Time-resolved structures of electrical discharges in gases: experiment and stochastic model

A.D.O. Bawagan, L. Fell, and J. Logan

Abstract: The time-resolved discharge patterns generated in a gaseous dielectric breakdown (DB) are imaged using a fast optical imaging system (≈40 ns exposure time). The discharge patterns from various gases (He, air, and SF_6) show general features consistent with their known dielectric strength. A new stochastic pattern-forming model that explicitly includes time is presented and is shown to produce theoretical DB patterns in qualitative agreement with the present experimental discharge patterns for air (N_2). The stochastic DB model (with time) also provides an approximation to the discharge current, which is in good agreement with published current wave forms.

Key words: gas discharge, electron scattering, fractal.

Résumé : Faisant appel à un système rapide d'imagerie optique (≈40 ns de temps d'exposition), on a enregistré des images des patrons de décharge résolus en fonction du temps obtenus lors d'une prédissociation gazeuse diélectrique (DB). Les patrons de décharge de divers gaz (He, air, SF_6) présentent des caractéristiques générales qui sont en accord avec les valeurs connues de leur force diélectrique. On présente un nouveau modèle stochastique de la formation des patrons qui inclut explicitement le temps et on montre qu'il conduit à des patrons théoriques de DB qui sont qualitativement en accord avec les données expérimentales pour les patrons de décharge de l'air (N_2). Le modèle stochastique de DB (incluant le temps) permet aussi d'obtenir une approximation du courant de décharge qui est en bon accord avec les formes de vague qui publiées actuellement.

Mots clés : décharge gazeuse, diffraction des électrons, fractal.

1. Introduction

The recent discovery (1) that electrical discharges in air can be a very energy-efficient method for decomposing volatile organic compounds (VOCs) has focussed attention to the long-established field of gaseous dielectric breakdown or, more generally, the field of nonthermal plasma chemistry. The term "gaseous dielectric breakdown" simply reflects the origins of the field and the predominance of its application in high-voltage insulation for power generation systems (2). The ubiquitous use of VOCs in the manufacturing and use of everyday consumer products (e.g., trichloroethylene for cleaning, carbon tetrachloride as solvent, etc.) and the recognition that these chlorinated VOCs are extremely toxic has led to a global search for cost-effective VOC abatement procedures. Nonthermal plasma techniques, such as electrical discharges and high-energy electron beams, are extremely efficient because most of the electrical energy goes into the production of energetic electrons (that lead to degradation of VOCs) rather than into gas heating. This new development has therefore led to a deeper understanding of the physico-chemical mechanisms (3–8) underlying electrical discharges in air or, more generally, gaseous dielectric breakdown.

In 1987 Dhali and Williams (3) presented a two-dimensional mathematical simulation of the gaseous dielectric breakdown problem in air, which captured the essential physico-chemical processes. They considered the simplest set of dynamical equations, which included the deterministic continuity equations for electrons and for positive ions, plus Poisson's law of electrostatics, which couples the electric field to the charges. Other theoretical methods, such as Monte Carlo methods (2), can also be used for simulating these nonstationary processes observed in gas discharges. It is now understood that the initial processes that lead to dielectric breakdown or to the formation of discharges are the so-called streamers or streamer leaders (9). The term "streamers" simply reflects the general shape of the transient phenomenon prior to discharges that have been observed using streak camera methods.[2]

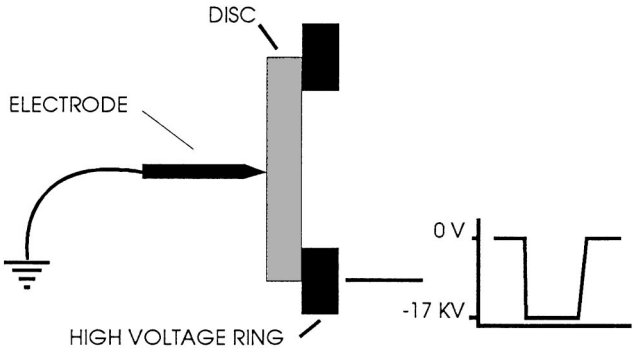
[2] The microscopic processes involved in a gas discharge are called streamers and leaders (8, 9). The initial process involves the formation of streamers, which have very low optical luminosity, followed by the leader discharge, which has a higher luminosity. The final stage is referred to as the "spark-over," which is characterized by extreme brightness and sometimes a "sonic boom." The present experiments are concerned only with the streamer and leader processes (i.e., breakdown).

© 1998 NRC Canada

Fig. 1. Basic schematic for the generation of a streamer–leader discharge. A positive high voltage is effectively introduced to the electrode by "grounding" the electrode. As the thyratron (see Fig. 2) switches on, the normally grounded ring becomes negative. This produces a potential between the electrode and the ring, which is of *positive* polarity.



Recently, Vitello et al. (4) performed a more accurate numerical simulation (2-D) of the dynamical evolution of streamers using the Dhali–Williams equations, and this revealed, for the first time, a realistic microscopic picture of the streamer morphology. In particular, Vitello et al. (4) showed that there are distinct phases in the time development of streamers, and that this development is driven by a very narrow streamer front (≈10 μm), also called a thin ionization wave. The separation of the length scale between the typical width of the streamer front (μm) and the length of the body of the streamer (mm) has led Ebert et al. (5) into an elegant analysis of the pattern-forming problem as an example of what they refer to as "front propagation into unstable states." These new numerical results (3, 4), coupled with more detailed experimental studies of the dynamics of streamer development (10–13), are leading to a convergent understanding of gaseous dielectric breakdown at the microscopic level.

On a larger scale, it is well known that a high-voltage discharge generates a "tree-like" branched pattern, also known as a Lichtenberg figure. Niemeyer and co-workers (6, 10) have shown that these tree-like structures can be described as a fractal or self-similar pattern (14). For a fractal structure in two dimensions, the total length $N(r)$ of all branches inside a circle of radius r is related as follows:

$$[1] \quad N(r) \approx r^D$$

A plot of log N versus log r will yield a linear relationship characterized by a slope equal to D, or what is referred to as the fractal dimension (14).

We have recently extended the Niemeyer-type (point-circle geometry) dielectric-breakdown experiment by incorporating a fast optical imaging system (15). A significant advantage of the present experiment is the capability to produce time-resolved images of the dielectric breakdown in the nanosecond range, compared to that conducted by Niemeyer et al. (6), which yields time-integrated photographs in the microsecond range. We showed (15) that the time development of the dielectric breakdown in air is also a fractal, as revealed by an analysis of each single frame from a single discharge.

In the present work, we extend the previous work and report the time-resolved dielectric-breakdown images in He, air (N_2), and SF_6, thus providing a broad cross section of chemical systems. We also present a new stochastic model of dielectric breakdown, which incorporates explicitly the dimension of time. This allows us to make direct (but still qualitative) comparisons with our time-resolved DB images, as well as other traditional experimental measurements such as discharge current.

This work therefore paves the way for our more distant goal of providing a "phenomenological link" between the microscopic gas-phase information (e.g., photo-ionization and electron-impact cross sections, reaction rates, thermal relaxation rates, etc.) and the macroscopic structures generated in a streamer–leader discharge. The recognition and acceptance of the important length and time scales relevant to the dynamic development of streamers in discharges in air (5) indicate that the resolution of the macroscopic pattern-forming problem in dielectric breakdown from first principles may be closer at hand.

2. Experimental details

The experimental apparatus has been reported earlier (15), and only a brief discussion is presented along with minor modifications. The gaseous dielectric breakdown experiment is shown schematically in Fig. 1. A positive high-voltage pulse (+22 kV max, 1 μs width) is introduced to a sharp stainless-steel electrode that is located in the center of a sapphire disc (2 mm in thickness, dielectric constant $\epsilon_r = 10.2$). The positive input voltage is referenced relative to a stainless-steel ring (20 mm inner radius) situated at the rim of the sapphire disc. The streamer–leader discharge that results is observed from the backside of the sapphire disc. The arrangement is very similar to the arrangement introduced by Niemeyer et al. (6), except that the present experiments are conducted at moderate pressures of He, air (N_2), and SF_6, as opposed to high-pressure SF_6. To a good approximation, this arrangement produces an equipotential channel system growing in a plane. The growth is therefore *two-dimensional,* even though the electric field lines are three-dimensional (6).

The fast high-voltage pulse is generated using a stable high-voltage DC supply (Brandenburg 25-P), a storage capacitor (1300 pF), and a grounded grid thyratron (EG&G HY-1102). The low impedance and stable switching ability of the thyratron allow the reproducible production of fast high-voltage pulses ($t_{rise} \approx 30$ ns). The fast optical imaging system is composed of several optical devices coupled together to achieve the maximum possible gain (Fig. 2). Because of the small exposure times necessary to observe the streamer–leader discharge and the low visible photon flux generated during the breakdown period, a total gain of $\geq 10^5$ was necessary. A macro lens (Canon) views the back end of the disc (Fig. 1), and then an image intensifier (Star-Tron MK 303ABN) operated at maximum gain (≈60 000) is used. The image generated by the Star-Tron MK 303ABN is then photographed using a streak camera (IMACON 790 with IMACON 50/40 intensifier) operated in framing mode with an exposure time of 40 ns per frame. The thyratron and the IMACON camera are both triggered by a pulse–delay generator (SRS DG535) with a 16.45 μs delay as shown in Fig. 2. This allows precise timing such that the leading edge of the high-voltage pulse is coincident with frame 1. A total of 6–8 frames are generated for each single discharge and are permanently recorded on Polaroid 612 film (20 000 ASA). The interframe time difference is ~160 ns, thus giving a total time record of 1600 ns for eight frames (i.e., for each discharge).

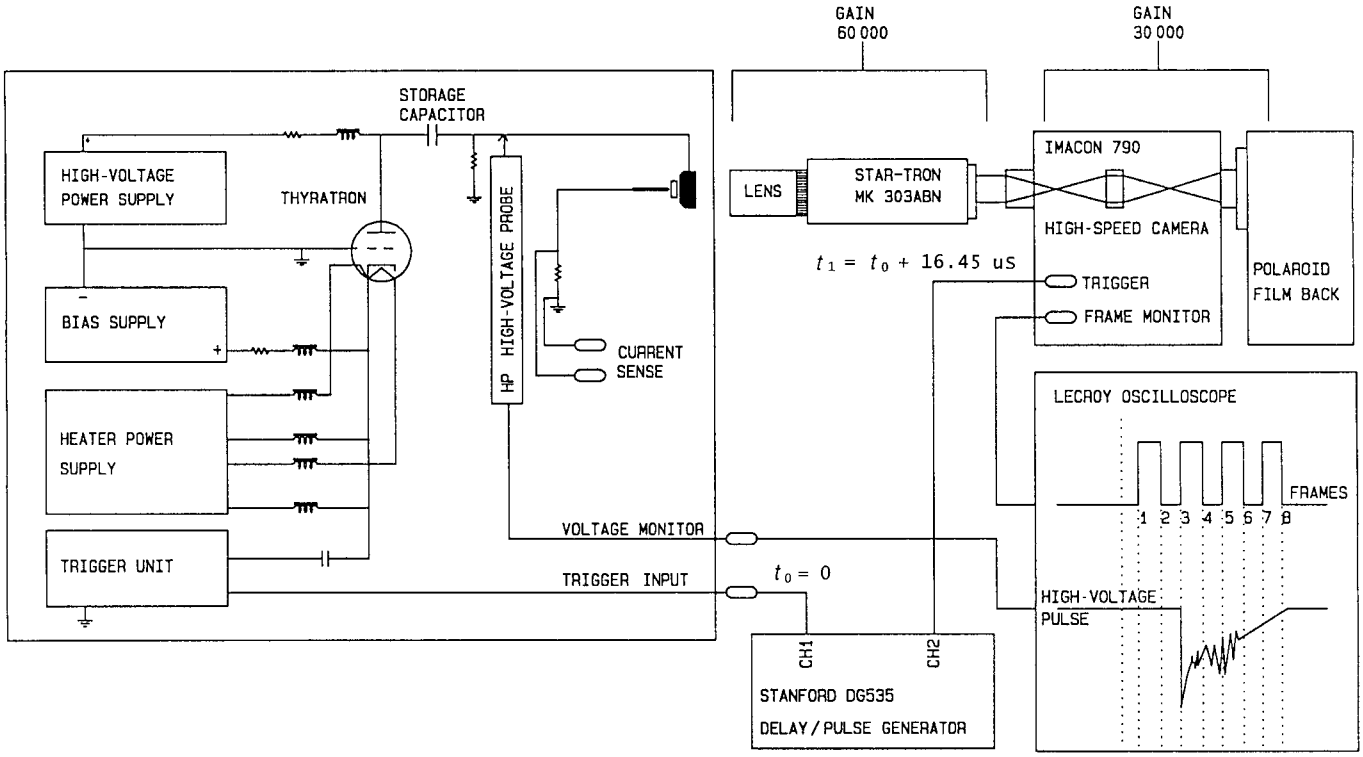
Fig. 2. Schematic of the dielectric breakdown apparatus (Carleton University) and the optical imaging system (Ontario Hydro Technologies). See text for details.



Nonlinear distortions of the optical system were studied using a fine-ruled grating and a He–Ne laser light source. Optical distortions were limited to the edges of the viewing field and were never greater than 10%. These distortions therefore do not affect any of the reported DB images.

3. Results and discussion

3.1 Experimental dielectric breakdown (DB) patterns

The IMACON images of the dielectric breakdown patterns of He, air (N_2), and SF_6 are shown in Fig. 3. The framed images obtained in the present experiment have an exposure time of 40 ns each, in stark contrast to the images obtained by Niemeyer et al. (6), which are *time-integrated* and are equivalent to ≈1 μs exposure time. Each frame captures an image of the dielectric breakdown as it progresses such that there are eight frames per dielectric breakdown. The frames are numbered consecutively (frames 1–8), as shown in Fig. 3*d,* against a backdrop of the full view of the imaging system. This full view was obtained by taking an image of the breakdown return spark or spark-over, which is extremely bright and illuminates the whole image intensifier. Frame 7 is missing because of a slight electronic misalignment in the IMACON camera.

The dielectric breakdown patterns for He, air (N_2), and SF_6 were obtained at 8.5 kV, 17.0 kV, and 21.7 kV, respectively. The DB patterns were not observed below these voltages. For a comparable value, the breakdown voltage value for SF_6 should actually be higher than 21.7 kV, since the DB image (Fig. 3*c*) is barely visible. We were unable to increase the voltage further because our experimental apparatus is currently limited to a maximum voltage of +22 kV. The present breakdown voltage values can be compared with the breakdown voltages reported in the literature under nonuniform field conditions (13, 16), scaled to the same pressure and gap distance (*Pd*) in Table 1. For reference, the breakdown voltages under uniform field conditions (17) are also shown. It should be noted that the general phenomenon of gaseous dielectric breakdown is extremely complex, and the reported breakdown voltages are very sensitive to the details of, for example, the voltage pulse, voltage polarity, conductor geometry, gas pressure, and insulator surface condition, etc. (2, 13, 16, 17). Thus detailed comparisons of the present experiment with other results should take these into consideration. Furthermore, the voltages we report are breakdown voltages, i.e., voltages just prior to breakdown. The comparison presented in Table 1 is therefore only used for *qualitative* purposes and illustrates that the relative order of dielectric strength of the various gases is reproduced. The order of dielectric strength (i.e., increasing breakdown voltage) for a nonuniform field (point-to-circle) as obtained from Fig. 3 is

[2] He << air (N_2) << SF_6

which is in good agreement with previous studies (13, 16, 17). The above order also indicates that the observed images are predominantly a result of the direct breakdown of the gas, as opposed to surface flashover, which is an alternative phenomenon discussed later.

It is not the goal of this study to obtain precise breakdown voltages (which is an important goal in itself) but rather to investigate the temporal characteristics of the DB patterns. The relation of the observed DB patterns to actual physico-chemical processes is our main interest, and it is hoped that the temporal characteristics of the DB patterns will provide support for the

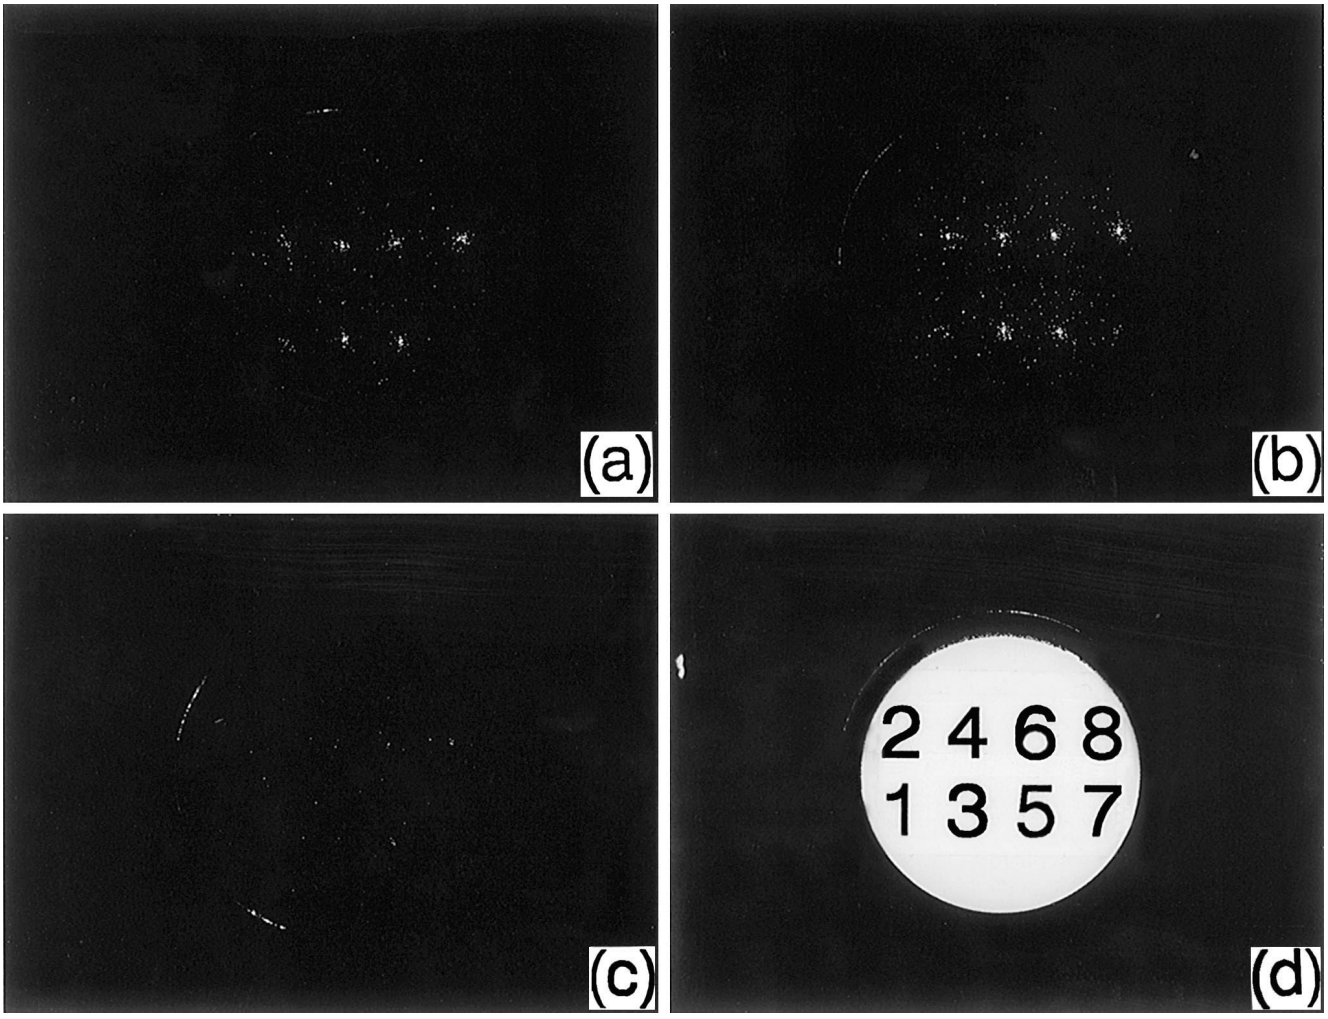
Fig. 3. Time-resolved IMACON images generated by a fast HV pulse with exposure time ≈40 ns per frame for (*a*) helium at 8.5 kV, (*b*) air (N_2) at 17.0 kV, and (*c*) sulfur hexafluoride at 21.7 kV. Some faint structures in the original Polaroid film may not appear in the reproductions. (*d*) Sequence order (1–8) of IMACON frames for each discharge.



development of suitable models of gaseous dielectric breakdown. In the next section, we provide a brief background of the relevant chemistry and physics of gaseous dielectric breakdown.

3.2 Streamer–leader theory

The possible scattering events involved in the avalanche generation observed in transient phenomena in the breakdown of gases are indicated below for a neutral molecule, M^0 :

[3] $e^- + M^0 \rightarrow e^- + e^- + M^+$

[4] $e^- + M^0 \rightarrow M^-$

[5] $e^- + M^0 \rightarrow e^- + M^0$

Gallimberti (9) has outlined the relevant chemical reactions in the dynamical development of streamers, which is now referred to as the streamer–leader theory (8, 9). The streamer–leader theory of breakdown is a response to the failure of the Townsend theory (18) to predict the relevant breakdown parameters in gases at atmospheric pressures or higher.[3] It is now recognized that breakdown in air (long gaps) involves a multi-step process whose elementary step is the so-called streamer. The existence of streamers was postulated by Raether (19) in 1939 and is basically a propagating thin channel of ionization. Although electrically neutral because of the equal number of positive and negative charges, under an external field (which may be weak) thin layers of charge or space charge develop at the tips of this thin filament, as shown in Fig. 4. The field developed by the space charges at the tip of the streamer can be quite significant and adds to the applied field yielding a *much-enhanced* total electric field. It is only recently (4, 5) that the precise magnitude of these fields has been determined.

[3] Townsend theory (18) is the first physical theory successfully developed for gas electrical breakdown. It postulates the electron impact ionization of free gas molecules and subsequent multiplication of electrons through a nonlocal, secondary electron mechanism. Townsend theory predicts the increase of electron density (n_e) to follow $dn_e/dt = \alpha(E)v_e n_e$, where $\alpha(E)$ is the Townsend or ionization coefficient, E is the local field, and v_e is the electron drift velocity. From the above equation, the theoretical breakdown voltage can be derived and is generally in agreement with experimental results at low gas pressures and uniform field conditions (16).

SF_6 (ref. 17)				150[c]

[a] Nonuniform field conditions; d = 2.0 cm with sapphire spacer.
[b] Nonuniform field conditions; data from Fig. 2 (1 atm, 1.5 cm) in ref. 13 (1 atm = 101.3 kPa).
[c] Uniform field conditions; data from Fig. 2 (20 bar mm) in ref. 17 (1 bar = 100 kPa).
[d] Breakdown voltages of air and N_2 are essentially the same under atmospheric conditions.
[e] Nonuniform field conditions; data from Fig. 5.22 (1 atm, 2.54 cm) in ref. 16.

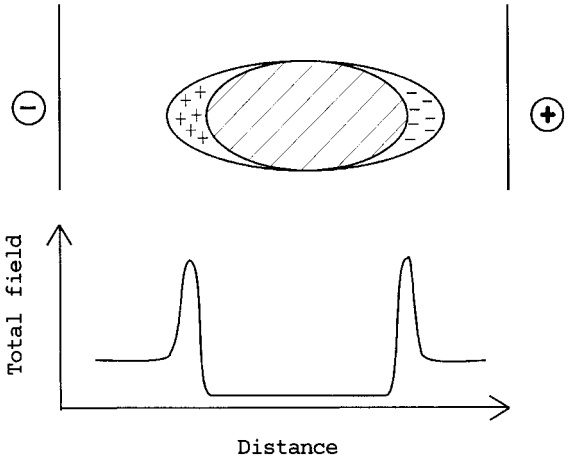
It is suggested that the quenching of the positive space charge at the tip (see Fig. 4) leads to photoemission, which subsequently photo-ionizes the gas molecules just ahead of the tip — the so-called active region (9). The photo-generated electrons are quite energetic and lead to an avalanche of electron–molecule reactions (see eq. [3]) (20). In fact, spectroscopic studies by Gallimberti (9) have revealed that the brightest (in the visible range) region of the streamer–leader is the *tip* of the growing streamer–leader formation. The enhanced electric field will generate considerable ionization of neighboring gases, which would then electronically relax, releasing the observed photons. The streamer tip also serves as the growth point for new streamers and, therefore, may be considered a *branch point*. The number of branch points $b(r)$ at large enough values of r is proportional to the number of branches, which in turn is related to $N(r)$ (6, 15),

$$[6] \qquad b(r) \approx \frac{\mathrm{d}N(r)}{\mathrm{d}r} \approx r^{D_f-1}$$

The slope of log b versus log r would then be equal to $D_f - 1$. As previously shown in our earlier work (15), these DB patterns can be characterized as fractal images with a fractal parameter, $D_f = 1.8$, which is in agreement with earlier measurements (6, 10) and extensive theoretical simulations (21). Our present understanding assumes that the observed "dots" in the DB images (Fig. 3) are the branch points of the growing streamer–leader of gaseous DB. We have explored alternative explanations (see below), but none provide as consistent an explanation as that presented above. Further support for our assumption is provided by a new stochastic DB model, which is presented in section 3.3.

Another possible explanation for the observed images in Fig. 3 is the phenomenon of surface flashover (22–24). Surface flashover refers to the observation of surface field emission of

Fig. 4. Schematic of growing streamer with enhanced total electric field at tips. The tip dimensions are exaggerated to highlight the space-charge effect.



electrons, followed by the conduction of a small current across the insulator, which is sandwiched by two electrodes that are at sufficiently high voltage. Thus, surface flashover can be initiated at any part of the insulator surface. Although surface flashover is generally observed only under vacuum conditions (22, 24), it can also occur at atmospheric pressure (23); however, it is quite difficult to separate the gas-mediated processes in this case. For example, surface flashover in sapphire has been observed and characterized only under high-vacuum conditions (lower than 10^{-6} torr) (1 torr = 133.3 Pa) (22, 24). Thus, at the pressures presently studied, surface flashover is not the major reason for the observed images; the images refer to breakdown of the respective gases (Fig. 3). This is also consistent with the observed trend in the breakdown voltages (see Table 1), which would have stayed fairly constant if surface flashover was the dominant mechanism responsible for the observed images.

3.3 Stochastic model of gaseous dielectric breakdown

The present model is an extension of an earlier DB model reported by Niemeyer et al. (6), also known as the NPW model. We assume the following assumptions:

(*a*) The DB pattern grows stepwise from an initial single seed at the center.

(*b*) At each step one bond is added to the pattern, linking a point of the pattern to a new point.

(*c*) To each of these dashed bonds a growth probability at site i, j (p_{ij}) is associated, which is a linear function of the local electric field (i.e., potential difference between the existing structure and the growth site).

$$[7] \qquad p_{ij} = \frac{\Phi_{ij}}{\Sigma\Phi_{ij}}$$

Since the potential is zero, $\Phi = 0$, in the existing structure, the potential difference is simply the local potential, Φ_{ij}.

(*d*) To each recently grown bond there is an elapsed time associated, given by

$$[8] \qquad \tau_{ij} = \frac{c}{\Phi_{ij}}$$

© 1998 NRC Canada

Fig. 5. (*a*) Computer simulation of the dielectric breakdown images using the present stochastic DB model with the explicit inclusion of time. Simulation of dielectric breakdown using a square 501 × 501 grid generates 20 350 bonds. The fractal dimension is 1.69 ± 0.01, which is very close to the accepted value of 1.70 (21). Quoted error refers only to the statistical error of the linear fit and does not include errors due to the grid (lattice) type. **(***b*) Time development of growing fractal. Absolute time scale was obtained from eq. [8].

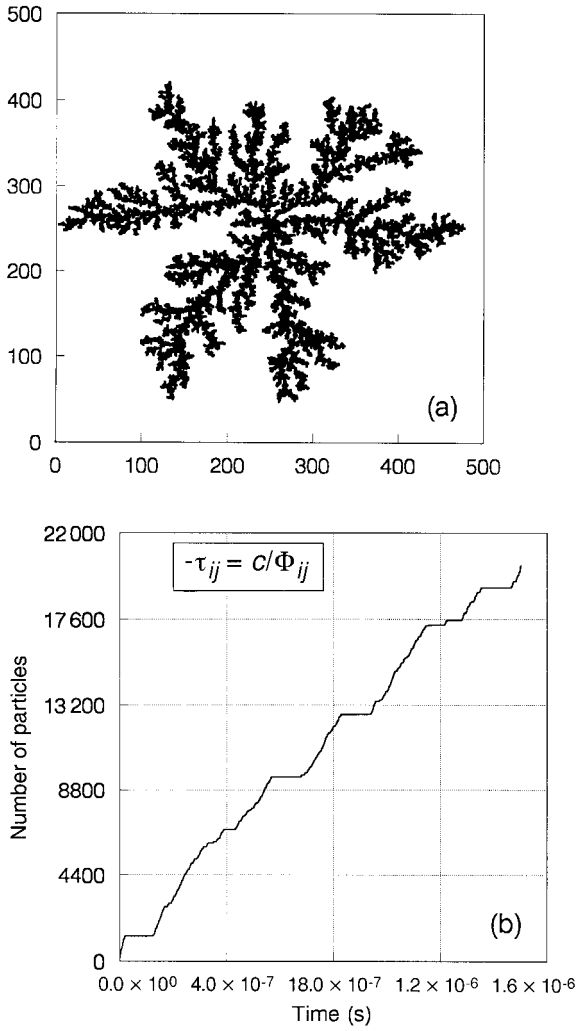


Fig. 6. Simulated discharge current as a function of time using (*a*) 501 × 501 and (*b*) 401 × 401 grids. Breakdown occurs at 1.5 μs. Approximate current is obtained from the derivative of the charge vs. time curve (Fig. 5*b*). Gaps in the time axis indicate the stochastic nature of the discharge, but the overall shape of the predicted current wave form is independent of the simulation grid dimensions. The parameters are chosen to be consistent for N_2 breakdown under nonuniform conditions. See text for details.

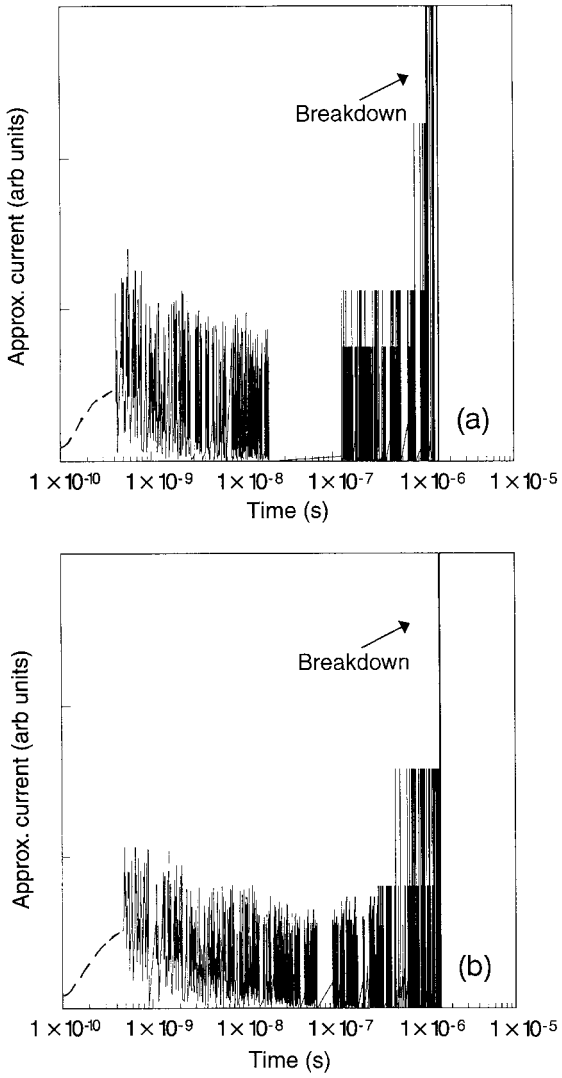


where Φ_{ij} is the potential at the point chosen and c is a defined constant.

(*e*) DB growth ends when one of the bonds reaches the edge of the circle.

The discharge pattern indicated by the dots (bonds) is considered equipotential ($\Phi = 0$), whereas $\Phi = 1$ outside the external circle, defined by the radius of the stainless steel ring (see Fig. 1). At each step (*b*), the Laplace equation,

$$[9] \quad \nabla^2 \Phi = 0$$

is solved using the finite-difference method. This step is the most CPU time-consuming aspect of the simulation.

Assumption (*d*) is a modification of the NPW model (6) and takes into account the temporal development of the DB pattern. The simplest, and perhaps most natural, expression for the elapsed time for each step in the simulation is that given in eq. [8], which can be derived from classical arguments. In the present work, the elapsed time for the growth of the bond is assumed to be consistent with the time scales predicted by the recent, highly accurate 2-D numerical simulations of Vitello et al. (4) as well as the mathematical analysis of Ebert et al. (5). We choose a time scale, $t_0 = (\alpha v_e E)^{-1} = 3$ ps, which is obtained for a voltage difference of 25 kV across a 0.5 cm gap in N_2, used in both published simulations (3, 4) and is reasonably similar to the DB experiments with air reported in the present study. The time scale refers to the amount of time an electron traverses the length scale ($\alpha_o^{-1} = 2.3$ μm) for a given drift velocity (v_e) and local field (E). Here, α_0 refers to the ionization constant, defined by the phenomenological Townsend ionization coefficient, $\alpha(E) = \alpha_0 e^{-E_0/E}$ (18). The time scale (t_0)

© 1998 NRC Canada

will naturally vary with the gaseous sample, but is ignored at present so as to focus on the general features brought about by the introduction of assumption (*d*). From this time scale, the constant *c* in eq. [8] can be estimated given the total time (t_{tot}) from inception to discharge, which is well described by Martin's semiempirical equation (25). The total time (in seconds) is given by,

$$[10] \quad t_{tot} = k\rho^{0.25}\left(\frac{d}{\Delta V}\right)^{3.5}$$

where $k = 1.1 \times 10^5$, ρ is the gas density (g/cm^3), *d* is the gap distance (cm), and ΔV is the gap voltage (kV) (25). For consistency we use the parameters appropriate for N_2 and our geometry, and we arrive at a total time of approximately 1.5 μs. Thus, to properly model the dielectric breakdown in air we would need at most 5×10^5 bonds (number of bonds = 1.5 μs/3 ps) on a 1001×1001 grid. This assumes that *on average* each bond is formed within the time scale prescribed by Ebert et al. (5). This requires a very huge numerical simulation beyond the capabilities of our present computer, thus a scaling study is performed at different grid sizes (and therefore total bonds). From the scaling study of grids of side lengths of 101, 201, 301, 401, and 501, we can find the appropriate constant that renders the time scale absolute as well as the maximum grid size that is physically meaningful within the context of the given time scale.

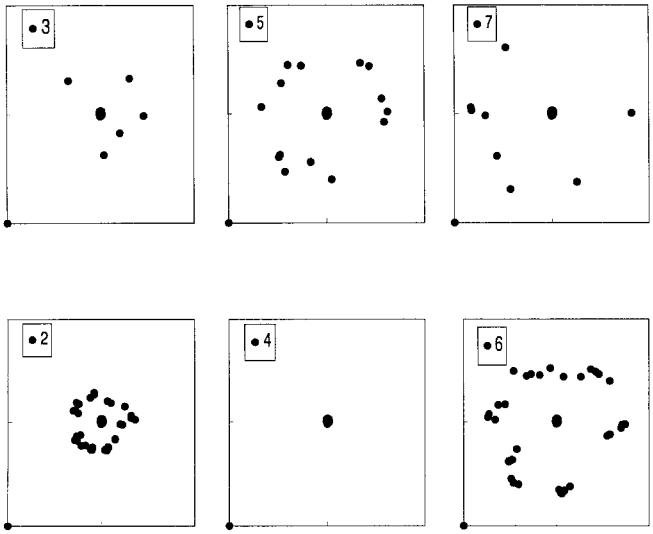
The predicted structure from the present DB stochastic model is shown in Fig. 5*a*, and the temporal characteristics of the corresponding structure is shown in Fig. 5*b*. The DB pattern is grown on a square 501×501 grid and is composed of about 20 000 bonds. The present numerical simulation took approximately 150 h in computing time on a Pentium workstation (133 MHz, 32 Mb RAM), using a custom-built Fortran program compiled with Lahey Fortran (LF90B). The calculated fractal (Hausdorff) dimension for this 2-D structure is 1.69 ± 0.01 and is very close to the generally accepted numerical simulation value of 1.70 (21). There is currently no analytical method that successfully predicts the fractal (Hausdorff) dimension for this 2-D structure although several attempts toward an analytical solution have been presented in literature (26). It is precisely the absence of an analytical solution to this "simple-looking" problem that makes pattern formation in dielectric breakdown particularly interesting.

The time development of the DB model pattern shown in Fig. 5*b* can also be interpreted in terms of the time development of charge, as suggested by Biller (27) and Kukhta et al. (28) who both used different algorithms for calculating physical time. Kukhta et al. (28) assumed time to be inversely proportional to an "average" potential of the growing fractal, and further assumed a variable dielectric constant for the growing structure. The model developed by Kukhta et al. (28) therefore has significantly more parameters than the original NPW model and the model we have presented. On the other hand, Biller (27) assumed a Poisson-like distribution for the probability that a bond grows at time τ (27). Each bond is then chosen and grown on the basis of the shortest growth time. Furthermore, Biller (27) presented his simulation results on a relative time scale and thus cannot be directly compared with any experimental result. It is important to note, however, that Biller's result (27) is in qualitative agreement with Fig. 5*b*.

To provide an approximation to the discharge current, which is a well-defined experimental quantity, the derivative of the charge vs. time curve (Fig. 5*b*) is obtained using the method of differences and is shown in Fig. 6. Two simulations (501×501 grid and 401×401 grid) are shown to illustrate features of the predicted discharge current in order to determine whether the current is dependent on the simulation grid dimensions. Clearly, the overall shape or profile of the predicted discharge current is independent of the details of the simulation. Several experimental current wave forms have been published (see Figs. 5 and 6 in ref. 11, Fig. 3.46 in ref. 16, Fig. 1 in ref. 29, Fig. 3.6 in ref. 30, and Fig. 2 in ref. 31), and all are in qualitative agreement with the present simulation in terms of the overall shape and the absolute decay times. The present simulation (Fig. 6) indicates the initial formation of a small current that decays slowly within the first 100 ns, in semiquantitative agreement with the recent, highly accurate simulation reported by Morrow and Lowke (see Figs. 1 and 2 in ref. 32) and the detailed experiments of Marode (Figs. 5 and 6 in ref. 11). The predicted circuit current then stays essentially flat until the explosive onset of breakdown at 1.5 μs. It is also quite interesting to note that the current wave forms and DB structures obtained by Yamada et al. (29) in a point-plane discharge in *liquid* carbon tetrachloride is strikingly similar to Fig. 6 and Fig. 5*a*, respectively. This is not surprising, since it has been suggested that these experiments in "liquid media are of a gaseous nature" (7) similar in some respect to the present gaseous DB experiments. To properly simulate the circuit current the flow of all positive and negative charges have to be considered. Nevertheless, the present approximation, which includes only the negative charges (i.e., the growing DB structure), is quite reasonable and captures the essential features of the discharge current.

In Fig. 7 we show simulated DB images extracted from the new stochastic DB model, which explicitly includes time, and

Fig. 7. Simulated time-resolved DB images on a 501×501 grid, based on the stochastic DB model with time. The first few branch points are assumed to be continuously active. Frames 2–7 are shown, corresponding to 40 ns each and 160 ns interframe separation. Frame 4 is not erroneous. The parameters are chosen to be consistent for N_2 breakdown under nonuniform conditions. See text for details.



© 1998 NRC Canada

thus can be reasonably compared with the present experiments (Fig. 3). Six time slices of the total simulation are taken, corresponding to 40 ns for each slice. The first few branch points of the simulation are kept, maintaining the assumption that the positive electrode at the center of the ring is "always active." Note that all the simulated photos display only the branch points, where we define a branch point as any point in the simulation with at least three bonds connected to the point. The qualitative agreement between the simulated DB images (Fig. 7) and the experimental DB images in air (Fig. 3*b*) is quite surprising, considering the approximations involved. Frame 4 in Fig. 7 may appear anomalous, but this simply reflects the stochastic nature of the predicted discharge. At some point in time the predicted discharge becomes "quiet" (see Fig. 6), and it is simply accidental that frame 4 falls into this quiet phase. Factors that are not considered in the present simulation include (*i*) the finite lifetimes of the excited neutral and ionic states responsible for most of the fluorescence, which can be larger than the IMACON exposure time, and (*ii*) the response function of the optical system. Further details of the simulation will be published elsewhere (33).

The case for SF_6 (Fig. 3*c*) is quite complicated and is understood to be due to the very different chemical processes involved in the breakdown of SF_6 molecules (34). It is well known that electron attachment (35) (see eq. [4]) becomes a dominant mechanism in the electrical breakdown of SF_6. Electron-attachment processes are not considered in the models reported by Dhali and Williams (3) and Vitello et al. (4).

4. Conclusions

In summary, we have presented time-resolved discharge patterns generated in a gaseous dielectric breakdown (DB). The discharge patterns from various gases (He, air, and SF_6) show general features consistent with their known dielectric strength. A new stochastic pattern-forming model that explicitly includes time is presented and is shown to produce theoretical DB patterns in qualitative agreement with the present experimental discharge pattern for air (N_2). The stochastic DB model (with time) also provides an approximation to the discharge current, which is in good agreement with published current wave forms. This level of agreement was made possible by the use of recent accurate numerical solutions of 2-D continuity equations for streamer growth (3, 4) which indicated the proper time scales. These new developments would seem to indicate that the macroscopic structures (i.e., tree-like structures) observed in dielectric breakdown may be understood from the microscopic mechanisms of streamer growth. For example, it would be interesting to see whether the stochastic DB model we have presented can be combined with the 2-D simulations of Dhali and Williams (3) and Vitello et al. (4). The introduction of a stochastic element to the Dhali–Williams equations (as suggested above) would produce fluctuations, which could lead to a global description of dielectric breakdown patterns from the micrometre scale all the way up to the centimetre scale.

Polyacrylic acid pore-filled microporous membranes and their use in membrane-mediated synthesis of nanocrystalline ferrihydrite

Françoise M. Winnik, André Morneau, Alicja M. Mika, Ronald F. Childs, Anna Roig, Elies Molins, and Ronald F. Ziolo

Abstract: A series of cation-exchange membranes were obtained by photoinitiated grafting of acrylic acid onto a polypropylene microporous support having 0.2 μm diameter pores. The poly(acrylic acid) was shown to be contained within the pores of the membrane. The ion-exchange capacities of these "pore-filled" membranes ranged from 65 to 80% of the theoretical values calculated on the basis of their measured graft yields, with water contents ranging from 72 to 77%. The membranes exhibited a chemical valve effect of flux as a function of pH. Treatment of a poly(acrylic acid) grafted membrane with a solution containing ferrous ions resulted in a large uptake of iron (>24% by weight of iron with a membrane containing 152% graft yield of poly(acrylic acid)). Subsequent alkaline (pH 14) oxidation at 70°C with either oxygen or hydrogen peroxide led to the formation of a superparamagnetic nanocrystalline form of ferrihydrite, $5Fe_2O_3 \cdot 9H_2O$. The oxide was identified by temperature-dependent Mössbauer spectroscopy recorded from 300 K to 4.2 K. TEM micrographs of sectioned membranes that were treated with H_2O_2 revealed the presence of two iron oxide morphologies, disk-shaped particles 3–4 nm in diameter and needle-like particles about 4 nm wide and 50 nm long. Only disk-shaped particles were observed in membranes treated with O_2. Magnetization measurements indicate that the membranes are superparamagnetic above 50 K with a room temperature magnetization of 3.3 emu g^{-1} at 20 kOe.

Key words: membrane, poly(acrylic acid); iron oxide, magnetic, Mössbauer spectroscopy; magnetization, photografting.

Résumé : On a obtenu une série de membranes échangeuses de cations en procédant à une greffe photoinitiée de l'acide acrylique sur un support microporeux de polypropylène comportant des pores de 0,2 μm de diamètre. On a montré que l'acide polyacrylique est inséré dans les pores de la membrane. Les capacités de ces membranes «à pores remplies» à agir comme échangeuses d'ion varient de 65 à 80% des valeurs théoriques calculées sur la base des rendements de greffe, avec des contenus en eau allant de 72 à 77%. Les membranes présentent un effet de valve chimique de flux en fonction du pH. Le traitement d'une membrane greffée avec de l'acide polyacrylique par une solution contenant des ions ferreux provoque une forte absorption de fer (>24% de fer, en poids, par une membrane contenant un rendement de greffe d'acide polyacrylique de 152%). Une oxydation alcaline (pH de 14) subséquente, à 70°C avec de l'oxygène ou du peroxyde d'hydrogène, conduit à la formation d'une forme nanocristalline supermagnétique de la ferrihydride, $5Fe_2O_3 \cdot 9H_2O$. On a identifié l'oxyde par spectroscopie de Mössbauer en fonction de la température, enregistrée de 4,2 à 300 K. Des micrographes «TEM» de membranes sectionnées traitées à l'aide de H_2O_2 ont permis de révéler la présence de deux morphologies d'oxyde de fer, des particules en forme de disque de 3 à 4 nm de diamètres et d'autres en forme d'aiguilles de 4 nm de largeur et 50 nm de longueur. On n'observe que les particules en forme de disque dans les membranes traitées avec de l' oxygène. Des mesures de magnétisation indiquent que les membranes sont superparamagnétiques au-dessus de 50 K; à la température ambiante, la magnétisation est de 3,3 emu g^{-1}, à 20 kOe.

Mots clés : membrane, acide polyacrylique; oxyde de fer, magnétique, spectroscopie Mössbauer; magnétisation; photogreffage.

Introduction

Polymer templates have proven to be extremely versatile hosts in the controlled synthesis of organic–inorganic nanocomposites. As hosts, they provide functionalities and structured frameworks for the synthesis and confinement of molecular clusters and nanoscale particulates. Over the past decade several research groups have examined the synthesis and properties of ultrafine iron-containing particles precipitated in the micropores of perfluorinated ion-exchange membranes such as Nafion7 (1–4). In these membranes, sulfonic acid groups can bind ions such as Fe^{2+} and Fe^{3+}, which upon further

© 1998 NRC Canada

treatment can be reacted to form precipitates of small inorganic particles within the membrane pores.

Recently, Mika et al. (5) reported a new type of anion-exchange membrane composed of a neutral porous substrate with grafted poly(4-vinylpyridine) filling the pores. Such membranes combine a high charge density with the mechanical strength, chemical inertness, and dimensional stability of a porous support. A key feature of these membranes is that the filling polyelectrolyte is flexible and can change its conformation. However, swelling of the polyelectrolyte in the presence of water is restricted by the microporous support. As a result, these membranes exhibit an outstanding pH valve effect of more than three orders of magnitude.

This pore-filling or "gel in shell" (6) construct of ion-exchange membranes can in principle be extended to cation-exchange materials by the incorporation of a negatively charged polyelectrolyte into the pores of a microporous substrate. In this paper we describe the preparation and characterization of cation-exchange membranes in which poly(acrylic) acid is anchored within the pores of a microporous polypropylene support. There are several reports of poly(acrylic) and poly(methacrylic) acid (7) being grafted onto the surface of microporous membranes and partial filling of the pores would appear to be occurring with some of these membranes (8). With the membranes described here we show that the anchored poly(acrylic) acid is located within the pores and not on the surface of the substrate.

In the present study, we demonstrate that these novel membranes can be used as templates for the in-situ preparation of nanoscale magnetic oxides. The incorporation of magnetic nanoparticulates in membranes provides new potential for the management and control of the membrane performance. Iron oxides were precipitated within the modified membranes by a two-step process comprising (*i*) an ion-exchange step to transfer ferrous ions into the grafted polyelectrolyte network and (*ii*) the oxidation of the ferrous ions by either oxygen or hydrogen peroxide in alkaline medium. This method has been demonstrated to yield superparamagnetic forms of iron oxides and (or) iron hydroxyoxides in a variety of polymeric templates (9, 10). The preparation and chemical, morphological, and magnetic properties of the new composite membranes are reported herein.

Experimental section

Materials

The porous membrane was a polypropylene (PP) microfiltration membrane supplied by the 3M Company (average pore diameter: 0.197 μm, porosity: 61.1% by volume, thickness: 51.1 μm). Acrylic acid (Aldrich Chemical Co.) was purified by vacuum distillation. Benzoin ethyl ether (Aldrich Chemical Co.) was used as a photoinitiator. Ferrous chloride ($FeCl_2 \cdot 4H_2O$) was purchased from Fisher Scientific. Sodium hydroxide and hydrogen peroxide (30% v/v) were obtained from BDH Inc. Water was deionized with a Barnstead NANOpure water purification system.

Instrumentation

UV spectra were recorded on a Hewlett Packard 8452A diode array spectrometer. Scanning electron microscopy (SEM) was carried out using an ISI DS130 instrument. Carbon coatings were used. Transmission electron microscopy (TEM) was performed with a Phillips CM-12 microscope, operated at 120 kV, equipped with an energy-dispersive X-ray spectroscopy (EDS) microanalysis system (McMaster University, Brockhouse Institute for Materials Research). For TEM analysis, membranes were solvent-exchanged with ethanol and embedded in a Spurr resin that was cured at 70°C overnight. Ultrathin sectioning (70 nm in thickness) of the resulting blocks was performed with an RMC MT-7 ultramicrotome equipped with a diamond knife. The sections were mounted on copper grids. Some sections were coated with carbon before observation. A superconducting quantum interference device (SQUID) Quantum Design magnetometer (McMaster University, Department of Physics and Astronomy) was used for determination of the magnetic properties. The sample (approximately 5 mg) was placed in a no. 3 gelatin capsule. This was inserted into a cylindrical sample holder (ca. 6 mm in diameter) placed in the sample compartment of the magnetometer. Mössbauer spectra were obtained using a constant acceleration Mössbauer spectrometer (Instituto de Ciència de Materiales de Barcelona) with a 10 mCi $^{57}Co/Rh$ source. The source was moved via a triangular velocity wave form and γ-ray counts were collected in a 512 multichannel analyzer. The data were folded, plotted, and fitted by a computer procedure. Velocity calibration was done using a 25 mm thick metallic Fe foil, and the Mössbauer spectral parameters are given relative to this standard at room temperature. The membrane samples, approximately 50 μm thick and with 24.4% by weight of Fe, were placed in the spectrometer as obtained.

Photografting of the membranes

The reactions were carried out in a photoreactor as has been described elsewhere (5). The substrate membrane (11.0 × 12.8 cm^2) was soaked in acetone for 16 h, dried in vacuum at room temperature, and weighed. It was placed against the inner wall of the reactor vessel. A solution of benzoin ethyl ether (1.0–1.5% by weight) in acrylic acid (3.0 mL) was poured into the reactor vessel. The reactor and its content were degassed by freeze-thawing. Subsequently the reactor vessel was rotated manually in order to wet the membrane with the monomer/initiator solution. The wet membrane was irradiated for 30 min in a Rayonet-type photoreactor equipped with 10 lamps, 5 lamps emitting at 300 nm and 5 lamps emitting at 350 nm. The irradiated membrane was removed from the reactor vessel and placed in a Soxhlet extractor. It was extracted with boiling water for 92 h. The water in the membrane was exchanged with ethanol. The membrane was dried in vacuum at room temperature and weighed in order to determine the grafting yield, which was taken as the percentage of mass increase of the substrate membrane(s). Membranes were conditioned by repeated treatments with 1 M HCl, water, and 1 M NaOH.

Determination of the membrane properties

Ion-exchange capacity

A conditioned membrane was washed thoroughly with deionized water. It was kept in contact with aqueous NaOH (100.0 mL, 0.0500 M) for 16 h. It was removed from the solution and rinsed carefully with water while held above the NaOH solution. The excess NaOH in solution was titrated with HCl in the presence of methyl red in order to determine the number of OH^- equivalents neutralized by the poly(acrylic

© 1998 NRC Canada

acid). The ion exchange capacity was calculated by taking the ratio of the membrane-neutralized OH^- equivalents to the mass of the dry grafted membrane.

Water uptake

The conditioned water-swollen membrane was placed between two sheets of wet filter paper and pressed gently to remove surface water. The water content (WU) was determined from the difference between the mass of the water-swollen and that of the dry membrane, using the following equation:

$$WU(\%) = 100\% \ (m_w - m_d)/m_w$$

where m_w is the mass of a water-swollen membrane sample and m_d the mass of the dry sample.

Permeability

Permeability of the grafted and nascent membranes was measured using a stirred ultrafiltration cell (Nuclepore, S76-400) with an active membrane area of 38.50 cm^2. The pressure applied was 100 kPa. The test solutions were stirred at a rate of 250–300 rpm. The pH of the feed solution was adjusted by addition of HCl or NaOH. Prior to each measurement, the membranes were equilibrated with the test solution under pressure until a stable flux was achieved, with the difference between two subsequent readings being less than 5%. The transmembrane flux (kg m^{-2} s^{-1}) was calculated as the mass of permeate collected from the unit of membrane surface area (m^2) over the unit of time (s). The flux was corrected to 25°C by using an experimental temperature correction factor (11). The membrane permeability was calculated by dividing the flux by the applied pressure.

Preparation of iron oxide containing membranes

The poly(acrylic acid) grafted membrane (ca. 10 × 10 cm) was placed in a solution of ferrous chloride, $FeCl_2 \cdot 4H_2O$ (5.0 g, 0.025 mol), in water (500 mL) and purged with nitrogen for 16 h. The membrane was removed from this solution and washed with water until the eluent was iron-free, as determined by the thiocyanate test (12). The membrane was then cut in two. Each piece was immersed in aqueous NaOH (200 mL, 1 N) and heated to 70°C. A constant stream of air was then bubbled through one of the solutions while heating for 4 h to oxidize Fe^{2+}. The solution was cooled to room temperature, whereupon the membrane was removed and washed with water until the pH of the eluent was neutral. The membrane, designated membrane A, was dried at room temperature under vacuum. A solution of hydrogen peroxide (12 mL, 30% by volume) in water (25 mL) was added dropwise to the solution containing the other half of the membrane, to oxidize Fe^{2+} more directly. At the end of the peroxide addition the mixture was kept at 70°C for 4 h. The membrane, designated membrane B, was removed from the cooled solution, washed with water until the pH of the eluent was neutral, and dried.

Spectrophotometric determination of the iron incorporated within the membranes

A known amount of the dry iron-containing membrane (ca. 10 mg) was treated with concentrated HCl (2 mL) for 30 min at room temperature. The mixture was filtered on a medium fritted glass funnel and washed with about 2 mL of water. The eluent was brought to 10 mL by addition of water. The amount of iron in this solution was determined spectrophotochemically using the tris(1,10-phenanthroline) iron(II) complex test (13).

Results and discussion

Preparation and characterization of the membranes

Photografting

The membranes used in this work were formed by grafting acrylic acid into the pores of a microporous polypropylene (PP) support membrane. The support membrane, which is prepared by a thermally induced phase separation process (14), has a highly porous structure (porosity 61.1% by volume) consisting of a series of fine fibrils linked together by nodules. The average pore diameter of the membrane is close to 0.2 μm.

The photochemical grafting of vinyl monomers onto polyolefin films was pioneered by Ang et al. (15) and by Ogiwara et al. (16). It has been used to functionalize porous materials such as cellulose filters (17). A number of monomers and monomer mixtures have been employed, including acrylic acid (18). In this work the photochemical method used was based on the techniques developed in these laboratories for grafting 4-vinylpyridine onto a range of microporous PP membranes (5). In this procedure the photoinitiator, benzoin ethyl ether, is dissolved in the neat monomer, acrylic acid. During the irradiation the membrane is supported on the walls of a glass vessel. Under these conditions ungrafted homopolymer, poly(acrylic acid) (PAA), is also formed. The homopolymer was removed by extraction from the PAA-grafted membrane using water at 100°C.

Various levels of PA grafting yields can be achieved depending on the intensity of the light used and the length of irradiation. The membranes were physically robust with incorporation levels below 200%. At higher graft yields, the membranes were fragile and broke readily when subjected to the extraction step. This fragility is likely the result of the large swelling pressures generated on hydration of the membranes with high graft yields.

The grafted membranes were characterized by measurement of their ion-exchange capacities and water content as well as by electron microscopy. Typically, the ion-exchange capacities were found to be in the range of 65–80% of the theoretical values calculated on the basis of their measured graft yield. In contrast to the hydrophobic polypropylene substrate, the grafted membranes are hydrophilic. The water content in the hydrated samples amounted to 72–77% of their weight.

SEM micrographs of the front and back surfaces (front being defined as the side of the membrane exposed to the light source) were indistinguishable from those of the nascent membrane. This finding parallels our previous work with poly(4-vinylpyridine) pore-filled membranes where SEMs of the freeze-substituted membranes similarly showed no discernible change in the membranes as compared to the starting base material (19). In the anhydrous conditions used in the SEM examination, presumably the poly(acrylic acid) tightly covers the surfaces of the polypropylene substrate.

Evidence for the distribution of poly(acrylic acid) incorporated in the membranes was obtained using SEM and TEM

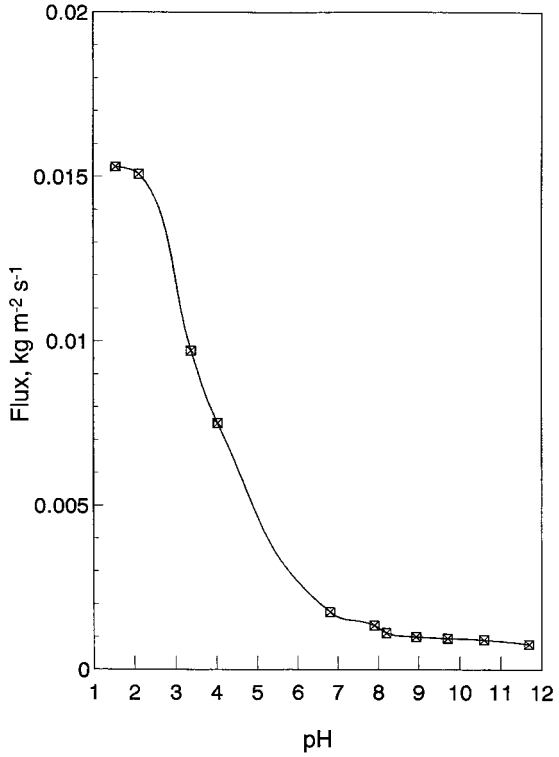
Table 1. The pH valves of poly(acrylic acid) and poly(4-vinylpyridine)-grafted membranes.

		Flux (kg m^{-2} s^{-1}) at pH			
Grafted polyelectrolyte	Graft yield %	2.6 ± 0.1	Valve position	7.0 ± 0.1	Valve position
None	0	—	—	0.32	—
Poly(acrylic acid)	56.0	0.0132	Open	0.0015	Closed
Poly(4-vinylpyridine)	35.9	0.00097	Closed	0.106	Open

Fig. 1. Flux vs. pH: the pH-valve effect recorded for a polypropylene membrane grafted with 56.0% of poly(acrylic acid). Applied pressure: 100 kPa.



(vide infra) and EDX analyses. For EDX analyses the poly(acrylic acid) was converted to its potassium salt and analyses for potassium of the front and back surfaces were carried out. Potassium was readily detected on both surfaces. However, there was a marked asymmetry in the loading of potassium on the front and back surfaces with there being four times more potassium present on the front surface. As with poly(4-vinylpyridine) based membranes of this type, this asymmetry probably results from evaporation of the monomer from the back surface during the photopolymerization (5).

The pH-dependent water permeability of the PAA-grafted membranes under pressure was measured at various pH values. The flux–pH relationship obtained with a 56%-grafted membrane at 100 kPa pressure is presented in Fig. 1. The curve representing this relationship has a characteristic shape indicating that the membrane is functioning as a chemical valve (3). There is one order of magnitude change in flux in the pH range of 3–6. Surface grafting of poly(methacrylic acid) or poly(acrylic acid) on the surface of microporous supports has also been shown to give pH-sensitive membranes (7).

Anchoring of poly(4-vinylpyridine) inside the pores of polypropylene or polyethylene microfiltration membranes produces membranes with a very large pH valve behaviour (5). Comparison of the membranes obtained by grafting poly-(4-vinylpyridine) and poly(acrylic acid) into pores of the same polypropylene substrate (Table 1) shows not only the expected difference in the point of closure of these two valves on the pH scale but also a very large difference in the magnitude of the valve effect. While the permeabilities (or fluxes at the same pressure) of these two types of membranes are similar when the valves are closed, they differ substantially when the valves are open. Poly(4-vinylpyridine) in the free base form is a hydrophobic polymer and adopts a tightly coiled conformation affecting the membrane permeability to a small extent as compared to the starting base membrane. However, in the case of poly(acrylic acid) the polymer is expected to form a hydrogel, even when in its un-ionized form. As a result, the open-valve flux with the poly(acrylic acid) membrane is substantially reduced from that of the ungrafted membrane. The valve effect seen with poly(acrylic acid) would seem to be due to ionization of the carboxylic acid functions at higher pH rather than the result of conformational changes occurring upon ionization of poly(4-vinylpyridine) grafted membranes.

Binding of Fe(II) by the grafted membrane

A membrane with a high degree of grafting, 152% graft yield, was selected for this study, in order to provide a high density of binding sites for the ferrous ions. The measured ion-exchange capacity of the dry membrane was 5.39 mequiv. g^{-1}, a value that is far higher than that normally encountered in ion-exchange membranes. It is, however, lower than the theoretical ion-exchange capacity of the membrane (8.38 mequiv. g^{-1}) calculated on the basis of the mass of incorporated poly(acrylic acid). Despite the incorporation of a large amount of poly(acrylic acid) into the base membrane, the water content of the grafted membrane (in Na^+ form) was 72% by weight, a value that exceeds the measured porosity of the base membrane.

The membrane (152% graft yield) was treated with an Fe(II) solution and then washed with deionized water until no further iron could be detected in the washings. The total concentration of iron taken up by the membrane, measured after the oxidation step (outlined below), was found to be 24.4% by weight, or 5.8 mmol g^{-1} of the dry grafted membrane. The amount of iron absorbed is essentially the same as the ion-exchange capacity of the membrane, indicating that one iron atom is absorbed per ionizable carboxylic group present in the membrane. Curiously, and unlike the parent membrane or the PAA-grafted membrane, the Fe(II) loaded membrane was brittle and had to be handled with care to prevent breaking. Presumably the brittleness results from a high level of "cross-linking"

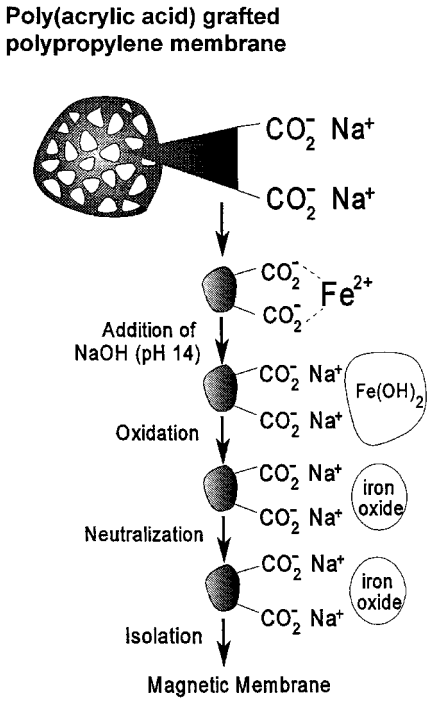
Fig. 2. Schematic representation of the process employed in the preparation of the iron oxide containing materials. Note: the intermediate formation of $Fe(OH)_2$ is postulated on mechanistic grounds and from the appearance of a green color in the substrate.



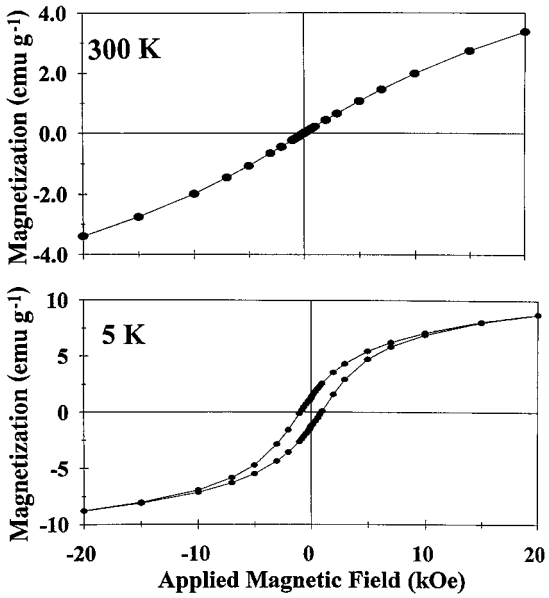
throughout the membrane (20) between carboxylic acid groups on the grafted chains and the bridging iron(II) ions.

The adsorption of metal ions such as Cu^{2+}, Co^{2+}, and Cr^{3+} by poly(acrylic acid) plasma-grafted onto polyethylene films has been reported by Osada and Iriyama (21). However, it is interesting that the amount of metal absorbed by their films ranged between 0.01 and 0.04 mol per repeat unit of PAA. This value is nearly two orders of magnitude lower than the amount of iron adsorbed by the pore-filled membrane used in this study and presumably reflects the different nature of the plasma-surface-grafted poly(acrylic acid) as compared to the pore-filled materials described here.

Oxidation of the membrane-bound Fe(II)

The Fe(II) loaded membranes were oxidized under the conditions outlined in Fig. 2. The iron content of each membrane was essentially identical (approximately 24% w/w Fe, based on the dry membrane). We note that, after oxidation, the membranes recovered their original mechanical properties and were no longer brittle. This observation further supports our hypothesis that Fe^{2+} serves as a cross-linking species in the preoxidized membranes.

Fig. 3. Magnetization curves of the membrane A. Top: zero-field cooled magnetic hysteresis loop at room temperature; bottom: at 5 K.



Magnetic properties of the membranes

Magnetic properties of the membranes are listed in Table 2. A plot of the room temperature magnetization as a function of magnetic field for the two membranes showed no hysteresis. At 5 K, the plots of magnetization versus magnetic field exhibited a hysteresis loop with coercivity values of 914 and 1000 Oe for membranes A and B, respectively. Figure 3 presents the curves recorded at 300 K (top) and 5 K (bottom) in the case of membrane A, with those for membrane B being nearly identical. These data suggest superparamagnetic rather than paramagnetic behavior of the membranes, consistent with the ultrasmall crystalline size of the precipitated oxide and with the Mössbauer data (vide infra).

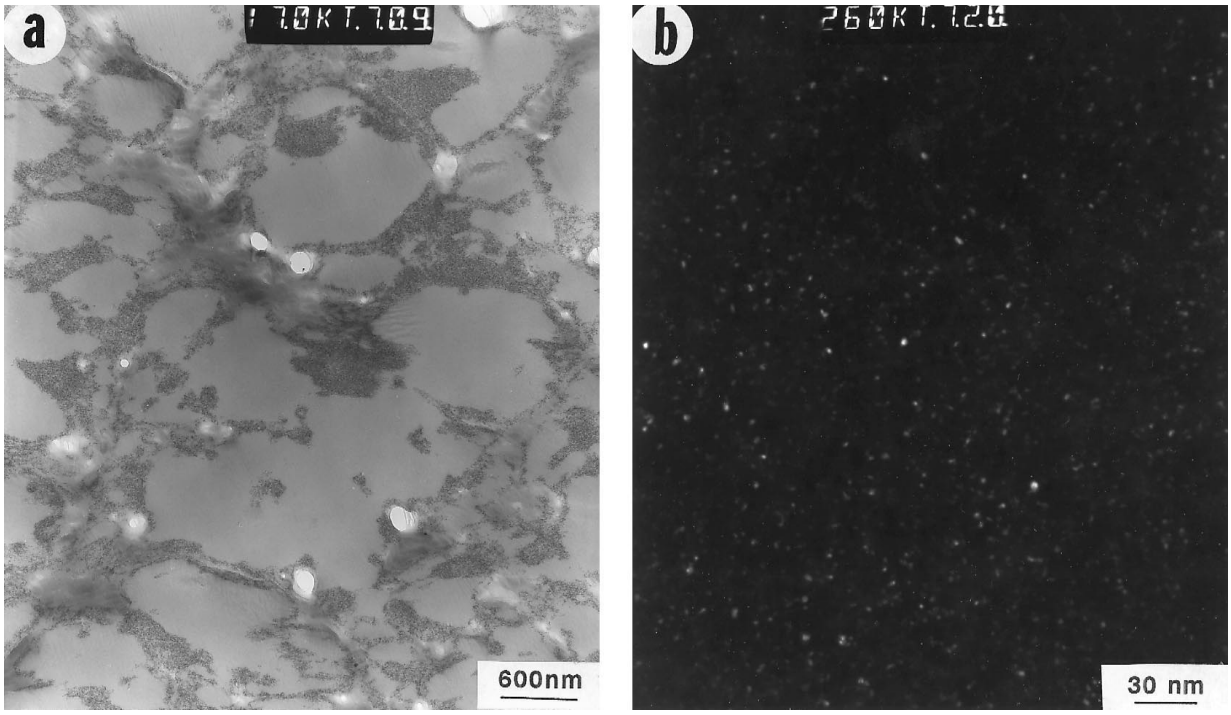
Morphology of the membranes and iron oxide characterization

Morphology

Transmission electron micrographs (TEMs) of the membranes that were embedded in a Spurr resin prior to examination are shown in Figs. 4 and 5. They reveal clusters of iron oxide

© 1998 NRC Canada

Fig. 4. TEM micrographs of sections of membrane A at two different magnifications: (*a*) 17 000, bright field; (*b*) 260 000, dark field.

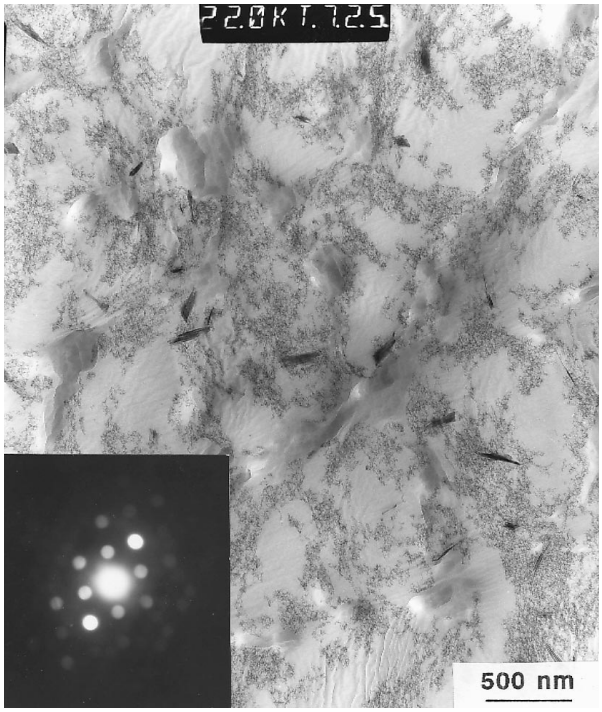


particles located in an interconnected network. It would appear that the clusters are giving an image of the poly(acrylic acid) filled pores of the microporous membrane. The area occupied by the clusters, however, is smaller than expected from the high porosity of the substrate membranes and may indicate a deformation of the membrane due to TEM sample preparation. The particles in membrane A (Fig. 4), which were formed by O_2 oxidation of Fe^{2+}, are disk-shaped and range in size from 3 to 4 nm. In membrane B, which had been treated with H_2O_2, similar particles were present along with needle-like particles about 50 nm long and 4 nm wide. The disk-shaped particles in both membranes were too small to yield resolvable diffraction patterns. Selected area electron diffraction of the needle-like particles (Fig. 5, inset), however, suggested the possibilities of ferrihydrite, $5Fe_2O_3 \cdot 9H_2O$, and ferroxyhyte, δ′-FeOOH, a poorly ordered form of δ-FeOOH. Electron energy loss spectra of the nanocrystalline particles in membrane B showed hexagonal crystal symmetry consistent with both forms of iron oxide.

Iron oxide characterization

To establish the identity of the nanoparticulate iron oxide, a Mössbauer study of both membranes was conducted. Table 3 shows the Mössbauer spectral parameters from 300 K to 4.2 K. The temperature variations of the spectra for each membrane are shown in Figs. 6 and 7. From 300 K to 69 K, the Mössbauer spectra consist of a paramagnetic component due to the fast superparamagnetic relaxation of the magnetic moments of the particles. Field-dependent magnetization data at 300 K for both membranes (Fig. 3) show the absence of hysteresis, consistent with superparamagnetic behavior. For membrane B, there is a magnetically split component that amounts to 10% of the total resonant area, consistent with the TEM results that show two types of particles of different size and morphology.

Fig. 5. TEM micrograph of a section of membrane B; inset: electron diffraction pattern obtained from several needle-like oxide particles.



At 4.2 K, the spectra for both membranes were completely split magnetically.

The superparamagnetic components of the spectra were fitted with two doublets. It was observed that this procedure improved the quality of the fit by lowering the χ^2 values. In the case of

[a] B_{hf} is the hyperfine field in tesla and corresponds to the average field of the distribution, and the standard deviation of the distribution, σ_{Bhf}, is given. ΔE_q, δ/Fe, and Γ are the quadrupolar splitting, the isomer shift (relative to α-Fe), and the full width at half maximum, respectively, all given in mm s^{-1}. The area of each subspectrum is given as a relative percentage. The χ^2 parameter is also given. The numbers in parentheses represent the errors in the given values.

Fig. 6. Temperature variation of the Mössbauer spectra between 300 K and 4.2 K for membrane A. Dots are experimental data; solid lines are computer-fitted spectra. The hyperfine parameters of the subspectra are given in Table 2.

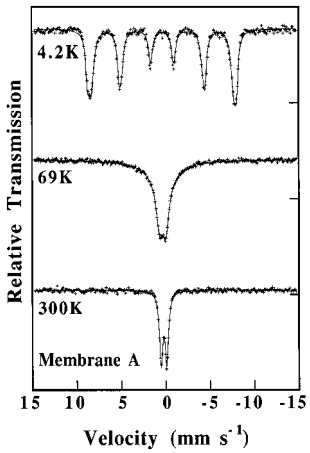

Fig. 7. Temperature variation of the Mössbauer spectra between 300 K and 4.2 K for membrane B (see caption of Fig. 5).

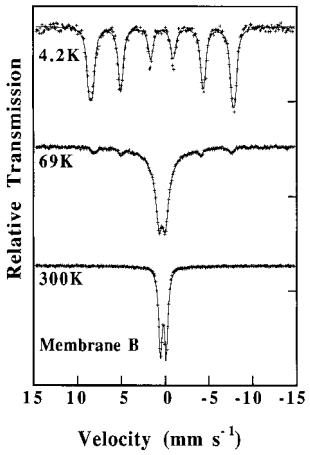

membrane B at 300 K, the χ^2 was 15.7 for one doublet and 5.5 for two doublets; this improvement is not as large in the other spectra. At the same time, this method was also used for comparing our results to previously reported data. The spectral values of the two doublets fitting for each membrane were found to be in agreement with those reported earlier for isometric nanocrystalline particles of ferrihydrite, $5Fe_2O_3 \cdot 9H_2O$, 2–6 nm in diameter (22, 23). This assignment is also consistent with the TEM data, which showed the main components of membranes A and B to be isometric particles 3–4 nm in diameter. In the absence of a matrix, ferrihydrite may be formed from the rapid hydrolysis of Fe(III) solutions (24). Ferrihydrite is a common biogenic mineral formed in matrix-mediated processes and it is known to exist in both a crystalline and an amorphous form (25).

The magnetically split spectra at 4.2 K were fitted with a distribution of hyperfine fields. At 4.2 K, the observed spectral parameters also coincide with those of ferrihydrite in a well-crystallized form, or so-called six-line ferrihydrite (16, 17, 26). The presence of a certain amount of feroxyhyte, δ′-FeOOH, can not be ruled out on the basis of the Mössbauer data (27). This is particularly true for membrane B, which, as shown by TEM, contains some larger needle-like particles. We assume that they are responsible for the magnetic split component of membrane B (approximately 10%) at 69 K. It is only visible at this temperature because at higher or lower temperatures it gets blurred by the main component, namely, the isometric particles of 3–4 nm in diameter. We note that reasonably well characterized δ′-FeOOH was prepared under similar conditions in solution (28).

We used the data obtained from the membrane A to evaluate the effective anisotropy constant, K_{eff}, since in this case, as shown by TEM, there is only one kind of particle morphology with an average diameter of 4 nm. The Mössbauer blocking temperature, defined as the temperature at which the spectra show 50% of unsplit component and 50% of split component, was evaluated to be 50 ± 10 K, within the error range previously reported (29). Using an Arrhenius law $\tau_m = \tau_0 \exp(K_{eff} V / k_B T_B)$,

© 1998 NRC Canada

where $\tau_0 = 10^{-10}$ s is a constant, and $\tau_m = 5 \times 10^{-9}$ s is the Mössbauer characteristic time, we obtain $K_{eff} = 8 \times 10^4$ J m^{-3}, a value that coincides with the previously reported value for ferrihydrite (30).

We note that the alkaline oxidation of ferrous ions, performed under similar conditions to those reported here but bound to different templates, resulted in the formation of different magnetic oxides. In the case of sulfonated macroporous polymeric microspheres having pore sizes from 50 to 200 nm, the major iron oxide was a superparamagnetic form of goethite, α-FeOOH (31). When the ferrous ions were confined within the pores of mesoporous sulfonated polymeric microspheres having pore sizes from 10 to 100 nm, the alkaline oxidation led to the formation of γ-Fe_2O_3 (maghemite) in addition to goethite (32). In the presence of sulfated latex particles, the reaction yielded predominantly $Fe(OH)_3$ (31). In the case of sulfonated, lightly cross-linked polystyrene, the alkaline oxidation of Fe(II) led exclusively to the formation of maghemite (9). These observations demonstrate, not unexpectedly, that the template, in addition to the macroscopically imposed reaction conditions, plays a critical role in controlling the phase, size, and shape of the precipitated iron oxide. We note that when carboxylated resins were used in place of the sulfonated polystyrenes in ref. 9, only non- or weakly magnetic forms of iron oxide resulted, as in the present case. Ferrihydrite, a weakly magnetic material, which forms the core component of the iron storage protein ferritin in numerous animal classes, enjoys a large abundance and a wide phyletic distribution in nature (25). It is apparently synthesized by matrix- and membrane-mediated mineralization processes.

Conclusions

In this work we have shown that a pore-filled cation-exchange membrane can be readily prepared by photografting acrylic acid into the pores of a microporous polypropylene support. The poly(acrylic acid) contained within the pores is flexible and this, combined with the very high ion-exchange capacities and water contents of the membranes, allows the facile loading of large amounts of a transition metal such as Fe(II). As such, these membranes form ideal hosts for the formation of nano-particles.

Energétique des liaisons inter- et intramoléculaires dans les trois isomères de l'aminopyridine

Raphaël Sabbah et Maria Ermelinda da Silva Eusébio

Résumé: Le présent travail porte sur l'étude thermodynamique des trois isomères de l'aminopyridine (AP) de formule générale : $C_5H_6N_2$. Il a été réalisé en utilisant trois techniques : la calorimétrie de combustion de faibles quantités de substance (quelques milligrammes par essai), la calorimétrie de sublimation et l'analyse thermique différentielle. Cette étude nous a permis : de déterminer les enthalpies de combustion, de sublimation et de fusion de ces composés ainsi que la température de leur point triple; de préciser la stabilité relative des trois isomères; de déterminer les énergies de conjugaison expérimentales et de les comparer aux valeurs théoriques; de déterminer les enthalpies d'atomisation des trois composés et de vérifier qu'elles sont compatibles aux valeurs calculées à partir des contributions énergétiques précédemment déterminées au laboratoire; de déterminer qualitativement et quantitativement les interactions intermoléculaires.

Mots clés : isomères de l'aminopyridine; enthalpie de combustion, de sublimation, de fusion, des liaisons inter- et intramoléculaires.

Abstract: The present work is concerned with a thermodynamic study of the three aminopyridine (AP) isomers (general formula: $C_5H_6N_2$). It was achieved using three techniques: combustion calorimetry of small amounts of substance (a few milligrams), sublimation calorimetry, and differential thermal analysis. From this study, it was possible to determine the enthalpies of combustion, sublimation, and fusion of these compounds and their triple point temperatures; to discuss the relative stability of the three molecules; to determine the experimental resonance energies and compare them with the theoretical values; to determine the atomization enthalpies and compare them with the values calculated from the energetical contributions previously determined in our laboratory; to determine the enthalpy of the intermolecular bonds.

Key words: aminopyridine isomers; enthalpy of combustion, of sublimation, of fusion, of inter- and intramolecular bonds.

1. Introduction

L'analyse des coupes lourdes du pétrole et des produits issus de la liquéfaction des charbons révèle l'existence dans ceux-ci à côté de molécules aromatiques, généralement polynuclées, d'hétérocycles contenant de l'oxygène, du soufre et de l'azote.

Diverses actions, entreprises depuis quelques années, ont eu pour but de valoriser ces coupes et produits. C'est le cas de l'opération d'hydrodénitrogénation (HDN) qui cherche à transformer les molécules renfermant de l'azote en hydrocarbures aromatiques correspondants afin d'obtenir des combustibles non polluants possédant un indice d'octane élevé.

Le calcul d'une chaleur de réaction, quelquefois difficile à déterminer directement à l'aide d'un calorimètre, d'un bilan énergétique, se heurte souvent au manque de données thermodynamiques précises concernant ce type de molécules.

Reçu le 28 juillet 1997.

2. Professeur auxiliaire au Département de chimie de l'Université de Coimbra (Portugal) en stage postdoctoral au laboratoire.

Possédant au laboratoire les moyens de déterminer certaines grandeurs thermodynamiques telles que l'enthalpie de formation à l'état condensé ou gazeux, l'enthalpie de sublimation/vaporisation, avec une exactitude suffisamment élevée tout en n'utilisant que peu de substance (une étude complète nécessite 200 mg environ de substance pure), nous avons, dans le présent travail, étudié les trois isomères de l'aminopyridine. Ce travail s'inscrit bien dans le cadre de notre thème de recherche «Energétique des liaisons inter- et intramoléculaires dans les substances organiques» et vise la mise en évidence du lien existant entre grandeurs énergétiques et structure. Cette étude a été réalisée par calorimétrie de combustion de faibles quantités de substance, de sublimation et par analyse thermique différentielle : mesure du degré de pureté de l'échantillon soumis à l'étude, de son enthalpie de fusion ainsi que de la température de son point triple.

De par la simplicité de leur structure, les aminopyridines, molécules conjuguées, sont souvent étudiées en vue d'utiliser les résultats dans la réalisation de modèles pouvant être appliqués à l'étude de molécules plus complexes.

Enfin, précisons que les aminopyridines sont des intermédiaires de synthèse, qu'elles sont aussi utilisées comme complexants en chimie organique et inorganique et que leurs dérivés sont utilisés en teinturerie et en biologie comme stimulants du système nerveux (1).

Les données thermodynamiques relatives aux aminopyridines et consignées dans la littérature sont très peu nombreuses (2, 3). Nous en reparlerons avec les résultats expérimentaux.

© 1998 NRC Canada

Il en est de même des informations relatant la structure cristalline de ces composés (4–6).

2. Partie expérimentale

2.1. Produits utilisés

Les trois substances étudiées sont des produits Aldrich de pureté supérieure ou égale à 99%. L'analyse thermique différentielle ayant confirmé ce résultat pour les deux isomères *ortho* et *para* (tableau 2), nous n'avons repurifié que l'isomère *méta* trois fois successivement par sublimation à 327 K et sous une pression résiduelle de 1,3 Pa.

Signalons, au passage, que ces trois substances sont nocives par inhalation, ingestion et contact avec la peau. Leur manipulation, réalisée sous hotte aspirante, a donc nécessité quelques précautions telles que le port de lunettes, masque et gants appropriés.

Afin d'éviter toute action de la lumière et de l'humidité sur les substances étudiées, celles-ci ont été stockées dans un dessiccateur en verre brun renfermant de la potasse.

2.2. Appareillages, techniques et modes opératoires

2.2.1. Analyse thermique différentielle

Nous avons utilisé la version moyenne température de l'analyseur thermique différentiel et les cellules expérimentales en verre décrites dans la référence 7.

Dans toutes nos expériences : (*i*) la vitesse de montée en température du four a été de 0,2 K min–1; (*ii*) la masse de substance utilisée a été d'environ 100 mg, déterminée par double pesée à l'aide d'une balance Mettler, type M5, sensible au μg et dont l'exactitude des pesées est de ±2 μg; (*iii*) la préparation des échantillons et leur mise en container ont été conduites de la façon décrite dans la référence 7.

La mesure des températures a été faite à l'aide de deux thermocouples (thermocoax, type 2ABI 15), l'un est solidaire de l'échantillon, l'autre de la référence (alumine-α). La différence entre les f.e.m. délivrées par ces deux thermocouples est amplifiée par un microvoltmètre AOIP, type EVA, sensibilité 100 μV pleine échelle. Le signal ainsi amplifié est envoyé simultanément à un enregistreur Sefram, type Gépérac, pour le visualiser, et à un multimètre Keithley, modèle 175, pour le digitaliser. Un autre multimètre Keithley, modèle 196, sensibilité 300 mV (résolution 100 nV) est utilisé pour mesurer la f.e.m correspondant à la température de l'échantillon. Les données issues de ces deux multimètres sont envoyées vers un ordinateur en vue de leur traitement à l'aide d'un programme écrit et mis au point au laboratoire. En appliquant l'équation de Clausius–Clapeyron et la loi de Raoult, ce programme permet de déterminer la pureté de l'échantillon, son enthalpie de fusion ainsi que la température de son point triple.

Comme indiqué dans la référence 7, l'étalonnage (*i*) en température, de notre analyseur thermique, a été réalisé à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque, diphénylacétique et anisique, de carbazole et d'anthraquinone, dont la température de leur point triple est bien connue dans la littérature; et (*ii*) en énergie, a été réalisé à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque et diphénylacétique, dont l'enthalpie de fusion est bien connue dans la littérature.

2.2.2. Calorimétrie de combustion

Les enthalpies de combustion de nos composés ont été déterminées en utilisant un calorimètre isotherme, à flux thermique, monopile, basculant, CRMT (sensibilité : 0,0623 V W^{-1}) équipé d'une microbombe en acier inoxydable (Superimphy 625) de volume interne égal à 43 cm^3 à la température ambiante.

