contributions (+1.19 D) more effectively cancel the charge contribution (−1.80 D), due to the large and positive dipole polarizations of the methyl carbons and their associated hydrogens. So the arguments of Staley and Beauchamp are incorrect — it is the (intrinsic) opposing dipole polarization of the methyl groups that reduces the total dipole moment of NMe_3 relative to NH_3, rehybridization of the nitrogen having a minor effect (the nitrogens have almost identical charges and similar dipoles in NH_3 and NMe_3).

A small "methyl-inductive" effect is apparent only in the phosphine atomic charges, the charge on the basic atom remaining virtually unchanged in NMe_3 and $AsMe_3$ compared to NH_3 and AsH_3. This is in contrast to the fluoro substituted compounds where a marked withdrawing effect (relative to nitrogen in NH_3) is always observed in the basic atom charge. There appears to be a relationship between the *change* in the basic atom charge on fluorination or methylation, and the corresponding reduction/enhancement of the PA (Fig. 1). It is also true that the basic atom is always energetically destabilized by fluorination and stabilized by methylation, although the magnitudes of the energy changes do not correlate with the reduction/enhancement of the PA.

In Paper I it was observed that so-called alkyl-inductive effects were not manifest in the charge distribution of substituted phosphine bases. Instead, the enhanced PAs of alkylated species could be explained by noting that methyl groups donated more charge than hydrogen or fluorine on protonation, which has the effect of stabilizing phosphorus (it loses less charge to the added proton). Figure 2 illustrates the same analysis applied to amines, phosphines, and arsines in this work, based on the MP2 atomic charges in Table 3. Indeed, the same effects do operate in amines and arsines: on protonation, methyl groups donate more charge (and fluorine groups donate less charge) to the basic atom, than does hydrogen. This therefore provides a general basis for understanding substituent effects in Group 15 compounds. The ability of a group or atom to donate charge on chemical change is certainly linked to the density functional concepts of chemical potential, softness and hardness (19). These indices have as their basis the relationship between total energy and changes in *electronic* population (i.e., $\delta E/\delta N$). In practice, the softness or hardness tensor for a molecule is computed in a finite difference approximation using the changes in atomic populations between the associated (open shell) anion and cation ($\delta N = 2$). Since protonation changes only the total nuclear charge of the system ($\delta N = 0$), the information contained in Fig. 2 would complement an analysis based on chemical potential equalization, i.e., this represents a distinct approach.

Fig. 1. Relationship between the change in PA on methylation/fluorination, and the change in basic atom net charge (MP2 level).

The basic atom dipole moment is slightly enhanced by methylation in amines and arsines, and more significantly enhanced by fluorination. This reflects the increase in lone pair electron density (verified by the analysis of $\nabla^2\rho$ reported in the next section) accompanying both methylation and fluorination, first noted for phosphines in Paper I. Curiously, in the phosphine compounds the phosphorus atomic dipole varies very little with substituent, even for fluorination.



Dipole polarizabilities (Tables 2 and 3)

In every case, methylation enhances the (lone-pair directed) α_{zz} component of the (total) α, and fluorination diminishes it. So this is a physical property that reflects substituent effects on basicity across all the compounds. It must be noted, however, that the difference in α_{zz} between NH_3 and NF_3 is sufficiently small that it could disappear at a higher level of theory. The α_{xx} component behaves similarly in the phosphines and arsines, but fails to reflect substituent effects in the same way as α_{zz} for the amines.

Fig. 2. Charge flow upon protonation (MP2 level).

At the atomic level, α_{zz} for the basic atom also reflects electron-withdrawing and -donating substituent effects quite well in the phosphines and arsines, but this breaks down for the amines, where both methylation and fluorination decrease α_{zz}. The α_{xx} component bears no relationship to substituent effects on basicity.

It should be pointed out that AIM α's are necessarily origin dependent, because of the finite charge transfer term (8). The AIM α's reported here are based only on the response of the basic atom's dipole moment to an applied field, i.e., the charge transfer term has been ignored (equivalently, the basic atom has been translated to the origin). The charge transfer terms obtained in the finite field calculations appeared to be unrelated to the substituent effects on the PA, so they are not reported.

Electric field gradients (Table 2)

There appear to be no previously reported studies on the relationship between EFGs of Group 15 atoms and basicity. This parameter, obtainable from nuclear quadrupole resonance spectroscopy, is known to be closely linked with the LP distribution of electrons in amines (20–22). Hence it is feasible that EFGs evaluated at the basic atom nuclei might reflect substituent effects on PA's.

In all cases, E_{xx} of the basic atom (X) in the XMe_3 compounds are more negative than in the corresponding XH_3 compounds. Fluorination causes even larger negative shifts in the E_{xx} of X, relative to its value in XH_3. Consequently, these EFGs don't correlate with substituent effects on the PAs. The E_{zz} (lone pair directed) components similarly fail to reflect substituent effects on the PAs, since both methylation and fluorination cause positive shifts relative to the E_{zz} values in XH_3.

Lone pair analyses (Table 4)

The electronic shell structure of atoms is revealed by $-\nabla^2\rho$: local maxima in $-\nabla^2\rho$ effectively locate lone pairs (LPs) and bonded pairs (BPs) of electrons (23–25). In Paper I it was shown that both electron-donating and -withdrawing substituents on phosphorus appear to increase the electron density in the LP region, so such LP properties do not correctly indicate substituent effects on PAs of phosphines. The values of ρ_c and $|\nabla^2\rho_c|$ reported in Table 4 verify that the same is true for amines and arsines — either methylation or fluorination produces an increase in the density and concentration of density at the LP centroid in amines and arsines, as well as phosphines. The HF results in Paper I for phosphines are borne out at the MP2 correlated level.

The analysis of the basic atom dipole moment in the previous section indicated that it may be misleading to characterize the LP by only monitoring its properties at the local maximum in $-\nabla^2\rho$. The Hessian eigenvalues $\{\mu_i\}$ of $-\nabla^2\rho$ at this point contain information on the shape of the LP (see Table 4). All three eigenvalues are necessarily negative: the most negative eigenvalue μ_3 corresponds to the curvature of $\nabla^2\rho$ along the C_3 axis. Taking the *product* of these eigenvalues provides a possible measure of the LP effective volume. However, since all three eigenvalues are increased in magnitude by substitution of an electron-withdrawing *or* -donating group/atom, it is evident that this product also fails to correlate with substituent effects on basicity.

[a] r_c is the distance from the basic atom nucleus to the lone pair CP.

$-\nabla^2\rho$ Distributions (Figs. 3*a*–3*i*)

Figures 3*a*–3*i* show the $-\nabla^2\rho$ distribution in a mirror plane, so each map represents a section through the LP critical point. The LP is seen as a charge concentration adjacent to the basic atom nucleus. The width of the valence shell of charge concentration (VSCC) along the direction from the basic atom nucleus through the LP centroid provides another way of estimating the LP effective volume, and it contradicts the previous LP volume measure considered earlier. Methylation or fluorination clearly increases the LP radial extent in the substituted amines and arsines (the expansion is less obvious for phosphines). This is in agreement with the atomic dipole moment analysis for the basic atom that we discussed earlier, where only phosphorus fails to register an increase on fluorination or methylation. So the $\{\mu_i\}$ are only indicative of the LP distribution of charge very near to the LP centroid, and do not accurately reflect the size of the LP region.

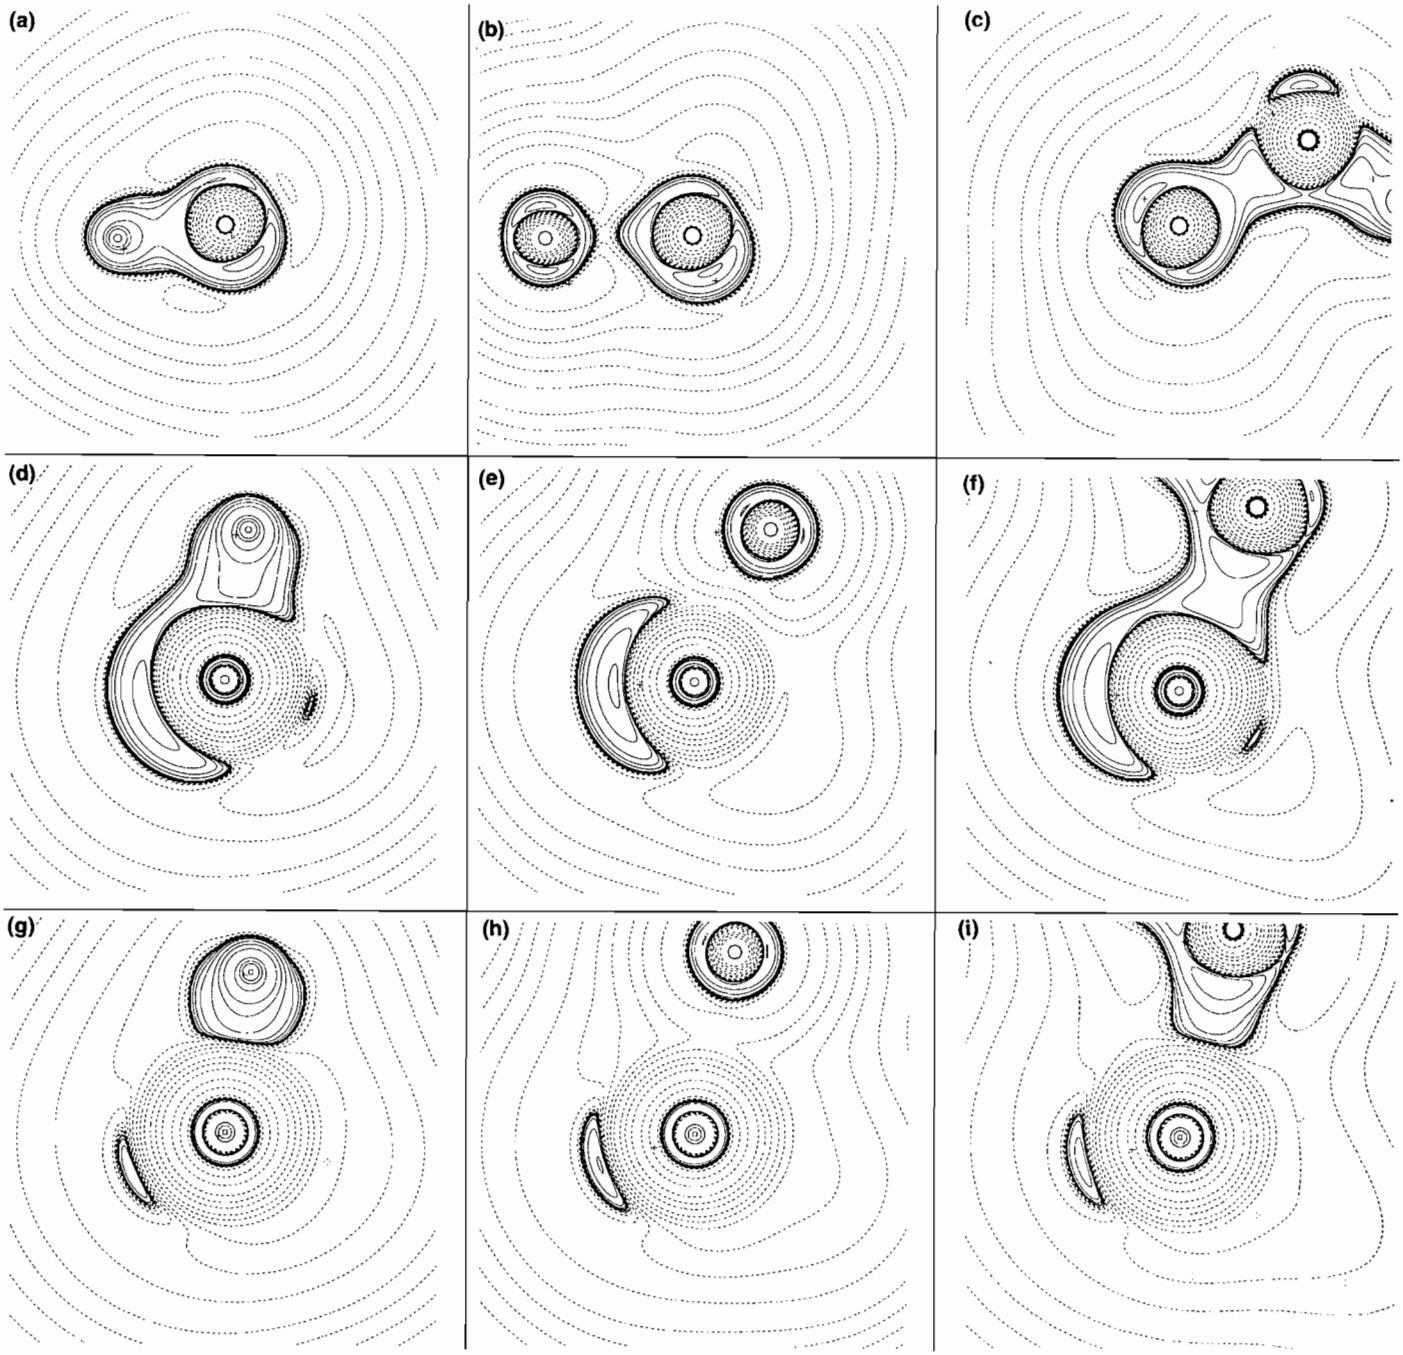
These maps computed at the MP2 level show the same polarization of the charge distribution in the bonds of NH_3 versus NF_3 and PH_3 versus PF_3 shown previously at the HF level (23). The $-\nabla^2\rho$ distribution in AsF_3 (Fig. 3*h*) similarly indicates substantial ionic character of these bonds. It is also noteworthy that the arsenic LP regions are much thinner in radial extent than those of nitrogen or phosphorus.

Conclusions

It seems that there is no electrostatic property (i.e., a property derived from the charge distribution of the unprotonated bases) that can act as a consistent indicator for substituent effects on basicity in amines, phosphines, and arsines. Changes in molecular dipole moments on substitution of hydrogen by Me or F correlate with substituent effects on proton affinities in phosphines and arsines, but not in amines. Looking at the atomic level does not help, since the basic atom dipole moment magnitude is enhanced by either methylation *or* fluorination in amines and arsines, and is reduced (slightly) by both substituents in phosphines. Other properties, such as the electric field gradient at the basic atom nucleus, show similar behaviour.

The α_{zz} component of the molecular dipole polarizability tensor seems to be the only physical property that follows substituent effects on the proton affinities of Group 15 compounds. Even in this case, it is a very "nonlinear" indicator, e.g., methylation of NH_3 increases its proton affinity and α_{zz} by 10% and ≈400%, respectively; fluorination causes corresponding decreases of 35% and 3%. Again, looking at the atomic level seems to be even less helpful in this case, since in amines the atomic dipole polarizability of nitrogen in both NF_3 *and* NMe_3 is lower than in NH_3.

The atoms-in-molecules analysis does reveal that *changes* in atomic charges and energies on protonation are clearly linked to substituent effects on basicity. Similar conclusions were reached in previous Hartree–Fock level studies on amines and alcohols (26), carbocations (27), and phosphines (2). Both the change in charge of the basic atom X, and the flow of charge $\Delta Q(Y)$ from Y→X on protonation of XY_3, correlate with the changes in basicity for a given Group 15 atom, i.e.,



$$\Delta Q(\text{Me}) > \Delta Q(\text{H}) > \Delta Q(\text{F})$$

On the face of it, this just reflects what we might have predicted on the basis of atomic/group electronegativity differences. Although the concept of charge flow on chemical bond formation is behind most χ scales, the χ values for an atom or group (Y) have always been based on indirect information, such as the mean of the atomic ionization energy and electron affinity, or the distance from Y to the bond critical point in YH (28). Looking at the charge flow on protonation, ΔQ is clearly a more direct way of analyzing substituent effects, and it differs in an important conceptual sense. Definitions of χ are invariably based on either properties of the associated free atom, or on the value of some theoretical/physical property of the atom in various compounds. ΔQ values as defined here measure how the charge distribution of an anisotropic atom Y bonded in a molecule is modified when the compound undergoes a subsequent chemical interaction (protonation). A systematic study of ΔQ values at a suitably high level of theory could therefore provide a valuable set of data

for interpretation and prediction of substituent effects on basicity.

Three ways of characterizing the size and amount of charge in the lone pair region were considered: (*i*) atomic dipole moment; (*ii*) ρ and $\nabla^2\rho$ at the lone pair centroid; (*iii*) the physical extent of the valence shell of charge concentration. All three methods agree that both withdrawing and donating substituents act to increase the charge density, the concentration of charge density, and the overall size of the lone pair in amines and arsines. (In phosphines, (*i*) and (*iii*) register only very small changes on substitution, which nevertheless do not fit in with this trend, while (*ii*) does behave as in amines and arsines.) So the phenomenon first reported for phosphines in ref. 2 occurs in general in Group 15 compounds. This enables us to generalize the main conclusion of the phosphine study — it is the ability (inability) of the methyl (fluoro)

group to donate charge *on protonation* which accounts for donating (withdrawing) substituent effects on proton affinities of trivalent Group 15 compounds. This contrasts with the essentially anecdotal belief that substituent effects on basicity in such compounds are due to a corresponding enhancement/depletion of density in the basic atom's lone pair.

This is an important point for experimental studies of charge densities. It tells us that the distribution of density in the lone pair region of an atom, even if it can be measured accurately, tells us little or nothing about the compound's basicity. It might be thought that these results reveal the Lewis concept of basicity as fundamentally incorrect, but that isn't necessarily the case. Lewis's definition refers to an atom's "ability to furnish a lone pair." If we read this as a dynamical statement about *how the lone pair atom modifies its charge distribution* when it bonds to a proton, or coordinates to a metallic centre, then there is nothing in these findings that contradicts Lewis's definition of basicity. If Lewis's definition has a failing, it is perhaps that it appears to identify basicity as an intrinsic lone pair property. It is evident from these results that basicity is only rationalized by looking at the response to the perturbation on a molecular scale.

Abstract: The C-3—C-9 main fragment of aspicilin was prepared via a fructose 1,6-diphosphate aldolase reaction. The same fragment was also synthesized by chemical transformation starting from D-arabinose.

Key words: aldolase, aspicilin, arabinose, synthesis.

Résumé : Le fragment principal (C-3 à C-9) de l'aspiciline a été préparé via une réaction de l'aldolase du fructose 1,6-diphosphate. Le même fragment a été obtenu par une série de réactions non-enzymatiques à partir du D-arabinose.

Mots clés : aldolase, aspiciline, arabinose, synthèse.

Introduction

The development of methods for stereoselective C—C bond formation using the aldol reaction is a major focus of interest in organic synthesis. Both chemical (1) and enzymatic (2) aldol reactions with high level of asymmetric induction have recently been developed. The use of aldolases in the synthesis of carbohydrates and close analogs (azasugars, cyclitols) has been amply demonstrated (2, 3). However, the application of aldolases for the synthesis of natural products other than sugars has received very little attention. The synthesis of brevicomin, an insect pheromone, represents a rare example of this strategy (4). More recently, Shimagaki et al. (5) reported the synthesis of the C-11—C-16 fragment of pentamycin using an aldolase catalyzed reaction as the key step. The most prominent and easily available representative of these enzymes is fructose-1,6-diphosphate aldolase (FDP aldolase). This aldolase catalyzes the reversible aldol reaction of dihydroxyacetone phosphate (DHAP) and a broad range of aldehydes with the formation of a C—C bond having the D-*threo* (3*S*, 4*R*) configuration.

In this paper, we describe a FDP aldolase catalyzed stereoselective C—C bond formation leading to the main (C-3—C-9) fragment of (+)-aspicilin. (+)-Aspicilin (**1**) is a 18-membered lactone isolated from the lichen *Aspicilia gibbosa* (6). Several different nonenzymatic approaches for the synthesis of (−) or (+)-aspicilin have been reported (7).

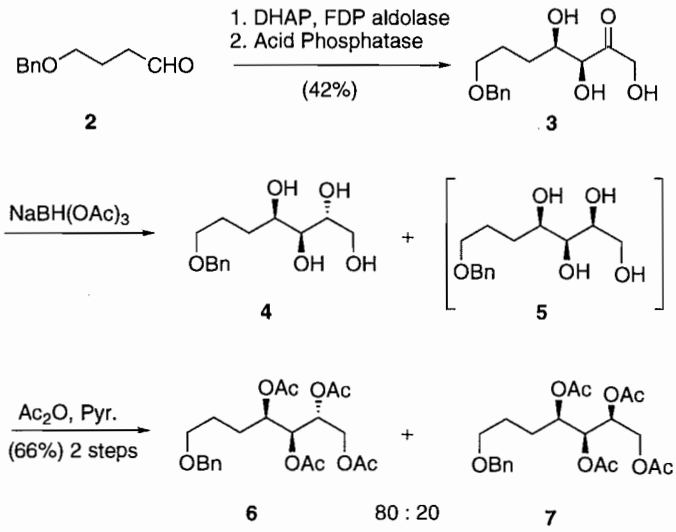
Results and discussion



The reaction of aldehyde **2** (7*c*) with DHAP in the presence of FDP aldolase in water/DMF (10/1), followed by hydrolysis in situ of the intermediate phosphate ester with acid phosphatase, afforded ketotriol **3** in 42% overall yield (Scheme 1). Ketotriol **3** was reduced by using a variety of reagents and conditions. Sodium or lithium borohydride gave low diastereoselectivity. Evans et al. (8) reported that reduction of acyclic β-hydroxyketones with tetramethylammonium triacetoxyborohydride consistently affords 1,3-*anti* diols with high diastereoselectivity. The proposed mechanism involves a ligand exchange of acetate for substrate alcohol by the triacetoxyborohydride; the resultant intermediate, presumably an alkoxydiacetoxyborohydride, reduces the ketone by intramolecular hydride delivery (8). Reduction of **3** with triacetoxyborohydrides gave the desired 1,3-*anti* diastereoisomer **4** as the dominant product along with some 1,3–*syn* diastereoisomer **5** (1,3-*anti* **4**/1,3-*syn* **5** ~ 4/1). The separation of these diastereoisomers by flash chromatography provided the desired *anti*-**4** in a pure form but the minor *syn*-**5** isomer was still contaminated. A sample of the mixture **4**–**5** was acylated by acetic anhydride in pyridine in the presence of 4-dimethylaminopyridine (DMAP) and the resulting diastereomeric esters **6**–**7** were separated by flash chromatography. The nature of the triacetoxy borohydrides (sodium or tetramethylammonium triacetoxyborohydride, tetramethylammonium borohydride in acetic acid) did not significantly affect the stereoselectivity of this reduction. The lower diastereoselectivity of our reduction reaction can be explained by the presence of three additional oxygen atoms interfering with the formation of the intermediate alkoxydiacetoxyborohydride. Presumably, several directed reduction reactions compete with opposite stereochemical preferences.

Compounds **4** and **6** are presumed to have the 2*R*,3*S*,4*R* absolute configuration. To prove this configuration beyond any doubt, we synthesized authentic (2*R*,3*S*,4*R*)-**4** and -**6** by chemical transformation starting from D-arabinose (Scheme 2).

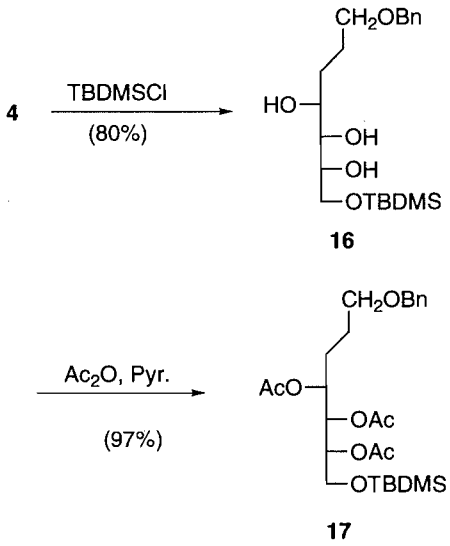
Scheme 2.

Scheme 3.



D-Arabinose was transformed into di-*O*-isopropylidene-D-arabinose **8** in a three-step sequence according to known procedures (9). The Wittig reaction of **8** with (carbomethoxymethylene)triphenylphosphorane in benzene afforded **9** as a mixture in which the *trans* isomer was predominant (*E*/*Z* ratio = 6). Catalytic hydrogenation of ester mixture **9** furnished the dihydro derivative **10**. Ester **10** was reduced with $LiAlH_4$ in ether to afford alcohol **11**. Alcohol **11** was benzylated with benzyl bromide in the presence of NaH to give **12**. Deprotection of isopropylidenes in **12** was achieved satisfactorily using acidic resin in water at 60°C to give tetraol **4**. A sample of tetraol **4** was acetylated with acetic anhydride in pyridine in the presence of DMAP. Compounds **4** and **6** prepared from D-arabinose were identical in all respects with the samples obtained via the enzymatic addition–reduction sequence. This correlation proved that the aldolase catalyzed reaction provided an addition product with a 3*S*,4*R* configuration and that the subsequent reduction gave the 2*R*,3*S*,4*R* tetraol **4** as the major product.

Compound **15** corresponding to the C-3—C-9 fragment of aspicilin was easily prepared in a few steps from tetraol **4** (from the enzymatic condensation) or from **12** (from arabinose). Compound **4** was treated with dimethoxypropane in acidic medium to give **12** (Scheme 3). Selective deprotection of **12** was achieved by treatment with methanol in the presence of an acidic resin (Dowex 50W-X8) (10). The primary alcohol of **13** was selectively acylated with acetyl chloride in the presence of collidine at −78°C in CH_2Cl_2 (11). Mono-alcohol **14** was converted into the corresponding 2-methoxyethoxymethyl (MEM) ether **15** in high yield by reaction with MEMCl in the presence of *N*,*N*-diisopropylethylamine (DiPEA). This sequence constitutes a formal synthesis of aspicilin since the transformation of **15** into aspicilin has been reported by Solladié et al. (7*c*).

Compound **4** has also been transformed in two steps into **17**, another compound corresponding to the C-3—C-9 fragment of aspicilin with orthogonal protection (Scheme 4). The primary alcohol of **4** was selectively protected by reaction with

Scheme 4.

tert-butyldimethylsilyl chloride (TBDMSCl) followed by acylation of the remaining alcohol functionalities in compound **16** with acetic anhydride.

In conclusion, we have completed a formal synthesis of (+)-aspicilin via an aldolase-catalyzed condensation. The main C-3—C-9 fragment was obtained in six steps and 10% overall yield. The same fragment was also prepared from D-arabinose in 10 steps and 22% overall yield. The synthesis of this fragment from D-arabinose not only provides unambiguous establishment of the relative and absolute stereochemistry of the intermediate but also provides an alternative pathway for the formal synthesis of (+)-aspicilin. The present work demonstrates that the aldolase-catalyzed condensation is an efficient process in the asymmetric synthesis of natural products other than carbohydrates. Applications of this strategy for the stereospecific synthesis of other non-carbohydrate natural products are underway.

Experimental section

Aldolase (D-fructose-1,6–biphosphate-D-glyceraldehyde-3-phosphate-lyase; EC 4.1.2.13, from rabbit muscle) and acid phosphatase (from wheat germ, EC 3.1.3.2) were purchased from Sigma Chem. Co. Melting points are uncorrected. NMR spectra were recorded at 300 MHz (^{1}H), 75.44 MHz (^{13}C).

(3*S*,4*R*)-7-Benzyloxy-1,3,4-trihydroxyheptan-2-one (3)
Aldehyde **2** (166.2 mg, 0.94 mmol) was added to a solution of DHAP (12) (180.0 mg, 1.06 mmol) in 10 mL of water containing 10% DMF under nitrogen atmosphere and the pH was adjusted to 6.8 with 1 N NaOH. Aldolase was added (8.6 mg, 102 U) and the mixture was shaken at room temperature. After 24 h, the pH was readjusted to 6.8, additional aldolase (7.8 mg, 92 U) and DHAP (98 mg, 0.58 mmol) were added, and the mixture was stirred for another 45 h. The pH was then set at 4.8 with 1 N HCl, the acid phosphatase (40 mg, 16 U) was added, and the mixture was stirred at room temperature for 12 h. Additional phosphatase (40 mg, 16 U) was added and the mixture was stirred for 12 h. The pH was then raised to 7 with 1 N NaOH. The solution was freeze-dried, the residue was taken up in ethyl acetate, and the solution was filtered and evaporated. The crude product was purified by flash chromatography on silica gel (CH_2Cl_2/MeOH, 19:1 as eluant) to afford **3** as an oil (106 mg, 42%). $[\alpha]_D^{23}$ +14.0 (*c* 3.1, $CHCl_3$); IR (neat): 3650–3000, 2980–2800, 1720, 1490, 1140–1000 cm^{-1}; ^{1}H NMR ($CDCl_3$): 7.31 (m, 5H), 4.51 (d, J = 19 Hz, 1H), 4.48 (s, 2H), 4.34 (d, J = 19 Hz, 1H), 4.14 (s, 1H), 3.91 (m, 1H), 3.89 (br s, 3H), 3.71 (m, 2H), 1.59–1.71 (m, 4H); ^{13}C NMR ($CDCl_3$): 211.87, 137.70, 128.37, 127.73, 77.82, 72.98, 72.03, 70.12, 66.56, 30.47, 26.05. MS (CI, isobutane) *m/e* (rel. intensity): 269 (MH^+, 25), 91 (100).

(2*R*,3*S*,4*R*)-7-Benzyloxy-1,2,3,4-tetrahydroxyheptane (4)
To a solution of sodium triacetoxyborohydride (127 mg, 0.60 mmol) in anhydrous acetic acid (4 mL) at 10°C was added dropwise a solution of **3** (40 mg, 0.15 mmol) in acetic acid (10 mL). The solution was stirred for 3 h at 10°C. Ice water (5 mL) was added and the solvent were eliminated by freeze-drying. Flash chromatography on silica gel (CH_2Cl_2/MeOH, 9:1) gave diastereoisomer **4** (24.4 mg, 60%) as a white solid along with a fraction of impure **5**. Compound **4**: mp 114.5–115.5°C (recrystallized from AcOEt:EtOH, 9/1); $[\alpha]_D^{23}$ +5.9 (*c* 0.7, MeOH); IR (neat): 3300–3600, 3000–3100, 2850–2990, 1100–1300 cm^{-1}; ^{1}H NMR (CD_3OD): 7.31 (m, 5H), 4.55 (s, 2H), 3.58–3.83 (m, 6H), 3.4 (dd, J_1 = 8.0 Hz, J_2 = 2.2 Hz, 1H), 1.5–1.8 (m, 4H); ^{13}C NMR (CD_3OD): 129.44, 128.96, 128.72, 74.71, 73.96, 73.28, 71.56, 71.41, 65.16, 31.46, 27.93. MS (CI, isobutane) *m/e* (rel. intensity): 271 (MH^+, 17.5), 145 (100). Anal. calcd. for $C_{14}H_{22}O_5$: C 62.20, H 8.20; found: C 62.22, H 8.39.

(2*R*,3*S*,4*R*) and (2*S*,3*S*,4*R*)-7-Benzyloxy-1,2,3,4-tetraacetoxyheptane (6 and 7)
The crude reduction product (40 mg, 0.15 mmol, mixture of **4** and **5**), DMAP (10 mg), and acetic anhydride (2 mL) were dissolved in pyridine (4 mL) and the solution was stirred for 36 h at room temperature. CH_2Cl_2 (75 mL) was added and the resulting organic layer was washed with 1 N HCl (3 × 30 mL), saturated aqueous $NaHCO_3$ (2 × 30 mL), brine (2 × 30 mL), and then dried over $MgSO_4$ and evaporated. Flash chromatography on silica gel (ether/petroleum ether, 3:2) gave diastereoisomer **6** (34 mg) and diastereoisomer **7** (9 mg). Total yield: 66%; compound **6**: mp 50–51°C; $[\alpha]_D$ + 13.8 (*c* 0.8, $CHCl_3$); IR (neat): 2990–3100, 2850–2980, 1740, 1490, 1100–1300 cm^{-1}; ^{1}H NMR ($CDCl_3$): 7.31 (m, 5H), 5.31 (dd, J_1 = 8 Hz, J_2 = 3 Hz, 1H), 5.17–5.25 (m, 2H), 4.47 (s, 2H), 4.24 (dd, J_1 = 12 Hz, J_2 = 3 Hz, 1H), 4.13 (dd, J_1 = 12 Hz, J_2 = 6 Hz, 1H), 3.46 (m, 2H), 2.11 (s, 3H), 2.04 (s, 9H), 1.61 (m, 4H); ^{13}C NMR ($CDCl_3$): 170.59, 170.39, 169.91, 169.82, 138.48, 128.35, 127.58, 72.83, 70.41, 69.51, 68.48, 61.97, 27.69, 25.50, 20.82, 20.68, 20.62. MS (CI, isobutane) *m/e* (rel. intensity): 439 (MH^+, 41), 289 (72), 229 (100). Anal. calcd. for $C_{22}H_{30}O_9$: C 60.26, H 6.89; found: C 60.44, H 6.90.

Diastereoisomer **7**: $[\alpha]_D^{23}$ +6.4 (*c* 0.4, $CHCl_3$); IR (neat): 3100–2990, 2850–2980, 1740, 1490, 1100–1300 cm^{-1}; ^{1}H NMR ($CDCl_3$): 7.32 (m, 5H), 5.30 (m, 3H), 4.48 (s, 2H), 4.35 (dd, J_1 = 12 Hz, J_2 = 6 Hz, 1H), 3.50 (m, 2H), 2.05 (m, 12H), 1.70 (m, 4H); ^{13}C NMR ($CDCl_3$): 170.15, 169.82, 138.27, 128.23, 127.55, 127.48, 72.78, 71.33, 69.44, 69.34, 61.85, 27.43, 25.16, 20.73, 20.57, 20.48, 20.23. MS (CI, isobutane)

m/e (rel. intensity): 439 (MH^+, 64), 229 (100); Anal. calcd. for $C_{22}H_{30}O_9$: C 60.26, H 6.89; found: C 60.30, H 7.11.

Methyl 2,3-dideoxy-4,5:6,7-di-O-isopropylidene-D-*arabino*-hept-2-enoate (9)

A solution of aldehyde **8** (1.730 g, 7.513 mmol) and carbomethoxymethylene triphenyl phosphorane (2.782 g, 8.32 mmol) in benzene (30 mL) was refluxed for 3 h. The solvent was evaporated and the crude product was purified by flash chromatography on silica gel (ethyl acetate/hexane 1:4) to give **9** as an oil (1.92 g, 89%). This compound was a *trans*/*cis* (6:1) mixture. *trans*-**9**: $[\alpha]_D^{25}$ −1.27 (*c* 2.62, $CHCl_3$) (lit. (13, 14) $[\alpha]_D^{19}$ −1.1 (*c* 3.0, ethanol); IR (neat): 2850–3000, 1735, 1660, 1375, 1385, 1000–1300 cm^{-1}; ^1H NMR ($CDCl_3$): 6.94 (dd, J_1 = 15.5 Hz, J_2 = 4.5 Hz, 1H), 6.1 (dd, J_1 = 15.5 Hz, J_2 = 1.6 Hz, 1H), 4.46 (m, 1H), 4.05 (m, 2H), 3.90 (m, 1H), 3.68 (s, 3H), 3.60 (t, *J* = 7.7 Hz, 1H), 1.35 (s, 3H), 1.33 (s, 6H), 1.27 (s, 3H); ^{13}C NMR ($CDCl_3$): 166.48, 145.17, 120.86, 110.12, 109.71, 81.06, 78.79, 77.30, 67.37, 51.45, 26.79, 26.57, 26.52, 25,02.

Methyl 2,3-dideoxy-4,5:6,7-di-*O*-isopropylidene-D-*arabino*-heptonate (10)

The *cis*/*trans* mixture of olefin **9** (600 mg, 2.1 mmol) was subjected to hydrogenation (18 h) at a 40 psi pressure (1 psi = 6.8-kPa) and room temperature in the presence of Pd/C (60 mg) in EtOH (30 mL). The suspension was then filtered and the solvent evaporated. The crude product was purified by flash chromatography (ethyl acetate/hexane 1:4) to give **10** (580 mg, 96%) as an oil; $[\alpha]_D^{23}$ +16.5 (*c* 2, $CHCl_3$); IR (neat): 3000–2850, 1730, 1300–1000, 1380, 1370 cm^{-1}; ^1H NMR ($CDCl_3$): 4.10 (dd, J_1 = 8.1 Hz, J_2 = 5.9 Hz, 1H), 3.95 (m, 1H), 3.89 (m, 2H), 3.64 (s, 3H), 3.52 (t, *J* = 7.7 Hz, 1H), 2.48 (m, 2H), 2.08 (m, 1H), 1.84 (m, 1H), 1.37 (s, 3H), 1.33 (s, 3H), 1.31 (s, 3H), 1.30 (s, 3H); ^{13}C NMR ($CDCl_3$): 173.71, 109.61, 109.03, 81.09, 79.45, 67.74, 51.50, 30.49, 28.81, 27.24, 26.98, 26.70, 25.27. MS (CI, isobutane) *m/e* (rel. intensity): 289 (MH^+, 16), 231 (100), 129 (70).

5,6-Dideoxy-1,2:3,4-di-*O*-isopropylidene-D-*lyxo*-heptitol (11)

To a suspension of $LiAlH_4$ (80 mg, 2.1 mmol) in 10 mL of ether was added dropwise a solution of ester **10** (1.32 mmol) in 5 mL of ether at 0°C. The mixture was stirred for 0.5 h at 0°C, then for 14 h at room temperature under dry atmosphere. The resulting mixture was cooled at 0°C and quenched with 1 N HCl (2 mL). Ether (50 mL) was added and the layers were separated. The organic layer was washed with water (1 × 25 mL), saturated aqueous $NaHCO_3$ (1 × 25 mL), and brine (2 × 25 mL), dried over $MgSO_4$ and concentrated. The residue was then purified by flash chromatography (ethyl acetate/hexane, 3:7) to afford alcool **11** (310 mg, 90%) as an oil; $[\alpha]_D^{25}$ +13.7 (*c* 2.1, $CHCl_3$); IR (neat): 3500–3000, 3000–2800, 1373, 1380 cm^{-1}; ^1H NMR ($CDCl_3$): 4.10 (dd, J_1 = 8 Hz, J_2 = 6 Hz, 1H), 4.00 (m, 1H), 3.93 (m, 2H), 3.64 (m, 2H), 3.52 (t, *J* = 7.7 Hz, 1H), 2.48 (br s, 1H), 1.9 (m, 1H), 1.72 (m, 2H), 1.58 (m, 1H), 1.37 (s, 3H), 1.36 (s, 3H), 1.32 (s, 3H), 1.31 (s, 3H); ^{13}C NMR ($CDCl_3$): 109.49, 108.75, 81.03, 80.28, 77.33, 67.57, 62.46, 30.13, 29.27, 27.14, 26.82, 26.53, 25.12. MS (CI, isobutane) *m/e* (rel. intensity): 261 (MH^+, 10), 203 (90), 145 (100).

7-*O*-Benzyl-5,6-dideoxy-1,2:3,4-di-*O*-isopropylidene-D-*lyxo*-heptitol (12)

To a suspension of NaH (36 mg, 1.5 mmol) in dry THF (2 mL) at 0°C and under dry nitrogen atmosphere was added dropwise a solution of **11** (260 mg, 1.00 mmol) in THF (20 mL). The mixture was stirred for 20 min at 0°C and then benzylbromide (256.5 mg, 1.5 mmol) and a catalytic amount (2 mg) of Bu_4NI were added. The mixture was stirred for 30 min at 0°C and then for 24 h at room temperature. The mixture was then filtered through Celite and the filtrate was evaporated. The residue was taken up by EtOAc (40 mL) and this organic phase was washed with water (2 × 15 mL), dried over $MgSO_4$, and evaporated. Flash chromatography on silica gel (EtOAc/hexane, 1:9) gave **12** (311 mg, 89%) as a colorless oil; $[\alpha]_D^{23}$ +13.9 (*c* 2.03, $CHCl_3$); IR (neat): 3000–3100, 2900–3000, 1380, 1370 cm^{-1}; ^1H NMR ($CDCl_3$): 7.33 (m, 5H), 4.52 (s, 2H), 4.11 (dd, J_1 = 7.65 Hz, J_2 = 5.85 Hz, 1H), 4.06 (m, 1H), 3.92 (m, 2H), 3.56 (m, 3H), 1.83 (m, 2H), 1.75 (m, 1H), 1.62 (m, 1H), 1.39 (s, 3H), 1.38 (s, 3H), 1.34 (s, 6H); ^{13}C NMR ($CDCl_3$): 138.73, 128.32, 127.55, 127.46, 109.55, 108.82, 81.33, 80.25, 76.61, 72.95, 70.13, 67.68, 30.29, 27.41, 27.06, 26.73, 26.18, 25.35; MS (CI, isobutane) *m/e* (rel. intensity): 351 (MH^+, 20), 293 (100), 185 (82.5).

Preparation of 4 from 12

A suspension of **12** (200 mg, 0.57 mmol) in water (10 mL) was stirred for 18 h at 60°C in the presence of an acidic Dowex 50 resin (3 g). The mixture was filtered and the filtrate was evaporated. Flash chromatography on silica gel (CH_2Cl_2/methanol, 9:1) provided **4** (148 mg, 96%). Physical and spectral data were identical with those reported above.

Preparation of 6 from 4 (sequence 12 → 4 → 6)

To a solution of **4** (140 mg, 0.52 mmol) and DMAP (3 mg, catalytic amount) in pyridine 3 mL at 0°C was added dropwise 4 mL of acetic anhydride. The solution was stirred for 18 h at room temperature. Ether (20 mL) was added and the resulting organic layer was washed with 3 N HCl (5 mL), water (2 × 10 mL), and brine (3 × 10 mL), and then dried over $MgSO_4$ and evaporated. Flash chromatography on silica gel (petroleum ether/ether, 3:2) afforded **6** (221 mg, 97%) as a colorless oil. Spectral and physical data were identical with those reported above.

Preparation of 12 from 4 (from the enzymatic reaction)

Dimethoxypropane (5.8 mmol, 0.71 mL) was added dropwise to a suspension of tetraol **4** (165 mg, 0.58 mmol) in CH_2Cl_2 (3 mL) in the presence of pyridinium *p*-toluenesulfonate (30 mg, 0.12 mmol). The solution was stirred for 3 h at room temperature under dry nitrogen atmosphere. Dichloromethane was added (25 mL) and the resulting organic layer was washed with water (1 × 10 mL), saturated aqueous $NaHCO_3$ (1 × 10 mL), and brine (2 × 10 mL), dried over $MgSO_4$, and evaporated. Flash chromatography (EtOAc/hexane, 1:9) provided **12** (170 mg, 86%). Physical and spectral data were identical to those described above.

7-*O*-Benzyl-5,6-dideoxy-3,4-*O*-isopropylidene-D-*lyxo*-heptitol (13)

To a solution of diacetonide **12** (140 mg, 0.40 mmol) in 90% methanol (10 mL) was added the Dowex 50W-X8 resin

(154 mg). The reaction mixture was stirred for 24 h at room temperature. The resin was removed by filtration and the solution was treated with aqueous saturated $NaHCO_3$ (1 mL), and evaporated. Ethyl acetate was added and the organic phase was washed with brine, dried over $MgSO_4$, and evaporated. Flash chromatography (gradient from EtOAc/hexane 1:9 to 3:7 and then pure EtOAc) provided **13** (75 mg, 60%) along with starting material (24 mg) and fully deprotected compound **4** (10 mg). Compound **13** (colorless oil): $[\alpha]_D^{23}$ +5.52 (*c* 4.5, $CHCl_3$); IR (neat): 3600–3200, 3100–2900, 2900–2800, 1390–1380, 1300–1100 cm^{-1}; ^1H NMR ($CDCl_3$): 7.32 (m, 5H), 4.49 (s, 2H), 4.0 (m, 1H), 3.6–3.8 (m, 4H), 3.52 (m, 2H), 2.65 (br s, 1H), 3.10 (br s, 1H), 1.6–1.9 (m, 4H), 1.37 (s, 3H), 1.34 (s, 3H); ^{13}C NMR ($CDCl_3$): 138.12, 128.27, 127.63, 127.52, 108.64, 80.90, 78.95, 72.80, 72.50, 70.07, 63.70, 30.73, 27.21, 26.92, 25.89. MS (CI, isobutane) *m/e* (rel. intensity): 311 (MH^+, 100), 253 (93).

1-*O*-Acetyl-7-*O*-benzyl-5,6-dideoxy-3,4-*O*-isopropylidene-D-*lyxo*-heptitol (14)

To a solution of **13** (44 mg, 0.14 mmol) in dry CH_2Cl_2 (3 mL) cooled at −78°C was added 2,4,6-collidine (12 μL, 2 equiv.). After stirring for 5 min, acetyl chloride (12 μL, 1.2 equiv.) was added dropwise and the solution was stirred for 2 h at −78°C. CH_2Cl_2 (25 mL) was added and the resulting organic phase was washed with water (1 × 10 mL), saturated aqueous $NaHCO_3$ (1 × 10 mL), and brine (2 × 10 mL), and then dried over $MgSO_4$ and evaporated. Flash chromatography on silica gel (hexane/EtOAc, 3:7) gave **14** (45 mg, 90%); $[\alpha]_D^{23}$ +18.76 (*c* 2.1, $CHCl_3$); IR (neat): 3600–3200, 2850–3000, 3050–3150, 1740, 1360 cm^{-1}; ^1H NMR ($CDCl_3$): 7.22 (m, 5H), 4.43 (s, 2H), 4.26 (dd, J_1 = 2.9 Hz, J_2 = 11.7 Hz, 1H), 4.04 (dd, J_1 = 6.7 Hz, J_2 = 11.7 Hz, 1H), 3.97 (m, 1H), 3.74 (m, 1H), 3.55 (t, J = 7 Hz, 1H), 3.45 (m, 2H), 2.54 (d, J = 4.8 Hz, 1H), 2.03 (s, 3H), 1.54–1.79 (m, 4H), 1.43 (s, 3H), 1.31 (s, 3H); ^{13}C NMR ($CDCl_3$): 171.3, 138.31, 128.23, 127.56, 127.43, 108.87, 80.08, 79.06, 72.75, 71.38, 70.03, 66.18, 30.89, 27.28, 26.92, 25.98, 20.74. MS (CI, isobutane) *m/e* (rel. intensity): 253 (MH^+, 100), 277 (38), 187 (54).

1-*O*-Acetyl-7-*O*-benzyl-5,6-dideoxy-3,4-*O*-isopropylidene-2-*O*-[2′-(methoxyethoxy)methyl]D-*lyxo*-heptitol (15)

To a solution of **14** (42 mg, 0.12 mmol) in CH_2Cl_2 (1 mL) at 0°C were added DIPEA (62 μL, 0.357 mmol, 3 equiv.) and MEMCl (34 μL, 0.298 mmol, 2.5 equiv.). The solution was stirred for 0.5 h at 0°C, then for 48 h at room temperature under dry atmosphere. CH_2Cl_2 (25 mL) was added and the organic layer was washed with water (1 × 10 mL), with saturated aqueous $NaHCO_3$ (2 × 10 mL), and with brine (2 × 10 mL), dried over $MgSO_4$, and evaporated. Flash chromatography on silica gel (EtOAc/petroleum ether, 3:7) provided **15** (45 mg, 87%) as a colorless oil; $[\alpha]_D^{25}$ +18.4 (*c* 1.1, acetone) (lit. (*7c*) $[\alpha]_D^{25}$ −18.7 (c. 1.87, acetone) for the opposite enantiomer). IR (neat): 2900–3100, 2800–2900, 1740, 1370, 1000–1200 cm^{-1}; ^1H NMR ($CDCl_3$): 7.31 (m, 5H), 4.84 (d, J = 7.1 Hz, 1H), 4.73 (d, J = 7.1 Hz, 1H), 4.48 (s, 2H), 4.1 (dd, J_1 = 6 Hz, J_2 = 12 Hz, 1H), 4.42 (dd, J_1 = 12 Hz, J_2 = 3 Hz, 1H), 4.02 (m, 1H), 3.85 (m, 1H), 3.77 (m, 1H), 3.68 (m, 2H), 3.47–3.59 (m, 4H), 3.51 (s, 3H), 2.05 (s, 3H), 1.59–1.85 (m, 4H), 1.37 (s, 3H), 1.34 (s, 3H); ^{13}C NMR ($CDCl_3$): 170.62, 138.48, 128.19, 127.45, 127.36, 108.89, 94.89, 79.54, 78.85, 75.64, 72.70, 71.53, 69.96, 67.33, 63.54, 58.89, 30.73, 27.30, 26.90, 26.20, 20.75. MS (CI, isobutane) *m/e* (rel. intensity): 441 (MH^+, 4), 365 (100), 307 (46), 157 (67).

(2*R*,3*S*,4*R*)-1-*tert*-Butyldimethylsilyloxy-7-benzyloxy-2,3,4-heptanetriol (16)

To a solution of **4** (135 mg, 0.50 mmol) in acetonitrile–pyridine (1:1, 2 mL) in the presence of TMG (12.5 μL, 0.1 mmol) was added TBDMSCl (90 mg, 1.2 equiv.) and the solution was stirred for 3.5 h at room temperature under dry nitrogen atmosphere. CH_2Cl_2 (20 mL) was added and the organic layer was washed with 1 N HCl (10 mL), saturated aqueous $NaHCO_3$ (10 mL), and brine (2 × 10 mL), and dried over $MgSO_4$ and evaporated. Flash chromatography on silica gel (EtOAc/hexane, 3:7) provided **16** (155 mg, 80%); $[\alpha]_D^{23}$ +4.0 (*c* 2.54, $CHCl_3$); IR (neat): 3100–3600, 3030–3090, 2850–3000, 1100–1200 cm^{-1}; ^1H NMR ($CDCl_3$): 7.23 (m, 5H), 4.42 (s, 2H), 3.34–3.76 (m, 7H), 1.60–1.74 (m, 4H), 0.88 (s, 9H), 0.06 (s, 6H); ^{13}C NMR ($CDCl_3$): 73.91, 72.83, 72.03, 70.33, 70.22, 64.29, 30.78, 26.14, 25.62, 17.99, −5.67. MS (CI, isobutane) *m/e* (rel. intensity): 385 (MH^+, 14), 270 (100).

(2*R*,3*S*,4*R*)-1-*tert*-Butyldimethylsilyloxy-7-benzyloxy-2,3,4-triacetoxyheptane (17)

To a solution of **16** (140 mg, 0.36 mmol) and DMAP (10 mg) in pyridine (1 mL) was added acetic anhydride (0.5 mL) and the solution was stirred for 24 h at room temperature. EtOAc (50 mL) was added and this organic layer was washed with 1 N HCl (3 × 10 mL), with saturated aqueous $NaHCO_3$ (2 × 10 mL), with brine (3 × 10 mL), then dried over $MgSO_4$ and evaporated. Flash chromatography on silica gel (EtOAc/hexane, 1:9) provided **17** (180 mg, 97%) as an oil; $[\alpha]_D^{23}$ +15.7 (*c* 2.8, $CHCl_3$); IR (neat): 3020–3090, 2850–3000, 1740, 1360, 1100–1300 cm^{-1}; ^1H NMR ($CDCl_3$): 7.29 (m, 5H), 5.29 (dd, J_1 = 8.3 Hz, J_2 = 3.3 Hz, 1H), 4.98 (ddd, J_1 = 8.3 Hz, J_2 = 5.1 Hz, J_3 = 3.6 Hz, 1H), 4.45 (s, 2H), 3.71 (dd, J_1 = 11.2 Hz, J_2 = 3.6 Hz, 1H), 3.61 (dd, J_1 = 11.2 Hz, J_2 = 5.1 Hz, 1H), 3.42 (m, 2H), 2.07 (s, 3H), 2.01 (s, 3H), 2.00 (s, 3H), 1.61 (m, 4H), 0.85 (s, 9H), 0.0 (s, 6H); ^{13}C NMR ($CDCl_3$): 170.39, 169.97, 169.63, 138.49, 128.30, 127.55, 127.46, 72.76, 71.13, 70.96, 70.72, 69.60, 61.50, 25.68, 27.76, 25.44, 20.68, 20.85, 20.91, 5.58. MS (CI, isobutane) *m/e* (rel. intensity): 511 (MH^+, 28), 451 (100), 303 (62), 228 (61).

Kinetic isotope effects from reactions of muonium atoms in water with various ketones, and acetaldehyde: contrasts with hydrogen atoms

John M. Stadlbauer, Krishnan Venkateswaran, and David C. Walker

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

Abstract: This paper presents data showing that in dilute aqueous solutions of butanone, 3-pentanone, cyclohexanone, di-*tert*-butyl ketone, and acetaldehyde the addition reaction of muonium atoms occurs with a rate constant close to 1×10^8 M^{-1} s^{-1}. The same value was obtained previously for acetone. Thus the reaction rate is virtually independent of the group attached to the C=O, be it a methyl, methylene, *tert*-butyl, or even a hydrogen atom. This is in sharp contrast to the reactivity of ordinary ^1H atoms, whose rate constants are much slower and dependent on adjacent groups. In fact muonium and ^1H react by different mechanisms, to form different products, so their rate ratio represents a complex kinetic isotope effect.

Key words: kinetic isotope effects, muonium atoms, muon spin rotation, ketones, hydrogen atom reactions.

Résumé : Dans ce travail, on présente des données montrant que, en solutions diluées, la butanone, la pentan-3-one, la cyclohexanone, l'acétaldéhyde et la di-*tert*-butylcétone conduisent à des réactions d'addition des atomes de muonium pour lesquelles la constante de vitesse est de l'ordre de 1×10^8 M^{-1} s^{-1}. La même valeur avait antérieurement été obtenue avec l'acétone. La constante de vitesse est donc virtuellement indépendante de la nature du groupe attaché au C=O, que ce soit méthyle, méthylène, *tert*-butyle ou même un atome d'hydrogène. Cette observation diffère considérablement de la réactivité des atomes de ^1H ordinaires pour lesquels les constantes de vitesse, beaucoup plus lentes, varient avec la nature des groupes adjacents. En fait, le muonium et le ^1H réagissent par des mécanismes différents et ils forment des produits différents; les rapports de leurs constantes de vitesse représentent donc un effet isotopique cinétique complexe.

Mots clés : effets isotopiques cinétiques, atomes de muonium, rotation de spin du muon, cétones, réactions des atomes d'hydrogène.

[Traduit par la rédaction]

Introduction

Hydrogen atoms are of special interest in the study of kinetic isotope effects (hereafter abbreviated to KIE) because H undergoes a variety of different types of reaction, and possesses four available isotopes, two of which can be studied via their radioactivity. Here we present data on the comparison of ^1H with muonium (Mu), the light radioactive isotope of hydrogen with a short-lived (2 μs) positive muon as nucleus with one-ninth the mass of a proton. These studies involve Mu reactions with solutes in dilute aqueous solution, where a 10^4-fold range of classical and quantum-mechanical KIEs has been reported in the past (1).

Acetone is a solute which was found to react with Mu atoms ~60 times faster than with ^1H atoms in water (1–4). Chemical analysis of the products of the ^1H-atom reaction revealed two competing processes occurring with comparable rates (33/67%) corresponding to "addition" and "abstraction" reactions (2). This competition is represented by reaction [1] for addition and reaction [2] for abstraction, given here for Mu:

[1] $\mathrm{Mu} + (\mathrm{CH_3})_2\mathrm{CO} \rightarrow (\mathrm{CH_3})_2\dot{C}(\mathrm{OMu})$

[2] $\mathrm{Mu} + (\mathrm{CH_3})_2\mathrm{CO} \rightarrow \mathrm{HMu} + \mathrm{CH_3CO\dot{C}H_2}$

The observed overall rate of reaction of Mu with acetone is virtually independent of pH (3, 5), and it is well documented that the $(\mathrm{CH_3})_2\dot{C}(\mathrm{OMu})$ radical is produced. This muonated free radical has been unequivocally characterized by both high-field muon spin rotation studies of pure liquid acetone and concentrated aqueous solutions (6), and by muon level-crossing resonance spectroscopy in dilute solutions in water, and hexane (5). There is some quantitative evidence that reaction [1] dominates for Mu in pure water, but that reaction [2] takes over in micelles (7). A lingering question was whether these effects are peculiar to acetone or common to other carbonyls where Mu-adduct radicals have been observed (8).

In recent studies of H atoms in dilute aqueous acidic solutions, Mezyk and Bartels (4) found butanone (methyl ethyl

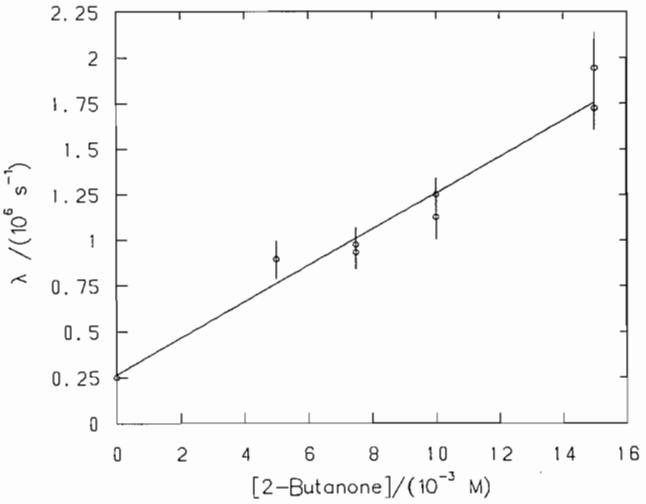
ketone) to react 20 times faster than acetone with ^{1}H, and aldehydes to be faster still. Consequently, we have undertaken a study of the dependence of Mu-atom reactions towards carbonyls with different alkyl groups adjacent to the C=O, to compare with this H-atom finding. To that end, we have determined the absolute reaction rate constants of Mu with butanone (one CH_3 + one CH_2 adjacent group), 3-pentanone (two CH_2 groups), cyclohexanone (all CH_2 groups, no CH_3 groups present), di-*tert*-butyl ketone (2,2,4,4-tetramethylpentanone) hereafter referred to as DTBK (no H atoms β to the carbonyl, only γ-CH_3 groups), and acetaldehyde (one H and one CH_3 group), for direct comparison with each other and with acetone, and to evaluate their KIEs where possible.

Experimental

Muonium atom rate constants were measured by the muon spin rotation method (μSR), fully described previously (1, 7, 8). This involved bombarding a solution with high-energy positive muons and observing the decay positrons in a low transverse magnetic field, one muon at a time. In dilute aqueous solutions only a small fraction of the incident muons formed thermalized Mu atoms at the end of the muon track; but most of those that did, reacted with additives in the water during the muon's microsecond lifetime. The rates of those reactions were then extracted from the overall muon decay signals by computer-fitting to a semiempirical analytical equation, which includes a decay constant (λ) for the component precessing at the characteristic frequency of Mu atoms. λ is thus equivalent to a pseudo-first-order chemical reaction constant for Mu in a given solution.



These experiments were conducted on the M9B "backward" muon channel of the TRIUMF cyclotron in Vancouver employing the SFUMu apparatus. Histograms from two counters were composed separately using at least 10 million events each and fitted independently to give a pair of values of λ for each solution. All solutions were prepared from reagent-grade chemicals or equivalent (acetone, butanone, 3-pentanone, cyclohexanone, di-*tert*-butyl ketone, acetaldehyde, *n*-heptane) and triply distilled water. They were all thoroughly deoxygenated by bubbling with pure nitrogen immediately prior to study. The experiments were conducted at 22 ± 1°C at neutral pH.

Results

Figure 1 shows λ increasing with the concentration of the solute in solution for the case of butanone. The intercept corresponds to a small "background" relaxation λ_0 (ostensibly due to fluctuations and inhomogeneities in the magnetic field, but possibly because of reaction with impurities in the water (9)). The slope equals the second-order rate constant, k_M, for reaction of Mu with the solute. Our values of k_M as determined this way are reported in Table 1.

All the data except for DTBK were obtained from direct measurements in water. DTBK was insufficiently soluble in water to allow a direct measurement, so a value for k_M was determined in *n*-heptane solution, and acetone was also measured in *n*-heptane. Mu reactions are faster in hydrocarbons than in water (acetone by a factor of ~10, evidently), so the DTBK result in *n*-heptane was "normalized" to water by assuming the water-to-heptane ratio for acetone would be similar to that for DTBK (see footnote (*d*) to Table 1).

Fig. 1. Plot of λ (/10^6 s^{-1}) against concentration of butanone (/10^{-3} M) in water at 295 K. (The two points at 5 mM coincide.)

Discussion

The major finding of this study is that Mu reacts at virtually the same rate with all these ketones, with $k_M = (10 \pm 2) \times 10^7$ M^{-1} s^{-1}. This means that the reaction rate is not affected significantly by which alkyl groups are attached to the carbonyl group, be they -CH_3, -CH_2, or -$C(CH_3)_3$. Even when -H is adjacent, as in acetaldehyde, the rate increases only by 75% or so. These data strongly imply that the abstraction reaction of a neighbouring hydrogen atom by Mu atoms, as in reaction [2], plays a very minor role. This then adds credence to the notion that the Mu reaction is predominantly that of addition to the carbonyl to give a muonated free radical, analogous to that indicated for acetone in reaction [1]. We take these results to mean that the addition reaction dominates when Mu reacts with any of these ketones (with acetaldehyde, perhaps, showing abstraction as well).

This is in sharp contrast to the situation for H-atom reactions, where the rate constant, k_H, depends significantly on the structure (and probably bond strength) of the groups adjacent to the carbonyl. Thus, k_H increases from 2×10^6 M^{-1} s^{-1} for acetone to 38×10^6 M^{-1} s^{-1} for butanone just as a result of replacing one of the CH_3 groups by a CH_2 group (4). It increases further to $\sim 1 \times 10^8$ M^{-1} s^{-1} for an adjacent H atom, as in propanal and butanal (4), though only to 3×10^8 M^{-1} s^{-1} for acetaldehyde (2). Although 3-pentanone, cyclohexanone, and DTBK do not seem to have been reported yet with regard to their H-atom reactivity, the k_H data that do exist are consistent with the notion that H reacts predominantly by "abstracting" a hydrogen atom from an adjacent site. In fact, abstraction was shown by chemical analysis of products to be 67% predominant in the case of acetone (2) and at least 95% so for butanone (4).

With different reactions occurring for Mu and H it is clear that the ratio of the observed rate constants, k_M/k_H, cannot be described as a single KIE. At best it is an admixture of two opposite isotopic effects. It equals the sum of Mu's addition

© 1997 NRC Canada

Table 1. Rate constants determined for the reaction of Mu with various carbonyl compounds in water at pH = 6–7 and T = 295(±1)K.

Solute	k_M	k_H	k_M/k_H
Acetone	10 (±1)[a]	0.17[b]	60
Butanone	9.9 (±1.0)	3.8[c]	2.6
3-Pentanone	8.4 (±1.5)	–	–
Cyclohexanone	11.7 (±2.0)	–	–
DTBK	6.5 (±~3)[d]	–	–
Acetaldehyde	17.5 (±2.0)	3.1[e]	5.6

All k's are given in units of 10^7 M^{-1} s^{-1}. Column 3 records the published data on the reaction with ^1H, where available, and the final column shows the observed "overall" KIE as k_M/k_H.

[a]This is already published data: $k_M = 1.1 \times 10^8$ M^{-1} s^{-1} for acetone at pH = 7 (5), and 0.87×10^8 M^{-1} s^{-1} at pH = 2 (3).

[b]Taking the more recent value for the "overall" k_H, ref. 4.

[c]From ref. 4.

[d]DTKB (2,2,4,4-tetramethylpentanone) was measured in n-heptane solution. The measured values of k_M in n-heptane for DTBK and acetone were, respectively, $(6.6 \pm 1.5) \times 10^8$ M^{-1} s^{-1} and $(10.5 \pm 2.0) \times 10^8$ M^{-1} s^{-1}. By assuming the same ratio in water-to-heptane for both acetone and DTBK, k_M for DTBK was deduced to be 6.5 based on the value of acetone in water. Because of this assumption and larger experimental errors in n-heptane due to its bigger background λ_0 due to impurities, an error bar of up to 50% seems appropriate. For the direct measurements in water an overall reproducibility error of < ±20% is estimated.

[e]From ref. 2.

plus abstraction rates divided by the sum of H's analogous rates; but due to the dominance of addition for Mu and abstraction for H, this reduces to k_M^{add}/k_H^{abst}. And as the addition rate constant for Mu (k_M^{add}) is almost constant, the changes seen in the observed k_M/k_H reflect directly the changes of k_H^{abst} for individual ketones

We suggest it is the differences in the quantum mechanical properties of zero-point vibrational frequency and tunneling efficiency that change the two reaction rates in opposite senses for Mu and H. This implies that tunneling is more important for the addition reaction, so that Mu as the lighter atom is favoured there; and that the abstraction reaction depends more on barrier height, so that the heavier H wins there (Mu has the higher barrier due to the higher zero point vibrational energy of its transition states).

Subtle differences in reaction paths for Mu and H have been noted before. Mu was found to be a weak nucleophile in its reactions towards substituted benzenes (10) and N-heterocyclic compounds (11), whereas H has always been known as a weak electrophile (12). Again, there are two competing reaction paths, one at an electron-rich centre, the other at an electron-deficient centre. These involve different "mechanisms," each path with its own KIE — and they must be of quite different magnitude to account for Mu and H adding to different sites on the aromatic rings. And its origin might be similar, namely, additions at electron-deficient sites carrying much larger tunneling probabilities than addition at electron-excess centres.

Such switches in reaction path do not seem to have been observed on interchanging ^1H with deuterium or tritium. They may require the particularly small atomic mass of Mu in order to occur, and to be detectable, especially at room temperature and in solution.

On sodium clusters in C_{60} fullerides

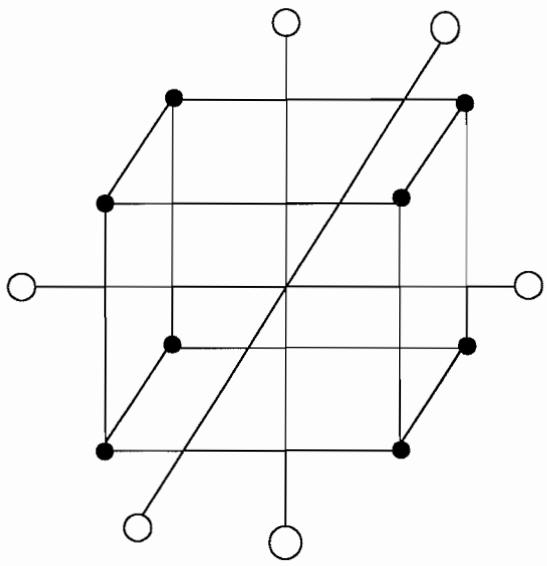
M. Apostol, F. Rachdi, C. Goze, and L. Hajji

Abstract: Sodium (Na) clusters in octahedral cages of Na-intercalated fullerides Na_6C_{60} and $Na_{11}C_{60}$ are studied within a Thomas–Fermi model. It is shown that the tetrahedral Na_4 cluster in Na_6C_{60} has an electric charge $\sim+2.7$ (in electron charge units), while the body-centered cubic Na_9 cluster in $Na_{11}C_{60}$ is almost electrically neutral.

Key words: sodium clusters, alkali fullerides, Thomas–Fermi theory, ionization charge.

Résumé : En faisant appel au modèle de Thomas–Fermi, on a étudié les agrégats de sodium (Na) dans des cages octaédriques de fullerures dans lesquels du sodium a été intercalé, Na_6C_{60} et $Na_{11}C_{60}$. On a établique l'agrégat tétraédrique de Na_4 dans le Na_6C_{60} a une charge électrique d'environ +2,7 eV alors que l'agrégat cubique à corps centré de Na_9 présent dans le $Na_{11}C_{60}$ est pratiquement neutre.

Mots clés : agrégats de sodium, fullerures alcalins, théorie de Thomas–Fermi, potentiel d'ionisation.



[Traduit par la rédaction]

Introduction

There has recently been a great deal of interest in studying the fullerene molecule and the alkali-doped fullerides by means of the Thomas–Fermi model. This approach has successfully been used to investigate the stability of the fullerene molecule (1) and the endohedral rare gas fullerenes (2). The Thomas-Fermi model for molecules, clusters, and solids has a long history, originating, probably, in ref. 3. In this paper we employ this model to study the sodium (Na) clusters embedded in fulleride solids, with the aim of computing their valence charges (4).

The nature of metallic clusters is currently receiving a great deal of interest (see, for example, the recent reviews in ref. 5). Metallic clusters trapped in zeolite cages can be studied by various magnetic resonance techniques (6–8) and, in this respect, the nature of chemical bonding, the distinction between metallic and covalent bonding, and the degree of ionicity of the clusters are of utmost importance. The existence of Na clusters in the octahedral cages of Na-doped C_{60}-fullerite has recently been suggested by X-ray analysis (9, 10). Similar clusters of calcium (Ca) in Ca-doped C_{60} were previously pointed out (11). Tetrahedral-shaped Na_4 clusters seem to build up in the octahedral cages of the face-centered cubic (fcc) Na_6C_{60} (9), with the Na atoms disposed alternately on the corners of a cube of side 2 Å. Similarly, body-centered cubes of nine sodium atoms (Na_9 cluster) seem to occur in the octahedral cages of the fcc-$Na_{11}C_{60}$ (10), with a cube side of 3.2 Å. A schematic configuration of these clusters

Fig. 1. A schematic cluster configuration in an octahedral cage of alkali-doped fullerites. The open circles represent the centres of the fullerene molecules, while the corners of the cube indicate the positions of the Na nuclei; an additional Na atom may be placed at the centre of the cube as in the case of the Na_9 cluster.

is shown in Fig. 1. This is in contrast with the C_{60}-fullerite doped with heavier species, such as A_6C_{60}, A = K, Rb, Cs, where the alkali cations push through the fcc structure of the host, pristine C_{60}, and distort it into a bcc structure, while acquiring a conventional ionic character (12). The stability and the chemical bonding of isolated, small-size alkali clusters, such as Na and Li clusters, have been extensively studied (13–16). Recently, the formation of Na clusters in Na_6C_{60} has been challenged on computational grounds (17). Here we present a Thomas–Fermi model of Na clusters in Na_6C_{60} and $Na_{11}C_{60}$, discuss its equilibrium, and compute the distri-

bution of electric charges and the degree of ionization of the clusters.

Results and discussion

We start with the main observation that the Na–Na distance in these Na clusters is much shorter than the Na–Na distance of 3.7 Å in bulk metallic sodium, though slightly larger than twice the Na^+ radius of 1.15 Å. Indeed, the Na–Na distance in the tetrahedral Na_4 cluster in $Na_6C_{60}(10)$ is $2\sqrt{2}$ Å = 2.82 Å, while in the cubic Na_9 cluster in $Na_{11}C_{60}$ (10) this distance (the shortest) is $3.2\sqrt{3}/2$ Å = 2.75 Å. This indicates that, in comparison with bulk metallic sodium, the Na clusters in doped C_{60} are squeezed (or compressed) in the octahedral cages provided by the neighbouring fullerene molecules. In the octahedral coordination of the fcc-C_{60} the fullerene molecules are placed at ~7.1 Å from the coordination centre (18, 19) and, allowing for the fullerene molecule radius of ~3.5 Å, one obtains a distance of ~3.6 Å from the coordination centre to the intersections of the fullerene molecules with the octahedral axes. The distance from the coordination centre to the plane passing through these intersection points may be taken as an average radius of the octahedral cage; we obtain thereby an average radius $R_0 = 3.6/\sqrt{3}$ Å = 2 Å for the octahedral cage (9, 10). For the tetrahedral Na_4 cluster, whose atoms are placed at $R = 2\sqrt{3}/2$ Å = 1.73 Å from the coordination centre, this cage provides an average atomic radius of $2^{1/3}$ (≅1.26) Å, and an average interelectron separation much smaller than the Bohr radius. This suggests that a Thomas–Fermi model is suitable for describing the Na_4 cluster. The confinement of the cluster in the octahedral cage is ensured by the electronic clouds of carbon atoms on the surface of the fullerene molecules, which, in order to be penetrated, require electrons of higher energy. They act as very high potential barriers. The confinement of electrons in the much narrower tetrahedral sites of the fcc-C_{60} (whose radius is estimated at ~1.12 Å (11) may certainly provide them with enough energy to make them capable of penetrating the confinement, which may explain the absence of clusters in these cages. Similar considerations apply for heavier-alkali atoms in the octahedral cages, and even for the Na_9 cluster in $Na_{11}C_{60}$, whose atoms, placed at $R = 3.2\sqrt{3}/2$ Å = 2.75 Å, are clearly exceeding the 2 Å limit found above. However, the penetration of the electronic clouds of the C atoms proceeds gradually and, in the octahedral cages, the C atoms provide another limit of about 4 Å in the (111) directions: this is the distance from the coordination centre to the octahedral faces passing through the centres of the fullerene molecules. We may take, tentatively, a mean value of these two limits (2 Å and 4 Å), and set up an average cage radius $R_0 \sim 3$ Å for the Na_9 cluster. This gives an average atomic radius $3^{1/3}$ (≅1.44) Å, which again justifies a Thomas–Fermi model for this Na_9 cluster. It is worth remarking at this point that the resistance of the cage walls to the penetrating electrons (which may also apply in the case of the zeolite cages) is an expression of the Pauli exclusion principle, which requires fast varying (in space) wave functions for the latter (and therefore higher energy) if they are going to penetrate into the space regions already occupied by atomic-core electrons. This confining effect of the cage boundaries on an atomic cluster may be formalized as an external field "pseudo-potential," much in the same manner as has already been done for bulk metals (20). It can easily be seen that these "pseudo-potentials" would vary strongly over short distances (as in the short-range parts of the interatomic Lennard–Jones or Born–Mayer potentials), and their functional dependence on distance (which would depend, among others, on the number of confined electrons) will provide an effective cage radius R_0 for a given cluster, as we shall discuss below in more detail.

As is well known, the Thomas–Fermi model is a quasi-classical theory of interacting electrons and atomic nuclei, which assumes that the Fermi wave vector k_F of the electrons, and the electron density n, vary slowly in space.

$$[1] \qquad n = \frac{1}{3\pi^2} k_F^3$$

This is true (except for distances very close to the nuclei) due to the effective screening of the nuclear charges accomplished by the high-density electrons. We shall see that this assumption is consistent also in the present Thomas–Fermi model of clusters. Under this assumption the particular shape of the atomic cluster is no longer very relevant, so that we may introduce an additional simplification by assuming that the total charge z of the nuclei is uniformly distributed over a spherical shell of radius R, plus a central Na nucleus of charge +11 (in electron charge units) in the case of the Na_9 cluster. We denote by V the electrostatic potential created by the distribution of positive charges, and note that its particular expression is not very important in subsequent calculations; the only requirement on the positive charge distribution is that of symmetry, from obvious reasons of stability, and the approximation made is that of radial symmetry. Later on in this paper we will estimate the error introduced by this approximation. In the high-density limit the electron exchange interaction is a higher order contribution (as well as other contributions to the electron interaction energy), and we may assume that an electrostatic potential φ is generated by the electron distribution, which does not depend on k_F. We may therefore set up the basic Thomas–Fermi relationship (in atomic units Bohr radius $a_H = \hbar^2/me^2 = 0.53$ Å, $e^2/a_H = 27.2$ eV, and $\hbar = 1$)

$$[2] \qquad \frac{1}{2} k_F^2 - \varphi - V - U = -\varphi_0$$

where U is the potential well of the cage and φ_0 is the chemical potential; the latter should be constant, in order to ensure the local equilibrium, and equal to the "pseudo-potential" of the external field at the cage frontier R_0, to prevent any flux of electrons pouring in and out of the cage. The variation of this external "pseudo-potential" over the distance R_0 may be taken as the depth U of the potential well. Using eqs. [1] and [2] we may rewrite the Poisson equation $\Delta\varphi = 4\pi n$ as

$$[3] \qquad \Delta(\varphi + V + U - \varphi_0) = \frac{8\sqrt{2}}{3\pi} (\varphi + V + U - \varphi_0)^{3/2}$$

everywhere except for $r = R$; introducing the reduced vari-

ables $x = r/R_0$ and

$$[4] \quad \varphi + V + U - \varphi_0 = \left(\frac{3\pi}{8\sqrt{2}R_0^2}\right)^2 \frac{\chi}{x}$$

we arrive at the Thomas–Fermi equation

$$[5] \quad x^{1/2}\chi'' = \chi^{3/2}$$

for any x between 0 and 1 except for $x = a = R/R_0$. Since n is a continuous function, φ and its first and second derivatives must be continuous functions; it follows that the function χ has a slope discontinuity (but is itself continuous) exactly as has the derivative of V, i.e., at $x = a$; the magnitude of this slope jump will be obtained below by Gauss' law. It is therefore convenient to define $\chi_1(x) = \chi(x)$ for $0 < x < a$ and $\chi_2(x) = \chi(x)$ for $a < x < 1$, with the continuity condition

$$[6] \quad \chi_1(a) = \chi_2(a)$$

The number of electrons inside a sphere of radius x is easily obtained from eqs. [1]–[5] as

$$[7] \quad N(x) = 4\pi R_0^3 \int_0^x dx \cdot x^2 n = \frac{9\pi^2}{128R_0^3} \int_0^x dx[x\chi' - \chi]$$

$$= \left\{ \begin{array}{ll} \dfrac{9\pi^2}{128R_0^3}[x\chi_1' - \chi_1 + \chi_1(0)], & 0 < x < a \\ \dfrac{9\pi^2}{128R_0^3}\{x\chi_2' - \chi_2 + a[\chi_1'(a) - \chi_2'(a)] + \chi_1(0)\}, & a < x < 1 \end{array} \right\}$$

and one notes that it is continuous at $x = a$. The total number of electrons in the cage is obtained from eq. [7] as

$$[8] \quad N = \frac{9\pi^2}{128R_0^3}\{\chi_2'(1) - \chi_2(1) + a[\chi_1'(a) - \chi_2'(a)] + \chi_1(0)\}$$

By Gauss' law we easily obtain the net charge inside the sphere of radius x as

$$[9] \quad q(x) = \frac{9\pi^2}{128R_0^3}(\chi - x\chi')$$

whence, by using eq. [7], we obtain the positive charge

$$[10] \quad q_{1+}(x) = \frac{9\pi^2}{128R_0^3}\chi_1(0)$$

inside the sphere of radius $x < a$. We note that, if it exists, it is concentrated at $x = 0$. Obviously, for the Na_4 cluster we should require

$$[11] \quad \chi_1(0) = 0$$

while for the body-centered cubic Na_9 cluster the corresponding boundary condition is

$$[12] \quad \frac{9\pi^2}{128R_0^3}\chi_1(0) = 11$$

The total charge inside the sphere of radius x, $a < x < 1$, given by eq. [9] consists of z positive charges distributed over the spherical shell of the cluster, a charge of +11 at the centre, if this is the case, and $-N(x)$ electron charges; whence, by using eq. [7], we obtain the magnitude

$$[13] \quad z = \frac{9\pi^2}{128R_0^3} a[\chi_1'(a) - \chi_2'(a)]$$

in the slope discontinuity of the function χ, as expected; eq. [13] provides the third boundary condition for our problem, with $z = 44$ for the Na_4 cluster and $z = 88$ for the Na_9 cluster. The fourth boundary condition needed for the unique solution of eq. [5] is provided by the equilibrium condition of the positive shell of the cluster. It is easy to get the electric self-field acting on the shell; in the absence of the central atom it is given by

$$[14] \quad E_s = z/2R^2$$

while in the case of the centered cluster we obtain

$$[15] \quad E_s = z/2R^2 + 11/R^2$$

The electric field on the shell due to the electrons is readily obtained as

$$[16] \quad E_e = -\frac{\partial\varphi}{\partial r}\bigg|_{r=R} = \frac{9\pi^2}{128R_0^5}\frac{1}{a^2}[\chi_1(a) - a\chi_1'(a) - \chi_1(0)]$$

(or equivalently in terms of χ_2), and we note that, in contrast to eqs. [14] and [5], it is negative, i.e., the electrons try to stabilize the exploding cluster shell. Using eq. [13] we arrive easily at the equilibrium condition

$$[17] \quad 2\chi_1(a) = a[\chi_1'(a) + \chi_2'(a)]$$

both for the noncentered and for the centered cluster. Equation [5] is solved numerically with the boundary conditions given by eqs. [6], [11]–[13], and [17], both for the Na_4 and the Na_9 clusters, and the results are described below. In each case we were especially interested in the total charge

$$[18] \quad q = \frac{9\pi^2}{128R_0^3}[\chi_2(1) - \chi_2'(1)]$$

in the cage, as given by eq. [9].

We note that eq. [5] is a second-order differential equation for two distinct functions, $\chi_1(x)$ over the range 0–a, and $\chi_2(x)$ over a–1; consequently, we need four boundary conditions in order to uniquely determine the solution, and they are indeed provided by eq. [6], one of eqs. [11] and [12], [13], and [17]. As a matter of fact, we start with $\chi_1(0)$ as given by eqs. [11] or [12] and with an arbitrary slope at $x = 0$; the values $\chi_1(a)$ and $\chi_1'(a)$ are then uniquely determined, and, from eqs. [6] and [13] we get $\chi_2(a)$ and $\chi_2'(a)$, so that the solution $\chi_2(x)$ is completely determined; finally, we look for that arbitrary initial slope at the origin, to satisfy eq. [17]. The physical solution is therefore completely determined and we compute the corresponding total charge in the cage, as given by eq. [18].

In the case of the Na_4 cluster we used $R = 1.73$ Å and $R_0 = 2$ Å ($a = R/R_0 = 0.86$), as suggested by the X-ray diffraction data (9, 11). The function χ is plotted versus x

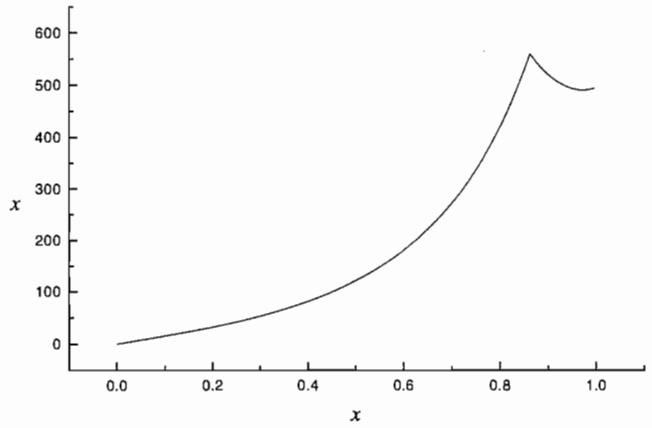
Fig. 2. The function χ vs. x for the Thomas–Fermi model of the Na_4 cluster with $z = 44, R = 1.73$ Å, and $R_0 = 2$ Å, corresponding to a total charge $q = +2.72$.



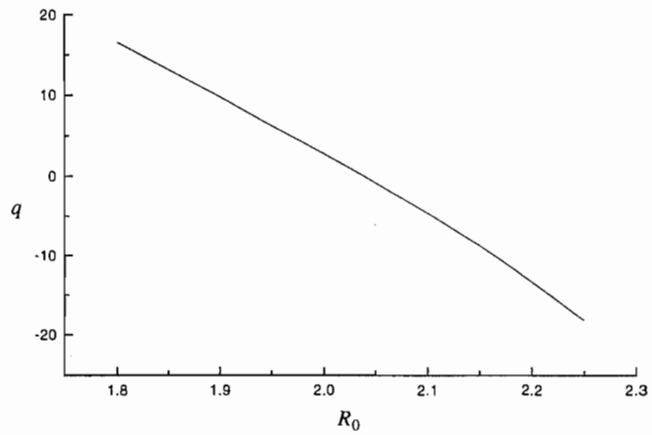


Fig. 3. The total charge q vs. the cage radius R_0 for the Na_4 cluster with $R = 1.73$ Å.

in Fig. 2; it corresponds to a total charge $q = +2.72$, i.e., an average charge of +0.68 for each Na ion. The variation of the total charge in this case is also plotted versus R_0 in Fig. 3. As discussed above, the numerical results obtained for the function χ are valid everywhere except for a range of about twice the Bohr radius around the position of the positive shell of charges, where the variation of χ/x is too large; even so, one can estimate that almost half of the electrons are located there, thus ensuring the screening of the positive charges. Another limitation of the present calculations occurs from the assumption of radial symmetry for the function χ. We can estimate the error introduced by this approximation as follows. Assuming the same variation of electron density per unit length in all directions, the relative contribution of the angular part of the variation of the potential derivative with respect to the radial part is $\delta\varphi_a'/\delta\varphi_r' \sim \sqrt{4\pi/s}$, for a cluster consisting of s atoms; on the other hand, as these small variations are proportional to the variations of the distance, we have $(\delta\varphi_r')^2 + 2\left(\delta\varphi_a'\right)^2 = (\delta\varphi_r')_0^2$, where the latter corresponds to neglecting the angular part. As the variations of the potential derivatives are also proportional to the charge (from the Poisson equation), we then easily find that the relative error made in estimating the charge is at most $\sim 1 - \sqrt{1 + 8\pi/s}/(1 + 2\sqrt{4\pi/s})$. In the case of the Na_4 cluster this amounts to $\sim 40\%$; one can see that the radial-symmetry approximation improves its accuracy for large s.

Increasing the amount of negative charge on the cluster, the position of the maximum value of χ moves toward smaller values of x (smaller values of R), and it exhibits the opposite behaviour on increasing the degree of ionization. The variation of χ with respect to the cage radius R_0 brings into discussion the energy of the cluster. One can easily check that the density of the electronic kinetic energy is given by

$$[19] \quad \varepsilon_{kin} = \frac{1}{2\pi^2} \int_0^{k_F} dk \cdot k^4 = \frac{9\,(3\pi/32)^3}{10R_0^{10}} \cdot \frac{\chi^{5/2}}{x^{5/2}}$$

where eqs. [2] and [4] have been used; from this the total kinetic energy of the electrons can be calculated:

$$[20] \quad \mathscr{E}_{kin} = \frac{3(3\pi/8)^4}{20R_0^7} \int_0^1 dx \cdot \frac{\chi^{5/2}}{x^{1/2}}$$

We similarly obtain the potential energy of the electrons

$$[21] \quad \mathscr{E}_{pot} = -\frac{(3\pi/8)^4}{4R_0^7} \int_0^1 dx \cdot \frac{\chi^{5/2}}{x^{1/2}} - N\varphi_0$$

so that the electronic energy may be expressed as $\mathscr{E}_{el} = \mathscr{E}_1 - N\varphi_0$, where

$$[22] \quad \mathscr{E}_1 = -\frac{(3\pi/8)^4}{10R_0^7} \int_0^1 dx \cdot \frac{\chi^{5/2}}{x^{1/2}}$$

The self-energy of the positive charges is given by $\mathscr{E}_s = \mathscr{E}_0 - zU$ for the noncentered cluster and $\mathscr{E}_s = \mathscr{E}_0 - (z+11)U$ for the centered one, where $\mathscr{E}_0 = z^2/2R$ in the former case and $\mathscr{E}_0 = z^2/2R + 11z/R$ in the latter. On the other hand, expressing the interaction energy of the shell with the electrons in two distinct ways, namely, $z\varphi(R) = -\int d\boldsymbol{r}nV$, we get

$$[23] \quad U - \varphi_0 = \frac{9\pi^2}{128R_0^4}\,\chi_2'(1)$$

Summing up all these contributions we obtain the total energy of the cluster as

$$[24] \quad \mathscr{E} = \mathscr{E}_0 + \mathscr{E}_1 + \mathscr{E}_2 - (2z - q)\varphi_0$$

where $\mathscr{E}_2 = -z(U - \varphi_0)$ as given above; in the case of the centered cluster we should replace z by $z + 11$ in eq. [24]. The numerical integration gives $\mathscr{E}_1 = -28$ and $\mathscr{E}_2 = -42$ for the Na_4 cluster, while $\mathscr{E}_0 = 296$; the total energy, consisting of eq. [24] and the energy of the electrons transferred to the cage walls, must be negative, in order that the cluster be formed. For small values of the total charge of the cluster the latter contribution to the total energy is small, so that we may estimate that the energy E given by eq. [24] must acquire negative values. Hence it follows that φ_0 must be of the order of $(296 - 28 - 42)/N \sim 2.6$ (for $N = 44$). On the other hand, φ_0 equals the external "pseudo-potential" at the cage frontier R_0, as we discussed before, whence one can estimate the magnitude of this "pseudo-potential." One can see, therefore, that it acquires high values, to ensure the con-

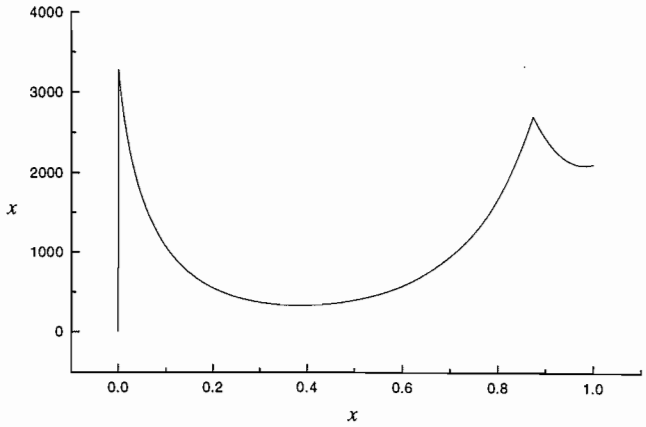
Fig. 4. Same as in Fig. 1 for the centered-cubic Na_9 cluster with $z = 88$, $R = 2.75$ Å, and $R_0 = 3.15$ Å, and a vanishing total charge ($q \sim 0$).



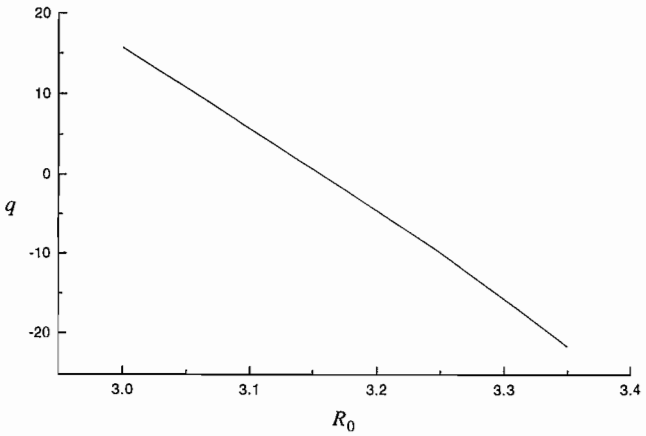


Fig. 5. The total charge q vs. the cage radius R_0 for the Na_9 cluster with $R = 2.75$ Å.

finement of the squeezed cluster within the R_0 range. In addition, as the present estimations are valid over a scale length larger than the Bohr radius, one can also see that the external "pseudo-potential" has a high variation over short distances. This illustrates again the gradual resistance developed by the inner-core electrons of the environment to the penetrating "pressure" of the confined cluster. The electron density also varies rapidly over short distances at the frontier of the cage, in order to ensure the delimitation of the compressed cluster from its confining environment. The "pressure" exerted by the cluster electrons on their environment results in the deformation of the electronic clouds of the surrounding atoms. Having determined φ_0 by the external "pseudo-potential" at the cage frontier R_0, the two remaining parameters R_0 and R will be obtained, within a complete theory, by minimizing the total energy of the cluster (given by eq. [24]) and the electrons transferred to the cage walls. Of course, this first requires the computation of the "pseudo-potential."

From the discussion above one can see that the results of the computation are very sensitive to the values of R and R_0; this sensitivity may result in a higher inaccuracy for clusters consisting of a greater number of atoms. This is evident in the case of the Na_9 cluster, where, according to the experimental data suggested by the X-ray analysis (10), we used $R = 2.75$ Å and $R_0 = 3.15$ Å ($a = R/R_0 = 0.87$). The function χ vs. x is plotted in Fig. 4; it corresponds, within errors of ± 0.03 Å in R and R_0, to a total charge of the cluster $q \sim \pm 1$. At this level of approximation we may conclude that the centered-cubic Na_9 cluster is practically neutral. The dependence of the total charge q on the cage radius R_0 is also included in Fig. 5 for this case. The same discussion regarding the screening and the value of the chemical potential φ_0 (~ 2.4) applies here as for the Na_4 cluster. It is worth noting that a similar calculation for a noncentered cubic cluster consisting of eight atoms of Na gives a total charge $q \sim +1$, for the same values of R and R_0. Finally, noticing that the theory contains the charge z only in the product zR_0^3 (see, for example, eqs. [12], [13], and [18]) we can say that similar clusters formed by lithium may also form in the octahedral cages of the fullerite with a smaller size or, equivalently, with a diminished cluster size and ionization charge.

Conclusions

In conclusion, one may say that the calculations presented here indicate a metallic bonding of the Na_4 and Na_{11} clusters squeezed into the octahedral cages of the Na-fullerites. We emphasize that this squeezing is a central feature of the picture presented here, whose direct consequence is that of affecting all the electron states in the cluster; enough electronic energy may be gained in this way to stabilize the cluster at lower values of R, as compared with R_0. This is in contrast, at least for the Na_4 cluster, with recent claims (17) that the Na atoms in Na_6C_{60} are fully ionized and that the octahedral Na ions are placed much further away from the coordination centre. These claims, based on numerical simulations within the local-density approximation, make use of a certain distinction between the valence and the core electrons, which may be inappropriate for the squeezed clusters. As we have seen from the present calculations, almost half of the electrons seem to be affected by the presence of the neighbouring atoms in the cluster, which indicates a drastic change in the inner electronic states of the isolated atoms. The metallic character of the alkali clusters in fullerites can be tested by various techniques, most notably by Raman and ^{23}Na NMR spectroscopies (see, for example, ref. 19). In addition, it is worth mentioning that metallic clusters squeezed in atomic cages may exhibit two types of collective modes, one associated with the vibrations of the positively charged ions, and another with the oscillations of the electron density. Preliminary calculations indicate that these two modes are in the range of ultraviolet optical spectroscopy and electron spectroscopy.

Abstract: The effects of β-cyclodextrin (β-CD) on the kinetics of the reaction of α-amino acid anions with *p*-nitrophenyl acetate (pNPA) and *p*-nitrophenyl hexanoate (pNPH) have been investigated. Pseudo-first-order rate constants obtained with various concentrations of nucleophile and β-CD, in aqueous solution at pH 9.88, were analyzed to yield rate constants for reaction of the nucleophiles with free ester (k_N) and with ester bound to β-CD (k_{cN}). For pNPA reacting with amino acids that bind weakly to β-CD, if at all, the ratio k_{cN}/k_N is very close to one, but for amino acids that bind appreciably to β-CD this ratio is greater than one (up to 3.5). Generally similar behaviour is observed for reactions with pNPH, but the rate ratios are smaller and all less than one. These findings are comparable to those obtained in this laboratory for the CD-mediated reactions of *p*-nitrophenyl alkanoate esters with other nucleophiles, including simple alkylamines that bind quite strongly to CDs, but they differ from those reported in an earlier study of the reaction of pNPA with amino acid anions (Can. J. Chem. **69**, 1124 (1991)) where the data analysis suggested more substantial catalysis by cyclodextrins.

Key words: amino acids, cyclodextrin, ester cleavage, kinetics, catalysis.

Résumé : On a étudié les effets de la β-cyclodextrine (β-CD) sur la cinétique de la réaction des anions des acides α-aminés avec l'acétate de *p*-nitrophényle («pNPA») et hexanoate de *p*-nitrophényle («pNPH»). On a analysé les constantes de vitesse de pseudo-premier ordre obtenues avec divers concentrations du nucléophile et de la β-CD, en solution aqueuse, à un pH de 9,88 et on en a tiré les constantes de vitesse pour la réaction des nucléophiles avec l'ester libre (k_N) et avec l'ester lié à la β-CD (k_{cN}). Pour la réaction du «pNPA» avec les acides aminés qui se lient, au mieux, faiblement à la β-CD, le rapport k_{cN}/k_N se rapproche de l'unité, mais pour les acides aminés qui se lient facilement à la β-CD, ce rapport est supérieur à un (jusqu'à 3,5). En général, on observe un comportement semblable pour les réactions avec le «pNPH»; toutefois, les rapports des vittesses sont plus faibles et, dans tous les cas, ils sont inférieurs à un. Ces résultats se comparent à ceux obtenus dans ce laboratoire pour les réactions, effectuées sous l'influence de la CD, des alcanoates de *p*-nitrophényle avec d'autres nucléophiles, y compris les alkylamines simples qui se lient fortement à la CD; ils diffèrent toutefois de ceux rapportés dans un travail antérieur sur la réaction du «pNPA» avec les anions des acides aminés (Can. J. Chem. **69**, 1124 (1991), dans lequel une analyse des données avait suggéré la présence d'une catalyse beaucoup plus substantielle par les cyclodextrines.

Mots clés : acides aminés, cyclodextrine, clivage des esters, cinétique, catalyse.

[Traduit par la rédaction]

Introduction

Three recent studies in this laboratory have been concerned with the effects of cyclodextrin hosts (1) on acyl transfer reactions of included esters (2, 3).[2] The first involved the reaction of *p*-nitrophenyl acetate (pNPA) and *p*-nitrophenyl hexanoate (pNPH) with four nucleophiles (NH_2OH, imidazole, $CF_3CH_2O^-$, and $HOCH_2CH_2S^-$) that do not bind appreciably to cyclodextrins (CDs). For these nucleophiles, it was found that pNPA bound to β-CD has 70–140% of the reactivity of free pNPA, but pNPH bound to β-CD has only 20–55% of the reactivity of the free ester, the actual percentage depending on the nucleophile (2). Similar results were obtained for esters with acyl chain lengths up to C_{10}, and the variation in reactivity of the CD-bound esters towards $CF_3CH_2O^-$ was rationalized in terms of a switch in the mode of ester binding in the transition state, from aryl group to acyl group inclusion (3). Overall, the binding of *p*-nitrophenyl esters to CDs affects their susceptibility to attack by simple nucleophiles, but not greatly so (2, 3).

By contrast, Barra and de Rossi reported earlier that the reaction of α-amino acid anions with pNPA bound to β-CD is accelerated, up to 20- or 30-fold (4). The catalytic effect was attributed to reaction within a weak ternary complex, {pNPA·CD·AA^-}, formed by hydrogen bonding of the carboxylate group of the amino acid anion (AA^-) to secondary hydroxy groups on the CD. Since the reaction of imidazole with pNPA (and pNPH) is not greatly affected by the presence of β-CD (2), we were interested to see whether the amino acid histidine, which has an imidazole side chain, and which was not studied previously (4), would also show appreciable catal-

ysis. If it did so, the enhanced reactivity could provide further support for the mechanism just mentioned. However, when we measured the reactivity of histidine with pNPA in the presence of β-CD we found that it reacted more slowly (vide infra); it did not show any catalysis.

In probing more deeply to understand the different behaviour of histidine, we discovered that the previous results on amino acids are not described particularly well by the parameters reported, raising doubts about the extent of catalysis. Consequently, in order to try to clarify matters, we carried out further studies of the effect of β-CD on the reaction of amino acid anions with pNPA, as well as with pNPH, which are reported below.

Results

Using stopped-flow spectrophotometry, we measured the kinetics of the reaction of several α-amino acids anions with *p*-nitrophenyl acetate (pNPA) and with *p*-nitrophenyl hexanoate (pNPH) in the presence and absence of β-CD, in basic aqueous solution. To keep our work comparable to that of Barra and de Rossi (4), the reaction medium was buffered at pH 9.88 where most of the amino acids are 50% or more as their anions, $NH_2CH(R)COO^-$. However, we generally used higher concentrations of the amino acids and β-CD than previously (4), to maximize the contribution of the aminolysis pathways, relative to the background reactions.

Pseudo-first-order rate constants obtained at various concentrations of amino acid, with and without β-CD, were analyzed to yield rate constants for reaction of the nucleophiles with free and CD-bound ester, using the same approach as in previous studies (2, 3).[2] This approach is based on consideration of four processes: hydrolysis of the ester (S) in the medium (eq. [1]); ester cleavage through an {ester·CD} complex (eq. [2]), or its kinetic equivalent (5); reaction of the free ester with the nucleophile (Nuc)(eq. [3]); reaction of the {ester·CD} complex with the nucleophile (eq. [4]).[3] These four reactions together require that k_{obs} varies with [Nuc] and [CD] in the manner expressed in eq. [5].

[1] $S \xrightarrow{k_u} \text{products}$

[2] $S + CD \underset{K_S}{\rightleftharpoons} S{\cdot}CD \xrightarrow{k_c} \text{products}$

[3] $S + Nuc \xrightarrow{k_N} \text{products}$

[4] $S{\cdot}CD + Nuc \xrightarrow{k_{cN}} \text{products}$

[5] $$k_{obs} = \frac{(k_u K_S + k_c[CD]) + (k_N K_S + k_{cN}[CD])[Nuc]}{(K_S + [CD])}$$

Fig. 1. Rate constants for the cleavage of pNPA in the presence of β-CD and L-alanine, at pH 9.88. The symbols correspond to the following concentrations of L-alanine (in mM): ◆, none; ■, 25; □, 50; ▼, 75; ∇, 100. The curves were calculated with eq. [5] and fitted parameters. Note that the addition of L-alanine causes comparable increases in k_{obs} at each [β-CD], meaning that free and CD-bound pNPA have very similar reactivities.

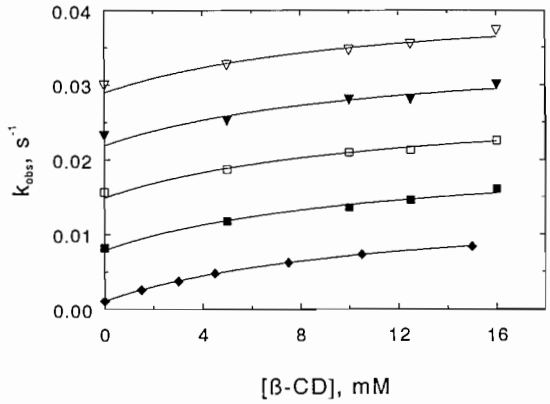

Fig. 2. The data for the cleavage of pNPA in the presence of β-CD and L-alanine, plotted according to eq. [6], with the same symbols as in Fig. 1. Multiple regression analysis of the 20 points for which [Nuc] ≠ 0 affords the values of k_N and k_{cN} given in Table 1.

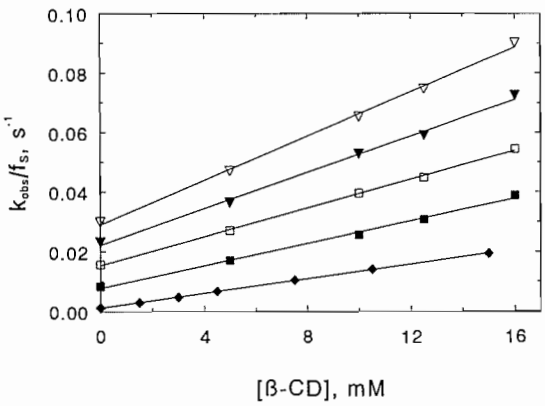

Figure 1 shows kinetic data for the cleavage of pNPA at various levels of β-CD and L-alanine, with curves drawn using eq. [5] and fitted constants. It is seen that the effect of the added nucleophile at each β-CD concentration is virtually the same, meaning that pNPA bound to β-CD has essentially the same reactivity as free pNPA towards L-alanine. This assertion is supported by the following analysis, which is based on eq. [5].

First, to simplify matters, eq. [5] is linearized by dividing it by $f_S = K_S/(K_S + [CD])$, the fraction of unbound ester, to give eq. [6].[4] According to this equation, plots of k_{obs}/f_S against

[2] O.S. Tee, T.A. Gadosy, and M.J. Boyd. Manuscript in preparation.

[3] The reaction of free ester and {CD·Nuc}, which is kinetically equivalent to the process in eq. [4], is considered explicitly in the Discussion.

[4] The form of f_S assumes that [CD] >> [S·CD] ≤ $[S]_0$, which was valid for the concentrations used. The value of K_S was determined in the normal way from experiments with varying β-CD concentration (6), and no added amino acid (i.e., the lowest curve in Fig. 1).

[a]At 25°C, in an aqueous borate (0.1 M) buffer of pH 9.88 (μ = 0.2 M, with KCl; 0.025 or 0.050% (v/v) CH_3CN). The values of K_N are taken from earlier work (6); K_S for pNPA was determined under the reaction conditions in this work; K_S for pNPH (16) is the same as used in previous studies (2, 3).

[b]The entry "large" under K_N indicates that no significant binding to β-CD was detected earlier (6). The rate constant k_{cN} is for reaction of CD-bound ester and free nucleophile (eq. [4]). The apparent dissociation constant $K_{TS} = k_N K_S/k_{cN}$, as previously (2, 3).

[c]Assumed to be nonbinding with β-CD.

[d]In a 0.1 M borate buffer at pH 8.00 (μ = 0.2 M, with KCl). The reaction takes place on the imidazole group.

[e]Reaction on the thiolate group.

[CD] should be linear for each fixed [Nuc], and such is the case for the alanine data of Fig. 1, as shown in Fig. 2. Multiple linear regression of the data in terms of eq. [6], with [Nuc], [CD], and [Nuc][CD] as three "X" variables, for [Nuc] ≠ 0, gives slope parameters that lead to the estimates of k_N and k_{cN} reported in Table 1 and used to calculate the curves in Fig. 1. From these rate constants, the ratio $k_{cN}/k_N = 0.99 \pm 0.01$, so bound and free pNPA have the same reactivity towards L-alanine, as surmised above.

$$[6] \quad k_{obs}/f_S = k_u + k_N[\text{Nuc}] + k_c[\text{CD}]/K_S + k_{cN}[\text{Nuc}][\text{CD}]/K_S$$

In their work, Barra and de Rossi made the reasonable assumption that the amino acids they studied did not bind significantly to CDs at the low concentrations used (4). Since we intended to use higher [β-CD] and much higher concentrations of the amino acids, wherever feasible, it was necessary to determine if such complexation (eq. [7]) is important under the reaction conditions. As reported recently, along with binding studies of other amino compounds (6), we found that α-amino acids with hydrophobic side chains do bind to β-CD and the strength varies with the size of the side chain (see K_N in Table 1), but amino acids with small side chains do not bind measurably. Since L-alanine and L-cysteine do not bind significantly to β-CD, and norvaline binds only very weakly (Table 1), we have assumed that glycine, glycylglycine, and histidine do not bind.

$$[7] \quad \text{CD} + \text{Nuc} \underset{K_N}{\rightleftharpoons} \text{CD}\cdot\text{Nuc}$$

The analysis based on eq. [6] is also valid for cases where the nucleophile binds to the cyclodextrin, as long both [CD] and [Nuc] are corrected for formation of the {CD·Nuc} complex.[2] Figure 3 shows data for the effect of different levels of β-CD on the reaction of L-leucine with pNPA, transformed according to eq. [6], and using corrected [CD] and [Nuc]. Multiple regression analysis of the data yields values of k_N and k_{cN} (Table 1) from which the ratio $k_{cN}/k_N = 2.15 \pm 0.04$, implying that pNPA bound to β-CD is about twice as reactive towards L-leucine as free pNPA.

The ability of eq. [5] to reproduce the experimental data can be judged from Fig. 4, which shows values of k_{calc}, calculated with fitted parameters, plotted against the corresponding values of k_{obs}, for the alanine and leucine data sets. All 40 points sit very close to the diagonal line of slope one, showing that

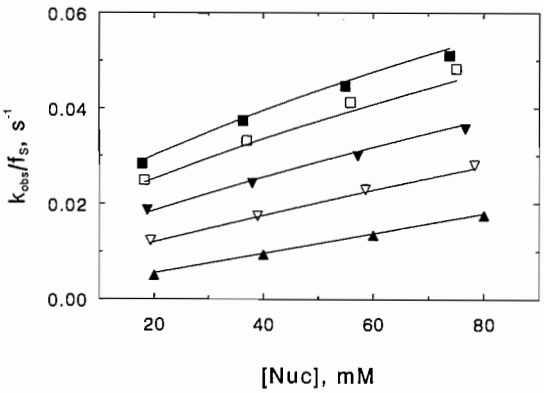
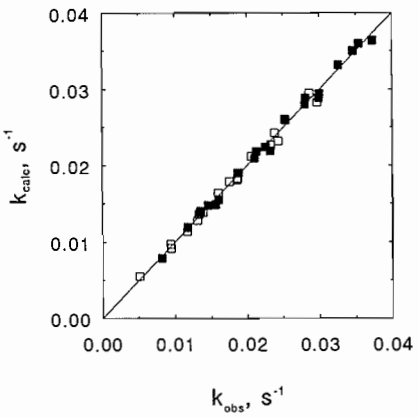
Fig. 3. Data for the cleavage of pNPA by β-CD and L-leucine, plotted according to eq. [6], with [CD] and [Nuc] corrected for binding between β-CD and the amino acid. The symbols are for the following [β-CD] (in mM): ▲, none; ▽, 4.0; ▼, 8.0; □, 12.0; ■, 15.0. Multiple regression analysis of all 20 data points affords the values of k_N and k_{cN} given in Table 1. The curves are calculated from eq. [6] and parameters from the regression.





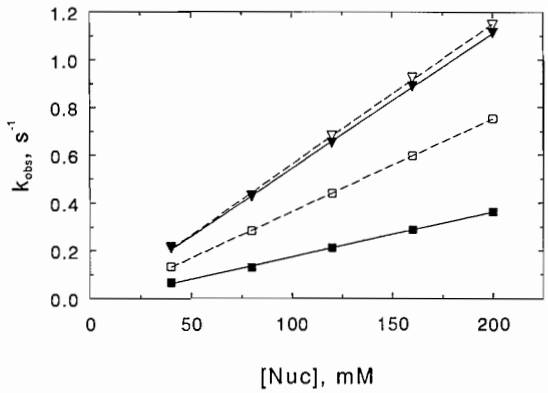


Fig. 4. Correlation between calculated rate constants (k_{calc}), obtained from eq. [5] and fitted parameters, and observed rate constants (k_{obs}) for reaction of pNPA with L-alanine (■) and L-leucine (□) in the presence of β-CD, corresponding to the data plotted in Figs. 2 and 3. The diagonal line has a slope of one and goes through the origin.

the analysis based on eq. [6] works well for the reaction of pNPA with alanine and leucine in the presence of β-CD, as it does for various other esters, nucleophiles, and cyclodextrins (2, 3).[2]

Having established the validity of eq. [5] for alanine and leucine, we used a simpler procedure for other amino acids and for the reactions with pNPH. This procedure, which entails fewer measurements and has been used before (2, 3), consists of two sets of experiments with varying [Nuc]: one at zero CD and the other with a high [CD], so that much of the ester is bound to the CD. In the absence of CD, $k_{obs} = k_u + k_N[Nuc]$, and k_N is simply the slope of k_{obs} vs. [Nuc]. With CD present, the full form of eq. [5] must be used and the slope of the linear plot of k_{obs} vs. [Nuc] is $(k_N K_S + k_{cN}[CD])/(K_S + [CD])$, from which k_{cN} can be estimated, knowing [CD], k_N, and K_S. This

Fig. 5. Rate constants for the cleavage of pNPA (▽,▼) and of pNPH (□, ■) by cysteine. The slopes of the lines through the open symbols (no added CD) are k_N. The slopes of the lines through the solid symbols (10 mM added β-CD) are $(k_N K_S + k_{cN}[CD])/(K_S + [CD])$, from eq. [5]. Note that for both esters the background reaction is negligible. Also, for pNPA it is clear that $k_{cN} \approx k_N$ whereas for pNPH $k_{cN} < k_N$ (Table 1).

approach furnished most of the values of k_N and k_{cN} for the amino acids that do not bind appreciably to β-CD.

Figure 5 shows data for the cleavage of pNPA and pNPH by L-cysteine[5] in the presence and absence of β-CD. For pNPA, the two series of rate constants are very close, meaning that the free and CD-bound forms of the ester have very similar reactivities ($k_{cN}/k_N = 0.92$) whereas pNPH reacts more slowly in the presence of β-CD because its bound form is less reactive ($k_{cN}/k_N = 0.40$, Table 1). Note that cysteine is sufficiently reactive that the background cleavage of the esters is negligible (Fig. 5) and so the rate constants k_N and k_{cN} can be determined with good precision. Similar considerations apply to the reactions of the esters with glycine, which has a comparable reactivity under the reaction conditions (Table 1).

Rate constants for the reaction of pNPA with glycylglycine and L-valine are plotted in Fig. 6. In the case of valine, the plotting and analysis allow for its binding to β-CD, even though this is weak ($K_N = 255$ mM). The data analysis was carried out by multiple linear regression of both data sets (with and without β-CD) because [CD] varies upon the addition of the nucleophile. For both amino acids, the strong parallelism of the two plots for reaction with and without added β-CD (Fig. 6), indicates that $k_{cN} \approx k_N$ (Table 1).

Finally, Fig. 7 presents data for DL-norleucine reacting with pNPA and pNPH. Again, the binding of the amino acid, though not particularly strong ($K_N = 158$ mM), is taken into account in the plotting and the data analysis. Clearly, the relative slopes of the plots[6] mean that $k_{cN} \approx k_N$ for pNPA and k_{cN}

[5] At pH 9.88, the amino group of cysteine is largely protonated and its thiol group is deprotonated, so that the reaction with pNPA and pNPH is a thiolysis, not an aminolysis (7).

[6] Because of complexation of the amino acid by β-CD, the plots should be curved when β-CD is present. However, the binding of valine and norleucine is sufficiently weak that the curvature is not apparent, and so in Figs. 6 and 7 we have simply drawn straight lines through the data. With tryptophan and phenylalanine, which bind more strongly, the curvature is quite noticeable.

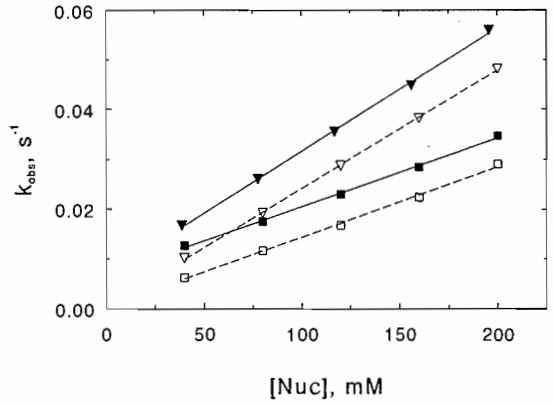
Fig. 6. Rate constants for the cleavage of pNPA by glycylglycine (□, ■) and by L-valine (▽,▼) in the absence of β-CD (open symbols) and in the presence of 10 mM β-CD (solid symbols). Clearly, for both amino acids, $k_{cN} \approx k_N$ (Table 1).



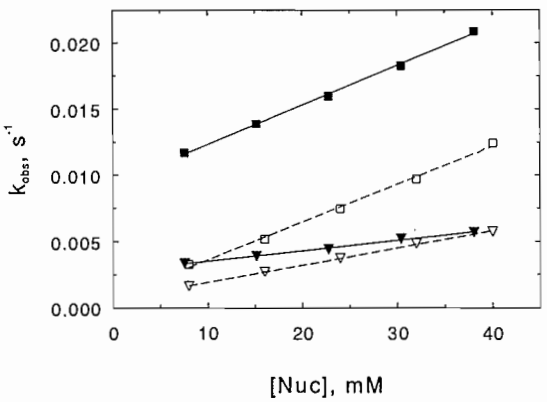


Fig. 7. Rate constants for the cleavage of pNPA (□, ■) and pNPH (▽, ▼) by DL-norleucine in the presence of no β-CD (open symbols) and 10 mM β-CD (solid symbols). Again, for pNPA it is apparent that $k_{cN} \approx k_N$ whereas for pNPH $k_{cN} < k_N$ (Table 1).

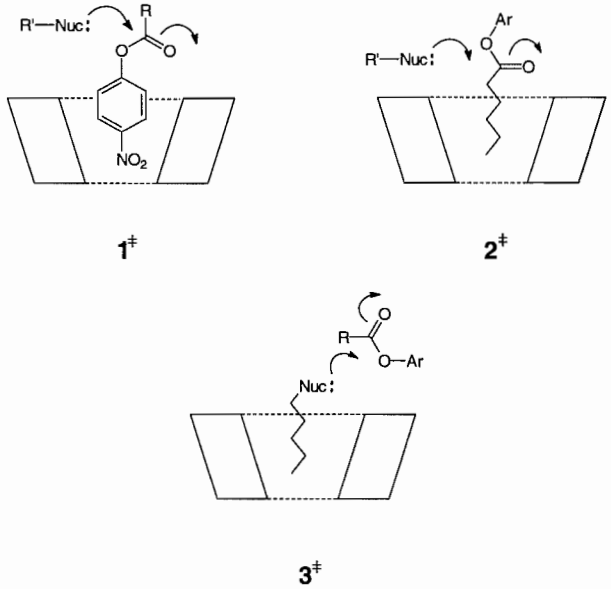

$< k_N$ for pNPH, as is the case with most of the amino acids studied (Table 1).

Before proceeding with the Discussion, we wish to point out that the rate constants k_N (Table 1) found for reaction of the free esters with amino acid anions (AA^-) are not exceptional. When allowance is made for the pH of the experiments and the pK_as of the nucleophiles, our results agree well with those in the literature for the reaction of pNPA with the anions of cysteine (7), glycine (8), glycylglycine (9), alanine, leucine, and tryptophan (4). Note also that values of k_N for amino acid anions with a simple alkyl substituent show little variation with structure and for steric reasons they are about five times smaller than k_N for glycine.[7] Likewise for normal steric reasons (10), the k_N values for pNPH are roughly half those for pNPA, as found for other nucleophiles (2, 3),[2] including hydroxide ion (10, 11).

Discussion

Attack by a simple nucleophile on a *p*-nitrophenyl alkanoate ester bound in a cyclodextrin cavity can basically occur in either of two ways: it can take place with the aryl group of the ester in the cavity ($\mathbf{1}^{\ddagger}$) or with its acyl group in the cavity ($\mathbf{2}^{\ddagger}$). Short-chain esters like pNPA react through the aryl-bound form ($\mathbf{1}^{\ddagger}$) but for longer esters ($\geq C_6$) the more stable, acyl-bound form (11) is more reactive ($\mathbf{2}^{\ddagger}$) (3). With nucleophiles such as alkylamines, which bind appreciably to CDs, reaction may also occur between the CD-bound nucleophile and free ester ($\mathbf{3}^{\ddagger}$). In particular cases, there may even be reaction through a transition state

$\mathbf{1}^{\ddagger}$ $\mathbf{2}^{\ddagger}$ $\mathbf{3}^{\ddagger}$

in which parts of both the nucleophile and the ester are bound to the CD, if its cavity is large enough to accommodate them. Evidence of all four of these situations has been presented in previous work (2, 3),[2] using the dependence of kinetic parameters on structure as the criterion of mechanism.

Our usual approach to discussing modes of reactions of CD-mediated processes involves explicit consideration of transition state binding (2, 3, 5, 11*b*). For this purpose we employ an apparent equilibrium constant (K_{TS}) for dissociation of the {transition state · CD} complex because variations of K_{TS} (and of $pK_{TS} = -\log K_{TS}$) with structure can serve as a probe of transition state binding (5, 12). In the case of CD-mediated nucleophilic attack, the constant is given by $K_{TS} = k_N K_S / k_{cN}$ (2, 3), and relevant values are listed in Table 1. Besides K_{TS}, we will also make use of reactivity ratios, such as k_{cN}/k_N, which focus attention on the apparent catalysis by specific pathways.

Reactivity ratios (k_{cN}/k_N and k_{Nc}/k_N)

The ratios k_{cN}/k_N measure the relative reactivities of the CD-bound and free ester towards nucleophiles. For the reaction of

[7] It is also noteworthy that for *n*-alkylamines (RCH_2NH_2) $k_2 \sim 15$ M^{-1} s^{-1} (8)[2] whereas for analogous amino acid anions ($RCH(CO_2^-)NH_2$) $k_2 \sim 0.5$ M^{-1} s^{-1} (after correction for pH). Thus, the presence of the negatively charged carboxylate group in AA^- appreciably reduces the nucleophilicity of the adjacent amino group, presumably for steric reasons and because negative charge is developed in the transition state for aminolysis.

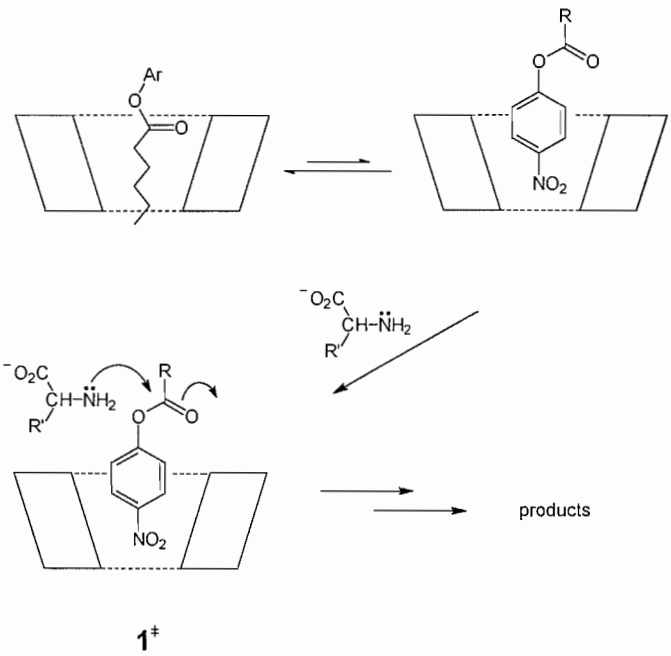
L-Tryptophan	45.1	1.98	8.5		
L-Phenylalanine	19.8	0.54	6.1		

[a]As in Table 1. The rate constant $k_{Nc} = k_{cN}K_N/K_S$ (see Discussion and footnote 9).



pNPA with amino acid anions[8] that bind weakly, if at all, to β-CD, the ratios are in the range 0.76–0.99 (Table 1), which are similar to those found for other nonbinding nucleophiles (2, 3) and consistent with the CD-mediated reaction taking place by nucleophilic attack upon pNPA bound to β-CD through its aryl group (**1**‡). That the rate ratio is close to one is taken to mean that pNPA, which is bound to β-CD by its *p*-nitrophenyl group (11*a*, 13), has its carbonyl group exposed to the bulk medium and fairly accessible to external nucleophiles (2).

Larger AA^- that bind more strongly to β-CD have reactivity ratios k_{cN}/k_N that increase modestly with the strength of binding, from 1.2 for L-valine (K_N = 255 mM) to 3.5 for L-phenylalanine (K_N = 19.8 mM). Since the efficiency of the CD-mediated reaction seems to be related to the strength of binding of the nucleophile to β-CD, it is appropriate to consider whether the reaction takes place by way of attack of CD-bound nucleophile on the free ester (eq. [8]), as in **3**‡. This process is kinetically equivalent to that in eq. [4], and so rate constants for it may be calculated easily from $k_{Nc} = k_{cN}K_N/K_S$.[9]

$$[8] \quad S + CD{\cdot}Nuc \xrightarrow{k_{Nc}} \text{products}$$

Values of k_{Nc} for amino acid anions that bind to β-CD are given in Table 2, along with the reactivity ratios k_{Nc}/k_N. For reaction with pNPA, these ratios range from 6.1 to 184, implying a modest to appreciable catalytic effect for reaction as in eq. [8] (transition state **3**‡). The highest ratio is for DL-norvaline, which binds very weakly to β-CD, and it seems more likely that this nucleophile reacts as in eq. [4] (transition state **1**‡) for which the ratio k_{cN}/k_N is modest (0.83), as it is for nonbinding AA^- (Table 1). Whether or not any of the amino acid anions react through the pathway in eq. [8] is considered again, later, in the discussion of transition state binding.

Scheme 1.

1‡

For the reaction of the hexanoate ester (pNPH) with AA^-, all of the reactivity ratios k_{cN}/k_N are less than one (0.22–0.58) (Table 1). Similar behaviour has been found for pNPH reacting with other nucleophiles that bind weakly or not at all to β-CD (2, 3) and only with *n*-alkylamines that bind strongly do such ratios approach or exceed one.[2] Since the dominant mode of binding of pNPH to β-CD is by its acyl chain (11), the rate constants k_{cN} and the ratios k_{cN}/k_N refer to reaction taking place as in **2**‡, rather than **1**‡. However, when pNPH is bound by its acyl chain it seems that its carbonyl group is more or less inside the CD cavity, so that it is not readily accessible to nucleophiles in the surrounding medium (3). As a result, nucleophilic attack may occur on the less stable, aryl-bound complex of the ester, in equilibrium with the major acyl-bound form (Scheme 1). Assuming that the aryl-bound complex has a dissociation constant K_S' = 10 mM (cf. K_S = 11.3 mM for pNPA), whereas the acyl-bound form has K_S = 1.6 mM, the rate constants for reaction of the aryl-bound complex with amino acid anions (k_{cN}') are 10/1.6 = 6.25 times larger than

[8] To be comparable to earlier experiments with imidazole (2), those with histidine were carried out at pH 8.00. Consequently, the reaction with histidine is on its imidazole moiety and not on the amino group, which is protonated at pH 8.

[9] The third-order rate constant for S + CD + Nuc → products is given by $k_3 = k_{cN}/K_S$ or k_{Nc}/K_N, depending on whether the reaction is viewed as taking place as in eq. [4] or as in eq. [8].

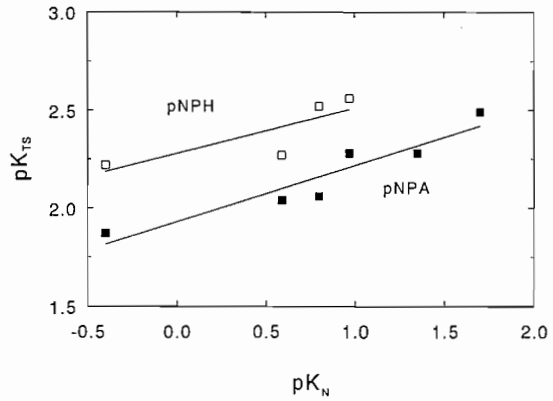
Fig. 8. Correlation of transition state binding (pK_{TS}) for the reaction of amino acid anions with pNPA (■) and with pNPH (□), mediated by β-CD, with pK_N for binding of the amino acid anions to β-CD. The slopes of the lines are 0.29 for pNPA and 0.23 for pNPH.



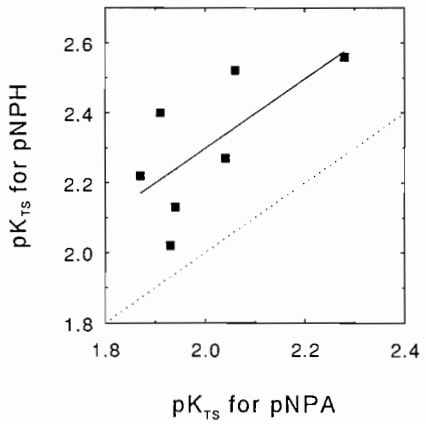


Fig. 9. Relation between the transition state binding (pK_{TS}) for the reaction of amino acid anions with pNPH and with pNPA, mediated by β-CD. Note that the slope of the correlation line is essentially one and that the values for pNPH are greater than those for pNPA – all the points are above the dotted line.

k_{cN}. More important, the appropriate reactivity ratios, k_{cN}'/k_N, are in the range 1.1–3.6, not very different from those for pNPA reacting with AA^- (Table 1) and other nucleophiles (2) by the same reaction mode ($\mathbf{1}^{\ddagger}$). Thus, it appears quite feasible that the reaction of pNPH with amino acid anions takes place as depicted in Scheme 1.

With amino acid anions that bind significantly to β-CD it is possible that pNPH reacts as free ester with CD-bound nucleophile (eq. [8] and $\mathbf{3}^{\ddagger}$). Values of k_{Nc} for this process are collected in Table 2, together with the ratios k_{Nc}/k_N. These ratios range from 39 to 418, suggesting a substantial catalytic effect *if* the reaction takes place as in $\mathbf{3}^{\ddagger}$. However, as with pNPA, the largest value is for the weakly binding DL-norvaline and we think it more likely that the free nucleophile reacts with CD-bound pNPH (eq. [4]), as in $\mathbf{2}^{\ddagger}$ ($k_{cN}/k_N = 0.27$, Table 1) or as in $\mathbf{1}^{\ddagger}$ (Scheme 1) ($k_{cN}'/k_N = 1.7$, assuming $K_S' = 10$ mM).

To try to get a clearer idea of how both pNPA and pNPH react with the amino acid anions, as in $\mathbf{1}^{\ddagger}$, $\mathbf{2}^{\ddagger}$, or in $\mathbf{3}^{\ddagger}$, or through some other pathway, we will look at transition state binding, and how it relates to binding of the nucleophiles.

Transition state binding (K_{TS} and pK_{TS})

For the CD-mediated reaction of pNPA with amino acid anions that do not bind measurably to β-CD, K_{TS} = 11–15 mM (Table 1), which is very close to K_S = 11.3 mM for substrate binding. These values are perfectly compatible with the reaction taking place through transition state $\mathbf{1}^{\ddagger}$, which has the aryl group of the ester in the CD cavity and the nucleophile external to it. Transition state binding is slightly stronger (K_{TS} = 3.3–9.2 mM) for amino acid anions that bind to β-CD (K_N = 20–255 mM) and there is a fair correlation between pK_{TS} and pK_N, as seen in Fig. 8, but the slope is only 0.29. For the reaction of pNPH, the trends are similar and the plot of pK_{TS} against pK_N has a slope of 0.23 (Fig.8). In neither case is the slope large enough to justify postulating reaction between free ester and CD-bound nucleophile (eq. [8] and transition state $\mathbf{3}^{\ddagger}$). In the case of pNPA, it probably means that reaction takes place as in $\mathbf{1}^{\ddagger}$, but for amino acid anions having hydrophobic side chains there is a weak interaction that provides a small, additional amount of stabilization to the CD-bound transition state. Assuming that pNPH reacts in the same way ($\mathbf{1}^{\ddagger}$), there must be an isomerization from the principal, acyl-bound form of the {ester·CD} complex to the aryl-bound form (Scheme 1), as well as some weak interaction of the amino acid side chain. Alternatively, pNPH could react through its acyl-bound form, as in $\mathbf{2}^{\ddagger}$, but there must still be some interaction of the amino acid side chains to account for the greater transition stabilization (larger pK_{TS}) for those AA^- that bind to β-CD.

Comparing the pK_{TS} values for pNPH and pNPA reacting with all the amino acid anions common to both esters, the correlation between the two sets is not particularly good, but the slope is about one (Fig. 9). What is more noteworthy is that for each nucleophile, pK_{TS} is larger for pNPH than for pNPA, implying some additional stabilization for the hexanoate ester. Conceivably, this could be evidence that pNPH reacts by way of acyl group binding ($\mathbf{2}^{\ddagger}$) whereas pNPA reacts by aryl group binding ($\mathbf{1}^{\ddagger}$). In previous work on a series of *p*-nitrophenyl alkanoates (C_2 to C_{10}) reacting with two nonbinding nucleophiles ($CF_3CH_2O^-$ and $HOCH_2CH_2S^-$) in the presence of β-CD, the chain length dependence of pK_{TS} and other parameters provided strong evidence of a switch in the mode of reaction from $\mathbf{1}^{\ddagger}$ to mode $\mathbf{2}^{\ddagger}$, with the break point coming precisely at the hexanoate ester (3).

Conclusions

The results presented above show that the reaction of pNPA with amino acid anions is not greatly affected by added β-cyclodextrin, and in most cases the CD-bound ester appears to have a reactivity very close to that of the free ester ($k_{cN} \sim k_N$); only with nucleophiles that bind appreciably to β-CD is the ratio $k_{cN}/k_N > 1$. Almost certainly, the CD-mediated reaction of pNPA takes place between CD-bound ester and free nucleophile, as in $\mathbf{1}^{\ddagger}$, rather than between free ester and CD-bound nucleophile ($\mathbf{3}^{\ddagger}$).

The behaviour of pNPH is generally similar but the ratios k_{cN}/k_N are all less than one, presumably because the carbonyl group of the acyl-bound ester is not so accessible to nucleophiles in the bulk medium. As a result, the reaction may take place by nucleophilic attack on a more reactive, aryl-bound form of the ester (Scheme 1, $\mathbf{1}^{\ddagger}$), rather than on the acyl-bound

For personal use only.

form ($\mathbf{2}^{\ddagger}$). On the other hand, transition state binding (pK_{TS}) is somewhat greater for pNPH than for pNPA, which could be due to pNPH reacting by its acyl-bound form ($\mathbf{2}^{\ddagger}$), as is the case for longer esters and other nucleophiles (3).

For the cleavage of both pNPA and pNPH, amino acid anions having hydrophobic side chains show slightly elevated reactivity in the CD-mediated reaction, implying that there is some additional transition state stabilization due to these substituents. However, the shallow dependence of the transition state binding (pK_{TS}) on structure, compared to binding of the nucleophile (pK_N), does not indicate a large component of nucleophile binding in the transition state and it does not support a complete switch from reaction of free nucleophile and CD-bound ester ($\mathbf{1}^{\ddagger}$ or $\mathbf{2}^{\ddagger}$) to reaction between CD-bound nucleophile and free ester ($\mathbf{3}^{\ddagger}$).

There remains the question of why our findings are different from those of Barra and de Rossi (4), specifically for the β-CD-mediated reaction of pNPA with alanine and leucine. The difference could have arisen from the fact that the kinetic effects they observed were not particularly large and the analysis of them was based upon subtraction of the contributions of the three processes [1]–[3]. Thus, any errors in estimating these contributions, *from whatever source*, could have a large effect on the estimated k_{cN} values. Compared to our results, the major deviations appear to be with the previous k_{obs} obtained with constant $[Nuc]_0$ and varying $[\beta\text{-CD}]_0$. It was precisely these results that were analyzed to find k_{cN}. In our experiments we tried to avoid problems by having both $[\beta\text{-CD}]_0$ and $[Nuc]_0$ high, to maximize the contribution of the CD-mediated aminolysis, and by estimating both k_N and k_{cN} from parallel or combined experiments carried out with solutions made up from common stock solutions. As seen in Figs. 1–7, the results obtained under these conditions show that k_{cN} is not very different from k_N for pNPA reacting with various amino acid anions.

Experimental

The reactants were purchased as follows: pNPA and pNPH from Sigma; amino acids from Sigma or ICN Biochemicals; β-cyclodextrin from Aldrich. These materials were used as supplied.

The pK_a of the ammonium group of L-alanine is 9.87 and values for other simple amino acids are very close (14). Barra and de Rossi carried out their studies at pH 9.878 ± 0.001 (μ = 0.2 M), and for ease of comparison we tried to do likewise. Obviously, at this pH the amino acids exist in their anionic forms, $NH_2CH(R)CO_2^-$, to the extent of about 50%.

A stock solution (A) of borate buffer (0.2 M) containing 0.2 M KCl was made up and its pH was adjusted to 9.878 ± 0.003. An amino acid was dissolved in some of solution A to give a stock nucleophile solution (B) and its pH was also adjusted. Other concentrations of amino acid were obtained by dilution of B with A. Ester solutions (C) (100 μM for pNPA and 50 μM for pNPH) were made by dilution of a stock ester solution (0.1 M) in acetonitrile into water. For low concentrations of β-CD, this was incorporated into stock solution A, and hence into B. However, for higher [β-CD] (>7 mM), the CD was added to A and thus B, and to the ester solution C, because β-CD is not particularly soluble (~16 mM) in water (1). Reactions were initiated by stopped-flow mixing of equal volumes of solutions B and C, so the final concentrations of the constituents were halved, except for β-CD if it was in both B and C. The range of $[Nuc]_0$ used in many of the experiments can be judged from Figs. 1, 3, 5–7. For other nucleophiles, the concentration ranges were: norvaline, 20–200 mM; phenylalanine, 16–80 mM; tryptophan, 5–25 mM; histidine, 25–100 mM. In the case of histidine, the pH of solutions A and B was adjusted to 8.000 ± 0.004.

Kinetic procedures were similar to those in previous, related studies (2, 3). Ester cleavage was followed by monitoring the first-order appearance of the *p*-nitrophenoxide ion at 405 nm, using an Applied Photophysics SX17MV stopped-flow spectrophotometer, with the cell maintained at 25.0 ± 0.1°C. Pseudo-first-order rate constants were obtained by fitting a single exponential function to the absorbance increases, and values of k_{obs} were taken as averages of 5–10 determinations, differing by <5%.

As outlined in the text, and detailed earlier (2, 3), analysis of the data from experiments with varying $[CD]_0$ and $[Nuc]_0$ was based on eq. [5] and its linear form eq. [6]. In many cases the analysis to find k_N and k_{cN} used multiple linear regression (15) in terms of eq. [6], with [CD], [Nuc], and [CD][Nuc] as three "X" variables. In several cases where binding of the amino acid to β-CD was unimportant, k_N and k_{cN} were obtained more simply from the slopes of the linear variation of k_{obs} with $[Nuc]_o$, for $[CD]_o$ = 0 and 10 mM, respectively (see text).

Where complexation of the amino acid by β-CD was important (6), the analysis was carried out with [CD] and [Nuc], corrected for formation of the CD·Nuc complex (eq. [7]), rather than $[CD]_0$ and $[Nuc]_0$. To find [CD] one solves the quadratic in [CD] obtained by expansion of:

$$K_N = [CD][Nuc]/[CD\cdot Nuc]$$

$$= [CD]([Nuc]_0 - [CD]_0 + [CD])/([CD]_0 - [CD])$$

which comes from the definition of K_N and the two equations for mass balance: $[Nuc]_0 = [Nuc] + [CD\cdot Nuc]$; $[CD]_0 = [CD] + [CD\cdot Nuc]$. The solution of the quadratic equation is $[CD] = \{-b + (b^2 + 4K_N[CD]_0)^{1/2}\}/2$, where $b = (K_N - [CD]_0 + [Nuc]_0)$. Then, by difference, $[Nuc] = [Nuc]_0 - [CD\cdot Nuc] = [Nuc]_0 - ([CD]_0 - [CD])$. All of the calculations involved in the data analysis were executed in spreadsheets, using Lotus 1-2-3 software (15).

The analysis based on eq. [6] requires a known value of K_S for binding of the ester to the CD. For pNPH the value of 1.60 mM was taken from earlier work (16), but for pNPA it was redetermined in the 0.10 M borate buffer at pH 9.88. Under these conditions, we found $k_u = 0.00111\ s^{-1}$ and nonlinear fitting of the normal saturation equation (5, 11*b*, 16) to the variation of k_{obs} with [β-CD] (lower curve in Fig. 1) gave $k_c = 0.0139 \pm 0.0003\ s^{-1}$ and $K_S = 11.3 \pm 0.4$ mM ($r = 0.9998$). By way of comparison, Barra and de Rossi (4) reported $k_u = 0.000815\ s^{-1}$ and nonlinear fitting to their kinetic data gives $k_c = 0.0112 \pm 0.0022\ s^{-1}$ and $K_S = 15.4 \pm 5.4$ mM ($r = 0.9938$), for reaction at pH 9.878, in 2% (v/v) aqueous DMSO, and apparently no buffer.

The values of K_N needed to account for binding of the amino acids to β-CD were determined by a fluorescent probe method, as reported earlier (6). Note that when K_N is large in relation to $[\beta\text{-CD}]_0$, as it was in most cases, the value of k_{cN}

(and hence k_{cN}/k_N) derived from the analysis in terms of eq. [6] is not particularly sensitive to the precise value of K_N. For example, for the reaction of pNPA with L-leucine, treatment of the data (Fig. 3) with the measured value of K_N = 107 mM (6) gave $k_{cN} = 0.44 \pm 0.03\ M^{-1}\ s^{-1}$ whereas for K_N = 250 mM it gives $k_{cN} = 0.37 \pm 0.03\ M^{-1}\ s^{-1}$. At the extreme, if binding of leucine was insignificant, then $k_{cN} = 0.31 \pm 0.03\ M^{-1}\ s^{-1}$.

Exploratory study of the quenching of photosensitizers by initiators of free radical "living" polymerization

J.C. Scaiano, Terrence J. Connolly, Nadereh Mohtat, and Claudette N. Pliva

Abstract: Several compounds of the type $PhCR^1R^2$-TEMPO (where TEMPO = 2,2,6,6-tetramethylpiperidine-*N*-oxide) have been prepared and examined as potential photosensitized initiators for "living" free radical polymerizations. For example, these compounds are excellent quenchers of triplet xanthone (rate constants in the range $(8.0–13) \times 10^8\ M^{-1}\ s^{-1}$) and result in the formation of benzylic and TEMPO radicals. The importance of excited state energy and nature of the excited triplet state have also been explored. We also tested pyrene as a possible singlet sensitizer. While pyrene fluorescence is efficiently quenched, the process does not lead to cleavage of the C—O bond. A model is proposed to account for this anomaly in the photosensitized decomposition of these TEMPO adducts.

Key words: TEMPO, laser flash photolysis, time resolved emission spectroscopy, sensitizers, quenching, photoinitiator.

Résumé : On a préparé plusieurs composés du type $PhCR^1R^2$-TEMPO (dans lesquels TEMPO = 2,2,6,6-tétraméthylpipéridine, *N*-oxyde de) et on a évalué leurs propriétés comme photosensibilisateurs potentiels de polymérisations par radicaux libres «vivants». Par exemple, ces composés sont excellents pour désactiver l'état triplet de la xanthone (constantes de vitesse de 8,0 à $13 \times 10^8\ M^{-1}\ s^{-1}$) et ils conduisent à la formation de radicaux benzylique et TEMPO. On a aussi étudié l'importante de l'énergie de l'état excité et de la nature de l'état triplet excité. On a aussi évalué les propriétés du pyrène comme sensibilisateur potentiel d'états singulets. Même si la fluorescence du pyrène est désactivée d'une façon efficace, le processus ne conduit pas à la rupture de la liaison C—O. On propose un modèle pour expliquer cette anomalie lors de la décomposition photosensibilisée de ces adduits avec TEMPO.

Mots clés : TEMPO, photolyse éclair au laser, spectroscopie d'émission résolue en fonction du temps, désactivation, photoinitiateur.

[Traduit par la rédaction]

Introduction

The 1993 report by Georges et al. (1) showing that low polydispersity polystyrene could be prepared by free radical polymerization of styrene in the presence of TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy, free radical) has triggered a widespread research effort in this area (2–14). The mechanism of polymerization is believed to involve reversible capping of the polystyrene chain by TEMPO, a stable radical that is known to scavenge a wide range of free radicals with rate constants somewhat below the diffusion limit (15–17). Thus, these TEMPO-capped polystyrene chains effectively become dormant polymers, ready to continue free radical polymer growth if the cap dissociates (14). The mechanism of reaction is shown in Scheme 1, where P_nT is the TEMPO capped dormant polymer, $P_n^{\cdot}$ is the active, growing polymer, and $T^{\cdot}$ is TEMPO.

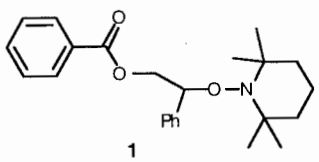
Scheme 1.

$$[1]\quad P_nT \underset{k_{-L}}{\overset{k_L}{\rightleftharpoons}} P_n^{\cdot} + T^{\cdot}$$

$$[2]\quad P_n^{\cdot} + \text{styrene} \xrightarrow{k_P} P_{n+1}^{\cdot}$$

Note that the self-reaction of two polymer chains ($P_m^{\cdot}$ + $P_n^{\cdot}$) to give polymer P_{m+n} has not been included in Scheme 1. It is now well established that under normal polymerization conditions, there is a steady state or residual TEMPO concentration, always present, which effectively makes reaction [1] much faster than reaction [3]. This has been observed experimentally, modeled successfully (9, 14), and can be readily predicted from work carried out by Fischer a decade ago (18, 19). Additionally, the concentration of active chain ends at any time is quite low, which makes bimolecular reactions less likely. Fukuda et al. recently estimated the equilibrium constant for eq. [1] to be 2.1×10^{-11} mol L^{-1} at 125°C (20).

$$[3]\quad P_m^{\cdot} + P_m \xrightarrow{k_T} P_{m+n}$$



The capping reaction (see eq. [1]) is not reversible at room temperature, where P_nT is stable, and polymerizations follow-

ing the mechanism of Scheme 1 are typically carried out at temperatures around 125°C, where k_{-L}, the rate constant for release of the growing polymer chain, is sufficiently large to activate the dormant polymer, P_nT.

A number of recent reports have dealt with the thermal and photochemical synthesis of initiators for living free radical polymerizations, such as molecules **1–6** (7, 10, 21–23).

1

2: $R^1=R^2=H$
3: $R^1=CH_3$; $R^2=H$
4: $R^1=Et$; $R^2=H$
5: $R^1=R^2=CH_3$
6: $R^1=H$;$R^2=Ph$

In addition to being good initiators for TEMPO-mediated thermal polymerizations, molecules **1–6** are also good models for the polymers themselves and have occasionally been described as "unimers." We are interested in establishing possible photochemical routes for dissociation of the TEMPO cap. Direct photolysis at wavelengths below 280 nm is known to cleave **2–6** readily, although it is likely that in polymers much of the energy will be absorbed away from the active site.

In this communication, we explore the possibility of photosensitized decomposition of **2–5** as a potential method for the initiation of "living" free radical polymerization. Such decomposition can potentially facilitate polymerizations at lower temperatures, not only allowing additional flexibility, but also avoiding some of the problems (e.g., autopolymerizations) of high-temperature styrene polymerization. To examine these reactions we have employed laser flash photolysis and time-resolved emission spectroscopy.

Experimental

Materials

All solvents used for synthesis and laser flash photolysis studies were of the highest grade commercially available (BDH, Omnisolv grade) and were used without further purification. Compounds **2–5** were prepared and purified as previously described (10). TEMPO and 4-benzoylbiphenyl (4-phenylbenzophenone) were purchased from Aldrich and used as received. Xanthone, pyrene, and thioxanthen-9-one were purchased from Aldrich and were recrystallized from ethanol. 1-Azaxanthone was purchased from Maybridge and was recrystallized from ethanol prior to use.

Laser flash photolysis

The samples, contained in 7×7 mm^2 Suprasil quartz cuvettes saturated with oxygen-free nitrogen at room temperature, were excited by pulses using the third harmonic, 355 nm, of a Surelite Nd/YAG laser ($\leq$ 25 mJ per 7 ns pulse). A Tektronix 2440 digitizer was used to capture the transient absorption signals from the monochromator–photomultiplier system. The data were transferred via GPIB interface to a PowerMacintosh computer that controls the experiment and provides processing facilities through a home-developed program using LabVIEW 3.1.1 software from National Instruments. Further details on similar laser systems have been provided elsewhere (24, 25).

Emission spectroscopy and lifetimes

A Hamamatsu C-4334 streak camera was used to measure the time-resolved luminescence from pyrene. Pyrene samples in acetonitrile were prepared in concentration low enough (0.035 mM) to ensure that interference from the excimer did not occur. Samples prepared as above were photoexcited at 355 nm with the third harmonic from the same Surelite Nd/YAG nanosecond laser, the beam of which was attenuated to $\leq$ 2 mJ/pulse.

Steady state irradiations

The samples of sensitizer, dissolved in 50 mM solutions of **2** in acetonitrile contained in 7×7 mm^2 Suprasil quartz cuvettes saturated with oxygen-free nitrogen at room temperature, were irradiated in a Rayonet photoreactor with six RPR 3500 lamps at 30°C. The concentration of sensitizer was adjusted so that the absorbance at 355 nm matched that for the sensitizer used in the laser flash photolysis experiments.

Laser drop photolysis

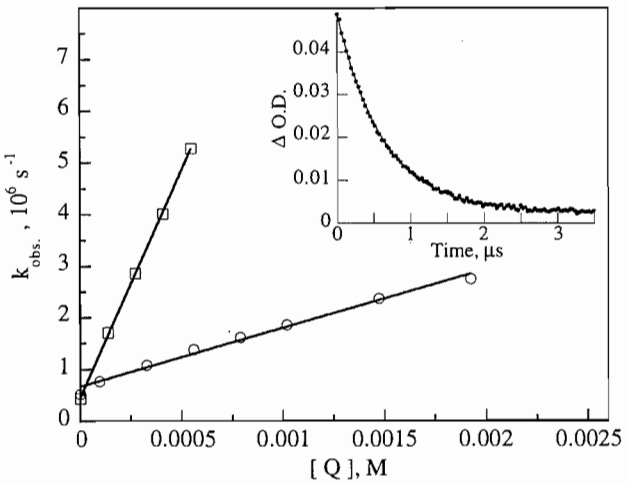
The beam from a Surelite Nd/YAG laser (355 nm, 30 mJ, 7 ns pulse) was focused using a quartz lens on a drop of a solution of xanthone (absorbance at 355 nm was 0.7) in 50 mM **2** in acetonitrile suspended from a needle (20 gauge) in a specially constructed cell. The flow rate of the solution was adjusted using a Sage Instruments model 355 syringe pump, so that each shot of the laser irradiated a fresh drop. Further details of our laser drop system have been published elsewhere (26, 27).

Results

This section is divided according to the multiplicity of the sensitizers used, since this property largely determines the experimental technique employed.

Excited triplet sensitizers

Laser flash photolysis with nanosecond resolution was the technique of choice in this case. We describe in some detail the case of xanthone, which is representative of the method employed in all cases.



Xanthone has an excited triplet energy of ~74 kcal/mol and its triplet state has predominant n,π^* character in nonpolar solvents and π,π^* character in polar or hydrogen-bonding media (24, 28). In acetonitrile, where our experiments were performed, the low-lying triplet has π,π^* character. Under these conditions, the triplet–triplet absorption of xanthone shows λ_{max} at 635 nm. Triplet decay was usually monitored at 640 nm. The triplet state was produced by 355 nm laser excitation, a wavelength at which xanthone has a suitable absorption, but where the quenchers **2–5** are transparent. The triplet is formed following rapid and efficient intersystem crossing of excited singlet xanthone. Typical triplet lifetimes in the absence of quenchers are in the 5–10 μs range, and are largely determined by self-quenching, nonradiative decay and possibly residual traces of oxygen. Addition of initiators **2–5** leads to a shortening of the triplet lifetime. The rate constant for quenching, k_q, can be derived from a plot of the observed pseudo-first-order rate constant for decay ($k_{obs} = \tau^{-1}$) as a function of the quencher concentration, eq. [4] and Fig. 1,

$$[4] \quad k_{obs} = k_o + k_q[Q]$$

Fig. 1. Quenching of xanthone triplets by TEMPO (□) and **3** (○) in acetonitrile. *Inset:* Decay of triplet xanthone monitored at 640 nm in the presence of 0.8 mM **3**.

where k_0 is the rate constant for triplet decay in the absence of added quenchers. All plots were linear, and lead to the rate constants of Table 1.

With all sensitizers, it is important to examine the quenching of the excited state by TEMPO itself, since sensitized decomposition of the initiators can lead to the formation of TEMPO according to reaction [5].

Recombination of the benzylic radical with TEMPO to reform starting material is usually slower than the combination of two benzylic radicals (15–17, 29), thus leading to some accumulation of TEMPO in the samples. While we have used fresh samples throughout this work, special care was taken whenever the quenching rate constant was 1% or less of the TEMPO value.

Among the other sensitizers, 1-azaxanthone (73 kcal/mol) has essentially the same triplet energy as xanthone, but its lowest triplet has n,π^* character in both polar and nonpolar media. Lower energy sensitizers, such as 4-phenylbenzophenone (61 kcal/mol) and thioxanthone (~65.5 kcal/mol) were also tested, although it soon became evident that not only were the quenching rate constants much slower than for xanthone and 1-azaxanthone but, in addition, the fraction of quenching events leading to fragmentation was very small. This is indicated in Table 1 by the signs "+" and "−" for detectable and undetectable benzylic radicals, respectively. Clearly, as the triplet energy decreases, the rate constant for quenching drops dramatically even for energies that are well in excess of the O—C bond energies. No radicals were detected in the case of 4-phenylbenzophenone. While interference from triplet–triplet absorption makes this experiment difficult, we are confident that the radical yield is very small or zero. Similarly, no radicals were detected in the case of thioxanthone. The case of azaxanthone is particularly difficult because samples that have a suitable absorption (usually ~0.3) at the laser wavelength (355 nm) are strongly absorbing in the 310–330 nm region where benzylic radicals absorb. In spite of these problems, it was possible to establish the presence of benzylic radicals in at least two systems (see Table 1).

In an attempt to determine the yield of benzylic radicals, the decomposition of adduct **2** was sensitized by xanthone. This sensitizer was chosen since results from the laser flash photolysis had shown that the benzylic radical was formed when the xanthone triplet was quenched. Steady state irradiation at 350 nm with a sensitizer concentration similar to that used in the laser flash photolysis study and a 50 mM concentration of adduct did not result in the detection of bibenzyl as would be expected from benzylic radical recombination. Most likely, accumulation of small amounts of TEMPO rapidly makes radical cross-combination (i.e., trapping by TEMPO) more favorable than self-reaction (18). In an attempt to increase the concentration of radicals without TEMPO accumulation, recourse was made to the laser drop technique. Although developed in our laboratory to study multiphotonic processes, it is also possible to use the technique to study monophotonic reactions, and increase the yield of transient species generated, thus favoring second-order processes. Laser drop photolysis of a 50 mM solution of **2** in acetonitrile containing enough xanthone to have an absorbance of 0.7 at 355 nm resulted in the formation of bibenzyl, detected by GC and confirmed by GC–MS with authentic samples. The yield of bibenzyl was 5%. Repeating the laser drop cycle did not increase the yield of bibenzyl, although this is not surprising given the fact that there will be an accumulation of TEMPO as the reaction proceeds, and the known efficiency of TEMPO quenching of the excited state.

Excited pyrene as a singlet sensitizer

Pyrene, with its long singlet lifetime and moderately high singlet excited state energy (~83 kcal/mol) was an obvious choice as a singlet sensitizer (30, 31). Quenching can be readily examined by monitoring the effect of quenchers **2**–**5** on the fluorescence from pyrene. The analysis is much the same as in the case of triplet sensitizers described earlier. Figure 2 shows quenching plots obtained using a static system. The rate constant for TEMPO was also examined and has been included in Table 2.

Discussion

Nitroxides are excellent quenchers of excited states, normally promoting intersystem crossing to the ground state in the case of triplets, and a mixture of crossing to the triplet state (32) and probably to the ground state in the case of excited singlets. Where data for TEMPO quenching are available from earlier work, our values agree well with those in the literature (32–38). As indicated earlier, it is important to know the quenching rate constants for TEMPO in order to evaluate accurately the possibility of quenching interference due to TEMPO released

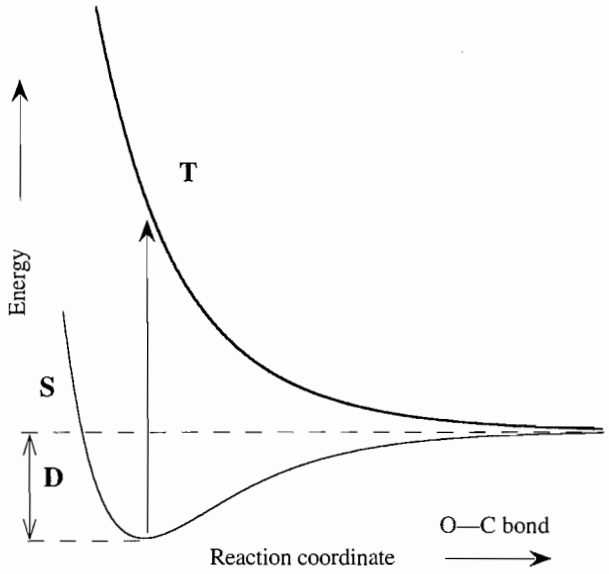
[a]Refers to benzylic radicals and is not applicable to the examples of TEMPO quenching.

Fig. 2. Quenching of pyrene fluorescence by **2** and **5** in acetonitrile at room temperature.

in the photoreactions under study. Given the fast rates measured (see Tables 1 and 2), and the fact that cleavage only occurs in the case of the faster triplet systems, it seems unlikely that minor traces of TEMPO will be enough to shorten significantly the lifetimes of excited sensitizers. To further verify this conclusion, in the case of xanthone we determined the rate constants using fresh samples (our standard procedure) and then repeated the determination with these pre-used (i.e., already exposed) samples. The rate constants obtained in the two experiments were identical, thus confirming that nitroxide accumulation is not a problem.

Table 2. Quenching rate constants for pyrene fluorescence in acetonitrile at room temperature.

Quencher	$k_q/M^{-1}\ s^{-1}$
TEMPO	$(1.6 \pm 0.1) \times 10^{10}$
2	$(6.6 \pm 0.4) \times 10^7$
3	$(6.1 \pm 0.1) \times 10^7$
4	$(6.8 \pm 0.4) \times 10^7$
5	$(4.5 \pm 0.2) \times 10^8$



The results of Tables 1 and 2 should be examined in the context of the bonds being broken. While there is still some question concerning the strength of the O—C (see eq. [5]) bond being broken, all estimates seem to fall in the 25–40 kcal/mol range (12–14, 22, 39). Bond energies in this range are also consistent with the failure to produce **5** by thermal methods (21). Thus, all the sensitizers employed carry enough excitation energy that the sensitized cleavage of reaction [5] should be at least 20 kcal/mol exothermic. However, some fail to sensitize this process, as reflected by slow rate constants for thioxanthone and 4-phenylbenzophenone, and the failure to detect benzylic radicals with these sensitizers even when quenching takes place. It is clear that generating a benzylic radical is key to sensitized decomposition. Turro and co-workers have reported that *O*-alkyl-TEMPO adducts do not quench benzophenone triplets (40).

The following trends are observed in the case of triplet sensitizers.

Fig. 3. Qualitative potential energy profile showing the energetics in the singlet and triplet surfaces as a function of the C—O bond length. The shape shown is based on Morse-type curves.

1. Only sensitizers with triplet energies ≥ 63 kcal/mol are efficiently quenched by all the substrates examined.
2. For comparable triplet energies, quenching is faster for n,π^* (1-azaxanthone) than for π,π^* (xanthone) triplet states.
3. Triplet energies of at least ~66 kcal/mol are required for cleavage to occur.
4. It seems reasonable to assume that O—C bond energies will follow the order **2** > **3** ≈ **4** > **5**. Quenching rate constants generally follow this order.

We believe that the simplest way to rationalize these results is to invoke a quenching mechanism similar to that proposed for peroxides. We have proposed that sensitized decomposition of peroxides involves energy transfer to the repulsive triplet surface associated with the O—O bond (41). We suggest that similar concepts apply in this case, as illustrated in Fig. 3. Clearly, reaching the triplet surface requires energies well in excess of the bond energy, "*D*." It seems that the critical energy for rapid quenching and efficient cleavage must be in the 65–70 kcal/mol. In the case of *O*-alkyl TEMPO adducts studied by Turro (40), the stronger C—O bond leads to an even slower rate of quenching.

Steric hindrance must increase in the order **2** < **3** ≈ **4** < **5**. Thus, we would have expected quenching by **5** to be the slowest if steric effects were rate determining. This order is not observed with any of the sensitizers. In the case of 4-phenylbenzophenone, where the energetics are probably borderline, only **5**, which is expected to have the weakest bond, shows significant quenching.

The excited singlet energy of pyrene is around 83 kcal/mol and is, by analogy with triplet states, sufficient to overcome energy requirements for bond cleavage. As expected, rates of quenching are very fast (see Table 2), although not diffusion limited. Yet, in all these systems we systematically failed to detect benzylic radicals, in spite of the efficient quenching and the intense absorption of the radicals in the UV region. It is tempting to suggest that this is due to rapid recombination within the solvent cage from which the radicals of reaction [5] never escape. However, this argument is probably flawed. For example, in the case of **2** the rate constant for benzyl radical scavenging by TEMPO in acetonitrile is $(9.5 \pm 0.7) \times 10^7$ M^{-1} s^{-1} (17). The value should be multiplied by four, since for a singlet radical pair in the solvent cage no correction for spin statistics is needed, in contrast with the case of random encounters where only one quarter can be effective. Even the corrected (×4) value is only $\sim 4 \times 10^8$ M^{-1} s^{-1}, significantly below the diffusion limit in acetonitrile, which is around 2×10^{10} M^{-1} s^{-1}. This implies that a pair of radicals (such as TEMPO and 1-phenylethyl) in a solvent cage are expected to undergo a considerable degree of separation. Thus, the two possible explanations for the low radical yield under pyrene sensitization are either that quenching does not involve cleavage of the C—O bond, or that the geminate radical pair is different from that formed in a random encounter in solution. We favor the latter explanation. We suggest that the reason why escape is not efficient is that many collisions take place in random encounters before one occurs with the correct orientation for reaction. In contrast, the nascent radical pair generated by singlet pyrene sensitization is born with the correct spin and orientation for recombination, with no solvent molecules separating the radical partners. Thus, under these unique "contact" conditions, back reaction may occur with remarkable efficiency.

From the perspective of initiation of living free radical polymerization, it is clear that triplet sensitizers should be preferred over singlet ones. Further, it would appear that energies near 70 kcal/mol are required for efficient quenching *and* formation of free radicals, albeit in low yields. However, efficient polymerization should still occur, since it is well established that the concentration of active "living" polymer is quite low in other thermal "living" systems . Among the sensitizers used here, xanthone should probably be preferred. It may appear upon cursory examination of the rate constants that 1-azaxanthone may be a better sensitizer. However, we note that 1-azaxanthone has an n,π^* triplet character in all solvents, which makes it very prone to radical-like reactions, such as hydrogen abstraction. In contrast, xanthone has a low-lying π,π^* state in polar or hydrogen-bonding solvents where it is a poor hydrogen abstractor. Thus, we expect fewer complications in the case of xanthone.

Abstract: Photodynamic therapy relies on the selective accumulation of photosensitizers within neoplastic tissue, followed by light activation to generate cytotoxic singlet oxygen. At present, Photofrin™, a preparation of hematoporphyrin derivatives (HPD) with the bulk of the porphyrin monomers removed, is the only clinically approved photosensitizer. Intravesical administration of Photofrin or HPD has failed to photosensitize bladder tumors. Bladder cancer is the second most common genitourinary malignancy. In 1994 there were an estimated 51 200 cases of bladder cancer with 10 600 deaths in the United States. The predominant histopathology is transitional cell carcinoma, occurring in 90–95% of these cases. Most patients (85%) have superficial disease at the time of initial diagnosis. Superficial bladder cancer is defined as disease involving the mucosa with carcinoma in situ or papillary lesions and invasion limited to submucosa. To address these limitations we have been conducting preclinical studies with perylenequinones (PQs). The majority of our effort has focused on developing and characterizing derivatives of PQs. Following site-directed modifications, we have identified certain congeners that warrant further preclinical development. These compounds are monomeric and do not effect cutaneous photosensitization beyond 24 h. With clinically relevant drug and light doses we have cured >90% of experimental subcutaneous murine tumors.

Key words: photodynamic therapy, perylenequinones, photobiology, photochemistry.

Résumé : La thérapie photodynamique repose sur l'accumulation sélective de photosensibilisateurs dans le tissu néoplastique, suivie d'une activation par la lumière pour générer l'oxygène singulet cytotoxique. Actuellement le seul photosensibilisateur approuvé cliniquement est la Photofrine™, une préparation à base de dérivés de l'hématoporphyrine (HPD) dans laquelle on a supprimé l'encombrement de la porphyrine monomère. L'administration intravésiculaire de la Photofrine n'a pas permis de photosensibiliser les tumeurs de la vessie. Le cancer de la vessie est en importance la deuxième des plus communes tumeurs malignes affectant les fonctions urinaires ou génitales. En 1994, aux États Unis, on dénombré environ 51 200 cas de cancer de la vessie dont 10 600 ont entraîné la mort. L'histopathologie prédominante est un carcinome de transition, se produisant dans environ 90–95% des cas. La plupart des patients (85%) ont des maladies superficielles au moment du premier diagnostique. Le cancer superficiel de la vessie est défini comme une maladie impliquant la muqueuse avec un carcinome in situ ou des lésions papillaires et une invasion limitée de la sous-muqueuse. Dans le but de comprendre ces limitations nous avons effectué des études précliniques avec des pérylènequinones (PQs). Nous avons concentré nos efforts dans le développement et la caractérisation des dérivés des PQs. Après des modifications de site, nous avons identifié certains congénères qui justifient un développement préclinique plus poussé. Ces composés sont des monomères et n'affectent pas la photosensibilisation cutanée après 24 h. Utilisant un médicament clinique appropriée et à des doses légères nous avons soigné plus de 90% des tumeurs sous-cutanées développées expérimentalement sur des cobayes.

Mots clés : thérapie photodynamique, pérylènequinones, photobiologie, photochimie.

[Traduit par la rédaction]

Introduction

The ultimate goal of pharmacology is the development of therapeutic agents that selectively destroy the target tissue while sparing the non-target tissue. Unfortunately, in many disorders including cancer, such a discrimination is hard to achieve. Recently, considerable attention has been paid to photodynamic therapy (PDT) to maximize the therapeutic ratio (1–8). This approach is based on the use of drugs (photosensitizers) that acquire the desired activity when excited by light, but that are relatively innocuous in the absence of light. It permits dual selectivity since the simultaneous presence of both photosensitizer and light is required, so ideally the healthy regions of the system are not affected. The selectivity depends on both the degree of preferential accumulation of the photosensitizer in the target tissue and the extent of spatial localization of light energy to the target tissue. In this modality, a photosensitizer is intravenously injected and then allowed to distribute within the animal (Fig. 1). When the concentration ratio of the photosensitizer between target and non-target tissues reaches a max-

imum, light is directed at the tumor, and then the PDT effect will affect primarily the target tissue. A typical protocol is available for Photofrin (9).

A photosensitizer can be activated by both Type I and (or) Type II pathways (10). Briefly, the photosensitizer is first excited into the short-lived singlet state following the absorption of light. The singlet state of the photosensitizer is converted into the triplet state via an intersystem crossing process, which results in more stable and longer lived species compared with the singlet state. Usually, photosensitization occurs via the triplet state; therefore, a high quantum yield of triplet state formation is required for efficient photosensitizers. The excited triplet state of the photosensitizer can undergo two kinds of reactions. It can directly react with substrate via electron and (or) hydrogen atom transfer to produce radical forms of the substrate and (or) the photosensitizer that, after interaction with oxygen, generate peroxides, hydroxy radical, superoxide anion radical ($O_2^{\cdot-}$), and other oxygenated products (Type I reaction) (9–11). The Type I mechanism is extremely concentration dependent, and is favored when the photosensitizers are bound or associated with readily oxidized biomolecules (12).

Alternatively, the triplet state of the photosensitizer can transfer its energy to the ground state of oxygen to generate singlet oxygen ($^1O_2$), a highly reactive species (Type II reaction). The electrophilic nature of $^1O_2$ makes it very efficient in producing oxidized forms of biomolecules and to initiate most types of PDT[3] damage (10, 11, 13, 17). The properties and biological roles of $^1O_2$ have been well documented (14–16, 18–20).

Type I and Type II reactions (Fig. 2) may occur simultaneously, and the relative contribution of the two processes depends on the nature and concentrations of the substrate and photosensitizer, oxygen concentration, and the binding of the photosensitizer to the substrate. From the above it is evident that the PDT effect should be oxygen dependent. For most photosensitizers, the PDT effect is mediated by $^1O_2$. There are several lines of evidence to suggest that $^1O_2$ is a major damaging species in PDT. However, other activated species, such as $O_2^{\cdot-}$ and hydroxy radical (·OH) may also be involved in some aspects of PDT damage (21, 22).

Although the concept of PDT was proposed 90 years ago (23), with eosin and acridine as prototype photosensitizers, substantial progress was not made until HPD (Fig. 3) was shown in clinical trials to have improved tumor localization properties (24, 25). Since then, extensive basic and clinical investigations have been made with HPD, and the results obtained, which are promising, are summarized in several excellent reviews (2, 3, 6, 8, 11, 26–31). Nowadays, the utilization of sophisticated electrooptical techniques (especially the application of optical fibers in PDT), and advances of knowledge on photophysical and photochemical processes occurring in microheterogeneous systems, have enhanced the efficacy of PDT (11, 32). A variety of phototherapeutic procedures have been developed, some of which have currently reached the stage of clinical application (1, 2, 6, 23, 33, 34).

As laser and optical techniques develop rapidly (such as the application of endoscopy illumination), PDT depends more and more critically on the development of photosensitizers with superior properties. These include, especially, strong absorption in the "phototherapeutic window" region from 600 to 950 nm, in which tissue light scattering is low and there is little competing absorption from endogeneous biomolecules, such as hemoglobin, melanin, and water. This would permit deep light penetration into tissue and render PDT potentially feasible for many clinically important tumors. In addition, high preferential tumor localization and minimal dark toxicity to enhance the therapeutic ratio, as well as rapid clearance from normal tissue to suppress prolonged photosensitivity side effects, would also have beneficial effects (17, 35).

Although promising results have been obtained with HPD, there are disadvantages with this agent. Specifically, HPD has little absorption in the "phototherapeutic window" region, limiting its PDT efficiency, and it is retained in several types of normal tissue, such as skin, for extended time (about 4–6 weeks), resulting in severe prolonged skin photosensitivity (3, 9). To overcome these problems with HPD, renewed interest in the synthesis and evaluation of new photosensitizers for the treatment of malignant and infectious disorders has arisen.

Perylenequinones

4,9-Dihydroxy-3,10-perylenequinones comprise a relatively small but growing group of natural pigments that possess unique chemical and biological properties (36–38). The natural PQs of this class identified to date include hypocrellins, cercosporin, phleichrome, elsinochromes, erythroaphins, and calphostins (see Fig. 4). Most of them are produced by a wide variety of molds and act as photodynamic phototoxins of their hosts, except that erythroaphins are isolated from aphids. Substantial progress has been made recently in the application of PQs in the PDT of human malignancies (38–40), anticancer (41), and possibly anti-HIV (42–44). The latter property was related to the potent specific inhibition of protein kinase C by PQs (45, 46).

Occurrence, isolation, and synthesis

Although fungi were considered as the richest sources of PQs, there exist other sources to produce PQs, such as certain kinds of soil and insects (36, 37). Erythroaphins were the first isolated and characterized members of the PQ class, after which elsinochromes, cercosporin, cladochrome, and phleichrome were isolated and identified. Recently, two new kinds of PQs, hypocrellins and calphostins, have been reported (38, 46–49).

Hypocrellin, which includes hypocrellin A (HA) and hypocrellin B (HB), derives its name from *Hypocrella bombuase (B. et Br) sacc.*, a parasitic fungus of *Sinarundinaria sp.* which grows abundantly in the northwestern region of Yunnan Province and the southeastern region of Xizang Autonomous Region of the People's Republic of China (P.R.C.) and also in

$${}^3PS + {}^3O_2 \longrightarrow PS + {}^1O_2 \qquad \text{(TYPE II)}$$

Requirements for Optimal PDT Photosensitizer

(1) Strong absorption above 600 nm.
(2) High quantum yield of triplet formation.
(3) High tumor-retained selectivity.
(4) Minimal dark toxicity
(5) Rapid clearence from normal tissue.

certain parts of Sri Lanka. Hypocrellin constitutes up to 4% of the fungus (37). *Shiraia bombusicola P. Heen* also contains the same pigments that are structurally related to the general class of pigments. In addition to hypocrellin, other perylenequinonoid pigments are isolated from other microbial sources found in other countries, such as cercosporin, phleichrome, elsinochrome A, B, C, and D, cladochrome, and erythroaphin. The structural similarities of these pigments led to some common properties among them and occasioned comparative studies between hypocrellin and the other related pigments. However, the fungus that generates individual perylenequinonoid pigments generally exists only in certain regions of the P.R.C. This has stimulated the study of methods by which the perylenequinonoid pigments can be totally synthesized (37).

Mei and Luo (50) reported the first case in which oral administration of hypocrellin caused hypericism, a state of skin sensitivity to visible light in animals. Twenty years later, it was proved that the photosensitizing effects caused by hypocrellin depend on the presence of oxygen, and thus it was recognized as a photodynamic action. Interestingly, hypocrellin has also been utilized as a potent phototherapeutic agent for white lesions of vulva, keloid, vitiligo, psorasis, tinea capitis, and lichen amyloidosis (38). Recently it has also been shown that HA has a strong PDT effect (39). In addition, hypocrellin has bactericidal and other physiological activities (38). In the past, the hypocrellin-containing *Hypocrella bambuase* was used to treat rheumatoid arthritis and gastric disease.

Although, as early as in 1954, Calderbank et al. prepared 4,9-dihydroxy-3,10-perylenequinone, the parent compound of the natural perylenequinonoid pigments (51), it was not until 1972 that Weisgraber and Weiss synthesized the first derivative of this class bearing methoxy groups, a characteristic substituent in natural perylenequinones, starting from commercial homoveratric acid (52*a*). However they later modified the assigned perylenequinonoid structure to be dinaphthofuranedione (52*bc*). Until recently, relatively few efforts have been devoted to the synthesis of perylenequinone structures. Dallacker and Leidig prepared a methoxylated perylenequinone but this compound still lacked some indispensable functionalized groups at appropriate positions (53). Subsequently Chao and Zhang synthesized another perylenequinone bearing methoxy groups and acetic ester side chains in their correct positions by two different methods, which were then modified to provide natural perylenequinone (54).

In the first route of Chao and Zhang, and in that of Dallacker and Leidig, a biphenyl, formed from an Ulmann coupling reaction, was elaborated into the desired pentacycle. The second route developed by Chao and Zhang utilized a double oxidative coupling reaction of a 5-bromo-1,2-naphthalenediol to generate the perylenequinonoid nucleus. However, the required 5-bromo-1,2-naphthalenediol in the second route of

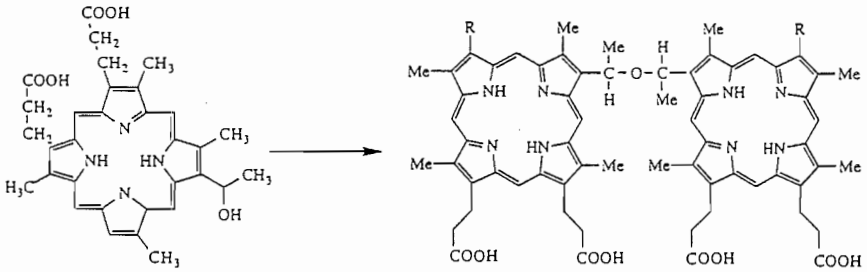
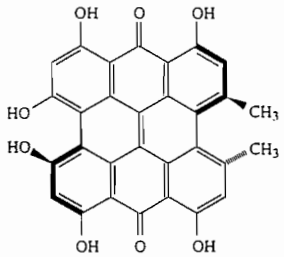
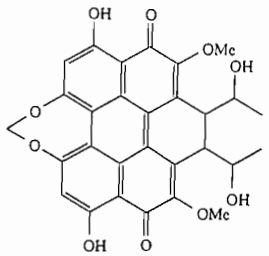
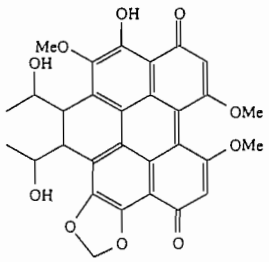
Fig. 3. Representative porphyrin photosensitizers.









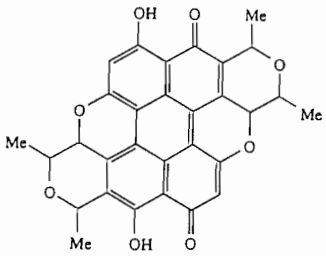


Fig. 4. Representative perylenequinone structures.

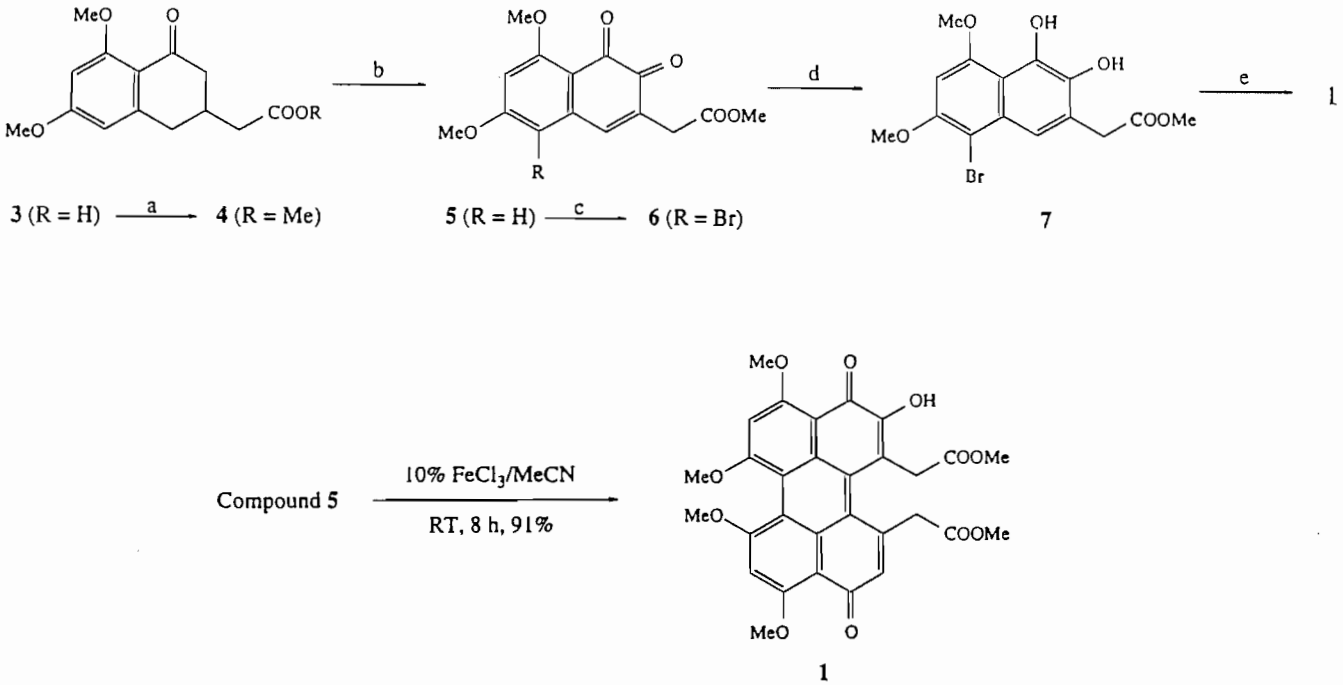
Chao and Zhang is difficult to prepare and readily decomposes (vide infra). An alternative route for the preparation of a 5-bromo-1,2-dioxygenated naphthalene, based on a Diels–Alder cycloaddition, was later developed by Coleman and Grant, but this naphthalene lacked the three carbon side chains found in natural perylenequinones (55). Subsequently, a selective and stereospecific approach was developed for the total synthesis of phleichrome, the first successful synthesis of a natural perylenequinone. However, this approach requires at least 26 steps starting from commercially available reagents, and several of these steps require stringent experimental conditions (56). Thus the procedure is inconvenient and ill-adapted for the preparation of various functionalized perylenequinones with different substituents at different positions. Therefore, we reexamined and attempted to improve upon the double coupling method of Chao and Zhang to synthesize certain perylenequinones. During this research, we developed a convenient and higher-yielding route to perylenequinones (Fig. 5).

Total synthesis of hypocrellin B



The synthetic approach toward HB that we have initiated is outlined in Fig. 6. Simplification of HB by a retro-aldol condensation of methyl ketone provides **1**; cleavage of the two biaryl bonds of **1** in a retrosynthetic sense affords 3-acetonyl-6,8-dimethoxy-1,2-naphthoquinone **2**. Takuwa et al. (57*a*) reported a one-pot photochemical reaction to prepare 3-(2-oxoalkyl)-1,2-naphthoquinone; however, it afforded only very low yield of the precursor **2**. Recently, Hauser and co-workers reported the total synthesis of calphostin D and gave a method to prepare precursor **3** in high overall yield (57*b*). Hydrolysis of **3** followed by oxidation affords **2** in high yield. The precursor **2** is unstable and was used immediately for the next coupling reaction by $FeCl_3$ or TFA, but no anticipated product was obtained.

An efficient total synthesis of HB was accomplished using another precursor **6** as shown in Fig. 6. The commercially available 3,5-dimethoxybenzaldehyde was converted to compound **5** via seven reaction steps according to the procedure of

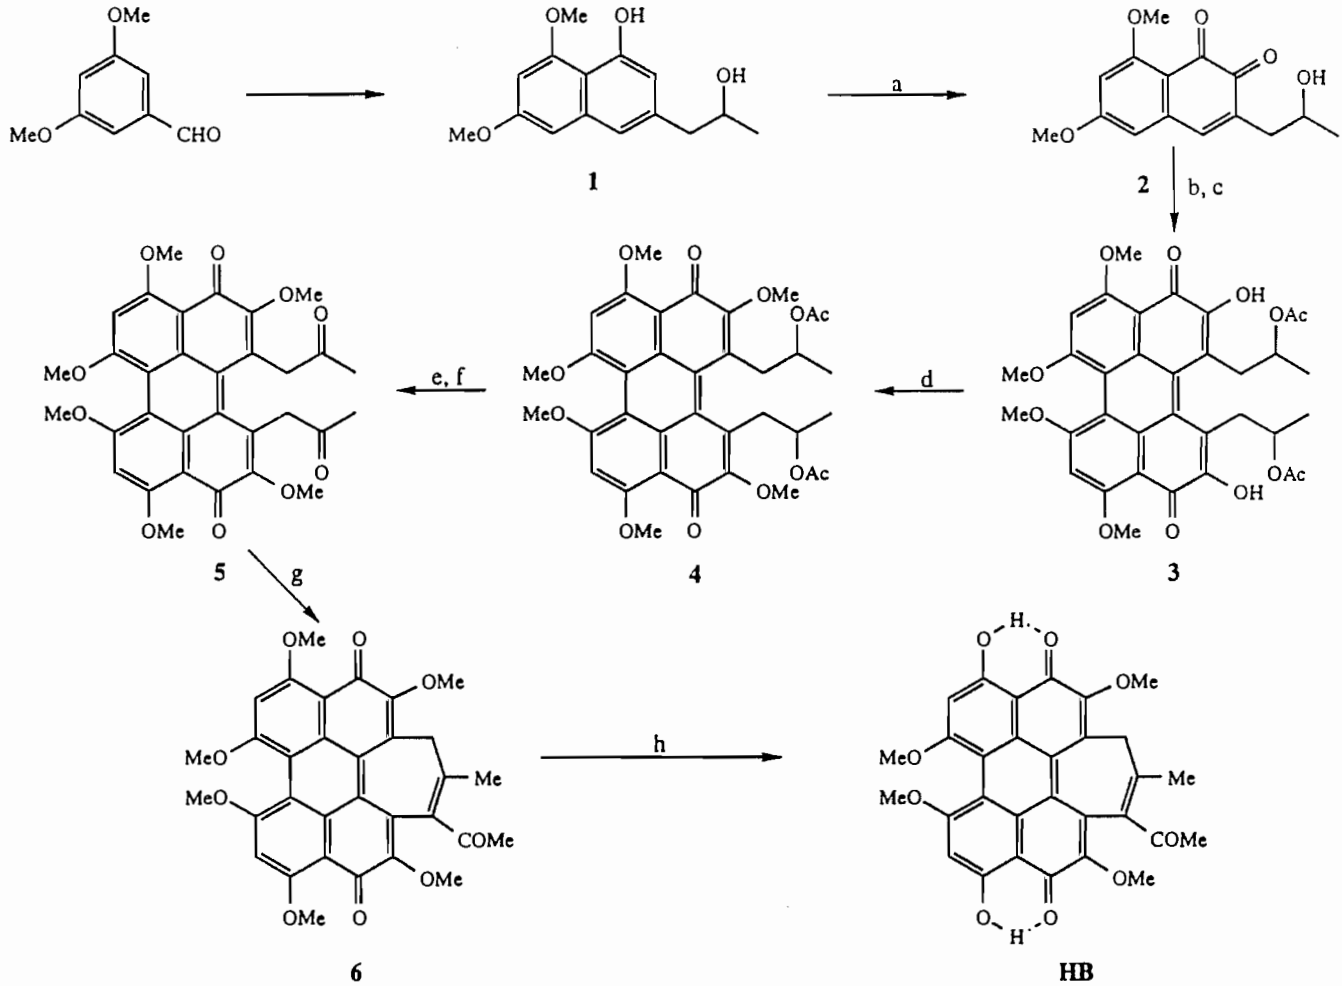
Fig. 5. Synthesis of perylenequinones from one-step double coupling reaction of 1,2-naphthoquinone. Reagents and conditions: a. MeOH/H_2SO_4, reflux, 95%; b. SeO_2/HAc, 80–90°C, 71%; c. NBS/H_2SO_4/THF, RT, 41%; d. SO_2/MeOH·H_2O, reflux, 96%; e. $FeCl_3$/MeCN, RT, 28%.

Hauser and co-workers (57*b*). Oxidation of **5** with benzeneseleninic anhydride in anhydrous THF gave the 1,2-naphthoquinone **6** in 87% yield (59). Attempted coupling of **6** to the corresponding perylenequinone by TFA and $FeCl_3$ was not successful but coupling of its ester, which was prepared in the presence of Ac_2O, pyridine, and a catalytic amount of DMAP in 95% yield, gave perylenequinone **7** in 88% yield. Methylation of **7** with methyl iodide and CsF in anhydrous THF led to compound **8** quantitatively. Hydrolysis of **8** in K_2CO_3 and MeOH·H_2O solution, followed by oxication with CrO_3 and pyridine in CH_2Cl_2, gave the methyl ketone **1** in 63% overall yield (60). Compound **9**, which was obtained from **1** in 85% yield by an intramolecular aldol condensation reaction, was demethylated selectively with 48% hydrobromic acid to afford a 1:1 mixture of enantiomers HB (90%), which was identical in all respects (TLC, IR, and NMR) with the natural product HB. This synthesis now provides an entry to the synthesis of other important perylenequinones (Fig. 6). We have reported additional synthetic routes to certain related perylenequinone structures (108).

Photophysical and photochemical properties of perylenequinones

In terms of photophysical and photochemical studies of natural PQs, hypocrellins and cercosporin have received the most attention. As a general rule, PQs have three visible absorption bands, which are respectively assigned to a $\pi\pi^*$ transition of their conjugated systems and charge transfer. Their fluorescence emission spectra consist of a major peak of the neutral species with a shoulder peak attributed to the zwitterions, which are formed via intramolecular proton transfer (37, 61). The excimers of hypocrellin A (HA) and hypocrellin B (HB) were detected both in concentrated solution and in the crystalline states of the hypocrellins (61). In addition, HA and HB may act as molecular probes for the diagnosis of cancer, since the environmental effects of their fluorescence spectra have been well characterized (37, 62).

The singlet states of PQs were investigated by means of static and time-resolved fluorescence spectroscopy (38, 63). Relatively few investigations have been made concerning the triplet states of PQs, since no phosphorescence or triplet–triplet absorption spectra were recorded. However, some significant triplet parameters (such as lifetime, energy level, and quantum yield) were indirectly estimated for HA, HB, and cercosporin on the basis of the relationship between delayed fluorescence and phosphorescence (38, 63).



PQs are an efficient class of $^1O_2$ generators with quantum yields comparable with those of porphyrins. In aerobic solution, the production of $^1O_2$ by PQs was detected by means of chemical trapping reactions, spin trapping, and $^1O_2$ luminescence (64, 65). On the basis of a series of comparative studies, the 4,9-dihydroxy-3,10-perylenequinonoid chromophore was determined to be the essential structural requirement for the generation of $^1O_2$ by the quinones, and the side chains of the quinones had little effect on the production of $^1O_2$. This conclusion is a key finding for the design of PDT agents, which are now required to contain the 4,9-dihydroxy-3,10-perylenequinonoid chromophore, efficiently producing $^1O_2$, appropriate side chains, promoting cellular uptake, and, ideally, the selective localization of the sensitizers in tumor tissue (22).

In addition to $^1O_2$, $O_2^{\cdot-}$ is also generated by PQs on illumination via the reduction of oxygen by the semiquinone radicals of the PQs in aerobic solution, but to a lesser extent than $^1O_2$. This process is significantly enhanced by the presence of electron donors (22). There were several lines of evidence for

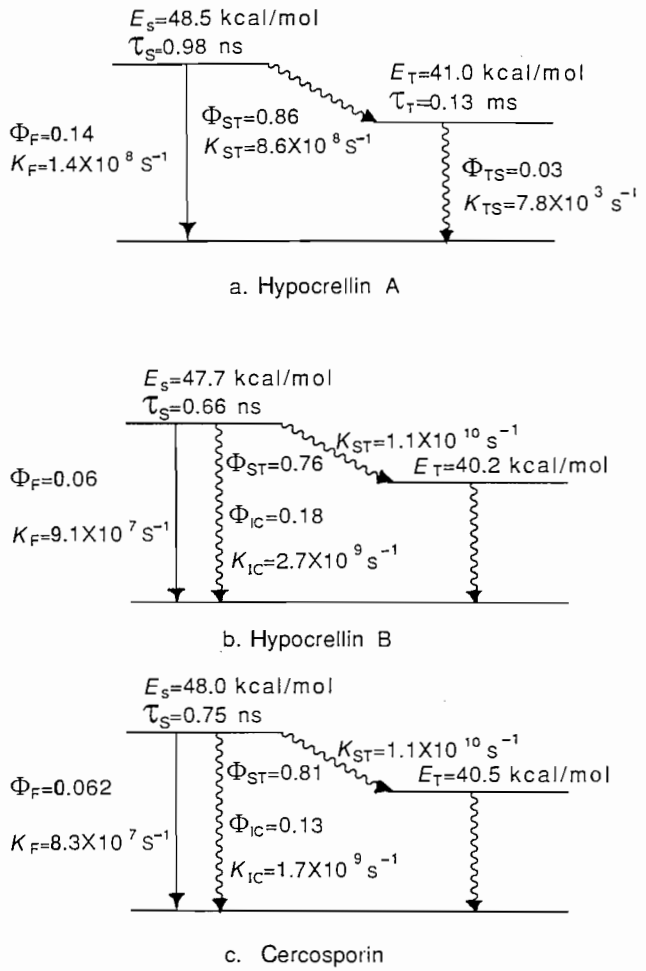
the photoproduction of OH by PQs, but for which the exact mechanism is still obscure (22, 65).

Besides the reactive oxygen species, semiquinone radicals of PQs were also detected in the photosensitizations of PQs. In anaerobic solution, the semiquinone radicals are predominantly photoproduced via self-electron transfer between excited and ground state species (38, 67). The semiquinone radicals of HA, HB, elsinochrome A, and cercosporin display well-defined EPR spectra, which were assigned by reference to simulated spectra. The presence of electron donors significantly promotes the production of the semiquinone radicals (66, 67).

Evidently the photodynamic action of PQs involves a number of processes (3, 22, 63, 67–70). Although $^1O_2$ was determined to be a major active intermediate for PQ photosensitization, the supplemental roles of other reactive species, such as $O_2^{\cdot-}$, $\cdot OH$, H_2O_2, and the semiquinone radicals of the sensitizers, should also be considered. Oxygen consumption and EPR studies confirmed that oxygen concentration plays a key role in the mutual transformation between $^1O_2$ (Type II) and the semiquinone radicals (Type I) (22).

The degradation of some biological molecules (such as amino acids, peptides, protein, bases, DNA, lipids) sensitized by HA has also been investigated extensively. These reactions may be mediated by Type I and (or) Type II pathways, depending upon the reaction conditions, such as the nature of substrate, oxygen concentration, pH, etc. (38). The photooxidations of tryptophan and its derivatives were demonstrated to have some biological relevance to the phototherapeutic mechanism of hypocrellins (71–73). Like many photosensitizers, hypocrellins, cercosporin, and calphostins were demonstrated to sensitize the inactivation of some enzymes, such as ATPase, GAPDHase, AcEase, and protein kinase C (38, 74).

Perylenequinonoid pigments, novel singlet oxygen sensitizers



The marked photosensitizing properties of perylenequinonoid pigments, now a promising class of the agents for photodynamic therapy of human tumors, have been recognized but quantitative information on their excited states are lacking. For the first time, some fundamental photophysical parameters of hypocrellins A, B and cercosporin in solution have been determined (63). For hypocrellin A, $K_F = 1.4 \times 10^8\ s^{-1}$,

Fig. 7. Energetics of photoexcitation processes for the representative perylenequinones hypocrellin A and B and cercosporin.

$\Phi_F = 0.14$, $\tau_s = 0.98$ ns, $E_s = 48.5$ kcal/mol, $\Phi_{ST} = 0.86$, $K_{ST} = 8.6 \times 10^8$ s^{-1}, $\Phi_{TS} = 0.03$, $K_{TS} = 7.8 \times 10^3$ s^{-1}, $\tau_T = 4.5$ μs (in the presence of oxygen), $\tau_T \geq 0.13$ ms (in the absence of oxygen), and $E_T = 41.0$ kcal/mol (63). For hypocrellin B, $K_F = 9.1 \times 10^7$ s^{-1}, $K_{IC} = 2.7 \times 10^9$ s^{-1}, $K_{ST} = 1.1 \times 10^{10}$ s^{-1}, $\Phi_F = 0.06$, $\Phi_{IC} = 0.18$, $\tau_s = 0.66$ ns, $E_s = 47.7$ kcal/mol, $\Phi_{ST} = 0.176$, and $E_T = 40.2$ kcal/mol. For cercosporin, $K_F = 8.3 \times 10^7$ s^{-1}, $K_{IC} = 1.7 \times 10^9$ s^{-1}, $K_{ST} = 1.1 \times 10^{10}$ s^{-1}, $\Phi_F = 0.062$, $\Phi_{IC} = 0.13$, $\tau_s = 0.75$ ns, $E_s = 48.0$ kcal/mol, $\Phi_{ST} = 0.81$, and $E_T = 40.5$ kcal/mol.

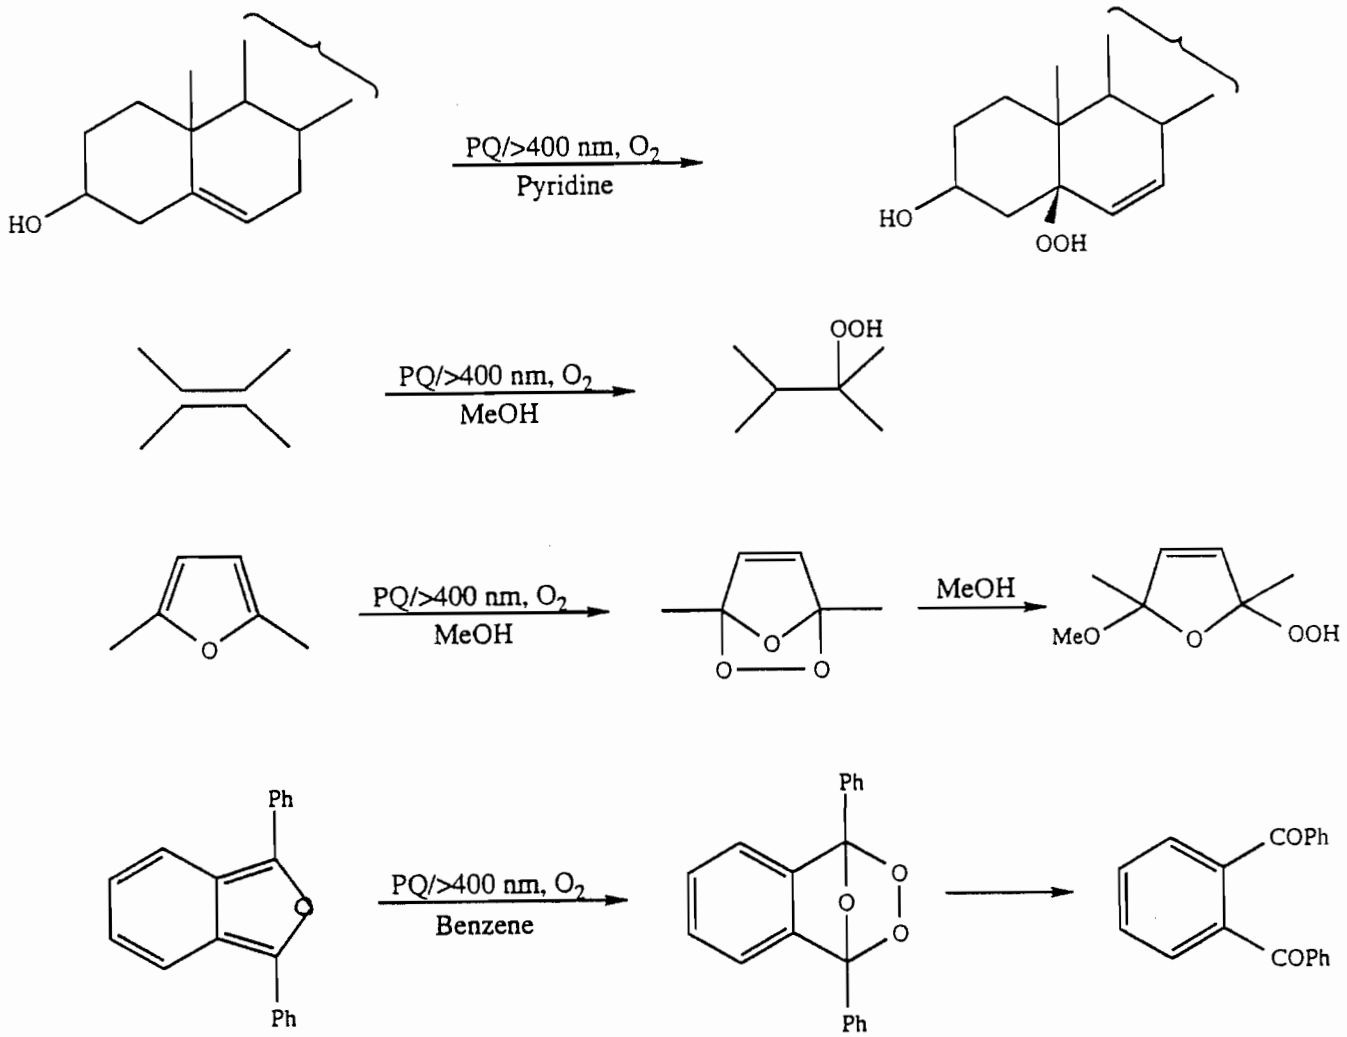
In addition, the energy diagrams of hypocrellins A, B and cercosporin were established (Fig. 7). Differences are apparent between the decay process of singlet hypocrellin A and those of singlet hypocrellin B and cercosporin. The quantum yields of singlet oxygen formation by these agents were also determined, $\Phi_{^1O_2}$ (HA) = 0.83, $\Phi_{^1O_2}$ (HB) = 0.76, and $\Phi_{^1O_2}$ (CP) = 0.81 (63). As well, these perylenequinonoid agents have been shown to act as excellent singlet oxygen sensitizers (Fig. 8). The characteristics of the sensitizer play a key role in any sensitized photooxygenations. The marked photophysical and photochemical characteristics of the PQ pigments qualify them as a new class of efficient $^1O_2$ sensitizers with the following advantages warranting their application in photosensitized reactions: (*i*) large molar absorptivity at the appropriate wavelength; (*ii*) high quantum yield of $^1O_2$ formation; (*iii*) large adaptability for solubility; (*iv*) small solvent effect to simplify photochemical reactions; (*v*) wide irradiation wavelength region; (*vi*) large concentration tolerance, and (*vii*) low tendency toward hydrogen abstraction and self-photooxidation, causing their bleaching and high thermal stability.

The photooxidation of hypocrellin A. A mechanism study using ^{18}O labelling

For the PDT of human tumors, the photooxidation of the sensitizer employed appeared to be a critical factor, which therefore needed to be comprehensively examined. On the one hand photooxidation of the sensitizer should be minimized because it destroys sensitizer, thereby decreasing photodynamic therapeutic efficiency, but on the other hand it can also be utilized as a basis for the selective destruction of the sensitizer following PDT treatment to obviate long-term photosensitivity (75).

Among the natural PQs, cercosporin, elsinochromes, and erythroaphins are not readily photooxidized, and only the photooxidations of hypocrellins and phleichrome have been observed (76). In 1981, Chen et al. (77) suggested that HA photooxidation results in an endoperoxide via the [2+4] addition of singlet oxygen ($^1O_2$) formed during irradiation to ground state HA.

However, they deduced this mechanism only on the basis of the assigned structure of the photooxidized product of HA, and did not supply any evidence for the involvement of $^1O_2$ in the photooxidation of HA (77). In fact, the assigned structure of the photooxidized products of HA has been also revised by Liang's X-ray diffraction data. In 1985, Zhang et al. (78) proposed that HA photooxidation proceeds via the reaction of excited (singlet and (or) triplet) HA with ground state oxygen (instead of $^1O_2$).



Subsequently Zhao et al. reassigned the main photooxidized product of HA as the dioxetane generated from the [2+2] addition of ground state oxygen to excited HA instead of the endoperoxide proposed by Chen et al. (77, 79). The correct structure of the photooxidized product of HA was established, by X-ray diffraction in 1988, to be a di-α-naphthoquinone compound (38).

Nevertheless, Arone et al. observed that the photooxidation of phleichrome, an HA analog, does form endoperoxides, typical $^1O_2$ photooxidized products, and that prolonged irradiation also leads to the formation of a di-α-naphthoquinone as in HA photooxidation (80, 81). Again, unfortunately, a mechanistic study of the photooxidation of phleichrome is not available. Consequently it appears that the photooxidation mechanism of HA is confusing, and that of phleichrome is ambiguous. It is evident that our knowledge of the photooxidation mechanisms of PQs is incomplete. For example, it was necessary to establish whether $^1O_2$ is involved in the photooxidation of PQ.

Hypocrellin A was selected as a representative structure for investigating the mechanism of the photooxidations of perylenequinonoid pigments. The following processes were determined to be involved in the photooxidation of perylenequinonoid pigments using ^{18}O atom labelling. After perylenequinonoid pigment is photoexcited, it tautomerizes and

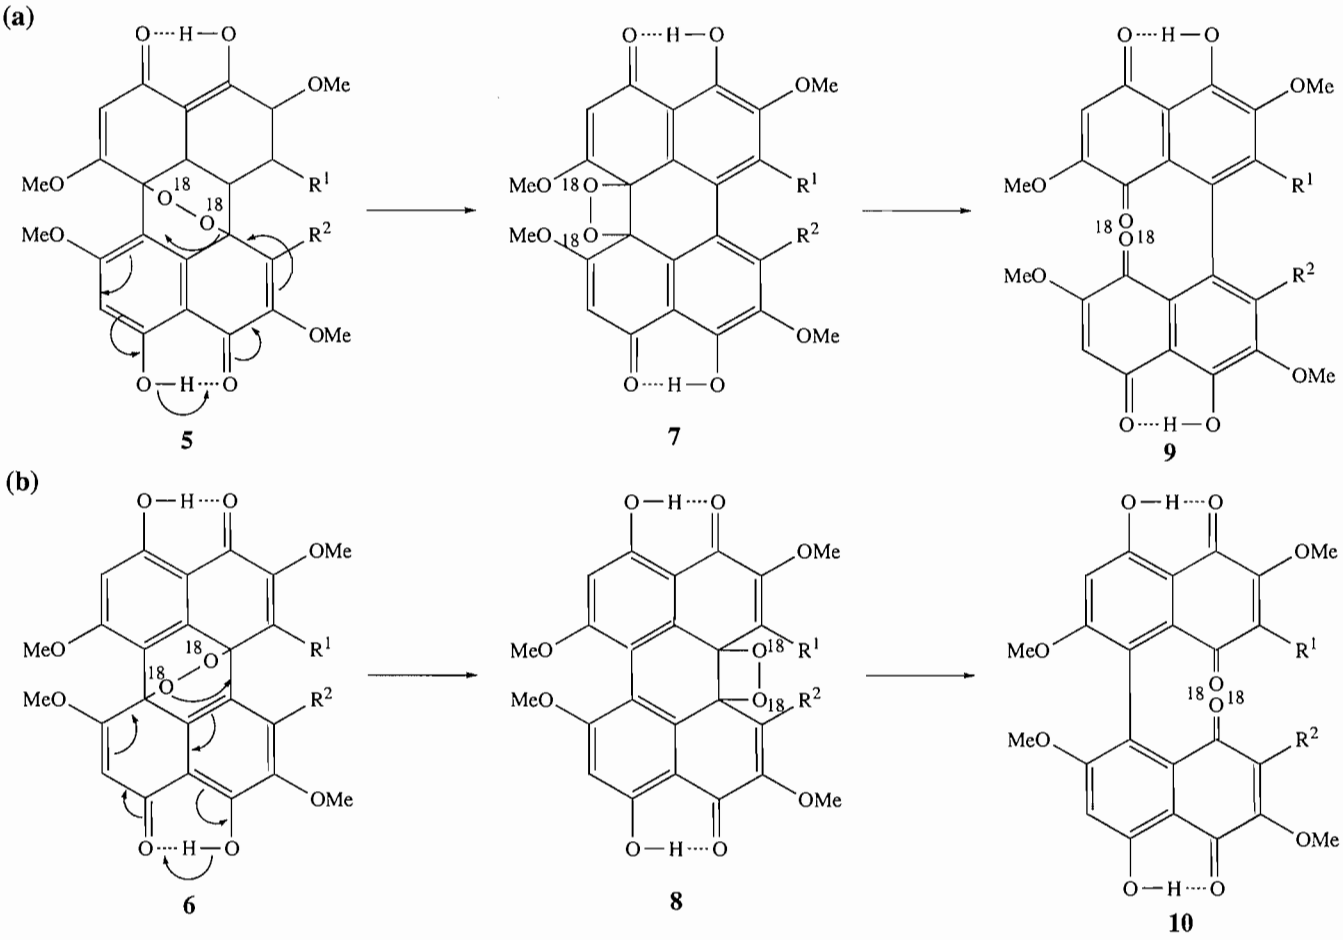
Fig. 8. Selection of characteristic photochemical processes sensitized by perylenequinones.

dissociates to produce the anion, which reacts with singlet oxygen generated during irradiation, resulting in formation of an *endo* peroxide. The *endo* peroxide then rearranges to form a dioxetane, which undergoes cycloreversion to produce the final product, a di-α-naphthoquinone (Fig. 9).

As demonstrated above, $^1O_2$ plays a crucial role in HA photooxidation. However, the photoexcitation of HA itself should also be considered. The pH of the solution, the nature of the solvent, and irradiation wavelength exert certain effects on HA photooxidation. Among these factors, the pronounced effect of pH on HA photooxidation has important biological implications in the PDT of human tumors. This specific effect can be taken advantage of as a basis for the selective localization of HA in tumor tissue since tumor tissue has a somewhat lower average pH than normal tissue (82, 83). On the basis of the proposed photooxidation mechanism of PQs, one can envisage the design and synthesis of improved PQ photosensitizers with selectivity for tumor tissue localization for the PDT of human malignancies by means of manipulating the pK_a of the photosensitizer. Consequently one can expect that a PQ photosensitizer with pK_a = ~7.0 should meet this condition where the photosensitizer in normal tissue (existing in the form of the anion) will be photooxidized much faster than that in tumor tissue (existing in the form of the neutral molecule). Therefore, the relative amount of HA in tumor tissue will increase substantially during photobleaching. Thus the administration of low HA concentrations and high light exposure may be advantageous in order to reduce the damaging effects of the treatment to normal tissue and to eliminate residual photosensitivity and phototoxicity that result from the use of hematoporphyrin derivatives.



Preparation and photodynamic properties of amino-substituted hypocrellin derivatives

We have shown that PQs are a new class of efficient singlet oxygen ($^1O_2$) generators and demonstrate some advantages over the established $^1O_2$ sensitizers (such as porphyrins, rose bengal, and methylene blue, etc.). These advantages include wide UV–VIS absorption, high quantum yield of $^1O_2$ generation, high stability, good solubility, and small solvent and concentration effects (63, 84). More significantly PQs have been proven to be potential sensitizers for the PDT of tumors, quite

Fig. 9. Mechanistic elucidation using ^{18}O labelling of the photooxidation of hypocrellin A to an inactive bis-naphthoquinone.

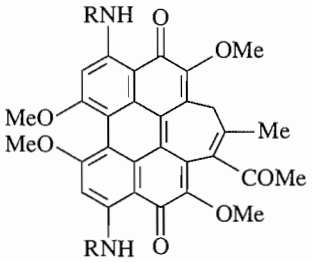
different in properties from the existing PDT porphyrins and phthalocyanines (3, 11, 39, 40, 85, 86).

Preliminary data have demonstrated that some PQs exert a much stronger photodynamic action on EMT6/Ed tumor cells than photofrin-II (39, 40, 70, 85). Hypocrellins, representative of PDT applications of PQs, exhibit several advantages over the presently used HPD, i.e., ready preparation and easy purification relative to HPD (58), low aggregation tendency (which decreases PDT efficiency in the case of HPD) (37), high triplet quantum yield (84), strong red light absorptivity, and significantly reduced normal tissue photosensitivity because of their rapid metabolism in vivo (39, 40, 85, 86).

Nevertheless, as in the case of HPD, natural PQs themselves do not exhibit absorptivity longer than 600 nm sufficiently strong for PDT, and this limits their PDT applications at present. Accordingly we prepared certain amino-substituted hypocrellin B derivatives (AHBDs), which demonstrate significantly enhanced red absorptivities and strong $^1O_2$-generating properties. These attributes are necessary for improved PDT performance (3, 11, 69). The photophysical and photochemical properties of the amino-substituted hypocrellin B derivatives were investigated, and their significantly enhanced red absorptivities and strong $^1O_2$-generating functions qualify them as promising photodynamic therapeutic agents. In addition, the superoxide anion radical was also determined to be implicated in the photosensitization of the amino-substituted hypocrellin B derivatives.

As discussed above, the new AHBDs have demonstrated several photodynamic therapeutic advantages over the commonly used HPD, especially their significantly enhanced red absorptivities and strong $^1O_2$-generating functions (Tables 1, 2), which qualify them as potential photodynamic therapeutic agents (Fig. 10). These in vitro studies have been corroborated by recent in vivo experiments in which complete eradication of implanted EMT6/Ed tumor in mice has been achieved employing HBEA-Ra (Fig. 11). The photosensitizations of AHBDs are primarily mediated by $^1O_2$, but the supplemental roles of other reactive oxygen species such as $O_2^{\cdot-}$, hydroxy radical, and hydrogen peroxide also need to be considered and further investigated.

Photodynamic action of perylenequinone derivatives



Perylenequinones as photosensitizers — molecular level studies

Comparative studies have shown that the 3,10-dihydroxy-4,9-perylenequinone moiety is essential for the photodynamic action of the perylenequinonoid pigments (86). This explains why amphicercosporin, neocercosporin, and protocercosporin

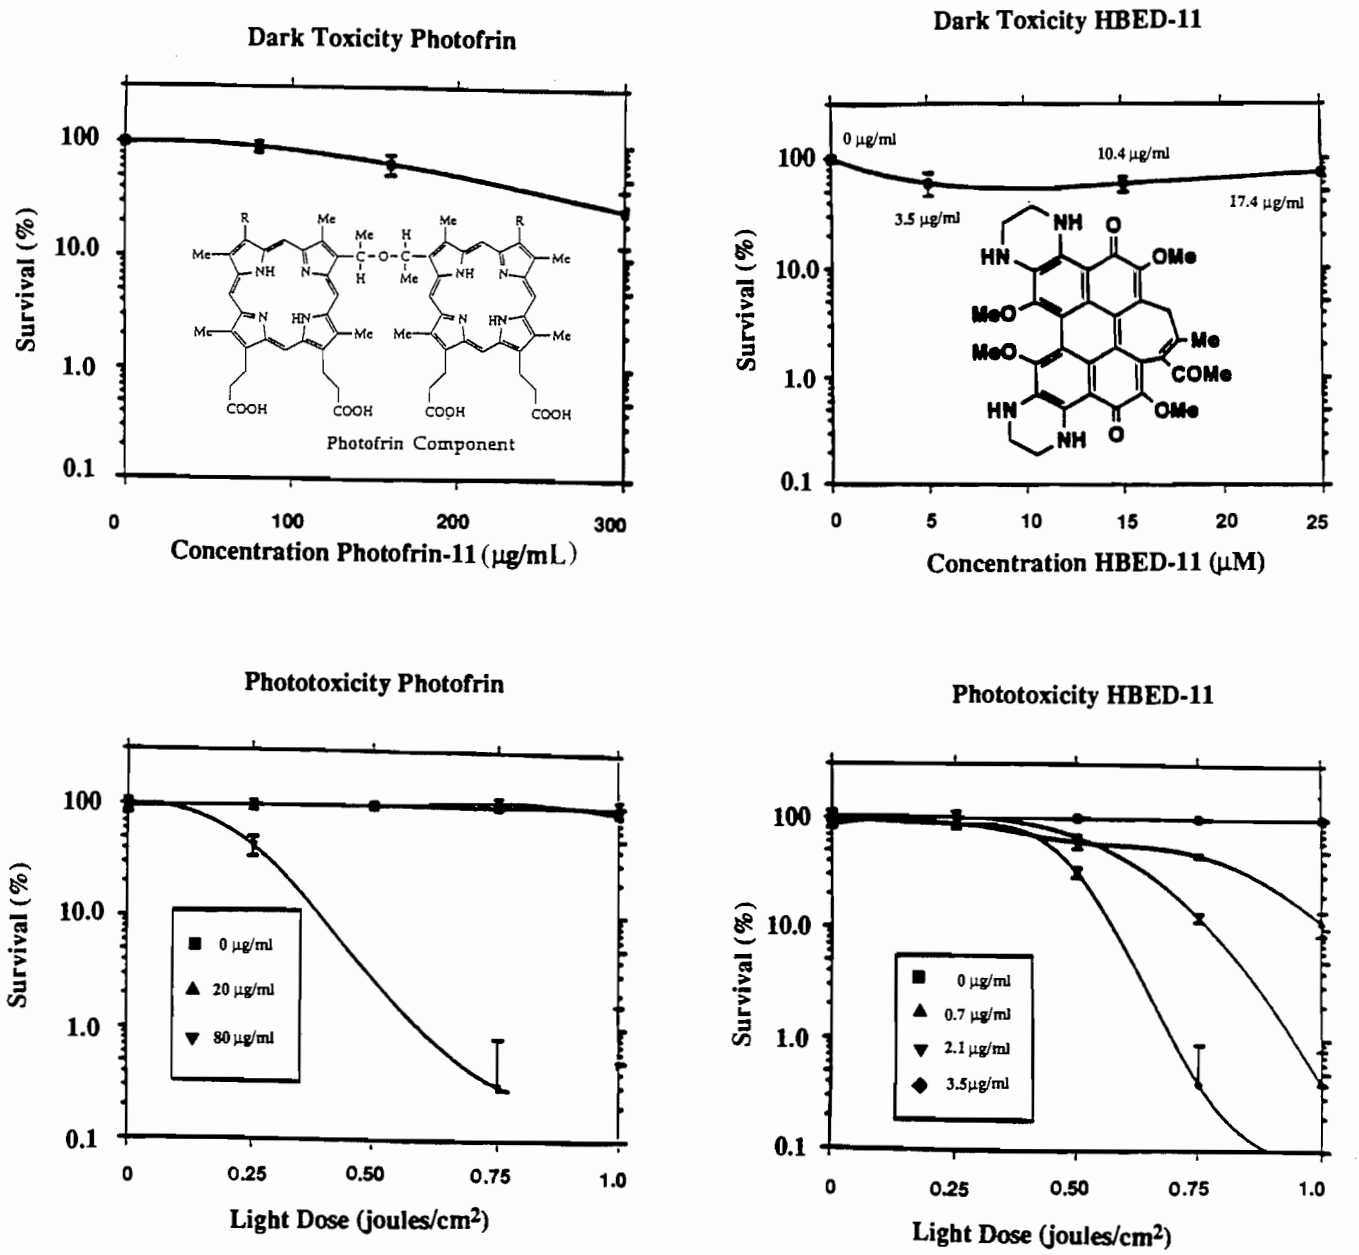
do not exhibit any photodynamic action although cercosporin shows photodynamic action on plant tissues (87).

It has been observed that activated oxygen species are produced by HA-photosensitization, including singlet oxygen ($^1O_2$), superoxide ($O_2^{\cdot-}$), hydroxy radical (·OH), and hydrogen peroxide (H_2O_2) (65, 84, 88, 89). $^1O_2$ is presumed to be generated by energy transfer from the excited triplet HA to ground state oxygen. Similarly $O_2^{\cdot-}$ is thought to be produced when ground state oxygen is reduced by the monovalent anion radical of HA, and H_2O_2 to be formed when ground state oxygen is reduced by its divalent anion. $^1O_2$, $O_2^{\cdot-}$, and H_2O_2 are formed in the primary reaction of the photosensitization by HA, but ·OH is produced only in the presence of some substrates (such as indole, tryptophan, and kynurenine) (84). The addition of reduced compounds (such as indole, lysine, histidine, methionine, tryptophan, 5-hydroxytryptophan, cysteine, hydroquinone, reduced glutathione, and ascorbic acid) markedly enhances the yield of $O_2^{\cdot-}$ by HA-photosensitization, as does cercosporin (68, 84). Zhang et al. (89) have demonstrated that HB can also produce $^1O_2$ and $O_2^{\cdot-}$ upon illumination with visible light like HA.



The HA-sensitized photooxidations of tetramethylethylene, 2,5-dimethylfuran, anthracene, 9,10-diphenylanthracene, reduced glutathione, furfuryl alcohol, fatty acids, cholesterol, prostaglandins, and histidine follow a reaction path similar to the photooxidations by other sensitizers, such as rose bengal, eosin, HPD, and methylene blue, i.e., wherein Type II is the main process (84, 88, 90–92). However, the photooxidation of *trans*-stilbene sensitized by HA is different from that sensitized by other sensitizers, and several novel products were isolated and identified (88). HA sensitizes the photooxidations of guanine and thymine in processes that are regarded as involving the participation of $^1O_2$, but does not sensitize those of cytosine and adenine.

Wang et al. (92) observed that HB sensitizes the photooxidation of purine bases. The photooxidations of caffeine and theophylline are mediated by $^1O_2$, and that of tetramethyl uric acid by $O_2^{\cdot-}$. However HB does not photosensitize pyrimidine bases. In micellar solution, visible light can also induce HA to produce $^1O_2$ to oxidize 1,3-diphenylisobenzofuran and bilirubin (93, 94). The HA-sensitized photooxidations of tyrosine, dopa, and aliphatic amines were ascribed to Type I processes (37, 94). In the HA-sensitized photooxidations of indoles, tryptophans, and indole alkaloids, $^1O_2$ appears to play an important role, although Type II processes cannot be excluded as a contributing factor, and some new reactive intermediates and products have been found (37, 86).

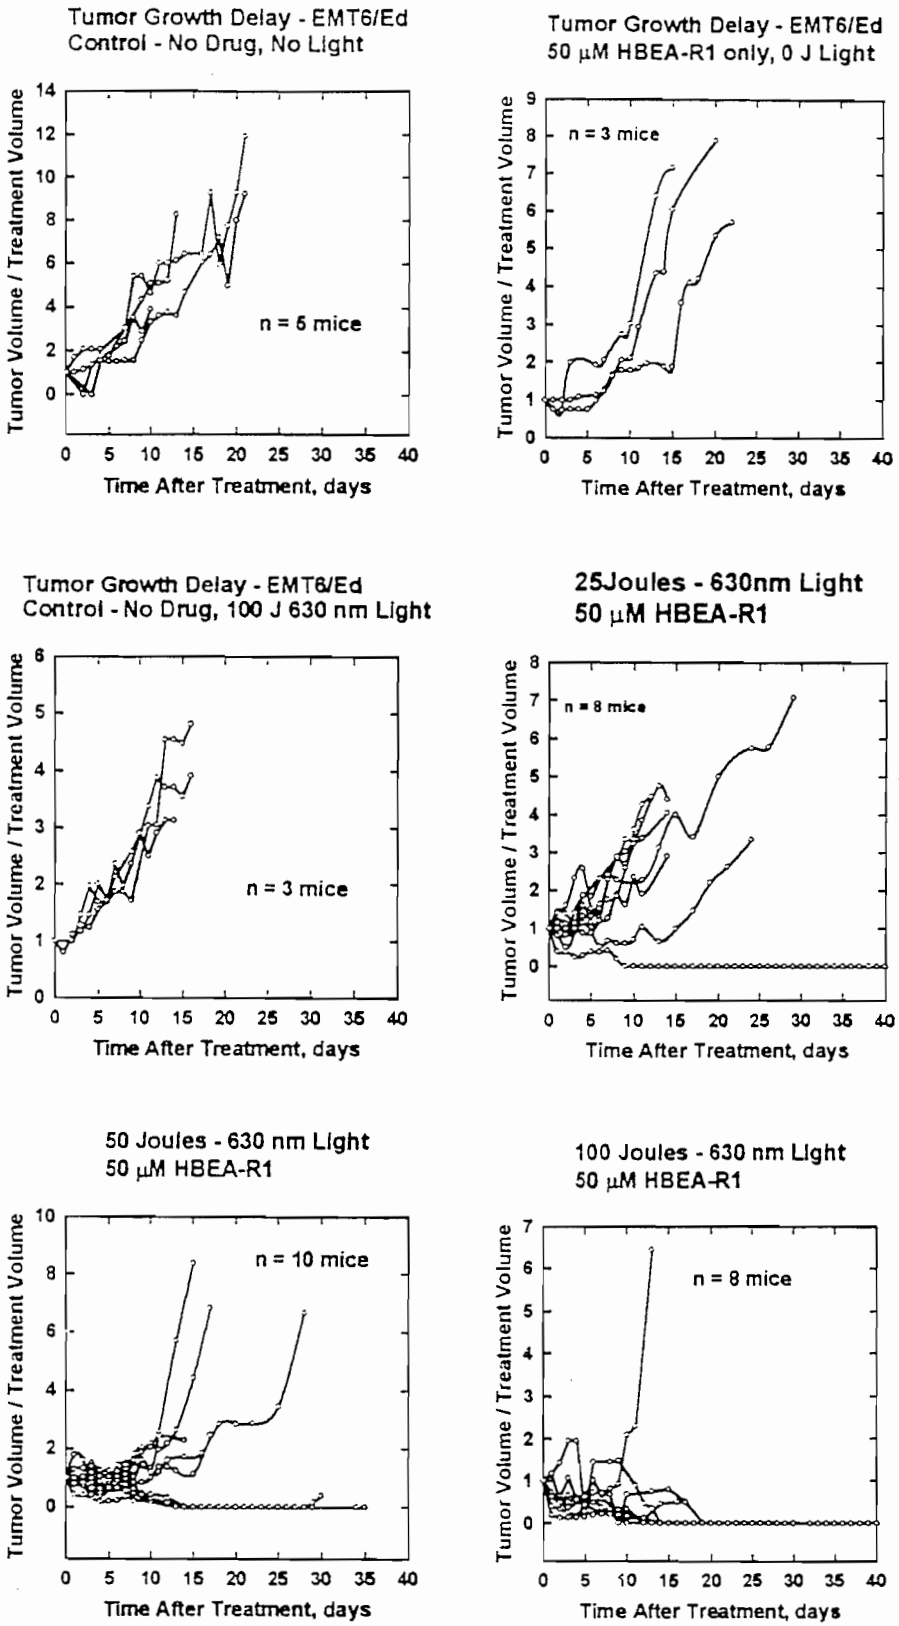
Fig. 10. EMT6 cancer cell survival illustrating the respective dark and light mediated toxicities of Photofrin and a representative aminoperylenequinone derivative HBED-II.

The mechanism of HA-sensitized photooxidation of diphenylamine markedly depends on the solvent; for example, in acetonitrile, the amine was oxidized to *N*-phenyl-*p*-benzoquinone via a Type II reaction, and in methanol via a Type I process (95). The HA-sensitized photooxidation of bilirubin is also affected by solvent. Thus in aprotic solvent, HA photooxidizes biliverdin and the degraded molecules via Type II, and in alkaline protic media by Type I. Thus Type II, and other free radical reactions, may be involved simultaneously (94). The HA-sensitized photooxidation of phenols was considered to proceed via a competition between Type I and Type II reactions.



Perylenequinones as photosensitizers for photodynamic therapy: a screening evaluation

Evidence from EMT6/Ed cells in vitro and in rodents suggests that hypocrellins, products of a fungal bamboo parasite, have demonstrable photosensitizing properties, with favorable properties of cytotoxicity and pharmacokinetics. In addition, the hypocrellins are characterized by high quantum yields of singlet oxygen ($^1O_2$), and are amenable to site-directed chemical modification to enhance any of the above properties. The parent hypocrellins A and B share an absorption peak at 648 nm. These molecules may therefore be considered as useful progenitors of derivatives that absorb more strongly in the red,

considering that the ideal sensitizer should absorb in the 650–800 nm range, beyond the absorption range of hemoglobin, and where light penetration in tissues is maximized through reduced scattering. A series of pure, monomeric PQ derivatives was tested for properties of cellular uptake, dark cytotoxicity, and photosensitizing potential by clonogenic assay in monolayer cultures of EMT6/Ed cells. Their respective toxicities are compared on a molar basis relative to one another. The in vitro screening assay has, to date, resulted in the selection of four agents for further development as photosensitizers for photodynamic therapy (85). Dose escalation studies are underway in rodents to establish nominal concentrations commensurate with adequate photosensitization of EMT6/Ed tumors grown in the flanks of Balb/c mice, with acceptable systemic toxicity.

Of the 21 hypocrellin derivatives screened to date, all have shown acceptable levels of cytotoxicity in vitro (Table 3). At least seven of the compounds photopotentiate toxicity by a factor of 10, with four of exceptional photopotentiating efficiency (Fig. 12). Direct molar comparison of the hypocrellin concentrations required to effect a given degree of cytotoxicity or photopotentiation with those for Photofrin-II is not possible, since the molecular weight of the photosensitizing component(s) of Photofrin-II can only be estimated. Under the conditions of preincubation employed in this screening study, Photofrin-II appeared to be a poor photosensitizer, possibly due to limited time of penetration and sensitization of the cells. Considering the low molecular weights characteristic of the hypocrellin derivatives, and their predominance as monomeric forms, we did not deem it necessary to adhere to the tradition of longer drug preincubation times characteristic of porphyrins. Preincubation kinetics studies confirm that varying the preincubation time for intervals up to 24 h has no significant effect on the drug concentration required to exert 50% cytotoxicity or photopotentiation of cell death. Preliminary cellular uptake studies using ^{14}C-HB confirm this concept, in that uptake occurs in a linear fashion for the first 10-12 min of incubation, and then plateaus for incubation times at least up to 120 min (85). Detailed uptake kinetic studies for selected photosensitizers were then undertaken (see below).

Perylenequinones as photosensitizers — cell studies

Gram positive bacteria were found to be sensitive to HA-photokilling, but Gram negative bacteria were not (96). This behavior is similar to that of porphyrins but different from that of cercosporin, which inhibits equally the growth of both Gram positive and Gram negative bacteria (97). In the case of elsinochromes, Gram positive bacteria are more sensitive to photosensitization than Gram negative bacteria (97, 98). Yamazaki et al. (97) and Guo et al. (98) have compared the inactivation of Chinese hamster ovary (CHO) cells induced by HA-photosensitization and that by UV exposure, and found that the photodamage caused by HA is greater than that by UV light. The analysis of survival curve parameters showed that the repair of sublethal damage and potential lethal damage of CHO cells induced by HA-photosensitization is less efficient than that induced by UV light. The results suggested that the main target of HA-photosensitization is the cell membrane, in which HA concentrates as a result of its lipophilicity.

Wang and Cheng (99) demonstrated that the binding of HA to erythrocyte membrane and liposomes is greater than to albumin, histone, and DNA. Accordingly, contractile protein bound to membrane is more sensitive to HA-photosensitization than is free contractile protein (100). Several types of membrane damage were found in the erythrocyte membrane treated with HA and light. For example, there was a considerable decrease in the content of some amino acids, especially tryptophan and cysteine, as well as amino and thiol groups in the membrane. Other reactions were observed, including lipid peroxidation, and the cross-linking of proteins, especially contractile protein (such as actin) (100); changes in membrane permeability, membrane mobility, and the configuration of membrane protein, which were thought to be partially related to the chelation of HA with metal ions in membrane (37); K^+ release, as well as photohemolysis and the inactivation of some enzymes (vide infra). The photooxidation of thiol groups and lipid peroxidation induced by HA and light are not inhibited by NaN_3, 1,4-diazabicyclo[2,2,2]octane (DABCO), or superoxide dismutase (SOD), suggesting that neither $^1O_2$ nor $O_2^{\cdot-}$ is involved in the two processes. The cross-linking of membrane proteins caused by HA-photosensitization is partially inhibited by NaN_3, which was considered to be an indication of the participation of $^1O_2$ to this process (101). Furthermore, it was shown, by the specific modification of different groups of membrane proteins, that the HA-sensitized cross-linking of membrane proteins is caused by the condensing reaction of the amino groups in the membrane with the carbonyl group-containing compounds derived from the photooxidations of amino acid residues, in which the photooxidized products of tryptophan and histidine were considered to play a key role (101). Finally, in the HA-photosensitization of erythrocyte membranes, the cross-linking of membrane proteins, photooxidation of the thiol groups and lipid peroxidation were deduced to be independent of one another (102).

As in the case of other perylenequinonoid pigments, HA sensitizes the inactivation of some enzymes. Cheng et al. found that HA sensitizes the inactivation of some enzymes in the following descending order of efficiency: Ca^{2+}–Mg^{2+} ATPase > Na^+–K^+ ATPase > GAPDHase > AcEase. Generally, the enzymes bound to membranes are more sensitive to photosensitization than free enzymes. The inactivation of AcEase was demonstrated to be mediated by $^1O_2$, and the inactivating mechanism of other enzymes is under investigation.

Cao and Cheng (103) made comparative studies between cellular DNA damage in Hela cells by HA-photosensitization and that by γ-ray irradiation, and found that there exists a considerable difference in the content and rate of repair of DNA single strand breaks between the two processes. At equivalent levels of strand breakage, the rate of repair for HA-sensitized strand breaks is smaller than that induced by γ-ray. The HA-sensitized photoconversion of closed circular DNA to open circular DNA was proved by NaN_3 inhibition to be mediated by $^1O_2$ (104).

Uptake kinetics and intracellular localization of hypocrellin by confocal microscopy

The availability of reliable markers for cellular organelles has facilitated detailed analysis of the intracellular distribution of several promising new hypocrellin photosensitizers varying

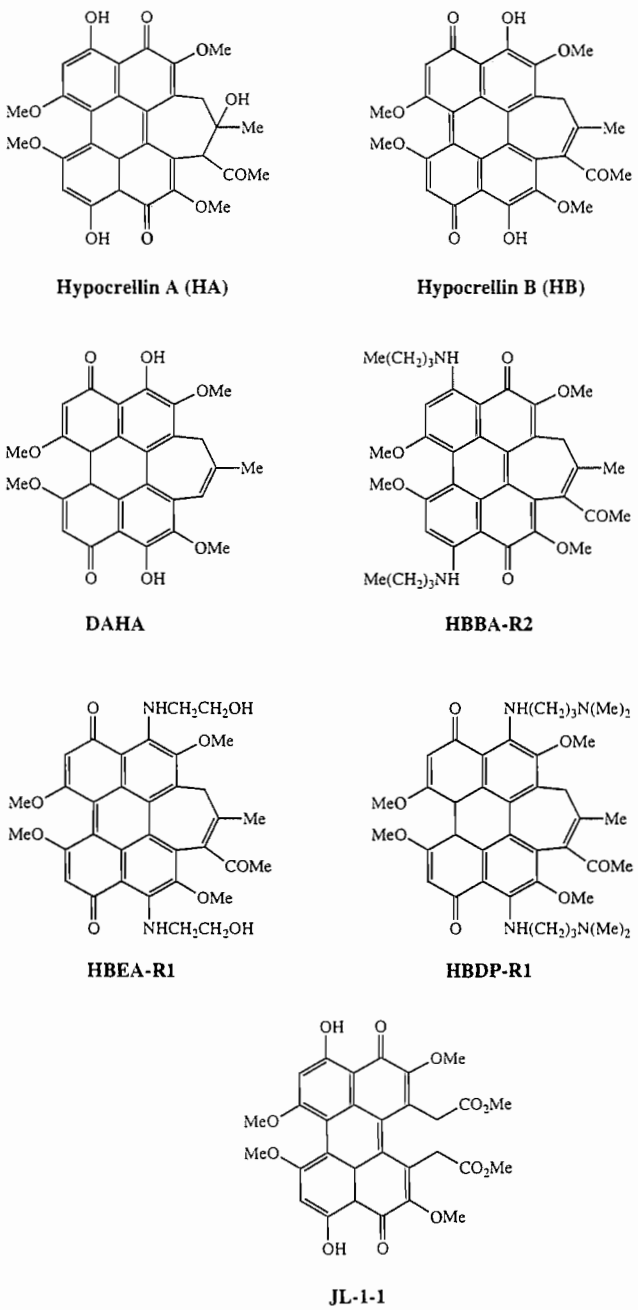
[a]Significant light absorption at 700 nm.



[b]Solvent unknown. HBBA-R2, HBDP-R1, HBEA-R1, and JL-1-1 demonstrate average, or lower than average toxicity, with excellent photopotentiation. N/A = not applicable/ ND, not done. For the purposes of the screening study, the LD_{50} light dose was not fixed. It may be seen in Fig. 4 that, for the compounds tested, this dose is 0.75–1.00 J/cm^2 of 630 nm light.

[c]Absorbance properties are quoted at 630 nm for comparison purposes since this is the wavelength customarily used in clinical PDT protocols.

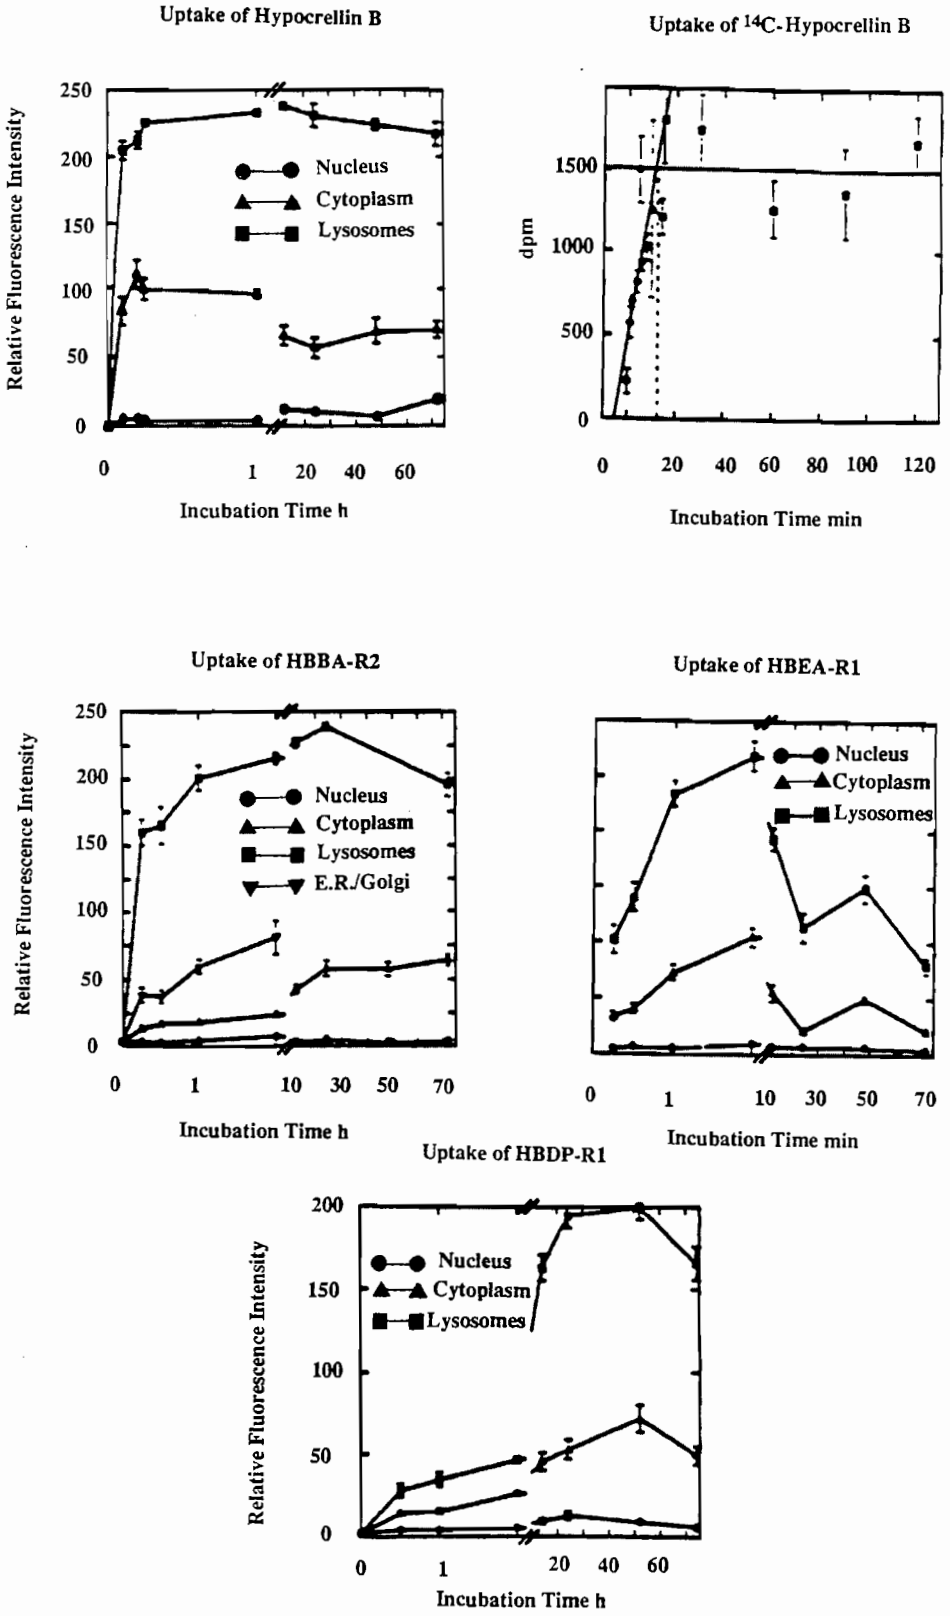
Fig. 12. Structures of the parent hypocrellin A and certain photoactive aminoperylenequinones.

with respect to charge and partition coefficient. The close agreement of uptake kinetics using ^{14}C-labelled HB vs. uptake determined by confocal microscopy indicates that the latter technique is a reliable means of determining the fate of fluorescent hypocrellins following administration in vitro and in vivo. The evident advantages of this approach are that it will be possible to estimate the optimal time of photoactivation, based on accumulation of a given sensitizer to its most sensitive intracellular target. Additionally, intratumoral compartmentalization characteristics of each compound are readily visualized, rendering valuable information on the mechanism(s) of tumor destruction. It will be possible to distinguish between likely mechanisms of photodynamic effects, including damage to tumor endothelium leading to stasis of vascular flow; or more direct tumoricidal mechanisms including stromal destruction; or ablation of tumor cell populations — based on patterns of fluorescence observed in histological material. Fluorescent markers for vascular functional patency, such as Hoechst 33342 (105), as well as for cellular hypoxia used in combination with the hypocrellins, will provide further detail on phototoxic mechanisms. It should be pointed out that measurement of sub-cellular drug localization by confocal microscopy is qualitative and may be subject to variations in yield of fluorescence according to the local environment.



The unique uptake kinetics demonstrated by each hypocrellin may provide a useful avenue of approach to optimize therapeutic ratios among different tumor/adjacent normal tissue combinations encountered clinically. For example, HB is incorporated to the full extent into lysosomes within 15 min. In contrast, lysosomal uptake of HBDP-R1 peaks some 20 h following administration. HBEA-R1 and HBBA-R2 peak in lysosomes at 2 h (Fig. 13). Comprehensive pharmacokinetic studies will be necessary to identify which tumor/normal tissue combinations are most amenable to treatment with a given hypocrellin congener, based on maximal tumor cell uptake vs. minimal uptake in critical targets of surrounding tissues. There are additional possibilities for combined administration of hypocrellins of differing uptake kinetics and fractionated illumination, provided that the first sensitizer does not act via stasis of vascular flow. It will be necessary to determine the relative contributions to phototoxicity of mitochondria, Golgi apparatus, plasma membrane, and endoplasmic reticulum, since it is premature to assume that phototoxicity is predicated uniquely upon the level of uptake. Since only a small number of hypocrellins (selected on the basis of excellent photopotentiation) was analyzed, it is not yet possible to establish general predictive estimates of intracellular distribution based on physicochemical properties. HBBA-R2 and HBEA-R1 (Fig. 11) are cationic congeners, while HB and HBDP-R1 are neutral. Mitochondrial uptake of HBEA-R1 is consistent with its cationic attributes. Each of the four compounds is insoluble in water under neutral conditions (63), which would be consistent with integration into cellular membranes, as well as uptake via the endosomal system, as has been demonstrated (106). Interestingly, a water-soluble, sulfonated derivative of HB did not demonstrate marked photopotentiation of EMT6/Ed cell killing in vitro (data unpublished). It will be useful to examine the intracellular distribution of this, and other, hydrophilic sensitizers to determine why they are generally less effective.

Preferential accumulation of each of the hypocrellins in the lysosomal compartment (106), coupled with their inherently low cytotoxicity and individual uptake kinetics, may render these fluorescent compounds extremely useful agents with which to observe the process of endocytosis in a wide variety of tumor and normal cell types (for review, see ref. 107).

Recent studies have shown that 688 nm light produces phototoxicity equivalent to that of 630 nm light when EMT6/Ed cells are illuminated in the presence of HBEA-R1 or HBBA-R2. Both compounds have been employed in dose-escalation studies in Balb/c mice, with no evidence of toxicity over a 30-

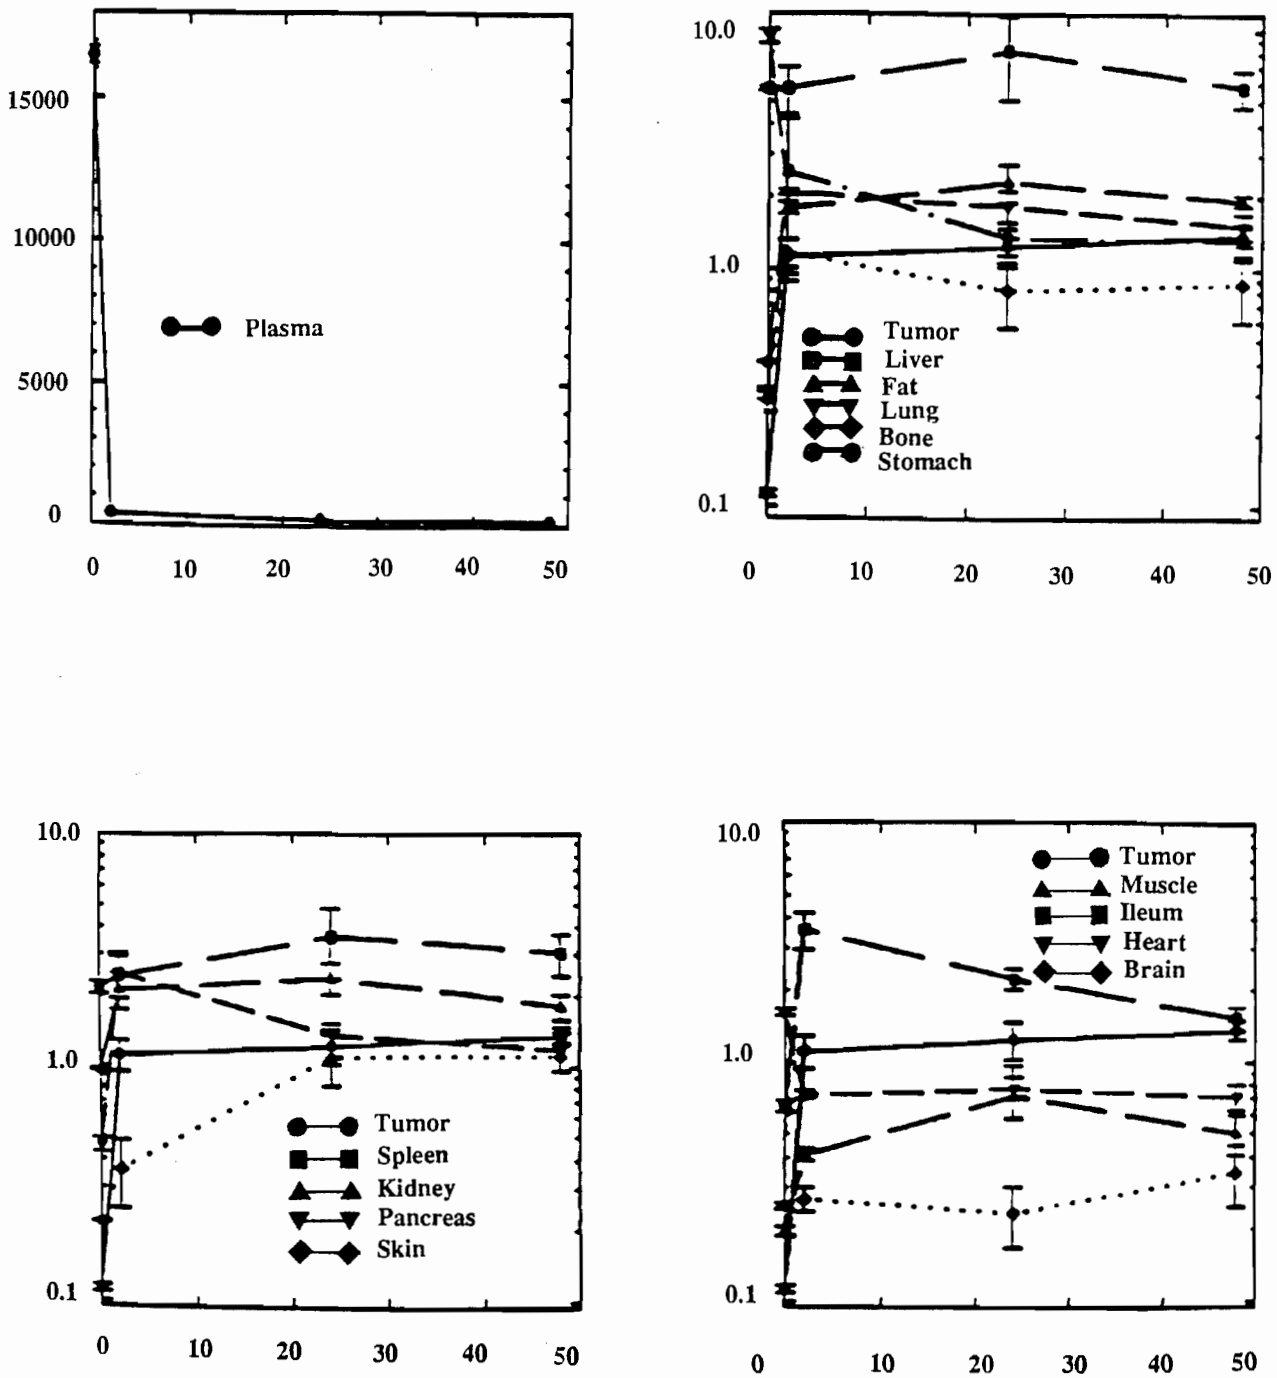
day test period, to maximum "total body" doses of 50 μM. Based on favorable findings related to photopotentiation and pharmacokinetics reported elsewhere, we are proceeding with tumor growth delay assays to establish whether the hypocrellin congeners reported here will have potential for use in the treatment of human tumors.

Synthesis and pharmacokinetics of ^{14}C-radiolabelled hypocrellin B

Radiolabelled hypocrellin B (HB) with the ^{14}C atom incorporated in either or both the 4- and 13-methoxy groups was synthesized with a specific activity of 2.11 mCi per mmol. The purified, ^{14}C-HB, prototype photodynamic therapy photosensitizer was used to determine the kinetics of uptake in EMT6/Ed cells in monolayer culture, and the kinetics of tumor and tissue distribution in Balb/c mice bearing the EMT6/Ed tumor (108).

In vitro cellular uptake studies were performed using EMT6/Ed experimental mammary tumor model. EMT6/Ed mouse mammary carcinoma cells were propagated as monolayer cultures in our laboratory as previously reported (109). Briefly, the cultures were serially passaged in Waymouth's medium containing 13% fetal calf serum (GIBCO) at 37°C, in a water-saturated atmosphere containing 5% CO_2. At 3-month intervals the tumor cells were routinely passaged in the flanks of Balb/c mice to maintain vigor of the tumor cell line.

Cellular uptake of ^{14}C-radiolabelled hypocrellin B



Cellular uptake of ^{14}C-HB (Fig. 14) was determined by plating 5.0×10^5 cells in 2 mL of Waymouth's medium containing 13% fetal calf serum in 35 mm Petri plates and incubating for graded time intervals with ^{14}C-HB at a final concentration of 11.79 μM {$(1.0 \times 10^5$ disintegrations per minute (dpm)}. Free ^{14}C-HB was removed from the plates by three gentle washes with 1.0 mL phosphate-buffered saline (pH 7.4). The cells were quantitatively lysed with 0.2 mL of 1.0 N NaOH and neutralized with an equal volume of 1.0 N HCl. The lysate was transferred to a scintillation vial and 15 mL of CytoScint (ICN) were added for counting. Cellular uptake was standardized to dpm/10^6 cells.

Pharmacokinetics of ^{14}C-radiolabelled hypocrellin B

Tissue and tumor distribution were assessed for 48 h following administration of ^{14}C-HB, in Balb/c mice bearing EMT6/Ed tumors bilaterally on the flanks (Fig. 15). Approximately 7 days before drug administration, 10^5 tumor cells were suspended in 100 μL of Hank's balanced salts solution and injected into each flank of each of 10 mice. When the tumors reached an approximate volume of 250 μL, 14C-HB was administered either intraperitoneally (i.p.), or intravenously in the caudal vein (i.v.) to a final "total body" concentration of HB of 11.79 μM (10^6 dpm). At intervals of 0, 2, 24, and 48 h, the mice were euthanized by i.p. injection of Euthanyl (MTC

Fig. 15. Uptake of ^{14}C-HB in various tissues of Balb/c mice bearing the EMT6/Ed tumor. Ordinate: a. dpm/g plasma; b–d. dpm/g tissue relative to plasma level. Abscissa: Time after administration of the radiolabelled compound, h.

Pharmaceuticals). Samples (10–80 mg) of various tissues and tumor were dissected from the mice, weighed, and placed in glass scintillation vials. Blood samples were centrifuged, and the resulting plasma aliquots were treated the same as tissue samples. For each time point, three animals were used, with two replicate tissue/plasma samples per animal. Tissue uptake was normalized to dpm/g, and the results were expressed as the ratio of tissue to plasma radioactivity.

Perylenequinones as photosensitizers for PDT

Although only preliminary information is available, it is clear that hypocrellin selectively accumulates in some types of tumor tissues, and efficiently sensitizers photodamage in such tissues. Animal experiments have shown that the maximum concentration of HA in tumor tissue is reached at the sixth hour after injection at which time its strongest PDT effect is evident. It was reported that Hela cells and implanted S-180

tumors in Kuming mice treated with 50 mg/kg HA undergo necrosis after irradiation with 200 J/cm^2 of 632 nm He–Ne laser (39). The mitochondria and microsomes of hepatoma cells were considered to be the targets of HA-photosensitization. With a 105 mW/cm^2 high-pressure sodium lamp illuminating hepatoma cells for 10 min in the presence of 25 μg/mL HA, the mitochondrial ATPase and microsomal G-6-Pase are extensively inhibited, but their mitochondrial monoamine oxidases are not affected. The sulfhydryl contents of the cells are significantly reduced, and lipid peroxidation is greatly enhanced (39). Dong et al. (109) observed that HA-photosensitization retards the synthesis of protein, RNA, and DNA in cancer cells. Cercosporin and phleichrome were also shown to cause photodamage of mitochondria and microsomes of mouse liver cells (110).

Although hypocrellin is phototoxic, it is eliminated from the living organism very quickly, i.e., within about 24 h. This greatly decreases its photosensitizing side effect in PDT. In the absence of light, hypocrellin is nontoxic. In fact, hypocrellin has been used for several hundred years as an oral Chinese traditional medicine. The metabolism of hypocrellin is similar to that of cercosporin. These agents distribute throughout the whole body except the central nervous system. In the dark, they are excreted via intraperitoneum → blood → liver → bile → duct → small intestine → feces, but in the presence of light, they are transported by blood, cell, and tissues before elimination, and thus are toxic to bacteria, mice, and plant cells only when illuminated (110, 111). Clearly more studies of the properties of hypocrellins as photosensitizers in vivo need to be carried out.

Conclusions and prospects

Whether for use in treatment, diagnosis, or prevention, an important aspect of drug pharmacology is selectivity, which is the key to chemotherapy. Advantages of photochemotherapy over other chemotherapeutic techniques are (*i*) the ability to control the duration of the reaction by light, e.g., one can "turn the reaction on or off" since no reaction occurs in the absence of light, and (*ii*) the dual selectivity that both the photosensitizer and the actinic light can be preferentially directed to the locations to be treated, so ideally the healthy regions of the system are not affected. So far some promising clinical results have been obtained with HPD. Therefore, the discovery, synthesis, and evaluation of new photosensitizers for the treatment of malignant and infectious disorders continues to be an active area of investigation. Structural modification of the dyes can then be made in order to improve their light absorption, tumor deliverability, and retention. Chemical alterations can also enhance their yields of light-induced reactive oxygen species. These efforts have led to a new generation of photosensitizers, as summarized above.

Since cancer is a large family of diseases with widely different clinical patterns, it is unlikely that a single sensitizer can serve all purposes. For example, in some cases, a highly selective uptake of the sensitizer in the tumor is required, whereas in other cases, the photosensitizing efficiency of the sensitizer may be the crucial factor. Therefore, it is necessary to develop various kinds of photosensitizers to treat various kinds of cancers. In addition, it may be feasible to devise a combination photochemotherapy, utilizing multiple photosensitizers, gaining the benefits of different localization phototoxicity of different photosensitizers.

The available information on the photochemical properties of the perylenequinones, as reviewed above, is encouraging and clearly suggests that PQs and their derivatives have an array of properties that could make them very valuable sensitizers for PDT. They are readily obtained, easily purified, very stable, low in toxicity, and do not form the aggregates that would decrease their photodynamic activity as is the case for HPD. In addition, some of these agents can utilize superior tissue-penetrating red light much more efficiently than the HPD presently being used for PDT. Therefore, full-scale studies are indicated for a wide variety of PQs as possible PDT anticancer agents. We may therefore see a rapid expansion of both basic and clinical aspects of research on these unique compounds in the near future.

Acknowledgments

The work described was carried out with a group of outstanding and dedicated students, postdoctoral fellows, and colleagues in the Department of Chemistry, University of Alberta, and in the Department of Surgery, W.W. Cross Cancer Institute, and their names appear on the quoted publications. We thank the National Cancer Institute of Canada for a Terry Fox Program Project, as well as the Alberta Heritage Foundation for Medical Research and the Alberta Cancer Foundation for support.

Reactions of dialkoxycarbenes with tethered triple bonds to form heterocyclic compounds

Karim Kassam and John Warkentin

Abstract: Dialkoxycarbenes with a tethered triple bond, generated from the corresponding oxadiazolines, undergo an intramolecular cyclization with the tethered alkyne moiety to give 3,3-dialkoxyvinylcarbene/1,3-dipole intermediates. The regioselectivity of the carbene cyclization is highly dependent upon the nature of the alkyne substituent. In the cases where an exocyclic vinylcarbene is generated, the vinylcarbene intermediate can undergo a synthetically useful [3+2] cycloaddition with either an appropriate olefin or an alkyne. This approach allows the rapid construction of some interesting heterocyclic ring systems.

Key words: carbene, dialkoxycarbene, vinylogous dialkoxycarbene, heterocycle.

Résumé : Les dialcoxycarbènes attachés à une triple liaison, générés à partir des oxadiazolines correspondantes, subissent une cyclisation intramoléculaire avec la portion alcyne auxquels ils sont attachés et ils conduisent à des intermédiaires 1,3-dipolaires, 3,3-dialcoxyvinylcarbènes. La régiosélectivité de la cyclisation du carbène dépend fortement de la nature du substituant alcyne. Dans les cas où il y a génération d'un vinylcarbène exocyclique, l'intermédiaire vinylcarbène peut alors subir une cycloaddition [3+2], utile d'un point de vue synthétique, soit avec une oléfine appropriée ou avec un alcyne. Cette approche permet de construire rapidement quelques systèmes hétérocycliques intéressants.

Mots clés : carbène, dialcoxycarbène, dialcoxycarbène vinylogue, hétérocycle.

[Traduit par la rédaction]

Introduction

It was recently demonstrated that oxadiazolines (**1**) are convenient and efficient thermal sources of a variety of interesting dialkoxycarbenes (**2**) (1). Oxadiazolines are easily prepared (1, 2), and are stable at room temperature. However, upon thermolysis at 110°C, in an inert solvent such as benzene or toluene, oxadiazolines yield the corresponding dialkoxycarbenes (Scheme 1). The major by-product, acetone, is easily removed following reaction of the carbene with an appropriate trap. That is one of a number of advantages of oxadiazolines over other well-established thermal dialkoxycarbene sources, such as norbornadienone ketals (3), diazirines (4), and other sources (5).

The potential of oxadiazolines for the efficient formation of ring systems was illustrated with the thermolysis (toluene/reflux) of oxadiazoline **3a**, which gave the tricyclic cyclobutanone ketal **4a** as the major product, in 74% yield (Scheme 2) by a remarkable cascade of reactions (1*d*, 6) (vide infra). This product has five contiguous stereocentres and was obtained as a single (±) diastereomer. The mechanism (1*d*, 7) that accounts for the formation of this tricyclic product comprises up to 10 sequential steps and involves an unprecedented intramolecular cyclization of a dialkoxycarbene (**5a**) onto a tethered triple bond to give a 3,3-dialkoxyvinylcarbene **6a**. The intermediacy of this novel endocyclic 3,3-dialkoxyvinylcarbene (**6a**), formed regioselectively, was of particular interest. There was no evidence for the generation of the alternative exocyclic vinylcarbene **7a**.

In an extensive study, Boger and Brotherton (8) have shown that simple acyclic 3,3-dialkoxyvinylcarbenes, which are isoelectronic with 1,3 dipoles, can be generated from the thermal ring opening of the corresponding cyclopropenone ketals, and have been found to undergo a variety of mechanistically interesting and synthetically useful reactions with a number of different substrates. One reaction of the 3,3-dioxyvinylcarbenes/1,3-dipoles that has considerable synthetic potential is a [3+2] cycloaddition with highly electron-deficient olefins, such as benzylidenemalononitrile, to give substituted cyclopentenes (Scheme 3). In this reaction, unique to this particular class of vinylcarbenes, the 3,3-dialkoxyvinylcarbene behaves formally as a 1,3-dipole. The mechanism for the "Boger cycloaddition" is believed likely to involve a single electron transfer from the electron-rich vinylcarbene to the electron-deficient alkene, followed by a subsequent radical-cation/radical-anion collapse (8*a*). In contrast to most [3+2] cycloadditions, which afford heterocycles (9), this transformation is one of a few known all-carbon [3+2] cycloadditions (10) and may provide a valuable complement to the Diels–Alder reaction. The endocyclic vinylcarbene **6a**, however, is different from the 3,3-dioxyvinylcarbenes studied by Boger in that it cannot undergo a similar [3+2] cycloaddition without forming a highly strained product with a bridgehead double bond.

Herein we report a study of the thermolysis of analogs of oxadiazoline **3a**, having either a methyl or a methoxycarbonyl substituent at the alkyne carbon atom. It was found that the alkyne substituent controlled the regioselectivity of dialkoxy-

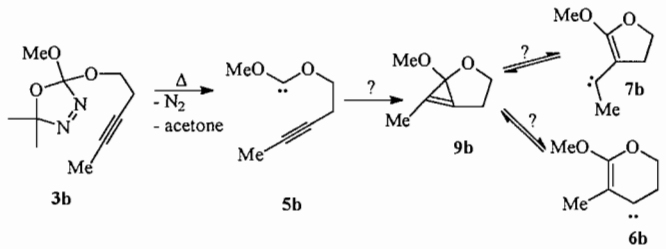
carbene cyclization completely, to allow the generation of either an endocyclic or an exocyclic 3,3-dialkoxyvinylcarbene. Moreover, in the cases where an exocyclic vinylcarbene was formed, it could be intercepted by a [3+2] cycloaddition reaction with an appropriate electron-deficient olefin or alkyne, for the rapid and efficient construction of some new heterocyclic compounds.

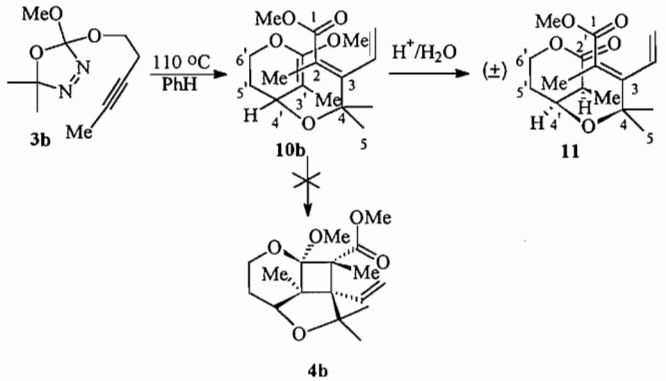
Results and discussion

Oxadiazoline **3b** was obtained in 67% yield by acid-catalyzed exchange (2) between the acetoxy methoxy oxadiazoline **8** and commercially available 3-pentyn-1-ol (eq. [1]). It was pre-

[1]



+ HOAc



3b was hydrolyzed during attempted purification by the same method.

The product obtained from the thermolysis of **3b** was shown to be **10b**, on the basis of spectroscopic data. As further evidence of the structure, **10b** (a ketene acetal) was hydrolyzed with dilute aqueous acid to give lactone **11**, as a single diastereomer that was isolated as the major product by chromatography. The magnitude of the coupling constant (^3J = 4.3 Hz) between the methine protons on the ring indicates that the hydrolysis had proceeded with π-facial selectivity, by proto-

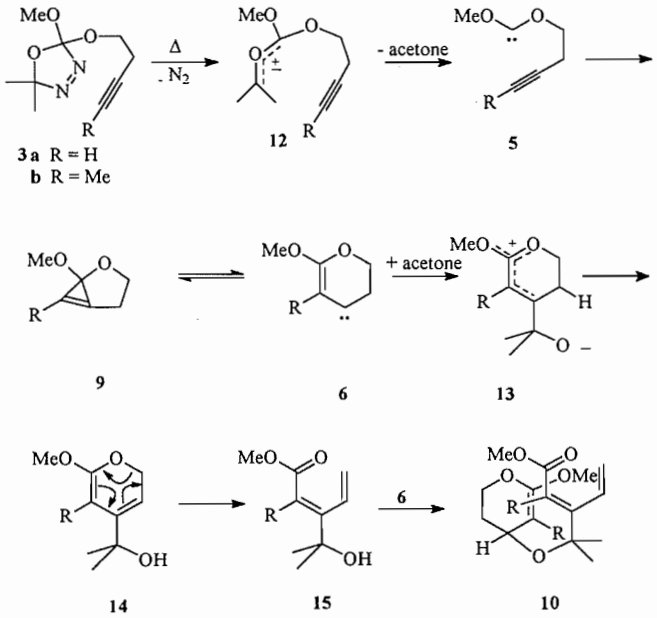
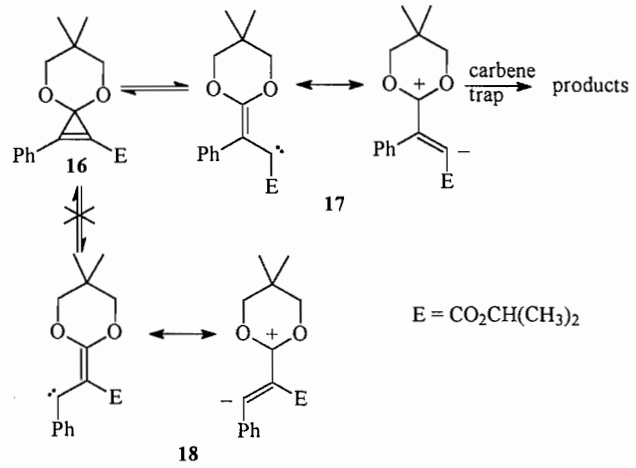
Scheme 5.



pared in order to check the possibility that **5a**, generated from **3a**, had cyclized regioselectively to the endocyclic vinylcarbene **6a** because of the choice of generating a secondary over a primary carbene site (Scheme 2). It is clear that the cyclization of **5b**, generated from **3b**, gives a secondary 3,3-dialkoxyvinylcarbene (**6b** or **7b**) in either case (Scheme 4). The cyclization could either be a concerted closure, followed by regioselective ring opening of a cyclopropenone ketal intermediate **9b**, as illustrated in Scheme 4, or a direct nucleophilic attack (not shown) of the dialkoxycarbene onto one of the two alkyne carbon atoms to afford **7b** and (or) **6b** directly.



Thermolysis of **3b** in benzene (110°C/sealed tube) afforded a single identifiable product (>80% by NMR) that had the mass of two carbene units and one unit of acetone. Although this product was of the correct composition to be a dimethyl analogue of **4a** (i.e., **4b**) (Scheme 5), its ^{13}C NMR spectrum differed significantly from that of **4a**. Furthermore, **4a** was easily purified by chromatography whereas the product from

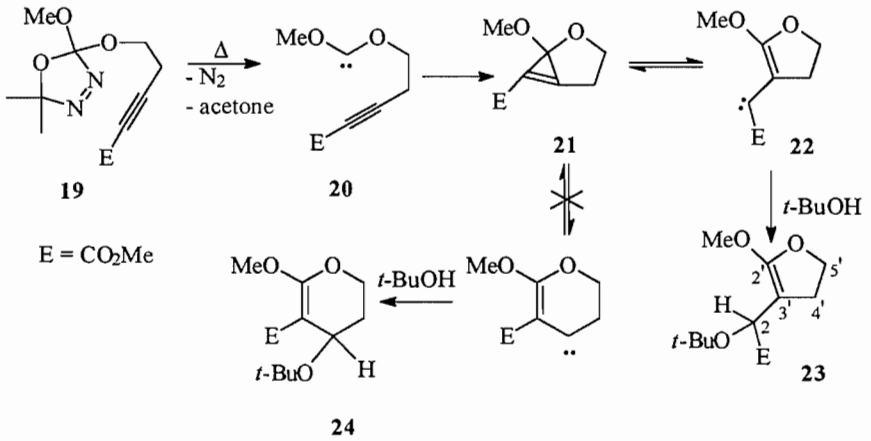
nation of the ketene acetal only on the face *anti* to the unsaturated ester moiety. A molecular mechanics calculation with PC Model gave $^3J(cis)$ = 4.4 Hz, consistent with the assignment of stereochemistry, and $^3J(trans)$ = 10.7 Hz.

Formation of **10b** can be attributed to a mechanism analogous to that proposed for the formation of **4a** (1*d*) with the exception that the final step, an intramolecular thermal [2+2] cycloaddition, does not proceed in this case. As shown in Scheme 6, the mechanism that gives **10b** begins with the thermal generation of dialkoxycarbene **5b** from oxadiazoline **3b** (1), either via fragmentation of an initially formed carbonyl ylide (**12b**) (11, 12) or by the concerted loss of both acetone and nitrogen, as proposed by Smith (7). Once formed, the dialkoxycarbene (**5b**) undergoes an intramolecular cyclization onto the tethered alkyne, either by direct nucleophilic attack of the carbene onto the methyl-substituted alkyne carbon atom, or via regioselective ring opening of a cyclopropenone ketal intermediate (**9b**) to give the endocyclic 3,3-dialkoxyvinylcarbene **6b** (8, 13). The high degree of *endo*-regioselectivity in this step is the same as that observed in the cyclization of **5a** and, therefore, the regioselective formation of **6a** does not seem to be attributable to the choice of a secondary over a primary carbene site. Vinylcarbene **6b** goes on to react with acetone, generated earlier in the decomposition of **3b**, to give **13b**. Dipole **13b**, whether formed directly from the nucleophilic attack of **6b** onto acetone or by other pathways (1*d*), affords **14b** by an intramolecular proton abstraction or by an analogous diradical mechanism. An electrocyclic ring opening (14) of **14b** then gives **15b**. The intermediacy of **15b**, from thermolysis of **3b**, is supported by the fact that **15a** was isolated previously in low yield (approx. 5%) from the thermolysis of **3a** (1*d*).

Since alcohols are highly efficient carbene traps (15), **15b** does not accumulate under the reaction conditions but reacts with **6b** by an overall O-H insertion to give the observed major product, **10b**. Compound **10b** does not undergo an intramolecular thermal [2+2] cycloaddition (16) between the electron-rich ketene acetal and the electron-deficient α,β-unsaturated ester, as observed for **10a**. This result is in agreement with findings of Scheeren's group that disubstituted ketene acetals do not undergo thermal [2+2] cycloadditions with electron-deficient olefins that have only one electron-withdrawing substituent (16*a*). Formation of **10b** (Scheme 6) verifies that **10a** is indeed an intermediate in the thermolysis of **3a** as postulated in our previous paper (1*d*). Moreover, the fact that **10b** was formed in high yield indicates that the cyclization of **5b** proceeds with the same high *endo*-regioselectivity as observed for **5a**.

Nakamura and co-workers (13) have reported that anion stabilizing groups, such as ester or phenylthio, exert control over the regioselectivity of the ring opening of cyclopropenone ketals. For example, the thermal ring opening of cyclopropenone ketal **16** (Scheme 7) proceeds at room temperature to give only the ester-substituted vinylcarbene/1,3-dipole **17** as inferred from various trapping experiments. Products derived from vinylcarbene/1,3-dipole **18** were not found.



Oxadiazoline **19** was prepared in order to investigate whether the ester functional group could be used to direct the cyclization of dialkoxycarbene **20**, which might involve an intermediate cyclopropenone ketal (**21**), toward the exocyclic vinylcarbene **22** (Scheme 8). Upon thermolysis of oxadiazoline **19** in the presence of *tert*-butyl alcohol at a low concentration (to prevent capture of the initially formed **20**), ketene acetal **23**, derived from the capture of carbene **22**, was obtained in high yield (>85% by ^{1}H NMR spectroscopy). The absence of other carbene + alcohol trapping products (e.g., **24**) detectable by GC–MS clearly implies that carbene **20** had undergone regioselective cyclization to give only the exocyclic vinylcarbene (**22**).

As mentioned previously, Boger et al. (8) demonstrated that 3,3-dialkoxyvinylcarbenes behave as highly efficient 1,3-dipoles in their reactions with benzylidenemalononitrile, and analogous highly electron-deficient olefins, to yield substituted cyclopentenone ketals (Scheme 3). The regioselective formation of the exocyclic vinyl carbene **22** led us to attempt to trap it with an olefin in a [3+2] cycloaddition reaction.

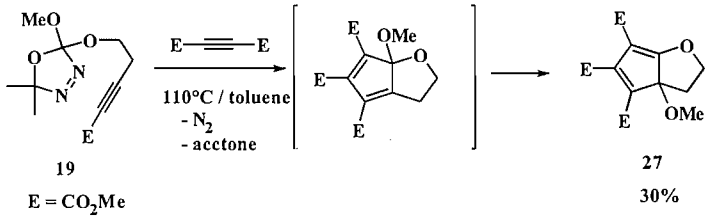
Scheme 8.

Thermolysis of **19** in the presence of benzylidenemalononitrile at a low concentration (to prevent reaction with the initially formed **20**) led to the clean formation of a diastereomeric mixture of cycloadducts, **25** and **26** (ratio 45:55), which were isolated by chromatography in a combined yield of 81% (eq. [2]). Although separation of the diastereomers by chromatography was not achieved, this tandem sequence, involving an intramolecular carbene cyclization followed by an intermolecular [3+2] cycloaddition, leads rapidly and efficiently to an interesting bicyclic ring system.

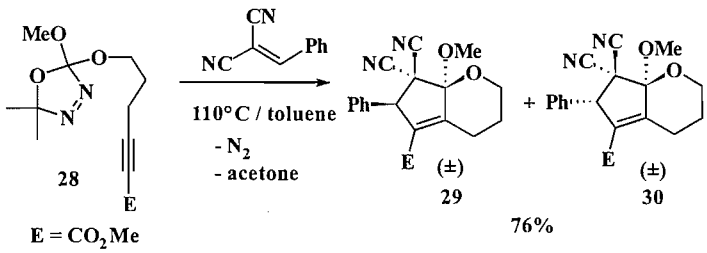
Thermolysis of oxadiazoline **19** in the presence of dimethyl acetylenedicarboxylate (DMAD) (low concentration) led to the formation of a bicyclic product (**27**) that was isolated in 30% yield (eq. [3]). Formation of this product is attributed to an initial [3+2] cycloaddition between the intermediate vinylcarbene **22** (Scheme 8) and DMAD, followed by an apparent[2] 1,5-sigmatropic methoxy shift. To the best of our knowledge, this is the first reported example of a 1,5-sigmatropic methoxy shift in a cyclopentadiene ring system, although an analogous chlorine shift is known (17). The ^{1}H NMR spectrum of the crude thermolysis product indicated that **27** was the major product (>80%) of this reaction although it was isolated in only up to 30% yield because of partial decomposition during chromatography. The initial [3+2] cycloadduct could not be detected (<3%) in the crude thermolysis product, indicating that the rearrangement is facile under the reaction conditions (refluxing toluene) and favours the formation of **27** thermodynamically. In contrast to the above result, Boger and Brotherton reported that the thermal generation of a 3,3-dialkoxyvinylcarbene, from the corresponding 3,3-dialkoxycyclopropenone ketal, in the presence of DMAD failed to give a [3+2] adduct (8*c*). The ester substituent may play a role in the successful cycloaddition of **22** with DMAD.

Extension of the alkyne tether by one methylene unit was found not to alter the observed chemistry of the oxadiazoline. Thermolysis of oxadiazoline **28** in the presence of benzylidenemalononitrile (low concentration) led to the clean formation of a diastereomeric mixture of **29** and **30** (46:54 ratio), which were isolated by chromatography in a combined yield of 76% (eq. [4]). In this case the diastereomers were separable by chromatography.

In contrast to the above thermal reaction of **19** with DMAD (eq. [3]), the thermolysis of oxadiazoline **28** in the presence of DMAD (low concentration) gave a mixture of two isomeric heterocycles, **31** and **32**, which were formed in 55:45 ratio as estimated from the ^{1}H NMR spectrum of the crude thermolysis product (eq. [5]). These compounds were separated by chromatography in 36% and 31% yield, respectively.



The formation of **31** can be attributed to a [3+2] cycloaddition between the intermediate vinylcarbene and DMAD. Product **32** may be derived from **31** by a thermal 1,5-methoxy shift as seen previously (eq. [3]). Heating a pure sample of either **31**



[2] A reviewer pointed out that the same result might be expected from conjugate addition followed by elimination. Although the methanol required for that mechanism was not present initially, the possibility that some was generated from adventitious water has not been excluded.

[3] 

[4] 

[5] 

or **32** at 110°C for 12 h gave a mixture of **31** and **32** in the same ratio as that observed for the crude thermolysis product, indicating that in this case the 1,5-methoxy shift is an equilibrium process with $K \cong 0.8$ (eq. [5]), and that equilibrium was established during the thermolysis.

Conclusion

As demonstrated first by Boger et al., and then by Nakamura and co-workers, 3,3-dialkoxyvinylcarbenes/1,3-dipoles are interesting and synthetically useful reactive intermediates. Both endocyclic and exocyclic 3,3-dialkoxyvinylcarbenes were generated selectively, in situ, by the intramolecular reaction of a dialkoxycarbene with a tethered triple bond. The regioselectivity of formation of the vinylcarbene is controlled by the alkyne substituent. A consequence of forming an exocyclic 3,3-dialkoxyvinylcarbene/1,3-dipole is efficient [3+2] cycloaddition with an appropriate olefin or alkyne, for the rapid construction of new bicyclic products. We are currently investigating the application of this methodology for the construction of other ring systems.

Experimental

General methods

NMR spectra were recorded on a Bruker AM-500, AC-300, or AC-200 spectrometer. Chemical shifts for ^{1}H NMR spectra were measured with TMS, C_6H_6 (δ = 7.15), or $CHCl_3$ (δ = 7.24) as internal reference, while ^{13}C NMR spectra were referenced to the chloroform-*d* triplet (δ = 77.0) or the benzene-d_6 triplet (δ = 128.0). Mass spectra were recorded on a ZAB-E double-focusing mass spectrometer or on a Hewlett Packard MSD GCMS. FTIR spectra were obtained with a Bio-Rad, FTS-40 instrument. Benzene, toluene, and THF were distilled from sodium benzophenone ketyl and dichloromethane was distilled from calcium hydride. Chromatography solvents (EtOAc, hexanes) were distilled before use. All reactions were carried out under a nitrogen atmosphere.

Preparation of 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (8) (ref. 2)

To an ice-cooled heterogeneous mixture of lead tetraacetate (162 g, 366 mmol) and acetic acid (2 mL) in CH_2Cl_2 (160 mL) was added a solution of the carbomethoxy hydrazone of acetone (42.0 g, 325 mmol) in CH_2Cl_2 (100 mL). Addition was slow, by means of an addition funnel, and the mixture was stirred with a mechanical stirrer and continuously purged with N_2. Following addition of the hydrazone, the ice-bath was removed and the mixture was allowed to warm slowly to room temperature with continued stirring (ca. 1 h). The mixture was then filtered (Buchner funnel/aspirator), and the filtrate was washed with aqueous (4%) bicarbonate. The organic layer was then collected and the aqueous layer was extracted (2 × 20 mL) with methylene chloride. The combined organic extracts were then dried over anhydrous sodium sulfate. Evaporation of the solvent in vacuo gave a mixture of **8** and a single impurity in a ratio of 75:25; combined yield of 90%. The impurity is an acyclic isomer of the oxadiazoline (2). Purification of the oxadiazoline is possible by slow bulb-to-bulb distillation but separation is not required and the mixture was used in the subsequent reactions.

2-Acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (ref. 2): FTIR (NaCl cell, CCl_4) cm^{-1}: 2993, 2951, 2849, 1832, 1771, 1715, 1462, 1443, 1380, 1369, 1260, 1214, 1208, 1180, 1158, 1085, 1061, 1013, 981, 924, 910, 851, 625, 561; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.51 (s, 3H), 1.62 (s, 3H), 2.10 (s, 3H), 3.58 (s, 3H); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 19.7, 21.7, 24.2, 52.6, 122.3, 134.0, 166.4; MS (e.i.) *m/z*: 129, 117, 73, 59, 43 (100 %) (mol. ion not observed); MS (c.i., NH_3) *m/z*: 206 $(M+NH_4)^+$, 189 $(M+H)^+$.

Typical procedure for the acetoxy exchange method. Preparation of Δ^3-1,3,4-oxadiazoline (3b)

To the above-mentioned crude 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**8**) (0.88 g, 3.5 mmol of oxadiazoline) in CH_2Cl_2 (20 mL) was added 3-pentyn-1-ol (0.30 g, 3.6 mmol) and acetic acid (ca. 1.0 mL). The resulting solution was allowed to stand at room temperature for 48 h. This mixture was concentrated in vacuo and then subjected to chromatography (Chromatotron, 2 mm plate, 10–20% EtOAc–hexanes) to give **3b** as a clear oil in 67% yield (0.50 g, 2.4 mmol). ^1H NMR (200 MHz, $CDCl_3$) δ: 1.47 (s, 3H, CH_3), 1.48 (s, 3H, CH_3), 1.73 (d, ^5J = 2.6 Hz, 3H, alkynyl CH_3), 2.44 (tq, ^3J = 7.3 Hz, ^5J = 2.6 Hz, 2H, CH_2), 3.43 (s, 3H, CH_3O), 3.72 (dt, ^3J = 7.3 Hz, ^2J = 9.5 Hz, 1H, CH_2O), 3.84 (dt, ^3J = 7.3 Hz, ^2J = 9.5 Hz, 1H, CH_2O); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 3.3 (CH_3), 20.0 (CH_3), 23.8 (CH_3), 24.0 (CH_2), 51.7 (CH_3O), 63.2 (CH_2O), 74.9 (*C*≡C), 76.9 (C≡*C*), 119.1 (C5), 136.7 (C2); MS (e.i.) *m/z* (rel. intensity): 129 (20), 125 (8), 111 (48), 67 (100) (mol. ion not observed); MS (c.i., NH_3) *m/z*: 230 $(M+NH_4)^+$.

Thermolysis of 2-methoxy-5,5-dimethyl-2-(3-pentynoxy)-Δ^3-1,3,4-oxadiazoline (3b)

At atmospheric pressure, 40 mL of benzene was distilled from a solution of 2-methoxy-5,5-dimethyl-2-(3-pentynoxy)-Δ^3-1,3,4-oxadiazoline (**3b**, 361 mg, 1.70 mmol) in 80 mL of dry benzene to remove adventitious water by azeotropic distillation. The solution was then sealed into a 100 mL glass tube after degassing at 0.1 Torr (1 Torr = 133.3 Pa) by three freeze–pump–thaw sequences. The tube was kept in an oil bath operating at 110 ± 0.1°C for 20 h before it was cooled and opened. The crude reaction mixture was concentrated in vacuo to yield a yellow oil (258 mg, ca. 49%). Spectroscopy of the residue showed that it consisted primarily (>90%) of methyl (*E*)-3-ethenyl-4-(5,6-dihydro-2-methoxy-3-methyl-2*H*-pyran-4-oxy)-2,4-dimethylpent-2-enoate (**10b**). The spectral data below are those of the crude thermolysis product, which was primarily (>90%) **10b**. ^1H NMR (500 MHz, C_6D_6) δ: 1.14 (s, 3H, CH_3), 1.24 (s, 3H, CH_3), 1.4–1.7 (m, complex, 2H, H5′a and H5′b), 1.83 (s, 3H, CH_3 on C3′), 2.22 (d, ^5J = 1.7 Hz, 3H, CH_3 on C2), 3.35 (s, 3H, OCH_3), 3.42 (s, 3H, OCH_3), 3.82 (m, $^2J_{6'a,6'b}$ = 10.2 Hz, $^3J_{5'a,6'a}$ = 3.7 Hz, $^3J_{5'b,6'a}$ = 3.7 Hz, $^4J_{4',6'a}$ = 1.2 Hz, 1H, H6′a), 3.98 (m, $^3J_{4',5'a}$ = 6.9 Hz, $^3J_{4',5'b}$ = 6.9 Hz, $^3J_{4',6'a}$ = 1.2 Hz, 1H, H4′), 4.04 (m, $^2J_{6'a,6'b}$ = 10.2 Hz, $^3J_{5'a,6'b}$ = 12.5 Hz, $^3J_{5'b,6'b}$ = 2.3 Hz, 1H, H6′b), 4.88 (dd, $^3J_{bx}$ = 10.9 Hz, $^2J_{ab}$ = 2.3 Hz, 1H, Hb), 5.10 (dd, $^3J_{ax}$ = 17.2 Hz, $^2J_{ab}$ = 2.3 Hz, 1H, Ha), 6.25 (m, $^3J_{ax}$ = 17.2 Hz, $^3J_{bx}$ = 10.9 Hz, $^5J_{x,Me}$ = 1.7 Hz, 1H, Hx); ^{13}C NMR (75 MHz, C_6D_6) δ: 13.2 (CH_3), 17.8 (CH_3), 26.6 (CH_3), 27.8 (CH_3), 31.5 (CH_2), 51.1 (OCH_3), 54.9 (OCH_3), 63.6 (C6′), 67.3 (C4′), 76.8 (C4), 83.5 (C3′), 116.9 (CH_2=*C*H), 130.7 (C2), 139.0 (*C*H_2=CH), 146.2 (C2′), 155.5 (C3), 172.0 (C=O); MS (e.i.) *m/z* (rel. intensity): 310 (M^+, 58), 295 ($M^+ - CH_3$, 18), 279 ($M^+ - CH_3O$, 9), 279 ($M^+ - CO_2CH_3$, 37), 168 (82),143 (100); MS (c.i., NH_3) *m/z*: 311 $(M + H)^+$.

Attempts to purify this ketene acetal by chromatography led to its hydrolysis to methyl (*E*)-3-ethenyl-4-(tetrahydro-4*H*-pyran-2-on-4-oxy)-2,4-dimethylpent-2-enoate (**11**) as the major isolated hydrolysis product, in 60–70% yield. ^1H NMR of **11** (500 MHz, C_6D_6) δ: 0.97 (s, 3H, CH_3), 1.05 (s, 3H, CH_3), 1.17 (d, ^3J = 7.0 Hz, 3H, CH_3 on C3′), 1.19–1.26 (m, complex, 1H, H5′), 1.55 (m, ^2J = 14.2, ^3J = 8.5, ^3J = 5.6 Hz, ^3J = 5.6 Hz, 1H, H5′), 2.05 (dq, ^3J = 7.0 Hz, ^3J = 4.3 Hz, 1H, H3′), 2.10 (d, ^5J = 1.7 Hz, 3H, CH_3 on C2), 3.34 (s, 3H, OCH_3), 3.36 (m, complex, 1H, H4′), 3.51 (m, $^2J_{6'a,6'b}$ = 11.5 Hz, $^3J_{5'a,6'a}$ = 5.1 Hz, $^3J_{5'b,6'a}$ = 8.5 Hz, 1H, H6′a), 3.90 (m, $^2J_{6'a,6'b}$ = 11.5 Hz, $^3J_{5'a,6'b}$ = 11.5 Hz, $^3J_{5'b,6'b}$ = 5.8 Hz, 1H, H6′b), 4.88 (dd, $^3J_{bx}$ = 10.9 Hz, $^2J_{ab}$ = 2.2 Hz, 1H, Hb), 5.03 (dd, $^3J_{ax}$ = 17.2 Hz, $^2J_{ab}$ = 2.2 Hz, 1H, Ha), 6.16 (m, $^3J_{ax}$ = 17.2 Hz, $^3J_{bx}$ = 10.9 Hz, $^5J_{x,Me}$ = 1.7 Hz, 1H, Hx). ^{13}C NMR (50 MHz, C_6D_6) δ: 12.9 (CH_3), 17.9 (CH_3), 26.1 (CH_3), 27.3 (CH_3), 29.7 (CH_2), 41.1 (C3′), 51.2 (OCH_3), 64.5 (C6′), 68.8 (C4′), 77.7 (C4), 117.3 (CH_2=*C*H), 131.1 (C2), 138.6 (*C*H_2=CH), 145.0 (C3), 172.0 (C=O), 172.4 (C=O); MS (e.i.) *m/z* (rel. intensity): 296 (M^+, 25), 281 ($M^+ - CH_3$, 5), 265 ($M^+ - CH_3O$, 13), 238 (9), 168 (100); MS (c.i., NH_3) *m/z*: 314 $(M + NH_4)^+$, 297 $(M + H)^+$.

2-(3-Butyn-1-oxy)-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (3a) (ref. 2)

Prepared in 86% yield by the acetoxy exchange method (2) (see above) using 3-butyn-1-ol. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.52 (s, 3H), 1.53 (s, 3H), 1.94 (t, ^4J = 2.7 Hz, 1H), 2.49 (dt, ^3J = 7.2 Hz, ^4J = 2.7 Hz, 2H), 3.42 (s, 3H), 3.76 (dt, ^3J = 7.2 Hz, ^2J = 9.3 Hz, 1H), 3.84 (dt, ^3J = 7.2 Hz, ^2J = 9.3 Hz, 1H); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 19.9, 24.0, 24.2, 51.9, 62.8, 69.7, 80.4, 119.4, 136.7; MS (e.i.) *m/z* (rel. intensity): 167, 129 (100), 111, 97, 73, 59 (mol. ion not observed); MS (c.i., NH_3) *m/z*: 216 $(M+NH_4)^+$. Combustion analysis, calcd. for $C_9H_{14}N_2O_3$: C 54.52, H 7.12, N 14.14; found: C 54.32, H 7.22, N 13.75.

2-Methoxy-2-(4-methoxycarbonyl-3-butyn-1-oxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (19)

A stirred solution of 2-(3-butyn-1-oxy)-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (0.76 g, 3.9 mmol) in dry THF was cooled at −78°C under nitrogen for 30 min. *n*-Butyllithium in hexanes (1.6 M, 2.4 mL, 3.8 mmol) was then added dropwise. This solution was stirred at −78°C for 1 h before addition of methylchloroformate (0.75 mL, 9.8 mmol). The reaction mixture was allowed to reach room temperature overnight with the cooling bath left in place. Water (25 mL) was then cautiously added and most of the THF was removed from the aqueous solution by rotary evaporation. The aqueous residue was extracted with CH_2Cl_2 (3 × 20 mL) and the combined extracts were dried over anhydrous Na_2SO_4, and then concentrated in vacuo. Chromatography (Chromatotron, 4 mm plate, 10% EtOAc–hexanes) gave **19** as a yellow oil in 76% yield. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.54 (s, 3H, CH_3), 1.56 (s, 3H, CH_3), 2.67 (t, ^3J = 6.9 Hz, 2H, CH_2), 3.43 (s, 3H, CH_3O), 3.75 (s, 3H, CH_3O), 3.88 (dt, ^3J = 6.9 Hz, ^2J = 9.7 Hz, 1H, ^1H of CH_2O), 3.96 (dt, ^3J = 6.9 Hz, ^2J = 9.7 Hz, 1H, ^1H of CH_2O); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 19.9 (CH_3), 23.6 (CH_3), 23.9

Thermolysis of 2-methoxy-2-(4-methoxycarbonyl-3-butyn-1-oxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (19) in the presence of *tert*-butyl alcohol

At atmospheric pressure, 20 mL of toluene was distilled from a solution of 2-methoxy-2-(4-methoxycarbonyl-3-butyn-1-oxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**19**) (119 mg, 0.465 mmol) in 130 mL of dry toluene, to remove adventitious water by azeotropic distillation. *tert*-Butyl alcohol (90 mg, 1.2 mmol) was added and the solution was refluxed under a nitrogen atmosphere for 20 h. Concentration of this solution in vacuo gave an oil. The spectral data of the residue indicated that it was primarily (>80%) methyl 2-*tert*-butoxy-2-(2-methoxy-4,5-dihydro-3-furanyl)-ethanoate (**23**). ^{1}H NMR (500 MHz, C_6D_6) δ: 1.32 (s, 9H, $(CH_3)_3$), 2.85 (m, $^2J_{4'\alpha,4'\beta}$ = 19.4 Hz, $^3J_{4'\alpha,5'\beta}$ = 7.9 Hz, $^3J_{4'\alpha,5'\alpha}$ = 7.9 Hz, $^4J_{2,4'\alpha}$ = 2.9 Hz, 1H, H4′α), 2.99 (m, $^2J_{4'\alpha,4'\beta}$ = 19.4 Hz, $^3J_{4'\beta,5'\beta}$ = 6.1 Hz, $^3J_{4'\beta,5'\alpha}$ = 8.1 Hz, $^4J_{2,4'\beta}$ = 2.8 Hz, 1H, H4′β), 3.09 (s, 3H, OCH_3), 3.36 (s, 3H, OCH_3), 3.61 (m, $^2J_{5'\alpha,5'\beta}$ = 8.0 Hz, $^3J_{4'\alpha,5'\beta}$ = 8.1 Hz, $^3J_{4'\beta,5'\beta}$ = 6.1 Hz, 1H, H5′β), 3.64 (m, $^2J_{5'\alpha,5'\beta}$ = 8.0 Hz, $^3J_{4'\alpha,5'\alpha}$ = 5.8 Hz, $^3J_{4'\beta,5'\alpha}$ = 7.9 Hz, 1H, H5′α), 6.26 (dd, $^4J_{2,4'\beta}$ = 2.8 Hz, $^4J_{2,4'\alpha}$ = 2.9 Hz, 1H, H2); ^{13}C NMR (75 MHz, C_6D_6) δ: 30.2 (+)(C4′), 30.3 (−)($(CH_3)_3$), 49.6 (−)(CH_3O), 50.8 (−)(CH_3O), 64.1 (+)(C5′), 64.2 (+)(*C*$(CH_3)_3$), 76.7 (+)(C3′), 114.0 (−)(C2), 158.9 (+)(C2′), 167.0 (+)(CO).

Typical [3+2] cycloaddition with dimethyl acetylenedicarboxylate (DMAD). Thermolysis of 2-methoxy-2-(4-methoxycarbonyl-3-butyn-1-oxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (19) in the presence of DMAD

Toluene (20 mL) was distilled from a solution of **19** (180 mg, 0.703 mmol) in dry toluene (180 mL) to remove adventitious water by azeotropic distillation. DMAD (140 mg, 0.986 mmol) was added before the solution was refluxed for 20 h. Following concentration in vacuo the crude thermolysis product was purified by chromatography (Chromatotron, 2 mm plate, 10–20 % EtOAc–hexanes) to give the [3+2] cycloadduct **27** as a yellow oil in 30% yield. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.18 (m, ^2J = 13.2 Hz, ^3J = 10.7 Hz, ^3J = 7.7 Hz, 1H, CH_2), 2.50 (m, ^2J = 13.2 Hz, ^3J = 4.1 Hz, ^3J = 0.0 Hz, 1H, CH_2), 3.23 (s, 3H, ether CH_3O), 3.73 (s, 3H, CH_3O), 3.75 (s, 3H, CH_3O), 3.91 (s, 3H, CH_3O), 4.99 (m, ^2J = 8.4 Hz, ^3J = 7.7 Hz, ^3J = 0.0 Hz, 1H, OCH_2), 5.38 (m, ^2J = 8.4 Hz, ^3J = 10.7 Hz, ^3J = 7.7 Hz, ^3J = 4.1 Hz, 1H, OCH_2); ^{13}C NMR (125 MHz, C_6D_6) δ: 34.5 (+)(C3), 51.1 (−)(CH_3O), 51.2 (−)(CH_3O), 51.9 (−)(CH_3O), 52.3 (−)(CH_3O), 86.0 (+)(OCH_2), 91.0 (+) (C4), 101.3 (+), 118.5 (+), 153.3 (+)(3 × vinyl), 161.3 (+)(2 × C=O), 164.5 (+)(C=O), 183.6 (+)(C8). Assignment of C4 was based on a two- and three-bond ^{1}H–^{13}C correlation (HETCOR) NMR experiment that showed correlation of the resonance at 91.0 ppm to the ether OCH_3 hydrogens. In addition, assignment of C8 was based on the fact that the resonance at 183.6 ppm showed a correlation to both C2 and C3 protons. MS (e.i.) *m/z* (rel. intensity): 312 (M^+, 100), 297 ($M^+ - CH_3$, 7), 281 ($M^+ - OCH_3$, 47), 269 (27), 253 ($M^+ - CO_2CH_3$, 59), 221 (55), 84 (100); MS (HR) *m/z*, calcd. for $C_{14}H_{16}O_8$(M^+): 312.0845; found: 312.0844.

Typical [3+2] cycloaddition with benzylidenemalononitrile. Thermolysis of 2-methoxy-2-(4-methoxycarbonyl-3-butyn-1–oxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (19) in the presence of benzylidenemalononitrile

Toluene (20 mL) was distilled from a solution of **19** (136 mg, 0.531 mmol) and benzylidenemalononitrile (90 mg, 0.58 mmol) in 150 mL of dry toluene to remove adventitious water by azeotropic distillation before the solution was refluxed for 20 h. Following concentration in vacuo the crude thermolysis product was purified by chromatography (Chromatotron, 1 mm plate, 5–15% EtOAc–hexanes) to give the [3+2] cycloadducts **25** and **26** as a 54:46 mixture of diastereomers in 81% combined yield. Chromatographic separation was not achieved. Melting point 140–158°C. ^{1}H NMR of **25** and **26** with approximate integrations based on ca. 1:1 ratio (300 MHz, $CDCl_3$) δ: 2.78–3.09 (m, 2H, allylic CH_2) , 3.22–3.45 (m, 2H, allylic CH_2), 3.50 (s, 3H, CH_3O), 3.54 (s, 3H, CH_3O), 3.67 (s, 3H, CH_3O), 3.76 (s, 3H, CH_3O), 4.45–4.57 (m, 2H, OCH_2), 6.62–4.75 (m, 2H, OCH_2), 5.05 (d, ^5J = 1.8 Hz, 1H, benzylic CH), 5.21 (dd, ^5J = 1.6 Hz, ^5J = 4.7 Hz, 1H, CH), 7.29–7.46 (m, 10H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 26.4 (2 × CH_2), 48.8 ($C(CN)_2$), 51.1 ($C(CN)_2$), 51.8 (CH_3O), 52.0 (CH_3O), 52.4 (CH_3O), 53.2 (CH_3O), 62.2 (CPh), 64.2 (CPh), 74.2 (CH_2O), 74.5 (CH_2O), 111.0 (OCO), 111.3 (OCO), 111.8 (CN), 114.0 (CN), 114.8 (CN), 116.0 (CN), 126.9, 127.6, 128.2, 128.6, 128.7, 129.1, 129.2 (8 × aryl + 2 C=*C*E), 155.1 (*C*=CE), 155.5 (*C*=CE), 162.9 (C=O), 163.3 (C=O); MS (e.i.) *m/z* (rel. intensity): 324 (M^+, 100), 309 ($M^+ - CH_3$, 3), 293 ($M^+ - OCH_3$, 8), 265 ($M^+ - CO_2CH_3$, 35), 237 (24), 205 (44), 111 (71); MS (HR) *m/z*, calcd. for $C_{18}H_{16}N_2O_4$ (M^+): 324.1110; found: 324.1100.

2-Methoxy-5,5-dimethyl-2-(4-pentyn-1-oxy)-Δ^3-1,3,4-oxadiazoline

Prepared in 78% by the acetoxy exchange method (2) with 4-pentyn-1-ol. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.50 (s, 3H, CH_3), 1.51 (s, 3H, CH_3), 1.81 (tt, ^3J = 6.2 Hz, ^3J = 6.9 Hz, 2H, CH_2), 1.91 (t, ^4J = 2.7 Hz, 1H, C≡CH), 2.26 (dt, ^3J = 6.9 Hz, ^4J = 2.7 Hz, 2H, CH_2), 3.42 (s, 3H, CH_3O), 3.74 (dt, ^3J = 6.2 Hz, ^2J = 9.7 Hz, 1H, OCH_2), 3.83 (dt, ^3J = 6.2 Hz, ^2J = 9.7 Hz, 1H, OCH_2); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 15.0, 24.0, 24.1, 28.4, 51.8, 63.0, 68.7, 83.3, 119.1, 136.9; MS (e.i.) *m/z* (rel. intensity): 181 ($M^+ - OCH_3$, 2), 129 ($M^+ - O(CH_2)_3CCH$, 10), (mol. ion not observed); MS (c.i., NH_3) *m/z*: 230 $(M+NH_4)^+$.

2-Methoxy-2-[5-methoxycarbonyl-4-pentyn-1-oxy]-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (28)

A stirred solution of 2-methoxy-5,5-dimethyl-2-(4-pentyn-1-oxy)-Δ^3-1,3,4-oxadiazoline (1.00 g, 4.72 mmol) in dry THF (50 mL) was cooled at −78°C for 30 min under nitrogen. *n*-Butyllithium in hexanes (1.6 M, 3.3 mL, 5.2 mmol) was then added dropwise. This solution was stirred at −78°C for 1 h before addition of methyl chloroformate (1.0 mL, 12 mmol). The reaction mixture was allowed to reach room temperature overnight with the cooling bath left in place. Water (25 mL) was then added cautiously and most of the THF was evaporated from the aqueous mixture by rotary evaporation. The aqueous residue was extracted with CH_2Cl_2 (3 × 20 mL) and the combined extracts were dried over anhydrous Na_2SO_4 and

For personal use only.

then concentrated in vacuo. Chromatography (Chromatotron, 4 mm plate, 10% EtOAc–hexanes) gave **30** as an oil in 60% yield. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.49 (s, 3H, CH_3), 1.50 (s, 3H, CH_3), 1.84 (m, ^3J = 7.2 Hz, ^3J = 6.5 Hz, ^3J = 6.0 Hz, 2H, CH_2), 2.41 (t, ^3J = 7.2 Hz, 2H, CH_2), 3.38 (s, 3H, CH_3O), 3.70 (s, 3H, CH_3O), 3.71 (dt, ^2J = 9.9 Hz, ^3J = 6.5 Hz, 1H, 1H of OCH_2), 3.80 (dt, ^2J = 9.9 Hz, ^3J = 6.0 Hz, 1H, 1H of OCH_2); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 15.4 (CH_2), 23.9 (CH_3), 24.1 (CH_3), 27.6 (CH_2), 51.8 (CH_3O), 52.5 (CH_3O), 62.8 (CH_2O), 73.2 (EC≡C), 88.4 (EC≡*C*), 119.2 (C5), 136.9 (C2), 154.0 (C=O); MS (e.i.) (rel. intensity) *m/z*: 239 ($M^+ - OCH_3$, 3), 169 (5), 239 ($M^+ - O(CH_2)_3C{\equiv}C$-E, 15), 125 (65), 93 (68), 59 (100); MS (c.i., NH_3) *m/z*: 288 $(M + NH_4)^+$.

Thermolysis of 2-methoxy-2-[5-methoxycarbonyl-4-pentyn-1-oxy]-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (28) in the presence of benzylidenemalononitrile

The typical procedure for [3+2] cycloaddition with benzylidenemalononitrile (above) was followed. Thermolysis of 2-methoxy-2-[5-methoxycarbonyl-4-pentyn-1-oxy]-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**28**) (134 mg, 0.496 mmol) in the presence of benzylidenemalononitrile gave **29** and **30** in 55:45 ratio. These products were separated by chromatography (Chromatotron, 2 mm plate, 5–10% EtOAc–hexanes) in a combined yield of 76%. They were distinguished from each other from the magnitudes of the homoallylic coupling constants (^5J) in the ^{1}H NMR spectra (18).

*Data for **29***: FTIR (NaCl) cm^{-1}: 2980–2849, 2250 (CN), 1724, 1456, 1438, 1281, 1252, 1051; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.83–1.93 (m, 2H, CH_2), 2.60 (m, ^2J = 15.1 Hz, ^3J = 10.2 Hz, ^3J = 8.0 Hz, ^5J = 2.2 Hz, 1H, allylic CH_2), 3.49 (m, ^2J = 15.1 Hz, ^3J = 3.9 Hz, ^3J = 3.9 Hz, ^4J = 1.7 Hz, 1H, allylic CH_2), 3.53 (s, 3H, CH_3O), 3.62 (s, 3H, CH_3O), 3.86 (m, ^2J = 10.7 Hz, ^3J = 8.5 Hz, ^3J = 6.2 Hz, 1H, OCH_2), 4.09 (m, ^2J = 10.7 Hz, ^3J = 3.2 Hz, ^3J = 3.2 Hz, ^4J = 1.7 Hz, 1H, OCH_2), 4.71 (d, ^5J = 1.7 Hz, 1H, allylic CH), 7.26–7.36 (m, 5H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 23.2 (CH_2), 25.0 (CH_2), 48.0 ($C(CN)_2$), 50.4 (CH_3O), 52.0 (CH_3O), 58.6 (CPh), 64.7 (CH_2O), 108.8 (OCO), 111.9 (CN), 114.5 (CN), 127.1, 128.7, 129.0, 134.8 (phenyl + C=*C*E), 149.9 (*C*=CE), 163.5 (C=O); MS (e.i.) *m/z* (rel. intensity): 338 (M^+, 70), 323 ($M^+ - CH_3$, 3), 307 ($M^+ - OCH_3$, 22), 279 ($M^+ - CO_2CH_3$, 23), 273 (100), 247 (32), 219 (35), 125 (87); MS (HR) *m/z*, calcd. for $C_{19}H_{18}N_2O_4$ (M^+): 338.1267; found: 338.1265.

*Data for **30***: IR (NaCl) cm^{-1}: 2965–2848, 2250 (CN), 1724, 1456, 1437, 1280, 1255, 1048; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.90–2.12 (m, 2H, CH_2), 2.53 (m, ^2J = 13.9 Hz, ^3J = 12.5 Hz, ^3J = 6.0 Hz, ^5J = 3.5 Hz, 1H, allylic CH_2), 3.48 (m, ^2J = 13.9 Hz, ^3J = 6.0 Hz, ^3J = 4.0 Hz, ^4J = 2.0 Hz, 1H, allylic CH_2), 3.56 (s, 3H, CH_3O), 3.65 (s, 3H, CH_3O), 3.94 (m, ^2J = 11.5 Hz, ^3J = 11.7 Hz, ^3J = 3.2 Hz, 1H, OCH_2), 4.11 (m, ^2J = 11.5 Hz, ^3J = 4.8 Hz, ^3J = 1.8 Hz, ^4J = 2.0 Hz, 1H, OCH_2), 4.80 (d, ^5J = 3.5 Hz, 1H, allylic CH), 7.13–7.38 (m, 5H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 26.8 (2 × CH_2), 50.9 ($C(CN)_2$), 49.3 (CH_3O), 51.8 (CH_3O), 58.2 (CPh), 64.9 (CH_2O), 108.7 (OCO), 111.3 (CN), 113.7 (CN), 126.7, 128.3, 128.9, 129.1 (phenyl + C=*C*E), 150.3 (C=CE), 163.7 (C=O); MS (e.i.) *m/z* (rel. intensity): 338 (M^+, 80), 323 ($M^+ - CH_3$, 5), 307 ($M^+ - OCH_3$, 22), 279 ($M^+ - CO_2CH_3$, 26), 273 (100), 247 (39), 219 (31), 125 (100); MS (HR) *m/z*, calcd. for $C_{19}H_{18}N_2O_4$ (M^+): 338.1267; found: 338.1247.

Thermolysis of 2-methoxy-2-[5-methoxycarbonyl-4-pentyn-1-oxy]-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (28) in the presence of DMAD

The typical procedure for [3+2] cycloaddition with DMAD (above) was followed. Thermolysis of 2-methoxy-2-[5-methoxycarbonyl-4-pentyn-1-oxy]-5, 5-dimethyl-Δ^3-1,3,4-oxadiazoline (**28**) (133 mg, 0.493 mmol) in the presence of DMAD gave two products **31** and **32** in 53:47 ratio, by ^{1}H NMR. These products, both oils, were isolated by chromatography (Chromatotron, 1 mm plate, 10–20% EtOAc–hexanes) in 36 and 31% yields, respectively. Heating either one of the two isolated isomeric cycloadducts (**31** or **32**) led to a 53:47 mixture of the two.

*Spectral data of **31***: ^{1}H NMR (300 MHz, C_6D_6) δ: 1.16–1.34 (m, 2H, CH_2), 2.06 (m, 1H, allylic CH_2), 3.03 (s, 3H, CH_3O), 3.28 (s, 3H, CH_3O), 3.33 (m, 1H, allylic CH_2), 3.36 (s, 3H, CH_3O), 3.39 (m, 1H, OCH_2), 3.71 (s, 3H, CH_3O), 3.81 (m, 1H, OCH_2); ^{13}C NMR (50 MHz, C_6D_6) δ: 24.9 (CH_2), 28.8 (allylic CH_2), 50.9 (CH_3O), 51.4 (2 × CH_3O), 52.1 (CH_3O), 61.5 (OCH_2), 105.8 (CH_3OCOCH_2), 123.2 (vinyl), 132.3 (vinyl), 147.7 (vinyl), 161.4 (C=O), 162.6 (C=O), 163.1 (C=O), 165.2 (E-C=*C*CH_2); MS (e.i.) *m/z* (rel. intensity): 326 (M^+, 100), 311 ($M^+ - CH_3$, 11), 295 ($M^+ - OCH_3$, 80), 283 (17), 267 ($M^+ - CO_2CH_3$, 82), 235 (50); MS (HR) *m/z*, calcd. for $C_{15}H_{18}O_8$ (M^+): 326.1002; found: 326.1001.

*Spectral data of **32***: ^{1}H NMR (500 MHz, C_6D_6) δ: 1.01 (m, ^2J = 17.4 Hz, ^3J = 6.1, ^3J = 4.7, ^3J = 4.2, 1H, CH_2), 1.26–1.35 (m, 2H, 1H of CH_2 and 1H of homoallylic CH_2), 2.72 (m, ^2J = 15.3 Hz, ^3J = 9.6 Hz, ^3J = 4.7 Hz, 1H of homoallylic CH_2), 2.96 (s, 3H, CH_3O), 3.49 (s, 3H, CH_3O), 3.54 (s, 3H, CH_3O), 3.76 (m, ^2J = 10.5 Hz, ^3J = 6.1 Hz, ^3J = 2.4 Hz, 1H, OCH_2), 4.32 (m, ^2J = 10.5 Hz, ^3J = 11.5 Hz, ^3J = 4.2 Hz, 1H, OCH_2); ^{13}C NMR (50 MHz, C_6D_6) δ: 17.2 (CH_2), 27.1 (CH_2), 51.1 (2 × CH_3O), 52.0 (CH_3O), 52.2 (CH_3O), 68.0 (OCH_2), 83.7 (CH_3OCCH_2), 105.3, 121.7, 150.1 (3 × vinyl), 161.4 (C=O), 161.9 (C=O), 165.5 (C=O), 175.0 (O*C*=C); MS (e.i.) *m/z* (rel. intensity): 326 (M^+, 79), 311 ($M^+ - CH_3$, 11), 295 ($M^+ - OCH_3$, 52), 283 (14), 267 ($M^+ - CO_2CH_3$, 100), 235 (60); MS (HR) *m/z*, calcd. for $C_{15}H_{18}O_8$ (M^+): 326.1002; found: 326.1002.

The oxidation of secondary alcohols by potassium tetraoxoferrate(VI)

Bruce E. Norcross, William C. Lewis, Huifa Gai, Nazih A. Noureldin, and Donald G. Lee

Abstract: The kinetics of the oxidation of 2-propanol, 1,1,1-trifluoro-2-propanol, 1,1,1,3,3,3-hexafluoro-2-propanol, 1-phenyl-2,2,2-trifluoroethanol, 1-(4-methylphenyl)-2,2,2-trifluoroethanol, 1-(3-bromophenyl)-2,2,2-trifluoroethanol, and 1-(3-nitrophenyl)-2,2,2-trifluoroethanol by potassium tetraoxoferrate(VI) have been studied under basic conditions. The products are ketones, formed in almost quantitative yields, iron(III) hydroxide, and dioxygen. The reactions are characterized by substantial enthalpies of activation (40–60 kJ/mol), very unfavorable entropies of activation, large primary deuterium isotope effects, and a positive Hammett ρ value. Both acid and base catalysis are observed. Acid catalysis is attributed to formation of a more reactive oxidant, $HFeO_4^-$, at low pH. Base catalysis is attributed partly to the conversion of the reductants to alkoxide ions at high pH, and partly to the reaction of hydroxide ion with tetraoxoferrate(VI) to give a five-coordinated species, $HOFeO_4^{3-}$, that reacts rapidly with nucleophiles. A reaction mechanism involving formation of an intermediate ferrate ester is proposed.

Key words: oxidation, alcohols, potassium tetraoxoferrate(VI), ferrate esters, base catalysis, acid catalysis.

Résumé : On a étudié, en milieu basique, la cinétique de l'oxydation des 2-propanol, 1,1,1-trifluoro-2-propanol, 1,1,1,3,3,3-hexafluoro-2-propanol, 1-phényl-2,2,2-trifluoroéthanol, 1-(4-méthylphényl)-2,2,2-trifluoroéthanol, 1-(3-bromophényl)-2,2,2-trifluoroéthanol et 1-(3-nitrophényl)-2,2,2-trifluoroéthanol par le tétraoxoferrate(VI) de potassium. Les produits sont des cétones, formées avec des rendements quasi-quantitatifs, le fer(III), l'hydroxyde et l'oxygène O_2. Les réactions sont caractérisées par des enthalpies d'activation substantielles (40–60 kJ/mol), par des entropies d'activation très défavorables, par des effets isotopiques primaires du deutérium assez importants, et par une valeur positive ρ de Hammett. On a observé à la fois la catalyse acide et basique. On attribue à une catalyse acide la formation d'un oxydant plus réactif $HFeO_4^-$ à pH faible. La catalyse basique est attribuée partiellement à la transformation du réducteur en ions alcoolates à fort pH, et partiellement à la réaction de l'ion hydroxyde avec le tétraoxoferrate(VI) pour donner une espèce pentacoordonnée, $HOFeO_4^{3-}$, qui réagit rapidement avec les nucléophiles. On propose un mécanisme réactionnel qui implique la formation d'un ester ferrate intermédiaire.

Mots clés : oxydation, alcools, tétraoxoferrate(VI) de potassium, esters ferrates, catalyse basique, catalyse acide.

[Traduit par la rédaction]

Introduction

Increasing environmental concerns over the possible spread of toxic heavy metals may eventually result in a required decrease in the use of some high-valent transition metal oxides as oxidants in organic synthesis. The response to such a requirement will involve the development of catalytic processes (coupled to dioxygen) that utilize only small amounts of transition metals and (or) the use of nontoxic oxidants. Both of these objectives can potentially be met by the utilization of iron oxides as catalysts or stoichiometric reagents.

Iron, because of its widespread occurrence in the environment, and the consequent large tolerance that living systems have to its presence, is considered to be environmentally benign. Whether or not the use of iron as an oxygen carrier in compounds such as hemoglobin and myoglobin (1) is a consequence of evolutionary development in an iron-rich environment remains a question for speculation and possible investigation. However, it is a fact that iron and iron oxides do not present a toxic threat to human life, nor to the lives of most other animals and plants.

Although the use of ferrate has not as yet found wide application in organic synthesis, it has been shown to be a good stoichiometric oxidant, particularly for alcohols. Primary alcohols are converted into aldehydes and secondary alcohols into ketones. The yields are highest for products in which the carbonyl is conjugated to an aromatic ring. For example, benzyl alcohol and its ring-substituted derivatives yield the corresponding benzaldehydes in 80–95% yield (2, 3) and 1-phenylethanol is converted into acetophenone in 90% yield (3). The reported yields for the oxidation of aliphatic alcohols are lower; about 30% for the formation of heptanal from 1-heptanol or cyclohexanone from cyclohexanol (3, 4). A useful selectivity has been observed when carbohydrates are oxi-

dized by ferrate; hydroxymethyls are oxidized much more readily than secondary hydroxyls (5, 6).

Amines are also oxidized by ferrate. For example, benzylamine and 1-amino-1-phenylethane are converted into benzaldehyde and acetophenone, respectively, both in 70% yield (3). In addition, it has been reported that sulfides are oxidized to sulfoxides by this reagent, but no yields were reported (7).

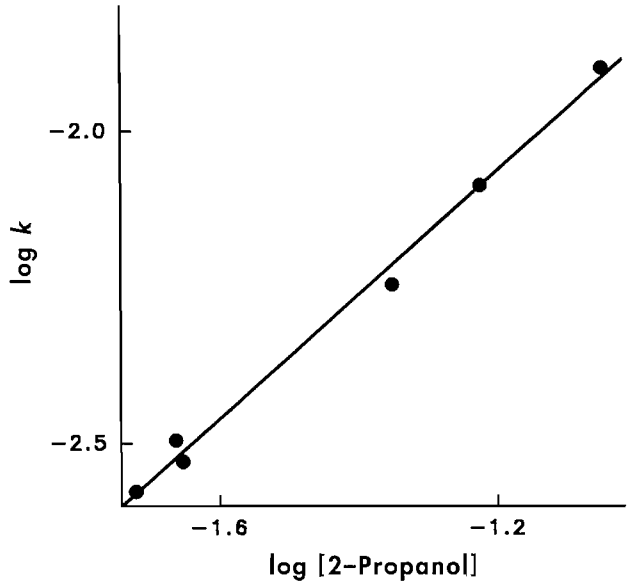
Ferrate has also been used as a selective oxidant for allylic and benzylic alcohols in a two-phase water–benzene system containing a phase transfer agent. For example, cinnanyl and benzyl alcohols were converted into the corresponding aldehydes in quantitative yields (8). Ferrate adsorbed on silica gel can also be used as a heterogeneous oxidant (9). The method is particularly effective for the oxidation of secondary aliphatic alcohols that often give low yields under homogeneous conditions.

The catalytic capabilities of iron porphyrins as oxidation catalysts are well known (10) and preliminary work has shown that noncomplexed iron-oxo compounds also have potential use as catalysts for the oxidation of organic compounds (11). Hence, it is important to achieve a better understanding of the chemical properties and potential applications of these reagents in both catalytic and stoichiometric reactions. Therefore, in this paper we wish to describe a kinetic study of the stoichiometric oxidation of alcohols by tetraoxoferrate(VI) (FeO_4^{2-}) under alkaline conditions. Since ferrate(VI) reacts rapidly with water in neutral or acidic solutions to give iron(III) and dioxygen, the study was limited to solutions with a pH of 8 or greater (12–16).

Experimental

Materials

Potassium tetraoxoferrate(VI) was prepared using procedures previously described in the literature (17–19). The purity of various batches of the oxidant, determined by titration with ferrous chloride using diphenylamine as an indicator (20), was found to be 90–99%.



2-Propanol was obtained commercially from Aldrich. 1,1,1-Trifluoro-2-propanol, 1,1,1,3,3,3-hexfluoro-2-propanol, 1-phenyl-2,2,2-trifluoroethanol, and 1-(4-methylphenyl)-2,2,2-trifluoroethanol were prepared by reduction of the corresponding ketones with lithium aluminum hydride and purified by use of gas–liquid chromatography (glc). The physical and spectroscopic properties of the products agreed with those reported in the literature (21–24).

1-(3-Bromophenyl)-2,2,2-trifluoroethanol was also prepared by the reduction of *m*-bromotrifluoroacetophenone with lithium aluminum hydride and purified by glc (10% polypropylene glycol on Chromasorb W, 45–60 mesh, 200°C) to give a liquid product (n_D^{29} = 1.5028; lit. (21) n_D^{27} = 1.5005) that crystallized on standing to give a white solid, mp 27–29°C. The yield obtained in this reaction was 89%.

1-(3-Nitrophenyl)-2,2,2-trifluoroethanol was prepared by the reduction of *m*-nitrotrifluoroacetophenone by potassium borohydride in methanol. A solution of the ketone (10 g, 0.045 mol) was added dropwise to a well-stirred solution of potassium borohydride (2.7 g, 0.05 mol) in 100 mL of methanol. The solution was stirred for 2 h at room temperature, acidified with HCl, and extracted with ether (3 × 50 mL). The ether extract was dried, flash evaporated, and the resulting brown oil distilled (104–106°C/2 Torr; 1 Torr = 133.3 Pa). The distillate slowly crystallized, giving pale yellow crystals, mp 45–52°C. Recrystallization from benzene and petroleum ether gave pale yellow crystals with mp 48–51°C (lit. (21) mp 47–48°C). 1-(3-Nitrophenyl)-2,2,2-trifluoroethanol-1-*d* was prepared by the reduction of *m*-nitrotrifluoroacetophenone with sodium borodeuteride using the procedure just described for preparation of the unlabelled compound, mp 48–51°C (lit. (22) mp 51.5–52.5°C).

2-Propanol-2-*d* and 1-phenyl-2,2,2-trifluoroethanol-1-*d* were prepared by reduction of the corresponding ketones with lithium aluminum deuteride and purified by fractional distillation and gas–liquid chromatography, respectively (22, 23).

Fig. 1. Plot of log k_{cor} vs. log[2-propanol] for defining the order of the reaction with respect to 2-propanol. [KOH] = 8.0 M. Temp. = 25.1°C. Slope = 1.00 ± 0.04; r = 0.997.

Kinetic methods

The rate of reduction of ferrate was determined by monitoring the decrease in absorbance at 508 nm using either a Cary model 14 or a Hewlett–Packard 8450A spectrophotometer equipped with a thermostated cell compartment. Thermostated solutions of ferrate and alcohol (of known concentrations) were mixed in either 5.0 or 10.0 cm quartz cells and placed in the spectrophotometer. When the concentration of alcohol was much higher than the concentration of ferrate, plots of ln(absorbance − final absorbance) vs. time were linear over 2–4 half-lives, indicating that the reaction is first order in oxidant. Because ferrate is also slowly reduced in the absence of organic reductants, it was necessary to correct the pseudo-first-order rate constants obtained for alcohol oxidation by subtracting the first-order-rate constants for the reaction that occurs in the absence of alcohol.

The corrected pseudo-first-order rate constants were found to be directly dependent on the concentration of alcohol (Fig. 1), indicating that the reaction is also first order with respect to the reductant. Second-order rate constants obtained from division of the pseudo-first-order rate constants by alcohol con-

[b]Isolated as 1,5-di(2-hydroxyphenyl)-1,4-pentadien-3-one, the product obtained from the condensation of acetone with salicylaldehyde (26).
[c]Yield, based on a 1:1 stoichiometry.

centration were then determined for several alcohols under a variety of conditions and temperatures.

For kinetic experiments in 0.5 M KOH, potassium fluoride (3.5 M) was added to prevent precipitation of iron(III) hydroxide, which interferes with spectrophotometric measurements.

Product isolation and identification

Acetone was identified as the product obtained from the oxidation of 2-propanol as its 2,4-dinitrophenylhydrazone derivative, mp 124–125°C (lit. (25) mp 126°C). Also, as indicated by the data in Table 1, when acetone was isolated after condensation with salicylaldehyde (26), one mole of acetone was produced for each mole of ferrate reduced. It has previously been observed that this reaction is accompanied by the formation of one equivalent of dioxygen (0.25 mol) as in eq. [1] (27).

[1] $$FeO_4^{2-} + CH_3CHOHCH_3 + 1.5H_2O \longrightarrow Fe(OH)_3 + CH_3COCH_3 + 0.25O_2 + 2OH^-$$

m-Nitrotrifluoroacetophenone was quantitatively isolated and identified from the reaction of 1-(3-nitrophenyl)-2,2,2-trifluoroethanol (82.1 mg, 0.372 mmol) with K_2FeO_4 (53.6 mg, 0.232 mmol) in 25 mL of 0.5 M KOH for 1 h at room temperature. The basic solution was acidified, extracted with ether (3 × 50 mL), dried over anhydrous magnesium sulfate, and chromatographed on a 3 in. × 3/8 in. column of Woeln activity V alumina using ether as the eluent. Evaporation of the ether left *m*-nitrotrifluoroacetophenone (54.7 mg, 0.25 mmol). The yield is therefore quantitative, assuming a 1:1 stoichiometry. The yields of the corresponding ketones obtained from the oxidation of 1-phenyl-2,2,2-trifluoroethanol, 1-(3-bromophenyl)-2,2,2-trifluoroethanol, and 1-(4-methylphenyl)-2,2,2-trifluoroethanol were determined by gas chromatography of the product mixtures to be 87%, 96%, and 95%, respectively.

Although the ratio of ferrate reduced to ketone produced when 1-phenyl-2,2,2-trifluoroethanols are oxidized is clearly 1:1, as described above, the amount of dioxygen produced was not quantified. However, it was noted that dioxygen evolution usually continued for a short time after all of the ferrate had been reduced (as evidenced by the fading of the characteristic purple color of FeO_4^{2-}). This suggests that dioxygen formation is due to the reaction of iron(IV) with water as in the following sequence:

[2] $$Fe(VI) + RCHOHR' \longrightarrow Fe(IV) + RCOR'$$

[3] $$Fe(IV) + H_2O \longrightarrow Fe(III) + 0.25O_2$$

The latter reaction (eq. [3]) has been observed to occur when iron(IV) pyrophosphate is dissolved in water at pH 10 (28, 29) and when Ba_2FeO_4 or Sr_2FeO_4 is treated with aqueous mineral acid (30).

The presence of ferric hydroxide in the product was indicated by the formation of a blood-red complex with thiocyanate ion (31). Carr et al. (12) have shown that the presence of small amounts of iron(II) in these products can be detected by complexing it with 1,10-phenanthroline and measuring the absorbance at 510 nm (ε = 10 880 M^{-1} cm^{-1}). Using this approach it was found that the product obtained contained 15–18% iron(II). However, in a separate experiment, iron(III) was found to be slowly reduced to iron(II) by alcohols under these conditions, suggesting that a slow reduction of iron(III) is responsible for the presence of iron(II) in the product.

The products obtained from the oxidation of cyclobutanol can be used to distinguish between one- and two-electron transfer oxidants (32); the use of two-electron transfer oxidants results in the formation of cyclobutanone while one-electron oxidants produce only acylic products (33–37). Therefore, to determine if ferrate was a two-electron oxidant, the products obtained from the oxidation of cyclobutanol were analyzed for the presence of cyclobutanone. When this was done, only two nonvolatile products (cyclobutanone and γ-butyrolactone) were detected, both in low yields. Attempts to improve the yields by varying the ratio of oxidant to reductant or changing the order of mixing the reactants were unsuccessful. Moreover, it was observed, in a separate experiment, that cyclobutanone and ferrate reacted very readily with the evolution of volatile products under these conditions. Cyclobutanone is therefore an intermediate rather than a final product, thus precluding the possibility of obtaining it in high yields. In a typical procedure, potassium ferrate (1.5 g, 7.6 mmol) was slowly added to cyclobutanol (0.50 g, 6.9 mmol) in 25 mL of buffer, pH = 9.3. The reaction, mildly exothermic, proceeded with the evolution of volatile products. After the addition was completed (1 h with stirring) the solution was acidified with concentrated HCl and extracted with ether. After drying over anhydrous magnesium sulfate, the ether extract was analyzed by gc–ms. The compounds present were cyclobutanol (94%), *m/z* (%): 72 (M^+, 0.3), 39(9), 27(17), 44(100); cyclobutanone (1.2%), *m/z* (%): 70 (M^+, 17), 27(19), 43(100); γ-butyrolactone (4.5%), *m/z* (%): 86 (M^+, 24), 56(22), 28(88), 42(100). The gc retention times for cyclobutanol and cyclobutanone were identical to those for authentic samples.

Results and discussion

When tetraoxoferrate(VI) is reduced by excess alcohol, good pseudo-first-order kinetics, as defined by eq. [4], are obtained (where k_{cor} is the observed first-order rate constant, k_{obs}, corrected for the slow reduction of ferrate in the absence of alcohol).

[4] $$-d[FeO_4^{2-}]/dt = k_{cor}[FeO_4^{2-}]$$

The observation that the values of k_{cor} are directly proportional to the concentration of alcohol indicates that the reaction is also first order in alcohol, as in eq. [5] where $k_2 = k_{cor}/[Alcohol]$.

[5] $$-d[FeO_4^{2-}]/dt = k_2[FeO_4^{2-}][Alcohol]$$

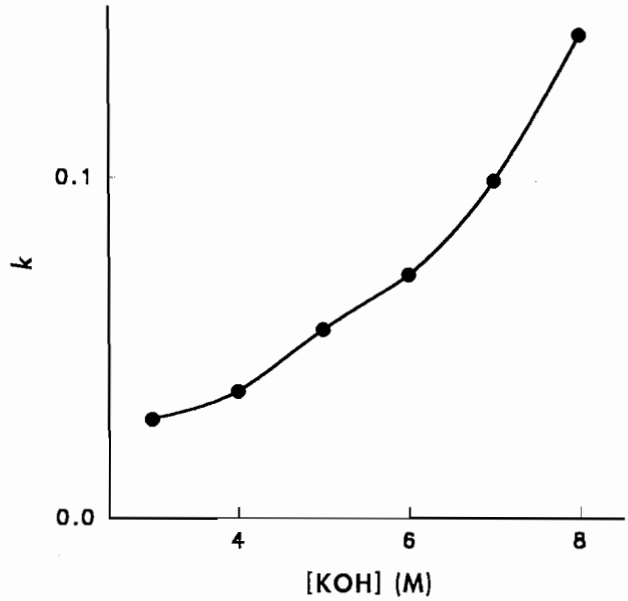
The second-order rate constants obtained in this way are dependent upon the pH of the solution, the temperature of the solution, the structure of the reductant, and isotopic substitutions. From a consideration of the way in which the magnitude of the rate constants change with each of these variables, it is possible to limit mechanistic options and to arrive at a "most probable" mechanism for these reactions. To begin with, however, it is necessary to consider the evidence available concerning the structure of ferrate ion in alkaline solutions.

Structure of the oxidant

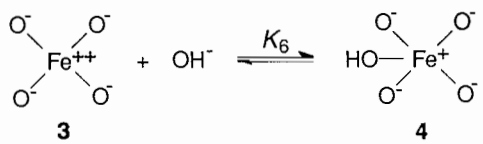
X-ray powder pattern studies have indicated that the ferrate ion is tetrahedral when present in solid K_2FeO_4 crystals (38). In aqueous solutions, the infrared spectrum of ferrate is also consistent with a tetrahedral geometry (39) and isotopic oxygen exchange studies have indicated that all oxygens are kinetically equivalent (40). From the knowledge that metal oxos are strongly polarized ($L_nM = O \leftrightarrow L_nM^+—O^-$) (41, 42), it can be concluded that the ferrate ion is best visualized as a positively charged iron cation surrounded by four equivalent oxygens, each bearing a partial negative charge; i.e., a resonance hybrid of three canonical structures, **1**–**3**.

1 **2** **3**

In a theoretical study, Ziegler, Rauk, and Baerends (43) concluded, using the Hartree–Fock–Slater Discrete Variational Method to investigate electronic structures, that tetrahedral oxyanions of transition metals would have *d*-orbital populations close to those of the corresponding M^{2+} ions; i.e., that **3** would be the most important canonical structure. An independent study using symmetry adapted cluster (SAC) and SAC – configuration interaction (SAC–CI) theories, reported by Jitsuhiro, Nakai, Hada, and Nakatsuji (44), predicted that the charge on the central metal of comparable compounds ranges from 1.04 to 1.44, suggesting that both **2** and **3** strongly contribute to the structure of ferrate.

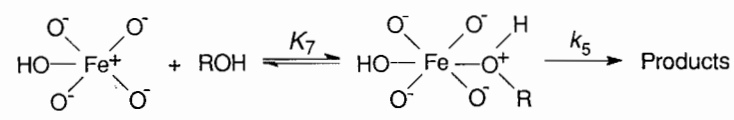


Base catalysis



It is apparent that the rate of reduction of ferrate by 2-propanol (Table 2) is subject to base catalysis; the observed second-order rate constants increase from 0.03 M^{-1} s^{-1} in 3.0 M KOH to 0.14 M^{-1} s^{-1} in 8.0 M KOH. By comparison with studies on the reduction of ferrate by water in alkaline solutions (14), it seems likely that this rate acceleration is associated with the formation of a reactive pentacoordinated iron(VI) oxyanion, **4**, as in eq. [6]. Reaction of **4** with a reductant such as 2-propanol would then give an octahedral intermediate, **5**, that could convert to products as described below. A five-coordinated species such as **4** would be expected to react readily with nucleophilic reductants to give an octahedral product, **5**, as in eq. [7].

A compound similar to **4**, formed by the reaction of hydroxide ions with $HFeO_4^-$, has been suggested as a possible intermediate in the exchange of isotopic oxygen between ferrate and water (40).



The rate law for a sequence consisting of reaction [6] followed by reaction [7] would be first order in hydroxide ion concentration (eq. [8]) and the second-order rate constants should be directly dependent on $[OH^-]$ (eqs. [9] and [10]). However, a plot of k_2 vs. $[OH^-]$ is not linear (Fig. 2) and a plot of log k_2 vs. log $[OH^-]$ has a slope much greater than unity in strongly basic solutions. This steep increase in rate at high basicities is likely due to ionization of 2-propanol ($pK_a = 17.1$ (45)) in these solutions; alkoxide ions, formed as in eq. [11], are known to be more rapidly oxidized by other comparable oxidants such as permanganate (46*a*, 47).

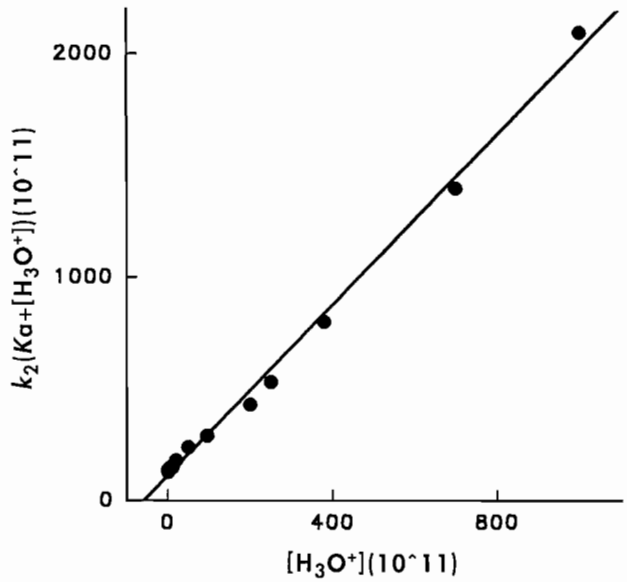
9.70	3.49 ± 0.04	3.43 ± 0.04	11.4 ± 0.1
9.95	2.82 ± 0.09	2.76 ± 0.09	9.20 ± 0.30
10.14	2.94 ± 0.05	2.87 ± 0.06	9.57 ± 0.20
10.69	3.01 ± 0.05	2.58 ± 0.07	8.60 ± 0.23

[a] k_{obs} is the observed pseudo-first-order rate constant obtained from the slope of a plot of $\ln(A - A_t)$ vs. time.

[b] k_{cor} is the observed pseudo-first-order rate constant minus the first-order rate constant for the reduction of ferrate in the absence of alcohol.

[c] $k_2 = k_{cor}/[1,1,1,3,3,3\text{-hexafluoro-2-propanol}] = k_{cor}/0.0030$ M.

Substitution of eq. [14] into eq. [12] gives eq. [15], from which an expression for the observed second-order rate constants can be derived (eq. [16]). The fact that plots of $k_2/[OH^-]$ vs. $1/h_-$ are linear (Fig. 3), as predicted from eq. [17], indicates that this reaction sequence is in quantitative agreement with the available data.



[15] $\text{Rate} = K_6(k_5K_7 + k_6K_{13}K_a/h_-)[FeO_4^{2-}][ROH][OH^-]$

[16] $k_2 = (k_5K_6K_7 + k_6K_6K_{13}K_a/h_-)[OH^-]$

[17] $k_2/[OH^-] = k_5K_6K_7 + k_6K_6K_{13}K_a/h_-$

Although it is not possible to obtain absolute values for the rate constants for the reduction of ferrate by 2-propanol and isopropoxide ion, relative values can be obtained from the ratio of the slope of the plot in Fig. 3 to its intercept; slope/intercept = $k_6K_{13}K_a/k_5K_7$. Since the value for K_a is known (7.84×10^{-18} (45)), the magnitude of k_6K_{13}/k_5K_7, which is the relative rate for the oxidation of isopropoxide ion compared to 2-propanol, can be calculated to be 5.3. Hence, it appears that the alkoxide is, as expected, oxidized more rapidly than the corresponding alcohol. It is not clear, however, if this acceleration is associated with the equilibrium constant for reaction [13] as compared to reaction [7] or if it is due to the rates at which **6** and **5**, respectively, are converted into products.

Fig. 4. Dependence of k_2 for the oxidation of 1,1,1,3,3,3-hexafluoro-2-propanol on $[H_3O^+]$. Slope = $(7.22 \pm 0.17) \times 10^{-4}$ M^{-2} s^{-1}. Intercept = $(9.94 \pm 0.68) \times 10^{-2}$ M^{-1} s^{-1}.

Acid catalysis

When the pH is less than 9, the reaction is subject to acid catalysis as indicated by the data in Table 3 for the oxidation of 1,1,1,3,3,3-hexafluoro-2-propanol. Since this alcohol is a very weak base, it can be assumed that the observed acceleration is not due to protonation of the reductant. Instead, it must be associated with formation of the hydrogen ferrate ion (pK_a = 7.8 (49)) as in eq. [18].

[18] $HFeO_4^- + H_2O \rightleftharpoons FeO_4^{2-} + H_3O^+$

The kinetics under these conditions could, therefore, be expressed as in eqs. [19]–[21], where $[Fe(IV)]_T$ indicates the total iron(VI) concentration.

[19] $\text{Rate} = (k_{11}[FeO_4^{2-}] + k_{12}[HFeO_4^-])[ROH]$

$= k_2[Fe(VI)]_T[ROH]$

[20] $k_2 = (k_{11}K_a + k_{12}[H_3O^+])/(K_a + [H_3O^+])$

[21] $k_2(K_a + [H_3O^+]) = k_{11}K_a + k_{12}[H_3O^+]$

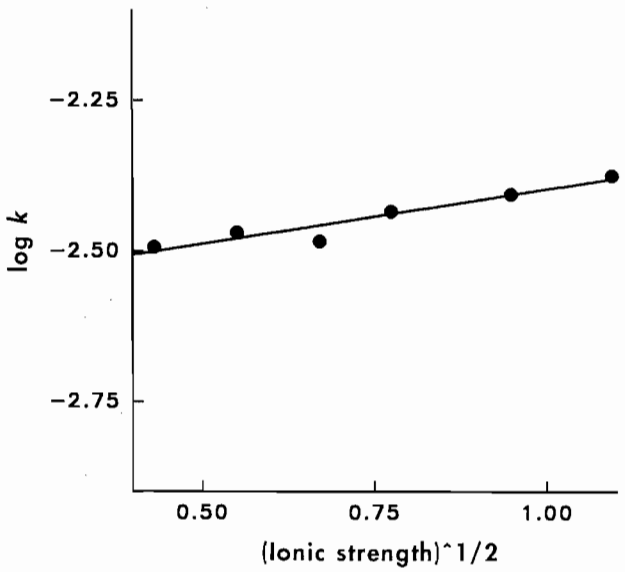
1-Phenyl-2,2,2-trifluoroethanol	0.5 M KOH,[a] 25.1°C	7.65 ± 0.45	1.45 ± 0.11	5.3 ± 0.7
1-(3-Nitrophenyl)-2,2,2-trifluoroethanol	0.5 M KOH,[a] 25.1°C	23.6 ± 0.4	3.74 ± 0.70	6.3 ± 1.5

[a]3.5 M KF.

Fig. 5. Effect of ionic strength on the rate constants for the oxidation of 1,1,1,3,3,3-hexafluoro-2-propanol by tetraoxoferrate(VI) at pH 9.33. Temp. = 25.0°C. Slope = 0.18 ± 0.03; r = 0.95.



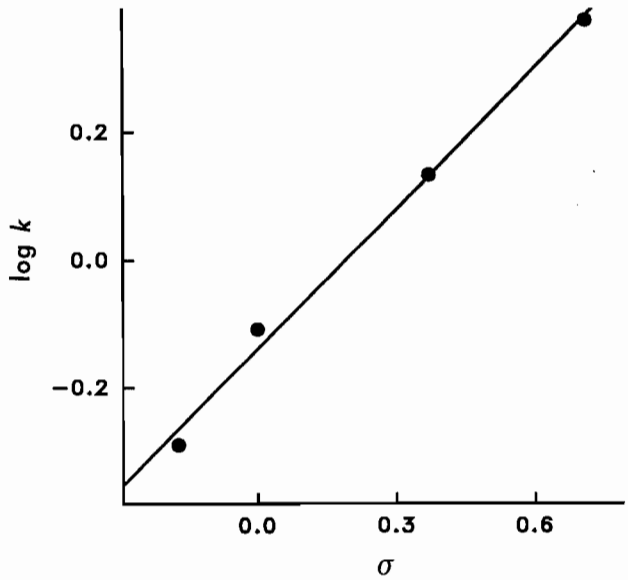


Fig. 6. Hammett plot for the oxidation of 1-aryl-2,2,2-trifluoroethanols by tetraoxoferrate(VI) in 0.50 M KOH containing 3.5 M KF. Temp. = 25.1°C. Slope = 0.73 ± 0.04; r = 0.997.

Values for k_{11} and k_{12} obtained from nonlinear curve fitting of eq. [20] are k_{11} = 0.0764 ± 0.0076 M^{-1} s^{-1} and k_{12} = 1.87 ± 0.04 M^{-1} s^{-1} (r^2 = 0.993).[2] Equation [20] can also be rearranged into a linear form as indicated in eq. [21]. From the corresponding plot, presented in Fig. 4, the values obtained for k_{11} and k_{12} are k_{11} = 0.0708 ± 0.0071 M^{-1} s^{-1} and 1.91 ± 0.04 M^{-1} s^{-1} (r^2 = 0.995). The ratio, k_{12}/k_{11}, indicates that hydrogen ferrate ($HFeO_4^-$) reacts with 1,1,1-trifluoro-2-propanol about 25 times faster than ferrate (FeO_4^{2-}) under comparable conditions. This observation is consistent with Stewart's conclusion that acid catalysis in similar reactions is also due to protonation of the oxidant (46). For example, the rates of permanganate (50), chromate (51), manganate (52), and ruthenate (53) oxidations all increase as the acidity of the medium is increased.

[2] Nonlinear plots were studied using the computer program, *Table Curve*, Jandel Corporation, 1986–1995.

Ionic strength

When the ionic strength of the medium was increased by increasing buffer concentrations, little or no effect on the reaction rate could be detected as indicated by the plot in Fig. 5. The polarities of the ground and transition states for this reaction must, therefore, be similar.

In highly basic solutions, where buffering is not possible, the addition of KF to prevent the precipitation of iron(III) hydroxide did cause an increase in rate as indicated by the last three entries in Table 2; however, such increases are most likely associated with an increase in basicity of the medium. Addition of KF would salt out the hydroxide ion, causing the basicity of the solution to increase.

Substituent effects

The oxidations of 1-phenyl-2,2,2-trifluoroethanol and its ring-substituted derivatives were carried out in 0.50 M KOH containing a high concentration of KF (3.5 M) to prevent precipitation of iron(III) hydroxide. As noted above, the effect of

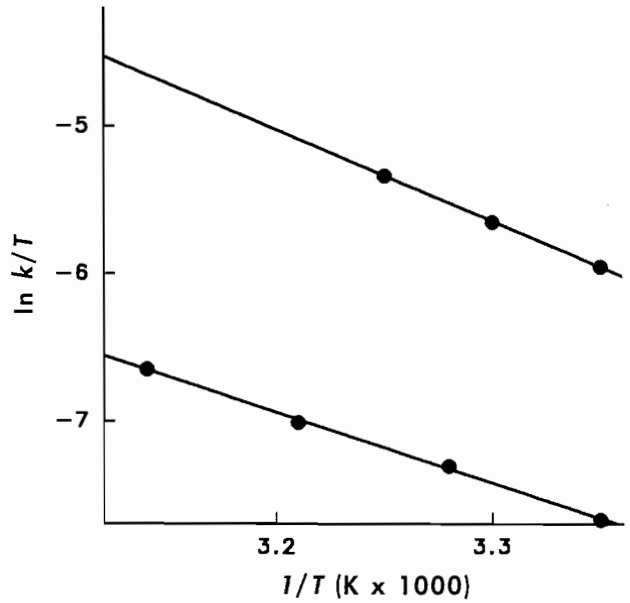
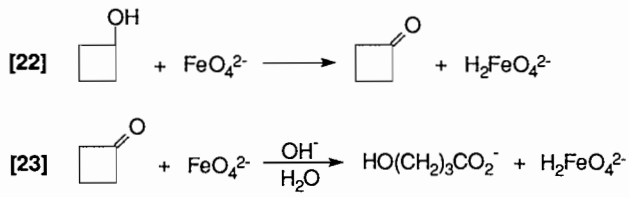
For personal use only.

this added salt will be to increase the basicity of these solutions beyond that of 0.5 M KOH (h_- = 13.7 (48)). Considering that 1-phenyl-2,2,2-trifluoroethanol has a pK_a of 11.90 (21), it would be at least 98.4% ionized under the conditions in which the data in Table 4 were collected. Similarly, the 4-methyl, 3-bromo, and 3-nitro derivatives, which have pK_a's of 12.04, 11.50, and 11.23 (21), would be ionized to at least 98.0%, 99.4%, and 99.7%, respectively, under these conditions. Consequently, it is possible to be confident that the Hammett ρ value does not contain a significant contribution from ionization equilibria occurring prior to oxidation; it is a consequence only of the change in electron density that occurs at the α-carbon as the oxidation reaction proceeds from the ground state to the transition state. Since the ρ value is positive (ρ = 0.73, Fig. 6) it is apparent that the electron density on the carbon adjacent to the aromatic ring must be greater in the transition state.

Isotope effect



Primary kinetic isotope effects were observed when the hydrogen adjacent to the hydroxyl group was replaced by deuterium. As the data in Table 4 indicate, the magnitude of the effect is much greater for 2-propanol than for 1-phenyl-2,2,2-trifluoroethanol or 1-(3-nitrophenyl)-2,2,2-trifluoroethanol, suggesting that C—H cleavage is more symmetrical for 2-propanol. According to the theory initially elaborated by Westheimer (54), the magnitude of an isotope effect is dependent on the symmetry of the transition state, with the largest effects being observed when bond cleavage and bond formation are approximately balanced. Since the Hammett ρ value is positive, the hydrogen must be transferred as a proton to an available base. The 1-aryl-2,2,2-trifluoroethanols would be more capable of accommodating proton loss from the α-carbon, suggesting that the smaller isotope effect occurs because proton transfer is more advanced in the transition state. The larger isotope effect observed for the oxidation of 2-propanol indicates a more symmetrical transition state with respect to proton transfer and the possible involvement of tunneling (55).



The oxidation of cyclobutanol

The products obtained from the oxidation of cyclobutanol were examined in an attempt to determine if ferrate(VI) is a one- or two-electron oxidant. Empirical evidence indicates that two-electron oxidants convert cyclobutanol into cyclobutanone; however, if free radicals are formed (by a one-electron transfer oxidant), the resulting cyclobutyl free radical undergoes rapid ring opening resulting in the formation of acyclic products (32–37). A previous report indicated that only traces of cyclobutanone along with a number of acyclic products are obtained from the oxidation of cyclobutanol by ferrate(VI) (19). A reexamination of this reaction has, however, led to the observation that cyclobutanone is also rapidly oxidized by ferrate(VI) under these conditions to yield only volatile products. Attempts to obtain a better yield of cyclobutanone from the oxidation of cyclobutanol by varying the relative amounts of oxidant and reductant, the temperature, and the order of mixing all resulted in the formation of primarily volatile products, along with small amounts of cyclobutanone (~1%) and γ-butyrolactone (~5%).

Although these results are not conclusive, a most likely scenario is that cyclobutanone and 4-hydroxybutanoate are formed in successive two-electron oxidations as in eqs. [22] and [23]. Acidification of the solution forms 4-hydroxybutanoic acid, which is isolated as its lactone as in eq. [24]. The volatile products would come from the oxidation of water to dioxygen by iron(IV), as previously described (28–30), and from the oxidative degradation of 4-hydroxybutanoate.

Fig. 7. Eyring plots for the oxidation of 1-phenyl-2,2,2-trifluoroethanol (top) and 2-propanol (bottom). For the top plot, slope = −6180 ± 80 K, intercept = 14.8 ± 0.3, r = 0.999. For the bottom plot, slope = −4810 ± 134 K, intercept = 8.45 ± 0.44; r = 0.999.

[24] $HO(CH_2)_3CO_2^- \longrightarrow HO(CH_2)_3CO_2H \longrightarrow O(CH_2)_3CO$

These results, therefore, appear to be most consistent with the suggestion that ferrate(VI) is a two-electron oxidant. However, because of the highly equivocal nature of this data, one-electron mechanisms must also remain under active consideration.

Temperature effects

Rate constants obtained for a range of temperatures were used to prepare Eyring plots (Fig. 7) from which activation parameters can be calculated (56). The results obtained from these studies, Table 5, indicate that the reaction of alcohols with ferrate(VI) is marked by relatively high activation enthalpies and large unfavorable activation entropies. The very unfavorable entropies of activation indicate that the transition state is more highly organized than the ground state.

Reaction mechanism

The oxidation of alkoxide ions most likely occurs in two steps,

Scheme 1. A possible mechanism for the oxidation of 1-aryl-2,22-trifluoroethanols by tetraoxoferrate(VI) under basic conditions.

an addition in which $HFeO_5^{3-}$, **4**, combines with an alkoxide ion to form an ester, **6**, followed by a reductive elimination resulting in the reduction of ferrate and the oxidation of the alkoxide ion. From the isotope and substituent effects it appears as if the reductive elimination must be accompanied by heterolytic cleavage of the α-C—H bond. This could be achieved by either a transfer of a proton to an external base (such as hydroxide ion) or an internal cyclic transfer to an oxygen attached to iron. The latter appears to be more likely because involvement of additional base in the rate-limiting step would not be consistent with the observed dependence of the rate on the basicity of the solution that was discussed above. A cyclic mechanism is also more consistent with the highly unfavorable entropies of activation observed in the temperature studies. Heterolytic cleavage of the Fe—O bond must occur in rapid succession of, or concurrently with, proton transfer as outlined in Scheme 1.

The third step in Scheme 1, which involves cleavage of the α-C—H bond, would be rate limiting as required by the observed isotope effect. The positive Hammett ρ value indicates an electron-rich transition state, suggesting that the rate-limiting step is initiated by proton transfer as indicated. The relatively low value of ρ (0.73) means, however, that there is only a small increase in the electron density at α-carbon in the transition state and is more consistent with a concerted mechanism in which electron transfer occurs concurrently with proton transfer. The insensitivity of the reaction rate to changes in the ionic strength is also consistent with a concerted mechanism.

The reaction depicted in Scheme 1 involves the transfer of a proton and two electrons to the oxidant; i.e., the overall result is hydride transfer. Therefore, another mechanism that could be considered would be direct hydride transfer as in eq. [25]. In such a reaction, however, the electron density at the α-carbon is decreasing and a negative ρ value would be expected. A direct hydride transfer is, therefore, not as consistent with the experimental evidence as the synchronized proton/2-electron mechanism depicted in Scheme 1.

[25] $RR'CHO^- + HOFeO_4^{3-} \longrightarrow RR'CO + HOFeO_3^{3-} + HO^-$

In addition, because the results obtained from the oxidation of cyclobutanol do not unambiguously establish that the reaction is a two-electron oxidation, a hydrogen atom transfer mechanism must also be considered as a possibility. As indicated by eq. [26], hydrogen atom transfer would lead to formation of a radical anion that could undergo a subsequent single electron transfer (eq. [27]).

[26] $RR'CHO^- + HOFeO_4^{3-} \longrightarrow RR'\dot{C}O^- + (HO)_2FeO_3^{3-}$

[27] $RR'\dot{C}O^- + (HO)_2FeO_3^{3-} \longrightarrow RR'CO + HOFeO_3^{3-} + HO^-$

© 1997 NRC Canada

Such a hydrogen atom transfer mechanism has been established for the oxidation of these same aryl-2,2,2-trifluoroethanols by permanganate under basic conditions (46*b*, 47). In that reaction, however, the Hammett ρ value is approximately zero, as might be expected for a process that does not cause much change in the electron density of the α-carbon (24). Hence, a direct hydrogen atom transfer, in common with a direct hydride ion transfer, is not as consistent with the experimental evidence as the mechanism depicted in Scheme 1.

Conclusions

It has been found that the oxidation of alcohols by ferrate(VI) is subject to both acid and base catalysis. The increased rate in acidic solutions has been proposed to be due to the formation of the acid ferrate ion, $HFeO_4^-$, a more reactive oxidant than FeO_4^{2-}. Rate acceleration under basic conditions has been attributed partly to formation of alkoxide ions, which are more reactive reductants than neutral alcohols, and partly to formation of $HOFeO_4^{3-}$, which, it has been proposed, is more susceptible to nucleophilic attack by alcohols and alkoxide ions.

The possible reactions can therefore be summarized as in eqs. [28]–[30].

$$[28]\quad HOFeO_4^{3-} + RO^- \xrightarrow{k_b} \text{products}$$

$$[29]\quad FeO_4^{2-} + ROH \xrightarrow{k_n} \text{products}$$

$$[30]\quad HFeO_4^- + ROH \xrightarrow{k_a} \text{products}$$

Kinetic studies on the oxidation of 2-propanol suggest that the ratio, k_b/k_n, is about 5, while similar studies on the oxidation of 1,1,1-trifluoro-2-propanol indicate that the ratio, k_a/k_n, is about 25. The results obtained from isotope and substituent effects, along with temperature and ionic strength studies, are most consistent with a mechanism that involves formation of an intermediate ferrate ester, **7**, as in Scheme 1.

Abstract: *N,N'*-[Dimethyl-(2,2'-dithiobisacetyl)]ethylenediamine (**1**) has been synthesized in 30% overall yield from *N,N'*-dimethylethylenediamine and thioacetic acid by an improved procedure involving simultaneous deprotection and oxidative cyclization with iodine. This cyclic diamide disulfide exists in solution as a mixture of two *Z,Z* and one *Z,E* disulfide, and amide ring conformers and has been characterized by nuclear Overhauser effect (NOE), ^1H–^1H, ^1H–^{13}C shift-correlated 2D-NMR and molecular modelling studies. Among the *Z,Z* ring conformers Z,Z_1 and Z,Z_2, the former predominates and interconverts with the latter isomer by rotation about the S—S bond with an activation energy of 14.5 ± 1.3 kcal/mol. Coalescence of N-CH_3 signals occurred at ca. 127°C (500 MHz), which corresponded to an approximate barrier to amide rotation of 19.3 kcal/mol. Aromatic solvent-induced shifts in C_6D_6 corroborated molecular mechanics and NOE predictions of amide stereochemistry. The structure of the *Z,E* stereoisomer of **1** has been determined by single-crystal X-ray diffraction at 296 K. A large geminal N-CH_2 inequivalence (>2 ppm in $CDCl_3$) was observed for the *Z,Z* conformers. Proton chemical shifts have been calculated for the conformers of **1** and related molecular fragments with DFT/GIAO theory. Absolute chemical shifts are modelled within 0.2 ppm of experiment. The unusual nonequivalence of geminal N-CH_2 and S-CH_2 protons can be understood as a combination of shielding mechanisms derived from short N-methyl contacts, amide group orientation, and sulfur lone-pair disposition. An implication of these results is the possibility of using α-C*H* (and eventually α-*C*H) shifts to probe the local conformational space in cyclic peptides and other conformationally constrained rings.

Key words: amide/disulfide rotamers, conformational analysis, density functional theory, DFT/GIAO NMR shift calculations, methylene nonequivalence, molecular modelling.

Résumé : On a synthétisé la *N,N'*-[diméthyl-(2,2'-dithiobisacetyl)]éthylènediamine (**1**), avec un rendement global de 30% à partir de la *N,N'*-diméthyléthylènediamine et de l'acide thioacétique, à l'aide d'une méthode améliorée impliquant une déprotection et une cyclisation oxydante simultanées sous l'influence de l'iode. En solution, ce disulfure diamide cyclique existe sous la forme d'un mélange de deux disulfures *Z,Z* et d'un *Z,E*, en plus des conformères du cycle amide; on l'a caractérisé par effet Overhauser nucléaire (eOn), par des études de RMN 2D avec corrélation de déplacements ^1H–^1H et ^1H–^{13}C et des études de modélisation moléculaire. Parmi les conformères *Z,Z* du cycle, Z,Z_1 et Z,Z_2, le premier est prédominant et les deux subissent une interconversion par le biais d'une rotation autour de la liaison S—S avec une énergie d'activation de 14,5 ± 1,3 kcal/mol. La coalescence des signaux se produit aux environs de 127°C (500 MHz); ceci correspond à une barrière de la rotation de l'amide d'environ 19,3 kcal/mol. Les déplacements induits par un solvant aromatique, C_6D_6, ont permis de confirmer les conclusions de la mécanique moléculaire et les prédictions basées sur l'eOn pour la stéréochimie de l'amide. On a déterminé la structure du stéréoisomère *Z,E* de **1** par diffraction des rayons X par un cristal unique, à 296 K. Avec les conformères *Z,Z*, on a observé une importante inéquivalence géminale pour le N-CH_2 (>2 ppm, dans $CDCl_3$). En se basant sur la théorie de la densité fonctionnelle («DGT/GIAO»), on a calculé les déplacements chimiques des protons des conformères du composé **1** et de fragments moléculaires apparentés. On peut faire la modélisation des déplacements chimiques absolus à 0,2 ppm près des valeurs observées expérimentalement. On peut expliquer la non équivalence exceptionnelle des protons géminés des N-CH_2 et S-CH_2 en se faisant appel à une combinaison de mécanismes de blindage dérivés des contacts à courte distance des N-méthyles, de l'orientation du groupe amide et de l'arrangement de la paire d'électrons non partagée du soufre. Ces résultats impliquent qu'il est possible

Introduction

Structures similar to *N,N'*-ethylenebis(2-thioacetamide) are frequent precursors to complexing reagents for technetium and have been used extensively in Tc-based radioimaging work both at research and clinical levels (1–5). In addition to forming very stable Tc complexes (5), these diamide disulfur (DADS) ligands are highly amendable to modification using standard synthetic techniques and commercial reagents and, as such, represent an attractive ligand system to systematically evaluate structure–activity requirements for the development of tissue-specific technetium chelates. To illustrate, N-C_α carboxylated analogues of DADS ligands are currently being investigated in the targeted delivery of radioactivity in bifunctional chelate strategies (5, 6). However, as examples of ^{99m}Tc radiopharmaceuticals employed for imaging the nonexcretory organs are few, further research in this area is highly desirable. This limited success of existing ^{99m}Tc complexes has been ascribed in part to a lack of sufficient lipid solubility required for adequate membrane transport through capillaries and other lipid barriers (7–9).

In a program to develop cyclic diamide disulfides into lipophilic, bifunctional DADS chelators for ^{99m}Tc radioimaging, we noted the complexity of NMR spectra in a number of nonsymmetric derivatives and the dearth of literature on the conformational properties and a reliable synthetic approach to such compounds. Hence, the preparation of the symmetric diamide disulfide **1** was undertaken as both a conformational and synthetic model and we present herein its synthesis, NMR properties, and solid state and solution state structures. An investigation into the conformational properties of such simple ring systems also allows for a better understanding of peptide conformation and an improved approach towards the rational design of conformationally constrained peptides that possess important biological activities (10).

1

Results and discussion

Synthesis

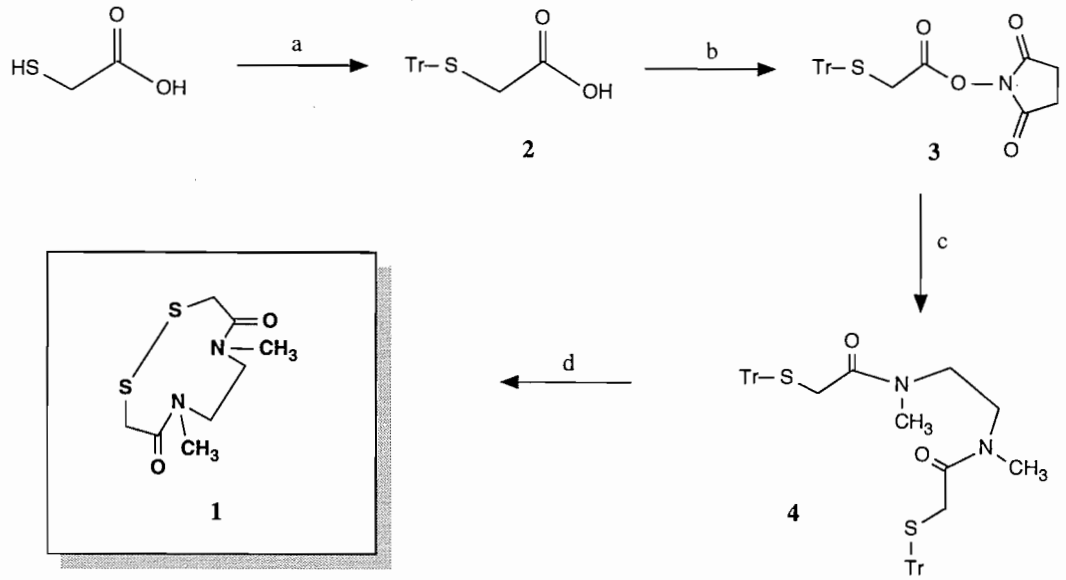
The 10-membered heterocycle **1** was synthesized from 2-mercaptoacetic acid and *N,N'*-dimethylethylenediamine in four steps in 30% overall yield as shown in Scheme 1. Tritylation of thioacetic acid under Lewis acid catalysis readily afforded the *S*-protected acid **2**, which was subsequently reacted with 1,3-dicyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide (NHS) to give the activated ester **3**. Treatment of two equivalents of **3** with *N,N'*-dimethylethylenediamine in dry dimethoxyethane allowed for the acylation of both nitrogens and the formation of the diamide **4** in 76% yield. Deprotection of **4** was effected with 1.1 equivalents of iodine in ethanol–acetonitrile and, by maintaining high dilution conditions to preclude intermolecular disulfide formation, in situ intramolecular oxidative cyclization readily generated the monomeric disulfide **1** in 66% yield.

The choice of the *S*-protecting group for thioacetic acid and the method for its cleavage were crucial for the efficiency of the synthesis. The S atom in these compounds is normally protected as aryl thioethers, hemithioacetals, or thioesters (11); however, deprotection frequently requires harsh conditions that can lead to decomposition when sensitive functional groups are present. Moreover, the sulfur products of these acidic or basic deprotection schemes can also engage in side reactions, including acid-catalyzed *N*- to *S*-acyl transfer initiated by SH attack to neighbouring amide groups[2] and disulfide polymerization via thiolate coupling (14, 15). The instability of unprotected sulfur atoms compounded with harsh deprotection methods makes this synthetic strategy less desirable for the development of radioimaging precursors.

For the development of chemically sensitive radiopharmaceuticals incorporating the DADS ligand, an exceedingly mild *S*-deprotection method was required. Iodine has been used in the removal of trityl groups from sulfur with facile, in situ oxidation to acyclic disulfides (16). Moreover, disulfides are stable, readily prepared, and easy to cleave with mild reductants (for example, $SnCl_2$) and as such represent attractive precursors to Tc chelants, particularly in the clinical setting. The synthesis was therefore undertaken with trityl as the sulfur protecting agent and iodine as the deprotectant.

Conformational analysis

(a) ^{1}H and ^{13}C NMR data



The product (**1**) ran as one spot when examined by thin-layer chromatography and melted over a 1.0°C range, indicating good sample homogeneity. Infrared, Raman, and mass spectra of the product were consistent with its proposed monomeric structure (see Experimental methods). The ^{1}H and ^{13}C NMR

[2] Decomposition of C_{11} substituted DADS fatty acid amide conjugates has been noted in our lab during *S*-detritylation using the CF_3COOH–Et_3SiH method (12). This is suspected to proceed via nucleophilic attack of the unmasked SH group to the C=O function at the C_{11} amide, resulting in a six-membered thiolactone and the corresponding 11-amino fatty acid. This mechanism is based on analogy to ref. 13.

analyses (Fig. 1 and Tables 1 and 2), however, showed dramatically complex signal profiles despite the established chemical purity of the sample and its symmetry-related, isolated sets of ^1H and ^{13}C nuclei. That this multiplicity of lines arose from the presence of different ring conformers was suggested from the ^{13}C spectrum, which showed 12 lines (Table 2) in the aliphatic region (δ 30–50) rather than the anticipated three.[3] This increased number of lines was rationalized by noting that each amide group can exist in either *Z* or *E* stereochemistry because of restricted amide rotation: this enables the cyclic disulfide to adopt, in principle, three conformations with the amide groups *Z,Z*, *Z,E*, and *E,E*.

(b) ^1H dynamic NMR studies

Variable-temperature ^1H NMR was employed to determine the presence of conformational isomers. Spectra recorded in the temperature range −61.5 to 30.0°C in $CDCl_3$ indicated that the proposed conformers were in slow exchange at room temperature and below. At higher temperatures in DMSO-d_6, interconversion rates increased, as evidenced from the gradual coalescence of all resonances (Fig. 2). However, it was not possible to observe the three signals expected in the regime of fast exchange at 500 MHz, as this would require heating the sample to an impractically high level.

To further confirm the exchange process as restricted amide rotation, the free energy of activation, $\Delta G^{\ddagger}$, was estimated using a modified form of the Eyring formulation (17):

$$[1] \quad \Delta G^{\ddagger} = RT_c[22.96 + \ln(T_c/\Delta\nu)]$$

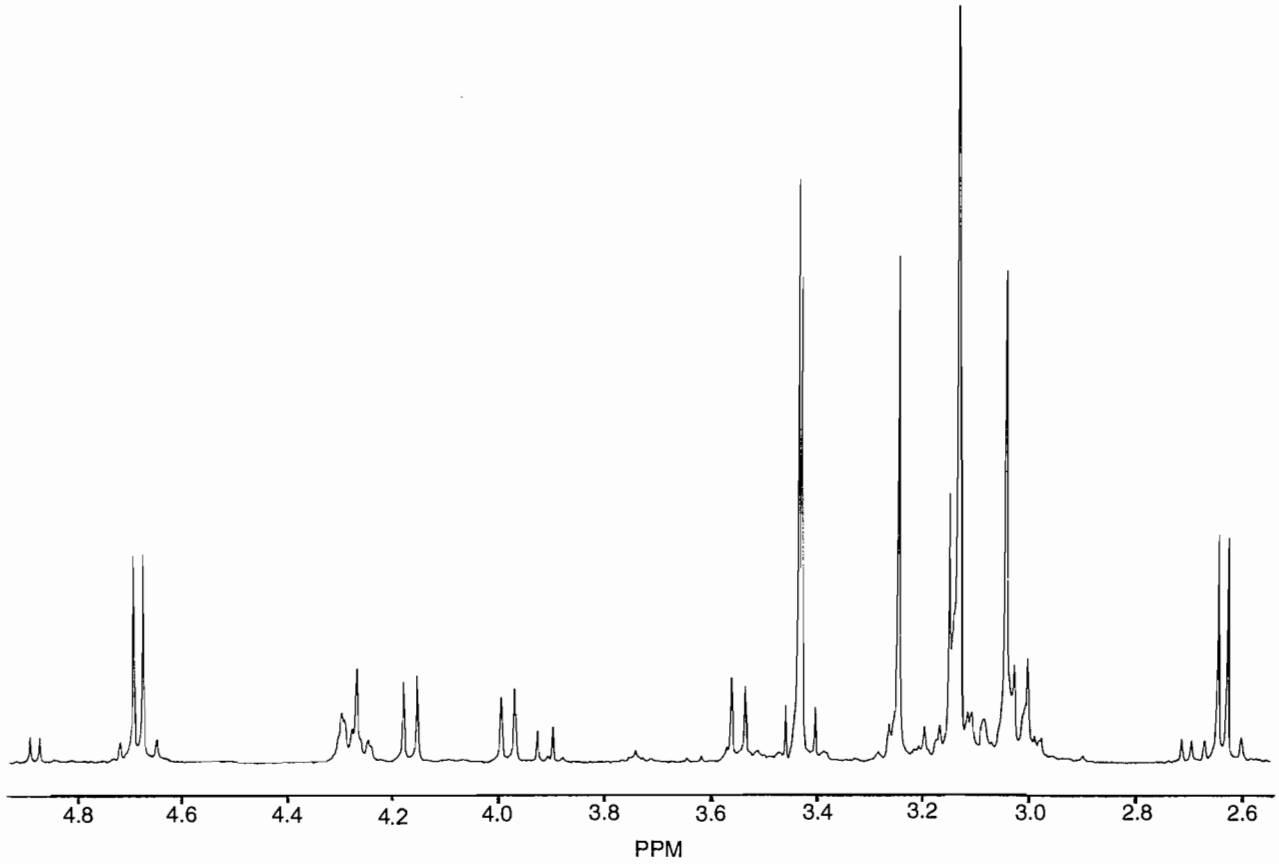
The coalescence temperature T_c was estimated from Fig. 2 to be about 127°C at 500 MHz, based on the coalescence of the singlets at 2.42 and 2.71 ppm.[4] This afforded $\Delta G^{\ddagger}_{127} \approx 19.3$ kcal/mol. The measured barrier is consistent with those typically reported for substituted *N,N'*-dimethylamides (e.g., dimethylacetamide, $\Delta G^{\ddagger}_{25.2} = 17.4$ kcal/mol; dimethylpropanamide, $\Delta G^{\ddagger}_{25.2} = 16.7$ kcal/mol) (18). Restricted rotation associated with the S—S linkage (19, 20)[5] and ring inversion presumably contributes to this composite $\Delta G^{\ddagger}$, thus magnifying it in relation to typical acyclic amide rotational barriers.

A heteronuclear ^1H–^{13}C 2D NMR shift-correlated experiment at room temperature identified the geminal pairs of diastereotopic protons for *three* geometric isomers and, with the aid of standard chemical shifts, permitted the location of their NCH_2CH_2N groupings (Fig. 3). Two of these appeared as sets of A_2B_2 (or AA'BB') spin systems in the F_1 (^1H) domain, consistent with two symmetrical isomers, and the third as a more complex ABCD spin system for an unsymmetrical isomer. The experiment also enabled the assignment of carbon signals associated with the three isomers. The ^1H–^1H connectivity patterns in each isomer were confirmed through a homonuclear 2D COSY-45 NMR experiment (data not shown).

The data from the 2D and dynamic NMR (DNMR) experiments, as well as patterns in signal multiplicity, were fully consistent with the presence of three, interconvertible, conformational isomers of **1** at room temperature. The amide configurations of these ring conformers have been assigned as Z,Z_1, *Z,E*, and Z,Z_2. The designation Z,Z_1 refers to the major *Z,Z* ring conformer while Z,Z_2 indicates the minor one. These proposed

[3] Signal averaging for lengthy periods revealed the presence of additional signals, which presumably arises from trace amounts of other ring conformers.

[4] Later ascribed to the N-CH_3 resonances of the unsymmetrical *Z,E* ring isomer.



[5] The barrier to S—S rotation in the ring conformers Z,Z_1 and Z,Z_2 is addressed later on.

geometries have been shown to be consistent with the results of other experiments, including benzene dilution ^{1}H NMR shifts, nuclear Overhauser effect (NOE) experiments, single-crystal X-ray diffraction studies, molecular modelling, and proton shielding calculations (vide infra).

Proton integrals and ^{13}C resonance intensities (Tables 1 and 2) suggested the following stability trend among the conformers: $Z,Z_1 > Z,E > Z,Z_2$. This finding can be rationalized from an analysis of the sterically driven, conformational preferences governing *N,N'*-dialkylamides: for large-membered lactams, the *Z* stereochemistry is energetically favored over *E* (21). Therefore, the *Z* configuration in **1** can be expected to be the predominant amide stereochemistry in solution. Based on the ratio of intensities of the N-CH_3 ^{13}C signals (Table 2) and, assuming a Boltzmann population distribution at 303 K, the Z,Z_1 ring conformer was favored over the *Z,E* by 0.61 kcal/mol and *Z,E* over the Z,Z_2 by 0.87 kcal/mol. Table 3 presents the corresponding percentage compositions in $CDCl_3$, as well as in DMSO-d_6 and C_6D_6 solvents. The results suggest that the isomeric composition of **1** appeared to be relatively independent of solvent.

The most noteworthy feature in the NMR spectrum of **1** is the large geminal shift differences ($\Delta\delta_{OBS}$) between the N-CH_2 protons of the *Z,Z* and, to a lesser extent, *Z,E* conformers. In $CDCl_3$, the largest $\Delta\delta_{OBS}$ was measured at 2.17 ppm for the minor Z,Z_2 isomer, while the Z,Z_1 and *Z,E* configurations recorded 2.04, 1.18, and 1.26 ppm, respectively (Table 1). The chemical shift differences were invariant with the concentration of **1** in $CDCl_3$, precluding any effects due to intermolecular association. These results suggested that the N-CH_2 (and S-CH_2) groups in the symmetrical *Z,Z* isomers are pairwise

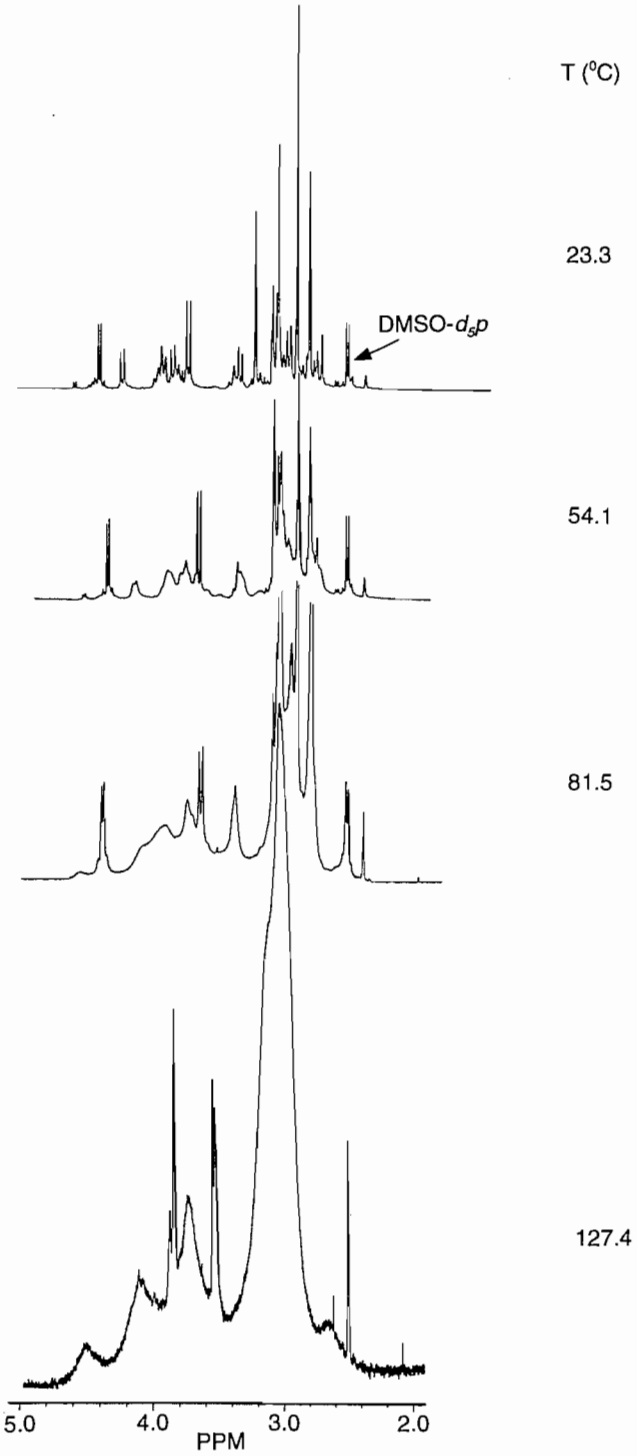
[a]Stereochemical assignments are based on the analysis of NOE and ^{1}H–^{13}C shift correlated data.

equivalent or enantiotopic and that the N-CH_2 protons have markedly different magnetic environments. Large geminal proton chemical shift differences have been observed in a few semi-rigid, polyamide systems (22–24). In cyclotetrasarcosyl, **5**, the isochronous pairs of the *N*-methylene protons are separated by about 2 ppm (in $CDCl_3$) (23), while one set of those for the tetrathiacyclododecane **6** have a chemical shift difference of 1.78 ppm (in $CDBr_3$) (24).