Le signal issu du calorimètre est amplifié par un microvoltmètre électronique AOIP, modèle EVA, sensibilité 100 mV pleine échelle, avant son envoi simultané sur un intégrateur électronique, conçu, réalisé et mis au point au laboratoire, qui détermine l'aire des thermogrammes $dQ/dt = f(t)$, et sur un enregistreur potentiométrique Sefram, modèle Servotrace, qui le visualise.

La rotation du calorimètre suivant plusieurs plans permet à toutes les génératrices de la bombe d'être lavées par l'eau déminéralisée placée en son fond (1 cm^3).

Comme indiqué dans la référence 8, les substances à étudier sont mises sous forme de pastilles. À cet effet, nous avons utilisé un ensemble piston-moule façonné dans un acier trempé, ce qui a pour effet d'éviter l'entraînement dans les pastilles de traces de métal et d'augmenter ainsi la qualité des résultats. Compte tenu de la volatilité de l'isomère *ortho* et d'une éventuelle oxydation des substances par l'oxygène sous 3,04 MPa en présence de vapeur d'eau (2), nous avons scellé nos pastilles dans des petits sachets en polyéthène confectionnés par nos soins à partir d'un film de 50 μm d'épaisseur.

Les pesées ont été effectuées sur une microbalance Mettler, modèle UM3, équipée d'un jeu de poids étalonnés par le N.I.S.T. Sa portée est de 3 g et sa sensibilité de 0,1 μg. L'erreur commise avec cette balance sur une pesée de quelques milligrammes est de l'ordre de ±0,2 μg. Dans toutes nos pesées, nous avons tenu compte des corrections de poussée de l'air pour calculer les masses réelles.

Une fois garnie, la bombe est remplie d'oxygène sous une pression de 3,04 MPa. L'oxygène N45, utilisé à cet effet, provient de l'Air Liquide et son degré de pureté est supérieur à 99,995% (fraction molaire d'azote $<10^{-5}$). La durée d'une expérience a toujours été de 90 min à partir du moment de la mise de feu.

Après chaque expérience, nous avons déterminé, dans la phase aqueuse, la concentration d'acide nitrique par titrage acido-basique en présence de phénolphtaléine avec une solution de soude préalablement titrée à l'aide de solutions d'acide oxalique de concentrations connues, et avons vérifié, à l'aide des tubes de Dräger, l'absence d'oxyde de carbone et d'oxydes d'azote (NO, NO_2) dans la phase gazeuse (sensibilité des tubes <1 ppm pour CO et <0,1 ppm pour NO et NO_2).

2.2.3. Calorimétrie de sublimation

Nous avons utilisé un calorimètre Tian–Calvet (sensibilité 0,0621 V W^{-1}) associé à un montage différentiel doté de cellules d'effusion de Knudsen pour déterminer les enthalpies de sublimation de nos composés. L'étalonnage de notre système calorimétrique a été réalisé par effet Joule avant et après chaque série d'expériences. Le mode opératoire a été décrit dans la référence 9. Précisons que :

(*i*) le signal issu du calorimètre est amplifié par un nanovoltmètre Keithley modèle 147, sensibilité 100 μV pleine échelle, puis digitalisé par un multimètre numérique Keithley

modèle 175 et enregistré sur un enregistreur potentiométrique Sefram, modèle Servotrace;

(*ii*) les trois isomères ont été étudiés à 298,15 K. Compte tenu de la faible pression de vapeur saturante des substances étudiées (4,7, 0,76 et 0,0071 Pa à 298,15 K respectivement pour les isomères *ortho*, *méta* et *para*), nous avons admis l'identité $\Delta_{sub}H_m(T) \equiv \Delta_{sub}H^\circ_m(T)$;

(*iii*) le diamètre des trous d'effusion pratiqués dans des joints en laiton de 0,1 mm d'épaisseur est de 0,2, 0,5 et 3 mm respectivement dans le cas de la 2-, 3- et 4-aminopyridine;

(*iv*) l'ouverture et la fermeture de l'orifice d'effusion des cellules sont pilotées par l'ordinateur;

(*v*) toutes les pesées ont été effectuées à l'aide d'une balance Mettler, type UM3.

L'acquisition et le traitement des données sont réalisés à l'aide d'un ordinateur et d'un programme conçu et mis au point au laboratoire. Il permet, entre autres, de déterminer l'aire des thermogrammes et, à partir du coefficient d'étalonnage, l'enthalpie de sublimation de nos composés à la température de l'expérience $\Delta_{sub}H^\circ_m(T)$.

Les différents calorimètres et analyseur thermique, leurs périphériques ainsi que les balances sont placés dans des salles thermorégulées à (19,0 ± 0,2)°C.

3. Résultats

Les constantes physiques de nos composés sont résumées dans le tableau 1.

3.1. Analyse thermique différentielle

Les résultats obtenus ainsi que ceux qui sont empruntés à la littérature sont rassemblés dans le tableau 2. Notons qu'aucune des trois substances ne semble se décomposer de façon appréciable entre la température ambiante et son point de fusion.

Les résultats de l'enthalpie de fusion, consignés dans la littérature, sont très peu nombreux et concernent l'isomère *para*. Notre valeur diffère de 4% de celle de Donnelly et al. (14). Signalons, au passage, que ces auteurs opèrent sur des échantillons de pureté 99,3% dont la masse est comprise entre 1,5 et 2 mg (exactitude ±0,2 mg) placés dans des godets en aluminium non scellés. De plus, leur calorimètre à balayage a été étalonné à partir d'un seul échantillon : l'indium, métal dont les propriétés de transfert thermique sont différentes de celles d'une substance organique.

Quant aux températures du point triple des trois isomères étudiés, celles-ci sont compatibles avec les résultats de la littérature (13, 14).

3.2. Calorimétrie de combustion

L'équivalent énergétique du système calorimétrique (U_{calor}) a été déterminé à partir de 14 combustions d'acide benzoïque échantillon 39 i du N.I.S.T. pour lequel $\Delta_c u^\circ$(cr, 298,15 K) = (–26 414 ± 3) J g^{-1} (15). Dans chaque expérience, nous avons utilisé de 7 à 16 mg d'acide et environ 0,2 mg de coton (dont l'énergie de combustion, préalablement déterminée au laboratoire, a pour valeur $\Delta_c u^\circ$(cd, 298,15 K) = (–16 399 ± 23) J g^{-1} (16)). Afin de mettre en évidence l'influence du polyéthène sur les résultats, neuf de ces expériences ont été réalisées avec des pastilles scellées dans des sachets confectionnés avec ce matériau ($\Delta_c u^\circ$(cd, 298,15 K) = (–46 347 ± 7) J g^{-1} (17). À l'issue de ces expériences nous n'avons noté aucune différence dans les résultats des combustions effectuées en présence de polyéthène. Nous avons trouvé U_{calor} = (15,465 ± 0,004) J V^{-1} s^{-1}.

Les enthalpies standard de combustion de nos composés concernent la réaction suivante :

$$C_5H_6N_2(cr) + \frac{13}{2}\,O_2\,(g) \rightarrow 5\,CO_2\,(g) + 3\,H_2O\,(l) + N_2\,(g)$$

et sont calculées, à l'aide de l' ordinateur et d'un programme écrit et mis au point au laboratoire, à partir de nos valeurs

expérimentales en tenant compte des corrections dites de Washburn.

La combustion des trois isomères s'est révélée complète, aucune trace de cendre ne subsistant dans le corps de la bombe et dans le creuset une fois l'expérience terminée et les dosages par tubes colorimétriques de Dräger n'ayant révélé aucune présence de CO et d'oxydes d'azote dans la phase gazeuse.

Les résultats relatifs à ces manipulations sont rassemblés dans les tableaux 3–5.

Nous avons remarqué qu'environ 12% de l'azote contenu dans nos composés se trouvaient, à l'issue de la combustion, sous forme d'acide nitrique. L'expérience a montré que la quantité d'acide nitreux formé est excessivement faible et peut être négligée.

Comparée aux seules valeurs de la littérature, obtenues par calorimétrie de combustion classique et reportées dans la référence 2, notre valeur expérimentale de l'enthalpie de combustion est compatible dans le cas de l'isomère *méta* (–2885,2 ± 0,5) kJ mol^{-1}; elle s'en écarte de 0,3% et de 0,1% respectivement dans celui de l'isomère *ortho* (–2864,4 ± 0,5) kJ mol^{-1} et *para* (–2866,8 ± 0,5) kJ mol^{-1}.

3.3. Calorimétrie de sublimation

Les enthalpies de sublimation de nos substances à 298,15 K sont consignées dans le tableau 6. Comparés aux seules valeurs de la littérature consignées dans la référence 2 (*ortho* : (78,7 ± 0,8) kJ mol^{-1}, *méta* : (84,0 ± 1,4) kJ mol^{-1}, *para* : (88,1 ± 1,1) kJ mol^{-1}), nos résultats présentent des écarts

m/mg	4,7887	3,7433	5,0099	3,6016	4,1351	4,9336	3,6091		
$\Delta_{sub}H^\circ_m$ / kJ mol^{-1}	87,34	85,81	86,48	86,63	89,01	87,37	87,02		
$\Delta_{sub}H^\circ_m$(298,15 K) = (87,09 ± 0,38) kJ mol^{-1}									

compris entre 1,3 et 4,1%. Toutefois, signalons qu'à notre avis, la procédure expérimentale utilisée par Bickerton et al.(2) ne conduit pas à la mesure d'une enthalpie de sublimation.

3.4. Enthalpie de formation à l'état gazeux

En utilisant les résultats expérimentaux obtenus par calorimétrie de combustion et de sublimation, nous avons calculé l'enthalpie molaire standard de formation à l'état gazeux de chacun des trois isomères. Celle-ci est égale à (107,5 ± 1,8) kJ mol^{-1}, (141,4 ± 1,6) kJ mol^{-1} et (125,9 ± 1,6) kJ mol^{-1} respectivement pour les isomères *ortho*, *méta* et *para*.

3.5. Enthalpie d'atomisation

À une température donnée, la réaction d'atomisation des aminopyridines s'écrit :

$$C_5H_6N_2\ (g) \rightarrow 5\ C(g) + 6\ H(g) + 2\ N(g)$$

En conséquence, à 298,15 K, l'enthalpie liée à cette réaction est égale à :

$$\Delta_{a,exp}H^\circ_m = 5\Delta_f H^\circ_m\ [C(g)] + 6\ \Delta_f H^\circ_m\ [H(g)] + 2\ \Delta_f H^\circ_m\ [N(g)] - \Delta_f H^\circ_m\ [C_5H_6N_2\ (g)]$$

Les valeurs de $\Delta_{a,exp}H^\circ_m$(298,15 K) de nos substances (tableau 7) ont été calculées en utilisant les valeurs de $\Delta_f H^\circ_m$(g,298,15 K) de C, H et N consignées dans la référence 18 et qui valent respectivement (716,67 ± 0,44), (217,997 ± 0,006) et (472,68 ± 0,40) kJ mol^{-1}.

Dans le présent travail, l'incertitude qui accompagne les résultats expérimentaux représente l'écart moyen, $\sigma_m = \{\Sigma(x - x_0)^2 \pm n(n-1)\}^{1/2}$, x étant chacune des n valeurs entrant dans le calcul de la moyenne x_0. Lorsque la valeur expérimentale est fonction de plusieurs variables, l'incertitude calculée tient compte de l'erreur sur chacune de ces variables.

4. Discussion

4.1. Energie de conjugaison

L'énergie de conjugaison est la différence entre l'énergie réelle de la molécule et l'énergie qu'elle aurait si les divers systèmes insaturés qu'elle comporte étaient indépendants. Sur le plan pratique, pour la déterminer, il suffit d'utiliser les enthalpies standard de combustion à l'état gazeux de la molécule réelle et de la molécule fictive non conjuguée. La première de ces grandeurs s'obtient expérimentalement et la seconde nécessite le recours aux systématiques. En ce qui nous concerne, nous avons utilisé celle de Klages qui est consignée dans la référence 19.

Nous avons également calculé l'énergie de conjugaison théorique à l'aide de la méthode de calcul indiquée dans la référence 20 et ce, en utilisant les paramètres suivants : α_N (pyridine) = α + 0,250 β_0; α_N (aniline) = α + 2,250 β_0; β_{CN} (pyridine) = 1,315 β_0; β_{CN} (aniline) = 0,750 β_0; β_0 est l'intégrale de recouvrement de la molécule de benzène; elle est égale à131,7 kJ mol^{-1}.

© 1998 NRC Canada

Tableau 7. Enthalpies d'atomisation expérimentales et calculées des trois isomères de l'aminopyridine.

Isomère	$\Delta_{a,exp}H^{\circ}_{m}$ (298,15 K) (kJ mol^{-1})	$\Delta_{a,calc}H^{\circ}_{m}$ (298,15 K) (kJ mol^{-1})
2-AP	5729,2 ± 2,2	5688,0
3-AP	5695,3 ± 2,0	5688,0
4-AP	5710,8 ± 2,0	5688,0

Tableau 8. Energies de conjugaison expérimentales et théoriques des trois isomères de l'aminopyridine.

Isomère	$E_{conj,exp}$ (kJ mol^{-1})	$E_{conj,théor}$ (kJ mol^{-1})
2-AP	182,6	174,0
3-AP	168,2	175,3
4-AP	182,9	174,2

Comme nous pouvons le constater, les valeurs de l'énergie de conjugaison expérimentale et théorique (tableau 8) ainsi obtenues sont compatibles.

4.2. Liaisons intramoléculaires dans les aminopyridines

Par définition, l'enthalpie d'atomisation d'une molécule est égale à la somme des liaisons intramoléculaires compte tenu des facteurs de stabilisation et de déstabilisation. Pour retrouver, par le calcul, l'enthalpie d'atomisation de nos composés, nous avons tenu compte du principe de la transférabilité et avons utilisé, entre autres, les valeurs énergétiques des liaisons intramoléculaires préalablement déterminées au laboratoire (21) : H ($C_b - C_b$) = 504,97 kJ mol^{-1}, H ($C_b - H$) = 415,88 kJ mol^{-1}, H (C – N = C) = 902,18 kJ mol^{-1}, H (C_b–NH_2) = 1102,37 kJ mol^{-1}).

Les valeurs ainsi calculées sont consignées dans le tableau 7 et sont en très bon accord avec les valeurs expérimentales (différence : 0,7%, 0,1% et 0,4% respectivement dans le cas des isomères *ortho*, *méta* et *para*).

4.3. Liaisons intermoléculaires dans les aminopyridines

L'enthalpie de sublimation d'une substance est liée aux interactions intermoléculaires. Dans le cas des aminopyridines, ces interactions sont du type van der Waals et concernent les forces de dispersion et d'interactions dipolaires. À côté de ces interactions, il existe aussi des liaisons hydrogène intermoléculaires (4–6). L'analyse des trois références 4 – 6 nous apporte les renseignements suivants :

1. Les molécules d'isomères *ortho* sont liés deux par deux par des liaisons hydrogènes intermoléculaires (4). Compte tenu que des trois valeurs d'enthalpie de sublimation, celle de l'isomère *ortho* est la plus faible, il est permis de penser qu'un certain nombre de molécules partent sous forme de dimères en phase gazeuse.

2. La distance N—H···N étant respectivement égale à 3,123 et 3,007 Å dans les cristaux d'isomère *méta* et *para* (5, 6), les liaisons hydrogène intermoléculaires sont plus faibles dans le cristal d'isomère *méta* qu'elles ne le sont dans celui d'isomère *para*. Ce résultat permet d'expliquer la raison pour laquelle la valeur de l'enthalpie de sublimation de l'isomère *méta* est plus faible que celle de l'isomère *para*.

Pour déterminer la part énergétique des forces de dispersion (London), nous avons considéré qu'elle est, en première approximation, égale à l'enthalpie de sublimation du méthylbenzène, composé isoélectronique des aminopyridines. Le méthylbenzène étant liquide à 298,15 K, pour déterminer son enthalpie de sublimation à cette température, nous avons, en première approximation, appliqué la relation :

$$\Delta_{sub}H^{\circ}_{m}(298{,}15\ \text{K}) = \Delta_{vap}H^{\circ}_{m}(298{,}15\ \text{K}) + \Delta_{fus}H_{m}(298{,}15\ \text{K})$$

Les valeurs de $\Delta_{vap}H^{\circ}_{m}(298{,}15\ \text{K})$ et de $\Delta_{fus}H_{m}(178{,}15\ \text{K})$ sont respectivement égales à 38,06 kJ mol^{-1} (22) et 6,64 kJ mol^{-1} (23). Nous avons calculé la valeur de $\Delta_{fus}H_{m}$ (298,15 K) en appliquant la règle de Sidgwich (24) :

$$\Delta_{fus}H_{m}(298{,}15\ \text{K}) = \Delta_{fus}H_{m}(T_{fus}) - 0{,}055\ (T_{fus} - 298{,}15)$$

Il s'en suit que $\Delta_{sub}H^{\circ}_{m}(298{,}15\ \text{K})$ pour la molécule de méthylbenzène est égale à 51,3 kJ mol^{-1}.

En considérant qu'en phase gazeuse les molécules d'isomères *méta* et *para* sont à l'état de monomère, à une température donnée (ici 298,15 K), la différence Δ_1 entre la valeur de l'enthalpie de sublimation de ces molécules et celle du méthylbenzène représente la part énergétique d'interaction dipolaire et de liaisons hydrogène intermoléculaires. Dans le cas présent, cette part est respectivement égale à 29,4 et 35,8 kJ mol^{-1}. Afin de déterminer la contribution énergétique des interactions dipolaires Δ_2, nous avons, après l'avoir calculée de la même façon que pour le méthylbenzène en utilisant les données consignées dans les références 22 et 25, comparé l'enthalpie de sublimation du chlorobenzène (composé isoélectronique du méthylbenzène et des aminopyridines, liquide à 298,15 K, qui présente un moment dipolaire mais ne forme pas de liaisons hydrogène intermoléculaires) à celle du méthylbenzène. La valeur obtenue est faible et égale à 3,1 kJ mol^{-1}. La différence $\Delta_1 - \Delta_2$, soit 26,3 et 32,7 kJ mol^{-1} respectivement dans le cas des isomères *méta* et *para*, représente la part énergétique pouvant être attribuée aux liaisons hydrogènes intermoléculaires mises en évidence par des études cristallographiques (4–6). Étant donné qu'il ne se forme que deux ponts hydrogène par molécule d'isomère 3- ou 4-aminopyridine, l'enthalpie d'une liaison hydrogène peut être estimée à 15 kJ mol^{-1}. Cette valeur est compatible avec toutes celles qui ont été précédemment déterminées au laboratoire (26–31).

Remerciements

L'un de nous (M.E.S.E.) remercie la Junta Nacional de Investigação Científica e Tecnológica ainsi que la Fundação Calouste Gulbenkian pour l'aide matérielle lui ayant permis d'effectuer un stage postdoctoral au Centre de thermodynamique et de microcalorimétrie du CNRS à Marseille. Ce travail a été réalisé au cours de ce stage.

A ^{1}H NMR study of cyclodextrin – hydrocarbon surfactant inclusion complexes in aqueous solutions

Lee D. Wilson and Ronald E. Verrall

Abstract: A ^{1}H NMR chemical shift (δ) study of a homologous series of hydrocarbon (hc) ($C_xH_{2x+1}CO_2Na$, x = 5, 7, 9, 11, 13) surfactants (S) has been carried out in water and in binary solvent (D_2O + cyclodextrin (CD)) systems at 22°C. Complementary ^{1}H NMR chemical shift (δ) data of the cyclodextrins in binary (D_2O + S) systems containing hc surfactants have also been obtained. Complex induced shift (CIS) values for selected host or guest protons were found to increase as the alkyl chain (C_x) length of the surfactant increased. The CIS values are found to depend on the following factors: (*i*) the magnitude of the binding constant (K_i, i = 1:1, 2:1), (*ii*) the chain length of the surfactant, (*iii*) the mole ratio of the host to guest species, (*iv*) the host–guest stoichiometry, and (*v*) the host–guest inclusion geometry. The CIS values of the CD–S systems have been analyzed using equilibrium models in which 1:1 complexes, 1:1 plus 2:1 complexes, and uncomplexed species are present. Differences in the binding affinity, stoichiometry, and inclusion geometry of the complexes formed between a given hc surfactant and the various cyclodextrins were observed.

Key words: cyclodextrin, surfactant, NMR, chemical shift, complex, binding constant.

Résumé : Opérant à 22°C, dans des solutions aqueuses et dans des systèmes de solvants binaires (D_2O + cyclodextrine (CD)), on a effectué une étude des déplacements chimiques (δ) en RMN du ^{1}H d'une série homologue d'agents de surface (S) hydrocarbonés (hc) ($C_xH_{2x+1}CO_2Na$, x = 5, 7, 9, 11, 13). On a aussi réalisé une étude complémentaire sur les déplacements chimiques (δ) en RMN du ^{1}H de cyclodextrines dans des systèmes binaires (D_2O + S) contenant des agents de surface hc. On a observé que les valeurs des déplacements induits par des complexes («CIS») de protons hôtes ou invités choisis augmentent avec une augmentation de la longueur de la chaîne alkyle (C_x) de l'agent de surface. On a observé que les valeurs de «CIS» dépendent des facteurs suivants: (*i*) la valeur de la constante d'association (K_i, i = 1:1, 2:1), (*ii*) la longueur de la chaîne de l'agent de surface, (*iii*) le rapport molaire des espèces hôtes et invitées, (*iv*) la stoechiométrie hôte–invité et (*v*) la géométrie d'inclusion hôte–invité. On a analysé les valeurs «CIS» des systèmes CD–S à l'aide de modèles en équilibre dans lesquels on retrouve des espèces qui ne sont pas complexées ainsi que des complexes 1:1 et 1:1 en présence de complexes 2:1. On a observé des différences d'affinités d'association, de stoechiométrie, et de géométrie d'inclusion des complexes formé entre un agent de surface hc donné et les diverses des cyclodextrines.

Mots clés : cyclodextrine, agent de surface, RMN, déplacement chimique, complexe, constante d'association.
[Traduit par la rédaction]

Introduction

Cyclodextrin (CD) hosts, because of their ability to form non-covalent complexes with inorganic and organic molecules in aqueous solution (1, 2), are an important class of oligosaccharide complexing agents that can be used in a wide range of technical applications. Alkyl derivatives of β-CD are particularly promising as pharmaceutical excipients because of their low toxicity and their greater solubility in water and organic solvents (3, 4). In comparison to β-CD, there have been relatively few studies carried out on the binding properties of the alkyl β-CD derivatives. Varying the structure of the host and guest species in a systematic manner is a useful approach to enable correlation of the chemical structure of the species with the binding affinity between the host and guest (5, 6). This information is a critical requirement if one is to obtain a better understanding of the key intermolecular interactions, leading to the stability of the complex.

In previous studies, we have used spectral displacement and apparent molar volume measurements to investigate the binding affinity (7–9) of β-CD and its alkyl derivatives with homologous series of both hc and fluorocarbon (fc) sodium alkyl carboxylate salts. NMR spectroscopy has also been shown (10–13) to be a useful technique to study these systems, since the ^{1}H NMR chemical shifts (δ) of both the interior protons of β-CD (14) and the guest nuclei (15) can be analyzed to provide information about the inclusion mode, stoichiometry, and binding affinity of the inclusion complexes. While there have been numerous reports of ^{1}H NMR studies (16–18) of CD – aromatic guest systems, primarily because of the anisotropic properties of the arene ring and the good spectral dispersion of the aromatic protons, there have been comparatively fewer studies employing aliphatic guest systems (19–22). There is a

Scheme 1. Types of host–guest stoichiometry, where CD = cyclodextrin and S = surfactant.

$$\beta\text{-CD} + S \overset{K_{1:1}}{\rightleftharpoons} \beta\text{-CD–S}$$

$$\beta\text{-CD} + 2\,S \overset{K_{1:2}}{\rightleftharpoons} \beta\text{-CD–S}_2$$

$$2\,\beta\text{-CD} + S \overset{K_{2:1}}{\rightleftharpoons} \beta\text{-CD}_2\text{–S}$$

need to carry out a comprehensive and complementary NMR study of such aliphatic guest systems in order to further investigate their complexation behavior with cyclodextrins. To this end, and to complement our previous studies of CD – sodium alkyl carboxylate systems, we have used the NMR technique to determine the binding affinities of various complexes formed between these host–guest systems.

We report the analysis of NMR chemical shift measurements of ^{1}H nuclei of hc surfactants and cyclodextrin compounds determined in both D_2O and in ternary (D_2O + CD + S) aqueous solutions in order to establish the self-consistency between the binding constants derived from the host and guest NMR data. The study of a homologous series of surfactants of increasing alkyl chain length (C_x) provides an opportunity to analyze the degree of alkyl chain coiling that occurs in the complexes as the number of carbon atoms in the chain increases. On the other hand, a study of β-CD and its alkyl derivatives provides an opportunity to investigate the effect of structural changes in the annulus region of the CD on the overall binding affinity of the complexes that are formed with a common guest surfactant. The alkyl β-CD derivatives used include 6-*O*-2 hydroxypropyl (HP-β-CD), 2,6-di-*O*-methyl (DM-β-CD), and 2, 3, 6-tri-*O*-methyl (TM-β-CD). Finally, the use of modeling techniques to account for the various types of CD–S stoichiometry (cf. Scheme 1), such as 1:1, 2:1, etc., can be quantitatively assessed.

Experimental

Instrumentation

NMR measurements were carried out using a Bruker AM-300 300 MHz spectrometer operating at 295 ± 0.1 K, with temperature regulated by means of a Haake temperature control system. Proton chemical shifts of the guest or host were referenced with respect to the protons of an external solution of 5×10^{-3} M DSS (4,4-dimethyl 4-silapentane sodium sulphonate) in D_2O (Aldrich, 99.9%) taken as 0 ppm. The precision in the chemical shift measurements is estimated to be $\pm 1 \times 10^{-3}$ ppm or better. In the case of the ROESY experiments (18), the standard pulse program provided by Bruker was utilized with a 250 ms spinlock time and a 600 μs relaxation delay.

Materials

DM-β-CD (Cyclolab, lot no. CY-2004.0, relative molar mass (M) = 1331 g mol^{-1}, degree of substitution (DS) = 14, purity >70% as 2,6-DM-β-CD regioisomer), HP-β-CD (Cyclolab, lot no. CY-2005.2, M = 1384 g mol^{-1}, DS = 4.6, purity ~95%), TM-β-CD (Am. Maize, research sample, M = 1429.6 g mol^{-1}, DS = 21, purity ~95%), β-CD (Aldrich, >99%), and α-CD (Aldrich, >99%) were used as received. The water content of the cyclodextrin compounds was determined using a Karl Fischer titration procedure, and it was taken into account in the calculation of concentration. To simplify the spectrum, β-CD was twice lyophilized from D_2O to effect an exchange of the hydroxyl protons with deuterium. The hc surfactants ($C_xH_{2x+1}CO_2Na$, x = 5, 7, 9, 11, 13) (Sigma, 99%) were purified as outlined previously (8). The p(H + D) was adjusted to 10.5, with the use of NaOD to minimize protonation of the carboxylate anion ($pK_b \approx 9$) and dissociation of the β-CD hydroxyl protons ($pK_a \approx 12$) (1).

In the study of the ^{1}H nuclei of β-CD, the concentration of the cyclodextrin (C_{CD}) was fixed, and the concentration of surfactant (C_S) was varied, where $C_S \leq$ CMC. In the case of the surfactant nuclei, C_S was fixed such that $C_S \leq$ CMC and C_{CD} was varied. All stock solutions were freshly prepared by volume and serially diluted.

Models and calculations

The chemical shift contributions of complexes having different stoichiometries were weighted according to their mole fraction content in solution, as shown in the following expressions:

$$[1] \quad \delta_{obs} = X_f\,\delta_f + X_{1:1}\delta_{1:1}$$

$$[2] \quad \delta_{obs} = X_f\,\delta_f + X_{1:1}\delta_{1:1} + X_{2:1}\delta_{2:1}$$

where X_f, $X_{1:1}$, and $X_{2:1}$ are the mole fractions of the unbound component (surfactant or CD), 1:1 complex, and 2:1 complex, respectively, and δ_f, $\delta_{1:1}$, and $\delta_{2:1}$ are the chemical shifts of the unbound species, 1:1 complex, and 2:1 complex, respectively. δ_{obs} is the observed chemical shift signal and it is a weighted average, comprised of bound and unbound species, due to fast exchange on the NMR time scale. Equations [1] and [2] can be expressed in terms of either host or guest ^{1}H NMR data. The equilibrium binding constants (K_i) are related to the mole fractions (X_i) of the unbound and bound species through the equilibrium relations describing the different complexes. The simulation of experimental NMR chemical shifts for solutions containing host and guest species was performed by using a nonlinear least-squares (NLLS) fitting program employing a Marquardt–Levenberg algorithm. K_i and δ_i were used as adjustable parameters whereas δ_f was obtained from the δ data for the host or guest in D_2O in the absence of a third component. In eq. [2], the Newton–Raphson method was employed to obtain the concentration of unbound species (23). The "best fit" to the experimental data was obtained by minimizing the sums of the squares of the residuals (SSR), $SSR = \sum (\delta_{obs,i} - \delta_{calc,i})^2$, where δ_{calc} and δ_{obs} are the calculated (according to eqs. [1] and [2]) and experimental values, respectively. The chemical shift data for the guest and host are presented graphically as a difference (Δδ), defined by eqs. [3] and [4], respectively.

$$[3] \quad \Delta\delta = \delta_{obs} - \delta_f$$

$$[4] \quad \Delta\delta = \delta_f - \delta_{obs}$$

where δ_{obs} and δ_f were previously defined. Positive Δδ values

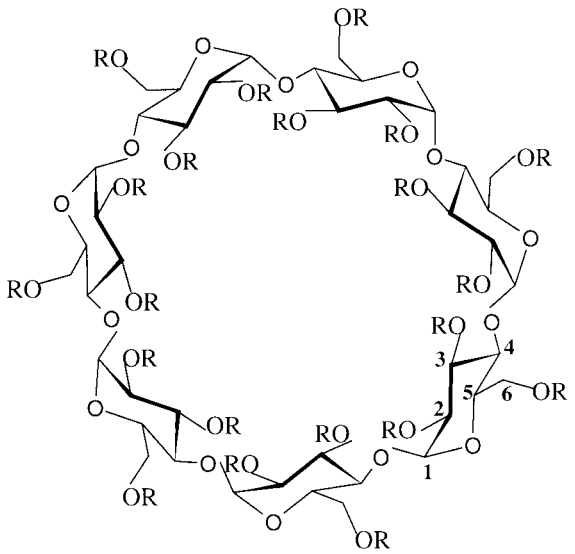
Scheme 2. Molecular structure and numbering scheme for the ^{1}H nuclei of β-cyclodextrin (β-CD; where R = H) and for alkyl-substituted β-CD (R-β-CD) host systems.



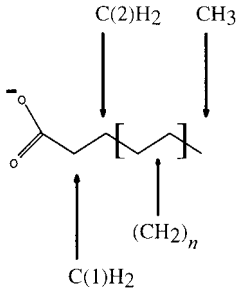
R = -H, -CH_3, -$CH_2CH(OH)CH_3$

for the surfactant nuclei refer to downfield (away from DSS) shifts, due to the lower resonance frequency of δ_f relative to δ_{obs}. Positive $\Delta\delta$ values for the host nuclei refer to upfield (towards DSS) shifts, due to the higher resonance frequency of δ_f relative to δ_{obs}. Chemical shift differences ($\Delta\delta$) are plotted as a function of mole ratio (R), where $R = C_S/C_{CD}$ or C_{CD}/C_S, for host and guest NMR data, respectively.

Results and discussion

Schemes 2 and 3 depict the molecular structure and numbering schemes utilized to identify the various host and guest ^{1}H nuclei for the compounds investigated in this study. Estimates of the binding constants (K_i) obtained from the NLLS analysis of the host (H(3) and H(5)) and guest (CH_3) ^{1}H nuclei for β-CD–S complexes are listed in Table 1. In most instances, the ^{1}H NMR data for C(1)H_2 and C(2)H_2 of the guest were not used to calculate K_i, because of the small magnitude of the complex induced shift (CIS) values. The collection of methylene ($(CH_2)_n$) protons (cf. Scheme 3) exhibits changes in chemical shift similar to that of the CH_3 group, however, the individual CH_2 groups were not well resolved and, therefore, they were not used in the calculation of K_i. The apolar cavity protons (H(3) and H(5)) of β-CD and those of the terminal CH_3 group of the surfactant displayed the largest CIS values, suggesting that the complex formed is one of inclusion and that the interactions occur primarily between the lipophilic regions of the host and guest, as expected for binding processes enhanced by hydrophobic effects (24, 25). In general, the CIS values for the guest nuclei are approximately 30–50% smaller than those for the host. Notwithstanding the differences in sensitivity of the host and guest nuclei to medium effects, the values of K_i estimated from these different data sets are consistent, as seen in Table 1. Generally, the magnitude of K_i increases as C_x increases, and the values are in reasonable agreement with those

Scheme 3. Molecular structure and numbering scheme for the guest protons of the surfactants examined in this work.



previously reported (7). β-CD – sodium tetradecanoate (ST) and β-CD – sodium dodecanoate (SDodec) formed both 1:1 and 2:1 complexes, whereas all of the other β-CD–S systems formed 1:1 complexes at the concentrations investigated in this study. Previous reports (26, 27) have also indicated that anionic and cationic surfactants of alkyl chain length comparable to SDodec and ST form 2:1 complexes with β-CD, and the values of $K_{1:1}$ exceed $K_{2:1}$ by one to two orders of magnitude, in agreement with the results given in Table 1.

Table 2 lists the values of K_i for complexes formed between different cyclodextrin compounds and the hc surfactants. They were obtained from the NLLS analysis of ^{1}H NMR data of the guest only (cf. Scheme 3). Spectral overlap of the H(3) and H(5) proton resonance spectra of the modified CDs with those of other ^{1}H host nuclei precluded their quantitative analysis to obtain estimates of K_i of the complexes. The magnitude of K_i increases as C_x increases for α-CD and the modified CDs in a manner similar to that observed for β-CD (Table 1). Differences in binding affinities are observed among the modified CDs, depending on the degree of alkyl substitution of the hydroxyl groups in the annulus of the CD. As well, the smaller cavity diameter of α-CD (4.5 Å), compared to β-CD (6.3 Å) (28), is expected to bind the hc surfactants more tightly due to the comparable van der Waals diameter of the methyl group (4 Å) (29) of the surfactant. Indeed, the magnitude of $K_{1:1}$ is greatest for α-CD when $x = 5$, however, β-CD binds more strongly for surfactants with longer chain length because of its increased cavity size. α-CD includes surfactants such that they adopt an all-*trans* conformation for the reason noted above. However, the larger diameter of the β-CD cavity enables the surfactant chain to coil by adopting gauche conformations. Park and Song (30) estimate that approximately eight methylene groups can be accommodated within β-CD if allowance is made for chain coiling. Correspondingly fewer groups can be included if the alkyl chain assumes an all-*trans* conformation (cf. Fig. 3, ref. 25), as is the case of inclusion within α-CD. Thus, the onset of the formation of 2:1 complexes for α-CD ($x = 9$) and β-CD ($x = 11$) is consistent with these facts. The greater binding affinity between β-CD and *n*-alkyl chain surfactants is consistent with the transfer of more alkyl groups from water to the apolar cavity and implicates the importance of the hydrophobic effect (24).

Alkyl substituted β-CD (R-β-CD) derivatives show similar features, however, there are specific differences in binding affinity that can be attributed to the nature of the substituted alkyl groups in the annular regions of R-β-CD. In contrast to α- and

β-CD, the R-β-CD derivatives form 1:1 complexes under the same conditions, due to their extended cavity length created by the alkyl groups in the annular regions. In previous work (9), differences in binding affinity between β-CD and R-β-CD were attributed to steric effects created by the close proximity of the carboxylate head group of the surfactant and the annular hydroxyl groups. The relative binding affinity of hc surfactants with the various CDs follows the order: β-CD > α-CD > DM-β-CD > TM-β-CD > HP-β-CD. The relative ordering of the R-β-CDs are consistent with steric effects imposed by the increasing degree of substitution (DS) of methyl groups from DM- to TM-β-CD. While HP-β-CD has a lower DS than DM-β-CD, the hydroxypropyl group is much larger than a methyl group. As well, the greater hydrophilicity of the hydroxypropyl group may create an additional steric effect due to hydration, and this effect would be absent in the case of the methyl substituted CDs. Thus, as the size of the alkyl group and the DS of cyclodextrin increase, greater steric hindrance impedes complex formation between the host and guest.

Figure 1 shows a plot of Δδ vs. mole ratio (R) for the β-CD–sodium octanoate (SO) system. This figure represents typical CIS values for the host and guest nuclei of a weakly bound β-CD–S complex. The CIS values for the host and guest increase as R increases and follow the order: Δδ H(5) > Δδ H(3) > Δδ CH_3. The CIS values of the host protons increase nonlinearly and become approximately constant at $R > 3$, which indicates that this is a weakly bound 1:1 CD–S complex, since an excess of either host or guest must be present in order to reach a saturation level of bound species ($X_{1:1}$) (13). The broken lines through the data points represent the best-fit line according to eq. [1].

Figure 2 is a plot of Δδ vs. mole ratio (R) for the β-CD – sodium dodecanoate (SDodec) system. This figure represents typical CIS values for the host and guest nuclei of a strongly bound β-CD–S complex. There is a marked leveling-off of the CIS values at $R \approx 1$, which is typical of complexes possessing large values of K_i (13). The CIS values for the nuclei of the host and guest increase linearly with increasing R and follow

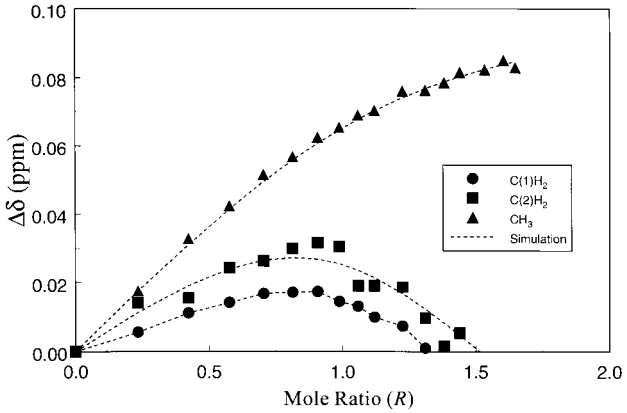

Fig. 4. Δδ vs. mole ratio (R), where $R = C_{DM\text{-}\beta\text{-CD}}/C_S$ for guests ($C(1)H_2$, $C(2)H_2$, and CH_3); ^{1}H NMR data of the DM-β-CD–$C_{11}H_{23}CO_2Na$ system at $T = 295$ K.

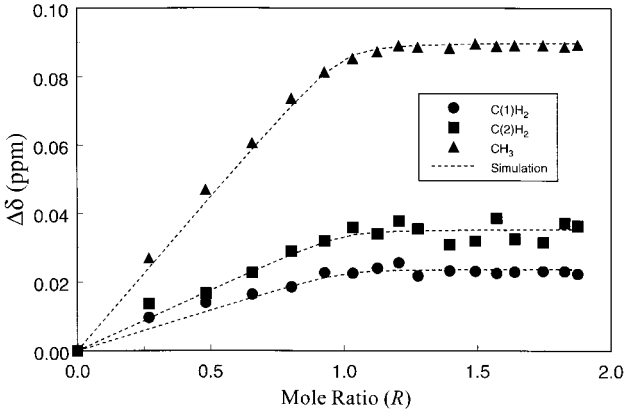

the order: Δδ H(5) > Δδ H(3) > Δδ CH_3 > Δδ $C(1)H_2$ ≈ Δδ $C(2)H_2$. The broken lines through the data points represent the best fit according to eq. [2]. Equation [1] provides a satisfactory fit up to $R = 1$; however, a poorer fit is observed for $R > 1$, suggesting that the stoichiometry is not simply 1:1 but a combination of 1:1 and 2:1 complexes. In general, $K_{1:1} >> K_{2:1}$ and, as is the case of the β-CD–SDodec system, the formation of 2:1 CD–S complexes is favored when $C_{CD} > C_S$, i.e., $R > 1$. This is in agreement with our previous results (8).

Figures 3–6 illustrate plots of Δδ vs. mole ratio (R) for the guest nuclei of various CD–SDodec complexes. Comparison of these diagrams with Fig. 2 shows how variation of the alkyl substitution of the hydroxyl groups of β-CD affects the binding affinity with a common guest. Figure 3 shows the α-CD–SDodec system, and the CIS values for $C(1)H_2$ and $C(2)H_2$ of the guest display a positive increase up to $R \approx 1$ and a sharp decrease when $R > 1$. The deshielding of these nuclei beyond $R \approx 1$ can be attributed to type (*c*) interactions, described below, due to the formation of a 2:1 "channel-type" complex (27), since the carboxylate head group becomes desolvated as it is drawn closer toward the annular hydroxyl region. Indirect support for changes in the solvation of the carboxylate head group has also been concluded from an emf study (31) of the β-CD–SDec system. It was rationalized as being due to an increase in the degree of sodium counterion binding to the surfactant head group when the head group is complexed. The importance of solvation of the carboxylate head group has also been alluded to in an earlier NMR study (32). However, a recent attempt to quantify the solvation component of polar functional groups through the Gibbs energy change of complex formation revealed that the relative contributions of solute–solute vs. solute–solvent interactions are difficult to model in host–guest binding phenomena (5, 6). The lower rate of increase of Δδ CH_3 vs. R beyond $R > 1$ can also be attributed to the role of type (*b*) interactions in the binding process. The magnitude of the CIS values for the guest nuclei follow the order: Δδ CH_3 > Δδ $C(2)H_2$ > Δδ $C(1)H_2$. The broken lines through the data points represent the best fit according to eq. [2]. Application of eq. [1] did not provide a suitable fit to the experimental data, which further corroborates that the stoichiometry is not simply 1:1 but a combination of 1:1 and 2:1 complexes. Castronuovo et al. (33) have reported that the formation of 2:1 α-CD–S complexes are unlikely for alkyl carboxylate salts having C_x, $x = 2$–11 due to the solvation

Fig. 5. Δδ vs. mole ratio (R), where $R = C_{TM\text{-}\beta\text{-}CD}/C_S$ for guests ($C(1)H_2$, $C(2)H_2$, and CH_3); ^1H NMR data of the TM-β-CD–$C_{11}H_{23}CO_2Na$ system at $T = 295$ K.

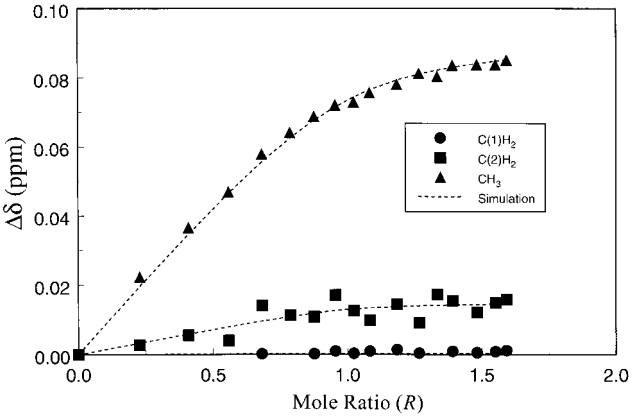

Fig. 6. Δδ vs. mole ratio (R), where $R = C_{HP\text{-}\beta\text{-}CD}/C_S$ for guests ($C(1)H_2$, $C(2)H_2$, and CH_3); ^1H NMR data of the HP-β-CD–$C_{11}H_{23}CO_2Na$ system at $T = 295$ K.

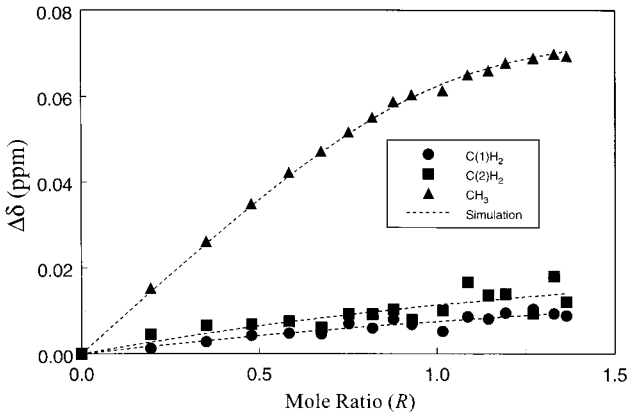

requirements of the carboxylate group. However, our results clearly show that 2:1 α-CD–S complexes are favored for systems with C_x, $x \geq 9$ and that such a stoichiometry optimizes apolar–apolar and minimizes apolar–polar interactions (24). This energy minimization is partly driven by the host system, α-CD, since its smaller cavity diameter and ability to adopt an "induced-fit" (34) favors an all-*trans* conformation of the alkyl chain, thereby requiring a second CD to include the surfactants when C_x, $x > 8$.

Figures 4 and 5 illustrate plots of Δδ vs. mole ratio (R) for DM- and TM-β-CD with SDodec, respectively. These figures show the effect of increasing the number of methyl groups in the host macrocycle on the binding affinity with SDodec. A comparison of these figures reveals that the DM-β-CD–SDodec system has larger CIS values for the guest protons and sharper breaks at the $R = 1$ mole ratio. As well, the CIS values for these protons level off beyond $R = 1$, whereas the CIS values of the $C(2)H_2$ and CH_3 groups of the guest in the TM-β-CD–SDodec system (Fig. 5) increase slightly beyond $R = 1$. These results are consistent with the formation of 1:1 complexes and the greater binding affinity of DM-β-CD, relative to TM-β-CD, with SDodec. The weaker binding affinity of TM-β-CD is probably due to greater steric hindrance in its annular region because of the increased degree of substitution. The broken lines in these figures represent the best fit of the experimental data according to eq. [1].

In previous work (8), it was determined that methyl derivatives of β-CD formed 1:2 CD–S complexes (cf. Scheme 1) with longer chain length surfactant systems. It is possible to fit the experimental data using a model that accounts for 1:2 complexes, using an expression analogous to eq. [2]. However, the molecular environment of a CH_3 group in a 1:1 or a 1:2 complex is anticipated to be similar ($\delta_{1:1} \approx \delta_{1:2}$), and it is difficult to justify the use of a four-parameter equation when eq. [1] seems to provide a suitable fit. In the case of the β-CD–SDodec system, a reasonable fit to eq. [1] was obtained up to $R = 1$, whereas eq. [2] provided a more suitable fit over the entire range of experimental data. For the β-CD–SDodec system ($K_{1:1} >> K_{2:1}$), 1:1 complexes are favored when $R \leq 1$ and 2:1 complexes are favored when $R > 1$, which is consistent with the excess of host at the latter condition. The above results indicate that it is possible to overlook additional complexation equilibria when obtaining experimental data in a limited concentration range, particularly when several complexes, having stability constants of vastly different magnitudes, are formed. It is also important to recognize that various experimental techniques are more or less sensitive to the bulk property being measured. The techniques can be divided into two categories: (*i*) those that measure, directly or indirectly, the concentration of bound or unbound species, and (*ii*) those that measure a physical property that is proportional to the concentration of bound or unbound species. The distinction between these two categories is the reason that there is a lack of agreement amongst K_i values for a given system, and this issue has been discussed elsewhere (7).

Figure 6 is a plot of Δδ vs. mole ratio (R) for HP-β-CD with SDodec. The magnitude of Δδ increases as R increases, and the CIS values at $R = 1$ follow the order: $\Delta\delta\ CH_3 > \Delta\delta\ C(2)H_2 > \Delta\delta\ C(1)H_2$. Figures 5 and 6 shows similar features; however, the CIS values for the host protons in Fig. 6 display a moderate increase beyond $R = 1$ and their magnitudes do not exceed those in Fig. 5, indicating that HP-β-CD has a lower binding affinity than TM-β-CD with SDodec. This can be attributed to steric effects, as mentioned in the discussion of results in Table 2. The broken lines through the experimental data represent the best-fit curves according to eq. [1].

Table 3 lists the CIS values of the guest nuclei at a 1:1 CD–S mole ratio ($R = 1$). The extensive overlap of the individual $(CH_2)_n$ protons, as shown by the appearance of a broad singlet in the NMR resonance, precluded a quantitative investigation of their component CIS values. An analysis of the Δδ data for the $C(1)H_2$, $C(2)H_2$, and CH_3 protons can provide insight into the geometry of the CD–S complex, since $C(1)H_2$ and $C(2)H_2$ are adjacent to the hydrophilic carboxylate group whereas the CH_3 group is located in a lipophilic environment. However, a thorough quantitative analysis of the CIS values is complicated by numerous antagonistic shielding and deshielding effects (35). For example: (*a*) H-bonding between the CD hydroxyl groups and the carboxylate head group is expected to reduce the intramolecular shielding on the $C(1)H_2$ and $C(2)H_2$ protons and result in positive CIS values; (*b*) the goodness of fit between the alkyl chain of the surfactant and host systems possessing narrower cavities, such as α-CD and TM-β-CD, may induce an all-*trans* conformation of the alkyl

chain. This maximizes the distance between adjacent CH_2 groups and decreases the intramolecular shielding within the alkyl chain, resulting in positive CIS values; and (*c*) the apolar environment of the CD interior and (or) alkyl substituents in the annular hydroxyl region results in shielding of the alkyl chain and contributes to negative CIS values. In Table 3, the CIS values of the CH_3 group protons increase as C_x increases, indicating the prominence of type (*b*) effects. However, for x = 13, this parameter shows a small decrease relative to x = 11 for α-CD and TM-β-CD. This may be due to the methyl group extending beyond the CD cavity and into the interfacial region, resulting in a decrease of type (*b*) effects (36). The prominence of type (*b*) interactions can be seen in a comparison of the CIS values for C(1)H_2 and C(2)H_2 groups for SHex, SO, and SDec, respectively. For the α-CD system, the CIS values decrease as C_x increases, whereas for β-CD, minimal changes in this parameter are observed. The decrease observed for α-CD–S systems can be attributed to the extension of the carboxylate head group further into the bulk phase as C_x increases thereby decreasing the magnitude of type (*b*) effects. In contrast to α-CD, the larger cavity diameter of β-CD does not induce an all-*trans* conformation of the alkyl chain of the surfactant, as seen by the similar CIS values for the C(1)H_2 and C(2)H_2 groups. Hence, as C_x increases for the β-CD–S systems, smaller CIS values are expected for C(1)H_2 and C(2)H_2 protons, due to smaller perturbations to the conformation of the surfactant alkyl chain (36) upon inclusion into the host cavity. These results are also consistent with previous conclusions that only weak interactions occur between an *n*-alkyl carboxylate anion and the annular hydroxyl groups of CD (7). Similar values of Δδ at R = 1 were found previously for the C(1)H_2, C(2)H_2, and CH_3 protons of a series of *n*-alkyl amine and *n*-alkyl carboxylic acid guests (22). As well, values of the change in heat capacity, ΔC_p°, for complexes formed between β-CD and a homologous series of *n*-alkylammonium and *n*-carboxylate ions were found to be similar. Thus, there is substantive evidence that suggests there is minimal solvent reorganization of highly hydrated groups of a guest species and of the hydroxyl groups of the cyclodextrin host upon complex formation (37). A comparison of CIS values for β-CD–S and R-β-CD–S systems indicates that alkyl substitution effects are not readily discernible because of the similarity in the magnitudes of the CIS values for the C(1)H_2 and C(2)H_2 groups of the guest. However, some evidence can be derived regarding the location of the CH_3 group in the host. These results indicate the primary importance of apolar–apolar interactions between the alkyl chain of the surfactant and the CD interior and the secondary importance of interactions between the head group of the surfactant and hydroxyl groups in the CD annular regions.

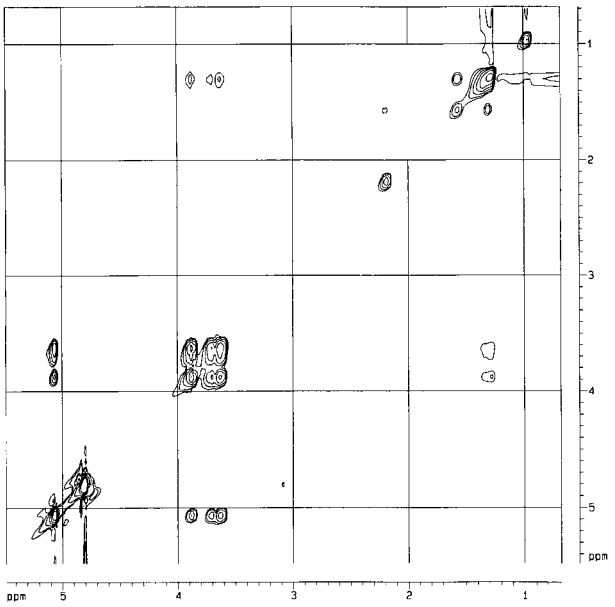
The C(1)H_2 and C(2)H_2 groups in the 2:1 α-CD–S ($x \geq 9$) and 2:1 β-CD–S ($x \geq 11$) complexes reflect type (*c*) effects, as seen by the decrease in the CIS values beyond R = 1. The effect is amplified for surfactants with longer chain length as the CIS values exhibit a decrease at R = 2 (not shown). The absence of 2:1 complexes for the R-β-CD hosts is consistent with their increased cavity depth (2). These few results illustrate that it is difficult to ascribe changes in CIS values unequivocally to one specific effect, since there are marked differences in stoichiometry, inclusion geometry, and binding affinity among these host–guest systems.

The CIS values for the ^{1}H nuclei of β-CD have not been listed, however, the trends for Δδ H(5) and Δδ H(3) of the host parallel those for Δδ CH_3 of the guest. The positive CIS values for the host nuclei reflect an increase in shielding during complex formation as C_x increases. This is a result of expulsion of water from the CD interior and its replacement by an apolar alkyl chain. The magnitudes of Δδ for H(5) and H(3) range from two to ten times that for a typical CH_3 group and may be attributed to the anisotropic properties of the CD cavity (14). At the 1:1 mole ratio, Δδ H(5) > Δδ H(3) for all β-CD–S systems, since the H(5) nuclei is located at the narrower end of the torus and experiences closer intermolecular contacts with the alkyl chain of the surfactant. The concentration dependence of the CIS values for H(3) and H(5) protons provide support for the existence of 2:1 complexes and corroborate the guest data for the β-CD–ST and β-CD–SDodec complexes. The inclusion mode for the 2:1 complexes appears to be a capping arrangement of a second β-CD onto the protruding apolar alkyl chain of the guest in the 1:1 complex. It is difficult to unequivocally ascertain whether it is the primary or the secondary hydroxyl end of the second CD that preferentially associates with the surfactant because of the similar trends in the CIS values for H(3) and H(5) protons of the host beyond the R = 1 mole ratio. This is somewhat surprising, since the primary hydroxyl end of β-CD is reported to be more lipophilic than the secondary hydroxyl end (28). The former is more dipolar in nature due to the less extensive participation of the hydroxyl groups in intramolecular H-bonding.

Figure 7 is a ROESY spectrum of the β-CD–SDodec system. It is difficult to ascertain for this complex whether the carboxylate head group is located at the wide or narrow end of the torus, due to the small CIS values for the C(1)H_2 and C(2)H_2 protons. As well, the absence of cross peaks for intermolecular interactions between these groups and other nuclei of β-CD in the ROESY spectrum may be due to weak interactions with the highly hydrated head group and (or) to inclusion of the surfactant within the CD interior in a random fashion. These reasons are consistent with the similar CIS values for

© 1998 NRC Canada

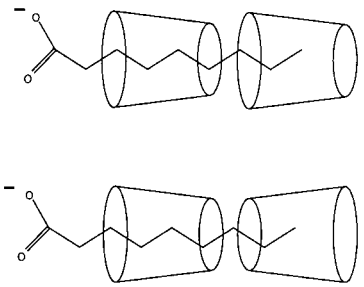
Fig. 7. ROESY spectrum for β-CD–$C_{11}H_{23}CO_2Na$ system at 293 K with spinlock time of 250 ms and a relaxation delay of 600 μs.



the C(1)H_2 and C(2)H_2 protons of the alkyl carboxylates in complexes with β-CD and R-β-CD hosts systems**.** Guest molecules possessing charged groups, such as the *p*-nitrophenolate anion, locate the charged group at the wider end annular region of β-CD(16). Tee et al. (38) have also proposed that the ester functional group locates at the same end, based on kinetic studies. The most intense cross peaks observed in the ROESY spectrum are for the protons of the methylene ($(CH_2)_n$) groups located toward the center of the alkyl chain of the guest and for the H(3) and H(5) host protons. The intensity of these peaks increases as the alkyl chain length of the surfactant increases. The correlations between the CH_3 group of the surfactant and host protons are negligible or absent, indicating that either there are weak interactions between the host and guest, due to rapidly changing inclusion geometries, and (or) there are competitive intramolecular relaxation pathways. The absence of any correlation between protons of the CH_3 group of the surfactant and those of the host are surprising, given the magnitude of the CIS values in Table 3 and the fact that, usually, there is a correlation between the magnitude of a CIS value and the extent of intermolecular contacts (18).

Scheme 4 illustrates the predicted structures of a 2:1 CD–S complex based on CIS values, ROESY data, and an analysis of the spectral lines of the collective methylene ($(CH_2)_n$) groups. The structure of a 1:1 CD–S complex is not shown, however, the alkyl chain of the surfactant is included in the CD interior and the carboxylate head group is located near either the primary or secondary annular hydroxyl groups. The stacking of a second CD onto the 1:1 complex, forming a 2:1 complex, likely occurs in a random fashion, based on the similar CIS values for the H(3) and H(5) host protons beyond $R = 1$, as shown by the two possible inclusion geometries. Figure 8 illustrates the resonance lines for the $(CH_2)_n$ protons for SDec, SDodec, and ST in the presence of α- and β-CD, respectively, at the $R = 2$ mole ratio. Recall that the signal for

Scheme 4. Proposed inclusion geometries for a 2:1 CD–S complex, as determined from ^{1}H NMR data.



the $(CH_2)_n$ protons appears as a broad singlet in the absence of any added CD. The appearance of asymmetry in this signal, in the presence of CD at $R = 2$, reflects nonequivalent molecular environments attributable to the formation of 1:1 and 2:1 complexes. The CIS values for the $(CH_2)_n$ groups are greater for α-CD ($\Delta\delta_{max} \approx 0.11$ ppm) and lower in β-CD ($\Delta\delta_{max} \approx 0.03$ ppm), which can be attributed to conformational changes of type (*b*), discussed above, between the uncomplexed and complexed guest. The asymmetry begins to appear for surfactants with $C_x \geq 9$ for α-CD and β-CD, respectively. The apparent lack of broadening and asymmetry in the signal for SDec with α-CD may indicate that the 2:1 complex is either weakly bound (cf. Table 2) and (or) interacting with the terminus of the protruding alkyl chain. The β-CD–SDec system forms 1:1 complexes, exclusively, and serves as a useful benchmark for analyzing line shapes of the 2:1 complexes. In Fig. 8*a*, the extreme upfield signal (closest to DSS) for SDodec and ST is due to unbound CH_2 groups residing in the bulk, since the CIS values are similar to a surfactant in D_2O alone, whereas the lower field component of the signal is due to 1:1 and 2:1 complexes. In Fig. 8*b*, the low field shoulder appearing in SDodec and ST is due to the 2:1 complex, whereas the high field components are assigned to the 1:1 complex. The integrated area of the low field component of the asymmetric peak (shown above the peak) and its CIS value are consistent with the end-capping of a second CD onto the 1:1 complex. Clearly, as C_x increases, the broadening of the line increases and the downfield resonance lines increase in intensity, indicating that additional CH_2 groups are bound in a 2:1 complex. From these results it appears that five CH_2 groups can be included within α-CD and seven or eight CH_2 groups within β-CD. The former values are in reasonable agreement with estimates derived from calorimetry (33), and the latter are in agreement with previous estimates (8, 30).

Conclusions

An investigation of the ^{1}H NMR chemical shifts (δ) of a homologous series of hydrocarbon (hc) ($C_xH_{2x+1}CO_2Na$, $x = 5$, 7, 9, 11, 13) surfactants (S) has been determined in water and in aqueous solutions containing various cyclodextrin compounds at 295 K. The chemical shifts of the ^{1}H nuclei of both the surfactants and cyclodextrin compounds were studied. The magnitudes of the complex induced shift (CIS) values of the ^{1}H nuclei of the surfactants and cyclodextrins were found to increase as the alkyl chain length (C_x) increased, irrespective

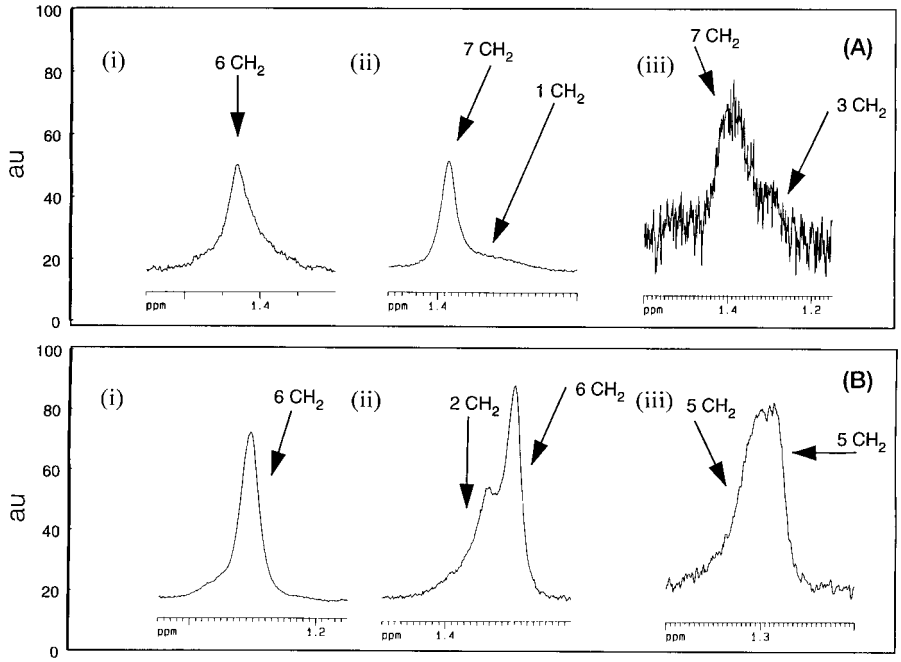
Fig. 8. Comparison of ^{1}H NMR signals of methylene $(CH_2)_n$ protons (cf. Scheme 3) for the surfactants (*i*) SDec, (*ii*) SDodec, and (*iii*) ST, complexed with (*A*) α-CD and (*B*) β-CD, at mole ratio $R = 2$ and $T = 293$ K.



of the type of CD. The CIS values were found to depend on the following factors: (*i*) the magnitude of the binding constant (K_i), (*ii*) the chain length of surfactant, (*iii*) the mole ratio of the host to guest species, (*iv*) the stoichiometry of the host–guest, and (*v*) the host–guest inclusion geometry.

The CIS values for the cyclodextrins and the surfactants have been analyzed in terms of the complexed and uncomplexed species using models that account for different types of host–guest complexes having 1:1 stoichiometry and 1:1 plus 2:1 stoichiometry. Binding constants have been obtained for the various CD–S systems and the magnitude of K_i was found to increase as C_x increases. As well, differences in the binding affinity, stoichiometry, and inclusion geometry of complexes formed between the hc surfactants and α-CD, β-CD, and modified CDs were observed. Most of the host systems formed 1:1 complexes except for α-CD and β-CD, which formed 2:1 complexes with surfactants when $x = 9$, 11, 13 and $x = 11$, 13, respectively. The binding affinity of the host systems with the hc surfactants follows the order: β-CD > α-CD > DM-β-CD > TM-β-CD > HP-β-CD.

The NMR data obtained in this study have provided quantitative and structural information about the nature of the complexes formed in the various CD–S systems. There is evidence that the binding constants of complexes formed between modified cyclodextrins and surfactants are affected by hydration and steric hindrance in the annular region of the macrocycle.

Facial selectivity in the addition of nucleophiles to the radical cations of substituted 2-methyleneadamantanes

Susan Swansburg, Kristin Janz, Gloria Jocys, Alexandra Pincock, and James Pincock

Abstract: The diphenylmethylenecyclohexane, **2**, and the substituted 2-methyleneadamantanes, **3**–**7**, have been prepared. The radical cation of each was generated by photochemical oxidation using 1,4-dicyanobenzene as the sensitizer, and their reactivity was examined in methanol–acetonitrile mixtures with added tetraethylammonium cyanide. Although compound **2** reacted only by tautomerization, the other compounds all gave addition products. For the monoaryl alkenes **3**, **4,** and **5**, comparable yields of both methanol and HCN addition products were obtained, resulting from nucleophilic attack at either end of the alkene radical cation. For the diphenylalkenes **6** and **7**, the regioselectivity favored nucleophilic attack at the adamantyl carbon, and the addition products were predominantly those of HCN addition. For the 5-methoxy compound **7**, HCN addition was facially selective with a *syn:anti* ratio of 58:42.

Key words: methyleneadamantanes, facial selectivity, radical cations.

Résumé : On a préparé le diphénylméthylènecyclohexane, **2**, ainsi que les 2-méthylèneadamantanes substitués **3**–**7**. On en a ensuite préparé les cations radicaux par une oxydation photochimique impliquant le 1,4-dicyanobenzène comme sensibilisateur et on a étudié leur réactivité dans des mélanges de méthanol–acétonitrile dans lesquels on a ajouté du cyanure de tétraméthylammonium. Même si le composé **2** ne réagit que par tautomérisation, tous les autres composés conduisent à des produits d'addition. Pour les monoarylalcènes **3**, **4** et **5**, on a obtenu des rendements comparables de produits d'addition de méthanol et de HCN provenant d'une attaque nucléophile à l'une des deux extrémités du cation radical de l'alcène. Pour les diphénylalcènes **6** et **7**, la régiosélectivité favorise l'attaque nucléophile sur le carbone adamantyle; les produits d'addition proviennent alors en prédominance d'une addition de HCN. Pour le composé 5-méthoxy **7**, l'addition du HCN se fait sélectivement sur une face et le rapport *syn : anti* est égal à 58 : 42.

Mots clés : méthylèneadamantanes, sélectivité faciale, cations radicaux.

[Traduit par la rédaction]

Introduction

The factors that control diastereoselectivity in additions to planar carbon atoms continue to attract considerable experimental (1–4) and theoretical (5) interest. In a pioneering study (6), le Noble and co-workers showed that substituted 5-X-2-adamantyl systems,[2] **1**, are particularly useful probes in these studies. Steric differences between the *syn* and *anti*[3] faces are minimized, there is none of the conformational ambiguity inherent in more flexible systems, and only two products can be formed. Therefore, the long-range electronic effect between the substituent and the reaction center at C2 can be assessed by the ratio of *syn* to *anti* products. With very few exceptions, *syn* attack is preferred. Because most of the X groups studied have been inductively electron withdrawing (relative to H at C7), *syn* represents attack on the same side as the electron-deficient σ bonds (C1—C9 and C3—C4) but antiperiplanar to the electron-rich σ bonds (C1—C8 and C3—C10). Current debate focuses mainly on whether the observed diastereoselectivities are controlled by hyperconjugative or electrostatic field effects.

Examples of the types of reactions that have been studied include nucleophilic additions to 2-adamantanones (1, 3), electrophilic additions to 2-methyleneadamantenes (3), solvolysis of 2-adamantyl compounds (6–8), radical trapping

[2] These numbers, depending on substituents, may or may not correspond to IUPAC numbering. They have been adopted by chemists studying the effect of substituents in adamantyl chemistry so that C2 is the site of interest and C5 is the position of the substituent.

[3] A variety of stereochemical designations have been used: *syn* = *zu* and *anti* = *en*. In reactions such as hydride or organometallic addition to 5-X-2-adamantanones, the carbonyl oxygen that becomes the alcohol of the product takes stereochemical nomenclature priority. Therefore, *syn* hydride reduction gives the *anti* or *E* product and *anti* attack gives the *syn* or *Z* product.

(9), sigmatropic rearrangements (Claisen) (10), and photochemical [2 + 2] cycloadditions of alkenes to 2-adamantanones (11, 12). Facial selectivity in the reactions of 5-aza (13), 5-azoxy (14), and perfluoro (15) adamantane derivatives have also been reported. To our knowledge, the reactivity of radical ions has not been studied. We now report on the syntheses of the derivatives **2**–**7** and the products obtained from their radical cations. These cations were generated by photochemical electron transfer using 1,4-dicyanobenzene (DCB) as the electron acceptor; the cations were then trapped by nucleophiles (methanol, cyanide ion) according to the well-established procedures developed by Arnold and Maroulis (16). The choice of substrates was made on the basis that aryl-substituted alkenes are readily oxidized by the excited singlet state of DCB, and that **5** and **7**, containing the 5-methoxy group, can both be prepared from commercially available 5-hydroxy-2-adamantanone.

Results and discussion

Syntheses of diphenyl alkenes 2, 6, and 7

The diphenylalkenes were synthesized from the corresponding 1,3-oxathiolan-5-ones **2a, 6a**, and **7a**, eq. [1], by pyrolysis at 250°C, in the presence of tris(diethylamino)phosphine. This twofold extrusion process, developed by Barton and Willis (17), provides a convenient route to these highly hindered alkenes. The 1,3-oxathiolan-5-ones were prepared by condensation of the appropriate ketone with thiobenzilic acid (*p*-toluenesulfonic acid catalysis) in benzene with azeotropic removal of water. For **2a** and **7a,** a mixture of diastereomers resulted; the ratio for both cases was close to 60:40. Separation of these isomers was possible by column chromatography but no attempt was made to assign the individual structures for **2a**. For **7a**, in the major isomer the sulfur was *syn* to the 5-methoxy group as determined by X-ray crystallography (Fig. 1).[4] We do not know if this represents a kinetic preference. Separation of the mixtures of **2a** and **7a** was not necessary for the next step as the stereochemical distinction is lost in the conversion to the alkene.

Syntheses of monophenyl alkenes 3, 4, and 5

Grignard reaction of 2-adamantanone or 5-methoxy-2-adamatanone with either benzyl chloride or 4-methoxybenzyl chloride gave alcohol products **3a**, **4a,** and **5a,** which were dehydrated in benzene (*p*-toluenesulfonic acid catalysis),

eq. [2]. The alcohol **3a** has been prepared previously by the same procedure but was converted to **3** by dehydration using phosphoric acid (18).

Photochemistry of 2

Although alkene **2** was prepared primarily to develop the synthetic and photochemical methodology required for the adamantyl systems, the reactivity of its radical cation is also of interest. The presence of the *tert*-butyl group at C4 locks the cyclohexane ring in a fixed conformation, making the approach of a nucleophile to the two faces of the carbon–carbon double bond very different for steric reasons. However, irradiation of alkene **2** with DCB as the sensitizer, in 3:1 acetonitrile:methanol, did not result in the formation of nucleophile addition products. Rather, the sole product observed was the tautomer of the starting material, **8** (eq. [3]), in which the carbon–carbon double bond is now endocyclic. In retrospect, this deconjugation reaction is not unexpected. Arnold and Mines (19) have reported several examples of photochemical tautomerization of alkenes, including diphenylmethylenecyclohexane, analogous to **2** but without the *tert*-butyl group. In their studies, 2,6-lutidine was added to facilitate the isomerization reaction but for alkene **2** no base was required.

The mechanism proposed (19) for these tautomerizations begins with photoinduced electron transfer to form the alkene radical cation (and the radical anion of DCB), followed by deprotonation at the allylic position. The acidity of these hydrogens is known to be enhanced in the radical cation. Reduction of the allylic radical by the radical anion of DCB gives the allylic anion, which on reprotonation by methanol results in either the starting alkene or its tautomer. The position of the equilibrium between the two isomers is controlled by their relative oxidation potentials. Between **2** and **8**, **2** has a considerably lower oxidation potential and is therefore photochemically converted to **8**, whereas **8**, with the higher oxidation potential, is not converted back to **2**. The efficiency of this conversion for **2**, relative to that of the other alkenes studied previously (19), is probably a result of the fact that the axial allylic carbon–hydrogen bond is fixed in an appropriate geometry for effective overlap with the singly occupied molecular orbital (SOMO) of the initially formed radical cation. Therefore, tautomerization occurs in preference to addition of methanol across the double bond. Even in the presence of

tetraethylammonium cyanide, addition products were not formed in detectable yield; again, only **8** was observed.

Photochemistry of 3

In the adamantyl analogues, the tautomerization reaction is unlikely, because of the high strain associated with placing double bonds in adamantane rings (thermodynamic rationale) and also because the allylic hydrogens are not oriented appropriately for favourable overlap with the SOMO of the radical cation (kinetic rationale).

Irradiation of alkene **3** with DCB and added tetraethylammonium cyanide (4.5 mM) in 9:1 (by volume) acetonitrile:methanol gave the four addition products shown in eq. [4]. These products were identified, in a preliminary way, by their mass spectra (GC–MS). In all cases, the spectra are simple, showing a few prominent ions that are easily assigned to fragments of the molecules. For instance, the base peaks have *m/z* values corresponding to the following fragments: **9** (91, $PhCH_2$+), **10** (211, 2-Ph-Ad^+), **11** (121, $PhCH\text{-}OCH_3$+), **12** (225, 2-CH_3O-Ad^+). The four products were separated by preparative-scale column chromatography on silica gel. Detailed ^1H and ^{13}C NMR spectral analyses support the proposed structures. In addition, the structures of the HCN addition products, **9** and **10**, were confirmed by X-ray crystallography (Figs. 2 and 3).[4] The cyano group is directly bonded to C2 of the adamantane ring in **9**, but is on the exocyclic carbon in **10**. In the latter structure, the phenyl group has migrated to the adamantyl carbon, C2. Ether **11** was not isolated from the reaction mixture but a synthetic sample was prepared by hydroboration of alkene **3** followed by conversion to the methyl ether by treatment with sodium hydride and methyl iodide. Integration of the ^1H NMR signals of the crude reaction mixture for the hydrogens α to the phenyl ring indicated that **11/12** are formed in a ratio of one to three.

The yields for the reaction of **3**, by calibrated GC–FID analysis (corrected for unreacted starting material at 50% conversion of **3**), are as follows: **9** (34%), **10** (24%), **11** plus **12** (25%); the mass balance is 81%. The yield of the two products resulting from addition of cyanide ion is greater than that of those resulting from addition of methanol, as expected based on the relative reactivities of the two nucleophiles. Johnston and Schepp (20, 21) have measured second-order rate constants for the addition of nucleophiles to a series of substituted styrene radical cations generated directly from the parent alkene by laser flash photolysis. For each radical cation studied, the rate constant for methanol addition was orders of magnitude slower than for any other nucleophile studied. For instance, the rate constant for reaction of the 4-methoxystyrene radical cation in 4:1 water:acetonitrile is 3×10^4 M^{-1} s^{-1} for methanol and 1.0×10^8 M^{-1} s^{-1} for cyanide ion.

The established mechanism for these addition reactions involves product-determining attack of the nucleophile on the radical cation. To confirm that the radical cation of **3** is formed efficiently, the quenching of DCB fluorescence by **3** was examined. The Stern–Volmer slope gave $k_q\tau_{DCB} = 17$ M^{-1}. Using 9.7 ns as the singlet lifetime of DCB (16), the calculated quenching rate constant is 1.8×10^{10} M^{-1} s^{-1}, comparable to the diffusional limits (22) in acetonitrile (1.9×10^{10} M^{-1} s^{-1}) and methanol (1.2×10^{10} M^{-1} s^{-1}), suggesting that formation of the radical cation will occur readily. As predicted by the Weller equation (23), oxidation of **3** by the excited singlet state of DCB should be exothermic if the oxidation potential of the alkene is below 2.2 V; the measured value for **3** is 1.37 V (CH_3CN versus SCE).

The cyano adducts **9** and **10** are formed in a ratio of 1.4:1, invariant with percent conversion. This ratio is, at least in part, a reflection of the relative stabilities of the benzyl and tertiary radicals formed by attack of cyanide ion at the two ends of the double bond of the radical cation of **3**. For addition to diphenylethylene, the nucleophile adds exclusively to the radical cation at the terminal carbon to give the more stable diphenylmethyl radical intermediate. Therefore, the result is anti-Markovnikov addition (16). For **3**, the two possible radical intermediates are of comparable stability. The benzylic radical is formed in slight preference to the tertiary one, and **9** is therefore the expected product. Cyanide ion attacks the radical cation at the 2-adamantyl position, and this is followed by reduction (by the radical anion of DCB) of the radical to the anion, and subsequent protonation of the anion by the solvent, methanol. In contrast, product **10** was unexpected. The phenyl group has migrated to C2 of the adamantane ring. A reasonable pathway for formation of this product requires several steps: attack of the cyanide ion on the radical cation to form the tertiary 2-adamantyl radical, 1,2-migration of the phenyl group to give the α-cyano radical, reduction of this radical to the

© 1998 NRC Canada

corresponding anion, and finally protonation of the anion by the solvent.

Several facts support this mechanism. First, the tertiary radical would be relatively long-lived. Oxidation potentials indicate that it will not be reduced by the radical anion of DCB, because the oxidation potential of the radical anion of DCB (1.6 V) (24) is lower than that of the *tert*-butyl anion (greater than 2.0 V) (25). Second, although radical rearrangements are uncommon, examples of 1,2-phenyl migrations are well known (26). For instance, this so-called neophyl rearrangement for the 2-phenyl-2-methylpropyl radical is shown in eq. [5]; Franz et al. (27) determined the rate constant for this 1,2-phenyl migration to be 764 s^{-1} at 298 K. A similar 1,2-phenyl shift can be proposed in the formation of **10**. Although the rearrangement should be slower, since the precursor radical

[5] 
is tertiary, the low concentration of the radical would allow this relatively slow unimolecular process to compete with bimolecular processes. Third, once formed, the α-cyano radical would be easily reduced to the corresponding cyano-stabilized anion. None of the possible product resulting from trapping of the initially formed tertiary radical in this sequence was detected.

Similar 1,2-phenyl migrations have been observed for the radical cation induced epoxidation of both **3** (28) and **6** (28, 29) but the rearrangements proceed by a secondary reaction of the radical cation of the first formed epoxide.

Another mechanism for cyanide addition to **3** is possible. As mentioned above, the reactions of the radical cations of a variety of substituted styrenes with nucleophiles have been studied by laser flash photolysis (20, 21). In some cases, the mechanism has been shown to involve initial electron transfer to regenerate the original alkene along with the oxidized nucleophile. Combination of these two species could give the same radical as is formed in the above mechanism. However, this possibility can probably be excluded. It was not observed in the laser flash experiments with cyanide ion as the nucleophile. Moreover, for this pathway to be efficient, the oxidation potential of **3** (1.37 V, CH_3CN versus SCE) must be higher than that of cyanide ion. The latter oxidation potential is quite solvent dependent (30), with a value of 1.3 V in acetonitrile and 1.7 V in the protic solvent, water. Because of the methanol used in the 9:1 acetonitrile:methanol medium in these photolysis reactions, the oxidation potential of cyanide ion is likely to be closer to the value for water. Therefore, reaction by electron transfer of the radical cation of **3** with cyanide ion is probably endergonic, making this second mechanistic possibility unlikely.

The two ether products, **11** and **12**, were not separated by GC and were therefore quantified together. As mentioned above, they were formed in a ratio of one to three as determined by ^{1}H NMR integration. These ethers are the two regioisomers resulting from reaction of methanol with either end of the carbon–carbon double bond of the radical cation of **3**. Again, addition favours formation of the benzylic radical over the tertiary one although the degree of selectivity differs somewhat for the two nucleophiles. Methanol (3:1) is more selective than cyanide ion (1.4:1). There is still no firm mechanistic rationale for the regioselectivity of methanol addition to the radical cations of phenyl-substituted alkenes (31). In the current proposals, methanol initially adds to the radical cation to give a distonic radical cation and this addition may proceed through an encounter complex. Until the two possible distonic radicals are deprotonated to give radicals, this addition process may be reversible. The observed regiochemistry may then result, in a complex way, from a combination of both the rates of formation and the thermodynamic stability of these intermediates.

A product analogous to **10**, resulting from migration of the phenyl group, was not detected in the methanol addition products. One possible explanation is that a methoxy substituent should not stabilize a radical centre to as great an extent as would a cyano substituent (32). Therefore, the neophyl rearrangement may not be energetically favorable.

As in the cyano case, the tertiary radical intermediate from methanol addition is not reduced by the radical anion of DCB. Therefore, ether **11** probably results from hydrogen abstraction by this radical rather than from protonation of the corresponding anion. To test this conclusion, the photoreaction was repeated using CH_3OD in the presence of added cyanide ion in 9:1 acetonitrile:methanol. The amount of deuterium incorporated into each of the four products was determined from single ion monitoring mass spectrometry (SIMS), using the intensities of the M, M + 1, and M + 2 peaks. As expected from the above mechanistic proposal, both cyano adducts, **9** and **10**, contained deuterium in 90% excess relative to natural abundance samples. The molecular ion of ether **12** was not intense enough to give reliable results, as it readily fragmented in the mass spectrometer, with the base peak corresponding to the 2-methoxy-2-adamantyl cation. However, SIMS analysis of the C_7H_7 fragment ions at *m*/*z* 91, 92, and 93 gave only 30% of deuterium in excess of natural abundance. This result must be interpreted with caution, as more than one mass spectral fragmentation pathway may lead to ions at these masses. However, the enhanced percentage of deuterium found for this fragment ion suggests that, at least part of the time, the precursor radical to **12** is reduced and protonated by the solvent. Ether **11** showed only 5% deuterium in excess of natural abundance, which is consistent with hydrogen atom abstraction as the major pathway from tertiary radical to product.

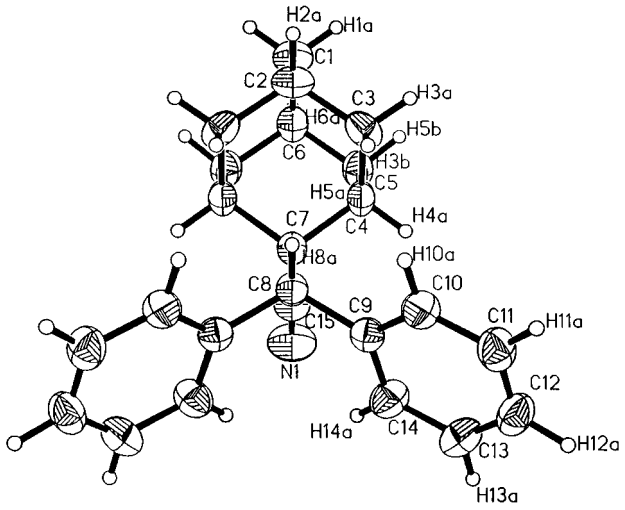
Photochemistry of 4 and 5

Because the product mixtures obtained from **3** were fairly complex, alkene **4** was also studied, with the hope that the added 4-methoxy group would improve the regioselectivity of the attack at C2 of the adamantane ring.

Photoreaction of alkene **4**, under the same conditions as used for **3**, gave the products **13**–**16**, also shown in eq. [4]. The ratio of (**13** + **14**) to (**15** + **16**) was 3.8:1. These products are structurally parallel to those formed upon reaction of alkene **3**, but the relative yields are quite different. The yield of cyano adduct **14**, involving migration of a phenyl group, was extremely low; integration of the ^{1}H NMR signals for the methylene protons suggested a ratio for **13**/**14** of approximately 10:1. In fact, **14** was detected mainly because its presence was expected based on the products from the reaction of **3**.

© 1998 NRC Canada

Fig. 4. ORTEP representation from the X-ray crystal structure of **17**.



As was the case with **3**, an HCN addition product derived from the unrearranged tertiary radical intermediate was not detected. These results demonstrate that cyanide ion addition to the radical cation of **4** is highly regioselective. Presumably, the presence of a 4-methoxy substituent on the phenyl ring stabilizes the benzyl radical, favouring its formation relative to the unsubstituted case. As with alkene **3**, the regioselectivity of addition is much less pronounced when methanol is the nucleophile as compared to cyanide ion. Integration of characteristic ^{1}H NMR signals from a spectrum of the product mixture gave a ratio of the ether products, **15:16**, equal to 1.5:1.

Some initial experiments towards studying facial selectivity in reactions of **5** were undertaken. The alkene was prepared, in low yield, but the product mixtures obtained in the photochemistry were complex and separations were difficult. These experiments were abandoned when the photochemistry of **6** indicated that **7** would be an easier probe to use than **5**.

Photochemistry of 6

Photolysis of **6** in 9:1 CH_3CN:CH_3OH with 9.8 mM tetraethylammonium cyanide gave one major product, **17**, and a minor one, **18**, eq. [6]. The ratio, by GC integration, was greater than 20:1. The structure of **17** was unambiguously established by X-ray crystallography, Fig. 4.[4] The minor product was not isolated and its structure was assigned only on the basis of its fragmentation in the GC–MS, where the base peak (*m/z*, 211) agreed with expected fragmentation of **18** to the 2-phenyl-2-adamantyl cation. The base peak for **17** (*m/z*, 177) corresponded to the diphenylmethyl cation. Evidence for low yields of methanol addition products was obtained by GC–MS, but these were not isolated either. By calibrated GC–FID analysis, a 61% yield of **17** was obtained after 85% conversion of **5**. These experiments show that the photochemistry of **5** is simpler than that of **3**. First, the regioselectivity of the addition reaction now greatly favors cyanide attack at the adamantyl tertiary carbon to give the diphenylmethyl radical. Second, the radical cation of the diphenyl alkene **6** is much more selective in its reaction with nucleophiles, cyanide ion reacting in preference to methanol. This is probably a result of its greater stability relative to the other radical cations studied and its consequent lower reactivity.

To confirm that photoinduced electron transfer was also efficient for this diphenyl derivative, fluorescence quenching experiments were again conducted. Stern–Volmer plots of the quenching of both DCB and 1,4-dicyanonaphthalene (DCN) by **6** were linear and gave $k_{eq}\tau$ values of 120 M^{-1} and 66 M^{-1}, respectively. Using the singlet lifetimes of 9.7 ns for DCB (16) and 10.1 ns for DCN (33) gives quenching rate constants of 1.3×10^{10} M^{-1} s^{-1} and 0.66×10^{10} M^{-1} s^{-1}, both values close to the diffusional limit, in agreement with expectations based on the Weller (23) equation and the oxidation potential of **6**,

1.58 V (CH_3CN, vs. SCE); a value of 1.56 V (CH_2Cl_2, vs. SCE) has been reported (29).

Photochemistry of 7

The above results for the alkenes **2**–**6** suggested that the 5-methoxy substituted diphenyl derivative, **7**, would be the best choice for studying the facial selectivity of addition to these radical cations. In the presence of cyanide ion, irradiation of **6** gives only one major product; with the added methoxy substituent in **7**, the two major products should be the diastereomers resulting from nucleophilic attack at the two faces, and analysis of their ratio should be simple.

This assumption proved to be correct. Photolysis of **7** (240 mg) in 9:1 CH_3CN:CH_3OH with 4.6 mM tetraethylammonium cyanide resulted in over 90% conversion in only 2 h. The products formed, with yields by calibrated GC–FID at 78% conversion of **7**, are shown in eq. [7]; mass balance for these three products is 81%. The gross structures of the two major products, **19** and **20**, were again easily assigned by GC–MS since the base peak in both at *m/z* 167 corresponded to the diphenylmethyl cation; the minor isomer, **21**, resulting from migration of phenyl group by the same mechanism as for the other adamantane derivatives, had a base peak at *m*/*z* 241 corresponding to the 5-methoxy–2-phenyladamantyl cation.

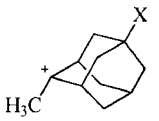
Pure samples of **19** and **20** were obtained by column chromatography and recrystallization. An X-ray structure for **19**, Fig. 5,[4] unambiguously assigns it to the *syn* isomer. This same assignment had been tentatively made by ^{13}C NMR spectra using both the chemical shifts for the unsubstituted HCN addition product, **17**, and the expected chemical shift effect of the added 5-methoxy group (34). The observed (calculated) δ values for the two compounds are, for **19**: C1,C3, 34.4 (34.2); C4,C9, 29.9 (29.8); C5, 28.6 (28.8); C6, 41.8 (41.6); C7, 70.5 (70.0); C8,C10, 38.2 (38.5) and for **20**: C1,C3, 34.9 (34.2); C4,C9, 35.1 (34.3); C5, 70.7 (70.0); C6, 40.7 (41.6); C7, 28.8 (28.8); C8, C10, 34.1 (34.1). The excellent agreement obtained is in accord with the assignments of the stereochemistry of **19** (and hence **20**) demonstrated by the crystal structure.

The ratio of the *syn* to *anti* isomers was obtained both by GC–FID (58:42) and by integration of the methoxy signals in the ^1H NMR spectrum (58:42) of the crude photolysis mixture. This ratio (GC–FID) remained constant as a function of percentage conversion of **7** because, as expected, the nitrile products are photochemically inert under the reaction conditions for their formation. Therefore the ratio obtained is a primary product ratio reflecting the facial selectivity in the nucleophilic attack of cyanide ion on the radical cation of **7**.

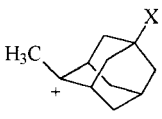
Previously reported literature values of *syn:anti* isomer ratios for a variety of reactions with very different mechanisms will put the value obtained for **7** in context. For instance (substrate, substituent, conditions, *syn:anti*): 2-adamantanone, 5-OCH_3, $NaBH_4/H_2O$/0°C, 64:36 (3); 2-adamantanone, 5-OCH_3, MeLi/ether/0°C, 63:37 (3); 2-adamantane carboxylic acid, 5-Ph, Br_2/CCl_4/40°C (Hunsdiecker reaction), 58:42 (9); 2-adamantanone, 5-F, hν, NC-CH═CH-CN, CH_3CN (Paterno–Büchi reaction), 57:43 (12). Trapping of 2-adamantyl cations gives higher *syn:anti* ratios: 2-methyleneadamantane, 5-OCH_3, HCl/CH_3NO_2/0°C, 85:14 (3); 2-methyleneadamantane, 5-F, HCl/CH_3NO_2/0°C, 100:0 (3); 2-methyladamantanol, 5-F, HCl/CH_2Cl_2/0°C, 83:13 (6).

The first observation is the relatively low variation in the *syn:anti* ratio with reaction type. For instance, in the Paterno–Büchi reaction, the product-determining step is the quenching of the excited singlet state of 2-adamantanone by the alkene; the rate constant is known to be diffusional (i.e., rate constant approaching 10^{10} M^{-1} s^{-1}). The rate is also very fast for trapping of the 2-adamantyl radical in the Hunsdiecker reaction. In contrast to these two reactions where the product ratio reflects the trapping of a reactive intermediate, the $NaBH_4$ reduction of 2-adamantanone is a relatively slow process; the product-determining step is now expressed in minutes (i.e., rate constant approximately 10^{-2} M^{-1} s^{-1}). Therefore reactions differing in rate constant by at least 10^{12} show similar facial selectivity! The reactivity/selectivity principle predicts that the photochemical reaction occurring at the diffusional limit might be expected to show considerably less selectivity and perhaps none at all.

A possible explanation for these observations is that the facial selectivity observed for the transient intermediates is a consequence of a nonplanar geometry at C2 of the adamantane ring. This is a reasonable possibility because the *n*–π* excited



22



23

singlet state of ketones (35) is, and tertiary radicals (ref. 35, pp. 264–267) may be, pyramidal. In fact, the interpretation for the very high facial selectivity observed for 2-adamantyl cations is that the substituent at C5 controls the equilibration between two diastereomeric pyramidal cations (free or intimate ion pairs), **22** and **23** (3). Because carbocations, unless they are highly stabilized, are known to be quenched by nucleophiles at the diffusional rate (36), the facial selectivity is determined

© 1998 NRC Canada

by the ratio of the concentration of **22** to that of **23** and not by their relative reactivity. The substituent exhibits a large effect because the equilibrium favors **22** over **23** as a result of the hyperconjugative interaction between the substituent and the full positive charge at the electrophilic center.

Because of these possibilities, the geometry of the radical cation of **7** is clearly an important factor to consider. MO calculations at both the AM1 level and STO–3G level[5] gave a planar geometry at C2 but this level of theory is probably not adequate to make a reliable prediction. The AM1 calculations gave spin densities of 0.50 and 0.22 at the adamantane C2 and the diphenylmethylene carbon, respectively; in contrast, the charge densities (0.08 and 0.09) are both very low. Thus, the radical cation of **7** might be expected to show the low facial selectivity characteristic of a radical reaction rather than that of a cation. This is indeed the case, the 58:42 *syn*:*anti* ratio being the same as that observed in the trapping of the 2-adamantyl radical by Br_2 (9). The regioselectivity for the addition of cyanide ion to the radical cations of both **6** and **7** highly favors nucleophilic attack at the endocyclic carbon. Because the charge density is essentially identical at these two carbons, this observation may reflect the higher stability of the product diphenylmethyl radical over the other possibility, the tertiary 2-adamantyl radical. For 1,1-diphenylethylene, the radical cation reacts exclusively at the C2 but, in this case, the calculated charge density is considerably higher at that carbon (0.21 versus 0.12 at the diphenylmethyl carbon) (37).

Experimental

General experimental

Proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (NMR) spectra were obtained in deuterated chloroform ($CDCl_3$) on either a Bruker AC 250F NMR spectrometer in automation mode or, as indicated, on an AMX 400 wide-bore NMR spectrometer. Proton chemical shifts are reported in parts per million (δ) relative to tetramethylsilane (0.00) as an internal standard. Reported coupling constants are experimental values. In many cases, coupling between ring protons in the adamantyl systems was unresolved, and the chemical shifts were reported as singlets. Carbon chemical shifts are reported relative to deuterated chloroform (triplet centred at δ 77.07). Multiplicities are abbreviated as follows: s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet. Carbon multiplicities were assigned from either DEPT with multiplicity analysis (DEM) or J modulation (JMOD) experiments.

Electron-impact mass spectra (MS) were run at 70 eV ionizing energy, either on a CEC 21-104 single focussing or a CEC 21-110B double focussing mass spectrometer. Ionizing energies are reported in parentheses for spectra not run at 70 eV. Samples were introduced directly into the mass spectrometer source using a glass or quartz probe and were heated until an adequate ion current was observed. Masses are reported as mass/charge (*m*/*z*) ratios. Ion intensities are given in parentheses relative to the base peak intensity (100). The molecular ion is indicated by M. Accurate mass determinations were made on the CEC 21-110B spectrometer with perfluorokerosene (PFK) as an internal standard at a resolution of approximately 10 000. Chemical ionization mass spectra (CIMS) were run on a Fisons/VG Quattro triple quadrupole mass spectrometer, using isobutane as the ionizing gas. Spectra are reported in the normal manner.

Ultraviolet (UV) spectra were obtained in acetonitrile–methanol on a Varian Cary 219 spectrometer using a 1 cm quartz cuvette. Wavelength maxima (λ_{max}) are reported in nanometres. Infrared (IR) spectra were obtained on a Nicolet 205 FT-IR spectrometer. Samples were run either neat or as a Nujol mull on sodium chloride plates. Frequencies are reported in wave numbers (cm^{-1}). Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Combustion analyses were carried out by Canadian Microanalytical Services Ltd., Delta, B.C., Canada.

GC–MS analyses were done on a Hewlett–Packard 5890A GC and a 5970 mass selective detector. The column used was 5% phenyl methyl silicon on fused silica with a film thickness of 0.25 μm and column dimensions of 25 m × 0.2 mm. Masses are reported in the same manner as described above. GC–FID analyses were carried out on a Perkin–Elmer Autosystem gas chromatograph using either a DB-5 column, 15 m × 0.53 mm, with a film thickness of 1.5 μm, or a BT-1 100% polymethylsilicone column, 12 m × 0.22 mm, with a film thickness of 0.25 μm. Data were analyzed using computer software written in-house. HPLC analyses were done using a Waters 6000 solvent delivery system and a Waters U6K injector under isocratic conditions with a flow rate of 2 mL/min using a Brownlee Lab Spheri-10 10 μL reverse-phase column (25 × 0.46 cm) with a Waters model 450 variable wavelength detector. UV detection was at either 254 or 280 nm.

Column chromatography was carried out using silica gel (60 Å, 70–230 mesh) from the Aldrich Chemical Company. Column solvents, hexane and ethyl acetate, were distilled prior to use. Fractions were monitored by either GC–FID or thin-layer chromatography (tlc) using silica-coated polyester plates, purchased from the Aldrich Chemical Company.

The following compounds were purchased from the Aldrich Chemical Company: benzilic acid, phenyl isothiocyanate, 4-*tert*-butylcyclohexanone, *p*-toluenesulfonic acid, 2-adamantanone, tris(diethylamino)phosphine, magnesium turnings, benzyl chloride, 4-methoxybenzyl chloride, 5-hydroxy-2-adamantanone, methyl iodide, sodium hydride (56–58% suspension in oil), 1.0 M borane – tetrahydrofuran complex, tetraethylammonium cyanide. These chemicals were used without further purification unless otherwise noted.

Synthesis of alkenes 2, 6, and 7

Thiobenzylic acid

The following procedure was adapted from that reported by Becker and Bistrzycki (38). Benzilic acid was recrystallized from water prior to use. Benzilic acid (8.88 g, 0.039 mol) and phenyl isothiocyanate (7.49 g, 0.055 mol) were combined, and were ground to a slurry using a mortar and pestle. After the slurry was transferred to an Erlenmeyer flask, glacial acetic acid (10 mL) was added as solvent and the mixture was stirred and cooled to 0°C in an ice–water bath. Concentrated sulfuric acid (5 mL) was added dropwise, and the resulting red slurry stirred at 0°C for 2 h, then at room temperature for 2 h longer. Stirring was stopped, and the mixture was left to sit overnight. The resulting pink paste was poured into a beaker of crushed

[5] M.S.W. Chan, Department of Chemistry, Dalhousie University, unpublished results, 1997.

© 1998 NRC Canada

ice, and the solid collected by suction filtration. Recrystallization from methanol–water gave the intermediate product, $PhN(H)C(O)SC(Ph)_2CO_2H$, as colourless crystals (8.80 g, 62% yield); mp 144–146°C (lit. (38) mp 140.5°C).

The product from above (8.80 g, 0.024 mol) was refluxed in 10% KOH (300 mL) for 5 h. After cooling, the solution was gravity filtered to remove a white solid. The filtrate was then acidified with aqueous hydrochloric acid and the resulting solid was collected by suction filtration. Recrystallization from 50% acetic acid gave thiobenzilic acid as white needles (5.17 g, 87% yield); mp 149–151°C (lit. (40) 147.5–149°C).

5-Methoxy-2-adamantanone

Sodium hydride (15 mol% excess), was washed with hexanes, then added to a stirred solution of 5 hydroxy-2-adamantanone (1.0 g, 0.060 mol) in dimethyl sulfoxide (DMSO, 15 mL). The solution became cloudy, and vigorous bubbling was observed. After 30 min methyl iodide (15 mol% excess) was added dropwise and the solution left to stir until clear (overnight). The reaction was quenched with water and extracted three times with dichloromethane. The combined organic layers were washed three times with water and twice with brine to remove the DMSO, then dried over anhydrous magnesium sulfate, and the solvent was removed under vacuum. The crude ether (81%) was purified by column chromatography (10:90 ethyl acetate:hexane). ^{13}C NMR data of the isolated oil agreed with literature values (34).

1,3-Oxathiolan-5-ones

This procedure was developed by Barton and Willis (17). Thiobenzilic acid (4.1 mmol), *p*-toluenesulfonic acid (1.5 mmol), and the appropriate ketone (4.1 mmol) were combined in a round-bottom flask fitted with a Dean–Stark trap and condenser. Benzene (70 mL) was added as solvent. The mixture was refluxed (5–8 h) under nitrogen with azeotropic removal of water. The resulting solution was cooled, washed four times with saturated sodium bicarbonate, then with water until the aqueous layer was neutral to pH paper. The organic layer was then dried over anhydrous magnesium sulfate and the solvent was removed under vacuum. The 1,3-oxathiolan-5-ones were purified by column chromatography to give colourless solids.

4-tert-*Butylcyclohexanespiro-2'-(4',4'-diphenyl-1',3'-oxathiolan-5'-one),* **2a**

4-*tert*-Butylcyclohexanone was recrystallized from low-boiling petroleum ether prior to use. The two product diastereomers (overall yield 96%) were separated once for characterization purposes, but otherwise the mixture was used for the next step.

Synthesis of alkenes 3, 4, and 5

Preparation of alcohols

2-Phenylmethyl-2-tricyclo[3.3.1.1^{3,7}]decanol, ***3a***
Magnesium turnings (0.33 g, 0.014 mol) and anhydrous ether (5 mL) were combined under nitrogen in an oven-dried three-neck flask equipped with a reflux condenser. A few drops of a solution of benzyl chloride (1.4 mL, 0.012 mol) in anhydrous ether (10 mL) were added via a dropping funnel. When no signs of reaction were observed, the flask was immersed in a warm water bath, a single crystal of iodine was added, and the magnesium turnings were broken into smaller pieces with a spatula, until the solution turned cloudy. The resulting solution was cooled to 0°C in an ice–water bath, and the remaining benzyl chloride was added over a period of half an hour, followed by 15 min of reflux. The solution was then cooled to 0°C followed by dropwise addition of 2-adamantanone (1.67 g, 0.011 mol) in anhydrous ether (20 mL). After the addition was complete, the resulting solution was refluxed for an additional 15 min, and cooled to room temperature. The ethereal solution was transferred to a separatory funnel containing cold, saturated ammonium chloride. The ether layer was removed, and the aqueous layer was extracted with ether. The combined ether layers were washed with water, dried over anhydrous magnesium sulfate, and the solvent removed by rotary evaporation. The crude oil was purified by column chromatography (10:90 ethyl acetate:hexane) to give the desired alcohol as a white solid (59% yield); ^{1}H NMR δ: 7.19 (s, 5H), 2.91 (s, 2H), 2.15 (d, 2H, J = 12.2 Hz), 2.04 (d, 2H, J = 12.8 Hz), 1.86 (s, 1H), 1.75–1.62 (m, 6H), 1.48 (s, 2H), 1.42 (s, 1H); ^{13}C NMR δ: 137.06, 130.35, 127.80, 126.01, 74.24, 43.59, 38.17, 36.50, 34.29, 32.66, 27.28, 27.14. The ^{1}H NMR spectrum of this alcohol agrees with that previously reported (18).

2-(4-Methoxyphenylmethyl)-2-tricyclo[3.3.1.1^{3,7}]decanol, ***4a***
Magnesium turnings (0.55 g, 0.023 mol) were activated by vigorous stirring under nitrogen for 3 days prior to reaction (39). Sufficient anhydrous ether (5 mL) was added to just cover the magnesium, and the mixture was cooled to 0°C. A few drops of a solution of 4-methoxybenzyl chloride (3.0 g, 0.019 mol) in anhydrous ether (20 mL) were added. Once the solution turned cloudy, signalling formation of the Grignard reagent, the remaining 4-methoxybenzyl chloride solution was added over a half-hour period. The resulting solution was stirred for an additional 15 min. A solution of 2-adamantanone (1.0 g, 0.007 mol) in anhydrous ether (20 mL) was added dropwise over a 1 h period. Stirring was continued overnight at room temperature, and the resulting solution worked up in the same manner as above for **3a**: ^{1}H NMR δ: 7.14 (d, 2H, J = 8.5 Hz), 6.84 (d, 2H, J = 8.5 Hz), 3.79 (s, 3H), 2.93 (s, 2H), 2.06–1.92 (m, 8H), 1.77 (d, 2H, J = 11.3 Hz), 1.68 (d, 2H, J = 11.3 Hz), 1.52 (d, 2H, J = 12.2 Hz); ^{13}C NMR δ: 158.33, 131.53, 129.16, 113.7, 74.54, 55.23,42.90, 39.27, 38.45, 36.83, 34.62, 33.02, 27.55.

5-Methoxy-2-phenylmethyl-2-tricyclo[3.3.1.1^{3,7}]decanol ***5a***
The method was the same as that used for **3a**, except that THF was used in place of ether as the solvent and, instead of heating at reflux, the solution was stirred overnight at room temperature prior to work-up. Two isomers, the (*E*) and the (*Z*) alcohol, were obtained. Spectral data were assigned based on literature data for (*E*)- and (*Z*)-5-methoxy-2-adamantanol.

(E)-Alcohol: 1H NMR δ: 7.32–7.21 (m, 5H), 3.28 (s, 3H), 3.01 (s, 2H), 2.12–2.08 (m, 5H), 1.85–1.74 (m, 6H), 1.39–1.34 (m, 3H); ^{13}C NMR δ: 136.79, 130.57, 128.46, 126.74, 74.00, 71.92, 48.40, 43.84, 41.10, 38.56, 37.85, 31.91, 29.30.

(Z)-Alcohol: ^{1}H NMR δ: 7.34–7.20 (m, 5H), 3.21 (s, 3H), 2.97 (s, 2H), 2.26–2.21 (m, 3H), 2.04–1.99 (m, 3H), 1.89 (s, 2H), 1.72–1.62 (m, 4H), 1.47–1.42 (m, 2H); ^{13}C NMR δ: 137.03, 130.54, 128.42, 126.70, 73.49, 71.51, 48.10, 43.13, 41.66, 38.94, 35.98, 33.44, 29.34.

Dehydration of alcohols
The alcohols **3a**, **4a,** and **5a** were dehydrated in benzene, in the presence of *p*-toluenesulfonic acid (10 mol%) as catalyst, using the same apparatus and procedure as for the preparation of 1,3-oxathiolan-5-ones.

Photochemistry

Either a 200 or 450 W Hanovia medium-pressure mercury lamp was used as the light source for photoreactions. Mixtures of acetonitrile and methanol were used as solvent in every case. Acetonitrile was purified by a four-step procedure: distillation from sodium hydride, distillation from phosphorus pentoxide, passage through basic alumina, and distillation from calcium hydride after 24 h reflux under nitrogen. Methanol was distilled from sodium prior to use. Dicyanobenzene (DCB) and 1,4-dicyanonaphthalene were available in our laboratory. DCB and the desired alkene were dissolved in acetonitrile–methanol in an immersion well (300 or 420 mL) equipped with a Pyrex filter. The solution was purged with nitrogen for 15 min prior to the irradiation. A positive pressure of nitrogen and magnetic stirring were maintained for the duration of the reaction. After the photolysis the solvent was removed under vacuum and the photoproducts were separated by column chromatography on silica gel and identified by spectroscopic methods.

Methyl 1-phenyl-2-(2-tricyclo[3.3.1.1^{3,7}]decanyl)ethyl ether, ***11***

This ether was not isolated from the photoreaction of **3** but was prepared as follows.

1-Phenyl-2-(2-tricyclo[3.3.1.1^{3,7}]decanyl)ethanol

A solution of alkene **22** (0.10 g, 4.46×10^{-4} mol) in THF (15 mL) was cooled to 0°C in an ice–water bath with stirring. Borane (1.0 M solution in THF, 2.5 mL, 0.0025 mol) was added dropwise and the resulting solution was warmed to room temperature and stirred for several hours. The reaction was then opened to the air, and water (1 mL), followed by aqueous sodium hydroxide (3 M, 2 mL), was added dropwise. Vigorous bubbling was observed. Hydrogen peroxide (30% solution, 2 mL) was added dropwise, after which the solution was left to stir for 5 min at 0°C, then for 20 min at room temperature. Water (10 mL) and ether (20 mL) were added to the reaction flask and the resulting mixture was left to stir for several minutes. The solution was transferred to a separatory funnel leaving a white solid behind, and was extracted three times with ether. The combined ether extracts were dried over anhydrous magnesium sulfate and the solvent removed under vacuum. Purification by column chromatography (95:5 hexane:ethyl acetate) gave the desired alcohol (0.10 g, 91% yield); ^{1}H NMR δ: 7.41–7.22 (m, 5H), 4.84 (d, 1H, *J* = 10.4 Hz), 2.32 (s, 1H), 2.08 (d, 1H, *J* = 12.8 Hz), 1.93–1.49 (m, 11H), 1.44 (d, 1H, *J* = 10.7 Hz), 1.20 (s, 1H); ^{13}C NMR δ: 144.05, 128.45, 127.67, 126.73, 74.69, 51.43, 39.06, 38.81, 38.25, 32.24, 31.66, 28.89, 28.19, 28.01, 27.84.

The ether **11** was prepared from the above alcohol by the same procedure as 5-methoxy-2-adamantone, above: ^{1}H NMR δ: 7.34–7.25 (m, 5H), 4.31 (d, 1H, *J* = 10.4 Hz), 3.16 (s, 3H), 2.35 (s, 1H), 2.05 (d, 1H, *J* = 12.8 Hz), 1.94–1.53 (m, 11H), 1.44 (d, 1H, *J* = 10.4 Hz); ^{13}C NMR δ: 141.49, 128.27, 127.55, 127.47, 84.26, 56.76, 50.88, 39.14, 38.82, 38.34, 31.96, 30.09, 29.42, 28.32, 28.16, 27.95; GC–MS *m/z*: 122 (16), 121 (100), 91 (23), 79 (12), 77 (24).

Photolysis of 3 in methanol-OD

The photoreaction of alkene **3** in the presence of added cyanide ion was repeated on 0.10 g of the alkene using deuterated methanol, CH_3OD. The reaction was stopped at low percentage conversion, and the photoproducts were not separated. The percentage deuterium in the products was obtained using the Single Ion Monitoring (SIMS) program on the GC–MS and software developed in-house.

Fluorescence quenching studies

A Perkin–Elmer MFP 66 fluorescence spectrometer at 25°C was used for fluorescence measurements. Samples were prepared with constant concentration of the sensitizer, either DCB or 1,4-dicyanonaphthalene, and varying concentration of alkene in either 9:1 or 3:1 acetonitrile:methanol. All samples were degassed by three freeze–pump–thaw cycles.

Cyclic voltametric measurements

Cylic voltammetry at a sweep rate of 100 mV/s was used to obtain the oxidation potentials of the alkenes. The apparatus has been described previously (40). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a platinum wire. The reference electrode was saturated calomel (SCE), which was connected to the solution (0.1 M TEAP, acetonitrile) through a Luggin capillary. The alkene concentration was ca. 0.005 M. Because the anodic wave was irreversible, the half-wave potential was taken as 0.028 V before the peak potential (41).

Molecular modelling and NMR studies of the caffeine dimer[1]

Michael Falk, Warren Chew, John A. Walter, Witold Kwiatkowski, Katherine D. Barclay, and Gerald A. Klassen

Abstract: A survey of crystal structures containing the xanthine ring shows that caffeine-like molecules tend to stack in parallel in a variety of stacking geometries, suggesting that a stacked pair of caffeine molecules has many conformations of comparable energy. Molecular modelling suggests that the caffeine dimer, the major associated species in aqueous solution, may occur in nine distinct conformations. In agreement with the crystal survey and the modelling results, NMR spectra of caffeine solutions exhibit intermolecular nuclear Overhauser enhancements (NOEs), consistent with a dynamic equilibrium of several conformations of the dimer of comparable energies.

Key words: caffeine, dimer, self-association, molecular modelling, intermolecular nuclear Overhauser enhancements (NOEs).

Résumé : Une revue des structures cristallines comportant un noyau xanthine montre que les molécules qui ressemblent à la caféine ont tendance à se superposer de façon parallèle en adoptant diverses géométries; ces données suggèrent qu'une paire de molécules de caféine peut adopter plusieurs conformations d'énergies comparables. La modélisation moléculaire suggère que le dimère de la caféine, l'espèce associée principale en solution aqueuse, peut adopter neuf conformations distinctes. En accord avec la revue des structures cristallines et des études de modélisation moléculaire, les spectres de RMN de la caféine en solution présentent des effets Overhauser nucléaires (EON) intermoléculaires qui correspondent avec un équilibre dynamique de plusieurs conformations du dimère d'énergies comparables.

Mots clés : caféine, dimère, autoassociation, modélisation moléculaire, effets Overhauser nucléaire (EON) intermoléculaires.

[Traduit par la rédaction]

Introduction

Caffeine (Fig. 1), or 1,3,7-trimethylxanthine, is the most widely ingested mood-altering substance (1). Its mode of action is within the central nervous system where it acts as a stimulant, perhaps by competitive blockade of endogenous adenosine at A_1 and A_2 receptors (2). In this context, the self-association of caffeine molecules in aqueous solution, which has been demonstrated by many different physical and spectroscopic methods (3–9), might have physiological significance. It is known that caffeine associates to form dimers, and to some extent also trimers and higher aggregates (9). That these aggregates involve the stacking of caffeine molecules is clearly shown by the existence of ring current shifts of ^{1}H resonances to high field, with increasing solution concentration (10). However, the actual geometry of the dimer has not been clarified (11–16). Even more uncertain is the geometry of the higher aggregates and their proportions. The commonly assumed isodesmic model assumes that the sequential equilibrium constants K_2, K_3, K_4, etc. are equal (7, 8, 17, 18), but infrared results (9) suggest that the dimerization constant K_2 is substantially larger than K_3.

In the present work we have addressed these problems in several ways. We have studied the caffeine–caffeine geometry by molecular modelling methods and by a survey of caffeine-like molecules in crystals. We have measured the intermolecular nuclear Overhauser enhancements (NOEs) of caffeine in aqueous solution, which do not appear to have been previously observed. The combination of these NOE results with molecular modelling and crystal data affords new insight into the structure of caffeine dimers, the preponderant species in solution. Our findings also apply to the stacking interactions of other aromatic molecules implicated in physiological phenomena (19).

Possible geometries of stacked caffeine molecules

To discuss the geometry of a pair of caffeine molecules stacked with their rings in parallel, we use a coordinate system (Fig. 1) such that the centroid of the *bottom* molecule is at the origin, its C_8—H_8 bond points in the *x* direction, its purine ring lies in

Fig. 1. Caffeine molecule showing the numbering of atoms and the coordinate system.

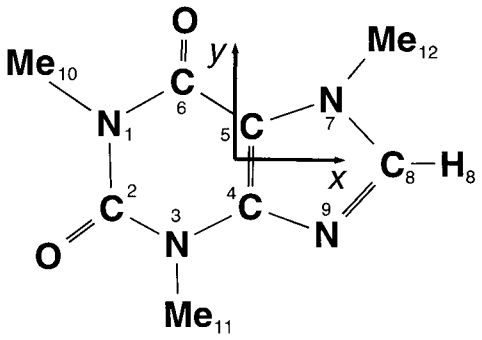

Table 1. Previously suggested dimer geometries.

Reference	Method	Dimer	Angle *R*
Thakkar et al. (11, 12)	^{1}H NMR	**B**	0°
Kikkert et al. (13)	UV spectra	**B**	0°
Fritzsche et al. (14)	^{1}H NMR	**A or B**	90° or 270°
Kan et al. (15)	^{1}H and ^{13}C NMR	**A**	90°
Yanuka et al. (16)	^{1}H NMR	**A**	0°

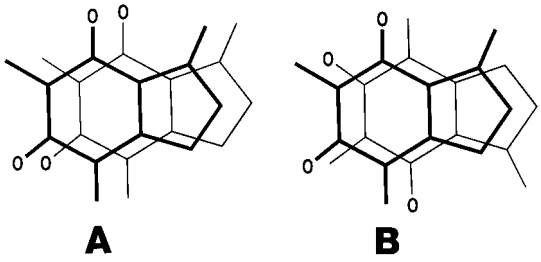
the *x*–*y* plane, and the top molecule is displaced from the bottom one in the positive *z* direction. There are two distinct ways in which a pair of caffeine molecules can stack (Fig. 2). In structure **A** ("top-to-bottom"), the two caffeines are related by a simple translation along the *z*-axis, followed by a rotation by an arbitrary angle about the *z*-axis, and a glide in the *x*–*y* plane. In structure **B** ("top-to-top"), the two caffeines are related by a translation along the *z*-axis, followed by a rotation of *either* the top molecule *or* the bottom molecule by 180° about the *x*-axis (again, followed by a rotation by an arbitrary angle about the *z*-axis, and a glide in the *x*–*y* plane). The two ways of generating **B** result in enantiomers.

Stacked caffeine pairs **A** and **B** possess four degrees of freedom for which we have employed the following four parameters: *R* (angle of clockwise rotation in the *x*–*y* plane of the top molecule with respect to the bottom molecule), *X* (translation of the top molecule along *x*-axis), *Y* (translation of the top molecule along *y*-axis), and *Z* (spacing between the two molecular planes).

It should be noted that **A** possesses mirror–plane symmetry (point group C_s) when $R = 0°$, and a centre of symmetry (point group C_i) when $R = 180°$, but becomes dissymmetric (point group C_1) for other values of *R*, so that pairs of structures corresponding to *R* and $360° - R$ are enantiomeric. Structure **B** possesses a two-fold symmetry axis (symmetry point group C_2) preserved for all values of *R* and is always dissymmetric, occurring as "right-handed" or "left-handed" enantiomers. The enantiomers cannot be distinguished by NMR spectra, or most other physical measurements, however, their occurrence and the symmetry of **A** and **B** play an important part in determining the relative weights of different conformational structures.

Earlier authors assumed that a caffeine dimer occurs in one preferred conformation, but have about equally favoured the two possible structures, **A** and **B,** with the angle *R* of either 0° or 90° (Table 1). Their conclusions have been based largely on NMR phenomena such as ring current effects, which, while

Fig. 2. Dimers **A** and **B,** after Kikkert et al. (13).



indicating that the rings are parallel and in close proximity, are not very sensitive to the relative orientation and displacement of the two component molecules. The earlier results, therefore, provide no secure basis for deciding in favour of a particular dimer geometry. The possibility that the dimer may exist as a dynamic mixture of energetically similar conformers does not appear to have been considered.

Geometries of caffeine-like molecules in crystals

Aromatic molecules in crystals tend to organize themselves in one of two different ways: face-to-face parallel stacking, with a characteristic spacing of about 3.4 Å, and edge-to-face or T-shape arrangement in which the rings approach at highly inclined angles, often perpendicular (20, 21). C···C interactions dominate in the parallel stacking, while H···C interactions dominate in the T-shape arrangement.

Crystalline benzene adopts the T-shape arrangement (20) but increasing molecular area, increasing ratio of carbons to hydrogens, heterosubstitution, and presence of carbonyl groups all favour parallel stacking over T-shape (20, 22, 23). Therefore, caffeine-like molecules may be expected to exhibit stacking strongly. This expectation is, indeed, confirmed by a survey of crystalline structures.

We have surveyed the Cambridge Structural Database (24) for crystal structures containing the xanthine skeleton, without bulky side groups, and containing no other structural elements except for water of hydration. Eleven such structures were found (25–35), involving 14 distinct stacking geometries, listed in Table 2. Every one of these structures involves parallel stacking of molecules with the characteristic 3.4 Å spacing. The T-shape approach was only encountered in two structures (**3** and **4** in Table 2) in which the stacking was particularly loose, as shown by the unusually large values of the offset parameter *X*. While all of the eleven structures involve stacking, there is a wide spread of geometries: the interplane spacing parameter *Z* varies from 3.25 to 3.57 Å, while the offset parameters *X* and *Y* vary from 0.11 to 4.44 Å, averaging 1.7 Å for *X* and 0.7 Å for *Y*. An offset of 1–2 Å is very common for stacked aromatic rings in crystals (20), and offset geometry has been said to correspond to the lowest energy of a pair of stacked rings (23).

The stacked molecules in these crystals adopt two arrangements. In the *infinite stack*, the more common arrangement, each molecule has two parallel neighbours, above and below. In the somewhat less common *stacked-pair* arrangement, each molecule has only one parallel neighbour. In seven crystals the arrangement of near-neighbours is "top-to-bottom,"

corresponding to structure **A**, while in four crystals it is "top-to-top," corresponding to structure **B**.

The relative orientation of the stacking molecules, given by the angle *R*, depends on their symmetry relation. If these molecules are crystallographically related by lattice translation, *R* is 0° (structures **1**, **2**, **4**, **7**, and **9**). If they are related by inversion, *R* is 180° (structures **3**, **5**, **6**, **10**, and **11**). In the latter case, the *second-nearest* neighbours are related by a lattice translation, and the values of parameters *X*, *Y*, and *Z* alternate along the stack (***a*** and ***b*** in Table 2). In structure **8** the stacking molecules are related by a screw axis, and the parameter *R* takes alternating non-zero values along the stack.

The survey of crystal data demonstrates a strong tendency of caffeine-like molecules to stack either as pairs or as infinite chains of parallel molecules, adopting either the top-to-bottom or the top-to-top arrangement. The wide spread of observed pair geometries is consistent with the existence of many possible interpair arrangements of comparable energy. The incidence of the T-shape geometry is low, suggesting that it is energetically less favourable than parallel stacking.

Molecular modelling

The method

A conformational study of the caffeine dimer was carried out by molecular modelling, using SYBYL software (SYBYL version 6.2, Tripos, Inc., St. Louis, Mo.) running on a Personal Iris 4D/35 TurboGraphic workstation (Silicon Graphics, Inc., Mountain View, Calif.) under the IRIX 5.2 operating system. The conformational search was carried out under the Tripos force field (36), including electrostatic terms based on atomic charges computed by the Gasteiger–Marsili algorithm (37, 38). The calculations were first carried out under the condition $\varepsilon = R_{ij}$, i.e., the dielectric constant ε set to equal the interatomic distance R_{ij} in Å, simulating the screening effect of a water-like solvent on the electrostatic charges (39). To assess the effect of the water medium on the relative energies of the dimer conformers, the calculations were repeated with ε = 1 corresponding to vacuum, then with ε = 80 corresponding to liquid water, and finally with ε = 1 but with a small cluster of water molecules surrounding the caffeine dimer. The water cluster was formed using the SYBYL solvent algorithm, which adds solvent molecules one at a time, with an energy minimization at each step. For hydrate clusters of up to five H_2O molecules, this procedure led to a unique minimized energy for all nine conformers. For larger clusters, however, repeated runs produced several alternative structures, so that a large computational effort would be needed to ensure that the structure of lowest energy had been identified. The energies of the dimer conformers were also calculated using the alternative force fields AMBER (39) (available within the SYBYL software) and MM+ (used with the Hyperchem software package supplied by Hypercube Inc., Waterloo, Ont.) The force field MM+ is an extended version of the MM2 force field developed by Allinger (40).

Preliminary survey of dimer stability

In a preliminary survey, we have repeatedly minimized the energy of a pair of caffeine molecules, starting from many arbitrary geometries. Energy minimization nearly always led to a parallel-stacked orientation. On rare occasions the molecular pair became "stuck" in a nonparallel orientation, which was invariably of much higher energy by at least 6 kcal/mol. Minimizations that started with the prepared T-shaped geometry, known to be stable for benzene dimers (20), also led to a parallel-stacked geometry. This geometry clearly corresponds to the stable form of caffeine dimer under the force fields used. Therefore, especially in view of the results of the crystal survey (previous section) and the recent report of Kollman and coworkers (41) on the greater relative stability of the parallel-stacked geometry of toluene dimers compared to benzene dimers, we have henceforth concentrated our conformation study on the parallel-stacked pairs of molecules.

Survey of energy as a function of parameters R, X, Y, *and* Z

To survey the shape of the potential of a pair of parallel-stacked caffeine molecules as a function of *R*, *X*, *Y*, and *Z*, we varied each of these parameters in turn, keeping the others constant. In this survey, we used the macro DIMER, written in SYBYL programming language by Chris van Dyke of Tripos Inc. and modified by Peter Spierenburg. In the DIMER procedure, one caffeine molecule is placed in the *x*–*y* plane at $z = 0$, its centre of mass being at (0, 0, 0). The second caffeine molecule is placed at height *Z* above the first one, either without

Fig. 3. Plot of energy as a function of rotation R about the z-axis for dimers **A** and **B**. Parameters $X = Y = 0$ Å, $Z = 3.4$ Å; Tripos force field; $\varepsilon = R_{ij}$.

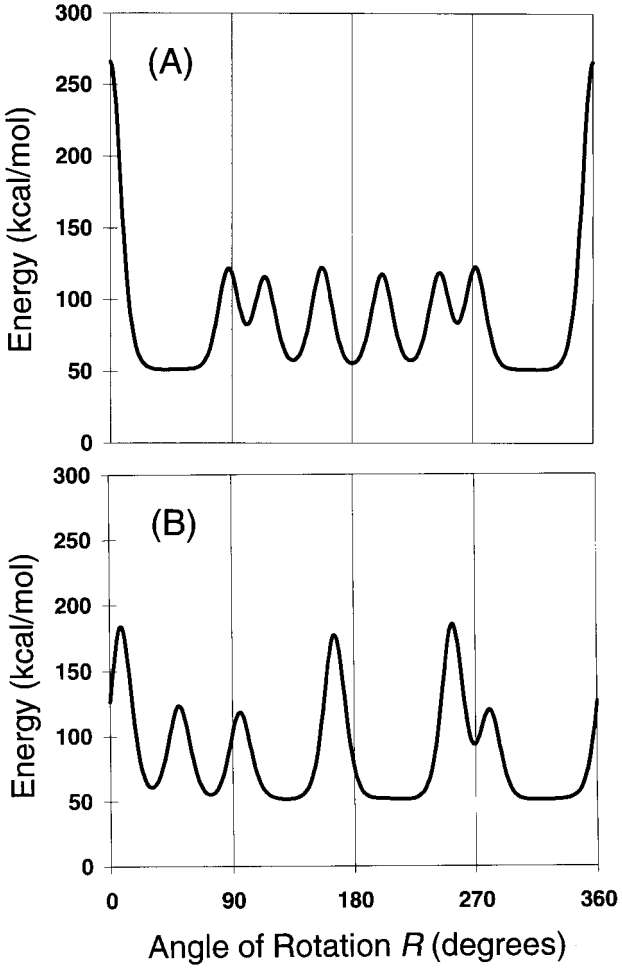

Fig. 4. Plot of energy as a function of the lateral movement (along X and Y) of the caffeine molecules in dimer **B**. (*a*) Near the global minimum; $R = 318°$, $Z = 3.4$ Å. (*b*) Near a local maximum; $R = 245°$, $Z = 3.4$ Å. The isocontour lines shown correspond to 51–57 kcal/mol. Tripos force field; $\varepsilon = R_{ij}$.

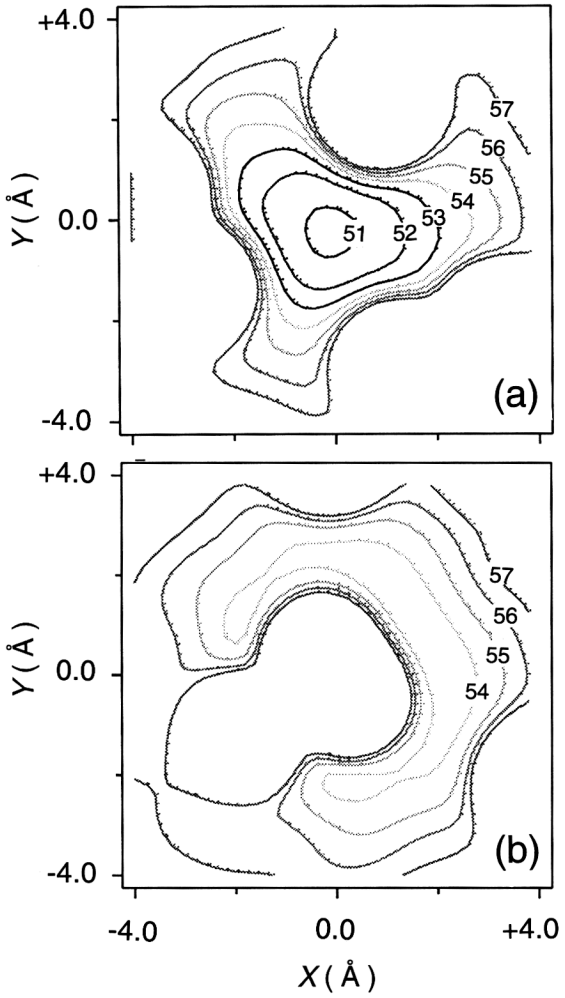

rotation (dimer **A**) or with 180° rotation about x (dimer **B**). The macro creates dimer structures for the specified ranges and intervals of parameters R, X, Y, and Z, computes their energy, and stores the structures in a database.

The dependence of the energy on the rotation angle R is shown in Fig. 3. To generate this plot, parameter R was varied in steps of 1°, the other parameters being kept constant: $Z = 3.4$ Å, $X = Y = 0$ Å. A series of energy minima are observed for each dimer, seven for **A** (six of them forming three equivalent pairs, due to symmetry) and six for **B**. Some of the minima are relatively flat. The minima are separated by relatively sharp energy maxima due to repulsive methyl contacts. The energy minima can be identified with regions of R where the three methyl groups of one caffeine avoid those of the other caffeine.

The dependence of energy on X and Y is shown in Fig. 4. Two distinct situations arise. For R values corresponding to conformations of relatively low energy, avoiding repulsive methyl contacts, the minimum is near $X = 0$, $Y = 0$, corresponding to maximum overlap of the two aromatic-ring systems. The potential well is then a centrally located circle, as in Fig. 4*a*. For R values corresponding to conformations of higher energy, methyl repulsions are avoided by moving the aromatic rings apart laterally. The potential well in these cases forms a circular or crescent-shaped valley surrounding an energy maximum near $X = 0$, $Y = 0$, as in Fig. 4*b*.

The dependence of energy on the interplanar spacing Z is shown in Fig. 5. It is qualitatively the same for all values of R, X, and Y, being governed by the van der Waals energy terms. There is one minimum, with a steep increase toward smaller separations and a less steep increase toward greater separations. However, the position and depth of the minimum depend strongly on the values of R, X, and Y. For combinations of these parameters that correspond to conformations of relatively low energy, the minimum occurs near $Z = 3.25$ Å as in Fig. 5*a*. For conformations of high energy, the minimum occurs at values of Z greater than 4 Å as in Fig. 5*b*.

Search for stable conformations

Figures 3–5 demonstrate the shape of the dimer potential with respect to the parameters R, X, Y, and Z. Keeping in mind this general shape, we searched for stable conformations of dimer **A** and **B**, using the macro DIMER as follows. For each of 72

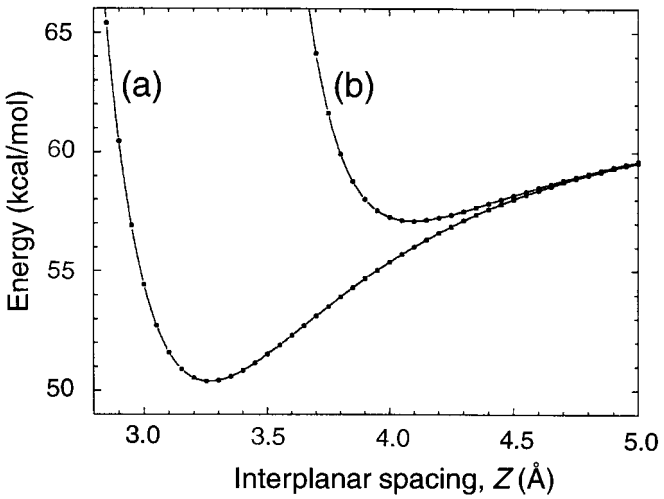
Fig. 5. Plot of energy as a function of the spacing Z between the planes of the two caffeine molecules in dimer **B**. $X = Y = 0$ Å, $R =$ 318° (case *a*), $R = 245°$ (case *b*). Tripos force field; $\varepsilon = R_{ij}$.



values of the angle R (range 0–360°, interval 5°), we generated $41 \times 41 = 1681$ structures with X and Y varying from –4 to +4 Å in steps of 0.2 Å, the value of Z being kept constant at 3.4 Å. Of each such set of 1681 structures we retained only the one of lowest energy. This led to 72 candidate structures, whose energies we then minimized. In these minimizations the two caffeine molecules were not constrained to parallel planes, and all atom coordinates were allowed to vary freely. Nevertheless, in agreement with our preliminary observations, all minimized structures ended up with the two caffeine molecules in parallel planes.

For dimer **A**, four distinct minima were found, **A1**–**A4**, corresponding roughly to the minima in Fig. 3*a*. Minimum **A4** occurs once, while **A1**, **A2**, and **A3** occur twice due to symmetry. For dimer **B**, five distinct minima were found, **B1**–**B5**, corresponding to the five deeper minima in Fig. 3*b*. The energies and geometric parameters of these nine minima are listed in Table 3. A thorough examination of the local conformation space confirmed that the nine minima correspond to distinct conformers with energies that are within 1.3 kcal/mol of one another. Conformer **A1** has a double energy minimum and all the other conformers a single energy minimum. When all geometric parameters are allowed to vary, energy barriers that separate the various minima are only of the order of 1–3 kcal/mol, much lower than those for rigid rotation (shown in Fig. 3), which amount to 50–100 kcal/mol. The reason for this difference is that for a given value of the angle R the repulsive methyl contacts can be very much diminished by the two molecules sliding laterally (increasing X and Y) and by spreading farther apart (increasing Z).

Four of the nine dimer conformations correspond to pair geometries found in crystals of caffeine-like molecules: **A1** corresponds to structures **1**, **2**, **4**, **7**, and **9**; **A4** corresponds to **6*a***, **6*b***, **10*a***, and **10*b***; **B3** corresponds to **3**, **5,** and **11**; and **B5** corresponds to **8*a*** and **8*b***. These correspondences are based on the A–B classification and the rough values of the angles R and R' (defined below). The values of the offset parameters X and Y generally do not match.

The nine conformers

The picture that emerges from molecular modelling is that of a caffeine dimer with many possible conformations of similar energy, likely to exist as a mixture. This mixture can be approximately represented as composed of the nine conformers **A1**–**A4** and **B1**–**B5**, with relative populations that can be determined from Boltzmann factors corrected for the multiplicity factors shown in Table 3 in which symmetry and the doublet structure of the potential well of dimer **A1** are taken into account. Table 3 records the energies and the calculated populations for the nine energy-minimized conformers, the parameters R', X, Y, and Z, which define dimer geometry, and the average intermolecular H···H approaches ($1/r^3$ averaging) for comparison with the observed NOE data. For the energy-minimized conformers, the parameter R' is the dihedral angle H_8'-C_8'-C_8''-H_8'' (where the primed and double-primed atoms refer to the two caffeine molecules), closely related to the z-rotation angle, R. The two quantities R' and R are equal when there is no lateral displacement of the two molecules, i.e., when $X = Y = 0$, but differ by as much as 40° when X or Y are large. The fully energy-minimized dimer conformers have the interplanar spacing Z about 3.1 Å (3.25–3.57 Å in crystals) and the lateral displacements X and Y in the range 0–1.8 Å, (0.1–4.4 Å in crystals).

The above results were obtained using the Tripos force field and distance-dependent dielectric constant $\varepsilon = R_{ij}$, which qualitatively simulates the water medium in which electrostatic interactions should die off more rapidly with distance than in vacuum (39). We have also re-minimized the dimer conformers under two alternate settings of the dielectric constant within the Tripos force field as well as under two other force fields, AMBER and MM+. As could be expected, the *absolute energies* of caffeine dimers, obtained in these alternative calculations, were considerably different. The *relative energies*, however, were similar (Table 4). The conformer with lowest energy was in every case the same, **B5**, and the total spread of energies of the conformers was 1.3 kcal/mol.

To further assess the applicability of our results to caffeine dimers in aqueous medium, we have re-minimized the nine conformers **A1**–**B5**, surrounded by water clusters consisting of one to five H_2O molecules. In these results (columns 5–7, Table 4), again **B5** remained the conformer with lowest energy, and the total spread of energies of the conformers was 2.9 kcal/mol. Since all these calculations, including those with explicit water molecules, have yielded comparable results, we conclude that our main finding that the dimer has nine conformers of comparable energies and hence of appreciable populations holds for caffeine in aqueous medium. The apparent insensitivity of the *relative energies* of the dimer conformers to the presence of water molecules implies that the hydrophobic forces stabilize the various stacked arrangements almost equally well.

Measurement of intermolecular NOE

The detection of intermolecular nuclear Overhauser enhancements (NOEs) offers the potential to distinguish between different models for the caffeine dimer. We undertook such measurements using the one-dimensional NOE-difference technique on caffeine solutions at four different concentrations, reasoning that intermolecular NOEs should appear to

increase with concentration due to the greater proportion of dimer in solution, whereas intramolecular NOEs should remain constant. Preliminary experiments indicated that other techniques for detecting NOE, such as NOESY, were not sufficiently sensitive with our instrument to measure very small intermolecular effects.

Experimental

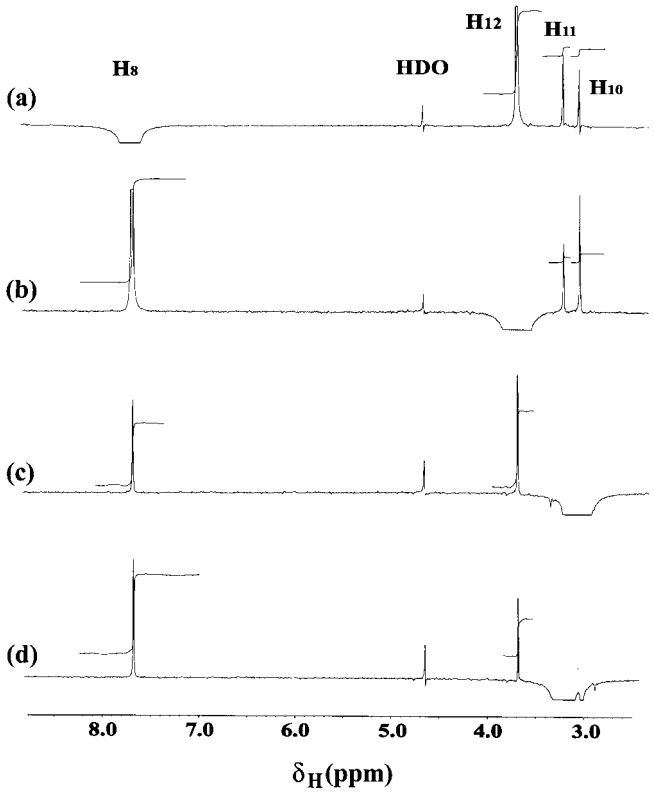
All experiments were performed with a Bruker AMX–500 spectrometer at 500.13 MHz with spectral width 4504 Hz, acquisition time 1.82 s, excitation pulse 6 μs (45°), temperature 20.0°C, and continuous irradiation for 5 s between data-acquisition periods. The power setting was 40–50 dB, sufficient to produce ca. 90% saturation of a single resonance. To ensure uniformity of conditions and to minimize drift, a cycle of interspersed on-resonance and off-resonance irradiations was repeated 12 or more times, with 16 scans added and 4 dummy scans at each repetition. Total transients added to each spectrum varied from 192 for the highest caffeine concentration to 944 for the lowest concentration. Solutions of caffeine (Sigma cat. no. C–0750) were made up by weight in "100%" D_2O (MSD Isotopes cat. no. MD–1743) to 0.001, 0.005, 0.010, 0.051, and 0.10 M, placed in Wilmad 535pp NMR tubes, and degassed by three to four successive freeze–pump–thaw cycles after which N_2 was injected over the solutions. Samples were not spun during acquisition. Spectra were processed under identical conditions of exponential weighting (LB (line broadening) 0.2 and 3.0 Hz) and phasing, and those corresponding to on-resonance irradiation were subtracted, without alteration of intensity scales, from the off-resonance spectra. NOEs (%) were measured from the difference spectra by integrating each resonance after calibrating the integral of the irradiated peak to 100 units for the H_8 resonance or 300 units for the methyl resonance and correcting for the number of protons represented by each peak. Linear base-line corrections were applied if necessary over ca. 0.1 ppm regions on either side of the peaks. As all ^1H resonances of caffeine are singlets, NOEs were detectable to very low levels (ca. 0.03% at 0.1 M, 0.10% at 0.001 M caffeine). Errors were estimated from the noise levels of integrals, and separate off-resonance spectra were subtracted from each other to check for exactness of cancellation. Results from a series of irradiations were discarded if separate off-resonance spectra, when subtracted, left residual integrals greater than the noise level. The chemical shift of the HOD peak was set to 4.67 ppm.

Results

The ^1H NMR spectrum of caffeine consists of four sharp singlet resonances, assigned as δ: 7.70 (H_8), 3.71 (H_{12}), 3.23 (H_{11}), 3.06 (H_{10}) (42). Figure 6 shows a series of NOE-difference

© 1998 NRC Canada

Fig. 6. One-dimensional NOE-difference spectra of caffeine at 0.1 M in D_2O, with irradiation of *(a)* H_8, (*b*) H_{12}, (*c*) H_{10}, and (*d*) H_{11}.



spectra, obtained from 0.1 M caffeine, in which NOEs are clearly detectable between all proton pairs except those for which partial saturation (ps) precludes observation. Similar results were obtained at the lower concentrations, the results of the complete series of NOE-difference experiments being summarized in Table 5.

A large positive NOE η_C was observed as expected between H_8 and H_{12}. The magnitude remained virtually constant with concentration, indicating that the intermolecular component was negligible compared to the intramolecular: ca. 2.3% NOE observed at H_{12} when H_8 was irradiated; ca. 14.9% for the reverse NOE. The NOEs in different directions between protons at a pair of positions are not expected to be identical, due to likely differences in relaxation pathways. Thus spin–rotation contributions to relaxation of unhindered methyl groups result in a lower NOE when H_8 is irradiated than when H_{12} is irradiated. All the other observable NOEs were also positive, and decreased as concentration was lowered, showing that these NOEs were predominantly intermolecular, without contributions from relayed NOE or exchange phenomena.

Approximate calculations of the contributions of intramolecular NOEs to total NOEs, and of the average intermolecular H—H distances from the remaining intermolecular NOEs, were based on the two-spin approximation (43).

All *intra*molecular H—H distances r_A other than H_8—H_{12} are in the range 5.24–7.40 Å, if calculated using molecular modeling. Assuming that the steady-state NOE is proportional to $\langle r^3 \rangle^{-2}$, appropriate for rapidly rotating methyl groups (43), and taking the averaged $\langle r^3 \rangle$ intramolecular H_8—H_{12} distance r_C (= 3.05 Å) as a calibration, the intramolecular NOE contribution η_A to the total NOE η_T for each proton pair was estimated from $\eta_A = \eta_C [r_C / r_A]^6$, yielding the numbers in Table 5.

The intermolecular contributions $\eta_E = (\eta_T - \eta_A)/(1 - p_M)$ were in turn used in calculations of average intermolecular H—H distances r_E, from $r_E = r_C [\eta_C / \eta_E]^{1/6}$. As intermolecular NOEs could occur only within dimers or higher oligomers, the mole fraction p_M of monomer calculated from isodesmic (18) or monomer–dimer–polymer (9) descriptions of caffeine equilibria was used as above to correct each intermolecular NOE contribution. This method of estimation of distance is supported by a recent study of solutions of trinitrotoluene complexes with aromatic hydrocarbons (44) in which good agreement was found between internuclear distances calculated from one-dimensional NOE difference experiments (as above) or from selective one-dimensional NOE build-up rates, with X-ray measurements of the solid complexes.

Intermolecular NOEs (Table 5) were clearly detected in at least one direction between the proton pairs H_8'-H_{10}'', H_8'-H_{11}'', H_{10}'-H_{12}'', H_{11}'-H_{12}'', where the single and double primes distinguish atoms of the two caffeine molecules of the dimer. For H_8'-H_{12}'' any intermolecular NOE was overwhelmed by the intramolecular effect. Certain NOEs denoted "ps" in Table 5, such as H_{10}'-H_{11}'', were not detectable even if they had been present, due to partial saturation resulting from closely-spaced resonances. For each pair, the total NOE is averaged over equivalent methyl protons and over dimers having the top and bottom caffeine molecules reversed.

Discussion

Analysis of NOE and modelling results

Table 3 records the average intermolecular H—H distances obtained from modelling for each conformer **A1**–**B5**, averaged over all contributing protons. It also gives the overall values of these distances, averaged over the nine conformers. The averaging was carried out in proportion to the inverse third power of the distance (43), according to eqs. [1]–[3] in Appendix.

Seven of the nine conformers have one or more interproton distances in the range of 6–8 Å, clearly too long to produce measurable internuclear NOEs. The other two conformers (**A2** and **A3**) yield no such long distances, but are of relatively high energy (under all force fields and dielectric constant settings investigated) and must be presumed to have low populations. Therefore, modelling implies that the observed NOE signals must originate in a mixture of conformers. Indeed, the four H—H distances averaged over all conformers (bottom line in Table 3) are about 4.7 Å, in excellent agreement with the average internuclear distance (4.6 ± 0.2 Å) calculated from the NOEs using the monomer–dimer–polymer model for caffeine equilibria. The same measured average based on the isodesmic model is lower (4.0 ± 0.2 Å), as this model predicts a smaller proportion of caffeine oligomers at a given concentration, and therefore a higher average intermolecular NOE per oligomer.

In view of the approximations used in deriving the intermolecular distances from the NOE data, and uncertainties in equilibrium constants, these observations do not decisively favour the monomer–dimer–polymer model over the isodesmic model, although in principle the models could be distinguished by sufficiently accurate measurements of this type. However,

[a] Each NOE-difference spectrum was independently processed and integrated three times. For each proton pair, the table shows the average total % NOE, with errors in parentheses, then the estimated intramolecular NOE contribution. NOEs that could not be measured due to partial saturation are marked "ps," and those that could not be measured due to other experimental causes are marked "nm." The average intermolecular distances, with errors in parentheses, calculated from the residual intermolecular NOE, after subtraction of the intramolecular component and correction for oligomers, is based on the monomer–dimer–polymer model (see text). The entries for 0.001 M caffeine are total NOEs, or upper limits; errors precluded intermolecular distance estimates at this concentration.

the conclusion that the most consistent description of caffeine dimerization is a dynamic exchange among nine dimer conformers of comparable energy is strongly supported, because intermolecular NOEs are observed between all proton pairs for which measurement was possible.

Conformations of higher caffeine aggregates

In the first approximation, the interactions between the molecules of the larger aggregates should closely correspond to those of the dimer. For example, formally the trimer can be of four possible types, **A-A**, **A-B**, **B-A**, or **B-B**, and further distinctions can be made between conformers such as **A1-A1**, **A1-A2**, . . . **B5-B5**, yielding a total of $9 \times 9 = 81$ possible trimer conformers. However, their energies are unlikely to be the exact sums of dimer energies, and it is possible that the higher aggregates are generally less capable of variation than the dimer. There is evidence from infrared spectroscopy that the C=O groups are accessible to water in the caffeine dimer but not in the higher aggregates (9), which may imply greater uniformity of the latter. Greater uniformity of the higher aggregates agrees with the equilibrium constant for their formation, which is much smaller than the constant for the dimerization, presumably due to entropic factors.

Possible physiological consequences

The mode of action of mood-altering drugs upon the central nervous system involves binding to tissue receptors in the agonist or antagonist mode (45). The stacking association of caffeine with itself and with other small molecules, such as adenosine, is likely to lead to a dynamic equilibrium between many complexes. This would affect the availability of caffeine and adenosine to bind with receptors.

Hirsh (46) has reviewed many of the anomalous responses of caffeine in the central nervous system, such as increasing locomotor activity in animals. If the dose is increased progressively, a maximum occurs and then further increases cause a progressive decrease in activity. As these effects are presumed to be related to caffeine's competitive binding to adenosine receptors in the brain (47), stacking may contribute to an anomalous dose–response curve. Preliminary work in our laboratory (G.A.K. and K.D.B.) has demonstrated that adenosine's dose–response curve as a vasodilator also has anomalies. For example, when adenosine was given with peptides such as angiotensin II or oxytocin, the physiological responses to the peptide were altered (19). Studies of the binding of caffeine, adenosine, and vasoactive peptides to solubilized adenosine receptors, with concurrent monitoring of the degree of self- and hetero-stacking, might elucidate these phenomena and help determine if the reported anomalies in caffeine responses are in fact connected with stacking interactions occurring under physiological conditions.

Appendix: averaging the H···H distances

The averaging of the H···H distances in each conformer was done proportionately to the inverse third power of the distance. Averaging over the n equivalent proton distances R_{ij} for the *i*th equivalent proton pair in conformer *j* was done as follows:

$$[1] \quad (1/R_{j,\mathrm{av}}) = [(1/n)\ \Sigma_i\ (1/R_{ij})^3]^{1/3}$$

Six proton pairs had to be thus averaged in the case of H_8'-H_{10}'' and H_8'-H_{11}'' (for example, in the latter case the pairs H_8'-H_{11a}'', H_8'-H_{11b}'', H_8'-H_{11c}'', H_8''-H_{11a}', H_8''-H_{11b}', and H_8''-$H11_c'$). Eighteen proton pairs had to be averaged in the case of H_{10}'-H_{12}'' and H_{11}'-H_{12}''.

Final averaging over the equivalent proton pairs and over the nine conformers was done as follows,

$$[2] \quad (1/R_{\mathrm{av}}) = \{\Sigma_j\ P_j\ [(1/n)\ \Sigma_j\ (1/R_{ij})^3]\}^{1/3}$$

where P_j is the population factor for conformer *j*. The population factors at temperature $T = 300$ K were calculated from the energies E_j and multiplicities M_j of the individual conformers by assuming a Boltzmann distribution:

$$[3] \quad P_j = M_j \exp(-E_j/RT) \,/\, \Sigma_j\ M_j \exp(-E_j/RT)$$

Coriolis coupling constants and inertial defect of B_2F_4 by ab initio calculations and the iterative method

Marcos Loroño, J.R. Anacona, and Anibal Sierralta

Abstract: Structural parameters, harmonic frequencies, and force constants of B_2F_4 were obtained in internal coordinates from ab initio RHF calculations with the 6-311G* basis set. The results obtained are used to calculate the Coriolis coupling constants and the inertial defect for $^{10}B_2F_4$ and $^{11}B_2F_4$ and to compare these values with those obtained by using the autoconsistency method. Both the ab initio and the iterative force fields, despite some significant differences, reproduce the vibrational wave numbers equally well and yield nearly the same Coriolis coupling constants and inertial defects. The calculated inertial defects for $^{10}B_2F_4$ and $^{11}B_2F_4$ are –0.942 and –0.919 amu Å^2, respectively.

Key words: Coriolis coupling constants, inertial defect, B_2F_4, harmonic frequencies, force constants.

Résumé : Faisant appel à des calculs ab initio RHF avec l'ensemble de base 6-311G*, on a déterminé les paramètres structuraux, les fréquences harmoniques et les constantes de force du B_2F_4 dans des coordonnées internes. On a utilisé ces résultats pour calculer les constantes de couplage de Coriolis et le défaut d'inertie du $^{10}B_2F_4$ et du $^{11}B_2F_4$ et on a comparé ces valeurs à celles obtenues en faisant appel à la méthode autocohérente. Les méthodes ab initio et d'itération des champs de force, malgré des différences importantes, permettent toutes les deux de reproduire aussi bien les nombres d'onde vibrationnels et elles conduisent pratiquement aux même constantes de couplage de Coriolis et aux même défauts d'inertie. Les défauts d'inertie du $^{10}B_2F_4$ et du $^{11}B_2F_4$ sont respectivement –0,942 et –0,919 amu Å^2.

Mots clés : constantes de couplage de Coriolis, défaut d'inertie, B_2F_4, fréquences harmoniques, constantes de force.

[Traduit par la rédaction]

Introduction

Diboron tetrafluoride, B_2F_4, has been shown (1) by X-ray diffraction to be planar in the crystalline state at –120°C with molecular symmetry D_{2h}. Gayles and Self (2) reported the infrared spectra of the gaseous and solid states and, by a comparison of these data, suggested that the spectral difference could be attributed to a structural change from D_{2h} in the solid to D_{2d} in the gaseous state.

Further spectroscopic data have been gathered for B_2F_4 in both gas (3, 4) and solid phases (4) as well as in matrix isolation (5). Interpretations of data from the earlier studies (2–4) as well as results of theoretical calculations (6–8) are in disagreement concerning the molecular conformation; however, the later infrared and Raman work (4) revealed no violation of the mutual exclusion rule, suggesting D_{2h} symmetry for the molecule in both gas and solid phases. The latest study of gaseous B_2F_4 by electron diffraction (9) confirms that the molecule has a planar equilibrium conformation.

No experimental information regarding Coriolis coupling constants for B_2F_4 has been published before and the precise calculation of these quantities can be extremely useful for the analysis of rotational structure and prediction of rovibrational band shapes. New methodologies have been proposed (10–12) to describe the classical dynamics of two vibrational modes of a polyatomic molecule coupled by Coriolis interaction to overall molecular rotation; however, in order to appreciate the influence of the force field on Coriolis coupling constant values we have used traditional methods (13) that are still applicable today. Thus, we carried out normal coordinate calculations to obtain force constants and vibrational wave numbers, utilizing the 6-311G* basis set. The iterative autoconsistency method was also applied in order to compare the results with those obtained from ab initio calculations. The results of these studies are reported herein.

Ab initio calculations

The HONDO-8 program from the MOTECC-90 (TM) package was used to carry out the LCAO-MO-SCF restricted Hartree–Fock calculations for diboron tetrafluoride in order to predict the molecular structures and also to provide the force constants and vibrational wave numbers. The energy minimum with respect to nuclear coordinates (–447.54 a.u.) was obtained by simultaneous relaxation of all geometric parameters using the gradient method of Pulay (14, 15). The 6-311G* basis set was utilized to carry out the calculations assuming a planar conformation (D_{2h} symmetry). The optimized geometric parameters do not differ

significantly from the experimental values determined from the electron diffraction study (9). There is excellent agreement between the calculated value of 1.31 Å for the B—F bond distance and the experimental value of 1.317(2) Å. Similar agreement is also noted between the calculated value of 1.74 Å for the B—B bond distance and the experimental value of 1.720(4) Å. The calculated value for the F-B-B angle (121.28°) also agrees well with the experimental value of 121.4(1)°. Interestingly, these results were the same when the smaller MIDI-3 basis set was used and they agree well with the reported values of ab initio optimized geometries for B_2F_4 with the 6-31G* basis set (16, 17).

A normal coordinate analysis was carried out in order to obtain a more complete description of the molecular motions involved in the fundamental vibrations as well as to provide a more definitive basis for the vibrational assignment. These analyses were performed utilizing ab initio calculations and Wilson's approach (18) to the force field problem of partitioning the secular equation determining the vibrational wave numbers into *F* and *G* matrices. Twelve symmetry coordinates constructed from fourteen internal coordinates (Table 1), along with the Cartesian coordinates obtained for the optimized structures, were used to calculate the *G* and *B* matrices. The internal coordinates are shown in Fig. 1 and they are the same as those defined previously for ethylene (19).

[a] Observed wave numbers from ref. 4.
[b] Calculated IR intensities in km/mol.

Unscaled 6-311G* vibrational wave numbers are listed in Table 2 in the columns labelled ab initio. It can be observed that the calculated wave numbers are significantly higher than those observed experimentally. Therefore, the force fields calculated with the 6-311G* basis set were subsequently scaled by using factors of 0.9 for all diagonal force constants. For the interaction force constants no geometric average of the scaling factors was used. With this procedure the calculated frequencies are in much better agreement with the observed frequencies. Table 2 also contains the predicted vibrational wave numbers with a different set of force constants obtained by the iterative method. The calculated dipole moment derivatives were used to evaluate the theoretical absolute infrared intensities for the ungerade motions of B_{1u}, B_{2u}, and B_{3u}, which are only IR active. The calculated values in km/mol are included in Table 2; the experimental values are not given, as no accurate measurements seem to have been carried out for B_2F_4. The scaled force fields in internal coordinates calculated by the HONDO-8 program with the 6-311G* basis set are shown in Table 3.

Iterative method (20)

To calculate the wave numbers of the normal molecular vibrations in the harmonic approximation, the following secular equations were used:

$$[1] \quad G_{^{10}B} F_{^{11}B} L^{cal}_{^{10}B} = L_{^{10}B} \Lambda_{^{11}B} \; ; \; G_{^{11}B} F_{^{10}B} L^{cal}_{^{11}B} = L_{^{11}B} \Lambda_{^{11}B}$$

where $G_{^{10}B}$and $G_{^{11}B}$ are the matrices of kinetic coefficients of isotopically substituted molecules containing ^{10}B or ^{11}B isotopes. F characterizes the molecular force field and the columns of the matrix L are the coefficients of the normal coordinates. The elements of the diagonal matrix Λ are vibrational frequency parameters. Under suitable conditions of normalization the experimental set of vibrational frequency parameters Λ^{exp} is reproduced exactly by the matrix F.

$$[2] \quad F_{^{10}B} = \tilde{L}^{-1}_{^{10}B} \Lambda^{exp}_{^{10}B} L^{-1}_{^{10}B} \quad ; \quad F_{^{11}B} = \tilde{L}^{-1}_{^{11}B} \Lambda^{exp}_{^{11}B} L^{-1}_{^{11}B}$$

Using eq. [2], with a starting F_0 matrix and $\Lambda^{exp}_{^{10}B}$ and $\Lambda^{exp}_{^{11}B}$ matrices, the secular equations of eq. [1] are solved iteratively until the following criteria are satisfied: the difference between $F_{^{10}B}$ and $F_{^{11}B}$ is minimized (<0.01%), the change in force field from one iteration to another is minimal, and the goodness of the fit between the experimental (4) and calculated values of the vibrational wave numbers. The in-plane and out-of-plane internal coordinates considered in the iterative method are similar to those considered in the ab initio calculations. The bond lengths and interbond angles used in the calculations are the experimental values (9). The vibrational representations of the planar configurations of B_2F_4 of D_{2h} symmetry are:

$$\Gamma = 3A_{1g} + A_{1u} + 2B_{1g} + B_{1u} + B_{2g} + 2B_{2u} + 2B_{3u}$$

The matrix G in internal coordinates is reduced by symmetry through the use of a U transformation matrix determined by molecular symmetry and, in order to have all force constants in mdyn Å^{-1}, the angle bending coordinates were scaled with the B—F bond distance. The symmetry coordinates used in the iterative method are listed in Table 1, whereas in Table 2 it can be observed that the calculated frequencies are concordant with the experimental values.

Coriolis coupling constants

To calculate the 23 nonvanishing elements of the Coriolis coupling constants the well-known matrix equation proposed by Meal and Polo (21) was used.

$$[3] \quad \zeta^{\alpha} = L^{-1} \, \tilde{C}^{\alpha} L^{-1}$$

where

$$C^{\alpha} = B \, M^{1/2} \, T^{\alpha} \, M^{1/2} \, \tilde{B}, \quad \alpha = x, y, z$$

T^{α} are matrices of dimension $3N \times 3N$ formed by N identical 3×3 blocks along the diagonal, M is a diagonal matrix whose elements are the atomic masses, B is the transformation matrix between internal and Cartesian coordinates, and L is the symmetrized transformation matrix between internal and normal coordinates. For $^{10}B_2F_4$ and $^{11}B_2F_4$ molecules the y-axis was taken to be perpendicular to the molecular plane and the z-axis to run along the B—B bond. Two L matrices of eigenvectors were used to solve eq. [3], one obtained from ab initio calculations and the other from application of the iterative method. The calculated Coriolis coupling constants are given in Table 4. Both sets of Coriolis coupling constants fulfill the sum rules derived by Meal and Polo (21) and Kuchitsu et al. (22) and were used to evaluate the inertial defect in the ground vibrational state.

Inertial defects

The general formula for the inertial defect of a planar molecule is

$$[4] \quad \Delta_{total} = \Delta_{vib} + \Delta_{cent} + \Delta_{elect}$$

where Δ_{vib} is the contribution to the inertial defect of the vibrational motion in the ground state and Δ_{cent} is a minor contribution due to centrifugal distortion. Δ_{elect}, the electronic contribution due to π-electrons, was not considered because, as can be seen in Table 3, the B–B stretching force constant has a value of 2.635 mdyn Å^{-1}, suggesting that there is no π-donation from halogen atom to boron, with some subsequent $p\pi$–$p\pi$ overlap between the two boron orbitals. Δ_{vib} is the major contribution to the total inertial defect and in the present case it was the only contribution calculated according to the formalism of Jeyapandian and Savari Raj (23).

$^{11}B_2F_4$	1.001	–1.920	–0.919	0.955	–1.909	–0.954

$$[5]\qquad \Delta_{vib,\ in\ plane} = \frac{h}{2\pi^2 c}\left\{\sum_S\sum_{S'}(\zeta^y_{SS'})^2\left[\frac{1}{\nu s}+\frac{1}{\nu s'}-\frac{1}{\nu s+\nu s'}\right]\right\}$$

$$[6]\qquad \Delta_{vib,\ out\ plane} = -\frac{h}{2\pi^2 c}\left\{\sum_S\sum_t[(\zeta^x_{St})^2+(\zeta^z_{St})^2]\left[\frac{1}{\nu s}-\frac{1}{\nu s+\nu t}\right]+\frac{1}{2}\sum_t\frac{1}{\nu t}\right\}$$

The in-plane and out-of-plane contributions to Δ_{vib} are given in Table 5.

Discussion

We have calculated two different sets of force constants; one of them was obtained by using the iterative method, which is an empirical method of carrying out a simultaneous fit for a pair of isotopically substituted molecules. The iterative procedure has the advantage that rather high variations in the matrix F_0 lead to little or no change in the final matrix F. The other set of force constants was obtained by ab initio Hartree–Fock calculations using the TZP basis, which provides harmonic force constants to a much better accuracy. The diagonal harmonic terms in internal coordinates are obtained within the reasonable accuracy of typically 10–30% and, more importantly, the deviations are very systematic in a qualitative sense.

Table 6. Comparison of force constants (mdyn Å^{-1}) for B_2F_4.

	Ab initio	Iterative
Stretch		
B–B (*D*)	2.655	6.739
B–F (*Q*)	6.896	6.011
Bend		
FBF (α)	0.899	0.485
BBF (β)	0.521	0.290
Stretch–stretch		
BB/BF	0.099	0.775
BF_4/BF_5	0.906	0.510
BF_4/BF_6	0.144	–0.587
BF_4/BF_3	0.112	–0.630
Stretch–bend		
BB/BBF	0.000	0.168
BB/FBF	–0.122	–0.337
BF/FBF (α_1)	0.242	0.146
BF/FBF (α_2)	–0.066	–0.121
BF/BBF (β_3)	0.229	0.150
BF/BBF (β_4)	–0.110	–0.183
Bend–bend		
F_4BF_5/F_3BF_6	0.052	–0.052
F_5BB/BBF_3	–0.139	–0.026
F_5BB/F_4BF_5	0.000	–0.242
F_3BB/BBF_6	0.000	0.026

The scaled ab initio force constants are listed in Table 6, along with those given by the iterative method, and there are some significant differences that should be noted. For example, the ab initio B–B stretch and the B–B/B–F interaction constants are significantly smaller than those obtained by the iterative method. The ab initio values for the BF_4/BF_6 and BF_4/BF_5 stretch–stretch and the F_4BF_5/F_3BF_6 bend–bend interaction constants are found to be positive, with values 0.144, 0.112, and 0.052 mdyn Å^{-1}, respectively, whereas negative values of –0.587, –0.630, and –0.052 mdyn Å^{-1}, respectively, were obtained through the iterative method. Finally, the iterative FBF and BBF bends and the BF_4/BF_5 interaction constant are about five-ninths of the scaled ab initio values.

The scaled ab initio force constant matrices show a large number of off-diagonal elements close to zero. However, there is only one unusually large value, the bond–bond interaction constant with values of $f_{B\text{-}F/B\text{-}F} = 0.906$. The scaled ab initio bond stretching force constants increase in the order $f_{B\text{-}B} < f_{B\text{-}F}$ with values 2.655 and 6.896 mdyn Å^{-1}, respectively, and they follow the reverse order of the stretching force constant values obtained by using empirical methods (3, 24). In general, the iterative force constants are not very close to those obtained from the scaled ab initio values; however, the differences in the force fields do not lead to large differences in the normal modes. In consequence, the Coriolis coupling constants show themselves to be only slightly sensitive to variations in the force constants. The largest zeta values are the (ν_1, ν_2) and (ν_8, ν_9) interactions along the *x*-axis, the (ν_1, ν_3) interaction along the *y*-axis, and the (ν_6, ν_{10}) interaction along the *z*-axis in all molecules. The Coriolis coupling constants follow sum rules with an average deviation of less than 0.02%. The calculated inertial defects follow the order $^{10}B_2F_4 < {}^{11}B_2F_4$, in agreement with the presence of heavier atoms in the molecule.

A kinetic study of the reactions of dimethyl sulfide bridged tetramethylplatinum(II) and octamethylplatinum(IV) complexes with dimethyl sulfide and bidentate ligands

Katsuyuki Nakayama, Yuichi Kondo, and Koji Ishihara

Abstract: Kinetics for the reactions of

[1] $[Pt^{IV}_2Me_8\ (\mu\text{-}SMe_2)_2] + 2\ Me_2S \underset{k_d}{\overset{k_f}{\rightleftharpoons}} 2\ [Pt^{IV}Me_4(SMe_2)_2]$

[2] $[Pt^{II}_2Me_4\ (\mu\text{-}SMe_2)_2] + 2\ Me_2S \overset{k_r}{\rightarrow} 2\ [Pt^{II}Me_2(SMe_2)_2]$

and

[3] $[Pt^{IV}_2Me_8\ (\mu\text{-}SMe_2)_2] + 2NN \rightarrow 2\ [Pt^{IV}Me_4(NN)] + 2\ Me_2S$

where NN = bipy or 4,4′-Me_2-bipy, have been studied at various temperatures and pressures. Reaction [3] was shown to consist of the rapid conversion of the dimer to a monomer and the much slower subsequent substitution of the dimethyl sulfide with bidentate ligand NN:

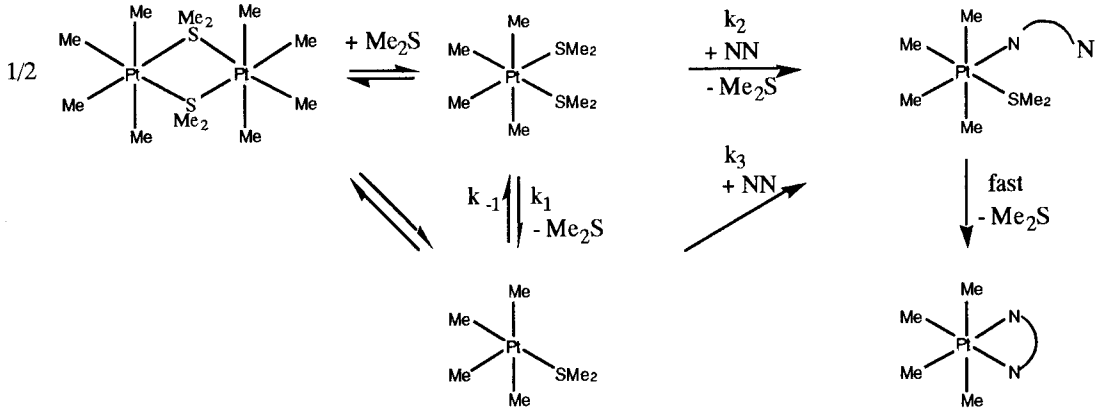
$[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2] + 2\ Me_2S \rightleftharpoons 2\ [Pt^{IV}Me_4(SMe_2)_2]$

and

$[Pt^{IV}Me_4(SMe_2)_2] + NN \rightarrow [Pt^{IV}Me_4(NN)] + 2\ Me_2S$

The rate constants and activation parameters for the reactions are as follows: $k_f = 3.16 \pm 0.06\ M^{-1}\ s^{-1}$ (25°C), $\Delta H^{\neq}_f = 51.8 \pm 1.7$ kJ mol^{-1}, $\Delta S^{\neq}_f = -61.0 \pm 5.8$ J mol^{-1} K^{-1}, $k_d = 1.18 \pm 0.22\ M^{-1}\ s^{-1}$ (25°C), $\Delta H^{\neq}_d = 65 \pm 22$ kJ mol^{-1}, $\Delta S^{\neq}_d = -26 \pm 73$ J mol^{-1} K^{-1} for reaction [1] in *n*-hexane; $k_f = 6.68 \pm 0.06\ M^{-1}\ s^{-1}$ (25°C), $\Delta H^{\neq}_f = 58.0 \pm 3.1$ kJ mol^{-1}, $\Delta S^{\neq}_f = -34.5 \pm 10.5$ J mol^{-1} K^{-1}, $\Delta V^{\neq}_f = -10.7 \pm 1.3$ cm^3 mol^{-1} for reaction [2] in dichloromethane; $k_2 = (7.09 \pm 1.89) \times 10^{-4}\ M^{-1}\ s^{-1}$, $\Delta H^{\neq}_2 = 95 \pm 21$ kJ mol^{-1}, and $\Delta S^{\neq}_2 = 18 \pm 70$ J mol^{-1} K^{-1}, $\Delta V^{\neq}_2 = 9 \pm 9$ cm^3 mol^{-1} for reaction [3] with bipy, and $k_1 = (1.10 \pm 0.10) \times 10^{-2}\ s^{-1}$, $k_3/k_{-1} = (4.33 \pm 0.30) \times 10^{-2}$, and $k_2 = (6.09 \pm 1.35) \times 10^{-4}\ M^{-1}\ s^{-1}$ for reaction [3] with 4,4′-Me_2-bipy. It was shown that reactions [1] and [2] proceed nucleophilically without any intermediates, and reaction [3] proceeds through a mainly k_2 path for NN = bipy and through both k_1 and k_2 paths for NN = 4,4′-Me_2-bipy, without appreciable participation of the direct reaction between the dimer and NN as shown by the following reaction scheme.

Key words: octamethylplatinum(IV) dimer, tetramethylplatinum(II) dimer, reaction mechanism, high-pressure kinetics.



Received June 27, 1997.

Résumé : Opérant à diverses températures et à diverses pressions, on a examiné la cinétique des réactions :

[1] $[Pt^{IV}_2Me_8\ (\mu\text{-}SMe_2)_2] + 2\ Me_2S \underset{k_d}{\overset{k_f}{\rightleftharpoons}} 2\ [Pt^{IV}Me_4(SMe_2)_2]$

[2] $[Pt^{II}_2Me_4\ (\mu\text{-}SMe_2)_2] + 2\ Me_2S \overset{k_f}{\rightarrow} 2\ [Pt^{II}Me_2(SMe_2)_2]$

et

[3] $[Pt^{IV}_2Me_8\ (\mu\text{-}SMe_2)_2] + 2NN \rightarrow 2\ [Pt^{IV}Me_4(NN)] + 2\ Me_2S$

dans laquelle NN = bipy ou 4,4′-Me_2-bipy. On a montré que la réaction [3] comporte une conversion rapide du dimère en un monomère et en une substitution subséquente beaucoup plus lente du sulfure de diméthyle par le coordinat bidentate NN :

$[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2] + 2\ Me_2S \rightleftharpoons 2\ [Pt^{IV}Me_4(SMe_2)_2]$

et

$[Pt^{IV}Me_4(SMe_2)_2] + NN \rightarrow [Pt^{IV}Me_4(NN)] + 2\ Me_2S$

Les constantes de vitesse et les paramètres d'activation des réactions sont les suivants : $k_f = 3{,}16 \pm 0{,}06\ M^{-1}\ s^{-1}$ (25°C), $\Delta H^{\neq}_f = 51{,}8 \pm 1{,}7$ kJ mol^{-1}, $\Delta S^{\neq}_f = -61{,}0 \pm 5{,}8$ J mol^{-1} K^{-1}, $k_d = 1{,}18 \pm 0{,}22\ M^{-1}\ s^{-1}$ (25°C), $\Delta H^{\neq}_d = 65 \pm 22$ kJ mol^{-1}, $\Delta S^{\neq}_d = -26 \pm 73$ J mol^{-1} K^{-1} pour la réaction [1] dans l'hexane; $k_f = 6{,}68 \pm 0{,}06\ M^{-1}\ s^{-1}$ (25°C), $\Delta H^{\neq}_f = 58{,}0 \pm 3{,}1$ kJ mol^{-1}, $\Delta S^{\neq}_f = -34{,}5 \pm 10{,}5$ J mol^{-1} K^{-1}, $\Delta V^{\neq}_f = -10{,}7 \pm 1{,}3$ cm^3 mol^{-1} pour la réaction [2] dans le dichlorométhane; $k_2 = (7{,}09 \pm 1{,}89) \times 10^{-4}\ M^{-1}\ s^{-1}$ (25°C), $\Delta H^{\neq}_2 = 95 \pm 21$ kJ mol^{-1}, $\Delta S^{\neq}_2 = 18 \pm 70$ J mol^{-1} K^{-1}, $\Delta V^{\neq}_2 = 9 \pm 9$ cm^3 mol^{-1} pour la réaction [3] avec la bipy et $k_1 = (1{,}10 \pm 0{,}10) \times 10^{-2}\ M^{-1}\ s^{-1}$ (25°C), $k_3/k_{-1} = (4{,}33 \pm 0{,}30) \times 10^{-2}$, et $k_2 = (6{,}09 \pm 1{,}35) \times 10^{-4}\ M^{-1}\ s^{-1}$ (25°C) pour la réaction [3] avec la 4,4′-Me_2-bipy. On a démontré que les réactions [1] et [2] sont nucléophiles, sans intermédiaires, et que la réaction [3] se produit principalement par une voie k_2 lorsque NN = bipy et par des voies tant k_1 que k_2 lorsque NN = 4,4′-Me_2-bipy, sans participation importante de la réaction directe entre le dimère et NN représentée par le schéma réactionnel précédent.