Invariably, such large (i.e., >1.5 ppm) N-carbinyl splittings appear to be associated with the sterically favored *Z* amide stereochemistry, which places these protons in or close to the respective amide planes pointing toward the C=O groups

(25).

(c) NOE data

To further define the solution state conformations of **1**, NOE experiments were carried out in $CDCl_3$ at 303 K on signals of the two major isomers. Representive difference NOE spectra for these isomers are shown in Figs. 4 and 5. The inserts illustrate NOE interactions for a given geometric isomer, together with their interatomic distances as determined from MM2-calculated structures.

Fig. 3. ^{1}H-^{13}C chemical shift correlated spectra of **1** in DMSO-d_6 at 303 K. The diastereotopic N-CH_2 protons of the *Z,Z* isomers are circled.

In the major isomer, irradiation of the AB S-CH_2 quartet at 3.43 ppm resulted in a large NOE of the *N*-methyl protons at 3.13 ppm (Fig. 4(*a*)), indicative of a pseudoaxial S-C*H* and N-CH_3 proximity about a *Z* amide configuration. This enhancement was not expected for an *E* stereochemistry, as a larger distance would separate the appropriate protons. The observation of a NOE between the shielded N-CH_2 (2.64 ppm) and N-CH_3 protons (Fig. 4(*b*)) was consistent with a *Z* geometry, where the former protons occupy a pseudoequatorial position *syn* to the adjacent CH_3 group. Irradiation of the N-CH_3 resonance caused NOEs at not only the expected positions of the shielded N-CH_2 and S-CH_2 protons, but also at the deshielded N-C*H* at 4.68 ppm (Fig. 4(*c*)). The weaker enhancement of the deshielded N-C*H* (relative to the shielded protons) suggested a transannular proximity with its *opposite* N-CH_3 group — an interaction made possible through pseudoaxial configurations[6] for both groups. Thus, a C_2 symmetric *Z,Z* conformation best matched the NOE observations noted for the major solution conformation of **1** (see **1a**, Fig. 8).

In the nonsymmetric isomer, irradiation of the S-C*H* signal at 3.55 ppm induced a strong enhancement of its geminal partner at 3.99 ppm as well as a weaker enhancement of the N-CH_2 protons at 4.27 ppm (Fig. 5(*a*)). According to molecular models, the latter NOE was only possible between the pseudoaxial S-C*H* (H(3b)) and the pro-*R* N-C*H* (H(6b))

[6] N-CH_2 protons that occupy either pseudoaxial or pseudoequatorial positions in the symmetrical *Z,Z* isomers are denoted as H_{ax} or H_{eq}, respectively.

about the *E* amide group. The X-ray structure and molecular mechanics calculations (Figs. 6 and 8, **1c**) supported this result: with an interatomic separation of 1.97 Å, the electron clouds of these protons were overlapping by about 0.4 Å. The positive N-CH_3 enhancement at 3.24 ppm was most likely a result of saturation transfer (26) to S-C*H* (H(10a)) at 4.16 ppm by which it is strongly relaxed (Fig. 5(*c*)). Barring geminal enhancements, NOEs were not observed for the second *E* S-C*H* (H(3a)) signal at 3.99 ppm: this was consistent with a pseudoequatorial position (Fig. 5(*b*)).

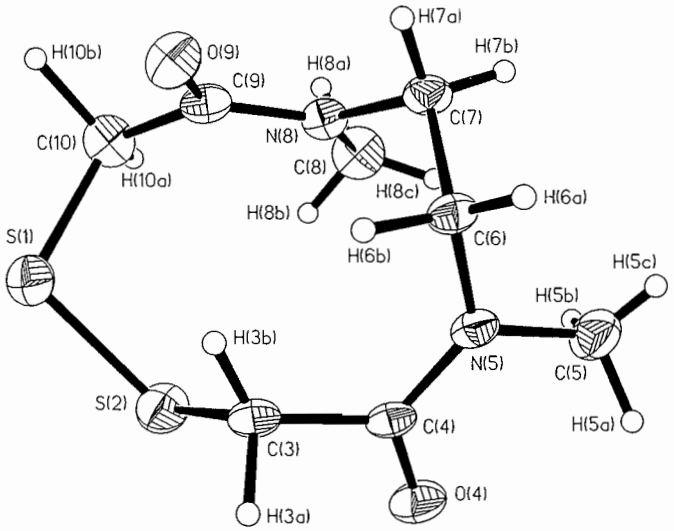
Fig. 5. 500 MHz NOE difference spectra (*a*)–(*d*) of the *Z,E* stereoisomer of **1** in $CDCl_3$ at 303 K. The irradiated peak is indicated at the arrowed frequency.

Irradiation of the S-C*H* (H(10a)) resonance at 4.16 ppm (Fig. 5(*c*)) induced strong enhancement of the downfield N-CH_3 protons at 3.24 ppm, which was indicative of a di-pseudoaxial disposition of protons about a *Z* amide bridge. Examination of the *Z,E* molecular model revealed that the point of closest approach of these protons was ca. 1.6 Å. The NOE was therefore consistent with a *Z* amide stereochemistry and supported the prediction (27) that the *downfield* N-CH_3 (and N-CH_3 by ^1H–^{13}C shift correlation, Fig. 3) belonged to the *Z* amide group in the *Z,E* conformer.

Irradiating the co-resonating, downfield N-CH_2 protons (H(6b) and H(7a)) at 4.27 ppm created moderate NOEs at 3.55, 3.10, and 3.01 ppm (Fig. 5(*d*)). The 3.55 ppm enhancement arises from interaction of H(6b) with H(3b) (as in Fig. 5(*a*)). The latter two enhancements most likely arose from geminal interactions with the shielded *Z* and *E* N-CH_2 protons (H(7b) and H(6a), respectively) and was further evidence that the nonsymmetric component of **1** (see **1c**, Fig. 8) possessed a *Z,E* geometry.



Unfortunately, it was not possible to obtain definitive NOE data for the Z,Z_2 isomer, largely because of its low abundance and intensity complications arising from saturation transfer from more abundant isomers. Although saturation transfer effects were also observed for the *Z,E* and, to a lesser extent,

the Z,Z_1 conformers, their relatively intense signals allowed for the extraction of useful conformational information from their NOE spectra.

(d) Aromatic solvent-induced shift (ASIS) studies

The lack of NOE data for the Z,Z_2 stereoisomer prompted an ASIS investigation to determine its solution state geometry. Studies on a variety of amides (28–31) have consistently showed that aromatic solvents shift the signals of the N-C_α protons *trans* to the carbonyl group *upfield* to a greater extent than those at the *cis* position. By comparison of their relative proton shifts in aromatic and nonaromatic solvents, these resonances can be assigned to a particular amide stereochemistry.

The ^{1}H NMR spectrum of **1** in benzene-d_6 revealed that the N-CH_3 (and N-CH_2) resonances of both major (Z,Z_1) and minor (Z,Z_2) isomers exhibited very similar upfield aromatic solvent-induced shifts (0.56 and 0.61 ppm relative to the $CDCl_3$ shifts, data not shown). Since the NOE experiments confirmed the major isomer to have the *Z,Z* geometry, the benzene dilution experiments suggested that the minor isomer also possesses the *Z,Z* configuration. The relatively large ASIS values were also consistent with a *Z* geometry (32). An *E,E* stereochemistry in the minor isomer would have resulted in a smaller ASIS value and an increased separation between the N-CH_3 resonances of the major and minor isomers upon benzene-d_6 dilution. It is worth noting that in benzene-d_6, the N-CH_2 splittings for the Z,Z_1 and Z,Z_2 ring conformers increased to 2.58 and 2.69 ppm, respectively.

(e) Solid state structure analysis

An X-ray diffraction study of **1** was undertaken to establish unambiguously the geometry that could give rise to the enormous NMR shift differences observed for the geminal methylene protons.

The geometry and numbering of the X-ray structure of **1** is shown in Fig. 6; atomic coordinates, bond length, and bond angles are listed in Tables 4–8. As the structure analysis revealed, **1** crystallized with the *Z,E* geometry. This was a surprising result since NMR data had shown the Z,Z_1 isomer to be the dominant geometry in solution (Table 3). A survey of the bond angles and bond lengths of **1** indicated no unusual deviations from normal values. The disulfide and amide torsional angles (Table 7) are very close to ground state values (i.e., 90° and planarity, respectively) indicating low torsional strain in the *Z,E* ring.

The unit cell contains two *Z,E* molecules of **1**, which are related by a center of inversion. Molecules stack in columns with a high degree of packing efficiency given the unsymmetrical nature of the *Z,E* isomer. The most significant intermolecular contact is O(4)···C(8), which is 3.23 Å. Intramolecular nonbonding contacts were observed between O(9) and H(7a), and between H(3b) and H(6b). These nuclei, separated by 2.35 Å and 2.01 Å, respectively, are within the sum of the accepted van der Waals radii for oxygen and hydrogen (1.4–1.6 and 1.2 Å, respectively) (33, 34). These contacts may contribute to the rather large NMR shift differences observed for geminal hydrogen nuclei of the *Z,E* conformation (vide infra).

The excellent agreement between the crystal structure of the *Z,E* isomer and the NOE-derived conformational model established a link to proton shift assignments. The direction and magnitude of proton shifts may be qualitatively explained by the positions of the geminal protons relative to

their adjacent carbonyl group: in general, a proton will be increasingly deshielding as it approaches the plane and (or) midpoint of a carbonyl group (25). In the *Z* amide system, H(7a) and H(7b) (see Fig. 6) are 10.4° and 13.9° out of the amide plane defined by atoms O(9)-C(9)-N(8) and are located 2.36 and 3.36 Å, respectively, from the midpoint of the C═O bond. Thus, H(7a) should resonate *downfield* (4.27 ppm) from H(7b) (3.01 ppm). Similarily, H(6b) and H(6a) of the *E* amide are 170.6° and 151.6° removed from the O(4)-C(4)-N(5) plane and are situated at distances of 3.27 and 3.65 Å, respectively, from the midpoint of the carbonyl bond. Since H(6b) is "closer" to its adjacent amide group, it should appear downfield (4.27 ppm) of its geminal partner (3.09 ppm). It is interesting to note that the very similar deshielding influences on H(7a) and H(6b) appear to result from two different orientations of the protons, namely, H(7a) is close to the O atom of one C═O group, while H(6b) is near the C atom of the other. The ab initio shift calculations (see Table 12) provided addi-

tional confirmation of the above qualitative assessment of proton assignments.

To further assess the relationship between the solution and solid state geometries of **1**, the cross-polarization, magic angle spinning (CP-MAS) ^{13}C NMR spectrum of a larger sample of crystalline **1** (0.10 g) was determined in the solid state at 25.2 MHz (Fig. 7). Unfortunately, excessive broadening of the ^{13}C resonances caused by dipolar coupling to ^{14}N nuclei, as well as signal overlap and sensitivity complications, prevented an unequivocal correlation of characteristic shifts between the solid state and solution state spectra in the 30–50 ppm range. Spectra recorded at a higher field and (or) higher sample concentration would probably resolve this inadequacy.

An interesting outcome of the solid state experiment, however, was noted in the carbonyl region: two broad signals of unequal intensity (167.30 and 174.39 ppm) suggested the presence of at least two conformers in the sample. If the recrystallized sample of **1** consisted *only* of the *Z,E* geometric isomer, then only two, *equally intense* resonances should be observed for the carbonyls. Based on chemical shift and intensity comparisons with the solution state ^{13}C data (Table 2), the more intense signal at 167.30 ppm was ascribed to the Z,Z_1 structure, while the unresolved resonance at 174.39 ppm was assigned to the *Z,E* conformer. The observation of two species in the solid state NMR could be rationalized by the presence of both *Z,Z* and *Z,E* crystals in the sample. The rather high barriers to amide isomerization could promote the crystallization of the *Z,Z* and *Z,E* amide ring conformers into *separate* lattice structures. Examples of acyclic monoamides have been reported to crystallize in either the *Z* or *E* geometry, with only one geometric rotamer in each unit cell (35).

Computational analysis

While the X-ray structure provided a link between the ^1H NMR chemical shift and geometry for the *Z,E* isomer, no such benefits were available for the *Z,Z* isomers. Consequently, a number of computational methods were investigated to aid in chemical shift assignment and to provide insight into the origins of the unusually large N-CH_2 anisochronism and its apparent absence for the S-CH_2 protons.

(a) MMX calculations

Molecular mechanics calculations were performed using PCMODEL (version 4.0) to evaluate the conformational geometries and energies of the Z,Z_1 and Z,Z_2 structures. From over 90 unique starting geometries, five conformers were found for **1** within 5 kcal/mol of the global minimum structure (Table 9, Fig. 8). Conformers **1a** (*Z,Z*), **1b** (*Z,Z*), and **1c** (*Z,E*) agreed well with the structural models inferred from NOE, thermodynamic, X-ray, and NMR symmetry data. Based on this correlation, the observed conformers in the NMR spectra of **1** — Z,Z_1, Z,Z_2, and *Z,E* — were proposed to have similar structures as **1a**, **1b**, and **1c**, respectively.

The *Z,E* isomer (Fig. 6) was taken as the source of the unsymmetrical set of NMR resonances and, among the set of *Z,E* isomers, **1c** provided the best correlation between calcu-

lated and experimental Boltzmann distributions (see Table 3). Moreover, when **1c** was overlapped with the X-ray structure in PCMODEL, it was evident that they were similar (RMS deviation of atoms = 0.037 Å). To achieve a more realistic comparison, conformational changes that might be imposed on **1** by crystal lattice forces were removed from the X-ray structure by subjecting the molecule to the PCMODEL force field energy minimization program. The observed change amounted to approximately 0.6 kcal/mol energy loss upon minimization. The resultant "minimized X-ray" structure was then superimposed on **1c** and **1d** to afford a virtually complete overlay with **1c** (RMS deviation of atoms = 0.021 Å) but gave a poorer alignment with **1d** (RMS deviation of atoms = 0.198 Å). Molecular mechanics had thus accurately predicted the solid

state geometry of the *Z,E* conformer. This fact, coupled with the strong similarities between NOE and computed structural models, suggested that the MM2 force field was a reasonable probe for generating the solution state conformations of **1**. Conformer **1e** is simply the enantiomer of **1c**.

Conformers **1a** and **1b** possess C_2 symmetry and an antiparallel,[7] *Z,Z* configuration with both amide functions essentially coplanar. This antiparallel *Z,Z* arrangement has been reported for other *N*-substituted polyamide heterocycles, including cyclic amides **5** and **6** (23, 24). Steric and electronic factors may account for the configurational preference found in these systems. For example, in the parallel conformation, transannular methyl–methyl contacts and a large internal dipole moment (resulting from the sum of the moments from the parallel C═O groups) will undoubtedly be quite destabilizing.

Analysis of the molecular modelling data and mechanical models led to the conclusion that isomers Z,Z_1 and Z,Z_2 are disulfide ring conformers. At room temperature, interconversion of these rotational isomers was sufficiently slow on the NMR time scale to allow detection by ^{13}C NMR spectroscopy (Table 2). Interconversion occurs presumably through the *cis* transition state by ca. 180° rotation about the asymmetric S—S bond (Fig. 9) and a ^{13}C DNMR study was carried out with the objective of validating the molecular modelling results.

(b) Measurement of the S—S rotational barrier for the $Z,Z_1 \rightleftarrows Z,Z_2$ *equilibrium via* ^{13}C *DNMR*

The simple Arrhenius equation (eq. [2]) was used because previous studies on conformational processes in reasonably inert solvents have shown that $\Delta G^{\ddagger}$ values vary only slightly with temperature (36) and lie within the range of experimental error.

$$[2] \quad k = A \exp(-\Delta G^{\ddagger}/RT)$$

Warming a sample of **1** in DMSO-d_6 from 25.0 to 56.7°C resulted in a temperature-dependent broadening and a subtle high-field migration of the Z,Z_2 N-C_α signal at 45.4 ppm. Rate constants, *k*, for this chemical exchange process were evaluated using the complete bandshape (CBS) method (37). Based on a two-site exchange of the Z,Z_1 and Z,Z_2 N-CH_2 resonances (43.4 and 45.4 ppm, respectively) between 27.0 and 40.2°C, the barrier to $Z,Z_1 \rightleftarrows Z,Z_2$ interconversion ($\Delta G^{\ddagger}$) was measured to be 14.5 ± 1.3 kcal/mol (Table 10). The height of this barrier lies close to the range reported for disulfide rotations in cyclic systems. For example, the barriers to inversion for 1,2-dithiane and 3,3,6,6-tetramethyl-1,2-dithiane have been reported to be 11.6 and 13.6 kcal/mol, respectively (38, 39).

Table 10. Calculated rate constants (from CBS analysis) and Arrhenius parameters for the $Z,Z_1 \rightleftarrows Z,Z_2$ conformational equilibrium.

T (K)	*k* (s^{-1})	1/*T* (K^{-1})	ln *k*
298.5	0.6	0.00335	–0.5108
300.0	0.9	0.00333	–0.1054
302.0	1.0	0.00331	0
304.2	1.2	0.00329	0.1823
306.3	1.2	0.00326	0.1823
309.8	1.8	0.00323	0.5878
311.1	2.2	0.00321	0.7885
313.2	2.4	0.00319	0.8755
317.6	2.7	0.00315	0.9932
329.7	4.6	0.00303	1.5261

The barrier of 14.5 kcal/mol was too low to be attributed to an amide rotation, particularly one occurring in a cyclic system and, although it was at the high end for reported disulfide rotations, it was reasonable to attribute the $Z,Z_1 \rightleftarrows Z,Z_2$ chemical exchange process to a disulfide rotational mechanism as illustrated in Fig. 9. A large component of the observed barrier is reflected in the energy profile of the acyclic disulfide bond, which has a maximum of ca. 8–10 kcal/mol at a CSSC dihedral angle of 0° (i.e., for the *S-cis* transition state) and a minimum at 90° (40) with the barrier considered to arise from the mutual repulsion between the unshared pairs of 3*pz* nonbonded electrons on adjacent sulfur atoms (41). In cyclic disulfides such as **1**, however, the presence of transannular electrostatic and steric interactions will increase the height of the disulfide rotational barrier. Moreover, the amide groups presumably confer additional rigidity to the ring and likely contribute to the relatively high barrier.

[7] The term antiparallel refers to the opposite relative orientation of the amide groups.

It is interesting to note that S—S rotation generated diastereomeric conformations, and not the enantiomers that are commonly observed in acyclic, unsymmetric disulfides (42). The asymmetric nature of the ring introduces a second source of chirality, which, in combination with asymmteric disulfide rotation, confers a diastereomeric relation between the Z,Z_1 and Z,Z_2 stereoisomers.

Unlike the Z,Z_2 isomer, the S-CH_2 protons in the Z,Z_1 structure did not possess pseudoaxial geometry (**1a**, Fig. 8). Analysis of space-filling, mechanical models of the Z,Z_2 structure indicated that a pseudoaxial, S-CH_2 configuration brought one set of lone electron pairs on oppositely related O and S atoms into close proximity. It appeared that the compromised, dipseudoequatorial geometry of the Z,Z_1 conformation defused this transannular interaction by directing the electrons away from each other. Moreover, a pseudoequatorial configuration of S-CH_2 protons was expected to be sterically preferable to a pseudoaxial one as 1,3-diaxial interactions with the methyl groups will destabilize the latter conformation. Some combination of these electronic and steric effects may serve to explain the calculated and observed population distributions between the Z,Z_1 and Z,Z_2 ring conformers (Table 3).

The calculated, MMX conformational energies agreed moderately well with those of the observed populations (Table 3). Since the molecular mechanics calculations mimic isolated molecules in their gaseous state, exact agreement between calculated and experimental populations is unattainable given the present level of computational sophistication. This situation arises from the inability to accurately incorporate solvent effects into the calculations. In addition, certain conformations may be differentially stabilized by solvation (43), particularly in higher energy geometries. In this case, the more energetic, gas-phase *Z,E* (**1c**) conformer will be stabilized to a greater extent than the lower energy Z,Z_2 structure, resulting in a thermodynamic reversal of solution state population levels. The effect may serve to rationalize the differences between calculated and experimental population distributions (Table 3), particularly for the *Z,E* structure.

In analogy to the chemical shift assignments made for protons of the *Z,E* crystal structure (vide supra), the orientation of a MMX-calculated N-CH proton, in relation to its adjacent C=O group, will primarily determine its chemical shift. Consequently, for isomers **1a** and **1b** (Fig. 8), one isochronous N-CH_{ax} pair occupied a pseudoaxial configuration that was essentially *cis* coplanar to the C=O group (i.e., 9.2° and 1.4° removed from the amide plane defined by the atoms O, C, and N) and, therefore, should be the low-field protons at 4.68 and 4.88 ppm, respectively. An interesting confirmation of this pseudoaxial geometry was noted in a ^1H–^1H COSY experiment, where the 4.68 ppm signal was weakly correlated to the N-CH_3 resonance at 3.13 ppm. This was indicative of a stereospecific, four-bond coupling originating from the "W" configuration (44) that is often observed between axial protons α to C-18 or C-19 methyl groups in steroids. Four-bond coupling to the methyl protons was not possible for the pseudoequatorial (H_{eq}) protons in this molecular configuration.

The second, isochronous set of geminal N-CH_{eq} protons in the Z,Z_1 and Z,Z_2 ring isomers occupied pseudoequatorial positions that were approximately 20.9° and 15.6° out of the amide plane. Their respective shifts at 2.64 and 2.71 ppm implied that they were shielded in comparison to the rotationally averaged, *Z,Z* N-CH_2 shift of 3.28 ppm for the open-chain precursor **4** (cf. Table 13). A comparison at a more quantitative level suggests that the H_{eq} protons were shielded by about 0.6 ppm, while the H_{ax} protons were deshielded by 1.5 ppm, respectively. Clearly, the shielding mechanisms (particularly the deshielding forces) at work in the conformational isomers of **1** were quite significant and worthy of further investigation.

Shielding calculations

The objective of this section is to investigate the extent to which it is possible to identify the origins of and to quantify the large N-CH_2 nonequivalences observed in the Z,Z_1 and Z,Z_2 conformers. In addition, we examine the pattern of S-CH_2 nonequivalencies for the *Z,Z* and *Z,E* conformations.

For the purpose of calculating chemical shifts, we have employed a combination of nonlocal density functional theory (DFT) and the guage-independent atomic orbital (GIAO) method using two common ab initio basis sets: Becke3LYP/3-21G* and Becke3LYP/6-31G*. Previous workers have successfully employed a similar level of theory for shift predictions of organic molecules using both DFT (45) and correlated as well as uncorrelated HF (46) methodologies.

*(a) Shift predictions for conformers **1a**, **1b**, and **1c***

The results are presented in Table 11 for the three proton environments as absolute shifts in ppm downfield from TMS. Three primary points derive from the tabulation. First, the calculated shift differences (Δδ) for the eight N-CH_2 and S-CH_2 geminal proton pairs accurately reproduce the measurement with a maximum deviation of 0.2 ppm (cf. Table 1). Second, the absolute shifts from TMS (δ^1H) for the same protons are only slightly less well reproduced, with the majority of deviations from experiment at 0.1–0.2 ppm. The N-CH_3 proton shifts are uniformly overestimated by 0.3–0.5 ppm. However, the calculated values are simple averages over a single N-methyl conformation and are thus subject to the greatest error. The numbers are still quantitatively representative of the spectroscopic outcome. Finally, the economical 3-21G* basis set performs as well as the extended 6-31G* version, both delivering impressive matches with the measured shifts.

(b) Origins of chemical shift differences

The observed chemical shift difference, $\Delta\delta_{OBS}$, between a geminal pair of protons can be broken down heuristically into a number of overlapping effects as depicted by eq. [3] (47).

$$[3] \quad \Delta\delta_{OBS} = \Delta\delta_{MAG} + \Delta\delta_{EL} + \Delta\delta_{SOL} + \Delta\delta_{VDW}$$

The terms $\Delta\delta_{MAG}$, $\Delta\delta_{EL}$, $\Delta\delta_{SOL}$, and $\Delta\delta_{VDW}$ refer to the *net* chemical shift between N-CH_2 or S-CH_2 protons ascribed to shielding contributions from magnetic anisotropy, electric field, solvent, and van der Waals effects of all neighbouring groups in the molecule.

The $\Delta\delta_{MAG}$ and $\Delta\delta_{EL}$ contributions arise from the perturbation of a proton by the magnetic field and electric dipoles of polar groups such as amide functionalities by an obtained through-space mechanism. Rough estimates can be estimated by applying modified forms of McConnell's (48) and Buckingham's (49) equations, respectively. The polar character of the amide group can also contribute to $\Delta\delta_{OBS}$ through the polarization of the solvent via a reaction field. However, this

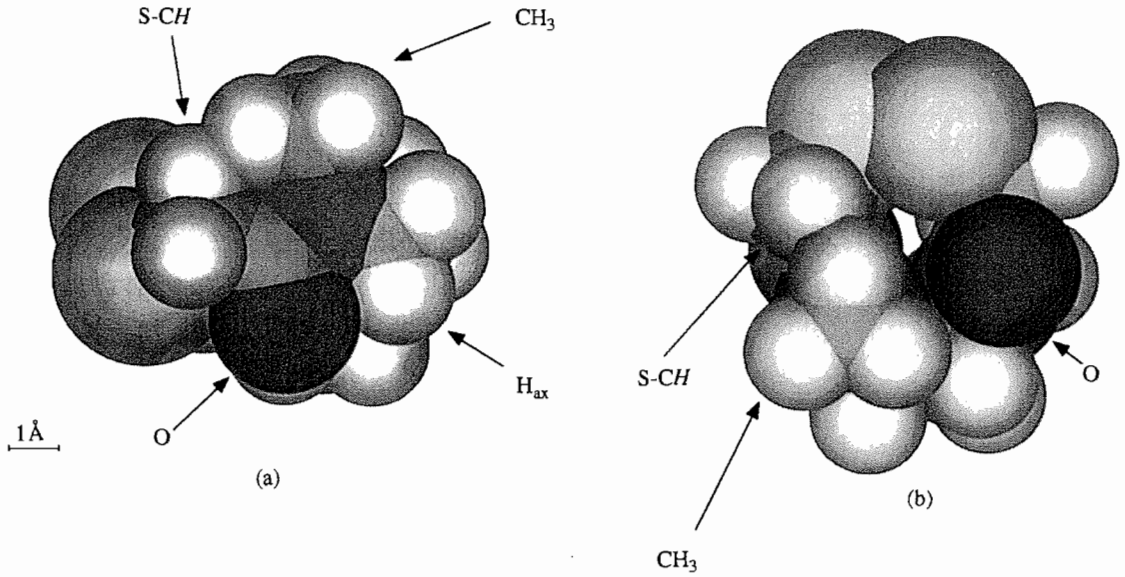
[a]Relative to TMS at the same basis set with MP2/6-31G* optimized geometry; isotropic ^{1}H shifts: 3-21G* 32.9 ppm; 6-31G* 32.3 ppm.

[b]Parenthetical values are the absolute chemical shift differences in ppm between the measured (Table 1) and calculated values.

[c]Tabulated chemical shifts are simple averages for the three methyl protons.

shift contribution from the solvent ($\Delta\delta_{SOL}$) was demonstrated by Clayden and Williams to be unimportant in determining the methylene nonequivalence in cyclotetrasarcosyl, **5** (50). The absence of exchangeable protons and a concentration dependence for the magnitude of the N-C*H*$_2$ shift difference in **1** indicates that specific solvent–solute and (or) solute–solute interactions are not likely shift factors either.



The expression $\Delta\delta_{VDW}$ reflects the operation of shielding effects when hydrogen atoms are subject to intramolecular steric or van der Waals interactions with proximate nuclei (51). Qualitatively, the direction of shielding can be associated with the net nuclear charge on the resonant proton, which, in turn, depends on the predominance of either an attractive or repulsive interaction. For example, if the resonant proton feels an *attractive* van der Waals interaction with a proximate group, its effective nuclear charge will be increased, resulting in an *upfield* shift (shielding) of the hydrogen nucleus. Conversely, in the *repulsive* van der Waals regime, electrostatic repulsion of interacting electron clouds will induce charge polarization in the H→C bond direction and will produce a *downfield* shift (deshielding) of the resonant proton (52). In general, intramolecular separations at, or smaller than, the sum of the van der Waals radii of the interacting groups usually result in repulsive van der Waals interactions, while attractive interactions will dominate at slightly larger interatomic distances. The attractive interaction is relatively weak compared to its stronger repulsive counterpart, so deshielding effects are generally much larger and more common than the shielding ones (53). Instances of such deshieldings have been observed mostly in rigid systems, where one or more hydrogen atoms is forced too close to other groups because of rigid geometrical constraints (51). For example, the magnitude of the δ_{VDW} shift and N-C*H*$_2$ nonequivalence in a series of hindered amides has been linearly correlated to the size and number of the interacting groups (54).

In contrast to **5** (50), a $\Delta\delta_{VDW}$ contribution to $\Delta\delta_{OBS}$ cannot be ruled out for **1** since van der Waals contacts involving the downfield H_{ax} protons were detected in the calculated MMX

and crystal structures. An example of these through-space contacts is illustrated for the Z,Z_2 conformer (Fig. 10). CPK space-filling representations are used to illustrate an "effective size" for each atomic electron cloud based on their characteristic van der Waals radii (r_{VDW}). Intra-atomic measurements showed that the oxygen (r_{VDW} = 1.5 Å) (34) and methyl (r_{VDW} = 2.0 Å) groups protrude into the electron cloud of the H_{ax} (r_{VDW} = 1.2 Å) protons by at least 0.2 and 0.1 Å, respectively. Thus, a downfield shift is predicted for the H_{ax} protons. In contrast, the H_{eq} protons are not expected to be influenced by a paramagnetic van der Waals shift given its sterically unencumbered, pseudoequatorial geometry. A quantitative assessment of the $\Delta\delta_{VDW}$ contributions to methylene shift nonequivalences was provided by ab initio shift calculations (vide infra).

(c) The N-CH_2 protons

Our strategy for deconvoluting the various intramolecular influences on the differential chemical shifts of geminal protons is to carve the molecule into smaller fragments of identical structural geometries and to compute the corresponding chemical shifts using the ab initio methodology employed for the whole molecule (Table 11). Consequently, seven substructures were prepared (see Experimental) and subjected to a DFT/GIAO evaluation for comparison with **1a-1c** (Table 12). The following analysis shows that the observed shieldings are a complex blend arising from the amide dipole, N–CH steric effects, and, in the case of S-CH_2 protons, the sulfur lone pairs.

Consider the 2.0 ppm difference between the geminal pseudoaxial and equatorial N-CH_2 protons in **1a** (Z,Z_1). A comparison of 1,2-diaminoethane, ((OHCN-CH_2)$_2$ and N-demethyl **1a** with the corresponding N-methyl structures (Table 12) demonstrates that methylation causes the geminal proton *syn* to the methyl group (H_{syn}) to shift upfield by 0.3–0.5 ppm. By contrast, H_{anti} is deshielded by 0.1–0.3 ppm upon methyl addition. The resulting difference is around 0.6 ppm. Further addition of the CHO unit induces a small deshielding of −0.1 to −0.2 for H_{syn}, but a much larger deshielding of −1.5 to −1.8 ppm results for H_{anti}. Overall, H_{syn} experiences an approximate 0.2–0.3 ppm upfield shift (relative to the protons in diaminoethane) largely as a result of an attractive van der Waals interaction with the N-methyl group. H_{anti}, on the other hand, is pulled 1.8 ppm downfield mainly by dipolar effects of the amide group, but supplemented by a small δ_{VDW} contribution from N-methyl contact. The net geminal proton separation is 2.0–2.1 ppm, as observed and predicted for **1a** (Table 11).

Precisely the same situation applies to the minor conformation **1b** (Z,Z_2). Here, the observed geminal splitting of 2.2 ppm is due to the effect of amide group deshielding (ca. 1.8–2.0 ppm) with a diminutive contribution of 0.3 ppm from steric interaction with the N-CH_3 group. The axial H_{anti} is somewhat nearer the C═O oxygen in **1b** than **1a** (2.41 vs. 2.44 Å, respectively), while the C═O and C—H bonds are closer to a common plane (ϕ(H—C---C═O) = 12.3° and 24.5°, respectively).

A similar analysis for the third conformer, **1c** (Z,E), shows that the presence or absence of the N-methyl function has little effect on the N-CH_2 shift difference (≤0.1 ppm, Table 12). The *trans* and *cis* amide groups contribute the most, providing 1.0 and 1.2 ppm, respectively, to the observed geminal splitting. On the *trans* half of the molecule, the axial N-CH_2 ($H_{anti,1}$) is situated 2.54 Å from the amide oxygen and twisted out of the H—C---C═O plane by 39°. Both factors cause a reduction in the geminal split relative to **1a** and **1b**, which is 1.1 ppm based on the fragment analysis (Table 12). On the *cis* side, the axial N-CH_2 proton ($H_{anti,2}$) is too far from the adjacent C═O to significantly experience any electronic effects, but lies only 2.7 Å cross-ring from the oxygen of the *trans* amide. A more revealing description of its location sites the proton 1.74 Å *above* the plane of the *trans* amide but shifted 2.01 Å away from the carbonyl oxygen (Fig. 11). This is to be compared with $H_{anti,1}$,

[a]H_{syn} is the CH_2 proton *syn* to CH_3 or H of the N-R group; H_{anti} is defined similarly. The shift values are given in ppm relative to TMS; cf. footnote *a*, Table 1.

[b]Parenthetical values are those calculated from the 6-31G* basis set.

[c]Δδ is the chemical shift difference between NCH_2 and SCH_2 geminal protons in ppm.

[d]*trans*-Amide values are listed first; *cis*-amide, second.

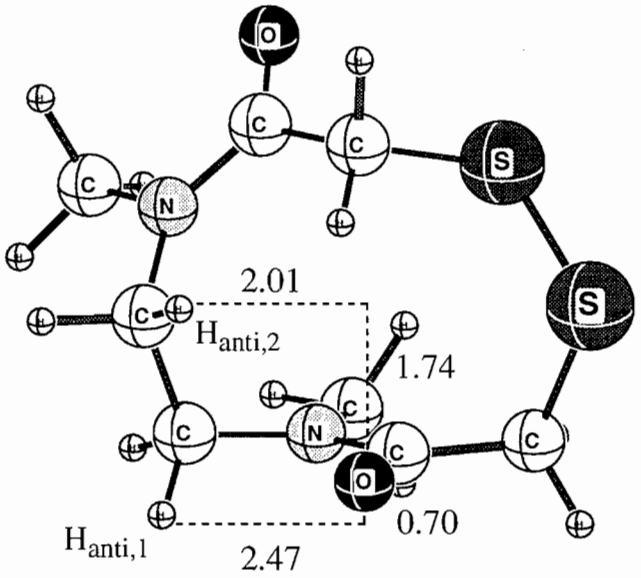
[e]Bis-*N*-demethyl **1**.

which is 0.70 Å *below* the *trans* amide plane and likewise shifted from the carbonyl oxygen by 2.47 Å.

Qualitatively, we can predict that both $H_{anti,1}$ and $H_{anti,2}$ are deshielded relative to their geminal partners because of their positions inside the deshielding space of the *trans* C=O shielding cone. Their observed shifts and splittings are accurately reproduced by the shift calculations (Table 11) and confirmed to be primarily a deshielding effect of the (*trans*) amide (Table 12) by the fragment shielding treatment. The latter analysis suggests a geminal separation of 1.3 ppm (H_{anti}: (H_2N-CH_2)$_2$ vs. (OHCNH-CH_2)$_2$, Table 12), in agreement with experiment.

(d) The S-CH_2 protons

The observed splittings for the geminal protons α to sulfur are considerably less than those α to nitrogen (Table 1). Superficially, one might conclude that the local "magnetic" environments are therefore similar. On the other hand, there is no obvious intuitive reason for drawing this inference based on molecular geometry. Both the N-CH_2 and S-CH_2 sites are equally asymmetric: a pseudoaxial and a pseudoequatorial proton residing at each center. Magnetic similarity must then arise from the near cancellation of effects. To accomplish the analysis, we examine chemical shifts in the S-CH_2 moieties of **1**, N-demethyl **1**, and the dimethyldisulfide fragment given in Table 12.



The abundant conformer **1a** (Z,Z_1) exhibits its S-CH_2 protons as magnetically equivalent (Tables 1 and 11). Yet, the dimethyldisulfide fragment reveals a 0.8 ppm difference between geminal protons (Table 12). This surprisingly large isochrony can be appreciated by recognizing that H_{anti} resides almost directly above the S—S bond and is consequently deshielded by both lone pairs on the adjacent sulfur (Fig. 8, **1a**). From MeSSMe to **1a**, H_{syn} experiences a 1.0 ppm downfield shift as a result of its position close to the amide plane and its steric interaction with the N-methyl group, the latter repulsive van der Waal contact contributing 0.4 ppm. H_{anti} is simultaneously deshielded by only 0.2 ppm, derived entirely from dipolar interaction with the amide. The net result is that both protons experience almost identical shifts, although each is influenced significantly and dissimilarly by the S—S, (N)Me, and amide moieties. A parallel analysis can also serve

Fig. 11. A ball and stick plot of the MMX diamide **1c**, showing the H_{syn} and H_{anti} positions relative to the *trans* carbonyl oxygen. Numerical values correspond to distances in Å.

to rationalize the S-CH_2 $\Delta\delta_{OBS}$ for **1b** (Z,Z_2). However, the shielding forces affecting H_{syn} and H_{anti} are greater (owing to their stricter pseudoaxial and pseudoequatorial geometries) and are manifest as a larger, geminal shift difference of 0.7 ppm (Table 1).

Conformer **1c** (*Z,E*) exhibits $\Delta\delta$'s of similar magnitude for protons α to N and S around the *trans*-amide functionality. While they arise from alternative factors, a decomposition analysis from values in Table 12 provides a quantitative assessment. Noteworthy is the situation for the geminal hydrogen pair adjacent to the *cis*-amide center, which sustains a rather small observed isochrony of 0.4 ppm (Table 1). The C—H bond containing H_{anti} is nearly eclipsed with the S—S bond (ϕ = 12.0°), while the same bond involves an unusually short, H---H van der Waals contact (1.97 Å) with a *cis*-disposed H_{anti} of the adjacent N-CH_2 group (respectively, H(3b) and H(6b), Fig. 5 inset). The combination promotes a 1.4 ppm deshielding that is matched by a nearly identical H_{syn} deshielding of 0.9 ppm from the *cis*-amide moiety (cf. MeSSMe and **1**, Table 12). Once again, large and compensatory effects lead to a diminutive geminal $\Delta\delta$.

Experimental

Materials

Acetonitrile was distilled from P_2O_5 and the distillate was redistilled from CaH_2, discarding the first 5 and the last 10%. Ethanol (EtOH) was dried and purified via distillation from magnesium turnings and stored over freshly activated 4 Å molecular sieves. All chemicals were purchased from Aldrich Chemical Company (Milwaukee, Wis.).

Melting points (mp) were recorded on a Gallenkamp capillary tube melting point apparatus and are uncorrected.

Analytical thin-layer chromatography (TLC) and column chromatography (according to the "flash" method of Still et al. (55)) were carried out on E. Merck silica gel 60 F_{254} coated Al plates of 0.2 mm thickness and 0.040–0.063 mm (230–400 mesh), respectively. TLC visualization was achieved using a combination of either a UV lamp at 254 nm or I_2 vapour and treatment with a phosphomolybdic acid spray (20 g of phosphomolybdic acid hydrate and 15 g $Ce(SO_4)_2$ dissolved in 1 L of 10% H_2SO_4) followed by heating to ca. 130°C.

Electrospray (ES) mass spectrometry (MS) was performed on a Fisons VG Platform LC–MS electrospray mass spectrometer. Other mass spectra were obtained on a VG ZAB-E mass spectrometer with sample introduction via a direct inlet system. Infrared spectra (IR) were recorded on a Perkin–Elmer 283 spectrometer using either liquid cells with methylene chloride or chloroform as solvents or potassium bromide pellets. The abbreviations (s) = strong, (m) = medium, and (w) = weak are used to describe the intensity of particular bands in the IR spectra.

X-ray diffraction

$C_8H_{14}N_2O_2S_2$ fw = 234.3

Triclinic, a = 7.0570(10), b = 8.071(2), c = 11.012(2) Å, α = 106.05(2)°, β = 93.41(1)°, γ = 114.93(1)°, V = 535.3(3) $Å^3$, Z = 2, ρ_c = 1.454 g cm^{-3}, μ = 4.342 mm^{-1} (23°C; CuKα_1, λ = 1.54178 Å)

Crystals of **1** were grown by very slow recrystallization from freshly distilled tetrahydrofuran at −15°C. A colorless plate having approximate dimensions of 0.20 × 0.05 × 0.15 mm was mounted on a glass fiber. All measurements were made on a Rigaku AFC6R diffractometer with graphite-monochromated CuKα radiation and a rotating anode generator.

Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 24 carefully centered reflections in the range 7.0 < 2θ < 45.0°. Based on packing considerations, a statistical analysis of intensity distribution and the successful solution and refinement of the structure, the space group was determined to be $P\bar{1}$ (no. 2).

The data were collected at a temperature of 23 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 110.1°. Scans of (1.21 + 0.30 tan θ)° were made at a speed of 32.0°/min (in ω). The weak reflections ($I < 10.0\sigma_I$) were rescanned (maximum of nine rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The diameter of the incident beam collimator was 0.5 mm and the crystal-to-detector distance was 400.0 mm.

Of the 1479 reflections that were collected, 1362 were unique (R_{int} = 0.032). The intensities of three representative reflections, which were measured after every 150 reflections, remained constant throughout data collection, indicating crystal and electronic stability (no decay correction was applied). The data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were placed geometrically and not refined. A correction was made for extinction (χ = 0.005(3) where $F^* = F[1 + 0.002\chi F^2/\sin 2\theta]^{-1/4}$) and an absorption correction was applied using the program DIFABS (56), employing transmission factors ranging from 0.69 to 1.20. Atomic scattering fac-

tors for all atoms and corrections for anomalous dispersion for C, O, N, and S were taken from the International Tables for Crystallography, Vol. C (57). Refinement minimized the function $\Sigma\omega(|F_o| - |F_c|)^2$, with $\omega = (\sigma^2F + 0.0008F^2)^{-1}$. The final solution, with $R = 4.67\%$ ($R = \Sigma(||F_o| - |F_c||)\Sigma F_o$) and $\omega R = 6.80\%$ for 1006 reflections ($I > 2\sigma_I$), showed no significant peaks in the final difference map. The goodness-of-fit was $S = 1.51$. The program SHELXTL PC was used for all calculations (58).[8]

NMR spectroscopy

Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on Varian EM 390, Bruker MSL-100, AC-200, WM-250, or AM-500 spectrometers, with the majority of experiments acquired at 500.135 MHz on the latter instrument using a 5 mm dual-frequency ^{1}H–^{13}C probe. Spectra were obtained in eight scans in 16K data points over a 5.000 kHz spectral width (1.638 s acquisition time). Sample temperature was maintained at 303 K by a Bruker BVT-1000 variable temperature unit. The free induction decay (FID) was processed using exponential multiplication (line broading: 0.2 Hz) and was zero-filled to 32K before Fourier transformation. The abbreviations s = singlet, d = doublet, t = triplet, q = quartet and m = multiplet refer to the multiplicities of the signals observed.

Broad band decoupled, natural abundance carbon-13 nuclear magnetic resonance (^{13}C NMR) spectra were recorded on a Bruker AM-500 spectrometer at 125.759 MHz using the 5 mm dual frequency ^{1}H–^{13}C probe, except in one experiment, which was acquired on a Bruker WP-80 instrument at 20.115 MHz. The spectra were acquired over a 30.0 kHz spectral width in 16K data points (0.279 s acquisition time). The ^{13}C pulse width was 2.5 μs (35° flip angle). A 0.5 s relaxation delay was used. For spectral editing, the standard *J*-modulated spin-sort pulse sequence was used, incorporating a 7.3 μs ^{13}C 90° pulse width and a relaxation delay of 2.5 s. The FIDs were processed using exponential multiplication (line broading: 3.5 Hz) and zero-filled to 32K before Fourier transformation.

NOE difference spectra were obtained by subtraction of the off-resonance control FID from the on-resonance FID under non-spinning conditions and employing a sweep rate of 19 Hz. The signal of interest was selectively saturated for 5 s and the decoupler was gated off during acquisition. This saturation period also served as the relaxation delay. Normally, eight scans were acquired for each irradiation with the cycle of irradiation repeated 10 times. Free induction decays were processed using exponential multiplication with a line broadening of 4.0 Hz before Fourier transformation. The sample was not degassed, so the enhancements are not quantitative.

The ^{13}C–^{1}H 2-D chemical shift correlation spectrum was acquired using the standard pulse sequence incorporating the BIRD pulse during the evolution period for the ^{1}H–^{1}H decoupling in F_1 (59–61). The spectra in F_2 were recorded over a spectral width of 3.76 kHz in 4K data points. The 256 FIDs in F_1 were obtained over a ^{1}H spectral width of 1.52 kHz. Each FID was acquired in 200 scans. The fixed delays in the pulse sequence were a 1.0 s relaxation delay, BIRD pulse and polarization transfer delays ($1/2\ ^1J_{CH}$) of 0.003 571 s, and a refocussing delay ($1/4\ ^1J_{CH}$) of 0.001 786 s. The ^{13}C 90° pulse width was 6.4 μs while the ^{1}H 90° pulse width through the decoupler channel was 18.6 μs. The data were processed using exponential multiplication (line broadening: 5.0 Hz) in F_2 and unshifted sine bell in F_1. Zero-filling in F_1 resulted in a 2048 × 1024 data matrix.

^{13}C DNMR spectra were recorded over a 2.066 kHz spectral width in 8K data points (1.98 s acquisition time) incorporating a 5.5 μs pulse width and a 9.0 s relaxation delay to optimize sensitivity and digital resolution. The sample and probe were allowed a 10 min equilibration period per 5°C increment. An external digital thermocouple was used to measure the probe temperature to an accuracy of ±0.5°C. Rate constants were estimated by visual fitting of experimental to computer-simulated spectra measured for a given temperature. The calculated spectra were generated on an IBM PS/2 model 30 (286) microcomputer equipped with a HP 7550A graphics plotter using the simulation program EXCHANGE (available from R.E.D. McClung, Department of Chemistry, University of Alberta, Edmonton, AB T6G 2G2, Canada). The intrinsic linewidth of 0.35 Hz was obtained from a measurement of the peak width at one-half peak height of the S-*C*H$_2$ resonance at 35.61 ppm at 25.5°C. The $\Delta G^{\ddagger}$ for disulfide rotation was calculated from the slope of the regression line derived from an Arrhenius plot of ln k versus $1/T$ in Quattro Pro (3.01). The data points corresponding to T = 298.5, 317.6, and 329.7 K were omitted from the regression analysis. The error in $\Delta G^{\ddagger}$ was measured by the standard deviation of the regression coefficient. The theoretical line was drawn by fitting the $1/T$ data series to the regression equation.

The solid state, CP-MAS ^{13}C spectrum was obtained at 25.18 MHz on a Bruker MSL-100 spectrometer operating at 2.35 T using a **1** ms contact time and a recycle time of 10 s. Crystals of **1** (0.10 g), obtained by slow evaporation of a THF solution of the compound, were pulverized and diluted with KBr prior to analysis.

The compounds analyzed via NMR were dissolved in either deuterated acetone, deuterated benzene, deuterochloroform, or deuterated dimethyl sulfoxide (CD_3COCD_3, C_6D_6, $CDCl_3$, or DMSO-d_6, respectively) obtained from MSD Isotopes. ^{1}H and ^{13}C chemical shifts are reported in parts per million (ppm) using either TMS (0.0 ppm) as an internal reference or the residual signal of the following solvents: CD_3COCD_3 (2.04; 29.8 ppm), C_6D_6 (7.15; 128.0 ppm), $CDCl_3$ (7.26; 77.0 ppm), and DMSO-d_6 (2.49; 39.5 ppm).

Molecular mechanics calculations

Steric energies and conformations were calculated and minimized in PCMODEL V4.0 (available from K. Gilbert, Serena Software, Box 3076, Bloomington, IN 47402-3076, U.S.A.) using the MMX force field derived from the MM2 force field of N.L. Allinger (available from Quantum Chemistry Pro-gram Exchange, Chemistry Department, Indiana University, Bloomington, IN 47405, U.S.A.). The calculations were performed on an IBM PS/2 model 70 (486) microcomputer. The MMX force field includes the parameters necessary for the minimization calculations. Calculated steric energies were reported relative to the global minimum structure. Vicinal coupling constants

measured from energy-minimized structures were calculated using the Altona modification of the Karplus equation, which takes into account substituent electronegativity (62).

To ensure a comprehensive search of conformational space, initial geometries were generated by either systematic or random methods (63). Systematic geometry searches were typically conducted by merging all combinations of accepted ground state geometries of the disulfide, amide, and ethyl functional groups of **1**; i.e., 90° torsional angle for the disulfide linkage, 180° (*trans*) and (or) 0° (*cis*) torsional angles for the amide groups, and a staggered configuration for the ethyl fragment. Random geometries were typically generated by either random or pseudorandom atomic variations on either minimized structures or two-dimensionally drawn images. After a crude starting geometry was produced, it was allowed to relax into an optimized geometry by the MMX force field. The search was terminated when new minima within 5 kcal/mol of the global minimum ceased be to found. Starting geometries were preminimized without hydrogen atoms and then reminimized with added hydrogens. This procedure avoids forcing hydrogens and lone electron pairs into high-energy configurations (64). Minimized structures were finally reminimized to ensure full convergence.

Shielding calculations

As a preliminary, the MMX optimized structures of **1a**, **1b**, and **1c** were modified by structural fragmentation. For example, the full structures were converted from N-CH_3 to N-H by eliminating the methyl protons and replacing the carbon by hydrogen with an N—H bond. Similarly, the other cut-down structures were generated from the three key conformations by retaining the MMX geometry, but eliminating various fragments. Heavy-atom replacements were made by hydrogen. The resulting N—H and C—H bond length were assigned values of 1.00 and 1.10 Å, respectively, but no additional changes to molecular geometry were made. The series of structures generated are listed in Tables 11 and 12. To obtain absolute chemical shifts, the structure of tetramethylsilane (TMS) was optimized with the MP2(Full)/6-31G* protocol to give r(Si—C) = 1.884 Å, r(C—H) = 1.094 Å, θ(Si-C-H) = 111.3° and θ(C-Si-C) = 109.47°.

All chemical shift evaluations were performed as single-point calculations on the original and modified structures using the Gaussian-94 series of programs (65). Becke's nonlocal density functional theory (DFT) (66, 67) was combined with two standard basis sets to generate the wave functions, Becke3LYP/3-31G* and Becke3LYP/6-31G*. Each calcula-

tion was followed with a Gauge-Independent Atomic Orbital (GIAO) (68) evaluation. The resulting isotropic magnetic shieldings are presented in Tables 11 and 12.

2-(Triphenylmethyl)thioacetic acid (2)

This synthesis was performed according to the method of Brenner et al. (12). A solution of triphenylmethanol (48.0 g, 184.0 mmol), mercaptoacetic acid (12.2 mL, 184.0 mmol), and glacial acetic acid (160 mL) was heated to 70°C. Boron trifluoride etherate (32.0 mL) was added and the resulting brown solution was stirred at room temperature for 50 min. The reaction mixture was poured into ice-cold distilled water, depositing a clear oil that solidified over 18 h at 5°C. The solid was broken and washed with distilled water, then with a small amount of diethyl ether, and was dried in vacuo to give a white solid (40.0 g, 65%). A further crop (4.3 g, 7%) was recovered from the ether washings and purified by recrystallization from toluene; mp 155.0–157.0°C (lit. (6, 12) mp 158.5–160.0°C).

***N*-Succinimido 2-(triphenylmethylthio) acetate (3)**

This synthesis was performed according to the method of Brenner et al. (12). To an ice-cooled solution of acid **2** (5.01 g, 15.00 mmol) and *N*-hydroxysuccinimide (1.72 g, 15.00 mmol) in DME (38 mL) was added DCC (3.20 g, 1.1 equiv., 15.5 mmol) such that the temperature remained at approximately 0°C. The resulting mixture was then stored at 5°C for 18 h and then filtered and washed with ice-cold CH_2Cl_2. The filtered, white crystalline solid (DCU) was collected and discarded. The combined CH_2Cl_2 filtrate and washings were pooled and concentrated in vacuo to afford a white solid. Residual amounts of DCU were removed via recrystallization from ethyl acetate to give large, opaque prisms (5.43 g, 84%); mp 178.5–180.0°C (lit. (6, 12) 178.5–179.5°C).

***N,N′*-{Dimethyl-bis[2-(triphenylmethyl)thioacetyl]}-ethylenediamine (4)**

To a stirred solution of the succinimidoyl ester **3** (1.00 g, 2.32 mmol) in acetonitrile (10 mL) was added a solution of *N,N′*-dimethylethylenediamine (120 μL, 1.1 mmol) in AN (1 mL) and NEt_3 (2 drops) under a N_2 atmosphere. After 12 h, the milky-white suspension was concentrated to 2 mL, diluted with 0.5 N HCl (100 mL), and extracted with CH_2Cl_2 (200 mL). The organic layer was backwashed with 0.5 N HCl (200 mL), with 0.5 N $NaHCO_3$ (200 mL), and dried over $MgSO_4$ for 1 h. Filtration and concentration of the filtrate in vacuo afforded a white solid (621 mg, 76%). Chromatographic purification of the resultant crude (stepwise elution: 100% CH_2Cl_2 followed by 2% MeOH in CH_2Cl_2) gave a white solid; mp 71.0–72.5°C; R_f 0.79 (10% MeOH in CH_2Cl_2); IR(KBr pellet): 3055(w) (aromatic C═C-H), 2930, 2850 (w)(aliphatic C-H); 1645(s) (C═O, amide I); 1485, 1440(s) (aromatic C═C); 1400(m), 735, 695(s) (monosubstituted aromatic C-H); ^{1}H NMR: see Table 13; ^{13}C NMR: see Table 14. MS(+ES), *m/z* (RI%): 766(4)[M + $2Na^+$], 759(3)[M + K^+], 743(7)[M + Na^+], 721(4)[M + 1], 243(100)[Tr^+].

***N,N′*-[Dimethyl-(2,2′-dithiobisacetyl)]ethylenediamine (1)**

This synthesis was a modification of the method of Kamber (16). Resublimed I_2 (848 mg, 1.1 equiv., 3.30 mmol) was added to a solution of tritylthio ether **4** (1.16 mg, 3.00 mmol) in a degassed 2:1 v/v mixture (1.5 L) of acetonitrile and absolute EtOH under a N_2 atmosphere. The amber solution was further degassed for 30 min under aspirator vacuum (15 Torr; 1 Torr = 133.3 Pa), vented to dry N_2 gas, and allowed to stir at room temperature. After 12 h, the solution was concentrated to 20 mL, diluted with doubly distilled H_2O, decolorized with 1.0 N $Na_2S_2O_3$, and extracted with diethyl ether. A white solid was seen at the solvent interface. The organic phase was decanted and, after salting the aqueous layer, the precipitate was extracted into $CHCl_3$ and dried over $MgSO_4$ for 2 h. Filtration and rotary evaporation of the filtrate afforded an off-white, semi-solid (466 mg, 66%). The residue was suspended in isopropyl alcohol, chilled at −15°C, and filtered to separate most of the insoluble trityl carbinol. Recrystallization from peroxide-free THF gave opaque, non-geometric plates; mp 139.0–140.0°C; R_f 0.49 (10% MeOH in CH_2Cl_2); IR(KBr pellet): 2930, 2853 (m)(C-H); 1629 (s) (C═O, amide I); 1458 (m); 1396 (m); Raman: 645 (m)(CH_2-S), 510 (s)(S-S); ^{1}H NMR: see Table 1; ^{13}C NMR: see Table 2; MS(+NH_3 DCI), *m/z*(RI%): 252(100)[M + 18], 235(48)[M + 1], 205(10).

Abstract: The electrochemical reduction behaviour of xylenol orange, XO, in aqueous medium was studied over a pH range of 2.3–9.6 at a hanging mercury drop electrode, HMDE, on the basis of cyclic voltammetric, and double-potential step chronoamperometric and chronocoulometric data. The experimental results indicate that in acid medium (pH 2.28) the reduction of XO proceeds via an ECEC, first-order mechanism giving a single two-electron diffusion-controlled cyclic voltammetric wave. It was concluded that the rate-determining step is the protonation of the protonated anion intermediate to the final product, with rate constant k_2 of 0.26 s^{-1}. At pH 7.25 the reduction follows an ECE kinetics along two cyclic voltammetric waves in which the first wave was attributed to an EC, first-order process and the second wave to an irreversible electron transfer step, E. On addition of lanthanum(III) to xylenol orange, it forms 1:1 and 1.2 La(III)–XO chelates, which are adsorbed and reduced on the HMDE at more negative potentials than the peak potential of free XO. The adsorptive cathodic stripping voltammetry, ACSV, of these chelates was studied using the square-wave, SW, method. It was found that the SW-ACSV of La(III)–XO can be applied to the determination of lanthanum at the nanomole level. Optimum conditions and the analytical method of determination were presented and discussed.

Key words: electrochemical, reduction mechanism, xylenol orange, lanthanum complex, double potential step chronoamperometry and chronocoulometry, stripping voltammetric determination.

Résumé : En se basant sur des données de voltampérométrie cyclique, de chronoampérométrie à double potentiel et de chronocoulométrie, on a étudié le comportement du xylénol orange, XO, lors de sa réduction électrochimique en solution aqueuse, à des pH allant de 2,3 à 9,6, par une électrode de mercure à goutte tombante, EMGT. Les données expérimentales indiquent que, en milieu acide (pH de 2,28), la réduction du XO se produit par le biais d'un mécanisme ECEC du premier ordre conduisant à une seule vague de voltampérométrie cyclique à deux électrons, contrôlée par la diffusion. On en conclut que l'étape qui détermine la vitesse de la réaction correspond à la protonation de l'anion intermédiaire protoné conduisant au produit final avec une constante de vitesse k_2 de 0.26 s^{-1}. À un pH de 7,25, la réduction suit une cinétique ECE le long de deux vagues de voltampérométrie cyclique dans lesquelles la première peut être attribuée à un processus EC du premier ordre et la deuxième à l'étape de transfert irréversible de l'électron, E. Par addition de lanthane(III) au xylénol orange, il se forme des chélates 1 : 1 et 1 : 2 de La(III)–XO qui sont adsorbés et réduits sur l'EMGT à des potentiels plus négatifs que celui du potentiel maximal de XO libre. On a étudié ces chélates par la voltampérométrie absorbante avec redissolution cathodique (VARC), en faisant appel à la méthode de l'onde carrée (OC). On a trouvé que l'on peut appliquer la technique de la VARC-OC à la détermination du lanthane au niveau de la nanomole. On présente et on discute des conditions optimales et de la détermination de la méthode analytique.

Mots clés : électrochimie, mécanisme de réduction, xylénol orange, complexe du lanthane, chronoampérométrie et chronocoulométrie avec étape à double potentiel, analyse par voltampérométrie avec redissolution.

Introduction

The rare earth elements are important components of some special technological and metallurgical materials. In general, analyses of small amounts of metals by means of voltammetric methods are easy to perform. Unfortunately, most of rare earth ions except Eu, Sm, and Yb are not reducible at the mercury electrode in aqueous solutions. On the other hand, several dyes and organic reagents that are reducible at the mercury electrode can be used as complexing ligands in which they form adsorptive complexes with the rare earths (2–7). For example, it was found previously that the phenolphthalein dyes, *o*-cresolphthalexon (5, 7) and thymolphthalexon (6), form adsorptive complexes with the rare earths. The adsorptive waves can then be used for the determination of trace rare earth contents in ores.

The electrochemical behaviour of xylenol orange is important due to its use as a metallochromic indicator (8) in the electrochemical microdetermination of europium in plants (9), in electrocatalysis of nitrite and nitric oxide reduction (10), and in adsorptive cathodic stripping voltammetry of lead in sea water (11). The kinetics of the electrochemical reduction of xylenol orange and the redox behaviour of its lanthanum(III) complex will be studied here. The applicability of square-wave cathodic adsorptive stripping voltammetry at the hanging mercury drop electrode, HMDE, for direct micro determination of La(III) will be tested.

In previous paper the electrochemical reduction mechanism of one of sulphonephthaleins, catechol violet, was studied (1). It shows a single diffusion-controlled two-electron cyclic voltammetric wave at lower pH (<7) and the reduction pathway follows an ECEC, first-order kinetics. At higher pH, two diffusion-controlled monoelectronic cv waves were seen and the reduction proceeds via an EEC, first-order process.

One objective of the present electrochemical investigation was to ascertain the kinetics of the reduction of another sulphonephthalein, xylenol orange, in aqueous solutions at the hanging mercury drop electrode. The study was performed utilizing a variety of electrochemical techniques including cyclic voltammetry, and double-potential step chronoamperometry and chronocoulometry. The second objective was to study the redox behaviour of a xylenol orange – lanthanum(III) complex. Finally, the study was extended to include the adsorptive cathodic stripping voltammetry, ACSV, of the La(III) complex using the square-wave, SW, voltammetric method. It was intended to lower the lanthanum detection limit to nanomole levels. The SW-ACSV method appears to combine the best features of the two methods. It was demonstrated that SW-ACSV gives a response 6 times greater than other stripping methods (12). It offers a method having a short analysis time and, in addition, surpasses the other pulse techniques in sensitivity and discrimination against the charging current background. Its utility has been demonstrated experimentally in conjunction with the stationary mercury drop electrode (13).

Experimental

Reagents and solutions

Rare earth nitrates of Y, La, interfering metal nitrates, anion salts, and xylenol orange sodium salt of analytical grade purity were used. Stock solutions of 5.0 mM in triply distilled water were prepared for the metal ions, anions, and XO and were diluted as required for standard solutions. The rare earth solutions were standardized chelatometrically. Britton–Robinson and acetic acid – sodium acetate buffer solutions were prepared from analytical grade chemicals.

Instrumentation

The cell and the instruments used for cyclic and square-wave voltammetry (SWV), chronoamperometry, and chronocoulometry have been described elsewhere (1). For all experiments, an Ag/Ag^+ electrode was used as the reference electrode. The HMDE in medium hanging drop mode was used throughout. The electrode area was 1.18×10^{-4} cm^2. For square-wave experiments, La(III)–XO complex characterization, calibration, and determination of La(III) measurements, the electrochemical analyzer was operated at a square-wave frequency, f, of 200 Hz since, as previously shown (14), the maximum sensitivity in SWV should be obtained for a maximum value of τ corresponding to a frequency of 200 Hz, and square-wave amplitude of 25 mV.

Procedure

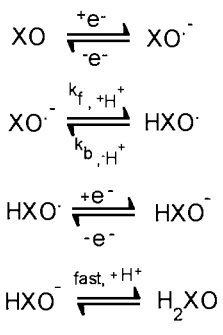
All measurements were obtained at 298 ± 0.1 K. The general procedure used to produce square-wave adsorptive stripping voltammograms was as follows: A 10 cm^3 analyte solution in 20 mM acetic acid – sodium acetate/0.1 mol dm^{-3} sodium perchlorate solution was used. Solutions were deaerated by purging with pure nitrogen. After formation of a new HMDE drop at a deposition potential of –0.30 V, the solution was stirred for 60 s (accumulation time) and equilibrated for 10 s. A negative potential scan was recorded using the square-wave mode.

Results and discussion

1. Xylenol orange, XO

Xylenol orange, 3,3′-bis(*N*,*N*-bis(carboxymethyl)amino)-methyl-*o*-cresol sulphonephthalein, has the structural formula shown in Scheme 1 and is abbreviated as XO or H_6 XO.

1a. Cyclic voltammetry



Cyclic voltammetric behaviour of XO was studied in aqueous Britton–Robinson buffer solutions at different pH's. The cyclic voltammogram of 1.0×10^{-3} mol dm^{-3} XO shows a single cathodic cv wave with a peak potential at –0.443 V versus Ag/Ag^+ at pH 2.28 and scan rate of 50 mV/s. No evidence of reversibility is noticed as indicated by the lack of an anodic partner corresponding to the oxidation of the product of reduction on reversing the potential. Since xylenol orange has the same reducible center as catechol violet, it is expected that the number of electrons and protons participating in the reduction process at lower pHs is two (1, 15, 16). The cv wave splits into two waves, each corresponding to one electron, in which the first one shifts to more negative potentials while the second does not change on increasing the pH of the solution (>2.3). This reveals that hydrogen ions participate in the reduction process along the first wave, whereas in the second one they do not. On plotting the peak potential, E_p, against the pH, two linear segments are obtained in the pH range 2.3 – 9.6. They are represented by the following linear least-square equations for the first cv wave:

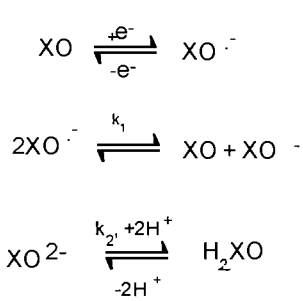
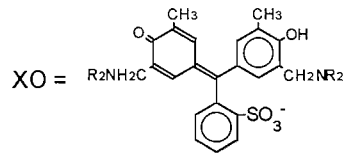
(b) ECEC, radical - radical dimerization



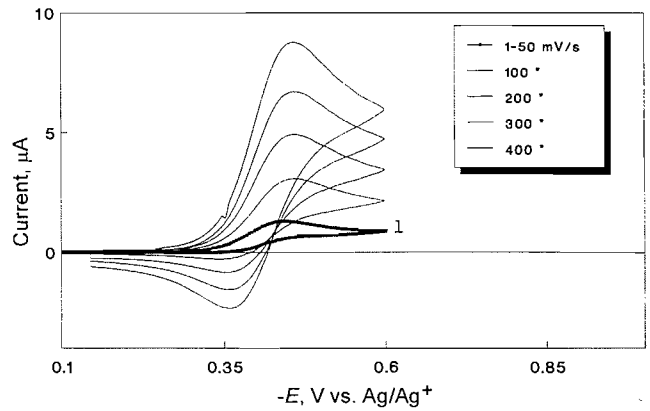
(c) ECEC, parent - radical dimerization



(d) ECEC, first order

(e) ECC, disproportionation

R=CH_2COOH



[1] $E_p = -0.330 - 0.959$ pH, $r = 0.994$

[2] $E_p = -0.151 - 0.086$ pH, $r = 0.995$

The two segments intercept at pH 6.7, which may correspond to dissociation of the -OH group. The number of protons involved during the first reduction step is calculated to be one from the relationship $S = (m/n) \times 59$ mV (at 298 K) (17) where S is the slope of E_p vs. pH, m is the number of protons, and n is the number of electrons.

At pH 2.28, xylenol orange exhibits a single irreversible cv wave at lower scan rates ($\nu = 50$ mV/s). On increasing the scan rate, the cv wave tends to be reversible (cf. Fig. 1). The anodic counterpart develops the peak current ratio, i_{pa}/i_{pc}, estimated according to Nicholson and Shain (18), increases with increasing scan rate and reaches unity at $\nu = 5.0$ V/s. Furthermore, the peak current, i_p, depends on the square root of the scan rate, $\nu^{1/2}$, with a correlation coefficient of 0.998. On increasing the scan rate, the peak potential does shift to more negative values, the current function, $i_p/\nu^{1/2}$, decreases, and the peak width, $E_p - E_{p/2}$, increases. These data suggest that the reduction of xylenol orange at pH 2.28 proceeds via a two-electron diffusion-controlled cv wave following an ECE mechanism in which the

Fig. 1. Cyclic voltammograms for the reduction of 1.0 mM xylenol orange on HMDE at pH 2.28 aqueous Britton–Robinson buffer solution at different scan rates.

difference between the standard electrode potentials for the two electron transfer steps, ΔE, equals 0 (18).

On the other hand, at higher pH's, the voltammograms of XO show two mono-electronic irreversible cv waves. At pH 7.25, the peak potentials of the two waves shift cathodically by

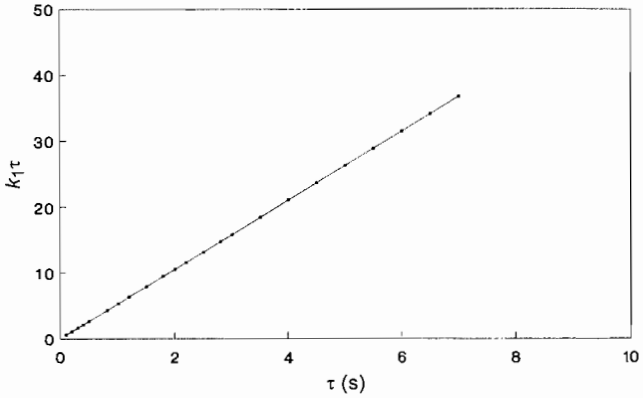
40.0 and 29.4 mV per decade for the first and second waves, respectively, on increasing the scan rate. Furthermore, the peak currents correlated with the square root of the scan rate (r = 0.996 and 0.999 for the first and second waves, respectively). The current function for the first wave decreases while for the second one it more or less has a constant value of 0.5 on increasing the scan rate. Thus, these findings lead to an initial suggestion that the electrochemical reduction of xylenol orange at higher pH's follows an EC mechanism for the first wave and an irreversible electron transfer process for the second (18). The overall kinetics of the reduction process is ECE.

1b. Chronoamperometry and chronocoulometry

Two basic electrochemical approaches were used for the investigation of the electrode mechanism, one-step and two-step methods. The one-step method, for example, includes the analysis of peak shape, potential, and current variations of the cyclic voltammetric waves. Unfortunately, the one-step methods are used in qualitative measurements and are subject to several limitations. The two-step methods, on the other hand, are more generally applicable for quantitative electrode mechanism studies. The two-step methods used herein are double-potential step chronoamperometry and chronocoulometry. In the first step of electrolysis, the potential is stepped to a value where the cathodic current is determined solely by diffusion of the subject ions to the electrode. Then at some switching time, τ, the potential is suddenly returned to the initial value. The resulting anodic current, which is determined by the diffusion-controlled reoxidation of the reduced form generated, gives a measure of the unreacted subject molecules.



At lower pH's (pH 2.28) the electrode potential is stepped from –0.1 V, at which no faradaic current flows, to –0.45 V, sufficiently cathodic, to the cyclic voltammetric peak potential. Then at variable switching duration times, τ, the potential is suddenly returned to the initial potential value of –0.1 V. The cathodic chronoamperograms and chronocoulograms are analysed using eqs. [3] and [4], respectively, where (i)(t) and

$$[3] \quad i(t < \tau) = \frac{nFAD^{1/2}C^*}{(\pi t)^{1/2}}$$

$$[4] \quad Q(t < \tau) = 2nFAD^{1/2}C^* \left[\frac{t}{\pi}\right]^{1/2}$$

$Q(t)$ are the current and charge, respectively, that have passed at time t since the application of the potential step, C^* and D^* are the concentration and diffusion coefficient of the substrate, respectively, A is the surface area of the electrode, and n and F have their usual significance. According to the Cottrell equation, eq. [3], the diffusion coefficient of xylenol orange is determined (a) from the slope of the ic vs. $t^{-1/2}$ plot or (b) from the linear least-squares intercept of $it^{1/2}$ vs. $t^{-1/2}$ plots. It has been reported that chronoamperometric data obtained at short times are often unreliable and that such data cannot be used for accurate determinations (19); thus, long-duration time experiments were used. Linear dependence was obtained for the ic and $it^{1/2}$ vs. $t^{-1/2}$ plots, with correlation coefficients of 0.999 for the entire range of duration times (1.0 – 7.5 s). This is indicative of the diffusion-controlled nature of the electrochemical reduction of the subject substrate. The diffusion coefficient of

Fig. 2. $k_1\tau$ vs. τ relationship for the ECEC, first-order mechanism for the reduction of xylenol orange at pH = 2.28.

XO was calculated and found to be (1.02 ± 0.02) × 10^{-6} cm^2/s. On analysing the chronocoulograms using eq. [4], it is seen that the charge, $Q(t < \tau)$, has a direct proportionality to the square root of time, $t^{1/2}$. Linear least-squares fits were obtained with a correlation coefficient of 0.999 for different duration times. This is in agreement with chronoamperometric results showing that the cathodic current for the subject compound at such conditions is controlled by diffusion. Moreover, the diffusion coefficient of XO was calculated to be (1.10 ± 0.04) × 10^{-6} cm^2/s. This value agrees well with those calculated above.

Analysis of the chronocoulometric data, the cathodic–anodic chronocoulograms, involves the measure of the charge ratio, Q_r, for a series of different duration times. The double-potential step chronocoulometric results were fitted using the theoretical working curves developed by Hanafey et al. (20) for various mechanisms, in an attempt to find a satisfactory match. The first few points of data arising from the double layer charging current were ignored. Different electrode reaction mechanisms, in addition to the ECE process, were considered as possible pathways for the electrochemical reduction of XO in such circumstances (cf. Scheme 1). These include ECEC, radical–radical dimerization; ECEC, parent–radical dimerization; ECEC, first–order; and ECC disproportionation. It is reasonable to exclude the dimerization and disproportionation pathways, since the resultant radical anion intermediate and the parent substrate are very bulky and sterically hindered species. Furthermore, it is found that he experimental results satisfactorily fit the theoretical working curves for the ECEC first-order mechanism with k_2/k_1 = 0.05. So the ECEC first-order pathway is likely the mechanism for the electrochemical reduction of xylenol orange. The rate-determining step is concluded to be the protonation of the protonated anion intermediate to the final product, with a rate constant of k_2. These results are similar to the electrochemical reduction mechanism of catechol violet studied elsewhere (1), since they have the same reducible center.

On plotting the values of $k_1\tau$, the kinetic parameter obtained from the matched experimental data plots of Q_r vs. log $k_1\tau$, as function of τ, the value of k_1 is estimated directly from the slope. Linear least-squares plots passing through the origin are obtained with correlation coefficients of 1.0. A typical plot is presented in Fig. 2. The rate constant k_1 obtained is found to be

Scheme 2.

At pH 7.25:
First cv wave:

(a) EC, first order

$$XO \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} XO^{\cdot -}$$

$$XO^{\cdot -} \underset{k_b,\ -H^+}{\overset{k_f,\ +H^+}{\rightleftharpoons}} HXO^{\cdot}$$

(b) EC, radical - radical dimerization

$$XO \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} XO^{\cdot -}$$

$$2XO^{\cdot -} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} {}^{\cdot}XO\text{-}XO^{\cdot -}$$

(c) EC, parent - radical dimerization

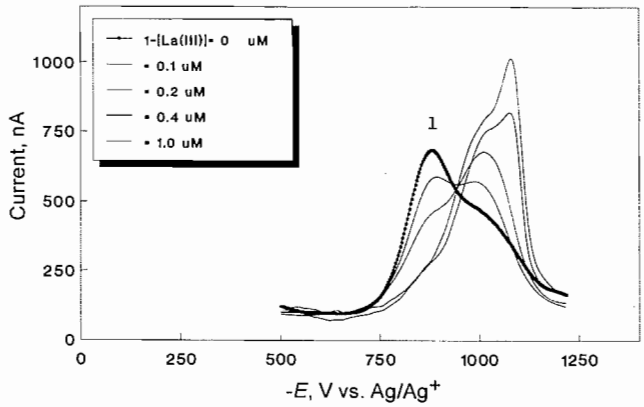
$$XO \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} XO^{\cdot -}$$

$$XO + XO^{\cdot -} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} {}^{\cdot}XO\text{-}XO^{\cdot -}$$

Second cv wave:

E, slow electron transfer

$$HXO^{\cdot} \xrightarrow{+e^-} HXO^-$$



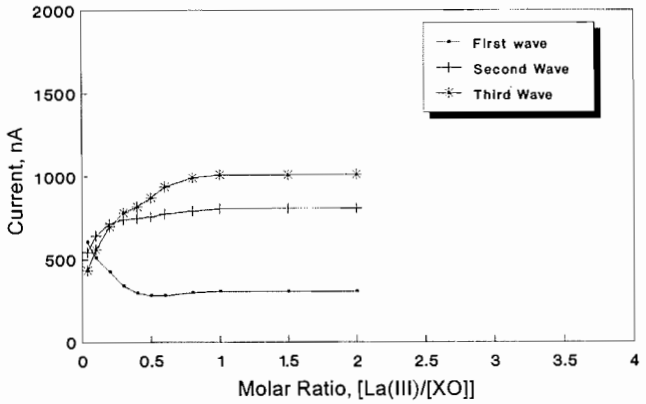
$$HXO^{\cdot} \underset{+H^+}{\overset{\text{fast},\ +H^+}{\rightleftharpoons}} H_2XO$$

$5.25 \pm 0.01\ s^{-1}$. The rate constant k_2 for the second protonation step is calculated to be $0.26 \pm 0.003\ s^{-1}$.

At higher pH's (7.25), the electrode potential was stepped from E_1 to E_2 to E_1 in which $E_1 = -0.60$ and $E_2 = -0.80$ V for the first wave. The cathodic chronoamperograms were analysed according to Cottrell equation. On plotting ic or $ict^{1/2}$ against $t^{-1/2}$, linear dependences with correlation coefficients of 0.999 were obtained. This reveals that the electrochemical reduction of XO at pH 7.25 is a diffusion-controlled process. Similar correlations were obtained on analysis of the chronocoulograms. The values of the diffusion coefficient of XO were determined and the average value is $(1.11 \pm 0.02) \times 10^{-6}\ cm^2/s$. This value is consistent with the value obtained at pH 2.28.

On matching the experimental charge ratio plots, Q_r vs. log τ with the theoretical working curves of Hanafey et al. (20), considering different possible electrode reaction pathways, it was found that the reduction of xylenol orange follows EC kinetics. These pathways are EC, first-order; EC, radical–radical dimerization; and EC, parent–radical dimerization (cf. Scheme 2). As stated before, the dimerization pathways are excluded. It was concluded that a good fit is obtained with the experimental data for the EC first-order mechanism in which $k_f/k_b = 0.01$. The first-order rate constant, k_f, was estimated following the method mentioned above. It was found to be 30.45 $\pm$ 0.04 s^{-1}. The rate constant, k_b, was calculated to be $0.30 \pm 0.02\ s^{-1}$. Thus the electrochemical reduction of XO at pH 7.25 in the entire range of potential for the first wave follows the EC first-order kinetics. The mechanism at higher pH's is ECE.

Fig. 3. Square-wave voltammograms of 1.0 μM xylenol orange containing different concentrations of lanthanum(III), in 20 mM acetic acid – acetate/0.1 M $NaClO_4$ buffer solution, pH 6.05, preconcentration time 60 s, frequency 200 Hz.



2. Lanthanum(III) – xylenol orange

Cyclic and square-wave voltammograms of 1.0×10^{-6} mol dm^{-3} xylenol orange mixed with concentrations of lanthanum(III) varying from 0 to 3.0 molar ratio, La(III)–XO, in 0.1 mol dm^{-3} acetate/0.1 mol dm^{-3} sodium perchlorate aqueous solution at pH 6.05, show three irreversible reduction waves in the entire voltage sweep, –0.1 to –1.4 V. These waves are located at peak potentials of –0.886, –1.015, and –1.077 v. The first wave attributed to the reduction of the uncomplexed XO, since it is located at the peak potential of free XO. The two more negative waves are due to the reduction of the La(III)–XO complexes, since the reduction wave of XO is shifted to more negative potentials on complexation with La(III). An enhancement of the voltammetric response is achieved after adsorption of the electroactive species on the HMDE on stirring the solution mixture. The SW-ADSV behaviour of La(III)–XO is presented in Fig. 3. It is worth emphasizing that the adsorbed complexes of La(III)–XO have the same peak potentials as those obtained in solution. On addition of La(III) to XO, a spontaneous colour, a decrease in the peak current of the XO reduction wave, and the development of a second wave at more negative potentials were observed. Thus the reaction between XO and La(III) is rapid. Increasing the concentration of La(III) shows a further decrease in the first wave and growth of the second. At molar ratios higher than 0.3, the third wave tends to develop. The third wave grows with further increase in the molar ratio of La(III). The composition of the metal complexes was determined by plotting the peak current versus molar ratio, [M]:[L] (21–23). The results are presented in Fig. 4. It is seen that the peak current for free XO, the first wave, decreases on increasing the mole ratio of La(III), reaching a more or less constant value at the 0.5 mole ratio. This is indicative of formation of a complex with a composition of 1:2, La(III):XO, under such conditions. Some authors (24–26) have reported the formation of 1:2 complexes with methyl thymol blue, which has a similar sulphonephthalein

Fig. 4. Variation of peak current with mole ratio of La(III) for La–XO system at the conditions cited in Fig. 3 for the three waves.

structure. On the other hand, for the second wave, the peak current increases on increasing the mole ratio [La(III)]/[XO] and levels off at a molar ratio of 1.0. The graph has two breaks at molar ratios of 0.5 and 1.0, which are due to the change of the composition of the reducible species. This reveals the formation of two types of complexes of 1:2 and 1:1 composition (La(III):XO). Moreover, from the i_p vs. [La(III)]/[XO] relationship, at the third wave, it is evident that La(III) forms complexes with XO with a stoichiometric ratio of 1:2 and 1:1 (La–XO). This supports the composition suggested from the data at the first and the second waves.

Xylenol orange has two 3-bis[*N*,*N*-bis(carboxymethyl)amino] methyl chelating groups on each side of the large sulphonephthalein molecule. It was reported that each chelating group reacts with metal ions independently (27). Thus, the donor atoms in the XO molecule are two carboxylic oxygens, a quinoyl oxygen, and a tertiary nitrogen. At the given pH, 6.05, the carboxylic groups dissociate and coordinate to the La(III) ion. The colour, and the cyclic and square-wave voltammetry corresponding to the complexes are quite different from those of the free XO. This suggests that the quinoyl oxygen is the other ligating site, since it is the electroactive center (28). At this pH, the tertiary nitrogen is protonated and is not involved in the coordination. Thus, XO behaves as a terdentate ligand and the lanthanum ion is hexa-coordinated to xylenol orange in the 1:2 (La–XO) chelates, thus using fully the three ligating sites. In 1:1 chelates, the metal ion tri-coordinates the subject ligand through its ligating sites and completes its hexa-coordination with three water molecules (29).

The peak potential for the reduction of adsorbed La–XO chelate does shift to more negative values on increasing the pH. It is evident from the dependence of E_p on pH that the maximum separation between the E_p of XO and La(III)–XO exists at pH 6.05. The peak current of La(III)–XO depends on the concentration of acetate, preconcentration time, and accumulation potential. The effect of these parameters was tested in order to optimize the conditions for the determination of lanthanum. The peak current of La(III)–XO decreases with increasing concentration of acetate. This is presumably due to the competitive complexation of La(III). The recommended buffer concentration of acetate is 20 mM. The adsorption peak for La(III)–XO is found to be dependent on the adsorption time. It grows with time to a limiting value and then levels off. From the data obtained, it is evident that the optimum preconcentration time is 60 s. The effect of accumulation potential on the height of the La(III)–XO adsorptive peak was investigated and it is revealed that the optimum accumulation potential is –0.30 V.

3. Characterization of adsorbed La(III)–XO

It was demonstrated that double-potential step chronocoulometry provides a useful method for the quantitative characterization of an adsorption process independent of both the relative reduction potentials of the diffusing and adsorbed species and the kinetics of their electrode reactions (30). On considering that only La–XO is adsorbed on the electrode surface, additional terms must be added to eq. [4] for the cathodic response.

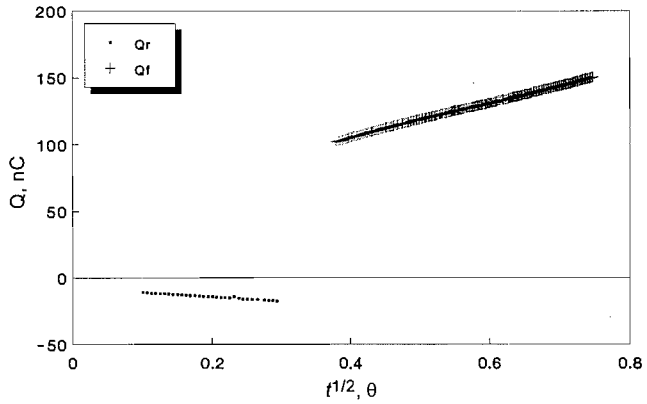
$$[5]\quad Q_f(t<\tau) = 2nFAD^{1/2}C^*\left[\frac{t}{\pi}\right]^{1/2} + nFA\Gamma_0 + Q_{dl}$$

where Γ_0 is the amount of the adsorbed reactant in mol/cm^2 and Q_{dl} is the charge consumed by the electrode – electrolyte double layer when the potential is changed from its initial to its final value. The terms on the right-hand side represent the contribution of dissolved, adsorbed, and double-layer charging, respectively. For the anodic response, according to the approximation of Christie et al. (31), the charge is given by the following equation:

$$[6]\quad Q_r(t>\tau) = 2nFAD^{1/2}C^*\left[\frac{1}{\pi}\right]^{1/2}\left[1+\frac{a_1nAFT_0}{Q_c}\right]\theta + a_0nFA\Gamma_0 + Q_{dl}$$

where $\theta = \tau^{1/2} + (t-\tau)^{1/2} - t^{1/2}$, Q_c is the total charge arising from the diffusing species during the forward step, and a_0 and a_1 are usually assumed to be –0.069 and –0.97, respectively.

On considering the quantity of change removed in the reversal step, $Q_r(t>\tau)$, which experimentally is the difference $Q(\tau) - Q(t>\tau)$, the anodic response is



$$[7]\quad Q_r(t>\tau) = 2nFAD^{1/2}C^*\left[\frac{1}{\pi}\right]^{1/2}\theta + Q_{dl}$$

The plot of $Q_r(t>\tau)$ versus θ should be linear with an intercept of Q_{dl}.

Chrononcoulometric data for a 1.0×10^{-6} mol dm^{-3} 1:1 La(III)–XO complex at pH 6.05 were obtained on stepping the electrode potential from –0.7 to –0.95 V and then returning it to its initial value (–0.70 V). The data were analysed according to eqs. [5] and [7], cf. Fig. 5. On plotting $Q_f(t<\tau)$ vs. $t^{1/2}$ and $Q_r(t>\tau)$ vs. θ, good straight lines were obtained with regression coefficients of 0.997 and 0.998, respectively. They have different slopes and intersect each other above, rather than on, the t-axis. This demonstrates the adsorption of the La(III)–XO chelate on the electrode surface. From the slope of the $Q_f(t<\tau)$ vs. $t^{1/2}$ plot, the diffusion coefficient of the chelate was calculated to be $(2.33 \pm 0.06) \times 10^{-7}$ cm^2/s which is lower than that of XO. The amount of adsorbed complex, the surface excess Γ_0, is determined from the difference between the intercepts of the two lines in Fig. 5, which is simply $nFA\Gamma_0$. This difference cancels Q_{dl} and leaves only a net faradaic

Fig. 5. Double-potential step chronocoulometric dependence of Q_f on $t^{1/2}$ and Q_r on θ for La–XO chelate.

charge due to adsorbate. The double layer charge is determined from the intercept according to eq. [7] to be 5.77 ± 0.5 *nC*.

4. Analytical determination of La(III)

According to the above-mentioned results, the optimum conditions for the analytical determination of La(III) by SW-ASCV at HMDE are as follows: pH 6.05, accumulation time 60 s, accumulation potential –0.30 V, SW height 25 mV, frequency 200 Hz, and the presence of 1.0×10^{-6} mol dm^{-3} xylenol orange. Under these conditions, the response of the peak current as a function of La(III) concentration is linear over the range 100.0 – 500 nM dm^{-3} La(III) at the three peak potentials, E_p, of –0.886, –1.0125, and –1.077 V. For concentrations beyond the above range, the calibration curve is no longer linear. However, higher La concentrations can be adjusted by dilution to bring them within the recommended concentration range or, alternatively, shorter deposition times may be used. Using standard La(III) solution, the method gave linear calibration curves. The slopes of the calibration lines obtained (sensitivity) with correlation coefficients of 0.994, 0.999, and 0.997, respectively, were 1.13, 1.18, and 1.39 nA/nM/60 s, for the three waves. The detection limit (DL) was estimated by sue of signal-to-noise ratio, r_d = 3, pooled standard deviation, *S*, and the slopes of calibration, *b*, from the formula DL = $r_d S/b$. It was found to be 1.06, 1.02, and 0.86 nM, respectively, for the first, second, and third waves.

The interference of a number of cations and anions was tested in the determination of La(III) using 1.0 nM xylenol orange with 0.1 nM La(III), with addition of various metal ions. It was found that electrochemically inactive ions such as Na^+, K^+, Ca^{2+}, as well as most commonly occuring anions, do not interfere with the determination of lanthanum. Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Pb(II), and Cd(II) do not interfere at the 0.5 mM dm^{-3} level. They form adsorbed complexes with XO under such conditions and are reduced at a lower potential than that for the reduction of the La(III)–XO complex. On the other hand, addition of Y(III) and Ce(III) shows peaks overlapping with those for La(III)–XO. Thus Y(III) and Ce(III) interfere and the peak current for La(III) decreases due to adsorption competition.

Abstract: Oligo-tridentate ligands based on alternating pyridines and pyrimidines were synthesised by Stille-type carbon–carbon bond-forming reactions. The terpyridine-like sites are designed to coalign upon metal complexation, giving rise to organized and rigidly spaced metal ions. Peripheral functionalization of the basic bis-tridentate framework was explored. The heterocycles in the ligands are in an all-*trans* conformation about the interannular bonds as indicated by comparison of their ^{1}H NMR spectra. An X-ray crystal structure analysis of the nonchiral tris-tridentate ligand **2***a* reveals a helical structure in the solid state. The seven heterocycles form a helical structure with resulting overlap of the terminal pyridines. Their centroid-to-centroid distance is 4.523 Å with 38.8° between the planes. NMR investigations support a helical conformation in solution as well. Electrochemical and UV absorption measurements indicate that the LUMO resides on the pyrimidine moiety of the ligands.

Key words: nitrogen-containing ligands, Stille coupling, helical structure, supramolecular chemistry.

Résumé : Nous avons développé une route synthétique pour la synthèse de ligands oligo-tridentates basée sur le couplage carbone–carbone de Stille. La disposition des sites tridentates a été conçue en vue de la complexation d'ions métalliques de façon colinéaire. La structure de base a été fonctionalisée de manière à construire des systèmes plus étendus. La structure rayons-X du ligand tris-tridentate **2***a* révèle sa forme hélicoidale. Les groupes pyridine terminaux s'empilent l'un sur l'autre à une distance centre–centre de 4.523 Å avec un angle de 38.8° entre les planes. Le spectre de RMN du proton est en accord avec l'existence de la forme hélicoidale aussi en solution. Les études d'électrochimie et d'absorption d'UV indiquent que la plus basse orbitale inoccupée est localisée principalement sur le groupe pyrimidine.

Mots clés : ligands azoté hétérocycliques, couplage Stille, structure hélicoidale, chimie supramoléculaire.

Introduction

Recent work that exploits hydrogen-bonding (1–3), metal–ligand (4, 5), and cation–π (6) interactions has demonstrated that information stored into molecular components may be read out by various non-covalent interactions to bring about a desired structure (7). Functional supramolecular structures are of current interest for the development of molecular-level devices (8, 9). Interesting structures exploiting metal–ligand interactions based on commercially available compounds have been constructed; however, most contain infinite lattices and some only exist in the solid state (10, 11). Increasingly, chemists must look to more and more complex components to assemble structures presenting desired properties. Molecular components with repeating sub-units simplify the overall synthesis of relatively complex target molecules (12) and this approach has been exploited here to synthesize oligo-tridentate ligands capable of binding metal ions in a predetermined arrangement (13).

We sought to develop models for information storage based on coordination *arrays*, multimetallic complexes of precise nuclearity and geometry, in particular inorganic architectures of two-dimensional geometries and $[m \times n]$ nuclearity. The basic geometries may be termed *racks* [*n*]R, *ladders* [2*n*]L, and *grids* $[m \times n]$G (Fig. 1), where the nuclearity of the R, L, and G species is given by [*n*], [2*n*], and $[m \times n]$, in sequence of increasing complexity. In addition to serving as centres for ligand binding and positioning, metal ions also introduce a range of electrochemical, photochemical, and reactional properties.

The metal-directed self-assembly of molecules of rack, ladder, and grid type requires judicious choice of metal and binding site. Transition metal ions with octahedral coordination geometry are expected to cover a wider range of elements and properties than ladder- (14) and grid-type (15) complexes with tetrahedral metal ions. The two ligand moieties, therefore, must be tridentate to maintain an orthogonal disposition about an octahedral metal ion (16). Terpyridine (tpy) forms stable complexes with a wide variety of octahedral metals (17) and is a well-suited tridentate motif. It also sustains a variety of oxidative and reductive conditions (18, 19), and has accessible π* orbitals (20).

Linking tpy's together in the 4, 3′ positions as depicted in Fig. 2*a* would produce a ligand strand where the individual tpy

sub-units may not coalign properly in the complex due to rotation about the interannular bonds. To enforce alignment and to promote metal–metal interaction (21), a condensed-ring structure was chosen by using bridging pyrimidines (Fig. 2*b*). The synthesis and characterization of the bis-tridentate (**1***a–f*) and tris-tridentate ligands (**2***a–c*) based on pyridine and pyrimidine is presented in the present work.

Experimental

2,2′-Bipyridine-*N*-oxide (22), 6-chloro-2,2′-bipyridine (23), 2-tributylstannylpyridine (24), 2-bromo-5-methylpyridine (25), and 4,6-dichloro-2-phenylpyrimidine (26) were prepared as described. Materials were obtained from commercial suppliers and used without further purification. Dimethylformamide (DMF) was purchased anhydrous from Aldrich Chemical Company. Diethyl ether (ether) and tetrahydrofuran (THF) were distilled under argon from sodium–benzophenone immediately prior to use in lithiation reactions. Dichloromethane (DCM) was dried over CaH_2. Organic extracts were dried over $MgSO_4$. Chromatography was carried out on Merck 60 silica gel (0.040–0.063 mm), Merck, activity II-III, alumina (0.063–0.200 mm). ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded at 200 and 50 MHz, respectively, on a Bruker AC 200 spectrometer in $CDCl_3$. ^1H NMR spectra were also recorded at 400 MHz on a Bruker AM 400 spectrometer in $CDCl_3$ where indicated. The chemical shifts were calibrated to the residual solvent peak. Melting points were measured on a digital Thomas–Hoover (Electrotherma) apparatus. Infrared absorption spectra were measured on a Perkin Elmer 1600 series FTIR spectrometer as KBr disks. Electronic absorption spectra were measured on a Cary 219 spectrometer in DCM, with λ_{max} in nm and 10^{-4} ε/dm^3 mol^{-1} cm^{-1}. Cyclic voltammograms were measured using a EDT potentiostat/galvanostat

with a Tacussel IG5-LN integrator and IFELEC-IF 3802 recorder: the working electrode was a platinum disc, the auxiliary electrode was a coiled platinum wire, and the reference electrode was a SCE.

Preparation of 6-bromo-2,2′-bipyridine (*6a*)

(i) Via 6-chloro-2,2′-bipyridine (5)

To 6-chloro-2,2′-bipyridine **5** (2.00 g, 10.5 mmol) was added phosphorous tribromide (50 mL) and the reaction mixture was stirred at 165°C for 5 h. The reaction mixture was cooled to room temperature, poured on crushed ice, carefully basicified with ammonia to basic pH (**Caution:** *exothermic reaction, continuous addition of crushed ice required*), and extracted with ether (4 × 50 mL). The combined organic phases were dried and evaporated. The black residue was extracted with pentane (2 × 100 mL) and the pentane was evaporated. The resulting pale, yellow solid was sublimed (0.75 Torr (1 Torr = 133.3 Pa), 75°C) giving **6***a* (2.30 g, 93%) as a white solid.

(ii) Via 2,6-dibromopyridine (9)

To 2-(tributylstannyl)pyridine **8***a* (43.0 g, 0.117 mol), 2,6-dibromopyridine **9** (48.0 g, 0.205 mol), and tetrakis(triphenylphosphine)palladium ($Pd(PPh_3)_4$) (1.86 g, 1.4 mol%) was added THF (100 mL) and the reaction mixture was stirred at reflux for 72 h. The solvent was evaporated and HCl (6 M, 100 mL) was added to the remaining tar. The aqueous phase was extracted with DCM (5 × 100 mL) and basified with ammonia. To the aqueous solution was added $NiCl_2 \cdot 6H_2O$ until a deep-green colour persisted. The aqueous solution was reextracted with DCM (7 × 200 mL) and the latter organic phases were combined, dried, and evaporated. Sublimation (0.75 Torr, 75°C) of the residue gave **6***a* (10.0 g, 36%) as a white solid, mp 70–71°C (lit. (23) mp 70–71°C). ^{1}H NMR, δ (ppm): 8.67 (d, $H_{6'}$, J = 4.7 Hz, 1H), 8.41 (dt, $H_{3'}$, J = 7.9, 0.9 Hz, 1H), 8.37 (dd, $H_{3\text{ or }5}$, J = 7.6, 0.9 Hz, 1H), 7.82 (td, $H_{4'}$, J = 7.6, 1.7 Hz, 1H), 7.67 (t, H_4, J = 7.8 Hz, 1H), 7.49 (dd, $H_{3\text{ or }5}$, J = 7.8, 0.9 Hz, 1H), 7.33 (ddd, $H_{5'}$, J = 7.5, 4.8, 1.2 Hz, 1H). ^{13}C{^{1}H} NMR (DEPT), δ (ppm): 149.0, 139.3, 137.4, 128.1, 124.4, 121.7, 119.9. MS *m/z*+ (EI): 235 (M+1, 6%), 234 (M, 52%), 155 (M−79 (−Br), 100%), 128 (M−107 (−CNH, Br), 14%). R_f: 0.68 on alumina (DCM).

Preparation of 2-tributylstannyl-5-methylpyridine (*8b*)

To a solution of 2-bromo-5-methylpyridine **7***a* (10.00 g, 0.058 mol) in THF (150 mL) was added *n*-butyllithium (37.6 mL, 1.6 M, 0.060 mol) while the solution temperature was kept at −78°C. After stirring 75 min at −78°C, tributyltin chloride (18.5 mL, 0.068 mol) was added during 15 min to the reaction mixture, which was further stirred for 4 h at −78°C. The temperature was left to rise to room temperature, at which time water (50 mL) was added and the phases separated. The aqueous phase was extracted with ether (3 × 100 mL) and the combined organic phases were dried and evaporated. The residue was distilled (Kugelrohr, 0.5 Torr, 130–135°C) and chromatographed on alumina, eluting with DCM, to afford **8***b* (5.09 g, 84%) as a colourless oil. ^{1}H NMR, δ (ppm): 8.58 (d, H_6, J = 0.5 Hz, 1H), 7.30 (dd, $H_{3\text{ or }4}$, J = 8.0, 0.5 Hz, 1H), 7.30 (d, $H_{3\text{ or }4}$, J = 1.2 Hz, 1H), 2.28 (s, H_{methyl}, 3H), 1.57 (m, H_{CH_2}, 6H), 1.37 (m, H_{CH_2}, 6H), 1.15 (m, H_{CH_2}, 6H), 0.87 (t, H_{CH_3}, 9H). ^{13}C{^{1}H} NMR, δ (ppm): 169.5, 151.3, 134.0, 131.8, 131.1, 29.1, 27.3, 18.5, 13.7, 9.7. MS *m/z*+ (FAB): 384 (M + 1, 11%), 326 (M − 58 (Bu + H), 17%), 268 (M − 112 (−2 Bu), 14%), 212 (M − 170 (−3 Bu), 100%). Anal. calcd. for $C_{18}H_{33}NSn$: C 56.57, H 8.70, N 3.67; found: C 56.29, H 8.53, N 3.64. R_f: 0.79 on alumina (CH_2Cl_2).

Preparation of 6-bromo-5′-methyl-2,2′-bipyridine (*6b*)

To 2-tributylstannyl-5-methylpyridine **8***b* (18.69 g, 0.049 mol), 2,6-dibromopyridine **9** (27.25 g, 0.116 mol), and $Pd(PPh_3)_4$ (1.84 g, 2.7 mol%) was added toluene (150 mL) and the reaction mixture was stirred at reflux for 72 h. The solvent was evaporated and HCl (6 M, 50 mL) was added to the remaining tar. The aqueous phase was extracted with DCM (5 × 100 mL) and basified with ammonia. To the aqueous solution was added $NiCl_2 \cdot 6H_2O$ until a deep-green colour persisted. The aqueous solution was reextracted with DCM (5 × 200 mL) and the latter organic phases were combined, dried, and evaporated. Chromatography of the residue on silica (CH_2Cl_2:CH_3OH 99:1) gave **6***b* (8.82 g, 72%) as a white solid, mp 126–128°C. ^{1}H NMR, δ (ppm): 8.48 (d, $H_{6'}$, J = 1.6 Hz, 1H), 8.33 (d, H_5, J = 7.8 Hz, 1H), 8.29 (d, $H_{3'}$, J = 7.8 Hz, 1H), 7.64 (t, H_4, J = 7.8 Hz, 1H), 7.61 (dd, $H_{4'}$, J = 7.8, 1.6 Hz, 1H), 7.45 (d, H_3, J = 7.8 Hz, 1H), 2.39 (s, H_{methyl}, 3H). ^{13}C{^{1}H} NMR (DEPT), δ (ppm): 157.5, 152.0, 149.7, 141.5, 139.1, 137.9, 134.1, 127.6, 121.0, 119.4, 18.4. MS *m/z*+ (FAB): 249 (M, 100%), 169 (M−79 (−Br), 28%). Anal. calcd. for $C_{11}H_9BrN_2$: C 53.04, H 3.64, N 11.25; found: C 53.09, H 3.59, N 11.39. R_f: 0.86 on alumina (DCM).

Preparation of 6-tributylstannyl-2,2′-bipyridine (*10a*)

To a solution of 6-bromo-2,2′-bipyridine **6***a* (3.02 g, 0.0128 mol) in ether (80 mL) was added *n*-butyllithium (8.0 mL, 1.6 M, 0.0128 mol) while the solution temperature was maintained at −90°C. After stirring 30 min, tributyltin chloride (3.63 mL, 0.0128 mol) was added to the reaction mixture over 10 min. The temperature of the solution was left to rise to room temperature, at which time water (30 mL) was added and the phases separated. The aqueous phase was extracted with ether (3 × 50 mL). The combined organic phases were dried and evaporated. The residue was distilled (0.5 Torr, 135–140°C) to afford **10***a* (5.09 g, 89%) as a pale brown oil. IR (neat): 2925, 1574, 1549, 1421, 1074, 770, 691. ^{1}H NMR, δ (ppm): 8.66 (d, $H_{6'}$, J = 4.8 Hz, 1H), 8.53 (d, $H_{3'}$, J = 8.0, 1.0 Hz, 1H), 8.25 (d, $H_{3\text{ or }5}$, J = 8.0, 1.3 Hz, 1H), 7.80 (td, $H_{4'}$, J = 7.6, 1.8 Hz, 1H), 7.63 (dd, H_4, J = 8.0, 7.3 Hz, 1H), 7.40 (dd, $H_{3\text{ or }5}$, J = 7.3, 1.3 Hz, 1H), 7.27 (ddd, $H_{5'}$, J = 7.6, 4.8, 1.2 Hz, 1H), 1.62 (m, H_{CH_2}, 6H), 1.37 (m, H_{CH_2}, 6H), 1.16 (m, H_{CH_2}, 6H), 0.90 (t, H_{CH_3}, 9H). ^{13}C{^{1}H} NMR, δ (ppm): 173.2, 157.0, 155.9, 136.6, 134.0, 132.3, 123.4, 121.1, 119.2, 119.1, 29.1, 27.3, 13.7, 10.1. MS *m/z*+ (FAB): 447 (M + 2, 90%), 389 (M − 58 (Bu + H), 65%), 333 (M − 112 (−2 Bu), 18%), 275 (M − 175 (bpy), 100%). Anal. calcd. for $C_{22}H_{34}N_2Sn$: C 59.34, H 7.71, N 6.29; found: C 59.04, H 7.66, N 6.44. R_f: 0.78 on alumina (5% CH_3CN – $CHCl_3$).

Preparation of 6-tributylstannyl-5′-methyl-2,2′-bipyridine (*10b*)

To a solution of 6-bromo-5′-methyl-2,2′-bipyridine **6***b* (6.94 g, 0.028 mol) in THF (200 mL) was added *n*-butyllithium (18.2 mL, 1.6 M, 0.029 mol) while the solution temperature was maintained at −90°C. After stirring 45 min, tributyltin

chloride (8.34 mL, 0.029 mol) was added to the reaction mixture over 15 min, while the solution warmed up to −78°C. The temperature of the solution was left to rise to room temperature, at which time water (100 mL) was added. Ether (50 mL) was added and the phases separated. The aqueous phase was extracted with ether (5 × 100 mL). The combined organic phases were dried and evaporated. The residue was distilled (Kugelrohr, 0.5 Torr, 150–155°C) and chromatographed on alumina, eluting with DCM to afford **10***b* (10.55 g, 82%) as a colourless oil. ^{1}H NMR, δ (ppm): 8.48 (dd, $H_{6'}$, J = 2.0, 0.8 Hz, 1H), 8.42 (d, $H_{3'}$, J = 8.1 Hz, 1H), 8.20 (ddd, H_5, J = 8.1, 8.0, 1.2 Hz, 1H), 7.61 (td, H_4, J = 8.0, 7.3 Hz, 1H), 7.61 (ddd, $H_{4'}$, J = 8.0, 2.0, 0.8 Hz, 1H), 7.37 (ddd, H_3, J = 8.0, 7.3, 1.2 Hz, 1H), 2.39 (s, H_{methyl}, 3H), 1.62 (m, H_{CH_2}, 6H), 1.37 (m, H_{CH_2}, 6H), 1.15 (m, H_{CH_2}, 6H), 0.89 (t, H_{CH_3}, 9H). ^{13}C{^{1}H} NMR, δ (ppm): 173.1, 156.0, 154.5, 149.3, 137.3, 134.0, 133.0, 132.0, 120.7, 118.9, 29.1, 27.4, 18.4, 13.7, 10.0. MS *m/z*+ (FAB): 461 (M+1, 48%), 403 (M − 58, 46%), 289 (M − 170, 100%). Anal. calcd. for $C_{23}H_{36}N_2Sn$: C 60.15, H 7.90, N 6.10; found: C 59.92, H 7.78, N 5.99. R_f: 0.73 on alumina (CH_2Cl_2).

Preparation of 4,6-dichloro-2-methylpyrimidine (11*b*)

A solution of 2-methyl-4,6-dihydroxypyrimidine (4.11 g, 32.6 mmol) in $POCl_3$ (170 mL) was heated to reflux for 5 h. The $POCl_3$ was evaporated, water (100 mL) was added to the residue, and the mixture was extracted with ether (4 × 50 mL). The combined organic phases were dried and evaporated. The crude solid was sublimed (0.1 Torr, 40°C) to afford **11***b* (3.40 g, 64%) as a white solid, mp 46–47°C (lit. (32) mp 46–48°C). ^{1}H NMR, δ (ppm): 7.20 (s, H_5, 1H), 2.65 (s, H_a, 3H). ^{13}C{^{1}H} NMR, δ (ppm): 169.7, 161.5, 118.3, 25.6.

Preparation of 2-(9-anthryl)-4,6-dichloropyrimidine (11*d*)

To 9-bromoanthracene (5.42 g, 0.0211 mol) in a two-necked, 250 mL, round-bottom flask fitted with a low-temperature thermometer and Ar inlet was added diethyl ether (150 mL). The mixture was cooled to −10°C and *n*-butyllithium (13.8 mL, 0.0221 mol) was added while maintaining the temperature below 0°C. The solution was stirred at 0°C for 20 min and then was cooled to −35°C. To this mixture was added 4,6-dichloropyrimidine (2.99 g) in diethyl ether (30 mL) over 15 min. After stirring at −30°C for 20 min, the temperature was left to rise to 0°C. To this mixture was added acetic acid (1.2 mL), water (0.2 mL), and THF (4 mL) followed by DDQ (4.50 g) in THF (20 mL). The solution was stirred at room temperature for 10 min, brought to 0°C, and NaOH (3 M, 8 mL) was added while vigorously stirring the solution. Water (20 mL) was added to the solution, the phases were separated, and the aqueous phase was extracted with ether (3 × 50 mL). The combined organic phases were dried, concentrated, and chromatographed on alumina, eluting with DCM to afford **11***d* (2.58 g, 40%) as a pale-yellow solid, mp 188.8–190.8°C. IR: 1529, 1306, 1276, 1106, 894, 862, 847, 820, 730, 637. UV–VIS: 249 (11.1), 256 (15.0), 366 (1.01), 385 (1.04). ^{1}H NMR, δ (ppm): 8.60 (s, H_{A10}, 1H), 8.06 (m, H_{A1}, 2H), 7.60 (m, H_{A4}, 2H), 7.59 (s, H_5, 1H), 7.52–7.43 (m, $H_{A2,A3}$, 4H). ^{13}C{^{1}H} NMR (DEPT), δ (ppm): 168.5, 162.4, 131.2, 129.6, 129.5, 128.7, 127.0, 125.3, 124.8, 119.7. MS *m/z*+ (CI): 325.2 (M+H, 100%), 289.2 (M−35 (Cl), 10%). Anal. calcd. for $C_{18}H_{10}N_2Cl_2$: C 66.48, H 3.11, N 8.62; found: C 66.42, H 8.53, N 3.25. R_f: 0.46 on silica (DCM/hexane, 1:1).

General procedure for the in situ preparation of 6-tributylstannyl-2,2′-bipyridines (10*a*,*b*)

To a stirred solution of **6***a* or **6***b* (1 equiv.) in THF at −90°C was added *n*-butyllithium (1.05 equiv.) over 15 min. The temperature of the mixture was maintained at −90°C for another 30 min and was brought to −70°C during the addition of tributyltin chloride (1.05 equiv. over 10 min). The mixture was stirred at −50°C for another 30 min. The THF was evaporated and the residue was used without purification in subsequent reactions. The estimated yield of **10***a*,*b* was 90%.

General procedure for the preparation of the bis-tridentate ligands (1*a*,*e*)

To the residue of **10***a* or **10***b* (2.1 equiv., prepared in situ, vide supra) was added 4,6-dichloro-2-*R*-pyrimidine (1 equiv.), bis(triphenylphosphine)dichloropalladium $Pd(PPh_3)_2Cl_2$ (0.1 equiv.), and dry DMF. The reaction mixtures were stirred at the temperatures and for the times indicated below. The reaction mixtures were cooled and the DMF was evaporated under reduced pressure. The resulting black residues were purified by the procedures described below.

*Preparation of 4,6-bis(2″,2′-bipyrid-6′-yl)pyrimidine (1*a*)*

To 6-tributylstannyl-2,2′-bipyridine **10***a* (prepared in situ from **6***a* (2.00 g, 8.51 mmol), *n*-butyllithium (5.6 mL, 1.6 M, 8.96 mmol), and tributyltin chloride (2.92g, 8.96 mmol)), 4,6-dichloropyrimidine (0.54 g, 3.65 mmol), and $Pd(PPh_3)_2Cl_2$ (0.54 g, 9 mol%) was added DMF (8 mL) and the reaction mixture was stirred at 100°C for 15 h. The DMF was evaporated and the residue was extracted with acetone–methanol (1:1, 3 × 25 mL). The remaining solid was recrystallized from acetonitrile–chloroform to afford **1***a* (0.34 g, 24%) as a off-white solid. The combined filtrates were concentrated and chromatographed on alumina, eluting with DCM to give more **1***a* (0.36 g, 25%). Total yield: 0.70 g (49%); mp: 233–236°C. IR: 1560, 1532, 1474, 1429, 1380, 827, 763, 653. ^{1}H NMR (400 MHz), δ (ppm): 9.78 (d, H_5, J = 1.3 Hz, 1H), 9.40 (d, H_2, J = 1.3 Hz, 1H), 8.79 (dt, $H_{3''}$, J = 8.0, 0.9 Hz, 2H), 8.75 (d, $H_{6''}$, J = 4.7 Hz, 2H), 8.61 (dd, $H_{3' \text{ or } 5'}$, J = 7.9, 1.0 Hz, 2H), 8.57 (dd, $H_{3' \text{ or } 5'}$, J = 7.8, 1.0 Hz, 2H), 8.05 (t, $H_{4'}$, J = 7.8 Hz, 2H), 7.89 (dt, $H_{4''}$, J = 7.7, 1.8 Hz, 2H), 7.39 (ddd, $H_{5''}$, J = 7.6, 4.8, 1.2 Hz, 2H). ^{13}C{^{1}H} NMR, δ (ppm): 164.0, 158.6, 155.9, 155.8, 153.4, 149.3, 138.2, 136.7, 124.0, 122.6, 121.7, 121.2, 114.0. MS *m/z*+ (EI): 389 (M+1, 12%), 388 (M, 57%), 387 (M−1, 100%), 360 (M−28 (CNH), 4%), 310 (M–78 (py), 3%). Anal. calcd. for $C_{24}H_{16}N_6$: C 74.20, H 4.16, N 21.64; found: C 73.95, H 4.02, N 21.43. R_f: 0.06 on alumina (DCM).

*Preparation of 4,6-bis(2″,2′-bipyrid-6′-yl)-2-methylpyrimidine (1*b*)*

To 6-tributylstannyl-2,2′-bipyridine **10***a* (prepared in situ from **6***a* (2.10 g, 8.93 mmol), *n*-butyllithium (6.1 mL, 1.6 M, 9.883 mmol), and tributyltin chloride (3.20 g, 9.83 mmol)), 4,6-dichloro-2-methylpyrimidine **11***b* (0.62 g, 3.83 mmol), and $Pd(PPh_3)_2Cl_2$ (0.56 g, 10 mol%) was added DMF (4 mL) and the reaction mixture was stirred at 110°C for 20 h. During this time, a precipitate formed and, upon cooling to 4°C, more solid precipitated out of solution. The solid was collected by filtration, washed with methanol (3 × 25 mL), dissolved in boiling chloroform, and filtered. The filtrate was evaporated and the unreacted starting material and by-products were sub-

limed (10^{-5} Torr, 180°C) and the residue was resublimed (10^{-5} Torr, 200°C) to give **1***b* (0.73 g, 48%) as a white solid, mp 274–276°C. IR: 2922, 1599, 1560, 1542, 1475, 1432, 1385, 993, 789, 764, 653. ^{1}H NMR, δ (ppm): 9.55 (s, H_5, 1H), 8.80 (d, $H_{3''}$, J = 8.0 Hz, 2H), 8.74 (d, $H_{6''}$, J = 4.8 Hz, 2H), 8.58 (d, $H_{3',5'}$, J = 7.8 Hz, 4H), 8.03 (t, $H_{4'}$, J = 7.8 Hz, 2H), 7.89 (td, $H_{4''}$, J = 1.8, 7.8 Hz, 2H), 7.38 (ddd, $H_{5''}$, J = 7.5, 4.8, 1.1 Hz, 2H), 2.94 (s, CH_3, 3H). ^{13}C{^{1}H} NMR (DEPT, CH), δ (ppm): 149.3, 138.2, 136.8, 124.1, 122.5, 121.8, 121.3, 111.1. MS *m/z*$^+$ (FAB): 403.2 (M+1, 100%). Anal. calcd. for $C_{25}H_{18}N_6$: C 74.60, H 4.52, N 20.88; found: C 74.57, H 4.49, N 20.79. R_f: 0.73 on alumina (5% CH_3CN–$CHCl_3$); 0.41 on alumina ($CHCl_3$).

*Preparation of 4,6-bis(2″,2′-bipyrid-6′-yl)-2-phenylpyrimidine (**1**c)*

To 6-tributylstannyl-2,2′-bipyridine **10***a* (prepared in situ from **6***a* (0.99 g, 4.21 mmol), *n*-butyllithium (2.8 mL, 1.6 M, 4.43 mmol), and tributyltin chloride (1.39 g, 4.43 mmol)), 4,6-dichloro-2-phenylpyrimidine **11***c* (0.406 g, 1.804 mmol), and $Pd(PPh_3)_2Cl_2$ (0.266 g, 9 mol%) was added DMF (5 mL) and the reaction mixture was stirred at 100°C for 15 h. The DMF was evaporated and the residue was washed with methanol (3 × 25 mL). The remaining solid was recrystallized from DCM giving **1***c* (0.43 g, 51%) as an off-white solid. The combined filtrates were concentrated and chromatographed on alumina, eluting with DCM to give more **1***c* (0.043 g, 5.1%). Total yield: 0.473 g (56%); mp 242–243°C. IR: 1551, 1531, 1475, 1430, 1376, 781, 753, 693, 651. ^{1}H NMR, δ (ppm): 9.69 (s, H_5, 1H), 8.84 (dt, $H_{3''}$, J = 0.9, 8.0 Hz, 2H), 8.78 (m, H_o, 2H), 8.78–8.74 (m, $H_{6'',3' \text{ or } 5'}$, 4H), 8.62 (dd, $H_{3' \text{ or } 5'}$, J = 7.9, 1.0 Hz, 2H), 8.08 (t, $H_{4'}$, J = 7.9 Hz, 2H), 7.91 (td, $H_{4''}$, J = 7.8, 1.8 Hz, 2H), 7.62–7.55 (m, $H_{m,p}$, 3H), 7.40 (ddd, $H_{5''}$, J = 7.5, 4.8, 1.2 Hz, 2H). ^{13}C{^{1}H} NMR (DEPT, CH), δ (ppm): 149.4, 138.2, 136.8, 130.8, 128.7, 128.5, 124.1, 122.6, 121.9, 121.4, 111.8. MS *m/z*+ (CI): 465.4 (M+H, 63%). Anal. calcd. for $C_{30}H_{20}N_6$: C 77.56, H 4.35, N 18.09; found: C 77.48, H 4.34, N 18.20. R_f: 0.65 on alumina ($CHCl_3$).

*Preparation of 2-(9-anthryl)-4,6-bis(2″,2′-bipyrid-6′-yl)-pyrimidine (**1**d)*

To 6-tributylstannyl-2,2′-bipyridine **10***a* (4.60 g, 0.0103 mol), 2-(9-anthryl)-4,6-dichloropyrimidine **11***d* (1.60 g, 0.00492 mol), and $Pd(PPh_3)_2Cl_2$ (0.72 g, 9 mol%) was added DMF (30 mL) and the reaction mixture was stirred at 105°C. After 36 h, TLC indicated the presence of starting material as well as product. Another aliquot of $Pd(PPh_3)_2Cl_2$ (0.20 g, 2 mol%) was added to the reaction mixture. After an additional 24 h, the DMF was evaporated and the resulting residue was extracted with boiling chloroform (8 × 25 mL) and filtered. The combined filtrates were evaporated and the resulting solid was washed with boiling ethanol (3 × 25 mL) and filtered. The solid was recrystallized from chloroform–hexane to afford **1***d* (1.66 g, 60%) as a pale-yellow solid. The filtrates were combined, concentrated, and filtered, giving more pure **1***d* (0.15 g, 5.4%) as a pale-yellow solid. Total yield: (1.81 g, 65%); mp 270–274°C. IR: 1560, 1531, 1474, 1430, 1379, 1262, 1080, 773, 742, 698, 653. ^{1}H NMR, δ (ppm): 9.92 (s, H_5, 1H), 8.90 (dt, $H_{3''}$, J =8.0 Hz, 2H), 8.78 (d, $H_{6''}$, J = 4.7 Hz, 2H), 8.64 (s, H_{A10}, 1H), 8.61 (dd, $H_{3' \text{ or } 5'}$, J = 8.0, 0.9 Hz, 2H), 8.57 (d, $H_{3' \text{ or } 5'}$, J = 7.7, 1.0 Hz, 2H), 8.11 (d, H_{A1}, J = 7.7 Hz, 2H), 7.96 (t, $H_{4'}$, J = 7.9 Hz, 2H), 7.95 (td, $H_{4''}$, J = 7.9, 1.3 Hz, 2H), 7.86 (d, H_{A4}, J = 8.8 Hz, 2H), 7.45 (m, $H_{5'', A2, A3}$, 6H). ^{13}C{^{1}H} NMR, δ (ppm): 167.0, 164.8, 156.1, 155.9, 153.7, 149.4 (CH), 138.3 (CH), 136.9 (CH), 134.2, 131.6, 130.0, 128.7 (CH), 128.3 (CH), 126.2 (CH), 126.1 (CH), 125.3 (CH), 124.1 (CH), 122.8 (CH), 122.4 (CH), 121.3 (CH), 112.0 (CH). Preparation of 4-(2″,2′-bipyrid-6′-yl)-6-chloro-2-methylpyrimidine (12*b*)

To 6-tributylstannyl-2,2′-bipyridine **10***a* (prepared in situ from **6***a* (3.76 g, 16.0 mmol), *n*-butyllithium (10.5 ml, 1.6 M, 16.8 mmol), and tributyltin chloride (5.21 g, 16.0 mmol)), 4,6-dichloro-2-methylpyrimidine **11***b* (2.77 g, 17.0 mmol), and $Pd(PPh_3)_2Cl_2$ (1.0 g, 9 mol%) was added DMF (25 mL); the reaction mixture was stirred at 90°C for 14 h and subsequently cooled to room temperature. To the mixture was added a saturated aqueous solution of KF (50 mL) and ether (100 mL). The mixture was stirred vigorously for 2 h. Water (300 mL) was added and the mixture was extracted with diethyl ether (3 × 150 mL). The combined organics were washed with water (3 × 50 mL), dried, and evaporated. The residue was filtered over a short alumina column, eluting with DCM to afford a crude yellow powder. Recrystallization from acetonitrile afforded white needles of **12***b* (2.83 g, 67%), mp 142°C. IR: 1561, 1537, 1472, 1424, 1393, 1344, 1324, 1260, 1154, 1068, 876, 848, 834, 787, 761, 740, 666. ^{1}H NMR, δ (ppm): 8.69 (d, $H_{6''}$, J = 4.7 Hz, 1H), 8.55 (d, $H_{3'}$, $H_{5'}$, J = 7.8 Hz, 2H), 8.48 (dd, $H_{3''}$, J = 7.8, 1.0 Hz, 1H), 8.35 (s, H_5, 1H), 7.97 (t, $H_{4'}$, J = 7.8 Hz, 1H), 7.87 (dt, $H_{4''}$, J = 7.8, 1.7 Hz, 1H), 7.34 (ddd, $H_{5''}$, J = 7.3, 4.7, 1.2 Hz, 1H), 2.79 (s, CH_3, 3H). ^{13}C{^{1}H} NMR, δ (ppm): 168.9, 164.6, 162.0, 155.9, 155.5, 152.2, 149.2, 138.1, 136.9, 124.1, 123.1, 122.0, 121.2, 114.6, 25.9. MS *m/z*+ (FAB): 283.1 (M+H, 100%), 206.1 (M−76 (py), 6%). Anal. calcd. for $C_{15}H_{11}ClN_4$: C 63.72, H 3.92, N 19.82; found: C 63.61, H 3.68, N 19.90. R_f: 0.66 on alumina (DCM).

Preparation of 4-(2″,2′-bipyrid-6′-yl)-6-chloro-2-phenylpyrimidine (12*c*)

To 6-tributylstannyl-2,2′-bipyridine **10***a* (prepared in situ from **6***a* (1.42 g, 6.04 mmol), *n*-butyllithium (4.15 mL, 1.6 M, 6.64 mmol), and tributyltin chloride (2.16 g, 6.64 mmol)), 4,6-dichloro-2-phenylpyrimidine **11***b* (0.42 g, 6.04 mmol), and $Pd(PPh_3)_2Cl_2$ (0.42 g, 10 mol%) was added DMF (25 mL); the reaction mixture was stirred at 90°C for 13.5 h and subsequently cooled to room temperature. To the mixture was added a saturated aqueous solution of KF (20 mL) and ether (30 mL). The mixture was stirred vigorously for 1 h. Water (100 mL) was added and the mixture was extracted with diethyl ether (3 × 50 mL). The combined organics were washed with water (3 × 50 mL), dried, and evaporated. The residue was chromatographed on alumina, eluting with DCM–hexane 1:1 to afford **12***c* (1.00 g, 48%) as a white solid, mp 187–189°C. IR: 1559, 1546, 1530, 1430, 1374, 1332, 1077, 826, 785, 754, 696, 650. ^{1}H NMR, δ (ppm): 8.73 (d, $H_{6''}$, J = 4.7 Hz, 1H), 8.69 (dd, $H_{3'}$ or $H_{5'}$, J = 7.8, 0.9 Hz, ^{1}H), 8.64–8.58 (m, $H_{3'}$ or $H_{5'}$, $H_{3'',o}$, 4H), 8.45 (s, H_5, 1H), 8.05 (t, $H_{4'}$, J = 7.8 Hz, 1H), 7.91 (td, $H_{4''}$, J = 7.8, 1.7 Hz, 1H), 7.58–7.51 (m, $H_{m,p}$, 3H), 7.38 (ddd, $H_{5''}$, J = 7.5, 4.8, 1.1 Hz, 1H). ^{13}C{^{1}H} NMR, δ (ppm): 165.1, 164.7, 162.7, 156.0, 155.6, 152.4, 149.3, 138.2, 137.0, 136.4, 131.5, 128.7, 124.2, 123.2, 122.2, 121.3, 115.3 (missing one C). Anal. calcd. for $C_{20}H_{13}ClN_4$: C 69.66, H 3.81, N 16.25; found: C 69.88, H 3.94, N 16.22. R_f: 0.48 on alumina (DCM/hexane, 1:1).

Preparation of 2,6-bis(tributylstannyl)pyridine (13)

To 2,6-dibromopyridine **9** (17.3 g, 0.0730 mol) in THF (240 mL) was added *n*-butyllithium (28 mL, 10.0 M, 0.28 mol) dropwise over 2 h while the solution temperature was maintained below −90°C. The solution was stirred for 2 h at −90°C and tributyltin chloride (75 mL, 0.28 mol) was added over 1 h while the solution temperature was kept below −75°C. The solution temperature was allowed to rise to room temperature and the THF was evaporated. Water (30 mL) was added to the residue and the aqueous phase was extracted with DCM (3 × 20 mL). The combined organic phases were dried and evaporated. The residue was purified by two Kugelrohr distillations (5 × 10^{-6} Torr, 140–150°C) to afford **13** (8.15 g, 17%) as a pale-brown oil. ^{1}H NMR, δ (ppm): 7.30–7.20 (m, $H_{3,4}$, 3H), 1.70–1.55 (m, CH_2, 6H), 1.46–1.21 (m, CH_2, 6H), 1.16–1.04 (m, CH_2, 6H), 0.92 (t, CH_3, 9H). ^{13}C{^{1}H} NMR, δ (ppm): 174.51 (C_2, J_{Sn-C} = 255, 28 Hz), 130.63 (C), 130.33 (C), 29.25 (CH2, J_{Sn-C} = 10.8 Hz), 27.48 (CH_2, J_{Sn-C} = 27.4 Hz), 13.81 (CH_3), 10.05 (CH_2, J_{Sn-C} = 37.2, 7.2 Hz). MS *m/z*+ (EI): 597 (M−58 (H + butyl), 100%), 540 (M−115 (H, 2 × butyl), 18%). Anal. calcd. for $C_{29}H_{57}NSn_2$: C 52.99, H 8.76, N 2.13; found: C 53.20, H 8.91, N 2.34. R_f: 0.80 on alumina ($CHCl_3$).

Preparation of 2,6-bis(6′-(2‴,2″-bipyrid-6″-yl)-pyrimidin-4′-yl)-pyridine (2*a*)

To 2,6-bis(tributylstannyl)pyridine **13** (0.4586 g, 0.6978 mmol), 4-(2′,2″-bipyrid-6′-yl)-6-chloropyrimidine **12***a* (0.4125 g, 1.535 mmol), and $Pd(PPh_3)_2Cl_2$ (0.108 g, 10 mol%) was added DMF (5 mL); the reaction mixture was stirred at 120°C for 48 h. The DMF was evaporated, DCM (50 mL) was added to the residue, and the organic phase was extracted with aqueous HCl (5 × 50 mL). The combined aqueous phases were extracted with DCM (4 × 50 mL), basified, and reextracted with DCM (5 × 75 mL). The latter organic phases were combined, dried, and evaporated. The residue was chromatographed on alumina, eluting with DCM to afford **2***a* (0.118 g, 31%) as a white solid, mp 292–293°C. IR: 1601, 1576, 1564, 1531, 1468, 1457, 1431, 1372, 1247, 1273, 990, 827, 771, 661. ^{1}H NMR (400 MHz), δ (ppm): 9.99 (d, H_5, J = 1.3 Hz, 2H), 9.44 (d, H_2, J = 1.3 Hz, 2H), 8.70 (d, $H_{3'''}$, J = 7.8 Hz, 2H), 8.62 (dd, $H_{3'\text{ or }5'}$, J = 7.7, 1.0 Hz, 2H), 8.38 (dd, $H_{3'\text{ or }5'}$, J

Preparation of 2,6-bis(6′-(2‴,2″-bipyrid-6″-yl)-2′-methylpyrimidin-4′-yl)-pyridine (2*b*)

To 2,6-bis(tributylstannyl)pyridine **13** (1.45 g, 2.2 mmol), 4-(2″,2′-bipyrid-6′-yl)-6-chloro-2-methylpyrimidine **12***b* (1.30 g, 4.6 mmol), and $Pd(PPh_3)_2Cl_2$ (0.25 g, 16 mol%) was added DMF (15 mL); the reaction mixture was stirred at 120°C for 44 h and subsequently cooled to room temperature. The solid precipitate was filtered off and it was washed thoroughly, first with DMF and then with acetonitrile. The combined filtrates were evaporated to dryness. The remaining residue was treated with a mixture of ether and hexane (1/1) to yield a second crop of the desired product. The crude product was suspended in chloroform and refluxed for 12 h. Filtration of the hot mixture yields **2***b* as an off-white powder (0.56 g, 45%), mp 334°C. IR: 1599, 1538, 1474, 1429, 1371, 1259, 1131, 1095, 1070, 993, 826, 788, 766, 742, 634. ^1H NMR, δ (ppm): 9.80 (s, H_5, 2H), 8.65 (d, $H_{3'''}$, J = 7.7 Hz, 2H), 8.63 (dd, $H_{3'}$ or $H_{5'}$, J = 7.9, 1.0 Hz, 2H), 8.40 (dd, $H_{3'}$ or $H_{5'}$, J = 7.9, 1.0 Hz, 2H), 8.37–8.34 (m, $H_{6''}$, $H_{3''}$, 4H), 8.10 (t, $H_{4'''}$, J = 7.7 Hz, 1H), 8.00 (t, $H_{4'}$, J = 7.7 Hz, 2H), 6.86 (ddd, $H_{5''}$, J = 7.4, 4.6, 1.2 Hz, 2H), 6.77 (td, $H_{4''}$, J = 7.9, 1.8 Hz, 2H), 2.97 (s, CH_3, 6H). $^{13}C\{^1H\}$ NMR, δ (ppm): insufficiently soluble. Preparation of 2,6-bis(6′-(2‴,2″-bipyrid-6″-yl)-2′-phenylpyrimidin-4′-yl)-pyridine (2*c*)

To 2,6-bis(tributylstannyl)pyridine **13** (0.194 g, 0.29 mmol), 4-(2′,2″-bipyrid-6′-yl)-6-chloro-2-phenylpyrimidine **12***c* (0.200 g, 0.580 mmol), and $Pd(PPh_3)_2Cl_2$ (0.06 g, 10 mol%) was added DMF (10 mL); the reaction mixture was stirred at 110°C for 60 h. The DMF was evaporated and the residue was washed with methanol (3 × 25 mL). The remaining solid was recrystallized from chloroform to afford **2***c* (0.0606 g, 30%) as a white solid. The combined filtrates were evaporated and the residue was washed with boiling diethyl ether and recrystallized from chloroform to give more pure **2***c* (0.0553 g, 27%). Total yield: 0.116 g (57%); mp 262–264°C. IR: 1560, 1538, 1476, 1429, 1368, 1261, 992, 823, 788, 757, 697, 652, 634. ^1H NMR (400 MHz), δ (ppm): 9.97 (s, H_5, 2H), 8.93 (d, $H_{3'''}$, J = 7.9 Hz, 2H), 8.85 (dd, $H_{3'\text{ or }5'}$, J = 7.7, 1.0 Hz, 2H), 8.83 (dd, H_o, J = 8.0, 1.8 Hz, 4H), 8.43 (d, $H_{3'\text{ or }5'}$, J = 8.2 Hz, 2H), 8.41 (d, $H_{3''}$, J = 7.6 Hz, 2H), 8.35 (d, $H_{6''}$, J = 5.0 Hz, 2H), 8.21 (t, $H_{4'''}$, J = 7.8 Hz, 1H), 8.07 (t, $H_{4'}$, J = 7.9 Hz, 2H), 7.65–7.58 (m, $H_{m,p}$, 6H), 6.87 (ddd, $H_{5''}$, J = 7.3, 5.0, 1.2 Hz, 2H), 6.78 (td, $H_{4''}$, J = 7.3, 1.8 Hz, 2H). $^{13}C\{^1H\}$ NMR (DEPT): δ (ppm): 148.5, 138.4, 139.0, 135.9, 130.9, 128.7, 128.6, 123.7, 123.2, 122.6, 121.5, 121.4, 111.8. MS *m/z*+ (FAB): 696.2 (M+H, 100%), 617 (M−78 (py), 4%); HRMS *m/z* calcd. for $C_{45}H_{30}N_9$ (MH^+): 696.2624; found: 696.2618. Anal. calcd. for $C_{45}H_{29}N_9 \cdot H_2O$: C 75.71, H 4.39, N 17.66; found: C 76.06, H 4.57, N 17.39. R_f: 0.33 on alumina (DCM).

Crystal structure determination

X-Ray data for **2**: ($C_{33}H_{21}N_9$), M = 543.6; colourless crystals; monoclinic; a = 12.396(3), b = 12.307(3), c = 17.358(5) Å, ß = 95.49(2)°, V = 2636.0 Å^3, Z = 4, ρ_{calc} = 1.370, μ = 6.502 cm^{-1}, space group $C2/c$. A suitable crystal of **2**, (0.28 × 0.20 × 0.14 mm^3) was mounted on the end of a glass fibre: 2891 + $h \pm k \pm l$ reflections were collected on a Philips PW1100/16 instrument at 20°C with Cu graphite monochromated radiation (λ = 1.5418 Å), θ/2θ flying step scans, step width = 0.03°, scan speed = 0.020° s^{-1}, scan width = 0.80 + 0.14 tg(θ)°, 3° < θ < 52°. Three standard reflections measured every hour during the data collection period showed no significant trend. The raw data were converted to intensities and corrected for Lorentz and polarization factors. The structure was solved using direct methods: 1036 independent reflections with $I > 3\sigma(I)$ were used to determine and refine the structure. Hydrogen atoms were introduced as fixed contributors by their computed coordinates (C—H = 0.95 Å) and isotropic temperature factors such as $B_H = 1.3\ B_{eqv}(C)$ Å^2. Empirical absorption corrections were applied (DIFABS): Molen on a Vax computer was used for all calculations. Final $R(F)$ = 0.035. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

Results and discussion

The basic ligand design is shown in Fig. 2*b*. Modification of the substituent in the pyrimidine 2-position will influence the metal-binding properties as well as the shape of the ligand upon metal complexation. Various R groups (hydrogen, methyl, phenyl, and 9-anthryl) were incorporated into the framework by attaching bipyridyl subunits onto substituted pyrimidines by carbon–carbon bond-forming reactions. To use such ligands as building blocks for larger systems requires the functionalization of the terminal pyridines; this was done by introducing a functionalized methyl group in the 5-position of the terminal pyridine ring, so as not to interfere with metal complexation.

The key material, 6-bromo-2,2′-bipyridine **6***a*, was synthesized in two different ways. In the first approach (Fig. 3), bipyridine (bpy) **3** and *m*-CPBA gave 2,2′-bipyridine-*N*-oxide **4** in 46% yield (22). Excess $POCl_3$ and **4** gave two chlorobipyridine isomers, 4-chloro-2,2′-bipyridine and 6-chloro-2,2′-bipyridine **5** in 99% yield (27). The 6-isomer is isolated by selectively complexing the 4-isomer with $Ni(II)Cl_2 \cdot 6H_2O$ in water (28). The bpy **5** is extracted into DCM and isolated in 45% yield and is converted to 6-bromo-2,2′-bipyridine **6***a* in 93% yield with excess PBr_3 heated to reflux. The overall yield of **6***a* from bpy over the four steps is 19% (Fig. 3).

We investigated whether **6***a* could be prepared by organotin chemistry in good yields in the steps outlined in Fig. 3. Other direct methods to synthesize **6***a* resulted in moderate yields or multistep procedures (29–31). 2-Tributylstannylpyridine (24)

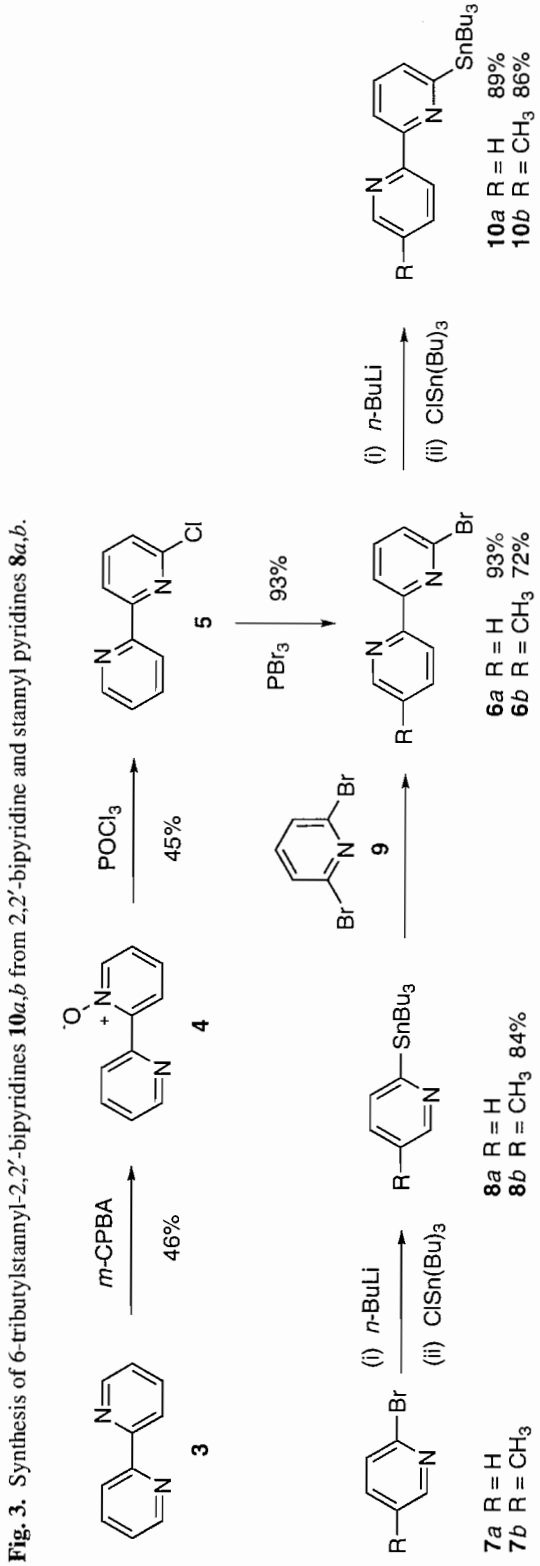

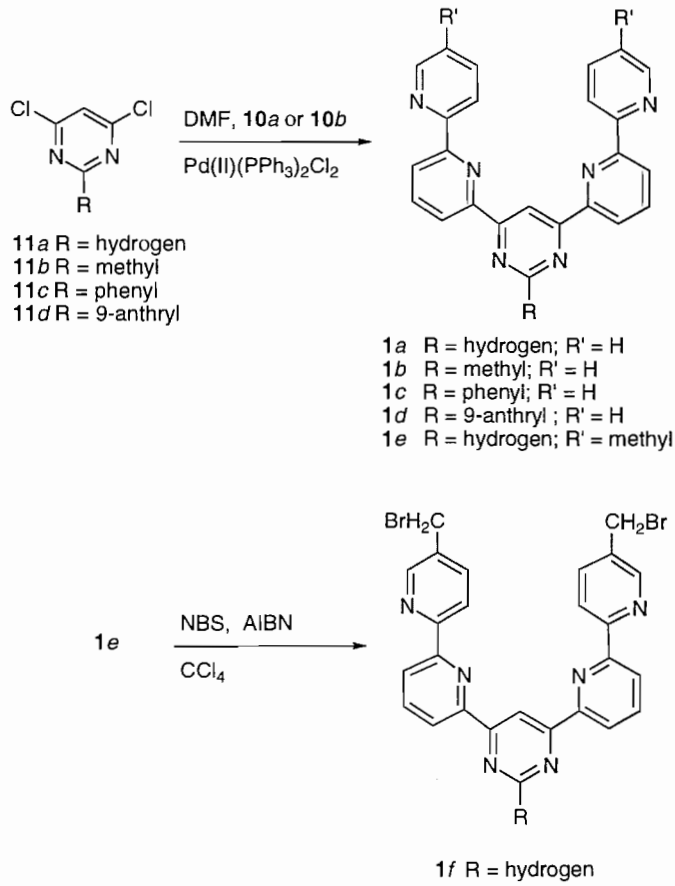

Fig. 3. Synthesis of 6-tributylstannyl-2,2′-bipyridines **10***a*,*b* from 2,2′-bipyridine and stannyl pyridines **8***a*,*b*.

Table 1. Reaction conditions for the synthesis of the bipyridine derivative **6***a* via Stille-type coupling.

	Reagent ratio[a]	
Conditions	1:1	1:2
Toluene 70°C, 73 h	35%	—
Toluene 90°C, 24 h	54%	67%
THF 67°C, 24 h	29%	36%
Dioxane 90°C, 21 h	43%	—
Dimethoxy ethylene glycol 70°C, 71 h	56%	—

[a]Ratio of **8***a* to **9**, 5 mol% $Pd(PPh_3)_4$ for all reactions except in THF, where 5 mol% $Pd(PPh_3)_2Cl_2$ was used.

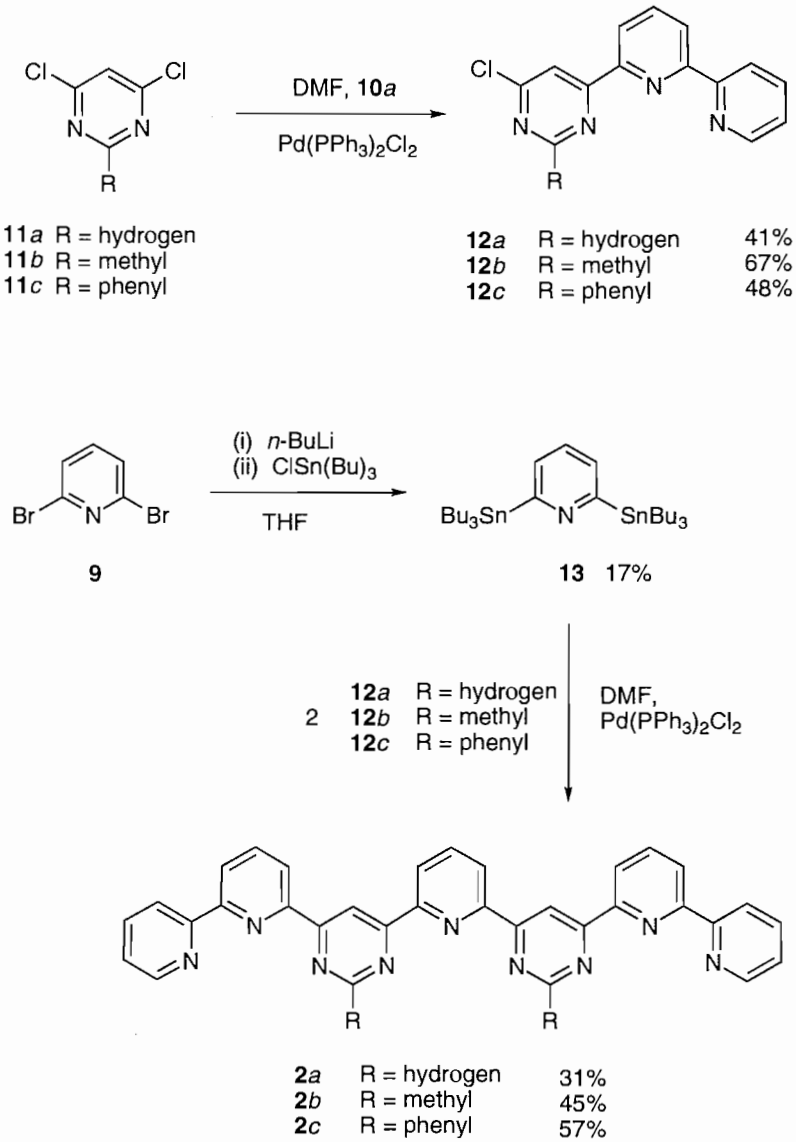

Fig. 4. Synthesis of the bis-tridentate ligands **1***a–e* and of the bromo-substituted ligand **1***f*.

8*a* and 2,6-dibromopyridine **9** are heterocoupled using the conditions listed in Table 1. The bpy **6***a* is easily separated from the starting materials and organotin by-products by acidification of the reaction mixture and subsequent extraction with organic solvents. Stannylpyridine **8***a*, 2,6-dibromopyridine **9**, and tributyltin chloride are extracted into the organic phase of a 1 M HCl – DCM mixture, whereas **6***a* and the side-product tpy are not. Nickel dichloride hexahydrate, added to the neutralized aqueous phase, separates tpy from **6***a* quantitatively following extraction with DCM. Excess **9** favours the formation of **6***a* over tpy. Unreacted **9** is recovered by column

Fig. 5. Synthesis of tris-tridentate ligands **2***a–c*.

chromatography along with the tributyltin bromide formed as a by-product. The synthesis can also be performed in a single procedure. The lithiation of 2-bromopyridine in THF at −78°C with *n*-butyllithium followed by the addition of tributyltin chloride gives pyridine **8***a*. After adding an excess of **9** and palladium catalyst, the reaction mixture is heated to reflux for 2 days. The bpy **6***a* and tpy are isolated as described above. Reaction times are shorter if one removes the THF under reduced pressure and replaces it with higher boiling solvents (Table 1).

To obtain 2-bromo-5-methyl-2,2′-bipyridine **6***b* we used a similar strategy starting from 2-bromo-5-methylpyridine, which is easily obtained from commercially available 2-amino-5-methylpyridine (25). Low-temperature lithiation and reaction with tributyltin chloride gave 2-tributylstannylpyridine **8***b*, which was heterocoupled with 2,6-dibromopyridine **9** to afford **6***b* in 72% yield. The reaction conditions and work-up procedures are similar to those described for **6***a*.

Following low-temperature lithiation of **6***a*,*b* with *n*-butyllithium, the lithiobipyridine is quenched with tributyltin chloride. Purification by distillation affords the 6-tributylstannyl functionalized bipyridines **10***a*,*b* in yields of 89 and 86%, respectively. Upon prolonged standing, small quantities of the dimerization product of **10***a*, 2,2′:6′,2″:6″,2‴-quaterpyridine, solidify out of the oil.

The pyrimidines are all synthesized in one step from commercially available materials. Reacting 4,6-dihydroxy-2-methylpyrimidine with $POCl_3$ gives 4,6-dichloro-2-methylpyrimidine **11***b*. Purification in an analogous fashion to that of **5**, followed by sublimation (instead of fractional distillation as reported (32)) affords **11***b* in 64% yield. 4,6-Dichloro-2-phenylpyrimidine **11***c* is produced by the addition of phenyllithium to **11***a*, followed by oxidation of the addition product with DDQ (26). In an analogous fashion, 9-lithioanthracene, generated by treatment of 9-bromoanthracene with *n*-butyllithium, reacts with **11***a* to afford 2-(9-anthryl)-4,6-dichloropyrimidine **11***d* in 40% yield. The reaction of two equivalents of bpy **10***a* with the 2-substituted-4,6-dichloropyrimidines

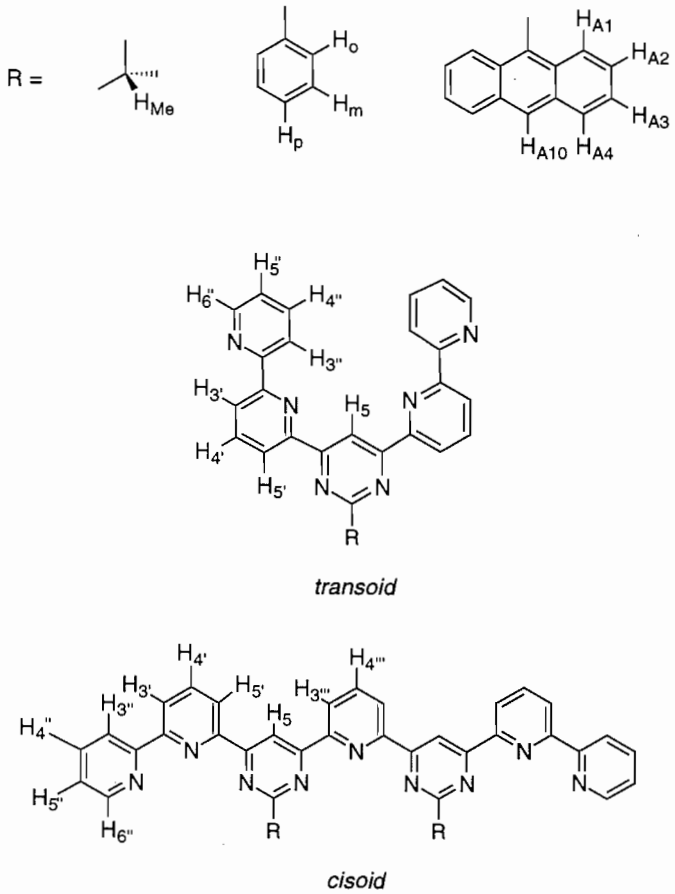
11*a–d* in DMF with $Pd(II)(PPh_3)_2Cl_2$ as catalyst yields the bis-tridentate ligands **1***a–d* in 49, 48, 56, and 65% yield, respectively (Fig. 4). Similarly, the terminal pyridine methyl-substituted bis-tridentate ligand **1***e* can be obtained in 49% yield. Further functionalization with NBS resulted in a mixture of different brominated products. The bisbromomethyl ligand **1***f* was isolated via column chromatography in 27% yield (Fig. 4).

2,6-Bis(tributylstannyl)pyridine **13** is obtained via transmetallation of 2,6-dilithiopyridine (33) with tributyltin chloride in 17% yield (Fig. 5). 4-(2′,2″-Bipyrid-6′-yl)-6-chloropyrimidines **12***a–c* are synthesized in an analogous manner to the bis-tridentate ligands (Fig. 5). The bpy **10***a* and an excess of pyrimidines **11***a–c* are reacted in DMF with $Pd(II)(PPh_3)_2Cl_2$ as the catalyst, giving **12***a–c* in yields of 41, 67, and 48%, respectively. The reaction of **13** with **12***a–c* proceeded under similar conditions to yield 31, 45, and 57% of the respective tris-tridentate ligands **2***a–c*.



Solution structure of **1***a–f* and **2***a–c*

Information concerning the orientation of the bis- and tris-tridentate ligands in solution was deduced from ^{1}H NMR chemical shifts (Fig. 6, Table 2). In the *cisoid* conformation, $H_{3''}$ would have no nitrogen lone pairs in proximity, whereas in the *transoid* conformation, $H_{3''}$ is close to two nitrogen lone pairs, accounting for its deshielding relative to H_3 in tpy. The chemical shifts of $H_{3'}$ and $H_{5'}$ are similar (a single doublet in **1***b* at 200 MHz), demonstrating that the pyrimidine N lone pair has

Fig. 6. Labelling of the *transoid* bis-tridentate and *cisoid* tris-tridentate ligands.

a similar deshielding effect to that of the pyridine N lone pair. The minor differences in the chemical shifts of H_2 in **11***a*, **12***a*, **1***a*, and **2***a* suggests that there is no intramolecular interaction between H_2 and the rest of the molecule. Intramolecular interactions involving H_5 are demonstrated by significant changes in its chemical shift in the aforementioned compounds. The greatest deshielding of H_2 and H_5 occurs after the addition of the first and second bipyridyl moieties to **11***a* (for **12***a*: +0.27 and +1.12, respectively; for **1***a*: +0.32 and +1.22 ppm, respectively). In **2***a*, the deshielding of H_2 (+0.04 ppm) and H_5 (+0.21 ppm) is modest relative to **1***a*. Evidently, the proximity of more nitrogen lone pairs deshields H_5. Although three nitrogen lone pairs point into a central cavity in **2***a*, one is far from H_5, resulting in only minor deshielding effects when compared to **1***a*.

The large upfield shift of the terminal pyridine protons in **2***a–c* may be attributed to shielding effects resulting from π–π interactions between the two terminal pyridines. Significant upfield shifts are observed when comparing **1***a* to **2***a*: −0.44, −0.54, −1.17, and −0.48 ppm for $H_{6''}$–$H_{3''}$, respectively. Similar upfield shifts occur between **1***b* and **2***b* (−0.38, −0.52, −1.12, and −0.44 ppm for $H_{6''}$–$H_{3''}$, respectively) and **1***c* and **2***c* (−0.41, −0.53, −1.13, and −0.43 ppm for $H_{6''}$–$H_{3''}$, respectively), suggestings similar environments for the terminal pyridines. The ^{1}H NMR spectra of **2***a–c* indicate similar solution structures.

The ^{1}H ROESY NMR spectrum of **2***a* reveals no interannular NOE interactions between adjacent heterocycles, supporting an all-*trans* conformation. The only prevalent NOE interaction occurs between $H_{3''}$ and H_5, indicating partial curling up of the ligand. The symmetry of the molecule on the NMR time scale does not allow differentiation of the three-ring (partial curling-up of the ligand) and five-ring (full curling-up of the ligand) interactions between $H_{3''}$ and H_5. No NOE interactions between $H_{3'''}$ and H_5 are observed, further supporting a *transoid* conformation at the central tridentate site.

The overlap between the terminal pyridines requires that the nonchiral linear molecule be curled up into a helical shape. Three basic features dictate this behaviour: (*a*) an alternating sequence of pyridine and pyrimidine units; (*b*) linkage of these units at appropriate positions; (*c*) *transoid* conformation around the linkage bonds based on the preference for a *trans* orientation of nitrogen sites and concomitant *cis* orientation of CH and N sites as found in 2,2′-bipyridine (12).

Solid state structure of 2*a*

X-ray crystallographic studies indicate a helical structure in the solid state (Figs. 7 and 8). The unit cell is centrosymmetric and contains the two enantiomeric helices. The molecule has a twofold rotation axis passing through the central pyridine N and C-4. Molecule **2***a* adopts an overall helical conformation in which the nitrogen sites have the expected *transoid* orientation about the interannular bonds. The interior of the helical strand is lined with alternating CH and N sites. The central cavity is 5.42 Å across and of a size comparable to that in cyclosexipyridine and 18-crown-6.

$H_{3''}$ is directed into the cavity formed by the helix, with a distance of 3.0 and 3.4 Å between $H_{3''}$ and H_5 for the three-ring and five-ring interaction, respectively. The angle between the least-squares planes (16.5 (2)°) is greatest between the pyrimidine (ring C) and central pyridine (ring D) (Fig. 8). The most coplanar rings are B and C (3.8 (8)°). The angle (8.6 (3)°) between the pyridine rings in the bipyridyl moieties is slightly greater than that found in terpyridine (5.1° and 7.1°) (34).

The interannular bond lengths in molecule **2***a* are typical of C—C single bonds between sp^2 hybridized carbon atoms, and lie between 1.484 (3) and 1.489 (4) Å. The pyridine and pyrimidine C—N bond lengths range from 1.334 (3) to 1.346 (4) Å and from 1.329 (4) to 1.344 (3) Å, respectively. The angles about the interannular bonds fall into two separate sets for the pyridines and pyrimidines: those which include a nitrogen atom and those which include a carbon atom. The C-C-C angles are between 3.5° and 9.2° greater than the N-C-C angles.

The interlamellar distance in graphite (3.354 Å) (35) is a reference for an optimal π-stacking distance. The terminal pyridines in **2***a* lie between an edge-to-face and a face-to-face orientation with a least-squares-planes angle of 38.8° and a centroid-to-centroid distance of 4.523 Å. The closest interactions between the terminal pyridines are those of C-3–C-3 (3.600 Å) and C-2-C-3 (3.755 Å), although C-3 and C-4 of the terminal pyridine are closer to the nitrogen of pyridine ring B, at 3.559 and 3.598 Å, respectively. The terminal pyridines are, therefore, slightly offset from one another, and are partially

[c]Irreversible wave.

above the B rings (least-squares-planes angle = 33.2(1)°). $H_{4''}$ is directed above the B ring, whereas $H_{3''}$, $H_{5''}$, and $H_{6''}$ are above the other terminal pyridine. These interactions lead to the significant upfield shift of the ^{1}H NMR signals of these protons (36).

Ring B and ring C′ from each of the two enantiomeric helices have a centroid-to-centroid distance of 3.79 Å (Fig. 7). The least-squares-planes angle between the rings is 3.8 (7)°. The rings are slightly offset from one another, which may lead to favourable π–π interaction (36). Based on the above observations, we conclude that the solid state and solution structures of this molecule are helical and similar.

Heterocyclic ligands exhibit electrochemical reduction potentials that approximate their relative π* levels (37). The bis-tridentate ligands **1** present a reversible pyrimidine-based reduction (between −1.43 and −1.49 V; $E^{\circ\prime}_{\text{pyrimidine}} = -1.87$ V (38)) followed by an irreversible pyridine-based reduction (between −2.06 and −2.17 V; $E^{\circ\prime}_{\text{pyridine}} = -2.09$ V (38)) in DMF (Table 3). The 9-anthryl substituted ligand **1***d* also shows another irreversible reduction at −1.96 V in DMF, presumably due to the 9-anthryl moiety ($E^{\circ\prime}_{\text{anthracene}} = -1.92$ V, 2.5 V (39)).

The tris-tridentate ligands **2***a* and **2***c* exhibit two reversible reductions, the first near −1.40 V and the second near −1.63 V (Table 3), which may be considered as pyrimidine based, with the first lower and the second higher in energy than the first reduction of the bis-tridentate ligands **1**. Clearly, the pyrimidine moieties provide electronic communication that may involve extended delocalization through the central pyridine and electrostatic interaction. No subsequent reductions of the

Fig. 8. Angles between the least-squares planes between heterocyclic rings A–D in **2***a*.

pyridyl groups are observed. The poor solubility of **2***b* precluded determination of its reduction potentials.

The absorption spectra of the bis-tridentate ligands **1***a–f* (Table 4) display high-energy absorption bands like those found in pyridine (251, 270 nm) and pyrimidine (243, 298 nm) (40). They contain common absorption bands near 236, 286, 308, and 320 nm. The lowest energy band is ascribed to a pyrimidine-based transition, while the high-energy ones may be due to either pyridine- or pyrimidine-based absorptions. The low-energy absorption is expected to occur at lower energies than those of pyridine and pyrimidine, as bpy and tpy low-energy bands are at lower energies than those of pyridine (41). The same was found in other polyaromatic compounds, where conjugative interaction gives an extended π-system with a lowered HOMO–LUMO energy gap (42).

The phenyl- (**1***c*) and 9-anthryl-substituted (**1***d*) ligands exhibit additional UV bands (256 and 333 nm; and 250, 257, 348, 366, and 386 nm, respectively) that correspond reasonably well to the absorption bands of benzene (204, 256 nm) and anthracene (221, 256, 375 nm) (40). The molar absorptivity of **1***d* is higher than that of the other bis-tridentate ligands at all the common wavelengths as the 9-anthryl moiety has higher ε values than the other R groups at these wavelengths. As for the absorption maxima, the molar absorptivities for the chromophoric components in the ligands are approximately additive.

The tris-tridentate ligands **2***a–c* exhibit absorption spectra similar to those of their bis-tridentate counterparts **1***a–c*. The molar absorptivities of the transitions are more intense due to the greater number of heterocycles present and the λ_{max} positions are closer together.

Conclusion

We have developed a synthetic pathway for the synthesis of bis- and tris-tridentate ligands for metal complexation based on pyridine and pyrimidine units. The stepwise synthesis of the ligands proceeded via Stille carbon–carbon bond-forming reactions. The solution structures of the ligands were deduced by ^{1}H NMR, exemplified by pronounced deshielding of the protons adjacent to the interannular bond. When seven alternating pyridine–pyrimidine heterocycles are connected together, a helical structure is formed, as indicated by solution and solid state data. Longer multisite versions of these ligands are being investigated. The ligands **1***e–f*, functionalized at the terminal pyridine, represent potential building blocks for more extended systems.

Reactions of hydroxamidovanadate with peptides: Aqueous equilibria and crystal structure of oxobis(hydroxamido)-glycylglycinatovanadium(V)[1]

Pradip C. Paul, Sarah J. Angus-Dunne, Raymond J. Batchelor, Frederick W.B. Einstein, and Alan S. Tracey

Abstract: Bis(hydroxamido)hydroxooxovanadate has been found to undergo favourable condensation reactions with simple peptides such as glycylglycine, glycylglycylglycine, or glycyltyrosine to afford, in each case, three products in the approximate ratio 1:3.5:0.2. The three products had the same ligand stoichiometry and, in the case of glycylglycine, an overall formation constant of 3.3×10^3 M^{-1} for the addition of GlyGly to bis(hydroxamido)vanadate. The ^{51}V chemical shift range of the products (close to −850 ppm) overlaps that of the starting complexes and the products may well have a coordination geometry similar to the parent complexes. The chemical shifts observed for these materials are in the range of chemical shifts observed for peroxovanadium complexes. A crystalline monomeric complex with a single glycylglycinato ligand was obtained and its crystal structure determined. The complex is zwitterionic and has a pentagonal bipyramidal coordination at vanadium with the glycine-NH_2 functionality coordinated in the plane of the two hydroxyalamine ligands and the amido carbonyl oxygen in the apical position. Some comparisons with peroxovanadium complexes are drawn. Crystal structure of $V(O)(ONH_2)_2(GlyGly)\cdot H_2O$: monoclinic, space group *Cc*; $Z = 4$; $a = 9.1340(9)$ Å; $b = 16.3355(15)$ Å; $c = 7.1149(6)$ Å; β (°) = 103.020(7); $V = 1034.31$ Å^3; $T = 295$ K; $R_F = 0.21$ for 2513 data ($I_0 \geq 2.5\sigma(I_0)$) and 197 variables.

Key words: vanadate, hydroxylamine, *N*-methylhydroxylamine, oxobis(hydroxamido)glycylglycinatovanadium(V), peptide complex, glycylglycine, ^{51}V NMR, crystal structure.

Résumé : Le bis(hydroxamido)hydroxooxovanadate selon une réaction de condensation favorable avec les peptides simples tels la glyglycine, la glycylglycylglycine, ou la glycyltyrosine conduit, dans chaque cas, à trois produits dans le rapport approximatif de 1 : 3, 5 : 0,2. La stoechiométrie du ligand est la même dans ces trois produits et, dans le cas de la glycylglycine, la constante globale de formation est de $3{,}3 \times 10^3$ M^{-1} pour l'addition de GlyGly sur le bis(hydroxamido)vanadate. L'intervalle des déplacements chimiques du ^{51}V de ces produits (voisin de −850 ppm) recouvre celui des complexes de départ et les produits peuvent bien avoir une géométrie de coordination similaire à celles des complexes dont ils sont issus. Les déplacements chimiques observés pour ces produits se situent dans l'intervalle des déplacements chimiques observés pour les complexes de peroxovanadium. On a obtenu un complexe monomère cristallin avec un seul ligand glycylglycinato et on a déterminé sa structure cristalline. Le complexe est un zwitterion et sa coordination est pentagonale bipyramidale au niveau du vanadium avec la fonction NH_2 de la glycine coordonnée dans le plan des deux ligands hydroxylamines et avec l'oxygène du carbonyle du groupe amide en position apicale. On a établi quelques comparaisons avec les complexes de peroxovanadium. Structure cristalline du $V(O)(ONH_2)_2(GlyGly)\cdot H_2O$: groupe d'espace monoclinique, *Cc*; $Z = 4$; $a = 9{,}1340(9)$ Å; $b = 16{,}3355(15)$ Å; $c = 7{,}1149(6)$ Å; $\beta(°) = 103{,}020(7)$; $V = 1034{,}31$ Å^3; $T = 295$ K; $R_F = 0{,}21$ pour 2513 données ($I_0 \geq 2{,}56\sigma(I_0)$) et 197 variables.

Mots clés : vanadate, hydroxylamine, *N*-méthylhydroxylamine, oxobis(hydroxamido)glycylglycinatovanadium(V), complexe de peptide, glycylglycine, ^{51}V RNM, structure cristalline.

Introduction

Vanadium is now known to be an important metal for the function of a number of enzymatic systems. It is found in marine algae (1) and a number of terrestial lichens (2) and fungi, (3, 4), where vanadate (V(V)) is required for the function of vanadium-dependent haloperoxidases (5, 6). Nitrogenases that require vanadium for their nitrogen-fixing function have also been found in bacteria (7–9). These discoveries have stimulated a great deal of interest in the aqueous chemistry of vanadate and of peroxovanadates. For the latter there has been interest in their formation (10–15), their reactivity with heteroligands (16–19), and in their oxidative capabilities (16–23). This interest has been further piqued by the insulin-mimetic properties of peroxovanadates (24–27) and by the fact that vanadate can activate some types (28) and inhibit other types (29) of phosphate-metabolizing enzymes.

Hydroxamidovanadates offer a convenient point of departure from the study of peroxovanadates. The ligands are isoelectronic with each other and hydroxylamine offers the advantage of being asymmetrical so that further details of the reactions are accessible. A detailed study of reactions of dimethylhydroxylamine[4] and of methylhydroxylamine and hydroxylamine[5] have revealed that, unlike the case with hydrogen peroxide, two distinct types of bisligand complexes are formed. If the bonds to the hydroxylamine ligand are formally treated as unidentate, then the crystal structure studies show a tetrahedral coordination about vanadium for one type of complex, the other type is thought to correspond to a trigonal bipyramidal coordination.[4] In the presence of certain heteroligands, it seems probable that further reaction of the bishydroxamidovanadate to generate additional products can occur, as is well known for bisperoxovanadate complexes (16–18). However, because of the occurrence of two types of coordination for the bis(hydroxamido)vanadate complex compared to only one type for for the corresponding bisperxovanadate complex, it is quite feasible that hydroxamido(heteroligand) vanadate complexes that are structurally different from those derived from peroxovanadate will be formed. Initial studies show that this, to an extent, is the case and, for the ligands of this study, the reaction scheme does not correspond to that for the peroxovanadates.

Experimental

Materials

Reagents used were of commercially available reagent grade quality. Hydroxylamine hydrochloride, N-methylhydroxylamine hydrochloride, glycylglycine, glycylglycineOEt, triglycine, glycyltyrosine, and tetraethylammonium hydroxide (20% aqueous solution) were obtained from Sigma Chemical Co. Vanadium(V) oxide (99.99%) and HEPES buffer were obtained from Aldrich Chemical Co. All chemicals were used as supplied.

Stock solutions of KCl (2 M), hydroxylamine(100 mM), HEPES buffer (200 mM), and of the heteroligands (100 mM) were prepared at pH 6.5. The vanadate stock solution (100 mM) was prepared at pH 9. The stock solutions were combined appropriately with added distilled water to give the final concentrations of reactants. All final solutions were prepared at 1.0 M ionic strength with added KCl, 20 mM HEPES buffer, the indicated amounts of hydroxylamine, and heteroligand at pH 7.1. Care was taken to ensure that pH adjustments on vanadate-containing solutions did not require addition of acid (stock solutions were adjusted appropriately, if necessary).

Under locally acidic conditions, vanadate rapidly oligomerizes to decavanadate, which hydrolyzes only very slowly.

Synthesis of $[VO(ONH_2)_2(GlyGly)]\cdot H_2O$

Vanadium pentoxide (0.10 g; 0.55 mmol), tetraethylammonium hydroxide (1 mL), and a small amount of water (~2 mL) was taken in a beaker. The resultant mixture was warmed to 60°C, with continuous stirring to get a clear solution of tetraethylammonium vanadate. The pH of the vanadate solution was about 11. To this vanadate solution a solution of hydroxylamine hydrochloride (0.15 g; 2.16 mmol) dissolved in water (2 mL) at pH 7 (adjusted by tetraethylammonium hydroxide) was added with continuous stirring. The pH was maintained between 8.5 and 9.5. This solution was cooled in an ice bath and glycylglycine (0.15 g; 1.1 mmol) dissolved in water (2 mL) was added with continuous stirring. The pH of the final solution was adjusted to 9.0. The reaction mixture was maintained at about 2°C. After about 30 min, pale yellow crystals were obtained. After crystallization was complete, the solution was filtered and the crystalline product washed with cold water and dried in vacuo. The compound was found to be stable at room temperature. Yield 0.17 g (60%).

The crystals were light yellow coloured and very hard in nature. They were not found to be soluble in water and common organic solvents. This precluded dissolution studies of this compound. The structure of this compound was determined from single crystal X-ray diffraction studies.

^{51}V NMR spectroscopy

Spectra were acquired at 105 MHz using a Bruker AMX400 NMR spectrometer. 4K data set sizes were obtained with 0.05 s aquisition times and 60° pulse widths. The spectra were zero filled to 16 K and a line-broadening factor of 40 Hz applied before Fourier transformation. Fourier transformation, baseline corrections and spectral integration were done using the instrument manufacturer's software.

Equilibrium analysis

Equilibrium expressions were obtained and the data analysis carried out as outlined in the text. Errors in parameters are reported at the 3σ level.

Crystal structure

A crystal was mounted on a glass fiber. Data were recorded at ambient temperature with an Enraf Nonius CAD4F diffractometer using graphite monochromatized Mo K_α radiation. Empirical absorption corrections were applied (30). Data reduction included corrections for Lorentz and polarization effects.

Coordinates for all atoms were refined. Two restraints were

Table 1. Crystallographic data for the structure determination of $V(O)(ONH_2)_2(GlyGly) \cdot H_2O$.

Parameter		Parameter	
Formula	$VO_7N_4C_4H_{13}$	Crystal system	Monoclinic
FW	280.11	Space Group	*Cc*
a (Å)[a]	9.1340(9)	ρ_c (g cm^{-3})	1.799
b (Å)	16.3355(15)	λ(Mo Kα_1) (Å)	0.70930
c (Å)	7.1149(6)	μ(Mo Kα) (cm^{-1})	9.6
β (°)	103.020(7)	min–max 2θ (°)	4–70
V (Å^3)	1034.31	Transmission[b]	0.818–0.867
Z	4	Crystal dimensions (mm)	0.25 × 0.28 × 0.35
T(K)	295	R_F[d]	0.022
GoF[c]	1.34	R_{wF}[e]	0.025

[a]Cell dimensions were determined from 48 reflections ($40° \leq 2\theta \leq 56°$).

[b]The data were corrected empirically for the effects of absorption using the product of the experimental ψ dependance and a (spherical) 2θ correction.

[c]GoF = $[\Sigma(w(F_o - F_c)^2)/\text{degrees of freedom}]^{1/2}$.

[d]$R_F = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, for 2513 data ($I_0 \geq 2.5\sigma(I_0)$).

[e]$R_{wF} = [\Sigma(w(|F_o| - |F_c|)^2)/\Sigma(wF_o^2)]^{1/2}$ for 2513 data ($I_0 \geq 2.5\sigma(I_0)$); $w = [\sigma(F_o)^2 + 0.0001F_o^2]^{-1}$.

used to fix the origin. Anisotropic thermal parameters were refined for all non-hydrogen atoms. Independent isotropic temperature factors for all hydrogen atoms were also refined. The Flack (31) enantiopole parameter, which refined to 0.00 (2), unambiguously established the correct polarity for the crystal. Of the incidentally measured sets of Friedel related reflections, for which $|F_c^+| - |F_c^-|/\sigma(F_o) \geq 5$, all 29 showed the correct sign of $|F_o^+| - |F_o^-|$, supporting the model. A weighting scheme based on counting statistics was applied such that $\langle w(|F_o| - |F_c|)^2 \rangle$ was near constant as a function of both $|F_o|$ and sin θ/λ. Final full-matrix least-squares refinement of 197 parameters for 2513 data ($I_0 \geq 2.5\sigma(I_0)$) converged at $R = 0.022$. Crystallographic details are summarized in Table 1. Final fractional atomic coordinates are listed in Table 2.

Analysis of the anisotropic thermal parameters, using a rigid-body (32) model for the non-hydrogen atoms of the complex, $V(O)(ONH_2)_2(GlyGly)$, yielded $R = 0.174$ for the agreement between observed and calculated U_{ij} and an r.m.s. discrepancy of 0.0035 Å^2. The resultant bond length corrections ranged from +0.001 to +0.005 Å.

The computer programs used were: DIFRAC (33) for data collection; NRCVAX (34) for absorption correction, data reduction, structure solution, and graphical output; and CRYSTALS (35) for structure refinement and rigid body thermal motion analysis. Complex scattering factors for neutral atoms (36) were used in the calculation of structure factors. Computations were carried out on a Pentium computer.

Results and discussion

Hydroxylamine, in the presence of vanadate under neutral aqueous conditions, gives rise to one major monoligand and four major bisligand products, their formation and relative proportions being highly pH dependent.[5] The four major products are readily separated into two groups of two complexes each. In the ^{51}V NMR spectrum at pH 7, one set of two broad signals and a second set of two relatively sharp signals are observed. With increase in pH the broad signals decrease in intensity relative to the sharp ones. In the presence of glycylglycine, the four signals are replaced by a set of three sharp signals occurring near −850 ppm. This suggests that the product complexes are coordinated similarly to the products corresponding to the sharp pair of the four signals in the precursor complexes. Figure 1 shows the spectra obtained in the absence (A) and presence (B) of glycylglycine. In Fig. 1A, the signal of the monohydroxamido complex is observed at −672 ppm while the signals of the bisligand complexes are centred near −840 ppm. As can be seen from Fig 1B, the product complexes also give signals near −840 ppm. The chemical shifts of these complexes are within the range of chemical shifts observed for peroxo (17, 37, 38) and hydroxamido-derived (37, 39) complexes of vanadate and this is consistent with a side-on coordination of the hydroxamido ligand. The only other product signal is found at −570 ppm and is thought to derive from an ester-like product formed from reaction at the hydroxyl group of hydroxylamine.

In the case of bis(dimethylhydroxamido)vanadate, it has been proposed,[4] on the basis of an X-ray study and dissolution studies, that the similarly broad signals observed in that system correspond to a six-coordinate complex (tetrahedral-like, if the bonds to the dimethylhydroxylamine are formally assumed to be monodentate) and this seems to correspond to the situation here. With this ligand, the broad signals also are retained in solution with decrease in pH while the single sharp signal vanishes from the spectrum. The opposite situation is obtained with increasing pH. The sharper signal has been assigned to a complex with a pentagonal bipyramidal coordination and this assignment is in agreement with observations here where the GlyGly products give rise to sharp signals.

It was possible to show that the three heteroligand products had the same ligand stoichiometry by varying the glycylglycine and hydroxylamine concentrations. It was found that the product ratio was independent of the glycylglycine concentration. Furthermore, if the glyclyglycine concentration was maintained at 20 mM in the presence of 1 mM total vanadate

[a] U_{eq} is the cube root of the product of the principal axes of the thermal ellipsoid.

and the hydroxylamine concentration varied between 2 and 20 mM, there also was no change in the product ratio of the three products. In this latter case, overall, the −850 ppm product signals increased relative to the −672 ppm signals. This is in keeping with a monohydroxamido (−672 ppm) and bishydroxamido (−850 ppm) stoichiometry. No evidence was obtained for the formation of a monohydroxamidoGlyGly–vanadate complex.

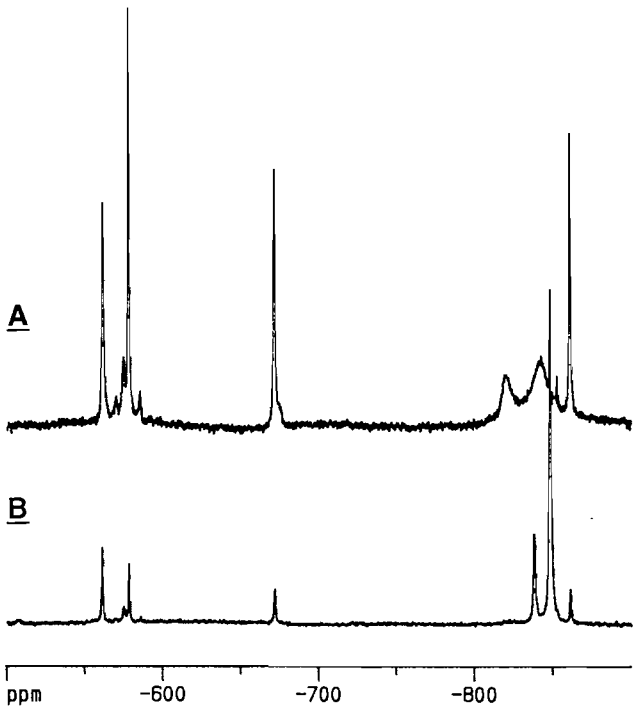
These preliminary studies suggested that product formation can be written as in eq. [1], where L refers to hydroxylamine and GG to glycylglycine. Equation [1] can be reexpressed as in eq. [2].

$$[1]\quad V + 2L + GG \overset{K_1}{\rightleftharpoons} VL_2GG$$

$$[2]\quad [L]^2K_1 = [VL_2GG]/[V][GG]$$

Figure 2 shows the experimental result when the concentration of NH_2OH was varied while the overall vanadate (3.0 mM) and glycylglycine (20.0 mM) were maintained constant. For this plot, the total integrated intensity for the three signals near −850 ppm was used. The individual products were found in the ratio of 1:3.5:0.23 for the −839, −848, and −861 ppm products, respectively. The overall formation constant of $(4.3 \pm 0.4) \times 10^8$ M^{-3} can then be partitioned according to the ratio of the individual products.

The formation constant for the GlyGly complex from VL_2 corresponding to the reaction of eq. [3] can be obtained from the value of K_1 for eq. [1] and the known formation constant, K', for VL_2



$$[3]\quad VL_2 + GG \overset{K_2}{\rightleftharpoons} VL_2GG$$

from vanadate and hydroxylamine for the pH of this study; $K' = (1.3 \pm 0.2) \times 10^5$ M^{-2} (footnote 5). K_1 is then equal to $K'K_2$ and $K_2 = (3.3 \pm 0.5) \times 10^3$ M^{-1}. There is no evidence from the study of bisperoxovanadates in the presence of glycylglycine or other dipeptides that products, similar to those found here, are formed. Indeed, only monoperoxopeptidovanadate complexes are formed to any appreciable extent and such products are highly favoured (40). Product formation is different in another way. With monoperoxovanadate, the N-terminal amino, the amido NH, and the C-terminal carboxylate are necessary for product formation. With the hydroxyamine–vanadate complex, three products with ^{51}V NMR chemical shifts and formation constants similar to those

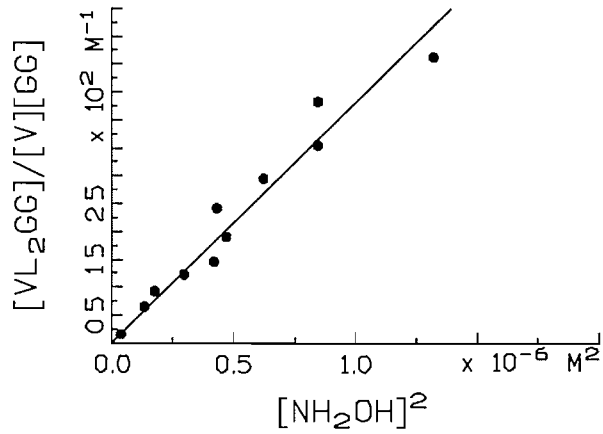
Fig. 1. ^{51}V NMR spectra showing the spectrum of the starting equilibrium mixture of compounds (A) and the result after addition of glycylglycine (B). The signals near −670 ppm arise from monohydroxamidovanadate complexes, those near −850 ppm from bis(hydroxamido)vanadate complexes. The signals near −570 ppm occur in the order, low to high field, V_1, V-ONH_2, V_2, V_4 and V_5. Conditions of the experiments: 1-A: 3.0 mM vanadate; 6.0 mM NH_2OH, pH 7.2; ambient temperature. 1-B: as for 1-A but with 20 mM glycylglycine.

from glycylglycine are obtained with GlyGlyOEt, GlyGlyGly, and glycyltyrosine. It is evident that the carboxylate group is not required for the product to form and it also appears that a bulky side chain has little influence on product formation. An isolated carboxylate group, as in acetate for instance, can react with bishydroxamidovanadate, but even 400 mM acetate at pH 7 converts only about one half of the reactant complex to products. For comparison, 20 mM GlyGly converts about 90% of the starting complex to products. Ethylamine does have some influence on the hydroxylamine complex, but much less so than does acetate.

Attempts to obtain a crystalline glycylglycinatohydroxamidovanadate complex proved successful. The crystalline complex was found to be zwitterionic ($V(O)(ONH_2)_2$(GlyGly)) and its structure is shown in Fig. 3. Bond distances and angles are given in Table 3. A single water of crystallization, (O(7)), was also found in the unit cell. The vanadium atom has a seven-coordinate, approximately pentagonal bipyramidal environment with O(3) and O(4) occupying the axial positions. Alternatively, the complex might be described as trigonal bipyramidal — considering the center of the N—O bond in each hydroxylamine as one vertex in the equatorial plane. The complex deviates from mirror symmetry and this, presumably, is a consequence of the intermolecular interactions. The coordination mode of the glycylglycine ligand (via the amide carbonyl oxygen and the amine nitrogen atoms) seems unusual. In

Fig. 2. Graphical display of the overall formation of the product complexes as function of added hydroxylamine at constant total glyclylglycine concentration. Conditions of the experiments: 20 mM glyclycine; 3 mM vanadate; pH 7.0; variable NH_2OH (0.5–6.0 mM).



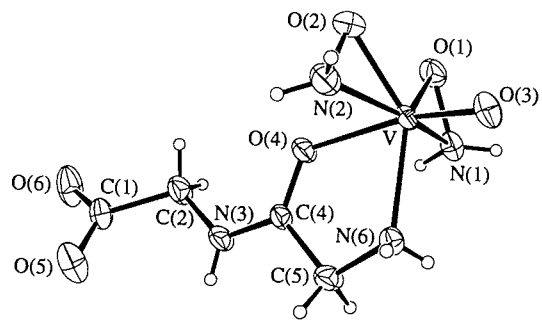


Fig. 3. The molecular structure of $V(O)(ONH_2)_2$(GlyGly) at 295 K. 50% probability thermal ellipsoids are shown for all non-hydrogen atoms. Hydrogen atoms are depicted by spheres of arbitrary radius.

the bisperoxovanadate case, similar complexes are not formed if this type of coordination is forced by esterifying the terminal carboxylate group. In this case no product was found (18, 38). The complex is zwitterionic, carrying a negative charge on the uncomplexed carboxylate group and the positive charge in the region of the vanadium. The form of the complex presumably is stabilized by the extensive intermolecular hydrogen bonding found in the crystal.

The relative orientations and dimensional parameters of the hydroxylamine ligands are similar to those for the dimethylhydroxylamine ligands of $[V(O)(ONMe_2)_2]_2O$ (footnote 4) and $[V(O)(ONEt_2)_2]_2O$ (41), in which, however, vanadium is only six-coordinate. Differences in the related bond angles at vanadium in these structures are commensurate with the introduction of a seventh coordinate bond. The most notable difference in analogous bond lengths is that the V—N bonds (2.0046(14) and 2.0160(19) Å, Table 3) average about 0.06 Å shorter than those in $[V(O)(ONMe_2)_2]_2O$ (2.066(2) and 2.069(2) C)[4] and about 0.07 Å shorter than those in $[V(O)(ONEt_2)_2]_2O$ (2.079(4), 2.061(4), 2.094(4), and 2.079(4), Å) (41). This difference is a reasonable consequence of the fact that in $V(O)(ONH_2)_2$(GlyGly) both of the hydroxylamine protons are involved in hydrogen bonds. The V—O(hydroxamido) bonds are perhaps very slightly longer in $V(O)(ONH_2)_2$(GlyGly) (see

[a] An analysis of the thermal parameters suggests bond length corrections in the range +0.001 – +0.005 Å (see text).

Table 3) than in $[V(O)(ONMe_2)_2]_2O$ (1.880(2) and 1.881(2) Å), while the N—O bond lengths are not significantly different.

A number of bisperoxovanadate complexes (42–46), which have a bidentate chelating ancillary ligand bonded to vanadium via one axial and one equatorial position are structurally very similar to the complex described here. Perhaps the best comparison is with the structures of the doubly anionic bisperoxovanadate complexes with pyridine-2-carboxylate and 3-hydroxypyridine-2-carboxylate (42). Both these ancillary ligands form five-membered chelate metallocycles having nitrogen in the equatorial position and oxygen in the axial position. In these complexes, the V—N bond lengths are 2.123(5) and 2.137(2) Å, respectively, and the V—O bond lengths are 2.290(4) and 2.314(2) Å, respectively (cf. V—N(6) 2.1211(19) Å and V—O(4) 2.1882(14) Å in the present structure). Very similar arrangements for the vanadium environment are also observed in related bisperoxovanadyl complexes having, instead, two monodentate ancillary ligands in these positions (47–49), although the axial ligand *trans* to the vanadyl oxygen is often only weakly coordinated.

Extensive hydrogen bonding in the crystals of $V(O)(ONH_2)_2(GlyGly)\cdot H_2O$ produces a three-dimensionally extended structure (see Figure 4). Every N-H or O-H hydrogen atom is involved in an intermolecular hydrogen bond. Each $V(O)(ONH_2)_2(GlyGly)$ unit is hydrogen bonded directly to eight different neighbouring complexes and to four different water molecules. In addition, each water molecule (O(7)) links four complexes by forming hydrogen bonds individually to O(6) and O(5) of two different carboxylate groups and also acts as an H-bond receptor for hydrogen atoms from a hydroxylamine and the (glycine)amine group of two additional neighbouring complexes. The oxygen atoms of the pendant carboxylate group (O(5) and O(6)) are each the receptors for two hydrogen bonds. The only "heteroatom" (O or N) not involved in hydrogen bonding is the carbonyl oxygen, O(4). A stereo diagram depicting all molecules that protrude into one unit cell and the hydrogen bonds between them is given in Fig. 4. The hydrogen-bonded interactions are summarized in Table 4. Additional crystallographic details, anisotropic thermal parameters, additional bond lengths and angles, torsion angles, and least-squares planes are provided as supplementary material.[6]

[6] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council, Ottawa, Canada K1A 0S2. Crystallographic details and tables of bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

The crystalline material is very hard and, despite the zwitterionic character of the complex, is virtually insoluble in water and dipolar aprotic solvents such as dimethyl sulfoxide and dimethylformamide. This insolubility, presumably, is a consequence of the extensive hydrogen-bonded network within the crystalline structure that makes dissolution thermodynamically unfavourable. Despite this inability to do dissolution studies, it seems very likely that the solution products have a coordination similar to that of the crystalline material. GlyGlyOEt and GlyGlyGly both give three products with a product distribution and ^{51}V chemical shifts virtually indistinguishable from those of the glycylglycine products. This clearly shows that the terminal carboxylate group is not required for the complex to form, as would be predicted from the crystal structure. There is no indication of any complex formation that cannot be assigned to the above possibility. The formation of the three solution complexes can then be accounted for quite simply from the structure of the solid. One product, probably the major one, can be assigned a structure similar to that found in the crystalline material where a *cis* arrangement, with the two oxygens of the two hydroxamide ligands in close proximity, is found. The other two crystal structures of hydroxylamine-derived complexes (footnote 4 and ref. 41) show the same arrangement, relative to each other, as the two hydroxylamine ligands in the complex here. This may suggest that there is an underlying principle giving rise to this preference for this orientation of the two ligands, perhaps steric but more likely electronic in origin. In some cases where heteroligands are also complexed (50), the two nitrogens, rather than the oxygens, are in close proximity to each other. The second product could correspond to the situation where both hydroxamido groups have undergone an end-to-end rotation so that the hydroxamido ligands are in the alternate *cis* orientation to one another. End-to-end isomerization has been shown to occur quite quickly in bis(dimethylhydroxamido)hydroxooxovanadate.[4] The third product would then correspond to the *trans* orientation where only one ligand has rotated. Although this offers a plausible explanation for the occurrence of three products, there are other possibilities that could include, for instance, a 180° rotation of the GlyGly ligand or a change in coordination.

The reaction of *N*-methylhydroxamidovanadate with gly-

Fig. 5. ^{51}V NMR spectrum showing the products formed in the equilibration of glycylglycine in the methylhydroxylamine–vanadate system. The signals near −652 ppm are from mono(*N*-methylhydroxamido)vanadate complexes, those in the range −760 to −820 ppm from bis(*N*-methylhydroxamido)GlyGly complexes. The signal at −505 ppm is from a glycylglycinatovanadate complex (52) while those near −570 ppm are from V_1, V-ONH_2, V_2, V_4, and V_5, respectively, from low to high field strength. Conditions of the experiments: 3 mM vanadate; 4 mM methylhydroxylamine; 20 mM glycylglycine; pH 7.5.

cylglycine follows closely the pattern of the non-methylated complex. Of some interest is the observation that a minimum of six product signals are observable in the vanadium NMR spectrum (Fig. 5). The observation of more than three signals shows that methyl group isomerization is quite slow, less than about 100 s^{-1}, as estimated from the chemical shift separations between signals. In principle, nine product signals might have been expected, three for each of the possible *cis* or *trans* N-O orientations. However, some signals may well be hidden under others or, as judged from Fig. 1, may simply be of an intensity too low to observe under the conditions of the experiments. It is unlikely that methyl group reorientation is stopped and it would be of interest to ascertain from kinetics experiments whether there is coupling between the end-for-end isomerization of the hydroxamido group and methyl reorientation.

The mode of complexation observed here, for the glycylglycinato ligand, involving the amine nitrogen and the carbonyl oxygen, is very different from that in the peroxovanadate system where the preferred product contains only one peroxo group and glycylglycine is complexed in a tridentate fashion through the terminal H_2N-, the terminal -CO_2^-, and the amide nitrogen, which is deprotonated in the complex (18, 38–40). This latter mode of coordination of a peptide is also found in oxovanadium(V) complexes (51, 52). Of course, bidentate complexation in the bisperoxovanadate system is well known (47, 48, 53), for instance with picolinic acid (47, 54) or oxalic acid (48, 55, 56). The differences in the chemistry toward additional ligands observed for the bishydroxamido complexes compared to the bisperoxo complexes will find its origin in the influence that the primary ligands have on the ability of the vanadium centre to accept electrons from the hetero-ligand and it may be that, with suitable ligands, similar products will be formed with bisperoxovanadate.

The coordination of dipeptides by vanadate found here by aqueous solution studies and established by the crystal structure analysis, coupled with the possibility of participation by side chains, opens up a potentially new means of complexation of vanadate by proteins. The functional groups on side chains such as those in serine, histidine, or lysine in conjunction with a peptide carbonyl oxygen provide the groups through which complexation could occur. Folding of a protein to bring the groups into an appropriate juxtaposition, as in the active site of an enzyme, certainly provides for the possibility of this mode of complex formation and it cannot be ignored.

Three-dimensional electron delocalization: a theoretical study based on the pentacyclo[3.3.1.1^{3,7}.0^{1,3}.0^{5,7}]decane system

Mary S.W. Chan and Donald R. Arnold

Abstract: The concept of electron delocalization, and the possibility of aromaticity in three dimensions has been introduced, but remains relatively unexplored. This work examines the structure and energy of a series of ions generated from pentacyclo[3.3.1.1^{3,7}.0^{1,3}.0^{5,7}]decane (**1**). The ions considered are the dication (**1**$^{2+}$), the radical cation (**1**$^{+\bullet}$), the radical anion (**1**$^{-\bullet}$), and the dianion (**1**$^{2-}$). The dication belongs to a small group of organic compounds that shows three-dimensional electron delocalization and it has been classified as "three-dimensionally homoaromatic." The relative stability of these ions is estimated by the enthalpy change of isodesmic and disproportionation reactions using energies obtained from HF, MP2, and DFT methods. The structural changes and the reorganization of the frontier orbitals when electrons are successively added to or removed from the neutral molecule (**1**) are also explored. The results confirm the three-dimensional electron delocalization in **1**$^{2+}$ and indicate that it is stable relative to a localized structure with similar features; however, it is highly unstable compared to the radical cation (**1**$^{+\bullet}$). The dianion (**1**$^{2-}$), on the other hand, did not show any evidence for electron delocalization and it is unstable relative to the radical anion (**1**$^{-\bullet}$).

Key words: three-dimensional aromaticity, electron delocalization, resonance, radical cations, radical anions.

Résumé : Le concept de la délocalisation des électrons et la possibilité d'aromaticité en trois dimensions a été proposé, mais ils n'ont pratiquement pas été explorés. Dans ce travail, on examine la structure et l'énergie d'une série d'ions générés à partir du pentacyclo[3.3.1.1^{3,7}.0^{1,3}.0^{5,7}]décane (**1**). Les cations considérés sont le dication (**1**$^{2+}$), le cation radical (**1**$^{+\bullet}$), l'anion radical (**1**$^{-\bullet}$), et le dianion (**1**$^{2-}$). Le dication appartient à un petit groupe de composés organiques qui présentent de la délocalisation électronique en trois dimensions et il a été classifé comme « tridimensionnellement homoaromatique ». On a évalué les stabilités relatives de ces ions par le biais des changements d'enthalpie des réactions isodesmiques et de dismutation en faisant appel aux énergies obtenues à l'aide des méthodes « HF », « MP2 » et « DFT ». On a aussi examiné les changements structuraux et la réorganisation des orbitales frontières résultant quand les électrons sont ajoutés ou enlevés successivement de la molécule neutre (**1**). Les résultats obtenus confirment la délocalisation tridimensionnelle des électrons dans l'espèce **1**$^{2+}$ et ils indiquent qu'elle est stable par rapport à une structure localisée comportant des caractéristiques semblables; toutefois, elle est hautement instable comparée au cation radical (**1**$^{+\bullet}$). Par ailleurs, aucune donnée suggère que le dianion (**1**$^{2-}$) présente de la délocalisation électronique et il est instable par rapport à l'anion radical (**1**$^{-\bullet}$).

Mots clés : aromaticité tridimensionnelle, délocalisation d'électrons, résonance, cations radicaux, anions radicaux.

[Traduit par la rédaction]

Introduction

Kekulé marked the beginning of a new era in organic chemistry in 1865 by referring to benzene and its derivatives as aromatic (1). The parent compound, benzene, has been considered the archetypical example of this class of compounds ever since. In the intervening years, aromaticity has become a vital concept in our understanding of organic chemistry because of the role it plays in explaining molecular structure, stability, and reactivity. Although the term "aromatic" now refers to a wider variety of structures, generally associated with enhanced stability and low reactivity, most of these examples are still two-dimensional, i.e., planar molecules. In fact, planarity was originally stated to be one of the requirements for aromaticity (for a general discussion of aromaticity see ref. 2)! The concept of electron delocalization, and therefore the possibility of aromaticity, in three dimensions remains relatively unexplored. However, this concept is becoming increasingly important because of the need for more sophisticated models to describe the bonding topology in unusual molecules like corannulene, buckminsterfullerene, and [5.5.5]trefoilene (3–5).

Three-dimensional electron delocalization in a polyhedral structure occurs in a variety of ways, and a number of theories have been developed for electron-counting rules to describe their bonding arrangements (6). This work is focused on electron delocalization in a volume contained by a polyhedron

[2] 

[3] 

[4] 

resulting from the mutual overlap of orbitals pointing towards the center of the structure. Electron delocalization of this type was first recognized in boron cage compounds with the general formulae $B_nH_n^{2-}$ ($6 \leq n \leq 12$) and $C_2B_{n-2}H_n$ ($5 \leq n \leq 12$). A number of theoretical models have been developed to explain the bonding in these electron-deficient clusters (7). A similar type of electron delocalization can be found in pyramidal cations (8). Three-dimensional electron delocalization in a hydrocarbon $(CH)_5^+$ was first suggested by Williams from analogy to the square pyramidal (D_{4d}) skeleton of pentaborane (9). This idea was further developed by Stohrer and Hoffman using molecular orbital calculations (10). Theoretical and experimental evidence for this square pyramidal cation intermediate has been presented for numerous substituted systems (11), even though the parent cation has now been shown to prefer a vinyl cyclopropene structure (12). A $4n + 2$ interstitial electron rule has been introduced to predict electron delocalization in these pyramidal (organic and inorganic) molecules (13).

A beautiful example of three-dimensional electron delocalization in a purely organic compound is Schleyer's dication: 1,3,5,7-tetradehydrotricyclo[3.3.1.1^{3,7}]decandiylium ($\mathbf{1}^{2+}$) (14). This dication adopts T_d symmetry with the four bridgehead carbon atoms forming the vertices of a tetrahedron. These atoms are strategically positioned such that one valence orbital from each atom points directly toward the center of the adamantyl cage. The in-phase combination of this set of atomic orbitals provides a bonding molecular orbital and, with the population of two electrons, this molecular orbital is a rare example of a four-center–two-electron bond. The structure of this dication has been confirmed by NMR spectroscopy and theoretical calculations (14, 15). The stability associated with this structure has also been demonstrated (14, 16). In particular, Schleyer chose to compare $\mathbf{1}^{2+}$ ($C_{10}H_{12}$) with tricyclo[3.3.1.1^{3,7}]decan-1,3-diylium (**2**) ($C_{10}H_{14}$), taking the enthalpy change of the isodesmic reaction [1] ($\Delta H = -197$ kJ/mol, MINDO/3) to be a measure of the stability for $\mathbf{1}^{2+}$. Schleyer classified $\mathbf{1}^{2+}$ as "three-dimensionally homoaromatic" based on these structural features and the enhanced stability estimated by reaction [1].

The structural features of a planar, cyclic, conjugated system are dictated in part by the number of π-electrons. Hückel molecular orbital theory demonstrated that for n-membered (n is an integer) monocyclic conjugated systems with D_{nh} symmetry, all π molecular orbitals are doubly degenerate except for the lowest bonding orbital and the highest anti-bonding orbital if n is even. If n is odd, all but the lowest bonding orbital are doubly degenerate. The degeneracy of these molecular orbitals leads to the well-known Hückel $4n + 2$ π-electron rule for predicting aromaticity in two dimensions (17).

The consequence of this rule is illustrated by the 1,3,5,7-cyclooctatetraene system. The neutral molecule **3** contains eight π-electrons and is an unstable open-shell system in the D_{8h} point group because of the degeneracy of the molecular

For personal use only.

orbitals. This molecule, therefore, distorts from planarity to a D_{2d} tub-shaped structure (18). The double bonds are localized and behave chemically as isolated unconjugated double bonds (19). However, if two electrons are removed, the dication ($\mathbf{3}^{2+}$) becomes a six π-electron system. According to the Hückel $4n + 2$ rule, this is the correct number of electrons to achieve a stable closed-shell configuration and the molecule becomes planar to achieve maximum π-orbital overlap for electron delocalization. Ab initio molecular orbital calculations have demonstrated the planar (D_{8h}) structure and enhanced stability of this dication (20). Although the dication of the parent compound is not known, experimental evidence for methyl-substituted systems has been reported. The chemical shifts from both ^{1}H and ^{13}C NMR spectroscopy confirm the coplanarity of the eight ring carbon atoms in the dications of 1,4-dimethyl and 1,3,5,7-tetramethyl-cyclooctatetraene (21). The dianion ($\mathbf{3}^{2-}$), obtained from adding two electrons to **3**, also has the right number of electrons to attain a closed-shell configuration in the D_{8h} point group. Semiempirical calculations found the structure $\mathbf{3}^{2-}$ to have equal carbon–carbon bond lengths and bond orders (22). Experimentally, $\mathbf{3}^{2-}$ can be readily produced by alkali metal reduction; both X-ray diffraction and NMR studies have confirmed it to be a planar (D_{8h}) aromatic species (23).

The enhanced stability associated with aromaticity has historically been related to resonance energies. A variety of methods based on this concept have been introduced. For all methods used, both $\mathbf{3}^{2+}$ and $\mathbf{3}^{2-}$ have more than two-thirds of the aromatic stability of benzene (24). Another method is to measure the thermodynamic stability from equilibrium constants. The classical illustration of the stability of the aromatic doubly charged anion in the cyclooctatetraene system is the disproportionation of the radical anion (reaction [2]). Experimental evidence showed that this equilibrium constant is dependent on the solvent and the counterion. The values range from 2×10^0 ($\Delta G = -1.7$ kJ/mol) in ammonia, with lithium as the counterion, to 3×10^8 ($\Delta G = -47.8$ kJ/mol) in tetrahydrofuran, with potassium as the counterion (25). Both $\mathbf{3}^{2+}$ and $\mathbf{3}^{2-}$ are considered to be aromatic because of these structural features and enhanced stability.

The behavior of the cyclooctatetraene system provides an interesting two-dimensional model for the study of aromaticity in three dimensions. For example, can such systems be expected to behave the same as two-dimensional aromatic systems and is there an analogy between Schleyer's dication and the cyclooctatetraene dication? The addition of two electrons to $\mathbf{1}^{2+}$ leads to a neutral species whose Lewis structure can be represented by pentacyclo[3.3.1.1^{3,7}.0^{1,3}.0^{5,7}]decane (**1**). Ab initio and density function theory (DFT) molecular orbital calculations were employed to determine the geometry and energy of the species necessary for a study analogous to the cyclooctatetraene system in the pentacyclo[3.3.1.1^{3,7}.0^{1,3}.0^{5,7}] decane system: $\mathbf{1}^{2+}$, $\mathbf{1}^{+\cdot}$, **1**, $\mathbf{1}^{-\cdot}$, $\mathbf{1}^{2-}$. To determine the stability of the doubly charged ions, the energies obtained from these calculations were used to estimate the enthalpy change for the disproportionation reaction of the radical cation ($\mathbf{1}^{+\cdot}$) (reaction [3]) and the radical anion ($\mathbf{1}^{-\cdot}$) (reaction [4]).

Computational details

The Gaussian 92 package of programs was employed for all ab initio molecular orbital calculations and the Gaussian 94 package was employed for DFT calculations (26, 27). The geometry of the closed-shell systems was fully optimized at the restricted Hartree–Fock level with the 6-31G* basis set (6-31+G* for anions).[2] The neutral molecule (**1**) was optimized using both basis sets. The Hartree–Fock geometry then served as a starting point for optimization using Becke's three-parameter exchange function with Predew and Wang's 1991 gradient-corrected correlation (B3PW91) (29, 30). The structures of the open-shell systems were obtained in the same manner using the unrestricted formalism. All of the structures were optimized using the Berny optimization procedure (31) without symmetry constraints and were confirmed, by harmonic frequency analysis, to be local minima on their respective potential energy surfaces. Single-point energies were calculated to second order in Møller–Plesset perturbation theory (MP2) using the 6-31G* basis set (6-31+G* for anions) at the HF/6-31G* (HF/6-31+G* for anions) optimized geometries, and were corrected for spin contamination where necessary (32). The charge and spin density distributions were obtained from Mulliken and natural population analyses (33, 34).

Results

It has been emphasized that higher levels of theory are required to accurately predict the structure and energy of nonclassical cations (35). Therefore we recalculated the enthalpy change of reaction [1] using ab initio molecular orbital theory up to the HF/6-31G* level. Geometry optimization of tricyclo[3.3.1.1^{3,7}]decane (**4**), commonly known as adamantane, gave the expected highly symmetric T_d structure. Both **2** and tetracyclo[3.3.1.1^{3,7}.0^{5,7}]decane (**5**) gave C_{2v} structures.

A pictorial representation of the B3PW91/6-31G* (B3PW91/6-31+G* for anions) fully optimized structures of the five species in the pentacyclo[3.3.1.1^{3,7}.0^{1,3}.0^{5,7}]decane system are shown in Figs. 1–5. Selected geometrical parameters can be found in Tables 1–5. The DFT optimizations were performed to include electron correlation in the optimization procedure. Conventional MP2 optimization was not possible for the anions due to the large memory requirements of this method. The MP2 optimized geometry of $\mathbf{1}^{+\cdot}$ is reported along with the DFT geometry in Table 2. The B3PW91 optimized geometry is very similar to the MP2 geometry with an average difference of 0.007 Å for bond lengths, 0.3° for bond angles, and 0.4° for dihedral angles. This is consistent with results obtained from other research groups (36).

Where appropriate, the charge and spin density distributions obtained from Mulliken and natural population analysis for these species are listed in Table 6. The two methods are generally within good agreement for the spin density of the two radical species $\mathbf{1}^{+\cdot}$ and $\mathbf{1}^{-\cdot}$. However, there are large discrepancies in their charge assignment. One of the limitations of Mulliken population analysis is evident in its charge assignment of the anions. It shows a tendency to place large positive charge density on the bridgehead carbon atoms with large negative charge density on the methylene groups to compensate.

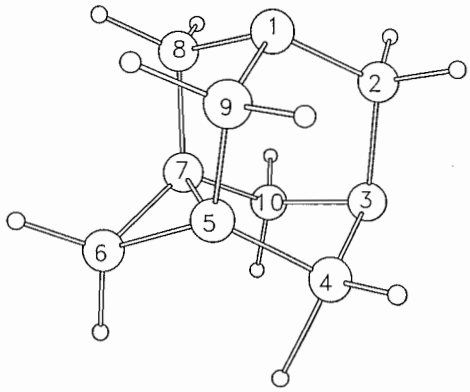
This charge separation is not observed in natural population analysis where the bridgehead carbon atoms carry more negative charge than the methylene groups. In general, the results obtained from natural population analysis are more consistent with the structures suggested by the optimized geometries, in agreement with previously reported results (37). A graphical representation of the frontier molecular orbitals of the closed-shell species for the pentacyclo[3.3.1.1^{3,7}.0^{1,3}.0^{5,7}]decane system is shown in Fig. 6.

Fig. 4. B3PW91/6-31+G* optimized structure of $\mathbf{1}^{-\cdot}$.



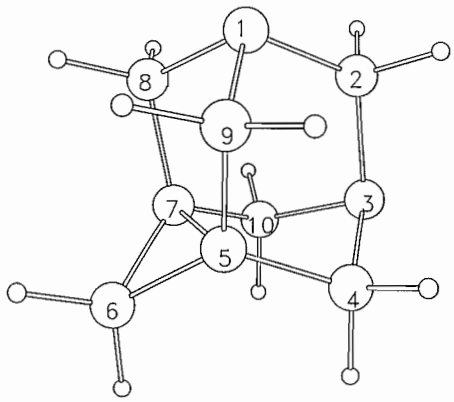


Fig. 5. B3PW91/6-31+G* optimized structure of $\mathbf{1}^{2-}$.

Geometry optimization of **1** produced a D_{2d} structure with completely localized σ-bonds. This fully optimized structure was used as the starting point for geometry optimizations of all ions in this series. Geometry optimization of $\mathbf{1}^{2+}$ using this procedure reproduced the T_d structure reported by Schleyer and co-workers (14). The structure of the radical cation $\mathbf{1}^{+\cdot}$, obtained in this manner, can be described as a C_{3v} distonic radical cation (38). The charge and spin distribution from both population analyses showed that the spin is located on C_1, whereas most of the charge is delocalized over the cyclohexyl moiety. The total overlap population between the remaining three bridgehead atoms in $\mathbf{1}^{+\cdot}$ is stronger than that in $\mathbf{1}^{2+}$, justifying the dotted-line representation shown in Fig. 2. The structure of the radical anion $\mathbf{1}^{-\cdot}$, shown in Fig. 4, does not show spin and charge separation. The spin density is concentrated on two bridgehead carbon atoms (C_1 and C_3). The same two atoms carry one-half of the negative charge, with the rest delocalized over the remaining bridgehead carbon atoms. Unlike the radical cation, the charge is not symmetrically distributed; C_1 and C_3 carry significantly more of the negative charge than the other two bridgehead carbon atoms (C_5 and C_7). As a result, the C_5—C_7 bond remains intact, distorting the structure to C_{2v} symmetry. The optimized structure of $\mathbf{1}^{2-}$ also belongs to the C_{2v} point group. It is similar to the structure of $\mathbf{1}^{-\cdot}$ in that the bond between C_1 and C_3 is broken while the bond between C_5 and C_7 remains. In fact, this bond (C_5—C_7)

is shorter than the corresponding bond in the neutral molecule (**1**).

The enthalpy changes (ΔH) of reactions [1], [3], and [4], calculated at various theoretical levels, are shown in Table 7. The ΔH values reported are estimated by taking the difference between the self-consistent field (SCF) energy of the products and reactants. The rotational, translational, and vibrational (including zero point) energies are not large enough to make a significant difference. The total of these components contributes less than 0.4% to ΔH at the HF/6-31G* level. Ab initio molecular orbital calculations predict reaction [1] to be exothermic, consistent with the MINDO results, although smaller in magnitude. The enthalpy change is positive for the disproportionation of both radical ions ($\mathbf{1}^{+\cdot}$ and $\mathbf{1}^{-\cdot}$), illustrated by reactions [3] and [4], for all theoretical models investigated.

Discussion

It is evident from Table 7 that the calculated enthalpy change (ΔH) for each reaction is dependent on the theoretical model employed. For reaction [1], the ΔH value does not change significantly when the split-valence (3-21G) basis set is used instead of the minimal (STO-3G) basis set. The total energies of the reactants and the products must decrease by about the same amount for there to be no significant change in ΔH. The magnitude of ΔH nearly doubles when the polarized (6-31G*)

Table 7. Estimated enthalpy changes for reactions [1], [3], and [4] calculated at various theoretical levels.

Theoretical model	Enthalpy change (kJ/mol)		
	Reaction [1]	Reaction [3]	Reaction [4]
HF/STO-3G//HF/STO-3G	−81	830	694
HF/3-21G//HF/3-21G	−83	716	600
HF/6-31G*//HF/6-31G*	−154	688	566
MP2/6-31G*//HF/6-31G*		544	
B3PW91/6-31G*//B3PW91/6-31G*		563	
HF/6-31+G*//HF/6-31+G*			509
B3PW91/6-31+G*//B3PW91/6-31+G*			427

basis set is employed. Closer inspection of the total energy of each species revealed that this change in ΔH is caused by a significant decrease in the total energy of $\mathbf{1}^{2+}$. This suggests that the polarization functions on the carbon atoms play a more important role in determining the bonding structure in $\mathbf{1}^{2+}$ than in the classical structure of compounds **2**, **4** and **5**. The enthalpy change at the HF/6-31G* level for reaction [1] shows that the delocalized dication $\mathbf{1}^{2+}$ is 154 kJ/mol more stable than **2**, in agreement with the principle that delocalization leads to stability. Geometry optimization of $\mathbf{1}^{2+}$, starting from the structure of the neutral molecule **1**, without symmetry constraints, gave the same structure as that reported by Schleyer and co-workers (14). The fact that identical structures were obtained starting from different geometries provides additional evidence that this non-classical structure is the most stable minimum on the potential energy surface of this system. Further evidence for the stability associated with the four-center–two-electron bonding arrangement similar to that observed in $\mathbf{1}^{2+}$ have been reported. Glukhovtsev et al. showed that the tetrahedral structure is the only minimum on the potential energy surfaces of Li_4^{2+} and Na_4^{2+} (39). The electron density distributions of these T_d structures showed that there is no direct bonding between the atoms. The four positively charged atoms are essentially held together by a large negative charge density located at the center of the tetrahedral. The Coulombic repulsion in these small, doubly charged species is significant; therefore the stability associated with this bonding arrangement must be very large in order to overcome the repulsion energy and produce a minimum.

The structural changes that occur upon sequential oxidation and reduction of **1** are quite interesting. The symmetry of **1** can be easily predicted from its Lewis structure. However, the optimized structure of **1** serves as a good reference to analyze the changes that occur when electrons are successively removed or added. Transformation to the structure of $\mathbf{1}^{+\cdot}$ involves cleavage of the C_1—C_3 bond to generate a radical center at C_1 and a cationic center at C_3 (Fig. 2). Delocalization of the positive charge due to electron donation to C_3 from the cyclopropane bond (C_5—C_7) produces the C_{3v} distonic radical cation. This delocalization requires dramatic structural changes and the driving force for this reorganization is the overlap of the valence orbitals on the remaining three bridgehead carbon atoms (excluding the one bearing the spin) to produce the molecular orbital that will lead to delocalization, forming a tris-homoaromatic ($4n + 2$, $n = 0$) species similar to the tris-homocyclopropenyl cation (40). The magnitude of the net stabilization gained by this type of homoaromatic interaction has been estimated to be 85 kJ/mol (41). The spin distribution, combined with the observation that the singly occupied molecular orbital of $\mathbf{1}^{+\cdot}$ is composed mainly of the one p orbital of C_1, indicates that the radical portion is essentially localized on this single atom. For this particular system, the stability achieved by the delocalization of two electrons to form the homoaromatic structure is obviously greater than that of spin delocalization.

The overall stability of $\mathbf{1}^{+\cdot}$ is illustrated by the energetics of reaction [3]. The ΔH value for reaction [3] decreases significantly when the 3-21G basis set is used instead of the STO-3G basis set. Inspection of the changes in the total energy of each species shows that this is primarily due to a large decrease in the total energy of **1**. The small change observed when the basis set is further increased to 6-31G* is a consequence of the large decrease in the total energy of $\mathbf{1}^{2+}$ and $\mathbf{1}^{+\cdot}$, but the total energy of **1** remained fairly constant; therefore, ΔH remains about the same. This observation implies that the split-valence basis set is more important in predicting the structure of **1**, presumably because of the high p character of the cyclopropane bonds. Electron correlation also has a significant effect on the ΔH value for this reaction. This is expected because the number of electron pairs is not equal on both sides of the equation. Becke's hybrid method gave similar results as the MP2 single point calculations: $\mathbf{1}^{+\cdot}$ is ~550 kJ/mol more stable than $\mathbf{1}^{2+}$. This indicates that more energy is required to remove an electron from $\mathbf{1}^{+\cdot}$ to produce $\mathbf{1}^{2+}$ than is necessary to convert **1** to $\mathbf{1}^{+\cdot}$. This result is not too surprising when factors other than aromaticity are taken into account. For example, in order to bring all four bridgehead atoms within bonding distance, the adamantane cage has to be compressed, which causes a decrease in the C-CH_2-C angles (87.1° in $\mathbf{1}^{2+}$). This large deviation from the normal tetrahedral angle (109°) of an sp^3 hybridized carbon atom creates a large strain energy. The structure of $\mathbf{1}^{2+}$ is a compromise between optimal overlap and strain energy. The result is that three of the C-CH_2-C bond angles are smaller in $\mathbf{1}^{2+}$ than in $\mathbf{1}^{+\cdot}$, with concomitant increases in strain energy. The effectiveness of delocalization in $\mathbf{1}^{2+}$ is reduced because of the longer distances between the bridgehead atoms so that optimal overlap cannot be achieved. The total overlap between the bridgehead atoms in $\mathbf{1}^{2+}$ is only

half the magnitude of the overlap between the bridgehead atoms in the cyclohexyl moiety of $\mathbf{1}^{+\cdot}$. Furthermore, since $\mathbf{1}^{2+}$ carries twice the charge in essentially the same volume, the total repulsion energy will be significantly higher than in $\mathbf{1}^{+\cdot}$. All of these factors increase the total energy of $\mathbf{1}^{2+}$ relative to $\mathbf{1}^{+\cdot}$. The enthalpy change of reaction [3] represents the difference between the first and second ionization potentials of **1**. The first ionization involves transformation from a localized molecule to an aromatic radical cation, while the second ionization only serves to expand the electron delocalization in $\mathbf{1}^{+\cdot}$ to the fourth bridgehead carbon atom. Evidently, the first process is more favorable.

The response of the neutral molecule **1** to the addition of electrons is also the cleavage of the C_1—C_3 bond. The B3PW91/6-31+G* optimized structures of the radical anion $\mathbf{1}^{-\cdot}$ and the dianion $\mathbf{1}^{2-}$ are similar. In the case of the radical anion, both Mulliken and natural population analysis agree that the spin and charge are essentially located on two bridgehead carbon atoms (C1 and C_3). These two carbon atoms also carry the highest charge density in the dianion, but in contrast to $\mathbf{1}^{-\cdot}$, the methylene groups also carry a significant amount of negative charge along with the remaining bridgehead carbon atoms. As a result of the large repulsion between the two anionic centers in $\mathbf{1}^{2-}$, the C_1—C_3 interatomic distance is significantly longer than in $\mathbf{1}^{-\cdot}$ (Tables 4 and 5). This also causes corresponding increases in the C_1-C_2-C_3 and C_3-C_4-C_5 angles that would alleviate some of the strain in $\mathbf{1}^{2-}$. Although natural population analysis assigns small negative charges to the methylene groups and the bridgehead atoms C_5 and C_7, the optimized geometry of $\mathbf{1}^{2-}$ suggests that the electrons in $\mathbf{1}^{2-}$ are largely localized on C_1 and C_3 rather than delocalized over the entire molecule as in $\mathbf{1}^{2+}$.

The enthalpy change for the disproportionation of the radical anion (reaction [4]) is positive for all theoretical models studied. The enthalpy change decreases as the basis set increases. The largest decrease occurred upon going from the minimal (STO-3G) to the split valence (3-21G) basis set. This is caused by a large decrease in the total energy of $\mathbf{1}^{2-}$, which again can be related back to the importance of the *p*-orbitals in describing the bonding of cyclopropane structures. The next largest decrease in the enthalpy change is upon the inclusion of electron correlation. Again, the most dramatic change in total energy was observed in $\mathbf{1}^{2-}$. The positive ΔH of reaction [4] indicates that more energy is required to add an electron to the radical anion than to the neutral molecule; $\mathbf{1}^{-\cdot}$ is more stable than $\mathbf{1}^{2-}$. The structures of these two species are very similar and hence the strain energy in $\mathbf{1}^{2-}$ should not be significantly higher than in $\mathbf{1}^{-\cdot}$. The instability of $\mathbf{1}^{2-}$ relative to $\mathbf{1}^{-\cdot}$ can be attributed to the Coulombic repulsion of the two negative charges in the dianion. The enthalpy change estimated at the B3PW91/6-31+G* level for this reaction is 427 kJ/mol. Since $\mathbf{1}^{-\cdot}$ does not show any special structural feature that would lead to significant stabilization (in contrast to $\mathbf{1}^{+\cdot}$), this large positive ΔH indicates that there is no special stabilization in $\mathbf{1}^{2-}$ either. The energies of these calculations confirm the conclusion reached from the structural analysis: $\mathbf{1}^{2-}$ does not exhibit extra stabilization due to electron delocalization.

All known organic molecules exhibiting three-dimensional electron delocalization contain two or six delocalized electrons (8, 11*c*, 42). These numbers follow the Hückel $4n + 2$ π-electron rule for two-dimensionally aromatic compounds. However, Fig. 6 shows that the frontier orbitals of the three closed-shell species in the pentacyclo[3.3.1.$1^{3,7}$.$0^{1,3}$.$0^{5,7}$]decane system do not resemble the pattern predicted by Hückel theory. The lowest unoccupied molecular orbital (LUMO) of $\mathbf{1}^{2+}$ is triply degenerate, suggesting that six more electrons have to be added in order to reach the next closed-shell configuration in the T_d point group. If Schleyer's dication $\mathbf{1}^{2+}$ is considered as the first member of an aromatic series with T_d symmetry in three dimensions, the next member of this series would contain eight delocalized electrons. Fig. 6 also shows how the frontier orbitals of the three-dimensional pentacyclo[3.3.1.$1^{3,7}$.$0^{1,3}$.$0^{5,7}$]decane system rearrange to accommodate additional electrons. When two electrons are added to $\mathbf{1}^{2+}$, an unstable open shell arrangement occurs in the T_d point group due to the degeneracy of the LUMO. Consequently, the neutral molecule **1** in this system distorts to a lower (D_{2d}) symmetry. This is similar to the behavior in the two-dimensional cyclooctatetraene system. However, the open shell configuration still remains when four electrons are added to produce the dianion $\mathbf{1}^{2-}$ because the LUMO of $\mathbf{1}^{2+}$ is triply degenerate. Therefore, instead of reverting to T_d symmetry, $\mathbf{1}^{2-}$ distorts further to a lower C_{2v} symmetry. The degeneracy of the frontier molecular orbitals observed for these three closed-shell species indicates that a different rule for predicting the number of delocalized electrons will be required for aromaticity in three dimensions.

The results from this study illustrate the importance of symmetry in determining the degeneracy of molecular orbitals, which in turn dictates the possible number of delocalized electrons a molecule may accommodate. The degeneracy of the molecular orbitals in any given molecular species is governed by the point group of the molecule. The Hückel $4n + 2$ π-electron rule for aromaticity in two dimensions depends on the presence of doubly degenerate levels ensured by the D_{nh} symmetry of the molecules for which this rule is normally invoked (43). A number of different symmetry groups, such as T_d and O_h, may facilitate delocalization of electrons in three dimensions. This implies that a number of different rules are required to predict the number of delocalized electrons for aromaticity in three dimensions: one for each conceivable point group.

Conclusion

The structure and charge density of $\mathbf{1}^{2+}$ obtained from these calculations confirm that two electrons are delocalized in a three-dimensional space in this dication. However, the results obtained in the same manner for the dianion $\mathbf{1}^{2-}$ are more consistent with a structure where the electrons are localized in σ-bonds and specific atoms rather than a delocalized structure. The fully optimized structure of $\mathbf{1}^{2-}$ did not reveal any unusual features that indicate special stabilization. The large positive enthalpy change of the disproportionation reaction for the radical anion, estimated by using the total energies of the appropriate species, also confirms that $\mathbf{1}^{2-}$ does not possess any special stability compared to the radical anion. The relative stability of $\mathbf{1}^{2+}$ was estimated by two different reactions (reactions [1] and [3]). Reaction [1] shows that the extra stabilization due to electron delocalization is on the order of 150 kJ/mol. However, reaction [3] indicates that the disproportionation reaction for the radical cation is endothermic by 563

For personal use only.

kJ/mol, implying that the radical species is much more stable than the dication.

The enthalpy change of reaction [1] confirmed that there is stability associated with electron delocalization in $\mathbf{1}^{2+}$. In spite of this, $\mathbf{1}^{+\cdot}$ is more stable than the dication as indicated by the large positive ΔH of reaction [3]. Reaction [4] shows that the dianion $\mathbf{1}^{2-}$ is also less stable than the radical anion $\mathbf{1}^{-\cdot}$. It is recognized that these are gas phase calculations, and that solvent and counterion effects may shift the equilibrium of these reactions. In the case of the cyclooctatetraene system, the enthalpy change of the disproportionation reaction for the radical anion (reaction [2]) is also positive in the gas phase, with magnitudes similar to those obtained with reactions [3] and [4] (44). In fact, the dianion has not been observed experimentally in the gas phase (45]). Once in solution, this equilibrium shifts to the right with the help of ion pairing and solvation effects. This leads to the conclusion that, in the gas phase, the Coulombic repulsion in the doubly charged ions is larger than the stabilization from aromatic electron delocalization. Therefore, it is plausible that solvent and counterion effects would also shift the equilibrium of reactions [3] and [4].

In contrast to the cyclooctatetraene system, the dianion $\mathbf{1}^{2-}$ does not revert to the same symmetry as the dication $\mathbf{1}^{2+}$ due to the fact that the pattern of the frontier orbitals for the closed-shell species of the three-dimensional pentacyclo[3.3.1.1^{3,7}.0^{1,3}.0^{5,7}]decane system does not resemble the Hückel pattern. This is to be expected since Hückel theory only applies to planar molecules with D_{nh} symmetry, and cannot be extended to aromaticity in three dimensions. The degeneracy of the frontier orbitals obtained from these calculations suggests that six more electrons must be added to $\mathbf{1}^{2+}$ to achieve the next closed-shell configuration in the T_d point group. This implies that for three-dimensional aromaticity different rules are needed to predict the number of delocalized electrons. Furthermore, symmetry dictates that more than one rule is necessary: one for each point group, which may facilitate electron delocalization in three dimensions.

Acknowledgments

We thank Dr. R. J. Boyd and his research team for their valuable assistance with computational details, Ms. V. Hannon at University Computing and Information Services (UCIS) at Dalhousie University for hardware support, Dr. N. Burford for helpful discussion on symmetry, and the Natural Sciences and Engineering Research Council of Canada for funding. Computer time was arranged through Dr. Boyd's group and UCIS at Dalhousie University.

Micellar catalysis of organic reactions. Part 37.[1] A comparison of the catalysis of ester and amide hydrolysis by copper-containing micelles

Trevor J. Broxton and Abdulla Nasser

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12

Abstract: The hydrolysis of a number of nitroactivated esters and amides has been studied in the presence of copper-containing metallomicelles at neutral pH. The relative rates of hydrolysis in the pure metallomicelle and in co-micelles with either cetyltrimethylammonium bromide (ctab) or Triton X-100 depends on the hydrophobicity of the substrate and whether it is completely solubilized by the copper micelle. Thus it depends on the concentration of the copper micelle. At low concentrations of copper micelle (0.2 mM) where the substrate is incompletely solubilized, the reaction is faster when 2 mM ctab is added. At higher concentrations (>0.6 mM) where the substrate may be almost completely solubilized by the copper micelle, the reaction is slower when 2 mM ctab is added. For ester hydrolysis the presence of either a carboxylic acid group or a heterocyclic nitrogen atom close to the reaction centre resulted in much larger catalysis by the metallomicelle than for model compounds without these additional groups. It is postulated that these groups coordinate with the metal ion and thus present the reaction centre close to a metal-bound hydroxyl resulting in a significant increase in the rate of bond formation, which is the rate-determining step for ester hydrolysis. For amide hydrolysis the presence of a carboxyl group *ortho* to the reaction centre did not lead to larger catalysis by the copper micelle than for the compound without this group. This difference is attributed to the different rate-determining steps for amide and for ester hydrolysis.

Key words: metallomicelles, ester and amide hydrolysis.

Résumé : Opérant à un pH neutre, en présence de métallomicelles contenant du cuivre, on a étudié l'hydrolyse d'un certain nombre d'esters et d'amides activés par des groupes nitro. Les vitesses relatives d'hydrolyse dans la métallomicelle pure et dans des comicelles comportant soit du bromure de cétyltriméthylammonium («ctab») soit du Triton X-100 dépend du caractère hydrophobe du substrat et de sa solubilité dans la micelle de cuivre. Elles dépendent donc de la concentration de micelle de cuivre. À de faibles concentrations de micelle de cuivre (0,2 mM), alors que le substrat ne se solubilise pas complètement, la vitesse de la réaction est accélérée par l'addition de 2 mM de «ctab». À des concentrations plus élevées (>0,6 mM), alors que le substrat est pratiquement solubilisé par la micelle de cuivre, la réaction est ralentie par l'addition de 2 mM de «ctab». Lors de l'hydrolyse de l'ester en présence soit d'un groupe acide carboxylique soit d'un atom d'azote hétérocyclique à proximité du centre réactionnel, la catalyse par la métallomicelle est beaucoup plus importante que dans les cas de composés modèles ne portant pas ces groupes. On fait l'hypothèse que ces groupes se coordonnent à l'ion métallique et rapprochent donc le centre réactionnel du groupe hydroxyle lié au métal; il en résulte une augmentation de la vitesse de formation de la liaison qui est l'étape déterminante dans l'hydrolyse de l'ester. Par rapport à l'hydrolyse de composés modèles ne comportant pas ces groupes, l'hydrolyse d'amides comportant un groupe carboxyle en position *ortho* du centre réactionnel ne conduit pas à des niveaux de catalyse par la micelle de cuivre plus élevés.

Mots clés : métallomicelles; hydrolyse, ester et amide.

[Traduit par la rédaction]

Introduction

The study of the catalysis of organic reactions by metallomicelles is currently of interest (1–4). We have previously reported (5) strong catalysis of amide hydrolysis in neutral solution by micelles formed after complexation of a hydrophobic ligand, *N,N,N′*-trimethyl-*N′*-hexadecylethylenediamine, with cupric chloride. The amide studied was 5-nitro-2-(trifluoroacetylamino)benzoic acid **1**. It is now of interest to determine whether the carboxylic acid group *ortho* to the amide reaction centre is essential for maximal catalysis by the copper-containing micelle and furthermore to compare ester and amide hydrolysis in pure metallomicelles and in the presence of co-micelles with either cetyltrimethylammonium bromide (ctab), a cationic surfactant, or with Triton X-100, a neutral surfactant. Engbersen and co-workers (6) reported stronger catalysis of the hydrolysis of phenyl picolinate in co-micelles of a copper-containing metallo-

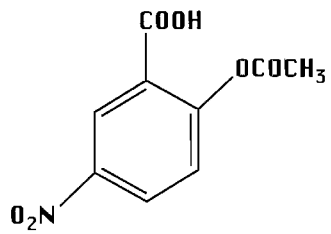
micelle with both ctab and with Brij 35 than in the pure metallo micelles.



We now report the catalyzed hydrolysis of amides 5-nitro-2-(trifluoroacetylamino)benzoic acid **1** and *N*-4-nitrophenyltrifluoroacetamide **2** and esters 2-acetoxy-5-nitrobenzoic acid **3**, 4-acetoxy-3-nitrobenzoic acid **4**, 8-acetoxy-5-nitroquinoline **5**, *p*-nitrophenylacetate **6**, and *o*-nitrophenyl acetate **7** in the presence of copper-containing metallomicelles. We have chosen to use the tetradecyl ligand *N,N,N′*-trimethyl-*N′*-tetradecylethylenediamine to prepare the metallomicelle, to avoid some solubility problems encountered with the hexadecyl compound.

Results and discussion

1. Amide hydrolysis

Pseudo-first-order rate constants for the hydrolysis of amides **1** and **2** are given in Table 1. With both the chloride and acetate salts, identical rate constants were obtained for reactions using solutions obtained by dissolving solid samples of the copper–ligand complex (method *a*), and for solutions obtained by preparing the complex in situ (method *b*), see experimental section. For the nitrate salt, the rate constants were only obtained by method *b*, i.e., in solutions obtained by mixing the copper nitrate and ligand in situ, see experimental section.

For both compounds, similar rates were obtained with the chloride, acetate, and nitrate metallomicelles and the maximum observed catalysis for each compound was also similar for each micelle. This indicates that the reaction of the amide substrate is with a copper-bound hydroxyl rather than with hydroxide ion from the bulk solution. In the latter case we would have expected significant differences between the rates obtained in chloride, acetate, and nitrate micelles based on the pseudophase ion exchange kinetic model of micellar catalysis (7, 8), because the hydroxide ion would be competing with different counterions for available sites on the micelle surface. This is consistent with conclusions drawn by Menger et al. (1) for the copper-catalyzed hydrolysis of phosphate esters.

In most cases it can be seen that the rate of hydrolysis of compound **1** is slightly faster (1.3- to 4.9-fold) than that for compound **2**. The maximum observed catalysis of the hydrolysis of both compounds is similar, ranging from 46 to 47.5 for compound **1** and from 41 to 48 for compound **2**.

The rate–detergent profile in the miceles with chloride counterions showed an increase in rate as the detergent concentration was increased from 0.2 to 2 mM. Even at 0.2 mM the rate of hydrolysis was more than 10 times faster than in pure water alone. This is consistent with a critical micelle concentration (cmc) of 0.18 mM as reported by Menger et al. (1) for this micelle.

Effect of co-micelles

For compound **1**, which should be well solubilized by the metallomicelle due to the electrostatic attraction between the ionized carboxylic acid group and the cationic micelle, the rate of hydrolysis in the presence of a co-micelle was slower than in the pure metallomicelle. This inhibiting effect was larger for ctab co-micelles than for Triton X-100 co-micelles.

For compound **2**, which is less well solubilized by the metallomicelle since it is a neutral compound, the addition of co-micelles of ctab at low concentrations of copper micelle (0.2–0.4 mM) resulted in a rate increase. At higher copper micelle concentrations the addition of co-micelles of ctab caused a reduction in the rate of hydrolysis. At all copper concentrations the addition of co-micelles of Triton X-100 resulted in a reduction in the rate of hydrolysis. The effect of these co-micelles on the rate of hydrolysis depends on how well the substrate is solubilized by the copper micelle alone and hence on the copper micelle concentration. If the substrate is completely solubilized by the copper micelle, then the addition of a co-micelle reduces the rate of hydrolysis, presumably as a result of the dilution of the substrate in the micellar pseudophase. On the other hand, if the substrate is not completely solubilized by the copper micelle, then the addition of a co-micelle improves solubilization of the substrate by the micelles and hence increases the rate of hydrolysis. Engbersen and co-workers (6) observed that the rate of hydrolysis of *p*-nitrophenylpicolinate in the presence of zinc- or copper-containing metallomicelles was increased by the addition of co-micelles of either ctab or Brij-35. This work was carried out at a low metallomicelle concentration (0.4 mM), so presumably the ester substrate was not fully solubilized and hence the addition of co-micelles increased solubilization of the substrate in the micellar pseudophase, thus increasing the observed rate of hydrolysis.

2. Ester hydrolysis

Pseudo-first-order rate constants for the hydrolysis of esters **3**, **4**, and **5** are given in Table 2. For 2-acetoxy-5-nitrobenzoic acid, **3**, the rate of hydrolysis increased to a maximum at 2 mM copper micelle. At this concentration the catalysis was 7100-fold compared to reaction in water. For *p*-nitrophenylacetate, a model compound without the acid group, the observed catalysis, was only 5-fold. For the isomer 4-acetoxy-3-nitro benzoic acid, **4**, the optimum rate of hydrolysis was also obtained at 2 mM copper micelle but in this case the catalysis was only 58-fold. The model compound without the acid group, *o*-nitrophenylacetate, had only a 4.5-fold catalysis. For 8-acetoxy-5-nitroquinoline, **5**, the rate increased to a maximum at 0.6 mM copper micelle, reflecting the hydrophobicity of this compound. The catalysis at this concentration was 66-fold. The model compound without the heterocyclic nitrogen atom, *p*-nitrophenyl acetate, had only 5-fold catalysis as above.

Thus the presence of an ionized carboxylate group *ortho* to the reaction centre (as in compound **3**) or a quinoline nitrogen atom close to the reaction centre (as in compound **5**) is very beneficial to the magnitude of catalysis of ester hydrolysis by copper-containing metallomicelles, in contrast to the situation observed above for amide hydrolysis. The beneficial effect of a pyridine nitrogen atom on the magnitude of catalysis of the hydrolysis of aryl esters of picolinic acid in metallomicelles has previously been reported (9). This was attributed to coordination of the nitrogen with the metal ion.

The presence of the carboxylic acid group *para* to the reaction centre, while beneficial to the magnitude of catalysis by copper metallomicelles, is less effective than one *ortho* to the reaction centre. This suggests that the effect of the ionized carboxylate group is not merely to assist in the solubilization of the substrate by the copper-containing cationic micelle, but rather to orient the substrate within the micelle so that the reaction centre is close to the metal ion and hence the metal-bound hydroxide. The quinoline nitrogen atom close to the reaction centre in compound **5** presumably has a similar effect.

The different behaviour of ester and amide hydrolysis to the copper-containing metallomicelles is of interest. It may possibly result from different rate-determining steps for the two reactions. For ester hydrolysis the rate-determining step is bond formation (10). However, for trifluoroacetanilides the rate-determining step has been shown to be solvent-assisted C—N bond breaking (11). Thus it follows that for ester hydrolysis with bond formation between the ester and the metal-bound hydroxide being rate determining, the proximity of these species within the micelle is catalytically important (see Scheme 1). For amide hydrolysis, however, with C—N bond breakage being rate determining, the substrate is already bound to the copper micelle and hence the orientational differences between compounds **1** and **2** in the micelle are not kinetically important.

As for amide hydrolysis, the rate of hydrolysis of the esters is faster in a pure metallomicelle solution than in the presence of co-micelles except at very low metallomicelle concentrations. At 0.2 mM $CuCl_2$ the hydrolysis of compound **5** is more than 8 times faster than the uncatalyzed hydrolysis in water, once again indicating a cmc less than 0.2 mM. Addition of ctab (2 mM) to this reaction mixture resulted in a fivefold rate increase. At higher $CuCl_2$ concentrations (0.6–2.0 mM), how-

Scheme 1. Proposed mechanisms of copper-catalyzed amide and ester hydrolysis.

Rate-determining transition state for ester hydrolysis

Rate-determining transition state for amide hydrolysis

ever, the addition of ctab resulted in a reduction of the rate of hydrolysis.

This difference is most likely due to the differences in the extent of solubilization of the substrate by the copper micelles as described above for amide hydrolysis. This effect is similar to that observed in micellar reactions at concentrations higher than the optimum micelle concentration. Typically the rate vs. detergent concentration profile shows a decrease in the rate of reaction once the optimum concentration of surfactant is exceeded. The optimum rate of hydrolysis of compound **5** is observed at 0.6 mM copper micelle, the rate decreasing at higher concentrations. This indicates that the substrate is indeed completely solubilized at 0.6 mM.

Experimental section

Materials

The required ligand was prepared by the method of Menger (1) using 1-bromotetradecane and *N,N,N'*-trimethylethylenediamine in basic solution. The complex with cupric chloride

© 1997 NRC Canada

was prepared in absolute ethanol and the resulting blue-green precipitate was recrystallized from acetonitrile to give blue crystals; mp 104–105°C (lit. (1) mp 104–105°C). The identity of this product was confirmed by electrospray mass spectrometry.

The complex with copper acetate, mp 88–90°C, was prepared in an analogous way. The positive ion electrospray mass spectra (ESMS) of all of the complexes were identical, with peaks corresponding to the protonated ligand m/z = 299.1 and $Cu(L)CH_3COO^+$ m/z = 420 and 422. The presence of acetate in the ion in all of the complexes was attributed to the ESMS mobile phase, which contained methanol, water, and acetic acid. The co-micellar ctab and Triton X-100 were available commercially (BDH).

Purified water was prepared from distilled water by treatment with a Millipore system to achieve a resistivity of at least 17 MΩ cm^{-1}.

Tris buffer pH 7.0 was prepared from Tris free base (50 mL, 0.1 M) and hydrochloric acid (46.6 mL, 0.1 M). This mixture was then diluted to 100 mL with purified water.

Substrates

Compound **1** was available from previous work (5). *N*-4-Nitrophenyltrifluoroacetamide **2**, mp 150°C (lit. (12) mp 147°C), was prepared by trifluoroacetylation of *p*-nitroaniline with trifluoroacetic anhydride in dry ether at 0–5°C. Iced water then added to the reaction mixture and the precipitate was filtered and recrystallized from a mixture of methanol and ethanol. Esters **3**, **4**, and **5** were prepared by acetylation of the corresponding phenols with acetic anhydride using the method of Ciampa (13): 2-acetoxy-5-nitrobenzoic acid **3**, mp 152–154°C (lit. (14) mp 153–154°C); 4-acetoxy-3-nitrobenzoic acid **4**, mp 150°C (lit. (15) mp 152°C); 8-acetoxy-5-nitroquinoline **5**, mp 110°C (lit. (16) mp 112–113°C).

Kinetics

(a) Using previously prepared complex ($Cu(L)Cl_2$ or acetate

A stock solution of the complex (10 mM) was prepared in purified water. The required volume of this solution was added to a volumetric flask; then the required volume of Tris buffer (pH 7.0) was added and the solution was diluted to the mark with purified water. A sample of this solution (3 mL) was then thermally equilibrated in a cuvette in the cell compartment of the Varian DMS 70 UV–VIS spectrophotometer. The reaction was initiated by the addition (microsyringe) of a stock solution (20 μL) of the required substrate (0.01 M) in acetonitrile. Product formation was followed at 375 nm for compounds **1** and **2**, at 380 nm for compounds **3** and **6**, at 415 nm for compounds **4** and **7**, and at 430 nm for compound **5** using a linear recorder. The infinity value and rate constant were calculated by a computer program designed to give the best straight line fit to data (time–absorbance pairs) collected over at least two half-lives. Good agreement between experimental and calculated rate constants and infinity values was obtained for all reaction systems.

(b) Using mixed solutions of ligand and $CuCl_2$, acetate, or nitrate

The required volumes of solutions of the copper salt in water and ligand in water were mixed to provide equimolar amounts of each species and then the required volume of Tris buffer was added. The reactions were initiated and followed as above (*a*).

(c) Using co-micelles

Required volumes of ligand and copper salt were mixed to obtain equimolar amounts of both species followed by aliquots of either ctab or Triton X-100 and Tris buffer (pH 7.0). The mixture was diluted to the mark with purified water. The reactions were initiated and followed as described above (*a*).

Mass spectra

Electrospray mass spectra were obtained on a VG Bio-Q triple quadrupole mass spectrometer (VG Bio Tech, Altringham, Cheshire, U.K.) using a mobile phase of 50:50 aqueous methanol also containing 1% acetic acid. Electrospray mass spectra of each preformed complex and the corresponding ligand – copper salt mixture were identical.

Abstract: Densities and vapor-liquid equilibria were determined for tetrahydrofuran with propan-1-ol and propan-2-ol systems at 298.15 K. From the experimental results, excess molar volumes and excess Gibbs free energies were calculated. Information could be obtained from the possible interaction between both chemical species in the two systems. The Prigogine–Flory–Patterson method was applied to calculate excess molar volumes. Liquid activity coefficients were calculated and correlated with different expressions existing in the literature.

Key words: excess molar volumes, vapor–liquid equilibria, activity coefficients, excess Gibbs free energies, tetrahydrofuran, propan-1-ol, propan-2-ol.

Résumé : Opérant à 298 K, on a déterminé les densités et les équilibres vapeur–liquide des systèmes formés de tétrahydrofurane et de propan-1-ol ou de propan-2-ol. Utilisant les données expérimentales, on a calculé les volumes molaires en excès ainsi que les énergies libres de Gibbs en excès. On a pu obtenir de l'information sur les interactions possibles entre les deux espèces chimiques dans chacun de ces deux systèmes. On a appliqué la méthode de Prigogine–Flory–Patterson au calcul des volumes molaires en excès. On a calculé les coefficients d'activité liquide et on a établi une corrélation avec les diverses expressions qui existent dans la littérature.

Mots clés : volumes molaires en excès, équilibres vapeur–liquide, coefficients d'activité, énergies libres de Gibbs en excès, tétrahydrofurane, propan-1-ol, propan-2-ol.

[Traduit par la rédaction]

Introduction

Excess thermodynamic properties such as excess molar volumes (V^E) and excess molar Gibbs free energies (G^E) were determined to obtain some information about interactions between molecules of tetrahydrofuran (THF) and the propanol (1-PR) and (2-PR) systems at 298.15 K. This is a continuation of our research on the thermodynamic properties of binary mixtures of non-electrolytes (1, 2).

With density data, V^E values have been calculated and the interactions between THF and propanols can be discussed in terms of Prigogine–Flory–Patterson (PFP) theory, which take into consideration only the physical aspects (Heintz and co-workers (3)). The chemical aspects can be calculated following ERAS's method (3), which takes into consideration the autoassociation of the alcohols, and gives great errors, probably because of the small values for V^E.

This paper presents also vapor–liquid equilibria (VLE) data on the two binary systems mentioned above. Different equations exist in the literature that calculate the activity coefficients in the liquid phase. In this work, some equations have been applied and the results compared with experimental data.

Experimental

The methods used in our laboratory have been described previously (1, 2). Densities were determined with an AP digital densimeter, model DMA 45. A thermostatically controlled bath constant to 0.01 K was used. Calibration was carried out with air and doubly distilled water, with an uncertainty of ±0.2 kg m^{-3}. Temperatures were read in a Digitec digital thermometer. Vapor–liquid equilibria data were determined using a modified version of the Boublik–Benson (4) still. Pressures were determined using a barocel transducer type 590, and a digital pressure display and controller model 1501 B. The estimated error was ±0.005 kPa in pressures.

The compositions of liquid and vapor condensed phases were determined from measurements of their densities at 298.15 K, using eq. [1]:

$$[1] \qquad \rho = x_1\rho_1 + x_2\rho_2 + x_1x_2\sum_{j=1}^{n} a_j(1-2x_1)^{j-1}$$

where x_1 and x_2 are the mole fractions of components 1 and 2, and ρ, ρ_1 and ρ are the densities of the solution and of the pure components, respectively. The parameters a_j were

In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error of estimate with n:

$$[2] \qquad \sigma = \{\sum(\rho_{obs} - \rho_{cal})^2/(n_{obs} - n)\}^{1/2}$$

(THF) (Merck puriss.) was used without further purification. (1-PR) and (2-PR) (Merck puriss.) were distilled and the middle fractions collected. Mixtures were prepared by mixing weighed amounts of the pure components. Caution was taken to prevent evaporation.

Results and discussion

Table 1 shows the densities and excess molar volumes of the two binary systems. Table 2 shows the adopted coefficients a_j and standard deviations of densities associated with the use of eqs. [1] and [2].

The excess molar volumes were calculated using the following expression:

$$[3] \qquad V^E = x_1 M_1(\rho^{-1} - \rho_1^{-1}) + x_2 M_2(\rho^{-1} - \rho_2^{-1})$$

where M_1 and M_2 are the molar masses of components 1 and 2, x_1 and x_2 are the mole fractions of the components, and ρ, ρ_1, and ρ_2 are the densities of the solutions and of the pure components. Each set of results was fitted using Redlich–Kister equations of the type:

$$[4] \qquad V^E = x_1 x_2 \sum_{k=1}^{n} a_k (1 - 2x_1)^{k-1}$$

and Table 3 shows the values of the coefficients a_k and their standard deviations defined by eq. [2].

Figure 1 shows the experimental values of V^E for the two systems at 298.15 K. The continuous curves were calculated from eq. [3], using the adopted values for the coefficients.

One of the systems (with 1-PR) shows a sigmoid curve for V^E, while the other system shows positive values of V^E. We deduce that, in a qualitative form, dispersion forces are dominant in the mixture with secondary alcohol, while in the mixture with 1-PR specific interactions exist. The alcohols are liquids associated by hydrogen bonds, and this association diminishes in the secondary alcohol. The addition of THF, which is a polar molecule but not associated in its pure state, produces a breaking in this association causing positive values of V^E in the mixture with 2-PR. In the other mixture, the addition of molecules of 1-PR to THF produces a breaking of association in the alcohol, leading to an association of alcohol monomers with THF of the type H—O- - -H (5) with a volume contraction greater than the dispersion forces. This effect is small; at $x_1 = 0.5$ it is about -0.25×10^{-6} m^3 mol^{-1}.

The application of ERAS's method in this case, assuming the constancy of autoassociation of the alcohol and equilibrium between the two components, gives great errors. Thus, we applied the PFP (6) theory, where V^E can be calculated with the following expression:

$$[5] \qquad \frac{V^E}{x_1 V_1^* + x_2 V_2^*} = \frac{(\tilde{V}^{1/3} - 1)\tilde{V}^{2/3}}{\frac{4}{3}\tilde{V}^{-1/3} - 1}\psi_1\theta_2\frac{X_{12}}{P_1^*} - \frac{(\tilde{V}_1 - \tilde{V}_2)^2(\frac{14}{9}\tilde{V}^{-1/2} - 1)}{(\frac{4}{3}\tilde{V}^{-1/3} - 1)\tilde{V}}\psi_1\psi_2 + \frac{(\tilde{V}_1 - \tilde{V}_2)(P_1^* - P_2^*)}{P_2^*\psi_1 + P_1^*\psi_2}\psi_1\psi_2 = \Delta V_{int} - \Delta V_F + \Delta V_{p*}$$

where the first term is the interactional contribution, the second term the free volume contribution, and the third one is the characteristic pressure contribution.

The various parameters involved in eq. [5] for the pure components (with subscripts) and the mixture (without subscripts) are obtained through the theory of Flory et al. (7). Table 4 shows the parameters used for the three substances, and Table 5 the values of X_{12} and the other contributions from eq. [5] and compared with experimental results.

Figure 1 shows the curves obtained with PFP theory, which agree well with experimental data in the THF (1) + 1-PR (2) system, showing a sigmoid curve, and indicating that the chemical interaction between the components is very small. In the other mixture, the agreement is not good when compared with experimental data.

Fig. 1. Excess molar volumes: (·····) THF(1) + 1-PR(2); (× × × ×) THF(1) + 2-PR(2) at 298.15 K. Continuous curves are calculated from eq. [3]. (— — —): curves calculated from eq. [5].

Analysis of the three contributions to V^E shows that the interactional contribution is the most important, negative in all cases, and larger than the free volume. The P^* also are important, due to the large difference that exists between the characteristic pressures.

The activity coefficients of the components in the liquid phase were calculated from the experimental data by employing the following equation:

$$[6] \qquad \ln \gamma_i = \ln \frac{y_i P}{x_i P_i} + \frac{(B_{ii} - V_i)(P - P_i)}{RT} + (1 - y_i)^2 \frac{P\delta}{RT}$$

Fig. 2. Vapor pressures vs. mole fractions of THF(1) + 1-PR(2) system at 298.15 K.

Figures 2 and 3 show the vapor pressure for both systems versus x_i and y_i.

The thermodynamic consistency of the VLE was determined using the method of Barker described by Fredenslund et al. (9).

Knowing activity coefficients, we can calculate the excess molar Gibbs free energies with the following expression:

$$[7] \qquad G^E = RT(x_1 \ln \gamma_1 + x_2 \ln \gamma_2)$$

which gives positive values for both systems. To calculate the entropy of these systems, we need enthalpies, which could be calculated by the UNIFAC method (10). For both systems the values of entropies are positive and small, indicating that dispersion forces are dominant in this case.

The experimental data of VLE were correlated with the three-suffix Margules (11) equation, Wilson (12) equations, NRTL (13) equations, and UNIFAC (14) methods.

The parameters in these equations were obtained by minimizing the root-mean-square deviations in P and y. The procedure is known as Barker's method. Values of P and y are calculated with the following expressions:

Fig. 3. Vapor pressures vs. mole fractions of THF(1) + 2-PR(2) system at 298.15 K.

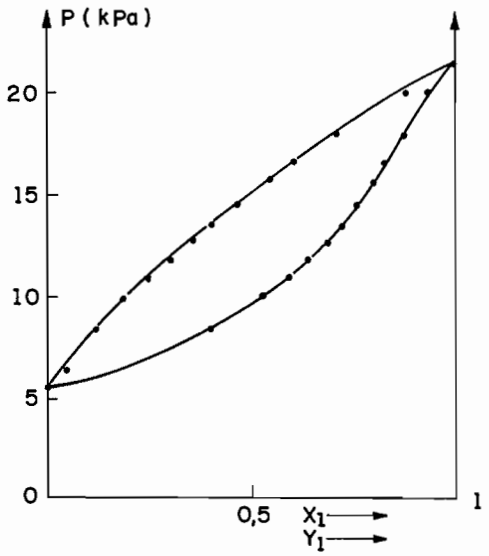

Table 8. Standard deviations in P and y for both systems at 298.15 K.

	THF(1) + 1-PR(2)		THF(1) + 2-PR(2)	
	SD_p (kPa)	SD_y	SD_p (kPa)	SD_y
Margules	0.07	0.005	0.05	0.007
Wilson	0.06	0.001	0.33	0.01
NRTL	0.05	0.002	0.34	0.01
UNIFAC	0.68	0.016	1.35	0.03

$$[8] \qquad P_{cal} = x_1\gamma_1 P_1^0 + x_2\gamma_2 P_2^0$$

$$[9] \qquad y_{cal} = x_1\gamma_1 P_1^0 / P_{cal}$$

over the complete concentration range, where P_i^0 is

$$[10] \qquad P_i^0 = P_i \exp\left[\frac{(V_i - B_{ii})(P - P_i)(1 - y_i)^2}{RT}\right]$$

The standard deviations (SD) in pressures and in vapor phase mole fractions are calculated by:

$$[11] \qquad SD = \left[\frac{\sum(M_{exp}^E - M^E)}{n}\right]^{1/2}$$

where M is P or y. These values are shown in Table 8.

Conclusions

From the Margules equations $A = 0.2896$ and $B = 0.6852$ for THF(1) + 1-PR(2) and $A = 0.3084$, $B = 0.4353$ for the THF(1) + 2-PR(2) system. For the Wilson equations

© 1997 NRC Canada

$\Lambda_{12} = 1.3479$ and $\Lambda_{21} = 0.3491$ for THF(1) + 1-PR(2) and $\Lambda_{12} = 1.4761$, $\Lambda_{21} = 0.3491$ for THF(1) + 2-PR(2). For the NRTL equations with $\alpha = 0.30$ as a constant, $A = 1.3359$, $B = 0.5553$ for THF(1) + 1-PR(2) and $A = 1.4558$, $B = 0.6511$ for the THF(1) + 2-PR(2) system. The contribution groups of UNIFAC theory (14) is the last method applied to the two systems. Table 8 shows that for mole fractions the Wilson equations agree very well with minor deviation, and the Margules equations for the THF(1) + 2-PR(2).

For pressures, NRTL for THF(1) + 1-PR(2) and the Margules equations for THF(1) + 2-PR(2) show minor deviation. The UNIFAC method gives great errors in both mole fractions and pressures.

Metal complexes of propane-1,2,3-triamine. Potentiometric and calorimetric investigations

Renzo Cini, Antonio Sabatini, Alberto Vacca, and Fabrizio Zanobini

Abstract: The complexes formed by the ions Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} with the ligand propane-1,2,3-triamine (L^1) in 0.15 mol dm^{-3} aqueous NaCl at 25°C have been studied by potentiometry and calorimetry (ligand to metal molar ratio, 1–3; pH range from 3.0 to 6.5–11.0). Stability constants have been obtained from potentiometric data by means of the least-squares program HYPERQUAD for the following species: $[M(L^1)]^{2+}$ and $[MH(L^1)]^{3+}$ for all four metal cations; $[M(L^1)_2]^{2+}$ and $[MH(L^1)_2]^{3+}$ for Ni^{2+}, Cu^{2+}, and Zn^{2+}; $[MH_2(L^1)_2]^{4+}$ for Ni^{2+} and Cu^{2+}; and $[M(OH)(L^1)]^{+}$ for Cu^{2+} only. Stabilities increase in the order Zn < Co < Ni < Cu. The complexes of L^1 have approximately the same stability as the corresponding ones formed by the related triamines 2-methyl (2-methylamine) propane-1,3-diamine (L^3) and 2-ethyl (2-methylamine)propane-1,3-diamine (L^4). The stability constants have been used to obtain, from the calorimetric titration experiments, the formation enthalpies of all the metal complexes except those for cobalt(II) as well as the corresponding entropy changes. The thermodynamic quantities are compared with the corresponding values previously found for L^3, in order to derive information about the coordination ability of the ligand. The analysis suggests that the unprotonated ligand forms a *fac*-tridentate complex in most cases, but for some species, such as $[Cu(L^1)_2]^{2+}$, $[CuH(L^1)_2]^{3+}$, and $[Zn(L^1)]^{2+}$, the thermodynamic quantities indicate that at least one of the nitrogen atoms of the triamine is either loosely bonded or not coordinated to the metal ion. A gas-phase molecular mechanics analysis shows that the strain energies of the *fac*-$[Co(L^1)_2]^{2+}$ and -$[Ni(L^1)_2]^{2+}$ symmetrical (s) and unsymmetrical (u) isomers are very similar. If the same solvation energy is assumed for the two isomers, each isomer will be present in roughly equal amounts in solution.

Key words: propane-1,2,3-triamine, potentiometry, calorimetry, complexation, cobalt, nickel, copper, zinc.

Résumé : On a étudié les complexes formés par les ions Co^{2+}, Ni^{2+}, Cu^{2+} et Zn^{2+} avec le ligand propane-1,2,3-triamine (L^1) dans du NaCl aqueux 0.15 mol dm^{-3} à 25°C en utilisant la potentiométrie et calorimétrie (ligand : métal = 1–3; dans des intervalles de pH compris entre 3 et 6,5–11,0). Les constantes de stabilité ont été obtenues à partir des données potentiométriques par la méthode des moindres carrés du programme HYPERQUAD pour les espèces suivantes : $[M(L^1)]^{2+}$ et $[MH(L^1)]^{3+}$ pour les quatre cations métalliques; $[M(L^1)_2]^{2+}$ et $[MH(L^1)_2]^{3+}$ pour les cations Ni^{2+}, Cu^{2+} et Zn^{2+}; $[MH_2(L^1)_2]^{4+}$ pour les cations Ni^{2+} et Cu^{2+} et $[M(OH)(L^1)]^{+}$ pour l'ion Cu^{2+} seulement. Les constantes de stabilité augmentent dans l'ordre Zn < Co < Ni < Cu. La stabilité des complexes de L^1 est approximativement la même que celle des complexes correspondants formés avec les triamines apparentées 2-methyl(2-méthylamine)propane-1,3-diamine (L^3) et 2-éthyl(2-méthylamine)propane-1,3-diamine (L^4). On a utilisé les constantes de stabilité pour obtenir, par titration calorimétrique, les enthalpies de formation de tous les complexes exceptés ceux du cobalt(II) ainsi que les variations d'entropie correspondantes. On a comparé les quantités thermodynamiques aux valeurs correspondantes, trouvées antérieurement pour L^3 dans le but d'obtenir des informations sur la capacité de coordination du ligand. L'analyse suggère que le ligand non protoné forme, dans la plupart des cas, un complexe *fac*-tridenté, mais pour quelques espèces comme $[Cu(L^1)_2]^{2+}$, $[CuH(L^1)_2]^{3+}$ et $[Zn(L^1)]^{2+}$, les valeurs des entités thermodynamiques suggèrent qu'au moins un des atomes de la triamine est faiblement lié ou pas du tout coordonné à l'ion métallique. Une analyse de mécanique moléculaire en phase gazeuse montre que les énergies de tension des isomères *fac*-$[Co(L^1)_2]^{2+}$ et -$[Ni(L^1)_2]^{2+}$ symétriques (s) et non symétriques (u) sont très similaires. Si on suppose que les deux isomères ont la même énergie de solvatation, chacun d'eux devrait alors être approximativement en quantités égales, dans la solution.

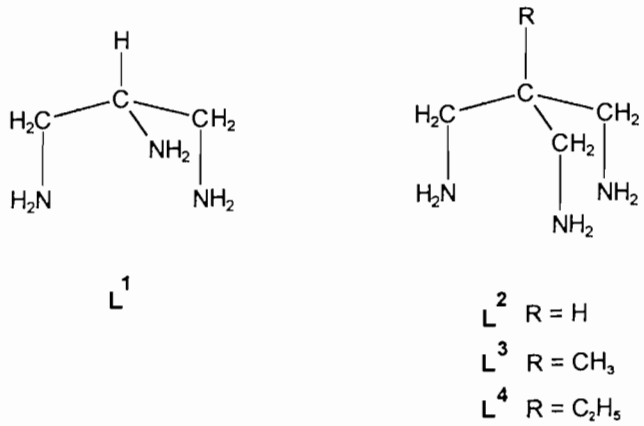
Introduction

Polyamines and metal cations have a very important place in the biochemistry of nucleic acids, in many processes of living cells, in the treatment of human diseases, and being useful as well as probes for the investigation of the structure of biopolymers (1–12). Natural polyamines like spermine, putrescine, and spermidine are required for optimal growth and development of cells (13). The presence of metal cations is often an important factor (either stimulating or inhibiting) in determining the activity of polyamines (13). As biological polyamines are linear aliphatic chain molecules, the interactions of branched polyamines with biopolymers have not been so extensively investigated. A knowledge of the coordination chemistry of polyamines is important for the understanding of structure–thermodynamic and structure–spectroscopic relationships; it is also crucial in the understanding of reaction mechanism pathways (14–16). We now report the results of a detailed investigation into the relationship between structure and coordinating ability in some small branched triamines. The complexes formed in aqueous solution between Co(II), Ni(II), Cu(II), and Zn(II) and the ligand propane-1,2,3-triamine (Scheme 1, L^1) have been examined by potentiometry and calorimetry. The careful analysis of the data has led to a deep speciation of the systems investigated. A ^{13}C NMR spectroscopy and molecular mechanics investigation on $[CoL^1]^{3+}$ was reported previously (17).

The four ligands shown in Scheme 1 are potentially tridentate and may form a *fac* octahedral complex. When all the nitrogen atoms are coordinated to the metal ion three chelate rings result. With L^2, L^3, and L^4 all three rings are six-membered, whereas with L^1 one ring is six-membered and the other two are five-membered. We have therefore been able to obtain some information regarding the strain energy associated with the formation of this type of condensed chelate ring system by molecular mechanics calculations.

Experimental



Materials

Propane-1,2,3-triamine (L^1) hydrochloride was obtained according to the procedure outlined in ref. 18. Preparation, recrystallization, and analysis of the hydrochloride, $L^1 \cdot 3HCl$, has been reported previously (19). A stock solution of 0.1 mol dm^{-3} $L^1 \cdot 3HCl$ was prepared by dissolving the crystalline solid in 0.15 mol dm^{-3} NaCl. The content of L^1 in the solution was measured by alkalimetric titration, by using the procedure previously described (19).

Analytical grade cobalt(II), nickel(II), copper(II), and zinc(II) chlorides were obtained from Merck and C. Erba. Suprapur NaCl was obtained from Merck. All the salts were used without any further purification. Approximately 0.1 mol dm^{-3} metal chloride stock solutions were prepared by dissolving the salts in 0.15 mol dm^{-3} NaCl. The metal content was accurately determined by standard analytical methods (20).

Solutions of HCl and NaOH were prepared by dilution of concentrated solutions taken from Merck ampoules. The NaOH solution was standardized as before (19). The potentiometric cell was calibrated by the Gran procedure (21). K_w in 0.15 mol dm^{-3} NaCl solution at 25°C was taken as 1.72×10^{-14} mol^2 dm^{-6} ($pK_w = 13.76$).

Scheme 1.

Potentiometric titrations

The titrations were carried out at 25.0 ± 0.1°C by using the same instrumentation and procedure described before (19). All the solutions were maintained under ultrapure nitrogen during the titrations. With the cobalt(II)–L^1 system either nitrogen, first passed through a 1/4 in. OXY-TRAP column (Alltech), or ultrapure argon were used.

The basicity constants of the ligand have been reported previously (19). The cobalt(II)–, nickel(II)–, copper(II)–, and zinc(II)–L^1 systems were studied by acid–base titrations performed with an experimental procedure similar to that used for the determination of the protonation constants. The solutions contained known amounts of $L^1 \cdot 3HCl$ (ca. 2 mmol dm^{-3}, 25 cm^3) and metal salts. The ligand–metal molar ratio ranged from 1.5 to 3.0. During the titrations of the cobalt(II)–, copper(II)–, and zinc(II)–L^1 systems, the emf values became stable within ca. 10 s from the titrant addition. The collection parameters were as follows. The time interval between two consecutive blocks of 10 readings, 3 s; the maximum allowed standard deviation and the tolerance between the first and the tenth mean value were both 0.05 mV. About 20 emf readings were usually enough to get steady values with Co, Cu, and Zn, but more readings were necessary in the Ni titrations because of the relative inertness of the Ni(II) complexes (22). The starting pH values for all the M–L^1 systems were about 3. There was no backwards drift in electrode readings up to pH 6.5, 11.0, 8.2, and 9.5 for the cobalt(II)–, nickel(II)–, copper(II)–, and zinc(II)–L^1 systems, respectively.

The formation constants of the metal complexes were calculated with the least-squares computer program HYPERQUAD (23). In this program the sum of the weighted squared residuals on the observed emf values is minimized. The weights were derived from the estimated errors in emf (0.2 mV) and titrant volume (0.002 cm^3). The most probable chemical model was selected by following a strategy (24) based on statistical inferences applied to σ^2. The sample standard deviation should be 1, in the absence of systematic errors and when a correct weighting scheme is used. However, the agreement is considered good for standard deviation values smaller than 3 ($\sigma^2 < 9$). Values of σ^2 lower than 7 were obtained for all the refined equilibrium models in the present work.

Calorimetric titrations

Stepwise titrations were performed using an LKB thermal activity monitor (model 2277) equipped with a perfusion/titration system and a Hamilton pump (model Microlab M). Both the calorimetric system and the Hamilton pump were controlled by means of a personal computer (IBM PS/2 model 30) running the program AUTOTAM (25). Chemical calibration of the apparatus was accomplished by measuring the heat of neutralization of hydrochloric acid by sodium hydroxide in aqueous 0.15 mol dm^{-3} NaCl. The value obtained, $\Delta H° = -56.0 \pm 0.2$ kJ mol^{-1}, is in excellent agreement with the values previously reported (26). A typical calorimetric titration consisted of 10–15 injections (10–15 mm^3 each) of 0.2 mol dm^{-3} aqueous NaOH into the reaction cell; the cell contained 1.5 cm^3 of a 2×10^{-3} mol dm^{-3} solution of $L^1 \cdot 3HCl$ in the presence of variable quantities of the appropriate metal(II) chloride (ligand to metal molar ratio ranging from 1 to above 2) in aqueous NaCl (0.15 mol dm^{-3}). The enthalpies of complex formation were calculated using the least-squares program KK95, an updated version of the program previously used by this group (27). The values of the enthalpies of stepwise protonation of the ligand used in the calculations ($\Delta H°_1 = 45.9 \pm 0.2$, $\Delta H°_2 = 46.3 \pm 0.3$, $\Delta H°_3 = 35.6 \pm 0.3$ kJ mol^{-1}) were taken from ref. 19. Calorimetric measurements involving the oxidizable cobalt(II) complexes have not been attempted since an inert atmosphere cannot be maintained inside the calorimeter.

Calculations

The strain energies of the complexes $[M(L^1)_2]^{2+}$ (M = Co, Ni) were computed as the sum of bond length deformation, valence angle deformation, torsional angle deformation, nonbonding interaction, and electrostatic contribution: $E_{tot} = E_b + E_\theta + E_\phi + E_{nb} + E_\varepsilon$. The MM2 force field (28) was used in the MacroModel package version 3.0 implementation (29). The force field was extended to take into account interactions between the metal center and the donor atoms. The atomic charges (see deposited material[2]) were computed through the molecular orbital extended-Hückel method of the ICONC&INPUTC package (30) without any optimization of the geometry and with distance-dependent weighted Wolfsberg–Helmholz formulas. The self-consistent charge interaction calculation on the Co and Ni atom was performed on the complex molecules. The VSIE (valence state ionization energy) parameters for the metal ions are those implemented in the ICONC&INPUTC package. The force field parameters were tested against the structure of s-*fac*-$[Co^{III}(L^1)_2]Cl_3$ (31) (s = symmetrical) and are in good agreement with values previously published (32). The starting structures of the s/u-*fac*-$[M^{II}(L^1)_2]^{2+}$ (u = unsymmetrical) complexes were generated from the s-*fac*-$[Co^{III}(L^1)_2]^{3+}$ structure via MacroModel at an Evans & Sutherland PS390 graphics terminal. Details of the molecular mechanics calculations are as before (33).

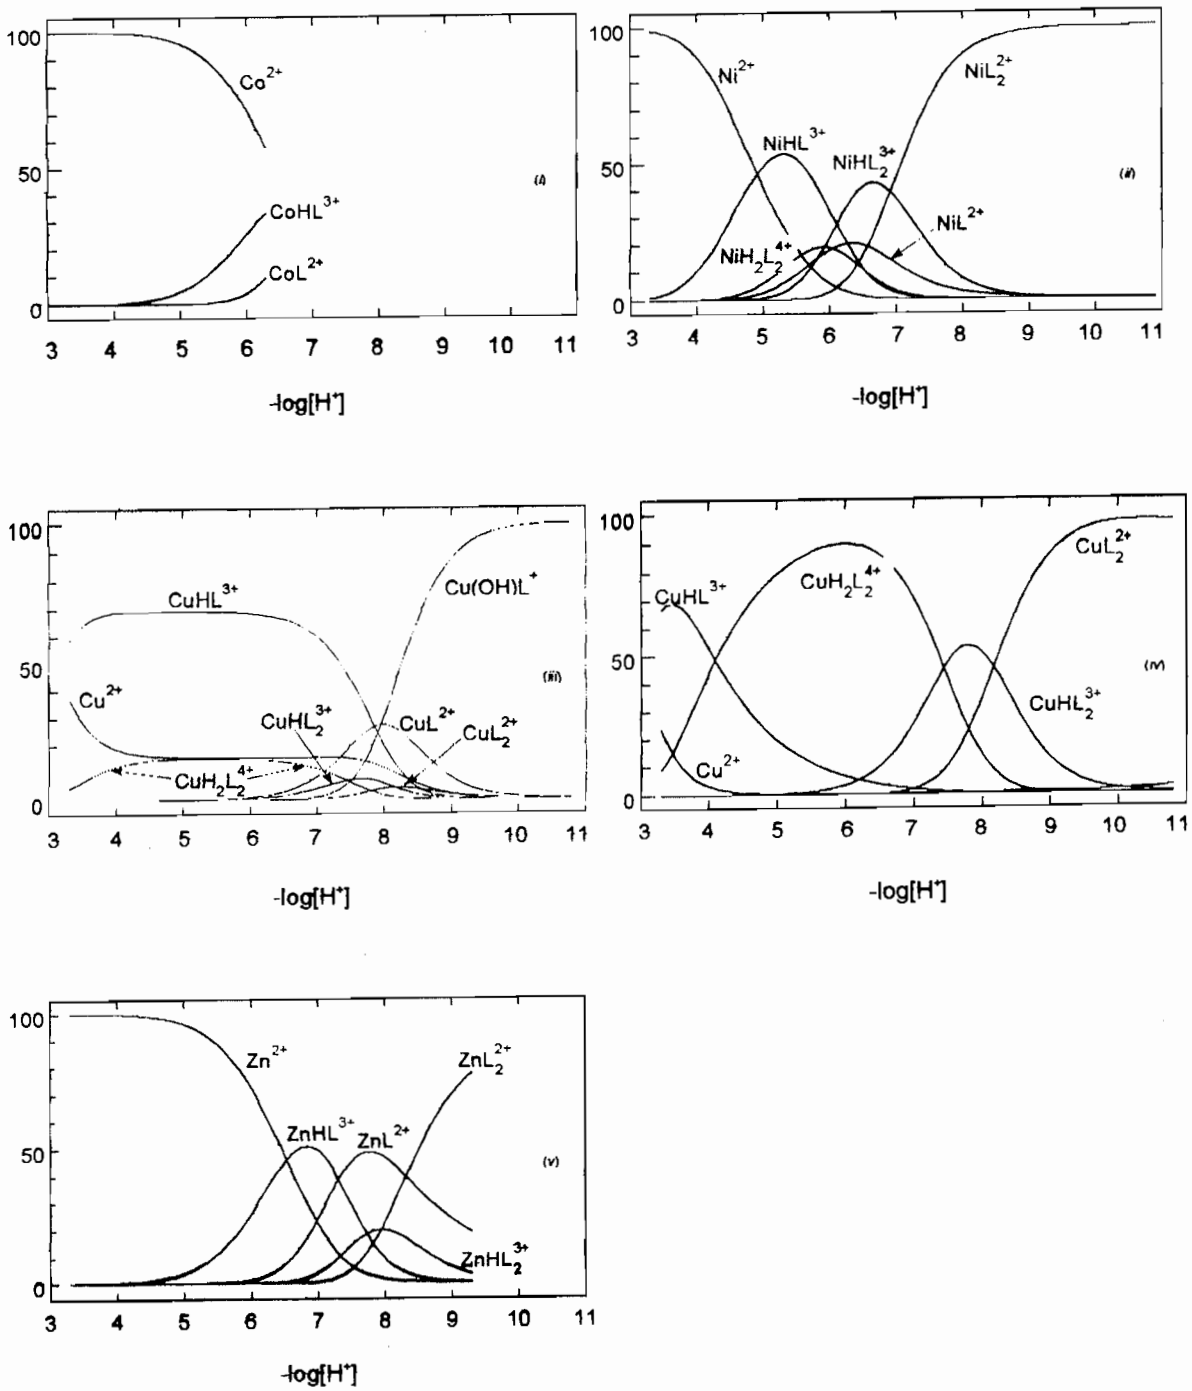
Results and discussion

Characterization of the equilibrium models

Table 1 shows the values of the logarithms of the cumulative formation constants of the metal complexes that have been identified as being present in appreciable concentrations under the experimental conditions of the titrations. The relevant equilibria are described by eq. [1] and the corresponding equilibrium constants β_{pqr} are defined as in eq. [2].

$$[1] \quad pM^{2+} + qH^+ + rL = M_pH_qL_r^{(2p+q)+}$$

$$[2] \quad [M_pH_qL_r^{(2p+q)+}] = \beta_{pqr}[M^{2+}]^p[H^+]^q[L]^r$$



The results can be compared both with those obtained previously for the same ligand (34) and with those of the other ligands shown in Scheme 1, 1,1,1-tris(aminomethyl)alkanes L^2 (35, 36), L^3 (37), and L^4 (38). Distribution curves for the M^{II}–L^1 systems are shown in Figure 1.

In the cobalt(II)–L^1 system, emf measurements could not be carried out above pH 6.5 owing to precipitation and (or) oxidation reactions in spite of stringent precautions. The limited pH interval does not allow extensive coordination of the metal ion to occur: only the $[CoHL^1]^{3+}$ and $[CoL^1]^{2+}$ complexes are formed, with a total degree of formation of less than 50%. The species that we have found are the same as those found by Prue and Schwarzenbach (34). The values of the equilibrium constants given by those authors for reactions at 20°C in the medium 0.1 mol dm^{-3} KCl, $\log \beta_{101} = 6.8$, $\log \beta_{111} = 13.7$, are in satisfactory agreement with the values obtained by us at 25°C in 0.15 mol dm^{-3} NaCl. In the cobalt(II)–L^2 system (36), the diprotonated complex $[CoH_2L^2]^{4+}$ was also characterized.

In the titration of a mixture of nickel(II) and L^1 (molar ratio 1:2) appreciable concentrations of $[Ni(L^1)]^{2+}$, $[NiH(L^1)]^{3+}$, $[Ni(L^1)_2]^{2+}$, $[NiH(L^1)_2]^{3+}$, and $[NiH_2(L^1)_2]^{4+}$ were found within the pH range studied. The complex $[Ni(L^1)_2]^{2+}$ is practically the only species present at pH above 9. The first two complexes were identified in an earlier investigation (34); the

Fig. 1. Distribution diagrams for the M–L^1 systems. The percentages of the complexes are calculated for titration curves where the analytical concentrations of metal ion and ligand are as follows: (*i*) T_{Co} = 2 mM, T_L = 2 mM; (*ii*) T_{Ni} = 1 mM, T_L = 2 mM; (*iii*) T_{Cu} = 2 mM, T_L = 2 mM; (*iv*) T_{Cu} = 1 mM, T_L = 2 mM; (*v*) T_{Zn} = 1 mM, T_L = 2 mM.

reported values of the formation constants, log β_{101} = 9.3 and log β_{111} = 15.6, are in excellent agreement with the corresponding values determined in the present study. With L^2, only $[NiL^2]^{2+}$ and $[NiHL^2]^{3+}$ were previously found (35, 36), whereas the same species identified in this study with L^1, except for $[NiH_2(L^1)_2]^{4+}$, had been found before in the case of L^3 and L^4 (37, 38).

Reaction of copper(II) with L^1 produces six different complexes, $[CuL^1]^{2+}$, $[CuHL^1]^{3+}$, $[Cu(L^1)_2]^{2+}$, $[CuH(L^1)_2]^{3+}$, $[CuH_2(L^1)_2]^{4+}$, and $[Cu(OH)L^1]^+$, corresponding to the set of species already identified with similar triamines: L^3 and L^4 (37, 38). Prue and Schwarzenbach (34) characterized only $[CuL^1]^{2+}$. The agreement between the values of the formation constants determined in that study (log β = 11.1, 18.4, 20.1, and 28.0) and those obtained in the present work is satisfactory. The formation of $[CuH_2L^2]^{4+}$ has also been reported (36).

The species $[Cu(L^1)_2]^{2+}$, $[CuH(L^1)_2]^{3+}$, and $[CuH_2(L^1)_2]^{4+}$ are formed even when the Cu:ligand ratio is 1:1, though their concentrations are relatively low. The protonated complex $[CuHL^1]^{3+}$ prevails in the acid region, whereas above pH 9 the hydroxo complex $[Cu(OH)L^1]^{+}$ appears to be the dominant species. When the Cu:ligand ratio is 1:2, $[CuHL^1]^{3+}$ is present at low concentration in the acidic region (it becomes the prevailing species below pH 4), with $[Cu(L^1)_2]^{2+}$, $[CuH(L^1)_2]^{3+}$, and $[CuH_2(L^1)_2]^{4+}$ being the dominant species over the whole pH range, $[Cu(L^1)_2]^{2+}$ dominating at high pH.

The four species that have been characterized in the zinc(II)–L^1 system are $[ZnL^1]^{2+}$, $[ZnHL^1]^{3+}$, $[Zn(L^1)_2]^{2+}$, and $[ZnH(L^1)_2]^{3+}$. Log β values for the first two species of 6.75 and 13.84 were reported previously (34), in very good agreement with the values obtained in this study. The ligand L^2 gave the two protonated complexes $[ZnHL^2]^{3+}$ and $[ZnH_2L^2]^{4+}$ (36), but with L^3 and L^4 the species $[ZnHL_2]^{3+}$ were not found before (37, 38). It should be noted that, although zinc–hydroxo complexes are usually found in systems like this, we were unable to confirm the presence of the species $[Zn(OH)L]^{+}$ and $[Zn(OH)_2L]$ that had been suggested before (37, 38).

Thermodynamics of complex formation

Values of the thermodynamic functions $-\Delta G°$, $-\Delta H°$ and $\Delta S°$ for the stepwise reactions involving metal complexes of L^1 are shown in Table 2. The values for the relevant L^3–metal complexes (39) are also given for comparison purposes.

The addition of one ligand molecule to a nickel(II) ion results in a less favourable free energy change for L^1 than for L^3 in the first step, whereas the opposite happens in the second step. These results may be ascribed to the less favourable enthalpy contribution in the first stage, whereas the entropy contribution outweighs the still unfavourable enthalpy change in the second step. The two enthalpy changes for the stepwise

M-N-H	110	0.15		0.10		0.12

[a]MM2 substructure (atom type from MacroModel) for the coordination sphere is: N3(.Z0(.N3)(.N3)(.N3))-C3-C3(-N3.2)-C3-N3(.2)

addition of L^1 are approximately equal and the entropy changes exhibit the usual decreasing trend. The $-\Delta H°$ values for the protonation of the coordinated ligand in $[NiL^1]^{2+}$, $[Ni(L^1)_2]^{2+}$, and even in $[NiH(L^1)_2]^{3+}$ are roughly equal and definitely lower than the corresponding value for the protonation of the free ligand (45.9 kJ mol^{-1}) (19). This is an indication that the triamine behaves as a tridentate ligand in both $[ML^1]^{2+}$ and $[M(L^1)_2]^{2+}$. Further support for this hypothesis is afforded by the result that the addition of the monoprotonated ligand HL^+ is clearly less exothermic than the addition of the neutral ligand.

The free energies of ligation in the copper complexes follow the same trends as in the nickel complexes, but for different reasons: the enthalpy contribution is less favourable with L^1 than with L^3 in the first step, but is more favourable in the second step. Protonation of the coordinated ligand is more exothermic for copper(II) than for nickel(II). The $-\Delta H°$ values for protonation of $[Cu(L^1)_2]^{2+}$ and $[CuH(L^1)_2]^{3+}$ are close to the value obtained for the protonation of the free ligand. This means that at least one of the unprotonated nitrogen atoms is either weakly bonded or even nonbonded to the metal in these complexes. On the other hand, protonation of $[CuL^1]^{2+}$ is less exothermic than the corresponding reaction of $[Cu(L^1)_2]^{2+}$ or $[CuH(L^1)_2]^{3+}$, indicating that, at least for this complex, all the nitrogen atoms are bonded to the copper ion. The values of the thermodynamic functions for the addition of the protonated ligand HL^{1+} to Cu^{2+} are consistent with a bidentate coordination in this case. The reaction of hydroxide ion with $[CuL^1]^{2+}$ is slightly exothermic and the corresponding entropy change is markedly positive owing to the decrease of the total ionic charge. Similar observations were made with L^3 and L^4.

The stepwise $-\Delta G°$ values for the formation of $[ZnL]^{2+}$ and $[ZnL_2]^{2+}$ (where L = L^1 and L^3) follow the same trends as just described for the corresponding nickel and copper complexes. The enthalpy change is less favourable for L^1 in the first step but more favourable in the second step. The $\Delta S°$ values for the two steps are close to those observed for the corresponding reactions of nickel, which suggests that the corresponding complexes have similar structures. The $-\Delta H°$ values for the addition of one ligand molecule fall in the range 22–26 kJ mol^{-1}, whereas the corresponding reactions of the monoprotonated HL^+ ion are slightly less exothermic (20 and 21 kJ mol^{-1}). The $-\Delta H°$ value for the protonation of the coordinated ligand in $[ZnL^1]^{2+}$ is high, being close to the first protonation enthalpy of the free triamine. These facts can be explained by postulating that in $[ZnL^1]^{2+}$ at least one of the amino groups of the ligand is only weakly bonded to the metal ion because of conformational strain.

Table 4. Total strain energy (kJ mol^{-1}) for the *fac*-$[ML^1_2]^{n+}$ complexes.

Isomer	Co^{III}	Co^{II}	Ni^{II}
s	386.70	65.58	69.59
u	386.82	65.99	69.10

The thermodynamic properties of the 1:1 complexes do not exhibit a regular pattern. Thus, while $[NiL]^{2+}$ and $[CuL]^{2+}$ are more stable for L^3 than for L^1 due to a more favourable enthalpy, the entropy term is nearly equal for the two ligands. In contrast, the two $[ZnL]^{2+}$ complexes (L = L^1, L^3) have about the same stability as the result of conflicting contributions from enthalpy (in favour of L^3) and entropy (in favour of L^1). The addition of a ligand molecule to both $[ML]^{2+}$ and $[MHL]^{3+}$ is always favoured for L^1 with respect to L^3, mainly because of the different enthalpy contribution. The $-\Delta H°$ values for the reaction of HL^+ with M^{2+} are strongly dependent on the metal ion (Zn < Ni < Cu) but nearly equal for the two ligands. The slightly higher values of the corresponding equilibrium constants for L^1 are the result of more favourable entropy terms. The addition of HL^+ to both $[ML]^{2+}$ and $[MHL]^{3+}$ is more spontaneous for L^1 than for L^3; this is probably the reason because the formation of $[MH_2(L^3)_2]^{4+}$ has not been observed.

Strain energies

The force field parameters and the total strain energy values for the energy-minimized structures of s-*fac*- and u-*fac*-$[Co^{III}(L^1)_2]^{3+}$, -$[Co^{II}(L^1)_2]^{2+}$, and -$[Ni^{II}(L^1)_2]^{2+}$ (see Scheme 2) are given in Tables 3 and 4. Selected geometrical parameters are listed in Table 5.

The total strain energy of s- and u-*fac* isomers for tridentate ligands related to L^1 has been the subject of debate (ref. 32*b* and refs. cited therein, ref. 17).

C(1)-C(2)-C(3)	113.4	113.9	113.9

Scheme 2.

It is evident that the u and s isomers have almost the same strain energy, the differences being -0.41 kJ mol^{-1} for the cobalt(II) complex and 0.49 kJ mol^{-1} for the nickel(II) complex. It should be noted that the difference is very small for both species. An important contribution to the strain energy comes from the valence angle deformation of M-N(2)-C(2). This effect contributes an average of 2.80 kJ mol^{-1} for the four structures of the Co^{2+} and Ni^{2+} complexes and it is almost 10 times larger than the contributions of the deformations of M-N(1)-C(1) and M-N(3)-C(3). Previous molecular mechanics studies on *fac*-$[Co(dien)_2]^{3+}$ (dien = diethylenetriamine) found almost identical strain energies for the s and u isomers (40) even though studies of the equilibrium isomer distributions in solution indicated that the u isomer is more stable than the s isomer by about 2.93 kJ mol^{-1}. Bond et al. (32*b*) computed a difference of ca. 5.86 kJ mol^{-1} between the more stable conformer of the u and s-*fac* isomers.

A difference of -0.10 kJ·mol^{-1} has been found for *fac*-$[Co(L^1)_2]^{3+}$ in this work and it compares well with the respective value reported in ref. 17 (-0.72 kJ mol^{-1}). If it is assumed that the s and u isomers of *fac*-$[Co(L^1)_2]^{2+}$ and -$[Ni(L^1)_2]^{2+}$ have the same solvation energy, which is a reasonable assumption, then the two isomers should be present in nearly equal amounts in solution.

Conclusions

The complex species that have been identified in this work are not the same as those that were reported previously (34–38). This can be largely attributed to the fact that earlier workers used graphical methods for the treatment of experimental data whereas we have used the more rigorous least-squares method. It must be noted that the chemical models selected for complexes of the ligand L^1 are, with minor exceptions, the same as the models found by least-squares methods for complexes of the ligands L^3 and L^4.

The stability constants of the complexes of L^1 are comparable to those of the analogous complexes of L^3 and L^4 even though L^1 is notably less basic than the other two ligands. It seems likely that when L^1 forms a tridentate complex containing two five-membered and one six-membered rings the strain energy is less than in tridentate complexes of L^3 and L^4 where there are three six-membered rings, and that the reduced strain energy compensates for the lower basicity of the ligand L^1.

Addition of L to $[ML]^{2+}$ is more favourable for L^1 than for L^3. Although this behaviour was observed for all the metals studied it happens for different reasons: a more favourable enthalpy term for copper(II) and zinc(II) but a more favourable entropy term for nickel(II). Lastly, it may be noted that the unsymmetrical ligand L^1 may form either u or s isomers of the bis-complex $[ML_2]^{2+}$. The results of molecular mechanics calculations indicate that the two isomers have nearly the same strain energies in the (hypothetical) gaseous state, so that both are likely to be present in equal amounts in solution.

Acknowledgements

We thank Dr. G. Giorgi (Centro Interdipartimentale de Analisi e Determinazioni Strutturali, University of Siena) for performing some of the titrations and for doing some preliminary molecular mechanics analyses during his work for the Tesi di Dottorato. We gratefully acknowledge the financial support of the European Community for the Human Capital and Mobility programme "Metals and Environmental Problems" (1995–1997) and the Italian Ministero dell'Università e della Ricerca Scientifica e Tecnologica.

^{1}H NMR study of paramagnetic rhenium(III) monomers with nitrogen heterocycles. Crystal structures of $ReCl_3L_2(PPh_3)$ complexes (L = pyridine, 3-picoline, and 1-methylimidazole)

Céline Pearson and André L. Beauchamp

Abstract: Rhenium(III) monomers of the type $ReCl_3L_n(PPh_3)_{3-n}$, where n = 1, 2, and 3, were prepared for simple nitrogen heterocyclic ligands L and characterized mainly by ^{1}H NMR and IR spectroscopies. Most of the ^{1}H NMR signals of these paramagnetic compounds were assigned by using methylated pyridines. A *mer-cis* octahedral geometry slightly distorted by triphenylphosphine was determined by X-ray diffraction for three $ReCl_3L_2(PPh_3)$ complexes: L = pyridine, triclinic, $P\bar{1}$, a = 11.379, b = 13.532, c = 18.160 Å, α = 80.16°, β = 89.57, γ = 86.27°, Z = 4, R = 0.076; L = 3-picoline, triclinic, $P\bar{1}$, a = 10.557, b = 12.580, c = 13.153 Å, α = 66.80°, β = 67.46°, γ = 75.89°, Z = 2, R = 0.021; L = 1-methylimidazole, monoclinic, $P2_1/c$, a = 15.437, b = 9.436, c = 18.607 Å, β = 92.23°, Z = 4, R = 0.046. The same structure was deduced from ^{1}H NMR data for these compounds in solution, whereas the other types of complexes were found to exist as the *mer,trans*-$ReCl_3L(PPh_3)_2$ and *mer*-$ReCl_3L_3$ isomers. In contrast with these complexes, which contain the *mer*-$ReCl_3$ core, the starting material $ReCl_3$(benzil)(PPh_3) is found to be the *fac* isomer in solution. The typical low-field shifted pattern of ^{1}H NMR signals for PPh_3 is not greatly perturbed by changes in the number or arrangement of the remaining ligands in the coordination sphere, but the signals for protons on conjugated systems directly bonded to the metal atoms are much more affected by the unpaired electrons.

Key words: paramagnetic NMR, crystal structures, rhenium(III) complexes, imidazole, pyridine, triphenylphoshine.

Résumé : Des monomères de formule $ReCl_3L_n(PPh_3)_{3-n}$, où n = 1, 2 et 3, ont été préparés pour certains hétérocycles azotés simples L et caractérisés principalement par spectroscopies RMN ^{1}H et IR. La plupart des signaux RMN ^{1}H de ces composés paramagnétiques ont pu être attribués en utilisant des pyridines méthylées. La géométrie octaédrique *mer-cis* légèrement déformée par la triphénylphosphine a été déterminée par diffraction des rayons X pour trois complexes $ReCl_3L_2(PPh_3)$: L = pyridine, triclinique, $P\bar{1}$, a = 11,379, b = 13,532, c = 18,160 Å, α = 80,16°, β = 89,57°, γ = 86,27°, Z = 4, R = 0,076; L = 3-picoline, triclinique, $P\bar{1}$, a = 10,557, b = 12,580, c = 13,153 Å, α = 66,80°, β = 67,46°, γ = 75,89°, Z = 2, R = 0,021; L = 1-méthylimidazole, monoclinique, $P2_1/c$, a = 15,437, b = 9,436, c = 18,607 Å, β = 92,23°, Z = 4, R = 0,046. D'après les données RMN ^{1}H, ces complexes conservent la même structure en solution, alors que les autres catégories de composés existent sous forme des isomères *mer,trans*-$ReCl_3L(PPh_3)_2$ et *mer*-$ReCl_3L_3$. Contrairement à ces systèmes renfermant le motif *mer*-$ReCl_3$, le composé de départ $ReCl_3$(benzil)(PPh_3) se trouve sous forme de l'isomère *fac*. Le déplacement des signaux RMN ^{1}H à champ faible, caractéristique de PPh_3, dépend relativement peu des changements apportés au nombre ou à l'arrangement des autres ligands dans la sphère de coordination, mais les signaux des protons de systèmes conjugués directement liés au métal sont beaucoup plus perturbés par les électrons non appariés.

Mots clés : RMN paramagnétique, structure cristalline, complexes de rhénium(III), imidazole, pyridine, triphénylphosphine.

Introduction

As part of our ongoing research on monomeric Re(III) complexes as routes to purine-bridged metal–metal bonded dimers (1) and to materials of interest for radioactive Re labelling in radiopharmacy (2), we noticed that preparative work was considerably hampered by the absence of standard guidelines for assigning signals and extracting structural information from the ^{1}H NMR spectra of these paramagnetic compounds. We therefore decided to search for useful trends in NMR data by systematically looking at a few series of simple complexes.

In our earlier paper (3), we reported that $ReCl_3(RCN)(PAr_3)_2$ complexes with various combinations of nitriles and arylphosphines gave relatively sharp ^{1}H NMR spectra in which couplings were often observed, and all protons could be identified from their constant patterns of chemical shifts. We have now moved one step further and examined compounds containing simple nitrogen heterocycles. The $ReCl_3py_2(PPh_3)$ and $ReCl_3py_3$ compounds, described and

briefly characterized by Rouschias and Wilkinson (4), were prepared. The sample was enlarged by including the related ligands 3-picoline (3-pic), 4-picoline (4-pic), and 1-methylimidazole (1-meim). $ReCl_3L(PPh_3)_2$ compounds with 1-methylimidazole and pyridine were also isolated for the first time.

Experimental section

Reactants and methods

$KReO_4$ and PPh_3 were used as received from Aldrich. $ReCl_3(MeCN)(PPh_3)_2$ (**1**) was prepared as described in the literature (4) and checked by ^1H NMR (3). All experiments were run under argon using Schlenk techniques. Toluene was distilled over sodium and CH_2Cl_2 over calcium chloride. Ligands (py, 3-pic, 4-pic, 1-meim) were dried over molecular sieves.

^1H NMR spectra were recorded on a Bruker AMX-300 spectrometer, spectral width: 160 to −160 ppm. The residual signals ($CDCl_3$, 7.27; CD_2Cl_2, 5.32; $(CD_3)_2CO$, 2.04 ppm) were used as internal standard and chemical shifts were converted to the usual TMS scale. Infrared spectra were recorded on a Perkin–Elmer 1600 FT-IR spectrometer as CsI pellets. The mass spectrometry data (FAB^+) were recorded on a VG-Autospec Q instrument in nitrobenzylic alcohol. Magnetic moments were determined at room temperature with an Evans magnetic susceptibility balance (Johnson–Matthey), calibrated with $HgCo(SCN)_4$ ($\chi = 16.44 \times 10^{-6}$ cgsemu). Corrections for diamagnetism were calculated from Pascal's constants (5). UV–visible spectra (230–800 nm) were recorded on a Varian Cary 5E spectrophotometer in CH_2Cl_2. Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Canada.

Preparative work

*$ReCl_3L_2(PPh_3)$ (L = py (**2**), 3-pic (**3**), 4-pic (**4**))*

These compounds were obtained by refluxing $ReCl_3(MeCN)(PPh_3)_2$ in a 50-fold excess of the dry neat pyridine ligand for 1 min, as described by Rouschias and Wilkinson (4) for pyridine. The orange-brown product was precipitated by addition of ether. Yields: 73% (py), 61% (3-pic), 49% (4-pic). μ (B.M.): 1.72 (py), 1.78 (3-pic), 1.70 (4-pic). UV–VIS. (λ nm ($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1})): L = py, 407 (4.58), 374 (4.72), 310 (4.58), 278 (sh, 6.65), 259(sh, 10.9); L = 3-pic, 407 (5.32), 372 (5.37), 309 (5.50), 259 (13.84); L = 4-pic, 407 (4.38), 369 (4.45), 306 (5.34), 240 (21.51). The same products were also obtained by refluxing a 1:2 mixture of $ReCl_3(MeCN)(PPh_3)_2$ and the pyridine ligand (as a 1% CH_2Cl_2 solution) for 6 h. The yields were lower, but this method could eventually be applied to other systems involving solid ligands where a large excess cannot be conveniently used.

*$ReCl_3(1\text{-}meim)_2(PPh_3)$ (**5**)*

A mixture of $ReCl_3(MeCN)(PPh_3)_2$ (3.0 g) and 1-methylimidazole (0.5 mL) in toluene (200 mL) was refluxed for 4 h. The brownish orange product was filtered under argon. Yield: 84%. μ (B.M.): 1.62. UV–VIS (λ nm ($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1})): 345 (2.74), 263 (9.35). Anal. calcd. for $C_{26}H_{27}N_4Cl_3PRe$: C 43.4, H 3.8, N 7.8, Cl 14.8; found: C 43.1, H 3.4, N 8.0, Cl 14.8.

*$ReCl_3(1\text{-}meim)(PPh_3)_2$ (**6**)*

$ReCl_3(MeCN)(PPh_3)_2$ (3.0 g) and 1-methylimidazole (0.25 mL) in toluene (125 mL) were refluxed for 3.5 h. The impure green precipitate was filtered under argon and purified by column chromatography on a precoated TLC plate (10 mm silica gel) using a 70:30 CH_2Cl_2:hexane mixture as eluent. The pure compound is yellow. Yield: 55%. UV–VIS. (λ nm ($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1})): 417 (2.00), 253 (24.8), 233 (31.8). Anal. calcd. for $C_{40}H_{36}N_2Cl_3P_2Re$: C 53.4, H 4.0, N 3.1, Cl 11.8; found: C 53.8, H 4.2, N 3.1, Cl 12.0.

*$ReCl_3py(PPh_3)_2$ (**7**)*

$ReCl_3(MeCN)(PPh_3)_2$ (0.2 g) and a 1% solution of pyridine in CH_2Cl_2 (1.9 mL) were refluxed for 20 min. Ether was added to precipitate the yellow solid. The reaction mixture contained a large amount of unreacted starting complex. To obtain the NMR spectrum, a small amount was purified by chromatography on silica gel using a 70:30 CH_2Cl_2:hexane mixture as eluent.

*$ReCl_3(benzil)(PPh_3)$ (**8**)*

The purple product was prepared as described in the literature (4). μ (B.M.): 1.66. UV–VIS. (λ nm ($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1})): 722 (0.13), 550 (15.98), 336 (9.90), 240 (30.98).

*$ReCl_3py_3$ (**9**)*

The red-brown product was obtained as described in the literature (4). Yield: 57%. μ (B.M.): 1.42. UV–VIS spectrum (λ nm ($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1})): 474 (6.32), 444 (6.95) 420 (6.74), 354 (5.47), 253 (16.84). FAB^+: m/z = 529 ($(ReCl_3py_3)^+$), 450 ($(ReCl_3py_2)^+$).

*$ReCl_3(4\text{-}pic)_3$ (**10**)*

A mixture of $ReCl_3(benzil)(PPh_3)$ (0.3 g) and 4-picoline (4.0 mL) was refluxed for 30 min, diluted with benzene (5 mL), and poured into ether (50 mL). Yield: 64%. μ (B.M.): 1.89. UV–VIS (λ nm ($\varepsilon \times 10^{-3}$ M^{-1} cm^{-1})): 431 (6.86), 352 (5.14), 289 (5.52), 253 (14.90).

*$ReCl_3(1\text{-}meim)_3$ (**11**)*

The compound was obtained by refluxing 0.3 g of $ReCl_3(benzil)(PPh_3)$ with 3.8 mL of 1-meim for 5 min. Benzene (4.0 mL) was added and the solution was poured into ether. Crystallization in CH_2Cl_2–benzene gave a brown-green solid. UV–VIS (λ nm (relative intensities)): 420 (0.01), 357 (0.02), 325 (0.15), 316 (0.20), 298 (0.30), 281 (0.30), 252 (0.47), 247 (0.54). Poor solubility precluded ε calculations.

Crystallographic work on the $ReCl_3L_2PPh_3$ compounds

In all cases, orange-brown crystals were grown in a CH_2Cl_2–ether mixture. X-ray work was carried out on an Enraf–Nonius CAD-4 diffractometer with graphite-monochromatized CuKα (L = py, 1-meim) or MoKα radiation (L = 3-pic). The reduced cells were determined from 25 centred reflections and the Niggli parameters clearly indicated that no higher symmetry was present. During data collection, orientation was monitored every 200 measurements and intensity was checked every hour with standard reflections. Crystallographic data and conditions of data collection are summarized in Table 1. Corrections for the effects of Lorentz, polarization, and absorption (Gaussian integration) were applied.

$^aR = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$.

The structures were solved by the heavy-atom method. The non-hydrogen atoms were refined anisotropically by the least-squares procedures of SHELX-76 (6) (L = py) or NRCVAX (7) (L = 3-pic, 1-meim). Hydrogen positions and temperature factors were fixed: C—H = 0.95 Å, $U_H = U_C + 0.01$ Å^2. Poor crystal quality for the pyridine compound led to a higher R factor, but the overall structure is nevertheless reliably defined. The refined coordinates are listed in Table 2. The thermal parameters and hydrogen coordinates are given as supplementary material.[2]

Results and discussion

$ReCl_3L_2(PPh_3)$ complexes with L = py (**2**), 3-pic (**3**), 4-pic (**4**), and 1-meim (**5**) were obtained by reacting excess ligand with $ReCl_3(MeCN)(PPh_3)_2$, as described by Rouschias and Wilkinson (4). The reaction was slower with 1-meim than with pyridines. Simple displacement of MeCN to obtain $ReCl_3L(PPh_3)_2$ was found to be difficult and gave poor yields: under mild conditions, conversion was only partial even after several hours, whereas more vigorous conditions led directly to $ReCl_3L_2(PPh_3)$. A satisfactory yield of the $ReCl_3L(PPh_3)_2$ compound could be obtained with the less reactive 1-meim ligand. $ReCl_3L_3$ compounds were prepared from $ReCl_3$(benzil)(PPh_3) as described (4). All compounds are paramagnetic with magnetic moments in the range 1.4–1.9 B.M. typical of low-spin d^4 Re(III) complexes.

^{1}H NMR spectroscopy

Two unpaired electrons in the Re(III) centre cause signal broadening and unusually large chemical shifts in the ^{1}H NMR spectra, as exemplified by the spectrum of $ReCl_3py_2(PPh_3)$ shown in Fig. 1. The NMR data are collected in Table 3.

The phosphine gives well defined peaks at 18.06 ppm (*ortho*), 10.09 ppm (*meta*), and 10.88 ppm (*para*). A similar pattern, in which the *ortho* protons close to the paramagnetic centre are the most displaced, has been observed for the $ReCl_3(RCN)(PR'_3)_2$ compounds (3) and other complexes with aryl-phosphines (8). Spin–spin couplings are not visible in Fig. 1, but have been detected for other cases discussed below. The signals of pyridine were more difficult to detect, because they correspond to a relatively small number of protons and their presence on a conjugated system directly connected to the paramagnetic centre results in greater signal displacement and line broadening than the remote phosphine protons. Nevertheless, two sets of signals were found, in agreement with the *mer-cis* geometry indicated by the X-ray diffraction work below. They follow the trends discussed by Davison and co-

[2] The supplementary material includes tables of refined temperature factors, hydrogen coordinates, interatomic distances and bond angles, and least-squares plane calculations (35 pages). workers (9) for $TcCl_3py_3$. The *meta* protons give sharp peaks at ~35 ppm, whereas the *ortho* and *para* protons are found at very high field. The *ortho* signals are assigned to the peaks at −58.59 and −76.53 ppm, broadened by their proximity to the paramagnetic centre. The weaker and sharper peaks at −46.88 and −77.66 ppm are due to the *para* protons.

These assignments are confirmed by the spectra of the picoline complexes (Table 3), where the signals occur at the same places. In the 4-picoline complex, the high-field *para* resonances are replaced by very low-field signals for the methyl protons at 70.64 and 100.11 ppm, respectively. With 3-picoline, only one *meta* resonance is found near 33 ppm for each ring, the methyl groups giving upfield signals at −14.23 and −22.29 ppm, respectively.

The alternation between upfield and downfield shifts around the ring and the lack of attenuation of isotropic shift for remote protons has been ascribed to spin delocalization occurring via the pyridine π-system (9, 10). The fact that the ring C-H protons and those of a methyl group bound to the same carbon show displacements in opposite directions is also consistent with this mechanism.

For each type of pyridine proton, the higher-field signal was assigned to the same ligand, as noted for $ReCl_3py_3$ (below) and $TcCl_3py_3$ (9). It is probably the one sitting *trans* to Cl,

Fig. 1. ^{1}H NMR spectrum of $ReCl_3py_2(PPh_3)$ in $CDCl_3$. * = Weak signals due to traces of unidentified impurities.

where metal-to-pyridine π bonding is more favoured than for the other position, where the pyridine and PPh_3 compete for π back-bonding.

$ReCl_3py(PPh_3)_2$ (**7**) must be the *trans*-PPh_3 isomer, since the spectrum contains a single set of phosphine signals, at slightly higher field than for the above compounds. The pyridine protons show spin–spin splitting, allowing unambiguous assignments from intensity and multiplicity: doublet at −4.00 ppm to the *ortho* protons, triplet at 11.57 ppm for the *meta* protons, and half-intensity triplet at 4.23 ppm to the *para* protons. The alternating *ortho/meta/para* pattern in the pyridine ring is similar to the one noted above, although the amplitudes are smaller. Interestingly, in *trans*-$[ReCl(py)(en)_2](PF_6)_2$, where py is also *trans* to Cl, the *ortho* and *meta* protons appear at roughly the same places, although their *para* proton occurs at much higher field (11). In contrast, the chemical shifts are drastically different for *cis*-$[ReCl(py)(en)_2](PF_6)_2$, showing that the remaining ligands in the coordination sphere play a crucial role.

The spectra obtained with the $ReCl_3L_3$ complexes of pyridine and 4-picoline raised particular questions. In contrast with the $TcCl_3L_3$ complexes, which give relatively narrow coupled peaks (9), very broad signals were obtained for the *ortho* and *para* protons in the $ReCl_3L_3$ analogues (Fig. 2): for instance, the linewidth of the *ortho* signal is ~35 Hz for $TcCl_3py_3$ and ~600 Hz for $ReCl_3py_3$. This does not reflect instrinsic trends for these two metal centres, since Duatti et al. (12) have noted that, for Schiff base complexes, Tc(III) gives broader peaks than Re(III). On the other hand, our chemical shifts are strikingly different from those recently reported by Tisato et al. (10)[3] for $ReCl_3py_3$: 3.16, 16.93, and −0.32 ppm for the *trans* ligands; 6.1, 13.9, and −2.4 ppm (values estimated from their Fig. 3) for the unique ligand. After testing different variables, the magnetic field was identified as being responsible for these differences: our spectra were recorded on 300 and 400 Hz instruments, those of Tisato et al. on a 200 MHz instrument. Thus, it appears that this particular set of compounds shows extreme sensitivity to field strength, probably because the electronic ground state of the metal centre changes between these two fields. Having identified the reason for these discrepancies, we believe comparisons can safely be made between our data and those of the $TcCl_3L_3$ compounds, which were also studied at 300 MHz (9). The presence of two sets of signals with different integrations is consistent with a *mer* geometry. The narrow *meta* protons (21.32 and 18.87 ppm) are shifted downfield from the free ligand, whereas the *ortho* and *para* protons between −11.0 and −16.3 ppm are shifted upfield. The proximity of the very broad *ortho* and *para* signals precluded reliable integration and unambiguous identification. From the Tc compound (9, 13), it was assumed that the signals in the mutually *trans* pair of ligands are downfield from those of the *unique* pyridine, since the former must compete for π-back-bonding. Again, the methyl signals for $ReCl_3(4\text{-pic})_3$ occur at very high field, that is, in the opposite direction to that for the *para* protons of

[3] Also, F. Tisato, private communication.

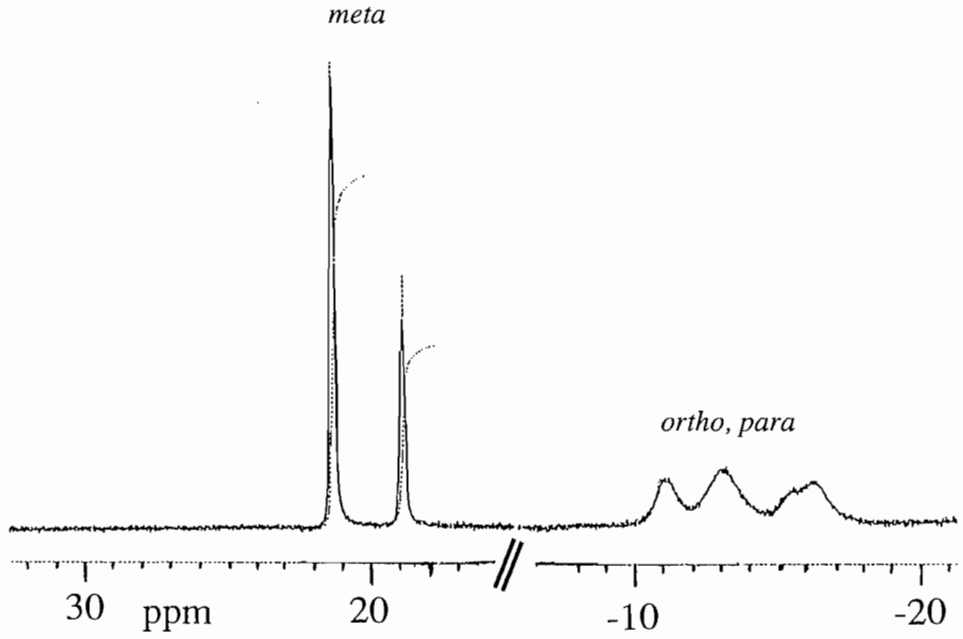
$ReCl_3py_3$. Thus, our data follow the trends observed for the $TcCl_3L_3$ compounds (9) and for the two above types of Re(III) complexes.

Spectra were recorded for the three types of 1-meim complexes. The ring protons of 1-meim were sometimes hard to detect, because they are nonequivalent and produce very weak peaks compared with those of the phosphine. Nevertheless, all signals were detected and they indicated the same stereochemistries as the pyridine analogs: a single set of PPh_3 signals was observed for *mer,trans*-$ReCl_3(1\text{-meim})(PPh_3)_2$ (**6**), two sets of 1-meim resonances of the same intensity for *mer,cis*-$ReCl_3(1\text{-meim})_2(PPh_3)$ (**5**), and two sets in a 2:1 ratio for *mer*-$ReCl_3(1\text{-meim})_3$ (**11**).



Although the PPh_3 protons could be readily assigned, the situation was less straightforward for those of 1-meim. Data on complexes with other metal centres indicate that the alternating pattern of chemical shifts of pyridines is not found for the five-membered imidazole ring. In a series of Ru(III) species (14, 15), the three ring protons of imidazole were shifted upfield in the order H2 > H4 > H5. In various Fe(III) compounds (16, 17), these protons were not found to occur in a uniform order, but H2 was always found to be the most displaced, although on the downfield side.

A NOE difference experiment was run for $ReCl_3(1\text{-meim})_2(PPh_3)$, from which the set of signals originating from the same type of ligand were identified. It allowed us to identify most of the ring protons, an ambiguity remaining concerning H4 and H5 in one of the rings. The ligand showing peaks at −13.11, −8.92, 5.88, and 5.75 ppm is believed to be *trans* to Cl, since $ReCl_3(1\text{-meim})(PPh_3)_2$ gives a similar pattern, which is assigned similarly. For $ReCl_3(1\text{-meim})_3$ (**11**), the set of resonances belonging to each type of 1-meim ligand can be identified from relative intensities, but assignments to individual ring protons are only tentative at this time.

Fig. 2. ^{1}H NMR spectrum of $ReCl_3py_3$ in $CDCl_3$ (300 MHz).

The spectrum of $ReCl_3$(benzil)(PPh_3) used as starting material to prepare the *mer*-$ReCl_3L_3$ complexes **9–11** was recorded. Besides the usual phosphine pattern, the ^{1}H spectrum in acetone shows a single set of signals for the benzil protons, whose couplings are clearly detected. This observation requires a *fac* arrangement of the chloride ligands in order to produce equivalency in the two benzil phenyl rings. Well-separated resonances at 15.23 and 0.44 ppm are found for the *para* and *meta* protons, respectively, whereas the *ortho* protons appear at ~8.65 ppm and are partly masked by the PPh_3 signal at 8.72 ppm. The shifts around the phenyl ring of benzil follow the alternating pattern found for pyridine, but the amplitude is much smaller and the peaks are very sharp. This is consistent with spin delocalization occurring via the π system, but at a greater distance from the metal centre.

Comparison of the data for PPh_3 protons in Table 3 shows that the *ortho* protons systematically occur downfield from the *meta* and *para* protons, which are sometimes not resolved. It is interesting to point out that the three resonances are displaced downfield for the three $ReCl_3L_2(PPh_3)$ compounds with pyridines, whereas the 13.5/8.5/8.5 ppm pattern of *mer,trans*-$ReCl_3(RCN)(PPh_3)_2$ is retained for the remaining compounds including *fac*-$ReCl_3$(benzil)PPh_3 and *mer*-$ReCl_3$(1-meim)$_2(PPh_3)$. Therefore, chemical shifts do not depend on a single feature such as ligand composition or stereochemistry, since they are sensitive to subtle changes such as replacing pyridine by imidazole. Systematic studies on other series of complexes are needed before general trends can be proposed.

Infrared spectroscopy

The 4000–600 cm^{-1} region includes a number of ligand bands that are not greatly affected by coordination. The more interesting 600–200 cm^{-1} region is presented in Table 4.

Bands at 544 and 496 cm^{-1} for $ReCl_3(4\text{-pic})_3$ (**10**) and 466/454 cm^{-1} for $ReCl_3py_3$ (**9**) are assigned to the pyridine ligands (18, 19). A pattern of two bands at 280 and 306 cm^{-1} (the latter containing a high-frequency shoulder) is consistently found in the present series of compounds and can be assigned to Re–Cl stretching, for which three IR active modes are expected in a *mer*-$ReCl_3$ unit. The absence of significant absorption at ~280 cm^{-1} for $ReCl_3(1\text{-meim})_3$ remains unclear. For related Rh and Ir complexes, bands near 280 cm^{-1} were assigned as M–N stretching (19, but the presence of this band in $ReCl_3(MeCN)(PPh_3)_2$ (**1**) and other pyridine-free $ReCl_3(RCN)(PAr_3)_2$ compounds (3) supports our assignments as ν(Re–Cl).

The remaining complexes all contain PPh_3, which shows two characteristic sets of bands. The typical triplet (3, 20, 21) with an intensity pattern opposite to that of free PPh_3 is observed at 523/513/498 cm^{-1} (first two components not resolved for **2**). Two weaker characteristic bands are also observed at 450 and 430 cm^{-1}, masking those of pyridine or picolines (18, 19). Nevertheless, a weak band is detected for $ReCl_3(4\text{-pic})_2(PPh_3)$ (**4**) at 545 cm^{-1}. A weak feature at ~380 cm^{-1} for $ReCl_3(1\text{-meim})_2(PPh_3)$ (**5**) and a stronger band at 391 cm^{-1} for $ReCl_3(1\text{-meim})_3$ (**11**) are likely due to an imidazole mode (22, 23). This absorption is probably too weak to be detected in the spectrum for $ReCl_3(1\text{-meim})(PPh_3)_2$ (**7**) dominated by the strong features of the two PPh_3 ligands. The ν(Re–Cl) pattern described above is not affected by the presence of PPh_3.

The ν(Re–P) bands should appear near 200 cm^{-1} (24, 25) and are not expected to show in our spectra. Weak bands at 247 and ~230 cm^{-1} in the $ReCl_3L_3$ compounds **9–11** could be due to ν(Re–N) motion. Weak features in the same region are detected for most other complexes with py, 3-pic, 4-pic, and 1-meim. However, since this spectral region is poorly defined and weak signals are also found for compounds **1** and **8** devoid of Re—N bonds, no assignments are attempted below 250 cm^{-1}.

				237 vw		236 vw	237 vw		234 vw	

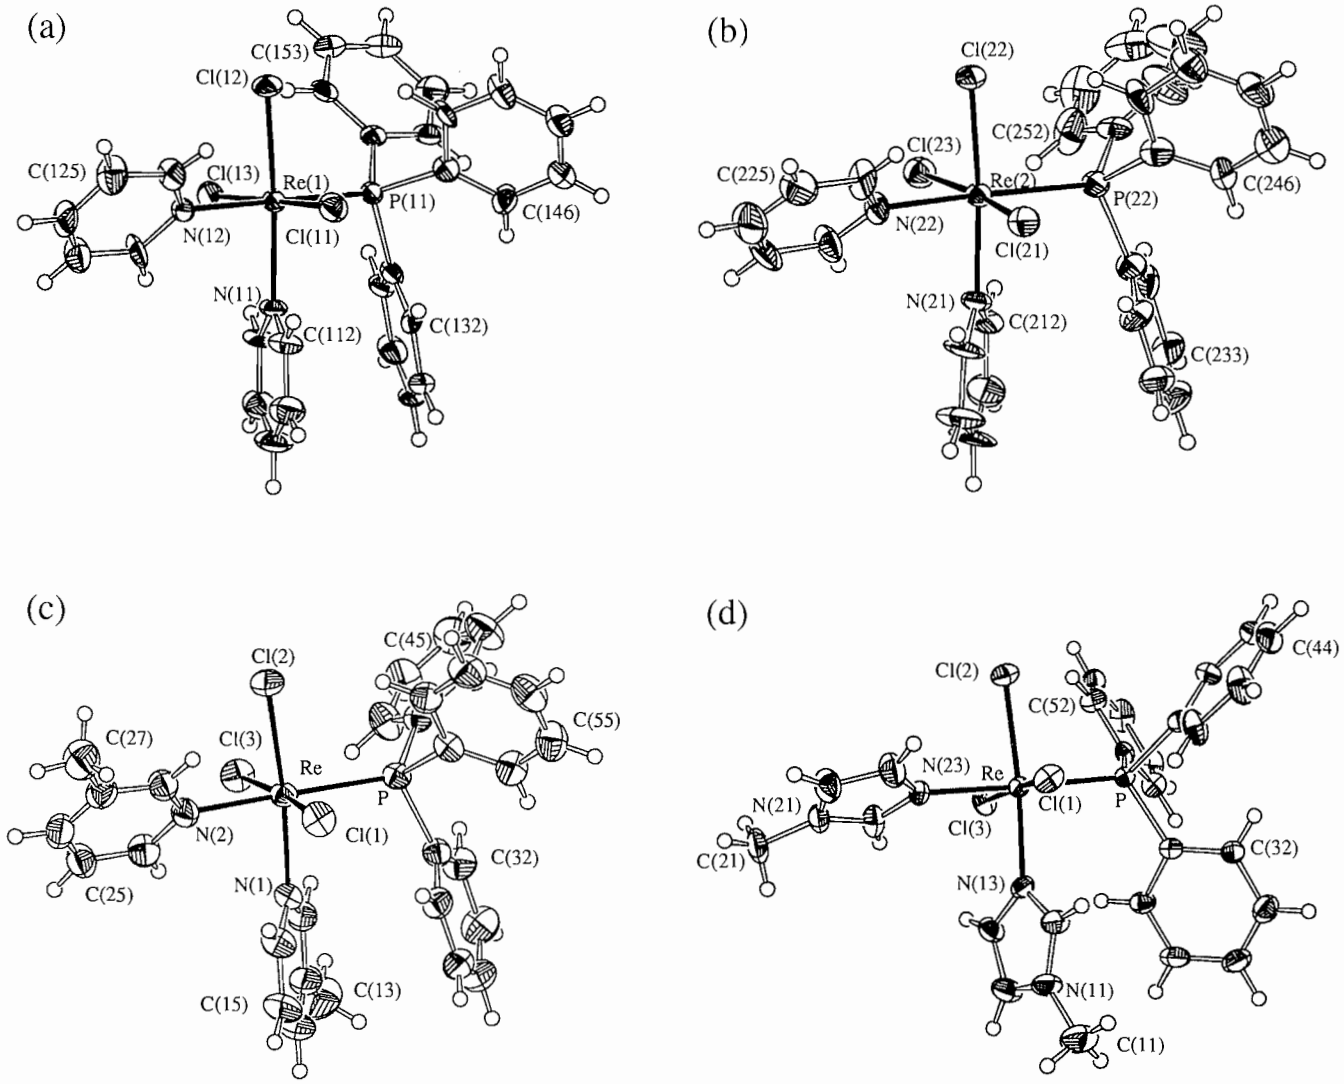
The spectrum of the $ReCl_3$(benzil)(PPh_3) complex used as starting material was also recorded. The ^1H NMR spectra discussed above indicate the presence of a *fac*-$ReCl_3$ unit in this molecule. The IR spectrum shows the typical features for PPh_3, as well as strong bands at 488 and 330 cm^{-1}, probably corresponding the 470 and 328 cm^{-1} bands, respectively, of uncoordinated benzil. The two remaining strong bands at 344 and 293 cm^{-1} probably originate from ν(Re–Cl) modes. Therefore, shifts to higher frequencies seem to take place between *mer* and *fac* configurations.

Crystallographic work

The $ReCl_3L_2(PPh_3)$ molecules with 3-picoline, pyridine (two crystallographically independent molecules), and 1-methylimidazole adopt the same *cis-mer* geometry (Figs. 3*a–d*). The 4-picoline analogue adopts the same arrangement, since its ^1H NMR spectrum shows two sets of proton signals for the picoline ring.

Interatomic distances and bond angles are listed in Table 5. The Re–Cl distances *trans* to a Re—N bond (mean 2.390 Å) are appreciably longer than the mutually *trans* Re—Cl bonds (2.369 Å). A similar *trans* influence of a pyridine ligand has already been noted in related Tc complexes (13), as well as for the complexes with Ti(III) (26) and Os(III) (27). However, this is not a general trend, since it is not followed by complexes with Fe(III) (28), Rh(III) (29), Mo(III) (30), Cr(III) (31), and V(III) (32). The Re—P distances (mean 2.436 Å) are slightly shorter than those found in $ReCl_3$(MeCN)(PPh_3)$_2$ (33) and related phosphines, where the presence of two PPh_3 ligands introduces greater steric hindrance. The Re—N bonds also show some significant differences: the Re—N(1) bond, *trans* to Cl, tend to be ~0.03 Å shorter than the other, *trans* to the phosphine.

A number of significant deviations from the ideal 90° value are noted around the metal, but they generally remain within 5°, which is relatively small considering that the van der Waals envelopes as seen from the metal are quite different for the phosphine and the heterocyclic ligands. However, a region of steric strain is found for the complexes with 3-picoline and pyridine (molecule 2), where the rotation about the Re—P bond and the orientation of the phosphine rings bring an *ortho* proton (C(46)-H and C(252)-H, respectively) close to Cl(3), increasing the P-Re–Cl(3) angle to ~100°. This steric effect does not seem to introduce repulsive contacts with the heterocyclic ligands (type 1) roughly coplanar with the $ReCl_3$ plane, since the dihedral angles (~18°) are smaller than for the other two cases (~33°), where the P-Re-Cl(3) angles are normal. The other heterocyclic ligands (type 2) make dihedral angles of ~45° with the underlying Re—Cl or Re—N bonds for the three molecules containing pyridine ligands, whereas 1-methylimidazole is rotated towards the Re–Cl(1)-Cl(3)-P plane, with which it makes a dihedral angles of 22°.



Concluding remarks

All the $ReCl_3L(PPh_3)_2$ and $ReCl_3L_2(PPh_3)$ compounds studied here show the typical pattern of three slightly downfield-shifted phosphine signals observed for $ReCl_3(RCN)(PAr_3)_2$

Fig. 3. ORTEP drawings of $ReCl_3L_2(PPh_3)$ molecules. (*a*) L = pyridine, molecule 1; (*b*) L = pyridine, molecule 2; (*c*) L = 3-picoline; (*d*) L = 1-methylimidazole. Thermal ellipsoids correspond to 50% probability. Hydrogens are shown as spheres of arbitrary size.

(3), but its position cannot be correlated at this time with a single variable in the complex, since it occurs approximately at the same place for *mer,trans*-$ReCl_3py(PPh_3)_2$, *mer,trans*-$ReCl_3(1\text{-meim})(PPh_3)_2$, *fac*-$ReCl_3(benzil)(PPh_3)$, and *mer,cis*-$ReCl_3(1\text{-meim})_2(PPh_3)$, but it is displaced several ppm downfield for the *mer,cis*-$ReCl_3L_2(PPh_3)$ complexes with pyridine, 3-picoline, and 4-picoline. In all cases, the pyridine protons were found to follow a systematic pattern: *ortho* and *para* upfield, *meta* downfield, opposite displacements for a given proton and those of methyl groups at the same position. The number of signals was useful to confirm the presence of a single stereoisomer in solution and identify its stereochemistry, but no obvious correlation with chemical shift values can be proposed at this time. As to the imidazole ligands, no definite pattern could be deduced. Our work suggests that useful structural information can be extracted from ^1H NMR spectra of these paramagnetic Re(III) compounds, but further work is needed to define guidelines allowing prediction of ligand composition and stereochemistry.

Acknowledgment

We wish to thank M. Simard and F. Bélanger-Gariépy for their assistance in collecting and interpreting the crystallographic data, Phan Viet Minh Tan for valuable assistance with the NOE experiment, and F. Sauriol for assistance in recording the 200 MHz NMR spectra. We are particularly grateful to Dr. F. Tisato, who provided data and samples of $ReCl_3py_3$ from which the extreme sensitivity of the ^1H NMR signals to field strength was uncovered. The financial support of the Natural

The design of radical clocks to probe the reactivity of the intermediates in arylmethyl ester photochemistry

Abstract: The photochemistry in methanol of the esters **1–6** was examined. These reactions normally proceed through radical pairs that result from homolytic cleavage of the carbon–oxygen bond in the excited singlet state. Each of the esters was designed to probe the intervention and reactivity of the substituted arylmethyl radical by incorporating a potential radical clock at the carbon of the reactive bond. For esters **1–5**, the products isolated indicated that the radical clock was not reactive enough to compete with the very rapid alternate processes of the radical pair, namely, electron transfer to form the corresponding ion pair and decarboxylation of the phenylacyloxy radical ($k = 4.6 \times 10^9$ s^{-1}). Ester **6**, which incorporates the extremely rapid fluorenylcyclopropylcarbinyl clock, showed very unusual reactivity. On thermal solvolysis in methanol, **6** rearranged quantitatively to the ester **20**. No methyl ethers were detected. In contrast, photolysis of **6** in benzene resulted in an alternate rearrangement to the cyclobutyl ester, **22**, resulting from the aryl version of the cyclopropyl–π-methane photochemical rearrangement. No ester cleavage occurred on excitation. A rationale for the latter conversion was based on stereoelectronic arguments provided by a crystal structure of **6**.

Key words: photochemistry of arylmethyl esters, radical clocks.

Résumé : On a étudié la photochimie des esters **1–6** en solution dans le méthanol. Ces réactions se produisent généralement par le biais de paires de radicaux résultant du clivage homolytique de la liaison carbone–oxygène dans l'état singulet excité. Chacun de ces esters a été synthétisé pour évaluer l'intervention et la réactivité du radical arylméthyle substitué en leur incorporant une horloge radicalaire potentielle au niveau du carbone de la liaison réactive. Dans les cas des esters **1–5**, les produits isolés indiquent que l'horloge radicalaire n'est pas assez réactive pour être en compétition avec les processus alternatifs très rapides de la paire de radicaux, soit le transfert d'électron conduisant à la formation de la paire d'ions correspondante et la décarboxylation du radical phénylacyloxy ($k = 4{,}6 \times 10^9$ s^{-1}). L'ester **6**, qui incorpore l'horloge extrêmement rapide fluorénylcyclopropylcarbinyle, présentait une réactivité très inhabituelle. Lors de sa solvolyse thermique dans le méthanol, le composé **6** se réarrange quantitativement en ester **20**. On ne peut détecter d'éthers méthyliques. Par ailleurs, la photolyse du produit **6** dans le benzène conduit à un réarrangement alternatif en ester cyclobutylique, **22**, qui découle de la version arylée du réarrangement photochimique cyclopropyl–π-méthane. Il ne se produit aucun clivage par excitation. On a expliqué cette dernière conversion en se basant sur des arguments stéréoélectroniques fournis par une structure cristalline du produit **6**.

Mots clés : photochimie d'esters arylméthyles, horloges radicalaires.

[Traduit par la rédaction]

Introduction

The photochemistry of arylmethyl compounds with leaving groups ($ArCH_2$-LG) leads to products derived from both radical ($ArCH_2{}^{\cdot}$ $^{\cdot}$LG) and ion ($ArCH_2{}^+$ $^-$LG) pairs (1–4) and the partitioning between these pathways is controlled by many variables that are not yet clearly understood. Our detailed observations (5) on arylmethyl esters are best explained by a mechanism dominated by homolytic cleavage of the arylmethyl–oxygen bond from the excited singlet state to give the radical pair ($ArCH_2{}^{\cdot}$ $^{\cdot}$O(CO)R). Product yields are then controlled by two rate constants: the rate constant for decarboxylation of the acyloxy radical and that for electron transfer converting the radical pair to the ion pair ($ArCH_2{}^+$ $^-$O(CO)R). Direct heterolytic cleavage of the excited state to form the ion pair seems to be of only minor importance.

One of the now standard ways of probing both the intervention and the reactivity of radicals is by the use of "radical clocks" (6). In fact, in ester photochemistry, the rate of decarboxylation of the acyloxy radical serves as the clock necessary to obtain rate constants for electron transfer for converting the radical pair to the ion pair. However, we have an interest in studying other leaving groups that do not have an internal radical clock.

The obvious solution for timing the radical reactivity is to put the clock on the arylmethyl carbon. Such an approach was taken by Givens and Singh (7) using the well-established 5-hexenyl clock in a benzylic phosphate, eq. [1]. The idea was to probe the reactivity (k_{rad}) of the initially formed radical pair by the competing cyclization (k_{cycl}). In the absence of the phenyl group, the rate constant for the cyclization is $\sim 10^5$ s^{-1} (8). Our

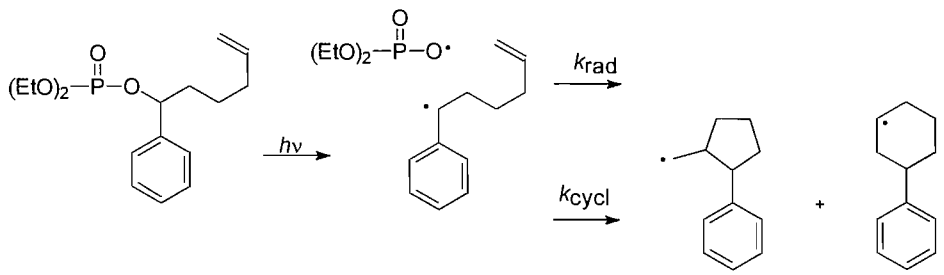
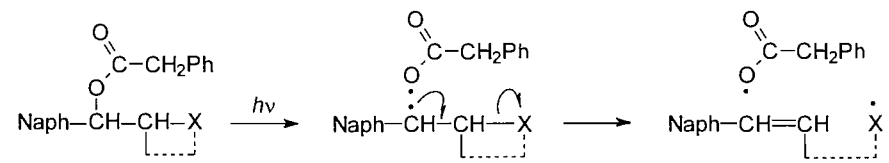
estimates of the rate constants for the reactivity of the radical pair in ester photochemistry are in the 10^9–10^{11} s^{-1} range. Therefore, a much faster radical clock is necessary in order to obtain significant yields of products from the clock process. This difficulty is apparent in the results from the phosphate in eq. [1] where only very low yields of cyclized products were obtained.



With this in mind we have synthesized and studied the photochemistry of six esters, **1**–**6**.[2] All were chosen so that the excitation would be localized in the chromophore of lowest energy, the naphthalene ring (Naph). Cleavage of the ester bond would then give the radical pair, eq. [2], and the clock built into **1r**–**6r** would then compete with the other processes of the radical pair, namely, electron transfer to give the ion



1 **2** **3**

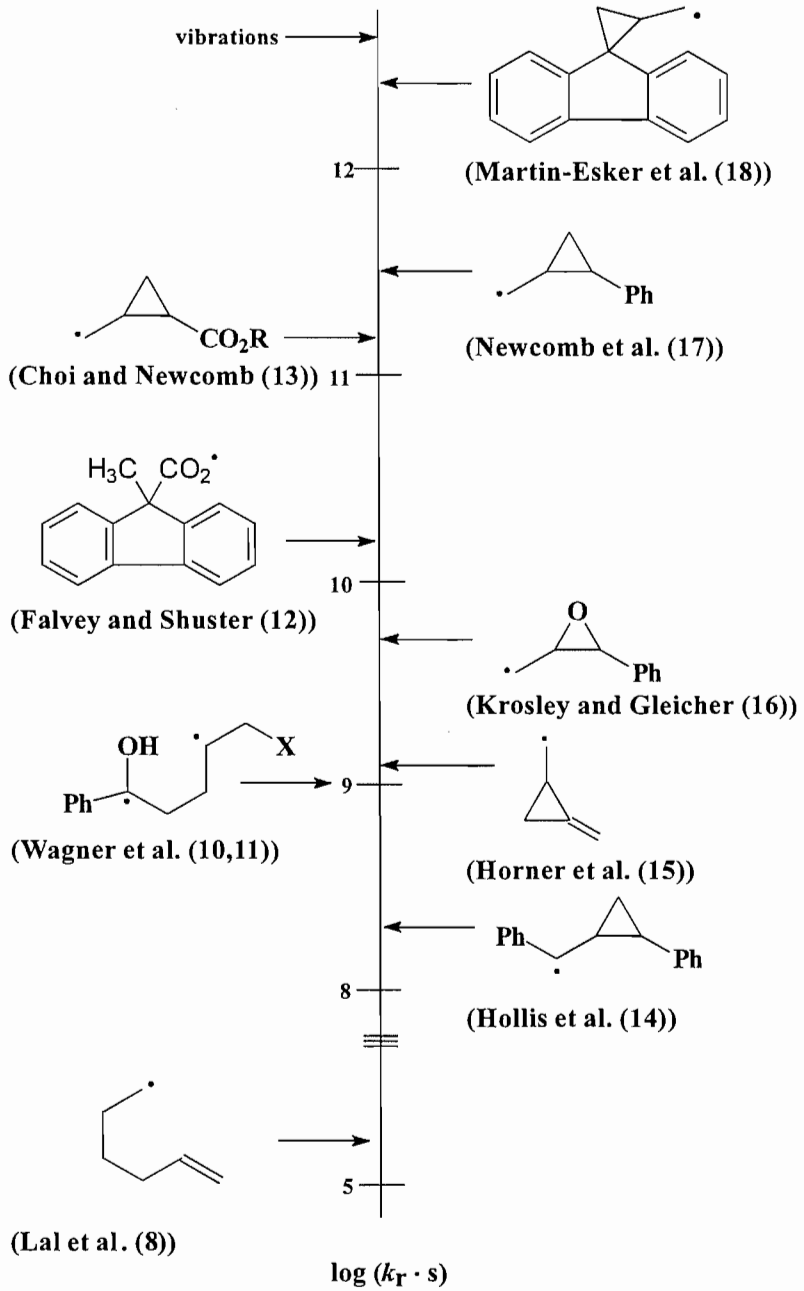
4 **5** **6**

[1]

[2]

1 - 6 **1r - 6r**

pair and decarboxylation of the acyloxy radical. Product yields could then be used to determine the radical clock rate constant.



The choice of this set of compounds was based on literature expectations for the reactivity of the radicals. For compounds **1**–**3**, the β-cleavage reaction of biradicals (without the 1-naphthyl group) generated in the Norrish type II reaction of δ-substituted arylketones has been reported (10, 11). For compounds **4**–**6**, the β-cleavage reaction opens the three-membered rings. A summary of rate constants and references (12–18) for their determination is given in Fig. 1 (adopted from a similar figure by Newcomb (19)).

The difficulties inherent in designing a fast arylmethyl radical clock are exemplified by the rate constants for ring opening obtained for three cyclopropylcarbinyl radicals. For the unsubstituted case (20), $k = 1 \times 10^8$ s^{-1}. For the phenyl-

[2] A preliminary account of the photochemistry of **6** has appeared (9).

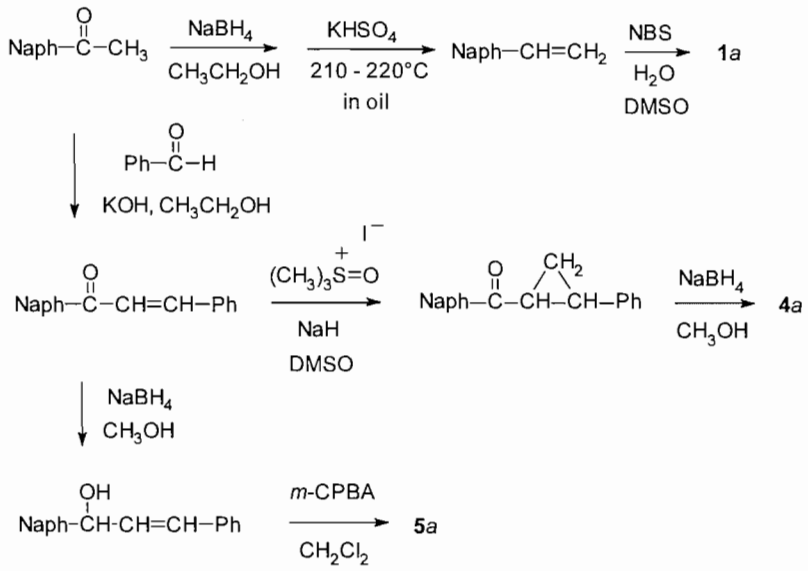
Fig. 1. Summary of rate constants for radical clocks.

substituted case, the value (17) increases by more than three orders of magnitude to $\sim 5 \times 10^{11}$ s^{-1}, reflecting the increased stability of the ring-opened radical. A second phenyl substitution on the carbinyl carbon decreases the rate constant (14), $k \sim 2 \times 10^{8}$ s^{-1}, nearly back to the original value for the unsubstituted case. The stabilization of the cyclopropylcarbinyl radical by aryl substitution slows down the ring-opening process.

As a historical note, compounds **1**–**6** are ordered in the same sequence in which they were studied. Thus, faster radical clocks were sought after the initial ones were shown to be unsuitably slow.

Results and discussion

Synthesis of esters 1–6



The esters were synthesized from the corresponding alcohols, **1***a*–**6***a*, with phenylacetyl chloride and pyridine in benzene for **1**, **5**, and **6** and with phenylacetic acid and *N,N*-carbonyldiimidazole for **2**, **3**, and **4**.

The successful synthetic routes to the alcohols are summarized in Scheme 1 for **1***a*, **4***a*, and **5***a*, in Scheme 2 for **2***a* and **3***a*, and in Scheme 3 for **6***a*. For all alcohols except **1***a*, the possibility of diastereomeric products created problems for both

yield and purification. For both **2***a* and **3***a*, with two stereogenic centers, only two diastereomers are possible. By ^{1}H NMR, two similar but distinct ABX patterns at nearly equal intensities were obvious. These diastereomers were not separated and the spectra were not assigned to specific isomers. For the esterification reactions, these mixtures were used in order to maximize yields.

For **4***a* and **5***a*, there are three stereogenic centers, but the

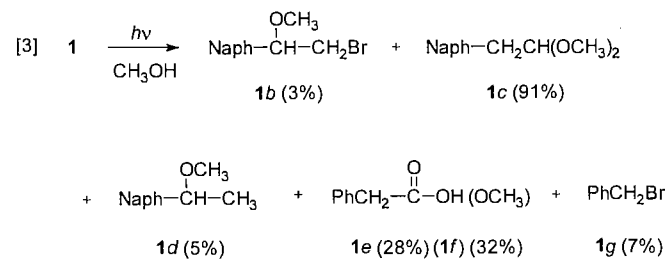
Scheme 4. Mechanism for the photolysis of **1** in methanol.

possibility of four isomers was reduced to two because of the more stable *trans* geometry through the cyclopropane and oxirane rings. This results because the precursor enone, synthesized by aldol condensation, is the *E* isomer. This assignment was confirmed for the oxirane, **5***a*, by the small coupling constant of 1.5 Hz for the *trans* protons in the three-membered ring (21). For **4***a*, the two diastereomers were formed in a 2:1 ratio, and for **5***a* in a 3:1 ratio. Neither of these mixtures was separated.



For **6***a*, with two stereogenic centers, the diastereomeric alcohols were formed in a ratio of greater than 9:1 and, in this case, separation and purification of the major isomer was achieved. An X-ray crystal structure determination,[3] Fig. 2, of the ester **6**, made from this isomer, showed that it is of the *R,R/S,S* configuration. The dihedral angle between the two hydrogens on these stereogenic centers is 166°; the large vicinal coupling constant of 10.1 Hz between these same two hydrogens strongly suggests that the stable conformation in solution has a similarly large dihedral angle (ref. 21, p. 197).

Photochemistry of esters 1–6

The esters were photolyzed in nitrogen-purged methanol using a Pyrex-filtered 200 W medium-pressure Hanovia mercury lamp. For preparative runs, high conversions were used. The products were then separated by silica gel chromatography and their structures determined by spectroscopic methods. Once again, the problems of diastereomeric products, as discussed above for the ester substrates, often complicated the separations. In some cases, where yields were low, authentic samples were prepared by independent synthesis. For quantitative runs, lower conversions were used and the yields of products were determined by calibrated HPLC. These yields are given in the equation for each photolysis.

Photochemistry of 1 in methanol

The products for the bromo ester, **1**, are shown in eq. [3]. The major product, **1***c*, was synthesized from 1-naphthylacetic acid by borane–THF reduction to the alcohol, chromium trioxide – pyridine oxidation to the aldehyde, followed by dimethylacetal formation using methanol and an ion exchange resin as the acid catalyst. The bromo ether, **1***b*, was prepared by addition of bromine to vinylnaphthalene in methanol. The other ether was prepared from 1-(1-naphthyl)ethanol using sodium hydride in DMF followed by methyl iodide. Control experiments with **1***b* demonstrated that it was converted to **1***c* by irradiation in methanol. This reaction did not occur in the dark. Therefore, the major product, **1***c*, is not a primary photoproduct. The ratio of **1***e*:**1***f* slowly decreased as a function of

irradiation time, indicating slow ground state esterification of the primary product, the carboxylic acid.

These products can be rationalized by the mechanism outlined in Scheme 4. Initial homolytic cleavage from the excited singlet state gives the radical pair, **1r**. The preferred reaction of the radical pair is electron transfer to give the ion pair, which is then trapped by methanol to give the ether, **1***b*, and phenylacetic acid. Based on the yields of **1***b* and **1***c*, this pathway accounts for 94% of the products. For the related compound, **7**, without the bromine clock, this channel accounts for 84% of the products.

The formation of the ether, **1***d*, is of interest because the

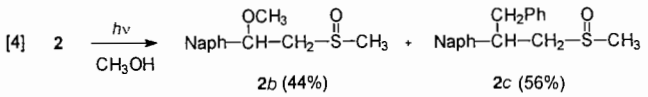
loss of bromine implies that the potential clock reaction of **1r** is competing, though not very efficiently, with the electron transfer process. Based on analogy with the photoprotonation reactions studied by McEwen and Yates (22), the initially formed 1-vinylnaphthalene would be expected to add methanol in the Markovnikov sense to give **1***d*, particularly since it will absorb at longer wavelengths and with a higher molar absorptivity than **1**. However, recent laser flash photolysis results on the closely related 2-bromo-1-(2-naphthyl)ethyl radical, **8**, show that it is very long lived (>5 μs) and that it

7



8

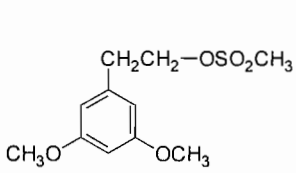
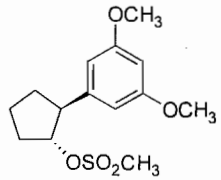
9*b*, X = $SOCH_2CH_2CH_2CH_3$
9*c*, X = SOPh

decays, not by unimolecular fragmentation to 2-vinylnaphthalene and a bromine atom, but in a bimolecular process (23). It is an unreasonable expectation that the positional change from 2-naphthyl to 1-naphthyl for the radical, **1r**, obtained in the photolysis of **1**, would increase the rate constant for this unimolecular process by more than three orders of magnitude. We had originally chosen **1** as a potential probe for arylmethyl reactivity based on the estimated rate constant of 3×10^8 s^{-1} for β-cleavage of the bi-radical **9***a*, obtained in the Norrish type II reaction (10, 11). Again we see that the change from an unsubstituted radical center, as in **9***a*, to an aryl-substituted one, as in **1r**, slows the rate of fragmentation by several orders of magnitude.

Therefore, the pathway for formation of 1-vinylnaphthalene and hence the ether, **1***d*, in the photolysis of **1** is probably not



[4] 2 $\xrightarrow[CH_3OH]{h\nu}$ Naph–CH(OCH$_3$)–CH$_2$–S(=O)–CH$_3$ + Naph–CH(CH$_2$Ph)–CH$_2$–S(=O)–CH$_3$

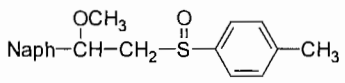


2*b* (44%) **2***c* (56%)

by unimolecular fragmentation of **1r**. A more likely possibility is suggested by the observation of the formation of benzyl bromide, **1***g*, in yields comparable to that for **1***d*. In-cage disproportionation by bromine atom transfer between the benzyl radical and **1r** gives benzyl bromide and 1-vinylnaphthalene. The transfer of the bromine atom from a 1° carbon to a benzylic one is endothermic by about 12 kcal/mol (24) but the compensating formation of the double bond makes this process highly exothermic. The rate constant for decarboxylation of the phenylacetyloxy radical (25), 4.6×10^9 s^{-1}, is great enough that benzyl radicals will be generated before cage escape.

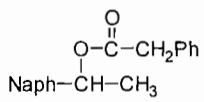
The photochemical conversion of **1***b* to **1***c* probably proceeds by the mechanism shown in Scheme 4. Photochemical activation of leaving groups by β-aryl participation has not been extensively studied (1) but there is precedent for phenonium ion intermediates. Photolysis of the methane sulfonates, **10** (26) and **11** (27), in methanol–water leads to products that result from symmetrical bridged (or equilibrating) species.

10



11

Photochemistry of 2 and 3 in methanol



The relative reactivity for loss of X from the radicals **9***a–c* has been estimated at 1:1.2:9.7 for X = Br, SO-$CH_2CH_2CH_2CH_3$, and SO-Ph (11). In the photolysis of **1**, eq. [3], unimolecular loss of a bromine atom from **1r** did not compete with other processes of the radical pair. Therefore, fragmentation of **2r** should also not compete with other processes.

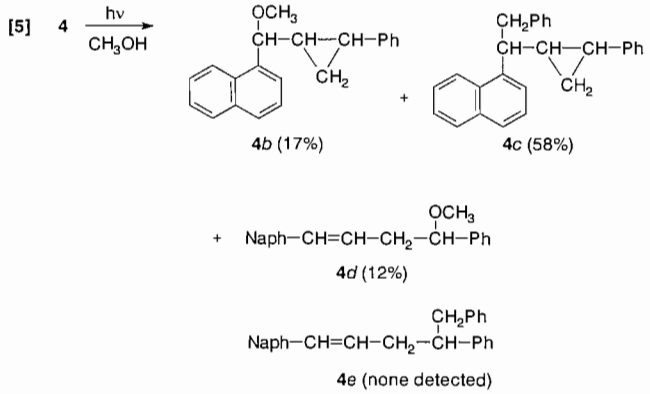
This was confirmed by the products observed, **2***b* resulting from trapping of the ion pair by methanol and **2***c* by in-cage coupling of the substituted 1-naphthylmethyl radical and the benzyl radical, eq. [4]. No products were detected that resulted from loss of the methane sulfinyl group.

The photochemistry of **3** was not studied in detail because preliminary experiments indicated it would not be a suitable precursor for an arylmethyl radical clock. All photolyses resulted in recovery, after chromatography, of less than 10% of the consumed starting material even when conversions were kept as low as 50%. One of the products isolated was the expected methyl ether, **3***b*, but another was **3***c*, resulting from carbon–sulfur bond cleavage at the sulfoxide functional

3*b*

3*c*

group. This bond cleavage was apparently competitive with the usual ester photochemistry. Both the poor mass balance and this unexpected alternate photochemical pathway precluded further study of compound **3**.



Photochemistry of 4 in methanol

Based on the results for esters **1–3**, a simple homolytic cleavage, even with weak C—X bonds, does not compete with other processes of the radical pair. The substrates, **4–6**, were chosen so that the rate for bond cleavage would be assisted by the thermodynamic driving force provided by cleavage of the three-membered ring. The products and yields for the photolysis of **4** are shown in eq. [5]. The cyclopropyl ether, **4***b*, was independently synthesized from the alcohol, **4***a*, using sodium hydride in DMSO followed by methyl iodide. Products **4***b* and **4***c*, which account for 75% of the mass balance, both retain the cyclopropane ring. The ratio of ether to hydrocarbon (0.29) is now considerably lower than observed (5.2) for the model compound **7**, suggesting that the electron transfer process to form the ion pair is considerably slower for the radical pair, **4r**.

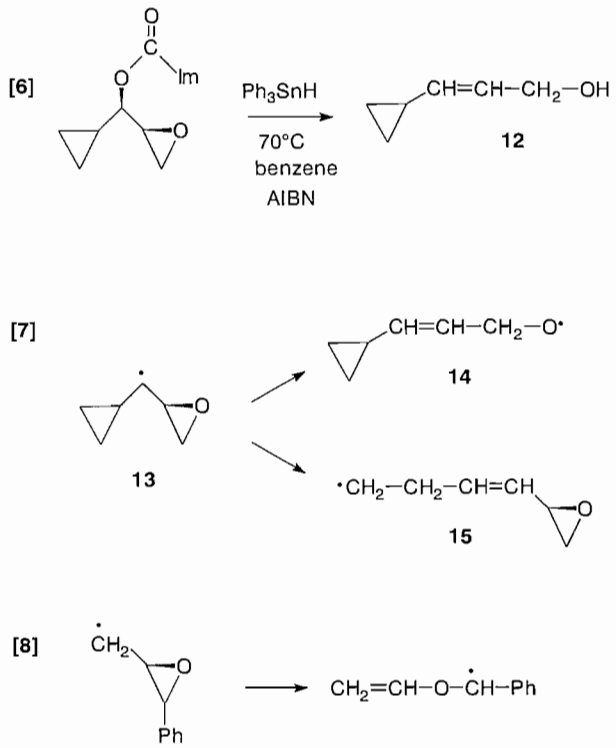
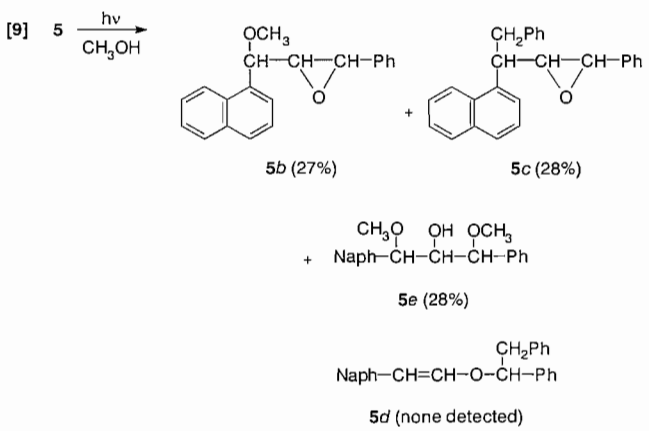
For personal use only.



The ring-opened ether **4***d* is clearly suggestive of radical clock reactivity. However, there are two quite distinct mechanistic possibilities for its formation. The first is ring opening at the radical stage followed by electron transfer oxidation to the cation; the second is initial formation by electron transfer of the ring-closed cation followed by ring opening. To probe the reactivity of the cation, the ground state solvolysis of **4** in methanol was examined. Complete conversion required refluxing in methanol (65°C) for 24 h. The ethers **4***b* and **4***d* were again formed but the ratio of 0.42 was considerably lower than the value of 1.42 observed in the room temperature photolysis. A likely explanation for this observation is that the higher temperature required for the solvolysis causes the rate of ring opening of the cation to be faster than trapping by the solvent, methanol. This experiment establishes the fact that the ring-opened cation can be formed, as expected, from the ring-closed one but does not rule out partial intervention of the radical clock possibility for the formation of the ether, **4***d*.

However, an important potential product, **4***e*, that would have established the radical clock pathway, was not detected. Careful examination of the hydrocarbon fraction from silica gel chromatography (which contained **4***c*) by ^{1}H and ^{13}C NMR did not reveal any signals that could be attributed to the alkene functional group. Since the yield of the ring-closed hydrocarbon, **4***c*, is 58%, an upper limit for the yield of **4***e* is probably around 2%. Assuming that the rate constant of electron transfer for the radical pair, **4r**, is $\sim 10^{10}$ s^{-1}, an upper limit for the rate of ring opening for **4r** is $\sim 2 \times 10^{8}$ s^{-1}, a value essentially identical to that previously observed for the 2-phenylcyclopropylcarbinyl radical with a second phenyl substituent at the carbinyl carbon (14).



Photochemistry of 5 in methanol

In 1993, Krosley and Gleicher (16) reported that oxiranylmethyl radicals are more reactive to ring opening than cyclopropylmethyl radicals by approximately two orders of magnitude. This was based on the exclusive formation (by NMR analysis) of **12**, eq. [6], the product expected from the radical **13** after rearrangement to **14**, eq. [7]. No evidence was obtained for the intervention of the alternate possibility, **15**. The authors comment that "...no report of chemical trapping or spectroscopic observation of these species prior to rearrangement has appeared." Moreover, oxiranylmethyl radicals that are aryl substituted on the three-membered ring are known to give products derived from ring opening of the carbon–carbon bond rather than the carbon–oxygen bond, eq. [8] (16). With these ideas in mind, we synthesized **5** as a potential clock probe for arylmethyl radical reactivity.

Photolysis of **5** in methanol gave the products shown in eq. [9]. Surprisingly, no products were isolated that were derived from the ring opening of the oxiranyl radical, **5r**, perhaps **5***d* being the most obvious choice. Again, careful examination of ^{1}H NMR spectra of fractions containing **5***c* gave no evidence for alkene hydrogens. The ring-opened product, **5***e*, is a secondary one, derived from addition of methanol to **5***b*, as has been observed in the photochemistry of other oxiranes (28).

One reason for the absence of **5***d* may be its expected high reactivity in methanol both because it is a vinyl ether and because it has a chromophore that will absorb at longer wavelengths than the starting ester. The mass balance in this photolysis is not extremely high (~70%) so the possibility certainly exists that degradation products of **5***d* account for some of this missing mass.

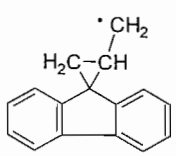
Of interest is the isolation of the coupling product, **5***c*, which must be derived from in-cage coupling of the benzyl radical with the ring-closed oxiranyl radical, **5r**, proving that under suitable conditions oxiranylalkyl radicals can be trapped, although not yet reported, in a bimolecular process.

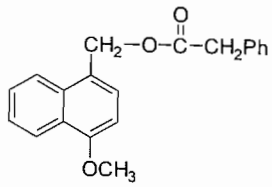
Recent results on trapping experiments for the radicals **16** and **17** derived from **15**, eq. [10], indicate that, although **16** is kinetically preferred, **17** is thermodynamically favoured and the conversion of **16** to **15** is reversible (29). As well, allyloxy radicals that are tertiary are capable of cyclizing to oxiranylcarbinyl radicals, so in those cases the equilibrium constant

[10] 



16 15 17

favours the closed form (30). These results all suggest that oxiranylcarbinyl radicals are more stable to ring opening than previously expected. Therefore, **5r**, the 1-naphthyl-substituted analogue of **15**, is stabilized enough by aryl substitution, as in the cyclopropylcarbinyl cases, so that it does not open as rapidly as required to be a useful clock in arylmethyl photochemistry.

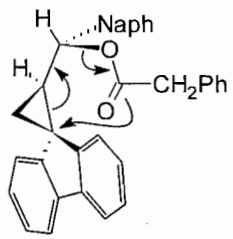


Photochemistry of 6 in methanol and benzene (ref. 9)

In 1994, Martin-Esker et al. (18) reported on the ring-opening reactivity of the (spiro[cyclopropane-1,9′-fluorene]-2-yl)-methyl radical, **18**, and, using bimolecular trapping experiments with benzeneselenol, estimated a rate constant of 6×10^{12} s^{-1}. Even with the assumption of a decrease of two orders of magnitude in this value for 1-naphthyl substitution at the methylene carbon, a value competitive with electron transfer in radical pairs seemed probable. We therefore synthesized the ester **6**.

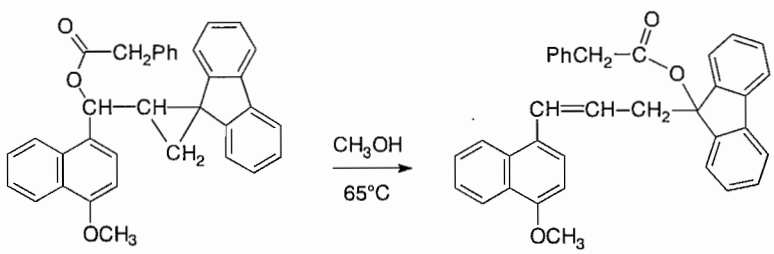
The change from naphthyl to 4-methoxy-1-naphthyl was necessary to insure that the excitation energy would still be localized in the naphthalene chromophore. This seemed essential in order to observe ester rather than fluorenylcyclopropane photochemistry. Irradiation through Pyrex glass would be quite selective for naphthalene excitation. This expectation was confirmed by fluorescence results in methanol for **6**, which gave a 0,0 value for the singlet excited state at 87.7 kcal/mol, very similar to the reported value of 89 kcal/mol (31) for 4-methoxynaphthalene. Fluorene has a significantly higher

18



19

singlet excited state energy of 95 kcal/mol (ref. 31, p. 27). Somewhat surprisingly, the quantum yield of fluorescence for **6** (0.12) was considerably lower than that observed (0.27) for the analogue, **19**, without the cyclopropylfluorene clock. This, of course, implies a higher excited state reactivity.



Preliminary irradiations in methanol were not encouraging since HPLC analysis indicated many minor products but no major one. However, the observation was made that **6** slowly underwent ground state conversion at room temperature to a new compound. With the idea that the identity of this compound would be useful in understanding the reactivity of the ion pair, the solvolysis of **6** was examined.

Refluxing **6** in methanol resulted in quantitative conversion to **20**, eq. [11]; the rate constant as determined by HPLC analysis of peak heights is 1.3×10^{-4} s^{-1} ($t_{1/2}$ = 1.4 h). The structure of **20** was established by spectral analysis. The lack of a stereogenic center in **20** removes the diastereotopic character of the benzylic CH_2, which now appears as a singlet in the ^1H NMR. Moreover, the fluorenyl moiety is now symmetric and has only six sp^2 carbon signals (2 singlets, 4 doublets) in the ^{13}C NMR in contrast to the 12 signals for **6**. The ^1H NMR spectrum of the allyl group could be simulated as an A_2XY pattern with J_{XY} = 15.9 Hz, the latter value indicating a *trans* geometry through the double bond.

This conversion was unexpected since all previous solvolysis studies of these esters in methanol resulted in the formation of methyl ethers. The contrast suggested that perhaps the mechanism was concerted via a Cope-like transition state, **21**. This possibility was dismissed after no rearrangement of **6**

21

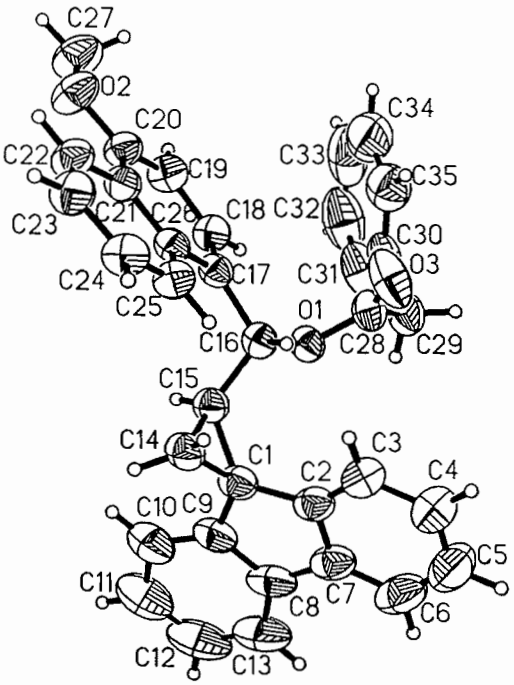
was observed after 24 h in either refluxing hexane or acetonitrile. The conclusion is that **6** rearranges to **20** by a very tight ion pair that does not allow trapping by methanol.



To understand the reactivity of the expected radical pair, **6** was subsequently photolyzed in benzene. In contrast to the results for methanol photolysis, only one major product, **22**, was observed (75% yield after 68% conversion of **6**), Scheme 5.[4] More extended photolysis resulted in disappearance of **22**. The same conversion occurred in acetonitrile but the maximum yield of **22** was lower. Careful silica gel chromatography allowed separation of **6** from **22**. Although **22** could be recrystallized from methanol, the solid samples obtained were inadequate for crystal structure determination. Therefore, proof of the structure of **22** relied entirely on spectroscopic analysis.

The fact that **22** was an ester, isomeric with **6**, was confirmed by IR (carbonyl band at 1720 cm^{-1}) and MS ($M^{\cdot+}$ at *m/z* 496). The assymetry in **22** was revealed by the benzylic methylene as a doublet of doublets (J = 15.5 Hz) in the ^1H NMR and the observation of 12 fluorenyl sp^2 carbons (4 singlets and 8 doublets) in the ^{13}C NMR. Decoupling experiments in the ^1H NMR showed that the lowest field (δ 5.91) cyclobutane hydrogen at the ester carbon (C3) was coupled only to the other methine hydrogen at C2. That methine hydrogen and the cyclobutyl methylene hydrogens could be simulated as an ABX system (calculated coupling constants are given in the experimental section). A hydrogen/carbon NMR HETCOR clearly established that the AB hydrogens were on the same carbon at δ 33.8. Enhancements between one of these hydrogens and a hydrogen (δ 7.56) at C1 of the fluorenyl moiety were shown by NOE experiments; a similar enhancement was seen between the same fluorenyl hydrogen and the cyclobutane hydrogen at C3. There was no enhancement between the two cyclobutane methine hydrogens at C2 and C3. This evidence is all consistent with structure **22** as shown in Scheme 5, including the *trans* substitution on the cyclobutane ring.

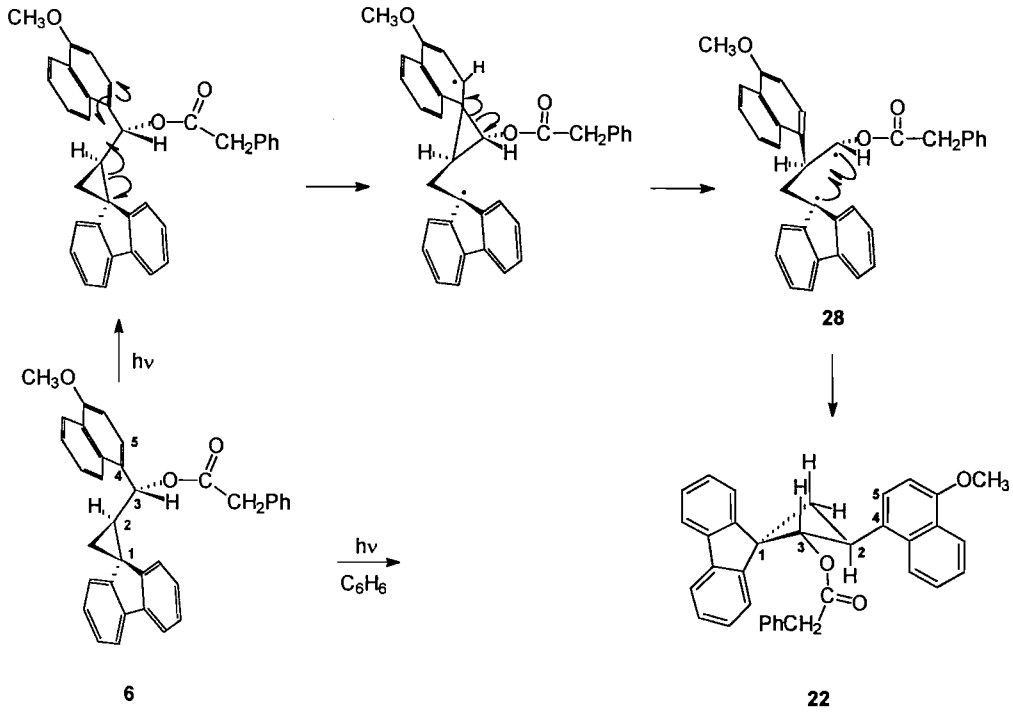
The suggested mechanism for conversion of **6** to **22** is also shown in Scheme 5. It represents the "aryl version of the cyclopropyl–π-methane photochemical rearrangement," a variant of the di-π-methane rearrangement. This variant was first suggested by Zimmerman and Carpenter (32) in their report on the photochemistry of **23**, Scheme 6.[5] The hoped-for rearrangement product, **26**, was formed only in trace quantities. The alkenes, **24** and **25**, were shown to be photoproducts of **26** (prepared by independent synthesis) but, in the irradiation of **23**, these alkenes were primary, not secondary, photoproducts. The conclusion was that the 1,4-biradical, **27**, preferentially fragmented to the alkenes rather than cyclizing to form **26**.

The reason for the differences in the photochemistry between the ester **6** and the cyclopropane **23** can be ascribed mainly to stereoelectronic effects. Examination of the X-ray structural data for **6**, Fig. 2, gives a calculated dihedral angle for the vicinal hydrogens of 166°, i.e., nearly *anti*. The large vicinal coupling constant of 10.1 Hz for the same two hydrogens strongly suggests that the solution conformation has a similarly large dihedral angle. One consequence of this geometry is that C4 of the naphthalene ring[4] is ideally placed to induce cyclopropyl C1 to C2 bond cleavage. The distance in the solid between C4 and C2 is only 2.46 Å and the C2-C3-C4-C5 dihedral angle is 98°. Apparently, this leads to enhanced excited state reactivity as indicated by the decreased quantum yield of fluorescence for **6** relative to **19**. The other consequence is that ester reactivity is not favourable from this geometry. The potentially reactive C—O bond of the ester is nearly orthogonal to the naphthalene chromophore; the O-C3-C4-C5 dihedral angle is only 19°. In fact, this compound is the first arylmethyl ester we have studied that does not undergo excited state C—O bond cleavage.

Fig. 2. X-ray structure of **6**.

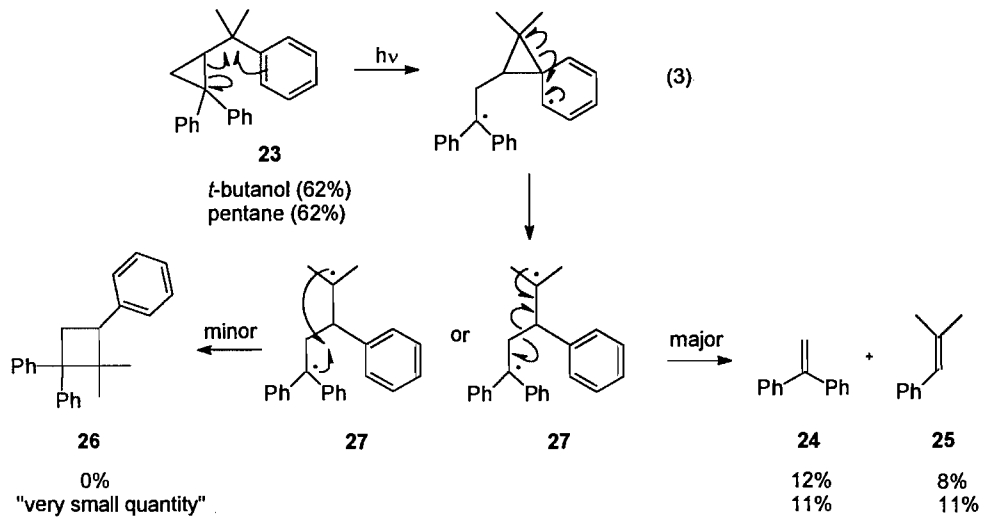
The difference in reactivity between the diradicals, **27** in Scheme 6 and **28** in Scheme 5, can also be ascribed to stereoelectronic effects. As predicted by Zimmerman and Carpenter (32) and observed for **28**, the biradical is formed in a *cisoid* geometry and collapses with inversion of configuration at C3 to the *trans* cyclobutane, **22**. In contrast, **27** is less likely to be formed in the required geometry so that conversion to **26** is disfavoured. Fragmentation to the alkenes **24** and **25** occurs. The possibility that **28** is still on the S_1 hypersurface, where collapse to cyclobutane is preferred (32), may also be a factor.

Conclusions



The principal conclusion from the results reported here is that we were unable to design a clock reaction capable of timing the reactivity of photochemically generated arylmethyl radicals. On a positive note, the difficulties in designing such a clock are now understood and will serve as a guide in future attempts. Particularly surprising was the reactivity of **6** where the potential clock never had a chance to operate because of an alternate, more efficient, photoreaction. If the reactivity of **6** is

[4] The numbering on the carbons of **6** and **22** in Scheme 5 does not follow nomenclature rules but rather shows the five carbons critical to the rearrangement mechanism.



[5] The percent values under **23** in Scheme 6 are for the yield of reisolated starting material.

controlled by the stereoelectronic effects suggested, then an interesting possibility is presented. These arguments are only likely to hold for the particular diastereomer studied, the *R,R*/*S,S* one. The other isomer, with reversed stereochemistry at the ester carbon, may have a geometry that favors ester photolysis and thus may allow the clock reaction to occur. Other possibilities are also suggested by the recent report of picosecond decarboxylations of acyloxy radicals (33).

Experimental

General experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (NMR) spectra were obtained in $CDCl_3$ on an AC 250 F NMR spectrometer in automation mode or on an AMX 400 NMR spectrometer. Some ^{1}H and ^{13}C NMR spectra were obtained on a Varian Gemini 200 as indicated. High-resolution mass measurements were done on a CEC 21-110B instrument. THF, previously dried with phosphorus pentoxide, was refluxed over sodium with benzophenone until the blue colour of the ketyl radical anion developed, and then distilled. Other general experimental details have been reported previously (34).

The following compounds were purchased from the Aldrich Chemical Company: 1-acetonaphthone, acrolein, benzalde-

hyde, *N*-bromosuccinimide, *N,N*-carbonyldimidazole, *m*-chloroperbenzoic acid, dibromoethane, fluorenone hydrazone, magnesium metal, mercuric oxide (yellow), 1-methoxynaphthalene, methyl iodide, methyllithium, 1-naphthaldehyde, 1-naphthylacetic acid, phenylacetic acid, phenylacetyl chloride, sodium borohydride, sodium hydride.

Synthesis of alcohols 1*a*–6*a*

2-Bromo-1-(1-naphthyl)ethanol, ***1****a*

Excess sodium borohydride (3.13 g, 8.24×10^{-2} mol) was slowly added to a solution of 1-acetonaphthone (40.2 g, 2.36×10^{-1} mol) in ethanol (200 mL) with stirring. During the addition of sodium borohydride, the reaction mixture was occasionally cooled to maintain a room-temperature solution. The reaction solution was stirred for 3 h and then water (100 mL) was added. The aqueous layer was extracted twice with dichloromethane (2×40 mL). The organic layers were combined and dried with anhydrous magnesium sulfate and the solvent was removed under reduced pressure to give the impure alcohol. Recrystallization from light petroleum ether gave fluffy, colourless crystals of 1-(1-naphthyl)ethanol: yield 15.4 g, 38%; mp 63.0–63.5°C (lit. (35) mp 66°C). The procedure for the dehydration of the alcohol of Klemm et al. (36) was used for the synthesis of 1-vinylnaphthalene: yield 8.9 g, 71%. The ^{1}H NMR spectrum was the same as previously reported (37).

The generalized procedure for formation of bromohydrins developed by Dalton et al. was used to synthesize 2-bromo-1-(1-naphthyl)ethanol (38). To a stirred solution of 1-vinylnaphthalene (8.9 g, 5.8×10^{-2} mol), DMSO (1 mL), and water (2.1 mL, 0.12 mol) at ~10°C was added *N*-bromosuccinimide (20.3 g, 0.114 mol) in one portion. The reaction mixture was stirred for 15 min, and then water (25 mL) was added. The product was then extracted into ether (25 mL). The ether was then washed with saturated sodium chloride solution and water to remove any excess DMSO, dried over anhydrous magnesium sulfate, and the solvent was removed to obtain the crude product. The resulting bromohydrin was purified using column chromatography, with dichloromethane as eluant to give a yellow oil: yield 3.48 g, 39%; ^{1}H NMR ($CDCl_3$) δ: 7.90 (d, 1H, J = 8.1 Hz), 7.89 (d, 1H, J = 8.5 Hz), 7.83 (d, 1H, J = 8.2 Hz), 7.70 (d, 1H, J = 7.3 Hz), 7.51 (m, 3H), 5.70 (dd, 1H, J = 9.6 and 2.5 Hz, C-H), 3.74 (dd, 1H, J = 10.6 and 2.5 Hz, CH_2-Br), 3.73 (dd, 1H, J = 10.6 and 9.7 Hz, CH_2-Br), 2.8 (bs, 1H, OH); ^{13}C ($CDCl_3$) δ: 133.9, 133.4, 130.7, 129.9, 126.7, 126.1, 125.3, 124.6, 122.6, 46.1, 33.6; GC–MS: 252 (18), 250 (17, M^+), 170 (11), 158 (12), 157 (100), 154 (15), 153 (38), 152 (24), 142 (10), 141 (47), 139 (10), 129 (88), 128 (51), 127 (33), 126 (12), 115 (24), 77 (11), 76 (12), 75 (11), 63 (12).