Mots clés : dimère de l'octaméthylplatine(IV), dimère du tétraméthylplatine(II), mécanisme réactionnel, cinétique à pression élevée.

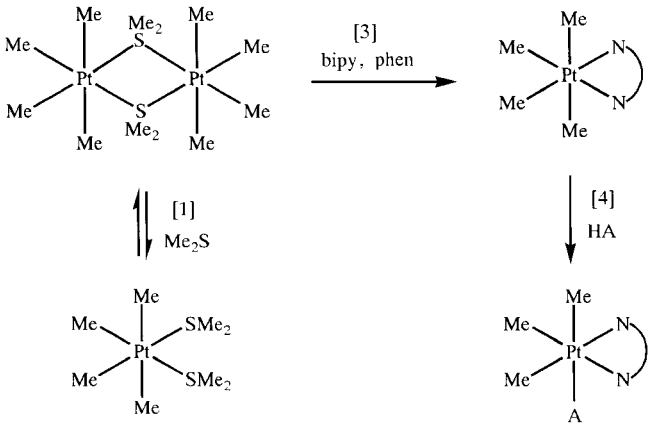
[Traduit par la rédaction]

Introduction

The ligand substitution mechanism of platinum(II) complexes, including organoplatinum(II) complexes such as *cis*-$[PtR_2X_2]$ (where R is an alkyl or aryl group), has been well exemplified by a number of studies (1–5). However, little is known about the substitution mechanism on inert platinum(IV) complexes, despite the fact that Pt(IV) complexes are perhaps no less common. Thus, it is well known that $PtCl_6^{2-}$ is easily produced in solution when platinum metal is dissolved in aqua regia. This gap in our understanding of Pt(IV) complexes is due mainly to the fact that substitution reactions on Werner complexes of Pt(IV) are always accompanied by redox catalysis (6, 7). On the other hand, substitution on comparatively labile methylplatinum(IV) complexes occurs straightforwardly without any side reactions, because of the strong electron-donating property of coordinated methyl groups. In addition, it is of interest mechanistically, because it would proceed electrophilically as well as nucleophilically.

Many mechanistically interesting reactions of methylplatinum(IV) complexes have been reported by Puddephatt et al. (8, 9), some of which are illustrated in Scheme 1. In this scheme, we have already studied kinetically reaction [4], the reaction of $[Pt^{IV}Me_4(NN)]$ (NN = 1,10-phenanthroline or 2,2′-bipyridine) with HA (HA = formic, acetic, benzoic, or salicylic acid), and have shown that it proceeds with an S_E2 mechanism (10). We report here on the ligand substitution mechanism for reactions [1] and [3], and the reaction of $[Pt^{II}_2Me_4(\mu\text{-}SMe_2)_2]$ with dimethyl sulfide as well.

Scheme 1



Experimental

Materials

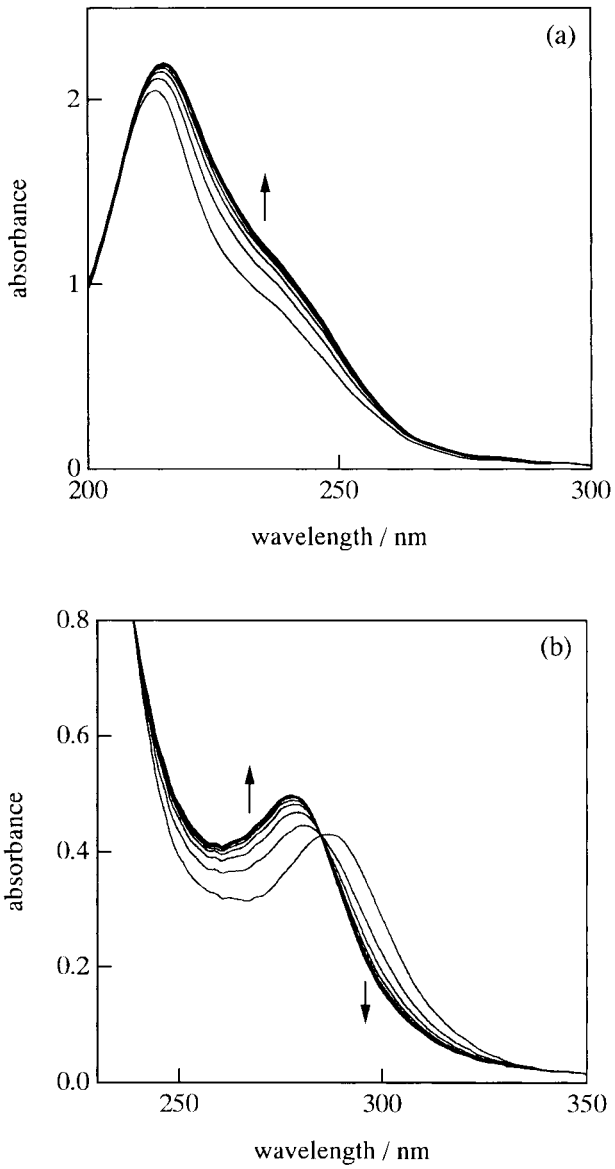
$[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2]$ and $[Pt^{II}_2Me_4(\mu\text{-}SMe_2)_2]$ were synthesized and recrystallized according to the literature (2, 8). Deuterated solvents (E. Merck), dehydrated solvents (Kanto Chemical Co. Inc., Tokyo), and the other reagent grade chemicals (Kanto) were used as received. Sample solutions were prepared just before use.

Measurements

Measurements were carried out in a similar manner to the

© 1998 NRC Canada

Fig. 1. UV spectra for the reactions of $[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2]$ in *n*-hexane (*a*) and of $[Pt^{II}_2Me_4(\mu\text{-}SMe_2)_2]$ in dichloromethane (*b*) with dimethyl sulfide at 25°C. (*a*) At every 2 min, $C_{Pt2} = 6.14 \times 10^{-5}$ M, and $C_{Me2S} = 1.34 \times 10^{-3}$ M; (*b*) at every 60 s, $C_{Pt2} = 6.20 \times 10^{-5}$ M and $C_{Me2S} = 3.16 \times 10^{-3}$ M.



previous study (9). The reactions of $[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2]$ and $[Pt^{II}_2Me_4(\mu\text{-}SMe_2)_2]$ with dimethyl sulfide, and $[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2]$ with 2,2′-bipyridine (bipy) and 4,4′-dimethyl-2,2′-bipyridine (4,4′-Me_2-bipy) were followed at 230, 290, 465, and 440 nm, respectively, under pseudo-first-order conditions. The first-mentioned reaction could not be followed at elevated pressures because of the nontransparency of a pair of sapphire optical windows mounted in a high-pressure vessel, which absorbs UV light shorter than 250 nm (11). The second reaction was started by mixing the equilibrated solution of $[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2]$ and dimethyl sulfide with the ligand solution. In the kinetic experiments, the total concentrations of the complex, C_{Pt2} ($Pt_2 = [Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2]$ or $[Pt^{II}_2Me_4(\mu\text{-}SMe_2)_2]$) and dimethyl sulfide, C_{Me2S}, were as follows: $C_{Pt2} = (6.30–7.88) \times 10^{-5}$ M and $C_{Me2S} = (0.928–2.45) \times 10^{-3}$ M for the reaction of $[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2]$ with Me_2S; $C_{Pt2} = (5.50–13.9) \times 10^{-5}$ M and $C_{Me2S} = (1.89–8.20) \times 10^{-3}$ M for the reaction of $[Pt^{II}_2Me_4(\mu\text{-}SMe_2)_2]$ with Me_2S; $C_{Pt2} = (6.38–6.95) \times 10^{-5}$ M and $C_{Me2S} = (0.984–2.25) \times 10^{-3}$ M for the reaction of $[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2]$ with NN (NN = bipy or 4,4′-Me_2-bipy) (see supplementary material, Tables S1–S4[2]). First-order plots were perfectly linear. The same spectrophotometers as those used in the previous study (10) were employed for acquiring data. Each ^{1}H NMR peak was assigned according to the literature (2, 8, 9, 12).

Results and discussion

Kinetics for dimer ⇌ monomer

$$[1] \quad [Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2] + 2\,Me_2S \underset{k_d}{\overset{k_f}{\rightleftharpoons}} 2\,[Pt^{IV}Me_4(SMe_2)_2]$$

$$[2] \quad [Pt^{II}_2Me_4(\mu\text{-}SMe_2)_2] + 2\,Me_2S \overset{k_f}{\rightarrow} 2\,[Pt^{II}Me_2(SMe_2)_2]$$

Figures 1*a* and 1*b* show the spectral change with time for reactions [1] and [2], respectively. Changes in the ^{1}H NMR spectra with time for reactions [1] and [2], shown in Figs. 2*a* and 2*b,* respectively, were consistent with those in spectrophotometry, i.e., the peaks of methyl protons of the dimers diminished with time, while those of methyl protons of the monomers grew. Figures 2*a* and 2*b* also show that reaction [2] proceeds to completion under the present conditions, since the peaks due to the Pt(II) dimer disappear completely, while reaction [1] reaches an equilibrium.

Reactions [1] and [2] were first order with respect to the concentration of the unreacted Pt(IV) or Pt(II) dimer, $[Pt_2]$, thus the rate equation is expressed by eq. [3], where k_{obs} is the conditional pseudo-first-order rate constant.

$$[3] \quad -d[Pt_2] / dt = k_{obs}[Pt_2]$$

For reaction [1], k_{obs} depends not only on the total concentration of the ligand (C_{Me2S}) but also on that of the complex, C_{Pt2}, as is evident in Figs. 3*a* and 3*b*. However, for reaction [2], k_{obs} depends only upon the ligand concentration, i.e., k_{obs} is independent of C_{Pt2} (see Figs. 4*a* and 4*b*), and the plot of k_{obs} vs. C_{Me2S} is linear with zero intercept. Thus, k_{obs} for reaction [2] is simply represented by eq. [4], albeit the expression of k_{obs} for reaction [1] is rather complicated because of the contribution of the reverse reaction.

$$[4] \quad k_{obs} = k_f C_{Me2S}$$

Under the present experimental conditions, $C_{Me2S} >> C_{Pt2}$, reaction [1] can be regarded as a simple equilibrium between a dimer and a monomer such as $A_2 = 2A$. Then, the equation used for the ultrasonic relaxation may be applicable to the present system (13). Thus, k_{obs} for reaction [1] is given by eq. [5] (vide Appendix).

[2] Tables S1–S4, showing numerical values of rate constants for the reactions of $[Pt^{IV}_2Me_8(\mu\text{-}SMe_2)_2]$ with Me_2S and NN, and of $[Pt^{II}_2Me_4(\mu\text{-}SMe_2)_2]$ with Me_2S at various temperatures and pressures (5 pages), have been deposited as supplementary material and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

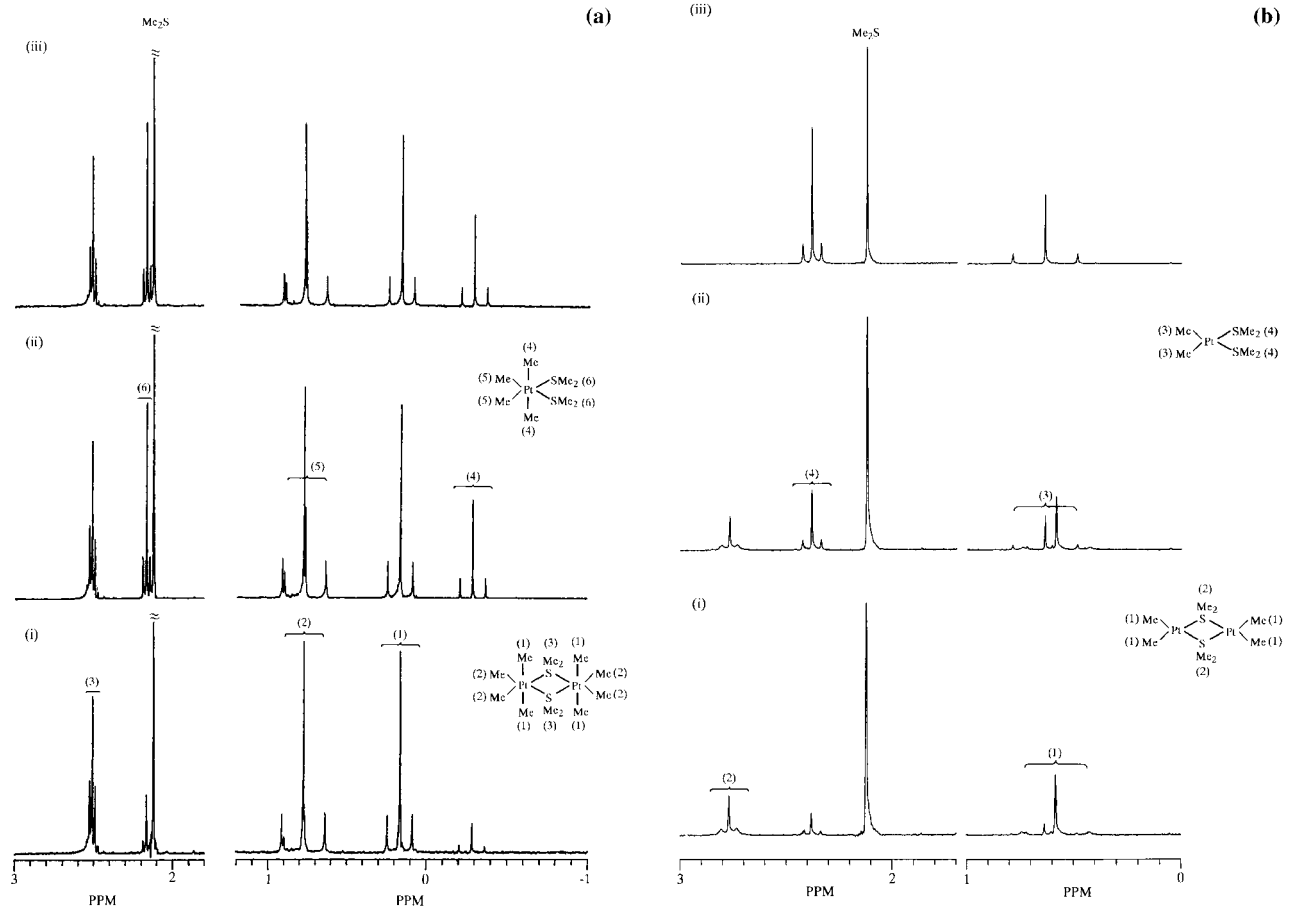
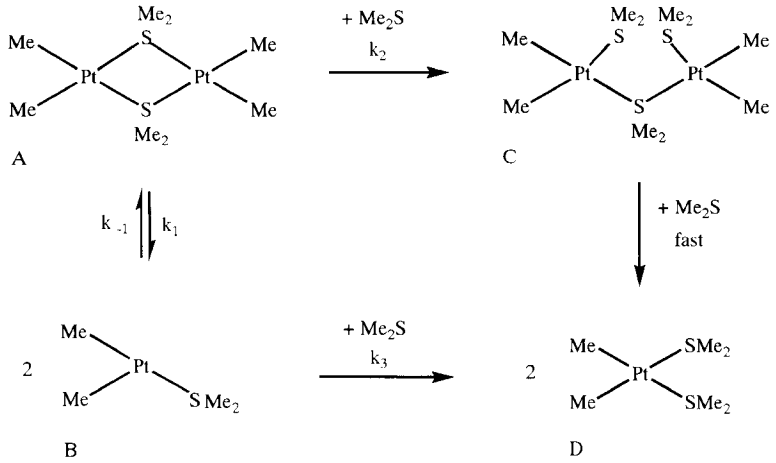
(*a*) $C_{Pt2} = 2.00 \times 10^{-3}$ M and $C_{Me2S} = 1.02 \times 10^{-2}$ M: (*i*) 1, (*ii*) 15, (*iii*) 30 min after the reaction started; (*b*) $C_{Pt2} = 1.29 \times 10^{-3}$ M and $C_{Me2S} = 6.47 \times 10^{-3}$ M at –20°C: (*i*) 1, (*ii*) 10, (*iii*) 160 min after the reaction started.



Scheme 2



[5] $$k_{obs}^2 / (C_{Pt2}\, C_{Me2S}) = k_f^2\, C_{Me2S} / C_{Pt2} + 16\, k_f\, k_d$$

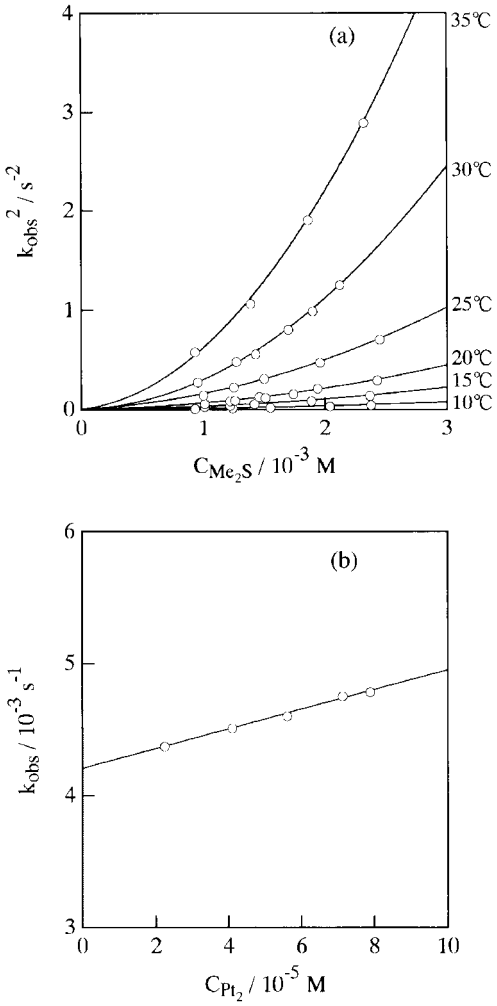
This equation explains well the experimental results as shown in Fig. 5. The activation parameters obtained are listed in Table 1.

The reaction of the Pt(II) dimer with Me_2S is expressed by Scheme 2, which consists of two reaction paths, k_2 and k_3, followed by a much faster step from intermediate C to final product D. Path k_2 involves no detectable intermediates, while path k_3 presumably involves intermediate B with reduced coordination number. When the steady-state approximation is applied to intermediate B, k_{obs} is given by eq. [6].

[6] $$k_{obs} = k_2[Me_2S] + \frac{k_1 k_3\, [Me_2S]}{k_{-1} + k_3[Me_2S]}$$

© 1998 NRC Canada

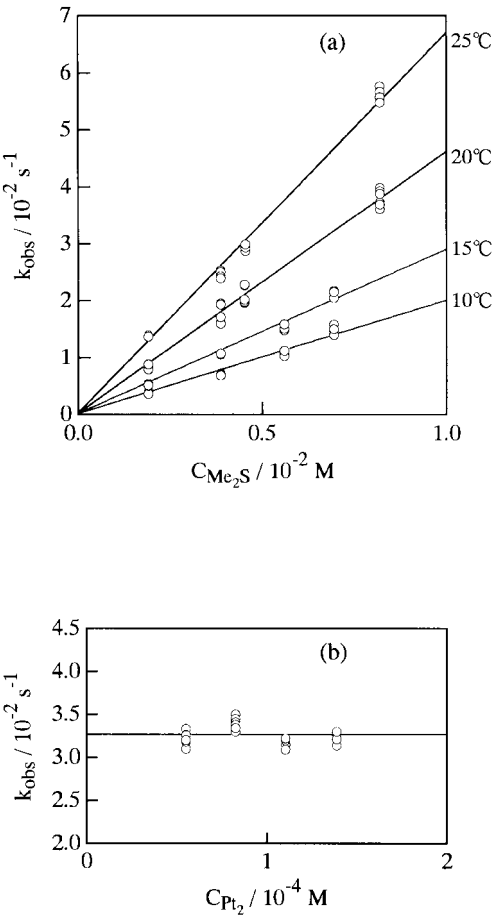
Fig. 3. Dependence of k_{obs} on C_{Me2S} (*a*) and on C_{Pt2} (*b*) for the reaction of $[Pt^{IV}{}_2Me_8(\mu\text{-}SMe_2)_2]$ with Me_2S in *n*-hexane at various temperatures. (*a*) $C_{Pt2} = (6.30–6.93) \times 10^{-5}$ M, $\lambda = 230$ nm; (*b*) $C_{Me2S} = 1.21 \times 10^{-3}$ M, $\lambda = 230$ nm, $T = 25°C$. Solid lines are the best-fit lines drawn by applying a nonlinear least-squares fitting to eq. [5].



The first and second terms on the right-hand side in eq. [6] refer to the k_2 and k_3 paths, respectively. Obviously, the plot of k_{obs} vs. C_{Me2S} ($C_{Me2S} \sim [Me_2S]$, since $C_{Pt2} << C_{Me2S}$) will become linear at higher C_{Me2S}, when the second term contributes significantly to $k_{obs,}$ and k_{-1} is comparable to $k_3[Me_2S]$ at lower C_{Me2S}, which is inconsistent with the present results (see eq. [4] and Fig. 4*a*). However, when $k_{-1} >> k_3[Me_2S]$, which seems to be the present case, the plot will always be linear. That is, the k_2 and k_3 paths are kinetically indistinguishable, though all the spectrophotometric analyses mentioned so far favor simple conversion of the Pt(II) dimer to the product, without an appreciable amount of intermediates.

The same is true for the reaction of the Pt(IV) dimer with Me_2S, namely, it is also kinetically indistinguishable whether or not the k_3 path coexists with the k_2 path in Scheme 3. Then, the same conclusion can be drawn for the Pt(IV) reaction as for the Pt(II) dimer. It is more likely that the observed reactions of the Pt(IV) and Pt(II) dimers proceed mainly through path k_2, because the negative entropies and volumes of activation

Fig. 4. Dependence of k_{obs} on C_{Me2S} (*a*) and on C_{Pt2} (*b*) for the reaction of $[Pt^{II}{}_2Me_4(\mu\text{-}SMe_2)_2]$ with Me_2S in dichloromethane at various temperatures. (*a*) $C_{Pt2} = 8.10 \times 10^{-5}$ M, $\lambda = 290$ nm; (*b*) $C_{Me2S} = 3.47 \times 10^{-3}$ M, $\lambda = 290$ nm, $T = 25°C$.



for these reactions in Table 1 are consistent with the associative interchange mechanism.

Substitution on $[Pt^{IV}{}_2Me_8(\mu\text{-}SMe_2)_2]$ for bidentate ligands

[7] $1/2\ [Pt^{IV}{}_2Me_8(\mu\text{-}SMe_2)_2] + NN \rightarrow [Pt^{IV}Me_4(NN)] + 2\ Me_2S$

(Nn = bipy or 4,4′-Me_2-bipy)

The change in spectra with time for reaction [7] was followed spectrophotometrically in the absence and in the presence, respectively, of excess Me_2S,when a much higher concentration of NN (C_{NN}) than C_{Pt2} was used to ensure pseudo-first-order conditions. In the absence of excess Me_2S, the first-order plots $\ln(A_\infty - A_t)$ vs. t (A_t and A_∞ are the absorbance at time t and at equilibrium, respectively) were curved; however, in the presence of added Me_2S they were entirely linear, which allows us to calculate k_{obs} in eq. [8].

[8] $d[Pt^{IV}Me_4(NN)] / dt = k_{obs}[Pt^{IV}Me_4(NN)]$

^{1}H NMR spectra for reaction [7] are shown in Fig. 6, and changes in peak height of the lines recorded at lower temperature are plotted against time in Fig. 7. The methyl protons of the dimer decrease towards zero with time; however, the methyl protons of both the free Me_2S and of the product complex keep increasing to a finite height even after the methyl

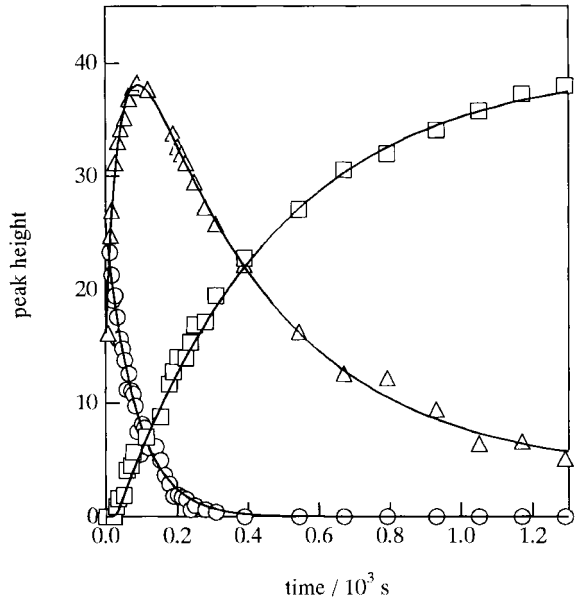
(○) at 0.18 ppm; (Δ) at –0.29 ppm; (□) at –0.62 ppm.



Scheme 4

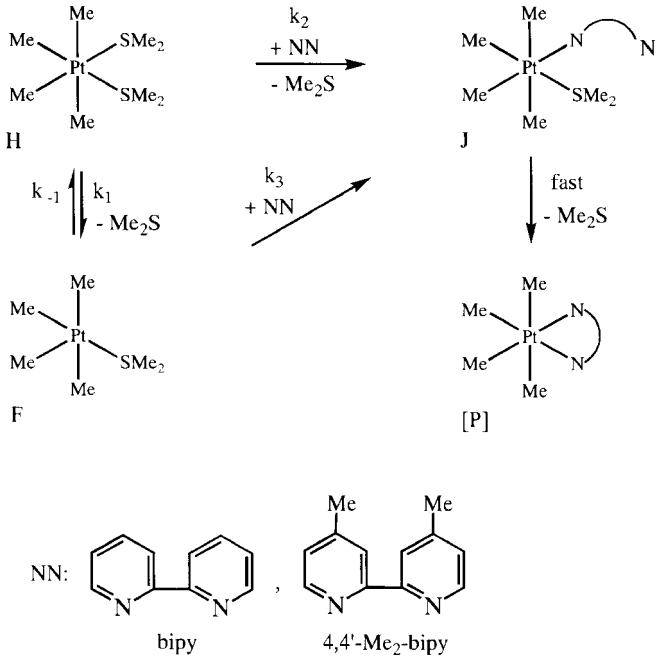


Fig. 7: the values $(1.19 \pm 0.04) \times 10^{-3}$ s^{-1} and $(2.22 \pm 0.09) \times 10^{-4}$ s^{-1} were calculated from the disappearance of the dimer and the appearance of the product, respectively. And the values $(2.39 \pm 0.74) \times 10^{-3}$ s^{-1} and $(2.14 \pm 0.12) \times 10^{-4}$ s^{-1} were estimated from the increase and decrease, respectively, of $[Pt^{IV}Me_4(SMe_2)_2]$. The rate constants for the faster reaction ($(1.19 \pm 0.04) \times 10^{-3}$ s^{-1} and $(2.39 \pm 0.74) \times 10^{-3}$ s^{-1}) indicate

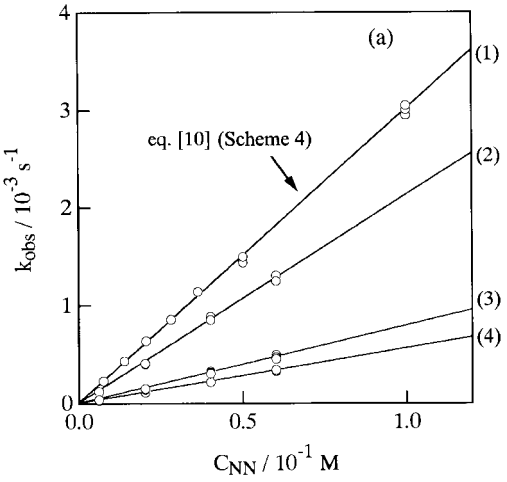
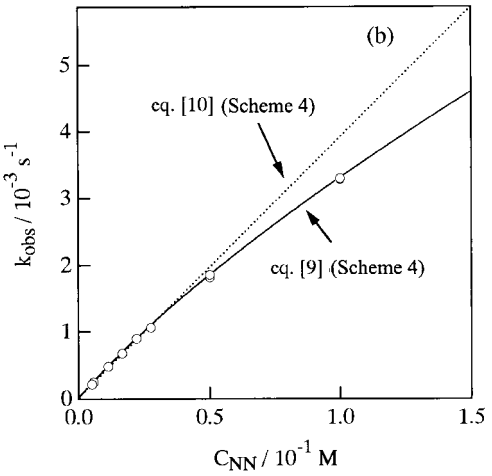
Fig. 8. Dependence of k_{obs} on C_{NN} for the reaction of $[Pt^{IV}{}_2Me_8(\mu\text{-}SMe_2)_2]$ with NN in dichloromethane at 25°C. (*a*) $C_{Pt2} = 1.43 \times 10^{-4}$ M, λ = 465 nm, $C_{Me2S} = 1.29 \times 10^{-2}$ M (1), 1.95×10^{-2} M (2), 5.60×10^{-2} M (3); 7.95×10^{-2} M (4) for NN = bipy; (*b*) $C_{Pt2} = 1.40 \times 10^{-4}$ M, λ = 440 nm, $C_{Me2S} = 1.05 \times 10^{-2}$ M for NN = 4,4′-Me_2-bipy.





that $-d[dimer]/dt = (1/2) \times d[Pt^{IV}Me_4(SMe_2)_2]/dt$ holds, as is required for reaction [1]. For the slower reaction, the rate constants ($(2.22 \pm 0.09) \times 10^{-4}$ s^{-1} and $(2.14 \pm 0.12) \times 10^{-4}$ s^{-1}) agree with each other within the experimental error. These results indicate that the dimer would be unreactive with NN and would be consumed mainly through the reaction of the more reactive $[Pt^{IV}Me_4(SMe_2)_2]$ with NN to form final product $[Pt^{IV}Me_4(NN)]$ without a reverse reaction. That is, the reaction would be stepwise: $[Pt^{IV}{}_2Me_8(\mu\text{-}SMe_2)_2] + 2Me_2S \rightleftharpoons 2[Pt^{IV}Me_4(SMe_2)_2]$ and $[Pt^{IV}Me_4(SMe_2)_2] + NN \rightarrow [Pt^{IV}Me_4(NN)] + 2Me_2S$, and the change in the UV–VIS spectra would correspond to the second step, i.e., from $[Pt^{IV}Me_4(SMe_2)_2]$ to final product $[Pt^{IV}Me_4(NN)]$ via an intermediate with an open chelate ring, because a much higher concentration of Me_2S was employed in the spectrophotometric measurements, which considerably shifts the equilibrium of reaction [1] towards the right-hand side.

© 1998 NRC Canada

The pseudo-first-order rate constant k_{obs} for the reaction with bipy depends linearly on C_{bipy}, although the reaction with 4,4′-Me_2-bipy deviates from a straight line at higher C_{NN}, as shown in Figs. 8*a* and 8*b*, respectively. In contrast, k_{obs} decreases drastically with increasing C_{Me2S} for the reactions of both bipy and 4,4′-Me_2-bipy, as shown in Fig. 9.

Reaction [7] is represented by Scheme 4. Application of the steady-state approximation to coordinatively unsaturated intermediate F gives eq. [9].

$$[9] \quad k_{obs} = k_2[NN] + \frac{k_1k_3[NN]}{k_{-1}[Me_2S] + k_3[NN]} = k_2[NN] + \frac{k_1[NN]}{(k_{-1}/k_3)[Me_2S] + [NN]}$$

In the case of NN = bipy, if $k_{-1}[Me_2S] >> k_3[NN]$ in the second term in eq. [9], then eq. [9] is reduced to eq. [10]. It can be seen from Fig. 9 that the second term in eq. [10] contributes significantly to k_{obs}. The results in Figs. 8*a* and 9 are explained well by eq. [10].

$$[10] \quad k_{obs} = k_2[NN] + \frac{k_1k_3[NN]}{k_{-1}[Me_2S]}$$

On the other hand, when NN = 4,4′-Me_2-bipy, the k_3[NN] term is not negligible compared to $k_{-1}[Me_2S]$, i.e., these two terms are comparable, which makes the plots in Fig. 8*b* curved at higher C_{NN}.

Alternatively, Scheme 5 may explain the results in Figs. 8 and 9, although the rate-determining chelate-ring closure seems to be less plausible in view of the strong *trans* effect of the methyl group (14). In this scheme, when the steady-state approximation is applied to intermediate J with an open chelate ring, and when the fast equilibrium between H and J is followed by rate-determining chelate-ring closure, eqs. [11] and [12] are obtained, respectively.

$$[11] \quad k_{obs} = \frac{k_2k_3[NN]}{k_{-2}[Me_2S] + k_3}$$

$$[12] \quad k_{obs} = \frac{k_2k_3[NN]}{k_{-2}[Me_2S] + k_2[NN]}$$

Equations [11] and [12] fit the experimental results well at $[Me_2S] < 0.1$ M in the case of NN = bipy, and at $[Me_2S] < 0.05$ M in the case of NN = 4,4′-Me_2-bipy, while eqs. [9] and [10] fit the results very well over the concentration range examined, as shown in Fig. 10. Thus, the experimental results agree with the mechanism presented in Scheme 4.

The values of the rate constants and activation parameters obtained are listed in Table 2. In this table, the values of k_1, k_2, and k_3/k_{-1} for the 4,4′-Me_2-bipy system were obtained from eq. [9]. For the bipy system, only the values of k_2 and k_1k_3/k_{-1} are obtainable from eq. [10]. The k_3/k_{-1} value was calculated with the values of k_1k_3/k_{-1} and k_1 for the 4,4′-Me_2-bipy system, which is common to both systems. The k_3/k_{-1} value reflects the reactivity of NN because k_{-1} is common to any NN. Thus, k_3 for the bipy system is slightly smaller than that for 4,4′-Me_2-bipy with higher basicity, which is in accordance with normal nucleophilic substitution. For path k_2, the large errors in the rate constants and activation parameters, which come from intercepts that are often not precisely determinable, make detailed discussion impossible. However, such kinetic parameters still suggest that the reaction of intermediate H with bipy would proceed with a Ia mechanism.

Salt effect on the solubility of *mer*-(+)-tris(L-alaninato)cobalt(III)

Yasuki Yoshimura

Abstract: The effect of NaF, NaCl, NaBr, NaI, $NaNO_3$, CH_3COONH_4, NaH_2PO_4, and $(NH_4)_2SO_4$ on *mer*-(+)-tris(L-alaninato)cobalt(III) (*mer*-(+)-[Co(L-ala)$_3$]) was examined by determining the solubility of the chelate. While the solubility of *mer*-(+)-[Co(L-ala)$_3$] (salting-in effect) increased with the addition of NaCl, NaBr, NaI, and $NaNO_3$, the solubility (salting-out effect) decreased with the addition of NaF, CH_3COONH_4, and NaH_2PO_4. In low salt concentration $(NH_4)_2SO_4$ caused slight salting-in, but in salt concentration >0.5 mol dm^{-3} $(NH_4)_2SO_4$ brought about salting-out. The magnitude of the salting-in effect increased in the order of NaCl < $NaNO_3$ < NaBr < NaI. The standard enthalpy (ΔH_s°) and entropy (ΔS_s°) of dissolution for *mer*-(+)-[Co(L-ala)$_3$] were estimated from the temperature dependence of the solubility. When ΔH_s° was plotted against $T\Delta S_s^\circ$, a single-correlation straight line was obtained for the salts that brought about the salting-in effect. On the basis of these findings, the origin of the salting-in effect was discussed. Furthermore, while NaF, NaCl, and NaBr showed larger salting-in effect on *fac*-tris(glycinato)cobalt(III) (*fac*-[Co(gly)$_3$]) than on *mer*-(+)-[Co(L-ala)$_3$], NaI greatly decreased the solubility of *fac*-[Co(gly)$_3$]. At the present stage, an explanation for this anomalous salting-out effect of NaI cannot be presented.

Key words: salt effect, solubility, thermodynamic parameters of dissolution, *mer*-tris(L-alaninato)cobalt(III), *fac*-tris(glycinato)cobalt(III).

Résumé : En se basant sur la solubilité du chélate, on a déterminé l'effet de NaF, NaCl, NaBr, NaI, $NaNO_3$, CH_3COONH_4, NaH_2PO_4 et $(NH_4)_2SO_4$ sur le *mer*(+)-tris(L-alaninato)cobalt(III) (*mer*-(+)-[Co(L-ala)$_3$]). Alors que le NaCl, le NaBr, le NaI et le $NaNO_3$ augmentent la solubilité du *mer*-(+)-[Co(L-ala)$_3$] (effet de relargage inversé), le NaF, le CH_3COONH_4 et la NaH_2PO_4 diminuent sa solubilité (effet de relargage). Le $(NH_4)_2SO_4$ provoque un relargage à des concentrations supérieures à 0,5 mol dm^{-3}; aux concentrations inférieures, il provoque un faible effet contraire. L'effet de relargage inversé augmente dans l'ordre NaCl < $NaNO_3$ < NaBr < NaI. Utilisant la relation entre la solubilité et la température, on a évalué l'enthalpie standard (ΔH_s°) ainsi que l'entropie de dissolution (ΔS_s°) du *mer*-(+)-[Co(L-ala)$_3$]. Quand on trace un graphique du ΔH_s° en fonction du $T\Delta S_s^\circ$, on obtient une seule ligne droite de corrélation pour les sels qui provoquent un effet de relargage inversé. Sur la base de ces constatations, on discute de l'origine de cet effet. De plus, même si le NaF, le NaCl et le NaBr provoquent un plus grand effet de relargage inversé sur le *fac*-tris(glycinato)cobalt(III) (*fac*-[Co(gly)$_3$]) que sur le *mer*-(+)-[Co(L-ala)$_3$], le NaI diminue fortement la solubilité du *fac*-[Co(gly)$_3$]. Sur la base des données actuelles, il n'est pas possible de présenter une explication pour cet effet anormal de relargage du NaI.

Mots clés : effet de sel, solubilité, paramètres thermodynamiques de dissolution, *mer*(+)-tris(L-alaninato)cobalt(III), *fac*-tris(glycinato)cobalt(III).

[Traduit par la rédaction]

Introduction

It has been extensively reported that the solubilities of nonelectrolytes in water decrease upon the addition of various inorganic salts (salting-out effect) (1–3). Long and McDevit (2) attributed the salting-out effect to an increase in the internal pressure, resulting from an ion–water interaction (2, 4). This theory predicts that many of the inorganic salts result in the salting-out effect on nonpolar nonelectrolytes. However, Sugunan (5) and Sugunan and Thomas (5) have reported that K_2SO_4 and KF markedly increase the solubilities of substituted benzoic acids (salting-in effect) and attributed the salting-in effect to hydrogen bond formation between the benzoic acids and SO_4^{2-} or F^-.

The author has also found that NaCl and Na_2SO_4 result in the salting-out effect on tris(2,4-pentanedionato)cobalt(III) ([Co(acac)$_3$]) but exhibit the salting-in effect on *fac*-(–)-tris(D-prolinato)cobalt(III) (*fac*-(–)-[Co(D-pro)$_3$]) (6). In this paper, (+) and (–) represent dextrorotatory and levorotatory at 589 nm, respectively. Especially, it is worthwhile to notice that $(NH_4)_2SO_4$, which is a well-known salting-out agent for protein, also exhibits a large salting-in effect on *fac*-(–)-[Co(D-pro)$_3$], with salt concentration less than 1 mol dm^{-3}. To elucidate the origin of the specific salting-in effect on *fac*-(–)-[Co(D-pro)$_3$], various experimental attempts are needed, but considerably low solubility of this chelate makes these attempts difficult.

In connection with the above-mentioned experimental

restriction, the salt effect on the solubility of *mer*-tris(amino acidato)cobalt(III) (*mer*-[Co(amino acidato)$_3$]), which is more soluble than the corresponding *fac*-isomer, can be examined more systematically by using a wide variety of salts. Such examination may be expected to provide helpful information concerning the explanation for the above salting-in effect on *fac*-(–)-[Co(D-pro)$_3$].

Amino acid residue in the peptide chain of proteins forms the peptide bonding between the amino group of one amino acid and the carboxyl group of another amino acid. On the other hand, the amino acid in *fac*- and *mer*-[Co(amino acidato)$_3$] binds to the cobalt ion through both the amino nitrogen and the carboxylato oxygen, and resembles the amino acid residue in the peptide chain in terms of the loss of amphoteric character. Thus, the elucidation of the salting-in effect on *fac*- and *mer*-[Co(amino acidato)$_3$] may be expected to present a new approach to the salt effect on proteins.

Furthermore, the solubilities of four isomers of tris(L- or D-amino acidato)cobalt(III) (*fac*-(+)-, *fac*-(–)-, *mer*-(+)-, and *mer*-(–)-isomers) considerably differ from one another (7), and at the present stage this difference seems not to be explained clearly (8). In connection with this problem, it is worthwhile to examine the difference in some properties between *fac*- and *mer*-isomers, such as the salt effect on their solubilities.

Thus, in this study the solubility of *mer*-(+)-tris(L-alaninato)cobalt(III) (*mer*-(+)-[Co(L-ala)$_3$]) in aqueous solutions of NaF, NaCl, NaBr, NaI, $NaNO_3$, $(NH_4)_2SO_4$, CH_3COONH_4, and NaH_2PO_4 is determined over the temperature range of 5–35°C, and the salt effect on *mer*-(+)-[Co(L-ala)$_3$] is compared with that on *fac*-(–)-[Co(D-pro)$_3$] and *fac*-tris(glycinato)cobalt(III) (*fac*-[Co(gly)$_3$]).

Experimental

The synthesis and separation of *mer*-(+)-[Co(L-ala)$_3$] were carried out in a manner reported in the literature (9), and the preparation of *fac*-[Co(gly)$_3$] was previously reported (10). The solubilities of *mer*-(+)-[Co(L-ala)$_3$] and *fac*-[Co(gly)$_3$] were accomplished by using the same procedure as previously reported (11).

The solubility in mol kg^{-1} (S_m) is defined as the moles of chelate molecules in 1 kg of an aqueous salt mixture, and the solubility in mol dm^{-3} (S_c) at 25°C is also obtained as previously reported (6). The chelate concentration used to calculate the solubility was determined spectrophotometrically by measuring the absorbances at 542 nm for *mer*-(+)-[Co(L-ala)$_3$] and at 520 nm for *fac*-[Co(gly)$_3$], except for the experiment in aqueous NaF solutions for *fac*-[Co(gly)$_3$] where the absorbance at 217 nm was measured. In the experiment in aqueous NaI solutions, the apparatus for solubility determination was covered with black cloth to prevent the formation of I_3^- species.

Commercial NaF, NaCl, NaBr, NaI, $NaNO_3$, NaH_2PO_4, CH_3COONH_4, and $(NH_4)_2SO_4$ (reagent grade, Wako Chemical Industries Ltd.) were used without further purification. NaF, NaCl, NaBr, NaI, $NaNO_3$, and NaH_2PO_4 were dried for 3 h at 120°C and stored in a silica-gel desiccator. CH_3COONH_4 and $(NH_4)_2SO_4$ were dried in a vacuum desiccator over concentrated H_2SO_4 for several days. For the solubility measurement, the salt concentration in the working solution of each salt was calculated in both mol kg^{-1} and mol dm^{-3} (m_s and c_s, respectively). Redistilled water was used.

Results

The S_m values in aqueous salt solutions are listed in Table 1 for *mer*-(+)-[Co(L-ala)$_3$] and in Table 2 for *fac*-[Co(gly)$_3$]. The S_c values at 25°C of these chelates are tabulated in Table 3.

The solubility measurement was repeated at least four times at each temperature in all cases. The solubilities given in these tables are the mean values of the individual experimental values. The errors given in parentheses denote the deviations at 95% confidence levels and are less than 2%, except for the solubility measurement for *fac*-[Co(gly)$_3$] in aqueous NaI solutions.

In the spectrophotometric determination of *fac*-[Co(gly)$_3$] in the aqueous NaI solutions, the absorbance at 520 nm became extremely small because of the large salting-out effect of NaI. In addition, the absorption of NaI at about 250 nm inhibited the spectrophotometric determination using the absorbance at 217 nm. For these reasons, the errors for the solubility measurement of *fac*-[Co(gly)$_3$] in the aqueous NaI solutions became considerably large. Furthermore, in the region of NaI concentration of 0.5–3.0 mol dm^{-3}, the absorbance at 520 nm was too small to determine the solubility of *fac*-[Co(gly)$_3$].

In the determination of solubility in the aqueous NaI solutions, an absorbance at about 365 nm became progressively large during the course of equilibration because of the formation of I_3^- species. However, since the formation of I_3^- was reduced by covering the apparatus with black cloth, the absorbances of *mer*-(+)-[Co(L-ala)$_3$] at 543 nm and of *fac*-[Co(gly)$_3$] at 520 nm were not affected.

To demonstrate the effect of salts on the solubilities of *mer*-(+)-[Co(L-ala)$_3$] and *fac*-[Co(gly)$_3$], the values of $\log(S_c^\circ/S_c)$ at 25°C are plotted against c_s in Figs. 1 and 2, respectively. S_c° is the solubility in mol dm^{-3} in water. The solubility of *mer*-(+)-[Co(L-ala)$_3$] decreased in the presence of NaH_2PO_4, CH_3COONH_4, and NaF (salting-out) and increased with the addition of NaCl, $NaNO_3$, NaBr, and NaI (salting-in). $(NH_4)_2SO_4$ showed the slight salting-in effect at low c_s values but resulted in the salting-out effect at c_s values >0.5 mol dm^{-3}. For *fac*-[Co(gly)$_3$], on the other hand, while the addition of NaF, NaCl, and NaBr resulted in the salting-in effect, the addition of NaI exhibited an extremely large salting-out effect.

Since the solubility values for *mer*-(+)-[Co(L-ala)$_3$] and *fac*-[Co(gly)$_3$] tabulated in Tables 1–3 are fairly small, these saturated solutions may be regarded as being ideal dilute solutions with respect to the chelates. Thus, without an activity correction the standard enthalpy (ΔH_s°) and entropy (ΔS_s°) of dissolution at 25°C for these chelates were estimated, based on the temperature dependence of ln S_m in the same manner as previously reported (12). The standard state for the chelate in solution is 1 mol kg^{-1}.

Discussion

To compare the magnitude of the salt effect on *mer*-(+)-[Co(L-ala)$_3$] with that on *fac*-[Co(gly)$_3$], the experimental data for $\log(S_c^\circ/S_c)$ illustrated in Figs. 1 and 2 were fitted to the following power series for the c_s values

$$[1] \quad \log (S_c^\circ/S_c) = A + k_s c_s + k_s' c_s 2 + \cdots\cdots$$

where k_s and k_s' are the salting coefficients, which indicate the

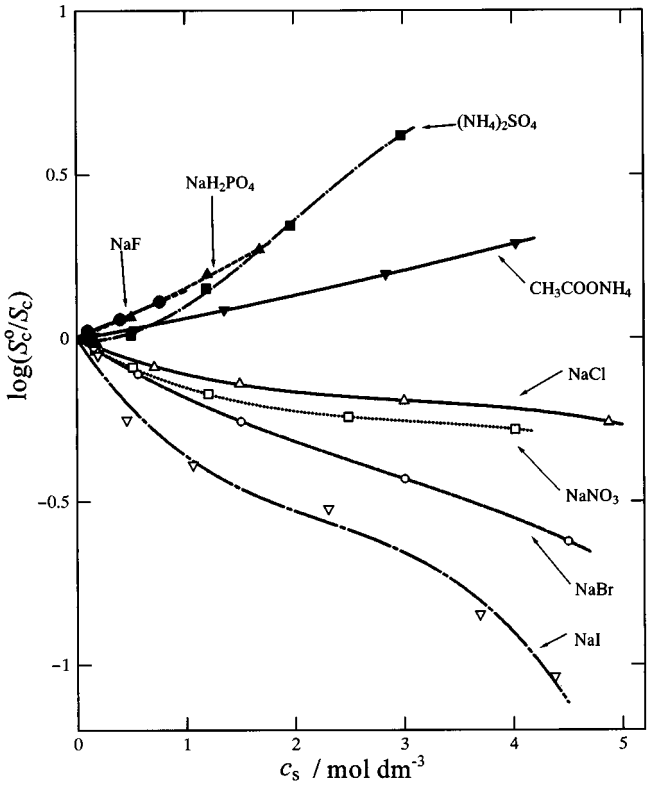
magnitude of the salt effect. The k_s values, which may be estimated as limiting slopes of the curves in Figs. 1 and 2 at $c_s = 0$ mol dm^{-3} (2), are listed in Table 4 where the k_s values for *fac*-(–)-[Co(D-pro)$_3$] reported in the preceding paper (6) are also tabulated. The k_s values of NaI for *fac*-[Co(gly)$_3$] could not be obtained due to the lack of solubility data for NaI concentrations of 0.5–3.0 mol dm^{-3}. A positive value for k_s represents the salting-out effect, and a negative value represents the salting-in effect.

In the preceding paper (6), it was postulated that hydrogen bond formation between the proton of the amino group in *fac*-[Co(amino acidato)$_3$] and SO_4^{2-} or Cl^- brings about the salting-in phenomenon. As shown in Table 4, the order of the magnitude of the salting-in effect on *mer*-(+)-[Co(L-ala)$_3$] is $NaCl < NaNO_3 < NaBr < NaI$, and NaF exhibits the salting-out effect. On the other hand, the tendency for hydrogen bond formation with F^- is greater than that with Cl^-. The hydrogen bond formation with Br^- and I^- seems to be improbable. In addition, the salts of SO_4^{2-}, $H_2PO_4^-$, and CH_3COO^-, which can form the hydrogen-bond, exhibit the salting-out effect. These results indicate that the hydrogen bond formation is not the origin of the salting-in phenomenon.

As an attempt to consider the salt effect using the thermodynamic parameters of dissolution, ΔH_s° is plotted against $T\Delta S_s^\circ$ in Fig. 3 for *mer*-(+)-[Co(L-ala)$_3$] and in Fig. 4 for *fac*-[Co(gly)$_3$]. For the salts that bring about the salting-in effect on *mer*-(+)-[Co(L-ala)$_3$], a single linear correlation between ΔH_s° and $T\Delta S_s^\circ$ is observed. The correlation can be expressed by

© 1998 NRC Canada

Fig. 1. Plot of $\log(S_c^\circ/S_c)$ against c_s for *mer*-(+)-[Co(L-ala)$_3$].



[2] $\Delta H_s^\circ = 1.7T\Delta S_s^\circ + 17.1, \quad \gamma = 0.981$

where γ is the correlation coefficient and the straight line passes through the data for water. The data for the salts that exhibit the salting-out effect deviate from the straight line with increasing salt concentration. As a typical example, the data in $(NH_4)_2SO_4$ solutions are plotted in Fig. 3. These findings indicate that the salting-in effect on *mer*-(+)-[Co(L-ala)$_3$] is caused by a decrease in ΔH_s°, and that the origin of the effect is common to NaCl, $NaNO_3$, NaBr, and NaI.

In the case of the salt effect on *fac*-[Co(gly)$_3$], linear correlation between ΔH_s° and $T\Delta S_s^\circ$ is found only for NaBr (solid line in Fig. 4) and is expressed by

[3] $\Delta H_s^\circ = 2.1T\Delta S_s^\circ + 7.5, \quad \gamma = 0.990$

While eq. [3] does not pass through the data for water, the data for water and for salt solutions with the lowest c_s give a separate correlation line (broken line in Fig. 4) expressed by

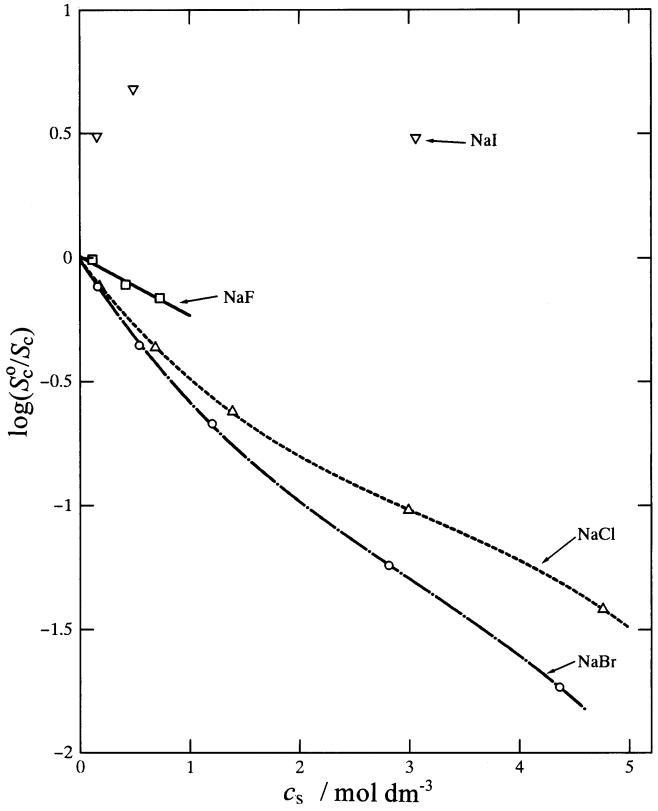
[4] $\Delta H_s^\circ = 1.3T\Delta S_s^\circ + 15.4, \quad \gamma = 0.992$

These results may suggest that the origin of the salting-in effect on *fac*-[Co(gly)$_3$] with high c_s values differs from that with low c_s values.

In the case of the salt effect on [Co(acac)$_3$], NaCl exhibits the salting-out effect in agreement with the prediction of the McDevit and Long (4) theory (k_s = 0.41 dm^3 mol^{-1}), and the salting-out effect is caused by an increase in ΔH_s° (6). It is well known that k_s of a more polar nonelectrolyte is smaller than k_s of a less polar one (2). It is not accurate to state that *mer*-(+)-[Co(L-ala)$_3$] and *fac*-[Co(gly)$_3$] are polar enough to make k_s negative for NaCl.

Sugunan (5) has found that the magnitude of the salting-in effect on 2-, 3-, and 4-nitrobenzoic acids decreases in the order $I^- > Br^- > NO_3^- > Cl^-$ and explained that hydrogen bond formation between carboxyl groups and water molecules liberated by structure-breaking action of the anions (the structure-breaking action also decreases in the order $I^- > Br^- > NO_3^- > Cl^-$) increases the solubilities of these benzoic acids (5). The above order of the salting-in effect on the substituted benzoic acids agrees with the order for *mer*-(+)-[Co(L-ala)$_3$] (see Table 4). The k_s values for *mer*-(+)-[Co(L-ala)$_3$] are comparable to those for nitrobenzoic acid. For example, k_s of NaCl for the latter is –0.19 dm^3 mol^{-1} (5). These findings may suggest that the origin of the salting-in effect on *mer*-(+)-[Co(L-ala)$_3$] is also the structure-breaking action of anions. The increasing hydrogen bond formation between the chelate and water molecules results in a decrease in both ΔH_s° and ΔS_s°.

Fig. 2. Plot of $\log(S_c^\circ/S_c)$ against c_s for *fac*-[Co(gly)$_3$]. Data for NaCl solutions were taken from ref. 6; data for NaI solutions over the c_s range of 0.5–3.0 mol dm^{-1} were not available (see text).



It has been reported that the α-carbon atom proton in α-amino acid is activated upon chelation (13). The possibility that the activated α-carbon atom proton plays a part in the salting-in phenomenon may be also pointed out, because the amino acid itself is subject to the salting-out effect of NaCl (6). In this connection, it is noteworthy to examine the effect of salts on the chelates of Co(III) with β- alanine and 2-aminoisobutylic acid. In any event, more extensive data on the salt effect for [Co(amino acidato)$_3$] is needed to clearly explain the salting-in phenomenon.

For all the salts studied other than NaI, k_s for *fac*-[Co(gly)$_3$] and *fac*-(–)-[Co(D-pro)$_3$] is smaller than k_s for *mer*-(+)-[Co(L-ala)$_3$]. While the origin of the salting-in effect on

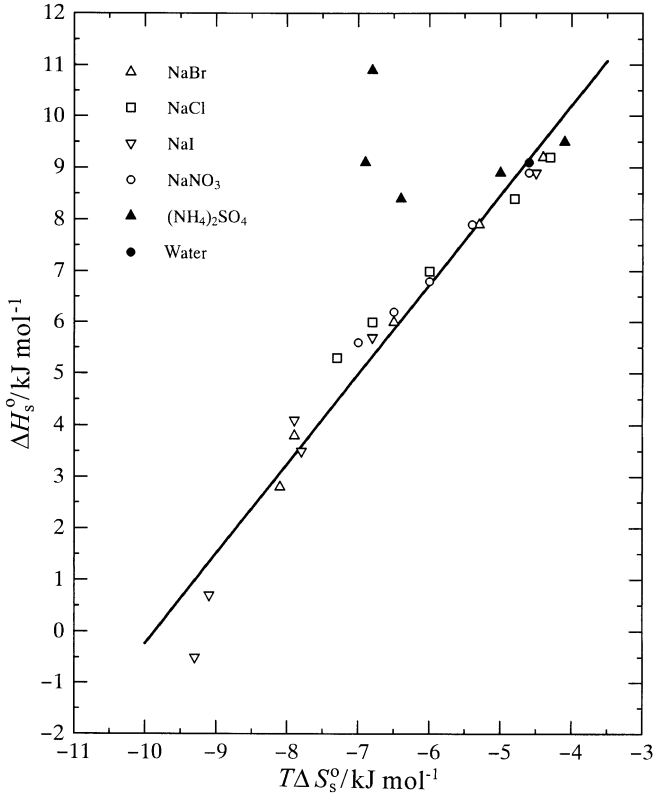

Fig. 4. Correlation between ΔH_s° and $T\Delta S_s^\circ$ for the salt effect on the solubility of *fac*-[Co(gly)$_3$]. Solid and broken lines are drawn by applying the least-squares method to the data for NaBr solutions and for the solutions with lowest c_s values, respectively.

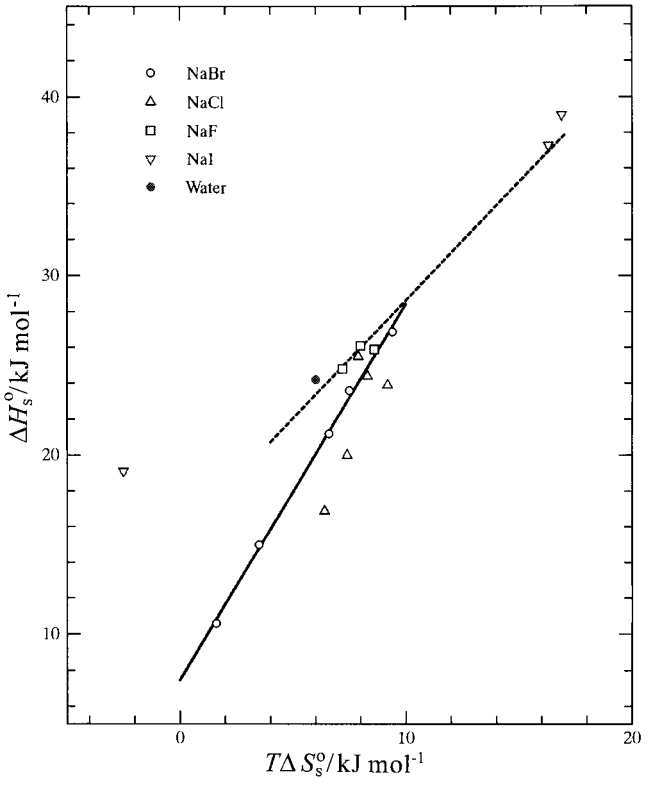

fac-[Co(amino acidato)$_3$] seems to be complicated, as shown in Fig. 4, the above finding may be attributed in part to the postulation that *fac*-[Co(amino acidato)$_3$] is more polar than *mer*-[Co(amino acidato)$_3$]. This postulation is reasonable on the basis of the geometric feature that in the *fac*-isomer three amino and carboxylato groups are mutually *cis*, but in the *mer*-isomer a set of amino and carboxylato groups are *trans*.

The marked salting-out effect of NaI on *fac*-[Co(gly)$_3$] (see Fig. 2) is particularly surprising in comparison with the fact that the salting-in effect of NaI on *mer*-(+)-[Co(L-ala)$_3$] is largest among sodium halides. At the present stage, this anomalous salting-out phenomenon of NaI cannot be explained because of the lack of available data.

Carbocation-like reactivity patterns in X′-substituted-4-biphenylylnitrenium ions

Daniel Ren and Robert A. McClelland

Abstract: 4-Azido-X′-substituted biphenyls (X′ = 4′-MeO, 4′-Me, 4′-F, 3′-Me, 4′-Cl, H, 3′-MeO, 3′-Cl, 4′-CF_3) have been prepared and subjected to 248 nm flash photolysis irradiation in 20:80 acetonitrile:water. Transient X′-substituted 4-biphenylylnitrenium ions **10** (Ar-C_6H_4-N^+H) are observed, with lifetimes ranging from 0.6 ms (4′-MeO) to 26 ns (4′-CF_3). These cations are quenched by azide ion, with values of k_{az} ranging from 6 to 10×10^9 M^{-1} s^{-1}, with the majority in the range $(9–10) \times 10^9$. This near constant k_{az} provides further evidence that arylnitrenium ions are quenched by azide ion at the diffusion limit. The solvent reactivities, plotted in a single-parameter Hammett plot against σ^+(X), exhibit a poor correlation, with the points for the *para* π-electron donors deviating from the correlation line based on the other substituents in the direction of requiring a more negative substituent parameter. The data are more satisfactorily fit to the two-parameter Yukawa–Tsuno equation; the parameter r^+ obtained in this fit is 2.8. Thus the resonance interaction of the *para* π-donor X′-substituents with the positive charge of the cation is underestimated by σ^+, a situation that has previously been observed with benzylic-type carbenium ions. The conclusion is made that, in their reaction with water, 4-biphenylylnitrenium ions behave like benzyl cations bearing two additional stabilizing vinyl groups, i.e., as if they had the structure Ar-C^+(C═C)$_2$. The inherent reactivity and the pattern of the aryl substituent effects are in fact similar to those in the carbocation series Ar-C^+(Ph)$_2$.

Key words: nitrenium, nitrene, aryl azide, photochemistry, lifetime.

Résumé : On a préparé des 4-azidobiphényles substitués par des groupes X′ (X′ = 4′-MeO, 4′-Me, 4′-F, 3′-M3, 4′-Cl, H, 3′-MeO, 3′-Cl, 4′CF_3) et on les a soumis à une irradiation de photolyse éclair à 248 nm, en solution dans un mélange 20 : 80 d'acétonitrile : eau. On a observé la présence des ions 4-biphénylylnitrénium substitués par les groupes X′ (**10**) (Ar-C_6H_4-N^+H) dont les temps de vie varient de 0,6 ms (4′-MeO) à 26 ns (4′-CF_3). On a piégé ces cations par l'ion azoture, avec des valeurs de k_{az} allant de 6 à 10×10^9 M^{-1} s^{-1} alors que la majorité se trouve entre 9 et 10×10^9 M^{-1} s^{-1}. Cette valeur pratiquement constante de k_{az} suggère une fois de plus que les ions arylnitrénium sont piégés par l'ion azoture à la limite de la diffusion. La courbe des réactivités de solvant avec un seul paramètre de Hammett σ^+(X) donne une mauvaise corrélation alors que les points pour les substituants *para* donneurs d'électrons π dévient de la droite de corrélation établie à l'aide des autres substituants; le sens de cette déviation suggère l'utilisation d'un paramètre de substituant plus négatif. Les données conduisent à une meilleure corrélation avec l'équation à deux paramètres de Yukawa–Tsuno; le paramètre r^+ ainsi obtenu est de 2,8. L'interaction de résonance entre les substituants X′ *para* donneurs d'électrons π et la charge positive du cation est donc sous-évaluée par σ^+; cette situation avait été observée antérieurement avec des ions carbénium de type benzylique. On en conclut donc que, lors de leur réaction avec l'eau, les ions 4-biphénylnitrénium se comportent comme des cations benzyliques portant deux groupes vinyliques additionnels, comme s'ils avaient une structure du type Ar-C^+(C═C)$_2$. L'activité inhérente et le patron des effets des substituants aryles sont en fait semblables à ceux observés dans la série des carbocations Ar-C^+(Ph)$_2$.

Mots clés : nitrénium, nitrène, azidobenzènes, photochimie, temps de vie.

[Traduit par la rédaction]

We recently reported the direct observation of the 4-biphenylylnitrenium ion (**1**, R = H) (1) and its N-acetyl analog (**1**, R = Ac) (2) in water using the technique of laser flash photolysis. The N-acetyl derivative was obtained upon photolysis of N-chloro and N-sulfatoxy precursors **2**, and the N-H derivative upon irradiation of the azide **3**, the cation forming via rapid solvent protonation of the singlet nitrene **4** formed by nitrogen extrusion (3).

Received June 13, 1997.

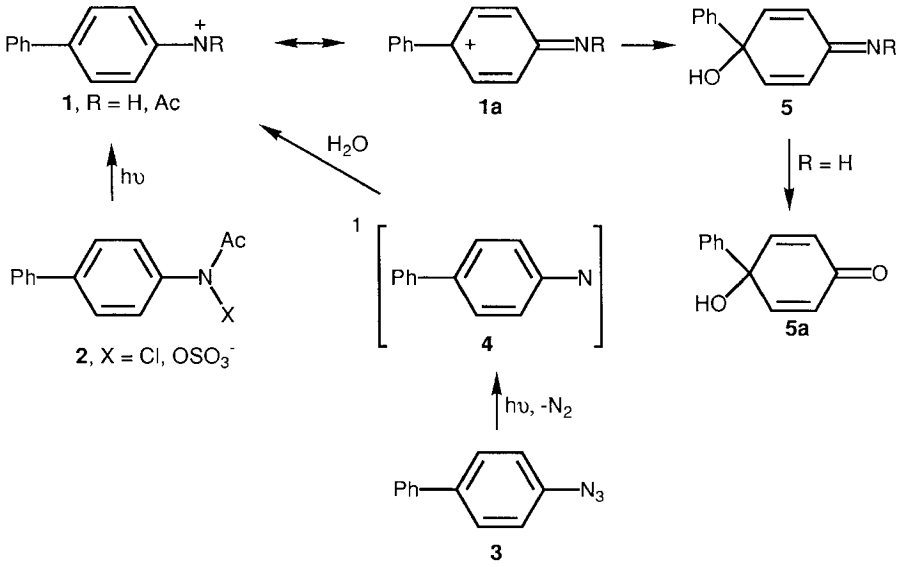
Excellent evidence exists pointing to these nitrenium ions as the reactive electrophiles responsible for DNA binding of the carcinogens 4-aminobiphenyl and 4-(acetylamino) biphenyl (4, 5). The flash photolysis experiments have provided direct information regarding their lifetimes in water, and their reactivities with added nucleophiles (6).

Like benzyl cations, additional resonance contributors for **1** can be written with the positive charge at the *ortho* and *para* positions, the latter as illustrated in Scheme 1 by structure **1a**. There is in fact experimental evidence that these carbenium ion contributors do indeed make a significant contribution.

(*i*) The cations **1** react with water at the ring carbon *para* to the nitrogen (1, 2, 7) to form as the initial product the cyclohexadienone imine **5**. In the case of the parent nitrenium ion (R = H) the imine is simply hydrolyzed to give the ketone **5a** (1, 7), while with the N-acyl derivative there are also

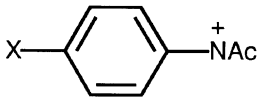
 © 1998 NRC Canada

Scheme 1.



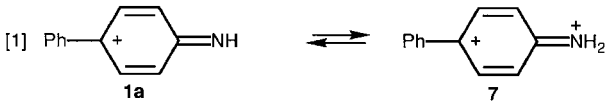
rearrangements to restore aromaticity (7). Also indicative of the delocalization of the positive charge to the ring is the very small difference in reactivity between the NH and N-acetyl cations, a factor of only three ((1, 7, 8). In other words, substituting the nitrogen with an electronegative group has little effect on reactivity, as if there was little positive charge localized on this nitrogen.

(*ii*) Novak et al. obtained aqueous lifetimes of a series of *p*-substituted phenylnitrenium ions **6** using the "azide-clock" approach (9). These lifetimes were found to correlate very poorly with the σ^+ constant of the *para* substituent. This lack of correlation is seen also with carbenium ions (see later). However, the plots for the nitrenium ions are highly scattered, indicating that the *para* substituents interact with the positive charge in a way that is very different from the interaction in an arylcarbenium ion.

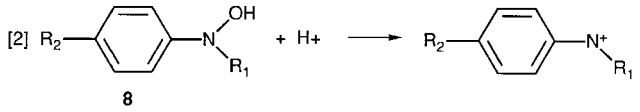


6, X = H, Cl, Me, MeO, Ph

(*iii*) The kinetic data for the decay of **1**, R = H, in acid solutions show that the cation equilibrates with a conjugate acid, presumably the dication **7**. The acidity constant K_a for **7** calculated from the kinetics is 0.8 (2). This is not inconsistent with a structure for the cation such as **1a**, an imine whose basicity is reduced because of a nearby positive charge.

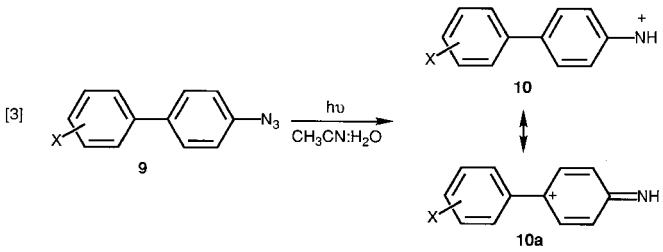


(*iv*) Williams and co-workers (10) reached similar conclusions about the importance of carbenium resonance contributors through the comparison of the rate constants for formation of nitrenium ions from hydroxylamines **8** under acidic conditions. They found little difference between the parent system (**8**, R_1 = H = R_2) and the system with an N-alkyl substituent (**8**, R_1 = Et, R_2 = H). Substitution at the *para* carbon (**8**, R_1 = H, R_2 = Me) resulted in a pronounced rate acceleration.



8

We present in this paper an examination of the lifetimes of 4-biphenylylnitrenium ions **10** bearing substituents in the phenyl ring distant from the formal nitrenium ion center. These cations can be generated from the appropriate azide precursor, in the same manner as the parent (1). Pronounced substituent effects are observed. Our analysis suggests that the substituents in this ring interact with the positive charge much as they do in benzylic carbocations, in other words, as if the positive charge was placed at the *para* carbon as in structure **10a**.



Results and discussion

Preparation of precursors

The substituents X chosen for this study are given in Table 1. The precursor azides **9** were prepared as shown in Scheme 2. The key step, the formation of the biphenyl skeleton, was achieved by palladium-catalyzed cross-coupling of *p*-bromoaniline and an appropriately substituted phenylboronic acid (11). The latter was prepared by the reaction of the appropriate

Grignard reagent with trimethyl borate, followed by hydrolysis (12). The 4-aminobiaryls were converted to the azides **9** by diazotization, followed by the addition of sodium azide (13).

Flash photolysis experiments

Flash photolysis experiments were carried out with laser irradiation at 248 nm in an aqueous solution containing 20% acetonitrile. As illustrated by the four representative spectra in Fig. 1, the substituted biphenyl azides show behaviour qualitatively similar to that previously seen with the parent 4-azidobiphenyl (1). This consists of a relatively intense transient with λ_{max} in the region from 460 to 500 nm. This decays with first-order kinetics, with rate constants given in Table 1. At the end of the decay there is little residual absorbance above 400 nm. Also present is a second peak in the region 300–350 nm that does not decay over 100 μs.

Based upon the similarity with the parent, the transient above 400 nm can be attributed to the appropriate arylnitrenium ion **10**. This assignment is corroborated by the demonstration that these transients are effectively quenched by azide ion, indeed with second-order rate constants similar to the value obtained for the parent (Table 1). Quenching by azide ion is one criterion that points to a cationic intermediate (14). In fact, in the case of the parent 4-biphenylylnitrenium ion, there is excellent agreement between the k_{az}:k_w ratio obtained with flash photolysis and the value determined by product analysis for a ground state solvolysis reaction (7).

The identity of the non-decaying transient below 400 nm is uncertain. This absorbance is also seen with the parent system, where product analysis reveals that there is not a 100% yield of nitrenium ion on irradiation in 20% acetonitrile (1). The latter observation indicates that the protonation forming the nitrenium ion (as shown in Scheme 1) is not the only fate of the singlet nitrene. We assume that the absorbance below 400 nm represents some species forming in the competing reaction (or reactions), possibly a triplet nitrene or a ring-expanded 1,2-didehydroazepine **13** (15).

Table 1. Rate constants at 20°C and absorption maxima for X′-substituted 4-biphenylylnitrenium ions in 20% acetonitrile:water.

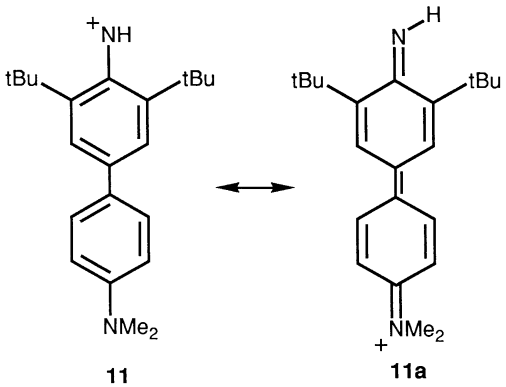
[b] Second-order rate constant for quenching by sodium azide.
[c] 2.84×10^6 s^{-1} (ref. 2).
[d] Because of very rapid decay in solvent alone.

Absorption maxima

As seen in Table 1, the substituents do have a small effect on the λ_{max} of the nitrenium ions **10**, λ_{max} in general increasing with greater electron donation. This trend is similar to that observed in benzylic-type cations. Thus, for example, the λ_{max} (in acetonitrile) for diarylmethyl cations 4-X-$C_6H_4C^+$HPh are 425 nm (X = CF_3), 435 (H), 436 (F), 456 (Cl), 450 (Me), and 455 (MeO) (16). Similarly, cumyl cations (4-X-$C_6H_4C^+(CH_3)_2$) in $(CF_3)_2$CHOH have λ_{max} at 325 nm (X = H), 340 (4-Me), and 360 (4-MeO) (17). While it is risky to base structural conclusions on absorption maxima, the similar behaviour with **10** is at least consistent with the idea that there is a significant benzylic-type interaction between the ring bearing the substituent and the positive charge.

Also worth noting is the λ_{max} at 502 nm of the persistent biphenylylnitrenium ion **11** obtained by anodic oxidation of the corresponding aniline derivative in acetonitrile (18). This cation is obviously analogous to **10** except for the additional *tert*-butyl groups *ortho* to the formal nitrenium ion center. While the effect of these groups is unknown, the λ_{max} for **11** clearly falls within the same pattern that we observe with **10**. One interesting feature with **11** is that the *tert*-butyl groups exhibit nonequivalent signals in the ^{1}H NMR spectrum (18).



11 **11a**

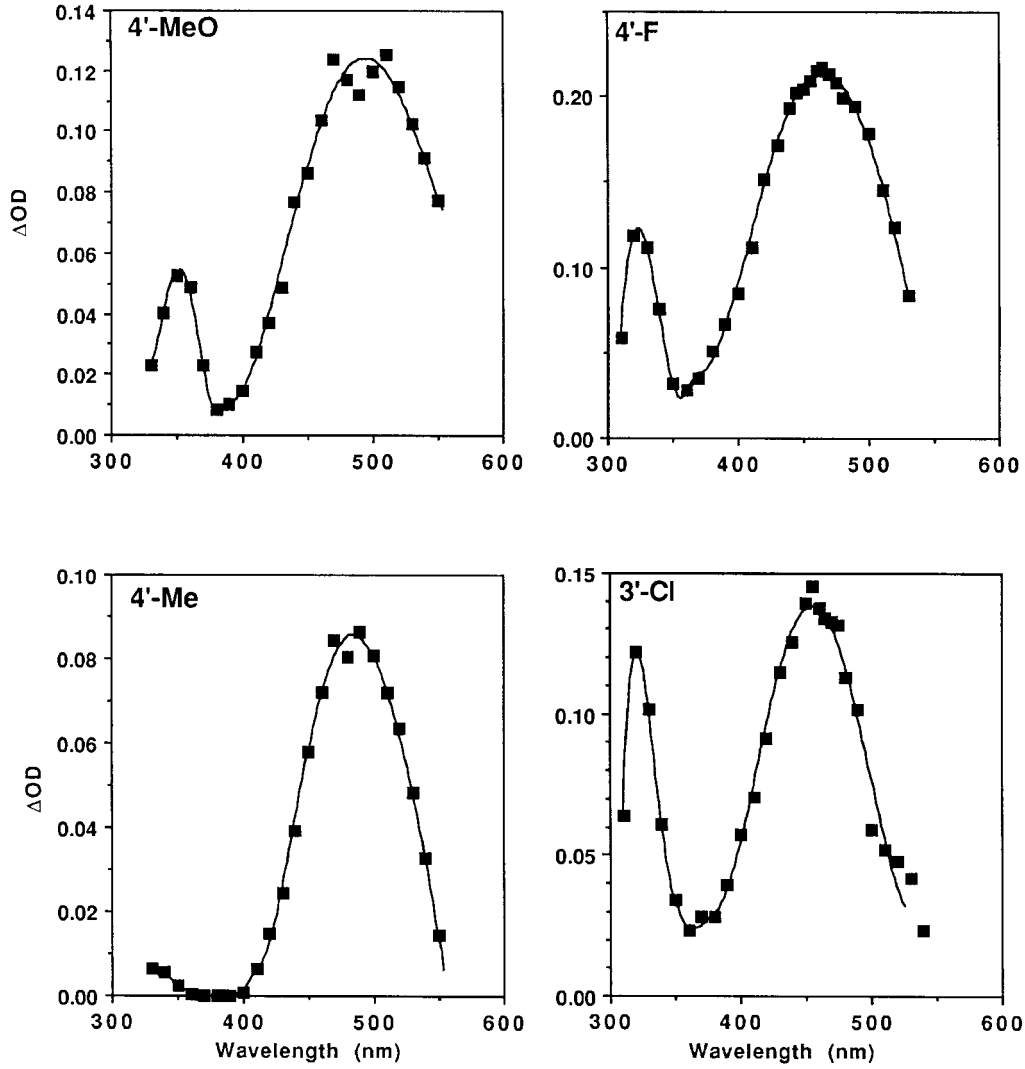
Fig. 1. Transient spectra following 248 nm irradiation of 50 μM solutions of 3′- or 4′-substituted 4-azidobiphenyls **10** in 20% acetonitrile. Spectra were obtained from the optical density change immediately after completion of the laser pulse.



This clearly points to a nonlinear -N^+-H moiety, whose geometry is fixed on the NMR time scale by extensive charge delocalization, such as shown in structure **11a**.

Rate constants for azide trapping

Azide ion has seen extensive use as a "clock" for obtaining absolute rate constants from selectivities measured by competition kinetics. The assumption is made that this nucleophile reacts with short-lived cations at a constant, diffusion-limited, rate constant, with assignment of a value of 5×10^9 M^{-1} s^{-1} for that limit. This approach was originally applied to reactivities of carbenium ions (19, 20), and still sees considerable use in this regard (21). Laser flash photolysis has provided direct evidence that the assumption is valid, through the observation that rate constants k_{az} for series of structurally related carbocations become independent of substituent (22). The limits are typical of encounter-controlled reactions, although in a given solvent there is a slight dependence on structural type. Thus, diarylmethyl cations in 20% acetonitrile have a limiting k_{az} of ~7×10^9 M^{-1} s^{-1}, while with triarylmethyl cations the limit would be ~5×10^9 M^{-1} s^{-1} (22).

Azide has also been employed to "clock" reactivities of arylnitrenium ions (6–9, 23). On the basis of the absolute k_{az} values for 4-biphenylyl- and 2-fluorenylnitrenium ions, the reaction with azide has indeed been suggested to be diffusion-limited (1, 2). The data in Table 1 now show that this is the case. Despite a change of over four orders of magnitude in the solvent rate constants, the values of k_{az} all lie within the range $6–10 \times 10^9$ M^{-1} s^{-1}, with the majority in the range $9–10 \times 10^9$ M^{-1} s^{-1}. The limit, ~1×10^{10} M^{-1} s^{-1}, is slightly higher than those of the di- and triarylmethyl cations. The rate constant calculated from the Debye–Smoluchowski equation for a diffusion-controlled cation–anion encounter in this solvent is ~1.5×10^{10} M^{-1} s^{-1} (22). The smaller observed limits can be explained through a model where there are nonproductive encounters in which the anion and cation cannot actually combine (22). The slightly higher limit with the arylnitrenium ion would suggest that there are fewer of these nonproductive encounters with this system.

It can be noted that the limit of 1×10^{10} M^{-1} s^{-1} obtained from the data in Table 1 refers to solutions that have effectively zero ionic strength. Addition of salts can have significant

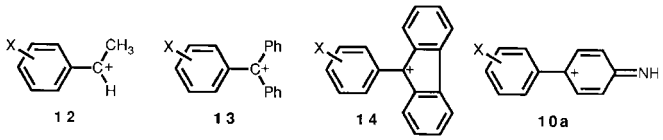
Table 2. Parameters from two-parameter analysis of rate constants for solvent addition to benzylic-type cations **12–14**[a] and to biphenylylnitrenium ions **10**.



ρ	+2.7	+1.3	+1.3	+1.8
$\rho^+ = r^+ \rho$	+6.1	+4.7	+2.8	+5.0
r^+	2.3	3.6	2.2	2.8
k_s(X = H) (s^{-1})	$\sim 1 \times 10^{11}$ [b]	1.5×10^5	1.5×10^7	2.7×10^6

[a]Data for **12** refer to 50:50 2,2,2-trifluoroethanol:water and are from ref. 20, using a value for X = 4-Me_2N from ref. 28. Data for **13** refer to 1:2 acetonitrile:water and are from ref. 27. Data for **14** refer to 1:4 acetonitrile:water and are from ref. 28.

[b]Estimate (ref. 20).

effects on the azide reactivity (24). In 20% acetonitrile containing 0.5 M $NaClO_4$, the limiting rate for the biphenylylnitrenium ions is $\sim 5 \times 10^9$ M^{-1} s^{-1} (1).

Solvent reactivities

Despite the fact that the change is taking place in the phenyl ring remote from the formal N^+ center, substituents have a pronounced effect on the lifetime of **10**. From the least reactive, 4′-methoxy, to the most reactive, 4′-trifluoromethyl, there is a change of over four orders of magnitude. In attempting a quantitative correlation, we initially constructed a single-parameter Hammett plot, employing σ^+ as the substituent constant. As shown in Fig. 2*a*, this correlation is poor, with the points for the *para* π-electron donors, especially 4′-methoxy, deviating significantly from the correlation line based on the other substituents. Moreover, the deviation of these points is in the unusual direction of requiring a more negative substituent parameter in order for the point to fit on the line. In other words, the σ^+ constant is underestimating the effect of the substituent.

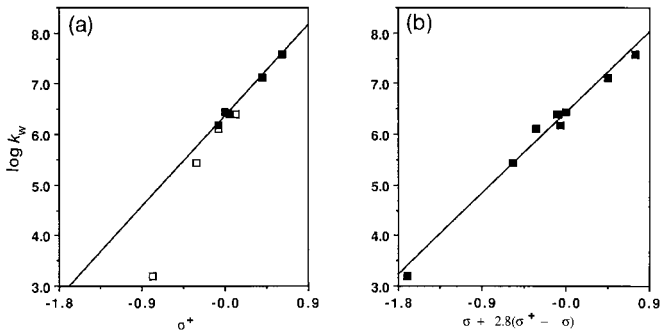
This type of behaviour has previously been observed (20, 27, 28) for benzylic-type cations **12**–**14** (see Table 2). The data are more satisfactorily fit to the two-parameter Yukawa–Tsuno equation (eq. [4]),

$$[4] \quad \log(k_w/k_w^\circ) = \rho\,[\,\sigma + r^+(\,\sigma^+ - \sigma)]$$

where k_w° is the rate constant for the unsubstituted compound, ρ has its normal meaning, and r^+ is a scaling parameter that effectively provides substituent parameters other than σ^+ and σ. The r^+ parameter was intended to lie between zero and one, representing substituent interactions intermediate between those described by σ and σ^+. As shown in Table 2, values significantly greater than one are required for the cation water reactivities. This is also true for **10**, where $r^+ = 2.8$ provides the best fit for the experimental data. This fit is illustrated in Fig. 2*b*; as shown in this figure, the methoxy substituent in **10** behaves as if it has a "σ" substituent constant of –1.7.

Table 2 provides a comparison of the ρ and r^+ parameters obtained with **10** and those previously found with **12**–**14**. Also listed is the ρ^+ parameter, the product of ρ and r^+, which is

Fig. 2. Linear free energy correlations. (*a*) A single-parameter correlation of log k_w versus the Hammett σ^+ substituent constant. The line drawn in this figure (slope = 2.0) is the least-squares line calculated for the solid squares, representing the 4′-CF_3, 3′-Cl, 3′-MeO, 3′-Me, and unsubstituted cations. (*b*) Plots log k_w versus $\sigma + r^+(\sigma^+ - \sigma)$, where the value of $r^+ = 2.8$ has been obtained from application of the two-parameter Yukawa–Tsuno equation (25). The line drawn in this figure (slope = 1.8) is the least-squares line for all the points. Values of σ and σ^+ are taken from ref. 26.



effectively a measure of the resonance effect of the substituents on the reaction (20). This comparison shows very clearly that substituents in **10** interact with the positive charge very much as if this cation were a benzylic cation, i.e., as if the structure were **10a**. This conclusion is particularly evident when the "inherent" reactivities, the rate constant for the derivative with X = H, are considered. The least stable and most reactive cation is phenethyl, which has only one other stabilizing substituent, a methyl group, on the C^+ center. This system has the largest values of ρ and ρ^+ , indicating the greatest interaction with the aryl ring. The most stable and least reactive cation is triphenylmethyl, where there are two additional stabilizing phenyl groups on the C^+ center. As expected, the series ArC^+Ph_2 has smaller values of ρ and ρ^+ since there is less demand for stabilization by substituents in the one ring. The biphenylylnitrenium ions, written as **10a**, can be viewed as benzylic cations with two stabilizing vinyl substituents. The reactivity of this system lies intermediate between phenethyl and triphenylmethyl, albeit closer to the latter. The substituent effects are also intermediate, again closer to triphenylmethyl.