2-Methylsulfinyl-1-(1-naphthyl)ethanol, ***2****a*

The procedure used was that of Corey and Chaykovsky (39). Sodium hydride (56–58% in mineral oil) (1.24 g, 2.90×10^{-2} mol) was washed twice with hexane. Under nitrogen, DMSO (15 mL) was added, and the reaction mixture was heated to 65–70°C until no more hydrogen was evolved (45 min). To the sodium salt was added 1-naphthaldehyde (1.70 mL, 1.25×10^{-2} mol) over 1 min, while cooling the reaction in a water bath at 15°C. The solution was stirred for 1 h at room temperature. Water (50 mL) was added to destroy any excess NaH. The aqueous layer was extracted with chloroform (2×50 mL). The organic layers were combined and washed with water and brine, dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure to give a mixture of diastereomers in a ratio of 1.3:1 based on ^{1}H NMR integration of the CH_3SO signals at δ: 2.60 (minor) and 2.55 (major). These could be separated by column chromatography on silica gel using chloroform as eluant. Diastereomer 1 (yield 0.22 g, 8%): ^{1}H NMR ($CDCl_3$) δ: 8.1–8.0 (m, 1H), 7.9–7.7 (m, 3H), 7.5–7.2 (m, 3H), 6.15 (dd, 1H, J = 8.6 and 3.7 Hz, C-H), 4.8 (bs, 1H, OH), 3.15–3.00 (m, 2H, CH_2-S(O)), 2.55 (s, 3H, CH_3-S(O)); MS: 234 (2, M^+), 200 (22), 185 (14), 184 (12), 170 (71), 169 (21), 158 (51), 157 (19), 153 (57), 152 (22), 141 (58), 129 (100), 128 (55), 127 (40), 115 (21). Diastereomer 2 (yield 0.26 g, 10%): mp 154–156°C; ^{1}H NMR ($CDCl_3$) δ: 8.1–8.0 (m, 1H), 7.9–7.7 (m, 3H), 7.5–7.2 (m, 3H), 6.18 (dd, 1H, J = 7.9 and 4.3 Hz, C-H), 4.6 (bs, 1H, OH), 3.15–3.00 (m, 2H, CH_2-S(O)), 2.60 (s, 3H, CH_3-S(O)); ^{13}C NMR ($CDCl_3$) δ: 137.7 (C), 133.7 (C), 129.5 (C), 129.0 (CH), 128.5 (CH), 126.6 (CH), 125.8 (CH), 125.6 (CH), 123.3 (CH), 122.5 (CH), 64.9 (CH), 61.8 (CH_2), 38.4 (CH_3).

2-(4-Methylphenylsulfinyl)-1-(1-naphthyl)ethanol, ***3****a*

The oxidation of methyl 4-methylphenyl sulfide to the sulfoxide used the procedure of Drabowicz and Mikolajczyk (40): yield 11.1 g, 99%; the ^{1}H NMR was the same as that described previously (41). To a stirred solution of the sulfoxide (1.64 g, 1.06×10^{-2} mol) in anhydrous THF (50 mL) under nitrogen at 0°C was slowly added methyllithium (1.4 M) (10 mL, 1.4×10^{-2} mol). The reaction mixture was stirred for 30 min, and then naphthaldehyde (2.22 g, 1.42×10^{-2} mol) was slowly added. The solution was stirred for a further 60 min, and then saturated ammonium chloride solution was added. The two layers were separated, and the aqueous layer was extracted with dichloromethane (3×50 mL), dried over anhydrous magnesium sulfate, and rotoevaporated to give the β-hydroxy sulfoxide as a mixture of diastereomers in a ratio of 1:1 (yield 0.9 g, 29%). These could be separated by column chromatography on silica gel using 40:60 ethyl acetate:hexane as eluant: Diastereomer 1: ^{1}H NMR ($CDCl_3$) δ: 7.9–7.2 (m, 11H, aromatic), 6.10 (d, 1H, J = 9.6 Hz), 4.4 (bs, 1H, OH), 3.25 (dd, 1H, J = 13.4 and 9.6 Hz, CH_2-S(O)), 3.15 (dd, 1H, J = 13.4 and 2.3 Hz, CH_2-S(O)), 2.42 (s, 3H, Ph-CH_3); ^{13}C NMR ($CDCl_3$) δ: 142.2 (C), 140.3 (C), 137.4 (C), 133.8 (C), 130.2 (CH), 129.5 (C), 129.2 (CH), 128.5 (CH), 126.5 (CH), 125.6 (CH), 124.2 (CH), 123.5 (CH), 122.3 (CH), 67.8, 63.4, 21.5 (CH_3). Diastereomer 2: ^{1}H NMR ($CDCl_3$) δ: 7.9–7.2 (m, 11H, aromatic), 6.10 (d, 1H, J = 9.0 Hz), 5.0 (bs, 1H, OH), 3.30 (dd, 1H, J = 14 and 9 Hz, CH_2-S(O)), 3.0 (d, 1H, J = 14 Hz, CH_2-S(O)), 2.44 (s, 3H, Ph-CH_3); ^{13}C NMR ($CDCl_3$) δ: 141.8 (C), 139.2 (C), 137.6 (C), 133.6 (C), 130.1 (CH), 129.4 (C), 129.0 (CH), 128.2 (CH), 126.3 (CH), 125.7 (CH), 125.5 (CH), 124.2 (CH), 123.4 (CH), 122.2 (CH), 65.1, 63.3, 21.4 (CH_3).

1-Naphthyl-2-(phenylcyclopropyl)methanol, ***4****a*

To a solution of potassium hydroxide (16.6 g, 0.297 mol) in water (110 mL) was added ethanol (100 mL). The resulting solution was cooled and 1-acetonaphthone (53.6 mL, 0.357 mol) was added with stirring. While keeping the solution at room temperature, benzaldehyde (38 mL, 0.374 mol) was added. The reaction mixture was stirred at room temperature for 1 h, and then left for 3 h at 0°C. The oil that resulted was

For personal use only.

extracted from the aqueous solution with dichloromethane. The organic layer was washed with 10% HCl and water, then dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure, and the α,β-unsaturated ketone was fractionally distilled: yield 80.1 g, 87%. The ^{1}H NMR was the same as that previously reported (42).

The α,β-unsaturated ketone was converted to the cyclopropane according to the procedure of Prestwich et al. (43). To a stirred solution of sodium hydride (56% in mineral oil) (3.25 g, 76 mmol) and trimethylsulfoxonium iodide (17.6 g, 80 mmol) in DMSO (75 mL) under nitrogen gas at 0°C was added 1-naphthyl-3-phenylpropenone (15.4 g, 60 mmol) in DMSO (75 mL). The reaction was stirred under nitrogen for a further 16 h at room temperature. The resulting reaction mixture was poured into water (100 mL), and extracted with ether (3 × 100 mL). The organic layers were combined, and washed with brine and water. The impure cyclopropyl ketone was isolated by drying the organic layer over anhydrous magnesium sulfate and removing the solvent under reduced pressure. The ketone was purified by recrystallization from 100% ethanol: yield 7.0 g, 43%. The ^{1}H NMR was identical with that described previously.

The cyclopropyl ketone was reduced according to the procedure of Dickinson et al. (44). To a solution of cyclopropyl ketone (9.57 g, 35 mmol) in methanol was added sodium borohydride (2.89 g, 70 mmol) in small portions. After stirring the solution for 1 h, the solvent was removed under reduced pressure. Ethyl acetate (25 mL) was added, and the organic layer was washed with water (2 × 25 mL). The solvent was dried over anhydrous magnesium sulfate, and rotoevaporated to give the crude alcohol as a pale yellow oil: yield 10.8 g, quantitative; ^{1}H NMR ($CDCl_3$) δ: 8.1–7.0 (m, 12H), 5.06 (d, 1H, J = 7.0 Hz) (the other minor diastereomer had a doublet at δ 4.96), 2.36 (bs, 1H, OH), 2.0–1.9 (m, 1H), 1.8–1.65 (m, 1H), 1.15–0.86 (m, 2H); ^{13}C NMR ($CDCl_3$) for the major diastereomer δ: 142.4 (C), 138.4 (C), 133.9 (C), 131.2 (C), 128.8 (CH), 128.4 (CH), 126.1 (CH), 125.9 (CH), 125.6 (CH), 125.4 (CH), 123.7 (CH), 73.6 (CH-OH), 29.4 (CH), 22.0 (CH_2), 14.0 (CH).

1-Naphthyl-3-(2-phenyloxiranyl)methanol, ***5***a

The procedure for the synthesis of the alcohol and the epoxy alcohol was that by Dickinson et al. (44). A solution of *m*-chloroperbenzoic acid (57–86%) (7.44 g, 25 mmol) in dichloromethane (40 mL) was slowly added to a stirred solution of the enol (4.53 g, 17 mmol) in dichloromethane (30 mL). After stirring for 3 h, the solution was washed with aqueous sodium sulphite (3 × 20 mL), saturated sodium bicarbonate (3 × 20 mL), and saturated sodium chloride solution (20 mL). The organic layer was dried over anhydrous magnesium sulfate and the solvent was removed under reduced pressure. The impure epoxy alcohol was chromatographed using 10:90 ethyl acetate:hexane. The epoxy alcohol, as a mixture of diastereomers, was isolated as a pale yellow oil: yield 2.84 g, 59%; ^{1}H NMR ($CDCl_3$) δ: 8.1–7.1 (m, 12H), 5.7 and 5.4 (two d's, 1H from each diastereomer), 4.1-4.0 (m, 1H), 3.5–3.4 (m, 1H), 3.1 (bs, 1H).

2-(Spiro[cyclopropane-1,9′-fluorene])(4-methoxy-1-naphthyl)methanol, ***6***a

The procedure of Schöberg et al. (45) was used for the synthesis of 9-diazofluorene: yield 18.5 g, 74%; mp 94–97°C (lit. (45) mp 94–97°C).

The spirocyclopropylfluorenyl aldehyde was synthesized, with minor alterations, according to the procedure of Martin-Esker et al. (18). To a stirred solution of acrolein (350 mL) at 0°C was added 9-diazofluorene (35.0 g, 0.208 mol) in one portion. After 15 min at 0°C, the solution was allowed to warm to room temperature. The excess acrolein was removed under reduced pressure. Some of the acrolein polymerized, and the resulting polymer was rinsed with dichloromethane to remove the aldehyde. The intermediate pyrazoline was then refluxed overnight in benzene. After removal of the benzene at reduced pressure, the aldehyde was chromatographed using 5:95 ethyl acetate:hexane. The aldehyde was a pale yellow oil: yield 19.9 g, 49%; ^{1}H NMR ($CDCl_3$)[6] (Varian) δ: 9.69 (d, 1H, J = 4.2 Hz), 7.86–7.80 (m, 2H), 7.45–7.10 (m, 5H), 7.09–7.06 (m, 1H), 2.95–2.84 (dt, 1H, J = 8.2 and 4.2 Hz), 2.68–2.60 (dd, 1H, J = 7.4 and 5.4 Hz), 2.31–2.24 (dd, 1H, J = 8.2 and 5.4 Hz); ^{13}C NMR ($CDCl_3$) (Varian) δ: 197.8 (CH═O), 146.2 (C), 142.4 (C), 141.5 (C), 140.4 (C), 127.9 (CH), 127.9 (CH), 127.5 (CH), 123.2 (CH), 120.8 (CH), 120.5 (CH), 119.3 (CH), 40.7 (CH), 40.0 (C), 20.9 (CH_2). The resulting aldehyde was sufficiently pure to use in the Grignard reaction.

The alcohol was synthesized using the procedure of Dickinson et al. (44). To a suspension of magnesium metal (0.63 g, 26 mmol) in THF was added dibromoethane (0.15 g, 0.8 mmol) and a small amount of 1-bromo-4-methoxynaphthalene (46). Once the reaction started, the remainder of the 1-bromo-4-methoxynaphthalene was added dropwise (total 4.08 g, 16 mmol). The solution was refluxed for 1 h and then stirred at room temperature for 1 h. To the stirred solution was then added the aldehyde (0.868 g, 3.9 mmol) at 0°C. This solution was stirred at 0°C for 1 h, and then overnight at room temperature. Saturated ammonium chloride solution was added to quench the reaction mixture. The aqueous solution was extracted with diethyl ether, and the organic layer was washed with water. After drying the ether layer with anhydrous magnesium sulfate and filtering, the solvent was removed under reduced pressure. This crude alcohol was chromatographed with 5:95 ethyl acetate:hexane to give the alcohol as an oil and as a mixture of diastereomers (9:1 ratio): yield 0.923 g, 63%. Major diastereomer: ^{1}H NMR ($CDCl_3$)[6] δ: 8.39–8.33 (m, 2H), 7.96–7.86 (m, 2H), 7.71–7.25 (m, 8H), 7.03 (d, 1H, J = 7.6 Hz), 6.86 (d, 1H, J = 7.9 Hz), 5.65 (d, 1H, J = 10.1 Hz), 4.04 (s, 3H), 2.73–2.62 (m, 1H, J = 10.1, 8.5 and 8.3 Hz), 2.04–1.93 (m, 2H), 1.70 (bs, 1H); ^{13}C NMR ($CDCl_3$) δ: 155.5 (C), 148.1 (C), 144.0 (C), 141.4 (C), 139.1 (C), 131.9 (C), 130.3 (C), 127.2 (CH), 127.0 (CH), 126.8 (CH), 126.7 (CH), 126.3 (CH), 126.1 (C), 125.1 (CH), 124.5 (CH), 123.8 (CH), 122.8 (CH), 121.1 (CH), 120.7 (CH), 120.0 (CH), 118.6 (CH), 103.2 (CH), 71.5 (CH-OH), 55.6 (OCH_3), 39.4 (CH), 34.8 (C), 23.0 (CH_2). Minor diastereomer: ^{1}H NMR ($CDCl_3$)[6] δ: 8.23–8.16 (m, 1H), 8.09–8.05 (m, 1H), 7.81–7.77 (m, 2H), 7.46–7.18 (m, 7H), 7.09–7.02 (m, 2H), 6.47 (d, 1H, J = 8.0 Hz), 5.49 (d, 1H, J = 7 Hz), 3.85 (s, 3H), 2.62–2.52 (m, 1H, J = 9.5, 7.2 and 7.0 Hz), 2.30–2.23 (m, 1H, J = 7.2 and 5.5), 2.20–2.13 (m, 2H, J = 9.5

and 5.5 Hz), 2.12 (bs, 1H, OH); ^{13}C NMR ($CDCl_3$) δ: 155.3 (C), 148.0 (C), 144.3 (C), 141.0 (C), 139.4 (C), 131.6 (C), 131.1 (C), 127.0 (CH), 126.6 (CH), 126.5 (CH), 126.2 (CH), 126.1 (CH), 126.0 (C), 125.0 (CH), 124.0 (CH), 123.8 (CH), 122.5 (CH), 121.8 (CH), 120.1 (CH), 119.7 (CH), 118.6 (CH), 102.8 (CH), 70.8 (CH-OH), 55.4 (OCH_3), 36.7 (CH), 35.4 (C), 21.8(CH_2).

Synthesis of esters 1–6

Method A for **1**, **5**, and **6**: by reaction of the alcohol with phenylacetyl chloride in benzene with pyridine (5).

Method B for **2**, **3**, and **4**: by reaction of phenylacetic acid with *N,N*-carbonyldiimidazole followed by the alcohol according to the procedure developed by Staab and Rohr (47) and Carpenter and Moore (48). Example of procedure for **2**: To a stirred solution of *N,N*-carbonyldiimidazole (0.69 g, 4.3×10^{-3} mol) in anhydrous THF (25 mL) was added phenylacetic acid (0.69 g, 5.07×10^{-3} mol) in anhydrous THF (25 mL). After stirring the solution for 1 h at room temperature, 2-methylsulfinyl-1-(1-naphthyl)ethanol, ***2a*** (0.51 g, 2.18×10^{-3} mol), in anhydrous THF (15 mL) was added in one portion, and a small piece of sodium metal was added. The reaction was refluxed until completion, while the extent of the reaction was monitored by HPLC. Upon completion of the reaction, the solvent was removed under reduced pressure. Water was added (50 mL) and the product was extracted into ether (3×25 mL). The organic layers were combined, washed with 1 M Na_2CO_3, water, and then dried over anhydrous magnesium sulfate. The solvent was rotoevaporated to give the crude ester, which was purified by column chromatography.

2-Bromo-1-(1-naphthyl)ethyl phenylacetate, ***1***: yield 93%; IR (neat): 1750 cm^{-1}, ^{1}H NMR ($CHCl_3$) δ: 8.02 (d, 1H, J = 8.6 Hz), 7.87 (d, 1H, J = 8.4 Hz), 7.78–7.82 (m, 1H), 7.45–7.67 (m, 2H), 7.25–7.40 (m, 7H), 6.70 (dd, 1H, J = 7.2 and 5.2 Hz, CH-O), 3.76 (dd, 2H, $PhCH_2$), 3.7–3.5 (m, 2H, CH_2-Br); ^{13}C NMR ($CHCl_3$) δ: 170.2 (C═O), 133.6 (C), 133.5 (C), 133.2 (C), 129.9 (C), 129.3 (CH), 129.2 (CH), 128.9 (CH), 128.4 (CH), 127.1 (CH), 126.7 (CH), 125.8 (CH), 125.1 (CH), 124.1 (CH), 122.4 (CH), 72.6 (CH-O), 41.2 (CH_2), 33.9 (CH_2); GC–MS: 370 (15), 368 (15, M^+), 235 (16), 233 (16), 171 (15), 170 (61), 157 (36), 155 (19), 154 (85), 153 (100), 152 (23), 127 (12), 91 (98), 65 (12); HRMS mass calcd. for $C_{20}H_{17}O_2Br$: 368.0412; found: 368.0420.

2-Methylsulfinyl-1-(1-naphthyl)ethyl phenylacetate, ***2***: yield 32%, as a mixture of diastereomers; ^{1}H NMR ($CDCl_3$) δ: 8.15–8.05 (m, 1H), 7.9–7.7 (m, 2H), 7.6–7.4 (m, 2H), 7.4–7.2 (m, 5H), 7.00–6.95 (m, 1H, CH-O), 3.76 (dd, 2H, Ph-CH_2), 3.4–3.2 (m, 2H, CH_2-S(O)), 2.54 (s, 3H, CH_3-S(O)); ^{13}C NMR ($CDCl_3$) (major diastereomer) δ: 169.8 (CO), 134.1 (C), 133.8 (C), 133.5 (C), 129.5 (CH), 129.4 (CH), 129.2 (CH), 129.0 (C), 128.7 (CH), 127.4 (CH), 127.3 (CH), 127.0 (CH), 126.1 (CH), 125.3 (CH), 123.2 (CH), 122.7 (CH), 67.7 (CH), 61.1 (CH_2), 41.5 (CH_2), 39.4 (CH_3); MS 352 (3, M^+), 170 (20), 154 (17), 153 (39), 92 (100). Characterization of photoproducts

Ethers **1**b–**5**b

2-Bromo-1-methoxy-1-(1-naphthyl)ethane, **1**b
A solution of bromine (0.95 mL, 1.85×10^{-2} mol) in methanol (10 mL) was slowly added to a solution of 1-vinylnaphthalene (prepared as described above) (2.85 g, 1.85×10^{-2} mol) in methanol (10 mL). The reaction mixture was poured into 5% sodium bisulfite (25 mL), and then was extracted into dichloromethane (2 × 25 mL). The organic layers were combined, washed with water (2 × 25 mL) and with saturated $NaHCO_3$ solution (2 × 25 mL), dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure. The product was purified using column chromatography with 90:10 hexane:dichloromethane as eluant. The resulting bromoether was isolated as a pale yellow oil: yield 1.15 g (23%); ^{1}H NMR ($CDCl_3$) δ: 8.03–7.14 (m, 7H), 4.97 (t, 1H, J = 7 Hz), 3.44 (d, 2H, J = 7 Hz), 3.18 (s, 3H); GC–MS: 266 (7), 264 (6), 172 (13), 171 (100), 153 (14), 152 (11), 141 (11), 128 (14); HRMS calcd. for $C_{13}H_{13}OBr$: 264.0150; found: 264.0147.

General synthesis of ethers **2**b–**5**b
To a stirred solution of the alcohol (15 mmol) in dimethyl sulfoxide (15 mL) was added sodium hydride (57% by weight in mineral oil) (25 mmol) under nitrogen gas. After stirring for 1 h, methyl iodide (50 mmol) in DMSO (10 mL) was added. After stirring for an additional hour, the reaction mixture was poured into water (10 mL), and the product was extracted with dichloromethane (15 mL). The organic layer was then washed with water (10 mL) and brine solution (10 mL) several times to remove any DMSO. The solvent was dried over anhydrous magnesium sulfate and then removed under reduced pressure. The resulting ether was purified using column chromatography with ethyl acetate:hexane as eluant. The spectra of these compounds are below.

Methyl 2-methoxy-2-(1-naphthyl)ethyl sulfoxide, **2**b: (major diastereomer) IR (neat): 1100 (C-O), 1040 (C-O), 782 (SO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 8.20 (d, 1H, J = 8 Hz), 7.92–7.82 (m, 2H), 7.65–7.47 (m, 4H), 5.52 (dd, 1H, J = 5.2 and 3.4 Hz), 3.40 (s, 3H, OCH_3), 3.2–3.1 (m, 2H), 2.62 (s, 3H, $CH_3(SO)$); ^{13}C NMR ($CDCl_3$) δ: 134.7 (C), 134.0 (C), 130.5 (C), 129.1 (CH), 128.8 (CH), 126.7 (CH), 125.9 (CH), 125.5 (CH), 123.8 (CH), 122.7 (CH), 74.6 (CH), 62.9 (CH_3), 57.4 (CH_2), 39.4 (CH_3); MS: 248 (6, M^+), 185 (14), 184 (66), 183 (13), 171 (29), 155 (10), 154 (20), 153 (100), 152 (16), 141 (27), 128 (11), 127 (11).

(2-Phenyl-1-cyclopropyl)(1-naphthyl)methyl methyl ether, **4**b: (as a mixture of diastereomers in a ratio of 3:1) ^{1}H NMR ($CDCl_3$) δ: 8.35–7.00 (12H); (major diastereomer) δ: 4.58 (d, 1H, J = 4.3 Hz), 3.30 (s, 1H), 1.97–1.92 (m, 1H), 1.80–1.74 (m, 1H),, 0.95–0.84 (m, 2H); (minor diastereomer) δ: 4.70 (d, 1H, J = 4.0 Hz), 1.10–1.00 (m, 1H); ^{13}C NMR ($CDCl_3$) δ: 142.5 (C), 136.3 (C), 134.0 (C), 131.5 (C), 128.9 (CH), 128.3 (CH), 126.0 (CH), 126.0 (CH), 125.6 (CH), 125.4 (CH), 125.0 (CH), 124.8 (CH), 124.1 (CH), 124.0 (CH); (major) δ: 84.2 (CH), 56.9 (OCH_3), 28.3 (CH), 22.8 (CH), 12.8 (CH_2); (minor) δ: 83.3 (CH), 56.7 (OCH_3), 28.1 (CH), 20.9 (CH), 14.4 (CH_2); MS: 288 (1, $M^{\cdot+}$), 185 (14), 184 (100), 171 (12), 141 (16), 134 (25), 128 (11); HRMS calcd. for $C_{21}H_{20}O$: 288.1514; found: 288.1513.

1-(1-Naphthylmethoxymethyl)-2-phenyloxirane, **5**b: (as a mixture of diasteremers) ^{1}H NMR ($CDCl_3$) (1st diastereomer) δ: 8.3–7.1 (m, 12H), 5.10 (d, 1H, J = 3.3 Hz), 4.12 (d, 1H, J = 1.9 Hz), 3.39 (s, 3H), 3.36 (dd, 1H, J = 3.3 and 2.1 Hz); (2nd diastereomer) δ: 8.3–7.1 (m, 12H), 4.89 (d, 1H, J = 5.5 Hz), 3.83 (d, 1H, J = 1.9 Hz), 3.42 (s, 3H), 3.5 (dd, 1H, J = 5.5 and 2.1 Hz); ^{13}C ($CDCl_3$) δ: 137.0 (C), 136.7 (C), 134.1 (C), 134.0 (C), 133.6 (2 C's), 131.4 (2 C's), 129.1 (CH), 129.0 (CH), 128.5 (CH), 128.2 (CH), 126.4 (CH), 125.8 (CH), 125.7 (CH), 125.6 (CH), 125.5 (CH), 125.5 (CH), 123.7 (CH), 123.5 (CH), 82.0 (CH), 80.1 (CH), 64.8 (OCH3), 64.3 (OCH3), 57.6 (CH), 57.2 (CH), 56.5 (CH), 56.4 (CH); MS: 290 (5, M^+), 199 (18), 186 (12), 184 (11), 172 (13), 171 (100), 141 (12), 128 (16).

1,1-Dimethoxy-2-(1-naphthyl)ethane, **1**c: The preparation of 2-(1-naphthyl)ethanol was by the general procedure of Brown and co-workers (49). To a stirred solution of 1-naphthylacetic acid (10.9 g, 6.36×10^{-2} mol) in anhydrous THF (25 mL) at 0°C was slowly added 1 M borane:THF solution (76 mL) under nitrogen. The solution was stirred for an hour at room temperature. A 1:1 water:THF solution (80 mL) was slowly added, and the resulting mixture was saturated with potassium carbonate. The product was extracted into ether (2 × 100 mL) and the organic layers were combined, dried over anhydrous magnesium sulfate, and concentrated to give the product as a colourless oil: yield 9.84 g, 90%; the ^{1}H NMR was the same as that previously reported (50).

The method of Ratcliffe and Rodehorst was used to synthesize 2-(1-naphthyl)ethanal (51).

Preparation of reagents: Chromium trioxide was stored overnight in a vacuum desiccator using phosphorus pentoxide as desiccant. Barium oxide was added to pyridine, and the pyridine was distilled and stored over 4 Å molecular sieves until needed. Dichloromethane was washed with concentrated sulfuric acid (100 mL), water (100 mL), and brine (100 mL) and then distilled and stored over 4 Å molecular sieves until needed.

To a stirred solution of pyridine (19.0 g, 0.24 mol) in dichloromethane (150 mL) was added chromium trioxide (12.5 g, 0.12 mol). The reaction vessel was kept at 0°C during the addition. The mixture was stirred for 15 min, and then 2-(1-naphthyl)ethanol (0.71 g, 4.13×10^{-3} mol) in dichloromethane (5 mL) was added to the reaction mixture in one portion. The reaction was stirred for a further 15 min. The dichloromethane was decanted off, and the residue was washed with ether (200 mL). The organic layers were combined, and then washed with 5% NaOH (3 × 100 mL), 5% HCl (100 mL), 5% $NaHCO_3$ (100 mL), and saturated NaCl solution (100 mL), dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure. The product was then diluted with dichloromethane (20 mL) and was washed with cold 5% HCl (4 × 75 mL) to remove the excess pyridine. The aldehyde was isolated as a pale yellow oil: yield 0.21 g, 30%; ^{1}H NMR ($CDCl_3$) δ: 9.74 (t, 1H, J = 2 Hz, C(O)H), 7.32–7.95 (m, 7H), 4.01 (d, 2H, J = 2 Hz).

Preparation of the ion exchange resin: Amberlite (IR-120

PLUS, Alfa) (50 g) was washed with 5% HCl until the solution was acidic, then washed with distilled water until the solution was neutral, and finally washed with Na distilled methanol to remove the water.

To a solution of 2-(1-naphthyl)ethanal (0.21 g, 1.23×10^{-3} mol) in methanol (200 mL) was added the Amberlite resin (1 g) and 3 Å molecular sieves. The reaction mixture was refluxed and the extent of the reaction was monitored by HPLC. After 1.5 h the ion exchange resin and the molecular sieves were filtered off and the solvent was removed under reduced pressure. The resulting acetal was purified using bulb-to-bulb distillation to give a yellow oil; ^{1}H NMR ($CDCl_3$) δ: 8.06 (d, 1H, J = 7 Hz), 7.82 (d, 1H, J = 7 Hz), 7.72 (t, 1H, J = 4.7 Hz), 7.55–7.35 (m, 4H), 4.71 (t, 1H, J = 5.5 Hz), 3.37 (d, 2H, J = 5.5 Hz), 3.32 (s, 6H); ^{13}C NMR ($CDCl_3$) δ: 133.8 (C), 133.2 (C), 132.2 (C), 128.8 (CH), 127.7 (CH), 127.2 (CH), 125.9 (CH), 125.5 (CH), 125.5 (CH), 125.43 (CH), 123.8 (CH), 104.8 (CH), 53.5 (CH_3), 36.9 (CH_2).

4-Methoxy-1-(1-naphthyl)-4-phenyl-1-butene, **4**d: ^{1}H NMR ($CDCl_3$) δ: 7.72–6.94 (m, 12H), 6.96 (d, 1H, J = 16 Hz), 6.07 (dt, 1H, J = 16 and 7.3 Hz), 4.20 (t, 1H, J = 6.5 Hz), 3.17 (s, 3H), 2.81–2.69 (m, 1H), 2.65–2.51 (m, 1H); ^{13}C NMR ($CDCl_3$) δ: 141.7 (C), 135.5 (C), 133.6 (C), 131.1 (C), 129.7 (CH), 129.6 (CH), 128.5 (CH), 128.4 (CH), 127.7 (CH), 127.5 (CH), 126.9 (CH), 125.8 (CH), 125.7 (CH), 124.1 (CH), 123.7 (CH), 84.0 (CH), 56.8 (OCH_3), 42.1 (CH_2); MS: 288 (3, $M^{\cdot+}$), 181 (12), 171 (13), 165 (23), 152 (12), 128 (13), 127 (12), 121 (100), 105 (11), 91 (35), 77 (15).

Methyl 2-(1-naphthyl)-3-phenylpropyl sulfoxide, **2**c: ^{1}H NMR ($CDCl_3$) δ: 8.14 (d, 1H, J = 8.3 Hz), 7.84 (m, 1H), 7.74 (m, 1H), 7.53–7.04 (m, 9H), 4.44 (m, 1H), 3.38–3.20 (m, 3H), 3.02 (m, 1H), 2.42 (s, 3H, CH_3(SO)); ^{13}C NMR ($CDCl_3$) δ: 138.4 (C), 137.6 (C), 134.0 (C), 131.1 (C), 129.3 (CH), 129.0 (CH), 128.2 (CH), 127.7 (CH), 126.4 (CH), 126.4 (CH), 125.7 (CH), 125.1 (CH), 122.6 (CH), 60.1 (CH_2), 40.4 (CH_2Ph), 38.9 (CH_3), 35.2 (CH); MS: 308 (13, $M^{\cdot+}$), 245 (23), 244 (81), 167 (14), 154 (56), 153 (100), 152 (33), 141 (12), 117 (15), 115 (11), 91 (88), 43 (16).

1-(1-Naphthyl)-1-(2-phenylcyclopropyl)-2-phenylethane, **4**c: (mixture of diastereomers) ^{1}H NMR ($CDCl_3$) δ: 8.13–6.83 (m, 17H), 3.41–2.90 (m, 3H), 1.54 (m, 1H), 1.07–1.00 (m, 1H), 0.94–0.86 (m, 1H), 0.75–0.65 (m, 1H); ^{13}C NMR ($CDCl_3$) δ: 143.2, 140.7, 140.4, 140.3, 140.2, 134.0, 131.9, 129.6, 129.4, 129.1, 128.2, 128.1, 128.0, 126.9, 126.8, 126.0, 125.7, 125.6, 125.4, 124.7, 124.5, 123.2, 46.6, 43.4, 43.2, 29.8, 28.8, 27.4, 25.0, 21.9, 17.1, 14.4; MS: 348 (0.2, $M^{\cdot+}$), 334 (25), 244 (17), 243 (75), 230 (11), 203 (11), 168 (32), 166 (27), 153 (10), 152 (16), 151 (33), 140 (12), 139 (43), 138 (12), 127 (32), 115 (20), 77 (100).

1-(1-(1-Naphthyl)-2-phenylethyl)-2-phenyloxirane, **5**c: IR (neat): 1598, 1495, 1455 (aromatic), 794 (C-O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 8.1–6.9 (m, 12H), 3.9–3.8 (m, 1H), 3.4–3.1 (m, 4H); ^{13}C NMR ($CDCl_3$) δ (major): 139.8 (C), 137.4 (C), 137.2 (C), 134.0 (C), 132.0 (C), 129.2 (CH), 129.0 (CH), 128.6 (CH), 128.2 (CH), 127.9 (CH), 127.5 (CH), 125.5 (CH), 125.5 (CH), 123.1 (CH), 65.6 (CH-Ph), 59.1 (*c*H-CH-Naph), 44.4 (Naph-CH), 39.6(CH_2); (minor): 139.0 (C), 137.1 (C), 137.0 (C), 133.9 (C), 131.7 (C), 129.3 (CH), 128.1 (CH), 128.0 (CH), 127.4 (CH), 126.4 (CH), 126.2 (CH), 126.4 (CH), 126.1 (CH), 125.6 (CH), 125.0 (CH), 124.8 (CH), 124.2 (CH), 123.0 (CH), 65.8 (CH-Ph), 58.3 (*c*H-CH-Naph), 44.4 (Naph-CH), 39.7 (CH_2). Accounting for all the aromatic methine carbons in the two diastereomers was not possible because some peaks were coincident. MS: 350 (9, $M^{\cdot+}$), 259 (34), 241 (12), 231 (11), 229 (10), 217 (13), 171 (24), 156 (13), 155 (23), 154 (14), 153 (100), 152 (40), 151 (10), 141 (13), 128 (22), 127 (26), 121 (60), 115 (13), 105 (11), 91 (51), 77 (23).

1-(Spiro[4-(4-methoxy-1-naphthyl)cyclobutane-2,9′-fluorene]) phenylacetate, **22**: mp 73–75°C; IR (film): 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 8.35–8.33 (m, 1H), 8.01 (d, 1H, J = 7.9 Hz), 7.89 (d, 1H, J = 7.4 Hz), 7.74 (d, 1H, J = 7.6 Hz), 7.68–7.66 (m, 1H), 7.6–7.1 (m, 10H), 7.18–7.16 (m, 2H), 6.88–6.84 (m, 2H), 5.91 (d, 1H, J = 8.2 Hz), 4.82 (m, 1H, J = 9.5, 8.5, and 8.2 Hz), 4.02 (s, 3H), 3.26 (dd, 2H, J = 15.5 Hz), 3.02 (m, 1H, J = 13 and 8.5 Hz), 2.74 (m, 1H, J = 13 and 9.5 Hz). The pattern for the cyclobutane hydrogens could be simulated as an ABX system giving the above coupling constants.[6] Decoupling experiments showed that the hydrogen at δ: 5.91 was only coupled to that at δ: 4.82. ^{13}C NMR ($CDCl_3$) δ: 169.8 (C═O), 154.8 (C), 149.0 (C), 145.6 (C), 141.4 (C), 139.6 (C), 133.6 (C), 132.5 (C), 129.3 (C), 129.2 (CH), 128.5 (CH), 127.8 (CH), 127.7 (CH), 127.1 (CH), 126.9 (CH), 126.7 (CH), 126.1 (C), 125.3 (CH), 124.7 (CH), 123.8 (CH), 122.9 (CH), 122.8 (CH), 120.1 (CH), 119.7 (CH), 103.3 (CH), 78.0 (CH-O), 55.6 (CH_3O), 55.0 (fluorenyl C9), 41.0 (CH_2Ph), 40.0 (CH), 33.9 (CH_2); MS ($M^{\cdot+}$): 496 (1.5) 360 (12), 318 (19), 284 (19), 257 (14), 256 (37), 202 (12), 186 (44), 185 (28), 180 (70), 178 (15), 171 (25), 152 (22), 131 (19), 129 (18), 128 (14), 119 (12), 91 (55), 83 (21), 76 (16), 73 (24), 69 (100), 57 (32); HRMS calcd. for $C_{27}H_{20}O$ ($M^{\cdot+}$ − $PhCH_2CO_2H$): 360.1514; found: 360.1528.

Ground state solvolysis of 2-(spiro[cyclopropane-1,9′-fluorene])(4-methoxy-1-naphthyl)methyl phenylacetate, 6: 9-fluorenyl-3-(1-[4-methoxy-naphthyl])-2-propene phenylacetate, 20

The ester, **6**, (180 mg) was refluxed in 100 mL of methanol. The progress of the reaction was monitored by HPLC. After 10 h, the methanol was removed by rotoevaporation and the residue taken up in CH_2Cl_2, which was then extracted with brine, dried ($MgSO_4$), and then rotoevaporated to give a quantitative yield of **20**; ^{1}H NMR ($CDCl_3$) δ: 8.20 (m, 1H), 7.60–7.18 (m, 18H), 6.69 (d, 1H, J = 16 Hz), 6.59 (d, 1H, J = 7.9 Hz), 5.75 (dt, 1H, J = 16 and 7.3 Hz), 3.89 (s, 3H), 3.04 (d, 2H, J = 7.3 Hz), 2.86 (s, 2H); ^{13}C NMR ($CDCl_3$) δ: 154.8 (CO), 145.1 (C), 140.8 (C), 131.9 (C), 131.1 (CH), 129.6 (CH), 129.0 (CH), 128.8 (CH), 128.3 (C), 127.7 (CH), 127.1 (C), 126.2 (CH), 126.2 (CH), 125.3 (C), 125.0 (CH), 124.5 (CH), 124.1 (CH), 123.9 (CH), 122.2 (CH), 120.0 (CH), 103.7 (CH), 88.2 (C), 55.5 (OCH_3), 51.7 (CH_2), 44.0 (CH_2); MS: 392 (35), 198 (18), 197 (84), 197 (100), 180 (39), 166 (11), 91 (24); HRMS calcd. for $C_{27}H_{20}O$ ($M^{\cdot+}$ − $PhCO_2H$): 360.1514; found: 360.1504.

Abstract: The results of studies of the kinetics of the reaction of oxygen with thin films of carbon are described with special emphasis on the role, in the mechanism of the reaction, of the stable complex formed between oxygen and the carbon surface. A key part of the proposed mechanism is the reaction between gaseous oxygen and the stable complex to form the product carbon dioxide. Measurements of the total pressure and the products formed as a function of time of the reaction have allowed estimates of the rate constants for the elementary reactions that make up the mechanism. This in turn has led to the application of computer modelling to the mechanism of the reaction and to the development of a more detailed mechanism involving two types of reactive sites on the carbon surface.

Key words: carbon, oxygen, kinetics, mechanism, computer modelling.

Résumé : On décrit les résultats d'études sur la cinétique de la réaction de l'oxygène avec des films minces de carbone, en insistant sur le rôle du complexe stable qui se forme entre l'oxygène et la surface du carbone dans le mécanisme de la réaction. La réaction entre l'oxygène gazeux et le complexe stable, conduisant à la formation du bioxyde de carbone, est une étape clé du mécanisme proposé. Des mesures de la pression totale et des produits formés en fonction du temps de la réaction ont permis d'évaluer les constantes de vitesse des réactions élémentaires impliquées dans le mécanisme. Celles-ci ont par la suite permis de faire un modelage par ordinateur du mécanisme de la réaction et de développer un mécanisme plus détaillé impliquant deux types de sites réactifs sur la surface du carbone.

Mots clés : carbone, oxygène, cinétique, mécanisme, modelage par ordinateur.

[Traduit par la rédaction]

Introduction

Carbon, as an element, plays an important role in the chemical world (for a summary of studies of the reactivity of carbon, see ref. 1). We are familiar with the two forms of carbon, graphite and diamond, and many teachers of chemistry are fond of pointing out the remarkable differences in the properties of these two forms as a result of what might be described as a minor difference in structure. The addition of a third form, fullerenes, has been an exciting development, which has generated intense interest over the past several years.

Graphite is, of course, the most common form of carbon. Carbon fibres and carbon composites provide a dense, strong material, valuable in the aerospace industry (2). As an adsorbent, carbon is indispensable in purification procedures and its high surface area makes a good catalyst support (3). As a reactant, carbon is decidedly inert. Reaction with hydrogen or water vapour, for example, requires temperatures in excess of about 900°C. Carbon will, however, be consumed by oxygen at lower temperatures and it is the kinetics of this reaction that I want to describe in this paper.

In a recent review of the kinetics of the reaction of carbon with oxygen, Walker, Taylor, and Ranish (4) state in the opening sentence: "The carbon–oxygen reaction is arguably the most important reaction known." Stoichiometrically the reaction is simple. Oxygen reacts with carbon to form carbon dioxide or carbon monoxide.

$$C + O_2 \rightarrow CO_2$$

$$C + \tfrac{1}{2} O_2 \rightarrow CO$$

The general features of the kinetics have been well documented (5). With moderate pressures of oxygen the rate becomes measurable at about 550°C and with low pressures rates may be measured up to about 900°C. The major product at low temperatures and high pressures of oxygen is carbon dioxide and the activation energy for its formation is in the range 160–200 kJ mol^{-1}. Carbon monoxide becomes important at higher temperatures and lower pressures of oxygen and the activation energy of its rate is larger, 250–300 kJ mol^{-1}. The order of the rate with respect to the pressure of oxygen varies between 1 and 0.5. But how does this reaction occur? By what series of elementary processes is solid carbon converted into carbon dioxide and carbon monoxide by reaction with gaseous oxygen?

In spite of decades of studies of the kinetics of this reaction,

Received June 14, 1996.

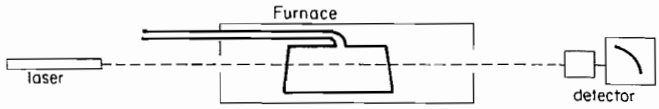
the elementary processes of adsorption, migration, rearrangement, dissociation, and desorption that make up the overall reaction have not been correlated into a general mechanism that can describe the rate over a range of temperature, of pressures of oxygen, and other conditions. One of the difficulties in formulating a general mechanism is the variation in the properties of carbon in its graphitic form, which depend heavily on the source and the method of preparation. Graphite from natural sources, for example, may contain heavy metals that act as catalysts. Also, a variety of techniques have been used for kinetic studies, for example, static or flow systems (6), shock tubes (7), molecular beams (8), and surface microscopy (9), each of which gives results under widely different conditions.



Of central importance in the oxidation reaction is the strongly bound complex formed on adsorption of oxygen on the surface of carbon (10). When oxygen is admitted to a carbon surface at about 300°C, oxygen is adsorbed, but reaction, to give carbon dioxide or carbon monoxide, does not occur. When unadsorbed oxygen is removed and the carbon is heated, no further oxygen is released, but beginning at about 700°C carbon monoxide and small amounts of carbon dioxide are evolved. This result has been interpreted to indicate that oxygen adsorbs dissociatively on a carbon surface, forming a strongly bound complex that is released only at high temperatures as carbon monoxide.

The properties of the complex have been studied by various techniques, including adsorption and desorption kinetics (11), spectroscopic measurements (12), and chemical analysis (13). Studies using electron microscopy have shown that the complex forms on edge carbon atoms of graphite crystals (14). The importance of the complex in the oxidation process was first recognized by Walker and co-workers through their extensive studies of the kinetics of the reaction (10). They proposed that the amount of carbon monoxide released could be correlated with a number of "active" carbon atoms on the surface and they converted this quantity into an Active Surface Area, ASA. The ASA for many samples of graphitic carbon was typically a few percent of the total surface area measured by the BET technique, that is, by using an adsorbent that does not chemically interact with the surface.

The role of the complex in the oxidation process has been difficult to define. It must first be realized that the reaction of oxygen with carbon cannot be described by a simple sequence of adsorption, formation of complex, and desorption to give products. First, reaction with oxygen begins at about 550°C, at least 100 degrees below temperatures at which the complex is released. Second, the complex is released as carbon monoxide and does not account for the formation of carbon dioxide. Third, the activation energy for formation of carbon dioxide is in the range of 160–200 kJ mol^{-1} and not the value of 280 kJ mol^{-1} required for desorption of the complex.

It should also be noted that the effect of the complex on the processes taking place on the surface is difficult to test experimentally. During a gasification reaction the carbon surface changes dramatically and such changes would have a profound influence on the properties and reactions of the complex. Some results have been interpreted to show that the complex blocks active sites and may actually inhibit the reaction (10). Other experiments have shown that the complex enters into the oxidation process and may be an intermediate in a series of surface processes (15). The importance of the complex in the kinetics was recognized but the identification of the elementary processes, the measurement of their rates, and the formulation of a general mechanism was not achieved.

Fig. 1. Schematic diagram of the reaction vessel showing the passage of the light beam from a He-Ne laser through the reaction vessel. The attenuation of the beam was measured by the photo diode detector and Keithley electrometer.

The purpose of our experiments was to explore in detail the kinetics of the reaction of carbon with oxygen with particular emphasis on the role of the complex in the mechanism. An important part of the study was a careful measurement of the time course of the reaction under a variety of conditions as a means of defining the mechanism in terms of concurrent and consecutive processes. A static system was used in which carbon was formed by pyrolysis of methane as a thin film on the surface of the reaction vessel. A technique had been developed in our laboratory for the quantitative measurement of the amount of carbon in the film and for the continuous monitoring of the removal of carbon during its reaction with oxygen (16). The results of these studies allowed further interpretation of the role of the complex in the reaction and this paper will describe these results and the general mechanism that was developed as an interpretation of the results.

Experimental

The reaction was studied in a static system. A detailed description has been given previously (16). Carbon was formed as a thin film on the surface of the quartz reaction vessel by pyrolysis of 40 Torr (1 Torr = 133.3 Pa) of methane at 1223 K. This produced a film of uniform thickness, usually between 10 and 20 nm, of high purity, and with surface area comparable to the geometric area of the reactor (17). The amount of carbon in the film was measured by the attenuation of a He-Ne laser beam passed axially through the vessel, as illustrated in Fig. 1. Calibration was made by oxidation of the carbon to carbon dioxide and carbon monoxide followed by analysis by gas chromatography. The absorbance was a linear function of the total amount of carbon in the film and an extinction coefficient of 2.2×10^6 cm^2mol^{-1} was obtained. The consumption of carbon by reaction with oxygen could thus be monitored continuously throughout the course of the reaction by the measurement of the light attenuation. The total pressure was also measured continuously and reactants and products were removed for analysis at the end of a reaction or at any stage during reaction. Following removal of reactants and products, the amount of complex adsorbed on the carbon surface at that point was measured by temperature-programmed desorption of the complex, followed by analysis of the products: carbon monoxide with minor amounts of carbon dioxide and traces of water. By such an analysis of the time course of the reaction in a static system the primary, secondary, and tertiary products may be distinguished and a better understanding of the mechanism achieved.

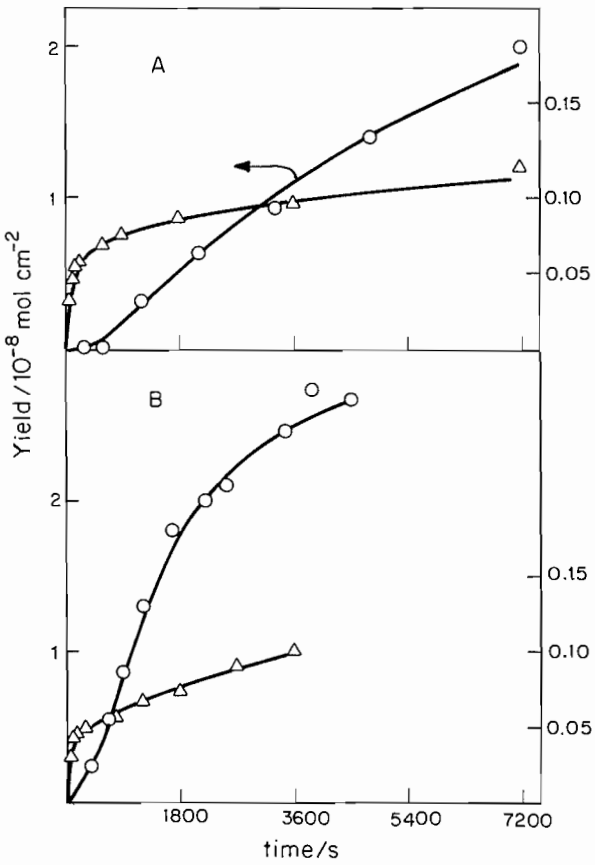
Results

The kinetics of the reaction were studied over a wide range of temperature, 750–1175 K, and of pressures of oxygen, 0.5–120 Torr. At temperatures below 898 K the formation of carbon monoxide was negligible and all the carbon was converted to carbon dioxide. Therefore we may write

$$-\frac{dC}{dt} = \frac{dCO_2}{dt}$$

$$P_T = P_{O_2} + P_{CO_2}$$



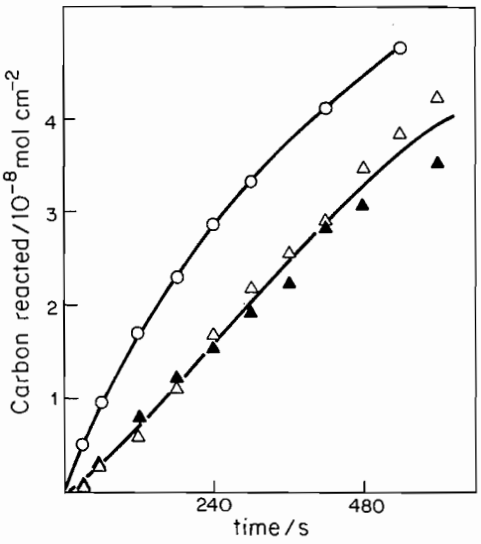
$$P_T - P^0_{O_2} = -\Delta P = O_2 \text{ adsorbed}$$

where P_T, P_{O_2}, and P_{CO_2} refer to the total pressure, the pressure of O_2, and the pressure of CO_2, respectively, at any time during the reaction. $P^0_{O_2}$ is the initial pressure of O_2. If no carbon monoxide is formed there will be no pressure increase. A pressure decrease will indicate adsorption of oxygen on the surface. We equated this decrease to the formation of the stable complex. In addition, the presence of the complex on the surface was confirmed by termination of the reaction at various stages in the conversion, removal of the reactants and products, followed by temperature-programmed desorption to recover the complex. These measurements of the complex correlated well with the values deduced from the pressure change. It should be pointed out that these measurements also show that adsorbed oxygen must be rapidly converted to the stable complex, since only the stable complex could remain on the surface following removal of reactants and products.

The results of the measurements of the loss of carbon and the total pressure are shown converted to formation of complex and of carbon dioxide in Fig. 2, where the left-hand scale refers to the yield of carbon dioxide and the right-hand scale, which is 10 times smaller, to the yield of complex. These yield–time curves obtained in the low-temperature region clearly show that formation of carbon dioxide involved an induction period whereas no induction period was observed for adsorption of oxygen on the carbon surface, as measured by the decrease in pressure, with subsequent formation of the stable complex. Furthermore, the maximum rate of formation of carbon dioxide correlates roughly with the maximum yield of complex. It is also evident that the induction period is shortened at higher temperatures. These results strongly suggest that the complex is an intermediate in the formation of carbon dioxide.

Several types of experiments were performed for the purpose of testing the role of the complex in the reaction. The experiments were designed to compare, in various ways, the rate of oxidation in the presence and absence of the complex. In one series a carbon film was allowed to react with oxygen in two stages, removing about 25% of the initial amount of carbon in each stage. In the first stage oxygen was admitted to the system and the rate was measured as usual. The reaction was stopped by evacuating the products and remaining reactant. A temperature-programmed desorption to 1223 K was then performed to remove the stable complex remaining on the surface. The temperature of the film was then reduced to the reaction temperature and the oxygen was readmitted for reaction in stage 2.

Fig. 2. Yield of carbon dioxide (left-hand scale) and formation of complex (right-hand scale) as a function of time in the low-temperature region. ○: CO_2; Δ: complex. *A*: 848 K; initial pressure of O_2: 1.0 Torr. *B*: 908 K; initial pressure of O_2: 0.8 Torr.



A second series of experiments with a new film, identical to the first, was performed, except that the complex was not removed after stage 1. Thus the difference between the two series of experiments is that, prior to reaction at stage 2, the complex was not present on the surface in the first series but was present in the second series. A typical result of these oxidations is shown in Fig. 3. This figure shows two important features of this set of experiments. First, the magnitude and the kinetic characteristics of the rate are practically the same for the oxidation in stage 1 with a new film and for the oxidation in stage 2 after removal of the complex. Thus the partial oxidation in stage 1 did not noticeably change the number of active sites on the surface. Second, the rate was signficantly increased when the complex was present on the surface before admission of oxygen. Furthermore, other types of experiments showed that the presence of the complex on the surface before the reaction shortened the induction period, an effect consistent with the interpretation of the complex as an intermediate in the reaction. The complex therefore played a significant role in the mechanism of the oxidation.

At temperatures higher than about 925 K the induction period was much shorter and carbon monoxide was an important product. In this region the decrease in pressure caused by the formation of complex was negligible compared to the

Fig. 3. Effect of the presence of the complex on the rate of removal of carbon. Initial pressure of O_2: 1.0 Torr. T = 998 K. Δ: Stage 1, new film; ▲: stage 2, complex removed after stage 1; ○: stage 2, complex not removed after stage 1.

increase caused by the production of carbon monoxide. Under these conditions we may write

$$-\frac{dC}{dt} = \frac{dCO_2}{dt} + \frac{dCO}{dt}$$

$$P_T = P_{O_2} + P_{CO_2} + P_{CO}$$

$$P_T - P^0_{O_2} = \Delta P = P_{CO}$$

Yield–time curves for the formation of products and loss of carbon obtained from these measurements at 1048 K are shown in Fig. 4.

The measured activation energy for the rate of formation of carbon monoxide was approximately 290 kJ mol^{-1}, a value similar to the energy required for desorption of the complex as measured by temperature-programmed desorption. It seems reasonable therefore that desorption of the complex is the source of carbon monoxide. An Arrhenius plot for the rate of formation of carbon monoxide is shown in Fig. 5.

In order that the activation energy for the rate of formation of carbon monoxide may be identified with the energy required for release of the complex, the rate of occupation of the active sites, or rate of formation of the complex, must be fast compared to the rate of desorption. In other words, complete coverage of the active sites must be maintained. As the temperature is increased and the rate of desorption increases, a point will be reached, observed first at low pressure, where complete coverage cannot be maintained. The rate of desorption will then no longer conform to the Arrhenius dependence observed at lower temperatures and will fall below a rate extrapolated from the low-temperature region. This effect is evident from the results shown in Fig. 5. This apparent decrease in activation energy at high temperatures is often observed in catalytic processes when the number of active sites on a surface can no longer be maintained. The effect is quite different from the decrease in rate observed in other experiments on the reaction of carbon with oxygen at temperatures above about 1200 K, which has been accounted for by diffusion effects (18).

As carbon monoxide accumulated in the products a secondary reaction with oxygen occurred and the ratio CO/CO_2 fell with increasing conversion. This secondary reaction was sometimes so rapid that we realized we were observing the explosive reaction of carbon monoxide and oxygen (19, 20). This reaction is catalyzed by traces of water vapour and in our system minute amounts of water vapour are formed as a gaseous product from oxidation of traces of hydrogen in the films of pyrolytic carbon.

Figure 6 shows a portion of the chart record of the pressure and the transmitted light intensity for an experiment where an explosion occurred. As the reaction proceeds, both the pressure and the transmitted light increase smoothly initially, indicating formation of carbon monoxide as well as carbon dioxide and consumption of carbon. After removal of a certain amount of carbon, the amount depending on the conditions of the experiment, a sudden drop in pressure occurs, reducing almost to the initial value, preceded by a momentary jump in pressure. This behaviour, which has been observed in comparable systems and discussed in detail by Bond, Gray, and Griffiths (21), indicates that an ignition has occurred. The momentary pressure pulse, also observed in previous studies, is a consequence of a temperature pulse caused by the exothermic reactions associated with the explosion. This figure also shows that the explosion was accompanied by a dramatic increase in the rate of gasification. The explosive reaction was studied in some detail and we were able to show that explosions occurred when the concentration of water vapour in the gas phase achieved the levels required to initiate the chain-branching reactions.

It was also shown that the presence of inert gas could prevent the explosion by stabilization of the intermediate, HO_2. The dissociative reaction of hydrogen atoms with oxygen is a critical step in the chain-branching reactions leading to explosion.

$$H + O_2 \rightarrow HO_2$$

$$HO_2 \rightarrow OH + O$$

$$HO_2 + M \rightarrow HO_2 + M$$

If HO_2 is stabilized branching does not occur. Effects of inert gases on the rate of oxidation of carbon (22), and some other catalytic processes (23), had previously been reported and explanations had, not very satisfactorily, invoked various types of surface processes, including effects on the reactivity of the active sites on carbon. On the other hand, the results of our experiments showed that at temperatures above about 900 K both water vapour and inert gases could induce radical reactions in the gas phase that had a profound effect on the rate of the overall reaction (24). Clearly, interpretation of the effects of water vapour and of inert gas on the kinetics of the carbon–oxygen reaction should not be confined to effects on the surface.

The mechanism

The picture of the oxidation process that emerges involves, as a first step, rapid adsorption of oxygen on the carbon surface

followed by formation of the stable complex. In the low-temperature region carbon dioxide is produced after accumulation of the complex on the surface. We suggested that this process occurs by reaction of the complex with gaseous oxygen in an Eley–Rideal type of mechanism (16). The following five reactions describe the main features of this picture, where C_F refers to an edge carbon atom (a free site), $C(O_2)$ refers to an adsorbed molecule of oxygen before formation of the complex, and $(CO)_C$ is the stable complex on the surface.

[1] $C_F + O_2 \rightarrow C(O_2)$

[2] $C_F + C(O_2) \rightarrow 2(CO)_C$

[3] $(CO)_C \rightarrow CO(g) + C_F$

[4] $C_F + (CO)_C + O_2 \rightarrow CO_2 + (CO)_C + C_F$

[5] $(CO)_C + C(O_2) \rightarrow CO_2 + (CO)_C + C_F$

Reactions [1] and [2] describe the formation of the complex, reaction [3] is the desorption of the complex to give carbon monoxide, and reactions [4] and [5] represent the reaction of

the complex with either gaseous or adsorbed oxygen to give carbon dioxide.

These latter two reactions are the most important feature of the mechanism and describe reactions, other than simple desorption, by which the complex could participate in the formation of products. The activation energy for the rate of formation of carbon dioxide was, from our measurements, 160 kJ mol^{-1}. Values in the range 160–200 kJ mol^{-1} have been reported. These values are much less than the energy required (about 280 kJ mol^{-1}) for desorption of the complex. The energy requirement for reactions [4] or [5] should be considerably less than required for simple desorption, since the process of conversion of the complex into gaseous carbon dioxide involves formation of new bonds as well as rupture of the carbon lattice. Interaction with the complex thus provides a low-energy path for formation of carbon dioxide. These reactions also account for the observed first-order dependence of the rate on the pressure of oxygen.

The formation of each product molecule, carbon monoxide and carbon dioxide, is accompanied by regeneration of a free site and the possibility of formation of another complex. The complex may thus be regarded as a catalyst. On this basis, the rate of reaction or, at low temperature, the rate of formation of carbon dioxide should be directly related to the concentration of the complex. Rates measured with a variety of different types of carbon and under a variety of reaction conditions should be comparable if the rates are normalized to the number of active sites, as measured by the complex. Ahmed and Back (16) examined rates of oxidation measured over a wide range of temperature and pressures of oxygen and for a variety of types and sources of carbon in systems where the active surface area, as defined by the concentration of complex, was reported. Remarkable agreement was observed among these normalized rates, taking into account the uncertainties expected from the extrapolations and interpolations required for the comparisons. Undoubtedly the surface complex provides some indication of the reactivity of the carbon surface. In reality, the complex itself is not a single structure and each carbon surface has different types of active centers so that the activity of a particular sample may not be fully described by the measurement of the complex present under particular conditions. It is not surprising that the role of the complex in the oxidation process is still not clearly understood.

Application of computer modelling

The ideas presented in the simple mechanism suggested here appeared to offer a plausible explanation for some features of the kinetics of the reaction and to at least provide a starting point for further development of a detailed mechanism. As a first step, quantitative evaluation of the importance of the individual elementary steps was required. Analytical solutions of rate equations based on steady-state assumptions are of limited value in achieving this understanding, partly because details of the mechanism may be obscured by the representation of the rate by a single rate constant. Computer modelling techniques, on the other hand, do not require an analytical solution and provide great sensitivity and scope for the evaluation of mechanisms. The main requirement is reliable measurements of the rate constants for each elementary process in the mechanism (25).

The measurements described in the previous section provided us with a basis for estimating the rate of each individual step in the mechanism, including adsorption, formation of complex, reactions of the complex, and desorption of the complex. Before making the kinetic measurements, the characterization of the carbon surface in terms of the number of active sites was estimated according to the procedures defined by Laine, Vastola, and Walker (10). The film was saturated with oxygen at about 573 K, followed by temperature-programmed desorption up to 1223 K, with analysis of the carbon monoxide and carbon dioxide desorbed. The number of active sites on the carbon surface at the beginning of a reaction, C_F^0, was given as

$$[6] \quad C_F^0 = CO + 2CO_2$$

With the films used in our experiments this quantity was always reproducible.

At temperatures below about 900 K, where the formation of carbon monoxide is negligible, the reaction does not involve a change in pressure. A small but measurable drop in pressure occurred in the early stages of the reaction, showing that oxygen was adsorbed on the surface. Because the initial rate of pressure drop was fast and the activation energy for the process was only about 40 kJ mol^{-1}, this rate was assumed to correspond to reaction [1] and the rate constant was calculated from the expression

$$[7] \quad -\frac{d[O_2]}{dt} k_1 C^0{}_F [O_2]^0$$

This equation assumes that in the initial stages reaction [2] is not important or, in other words, that conversion of $C(O_2)$ into the strongly bound complex is slow compared to its formation. As an estimate, k_2 was taken as 0.1 k_1 at 748 K and its value was allowed to vary with temperature with an activation energy of some 80–120 kJ mol^{-1}. The ratio k_2/k_1 was subsequently adjusted in developing the kinetic model, but the changes did not invalidate the use of eq. [7].

The rate of reaction [3] was estimated from the results of temperature-programmed desorption measurements, which gave an average activation energy for desorption of 270 kJ mol^{-1}. Assuming a frequency factor of 10^{13} s^{-1}, direct desorption is negligible compared to the overall rate of the reaction below about 900 K, in agreement with the dominance of carbon dioxide in the product.

Estimation of the rate constants for reactions [4] and [5] required values for the concentration of each complex on the surface, $C(O_2)$ and $(CO)_C$, as well as the concentration of free sites, C_F, at any time. The concentration of the strongly bound complex, $(CO)_C$, was obtained, at any stage of the reaction, by removing reactants, products, and $C(O_2)$ by evacuation, leaving only $(CO)_C$ on the surface. Temperature-programmed desorption to 1223 K, with measurement of the carbon monoxide and carbon dioxide evolved, gave directly the number of moles of $(CO)_C$.

Since two complexes must interact to give CO_2

$$2(CO)_C = CO_2 + C_F$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.146.161.215 on 09/08/12

therefore the total moles of complex will be given as follows:

[8] $(CO)_C = CO + 2CO_2$

At any time during the reaction the difference between the measured pressure and the initial pressure indicated formation of both $C(O_2)$ and $(CO)_C$ as follows,

[9] $-\Delta P = -\Delta O_2 = 2(CO)_C + C(O_2)$

Thus from eqs. [8] and [9] the quantity of $C(O_2)$ was obtained.

Finally, C_F, the concentration of free sites at any time, was given as the difference between the initial value, C_F^0, and the sum of sites occupied by $C(O_2)$ and $(CO)_C$:

[10] $C_F = C_F^0 - [(CO)]_C + C(O_2)]$

The rate constants for reactions [4] and [5] were estimated by two approaches. The rate of disappearance of oxygen after the initial stage of the reaction and the rate of formation of carbon dioxide are given by the equations:

[11] $$-\frac{d[O_2]}{dt} = k_1 C_F[O_2] + k_4 C_F[(CO)_C][O_2]$$

[12] $$\frac{d[CO_2]}{dt} = k_4 C_F[CO)_C][O_2] + k_5[(CO)_C][O_2]$$

Using the value of k_1 calculated from the initial rate of disappearance of oxygen, eq. [7], and the estimates of C_F and $(CO)_C$ described, k_4 may be obtained from eq. [11]. Using this value of k_4 in eq. [12] gives a value for k_5. Alternatively, k_4 and k_5 may be obtained from simultaneous solutions of eq. [12] using rates of formation of carbon dioxide measured at different times during the course of the reaction. These procedures gave values of k_4 and k_5 in agreement within a factor of two.

The rates of formation of products calculated on the basis of the simple mechanism provided an accurate picture of the early stages of the reaction but were not adequate to describe the observed variations of reactant and products during the complete course of the reaction. Significant improvement was achieved by the introduction of two types of reactive sites on the carbon surface, a feature long recognized from a variety of experimental studies (for a summary, see ref. 1*b*). One site, designated CA, adsorbs oxygen rapidly and is identified as the site responsible for the initial sharp decrease in the oxygen pressure. Such sites are quickly saturated and play only a small part in the subsequent chemistry. A second kind of site, designated CB, adsorbs oxygen much more slowly. Its concentration therefore decreases slowly and it is able to participate in other reactions without requiring unacceptably large rate constants.

This extension of the mechanism gave partial improvement, but much better agreement between calculated and observed yields was obtained by allowing some interchange between the chemical reactions of A and B sites. A detailed discussion of the types of reactions of the complexes on both sites and of the sensitivitity analysis that identifies the important reactions has been given previously (26). The final minimum set of reactions required to give quantitative agreement with experimental measurements is given below.

[1A] $CA + O_2 \rightarrow C(O_2)_A$

[2A] $CA + C(O_2)_A \rightarrow 2(CO)_{CA}$

[3B] $(CO)_{CB} \rightarrow CO + CB$

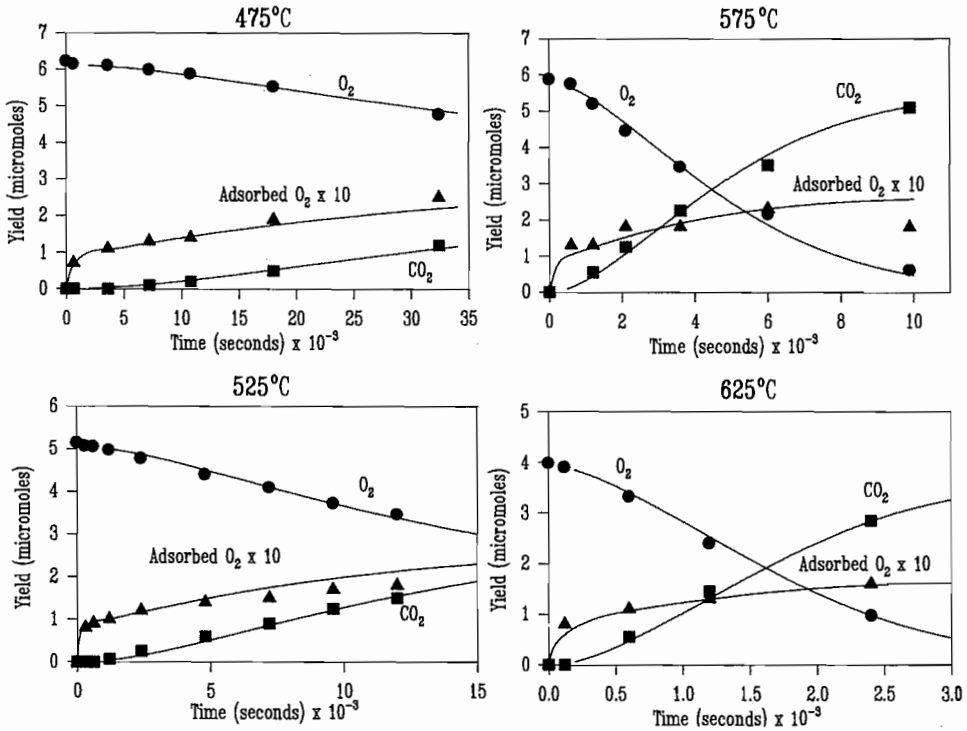
[1B] $CB + O_2 \rightarrow C(O_2)_B$

[13B(*a*)] $CB + (CO)_{CB} + O_2 \rightarrow CO_2 + (CO)_{CB} + 2\,CB$

[13B(*b*)] $CB + (CO)_{CB} + O_2 \rightarrow CO_2 + (CO)_{CB} + CB$

[13B(*c*)] $CB + (CO)_{CA} + O_2 \rightarrow CO_2 + (CO)_{CB} + CA$

[14A] $CB + C(O_2)_A \rightarrow (CO)_{CA} + (CO)_{CB}$



Because reaction with oxygen has been generally observed to increase reactivity of the surface, reaction [13B(*a*)] is written to allow for an increase in the number of sites. The relative rates of reactions [13B(*a*)] and [13B(*b*)] were adjusted to give the increase in rate observed. The mechanism does not include a loss process for $C(O_2)_B$ because direct conversion of oxygen adsorbed on B sites to form $(CO)_{CB}$ is too slow in the low-temperature region to make a significant contribution. Formation of the complex on B sites occurs more readily by reactions [13B(*c*)] and [14A]. Only a small loss of oxygen occurs by reaction [1B]. The yields of products calculated on the basis of this mechanism are shown as the solid lines in Fig. 7 with the experimental measurements as the points. The mechanism thus provides a satisfactory description of the reaction in the low-temperature region.

The values of the rate constants used in the computation together with the Arrhenius parameters were listed in an earlier paper (26). Although the reactions as written may not be truly elementary processes, nevertheless the rate constants conform to an Arrhenius temperature dependence, at least in the low-temperature region. In fitting a model to experimental results adjustment of rate constants is constrained by the experimental measurements and is guided by sensitivity analysis. This procedure identifies the rate constants that require the smallest change for the largest effect on the rate and allows the elimination of reactions that make negligible contributions to the rate.

The model provided a reasonably quantitative description of the processes occurring during the reaction of oxygen with carbon in the temperature range 750–900 K at oxygen pressures in the neighbourhood of 100 Pa (1 Torr). A more demanding test of a model is its application to results obtained outside the range of conditions for which it was developed. For this we chose the detailed yield–time data obtained by Laine, Vastola, and Walker (10) where measurements were made with a different type of carbon, Graphon (highly purified graphitized carbon black), at much lower pressures (10^{-3} Torr) than used in the experiments of Ahmed and Back. By introducing two alterations to the mechanism good agreement was obtained between the calculated and observed results (27). First, the reactivity of the A sites was increased by increasing the rate constants for reactions [1A] and [3A]

© 1997 NRC Canada

Fig. 7. Comparison of experimental measurements and calculated values for consumption of oxygen and formation of products at four temperatures. Experimental data are represented by points. Calculated values are represented by lines. ●: O_2; ▲: complex; ■: CO_2.

[3A] $(CO)_{CA} \rightarrow CO + CA$

by factors of 14 and 120, respectively. Such changes in reactivity would be expected between different types of carbon and are in accord with the high reactivity of Graphon. A second adjustment was the addition of a new type of adsorption site, designated C_{AA}, which rapidly but loosely binds oxygen and provides a new route to the formation of $(CO)_A$. Again this type of adjustment reflects differences in the structure and hence in types of active sites of carbon formed from different sources. The new reactions were

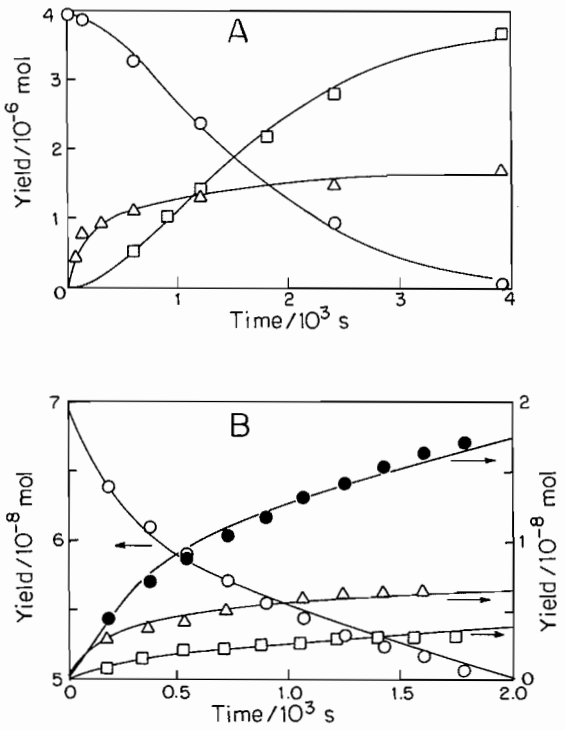
[15] $C_{AA} + O_2 \rightarrow C(O_2)_{AA}$

[16] $C_A + C(O_2)_{AA} \rightarrow (CO)_{AA} + (CO)_A$

The rate of reaction [15] is the key factor in reproducing the decay curves of oxygen observed by Laine, Vastola, and Walker (10). The new type of site binds a single oxygen atom particularly strongly and may be the very stable complex suggested by these authors.

Calculated and experimental results are shown in Fig. 8 for the results of both Ahmed and Back (16), using the original mechanism, and Laine, Vastola, and Walker (10), with the revised mechanism, at the same temperature. The major difference between the two sets of results is in the product distribution. At pressures of 1 Torr, carbon dioxide is the major product because the rate of reaction [13] greatly exceeds that of reaction [3], the desorption of carbon monoxide. At pressures of 10^{-3} Torr, on the other hand, carbon monoxide is the major product. At such low pressures the rate of reaction [13] is reduced and reaction [3] is now the faster.

Discussion



The most significant features of the model are the existence of at least two distinct types of active sites on the carbon surface, with different reactivities, and the introduction of the general type of reaction given by eq. [4], where a gas-phase molecule of oxygen reacts with the chemisorbed complex. The idea that the carbon surface may contain more than one type of active site has been suggested many times, based on results from a variety of studies. The sites labelled CA are the most active in terms of adsorption of oxygen and are rapidly saturated. Oxygen therefore is initially rapidly adsorbed, followed by a more gradual loss as sites CB contribute. CA sites do not contribute appreciably to subsequent reactions to produce carbon dioxide, which all involve CB sites. The very different nature of adsorption on CB sites is reflected in the larger activation energy of reaction [1B], 190 kJ mol^{-1}, compared to that for reaction [1A], 50 kJ mol^{-1}. The two adsorbed oxygen species, $C(O_2)_A$ and $C(O_2)_B$, also had different reactivities. Reaction of $C(O_2)_A$ with CB sites was the dominant mechanism for formation of the complex and the corresponding reaction with $C(O_2)_B$ did not contribute. Conversion of the complexes $(CO)_A$ and $(CO)_B$ into carbon dioxide probably occurs following adsorption of oxygen on a neighbouring CB site. Interaction of the adsorbed oxygen with the complex leads to formation of carbon dioxide. Following desorption of carbon dioxide a new complex and new active sites remain on the surface. These reactions regenerate the appropriate proportions of CA and CB sites at all stages in the reaction.

An additional feature of the mechanism is the prediction, often suggested by various experimental measurements, that

the concentration of oxide complex on the surface rapidly rises to a small value that remains nearly constant as the reaction proceeds, as a result of the balance between the rates of formation and disappearance. The complex is an intermediate in the reaction, continuously occupying and releasing new active carbon atoms. Thus the role of the complex resembles that of active sites in a catalytic process.

The results of this first attempt at computer modelling of the carbon–oxygen reaction represent only a beginning in the development of a mechanism that may, with suitable values for the rate constants for each individual step, describe the kinetics of the reaction under all conditions. The rate constants used in the present calculations were based on measurements made with a particular type of carbon and the relative values for these rate constants as well as the relative concentrations of the sites would be expected to change with different types of carbon. Nevertheless the basic features of the mechanism should be generally applicable. The value of the method lies in its ability to test, under a range of conditions, a complex mechanism involving a wide variety of elementary steps. The results of the tests clearly show the importance of certain types of reactions as opposed to the ineffectiveness of others. The mechanism presented undoubtedly needs additions and modifications and improved estimates for rate constants. As new measurements provide these, the mechanism may be developed in ways that will provide new insights into the complexities of the reaction and the role of the various surface oxides in the gasification process.

Acknowledgments

The author acknowledges the contributions of C.-J. Chen, in the development of the method of formation and analysis of carbon, of S. Ahmed, in the measurements of the kinetics of the reaction of carbon with oxygen, and of Professor J.R. Roscoe in the computer modelling of the mechanism of the reaction. The author also expresses her appreciation of the many valuable discussions with her late husband, Robert A. Back, while these ideas were brought to fruition. Abstract: Experimental solubilities are reported at 25.0°C for *trans*-stilbene dissolved in 28 different organic nonelectrolyte solvents containing methyl, ether, hydroxy, and *tert*-butyl functional groups. Results of these measurements are used to test the applications and limitations of expressions derived from Mobile Order theory. For the 20 solvents for which predictions could be made, computations show that Mobile Order theory does provide fairly reasonable (although by no means perfect) estimates of the saturation mole fraction solubilities. Average absolute deviation between predicted and observed values is ca. 24%. In comparison, the average absolute deviation increases significantly to 935% when ideal solution behavior is assumed.

Key Words: *trans*-stilbene solubilities, organic nonelectrolyte solvents, solubility predictions.

Résumé : On a déterminé les solubilités expérimentales, à 25°C, du *trans*-stilbène dissous dans 28 solvants organiques non-électrolytiques différents comportant des groupes fonctionnels méthyle, éther, hydroxy et *tert*-butyle. On a utilisé les valeurs ainsi obtenues pour évaluer les applications et les limitations d'expressions dérivées de la théorie de l'ordre mobile. Les 20 solvants pour lesquels il est possible de faire des prédictions à l'aide de calculs montrent que la théorie de l'ordre mobile permet d'obtenir des évaluations assez correctes (même si elles sont loin d'être parfaites) de solubilité à saturation des fractions molaires. Les déviations moyennes absolues entre les valeurs prédites et observées sont d'environ 24%. En comparaison, la déviation moyenne absolue augmente d'une façon phénoménale à 935% lorsqu'on fait l'hypothèse que le comportement de la solution est idéal.

Mots clés : solubilités du *trans*-stilbène, solvants organiques non-électrolytiques, prédictions des solubilités.

[Traduit par la rédaction]

Introduction

Solid–liquid equilibrium data of organic nonelectrolyte systems are becoming increasingly important in the petroleum industry, particularly in light of present trends towards heavier feedstocks and known carcinogenicity/mutagenicity of many of the larger polycyclic aromatic compounds. Solubility data for a number of polycyclic aromatic hydrocarbons (e.g., anthracene and pyrene) and heteroatom polynuclear aromatics (e.g., carbazole, dibenzothiophene, and xanthene) have been published in the recent chemical literature (for listing of references see Acree (1–3)). Despite efforts by experimentalists and scientific organizations, both in terms of new experimental measurements and critically evaluated data compilations, there still exist numerous systems for which solubility data are not readily available.

To address this problem, researchers have turned to group contribution methods and semiempirical expressions to predict desired quantities. Group contribution methods have proved fairly successful in estimating solid solubility in pure and binary solvent mixtures from structural information (4–11). Practical application, however, is limited to systems for which all group interaction parameters are known. Interaction parameters can be evaluated from liquid–vapor, liquid–liquid, and solid–liquid equilibria data. It is important that the data base contain as many different functional groups as possible, preferably with adequate representation from both mono- and multi-functional solute/solvent molecules to permit evaluation of potential synergistic effects. The data base should contain sufficient experimental values near infinite dilution in the event that one wishes to determine separate interaction parameters for finite concentration and infinite dilution activity coefficient predictions. For this reason, we have measured *trans*-stilbene solubilities in 28 different organic solvents. Functional groups represented include ethers, and hydroxy and saturated hydrocarbons. These measurements will be used to further test the applications and limitations of predictive expressions derived from Mobile Order theory.

(Aldrich, 99.9+%), 1-propanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich HPLC, 99.8+%), 2-butanol (Aldrich, 99+%, anhydrous), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), 2-methyl-2-butanol (Acros, 99+%), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 3-methyl-1-butanol (Aldrich, 99+%, anhydrous), 1-octanol (Aldrich, 99+%, anhydrous), 2-pentanol (Acros, 99+%), 4-methyl-2-pentanol (Acros, 99+%), 2-ethyl-1-hexanol (Aldrich, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), dibutyl ether (Aldrich, 99%), methyl *tert*-butyl ether (Arco, 99.9+%), *tert*-butylcyclohexane (Aldrich, 99+%), *n*-hexane (Aldrich, 99%), *n*-heptane (Aldrich, HPLC), *n*-octane (Aldrich, 99+%, anhydrous), cyclohexane (Aldrich, HPLC), methylcyclohexane (Aldrich, 99+%, anhydrous), cyclooctane (Aldrich, 99+%), 2,2,4-trimethylpentane (Aldrich, HPLC), and cyclopentanol (Aldrich, 99%) were stored over molecular sieves before use. Gas chromatographic analysis showed solvent purities to be 99.7 mol% or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1°C for at least 3 days (often longer). Attainment of equilibrium was verified both by repetitive measurements after several additional days and by approaching equilibrium from supersaturation by pre-equilibrating the solutions at a higher temperature. Aliquots of saturated *trans*-stilbene solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample, and were diluted quantitatively with methanol for spectrophotometric analysis at 294 nm on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance versus concentration working curve for nine standard solutions ranging in concentration from 1.38×10^{-5} to 4.62×10^{-5} M. The calculated molar absorptivity of $\varepsilon \approx 28\,750$ L mol^{-1} cm^{-1} was constant over the concentration range. Experimental molar concentrations were converted to (mass/mass) solubility fractions by multiplying by the molar mass of *trans*-stilbene, volume(s) of volumetric flask(s) used, and any dilutions required to place the measured absorbances on the Beer–Lambert law absorbance versus concentration working curve, and then dividing by the mass of the saturated solution analyzed. Mole fraction solubilities were computed from (mass/mass) solubility fractions using the molar masses of the solute and solvent. Experimental *trans*-stilbene solubilities, X_A^{sat}, in 28 organic solvents studied are listed in Table 1. Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±2%.

Results and discussion

Solvents studied include both noncomplexing alkanes and self-associating alcohols. Of the many solution models proposed in recent years, Mobile Order theory is perhaps the only one that is capable of describing solute behavior in such a wide range of solvent mixtures. The basic model (12–19) assumes that all molecular groups perpetually move, and that neighbors of a given kind of external atom in a molecule constantly change identity. All molecules of a given kind dispose of the same volume, equal to the total volume V of the liquid divided by the number N_A of molecules of the same kind, i.e., Dom A = V/N_A. The center of this domain perpetually moves. The highest mobile disorder is achieved whenever groups visit all parts of their domain without preference. Preferential contacts lead to deviations with respect to this "random" visiting. This is especially true in the case of hydrogen bonding, as specific interactions result in a specific orientation of the "donor" molecule with respect to an adjacent "acceptor" molecule.

In the case of an inert crystalline solute dissolved in a self-associating solvent, Mobile Order theory expresses the volume fraction saturation solubility, ϕ_A^{sat}, as

$$[1]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta_A' - \delta_{solvent}')^2(RT)^{-1} - r_{solvent}(V_A/V_{solvent})\phi_{solvent}$$

where the $r_{solvent}(V_A/V_{solvent})\phi_{solvent}$ term represents the contributions resulting from hydrogen-bond formation between the solvent molecules. For most of the published applications, $r_{solvent}$ was assumed to be unity for strongly associated solvents with single hydrogen-bonded chains such as monofunctional alcohols, to be two for water or diols, and to equal zero for nonassociated solvents such as saturated hydrocarbons. A more exact value for alcoholic solvents can be calculated based upon

1-Heptanol	0.010 92	0.008 58	−21.4
1-Octanol	0.012 51	0.006 18	−50.6

[a]Deviations (%) = 100 $[(X_A^{sat})^{calc} - (X_A^{sat})^{exp}]/(X_A^{sat})^{exp}$.

$$[2] \quad r_{solvent} = (K_{solvent}\phi_{solvent}/V_{solvent})/(1 + K_{solvent} \times \phi_{solvent}/V_{solvent})$$

with a numerical value of $K_{solvent}$ = 5000 cm^3 mol^{-1} assumed for all monofunctional alcohols.

If complexation does occur between the crystalline solute and solvent, then an additional term involving the solute–solvent equilibrium constant, $K_{ASolvent}$, must be introduced to describe the solubility enhancement that arises as a result of specific interactions. A slightly more complex expression applies in the case of solute complexation with a self-associating solvent. The symbols δ_A' and $\delta_{solvent}'$ denote the modified solubility parameters of the solute and solvent, respectively, V_i is the molar volume, and a_A^{solid} is the activity of the solid solute. This latter quantity is defined as the ratio of the fugacity of the solid to the fugacity of the pure hypothetical supercooled liquid. The numerical value of a_A^{solid} can be computed from the solute's molar enthalpy of fusion, ΔH_A^{fus}, at the normal melting point temperature, T_{mp}. Contributions from nonspecific interaction are incorporated into Mobile Order theory through the $\phi_{solvent}^2 V_A(\delta_A' - \delta_{solvent}')^2(RT)^{-1}$ term. Ruelle and co-workers (15–19) have presented a very impressive set of comparisons between experimental and predicted values for anthracene, naphthalene, pyrene (see also Powell et al. (20)), biphenyl, carbazole, benzil (see also Fletcher et al. (21)), *p*-benzoquinone, tricosane, octacosane, 10-nonadecanone, 11-heneicosanone, and 12-tricosanone in a wide range of both noncomplexing and complexing solvents to document the predictive ability of Mobile Order theory.

Table 3. Solvent and solute properties used in Mobile Order predictions.

Component (i)	V_i(cm^3 mol^{-1})	δ_i'/(MPa$^{1/2}$)[a]
n-Hexane	131.51	14.56
n-Heptane	147.48	14.66
n-Octane	163.46	14.85
Cyclohexane	108.76	14.82
Methylcyclohexane	128.32	15.00
2,2,4-Trimethylpentane	166.09	14.30
Cyclooctane	134.9	15.40
tert-Butylcyclohexane	173.9	15.50
Dibutyl ether	170.3	17.45
Methanol	40.7	19.25
Ethanol	58.7	17.81
1-Propanol	75.10	17.29
2-Propanol	76.90	17.60
1-Butanol	92.00	17.16
2-Butanol	92.4	16.60
2-Methyl-1-propanol	92.8	16.14
1-Pentanol	108.6	16.85
1-Hexanol	125.2	16.40
1-Heptanol	141.9	16.39
1-Octanol	108.6	16.38
trans-Stilbene[b]	177.0	19.69[c]

[a]Tabulated values are taken from a compilation given in Ruelle et al. (15, 16, 19).

[b]The numerical value of a_A^{solid} = 0.062 27 was calculated from the molar enthalpy of fusion, ΔH_A^{fus} = 27 400 J mol^{-1} (22) at the normal melting point temperature of the solute, T_{mp} = 398.15 K.

[c]Numerical value was calculated using the measured *trans*-stilbene mole fraction solubilities in *n*-hexane, *n*-heptane, and *n*-octane, in accordance with eqs. [1] and [3]; with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0.

$$[3] \quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta_A' - \delta_{solvent}')^2(RT)^{-1} + \ln [1 + \phi_{solvent}(K_{Asolvent}/V_{solvent})]$$

$$[4] \quad \ln a_A^{solid} = -\Delta H_A^{fus}(T_{mp} - T)/(RTT_{mp})$$

Predictive application of eqs. [1] and [3] is relatively straightforward. First, an average numerical value of $\delta_{stilbene}'$ = 19.69 MPa$^{1/2}$ is computed by requiring that each equation (with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0) perfectly describes our *trans*-stilbene mole fraction solubility data in *n*-hexane ($\delta_{stilbene}'$ = 19.78 MPa$^{1/2}$), *n*-heptane ($\delta_{stilbene}'$ = 19.68 MPa$^{1/2}$), and *n*-octane ($\delta_{stilbene}'$ = 19.60 MPa$^{1/2}$). The numerical value of a_A^{solid} = 0.062 27 is calculated using eq. [4] with ΔH_A^{fus} = 27 400 J mol^{-1} (22), and T_{mp} = 398.15 K. A numerical value of $V_{stilbene}$ = 177 cm^3 mol^{-1} was used for the molar volume of the hypothetical subcooled liquid solute.

Table 2 summarizes the predictive ability of Mobile Order theory for the 20 different organic solvents for which both *trans*-stilbene solubility data and modified solubility parameters could be found. Solvent molar volumes and modified solubility parameters are listed in Table 3. The modified

© 1997 NRC Canada

solubility parameters account for only nonspecific interactions, and in the case of the alcoholic solvents the hydrogen-bonding contributions have been removed. Numerical values of $\delta'_{solvent}$ were obtained from published compilations (15, 16, 19), and were either deduced by regressing actual solubility data of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (23) or estimated using known values for similar organic solvents. Examination of the entries in Table 2 reveals that Mobile Order theory does provide fairly reasonable (though by no means perfect) estimates of the solubility behavior of *trans*-stilbene in a wide range of organic solvents. Average absolute deviation between predicted and observed values is circa 24%. Readers are reminded that in evaluating the applicability of Mobile Order theory one must realize that many of these particular systems are highly nonideal, and that the experimental solubility data cover up to a 14-fold range in mole fraction. Had an ideal solution been assumed, then the predicted mole fraction solubility would be $X_A^{sat} = a_A^{solid} = 0.062\ 27$ for each solvent. The ideal solution approximation corresponds to a considerably larger average absolute deviation of 935% between predicted and observed values.

Chemical modification of chlorophyll *a*: synthesis of new regiochemically pure benzoporphyrin and dibenzoporphyrin derivatives

Lifu Ma and David Dolphin

Abstract: Starting from pheophorbide *a* methyl ester (**5**), a degradation product of chlorophyll *a*, routes for the preparation of 3-vinylporphyrins **6** and **9** and of an [A,C]-divinylporphyrin **16** are described. These porphyrins were obtained as a result of chemical modification of **5** on ring D and the exocyclic ring E. Diels–Alder reactions of these (di)vinylporphyrins with dimethyl acetylenedicarboxylate, to afford new regiochemically pure benzoporphyrin derivatives **29** and **30** and dibenzoporphyrin derivative **33** for potential use as sensitizers in photodynamic therapy of tumors, were also investigated.

Key words: Diels–Alder, (di)vinylporphyrins, (di)benzoporphyrins, photodynamic therapy, chlorophyll.

Résumé : On décrit des voies de synthèse pour la préparation des 3-vinylporphyrines **6** et **9** et d'une [A,C]-divinylporphyrine (**16**) à partir de l'ester méthylique de l'acide phéophorbide *a* (**5**). On a obtenu ces porphyrines par modification chimique du cycle D et du cycle exocyclique E du produit **5**. On a aussi examiné les réactions de Diels–Alder de ces (di)vinylporphyrines avec l'acétylènedicarboxylate de diméthyle pour préparer les dérivés benzoporphyrines **29** et **30** et le dérivé dibenzoporphyrine **33** régiochimiquement purs, qui pourraient s'avérer utiles comme sensibilisateurs dans la thérapie photodynamique des tumeurs.

Mots clés : Diels–Alder, (di)vinylporphyrines, (di)benzoporphyrines, thérapie photodynamique, chlorophylle.

Introduction

Among long-wavelength absorbing photosensitizers, chlorins and bacteriochlorins have received increasing attention as potential candidates for use in photodynamic therapy (PDT) since they absorb strongly in the red region (>670 nm) and thereby enable deeper penetration of light through tissues (1). Some naturally occurring chlorins and bacteriochlorins have previously been reported as effective photosensitizers both in vitro and in vivo (2). However, these compounds, by virtue of their di- and tetrahydro reduction states, can be readily oxidized back to the parent porphyrin accompanied by the loss of their long-wavelength absorption bands (3). This potential lack of stability has led us to examine other ways of producing chlorin-like and bacteriochlorin-like chromophores.

A number of years ago Johnson and co-workers (4) reported a facile synthesis of compounds possessing the chlorin-like chromophore by using the Diels–Alder reaction on vinylporphyrins. We extended this methodology to vinyl- and [A,C]-divinylporphyrins and prepared a series of benzoporphyrin derivatives (BPD) (5) and dibenzoporphyrin derivatives (DBPD) (6) (bacteriochlorins). In the BPD series, benzoporphyrin derivative monoacid A (BPD-MA) (**1**), a second-generation photosensitizer that has shown promising photophysical properties, is currently in Phase II clinical trials and has been proposed as a possible alternative to Photofrin™, a commercial variant of hematoporphyrin derivative, used in the clinic for the treatment of solid tumors (7). Preliminary biological evaluation also indicated that the dibenzoporphyrin (**2**) is highly photocytotoxic and has potential as a useful therapeutic compound (8).

Further biological investigation of DBPD (**2**) as a potential phototoxin in PDT was complicated by problems associated with the availability of the [A,C]-divinylporphyrin **3** since the total synthesis of **3**, via a stepwise route from pyrrolic precursors using the MacDonald dipyrromethane approach, requires a large number of steps and therefore considerable effort in order to obtain the quantities required for biological investigations (6, 9). For the synthesis of BPD-MA (5), protoporphyrin IX dimethyl ester (**4**) is reacted with dimethyl acetylenedicarboxylate (DMAD) in refluxing toluene (Scheme 1). The ring A Diels–Alder adduct (i.e., 1,4-cyclohexadiene derivative) is then separated by crystallization from the ring B adduct and is subsequently rearranged with base (DBU). The rearranged

Scheme 1

ring "A" 1,3-cyclohexadiene derivative is then partially hydrolyzed to afford, after purification, the two regioisomers, $\mathbf{1}_{ac}$ and $\mathbf{1}_{ad}$, which are used for biological studies (5). From the biological data reported so far, photodynamic activity is maximized for BPD when: (*a*) "ring A" of the porphyrin nucleus is modified by the Diels–Alder cycloaddition – base rearrangement procedure; (*b*) only one of the two methyl propionate groups is hydrolyzed to the free acid (7).

To eliminate the problem of regioisomer formation in the preparation of BPD-MA, we sought to acquire vinylporphyrins that contain one vinyl group (in ring A) and one propionic side chain. Similar studies were recently reported by Pandey et al. after the submission of this paper (10). These vinylporphyrins should thus afford regiochemically pure BPD-MA derivatives and would subsequently lead to less ambiguity at the biological screening stage. Further, it was envisioned that performing a partial synthesis of [A,C]-divinylporphyrins, from readily available natural tetrapyrroles, might facilitate and greatly simplify the synthetic sequence to [A,C]-divinylporphyrins.

Results and discussion

With our recent progress on chemical modifications of chlorophyll derivatives on ring D and the exocyclic ring E (11–15), the way was opened for synthesis of vinylporphyrins and [A,C]-divinylporphyrins from a chlorophyll degradation product. More specifically, these studies demonstrated the feasibility of transforming pheophorbide *a* methyl ester (**5**), readily available from the blue alga, *Spirulina maxima*, into 3-vinylporphyrin **6** (13). This substance, with a vinyl group at position 3, will produce only a ring "A" chlorin (after the Diels–Alder reaction) and only one propionic ester side chain, which can be hydrolyzed to the corresponding monocarboxylic acid at the final step of the synthesis, and serves as an ideal precursor to a regiochemically pure BPD-MA derivative. As a

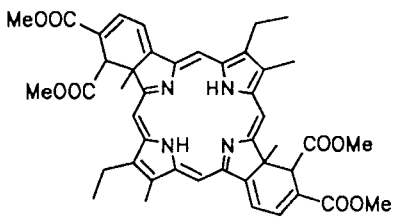
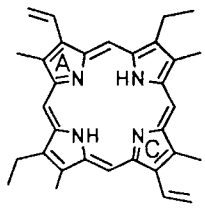
continuation of our research on chemical modifications of chlorophyll *a*, pheophorbide *a* methyl ester (**5**) was chosen as the key intermediate in this work.

A. Preparation of 3-vinylporphyrins 6 and 9



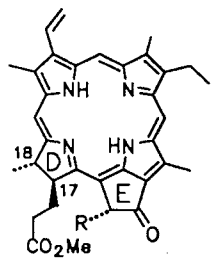
3-Vinylporphyrin **6** was obtained by the direct transformation of 13^1-hydroxychlorin **7** using a procedure described in a recent report (13). Demethoxycarbonylation of pheophorbide *a* methyl ester (**5**) in collidine afforded pyropheophorbide *a* methyl ester (**8**), which was reduced by NaBH4 to give a diastereomeric mixture of 13^1-deoxo-13^1-hydroxypyropheophorbide *a* methyl ester (**7**). Reaction of **7** with 1.2 equivalents benzoyl chloride in DMF gave vinylporphyrin **6** in 73% yield after recrystallization from dichloromethane–hexane.

3-Vinylrhodoporphyrin XV dimethyl ester (**9**), another substrate suitable for the synthesis of regiochemically pure BPD derivatives, was prepared from the oxidation of purpurin-7 trimethyl ester (**10**) (16), which was obtained from two routes. Thus, pheophorbide *a* methyl ester (**5**) was transformed into **10** by dissolution in pyridine, dilution with ether, and addition of KOH in *n*-propanol. After aeration for 30 min Fischer's "unstable chlorin" was obtained (16). Esterification of "unstable chlorin" (**11**) with diazomethane gave purpurin-7 trimethyl ester (**10**). The overall yield from **5** was 58%. Deglyoxylation and concomitant oxidation of purpurin-7 trimethyl ester in collidine furnished a 76% yield (44% overall yield from **5**) of 3-vinylrhodoporphyrin XV dimethyl ester (**9**).



One important characteristic of the above method is that **11** was somewhat unstable and had a tendency to oxidize further in the aerial oxidation step. The esterification with diazomethane therefore produced both purpurin-18 methyl ester (**12**) in addition to the desired purpurin-7 trimethyl ester (**10**). Separation of purpurin-18 methyl ester from purpurin-7 trimethyl ester by chromatography is difficult due to their very close structures and polarities. Based on our synthetic methods (11, 12, 14) developed in the research of natural antioxidative chlorins, an alternate route to synthesize purpurin-7 trimethyl ester (**10**) was via 15^1-hydroxypurpurin-7-lactone methyl ester (**13**). Hydroxylation (14) of pheophorbide *a* methyl ester (**5**) using commercially available (−)-(1*R*)-(10-camphorsulfonyl)oxaziridine and 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) (17) gave 13^2*R*-hydroxypheophorbide *a* methyl ester (**14**(*R*)) (90% d.e.) in 94% yield. Periodate oxidation of 13^2*R*-hydroxypheophorbide *a* methyl ester to 15^1-hydroxypurpurin-7-lactone methyl ester, followed by esterification with diazomethane, gave purpurin-7 trimethyl ester (**10**) in 79% yield (73% overall yield from **5**). This route has the advantages of higher yield and facile separations although it necessitates two extra steps compared to the original aerial oxidation of pheophorbide *a* methyl ester.

B. Synthesis of [A,C]-divinylporphyrin 16 via 3-vinylpurpurin 15



Attention was then focused on the development of a new and efficient route to obtain an [A,C]-divinylporphyrin from a chlorophyll derivative. To keep the number of chemical modifications involved in this sequence to a minimum, 3-vinylpurpurin **15** was chosen as the required precursor to an [A,C]-divinylporphyrin. With a 3-vinyl group at ring A and a 13-formyl group at ring C, purpurin **15** was subjected to a Wittig olefination reaction on the 13-formyl group to form a second vinyl group at ring C and, after further decarboxylation and oxidation, to give the desired target [A,C]-divinylporphyrin **16**. It was reasoned that the glyoxylic ester group at position 15 of the purpurin **15** could be lost with concomitant oxidation of the chlorin macrocycle into the porphyrin **17** in a one-pot procedure as was used in the transformation of purpurin-7 trimethyl ester (**10**) into

3-vinylrhodoporphyrin XV dimethyl ester (**9**) (18) in collidine at 170°C. Further, Wittig olefination of the resulting **17** with methylene triphenylphosphorane would furnish the desired [A,C]-divinylporphyrin **16**. Alternatively the [A,C]-divinylporphyrin **16** may be formed first by a Wittig olefination of the purpurin **15**, to furnish the [A,C]-divinylpurpurin **18**, followed by deglyoxylation of the ester and oxidation in situ in refluxing collidine. Both pathways appeared plausible because of the known transformation procedures and the ready availability of the starting material **15** from the synthetic method described above.

For the preparation of 3-vinylpurpurin **15**, two synthetic pathways were investigated and the one giving the higher overall yield was subsequently used to make **15** on a 400 mg scale. Initially, 3-vinylpurpurin **15** was derived from the photooxidation of 13^1-deoxo-13^1,13^2-dehydropheophorbide *a* methyl ester (**19**) (13). In this synthetic approach, the first step was $NaBH_4$ reduction of pheophorbide *a* methyl ester (**5**) to give a diastereomeric mixture of 13^1-deoxo-13^1-hydroxypheophorbide *a* methyl ester (**20**) (13, 19), followed by elimination of a molecule of trifluoroacetic acid (via proton sponge), to provide the desired compound **19** in 80% yield. Although **19** (mp >300°C) has high thermal stability, it is extremely photosensitive, and reaction (in dichloromethane solution) in air with sunlight (20 min) oxidatively cleaved the 13^1-13^2 double bond to quantitatively give vinylpurpurin **15**. In a second method, 3-vinylpurpurin **15** was derived from the periodate oxidation of the diastereomeric mixture, 13^2-deoxo-13^1-hydroxy-13^2R-hydroxypheophorbide *a* methyl ester (**21**), which was in turn obtained from the $NaBH_4$ reduction of 13^2R-hydroxypheophorbide *a* methyl ester (**14**(*R*)) (13). Using this second method, purpurin **15** has been obtained in 67% overall yield from pheophorbide *a* methyl ester (**5**), in contrast to an 80% overall yield from **5** in the first method by means of photooxidation.

When purpurin **15** was heated in collidine at 170°C for 45 min, 13-decarboxy-13-formyl-3-vinylrhodoporphyrin XV methyl ester (**17**) was obtained in only 15% yield; the remainder of the starting material decomposed or was overoxidized under these conditions. Attempts to avoid these side reactions by reducing reflux time and temperature (using pyridine instead of collidine) were all unsuccessful. The problem seemed to be due to the susceptibility of the 13-formyl group, which led to overoxidation during the purpurin-into-porphyrin conversion. Protection of the 13-formyl function to circumvent this unwanted side reaction was therefore considered

next. The ethylene acetal **22** was readily formed in 90% yield by heating purpurin **15** with ethylene glycol in THF and *p*-toluenesulfonic acid as catalyst. The salient features of the electronic spectrum of acetal **22** (λ_{max} = 660 nm), which looks similar to such hydroxychlorins as **7** and **20**, are the hypsochromic shift of its Q band (λ_{max} = 660 nm) in comparison with that of the purpurin **15** (λ_{max} = 686 nm) and the appearance of a strong absorption band at 496 nm, which suggested that the electron-withdrawing group at C-13 was removed.

Unfortunately, when the ethylene acetal **22** was refluxed in collidine even for 4 h, no reactions occurred and the starting material was recovered. Various attempts to achieve the purpurin-into-porphyrin conversion for the ethylene acetal **22** were all unsuccessful. It appears that an electron-withdrawing group at position 13 is required for the loss of the 15-glyoxylic ester group and concomitant oxidation of a purpurin macrocycle to a porphyrin, as observed with purpurin-7 trimethyl ester (**10**) and purpurin **15**. The key reason appears to be the dramatic change in the oxidation potential of the ethylene acetal **22** with the protection of the 13-formyl group. The presence of an electron-withdrawing group at position 13 in these purpurins seems to render the molecule easier to oxidize than the corresponding protected derivative.

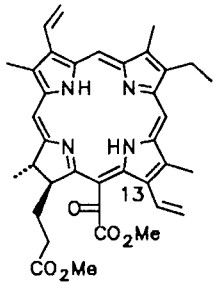
The conversion of purpurin-7 trimethyl ester (**10**) into 3-vinylrhodoporphyrin XV dimethyl ester (**9**) was originally investigated by Fischer and Orth (20), who found the loss of the glyoxylic ester residue from purpurin-7 trimethyl ester (**10**) occurred upon refluxing in pyridine. Later, Kenner et al. (18) reported that the use of refluxing collidine in place of pyridine results in higher yield for the purpurin-into-porphyrin conversion, because prolonged reflux in pyridine often gives rise to decomposition products. Interestingly, we found that the presence of oxygen in the reaction medium has a beneficial effect on the conversion, but is not required, since the conversion was also observed under oxygen-free conditions.

Given the anticipated difficulty in the purpurin-into-porphyrin conversion for the [A,C]-divinylpurpurin **18**, a purpurin with a non-electron-withdrawing group (i.e., vinyl) at position 13, the planned synthetic route to [A,C]-divinylporphyrin **16** via the [A,C]-divinylpurpurin **18** was abandoned. Finally, we came back to the direct conversion of purpurin **15** and prepared sufficient 13-decarboxy-13-formyl-3-vinylrhodoporphyrin XV methyl ester (**17**) by refluxing purpurin **15** in collidine. Treatment of **17** with zinc(II) acetate in methanol–dichloromethane gave a zinc complex, which was subjected to a Wittig reaction to give, after removal of the zinc by treatment with trifluoroacetic acid, a 71% yield of the desired [A,C]-divinylporphyrin **16**. With this synthetic approach the [A,C]-divinylporphyrin **16** was obtained in six steps from pheophorbide *a* methyl ester (**5**) in 9% overall yield. Compound **16** has a very similar electronic absorption spectrum to that of the divinylporphyrin **3** reported by Dolphin and coworkers (6).

C. Synthesis of [A,C]-divinylporphyrin 16 via porphyrin 9

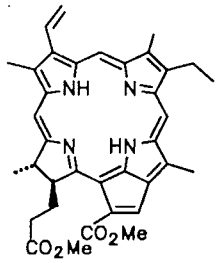
At this point, it was felt that the 15% yield of the formylrhodoporphyrin XV (**17**) obtained by the oxidation and deglyoxylation of purpurin **15** in collidine was unsatisfactory and should be improved upon by pursuing an alternative approach. Previous studies led us to conclude that the 13-methoxycarbonyl group and other (non-formyl) groups are advantageous in this regard. 3-Vinylrhodoporphyrin XV dimethyl ester (**9**) was chosen as the starting material since it is readily available from the oxidation of purpurin-7 trimethyl ester (**10**) as described above.

In this approach, 3-vinylrhodoporphyrin XV dimethyl ester (**9**) was hydrolyzed to its diacid form and was partially remethylated on the propionic side chain using 5% H_2SO_4 in methanol to give the 3-vinylrhodoporphyrin XV monomethyl ester (**23**) in 70% overall yield (21). The resulting monomethyl ester (**23**) was added to a solution of *N,N'*-carbonyldiimidazole in THF and heated to reflux for 30 min (22). The desired imidazolide **24** was obtained in 91% yield after flash chromatography on silica gel. The nucleophilic displacement (21) of the imidazolide **24** with the magnesium salt of methyl hydrogen malonate (23) gave the expected β-keto-ester **25** in 70% yield. This step was based on a method that was introduced by Bram and Vilkas (23) and later improved by Kenner and coworkers (21). The magnesium salt of methyl hydrogen malonate was prepared by treatment of methyl hydrogen malonate with 2 equivalents of isopropylmagnesium bromide in THF. The advantage of this procedure was its selectivity, which allowed the reaction to proceed without deprotonation of the porphyrin macrocycle to the green dianion.



With the enolizable β-keto-ester **25** in hand, we were able to attempt the decarboxylation step. A high yield of the desired acetylporphyrin **26** was obtained by modifying the decarboxylation method described by Taber et al. (24). In this reaction, the β-keto-ester **25** was stirred in a solution of 4-(dimethylamino)pyridine (4-DMAP) in phosphate buffer (pH = 7) at 90°C for 12 h under nitrogen to effect the demethoxycarbonylation (75% yield). The progress of the reaction was monitored by TLC and its completion was indicated by the disappearance of the less mobile enolizable β-keto-ester **25**. The electronic spectrum of this compound was almost the same as that of the imidazoylporphyrin **24** (oxorhodo-type spectrum). The ^{1}H NMR spectrum of porphyrin **26** showed the H-13^2 (i.e., 13-$COCH_3$) appearing as a singlet at δ 3.32 ppm. This observation indicated the presence of the desired 13-$COCH_3$ moiety.

The acetylporphyrin **26** was reduced with $NaBH_4$ in THF to give the expected hydroxyporphyrin **27**. With the absence of an electron-withdrawing group at position 13, hydroxyporphyrin **27** exhibited a rhodo-type electronic spectrum in contrast to an oxorhodo-type spectrum in the starting material **26**, suggesting that only one rhodofying group (i.e., the 3-vinyl moiety) was present in the molecule. The last step in the synthetic sequence involved the generation of the 13-vinyl group. This transformation was achieved by subjecting the hydroxyporphyrin **27** to benzoyl chloride in DMF at 105°C for 2 h (25). Under these conditions, the hydroxyporphyrin **27** was dehydrated to give the desired [A,C]-divinylporphyrin **16** in 60% yield after chromatography. This material was found to be identical to the divinylporphyrin prepared from the Wittig reaction of 13-formylporphyrin **17**. With this synthetic approach, the [A,C]-divinylporphyrin **16** was prepared in nine steps from pheophorbide *a* methyl ester (**5**) in 12% overall yield.



Diels–Alder reactions on vinylporphyrins

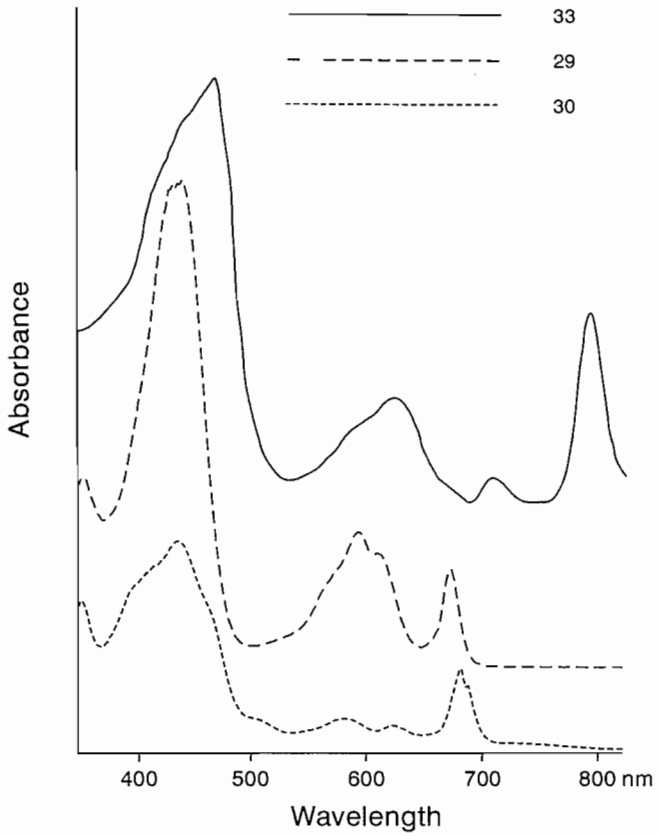
27

cycloadduct **28** in 50% yield. The ring A 1,4-cyclohexadiene derivative **28** was treated with DBU in dichloromethane to provide the chlorin-like BPD 1,3-cyclohexadiene dimethyl ester **29** in 90% yield after chromatography (45% overall yield from **9**). This rearrangement gave the thermodynamically more stable product, i.e., the carbomethoxy substituent attached at 2^1 and the angular methyl group located at C-2 are in a *trans* orientation. This *transoid* orientation was confirmed by a positive nOe effect observed for the C-2^1 proton (δ 5.04 ppm) and the methyl group at C-2 (δ 1.79 ppm).

The absorption spectrum (Fig. 1) of BPD **29** is characteristic of a chlorin-like chromophore but it has an unusually broad Soret band and the lowest energy absorption (Q band) at 672 nm (ε 14 600) is blue-shifted some 18 nm in comparison with that (690 nm) (5) of BPD-MA. This difference is due to the presence of an 8-vinyl group in BPD-MA, which extends the conjugation of the molecule. Pandey et al. (26) have recently exploited chemistry similar to that described above, and obtained a similar Diels–Alder adduct **29** from 3-vinylrhodoporphyrin XV dimethyl ester and DMAD. However, these authors reported a 23% overall yield (**29** from **9**) in contrast to a 45% total yield for the same reaction sequence in our hands.

For the preparation of BPD **30**, reaction of porphyrin **6** with DMAD in refluxing toluene under nitrogen gave the desired chlorin **31** in 42% yield. Compound **31** was then treated with DBU in dichloromethane to provide the fully conjugated chlorin **30** in 91% yield (36% overall yield) after chromatography. The reaction progress was monitored by UV–VIS spectroscopy, which showed a new absorbance at 686 nm (ε 37 000) (Fig. 1) and the disappearance of the peak at 648 nm of compound **31**.



As has already been mentioned, the synthetic strategy for the [A,C]-dibenzoporphyrin derivative relied on two cycloaddition reactions on an [A,C]-divinylporphyrin system. Refluxing the [A,C]-divinylporphyrin **16** with 100-fold molar excess of DMAD in toluene for 3 days gave a mixture with a strong absorption at 720 nm, a bacteriochlorin-like chromophore. The desired bis-adduct **32** was obtained as the major product along with a small amount of chlorin in which only one of the vinyl groups (either ring A and ring C) was transformed (identified by spectrophotometry). The best reaction time was found to be 80 h with a yield of ~30%, while prolonged reflux resulted in decomposition and thus gave the product **32** in a lower yield. Flash chromatography on a silica gel column followed by further purification by preparative TLC plate gave the bis-adduct **32** in 25% yield.

Fig. 1. UV–VIS spectra (CH_2Cl_2) of regiochemically pure benzoporphyrin derivatives **29** and **30**, and [A,C]-dibenzoporphyrin derivative **33**.

When the above bis-adduct **32** was stirred overnight with DBU at room temperature, a dramatic bathochromic shift was observed (λ_{max} = 784 nm, ε = 38 000) (Fig. 1). This [A,C]-dibenzoporphyrin derivative **33** showed almost the same electronic spectrum as the DBPD **2** reported by Dolphin and coworkers (6). The most significant features in the ^{1}H NMR spectrum of the new adduct **33** were the appearance of a signal at δ 4.89 ppm for the new sp^3 center generated at C-2^1 and C-12^1 and two doublets at δ 7.30 and δ 7.81 ppm for the new sp^2 centers. This observation indicated an isomerization of the double bonds in both 1,4-cyclohexadienes, thus extending the conjugation in the molecule.

As described earlier, the monocarboxylic acid analogue of benzoporphyrin derivative BPD-MA shows better photosensitizing efficacy than its corresponding diester. Therefore, to parallel the structural requirements for this biologically active benzoporphyrin derivative and to satisfy our originally planned goals, the new regiochemically pure benzoporphyrin derivatives **29** and **30**, and the [A,C]-dibenzoporphyrin derivative **33** were partially hydrolyzed with 25% HCl at the propionic ester side chain to afford the corresponding monocarboxylic acids **34**, **35**, **36** (i.e., propionic acid analogues). These monocarboxylic acids, together with their corresponding esters described herein, are being evaluated for their photodynamic ability.

Conclusion

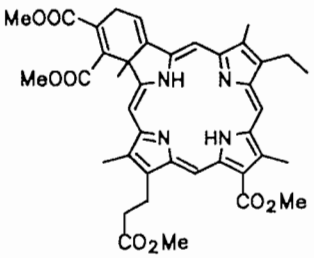
Two series of new regiochemically pure benzoporphyrin derivatives **29** and **30** have been synthesized from Diels–Alder reactions on 3-vinylrhodoporphyrin XV dimethyl ester (**9**) and 3-vinylporphyrin (**6**) with dimethyl acetylenedicarboxylate. The corresponding monocarboxylic analogues of these new regiochemically pure BPDs have been prepared by partial hydrolysis. These new photosensitizers have characteristics that meet or exceed the promising chemical features of BPD-MA, a second-generation photosensitizer in Phase-II clinical trials. The [A,C]-divinylporphyrin **16** was synthesized via two routes and its Diels–Alder reaction with dimethyl acetylenedicarboxylate was studied. The resulting bis-adduct **33**, being a stable bacteriochlorin-like chromophore, absorbs strongly at 784 nm, a fact that, according to current thinking, renders it eminently desirable as a photosensitizer for treatment of large tumors or tumors that are deeply seated within the body.

In conclusion, the present work has led to the synthesis of a class of compounds, via chemical modifications of chlorophyll *a*, with potential as future drugs in the field of photodynamic therapy.

Experimental

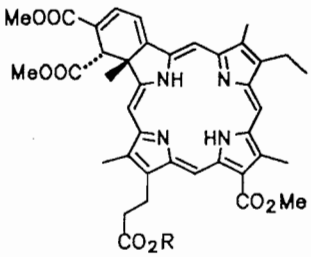
General procedures

Melting points were measured on a Thomas–Bristoline microscopic hot stage apparatus and are uncorrected. ^{1}H NMR spectra were recorded using a Bruker WH-400 or Bruker AC-200 spectrometer and ^{13}C NMR spectra were run on a Varian XL-300 or a Bruker AMX-500 spectrometer (residual $CHCl_3$ as internal standard, δ_H 7.24 ppm, δ_C 77.0 ppm). Silica gel 60 (70–230 mesh, Merck; usually silica III, i.e., deactivated with 6% water, or silica V, i.e., deactivated with 15% water) or neutral alumina (usually Brockman Grade III, deactivated with 6% water, or Brockman Grade V, deactivated with 15% water) was used for column chromatography. Preparative thin-layer chromatography was carried out on 20 × 20 cm glass plates coated with Merck G_{254} silica gel (0.5 mm, 1 mm thick). The deactivated silica gel plates, when necessary, were prepared by a blank development with 10% methanol in dichloromethane followed by air drying before use. Electronic absorption spectra were measured using a HP 8452A diode array spectrophotometer. Mass spectra were recorded by fast atom bombardment (FAB) and electron impact (EI). Elemental analyses were carried out in the departmental microanalytical laboratory at UBC using a Carlo Erba elemental analyzer 1106. Reactions were monitored by TLC and spectrophotometry and were carried out under nitrogen and in the dark. Pheophorbide *a* methyl ester (**5**) was obtained from *Spirulina maxima* alga using a literature method (15). Pyropheophorbide *a* methyl ester (**8**) was obtained (98% yield) from decarboxylation of pheophorbide *a* methyl ester (**5**) in collidine (15, 27). Tetrahydrofuran (THF) and dioxane were dried overnight with calcium hydride and distilled from sodium wire and benzophenone; other solvents were of reagent grade.



Synthesis of 3-vinylporphyrins 6 and 9

13^1-Deoxo-13^1-hydroxypyropheophorbide a *methyl ester (7)*



Pyropheophorbide *a* methyl ester (**8**) (150 mg, 0.274 mmol)

was dissolved in 100 mL of pyridine–methanol solution (pyridine:methanol = 1:1) and the solution was stirred at room temperature. $NaBH_4$ (200 mg) was added and the reaction mixture was stirred for 2 h, at which time the UV–VIS spectrum indicated no more starting material. The green reaction mixture was poured into cooled 2 N HCl and the chlorin was extracted with CH_2Cl_2. The organic layer was carefully washed once with water, twice with saturated $NaHCO_3$, three times with water, and then dried over anhydrous Na_2SO_4, filtered, and evaporated. The residue was purified by flash chromatography on silica III, eluting with 1% MeOH in CH_2Cl_2. The main band was collected, evaporated, and recrystallized from CH_2Cl_2–hexane to give the title compound (129 mg, 86% yield) as a dark-green powder; mp 178–180°C; UV–VIS λ_{max} (CH_2Cl_2): 402 nm (ε 117 600), 502 (9100), 654 (32 900); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 9.98 (s, 1H, H-10), 9.82 (s, 1H, H-5), 9.05 (s, 1H, H-20), 8.30 (dd, 1H, H-3^1), 6.45 (dd, 1H, H-3^2(*E*)), 6.32 (s, 1H, H-3^2(*Z*)), 6.27 (dd, 1H, H-13^1), 5.30 (m, 1H, H-13^1), 4.48 (m, 2H, 13^2), 4.20 (m, 1H, H-18), 4.10 (m, 1H, H-17), 3.90 (q, 2H, H-8^1), 3.83, 3.72, 3.65, 3.40, 3.15 (5s, 12H, H-2^1, H-7^1, H-12^1, and H-17^4), 2.70 (m, 2H, H-17^1), 2.30 (m, 2H, H-17^2), 1.95 (d, 3H, H-18^1), 1.82 (t, 3H, H-8^2), −1.40 (br s, 1H, NH), −3.10 (br s, 1H, NH); LREIMS (*m/z*): 550 (M^+, 5%), 532 ($M^+ - H_2O$, 100%); LRFABMS (*m/z*): 551 ([M + H]$^+$, 100%); HREIMS, $C_{34}H_{36}N_4O_2$ ([M − H_2O]$^+$), calcd.: 532.2838; obsd.: 532.2828; HRFABMS, $C_{34}H_{39}N_4O_3$ ([M + H]$^+$), calcd.: 551.3021; obsd.: 551.3019.

*3-Vinyl-13^1-deoxo-phytoporphyrin methyl ester (**6**)*

13^1-Deoxo-13^1-hydroxypyropheophorbide *a* methyl ester (**7**) (105 mg, 0.191 mmol) was dissolved in dry DMF (50 mL) and the solution was stirred at 100°C under N_2. Benzoyl chloride (0.250 mmol) was added via a syringe and the reaction mixture (which turned red after 40 min) was stirred at this temperature for a further 120 min, at which time the UV–VIS spectrum indicated no more starting material. The reaction mixture was poured into ice-cooled 10% NaOH and the porphyrin was extracted with CH_2Cl_2. The organic layer was washed three times with water, and then dried over anhydrous Na_2SO_4, filtered, and evaporated. The residue was purified by flash chromatography on silica, eluting with CH_2Cl_2. The main band was collected, evaporated, and the residue was recrystallized from CH_2Cl_2–hexane to give the title compound (74.0 mg, 73% yield) as a purple solid; mp >300°C; UV–VIS λ_{max} (CH_2Cl_2): 404 nm (ε 161 300), 504 (15 900), 540 (7800), 566 (8300), 620 (5800); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.10 (s, 1H, H-10), 9.99 (s, 1H, H-5), 9.93 (s, 1H, H-20), 8.26 (dd, 1H, H-31, *J* = 17.9 and 11.6 Hz), 6.27 (dd, 1H, H-3^2(*E*), *J* = 17.9 and 1.7 Hz), 6.11 (dd, 1H, H-3^2(*Z*), *J* = 11.6 and 1.7 Hz), 5.20 (br s, 2H, H-13^2), 4.25 (t, 2H, H-17^1, *J* = 8.3 Hz), 4.10

(q, 2H, H-8^1, J = 7.1 Hz), 3.96 (br s, 2H, H-13^1), 3.78 (s, 3H, H-12^1), 3.65 (s, 6H, H-17^4 and H-7^1), 3.59 (s, 3H, H-18^1), 3.52 (s, 3H, H-2^1), 3.03 (t, 2H, H-17^2, J = 8.3 Hz), 1.86 (t, 3H, H-8^2, J = 7.1 Hz), −3.02 (br s, 1H, NH), −3.89 (br s, 1H, NH); LREIMS (*m/z*): 532 (M^+, 100%), 459 ($M^+ - CH_2COOMe$, 47%); HREIMS, $C_{34}H_{36}N_4O_2$ (M^+); calcd.: 532.2838, obsd.: 532.2835; Anal. calcd. for $C_{34}H_{36}N_4O_2$: C 76.66, H 6.81, N 10.52%; found: C 76.50, H 6.85, N 10.58%.

*Purpurin-7 trimethyl ester (**10**) (14, 18, 28)*

Pheophorbide *a* methyl ester (**5**) (1.09 g, 1.75 mmol) was dissolved in warm pyridine (25 mL) and the solution was diluted with ether (700 mL). The solution was stirred with a stream of air passing through it, and a solution of potassium hydroxide (11.5 g) in *n*-propanol (40 mL) was added. The bright-green mixture (containing precipitated KOH) was stirred and aerated for 30 min and then extracted with water (2 × 300 mL). The ethereal solution was discarded; the aqueous extracts were combined, acidified with concentrated H_2SO_4 (11.5 mL) in water (60 mL), and then extracted with methylene chloride (2 × 350 mL). The extracts were washed with water (350 mL) and immediately treated with an excess of ethereal diazomethane. The brownish-purple solution was left at room temperature for 10 min, and then evaporated in vacuo. Chromatography (alumina V) of the residue (elution with methylene chloride) gave a major band that was collected, evaporated, and subjected to preparative TLC separation on deactivated silica plates (elution with 0.5% MeOH in CH_2Cl_2) to give the desired product (660 mg, 58% yield) after crystallization from CH_2Cl_2–hexane, along with 35 mg of a unseparated mixture of purpurin-18 methyl ester (**12**) and purpurin-7 trimethyl ester (**10**) as the other products.

*3-Vinylrhodoporphyrin XV dimethyl ester (**9**) (18)*

Purpurin-7 trimethyl ester (**10**) (450 mg, 0.69 mmol) was heated in an oil bath at 180–185°C in 2,4,6-collidine (60 mL) for 2 h. After cooling, the solvent was evaporated at 0.5 Torr (1 Torr = 133.3 Pa) and the residue was recrystallized from $CHCl_3$–CH_3OH, giving the title porphyrin (295 mg, 76%) as purple needles; mp 266–267°C (lit. (18) mp 271–272.5°C); UV–VIS λ_{max} (CH_2Cl_2): 408 nm (ε 187 000), 514 (10 000), 552 (20 000), 576 (11 000), 636 (1600); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.81, 9.89, 9.82, 9.68 (4s, 4H, H-5, H-10, H-15, and H-20), 8.12 (dd, 1H, H-3^1, J = 18.4 and 11.8 Hz), 6.23 (dd, 1H, H-3^2(*E*), J = 18.4 and 1.6 Hz), 6.10 (dd, 1H, H-3^2(*Z*), J = 11.8 and 1.6 Hz), 4.42 (s, 3H, H-13^2), 4.30 (t, 2H, H-171, J = 8.0 Hz), 3.93 (q, 2H, H-8, J = 8.0 Hz), 3.84, 3.67, 3.52, 3.50, 3.48 (5s, 15H, H-2^1, H-7^1, H-12^1, H-18^1, and H-17^4), 3.23 (t, 2H, H-17^2, J = 8.0 Hz), 1.79 (t, 3H, H-8^2, J = 8.0 Hz), −4.50 (br s, 2H, NH); LREIMS (*m/z*): 564 (M^+, 100%); Anal. calcd. for $C_{34}H_{36}N_4O_4$: C 72.32, H 6.43, N 9.92%; found: C 71.98, H 6.45, N 9.65%.

Synthesis of [A,C]-divinylporphyrin 16 via purpurin 15

13^1-Deoxo-13^1-hydroxypheophorbide a *methyl ester (**20**)*

Pheophorbide *a* methyl ester (**5**) (100 mg, 0.16 mmol) was dissolved in 50 mL of pyridine–methanol solution (pyridine:methanol = 1:1) and the solution was stirred at room temperature. $NaBH_4$ (90 mg) was added and the reaction mixture was stirred for 2 h, at which time the UV–VIS spectrum indicated that the starting material had been consumed. The reaction mixture (bright green) was poured into cooled 2 N HCl and the chlorin was extracted with CH_2Cl_2. The green organic layer was carefully washed once with water, twice with saturated $NaHCO_3$, three times with water, and then dried over anhydrous Na_2SO_4, filtered, and evaporated. The residue was chromatographed on an alumina III column, eluting with 1% MeOH in CH_2Cl_2. The main band was collected, evaporated, and recrystallized from $CHCl_3$–hexane to give the required compound (83.7 mg, 86% yield) as a dark-green powder; mp 135-136°C; UV–VIS λ_{max} (CH_2Cl_2): 400 nm (ε 124 400), 498 (12 000), 656 (35 800); ^{1}H NMR (200 MHz, $CDCl_3$) δ (the major epimer): 9.84 (s, 1H, H-10), 9.60 (s, 1H, H-5), 8.88 (s, 1H, H-20), 8.20 (dd, 1H, H-3^1), 6.63 (dd, 1H, H-13^1), 6.34 (dd, 1H, H-3^2(*E*)], 6.18 (s, 1H, H-3^2(*Z*)), 5.90 (s, 1H, H-13^2), 4.60 (m, 1H, H-18), 4.45 (m, 1H, H-17), 3.81, 3.55, 3.55, 3.39, 3.22 (5s, 15H, H-2^1, H-7^1, H-12^1, H-13^4, and H-17^4), 3.80 (q, 2H, H-8^1), 2–2.70 (m, 4H, H-17^1 and H-17^2), 1.90 (d, 3H, H-18^1), 1.75 (t, 3H, H-8^2), −1.39 (br s, 1H, NH), −3.05 (br s, 1H, NH); LREIMS (*m/z*): 608 (M^+, 100%); HREIMS, $C_{36}H_{40}N_4O_5$ (M^+), calcd.: 608.2999; obsd.: 608.2993; Anal. calcd. for $C_{36}H_{40}N_4O_5$: C 71.03, H 6.62, N 9.20%; found: C 70.81, H 6.79, N 8.97%.

13^1-Deoxo-13^1,13^2-dehydropheophorbide a *methyl ester (**19**)*

13^1-Deoxo-13^1-hydroxypheophorbide *a* methyl ester (**20**) (50 mg, 0.0822 mmol) was dissolved in pyridine (20 mL) and the solution stirred at 0°C under N_2. Excess trifluoroacetylimidazole (150 mg) was added via a syringe and the reaction mixture was stirred for 5 mins. After addition of proton sponge (1.81 mmol), the reaction mixture was kept at 0°C for 30 min and then at 25°C for 3 h, at which time the UV–VIS spectrum indicated no more starting material. The reaction mixture (bright green) was poured into water and the chlorin was extracted with CH_2Cl_2. The green organic layer was washed three times with water, and then dried over anhydrous Na_2SO_4, filtered, and evaporated. The residue was chromatographed on a silica column eluting with CH_2Cl_2. The main band was collected, evaporated, and the residue was recrystallized from $CHCl_3$–MeOH to give the title compound (45.6 mg, 94% yield) as a dark-green powder; mp >300°C; UV–VIS λ_{max} ($CHCl_3$): 354 nm (ε 55 600), 434 (67 900), 586 (4100), 630 (11 600), 760 (4100), 820 (4100); ^{1}H NMR (400 MHz, 1.5 mg/0.6 mL $CDCl_3$) δ: 8.41(s, 1H, H-10), 8.33 (s, 1H, H-5), 7.42 (s, 1H, H-20), 7.42 (dd, 1H, H-3^1, J = 18.5 and 11.8 Hz), 7.19 (s, 1H, H-13^1), 6.01 [d, 1H, H-3^2(*E*), J = 18.5 Hz), 5.94 (d, 1H, H-3^2(*Z*), J = 11.8 Hz), 4.77 (d, 1H, H-17, J = 8.6 Hz), 3.93 (s, 3H, H-13^4), 3.77 (q, 1H, H-18, J = 8.5 Hz), 3.57 (s, 3H, H-17^4), 3.25 (q, 2H, H-8^1, J = 7.1 Hz), 2.96 (s, 3H, H-12^1), 2.91 (s, 3H, H-2^1), 2.80 (s, 3H, H-7^1), 2.44 (dd, 1H, H-17^1, J = 8.6 Hz), 2.20 (dd, 2H, H-17^2), 1.85 (dd, 1H, H-17^1), 1.69 (d, 3H, H-18^1, J = 8.5 Hz), 1.45 (t, 3H, H-8^2, J = 7.1 Hz); LREIMS (*m/z*): 590 (M^+, 100%); HREIMS, $C_{36}H_{38}N_4O_4$ (M^+); calcd.: 590.2893; obsd.: 590.2895; Anal. calcd. for $C_{36}H_{38}N_4O_4$: C 73.21, H 6.48, N 9.48%; found: C 72.73, H 6.53, N 9.21%.

*13^1-Deoxo-13^1-hydroxy-13^2*R*-hydroxypheophorbide* a *methyl ester (**21**)*

13^2*R*-Hydroxypheophorbide *a* methyl ester (**14**) (90% d.e.) (11, 14) (50 mg, 0.0803 mmol) was dissolved in 25 mL of

For personal use only.

pyridine–methanol solution (pyridine:methanol = 1:1) and the solution was stirred at room temperature. $NaBH_4$ (70 mg) was added and the reaction mixture was stirred for 3 h, at which time the UV–VIS spectrum indicated the absence of starting material. The reaction mixture was poured into ice-cooled 2 N HCl and the chlorin was extracted with CH_2Cl_2. The organic layer was carefully washed once with water, twice with saturated $NaHCO_3$, three times with water, and then dried over anhydrous Na_2SO_4, filtered, and evaporated. The residue was purified by flash chromatography on silica III, eluting with 1% MeOH in CH_2Cl_2. The main band was collected (44.5 mg, 89% yield) and was analyzed by ^{1}H NMR to be a diastereomeric mixture of 56% 13^1-deoxo-13^1*R*-hydroxy-13^2*R*-hydroxypheophorbide *a* methyl ester (**21***RR*) and 44% 13^1-deoxo-13^1*S*-hydroxy-13^2*R*-hydroxypheophorbide *a* methyl ester (**21***SR*). Further purification of this diastereomeric mixture (20 mg) by preparative TLC on silica (developed by 2% MeOH, 5% acetone in dichloromethane) gave the optically pure 13^1-deoxo-13^1*R*-hydroxy-13^2*R*-hydroxypheophorbide *a* methyl ester (**21***RR*) (100% d.e. from ^{1}H NMR) (8.5 mg) as a green solid after recrystallization from CH_2Cl_2–hexane; mp 180°C; UV–VIS λ_{max} (CH_2Cl_2): 400 nm (ε 114 100), 498 (10 700), 656 (33 700), 682 (6200); ^{1}H NMR (400 MHz, 1.4 mg/0.6 mL $CDCl_3$) δ: 9.80 (s, 1H, H-10), 9.65 (s, 1H, H-5), 8.80 (s, 1H, H-20), 8.20 (dd, 1H, H-3^1, *J* = 18.3 and 12.0 Hz), 6.42 (br s, 1H, OH-13^2), 6.33 (dd, 1H, H-3^2(*E*), *J* =18.3 and 1.4 Hz), 6.16 (dd, 1H, H-3^2(*Z*), *J* = 12.0 and 1.4 Hz), 5.60 (s, 1H, H-13^1), 4.93 (d, 1H, H-17, *J* = 8.2 Hz), 4.59 (q, 1H, H-18, *J* = 7.5 Hz), 4.48 (m, 2H, 13^2), 3.81 (q, 2H, H-8^1, *J* = 7.6 Hz), 3.57 (s, 3H, H-17^4), 3.55 (s, 3H, H-13^4), 3.54 (s, 3H, H-12^1), 3.53 (s, 3H, H-7^1), 3.38 (s, 3H, H-2^1), 2.45 (ddd, 1H, H-17^1), 2.32 (ddd, 1H, H-17^2), 2.10 (ddd, 1H, H-17^1), 1.96 (ddd, 1H, H-17^2), 1.74 (d, 3H, H-18^1, *J* = 7.5 Hz), 1.71 (t, 3H, H-8^2, *J* = 7.6 Hz), −1.40 (br s, 1H, NH), −3.10 (br s, 1H, NH); ^{13}C NMR (75 MHz, 12 mg/1.0 mL $CDCl_3$) δ: 176.03 (C-13^3), 173.81 (C-17^3), 167.27 (C-19), 163.05 (C-16), 150.59 (C-6), 150.48 (C-9), 143.18 (C-14), 142.49 (C-8), 139.81 (C-1), 138.18 (C-11), 136.49 (C-3), 135.63 (C-4), 134.48 (C-7), 132.21 (C-2), 129.88 (C-3^1), 128.83 (C-12), 128.41 (C-13), 121.56 (C-3^2), 108.87 (C-15), 99.75 (C-10), 99.29 (C-5), 95.00 (C-13^2), 93.46 (C-20), 82.41 (C-13^1), 53.32 (C-13^4), 51.57 (C-17^4), 50.98 (C-17), 49.95 (C-18), 30.66 (C-17^1), 29.33 (C-17^2), 23.54 (C-18^1), 19.64 (C-8^1), 17.71 (C-8^2), 12.31 (C-12^1), 11.43 (C-2^1), 11.43 (C-7^1); LREIMS (*m/z*): 624 (M^+, 38%); HREIMS, $C_{36}H_{40}N_4O_6$ (M^+), calcd.: 624.2948; obsd.: 624.2938; Anal. calcd. for $C_{36}H_{40}N_4O_6$: C 69.20, H 6.46, N 8.97%; found: C 68.97, H 6.44, N 8.70%.

*13-Decarboxy-13-formyl-purpurin-7 dimethyl ester (**15**)*

Method A: A solution of 13^1-deoxo-13^1,13^2-dehydropheophorbide *a* methyl ester (**19**) (20 mg, 0.0339 mmol) in CH_2Cl_2 (100 mL) was stirred in Vancouver sunlight for 20 min. Removal of solvent in vacuo and crystallization from CH_2Cl_2–hexane gave a brown powder of the aldehyde **15** (21 mg, 100% yield).

Method B: A solution of 13^2-deoxo-13^1-hydroxy-13^2*R*-hydroxypheophorbide *a* methyl ester (**21**) (31 mg, 0.05 mmol) in dioxane (20 mL) was stirred with an aqueous solution (20 mL) of periodic acid dihydrate (900 mg, 3.95 mmol) at room temperature for 20 h before the mixture was extracted with dichloromethane (2 × 40 mL). The organic layer was dried over sodium sulfate, filtered, and evaporated in vacuo. The residue was purified by flash chromatography on silica III, eluting with dichloromethane. Recrystallization from dichloromethane–hexane gave the title compound as a brown powder (24.8 mg, 80%); mp 216-217°C; UV–VIS λ_{max} (CH_2Cl_2): 414 nm (ε 113 200), 508 (7400), 544 (10 600), 630 (7000), 680 (35 400), 686 (31 700); ^{1}H NMR (400 MHz, 1.5 mg/0.6 mL $CDCl_3$) δ: 10.93 (s, 1H, H-13^1), 9.50 (s, 1H, H-10), 9.20 (s, 1H, H-5), 8.45 (s, 1H, H-20), 7.90 (dd, 1H, H-3^1, *J* = 18.2 and 11.9 Hz), 6.30 (d, 1H, H-3^2(*E*), *J* = 18.2 Hz), 6.11 (d, 1H, H-3^2(*Z*), *J* = 11.9 Hz), 4.48 (dd, 1H, H-17, *J* = 9.4 Hz), 4.28 (q, 1H, H-18, *J* = 9.0 Hz), 3.93 (s, 3H, H-12^1), 3.66 (s, 3H, H-17^4), 3.61 (q, 2H, H-8^1, *J* = 7.5 Hz), 3.52 (s, 3H, H-15^3), 3.30 (s, 3H, H-2^1), 3.13 (s, 3H, H-7^1), 2.35 (m, 1H, H-17^1), 2.10 (m, 2H, H-17^2), 1.80 (m, 1H, H-17^1), 1.73 (d, 3H, H-18^1, *J* = 9.0 Hz), 1.65 (t, 3H, H-8^2, *J* = 7.5 Hz), 0.2 (br s, 2H, NH); ^{13}C NMR (75 MHz, 15 mg/1.0 mL $CDCl_3$) δ: 186.83 (C-13^1), 184.92 (C-15^1), 174.85 (C-15^2), 173.30 (C-17^3), 168.22 (C-19), 163.28 (C-16), 157.05 (C-6), 149.12 (C-9), 145.98 (C-14), 143.24 (C-8), 140.40 (C-1), 137.34 (C-11), 136.62 (C-3), 135.97 (C-4), 134.20 (C-7), 131.90 (C-2), 129.56 (C-12), 124.36 (C-13), 128.57 (C-3^1), 122.89 (C-3^2), 106.90 (C-5), 105.80 (C-15), 100.45 (C-10), 93.74 (C-20), 53.27 (C-17), 52.63 (C-15^3), 51.53 (C-17^4), 49.71 (C-18), 31.44 (C-17^2), 30.93 (C-17^1), 22.78 (C-18^1), 19.40 (C-8^1), 17.47 (C-8^2), 11.90 (C-12^1), 11.39 (C-2^1), 11.06 (C-7^1); LREIMS (*m/z*): 622 (M^+, 15%), 563 (M^+ − COOMe, 27%), 535 (M^+ − COOMe − CO, 27%); HREIMS, $C_{36}H_{38}N_4O_6$ (M^+), calcd.: 622.2791; obsd.: 622.2786; Anal. calcd. for $C_{36}H_{38}N_4O_6$: C 69.44, H 6.15, N 9.00%; found: C 69.11, H 5.93, N 8.92%.

*13-Decarboxy-13-formyl-3-vinylrhodoporphyrin XV methyl ester (**17**)*

Purpurin **15** (150 mg, 0.24 mmol) was heated in an oil bath at 180–185°C in 2,4,6-collidine (30 mL) for 45 min. After cooling, the solvent was evaporated at 0.5 Torr and the residue was recrystallized from $CHCl_3$–CH_3OH, giving the title porphyrin (19.3 mg, 15% yield) as purple needles; mp 245–246°C; UV–VIS λ_{max} (CH_2Cl_2): 414 nm (ε 189 000), 518 (9000), 560 (21 400), 582 (15 300), 636 (2500); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 11.40 (s, 1H, 13-CHO), 10.70, 9.92, 9.88, 9.76 (4s, 4H, H-5, H-10, H-15, and H-20), 8.15 (dd, 1H, H-3^1, *J* = 17.5 and 11.0 Hz), 6.29 (dd, 1H, H-3^2(*E*), *J* = 17.5 and 1.0 Hz), 6.15 (dd, 1H, H-3^2(*Z*), *J* = 11.0 and 1.0 Hz), 4.37 (t, 2H, H-17^1, *J* = 7.5 Hz), 4.00 (q, 2H, H-8^1, *J* = 8.3 Hz), 3.80, 3.69, 3.58, 3.58, 3.58 (5s, 15H, H-2^1, H-7^1, H-12^1, H-18^1, and H-17^4), 3.23 (t, 2H, H-17^2, *J* = 7.5 Hz), 1.80 (t, 3H, H-8^2, *J* = 8.3 Hz), −4.50 (br s, 2H, NH); LREIMS (*m/z*): 534 (M^+, 100%); HREIMS, $C_{33}H_{34}N_4O_3$ (M^+); calcd.: 534.2631; obsd.: 534.2634.

*13-Decarboxy-13-(ethyleneacetal)-purpurin-7 dimethyl ester (**22**)*

The foregoing purpurin **15** (20 mg, 0.032 mmol) in dry THF (50 mL) under nitrogen was stirred in a three-necked round-bottom flask equipped with a Soxhlet apparatus containing 4Å molecular sieves. Ethylene glycol (0.9 mL) and *p*-toluenesulfonic acid (2 mg) were added to the solution and the reaction mixture was brought to reflux. Progress of the reac-

For personal use only.

tion was followed by spectrophotometry, using the change in absorption spectrum from λ_{max} = 686 nm to λ_{max} = 660 nm; the reaction was complete after 1 h. The mixture was diluted with methylene chloride (50 mL), washed with water (3 × 50 mL), dried over Na_2SO_4, and evaporated to dryness. The residue was chromatographed on alumina V (elution with methylene chloride) to give the principal green band. Removal of solvent in vacuo and recrystallization from CH_2Cl_2–hexane gave a dark-green powder of the title acetal **22** (19.2 mg, 90% yield); mp 265°C; UV–VIS λ_{max} (CH_2Cl_2): 400 nm (ε 149 000), 496 (13 000), 606 (5000), 660 (39 000); ^{1}H NMR (400 MHz, 1.5 mg/0.6 mL $CDCl_3$) δ: 10.93 (s, 1H, H-13^1), 9.75 (s, 1H, H-10), 9.68 (s, 1H, H-5), 8.80 (s, 1H, H-20), 8.12 (dd, 1H, H-3^1, *J* = 18.3 and 11.7 Hz), 6.33 (d, 1H, H-3^2(*E*), *J* = 18.3 Hz), 6.15 (d, 1H, H-3^2(*Z*), *J* = 11.7 Hz), 4.70 (m, 1H, 13^1-OCH_2OCH_2), 4.40 (q, 1H, H-18, *J* = 7.3 Hz), 4.18 (dd, 1H, H-17, *J* = 13.3 and 3.6 Hz), 4.06 (s, 3H, 15^1-$COOCH_3$), 4.01 (m, 3H, 13^1-OCH_2OCH_2), 3.79 (q, 2H, H-8^1, *J* = 7.56 Hz), 3.59 (s, 3H, H-17^4), 3.50 (s, 3H, H-12^1), 3.44 (s, 3H, H-2^1), 3.33 (s, 3H, H-7^1), 2.38 (m, 1H, H-17^1), 2.20 (m, 1H, H-17^2), 1.89 (m, 1H, H-17^1), 1.82 (d, 3H, H-18^1, *J* = 7.3 Hz), 1.80 (m, 1H, H-17^2), 1.73 (t, 3H, H-8^2, *J* = 7.6 Hz), −1.85 (br s, 1H, NH), −2.03 (br s, 1H, NH); LREIMS (*m/z*): 666 (M^+, 100%); HREIMS, $C_{38}H_{42}N_4O_7$ (M^+), calcd.: 666.3053; obsd.: 666.3061.

13-Decarboxy-3,13-divinylrhodoporphyrin XV methyl ester (16)

Method A: 13-Decarboxy-13-formyl-3-vinylrhodoporphyrin XV methyl ester (**17**) (18 mg, 0.0337 mmol) was dissolved in methylene chloride (10 mL), and a saturated solution of $Zn(OAc)_2$ in methanol (0.5 mL) was added. The resulting solution was stirred at room temperature for 3 h, at which time TLC and UV–VIS spectroscopy showed full conversion to the desired compound. The solvent was removed by evaporation in vacuo and the product was redissolved in methylene chloride, filtered through a short bed of alumina V, and evaporated to dryness. The Zn(II) porphyrin was further dried, under vacuum, at 0.5 Torr, for 4 h.

Dry methyltriphenylphosphonium bromide (30 mg, 0.084 mmol) in dry THF (25 mL) and diisopropylamine (0.5 mL) were treated with *n*-butyllithium in *n*-hexane (50 mL, 1.6 M). The resulting ylide was stirred at 0°C under nitrogen gas and a THF solution (10 mL) of the above Zn(II) porphyrin was added via a cannula. After 30 min the solution was evaporated to dryness to give a residue that was taken into methylene chloride (30 mL), filtered through anhydrous sodium sulfate, and then evaporated again to dryness. The residue was dissolved in trifluoroacetic acid (3 mL) and washed twice with water (30 mL). The organic phase was evaporated to dryness and the residue was chromatographed on alumina III (elution with methylene chloride). The red eluates were evaporated to dryness to furnish a residue that was recrystallized from $CHCl_3$–hexane to give the title porphyrin (12.6 mg, 71%) as a purple-red powder.

Method B: The foregoing hydroxyporphyrin **27** (55 mg, 0.1 mmol) was dissolved in dry DMF (20 mL) and stirred at 105°C under nitrogen. Benzoyl chloride (1 mL) was added to this solution via a syringe and the mixture was kept at this temperature for 2 h. The solution was then diluted with methylene chloride (100 mL), and successively washed with 2 M sodium hydroxide (75 mL) and water (2 × 100 mL). The organic layer was dried over $MgSO_4$, filtered, and evaporated in vacuo. The residue was chromatographed on silica III (elution with methylene chloride) to give a major red band. The appropriate fractions were collected, evaporated, and recrystallized from CH_2Cl_2–hexane to give the title divinylporphyrin **16** (31.9 mg, 60%) as a purple-red solid. This material was found identical to the compound prepared from the Wittig reaction of 13-formylporphyrin **17**; mp 227°C; UV–VIS λ_{max} (CH_2Cl_2): 404 nm (ε 108 000), 506 (7500), 544 (9800), 572 (5600), 630 (1500); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.16, 10.15, 10.08, 10.07 (4s, 4H, H-5, H-10, H-15, and H-20), 8.27 (dd, 2H, H-3^1 and H-13^1), 6.33 (dd, 2H, H-3^2(*E*) and H-13^2(*E*)), 6.15 (dd, 2H, H-3^2(*Z*) and H-13^2(*Z*)), 4.42 (t, 2H, H-17^1, *J* = 7.6 Hz), 4.10 (q, 2H, H-8^1, *J* = 7.5 Hz), 3.69, 3.67, 3.66, 3.65, 3.63 (5s, 15H, H-2^1, H-7^1, H-12^1, H-18^1, and H-17^4), 3.26 (t, 2H, H-17^2, *J* = 7.6 Hz), 1.86 (t, 3H, H-8^2, *J* = 7.5 Hz), −3.75 (br s, 2H, NH); LRFABMS (*m/z*): 533 (M^+, 100%); HRFABMS, $C_{34}H_{37}N_4O_2$ (M^+); calcd.: 533.2916; obsd.: 533.2916.

Synthesis of [A,C]-divinylporphyrin 16 via porphyrin 9

3-Vinylrhodoporphyrin XV methyl ester (23) (21)

Vinylrhodoporphyrin XV dimethyl ester (**9**) (850 mg) in warm pyridine (175 mL) was refluxed for 4 h with a solution of potassium hydroxide (20 g) in water (25 mL) and methanol (150 mL). The solution was cooled, diluted with ice-water (1 L), acidified with concentrated sulfuric acid (15 mL) in water (100 mL), and then stirred for 10 min. The precipitated porphyrin diacid was filtered onto Celite, and washed with warm water followed by dry methanol. A mixture of dry methanol (650 mL) and concentrated sulfuric acid (20 mL) was passed slowly through the bed of Celite, thereby dissolving the porphyrin, and the resultant solution was kept at room temperature in the dark for 16 h before addition to water (1.5 L). The porphyrin was extracted with methylene chloride (3 × 500 mL) and the extracts were washed with water (1 L), dried over anhydrous $MgSO_4$, and evaporated. The residue was recrystallized from THF–benzene to give the title porphyrin monocarboxylic acid (605 mg, 70%) as a dark-red powder; mp >300°C (lit. (21) mp >300°C); UV–VIS λ_{max} (CH_2Cl_2): 408 nm (ε 154 000), 514 (7900), 554 (16 300), 578 (9500) (lit. (21) λ_{max} (pyridine): 409 nm (ε 189 000), 511(10 000), 552 (17 200), 579 (9200); λ_{max} ($CHCl_3$–HCl): 427 nm (ε 206 000), 569 (12 000), 620 (12 900); λ_{max} (0.1 M NaOMe – MeOH): 399 nm (ε 146 000), 503 (10 500), 550 (12 000), 572 (6700), 624 (1900)); ^{1}H NMR (400 MHz, CF_3COOD) δ: 11.90, 11.20, 11.00, 10.95 (4s, 4H, H-5, H-10, H-15, and H-20), 8.28 (dd, 1H, H-3^1, *J* = 18.3 and 11.0 Hz), 6.65 (d, 1H, H-3^2(*Z*), *J* = 11.0 Hz), 6.40 (d, 1H, H-3^2(*E*), *J* = 18.3 Hz), 4.62 (t, 2H, H-17^1), 4.25 (q, 2H, H-8^1), 4.19, 3.80, 3.78, 3.76, 3.72 (5s, 15H, H-2^1, H-7^1, H-12^1, H-18^1, and H-17^4), 3.40 (t, 2H, H-17^2), 1.82 (t, 3H, H-8^2); LREIMS (*m/z*): 550 (M^+, 100%), 506 ($M^+ - CO_2$, 30%); HREIMS, $C_{33}H_{34}N_4O_4$ (M^+), calcd.: 550.2580; obsd.: 550.2580; Anal. calcd. for $C_{33}H_{34}N_4O_4$: C 71.98, H 6.22, N 10.17%; found: C 71.93, H 6.16, N 9.86%.

*13-Imidazoyl-3-vinylrhodoporphyrin XV methyl ester (**24**)*

A mixture of 3-vinylrhodoporphyrin XV methyl ester (**23**) (600 mg, 1.09 mmol) and *N,N'*-carbonyldiimidazole (600 mg) was refluxed for 30 min in THF (125 mL). The solution was evaporated to about 60 mL and then applied to a short alumina column (Brockman Grade V; elution with methylene chloride). The appropriate eluates were evaporated and the residue was recrystallized from CH_2Cl_2–benzene to give the title porphyrin (595 mg, 91%) as a dark-red powder; mp 239°C; UV–VIS λ_{max} (CH_2Cl_2): 408 nm (ε 160 000), 514 (6900), 554 (15 300), 574 (9900); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.01, 9.97, 9.88, 9.70 (4s, 4H, H-5, H-10, H-15, and H-20), 8.38 (s, 1H, H-imidazole), 8.12 (dd, 1H, H-3^1, J = 17.5 and 12.0 Hz), 7.95 (s, 1H, H-imidazole), 7.35 (s, 1H, H-imidazole), 6.29 (dd, 1H, H-3^2(*E*), J = 17.5 and 1.5 Hz), 6.15 (dd, 1H, H-3^2(*Z*), J = 17.5 and 1.5 Hz), 4.25 (t, 2H, H-17^1, J = 8.1 Hz), 4.00 (q, 2H, H-8^1, J = 8.0 Hz), 3.67, 3.65, 3.55, 3.53, 3.51 (5s, 15H, H-2^1, H-7^1, H-12^1, H-18^1, and H-17^4), 3.18 (t, 2H, H-17^2, J = 8.1 Hz), 1.80 (t, 3H, H-8^2, J = 8.0 Hz), −4.30 (br s, 2H, NH); LRFABMS (*m/z*): 601 ([M + H]$^+$, 73%), 533 (M$^+$ − C_3H_3N2, 100%); LREIMS (*m/z*): 533 (M$^+$ − $C_3H_3N_2$, 100%); HRFABMS, $C_{36}H_{37}N_6O_3$ ([M + H]$^+$); calcd.: 601.2927; obsd.: 601.2929; HREIMS, $C_{33}H_{33}N_4O_3$ (M$^+$ − $C_3H_3N_2$): calcd.: 533.2552; obsd.: 533.2551.

*13-Decarboxy-13-methoxycarbonylacetyl-3-vinylrhodoporphyrin XV methyl ester (**25**) (21)*

A solution of 2-PrMgBr was prepared by refluxing, under dry nitrogen, a mixture of Mg turnings (1.2 g) and 2-PrBr (4 g) in freshly distilled THF (150 mL). When the metal had dissolved, the solution was cooled to 0°C and redistilled methyl hydrogen malonate (23) (3 g) in dry THF (30 mL) was added via a cannula. The mixture was warmed to 65°C and stirred for 10 min before introduction of a solution of 13-imidazoyl-3-vinylrhodoporphyrin XV methyl ester (**24**) (400 mg) in dry THF (200 mL). Stirring was maintained for 2.5 h while heating under reflux, and glacial acetic acid (15 mL) was then added. Heating and stirring were continued for a further 15 min, after which the mixture was diluted with chloroform (1400 mL), washed with 0.1 M HCl (1100 mL) and water (2 × 800 mL), and then dried over anhydrous Na_2SO_4 and evaporated to dryness. The residue was chromatographed on alumina V (elution with 5% acetone in methylene chloride) and after evaporation of the appropriate eluates the product was recrystallized from CH_2Cl_2–hexane to give the required porphyrin-β-ketoester **25** (280 mg, 70%) as a dark-red solid; mp 270–274°C (lit. (21) mp 250–254°C); UV–VIS λ_{max} (CH_2Cl_2): 410 nm (ε 140 000), 512 (7400), 552 (14 000), 576 (9200) (lit. (21) λ_{max} (CH_2Cl_2): 409 nm (ε 176 000), 512 (7200), 553 (15 400), 574 (9900), 635 (1300); λ_{max} (CH_2Cl_2–CF_3COOH): 412 nm (ε 267 000), 559 (12 200), 608 (8600); λ_{max} (0.1 M NaOMe – MeOH): 401 nm (ε 154 000), 504 (10 500), 542 (12 400), 572 (6900), 625 (2200)); ^{1}H NMR (400 MHz, $CDCl_3$) δ (the enol tautomer): 13.30 (s, 1H, OH), 10.62, 10.62, 10.42, 9.75 (4s, 4H, H-5, H-10, H-15, and H-20), 6.10 (s, 1H, H-13^2); δ (the ketone tautomer): 9.98, 9.97, 9.86, 9.85 (4s, 4H, H-5, H-10, H-15, and H-20), 4.70 (s, 2H, H-13^2); δ (their mixture): 8.10 (m, 1H, H-3^1), 6.25 (m, 1H, H-3^2(*E*)), 6.12 (m, 1H, H-3^2(*Z*)), 4.41 (t, 2H, H-17^1), 3.98 (q, 2H, H-8^1), 4.02–3.45 (6s, 18H, H-2^1, H-7^1, H-12^1, H-18^1, H-17^4, and 13^2-$COOCH_3$), 3.25 (t, 2H, H-17^2), 1.83 (t, 3H, H-8^2), −4.26 (br s, 1H, NH), −4.30 (br s, 1H, NH); LRFABMS (*m/z*): 607 ([M + H]$^+$, 16%); HRFABMS, $C_{36}H_{39}N_4O_5$ ([M + H]$^+$); calcd.: 607.2920; obsd.: 607.2919.

*13-Acetyl-13-decarboxy-3-vinylrhodoporphyrin XV methyl ester (**26**)*

A mixture of porphyrin-β-ketoester **25** (180 mg, 0.297 mmol), 4-(dimethylamino)pyridine (36 mg, 2.92 mmol), 1.0 M phosphate buffer (pH = 7) (40 mL), and toluene (150 mL) was stirred at 90°C for 12 h, at which time TLC analysis showed the full disappearance of the porphyrin-β-ketoester band and appearance of a more mobile red band. The reaction mixture was extracted with ethyl acetate (250 mL) and the organic layer was washed once with saturated NH_4Cl, twice with water (200 mL), dried over $MgSO_4$, filtered, and evaporated. The residue was chromatographed on silica III (elution with methylene chloride) to give a major red band. The appropriate eluates were evaporated and the residue was recrystallized from CH_2Cl_2–hexane to give the title acetylporphyrin (122 mg, 75%) as purple-red small leaves; mp 284°C; UV–VIS λ_{max} (CH_2Cl_2): 410 nm (ε 147 000), 514 (7400), 554 (13 800), 576 (8600), 608 (1300); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.75, 10.10, 10.07, 9.98 (4s, 4H, H-5, H-10, H-15, and H-20), 8.20 (dd, 1H, H-3^1, J = 17.4 and 12.5 Hz), 6.30 (d, 1H, H-3^2(*E*), J = 17.4 Hz), 6.12 (d, 1H, H-3^2(*Z*), J = 12.5), 4.43 (t, 2H, H-17^1, J = 7.5 Hz), 4.09 (q, 2H, H-8^1, J = 8.8 Hz), 3.88, 3.67, 3.65, 3.61, 3.61 (5s, 15H, H-2^1, H-7^1, H-12^1, H-18^1, and H-17^4), 3.33 (t, 2H, H-17^2, J = 7.5 Hz), 3.32 (s, 3H, H-13^2), 1.85 (t, 3H, H-8^2, J = 8.8 Hz), −3.80 (br s, 2H, NH); LRFABMS (*m/z*): 549 ([M + H]$^+$, 100%); HRFABMS, $C_{34}H_{36}N_4O_3$ ([M + H]$^+$); calcd.: 549.2865; obsd.: 549.2861.

*13-Decarboxy-13-(α-hydroxy)ethyl-3-vinylrhodoporphyrin XV methyl ester (**27**)*

To a mixture of the foregoing porphyrin **26** (100 mg, 0.182 mmol) in methylene chloride (80 mL) and methanol (15 mL) was added sodium borohydride (80 mg). The mixture was stirred for 90 min at room temperature, after which time TLC monitoring indicated reduction of the acetyl group to be complete. The reaction was quenched by slow addition of ice-cooled 1 M HCl. The organic layer was separated, washed twice with water, dried over $MgSO_4$, filtered, and evaporated. The residue was chromatographed on silica V (elution with 0.5% methanol in methylene chloride) to give a major red band. The appropriate eluates were evaporated and the residue was recrystallized from CH_2Cl_2–hexane to give the title hydroxyporphyrin (82 mg, 82%) as a purple solid; mp 219°C; UV–VIS λ_{max} (CH_2Cl_2): 404 nm (ε 178 000), 502 (10 600), 540 (12 000), 572 (9300), 624 (2700); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.18, 10.00, 9.88, 9.88 (4s, 4H, H-5, H-10, H-15, and H-20), 8.20 (dd, 1H, H-3^1, J = 17.1 and 11.4 Hz), 6.31 (dd, 1H, H-3^2(*E*), J = 17.1 and 1.9 Hz), 6.15 (dd, 1H, H-3^2(*Z*), J = 12.5 and 1.9 Hz), 4.27 (t, 2H, H-17^1, J = 8.5 Hz), 4.00 (q, 2H, H-8^1, J = 8.2 Hz), 3.58, 3.58, 3.54, 3.51, 3.49 (5s, 15H, H-2^1, H-7^1, H-12^1, H-18^1, and H-17^4), 3.45 (q, 1H, H-13^1, J = 7.0 Hz), 3.16 (t, 2H, H-17^2, J = 8.5 Hz), 2.72 (br s, 1H, OH-13^1), 2.14 (d, 3H, H-13^2, J = 7.0 Hz), 1.81 (t, 3H, H-8^2, J = 8.2 Hz), −4.30 (br s, 2H, NH); LRFABMS (*m/z*): 551 ([M + H]$^+$, 100%); HRFABMS, $C_{34}H_{39}N_4O_3$ ([M + H]$^+$): calcd.: 551.3022; obsd.: 551.3011.

Diels–Alder reactions with vinylporphyrins

*$2^1,2^2$-Bis(methoxycarbonyl)-8-ethyl-13-methoxycarbonyl-17-methoxycarbonylethyl-2,7,12,18-tetramethyl-2^3-hydrobenzo[*b*]porphyrin (**28**)*

3-Vinylrhodoporphyrin XV dimethyl ester (**9**) (57 mg, 0.1 mmol) and DMAD (710 mg, 5 mmol) were suspended in degassed toluene (N_2) (20 mL) and the mixture heated at 110°C for 28 h. After removal of the toluene in vacuo, the residue was chromatographed on silica (methylene chloride eluant). After elution of the excess dienophile, the solvent polarity was increased to 2% methanol in methylene chloride to elute the major reaction product. After evaporation to dryness, the residue was recrystallized from CH_2Cl_2–hexane to afford the 1,4-cyclohexadiene adduct **28** as a green solid (35 mg, 50% yield); mp 244-245°C; UV–VIS λ_{max} (CH_3COCH_3): 410 nm (peak ratio, 1.40), 516 (0.119), 646 (0.138); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.75, 9.80, 9.25, 9.01 (4s, 4H, H-5, H-10, H-15, and H-20), 7.40 (dd, 1H, H-3^1, J = 7.4 and 2.1 Hz), 4.31 (t, 2H, H-17^1, J = 8.3 Hz), 3.95 (dd, 1H, H-2^3, J = 3.0 and 0.5), 3.94 (q, 2H, H-8^1, J = 7.5 Hz), 3.62 (s, 1H, H-2^3, J = 3.3 and 0.5 Hz), 3.25 (t, 2H, H-17^2, J = 8.3 Hz), 4.33, 4.02, 3.89, 3.75, 3.69, 3.45, 3.41 (7s, 21H, H-7^1, H-12^1, H-18^1, H-17^4, 2^1-$COOCH_3$, and 2^2-$COOCH_3$), 2.07 (s, 3H, 2-CH_3), 1.78 (t, 3H, H-8^2, J = 7.5 Hz), −2.26 (br s, 1H, NH), −2.30 (br s, 1H, NH); LREIMS (*m/z*): 706 (M^+, 100%), 690 ($M^+ - CH^4$, 60%).

*$2^1,2^2$-Bis(methoxycarbonyl)-8-ethyl-13-methoxycarbonyl-17-methoxycarbonylethyl-2,7,12,18-tetramethyl-2^1-hydrobenzo[*b*]porphyrin (**29**)*

The adduct **28** (32 mg, 0.045 mmol) was dissolved in methylene chloride and a few drops of DBU were added. The reaction mixture was stirred in the dark and monitored by visible spectroscopy (complete in 4 h). The mixture was poured into 1 M HCl and extracted with methylene chloride. The organic layer was washed twice with brine, once with water, and dried over anhydrous magnesium sulfate. The solvent was evaporated in vacuo and the compound was chromatographed on silica gel (1% MeOH in CH_2Cl_2 eluent). The pure 1,3-cyclohexadiene fraction was evaporated in vacuo yielding 29 mg (90% yield) of tiny dark-green needles after recrystallization from CH_2Cl_2–hexane; mp 248–249°C; UV–VIS λ_{max} (CH_2Cl_2): 356 nm (ε 27 000), 440 (70 400), 592 (19 900), 672 (14 600); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.70, 9.80, 9.30, 8.90 (4s, 4H, H-5, H-10, H-15, and H-20), 7.80 (d, 1H, H-2^4, J = 6.0 Hz), 7.42 (d, 1H, H-2^3, J = 6.0 Hz), 5.40 (s, 1H, H-2^1), 4.29 (t, 2H, H-17^1, J = 7.7 Hz), 3.92 (q, 2H, H-8^1, J = 7.9 Hz), 3.25 (t, 2H, H-17^2, J = 7.7 Hz), 4.34, 3.98, 3.75, 3.70, 3.43, 3.40, 2.98 (7s, 21H, H-7^1, H-12^1, H-18^1, H-17^4, 2^1-$COOCH_3$, and 2^2-$COOCH_3$), 1.79 (s, 3H, 2-CH_3), 1.76 (t, 3H, H-8^2, J = 7.9 Hz), −1.95 (br s, 1H, NH), −2.00 (br s, 1H, NH); LREIMS (*m/z*): 706 (M^+, 100%); HREIMS, $C_{40}H_{42}N_4O_8$ (M^+); calcd.: 706.3002, obsd.: 706.3010; Anal. calcd. for $C_{40}H_{42}N_4O_8$: C 67.97, H 5.99, N 7.93%; found: C 68.03, H 5.96, N 7.92%.

*$2^1,2^2$-Bis(methoxycarbonyl)-13,15-ethano-8-ethyl-17-methoxycarbonylethyl-2,7,12,18-tetra-methyl-2^1-hydrobenzo[*b*]porphyrin (**30**)*

3-Vinylporphyrin **6** (27 mg, 0.05 mmol) and DMAD (360 mg, 25 mmol) were suspended in degassed toluene (N_2) (20 mL) and the mixture was heated at 110°C for 30 h. After removal of the toluene in vacuo, the residue was chromatographed on silica (methylene chloride eluant). After elution of the excess dienophile, the solvent polarity was increased to 2% methanol in methylene chloride to elute the major reaction product. After evaporation to dryness, 14 mg (42% yield) of the 1,4-cyclohexadiene adduct **31** (λ_{max} = 404, 550, 650 nm) was obtained.

The adduct **31** (14 mg, 0.02 mmol) was dissolved in methylene chloride and a few drops of DBU were added. The reaction mixture was stirred in the dark and monitored by visible spectroscopy (completed in 6 h). The mixture was poured into 1 M HCl and extracted with methylene chloride. The organic layer was washed twice with brine, once with water, and dried over anhydrous magnesium sulfate. The solvent was evaporated in vacuo and the compound was chromatographed on silica gel (1% MeOH in CH_2Cl_2 eluent). The pure 1,3-cyclohexadiene fraction was evaporated in vacuo, yielding 12.7 mg (91% yield) of tiny dark-green needles after recrystallization from CH_2Cl_2–hexane; mp 258°C; UV–VIS λ_{max} (CH_2Cl_2): 354 nm (ε, 86 000), 438 (120 000), 580 (18 000), 620 (14 000), 680 (47 000), 686 (37 000); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 9.59 (s, 1H, H-10), 9.30 (s, 1H, H-5), 8.95 (s, 1H, H-20), 7.83 (d, 1H, H-2^4, J = 5.8 Hz), 7.45 (d, 1H, H-2^3, J = 5.8 Hz), 5.20 (t, 2H, H-13^2), 5.05 (s, 1H, H-2^1), 4.30 (m, 2H, H-17^1), 3.93 (m, 2H, H-13^1), 3.93 (q, 2H, H-8^1, J = 7.9 Hz), 3.10 (t, 2H, H-17^2), 3.97, 3.78, 3.46, 3.42, 3.39, 2.92 (6s, 18H, H-7^1, H-12^1, H-18^1, H-17^4, 2^1-$COOCH_3$, and 2^2-$COOCH_3$), 1.78 (t, 3H, H-8^2, J = 7.9 Hz), 1.77 (s, 3H, 2-CH_3), −1.42 (br s, 1H, NH), −2.22 (br s, 1H, NH); LRFABMS (*m/z*): 675 ($[M + H]^+$, 100%); HRFABMS, $C_{40}H_{43}N_4O_6$ ($[M + H]^+$); calcd. 675.3182; obsd.: 675.3176.

*$2^1,2^2,12^1,12^2$-Tetrakis(methoxycarbonyl)-8-ethyl-17-methoxycarbonylethyl-2,7,12,18-tetramethyl-$2^3,12^3$-dihydrobenzo[*b*,*l*]porphyrin (**32**)*

The foregoing 3,13-divinylporphyrin **16** (30 mg, 0.0564 mmol) and DMAD (800 mg, 5.6 mmol) were suspended in degassed toluene (N2) (20 mL) and the mixture heated at 110°C for 80 h. After removal of the toluene in vacuo, the residue was chromatographed on silica (methylene chloride eluant). After elution of the excess dienophile, the solvent polarity was increased to 2% methanol in methylene chloride to elute the major reaction product. After evaporation to dryness, the resulting residue was subjected to preparative TLC on silica (1 mm thick plate; elution with 2% methanol in methylene chloride). The more mobile band was found to be the mono-adduct (exhibiting a band at 656 nm), present in a trace amount; the major band was found to be the bis-adduct, which was recrystallized from CH_2Cl_2–hexane to afford the bis-adduct **32** as a green solid (10.8 mg, 25% yield); mp 198°C; UV–VIS λ_{max} (CH_3COCH_3): 406 nm (peak ratio, 1.10), 484 (0.21), 538 (0.15), 666 (0.13), 720 (0.338); LREIMS (*m/z*): 816 (M^+, 100%).

*$2^1,2^2,12^1,12^2$-Tetrakis(methoxycarbonyl)-8-ethyl-17-methoxycarbonylethyl-2,7,12,18-tetra-methyl-$2^1,12^1$-dihydrobenzo[*b*,*l*]porphyrin (**33**)*

The bis-adduct **32** (9 mg, 0.011 mmol) was dissolved in methylene chloride and a few drops of DBU were added. The reaction mixture was stirred in the dark and monitored by visible spectroscopy (completed in 16 h). The mixture was poured

FTIR spectroscopic investigation of matrix-isolated isomerization and decomposition products of ionized acetone: generation and characterization of 1-propen-2-ol

Xiaokui K. Zhang, J. Mark Parnis, Errol G. Lewars, and Raymond E. March

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12

Abstract: An electron bombardment – matrix isolation apparatus was used to generate and isolate products from acetone isomerization and decomposition for infrared spectroscopic examination. Bombardment of a dilute acetone/argon gas mixture (1:400) above a 12 K matrix isolation substrate leads to the direct observation of neutral fragmentation and isomerization products. A major product is 1-propen-2-ol, the enolic tautomer of acetone, whose IR absorption spectrum, and that of its perdeutero analog, are interpreted with the aid of ab initio computations. The observation of matrix-isolated decomposition products of acetone such as acetyl radicals, ketene, methane, and CH_3· is interpreted in terms of ion and neutral decomposition processes occurring in the gas phase above the matrix surface and during matrix condensation. The detection of matrix-isolated 1-propen-2-ol is consistent with a process involving acetone ionization, isomerization, neutralization, and stabilization, an approach that may have general utility in the generation of other thermodynamically unfavourable neutral isomers of organic molecules.

Key words: enol, isomerization, acetone, infrared, ionization, 1-propen-2-ol.

Résumé : On a utilisé un appareil de bombardement électronique avec isolement dans une matrice pour générer et isoler les produits d'isomérisation et de décomposition de l'acétone à des fins d'études par spectroscopie infrarouge. Le bombardement d'un mélange gazeux dilué d'acétone dans l'argon (1 : 400) au-dessus d'un substrat matriciel d'isolement maintenu à 12 K permet d'observer directement la fragmentation neutre et les produits d'isomérisation. Un des produits majeurs est le prop-1-én-2-ol, le tautomère énolique de l'acétone, dont le spectre d'absorption IR et celui de son analogue perdeutéré ont pu être interprétés à l'aide de calculs ab initio. L'observation de produits de décomposition l'acétone, comme les radicaux acétyles, le cétène, le méthane et le radical CH_3·, isolés dans une matrice peut être interprétée en fonction de processus de décompositions neutres et ioniques se produisant en phase gazeuse au-dessus de la surface matricielle et au cours de la condensation de la matrice. La détection de prop-1-én-2-ol isolé dans la matrice est en accord avec un processus impliquant l'ionisation, l'isomérisation, la neutralisation et la stabilisation de l'acétone, une approche qui peut être d'une utilité générale pour la production d'autres isomères neutres, thermodynamiquement défavorisés, de molécules organiques.

Mots clés : énol, isomérisation, acétone, infrarouge, ionisation, prop-1-én-2-ol.

Introduction

The investigation of decomposition and isomerization processes that follow the ionization of gaseous molecules is one of the central and fundamental foci of mass spectrometry. Due to the ease with which they may be detected and manipulated, ionic products generated in the ionization process have been, in general, the predominant source of information used in the investigation of the structure and decomposition mechanisms of precursor molecules. In contrast, investigation of neutral products of ion fragmentation processes cannot be carried out directly by mass spectrometry unless the neutral species are reionized, such as in neutralization–reionization mass spectrometric (NRMS) techniques (1). Most neutral products of ion decomposition remain implicated but undetected players in the overall picture of the events that follow gas-phase ionization.

Matrix isolation has been used successfully for the isolation of highly unstable or very short-lived neutral and ionic species for spectroscopic investigation (2). A number of efforts (3–5) have been made to link matrix isolation techniques with gas-phase ionization methods, mainly to collect and to investigate spectroscopically ionic species generated in an ionization process. Recently, some success has been met in the matrix isola-

tion of mass-selected ions, such as CF_3^+ and CO_2^+ (5). Much less effort has been dedicated to the stabilization and observation of neutral products of ionization processes, which could include both neutral decomposition fragments and neutralized ionic species. In principle, the spectroscopic investigation of such isolated neutral species would provide information that would otherwise not be accessible by conventional mass spectrometry. With this idea in mind, a series of experiments has been carried out in our laboratory, combining a conventional matrix isolation apparatus with either an electron bombardment source or a quadrupole ion trap, for the isolation and spectroscopic characterization of neutral or ionic species generated in the ionization processes of organic molecules. In this paper, we report the results of our investigation into the isomerization and decomposition processes occurring following the ionization of acetone.

In this work, the enol form of acetone, 1-propen-2-ol, was isolated in a cryogenic matrix, providing evidence for its participation, or that of its ionic precursor, in acetone ionization processes. Several fragments, including the acetyl radical, are also identified and their roles in the overall decomposition processes are discussed. Acetone is an appealing choice of organic molecule in the context of this work, since it is one of the simplest members of a group of carbonyl compounds of the [CH_3COR] type. In this group, which includes aliphatic aldehydes, ketones, acids, and esters, the relative thermodynamic stability of the enol to the keto forms of a given ion is reversed with respect to that of the corresponding neutral forms (6, 7). The gas-phase heats of formation of the enolic ions of these compounds have been measured by Holmes and Lossing (6), showing that the enolic ions studied are 59–130 kJ/mol more stable thermochemically than their ketonic counterpart ions; the neutral keto forms are generally more stable than the corresponding neutral enol forms. The endothermic isomerization of enol acetone cation to its keto form prior to dissociation has been studied by a few groups (8, 9) in the context of the nonergodic decomposition of the enol ion. The reverse exothermic isomerization of the keto molecular ion to its enol form has never been observed directly even though it has been implicated (7, 10) in studies on the dissociation behaviour of the acetyl cation with acetone as a precursor molecule (see below).

Experimental approach

The apparatus used in this work was a modification of the design of Szczepanski et al. (11) and is illustrated schematically in Fig. 1. It consists of an electron source, an ionization zone through which accelerated electrons pass and intersect a stream of matrix support gas containing acetone, and a matrix condensation region where products are trapped. The filament was biased at −70 to −100 V, and a current at 3.0–3.5 A was passed through it to generate thermionically emitted electrons. A centre-meshed steel plate, which served as an electron extractor for acceleration of the electron beam, had an applied positive voltage of +20–30 V. A piece of very thin metal placed perpendicularly to the cold crystal surface on one side of the copper block functioned as a Faraday plate for measurement of electron current, to which a voltage between +50–130 V was applied. Typical kinetic energies of the electron beam ranged from 120 to 250 eV. To minimize undesired interference from photons emitted from the filament, the copper block was rotated about 45 degrees with respect to the central axis during matrix deposition. In the absence of a gas sample, the current reading on the Faraday plate represents the actual number of electrons entering the ionization zone, and was typically 4–10 μA. During sample preparation, the current was observed to increase by two- to three fold. The accelerated electron beam intersected the gas sample flow almost perpendicularly, and immediately above the surface of the cold window. Ionization products, together with the neutral precursor and excess Ar gas, were then co-condensed to form the matrix.

Fig. 1. Details of the ionization housing for the electron impact/matrix isolation (EI/MI) apparatus, showing the electron trajectory profile.

The CsI substrate was cooled to 12 K by means of an APD Cryogenics Displex closed-cycle helium refrigeration system. Acetone (Caledon) or d_6-acetone (MSD Isotopes) was degassed in a series of freeze–pump–thaw cycles in an all-metal, high-vacuum line. Research grade argon gas (>99.9995%) was supplied by Matheson Canada. Mole ratios of Ar/acetone vapour were of the order of 250/1 to 800/1. The premixed gas was introduced through the gas inlet line, which pointed directly at the cold surface (see Fig. 1). The flow of the gas mixture was controlled by a MKS mass-flow controller, typically set to 0.8 cm^3/min. The voltages on the cathode and anode were further adjusted within a small range to maintain a current reading at 80–120 μA. The deposition time was normally 8–12 h.

Fourier-transform infrared absorption spectra were recorded using a Bomem-102 FTIR spectrometer. Minor modifications were made to the sample compartment to accommodate the vacuum manifold. Typical spectra were taken at 1 cm^{-1} resolution with 300–600 scans averaged per spectrum. After the infrared spectrum of the initial deposition was collected, the prepared matrix was exposed to the full (200–1000 nm) or filtered irradiation (cut-off filter: >590 nm and >300 nm) from a xenon arc lamp (150 W). Irradiation time varied from 30 to 60 min for each individual experiment (see below).

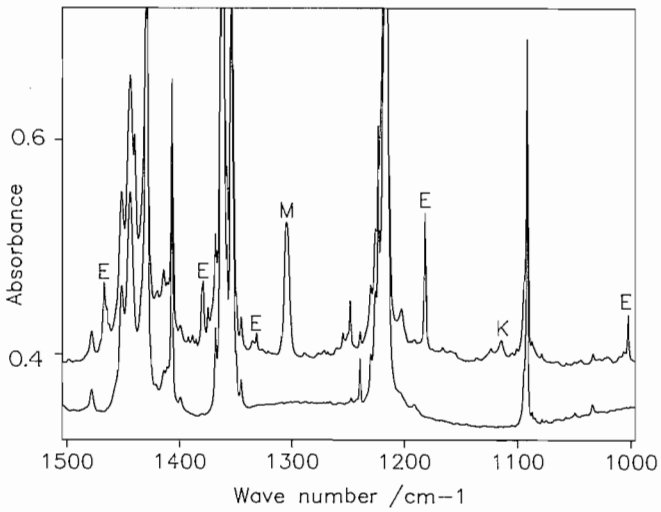

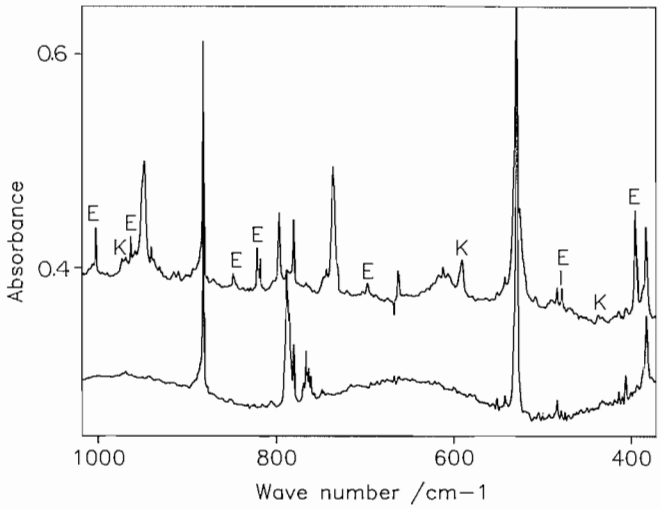

Fig. 3. Infrared spectra of an ionized mixture (upper spectrum) and a non-ionized mixture (lower spectrum) of acetone in argon (1:400) in the range 1000–375 cm^{-1}. New absorptions only observed following ionization are annotated as E (1-propen-2-ol) and K (ketene).

Computational methods

All calculations were done with Spartan[5] except for the potential energy surface scans, and normal mode frequency calculations used for comparison with experiment, for which GAUSSIAN 92 (12) was used; the ab initio (13) HF/6-31G*-optimized geometry and analytical second derivatives were used for the HF/6-31G* frequencies reported here. The semiempirical AM1 method (14) and the ab initio HF/3-21G level were used for PES scans to locate stationary points, and these yielded qualitatively similar surfaces. Examination of the stationary points by geometry optimization and normal-mode vibrational frequencies at the AM1 and the ab initio HF/3-21G and HF/6-31G* levels showed that, at these levels, conformers **1** and **2** are the only minima (see below).

Experimental results

A series of experiments was carried out in which a mixture of Ar/acetone or Ar/d_6-acetone (400:1) was ionized under the conditions outlined above. Spectra obtained under these conditions are hereafter referred to as ionization spectra. For purposes of comparison, similar matrices were also made in which all conditions were held constant except that the electron beam was turned off. With the electron beam on or off, matrices were formed that exhibited absorptions associated with isolated neutral acetone (15), and the hydrogen-bonded acetone–water complex (16). Absorptions due to the common impurities of the vacuum system, CO_2, H_2O, and CO, increased dramatically in the ionization mode, presumably due to the more vigorous outgassing of the filament or metal surfaces. Many new absorption features were also observed only under ionization conditions (see Figs. 2 and 3). The relative intensity of these new absorptions following various irradiations are summarized in Table 1.

The dominant new spectral features observed only under ionization conditions were intense absorptions assigned below to 1-propen-2-ol; the fundamental vibrational mode wave numbers and their associated spectroscopic assignments are listed in Table 2. Selected regions of the absorption spectra are illustrated in Figs. 2 and 3, together with the absorption spectrum of neutral acetone, for comparison. The intensities of the 1-propen-2-ol absorption bands did not change systematically when the electron energy was varied over the range 120–250 eV, and no change followed irradiation of matrices with light in the range of 200–1000 nm for periods in excess of 1 h. The isotopic counterparts of these absorption features were observed following ionization of Ar containing d_6-acetone, and are listed in Table 2.

Other neutral species generated in the ionization process were identified by the behaviour of spectral absorption features following various periods of filtered irradiation (see Table 1), and by comparison with published data. New spectral features observed at 1875, 1321, and 3678 cm^{-1} disappeared following irradiation with >590 nm light for 30 min. The positions of these bands agree very well with three relatively intense bands of the six absorption bands assigned by Jacox (17) to acetyl radicals, generated by abstraction of CHO hydrogen atoms from CH_3CHO molecules by F atoms. No isotopic counterparts for these absorptions were detected in the d_6-acetone experiment. The absorptions at 607 cm^{-1} and the pair at 2138 and 2142 cm^{-1} are attributed to CH_3˙ (18*a*) and CO (18*b*), respectively. These absorptions showed a slight increase in intensity following >590 nm irradiation. The photodecomposition threshold of CH_3CO˙ to form CH_3˙ and CO has been measured at approximately 600 nm (17), which is consistent with the observation in the present study. Clearly identifiable as other neutral products are ketene CH_2CO (19) and CH_4 (20), which are responsible for the absorption features listed in Table 1.

Discussion

Spectral assignment of 1-propen-2-ol

The major new absorption features observed following ionization of acetone are consistent with the fundamental vibrational mode frequencies of matrix-isolated 1-propen-2-ol (CH_3-C(OH)=CH_2), the enol isomer of acetone. In Table 2 are summarized the wave numbers of absorptions attributed to 1-propen-2-ol, together with the corresponding isotopically shifted absorption wave numbers observed in experiments with d_6-acetone. Also included in Table 2 are the scaled (21) wave number predictions for h_6- and d_6-1-propen-2-ol, based upon ab initio SCF calculations of the equilibrium geometry and energy of 1-propen-2-ol. Several of the absorption features attributed to 1-propen-2-ol are similar to those of matrix-isolated vinyl alcohol CH_2=CHOH, the enolic tautomer of acetaldehyde (22). For example, the OH and C=C stretching modes of vinyl alcohol (OH stretching: 3625.0 cm^{-1}; C=C stretching: 1631.0 cm^{-1}) are similar to those of 1-propen-2-ol (OH stretching: 3622.4 cm^{-1}; C=C stretching: 1673.1 cm^{-1}). The main difference between the two spectra is the observation of stretching, deformational, and rocking modes that are characteristic of a methyl group in 1-propen-2-ol; in the vinyl alcohol spectrum these absorption features are absent.

The spectral assignment is supported by the remarkable agreement between the observed and calculated wave numbers of the h_6 and d_6 forms of 1-propen-2-ol. This agreement is illustrated for 1-propen-2-ol in Fig. 4. Two closely related local minimum energy conformations (**1** and **2**, Fig. 5), both of C_s symmetry, were found for 1-propen-2-ol in computations performed using both 3-21G and 6-31G* basis sets. The total energies for conformations **1** and **2** are −191.932 342 and −191.937 924 hartrees (6-31G*), respectively. Therefore, conformation **1**, with energy 14.7 kJ/mol lower than that of conformation **2**, is predicted to be the minimum energy conformation. With either the 6-31G* or 3-21G basis sets, the predicted wave numbers for conformation **1** generally match the experimental data better than do those for conformation **2**,

[b]Assignment refers to configuration **1** of h_6-1-propen-2-ol described in the text. The labels sym. and asym. refer to symmetric and antisymmetric motions under its local symmetry. Modes for which more than one qualitative descriptor are given indicate those involving strong coupling.

suggesting that matrix-isolated 1-propen-2-ol is likely to be in conformation **1**. Most observed vibrational frequencies agree with the 6-31G* predicted values within ± 10 cm^{-1} when a scaling factor of 0.89 is employed (21), except for some vibrational mode frequencies, such as OH stretching and the asymmetric CH stretching modes, for which agreement is less satisfactory.

Assignment of the vibrational modes of 1-propen-2-ol was made in conjunction with the calculated normal mode wave numbers and their predicted atomic displacement descriptions. The normal modes of 1-propen-2-ol are predicted to involve strong coupling between C–O stretching and C–C stretching or CH_3 deformational motions, the former giving rise to essentially symmetric and antisymmetric coupled stretching motions. The C–O stretching motion is predicted to be coupled also to the framework C═C-C bending motion. Thus, calculations suggest that there is no clearly assignable C–O stretching mode in this molecule, since significant C–O stretching is involved in each of ν_9, ν_{10}, ν_{11}, and ν_{14}. In addition, the scissoring motion of the CH_2 group is coupled strongly to the CH_3 umbrella-type deformation and the C–C stretch.

Mechanistic considerations

Since the only significant decomposition process for acetone cations in gas-phase electron impact and collision-induced dissociation experiments is formation of acetyl cations and methyl radicals following C—C bond cleavage (23), it is necessary to consider additional neutralization processes in order to explain the origin of the products observed in the present study. The relatively large internal energy associated with cation–electron recombination processes, implicated in the present work by the observation of predominantly neutral products, appears to allow a significantly richer chemistry to occur.

The presence of free electrons in the ionization region above the matrix surface, along with the requirement of charge balance in the matrix, suggests that many cationic species formed above the matrix surface would be neutralized as they are carried by the matrix gas flow toward the cold substrate, or following matrix condensation. That such processes are important in the present work would appear to be evidenced by the absence of spectral features attributable to cationic species. When neutralization occurs far from the matrix surface,

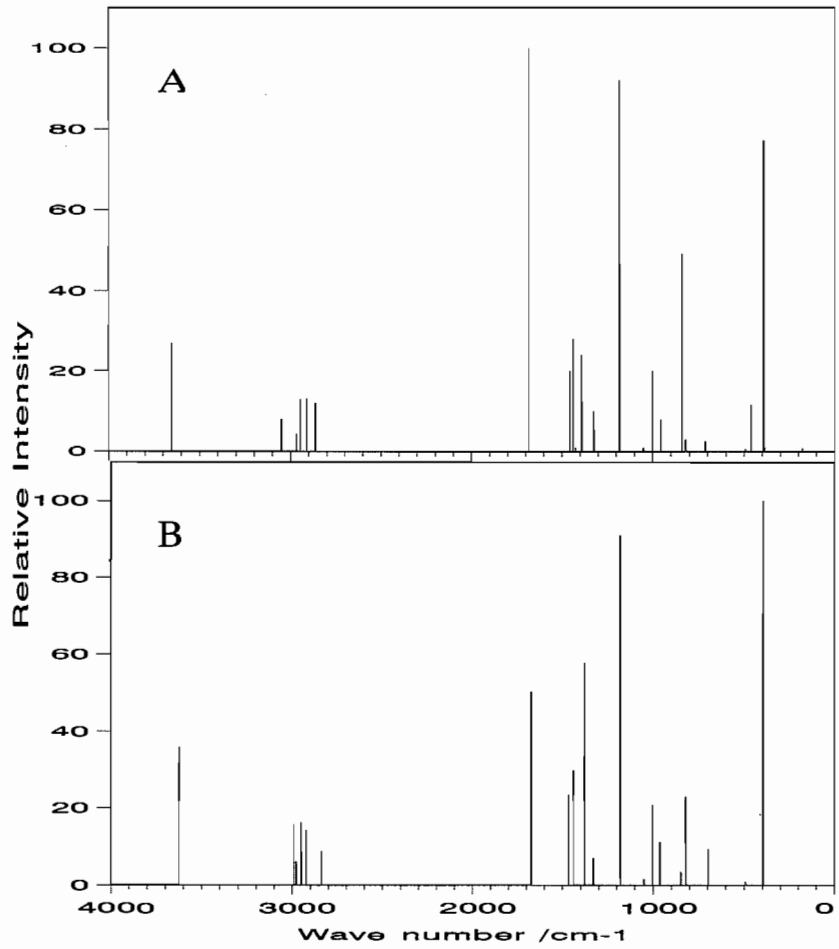
Fig. 4. Spectral line diagrams illustrating the (*A*) calculated 6-31G* and (*B*) observed wave number positions and intensities for vibrational modes of 1-propen-2-ol. The calculated wave number positions have been scaled by a factor of 0.89.



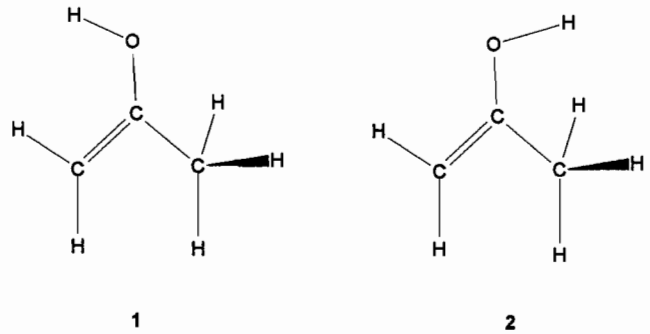


Fig. 5. Illustration of the 6-31G* optimized geometries of conformations **1** and **2** of 1-propen-2-ol.

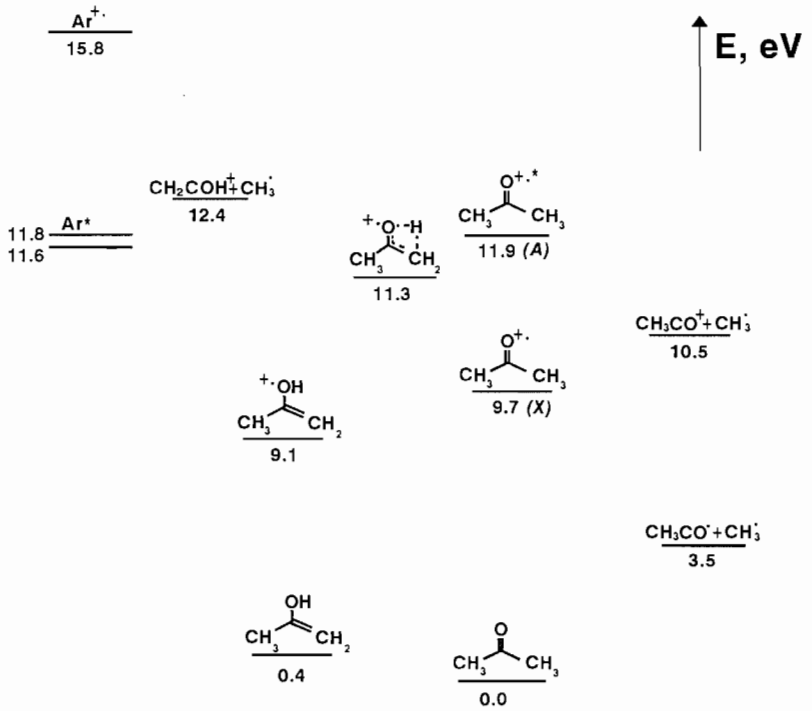

gas-phase unimolecular decomposition of the newly formed neutral species would be expected to dominate due to the extremely large amounts of energy involved in cation–electron recombination processes. In the case of acetone, energy of the order of its ionization potential (9.71 eV) would be released, which is much greater than the endothermicity associated with the activation energy for decomposition of acetone to $CH_3CO^{\cdot}$ + $CH_3^{\cdot}$, given that the homolytic bond dissociation energy of neutral acetone to form $CH_3CO^{\cdot}$ + $CH_3^{\cdot}$ is 3.56 eV (24). Indeed, sufficient energy is available to allow decomposition to 2 CH_3 + CO to occur as well. Should neutralization occur at or beneath the matrix surface, the neutralized species would be expected to lose excess energy rapidly through energy transfer interactions with Ar atoms. When energy transfer to the matrix quenches unimolecular decomposition, or when cage effects significantly inhibit dissociation processes through matrix-induced fragment recombination, the neutralized species would be stabilized and isolated in the rigid Ar matrix. Thus, the fate of ions neutralized by electron recombination processes is expected to depend heavily upon whether recombination occurs in the gas phase above the matrix, or within the matrix solid.

Electron bombardment of dilute mixtures of acetone vapour in Ar can lead to the ionization of acetone molecules by direct electron impact, or via charge exchange and Penning ionization. The large excess of Ar atoms in the gas mixture suggests that the primary electron impact processes would be ionization of Ar atoms (IE(Ar)) = 15.76 eV (24) and electronic excitation of neutral Ar atoms, for which the minimum excitation energy is 11.6 eV (25) (see Fig. 6). Ionization of acetone can then

Fig. 6. Energy level diagram for neutral and ionized acetone, 1-propen-2-ol, and Ar, and associated fragments in the acetone system. Relative energies are cited from refs. 9, 24, 26, and 30.

occur by both charge exchange (CE) reactions (transfer of an electron from acetone to Ar^+) and Penning ionization (PI) reactions (ionization of acetone following collision with Ar^*). Both processes are highly exothermic, and would lead directly to formation of acetone cations with up to about 6 eV (CE) or 2 eV (PI) excess internal energy. This excess is much greater than the 0.8 eV endothermicity associated with the activation energy of the lowest energy decomposition pathway for the ground electronic state *X* of acetone cations, leading to the formation of acetyl cations and methyl radicals (24). Given that acetone cations are known to decompose from the *X* state on a picosecond time scale following collisional excitation (27), it is likely that any acetone cations formed in the X state would decompose essentially instantaneously in the gas phase above the matrix surface. It is, therefore, unlikely that isomerization of the acetone radical cation in its ground *X* state would be a viable source of enol cations. The presence of methyl radicals in the matrix spectra of ionized acetone is likely due in part to this primary decomposition process. Subsequent hydrogen atom abstraction from acetone or scavenging of H-atoms by methyl radicals is a likely source of methane.

The absence of spectral features attributable to the acetyl cation suggests that any such cations formed in decomposition of ground state acetone cations are subject to subsequent ion decomposition, or neutralization through electron capture. However, it is known that acetyl cations do not survive electron transfer in NRMS experiments (23), suggesting that acetyl radical decomposition fragments, and not acetyl radicals themselves, should be observed here as the final products of acetone cation recombination processes, should recombination occur in the gas phase. Such a process may contribute to the formation of ketene, a major product in this work, since ketene ions are the major product of acetone cation neutralization–reionization experiments when K vapour is employed as a neutralization gas (23).[6] Alternately, electron recombination following isolation of the acetyl cation in the matrix solid would favour stabilization of the intact acetyl radical and is likely the major source of the acetyl observed in this work.

Formation of the 1-propen-2-ol cation directly from the ground-state acetone cation would appear to be highly unlikely. However, several studies have implied that the first excited electronic *A* state of the acetone cation is also formed in small amounts following electron impact ionization of acetone (27, 28). Molecular ions formed in the *A* state are stable for at least 30 μs (29, 30), and Bombach et al. (27) have attributed this unusually long lifetime to a reversible, symmetry-allowed isomerization to form the 1,2-epoxypropane radical cation in its electronic ground state. Metastable 1,2-epoxypropane cations may also isomerize to form the 1-propen-2-ol radical cation. Therefore, formation of the *A* state of the acetone radical cation may be a route to formation of the enol cation, via the following scheme:

$$\text{Acetone (A)}^+ \rightleftharpoons \text{1,2-epoxypropane}^+ \rightleftharpoons \text{1-propen-2-ol}^+$$

Other experimental evidence to support the feasibility of such keto→enol cation isomerization is provided by unimolecular

[6] Note that ketene ion formation is not observed when Xe is used as the neutralization gas, suggesting that the formation of ketene is a high-energy process. In the present work, neutral acetone formed by electron capture would have nearly twice the 5.37 eV internal energy released in K vapour NRMS, such that the high-energy route to ketene formation would likely be highly favoured.

(7) and collision-induced dissociation (10) studies of $C_2H_3O^+$ ions generated by electron impact ionization of acetone, both of which suggest that a minor fraction of ionized acetone converts to the enol form prior to decomposition.

If the 1-propen-2-ol cation were formed as a result of isomerization from the long-lived *A* state of the acetone cation, its fate following neutralization would depend also upon where the subsequent neutralization reaction occurred. If the neutralization happens far from the matrix surface, the 1-propen-2-ol molecule would most likely isomerize back to acetone due to its high relative thermodynamic instability and the relatively modest barrier[7] to enol–keto isomerization compared with the energy of electron–cation recombination. If the neutralization reaction occurs during the condensation process, the newly formed and highly energized neutral 1-propen-2-ol molecule might be stabilized through energy transfer to the matrix solid and isolated by the surrounding Ar atoms, thereby allowing it to retain its enol configuration. Once stabilized, the barrier to enol–keto isomerization would be formidable, given the limited internal energy present at 12 K. We consider this route to be the most likely source of the 1-propen-2-ol in the matrix following ionization of acetone.

Further spectroscopic studies of the products of electron bombardment of dihalomethanes, in combination with mass spectroscopic studies and theoretical calculations, have demonstrated that this experimental approach also leads to the generation of iso-dihalomethanes, which will be described elsewhere (32).

Conclusion

This work has shown that a small fraction of acetone molecular ions may tautomerize to 1-propen-2-ol ions, possibly via the *A* state. In addition, infrared spectra of the highly unstable neutral 1-propen-2-ol and its deuterated analog are presented for the first time. These observations signal a new approach for synthesis and stabilization of highly unstable organic species in the matrix environment, which we refer to as the ionization–isomerization–neutralization–stabilization method. It is possible that this synthesis technique can be developed further to generate and to isolate other unstable organic isomers, so long as their ionic counterparts can be formed, either through isomerization or decomposition, in the ionization process.

Equilibrium acidities of some carbon acids in acetonitrile

W. Galezowski, M. Stanczyk, and A. Jarczewski

Abstract: The pK_a values for C-acids (4-nitrophenylnitroalkanes, 4-nitrophenyl-(4-X-phenyl)cyanomethanes, 2,4,6-trinitrotoluene, and 9-cyanofluorene) in acetonitrile have been measured. These values were determined spectrophotometrically in buffer solutions consisting of a strong amine base and its picrate or perchlorate using known potentiometric pK_a's of amines, and they range from 19 for bis(4-nitrophenyl)cyanomethane to 25.1 for ethyl bis(4-nitrophenyl)acetate.

Key words: C-acids, pK_a values, equilibrium, reactivity, proton transfer reaction.

Résumé : On a mesuré les pK_a de C-acides (4-nitrophénylnitroalcanes, 4-nitrophényl-(4-X-phényl)cyanométhanes, 2,4,6-trinitrotoluène et 9-cyanofluorène) en solution dans l'acétonitrile. On a déterminé ces pK_a d'une façon spectrophotométrique, en solutions dans des tampons formés d'une amine fortement basique et de son picrate ou de son perchlorate, en utilisant des pK_a potentiométriques connus d'amines; ces valeurs varient de 19 pour le bis(4-nitrophényl)cyanométhane à 25,1 pour le bis(4-nitrophényl)acétate d'éthyle.

Mots clés : C-acides, valeurs de pK_a, équilibre, réactivité, réaction de transfert de proton.

Introduction

Over several years the mechanism of proton transfer reactions in solutions has attracted the attention of a number of laboratories (1–5). One of the most useful solvents for carrying out the kinetic and equilibrium experiments appears to be acetonitrile (6–9). This highly polar, aprotic solvent was successfully used to study the effect of the polarity on deuterium kinetic isotope effects (KIE) (10, 11). The KIE is sensitive to the symmetry of the transition state, which is a function of the strength of the C-acid and of the base (1, 2, 12, 13). Therefore the pK_a values of reacting bases and C-acids are of interest. The reaction products in acetonitrile were thought to be ion pairs, and pseudo Benesi–Hildebrand equilibrium constants were measured (8, 10). In addition to the fact that they had no physical meaning, the equilibrium constants derived from equilibrium and kinetic measurements were often different from each other. This stemmed, in part, from the non-reproducible concentration of the amine cation. Therefore, taking advantage of the fact that the potentiometric pK_a's of numerous amine bases in acetonitrile are known, pK_a's of some C-acids have been conveniently determined in appropriate buffer solutions. For years most of the C-acids have been used extensively in proton transfer studies focused on kinetic isotope effects and proton tunneling.

Results and discussion

At spectrophotometric concentrations, the product of the reaction of a relatively strong carbon acid with amine bases in acetonitrile is extensively dissociated into free ions (8, 10). The equilibrium can be described by eq. [1]:

$$[1] \quad K = f^2[BH^+][A^-]/([B][AH])$$

The measurements should be carried out in buffers consisting of a base and its salt, so that the concentration of BH^+ can be controlled.

At a constant concentration of BH^+ a Benesi–Hildebrand equation is followed,

$$[2] \quad C_{AH}/A = 1/\varepsilon + 1/(\varepsilon K_{Ben} C_B)$$

where A is the absorbance of the product, ε the molar extinction coefficient, and K_{Ben} the pseudo equilibrium constant by the Benesi–Hildebrand method. K_{Ben}'s and ε's are found from a C_{AH}/A vs. $1/C_B$ plot at a constant C_{AH} and $[BH^+]$.

The values of K, quoted in Table 1, were calculated using eq. [3].

$$[3] \quad K = K_{Ben} f^2[BH^+]$$

In this paper, for some C-acids, K_{Ben} values were determined for several concentrations of $[BH^+]$ and the resulting equilibrium constants K did not depend significantly on $[BH^+]$.

The pK_a values were calculated using eq. [4]. The results are summarized in Table 2. The average pK_a values were taken.

$$[4] \quad pK_a = -\log K + pK_{BH^+}$$

Table 2. Equilibrium acidities of C-acids ($CHR^1R^2R^3$) in acetonitrile at 25°C.

C-acid	R^1	R^2	R^3	pK_a	Relevant kinetic studies
1	NO_2	4-Nitrophenyl	H	20.7, 20.6 (13)	22, 23
2	NO_2	4-Nitrophenyl	Ethyl	23.9	8
3	NO_2	4-Nitrophenyl	i-Pr	25.9 (10)	8
4	2,4,6-Trinitrophenyl	H	H	23.2	24, 25
5	CN	4-Nitrophenyl	H	25.4 (10)	7
6	CN	4-Nitrophenyl	Phenyl	22.7	7, 12, 26, 27
7	CN	4-Nitrophenyl	4-Methoxyphenyl	23.1	27
8	CN	4-Nitrophenyl	4-Bromophenyl	21.3	27
9	CN	4-Nitrophenyl	4-Nitrophenyl	19.0	27, 28
10	COOEt	4-Nitrophenyl	4-Nitrophenyl	25.1	29
9-Cyanofluorene (**11**)				20.8	

Activity coefficients were calculated using a partially extended Debye–Hückel equation (14).

$$[5] \quad -\log f = 1.53\ \mu^{1/2}/(1 + (4.8 \times 10^7)a\mu^{1/2})$$

An a value of 6 Å was taken for all ions.

For some C-acids, measurements were run with amine perchlorates and picrates as the salt component of the buffer and satisfactory agreement was achieved. For example, see results for **6** in Table 1. The pK_a's seem reliable within 0.1 pK unit.

Some ion association can be expected for alkanenitronates (15), which would lead to an overestimation of equilibrium acidity as defined by eqs. [1] and [4]. For instance, the dissociation constant for tetramethylguanidinium 4-nitrophenyl methanenitronate is 6.9×10^{-3} (conductometric value) (15) or $(8.4–9) \times 10^{-3}$ (spectrophotometric values) (15). Therefore for the 4-nitrophenylnitromethane reaction, measurements were run at low cation concentration and the resulting pK_a is identical within 0.1 pK unit with that reported by Gandler and Bernasconi (13), who used benzoate buffer. With TNT and nitrophenylcyanoalkanes, ion association is negligible (15). A change in ε, as determined from eq. [2], with $[BH^+]$ would be symptomatic of ion association. Such changes were observed with 9-cyanofluorene and this could distort its pK_a. Again, as in the case of nitroalkanes, a small concentration of the salt was used to minimize ion-association effects.

Using amine bases to determine pK_a has some disadvantages as compared to anionic bases. One possible threat is the homoconjugation of the BH^+ cation. This should not influence our results in the ranges of concentrations used. Tributylam-

For personal use only.

monium cations do not form homoconjugates $(Bu_3N)_2H^+$ (16). With guanidines, homoconjugation constants determined potentiometrically are not large: 5.3 and 1.9 M^{-1} for TMG and PhTMG (17). Some absorbances were measured in the base concentration range in which homoconjugation becomes important, to make estimation of ε exact, but they had little impact on the slopes of the Benesi–Hildebrand plots and thus on the K_{Ben}'s. Molar absorptivities of the anions should not be affected by homoconjugation of the base. There are also reports of extensive dimerization of TMG base (18). This would complicate the system. However, our differential vapor pressure measurements showed that there is no substantial dimerization up to 1 M TMG (17).

A number of pK_a's for various C-acids have been determined in DMSO (19), but most of the C-acids were weaker than those studied in this work. The values that can be compared are 12.3 (20), 8.3 (19), and 8.6 (21) for **5**, **11**, and **1**, respectively. The resulting $\Delta pK_{a\ (MeCN-DMSO)}$ values of 13.1, 12.5, and 12.1 (for **5**, **11**, and **1**, respectively) are similar to that of 12.9 for phenolphthalein (31).

Using data from ref. 27 and Table 2 a Brönsted plot for the reaction of C-acids **6–9** with TMG was constructed. It gave $\alpha = 0.46 \pm 0.02$ for proton transfer and $\alpha = 0.50 \pm 0.03$ for deuteron transfer, with good correlation coefficients.

Experimental

The syntheses of C-acids have been described elsewhere: 4-nitrophenylnitromethane (**1**) (6), 4-nitrophenyl-1-nitropropane (**2**) (8), 4-nitrophenylphenylcyanomethane (**6**) (32), 4-methoxyphenyl-4-nitrophenylcyanomethane (**7**) (33), 4-bromophenyl-4-nitrophenylcyanomethane (**8**) (33), bis(4-nitrophenyl)cyanomethane (**9**) (10), ethyl bis(4-nitrophenyl)acetate (**10**) (34), and 9-cyanofluorene (**11**) (35). All C-acids were recrystallized from alcohol except **9** (10).

1,1,3,3-Tetramethylguanidine (**TMG**), the commercial product by Aldrich, was stored over KOH pellets and fractionally distilled at 4 Torr (1 Torr = 133.3 Pa). 2-Phenyl-1,1,3,3-tetramethylguanidine (**PhTMG**) was synthesized according to the method of Bredereck (36) and purified as described above for **TMG**. Tributylamine from Aldrich was stored over KOH pellets and fractionally distilled.

The bases were protected from atmospheric moisture and carbon dioxide. Picrates of amine bases were readily obtained and recrystallized from alcohol. Melting points were the same as previously reported.

Perchlorates of TMG and PhTMG were prepared by mixing aliquots of the base and 70% perchloric acid in alcohol. With PhTMG, upon removal of the solvents under vacuum, at temperatures up to 50°C, white crystals formed. These were dissolved in absolute ethanol and the solvent was removed again. These operations were repeated until the weight of residue corresponded to the stoichiometric amount of the salt.

With $TMGHClO_4$, crystallization did not occur unless initiated with Dry Ice. The perchlorates were dissolved in dry acetonitrile to obtain stock solutions of the salts. Acetonitrile, a good spectrometric grade from Romil, was shaken with CaH_2, distilled from P_2O_5, then fractionally distilled from CaH_2. The distillate was protected from CO_2 and moisture.

Most of the absorbances were measured on an HP 8452 diode-array spectrophotometer fitted with thermostated cell holder. The solutions of base and C-acid were prethermostated before mixing to minimize the time needed for equilibration and thus the effect of oxidation. Product decay was particularly important for nitriles and **10**. Except for **10**, within some 15 min the decrease in absorbance did not affect K_{Ben} values, but did affect the ε's. This weak dependence of K_{Ben} on time of measurement may stem from comparable rates of product decay in cells with different C_B. If the analytical concentration of C-acid was at any moment the same in all solutions, i.e., decreasing with time but independent of C_B, using the initial value of C'_{AH} in eq. [2] instead of the true value C_{AH} would make both the slope and intercept of the Benesi–Hildebrand plot C'_{AH}/C_{AH} times larger than the correct values, and this would result in reduced $\varepsilon' = \varepsilon C_{AH}/C'_{AH}$ and unchanged $K'_{Ben} = K_{Ben}$.

Taking advantage of the fact that ionization of nitriles is faster than product decay, for some reactions an Applied Photophysics stopped-flow spectrophotometer was used to avoid ambiguities. The ε's were somewhat higher than those obtained with the HP diode array but there was no essential change in pK_a.

The product of the relatively slow ionization reaction of **10** is very susceptible to oxidation. Reproducible results were obtained on the diode array spectrophotometer when a small amount of antioxidant, ascorbic acid, was used. The concentration of the antioxidant in the cell was 8×10^{-5} M, which was about three times higher than the concentration of the C-acid.

Product decay can lead to unreasonably large differences in ε's for the same ion of C-acid in acetonitrile, for instance, for reactions of the same C-acid with different bases (37). Therefore the stopped-flow technique should be used for equilibrium measurements of fast reactions with unstable products.

Except for **11**, the intense absorption bands of the products do not interfere with absorption of the buffer solutions, even when picrates are used, and absorbances measured at λ_{max} of the product were taken for calculations of K_{Ben} and ε, as follows: **1** (490 nm), **2** (504 nm), **4** (520 nm), **6** (580 nm), **7** (582 nm), **8** (582 nm), **9** (648 nm), **10** (630 nm). With **11**, perchlorate needed to be used, and the analytical wavelength was 300 nm. Small corrections for absorbance of buffer solution were applied where needed.

Photolysis of 5,5-dibenzyl-Δ^3-1,3,4-oxadiazolines[1]

John Warkentin and John McK.R. Woollard

Abstract: Photolysis of dibenzyl-Δ^3-1,3,4-oxadiazolines (**3**) in the presence of dimethyl acetylenedicarboxylate (DMAD) gives only modest yields of the expected symmetrical 3,3-dibenzylcyclopropenes (**4**), but these are accompanied by more than six by-products, including unsymmetrical cyclopropenes, methylenecyclopropanes, and various pyrazoles. The origin of this array of products can be explained by a series of steps starting with photolysis of **3** to form a diazoalkane that undergoes 1,3-dipolar cycloaddition to DMAD, generating a 3*H*-pyrazole as initial product. The latter is further photolyzed to a symmetrical cyclopropene in competition with benzyl group migration by thermal 1,5-sigmatropic or ion-pair rearrangement to afford a 4*H*-pyrazole. The 4*H*-pyrazole in turn undergoes photolysis to an unsymmetrical cyclopropene, which rearranges to a methylenecyclopropane. The 4*H*-pyrazole also undergoes autoxidation, in the presence of air, to afford a benzoyl-4*H*-pyrazole. Additionally, in competition with rearrangement, the various pyrazoles lose a benzyl group or a methoxycarbonyl group to afford pyrazoles with one less substituent.

Key words: 5,5-dibenzyl-Δ^3-1,3,4-oxadiazolines, photolysis of; 3,3-dibenzyl-3*H*-pyrazoles, rearrangement of; 3,4-dibenzyl-4*H*-pyrazoles, autoxidation of; 3,4-dibenzyl-4*H*-pyrazoles, photolysis of; cyclopropenes, rearrangement to methylenecyclopropanes.

Résumé : La photolyse des dibenzyl-Δ^3-1,3,4-oxadiazolines (**3**) en présence d'acétylènedicarboxylate de diméthyle (ADCD) ne fournit que de faibles rendements des 3,3-dibenzylcyclopropènes (**4**) symétriques attendus; toutefois, ceux-ci sont accompagnés par plus de six sous-produits incluant des cyclopropènes non symétriques, des méthylènes cyclopropanes et divers pyrazoles. On peut expliquer l'origine de cette série de produits par une série d'étapes commençant par la photolyse du produit **3** conduisant à un diazoalcane qui subit une cycloaddition 1,3-dipolaire sur l'ADCD pour conduire au 3*H*-pyrazole comme produit initial. Ce dernier peut subir une photolyse subséquente en cyclopropène symétrique, en compétition avec une migration sigmatropique-1,5 thermique du groupe benzyle ou une transposition de la paire d'ions qui conduit à un 4*H*-pyrazole. Le 4*H*-pyrazole subit à son tour une photolyse en cyclopropène non symétrique qui se réarrange en un méthylènecyclopropane. Le 4*H*-pyrazole subit aussi une autooxydation, en présence d'air, qui conduit au benzoyl-4*H*-pyrazole. De plus, en compétition avec les réarrangements, les divers pyrazoles perdent un groupe benzyle ou un groupe méthoxycarbonyle pour fournir des pyrazoles important un substituant de moins.

Mots clés : photolyse de 5,5-dibenzyl-Δ^3-1,3,4-oxadiazolines, réarrangement de 3,3-dibenzyl-3*H*-pyrazoles, autooxydation et photolyse de 3,4-dibenzyl-4*H*-pyrazoles, réarrangement de cyclopropènes, à méthylènecyclopropanes.

[Traduit par la rédaction]

Introduction

As part of our ongoing studies of reactive intermediates, we wished to prepare a series of dibenzylcyclopropenes with the general structure **4***a–e*. Earlier experience with three-membered rings indicated that **4** ought to be formed by extended photolysis of a mixture of dimethyl acetylenedicarboxylate (DMAD) and appropriate Δ^3-1,3,4-oxadiazolines (**3**), available in good yield from simple dibenzylketones (**1***a–e*) by oxidation of their acetylhydrazones (**2**) using lead tetraacetate (LTA) (1–3) (Scheme 1).

The crucial photolysis stage giving **4** would consist of a sequence of five steps, for each of which there is ample precedence. First, photolytic cleavage of **3** would form diazoalkane **5**, which would be trapped by DMAD to give 3*H*-pyrazole **6** (2). Further irradiation in situ would convert **6** into vinyl diazo compound **7**. This in turn would readily lose nitrogen on continued photolysis to give a vinyl carbene (**8**), which characteristically can collapse to the desired cyclopropene (**4**) (4–8) (Scheme 2).

Judging from previous reports, the conversion of a 3*H*-pyrazole to a cyclopropene is highly efficient, normally occurring with yields approaching 100% (4, 6, 9), and the method can even be used to generate more highly strained ring systems such as cyclopropabenzenes (10); similarly the

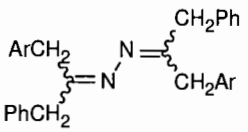
(R as in Scheme 1, *a* - *e*)

3*H*-pyrazole is obtained from the oxadiazoline typically in yields of about 70% (2). Although the photolytic steps each require somewhat different wavelengths for optimum efficiency, in practice either a Hanovia medium-pressure mercury lamp (4) or a Rayonet apparatus with 300 nm lamps (2) can provide enough spectral width to make a "one-pot" process feasible. We had anticipated, then, that this composite photolysis stage would give something like 60% of the desired three-membered ring and that, overall, we would have an attractive and simple route to our target molecules. It was thus surprising and disappointing to discover that the cyclopropenes (**4**) were produced in only low yields during the photolysis, and that they were accompanied by a wide range of other products in comparable amounts. One of these additional products has already been reported (3), and it is the purpose of this paper to clarify the nature of the other products, to suggest their origins, and to present details of a set of versatile and potentially useful reactions.

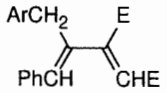
Results and structural assignments

As outlined above, the major products from the photolysis of Δ^3-1,3,4-oxadiazolines in the presence of DMAD were expected to be cyclopropenes (**4**). As for possible by-products, inspection of the literature suggested that these would include azines (**9**) formed by self-reaction of two molecules of the diazoalkanes (2), dienes (**10**) formed from vinyl carbenes (**8**) by a hydrogen shift (4, 7), 1:2 adducts (**11**) formed by cycloaddition of a molecule of a diazoalkane to a 3*H*-pyrazole such as **6** (11), oxiranes (**12**) formed by loss of nitrogen from the oxadiazolines (2), and 4*H*-pyrazoles (**13**) produced by migration of a group from the 3-position of 3*H*-pyrazoles (**6**) (6).



In practice, it was found that not only were the desired cyclopropenes formed in yields of merely 10–30%, but also that the six or more by-products fitted none of the precedents described above. Thus the mixture of by-products nearly always included 1,3-diarylpropenes (**14** and **15**), unsymmetrical cyclopropenes (**16**), methylenecyclopropenes (**17** and **18**), dibenzylpyrazoles (**19**), monobenzylpyrazoles (**20**), and pyrazole N-oxides (**25**), plus frequently one or more of the benzoyl pyrazoles **21**, **22**, and **23**.

Separation and isolation of the various products was achieved using centrifugal chromatography, a particularly sensitive process in this study owing to the presence of strongly absorbing chromophores in all the products. Structures followed from analysis of their spectroscopic properties, and some of the more significant features of those spectra are given below. Assignment of structure to compounds in the series **16** has already been outlined (3) and ^{13}C NMR data are summarized in Table 1.



The compounds **17** and **18** initially presented a challenge, since they co-eluted under every elution condition tried. Moreover when a *para* substituent was present in the starting material, there were generally two isomers of each, giving a total of four isomers in the mixture. Fortunately, the last system examined proved to be an exception; with a *para*-trifluo-

romethyl group present, *only two* isomers were produced, **17***h* and **18***h*, which, with some care, could be cleanly separated, and their formulae established. Furthermore, their spectra permitted disentanglement of the spectra of the mixed isomers from other experiments. In their ^{1}H NMR spectra each compound showed one proton (δ ca. 3.4 ppm) coupled (J = 2 Hz) to a single vinyl proton (δ ca. 6.7 ppm), and both sets of compounds had signals from one methylene group. In the series **17** this was a singlet, by coincidental equivalence of diastereotopic protons, whereas in series **18** the CH_2 signal was an AB quartet, presumably in consequence of the closer proximity of the other aryl group. Long-range C-H correlation spectra for **17***h* confirmed that the *para*-trifluoromethylphenyl group was bonded to the vinyl group, and a similar investigation on a mixture enriched in **18***a* identified a carbonyl carbon (δ = 170.3 ppm in the ^{13}C NMR spectrum; see Table 2) as being close to the methylene group. The geometry indicated for these compounds followed from NOE experiments. Thus in **17***h*, irradiation at the frequency of the methylene hydrogens gave signal enhancement for both the vinyl-H and the *ortho*-H of the phenyl ring, whereas irradiation of the methine-H caused signal enhancement for the *ortho*-H of the trifluoromethylphenyl group but not of the vinyl or the methylene hydrogens, showing that the methine-H was close to the aryl group on the exocyclic double bond, and *trans* to the methylene group. In contrast, irradiation of the methine-H in **18***a* gave no enhancement of the signal from the methylene hydrogens but a small enhancement of the vinyl-H signal.

Although compounds **21**, **22**, and **23** were isolated directly from the photolysis mixtures on different occasions, they were also formed regularly, although in varying amounts, from an unstable compound, described below, and it thus appeared they were closely related. In support of this hypothesis, the three products **21***a*, **22***a*, and **23***a*, apparently derived from **6**, all showed strong peaks in their mass spectra at m/z = 105, suggestive of the benzoyl fragment, whose presence was also indicated by a series of characteristic signals in their ^{1}H NMR spectra. Both **22***a* and **23***a* had prominent IR peaks at ca. 3300 cm^{-1} indicating the presence of an N-H group, and the ^{13}C NMR spectrum of **23***a* made an excellent fit with that for the corresponding acetyl compound **23***d* (12). The ^{1}H NMR spectra of compounds **22** showed that they had one ester group and one benzyl group. The signal from the methylene group of the latter, at ca. 4.5 ppm, indicated a fairly deshielded environ-

ment, consistent with the placement shown. Compounds **21** gave infrared spectra without N-H peaks. In the ^{1}H NMR spectrum of **21***a* the methylene group appeared as an AB quartet at ca. 3.8 ppm suggesting the presence of a benzyl group bonded to a quaternary carbon, and in the ^{13}C NMR spectrum there was one signal at ca. 78 ppm, typical of a quaternary carbon bearing electron-withdrawing groups. Further information was obtained from a long-range C-H correlation investigation. Thus the hydrogens of the methoxyl at 3.7 ppm coupled with the ester carbonyl carbon at 163 ppm, and those at 4.1 ppm coupled with the carbonyl carbon at 160 ppm, thus indicating clearly which low-field carbons were from carbonyl groups, the former presumably being from the sp^3-bound ester group. Consequently, the signals at 173 and 168 ppm have to be assigned to the ring sp^2 carbons, and appropriately both showed coupling with the methylene hydrogens, which in turn also couple with the quaternary carbon at ca. 78 ppm. These relationships, plus mass constraints and the fact that the quaternary carbon of a 4*H*-pyrazole typically absorbs at ca. 63–80 ppm (13, 14), dictate that compounds **21** must have a 4*H*-pyrazole nucleus.

The common source of **21**, **22**, and **23** appeared to be a yellow compound that was formed consistently in all experiments. Although the yellow material could be preserved for months when stored under N_2, exposure to air quickly gave rise to mixtures of **21**, **22**, and smaller amounts of **23**. The assignment of a structure for this yellow precursor proved to be difficult. In the UV spectra there were longer wavelength absorption maxima at 282 and 372 nm and in the IR spectra there were strong peaks at 3300 cm^{-1} pointing to an OH or NH group, a feature confirmed by the effect of added D_2O (exchange) on the ^{1}H NMR spectrum. In the ^{1}H NMR spectra, signals included a one-proton exchangeable singlet at ca. 8.0 ppm, a one-proton singlet at ca. 5.7 ppm, and an AB quartet with signals located at ca. 3.3 and 3.8 ppm, along with two methyl ester groups and an appropriate number of aromatic hydrogens (without any indication of pronounced deshielding). Apparently one benzyl group had been modified in some way at the methylene group, while the other evidently remained intact. In the ^{13}C NMR spectra, salient features included two sp^2 carbon signals very close together at ca. 143 ppm, a methine carbon signal at ca. 100 ppm, a quaternary carbon signal at ca. 64 ppm, and one methylene carbon signal at ca. 43 ppm. A single-bond C-H correlation spectrum of the yellow compound from **3***d* confirmed that there were no other methine groups, and that the proton giving the signal at 8.1 ppm was not attached to a carbon. Long-range C-H correlation experiments on the yellow compounds from both **3***a* and **3***c* showed coupling of the methylene protons to both the carbon at 64 ppm and one (or both?) of the carbons at 143 ppm, but unfortunately did not pick out any coupling between the methine-H and nearby carbons, nor other helpful structural

Scheme 3.

relationships. In NOE experiments on the yellow compound from **3***d*, irradiation of either of the methylene hydrogens caused enhancement of the signal at 8.0 ppm and that at 5.7 ppm, as well as of that of an *ortho*-H of the unsubstituted phenyl group. Irradiation of the proton absorbing at 5.7 ppm caused enhancement of the signal at 8.0 ppm as well as of those *ortho*-H of the bromophenyl group and one of the methylene protons. Lastly, irradiation of the proton at 8.0 ppm caused enhancement of the signal from the *ortho*-H of the bromophenyl group.

Bearing in mind that the yellow materials in question decomposed to benzoyl pyrazoles (**21**–**23**) and absorbed at 3300 cm^{-1} in the infrared, hydroperoxide **24** was first considered as a possible structure. In this, the groups are disposed suitably to fit the observed interactions in the long-range correlation experiments, and the quaternary carbon signal at 64 ppm well suits C4 of a 4*H*-pyrazole (13, 14). Moreover, this structure is mechanistically reasonable, for it is known that 4*H*-pyrazoles are readily formed from 3*H*-pyrazoles (6, 15), and autoxidation of benzylic compounds, such as cumene, to hydroperoxides is well precedented. It had to be noted, however, that in similar 4*H*-pyrazoles the sp^2 carbons of that ring usually give signals at 160–180 ppm rather than at ca. 143 ppm as observed (cf. compounds **21**, **27**, and **34**, and examples in refs. 13 and 14), and it was not clear how a hydroperoxy group could significantly affect the chemical shifts of the sp^2 carbons of the pyrazole ring. Further, the yellow colour was not an obvious consequence of the structure **24**. Nevertheless **24** is a plausible product from **13**, and a solution to the puzzle was sought based on the premise that **24** is indeed formed by radical chain autoxidation of **13**, but it is then converted swiftly to the yellow compound **25**.

Given that hydrogen peroxide or peracids are effective reagents for converting *N*-heterocycles to corresponding *N*-oxides, we propose that **24** are rapidly converted to corresponding pyrazole *N*-oxides (**25**) by intramolecular reaction. Models for **25** do have absorptions in the UV/visible spectrum (16, 17) and the exchangeable OH, the IR, and the NOE results fit well. Moreover, with an *N*-oxide structure, the chemical shifts of the ring carbons should be significantly affected. Finally, the formation of benzoyl pyrazoles **21**, **22**, and **23** from **25** can be accounted for nicely, as described in the Discussion.

Discussion

The origin of the various products can be ascribed to transformation of the diazoalkane **5** by one minor and two major pathways, each followed by further reaction as in Scheme 3. The minor pathway is loss of nitrogen from **5** to give a carbene, but both major pathways derive from trapping of **5** by the DMAD to produce the 3*H*-pyrazole **6**. This then either rearranges (path ii) or loses nitrogen (path i) to give the vinyl carbene **8** that collapses to some of the products of Scheme 3.

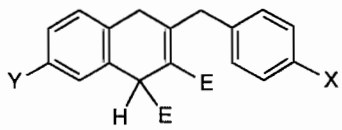
This basic scheme is supported by the results from photolysis of oxadiazoline **3***a* (without DMAD) at −70°C in toluene-d_8. After 4 h it had been converted almost totally to methyl acetate and the diazoalkane **5***a*, in whose carbon spectrum the diazocarbon appeared at 48 ppm. During storage at −20°C for 15 h, approximately 70% of the compound had decomposed to azine **9***a* plus smaller amounts of propenes **14***a* and **15***a*, and after 5 days the decomposition was complete. In no other experiment was any trace of such an azine found, indicating that the rate of reaction of the diazoalkane with DMAD is substantially faster than its self-reaction. On the other hand, since propenes were consistently found in modest amounts in both this and all other photolysis experiments, photolytic loss of nitrogen from **5** was competitive with dipolar cycloaddition to DMAD. Once a carbene was generated by nitrogen loss, a rapid H-shift gave propenes. Moreover, since only hydrogen shifts seem to have occurred, without any evidence for a phenyl shift, the precursor carbene presumably reacted from the singlet state (18). As might be expected, when propenes **14** and **15** were produced, the yields of *trans* isomer tended to exceed those of the *cis* isomer, and when a *para* substituent was present in **3**, both positional isomers of the two propenes were produced in essentially equal amounts.



The nitrogen-loss pathway (i) from the 3*H*-pyrazole (Scheme 3) was the route we had expected the bulk of the material to follow. Although the expected cyclopropenes (**4**) were indeed produced, the yields were low and the product mixtures also included, on occasion, small amounts of dihydroazulenes (**28**) and substances believed to be dihydronaphthalenes (**29**). Those compounds are also produced in small amounts by thermolysing the pure cyclopropenes (**4**) in an inert solvent, and presumably arise by attack of the intermediate vinyl carbene **8***a* on one of the aromatic rings (3, 19, 20). Additional evidence for the intermediacy of the carbene **8***a* was provided by photolysis of **3***a* in methanol (in the presence of DMAD), when ether **30** was produced, in an amount comparable to that of symmetric cyclopropene **4***a*, by carbene insertion into the O—H bond of the alcohol (18–20). In principle, carbene insertion can follow several pathways (21–25), including direct insertion into the O—H bond, attack on the carbene by the nucleophilic oxygen to give a zwitterion that then undergoes an H-shift, and protonation of the carbene to give a cation that combines with the counterion. Which pathway occurs is dependent on the structure of the carbene, but the last pathway is known for at least some vinyl carbenes (26). If this last pattern were followed, protonation of vinyl carbene **8***a* would form an allylic cation that ought to give two ethers, **30** and **31**, of which, if anything, **31** should be favoured. However, since **31** could not be detected, it seems unlikely that a cationic pathway is followed in this system.

36

That the other major pathway for reaction of the 3*H*-pyrazole was rearrangement is supported by the finding, in every case, of compounds **16**, **19**, and **17** and **18** (Scheme 3). The thermal rearrangement of 3*H*-pyrazoles has been called the VanAlphen–Hüttel rearrangement after its discoverers (27), and in most cases can be considered as taking place by a thermally allowed [1,5]-sigmatropic shift of a group from the 3-position either to the 1-position, or to the 4-position (6, 15,

For personal use only.

28–31). Although 1*H*-pyrazoles are more stable than 4*H*-pyrazoles, the latter frequently constitute the predominant rearrangement product, pointing to kinetic control and late development of aromatic character in the transition state (5). Not surprisingly, ease of migration is a function of substituent, and it has been found that ester and acyl groups are much more mobile than alkyl, aryl, or benzyl groups, so that 3*H*-pyrazoles with ester or acyl groups in the 3-position rearrange rapidly at room temperature (29, 30), frequently not even being isolable (31). One explanation for this, based on careful work with the comparable indene system, is that the energy barrier for the process is reduced by secondary interaction between a vacant π^* orbital of the migrating group and an occupied orbital of the five-membered ring (32). Although steric factors also play a part, clearly when there is no π^* orbital, i.e., with alkyl and benzyl groups, no such lowering of the barrier is possible, and the rearrangement should be slow. Thus for our systems we would not have expected a rapid rearrangement.

On the other hand, the conjugate acid of the pyrazole can also undergo concerted rearrangement (33) and in acetic acid solution benzyl groups do migrate much faster than other alkyl groups. This suggests there is substantial charge transfer in the transition state for such reactions, and that migrating tendency then also becomes a function of ability to stabilize a positive charge (33). However, the rearrangement of 3*H*-pyrazoles is not always concerted, and we recently reported strong evidence for a two-step process in which an ion pair is formed when the migrating group can form a particularly stable cation (34). There thus appears to be a mechanistic spread ranging from a one-step (concerted) process to a two-step, ion-pair process.

To check whether the benzyl migration was being catalyzed by adventitious acid, some photolyses were performed in tubes that had been washed with ammonia and others in solvents containing a small amount of triethylamine. However, those precautions made no significant difference to the proportion of products arising from rearrangement. Temperature also seemed to have little effect. Although most experiments were run at ambient temperature, essentially identical results were found in one experiment performed using dichloromethane as solvent with the temperature maintained at or below −15°C until work-up. It was also striking that, in contrast to earlier work, in our reactions there was no evidence for any ester migration from the putative 4*H*-pyrazole intermediate **13**, which might have been expected to behave this way (27, 30, 34).

In light of these findings, we believe that 3, 3-dibenzyl-3*H*-pyrazoles (e.g., **6**) rearrange by the two-step, ion-pair mechanism (cf. ref 34). Calculations have shown that such a process is reasonable for cyclopentadiene systems (35) and, in the present case, five observations support this interpretation. First, although 1-benzyl-1*H*-pyrazoles were produced, there was always formed a small amount of debenzylated compound (**20***a–e*), indicating that the migrating benzyl group could become detached. The result is formally similar to the debenzylation reported by others (36) from reactions at a much higher temperature (205°C). Secondly, when photolysis of **3***a* was performed in the more polar solvent methanol, the yield of debenzylated product **20***a* from unrearranged 3*H*-pyrazole was increased at the expense of the yield of cyclopropene **4***a*. Thirdly, the *para*-substituted systems (**6***b–e*) gave evidence of preferential migration in the sense *p*-$MeOC_6H_4CH_2$ > $C_6H_5CH_2$ > *p*-$CF_3C_6H_4CH_2$, paralleling ability to support a benzylic cation. Fourthly, with *p*-methoxybenzyl, the isomeric 1*H*-pyrazole **32** was also formed, a compound most simply accounted for by assuming that the ion-pair intermediate is loose enough for collapse to occur at either nitrogen. Lastly, in the photolysis of the related oxadiazoline **3***f* in methanol-d_4, the products included not only both cyclopropenes **4***f* and **16***j* and the 1-benzyl-1*H*-pyrazole **19***j*, but also the 4-benzyl-4*H*-pyrazole **33** and the debenzylated 1*H*-pyrazole **20***d*.

Additional evidence for Scheme 3 came from the finding that, if the diazoalkane was first generated (at low temperature) and then DMAD was added, the "missing" 3*H*-pyrazoles (**6***a*, **6***b*, and **6***d*) could be isolated. They are not stable at room temperature, decomposing to give a product mixture similar to that from direct photolysis. Moreover, it was not possible to isolate **6***c* under these conditions, suggesting that the *p*-methoxybenzyl group can migrate rapidly even at room temperature.

Thus the crucial steps proposed in Scheme 3 for the production from **6** of products **16**, **17** and **18**, and **19** are the following. First, there is a shift of a benzyl group, by a pathway involving a tight ion-pair intermediate (loose in the case of *p*-$MeOC_6H_4CH_2$) to give some **19** but mainly the 4*H*-pyrazole **13** (compare findings in ref. 37), as well as small amounts of **20**, by complete loss of the migrating group. Then **13** generates the unsymmetrical cyclopropene **16** by photochemical loss of nitrogen (3). The two isomeric methylenecyclopropenes (**17** and **18**) are then produced from **16** either by a base-catalyzed proton shift or by [1,5]-sigmatropic rearrangement to the more acidic ester enol (not shown), which then undergoes a base-catalyzed allylic rearrangement. There are many precedents in cyclopropene chemistry for base-catalyzed rearrangements (38), and since a benzylic hydrogen vinylogous to an ester is weakly acidic, strong bases do not have to be sought. Either the traces of base introduced deliberately or, in cases where that was omitted, the diazoalkane (39), can be assigned to that role. In the latter case, some of the diarylpropenes (**14** and **15**) would have originated from 1,3-diaryl-2-propyl cations, rather than from carbenes. It is possible that **17** and **18** are also subject to photochemical interconversion, but this was not investigated.

Base-catalyzed isomerization of **16** was confirmed by two observations. First, when the photolysis of **3***a* was conducted in the presence of added base, no **16***a* was present in the product mixture, although both **17***a* and **18***a* were found. Secondly, treatment of pure cyclopropene **16***a* with triethylamine in chloroform caused total isomerization within a few minutes. In the latter case, along with **17***a* and **18***a* in approximately equal amounts, there were found much smaller amounts of **34** and **35**, whose structures followed from their NMR spectra and NOE experiments. Since the isomerization is presumably equilibrium controlled, structures **17** and **18** must be more stable than both cyclopropene **16**, and its isomers **34** and **35**. The fact that **34** and **35** were not observed as co-products of the photolyses could simply mean that the yields of these compounds were too small.

The sequence of reactions leading to benzoyl pyrazoles **21**, **22**, and **23** is probably the following. First **6** rearranges, by preferential migration of that benzyl group with the better cationic stabilization, to afford 4*H*-pyrazole **13**. The doubly acti-

© 1997 NRC Canada

vated methylene group of **13** then undergoes autoxidation, by a radical chain mechanism, to afford hydroperoxide **24**, which is short lived, undergoing intramolecular *N*-oxidation to afford the yellow pyrazole-*N*-oxide **25**. A 1,4-sigmatropic H-shift in **25** affords the enolic hydroxylamine **26**, which leads to acyl pyrazole **21** in one of two ways. One of these is 1,4-elimination of water and the alternative involves ketonization followed by 1,2-elimination of water. The 4*H*-pyrazoles **21** can also generate 5-acylpyrazoles **22** and **23** by loss of one of the groups at C4, the driving force presumably being the fact that the products are aromatic. The route may involve ion pairs or nucleophilic attack on the ester group that is lost.

Conclusion

Dimethyl 3,3-dibenzyl-3*H*-pyrazole-4,5-dicarboxylates, produced by photolysis of oxadiazolines in the presence of DMAD, undergo benzyl shifts at ambient temperatures by an ion-pair mechanism, to give mainly 3,4-dibenzyl-4*H*-pyrazole-4,5-dicarboxylates as initial products. The latter undergo further photolysis to afford cyclopropenes by loss of nitrogen. These 4*H*-pyrazoles are unusually sensitive to air, and are also converted, through unstable hydroperoxide and *N*-oxide intermediates, to benzoyl pyrazoles **21**, **22**, and **23**.

Experimental

Melting points were determined on a Thomas Hoover capillary melting point apparatus. NMR spectra were recorded on Varian EM-390, Bruker AM-500, or, when unspecified, Bruker AM-200 spectrometers using $CDCl_3$ as solvent and for internal reference either TMS (proton spectra) or solvent $CDCl_3$ (δ = 77.20 for ^{13}C spectra). Centrifugal chromatography was carried out on silica gel (Merck Kieselgel 60 PF_{254}) plates in a model 7924T Chromatotron apparatus, under nitrogen, using a gradient elution protocol starting with low-boiling petroleum spirit containing 5% diethyl ether plus 0.1% methanol, and finishing with neat acetonitrile. Infrared spectra were recorded as thin films for liquids or Nujol mulls for solids.

General procedure for preparation of dibenzylketones (1)
For those which were not commercially available, an adequate synthesis was available (40) by reaction of dibenzyl cadmium with the appropriate 4-substituted phenylacetyl chloride, obtained from the corresponding acid using thionyl chloride (41). Brief characteristics of compounds, some of them new, follow.

(4-Trifluoromethylphenyl)acetyl chloride, a clear oil, bp 75–80°C/0.5 Torr (1 Torr = 133.3 Pa). ^1H NMR, δ: 7.58 (d, J = 8.0 Hz, H-3, H-5), 7.34 (d, J = 8.0 Hz, H-2, H-6), 4.15 (s, CH_2).

*1-(4-Methylphenyl)-3-phenylpropan-2-one (1*b*)*, clear oil (44%), bp 148–155°C/0.4 Torr (lit (40*a*) bp 143°C/0.3 Torr). IR (cm^{-1}): 3035 w, 2925 w, 1719 s, 1603 w, 1514 m, 1496 m, 1453 m. ^1H NMR (90 MHz) δ: 7.35–7.00 (m, 9H), 3.68 (s, 2H), 3.65 (s, 2H), 2.31 (s, 3H); this fits well the published ^1H NMR data (40*b*).

*1-(4-Methoxyphenyl)-3-phenylpropan-2-one (1*c*)*, a clear oil (29%), bp 175–185°C/0.7 Torr (lit (40*a*) bp 152–154°C/0.4 Torr. ^1H NMR (90 MHz) δ: 7.35-6.80 (m, 9H), 3.77 (s, 3H), 3.68 (s, 2H), 3.62 (s, 2H).

*1-(4-Bromophenyl)-3-phenylpropan-2-one (1*d*)*, yellowish oil (44%), bp 180–200°C/0.02 Torr (lit. (42) mp 54°C). IR (cm^{-1}): 3085 w, 3065 w, 3030 w, 2920 w, 1718 s, 1600 m, 1590 m, 1487 s, 1451 m, 1404 m. ^1H NMR (90 MHz) δ: 7.50–7.05 (m, 9H), 3.68 (s, 2H), 3.62 (s, 2H).

In one preparation of **1***d*, dibenzyl(4-bromobenzyl)carbinol was also produced, as a pasty solid. IR (mull) cm^{-1}: 3570(sharp) m, 3025 m, 1598 w, 1483 s. ^1H NMR, δ: 7.40 (d, J = 8.3 Hz, 2H, H-3, H-5 of Ar), 7.31–7.17 (m, 10H), 7.09(d, J = 8.3 Hz, 2H, H-2, H-6 of Ar), 2.73 (s, 4H), 2.70 (s, 2H).

*1-Phenyl-3-(4-trifluoromethylphenyl)propan-2-one (1*e*)* (38%), bp 130–140°C/0.3 Torr. IR (cm^{-1}): 3065 w, 3035 w, 2915 w, 1722 s, 1618 m, 1605(sh), 1585 m, 1494 m, 1452 w, 1418 m. ^1H NMR, δ: 7.55 (d, J = 8.0 Hz, 2H, H-3, H-5 of Ar), 7.4–7.3 (m, 3H), 7.25–7.15 (m, 4H), 3.78 (s, 2H), 3.74 (s, 2H). ^{13}C NMR, δ: 204.8 (CO), 138.1(br, Ar-C1), 133.7 (Ph-C1), 130.0 (Ar-C2), 129.6 (Ph-C2), 129.0 (Ph-C3), 127.5 (Ph-C4), 125.6 (q, J_{CF} = 3.8 Hz, Ar-C3), 49.9 (C3), 48.5 (C1), signals from Ar-C4 and CF_3 too dispersed for detection.

Also produced with **1***e* was dibenzyl(4-trifluoromethylbenzyl)carbinol (11%), bp 185–190°C/0.5 Torr. IR (cm^{-1}): 3580 m, 3070 w, 3060 w, 3035 m, 1615 m, 1600 m, 1581 w, 1491 m, 1445 s, 1413 s. ^1H NMR, δ: 7.50 (d, 2H, H-3, H-5 of Ar), 7.40–7.15 (m, 12H), 2.81 (s, 2H), 2.77 (s, 2H), 1.49 (s, OH). MS (ci, NH_3) *m/z*: 388 (M + NH_4^+, 100%), 108 (15%), 91 (22%); MS (ei) *m/z*: 279 (M − Bn^+, 30%), 261 (5%), 211 (M − $ArCH_2^+$, 10%), 159 ($ArCH_2^+$, 25%), 119(10%), 91 (100%).

General procedure for preparation of oxadiazolines (3)
A two-step process was used, involving oxidation of the acetylhydrazone (**2**) formed from the corresponding dibenzyl ketone. Virtually quantitative yields of the hydrazone were obtained by overnight refluxing of equimolar amounts of the ketone and acetylhydrazine in methanol, in the presence of a trace of acetic acid.

Acetylhydrazones (2)

*Hydrazone (2*a*)*, mp 118–119°C. IR, cm^{-1}: 3240 m, 3205 m, 3060 m, 3030 m, 2855 m, 1687 m, 1667 m, 1631 m, 1602 w, 1532 m, 1493 m, 1439 m, 1427 m, 1405. ^1H NMR (90 MHz), δ: 9.4 (s, NH), 7.3–7.0 (m, 10H), 3.56 (s, 4H), 2.24 (s, 3H, MeCO). ^{13}C NMR, δ: 173.7 (CO), 151.7 (C—N), 136.8 and 134.3 (2 × Ph-C1), 129.4 and 129.3 and 128.8 and 128.5 (2 × Ph-C2 and 2 × Ph-C3), 127.3 and 127.0 (2 × Ph-C4), 44.1 and 34.3 (2 × CH_2), 20.6 (Me).

*Hydrazone (2*b*)*, mixture of two isomers. IR (cm^{-1}): 3210 m, 3090(sh), 3055(sh), 3035 m, 2925 m, 1710(sh), 1673 s, 1615 m, 1513 m, 1495 m, 1450 m, 1423 m. ^1H NMR (90 MHz), δ: 8.6(br, NH), 7.3–6.9 (m, 9H, aryl-H), 3.57 and 3.53 and 3.48 and 3.45 (all s, 4H, 2 pairs of CH_2), 2.32 (s, 3H, MeCO), 2.30 and 2.29 (both s, 3H, ArMe).

*Hydrazone (2*c*)*, mixture of two isomers, mp 115–117°C. IR (cm^{-1}): 3190 m, 3110 w, 3080 w, 3025 w, 1671 s, 1630 w, 1610 w, 1583 w, 1509 m, 1492 m. ^1H NMR (90 MHz) δ: 8.63 (br, 1H, NH), 7.4–6.8 (m, 9H aryl-H), 3.80 (s, 3H, OMe), 3.57 and 3.50 and 3.47 and 3.42 (all s, 4H, 2 pairs of CH_2), 2.28 (s, 3*H*, MeCO).

*Hydrazone (**2**d)*; initial solid was essentially a single isomer, mp 121-124°C. IR (cm^{-1}): 3180 m, 3085 w, 3065 w, 3030 w, 1717 w, 1687 s, 1635 w, 1483 m. ^1H NMR (90 MHz) δ: 9.25 (s, br, 1H), 7.45–7.00 (m, 7H), 6.89 (d, 2H, H-3, H-5 of Ar), 3.54 (s, 2H), 3.49 (s, 2H), 2.24 (s, 3H, MeCO). Later crops of crystals were mixtures of both isomers.

*Hydrazone (2*e*)*; mixture of two isomers, first batch mp 113–126°C, second batch mp 131–137°C. ^1H NMR, δ: 9.45 and 9.28 (both s, br, 1H, NH), 7.54 (d, J = 7.5 Hz, 2H, 3-H, 5-H of Ar), 7.4–7.0 (m, 7H), 3.60 and 3.56 (both s, 4H, 2 × CH_2), 2.25 and 2.22 (two s, 3H, MeCO).

*Oxadiazolines (**3**)*

The oxidation of the hydrazones was accomplished using lead tetraacetate (1–3), and gave mixtures of by-products similar to those reported (3). Characterizations of new compounds are given below; first the target molecules, then the by-products.

*5-Benzyl-2-methoxy-2-methyl-5-(4-methylbenzyl)-Δ^3-1,3,4-oxadiazoline (**3**b)*; (80%), colourless oil, approximately equal amounts of the two isomers. IR (cm^{-1}): 3030 s, 3005 s, 2940(sh), 2930 s, 1738 m, 1605 w, 1575 w, 1515 s, 1498 s, 1454 s, 1433 s, 1405 m. ^1H NMR, δ: 7.30–6.85 (m, 9H), 3.31 and 3.26 (two d, J = 14.1 Hz, 2H, two halves of two AB quartet from CH_2 groups), 3.24 (d, J = 14 Hz, 2H, two coincident halves of two AB quartets from CH_2 groups), 3.17 and 3.13 (two s, 3H, 2 × OMe), 3.04 and 2.99 and 2.93 and 2.89 (four d, J = 14 Hz, 4H, two AB quartets from CH_2 groups), 2.32 and 2.24 (two s, 3H, 2 × ArMe), 1.00 and 0.93 (two s, 3H, 2 × 2-Me).

*5-Benzyl-2-methoxy-5-(4-methoxybenzyl)-2-methyl-Δ^3-1,3, 4-oxadiazoline (**3**c)* (73%), colourless oil consisting of the two isomers. ^1H NMR, δ: 7.4–6.9 (m, 9H), 3.81 and 3.74 major (two s, 3H, ArOMe); 3.33 and 2.93 (two d, J = 14.2 Hz), and 3.28 and 3.01 (two d, J = 14.4 Hz) (2 × CH_2, minor); 3.29 and 3.06 (two d, J = 14.2 Hz) and 3.24 and 2.90 (two d, J = 14.4 Hz) (2 × CH_2 major); 3.21 and 3.19 major (two s, 3H, 2-OMe); 1.04 major and 0.96 (two s, 2-Me). ^{13}C NMR, δ (major): 158.7 (Ar-C4), 134.3 (Ph-C1), 133.7 (C2), 131.6 (Ar-C2), 131.0 (Ph-C2), 127.9 (Ph-C3), 126.9 (Ph-C4), 126.8 (Ar-C1), 124.0 (C5), 113.7 (Ar-C3), 55.1 (ArOMe), 51.0 (2-OMe), 43.3 and 42.6 (2 × CH_2), 20.6 (Me); (minor): 158.8 (Ar-C4), 134.9 (Ph-C1), 133.7 (C2), 132.0 (Ar-C2), 130.6 (Ph-C2), 128.3 (Ph-C3), 127.0 (Ph-C4), 126.1 (Ar-C1), 124.2 (C5), 113.3 (Ar-C3), 55.0 (ArOMe), 50.9 (2-OMe), 41.47 and 40.7 (2 × CH_2), 20.4 (Me).

*5-Benzyl-5-(4-bromobenzyl)-2-methoxy-2-methyl-Δ^3-1,3,4-oxadiazoline (**3**d)* (62%), colourless oil consisting of the two isomers. IR (cm^{-1}): 3065 m, 3035 m, 3000 m, 2940 m, 2915(sh), 2840 w, 1740 m, 1605 w, 1595 w, 1575 w, 1490 s, 1455 m. ^1H NMR, δ (major): 7.45 (d, J = 8.3 Hz, H-3, H-5 of Ar), 7.30–7.15 (m, 3H of Ph), 7.04 (m, 2H of Ph), 6.89 (d, J = 8.2 Hz, H-2, H-6 of Ar); 3.25 and 2.89 (two d, J = 14.2 Hz, CH_2), 3.22 and 3.03 (two d, J = 14.0 Hz, CH_2); 3.21 (s, OMe), 1.07 (s, 2-Me); (minor): 7.30–7.15 (m, aryl-H); 3.31 and 2.92 (two d, J = 14.2 Hz, CH_2); 3.25 and 3.01 (two d, J = 14.2 Hz, CH_2); 3.19 (s, OMe), 0.98 (s, 2-Me). ^{13}C NMR, δ (major): 134.8 (Ph-C1), 134.1 (C-2), 133.4 (Ar-C1), 132.8 (Ar-C2), 131.6 (Ar-C3), 131.2 (Ph-C2), 128.6 (Ph-C3), 127.3 (Ph-C4), 123.7 (C5), 121.3 (Ar-C4), 51.3 (OMe), 43.7 and 41.1 (2 × CH_2), 20.6 (Me); (minor): 134.1 (Ph-C1), 134.0 (C2), 133.9 (Ar-C1), 132.5 (Ar-C2), 131.1 (Ar-C3), 130.7 (Ph-C2), 128.1 (Ph-C3), 127.2 (Ph-C4), 123.7 (C5), 121.2 (Ar-C4), 51.3 (OMe), 43.1 and 41.8 (2 × CH_2), 20.3 (2-Me).

*5-Benzyl-2-methoxy-2-methyl-5-(4-trifluoromethylbenzyl)-Δ^3-1,3,4-oxadiazoline (**3**e)* (31%), a mixture of the two isomers one of which formed crystals preferentially. IR (cm^{-1}): 3070 w, 3035 w, 3000 w, 2945 w, 2840 w, 1740 w, 1620 m, 1575 w, 1492 w, 1435 m, 1429 m, 1418 m. ^1H NMR, δ: 7.59 (d, J = 8.2 Hz, 2H, H-3, H-5 of Ar), 7.43 (d, J = 8.0 Hz, 2H, H-2, H-6 of Ar), 7.25–7.19 and 7.0 (m, 5H of Ph); 3.35 and 2.95 and 3.34 and 3.15 (two AB quartets, J = 14.2 Hz, 2 × CH_2); 3.20 (s, OMe), 0.98 (s, 2-Me). ^{13}C NMR, δ: 139.1 (Ar-C1), 134.2 (Ph-C1), 133.9 (C2), 131.14 (Ar-C2), 131.11 (Ph-C2), 128.1 (Ph-C3), 127.3 (Ph-C4), 125.3 (q, J_{CF} = 3.7 Hz, Ar-C3), 123.7 (C5), 51.4 (OMe), 43.5 and 41.9 (2 × CH_2), 20.1 (2-Me). Other isomer (from spectra of mixture): ^1H NMR, δ: 7.6–7.4 (m, H-3, H-5 of Ar), 7.4–7.0 (m, H-2, H-6 of Ar and 5H of Ph); 3.38 and 3.05 and 3.29 and 3.04 (two AB quartets, J = 14.2 Hz, 2 × CH_2); 3.23 (s, OMe), 1.03 (s, 2-Me). ^{13}C NMR, δ: 138.6 (Ar-C1), 134.7 (Ph-C1), 133.9 (C2), 131.5 (Ar-C2), 130.7 (Ph-C2), 128.6 (Ph-C3), 127.4 (Ph-C4), 124.9 (q, J_{CF} = 3.9 Hz, Ar-C3), 123.7 (C5), 51.3 (OMe), 43.7 and 41.3 (2 × CH_2), 20.3 (Me).

By-products from LTA oxidation

2-Methoxy-1-(4-methoxyphenyl)-3-phenylpropane: ^{13}C NMR, δ: 158.1 (Ar-C4), 139.2 (Ph-C1), 131.1 (Ar-C1), 130.5 (Ar-C2), 129.6 (Ph-C2), 128.4 (Ph-C3), 126.2 (Ph-C4), 113.8 (Ar-C3), 83.9 (C2), 57.6 (2-OMe), 55.3 (Ar-OMe), 40.3 and 39.4 (2 × CH_2).

2-Methoxy-1-phenyl-3-(4-trifluoromethylphenyl)propane: IR (cm^{-1}): 3065 w, 3030 w, 2930 m, 2825 w, 1615 w, 1490 w, 1450 w, 1432 w, 1412 w. ^1H NMR, δ: 7.52 (d, J = 8.0 Hz, 2H, H-3, H-5 of Ar), 7.35–7.20 (m, 7H, H-2, H-6 of Ar and Ph-H_5), 3.60 (quintet, J = 6.2 Hz, 1H, H-2), 3.24 (s, 3H, OMe), 2.7–2.9 (m, 4H, 2 × CH_2); ^{13}C NMR, δ: 143.4 (br, Ar-C1), 138.7 (Ph-C1), 129.9 (Ar-C2), 129.6 (Ph-C2), 128.5 (Ph-C3), 126.4 (Ph-C4), 125.2 (q, J_{CF} = 4 Hz, Ar-C3), 83.3 (C2), 57.7 (OMe), 40.3 and 40.1 (C1 and C3).

Co-eluting with **3***d* was a small amount of 2-acetoxy-1-(4-bromophenyl)-3-phenylpropane (7%), its presence being deduced from characteristic NMR signals in the mixture. ^1H NMR (partial), δ: 5.26 (quintet, J = 6.6 Hz, H-2), 2.79 (d, J = 6.6 Hz, 2 × CH_2), 1.91 (s, MeCO). ^{13}C NMR (partial), δ: 170.5 (CO), 137.5 (Ph-C1), 136.5 (Ar-C1), 131.3 (Ar-C2), 129.5 (Ph-C2), 128.5 (Ph-C3), 126.8 (Ph-C4), 75.0 (C2), 39.8 (CH_2).

Co-eluting with **3***e* was a small amount of 2-acetoxy-1-phenyl-3-(4-trifluoromethylphenyl)propane (8%). IR (cm^{-1}): 3065 w, 3030 w, 2950 w, 2925 w, 2850 w, 1740 s, 1616 w, 1605(sh), 1581 w, 1490 w, 1450 w, 1432 w, 1413 w. ^1H NMR, δ: 7.53 (d, J = 8.0 Hz, H-3, H-5 of Ar), 7.34–7.16 (m, H-2, H-6 of Ar and Ph-H_5), 5.31(quintet, H-2), 2.9–2.8 (m, 2 × CH_2), 1.93 (s, MeCO). ^{13}C NMR, δ: 170.4 (CO), 141.8 (Ar-C1), 137.2 (Ph-C1), 129.9 (Ar-C2), 129.6 (Ph-C2), 128.7

(Ph-C3), 126.9 (Ph-C4), 125.4 (q, J_{CF} = 3.7 Hz, Ar-C3), 74.9 (C2), 40.3 and 39.9 (C1 and C3), 21.2 (COMe).

2-Acetoxy-5-benzyl-2-methyl-5-(4-methylbenzyl)-Δ^3-1,3,4-oxadiazoline (9%), a mixture of the two isomers. IR (cm^{-1}): 3060 w, 3030 w, 2940(sh), 2925 w, 1760 s, 1724 m, 1606 w, 1515 w, 1498 w, 1453 m, 1436 m. ^{1}H NMR (90 MHz), δ: 7.3–7.0 (m, 9H), 3.7–2.9 (m, 4H, two pairs of CH_2); 2.32 and 2.26 (two s, 3H, ArMe), 1.79 (s, 3H, MeCO), 1.20 and 1.16 (two s, 3H, two 2-Me).

2-Acetoxy-5-benzyl-5-(4-methoxybenzyl)-2-methyl-Δ^3-1,3,4-oxadiazoline (12%), a mixture of the two isomers. IR (cm^{-1}): 3065 w, 3035 w, 3003 w, 2950(sh), 2930 w, 2838 w, 1755(br) s, 1611 s, 1583 m, 1510 s, 1498 s, 1455 m, 1440 m. ^{1}H NMR (90 MHz) δ: 7.3–6.7 (m, 9H); 3.78 and 3.76 (two s, 3H, 2 × ArOMe); 3.6–2.9 (m, 4H, 2 × CH_2); 1.82 and 1.79 (two s, 3H, 2 × MeCO); 1.27 and 1.25 (two s, 3H, 2 × 2-Me). ^{13}C NMR, δ (major): 168.0 (CO), 159.0 (Ar-C4), 134.4 (Ph-C1), 132.3 (Ar-C2), 131.2 (C2), 130.9 (Ph-C2), 128.5 (Ph-C3), 128.38 (C5), 127.3 (Ph-C4), 125.7 (Ar-C1), 113.6 (Ar-C3), 55.4 (Ar-OMe), 43.7 and 41.8 (2 × CH_2), 21.9 (MeCO), 21.0 (Me); (minor): 168.0 (CO), 159.0 (Ar-C4), 133.8 (Ph-C1), 131.9 (Ar-C2), 131.3 (Ph-C2), 128.4 (C5), 128.2 (Ph-C3), 127.3 (Ph-C4), 126.3 (Ar-C1), 114.0 (Ar-C3), 55.4 (Ar-OMe), 43.0 and 42.4 (2 × CH_2), 21.2 (MeCO), 20.9 (Me), C2 not observed.

2-Acetoxy-5-(4-bromobenzyl)-5-benzyl-2-methyl-Δ^3-1,3,4-oxadiazoline (12%), as a 7:3 mixture of the two isomers, mp 78–95°C. ^{1}H NMR, δ (major): 7.4–6.9 (m, aryl-H); 3.53 and 3.33 and 3.17 and 3.08 (two AB quartets, J = 14.2 Hz, 2 × CH_2); 1.79 (s, MeCO), 1.15 (s, Me); (minor): 7.4–6.9 (m, aryl-H); 3.47 and 3.00 (AB quartet, J = 14.2 Hz, one CH_2; signals from other CH_2 obscured); 1.82 (s, MeCO), 1.29 (s, Me). ^{13}C NMR, δ (major): 167.8 (CO), 133.4 (Ph-C1), 133.2 (Ar-C1), 132.6 (Ar-C2), 131.6 (Ar-C3), 131.5 (C2), 131.2 (Ph-C2), 128.2 (Ph-C3), 127.8 (C5), 127.5 (Ph-C4), 121.5 (Ar-C4), 43.0 and 42.8 (2 × CH_2), 21.8 (MeCO), 20.9 (Me); (minor): 167.8 (CO), 134.1 (Ph-C1), 132.9 (Ar-C2), 131.4 (Ar-C3), 131.2 (C2), 130.8 (Ph-C2), 128.6 (Ph-C3), 127.7 (C5), 127.5 (Ph-C4), 121.5 (Ar-C4), 43.8 and 41.7 (2 × CH_2), 21.8 (COMe), 21.1 (Me), Ar-C1 not observed.

General procedure for photolysis of oxadiazolines (3)

In the general method adopted (3) the oxadiazoline (typically 1.5 mmol) and dimethyl acetylenedicarboxylate (in 10% excess) were mixed in benzene (typically 6.0 mL, giving a concentration of ca. 0.25 M) in a quartz tube, and photolyzed with 300 nm light in a Rayonnet apparatus. The reaction mixture became yellow almost at once, and a gentle stream of gas (presumably nitrogen) was evolved. For the initial runs, progress of the reaction was monitored by running ^{1}H NMR spectra at hourly intervals, and typically after 5 h the amount of starting oxadiazoline had dropped to about 5%. In later experiments, therefore, photolysis was halted at this time. The solvent was removed on a rotary evaporator, and the residue was separated by centrifugal chromatography on 4 mm silica gel plates. Between 10 and 17 distinct bands were usually present, although not all fractions could be satisfactorily identified. As a general picture, the first fraction from the plate would be mixed 1, 3-diarylpropenes (**14** and **15**), followed by unchanged starting materials, followed by methylenecyclopropene isomers (**17** and **18**), closely followed by symmetrical cyclopropene **4** and unsymmetrical cyclopropene **16**, followed by the unstable yellow compound **25**, just in front of 1, 5-dibenzyl-1*H*-pyrazole (**19**) and, lastly, 5-benzyl-1*H*-pyrazole (**20**). A variety of other compounds were formed on one or two occasions only. Usually several fractions needed further purification on thinner plates; sometimes equivalent fractions from different runs were combined for this. Yields are of isolated material and are corrected for recovered starting material.

*Photolysis of dibenzyl oxadiazoline (**3**a) (12 runs)*

Typical results from one run are as follows. Similar results were found in other runs, but percentages varied with run and conditions, as did the presence of occasional minor products, which are detailed later.

The known (3) *1,3-diphenylpropenes **14**a and **15**a* (2%).

*Dimethyl 3,3-dibenzylcyclopropene-1,2-dicarboxylate (**4**a)* (35%), was obtained as a pale yellow oil, together with dimethyl (*E*)-1-benzyl-3-(phenylmethylene)cyclopropane-*trans*-1,2-dicarboxylate (**17***a*) and dimethyl (*Z*)-1-benzyl-3-(phenylmethylene)cyclopropane-*trans*-1,2-dicarboxylate (**18***a*) (3%) in approximately 1:1 ratio. It proved impossible to separate these cleanly using the Chromatotron, but partial enrichment of each allowed assignment of signals in NMR spectra. For **17***a*, ^{1}H NMR, δ: 7.5–7.2 (m, Ph-H), 6.79 (d, J = 2.4 Hz, vinyl-H); 3.69 and 3.66 (two s, 2 × OMe); 3.47 (d, J = 2.3 Hz, methine-H), 3.38 (s, CH_2). In an NOE experiment, irradiation of the doublet at 6.79 δ gave enhancement of a phenyl-H signal at 7.4 δ, irradiation of doublet at δ = 3.47 gave enhancement of a phenyl-H signal at 7.3 δ, and irradiation of singlet at δ = 3.38 gave enhancement of vinyl-H at 6.79 δ and of phenyl-H at 7.3 δ. For ^{13}C NMR data see Table 2. MS (ei) on mixture, *m/z*: 336 (M^+, 5%), 304 (15%), 276 ($M - EH^+$, 15%), 245 ($M - Bn^+$, 25%), 217 ($276 - E^+$, 65%), 214 (5%), 202 (35%), 189 (10%), 115 (65%), 91 (100%), 77 (35%). MS (ci, NH_3) *m/z*: 354 ($M + NH_4^+$, 100%), 337 ($M + H^+$, 12%), 305 ($M - OMe^+$, 10%), 252 (12%), 228 (10%), 202 (5%), 121 (7%).

For **18***a*, ^{1}H NMR, δ: 7.5–7.2 (m, Ph-H), 6.88 (d, J = 2 Hz, vinyl-H); 3.91 and 3.11 (AB quartet, J = 16 Hz, CH_2); 3.70 and 3.55 (two s, 2 × OMe); 3.44 (d, J = 2 Hz, methine-H). In an NOE experiment, irradiation of the doublet at δ = 6.88 gave enhancement at phenyl-H signal at 7.38 δ, and slight enhancement of doublet at 3.44 δ. Irradiation of doublet at δ = 3.44 gave possible enhancement at 6.88 δ, but not of methylene signals.

*Dimethyl 2,3-dibenzylcyclopropene-1,3-dicarboxylate (**16**a)* (14%), pale yellow oil. ^{1}H NMR (500 MHz) δ: 7.27 (t, br, J = 7 Hz, 3*H* of Ph), 7.24–7.16 (m, 3*H* of Ph), 7.10 (d, J = 7 Hz, 2H, H-2, H-6 of Ph), 7.04 (d, J = 7 Hz, 2H, H-2, H-6 of Ph); 3.77 and 3.67 (AB quartet, J = 17.8 Hz, 2H, 2-CH_2); 3.71 and 3.55 (two s, 6H, 2 × OMe); 3.32 and 3.24 (AB quartet, J = 14.2 Hz, 2H, 3-CH_2); for ^{13}C NMR see Table 1.

The known (3) *dihydroazulene **28**a*, (2%).

*Pyrazole-N-oxide (**25**a)*, bright yellow oil. UV (1.66 mg/mL MeOH) λ_{max}, nm: 282 (ε = 550), 372 (ε = 420). ^{1}H NMR, δ:

[c]Parentheses indicate presumed position of signal, obscured by others in sample.

H-5 of Bz); 3.97 and 3.83 (two s, 6H, 2 × OMe). ^{13}C NMR, δ: 186.2 (PhCO), 163.4 (COOMe), 159.1 (COOMe), 147.9 (C3, C5), 136.2 (Ph-C1), 135.2 (C4), 133.8 (Ph-C4), 130.3 (Ph-C2), 128.7 (Ph-C3), 119.4 (C4), 53.2, 53.1. MS (ei) *m/z*: 288 (M^+, 5%), 257 (M − OMe^+, 10%), 225 (10%), 105 (Bz^+, 63%), 91 (60%), 77 (100%). MS (ci, NH_3) *m/z*: 289 (M + H^+, 100%), 275 (15%), 257 (8%). HRMS, Exact Mass calcd. for $C_{14}H_{12}N_2O_5$: 288.0746; found: 288.0755.

Other products from photolysis of ***3****a in the presence of DMAD*

On several occasions dimethyl 1,3,5,7-cyclooctatetraene-1,8-dicarboxylate was isolated (ca. 8%). IR (cm^{-1}): 3060 w, 3020 m, 2955 m, 2910 w, 2850 w, 1722 s, 1656 m, 1640 m, 1605 w, 1495 w, 1435 m. ^1H NMR, δ: 7.19 (d, *J* = 3.3 Hz, 2H, H-2, H-7), 6.07 (dd, *J* = 11.5, 3.3 Hz, 2H, H-3, H-6), 5.95 (d, *J* = 11.1 Hz, 2H, H-4, H-5), 3.88 (s, 6H, OMe). ^{13}C NMR, δ: 166.1 (CO), 143.2 (C-2), 132.8 and 130.2 (C-3 and C-4), 132.2 (C-1), 52.3 (OMe). MS (ei) *m/z*: 220 (M^+, 35%), 188 (35%), 161 (M − E^+, 75%), 160 (100%), 133 (90%), 102 (85%), 91 (75%), 76 (35%). MS (ci, NH_3) *m/z*: 238 (M + NH_4^+, 30%), 221 ($M+H^+$, 100%), 189 (M − OMe^+, 10%), 160 (5%). The NMR data fit well with those in the literature (43), and the IR data fit moderately well with published mull data (44).

On one occasion, a small amount of an unidentified compound was obtained with ^1H NMR, δ: 9.3 (s, br, 1H), 7.20 (dd, *J* = 6.6 Hz, 2.1 Hz, ca. 2H), 6.85 (dd, *J* = 6.6 Hz, 2.1 Hz, ca. 2H), 3.79 (s, 3H, OMe), 3.59 (s, 2H, CH_2), 2.01(s, 3H, Me). ^{13}C NMR (spin sort mode) δ: 176.8 (CO), 167.9 (CO), 158.9 (), 130.5 (intense, =CH-), 125.8 (), 114.2 (intense, =CH-), 102.6 (quat-C), 55.4 (OMe), 40.3 (CH_2), 20.7 (Me).

On a few occasions, and contaminated with other components, small amounts of what is probably the dihydronaphthalene ***29****a* (ca. 1.5%), were isolated. Partial spectrum: ^1H NMR, δ: 4.91(s, br, 1H), 4.16 and 4.10 (AB quartet, *J* = 14.2 Hz, 2H, CH_2), 3.80 and 3.66 (two s, 2 × OMe), 3.34 (d, *J* = 20 Hz, 1H, upfield half of an AB quartet).

*Photolysis of oxadiazoline (****3****a) in methanol (1 run)*

Oxadiazoline (***3****a*) was photolyzed as described above, but using methanol as solvent. The majority of the products were the same as with benzene as solvent, but one new component was methyl 4-benzyl-3-methoxycarbonyl-2-methoxy-5-phenylpent-3-enoate (**30**) (4%). IR (cm^{-1}): 3080 w, 3065 w, 3030 w, 3000 w, 2955 m, 2830 w, 1760 s, 1729 s, 1652 w, 1600 w, 1490 m, 1450 m, 1433 m. ^1H NMR (500 MHz) δ: 7.30–7.25(m, 4H of Ph), 7.22(t, *J* = 7 Hz, 2H of Ph), 7.17 (d, *J* = 7 Hz, 2H, H-2, H-6 of Ph), 7.14 (d, *J* = 7 Hz, 2H, H-2, H-6 of Ph), 4.86 (s, 1H, methine-H), 3.81 (s, 3H, 1-OMe), 3.77 (s, 3H, 3-COOMe); 3.63 and 3.59 (AB quartet, *J* = 14.5 Hz, 2H, CH_2 *cis* to 3-E); 3.53 (s, 2H, CH_2 *cis* to CHEOMe), 3.41 (s, 3H, 2-OMe). ^{13}C NMR, δ: 170.6 (C1, i.e., *C*OOMe), 167.9 (3-*C*OOMe), 150.0 (C4), 138.4 and 137.9 (2 × Ph-C1), 131.3 (C3), 129.3 and 129.1 and 128.8 and 128.7 (C2

Low-temperature photolysis of **3**a *(2 runs)*

Compound **3***a* was photolyzed in the presence of DMAD in toluene at −40°C, using a thin-walled NMR tube. After 5 h the mixture contained the unstable 3*H*-pyrazole **6***a*, but only about half the oxadiazoline had reacted. Also present was a small amount of symmetric cyclopropene (**4***a*), but apparently no unsymmetrical cyclopropene (**16***a*). After 4 days in solution, compound **6***a* had disappeared, and some of the new signals could be assigned to the 1, 5-dibenzyl 1*H*-pyrazole **19***a*.

In a repeat run, most of the oxadiazoline had been consumed after 10 h. Separation gave propenes **14***a* and **15***a* (2%), unchanged starting material, cyclopropene **4***a* (22%), as well as an unidentified compound with ^1H NMR, δ: 7.35–7.15 (m, ca. 8H), 7.02 (d, *J* = 7 Hz, 2H), 3.89 (s, 2H, CH$_2$), 3.80 and 3.76 (two s, 2 × OMe), 3.49 (s, 2H, CH$_2$). ^{13}C NMR, δ: 166.8 and 158.1 (2 × CO), 138.1 and 137.3 (2 × C1 of Ph), 129.2 and 128.9 and 128.8 (CH of Ph), 126.9 and 126.7 (2 × C4 of Ph), 52.5 (2 × OMe), 40.4 and 38.8 (2 × CH$_2$). Final components were unsymmetric cyclopropene **16***a* (11%), benzoyl 4*H*-pyrazole **21***a* (5%), and monobenzyl 1*H*-pyrazole **20***a* (2%).

*Photolysis of oxadiazoline (***3**b*) (1 run)*

Separation gave a mixture of 1, 3-diarylpropenes (**14***b*, **14***c*, **15***b*, and **15***c*) in ratio approximately 3:3:1:1 (3%), and the following additional compounds in this order. Methylenecyclopropanes **17***c* and **18***c* in approximately equal amounts, but each occurring with about 25% of the positional isomers **17***b* and **18***b* (combined total yield: 10%). This mixture of four components could not be separated on the Chromatotron. IR (mixture) (cm^{-1}): 3030 w, 3005 w, 2950 w, 2925 w, 1728 s, 1510 w, 1494 w, 1448(sh), 1431 m. ^1H NMR (**18***c*), δ: 7.45–7.00 (m, aryl-H), 6.87 (d, *J* = 2.0 Hz, vinyl-H); 3.85 and 3.08 (AB quartet, *J* = 15.7 Hz, 2H, CH$_2$), 3.70 and 3.58 (two s, 2 × OMe), 3.40 (d, *J* = 2.2 Hz, 1H, methine-H), 2.28 (s, 3H, ArMe); **18***b* includes 6.85 (d, *J* = 2.0 Hz, vinyl-H); 3.92 and 3.09 (AB quartet, *J* = 15.9 Hz, CH$_2$); 3.54 (s, OMe), 2.36 (s, ArMe); **17***c* includes 6.75 (d, *J* = 2.3 Hz, vinyl-H); 3.69 and 3.65 (two s, 2 × OMe); 3.45 (d, *J* = 2.3 Hz, methine-H), 3.33 (s, CH$_2$), 2.32 (s, ArMe); (**17***b*) includes 6.79 (d, *J* = 2.3 Hz, vinyl-H), 3.37 (s, CH$_2$), 2.34 (s, ArMe).

*Dimethyl 3-benzyl-3-(4-methylbenzyl)cyclopropene-1,2-dicarboxylate (***4**b*) (16%). IR (cm^{-1}): 3030 w, 2955 w, 2915 w, 2850 w, 1833 m, 1713 s, 1605 w, 1510 w, 1491 w, 1445(sh), 1430 m. ^1H NMR, δ: 7.4–6.9 (m, 9H), 3.74 (s, 6H, 2 × OMe); 3.11 and 3.08 (two s, 2 × CH$_2$), 2.28 (s, 3*H*, ArMe). ^{13}C NMR, δ:160.0 (CO), 138.3 (Ph-C1), 135.9 (Ar-C4), 135.1 (Ar-C1), 129.8 (Ph-C2), 129.7 (Ar-C2), 129.2 (Ar-C3), 128.5 (Ph-C3), 126.8 (C1 and C2), 126.5 (Ph-C4), 52.7 (OMe), 43.0 and 42.6 (2 × CH$_2$), 41.3 (C3), 21.2 (Ar-Me).

*Dimethyl 2-benzyl-3-(4-methylbenzyl)cyclopropene-1,3-dicarboxylate (***16**b*) and dimethyl 3-benzyl-2-(4-methylbenzyl)-cyclopropene-1,3-dicarboxylate (***16**c*)* as a 2:1 mixture (25%). The isomers could not be separated. IR (of mixture) cm^{-1}: 3030 w, 3005 w, 2950 w, 2920 w, 1867 m, 1720 s, 1605 w, 1510 m, 1492 w, 1445 (sh), 1430 m. ^1H NMR of **16***b* (from the

For personal use only.

mixture), δ: 7.3–6.9 (m, aryl-H), 3.72 and 3.54 (two s, 2 × OMe); 3.8–3.5 (m, 2-CH_2; partly obscured), 3.29 and 3.18 (AB quartet, J = 14.4 Hz, 3-CH_2); 2.28 (s, ArMe). Partial ^{1}H NMR of **16***c* (remaining signals obscured by those of **16***b*), δ: 3.71 and 3.56 (two s, 2 × OMe); 3.31 and 3.22 (AB quartet, J = 14 Hz, 3-CH_2) 2.31 (s, ArMe).

Pyrazole-N-*oxide* (**25**b), bright yellow oil (3%). ^{1}H NMR, δ: 8.06 (s, br, 1H, OH), 7.4–6.9 (m, 9H), 5.75 (s, 1H, >CH-), 3.90 and 3.77 (two s, 2 × OMe), 3.72 and 3.28 (AB quartet, J = 13.5 Hz, CH_2) 2.25 (s, ArMe). This compound was unstable, and after 2 weeks' exposure to air at room temperature had changed to a complex mixture. Based on the major signals in the ^{1}H NMR spectrum of the mixture the principal component was methyl 5-benzoyl-4-(4-methylbenzyl)-1*H*-pyrazole-3-carboxylate (**22***b*). ^{1}H NMR, δ: 8.02 (d, J = 7 Hz, 2H, H-2, H-6 of Bz), 7.56 (t, J = 7 Hz, 1H, H-4 of Bz), 7.44 (t, J = 7 Hz, 2H, H-3, H-5 of Bz), 7.16 (d, J = 8.0 Hz, 2H, H-2, H-6 of Ar), 7.02 (d, J = 8.0 Hz, 2H, H-3, H-5 of Ar), 4.46 (s, 2H, 4-CH_2), 3.94 (s, 3*H*, OMe), 2.26 (s, 3H, Ar-Me).

*Dimethyl 5-benzyl-1-(4-methylbenzyl)-1*H*-pyrazole-3,4-dicarboxylate (19*b) (6%). IR (cm^{-1}): 3035 w, 3005 m, 2955 m, 2930 (sh), 2860 w, 1730 s, 1602 w, 1531 w, 1511 w, 1491 m, 1477 m, 1445(sh), 1432 s. ^{1}H NMR, δ: 7.3–6.9 (m, 9H), 5.13 (s, 2H, N-CH_2), 4.16 (s, 2H, 5-CH_2), 3.96 and 3.81 (two s, 2 × OMe); 2.31 (s, 3H, ArMe). ^{13}C NMR, δ: 163.6 and 162.8 (2 × CO), 145.3 (C3), 138.1 (Ar-C4), 136.1 (Ph-C1), 132.0 (Ar-C1), 129.7 (Ar-C3), 129.0 (Ph-C3), 128.3 (Ph-C2), 127.1 (Ph-C4), 127.0 (Ar-C2), 114.2 (C4), 54.3 (*N*-CH_2), 52.7 and 52.1 (2 × OMe), 30.3 (5-CH_2), 21.3 (Ar-Me), signal from C5 not clearly visible. MS(ei) *m/z*: 378 (M^+, 10%), 346 (M − $MeOH^+$, 10%), 314 (5%), 273 (M − $ArCH_2^+$, 25%), 241 (20%), 105 ($ArCH_2^+$, 100%), 91 (25%), 77 (20%). HRMS, Exact Mass calcd. for $C_{22}H_{22}N_2O_4$: 378.1580; found: 378.1583.

Compound **20**a *and dimethyl 5-(4-methylbenzyl)-1*H*-pyrazole-3,4-dicarboxylate (**20**b)* as a 3:2 mixture (ca. 4%). Because of overlap by signals from **20***a*, only partial spectra are available for **20***b*. ^{1}H NMR, δ: 4.23 (s, CH_2); 3.92 and 3.84 (two s, 2 × OMe); 2.33 (s, ArMe). ^{13}C NMR, δ: 163.3 and 162.3 (2 × CO), 137.2 (Ar-C4), 133.3 (Ar-C1), 129.9 (Ar-C3), 129.0 (Ar-C2), 52.8 and 52.0 (2 × OMe), 21.2 (Ar-Me).

Photolysis of para-*methoxybenzyl oxadiazoline (***3**c*) (1 run)* Separation gave first a mixture of the 1,3-diarylpropenes **14***d*, **14***e*, **15***d*, and **15***e* in approximate ratio 2:2:1:1 (2%), then the following additional products.

*Dimethyl 3-benzyl-3-(4-methoxybenzyl)cyclopropene-1,2-dicarboxylate (**4**c)* (6%). IR(cm^{-1}): 3065 w, 3030 w, 3005 w, 2955 m, 2915 m, 1834 m, 1715 s, 1610 m, 1581 w, 1509 m, 1495 m, 1450 m, 1430 s. ^{1}H NMR (90 MHz) δ: 7.17–7.10 (m, 3H of Ph), 7.05–7.01 (m, 2H of Ph), 6.92 (d, J = 8.6 Hz, 2H, H-2, H-6 of Ar), 6.69 (d, J = 8.6 Hz, 2H, H-3, H-5 of Ar), 3.68 (s, 9H, ArOMe and 2 × COOMe), 3.03 and 2.99 (two s, 2 × CH_2). ^{13}C NMR, δ: 160.1 (CO), 158.3 (Ar-C4), 138.4 (Ph-C1), 130.8 (Ar-C2), 130.3 (Ar-C1) 129.8 (Ph-C2), 128.5 (Ph-C3), 126.9 (C1 and C2), 126.5 (Ph-C4), 114.0 (Ar-C3), 55.3 (Ar-OMe), 52.7 (COO*Me*), 43.0 and 42.2 (2 × CH_2), 41.5 (C3).

*Dimethyl (*E*)-1-(4-methoxybenzyl)-3-phenylmethylenecyclopropane*-trans-*1,2-dicarboxylate (**17**e) and dimethyl (*Z*)-1-(4-methoxybenzyl)-3-phenylmethylenecyclopropane*-trans-*1, 2-dicarboxylate (**18**e)* in 1:1 ratio, as a mixture (2.5%). Characteristic ^{1}H NMR signals were discernable as follows; for **17***e*, δ: 6.77 (d, J = 2.2 Hz, vinyl-H), 3.70 and 3.66 (two s, 2 × OMe), 3.44 (d, J = 2.3 Hz, methine-H), 3.30 (s, CH_2); for **18***e*, δ: 6.87 (d, J = 2.0 Hz, vinyl-H), 3.71 and 3.60 (two s, 2 × OMe), 3.38 (d, J = 1.9 Hz, methine-H), 3.06 (d, J = 15.6 Hz, half of CH_2 AB quartet; other half obscured by ester signals).

*The methoxy analogue of **29**a*, as a mixture of two isomers; presumably **29***b* and **29***c*. Distinguishable signals in the ^{1}H NMR spectrum: major isomer, δ: 4.86 (s, br, 1H), 4.19 and 4.06 (AB quartet, J = 14.4 Hz, CH_2), 3.72 and 3.71 and 3.60 (three s, 2 × COOMe and ArOMe); minor isomer, δ: 4.90 (s, br, 1H), 4.10 and 3.99 (AB quartet, J = 13.8 Hz, CH_2), 3.73 and 3.70 and 3.59 (three s, 2 × COOMe and ArOMe).

*Dimethyl 2-benzyl-3-(4-methoxybenzyl)cyclopropene-1,3-dicarboxylate (**16**d)*. ^{1}H NMR, δ: 7.3–7.1 (m, 5H of Ph), 6.92 (d, J = 8.7 Hz, 2H, H-2, H-6 of Ar), 6.74 (d, J = 8.7 Hz, 2H, H-3, H-5 of Ar), 3.79 (m, 2H, 2-CH_2), 3.76 and 3.72 (two s, 9H, 2 × COOMe and ArOMe), 3.22 (m, 2H, 3-CH_2).

*Dimethyl 3-benzyl-1-(4-methoxybenzyl)-1*H*-pyrazole-4,5-dicarboxylate (**32**)* (5%), as a yellow oil. IR (cm^{-1}): 3060 w, 3030 w, 3000 w, 2950 m, 2835 w, 1725 s, 1610 m, 1582 w, 1535 m, 1510 s, 1491 m, 1461 m, 1451 m, 1431 m. ^{1}H NMR, δ: 7.26–7.18 (m, 5H of Ph), 7.16 (d, J = 8.6 Hz, 2H, H-2, H-6 of Ar), 6.88 (d, J = 8.6 Hz, 2H, H-3, H-5 of Ar), 5.40 (s, 2H, N-CH_2), 4.18 (s, 2H, 3-CH_2), 3.82 and 3.78 and 3.74 (three s, 2 × COOMe and ArOMe). In an NOE experiment, irradiation at δ = 5.40 caused enhancement of the doublet at 7.16 δ but had no effect on the singlet at 4.18 δ; equally, irradiation at δ = 4.18 enhanced the multiplet at δ = 7.2, but had no effect on the singlet at δ = 5.4. ^{13}C NMR, δ: 163.3 and 161.1 (2 × CO), 159.4 (Ar-C4), 152.0 (C3), 139.1 (C5), 135.7 (Ph-C1), 129.3 and 128.9 (Ar-C2 and Ph-C3), 128.1 (Ph-C2), 126.3 (Ph-C4 and Ar-C1(?)), 114.3 (C4), 113.6 (Ar-C3), 55.4 (ArOMe), 54.7 (N-CH_2), 53.0 and 51.8 (2 × COO*Me*), 33.4 (3-CH_2). MS(ei) *m/z*: 394 (M^+, 10%), 362 (M − 32$^+$, 10%), 307 (15%), 275 (5%), 121 ($MeOBn^+$, 100%), 91 (Bn^+, 20%).

Pyrazole-N-*oxide* (**25**c) as a bright yellow oil. IR (cm^{-1}): 3350(br) w, 3030 w, 3000 w, 2955 w, 2835 w, 1740 s, 1710 s, 1655 m, 1611 w, 1600 w, 1555 m, 1511 m, 1450 s, 1411 m. ^{1}H NMR, δ: 8.04 (s, br, OH), 7.40–7.35 (m, 2H of Ph), 7.25–7.18 (m, 3H of Ph), 6.98 (d, J = 8.7 Hz, 2H, H-2, H-6 of Ar), 6.70 (d, J = 8.7 Hz, 2H, H-3, H-5 of Ar), 5.74 (s, 1H, >CH-), 3.96 and 3.77 (two s, 2 × COOMe), 3.74 (s, ArOMe), 3.71 and 3.27 (AB quartet, J = 13.7 Hz, CH_2). MS (ei) *m/z*: 394 (M^+, 5%), 121 ($MeOBn^+$, 100%), 105 (10%), 77 (12%). On exposing the solution to the atmosphere for several days, **25***c* was converted primarily to methyl 5-benzoyl-4-(4-methoxybenzyl)-1*H*-pyrazole-3-carboxylate (**22***c*). IR (cm^{-1}): 3270(br) m, 3070 w, 3040 w, 3005 w, 2960 m, 2842 w, 1730 s, 1655 s, 1613 m, 1601 m, 1582 w, 1511 s, 1452 s, 1442 s. ^{1}H NMR, δ: 8.02 (d, J = 7.0 Hz, 2H, H-2, H-6 of Bz), 7.59 (t, J = 7.3 Hz, 1H, H-4 of

For personal use only.

Bz), 7.46 (t, J = 7.7 Hz, 2H, H-3, H-5 of Bz), 7.20 (d, J = 8.7 Hz, 2H, H-2, H-6 of Ar), 6.76 (d, J = 8.7 Hz, 2H, H-3, H-5 of Ar), 4.44 (s, 2H, CH_2), 3.97 (s, 3H, COOMe), 3.74 (s, 3H, ArOMe). ^{13}C NMR, δ (partial spectrum): 189.1 (PhCO), 160.1 (*C*OOMe), 158.1 (Ar-C4), 137.9 (Ph-C1), 133.0 (Ph-C4), 132.8 (Ar-C1), 129.8 (Ar-C2), 128.4 (Ph-C3), 113.9 (Ar-C3), 55.4 (Ar-OMe), 52.5 (COO*Me*), 28.2 (CH_2).

*Dimethyl 5-benzyl-1-(4-methoxybenzyl)-1*H*-pyrazole-3,4-dicarboxylate (**19**d)* (25%). IR (cm^{-1}): 3050 w, 3025 w, 2995 w, 2945 m, 2830 w, 1735 s, 1718 s, 1611 m, 1584 w, 1531 m, 1512 s, 1493 s, 1477 s, 1453 s, 1438 s. ^{1}H NMR, δ: 7.2 (m, 3H of Ph), 7.06 (m, 2H of Ph), 6.96 (d, J = 8.8 Hz, 2H, H-2, H-6 of Ar), 6.79 (d, J = 8.6 Hz, 2H, H-3, H-5 of Ar), 5.11 (s, 2H, N-CH_2), 4.19 (s, 2H, 5-CH_2), 3.96 and 3.81 (two s, 2 × COOMe), 3.77 (s, 3H, ArOMe). ^{13}C NMR, δ: 163.4 and 162.7 (2 × CO), 159.6 (Ar-C4), 145.1 (C3), 143.0 (C5), 136.0 (Ph-C1), 129.0 (Ph-C3), 128.6 (Ar-C2), 128.2 (Ph-C2), 127.1 (Ar-C1), 127.0 (Ph-C4), 114.3 (Ar-C3), 114.0 (C4), 55.4 (Ar-OMe), 53.9 (N-CH_2), 52.6 and 52.0 (2 × COO*Me*), 30.2 (5-CH_2).

Finally, dimethyl 5-benzyl-1*H*-pyrazole-3, 4-dicarboxylate (**20***a*) (7%) was isolated.

Photolysis of para*-bromobenzyl oxadiazoline (**3**d) (2 runs)*
Separation after first run gave a mixture of 1,3-diarylpropenes **14***f*, **14***g*, **15***f*, and **15***g* (5%), then the following compounds in this sequence. First a ca. 4:4:3:2 mixture of methylenecyclopropenes **18***g*, **17***f*, **17***g*, and **18***f* (combined yield, 3%). The isomers could not be cleanly separated, and the spectra are those of mixtures, with not all signals being resolved. ^{1}H NMR data, partial spectra: dimethyl 3-(*E*)-(4-bromophenylmethylene)-1-benzylcyclopropane-*trans*-1,2-dicarboxylate (**17***f*), δ: 6.75 (d, J = 2.4 Hz, 1H, vinyl-H), 3.72 and 3.66 (two s, 2 × OMe), 3.46 (d, J = 2.4 Hz, 1H, methine-H), 3.22 (s, 2H, CH_2); dimethyl 1-(4-bromobenzyl)-3-(*E*)-(phenylmethylene)cyclopropane-*trans*-1,2-dicarboxylate (**17***g*), δ: 6.72 (d, J = 2.3 Hz, 1H, vinyl-H), 3.69 and 3.67 (two s, 2 × OMe), 3.45 (d, J = 2.4 Hz, 1H, methine-H), 3.36 (s, 2H, CH_2); dimethyl 1-benzyl-3-(Z)-(4-bromophenylmethylene)cyclopropane-*trans*-1,2-dicarboxylate (**18***f*), δ: 6.83 (d, J = 2.0 Hz, 1H, vinyl-H), 3.82 and 3.13 (AB quartet, J = 15.8 Hz, CH_2), 3.57 (s, OMe); dimethyl 1-(4-bromobenzyl)-3-(*Z*)-(phenylmethylene)cyclopropane-*trans*-1,2-dicarboxylate (**18***g*), δ: 6.89 (d, J = 2.0 Hz, 1H, vinyl-H), 3.77 and 3.11 (AB quartet, J = 15.8 Hz, CH_2), 3.71 and 3.60 (two s, 2 × OMe), 3.39 (d, J = 1.8 Hz, 1H, methine-H).

A minor component, eluting with the methylenecyclopropenes, was not fully purified. Based on comparison with literature data (3), it was probably *2-benzyl-6-bromo-3,3a-bis(methoxycarbonyl)-1,3a-dihydroazulene (**28**b)*. ^{1}H NMR (500 MHz) includes δ: 6.47 and 6.36 (two d, J = 2.6 Hz, 2 × =CH-), 6.09 and 5.75 (two d, J = 5.8 Hz, 2 × =CH-), 4.17 and 3.86 (AB quartet, J = 14.5 Hz, 2-CH_2), 3.77 and 3.64 (two s, 2 × OMe), 2.96 and 2.52 (AB quartet, J = 18.5 Hz, 2 × H-1). ^{13}C NMR (125 MHz), tentative assignments, δ: 173.0 (3a-*C*OOMe), 165.6 (3-*C*OOMe), 157.1 (C2), 143.2 and 139.6 (2 × CH), 138.1 (Ph-C1), 136.0 and 133.4 (2 × CH), 132.1 (C8a), 131.1 (C3 or C6), 129.0 and 128.7 (Ph-C2, Ph-C3), 127.6 (C6 or C3), 126.6 (Ph-C4), 60.8 (C3a), 52.3 and 51.3 (2 × OMe), 47.4 (C1), 36.5 (2-CH_2).

*Dimethyl 3-benzyl-3-(4-bromobenzyl)cyclopropene-1,2-dicarboxylate (**4**d)* (16%). IR (cm^{-1}): 3075 w, 3055 w, 3020 w, 2995 w, 2945 m, 2910 w, 2835 w, 2075 w, 1835 m, 1720 s, 1600 w, 1485 m, 1431 m. ^{1}H NMR, δ: 7.35 (d, J = 8.3 Hz, 2H, H-3, H-5 of Ar), 7.3–7.1 (m, 3H, Ph-H), 7.07 (d, J = 7 Hz, 2H, H-2, H-6 of Ph), 6.97 (d, J = 8.3 Hz, 2H, H-2, H-6 of Ar), 3.76 (s, 6H, 2 × OMe), 3.09 and 3.07 (two s, 2 × CH_2). ^{13}C NMR δ: 159.9 (CO), 138.0 (Ph-C1), 137.2 (Ar-C1), 131.6 (Ar-C2 and Ar-C3), 129.8 (Ph-C2), 128.6 (Ph-C3), 126.7 (C1 and C2), 126.6 (Ph-C4), 120.5 (Ar-C4), 52.8 (OMe), 43.1 and 42.4 (2 × CH_2), 40.8 (C3).

An approximately 10:7 mixture of the asymmetric cyclopropenes, *dimethyl 2-benzyl-3-(4-bromobenzyl)cyclopropene-1,3-dicarboxylate (**16**f) and dimethyl 3-benzyl-2-(4-bromobenzyl)cyclopropene-1,3-dicarboxylate (**16**g)*. ^{1}H NMR assignments from spectrum of mixture: **16***g*, δ: 7.4–6.8 (m, 9H), 3.8-3.6 (m, 2-CH_2), 3.73 and 3.55 (two s, 2 × OMe), 3.23 and 3.13 (AB quartet, J = 14.6 Hz, 3-CH_2); **16***f*, partial spectrum, δ: 3.71 and 3.59 (two s, 2 × OMe), 3.38 and 3.25 (AB quartet, J = 14.6 Hz, 3-CH_2). MS (ei) of mixture *m/z*: 416/414 (M^+, 8%), 384/382 (9%), 357/355 (10%), 325/323 (M − Bn^+, 5%), 297/295 (8%), 245 (20%), 215 (100%), 171/169 (*p*-$BrBn^+$, 60%), 115 (5%), 91 (50%).

Pyrazole-*N*-oxide (**25***d*) eluted in ca. 1:1 ratio with 1*H*-pyrazole (**19***g*) (ca. 3%).
*Compound (**25**d)*. ^{1}H NMR, δ: 7.99 (s, 1H, OH; disappears on shaking with D_2O), 7.47 (d, J = 8.4 Hz, 2H, H-3, H-5 of Ar), 7.4–7.1 (m, 3H, of Ph), 7.07–7.02 (m, 4H, H-2, H-6 of Ar and Ph), 5.66 (s, 1H, >CH-), 3.91 and 3.78 (two s, 2 × OMe), 3.31 (d, J = 13.6 Hz, upfield half of CH_2 AB quartet: other half presumably hidden by ester signals). A one-bond C-H correlation experiment confirmed the assignments as given. In an NOE experiment irradiation of the doublet at δ = 3.31 gave enhancement at 7.99, 5.66, and 3.78 δ whereas irradiation at δ = 3.76 gave enhancement at 7.99, 7.02(d, *ortho*-H of Ph), and 3.31 δ and negative enhancement at 5.67 δ. Irradiation of singlet at δ = 5.67 gave enhancement of signals at 7.99, 7.07(d, *ortho*-H of Ar), and slightly at 3.31 δ. Irradiation of singlet at δ = 7.99 gave enhancement of the signal at δ = 7.07(d, of Ar). There was no change on keeping the mixture with D_2O under nitrogen at −15°C for 4 months.

*Dimethyl 1-benzyl-5-(4-bromobenzyl)-1*H*-pyrazole-3,4-dicarboxylate (**19**g)*. ^{1}H NMR, δ: 7.36 (d, J = 8.4 Hz, 2H, H-3, H-5 of Ar), 7.3–7.0 (m, 5H, of Ph), 6.89 (d, J = 8.5 Hz, 2H, H-2, H-6 of Ar), 5.19 (s, 2H, *N*-CH_2), 4.12 (s, 2H, 5-CH_2), 3.97 and 3.82 (two s, 2 × OMe). ^{13}C NMR, δ: 163.4 and 162.7 (2 × CO), 144.9 (C3), 143.3 (C5), 135.0 (Ph-C1), 134.9 (Ar-C1), 132.1 (Ar-C3), 129.9 (Ar-C2), 129.1 (Ph-C3), 128.4 (Ph-C4), 127.0 (Ph-C2), 121.1 (Ar-C4), 114.2 (C4), 54.5 (*N*-CH_2), 52.8 and 52.1 (2 × OMe), 29.8 (5-CH_2); MS (ei) *m/z*: 444/442 (M^+, 8%), 412 (12%), 380/378 (10%), 353/351 (M − Bn^+, 13%), 331 (5%), 240 (15%), 171/169 (*p*-$BrBn^+$, 10%), 115 (10%), 91 (100%). HRMS, Exact Mass calcd. for $C_{21}H_{19}{}^{79}BrN_2O_4$: 442.0528; found: 442.0522.

The final compound eluted was **20***a* mixed with about 20%

© 1997 NRC Canada

*dimethyl 5-(4-bromobenzyl)-1*H*-pyrazole-3,4-dicarboxylate (**20***c*). Overlap meant that only partial ^{1}H NMR data could be determined for **20***c*, signals for which included (δ): 7.44 (d, *J* = 8.4 Hz, H-3, H-5 of Ar), 7.10 (d, *J* = 8.4 Hz, H-2, H-6 of Ar), 4.22 (s, CH_2), 3.93 and 3.83 (two s, 2 × OMe). ^{13}C NMR, δ: 132.2 (Ar-C3), 130.7 (Ar-C2), 32.0 (5-CH_2). HRMS (on high molecular mass component of mixture), Exact Mass calcd. for $C_{14}H_{13}{}^{79}BrN_2O_4$: 352.0059; found: 352.0056.

On exposure to the atmosphere for several days, the solution of **25***d* was converted to *dimethyl 4-benzyl-5-(4-bromobenzoyl)-4*H*-pyrazole-3,4-dicarboxylate **21**d* (2% overall). IR (cm^{-1}): 3340(br) w, 3090 w, 3070 w, 3040 w, 2960 m, 2930 m, 2855 w, 1765 s, 1733 s, 1657 m, 1585 m, 1568 w, 1487 m, 1438 m. ^{1}H NMR, δ: 7.93 (d, *J* = 8.6 Hz, 2H, H-2, H-6 of Ar), 7.61 (d, *J* = 8.6 Hz, 2H, H-3, H-5 of Ar), 7.2–7.0 (m, 3*H*, of Ph), 6.76 (d, *J* = 6.6 Hz, 2H, H-2, H-6 of Ph), 4.08 and 3.73 (two s, 2 × OMe), 3.9–3.8 (m, 2H, CH_2). ^{13}C NMR, δ (partial spectrum): 185 (Ar-CO), 173 (C3 or C5), 133.4 (Ph-C1), 132.7 (Ar-C2), 132.2 (Ar-C3), 128.8 (Ph-C2), 128.7 (Ph-C3), 128.3 (Ph-C4), 54.1 and 53.8 (2 × OMe), 37.5 (CH_2).

Performing the photolysis of **3***d* in the presence of triethylamine (1 drop) gave a similar mix of products, but also included dimethyl 1-(diethylamino)maleate. IR (cm^{-1}): 2995 m, 2960 m, 1750 s, 1701 s, 1661 m, 1575 s, 1519 w, 1450 s, 1440 s, 1428 m, *cf.* values in ref 45. ^{1}H NMR, δ: 4.61 (s, 1H), 3.94 and 3.63 (two s, 2 × OMe), 3.18 (q, *J* = 7.1 Hz, 4H, 2 × CH_2), 1.18 (t, *J* = 7.1 Hz, 6H, 2 × CH_3). This spectrum is in good agreement with that published (45, 46). ^{13}C NMR, δ: 168.5 and 166.3 (2 × CO), 129.1 (=C<), 83.1 (=CH-), 54.3 and 50.8 (2 × OMe), 45.1 br (CH_2), 12.8 br (CH_3). This is reasonably concordant with values tabulated for the corresponding dimethyl compound (47).

Photolysis of para*-trifluoromethylbenzyl oxadiazoline (**3**e) (2 runs)*

Separation gave a mixture of 1,3-diarylpropenes **14***h*, **14***i*, **15***h*, and **15***i* as well as the following additional products.

Dimethyl (E)*-1-benzyl-3-(4-trifluoromethylphenylmethylene)-cyclopropane*-trans*-1,2-dicarboxylate (**17**h)* (5%). IR (cm^{-1}): 3080(sh), 3060 w, 3030 w, 3005 w, 2955 m, 2930 w, 2850 w, 1733 s, 1615 m, 1491 w, 1445(sh), 1434 m, 1421(sh), 941 m, 872 m, 822 m, 795 w. ^{1}H NMR, δ: 7.60 (d, *J* = 8.4 Hz, 2H, H-3, H-5 of Ar), 7.51 (d, *J* = 8.3 Hz, 2H, H-2, H-6 of Ar), 7.3–7.2 (m, 5H, of Ph), 6.81 (d, *J* = 2.2 Hz, 1H, vinyl-H), 3.70 and 3.68 (two s, 2 × OMe), 3.50 (d, *J* = 2.2 Hz, 1H, methine-H), 3.37 (s, 2H, CH_2). MS (ei) *m/z*: 404 (M^+, 7%), 385 (M − F^+, 3%), 372 (17%), 344 (M − EH^+, 12%), 313 (M − Bn^+, 15%), 285 (50%), 215 (25%), 183 (10%), 159 (*p*-$CF_3C_6H_4CH^+2$, 22%), 115 (30%), 91 (100%). HRMS, Exact Mass calcd. for $C_{22}H_{19}F_3O_4$: 404.1235; found: 404.1241.

Dimethyl (Z)*-1-benzyl-3-(4-trifluoromethylphenylmethylene)-cyclopropane*-trans*-1,2-dicarboxylate (**18**h)* (3%). IR (cm^{-1}): 3080(sh), 3060 w, 3030 w, 2955 m, 2925 m, 2845 w, 1731 s, 1613 w, 1490 w, 1445(sh), 1432 m, 1420(sh), 964 w, 914 w, 869 m, 839 w, 821 w. ^{1}H NMR, δ: 7.57 (d, *J* = 8.3 Hz, 2H, H-3, H-5 of Ar), 7.43 (d, *J* = 8.3 Hz, 2H, H-2, H-6 of Ar), 7.15 (s, br, 5H, of Ph), 6.93 (d, *J* = 2.0 Hz, 2H, vinyl-H), 3.80 and 3.16 (two d, *J* = 15.7 Hz, CH_2), 3.73 and 3.59 (two s, 2 × OMe), 3.42 (d, *J* = 1.8 Hz, 1H, methine-H). MS(ei) *m/z*: 404 (M^+, 12%), 385 (M − F^+, 7%), 372 (M − 32^+, 55%), 344 (M − EH^+, 35%), 329 (5%), 313 (45%), 285 (100%), 215 (55%), 183 (22%), 159 (25%), 115 (22%), 91 (93%). HRMS, Exact Mass calcd. for $C_{22}H_{19}F_3O_4$: 404.1235; found: 404.1243.

*Dimethyl 2-benzyl-3-(4-trifluoromethylbenzyl)cyclopropene-1,3-dicarboxylate (**16**h)* (ca. 5%). ^{1}H NMR, δ: 7.45 (d, *J* = 8.1 Hz, 2H, H-3, H-5 of Ar), 7.3–7.05 (m, 7H), 3.72 and 3.57 (two s, 2 × OMe), ca. 3.7 (m, 2H, 2-CH_2), 3.35 and 3.19 (two d, *J* = 14.5 Hz, 3-CH_2).

*Dimethyl 3-benzyl-2-(4-trifluoromethylbenzyl)cyclopropene-1,3-dicarboxylate (**16**i)* (5%). IR (cm^{-1}): 3080 w, 3055 w, 3025 w, 2945 m, 2840 w, 1863 w, 1719(br) s, 1611 w, 1578 w, 1488 w, 1442(sh), 1428 m, 1413 m. ^{1}H NMR, δ: 7.52 (d, *J* = 8.0 Hz, 2H, H-3, H-5 of Ar), 7.26–7.15 (m, 5H), 7.05–7.00 (m, 2H), 3.71 and 3.59 (two s, 2 × OMe), 3.7 (m, 2H, 2-CH_2), 3.44 and 3.21 (two d, *J* = 14.3 Hz, 3-CH_2).

*Dimethyl 3-benzyl-3-(4-trifluoromethylbenzyl)cyclopropene-1,2-dicarboxylate (**4**e)* (12%). IR (cm^{-1}): 3065 w, 3035 w, 2955 w, 2925 w, 2845 w, 1837 m, 1722 s, 1617 w, 1602 w, 1491 w, 1448(sh), 1443 s, 1418 m. ^{1}H NMR, δ: 7.5–7.4 (m, 4H, of Ar), 7.30–7.17 (m, 3H, of Ph), 7.10–7.06 (m, 2H, of Ph), 3.76 (s, 6H, 2 × OMe), 3.17 and 3.11 (two s, 2 × CH_2). ^{13}C NMR, δ: 159.9 (CO), 142.4 br (Ar-C1), 137.9 (Ph-C1), 130.2 (Ar-C2), 129.8 (Ph-C2), 128.7 (Ph-C3), 126.8 (C1 and C2), 126.6 (Ph-C4), 125.4 (q, J_{CF} = 3.6 Hz, Ar-C3), 52.9 (OMe), 43.1 and 42.9 (2 × CH_2), 40.7 (C3), signals for Ar-C4 and CF_3 too dispersed for detection. *Pyrazole*-N*-oxide (**25**e)* as a yellow oil. IR (cm^{-1}): 3350 w, 3065 w, 3035 w, 2955 w, 1740 s, 1713 s, 1652 m, 1611 m, 1565 s, 1490 w, 1445 s, 1439(sh). ^{1}H NMR, δ: 8.08 (s, 1H, HO), 7.61 and 7.29 (two d, *J* = 8.2 Hz, 4H of Ar), 7.20–7.15 (m, 3H, Ph-H), 7.07–7.01 (m, 2H, Ph-H), 5.76 (s, 1H, >CH-), 3.92 and 3.79 (two s, 2 × OMe), 3.78 and 3.34 (AB quartet, *J* = 13.5 Hz, CH_2).

*Dimethyl 1-benzyl-5-(4-trifluoromethylbenzyl)-1*H*-pyrazole-3,4-dicarboxylate (**19**i)* (34%). IR (cm^{-1}): 3065 w, 3055 w, 3000 w, 2955 w, 1736 s, 1724 s, 1617 w, 1541 w, 1476 m, 1451 m, 1435 m, 1418 m. ^{1}H NMR, δ: 7.47 (d, *J* = 8.2 Hz, 2H, H-3, H-5 of Ar), 7.26–7.22 (m, 3H, of Ph), 7.11 (d, *J* = 7.9 Hz, 2H, H-2, H-6 of Ar), 6.98–6.94 (m, 2H, of Ph), 5.21 (s, 2H, N-CH_2), 4.25 (s, 2H, 5-CH_2), 3.98 and 3.82 (two s, 2 × OMe). ^{13}C NMR, δ: 163.4 and 162.7 (2 × OMe), 144.5 (C3), 143.4 (C5), 140.1 (Ar-C1), 134.7 (Ph-C1), 129.1 (Ph-C3), 128.6 (Ar-C2), 128.5 (Ph-C4), 126.9 (Ph-C2), 125.9 (q, J_{CF} = 4.0 Hz, Ar-C3), 114.3 (C4), 54.6 (N-CH_2), 52.8 and 52.2 (2 × OMe), 30.2 (5-CH_2), Ar-C4 and CF_3 signals too dispersed for detection.

Compound **25***e* was stable in $CDCl_3$ under nitrogen at −20°C for over 4 weeks, but on exposure to air, gave *methyl 4-benzyl-5-(4-trifluoromethylbenzoyl)-1*H*-pyrazole-3-carboxylate (**22**e)*. ^{1}H NMR, δ: 8.15 (d, *J* = 8.0 Hz, 2H, H-2, H-6 of Ar), 7.71 (d, *J* = 8.2 Hz, 2H, H-3, H-5 of Ar), 7.2–7.1 (m, 5H, of Ph), 4.54 (s, 2H, CH_2), 3.98 (s, 3H, OMe). ^{13}C NMR, δ: 193.2 (ArCO), 159.9 (COOMe), 148.5 (C3 and C5), 140.7 (Ar-C1), 140.2 (Ph-C1), 133.7 (C4), 130.8 (Ar-C2), 128.7 (Ph-C2), 128.5 (Ph-C3), 126.3 (Ph-C4), 125.3 (q, J_{CF} = 3.6 Hz, Ar-C3), 52.6 (OMe), 29.1 (CH_2), signals from Ar-C4

and CF_3 too dispersed for detection. HRMS, Exact Mass calcd. for $C_{20}H_{15}F_3N_2O_3$: 388.1035; found 388.1031.

Photolysis of benzyl methyl oxadiazoline ***4f*** *in methanol (1 run)*

Oxadiazoline ***3f*** (0.5 mmol) in methanol-d_4 (1 g) in a thin-walled NMR tube was photolyzed for 5 h. Standard work-up and separation gave the known (ref. 3) symmetrical cyclopropene ***4f*** (9%), and unsymmetrical cyclopropene ***16j*** (4%), along with the pyrazoles described below.

*Dimethyl 1-benzyl-5-methyl-1*H*-pyrazole-3,4-dicarboxylate (**19**j)* (13%). IR (cm^{-1}): 3060 w, 3035 w, 3000 w, 2950 m, 2850 w, 1737 s, 1720 s, 1605 w, 1548 m, 1480 m, 1452 m, 1439 s. ^{1}H NMR, δ: 7.30–7.26 (m, 3H of Ph), 7.14–7.09 (m, 2H, H-2, H-6 of Ph), 5.36 (s, 2H, CH_2), 3.95 and 3.84 (two s, 2 × OMe), 2.39 (s, 3H, 5-Me). In an NOE experiment, irradiation of the singlet at δ = 2.39 caused enhancement of signals at both 5.36 and 7.1 δ. ^{13}C NMR, δ: 163.6 and 162.8 (2 × CO), 144.0 and 143.1 (C3 and C5), 135.7 (Ph-C1), 129.1 (Ph-C3), 128.4 (Ph-C4), 127.0 (Ph-C2), 113.2 (C4), 54.2 (*N*-CH_2), 52.7 and 51.9 (2 × OMe), 11.0 (5-Me). HRMS, Exact Mass calcd. for $C_{15}H_{16}N_2O_4$: 288.1110; found 288.1109.

*Dimethyl 4-benzyl-5-methyl-4*H*-pyrazole-3,4-dicarboxylate (**33**)* (18%). ^{1}H NMR, δ: 7.2 (m, 3*H* of Ph), 6.95 (m, 2H of Ph), 3.96 and 3.72 (two s, 2 × OMe), 3.84 and 3.50 (two d, *J* = 14 Hz, 4-CH_2), 2.39 (s, 3H, 5-Me). In an NOE experiment, irradiation of singlet at δ = 2.39 gave enhancement of the methylene-H at 3.50 δ and an *ortho*-H at 6.9 δ. ^{13}C NMR, δ: 176.4 (C3), 166.8 (C5), 165.4 (4-CO), 160.9 (3-CO), 132.8 (Ph-C1), 128.9 and 128.6 (C2 and C3 of Ph), 128.2 (Ph-C4), 76.4 (C4), 53.9 and 53.3 (2 × OMe), 37.6 (CH_2), 14.0 (5-Me).

*Dimethyl 5-methyl-1*H*-pyrazole-3,4-dicarboxylate (**20**d)* (5%). IR (cm^{-1}): 3500(sh) br, 3250(br) s, 2950 s, 2925 s, 2855 s, 1710 s, 1565 m, 1490 m, 1445 s. ^{1}H NMR, δ: 3.94 and 3.86 (two s, 2 × OMe), 2.53 (s, 5-Me). ^{13}C NMR, δ: 163 and 162.4 (2 × CO), 146.2 (C3), 114 (C4), 52.8 and 52.0 (2 × OMe), 11.7 (5-CH_3), C5 not clearly visible. MS (ei) *m/z*: 198 (M^+, 20%), 167 (M − OMe^+, 95%), 166 (100%), 135 (40%), 79 (20%). MS(ci, NH_3) *m/z*: 199 (M + H^+, 40%), 167 (M − OMe^+, 100%), 152 (5%).

Isolation of diazoalkane **5**a

Oxadiazoline (***3a***) (0.21 mmol) in toluene-d_8 (0.5 mL) in a thin-walled NMR tube was photolyzed at −70°C for 4 h, giving the typical pinkish-yellow solution observed in all of the above procedures. The solution was transferred at the temperature of liquid nitrogen to the precooled probe of the 500 MHz NMR spectrometer, and spectra were recorded as the temperature was gradually raised to ambient. The proton spectrum showed that negligible amounts of starting material remained, while the new signals were consistent with the presence of methyl acetate and 2-diazo-1,3-diphenylpropane (***5a***). ^{1}H NMR (in C_7D_8) δ: 7.10–7.05 (m, 6H), 6.85 (d, *J* = 6.9 Hz, 4H), 2.81 (s, 4H). ^{13}C NMR, δ: 138.2 (Ph-C1), 128.76 and 128.67 (Ph-C2 and Ph-C3), 126.8 (Ph-C4), 48.1 (), 32.3 (CH_2). There was little change during the 2 h needed to warm up to −20°C, and even after being kept overnight in the freezer (at ca. −15°C), about 30% of diazo-alkane was left intact. After a further 3 days at −15°C, the diazo-alkane had gone completely and the solution was virtually colourless. About 7% of the diazo-alkane had been converted to the 1,3-diphenylpropenes ***14a*** and ***15a*** in about 2:1 ratio, but the major product was the azine ***9a***. IR (cm^{-1}): 3080 w, 3060 m, 3030 s, 2920 m, 1737 s, 1630 m, 1600 m, 1493 s, 1451 w, 1426 m. ^{1}H NMR, δ: 7.34–7.14 (m, 6H), 7.06–7.01 (m, 4H), 3.70 and 3.58 (two s, 2 × CH_2). ^{13}C NMR, δ: 165.2 (), 138.0 and 137.2 (2 × Ph-C1), 129.6 and 129.5 and 128.7 and 128.6 (2 × Ph-C2 and 2 × Ph-C3), 126.7 and 126.5 (2 × Ph-C4), 42.9 and 36.2 (2 × CH_2). MS (ei) *m/z*: 416 (M^+, 1%), 325 (M − Bn^+, 1%), 194 (22%), 91 (100%). MS (ci, NH_3) *m/z*: 417 (M + H^+, 1%), 314 (3%), 272 (41%), 228 (100%).

Sequential trapping experiments

Oxadiazoline **3** in toluene containing one drop of triethylamine was photolyzed at −65°C for several h, before addition of a solution of dimethyl acetylenedicarboxylate in toluene. Then the solvent and excess volatiles were removed by a stream of nitrogen as the solution warmed up to ambient. Typically this gave a viscous yellow residue.

The product from ***3a*** was essentially pure *dimethyl 3,3-dibenzyl-3*H*-pyrazole-4,5-dicarboxylate (**6**a)*. ^{1}H NMR, δ: 7.35–7.10 (m, 6H), 7.05–6.90 (m, 4H), 3.87 and 3.79 (two s, 2 × OMe), 3.86 and 3.46 (two 2H d, *J* = 13.4 Hz, 2 × CH_2). ^{13}C NMR, δ: 162.6 and 160.3 (2 × CO), 148.7 (C5), 148.1 (C4), 133.6 (Ph-C1), 129.6 (Ph-C3), 128.1 (Ph-C2), 127.4 (Ph-C4), 105.1 (C3), 52.8 and 52.7 (2 × OMe), 41.3 (CH_2).

This solution was divided into two: one portion (still in $CDCl_3$) was photolyzed at −65°C for a further 6 h. The ^{1}H NMR spectrum of the product mixture indicated that 1,5-dibenzyl-1*H*-pyrazole ***19a***, yellow pyrazole-*N*-oxide ***25a***, and unsymmetrical cyclopropene ***16a*** were major components, in ratio ca. 1:1:2, along with the symmetrical cyclopropene ***4a*** as a minor component.

The other portion was stored at room temperature for some days, before separation of decomposition products. The following were isolated: yellow pyrazole-*N*-oxide ***25a*** (22%) and 1,5-dibenzyl-1*H*-pyrazole ***19a*** (20%). The solution of ***25a*** was fairly stable when stored in $CDCl_3$ under nitrogen at −20°C, but after 10 weeks the ***25a*** had been converted exclusively to benzoyl 4*H*-pyrazole (***21a***).

Similarly, oxadiazoline ***3b*** gave *dimethyl 3-benzyl-3-(4-methylbenzyl)-3*H*-pyrazole-4,5-dicarboxylate (**6**b)*: IR (cm^{-1}): 3055 w, 3030 w, 2955 w, 2925 w, 1730 s, br, 1655 w, 1635 w, 1600 w, 1545 w, 1513 w, 1495 m, 1450 m, 1438 m. ^{1}H NMR, δ: 7.23–7.10 (m, 3*H* of Ph), 7.00–6.86 (m, 6H), 3.89 and 3.76 (two s, 2 × OMe), 3.86 + 3.83 and 3.45 + 3.41 (four d, *J* = 13.4 Hz, 2 × CH_2 as AB quartets), 2.23 (s, ArMe). The solvent was removed, the residue was taken up in benzene-d_6, and the resulting solution was heated at 65°C in a sealed tube. After 20 min, signals from the dibenzyl 1*H*-pyrazole ***19b*** began to be evident, and within 3.5 h those of starting material had virtually disappeared. Based on the ^{1}H NMR spectra, the final mixture contained ***19b*** and ***25b*** in the ratio 4:3. As judged from satellite peaks in the ^{1}H NMR spectrum, compound ***19b*** was also contaminated by approximately 10% of the positional isomer ***19c***.

In the same way, oxadiazoline ***3d*** gave ***6d***, as evidenced by

For personal use only.

appearance of two overlapping doublets at ca. 3.44 and 3.43 ppm in the crude photolysate. After further photolysis, these signals disappeared, and in the spectrum of the crude product the only signals assignable belonged to isomeric 1,5-dibenzyl-1*H*-pyrazoles **19***f* and **19***g*. Chromatography gave the following compounds: the isomeric 1, 3-diarylpropenes **14***f*, **14***g*, **15***f*, and **15***g* (together ca. 5%); cyclopropene **4***d* (5%); benzoyl 4*H*-pyrazole **21***d* (4%); and its isomer, *dimethyl 5-benzoyl-4-(4-bromobenzyl)-4*H*-pyrazole-3,4-dicarboxylate (**21***e*)* (8%): IR (cm^{-1}): 3300(br) w, 3070 w, 3035 w, 2965 s, 2925(sh), 2855 w, 1765 s, 1732 s, 1656 s, 1585 m, 1488 m, 1443 s, 1405 m. ^{1}H NMR, δ: 8.12 (d, J = 7.4 Hz, 2H, H-2, H-6 of Bz), 7.63 (m, 1H, H-4 of Bz), 7.50 (t, J = 7.2 Hz, 2H, H-3, H-5 of Bz), 7.21 (d, J = 8.3 Hz, 2H, H-3, H-5 of Ar), 6.69 (d, J = 8.3 Hz, 2H, H-2, H-6 of Ar), 4.06 and 3.73 (two s, 2 × OMe), ca. 3.86 and ca. 3.80 (AB quartet, only centre two lines visible, CH_2). An approximately 2:1 mixture of dibenzyl 1*H*-pyrazole **19***g* and its isomer, dimethyl 5-benzyl-1-(4-bromobenzyl)-1*H*-pyrazole-3,4-dicarboxylate **19***f*, with partial ^{1}H NMR, δ: 6.89 (d, J = 8.4 Hz, H-2, H-6 of Ar), 5.12 (s, N-CH_2), 4.18 (s, 5-CH_2), 3.97 and 3.83 (two s, 2 × OMe), and, finally, monobenzyl 1*H*-pyrazoles **20***a* and **20***c* (ca. 6% together), were obtained.

In contrast, the same procedure applied to methoxy oxadiazoline **3***c* did not appear to give any **6***c*. Chromatography gave 1,3-diarylpropenes **14***d*, **14***e* and **15***d*, **15***e* (together 13%), dibenzyl 1*H*-pyrazole (**19***d*) (42%), and pyrazole-*N*-oxide **25***c*. Compound **25***c* was fairly stable when stored in $CDCl_3$ under nitrogen at −20°C for over four weeks, but gradually decomposed to benzoyl monoester **22***c*, plus an unidentified compound with the following partial ^{1}H NMR spectrum, δ: 7.4–7.3 (m, 5H), 7.20 (d, J = 8.6 Hz, 2H, H-2, H-6 of Ar), 6.84 (d, J = 8.6 Hz, 2H, H-3, H-5 of Ar), 6.47 (s, 1H), 5.50 (s, 2H), 3.85 (s, 3H) and 3.78 (s, 3H) (2 × OMe), 3.71 (s, 3H, ArOMe). Irradiation of the singlet at δ = 5.50 gave enhancement at 7.20 δ, while irradiation at δ = 6.47 gave enhancement at 7.34 δ. The implication is that the compound contains the unit *p*-MeO-C_6H_4-CH_2-, in a rather deshielded environment, but that there is no benzoyl group.

*Base-catalyzed isomerization of unsymmetric cyclopropene **16**a*

To unsymmetrical dibenzylcyclopropene **16***a* (0.2 mmol) in $CDCl_3$ (0.4 mL) was added triethylamine (1 drop). The solution changed from yellow to rich gold, and an ^{1}H NMR spectrum run at once showed no sign of starting material. Separation gave a mixture of methylenecyclopropanes **17***a* and **18***a* in approximately equal amounts (42%), followed by a 3:2 mixture (10%) of *dimethyl 1-benzyl-3-(*E*)-(phenylmethylene)cyclopropane-*cis*-1,2-dicarboxylate (**34**) and its (*Z*) isomer (**35**)*. For **34**: ^{1}H NMR (500 MHz) δ: 7.46 (d, J = 8 Hz, 2H, H-2, H-6 of Ph), 7.34–7.15 (m, 8H), 6.95 (d, J = 2.4 Hz, 1H, vinyl-H), 3.69 and 3.63 (two s, 2 × OMe), 3.59 and 2.79 (two d, J = 14.0 Hz, CH_2), 2.75 (d, J = 2.4 Hz, 1H, methine-H). In an NOE experiment, irradiation of doublet at δ = 6.95 enhanced the signal at 7.46 δ (*ortho*-H of vinyl-Ph), but apparently none of the signals at 2.75, 3.59, or 2.79 δ; the remaining signals from the mixture were too close together for unambiguous results. ^{13}C NMR, δ: 169.7 and 168.8 (2 × CO), 137.3 and 135.6 (2 × Ph-C1), 129.2 and 128.83 and 128.6 and 127.7 (2 × Ph-C2 and 2 × Ph-C3), 128.4 and 127.2 (2 × Ph-C4), 123.7 (C3), 122.5 (=CH-), 52.57 and 52.54 (2 × OMe), 41.0 (C1), 31.5 (CH_2), 27.9 (C2). IR (of mixture)(cm^{-1}) 3070 w, 3035 m, 3010 w, 2960 m, 2850 w, 1730(br) s, 1603 w, 1495 m, 1450(sh), 1435 s. MS (ei) on mixture *m/z*: 336 (M^+, 10%), 304 (15%), 276 (10%), 245 (M − Bn^+, 20%), 217 (50%), 202 (20%), 115 (45%), 91 (100%). MS (ci, NH_3) *m/z*: 354 (M + NH_4^+, 100%), 337 (M + H^+, 45%), 322 (10%), 305 (10%), 217 (5%). For **35**; ^{1}H NMR (500 MHz) δ: 7.44 (d, J = 8 Hz, 2H, H-2, H-6 of Ph), 7.34–7.15 (m, 6H), 7.08–7.06 (m, 2H, H-2, H-6 of Bn), 6.87 (d, J = 2.0 Hz, 1H, vinyl-H), 3.69 and 3.68 (two s, 2 × OMe), 3.38 (s, 2H, CH_2), 2.37 (d, J = 2.0 Hz, 1H, methine-H). In an NOE experiment, irradiation of doublet at δ = 6.87 gave enhancement at 7.44 δ (*ortho*-H of vinyl-Ph) and 2.37 δ; whereas irradiation of singlet at δ = 3.38 enhanced the signal at 7.07 δ (*ortho*-H of Bn) and methine doublet at 2.37 δ. ^{13}C NMR (assignments tentative), δ: 170.1 and 169.2 (2 × CO), 136.1 and 135.5 (2 × Ph-C1), 130.0 and 128.78 and 128.5 and 128.0 (2 × Ph-C2 and 2 × Ph-C3), 128.3 (1 × Ph-C4; other C4 obscured), 123.8 (C3), 124.0 (=CH-), 52.7 and 52.45 (2 × OMe), 37.6 (C1), 38.6 (CH_2), 34.3 (C2).

Excess enthalpies of ternary mixtures of an *n*-alkane with methyl *tert*-butyl ether and di-*n*-butyl ether

Zhangfa Tong, Dankui Liao, George C. Benson, and Benjamin C.-Y. Lu

Abstract: Excess molar enthalpies, measured at 298.15 K, are reported for the two ternary systems consisting of either *n*-heptane or *n*-decane, together with methyl *tert*-butyl ether and di-*n*-butyl ether. Smooth representations of the results were used to construct constant enthalpy contours on Roozeboom diagrams. It was found that the Flory theory can provide good estimates of the ternary enthalpies.

Key words: excess enthalpies, ternary mixtures, *n*-alkanes, ethers, Flory theory.

Résumé : Opérant à 298,15 K, on a mesuré les enthalpies molaires en excès de deux systèmes ternaires formés soit d'heptane ou de décane en mélange avec de l'oxyde de *tert*-butyle et de méthyle et de l'oxyde de dibutyle. On a utilisé des représentations aplanies pour construire des contours d'enthalpie constante sur des diagrammes de Roozeboom. On a trouvé que la théorie de Flory peut conduire à de bonnes évaluations des enthalpies ternaires.

Mots clés : enthalpies en excès, mélanges ternaires, *n*-alcanes, éthers, théorie de Flory.

Introduction

The use of ethers as oxygenating agents in gasoline technology has resulted in an increased interest in the thermodynamic properties of hydrocarbon + ether systems. A recent paper (1) from our laboratory described measurements of the excess molar enthalpies of ternary mixtures containing either *n*-heptane (nC7) or *n*-decane (nC10), together with methyl *tert*-butyl ether (MTBE) and *tert*-amyl methyl ether (TAME). As a continuation of that investigation, we have made similar measurements for the analogous systems where di-*n*-butyl ether (DNBE) replaced the TAME used previously.

Experimental

Pure Grade nC7 from the Phillips Chemical Co. was used in the present work. The nC10, MTBE (HPLC Grade), and DNBE (Gold Label) were obtained from the Aldrich Chemical Co. In all cases, the purities stated by the manufacturers exceeded 99 mol%, and all of the component liquids were used without further purification. Their densities, measured at 298.15 K, were 679.79, 726.37, 735.58, and 764.02 kg m^{-3}, for nC7, nC10, MTBE, and DNBE, respectively. These values are in reasonable agreement with the literature (2, 3).

Received October 8, 1996.

An LKB flow microcalorimeter (model 10700-1) was used to measure excess molar enthalpies H^E_m at (298.150 ± 0.003) K. Details of this equipment and its operation have been described previously (4). The excess molar enthalpies of the ternary mixtures were investigated by measuring the excess molar enthalpies $H^E_{m,1+23}$ for several pseudo-binary mixtures, in which component 1 (either nC7 or nC10) was added to binary mixtures of components 2 (MTBE) and 3 (DNBE), having a fixed mole ratio x_2/x_3. These binaries were prepared by weighing. The excess molar enthalpy $H^E_{m,123}$ of the ternary mixture was then obtained from the relation:

$$[1] \quad H^E_{m,123} = H^E_{m,1+23} + (1 - x_1)H^E_{m,23}$$

where $H^E_{m,23}$ is the excess molar enthalpy of the particular MTBE + DNBE binary. Over most of the mole fraction range, the errors in the excess molar enthalpies are estimated to be less than ±0.5%. Errors in the mole fractions of the ternary mixtures are estimated to be less than 5×10^{-4}.

Results and discussion

Excess molar enthalpies $H^E_{m,ij}$ $(i < j)$, at 298.15 K, for four of the five constituent binaries of present interest, have been reported in the literature: nC7 + MTBE (1), nC7 + DNBE and nC10 + DNBE (5), nC10 + MTBE (6). Table 1 summarizes the present experimental measurements for the binary ether system MTBE + DNBE. The smoothing function:

$$[2] \quad H^E_{m,ij} = x_i(1 - x_i) \sum_{k=1}^{n} h_k(1 - 2x_i)^{k-1}$$

was fitted to these results by the method of least squares with

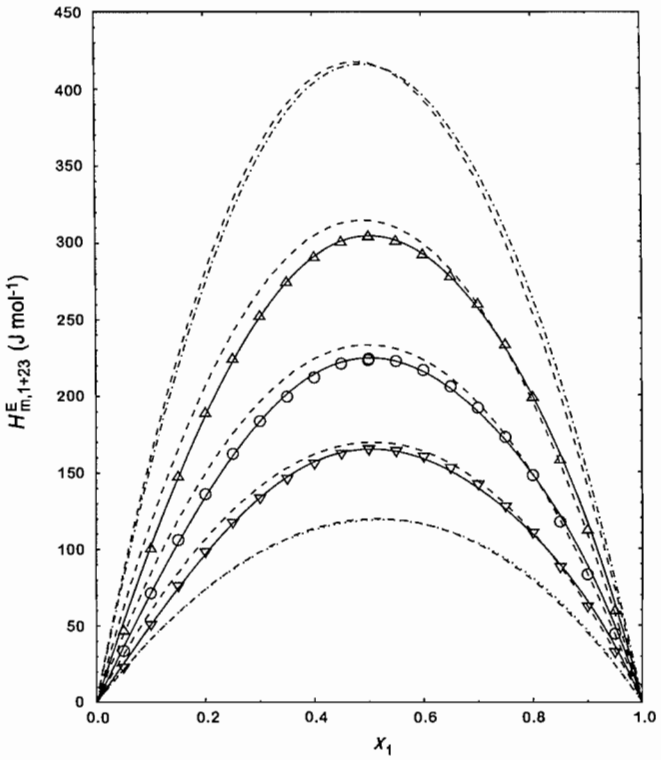
Fig. 1. Excess molar enthalpies, $H^E_{m,1+23}$ at 298.15 K, for the addition of nC7 to binary mixtures of MTBE + DNBE to form $x_1CH_3(CH_2)_5CH_3 + x_2(CH_3)_3COCH_3 + x_3[CH_3(CH_2)_3]_2O$. Experimental results: △, $x_2/x_3 = 3.0128$; ○, $x_2/x_3 = 1.0006$; ▽, $x_2/x_3 = 0.3352$. Curves: •—•—, $x_3 = 0$, Tong et al. (1); ····, $x_2 = 0$, Benson et al. (5); —, calculated from the representation of the results by eqs. [3] and [4], using the ternary term $H^E_{m,T}$ given in the footnote of Table 3; ----, estimated from the Flory theory.



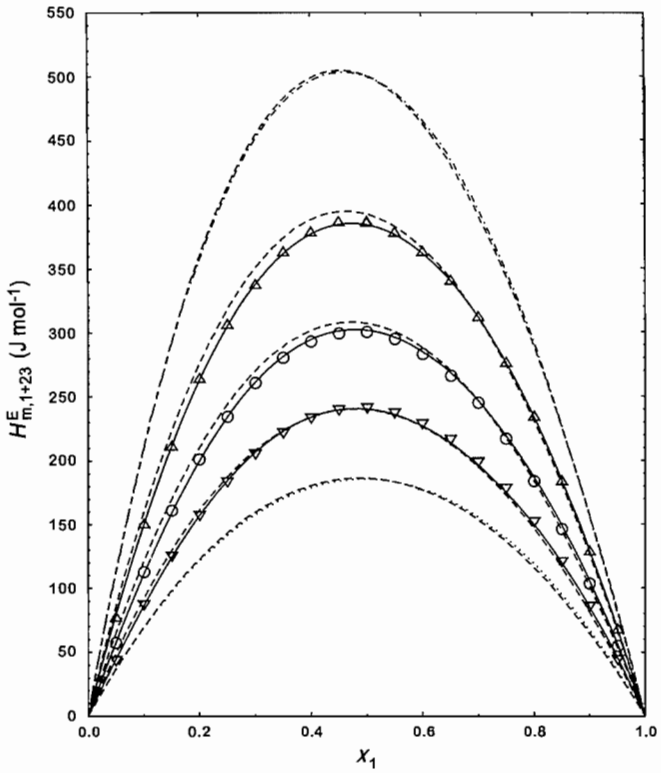


Fig. 2. Excess molar enthalpies, $H^E_{m,1+23}$ at 298.15 K, for the addition of nC10 to binary mixtures of MTBE + DNBE to form $x_1CH_3(CH_2)_8CH_3 + x_2(CH_3)_3COCH_3 + x_3[CH_3(CH_2)_3]_2O$. Experimental results: △, $x_2/x_3 = 3.0006$; ○, $x_2/x_3 = 0.9973$; ▽, $x_2/x_3 = 0.3352$. Curves: •—•—, $x_3 = 0$, Wang et al. (6); ····, $x_2 = 0$, Benson et al. (5); —, calculated from the representation of the results by eqs. [3] and [4], using the ternary term $H^E_{m,T}$ given in the footnote of Table 4; ----, estimated from the Flory theory.

all points weighted equally. The number, n, of coefficients employed in the fit was selected on the basis of the changes in the values of the standard deviation s, for increasing values of n (F-test). Values of the coefficients h_k are listed in Table 2, along with those for the representations of the four other binary systems. Also included in Table 2 are the values of the standard deviation s for each of the representations.

The experimental results for $H^E_{m,1+23}$ and the corresponding values of $H^E_{m,123}$ are listed in Tables 3 and 4 for the nC7 and nC10 ternary systems, respectively. Plots of $H^E_{m,1+23}$ against x_1 are given in Figs. 1 and 2. Also included in these figures are the smooth representations of the excess molar enthalpies of the constituent binaries, corresponding to the cases $x_2 = 0$ and $x_3 = 0$. These were calculated from eq. [2] using the coefficients in Table 2. In all cases, the maximum values of $H^E_{m,1+23}$ and $H^E_{m,123}$ occur near $x_1 = 0.5$ and, for comparable values of x_2/x_3, the maximum is larger for the mixture with nC10. The enthalpies increase as x_2/x_3 increases, for both systems at constant x_1.

As in our previous work (1), the values of $H^E_{m,1+23}$ were represented as a sum of binary terms with an added ternary correction:

$$[3] \quad H^E_{m,1+23} = [x_2/(1 - x_1)]H^E_{m,12} + [x_3/(1 - x_1)]H^E_{m,13} + H^E_{m,T}$$

where the values of the $H^E_{m,ij}$ were calculated from the appropriate smoothing functions. The ternary term was assumed to have the form:

$$[4] \quad H^E_{m,T}(\text{J mol}^{-1}) = x_1x_2x_3(c_0 + c_1x_1 + c_2x_2 + c_3x_1^2 + c_4x_1x_2 + c_5x_2^2 + \cdots)$$

and the values of the parameters c_k were obtained from least-squares analyses, in which eqs. [3] and [4] were fitted to the experimental $H^E_{m,1+23}$ in Tables 3 and 4. The results of these analyses are given in the footnotes of the tables, where the standard deviations s of the representations are also indicated. The solid curves in Figs. 1 and 2 were calculated from these representations.

[a]Ternary term for representation of $H^E_{m,1+23}$ by eqs. [3] and [4]: $H^E_{m,T}$ (J mol^{-1}) = $x_1x_2x_3(-1314.44 + 4197.67x_1 - 634.45x_2 - 6200.96x_1^2 - 3142.80x_1x_2)$, s = 1.6.

Equations [1]–[4] were also used to calculate the constant $H^E_{m,123}$ contours plotted on the Roozeboom diagrams in Figs. 3*a* and 4*a*. The general characteristics of these are very similar and are similar to those found for the corresponding systems with TAME (1). All of the contours extend to the edges of the triangle and there is no indication of an extremum lying within the triangle.

For the analogous systems containing TAME (1) in place of DNBE, it was found that the Flory theory (7), as applied to multicomponent systems (8), provided reasonable estimates of the ternary enthalpies, when only properties of the pure components and their binary mixtures were used. The same approach was investigated for the present systems. The equations for the treatment have been outlined by Wang et al. (6), and will not be repeated here.

The parameters used in the calculations are summarized in Table 5. The characteristic pressures p^*, molar volumes V^*_m, and temperatures T^* were taken from our previous publications (5, 6), where sources of the values of the primary thermodynamic properties are indicated. In evaluating the ratio of molecular surface areas of contact per segment between components i and j, it was assumed that the molecules were spherical. The values of the interchange-energy parameters X_{ij}, given in the footnotes of the table, were obtained by fitting the Flory formula for $H^E_{m,ij}$ to the smooth representations of the experimental results for each binary mixture by eq. [2].

Using the values of the parameters given in Table 5, $H^E_{m,1+23}$ and $H^E_{m,123}$ were estimated for the present ternary mixtures. The results for $H^E_{m,1+23}$ are shown as broken curves in Figs. 1 and 2. In general, these estimates tend to be higher than the experimental results at low alkane mole fractions and to fall below the results at higher mole fractions. The mean absolute relative deviations of the 60 points for the nC7 system in Table 3 and the 60 points for the nC10 system in Table 4 amount to 3.6% and 2.2%, respectively.

Constant $H^E_{m,123}$ contours were also estimated on the basis of the Flory theory. For both systems, the overall characteristics of these are quite similar to those derived from the representations of the experimental data by eqs. [1]–[4]. The results of the estimations are shown on the Roozeboom diagrams in Figs. 3*b* and 4*b*. It is clear from a comparison of parts (*a*) and (*b*) in these figures that, for the present type of systems, the Flory theory provides useful estimates of $H^E_{m,123}$ without requiring the direct investigation of the excess enthalpies of any ternary mixtures.

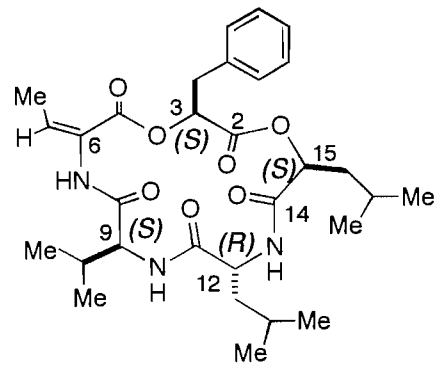
Determination of the absolute configuration of the fragments composing the phytotoxin phomalide

M. Soledade C. Pedras

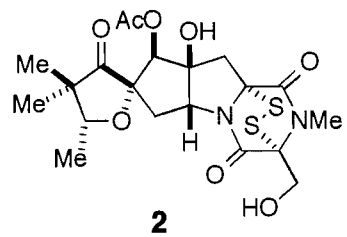
Abstract: The absolute configurations of the residues constituting phomalide (**1**) were determined on the products resulting from acidic hydrolysis. The configurations of the amino acids Val and Leu were determined as (*S*) and (*R*), respectively, by chiral GC analysis (Chirasil-Val capillary column), employing *N*-trifluoroacetyl (TFA) amino acid methyl ester derivatives. The configurations of the hydroxy acids O-Phe and O-Leu were determined as (*S*) by ^{1}H NMR of the Mosher's esters of the isopropyl ester derivatives. The method described allowed for the unambiguous assignment of the absolute configuration of the α-amino and α-hydroxy acid residues composing phomalide (**1**).

Key words: absolute configuration, depsipeptide, Mosher's ester.



Résumé : En se basant sur les produits de son hydrolyse acide, on a déterminé les configurations absolues des divers résidus formant le phomalide (**1**). Grâce à une analyse par CG chirale (colonne capillaire Chirasil-Val) sur les dérivés *N*-trifluoroacétyles (TFA) des esters méthyliques des acides aminés, on a déterminé que les configurations absolues des acides aminés Val et Leu sont respectivement (*S*) et (*R*). Faisant appel à la RMN du ^{1}H des esters isopropyliques des esters de Mosher, on a déterminé que les configurations des acides hydroxylés O-Phe et O-Leu sont (*S*). La méthode décrite permet d'attribuer sans ambiguïté la configuration des acides α-aminés et α-hydroxylés formant le phomalide (**1**).

Mots clés: configuration absolue, depsipeptide, ester de Mosher.



[Traduit par la rédaction]

The depsipeptide phomalide (**1**) is a host-selective toxin produced by the blackleg fungus (*Leptosphaeria maculans* (Desm.) Ces. et de Not., asexual stage *Phoma lingam* (Tode ex Fr.) Desm.) of brassicas (1). Diverse phytotoxic depsipeptides are produced by phytopathogenic fungi, as for example the destruxins from *Alternaria brassicae* (2) and AM-toxins from *A. mali* (3). Phomalide is, however, an unusual depsipeptide in that it has a 15-membered ring composed of five residues; more common depsipeptides, and cyclic peptides as well, incorporate typically either four or more than five residues (4). Remarkably, phomalide is produced by the blackleg fungus in liquid cultures only for a short period (24–60 h); older fungal cultures produce nonselective phytotoxins (epipolythiodioxopiperazines) such as sirodesmin PL (**2**).[2] This unusually short production period was attributed to an inhibitory effect of sirodesmin PL (**2**) on the biosynthesis of phomalide.

The structure of phomalide (**1**) was assigned from analysis of spectroscopic data, including HMBC and HMQC (1). The

1

2

configuration of the double bond of the rare amino acid dehydrothreonine (DhThr) residue was assigned as (*E*) based on NOE experiments on phomalide (1); chemical degradation was required to establish the absolute configuration of the four stereogenic centers. However, due to the small quantities of compound obtained from fungal cultures and the need for its

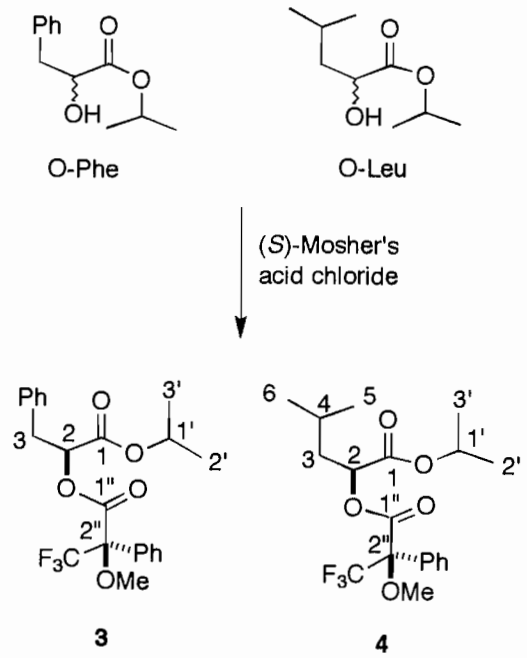
biological evaluation, the use of chemical degradation presented a significant dilemma. Additionally, while the absolute configuration of the amino acid residues valine (Val) and leucine (Leu) present in phomalide (**1**) could be determined by microscale chiral GC analysis of the derivatized hydrolysis products (6), the determination of the absolute configuration of the hydroxy acid residues 3-phenyllactic acid (O-Phe) and leucic acid (O-Leu) required the development of specific methodology. The determination of the absolute configurations of the four stereogenic centers present in phomalide (**1**) is now reported here.



Results and discussion

The absolute configurations of the residues composing phomalide (**1**) were determined by analysis of the products resulting from acidic hydrolysis. The configurations of the amino acids Val and Leu were determined as (*S*) and (*R*), respectively, by chiral GC analysis (Chirasil-Val capillary column), employing the *N*-trifluoroacetyl (TFA) amino acid methyl ester derivatives. The configurations of the hydroxy acids O-Phe and O-Leu were determined as (*S*) by ^{1}H NMR analysis of the Mosher's esters of the isopropyl ester derivatives, as described below.

Initially, efforts were made to determine the absolute configuration of the two hydroxy residues by chiral GC analysis of the corresponding methyl, 2-propyl, and 3-pentyl ester derivatives (7). Although chiral GC analysis of the 2-propyl ester of racemic O-Leu acid indicated the presence of the enantiomeric pair (confirmed by chiral GC–MS), similar analysis could not resolve the 2-propyl, the 3-pentyl, or the methyl esters of racemic O-Phe acid (8).[3] Next, different diastereomeric derivatives of 2-propyl esters of racemic O-Phe and O-Leu were prepared to identify a suitable derivative for assignment of the absolute configuration. Thus, esterification of the O-Phe and O-Leu 2-propyl esters with (*S*)-2-methoxy-2-phenylacetyl chloride and with (*S*)-2-methoxy-2-trifluoromethyl-2-phenylacetyl chloride (Mosher's acid chloride, MPTACl) gave diastereomeric mixtures, which were analyzed by TLC and ^{1}H NMR. The two pairs of diastereomeric products resulting from reaction with the (*S*)-MPTACl were clearly distinguishable by ^{1}H NMR spectroscopy, and separable by TLC. Although the diastereomeric products resulting from reaction of 2-propyl (*R,S*)-O-Leu ester with (*S*)-2-methoxy-2-phenylacetyl chloride could be separated by TLC, those from 2-propyl (*R,S*)-O-Phe ester were inseparable. Therefore, determination of the configurations of the O-Leu and O-Phe residues present in phomalide proceeded employing derivatization of the 2-propyl esters with (*S*)-MPTACl.[4]

Phomalide was hydrolyzed by heating in aqueous HCl in a sealed tube, and the reaction mixture was extracted with Et_2O. Both the Et_2O extract (containing hydroxy acids) and the remaining aqueous phase (containing amino acids) were concentrated to dryness. The amino acid fraction was methylated with CH_2N_2, followed by acetylation with TFAA. The resulting mixture was analyzed by chiral GC and the retention times compared with authentic standards of the (*S*), (*R*), and racemic *N*-TFA amino acid methyl ester derivatives. The hydroxy acid fraction was first esterified with 2-propanol, followed by reaction with the (*S*)-MPTACl (9). The ^{1}H NMR spectrum of the reaction mixture showed characteristic proton signals due to the MeO groups at δ 3.33 and 3.53 (q, J = 1.0 Hz). These two signals allowed the unambiguous assignment of the configurations; since the signal at δ 3.33 could only be due to the derivative of (*S*)-O-Phe (**3**, cf. experimental section), the signal at δ 3.53 had to result from the (*S*)-O-Leu derivative (**4**). Analysis of the remaining proton signals of the mixture confirmed these assignments; for example, the two doublets at δ 0.92 and 0.91 (J = 6.2 Hz) due to H-5/H-6 confirmed the presence of the (*S*)-O-Leu derivative (cf. δ 0.82 and 0.80 for the (*R*)-O-Leu derivative). Furthermore, the coupling constants for the proton signal at δ 5.34 (dd, J = 10.0, 3.7 Hz, H-2) corroborated the presence of the (*S*)-O-Phe derivative (**3**) (cf. J = 8.2, 4.2 Hz, H-2, for the (*R*) isomer). These assignments have now been confirmed by the total synthesis of phomalide (10).

Scheme 1. Absolute configuration of phomalide fragments.

In summary, a method for determining the absolute configuration of small amounts of depsipeptides was developed. The method described allowed for the unambiguous assignment of the absolute configuration of the α-hydroxy acid residues composing phomalide (**1**). This method may also be applicable to other hydroxy acids of various depsipeptides.

Experimental

General

All chemicals were purchased from Aldrich Chemical Company, Inc., Madison, Wis., or Sigma Chemical Company,

[3] It appears that chiral GC methods are less likely to resolve α-hydroxy acids than α-aminoacids; see for example ref. 8.

[4] Note that the *R,S* descriptor for the absolute configuration of MPTACl is opposite to that of the precursor acid or the derived ester because the presence of the chlorine atom changes the relative Cahn–Ingold–Prelog priorities.

St. Louis, Mo. All solvents were HPLC grade and used as such, unless indicated otherwise. Preparative TLC: (Merck, Kieselgel 60 F_{254}), 20 × 20 cm × 0.25 mm; analytical TLC (Merck, Kieselgel 60 F_{254}, aluminum sheets) 5 × 2 cm × 0.2 mm; compounds were visualized by exposure to UV light and by dipping the plates in a 5% aqueous (w/v) phosphomolybdic acid solution containing a trace of ceric sulfate and 4% (v/v) H_2SO_4, followed by heating at 200°C.

GC analysis was carried out with a Hewlett–Packard 5880 gas chromatograph, equipped with a chiral capillary column (Chirasil-Val® column, Alltech, 25 m × 0.32 mm id, film thickness 0.2 μm), with He as carrier gas (flow 30 cm/s, measured at 50°C); detector at 250°C; injector at 220°C; oven temperature 70–200°C, at 4°C min^{-1}; samples were injected in split mode (ca. 1:30) with CH_2Cl_2 as solvent. NMR spectra were recorded on a Bruker AMX 500 or AM 360 spectrometer; for ^1H (360 MHz), δ values were referenced to $CHCl_3$ (7.24 ppm) and for ^{13}C (125.8 MHz) referenced to $CDCl_3$ (77.0 ppm). Mass spectra (MS) were obtained on a VG 70-250 SEQ hybrid mass spectrometer or a Finnigan Mat model 4500 mass spectrometer (electron impact (EI), or chemical ionization (CI) with ammonia as carrier gas), employing a solids probe in both cases.

Hydrolysis of phomalide

Degassed 6 M HCl (1 mL) was added to phomalide (**1**) (4 mg, 0.007 mmol) and the mixture was heated in a sealed tube at 110°C for 20 h. The reaction mixture was diluted with distilled H_2O (5 mL) and extracted with Et_2O (4 × 5 mL). The Et_2O extract, containing the hydroxy acids, was dried, filtered through a cotton plug, concentrated, and derivatized as described below. The aqueous extract, containing the amino acids, was concentrated to dryness and derivatized as described below.

Derivatization of hydrolysis products: preparation of *N*-trifluoroacetyl methyl esters of α-amino acids

One third of the residue from the aqueous extract (containing amino acid mixture) obtained from hydrolysis of phomalide was dissolved in MeOH (200 μL) and excess ethereal CH_2N_2 (1 mL) was added. After 15 min, the reaction mixture was concentrated (rotary evaporator), dissolved in CH_2Cl_2 (200 μL), and a solution of TFAA in CH_2Cl_2 (10 μL of a 25% solution, v/v) was added (6). After 1 h at room temperature, the reaction mixture was concentrated with a slow stream of N_2. The *N*-trifluoroacetyl amino acid methyl ester derivatives were analyzed by chiral GC employing a chiral capillary column.

Derivatization of hydrolysis products: preparation of 2-propyl Mosher's esters of α-hydroxy acids

The residue from the Et_2O extract (containing hydroxy acid mixture) obtained from hydrolysis of phomalide (above) was dissolved in 2-propanol (200 μL) containing 10% AcCl (v/v) in a ReactiVial and heated at 110°C for 15 min. The reaction mixture was concentrated (rotary evaporator), the residue was dissolved in $CHCl_3$ (300 μL), and Et_3N (4 μL, 0.03 mmol) and DMAP (4 mg, 0.033 mmol) were added. This solution was added to the neat (*S*)-MPTACl (6.5 mg, 0.026 mmol) (9). After 10 min the reaction mixture was concentrated (rotary evaporator) and analyzed by TLC and ^1H NMR.

Preparation of *N*-trifluoroacetyl methyl esters of Val and Leu

The *N*-trifluoroacetyl methyl esters (*N*-TFA) of both (*R*)-valine, (*R*)-leucine, and of both (*R,S*)-valine and (*R,S*)-leucine were prepared by a modification of an established method (6). Typically, to the amino acid (7.7 μmol) solution in MeOH (200 μL), a solution of CH_2N_2 in Et_2O (1.5 mL) was added at room temperature. After 30 min, the reaction mixture was concentrated (rotary evaporator) and the residue was dissolved in 25% TFAA in CH_2Cl_2 (v/v). Subsequent evaporation of the TFAA solvent with a gentle N_2 stream yielded the *N*-TFA methyl esters of the amino acids. GC analysis of the amino acid derivatives dissolved in CH_2Cl_2 and of the standards purchased from Sigma were carried out as described above; under those conditions the retention times were the following: *N*-TFA-(*R*)-Val Me ester, 5.6 min; *N*-TFA-(*S*)-Val Me ester, 6.0 min; *N*-TFA-(*R*)-Leu Me ester, 10.1 min; *N*-TFA-(*S*)-Leu Me ester, 9.2 min.

Preparation of Mosher's esters of 2-propyl O-Leu and 2-propyl O-Phe

The 2-propyl esters of hydroxy acids (*R*)-O-Leu, (*R*)-O-Phe, (*R,S*)-O-Leu, and (*R,S*)-O-Phe were prepared by a modification of an established method (7). Typically, a solution of the hydroxy acid (0.028 mmol) in AcCl–2-propanol (10:90, v/v, 200 μL) was heated to 110°C for 60 min. After concentration (rotary evaporator), Et_3N (15 μL) and DMAP (1 mg) were added to the reaction mixture dissolved in $CHCl_3$ (500 μL); this solution was added to the neat acid chloride of the (*R*) Mosher's acid ((*R*)-2-methoxy-2-phenyl-2-trifluoromethylacetic acid), prepared according to published procedure (9). The diastereomeric products (ca. 90% yield) obtained from derivatization of (*R,S*) O-Phe were separated by prep TLC (hexane–EtOAc, 10:1, v/v; multiple development); the diastereomeric products obtained from derivatization of (*R,S*) O-Leu were separated by prep TLC (hexane–EtOAc, 20:1, v/v; multiple development).

*1′-Methylethyl (*R*)-2-[(*R*)-2″-methoxy-2″-phenyl-2″-trifluoromethyl] acetoxy-3-phenylpropanoate*: ^1H NMR (360 MHz, $CDCl_3$) δ: 7.50–7.05 (m, 10 H's), 5.32 (dd, J = 8.2, 4.2 Hz, H-2), 5.05 (sept, J = 6.3 Hz, H-1′), 3.53 (q, J = 1.0 Hz, OMe), 3.18 (dd, J = 14.4, 4.2 Hz, H-3), 3.09 (dd, J = 14.4, 8.2 Hz, H-3), 1.20 (d, J = 6.3 Hz, H-2′/H-3′), 1.17 (d, J = 6.3 Hz, H-3′/H-2′); ^{13}C NMR (90.5 MHz, $CDCl_3$) δ: 168.0, 166.1, 135.1, 132.0, 129.4 (2 C's) 129.3 (2 C's), 128.33 (2 C's), 128.27 (2 C's), 127.4, 127.0, 123.0 (q, J_{C-F} = 289 Hz), 84.4 (q, $^2J_{C-F}$ = 28 Hz) 74.9, 69.8, 55.6, 37.1, 21.6, 21.6; CIMS (NH_3) *m/z*: (relative abundance): 442 (M + 18, 100); EIMS *m/z*: 189 (100), 148 (23).

Synthesis and characterization of 4-alkenyl and 4,4′-dialkenyl-2,2′-bipyridyl ligands bearing π-donor substituents

Manuel Bourgault, Thierry Renouard, Barbara Lognoné, Chakour Mountassir, and Hubert Le Bozec

Abstract: The synthesis of a new series of π-donor mono- and disubstituted vinyl bipyridines (donor = 4-R_2N-C_6H_4-; 4-RO-C_6H_4-; (C_5H_5)Fe(C_5H_4-); (C_5H_5)Ru(C_5H_4-)) has been achieved by reaction of the mono- and dilithio species of 4,4′-dimethyl-2,2′-bipyridine and the monolithio species of 4-nonyl-4′-methyl-2,2′-bipyridine with the appropriate aldehydes. Their ^{1}H NMR and UV–visible characterizations are reported.

Key words: 2,2′-bipyridines, π-donor substituents, UV–visible, ^{1}H NMR, nonlinear optics.

Résumé : La synthèse d'une nouvelle série de ligands mono- et di-alcényles 2,2′-bipyridines substitués par des groupements conjugués π-donneurs (donneur = 4-R_2N-C_6H_4-; 4-RO-C_6H_4-; (C_5H_5)Fe(C_5H_4-); (C_5H_5)Ru(C_5H_4-)) a été réalisée par réaction des espèces mono- et di-lithiées de la 4,4′-diméthyl-2,2′-bipyridine et mono-lithiée de la 4-nonyl-4′-méthyl-2,2′-bipyridine avec les aldéhydes appropriés. Leurs caractérisations RMN ^{1}H et UV–visible sont également décrites.

Mots clés : 2,2′-bipyridines, substituants π-donneurs, UV–visible, RMN ^{1}H, optique non lineaire.

Introduction

Recent work in our laboratory has focused on the design, synthesis, and second-order nonlinear optical (NLO) properties of new bipyridyl metal complexes. We have previously reported the synthesis of a series of 4-alkenyl-4′-methyl-2,2′-bipyridine complexes of rhenium, zinc, and mercury, in which the alkenyl fragment bears a π-donor group such as di-*n*-butylaminophenyl (1). The molecular hyperpolarizabilities of these new dipolar organometallic compounds were examined using the EFISH technique and large β values were found, especially for the bipyridyl zinc complex (**I**). In addition, we have recently discovered a giant octupolar nonlinearity, among the highest β values ever reported, for the octahedral trisubstituted ruthenium complexes (**II**) containing the bis-4,4′-di-*n*-butylaminostyryl-2,2′-bipyridine ligand (2). To gain insight into the potential scope of dipolar and octupolar bipyridyl metal complexes as NLO materials, we have carried out the preparation of a series of donor-substituted bipyridines. In this paper we report the synthesis and spectroscopic and electronic characterizations of 4-alkenyl- and 4,4′-dialkenyl-2,2′-bipyridyl ligands containing π-donor dialkylaminophenyl, alkoxyphenyl, or metallocenyl groups.

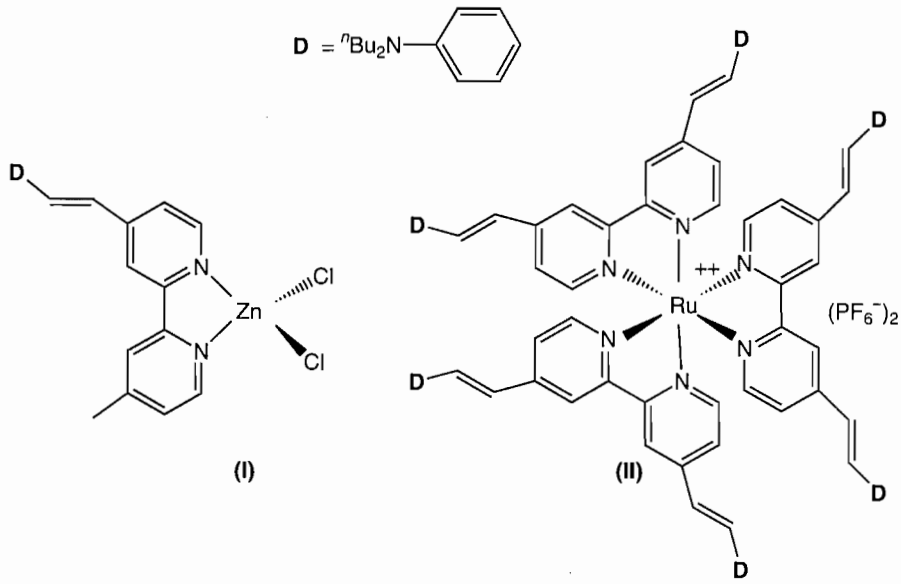
Results and discussion



The 4-alkenyl-2,2′-bipyridyl ligands were prepared from 4,4′-dimethyl-2,2′-bipyridine **1** by an approach analogous to that used by Beer et al. in the preparation of 4-methyl-4′-ferrocenylvinyl-2,2′-bipyridine **6** (3). Reaction of **1** with one equivalent of lithium diisopropylamide (LDA) is known to generate the mono-lithio species (4). The reaction of this anion with the appropriate aldehydes gave the corresponding alcohols, and subsequent treatment with *p*-toluenesulfonic acid yielded the respective 4-methyl-4′-alkenyl-2,2′-bipyridines **3***a–d*, **4**, **6**, and **7** in 49–96% yield (Scheme 2). The dialkylaminobenzaldehyde precursors were obtained by formylation (Vilsmeier reaction) of the aniline derivatives (5) whereas the 4-alkoxybenzaldehydes were synthesized from 4-hydroxybenzaldehyde and the appropriate alkyl bromide or mesylate reagents (see experimental section) (6). To enhance the solubility of the resultant complexes in common organic solvents, which is the prerequisite condition to measure the dipole moments μ and the molecular hyperpolarizabilities β, the synthesis of 4-nonyl-4′-alkenyl-2,2′-bipyridines **5** and **8** was attempted. Compound **5** was synthesized in 37% yield from 4-nonyl-4′-methyl-2,2′-bipyridine **2** (7, 8) by using the same previous procedure, whereas **8** was conveniently prepared (68% yield) in a one-pot reaction from **1** using a step by step lithiation and the successive addition of ferrocene carbaldehyde and octyl bromide (Scheme 2).

The symmetrical 4,4′-disubstituted 2,2′-bipyridines compounds were obtained from **1** upon treatment with two equivalents of LDA followed by addition of the appropriate aldehydes (Scheme 3) (6, 9, 10). Dehydration of the dialdehydes was accomplished either with *p*-toluenesulfonic acid or with pyridium *p*-toluenesulfonate and afforded the new bis-4,4′-alkenyl-2,2′-bipyridines **9**, **10**, and **12** in moderate to

Scheme 1.

good yield (Table 1). Ligands **11** and **13** were also synthesized from the chiral (S)-(+)-4-[*N*-methyl-*N*-(2-methylbutyl)amino]benzaldehyde and (*S*)-(+)-4-(2-methylbutoxy)benzaldehyde, respectively, in order to promote the noncentrosymmetric crystallization of the corresponding organometallic materials (Scheme 3).

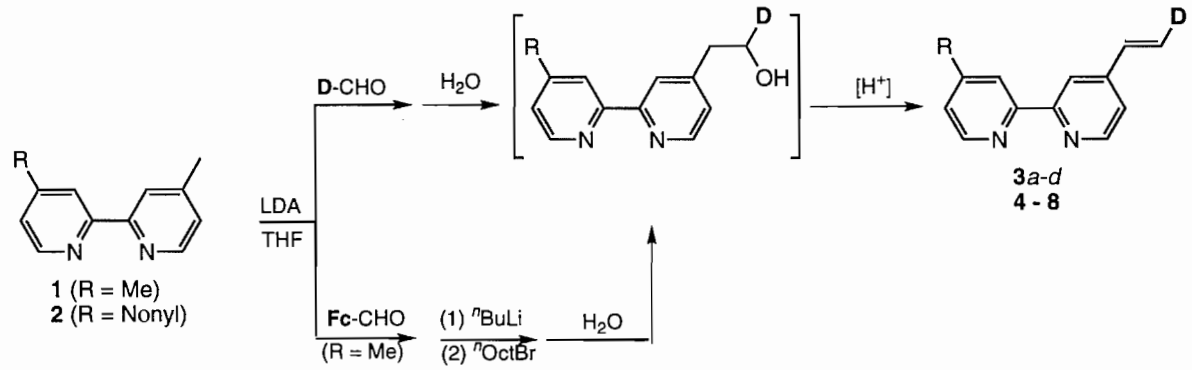
These compounds were easily characterized by means of their analytical data (see experimental section) and ^{1}H NMR and UV–visible data (Table 1). The configuration of the double bond formed after dehydration was in every case established as *E* on the basis of the proton-proton coupling constant, $J_{H^7H^8} \approx 16$ Hz. The aromatic region of **3–8** shows six different signals ($H^{3,3'}$, $H^{5,5'}$, $H^{6,6'}$) characteristic of disymmetric substituted bipyridines. In all cases the lowest field resonances are H^6 and $H^{6'}$ as expected from the deshielding by the adjacent nitrogen. The protons H^3 and $H^{3'}$ are also found at lower field than H^5 and $H^{5'}$, which is known to be due to the *transoid* conformation of the bipyridines (11). In the case of symmetric ligands **9–13** the aromatic region gives rise, as expected, to only three signals. The optical absorption spectra for the mono- and bis-dialkylaminostyryl bipyridines are all characterized by intense broad transitions in the region 350–400 nm (**3***a–c*: $\varepsilon \approx 22\,000$; **9–11**: $\varepsilon \approx 50\,000$), which are assigned to intramolecular charge transfer transitions (ICT). In addition, this absorption band exhibits a solvatochromic shift characteristic of a large dipole moment change between the ground and the excited states and suggestive of appreciable microscopic nonlinearities. A less intense ICT band is observed at higher energy for compounds **3***c*, **4**, **5**, **12**, and **13** ($\lambda \approx 330$–350 nm), which is consistent with the following relative ordering of donor strength: $N(^nBu)_2 > N(Me)_2 > N(Et)(Ar) > O(Alk)$. The visible absorption spectra of the ferrocenylvinyl bipyridines **6** and **8** exhibit two broad bands at ca. 475 and 375 nm that can be assigned to metal-to-ligand charge transfer and π–π^* transitions, respectively (12). These two bands are hypsochromically shifted ($\lambda = 310$ and 345 nm) for the ruthenium analog **7**, as expected for the replacement of ferrocene by the less electron-rich ruthenocene (12). An extensive investigation regarding the coordination studies of these ligands to form mono- and tris-bipyridine metal complexes, along with studies of their optical nonlinearities, will be described in the future.

Experimental

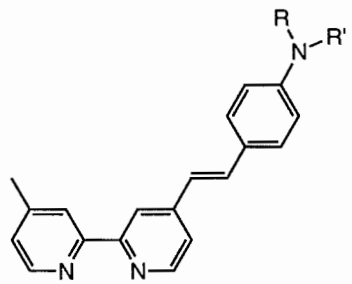
All reactions were conducted under argon or nitrogen atmosphere. The solvents were dried by standard methods. Infrared spectra were recorded on a Nicolet 205 FT-IR spectrometer. Electronic absorption spectra were recorded on a Uvikon 941+ spectrophotometer. Proton (300.13 MHz) NMR spectra were recorded on a Bruker AM 300 spectrometer at 297 K using $CDCl_3$ as solvent and referenced to TMS. High-resolution mass spectra were obtained on a Varian MAT 311 at CRMPO, University of Rennes. Elemental analyses were performed by the Service Central de Microanalyses du CNRS at Lyon, France. Melting points, uncorrected, were taken on a Kofler apparatus.

Materials

4,4′-Dimethyl-2,2′-bipyridine (13) and ruthenocenecarbaldehyde (14) were prepared by described procedures. 4-(*N,N*-Dimethylamino)benzaldehyde, 9-ethyl-3-carbazole carboxaldehyde, 4-methoxybenzaldehyde, and ferrocenecarbaldehyde were commercial products (Aldrich or Acros).



4-(*N,N*-Di-*n*-butylamino)benzaldehyde (ref. 5)



Dimethylformamide (10 mL) was cooled to 0°C and treated dropwise with phosphorus oxychloride (2.1 mL, 22.5 mmol). The solution was stirred at 0°C for 1 h and then at room temperature for 1 h. To the red solution was added dropwise *N,N*-di-*n*-butylaniline (4.53 mL, 20 mmol). The mixture was heated at 60°C for 10 h and then cooled to 0°C. A solution of 2 g of sodium acetate in 20 mL of cold water was added slowly with stirring. The reaction mixture was then stirred for an additional 1 h, and the resulting solution was extracted with

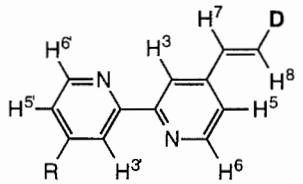
ether. The combined extract was washed with saturated aqueous sodium bicarbonate and then with water, and the organic layer was dried over $MgSO_4$. The solvent was removed under reduced pressure, and the residue was distilled in vacuum at 147–150°C/1 Torr (= 133.3 Pa) to yield 4-(*N*,*N*-di-*n*-butylamino)benzaldehyde as a yellow liquid (4.37 g, 90%); IR, ν_{max}(cm^{-1}): 1686 (C=O); ^{1}H NMR, δ: 9.67 (s, 1H, CHO), 7.66 (dd, 2H, *J* = 9.0 and 2.7 Hz, C_6H_4-), 6.62 (dd, 2H, *J* = 9.0 and 2.7 Hz, C_6H_4-), 3.32 (t, 4H, *J* = 7.7 Hz, N-CH_2-), 1.58 (m, 4H, CH_2-), 1.35 (m, 4H, CH_2-), 0.35 (t, 6H, *J* = 7.3 Hz, CH_3).

(*N*-Methyl-*N*-octyl)aniline

To an ice-cooled solution of *N*-methylaniline (6.5 g, 60 mmol) in 20 mL of freshly distilled THF was added 1.6 M *n*-butyllithium (40 mL, 66 mmol) dropwise. The resulting mixture was stirred for 0.5 h and octylbromide (11.5 mL, 66 mmol) was added slowly. The solution was allowed to warm to room temperature. The orange solution was cooled in an ice-water bath and hydrolysed with 10 mL of water. The organic layer was separated, dried over $MgSO_4$, and filtered, and the solvent was evaporated to dryness. The title compound was obtained as an orange oil (11.8 g; 90%); ^{1}H NMR, δ: 7.33 (dd, 2H, *J* = 7 and 8.8 Hz, C_6H_5-), 6.80 (m, 3H, C_6H_5-), 3.40 (t, 2H, *J* = 7.5 Hz, N-CH_2-), 3.02 (s, 3H, N-CH_3), 1.68 (m, 2H, N-CH_2-CH_2-), 1.41 (m, 10H, $(CH_2)_5$-), 1.01 (t, 3H, *J* = 7.5 Hz, CH_2-CH_3).



4-(*N*-Methyl-*N*-octylamino)benzaldehyde

The title compound was obtained as an orange oil (12.5 g, 74%) from (*N*-methyl-*N*-octyl)aniline (15 g, 73 mmol), phosphorus oxychloride (7 mL, 75 mmol) and dimethylformamide (30 mL); bp 110°C at 0.03 Torr; IR, ν_{max}(cm^{-1}): 1682 (C=O);

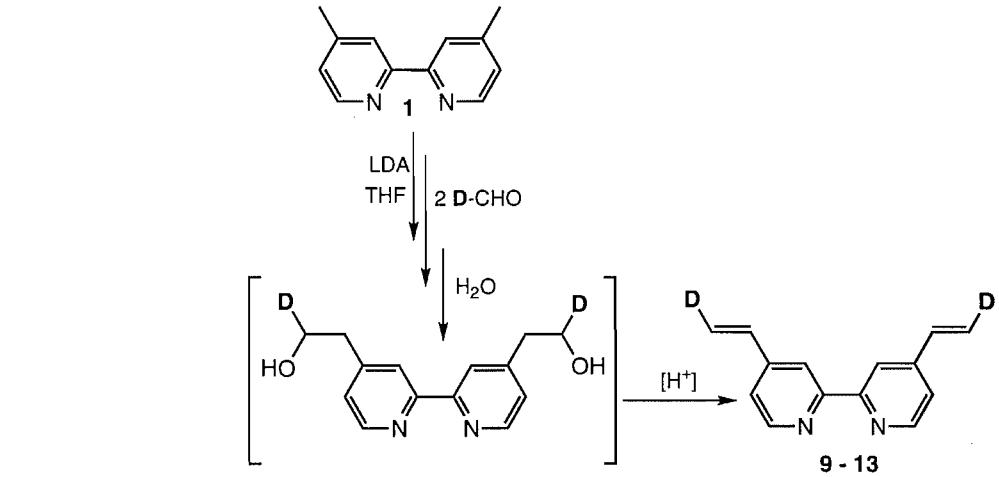
The title compound was obtained as a yellow oil (3.54 g, 66%) from *N*-methylaniline (3.2 g, 30 mmol), (*S*)-(+)-2-methylbutylmesylate (5.5 g, 33 mmol), and 1.6 M *n*-butyllithium (20 mL, 32 mmol) in 20 mL of freshly distilled THF; ^{1}H NMR, δ: 7.30 (m, 2H, C_6H_5-), 6.76 (m, 3H, C_6H_5-), 3.21(2 × q, 2H, J = 6.8 and 14.5 Hz, N-CH_2-), 3.03 (s, 3H, N-CH_3), 1.92 (m, 1H, CH-CH_3), 1.56 (m, 1H, CH_2-CH_3), 1.20 (m, 1H, CH_2-CH_3), 1.02 (t, 3H, J = 7.3 Hz, CH_2-CH_3), 0.99 (d, 3H, J = 6.7 Hz, CH-CH_3).