The fluorenyl cations **13** are not considered in these comparisons, since the aryl ring is significantly twisted from coplanarity (28), attenuating the substituent effects. In this respect it is interesting that the biphenylylnitrenium ions do show such a strong resonance interaction with the substituents in the distal ring. Biphenyls would normally be regarded as being significantly twisted but this clearly is not the case for the nitrenium ions. For a substituent such as 4′-methoxy to have such a strong stabilizing effect, the two rings must be fairly close to being coplanar. This is obviously part of the reason that 4-biphenylylnitrenium ions can be formed so readily both thermally and photochemically.

Conclusions

The qualitative observation of very significant substituent effects on the lifetime and the quantitative comparisons just discussed provide further experimental support for the idea that

© 1998 NRC Canada

arylnitrenium ions are better regarded as carbocations, with a significant portion of the positive charge at the ring carbons. The 4-biphenylylnitrenium ions, in their reaction with water, behave very much like benzyl cations bearing two additional stabilizing vinyl groups, i.e., Ar-C^+(C═C)$_2$. Their inherent reactivity and the pattern of their aryl substituent effects are very similar to those in the carbocation series Ar-C^+(Ph)$_2$.

Experimental section

Flash photolysis experiments were carried out in the normal manner with ca. 20 ns pulses at 248 nm (ca. 60 mJ per pulse) from a Lumonics excimer laser (KrF emission). Solutions of the 4-azidobiphenyl precursors in 20% acetonitrile were 20–50 μM, and the experiments were carried out under air. The rate constants k_{az} were calculated as the slope of the plot of k_{decay} versus [NaN_3], for five or six concentrations of sodium azide over the range 0–1 mM. Rate constants for the 4′-methoxy compound were determined with both the laser flash photolysis apparatus where the rate is at about the longest time limit possible, and with a conventional flash photolysis apparatus (29). Excellent agreement was observed between the two.

Synthesis. General coupling procedure

A 50 mL flask was charged under argon with 0.35 g of $Pd(PPh_3)_4$ (0.3 mmol), 20 mL of benzene, 1.72 g of *p*-bromoaniline (10 mmol), and 10 mL of 2 M aqueous Na_2CO_3 solution, and then 10 mmol of arylboronic acid in a minimum amount of 95% ethanol was added. The mixture was refluxed overnight under vigorous stirring. After the reaction was completed, the product was extracted with ether, washed with a saturated NaCl solution, dried over $NaSO_4$, and the solvent was removed. The crude product was further purified by column chromatography on silica gel, eluting with ethyl acetate – hexanes, and was recrystallized in aqueous ethanol.

General procedure for the syntheses of biaryl azides

The 4-aminobiphenyl (10 mmol) was dissolved in 40 mL of glacial acetic acid containing 10 mL of concentrated sulfuric acid. The solution was cooled to below 5°C in an ice bath and diazotized with a solution of 0.76 g of $NaNO_2$ (11 mmol) in 7 mL of distilled water. After 1 h of stirring, 100 mL of ice-water was added. Enough urea was added to destroy the excess nitrous acid, and 0.5 g of Norite was then added. The cold suspension was stirred for 15 min and was then rapidly filtered into a flask immersed in an ice bath. The clear, yellow filtrate was treated with 1.34 g of NaN_3 (20 mmol) in 10 mL of water at 0°C. Nitrogen was immediately evolved, the solution became turbid, and a light tan precipitate formed in a few minutes. The mixture was kept in the ice-bath and stirred for 1 h after the addition of NaN_3 was completed, and was then allowed to warm up to room temperature and stand overnight. The precipitate was filtered off, and washed first with 10% Na_2CO_3 and then with water. The crude product was purified by column chromatography on silica gel eluted with ethyl acetate – hexanes and was recrystallized in hexanes.

The following azides were prepared by the procedure described above.

4-Azido-4′-methoxybiphenyl: ^{1}H NMR (500 MHz, $CDCl_3$), δ: 7.51 (2H, d, J = 8.5 Hz), 7.47 (2H, d, J = 8.5 Hz), 7.05 (2H, d, J = 8.5 Hz), 6.95 (2H, d, J = 8.5 Hz), 3.83 (3H, s); HRMS *m*/*z*, calcd. for $C_{13}H_{11}N_3O$: 225.0902; found: 225.0891; calcd. for $C_{13}H_{11}NO$ (M –N_2): 197.0841; found: 197.0837.

4-Azido-4-methylbiphenyl: ^{1}H NMR (500 MHz, $CDCl_3$), δ: 7.54 (2H, d, J = 8.5 Hz), 7.44 (2H, d, J = 8.5 Hz), 7.23 (2H, d, J = 8.5 Hz), 7.06 (2H, d, J = 8.5 Hz), 2.37 (3H, s); HRMS *m*/*z*, calcd. for $C_{13}H_{11}N_3$: 209.0953; found: 209.0951.

4-Azido-4′-fluorobiphenyl: ^{1}H NMR (500 MHz, $CDCl_3$), δ: 7.51–7.47 (4H, m), 7.12–7.06 (4H, m); HRMS *m*/*z*, calcd. for $C_{12}H_8N_3F$: 213.0702; found: 213.0694.

4-Azido-4′-chlorobiphenyl: ^{1}H NMR (500 MHz, $CDCl_3$), δ: 7.52 (2H, d, J = 8.5 Hz), 7.46 (2H, d, J = 8.5 Hz), 7.38 (2H, d, J = 8.5 Hz), 7.08 (2H, d, J = 8.5 Hz); HRMS *m*/*z*, calcd. for $C_{12}H_8N_3Cl$: 229.0407; found: 229.0409.

4-Azido-4′-trifluoromethylbiphenyl: ^{1}H NMR (500 MHz, $CDCl_3$), δ: 7.67 (2H, d, J = 8.5 Hz), 7.64 (2H, d, J = 8.5 Hz), 7.57 (2H, d, J = 8.5 Hz), 7.11 (2H, d, J = 8.5 Hz); HRMS *m*/*z*, calcd. for $C_{13}H_8N_3F_3$: 263.0670; found: 263.0668.

4-Azido-3′-chlorobiphenyl: ^{1}H NMR (500 MHz, $CDCl_3$), δ: 7.54–7.52 (3H, m), 7.42–7.4 (1H, m), 7.334 (1H, t, J = 8.0 Hz), 7.31–7.29 (1H, m), 7.08 (2H, d, J = 8.5 Hz); HRMS *m*/*z*, calcd. for $C_{12}H_8N_3Cl$: 229.0407; found: 229.0411.

4-Azido-3′-methylbiphenyl: ^{1}H NMR (500 MHz, $CDCl_3$), δ: 7.55 (2H, d, J = 8.5 Hz), 7.36–7.3 (3H, m), 7.16–7.14 (1H, m), 7.07 (2H, d, J = 8.5 Hz); HRMS *m*/*z*, calcd. for $C_{12}H_8N_3Cl$: 209.0953; found: 209.0957.

4-Azido-3′-methoxybiphenyl: ^{1}H NMR (500 MHz, $CDCl_3$), δ: 7.59 (2H, d, J = 8.5 Hz), 7.37 (1H, t, J = 8.0 Hz), 7.18–7.08 (3H, m), 6.94–6.90 (1H, m), 3.88 (3H, s); HRMS *m*/*z*, calcd. for $C_{13}H_{11}N_3O$: 225.0902; found: 225.0891; calcd. for $C_{13}H_{11}NO$ (M–N_2): 197.0841; found:197.0897.

Synthesis, electrochemistry, structure, and magnetic susceptibility of 5-*tert*-butyl-1,3-bis-(1,2,3,5-dithiadiazolyl)benzene. Structural effect of the bulky substituent[1]

Richard A. Beekman, René T. Boeré, Klaus H. Moock, and Masood Parvez

Abstract: The crystal structure of the title compound was determined at 250 K in space group $I\bar{4}2m$, $a = 20.661(5)$ Å, $c = 6.764(7)$ Å, $Z = 8$. The individual dithiadiazole rings form two sets of contrarotatory 4-member pinwheels clustered around a 4-fold rotation–inversion axis located halfway along the unit cell edges, describing an infinite channel lined with sulfur atoms but in which there are short intra-stack contacts through only one S atom of each CN_2S_2 group. The double-layer stacking occurs in order to accommodate the bulk of the ^{t}Bu group, and the spacing between layers is very regular, with short and long S···S contacts of 3.48(2) and 3.61(2) Å and considerable thermal motion in the *c* direction. The title compound and its SbF_6^- salt are oxidized at +0.81 V (in CH_2Cl_2) and at +0.61 V (in CH_3CN), while a reduction process is observed only in CH_2Cl_2 at –0.73 V vs. SCE. Magnetic susceptibility data between 5 and 400 K demonstrate at very low temperature that the sample follows the Curie–Weiss law, $\theta = 0$ K, and $\chi_0 = -156$ ppm emu mol^{-1}. The free-spin concentration at $T = 0$ K is ≈1.3%, due to paramagnetic defects in an essentially diamagnetic structure. The diamagnetism starts to lift above 210 K; above 260 K, a strong antiferromagnetic exchange is operative. These results are consistent with the lifting of the Peierls distortion in this structure, starting above ≈200 K. The crystal structure of the parent diamidine 5-*tert*-butyl-1,3-$[(Me_3Si)_2NCNSiMe_3]_2C_6H_3$ was determined in $C2/c$ with $a = 10.0788(3)$, $b = 21.328(5)$, $c = 20.876(5)$ Å, $\beta = 99.41(2)°$, $Z = 4$. The two amidine functional groups are equivalent by crystal symmetry.

Key words: dithiadiazole, diradical, magnetic susceptibility, crystal structure, bulky substituent.

Résumé : On a déterminé la structure cristalline du composé mentionné dans le titre à 250 K; il cristallise dans le groupe d'espace $I\bar{4}2m$ avec $a = 20{,}661(5)$ Å, $c = 6{,}754(7)$ Å et $Z = 8$. Les noyaux dithiadiazoles individuels forment deux ensembles à sens contraire, en forme de moulinet à quatre membres, regroupés autour d'un axe de rotation–inversion quaternaire situé à mi-chemin le long des arêtes du motif élémentaire et décrivant un canal infini bordé d'atomes de soufre; on n'y observe toutefois qu'un seul point de contact court entre les empilements et il se produit entre un atome de soufre de chaque groupe CN_2S_2. L'empilement à deux couches se produit de façon à accommoder l'encombrement du groupe *tert*-butyle et la distance entre les couches est très régulière alors que les distances S···S courtes et longues sont respectivement de 3,48(2) et 3,61(2) Å et qu'on observe beaucoup de mouvement thermique dans la direction *c*. Le composé mentionné dans le titre et son sel de SbF_6^- sont oxydés à +0,81 V (dans le CH_2Cl_2) et à +0,61 V (dans le CH_3CN) alors que l'on n'observe le processus de réduction que dans le CH_2Cl_2, à –0,73 V vs. SCE. Les données de susceptibilité magnétique entre 5 et 400 K démontrent que, à température très basse, l'échantillon obéit à la loi de Curie–Weiss, $\theta = 0$ K et $\chi_0 = -156$ ppm emu mol^{-1}. La concentration libre de spin à $T = 0$ K est égale à 1,3% à cause de défauts paramagnétiques dans une structure essentiellement diamagnétique. Le diamagnétisme commence à s'éliminer et, au-dessus de 260 K, un important échange antiferromagnétique est en action. Ces résultats sont en accord avec l'élimination progressive de la distorsion de Peierls dans cette structure à partir d'environ 200 K. On a déterminé la structure cristalline de la diamine parent, 5-*tert*-butyl-1,3-$[(Me_3Si)_2NCNSiMe_3]_2C_6H_3$, qui cristallise dans le groupe d'espace $C2/c$, avec $a = 10{,}0788(3)$, $b = 21{,}328(5)$ et $c = 20{,}876(5)$ Å, $\beta = 99{,}41(2)°$ et $Z = 4$. Les deux groupes fonctionnels amidines sont équivalents par symétrie cristalline.

Mots clés : dithiadiazole, diradical, susceptibilité magnétique, structure cristalline, substituant encombrant.

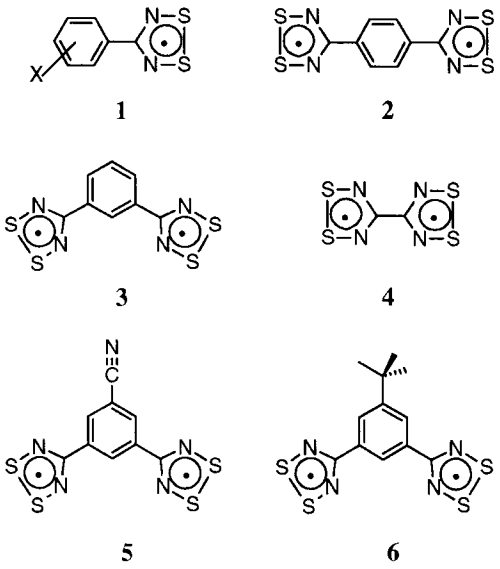
Introduction

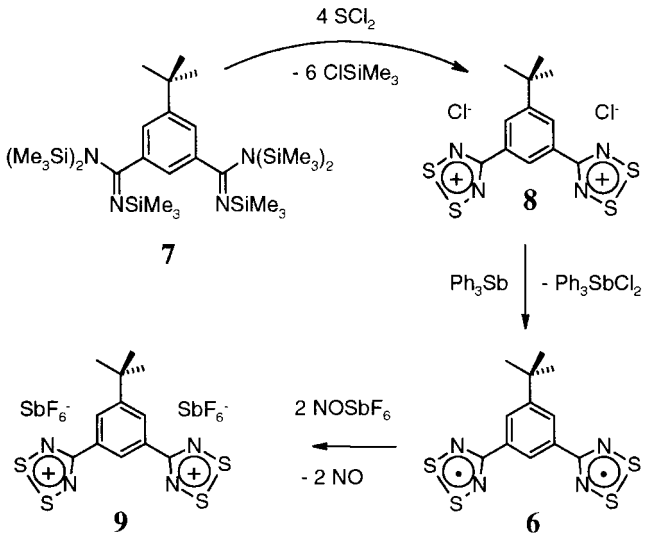
1,2,3,5-Dithia- and diselena-diazoles, **1**, have been extensively investigated as potential single-component molecular conductors (1). Early examples formed isolated dimer pairs, as in the first structurally characterized compound, 4-phenyl-1,2,3,5-dithiadiazole (2). Molecular engineering has focused on obtaining solids in which the heterocycles are stacked into infinite arrays in the solid, yet in all cases where stacking is observed for neutral systems, the *spacing* of the layers alternates between short and long separation. This has been interpreted as the result of a Peierls distortion (3). There is evidence from magnetic measurements that this distortion may be overcome at a higher temperature for the neutral derivatives, and it



is overcome in some systems by partial oxidation (4). Up till now the main strategies used to overcome this inherent tendency to distortion have been (*i*) to minimize the bulk of the R-group, e.g., **1**, but with the aromatic ring replaced only by an H atom (5), or by increasing the nuclearity of the dithiadiazole centres to include bi- and tri-functional species such as **2** (6), **3** (7), or **4** (8); and (*ii*) through the inclusion of ancillary donor sites (e.g., nitrile on (9–11) or nitrogen *within* (12) the aryl backbone), as in **5** (9). Recently, the latter strategy applied to 4-$NCC_6F_4CN_2S_2$ resulted, due to strong interaction with the nitrile groups, in a sheet structure that, while evenly spaced, has no vertical stacks at all; consistently this material behaves as a bulk paramagnet (13). A second phase of this material undergoes a phase transition to a "canted antiferromagnetic" state at 36 K (14).

Bulky substituents have, on the other hand, not been employed before. We report here the synthesis and characterization of **6** in which a *tert*-butyl (^{t}Bu) group is located in the 5-position of the aromatic backbone. The effect of the bulky substituent on the structure is profound. Whereas **3** and **5** form stacked structures in which the molecules overlay directly, **6** has a stacked structure with every second layer reversed in order to accommodate the *tert*-butyl groups. It is the first example of a dithiadiazole that forms such *double-layer* stacks. Spacing within the stacks is much more regular than in

Scheme 1



2, **3,** or **5**. The observed structure is consistent with a material that is stabilized *above* the Peierls distortion at room temperature, a conclusion substantiated by the magnetic susceptibility profile measured between 5 and 400 K.

In addition to a strong structural influence, the ^{t}Bu group has a solubilizing effect that has allowed measurements of the solution electrochemistry of **6**. Previously, **2** had been the only bifunctional dithiadiazole characterized by solution electrochemistry (15). The electrochemical behaviour of **6** supports previous conclusions that the two CN_2S_2 groups act as independent redox centres.

Results and discussion

Synthesis

Starting from the known 5-*tert*-butyl-1,3-dicyanobenzene (16), the persilylated amidine **7** was prepared using methods we have recently described in detail (17). Amidine **7** was fully characterized by chemical methods and by X-ray crystallography. In particular, it was important to be certain that both nitrile groups were derivatized to the amidine. Results of the structure determination are discussed below, while the spectroscopic properties are listed in the experimental section. Scheme 1 indicates the sequence of synthetic reactions used to prepare the title compound. **7** was condensed with sulfur dichloride (excess), and the resulting orange bisdithiadiazolium dichloride **8**, which was not further characterized, was reduced to the neutral diradical **6** using triphenylantimony. Purification of the crude diradical was performed by repetitive vacuum sublimation in a three-zone tube furnace at 10^{-2} Torr (1 Torr = 133.3 Pa), and crystals suitable for a diffraction study were grown in a furnace gradient of 50/100/180°C.

Oxidation of the diradical using nitrosyl hexafluoroantimonate afforded the SbF_6^- salt of the dication, **9**, which could be recrystallized as an orange solid containing solvent of crystallization. Compound **9** was used in the electrochemical studies described next.

[f] Separation between anodic and cathodic peak of 30 mV.

Voltammetry and ESR spectroscopy

A combination of cyclic and a.c. voltammetry in typical organic solvents (CH_2Cl_2 and CH_3CN) was employed in an evacuated cell (18). We had previously investigated the electrochemical behaviour in solution of substituted aryl dithiadiazole radicals **1** as a function of substituent **X**, in a very rigorous procedure in which we obtained data in *both* solvents starting from either the free radical or a salt of a non-interacting anion (15, 19). We were also able to obtain acceptable cyclic voltammograms for the bifunctional diradical **2**, but only from CH_2Cl_2 solutions; similarly a salt of its dication could only be measured in CH_3CN. However, the isomeric **3** proved to be too insoluble for such studies. The ^{t}Bu group in **6** has a solubilizing effect, so that we were able to obtain reversible redox potentials for this compound in dichloromethane, and for the salt **9** in acetonitrile. For **6** in CH_2Cl_2 the oxidation process occurs at +0.81 V and the reduction at –0.79 V (vs. SCE). For the SbF_6^- salt, soluble only in CH_3CN, the 2-electron oxidation is observed at +0.61 V.

Voltammetric data for **6**, **9,** and **2** are compiled in Table 1. The redox potentials measured for the $2^+/2\cdot$ ("oxidation") and the $2\cdot/2^-$ ("reduction") processes are remarkably similar for the two forms **6** and **9** and the analogous versions (diradical and dication) of **2**. This confirms that the substituent effect of one dithiadiazole group attached to an aromatic ring on another similarly attached group is extremely small, and is independent of *meta* or *para* geometry. The two CN_2S_2 rings seem to behave independently. The 0.2 V difference between the potentials in acetonitrile and dichloromethane are typical for this ring system (15). The cell potentials, i.e., $\Delta E_{1/2}$, are also comparable to other dithiadiazole systems, and are larger than those observed for diselenadiazoles (15).

A typical steady-state cyclic voltammogram for the diradical measured in CH_2Cl_2 is presented in Fig. 1. There is a large separation between the anodic and cathodic peaks for both waves, with 250 mV for the oxidative and 190 mV for the reductive process. This is most likely due to the extremely low solubility of **6** in dichloromethane. (Thus a solution prepared by adding crystals of **6** to highly purified CH_2Cl_2 remains colourless, but has detectable ESR signals and voltammetric waves. However, the bulk solubility is negligible.) Similarly, with its concentration adjusted to that of the compound being studied, the reference compound, ferrocene, is almost equally broadened with a separation of 180 mV. The solubility of the cation from the salt **7** is considerably greater in acetonitrile, a solvent whose dielectric properties generally favour more "ideal" voltammograms. Only the oxidation process is reversible for this compound, a situation noted previously for monofunctional dithiadiazole cations. The absence of a reversible "reduction" wave, technically the second reduction starting from the dication, was attributed to a rapid comproportionation reaction between the small amount of anion formed and the large excess of cation (20).

There has been some discussion in the literature regarding the nature of the electron transfer processes in bifunctional dithiadiazoles (8, 21). Are the two groups on a single ring *simultaneously* oxidized or reduced? Can a radical cation or a radical anion be formed? These effects normally show up in the shapes of the cyclic voltammograms and size of the anodic–cathodic peak separations. We believe that a verdict has not been reached on this question. The data obtained for the "oxidation" process in acetonitrile (first reduction of the dication from **9**) are indicative of a two-electron step in which ΔE = 0, producing single peaks with a separation between anodic and cathodic peak of 40 mV, intermediate between those of a single (58 mV) and a two-electron (29 mV) process (22). However, the solubility of all bifunctional compounds prepared thus far is simply too low to draw authoritative conclusions.

ESR measurements show that there is a weak intramolecular exchange between the two radical centers on a single molecule at room temperature; intermolecular effects can be ruled out at the extremely low concentrations involved. Figure 2 shows limiting spectra in dichloromethane. At 250 K, a simple 5-line pattern due to hyperfine interaction to two equivalent ^{14}N nuclei is observed, with a_N = 0.51 mT. On warming, a more complex pattern develops, consistent with an intramolecular exchange coupling J_{ex} between radical centres that has probably not yet reached its limit at 340 K; at higher temperatures, the solvent boiled out of the resonant cavity. Exchange effects have been noted previously for diradicals, and the magnitude of the exchange process for **6** is intermediate between that of **2** and **3** (6, 7). The apparent absence of exchange phenomena in the electrochemistry may simply reflect

differences in the time scales of the cyclic voltammetry and ESR experiments.

In summary, the *tert*-butyl group is responsible for a marginal increase in solubility for the 1,3-bisdithiadiazole ring system, allowing the measurement of solution redox potentials for the first time. However, the solubility is still too low either for definitive electrochemical work on any cooperative effects between the two CN_2S_2 rings on a single molecule, or for detailed study of the intramolecular spin exchange mechanism by ESR. The preparation of more soluble derivatives is underway.

Crystal and molecular structure of 7

A suitable single crystal of **7** was obtained by slow sublimation in a large round-bottomed sublimer, data crystals forming on the outside, air-cooled, region of the device. Data collection at low temperature helped to limit thermal motion of the many methyl groups in the molecule, and an *R*-factor of 6% was obtained with a data to parameter ratio of 10:1. Details of the structure determination and metric parameters are found in Tables 2–5. An ORTEP representation of the structure is presented in Fig. 3. The structure was refined in space group $C2/c$ with four molecules per unit cell. The molecule consistently occupies a special position, with C12, C14, and C15 all lying on a twofold rotation axis. This requires disorder in the positions of the three ^{t}Bu methyl groups. The disorder was modeled using two sets of methyl groups at half-occupancy with bond lengths constrained to 1.50 Å and isotropic temperature factors. The two amidine functional groups are crystallographically identical. The C10—N1 and C10—N2 distances are 1.410(5) and 1.264(5) Å, consistent with a C—N single and C═N double bond, respectively. For comparison, the distances in hexakis(trimethylsilyl)-1,4-benzdiamidine are 1.413(3) and 1.271(3) Å (23). All other molecular distances are unexceptional.

Crystal and molecular structure of 6

Several attempts to obtain data sets at lower temperatures did not lead to a satisfactory solution, but the data set collected at 250 K solved successfully. Details of the structure determination and metric parameters are found in Tables 2–5. An ORTEP representation of a single molecule is given in Fig. 4, which provides the atomic numbering scheme. In the molecular structure, the S—S, S—N, and N—C bond lengths agree closely with the experimental and calculated (square bracketed) values found for the $(HCN_2S_2)_2$ dimer: 2.07(3) [2.071]; 1.64(6) [1.635]; 1.32(8) [1.323] (24). They also compare closely with those found in **3**, which also crystallizes in a tetragonal space group, $I4_1/a$, and possesses a different layered structure, with pinwheel arrangement within the layers (6).

Much more interesting is the intermolecular structure. Two views of the crystal structure are presented in Figs. 5 and 6.

There are eight molecules per unit cell. At the center of the cell is located a $\bar{4}$ symmetry axis, perpendicular to the plane shown in Fig. 5, and passing through the point {1/2,1/2,0}. This axis defines the packing of the ^{t}Bu groups: diagonally opposed groups are at the same level; neighbouring groups are half a *c* translation apart, resulting in a double helical staircase of ^{t}Bu groups surrounding an infinite channel lined by hydrogen atoms. A more complex channel is located at the other $\bar{4}$ axis perpendicular to *c*, which passes through the family of points {1/2,0,0}. To depict this channel more accurately, four additional molecules have been added to the unit cell in the *–b* direction in Fig. 5.[3] In all, eight CN_2S_2 rings contribute to the two layers of the depicted channel. Consistent with the $\bar{4}$ symmetry, the pinwheel geometry of four CN_2S_2 rings is *reversed* every second layer, so that the infinite channel lined by sulfur atoms is defined by two *contrarotating* pinwheel groups of dithiadiazole rings. Whereas the pinwheel motif has been seen in numerous dithiadiazole structures, this is the first example of contrarotating double layers of pinwheels.

Each molecule of **6** is centred on a 2_1 screw axis parallel to *c* and passing through the point {1/4,1/4,0}, defining a forward–backward packing motif for each subsequent molecule of **6** in an infinite stack. That this motif is adopted in order to accommodate the bulky ^{t}Bu groups while maintaining as many intermolecular S···S and S···N contacts as possible seems almost certain, since both **3** and **5** have structures in which the

[3] The channel is quite narrow, having a diameter of only 1.3 Å when the van der Waals' radius of sulfur is taken as 1.80 Å.

Fig. 3. ORTEP representation, showing the atom numbering scheme, of a single molecule of **7** as it is found in the crystal structure. The molecule lies on a twofold rotation axis, and the *t*Bu group is disordered. In the refinement two constrained groups (half-occupancy) with isotropic temperature factors were allowed; only a single group has been drawn in the picture.

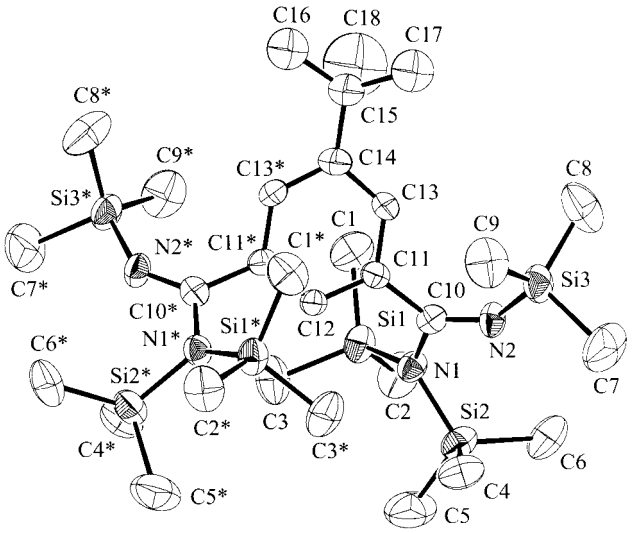

Fig. 4. ORTEP representation, showing the atom numbering scheme, of a single molecule of **6** as it is found in the crystal structure.

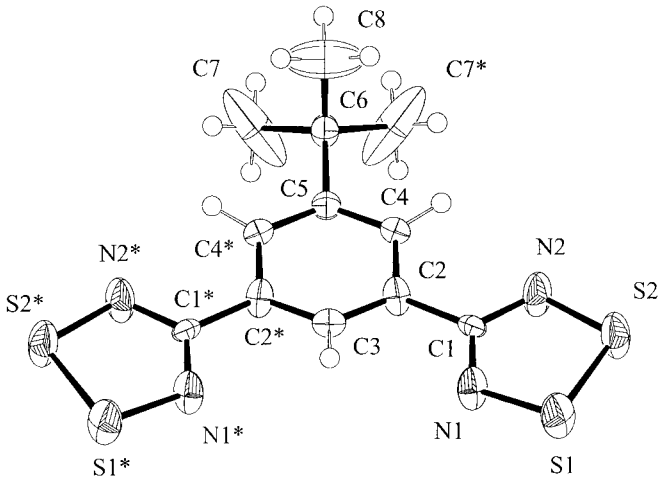

bent 1,3-$(S_2N_2C)C_6H_3$ units lie directly above one another in a superimposed infinite stack. Spacing between the layers in **6** is much more even than in either **3** or **5**. This is shown very clearly in Fig. 6, which is a view perpendicular to the *a* axis depicting only the CN_2S_2 units of a single sulfur channel. The unit cell diagonals are mirror planes; consistently, the two halves of each molecule of **6** are identical by symmetry and the *t*Bu groups are ordered. The crystal symmetry does not require planarity of the molecules. Consistently, the CN_2S_2 rings are both canted and cupped slightly at the equilibrium distance of the structure determined at 250 K. However, the thermal ellipsoids (Fig. 4) are elongated in the perpendicular direction, so that we expect there to be considerable rocking vibration. At the equilibrium distances determined in the structure, each layer is separated by two slightly longer and two slightly shorter interstack S···S distances, at 3.48(2) and 3.61(2) Å. These distances should be compared to the mean short and long distances in **3** (3.140 and 3.966 Å) and in **5** (3.12 and 3.89 Å). The mean distances are much more comparable: 3.55 in **3** and **6**, 3.51 in **5**. However, since the S···S contacts in **6** are at an angle to the perpendicular, it follows that the ring centroid-to-centroid distance in **6** at 3.382 Å is considerably

Fig. 5. PLUTO representation of the crystal packing observed in the solid-state structure of **6**. The view is down the *c* axis, and the range of indices plotted is *a*: 0–1; *b*: –1/2–1; *c*: 0–1. Heavy solid and broken lines represent the intermolecular sulfur–sulfur contacts at S2 on the upper (black) and lower (gray) layers, as well as between layers at S1.

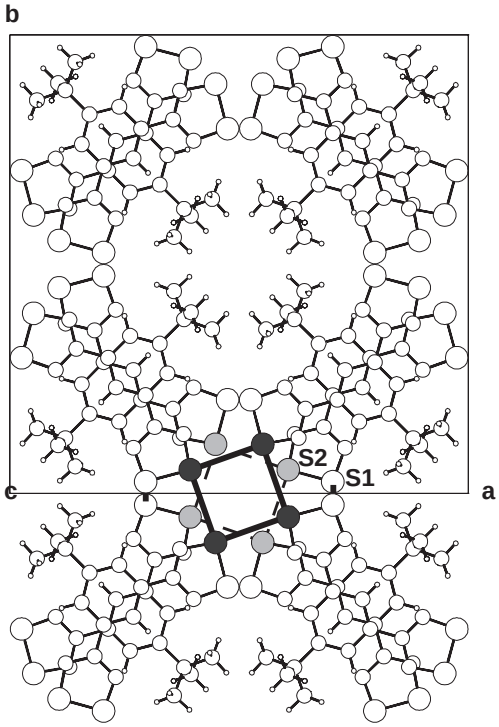

Fig. 6. Side view of portion of a single infinite sulfur-lined channel centred on a $\bar{4}$ axis. Only the CN_2S_2 rings are drawn in this PLUTO representation. The larger diameter spheres are the sulfur atoms.

shorter than that in **3** (3.631) and **5** (3.52 Å). Indeed in **6** the separation approaches that in graphite (3.35 Å) (25). The offset packing of the benzene rings in **6** is highly reminiscent of the ground-state structure of graphite, while in **3** and **5** the C_6 rings are directly superimposed.

The pinwheels in each layer are identical except for the direction of rotation. The cross-ring contacts are all 3.474(2) Å between the S2 atoms on adjacent rings. These contacts are noticeably *longer* than in **3** (3.140 and 3.284 Å), which has a pinwheel structure (6), but shorter than the interactions in the lower-symmetry structure of **5** (9). It may be that despite the central $\bar{4}$ symmetry, the ^{t}Bu groups generate considerable steric hindrance and that this prevents the S1 atoms from lining up into a truly vertical column. The calculated density of the structure is consistently the lowest of any bifunctional neutral dithiadiazole (1.57 g cm^{-3}, vs. a range of 1.61– 2.26 for a variety of bifunctional species (6–8)).

In summary, the crystal structure of **6** is a unique double-layered stacking type. This structure is adopted to accommodate the bulk of the ^{t}Bu groups while still maintaining interlayer contacts among the sulfur atoms. Contrary to previous belief, bulky substituents can be useful molecular engineering tools for the development of stacking dithiadiazole radicals. There are no secondary S–X interactions since there are no other donor sites in the molecules. However, steric repulsion among the bulky substituents may be hindering an even more efficient packing, as reflected in the long cross-stack distances. It may be that modification of the substituents while maintaining bulk (^{i}Pr, CF_3, CCl_3), with or without symmetry lowering, may lead to other double-layer stacked structures with tighter packing within the stacks.

Magnetism and conductivity

The magnetic susceptibility of the title compound was measured as a function of temperature and the results are presented in Fig. 7.[4] The response of the sample to magnetization is complex, typical of bifunctional dithiadiazole systems (4, 6, 7). At very low temperature the sample obeys the Curie–Weiss Law, with $\theta = 0$ K and $\chi_0 = -156$ ppm emu mol^{-1}. The free-spin concentration at absolute zero is estimated to be 1.3%, reflecting paramagnetic defects in an essentially diamagnetic structure. The diamagnetism starts to lift above 210 K, and there is a distinct kink in the susceptibility v*s. T* response at 260 K. A plot of χT vs. *T* (Fig. 7*b*) is linear for the points recorded above 260 K, indicative of an antiferromagnetic exchange interaction in this temperature range. At room temperature, the magnetization corresponds to approximately 0.30 unpaired electrons *per molecule*. The susceptibility data bear remarkable similarity to those of **3** and **5**, *except that the onset of paramagnetism is found 200 K lower in the title compound*. The room temperature pressed-pellet conductivity of the material is less than 10^{-7} S cm^{-1}; this absence of conductivity, given a rich source of carriers, is often observed for neutral dithiadiazoles, leading to the conclusion that their bandwidths are narrow (4). In effect they are Mott insulators (26). The observed structure, consistent with the magnetic behaviour, suggests that the orientation imposed on the title compound by the bulky ^{t}Bu group has stabilized it *above* the Peierls distortion at room temperature, the first stacking neutral dithiadiazole for which this has been achieved. The crystal symmetry of the 250 K structure allows a range of structures from alternating long–short–long S1···S1 distances to completely even spacing. It is possible that below 210 K a greater distortion sets in to produce a fully diamagnetic structure, and in support of this hypothesis several X-ray data sets collected between 150 and 250 K did not lead to satisfactory solutions.

In summary, the novel "double-layer" geometry adopted by the title compound is a consequence of having to pack the large ^{t}Bu group efficiently while preserving intermolecular S···S and S···N contacts. This leads to the unusual dithiadiazole stacking pattern in which a *single* sulfur atom chain maintains contacts down the stack, but with weak interstack interactions. The most dramatic effect of the structure adopted by **6** is on the magnetic behaviour, with the onset of paramagnetism 200 K lower in temperature than in **3** or **5**. Recently some distorted bifunctional dithiadiazoles with biphenyl spacers have shown a slight lowering of the onset temperature (ca. 50 K),[5] but nothing as dramatic as in **6**. Optimization of the spacing substituent may finally allow the preparation of densely stacked neutral dithiadiazoles with equal spacing at room temperature and a sufficiently high bandwidth to achieve a conducting state. Alternatively, bulky groups may find great utility in designing molecular magnets from isolated dithiadiazole groups, a goal recently advanced by others (14). Efforts in both of these directions are underway.

Experimental section

Starting materials and general procedures

5-*tert*-Butylisophthalic acid, sulfur dichloride, 1,1,1,3,3,3-hexamethyldisilazane, *n*-butyllithium, thionyl chloride, ammonium hydroxide, chlorotrimethylsilane, nitrosonium hexafluoroantimonate, and triphenylantimony were all obtained commercially (Aldrich). Sulfur dichloride was distilled before use. Lithium bis(trimethylsilyl)amide diethyl etherate was prepared as described previously (17). Acetonitrile (Fisher HPLC grade) was distilled from phosphorus pentoxide, and toluene from sodium metal. All reactions were performed under an atmosphere of dry nitrogen. NMR spectra were acquired at 250.13 (^{1}H) and 62.90 (^{13}C) MHz on a Bruker AC250-F spectrometer, and ESR spectra on a Bruker EMX instrument. Infrared spectra were obtained as Nujol mulls or KBr pellets on a Bomen MB102 instrument. Elemental analyses were performed by MHW Laboratories, Phoenix, Ariz., and mass spectra were recorded by the Mass Spectrometry Center, University of Alberta, Edmonton.

Preparation of 5-*tert*-butyl-1,3-[$(Me_3Si)_2NCNSiMe_3]_2C_6H_3$, (5-^{t}Bu-1,3-DIBADS)

Solid 5-*tert*-butylisophthalonitrile (46.06 g, 250 mmol) (16) was added to a slurry of lithium bis(trimethylsilyl)amide diethyl etherate (120.75 g, 500 mmol) in 1500 mL of toluene and the mixture was then stirred overnight at 50–70°C. Chlorotrimethylsilane (96 mL, 750 mmol) was added and the mixture

[4] The measurement was performed by R.C. Haddon and T.T.M. Palstra at Bell Laboratories (Lucent Technologies, Murray Hill, N.J.) using a SQUID magnetometer operating at 1 tesla.

[5] T.M. Barclay, A.W. Cordes, N.A. George, R.T. Oakley, and R.C. Haddon, 80th Canadian Society for Chemistry Conference, Windsor, Ontario, July 1–4, 1997. Abstract No. 335.

© 1998 NRC Canada

heated to a gentle reflux for an additional 48 h. The mixture was then cooled and filtered (LiCl) and the solvent removed in vacuo. The residual oil was dissolved in 30 mL of hot toluene and 20 mL of acetonitrile was added while the solution was still hot. After cooling to room temperature an additional 20 mL acetonitrile was added to the solution after which it was cooled to –30°C overnight to give crystalline 5-^{t}Bu-1,3-DIBADS (56.89 g, 0.0873 mol, 35%), mp 118–120°C. IR (KBr pellet): 2972 (vs), 2905 (sh), 1638 (br), 1481 (m), 1362 (m), 1310 (m), 1252 (vs), 1215 (vs), 1148 (s), 1119 (m), 1036 (m), 1011 (m), 907 (vs), 841 (br), 747 (s), 724 (s), 694 (s), 658 (m), 629 (m), 585 (w), 555 (w), 497 (w), 424 (m), 379 (w), 345 (m). ^{1}H NMR (δ, $CDCl_3$): 0.066 (s, 54 H, $SiMe_3$), 1.32 (s, 9 H, ^{t}Bu), 7.17 (t, 1.55 Hz, 1 H, phenylene), 7.33 (d, 1.55 Hz, 2 H, phenylene). ^{13}C NMR: 2.66, 31.2, 34.8, 124.9, 126.9, 142.6, 149.7, 167.0. Mass spectrum, *m/z:* 651 ($C_4H_9C_6H_3[CN_2Si(CH_3)_3]_2^+$, 42%), 635 ($C_3H_6C_6H_3[CN_2(Si(CH_3)_3]_2^+$, 12%), 547 ($C_4H_8C_6H_3CN_2$-$(Si(CH_3)_3)_3CN_2(Si(CH_3)_3)_2^+$, 13%), 506 ($C_4H_7C_6H_3[CN_2$-$(Si(CH_3)_3]_2^+$, 6%), 490 ($C_3H_3C_6H_3[CN_2(Si(CH_3)_3)_2]_2^+$, 12%), 390 ($C_4H_7C_6H_3CN_2(Si(CH_3)_3)_3^+$, 13%), 259 ($CN_2(Si(CH_3)_3)_2^+$, 14%), 73 ($Si(CH_3)_3^+$, 100%). Anal. calcd. for $C_{30}H_{66}N_4Si_6$: C 55.32, H 10.21, N 8.60%; found: C 55.32, H 9.96, N 8.60%.

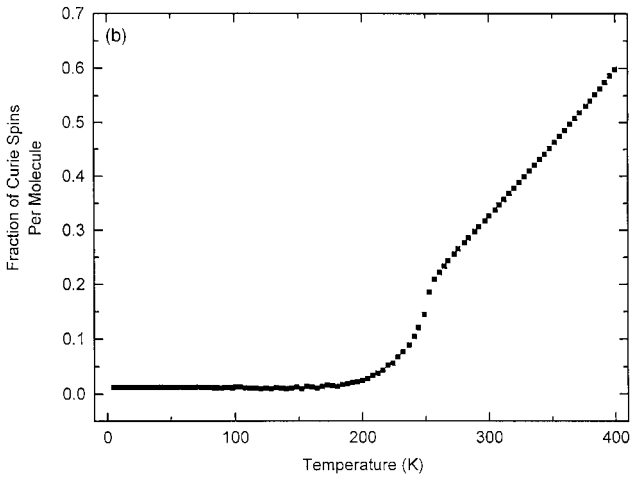
Preparation of 5-*tert*-butyl-1,3-$(S_2N_2C)_2C_6H_3$

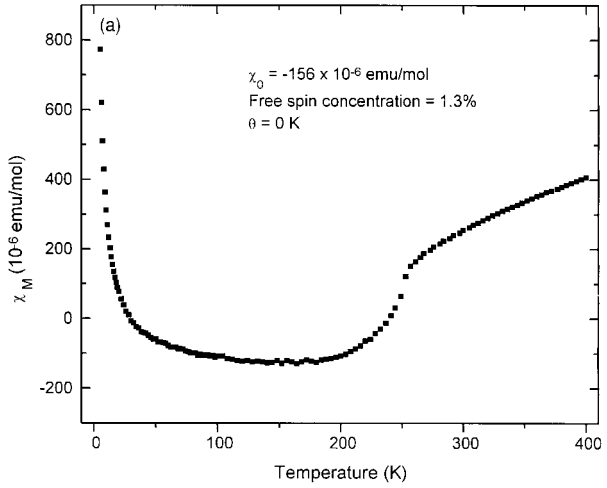
Sulfur dichloride (7.5 mL, 120 mmol) was added, while stirring, to a slurry of 5-^{t}Bu-1,3-DIBADS (6.1 g, 9.36 mmol) in 150 mL of acetonitrile. The resulting mixture was heated to a gentle reflux for 3 h and then filtered to afford crude 5-^{t}Bu-1,3-$[(S_2N_2C)_2C_6H_3]^{2+}(Cl^-)_2$ (2.56 g, 6.22 mmol, 80%) as an orange solid that was dried in vacuo overnight. Ph_3Sb (2.42 g, 6.84 mmol) was added to a stirring slurry of the orange solid in 65 mL of degassed CH_3CN and the mixture was refluxed for 2 h. The crude product (2.01g, 5.9 mmol, 95%), which is both oxygen and moisture sensitive, was then slowly sublimed in a three-zone (50/100/170–180°C) tube furnace over 4 days at 1×10^{-2} Torr to produce large black crystals, collected in the 170°C range (0.589 g, 1.73 mmol, 28%), that are much less air sensitive than the crude product. This was resublimed to produce analytical samples of product, mp 258–262°C. IR (1700–250 cm^{-1}): 1678 (w), 1603 (w), 1551 (w), 1339 (vs), 1273 (m), 1217 (w), 1103 (br), 993 (m), 951 (w), 910 (w), 891 (w), 837 (w), 799 (vs), 706 (w), 691 (vs), 679 (sh), 577 (w), 511 (m). Mass spectrum, *m/z:* 340 ($C_4H_9C_6H_6(CN_2S_2)_2^+$, 100%), 325 ($C_3H_6C_6H_3(CN_2S_2)_2^+$, 18%), 294 ($C_4H_9C_6H_3$-$CN_2S_2CNS^+$, 16%), 262 ($C_4H_9C_6H_3CN_2S_2CN^+$, 67%), 247 ($C_3H_6C_6H_3CN_2S_2CN^+$, 14%), 169 ($C_3H_6C_6H_3(CN)_2^+$, 23%), 141 ($C_3H_6C_6H_3C_2^+$, 31%), 78 ($S_2N^+$, 55%). Anal. calcd. for $C_{12}H_{12}N_4S_4$: C 42.33, H 3.55, N 16.45%; found: C 42.44, H 3.40, N 16.51%.

Preparation of 5-*tert*-butyl-1,3$[(S_2N_2C)_2C_6H_3]^{2+}$ $(SbF_6^-)_2$

5-^{t}Bu-1,3$[C_6H_3(CN_2S_2)_2]^{2+}$ $(Cl^-)_2$ (1.0 g, 2.43 mmol) and nitrosonium hexafluoroantimonate (1.29 g, 4.86 mmol) were added to a 250 mL side-arm flask followed by 5 mL acetonitrile. After gentle reflux for 1 h, the solvent was evaporated in a stream of N_2 (g). The crude product was dissolved in 60 mL of dichloromethane and a minimum amount of acetonitrile (15–20 mL). After cooling to –30°C, crystalline **9** was collected by cold filtration. Yield 0.71 g, 0.874 mmol, 36%, mp (dec.) 205–211°C. IR (1700–250 cm^{-1}): 1689 (w), 1603 (w), 1418 (m), 1356 (vs), 1271 (m), 1211 (w), 1123 (br), 1038 (w), 1017 (w), 968 (w), 899 (m), 837 (sh), 720 (m), 662 (vs), 552 (w), 289 (s). Anal. calcd. for $C_{12}H_{12}N_4S_4Sb_2F_{12}$: C 17.75, H 1.49, N 6.90%; found: C 17.65, H 1.44, N 6.78%. The solid was insufficiently volatile to yield a mass spectrum.

Fig. 7. Plots of (*a*) the magnetic susceptibility of **6** as a function of temperature, and (*b*) the fraction of Curie spins per molecule, determined from the susceptibility data, as a function of temperature.





Crystal structure determination.

Crystallographic data appear in Table 2. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 20.2°–30.0° for **7** and for 14 reflections with 2θ = 18.5°–21.5° for **6**. Hydrogen atoms were included at geometrically idealized positions (C—H 0.95 Å), but were not refined. All non-hydrogen atoms were refined anisotropically. Scattering factors were those of Cromer and Waber (27), and allowance was made for anomalous dispersion (28). Computer programs used at Calgary include SAPI91 (29), DIRDIF94 (30), and teXsan (31); and, at Lethbridge, NRC386, a PC version of NRCVAX (31). Final fractional coordinates and B_{eq} appear in Table 3, selected interatomic distances in Table 4, and selected bond angles in Table 5. ORTEP diagrams showing the atomic numbering scheme are presented in

Fig. 3 (**7**) and Fig. 4 (**6**). Crystal structure reports, and additional tables of final positional parameters, bond lengths and angles, hydrogen atom coordinates, and anisotropic displacement parameters for both **6** and **7** have been deposited as supplementary material.[6]

Electrochemistry

For the voltammetric experiments the vacuum-tight all-glass cell with Pt electrodes that has been described previously (18) was employed. The cell was charged with electrolyte ($N^nBu_4PF_6$) and the solvent, dry degassed CH_3CN or CH_2Cl_2, was transferred on a vacuum line. Samples and ferrocene as an internal reference were added to the cell using break-seal techniques. The ferricenium/ferrocene couple is observed in this system at +0.38 V (CH_3CN) and +0.48 V (CH_2Cl_2) vs. SCE at 25°C. Cyclic voltammetric (scan rates $\nu = 20–500$ mV s^{-1}) and phase-sensitive alternating current experiments ($\omega = 610$ Hz, $\nu = 10$ mV s^{-1}) were carried out with a PAR 170 electrochemical system.

Acknowledgments

We thank Prof. Robert Thompson, University of British Columbia, for a preliminary magnetic susceptibility measurement at room temperature, and Dr. Robert Haddon, Bell Labs, for the VT measurements. Dr. Ralph Weber of Bruker, U.S.A., provided time on the EMX spectrometer, and we thank the staff at Bruker for their assistance. The Natural Sciences and Engineering Research Council of Canada and the University of Lethbridge Research Fund provided financial support.

Total synthesis of (±)-9-deoxygoniopypyrone. Application of the iodocyclofunctionalization reaction of α-allenic alcohol derivatives

Richard W. Friesen and Suzanne Bissada

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Peking University on 09/05/12
For personal use only.

Abstract: The synthesis of (±)-9-deoxygoniopypyrone (**1**) from the α-allenic alcohol **5** is described. Iodocyclofunctionaliztion of the *N*-tosyl carbamate derivative of **5** using I_2 and Ag_2CO_3 provided, in a highly diastereoselective and regioselective fashion, the vinyl iodo *syn*-vicinal diol **4**. Two routes were explored in order to introduce the third stereogenic centre in the molecule. Reductive deiodination of the vinyl iodide and diastereoselective epoxidation of the derived acetonide **14** using mCPBA provided a mixture of epoxides **15** and **16** (2:1) in which the desired *threo* diastereomer predominated. Alternatively, dihydroxylation of acetonide **14** (OsO_4, NMO) yielded a mixture of diols **21** and **22** (2:3) which were separated after monosilylation (TBDMSCl) of the primary alcohol. The major silyl ether *erythro* diastereomer **24** was converted to the desired epoxide **15** by mesylation (MsCl, Et_3N) and epoxide formation (TBAF) with inversion of stereochemistry. The minor *threo* diastereomer **23** was also converted to the desired epoxide **15** (TBAF; $ArSO_2Cl$; NaOMe). Epoxide opening was effected with lithium acetylide and the resulting alkyne **27** was carbonylated (MeLi, $ClCO_2Me$) to afford the α,β-acetylenic ester **28**. Semi hydrogenation over Lindlar's catalyst followed by protecting- group removal under acidic conditions provided (±)-8-epigoniodiol **30**. Finally, conversion of **30** to (±)-9-deoxygoniopypyrone **1** was effected under basic conditions (DBU).

Key words: (±)-9-deoxygoniopypyrone, α-allenic alcohol, iodocyclofunctionalization, *syn*-diol.

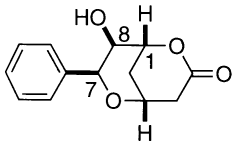
Résumé : On décrit la synthèse de la (±)-9-désoxygoniopyrone (**1**) à partir de l'alcool α-allénique **5**. L'iodocyclofonctionnalisation du dérivé *N*-tosylcarbamate du produit **5** à l'aide de I_2 et de Ag_2CO_3 a conduit au vinyl iodo diol *syn*-vicinal **4** avec une diastéréosélectivité et une régiosélectivité élevées. Dans le but d'introduire le troisième centre stéréogénique de la molécule, on a exploré deux voies. D'une part, la déiodation réductrice de l'iodure de vinyle et l'époxydation diastéréosélective du dérivé acétonide **14** à l'aide de l'acide *m*-chloroperbenzoïque (AmCPB) conduisent à un mélange d'époxydes **15** et **16** (2 : 1) dans lequel le diastéréomère *thréo* recherché prédomine. D'autre part, la dihydroxylation de l'acétonide **14** (OsO_4, NMO) fournit un mélange des diols **21** et **22** (2 : 3) qui ont pu être séparés après monosilylation («TBDMSCl») de l'alcool primaire. On a transformé l'éther silylé du diastéréomère *érythro* (**24**) prépondérant en époxyde **15** recherché en procédant à une mésylation («MsCl», Et_3N) suivie de la formation d'un époxyde («TBAF») avec inversion de stéréochimie. Le diastéréomère *thréo* (**23**) minoritaire a aussi été transformé en époxyde **15** recherché («TBAF»; $ArSO_2Cl$; NaOMe). On a effectué l'ouverture de l'époxyde à l'aide d'acétylure de lithium et on a effectué une décarbonylation de l'alcyne **27** qui en résulte (MeLi, $ClCO_2Me$) pour conduire à l'ester α,β-acétylénique **28** qui, par semihydrogénation sur du catalyseur de Lindlar suivie de l'élimination des groupes protecteurs dans des conditions acides, fournit le (±)-8-épigoniodiol **30**. Enfin, on a effectué la conversion du composé **30** en (±)-9-désoxygoniopyrone (**1**) dans des conditions basiques («DBU»).

Mots clés : (±)-9-désoxygoniopyrone, alcool α-allénique, iodocyclofonctionnalisation, *syn*-diol.

[Traduit par la rédaction]

Introduction

The cytotoxic (ED_{50} 7.4 μg/mL against HT-29 cells) bicyclic styryl lactone (+)-9-deoxygoniopypyrone (**1**) was isolated in 1990 from the stem bark of *Goniothalamus giganteus* Hook. f. & Thomas (Annonaceae) (1). (+)-9-Deoxygoniopypyrone (**1**) possesses several interesting structural features, including the novel 2,6-dioxabicyclo[3.3.1]nonan-3-one molecular scaffold, that make it attractive as a synthetic target. Within this framework, the key substructure in terms of synthesis is the triol



1

moiety in which the three contiguous oxygen-bearing stereocentres (C7/C8/C1) are in a *syn*,*syn* relationship (see **2**).

We have been interested in the synthesis of natural products using our recently described method for the highly diastereoselective conversion of the *N*-tosyl carbamate derivatives of secondary α-allenic alcohols such as **5** into vinyl iodo *syn*-vicinal diols **4** (2–6). We felt that the implementation of

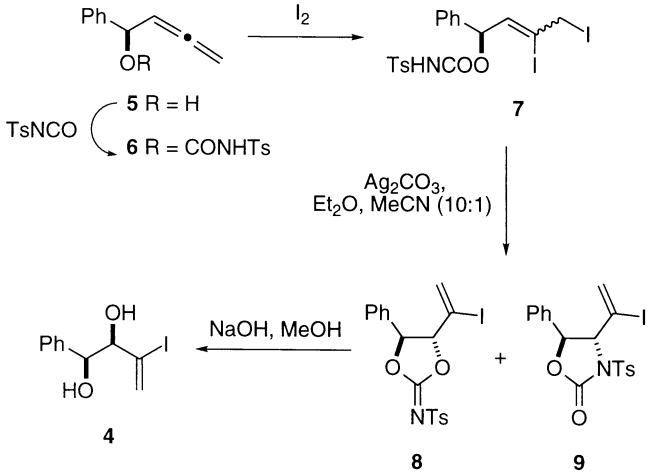
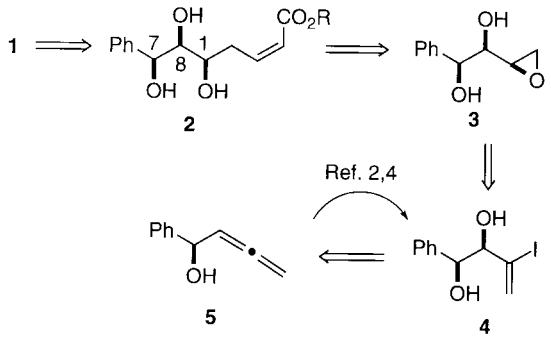
Scheme 1.



this iodocyclofunctionalization strategy would allow us to address the structurally interesting features in **1**. According to our retrosynthetic plan, the relative stereochemistry between the C7/C8 hydroxy moieties in **1** (natural product numbering used throughout) would be readily established using this method. Following reductive deiodination of the vinyl iodide moiety in **4**, diastereoselective oxidation (epoxidation or dihydroxylation) of the resulting olefin would introduce the third stereocentre and provide the epoxide **3**. Homologation of **3** would afford the α,β-unsaturated ester **2**, the immediate precursor to **1**. Herein, we describe the full details of the synthesis of (±)-**1** (Schemes 1–3) according to this strategy.[2]

Two syntheses of (+)-**1** have been reported in the literature. The first synthesis by Honda and co-workers (7), which utilized 2,3-*O*-isopropylidene-D-glyceraldehyde as the chiral



starting material, demonstrated that the absolute configuration of the natural product (+)-**1** is as depicted. Subsequent to our published synthesis of (±)-**1**,[2] Yang and Zhou described the synthesis of (+)-**1** from methyl cinnamate using Sharpless asymmetric dihydroxylation technology (8). In contrast to our synthesis, both of these groups introduced one of the three contiguous hydroxy-bearing stereocentres by the nucleophilic addition of a metalated aromatic to an α-alkoxy aldehyde.

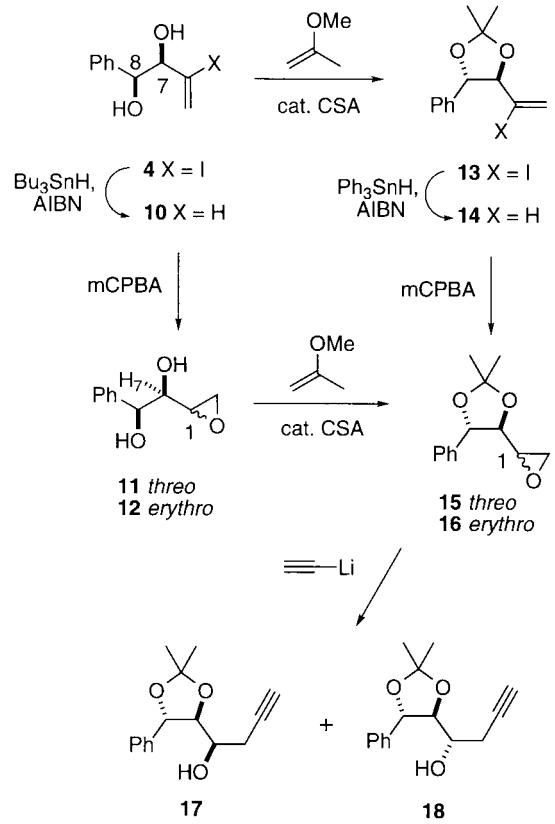
Results and discussion

The vinyl iodo *syn*-diol **4** was prepared from the racemic α-allenic alcohol **5**,[3] using our previously reported

[2] For a preliminary account of this work, see ref. 3.

[3] Although **5** is racemic, only a single enantiomer has been drawn throughout.

Scheme 2.



iodocyclofunctionalization procedure (2, 4) (Scheme 1). Thus, alcohol **5** was treated sequentially with TsNCO and I_2 to provide an *E/Z* mixture of diiodides **7** (5) that was cyclized by treatment with Ag_2CO_3 in ether–MeCN (10:1). Filtration of the silver salts and concentration of the reaction mixture provided the crude cyclization products. In accord with our earlier observations (2, 4), inspection of the ^{1}H NMR spectrum of the crude reaction mixture revealed that the imino carbonate **8** was obtained in a highly diastereoselective fashion (diastereoselectivity >50:1) together with minor amounts (<5%) of the related carbamate **9** (9). From a practical point of view, it is important to point out that it is essential to wash the solid silver salt cake extensively with ethyl acetate and methanol in order to achieve optimum recovery of the initial cyclization products. Hydrolysis of the crude mixture with methanolic sodium hydroxide yielded the desired vinyl iodo *syn*-diol **4** in 66% overall yield after chromatography. Reductive deiodination of **4** using *n*-Bu_3SnH–AIBN provided the unsaturated diol **10** in 81% yield (Scheme 2).

The strategy for the synthesis of **1** from *syn*-diol **10** required that the installation of the C1 oxygen occur with *threo* diastereoselectivity relative to the hydroxy moieties at C7 and C8. In keeping with the plan that chain extension to an intermediate such as **2** would be required, epoxidation of **10** appeared to be an obvious strategy. The directed diastereoselective epoxidation reactions of allylic and homoallylic alcohols or diols are well documented (10–15). Typically, transition metal (Ti, V) mediated epoxidations of such olefins, including monosubstituted alkenes, afford the *erythro* diastereomers with good to excellent stereoselectivity. Conversely, epoxidations of both

For personal use only.

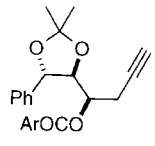
allylic and homoallylic alcohols with mCPBA are marginally diastereoselective in favour of the *threo* epoxides. For example, upon treatment of 3-buten-2-ol or 4-penten-2-ol with mCPBA, the corresponding *threo* epoxide isomers are obtained in ratios of 3:2 and 1.2:1, respectively (10–12). Not surprisingly, exposure of ene diol **10** to mCPBA at room temperature provided a mixture of epoxides **11**/**12** in a ratio of 2:1 (51%) (Scheme 2).

The stereochemical assignments of the epoxy diol diastereomers **11**/**12** are based on comparison of their ^{1}H NMR spectral data with those of structurally similar epoxy alcohols (13–15). The characteristic proton resonance in these spectra is that of H7. Typically, the resonance frequency of this proton is observed at higher field in the *threo* isomer than in the *erythro* isomer. In the case of epoxy diols **11**/**12**, the chemical shift of H7 in the major isomer (δ 3.68) is 0.25 ppm upfield relative to the corresponding resonance in the minor isomer (δ 3.93). This observation is consistent with the reported literature data (13–15) and suggests that the major isomer is in fact the *threo* epoxy diol **11**.

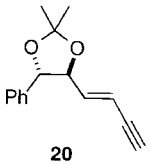
A variety of methods, including metal-catalyzed directed epoxidation (Ti, V) (10–12), were attempted in an effort to increase the *threo* diastereoselectivity in the epoxidation of **10** but without any improvement in selectivity. In addition, several monoprotected alcohol derivatives of **10** (MOM, TBDMS) (6) were also oxidized using mCPBA or the VO(acac)$_2$–*t*-BuOOH epoxidation system (10–12). All of these reactions were unsatisfying since they resulted in low diastereoselectivity and were also plagued by low conversion or competing side reactions such as benzylic oxidation. As far as we are aware, the general *threo* diastereoselective epoxidation of this class of monosubstituted olefinic alcohols (or diols) remains an unsolved problem in organic synthesis.[4]

We then turned our attention to the epoxidation of a protected diol, the acetonide **14** (Scheme 2). Thus, treatment of **14** with mCPBA at room temperature for 3 days provided the epoxides **15** and **16** as an inseparable 2:1 mixture in a combined isolated yield of 96%. Although in this reaction the diastereoselectivity was no better than that observed in the epoxidation of diol **10**, the yield was substantially better. Furthermore, it was anticipated that the stereocentre at C1 in isomer **16** could be inverted at a later stage in the synthesis and thus the epoxide mixture **15**/**16** was carried forward. The assignment of the relative stereochemistry in the major epoxide diastereomer **15** was only tentative and was made primarily by correlation with the products derived from the epoxidation of **10** described earlier. The epoxide mixture **11**/**12** derived from **10** was converted into the corresponding mixture of acetonides **15**/**16** (2:1) and the major isomer from this mixture was identical with the major epoxide **15** obtained upon epoxidation of **14**. The eventual conversion of **15** to **1** (vide infra) confirmed this stereochemical assignment.

The epoxide mixture **15**/**16** was treated with the dianion of propiolic acid according to the conditions of Carlson and Oyler (17). This reaction was extremely capricious and we were never able to find conditions that would bring about the epoxide opening of **15**/**16** in a reproducible fashion on a quantity of material. However, treatment of the epoxide mixture **15**/**16** with lithium acetylide – EDA complex in THF–HMPA at



19



20

room temperature afforded the readily separable acetylenic alcohols **17** and **18** in isolated yields of 55% and 26%, respectively. Omission of the HMPA from this reaction mixture resulted in only low (<10%) conversion. The inversion of the C1 alcohol stereocentre in **18** was attempted using Mitsunobu chemistry. The conditions described by Martin and Dodge (18) using *p*-nitrobenzoic acid and DEAD in PhMe provided predominantly the *E*-enyne **20** (76%) along with only 7% of the desired benzoate **19,** which was subsequently hydrolyzed to the alcohol **17**. Other related methods that were attempted for the inversion of the C1 stereocentre in **18**, including a two-step oxidation–reduction sequence, were also unsatisfactory.

Due to our inability to invert the C1 (natural product numbering) stereocentre in the acetylenic alcohol **18**, we then considered the possibility of carrying out a dihydroxylation of olefin **14** in order to introduce the desired oxygenation pattern. It was anticipated, based on Kishi's rules (19) and additional literature precedent (20), that the bishydroxylation of monosubstituted olefin **14** would not be highly diastereoselective and that the major diastereomer would possess the undesired *erythro* relative stereochemistry at C1. However, it was expected that *both* diol diastereomers resulting from dihydroxylation could be efficiently converted into the desired epoxide **15**. Although this route would be more lengthy than direct epoxidation of the olefin, it would ultimately provide a single epoxide with the correct relative stereochemistry at C1.

In the event, olefin **14** was treated with catalytic OsO_4 and NMO to provide a 2:3 (by inspection of the integrated ^{1}H NMR spectrum) mixture of diols **21** and **22**, respectively (Scheme 3). The major diastereomer **22** was assigned the *erythro* configuration based upon literature precedent (19, 20). The crude diol mixture was silylated using TBDMSCl at 0°C and the readily separable monosilylated diols **23** and **24** were obtained in overall isolated yields of 37 and 57%, respectively, from olefin **14**. A two-step reaction sequence, involving formation of the mesylate **26** (MsCl, Et_3N, 0°C) followed by intramolecular displacement using TBAF at room temperature, effected the transformation of the major diastereomer **24** into the desired epoxide **15** in 86% overall yield. Desilylation (TBAF) of silyl ether **23** followed by conversion of the primary alcohol to the aryl sulfonate **25** using 2-mesitylenesulfonyl chloride (0°C to room temperature) was accomplished in 92% yield. Treatment of **25** with K_2CO_3 in MeOH provided epoxide **15** in 97% yield. Therefore, the overall conversion from **14** to **15** via the dihydroxylation strategy illustrated in Scheme 3 is an acceptable 82%.

With pure epoxide **15** now in hand, alkylation with lithium

[4] Roush and Michaelides have reported that a MOM monoprotected *syn*-diol related to **10** is epoxidized with exceptionally high *threo* diastereoselectivity usingVO(acac)$_2$–*t*-BuOOH (16). However, in this literature example, the unprotected non-benzylic homoallylic alcohol is flanked by a group that is much more sterically bulky than the phenyl group of **10**.

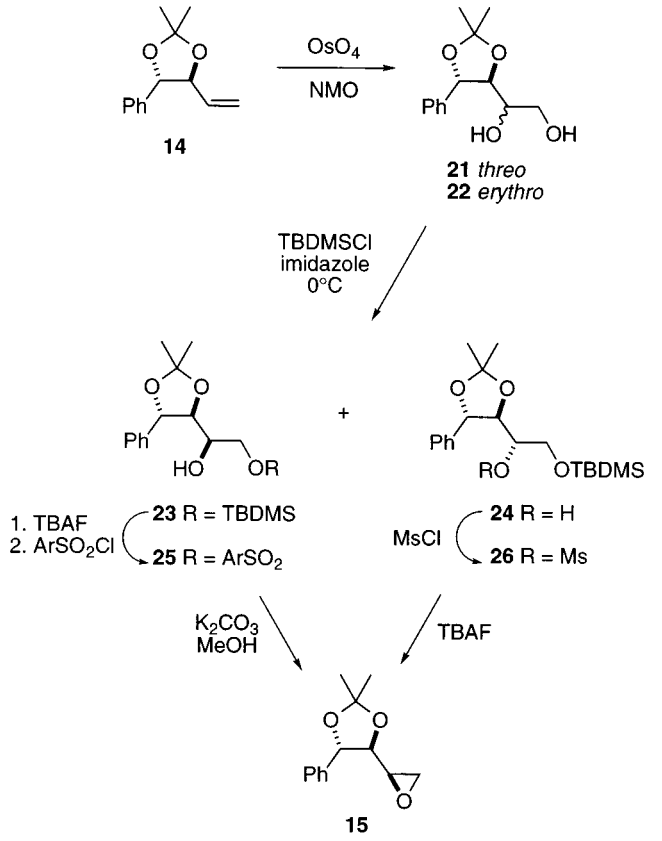
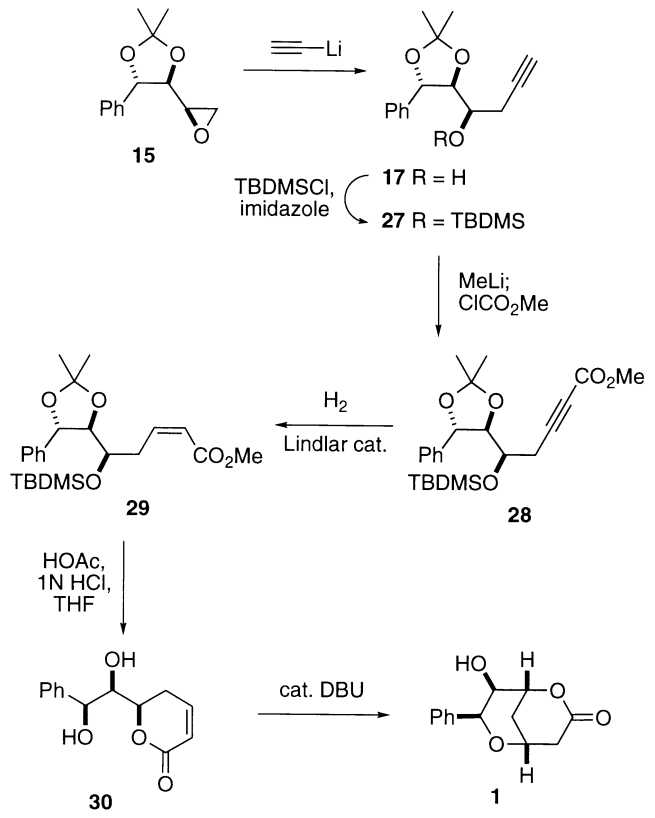
Scheme 3.



Scheme 4.



acetylide – EDA complex in THF–HMPA at room temperature as described previously led to the acetylenic alcohol **17** (88%) (Scheme 4). Protection of the alcohol **17** (TBDMSOTf, Et_3N; 96%) followed by methoxycarbonylation (MeLi; $ClCO_2Me$; 91%) provided the α,β-acetylenic ester **28**. The three-step sequence from **15** to **28** (alkylation, silylation, methoxycarbonylation), while somewhat more lengthy than the originally anticipated reaction with propiolic acid dianion (vide supra), proceeds in excellent overall yield.

The conversion of the α,β-acetylenic ester **28** to the dihydropyran-2-one **30**, the immediate precursor to **1**, followed the strategy described by Carlson et al. for the synthesis of simple dihydropyran-2-ones (17). Thus, semi hydrogenation of the alkyne **28** over Lindlar's catalyst (5% Pd on Ca_2CO_3) cleanly provided the *Z* olefin **29**. The ^1H NMR spectrum of the crude material indicated the clean conversion of **28** to **29** without competing over-reduction or olefin *E*/*Z* isomerization. The crude reaction mixture was treated with a mixture of HOAc, 1 N HCl, and THF (1:1:1 v/v/v) at 65°C, resulting in the complete deprotection of the triol and subsequent cyclization to the lactone **30** (8-epigoniodiol) (7). Again, analysis of the crude reaction mixture (^1H NMR) revealed that a small amount of **30** had undergone cyclization to **1** under these reaction conditions. Thus, once again, the crude reaction mixture was used and the cyclization was completed using conditions that had been described by Honda and co-workers (1% DBU in THF) (7). Synthetic (±)-9-deoxygoniopypyrone (**1**) (mp 185–186°C, EtOH) was isolated in 60% yield for the three steps from **28** and exhibited spectral data (^1H and ^{13}C NMR, IR) identical to the data reported (1) for the natural product.

Experimental

General information

^1H NMR spectra were recorded at 300, 400, or 500 MHz in acetone-d_6 or $CDCl_3$ as specified. Broad-band proton-decoupled ^{13}C NMR spectra were recorded at 100 or 125 MHz in $CDCl_3$. IR spectra were recorded on neat samples unless stated otherwise. Solvents were anhydrous and were transferred via syringes under an atmosphere of argon or nitrogen. Work-up procedures involving the drying of organics were carried out with $MgSO_4$. Flash column chromatography (referred to as chromatography) was performed with 230–400 mesh silica gel, eluting with the solvents indicated (v/v). Elemental analyses were performed by Oneida Research Services, Inc., Whitesboro, N.Y., or the Laboratoire d'analyse élémentaire, Université de Montréal. Compounds for which high-resolution mass measurements are given were homogeneous by TLC analysis and gave satisfactory spectroscopic data indicative of their purity.

3,4-Dihydroxy-2-iodo-phenyl-1-butene ***4***

To a solution of 1-phenyl-2,3-butadien-1-ol **5** (10.5 g, 71.8 mmol) in ether (350 mL) at room temperature was slowly added *p*-TsNCO (12.0 mL, 1.1 equiv.). The mixture was stirred at room temperature for 30 min and then solid I_2 (18.2 g, 1.0 equiv.) was added in several portions over 1 h. Ag_2CO_3 (29.7 g, 1.5 equiv.) and MeCN (35 mL) were added sequentially and the resulting mixture was stirred at room temperature for 15 h. The reaction mixture was filtered through Celite, and the filter pad was washed extensively with ethyl acetate

(approximately 2 L) followed by methanol (approximately 500 mL). The filtrate was concentrated, the crude mixture was dissolved in methanol – 1 N NaOH (3:1 v/v, 320 mL) and stirred at room temperature for 15 h. The methanol was evaporated and the solution was neutralized to ~pH 7 by the addition of 1 N HCl. The mixture was extracted with CH_2Cl_2 (3 × 500 mL) and the combined organics were dried and concentrated. Chromatography (toluene–acetone, 6:1 to 5:1) of the residual material provided the diol **4** (13.7 g, 66%) as a white solid, mp 68.5–69.5°C. IR ($CHCl_3$): 3590, 1630, 1275 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 3.09 (br s, 1H), 3.23 (br s, 1H), 3.72 (br d, 1H, J = 6.0 Hz), 4.77 (d, 1H, J = 6.5 Hz), 5.80 (d, 1H, J = 1.8 Hz), 6.10 (dd, 1H, J = 1.0, 1.8 Hz), 7.26–7.39 (m, 5H); ^{13}C NMR δ: 75.8, 81.5, 111.6, 126.7, 128.2, 128.3, 128.6, 139.5. Anal. calcd. for $C_{10}H_{11}IO_2$: C 41.40, H 3.82; found: C 41.24, H 3.69.

3,4-Dihydroxy-4-phenyl-1-butene ***10***

To a solution of vinyl iodide **4** (8.0 g, 27.6 mmol) in refluxing benzene (333 mL) was added *n*-Bu_3SnH (8.2 mL, 1.1 equiv.) and AIBN (100 mg) and the solution was refluxed for 15 h. The solution was cooled to room temperature and then 10% KF (300 mL) and EtOAc (300 mL) were added. After 45 min, the white precipitate was filtered off and the filtrate was extracted with EtOAc (2×). The combined organics were washed with 10% KF and with brine, dried, and concentrated. Chromatography (hexane followed by hexane–EtOAc, 3:2) of the residue provided the diol **10** (3.66 g, 81%) as a colourless oil. IR: 3300, 1050 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 2.50 (br s, 2H), 4.21 (ddt, 1H, J = 5.5, 6.9, 1.5 Hz), 4.48 (d, 1H, J = 6.9 Hz), 5.13 (dt, 1H, J = 10.6, 1.5 Hz), 5.23 (dt, 1H, J = 17.3, 1.5 Hz), 5.71 (ddd, 1H, J = 5.5, 10.6, 17.3 Hz), 7.25–7.44 (m, 5H); ^{13}C NMR δ: 76.9, 77.6, 117.0, 127.0, 128.1, 128.4, 136.3, 140.2. Anal. calcd. for $C_{10}H_{12}O_2$: C 73.15, H 7.37; found: C 73.27, H 7.66.

Epoxidation of 3,4-dihydroxy-4-phenyl-1-butene ***10*** *(epoxides* ***11*** *and* ***12****)*

To a solution of diol **10** (116 mg, 0.71 mmol) in CH_2Cl_2 (3 mL) at room temperature was added mCPBA (458 mg, 3.0 equiv.) and the mixture was stirred for 16 h. Saturated sodium carbonate was added and the mixture was extracted with EtOAc (2×). The combined organics were washed with 1 N NaOH and brine, dried, and concentrated. Inspection of this crude reaction mixture by ^1H NMR spectroscopy indicated a 2:1 mixture of isomers. Chromatography (hexane–EtOAc, 1:2) of the residue provided a mixture of the epoxy diols **11** and **12** (65 mg, 51%) as a colourless oil. Major isomer **11:** ^1H NMR (500 MHz, $CDCl_3$) δ: 2.55 (dd, 1H, J = 2.8, 4.9 Hz), 2.65 (dd, 1H, J = 4.2, 4.9 Hz), 2.97 (ddd, 1H, J = 2.8, 3.8, 4.2 Hz), 3.68 (dd, 1H, J = 3.8, 7.4 Hz), 4.73 (d, 1H, J = 7.4 Hz), 7.35 (m, 5H). Minor isomer **12:** ^1H NMR (500 MHz, $CDCl_3$) δ: 2.77 (dd, 1H, J = 4.0, 5.0 Hz), 2.86 (dd, 1H, J = 2.8, 5.0 Hz), 2.94 (ddd, 1H, J = 2.8, 3.6, 4.0 Hz), 3.93 (dd, 1H, J = 3.6, 5.9 Hz), 4.70 (d, 1H, J = 5.9 Hz), 7.35 (m, 5H).

Acetonide ***13***

A solution of diol **4** (1.8 g, 6.2 mmol), 2-methoxypropene (0.9 mL, 1.5 equiv.), and camphorsulfonic acid (25 mg) in DMF (10 mL) was stirred at room temperature for 2 h. The mixture was poured into ammonium acetate buffer and extracted with ether (4×). The combined organics were washed with water and brine, dried, and concentrated. Chromatography (hexane–ether, 10:1) of the residue provided the acetonide **13** (1.89 g, 92%) as a colourless oil. IR: 1050 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.59 (s, 3H), 1.63 (s, 3H), 3.63 (dd, 1H, J = 0.8, 8.0 Hz), 4.83 (d, 1H, J = 8.0 Hz), 5.99 (d, 1H, J = 1.5 Hz), 6.28 (dd, 1H, J = 0.8, 1.5 Hz), 7.28–7.38 (m, 5H); ^{13}C NMR δ: 27.4, 27.5, 82.8, 88.0, 109.0, 110.3, 126.5, 128.36, 128.42, 130.0, 136.7. Anal. calcd. for $C_{13}H_{15}IO_2$: C 47.29, H 4.58; found: C 46.88, H 4.50.

Olefin ***14***

A mixture of vinyl iodide **13** (1.8 g, 6.2 mmol), triphenyltin hydride (2.6 g, 1.2 equiv.), and AIBN (20 mg) in benzene (40 mL) was heated at reflux for 90 min. The solution was cooled to room temperature and then 10% KF (100 mL) and EtOAc (100 mL) were added. After 15 min, the white precipitate was filtered off and the filtrate was extracted with EtOAc (2×). The combined organics were washed with 10% KF and brine, dried, and concentrated. Chromatography (hexane–ether, 15:1) of the residue provided the olefin **14** (1.09 g, 87%) as a colourless oil. IR: 2980, 1365, 1230, 1050 cm^{-1}; ^1H NMR: (300 MHz, $CDCl_3$) δ: 1.53 (s, 3H), 1.57 (s, 3H), 4.17 (app t, 1H, J = 8.4 Hz), 4.64 (d, 1H, J = 8.4 Hz), 5.20–5.27 (m, 2H), 5.87 (m, 1H), 7.26–7.58 (m, 5H); ^{13}C NMR δ: 27.0, 27.1, 82.9, 84.7, 109.3, 119.3, 126.4, 128.2, 128.4, 133.9, 137.2. Exact Mass calcd. for $C_{13}H_{17}O_2$ $(M+H)^+$: 205.1229; found: 205.1228.

Epoxidation of olefin ***14*** *(epoxides* ***15*** *and* ***16****)*

To a solution of olefin **14** (950 mg, 4.65 mmol) in dichloromethane (50 mL) at 0°C was added mCPBA (3.0 g, 3 equiv.). After 30 min, the cold bath was removed and the mixture was stirred at room temperature for 72 h. Saturated $NaHCO_3$ (100 mL) was added and the mixture was extracted with dichloromethane (2×). The combined organics were washed with saturated $NaHCO_3$ (2×), water, and brine, then dried and concentrated. Chromatography (hexane–EtOAc, 9:1) of the residue provided an inseparable mixture of the epoxides **15** and **16** (983 mg, 96%) as a colourless oil. Inspection of this mixture by ^1H NMR spectroscopy indicated a 2:1 mixture of isomers. Major isomer **15:** ^1H NMR (300 MHz, $CDCl_3$) δ: 1.50 (s, 3H), 1.55 (s, 3H), 2.48 (dd, 1H, J = 2.6, 5.3 Hz), 2.75 (dd, 1H, J = 4.2, 5.3 Hz), 3.06 (ddd, 1H, J = 2.6, 4.2, 5.0 Hz), 3.62 (dd, 1H, J = 5.0, 8.7 Hz), 4.91 (d, 1H, J = 8.7 Hz), 7.35 (m, 5H). Minor isomer **16:** ^1H NMR (300 MHz, $CDCl_3$) δ: 1.52 (s, 3H), 1.54 (s, 3H), 2.67 (dd, 1H, J = 2.6, 5.0 Hz), 2.81 (dd, 1H, J = 4.0, 5.0 Hz), 3.14 (ddd, 1H, J = 2.6, 4.0, 5.1 Hz), 3.73 (dd, 1H, J = 5.1, 8.1 Hz), 4.94 (d, 1H, J = 8.1 Hz), 7.35 (m, 5H).

Alkynes ***17*** *and* ***18***

Lithium acetylide – EDA complex (540 mg, 1.3 equiv.) was added portionwise over 2 min to a solution of the epoxide mixture **15**/**16** (887 mg, 4.03 mmol) in THF (10 mL) and HMPA (4 mL). The resulting mixture was stirred at room temperature for 15 h and then water was carefully added. The mixture was extracted with EtOAc (3×), and the combined organics were washed with 10% HCl (3×), water, and brine, then dried and concentrated. Chromatography (toluene–EtOAc, 10:1) of the residue provided the alkynes **17** and **18**. The first compound to

*Enyne **20** and benzoate **19***

To a solution of alcohol **18** (144 mg, 0.58 mmol) in toluene (12 mL) at room temperature was added sequentially Ph_3P (307 mg, 2 equiv.), DEAD (0.18 mL, 2 equiv.), and *p*-nitrobenzoic acid (195 mg, 2 equiv.). The resulting mixture was stirred for 2 h and then hexane (30 mL) was added. The white preciptate was filtered through Celite and to the filtrate was added EtOAc. The combined organics were washed with saturated $NaHCO_3$ (3×), dried, and concentrated. Chromatography (hexane–EtOAc, 9:1 to 4:1) of the residue first provided the enyne **20** (101 mg, 76%) as a white solid, mp 52–53°C. IR ($CHCl_3$): 3300, 1490, 1450, 1380, 1050, 690 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.52 (s, 3H), 1.57 (s, 3H), 2.90 (d, 1H, J = 2.3 Hz), 4.20 (ddd, 1H, J = 1.3, 6.4, 8.4 Hz), 4.65 (d, 1H, J = 8.4 Hz), 5.68 (ddd, 1H, J = 1.3, 2.3, 15.9 Hz), 6.21 (ddd, 1H, J = 0.5, 6.4, 15.9 Hz), 7.27–7.37 (m, 5H); ^{13}C NMR δ: 26.9, 27.0, 78.7, 81.2, 82.8, 83.3, 109.7, 112.1, 126.4, 128.4, 128.6, 136.7, 140.0. Anal. calcd. for $C_{15}H_{16}O_2$: C 78.92, H 7.06; found: C 79.30, H 7.15. Further elution provided the benzoate **19** (17 mg, 7%), which was obtained as a white solid. Benzoate **19** was dissolved in MeOH (2 mL) and water (0.1 mL) and treated with K_2CO_3 (2 mg). After 24 h, the mixture was concentrated and subjected to chromatography (9:1 toluene–EtOAc). The alkynol **17** was obtained as a white solid (4 mg, 95%).

*Silyl ethers **23** and **24***

To a solution of alkene **14** (1.0 g, 4.9 mmol) and $NMO{\cdot}H_2O$ (1.4 g, 2.1 equiv.) in acetone (20 mL) and water (2 mL) at room temperature was added a solution of OsO_4 (1 mL of a 4% solution in water) and the mixture was stirred for 15 h. A saturated solution of Na_2SO_3 (30 mL) was added and the resulting mixture was stirred for 1 h. The mixture was extracted with EtOAc (2×) and the organics were washed successively with saturated Na_2SO_3, water, and brine and then dried and concentrated. The residual oil so obtained (analysis by ^1H NMR spectroscopy indicated it to be a 3:2 mixture of diastereomers) and imidazole (790 mg, 2.4 equiv.) were dissolved in CH_2Cl_2 (18 mL) and cooled to 0°C. TBDMSCl (875 mg, 1.2 equiv.) was added as a solid and the resulting mixture was stirred at 0°C for 2 h. Water (50 mL) was added and extracted with EtOAc (2×). The organics were washed with brine and concentrated. The residual oil was subjected to chromatography (hexane–EtOAc, 10:1). The major diastereomer, silyl ether **24** (985 mg, 57%), was eluted first and was obtained as a colourless oil. IR: 3480, 840 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) δ: 0.02 (s, 3H), 0.03 (s, 3H), 0.86 (s, 9H), 1.48 (s, 3H), 1.53 (s, 3H), 2.48 (d, 1H, J = 4.8 Hz), 3.61 (dd, 1H, J = 6.5, 10.1 Hz), 3.71 (dd, 1H, J = 3.9, 10.1 Hz), 3.83 (m, 1H), 3.92 (dd, 1H, J = 6.8, 7.7 Hz), 5.03 (d, 1H, J = 7.7 Hz), 7.26–7.47 (m, 5H); ^{13}C NMR (125 MHz) δ: –5.6, –5.5, 18.2, 25.7, 27.0, 27.1, 64.0, 72.9, 81.1, 82.3, 109.3, 127.2, 128.0, 128.3, 138.9. Anal. calcd. for $C_{19}H_{32}O_4Si$: C 64.73, H 9.15; found: C 64.89, H 9.42. Further elution provided the minor diastereomer, silyl ether **23** (648 mg, 37%), as a colourless oil. IR: 3480, 830 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) δ: –0.04 (s, 3H), –0.01 (s, 3H), 0.81 (s, 9H), 1.51 (s, 3H), 1.55 (s, 3H), 2.45 (d, 1H, J = 7.3 Hz), 3.54 (m, 1H), 3.59–3.64 (m, 2H), 3.87 (dd, 1H, J = 1.8, 8.7 Hz), 4.99 (d, 1H, J = 8.7 Hz), 7.27–7.41 (m, 5H); ^{13}C NMR (125 MHz) δ: –5.6, –5.5, 18.1, 25.7, 26.9, 27.2, 64.7, 68.7, 79.0, 82.2, 109.3, 126.8, 128.3, 128.5, 137.5. Anal. calcd. for $C_{19}H_{32}O_4Si$: C 64.73, H 9.15; found: C 64.48, H 9.06.