(*S*)-(+)-4-(*N*-Methyl-*N*-(2-methylbutyl)amino)-benzaldehyde

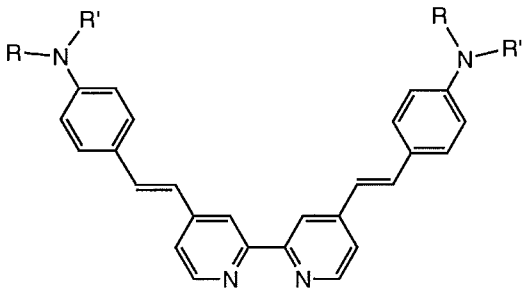
The title compound was obtained as an orange oil (3.5 g, 85%) from (*N*-methyl-*N*-2-methylbutyl)aniline (3.54 g, 20 mmol), $POCl_3$ (2 mL, 20 mmol), and DMF (10 mL); $[\alpha]_D$ +26 (c = 1.0, CH_2Cl_2); IR, ν_{max}(cm^{-1}): 1684 (C═O); ^{1}H NMR, δ: 9.64 (s, 1H, CHO), 7.63 (d, 2H, J = 9.0 Hz, C_6H_4-), 6.60 (d, 2H, J = 9 Hz, C_6H_4-), 3.17 (2 × q, 2H, J = 6.8 and 14.6 Hz, N-CH_2-), 2.97 (s, 3H, N-CH_3), 1.77 (m, 1H, CH-CH_3), 1.37 (m, 1H, CH_2-CH_3), 1.07 (m, 1H, CH_2-CH_3), 0.86 (t, 3H, J = 7.4 Hz, CH_2-CH_3), 0.82 (d, 3H, J = 6.6 Hz, CH-CH_3).

4-Octyloxybenzaldehyde (ref. 6)

To a solution of 4-hydroxybenzaldehyde (6.11 g, 50 mmol) in 300 mL of ethanol was added potassium carbonate (17 g, 123 mmol). The resulting mixture was stirred for 0.5 h at room temperature and octylbromide (8.6 mL, 50 mmol) was added slowly. The yellow solution was refluxed for 70 h and then cooled to room temperature. The mixture was filtered and the solvent evaporated. The yellow residue was dissolved in ether and washed with water (until the washings were neutral). The solution was dried over $MgSO_4$, and the solvent evaporated to dryness. The title compound was obtained as a yellow oil (9.6 g, 82%); IR, ν_{max}(cm^{-1}): 1696 (C═O); ^{1}H NMR, δ: 9.84 (s, 1H, CHO), 7.79 (dd, 2H, J = 8.8 and 2.6 Hz, C_6H_4-), 6.95 (dd, 2H, J = 8.8 and 2.6 Hz, C_6H_4-), 4.0 (t, 2H, J = 6.5 Hz, O-CH_2), 1.78 (m, 2H, CH_2-), 1.5–1.1 (m, 10H, $(CH_2)_5$-), 0.86 (t, 3H, J = 6.6 Hz, CH_3).



(*S*)-(+)-4-(2-Methylbutoxy)benzaldehyde



The title compound was obtained as a yellow oil (3.3 g, 57%) from 4-hydroxybenzaldehyde (3.66 g, 30 mmol), potassium carbonate (17 g, 123 mmol), and 4.98 g of (*S*)-(+)-2-methylbutylmesylate; $[\alpha]_D$ +7 (c = 1.6, CH_2Cl_2); IR, ν_{max}(cm^{-1}): 1694 (C═O); ^{1}H NMR, δ: 9.72 (s, 1H, CHO), 7.67 (dd, 2H, J = 8.8 and 2.6 Hz, C_6H_4-), 6.84 (dd, 2H, J = 8.8 and 2.6 Hz, C_6H_4-), 3.74 (dd, 1H, J = 9.1 and 6.0 Hz, O-CH_2-), 3.66 (dd, 1H, J = 9.1 and 6.0 Hz, O-CH_2-), 1.74 (m, 1H, CH-CH_3), 1.42 (m, 1H, CH_2-), 1.12 (m, 1H, CH_2-), 0.88 (d, 3H, J = 6.7 Hz, CH_3), 0.80 (t, 3H, J = 7.4 Hz, CH_3).

4-Nonyl-4′-methyl-2,2′-bipyridine 2

A solution of 4,4′-dimethyl-2,2′-bipyridine **1** (1.84 g, 10 mmol) in 30 mL THF was added dropwise to a stirred solution of freshly prepared LDA (12.9 mmol) in 40 mL THF at 0°C. The resulting red mixture was stirred 1 h at 0°C. Octylbromide (2 mL, 10 mmol) was added and the mixture was stirred for an additional 1 h at 0°C, treated with water, and evaporated in vacuo. The yellow oil was dissolved in 100 mL CH_2Cl_2, washed with water (2 × 75 mL), dried over $MgSO_4$, and evaporated. Recrystallization from hexane (15 mL) yielded **2** as white crystals (2.21 g); mp 42–45°C; ^{1}H NMR, δ: 8.47 (d, 2H, $H^{6,6'}$), 8.23 (m, 2H, $H^{3,3'}$), 7.11 (m, 2H, $H^{5,5'}$), 2,66 (t, 2H, J = 8.0 Hz, CH_2-), 2.40 (s, 3H, CH_3), 1.65 (m, 2H, CH_2-), 1.40–1.15 (m, 12H, $(CH_2)_6$-), 0.85 (t, 3H, J = 8.0 Hz, CH_3). Anal. calcd. for $C_{20}H_{28}N_2$: C 81.03; H 9.52; found: C 80.96, H 10.39.

4-[*p*-(*N*,*N*-Dibutylamino)styryl]-4′-methyl-2,2′-bipyridine *3a*

To a stirred solution of freshly prepared LDA (51.6 mmol) in 60 mL of THF at −78°C was added dropwise a solution of **1** (7.9 g, 43 mmol) in 120 mL of THF. The red solution was stirred for 15 min at −78°C and 1 h at 0°C. A solution of 4-(*N*,*N*-dibutylamino)benzaldehyde (10 g, 43 mmol) in 40 mL of THF was then added dropwise and the yellow-green solution was stirred for 2 h at 0°C and overnight at room temperature. The mixture was quenched with 50 mL of water and extracted with CH_2Cl_2 (3 × 100 mL). The combined extract was dried over $MgSO_4$ and evaporated in vacuo. The crude product was chromatographed on silica gel with dichloromethane–methanol – ammonium hydroxide (100/5/1) as the eluant. The resulting alcohol was then dissolved in 250 mL of toluene and treated with *p*-toluenesulfonic acid monohydrate (500 mg, 2.6 mmol). The mixture was refluxed for 4 h, then cooled to room temperature, washed with saturated aqueous sodium bicarbonate, dried over $MgSO_4$, and evaporated in vacuo to give **3***a* as an orange oil (16.4 g); UV, λ_{max} (nm): 382 (toluene), 388 (CH_2Cl_2), 397 (DMF); ^{1}H NMR, δ: 8.53 (d, 1H, J = 5.1 Hz, H^6), 8.50 (d, 1H, J = 5.0 Hz, $H^{6'}$), 8.48 (d, 1H, J = 1.6 Hz, H^3), 8.27 (s, 1H, $H^{3'}$), 7.40 (d, 2H, J = 9.0 Hz, C_6H_4-), 7.35 (d, 1H, J = 16.2 Hz, CH=), 7.30 (dd, 1H, J = 5.1 and 1.6 Hz, H^5), 7.11 (dd, 1H, J = 5.0 and 0.9 Hz, $H^{5'}$), 6.88 (d, 1H, J = 16.2 Hz, CH=), 6.63 (d, 2H, J = 9.0 Hz, C_6H_4-), 3.29 (t, 4H, J = 7.8 Hz, N-CH_2-), 2.42 (s, 3H, CH_3), 1.57 (m, 4H, CH_2-), 1.35 (m, 4H, CH_2-), 0.95 (t, 6H, J = 7.3 Hz, CH_3). Anal. calcd. for $C_{27}H_{33}N_3$: C 81.16, H 8.32, N 10.52; found: C 81.32, H 8.59, N 10.21.

4-[*p*-(*N*,*N*-Dimethylamino)styryl]-4′-methyl-2,2′-bipyridine *3b*

The title compound was prepared analogously as described for

3*a*, using **1** (2.76 g, 15 mmol) and 4-(*N*,*N*-dimethylamino)benzaldehyde (2.4 g, 15 mmol) as starting materials, and was isolated as yellow-orange microcrystals after recrystallization from dichloromethane–ether (3.54 g); mp 140°C; ^{1}H NMR, δ: 8.59 (d, 1H, J = 5.2 Hz, H^6), 8.58 (d, 1H, J = 4.9 Hz, $H^{6'}$), 8.48 (d, 1H, J = 1.2 Hz, H^3), 8.30 (s, 1H, $H^{3'}$), 7.47 (d, 2H, J = 8.9 Hz, C_6H_4-), 7.42 (d, 1H, J = 16.3 Hz, CH═), 7.36 (dd, 1H, J = 5.2 and 1.7 Hz, H^5), 7.16 (dd, 1H, J = 4.9 and 1.7 Hz, $H^{5'}$), 6.92 (d, 1H, J = 16.3 Hz, CH═), 6.73 (d, 2H, J = 8.9 Hz, C_6H_4-), 3.02 (s, 6H, N-CH_3), 2.46 (s, 3H, CH_3). Anal. calcd. for $C_{21}H_{21}N_3$: C 79.97, H 6.71, N 13.32; found: C 79.23, H 6.76, N 13.00. HRMS *m/z*, calcd.: 315.1735; found: 315.1733.

4-[*p*-(*N*-Methyl-*N*-octyl)aminostyryl]-4′-methyl-2,2′-bipyridine 3*c*

The title compound was prepared analogously as described for **3***a*, using **1** (0.92 g, 5 mmol) and 4-(*N*-methyl-*N*-octyl)aminobenzaldehyde (1.25 g, 5.1 mmol) as starting materials, and was isolated as an orange oil after flash chromatography on silica gel with dichloromethane–methanol (90:10) as the eluant (1.26 g); ^{1}H NMR, δ: 8.51 (d, 1H, J = 5.2 Hz, H^6), 8.50 (d, 1H, J = 4.0 Hz, $H^{6'}$), 8.46 (d, 1H, J = 1.2 Hz, H^3), 8.25 (s, 1H, $H^{3'}$), 7.42 (d, 2H, J = 8.9 Hz, C_6H_4), 7.36 (d, 1H, J = 16.3 Hz, CH═), 7.31 (dd, 1H, J = 5.2 and 1.7 Hz, H^5), 7.13 (dd, 1H, J = 4.8 and 0.9 Hz, $H^{5'}$), 6.89 (d, 1H, J = 16.3 Hz, CH═), 6.66 (d, 2H, J = 8.9 Hz, C_6H_4-), 3.32 (t, 2H, J = 7.7 Hz, N-CH_2-), 2.94 (s, 3H, N-CH_3), 2.41 (s, 3H, CH_3), 1.56 (m, 2H, CH_2-), 1.28 (m, 10H, $(CH_2)_5$-), 0.86 (t, 3H, J = 6.9 Hz, CH_3); HRMS *m/z* calcd. for $C_{28}H_{35}N_3$: 413.2831; found: 413.2847.

4-[(9-Ethyl-3-carbazolyl)vinyl]-4′-methyl-2,2′-bipyridine 3*d*

The title compound was prepared analogously as described for **3***a*, using **1** (2.76 g, 15 mmol) and 9-ethyl-3-carbazole carboxaldehyde (3.33 g, 15 mmol) as starting materials, and was isolated as a yellow solid after flash chromatography on alumina with dichloromethane–acetonitrile (90:10) as the eluant (3.0 g); mp 174°C; ^{1}H NMR, δ: 8.62 (d, 1H, J = 5.1 Hz, H^6), 8.59 (d, 1H, J = 5.0 Hz, $H^{6'}$), 8.55 (d, 1H, J = 1.5 Hz, H^3), 8.27 (s, 2H, $H^{3'}$ and H arom), 8.13 (d, 1H, J = 7.7 Hz, H arom), 7.71 (dd, 1H, J = 8.5 and 1.5 Hz, H arom), 7.66 (d, 1H, J = 16.3 Hz, CH═), 7.49 (m, 1H, H arom), 7.49 (m, 3H, H^5 and H arom), 7.26 (m, 1H, H arom), 7.16 (dd, 1H, J = 5.0 and 0.9 Hz, $H^{5'}$), 7.15 (d, 1H, J = 16.3 Hz, CH═), 4.36 (q, 2H, J = 7.2 Hz, CH_2-), 2.45 (s, 3H, CH_3), 1.44 (t, 3H, J = 7.2 Hz, CH_3). Anal. calcd. for $C_{27}H_{23}N_3$: C 83.26, H 5.95, N 10.79; found: C 82.35, H 5.99, N 10.55. HRMS *m/z*, calcd.: 389.1892; found: 389.1892.

4-[*p*-(Octyloxy)styryl]-4′-methyl-2,2′-bipyridine 4

The title compound was prepared analogously as described for **3***a*, using **1** (1 g, 5.4 mmol) and 4-octyloxybenzaldehyde (1.27 g, 5.4 mmol) as starting materials, and was isolated as a white solid after recrystallization from ethyl acetate (1.51 g); mp 60–62°C; ^{1}H NMR, δ: 8.61 (d, 1H, J = 5.1 Hz, H^6), 8.57 (d, 1H, J = 5.0 Hz, $H^{6'}$), 8.48 (s, 1H, H^3), 8.25 (s, 1H, $H^{3'}$), 7.48 (d, 2H, J = 8.7 Hz, C_6H_4-), 7.40 (d, 1H, J = 16.3 Hz, CH═), 7.33 (dd, 1H, J = 5.1 and 1.6 Hz, H^5), 7.15 (dd, 1H, J = 5.0 and 0.9 Hz, $H^{5'}$), 6.97 (d, 1H, J = 16.3 Hz, CH═), 6.91 (d, 2H, J = 8.7 Hz, C_6H_4-), 3.98 (t, 2H, J = 6.5 Hz, O-CH_2-), 2.44 (s, 3H, CH_3), 1.78 (m, 2H, CH_2-), 1.50–1.20 (m, 10H, $(CH_2)_5$-), 0.89 (t, 3H, J = 6.9 Hz, CH_3). Anal. calcd. for $C_{27}H_{32}N_2O{\cdot}0.5\ H_2O$: C 79.22, H 8.31, N 6.85; found: C 79.08, H 7.87, N 7.07.

4-[*p*-(Methoxy)styryl]-4′-nonyl-2,2′-bipyridine 5

The title compound was prepared analogously as described for **3***a*, using **2** (1.73 g, 5.8 mmol) and 4-methoxybenzaldehyde (1.12 g, 7 mmol), and was isolated as a white solid after flash chromatography on silica gel with dichloromethane–ethanol as the eluant (0.88 g); mp 62–64°C; ^{1}H NMR, δ: 8.56 (d, 1H, J = 5.1 Hz, H^6), 8.52 (d, 1H, J = 5.0 Hz, $H^{6'}$), 8.51 (s, 1H, H^3), 8.26 (s, 1H, $H^{3'}$), 7.51 (d, 2H, J = 8.7 Hz, C_6H_4-), 7.40 (d, 1H, J = 16.4 Hz, CH═), 7.34 (dd, 1H, J = 5.1 and 1.7 Hz, H^5), 7.14 (dd, 1H, J = 5.0 and 1.6 Hz, $H^{5'}$), 7.0 (d, 1H, J = 16.4 Hz, CH═), 6.91 (d, 2H, J = 8.7 Hz, C_6H_4-), 3.81 (s, 3H, CH_3), 2.68 (t, 2H, J = 7.4 Hz), 1.67 (m, 2H, CH_2-), 1.35–1.20 (m, 12H, $(CH_2)_6$-), 0.85 (t, 3H, J = 6.9 Hz, CH_3); HRMS *m/z* calcd. for $C_{28}H_{34}N_2O$: 414.2671; found: 414.2670.

4-Ferrocenylvinyl-4′-methyl-2,2′-bipyridine 6 (ref. 4)

The title compound was prepared analogously as described for **3***a*, using **1** (2.76 g, 15 mmol) and ferrocenecarbaldehyde (3.21 g, 15 mmol) as starting materials, and was isolated as a red solid after flash chromatography on alumina with dichloromethane–methanol as the eluant (3.97 g); mp 156°C (dec.); ^{1}H NMR, δ: 8.53 (d, 1H, J = 5.2 Hz, H^6), 8.52 (d, 1H, J = 5.4 Hz, $H^{6'}$), 8.45 (d, 1H, J = 1.6 Hz, H^3), 8.27 (d, 1H, $H^{3'}$), 7.29 (dd, 1H, J = 5.2 and 1.7 Hz, H^5), 7.28 (d, 1H, J = 16.1 Hz, CH═), 7.15 (d, 1H, J = 4.9 Hz, $H^{5'}$), 6.73 (d, 1H, J = 16.1 Hz, CH═), 4.51 (t, 2H, J = 1.8 Hz, C_5H_4-), 4.33 (t, 2H, J = 1.8 Hz, C_5H_4-), 4.13 (s, 5H, C_5H_5), 2.42 (s, 3H, CH_3). Anal. calcd. for $C_{23}H_{20}N_2Fe$: C 72.65, H 5.30, N 7.37; found: C 72.22, H 5.17, N 7.45. HRMS *m/z*, calcd.: 380.0976; found: 380.0980.

4-Ruthenocenylvinyl-4′-methyl-2,2′-bipyridine 7

The title compound was prepared analogously as described for **3***a*, using **1** (1.5 g, 8.15 mmol) and ruthenocenecarbaldehyde (2.1 g, 8.15 mmol), and was isolated as a pale yellow solid after recrystallization from ethyl acetate–pentane (1.7 g); mp 120°C (dec.); ^{1}H NMR, δ: 8.50 (d, 1H, J = 4.8 Hz, H^6), 8.49 (d, 1H, J = 4.6 Hz, $H^{6'}$), 8.39 (d, 1H, J = 1.5 Hz, H^3), 8.25 (s, 1H, $H^{3'}$), 7.20 (dd, 1H, J = 5.1 and 1.7 Hz, H^5), 7.14 (d, 1H, J = 16.2 Hz, CH═), 7.12 (dd, 1H, J = 4.6 and 0.9 Hz, $H^{5'}$), 6.65 (d, 1H, J = 16.2 Hz, CH═), 4.90 (t, 2H, J = 1.7 Hz, C_5H_4-), 4.64 (t, 2H, J = 1.7 Hz, C_5H_4-), 4.52 (s, 5H, C_5H_5), 2.40 (s, 3H, CH_3). Anal. calcd. for $C_{23}H_{20}N_2Ru$: C 64.94, H 4.71, N 6.59; found: C 64.85, H 4.89, N 6.90.

4-Ferrocenylvinyl-4′-nonyl-2,2-bipyridine 8

To a stirred solution of freshly prepared LDA (6.0 mmol) in 10 mL THF at −78°C was added dropwise a solution of **1** (1.0 g, 5.4 mmol) in 50 mL THF. The red solution was stirred for 15 min at −78°C and 1 h at 0°C. A solution of ferrocenecarbaldehyde (1.16 g, 5.4 mmol) in 40 mL THF was added dropwise and the yellow-green solution was stirred for 2 h at 0°C. The reaction mixture was then cooled to −78°C and treated with 1.6 M butyllithium solution in hexane (3.8 mL, 6.1 mmol). After being stirred for 1 h at 0°C, octylbromide (1.05 g, 5.4 mmol) was slowly added and the solution was stirred for 2 h at 0°C and then overnight at 25°C. The mixture was quenched with 50 mL water, extracted with ethyl acetate (3 × 75 mL), dried over $MgSO_4$, and evaporated. The crude product was

For personal use only.

purified by chromatography on alumina using ether–ethanol as the eluant. The resulting red oil was dissolved in 125 mL dry toluene, *p*-toluenesulfonic acid monohydrate (500 mg, 2.6 mmol) was added, and the mixture was refluxed for 4 h and then cooled to room temperature. The solution was washed with 100 mL saturated water solution of $NaHCO_3$, dried, and evaporated in vacuo. Recrystallization from ethyl acetate yielded **8** as red crystals (1.8 g); ^{1}H NMR, δ: 8.58 (d, 2H, J = 5.0 Hz, H^6 and $H^{6'}$), 8.43 (d, 1H, J = 1.5 Hz, H^3), 8.25 (d, 1H, J = 1.0 Hz, $H^{3'}$), 7.27 (d, 1H, J = 16.1 Hz, CH═), 7.27 (dd, 1H, J = 5.0 and 1.5 Hz, H^5), 7.15 (dd, 1H, J = 5.0 and 1.5 Hz, $H^{5'}$), 6.70 (d, 1H, J = 16.1 Hz, CH═), 4.50 (t, 2H, J = 1.8 Hz, C_5H_4-), 4.36 (t, 2H, J = 1.8 Hz, C_5H_4-), 4.14 (s, 5H, C_5H_5), 2.69 (t, 2H, J = 7.7 Hz, CH_2-), 1.69 (m, 2H, CH_2-), 1.40–1.10 (m, 12H, $(CH_2)_6$-), 0.86 (t, 3H, J = 7.0 Hz, CH_3). Anal. calcd. for $C_{31}H_{36}N_2Fe$: C 75.63, H 7.32, N 5.69; found: C 75.82, H 7.32, N 5.73.

4,4′-Bis[*p*-(*N*,*N*-dibutylamino)styryl]-2,2′-bipyridine 9

To a stirred solution of freshly prepared LDA (21 mmol) in 30 mL THF at −78°C was added slowly a solution of **1** (1.84 g, 10 mmol) in 75 mL THF. The red-brown solution was stirred for 1.5 h at −78°C. A solution of 4-(*N*,*N*-dibutylamino)benzaldehyde (4.66 g, 20 mmol) in 20 mL THF was then added dropwise and the yellow-green solution was stirred for 2 h at −78°C and then overnight at 25°C. The mixture was quenched with 100 mL water and extracted with CH_2Cl_2 (2 × 100 mL). The combined extract was dried over $MgSO_4$ and evaporated in vacuo. The crude product was purified by chromatography on silica gel with dichloromethane–methanol – ammonium hydroxide (100/5/1) as the eluant. The resulting diol was then dissolved in 250 mL toluene and treated with pyridinium *p*-toluene sulfonate (0.1 g, 0.4 mmol). The mixture was refluxed for 4 h, then cooled to room temperature, washed with saturated aqueous sodium bicarbonate, dried over $MgSO_4$, and evaporated in vacuo. Recrystallization from ethyl acetate yielded **9** as orange microcrystals (5.2 g); mp 140°C; ^{1}H NMR, δ: 8.60 (d, 2H, J = 5.1 Hz, $H^{6,6'}$), 8.46 (d, 2H, J = 1.1 Hz , $H^{3,3'}$), 7.42 (d, 4H, J = 8.8 Hz, C_6H_4-), 7.38 (d, 2H, J = 16.2 Hz, CH═), 7.33 (dd, 2H, J = 5.1 and 1.1 Hz, $H^{5,5'}$), 6.88 (d, 2H, J = 16.2 Hz, CH═), 6.63 (d, 4H, J = 8.8 Hz, C_6H_4-), 3.30 (t, 8H, J = 7.6 Hz, N-CH_2-), 1.59 (m, 8H, CH_2-), 1.36 (m, 8H, CH_2-), 0.96 (t, 12H, J = 7.3 Hz, CH_3). Anal. calcd. for $C_{42}H_{54}N_4$: C 82.04, H 8.85, N 9.11; found: C 81.96, H 8.73, N 8.94.

4,4′-Bis[p-[(*N*-methyl-*N*-octyl)amino]styryl]-2,2′-bipyridine 10

The title compound was prepared analogously as described for **9**, using **1** (1.84 g, 10 mmol) and 4-(*N*-methyl-*N*-octylamino)benzaldehyde (5.0 g, 20 mmol) as starting materials, and was isolated as orange microcrystals after recrystallization from ethyl acetate (5.0 g); mp 136°C; ^{1}H NMR, δ: 8.60 (d, 2H, J = 5.2 Hz, $H^{6,6'}$), 8.46 (s, 2H, $H^{3,3'}$), 7.44 (d, 4H, J = 8.8 Hz, C_6H_4-), 7.39 (d, 2H, J = 16.2 Hz, CH═), 7.33 (dd, 2H, J = 5.2 and 1.5 Hz, $H^{5,5'}$), 6.90 (d, 2H, J = 16.2 Hz, CH═), 6.67 (d, 4H, J = 8.8 Hz, C_6H_4-), 3.33 (t, 4H, J = 7.5 Hz, N-CH_2-), 2.97 (s, 6H, N-CH_3), 1.59 (m, 4H, CH_2-), 1.29 (m, 20H, $(CH_2)_5$-), 0.88 (t, 6H, J = 6.6 Hz, CH_3); HRMS *m/z*, calcd. for $C_{44}H_{58}N_4$: 642.4661; found: 642.470.

(*S*)-(+)-4,4′-Bis[*p*-[*N*-methyl-*N*-(2-methylbutyl)amino]-styryl]-2,2′-bipyridine 11

The title compound was prepared analogously as described for **9**, using **1** (1.48 g, 8 mmol) and 4-[*N*-methyl-*N*-(2-methylbutyl)amino]benzaldehyde (3.4 g, 16 mmol) as starting materials, and was isolated as yellow-orange microcrystals after recrystallization from ethanol (2.3 g); mp 184°C; $[\alpha]_D$ = +12 (c = 1.0, CH_2Cl_2); ^{1}H NMR, δ: 8.60 (d, 2H, J = 5.2 Hz, $H^{6,6'}$), 8.47 (s, 2H, $H^{3,3'}$), 7.44 (d, 4H, J = 8.9 Hz, C_6H_4-), 7.39 (d, 2H, J = 16.2 Hz, CH═), 7.33 (dd, 2H, J = 5.2 and 1.5 Hz, $H^{5,5'}$), 6.90 (d, 2H, J = 16.2 Hz, CH═), 6.67 (d, 4H, J = 8.9 Hz, C_6H_4-), 3.28 (dd, 2H, J = 14.6 and 6.8 Hz, N-CH_2-), 3.10 (dd, 2H, J = 14.6 and 7.9 Hz, N-CH_2-), 3.00 (s, 6H, N-CH_3), 1.86 (m, 2H, CH-), 1.46 (dq, 2H, CH_2-), 1.13 (dq, 2H, CH_2-), 0.91 (m, 2 × 6H, CH-CH_3 and CH_2-CH_3). Anal. calcd. for $C_{38}H_{46}N_4$: C 81.68, H 8.30, N 10.03; found: C 80.53, H 8.26, N 9.76. HRMS *m/z*, calcd: 558.3722; found: 558.368.

4,4′-Bis[*p*-(octyloxy)styryl]-2,2′-bipyridine 12

The title compound was prepared analogously as described for **9**, using **1** (1.50 g, 8.14 mmol) and 4-octyloxybenzaldehyde (3.81 g, 16.28 mmol) as starting materials, and was isolated as white microcrystals after recrystallization from ethyl acetate (1.0 g); mp 146°C; ^{1}H NMR, δ: 8.64 (d, 2H, J = 5.2 Hz, $H^{6,6'}$), 8.51 (d, 2H, J = 1.6 Hz, $H^{3,3'}$), 7.49 (d, 4H, J = 8.7 Hz, C_6H_4-), 7.41 (d, 2H, J = 16.3 Hz, CH═), 7.36 (dd, 2H, J = 5.2 and 1.6 Hz, $H^{5,5'}$), 6.98 (d, 2H, J = 16.3 Hz, CH═), 6.91 (d, 4H, J = 8.7 Hz, C_6H_4-), 3.98 (t, 4H, J = 6.6 Hz, O-CH_2-), 1.79 (m, 4H, CH_2-), 1.60–1.20 (m, 20H, $(CH_2)_5$-), 0.88 (t, 6H, J = 6.6 Hz, CH_3). Anal. calcd. for $C_{42}H_{52}N_2O_2$: C 81.78, H 8.50, N 4.54; found: C 81.20, H 8.54, N 4.27.

(*S*)-(+)-4,4′-Bis[*p*-[(2-methyl)butoxy]styryl]-2,2′-bipyridine 13

The title compound was prepared analogously as described for **9**, using **1** (1.19 g, 6.45 mmol) and 4-(2-methylbutoxy)benzaldehyde (2.48 g, 12.90 mmol) as starting materials, and was isolated as pale yellow microcrystals after recrystallization from ethyl acetate (0.8 g); mp > 200°C; ^{1}H NMR, δ: 8.64 (d, 2H, J = 5.2 Hz, $H^{6,6'}$), 8.51 (d, 2H, J = 1.7 Hz, $H^{3,3'}$), 7.49 (d, 4H, J = 8.7 Hz, C_6H_4-), 7.41 (d, 2H, J = 16.3 Hz, CH═), 7.36 (dd, 2H, J = 5.2 and 1.7 Hz, $H^{5,5'}$), 6.98 (d, 2H, J = 16.3 Hz, CH═), 6.91 (d, 4H, J = 8.7 Hz, C_6H_4-), 3.85 (dd, 4H, J = 9.0 and 6.0 Hz, O-CH_2-), 1.86 (m, 2H, CH-), 1.56 (m, 2H, CH_2-), 1.25 (m, 2H, CH_2-), 0.95 (t, 6H, J = 6.7 Hz, CH_3), 0.95 (t, 6H, J = 7.4 Hz, CH_3). Ketene acetals from thermolysis of aryloxy methoxy oxadiazolines. Evidence for carbonyl ylide intermediates

Philippe Couture, Manal El-Saidi, and John Warkentin

Abstract: Thermolysis of oxadiazolines (**5**) in benzene at 110°C leads to ketene acetals (**11**) as minor products. Carbonyl ylide intermediates (**6**), and oxiranes (**7**), presumably in equilibrium with those ylides, are implicated as unstable precursors of the ketene acetals although none of the oxiranes (carbonyl protected α-lactones) were isolable and only one of the ketene acetals was isolable in pure form. The evidence points to the two-step sequence of thermolysis of oxadiazolines, namely, initial cycloreversion to N_2 and carbonyl ylide (**6**), rather than concerted fragmentation to N_2, acetone, and carbene (**12**). The first-formed ylide does fragment to carbene and acetone in a second step that competes with oxirane formation. A tentative mechanism for reaction of **7** with **12**, to afford **11**, is advanced.

Key words: carbonyl ylide, dioxy oxirane, ketene acetal, oxadiazoline.

Résumé : La thermolyse des oxadiazolines (**5**), dans le benzène à 110°C, conduit à des acétals de cétènes (**11**) comme produits mineurs. Des intermédiaires ylures de carbonyle (**6**), et les oxiranes (**7**) qui sont probablement en équilibre avec ces ylures, sont impliqués comme précurseurs instables des acétals de cétènes, même s'il n'est pas possible d'isoler d'oxiranes (α-lactones dont le carbonyle est protégé) et qu'un seul des acétals de cétènes a pu être isolé à l'état pur. Des données suggèrent que la thermolyse des oxadiazolines se fait en deux étapes, avec cycloréversion initiale en N_2 et en ylure de carbonyle (**6**), plutôt qu'une fragmentation concertée en N_2, acétone et carbène (**12**). L'ylure qui se forme en premier se fragmente en carbène et en acétone dans une deuxième étape qui est en compétition avec la formation de l'oxirane. On propose un mécanisme pour la réaction des produits **7** et **12** conduisant au produit **11**.

Mots clés : ylure de carbonyle, dioxy-oxirane, acétal de cétène, oxadiazoline.

Introduction

2,2-Dialkoxy oxadiazolines (1–12) and 3,3-dialkoxy diazirines (13–16) are now established precursors of dialkoxycarbenes (**2a**). Methoxyphenoxycarbene (**2b**) also has been generated by the latter route (17). Oxadiazolines have the advantage of shelf stability, over corresponding diazirines (14–18) but, unlike the latter, the oxadiazolines are only converted thermally to those carbenes, Scheme 1. Photolysis of 2-alkoxy or 2,2-dialkoxy oxadiazolines with 300 nm light leads to diazoalkanes (**3**) (19–21).

The mechanism of thermolysis of oxadiazolines **1** has long been thought to involve successive fragmentation rather than a single step (8, 12, 21–25). The stepwise mechanism, Scheme 2, seemed likely, the first step being an orbital-symmetry-allowed [4π + 2π] cycloreversion analogous, except for its reverse sense, to the numerous and well-known 1,3-dipolar cycloadditions (26–31). Many, but not all, such cycloadditions appear to be concerted reactions (28). In the case of ylide **4**, the mechanism of the reverse reaction (with N_2 to form **1**) is not known, of course, because such cycloadditions do not occur.

Recently, Smith presented computational results to indicate that a dioxy oxadiazoline (**1**, $R^1 = R^3 = R^4 = Me$, R^2 = 3-butynyl) may thermolyze by a concerted mechanism, avoiding a carbonyl ylide intermediate altogether (32). While those results pertain to only one 2,2-dialkoxy oxadiazoline, the implication that concerted decomposition could be a more general feature of the chemistry of related oxadiazolines comes naturally to mind.[2] We now present evidence for carbonyl ylide intermediates **6**, and therefore for stepwise fragmentation of oxadiazolines **5**, Scheme 3. Evidence for the first carbonyl-protected α-lactones (**7**) as unstable intermediates is also presented.[3]

Methods, results, and discussion

Oxadiazolines **5** were prepared from the appropriate phenols and 2-acetoxy-2-methoxy-Δ^3-1,3,4-oxadiazoline (**8**), by the

[2] Smith was careful to restrict his conclusions to the system that he had investigated (32).

[3] None of these compounds could be isolated. Given that they were present in very low concentration, together with other products at much higher concentration, it was impossible to gather any NMR data. Only GC–MS data could be obtained and therefore the structures were not established with the customary rigour.

exchange method (7), Scheme 4. They were stable enough to be purified by chromatography on basic silica and their identities followed from their ^{13}C NMR spectra, which showed the C2 and C5 signals, at 134–136 and 120–121 ppm, respectively, characteristic of 2,2-dioxyoxadiazolines (8, 12, 33), indicating that the azo functional group was present. Thermolyses were carried out with benzene solutions of **5** (ca. 5×10^{-4} mol of **5** in 10 mL of benzene) sealed into glass tubes.

Thermolysis of **5a** resulted in a complex mixture of products, including carbonate **9a**, *E*- and *Z*-dimers (**10a**) of an apparent aryloxymethoxycarbene intermediate, and, in ca. 7% yield, ketene acetal **11a**, Scheme 5. While **11a**, like other ketene acetals, was sensitive to moisture, its hydrolysis to *p*-nitrophenol and methyl isobutyrate during chromatography (Chromatotron plate coated with SiO_2, pre-treated with Et_3N)

Scheme 5.

11e	3.47	1.56, 1.74

was incomplete. This circumstance, undoubtedly attributable to the nitro group, permitted isolation of pure **11a** and acquisition of its ^1H and ^{13}C NMR spectra as well as a high-resolution mass spectrum. The ^1H NMR characteristics could then be used to infer the presence of less stable ketene acetals (**11b–11e**) in crude product mixtures from the corresponding oxadiazolines **5b–5e**. Those ketene acetals hydrolyzed too rapidly upon exposure to the atmosphere to permit their isolation by chromatography. Given their sensitivity, and the fact that they constituted less than 10% of the products, only partial ^1H NMR data, assigned by analogy to the ^1H NMR spectrum of **11a**, could be acquired. The available methoxy and methyl chemical shifts are listed in Table 1.

Gas chromatography did separate the ketene acetals (**11**) from other products, and mass spectra could be acquired by GC–MS. In each case a species with the mass of the molecular ion was observed as a relatively intense signal, comprising 18–36% of the intensity of the base peak. The latter corresponded, in each case, to M − 59. This pattern also is in keeping with a common connectivity, but the identity of the

fragment giving rise to the M − 59 signal is not known. One possibility is that M − 59 is the cation $ArCMe_2$, formed by loss of MeO and CO from the molecular ion.

Given that a ketene acetal **11** is formed during thermolysis of each **5**, it was of interest to probe for their origin. The fact that the *gem* dimethyl portion of **5** is retained in **11** is strongly indicative of one or other of the mechanisms of Scheme 6. In the first of these, a carbonyl ylide (**6**) from [3+2] fragmentation of the oxadiazoline precursor cyclizes to the corresponding oxirane (**7**), thereby forming the new CC bond required for **11**. In the second mechanism, the carbonyl ylide fragments to carbene **12** and acetone. Subsequent attack of the carbene at the carbonyl carbon of acetone to afford dipole **13**, which cyclizes, or else direct [1+2] cycloaddition of **12** to acetone, leads to the same oxirane (**7**).

The basic mechanisms are distinguishable because one of them should result in incorporation of added acetone from solution. Precedents for attack of dialkoxycarbenes on acetone are unknown, although methoxymethylcarbene attacks acetone (25) and a vinylogous dialkoxycarbene does so as well (8). Two probes were applied with **5a**, one involving addition of acetone-d_6, and the other of cyclopentanone, to the solvent prior to thermolysis. In each case, the cross product expected if ketone from solution had been incorporated was not detectable. Thus the mechanism involving reaction of a free carbene intermediate (**12**) with acetone to form **13**, or a concerted attack of **12** on acetone to afford **7** directly, is unlikely to be correct, leaving the contentious (32) carbonyl ylide mechanism as the most obvious alternative.

The carbonyl ylide mechanism requires the intermediacy of oxiranes **7** ("acetals" of α-lactones), which are unknown as a class. Kopecky et al. (34) have considered tetramethoxyoxirane as a potential reactive intermediate from ozonolysis of tetramethoxyethylene. They were unable to detect it and concluded that it must be very short lived, even at −90°C, if it had actually been formed at all. In the present study it was possible (in five cases out of six) by means of GC, but not ^{1}H NMR, to see an intermediate to which we have tentatively assigned structure **7**. Each **5** except **5a** afforded a species that eluted ahead of the corresponding ketene acetal **11**. The mass spectra (GC–MS) of the species **7b–f** gave highest *m/z* signals, corresponding to dioxycarbene + H (aryloxymethoxymethyl cation) or for an isomeric structure, of course.

Experiments to support the assignment of the oxirane structure to **7** were based on the expectation that the yield ratio (**11**:**7**) might be sensitive to the initial concentration of oxadiazoline precursor. Compound **5c** was chosen, and thermolyses were carried out with the initial concentrations shown in Table 2, and with the same thermolysis time. The ratios of yields (**11c**:**7c**) were determined by GC, with ethyl benzoate as added standard. It is clear that the ratio increased, from about 3 to about 11, as a result of changing the initial oxadiazoline concentration from 36.5 to 194 mM. That is the expected trend[4] for a scenario in which **7**, by reaction with an intermediate from **5**, serves as the precursor of **11**. Yields of carbonate

[4] The kinetic scheme is complicated, but ketene acetal formation is of higher order in oxadiazoline than oxirane formation. Presumably the ratio is also time dependent, if **7** is only moderately stable at 110°C, and it was for this reason that the time was kept the same for the series of experiments.

9c were independent of initial oxadiazoline concentration, within experimental error, and much higher than expected if the only source of carbonate were deoxygenation of oxirane. The source of additional carbonate is under investigation at this time; competitive fragmentation of the oxadiazoline to diazopropane and carbonate is one possibility.

A simple mechanism, then, that accounts for the ketene acetal has the initial ylide formation of Scheme 6, and subsequent attack of carbene (**12**) on oxirane (**7**). Although there are precedents for deoxygenation of oxiranes by carbenes, the carbenes known to do so are electrophilic or ambiphilic species that attack at oxygen to afford an ylide intermediate (35). Nucleophilic carbenes might be expected to attack oxiranes at carbon. The carbenes in this study should range from nucleophilic to ambiphilic (14, 36–40). Unfortunately the yields were too low, with a large uncertainty as a consequence, to permit any inference about effects of substituents on the efficiency of ketene acetal formation.[5] We assume for simplicity that the carbene intermediates did attack corresponding oxiranes at oxygen, although a more complex mechanism can also accommodate the results.[6]

Carbene dimers (**10**) were formed with small *Z* vs. *E* discrimination as indicated in the Experimental. That is not a surprising result, for the coupling results in two new bonds and must therefore be very exothermic. Consequently the transition state should resemble starting material (41), with those new bonds only poorly developed and with only a moderate difference in steric hindrance between transition states leading to *Z* and *E* isomers. The fact that the *Z*:*E* ratio exceeds unity for the unsubstituted case and for some of the donor-substituted systems (GC data) was surprising, and suggests that there is a favourable nonbonded interaction between the aromatic rings at the transition state that can overcome the moderate steric hindrance for carbene coupling.

In summary, thermolysis of alkoxyaryloxyoxadiazolines **5** is a sequential process involving corresponding carbonyl ylide intermediates. A fraction of those ylides undergo fragmentation to acetone and the appropriate alkoxyaryloxycarbenes (**12**). The carbenes dimerize and presumably deoxygenate oxirane **7**, formed by electrocyclic ring closure of the ylides, to afford ketene acetals **11**, Scheme 6. Although it does not follow that dialkoxy oxadiazolines fragment by an analogous mechanism, it is possible to rationalize their chemistry in the same way, simply by recognizing that corresponding ylides probably fragment more rapidly, to afford more stabilized carbenes, and therefore afford oxiranes in undetectable (or zero) yields.

Experimental

General

^{1}H NMR spectra were obtained with Bruker instruments operating at 200, 300, or 500 MHz. ^{13}C NMR spectra were run on Bruker instruments operating at the frequencies indicated. Mass spectra (ei) were obtained with a Hewlett Packard MSD GC–MS and chemical ionization, as well as high-resolution mass spectra, with a ZAB-E double focusing instrument. MS peaks less intense than 5% of the base peak are not included unless they were of highest or next highest *m/z*, and fragments with *m/z* less than 55 are also excluded. Weak IR bands are not labelled; medium and strong bands have symbols m and s, respectively, attached.

Chromatography refers to elution from a layer of silica gel coated onto a glass plate in a Chromatotron apparatus.

Synthesis of 2-aryloxy-2-methoxy-Δ^3-1,3,4-oxadiazolines (**5**)

To a mixture of 2-acetoxy-2-methoxy-Δ^3-1,3,4-oxadiazoline (**8**, 0.9 g, 3.6 mmol) and acyclic isomer (7) (ca. 70% oxadiazoline) in CH_2Cl_2 (35 mL) was added the appropriate phenol (7.2 mmol) and acetic acid (1.0 mL). The resulting solution was refluxed for 72 h before it was cooled and most of the solvent was stripped off. KOH pellets (ca. 2.0 g) were added and, after stirring for 1 h, water (50 mL) was added to the heterogeneous mixture. After further stirring (10 min), the organic layer was separated and dried over $MgSO_4$. Evaporation of the solvent left **5**, in some cases in nearly pure form. Chromatography on SiO_2 was used in all cases to remove remaining impurities.

*2-Methoxy-5,5-dimethyl-2-(4-nitrophenoxy)-Δ^3-1,3,4-oxadiazoline (**5a**)*

Off-white solid, mp 55–57°C, yield 60%. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.49 (s, 3H), 1.66 (s, 3H), 3.54 (s, 3H), 7.39 (d, 2H, ^3J = 9.3 Hz), 8.22 (d, 2H, ^3J = 9.3 Hz). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 22.3 (Me), 22.5 (Me), 51.1 (OMe), 118.4 (C7), 120.3 (C5), 123.7 (C8), 134.3 (C2), 142.2 (C9), 155.8 (C6). MS (ei) *m/z* (rel. intensity): 236 (M^+ − OMe, 4), 180 (19), 150 (22), 129 (100), 122 (14), 108 (9), 92 (10), 73 (12), 59 (11). MS (ci, NH_3) *m/z*: 285 ($(M + NH_4)^+$,14) 182 (30), 152 (32), 129 (100), 110 (31), 60 (19).

*2-Methoxy-5,5-dimethyl-2-(4-trifluoromethylphenoxy)-Δ^3-1,3,4-oxadiazoline (**5b**)*

Oil, yield 58%. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.42 (s, 3H), 1.62 (s, 3H), 3.55 (s, 3H), 7.34 (d, ^3J = 8.6 Hz, 2H), 7.57 (d, ^3J = 8.6 Hz, 2H).^{13}C NMR (50 MHz) δ: 23.9 (Me), 23.9 (Me), 52.5 (OMe), 120.1 (C5), 120.5 (C7), 124.1 (q, $^1J_{CF}$ = 271 Hz, CF_3), 126.2 (q, $^2J_{CF}$ = 33 Hz, C9), 126.6 (C8), 136.1 (C2), 154.7 (C6). ^{19}F NMR (282.4 MHz, ref. ext CF_3Cl) δ: −62.2. MS (ei, ZAB-E instrument) *m/z*: 290 (M^+, ca. 0.3%, clear signal at 300-fold amplification; CA on the fragment with *m/z* = 290 showed it to be linked to the base peak at *m/z* = 129), 275 (M^+ − Me, ca. 0.2%), 259 (9), 203 (23), 173 (95), 145 (21), 129 (100). MS (ci, NH_3) *m/z*: 308 ($(M + NH_4)^+$, 27), 261 (27), 220 (30), 205 (80), 203 (52), 188 (100), 171 (11), 129 (100), 58 (51).

*2-(4-Chlorophenoxy)-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**5c**)*

Oil, yield 68%. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.35 (s, 3H) 1.59 (s, 3H), 3.58 (s, 3H), 7.14 (d, ^3J = 6.6 Hz, 2H), 7.27 (d, ^3J = 6.6 Hz, 2H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 23.8 (Me), 24.1 (Me), 52.5 (OMe), 120.8 (C5), 122.7 (C7), 129.2 (C8), 129.7

[5] It is also recognised that the yields of ketene acetals may be determined in part by other factors, such as competitions from other primary processes that consume **5**.

[6] For example, a carbene **12** could react with **7** in a nucleophilic ring-opening reaction that could lead to an oxetane. Fragmentation of the latter could then afford **11** and carbonate **9**.

Thermolyses of oxadiazolines 5 and thermolysis products

A solution of an oxadiazoline (**5**, 0.5 mmol) in dry benzene (10 mL) was sealed into a glass tube after three cycles of freeze–pump–thaw degassing at 10^{-2} Torr (1 Torr = 133.3 Pa). The tube was kept in an oil bath at 110 ± 0.1°C for 24 h before it was opened at room temperature for stripping off solvent and volatile products with a rotary evaporator. Spectra of the residue, including GC–MS, were recorded before it was placed on a 1 mm silica plate for centrifugal chromatography, with 5–20% ethyl acetate in hexanes as eluting solvent. This procedure usually separated most of the aryl methyl carbonates (**9**) from the diaryloxydimethoxy ethylenes (**10**) but the latter were not always cleanly separated from one another. Only in the case of **5a** was the ketene acetal (**11a**) isolable by chromatography. The NMR spectra of the carbene dimers (below) are those of *E/Z* mixtures, except in cases where a separation was accomplished, and it is assumed that the isomer eluting first from silica or from GC columns was the *E* isomer, with zero dipole moment. The carbonates eluted first from silica gel followed closely by the *E* isomers, usually slightly contaminated with carbonate, and then by the *Z* isomers. Proton spectra of the carbonates could be subtracted from composite spectra. Some ^{13}C NMR signals were also assigned tentatively on the basis of relative intensities of signals from corresponding atoms of *E* and *Z* isomers, but others could not be assigned with confidence, in part because there was generally a shortfall from the number of signals expected, suggesting coincidence of some signals from *E* and *Z* isomers. Mass spectra of separated *E/Z* isomers were not significantly different and they are therefore not reported separately. Those spectra, by GC–MS, are not contaminated with signals from corresponding carbonates.

Thermolysis of 5a in the presence of acetone-d_6

The procedure described above was used with **5a** (50 mg, 0.19 mmol) and 0.44 g (6.9 mmol) of acetone-d_6 in enough benzene to make 6 mL of solution. In the ^1H NMR spectrum of **11a** in the crude product, the integral for each C-CH_3 signal was the same as the integral of the O-CH_3 signal, indicating non-incorporation of acetone from solution. The GC–MS of the product mixture was not distinguishable from that of the analogous mixture arising from reaction without added acetone-d_6.

Thermolysis of 5a in the presence of cyclopentanone

The procedure described above was used with **5a** (135 mg, 0.51 mmol) and cyclopentanone (92 mg, 1.1 mmol) in enough benzene to make 9 mL of solution. Analysis of the product mixture by means of ^1H NMR spectroscopy and GC–MS revealed **11a** but not the analogous compound from incorporation of cyclopentanone.

Methyl isobutyrate: ^1H NMR (200 MHz, $CDCl_3$) δ: 1.18 (d, ^3J = 7.0 Hz, 6H), 2.58 (sept, ^3J = 7.0 Hz, 1H), 3.69 (s, 3H).

Acknowledgments

Financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC) is gratefully acknowledged. Dr. Richard Smith and Mr. Fajar Ramelan acquired the high-resolution mass spectra and some other mass spectra. We are indebted to Prof. J.K. Terlouw and Dave Lavorato who took special care to obtain the mass spectrum of **5b**. Dr. Don Hughes and Mr. Brian Sayer assisted with the ^{19}F NMR spectra. M. E.-S. was the recipient of a Canadian International Development Agency scholarship and P.C. held an Ontario Graduate Scholarship award.

Spectroscopic and crystallographic studies of phosphino adducts of gallium(III) iodide

Martyn A. Brown, Jesus A. Castro, and Dennis G. Tuck

Abstract: The solid state structures of the compounds $GaI_3 \cdot PPh_3$ and $Ga_2I_6 \cdot$dppe (dppe = 1,2-bis(diphenylphosphino)ethane) have been determined. For the former, in which the GaI_3P core has C_{3v} symmetry, the structure is trigonal, with a = 14.961(2) Å, c = 16.509(3) Å, V = 3199.5(4) Å^3, Z = 6, space group $R\bar{3}$. In $Ga_2I_6 \cdot$dppe, the ligand bridges two GaI_3P centres; the structure is monoclinic, a = 10.196(7) Å, b = 15.363(1) Å, c = 23.027(9) Å, β = 98.735(4)°, V = 3565.1(3.2) Å^3, Z = 4, space group $P2_{1/n}$. The use of ^{31}P NMR spectroscopy shows that $GaI_3 \cdot PPh_3$ is slightly dissociated in nonaqueous solution, and the effect of adding Ph_3P or I^- has been investigated. Similar studies with $Ga_2I_6 \cdot$dppe are also reported. In each system, four-coordination at gallium is dominant; an equally important factor is the dimerization of uncomplexed GaI_3 to Ga_2I_6 in these solutions.

Key words: gallium(III) iodide, complexes, phosphorus, NMR, crystallography.

Résumé : On a déterminé les structures des composés $GaI_3 \cdot PPh_3$ et $Ga_2I_6 \cdot$dppe (dppe = 1,2-bis(diphénylphosphino)éthane) à l'état solide. Dans le cas du premier composé, dans lequel la symétrie du groupe GaI_3P fondamental est C_{3v}, la structure est trigonale, groupe d'espace $R\bar{3}$, avec a = 14,961(2) et c = 16,509(3) Å, V = 3199,5(4) Å^3 et Z = 6. Dans le composé $Ga_2I_6 \cdot$dppe, le coordinat fait le pont entre deux centres GaI_3; la structure est monoclinique, groupe d'espace $P2_{1/n}$, avec a = 10,196(7), b = 15.363(1) et c = 23.027(9) Å , β = 98,735(4)°, V = 3565,1(3.2) Å^3 et Z = 4. La spectroscopie RMN du ^{31}P permet de démontrer que le $GaI_3 \cdot PPh_3$ est légèrement dissocié en solution non aqueuse et d'étudier l'effet de l'addition de PPh_3 ou de I^- sur cette dissociation. On a aussi effectué des études semblables avec le $Ga_2I_6 \cdot$dppe. Dans chacun de ces systèmes, le gallium tétracoordinant est dominant; un facteur qui est aussi important est la dimérisation du GaI_3 non-complexé en Ga_2I_6 dans ces solutions.

Mots clés : iodure de gallium(III), complexes, phosphore, RMN, cristallographie.

[Traduit par la rédaction]

Introduction

The adducts formed by the trihalides of the Group III elements (B, Al, Ga, In, Tl) with neutral or anionic donors have played a fundamental role in the overall development of coordination chemistry, and a variety of investigations have established the basic features of both the solid state and solution chemistry. In a recent paper (1), we used multinuclear NMR spectroscopy and X-ray crystallography to extend the understanding of the behaviour of the InI_3/Ph_3P system, and showed that the 1:1 and 1:2 complexes are closely related in their solution and crystal chemistry, and that both four- and five-coordinate adducts can be formed. With InI_3/dppe (dppe = bis(diphenylphosphino)ethane) the 1:1 adduct is a five-coordinate linear polymer, but four-coordinate species are important in solution.

In addition to the intrinsic interest of such complexes, their solution chemistry is germane to that of *ortho*- and *para*-quinone complexes, currently under investigation in this laboratory. An important factor in all of these studies is the effect of the size, and hence maximum coordination number, of the metallic elements in question, and it therefore seemed reasonable to investigate the chemistry of gallium compounds analogous to the indium species discussed in ref. 1. We have identified significant differences in the behaviour of these two groups of compounds in both the solid and solution state.

Two earlier investigation of GaI_3/Ph_3P and GaI_3/dppe systems have been reported. Balls, Greenwood, and Straughan (2) prepared a number of phosphino derivatives of the gallium(III) halides, and analysed the infrared spectra, while Carty (3, 4) used both infrared and conductivity measurements in attempts to identify the structures of these compounds in the solid state and in solution.

Received November 1, 1996.

Experimental section

General techniques

Gallium(III) iodide was prepared by reacting gram quantities of the elements in refluxing xylene. Triphenylphosphine and bis(diphenylphosphino)ethane (Aldrich) were recrystallized before use. Solvents were distilled from suitable drying agents, and stored over molecular sieves.

Phosphorus-31 NMR spectra were recorded on a Bruker 300 instrument, operating at 81.0 MHz, with 85% H_3PO_4 = 0. Infrared spectra were run on a Nicolet 4DX instrument, and the Raman spectra of finely ground solids were recorded with a Jobin Yvon S3000 spectrometer. Microanalysis was by Canadian Microanalytical Services Ltd.

Preparative

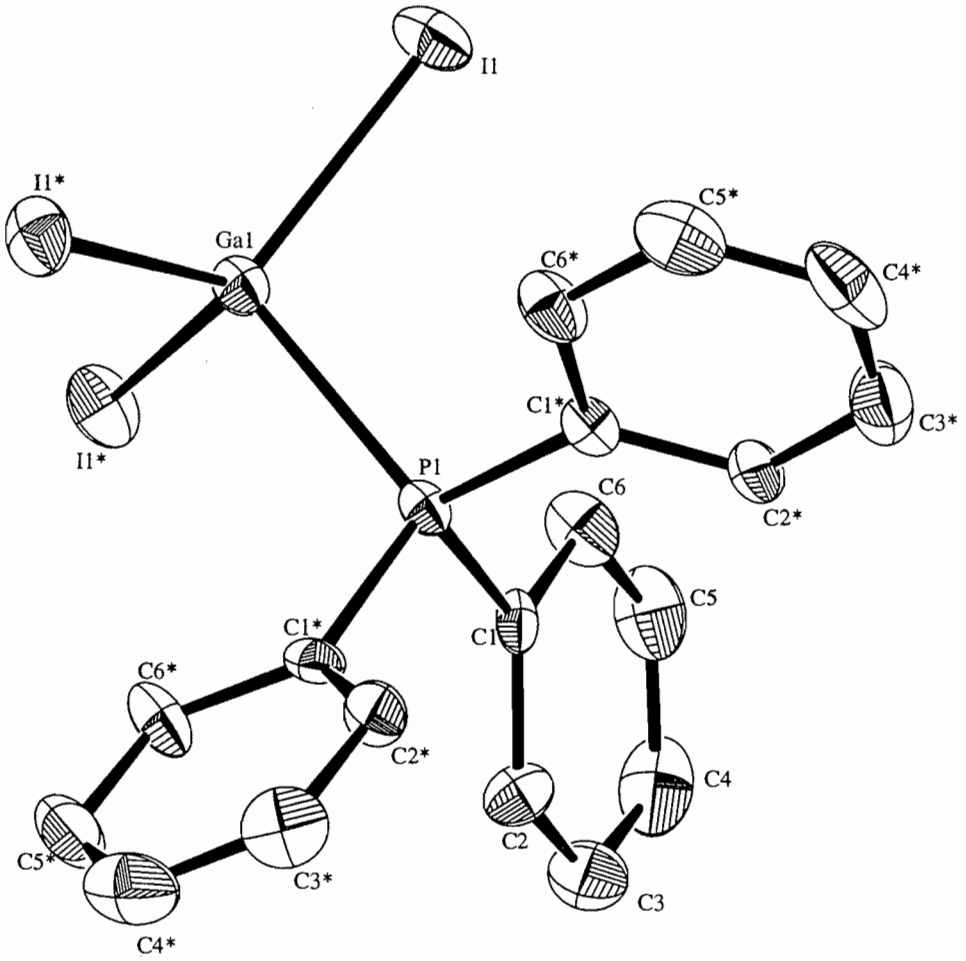
Triphenylphosphine adduct: the procedure involved mixing solutions of GaI_3 and PPh_3 in toluene, following the method of Carty (3). The precipitate was recrystallized from toluene. Anal. calcd. for $C_{18}H_{15}GaPI_3$: C 30.3, H 2.12; found: C 30.7, H 2.17.

Immediate precipitation occurred when ethyl acetate solutions of GaI_3 (0.45 g, 1 mmol) and dppe (0.20 g, 0.5 mmol) were mixed, and the product, Ga_2I_6·dppe, was collected, washed, and recrystallized from the same solvent. Anal. calcd. for $C_{26}H_{24}Ga_2P_2I_6$: C 24.0, H 1.86; found: C 24.2, H 2.01.

Crystallographic analysis

(*i*) In the study of GaI_3·PPh_3, **1**, a colourless crystal mounted on a glass fibre was sited in a Rigaku AFC6S diffractometer, equipped with graphite-monochromated Mo-Kα radiation (λ = 0.71069 Å) and a rotating anode generator. Cell constants, and orientation matrices for data collection, were obtained from least-squares refinements, using 20 carefully centred reflections in the range 8.59° < 2θ < 16.07°. Based on the systematic absences *hkl*: $-h + k + l \neq 3n$, the space group was uniquely identified as $R\bar{3}$ (No. 148), and this was confirmed by subsequent solution and refinement of the structure. Details of the intensity collection are given in Table 1.

The intensities of three representative reflections were measured after every 150 reflections. Over the course of data collection, the standard increased 1%, and a linear correction factor was applied to the results. The linear absorption coefficient (57.05 cm^{-1}) required an absorption correction, using PSI Scan, with transmission factors between 0.80 and 1.00. The results were also corrected for Lorentz and polarization effects. The structure was solved by direct methods, and expanded using Fourier techniques. The non-hydrogen atoms were refined isotropically; hydrogen atoms on carbon were included in ideal positions but were not refined. The final cycle of full-matrix least-squares refinement was based on 761 observed reflections ($I > 3\sigma(I)$) and 71 variable parameters, and the solution converged at $R = 0.040$ and $R_w = 0.034$. A final Fourier difference map calculation showed no peaks of chemical significance; the maximum and minimum peaks corresponded to + and − 0.67 e Å^{-3}, respectively.



(*ii*) The structural study of crystals of Ga_2I_6·dppe, **2**, followed essentially the same procedure. The space group was identified as $P2_{1/n}$ (No. 14). The data were corrected for decay absorption, Lorentz and polarization effects, and the structure was again solved by direct methods. The final Fourier calculation showed no peaks of chemical significance; the maximum and minimum peaks corresponded to 1.47 and −1.54 e Å^{-3}, respectively. The solution converged at $R = 0.063$ and $R_w = 0.058$.

In both sets of calculations, neutral-atom scattering factors were taken from Cromer and Waber (5). Anomalous dispersion effects were included in the calculations (6); the values for $\Delta f'$ and $\Delta f''$ were those published by Cromer (7). All calculations were performed using the TEXSAN (8) crystallographic software package. The structure of the molecules are shown in Figs. 1 and 2; the positional parameters are in Tables 2 and 4, and important bond distances and angles in Tables 3 and 5.

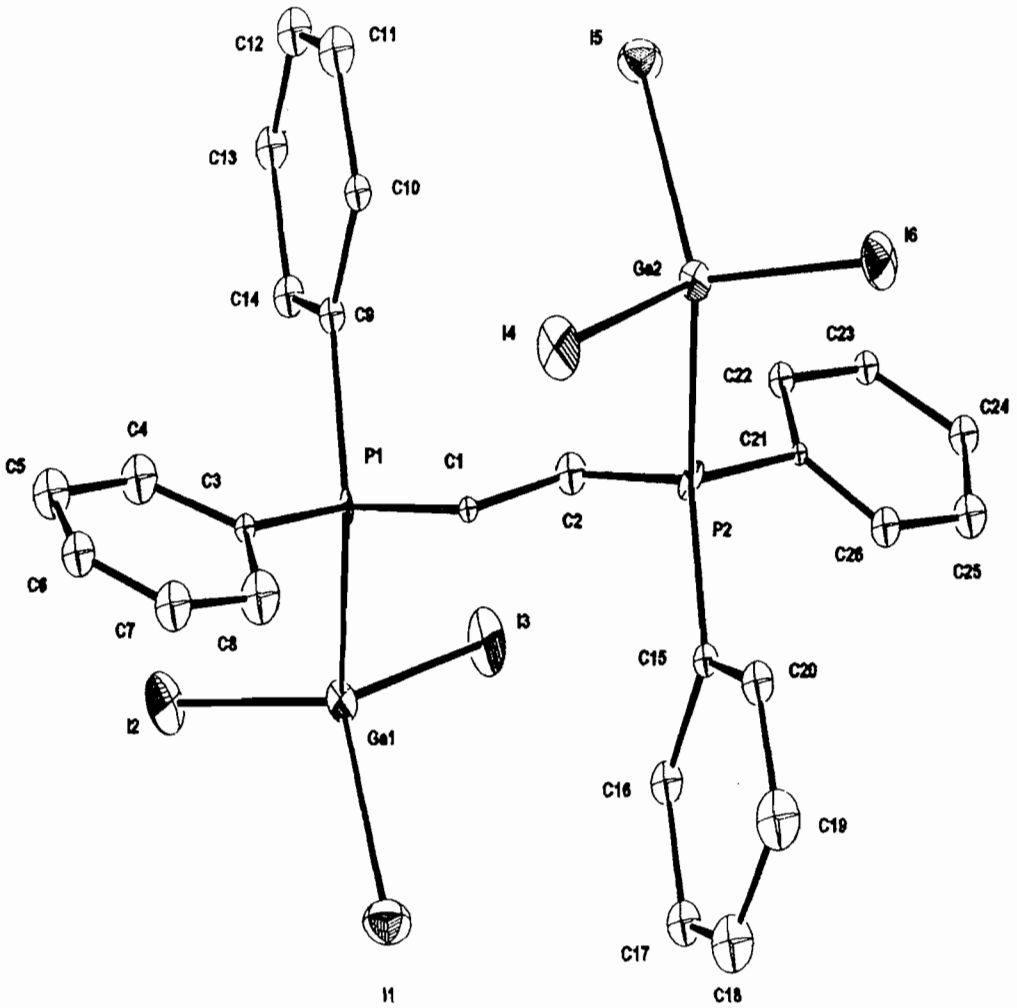
lengths and angles other than those in Tables 3 and 5, are available as supplementary data.[3]

Results and discussion

Crystallographic studies

The triphenylphosphine adducts of GaI_3 (**1**) and InI_3 are, not surprisingly, isostructural, with the stereochemistry at metal and phosphorus being essentially C_{3v} in each case. The complex **2** shows the same structural features at the metal centre, and differs from **1** only in the sense that the ligand is effectively $P(C_6H_5)_2CH_2^-$. This structure represents a departure from $InI_3 \cdot$dppe, in which an infinite chain of planar InI_3 units is linked by bridging dppe to give five-coordinate indium. The Ga—I bond distance in **1** is 2.5212(9) Å, to be compared with the range of 2.533(5)–2.481(5) Å in **2**, for which the average r(Ga—I) is 2.513 Å. The average Ga—P bond distances in **1** (2.416(5) Å) and **2** (2.407(9) Å) are also identical within the experimental error, all of which emphasizes the close relationship in the structural chemistry of the gallium centres in these two molecules in the solid state, and the predominance of four-coordination, in contrast to the analogous indium complexes.

Preparative



The first point to note is that the preparative chemistry of the GaI_3/PPh_3 system appears much simpler than for the indium analogue, in which both 1:1 and 1:2 adducts were characterized and shown to readily interconvert in nonaqueous solution (1). None of the previous workers reported such behaviour in the gallium system, and our results are in keeping with their findings (2–4). Similarly, the reaction with dppe gives a single species, whereas with indium triiodide and dppe, both $[InI_3(dppe)]_\infty$ and $(InI_3)_3(dppe)_2$ have been identified crystallographically (1, 9). These comparisons and contrasts emphasize that here, as in other parts of this paper, the maximum coordination number for gallium in these systems is four, and the apparent inability to exceed this underlies the differences between gallium and indium.

^{31}P NMR studies of GaI_3·PPh_3

A solution of GaI_3·PPh_3 in acetone (0.1 M) at 23°C has two ^{31}P resonances, at 28.35 ppm, half-width 10.1 Hz, and −3.91 ppm, half-width 46.5 Hz. Since triphenylphosphine in the same solvent gives a signal at −4.77 ppm, $w_{1/2}$ = 9 Hz, this spectrum establishes immediately that the 1:1 complex, for which $\delta(^{31}P)$ = 28.35 ppm, undergoes partial dissociation, with the simplest equilibrium being

[1] $GaI_3 \cdot PPh_3 \rightleftharpoons GaI_3 + PPh_3$

The ratio of the peak heights for complex:PPh_3 is 12.0, so that the equilibrium constant for eq. [1] is ca. 0.08 mol L^{-1}. The rather large half-width for Ph_3P in this solution suggests a relatively slow exchange process in eq. [1], which is at first sight surprising, since adduct formation is presumed to be fast (but see below). There is a smooth change in the ratio of the peak heights for the complex and free PPh_3 as PPh_3 is added (Fig. 3*a*) and the half-width for free PPh_3 also decreases over the range studied (Fig. 3*b*).

Figure 4 shows the effect of adding iodide ion (as *n*-Bu_4NI) to the solution. At low I^-:complex ratios, PPh_3 is released as the result of the reaction

[2] $GaI_3 \cdot PPh_3 + I^- \rightarrow GaI_4^- + PPh_3$

but beyond an I^-:complex mole ratio of 0.6, a sharp rise in the amount of free PPh_3 is detected. The interpretation of these results is complicated by the presence of a small quantity of PPh_3 in the solution due to the dissociation described in eq. [1], and clearly the quantity of GaI_3·PPh_3 is also lowered by the effect of eq. [2]. At I^- = 0, the quantity of PPh_3 from dissociation of GaI_3·PPh_3 is ca. 8% (see above), which accounts for the point at −4.7 ppm, peak height = 0.1, in Fig. 4. At added I^- = 0.05 M, the quantity of free PPh_3 is more than 10 times greater, and the correction for eq. [1] is of the order of 1% and therefore negligible. The dotted line in Fig. 4 is an approximate correction to allow for PPh_3 arising via eq. [1] rather than eq. [2].

With or without this correction, Fig. 4 shows a linear dependence up to a mole ratio of approx. 0.5, followed by a steep rise in the quantity of Ph_3P released, reaching a maximum at the equimolar point. Further addition of iodide beyond this

point produces no change. The half-width of the ^{31}P resonance of the complex is constant at 12.3 ± 0.1 Hz throughout this series, whereas the value for the free ligand changes monotonically from a value of 46.5 Hz for $I^- = 0$ to 15.5 Hz at the equimolar point; this latter is characteristic of free Ph_3P in acetone (see above).

These results, and those for the addition of Ph_3P, suggest a set of equilibria more complicated than eqs. [1] and [2]. The

most important factor is that the dimerization of gallium(III) halides is an important process in nonaqueous solution, and that ligand addition, and hence dissociation, must go via this dimer (10–12). We therefore rewrite eq. [1], and add the successive processes

[3] $2\ GaI_3 \cdot PPh_3 \rightleftharpoons 2\ GaI_3 + 2PPh_3$

[4] $2\ GaI_3 \rightleftharpoons Ga_2I_6$

[5] $Ga_2I_6 + PPh_3 \rightleftharpoons Ga_2I_6 \cdot PPh_3$

[6] $Ga_2I_6 \cdot PPh_3 \rightleftharpoons GaI_3 + GaI_3 \cdot PPh_3$

The sum of eqs. [3]–[6] is of course eq. [1]. We postulate that the equilibria [3] and [4] are rapidly established, and that [4] lies strongly to the right. In the presence of added PPh_3, eq. [5] becomes important, since this step accounts for the uptake of the ligand to yield the complex $GaI_3 \cdot PPh_3$ via eqs. [5] + [6]. We further suggest that eq. [5] is the rate-controlling step in the sequence, and that the decreasing ^{31}P line width shown in Fig. 3*b* is caused by increasingly rapid exchange between PPh_3 as the quantity of free ligand is increased.

Similar equilibria can also be used to understand the processes implicit in the addition of I^- (Fig. 4). Equations [3] and [4] are here followed by

[7] $Ga_2I_6 + I^- \rightleftharpoons Ga_2I_7^-$

[8] $Ga_2I_7^- \rightleftharpoons GaI_4^- + GaI_3$

[9] $GaI_3 + I^- \rightleftharpoons GaI_4^-$

The addition of I^- to a solution of $GaI_3 \cdot PPh_3$, already in equilibrium via eqs. [1] and [2] with Ga_2I_6 and PPh_3, leads via eq. [7] to $Ga_2I_7^-$, which is the anionic analogue of $Ga_2I_6 \cdot PPh_3$ (eq. [5]). If eq. [7] lies to the right, then the formation of a steady concentration of $Ga_2I_7^-$ will occur at the mole ratio

I^-:GaI_3·PPh_3 = 0.5, and only beyond that point can further uptake of I^- (and hence further dissociation of GaI_3·PPh_3) occur by eqs. [8] and [9]. This mechanism accepts that direct nucleophilic attack of I^- on GaI_3·PPh_3 via a five-coordinate intermediate cannot be important, and in this context the molecular structure of Ga_2I_6·dppe, in which gallium prefers four-coordination to the alternative GaI_3P_2 mode, is significant. An important conclusion of these studies is that four-coordination at gallium(III) is predominant in the solution chemistry of GaI_3/PPh_3/I^- systems.

We also investigated the effect of temperature change on the ^{31}P spectra of GaI_3·PPh_3, in the hope of identifying some of the kinetic parameters. For a 0.1 M solution in acetone at 283 K, the only resonance observed is at 27.4 ppm, with $w_{1/2}$ = 15 Hz. Over the temperature range 283–323 K, the resonance of free PPh_3 appears at −5.7 ppm, but we did not observe any signs of coalescence, and therefore chose not to extend these studies.

Scheme 1.

^{31}P NMR studies of GaI_3·dppe

The ^{31}P spectrum of a solution of Ga_2I_6·dppe in acetone (0.1 M) at 23°C consists of two sharp doublets at 33.61, 33.46 and −(11.87, 11.52) ppm. The half-width for each is ca. 75 Hz. These resonances are assigned to the bound and terminal

phosphorus atoms of the species based on the ^{31}P resonance of dppe in acetone, at −12.45 ppm, $w_{1/2}$ = 14 Hz, and the positive shift observed for this ligand, and for PPh_3, on coordination (ref. 1, and above). This pair of doublets is observed in all experiments in which $Ga_2I_6 \cdot dppe$ is present in solution, and the average value of J = 42 Hz is ascribed to long-range P–P coupling. The four-coordinate complex of Scheme 1 arises from the processes

[10] $Ga_2I_6 \cdot dppe \rightleftharpoons GaI_3 \cdot dppe + GaI_3$

[11] $GaI_3 \rightleftharpoons \frac{1}{2} Ga_2I_6$

in which all the species are undergoing exchange. The addition of dppe causes no initial change in the ^{31}P NMR spectrum, since the process

[12] $\frac{1}{2} Ga_2I_6 + dppe \rightleftharpoons GaI_3 \cdot dppe$

removes free ligand. As more dppe is added, the ^{31}P spectrum remains essentially constant, but at the mole ratio dppe:$Ga_2I_6 \cdot dppe$ = 1.0, a new signal appears at −12.1 ppm, indicating the presence of free dppe, and the absence of uncomplexed GaI_3 (or Ga_2I_6). Beyond this point, the addition

of dppe (up to a mole ratio of 1.8) causes an increased intensity of the resonance at −12.15 ppm, which masks that assigned to P_t (Scheme 1); the doublet at ca. 34 ppm remains throughout this sequence. Similarly the addition of Ga_2I_6 causes the gradual disappearance of the P_t resonance, which is completely absent beyond the equimolar point. In this region, the ^{31}P spectrum consists of a doublet at 33.71, 33.38, establishing the presence of $I_3Ga{\cdot}dppe{\cdot}GaI_3$ (i.e., the solid state structure **2**) in the solution. We conclude that although $GaI_3{\cdot}$dppe does not give rise to a crystalline 1:1 adduct under the preparative conditions used in this, and earlier (2–4), work, this molecule can exist in nonaqueous solution, as described by eq. [10]. Equally, the solid state species in which dppe bridges two four-coordinate gallium(III) entities can also be formed in solution in the presence of excess gallium(III) iodide. These results provide yet another example of the effect of differing solution and solid state stabilizing factors on the properties, and especially the stoichiometry, of such adducts.

Following eqs. [10] and [11], the addition of I^- to a solution of $Ga_2I_6{\cdot}$dppe in fact involves the interaction of I^- with $GaI_3{\cdot}$dppe and (or) Ga_2I_6. At low I^-:complex mole ratios, there is no change in the ^{31}P spectrum, since the dominant process is

[13] $\frac{1}{2}\,Ga_2I_6 + I^- \rightleftharpoons GaI_4^-$

When sufficient I^- has been added to complex all the Ga_2I_6 as the stable GaI_4^- anion, displacement of dppe from $GaI_3{\cdot}$dppe occurs

[14] $GaI_3{\cdot}dppe + I^- \rightleftharpoons GaI_4^- + dppe$

and this release of dppe results in the growth of the resonance at −12.2 ppm. The continued addition of I^- causes an increase in the height of this signal relative to that for bound dppe; at the mole ratio I^-:Ga_2I_6 = 1.4, approximately 48% of the dppe has been displaced, and at a mole ratio of 2.0, this rises to 96%. Beyond this ratio, only free dppe is detected in the ^{31}P spectrum since all the gallium is present as GaI_4^-. The half-width of the ^{31}P resonance is almost constant at 80 Hz throughout.

Vibrational spectroscopy

The earlier investigations of the phosphino complexes of gallium(III) iodide depended in large measure on infrared spectroscopy for the elucidation of the solid state structures (2–4). We have recorded the Raman and far infrared spectra of both $GaI_3{\cdot}PPh_3$ and $Ga_2I_6{\cdot}$dppe, with the results shown in Table 6. Given the similarities in the coordination kernels of the two complexes, it is not surprising that the vibrational spectra are very similar in the metal–ligand stretching region. This conclusion is easily reached in the light of the crystallographic results not available to the earlier workers.

General conclusions

It is useful to compare and contrast the behaviour of gallium and indium in terms of the complexation of MI_3 with PPh_3 and dppe. Four-coordination is an exclusive feature of gallium chemistry in such systems, and this factor also accounts for the significance of Ga_2I_6 in nonaqueous solution. For indium, four-coordination is important, but five-coordinate species are also found in crystalline $InI_3(PPh_3)_2$ and $[InI_3(dppe)]_\infty$. The bisphosphino adduct of InI_3 dissociates completely in nonaqueous solution to the 1:1 adduct, but this process can be reversed somewhat by the addition of excess ligand. The preparative chemistry of InI_3–PPh_3 and InI_3–dppe systems is therefore complicated to an extent which is not apparent in the analogous gallium chemistry. The spectroscopic investigations of these various species in nonaqueous solution provide an explanation in terms of the different equilibria involved. No doubt comparable dissimilarities will be found in further investigations of related systems.

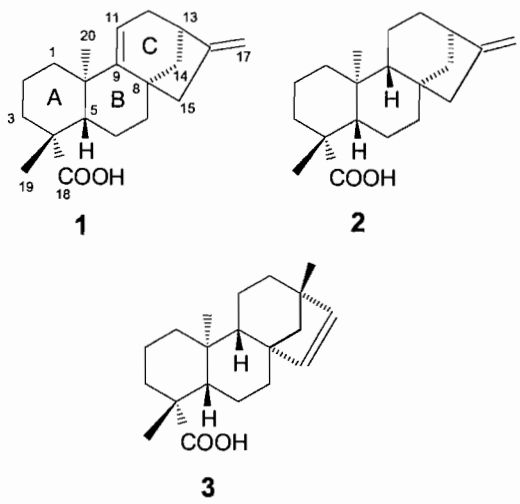
Comparison of crystal and solution structures and ^{1}H and ^{13}C chemical shifts for grandiflorenic acid, kaurenoic acid, and monoginoic acid

Raul G. Enriquez, Julie Barajas, Benjamin Ortiz, Alan J. Lough, William F. Reynolds, Margaret Yu, Ismael Leon, and Dino Gnecco

Abstract: The crystal structure of monoginoic acid, **3**, is determined and compared with previously reported structures of kauradienoic acid, **1**, and kaurenoic acid, **2**. ^{1}H and ^{13}C chemical shifts are assigned for all three diterpenes and solution and crystal structure conformations are confirmed with the aid of solution NOE measurements. The overall shapes of **2** and **3** are very similar while **1** is significantly dissimilar. These differences may be partially responsible for the reported greater in vitro uterotropic activity of **1**, relative to **2** and **3**.

Key words: monoginoic acid, kaurodienoic acid, kaurenoic acid.



Résumé : On a déterminé la structure cristalline de l'acide monoginoïque, **3**, et on l'a comparée aux structures rapportées antérieurement pour les acides kauradiénoïque, **1**, et kaurénoïque, **2**. On a attribué les déplacements chimiques du ^{1}H et du ^{13}C pour les trois diterpènes et les conformations des structures cristallines et de celles en solution ont pu être confirmées à l'aide de mesures d'EON en solution. Les formes globales des composés **2** et **3** sont très semblables alors que celle du composé **1** est très dissimilaire. Il est possible que ces différences soient partiellement responsables de l'activité utérotropique in vitro plus élevée rapportée pour le composé **1** par rapport aux composés **2** et **3**.

Mots clés : l'acide monoginoïque, l'acide kaurodiénoïque, l'acide kaurénoïque.

[Traduit par la rédaction]

Introduction

The plant known as "zoapatle" (*Montanoa tomentosa* Cerv. ssp. *tomentosa*) is widely used in Mexican traditional medicine, both as an abortifacient in early stages of pregnancy and to induce labour in late stages of pregnancy (1). Among the secondary metabolites isolated from zoapatle are three kaurane derivatives: grandiflorenic acid ((4α)-kaura-9(11),16-dien-18-oic acid), **1**, kaurenoic acid ((4α)-kaur-16-en-18-oic acid), **2**, and monoginoic acid (13-methyl-(4α)-norkaur-15-en-18-oic acid), **3** (2). There are conflicting reports concerning the possible role of any or all of these three derivatives in the pharmacological activity of zoapatle. For example, Gallegos, in a patent, reported in vivo (uterine evacuating) activity for all three compounds, with **1** being most effective (3). In vitro uterine stimulating activity has been reported for **1** and **2** (4) and it has also been reported that a mixture of **1** and **2** shows even higher levels of activity (5). However, other workers, while confirming the in vitro activity of **1**, failed to find evidence of in vivo activity for any of the three compounds (6, 7). Interestingly, **1** and **2** were also recently isolated from the leaves of *Aspilia mossambicensis* (8). The leaves of this plant and others of the genus *Aspilia* are consumed preferentially by female chimpanzees in Africa, possibly as fertility regulators (8).

Fig. 1. ORTEP drawing of **3**, illustrating the hydrogen-bonded dimer and giving numbering of molecules A and B in unit cell.

There have also been conflicting reports on whether **1**–**3** are present in aqueous herbal extracts of zoapatle (9, 10). This is critical since the absence of these compounds from the aqueous "tea" would rule out any role for them in the pharmacological activity of this traditional medicine. However, we recently conclusively demonstrated the presence of significant amounts of **1**–**3** in the aqueous herbal extracts by using GC–MS measurements in conjunction with 2D NMR measurements (11). This positive result has encouraged us to further investigate possible structure–activity relations.

We previously reported complete ^{1}H and ^{13}C spectral assignments for **1** (12) and, more recently, a crystal structure determination for the same compound (13). A crystal structure has also been reported for **2** (14). We believed that it would be useful to have complete spectral assignments and crystal structure determinations for all three compounds as a starting point for better understanding of the disputed structure–activity relationships for these derivatives. The crystal structure of **3** and complete ^{13}C and ^{1}H spectral assignments for **2** and **3** are provided here, along with comparisons of the solid state and solution structures for the three compounds.

Results and discussion

X-ray crystal structures of 3

The atomic coordinates for **3** are summarized in Table 1 while an ORTEP drawing is given in Fig. 1. Inspection of the structure shows that all three six-membered rings are in chair or near-chair conformations while most bond lengths and bond angles are unexceptional. Tables of bond lengths, bond angles, H-atom coordinates, and anisotropic thermal parameters are available as supplementary material.[2]

When comparing the crystal structures of **1**, **2**, and **3**, one finds significant differences, particularly between **1** and the other two compounds. The geometry of ring A is very similar in all three cases. However, in **1**, ring B adopts a boat conformation, probably due to the 9,11 double bond (13). As a result, the 16,17 double bond is well above the β face of the molecule while ring C is near the plane formed by ring A. On the other hand, ring B of **2** is in a chair form. However, due to the *cis* B–C ring junction in **2**, ring C is well below (i.e., on the α face of) the mean plane of the ring carbons of ring A (but still in a chair conformation) while the exocyclic 16,17 double bond is near this mean plane. In **3**, due to the *trans* B–C ring junction, rings A, B, and C form essentially a single plane with all three rings in chair conformations. The double bond is well below this plane while the C-20 methyl carbon is almost in the same location as the C-17 methylene carbon in **2**. The overall "shapes" of **2** and **3** are surprisingly similar.

These features are illustrated in Figs. 2 and 3. Figure 2 shows a side view of structures **1** and **3** with ring A superimposed while Fig. 3 provides a similar view of **2** and **3**. The dif-

[a]Equivalent isotropic U defined as one third of the trace of the orthogonalized U_{ij} tensor.

ferent locations of the exocyclic double bond in **1** and **2** are clearly seen while **2** and **3** are more nearly superimposed. Top views (not shown) confirm the similarity in overall shape of **2** and **3**, with **1** being significantly different. However, before one can reach any conclusions about whether these differences might be pharmacologically significant, it is first necessary to determine whether the molecules adopt similar conformations in solution.

^{13}C and ^{1}H spectral assignments and preferred conformations of 1–3 in solution

Complete ^{1}H and ^{13}C spectral assignments for **1–3** are given in Table 2. The data for **1** are essentially the same as those reported previously (12), except for minor chemical shift changes since the spectra were obtained for a more dilute solution than originally used. ^{1}H and ^{13}C spectral assignments were carried out with the aid of COSY (15), HETCOR (16),

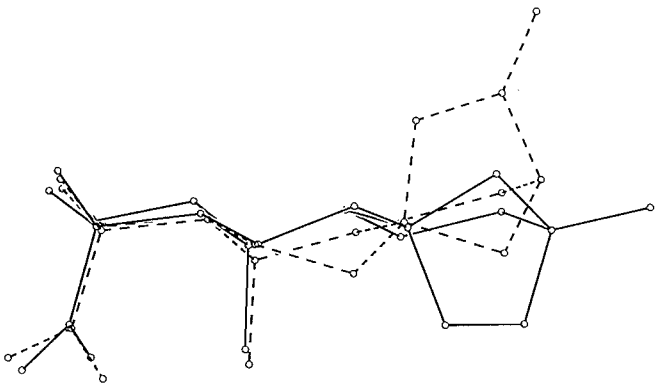
Fig. 2. Side view of crystal structures of **1** (broken lines) and **3** (solid lines) with ring A atoms superimposed as closely as possible.



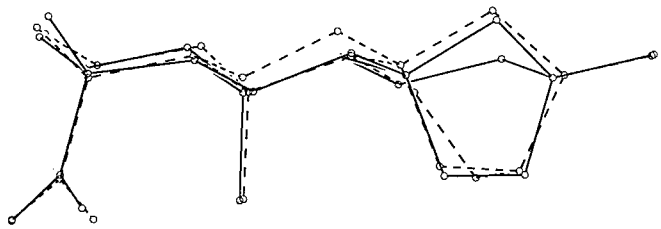


Fig. 3. Side view of crystal structures of **2** (broken lines) and **3** (solid lines) with ring A atoms superimposed as closely as possible.

HMQC (17), FLOCK (18), and HMBC (19) spectra, using methodologies similar to those reported earlier (12).

Solution conformations were investigated with the aid of NOESY and NOE difference spectra. In addition, cross sections for the HETCOR or HMQC spectra at specific ^{13}C frequencies allowed determination of the numbers of large splittings (*anti*-vicinal and geminal) for each proton, aiding in assignment of protons as axial or equatorial and, consequently α or β. However, the most important evidence for confirming the close similarity of solution and crystal structures was provided by NOE difference and NOESY experiments. For example, irradiation of the H-20 methyl protons of **1** resulted in an 7% enhancement of the proton assigned as H-7_α, confirming the boat conformation for ring B in **1**, since this kind of 1–4 ("flagpole") interaction is only possible for a boat conformation. In the case of **3**, the key observation is a strong NOE enhancement of 10% for the olefinic proton H-15 on irradiation of H-20. There are also significant enhancements of both H-16 and H-6_α on irradiation of H-15, as expected from the crystal conformation. Similarly in **2**, a 9% NOE enhancement is observed for H-14_α on irradiating H-20, suggesting that ring C is locked in a single chair conformation, identical to that in the solid state, even though it has a *cis* ring junction. A complete listing of significant NOESY cross peaks for the three compounds is provided in Table 3.

Comparisons of ^1H and ^{13}C chemical shifts for **1**–**3** show that, for ring A, carbons 2, 3, 4, 18, and 19 as well as the C-2 and C-3 methylene proton chemical shifts are quite similar for all three compounds. However, there are significant differ-

ences for C-1, H-1_α, H-1_β, C-5, H-5_β, C-10, and particularly for C-20 and H-20, reflecting structural differences in rings B and C. The unusual ^{1}H chemical shift for H-20 in **3** may also be due to the anisotropic shielding effect of the proximal C=C bond. In the case of ring B, all of the ^{13}C and ^{1}H chemical shifts for **1** are significantly different from those in **2** and **3**, reflecting the difference between boat and chair conformations. Between **2** and **3**, C-5, H-5, C-6, H-6_α, H-6_β, and C-7 chemical shifts are generally similar while H-7_α and H-7_β show significant differences, possibly reflecting different anisotropic shielding effects of the different double bond locations. C-8 and C-9 also show significant chemical shift differences, probably due to the different B–C ring junctions in **2** and **3**. Comparisons for ring C are generally meaningless due to the different structures of the three compounds. However, the much larger δ value for C-14 in **3** than in to **1** and **2** is noteworthy.

Conclusion

Each of the kaurane derivatives, **1–3**, has similar solid state and solution conformations. There are at least four differences among these compounds that could account for differences in pharmacological activity. The first two are the obvious structural differences, i.e., the additional double bond in **1** and the endocyclic double bond in **3** compared to the exocyclic double bonds in **1** and **2**. However, the two additional differences revealed in this investigation are the significantly different spatial locations of the endocyclic or exocyclic double bond in the three compounds and the fact that **2** and **3** have very similar shapes while **1** has a significantly different shape. These differences may allow an understanding of the structure–activity relationships between these compounds, once their in vivo pharmacological activities have been unambigously established.

Experimental

Isolation of 1–3

Dried roots of *Montanoa tomentosa* (300 g) were ground to a coarse power and macerated three times with CH_2Cl_2 for periods of 24 h. The combined extracts were evaporated in vacuo, yielding 18 g of a viscous oily residue. The latter was submitted to column chromatography with SiO_2, eluting with a gradient of hexane: ethyl acetate from a 9:1 to a 7:3 ratio. **2** (mp 179–181°C (lit. (20) mp 179–180°C)) was clearly separated while **1** and **3** occurred in nearby fractions with **1** as the major component. Fractional crystallization was used to separate pure **1** (mp 154–156°C, (lit. (21) mp 155–157°C)) while **3** was further purified using 2 mm SiO_2 preparative thin-layer chromatography, eluting three times with a 93:7 ratio of hexane: ethyl acetate (mp 179–180°C, (lit. (2) mp 180°C)). **3** was subsequently recrystallized from slowly cooled hot hexane to obtain crystals suitable for X-ray diffraction.

Crystal structure determination

X-ray intensity data were collected on an Enraf–Nonius CAD-4 diffractometer at room temperature, using graphite monochromated Mo K^α radiation (λ = 0.71073 Å). The ω–2θ scan technique was applied with variable scan speeds (1.83–5.49°/min in ω). Accurate cell dimensions were determined from the

© 1997 NRC Canada

setting angles of 24 reflections in the range $20° < 2\theta < 25.2°$. Two standard reflections measured every two hours showed no decrease in intensity. The data were corrected for Lorentz and polarization effects but not for absorption.

The structure was solved by direct methods. C and O atoms were refined anisotropically by full-matrix least squares to minimize $\Sigma w(F_o - F_c)^2$, where $w^{-1} = \sigma^2(F) + gF^2$. Hydrogen atoms were positioned on geometric grounds (C—H 0.96 Å) and included in the calculations as riding atoms. An overall hydrogen atom thermal parameter refined to a value of 0.082(4) $Å^2$. The electron density contours of the hydroxyl hydrogen atoms were visible from a difference Fourier map calculated in the plane of the four oxygen atoms of the dimer molecule. In the final cycles of least-squares the hydroxyl hydrogen atoms were included in the refinement in calculated positions and fixed thermal parameters (O—H 0.87 Å, 0.08 $Å^3$).

Crystal data, data collection, and least-squares parameters are listed in Table 4. All calculations were performed using SHELXTL PC (22) on a 486-66 personal computer.

NMR spectroscopy

Spectra were obtained on Varian Unity-400 and Unity-500 spectrometers, the former fitted with a computer-switchable ^{1}H-heteronuclear probe optimized for ^{13}C detection while the latter was equipped with a 5 mm inverse detection probe. Initial 2D NMR measurements were carried out on the Unity-400, using ca. 30 mg of sample dissolved in 1 mL $CDCl_3$ while ^{13}C and ^{1}H spectra were obtained using 3 mg of sample. Further inverse detection experiments were carried out on the UNITY-500 using the more dilute samples since there seemed to be significant dilution shifts, particularly for protons and carbons close to the carboxylic acid function.

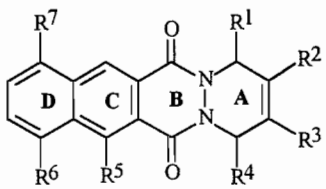
The steric course of some electrophilic additions to the tetrahydropyridazine ring moiety of benzo[*g*]pyridazino[1,2-*b*]-phthalazine-6,13-dione derivatives. II.[1]

María del Carmen Cano, Fernando Gómez-Contreras, Ana María Sanz, and María Josefa Rodríguez Yunta

Abstract: The stereochemical features involved in electrophilic additions to the ring A moiety in diazatetracyclic analogues of anthracyclinones have been investigated. The 1-methyl and 1,3-dimethyl derivatives **2a** and **2b** were selected as the substrates and made to react with bromine azide, iodine azide, and NBS–EtOH in order to evaluate the influence of the C-1 substituent on the product distributions. Electrophilic attack at the C-2/C-3 double bond occurs mainly in the less hindered *anti* fashion. The nucleophilic step governs the stereochemistry of the reaction products. Conformational factors are predominant over the steric and electronic effects originated by the ring A substituents, since axial antiparallel attack of the nucleophile on the intermediate epihalonium ion is clearly preferred to the equatorial approach.

Key words: diazatetracycles, Diels–Alder reaction, electrophilic addition, anthracyclinone analogues, pyridazine ring.



Résumé : On a étudié les caractéristiques stéréochimiques impliquées dans les additions électrophiliques sur le cycle A d'analogues diazatétracycliques d'anthracyclinones. Dans le but d'évaluer l'influence du substituant en C-1 sur la distribution des produits, on a choisi les dérivés 1-méthylé et 1,3-diméthylé, **2a** et **2b**, comme substrats pour des réactions avec les azotures de brome et d'iode ainsi qu'avec le NBS–EtOH. L'attaque électrophilique sur la double liaison en C-2/C-3 se fait principalement de la façon *anti* la moins empêchée. L'étape nucléophilique détermine la stéréochimie des produits réactionnels. Les facteurs conformationnels prédominent sur les effets stériques et électroniques provenant des substituants présents sur le cycle A; cette conclusion découle du fait que l'attaque axiale antiparallèle du nucléophile sur l'ion épihalogénium est nettement favorisée par rapport à celle impliquant un rapprochement équatorial.

Mots clés : diazatétracycles, réaction de Diels–Alder, addition électrophilique, analogues d'anthracyclinone, noyau pyridazine.

[Traduit par la rédaction]

Quite a number of papers have appeared concerning the total synthesis of anthracyclinones, the aglycons of the highly active anticancer anthracyclines (1). Diverse strategies have been also developed for the preparation of non-natural analogues (2), in an effort to minimize the dose-dependent cardiotoxicity shown by most of the known anthracyclines (3). The modification of redox properties by introducing heteroatoms in the carbocyclic backbone appears as a promising means of reducing toxicity and improving neoplastic activity (4).

In earlier publications (for a review, see ref. 5) we described an efficient method for the synthesis of the benzo[*g*]-pyridazino[1,2-*b*]phthalazine-6,13-dione system, **1**, via the Diels–Alder cycloaddition of benzo[*g*]phthalazine-1,4-dione, an unstable compound available by the in situ lead tetraacetate oxidation of benzo[*g*]phthalic hydrazide (6), with substituted 1,3-butadienes. These diazatetracyclic compounds exhibit the main features required for the intercalating action of anthracyclinones: an aromatic moiety providing an adequate planar area, a quinone-like system, and a conformationally flexible ring A that can be functionalized in order to allow the proper intermolecular binding to the third pair of DNA bases (7).

Scheme 1.

The introduction of electronegative substituents into the terminal tetrahydropyridazine ring moiety of **1** is essential for achieving the required interaction with DNA chains. Furthermore, both the stereochemistry of these substituents and the conformation adopted by ring A have a decisive influence on the intercalating properties of anthracyclinones (7). In the preceding paper of this series (8) we reported on the steric course of some electrophilic additions to the C-2/C-3 double bond of 2-methyl and 2,3-dimethyl-substituted diazatetracyclic compounds of type **1**, in an effort to evaluate the electronic and stereoelectronic factors involved. However, the stereochemical influence of substituents at the C-1 or C-4 positions has not yet been evaluated. In this respect, it should be noted that substitution at C-1 greatly affects the geometry of ring A (9), because destabilizing interactions with the C=O groups at the ring B moiety arise when the substituent is equatorially oriented.

Therefore, we report in this paper on some electrophilic additions to the 1-methyl and 1,3-dimethyl-substituted substrates **2a** and **2b**. As in the preceding paper (8), bromine azide, iodine azide, and *N*-bromosuccinimide–EtOH were the reactants of choice. As usual, high amounts of unchanged **2** were recovered in every reaction performed, due to the lack of reactivity caused by the electron-withdrawing effect of the amido groups. The use of more stringent reaction conditions led to ring opening and gave large amounts of benzo[*g*]phthalic anhydride. Conditions described in the experimental part are those combining the highest yield of addition products with the least extent of ring opening. In fact, the formation of ring-opening products was not detected under the conditions reported here. A range of experiments were run for every reaction in order to confirm the reproducibility of the regio- and stereochemical results.

Scheme 1 displays the compounds obtained by treatment of 1-methyl-1,4-dihydrobenzo[*g*]pyridazino[1,2-*b*]phthalazine-6,13-dione **2a** with every reactant. The reaction with NBS–EtOH–H_2SO_4 at 50°C afforded exclusively the *t*-3-bromo-*c*-2-ethoxy-*r*-1-methyl (**3**) derivative. Bromine azide in dichloromethane–nitromethane at room temperature gave the *t*-4,*c*-2-diazido-*c*-3-bromo-*r*-1-methyl (**4**) and *t*-2,*t*-4-diazido-*c*-3-bromo-*r*-1-methyl (**5**) derivatives,[4] together with a small amount of the dibromo compound (**6**), in relative percentages of 47:44:9. Iodine azide in chloroform–acetonitrile yielded the *c*-2,*t*-4-diazido-*c*-3-iodo-*r*-1-methyl (**7**) and *t*-2,*t*-4-diazido-*c*-3-iodo-*r*-1-methyl (**8**) derivatives,[4] together with allylazide (**9**), in a 44:26:30 relation. The products were isolated after laborious preparative TLC work, and 300 MHz ^{1}H NMR spectroscopic analyses were made previously in order to confirm that no structural changes had occurred during the purification procedure. Distribution of the addition derivatives

[4] Addition products have been numbered in all cases by assigning the lower number to the carbon atom attached to the methyl group, in order to make easier the discussions on stereochemical features.

[b]Measured under conditions described in the experimental part.

Scheme 2.

in the reaction mixtures was calculated from integration of the methyl group signals in the ^1H NMR spectra. Table 1 displays some analytical properties concerning the products of addition to **2a**.

As established in previous work for the 2-methyl and 2,3-dimethyl-substituted substrates (8), bromodiazides **4** and **5** should be formed from the addition products **10** and **11**, respectively, through dehydrohalogenation of the initial electrophilic addition product and further regiospecific addition to the C-1/C-2 double bond, according to the sequences shown in (Scheme 2). In the case of **4**, it implies nitrogen inversion of the intermediate allylazide favored by the decrease of steric hindrance between the carbonyl group at ring B and the C-1 methyl, as the latter moves from a pseudoequatorial to a pseudoaxial orientation (9). In a similar way, iododiazides **7** and **8** should derive from iodoazides **12** and **13**, the former via the isolated allylazide **9.**

Stereo- and regiochemical features in the ring A moiety have been elucidated mainly on the basis of high-resolution ^1H NMR spectra (Table 2). In contrast to the behaviour of less substituted analogues (10), the tri- and tetrasubstituted compounds isolated have been shown to be conformationally homogeneous. Proton chemical shifts at ring A are strongly affected by the nature of the substituent attached to the same carbon ($\delta_{H\text{-}C\text{-}Br}$, $\delta_{H\text{-}C\text{-}I} > \delta_{H\text{-}C\text{-}OEt}$, $\delta_{H\text{-}C\text{-}N3}$). This fact has been used for assignment purposes (11) (see, for instance, H-2 and

H-3 chemical shifts in **6**). On the other hand, vicinal and long-range coupling constants can be easily applied to determine the relative orientations of the substituents, as there are protons attached to every carbon of the ring. The C-1 methyl group is axially oriented in compounds **4**, **5** and **7–9**, but it has an equatorial position in **3** and **6** (hashed bonds).

From the experimental J_{H2-H3} and J_{H1-H2} values obtained for the tetrasubstituted derivatives **4** and **7**, substantial deviations from the pure chair conformations can be assumed (12). This is due to the coexistence of a diversity of unfavored steric interactions: *syn*-1,3-diaxial between the C-1 and C-3 substituents, $A^{1,3}$ between the C-1 and C-4 substituents and the neighbouring carbonyls (9), and also *gauche* between the C-2 azido group and the halogen at C-3. In fact, J_{H2-H3} and J_{H3-H4} are higher in **7** (8.1 and 3.4 Hz) than in **4** (7.5 and 2.4 Hz) owing to the presence of the bulky iodine atom in **7**. Conversely, the axial orientation of the C-2 azido group in **5** and **8** reduces steric hindrance and, therefore, coupling constants are closer to those expected for a chair form (13). *W* long-range couplings are not observed due to the lack of coplanarity between 1,3-diequatorial protons. However, trisubstituted derivatives **3** and **6** present long-range J_{H2-H4e} couplings (1.0 and 1.5 Hz), confirming both the axial orientation of the substituents at C-2 and C-3 and the prevalence of a classical chair conformation.

Calculation of the torsion angles from the experimental coupling constants by means of the Altona equation (14) (Table 3) confirms a significant flattening of the C-1/C-2/C-3/C-4 moiety in **4** and **7**, which is increased when the C-2 substituent is an iodine atom. On the contrary, the less hindered dibromo (**6**) and bromoethoxy (**3**) derivatives exhibit much less distorted geometries.

Analogous treatment of 1,3-dimethyl-1,4,6,13-tetrahydrobenzo[*g*]pyridazino[1,2-*b*]phthalazine-6,13-dione, **2b**, led to results displayed in Scheme 3. The reaction of **2b** with NBS–EtOH–H_2SO_4 afforded the *c*-2-bromo-*t*-3-ethoxy-*r*-1-methyl (**14**), *t*-3-bromo-*c*-2,*c*-4-diethoxy-*r*-1-methyl (**15**), and *c*-2-ethoxy-*r*-1-methyl (**16**) derivatives in 25:56:19 ratio. As usual (8), compound **15** arises from the dehydrohalogenation of **17** and further regiospecific addition of bromine and ethoxyl (Scheme 4). Treatment with bromine azide led to isolation of the isomeric *c*-2,*t*-4-diazido-*c*-3-bromo-*r*-1-methyl (**18**) and *c*-2,*c*-4-diazido-*t*-3-bromo-*r*-1-methyl (**19**) derivatives, accompanied by the *c*-allylazide **20** and the dibromide **21**, in relative percentages of 34:25:16:25. Compounds **18–20** should derive from the bromoazide **22** as shown in Scheme 4 (nitrogen inversion of the elimination product to give allylazide **20** is sterically favored due to the pseudoaxial orientation of the C-1 methyl group (9)) In the presence of iodine azide, the stereoisomeric azidoiodo derivatives **23** and **24** were characterized together with allylazide **20** in 22:22:56 percentages. In this last reaction analytical TLC showed the presence of much smaller amounts of two other compounds that could not be isolated or identified.

The higher percentages of halodiazides obtained from both **2a** and **2b** with bromine azide (and also from other substrates (8)) can be explained on the basis of the more electrophilic character of the bromonium ion.

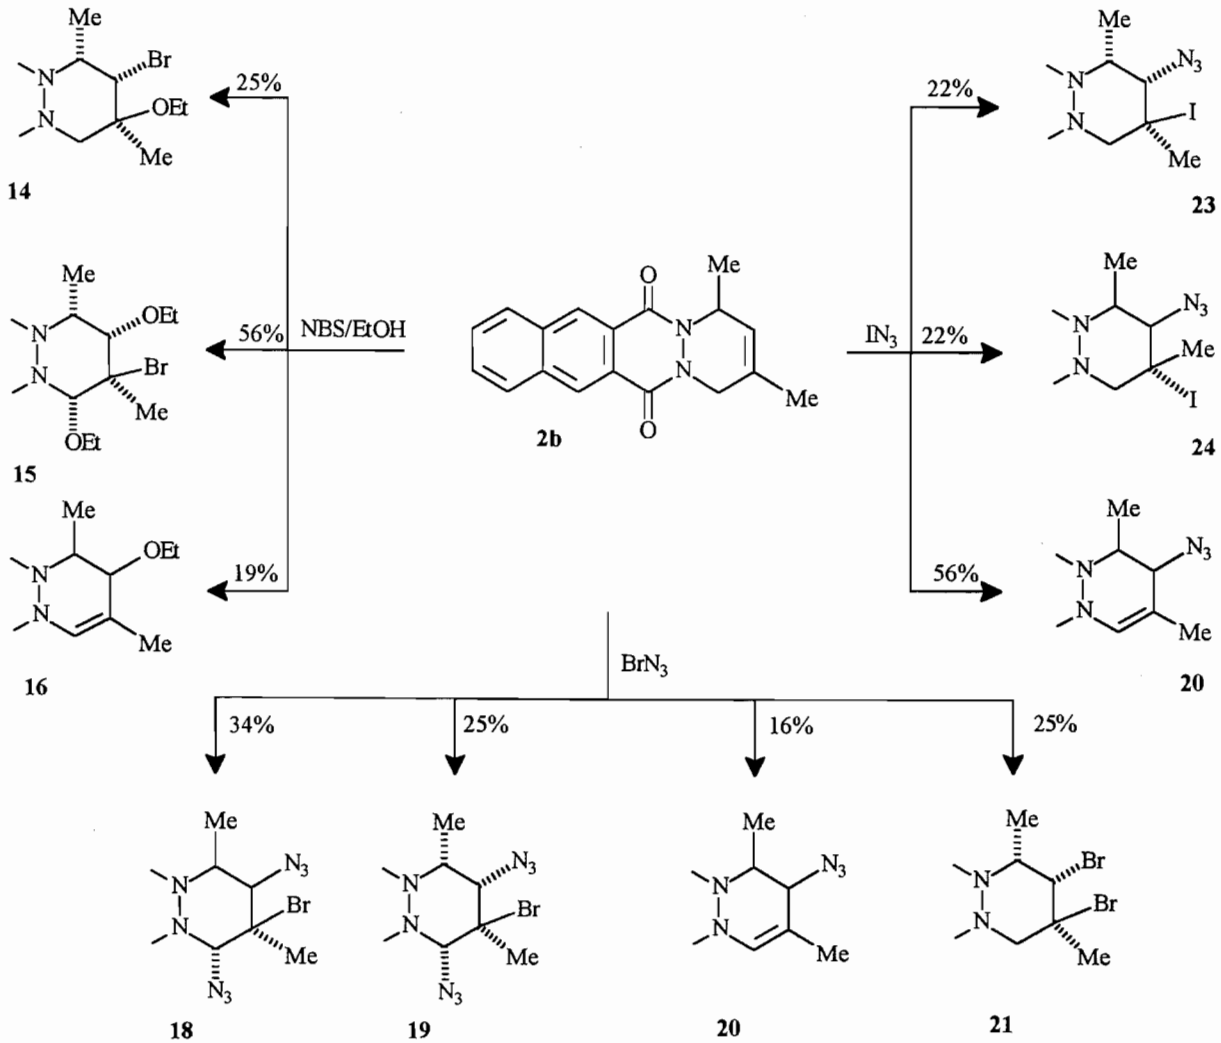

Table 4 displays the chemical shifts and coupling constants of ring A protons obtained from the 300 MHz ^{1}H NMR spectra, which were used to assign the position and orientation of the ring substituents. As in previous series, the nature of the C-3 substituents can be accurately deduced from the δ values measured for the C-3 methyl groups (8), and the same applies for the C-4 substituents and the H-4 chemical shifts, as $\delta_{CH\text{-}OEt} > \delta_{CH\text{-}N3}$. J_{H1-H2} coupling constants show the stereochemical relationship between the C-1 methyl and the C-2 substituent (J_{He-Ha} values are high owing to chair deformations due to steric hindrance). The C-1 methyl stereochemistry is confirmed from $J_{Me\text{-}C1}$ values, which increase when the methyl group is axially oriented.[5] On the other hand, *W* long-range

[5] This fact is due to the antiperiplanar arrangement that may adopt the hydrogen atoms of an axial methyl group with respect to the neighbouring bridgehead nitrogen, which reduced the *J* value. That arrangement is not possible when the alkyl substituent is equatorially oriented because of steric hindrance with the neighbouring carbonyl group at ring B. Such effects will be considered in full in the following part of this series.

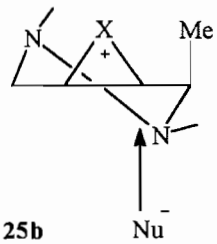
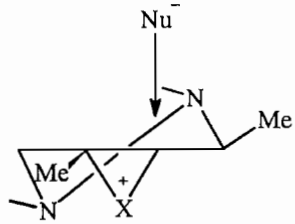
[a]TMS as internal standard.

couplings between H-2 and H-4e are found in compounds **14**, **15**, **21**, and **23**, confirming the axial orientation of the substituents attached to C-2 and C-4. The only exception is bromodiazide **19**, in which substitution at C-4 leads to 1,3-*syn*diaxial interaction between the two azido groups that must preclude coplanarity between H-2 and H-4. Last, the C-3 methyl group of **24** is deshielded by 0.21 ppm with respect to that of **23**, in spite of having the same substituents at C-2 and C-3. This may be due to the 1,3-*syn*diaxial interaction between the two methyls of iodoazide **24** (15), and agrees with the stereochemical assignments described above.



If we consider now the regio- and stereochemical implications of the product distributions obtained from these substrates, it should be pointed out that the presence of the C-1 methyl group in both **2a** and **2b** introduces a new steric factor with respect to the 2-methyl and 2,3-dimethyl-substituted substrates studied in the previous work (8). The stereoselectivity of the electrophilic attack is shown in Table 5 for the different reactants employed. Attack occurs preferentially over the less hindered side of ring A to give the sterically favored *anti* epihalonium ion. This implies a remarkable steric effect of the C-1 methyl, probably due to its high tendency to move away from the neighbouring carbonyl group at ring B (9). With respect to the nucleophilic step, different explanations should be considered regarding the behaviour of **2a** and **2b**. In **2a**, opening of the *trans* epihalonium ion takes place always through axial antiparallel attack over C-2, conformationally more favored than equatorial attack at C-3 (16), in spite of the steric hindrance involved with the pseudoequatorial C-1 methyl (**25a**). The *cis* epihalonium ion is opened by antiparallel attack on C-2, with the C-1 methyl in a pseudoaxial orientation (**25b**). Therefore, it is shown that conformational requirements prevail in all cases both over steric and electronic considerations.

The 1,3-dimethyl-substituted substrate matches the steric effect of the C-1 methyl with the electronic one of the second methyl group. However, the influence of the latter seems to be negligible, since Table 5 shows that the nucleophile attaches very selectively to the C-2 position. As seen for **2a**, axial antiparallel attack on C-2 with the C-1 methyl pseudoequatorially oriented is clearly predominant in the nucleophilic step (**25c**).



In consequence, it may be concluded that the C-1 methyl orientation is the essential factor controlling the regioselectivity, since the substituent directs nucleophilic attack towards C-2 or C-3 according to its axial or equatorial disposition. The high predominance of *anti* addition products with the C-1 methyl equatorially oriented indicates that *syn*-1,3-diaxial interactions between the methyl group and the nucleophile are more destabilizing than $A^{1,3}$ hindrance between the equatorial methyl and the nearby carbonyl group. These facts should be taken into account when making electrophilic additions to the ring A moiety in order to achieve stereochemical results approximating the geometry of the anthracyclinone models.

Me_4Si as internal reference. Assignments were made by appropriate decoupling experiments and comparison of the spectra of related structures. Direct inlet mass spectra were measured on a Hitachi Perkin–Elmer RMV-GM6 spectrometer. Chromatographic separations were carried out by using 20 × 20 cm preparative TLC plates coated with a 2 mm layer of silica gel $60PF_{254}$ Merck. Dichloromethane was refluxed over P_2O_5 and distilled. Chloroform was purified by washing with 2 N NaOH, concentrated H_2SO_4, and water, drying with K_2CO_3, and distillation, and was used immediately. Dry ethanol was obtained via the formation of the magnesium ethanolate and distillation. Nitromethane was purified by standing for a day with H_2SO_4, washing with water, drying over $MgSO_4$, and distillation. Acetonitrile was shaken with molecular sieves and, subsequently, with CaH_2 until no further hydrogen was evolved, and was fractionally distilled over CaH_2. $MgSO_4$ was always used as the drying agent in the work-up for addition reactions.

Benzo[*g*]phthalic hydrazide was obtained from α,α,α′,α′-tetrabromo-*o*-xylene and maleic anhydride according to Cava et al. (17). Substrates **2a** and **2b** were prepared by oxidation of the hydrazide in the presence of the appropriate diene, following a procedure previously described (9).

The haloazide solutions were prepared as follows:

Bromine azide: To a suspension of 0.05 mol of sodium azide in 30 mL of dichloromethane, 7 mL of 37% HCl were added. The heterogeneous mixture was stirred for 10 min at 0°C and 0.05 mol of molecular bromine was addded. After 30 min stirring, the organic layer was collected and used without further purification.

Iodine azide: Commercial chlorine iodide (0.006 mol) was added to a solution of 0.01 mol of sodium azide in 30 mL of dry acetonitrile cooled to 0°C. The mixture was stirred for 10 min and used without further purification.

The reaction mixtures of the electrophilic additions consisted of an appreciable amount of unreacted alkene and the addition products described above, and the percentages were calculated from integration of the signals displayed by the methyl groups in the 300 MHz ^1H NMR spectra. Several runs were carried out for every condition and results reported are average values. The reaction mixtures were chromatographed, and IR, NMR, and mass spectra were obtained for each one of the recovered fractions in order to confirm the identity and solve the stereochemistry of the compounds involved. The stereoisomeric mixtures **4/5**, **7/8**, **18/19**, and **23/24** could not be separated, as they gave only one spot in analytical TLC, but were assigned on the basis of the NMR spectra.

Addition reaction conditions

(a) With NBS–EtOH

Equimolecular amounts of **2a,b** and *N*-bromosuccinimide were suspended in dry ethanol and stirred for 5 h at 50°C. After addition of water, the solvent was removed to half of the initial volume and the remaining solution was filtered. The precipitate was repeatedly washed with water, dried, and submitted to preparative TLC over silica gel by using toluene/ethanol (98:2) as the eluent.

(b) With BrN_3

2a,b (0.03 mol) in 30 mL of nitromethane was added to 35 mL of a solution of bromine azide in dichloromethane prepared as described above. After 30 min stirring at room temperature the solvent was evaporated at reduced pressure to give a yellow residue, which was submitted to preparative TLC over silica gel by using toluene/ethanol (98/2) as the eluent.

(c) With IN_3

2a,b (0.03 mol) in 30 mL of chloroform was added to 35 mL of a solution of iodine azide in acetonitrile prepared as described above. After 24 h stirring at room temperature the reaction mixture was poured into 100 mL of cold water, extracted three times with 50 mL of chloroform, and the organic layer was successively washed with 0.1 N NaOH, 0.1 N HCl, and aqueous sodium bicarbonate. After drying and evaporation of the solvent under reduced pressure, the residue was submitted to preparative TLC over silica gel by using toluene/ethanol (98/2) as the eluent.

Energétique des liaisons inter- et intramoléculaires dans les trois isomères du benzènediamine

Raphaël Sabbah et Laurence Perez

Résumé : Le présent travail porte sur l'étude thermodynamique des trois isomères du benzènediamine (BDA) de formule générale : $C_6H_8N_2$. Il a été réalisé en utilisant quatre techniques : la calorimétrie de combustion de faibles quantités de substance (quelques milligrammes par essai), la calorimétrie de sublimation, l'analyse thermique différentielle et la mesure de capacités calorifiques. Cette étude nous a permis : de déterminer les enthalpies de combustion, de sublimation et de fusion de ces composés ainsi que la température de leur point triple; de préciser la stabilité relative des trois isomères; de déterminer les énergies de conjugaison expérimentales et de les comparer aux valeurs théoriques; de déterminer les enthalpies d'atomisation des trois composés et de vérifier qu'elles sont compatibles avec les valeurs calculées à partir des contributions énergétiques précédemment obtenues au laboratoire; de déterminer qualitativement et quantitativement les interactions intermoléculaires; de discuter de l'existence d'une liaison hydrogène intramoléculaire dans l'isomère *ortho*.

Mots clés : isomères du benzènediamine; enthalpie de combustion, de sublimation, de fusion, des liaisons inter- et intramoléculaires.

Abstract: The present work is concerned with a thermodynamic study of the three benzenediamine (BDA) isomers (general formula: $C_6H_8N_2$). It was achieved using four techniques: combustion calorimetry of small amounts of substance (a few milligrams), sublimation calorimetry, differential thermal analysis, and heat capacity measurements. From this study it was possible: to determine the enthalpies of combustion, sublimation, and fusion of these compounds as well as their triple point temperatures; to discuss the relative stability of the three molecules; to determine the experimental resonance energies and to compare them with the theoretical values; to determine the atomization enthalpies and to compare them with the values calculated from the energetical contributions previously obtained in our laboratory; to determine the intermolecular enthalpy bonds; to consider the existence of an intramolecular hydrogen bond in the *ortho* isomer.

Key words: benzenediamine isomers; enthalpy of combustion, of sublimation, of fusion, of inter- and intramolecular bonds.

1. Introduction

Les trois isomères *ortho*, *méta* et *para* du benzènediamine (BDA) possèdent de multiples applications industrielles : tous trois entrent dans la composition de nombreux pigments colorés mais aussi de certains fongicides (isomère *ortho*) (1, 2). Par ailleurs, et depuis peu, l'isomère *para* trouve également sa place dans le domaine de la chimie des matériaux, ses propriétés durcissantes faisant de lui un produit intermédiaire dans la synthèse de polymères (3). Ces substances, toxiques de surcroît, peuvent donc, selon leur comportement, avoir un sérieux impact sur l'environnement et la santé de l'homme. Il est à noter que l'isomère *para* semble être le plus nocif (4).

Les données thermodynamiques relatives aux benzènediamines, rapportées dans la littérature, sont rares (5–7). Il en est de même des informations relatant la structure cristalline de ces composés et concernant essentiellement l'isomère *para* (8, 9).

Ce travail a pour but de mettre en évidence le lien existant entre les grandeurs énergétiques des substances étudiées et leur structure moléculaire. Il trouve sa place aussi bien dans le domaine de la recherche fondamentale qu'appliquée et, notamment, dans celui de la protection de l'environnement (aptitude à la dégradation et au stockage de ces substances, problèmes liés à l'élimination des déchets par incinération, dépollution de l'eau, dépollution de l'atmosphère...).

2. Partie expérimentale

2.1. Produits utilisés

Les trois substances analysées sont des produits Aldrich de pureté supérieure à 99%. L'analyse thermique différentielle ayant confirmé ce résultat, les trois isomères ont été étudiés sans repurification préalable. Signalons, au passage, que ces trois substances sont nocives par inhalation, ingestion et contact avec la peau. Leur manipulation, réalisée sous hotte aspirante, a donc nécessité quelques précautions telles que le port de masque et gants appropriés.

Enfin, ces composés sont photosensibles et brunissent lorsqu'ils sont exposés à la lumière. Aussi, les avons-nous stockés à l'abri de celle-ci.

Reçu le 8 octobre 1996.

R. Sabbah[1] **et L. Perez.** Centre de thermodynamique et de microcalorimétrie du Centre national de la recherche scientifique, 26, rue du 141ème R.I.A., 13331 Marseille, Cedex 03, France.

2.2. Appareillages, techniques et modes opératoires

2.2.1. Analyse thermique différentielle

Nous avons utilisé la version moyenne température de l'analyseur thermique différentiel et les cellules expérimentales en verre décrites dans la référence 10.

Dans toutes nos expériences : (*i*) la vitesse de montée en température du four a été de 0,2 K min^{-1}; (*ii*) la masse de substance utilisée a été d'environ 100 mg, déterminée par double pesée à l'aide d'une balance Mettler, type M5, sensible au μg et dont l'exactitude des pesées est de ±2 μg; (*iii*) la préparation des échantillons et leur mise en container ont été conduites de la façon décrite dans la référence 10.

La mesure des températures a été faite à l'aide de deux thermocouples (thermocoax, type 2ABI 15); l'un est solidaire de l'échantillon, l'autre de la référence (alumine-α). La différence entre les f.e.m. délivrées par ces deux thermocouples est amplifiée par un microvoltmètre AOIP, type EVA, sensibilité 100 μV pleine échelle. Le signal ainsi amplifié est envoyé simultanément à un enregistreur Sefram, type Gépérac, pour le visualiser, et à un multimètre Keithley, modèle 175, pour le digitaliser. Un autre multimètre Keithley modèle 196, sensibilité 300 mV (résolution 100 nV), est utilisé pour mesurer la f.e.m correspondant à la température de l'échantillon. Les données issues de ces deux multimètres sont envoyées vers un ordinateur en vue de leur traitement à l'aide d'un programme écrit et mis au point au laboratoire. En appliquant l'équation de Clausius–Clapeyron à l'équilibre solide ⇔ liquide et la loi de Raoult, ce programme permet de déterminer la pureté de l'échantillon, son enthalpie de fusion ainsi que la température de son point triple.

Comme indiqué dans la référence 10, l'étalonnage (*i*) en température, de notre analyseur thermique a été réalisé à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque, diphénylacétique et anisique, de carbazole et d'anthraquinone, dont la température de leur point triple est bien connue dans la littérature; celle-ci est comprise entre 353 et 558 K; (*ii*) en énergie, a été réalisé à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque et diphénylacétique, dont l'enthalpie de fusion est bien connue dans la littérature.

2.2.2. Calorimétrie de combustion

Les enthalpies de combustion de nos composés ont été déterminées en utilisant un calorimètre isotherme, à flux thermique, monopile, basculant, CRMT (sensibilité : 0,0623 V W^{-1}) équipé d'une microbombe en acier inoxydable (Superimphy 625) de volume interne égal à 43,3 cm^3 à la température ambiante.

Le signal issu du calorimètre est amplifié par un microvoltmètre électronique AOIP, modèle EVA, sensibilité 30 mV pleine échelle, avant son envoi simultané sur un intégrateur éléctronique, conçu, réalisé et mis au point au laboratoire, qui détermine l'aire des thermogrammes $dQ/dt = f(t)$, et sur un enregistreur potentiométrique (Sefram, modèle Servotrace) qui le visualise.

La rotation du calorimètre suivant plusieurs plans permet à toutes les génératrices de la bombe d'être lavées par l'eau déminéralisée placée en son fond (1 cm^3).

Comme indiqué dans la référence 11, les substances à étudier sont mises sous forme de pastilles. À cet effet, nous avons utilisé un ensemble piston-moule façonné dans un acier trempé, ce qui a pour effet d'éviter l'entraînement dans les pastilles de traces de métal et d'augmenter ainsi la qualité des résultats.

Les pesées ont été effectuées sur une microbalance Mettler, modèle UM3, équipée d'un jeu de poids étalonnés par le N.I.S.T. Sa portée est de 3 g et sa sensibilité de 0,1 μg. L'erreur commise avec cette balance sur une pesée de quelques milligrammes est de l'ordre de ±0,2 μg. Dans toutes nos pesées, nous avons tenu compte des corrections de poussée de l'air pour calculer les masses réelles.

Une fois garnie, la bombe est remplie d'oxygène sous une pression de 3,04 MPa. L'oxygène N45, utilisé à cet effet, provient de l'Air Liquide et son degré de pureté est supérieur à 99,995% (fraction molaire d'azote < 10^{-5}). La durée d'une expérience a toujours été de 120 min à partir du moment de la mise de feu.

Après chaque expérience, nous avons déterminé, dans la phase aqueuse, les concentrations d'acide nitrique par titrage acido-basique en présence de phénolphtaléine avec une solution de soude préalablement titrée à l'aide d'une solution d'acide chlorhydrique de concentration connue; et vérifié, à l'aide des tubes de Dräger, l'absence d'oxyde de carbone et d'oxydes d'azote (NO, NO_2) dans la phase gazeuse (sensibilité des tubes < 1 ppm pour CO et < 0,1 ppm pour NO et NO_2).

2.2.3. Calorimétrie de sublimation

Nous avons utilisé un calorimètre Tian–Calvet (sensibilité 0,0621 V W^{-1}) associé à un montage différentiel doté de cellules d'effusion de Knudsen pour déterminer les enthalpies de sublimation de nos composés. L'étalonnage de notre système calorimétrique a été réalisé par effet Joule avant et après chaque série d'expériences. Le mode opératoire a été décrit dans la référence 12. Précisons que :

(*i*) le signal issu du calorimètre est amplifié par un nanovoltmètre Keithley modèle 147, sensibilité 100 μV pleine échelle, puis digitalisé par un multimètre numérique Keithley modèle 175 et enregistré sur un enregistreur potentiométrique, Sefram, modèle Servotrace;

(*ii*) l'isomère *ortho* a été étudié à 298,15 K alors que les deux autres isomères l'ont été à 319 K en raison de leur faible pression de vapeur saturante (égale à 0,09 Pa à 298,15 K, 0,6 et 0,2 Pa à 319 K respectivement dans le cas du 1,2-, 1,3- et 1,4-BDA). Compte tenu de ces faibles valeurs, nous avons admis l'identité $\Delta_{sub}H_m(T) \equiv \Delta_{sub}H^\circ_m(T)$

(*iii*) le diamètre des trous d'effusion pratiqués dans des joints en téflon de 0,2 mm d'épaisseur est de 1,5, 0,7 et 1 mm respectivement dans le cas du 1,2-, 1,3- et 1,4-BDA;

(*iv*) l'ouverture et la fermeture de l'orifice d'effusion des cellules sont pilotées par l'ordinateur;

(*v*) toutes les pesées ont été effectuées à l'aide d'une balance Mettler, type UM3.

L'acquisition et le traitement des données sont réalisés à l'aide d'un ordinateur et d'un programme conçu et mis au point au laboratoire. Il permet, entre autres, de déterminer l'aire des thermogrammes et, à partir du coefficient d'étalonnage, l'enthalpie de sublimation de nos composés à la température de l'expérience $\Delta_{sub}H^\circ_m(T)$.

2.2.4. Mesure des capacités calorifiques

Pour calculer $\Delta_{sub}H^\circ_m$ (298,15 K) à partir de $\Delta_{sub}H^\circ_m(T)$, il est

nécessaire de connaître : (*i*) le comportement thermique de nos substances entre 298,15 K et *T*. Nous nous sommes donc assurés que nos substances ne présentaient aucun changement de phase dans cet intervalle; (*ii*) la capacité calorifique à pression constante des phases condensée et gazeuse des substances étudiées à 298,15 K et *T* de façon à pouvoir appliquer la relation suivante :

$$\Delta_{sub}H^\circ_m(298{,}15\ \text{K}) = \Delta_{sub}H^\circ_m(T) + \int_T^{298{,}15\ \text{K}} [C^\circ_{p,m}(\text{g}) - C^\circ_{p,m}(\text{s})]\, dT$$

La différence enthalpique $H^\circ_m(T) - H^\circ_m(298{,}15\ \text{K})$ à l'état solide a été calculée par la méthode de chute à l'aide d'un calorimètre Tian–Calvet et d'un four maintenus respectivement à 298,15 K et *T*. Le calorimètre a été préalablement étalonné en utilisant des échantillons d'alumine-α.

Quant aux valeurs des capacités calorifiques à l'état gazeux $C^\circ_{p,m}(\text{g})$ et aux températures 298,15 K et *T*, elles ont été déterminées à partir d'une méthode incrémentale en utilisant, à chacune de ces deux températures, les capacités calorifiques à l'état gazeux des molécules de benzène et d'aniline (13). Ceci nous a permis, dans un premier temps et à chacune de ces deux températures, de déterminer la part du chaînon NH_2, puis, de calculer une valeur moyenne de $C^\circ_{p,m}$ pour les trois isomères du benzènediamine en ajoutant cette quantité au $C^\circ_{p,m}$ de l'aniline.

Les différents calorimètres et analyseur thermique, leurs périphériques ainsi que les balances sont placés dans des salles thermorégulées à (19,0 ± 0,2) °C.

3. Résultats

Les constantes physiques de nos composés sont résumées dans le tableau 1.

3.1. Analyse thermique différentielle

Les résultats obtenus ainsi que ceux qui sont empruntés à la littérature sont rassemblés dans le tableau 2. Notons que :

(*i*) Le 1,3-BDA reste en surfusion à température ambiante; d'où la nécessité de le recristalliser avant chaque expérience en l'abandonnant au réfrigérateur pendant une vingtaine de minutes.

(*ii*) Le 1,4-BDA prend une teinte bleutée après la première fusion et la conserve par la suite. L'analyse par diffraction de rayons X nous a permis de conclure à une très légère dénaturation.

(*iii*) Aucune des trois substances ne semble se décomposer de façon appréciable entre la température ambiante et son point de fusion.

Comme on peut le constater, à partir du tableau 2, si les valeurs relatives à la température du point triple sont peu différentes de celles de la référence 5, il n'en est pas de même pour les valeurs des enthalpies de fusion. À ce sujet, nous nous permettons d'émettre certaines critiques quant au mode opératoire adopté par les auteurs de cette référence. Tout d'abord, le type de cellule de travail utilisée (conçue en acier inoxydable et sertie d'un joint en aluminium) n'exclut pas toute possibilité de réaction avec l'échantillon à analyser. De plus, l'étalonnage du système calorimétrique a été réalisé par effet Joule dans des conditions qui diffèrent des conditions expérimentales. Enfin, la vitesse de montée en température utilisée est, à notre avis, trop élevée (2 K min^{-1}) lorsque l'on souhaite déterminer une enthalpie de fusion avec fiabilité.

3.2. Calorimétrie de combustion

L'équivalent énergétique du système calorimétrique (U_{calor}) a été déterminé à partir de neuf combustions d'acide benzoïque, échantillon 39i du N.I.S.T. pour lequel $\Delta_c u°$(cr, 298,15 K) = (−26 414 ± 3) J g^{-1} (16). Dans chaque expérience, nous avons utilisé environ 5 mg d'acide et 0,2 mg de coton (dont l'énergie de combustion, préalablement déterminée au laboratoire, a pour valeur $\Delta_c u°$(cr, 298,15 K) = (−16 399 ± 23) J g^{-1} (17)). Nous avons trouvé U_{calor} = (16,209 ± 0,006) J V^{-1} s^{-1}.

Les enthalpies standard de combustion de nos composés concernent la réaction suivante :

$$C_6H_8N_2(cr) + 8\ O_2(g) \rightarrow 6\ CO_2(g) + 4\ H_2O(l) + N_2(g)$$

et sont calculées, à l'aide d'un ordinateur et d'un programme écrit et mis au point au laboratoire, à partir de nos valeurs expérimentales en tenant compte des corrections dites de Washburn.

La combustion des trois isomères s'est révélée complète, aucune trace de cendre ne subsistant dans le corps de la bombe et dans le creuset une fois l'expérience terminée et les dosages par tubes colorimétriques de Dräger n'ayant révélé aucune présence de CO dans la phase gazeuse.

Les résultats relatifs à ces manipulations sont résumés dans le tableau 3.

Nous avons remarqué qu'environ 11% de l'azote contenu dans nos composés se trouvaient, à l'issue de la combustion, sous forme d'acide nitrique. L'expérience a montré que la quantité d'acide nitreux formé est excessivement faible et peut être négligée.

La comparaison de nos résultats avec les très rares données de la littérature montre un accord satisfaisant. En effet et comme nous pouvons le constater, nos valeurs expérimentales de l'enthalpie de combustion s'écartent d'environ ±0,2% des valeurs reportées dans la littérature pour les isomères *ortho* ((−3504,1 ± 4,2) kJ mol^{-1} (7)) et *para* ((−3509,3 ± 0,6) kJ mol^{-1} (6)). En revanche, le résultat obtenu pour le 1,3-BDA est parfaitement compatible avec celui de la référence 7 ((−3496,6 ± 4,2) kJ mol^{-1}). Signalons, au passage, que les résultats de la littérature ont été obtenus par calorimétrie de combustion classique.

	7,7744	91,41				

[a]1,2-BDA: T = 298,15 K; 1,3- et 1,4-BDA: T = 319 K.

3.3. Calorimétrie de sublimation et mesures des capacités calorifiques

Les enthalpies de sublimation de nos substances ainsi que les variations enthalpiques à l'état solide et gazeux entre 319 et 298,15 K sont consignées dans le tableau 4.

Il est à noter que nous n'avons trouvé dans la littérature aucune donnée relative aux enthalpies de sublimation et aux pressions de vapeur saturante de nos substances.

3.4. Enthalpie de formation à l'état gazeux

En utilisant les résultats expérimentaux obtenus par calorimétrie de combustion et de sublimation, nous avons calculé l'enthalpie molaire standard de formation à l'état gazeux de chacun des trois isomères. Celle-ci est égale à (92,0 ± 1,3) kJ mol^{-1}, (84,0 ± 1,4) kJ mol^{-1} et (88,7 ± 1,4) kJ mol^{-1} respectivement pour les isomères *ortho*, *méta* et *para*.

3.5. Enthalpie d'atomisation

À une température donnée, la réaction d'atomisation des BDA s'écrit :

$$C_6H_8N_2\ (g) \rightarrow 6\ C(g) + 8\ H(g) + 2\ N(g)$$

En conséquence, à 298,15 K, l'enthalpie liée à cette réaction est égale à :

$$\Delta_{a,exp}H°_m = 6\ \Delta_fH°_m\ [C(g)] + 8\ \Delta_fH°_m\ [H(g)] + 2\ \Delta_fH°_m[N(g)] - \Delta_fH°_m\ [C_6H_8N_2\ (g)]$$

Les valeurs de $\Delta_{a,exp}H°_m$(298,15 K) de nos substances (tableau 5) ont été calculées en utilisant les valeurs de $\Delta_fH°_m$(g, 298,15 K) de C, H et N consignées dans la référence 18 et qui valent respectivement (716,67 ± 0,44), (217,997 ± 0,006) et (472,68 ± 0,40) kJ mol^{-1}.

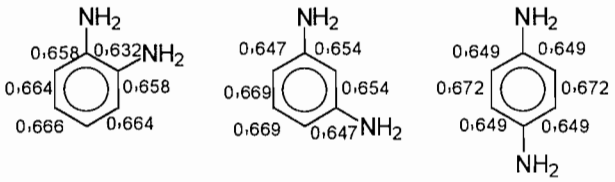
Tableau 5. Enthalpies d'atomisation expérimentales et calculées des trois isomères du BDA.

Isomère	$\Delta_{a,exp}H°_m$(298,15 K) (kJ mol^{-1})	$\Delta_{a,calc}H°_m$(298,15 K) (kJ mol^{-1})
1,2-BDA	6897,4 ± 1,9	6893,6
1,3-BDA	6905,4 ± 2,0	6893,1
1,4-BDA	6900,7 ± 2,0	6893,1

Dans le présent travail, l'incertitude qui accompagne les résultats expérimentaux représente l'écart moyen, $\sigma_m = \pm \{(x - x_0)^2 / n(n-1)\}^{1/2}$, x étant chacune des n valeurs entrant dans le calcul de la moyenne x_0. Lorsque la valeur expérimentale est fonction de plusieurs variables, l'incertitude calculée tient compte de l'erreur sur chacune de ces variables.

4. Discussion

4.1. Energie de conjugaison



L'énergie de conjugaison est la différence entre l'énergie réelle de la molécule et l'énergie qu'elle aurait si les divers systèmes insaturés qu'elle comporte étaient indépendants. Sur le plan pratique, pour la déterminer, il suffit d'utiliser les enthalpies standard de combustion à l'état gazeux de la molécule réelle et de la molécule fictive non conjuguée. La première de ces grandeurs s'obtient expérimentalement et la seconde nécessite le recours aux systématiques. En ce qui nous concerne, nous avons utilisé celle de Klages qui est consignée dans la référence 19.

© 1997 NRC Canada

Tableau 6. Energies de conjugaison expérimentales et théoriques des trois isomères du BDA.

Isomère	$E_{conj,exp}$ (kJ mol^{-1})	$E_{conj,théor}$ (kJ mol^{-1})
1,2-BDA	165,1	179,5
1,3-BDA	170,1	179,1
1,4-BDA	165,4	179,4

Fig. 1. Indices de liaison des trois isomères du BDA.

1,2-BDA 1,3-BDA 1,4-BDA

Nous avons également calculé l'énergie de conjugaison théorique à l'aide de la méthode de calcul indiquée dans la référence 20 et ce, en utilisant les paramètres suivants : $\alpha_N = \alpha + 2{,}250\ \beta_0$; $\beta_{(C\text{-}N)} = 0{,}750\ \beta_0$ (β_0 est l'intégrale de recouvrement de la molécule de benzène; elle est égale à 131,7 kJ mol^{-1}).

Les valeurs de l'énergie de conjugaison expérimentale et théorique (tableau 6) ainsi obtenues sont compatibles. Toutefois, nous pensons que le fait que les valeurs de l'énergie de conjugaison théorique soient supérieures aux valeurs expérimentales peut s'expliquer par un manque de planéité des molécules réelles.

4.2. Liaisons intramoléculaires dans les BDA

Par définition, l'enthalpie d'atomisation d'une molécule est égale à la somme des liaisons intramoléculaires compte tenu des facteurs de stabilisation et de déstabilisation. Pour retrouver, par le calcul, l'enthalpie d'atomisation de nos composés, nous avons tenu compte du principe de la transférabilité et avons utilisé, entre autres, les valeurs énergétiques des liaisons intramoléculaires préalablement déterminées au laboratoire.

Pour ce qui est des liaisons C_b—C_b du cycle benzénique, nous avons adopté le procédé de calcul consigné dans la référence 11. Celui-ci fait intervenir un paramètre lié à la géométrie de la molécule, l'indice de liaison l_{rs} entre deux atomes directement liés r et s, obtenu à partir du calcul théorique de l'énergie de conjugaison (fig.1). La relation reliant H_{rs} à l_{rs} s'écrit (H_{rs} / kJ mol^{-1}) = 246,0 l_{rs} + 342,6. Quant à H(C_b—H) et H(C_b—NH_2), nous avons respectivement utilisé les valeurs 415,88 (21) et 1102,37 kJ mol^{-1} (21)

Les valeurs ainsi calculées sont consignées dans le tableau 5 et sont en très bon accord avec les valeurs expérimentales (différence $\leq$ 0,18%).

4.3. Liaisons intermoléculaires dans les BDA

L'enthalpie de sublimation d'une substance organique est liée aux interactions intermoléculaires. Dans le cas des BDA, ces interactions sont du type van der Waals et concernent les forces de dispersion et d'interactions dipolaires. À côté de ces interactions, il existe aussi des liaisons hydrogène intermoléculaires. Il nous a donc paru intéressant de déterminer la part énergétique de chacune d'elles. Pour ce faire, nous avons appliqué un procédé de calcul déjà utilisé au laboratoire (22–27). Il consiste, dans notre cas, à déterminer la contribution énergétique des forces de dispersion (London) en considérant qu'elle est égale à l'enthalpie de sublimation des diméthylbenzènes, composés isoélectroniques des BDA.

À une température donnée (ici 298,15 K), la différence Δ_1 des enthalpies de sublimation des BDA et des diméthylbenzènes correspondants représente la somme des énergies d'interaction dipolaire et des liaisons hydrogène intermoléculaires (tableau 7).

Afin de déterminer la contribution énergétique des interactions dipolaires Δ_2, nous avons comparé les enthalpies de sublimation des dichlorobenzènes (composés isoélectroniques des BDA et des diméthylbenzènes, qui présentent un moment dipolaire mais ne forment pas de liaisons hydrogène intermoléculaires) à celles des diméthylbenzènes correspondants. Comme on peut le constater, celle-ci est faible.

La différence $\Delta_1 - \Delta_2$, soit 27,07 kJ mol^{-1}(en prenant la molécule de 1,4-BDA comme référence), représente la part énergétique pouvant être attribuée à la somme des liaisons hydrogène intermoléculaires mises en évidence par des études cristallographiques (8, 9). Étant donné qu'il ne se forme que deux ponts hydrogène par molécule de 1,4-BDA, l'enthalpie d'une liaison hydrogène peut être estimée à (27,07/2) = 13,54 kJ mol^{-1}. Cette valeur est compatible avec toutes celles qui ont été précédemment déterminées au laboratoire (22, 24–27).

4.4. Existence d'une liaison hydrogène intramoléculaire dans l'isomère *ortho*

Si nous comparons entre elles les valeurs des enthalpies de sublimation des isomères *ortho* et *para*, nous observons que la première est plus faible de 6,71 kJ mol^{-1}. Cette différence pourrait être attribuée au fait que le 1,2-BDA présente moins de liaisons hydrogène intermoléculaires que l'isomère *para* en raison d'une possible formation de liaison hydrogène intramoléculaire.

Bien que la seule référence 9 traitant de la structure de l'isomère *ortho* n'y fasse pas allusion, quelques observations faites sur les propriétés physico-chimiques des BDA laisseraient supposer l'existence de cette liaison hydrogène intramoléculaire dans ce composé :

1. L'isomère 1,2-BDA a pu être sublimé à 298,15 K alors que les deux autres isomères n'ont pu être étudiés, par calorimétrie de sublimation, qu'à 319 K. En conséquence, la pression de vapeur saturante du 1,2-BDA est plus forte que celle du 1,4-BDA.

2. La température du point triple et l'enthalpie de fusion, qui renseignent sur la force des liaisons intermoléculaires, sont plus élevées dans le cas de l'isomère *para* que dans celui de l'isomère *ortho*.

3. L'isomère *para* est soluble dans un solvant polaire tel que l'eau alors que l'isomère *ortho* peut être dissous dans un solvant apolaire comme le benzène (28). Ceci est dû au fait que la première molécule présente avec le solvant des associations intermoléculaires par liaisons hydrogène plus nombreuses que la seconde.

Comme il a été fait mention dans le cas de la molécule de 1,2-aminophénol (22*a*), on pourrait expliquer les quelques observations précédentes en supposant que les liaisons

Tableau 7. Comparaison des enthalpies de sublimation des BDA, diméthyl- et dichlorobenzènes.

	$\Delta_{sub}H°_m$(298,15 K) (kJ mol^{-1})		
	ortho	*méta*	*para*
di-NH_2 A	85,51	90,36	92,22
di-Cl B	64,35 (13, 31)	62,78 (13, 31)	65,15 (13, 31)
di-CH_3 C	59,82 (13, 31)	58,26 (13, 31)	60,18 (13, 31)
Δ_1 = A–C	25,69	32,10	32,04
Δ_2 = B–C	4,53	4,52	4,97
$\Delta = \Delta_1 - \Delta_2$	21,16	27,58	27,07

hydrogène intermoléculaires, qui associent les molécules par deux dans l'isomère *ortho*, soient suffisamment fortes pour qu'un certain nombre de ces molécules passe de l'état solide à l'état gazeux sous forme de dimères. Dans ce cas, l'enthalpie de sublimation de cet isomère ne tiendrait pas compte de toutes les liaisons hydrogène intermoléculaires et serait inférieure à l'enthalpie de sublimation de l'isomère *para* pour lequel seules des molécules monomères existent en phase gazeuse.

Enfin, il y a lieu de préciser que si elle existe, cette liaison hydrogène intramoléculaire est faible et du même ordre de grandeur que celles que l'on rencontre dans le cas du 1,2-dihydroxybenzène (6,63 kJ mol^{-1}) (24) et du 1,2-aminophénol (6,73 kJ mol^{-1}) (22a).

4.5. Calcul de l'enthalpie de sublimation du 1,4-BDA par voie incrémentale

Nous avons tenté de retrouver l'enthalpie de sublimation de l'isomère *para* à partir de valeurs incrémentales. Pour cela, nous avons déterminé la contribution du chaînon NH_2 en retranchant à la valeur de $\Delta_{sub}H°_m$(298,15 K) de la molécule d'aniline celle de la molécule de benzène. Ces dernières sont, en première approximation, calculées à partir de la relation :

$$\Delta_{sub}H°_m(298{,}15\ \text{K}) = \Delta_{fus}H_m(298{,}15\ \text{K}) + \Delta_{vap}H°_m(298{,}15\ \text{K})$$

où $\Delta_{fus}H$(298,15 K) est obtenue à l'aide de la règle de Sidgwick (29) :

$$\Delta_{fus}H_m(298{,}15\ \text{K}) = \Delta_{fus}H_m(T_{fus}) - 0{,}055\ (T_{fus} - 298{,}15\ \text{K})$$

Les valeurs relatives à la molécule de benzène sont empruntées aux références 30 et 31, celles correspondant à l'aniline aux références 32 et 33. Après calcul, nous trouvons que $\Delta_{sub}H°_m$(298,15 K) est égale à 44,86 kJ mol^{-1} et à 68,08 kJ mol^{-1} respectivement pour le benzène et l'aniline. La part du chaînon NH_2 est donc estimée à 23,22 kJ mol^{-1}.

Il s'ensuit que l'enthalpie de sublimation du 1,4-BDA, à 298,15 K, calculée en ajoutant à l'enthalpie de sublimation du benzène deux fois la contribution énergétique du chaînon NH_2 à cette température, est égale à 91,30 kJ mol^{-1}. Elle diffère seulement d'environ 1% de la valeur expérimentale.

Abstract: Electronic absorption spectra of 18 hydroxycoumarin derivatives and their ionized forms have been studied. Close agreement between experimental and the PPP CI calculated electron absorption band energies has been found in most cases. Strong polarization of the carbonyl function of the pyrone ring in the 7-hydroxycoumarin derivatives, H-bonding between the hydroxyl group and neighboring substituent in the *ortho*-substituted hydroxycoumarins, as well as their tautomeric transformations, have been suggested in the discussion of the electronic absorption spectra of the hydroxycoumarin derivatives. In accord also with calculational results, ionization of the hydroxyl function leads to a bathochromic shift of the longest-wavelength absorption bands in the spectra of 7-hydroxycoumarin derivatives. The ionization has no effect on the electronic absorption of the 4-hydroxycoumarin derivatives. Relative stabilities of the tautomeric forms of hydroxycoumarin derivatives and their ionized forms have also been compared by MNDO calculations.

Key words: hydroxycoumarins, intramolecular H-bonding, ionization, electronic absorption spectra, keto–enol tautomerism.

Résumé : On a étudié les spectres d'absorption électronique de 18 dérivés de l'hydroxycoumarine et de leurs formes ionisées. Dans la plupart des cas, il existe un bon accord entre les énergies expérimentales des bandes d'absorption électronique et celles calculés par la méthode «PPP CI». Dans la discussion des spectres d'absorption électronique des dérivés de l'hydroxycoumarine, on a suggéré l'existence d'une forte polarisation de la fonction carbonyle du cycle pyrone des dérivés 7-hydroxycoumarines, l'existence d'une liaison hydrogène entre le groupe hydroxyle et le substituant voisin des hydroxycoumarines substituées en *ortho*, ainsi que la possibilité de leurs transformations tautomériques. En accord encore une fois avec les résultats des calculs, la valeur de l'ionisation de la fonction hydroxyle conduit, dans les spectres des dérivés de la 7-hydroxycoumarine, à un déplacement bathochromique des bandes d'absorption aux longueurs d'onde les plus élevées. En se basant sur des calculs «MNDO», on a comparé les stabilités relatives des formes tautomériques des dérivés de l'hydroxycoumarine et de leurs formes ionisées.

Mots clés : hydroxycoumarines, liaison hydrogène intramoléculaire, ionisation, spectres d'absorption électronique, tautomérie céto–énolique.

Introduction

Natural hydroxycoumarins and their derivatives possess many remarkable properties. Some of these coumarins, viz, 7-hydroxycoumarins, are known for their high photosensitivity, lasing effect, and application as luminescent colorants for biosubstrates and fluorescent whiteners for polyester and polyamide fabrics (1, 2). Many oxygenated coumarins, e.g., 4-hydroxycoumarin derivatives, show marked biological activity, such as enzyme inhibition, hypotoxicity, and carcinogenicity, and anticoagulant and antibiotic action. Therefore, the electronic structure of hydroxycoumarins, including their UV light absorption ability, has become the subject of much interest (3–12).

A reasonable interpretation of the electronic absorption spectra of coumarin and 4-hydroxycoumarin has already been elaborated (6–9). Three long-wavelength absorption bands of coumarin have been assigned to the $\pi \rightarrow \pi^*$ transitions. The high intensity as well as solvent independence of these bands agree with this assignment. For example, the maximum positions of electronic absorption for the coumarin derivatives in ethanol are very close to those in cyclohexane (9). In accord with the $\pi \rightarrow \pi^*$ assignment, the long-wavelength bands have been accurately predicted by PPP CI calculations.

The first absorption band of coumarin belongs to the one-configurational transition, possessing 85% HOMO→LUMO participation (9). This transition is mostly localized on the carbon atoms of the benzene ring and the lactone ethylene

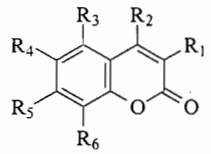
bond. The first band is polarized near the long axis of the coumarin molecule. The second spectral band is due to the (HOMO-1)→LUMO transition; the direction of its polarization is close to that of the first transition (the angle between directions is equal to 14°). The third band belongs to the transition between the HOMO and the (LUMO+1). The direction of polarization of this transition is very different from those of the first and the second transitions, as it is close to being perpendicular to the first transition moment (7).



Although these results have mainly been provided by quantum chemical calculations in the *p*-approximation, EHMO and CNDO calculations (where all valence atomic orbitals are included in the basis set) agree with the main conclusions (6, 7) .

The effect of the hydroxyl function on the electronic absorption spectra of coumarins has also been discussed (9, 10), even though some results seem to be rather controversial. Generally, the electronic absorption of a hydroxycoumarin depends on the hydroxyl group location. The hydroxyl function, which is located in position 4, changes the spectral properties of coumarin only slightly (6, 7). The angle between the first and second band transition moments decreases to 14°, while the third transition is also polarized in a direction perpendicular to the first and the second transitions.

The results of a study of the 7-hydroxycoumarin electronic absorption spectrum are not so definite (7–11). Since the longest-wavelength band is shifted in this spectrum to lower energy, its $\pi\rightarrow\pi^*$ assignment has been assumed. Abu-Eitah Rafie et al. suggested that the band at 370 nm is due to the first $\pi\rightarrow\pi^*$ transition in the electronic absorption spectrum of 7-hydroxycoumarin (10). However, this band can be assigned to the absorbance of its ionized form (4, 13). The appearance of this form cannot be excluded when electronic absorption spectra of hydroxycoumarins are recorded in basic and ionizing solvents. It is known that hydroxycoumarins are rather acidic and partly ionized even in the presence of water (13). The absorption of 7-hydroxycoumarin at 324 nm seems to be more reasonably assigned to the longest-wavelength $\pi\rightarrow\pi^*$ transition (10). Its bathochromic shift when compared to the coumarin absorption has been explained by charge transfer between the 7-hydroxyl function and the carbonyl group.

Electronic absorption spectra of substituted hydroxycoumarins have not yet been systematically studied. We have analyzed the electron absorption spectra of 18 substituted 4- and 7-hydroxycoumarins, studying the effect on the spectral properties of methyl, phenyl, acetyl, and hydroxyl functional groups as substituents. Analysis is based on quantum chemical calculations by the PPP CI method. The effect of intramolecular H-bonding on the electronic absorption of *ortho*-substituted hydroxycoumarins has been evaluated from the calculations. Electronic absorption spectra of ionized forms of substituted hydroxycoumarins have also been studied. The heats of formation, $\Delta H_f°$, of neutral and ionized forms of hydroxycoumarin derivatives have been calculated by the MNDO method.

The structures of the hydroxycoumarin derivatives studied are shown as follows (substituents R different from H are only listed for the compounds **2**–**18**):

1: R_1–R_6 = H;
2: R_2 = OH;
3: R_5 = OH;
4: R_2 = Me, R_5 = OH;
5: R_1 = Ph, R_5 = OH;
6: R_2 = Ph, R_5 = OH;
7: R_2 = Me, R_4 = OH;
8: R_2 = OH, R_4 = Me;
9: R_1 = C(O)Me, R_2 = OH;
10: R_1 = C(O)Me, R_2 = OH, R_4 = Me;
11: R_5 = OH, R_6 = C(O)Me;
12: R_2 = Me, R_5 = OH, R_6 = C(O)Me;
13: R_2 = R_3 = OH;
14: R_2 = R_5 = OH;
15: R_4 = R_5 = OH;
16: R_2 = Me, R_4 = R_5 = OH;
17: R_2=Me, R_5 = R_6 = OH;
18: R_4 = OMe, R_5 = OH.

Experimental section

Materials and UV spectra

Compounds **1**–**14** and **16** were synthesized by known procedures and purified by recrystallization. Their melting points (uncorrected) are in agreement with literature data and are listed in Table 1.

Electronic absorption spectra of neutral forms of hydroxycoumarin were recorded in 95% ethanol, at a concentration of 5.0×10^{-5} mol/L, using a Perkin–Elmer model 323 UV–VIS–IR spectrophotometer. Electronic absorption spectra of *ortho*-substituted hydroxycoumarins, where intramolecular H-bonding is possible, were also recorded in *n*-hexane and carbon tetrachloride. Electronic absorption spectra of the ionized forms of hydroxycoumarin were recorded in 95% ethanol mixed in 5-mL cuvettes with one drop of 10% NaOH aqueous solution. The experimental procedure of hydroxycoumarin derivative ionization was developed in accordance with previously published methods (13–16).

Methods of MO calculations

The Pariser–Parr–Pople CI method was used for quantum chemical calculations of the electronic absorption spectra in the *p*-approximation (17). The standard values of parameters only were used for the calculations of electronic absorption spectra of hydroxycoumarin derivatives in their neutral forms (17). Electronic absorption spectra of hydroxycoumarins in their ionized forms were calculated using both the standard parameter values of phenoxide oxygen and new parameters of the ionized OH group, which turned out to be in the best agreement with experimental data. All parameters of neutral, H-bonded, and ionized hydroxyl functions used are listed below:

	J, eV	*A*, eV
OH group, neutral	32.90	11.40
OH group, H-bonded	28.00	10.00
O^-, phenoxide oxygen standard parameters	17.70	2.47
O^- group (ionized OH group new parameters)	20.00	5.00

Standard parameters only were used in the MNDO calculations of heats of formation, $DH_f°$. Input atomic coordinates were evaluated via MMX calculations.

Results and discussion

Partial results of the PPP CI calculations of absorption spectra of the hydroxycoumarin derivatives are given in Tables 2 and 3. The calculated longest-wavelength band positions (and intensities), λ_{max} (lg ε), the frontier orbital energies, E_{HOMO} and E_{LUMO}, the frontier orbital transition participation, HOMO→LUMO, %, and the parameter $\beta_{C=O}$ values used are listed. We found good agreement between the experimental and calculated results in most cases. First of all, it was certainly true for the 4-hydroxycoumarin derivatives: the electronic absorption of 4-hydroxycoumarin itself is only slightly changed when compared with that of coumarin. The longest-wavelength band has 87% participation of the HOMO→LUMO transition in the spectrum of 4-hydroxycoumarin and 84% of that in the spectrum of coumarin. The electron density at the oxygen atom of the carbonyl group in 4-hydroxycoumarin is also, as is that of coumarin, greatly changed under UV excitation: the O(C=O) charge is equal to −0.36 in the ground state and to −0.06 in the first excited state. The decrease of electron density at the carbonyl group is in accord with its increase at the carbon–carbon double bond of the pyrone ring and carbon atoms of the benzene moiety. The corresponding data are listed in Table 2. The shapes of the frontier molecular orbitals and polarization directions of the first, second, and third transitions of compounds **1**–**3** are compared in Fig. 1.

On the whole, energies (and oscillator strengths) of the long-wavelength bands are rather close to previously published results (6, 7). However, the calculated directions of the electronic transition polarizations turned out to be somewhat different from those reported earlier. According to Moore et al. (7), both the first and second transition directions in the electronic absorption spectra of coumarin and 4-hydroxycoumarin are nearly parallel to the long axis of the molecules. The angles between their polarization directions are not higher than 16°. Our results show the first electronic transition polarization directions to be perpendicular to the long axis both for coumarin and 4-hydroxycoumarin (as can be seen in Fig. 1).

Fig. 1. Frontier orbital shapes and polarization directions of three π→π* transitions in coumarin **1**, 4-hydroxycoumarin **2**, and 7-hydroxycoumarin **3** predicted by the PPP CI calculations.

Moreover, the second transition has been found to be HOMO→(LUMO+1) and the third transition is due to (HOMO-1)→LUMO. This sequence is the reverse of that previously published (7).

The introduction of a methyl group into position 6 of 4-hydroxycoumarin does not change the electronic absorption spectrum parameters of the molecule. The longest-wavelength band positions, changes of electron densities on atoms under UV excitation, and polarization directions of the first bands are very close for both hydroxycoumarins **2** and **8**.

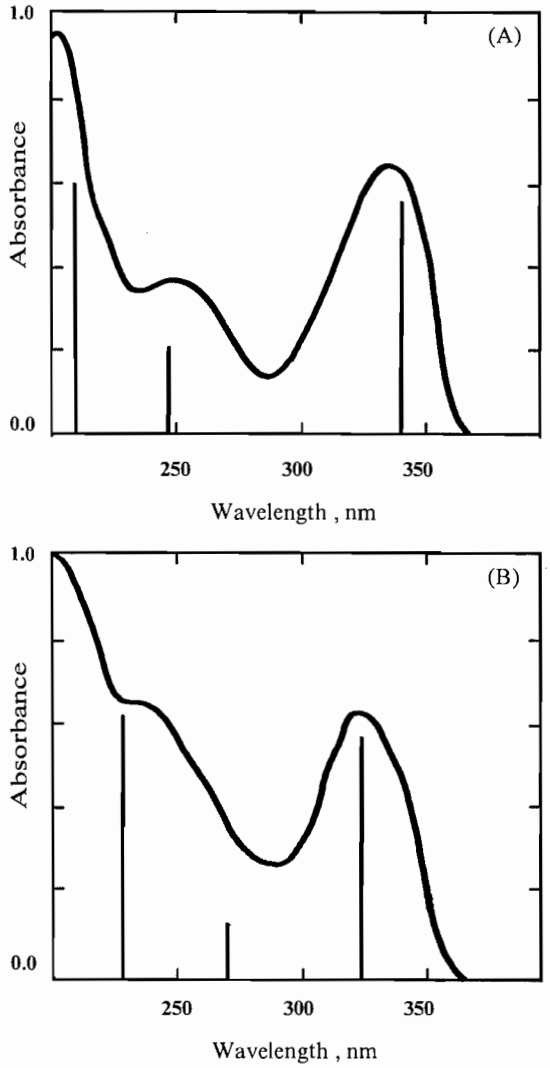
In contrast with the coumarin and 4-hydroxycoumarin derivatives, the standard value of the resonance integral $\beta_{C=O}$ = −2.46 eV does not provide satisfactory results in calculations of the electronic absorption spectra of 7-hydroxycoumarin derivatives. A strong intramolecular interaction between the 7-hydroxyl group and the carbonyl group (cf. resonance structure **3–1**) can be suggested as an explanation of this result. Significant participation of structure **3–1** in the *p*-electron delocalization of 7-hydroxycoumarin has already

3 − 1

λ_{max} (PPP)=322 nm

been suggested (10, 20). However, the specificity of intramolecular charge transfer beween the 7-hydroxyl group and the carbonyl function of the lactone ring has never been analyzed in terms of parameterization of the PPP quantum chemical calculations.

We have approximated the decrease of covalence of the carbonyl group in 7-hydroxycoumarins by changing the resonance integral $\beta_{C=O}$ from the standard value of −2.46 eV to a value of −2.0 eV. In Table 2 one can see better agreement between the 7-hydroxycoumarin experimental data and the results calculated with this value of the resonance integral $\beta_{C=O}$. Since the longest-wavelength band is mostly due to the excitation of electrons between the frontier orbitals of hydroxycoumarins, the increase in energy of the highest occupied molecular orbital, equal to 0.42 eV, seems to be responsible for the observed bathochromic shift of the first absorption band of 7-hydroxycoumarin. The increase in energy of the LUMO is much smaller and equal to 0.12 eV. It should also be mentioned that the HOMO has a rather large value of the eigencoefficient at position 7.



One should note that the bathochromic shift of the 7-hydroxycoumarin electronic absorption is much larger than that of coumarin; the intensive long-wavelength bands in the benzene and phenol EA spectra are located at 203 and 210 nm, respectively.

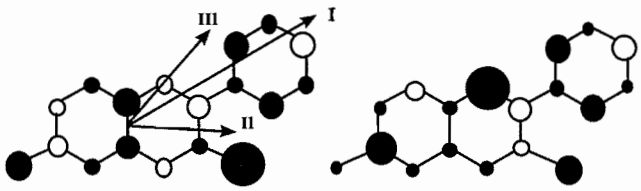
As shown in Fig. 1, the HOMO→LUMO transition character (88% participation) of the first electronic transition of 7-hydroxycoumarin and the direction of its polarization are rather close to those of coumarin and 4-hydroxycoumarin. The second electronic transition direction is nearly parallel to the long axis of the molecule.

As in the series of 4-hydroxycoumarins, introduction of a methyl group into position 4 of 7-hydroxycoumarin has no effect on the parameters of the electronic absorption spectra. According to the PPP calculations, a methyl group slightly increases the energies of both the HOMO and the LUMO.

On the other hand, the effect of a phenyl group on electronic transitions in the 7-hydroxycoumarins is much larger. Electronic absorption spectra of the 3- and 4-phenyl-7-hydroxy-

Fig. 2. Electron absorption spectra of 7-hydroxy-3-phenylcoumarin **5** (curve *A*) and 7-hydroxy-4-phenylcoumarin **6** (curve *B*) in ethanol. The PPP CI calculated band positions λ_{max} and oscillator strengths *f* are indicated by the vertical lines.

coumarins are compared in Fig. 2 (curves *A* and *B*, respectively). Comparison of the experimental and calculated electronic absorption data is also shown. On the whole, the introduction of a phenyl group leads to extension of the *p*-conjugated system and provides definite bathochromic shifts of the first absorption bands, of 18 and 8 nm, respectively. Since these bands are still based on one-configurational transitions, their bathochromic shifts in both spectra are due to the corresponding changes of the frontier orbital energies: the increase of the HOMO energies, 0.2 and 0.11 eV, and the decrease of the LUMO energies, 0.23 and 0.33 eV, for 3- and 4-phenyl-7-hydroxycoumarins, respectively. The phenyl group in position 3 has no noticeable effect on the polarization of the first band of 7-hydroxycoumarin. As can be seen from the diagrams given in Fig. 3, electron densities on the carbon atoms of the phenyl ring are not much changed under the first electronic excitation in compound **5**.



The introduction of a phenyl group in position 4 of umbel-

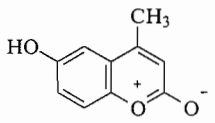
HOMO LUMO

7-Hydroxy-4-phenylcoumarin **6**

HOMO LUMO



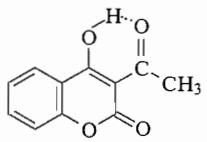
lyferone affects the electronic transition parameters to a larger extent. It changes the direction of polarization of the first electronic transition due to definite changes of electron densities on the phenyl-substituted carbon atoms under UV excitation. Shapes of the frontier molecular orbitals of compound **6** are also shown in Fig. 3.

A hydroxyl group in position 6 of coumarin provides an even larger bathochromic shift in the electronic absorption spectrum of 6-hydroxycoumarin when compared with that of 7-hydroxycoumarin. One can note the higher transfer of electron density from the hydroxyl group located at position 6 under UV excitation and the maximal value of the HOMO eigencoefficient at that position in the 6-hydroxycoumarin molecule. Better agreement between experimental data and calculated results can be seen when higher electron donation of the position-6 hydroxyl group has been taken into consideration via parameterization of the PPP calculations (see Table 2):

	J, eV	*A*, eV
OH-group, increased electron-donation parameters	28.00	10.00

This suggestion is in accord with a partial positive charge located at the lactone oxygen atom, in *para*-position to the hydroxyl group in compound **7** as seen in the resonance form **7–1**.

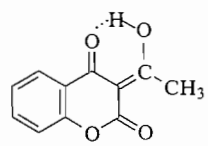
Electronic absorption spectra of *ortho*-acetylhydroxycoumarins have never been discussed. Absorption spectra of neutral forms of 8-acetyl-7-hydroxycoumarin and 3-acetyl-4-hydroxycoumarin are shown in Fig. 4. The bathochromic shifts of the first absorption bands in spectra of both 4-hydroxycoumarin and 7-hydroxycoumarin acetyl derivatives, recorded in ethanol, are about 12–13 nm when compared with unsubstituted 4- and 7-hydroxycoumarins, respectively. In accordance with the calculated results, a carbonyl function adjacent to a hydroxyl group in hydroxycoumarin derivatives does not change the nature of the longest-wavelength band. This band continues to be due to the frontier orbital electronic transition.



7 – 1

λ_{max} (PPP)=341 nm

H-Bonding between neighboring carbonyl and hydroxyl functions may be at least partly responsible for the bathochromic shifts mentioned. H-Bonding effects were approximated as an electrostatic interaction between the corresponding functional groups in previous quantum chemical calculations (21). Some attempts were also made to account for H-bonding effects in the PPP calculations (17). We carried out PPP CI calculations of the electronic absorption spectra of compounds **9–12** with the standard "H-bonded" parameters given above (see Experimental section). These parameters provide better agreement between the experimental data and the calculational results for all *ortho*-acetyl substituted hydroxycoumarins **9–12** (the corresponding data are compared in Table 3).



3-Acetyl-4-hydroxycoumarins **9**, **10** and 8-acetyl-7-hydroxycoumarins **11**, **12** turned out to be very different in respect to the solvent effect on their electronic absorption spectra. As can be seen in Fig. 4, absorption curves of 3-acetyl-4-hydroxycoumarin recorded in ethanol – carbon tetrachloride mixtures show an isobestic point. Tautomeric transformations of compound **9** are suggested in explanation, since none of these solvents can provide ionization of the hydroxyl function at position 4 of the coumarin ring.

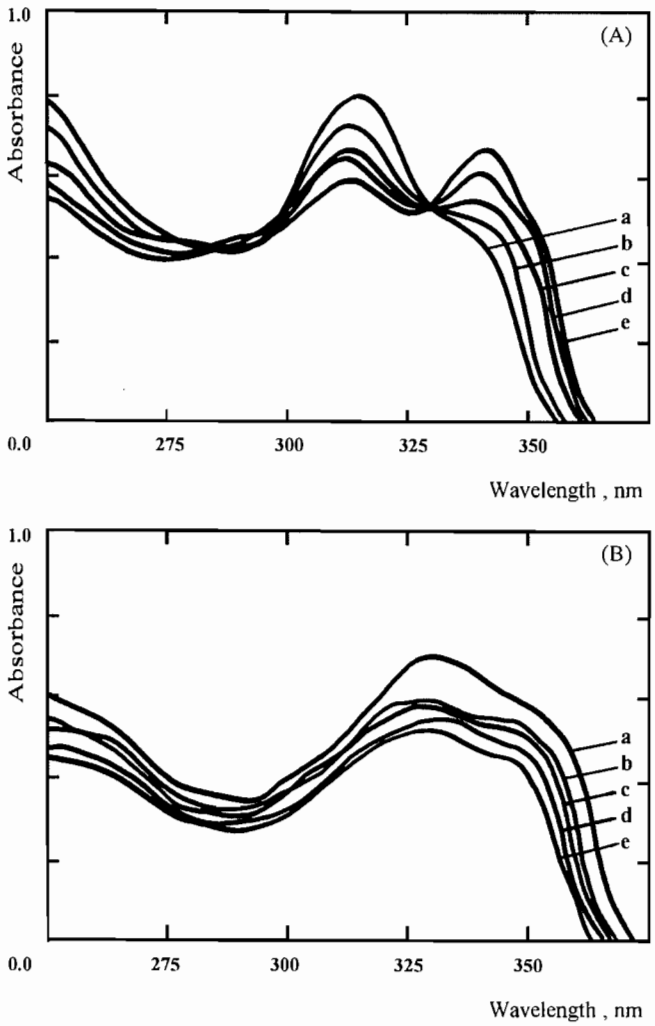
9 – 1

ΔH_f°(MNDO)= – 124.5 kcal/mol

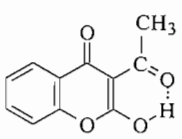
λ_{max} (PPP)=341 nm

9 – 2

ΔH_f°(MNDO)= – 122.9 kcal/mol



λ_{max} (PPP)=318 nm



Compound **9** can be considered to exist in the following tautomeric forms: **9-1**, **9-2**, **9-3**, **9-4**, and **9-5**. According to MNDO calculational results, forms **9-4** and **9-5** are distinguished by rather large heats of formation ΔH_f°. As a result, these structures do not seem to participate strongly in the electronic absorption of the neutral form of compound **9**. According to both the PPP CI calculated longest-wavelength band positions and the MNDO calculated heats of formation, the 3-acetyl-4-hydroxycoumarin H-bonded form **9-1** can be suggested to be predominant in nonpolar solvents (carbon tetrachloride, *n*-hexane). On the other hand, for the enol form of

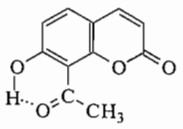
Fig. 5. Frontier orbital shapes and polarization directions of three $\pi \rightarrow \pi^*$ transitions in 3-acetyl-4-hydroxycoumarin **9** and 8-acetyl-7-hydroxycoumarin **11** predicted by the PPP CI calculations.

3-acetyl-2,4-chromandione, **9-2**, the calculated results are in better agreement with the electronic absorption spectrum of compound **9** recorded in a polar solvent, such as ethanol, even though the form **9-2** and 3-acetyl-2-hydroxy-4-chromenone form **9-3** are rather close in their MNDO-calculated ΔH_f° values.

The 2,4-chromandione tautomeric forms (similar to **9-2** and **9-4**) have often been discussed in the study of keto–enol tautomerism of 4-hydroxycoumarin derivatives. Some of the 2,4-chromandione derivatives have been found as reactive intermediates (22–24). Other derivatives have even been isolated as stable final structures (25, 26).

Predominance of the form **9-1** in nonpolar solvents is worthy of additional comment, since according to both the MNDO and PPP calculations this form is more polar than the form **9-2**: e.g., the PPP-calculated dipole moment values of these two forms are 5.58 and 3.3 D, respectively. The relative stability of form **9-1** seems to be due to its stronger intramolecular H-bonding than that of form **9-2**. Nonpolar solvents, e.g., *n*-hexane and carbon tetrachloride, do not affect intramolecular H-bonds, accounting for the predominance of form **9-1**.



No notable changes in the electronic absorption spectra of compound **11** can be seen when these spectra are recorded in nonpolar and polar solvents (Fig. 4). PPP CI calculational results for the 8-acetyl-7-hydroxy-2-chromenone form **11-1** are in good agreement with the experimental spectra. The enol structure **11-2** of 8-acetyl-7-hydroxycoumarin **11** turned out to be invalid according to both the MNDO-calculated heat of formation data and the PPP CI-calculated longest-wavelength absorption band positions.

The differences between *ortho*-acetyl-substituted 4- and 7-hydroxycoumarins can also be seen from the calculational results. The shapes of the frontier molecular orbitals of compounds **9** and **11** are shown in Fig. 5. The minimal value of the

negative charge on the acetyl oxygen atom in compound **11** (structure **11-1**) agrees well with a weakness of the H-bond

11–1

ΔH_f^o(MNDO)= – 125.9 kcal/mol

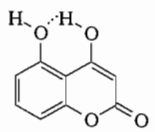
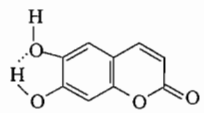
11–2

ΔH_f^o(MNDO)= – 107.6 kcal/mol



λ_{max} (PPP)=430 nm

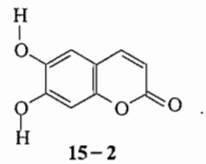
between the hydroxyl and carbonyl functions in the 7-hydroxycoumarin derivatives. On the other hand, high negative charge on the acetyl oxygen atom in compound **9** (structure **9-1**) supports the suggestion concerning the strong intramolecular H-bonding in the 4-hydroxycoumarin derivatives, **9** and **10**.



Intramolecular H bonding increases significantly changes of electron density on the hydroxyl oxygen atoms under UV excitation. According to the calculational results, an H-bonded hydroxyl function provides a stronger electron donation along the first electron transition than does a free hydroxyl group (the corresponding data are given in Table 4). Increase of electron donation of the oxygen atom of the hydroxyl function via H-bonding (or ionization, see further discussion) seems to be one of the reasons for the recorded bathochromic shifts of the longest-wavelength bands in electronic absorption spectra of *ortho*-hydroxyl- and *ortho*-acetyl-substituted hydroxycoumarins. Increased electron donation of the H-bonded hydroxyl function is evident from comparison of parameter values of free, H-bonded, and ionized hydroxyl groups. As seen in the Experimental section, parameters J and A of the H-bonded hydroxyl function are intermediate in value between those of the neutral and ionized forms.

The differences between the 3-substituted 4-hydroxycoumarins and the 8-substituted 7-hydroxycoumarins can also be illustrated by their reactivity. While studying ionization phenomena of some hydroxycoumarin derivatives, we found that introduction of an acetyl group into position 8 of 7-hydroxycoumarin increases the ionization constant K_{ion} due to stabilization of the resulting conjugate base by the electron-withdrawing effect of the acetyl function (compare compounds **3** and **11**). On the other hand, introduction of an acetyl group into position 3 definitely decreases the ionization potential of the 4-hydroxycoumarins.[2] These data can be explained by the acetyl group in position 3 transforming the corresponding 4-hydroxycoumarin derivative to another tautomeric form, which seems to be characterized by a different ionization potential. In such cases, comparison of the ionization constants of compounds **2** and **9** becomes meaningless.

PPP CI calculations with standard parameters also provide a good representation of energies and intensities of the longest-wavelength bands in the electronic absorption spectra of some dihydroxycoumarins. We refer, first of all, to the electronic absorption experimental data and calculated results for 4,7-dihydroxycoumarin **14** (these data are also listed in Table 2). The differences between experimental and calculated data become larger for the dihydroxycoumarins **13**, **15**, and **16**, which have neighboring hydroxyl functions: e.g., the differences between the experimental data and the calculated longest-wavelength band positions in the 6,7-dihydroxycoumarin electronic absorption spectra are 13–15 nm. H-Bonding between neighboring hydroxyl groups can be suggested as a structural effect that is responsible for the observed discrepancy. The corresponding structures **13-1**, **15-1**, and **17-1** are listed below.



13–1

15–1

17–2

ΔH_f^o(MNDO)= – 134.4 kcal/mol

λ_{max} (PPP)=316 nm

We have found that the H-bonded 6-hydroxyl group model (structure **15-1**) provides the best agreement between experimental and calculated electronic transition energies of 6,7-dihydroxycoumarin when those of the non-H-bonded hydroxyl group model (structure **15-2**) and those of the H-bonded 7-hydroxyl group model are compared. Significantly different acidities of the hydroxyl functions located at different positions of the coumarin ring are in accord with these results. The 7-hydroxyl group is known to be much more acidic than the 6-hydroxyl group (pK_a values of the 7- and 6-hydroxycoumarins are 7.45 and 9.05, respectively (9)).

The same is true for 6,7-dihydroxy-4-methylcoumarin **16** and 7,8-dihydroxy-4-methylcoumarin **17**. For example, electronic transition energies calculated for the structure **17-1** (hydroxyl group at position 8 is H-bonded) are in better agreement with the experimental data than the results calculated for the structure in which the hydroxyl group at position 7 is H-bonded, and the structure **17-2** (where no H-bonds are possible at all).

The preference for structures **15-1** and **17-1** compared with structures **15-2** and **17-2** has also been confirmed by MNDO

[2] We have measured the K_{ion} values of compounds **3** and **11** using piperidine as a base, and of compounds **2** and **9** using imidazole as a base. These values are given below (compound number and the K_{ion} value are listed): **3**, 0.030; **11**, 0.064; **2**, 0.94; **9**, 0.22. These data will be published in detail elsewhere (for a preliminary report, see ref. 27).

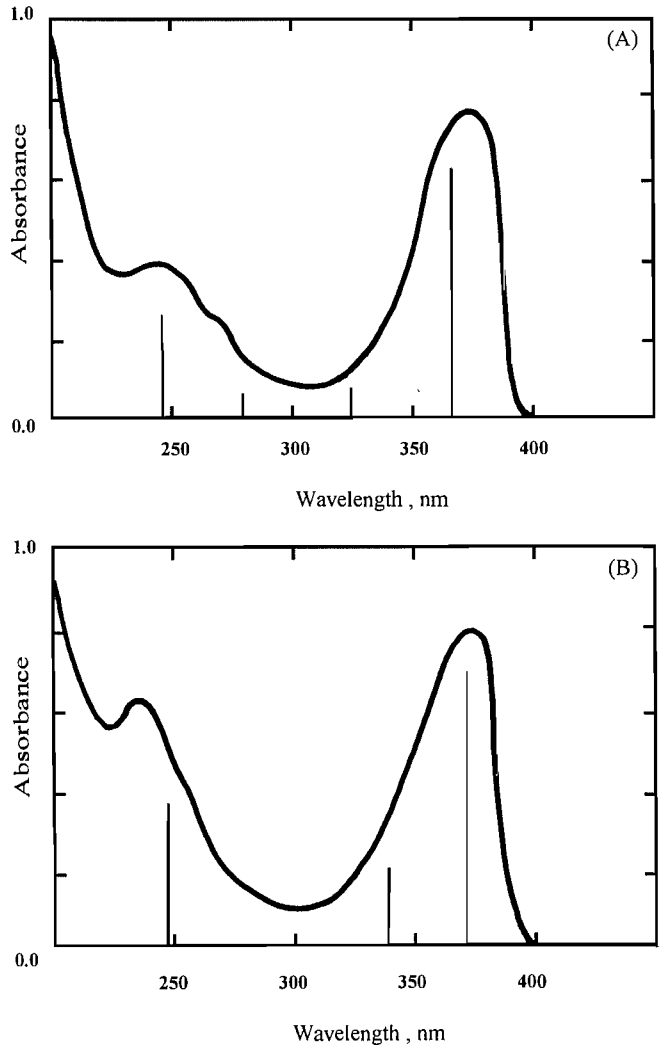
16-1	−0.0310	−0.0700	−0.0900

calculations (the heats of formation $\Delta H_f°$ are given under the formulas): H-bonded structures **15-1** and **17-1** turned out to be 1–2 kcal/mol more stable.

The hypothesis of H-bonding in *ortho*-dihydroxycoumarins is supported by good agreement between the calculated and experimental electronic absorption spectra of 7-hydroxy-6-methoxycoumarin **18**: the H-bonded methoxyl group (structure **18-1**) is used in the calculations, since H-bonding of the 7-hydroxyl group in this compound is impossible (see data in Table 2 for illustration).



18 – 1

In previous studies electronic absorption spectra of ionized forms of hydroxycoumarin were mostly used for analytical purposes (14–16). Only a few reports discuss the absorption spectra of the ionized forms in a quantitative way (4, 28). Perel'son has calculated these spectra by the Hückel MO method and suggested that the decrease of parameter *d* under ionization of the hydroxyl function is due to the corresponding increase of its electron donation (4). Chatterjee and Douglas analyzed a dependence of the PPP calculational results on the resonance integral *b*, ionization potential *J*, and electron affinity *A* parameters (28). The parameters *J* were found to be the most effective in providing good agreement between the experimental data and the calculated results. On the other hand, resonance integral *b* changes show no significant effect.

We have also recorded electronic absorption spectra of hydroxycoumarin derivatives in their ionized forms. These spectra are partly shown in Figs. 6 and 7. On the whole, better agreement between the experimental data and the calculated results was found when the standard parameters of phenoxide oxygen atom were changed for the new parameters (see Experimental section and Table 5 data). First, this is true for the 7-hydroxycoumarin derivatives, which show excellent agreement of the experimental and calculated longest-wavelength band positions. One can see that ionization of the 7-hydroxycoumarin derivatives leads to a significant bathochromic shift of the longest-wavelength absorption bands (compare spectra given in Fig. 6 as an example). This shift is due to an increase in electron donation of the hydroxyl function upon ionization. The phenoxide-like ionized form is a result of ionization of the 7-hydroxycoumarin derivative. The ionization leads to a significant increase of HOMO energy in 7-hydroxycoumarins (compare also Table 4 data) and thus to bathochromic band shifts in their electronic absorption spectra.

Fig. 6. Electronic absorption spectra of 7-hydroxycoumarin **3** (curve *A*) and 8-acetyl-7-hydroxycoumarin **11** (cruve *B*) ionized forms in ethanol. The PPP CI calculated band positions λ_{max} and oscillator strengths *f* are indicated by the vertical lines (parameters used: J_{O^-} = 20.0 eV, A_{O^-} = 5.0 eV, $\beta_{C=O}$ = −2.00 eV).

On the other hand, ionization of the hydroxyl function

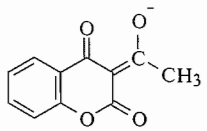
For personal use only.

© 1997 NRC Canada

located at position 4 has no significant effect on the electronic absorption spectra of the monohydroxycoumarin derivatives (compare data in Tables 2 and 5). 4-Hydroxycoumarin and 4-hydroxy-6-methylcoumarin have no shifts of their longest-wavelength bands in the EA spectra under ionization, although the eventual direction of polarization of the corresponding transitions turned out to be definitely different. Moreover, parameters of the negatively charged oxygen atom (which are well suited for calculations of the phenoxide-like ionized form of 7-hydroxycoumarin) seem to be unsuccessful for the ionized form of 4-hydroxycoumarin as can be seen from the data in Table 5. 4-Hydroxy-2-chromenone seems to undergo a tautomeric transformation under ionization (see more detailed discussion below).

The ionized form of 8-acetyl-7-hydroxycoumarin has an electronic absorption spectrum that is very similar to the spectrum of the ionized form of 7-hydroxycoumarin (these spectra are compared in Fig. 6). This similarity supports the assumption that H-bonding is responsible for the bathochromic shifts in the electronic absorption spectra of neutral forms of 7-hydroxycoumarins **11** and **12**. As a whole, the PPP CI calculated results provide a good approximation of the electronic absorption spectra of 7-hydroxycoumarin derivatives in both their ionized and neutral forms. The 8-acetyl-7-hydroxycoumarins **11** and **12** do not show any tautomeric transformations under ionization, and the ionized form of structure **11-1** seems to be a good model for the ionization phenomena of these 7-hydroxycoumarins.



It is not surprising that calculational results of the ionized form of 3-acetyl-4-hydroxycoumarin (obtained with both standard and new atomic parameters for phenoxide oxygen) are not close to the experimental electronic absorption spectrum data (see Fig. 7). Effective delocalization of negative charge in the ionized form of 3-acetyl-4-hydroxycoumarin can be suggested as an explanation. As seen from the MNDO calculated heats of formation, ΔH_f° (values given below the structure numbers), the enolate ion forms **9i-1** and **9i-2**, as well as the carbanion form **9i-4**, seem to be almost equivalent in their stabilities. The 3-acetyl-2-hydroxy-4-chromenone ionized form **9i-3** and the enolate ion form **9i-5** are the least stable ones. On the whole, the structure of the enolate ion form **9i-2** appears to be the form most fitted to the experimental data and the calculational results, even though participation of the carbanion form **9i-4** in electronic absorption cannot reliably be evaluated by the PPP CI calculations due to lack of parameters for the negatively charged carbon atom.

It is quite reasonable that ionization of both 3- and 4-phenyl-substituted 7-hydroxycoumarins **5** and **6** does not remove the bathochromic shift that is seen in the absorption spectra of their neutral forms (when compared with 7-hydroxycoumarin itself), since intramolecular H-bonding has no effect on their neutral molecules.

It is worth noting that electronic absorption spectra of ionized forms of the dihydroxycoumarin derivatives are also in good accord with the calculational results. Ionization of both hydroxyl groups was assumed in the PPP CI calculations. The largest bathochromic shift (about 65 nm) was recorded in the electronic absorption spectrum of the ionized form of 4,5-dihydroxycoumarin. The ionization of two hydroxyl groups in this compound increases the HOMO energy and does not appreciably change the LUMO energy of this molecule.

On the other hand, ionization of two hydroxyl functions in the 4,7-dihydroxycoumarin increases both the HOMO and the LUMO energies and thus provides a rather small bathochromic shift, about 13 nm.

Conclusions

Electronic absorption spectra of hydroxycoumarins depend on the location of the hydroxyl function, its intramolecular H-bonding with a neighboring substituent, and ionization via interaction of hydroxycoumarin with a base.

7-Hydroxycoumarin and its methyl-, phenyl-, hydroxyl-, and acetyl-substituted derivatives exist in the 2-chromenone tautomeric form both in polar (ethanol) and in nonpolar (carbon tetrachloride and *n*-hexane) solvents. Ionization of these derivatives yields phenoxide-like ionized forms. The following parameters of the negatively charged oxygen atom (J = 20.0 eV, A = 5.00 eV) and resonance integral $\beta_{C=O}$ equal to −2.00 eV provide close agreement between the calculated and experimental electronic absorption spectral data.

3-Acetyl-4-hydroxycoumarins exist in the 4-hydroxy-2-chromenone tautomeric form in nonpolar solvents. The 2,4-chromandione enol form of this compound seems to be predominant in polar solvents. Ionization of 4-hydroxycoumarin derivatives seems to lead to their transformation to the 2,4-chromandione ionized forms.

H-Bonding of the hydroxyl function and its ionization produce a bathochromic shift of the longest-wavelength bands in the electronic absorption spectra of substituted hydroxycoumarins due to an increase of its electron donation under UV excitation.

Keto–enol tautomerism, NMR spectra, and H–D exchange of 4-hydroxycoumarins

Valery F. Traven, Vadim V. Negrebetsky, Larisa I. Vorobjeva, and Edward Andrew Carberry

Abstract: 4-Hydroxycoumarin **1**, 4,5-dihydroxycoumarin **2**, and 4,7-dihydroxycoumarin **3** undergo H–D exchange at the C(3) atom of the lactone ring. Although only the 4-hydroxy-2-chromenone tautomeric forms are seen in the ^{1}H and ^{13}C NMR spectra of compounds **1–3**, the equilibrium between the 4-hydroxy-2-chromenone and 2,4-chromandione forms is suggested to be the key step in the H–D exchange reaction. 4,5-Dihydroxycoumarin shows the highest rate of the reaction, since H-bonding between 5-hydroxyl and 4-keto functional groups can provide relative stability to the 5-hydroxy-2,4-chromandione tautomeric form, a probable intermediate of the exchange. NMR spectra and tautomeric transformations of 3-(4-methoxyphenylazo)-4-hydroxycoumarin **4** and 3-acetyl-4-hydroxycoumarin **5** are also discussed. The stabilities of different tautomeric forms of compounds **1–5** have been evaluated by MNDO calculations.

Key words: 4-hydroxycoumarin derivatives, keto-enol tautomerism, H–D-exchange.

Résumé : Les 4-hydroxycoumarine (**1**), 4,5-dihydroxycoumarine (**2**) et 4,7-dihydroxycoumarine (**3**) subissent un échange H–D au niveau de l'atome C(3) du noyau lactonique. Même si on n'observe que les formes tautomériques 4-hydroxychrom-2-énones dans les spectres RMN ^{1}H et ^{13}C des composés **1–3**, on est porté à croire que l'existence d'un équilibre entre les formes 4-hydroxychrom-2-énone et chromane-2,4-dione est l'étape clé dans la réaction d'échange H–D. La 4,5-dihydroxycoumarine présente la vitesse de réaction la plus élevée; ce résultat découle probablement de l'existence d'une liaison hydrogène entre les groupes fontionnels 5-hydroxyle et 4-céto qui fournit une stabilité relative accrue à la forme tautomérique 5-hydroxychromane-2,4-dione, l'intermédiaire probable de l'échange. On discute aussi des spectres RMN et des transformations tautomériques des 3-(4-méthoxyphénylazo)-4-hydroxycoumarine (**4**) et 3-acétyl-4-hydroxycoumarine (**5**). On a évalué les stabilités des diverses formes tautomériques des composés **1–5** par le biais de calculs «MNDO».

Mots clés : dérivés de la 4-hydroxycoumarine, tautomérie céto-énolique, échange H–D.

[Traduit par la rédaction]

Introduction

Natural hydroxycoumarins are of great interest, since many of them show prominent biological activity (1, 2). Some 3-substituted 4-hydroxycoumarins are the most effective anticoagulant drugs known for prevention and treatment of thromboembolic disorders (3–5). It has been suggested that enol–keto tautomeric transformations of the 4-hydroxycoumarin moiety are responsible for that activity. The 2,4-chromandione form has been proposed to react with nucleophilic centers of the enzyme Vitamin K Epoxide Reductase, thus inhibiting the Vitamin K – Vitamin K Epoxide cycle that provides the prothrombin synthesis (5).

The following tautomeric forms of 4-hydroxycoumarin **1** and its derivatives have been discussed in most earlier studies: 4-hydroxy-2-chromenone **1***a*, 2.4-chromandione **1***b*, and 2-hydroxy-4-chromenone **1***c*. The possible transformations of these forms have been intensively examined by different methods. Some of the conclusions were based on chemical reactivity data (6–14). Arndt et al. have suggested the existence of the forms **1***a* and **1***c* under treatment of 4-hydroxycoumarin by CH_2N_2 (6). The 2,4-chromandione form **1***b* (an ionized state) has been suggested as an intermediate in the 4-acetoxycoumarin rearrangement to 3-acetyl-4-hydroxycoumarin (7). 3-Substituted 2,4-chromandione forms have also been suggested as intermediates in the 1,2-addition of α,β-unsaturated aldehydes to 4-hydroxycoumarin (10). Treatment of 3,3′-alkylidene-4,4′-dihydroxybis(coumarins) with $NaBH_3CN$ in refluxing methanol has been suggested to lead to the formation of 3-alkylidene-2,4-chromandiones as intermediates. These intermediates have been trapped using hydride ion in several reactions with dienes and dienophiles (11, 12).

Although 2,4-chromandione **1***b* has never been isolated as a stable product or as an intermediate, 3,3′-disubstituted 2,4-chromandiones have been shown to be stable final products in some reactions. For example, 3,3′-dialkyl-2,4-chromandiones have been prepared under treatment of the silver salt of 4-hydroxycoumarin by alkyl halides (8). Also, 3-arylhydrazono-2,4-chromandiones were found to be stable products of the

1*a* - **5***a* **1***b* - **5***b* **1***c* -**5***c*

azo-coupling reaction between 4-hydroxycoumarin and arene diazonium compounds (14).

Tautomeric transformations of 4-hydroxycoumarins have also been studied by spectroscopic and calculational methods (15–24). Knobloch et al. studied the electronic absorption spectra of 4-hydroxycoumarin and reported the existence of both tautomeric forms 4-hydroxy-2-chromenone **1***a* and 2-hydroxy-4-chromenone **1***c* (15). Wolfbeis and Uray concluded that the fluorescence spectra of 4-hydroxycoumarin derivatives show the predominance of the tautomeric form **1***c* (16).

Experimental section

Compounds **1**–**6** were synthesized by known procedures and purified by recrystallization from ethanol or acetic acid. Their melting points (uncorrected, in °C) are given below (reference data are shown in parentheses): **1**, 216–218 (217–218 (25)); **2**, 216–218 (218–219 (26)); **3**, 273–274 (274–275 (27)); **4**, 236–237 (236 (14)); **5**, 136–137 (137–139 (28)); **6**, 125 (125 (6)).

^{1}H and ^{13}C NMR spectra were recorded on a Bruker NMR spectrometer (200 MHz); DMSO-d_6 and methanol-d_4 were used as solvents. The ^{13}C NMR spectra of compounds **4** and **5** were not recorded in methanol-d_4 due to their low solubility.

The H–D exchange reactions were studied by measurement of the intensity of the H(3) signal in the corresponding 4-hydroxycoumarin ^{1}H NMR spectra at room temperature. Methanol-d_4 was used as solvent in reactions of compounds **1**–**3** and **6**. An acetonitrile-d_3 – methanol-d_4 mixture (3:1 ratio) was used in measurements of the reaction rate of compound **4** because of the compound's low solubility in pure methanol-d_4. Measured concentrations were treated by the first-order reaction law; the accuracy of measurement of the H–D exchange rate constant was equal to 10%.

Quantum chemical calculations were done by the MNDO method using standard programs and parameters (29). Starting atomic coordinates were evaluated via PC Model calculations.

Results and discussion

The MNDO method was successfully used for the calculation of ground state parameters of organic compounds, including π-conjugated heteroarenes (29, 30). We evaluated the stabilities of compounds **1**–**6** in different tautomeric forms by calculation of their heats of formation $\Delta H_f°$. These data, dipole moments μ, ionization potentials IP_1, and electron affinities EA_1 are given in Table 1.

Although an equilibrium between the 2- and 4-chromenone forms **1***a* and **1***c* has been suggested in the discussion of 4-hydroxycoumarin electronic absorption spectra, Song reported excellent agreement between the experimental data and PPP CI calculational results for the form **1***a* (18). Porter and coworkers studied infrared spectra of the 2-^{13}C and 3-D labelled

Table 1. Heats of formation ($H_f°$ (kcal/mol), dipole moments μ(D), ionization potentials IP_1 (eV), electron affinities EA_1 (eV) of tautomeric forms of 4-hydroxycoumarin derivatives.

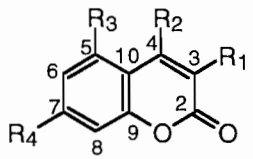
4-hydroxycoumarins in solution, and found no sign of the tautomeric form **1***c* (19, 20).

^{13}C NMR spectra of 4-hydroxycoumarin and its derivatives have also been recorded (21–23) and did not show the presence of any other tautomeric forms than 4-hydroxy-2-chromenone form *a*.



Some calculational results should also be mentioned. The resonance energies (calculated in the *p*-approximation) did not differentiate between the 4-hydroxy-2-chromenone and the 2-hydroxy-4-chromenone tautomeric forms **1***a* and **1***c* but showed a definite predominance of the 2,4-chromandione tautomeric form **1***b* (24).

As one can see, tautomeric transformations of 4-hydroxycoumarin and its derivatives are important for understanding their reactivity and spectral properties, even though some of the conclusions reported seem to be rather controversial.

We have studied the keto–enol tautomerism of 4-hydroxycoumarin and its derivatives, recording their ^{1}H and ^{13}C NMR spectra and looking for the H–D exchange reaction at the 3 position of the coumarin ring. The compounds studied (4-hydroxycoumarin **1**, 4,5-dihydroxycoumarin **2**, 4,7-dihydroxycoumarin **3**, 4-hydroxy-3-(4′-methoxyphenylazo)-coumarin **4**, 3-acetyl-4-hydroxycoumarin **5** and 4-methoxycoumarin **6**) are listed as follows (only R substituents different from H are given):

1: R^2 = OH; **4**: R^1 = *p*-CH_3O-C_6H_4-N = N-, R^2 = OH;
2: $R^2 = R^3$ = OH; **5**: R^1 = $C(O)CH_3$, R^2 = OH;
3: $R^2 = R^4$ = OH; **6**: R^2 = OCH_3.

4-Hydroxy-2-chromenone forms **1***a*–**5***a* turned out to be the most stable forms for each of the compounds **1**–**5**, since these forms have minimal values of heats of formation $\Delta H_f°$. On the whole, 2,4-chromandione forms **1***b*–**5***b* are less stable than the forms **1***a*–**5***a*. However, the forms **1***b*–**5***b* differ in their unstability. The differences of the values $\Delta H_f°$ between forms **1***a*–**5***a* and forms **1***b*–**5***b* turned out to be −0.86, 0.06, −1.04, −7.34 and −6.0 kcal/mol, respectively.

The highest relative stability of the 2,4-chromandione tautomeric form **2***b* of 4,5-dihydroxycoumarin can be understood in terms of the possible intramolecular H-bonding between the 4-keto and the 5-hydroxyl functional groups. H-Bonding of the same energy is out of the question in the tautomeric form **2***a*.

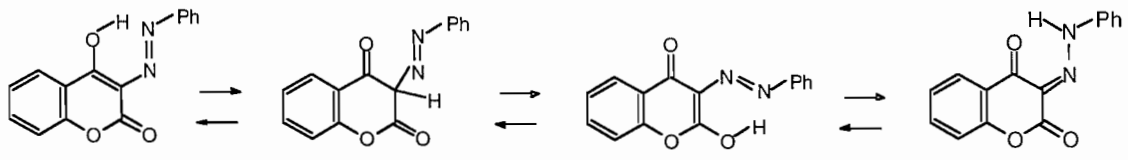
2*b*

Tautomerism of compound **4** is worth additional comments. Even though the 4-hydroxy-3-(4-methoxyphenylazo)-coumarin form **4***a* turns out to be more stable according to the MNDO calculations, form **4***d* should also was taken into consideration in accordance with reference data (14) (see discussion below).

Forms **1***a*–**5***a* seem to be preferable to forms **1***b*–**5***b* and **1***c*–**5***c* in polar solvents (methanol and dimethyl sulfoxide) due to the higher values of the dipole moments calculated by the MNDO method and given in Table 1.

The first ionization potentials and electron affinity values of the tautomeric forms of compounds **1**–**6** calculated by the MNDO method are also listed in Table 1. As one can see, 2,4-chromandione forms **1***b*–**3***b* exhibit increased electron affinity values. These results are in good accord with the proposed higher reactivity to nucleophilic reagents of the 2,4-chromandione forms of 4-hydroxycoumarin derivatives, when these forms are available, due to the corresponding structural effects (5).

The 2-hydroxy-4-chromenone enol forms **1***c*–**3***c* turned out to be the least stable forms. These conclusions agree well with most of experimental data (6–18).



We have recorded the ^1H and ^{13}C NMR spectra of compounds **1**–**6**. The ^1H NMR spectral data are listed in Table 2. Assignment of the spectral patterns was made by using homonuclear ($^1H - ^1H$) (COSY) and heteronuclear ($^1H - ^{13}C$) correlation of chemical shifts. Quaternary and carbonyl carbon atom signals were assigned with use of the APT method and heteronuclear correlation of long-range coupling constants (HETCOR $^3J_{CH}$). The coupling constants $^1J_{CH}$ and $^3J_{CH}$ were determined by the GATE technique (31).

NMR spectral patterns were compared with the MNDO calculational results. In agreement with the quantum chemical calculations, only the 4-hydroxy-2-chromenone forms **1***a* and **3***a* were registered in the ^1H NMR spectra of compounds **1** and **3**. As one can see from the data given in Table 2, there is no sign of the presence of 2,4-chromandione form *b* in these ^1H NMR spectra. Surprisingly, the same is true for 4,5-dihydroxycoumarin **2** although forms **2***a* and **2***b* have almost the same MNDO-calculated heat of formation values. The ^1H NMR spectrum does not show an equilibrium between these forms, since proton signals are noted only for form **2***a*.

Analysis of the ^{13}C NMR spectra supports these conclusions. The corresponding data are listed in Tables 3 and 4. For example, signals at 161.79 and 165.52 ppm in the low-field ^{13}C NMR spectrum of compound **1** belong to the C(2) and to C(4) atoms, respectively. Splitting pattern analysis of ^{13}C NMR spectra shows the signal of the C(2) atom to be a doublet ($^2J_{CH}$, 2.3 Hz) due to its interaction with the only proton at position 3. If the form **1***c* were predominant, an additional splitting on the 2-hydroxyl group proton should also be registered. The signals of the C(4) atoms in the ^{13}C NMR spectra of coumarins **1** and **3** are multiplets (doublets of doublets) due to splitting on the H(3) and H(5) atoms. These signals are also broadened due to their scalar interaction with the solvated proton of the hydroxyl group.

Although signals of the 2,4-chromandione forms **1***b*–**3***b* have not been noted in the ^1H and ^{13}C NMR spectra even at different temperatures (from +30 to −60°C), the use of methanol-d_4 instead of DMSO-d_6 broadens the signals in the ^1H NMR spectra. 2-Carbon and 4-carbon atoms seem to become more equivalent in methanol, since the difference between C(2) and C(4) chemical shifts in the ^{13}C NMR spectra is diminished in this solvent: 2.35 ppm (CD_3OD) instead of 3.73 ppm (DMSO-d_6).

4-Hydroxycoumarins are more strongly solvated in methanol. We suggest that this solvation may provide the 2,4-chromandione tautomeric form *b*, even at a relatively low concentration. We have already shown that alcohols provide keto–enol tautomeric transformations in a series of 4-hydroxycoumarin derivatives (32). In particular, this was noted in the electronic absorption spectra of 3-acetyl-4-hydroxycoumarins when nonpolar solvents (such as *n*-hexane or carbon tetrachloride) are exchanged for polar solvents such as ethanol or methanol, transforming the 3-acetyl-4-hydroxy-

2-chromenone tautomeric form **5***a* to the 3-acetyl-2,4-chromandione derivative form **5***d*.

5*d*

We also have found that methanol allows the H–D exchange reaction at the C(3) atom in compounds **1–3** and **4**. The H–D exchange proceeds by a pseudo-first-order reaction in methanol-d_4. The measured rate constants k_1 are given below.

Compound	**1**	**2**	**3**	**4**
k_1,s^{-1}	1.1×10^{-3}	1.8×10^{-2}	1.0×10^{-3}	1.0×10^{-4}

Two possible mechanisms for the H–D exchange in 4-hydroxycoumarins can be suggested. One of them is an electrophilic aromatic substitution mechanism $S_E(Ar)$, leading to H–D exchange in aromatic hydrocarbons and heteroarenes (33). This scheme might work with the 4-hydroxycoumarins as well, since heteroaromaticity of the coumarin moiety (including the 2-pyrone ring) has been illustrated many times. Some electrophilic reactions of 4-hydroxycoumarin at position 3 (including bromination (34) and formylation (35)) can be used as examples.

As a rule, $S_E(Ar)$ reactions in arenes and heteroarenes proceed according to orbital control in their orientation patterns: the HOMO electron densities of a substrate determine whether it will be attacked by electrophilic reagents (36, 37).

Graphical representations of the HOMOs of compounds **1–3**, and **6** in their most probable tautomeric forms **1***a*–**3***a*, and **6***a* are shown in Fig. 1. The values of the eigencoefficients are proportional to the sizes of the circles on the given atoms. As one can see, these compounds are certainly different in their frontier molecular orbitals. The HOMOs of the tautomers **1***a*, **3***a*, and **6***a* have maximal eigencoefficient values at position 3. However, these HOMO electron densities do not seem to correlate with the relative rates of position 3 H–D exchange for the 4-hydroxycoumarins. For example, 4,5-dihydroxycoumarin **2** does not have the highest electron density at position 3 in the HOMO of the tautomeric form **2***a*, but this compound shows the maximal rate of the H–D exchange. On the other hand, 4-methoxycoumarin **6** has maximal eigencoefficient value at position 3 in the HOMO of the tautomeric form **6***a*, but this compound does not show any sign of the H–D exchange at all.

Conjugated addition of D^+ (in CD_3OD) to the ionized form of 4-hydroxycoumarin **1***a* followed by the formation of 2,4-chromandione tautomeric form **1***b* seems to be a more reason-

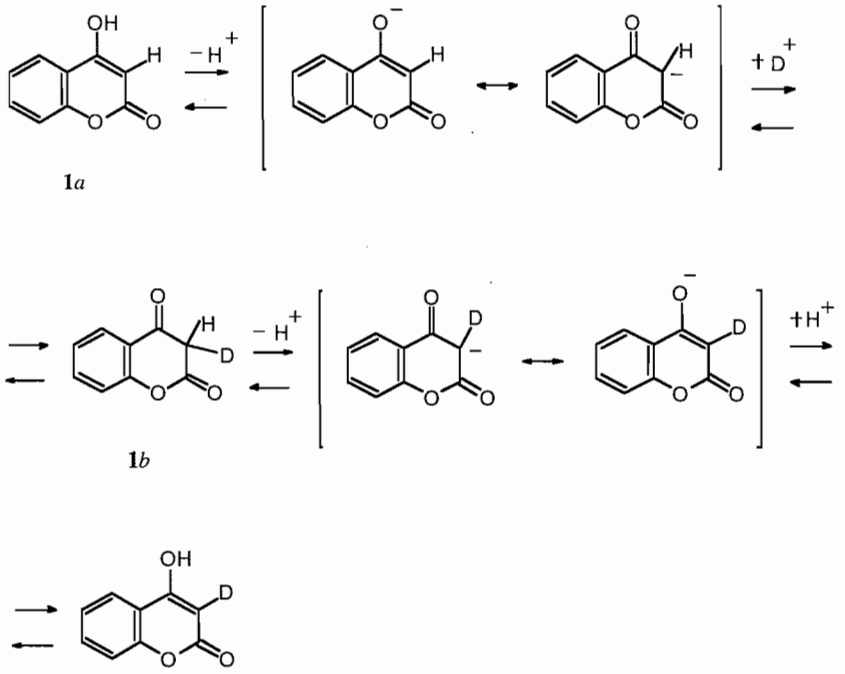
Scheme 1.



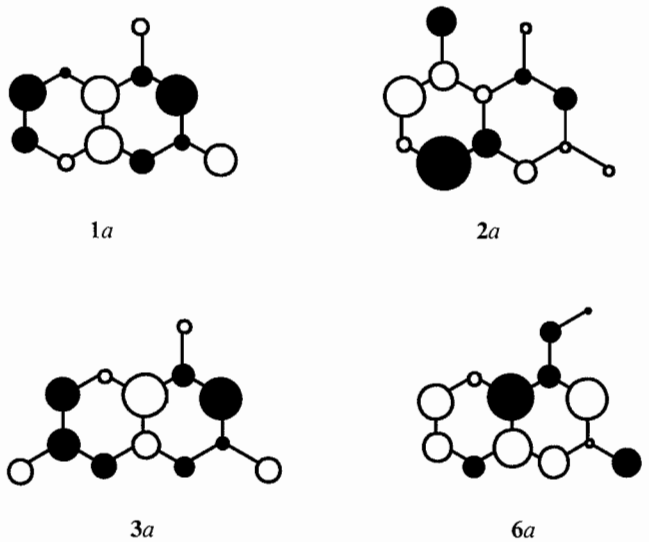


Fig. 1. Highest occupied molecular orbital (HOMO) shapes of compounds **1–3** and **6** in their 4-hydroxy-2-chromonone tautomeric forms *a* (according to the MNDO calculations).

able path (as shown in Scheme 1 for D-incorporation into position 3 of the 4-hydroxycoumarin substrate). Partial ionization of 4-hydroxycoumarin in methanol seems to be reasonable because of the high acidity of the 4-hydroxyl function in hydroxycoumarins (38).

In terms of this mechanism, any effect in 4-hydroxycoumarins that provides relative stability of 2,4-chromandione form *b* would increase the rate of H–D exchange at position 3. Following this proposal, the highest rate of H–D exchange in 4,5-dihydroxycoumarin **2** would be due to the relative stability of its 2,4-chromandione form **2***b* because of H-bonding between 5-hydroxyl and 4-keto functions in its structure (see discussion above).

In agreement with the conjugated D^+ addition scheme, the 2,4-chromandione forms *b* themselves do not seem to be reactive in the H–D exchange. Although the ^{1}H NMR spectrum of 4-hydroxy-3-(4-methoxyphenylazo)coumarin **4** indicates the existence of forms **4***b* and **4***d* (compare the Table 2 data and results given in ref. 14), it shows a rather low rate of H–D exchange. The intensity of the H(3) signal was decreased by only a factor of 3 after 3 h in the presence of methanol-d_4 (acetonitrile-d_3 had been used as solvent). The low reactivity of compound **4** in the H–D exchange agrees well with the low content of the 4-hydroxyl enol form **4***a* in its tautomeric equilibrium. According to the ^{1}H NMR spectra, compound **4** exists predominantly in the form **4***b* (50% in dimethyl sulfoxide-d_6 and 83% in acetonitrile-d_3 as a solvent).[2]

The suggestion that the H–D exchange at position 3 is based on the equilibrium between tautomeric forms 4-hydroxy-2-chromenone *a* and 2,4-chromandione *b* also seems to be true for compound **5**. Its ^{1}H NMR spectrum does not contain signals for 3-acetyl-2,4-chromandione form **5***b*. This form also was not found in a study of electronic absorption spectra of ketone **5** (32).

The importance of 2,4-chromandione forms *b* in the H–D exchange reaction is also illustrated by the complete lack of D-incorporation into position 3 of compound **6**, since no keto–enol tautomeric transformations of this 4-hydroxycoumarin analog are possible.

[2] NMR spectra and tautomerism of azo dyestuffs based on hydroxycoumarins will be discussed in more detail elsewhere.

Conclusions

Keto–enol tautomerism of 4-hydroxycoumarins depends on their structure. Substituents located at positions 3 and 5 affect the tautomeric transformations. The 5-hydroxyl functional group is supposed to stabilize the 2,4-chromandione tautomeric form via intramolecular H-bonding to thus provide H–D exchange at position 3. Introduction of the phenylazo functional group at position 3 transforms the 4-hydroxy-2-chromenone tautomeric form to the 2,4-chromandione derivative tautomeric forms, one of which undergoes H–D exchange. H–D exchange is not observed in 3-acetyl-4-hydroxycoumarin, since its most probable tautomeric forms do not contain an H atom at position 3.

The importance of conformational effects on the carbon–carbon bond cleavage of β-phenethyl ether radical cations[1]

A.L. Perrott, H.J.P. de Lijser, and D.R. Arnold

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.146.161.215 on 09/08/12
For personal use only.

Abstract: The photosensitized (electron transfer) bond cleavage of some β-phenylethyl ether radical cations has been investigated. In previous studies the feasibility of the bond cleavage was thought to depend on the bond dissociation energy (BDE). However, this simple hypothesis led to several incorrect predictions and therefore additional criteria, conformational effects, were added to the hypothesis. This study has now been extended and additional examples of the importance of the conformation on the carbon–carbon bond cleavage of radical cations are provided. The four β-phenylethyl ethers studied are 2-methoxy-3-phenylbutane (**9**, both diastereomers), and *cis*- and *trans*-2-methyl-3-phenyltetrahydropyran (**10***c*, **10***t*). Generally, bond cleavage will occur if the (calculated) BDE in the radical cation is less than 55 kJ/mol, and if there is significant overlap between the singly occupied molecular orbital (SOMO) and the vulnerable (C—C or C—H) bond. In the case of a β-phenylethyl ether radical cation, the alkoxy group must also be oriented so that an oxygen lone pair of electrons can overlap with the C—C *sigma* antibonding (σ*) orbital. The calculated BDE values of the vulnerable C—C bond in the radical cations of the four ethers studied here are well below the threshold value, 55 kJ/mol, and C—C cleavage will therefore be governed by conformational effects. Molecular mechanics (MM3) calculations were used to identify the most stable conformers of the neutral molecules. Based on the calculated angles and overlap between orbitals it was predicted that the global-minimum conformers of the ethers **9** and **10***c* would not give C—C bond cleavage products or deprotonation to any significant extent. The global minimum of ether **10***t* is well oriented for C—C cleavage but not for deprotonation. Irradiation of an electron-accepting photosensitizer, 1,4-dicyanobenzene (**2**), in the presence of the ethers showed that the ethers **9** did not cleave efficiently; no deprotonation or isomerization was observed. This is in good agreement with the predictions based on the MM3 calculations. Both ethers **10***c* and **10***t* gave reasonable yields of the C—C cleavage products; in fact, ether **10***c* cleaved more efficiently than **10***t*. This can be explained by the fact that a conformer of **10***c*, only 4.35 kJ/mol higher in energy than the global minimum, is perfectly aligned for cleavage. Ether **10***t* did not show any evidence for deprotonation whereas **10***c* did. This is also in good agreement with the calculations.

Key words: photoinduced electron transfer, radical cations, bond cleavage, conformation, molecular mechanics calculations.

Résumé : On a étudié le clivage photosensibilisé (transfert d'électron) de quelques cations radicaux d'éthers comportant un groupe β-phényléthyle. Dans des études antérieures, on croyait que la possibilité de cliver la liaison dépendait de l'énergie de dissociation de la liaison (EDL). Toutefois, cette hypothèse simple a conduit à plusieurs prédictions incorrectes et on a donc ajouté des critères additionnels, comme les effets conformationnels, à cette hypothèse. On a maintenant étendu cette étude et on présente de nouveaux exemples démontrant l'importance de la conformation sur le clivage de la liaison carbone–carbone de cations radicaux. On a étudié les quatre éthers β-phényléthylés suivants : 2-méthoxy-3-phénylbutane (**9**, deux diastéréomères) et les *cis*- et *trans*-2-méthyl-3-phényltétrahydropyranes (**10***c*, **10***t*). En général, le clivage de la liaison a lieu lorsque l'EDL (calculée) est inférieure à 55 kJ mol^{-1} et s'il existe un recouvrement significatif entre l'orbitale moléculaire à un seul occupant («SOMO») et la liaison vulnérable (C—C ou C—H). Dans le cas d'un cation radical d'éther β-phényléthylé, le groupe alcoxyle doit être orienté d'une façon telle que la paire d'électrons non appariée de l'oxygène puisse effectuer un recouvrement avec l'orbitale antiliante (σ*) *sigma* de C—C. Les valeurs calculées d'EDL de la liaison C—C vulnérable des cations radicaux des quatre éthers étudiés sont bien inférieures à la valeur limite de 55 kJ mol^{-1}; il en découle que le clivage de la liaison C—C sera gouvernée par les effets conformationnels. On a utilisé des calculs de mécanique moléculaire (MM3) pour identifier les conformères les plus stables des molécules neutres. Sur la base des angles et des recouvrement calculés des orbitales, il a été possible de prédire que les conformères d'énergie globale minimale des éthers **9** et **10***c* ne pourraient pas conduire à des degrés importants de produits de clivage de la liaison C—C ou de déprotonation. Dans sa conformation d'énergie globale minimale, le composé **10***t* est bien orienté pour donner un clivage C—C, mais ce n'est pas le cas pour la déprotonation. L'irradiation d'un photosensibilisateur pouvant accepter des électrons, le 1,4-dicyanobenzène (**2**), en présence des éthers a permis de monter que

les éthers **9** ne se clivent pas d'une façon efficace; on n'a observé ni déprotonation ni isomérisation. Ces observations sont en bon accord avec les prédictions faites sur la base des calculs MM3. Les éthers tant **10***c* que **10***t* donnent des rendements raisonnables de produits provenant d'un clivage C—C; en fait, l'éther **10***c* se clive d'une façon plus efficace que le produit **10***t*. On peut expliquer cette différence par le fait qu'un conformère du produit **10***c*, dont l'énergie ne se trouve qu'à 4,35 kJ mol^{-1} au-dessus de celle du conformère d'énergie minimale, est parfaitement aligné pour donner le clivage. Avec l'éther **10***t*, on n'observe aucune indication de déprotonation alors que le composé **10***c* en donne. Ceci aussi est en accord avec les calculs.

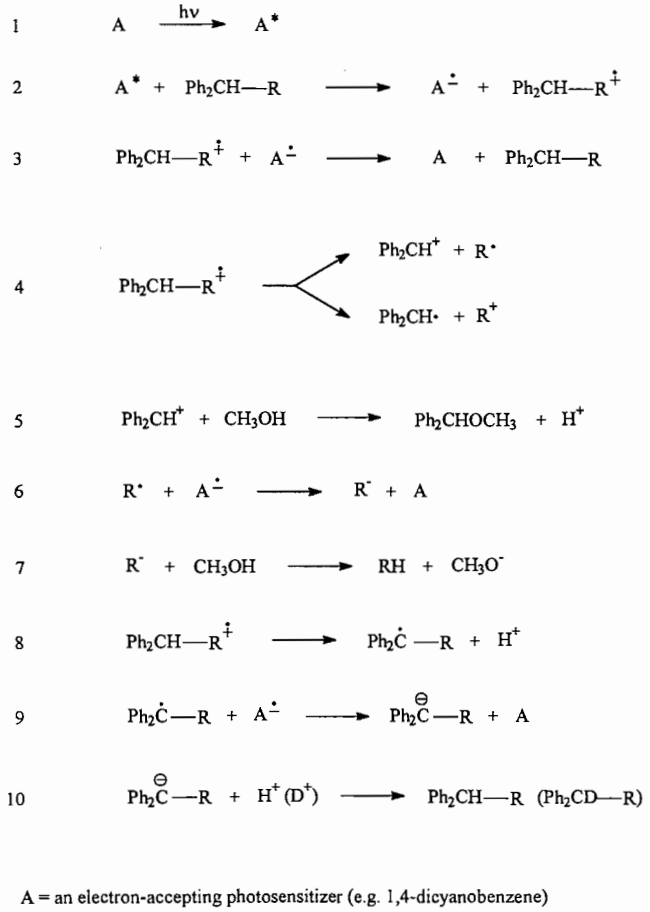
Introduction

Several examples of photosensitized (electron transfer) carbon–carbon bond cleavage have been reported (3). One of the first examples of this type of reaction was the C—C bond cleavage of methyl 2,2-diphenylethyl ether (**1**) when irradiated in the presence of 1,4-dicyanobenzene (**2**) in an acetonitrile–methanol (3:1) solution (reaction [1]) (3*a*).

Reaction [1] (3a)

1



2 = 1,4-dicyanobenzene

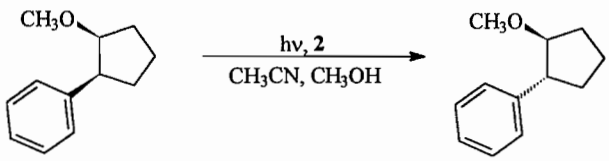
The mechanism proposed for the photosensitized (electron transfer) bond cleavage is shown in Scheme 1 where A is an electron-accepting photosensitizer (e.g., 1,4-dicyanobenzene (**2**)). Step 4 shows the actual cleavage of the radical cation to yield radical and cationic fragments. Cleavage can obviously occur in two ways and the preferred mode can be predicted based on the oxidation potentials of the alternative radical fragments (3*a*,*h*).

The feasibility of photosensitized (electron transfer) carbon–carbon bond cleavage is known to depend on the dissociation energy of the vulnerable bond in the radical cation and on the conformation of the radical cation.[3] From previous studies, an upper threshold of 55 kJ/mol has been estimated for the bond dissociation energy (BDE) in the radical cation (3*h*). When the BDE of the radical cation is well below this threshold, cleavage of the radical cation usually occurs readily. If the BDE is above the threshold, no cleavage is observed. Generalizations are more difficult when the BDE approaches the threshold value and using the BDE as the only criterion for cleavage has led to some erroneous predictions. For example, although the calculated BDE for cleavage of the radical cation of *cis*-1-methoxy-2-phenylcyclopentane (**3**) is only 18 kJ/mol

[3] It must be noted that under these conditions (photosensitized electron transfer) there is a third factor involved, namely back electron transfer (BET). Carbon–carbon bond cleavage is in competition with BET and the overall efficiency of the cleavage reaction might be decreased when BET becomes more important.

Scheme 1. Proposed mechanism for the photosensitized carbon–carbon and carbon–hydrogen bond cleavage of radical cations.

A = an electron-accepting photosensitizer (e.g. 1,4-dicyanobenzene)



(4), no bond cleavage was observed experimentally (reaction [2]). Deprotonation of the radical cation, reduction of the radical, and reprotonation leads ultimately to the *trans* isomer. To improve the predictive power of the hypothesis, conformational criteria were included.

It has been well established that the acidity of a radical cation is much greater than that of the neutral molecule (5). However, in order for deprotonation to take place, the singly occupied orbital of a radical cation must overlap with the C—H bond that is breaking. This was clearly shown by studying *cis*- and *trans*-1-methyl-2-phenylcyclopentane (**4***c*, **4***t*). The *cis* isomer, when irradiated in acetonitrile in the presence of an electron-accepting photosensitizer (1,4-dicyanobenzene (**2**)) and a non-nucleophilic base (2,4,6-collidine), was

converted into the *trans* isomer. Under the same conditions, the *trans* isomer did not react (reactions [3], [4]). When the reaction was carried out in a 3:1 acetonitrile–methanol-*O-d* solution, starting with the *cis* isomer, deuterium was incorporated in both the *cis* and *trans* isomers. No deuterium was incorporated under these conditions, starting with the *trans* isomer (reactions [5], [6]). Molecular mechanics calculations revealed that the angle between the plane of the phenyl ring and the benzylic C—H bond (ϕ) in the global minimum of the *trans* isomer is 1°. The orbital overlap between the singly occupied molecular orbital (SOMO) and the benzylic C—H bond will be maximum when the angle between the C—H bond and the plane of the phenyl ring (ϕ) is 90°. The magnitude of this interaction follows a $1 - \cos^2(\phi)$ relationship, i.e., the orbital overlap in the *trans* isomer is ca. 0%. The calculated angle (ϕ) in the global minimum of the *cis* isomer was 34° (31% effective orbital overlap, MM3; 51°, 60%, MMP2). Despite the fact that the overlap between the SOMO and the benzylic C—H bond is not optimal, deprotonation does occur and isomerization to the *trans* isomer is observed.

Based on these results for C—H bond cleavage it seemed reasonable to suggest that, in order for C—C bond cleavage to occur, the SOMO must also overlap with the vulnerable C—C bond; methyl *cis*- and *trans*-2-phenylcyclohexylether (**7**) and 6-phenyl-1,4-dioxaspiro[4.5]decane (**8**) were therefore expected to cleave. However, whereas the diphenyl systems (**5** and **6**) did show C—C bond cleavage, the monophenyl systems (**7** and **8**) did not (Reactions [7]–[10]). The new hypothesis that was formulated recognized that in order for the radical cation of a β-phenylethyl ether to cleave, the alkoxy group must also be oriented so that a lone pair of electrons on the oxygen can overlap with the C—C *sigma* antibonding (σ^*) orbital. The preferred conformation for cleavage is shown in Fig. 1.

The goal of this research was to provide additional examples of C—C bond cleavage in β-phenylethyl ether radical

cations and to formulate rules useful for predicting this reactivity. The diastereomers of 2-methoxy-3-phenylbutane (**9**) and the *cis* and *trans* isomers of 2-methyl-3-phenyltetrahydropyran (**10**) were chosen as analogues of the methyl 2-phenylcycloalkyl ethers investigated previously (reactions [3]–[6]) (3*j*). The BDE of these radical cations are similar to those of the cycloalkyl compounds; differences in reactivity can therefore be attributed to differences in conformation. The preferred conformations of the neutral species have been identified using molecular mechanics calculations (6). The conformers of these neutral species have been used to rationalize the reactivities of their corresponding radical cations. This is a valid approach: the SOMO in the radical cations of these β-phenylethyl ethers will be largely associated with the phenyl group and the relative energies of the conformers should therefore not be greatly affected upon formation of the radical cation. It must be noted that in some cases removal of an electron could lead to a significant change in geometry, especially if the C—C or C—H bond that is about to be cleaved may provide hyperconjugative stabilization to the π radical cation and does not do so in the neutral compound. However, in all the cases studied in the past, the results of the MM calculations (on the neutral molecules) have been in good agreement with the results of the experiments (involving the radical cations), indicating that this assumption is valid.

Cleavage of the C—C bond in these ethers will lead to 1,6-radical cations. These species could have significant synthetic utility, and a general rule for predicting whether radical cations will undergo C—C bond cleavage or deprotonation is important.

Results

Molecular modeling (MM3)

The structures of both diastereomers of 2-methoxy-3-phenylbutane (**9**) and the *cis* and *trans* isomers of 2-methyl-3-phenyltetrahydropyran (**10**) were optimized (steric energies were minimized) with the 1988 force field of the MM3 program. The initial geometries of these molecules were obtained by using PCModel.[4] For each molecule, a number of starting conformations were considered and the stochastic search option was used to find stationary points. Not all initial conformations led to distinct conformers. Selected dihedral angles for all of the conformers identified are tabulated in Tables 1–4.

Preparation of starting materials

The syntheses of the ethers, 2-methoxy-3-phenylbutane (**9**) (both diastereomers) and *cis*- and *trans*-2-methyl-3-phenyltetrahydropyran (**10**), are outlined in Schemes 2–4. The details of these syntheses are given in the experimental section.

Irradiations

Solutions of the ether and 1,4-dicyanobenzene (**2**), the electron-accepting photosensitizer, in acetonitrile–methanol (3:1) solution were degassed by nitrogen ebullition and irradiated with a medium-pressure mercury vapour lamp, through Pyrex, in a constant temperature bath held at 10°C. Reaction progress was followed by gas chromatography with a flame ionization detector (gc/fid) and gas-chromatography with a mass-selective detector (gc/ms). The results of the irradiations are summarized in reactions [11] and [12].

All four of the ethers cleaved, some inefficiently. The two diastereomers of 2-methoxy-3-phenylbutane (**9**) give the same products in almost the same yield (reaction [11]). Identification of the products was made by comparison of gc/ms retention times and mass spectra with those of authentic samples, and from ^{1}H and ^{13}C nmr spectra. Identification (tentatively) of trace amounts of the diastereomers of 2,3-diphenylbutane (**13**) rests on the observed mass spectra. The crude photolysates from the irradiations of the diastereomers of **9** were chromatographed on silica gel: the yield of 1-(4-cyanophenyl)-1-phenylethane (**12**) was determined by analysis of ^{1}H nmr spectra of fractions containing a mixture of **12** and recovered ether **9**. The yield of ethylbenzene (**11**) was determined by calibrated gc/ms and gc/fid using cyclododecane as an internal standard.

The cleavage products obtained upon irradiation of *cis*- and *trans*-2-methyl-3-phenyltetrahydropyran (**10***c*, **10***t*) were 4-phenylbutyl (1-methoxyethyl) ether (**14**), and 4-(4-cyanophenyl)-4-phenylbutyl (1-methoxyethyl) ether (**15**)

(reaction [12]). These compounds were identified after acid hydrolysis of the reaction mixture to yield 4-phenyl-1-butanol (**16**) and 4-(4-cyanophenyl)-4-phenyl-1-butanol (**17**). The retention time and mass spectrum of alcohol **16** were compatible with an authentic sample. Alcohol **17** was isolated and fully characterized. The percent conversion of the starting materials and the yields of the alcohols **16** and **17** were determined by using calibrated gc/ms, with cyclododecane as an internal standard.

Deuterium incorporation studies were carried out as described above, using acetonitrile–methanol-*O*-*d* (3:1) solutions. The reactions were followed by gc/ms, using selected ion monitoring. There was no evidence of deuterium incorporation in either diastereomer of **9**, or in ether **10***t*. Ether **10***c* did show some deuterium incorporation. Isomerization was also observed: ether **10***t* was formed from **10***c* and vice versa.

Oxidation potentials of the ethers were determined by cyclic voltammetry. The free energies of the electron transfer reactions were calculated by using the Weller equation (eq. [1]) (7). The values are summarized in Table 5.

Discussion

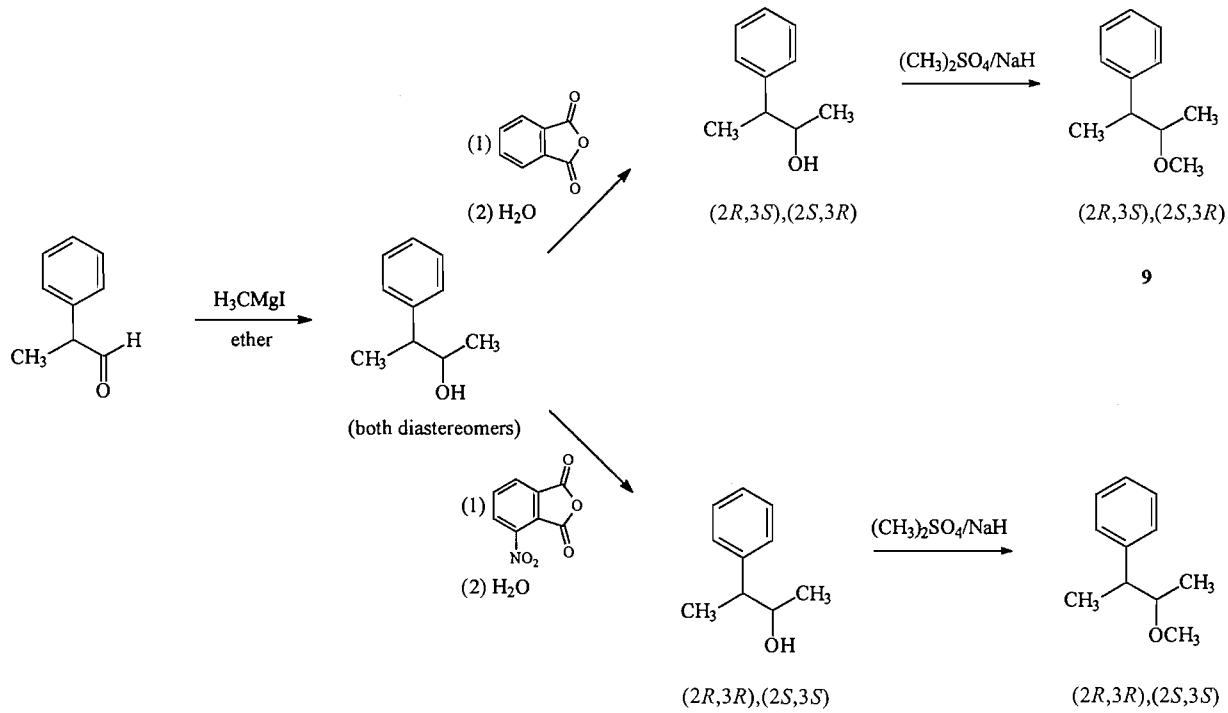
The first three steps of the proposed mechanism for the cleavage reaction (Scheme 1) should occur readily. Calculated values of the free energy for electron transfer between the singlet excited state of 1,4-dicyanobenzene (**2***) and the ethers are all exergonic by more than −20 kJ/mol (Table 1); electron transfer should take place at the diffusion-controlled rate (7). Back electron transfer (step 3) is extremely exergonic: this deactivation pathway is the most likely for the radical cation.

Step 4 is the actual carbon–carbon bond cleavage of the radical cation. For all of the ethers considered in this investigation, the BDEs of the radical cations are expected to be below the threshold value. Therefore, if the conformations are suitable, the radical cations of the diastereomers of 2-methoxy-3-phenylbutane (**9**) and the two isomers of 2-methyl-3-phenyltetrahydropyran (**10**) should undergo photosensitized (electron transfer) carbon–carbon bond cleavage.

In previous cases (3*i*,*j*), lack of reactivity has been attributed to insufficient overlap of the singly occupied molecular orbital (SOMO) with the carbon–carbon bond expected to cleave and (or) due to a lack of overlap between the lone pair of electrons on the oxygen with the adjacent C—C *sigma* antibonding (σ*) orbital. In the radical cations of all the compounds under investigation, the SOMO is largely associated with the phenyl group. Therefore, the optimum orientation for cleavage to occur has the plane of the phenyl ring perpendicular to the benzylic C—C bond. Also, the O-R moiety of the ether should be *gauche* to the vulnerable C—C bond.

Step 8 is the deprotonation step of the radical cation. This is a fragmentation pathway in competition with the C—C bond cleavage; the conformation of the radical cation is also important here. The SOMO must overlap with the benzylic C—H bond in order for deprotonation to take place.

A Karplus-type relationship can be used to evaluate the degree of overlap between orbitals as a function of angle (8). The fraction of maximum overlap is $(1 - \cos^2\phi_{Ph\text{-}CH})$, where $\phi_{Ph\text{-}CH}$ is the dihedral angle between the C—H bond and the plane of the phenyl ring. The overlap between the SOMO and the benzylic C—H bond is maximum when the angle between the phenyl group and the C—H bond is 90°. Similarly, in order for carbon–carbon bond cleavage to take place, the dihedral angle between the plane of the phenyl group and the C—C bond should approach 90°: the magnitude of orbital overlap is $(1-\cos^2\phi_{Ph\text{-}CC})$. If ϕ_{OCH_3} is the dihedral angle between the C—C bond and the O-CH_3 bond, then the degree of overlap between an sp^3-type lone pair of electrons on oxygen and the C—C *sigma* antibonding (σ*) orbital is $\cos^2(\phi_{OCH_3} - 60°)$; 60° is the angle at which this overlap will be maximum.



The results of the calculations on the (2*R*,3*R*) isomer of 2-methoxy-3-phenylbutane (**9**) are tabulated in Table 2. The global minimum conformer is predicted not to cleave, due to an unfavourable orientation of the OCH_3 group. Because the plane of the phenyl group is parallel to the geminal hydrogen, deprotonation is also unlikely. However, two potentially reactive conformers were found 9.83 and 10.8 kJ/mol above the global minimum. Both of these conformers could undergo carbon–carbon bond cleavage; the (2*R*,3*R*) isomer will cleave if the populations of these conformers are sufficient. No conformers that might undergo deprotonation (isomerization) were found.

Similarly, the global-minimum conformer of the (2*S*,3*R*) isomer was predicted to be inert under the irradiation conditions (Table 3). The orientation of the methoxy group would prevent the cleavage of the three most stable conformers. However, a conformer was found 4.77 kJ/mol above the global minimum in which the methoxy group is more favourably

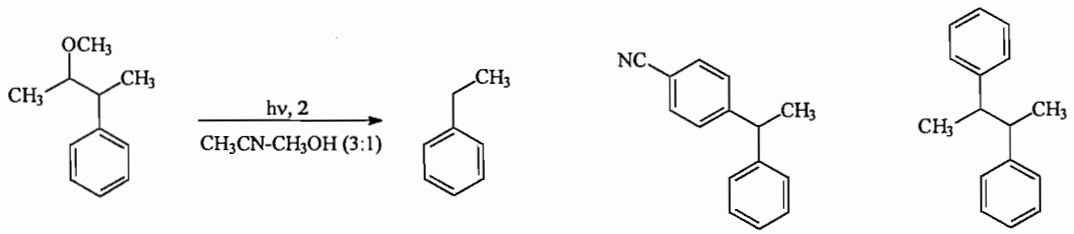
aligned. Therefore, cleavage of the (2*S*,3*R*) isomer also seemed feasible.

Although there was no evidence for deprotonation of either diastereomer, it was found that both diastereomers of **9** cleaved inefficiently when subjected to the standard irradiation conditions. Cleavage of **9** produces a secondary 1-phenylethyl radical and a secondary α-oxy carbocation. Reduction of the radical by the radical anion of the sensitizer ($\mathbf{2}^{-\bullet}$) and subsequent protonation gives ethylbenzene (observed in ca. 7% yield, calibrated gc/ms). Coupling of the radical fragments gives 2,3-diphenylbutane (**13**, two diastereomers, which were detected in trace amounts). Coupling of the radical fragment at the *ipso* position of $\mathbf{2}^{-\bullet}$ followed by loss of cyanide anion yields 1-(4-cyanophenyl)-1-phenylethane (**12**), which was the major product from both diastereomers.



All of the observed products involve the initial formation of the benzylic radical fragment. The relative amounts of these products are related to the reduction potential of the radical.

Reaction [11]

9 **11** **12** **13**

[a]	(2*R*,3*S*),(2*S*,3*R*)	8%	20%	trace
[b]	(2*R*,3*R*),(2*S*,3*S*)	6%	24%	trace

Reaction [12]

10 **10** **14** **15**

[a]	*cis*	*trans*: 6%	20%	31%
[b]	*trans*	*cis*: 1%	23%	37%

The reduction potential of **2** is −1.66 V (vs. SCE), while the reduction potential of the 1-phenylethyl radical is −1.60 V (9). Therefore, reduction of the radical to the carbanion by $\mathbf{2}^{-\bullet}$ should be exergonic. However, the difference between these two reduction potentials is not great, and it is not surprising that products resulting from reaction of both the radical and the carbanion are formed.

2-Methyl-3-phenyltetrahydropyran (**10**) was of special interest. The rotational barriers in the acyclic systems are low and it is difficult to predict a priori which conformation(s) will be most favourable. However, since tetrahydropyrans can be expected to adopt chair conformations, the equatorial lone pair of electrons on the oxygen atom will be antiperiplanar to the C—C bond to be cleaved.

An MM2 study by Allinger and Tribble (10) has shown that the most stable conformer of phenylcyclohexane has the phenyl group in the equatorial position, with the ring parallel to the geminal C—H bond. This orientation minimizes repulsive interactions between the *ortho* hydrogens and the equatorial hydrogens on C2 and C6. However, if additional substituents on the cyclohexane ring force the phenyl ring to be in the axial position, the most favourable conformer will have the phenyl ring perpendicular to the geminal C—H bond. In this conformation, the repulsive interactions between the *ortho* hydrogens of the phenyl group and the axial hydrogens on the cyclohexane ring are minimized. The free energy difference between these two conformers of phenylcyclohexane (i.e., the *A*-value) is 8.4 – 13 kJ/mol in favour of the equatorial conformer (11). Allinger has calculated the free energy difference to be 15.3 kJ/mol. Since there is no substituent geminal to the phenyl group in **10**, it was initially expected that the phenyl group would be in the equatorial position, oriented parallel to the geminal C—H bond. Although this would make deprotonation unlikely, it would give reasonably good overlap

Scheme 5. Possible mechanism for the isomerization of *trans*-2-methyl-3-phenyltetrahydropyran (**10***t*) to *cis*-2-methyl-3-phenyltetrahydropyran (**10***c*).

10*t* **10***c*

between the SOMO and the C—C bond. As mentioned above, the orientation of a lone pair of electrons on oxygen is favourable.

Two of the starting conformers used in the optimization of **10***c* were based on a chair structure: one with the phenyl group in the axial position and the other with the phenyl group equatorial. Structures with the six-membered ring in a boat conformation were all at least 21.4 kJ/mol higher in energy than the chair-based global minimum.

The global-minimum structure of **10***c* does not have the phenyl group in the equatorial position; the conformer with the axial phenyl group is 4.35 kJ/mol more stable than the equatorial conformer. This calculated result is supported by the ^{1}H nmr spectrum of the compound. The proton geminal to the phenyl group has no coupling constant larger than 4 Hz, indicating that this proton must be in the equatorial position. In retrospect, this result is not surprising. In this conformation of the tetrahydropyran ring, the axial phenyl group has a 1,3-diaxial interaction with only one hydrogen. Although the conformation of the ring does indeed guarantee that one lone pair of electrons can assist the C—C bond cleavage, the axial phenyl group is twisted so that overlap of the C—C bond and the SOMO is only 41% of the maximum (Table 4). At best, cleavage of this conformer would be inefficient. The higher-energy conformer, with the phenyl group in the equatorial position, is perfectly aligned for cleavage. The energy gap between this conformer and the global-minimum is only 4.35 kJ/mol (Table 4). Calculation of the Boltzmann distribution at 10°C leads to a value of 0.16, i.e., one out of six molecules will be populating the higher-energy conformer.

Irradiating the *cis* isomer under standard conditions resulted in ca. 60% conversion of the starting material. This was more than expected based upon reaction of just the global minimum. This indicates clearly that the other low-energy conformer is also present. The two observed C—C bond cleavage products are the acetals **14** and **15**. Acid hydrolysis yielded the alcohols **16** and **17**, which were isolated and fully characterized. The relative yields of **16** (20%) and **17** (31%) show again that there is a competition between reduction of the intermediate benzylic radical and addition of the radical to the radical anion of the electron acceptor. The competition is in favour of addition, which is consistent with the results from the irradiation of the diastereomers of **9**.

There is some overlap between the benzylic C—H bond and the SOMO of the phenyl ring in both of these conformers and therefore some deprotonation can be expected. Irradiation of the *cis* isomer in acetonitrile–methanol-*O*-*d* (3:1) in the presence of a sensitizer (**2**) showed that deprotonation does indeed take place. Isomerization to the *trans* isomer (6%) was also observed.

Only chair conformations of the *trans* isomer (**10***t*) were considered. This isomer was calculated to be 12.0 kJ/mol more stable than the *cis* isomer. In this isomer (**10***t*), the structure with the equatorial phenyl group was indeed found to be lower in energy than the conformer with the phenyl group in the axial position. This was confirmed by the ^{1}H nmr spectrum of this compound; the proton (δ 4.07) adjacent to the benzylic hydrogen has a coupling constant (^3J) of 11.25 Hz, which is also present in the signal of the benzylic proton (δ 2.41) indicating that both these protons are in the axial position. In agreement with the original expectations, the most stable conformer had the equatorial phenyl group aligned parallel to the geminal hydrogen. This orientation would inhibit deprotonation and subsequent isomerization to the *cis* isomer. However, this conformer is well aligned for C—C bond cleavage.

As predicted, no deuterium incorporation was observed when the irradiation was performed in acetonitrile–methanol-*O*-*d*. However, there was some (≈1%) isomerization to the *cis*

isomer. This indicates that isomerization may occur without the deprotonation-reprotonation steps. Obviously, another possible pathway involves C—C bond cleavage followed by isomerization, back electron transfer, and C—C bond formation (Scheme 5). This mechanism for isomerization has been observed before (*1f*).

The *trans* isomer also undergoes efficient C—C bond cleavage under the standard irradiation conditions but this process is somewhat less efficient than that of the *cis* isomer; 44% conversion was observed. This is surprising when only the global minima of the *cis* and *trans* isomers are considered. However, as pointed out earlier, other low- energy conformers are involved in the reaction as well. In the case of the *cis* isomer this results in a more efficient cleavage (the higher-energy conformer is favourably aligned for cleavage) whereas there is no such conformer available for the *trans* isomer.

Conclusions

The carbon–carbon and carbon–hydrogen bond cleavage in radical cations is governed by energetic (bond dissociation energy) and conformational criteria. Radical cations can undergo carbon–carbon bond cleavage when the activation barrier is lower than 55 kJ/mol. When the conformation is suitable, the bond dissociation energy is a good estimate of the activation barrier for cleavage. However, when the plane of the phenyl group is parallel to the vulnerable benzylic bond or when the alkyl portion of the alkoxy group is antiperiplanar to the C—C bond, the barrier is substantially higher than the bond dissociation energy, and cleavage becomes much less likely.

The radical cations that were considered in this study, (2*R*,3*R*)- and (2*S*,3*R*)-2-methoxy-3-phenylbutane (**9**) and *cis*- and *trans*-2-methyl-3-phenyltetrahydropyran (**10***c*, **10***t*), all have C—C bond dissociation energies below the threshold value. Molecular mechanics (MM3) calculations have been used to determine whether the radical cations of these ethers are suitably aligned for cleavage. The global minimum conformers of the diastereomers of **9** and of the *cis* isomer of **10** were all predicted to be unreactive toward C—C bond cleavage and deprotonation. However, for all three of these ethers, other higher-energy conformers that might undergo C—C cleavage were identified. The *trans* isomer of 2-methyl-3-phenyltetrahydropyran (**10***t*) was expected to cleave efficiently since the global minimum conformer is aligned for C—C bond cleavage but not for deprotonation.

The two diastereomers of **9** both cleaved inefficiently and no deprotonation or isomerization was observed. This is in good agreement with the predictions. The *cis* isomer of ether **10** cleaved efficiently and also showed evidence of deprotonation. This can only be explained on the basis of the reactivity of both the global minimum and a higher-energy conformer. The cleavage of the *trans* isomer was less efficient than that of the *cis* isomer. No deprotonation was detected; however, some isomerization to the *cis* isomer did occur, indicating that isomerization could occur through C—C bond cleavage. All the observations can be explained on the basis of the molecular mechanics calculations. These calculations are a valuable tool when predicting C—C and (or) C—H bond cleavage reactions.

Experimental

General information

The ^{1}H and ^{13}C nmr spectra were recorded on a Nicolet Instruments Corp. narrow-bore 360-MHz spectrometer or on a Bruker AC250 spectrometer as noted. Chemical shifts are reported in parts per million relative to tetramethylsilane. Infrared spectra were recorded on a Perkin–Elmer 283B spectrometer or a Nicolet 205 FT-IR spectrometer and frequencies are reported in cm^{-1}. Exact Mass determinations were obtained using a CEC 21-110B spectrometer. Gas chromatography with mass selective detection (gc/ms) was carried out on a Hewlett Packard (HP) 5890 gc coupled to an HP 5970 mass selective detector. Samples were analyzed on a 25 m × 0.2 mm, 5% phenyl methyl silicone on fused silica column (film thickness: 0.25 μm). Gas chromatography with flame ionization detection (gc/fid) was carried out on an HP 5890 gc equipped with a 25 m × 0.25 mm OV-1701 fused silica column. Preparative gas chromatography (prep-gc) was carried out using a Varian Aerograph 920 equipped with an SE-30 (20%) on Chromosorb W 60/80 column (6 ft. × 1/4 in.) and a thermal conductivity detector. Combustion analyses were performed by Canadian Microanalytical Service Ltd., Delta, B.C.

Electrochemical measurements

Oxidation potentials were obtained by cyclic voltammetry in acetonitrile solution using a three-electrode cell that has been described previously (12). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a platinum wire. The electrolyte was 0.1 M tetraethylammonium perchlorate (TEAP) in acetonitrile. Substrate concentrations were approximately 1 mM. The peak potentials were measured with a 100 mV/s sweep rate. Since the anodic wave was irreversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (13).

Materials

Solvents were distilled prior to use. Acetonitrile and 1,4-dicyanobenzene (**2**) (Aldrich) were purified as reported previously (*3f*). Tetrahydrofuran (BDH) was distilled from sodium. DL-2-Phenylpropionaldehyde, phthalic anhydride, 3-nitrophthalic anhydride, dimethyl sulfate, 4-phenyl-1-butanol (**15**), 4-chlorobutyrophenone, (ethyl)triphenylphosphonium bromide, sodium amide, and borane–tetrahydrofuran complex (1.0 M) were all obtained from Aldrich Chemical Company and were used as received. Iodomethane and sodium hydroxide were obtained from BDH, acetophenone and hydrogen peroxide (30%) were obtained from Fisher, lithium bromide was obtained from Sigma, and cyclododecane was obtained from K&K laboratories.

Calculations

Molecular mechanics calculations were carried out on a VAX 8800 mainframe computer. The 1988 force field of MM3 was used. PCModel[4] was used for the initial molecular mechanics calculations.

Preparations

Preparation of 3-phenyl-2-butanol

Phenyl-2-butanol was prepared from DL-2-phenylpropionalde-

For personal use only.

hyde via a Grignard reaction. Iodomethane (100 mL, 228 g, 1.61 mol) was added dropwise with stirring to magnesium metal (50 g, 2.1 mol) in anhydrous diethyl ether. The flask was chilled in an ice bath throughout the addition. After the addition was complete, DL-2-phenylpropionaldehyde (106 mL, 107 g, 0.799 mol) was added dropwise. The resulting mixture was stirred for 16 h and then poured into a slurry of saturated NH_4Cl and ice. Concentrated HCl was added until the aqueous layer was acidic. The aqueous layer was extracted several times with ether; the combined organic extracts were washed with 5% $NaHCO_3$, dilute $NaHSO_3$, and distilled water. The solution was dried over anhydrous $MgSO_4$ and the ether was evaporated. A mixture of the diastereomers of 3-phenyl-2-butanol was obtained by vacuum distillation (107.8 g, 89.8% yield).

Separation of the diastereomers of 3-phenyl-2-butanol

The diastereomers were separated with a few slight modifications of Cram's procedure (14*a*). A mixture of the isomers of 3-phenyl-2-butanol (80.5 g, 0.536 mol) was refluxed with phthalic anhydride (60.0 g, 0.405 mol) and pyridine (100 mL) for 2 h. The mixture was cooled and diluted with an equal volume of benzene. The solution was washed with excess 1 M H_2SO_4 and with water, and was then dried over $MgSO_4$. The solvent was evaporated, and the residue was diluted with two volumes of ethyl acetate. Low-boiling petroleum ether was added until the solution became slightly turbid. The crystals that formed upon standing were recrystallized from ethyl acetate and petroleum ether to yield 21.4 g of the acid phthalates of the (2*R*,3*S*) and (2*S*,3*R*) enantiomers of the alcohol (14*b*). Some of these crystals (10.0 g) were hydrolyzed back to the alcohol by refluxing for 16 h with a solution of NaOH (8.0 g) in water (40 mL). The crude hydrolysis mixture was extracted with diethyl ether, and the organic layer was washed with water. The solution was dried over $MgSO_4$, and the ether was evaporated. The conversion from the acid phthalate to the alcohol was quantitative.

The (2*R*,3*R*),(2*S*,3*S*) pair of isomers (14*b*) was obtained by refluxing a mixture of the alcohol diastereomers (24.3 g, 0.162 mol) with 3-nitrophthalic anhydride (23.4 g, 0.121 mol) in pyridine (35 mL) for 1 h. The solution was diluted with an equal volume of benzene, washed with excess 1 M H_2SO_4 and distilled water, and dried over $MgSO_4$. The solvent was evaporated, and the crude reaction mixture was chromatographed on silica gel, using ethyl acetate as the eluant. Some of the fractions were induced to crystallize by adding two volumes of ethyl acetate, followed by sufficient petroleum ether to produce turbidity. The resulting solid was recrystallized from ethyl acetate and petroleum ether to yield 1.2 g of the acid 3-nitrophthalate. This ester was hydrolyzed to the alcohol by refluxing for 14 h with a solution of NaOH (2.0 g) in water (20 mL); work-up of the reaction mixture as before yielded the diastereomeric alcohol in 77% yield.

*Preparation of 2-methoxy-3-phenylbutane (**9**)*

The separated diastereomers of 3-phenyl-2-butanol were methylated with dimethyl sulfate. The (2*R*,3*S*),(3*R*,2*S*) alcohol mixture (5.20 g, 0.0346 mol) was dissolved in anhydrous diethyl ether (150 mL). NaH (6.0 g of a 60% suspension in mineral oil, 0.15 mol) was added, followed by dropwise addition of dimethyl sulfate (14 mL, 19 g, 0.15 mol). After the suspension was refluxed for 29 h, more dimethyl sulfate (10 mL, 13 g, 0.11 mol) was added and the mixture was refluxed for an additional 23 h. The reaction was quenched by the addition of distilled water. The aqueous layer was extracted with diethyl ether and the combined organic extracts were washed with concentrated NH_4OH and saturated NaCl. This solution was dried over anhydrous $MgSO_4$ and the solvent was removed from the potentially volatile ether by distillation through a fractionating column. The residue was chromatographed on silica gel using CH_2Cl_2–hexanes (1:4) to give 2-methoxy-3-phenylbutane (**9**) in quantitative yield; integration of the gc/ms spectrum gave the ratio of diastereomers as 95:5. The ^1H nmr spectrum corresponded to the one reported in the literature (14*b*): ^1H nmr (AC250, $CDCl_3$), δ: 7.23 (m, 5 Hz), 3.43 (dq, 1H, 6.3 Hz, 5.8 Hz), 3.27 (s, 3H), 2.93 (dq, 1H, 7.2 Hz, 5.8 Hz), 1.25 (d, 3H, 7.2 Hz), 1.05 (d, 3H, 6.3 Hz).

The same procedure was used to methylate the (2*R*,3*R*),(2*S*,3*S*) isomers of 3-phenyl-2-butanol (78% yield, 96:4 ratio of diastereomers). The recorded ^1H nmr spectrum corresponded to that reported in the literature (14*b*): ^1H nmr (AC250, $CDCl_3$), δ: 7.31–7.16 (m, 5H), 3.35 (s, 3H), 3.34 (dq, 1H, 6.1 Hz, 6.6 Hz), 2.73 (dq, 1H, 7.2 Hz, 6.6 Hz), 1.25 (d, 3H, 7.2 Hz), 0.96 (d, 3H, 6.1 Hz).

Preparation of cis*-2-methyl-3-phenyltetrahydropyran (**10**c)*

2-Methyl-3-phenyl-5,6-dihydropyran was prepared via a two-step synthesis, following the method of Descotes et al. (15). The first step involved the synthesis of α-methylphenyltetrahydrofuryl carbinol. A stirred solution of acetophenone (12 mL, 12 g, 0.10 mol) in tetrahydrofuran (200 mL, 177 g, 2.46 mol) was irradiated through Pyrex with a 450-W medium-pressure mercury vapour lamp. Nitrogen was bubbled through the solution during the irradiation; the total irradiation time was 24 h. Evaporation of the excess THF left 28 g of a mixture containing the carbinol. This crude mixture was used in the next step without purification.

α-Methylphenyltetrahydrofuryl carbinol was converted to 2-methyl-3-phenyl-5,6-dihydropyran by pyrolysis on neutral alumina (activity 1). The pyrolysis was carried out in a cylindrical electric multiple-unit furnace (Cenco) at 320°C. The alumina (14 g) was packed into a Pyrex tube (2 cm diameter), which was clamped vertically in the furnace. The crude carbinol mixture was pyrolyzed in batches of ca. 5 g each. With the entire apparatus under vacuum (0.25 Torr; 1 Torr = 133.3 Pa), the carbinol was allowed to drop onto the alumina, and the product was collected in a flask immersed in liquid nitrogen. On average, about 40% of the mass of the carbinol mixture was recovered. The pyrolysis mixture was chromatographed on silica gel, using a 1:1 mixture of CH_2Cl_2 and hexanes. The fractions containing the pyran were combined and hydrogenated, at atmospheric pressure, over 10% Pd on activated carbon. Filtration of the suspension and careful distillation of the solvent from the volatile product gave 1.0 g of product.

cis*-2-Methyl-3-phenyltetrahydropyran* (**10**c, 6% yield): ir (PE, neat), ν: 3080 (w), 3050 (w), 3020 (w), 2940 (s), 2840 (s), 1600 (m), 1495 (s), 1450 (s), 1380 (s), 1340 (m), 1270 (s), 1225 (s), 1190 (s), 1140 (m), 1110 (s), 1090 (s), 1075 (s), 1040 (s), 1030 (m), 960 (w), 930 (w), 880 (w), 850 (s), 835 (w), 810 (w), 745 (s), 730 (m), 690 (s), 655 (w); ^1H nmr (360 MHz,

$CDCl_3$), δ: 7.42–7.14 (m, 5H), 4.03 (m, 1H), 3.92 (dq, 1H, 3.26 Hz, 6.7 Hz), 3.61 (m, 1H), 2.83 (m, 1H), 1.91 (m, 4H), 1.04 (d, 3H, 6.7 Hz); ^{13}C nmr (90 MHz, $CDCl_3$), δ: 142.6 (s), 129.2 (d), 128.0 (d), 125.9 (d), 75.4 (d), 66.5 (t), 44.7 (d), 28.8 (t), 22.1 (t), 17.6 (q); ms, *m/z*: 176 ($M^{+\bullet}$, 12%), 132 (10), 117 (14), 115 (10), 104 (100), 91 (20). Anal. calcd. for $C_{12}H_{16}O$: C 81.77, H 9.15; found: C 81.42, H 9.08.

Preparation of trans-*2-methyl-3-phenyltetrahydropyran* (***10t***)
A mixture of 1.0 g (2.56×10^{-2} mol) sodium amide and 10.0 g (2.69×10^{-2} mol) (ethyl)triphenylphosphonium bromide in 50 mL tetrahydrofuran (THF) was refluxed for 1 h. The orange-red coloured solution was cooled to room temperature and a mixture of 1.75 g (9.58×10^{-3} mol) 4-chlorobutyrophenone and 1.1 g (1.27×10^{-2} mol) LiBr in 10 mL THF was added dropwise. The solution was stirred for 2 h after which the solid residue was filtered off. The solvent was evaporated and the residue was chromatographed on silica gel to yield 0.35 g of the alkene (both *cis* and *trans* isomers), which was used without further purification in the next step.

A solution of 0.35 g (1.81×10^{-3} mol) of the alkene from step 1 in 30 mL THF was flushed with nitrogen for 15 min. After this period 15 mL of a 1.0 M BH_3–THF complex was added dropwise and this solution was then refluxed for 10 h. The mixture was poured into water and cooled in an ice bath. A solution consisting of 8 mL 6 M NaOH and 6 mL H_2O_2 (30% aqueous solution) was added dropwise and the resulting mixture was stirred for 2 h. The solution was extracted with ether and the combined ether layers were washed with distilled water, saturated NH_4Cl, and saturated NaCl, and dried over anhydrous $MgSO_4$. The mixture of alcohols (0.27 g) that was obtained after evaporation of the solvent was used in the third step without further purification.

The alcohol (0.27 g, 1.27×10^{-3} mol) was added to 25 mL of a 6 M NaOH aqueous solution and refluxed for 10 h. The aqueous solution was extracted with ether and the combined ether layers were dried over anhydrous $MgSO_4$. Evaporation of the solvent followed by column chromatography of this residue on silica gel yielded pure *cis*- (40 mg) and *trans*-2-methyl-3-phenyltetrahydropyran (0.12 g). These compounds were further purified by prep-gc.

trans-*2-Methyl-3-phenyltetrahydropyran* (**10***t*, 0.12 g): ir (Nicolet, $CDCl_3$), ν: 3082 (w), 3061 (w), 3029 (w), 2961 (s), 2932 (s), 2850 (s), 1603 (w), 1494 (m), 1452 (m), 1378 (m), 1343 (w), 1264 (s), 1221 (m), 1186 (w), 1103 (s), 1083 (s), 1022 (s), 939 (w), 901 (w), 870 (m), 854 (m), 848 (m), 800 (s), 757 (m), 701 (s); ^1H nmr (360 MHz, $CDCl_3$), δ: 7.35–7.15 (m, 5H), 4.07 (dd, 1H, 2.45 Hz, 11.25 Hz), 3.57 (m, 1H+1H), 2.41 (m, 1H), 1.97 (m, 2H), 1.73 (m, 2H), 0.98 (d, 3H, 5.86 Hz); ^{13}C nmr (90 MHz, $CDCl_3$), δ: 143.79 (s), 128.48 (d), 127.69 (d), 126.44 (d), 78.25 (d), 68.43 (t), 50.61 (d), 32.24 (t), 26.55 (t), 20.07 (q); ms, *m/z*: 176 ($M^{+\bullet}$, 14%), 132 (9), 117 (19), 115 (13), 104 (100), 91 (21), 78 (15), 77 (13), 65 (7), 59 (7), 51 (9); actual mass of ion $C_{12}H_{16}O$: 176.1201; measured: 176.1199.

Irradiations

All irradiations were carried out in Pyrex tubes, at 10°C, using a General Electric 1-kW medium-pressure mercury vapour lamp. The samples were degassed by nitrogen ebullition for five minutes prior to irradiation.

*Irradiation of a mixture of (2R,3S)- and (2S,3R)-2-methoxy-3-phenylbutane (**9**) and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol (3:1) (reaction [11a])*
A solution of 2-methoxy-3-phenylbutane (**9**, (2*R*,3*S*) and (2*S*,3*R*) enantiomers) (0.2085 g, 1.27×10^{-3} mol), 1,4-dicyanobenzene (**2**) (0.1147 g, 8.95×10^{-4} mol), and cyclododecane (38.0 mg, 2.26×10^{-4} mol) in acetonitrile–methanol (3:1) (30 mL) was irradiated through Pyrex (nmr tubes) for 1 week. The conversion of **9** after this period was 22%. The yield of ethylbenzene (**11**) was 8% (calibrated gc/ms). Trace amounts of the diastereomers of 2,3-diphenylbutane (**13**) were also detected. The identification of these diastereomers is based on the observed mass spectra (see below). The solvent was evaporated and the residue was chromatographed on silica gel with hexanes and CH_2Cl_2. The attempt at chromatographic separation was only partially successful: the yield of 1-(4-cyanophenyl)-1-phenylethane (**12**, 20%) was determined by analysis of fractions containing **12** and recovered starting material (**9**).

1-(4-Cyanophenyl)-1-phenylethane (***12***): ^1H nmr (AC 250, $CDCl_3$), δ: 7.56 (d, 2H, 6.6 Hz), 7.32–7.16 (m, 7H) 4.19 (q, 1H, 7.1 Hz), 1.64 (d, 3H, 7.1 Hz); ^{13}C nmr (AC 250, $CDCl_3$), δ: 151.9, 144.7, 132.3, 129.1, 128.7, 128.4, 127.5, 119.0, 110.0, 44.9, 21.4; ms, *m/z*: 207 ($M^{+\bullet}$, 38%), 192 (100), 165 (35), 105 (5), 77 (18).

2,3-Diphenylbutane (**13**, trace): *m/z*: 210 ($M^{+\bullet}$, 1%), 105 (100), 77 (14).

*Irradiation of a mixture of (2R,3S)- and (2S,3R)-2-methoxy-3-phenylbutane (**9**) and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol-*O*-d (3:1)*
A solution of 2-methoxy-3-phenylbutane (**9**, (2*R*,3*S*) and (2*S*,3*R*) enantiomers) (45.4 mg, 2.76×10^{-4} mol) and 1,4-dicyanobenzene (**2**) (27.0 mg, 2.11×10^{-4} mol) in 3:1 acetonitrile–methanol-*O-d* (2 mL) was irradiated for 7 d through Pyrex. The reaction was monitored by gc/ms with selected ion monitoring. There was no evidence for deuterium incorporation in the starting material.

*Irradiation of a mixture of (2R,3R)- and (2S,3S)-2-methoxy-3-phenylbutane (**9**) and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol (3:1) (reaction [11b])*
A solution of 2-methoxy-3-phenylbutane (**9**, (2*R*,3*R*),(2*S*,3*S*) enantiomers) (0.1491 g, 9.08×10^{-4} mol), 1,4-dicyanobenzene (**2**) (0.0791 g, 6.17×10^{-4} mol), and cyclododecane (35.1 mg, 2.09×10^{-4} mol) in acetonitrile–methanol (3:1) (20 mL) was placed in nmr tubes and irradiated for 7 d through Pyrex, resulting in a 22% conversion of **9**. The yield of ethylbenzene (**11**) was 6% (calibrated gc/ms). Trace amounts of the diastereomers of 2,3-diphenylbutane (**13**) were also detected. The solvent was evaporated and the residue was chromatographed on silica gel using a hexanes–CH_2Cl_2 gradient. The yield of 1-(4-cyanophenyl)-1-phenylethane (**12**) was determined as before (24% yield).

*Irradiation of a mixture of (2R,3S)- and (2S,3R)-2-methoxy-3-phenylbutane (**9**) and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol-*O*-d (3:1)*
A solution of 2-methoxy-3-phenylbutane (**9**, (2*R*,3*R*),(2*S*,3*S*) enantiomers) (21.3 mg, 1.30×10^{-4} mol) and 1,4-dicyanoben-

For personal use only.

zene (**2**) (16.3 mg, 1.27×10^{-4} mol) acetonitrile–methanol-*O-d* (3:1) (1 mL) was irradiated for 7 d through Pyrex. Monitoring of the reaction by gc/ms with selected ion monitoring showed that there was no evidence for isomerization or deuterium incorporation in the starting material.

Irradiation of cis-*2-methyl-3-phenyltetrahydropyran (**10**c) and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol (3:1): identification of products*

A solution of *cis*-2-methyl-3-phenyltetrahydropyran (**10***c*) (0.197 g, 1.12×10^{-3} mol), 1,4-dicyanobenzene (**2**) (0.1025 g, 8.01×10^{-4} mol), and cyclododecane (25 mg, 1.49×10^{-4} mol) in acetonitrile–methanol (3:1) (8 mL) was irradiated for 84 h through Pyrex. Analysis by gc/ms indicated the presence of two cleavage products: the acetals **14** and **15**. The solvent was removed by rotary evaporation and the residue was subjected to acid hydrolysis by adding 5 N HCl (10 mL) and refluxing the solution for 1 h. The mixture was extracted with ether and the combined organic layers were washed with saturated $NaHCO_3$ and with water before drying with $MgSO_4$. Analysis of the mixture by gc/ms before and after the acid hydrolysis showed the disappearance of the acetal peaks and the appearance of two new (alcohol) peaks, attributed to 4-phenyl-1-butanol (**16**) and to 3-(4-cyanophenyl)-4-phenyl-1-butanol (**17**). Dry column flash chromatography (16) was used to separate the two alcohols. Alcohol **16** (10.5 mg, 12%) was positively identified after comparison of the retention time (gc/fid and gc/ms) and the mass spectrum with an authentic sample (Aldrich).

3-(4-Cyanophenyl)-4-phenyl-1-butanol (**17**, 29 mg, 21%): ir (Nicolet, $CDCl_3$), ν: 3636 (w), 3407 (s), 3061 (m), 3030 (m), 2939 (s), 2871 (m), 2229 (s), 1604 (m), 1497 (m), 1452 (m), 1413 (m), 1384 (w), 1346 (w), 1304 (w), 1174 (w), 1116 (w), 1059 (s), 1030 (m), 992 (w), 914 (m), 833 (m), 805 (m), 764 (m), 732 (s), 702 (s), 648 (m), 618 (m); ^{1}H nmr (360 MHz, $CDCl_3$), δ: 7.58–7.52 (d, 2H, 8.31 Hz), 7.38–7.32 (d, 2H, 8.32 Hz), 7.32–7.16 (m, 5H), 5.29 (s, 1H), 3.97 (t, 2H, 7.83 Hz), 3.65 (t, 2H, 6.36 Hz), 2.14 (m, 2H), 1.52 (m, 2H); ^{13}C nmr (90 MHz, $CDCl_3$), δ: 150.63 (s), 143.24 (s), 132.30 (d), 128.75 (d), 128.63 (d), 127.80 (d), 126.75 (d), 118.90 (s), 110.04 (s), 62.50 (t), 51.20 (d), 31.50 (t), 30.97 (t); ms, *m/z*: 251 ($M^{+\bullet}$, 5%), 233 (33), 218 (7), 205 (58), 192 (100), 190 (49), 177 (9), 165 (42), 152 (6), 140 (5), 115 (6), 91 (6), 51 (5); actual mass of ion $C_{17}H_{17}NO$: 251.1310; measured: 251.1316.

Irradiation of cis-*2-methyl-3-phenyltetrahydropyran (**10**c) and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol (3:1) (reaction [12a])*

A solution of *cis*-2-methyl-3-phenyltetrahydropyran (**10***c*) (32 mg, 1.82×10^{-4} mol), 1,4-dicyanobenzene (**2**) (28 mg, 2.19×10^{-4} mol), and cyclododecane (4.5 mg, 2.68×10^{-5} mol) in 3:1 CH_3CN–CH_3OH (2 mL) was irradiated for 36 h through Pyrex. The irradiation resulted in a 61% conversion of the starting material. Isomerization to the *trans* isomer accounted for 6% of the conversion. Yields of the cleavage products were determined after acid hydrolysis by calibrated gc/ms using cyclododecane as an internal standard: 4-phenyl-1-butanol (**16**): 20%; 3-(4-cyanophenyl)-4-phenyl-1-butanol (**17**): 31%.

Irradiation of cis-*2-methyl-3-phenyltetrahydropyran (**10**c) and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol*-O-d *(3:1)*

A solution of *cis*-2-methyl-3-phenyltetrahydropyran (**10***c*) (30 mg, 1.70×10^{-4} mol) and 1,4-dicyanobenzene (**2**) (25 mg, 1.95×10^{-4} mol) in acetonitrile–methanol-*O-d* (3:1) (2 mL) was irradiated for 36 h through Pyrex. Selected ion monitoring with the gc/ms showed that deuterium was incorporated in the molecular ion.

Irradiation of trans-*2-methyl-3-phenyltetrahydropyran (**10**t) and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol (3:1) (reaction [12b])*

A solution of *trans*-2-methyl-3-phenyltetrahydropyran (**10***t*) (30 mg, 1.70×10^{-4} mol), 1,4-dicyanobenzene (**2**) (24 mg, 1.90×10^{-4} mol), and cyclododecane (3.5 mg, 2.08×10^{-5} mol) in acetonitrile–methanol (3:1) (2 mL) was irradiated for 36 h through Pyrex. The irradiation resulted in a 44% conversion of the starting material. Isomerization to the *cis* isomer accounted for 1% of the conversion. Yields of the cleavage products were determined as before: 4-phenyl-1-butanol (**16**): 23%; 3-(4-cyanophenyl)-4-phenyl-1-butanol (**17**): 37%.

Irradiation of trans-*2-methyl-3-phenyltetrahydropyran (**10**t) and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol*-O-d *(3:1)*

A solution of *trans*-2-methyl-3-phenyltetrahydropyran (**10***t*) (30 mg, 1.70×10^{-4} mol) and 1,4-dicyanobenzene (**2**) (25 mg, 1.95×10^{-4} mol) in acetonitrile–methanol-*O-d* (3:1) (2 mL) was irradiated for 36 h through Pyrex. Selected ion monitoring with the gc/ms showed that there was no (within experimental error) deuterium incorporation in the molecular ion.

For personal use only.

Abstract: Substituted benzoic and cinnamic acids were studied by FAB mass spectrometry using matrix-based Al(III) ions. Complex ions derived from these acids, such as $(M + 117)^+$ (117 = (Al + glycerol − 2H)$^+$), $(M + 159)^+$ (159 = [2Al + 2glycerol − 5H − 74(epoxypropanol)]$^+$), and $(M + 233)^+$ (233 = (2Al + 2glycerol − 5H)$^+$), when subjected to collisionally activated dissociation (CAD), gave an ion corresponding to $(M - OH)^+$. Formation of this ion was explained by the transfer of the carboxylic -OH group to the (Al + glycerol − 2H)$^+$, (2Al + 2glycerol − 5H − 74)$^+$, and (2Al + 2glycerol − 5H)$^+$ portion of the complexes. This transfer is more pronounced in the case of *meta*- and *para*-substituted acids. The CAD of the $(M + 117)^+$ ions yielded $(M + Al(III))^+$ ions resulting from the insertion of Al(III) into the carboxylic acid, which was followed by the elimination of CO to produce $(M + Al(III) - CO)^+$ ions. Interpretation of spectral data was clarified by study of the formation and fragmentation of ions produced from deuterated benzoic and cinnamic acids.

Key words: substituted benzoic and *trans*-cinnamic acids, Al(III)–glycerol, FAB mass spectrometry, ionic metal complexes, collisionally induced dissociation, Al(III) insertion, carbonyl cations.

Résumé : On a étudié une série d'acides benzoïques et cinnamiques substitués par spectrométrie de masse «FAB», en utilisant des ions d'Al(III) insérés dans des matrices. Les ions complexes obtenus à partir de ces acides, tels que ceux à $(M + 117)^+$ (117 = (Al + glycérol − 2H)$^+$), $(M + 159)^+$ (159 = [2Al + 2glycérol − 5H − 74(époxypropanol)]$^+$) et $(M + 233)^+$ (233 = (2Al + 2glycérol − 5H)$^+$), soumis ensuite à une dissociation activée par collision (DAC), conduisent à un ion correspondant à $(M - OH)^+$. On a expliqué la formation de cet ion par le transfert du groupe -OH du carboxyle aux portions (Al + glycérol − 2H)$^+$, (2Al + 2glycérol − 5H − 74)$^+$ et (2Al + 2glycérol − 5H)$^+$ des complexes. Ce transfert est plus important dans les cas des acides substitués en *méta* et en *para*. La DAC des ions $(M + 117)^+$ conduit aux ions $(M + Al(III))^+$ qui résultent de l'insertion du Al(III) dans l'acide carboxylique, suivie d'une élimination de CO conduisant aux ions (M + Al(III) − CO). L'interprétation des données spectrales a été clarifiée par l'étude de la formation et de la fragmentation des ions produits à partir d'acides benzoïques et cinnamiques deutérés.

Mots clés : acides benzoïques et *trans*-cinnamiques substitués, Al(III)–glycérol, spectrométrie de masse «FAB», complexes métalliques ioniques, dissociation induite par collision, insertion de Al(III), cations carbonyles.

[Traduit par la rédaction]

Introduction

Reactions of metal ions with amino acids (1), peptides (2), nucleotides (3), and crown ethers (4) have been studied by fast atom bombardment and electrospray mass spectrometry. However, the gas phase chemistry of the aluminum ion has not been as well explored as that of alkali, alkaline earth, and transition metal ions. There are a few reports on gas phase ion–molecule reactions of Al^+, generated from aluminum foil or $AlCl_3$, with alkyl halides, alcohols, ketones, and esters (5). We reported that aluminum chloride in a glycerol matrix, under FAB ionization conditions, generated a complex ion (Al + Gly − 2H)$^+$ (Gly = glycerol) in addition to some other matrix-based Al(III) ions (6).

Reactions of (Al + Gly − 2H)$^+$ ions (*m/z* 117) have been studied with α-amino acids (7), peptides (7), and polydentate ligands such as crown ethers (6), polyethylene glycols (6), and nucleobase-substituted glymes (8). All these ligands formed abundant ionic complexes with the (Al + Gly − 2H)$^+$. Nucleobase-substituted glymes also formed $(M + 141)^+$ (M = analyte) ions by displacement of amide protons of the nucleobase, i.e., formation of a covalent bond between Al(III) and N_3 of two nucleobases (8). Complex ions generated from α-amino acids and Al(III) species on collisionally activated decomposition (CAD) gave fragment ions where the Al(III) is covalently bound to amino and carboxylic groups by substitution of acidic protons (7). The acidic protons of these amino and carboxylic groups were involved in the elimination of glycerol attached to the Al(III). Similar elimination of glycerol was also observed in the fragmentation of adduct ions derived from peptides by substituting the amide protons with Al(III) (7). The CAD spectra of cluster ions obtained from crown

ethers and polyethylene glycols also appeared in the formation of covalently bound $(M + AlO)^+$ ionic complexes, which was followed by the loss of neutral C_2H_4O units (6). In this study we discuss the reactions of Al(III)–glycerol ions with benzoic and *trans*-cinnamic acids.

Results and discussion

Cluster ions generated by fast atom bombardment of a matrix mixture consisting of glycerol (25–30 mg), $AlCl_3$ (3–4 mg), TFA (2,2,2-trifluoroacetic acid, 2 μL), and H_2O (2 μL) are observed at *m/z* 117 $(Al + Gly - 2H)^+$, 231 $(Al + Gly + TFA - 2H)^+$, and 233 $(2Al + 2Gly - 5H)^+$ (Gly = glycerol), along with the species produced by substitution of one hydroxy proton of these with 116u (Al + Gly − 3H) and 114u (TFA), as observed in our earlier studies (6–8). All substituted aromatic carboxylic acids form significant adduct ions such as $(M + 117)^+$, $(M + 159)^+$, $(M + 233)^+$, $(M + 347)^+$, and $(M + 349)^+$ (M = analyte). The relative intensities of the ions containing Al(III) produced by the reactions between aromatic carboxylic acids **1**–**15** (Fig. 1) and Al(III)–glycerol ions are listed in Table 1. From methyl (**2** and **3**) and methoxy (**6**–**11**) substituted acids, ions corresponding to $(M + 103)^+$ are observed in addition to other cluster ions. The formation of a number of cluster ions depends on the amount of $AlCl_3$ added to the glycerol matrix. The solubility of the carboxylic acids in the matrix mixture could be increased by the addition of a mixture of ethyl acetate and ethyl alcohol to the matrix. These solvents do not interfere with the formation of ions from these acids. Addition of TFA to the matrix results in the formation of the protonated analyte, which is followed by dehydration of the $(M + H)^+$ ions. Metal-chelated ions are also observed in significant abundances. Accurate mass measurements on the $(M + 117)^+$ ion of **3** give $C_{11}H_{14}O_5Al$ as the elemental composition with a 2.5 ppm deviation (theor. 253.06565; obsd. 253.06630). Similar experiments on the $(M + 159)^+$ ion of **6** fit the molecular formula $C_{11}H_{13}O_7Al_2$ (theor. 311.02919; obsd. 311.02883, Δ = 1.1 ppm). The elemental composition, $C_{14}H_{19}O_9Al_2$, is in agreement within an error of 3.5 ppm for the $(M + 233)^+$ ion of **6** (theor. 385.06597; obsd. 385.06735).

The FAB mass spectra of *trans*-cinnamic acids **16**–**22** (Fig. 1) show abundant metal-complexed ions at $(M + 117)^+$, $(M + 159)^+$, $(M + 233)^+$, $(M + 347)^+$, and $(M + 349)^+$. The relative abundances of metal-coordinated ions are given in Table 2. Aliphatic carboxylic acids also react with Al(III)–glycerol species and form adduct ions. With the increase of alkyl chain length the solubility of aliphatic acids is reduced. Therefore, further studies on these systems were not carried out. The site of coordination of the metal ion is likely at the carboxylate group.

The FAB spectra obtained with *d*-labelled acids such as **3**, **6**, **7**, **10**, **14**, **15**, **18**, and **21** with $AlCl_3$ and glycerol-d_3, TFA, and D_2O show an increase of 2, 1, and 2 mass units in the formation of $(M + 117)^+$, $(M + 159)^+$, and $(M + 233)^+$ ions, respectively. In the case of hydroxy (M = **18**) and amino (M = **14**, **15**) substituted acids, there is observed an additional increase of mass by 1 and 2u. The $(M + 103)^+$ ion from **3** and **6** shows an increase of 3u in the mass.

1. The collisionally activated dissociation of adduct ions from benzoic acids

(a) $(M + 117)^+$ ($P^+ = (M + Al + Gly - 2H)^+$)

The CAD of $P^+ = (M + 117)^+$ ions of **3**–**7**, **9**, **10**, **14**, and **15** were studied using "daughter ion" linked scans by keeping the *B/E* ratio constant. The fragmentation of $P^+ = (M + 117)^+$ ions of **3**–**7** gives ions due to $(P - OH)^+$, $(P - H_2O)^+$, $(P - CH_2O)^+$, $(P - 44)^+$, $(P - RH)^+$, and $(P - R)^+$ (R = substituent). The formation of the $(P - H_2O)^+$ ion is always followed by the loss of CH_2O to give the $(P - 48)^+$ ion. Other abundant ions observed are $(P - 28)^+$, $(P - 74)^+$, $(P - 90)^+$, $(P - 118)^+$, and $(P - 134)^+$ or substituted benzoyl cations. Loss of 74u (epoxypropanol) from the P^+ ion yielding the $(M + AlO)^+$ ion is consistent with our previous observations (6, 7). The $(P - 90)^+$ ion can be formed by the insertion of Al(III) into the carboxylate group after the elimination of the neutral dideprotonated glycerol moiety attached to the metal ion. Hydroxy acids **4** and **5** also show a $(P - 90)^+$, i.e., $(M + Al(III))^+$ ion at *m/z* 165, which is common in other acids. From this ion, elimination of a carbonyl group gives a significant ion at *m/z* 137, i.e., the $(P - 118)^+$ or $(M + Al(III) - CO)^+$ ion. The $(P - 92)^+$ ion is observed only from **4**, which involves the elimination of

Unless otherwise noted the base peak is $(MH - H_2O)^+$.

a glycerol molecule to form a six-membered ring. The fragmentation of the adduct ions of **6** and **7** also produces $(P - CH_2)^+$, $(P - CH_3)^+$, $(P - CH_4)^+$, $(P - CO)^+$, $(P - CH_2O)^+$, $(P - CH_2, CO)^+$/$(P - CO_2)^+$ equal to $(P - 44)^+$, $(P - 74)^+$, $(P - 90)^+$, or $(M + Al(III))^+$ and $(P - 118)^+$ or $(M + Al - CO)^+$ ions, in addition to other less abundant ions at *m/z* 121, 92, and 77. The formation of product ions from **3** and **6** is confirmed by the dissociation of labelled P^+ ions.

The fragmentation of $P^+ = (M + 117)^+$ ions for positional isomers **9** and **10** yields enormous differences in the abundance of the $(P - H_2O)^+$ and $(P - 90)^+$ ions. The ion due to the insertion of Al(III) into the carboxylic acid group at *m/z* 209 ($(P - 90)^+$ or $[M + Al(III)]^+$) is the base peak in the spectrum of **10**, whereas, M = **9** produces a $(P - H_2O)^+$ ion as the most abundant ion. Formation of other ions from these two compounds, such as $(P - CH_2O)^+$, $(P - 134)^+$, and the loss of CH_4 from the parent ion as well as from the $(P - CH_2O)^+$ ion is quite similar to the fragmentation of $(M + 117)^+$ ions from other compounds. The CAD of the deuterated P^+ ion (*m/z* 301) of **10** gives ions at *m/z* 210, 211, and 212 that correspond to the ion at *m/z* 209 in the unlabelled P^+ ion. Therefore, the ion at *m/z* 209 (301 deuterated) may undergo H/D exchange in the exited state after collisional activation.

The dissociation of the P^+ complex of **14** and **15** also yields $(P - OH)^+$, $(P - H_2O)^+$, $(P - 74)^+$, $(P - 90)^+$, $(P - 118)^+$, and $(P - 134)^+$ ions. The *d*-labelled $(M + 117)^+$ ion of **14** and **15** appears at *m/z* 258. On fragmentation, this ion gives three ions at *m/z* 238, 239, and 240. The ion at *m/z* 240 may be due to the loss of OD. Since there is no acidic H that is unlabelled in this ion, the loss of an HDO molecule from the parent ion would not explain the ion at *m/z* 239. Therefore, this ion may be related to the loss of neutral ND_2H, which would have the same mass as an OH group in the unlabelled adduct ion. Since the elimination of ND_3 or D_2O accounts for the same mass, we cannot be clear whether or not the hydroxy proton of the reagent is involved in the elimination of ammonia. However, the loss of ND_2H does indicate the involvement of aromatic hydrogen. Ions due to $(P - D_2O/ND_3)^+$ and $(P - ND_2H)^+$ are equally abundant. The fragmentation of labelled P^+ ion also yields the loss of one deuterium atom in the formation of $(P - 74)^+$, $(M + Al(III))^+$ ions and amino benzoyl cations ($(P - 134)^+$). The formation of the $(M + H)^+$ ion is not a common process in the decomposition of an $(M + 117)^+$ ion. However, dissociation of the $(M + 117)^+$ ion of **14** yields a low-abundance $(M + H)^+$ ion. This can be attributed to the higher proton affinity of aminobenzoic acids compared to the other substituted acids studied.

We explain the production of substituted benzoyl cations

Table 2. Relative abundances of metal-containing ions obtained from substituted cinnamic acids **16–23** using Al(III)/glycerol/TFA/H_2O.

Compound no.	$(M + 117)^+$	$(M + 159)^+$	$(M + 233)^+$	$(M + 347)^+$	$(M + 349)^+$
16	29	26	28	12	7
17	82	27	27	12	8
18	34	47	31	24	9
19	29	20	19	9	9
20	16	46	54	17	18
21	16	29	35	18	12
22	7	31	49	25	12

Other metal-containing ions, *m/z* (%)

16: 265 (19), 267(15), 323(14), 435(14), 479(8), 487(6)
17: 373(19), 489(12)
18: 373(9), 437(12), 489(9), 529(12), 533(7)
19: 373(6), 437(6), 489(6)
20: 281(21), 301(19), 307(19), 323(17), 327(13)
21: 281(16), 283(14), 307(14)
22: 283(13), 479(24), 503(19), 547(15), 575(11)

Unless otherwise noted the base peak is $(MH - H_2O)^+$.

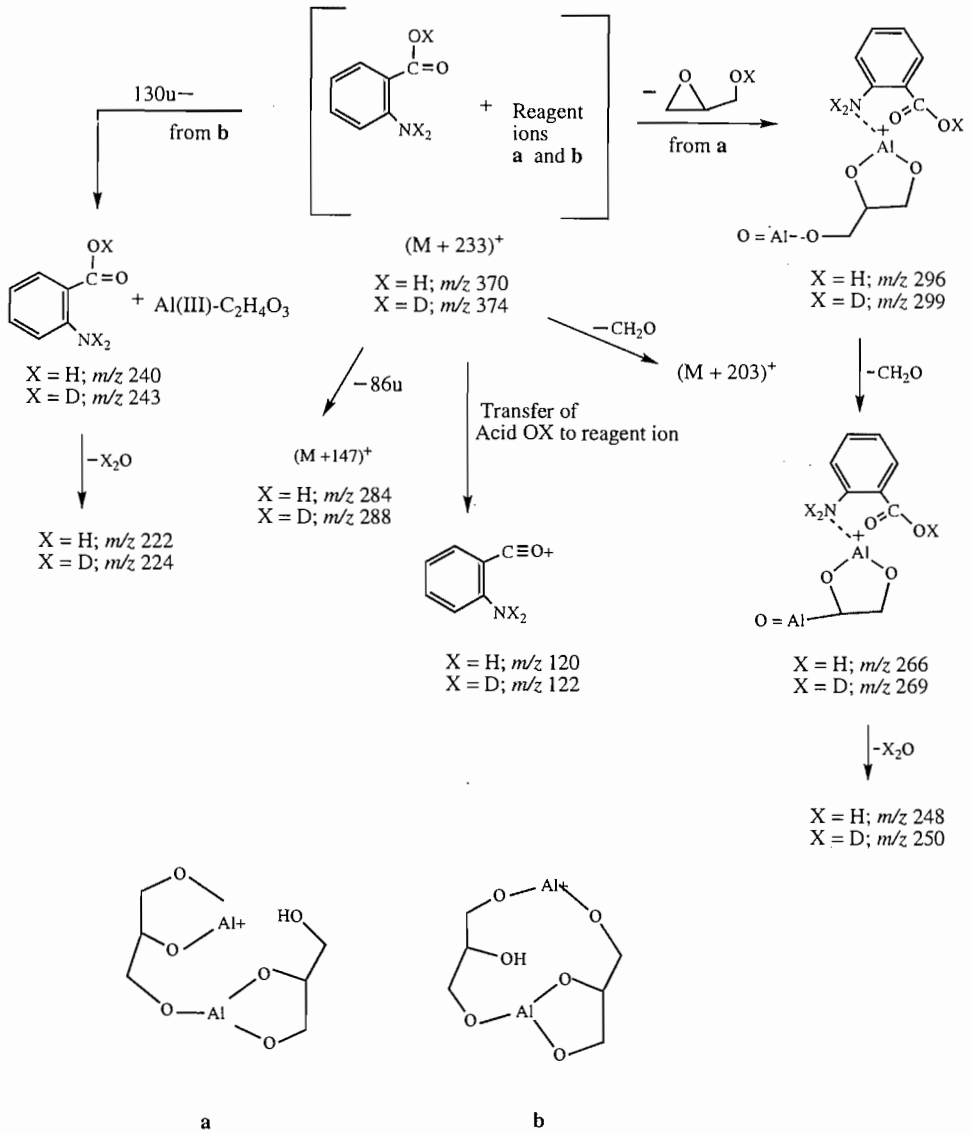
$((P - 134)^+)$ as the transfer of the OH group of the acids to Al(III). The amount of the benzoyl cation formed depends on the ease of cleavage of the C—OH bond and the approach of the metal ion to transfer the OH to the $(Al + Gly - 2H)^+$ portion of the P^+ ion. Among the positional isomers, the abundance of the benzoyl cation $((P - 134)^+)$ is greater in *meta*- and *para*-substituted acids, which are sterically less hindered to the approach of the $(Al + Gly - 2H)^+$ ion than are the *ortho*-substituted acids.

(b) $(M + 233)^+$ ($C^+ = (M + 2Al + 2Gly - 5H)^+$)

The CAD of the $C^+ = (M + 233)^+$ ion from **2–4**, **6–8**, **14**, and **15** yields $(C - 74)^+$, $(C - 104)^+$, $(C - 86)^+$, and $(C - 130)^+$ ions. However, the formation of the $(M + 117)^+$ ion is a very minor process. The formation of a benzoyl cation is observed from all these acids. Production of an ion corresponding to the $(M + 103)^+$ or $(C - 130u)^+$ ion from **2–4**, **6–8**, **14**, and **15** is explained with reference to the fragmentation of *d*-labelled $(M + 233)^+$ ions from **6** and **14** (Scheme 1). The CAD spectra of labelled C^+ of these acids show a loss of one deuterium each in the formation of the $(C - 74)^+$ (i.e., loss of $CH_2(O)CHCH_2OD$) and $(C - 130)^+$ ions and retention of all deuteriums in the $(C - 86)^+$ ion. The $(C - 130)^+$ and $(C - 86)^+$ ions are abundant for all acids studied and no substituent effect is involved in their formation. Thus, we conclude that the ion from which these two originate is from the $(2Al + 2Gly - 5H)^+$ ion. It follows that the $(C - 130)^+$ ion is an adduct of an Al(III)–glycerol species corresponding to 103u plus the analyte $((M + 103)^+)$. From the $(C - 130)^+$ ion, the loss of a water molecule can give rise to an ion at *m/z* 222 and 223 from **14** or **15** and **4**, respectively, because loss of substituent **2** shows the loss of 16u from the $(M + 103)^+$ ion. If the structure of the ion at *m/z* 233 generated from the matrix is "**a**", as proposed in our earlier studies, then there will be facile routes to formation of the $(M + 117)^+$ ion, as already observed for amino acids and peptides (7). The formation of the $(M + 117)^+$ ion is insignificant in the CAD spectra of the $(M + 233)^+$ ion. Therefore, we suggest that the ion at *m/z* 233 from the matrix may have another isomeric structure "**b**", dependent on the pH of the matrix solution.

The fragmentation of the $(M + 103)^+$ ion of **2**, **3**, **6**, and **7** gives an abundant ion corresponding to a substituted benzoyl cation. The $(M + 103)^+$ ion at *m/z* 239 from **2** and **3** and at *m/z* 255 from **6** and **7**, formed from the $(M + 117)^+$ ion on dissociation, is due to the loss of a methylene group. It follows that the fragmentation of the $(M + 103)^+$ ion should give a fragment ion corresponding to the $(M + 103 - CH_2OCHCH_2OH)^+$ ion due to the loss of epoxypropanol. This is a commonly observed fragment ion from the dissociation of the $(M + 117)^+$ ion. It also follows that there should not be the formation of a substituted benzoyl cation at *m/z* 119 for M = **2** and **3** and at 135 for M = **6** and **7** and loss of CH_4 from the $(M + 103)^+$ ion. Therefore, the $(M + 103)^+$ ion is something different from the $(M + 117 - CH_2)^+$ ion. The high-resolution measurements on the $(M + 103)^+$ ion from **6** show that it is composed of two ions, resolved at 10 000 resolving power. The less abundant ion of mass 255.04570u shows a 3.0 ppm deviation from the molecular formula $C_{10}H_{12}O_6Al$ (theor. 255.04492). The higher-abundance ion observed at *m/z* 255.0023 shows 2.6 ppm deviation from the elemental composition $C_8H_9O_6Al_2$ (theor. 255.00297; obsd. 255.0023). The dissociation of the $C^+ = (M + 233)^+$ ion shows an increase of one mass unit when compared with the dissociation of the labelled $(M + 233)^+$ ion of **6** and **14**. The $(M + 103)^+$ ion from **3** and **6** overlaps with other ions in D_2O exchange experiments. Therefore, the structure of this ion has not been established.

2. Dissociation of adduct ions from *trans*-cinnamic acids



(a) $(M + 117)^+$ ($P^+ = (M + Al + Gly - 2H)^+$)

The decomposition of $P^+ = (M + 117)^+$ ions from **17–19** gives $(P - OH)^+$, $(P - H_2O)^+$, $(P - CH_2O)^+$, $(P - 44)^+$, $(P - 72)^+$,

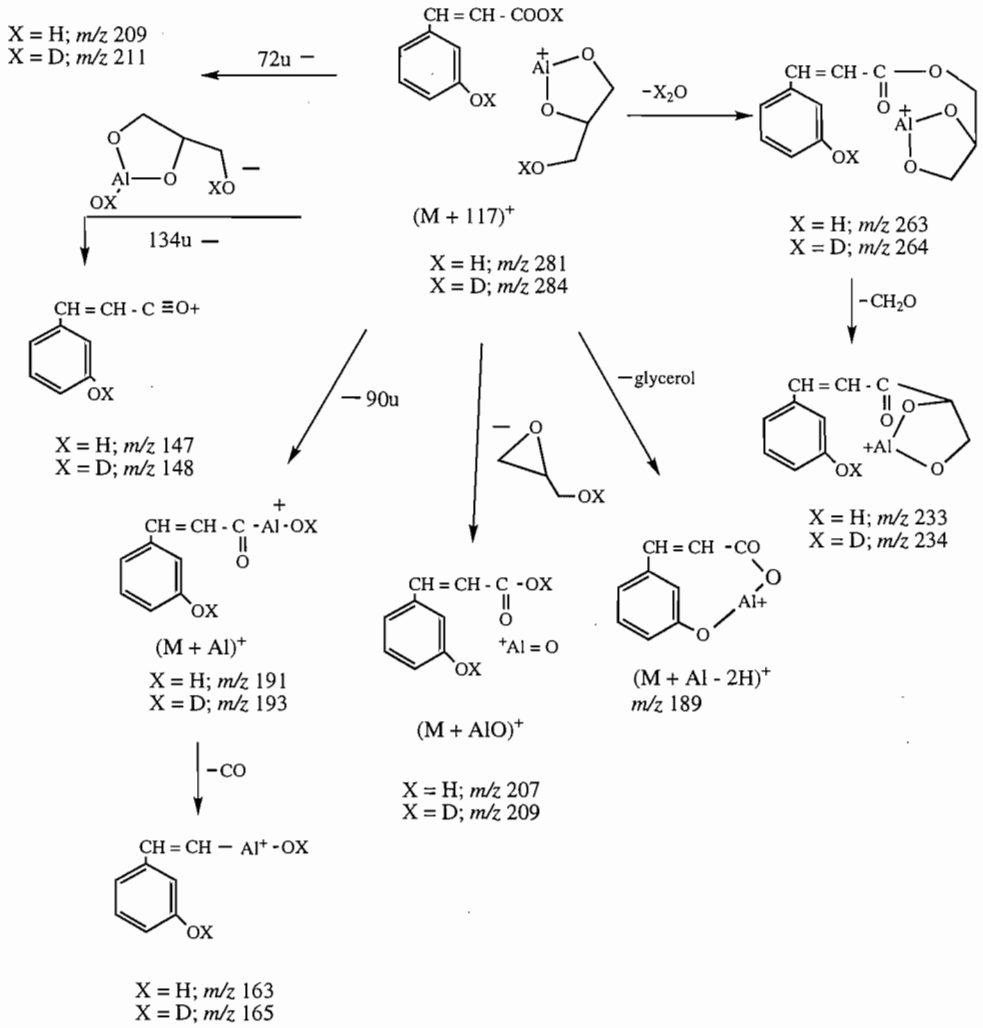
Scheme 1. The collisionally activated dissociation of the $(M + 233)^+$ ion from **14**.

$(P - 74)^+$, $(P - 90)^+$, $(P - 92)^+$, $(P - 118)^+$, and $(P - 134)^+$ and is followed by loss of CH_2O neutral (formaldehyde) from the $(P - H_2O)^+$ ion. The loss of water from the $(P - CH_2O)^+$ ion may also give rise to the ion at $(P - 48)^+$. The $(P - 74)^+$ ion is an adduct of AlO^+ with analyte, i.e., $(M + AlO)^+$ formed by the loss of epoxypropanol. The ion at *m/z* 209 ($(P - 72)^+$) can be formed from these acids by the removal of an acrylic acid unit (72u). Insertion of Al(III) into the carboxylic acids can form the $(P - 90)^+$ or $((M + Al(III))^+$ ion by removal of the neutral dideprotonated glycerol moiety. The loss of CO from the $(M + Al(III))^+$ ion gives the $(M + Al(III) - CO)^+$ ion at *m/z* 163. The $(P - 92)^+$ ions are due to the substitution of acidic protons with Al(III), i.e., the formation of $(M + Al - 2H)^+$ ions by elimination of the glycerol molecule from the $P^+ = (M + 117)^+$ ion of **17**. Its intensity is reduced significantly where M = **18** and **19**. The transfer of the OH group from the carboxylic acid to $(Al + Gly - 2H)^+$ ions leads to the formation of carbonyl cation at *m/z* 147 ($(P - 134)^+$) as observed for benzoic acids. Ions $(P - CH_2)^+$, $(P - CH_3)^+$, $(P - CH_4)^+$, $(P - OH)^+$, $(P - H_2O)^+$, $(P - CH_2O)^+$, $(P - CO)^+$, $(P - 44)^+$, $(P - 72)^+$, and $(P - 74)^+$ are observed from the dissociation of the P^+ ion of methoxy-substituted acids **20–22**. The loss of C_2H_2/26u from the $(P - CH_2O)^+$ and $(P - CO)^+$ ions, and an ion at *m/z* 161 corresponding to the carbonyl cation ($(P - 134)^+$) from the analyte was also observed. These $(P - CH_2O)^+$ and $(P - CO)^+$ ions are more significant in **21** and **22**. The fragmentation of the P^+ ion of **20** gives the $(P - CH_2)^+$ ion as the base peak whereas the other two acids **21** and **22** produce the $(P - H_2O)^+$ ion as the base peak. The fragmentation of $(M + 117)^+$ ions from methoxy and hydroxy acids is established based on the dissociation of labelled P^+ ions as illustrated in Scheme 2.



(b) $(M + 233)^+$ ($C^+ = (M + 2Al + 2Gly - 5H)^+$)

The CAD dissociation of the $C^+ = (M + 233)^+$ ion from **17–19** gives $(M + 159)^+$, i.e., $(C - 74)^+$, as the most abundant ion in the spectrum as well as less-abundant $(C - 86)^+$ and $(C - 130)^+$ ions. The loss of CH_2O and 72u (CH_2=CH-COOH)

Scheme 2. The collisionally activated dissociation of the $(M + 117)^+$ ion from **18**.

from the $(M + 159)^+$ ion gives rise to ions at *m/z* 293 and 251, respectively. The ion at *m/z* 293 gives an ion at *m/z* 249 by the loss of CO_2 (44u). However, there is less probability of formation of the $(M + 117)^+$ ion from the C^+ of **17–19**. The CAD of the $C^+ = (M + 233)^+$ ion from **20–22** also yields an $A^+ = (M + 159)^+$ ion with a high abundance. The significant ions at *m/z* 307 and 161 correspond to $(C - 104)^+$ and the carbonyl cation $(C - 250)^+$, respectively. From the C^+ ion, the transfer of an OH group to the $(2Al + 2Gly - 5H)^+$ ion produces $(C - 250)^+$ ions as observed for benzoic acids. These fragmentation pathways are confirmed by comparing the fragmentation of *d*-labelled adduct ions.

The dissociation of $A^+ = (M + 159)^+$ ions from **20–22** yields $(A - CH_2)^+$, $(A - CH_4)^+$, $(A - CO)^+$, $(A - CH_2O)^+$, $(A - 40)^+$, $(A - 42)^+$, $(A - 44)^+$, and ions at *m/z* 161 and 265. The $(M + 159)^+$ ion from the hydroxy acids **17–19** appears at *m/z* 323. The ion generated from the matrix corresponding to $(Al + 2Gly + TFA - 2H)^+$ also appears at *m/z* 323. Therefore, the *B/E* analysis of *m/z* 323 was used to determine that the fragments from this species are primarily due to the matrix.

Conclusions

Though the solubility of substituted benzoic acids and cinnamic acids is low in the highly polar matrix glycerol, we were able to study them with the addition of a mixture of ethyl acetate and ethanol to the matrix, without affecting the spectra significantly. The dissociation of $P^+ = (M + 117)^+$ ions produced an interesting fragment ion due to insertion of Al(III) into carboxylic acids, which is followed by the elimination of CO to yield $(M + Al(III) - CO)^+$ ions. The formation of $(P - 134)^+$ or carbonyl cations from the dissociation of $(M + 117)^+$, $(M + 159)^+$, and $(M + 233)^+$ ions depends on the ease of transfer of the hydroxyl anion to the metal ion. In contrast with the fragmentation of the same ions derived from amino acids and peptides, the production of fragment ions from the dissociation of $(M + 233)^+$ ions is attributed to the difference in the pH of the matrix solution.

Experimental

All experimental work was carried out using a Kratos (Manchester, U.K.) Concept 1S double focusing (EB geome-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.146.161.215 on 09/08/12

try) mass spectrometer, equipped with an Ion Tech (Teddington, U.K.) fast atom gun. The standard FAB source was used for the FAB spectra of carboxylic acids (2–3 mg) in a mixture of glycerol (25–30 mg) with $AlCl_3$ (3–5 mg), TFA (2 μL), and H_2O (2 μL) as a matrix. Where noted, a mixture of 2 μL of ethyl acetate and ethyl alcohol (~1:2 v/v) was added to the matrix solution to increase the solubility of some analytes. For each sample, 1 μL of prepared solution was loaded on to the 1 mm wide FAB probe tip and bombarded with xenon fast atoms produced at 6–8 kV using an emission current of 0.5–1 mA. The source housing pressure was maintained at (1–2) × 10^{-5} Torr (1 Torr = 133.3 Pa). The ions produced were accelerated to 8 kV. All the spectra were acquired at a resolution of ~1100 at a scan rate of 8 s/decade with an inter scan delay of 2 s over a mass range of 11–950 amu. All experiments were repeated three to four times to check the reproducibility. Each spectrum was the result of an average of 6–9 scans. The background was subtracted using the Kratos DART/MACH3 data system running on a SUN SPARC Station 10. Collisionally activated dissociation spectra were recorded by colliding the ion beam with helium in the first field-free region, which caused reduction of main beam intensity by 40–50%. Accurate mass measurements were made at a resolving power of 10 000 and 8 kV accelerating potential.

All the materials used are commercially available (Aldrich, Milwaukee, Wis.; Chem Service, West Chester, Pa.). Deuterium labelled acids and glycerol-d_3 were prepared by repeating the addition and evaporation of deuterium oxide.

Abstract: The equilibrium reactions between deprotonated D-lactobionic acid (4-*O*-β-D-galactopyranosyl-D-gluconic acid) and cobalt(II), nickel(II), copper(II), zinc(II), cadmium(II), and mercury(II) have been studied by potentiometric and spectrophotometric methods in aqueous solution. All measurements have been carried out at a temperature of 20.0 ± 0.1°C and at an ionic strength of 0.100 M ($NaNO_3$) with the corresponding stability constants calculated by applying computational methods. The interactions between the proposed cations with deprotonated D-lactobionic acid were compared with those corresponding to D-gluconic acid. Compounds of type: $Co(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot C_2H_5OH$, $Ni(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot C_2H_5OH$, $Cu(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot C_2H_5OH$, $Zn(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot C_2H_5OH$, and $Cd(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot 0.5C_2H_5OH$ have been isolated. These metal–sugar salts were characterized by elemental, thermogravimetric, and susceptibility analyses and FT-IR, UV–visible absorption, diffuse reflectance, and ^{13}C NMR spectroscopies.

Key words: D-lactobionate, metal complexes, equilibrium constants, potentiometry, solid state studies.

Résumé : Opérant en solutions aqueuses et faisant appel à des méthodes potentiométriques et spectrophotométriques, on a étudié les réactions d'équilibre entre l'acide D-lactobionique déprotoné (acide 4-*O*-β-D-galactopyranosyl-D-gluconique) et des ions cobalt(II), cuivre(II), zinc(II), cadmium(II) et mercure(II). Toutes les mesures ont été effectuées à une température de 20,0 ± 0,1°C, à une force ionique de 0,100 M ($NaNO_3$); les constantes de stabilités correspondantes ont été calculées en appliquant diverses méthodes de calcul. On a comparé les interactions entre les cations proposés et l'acide D-lactobionique déprotoné avec les interactions correspondantes avec l'acide D-gluconique. On a pu isoler des composés des types : $Co(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot C_2H_5OH$, $Ni(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot C_2H_5OH$, $Cu(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot C_2H_5OH$, $Zn(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot C_2H_5OH$ et $Cd(C_{12}H_{21}O_{12})_2 \cdot 2H_2O \cdot 0{,}5C_2H_5OH$. On a caractérisé ces sels métalliques de sucre par des analyses élémentaires, thermogravimétriques et de susceptibilité ainsi que par spectroscopies «FT-IR», d'absorption UV–visible, de réflexion diffuse et de RMN du ^{13}C.

[Traduit par la rédaction]

Introduction

As part of our program on the coordination chemistry of sugar acids (1–7) we have set out to elucidate the complexometric behavior of deprotonated D-lactobionic acid (4-*O*-β-D-galacto-pyranosyl-D-gluconic acid) with Co(II), Ni(II), Cu(II), Zn(II), Cd(II), and Hg(II) ions. We have already reported that the importance of studying the interaction between D-gluconic acid and transition metal ions is related to the use of this natural ligand as a sequestering agent for both essential and toxic metal ions present in biological media (1, 5). D-Lactobionic acid (LBA) (Scheme 1) is a natural disaccharide constituted by D-galactose and D-gluconic acid joined through a glycosidic linkage, which is usually employed by nature in biological media as a chelating agent of transition and heavy metal

ions. Presently, LBA is employed to chelate Cu(II) for its incorporation in milk as a nutritional supplement (8).

The interaction of sugar acids containing both carboxylate and hydroxyl groups with metal ions is of great interest in the biochemistry of these metals related to environmental and toxicological problems. We have studied the composition of some isolated lactobionate complexes with the metal ions indicated above. Structural information was obtained by means of elemental, thermogravimetric, and susceptibility analyses, complemented by ^{13}C NMR, UV–visible, and diffuse reflectance spectroscopies, and the investigation was extended to the coordination in aqueous solution. The computer program selected to process the data allowed us to provide an accurate description of the aqueous coordination chemistry of the systems under investigation.

Experimental

Reagents

D-Lactobionic free acid was obtained from Sigma. Its purity was checked by elemental analysis and pH titration. The stability of lactobionic acid in acidic and basic media was confirmed by paper chromatography. Stock solutions of Co(II), Ni(II), Cu(II), Zn(II), Cd(II), and Hg(II) (0.010–0.020 M) were prepared from their nitrates of analytical grade (Merck). With the purpose of avoiding the Hg(II) hydrolysis, its solution was prepared in 0.05 M nitric acid and the exact amount of this acid was evaluated by a Gran's plot (9). The exact concentrations of the cation solutions were determined by titration with ethylenediaminetetraacetic acid (EDTA) solution (10). Stock solutions of NaOH and HNO_3 were standardized against potassium hydrogenphthalate and sodium carbonate, respectively. Gran's method was applied for the determination of carbonate on NaOH solutions (9).

Potentiometry

The equilibrium constants for D-lactobionate metal complexes were determined by using a Corning 350 research pH meter equipped with glass and calomel reference electrodes calibrated with HNO_3 and acetic acid at an ionic strength (μ) of 0.100 M to read pH as p[H]. Titrations were carried out under a nitrogen atmosphere. The temperature was maintained at 20.0 ± 0.1°C and μ was adjusted to 0.100 M by addition of $NaNO_3$. The solutions of metal and D-lactobionic acid were diluted, in different ratios, to a volume of 100 mL, with final concentrations in the range $(1–3) \times 10^{-3}$ M. In this way, those low concentrations did not contribute significantly to the ionic strength of the medium.

Equilibrium pH values were determined at every incremental addition of NaOH or HNO_3 to the experimental solutions. These increments were sufficiently small as to provide a ratio of experimental points per a value of higher than 10:1 (a = moles of base per mol of D-lactobionic acid or metal). Reversibility of the reactions was suggested by the fact that the direct and inverse titration data were coincident, within the investigated pH range (2.5–11).

Potentiometric equilibrium constants calculation

Since all the complexes studied were not fully formed at low pH, their stability constants could be determined by direct potentiometric titration, with the aid of the BEST program (11*a*).

Spectrophotometric measurements

The spectra were recorded on a Metrolab 1700 spectrophotometer. The spectrophotometric titrations were performed in the visible region of the spectra in order to evaluate the equilibrium constants for the complexes produced by Cu(II) and Ni(II) ions, respectively. For the Cu(II) system the metal to D-lactobionic acid ratios were 1:1 and 1:2, while for Ni(II) it was 1:1. The system produced between D-lactobionate and Co(II) could not be evaluated employing the present method because in alkaline media (the region where complex formation takes place) the required high concentrations of reactants led to oxidation of the metal ion. The metal concentrations employed in the spectrophotometric experiments were in the range 2×10^{-3} to 1×10^{-2} M and those for the D-lactobionic acid in the range 4×10^{-3} to 2×10^{-2} M. Beer's law was checked previous to performing each experiment. The titrations were carried out under nitrogen at 20.0 ± 0.1°C at μ = 0.100 M ($NaNO_3$). An excess of 0.5 M NaOH was added to the experimental solution and a back titration was performed with 0.1 M HNO_3. After each addition of acid, an exact aliquot of the solution was extracted and the absorbance measured at the wavelength at which the absorbance is a maximum for each system under study: 652, 666, and 391 nm for 1:2 Cu(II) – D-lactobionic acid, 1:1 Cu(II) – D-lactobionic acid, and 1:1 Ni(II) – D-lactobionic acid systems, respectively.

The plots of absorbance vs. pH were computationally processed employing the EPSILON program (12), which allows estimation of the value of equilibrium constants and molar absorptivities of the species proposed on each system.

^{13}C NMR

All spectra were acquired on a Bruker AC-200 E pulsed Fourier-transform instrument with a 4.3 T supercon magnet, at a carbon-13 resonance frequency of 50.1 MHz. All measurements were conducted at 22°C. The samples were prepared by dissolving D-lactobionic acid in distilled water until a concentration of 0.3 M with 10% D_2O to provide the deuterium lock. For the diamagnetic metal ions the metal concentration was equal to that of the D-lactobionic acid, whereas for the paramagnetic ion a metal concentration ranging from 2×10^{-3} to 2×10^{-2} M was employed.

Preparation of metal ion – D-lactobionate complexes in the solid state

The metal ion – D-lactobionate complexes were synthesized following the procedure described by Melson and Pickering (13). Specifically, the metal ion (0.0075 mol) as either carbonate (Co(II), Ni(II), and Cu(II)) or oxide (Zn(II) and Cd(II)) was added to a previously boiled (5 min) aqueous solution containing 0.015 mol of free D-lactobionic acid. The final mixture was boiled for 2 h. To avoid a redox reaction (production of copper(I) oxide), the copper(II) – D-lactobionic acid solution was boiled for only 45 min. Ethanol was added to the solution until a precipitate was obtained. The solid was removed by filtration, and recrystallized three times from (1:1) ethanol–water. The final product was washed with ethanol, dried under vacuum over phosphorus pentoxide at room temperature, ground to a fine powder, and again dried at 80°C under vacuum over P_2O_5.

The purity of the isolated salts was checked by elemental analysis.

Analysis of the solid complexes

Microanalyses of C and H were determined by the Center of Scientific Research of the University of Granada, using a Fisons 1108 CHNS microanalyser. The metal percentages in the complexes were determined by complexometric titration with EDTA employing appropriate indicators (10). DSC data were obtained on a Shimadzu DSC-50 differential scanning calorimeter, using a heating speed of 10°C min^{-1}. Thermogravimetric curves were obtained in an atmosphere of pure air using a Shimadzu TGA-50H, with a heating speed of 20°C min^{-1}, equipped with a Nicolet model 550 IR gas analyzer and Fisons model Thermolab mass detector. IR spectra were recorded on a FTIR Nicolet 20 SX8 spectrophotometer. Magnetic measurements were carried out on a Manics DSM-8 instrument in the 80–290 K temperature range. The diffuse reflectance spectra of the solid complexes were obtained with a Cary-5E refractometer provided with a praying mantis module.

Results and discussion

Studies in solution

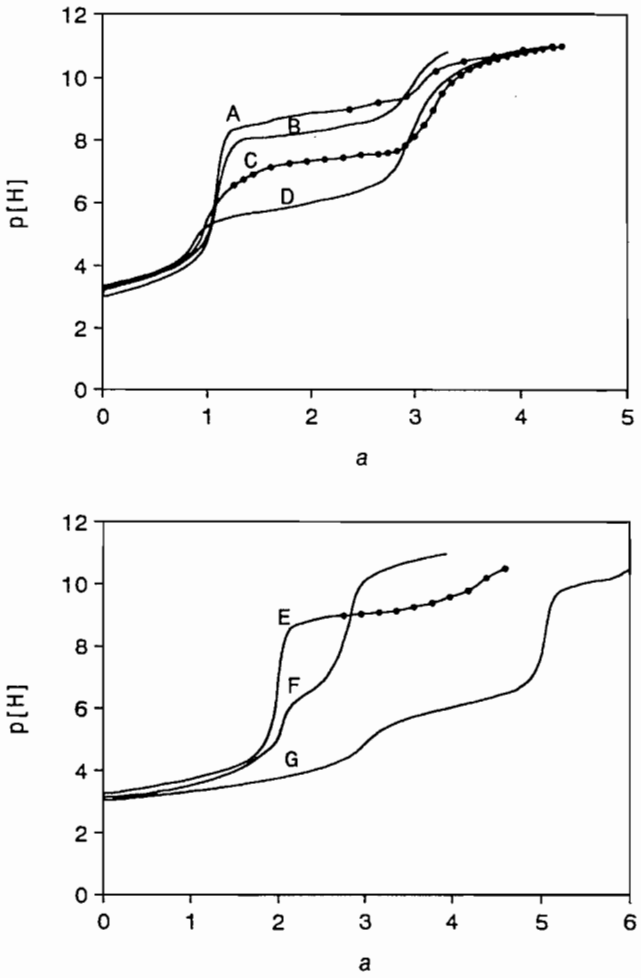
Potentiometric measurements

Figure 1 shows selected potentiometric profiles of the systems under study (the figure is divided into two plots for clarity). Table 1 displays the equilibrium constant values for the complexes formed in such systems. The D-lactobionic acid protonation constant used in the calculation is log K_H = 3.53 (4). The log K_w employed throughout the whole work is −13.87 (20°C, μ = 0.1 M) (14). The overall hydrolysis constants for Co(II) and Hg(II) metal ions are log K_{CoH-1} = −9.85 and log K_{HgH-1} = −3.60 respectively (15*a*, 15*b*). There was no need of invoking hydrolytic species for the other metal ions involved in the present study.

Co(II) – D-lactobionate system

A blue precipitate was observed around pH 9 that was attributed to a basic cobalt(II) salt. In the soluble region the $[CoLH_{-2}]^-$ complex was detected. The negative stoichiometric coefficient under the H represents the number of protons displaced upon complex formation, which could arise either from D-lactobionic acid hydroxyl groups or from coordinated water molecules. It was not necessary to introduce either intermediates $[CoL^+]$ and $[CoLH_{-1}]$ or other complexes with different metal to D-lactobionic acid ratios.

Ni(II) – D-lactobionate system



The potentiometric curves of Ni(II) – D-lactobionic acid did not show precipitation, independently of the metal to D-lactobionic acid ratio. Only two species were detected: $[NiL]^+$ and $[NiLH_{-2}]^-$. This case differs from the systems produced between Ni(II) and D-gluconic acid, where only species of 1:2 stoichiometry were detected (1).

Cu(II) – D-lactobionate system

1:1, 1:2, and higher metal to D-lactobionic acid ratios were tried, and no precipitation took place during the potentiometric determination. For the 1:1 ratio, the potentiometric profile showed a first break at a = 1 and a second one at a = 3. This was indicative of a total displacement of three moles of hydrogen ion due to the chelation process between the metal ion and the aldobionic acid. The titration curves were fitted by considering $[CuL]^+$ and $[CuLH_{-2}]^-$ as the major complex species. The first mole of the released proton was attributed to dissociation of the carboxylic group of the D-lactobionic acid and the other two might be attributed either to the deprotonation of coordinated water molecules or to the hydroxyl group of the saccharidic chain being dissociated. The $[CuL]^+$ species only reaches a maximum of 11% with respect to the total analytical metal ion concentration. Thus, the equilibrium constant was determined from five replicates and the error was informed with a 95% confidence level by applying the Student test (Table 1). The second complex species was detected above pH 5.6 and is predominant above pH 9.6.

When 1:2 and higher Cu(II) – lactobionic acid ratios were employed, $[CuL_2]$, $[CuL_2H_{-1}]^-$, $[CuL_2H_{-2}]^{-2}$, and $[CuL_2H_{-4}]^{4-}$

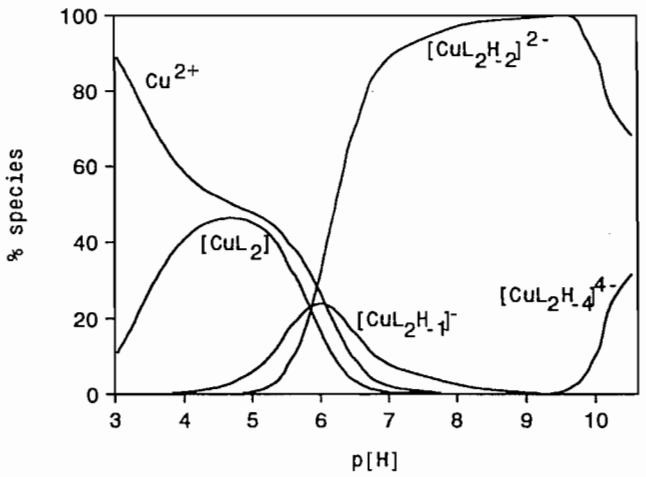
complexes were identified (Fig. 2) that were coincident with the ones reported by Bouhsina et al. (16).

Zn(II) – D-lactobionate system

The titration curve shown in Fig. 1 is very similar to the one found for the Zn(II) – D-gluconic acid system (1). Two breaks can be observed, one at $a = 1$ (dissociation of carboxylate group) and the second one at $a = 3$. This latter inflection may be explained by the $[ZnH_{-2}L]^-$ complex formation.

Unfortunately, the solid phase produced at pH 7 prevented the stability constant computation. In the present experimental conditions, the formation of chelate containing a 1:2 metal to D-lactobionic acid ratio was not detected.



Cd(II) – D-lactobionate system

In this system, and for different metal to D-lactobionic acid ratios, $Cd(OH)_2$ precipitates above pH 8. In the soluble region, only $[CdLH_{-2}]^-$ was found as the principal species. This differs from the Cd(II) – D-gluconic acid system, where an additional complex was detected: $[CdL]^+$. Through the equilibrium constant value, it can be seen that the $[CdLH_{-2}]^-$ species (where L is the D-lactobionate) shows the same stability as the analogous one in the D-gluconic acid system (log $K_{CdGH-2} = -15.7$) (1). Owing to its low concentration in solution (not higher than 20% with respect to the analytical concentration of the metal ion), its equilibrium constant has a considerable uncertainty. Therefore, it is reported with a 95% confidence limit, employing the Student test parameter for six potentiometric determinations. Each potentiometric measurement afforded a σ_{fit} of less than 0.01 (11*b*).

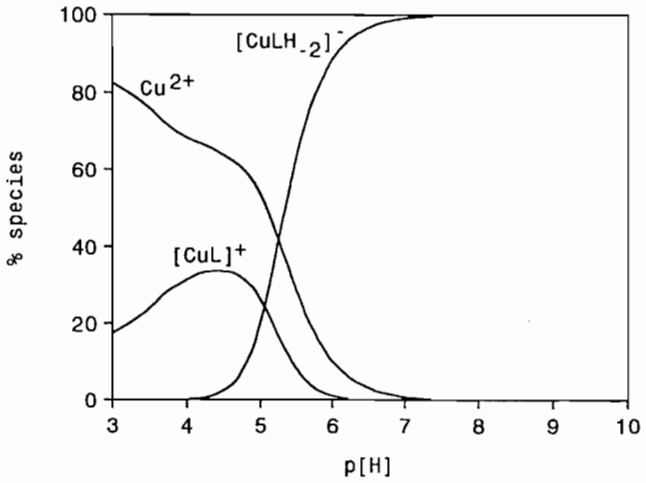
Hg(II) – D-lactobionate system

No precipitation was observed within the pH range studied. To explain the potentiometric results for the Hg(II) system, the presence of $[HgLH_{-1}]$ and $[HgLH_{-2}]^-$ complexes was proposed, similar to those found for the Hg(II) – D-gluconic acid system. The complex species arising from the interaction of Hg(II) with D-gluconic acid are more stable (log $K_{HgGH-1} = -0.09$ and log $K_{HgGH-2} = -4.03$) (1) than those produced in the Hg(II) – D-lactobionate system.

Fig. 2. Distribution of species as a function of p[H] in the 1:3 Cu(II) – D-lactobionic acid system. $C_M = 1.002 \times 10^{-3}$ M, $C_L = 3.005 \times 10^{-3}$ M; μ = 0.100 M ($NaNO_3$); t = 20.0°C.

Spectrophotometric determinations

The electronic spectral patterns at different pH values of the colored Cu(II) – D-lactobionate system present weak bands in the visible region that are due to *d–d* transitions. The signals in the UV region can be assigned to charge transfer bands (17).



The spectrophotometric titrations of 1:1 metal – D-lactobionic acid solutions afforded the same species found during the potentiometric determination: $[CuL]^+$ and $[CuLH_{-2}]^-$. The equilibrium constant values obtained through these two inde-

Fig. 3. Distribution of species as a function of p[H] in the 1:1 Cu(II) – D-lactobionic acid system obtained from spectrophotometric titration data; $C_M = 1.260 \times 10^{-3}$ M, $C_L = 1.262 \times 10^{-3}$ M; $\mu = 0.100$ M ($NaNO_3$); $t = 20.0$°C.

pendent methods were very similar (Table 1). Hydrolytic species of Cu(II) ion were not found. According to the species distribution plot (Fig. 3) the cationic $[CuL]^+$ species is predominant at pH 4.5 and the anionic $[CuLH_{-2}]^-$ species at alkaline pH. At pH lower than 3.7, where no complex formation was detected, the only band present was at 808 nm, which has been attributed to the Cu(II) aqueous complex (17, 18*a*).

The computational processing of the spectrophotometric data for a 1:2 metal to D-lactobionic acid ratio only yielded the presence of both $[CuL_2]$ and $[CuL_2H_{-2}]^{2-}$ chelates. In this case the spectrophotometric method was ambiguous for determining the other complex species, which were detected potentiometrically. At the same time, overlapping of the absorbance bands for the different complex species in equilibrium at different pH impeded the assignment of the correct absorption band of the electronic spectra for the 1:2 system. Nevertheless, when the pH was lowered, the wide band at 666 nm (pH 11.7) shifted to higher wavelengths, and thus a distorted octahedral geometry was proposed for the Cu(II)–D-lactobionic species detected through the present method (19*a*).

The visible spectra of nickel(II) complexes show three distinct absorption maxima at pH 12: 391, 671, and 1073 nm, which are in agreement with *d–d* transitions in an octahedral structure (18*b*, 19*b*).

The spectrophotometric titration of the 1:1 Ni(II) – D-lactobionic acid system showed the presence of two main bright-green complexes: $[NiL]^+$ and $[NiLH_{-2}]^-$. The stoichiometry and equilibrium constant values for both complexes were similar to that found through the potentiometric method (Table 1).

^{13}C NMR spectra

The observation of selective line broadening and (or) chemical shift displacement of signals in the ^{13}C NMR spectra of metal complexes is a useful means of obtaining qualitative information about possible coordination sites (20). We previously analyzed and assigned the solution (D_2O) ^{13}C NMR spectra of D-lactobionic acid alone (6). This work compares the present results with those obtained with D-gluconic acid (1).

The ^{13}C NMR spectra of the Co(II)–D-lactobionate system were obtained at pH 9, where the main complex species was $[CoLH_{-2}]^-$. The signals ascribed to C-1, C-2, and C-3 of the D-lactobionic acid suffer significant broadening. Taking into account these results, we suggest that in the chelation process the carboxylate group and the deprotonated hydroxyl of C-2 and C-3 are involved in the chelate ring. This is coincident with the conclusions obtained at pH 10 for the Co(II) – D-gluconic acid system (1).

The NMR experiments in the Ni(II)–D-lactobionate system were performed at pH 10, where the main complex is $[NiLH_{-2}]^-$. The ^{13}C NMR spectra recorded for the Ni(II) complex showed both broadening and changes in the chemical shifts for C-1, C-2, and C-4. This fact suggests that in the coordination of the Ni(II) complex the metal ion is octahedrally bonded to the carboxylate group, to the deprotonated hydroxyl group at C-2, and to the lone electron pair of the C-4 oxygen. In agreement with the complex stoichiometry and the ^{13}C NMR data, the additional mole of displaced proton may belong to a coordinated water molecule.

The species distribution plot for the Cu(II)–D-lactobionate system showed the predominance at pH 8 and 11 of the following chelates: $[CuL_2H_{-2}]^{2-}$ and $[CuL_2H_{-4}]^{4-}$, respectively. The ^{13}C NMR experiments performed at both pH's showed that the most affected (broadened) signals were for C-1, C-2, and C-3 for $[CuL_2H_{-2}]^{2-}$ and C-2, C-3, and C-5 for $[CuL_2H_{-4}]^{4-}$. For the first complex, the metal ion should coordinate with the carboxylate group and the deprotonated hydroxyl groups at C-2 and C-3, while with the second complex only deprotonated hydroxyl groups would be involved, belonging to C-2, C-3, and C-5, without participation of the carboxylate group. It should be noticed that, both for $[CuL_2H_{-2}]^{2-}$ and $[CuL_2H_{-4}]^{4-}$, there are more non-carboxylic affected carbons than protons released per ligand. Therefore, in each complex, the lactobionate units should coordinate through different carbons. Specific assignments may not be obtained from this kind of experiments. Bouhsina et al. (16) indicated this possible coordination mode, although we were able to identify the hydroxyl groups involved.

The ^{13}C NMR spectra in the Zn(II)–D-lactobionate system were registered at pH 8, avoiding high pH values due to the hydroxide precipitation. Table 2 shows small changes in the signals of C-1, C-3, and C-4. The $[ZnLH_{-2}]^-$ species might be predominant at this pH, which means that the Zn(II) interacts with the carboxylate group, the deprotonated hydroxyl group bonded to C-3, and the lone pair electrons of the glycosidic linkage. The second mole of displaced protons should belong to a coordinated water molecule. For the Zn(II) – D-gluconic acid system the most affected signals were C-1, C-2, and C-3 (1).

The ^{13}C NMR spectra registered for the Cd(II) system at pH 8 (where the main complex species is $[CdLH_{-2}]^-$) showed that the affected carbons were C-1, C-3, and C-5 (see Table 2). This kind of chelation implies two chelate rings, which help to increase the thermodynamic stability of the system. The ^{13}C NMR spectra registered for the Cd(II) – D-gluconic acid system at pH = 4.5 and 10 showed that the affected carbons were C-1, C-2, and C-4, involving a coordination to the carboxylate groups and the deprotonated hydroxyl group of C2 and C4 (1). D-Lactobionic acid bears no free hydroxyl group at C-4, and that at C-5 is involved in the coordination process, instead of a

coordinated water molecule. This makes a difference when compared with the same kind of complex suggested for Zn(II)–D-lactobionate.

Under the NMR experimental conditions for the mercury system, precipitation of the corresponding oxide is detected above pH 3. Therefore, the spectrum was measured at this pH value. In this system carbons C-1 and C-2 suffer chemical shift modifications (Table 2). Since the predominant complex species is $[HgLH_{-1}]$, the 1,2 chelation mode is proposed.

Solid state analysis

The analytical results of the solid complexes formed between D-lactobionate and the metal ions under investigation are reported in Table 3. All the complexes were obtained in solvated form. Coordinated molecules of water and ethanol were observed, although all samples were dried under vacuum at 80°C over 2 h. For the complex species with the diamagnetic metal ions Zn(II) and Cd(II), the content of ethanol was determined by ^1H NMR spectroscopy. Since a redox reaction took place, it was not possible to isolate the Hg(II) – D-lactobionate solid complex.

Thermogravimetric curves

The main process occurring in the TGA curves is a pyrolytic decomposition that takes place above 200°C. Usually, this is accompanied by a previous loss of solvent in the range 100–190°C (see Table 3 for composition of complexes). The release of ethanol is detected together with the dehydration process, except for the solid complexes of Cd(II) and Ni(II) with D-lactobionate, where the loss of organic solvent takes place at a temperature above 200°C. These results were confirmed by IR spectra of the lost products. The temperature for loss of water and ethanol molecules might indicate that these molecules are coordinated to the metal.

Figure 4 shows a typical thermal decomposition of the solid complexes under study, in this particular case for the Cd(II)–D-lactobionate complex.

The Cd(II) and Ni(II) lactobionates suffered dehydration in one step (DGTA maxima: 155 and 165°C, respectively); Cu(II)–D-lactobionate dehydrates and partially loses ethanol in one step (DGTA maximum: 171°C), and Co(II) and Zn(II) complexes release water and ethanol in two steps (DGTA maxima at 151, 182°C and 155, 179°C respectively).

The pyrolytic process of the ligand took place at 200°C in three steps except for the Cu(II) complex, which presented a four-step pyrolytic process. The pyrolytic products were water, carbon monoxide, carbon dioxide, and ethanol. The final pyrolytic residues at 400–600°C were determined as

mixtures of carbonates and oxides of the corresponding metal ion.

Magnetic susceptibility

In Table 4 the magnetic data obtained for the isolated compounds have been collected. The Curie–Weiss law ($\chi_m = C/(T-\theta)$, where χ_m is the molar susceptibility, C is the Curie constant, T is absolute temperature, and θ is the Weiss constant) was applied. The equation used to calculate magnetic moments was $\mu_{eff} = 2.84\sqrt{C}$. Corrections for diamagnetism were done using the values of -157×10^{-6} and -12.8×10^{-6} for the diamagnetic susceptibilities of D-lactobionate and the metal ions, respectively.

The magnetic moment for Co(II) reveals a high-spin octahedral geometry. The value of $\mu_{eff} = 5.21$ MB was higher than the theoretical value of 3.87 MB, consistent with a distorted octahedral geometry (see below). The same situation was found for the Ni(II) complex.

The magnetic susceptibility values for the Cu(II) complex suggested magnetic interactions at low temperatures. Presently, we are performing experiments at liquid helium temperatures.

Reflectance spectra

The diffuse reflectance spectra of Co(II), Ni(II), and Cu(II) complexes were measured and the corresponding bands are shown in Table 5.

The bands of the spectra of both Co(II) and Ni(II) com-

plexes were those expected for the electronic transitions of d^7 and d^8 metal ions in octahedral arrangements, respectively. The assignments given for the Co(II) complex are in agreement with those observed for octahedral cobalt(II) oxo complexes (19*c*).

The second band of the Ni(II) spectrum (704 nm) was found to be split into two signals, probably due either to spin-orbit coupling or to interactions with the nearest electronic level ^1E_g. The relationship between the first two bands in this case gave a value of 1.76, which was an indication that the metal ion should be involved in an octahedral arrangement. The energy value corresponding to the first transition (8.53×10^3 cm^{-1}) gives the magnitude of the splitting field Δ_0.

The reflectance spectra for the Cu(II)–D-lactobionate showed a single wide band at 807 nm, which was coincident with the value of the crystal field splitting and belongs to the electronic transition $^2T_{2g} \leftarrow {}^2E_g$. This result was in agreement with a tetragonal distortion of the octahedral geometry.

FT-IR spectra

IR spectra for the solid complexes were recorded in the region 4000–400 cm^{-1} and the interpretation was based on a comparison with the free D-lactobionic acid and structurally related compounds.

The intense broad band observed at ca. 3500–3100 cm^{-1} in the spectra of the free D-lactobionic acid was assigned to the strongly hydrogen-bonded OH groups. The interaction between the sugar hydroxyl groups and the metal produces broadening but no shift of the sugar OH stretching vibrations. The CH and CH_2 stretching vibrations, which appear at 2800–3000 cm^{-1} in the infrared spectra of the complexes, are similar to those found in the spectrum of the free D-lactobionic acid. The main change was observed in the carbonyl stretching vibration region, which appears at 1744 cm^{-1} in the free D-lactobionic acid. This band disappears in the solid complexes and a new band appears at 1610 cm^{-1}, assigned to an antisymmetric stretching carboxyl frequency (21). The concomitant carboxylate symmetric frequency (usually appearing at 1400–1100 cm^{-1}) could not be assigned due to overlapping with strong sugar C–O stretching vibrations. Because of this it was not possible to evaluate the difference in values between both types of bands and to obtain additional coordination data.

Conclusions

The interaction between D-lactobionate and bivalent metal ions afforded mainly 1:1 species, except for the Cu(II) system where the 1:1 and 1:2 complex species were found. The equilibrium constant values for the D-gluconate complexes were higher than those for D-lactobionate complexes. This could be attributed to the preferred rigid conformation of the acid disaccharide in solution, which restricts the coordination modes. The stoichiometric ratios and equilibrium constant values determined by the potentiometric and spectrophotometric methods were coincident. ^{13}C NMR spectroscopy allowed us to determine which hydroxyl groups of the D-lactobionic acid chain were involved in the chelation process, with concomitant participation of coordinated water molecules.

In the solid phase, the complexes produced between the metal ions employed in the present study and D-lactobionate presented a 1:2 stoichiometry and the spectroscopic studies allowed us to determine that the preferred coordination mode is the octahedral one.

Electrolytic conductivity of crystal violet based quaternary ammonium polyelectrolytes in *N,N′*-dimethylformamide and dimethyl sulfoxide

Meenakshi Singh, Anil Kumar, Shirley Easo, and B.B. Prasad

Abstract: Electrolytic conductivities of crystal violet based quaternary ammonium polyelectrolytes in very dilute solutions of dimethylformamide and dimethyl sulfoxide at 25°C have been investigated. The electrolytic conductivity (κ) as a function of concentration for systems having a reduced charge density (ξ) greater than unity revealed a very narrow range of linearity in the dilute region. A modest correlation has been made with the counterion condensation and the polycation conformations in order to explain the relative magnitude of limiting equivalent conductivities.

Key words: conductance, polyelectrolyte, aprotic solvent, solvation, counterion condensation.

Résumé : Opérant à 25°C, on a mesuré les conductivités électrolytiques de solutions très diluées de polyélectrolytes de sels d'ammonium quaternaire reliés au cristal violet dans le diméthylformamide et de diméthylsulfoxyde. Un examen de la relation entre la conductivité électrolytique (κ) et la concentration des systèmes ayant des densités de charge réduite (ξ) plus grande que l'unité permet de mettre en évidence une plage très étroite de linéarité dans la région diluée. Il a été possible d'établir une modeste corrélation entre le degré de condensation du contreion et les conformations du polycation qui devrait permettre d'expliquer l'amplitude relative des conductivités équivalentes limites.

Mots clés : conductance, polyélectrolyte, solvant aprotique, solvation, condensation du contreion.

[Traduit par la rédaction]

Introduction

Macroion mobility has proved to be an important property for providing an insight into the sizes, frictional coefficients, as well as conformations of polyelectrolytes (1–4). In dilute polyelectrolyte solutions, which still involve long-range intermolecular interactions, their conformational alterations are unexpectedly pronounced. The rapid increase of equivalent conductivity in dilute solution characterizes the behaviour of most polyelectrolyte solutions. However, counterion condensation may play a key role in determining the limiting equivalent conductivity of the polyions. In this sense, the present paper explores the typical behaviour of a few nitrogen-based polyelectrolytes in dipolar aprotic solvents, viz., *N,N′*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO). The polyions studied have distinctive structural constituents carrying ethylene, xylylene, and 2,5-thiophenylene links in their repeating units of the polymeric chain. This covers a wide range of quaternary nitrogen centres: (*i*) where quaternary nitrogens are located on the main chain (not as side-chain constituents); (*ii*) where backbone quaternary centres constitute a parallel cationic track with quaternized nitrogens on the side groups of the molecules; and (*iii*) where the heterocyclic ring nitrogens are quaternized with acyl derivatives in the repeating unit of the chain. The surge of interest for investigation in DMF and DMSO is primarily due to their dipolar aprotic characteristics, which avoid any proton interference with the conductivity of the polyions. The solubility restriction in the present instance in media of high dielectric constant does not allow for characterization of transport properties over a range of varying dielectric constants. Nevertheless, the moderately intermediate dielectric constant values at 25°C (DMF 36.1 and DMSO 46.6) and reasonably large Gutmann's donor number (DMF 26.6 and DMSO 29.8 kcal mol^{-1}) result in their good solvent behaviour, particularly that for which ion–dipole-type solute–solvent interactions are preferred. The anion solvation ability of DMF and DMSO (5) is negligibly small. Therefore, the interactions of a polycationic system with intermediate environments of varying dielectric constants are considered worthy of investigation in aprotic solvents.

Experimental

Solvents DMF and DMSO (99% pure, Sarabhai-Merck, stated purity 99 mol% (CO_2 < 0.02 mol%; H_2O < 0.03 mol%; conductivities, 1.6×10^{-8} S cm^{-1} (25°C) (DMF) and 1.1×10^{-8} S cm^{-1} (25°C) (DMSO)) were purified and stored as described elsewhere (6). All other chemicals were either high-purity materials or were purified before use. An automatic burette fitted into a sealed container was used as the solvent dispenser under pure nitrogen gas to avoid contamination with CO_2 and water from the air. Materials that fulfill the desired structural

Fig. 1. Structures of the polyelectrolytes.

distinctions as stated above are as follows: **A**, poly(*N*-ethylene monohydroxy crystal violet dibromide]; **B**, poly[*N*-*p*-*x*ylylene crystal violet trimethoxide]; **C**, poly[*N*-2,5-diacylthiophenylene crystal violet trichloride], and **D**, poly[*N*-2, 5-diacylthiophenylene-4,4′-bipyridinium dichloride]. Details of the syntheses, characterizations, and purity of these polycations (structures in Fig. 1) have been reported elsewhere (7).

The reported equivalent conductances are calculated on the basis of equivalents of counterions available per mole of the different compounds studied, and are corrected for the solvent conductance.

The effect of possible adsorption in very dilute solution of the polycations was apparently negligible, as the conductivity for a certain concentration was always found to be very reproducible with a variation within $\pm 1 \times 10^{-7}$ S cm^{-2} after the attainment of thermal equilibrium. All conductances were measured at (25 ± 0.05)°C in the conventional way (8) using an immersion-type special conductivity cell with bright platinum electrodes having cell constant 0.6055 cm^{-1}. A Beckman RC 18 A conductance bridge and a WTW (model LBR/B) instrument were used; no significant variations in resistances were noted at frequencies 0.05, 1, and 3 kHz.

Furthermore, the possible absorption of traces of water molecules with nonaqueous solution over long periods of exposure in air (20 ± 5 h) did not affect the measurement, as repeated measurements with a given solution, between which the cell was conditioned with solutions of different concentrations, always led to identical results. The relative standard

deviation or coefficient of variation was found to be less than 0.03% in DMF and 0.02% in DMSO for five successive measurements with the level of certainty better than 95% (χ-test). However, as a preventive measure, all experiments were carried out using freshly prepared solutions, which were found by Karl Fischer titrations to be devoid of any detectable traces of water.

Theoretical background

The limiting equivalent conductivity of an electrolyte is generally obtained by extrapolation of the plot of Λ_c vs. $C^{1/2}$. However, this is not feasible in the case of a polyelectrolyte since equivalent conductivities (Λ_C) may vary upward or downward due to the changes in conformation and (or) counterion condensation. Thus, an alternative procedure for extrapolation is considered by using the equation

$$[1] \quad \kappa = \kappa_0 + \Lambda_0 \cdot C + C \cdot \phi(C)$$

where κ and κ_0 are electrolytic conductivities of the solution and solvent, respectively, C is the equivalent concentration, and the function $\phi(C)$ denotes the effect of interionic interactions. The slope ($d\kappa/dc$) of a plot of κ against C approximates the limiting conductivity (Λ_0), provided other derivatives $d\kappa_0/dC$ and $d[C\,\phi(C)]/dC$ in the differential form of the eq. [1] are neglected as compared to Λ_0. However, Λ_0 may be determined from conductivity data obtained at extreme dilution, provided the κ vs. C curve is linear over a sufficiently wide range of concentration (4).

$$[2] \quad \frac{d\kappa}{dC} = \frac{d\kappa_0}{dC} + \Lambda_0 + \frac{d}{dC}[C \cdot \phi(C)]$$

Another empirical approach for evaluation of polyion limiting conductivities from the conductance data is based on the Lattey equation (9):

$$[3] \quad \Lambda_0 - \Lambda_c = \frac{\sqrt{C}}{D + G\sqrt{C}}$$

which was originally suggested for simple electrolytes and has the same form as that of the relationship proposed by Robinson and Stokes (10) from an extension of the Onsager theory for ions of finite sizes. However, unlike the Onsager theory, the values of D and G in the case of polyelectrolytes are unfortunately not physically interpretable.

Expressing Λ_0 in terms of the limiting equivalent conductivities of the individual ions, one obtains the equation

$$[4] \quad \Lambda_0 = \Lambda_{0_{ip}} = f[\lambda_{0_i} + \lambda_{0_p}]$$

where $f \leq 1$ is an interaction parameter denoting the apparent degree of ionization and the fraction of free counterions (11). (The subscripts i and p denote the counterion and polyion, respectively.) The parameter f is expressed by

$$[5a] \quad f = 1 - [0.55\,\xi^2/(\pi + \xi)]; \qquad \xi \leq 1$$

$$[5b] \quad f = 0.866\,\xi^{-1}; \qquad \xi \geq 1$$

The model chosen for the polyion, which is used to obtain the equilibrium structure of the solution, is an infinitely long line charge. This is characterized by a dimensionless charge density parameter (reduced charge density) ξ (4, 12) as given by the expression

$$[6] \quad \xi = \frac{l_B}{b} = \frac{e^2}{\epsilon\, k_B\, Tb}$$

where l_B is the Bjerrum length at which two electronic charges (e) in a solvent of permittivity (ϵ) interact with an energy k_BT and b is the average charge spacing along the axis of real polyion chain (i.e., contour length divided by number of charged groups) (b = 9.40 (**A**), 8.20 (**B**), 10.20 (**C**), and 7.00 cm (**D**)). For dilute solutions of polyions, Manning's theory (12) states that the effective spacing of the charged groups on the polyion can not be less than a critical value corresponding to $\xi = 1$ in the case of monovalent charge groups and monovalent counterions. Therefore, for $\xi > 1$, the fraction $(1 - \xi^{-1})$ of counterions will condense on the polyion to lower the effective value of ξ and the dissociated counterions behave in accordance with the Debye–Hückel approximation.

The limiting equivalent conductivity of the polyion (λ_{0_p}) also depends directly on α, the degree of ionization, according to the relation

$$[7] \quad \lambda_{0_p} = \frac{F^2\,\alpha\,|Z_p|}{f_{pw}}$$

where F is the Faraday constant, $|Z_p|$ is the stoichiometric charge number of the polyion, and f_{pw} is its hydrodynamic friction coefficient, that is, the interactions resulting on account of the viscous drag exerted by the polyion on the electroneutral solvent. For $\xi < 1$, α becomes unity, whereas for $\xi > 1$, α approximates to the reciprocal of the charge density. The parameter f_{pw} could be related to the respective diffusion coefficients (D) on the basis of the Einstein relation (4), i.e.,

$$[8] \quad D = RT/f_{pw}$$

Results and discussion

The results of conductivity measurements on polyelectrolyte systems **A**, **B**, **C**, and **D** in DMF and DMSO at 25°C are presented in Tables 1 and 2 (the system **A** could not be studied in DMF because of the solubility restriction). In the case of DMF-soluble systems, the nature of Λ_c vs. $\sqrt{C}$ curves (Figs. 2 and 3) is very interesting. For systems **B** and **C**, the curves do not, as generally observed, increase uninterruptedly but surprisingly bend downward at very low concentrations, giving rise to a maximum at $3.70_5 \times 10^{-3}$ g-equiv L^{-1} for **B** and 0.70×10^{-3} g-equiv L^{-1} for **C**. However, the "normal" behaviour (increasing equivalent conductivity with dilution) is observed for the compound **D** in DMF (Fig. 3). It should be noted that reduced viscosities also assume a maximum in their respective concentration plots (13). One may find the rationale for this typical behaviour in terms of specific solvation characteristics of the system concerned. The decreasing trend of Λ_c with dilution in the case of compounds **B** and **C** resembles in every respect their corresponding partial molar volume (14) and viscosity behaviours (13). These behaviours are in conformity with the transition, as suggested for branched polyelectrolytes

(4), into a more compact bent-rod (semicircular arc model) conformation owing to the possible contraction of the polyion chain, in extremely dilute solutions. The contraction in molecule **B** is chiefly due to crystal violet shrinkage, whereas the major constriction in compound **C** involves intramolecular Coulombic interactions in crystal violet and in 2,5-diacylthiophene moieties as well (14). The subsequent decrease of Λ_0 beyond maximum with increasing concentration is due to an increased screening of polyion charges through counterion associations. On the other hand, the concomitant increase of Λ_c upon dilution in the case of **D** conforms to normal polyelectrolyte behaviour (4). This is associated with the curled shape assuming an "impermeable coil" model under the force of common counterions associated with the bare quaternary nitrogens and including, to some extent, the intramolecular Coulombic attraction in diacylthiophenylene residues of the polycations (13, 14). However, the observed decrease in Λ_c, until a minimum (a characteristic kink, Fig. 3) is attained at the relatively higher concentration (3.49×10^{-3} g-equiv L^{-1}), reflects an increased counterion binding toward the concentrated region. The reason for the observed minimum in the Λ_c–$\sqrt{C}$ plot (Fig. 3) is perhaps due to the complete overlapping of the domains of individual molecules, yielding an optimum compact entanglement under the pool of common associated counterions, with increasing population of polyions. This facilitates an easier mode of incorporation of the solvent into the free volume of intermolecular spacings (14) and, consequently, a minimum in conductance is observed. However, at higher concentrations beyond this minimum, further addition of polyions may eventually destabilize the entanglement, leading to the separation of individual molecules. This results in lower hydrodynamic friction coefficients (f_{pw}, cf. Table 3) and thereby increased conductivity after the minimum.

A close perusal of the conductivity curves (Λ_c vs. $\sqrt{C}$) for **B**, **C**, and **D** in DMF (Figs. 2 and 3) reveals the following interesting facts: the conductivity is higher for **C** over the wide range of concentrations studied despite its larger molecular weight. The appreciable magnitude of Λ_c for **C** and the drastic reduction in conductivity for **B** (**B** and **C** have somewhat similar molecular weight) over the entire range of concentrations are expected, due to the lesser degree of counterion condensation arising from the lower charge density parameter (ξ) of **C** in comparison with **B** (Table 3). This ensures that equivalent conductance is based largely on the nature of the polyelectrolyte under study rather than on its molecular weight. Despite the observed constrictions and bent-rod conformations of both compounds **B** and **C**, the extremely small equivalent conductivity of **B** is the consequence of higher degree of counterion condensation and thereby screening of the positive charge by methoxide counterions. Irrespective of the high charge density (Table 3) of the polymeric chain of **D**, it is the geometrical conformation (impermeable coil) (14) of **D** in DMF that augments the transport phenomenon to an appreciable magnitude to render higher conductivity.

The concentration dependence of electrolytic conductivity (κ) for DMF-soluble systems is depicted in Fig. 4. This reveals an interesting feature of a very narrow range of linearity, indicating that the term $d\kappa_0/dc$ has a dominating influence on eq. [2] due to the presence of polyion (4). Furthermore, all the systems have considerable interionic interactions (including counterion condensation and intramolecular bending as revealed from ϕ_v (14) and η_{sp}/C (13) results) throughout the wide range of concentrations studied. Therefore, the derivative $d[C\cdot\phi(C)]/dC$ cannot be ignored in comparison with Λ_0, and measurements in this region have to be discarded in the determination of Λ_0. Despite these restrictions, limiting equivalent conductivities were evaluated from the limiting slope of smaller linear portions of the κ vs. C curve, assuming that the interionic interactions in this range of concentration are limited to interaction between the polyion and its counterion atmosphere. The accuracy of the evaluated Λ_0 values appeared highly questionable and erroneous through this treatment. Thus, no critical appraisal of the Λ_0 values seems possible in the present instance. However, the order **C** (46.46) > **D** (39.05) > **B** (4.21), in which the Λ_0 values appear, is based primarily on the chemical nature irrespective of such other parameters as size and molecular weight of the individual system concerned. The accurate determination of Λ_0 through the treat-

ment based on the Lattey equation is no longer feasible in the present instance because of the unusual constrictions of polyelectrolytes in the dilute range of concentrations in DMF. Moreover, polyion–polyion interactions become significant at higher concentrations, bringing further complications. Therefore, the existing models for linear polyelectrolytes seem inapplicable to the present systems.

In DMSO, all the systems demonstrated normal linear polyelectrolyte behaviour, as the limiting equivalent conductivities increased uninterruptedly with decreasing concentration (Figs. 5–7). However, there was levelling in the $\Lambda_c - \sqrt{C}$ plots beyond ~0.0036 g-equiv L^{-1} for systems **A** and **B**, due to the possible optimization of agglomeration at the higher concentrations. This offers somewhat constant frictional coefficients (f_{pw}, Table 3) to the transport processes. The conductivity curves representing κ vs. C for DMSO-soluble systems **A**, **B**,

Fig. 4. Concentration dependence of electrolytic conductivity in dimethylformamide: **B** (○), **C** (×), and **D** (▲).

C, and **D** are depicted in Fig. 8. The linear parts of the κ vs. *C* curves are apparently shrinking for polyelectrolytes **B**, **C**, and **D**, which unfortunately does not favour the measurement of Λ_0 on the basis of the treatment suggested by eq. [1]. The dimeric system **A**, however, which has a lower charge density all along the polyion chain, shows largely linear variations of κ with concentration. Moreover, the effect of interionic interactions ϕ(C) and counterion binding may apparently be marginal in a medium like DMSO (ϵ = 46.6) at finite dilution. This allows the estimation of Λ_0 (36.36 ohm^{-1} cm^2 equiv^{-1}) in this instance from the slope of the linear region of the κ vs. *C* plot.

A modest attempt was made to evaluate Λ_0 values by the application of the Lattey equation, since all systems follow the usual polyelectrolyte behaviour in DMSO and no complica-

tions as were observed for DMF arose in the present case. A representative Lattey equation plot in the form $\sqrt{C}/(\Lambda_0-\Lambda_c)$ vs. $\sqrt{C}$ is shown in Fig. 9 for system **A** in DMSO, for which the different trial values of Λ_0 that yielded a linear plot were chosen as the limiting equivalent conductance of the system concerned. The values of the limiting conductances thus obtained are: 55 (**A**), 30 (**B**), 124 (**C**), and 80 (**D**) ohm^{-1} cm^2 equiv^{-1}. The least-squares values of **D** and **G** obtained for the minimum Λ_0 line are given in Table 4. System **C** has larger value of Λ_0 in DMSO in spite of its larger molecular weight and the larger partial molar volume (14). With the least counterion association in comparison to other systems in DMSO (Table 3) this system enjoys the highest degree of coiling to attain a "globular" model, which resulted in smaller hydrodynamic resistances during the dynamic flow of the solution in viscosity measurements (13) and thereby larger mobility. Excluding the exceptional case of **A**, for which Λ_0 is somewhat unexpectedly small despite its lower molecular weight and smaller size with rigid-rod conformation (13), the Λ_0 values derived for other three systems **B**, **C**, and **D** follow the sequence **C** > **D** > **B**. This seems to agree with the observed trend of intrinsic viscosities (0.410, 0.568, and 0.754_5 dL/g at 25°C (14)) and in all possibility may reflect the effect of an increase in hydrodynamic sizes of the respective systems in that order. The systems **B** and **D** are reported, from a viscosity study, to possess a free-draining coil. Furthermore, despite the larger f_{pw}, molecular weight, and the least ξ (Table 3), the coiling tendency of **C** is considered to be a main factor in determining its position in the conductivity sequence. The higher f_{pw} approximates its conformation to a loose extended coil that is being changed to an impermeable "globular" shape during the solution transport. The Λ_0 values determined from both treatments (36.36 ohm^{-1} cm^2 equiv^{-1} from the κ–C plot, 55 ohm^{-1} cm^2 equiv^{-1} from the Lattey equation plot) for **A** are somewhat dissimilar; however, its decreased value might be attributed to the screening of positive charge density by the lone-pair electrons of the unquaternized nitrogens of the pendant moieties. The dramatic decrease in the limiting conductivity of **B** in DMSO is due to the reduction of the effective charge of the polyion with a subsequent decrease in the number of "free" counterions as a result of the higher tendency of counterion binding of methoxide ions, even at infinite dilution. It is to be noted that the effect of ion pairing for this system is more pronounced in the relatively low dielectric constant medium DMF, which gives rise to an extremely small Λ_0. It should be further mentioned that limiting conductivities are found mainly dependent on the extent of counterion condensations in DMF, whereas the DMSO-soluble systems display Λ_0 values primarily in accordance with their sizes and conformations in the solution. This reveals an active role of DMF, as compared with DMSO, that demonstrates specific polymer–solvent contacts.

On further inspection of the results listed in Table 3, it is observed that the hydrodynamic friction coefficient (f_{pw}) decreases steadily with increasing charge density of the polyelectrolytes studied in both solvents. This is because the extent of counterion condensation is reasonably enhanced with the increase of charge density that alters the polymer conforma-

[a] $C^{1/2} / (\Lambda_0 - \Lambda_c) = D + GC^{1/2}$

tion with appreciable coiling in the solution. The exceptionally high value of Λ_0 for **C** in DMSO is because of unusual coiling of **C**, as already explained.

It should be noted that deviation from Manning's condensation theory is quite likely because an isolated molecule of a high molecular weight flexible polyelectrolyte cannot maintain a rodlike conformation, even in very dilute solutions. The current polyelectrolyte theories based on simple electrostatic models are unable to rationalize the conductivity behaviour of such flexible polyelectrolytes and, therefore, a judicious scrutiny of the solvation effect in support of the conformational alterations of polycations has to be adopted.

Quinones and hydroxyquinones as generators and quenchers of singlet molecular oxygen

Isela Gutiérrez, Sonia G. Bertolotti, M.A. Biasutti, Arnaldo T. Soltermann, and Norman A. García

Abstract: The role of quinones and hydroxyquinones as sensitizers and as quenchers in Type II photooxygenations has been examined. The second aspect is discussed here, through a systematic study, for the first time in the open literature. Quinonic compounds are excellent generators of $O_2(^1\Delta_g)$ in aprotic solvents (excluding those quinones possessing substituents in positions adjacent to the carbonyl groups, in the case of anthraquinone derivatives). Benzoquinones, anthraquinones, and hydroxy derivatives are good $O_2(^1\Delta_g)$ quenchers upon dye-sensitized photoirradiation. The excited oxygen species is deactivated with rate constants in the range 10^6–10^7 M^{-1} s^{-1} depending on the solvent employed. The quenching process deactivates $O_2(^1\Delta_g)$ without further destruction of the quinone. The main interaction with $O_2(^1\Delta_g)$ is driven by the quinone moiety, in spite of the presence of potentially active nuclear substituents. The quenching mechanism could involve a reversible charge transfer intermediate, with the quinonic compound acting as an electron donor.

Key words: photooxidation, quenching, quinones, rose bengal, singlet oxygen.

Résumé : On a évalué le rôle des quinones et des hydroxyquinones dans la sensibilisation et la désactivation des réactions de photooxygénations de type II. Grâce à une revue systématique de la littérature effectuée pour la première fois, on peut discuter ici du deuxième aspect. Les composés quinoniques sont d'excellents générateurs d'$O_2(^1\Delta_g)$ dans les solvants aprotiques (à l'exception des dérivés de l'anthraquinone possédant des substituants dans les positions adjacentes aux groupes carbonyles). Lors d'irradiations sensibilisées par des colorants, les benzoquinones, les anthraquinones et leurs dérivés hydroxylés sont de bons désactivateurs d'$O_2(^1\Delta_g)$. La vitesse de désactivation de l'oxygène excité est de l'ordre de 10^6–10^7 M^{-1} s^{-1}, dépendant de la nature du solvant utilisé. Le processus de désactivation d'$O_2(^1\Delta_g)$ se fait par la portion quinone, malgré la présence de substituants nucléaires potentiellement actifs. Le mécanisme de désactivation pourrait impliquer un intermédiaire de transfert de charge réversible qui transformerait le composé quinonique en un électrodonneur.

Mots clés : photooxydation, désactivation, quinones, rose de Bengale, oxygène singulet.

[Traduit par la rédaction]

Introduction

Quinones and hydroxyquinones belong to an important class of biologically active and commercially valuable compounds. They are involved in a huge number of electron transfer processes representing individual steps in a variety of enzymatic systems. The participation of quinone derivatives in light-induced processes therefore constitutes a topic of special interest. Quinones have been extensively studied in connection to their near-uv–visible absorbing characteristics and potential photosensitizing properties for Type I and Type II photoreactions (1–8). In this area, Gollnick and Held (6) in 1992 published a study on hydroxyanthraquinones as sensitizers for singlet molecular oxygen ($O_2(^1\Delta_g)$) photooxidations. Subsequently Gollnick et al., in 1993, reported (7) on the properties of the same compounds as sensitizers for electron transfer reactions. As well, photosensitizing mechanisms of the antitumor agents represented by aminoanthraquinones (4) and anthracyclines (2, 5) have been widely investigated. As a final example of photosensitization we can cite anthraquinone itself, which is a photosensitizer often detected in sea water, frequently employed to mimic natural photooxidation processes in the marine environment (3, 8). These few cases illustrate the significance of the interaction of quinonic derivatives with light in nature and in technology and, in this context, the importance of the photosensitizing action of quinones for Type II reactions (photopromoted $O_2(^1\Delta_g)$ generation) becomes evident.

The quality of a given sensitizer, such as the quinone family in the present case, must be evaluated in conjunction with the properties as eventual selfquenchers of the transient species generated in the sensitizing process. In this manner, the information obtained can contribute to the interpretation of experiments or events in which direct irradiation of quinones is carried out. However, almost no information about the behaviour of these derivatives as potential $O_2(^1\Delta_g)$ quenchers is available.

Following this line, in this work we carried out a kinetic study on the properties of different quinones and hydroxy-

quinones as $O_2(^1\Delta_g)$ deactivators. In parallel, the quantum yields for $O_2(^1\Delta_g)$ generation (Φ_Δ) of several quinonic derivatives of interest, not previously reported in the literature, were determined.

Experimental

Materials

Rose bengal (RB) and rubrene (R) were from Sigma Chem. Co. Perinaphthenone (1*H*-phenalen-1-one, PN), 9,10-dimethylanthracene (DMA), furfuryl alcohol (FFA), and the quinones benzoquinone (BQ), tetramethyl benzoquinone (DQ), anthraquinone (AQ), 2,6-dihydroxyanthraquinone (2,6-DOHAQ), 1,8-dihydroxyanthraquinone (1,8-DOHAQ), 1,2-dihydroxyanthraquinone (1,2-DOHAQ), anthraquinone-2-sulfonic acid (2-SAQ), and anthraquinone-1,5-disulfonic acid (1,5-DSAQ) were purchased from Aldrich. The compounds 2,6-dihydroxyanthraquinone (2,6-DOHAQ) and 1,5-dihydroxyanthraquinone (1,5-DOHAQ) were from Pfaltz and Bauer. Perinaphthenone-2-sulfonic acid (1*H*-phenalen-1-one-2-sulfonic acid PNS) was synthesized as described in the literature (9). For the kinetic determinations the following solvents were employed: benzene (Bz), acetonitrile (MeCN), and ethanol (EtOH) all from Sintorgan, 2-propanol (iPrOH) from Mallinkrodt, and D_2O (99.9% D) from Sigma Chem. Co. Water was triply distilled.

Molecule	A	B	C	D	E
AQ	H	H	H	H	H
2,6DOHAQ	H	OH	H	OH	H
1,5 DOHAQ	OH	H	OH	H	H
1,8 DOHAQ	OH	H	H	H	OH
1,2 DOHAQ	OH	OH	H	H	H
2 SAAQ	H	SO_3H	H	H	H
1,5 DSAAQ	SO_3H	H	SO_3H	H	H

The quinones were purified as follows: 1,5-DSAAQ was recrystallized from acetic acid. DQ and 1,5-DOHAQ were sublimated. The dihydroxy derivatives 1,8-DOHAQ and 1,2-DOHAQ were passed through a chromatographic column of silica gel, employing as eluents Bz and Bz – ethyl acetate 85:15 (v:v), respectively. The quinones BQ, AQ, and 2-SAAQ were used as received.

Methods

Kinetic measurements

(a) Time-resolved phosphorescence detection (TRPD): The laser kinetic spectrophotometer has been previously described (10). Briefly, it consists of a Laser Optics nitrogen laser with pulses of 5 mJ and 7 ns (337 nm) halfwidth as the excitation source. The emitted radiation (mainly 1270 nm) is detected at right angles (using an amplified Judson J16/8Sp germanium detector) after having passed through appropriate filters. The output of the detector is coupled to a digital oscilloscope and to a personal computer to carry out the signal processing. Usually 16 shots were needed for averaging, in order to get a good signal/noise ratio, from which the decay times were calculated. The sensitizer (RB or PN in organic solvents and PNS in D_2O) had an Abs_{336} = 0.5–0.6. The $O_2(^1\Delta_g)$ lifetimes in Bz, MeCN, and D_2O were 28, 40, and 64 μs, respectively.

The $O_2(^1\Delta_g)$ lifetimes were evaluated in the absence (τ^0) and in the presence (τ) of the quencher, and their ratio plotted as a function of quinone concentration, according to a simple Stern–Volmer treatment (eq. [1]):

$$[1] \quad \tau^0/\tau = 1 + k_t\tau^0\,[\text{quinone}]$$

k_t (the *total* or *overall* rate constant for $O_2(^1\Delta_g)$ quenching) is given by the addition of the respective rate constants for *physical* deactivation to ground-state molecular oxygen $O_2(^3\Sigma_g)$ (k_q, eq. [2]) and *chemical* or *reactive* quenching (k_r, eq. [3]).

$$[2] \quad O_2(^1\Delta_g) + \text{quinone} \xrightarrow{k_q} O_2(^3\Sigma_g^-) + \text{quinone}$$

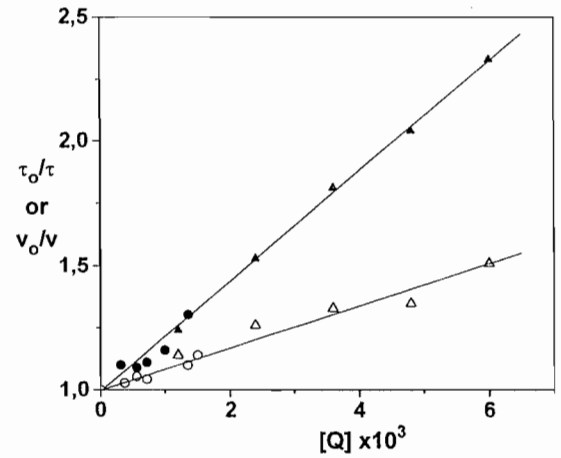
$$[3] \quad O_2(^1\Delta_g) + \text{quinone} \xrightarrow{k_r} P$$

For solvents such as EtOH and iPrOH, k_t was evaluated employing the method of Carlsson et al. (11), given that the $O_2(^1\Delta_g)$ lifetime in the presence of quenchers was too low to be determined by our TRPD instrument (time response approximately 4 μs). This method is based on the self-sensitized photooxidation of rubrene. The ratio of initial rates of rubrene photooxidation in the absence (V_0) and in the presence (V) of different concentrations of the quinone was plotted against the quinone concentration, and k_t was calculated from eq. [4]:

$$[4] \quad V_0/V = 1 + k_t[\text{quinone}]/(k_d + k_{rR}[R])$$

In the present case $k_{rR}[R] \sim 370\ s^{-1}$ (assuming $k_{rR} = 4.4 \times 10^7\ M^{-1}\ s^{-1}$, see ref. 11). Under these conditions the denominator of eq. [4] can be practically taken as equal to k_d. The values for $1/k_d$ employed in the calculations were 11 and 15 μs, respectively, for EtOH and iPrOH, obtained from TRPD experiments.

(b) Static photolysis: The irradiation device, including the specific oxygen electrode, has been described elsewhere (12). A set of cutoff filters was employed to ensure that all electromagnetic radiation was absorbed only by the sensitizers.



Determination of the photooxidizability of quinones

The reactivity of quinones (i.e., their effectiveness for chemical reaction with $O_2(^1\Delta_g)$) was determined by different comparative methods (already described (13)), depending on the solvent. In all cases, knowledge of the reactive rate constant for the sensitized photooxidation of a reference compound (Ref) is required. In water the rates of oxygen uptake for the quinones and the reference compound, upon sensitized irradiation, were compared. Ref was FFA with $k_r = 1.2 \times 10^8\ M^{-1}\ s^{-1}$

(14) and the sensitizer RB (Abs_{560} = 0.5). The oxygen electrode (Orion 97-08) has a membrane that can be used only in media containing a high percent of water (typically, more than 95%). Ref was 9,10-dimethylanthracene (DMA), whose k_r value, determined by TRPD, is 5.5×10^7 M^{-1} s^{-1} in MeCN. In organic media the method for k_r determination was essentially the same as in water, except that in this case the loss of substrate and of reference compound must be compared. The loss of DMA upon sensitized irradiation was monitored spectrofluorimetrically employing 395 nm and 450 nm, respectively, as excitation and emission wavelengths. The eventual loss of quinones was monitored through their absorption spectrum.

Ground state absorption measurements were carried out with a Hewlett Packard 8452A diode array spectrophotometer.

Determination of singlet oxygen quantum yields

The determination of Φ_Δ was made by the comparative method already described (15). Briefly, the dependence of $O_2(^1\Delta_g)$ phosphorescence intensity I_0 on the laser fluence E_L extrapolated to zero time was measured for solutions of the quinones. Several absorbances of the quinones were employed, at the laser emission wavelength, 337 nm. The laser fluence was varied, employing filters of neutral density. The Φ_Δ values were calculated by comparison of the slopes of the linear plots I_0 vs. E_L × fraction of absorbed light, for the reference and sample. The references were PN in MeCN (Φ_Δ = 0.95)(9) and PNS in D_2O (Φ_Δ = 1)(9).

Results

Overall interaction quinones–$O_2(^1\Delta_g)$

As described in the experimental section, k_t values were calculated from the lifetimes measured by TRPD, through a simple Stern–Volmer plot (typical cases, for BQ and AQ in Bz are shown in Fig. 1). For some quinones, in organic media, k_t was also determined according to the method of Carlsson et al. (11). As can be seen in Fig. 1, the set of experimental points employing this method lie exactly on the same curve as those corresponding to the time-resolved results.

Table 1. Rate constants for overall quenching of $O_2(^1\Delta_g)$ by quinones and derivatives (k_t, M^{-1} s^{-1}), and quantum yields for $O_2(^1\Delta_g)$ generation in MeCN by the same compounds, upon direct 337-nm photoirradiation.

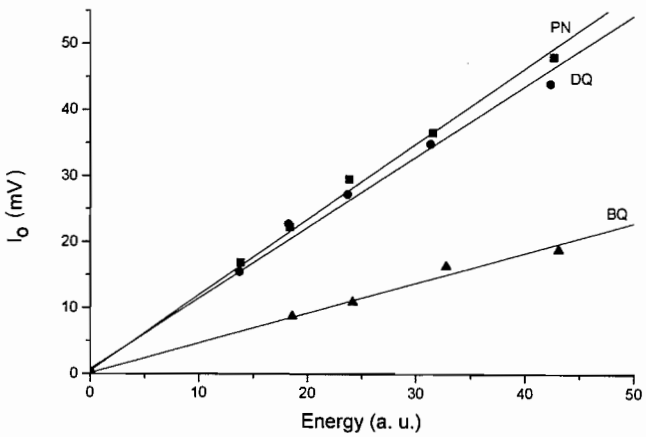
Results (Table 1) reveal that quinones are good $O_2(^1\Delta_g)$ quenchers. Solvents of different characteristics were explored. It is worth mentioning at this stage that k_t increases in alcoholic solvents, as compared to non-protic solvents, whereas the higher k_t values were obtained for the sulfonic derivatives in heavy water.



The absence of chemical reaction of singlet molecular oxygen $O_2(^1\Delta_g)$ with quinones

We attempted the evaluation of the hypothetical k_r values for quinones, employing the comparative methods described in the experimental section. After prolonged sensitized irradiation no changes in the absorption spectrum of the quinones could be observed. We employed the well-known $O_2(^1\Delta_g)$ chemical scavenger 9,10-DMA for comparative purposes. Under identical experimental conditions this reference compound was practically completely consumed after a period 50 times shorter than that employed as a photolysis time for the quinones.

Fig. 2. Laser fluence dependence of the amplitude at zero-time I_0 of the $O_2(^1\Delta_g)$ phosphorescence signal in MeCN for PN, DQ, and BQ.

For water-soluble sulfonic derivatives, we assayed the measurement of oxygen consumption upon sensitized irradiation. Again, a relatively fast oxygen consumption was observed for the reference compound (FFA). After a few minutes it was totally oxidized via an $O_2(^1\Delta_g)$-mediated process, as estimated by auxiliary spectroscopic determinations. In contrast, no oxygen consumption could be detected for quinones, even when the irradiation time was several times greater than that employed for FFA.

On the basis of the above-mentioned results and considering the detection limits of the apparatus and methodologies employed, we can roughly estimate a value of $10^4\ M^{-1}\ s^{-1}$ as an upper limit for k_r for the quinones listed in Table 1.

The Φ_Δ values for quinonic compounds

The capacity of several quinones for $O_2(^1\Delta_g)$ generation upon direct irradiation, Φ_Δ, was investigated in MeCN and D_2O solutions. The quantum yield for singlet oxygen formation is given by the sum of contributions from oxygen quenching of the lowest singlet (S) and triplet (T) excited states of the quinones.

$$[5] \quad \Phi_\Delta = \Phi_\Delta(S) + \Phi_\Delta(T)$$

For air-saturated solutions (oxygen concentration in MeCN 1.9 mM (16)) the contribution from the quinones excited singlet state (lifetime in the order of nanoseconds or subnanoseconds (6)) can be neglected. Hence, the expression for the quantum yield of $O_2(^1\Delta_g)$ formation is reduced to:

$$[6] \quad \Phi_\Delta = S_\Delta\, \Phi_T$$

Where S_Δ represents the proportion of triplet quinone–$O_2(^3\Sigma^-_g)$ that leads to the formation of $O_2(^1\Delta_g)$ and Φ_T is the quantum yield for excited triplet state generation.

The Φ_Δ values for AQ, DQ, 1,5-DOHAQ, and the sulfonic derivatives from Table 1 have not been previously reported, according to our knowledge. In Fig. 2 are shown typical experimental results, in this case allowing the determination of Φ_Δ values for DQ and BQ in MeCN.

As shown in Table 1, we obtained a value of 0.034 for 1,2-DOHAQ, in good agreement with the value of 0.03 reported by Gollnick and Held (6). For 1,5-DOHAQ in MeCN and the for the sulfonated derivatives in D_2O no signal at all for $O_2(^1\Delta_g)$ generation could be detected.

Discussion

The total absence of evidence for quinone photooxidation, as monitored by substrate and oxygen consumption, clearly indicates that the interaction with $O_2(^1\Delta_g)$ must be largely ascribed to a physical process.

Only two inconclusive references regarding kinetic data on the interaction quinones–$O_2(^1\Delta_g)$ have been published (17, 18). The first one (Koka and Song) concerns the protective effect by several substrates, including benzoquinone, against $O_2(^1\Delta_g)$-mediated photooxidation of chlorophyll *a*. In it, k_t values of 3.40 and $1.60 \times 10^7\ M^{-1}\ s^{-1}$ for benzoquinone in EtOH and EtOH–Bz, respectively, were reported. The second reference (18) (Croux et al.) reports k_t values of 1.8 and $0.59 \times 10^7\ M^{-1}\ s^{-1}$ for 5- and 6-hydroxy-1,4-naphthoquinone in MeOH, respectively. No comment on photooxidation of the naphthoquinones was made.

Turning to our data in Table 1, we can distinguish two sets of compounds: the *pure* quinonic derivatives and the dihydroxyquinones. The presence of -OH groups as aromatic ring substituents in the second set suggests the possibility that some of these compounds could behave as phenolic derivatives, from the point of view of their reactivity towards $O_2(^1\Delta_g)$. It is known that phenols are efficient $O_2(^1\Delta_g)$ quenchers (19). Typical k_t values for phenolic derivatives such as phenol itself and some dihydroxybenzenes range from 10^6 to $10^8\ M^{-1}\ s^{-1}$ in organic solvents (19). Besides, k_t values for phenols dramatically increase with the increase of solvent polarity. This argument is not supported by our data in Table 1. The k_t values are practically the same when the solvents Bz and MeCN are compared, the respective rate constants in EtOH and iPrOH being definitely higher. Nevertheless, the differences between k_t for both alcohols are not significant. The alcohols and MeCN possess similar values for their respective dielectric constants and both are much higher than the dielectric constant for Bz (16). Hence we can neglect the possibility of a solvent polarity effect on k_t, for the case of quinones. Furthermore, if the k_t values for anthraquinone and the four dihydroxy derivatives from Table 1 are compared, only a slight difference in favour of the hydroxyquinones can be observed. This is clear evidence that the main interaction for these compounds with $O_2(^1\Delta_g)$ is driven by the quinonic moiety.

The increase in the rate constant observed in alcoholic solvents when compared to Bz as a solvent was already detected by Koka and Song (17) for BQ, going from EtOH to an EtOH-Bz mixture, but this observation was not discussed further. It could in principle be related to the fact that the quinonic structure in protic solvents is in equilibrium with the corresponding hydroquinone derivative, which is an efficient $O_2(^1\Delta_g)$ scavenger as stated earlier. Nevertheless, the absence of reaction products, typical in the photooxidation of dihydroxybenzenes (19), even upon prolonged sensitized irradiation, imposes some doubts about this possibility. At the same time, the similarity between k_t values obtained in EtOH and iPrOH also makes improbable the involvement of reversible hydrogen atom abstraction in the reaction mechanism for $O_2(^1\Delta_g)$ quenching.

Several authors have examined the reactivity of $O_2(^1\Delta_g)$ toward different families of aromatic compounds. In most of the cases, the initial formation of an intermediate complex with some degree of charge transfer character, leading to physical and (or) chemical quenching, was postulated (20, 21). The occurrence of an exclusive reversible charge transfer process within the complex should lead to predominant physical quenching, such as that observed in the present case for quinone derivatives. In this field there can be cited a number of examples of $O_2(^1\Delta_g)$ physical quenching by amines, indoles, phenols, and sulfides (for a review see ref. 19) acting in all cases as the electron donors. This kind of interaction, involving a reverse electron transfer process, was also invoked by Darmayan in 1993 (23) to explain the interaction of $O_2(^1\Delta_g)$ with solvent molecules. The author, through experimental evidence, demonstrated that a charge transfer process to $O_2(^1\Delta_g)$ occurs from organic molecules possessing ionization potentials (Ip) as high as 11 eV. The parent compounds in Table 1 (BQ and AQ) exhibit Ip values of 10 and 9.24 eV, respectively (16). Furthermore, the difference in their respective k_t values may reflect the aforementioned tendency for electron-donor activity.

In the present case, no solvent polarity effect on k_t could be observed when aprotic solvents were employed. The higher values of k_t in protic solvents might be explained on the basis of the higher polarization of the quinone molecule due to solvent–hydrogen bonding, favouring the charge transfer interaction and increasing the stabilization of the transition state.