*Epoxide **15** from the major silyl ether diastereomer **24***

To a solution of alcohol **24** (885 mg, 2.51 mmol) and Et_3N (1.05 mL, 3 equiv.) in CH_2Cl_2 (10 mL) at 0°C was added methanesulfonyl chloride (0.29 mL, 1.5 equiv.). After 15 min, water was added and the resulting mixture was stirred at room temperature for 15 min. The mixture was extracted with EtOAc (2×) and the organics were washed with water, dried, and concentrated. The colourless residue was dissolved in THF (10 mL) and TBAF (5.0 mL, 2 equiv.) was added. The reaction mixture was stirred at room temperature for 15 h and then water was added. The mixture was extracted with EtOAc (2×) and the organics were washed with water and brine, dried, and concentrated. Chromatography (hexane–EtOAc, 6:1) of the residual oil provided epoxide **15** (477 mg, 86%) as a colourless oil. IR: 1235 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.50 (s, 3H), 1.55 (s, 3H), 2.48 (dd, 1H, J = 2.6, 5.3 Hz), 2.75 (dd, 1H, J = 4.2, 5.3 Hz), 3.06 (ddd, 1H, J = 2.6, 4.2, 5.0 Hz), 3.62 (dd, 1H, J = 5.0, 8.7 Hz), 4.91 (d, 1H, J = 8.7 Hz), 7.35 (m, 5H); ^{13}C NMR (125 MHz) δ: 26.6, 26.9, 43.7, 50.2, 80.0, 83.2, 109.8, 126.3, 128.3, 128.6, 137.4. Anal. calcd. for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 70.54, H 7.34.

*Aryl sulfonate **25***

To a solution of silyl ether **23** (741 mg, 2.10 mmol) in THF (10 mL) was added TBAF (2.3 mL, 1.1 equiv.) and, after 1 h, water was added. The mixture was extracted with EtOAc (3×) and the organics were washed with water and brine, dried, and concentrated. The residual white solid was dissolved in pyridine (10 mL) and cooled to 0°C. 2-Mesitylenesulfonyl chloride (520 mg, 1.1 equiv.) was added as a solid and the resulting mixture was stirred at 0°C for 1 h and then gradually warmed to room temperature over 6 h. After stirring at room temperature for 16 h, 1 N HCl was added and the resulting mixture was extracted with EtOAc (2×). The organics were washed with 1 N HCl and brine, dried, and concentrated. Chromatography (hexane–EtOAc, 3:1) of the residual oil provided the aryl sulfonate **25** (813 mg, 92%) as a colourless glass. IR: 3500, 1380 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) δ: 1.47 (s, 3H), 1.51 (s, 3H), 2.28 (s, 3H), 2.43 (d, 1H, J = 8.9 Hz), 2.54 (s, 6H), 3.72 (dd, 1H, J = 1.5, 8.6 Hz), 3.77 (m, 1H), 3.94 (dd, 1H, J = 5.3, 10.4 Hz), 3.98 (dd, 1H, J = 7.1, 10.4 Hz), 4.96 (d, 1H,

For personal use only.

J = 8.6 Hz), 6.92 (s, 2H), 7.30–7.38 (m, 5H); ^{13}C NMR (125 MHz) δ: 21.0, 22.4, 26.8, 27.1, 66.0, 70.3, 78.7, 81.9, 109.8, 126.6, 128.6, 128.7, 130.3, 131.7, 136.8, 139.9, 143.4. Anal. calcd. for $C_{22}H_{28}O_6S$: C 62.84, H 6.71; found: C 62.45, H 6.77.

*Epoxide **15** from the aryl sulfonate **25***

A mixture of aryl sulfonate **25** (761 mg, 1.81 mmol) and solid K_2CO_3 (500 mg, 2 equiv.) in MeOH (20 mL) was stirred at room temperature for 90 min and then saturated NH_4Cl was added. The mixture was extracted with EtOAc (2×) and the combined organics were washed with water and brine, dried, and concentrated. Chromatography (hexane–EtOAc, 7:1) of the residual oil provided epoxide **15** (387 mg, 97%) as a colourless oil.

*Alkyne **17***

Following the procedure described above for the alkynylation of the epoxide mixture **15**/**16**, the pure epoxide **15** (853 mg, 3.87 mmol) was converted to alkyne **17** (839 mg, 88%).

*Silyl ether **27***

To a solution of alcohol **17** (450 mg, 1.83 mmol) and Et_3N (0.6 mL, 2.4 equiv.) in dichloromethane (15 mL) at 0°C was added TBDMSOTf (0.5 mL, 1.2 equiv.). The mixture was stirred at 0°C for 30 min and then at room temperature for 2 h. Ammonium acetate buffer was added and the mixture was extracted with dichloromethane (3×). The combined organics were dried and concentrated. Chromatography (hexane–ether, 20:1) of the residue provided the silyl ether **27** (633 mg, 96%) as a white solid, mp 60.5–61.5°C. IR ($CHCl_3$): 3310, 1250, 1065, 830 cm^{-1}; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.07 (s, 3H), 0.12 (s, 3H), 0.89 (s, 9H), 1.50 (s, 3H), 1.55 (s, 3H), 1.93 (t, 1H, J = 2.7 Hz), 2.39 (ddd, 1H, J = 2.7, 6.0, 16.6 Hz), 2.58 (ddd, 1H, J = 2.7, 7.1, 16.6 Hz), 3.90 (ddd, 1H, J = 3.0, 6.0, 7.1 Hz), 4.07 (dd, 1H, J = 3.0, 8.4 Hz), 4.97 (d, 1H, J = 8.4 Hz), 7.34 (m, 5H); ^{13}C NMR δ: –4.5, –4.2, 18.1, 24.2, 25.8, 27.0, 27.4, 69.6, 70.4, 78.6, 81.1, 84.2, 109.1, 127.2, 128.2, 128.5, 138.3. Anal. calcd. for $C_{21}H_{32}O_3Si$: C 69.96, H 8.94; found: C 70.23, H 9.12.

*Ester **28***

To a solution of alkyne **27** (543 mg, 1.51 mmol) in THF (15 mL) at –78°C was added MeLi (1.6 mL of a 1.4 M solution in ether, 1.5 equiv.) and the resulting mixture was stirred at –78°C for 5 min, and at 0°C for 30 min. Methyl chloroformate (0.2 mL, 1.5 equiv.) was then added and the mixture was stirred for a further 30 min at 0°C. Ammonium acetate buffer was added and the mixture was extracted with EtOAc (3×). The combined organics were dried and concentrated. Chromatography (hexane–ether, 9:1) of the residue provided the ester **28** (576 mg, 91%) as a white solid, mp 50.5–51.5°C. IR ($CHCl_3$): 2220, 1710, 1250, 1065, 835 cm^{-1}; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.02 (s, 3H), 0.11 (s, 3H), 0.84 (s, 9H), 1.47 (s, 3H), 1.52 (s, 3H), 2.49 (dd, 1H, J = 6.2, 17.0 Hz), 2.69 (dd, 1H, J = 5.7, 17.0 Hz), 3.71 (s, 3H), 3.96–4.08 (m, 2H), 4.91 (d, 1H, J = 8.0 Hz), 7.25–7.40 (m, 5H); ^{13}C NMR δ: –4.6, 18.0, 24.3, 25.7, 26.9, 27.3, 52.4, 69.3, 74.4, 78.6, 84.3, 86.3, 109.2, 127.2, 128.3, 128.5, 138.0, 153.8. Anal. calcd. for $C_{23}H_{34}O_5Si$: C 66.00, H 8.18; found: C 66.34, H 8.40.

*Pyranone **30** ((±)-8-epigoniodiol)*

A mixture of ester **28** (330 mg, 0.79 mmol) and Lindlar's catalyst (33 mg) in THF (60 mL) was stirred under an atmosphere of hydrogen gas (1 atm (101.3 kPa)) for 1 h. The mixture was filtered through Celite, washing with EtOAc. The filtrate was concentrated and inspection by ^{1}H NMR spectroscopy indicated the absence of starting material and the presence of one olefin isomer (**29**). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.01 (s, 3H), 0.05 (s, 3H), 0.82 (s, 9H), 1.48 (s, 3H), 1.51 (s, 3H), 2.89 (m, 2H), 3.66 (s, 3H), 3.85–3.96 (m, 2H), 4.90 (d, 1H, J = 8.2 Hz), 5.74 (td, 1H, J = 1.8, 11.5 Hz), 6.30 (td, 1H, J = 7.3, 11.5 Hz), 7.25–7.40 (m, 5H). The crude mixture was stirred in a mixture of THF (2 mL), 1 N HCl (1 mL), and glacial HOAc (1 mL) at 65°C for 3 h. The solution was cooled to room temperature and then co-evaporated with toluene (3×). Ammonium acetate buffer was poured into the residue and the mixture was extracted with EtOAc (4×). The combined organics were dried and concentrated. A small portion of this material was purified by chromatography (toluene–EtOAc, 4:1) to provide the pyranone **30** as a white solid, mp 99–100°C. IR (KBr): 3400, 1710, 1250 cm^{-1}; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.11 (dddd, 1H, J = 0.7, 3.8, 6.3, 18.6 Hz), 2.81 (tdd, 1H, J = 2.4, 12.6, 18.6 Hz), 3.31 (br s, 1H), 3.44 (br s, 1H), 3.63 (br m, 1H), 4.18 (ddd, 1H, J = 2.2, 3.8, 12.6 Hz), 4.95 (d, 1H, J = 7.3 Hz), 5.92 (ddd, 1H, J = 0.7, 2.4, 9.8 Hz), 6.84 (ddd, 1H, J = 2.4, 6.3, 9.8 Hz), 7.33 (m, 5H). Exact Mass calcd. for $C_{13}H_{15}O_4$ $(M+H)^+$: 235.0971; found: 235.0970. The remainder of the material was used directly in the subsequent reaction.

*(±)-9-Deoxygoniopypyrone (**1**)*

The crude material containing the pyranone **30** was stirred in a solution of 1% DBU in THF (3 mL) at room temperature for 15 h. The mixture was concentrated and the residual material was subjected to chromatography (toluene–EtOAc, 17:3). (±)-9-Deoxygoniopypyrone (**1**) (111 mg, 60% from **28**) was obtained as a white solid, mp 183–184°C. IR (KBr): 3450, 1740, 1720, 1270 cm^{-1}; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.55 (br s, 1H), 1.83 (dd, 1H, J = 4.0, 14.1 Hz), 2.58 (d quintet, 1H, J = 14.1, 2.1 Hz), 2.85 (dd, 1H, J = 5.1, 19.3 Hz), 2.96 (dm, 1H, J = 19.3 Hz), 3.94 (m, 1H), 4.51 (m, 1H), 4.86 (app septet, 1H, J = 1.8 Hz), 4.95 (d, 1H, J = 1.6 Hz), 7.30–7.42 (m, 5H); ^{13}C NMR δ: 24.1, 36.4, 66.2, 68.4, 70.6, 74.7, 126.2, 128.4, 129.0, 136.8, 169.3. Anal. calcd. for $C_{13}H_{14}O_4$: C 66.46, H 6.02; found: C 66.20, H 6.19.

Transverse compression and the secondary H/D isotope effects in intramolecular S_N2 methyl- transfer reactions

Saul Wolfe, Chan-Kyung Kim, Kiyull Yang, Noham Weinberg, and Zheng Shi

Abstract: Using ab initio molecular orbital theory mainly at the 3-21+G level, intramolecular S_N2 methyl transfer between two oxygens confined within a rigid template is found to proceed exclusively by a high energy retention mechanism when the oxygens are separated by three or four bonds, and by a high energy inversion mechanism when the oxygens are separated by six bonds. Both mechanisms exist when the oxygens are separated by five bonds. The CH_3/CD_3 kinetic isotope effects are normal (1.21–1.34) in the retention processes and inverse (0.66–0.81) in the inversion reactions. In the case of inversion, compression of C—H bonds of the transition state by structural effects in the plane perpendicular to the O-C-O plane increases the inverse isotope effect. The retention barriers are high because retention is inherently unfavorable, even when pericyclic stabilization of the transition state is possible. The inversion barriers are high because a rigid template cannot accommodate a linear O-CH_3-O structure, and the O-C-O bending vibration is stiff (the Eschenmoser effect). Using a novel design strategy, a nonrigid template has been found in which the barrier and the CH_3/CD_3 kinetic isotope effect are the same as in an intermolecular reaction.

Key words: Eschenmoser effect, isotope effect, compression, S_N2, sigmatropic rearrangement.

Résumé : En se basant sur des calculs ab initio d'orbitales moléculaires au niveau 3-21+G, on peut conclure que le transfert intramoléculaire S_N2 d'un groupe méthyle entre deux oxygènes maintenus de façon rigide dans une matrice rigide se fait avec un mécanisme de rétention de haute énergie lorsque les oxygènes sont séparés par trois ou quatre liaisons et par un mécanisme d'inversion de haute énergie lorsque les oxygènes sont séparés par six liaisons. Les deux mécanismes existent lorsque les oxygènes sont séparés par cinq liaisons. Les effets isotopiques cinétiques CH_3/CD_3 sont normaux (1,21–1,34) dans le processus avec rétention et inversés (0,66–0,81) dans les réactions de rétention. Dans le cas de l'inversion, une compression des liaisons C—H de l'état de transition résultant d'effets structuraux dans le plan perpendiculaire au plan O-C-O provoque une augmentation de l'effet isotopique inverse. Les barrières à la rétention sont élevées parce que la rétention est intrinsèquement défavorisée même quand la stabilisation péricyclique de l'état de transition est possible. Les barrières d'inversion sont élevées parce qu'une matrice rigide ne peut accommoder une structure linéaire O-CH_3-O et que la vibration de déformation O-C-O est importante (effet Eschenmoser). Utilisant une nouvelle stratégie de conception, on a développé une matrice non rigide dans laquelle la barrière ainsi que l'effet isotopique cinétique CH_3/CD_3 sont les mêmes que dans la réaction intermoléculaire.

Mots clés : effet Eschenmoser, effets isotopiques, compression, S_N2, réarrangement sigmatropique.

Introduction

Steric compression and the S_N2 transition state

Over half a century elapsed between Baeyer's postulate of *Spannung* (1), Kehrmann's discussion of *Raumerfüllung* (2), Meyer's *Gesetze der sterischen Behinderungen* (3), and the first attempts to quantify the concept of steric compression. Following a suggestion that the low reactivities of neopentyl halides in bimolecular substitution reactions are caused by compression of their S_N2 transition states (4), Dostrovsky, Hughes, and Ingold (5) developed a rudimentary force field to calculate this compression and to pattern reactivity trends in a series of identity reactions (eq. [1])

[1] $$X^- + R\text{-}X \rightarrow X\text{-}R + X$$

with R = methyl, ethyl, *n*-propyl, isopropyl, isobutyl, *t*-butyl, and neopentyl. Because the information needed to treat bond stretching and bending at the reactive carbon was not yet very accurate or complete, an idealized transition state model was assumed in which the reactive carbon atom and the entering and leaving groups were collinear, with C—X bond lengths that remained constant throughout the series. Compression

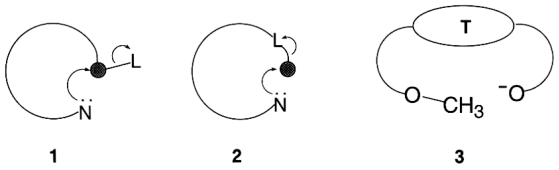
was then calculated by the assumption of an appropriate functional form for the van der Waals repulsions between nonbonded atoms. Although the specific choices made by these authors could be criticized (6), and later workers found the calculations to be "so cumbersome that few...have felt able to discuss the method...in any detail" (7), this daring intellectual exercise, together with an important contemporaneous



suggestion by T.L. Hill (8) and Westheimer's treatment of biphenyl atropisomerism (9), are the foundations of today's sophisticated molecular mechanics procedures (10).

The force field treatment of S_N2 transition states was refined by the Ingold school (11) and then by Abraham et al. (7) and de Tar et al. (12). In the latter work, for the series X = Br and R = *n*-propyl, isobutyl, and neopentyl, increasing steric compression in the transition states was seen in a gradual increase in the C—Br bond lengths (2.22, 2.23, 2.28 Å) and a systematic decrease in the Br-C-Br bond angles (161.4, 155.3, 143.2°). These geometric trends reflect the use of a bending force constant (3×10^{-5} mdyn Å deg^{-2} molecule^{-1}) (1 dyn = 10 μN) that allows compression in the β-series to be more easily relieved by bending than by stretching (force constant 6.6×10^{-2} mdyn Å^{-1} molecule^{-1}). It is noteworthy that AM1 calculations (13, present work, 14) reproduce the force-field trends in the C—Br bond lengths (2.29, 2.30, and 2.31 Å, respectively), and the Br-C-Br bond angles (159.4, 155.5, and 145.3°) of the transition structures.

Longitudinal compression of the S_N2 transition state

There is an obvious relationship between the classical alkyl halide reactivity sequence (ethyl > propyl > isobutyl > neopentyl) (3, 4) and the calculated *longitudinal* compression of their S_N2 transition structures, by which we mean the compression of these structures in the X–C–X plane. Eschenmoser and co-workers (15) were the first to recognize and prove that although the formation of five- and six-membered rings by exocyclic S_N2 ring closure, i.e., **1**, is highly favored over competing intermolecular reactions (16, 17), the deceptively enticing methyl transfer depicted in **2** is so inhibited by longitudinal compression in a five- or six-membered cyclic *transition state* that only intermolecular reactions are observed. Subsequent work by King and McGarrity (18) confirmed that the "failure to observe the endocyclic reaction arises not because the intermolecular reaction is inordinately fast but simply because the intramolecular reaction is slow" and undetectable when the endocyclic transition state contains fewer than nine atoms. There are now many examples of endocyclic restriction of the S_N2 mechanism (19), and the synthetic implications of this effect have been the subject of much interest (20).

Longitudinal compression and secondary H/D isotope effects

We have recently discussed the effect of longitudinal compression on the barriers and secondary kinetic CH_3/CD_3 isotope effects (k_H/k_D) of intermolecular methyl-transfer reactions (21). The isotope effects are inverse ($k_H/k_D < 1$), primarily as a result of the increase in C-H (C-D) stretching frequencies that accompanies the tetrahedral to trigonal change in geometry of the methyl group (22).[4] Because the X-C-Y bond angles of the transition structures of such reactions are close to 180°, compression has implied a tightening (23) of C—X and C—Y bond lengths in the transition state. In both identity (X = Y) and nonidentity (X ≠ Y) reactions, this kind of compression is found to be associated with a decrease in the barrier and an increase in k_H/k_D. We have noted that these findings create a problem for the contention (24) that k_H/k_D decreases in enzymic methyl transfer because of specific compression of the enzymic transition state and that this compression may represent the source of the enzymatic catalysis.[5]

Transverse compression

The present work was undertaken to explore the consequences of both longitudinal and transverse compression on the barriers and secondary isotope effects of intramolecular methyl-transfer reactions. By transverse compression we mean compression in the plane perpendicular to the X–C–Y plane and, specifically, compression of C—H bonds in the transition

[4] Some recent discussions of this subject, referring specifically to nonidentity methyl-transfer reactions (22*a*, *b*), are flawed (*i*) by a failure to recognize that the isotope effects in such reactions are determined, inter alia, by the isotope effects of the two identity reactions and the reaction enthalpy (21*b*); (*ii*) by the contention that ion–molecule complexes do not have to be taken into account. Further discussion of this latter point can be found in footnote 81 of ref. 22*c*.

[5] See ref. 24*e* for more recent work on this subject, leading to the conclusion that the enzymatic and nonenzymatic transition structures are very similar.

structure. It was reasoned that because the change in these bond lengths had already been found to be primarily responsible for the inverse isotope effect, any structural factor that causes additional compression of these bonds should lead to a more inverse isotope effect, and that this might be achieved with a reactant such as **3** in which **T** is a template whose dimensions are to be determined. Ideally, **T** would provide both compression of the transition structure and catalysis of the reaction.

Results and discussion

Anionic intermolecular methyl transfer between two oxygens. The optimized retention and inversion transition structures

The problem was approached in stages. In the first stage, the compression effects encountered during methyl transfer between two oxygens were examined using, as a benchmark, 3-21+G calculations[6] (25) on the reaction of eq. [2]. The calculated barrier for

[6] All ab initio calculations were performed using Gaussian 92 (25*c*).

intermolecular methyl transfer with inversion of configuration is 25.4 kcal/mol, and the transition structure (Fig. 1, upper) has C—O bond lengths of 1.90 Å, an O—O distance of 3.8 Å, and an O-C-O angle of 178.2°. The transition structure for intermolecular methyl transfer with retention of configuration was also found. This structure (Fig. 1, lower) has C—O bond lengths of 1.95 and 1.92 Å, an O—O distance of 2.63 Å, an O-C-O angle of 85.6°, and it is 51.2 kcal/mol less stable than the structure of Fig. 1 (upper). This energy difference is so large (26) that nucleophilic displacement at carbon with apparent retention of configuration must be regarded as definitive evidence of a multistep process that includes an even number of inversion steps (27).

In the second stage, the effect of longitudinal compression on the energetics of intramolecular methyl transfer was estimated from the O–C–O bending force constant of the inversion transition structure of Fig. 1.[7] This 3-21+G force constant is part of the Gaussian output and is calculated to be 0.2634 hartree/bohr^2 (0.0503 kcal mol^{-1} deg^{-2}). Using the harmonic approximation ΔE (kcal/mol) = $k\theta^2/2$, where θ (degrees) is the deviation of the O-C-O angle from linearity, leads to ΔE = 2.52 and 5.66 kcal/mol for θ = 10° and θ = 15°, respectively. Since two competing reactions whose activation energies differ by 2.52 and 5.66 kcal/mol will differ in reactivity by factors of 70 and 14 000, respectively, at 298 K, a compression of as little as 10° in the O-C-O angle of an inversion transition structure would be sufficient to make intramolecular methyl transfer with inversion of configuration difficult to detect with respect to a competing unconstrained intermolecular inversion process.

CH_3/CD_3 isotope effects in intramolecular methyl transfer between oxygens separated by three, four, five, and six bonds. The retention and inversion mechanisms exhibit different isotope effects

Figures 2–4 show the results of 3-21+G calculations of intramolecular methyl transfer in the β, γ, δ, and ε-methoxyalkoxides **4**–**11**. These substrates have oxygens separated by three, four, five, or six bonds, and the relative positions of the oxygens are constrained by the templates. With the exception of **5** ⇌ **6**, all of the reactions are identity methyl transfers. Table 1 gives the enthalpies of activation calculated at MP2(= FC)/6–31+G*//3-21+G, the C—H bond lengths of the transition structures, the H/D isotope effect for each hydron, and the CH_3/CD_3 isotope effects.[8]

Only the retention mechanism was found in the cases of **4**–**7**, and only inversion was found for **9**–**11**. Both mechanisms were seen in the case of **8**.

The isotope effects in the inversion reactions constitute evidence for the postulated transverse compression of the S_N2 transition state. As noted in several studies (21, 30), C—H bond lengths in the transition structures of intermolecular methyl-transfer reactions do not depend strongly upon the nature of the entering and leaving groups. In the inversion transition structure of Fig. 1, the average C—H bond length is 1.064 Å. In the inversion transition structure of Fig. 3, one

methyl hydron (H_1) is antiperiplanar to the π-system of the cyclohexadiene template, and its C—H bond is lengthened slightly (1.076 Å). The other hydrons (H_2 and H_3) are imbedded in the π-system, and their bond lengths are compressed to 1.046 Å. The isotope effect for H_1 is normal (1.15), but for H_2 and H_3 it is inverse (0.83). The stretching and bending contributions to the overall CH_3/CD_3 isotope effect of 0.81 are 0.69 and 1.17, respectively.

In the transition structure of **9** (Fig. 4, left), one methyl hydron (H_1) is antiperiplanar to the azadecalin skeleton, and its C—H bond length (1.069 Å) is normal. The isotope effect is also normal (1.01). The side view of this transition structure shows that a second methyl hydron (H_2) is compressed, by interaction with the equatorial hydrogens adjacent to nitrogen, to a bond length of 1.051 Å. Its isotope effect is 0.86. The third methyl hydron (H_3) lies under the nitrogen lone pair, and it is compressed to a bond length of 1.041 Å. Its isotope effect is 0.80. The CH_3/CD_3 isotope effect is 0.70.

In the transition structure of **10** (Fig. 4, center), H_1 is antiperiplanar to the bicyclic template, and it has the longest bond length (1.066 Å). A second hydron, H_3, is *endo* to the bicyclic system, and it has the shortest bond length (1.049 Å). The *exo* hydron, H_2, is *syn* to the carbonyl groups, and it has a bond length of 1.059 Å. The CH_3/CD_3 isotope effect is 0.69.

In the transition structure of **11** (Fig. 4, right), H_1 is antiperiplanar to the bicyclic template, and it has the longest bond length (1.065 Å) and highest k_H/k_D (0.94). The CH_3/CD_3 isotope effect is 0.66.

There is a significant difference in the isotope effects of the retention and inversion processes. The origin of this difference is best seen by examination of the retention and inversion transition structures of Fig. 3, which have (unscaled) imaginary frequencies of 834*i* and 860*i*, respectively. In the inversion structure, the imaginary frequency is the O–C–O antisymmetric stretch. In the retention structure, the imaginary frequency is a rocking motion about the C—H_1 bond as a pivot. The isotope effects are 1.06 for H_1 and 1.12 for H_2 and H_3. The CH_3/CD_3 isotope effect of 1.34 contains a stretching component of 1.07, a bending component of 1.34, and a stretch–bend component of 0.90. The principal contribution to the bending component of the isotope effect (k_{CH_3}/k_{CD_3} = 1.22) is made by a vibration, similar to that of the imaginary frequency, which has a frequency (uncorrected) of 958 cm^{-1}. This is shown as a series of instant structures at the left of Fig. 5,[9] together with the corresponding vibration in the inversion structure, which has a frequency (unscaled) of 1159 cm^{-1}, and contributes 0.97 to the overall 0.81 CH_3/CD_3 isotope effect.

The retention mechanisms found for **4** (Fig. 2, left) and **7** (Fig. 2, right) also exhibit normal isotope effects, 1.21 in each case. For **5** ⇌ **6** (Fig. 2, center), the isotope effects are 1.29 in the exoergic direction, and 1.27 in the endoergic direction.

The difference in the retention and inversion isotope effects appears to be large enough to offer an alternative to the chiral methyl group (32) for the determination of the stereochemical course of methyl transfer (33). More importantly (34), the difference in isotope effects can allow retention and double inversion mechanisms to be distinguished.

Barriers to methyl transfer in the rigid templates 4–11

All of the activation enthalpies shown in Table 1 are much larger than the barrier for intermolecular methyl transfer with inversion of configuration (25.4 kcal/mol). This is the expected result in the case of the retention mechanisms (26). In the case of the inversion mechanism for **8**, most of the excess energy of the transition structure originates in the longitudinal compression associated with an O-C-O angle of 133°.

In the case of **9**, the barrier is more than 20 kcal/mol higher than that of an intermolecular methyl transfer. Approximately half of this increase (9 kcal/mol) can be attributed to the longitudinal compression associated with the O-C-O angle of 161°. The remainder is caused by the compression of the template itself in the formation of the transition structure. For example, as summarized in Fig. 6, reoptimization of the reactant **9r** as **9r(t)**, with the azadecalin skeleton constrained to the geometry of the transition structure **9t**, destabilizes the structure by 18.2 kcal/mol. Replacement of the oxygen atoms of **9r** and **9t** by hydrogens (**9r(H)** and **9t(H)**) and reoptimization with all other geometrical parameters constrained to those of **9r** and **9t**, reveals that the distortion of the azadecalin backbone amounts to 10 kcal/mol. The energy difference between **9t** and **9r(t)** is 28.8 kcal/mol, close to the 28.4 kcal/mol calculated when the carbon atoms geminal to oxygen in **9r** and **9t** are replaced by hydrogens, and the resulting structures **9rc** and **9ts** are reoptimized.

It is evident that the azadecalin backbone is too rigid, and

[9] These structures were generated using the programme XMol (31).

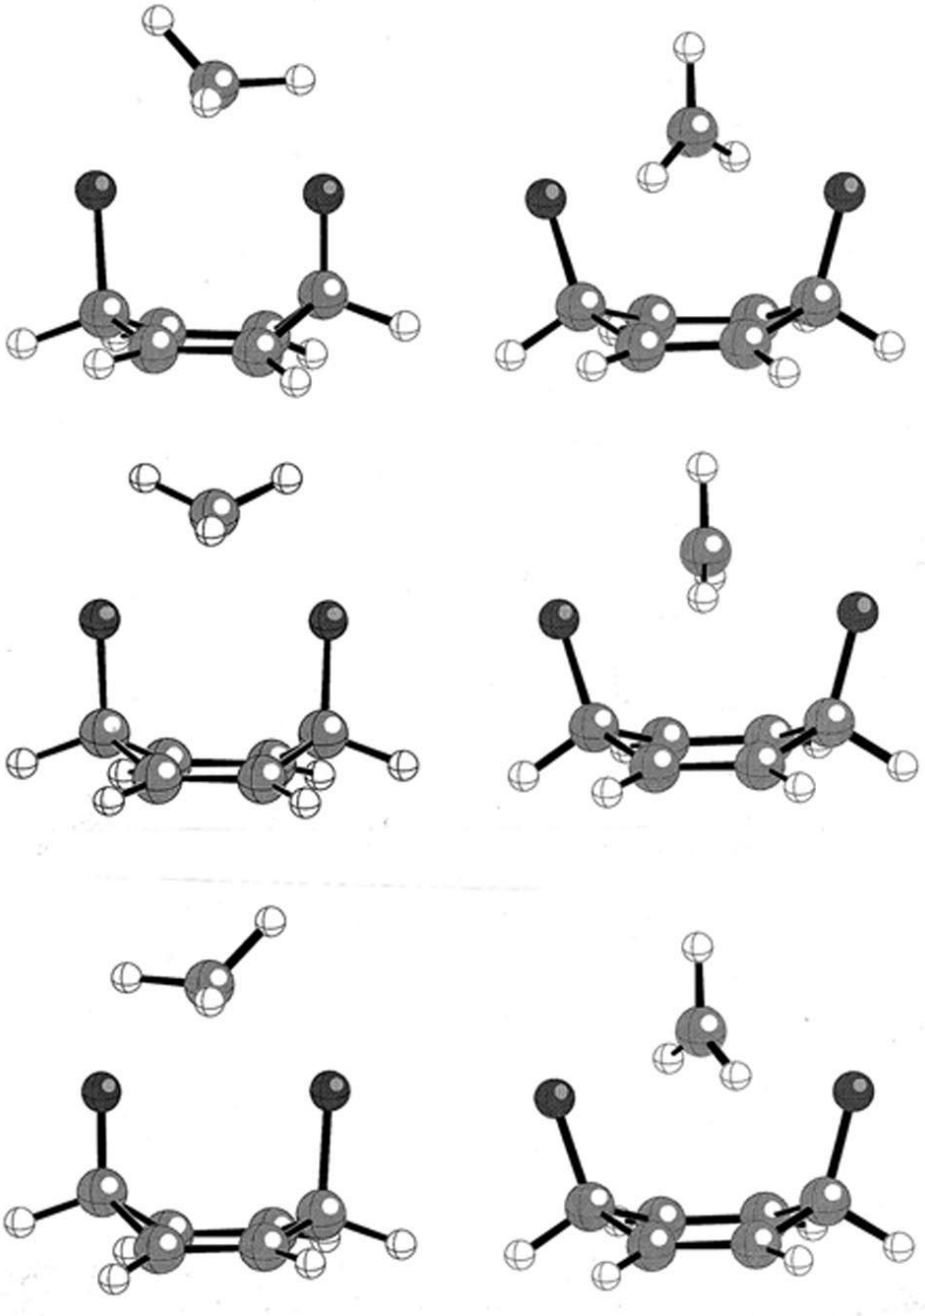
Fig. 5. A series of instant structures (top to bottom) showing the vibration that leads to the 958 cm^{-1} frequency in $\mathbf{10}_{ret}$ (left); secondary H/D isotope effects, 1.22; total, 1.34. The corresponding vibration in $\mathbf{10}_{inv}$ (right) has a frequency of 1159 cm^{-1}.



that the geometry of **9** does not permit a linear methyl transfer. The sum of the angles at nitrogen in the transition structure **9t** is 359.1°, and in **9r** it is 344.8°. Inspection of **9r(H)** and **9t(H)** in Fig. 6 suggests that the planar configuration at nitrogen in the transition structure contributes 10 kcal/mol to the destabilization of the structure. This potential for distortion is avoided in **10** and **11**, because the bridgehead atoms are planar in both the reactant and the transition structure. Using AM1, the geometry of **12** was optimized for (n, m) = (1, 1), (1, 2), (2, 2), (2, 3), and (3, 3), and the O—O distances, O-C-O angles, and methyl-transfer barriers were examined in each case. This strategy led to the (3, 3) systems seen in **10** and **11**, in which the methyl-transfer barriers are reduced to 35.6 and 32.6 kcal/mol, respectively. However, although the longitudinal compression associated with the 170° O-C-O angle in the transition structure of **11** is estimated to be only 2.5 kcal/mol, the template is not entirely free of compression, and the barrier is still 7 kcal/mol higher than that of the parent intermolecular methyl-transfer reaction.

Design of a flexible template for intramolecular methyl transfer

Although transverse compression of the methyl-transfer transition state has thus been found to produce a more inverse

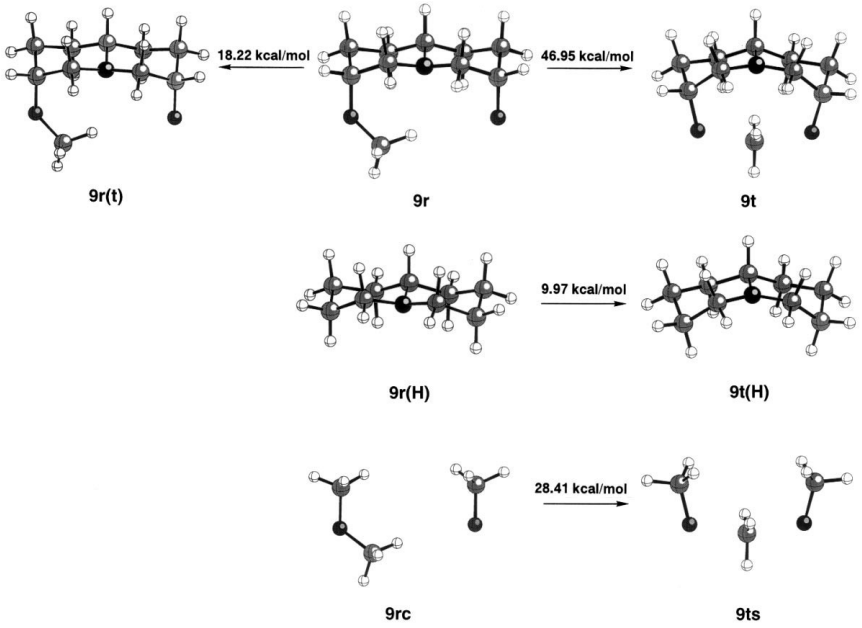

Fig. 7. Design of a flexible template for intramolecular methyl transfer.

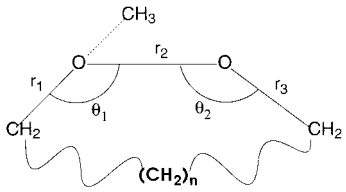

secondary isotope effect, the additional compression introduced by the use of a rigid template overcomes any potential for catalysis of the process. It was, therefore, necessary to design an acyclic, flexible structure.

We have recently reported a novel stochastic search strategy for the conformational analysis of cyclic structures (35). Since the reactant (RC) and transition state (TS) of an intramolecular methyl transfer are pseudocyclic structures, it was possible to adapt this stochastic strategy to the search for superimposable RC and TS templates. The system was treated as an $(n + 4)$-membered ring (Fig. 7) containing an O···O "bond," with the bond lengths r_1, r_2, and r_3, and the bond angles θ_1 and θ_2 constrained to the values seen in the transition state and reactant of the intermolecular reaction. All other bond lengths and bond angles were found by MM3 minimization (36). The torsion angles of the $(CH_2)_n$ chain were obtained by random variation, as described previously (35). Using a 30° torsional increment, a total of 3733 RC rings and 3860 TS rings were produced from 10 000 randomly generated structures. Two thousand each of RC and TS rings were then minimized using MM3, with the bond lengths and bond angles at the reaction center frozen. This was achieved by the definition of atom types having $k_{stretch} = 100$ mdyn/Å (cf. $k_{CC} = 4.5$ mdyn/Å) and $k_{bend} = 10$ mdyn Å rad^{-2} (cf. $k_{CCC} = 0.67$ mdyn Å rad^{-2}). All other parameters of these atoms were taken from the values employed in MM3.

For the case of a 12-membered ring ($n = 8$), this strategy afforded 255 RC minima and 208 TS minima. These were then matched to identify structurally similar (RC, TS) pairs using the rms deviations of the torsion angles of the $(CH_2)_8$ chain as a criterion. The lowest energy pair was found to be the second lowest RC minimum (0.38 kcal/mol above the lowest minimum) and the second lowest TS minimum (0.34 kcal/mol above the lowest minimum). To complete the design process, the methyl group to be transferred was added.

Both of these structures were then subjected to 3-21+G minimization, and were optimized successfully. The results are summarized in structures **13-RC** and **13-TS** of Fig. 8, which also includes an optimized RC[10] and TS (cf. Fig. 1, left) of the intermolecular methyl-transfer reaction.

It can be seen that the reactive centers of the two reactants and the two transition structures are virtually superimposable. The CH_3/CD_3 kinetic isotope effects calculated for RC → TS are also the same, and the free energies of activation differ by only 1.2 kcal/mol. The strategy employed to discover **13** thus appears to lead to a template for efficient intramolecular methyl transfer in the gas phase. Moreover, close examination of the CH_3 bond lengths included in Fig. 8 indicates that the methyl hydrogen that points towards the concave face of **13-TS** exhibits transverse compression. It should be possible to alter the properties of such templates by incorporation of substituents on the concave face of the chain, and initial studies in this direction suggest that structures having $n > 8$ will be of interest.

The inversion barriers, geometrical parameters, and CH_3/CD_3 isotope effects of intramolecular methyl transfer are coupled

Figure 9 applies the Walsh–Gimarc rules (37) to the internal geometries of methyl groups having D_{3h} (**14**) and C_{2v} (**15**)

[10] This structure is not the global minimum at 3-21+G (29*b*), but it is a genuine stationary point having no imaginary frequencies.

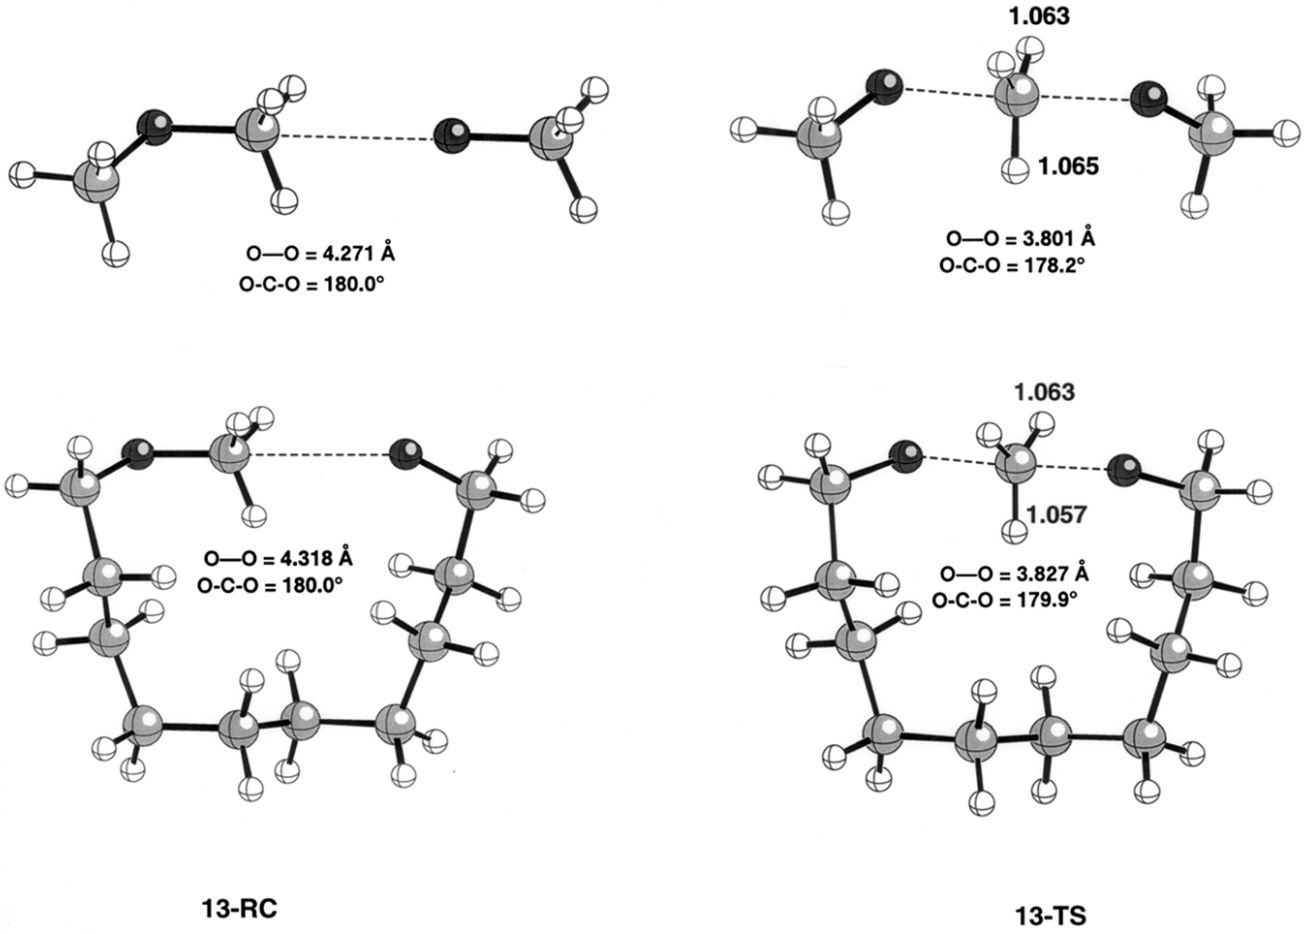
Fig. 8. Intramolecular methyl transfer with inversion of configuration in the parent system (upper) and in the flexible template **13** (lower).

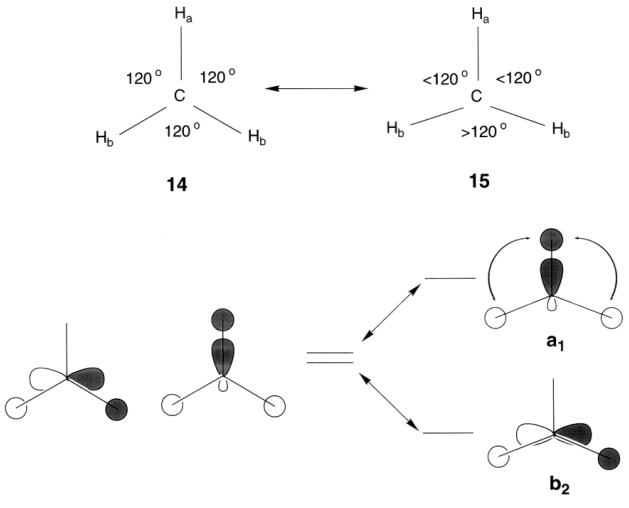


symmetry. In **14**, the π-type *e* orbitals are degenerate. In **15**, the orbitals are nondegenerate; an increase in the H_b-C-H_b angle stabilizes the b_2 orbital and destabilizes the a_1 orbital. The destabilization is caused by the increased out-of-phase interaction between the 1*s* coefficients of H_b and the 1*s* coefficient of H_a, which is relieved by an increase in the C—H_a bond length.[11]

As we have seen, there is a systematic decrease in the methyl-transfer barriers in the series **8** (Fig. 3), **9**, **10**, **11** (Fig. 4), and **13** (Fig. 8), mainly because the O-C-O angles of the transition structures increase from 133.2 to 179.8°. The decrease in the barriers is accompanied by a decrease in the H_2-C-H_3 angles, from 128.5° in **8** to 119.9° in **13-TS**, leading to an inverse relationship between the O-C-O and H_2-C-H_3 angles. This is shown in Fig. 10*a*, and is undoubtedly steric in origin. In accord with the Walsh–Gimarc rules, the decrease in the H_2-C-H_3 angle is accompanied by a decrease in the C—H_1 bond length (Fig. 10*b*), and the C—H_1 bond length therefore decreases as the barrier decreases (Fig. 10*c*). As a result, the contribution of H_1 to the secondary CH_3/CD_3 isotope effect changes from normal to inverse as the barrier decreases (Fig. 10*d*).

[11] These predictions have been confirmed by calculations on $CH_aH_bH_b^+$: as the H_b-C-H_b angle is increased, the C—H_a bond length is increased, the b_2 orbital is stabilized, and the a_1 orbital is destabilized.

Fig. 9. Application of the Walsh–Gimarc rules to the frontier orbitals of methyl groups having D_{3h} (**14**) and C_{2v} (**15**) symmetries.



The overall CH_3/CD_3 isotope effect also becomes more inverse as the barrier decreases (Fig. 11), but in the case of this property, **13** does not correlate with **8**–**11**. The reason for this is that intramolecular methyl transfer in **13** proceeds without longitudinal compression, and therefore resembles

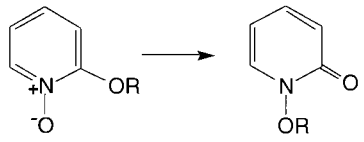
intermolecular methyl transfer, but the transverse compression of H_2 and H_3 in the transition structures of **8**–**11** causes the isotope effects to become more inverse.

Methyl transfer with retention of configuration. Can a [1*s*,4*s*] sigmatropic rearrangement be observed?

In the intramolecular methyl-transfer reactions of **4**–**8** (Figs. 2 and 3), the barrier is never less than 20 kcal/mol higher than that of an unconstrained inversion process and, in each case, the imaginary frequency of the retention transition structure is the rocking vibration discussed in Fig. 5. It is noteworthy that the transition structure of **4** (Fig. 2) exhibits no particular stabilization, because retention of configuration and a barrier less than 20 kcal/mol in the related reaction, the thermal rearrangement of 2-alkoxypyridine-1-oxides to 1-alkoxy-2-pyridones (**16** → **17**) have been thought to be consistent with a [1*s*,4*s*] sigmatropic rearrangement mechanism (38, 39). This interpretation is based on the orbital analysis shown at the top of Fig. 12, which suggests that a 1,4-suprafacial migration of a methyl group is thermally allowed. Although the HOMO of **4**, also shown in Fig. 12, seems to support this interpretation, the argument does not take into account the repulsive, out-of-phase relationship between the orbital of the migrating group and the orbitals at the 2- and 3-positions, which will force this group towards the nodal plane of the π-system. The situation is analogous to that encountered in the frontier molecular orbital treatment of nucleophilic addition to a carbonyl group (Fig. 12, bottom). In the latter case, the well-known (40) nonperpendicular attack of the nucleophile can be rationalized as the result of the out-of-phase relationship between the orbital of the attacking nucleophile and the *p*-orbital on oxygen (41).



16 **17**

Examination of a side view of the intramolecular methyl-transfer transition structure of **4** (Fig. 13, top) shows that the migrating carbon is only 6° out of the plane of the aromatic system. To check whether this is a basis set effect, the reactant and transition structure of **4** were reoptimized at MP2/6–31+G*. The out-of-plane angle of the migrating methyl group increased to 29° (Fig. 13, bottom), but the barrier remained high (51.5 kcal/mol). Thus, although the 3-21+G basis set overemphasizes the nonperpendicular character of the transition structure of an intramolecular [1*s*,4*s*] sigmatropic methyl rearrangement, it is clear that competing, intermolecular reactions will make an intramolecular reaction experimentally unobservable. The work of Hoppe and Schöllkopf (38) therefore requires reexamination and reinterpretation (34).

Theoretical procedures

Transition structures were located by the reaction coordinate method. The C···O bonds of the entering and leaving groups were fixed at several values near 1.9 Å, all other geometrical parameters were optimized, and the magnitudes and signs of the gradients of the two reaction coordinates were used to improve the trial values. When a structure close to the saddle point was reached, a final refinement was usually achieved using the OPT = CALCALL option of Gaussian 92 (25*c*) in

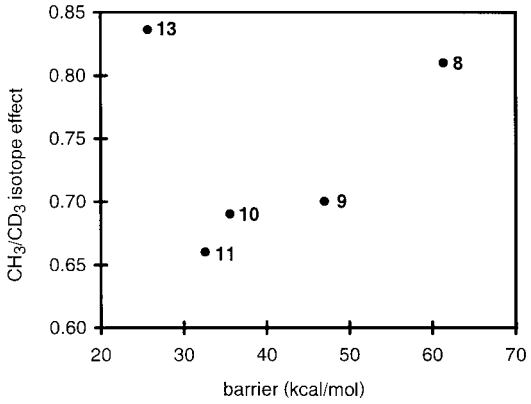

Fig. 12. Top left: orbital interaction between the HOMO of a 4π system and the LUMO of a methyl group; the phase relationship is correct for [1,4] sigmatropic rearrangement with retention of configuration, if the out-of-phase interactions (double-headed arrows) are ignored. Top right: the HOMO of **4**. Bottom: orbital interaction diagram proposed to explain nonperpendicular attack of a nucleophile on a carbonyl group.

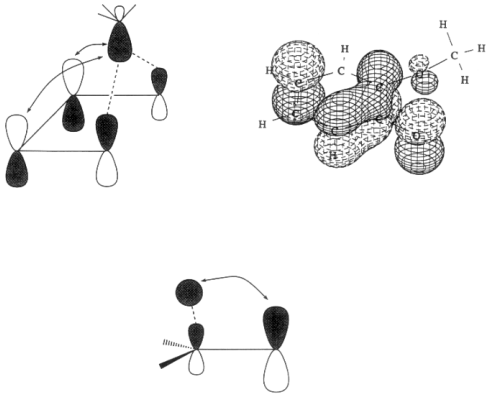


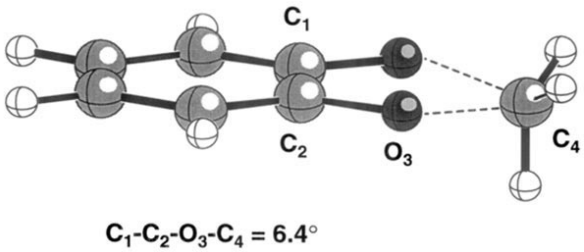
which force constants are calculated in every iteration. For calculations of isotope effects, the frequencies employed as input to the Bigeleisen equation were obtained by scaling of the computed values by 0.9 (29).[12]

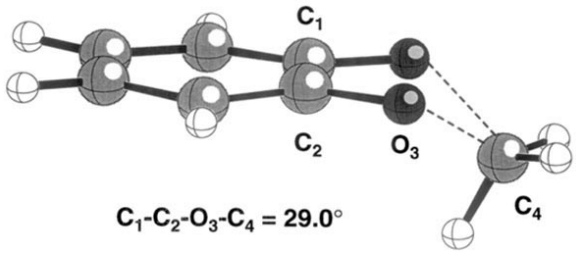
Summary and conclusions

Using ab initio molecular orbital theory mainly at the 3-21+G level, the CH_3/CD_3 kinetic isotope effects in intramolecular S_N2 methyl transfer between two oxygens have been found to be normal (1.21–1.34) for retention and inverse (0.66–0.81) for inversion of configuration. It is suggested that the difference in the retention and inversion isotope effects is large enough to constitute an alternative to the chiral methyl group for the determination of the stereochemical course of displacement at methyl, and to allow a genuine retention process to be distinguished from an even number of inversions.

[12] The structures calculated in this work are available as supplementary material, which may be purchased from: the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Fig. 13. Side view of the transition structure for intramolecular methyl transfer in **4**; the methyl carbon is not perpendicular to the aromatic ring. Upper: 3-21+G optimization. Lower: MP2/6–31+G* optimization.





The normal isotope effect in the retention mechanism is the result of a torsional motion about one of the C—H bonds as the methyl carbon rocks between the two oxygens. In the case of inversion, compression of C—H bonds by structural effects in the transition state, here termed transverse compression, increases the inverse isotope effect. The geometry of the methyl group is coupled to the O-C-O angle of the transition structure, so that the methyl C—H bond lengths, the O-C-O angle, the barrier, and the CH_3/CD_3 kinetic isotope effect are all coupled. A 10° deviation from linearity of the O-C-O angle of the inversion transition structure is sufficient to make an intramolecular reaction kinetically noncompetitive with respect to intermolecular processes.

For intramolecular methyl transfer within a rigid template, only a high energy retention mechanism can be found when the oxygens are separated by three or four bonds, and only inversion is seen when the oxygens are separated by six bonds. Both mechanisms exist when the oxygens are separated by five bonds. Since nonlinear methyl transfer occurs within all of the rigid templates examined so far, none of these provides catalysis of the inversion mechanism. However, treatment of the reactant and transition structure of an intramolecular methyl transfer as pseudocyclic structures, and extension to such structures of a recently described stochastic approach to conformational analysis, has led to the discovery of a nonrigid template that permits linear methyl transfer to take place. This template has two oxygens separated by 10 carbons, and the intramolecular methyl-transfer barrier and CH_3/CD_3 isotope effect are the same as in the intermolecular reaction.

There is no evidence for pericyclic stabilization of a [1*s*,4*s*] intramolecular sigmatropic retention process in the degenerate rearrangement of the anion of *o*-catechol *O*-methyl ether. The

© 1998 NRC Canada

reason for this is that the out-of-phase interaction between the *p*-orbital of the migrating group and *p*-orbitals of the aromatic ring forces the methyl group towards the nodal plane of the π-system.

Hydration of the carbonyl group. Further evidence for a cooperative mechanism from experimental and theoretical studies of the hydrations of formaldehyde, acetaldehyde, acetone, and cyclohexanone

Saul Wolfe, Zheng Shi, Kiyull Yang, Stephen Ro, Noham Weinberg, and Chan-Kyung Kim

Abstract: The experimental pseudo-first-order rate constant for the neutral hydration of acetone by $H_2{}^{18}O$ has been determined by taking advantage of the ^{18}O isotope shift in the ^{13}C NMR spectrum of 2-^{13}C-labelled acetone. With the inclusion of this result, a previously reported computational procedure has been extended, with some refinements, to the neutral hydrations of formaldehyde, acetaldehyde, acetone, and cyclohexanone by different-sized water clusters in water solvent. Excellent agreement has been achieved between the experimental free energies of activation and the free energies of activation calculated for a cyclic mechanism in which the principal reaction channel contains four nonspectator water molecules. The computational procedure predicts that the cyclic water tetramer and the cubic water octamer are the principal constituents of bulk water, in agreement with Benson's tetramer–octamer model.

Key words: isotope shift, basis set superposition error (BSSE), self-consistent reaction field (SCRF), water clusters, hydration.

Résumé : On a déterminé la constante de vitesse expérimentale du pseudo-premier ordre pour la réaction d'hydratation neutre de l'acétone par le $H_2{}^{18}O$ en tirant profit du déplacement isotopique du ^{18}O dans le spectre RMN du ^{13}C de l'acétone marquée au ^{13}C en position 2. Après l'inclusion de ce résultat et en y apportant quelques améliorations, la méthode de calcul rapporté précédemment a éte étendu aux hydratations neutres du formaldéhyde, de l'acétaldéhyde, de l'acétone et de la cyclohexanone par des agrégats d'eau de diverses grosseurs dans l'eau comme solvant. On a obtenu d'excellents accords entre les énergies libres d'activation expérimentales et les valeurs correspondantes calculées pour un mécanisme cyclique dans lequel la voie de réaction principale comporte quatre molécules d'eau comme non spectateurs. La méthode de calcul permet de prédire que le tétramère cyclique et l'octamère cubique de l'eau sont les constituants principaux de l'eau dans son ensemble, en accord avec le modéle tétramère–octamère de Benson.

Mots clés : déplacement isotopique, erreur dérivée de la superposition d'ensemble de fonctions de base (« BSSE »), champ réactionnel autocohérent (« SCRF »), agrégats d'eau, hydratation.

[Traduit par la rédaction]

Introduction

The stepwise neutral hydration of a carbonyl group, e.g., eqs. [1]–[3], proceeds via

[1] $RR'C{=}O + H_2O \rightleftarrows RR'C{=}OH^+ + OH^-$

[2] $H_2O + RR'C{=}OH^+ \rightleftarrows H_2O^+\text{-}CRR'\text{-}OH$

[3] $H_2O + H_2O^+\text{-}CRR'\text{-}OH \rightleftarrows H_3O^+ + HO\text{-}CRR'\text{-}OH$

charged intermediates. If these intermediates were formed in water solvent, they would undergo continuous solvation and desolvation as they appeared and disappeared. Eigen (1) pointed out in 1965 that this sequence of events might be disfavored with respect to a cyclic, "cooperative" mechanism, and the subsequent experimental work of Bell et al. (2) quickly lent support to this idea. However, apart from numerous computational studies of the gas-phase hydration of formaldehyde by one or two water molecules (3), the cooperative mechanism has received only limited consideration (4), and the possibility

that nonionic pathways contribute significantly to hydrolytic processes in water solvent is usually disregarded.

We have suggested (5, 6) that penicillin-recognizing enzymes react via a cooperative mechanism. This proposal was advanced initially because of the presence of a small number of conserved water molecules in these enzymes, whose locations in the active sites are compatible with their participation in cyclic processes. A first test of the proposal, which employed gas-phase ab initio molecular orbital calculations to study the effect of one or two water molecules on the neutral alcoholysis of β-lactam rings (6–8), gave encouraging results and led to a more detailed theoretical examination of the cooperative mechanism, including quantitative connections to real experiments conducted in solution (9).

To treat the hydration of formaldehyde in water solvent, the self-consistent reaction field (SCRF) method (10) was first used to calculate the standard Gibbs free energies of the stationary structures summarized by the network of reactions depicted in Fig. 1, where RC*n* is a reactant complex of the type cyclo-CH_2O-$[H_2O]_n$ that proceeds over a transition state TS*n* to a product complex cyclo-$[HO\text{-}CH_2\text{-}OH][H_2O]_{n-1}$. The free energies were then corrected for basis set superposition error (BSSE) (11) and entropic effects associated with the loss of translational and rotational motion in solution. This provided the rate and equilibrium constants of the elementary steps of the reaction network, and the overall rate of hydration of formaldehyde was calculated as the sum of the contributions from reaction channels that involve one, two, three, or four water molecules. The final theoretical pseudo-first-order rate constant of 11.2 s^{-1} at 298 K agreed well with the estimated experimental value of 9.2 s^{-1} (12), and over 99% of the reaction was calculated to proceed via the cyclic complex **1** in which $n = 3$. This prediction is consistent with the experimental results of Bell et al. (2*a*), who concluded that the neutral hydration of a carbonyl group in dioxane solvent is catalyzed by two

additional water molecules. The calculations also predicted that water dimer is a major constituent of bulk water. This does not agree with the Benson and Siebert (13) tetramer–octamer model.

The foregoing strategy has now been extended, with some refinements, to the neutral hydrations of acetaldehyde, acetone, and cyclohexanone in water solvent at 298 K. In the case of acetone, the experimental pseudo-first-order rate constant for the neutral hydration at 298 K, previously available as an estimate (14), was redetermined. In the case of acetaldehyde, two directions of attack are possible in each of the reaction channels, since addition may occur *syn* to hydrogen or *syn* to methyl, as shown in **2** and **3** for the one-water mechanism. In the case of cyclohexanone, there is axial and equatorial attack in each of the reaction channels. All of these pathways were examined.

Theory

Computations were performed using the Gaussian 92 (15) and Gaussian 94 (16) programmes, with the 3–21G basis set (17). This choice was dictated by the sizes of the systems to be treated, and is validated by the earlier finding (9) that, in the case of formaldehyde, HF/3–21G and MP2/6–31G(d) (18) calculations produce very similar results. The gas-phase reaction networks were calculated first, to obtain estimates of the radii of the spherical cavities needed for the application of the SCRF procedure with a dielectric constant of 78.5 (9, 10). All stationary points were verified by frequency calculations.

Fig. 4. A comparison of the experimental free energies of activation for the neutral hydrations of formaldehyde, acetaldehyde, acetone, and cyclohexanone, and the free energies of activation calculated using the strategy of ref. 9.

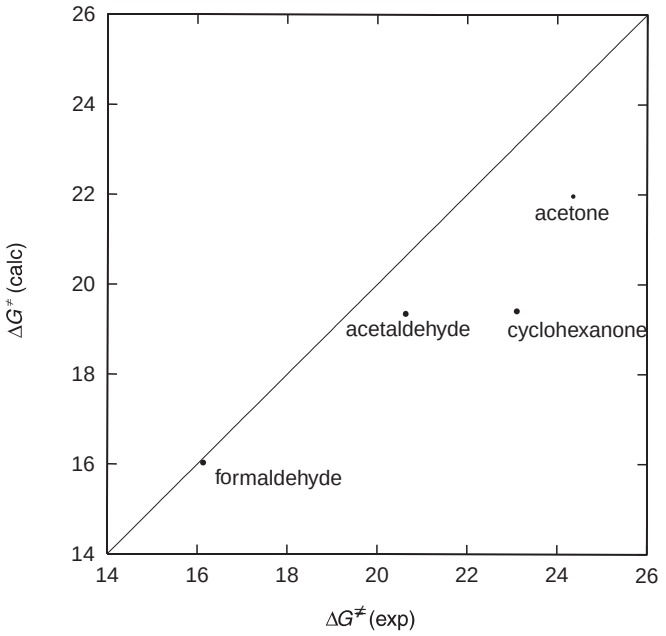

Fig. 6. Modification of Fig. 4, with theoretical free energies of activation calculated using the new BSSE procedure.

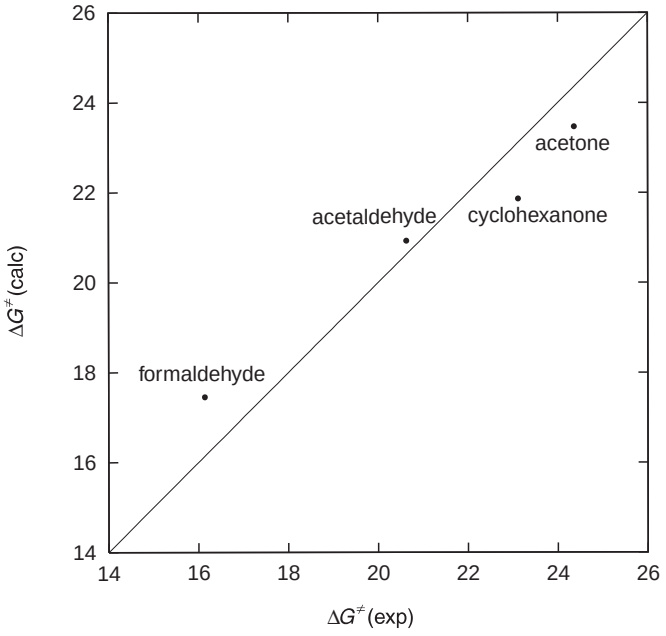
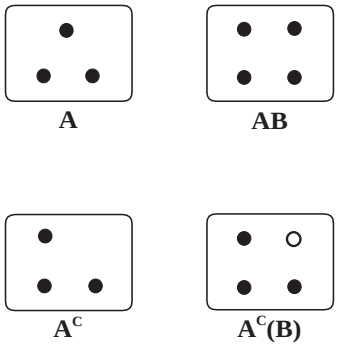


Experimental

A 2 mL vial was washed, dried for 24 h at 140°C, cooled under nitrogen, and charged successively with 98.5% enriched $H_2{}^{18}O$ (51 μL) (Aldrich) and $H_2{}^{16}O$ (49 μL), obtained from a MilliQ Plus ultrapure water system. The mixture was transferred immediately to a micro NMR tube maintained at 298 ± 0.1°C in the probe of a Bruker 600 AMX spectrometer

Fig. 5. Schematic representation of the strategy for the computation of basis set superposition error in ref. 9.



operating at a frequency of 150.03 MHz. Temperature control was achieved with a Euroterm VT temperature regulator. The hydration of acetone was initiated by injection of 12.5 μL of 99% atom-enriched 2 -^{13}C-acetone to produce a 1.7 M solution and a molar ratio of water to acetone of 35:1. The proton-decoupled ^{13}C NMR spectrum was recorded as a single scan every 60 min to obtain the peaks of $(Me)_2{}^{13}C{=}{}^{16}O[^{16}O]$ and $(Me)_2{}^{13}C{=}{}^{18}O[^{18}O]$, whose chemical shifts differ by 0.05 ppm (19). Figure 2 shows a typical set of spectra. These spectra were integrated to obtain the $[^{18}O]/[^{16}O]$ ratio (ρ) as a function of time.

The data were analyzed in terms of the equilibria shown in eq. [4]. The assumptions

$$[4] \qquad [^{16}O] \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [diol]^* \underset{k_1}{\overset{k_2}{\rightleftharpoons}} [^{18}O]$$

of steady-state kinetics, a constant concentration of solvent, and a kinetic isotope effect of unity lead to eq. [5], where k_1 is the pseudo-first-order rate constant of interest.

$$[5] \qquad \ln\left(\frac{1-\rho}{1+\rho}\right) = -k_1 t$$

Results

Neutral hydration of acetone

Figure 3 is a plot of eq. [5] for the experiment described in the experimental section. The pseudo-first-order rate constant (average of two experiments) is $(8.9 \pm 0.4) \times 10^{-6}$ s^{-1}.

Application of the theoretical procedure of ref. 9 to the hydrations of acetaldehyde, acetone, and cyclohexanone

Table 1 summarizes the primary computational data. Full details of all stationary structures are available as supplementary data.[5] Table 2 gives the experimental pseudo-first-order rate constants at 298 K, the theoretical pseudo-first-order rate constants calculated using the strategy of ref. 9, and the experimental and theoretical Gibbs free energies of activation for the neutral hydrations of the four compounds. As can be seen in Fig. 4, only formaldehyde exhibits acceptable agreement between the experimental and theoretical activation barriers.

Fig. 7. Modification of Fig. 4, with theoretical free energies of activation calculated using mass-weighted corrections to entropies.

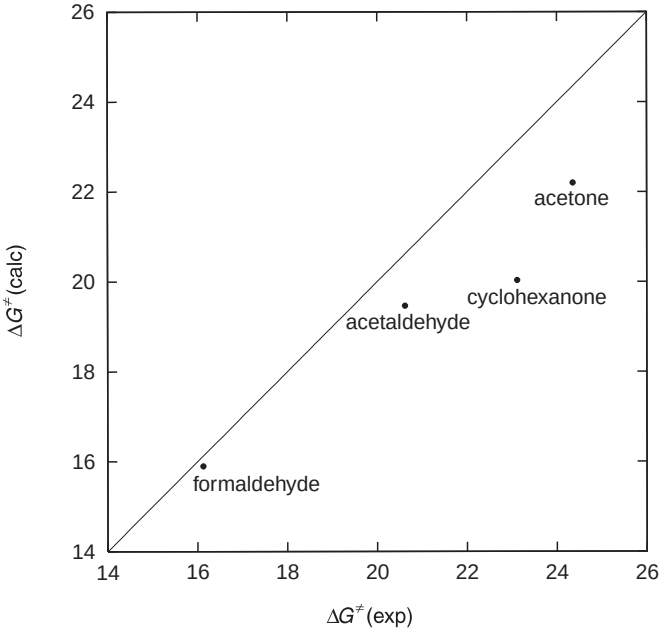

Fig. 8. Corrected free-energy changes (kcal/mol) in the network of reactions that describe the neutral hydration of formaldehyde. The transition structure of the principal reaction channel is shown.

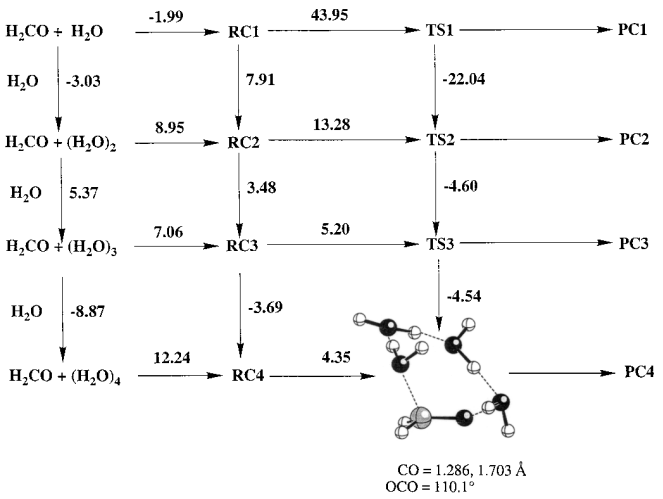

Fig. 9. Corrected free-energy changes (kcal/mol) in the network of reactions that describe the neutral hydration of acetaldehyde, with attack from the direction *syn* to hydrogen. The transition structure of the principal reaction channel is shown.

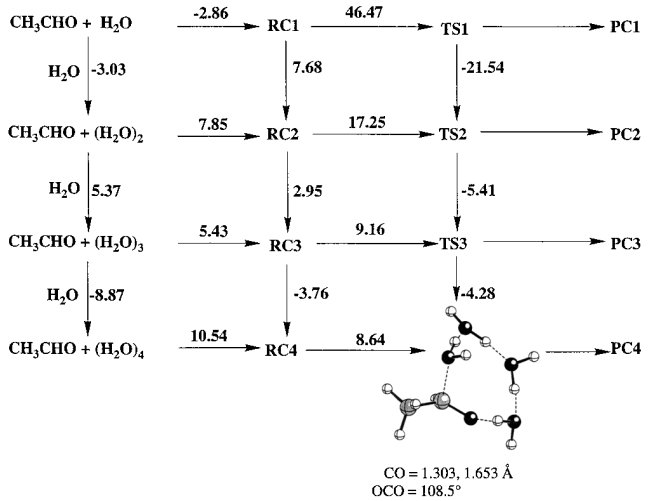

Fig. 10. Corrected free-energy changes (kcal/mol) in the network of reactions that describe the neutral hydration of acetaldehyde, with attack from the direction *syn* to the methyl group. The transition structure of the principal reaction channel is shown.

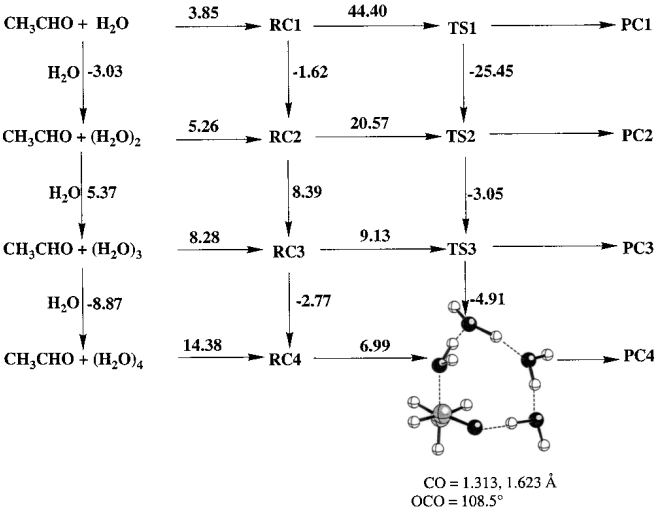

Over the complete data set, the rms deviation from the line of unit slope is 2.29 kcal/mol.

A consideration of possible origins of this deviation led to a re-examination and refinement of the BSSE and low-frequency corrections employed in ref. 9 and in the theoretical kinetic analysis of Fig. 4. These comprised a potential source of error, because the concentrations of $(H_2O)_n$ and RC*n* that are employed in the kinetic analysis are determined by their free energies, which depend upon the magnitudes of the BSSE corrections to the enthalpies, and the low-frequency corrections to the entropies calculated by Gaussian 94.

Re-examination and refinement of BSSE corrections to enthalpies

In our earlier study (9), a stepwise approach was used in which a BSSE correction was calculated for each elementary step (A + B → AB) of the overall process using eq. [6],

$$[6] \qquad E^{\mathrm{BSSE}} = (E^{\mathrm{C}}_{\mathrm{A}} - E^{\mathrm{C}}_{\mathrm{A(B)}}) + (E^{\mathrm{C}}_{\mathrm{B}} - E^{\mathrm{C}}_{\mathrm{B(A)}})$$

in which $E^{\mathrm{C}}_{\mathrm{A(B)}}$ and $E^{\mathrm{C}}_{\mathrm{A}}$ ($E^{\mathrm{C}}_{\mathrm{B(A)}}$ and $E^{\mathrm{C}}_{\mathrm{B}}$) are the energies of A(B) at the geometry of A(B) in AB, in the presence and absence of the ghost orbitals of B(A). The strategy is depicted schematically in Fig. 5. If A is water trimer and AB is water tetramer, the structures of A^C and $A^C(B)$ are as shown, where the open circle represents the ghost molecule B.

When defined in this way, the BSSE correction takes into account the energy difference between A and A^C (a deformation energy), and it is thought to be applicable when the geometry of an isolated species A differs significantly from the geometry of A in AB. However, this approximation makes the

Fig. 11. Corrected free-energy changes (kcal/mol) in the network of reactions that describe the neutral hydration of acetone. The transition structure of the principal reaction channel is shown.

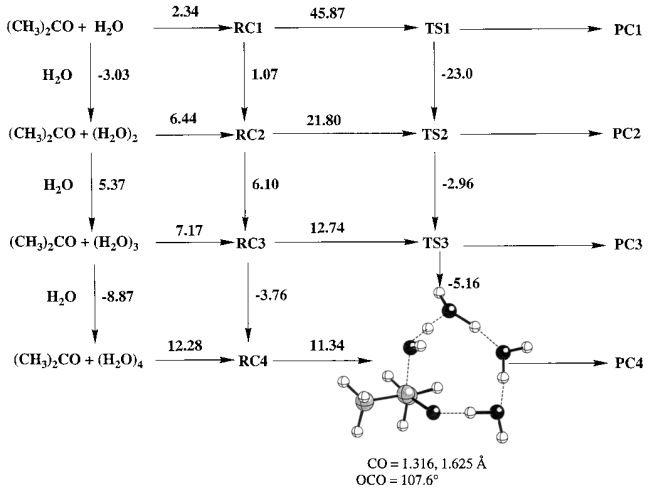

Fig. 12. Corrected free-energy changes in the network of reactions that describe the neutral hydration of cyclohexanone, with attack from the equatorial direction. The transition structure of the principal reaction channel is shown.

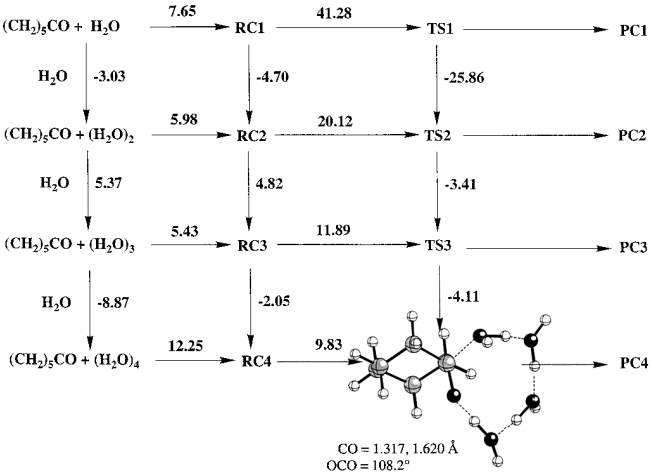

unjustifiable assumption that the BSSE is the same for A and A^C. If the variations in the geometries of the participating species are significant in each step, different BSSE corrections will be calculated for the different pathways of a two-step process A + B + C → ABC, i.e., A + B + C → AB + C → ABC and A + B + C → A + BC → ABC may have different BSSE corrections.

One way to avoid such problems is to recognize that each node of a reaction network comprises a thermodynamic state that is characterized by a unique set of thermodynamic parameters, and the values of these parameters do not depend on how this state is reached. Consequently, if a parameter can be reliably determined for one of the paths, its value can be used to calculate the variation over other paths. For example, for the process A + B + C → ABC, there is no ambiguity regarding the deformation energies of the monomers. The BSSE correction to the energy change will, therefore, take the simple form shown in eq. [7]. This strategy allows a BSSE-corrected energy to be assigned, without ambiguity, to

$$[7]\quad E^{\mathrm{BSSE}} = (E^{\mathrm{C}}_{\mathrm{A}} - E^{\mathrm{C}}_{\mathrm{A(BC)}}) + (E^{\mathrm{C}}_{\mathrm{B}} - E^{\mathrm{C}}_{\mathrm{B(AC)}}) + (E^{\mathrm{C}}_{\mathrm{C}} - E^{\mathrm{C}}_{\mathrm{C(AB)}})$$

each component of the reaction network.

For the water complexes w_n and the reactant complexes w_nc, the new BSSE corrections are now introduced through eqs. [8] and [9]. Table 3 summarizes the new BSSE

[a] Data from Table 2.

[8] $n\mathrm{w} \rightarrow \mathrm{w}_n$,
$E(\mathrm{w}_n) = \Delta E_{\mathrm{uncorr}} + E^{\mathrm{BSSE}} + nE(\mathrm{w})$

[9] $n\mathrm{w} + \mathrm{c} \rightarrow \mathrm{w}_n\mathrm{c}$,
$E(\mathrm{w}_n\mathrm{c}) = \Delta E_{\mathrm{uncorr}} + E^{\mathrm{BSSE}} + nE(\mathrm{w}) + E(\mathrm{c})$

corrections, and the resulting refined values of ΔH are given in Table 4. These lead to the modification of Fig. 4 to Fig. 6. With an rms deviation of 1.02 kcal/mol from the line of unit slope, this represents a significant improvement.

Re-examination of low-frequency vibrations and corrections to entropies in solution

The ideal-gas statistical mechanical procedure is used in Gaussian 92 and Gaussian 94 to calculate thermodynamic parameters, not only in the gas phase but also in the SCRF treatment. This approximation is reasonable for the description of the enthalpy of a reaction in solution, but entropic effects are greatly overestimated. The reason for this is that, in the gas phase, the major contribution to the entropy change calculated for an association reaction A + B → AB arises from the loss of six degrees of freedom, representing free translations and rotations of A and B, and the conversion of these into six vibrational modes of AB. In solution, rotational and translational motions are restricted and are better described by a set of low-frequency vibrations (22), which can be represented by a single effective frequency ν (9, 23). The assumption that ν is approximately the same for A, B, and AB then leads to eq. [10] for a free-energy change in

$$[10] \quad \Delta G_{\mathrm{liq}} = \Delta H_{\mathrm{gas}} + T\Delta S_{\mathrm{v}} - 6RT\left[\frac{h\nu/\kappa T}{\exp(h\nu/\kappa T) - 1} - \ln[1 - \exp(-h\nu/kT)]\right]$$

solution, where ΔH_{gas} and ΔS_{v} are, respectively, the BSSE-corrected SCRF enthalpy change and the contribution of intramolecular vibrations to the entropy change calculated by the Gaussian programme.

© 1998 NRC Canada

In ref. 9, an effective frequency $\nu = 115$ cm was obtained, using eq. [11],

$$[11] \quad v = \frac{1}{2\pi}(k/m)^{1/2}$$

from calculations on water, which yielded an effective force constant $k = 1.7 \times 10^4$ dyn cm^{-1} (1 dyn = 10 μN). This effective frequency was used in eq. [44] of ref. 9 (≡ eq. [10]) for the final calculation of all free-energy changes. A refinement of this approach is to employ different effective frequencies for the stationary structures of the reaction network by taking the different masses of these structures into account, i.e., $\nu_i = (m_j/m_i)^{1/2}\nu_j$. The resulting corrected entropies are included in Table 4 and, with this refinement and the original treatment of BSSE, Fig. 4 is modified to Fig. 7, which exhibits an rms deviation of 1.96 kcal/mol from the line of unit slope.

Combining the refined BSSE and low-frequency corrections

The free-energy changes shown for the different water clusters in Table 4 lead to the important conclusion that the formation of $(H_2O)_{2n}$ from $(H_2O)_n$ is exoergic for each of $n = 1$, 2, and 4. Consequently, in terms of the equilibria examined in the present work, the "'cubic-shaped octamer' and 'two cyclic tetramers' appear to be the principal species present in liquid water" (13).The corrected free-energy changes in the hydration reactions are shown in Figs. 8–13, and the kinetic analyses, based on these free-energy changes, are summarized in Table 5. The final results are included in Table 2 and plotted in Fig. 14, which show that the rms deviation from the line of unit slope has been reduced to 0.67 kcal/mol. The success of the overall correlation validates Eigen's original proposal (1) regarding the neutral hydration of a carbonyl group.

Inspection of the final column of Table 5 leads to the following additional conclusions: (*i*) *the four-water molecule channel predominates*. The transition structures of these channels are included in Figs. 8–13, and they have the expected (24) nonperpendicular attack angle; (*ii*) *hydration of acetaldehyde proceeds from the direction* syn *to hydrogen*; (*iii*) *equatorial hydration of cyclohexanone is two orders of magnitude faster than axial hydration*. The stereoelectronic implications of (*iii*) and the application of the strategy of the present work to compounds of the type XCH_2CHO will be discussed in a forthcoming paper. Extensions of the approach to carboxylic acid-catalyzed hydration, and neutral, carboxylic acid-catalyzed and enzyme-catalyzed ester and amide hydrolysis have also been completed and will soon be submitted for publication.

1,2-Bis(1-aryl-3-alkyltriazen-3-yl)ethanes and related compounds

Donald L. Hooper, Ian R. Pottie, Marc Vacheresse, and Keith Vaughan

Abstract: A series of novel bistriazenes, the 1,2-bis(1-aryl-3-methyltriazen-3-yl)ethanes, Ar-N═N-NMe-CH_2CH_2-NMe-N═N-Ar, have been synthesized by diazonium coupling with *N,N′*-dimethylethylenediamine. These bistriazenes are stable crystalline compounds and have been unequivocally characterized by IR and NMR spectroscopy (^{1}H and ^{13}C), and elemental analysis. The structures of two compounds in the series have been confirmed by X-ray crystallography. The ^{1}H NMR spectra show significant line broadening of the N-methyl resonances arising from the restricted rotation around the N2—N3 bond of the triazene units. The presence of strongly electron-withdrawing groups on the aryl ring restricts the rotation to the point where the N-methyl signals of the rotamers are distinct even at room temperature; four resonances of the N-methyl signal are clearly evident and these can be assigned to the *anti–anti*, *syn–syn,* and *syn–anti* conformations of the bistriazene. Diazonium coupling with *N,N′*-diethylethylenediamine affords the N,N′-diethyl homologues of the bistriazenes, which have been similarly characterized. As model compounds to assist in spectroscopic analysis, a series of related triazenes, the 1-(1-aryl-3-methyltriazen-3-yl)-*N,N*-dimethyl-2-ethanamines, were prepared by diazonium coupling with *N,N,N′*-trimethylethylenediamine. These dialkyltriazenes exist mainly as oils, but characterization was achieved by IR, ^{1}H NMR, and ^{13}C NMR spectroscopy, also showing the presence of two rotamers in solution when strongly electron-withdrawing substituents are bonded to the aryl moiety.

Key words: triazene, bistriazene, diazonium, ethylenediamine, molecular dynamics, NMR.

Résumé : On a synthétisé une série de nouveaux bistriazènes, les 1,2-bis(1-aryl-3-méthyltrizén-3-yl)éthanes Ar-N═N-NMe-C_2-C_2-NMe-N═N-Ar, par couplage de diazonium avec la *N,N′*-diméthyléthylènediamine. Ces bistriazènes sont des composés cristallins stables et on les a caractérisés sans équivoque par leurs analyses élémentaires et par spectroscopies IR et RMN (du ^{1}H et du ^{13}C). On a confirmé les structures de deux composés de la série par diffraction des rayons X. Dans les spectres de RMN du ^{1}H, on observe un élargissement important des raies dues aux résonances des groupes N-méthyles résultant d'une rotation empêchée autour de la liaison N2—N3 des unités triazènes. La présence de groupes fortement électroaffinitaires sur le noyau aryle provoque une restriction de la rotation telle qu'elle que l'on peut observer des signaux distincts pour les groupes N-méthyles, même à la température ambiante; on peut facilement observer quatre raies de résonance comme signal du N-méthyle et celles-ci peuvent être attribuées aux conformations *anti–anti, syn–syn* et *syn–anti* du bistriazène. Le couplage de diazonium avec la *N,N′*-diéthyléthylènediamine conduit aux analogues N,N′-diéthylés des bistriazènes qui ont été caractérisés de la même manière. Dans le but d'avoir des composés modèles permettant d'aider dans les analyses spectroscopiques, on a préparé une série de triazènes apparentés, les 1-(1-aryl-3-méthyltraizén-3-yl)-*N,N*-diméthyl-2-éthanamines, par couplage de diazonium avec la *N,N,N′*-triméthyléthylènediamine. Ces dialkyltriazènes existent principalement sous la forme d'huiles qui ont été caractérisées par spectroscopies IR et RMN du ^{1}H et du ^{13}C; quand la portion aryle comporte des substituants fortement électroaffinitaires, on y détecte aussi la présence de deux rotamères en solution.

Mots clés : triazène, bistriazène, diazonium, éthylènediamine, dynamique moléculaire, RMN.

[Traduit par la rédaction]

Introduction

The trivial name "bistriazene" has been used to describe a number of organic molecules that contain more than one triazene unit (N═N-N). The synthesis of 1,2-bis(alkyltriazeno)ethanes (**1**) was reported by Blumenstein and Michejda (1) from the reaction of an alkyllithium reagent with the diazide, $N_3CH_2CH_2N_3$; these triazenes are potently cytotoxic and are believed to have the ability to cross-link DNA. The hydroxymethyltriazenes, Ar-N═N-NR-CH_2OH, another class of cytotoxic triazene, are produced in the coupling reaction of a formaldehyde–methylamine mixture with a series of diazonium ions (2). A bistriazene by-product of this reaction, the *N,N*-bis(1-aryl-3-methyltriazen-3-ylmethyl)methylamine (**2**), is formed when there is an absence of M groups within the aryl ring and a low formaldehyde/methylamine ratio is used (3).

Recently we reported the synthesis of a different type of bistriazene; the 1,2-bis[4′-(triazenyl)phenyl]ethanes (**3**) were

synthesized by bis-diazotization of 4,4′-ethylenedianiline and coupling of the resulting bisdiazonium salt with the appropriate alkylamine (4). This paper reports the synthesis of a new type of bistriazene, the 1,2-bis(1-aryl-3-methyltriazen-3-yl)ethanes (**4**) and the N-ethyl homologues (**5**), by the reaction of the appropriate diazonium salt with the *N,N*′-dialkylethylenediamine. We also report here the synthesis of novel dialkyltriazenes, the 1-(1-aryl-3-methyltriazen-3-yl)-*N,N*-dimethyl-2-ethaneamines (**6**), by the reaction of the appropriate diazonium salt with *N,N,N*′-trimethylethylenediamine. It is anticipated that triazenes of series **4** and **6** will have antitumour activity of the same order as that reported (5) for the 1-aryl-3,3-dimethyltriazenes, Ar-N═N-NMe_2.

Experimental

All reagents were reagent grade materials purchased from Aldrich Chemical Co. Ltd. and were used without further purification. Melting points were determined on a Reichert hot-stage microscope and are uncorrected. Infrared spectra were obtained using Nujol mulls, unless otherwise stated, on a Perkin–Elmer 299 spectrophotometer. ^1H and ^{13}C NMR spectra were obtained on a Bruker 250 MHz spectrophotometer at the Atlantic Regional Magnetic Resonance Center at Dalhousie University in Halifax, Nova Scotia. Chemical shifts were recorded in $CDCl_3$ solutions at 20°C, and are relative to TMS as internal standard. Crystal structures were determined on an Enraf–Nonius CAD-4 diffractometer. Elemental analyses were performed by the Canadian Microanalytical Service Ltd., Delta, B.C.

1,2-Bis(1-aryl-3-alkyltriazen-3-yl)ethanes 4 and 5

General procedure

The arylamine $ArNH_2$ (0.01 mol) was dissolved in 2 N hydrochloric acid (25 mL) and gently heated if necessary to obtain a clear solution. (Arylamines with *ortho* substituents were dissolved in 3 N HCl to prevent precipitation during diazotization.) The solution was cooled in ice–salt and kept at 0–5°C while being diazotized with a solution of sodium nitrite (0.011 mol) in deionized water (10 mL). The diazonium salt solution was stirred for a further 0.5 h and any insoluble impurities were removed by vacuum filtration. The *N,N*′-dialkyl-1,2-ethanediamine (0.005 mol) was dissolved in deionized water (5 mL) and then added to the cold diazonium salt solution, keeping the temperature at 0–5°C. The resulting mixture

was stirred for 0.5 h and then the pH was adjusted to the alkaline region (approx. pH = 8) using saturated $NaHCO_3$. The product then precipitated from solution as an oil or as a solid.

Solid precipitates were isolated by vacuum filtration and purified by recrystallization from an appropriate solvent (see Table 1). Oils were recovered by extraction into dichloromethane (3 15-mL aliquots), and the extract was dried over anhydrous sodium sulphate. The extract was filtered and rotoevaporated under vacuum to remove the solvent. The residual oil was purified by either (*a*) column chromatography using Hi-Flosil (60–200 mesh) with 10:1 hexanes/ethyl acetate as eluent, or (*b*) by dissolving the oil (e.g., compound **5f**) in hot hexane – ethyl acetate and cooling to afford an oil of greater purity. The crude oils usually showed two or three dots on TLC; when the crude oil was purified by method (*b*), the TLC became much cleaner — the two impurities would usually disappear from the TLC plate and the NMR spectra were also much cleaner.

Physical data for compounds **4a–4p** are reported in Table 1 and NMR data can be found in Tables 2 and 3. The data collected for compounds **5a–5g** can be found in Tables 4–6. The identities of compounds **4b**, **4e**, **4h**, **4j**, **4o**, and **5a** were confirmed by elemental analysis (Table 7).

1-(1-Aryl-3-methyltriazen-3-yl)-*N,N*-dimethyl-2-ethanamine 6

General procedure

The general procedure for the synthesis of series **4** and **5**, above, was reproduced using *N,N,N′*-trimethyl-1,2-ethylenediamine to couple with one equivalent of the diazonium salt. However, with series **6** it was found necessary to use saturated aqueous KOH to adjust the alkalinity to approximately pH = 12, in order to precipitate these triazenes. The products were mainly oils or solids (Table 8). Solids were purified by crystallization. Oils were purified as described above. None of the products formed as oils showed impurities in the

NMR spectra and they show one spot on TLC. NMR spectroscopic data are shown in Tables 9 and 10.

Discussion

Synthesis

The 1,2-bis(1-aryl-3-methyltriazen-3-yl)ethanes (**4**) were synthesized in excellent yields by diazonium coupling with *N,N′*-dimethyl-1,2-ethylenediamine; yields are in the range 50–98% depending on the substituent in the aryl group. Likewise, diazonium coupling with *N,N′*-diethyl-1,2-ethylenediamine afforded the homologous ethyl bistriazenes (**5**). Most of the compounds in series **4** and **5** are crystalline solids. The 1-(1-aryl-3-methyltriazen-3-yl)-*N,N*-dimethyl-2-ethanamines (**6**), which were required as model compounds for spectroscopic analysis, were obtained in good yield (65–99%) by diazonium coupling with *N,N,N′*-trimethyl-1,2-ethylenediamine. However, these dialkyltriazenes (**6**) did not come out of solution when neutralization with sodium bicarbonate, our usual procedure, was attempted; it was found necessary to use potassium hydroxide as the base to get these triazenes to separate from solution and most of the products were oils. Only compounds **6b** and **6f** were obtained as crystalline solids.

Table 7. Elemental analysis for selected compounds.

	Calculated			Found		
Compound	%C	%H	%N	%C	%H	%N
4b	62.41	5.24	32.35	62.32	5.35	32.29

4j	62.41	5.24	32.35	62.22	5.23	32.59
4o	60.66	6.79	23.58	60.63	6.85	23.40
5a	64.17	5.88	29.95	64.15	5.92	29.98
6f	52.58	6.82	27.87	52.83	6.80	27.88

Infrared spectra

The IR spectra of compounds in all three series, **4**, **5,** and **6**, are in accord with the assigned structures. The out-of-plane bending vibrations are consistent with the position of substitution: *ortho*-substituted compounds give a single band in the range 720–740 cm^{-1} and *para*-substituted compounds give a single band at ca. 800 cm^{-1} Diagnostic functional group bands are consistent with the substituent in the aryl ring. For example, the ester substituents of compounds **4c**, **4d**, **4k**, **4l**, **5b**, **5c**, **6c**, **6d**, **6k,** and **6l** show carbonyl group stretching vibrations between 1680 and 1715 cm^{-1} A nitrile group band at 2180 cm^{-1}

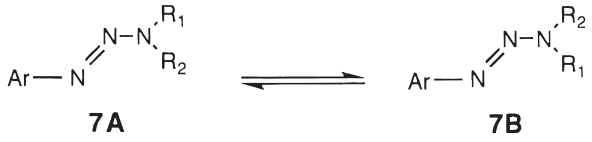
is present in the spectra of compounds **4b**, **4j,** and **6j**. The spectra of **4f**, **4n**, and **5e** contain the symmetric and assymmetric vibrations of the nitro group at 1320/1490, 1360/1500, and 1320/1490 cm^{-1}, respectively. Compounds **4i** and **6i** show strong bands at 1040 and 1050 cm^{-1}, respectively, which may be assigned to the aryl bromide.

NMR spectra

^1H NMR

Proton NMR spectra provided unequivocal evidence for the structures of the bistriazene series, **4** and **5**, and the triazenes, **6**. For example, the aromatic signals of the *para*-substituted bistriazenes **4b**–**4i** were found between 6.84 and 8.01 ppm and exhibited the general splitting pattern of an AA′BB′ system (Table 2). Compounds **4j**–**4p** showed complex aromatic splitting patterns at 6.86–7.76 ppm due to the *ortho* substituent. O-Methyl protons in the ester substituents of **4c** and **4k** and the alkoxy substituents of **4g** and **4o** gave signals in the range 3.80–3.90 ppm; the acetyl Me groups in **4h** and **4p** resonated at 2.58 and 2.46 ppm, respectively. The chemical shift of the N-CH_2 protons in the ethylene link was typically in the range 4.0–4.2 ppm, and the N-CH_3 protons were generally found between 3.22 and 3.32 ppm.

A number of the compounds of type **4** show significant broadening of the N-methyl and N-methylene signals in the ^1H NMR spectra. The spectra of 1-aryl-3,3-dialkyltriazenes, Ar-N═N-NMe_2, frequently show broadening of the NMR N-alkyl signals; this has been attributed to restricted rotation around the N2—N3 bond and the equilibrium between rotamers **7A** and **7B** (6):

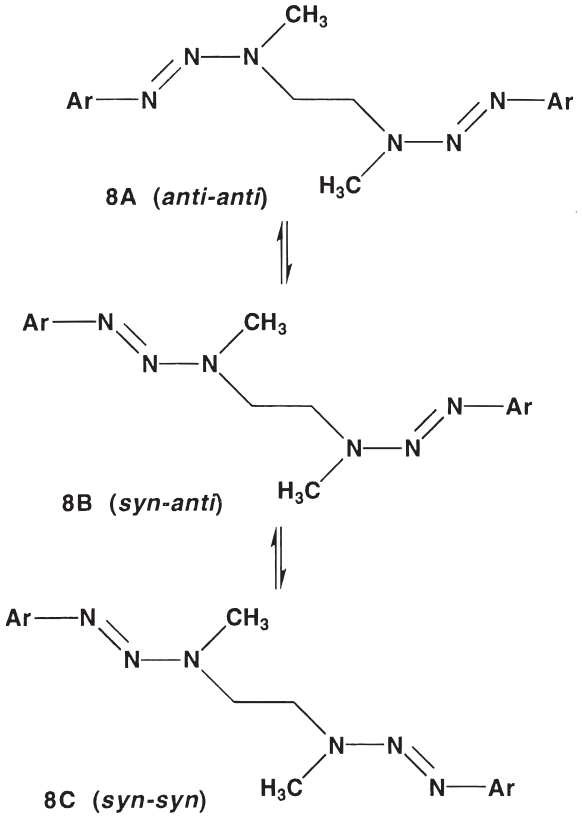


7A **7B**

Indeed, some of the compounds of series **4** have NMR spectra in which the signals of the N-methyl protons of the rotamers are resolved at room temperature, e.g., bistriazene **4j**. Further examination of this phenomenon has been investigated by a variable temperature (VT) NMR study (see later discussion).

Proton NMR spectra also confirmed the structures of the series of N-ethyl bistriazenes **5a–5g**; all compounds had a characteristic AA′BB′ pattern in the range 6.86–8.05 ppm. The spectra exhibit the appropriate signals of the *para* substituents. The N-CH_2 protons of the ethylene link give rise to a slightly broadened singlet at 3.93–4.08 ppm. The N-ethyl moiety exhibits, as expected, two sets of protons with an integral ratio 2:3. The two-proton signal of the N-methylene group appears as a quartet in the range 3.74–3.87 ppm, while the appearance of the methyl protons of the ethyl groups depends on the nature of the aryl substituent. When the substituent on the aryl ring is electron donating, as in **5d** and **5f**, the methyl protons are resolved as a clear triplet at 1.26 ppm. However, when the substituent is electron withdrawing, as in **5a**, **5b**, **5c**, and **5g**, the methyl protons appear as a broad singlet. In one case, that of the *para*-nitro bistriazene **5e**, the methyl protons of the N-ethyl group resolve into two slightly broadened triplets at 1.24 and 1.40 ppm.

Scheme 1.



The lineshapes of these signals from the N-ethyl groups in the compounds of series 5 would logically have something to do with the restricted rotation around the N2—N3 bond in the triazene units. However, there is no immediate explanation for the anomalous observation that the line-broadening is only observed for the more distant methyl protons of the N-ethyl groups.

The ^1H NMR spectra of the triazenes **6a–6p** corroborate the assigned structures and show features consistent with restricted rotation around the N2—N3 bond in the triazene unit. The signals of the aromatic protons and the protons of the aryl substituents are all as expected. The methylene groups of the ethylene moiety are not equivalent and appear as two triplets integrating for two protons each. The methylene group adjacent to the triazene unit is deshielded by the triazene moiety and resonates as a sharp signal at δ 3.82–3.94; the other methylene group is more shielded, appearing at δ 2.52–2.63, and in some cases (when the aryl substituent is strongly electron withdrawing) is significantly broadened. The protons of the N-dimethyl groups give rise to a sharp signal in the range δ 2.27–2.30, with the exception of the *ortho*-cyano derivative **6j**, which has two signals resolved at δ 2.29 and 2.31. The triazene N-methyl protons give rise to a distinctly broadened singlet in the range δ 3.21–3.29; when there is a strongly electron withdrawing nitro or cyano group in the *ortho* or *para* position of the aryl ring, these N-methyl signals are resolved into two signals at δ 3.23–3.32 and δ 3.57–3.60. These observations are indicative of an equilibrium between the *syn* and *anti* forms of the triazene (**6A** and **6B**) due to the restricted rotation around the N2—N3 bond of the triazene:

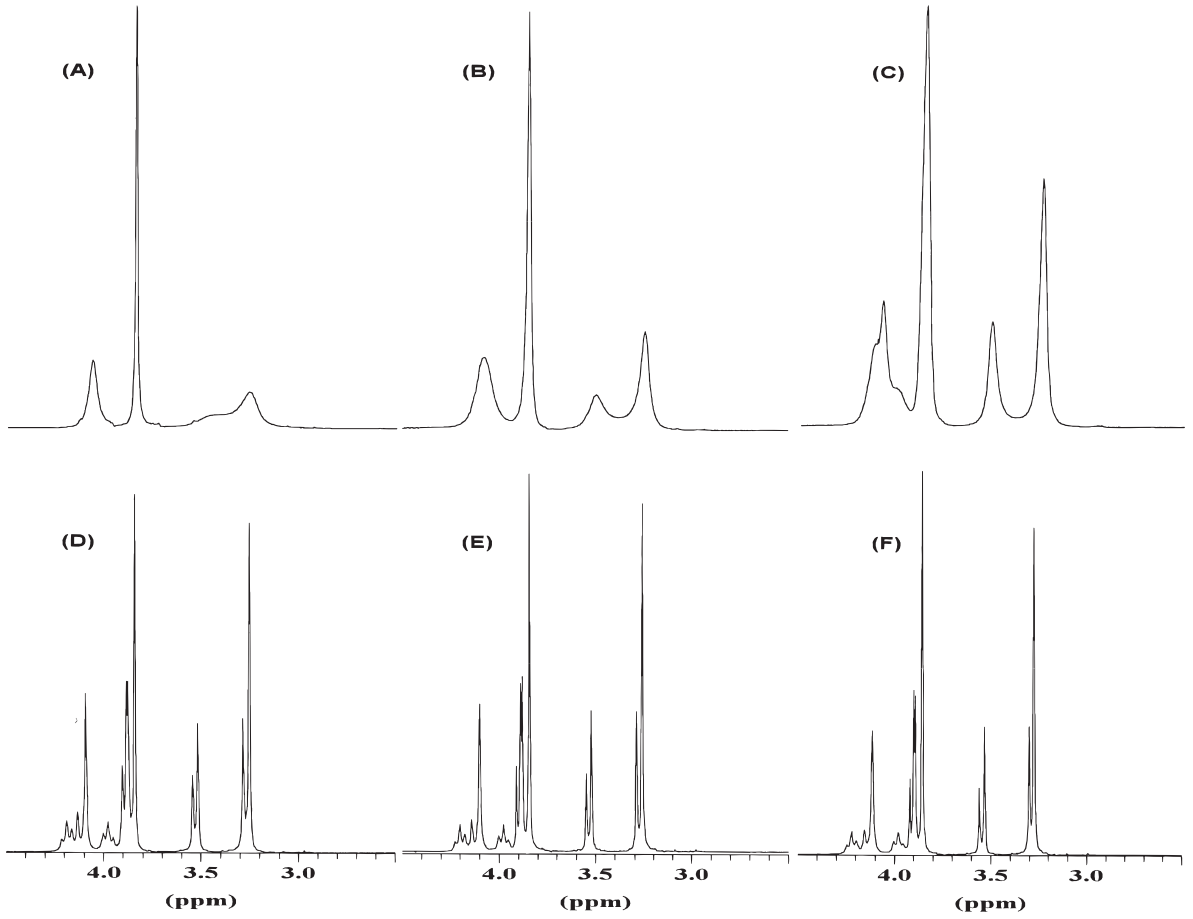
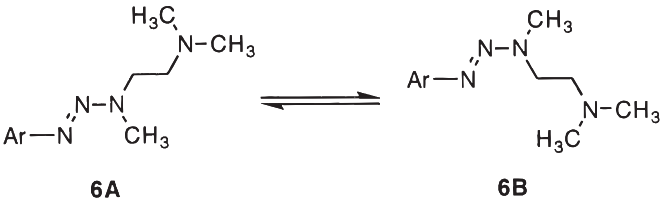
Fig. 1. Variable temperature NMR spectra of the bistriazene **4k** in the N-alkyl resonance region at the following temperatures: (*A*) 295 K; (*B*) 283 K; (*C*) 273 K; (*D*) 253 K; (*E*) 243 K; (*F*) 233 K.





6A **6B**

Compounds of series **6** proved to be good model compounds for prediction of chemical shifts of comparable protons in the bistriazenes **4**. In **6**, the N-methyl group adjacent to the triazene unit occurs in the range 3.21–3.32 ppm, compared to the range 3.22–3.32 ppm for the N-methyl protons in **4**. The N-methylene protons adjacent to the triazene in **6** resonate in the range 3.82–3.94 ppm; the N-methylene protons in **4** are slightly more deshielded by the presence of the second triazene unit and occur in the range 4.00–4.30 ppm.

^{13}C *NMR*

The structures of the bistriazenes in series **4** were corroborated by ^{13}C NMR spectroscopy (Table 3). The aromatic resonances of compounds **4a**–**4i** were observed as four signals in the range 114.0–157.8 ppm, whereas the *ortho*-substituted compounds **4j**–**4p** showed six aromatic resonances between 110.7 and 153.05 ppm. A greater number of aromatic signals were resolved in the spectrum of compound **4j** due to the dynamic equilibrium of the rotamers. O-Methyl carbons in the esters (**4c**, **4k**) and alkoxy (**4g**, **4o**) substituents had signals in the range δ 52–56. These signals were very close to the N-methylene carbon signals within the spectrum, but the N-methylene signals were weak and easily distinguished from the stronger methyl carbon resonances. Confirmation of the assignments was obtained from DEPT experiments. The N-methyl carbons give rise to weak signals (not always observed) at δ 35–36, and the N-methylene carbons, when observed, are also weak in the range δ 52–54. The weak signals may be due to the low nuclear Overhauser enhancement of the signals. The spectrum of the *ortho*-cyano compound **4j** is unique in that the resonances of four distinct N-methyl carbons are observed, along with four different N-methylene signals; these observations can be accounted for by the presence of three rotamers in solution (see later discussion of VT-NMR and Scheme 1).

^{13}C NMR spectra of the bistriazenes of series **5** follow a similar pattern to those above (Table 6), and the ^{13}C NMR spectra of the triazene series **6** are consistent (Table 10). The signal from the methyl carbons of the N-Me_2 unit are strong, with resonance in the range 45.45–45.73 ppm, whereas the triazene N-methyl group gives a weak carbon signal in the range 34–35 ppm. Two weak signals are observed for the N-methylene carbons in **6** at δ 52–54 and δ ca. 57.

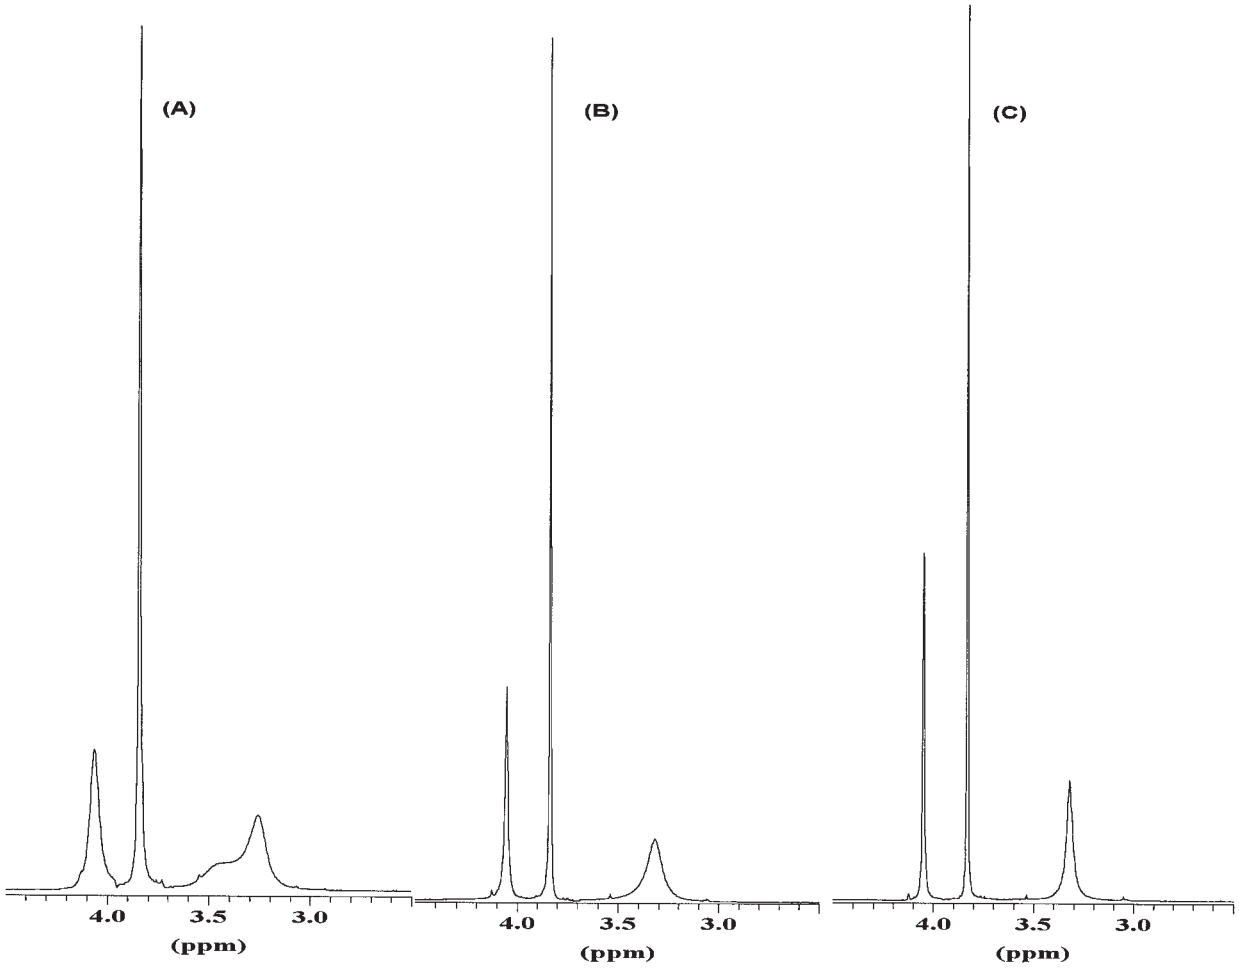
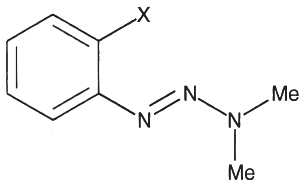
Fig. 2. Variable temperature NMR spectra of the bistriazene **4k** in the N-alkyl resonance region at the following temperatures: (*A*) 295 K; (*B*) 303 K; (*C*) 313 K.



Variable temperature ^1H NMR spectroscopy

Variable temperature ^{1}H NMR experiments were conducted on two *ortho*-substituted compounds in the bistriazene series, namely, the ester **4k** and the nitrile **4j**. The results for the ester **4k** are shown in Figs. 1 and 2. In the room temperature spectrum, Fig. 1*A*, the N-methyl signals are broadened considerably. When the temperature is raised, Fig. 2, the N-methyl signals become sharper and, at 313 K (Fig. 2*C)*, a single, averaged-out, N-methyl signal is observed at δ 3.35 ppm. When the temperature of a solution of **4k** is lowered (Fig. 1 *A–F*), the signals sharpen and resolve at 253 K into four distinct N-Me signals, which can be assigned to the three rotamers, **8A**, **8B,** and **8*C*** (Scheme 1). The strongest signal of the group at δ 3.25 ppm is assigned to the equivalent N-methyl groups of the predictably predominant *anti–anti* rotamer (**8A**) and the weakest signal at δ 3.54 is assigned to the equivalent N-methyl groups of the *syn–syn* rotamer (**8C**). The two equal-intensity signals at δ 3.28/3.51 ppm are assigned to the nonequivalent N-methyl groups of the *syn–anti* rotamer (**8B**); the percent population of the three rotamers can be estimated from the relative heights of these N-methyl signals to be 50% **8A**, 40% **8B**, and 10% **8C**.

Evaluation of the temperature dependence of the NMR spectra of **4k** by the line-width method described by Akhtar et al. (6) afforded useful information about the dynamics of the rotation around the N2—N3 bond in this molecule. The free energy of activation ($\Delta G^{\ddagger}$) at 295 K was calculated to be 14.6 kcal/mol with a rate constant $k = 92.4$ s^{-1}. It is interesting



9 (a) X = CO_2Me
(b) X = CN

to compare these kinetic data with the unpublished data[2] for the analogous 1-aryl-3,3-dimethyltriazene **9a** containing the same aryl substituent, *ortho*-CO_2Me, as compound **4k**. For compound **9a** the $\Delta G^{\ddagger}$ was found to be 14.5 kcal/mol at 297 K; thus the barrier to rotation around the N2—N3 bond in the triazene moiety of the bistriazene is virtually identical to that in a simple 1-aryl-3,3-dialkyltriazene.

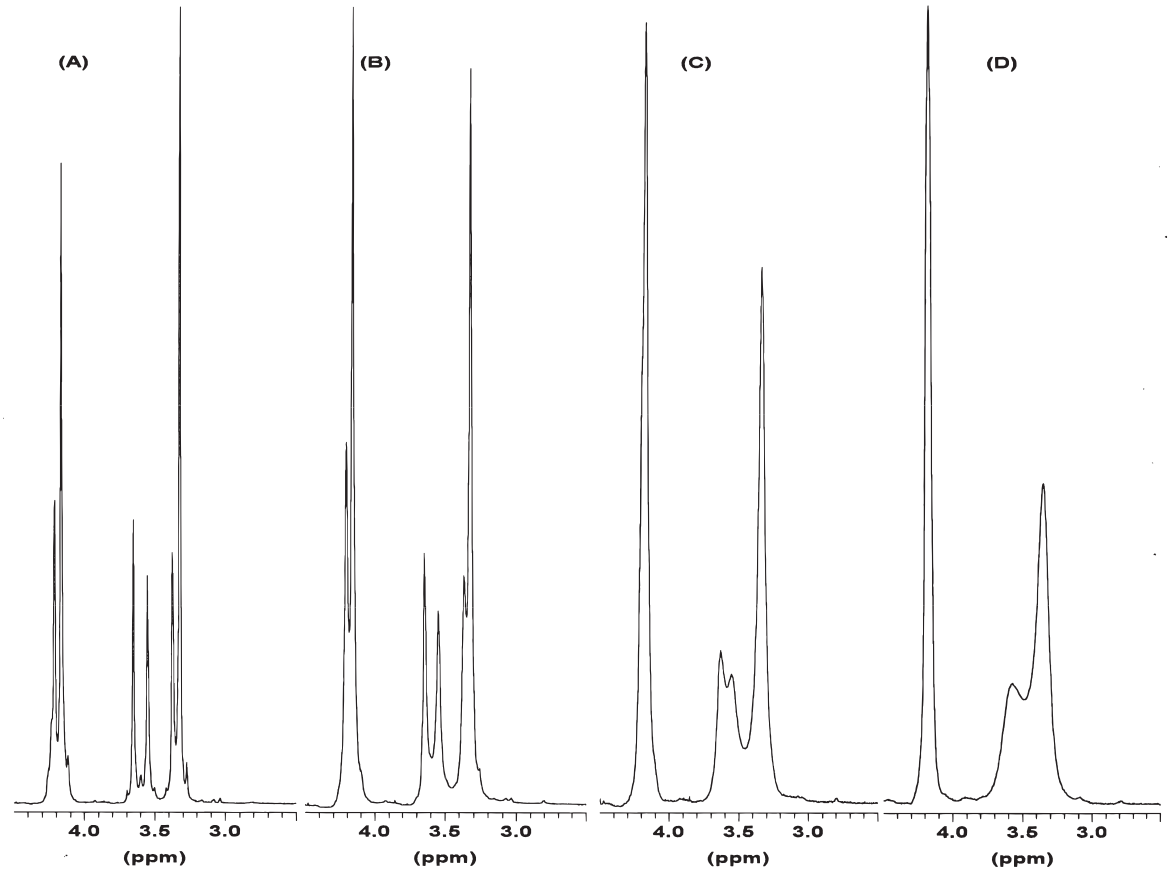
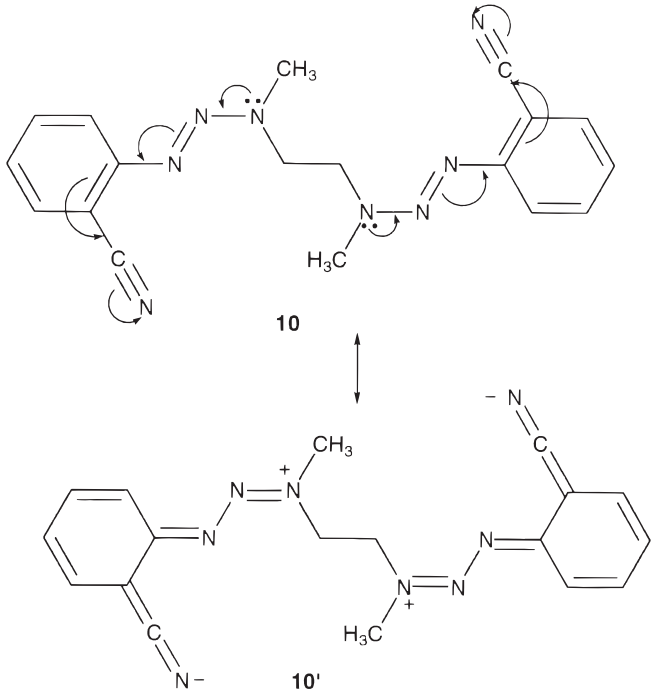
Fig. 3. Variable temperature NMR spectra of the bistriazene **4j** in the N-alkyl resonance region at the following temperatures: (*A*) 295 K; (*B*) 303 K; (*C*) 313 K; (*D*) 323 K.



Scheme 2. The resonance structures of compound **10** (cf. **4j**) arising from through-conjugation with the nitrile group; the repulsion between the positively charged nitrogen atoms causes the molecule to adopt the staggered conformation.



In the NMR spectrum of the *ortho*-cyano bistriazene **4j**, the N-methyl signals of the three rotamers are resolved in the room temperature spectrum, which has the exact same appearance as the 253 K spectrum of **4k**. Figure 3 shows the effect of raising the temperature on the NMR spectrum of **4j**; the peaks broaden and begin to coalesce. Analysis of the spectra in Fig. 3 by the line-width method affords a free energy of activation of 16.0 kcal/mol at 297 K, corresponding to a rate constant k = 10.1 s^{-1}. This value compares closely with the observed barrier to rotation in the analogous 1-aryl-3,3-dimethyltriazene **9b**, which has a $\Delta G^{\ddagger}$ value of 15.3 kcal/mol at 283 K.[2] When we compare the k values for the two bistriazenes, it appears that the rotation in the *ortho*-cyano compound **4j** is about 10 times slower than the rotation in the ester **4k**, indicating that the bond order of the N2—N3 bond is greater in **4j** than in **4k**. The greater double bond character of the N2—N3 bond in **4j** may be attributed to the contribution of the resonance delocalization to the overall structure as depicted in Scheme 2; it is significant to this argument that the two cyano-substituted triazenes **4b** and **4j** have IR absorptions at 2180 cm^{-1}, lower than the normal frequency for an aryl nitrile (>2200 cm^{-1}). Analogous changes are observed in the N-methylene region of the NMR spectrum of **4j** when the temperature is raised. At room temperature there are two distinct resonances, at δ 4.15 and 4.22, for the protons of the N-CH_2CH_2-N moiety. When the temperature is raised, these signals coalesce (Fig. 3).

Fig. 4. ORTEP diagram of the *ortho*-cyano-substituted bistriazene **4j**.

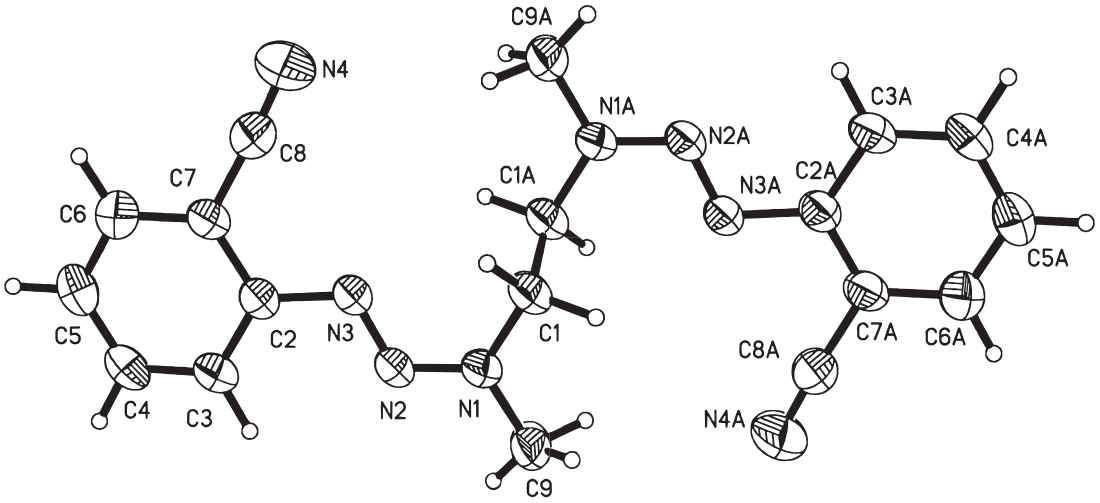

Fig. 5. ORTEP diagram of the *ortho*-methoxy-substituted bistriazene **4o**.

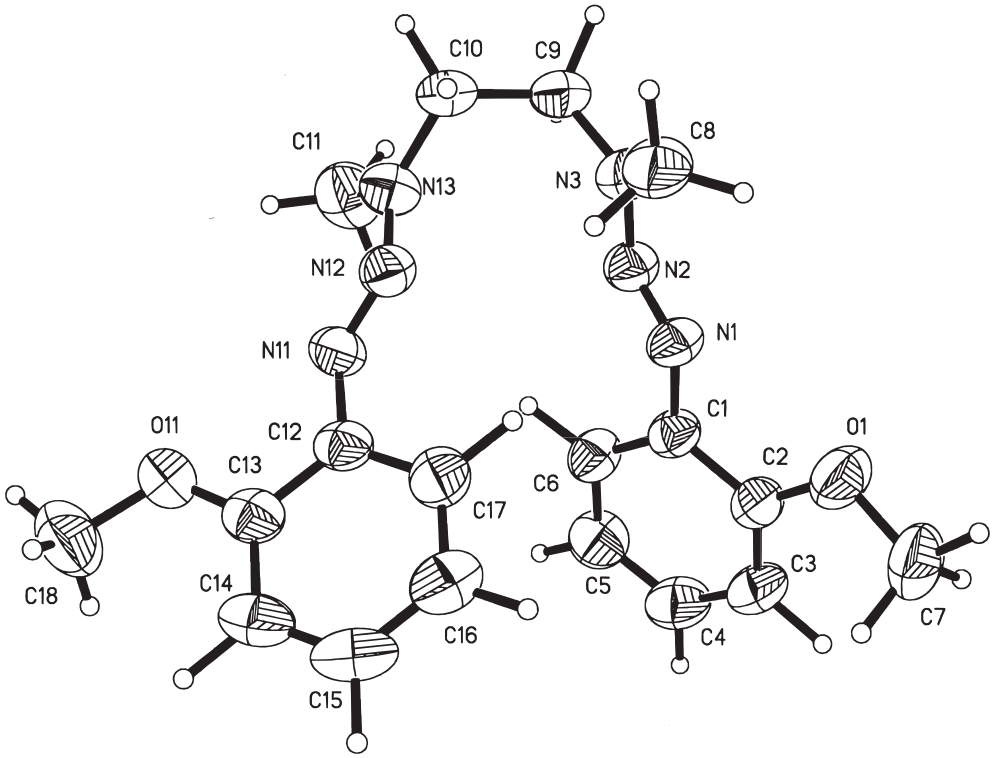
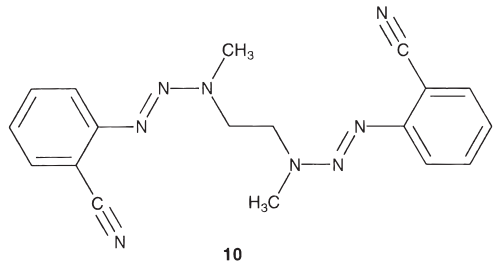


X-ray crystallography

The structures of the *ortho*-cyano-substituted bistriazene **4j** and of the *ortho*-methoxy analogue **4o** have been determined by X-ray crystallography (7). In the solid state (Fig. 4), the *o*-cyano compound **4j** adopts the *anti–anti* structure (**10**; the analogue of structure **8A** in Scheme 1), consistent with the NMR data of this compound. The solid state structure is the same as the preferred rotamer seen in a solution of this compound by NMR. Predictably, **4j** assumes the "staggered" conformation with respect to the orientation around the C—C bond of the ethane link. In contrast, the *o*-methoxy analogue **4o** exists in the solid state (Fig. 5) with the "*gauche*" conformation around the C—C bond of the ethane unit and adopts the *syn–syn* configuration around the N2—N3 bonds of the triazene units. The electron-donating capabilities of the *ortho*-methoxy group would not be expected to increase the bond



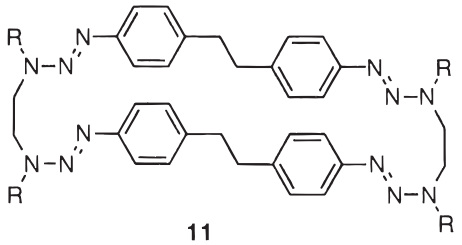
10

© 1998 NRC Canada

order of the N2—N3 bonds. Thus there is free rotation around the N2—N3 bond in compound **4o**, which enables the molecule to fold over onto itself. Full details of these X-ray crystal structures will be published elsewhere (7).

Conclusions

This paper has shown that 1,2-bis(1-aryl-3-alkyltriazen-3-yl)ethanes **4** and **5** can be readily synthesized; the bistriazenes have been fully characterized by spectroscopic methods, and the rotational properties of the molecules around the N2—N3 bond of the triazene have been explored by variable temperature NMR spectroscopy. X-ray crystallography has confirmed



11

the structure of two examples of the bistriazene series. The synthesis and identification of these bistriazenes opens up the possibility of the design and synthesis of macrocyclic triazene-containing molecules. By combining the structural elements of the bistriazenes of types **3** and **4** into one unit, it should be possible to isolate macrocyclic tetrakistriazenes represented by structure **11**. These macrocyclic molecules could have a multitude of applications, especially in host–guest chemistry. The abundance of hydrogen bond acceptors could make it possible to place hydrogen bond donors or cationic metals within the cavity of the tetrakistriazene. Such a macrocycle may also have useful biological activity due to the presence of four potentially cytotoxic triazene units within the same molecule.

Frondoside C, a new nonholostane triterpene glycoside from the sea cucumber *Cucumaria frondosa*: structure and cytotoxicity of its desulfated derivative

Sergey A. Avilov, Olga A. Drozdova, Vladimir I. Kalinin, Anatoly I. Kalinovsky, Valentin A. Stonik, Elena N. Gudimova, Ricardo Riguera, and Carlos JimØnez

Abstract: Frondoside C (**1**) is a new sulfated nonholostane triterpene glycoside obtained (with the glycosides closed by aglycone structure as impurities) from the sea cucumber *Cucumaria frondosa*. Its structure has been elucidated on the basis of spectral data (NMR and MS) of compound **1** and of its desulfated derivative (**2**) obtained by solvolysis. Frondoside C (**1**) is just the seventh glycoside reported from sea cucumbers, having a lanostane-type aglycone devoid of the typical 18(20)-lactone ring.

Key words: *Cucumaria frondosa*, sea cucumbers, frondosides, triterepene glycosides, antitumor activity.

Résumé : On a isolé un nouveau glycoside sulfaté du triterpène nonholostane, le frondoside C (**1**) (comportant des glycosides de la structure aglycone comme impuretés), à partir du concombre de mer *Cucumaria frondosa*. On a déterminé sa structure en se basant sur des données spectrales (RMN et SM) du composé **1** et de son dérivé désulfaté (**2**) obtenu par solvolyse. Le frondoside C (**1**) n'est que le septième glycoside à avoir été observé dans les concombres de mer, avec un aglycone de type lanostane ne comportant pas de cycle lactone typique en 18(20).

Mots clés : *Cucumaria frondosa*, concombres de mer, frondosides, glycosides de triterpène, activité antitumorale.

[Traduit par la rédaction]

The sea cucumber *Cucumaria frondosa* Gunnerus (*Cucumariidae*) is a widespread benthic animal inhabiting the North Atlantic and western Arctic seas. Previous studies of this sea cucumber have yielded two new holostane pentaglycosides, the monosulfated frondoside A (1) and the disulfated frondoside B (2). More recently, we have isolated a new minor monosulfated tetraoside frondoside A_1, along with frondoside A, from specimens of *C. frondosa* collected in Barents Sea (3).

Continuing with our investigations on bioactive secondary metabolites of marine origin, we report here our results on the study of the more polar triterpene glycosides from *C. frondosa,* with the isolation of a new saponin that we named frondoside C. Column chromatography on polychrom-1 (powdered Teflon) of the ethanolic extract of *C. frondosa* gave a mixture of glycosides that was separated by column chromatography on silica gel, affording frondoside C (**1**) accompanied by very small amounts of other polar glycosides with identical carbohydrate chain. Attempts to purify **1** by HPLC were unsuccessful. To establish wholly its structure, we resorted to spectroscopic analysis of impure **1** and the pure compound **2** that resulted from solvolysis of **1**. Thus, solvolysis of **1** with pyridine–dioxane mixture afforded, after HPLC purification, the pure desulfated derivative **2**.

The presence of five doublets in the ^{1}H NMR of **2** (J = 7.1–7.5 Hz) at δ 4.75, 4.86, 5.05, 5.12, and 5.20 ppm, produced by the anomeric protons correlated by HMQC (heteronuclear multiple quantum correlation) to the corresponding anomeric carbons (Table 1), were indicative of a pentaglycoside chain. The characteristic proton resonances of the methyl groups at δ 1.59 ppm (d, J = 6.4 Hz) and δ 3.79 (s) indicated the presence of a quinovose and 3-*O*-methyl glucose residues in the oligosaccharide chain. Comparison of the carbon resonances due to the carbohydrate chain of **1** and **2** (Table 1) showed complete coincidence with those of the trisulfated pentaoside cucumarioside A_7-1, isolated from *Cucumaria japonica* (4), and those of the desulfated derivative of cucumarioside A_7-1, respectively. Therefore we assume that compound **1** and cucumarioside A_7-1 share identical carbohydrate chains. The location of sulfate groups of **1** at C-4 of internal xylose (Xyl_1) and at C-6 of glucose and 3-*O*-methyl glucose units was confirmed by the comparison of the carbon resonances of **1** with those of its desulfated derivative **2** (Table 1) and other holostane and nonholostane sea-cucumber glycosides (4–6).

Comparison of the spectral data of the aglycone part of **2** with those published for the desulfated penaustrosides A and B from *Pentacta australis* (5) suggested the same Δ^9 lanostane skeleton for **1** and **2**, featuring a 20-hydroxy group but bearing a different side chain. In fact, the carbon chemical shifts corresponding to C-1 through C-16, C-18, C-19, and C-30 through C-32 of **2** are practically identical to those of desulfated penaustrosides A and B. The 9(11)- double bond was corroborated by chemical shifts at δ 149.9 (s, C-9) and 115.2 (d, C-11) that correlated by HMQC with the olefinic proton at δ 5.17 (m, H-11), while the carbon signal at δ 76.4 (s, C-20) indicated the presence of a tertiary carbon bonded to a hydroxyl group.

The remaining proton and carbon resonances allowed us the elucidation of the side-chain moiety. The presence of a terminal isopropylidene group in the side chain of **2** was deduced by the carbon chemical shifts at δ 133.3 (s, C-25) and 121.7 (d, C-24) (correlated to the olefinic proton δ 5.21 (1H, brt, H-24)) and the vinyl methyl signals at δ 26.0 (q, C-26) and 18.1 (q, C-27) (correlated to δ 1.61 and 1.62 (each 3H, s) by HMQC). Lastly, an acetoxy group (δ 170.8 (s) and 21.7 (q)/ 2.12 (3H, s)) was located at C-22 by comparison of the carbon resonances of **2** with those of desulfated penaustroside A (5). The shifts to higher field observed for C-20 (δ 76.4; Δ = 2.2 ppm) and to lower field for C-21 (δ 21.3; Δ = –5.0 ppm) and C-17 (δ 50.6; Δ = –2.7 ppm) correspond to the β- and γ-shift effects of acetate groups (7) predicted for that position in **2**. On the other hand, the carbon chemical shifts of the side chain of **2** are very similar to those of protoreasteroside, isolated from the starfish *Protoreaster nodosus*, containing a 5α-cholesta-9(11),24(25)-diene-3β,6α,20,22-tetraol as aglycone (8). Furthermore, this structure was supported by HMQC, ^{1}H-^{1}H COSY, and selective homonuclear decouplings of **2**, thus irradiation of the signals at δ 5.20 (1H, m, H-22) and δ 5.21 (1H, brt, H-24) produced the collapse of the allylic methylene at δ 2.00–2.40 (2H, brm, H-23).

The 20*R*,22*R* configurations for the hydroxy group at C-20 and the acetoxy group at C-22 in **2** were suggested by the almost coincidence of the corresponding carbon chemical shifts of **2** and the known 2β,3β,22(*R*)-triacetoxy-14α,20(*R*),25-trihydroxy-5β-cholest-7(8)-en-6-one (9). This hypothesis was supported by the comparison of spectral data of **2** with those of the four stereoisomers of 5α-cholestane-3β,20,22-triol with respect to C-20 and C-22, synthesized by Hikino et al. (10), taking into consideration shifted effects of an acetoxy group at C-22. Thus, the higher field of the methyl group C-21 at δ 21.3 for **2** was indicative of a 20(*R*) configuration.[2] In the same way, the value of the C-21 methyl protons at δ 1.50 (3H, s) in the ^{1}H NMR (C_5D_5N) of **2** suggested a 22*R* configuration.[3]

The structure proposed (Fig. 1) was confirmed by MS. Thus, the positive FABMS of desulfated frondoside C (**2**) shows the pseudomolecular ions at m/z 1271 $[M + Na]^+$ and 1287 $[M + K]^+$ (molecular formula $C_{61}H_{100}O_{26}$), and a significant fragment ion at m/z 507 [aglycone + Na + H]$^+$ due to the loss of the carbohydrate chain from the pseudomolecular ion. Other ions confirmed the presence of the acetoxy group in the side chain of **2** (m/z 1129, 1130, 163, 164, and 165) and the sequence of the monosaccharide units in the oligosacharide

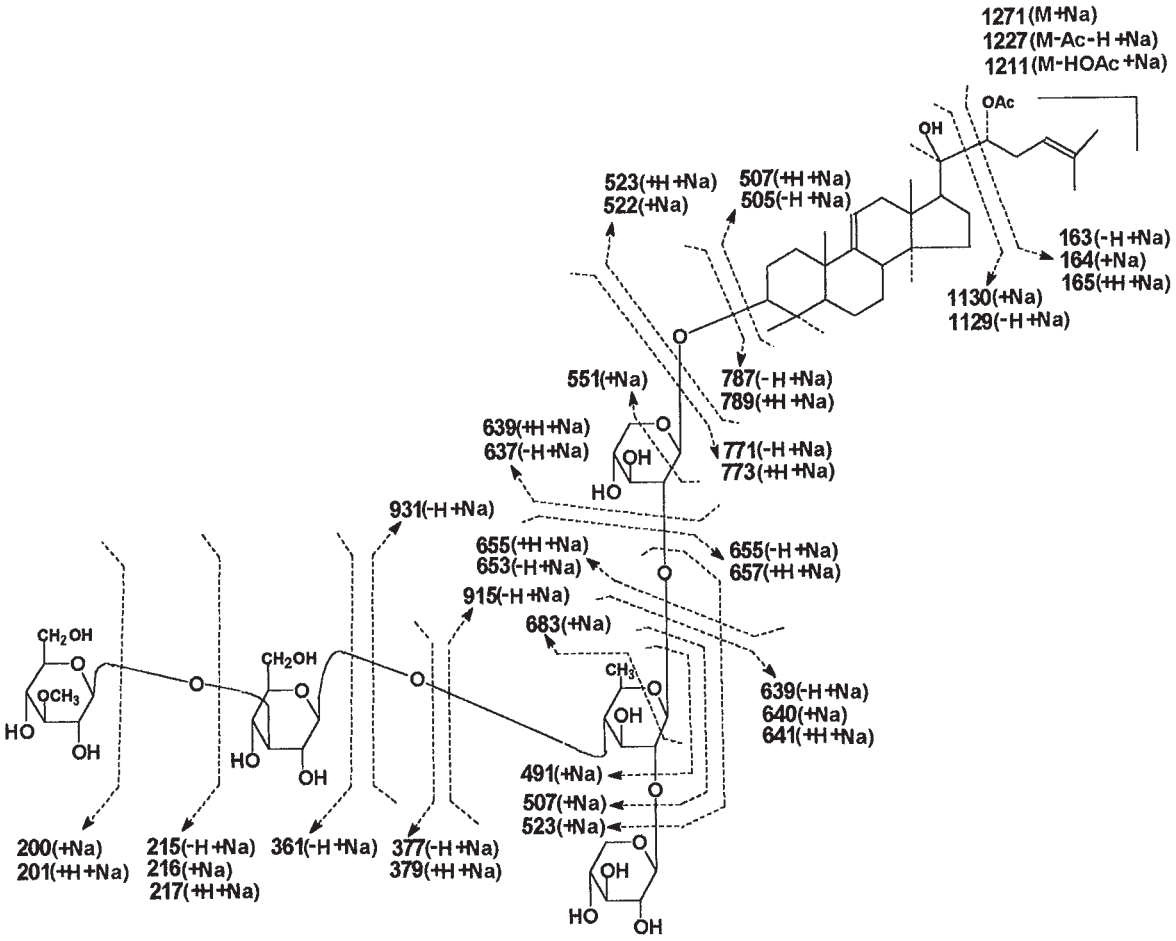
Fig. 1. Fragmentation of **2** in the positive FABMS.



chain as depicted in Fig. 1. Assuming that the sugars belong to the *D*-configuration family and the ions at sulfate groups are sodium and potassium, as is the case in related sea-cucumber glycosides (1, 2), we conclude that frondoside C (**1**) has the structure 20(*R*)-hydroxy,22(*R*)-acetoxy-3β-*O*-{[3-*O*-methyl-β-*D*-6-sulfonato-glucopyranosyl-(1→3)-*O*-β-*D*-6-sulfonato-glucopyranosyl-(1→4)]-*O*-[β-*D*-xylopyranosyl-(1→2)]-*O*-β-*D*-quinovopyranosyl-(1→2)-*O*-β-*D*-4-sulfonatoxylopyranosyl}-lanosta-9(11), 24(25)-diene sodium (or potassium) salt.

Most of sea-cucumber triterpene glycosides reported so far in the literature (more than 70) belong to the so-called holostane series, characterized by the presence of an 18(20)-lactone ring in the aglycone moiety (11–13). Sea-cucumber lanostane glycosides devoid of the 18(20)-lactone are rare and, in fact, only six have been published. These are kurilosides A and C from *Duasmodactyla kurilensis* (14), psolusoside B from *Psolus fabricii* (15), Ds-penaustrosides A and B from *Pentacta australis* (5), cucumarioside G_2 from *Eupentacta fraudatrix* (16), and koreoside A from *Cucumaria koraiensis* (17). Frondoside C (**1**) reported in this paper is the seventh lanostane glycoside without the 18(20)-lactone found in sea cucumbers.

The desulfated frondoside C (**2**) was found to present intense cytotoxic activity (IC_{50} = 1 μg/mL) when tested in vitro against several standard mice and human tumoral cell lines (P-388, Schabel, A-549, HT-29, and Mel-28).

Experimental section

General experimental procedures

All melting points were determined with a Kofler thermogenerate apparatus. Specific rotation was measured on a Perkin–Elmer 141 polarimeter. One- and two-dimensional NMR spectra were obtained on a Bruker WM-250 spectrometer at 250 MHz (^{1}H), 500 MHz (^{1}H), and 62.7 MHz (^{13}C) in C_5D_5N:D_2O (4:1) with TMS as an internal reference. The FABMS (positive ion mode) was performed on a Fission VG-Quattro spectrometer and obtained with Cs atoms at 7–9 keV and a matrix of glycerol–thioglycerol + NaCl. HPLC was performed with a Dupont 8800 chromatograph equipped with a RIDK–102 differential refractometer (Laboratorni Pristroje, Prague).

Animal material

The sea cucumber *Cucumaria frondosa* (family *Cucumariidae*; order *Dendrochirotida*) was collected in Dalnezelenetskaya Bay (Kolsky Peninsula, Barents Sea) in August 1988. The collection was carried out with scuba divers at 10–15 m in depth. A voucher specimen is on deposit in the collection of Murmansk Marine Biological Institute of Kolsky Scientific Center of the Russian Academy of Sciences, Dalnyje Zelentsy, Murmansk District, Russia. The specimens were kept in EtOH.

© 1998 NRC Canada

Extraction and isolation of 1

The specimens (30 kg) were cut into pieces and extracted twice with hot ethanol. The combined extracts were concentrated to dryness under low pressure, and the residue was chromatographed on a polychrom-1 column (powdered Teflon, Biolar, Latvia) previously filled with EtOH. Inorganic salts and polar impurities were washed out with H_2O, and the fraction containing the glycosides was then eluted with 50% ethanol. This fraction was further chromatographed on a silica-gel column, eluting with a $CHCl_3$–EtOH–H_2O (100:100:17) system and affording two main fractions, the first one composed by monosulfated glycosides (4.1 g) and the second one by the most polar glycosides (2.4 g). This last fraction was repeatedly chromatographed on a silica-gel column, with the $CHCl_3$–MeOH–H_2O (650:300:54) system, affording impure frondoside C (**1**) (323 mg) and also containing the glycosides closed by aglycone structure as impurities, which were directly converted into **2** by solvolysis. See Table 1 for ^{13}C NMR data.

Solvolysis of frondoside C

To a solution of 323 mg of **1** (with impurities) in 10 mL of H_2O, 50 mg of resin DOWEX (H^+) was added (rt, 20 min). The resin was filtered off, washed with H_2O (35 mL) and EtOH (25 mL). The combined filtrates were evaporated to dryness under low pressure, and the residue dissolved in 10 mL of dioxane–pyridine (1:1) was refluxed for 1 h. The reaction mixture was concentrated under low pressure and repeatedly chromatographed on a silica-gel column, eluting with the $CHCl_3$–MeOH–H_2O (650:150:22) system. The residue (270 mg) was submitted for HPLC on a Silasorb C-18 column (80% MeOH, 20% water), producing 50 mg of pure desulfated derivative **2**.

Desulfated frondoside C (2)

$[\alpha]_D^{20}$ –21 (*c* 0,1, pyridine), mp 262–264°C, ^1H NMR (δ, ppm): 5.20 (1H, $J = 7.5$ Hz, H1-Xyl_1), 5.12 (1H, $J = 7.1$ Hz, H1-Xyl_2), 5.05 (1H, $J = 7.1$ Hz, H1-Qui), 4.86 (1H, $J = 7.5$ Hz, H1-Glc), 4.75 (1H, $J = 7.1$ Hz, H1-MeGlc), 3.79 (3H, s, OMe of MeGlc), 1.59 (3H, d, $J = 6.4$ Hz, Me6-Qui). See Tables 1 and 2 for ^{13}C NMR data and Table 2 for aglycone moiety data. FABMS (positive ion mode) *m*/*z* (rel. intensity): 1287 ($C_{61}H_{100}O_{26}S_2K$, $[M + K]^+$, 3.5), 1271 ($[M + Na]^+$, 1.9), 1227 ($[M - Ac - H + Na]^+$, 2.2), 1211 ($[M - HOAc + Na]^+$, 1.5), 1129 (2.7), 1130 (1.5), 931 ($[M–177–162–H + Na]^+$, 1.6), 639 ($[M–177–162–H + Na]^+$, 4.6), 507 ([aglycone + Na + H]$^+$, 7), 523 (12), 491 (23), 173 (100), 165 (78), 164 (8), 163 (28).

Antitumor activity

Antitumor activity was determined in the cell lines P-388 (mouse lymphoma ATCC:CCL 46), Schabel (mouse lymphoma MDR), A-549 (human lung carcinoma ATCC: CCL 35), HT-29 (human colon carcinoma ATCC: HTB 38), and Mel-28 (human melanoma ATCC: HTB 72).

Synthesis of *cis*-*p*-dioxano-12-crown-4 and X-ray crystallography of the (1:1) complex with lithium thiocyanate

Alex B. Driega, Gerald W. Buchanan, and Corinne Bensimon

Abstract: The synthesis of a novel 12-crown-4 analogue (*cis*-*p*-dioxano-12-crown-4 or *cis*-3,6,9,13,15-pentaoxabicyclo[9.3.1]pentadecane) is described. The (1:1) LiNCS complex crystallizes in the monoclinic *Cc* space group; $a = 8.4973(2)$ Å, $b = 18.0659(4)$ Å, $c = 8.9168(1)$ Å, and $\beta = 90.713(1)°$ with $Z = 4$. The crown adopts C_1 symmetry to which the Li^+ is coordinated in a rectangular pyramid with an apical $^-$NCS.

Key words: crown ethers, structure, complexation.

Résumé : On décrit la synthèse d'un nouvel analogue d'une 12-couronne-4 (*cis*-*p*-dioxano-12-couronne-4 ou *cis*-3,6,9,13,15-pentaoxabicyclo[9.3.1]pentadécane). Le complexe (1:1) avec le LiNCS cristallise dans le groupe d'espace monoclinique *Cc*, avec $a = 8{,}4973(2)$ Å, $b = 18{,}0659(4)$ Å et $c = 8{,}9168(1)$ Å, $\beta = 90{,}713(1)°$ et $Z = 4$. La couronne adopte une symétrie C_1 dans laquelle la coordination du Li^+ est s'effectue dans une pyramide rectangulaire avec un $^-$NCS apical.

Mots clés : éthers couronnes, structure, complexation.

[Traduit par la rédaction]

Introduction

The known solid-state conformations of 12-crown-4 ether (12C4) or 1,4,7,10-tetraoxadodecane fall into three symmetry classes C_i, C_4, and C_s. The free ligand adopts C_i symmetry (1), while in non-tetradentate complexes all three classes are encountered (C_i symmetry in ref. 2, C_4 symmetry in refs. 2*c* and 3, C_s symmetry in ref. 4). In complexes where the four oxygens are coordinated to a metal cation, the crown adopts C_4 symmetry (5–7), with the exception of one C_s transition-metal complex (8). However the *cis*-*syn*-*cis*-dicyclohexano-12C4 analogue, upon (1:1) complexation with LiNCS, crystallizes with an asymmetric geometry (9).

Force-field calculations on 12C4 utilizing AMBER (10), MM2 (11), MM3 (12), and WBFF (13) each report anywhere from 4 to 55 low energy conformations, designated by *gauche*/*anti* torsion angle codes, with no shared global minimum. These studies consistently locate the C_i, C_4, and C_s conformers amongst the lowest in energy. To date, the C_i conformer has not been located as a global minimum,[2] which indicates that the solid-state geometry may be dominated by crystal packing forces (14, 15).

Herein is presented the stereospecific synthesis of *cis*-*p*-dioxano-12C4 (*cis*-3,6,9,13,15-pentaoxabicyclo[9.3.1]pentadecane) **1** and **1**·LiNCS. The crown nature of **1**, with a diequatorial dioxane chair, is that of 12C4 in which C_i and C_4 symmetry are forbidden. Hence X-ray crystallographic studies on **1** have the potential to complement those on 12C4 itself. Conversely, with a flattened diaxial dioxane chair, or a diequatorial boat, **1** can adopt a 14C4 nature. In this light, complexation with Li^+ is of particular interest, owing to the high affinity of this metal ion to 14C4 moieties (16). The morpholino analogue of **1** is known (mixture of *cis* and *trans* stereoisomers), but no structural information is available (17).

Results and discussion

Crystallographic data for **1**·LiNCS are presented in Table l*a*. Atomic bond lengths are in Table l*b*, while bond angles are in Table 1*c*. Torsion angles for networks not involving H atoms are collected in Table 1*d*. Atomic parameters and anisotropic temperature factors are available as supplementary data.[3]

Structure of 1·LiNCS

In the ORTEP diagram of **1**·LiNCS, the substituents bonded to C1 and C11 of the dioxane chair are equatorial (Fig. 1), hence the C2-C1-O15-C11-C10 unit is *anti*-*anti*. All oxygen lone pairs are oriented to one side of the crown cavity, therefore three 12C4 conformations are possible: conformation **A** with

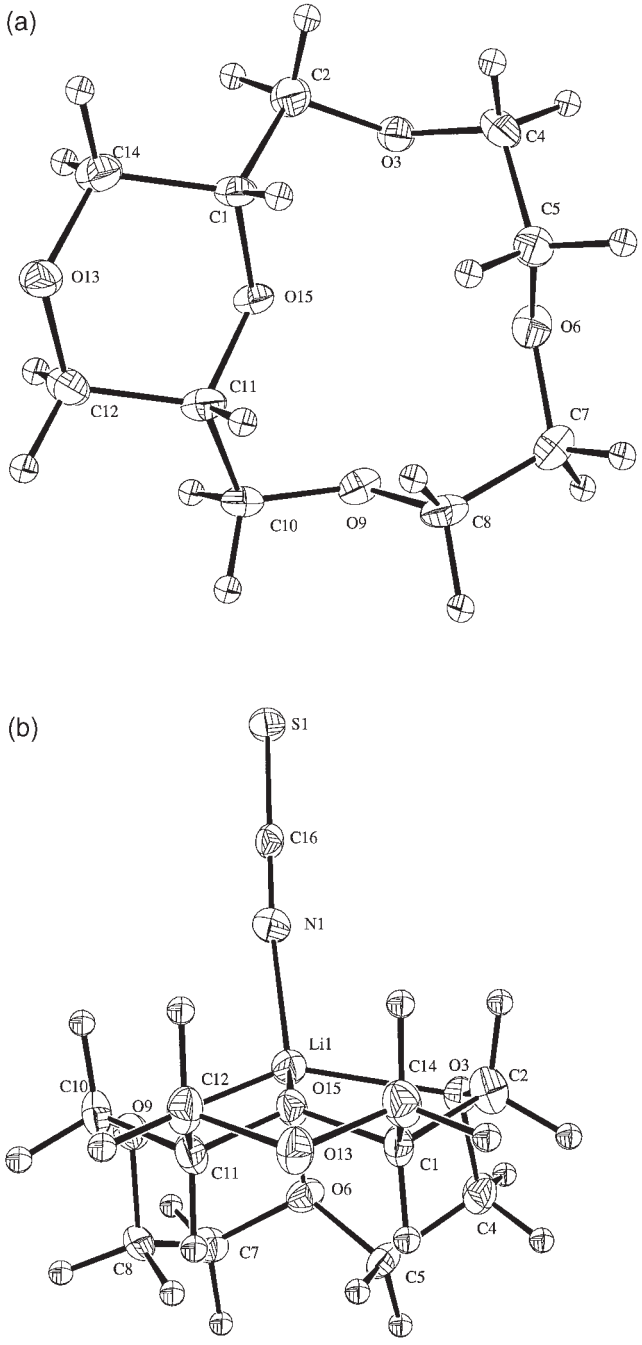
Fig. 1. (*a*) ORTEP plot of **1**·LiNCS showing ligand conformation only. (*b*) ORTEP plot of **1**·LiNCS, perpendicular view, showing Li complexation.



C_2 symmetry (*a*+*g*+*g* –*g*–*ga* *a*+*g*+*g* –*g*–*ga*)[4] superimposable on the diamond lattice, and a rectangular [2,4,2,4] [5] crown cavity (11); conformation **B** with C_2 symmetry (*a*+*g*+*g* *a*+*g*+*g* –*g*–*ga* –*g*–*ga*) and a square [2,3,4,3] crown cavity; or conformation **C** with C_1 symmetry (*a*+*g*+*g* *a*+*g*+*g* *a*+*g*+*g* –*g*–*ga*) possessing traits intermediate [2,3,3,4] between the previous two.

[4] The first torsion angle is defined by a C-O-C-C network where +*g*(0°→120°), –*g*(0°→ –120°), *a*(120°→ –120°).

[5] Denotes corners, i.e., the number of bonds between *a*+*g*+*g* or *a*–*g*–*g* segments.

Note that the *cis-syn-cis*-dicyclohexano-12C4 analogue, which lacks an *anti-anti* constraint (9), adopts conformation **C** upon (1:1) complexation with LiNCS.

The crown cavity of **1**·LiNCS is somewhat rectangular with diagonal 0···0 distances of 3.3 and 4.1 Å. The mean deviation of the least-squares plane defined by the binding oxygens is 0.24 Å, and the Li^+ is situated 0.90 Å from this plane, capped by the nitrogen of the anion. The mean Li···0 distance is 2.09 Å which, considering the known 12C4·Li^+ complexes, compares favourably with 12C4·LiNCS (2.08 Å) (5) and *cis-syn-cis*-dicyclohexano-12C4·LiNCS (2.11 Å) (9), but is considerably shorter than 12C4·$LiNPh_2$ (2.20 Å) and 12C4·$LiN(SiMe_3)_2$ (2.23 Å) (6). These trends reflect the degree of conformational freedom of the macrocycle within the lattice, since all Li···N distances remain nearly constant (1.97–2.00 Å). A similar observation is made by Kamitori et al. (7) for a $(12C4)_2$·Li^+ species included in a γ-cyclodextrin framework, where the mean Li···0 distance is about 0.16 Å longer than usual (6).

Inspection of the macrocyclic torsion angles (Table 2) reveals that **l**·LiNCS adopts conformation **C**. Note that the lower half of the macrocycle (Fig. 1*a*) has the extended boat geometry of conformation **B**, while the upper half has the geometry of conformation **A**.There are two small O-C-C-O torsion angles in the range of 40–50°, in keeping with other 12C4·Li^+ complexes (5, 6, 9), which provide focused C-O dipoles for optimal directional coordination. In 12C4 sandwich complexes (4*a*, 6, 7), the metal resides further out of the crown cavity, and the O-C-C-O angles are similar to those in the dioxane ring of **l**·LiNCS (Table l*d*) (18). Differential scanning calorimetry measurements on **1**·LiNCS show no phase transitions between –100°C and the decomposition point at 218–222°C.

Conformational analysis

Of the three possible 12C4 tetradentate complexation geometries, the results of AMBER (10), MM2 (11), and MM3 (12) force-field calculations all favour conformation **C**. Indeed, the AMBER study locates this geometry (conformer **IIc**) as the third lowest overall in energy (10).[2] The detailed torsion angles reported in the MM2 study (conformer **19**) (11) are in excellent agreement with the experimental **1**·LiNCS geometry, the largest difference being 10° with a mean deviation of 5° (Table 2). Our MM2 minimization of **1** in the X-ray geometry keeps all torsion angles to within 15° of the experimental geometry, with a mean deviation of 6°. Evidently the dioxane ring contributes little strain[6] to the macrocycle in conformation **C**.

Our MM2 minimization of **1** in conformation **B** reveals that, although the cavity dimensions are appropriate for (1:1) Li^+ complexation with diagonal O···O distances of 3.8 and 4.1 Å, the lone pairs on O3 and O9 face too far outward. However, by flattening the extended boat into a geometry suitable for

[6] When correlating theory to experiment between parent compounds and their analogues based on torsion angle codes, caution must be exercised. An illustrative example is that *cis-syn-cis*-dicyclohexano-12C4 crystallizes with the crown in C_4 symmetry (*a*+*g*+*g* *a*+*g*+*g* *a*+*g*+*g* *a*+*g*+*g*), but the (1:1) LiNCS complex does not (9). Here pseudorotation into a C_4 complexation geometry results in severe compression of the ethylene glycol O-C-C-O networks due to the relatively inflexible cyclohexane moieties.

[c] Conformation **19** (see ref. 11).

complexation, the bridge O-C-C-O networks become seriously compressed to <40° due to the inflexible dioxane ring. Finally, for conformation **A**, tetradentate complexation is deemed unlikely due to the oblong dimensions of the crown cavity as reflected in the diagonal O···O distances of 2.7 and 4.1 Å.

It is noteworthy that the (1:1) LiNCS complexes of two structurally diverse 12C4 analogues crystallize with the same asymmetric [2,3,3,4] conformation (Table 2). This behaviour is anticipated to be of importance in the design of Li^+ selective complexing agents. Investigation into the preferred conformation of **1** in solution at low temperature (15, 19) is in progress. In this regard the C_s conformation of 12C4, which contains a plane of symmetry, is a likely candidate (8, 10–13, 14).

Experimental

Materials

cis-*3,6,9,13,15-pentaoxabicyclo[9.3.1]pentadecane (**1**)*
A mixture of *cis*-2,6-bis(iodomethyl)-*p*-dioxane (20) (2.00 g, 5.4 mmol), $NaHCO_3$ (1.00 g, 12.0 mmol), 4 mL H_2O, and 20 mL DMF was stirred at 110°C for 17 h. The solution was then filtered, the solvents removed in vacuo, and the residue pyrolyzed in a Kugelrohr distillation apparatus at 135–140°C (0.6 mm) to obtain *cis*-2,6-bis(hydroxymethyl)-*p*-dioxane (95% pure by ^{13}C NMR) as an oil; 60% yield. To a stirred mixture of *t*BuOLi (648 mg, 10.8 mmol) in 20 mL *t*BuOH was added dropwise the diol (400 mg, 2.7 mmol) in 5 mL *t*BuOH, and then the nonhomogeneous solution refluxed at 80°C in an oil bath for 4 h with a $CaCl_2$ drying tube connected to the top of the condenser. Then bis-2-chloroethoxy ether (386 mg, 2.7 mmol) was added, followed by LiBr (234 mg, 2.7 mmol), and the gentle reflux continued for 2 weeks. The solution (blue to litmus) was then neutralized with 6 M HCl, and the solvent removed in vacuo. The residue was taken up in 20 mL of H_2O, acidified with HCl, and then extracted with $CHCl_3$ (3 × 20 mL). The combined organic phases were dried over anhydrous Na_2SO_4, and the solvent removed by rotary evaporation. The residue was eluted with $CHCl_3$:MeOH 15:2 on a preparative silica TLC plate, 1 mm thickness, $R_f = 0.65$, with detection by phosphomolybdic acid in EtOH (20% w/w), to give **1** as a colourless oil; 14% yield. ^1H NMR ($CDCl_3$) δ: 3.34–3.56 (m, 2H), 3.59–3.91 (m, 7H); ^{13}C NMR ($CDCl_3$) δ: 66.9 (t, $^1J_{C\text{-}H}$ = 141 Hz), 68.6 (t, $^1J_{C\text{-}H}$ = 138 Hz), 69.8 (t, $^1J_{C\text{-}H}$ = 140 Hz), 71.2 (t, $^1J_{C\text{-}H}$ = 142 Hz), 74.7 (d,$^1J_{C\text{-}H}$ = 143 Hz).

cis-*3,6,9,13,15-pentaoxabicyclo[9.3.1]pentadecane·LiNCS (**1**·LiNCS)*
To **1** (30 mg, 0.14 mmol) in 1 mL of Me_2CO was added LiNCS (25% H_2O w/w, 15 mg, 0.17 mmol), and after 30 min crystallization commenced. The solvent was allowed to slowly evaporate to about 0.5 mL in volume whereupon X-ray grade crystals in the form of hexagonal plates were collected; mp 218–222°C (d).

X-ray crystallographic measurements and structure solution

A summary of the crystallographic data is given in Table 1*a*. Diffraction intensities were collected on a Rigaku diffractometer using Mo*K*α radiation at –100°C. The Θ/2Θ scan technique was used to a maximum 2Θ value of 57.0°.

The systematic absences gave a choice of two space groups, namely *Cc* and *C*2/*c*. The structure was solved in the lowest symmetry *Cc* and then was checked for missing symmetry. No missing symmetry was found, thus confirming that *Cc* was the correct space group. Unit cell parameters were obtained from least-squares refinement using the setting angles of 4632 reflections in the range $3 < 2\Theta < 57°$.The data were corrected for Lorentz and polarization effects. No absorption correction was made. The structure was solved by direct methods plus Fourier maps and was refined by full-matrix least-squares analysis with weights based on counting statistics. The non-hydrogen atoms were refined anisotropically, and H atoms were calculated. No crystal decay was noted during data collection. All calculations were performed using the NRC VAX crystal structure programs (21). Structure factor tables and anisotropic temperature factors are available as supplementary data.[3]

The stereochemistry of hippurate alkylation

John M. McIntosh, E. Jay Kiser, and Zhigang Tian

Abstract: Alkylation of the hippurate esters of *trans* 2-(*p*-substituted phenyl)cyclohexanol with benzyl bromide affords phenylalanine derivatives in high chemical yield. The reaction stereoselectivity varies from 20 to >98% depending on the aromatic group in the cyclohexyl auxiliary. A model that correctly predicts the sense of the induction is proposed.

Key words: enolate conformation, π-stacking, 2-phenylcyclohexanol, chiral auxiliary.

Résumé : L'alkylation des hippurates du *trans* 2-(phényl *p*-substitué) cyclohexanol avec le bromure de benzyle conduit à des dérivés de la phénylalanine, avec un rendement chimique élevé. La stéréosélectivité de la réaction varie de 20 à >98% dépendant du groupe aromatique fixé sur l'auxiliaire cyclohexyle. On propose un modèle qui prédit correctement le sens de l'induction.

Mots clés : conformation de l'énolate, empilement π, 2-phénylcyclohexanol, auxiliaire chiral.

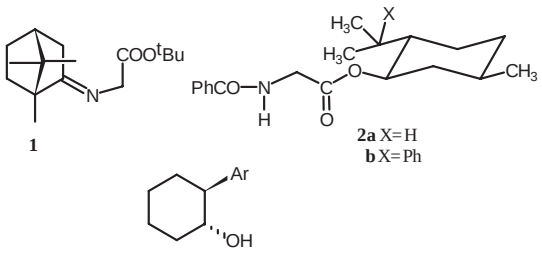
[Traduit par la rédaction]

Introduction

Significant success in controlling stereochemical aspects of reactions has traditionally been limited to using steric effects as the control elements. Results of enolate reactions that have well-understood, rigid, transition state structures enforced by cyclic and intermolecular coordination (e.g., the aldol condensation and Lewis acid catalyzed Diels–Alder reactions) are relatively easily interpreted. Conversely, reactions that do not normally have these coordinations (e.g., enolate alkylations) are much less well understood and predictable. However, there are increasingly frequent reports of the alteration of a stereochemical result by the presence of an aromatic residue that appears to be remote from the reacting center. Perhaps the first specific observations of this effect were made by Corey et al. (1) in the chiral reduction of a ketone in the prostaglandin series and by Posner and Lentz (2) in the alkylation of a cyclopentanone derivative. The apparent influence of π-systems has been noted in many other instances where 8-phenylmenthol has been used in place of menthol (see refs. 3–12) and, in particular, in the use of *trans* 2-phenylcyclohexanol as a chiral auxiliary (4, 13–15). The concept of π-stacking has been promulgated as a major contributor to these effects (16–18) and this aspect has been summarized in a review (19).

For some time we have been examining the factors underlying this effect in alkylation reactions and we have uncovered some interesting electronic effects (20, 21). Those experiments, which involved imine **1** as the alkylation substrate, were relatively easily interpreted since imine **1** is relatively rigid and the enolate is monoanionic. We have also reported that benzylation of **2a** gave modest stereoselectivity (56% de) whereas **2b** provided much improved results (85% de) (22), again emphasizing the significance of π-unsaturation in inducing asymmetry.

Ester enolates can exist in two configurations (*cis* and *trans* (23)). Incorporation of chirality with its associated conformational mobility into an ester enolate, in combination with the configurational questions, makes prediction of the stereochemical outcome of a reaction of such species much more difficult. It has been noted that nucleophilic reactions of ester enolates derived from cyclohexane-based auxiliaries do not provide the high levels of stereochemical control seen with electrophilic reactions (14). Further complicating the picture when hippurate esters are used is the dianionic nature of the enolates.



1

2a X = H
b X = Ph

3a Ar = Ph
b Ar = *p*-F-phenyl
c Ar = *p*-CF_3-phenyl
d Ar = *p*-MeO-phenyl
e Ar = *p*-CH_3-phenyl
f Ar = 1-naphthalenyl
g Ar = *p*-^{t}Bu-phenyl

The typical approach to selecting an effective chiral auxiliary is to determine which gives the best level of induction and then choose the enantiomer that gives the desired product stereoisomer. The associations that lead to effective chirality transfer are very complicated and an empirical model that predicts the stereochemical outcome of alkylation reactions would be a valuable tool. In an attempt to construct such a predictive model for cyclohexane-based auxiliaries (14) and to determine whether a relationship between π-electron density and stereoselectivity exists in this system, we prepared a series

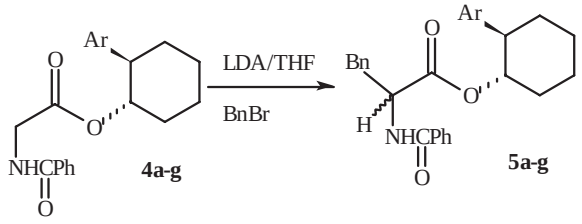
[a] Overlapping.

of alcohols (**3a–g**) and their hippurate esters **4** and benzylated the esters under the previously established (22) conditions (eq. [1]).

[1]



The alcohols **3a**–**e** were prepared either by opening cyclohexene oxide with the appropriate organometallic reagent (24) or, less desirably, by hydroboration–oxidation of the corresponding alkene. Acid-catalyzed condensation with hippuric acid routinely afforded the hippurate esters **4**. The two protons of the glycine methylene in **4** were highly diastereotopic as evidenced by their NMR absorptions, a fact that augured well for good diastereoselection (13). Alkylation of **4** with benzyl bromide afforded the corresponding phenylalanine derivatives **5** in generally excellent yield (>85%). Separation of unreacted starting material without separation of the diastereomers of **5** was easily achieved by column chromatography.

HPLC analysis of the mixture of diastereomers was difficult. The separations were small at best and were strongly dependent on the aromatic substituent, necessitating the development of new separation parameters for each derivative. This difficulty was overcome by the serendipitous observation that the minor diastereomer (see Table 1) formed in the alkylation reaction exhibited a unique NMR signal at δ 6.45. Extensive decoupling and 2D NMR experiments identified this signal as arising from the two *ortho* protons of the aromatic residue of the benzyl group. This was further confirmed by performing the alkylation with benzyl bromide-d_7 (25) and noting the absence of the δ 6.45 signal. Preparation of an authentic sample of each diastereomer of **5a** from optically pure (1*R*,2*S*)-**3a** and *N*-benzoyl-(*S*)-phenylalanine and *N*-benzoyl-(*R*)-phenylalanine revealed that this signal was absent in the NMR spectrum of the former. Therefore, the major diastereomer formed in the alkylation reaction (see Table 1) must have the (*S**, 1*R**,2*S**) configuration. Although the signal for the amino acid methine proton (b, Table 1) in the minor diastereomer was partially merged with that of the carbinol protons (e) on the auxiliary at 300 MHz, the corresponding signal of the **major** diastereomer was well separated from all other signals. Integration of the NMR absorptions for the *ortho* protons (f) of the minor diastereomer and the absorption for the amino acid methine proton (b) in the major diastereomer allowed direct assessment of the reaction stereoselectivity. The doublet of AB quartets due to the benzylic protons (c) in each diastereomer were well resolved from each other, but in some cases the benzylic proton (d) on the auxiliary obscured one of these signals. In every case, however, there were sufficient resolved signals to be able to measure the de as accurately as the NMR technique would inherently allow. Where more than one set of signals could be used, the agreement between the calculations was excellent. A listing of the relevant NMR signals and their assignments in **5a**, which are representative of all **5,** is shown in Table 1.

The stereochemical results of the alkylation reactions are shown in Table 2 along with the results from the menthyl and 8-phenylmenthyl esters previously reported.

Conclusions

Both the size and sense of the stereochemical induction require comment. It is clear from comparison with authentic ester **5a** that esters derived from (1*R**,2*S**)-**3** afford the *S** configuration at the alkylation center as the major product in every case. The predictive model we proposed previously (22) can also be applied here. The preferred conformation of acetals and dialkoxycarbenium ions is *anti–gauche* ("anomeric effect") (26). This conformation minimizes the repulsion between the oxygen lone pairs of electrons. If the cyclohexane ring is constrained to the all-equatorial form and a cyclic coordination between the lithium cation, the enolate oxygen atom, and the nitrogen atom is invoked (*trans* enolate), the *anti–gauche*

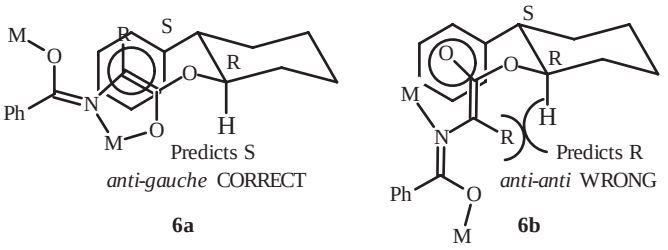
[a] See ref. 22.

conformation **6a** uniquely predicts the correct stereochemical result, whereas the *anti–anti* conformation **6b** predicts the opposite result. It is interesting to note that Berkowitz and coworkers have suggested (4, 27) the same model for alanine alkylation but they base their arguments on an extended enolate (**6a**) vs. a folded one (**6b**). The argument advanced in that case, based on the steric effect, relied on the interaction of a methyl substituent on the nucleophilic carbon (**6**, R = Me) with a hydrogen at C-1 of the auxiliary that destabilizes conformer **6b**. In our case, this interaction is missing, but the model still obtains. Further, Berkowitz finds the stereoselectivity to be much higher with 8-phenylmenthol than with **3a** as the auxiliary, a result that does not apply in our examples. In any event, the model is useful in a predictive sense but, in the absence of more



information, cannot be considered theoretically meaningful.

In contrast to the results reported for the alkylation of imine **1**, there appears to be no correlation of the stereoselectivity with the electron density in the aromatic ring. The substituent clearly has an effect but further work is required to define this. The dianionic form of the enolate is a major difference, which must be taken into consideration. Nevertheless, compared to the purely aliphatic substituents (menthol), the presence of a simple phenyl group enhances dramatically the stereochemical control and the naphthalenyl substituent appears to impart a level of control that, if general, may have some practical applications. We are currently investigating the effect of changing the electronic character of the alkylation agent in this system and will report these results in the near future.

Experimental

Unless otherwise noted, all ^{1}H NMR data were obtained at 300 MHz on Bruker AC300 or DPX300 instruments in $CDCl_3$; the ^{13}C NMR spectra were obtained on the same instruments at 75 MHz in the same solvent.

(±) *trans* 2-(4-Fluorophenyl)cyclohexanol (3b). Example of preparation of alcohols from the alkene

To 6.6 g (0.0375 mol) of 1-(4-fluorophenyl)cyclohexene (29, 30) in 50 mL THF was added 50 mL of borane–THF solution (1.0 M). The reaction was stirred for 1 h at ambient temperature, water was added very slowly via syringe until gas evolution ceased, and then 4 mL of 3 M NaOH solution was added. 30% Hydrogen peroxide (4 mL) was added slowly; the reaction was stirred for 1 h at ambient temperature, poured into water, and extracted with ether. The extracts were dried and evaporated to afford 7.06 g (97%) of **3b** (28) as a clear oil; ^{1}H NMR: 7.18 (dd, 2H, J = 5.7, 8.4 Hz), 6.99 (t, 2H, J = 8.7 Hz), 3.58 (m, 1H), 2.39 (t, 1H, J = 12.9 Hz), 2.25–0.8 (m, 9H); ^{13}C NMR: 161.7 (d, J = 242 Hz), 139.9, 129.2 (d, J = 9.5 Hz), 115.4 (d, J = 22 Hz), 74.4, 52.4, 34.6, 33.5, 26.0, 25.0; *m/z*: 194, 148, 135, 122, 109.

All alcohols were also prepared from copper-catalyzed reaction of the appropriately substituted phenylmagnesium halide with cyclohexene oxide using the method of Whitesell as modified by Basavaiah and Rao (24). The products were identical in every respect with those prepared from the alkenes.

In the same manner alcohols **3d** (28), **3e** (31), **3f** (28, 32, 33), and **3g** (28) were prepared.

(±) *trans* 2-Phenylcyclohexyl hippurate (4a). Example of preparation of hippurate esters

A mixture of 5.7 mmol of alcohol, 6 mmol of hippuric acid, and 0.5 mmol tosic acid was dissolved in 25 mL of toluene and refluxed for 12 h under a Dean–Stark water trap. After cooling to ambient temperature, 1 mL of saturated aqueous $NaHCO_3$ was added and the mixture was stirred vigorously for 5 min and transferred to a separatory funnel with the aid of 25 mL of ethyl acetate. The layers were separated and the aqueous layer extracted with 3 × 10 mL of EtOAc. The combined organic layers were washed successively with 5 mL of water and 5 mL of saturated brine, and dried over magnesium sulfate. Evaporation afforded the crude ester, which was recrystallized from

Preparation of authentic *trans* 2-phenylcyclohexyl *N*-benzoylphenylalaninate diastereomers (5a)

*(a) (1*R*,2*S*)-2-Phenylcyclohexyl* N*-benzoyl-(*S*)-phenylalaninate*
A mixture of 200 mg (1.13 mmol) of (–)-(1*R*,2*S*)-*trans*-2-phenylcyclohexanol (Aldrich), 350 mg (1.36 mmol) *N*-benzoyl-(*S*)-phenylalanine, and 25 mg of tosic acid was refluxed in 25 mL of benzene under a Dean–Stark water separator for 20 h. The solution was cooled to room temperature, treated with 2 mL of saturated aqueous $NaHCO_3$ solution with vigorous stirring, and diluted with 25 mL of EtOAc. The layers were separated; the organic layer was washed with water and brine, dried ($MgSO_4$), and evaporated to give 420 mg of crude ester. ^{1}H NMR indicated 76% de. The crude material was recrystallized from EtOAc at –15°C. The ^{1}H NMR of the product showed only the major diastereomer of **5a**; mp 158°C, $[\alpha]_D$ +24.4 (*c* 1.0, $CHCl_3$); ^{1}H NMR: 7.63–7.06 (m, 15H), 6.29 (d, 1H, J = 7.3 Hz), 4.98 (m, 1H), 4.72 (q, 1H, J = 6.0 Hz), 3.10 (d, ½ ABq, 1H, J = 13.8, 6.0 Hz), 3.00 (d, ½ABq, 1H, J = 13.8, 5.0 Hz), 2.70 (dt, 1H, J = 12.2, 3.2 Hz), 2.15 (m, 1H), 2.10–1.25 (m, 7H); ^{13}C NMR: 171.02, 166.87, 142.91, 136.45, 132.02, 129.94, 128.93, 128.81, 128.76, 127.79, 127.33, 127.07, 78.38, 53.81, 50.08, 37.83, 33.89, 32.55, 26.09, 25.14; HRMS, *m/z* calcd. for $C_{28}H_{29}NO_3$: 427.21474; found: 427.21388.

*(b) (1*R*,2*S*)-2-Phenylcyclohexyl* N*-benzoyl-(*R*)-phenylalaninate*
In exactly the same way as described above, but using *N*-benzoyl-(*R*)-phenylalanine, an authentic sample of the minor diastereomer obtained from the alkylation reaction was prepared; mp 155–157°C, $[\alpha]_D$ –30.0 (*c* 1.0, $CHCl_3$); ^{1}H NMR (500 MHz): 7.63–7.09 (m, 13H), 6.44 (d, 1H, J = 6.9 Hz), 6.29 (d, 1H, J = 7.3 Hz), 4.98 (m, 1H), 4.89 (m, 1H), 2.88 (d, ½ ABq, 1H, J = 14.3, 5.5 Hz), 2.55 (d, ½ABq, 1H, J = 14.3, 5.1 Hz), 2.78 (dt, 1H, J = 12.2, 3.6,Hz), 2.15 (m, 1H), 2.10–1.25 (m, 7H); ^{13}C NMR (125 MHz): 170.93, 166.76, 135.62, 134.17, 131.65, 129.44, 128.71, 128.57, 128.33, 127.86, 127.10, 127.00, 126.83, 78.57, 53.27, 49.73, 37.19, 33.84, 32.33, 25.79, 24.74; HRMS, *m/z* calcd. for $C_{28}H_{29}NO_3$: 427.21474; found: 427.21295.

Alkylation of hippurate esters 4: preparation of phenylalaninates 5

A solution of 120 µL (0.8 mmol) of diisopropylamine in 3 mL dry THF was cooled to 0°C under N_2. nBuLi (0.8 mmol, 2.32 M in hexanes) was added and the mixture was stirred at 0°C for 30 min. The solution was cooled to –78°C and 0.4 mmol of

© 1998 NRC Canada

hippurate **4** in 2 mL of THF was added slowly. A bright yellow color formed immediately that turned to dark orange. The solution was stirred for 90 min at –78°C and then 0.40 mmol of benzyl bromide in 2 mL of THF was added dropwise. After stirring for another 90 min at –78°C, the color reverted to light yellow; 1 mL of 3 M HCl was added and the solution was allowed to warm to room temperature while vigorous stirring was continued. The solution was diluted with 5 mL of ether, the layers were separated, and the aqueous layer was extracted with 3 × 5 mL of $CHCl_3$. The combined organic phases were dried ($MgSO_4$) and evaporated to afford the crude product. Purification without separation of the diastereomers was achieved by column chromatography on silica gel (3:1 petroleum ether:EtOAc). The chemical yields were in excess of 80%. The ratio of stereoisomers present was determined using ^{1}H NMR as described in the text. In all cases, except that of the naphthalenyl derivative **5f**, mixtures of diastereomers were obtained. In the case of **5f**, the product was obtained diastereomerically pure, mp 180–181°C; ^{1}H NMR: 8.13 (m, 1H), 7.75 (m, 1H), 7.70 (d, 1H, J = 7.2 Hz), 7.51–7.18 (m, 12H), 6.93 (m, 2H), 5.99 (d, 1H, J = 7.2 Hz), 5.21 (m, 1H), 4.50 (ABq, 1H, J = 7.3, 6.1 Hz), 3.66 (m, 1H), 2.87 (d, ½Abq, 1H, J = 6.0, 13.9 Hz), 2.55 (d, ½Abq, 1H, J = 8.0, 13.9 Hz), 2.26 (m, 1H), 2.15–1.25 (m, 7H); ^{13}C NMR:170.9, 166.8, 139.2, 136.4, 134.4, 134.3, 132.5, 131.9, 129.8, 129.5, 128.9, 128.7, 127.4, 127.2, 126.2, 126.1, 125.8, 123.4, 78.6, 53.8, 37.6, 34.0, 32.9, 26.4, 25.2; HRMS, *m/z* calcd. for $C_{32}H_{31}NO_3$: 477.23039; found: 477.23144.

Preparation and use of benzyl bromide-d_7

Toluene-d_8 was reacted with *N*-bromosuccinimide according to the method of Greenwood et al. (34). The solid was removed by filtration and the solvent removed under vacuum. The residue was used in the alkylation reaction as described above. The NMR of the product gave no indication of an absorption between δ 6.3 and 7.0 and the absorption at δ 4.72 was a clean doublet.

Acknowledgements

This work was supported by the Natural Sciences and Engineering Research Council of Canada through operating grants to J.M.M. and grants for the purchase of the NMR spectrometers. The assistance of M. Fuerth, V. Lazarescu, and H. Ganjavi in obtaining some of the data is gratefully acknowledged.

Rate enhancement of nickel(II) complexation in dilute anionic surfactant solutions

Catherine E. Drennan, Rachelle J. Hughes, Vincent C. Reinsborough, and Oladega O. Soriyan

Abstract: Kinetic studies through stopped-flow spectroscopy were undertaken in the dilute solution range of anionic surfactants where pronounced rate enhancement or inhibition of Ni^{2+}–ligand complexations is often observed at surfactant concentrations much below the critical micelle concentration (CMC). The results are interpreted in terms of Ni–surfactant micelles as the agents responsible for the rate changes in dilute surfactant solution. At higher surfactant concentrations these micelles are transformed into mixed micelles (counterion and size changes), eventually becoming normal surfactant micelles close to the CMC. Surface tension, dye solubility, conductivity, and fluorescent probe investigations support this interpretation.

Key words: micellar catalysis, sodium dodecyl sulfate, micelles, critical micelle concentration, premicelles, Ni^{2+}–ligand complexations.

Résumé : On a réalisé des études cinétiques par spectroscopie à flux stoppé sur des solutions diluées d'agents de surface anioniques, à des concentrations très inférieures à la concentration micellaire critique (CMC) auxquelles on observe souvent des effets importants d'accélération ou d'inhibition des vitesses de complexations Ni^{2+}–ligand. On interprète les résultats en fonction de micelles Ni – agent de surface qui agissent comme agents responsables pour les changements de vitesse en solutions diluées d'agent de surface. À des concentrations supérieures d'agent de surface, ces micelles se transforment en micelles mixtes (changements de contre-ion et de grosseur) qui deviennent éventuellement des micelles normales d'agent de surface lorsqu'on approche de la CMC. Les données relatives à la tension superficielle, la solubilité des colorants et la conductivité ainsi que les études à l'aide de sondes fluorescentes sont en accord avec cette interprétation.

Mots clés : catalyse micellaire, dodécylsulfate de sodium, micelles, concentration micellaire critique, prémicelle, complexations Ni^{2+}–ligand.

[Traduit par la rédaction]

Introduction

In surfactant solutions, anomalies in phyiscochemical properties occurring below the generally accepted value of the critical micelle concentration (CMC) are usually ascribed to premicellar aggregates. The latter are thought to adopt various forms, e.g., surfactant dimers (1), oligomers (2), dye surfactant enwrapments (3, 4), surfactant clusters centered by a metal ion (5), substrate–surfactant complexes (6), depending upon the solutes accompanying the surfactant in solution. Since the characterization of the aggregates is not an easy problem, and is usually peripheral to the main thrust of the surfactant investigation at hand, little effort has been made to investigate the phenomenon more generally. We report here on a surfactant solution situation where premicellar aggregation has been speculated: supposedly micelle-mediated rate changes of a probe reaction commencing well below the reported CMC of the surfactant. In an effort to understand surfactant catalysis more completely, we set out to uncover the solution aggregates promoting rate enhancement below the CMC in these systems. A critical look at the situation leads us to discount premicelles as the responsible species.

In our kinetic studies over the past two decades, in which the complexation of $Ni^{2+}_{(aq)}$ with the neutral bidentate ligand pyridine-2-azo-*p*-dimethylaniline (PADA) has been commonly used as a probe reaction in anionic surfactant solutions to test for micellar catalysis, rate enhancements were noted at surfactant concentrations well below the literature values of the CMC (7, 8). A model that has enjoyed considerable success in the post-CMC region ascribes the rate promotion to the favourable partitioning from bulk solution of both reactants into or onto the anionic micelles. Micelles of constant size and composition are critical to the discussion. This modelling has been so refined that variations in parameters can confidently be attributed to changes in the structure of the underlying micelle (9). Early work with this particular catalysis effect noted that it commenced in the premicellar range and speculated that the aggregates below the CMC were probably complexes consisting of a few surfactant molecules and a solubilized PADA molecule (10). There have been no further attempts to characterize these premicellar complexes. The focus of all studies undertaken in this system has been the concentration range well above the CMC where the micelles are

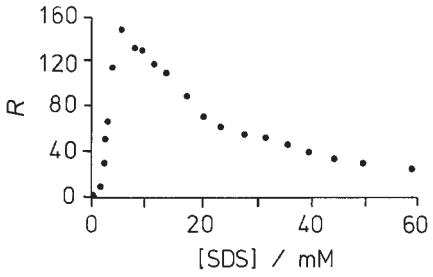
Fig. 1. Rate enhancements (R) of Ni^{2+}–PADA complexation in SDS solutions with 0.50 mM Ni^{2+}.



presumably better behaved and premicellar aggregates do not exist.

It is somewhat intriguing and, at the same time, disconcerting that the successful model does not allow for any premicellar activity. Yet, the maximum rate enhancement is usually attained in the vicinity of the literature value of the CMC. In a similar reactive situation, in the electron transfer between substituted and unsubstituted Fe^{2+} and Fe^{3+}, Pelizzetti and Pramauro (11) observed that in sodium dodecyl sulfate solutions the rate increase phenomenon was almost entirely confined to the pre-CMC concentration region as defined by the reported value of the CMC for that surfactant. Ionic additives normally depress the CMC but not to the extent that has been noted in these studies. The aim of the present study was to identify, if possible, the solution aggregates responsible for the dilute solution or pre-CMC rate enhancements observed in metal ion complexations in anionic surfactant solutions and to relate these to the micelles that are present in more concentrated solutions.

The kinetics of the formation of the Ni^{2+}–murexide complex was also investigated as a complementary study to the Ni^{2+}–PADA complexation reaction. In contrast to the neutral PADA molecule, the murexide ion is negatively charged in the pH region studied and thus the formation of anionic micelles inhibits rather than promotes Ni^{2+}–murexide complexation. The positively charged metal ions are attracted to the micelles whereas the negatively charged ligands remain predominantly in solution. This means that the CMC should be revealed by a sudden decrease in the observed rate coefficient for the murexide complexation.

Sodium and nickel dodecyl sulfates were the chief surfactants used but other anionic and cationic surfactants were also investigated in solution to provide corroborative evidence and further insight. Conductivity, dye solubility, dye fluorescence, and surface tension measurements furnished independent assessments of the CMC values.

Experimental

The stopped-flow technique as described previously (7, 12) was used to obtain rate coefficients for the Ni^{2+}–PADA and Ni^{2+}–murexide complexation reactions. Pseudo-first-order conditions (the metal ion was typically millimolar in concentration while the ligand was 10^{-5} M) pertained at 25.0°C for the formation of the Ni^{2+}–PADA and the Ni^{2+}–murexide complexes at pH 8.0 and pH 4.5 (no buffers), respectively.

Independent measurements of the CMC were obtained directly from solution conductivities and surface tensions and, indirectly, from fluorescence spectroscopy. The latter technique used the fluorophore, trisbipyridyl Ru^{2+} ion, which fluoresces more intensely in a micellar environment than in water. The CMC was taken to be the break in the fluorescence vs. surfactant concentration curve but, because the fluorophore itself may be involved in the micellization process (3), the results were not given the same weight as the other two methods. Conductivity measurements were obtained with a Radiometer CDM83 bridge with the solutions thermostatted at 25.0°C. Plots of specific conductivity against surfactant concentration were used to determine the CMC as the intersection of the straight-line portions of the curve. A du Nouy tensiometer was used to detect the CMC by the break in the surface tension vs. log[surfactant] curve.

All chemicals were the best available commercially and were not further treated. The purity of the sodium dodecyl sulfate used in the surface tension measurements was >99% and deemed acceptable as it showed only a small minimium in the solution surface tension (<1 dyne cm^{-1}). Nickel dodecyl sulfate ($Ni(DS)_2$) was prepared by crystallization from aqueous solution containing SDS and a slight stoichiometric excess of $NiCl_2$. Recrystallizations were effected in aqueous ethanol and deionized water. Analysis by Desert Analytics (Tucson, Arizona) showed that the pale green crystals contained 8.80% Ni (9.96% expected), 8.79% H (8.55% expected), 0.02% Na, and less than 0.05% Cl. Water of crystallization had likely been incorporated into the solid $Ni(DS)_2$, which could account for the low Ni and high H contents. The important point is that this ion replacement process had eliminated Na as a possible counterion in aqueous solutions of the prepared $Ni(DS)_2$.

Results and discussion

For the Ni^{2+}–PADA reaction in dilute sodium dodecyl sulfate (SDS) solutions, the observed rate coefficient (k_{obs}) did not change from the no-SDS-in-solution value ($k°_{obs}$) until a specific SDS concentration was reached. Beyond this concentration, k_{obs} rose sharply to a maximum followed by a more gradual decrease with increasing SDS concentration to kinetic values approaching $k°_{obs}$. With $[Ni^{2+}] = 0.50$ mM, the maximum in k_{obs} was approximately 160 times the $k°_{obs}$ value (cf. Fig. 1 where R is the ratio of k_{obs} to $k°_{obs}$). The initial point of departure of the k_{obs} value from the $k°_{obs}$ or the "specific SDS concentration" alluded to above should be where micelles first form in solution, i.e., it should locate the critical micelle concentration or CMC of SDS. However, these apparent CMC values or ACMCs are found in the 1–4 mM SDS range whereas the CMC of SDS is well known to be 8.1 mM at 25.0°C (13).

Figure 2 reveals that the ACMC for SDS is markedly dependent on the Ni^{2+} ion concentration used in the complexation reaction. One possibility that this Ni^{2+} dependence suggests is that an Atherton–Dymond type of cluster consisting of a Ni^{2+} ion surrounded by a number of surfactant monomers (5) is formed at the ACMC and provides the preferred reaction site for the complexation. The PADA molecule may also be attracted hydrophobically or by some other mechanism to the cluster, resulting in the complexation rate being promoted below the CMC. For SDS concentrations greater than the CMC, these clusters will presumably be less stable than SDS micelles and "micellar" catalysis can then properly be

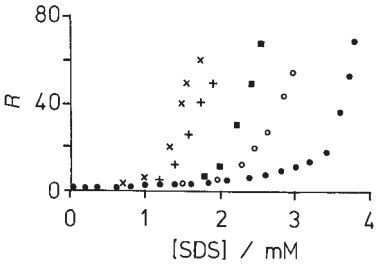

Fig. 3. Surface tension (ST) of SDS solutions containing 1.00 mM Ni^{2+}.

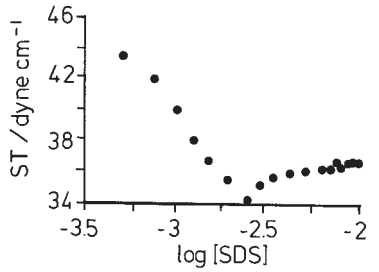

said to occur. The argument against premicellar clusters of this type is that there are no obvious discontinuities in solution properties where clusters may be said to have become micelles and, in the surfactant concentration from the ACMC to the CMC, solution characteristics are those typical of micellar behaviour. A demonstration of the latter is the surface tension of Ni^{2+} ion doped solutions of SDS where the ACMC is indicated by the beginning of the plateau in the surface tension vs. log[SDS] curve in standard micellar fashion (Fig. 3). Clusters of the type described above would not depress the surface tension as radically and, moreover, in yielding to micelles in more concentrated solutions, should cause the surface tension to experience a further decrease instead of the observed constancy in value.

But what type of micelle could be present in these Ni^{2+} ion doped, dilute surfactant solutions? Normal SDS micelles would not be expected to be present at concentrations almost an order of magnitude less than the CMC for SDS. From the observation that the ACMC is influenced by the amount of Ni^{2+} in solution, the formation of Ni dodecyl sulfate or $Ni(DS)_2$ micelles at the apparent CMC is a possibility. The literature value for the CMC of $Ni(DS)_2$ at 30°C is 1.2 mM $Ni(DS)_2$ (14) and, at the highest concentrations of Ni^{2+} used, the ACMC is approaching this value (Fig. 2). Since this evaluation was important to the argument, the CMC of $Ni(DS)_2$ was redetermined from surface tension and conductivity data (Fig. 4) and found to agree with the literature value. Thus, it is conceivable that, in a 2 mM SDS solution containing 1 mM Ni^{2+}, $Ni(DS)_2$ micelles may initially be formed. On further addition of SDS, a mixed micelle will appear, with the Ni^{2+} ions being eventually displaced by Na^+ ions as counterions. When the CMC for SDS is achieved, Na^+ ions are about 10 times more numerous in solution than Ni^{2+} ions in 1 mM Ni^{2+} and the micelles are essentially SDS micelles, with a smooth transition having

occurred from almost pure $Ni(DS)_2$ micelles to almost pure SDS micelles.

Kinetic studies were conducted in several anionic surfactant systems to test the universality of the dependence of the ACMC on Ni^{2+} concentration. For shorter chained alkyl sulfates than SDS, the catalytic effect was less pronounced but again an apparent CMC appeared and its dependence on the Ni^{2+} concentration consistently occurred. Figure 5 displays the kinetic data for the Ni^{2+}–PADA reaction in sodium octyl sulfate (SOS) at various Ni^{2+} concentrations. Figure 6 shows that fluorocarbon anionic surfactants such as sodium perfluorooctanoate (SPFO) exhibit similar kinetic behaviour towards Ni^{2+} when it is a constituent of the solution background. The CMC value for SOS at 25.0°C is 0.12 M (13, 15) but ACMC values were as low as 0.02 M SOS. Similarly, SPFO has a CMC of 25 mM (16, 17), which is much higher than the first appearance of catalytic activity in this system. The tendency of increasing [Ni^{2+}] bringing about a decrease in the apparent CMC appears to be independent of the length or nature of the tail of the anionic surfactant. Once again, Ni^{2+} ion is implicated

Fig. 7. Rate coefficients (k_{obs}) of Ni^{2+}–PADA complexation in dodecyltrimethylammonium bromide (DTAB) solutions.

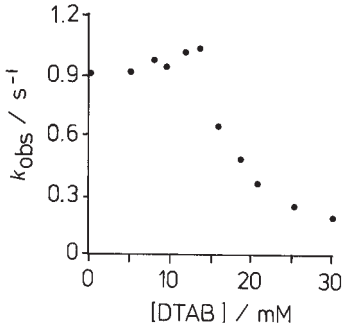

Fig. 8. Rate coeficients (k_{obs}) for Ni^{2+}–murexide complexation in SDS solutions at various Ni^{2+} concentrations: ■, 0.30 mM Ni^{2+}; □, 0.50 mM Ni^{2+}; ●, 1.00 mM Ni^{2+}; ○, 2.00 mM Ni2+.

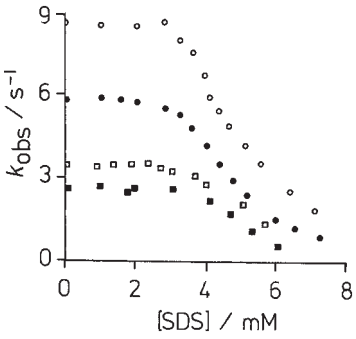

as playing a major role in the solution aggregate responsible for the rate enhancements.

Another way to confirm the essential role of the Ni^{2+} ion in this phenomenon is to carry out the Ni^{2+}–PADA reaction in the presence of a cationic surfactant such as dodecyltrimethylammonium chloride or DTAB. Micellar inhibition occurs because only PADA and not Ni^{2+} ion is preferentially partitioned into the positively charged micelle. As a result, k_{obs}values do not change until the CMC is reached on DTAB addition and above this concentration they decrease (Fig. 7). As opposed to the kinetic studies in anionic surfactant micellar systems reported above, no anomalous lowering of the CMC (15 mM DTAB (13)) was detected for any background Ni^{2+} concentrations. This supports the contention that Ni^{2+} and not PADA is essential to the composition of the solution aggregate that gives rise to the CMC decreases noted in anionic surfactant systems.

Still another variation on the Ni^{2+} complexation theme is available and that is to change the ligand from neutral PADA to a negatively charged species such as murexide ion, and to return to SDS solutions to observe complex formation (Fig. 8). Now the roles of the reactants, Ni^{2+} and ligand, are switched as it is the latter rather than the former that remains in solution at SDS concentrations greater than the CMC. The end result (Fig. 8) is a curve similar to Fig. 7 except that the breakpoint is lower than the reported CMC and is dependent upon the Ni^{2+} concentration in similar fashion to the ACMC values for the Ni^{2+}–PADA complexation reaction. The similarity of the breakpoints or ACMC values for the two Ni^{2+} complexations

[a] Second breakpoint.

is remarkable given the opposite directions in which the kinetic rates are affected in SDS solutions. This implies that the same solution species is responsible for the departure from normality in both reactive systems despite the use of two different ligands, i.e., the ligand is not incorporated into the "premicellar" aggregate. Reinforcing this conclusion is that a Ni^{2+}-containing solution aggregate into which the neutral PADA molecule and the negatively charged murexide ion are indiscriminately included is problematic. The dependence of ACMC upon [Ni^{2+}] reiterates that Ni^{2+} is an important constituent of the responsible solution aggregate.

Corroborative evidence that the ligand does not play a major role, if any, in the solution aggregation process is found in the relationship between PADA solubility and SDS concentration (Fig. 9). The breakpoint in the solubility curve corresponds approximately to the literature value of the CMC for SDS (Table 1; dye solubility and fluorophore detection methods for the CMC are approximate because the "foreign" probes must impact upon the micellization process at the probe concentrations used). The lack of anomalous behaviour in the PADA solubility data close to the CMC implies that the ligand is not associating with the surfactant except in micelle solubilization.

That the CMC in ionic surfactant solutions is depressed by salts is well known. A concomitant observation is that the micellar size also increases with increasing salt background. The reason commonly given for this is that the ionic atmosphere lessens the repulsion between the polar head groups, allowing the hydrophobic attraction between the surfactant tails to dominate at an earlier surfactant concentration and resulting in "premature" micelle formation (18). Although in this picture there are no premicellar aggregates but only micelles that form at the ACMC, the micelle structure is unspecified and the implication is that the extra ions are essentially

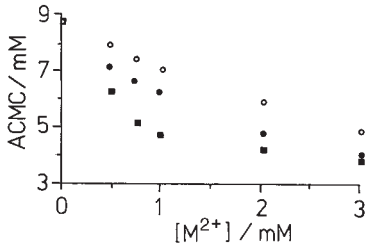
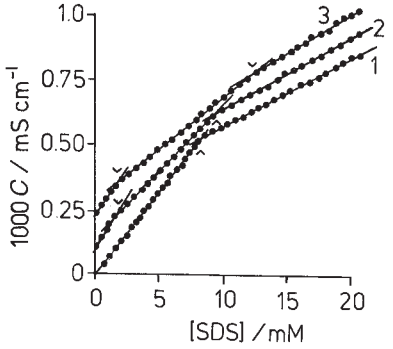
Fig. 10. ACMC values for SDS in divalent metal nitrate solutions determined with a fluorescent probe: ○, Zn^{2+}; ●, Mn^{2+}; ■, Ni^{2+}.



spectators to the micelle formation process. Values of the ACMC for SDS in various salt backgrounds were determined by conventional methods to ascertain whether they corresponded to the breakpoints seen kinetically in the present study. Spectrofluorometrically determined CMC values in SDS solutions with $Ni(NO_3)_2$ as additive decreased with increasing $[Ni^{2+}]$ (Fig. 10) but not to the same extent as indicated by the onset of catalytic activity for the Ni^{2+}–PADA reaction (Fig. 2 and Table 1). Parenthetically, other divalent ions such as Zn^{2+} and Mn^{2+} were found to be less effective than Ni^{2+} ion in lowering the CMC, which suggests an ion specificity not considered in the usual explanation for CMC lowering through electrolyte addition. On the other hand, because the fluorescence technique is an indirect method (see Experimental) and, as explained above, "interferes" with the micelle formation process, these results can be given only qualitative significance. Oftentimes, dyes such as the trisbipyridyl probe are directly involved in premicellar association (3, 4). The PADA solubility method of detecting the CMC can be faulted on similar grounds and the slightly low value of the CMC for SDS as determined from Fig. 9 is likely a result of some interaction between SDS and PADA.

CMC determinations can be made more confidently through the direct methods of surface tension and conductivity. The CMC determinations from the breaks in the surface tension plots in Ni^{2+}-doped SDS solutions agree with the catalytic activity results although the minimum in the surface tension plot normally seen when surface-active additives and impurities are present tends to blur the exact location of the CMC (Fig. 3). The dependence of the solution conductivity on surfactant concentration is often used to obtain micellar parameters in an experimentally and theoretically straightforward manner (19). The CMC is revealed as the intersection of two straight lines. In Ni^{2+}-doped SDS solution systems, since the Ni^{2+} ion contributes much more to solution conductivity than does the SDS ion, the background Ni^{2+} ion concentration must be kept low (less than 2 mM Ni^{2+}) to detect any appreciable conductivity change on micellization. When this is done, two breaks in the conductivity curve are discernible and they consistently occur with linear portions between them (Fig. 11). The first point of intersection decreases with increasing Ni^{2+} ion concentration while the second one approximates the expected CMC value for SDS and increases slightly with Ni^{2+} concentration (Fig. 11 and Table 1). The reasonable agreement between the first conductivity breakpoints and the SDS concentrations at which micellar catalysis begins in earnest in the Ni^{2+}–PADA reaction suggests that the same phenomenon is responsible. Thus, the conclusion drawn from the CMC lowerings of Table 1 is that the fluorescence, conductivity, surface

Fig. 11. Specific conductivity (*C*) of SDS solutions for three representative Ni^{2+} backgrounds: curve 1, in 0.00 mM Ni^{2+}; curve 2, in 0.50 mM Ni^{2+}; curve 3, in 1.00 mM Ni^{2+}. Carets indicate the breakpoints. Data for 0.30 mM Ni^{2+} omitted for clarity (cf. Table 1).



tension, and the two kinetic techniques are sensing the same associative process at the ACMC but the first-mentioned method is susceptible to more error.

Conclusion

With this agreement in ACMC values among the different techniques and the kinetic findings, the conclusion is that micelles with Ni^{2+} as the predominant counterion form at the ACMC. These micelles are probably twice the size of the "normal" micelles of the system. Magnesium dodecyl sulfate micelles are known to be roughly twice the size of SDS micelles (20). As the surfactant concentration is increased beyond the ACMC, the surfactant cation gradually replaces Ni^{2+} ion as the micellar counterion to form mixed micelles. This micelle transformation is essentially completed in the vicinity of the CMC value of the pure surfactant and is signalled by a change in slope of the conductivity curve (Fig. 11). The conversion from mixed to normal micelles is raised to greater surfactant concentrations for greater Ni^{2+} backgrounds. Corkill and Goodman (21), from conductivity measurements, have postulated similar mixed micelles for the $Ca(DS)_2$ + SDS system.

Carlsson et al. (22) have pointed out that the competition between divalent counterions with monovalent counterions in the micellar situation can have far-reaching effects. These considerations must be borne in mind when modelling the kinetic behaviour of probe reactions in the mixed micelle region, which, as this study suggests, exists between the ACMC and the CMC. Only beyond this latter surfactant concentration can micelles totally characteristic of the surfactant be expected to exist. This explains in part why the micellar catalysis modelling of this portion of the surfactant concentration range has been successful. Experimentalists have simply avoided this region and worked in the range of 1.5 to 5 times the CMC where it can reasonably be assumed that the micelles are more representative of the surfactant and are constant in size.

It remains to be seen whether this explanation is more widely applicable to surfactant systems containing ions other than Ni^{2+}. The widely different ACMCs for Ni^{2+} as compared with those for other divalent ions suggests that this may be the case (Fig. 10); i.e., more than just the charge on the added ion

must be taken into account. Mixed micelle theory should be of assistance here in clarifying the picture.

Pressure-tuning infrared and Raman spectroscopic study of (2,2′-bipyridine)tetracarbonylchromium(0)

Steven M. Barnett, Anton n Vlček, Jr., and Ian S. Butler

Abstract: Pressure-tuning infrared and Raman spectroscopic studies were performed on (2,2′-bipyridine)tetracarbonylchromium(0), $Cr(CO)_4(bpy)$. Previous bpy ring mode assignments were confirmed with new assignments offered by examination of the pressure-induced alterations in the vibrational spectra. The electron-density distribution of the bipyridyl ligand (and consequently, the electron-donating ability to the central metal) is modulated by the application of pressure. The pressure dependence of the carbonyl moieties reveals that the bipyridyl ligand can accommodate a significant portion of the molecular compressibility at higher pressures.

Key words: infrared, Raman, pressure, $Cr(CO)_4(bpy)$, metal carbonyl.

Résumé : On a réalisé des études spectroscopiques, Raman et infrarouge sous pression, sur le (2,2′-bipyridine)chrome(0)-tétracarbonyle, $Cr(CO)_4(bpy)$. On a ainsi pu confirmer les attributions antérieures faites à l'aide du bpy en utilisant les nouvelles possibilités d'attribution offertes par l'étude des déformations induites sous pression dans les spectres de vibration. La distribution de la densité électronique du ligand bipyridyle (et conséquemment la capacité du centre métallique à donner des électrons) est modulée par l'application de la pression. L'effet de la pression sur les unités carbonyles révèle que le ligand bipyridyle joue un rôle important dans la compressibilité moléculaire à des pressions plus élevées.

Mots clés : infrarouge, Raman, pression, $Cr(CO)_4(bpy)$, carbonyle metallique.

[Traduit par la rédaction]

Introduction

The photochemical, electrochemical, and physical properties of species with the general structure $M(CO)_4(bpy)$ (M = Cr, Mo, W; bpy = 2,2′-bipyridine) have been extensively studied (1–16). The weak luminescence observed on photoexcitation of $M(CO)_4(bpy)$ (M = Cr, Mo, W) complexes (17) has been explained by an energetically low metal-to-ligand change-transfer (MLCT) excited state. The presence of a low-lying unoccupied π^* orbital on the bpy ligand permits the reduction of $Cr(CO)_4(bpy)$ without loss of a carbonyl (18, 19). Recent studies have described the energy and character of the lowest MLCT transition (20, 21) as well as the mechanism for ^{1}MLCT and ^{3}MLCT relaxation to the ground state and for CO photodissociation (22).

Pressure-tuning spectroscopic studies can be extremely powerful in elucidating structural features of complicated organic and organometallic systems (23–27). While pressure-tuning infrared spectroscopic studies using diamond anvil cells (DAC) are relatively simple with the increased speed and sensitivity of Fourier transform (FT) spectrometers and the use of infrared microscopes which greatly facilitate sample alignment, information on the structural changes characterized by low-frequency vibrations (such as metal–ligand vibrations) cannot be studied (28, 29). Furthermore, the strong diamond absorbance of the DAC in the 2400–1800 cm^{-1} region does not permit the direct observation of many functional groups such as metal carbonyls, nitriles, and alkynes. Pressure-tuning Raman spectroscopic studies provide information on these excluded regions of the infrared spectra. However, weak features cannot be observed in conventional pressure-tuning Raman experiments using visible laser excitation due to the intense fluorescent background of the type IIA diamonds in the DAC, as well as decomposition and fluorescence observed in many organometallic complexes, resulting in poor spectra and spectral artifacts which may be difficult to interpret.

For organic molecules, an increase in the energy of most vibrational modes is observed with increasing pressure (i.e., a positive pressure dependence) accompanied by a decrease in the interatomic distances. However, in metal carbonyls, the application of pressure increases the π-backbonding between the central metal atom and the carbonyl ligands, which forces

more electron density into the CO π^* orbitals, leading to decreased (30) or negative (31) pressure dependences for many carbonyl ligands in organometallic complexes, especially with an electron-donating ligand bound to the metal atom.

Spectroscopic studies of bipyridine and organometallic complexes containing bipyridyl ligands have been performed using infrared (32, 33), Raman (34, 35), and resonance Raman (36–38) spectroscopies as well as studies incorporating the effect of pressure in conjunction with these techniques (39–43) and with surface enhanced Raman spectroscopy (SERS) (44). Normal mode analyses for the assignment of vibrationally active bands have been performed on free 2,2′-bipyridine (45, 46), and a normal coordinate analysis (NCA) has been performed on tris(bipyridine)ruthenium(II) (47). The study of complexes such as $Cr(CO)_4$(bpy) and $W(CO)_4$(phen) provide an excellent opportunity to evaluate the electronic structure of bipyridyl ligand binding in organometallic systems (20, 48).

In an attempt to combine the large spectral range available in pressure-tuning Raman spectroscopic studies with the lack of sample decomposition using near-infrared excitation, the pressure-tuning Raman experiment was recently adapted to a FT–Raman spectrometer using near-IR (1064 nm) laser illumination (49, 50). In this work, pressure-tuning infrared and Raman spectroscopic studies were performed on $Cr(CO)_4$(bpy) to investigate the bonding and electronic structure of organometallic complexes containing bipyridyl ligands.

Experimental

Materials

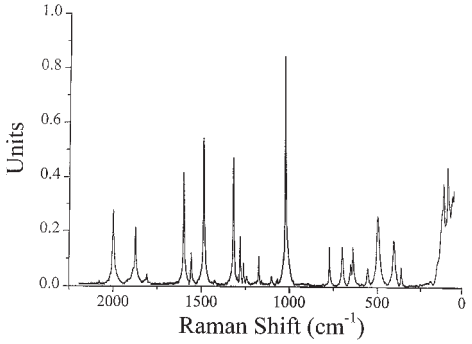
(2,2′-Bipyridine)tetracarbonylchromium(0), $Cr(CO)_4$(bpy), was synthesized, as described previously (22), by refluxing a toluene solution containing $Cr(CO)_6$ and bipyridine (1:1 molar ratio) for 2 h under an Ar atmosphere. The crude product precipitated after cooling was purified by crystallization from a CH_2Cl_2–isooctane mixture after most of the CH_2Cl_2 was distilled off. The purity was verified by infrared and UV-vis absorption spectroscopy.

Instrumentation

Infrared and Raman spectroscopy

Infrared spectra were obtained at 1 cm^{-1} resolution on a Bruker IFS-48 spectrometer equipped with an A-590 infrared microscope, a Sony color video system, and a mercury cadmium telluride (MCT) detector cooled by liquid N_2. Near-IR FT–Raman measurements were obtained at 2 cm^{-1} resolution on a Bruker IFS-88 spectrometer equipped with a Bruker FRA-106 Raman attachment coupled to a Nikon Optiphot-2 microscope by two 1.0 m fiber-optic cables. Sample illumination and collection of the scattered light were performed through a Nikon 20X objective with a working distance of 10 cm. The typical laser power was 100 mW from a Nd:YAG laser operating at 1064.1 nm. Rejection of the intense Raman scattering of diamond from the DAC was performed by placing a holographic notch filter between the DAC and the interferometer in the optical train. The filter had its maximum rejection at 1240.0 nm which corresponds to a 1332 cm^{-1} shift from the 1064.1 nm wavelength of the Nd:YAG laser.

Fig. 1. Near-infrared FT–Raman spectrum from 2200 to 50 cm^{-1} of $Cr(CO)_4$(bpy) in the solid state (spectrum ratio based on the instrument response function).



Diamond anvil cell (DAC)

The DAC for pressure-tuning infrared and Raman spectroscopic measurements was obtained from High-Pressure Diamond Optics (Tucson, Ariz.) A 300-mm hole drilled in the center of a stainless-steel gasket 370 mm in thickness was used to hold the sample between the parallel faces of two type IIA diamonds. Infrared and Raman spectra were obtained up to 25 kbar with pressure calibration performed by the sodium nitrate method. The shift in frequency of the intense, antisymmetric stretching mode of the NO_3– anion at 1401.3 cm^{-1} was used to calibrate the pressure according to the equation (51):

$$P = 1.775\Delta\nu - (0.795\Delta\nu e^{-\Delta\nu/78})$$

where $\Delta\nu$ is the difference (in wave numbers) between the peak position at pressure P (in kbar) and at atmospheric pressure.

Results and discussion

The near-IR FT–Raman spectrum of $Cr(CO)_4$(bpy) is shown in Fig. 1. The frequency of each vibrationally active feature was obtained by constructing a plot relating the frequency of the vibrational mode as a function of pressure and subsequently calculating the frequency at 1 bar (atmospheric pressure) (1 bar = 100 kPa). The pressure dependences ($d\nu\, dP^{-1}$) of the infrared and Raman active modes in $Cr(CO)_4$(bpy) are listed in Table 1 with comments that describe the atomic motions constituting the potential energy distribution (PED) from the NCA of $[Ru(bpy)_3]^{3+}$, listed in descending order of their contribution (47). For example, the infrared and Raman active vibrations at ~1071 cm^{-1} are composed of ν(CC), δ(CCH), and ν(CN) atomic motions in decreasing order of importance.

Vibrational assignments

Most of the assignments in Table 1 for the bpy ligand are based on the NCA (47) analysis of $[Ru(bpy)_3]^{3+}$, since most bipyridyl ring modes should not appreciably change in frequency for $Cr(CO)_4$(bpy). Vibrational modes involving the central metal could show a change in frequency arising from a decrease in the mass of the metal (which would increase the frequency relative to $[Ru(bpy)_3]^{3+}$) as well as changes in both the metal–bpy force constant and in the PED for that mode (which could increase or decrease the observed frequency).

Bipyridyl ring modes

The bipyridyl ring modes observed in $Cr(CO)_4$(bpy) correlate well with those observed in previous works and in the NCA analysis of $[Ru(bpy)_3]^{3+}$. Some modes with a metal–nitrogen stretching or bending component in their PED did shift in frequency but, in general, there is excellent correlation between the frequencies observed here and in previous investigations.

The low pressure sensitivities (0.05–0.18 cm^{-1} $kbar^{-1}$) of the infrared spectroscopic features between 700 and 1000 cm^{-1} (i.e., 995, 965, 887, 808, 761, and 735 cm^{-1}) verify the γ(CH) mode assignment made from experiments on $[Ru(bpy)_3]^{3+}$ (47). The frequency of these γ(CH) modes also correlates well with pressure-insensitive bands observed in the Raman spectra of other systems containing bipyridyl ligands, and their weak Raman activity is typical for C–H bending modes. The feature at 1045 cm^{-1} in the infrared spectrum was not assigned in the $[Ru(bpy)_3]^{3+}$ study (47), but the low pressure dependence (0.17 cm^{-1} $kbar^{-1}$) confirms the assignment of a C–H bend for $Eu(bpy)_2Cl_3$, as proposed by Bayer and Ferraro (39). The low pressure sensitivity (0.13 cm^{-1} $kbar^{-1}$) of the band assigned to ν_{31} (1201 cm^{-1} in the infrared), which was predicted at 1185 cm^{-1} in NCA calculations (47), corresponds well with a δ(CCH) mode in the bipyridyl ring. It has previously been observed between 1227 and 1210 cm^{-1} in studies on $Pd(bpy)Cl_2$ (32), $Ni(py)_4Cl_2$ (py = pyridine) (43), and $[Ru(bpy)_3]^{3+}$ (47).

The infrared-active arene mode assigned to ν_{15} (1020 cm^{-1}) corresponds with a prominent 1020 cm^{-1} resonance Raman band[1] and was calculated to appear at 1036 cm^{-1} in $[Ru(bpy)_3]^{3+}$ (47). This feature has a pressure dependence of 0.40 cm^{-1} $kbar^{-1}$ and corresponds well with features observed in the spectra of complexes containing bipyridyl ligands bound to Eu, Ni, and Co (39); with the pressure dependence of this mode exhibited by pyridine coordinated to Zn and Ni (0.43 cm^{-1} $kbar^{-1}$) (43), and with the pressure dependence exhibited in the SERS spectrum of pyridine on silver (0.30 cm^{-1} $kbar^{-1}$) (44).

The feature at 1066 cm^{-1} has been observed in other organometallic complexes containing bipyridyl ligands (32) and has an extremely high pressure dependence (0.80 cm^{-1} $kbar^{-1}$). Large shifts in the frequency of vibrational features with pressure, such as for the 1066 cm^{-1} feature, are typically observed in inorganic systems or as overtones and combinations of organic vibrational modes. It has tentatively been assigned to a combination of two or more modes since no mode involving metal–ligand vibrations would be expected to appear at this frequency in $Cr(CO)_4$(bpy). The most likely assignment for this band is a combination of the ν_{36} and ν_{38} modes. The ν_{38} mode, comprised of ring twisting motions, is calculated to be near 460 cm^{-1} in $[Ru(bpy)_3]^{3+}$ (47). However, it has not been observed in this study and the fundamental probably has very weak Raman activity. This combination is likely responsible for the 1060 cm^{-1} feature, since the PED of both the ν_{36} and ν_{38} features is comprised of approximately 50% bipyridyl ring twisting motion.

Pressure dependence of modes involving Cr–N vibrations

The vibrations modes which include Cr–N stretching or bending provide insight into the metal–ligand binding in $Cr(CO)_4$(bpy). While some similarities would be expected from previous studies on $[Ru(bpy)_3]^{3+}$, many of these modes are difficult to assign, since the ligands and central metal atoms are different, leading to different PEDs and vibrational frequencies for the normal modes.

The feature at 637 cm^{-1} is assigned to ν_{17} which consists of bipyridyl ring twisting and Ru–N stretching motions in $[Ru(bpy)_3]^{3+}$; its behavior under pressure (~0.29 cm^{-1} $kbar^{-1}$) reflects the metal–ligand stretching components more than the α(CCC) component, providing further evidence for the small contribution from ν(Cr–CO) or δ(CrCO) motions attributed in resonance Raman studies of ^{13}C-labeled $Cr(CO)_4$(bpy) (ref.). This mode is sensitive to the presence of the central metal, since it shifted 40–50 cm^{-1} up in frequency (compared with free pyridine) and was insensitive to pressure on binding to Zn (43). In pressure-tuning studies of $Eu(bpy)_2Cl_3$, this mode absorbed at 710 cm^{-1} with a pressure sensitivity of 0.2 cm^{-1} $kbar^{-1}$ (39). However, the pressure sensitivity of ν_{17} here (0.35–0.40 cm^{-1} $kbar^{-1}$) indicates that in $Cr(CO)_4$(bpy) the PED has a higher degree of ν(M–N) component than in $[Ru(bpy)_3]^{3+}$ or $Eu(bpy)_2Cl_2$, revealing that the bipyridyl electronic structure is sensitive to the size of the metal.

Pressure dependence of carbonyl stretching and bending modes

There are four C–O stretching modes of $Cr(CO)_4$(bpy) with symmetry b_2, a_1, b_1, and a_1 in increasing energy (11, 52). Two of these features have been assigned to the asymmetric vibrations involving the carbonyls *trans* and *cis* to bipyridine (i.e., $\nu_{as}(CO)^{trans}$ and $\nu_{as}(CO)^{cis}$) (30, 53). The bipyridyl ligand is a four-electron donor which increases the electron density at the metal and the π-backbonding to the carbonyl ligands, lowering the ν(CO) frequencies in the *trans* carbonyls relative to the *cis* carbonyls, as shown in Table 1. There is strong mixing of the two symmetric ν(CO) bands which do not permit the carbonyls to be distinguished as purely *cis* or *trans*.[4]

[4] A. Vlček, Jr., F.-W. Grevels, T.L. Snoeck, and D.J. Stufkens. Unpublished data.

© 1998 NRC Canada

In a previous pressure-tuning infrared spectroscopic study of *cis*-$Cr(CO)_4(CNBut\text{-}t)_2$ (30), two ν(Cr–CO) bands were assigned at 409 and 490 cm^{-1}. However, the low pressure dependence of the $Cr(CO)_4(bpy)$ feature at 496 cm^{-1} (0.04 $cm^{-1}\,kbar^{-1}$) excludes any prominent metal–ligand stretching component; this feature has recently been assigned to a δ(CrCO) mode in resonance Raman studies of ^{13}C-labeled $Cr(CO)_4(bpy)$ (ref.). For $Cr(CO)_4(bpy)$, the two ν(Cr–CO) modes are assigned to the bands at 407 and 555 cm^{-1} in the Raman spectra (assigned from the pressure dependences of these two modes).

Electronic structure of organometallic complexes containing bipyridyl ligands

In using the metal carbonyl vibrational modes as probes of bipyridyl electronic structure, the results presented in this study provide an interesting examination of metal–ligand binding in organometallic complexes containing bipyridyl ligands. The presence of bpy affects the frequencies of the ν(CO) and ν(Cr–CO) modes for the *trans* carbonyls, as would be expected by the donation of electron density from the bipyridyl ligand to the metal center, resulting in a decrease in the frequency of the $\nu(CO)^{trans}$ modes and an increase in the $\nu(Cr–CO)^{trans}$ frequency. The effect of the *trans* ligands was also observed in similar pressure-tuning infrared and Raman spectroscopic studies on $Cr(CO)_4(CNBut\text{-}t)_2$ where the frequency of the $\nu(CO)^{trans}$ modes was lower than the frequency of the $\nu(CO)^{cis}$ mode, and the pressure dependence of the *trans* carbonyls was markedly lower than for the *cis* carbonyls due to increased backbonding at higher pressures (e.g., $d\nu_s[CO]^{cis}\,dP^{-1} = 0.99\ cm^{-1}\,kbar^{-1}$; $d\nu_s[CO]^{trans}\,dP^{-1} = 0.21\ cm^{-1}\,kbar^{-1}$) (30). In $Cr(CO)_4(bpy)$, the pressure dependence of the *cis* carbonyl modes was much lower than that observed in $Cr(CO)_4(CNBut\text{-}t)_2$ (cf. Table 1). Some of the decreased pressure dependence may be attributed to the bipyridyl ligand accommodating a greater portion of the molecular compressibility at higher pressures, since it is larger (and more pressure sensitive) than the CNBut-*t* ligands in $Cr(CO)_4(CNBut\text{-}t)_2$.

The electron density distribution of the bipyridyl ligand (and consequently, the electron-donating ability to the central metal) appears to be modulated by the application of pressure. This variability in electron density within the bipyridyl ligand is likely related to the great diversity of MLCT states which are exhibited by the series of organometallic complexes with bipyridine or bipyrazine ligands. Further pressure-tuning studies of organometallic complexes involving bipyridine and bipyrazine will reveal the nature of the vibrational systems in these complexes and ultimately aid in elucidating the complex photochemistry of these diverse systems.

Stereoelectronic effects in sulfonyl compounds: axial orientation of an *N*-methyl group in a six-membered sultam[1,2]

James Frederick King, Gay Yuyitung, Manjinder Singh Gill, Jeffrey Charles Stewart, and Nicholas Charles Payne

Abstract: The *trans* form of octahydro-1-methyl-1*H*-2,1-benzothiazine 2,2-dioxide, in which a six-membered sultam unit is *trans*-fused to cyclohexane, has been synthesized. The single-crystal X-ray structure shows the molecule to have the *N*-methyl group in the *axial* orientation. The generalized anomeric effect believed to be responsible for the axial preference is estimated at ≥2 kcal mol^{-1}.

Key words: generalized anomeric effect, negative hyperconjugation, sulfonamides, sultams, X-ray crystallography.

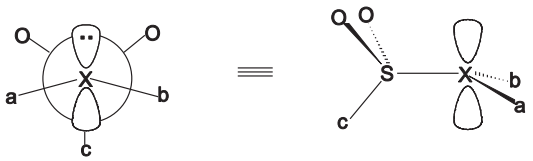
Résumé : On a synthétisé la forme *trans* du 2,2-dioxyde de l'octahydro-1-méthyl-1*H*-2,1-benzothiazine dans laquelle une unité sultame à six chaînons est liée de façon *trans* à un cyclohexane. Une détermination de structure par diffraction des rayons X par un cristal unique montre que le groupe *N*-méthyle occupe une orientation *axiale*. On évalue que l'effet anomère généralisé qui serait responsable de la préférence axiale est de l'ordre de 2 kcal mol^{-1}.

Mots clés : effet anomère généralisé, hyperconjugaison négative, sulfonamides, sultames, diffraction des rayons X.

[Traduit par la rédaction]

Introduction

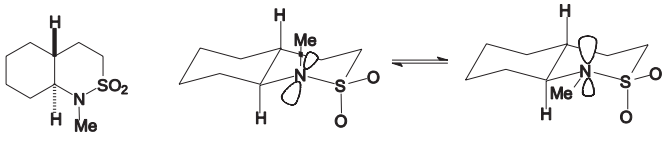
There is good evidence for the existence in sulfonyl compounds of the general formula $-SO_2-\ddot{X}$, where X = OR, NR_2, C^-R^2, etc., of delocalization as indicated by $-SO_2-\ddot{X} \leftrightarrow -\overline{S}O_2 \equiv X^+$, and that this delocalization depends on the orientation of the free



1

electron pair, i.e., that it is a stereoelectronic effect which may be included under the heading of a "generalized anomeric effect" (2) or "negative (or anionic) hyperconjugation"(3). Much of the support for this picture derives from the extensive experimental and theoretical studies on α-sulfonyl carbanions (for summaries see refs. 4 and 5 and sources cited). Theoretical studies currently concur in favouring depiction of the delocalization as involving, primarily, not *d*-orbitals as had been earlier proposed (see, for example, refs. 6 and 7), but rather $n \rightarrow \sigma^*$ donation (8–10). The more limited studies on sulfonamides and related species (11–16) and on sulfonic esters (14–16) point to a similar, if smaller, delocalization in these species. Structure **1** shows the lowest energy conformation about the S—X bond as indicated by a variety of procedures (11–15). Note that the typical projected *a*–X–*b* angle is neither 120° (as expected for sp^3 hybridization) nor 180° (for sp^2 hybridization), but is rather something in between, ranging from 130° to 175° with sulfonamides.

Among the various estimates for the energy barrier to rotation around the S—X bond we note Bors and Streitwieser's calculated value of about 14 kcal mol^{-1} for CH_2—SO_2CH_3 (9)



2 2a 2b

and Jennings and Spratt's determination by ^{1}H NMR spectrometry of 11.5 kcal mol^{-1} assigned to rotation around the S—N bond in Et_2NSO_2Cl (12); the latter method was not applicable to other sulfonamides (e.g., Et_2NSO_2Me), and it was surmised that the rotational barrier in such species is lower.

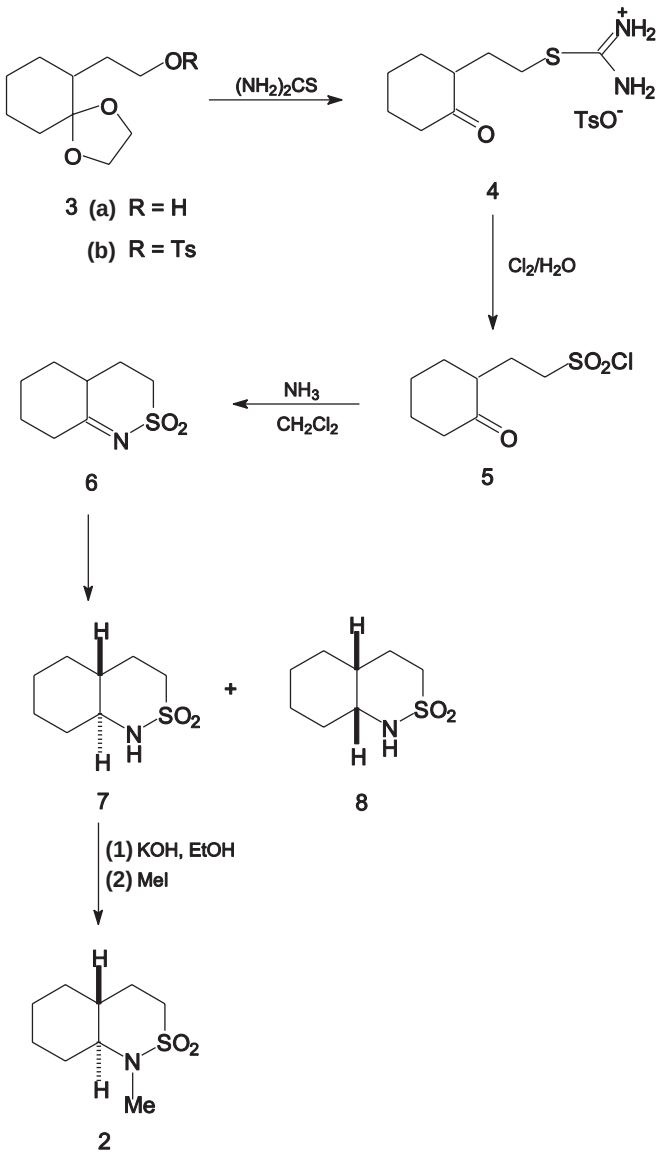
Scheme 1.



In the present study we have sought information on the energetics and chemical effects of the generalized anomeric effect in sulfonamides by synthesizing a sulfonamide in which the steric and stereoelectronic effects must compete. The specific example chosen was the sulfonamide **2**, in which the favourable "anomeric effect geometry" shown in **1** may be achieved only at the expense of placing the methyl group in an axial conformation. The competition is illustrated in structures **2a** ⇌ **2b**; **2a** has the stereoelectronically preferred arrangement as in **1**, but **2b** has the sterically preferred equatorial orientation of the methyl group. The question we sought to answer is, which orientation is favoured, or, perhaps rather optimistically, what is $\Delta G°$ for the equilibrium **2a** ⇌ **2b**?

Results and discussion

Scheme 1 shows the synthesis of the bicyclic sultam **2**. The ultimate starting materials, cyclohexanone and ethyl bromoacetate were converted to the hydroxyacetal **3a** as described by Segre et al. (17). The sulfonyl chloride (**5**) was obtained from **3a** by tosylation to **3b**, S_N2 displacement with thiourea with accompanying hydrolysis of the acetal to form **4**, followed by aqueous chlorination. Reaction of **5** with ammonia gave, presumably by way of the keto-sulfonamide, the sulfonimine **6**. Reduction of **6** with $LiAlH_4$ in THF gave a 60:40 mixture of stereoisomers (mp 123–125°C and 134–135°C, respectively) separable by thick-layer chromatography. The stereochemistry of the products was tentatively assigned from the ^{1}H NMR spectra. In the lower melting isomer the methine attached to the nitrogen gave a triplet of doublets (each peak slightly broadened) at ~3.0 ppm, consistent with an axial hydrogen split by two axial neighbours and one equatorial neighbour as in the *trans* isomer **7**. In the higher melting isomer the methine hydrogen showed a relatively narrow signal at 3.8 ppm, indicating a hydrogen with only small coupling constants with neighbours, as would be the case for the conformer of **8** with the methine C-H equatorial to the cyclohexane ring. This assignment was confirmed by a single-crystal X-ray structure

Fig. 1. A view of **7**. Thermal ellipsoids are drawn at the 50% probability level.

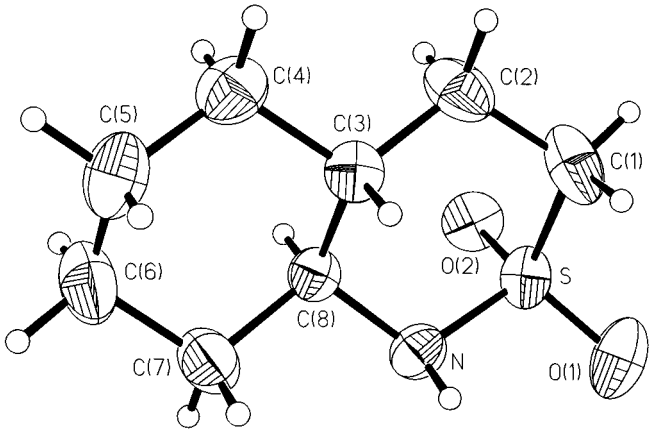


Fig. 2. A view of **2**. Thermal ellipsoids are drawn at the 50% probability level.

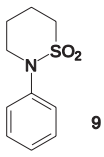
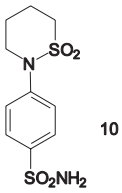
determination of the low-melting isomer (Fig. 1) that showed it to be the *trans* isomer **7**.

Methylation of **7** with methyl iodide in the presence of base gave the *N*-methyl sultam **2** as a crystalline solid melting at 58–60°C. The single crystal X-ray structure (Fig. 2) is in full accord with the assigned structure and clearly shows the methyl group to be in the *axial* position.

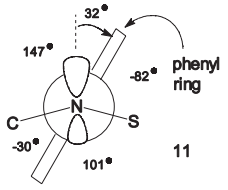
If we may assume that the structure of **2** given by the X-ray diffraction analysis is, in fact, that of the lowest energy conformation, then this result accords well with the view that the generalized anomeric effect in sulfonamides leads to a substantial stabilization of the conformation that maximizes this effect. In this instance it is sufficient to overcome completely the usual preference for the equatorial orientation of a substituent on a six-membered ring. In methylcyclohexane itself, $\Delta G°$ for the conformational change axial $\rightleftharpoons$ equatorial is –1.74 kcal mol^{-1} (18). Obviously there are important points of difference between **2** and methylcyclohexane, notably: (*a*) the partial flattening of the nitrogen atom (from increased *p* character, as discussed above) accompanying delocalization of the electrons into the sulfonyl group, (*b*) the longer bond lengths associated with the sulfur atom, and (*c*) the presence of oxygen atoms on the sulfur. We note, however, that the H–H non-



9



10



11

bonding distance between the hydrogens on C-3 and the hydrogens on C-9 (see Fig. 2 for numbering), i.e., the axial ring juncture hydrogen and the nearest hydrogen of the axial methyl group, is 2.36 Å, a number close to the 2.34 Å found by MMX (PC Model) calculations for the analogous hydrogen–hydrogen interactions in methylcyclohexane. This suggests that the axial *N*-Me group in **2** is indeed subject to nonbonding repulsions of comparable or perhaps slightly diminished magnitude with respect to those on axial methylcyclohexane. If we take a conservative estimate of the steric energy of the axial methyl group in **2** as –1 kcal mol^{-1} (i.e., distinctly less than the 1.74 kcal mol^{-1} in axial methylcyclohexane), and if, indeed, the axial conformation of **2** is the substantially favoured form as suggested by the X-ray result, then, keeping in mind the reservations noted above, we may suggest a value of ≥2 kcal mol^{-1} for the anomeric effect in **2**.

This result is to be contrasted with that observed with *N*-phenyl six-membered sultams **9** and **10**, both of which were found in X-ray crystallographic studies to have the phenyl group in the *equatorial* position (19, 20). The phenyl group is distinctly larger than the methyl group (the *A* value for phenyl is 2.8 vs. 1.74 kcal mol^{-1} for methyl) (21). If this is the only factor, these results could be interpreted as indicating that the anomeric effect is simply not large enough to counter the larger "size" of the phenyl group (and hence must be assigned a value of less than, say, 2.5 kcal mol^{-1}). Such an interpretation must be viewed with caution, however, because the electrons in *N*-alkyl and *N*-aryl sulfonamides may well show different intrinsic anomeric effects, because of the greater electronegativity of aryl (vs. alkyl) groups and (or) partial delocalization of the *N*-aryl free electron pair into the aromatic ring, thereby making it less available for delocalization into the sulfonyl group. The latter factor would not appear to be particularly important with **9** or **10**, however, because the free electron pair and the phenyl ring do not seem to be well oriented for effective delocalization. As may be seen from the Newman projection (**11**) of the N-aryl bond in **9**, the orbital of the free electron pair makes an angle of only 32° with the phenyl ring, rather than the optimal 90° (the other numbers are the observed torsional angles (18)).

Further structure descriptions

The crystal structure of **7** is built up from molecules linked by hydrogen bonds N—H...O(2) at (x, $-½ - y$, $z - ½$) (N—H 0.90, H...O(2) 2.10 Å, N—H...O(2) 174°). The closest nonbonding

© 1998 NRC Canada

approach is H(8)...H(4A) at (x, ½ – y, ½ + z) 2.55 Å. All distances and angles within the molecule are normal, and the H atom on the nitrogen clearly occupies an axial position. The crystal structure of **2** is built up from separate molecules. The closest nonbonding approach is H(1B)...O(2) at (1 – x, 1 – y, –z) 2.45 Å. Selected interatomic distances and angles for both compounds are given in Table 1. Distances and angles within molecule **2** are normal, and agree well with those in **7**. The projected C-N-C angle in **7** (136.0(3)°), which is obtained from the difference of the C1-S-N-C9 and C1-S-N-C8 torsional angles (respectively, –78.0(2)° and 58.0(2)°), is in the low end of the range (130°–175°) quoted above.

There is a significant difference between the S—O bond lengths in each compound. Thus the S—O(equatorial) distance is significantly shorter than the S—O(axial) distance (λ = 4.3 in **7** and 3.2 in **2**).

Comparison with published ab initio calculations

Katzenellenbogen and co-workers (16) have reported ab initio calculations on *N*-methyl methanesulfonamide and methyl methanesulfonate. Because their conclusions are in some important ways at variance with both our present and our earlier results (15) (which they do not appear to have noticed), a comment at this stage would appear to be in order. Their MO calculations lead them to conclude that the lowest energy conformation of methyl methanesulfonate has a C-S-O-C torsion angle of 179.9°. They also reported an X-ray single-crystal structure determination of a sulfonic ester, which showed a C-S-O-C torsion angle of 173.1°. With the sulfonamide, two energy minima were calculated; the higher energy form (by 1.5–1.9 kcal mol^{-1}) showed a C-S-N-C torsion angle of 72° (much like **1**), but in the lower energy conformation the C-S-N-C angle was 98.7°, with the major lobe of the orbital containing the free electron pair eclipsed with the S—C bond and the N—H bond eclipsed with S—O bond. They compared the sulfonamide MO calculation results with a previously published X-ray structure of methanesulfonanilide (CH_3SO_2NHPh).

In our earlier study (15) of crystal structures of sulfonic esters reported in the Cambridge Datafile (for 1986), we found a total of 106 "hits" (compounds) giving 121 dihedral angles; of these 101 were in the range 60°–120°, and 5 in the range 160°–180°. Evidently neither Katzenellenbogen's MO calculations nor his single compound determined by X-ray crystallography adequately represent the structures of sulfonic esters, at least in the solid phase.

In the earlier paper (15) we also looked at the structures of *N,N*-disubstituted sulfonamides and found that 124 of 140 C-S-N-C torsion angles were in the range 60°–120°, and only one example, N-phenylsulfonyl-2,2,6,6-tetramethyl-4-oxopiperidine (22), had the free electron pair eclipsed with the S—C bond, corresponding to the lower energy minimum in the calculations of Katzenellenbogen. It should also be noted that the X-ray structure of methanesulfonanilide mentioned by Katzenellenbogen and co-workers has C-S-N-C and C-S-N-H angles of –62.2° and 70.4°, respectively, i.e., in the same range as most of the corresponding disubstituted sulfonamides in our earlier study described above. Katzenellenbogen and co-workers suggested that "crystal lattice forces and the presence of functional groups which might be involved in interactions (e.g., hydrogen bonding) can play a significant role in determining torsional angles." In the disubstituted sulfonamides there is no N—H bond and such hydrogen bonding cannot be a factor; in addition, it seems extremely improbable to us that crystal lattice forces would provide such a clear trend favouring the 60°–120° torsional angle if it were opposed to a significant factor in favour of another conformation, e.g., that corresponding to Katzenellenbogen's minimum energy conformation.

Another way of looking at these results emerges from MO calculations done on methanesulfonamide ($CH_3SO_2NH_2$) in this department (D.F. Klassen and N.C. Baird, personal communication); the calculations were carried out with the GAUSSIAN 86 package using the 6-31G* basis set with *d*-orbitals on the sulfur atom only. The minimum energy structure showed *both* N—H bonds eclipsed with the S—O bonds. The X-ray crystal structure of $CH_3SO_2NH_2$, on the other hand (ref. 23 and also N.C. Payne, unpublished results), shows each sulfonyl oxygen to be hydrogen-bonded to the hydrogen on the nitrogen of an adjacent molecule, which is then associated with the first molecule by the complementary N—H—O—S hydrogen bond; thus each molecule is attached by two hydrogen bonds to two other methanesulfonamide molecules. These results are consistent with two notions: (*a*) that the N—H—O—S hydrogen bond (whether inter- or intramolecular) is strong, and (*b*) that the synperiplanar anomeric effect, in which the (electron pair)-N-S-C torsion angle in sulfonyl compounds is ~0°, may well be of comparable energy with the more usual antiperiplanar (with (electron pair)-X-S-C angle ~180°) conformation; evidence for the synperiplanar effect in acetal reactions (24) and α-sulfonyl carbanion formation (25) has been described. For the *N,N*-disubstituted sulfonamides of our previous study, the observed preference for the C-S-N-C torsion angle of 90 ± 30° (i.e., the antiperiplanar conformation) over the synperiplanar conformation is probably due primarily to the extra energy of the eclipsing interactions between the sulfonyl oxygen atoms and the substituents on the nitrogen atom. When the N-substituent is a hydrogen atom the nonbonding interaction is small and may well be more than compensated by the hydrogen bonding discussed above. With most other groups, and certainly with simple alkyl and aryl groups, these eclipsing interactions may be expected to be destabilizing, and hence the antiperiplanar conformation to be the more stable conformation except perhaps with mono-*N*-substituted sulfonamides with a small substituent, or conceivably, very cluttered *N,N*-disubstituted sulfonamides; the exception noted above, *N*-phenylsulfonyl-2,2,6,6-tetramethyl-4-oxopiperidine, which shows the synperiplanar form (and a twist-boat six-membered ring) in the crystal (22), may be an example of this.

The MO calculations of Katzenellenbogen and co-workers and of Klassen and Baird agree in assigning a low energy barrier (~2 kcal mol^{-1}) to inversion at the nitrogen; it seems highly likely that we are dealing with products of complete equilibration (as implied by **2a** ⇌ **2b**, above) in all cases.

Finally we point to the similarity in geometry between **2** and **7**. The fact that the N-H is axial is of course in good agreement with the operation of the anomeric effect (negative hyperconjugation). This N-H is also, however, hydrogen bonded to the sulfonyl oxygen of the neighbouring molecule (see above) and for the reasons discussed in the above paragraphs it would seem imprudent to ascribe the axial orientation of the hydrogen on nitrogen exclusively to the anomeric effect.

Experimental

Instruments and general procedures

^1H and ^{13}C NMR data were obtained using Varian Gemini 200, XL200, and XL300 instruments and are normally of solutions in $CDCl_3$; chemical shifts were determined relative to TMS. IR spectra were obtained on $CHCl_3$ solutions (0.1 mm) using an IFS/32 FTIR Bruker or a Perkin Elmer 2000 FT-IR spectrometer. Melting points were determined using either a Fisher-Johns melting point apparatus or a Kofler Hot Stage and are uncorrected. Kiesel Gel, silica gel for TLC (containing 5% $CaSO_4$, from InterScience, Markham, Ontario), was used for thin-layer chromatography and thick-layer preparative plates. Reagent grade chemicals and solvents were used, unless otherwise noted. Work-up refers to (*a*) partitioning of reaction mixture between water and an organic solvent, (*b*) making the aqueous phase acidic with 1 M H_2SO_4, (*c*) extraction with organic solvent, and (*d*) drying of the organic layer with anhydrous magnesium sulfate and evaporation of the organic solvent using a Büchi rotary evaporator attached to a water aspirator. Mass spectra were determined with a Finnigan MAT-311A spectrometer (at 70 eV).

Ethylene ketal of 2-[2 hydroxyethyl]cyclohexanone (3a)

The procedure of Segre et al. (17) gave **3a** as a clear liquid. ^1H NMR δ: 1.08–2.05 (m, 11H), 2.83 (s, 1H), 3.37–3.80 (m, 2H), 3.87–4.12 (s, 4H); ^{13}C NMR δ: 23.6, 24.4, 30.2, 32.0, 34.2, 41.6, 61.2, 64.2, 64.5, 110.5.

6-[2-(4-Methylphenylsulfonyloxy)ethyl]-1,4-dioxospiro-[6,5]decane (3b)

p-Toluenesulfonyl chloride (14.63 g, 76.8 mmol), freshly recrystallized from petroleum ether (bp 35–60°C), was added to a solution of **3a** (11.95 g, 64 mmol) in dry pyridine. After 23 h in the refrigerator, the reaction mixture was hydrolysed with ice, acidified with 2 M HCl, then extracted with dichloromethane. Evaporation of the solvent gave **3b** (16.86 g, 78%) as a light brown liquid. ^1H NMR δ: 0.97–2.15 (m, 11H), 2.45 (s, 3H), 3.78–3.99 (m, 4H), 4.12 (t, 2H), 7.21–7.92 (dd, 4H). ^{13}C NMR δ: 21.6, 23.5, 24.4, 28.1, 29.3, 34.3, 40.7, 64.4, 64.6, 69.7, 110.0, 127.8, 129.6, 133.1, 144.5.

S-[2-(2-Oxocyclohexyl)]ethylthiouronium *p*-toluenesulfonate (4)

A solution of **3b** (16.5 g, 49 mmol) and thiourea (4.2 g, 55 mmol) was refluxed in absolute ethanol (75 mL) for 15 h; the solvent was removed in vacuo, to give a yellowish liquid. Recrystallization from water gave **4** as a white crystalline solid (12 g, 60%), mp 160–162°C; ^1H NMR (CD_3OD) δ: 1.3–2.20 (m, 8H), 2.37 (s, 3H), 2.30–2.68 (m, 2H), 2.90–3.28 (m, 2H), 3.30 (m, 1H), 7.21–7.73 (dd, 4H); ^{13}C NMR (CD_3OD) δ: 21.3, 26.2, 29.1, 29.2, 30.8, 35.4, 42.9, 50.2, 126.9, 129.9, 141.8, 143.4, 173.1, 215.8.

2-(2-Chlorosulfonylethyl) cyclohexanone (5)

A solution of **4** (5 g, 12 mmol) in water was added quickly to an ice-cooled saturated solution of chlorine in water. The reaction mixture was stirred vigorously for 1 min with a constant flow of chlorine. Extraction with dichloromethane was quickly followed by brief washings with a small amount of aqueous sodium bisulfite. Evaporation of the solvent gave **5** as a colourless liquid (2.27 g, 84%). IR ν_{max}: 2939 (m), 2864 (m), 1709 (s), 1375 (s), 1169 (s) cm^{-1}; ^1H NMR δ: 1.33–2.45 (m, 10H), 2.48–2.67 (m, 1H), 3.64–3.99 (m, 2H); ^{13}C NMR δ: 24.7, 24.9, 27.7, 34.3, 41.9, 48.1, 63.3, 211.4.

3,4,4a,5,6,7,8-Hexahydro-1*H*-2,1-benzothiazine 2,2-dioxide (6)

Anhydrous ammonia was bubbled into dichloromethane and **5** (224 mg, 1 mmol) was added quickly. The reaction mixture was stirred for 1 h with a constant flow of ammonia. Work-up gave **6** as a light yellow liquid (166 mg, 88%). IR ν_{max}: 3256–3277 (br, m), 2938 (s), 2864 (s), 1620 (s), 1323 (s), 1155 (s) cm^{-1}; ^1H NMR δ: 1.11–2.72 (m, 11H), 2.96–3.46 (m, 2H); ^{13}C NMR δ: 24.9, 25.5, 26.8, 33.9, 39.0, 39.7, 44.5, 188.5.

trans- and *cis*-Octahydro-1*H*-2,1-benzothiazine 2,2-dioxide (7 and 8)

$LiAlH_4$ (0.5 g, 13 mmol) was added to a solution of **6** (2 g, 10 mmol) in dry THF and the reaction mixture was stirred for 1 h at room temperature. Work-up gave a mixture of the *trans* and *cis* isomers (**7** and **8**) in a 60:40 ratio as judged from the ^1H NMR of the reaction mixture, as an oil (1.7 g, 85%). The reaction mixture was separated on thick-layer preparative plates; eluting three times with 1:3 ethyl acetate:petroleum ether (bp 35–60°C) gave **7** (*trans* isomer) as the upper band and **8** (*cis* isomer) as the lower band, both as white solids; **7**: recrystallized from ether; mp 123–125°C, IR ν_{max}: 3364 (br, w), 2936 (m), 1451 (w), 1402 (m), 1339 (s), 1281 (w), 1153 (s), 1113 (w) cm^{-1}; ^1H NMR δ: 0.98–1.40 (m, 5H), 1.67–2.10 (m, 6H), 2.95–3.06 (m, 1H), 3.12 (td, 1H, J = 11 Hz, J = 3.5 Hz), 3.25 (dt, 1H, J = 13 Hz, J = 3.5 Hz), 4.1 (d, 1H); ^{13}C NMR δ: 24.7, 25.4, 30.4, 30.9 32.5, 41.1, 50.3, 59.6; Exact Mass calcd. for $C_8H_{15}NO_2S$: 189.0823; found: 189.0819; **8**: recrystallized from ether; mp 134–135°C, IR ν_{max}: 3380 (br, w), 2935 (m), 1450 (w), 1404 (w), 1323 (s), 1288 (w), 1176 (s), 1148 (s) cm^{-1}; ^1H NMR δ: 1.22–2.05 (m, 10H), 2.28–2.45 (m, 1H), 2.96–3.10 (m, 2H), 3.77 (s, 1H), 4.72 (s, NH, 1H); ^{13}C NMR δ: 19.8, 23.8, 25.0, 28.8, 30.2, 32.6, 44.5, 54.5; Exact Mass calcd. for $C_8H_{15}NO_2S$: 189.0823; found: 189.0817.

trans-Octahydro-1-methyl-1*H*-2,1-benzothiazine 2,2-dioxide (2)

Compound **7** (99 mg, 0.52 mg) was added to a solution of KOH (70 mg) in ethanol (5 mL); the reaction mixture was stirred for 20 min, after which methyl iodide (5 mL, large excess) was added. The above reaction mixture was stirred for 23 h at room temperature. The ethanol was removed on the rotary evaporator and then worked up to give **2** as a white solid (91 mg, 85%), which was recrystallized from ether:petroleum ether (bp 35-60°C), mp 58-60°C; IR ν_{max}: 2940 (m), 1337 (s), 1288 (w), 1153 (s), 1128 (m), 907 (m) cm^{-1}; ^1H NMR δ: 1.0–1.56 (m, 5H), 1.67–2.05 (m, 6H), 2.75 (s, 3H), 2.92–3.15 (m, 2H), 3.40 (td, J = 11 Hz, J = 3.7 Hz); ^{13}C NMR δ: 25.0, 25.3, 29.4, 30.5, 30.6, 31.8, 34.0, 45.5, 63.0; Exact Mass calcd. for $C_9H_{17}NO_2S$: 203.0980; found: 203.0980. ^1H and ^{13}C NMR spectra (Gemini 300) of **2** in CD_2Cl_2 or in CD_2Cl_2:$CFCl_3$ (1:1) from room temperature to –90°C showed only broadening of peaks assignable to the low solubility of **2** at low temperature, and no sign of additional signals.

X-ray crystallography

Structure solution and refinement

Crystals of *trans*-octahydro-1*H*-2,1-benzothiazine-2,2-dioxide (**7**) are colorless transparent prisms. A preliminary examination carried out on a Siemens P4 diffractometer, using the XSCANS software (26) running on a PC, established the space group and cell dimensions. The crystal density was measured by the neutral buoyancy method in aqueous zinc chloride solution. Data collection of one quadrant was carried out in the ω–2θ scan mode at variable scan speeds within a maximum time per datum of 60 s. Stationary background estimates were made at scan limits. Standard reflections were monitored every 180 min of X-ray exposure time and showed no change. Lorentz, polarization, and decay corrections were applied using the Siemens XSCANS program, but no absorption correction was made. In all there were 1660 unique data for structure solution and refinement.

Crystals of *trans*-octahydro-1-methyl-2,1-benzothiazine-2,2-dioxide (**2**) are colorless transparent prisms. A preliminary examination carried out on an Enraf–Nonius CAD4 diffractometer using the EXPRESS software (27) running on a Microvax II established the space group and cell dimensions. The crystal density was measured by the neutral buoyancy method in aqueous zinc chloride solution. Data collection of one quadrant was performed in the ω–2θ scan mode at variable scan speeds within a maximum time per datum of 60 s. Background estimates were made at 25% scan extensions on each side. Standard reflections were monitored every 180 min of X-ray exposure time, and did not vary. Lorentz, polarization, and decay corrections were applied, but no absorption correction. There was a total of 3080 unique data for structure solution and refinement. Crystal and experimental data for both compounds are summarized in Table 2.

The structures were solved by direct methods (SHELXS) (28) and refined by full-matrix least-squares techniques on F^2 (SHELX93) (29). All but H atoms were assigned anisotropic thermal parameters. All hydrogen atoms were located successfully by difference Fourier methods, placed in calculated positions (C—H = 0.95 Å), and included in the structure factor calculations in riding mode (29). The H atom positions of the methyl group in compound **2** were optimized through a rotating group refinement. The H(N) atom in compound **7** was clearly axial in a difference Fourier synthesis. No secondary extinction corrections were required. Analyses of variance suggested that the weighting schemes were appropriate. Refinement on F^2 converged, for compound **7** at agreement factors R = 0.0324 and R_2 = 0.0824 for 110 variables and 1659 data, and for compound **2** at values of R = 0.0465 and R_2 = 0.1183 for 119 variables and 3078 data. Total difference Fourier syntheses contained no unusual features.

Final positional parameters are given in Table 3 for both compounds, while anisotropic thermal parameters and

Cooperative antioxidant effects of ascorbate and thiols with di-*tert*-butylcatechol during inhibited peroxidation in solution and in sodium dodecyl sulfate (SDS) micelles

Fengde Xi and L. Ross C. Barclay

Abstract: The antioxidant activities, k_{inh}, of catechol, **1**, 4-*tert*-butylcatechol, **2**, and 3,5-di-*tert*-butylcatechol (DTBC), **3**, determined by the inhibited oxygen-uptake method during peroxidation of styrene initiated by AIBN are 55.0×10^4, 88.4×10^4, and 149×10^4 $M^{-1}s^{-1}$, respectively, and the stoichiometric factors (n) were 2.1–2.3. A decrease by 50-fold in k_{inh} for **3** and a drop of 1.1–1.4 in n observed during inhibited peroxidation of methyl linoleate in aqueous sodium dodecyl sulfate (SDS) initiated by di-*tert*-butylhyponitrile (DBHN) is attributed to hydrogen bonding by water on the antioxidant and on the intermediate di-*tert*-butylsemiquinone radical, **5**, formed in the inhibition step. Combinations of ascorbyl palmitate with **3** exhibited cooperative (not synergistic) antioxidant effects during inhibited peroxidation of styrene in solution. Combinations of ascorbic acid with **3** exhibited synergistic effects during inhibited peroxidation of methyl linoleate initiated by DBHN in SDS micelles. A profile of the effect of concentration of ascorbate on this synergism indicates a mole of **3** is regenerated per mole of ascorbate. The thiols, homocysteine, and polyethylene glycol thiol (polythiol) also exhibited synergistic effects with DTBC in this inhibition. Either ascorbate or polythiol rapidly reduces di-*tert*-butyl-*ortho*-quinone (DTBQ), **4**, to **3** in methanol or in SDS micelles, and the combination of **3** + ascorbate acted as an efficient inhibitor in this medium. The esr studies indicate the semiquinone radical, **5**, produced photochemically from **3** or spontaneously from **3** + **4** in solution, to be very persistent at room temperature. A pathway, mediated by **5**, is proposed to account for the cooperative and synergistic effects observed and for the additional combination effect discovered when the three inhibitors: **3**, ascorbate, and a thiol are used in the SDS medium. Combinations of such antioxidants are expected to be useful for inhibition of yellowing of pulps and paper with high lignin content, and to be significant in the in vivo reductions of *ortho*-quinones and semiquinone radicals formed during oxidations of various biomolecules.

Key words: catechols, ascorbate, thiols, radicals, antioxidants.

Résumé : Les activités antioxydantes, k_{inh}, du catéchol, **1**, du 4-*tert*-butylcathécol, **2**, et du 3,5-di-*tert*-butylcathécol (DTBC), **3**, déterminées par la méthode d'absorption d'oxygène inhibé pendant la peroxydation du styrène initiée par le AIBN sont respectivement de 55.0×10^4, 88.4×10^4 et 149×10^4 $M^{-1}s^{-1}$ et les facteurs stoechiométriques (n) vont 2.1–2.3. On observe une diminution de 50 fois de la valeur k_{inh} pour le composé **3** et une diminution de la valeur de n jusqu'à 1.1–1.4 lors de la peroxydation inhibée du linoléate de méthyle, dans une solution aqueuse de dodécyl sulfate de sodium (DSS), initiée par le di-*tert*-butylhyponitrile (DBHN). On attribue ces diminutions aux liaisons hydrogènes de l'eau sur l'antioxydant et sur le radical intermédiaire di-*tert*-butylsemiquinone, **5**, formé pendant l'étape d'inhibition. La combinaison du palmitate d'ascorbyle avec le radical **3** a un effet antioxydant coopératif (pas synergique) lors de la peroxydation inhibée du styrène en solution. La combinaison de l'acide ascorbique avec le radical **3** provoque un effet synergique pendant la peroxydation inhibée du linoléate de méthyle initiée par le DBHN dans des micelles de DSS. Un profil de l'effet de la concentration de l'ascorbate sur cet effet synergique indique qu'une mole du radical **3** est régénérée par mole d'ascorbate. Les thiols, l'homocystéine et un polyéthylène glycol thiol (polythiol) ont également des effets synergiques avec le DTBC lors de cette inhibition. L'ascorbate ou le polythiol réduit rapidement la di-*tert*-butyl-*ortho*-quinone (DTBQ), **4**, en **3** dans le méthanol ou dans des micelles de DSS, et la combinaison de **3** + l'ascorbate agit comme un inhibiteur efficace dans ce milieu. Les études de rpe indiquent que le radical semiquinone, **5**, produit photochimiquement à partir de **3** ou spontanément à partir du mélange de **3** + **4** en solution, est très persistant à la température ambiante. On propose un mécanisme impliquant le radical **5** pour tenir compte des effets coopératif et synergique observés et de l'effet de combinaison additionnelle découvert lorsque les trois inhibiteurs : le composé **3**, l'ascorbate et un thiol sont utilisés dans une solution aqueuse de DSS. On s'attend à ce que les combinaisons de tels antioxydants soient utiles pour l'inhibition du jaunissement des pulpes et du papier riches en lignine, et soient importantes dans les réductions in vivo des radicaux *ortho*-quinones et semiquinones formés pendant l'oxydation de diverses biomolécules.

Mots clés : catéchols, ascorbate, thiols, radicaux, antioxydants.

Introduction

The formation of coloured *ortho*-quinonoid structures, from intermediate substituted aryloxyl radicals, in lignin is known to be responsible for the major portion of the undesirable yellowing that develops when mechanical pulps are exposed to light and oxygen (1–3). However, both polymeric thiols and ascorbate are able to readily reduce *ortho*-quinones to colourless hydroquinones (4, 5), and the natural thiol amino acid, homocysteine, is known to rapidly regenerate ascorbate from its oxidation product, dehydroascorbic acid (6). Consequently, a combination of ascorbate with thiols is expected to be a possible strategy to inhibit the yellowing of mechanical pulps and paper with high lignin content. In this study we used catechol, **1**, 4-*tert*-butylcatechol, **2**, 3,5-di-*tert*-butylcatechol, (DTBC) **3**, as antioxidants. 3,5-Di-*tert*-butyl-*ortho*-quinone (DTBQ), **4**, derived from **3** is used as a model for the *thermal* oxidative yellowing. This study employs free-radical chain peroxidation under controlled conditions using azo initiators so that the antioxidant activities of **1**–**3** are determined. In addition, these quantitative kinetic studies permit evaluations of the effect of combinations of antioxidants. Ascorbate, thiols, and combinations of these with **3** are used as inhibitors to evaluate cooperative or synergistic antioxidation and to study the reductive regeneration of **3** from **4**.

The quantitative kinetic method of autoxidation is a very useful method to determine the activities of antioxidants and to examine the effects of combinations of antioxidants for possible cooperative or synergistic action. Uninhibited autoxidation of organic substrates follows the free-radical mechanism shown in eqs. [1]–[4] when oxidation is initiated by an azo initiator.

Initiation:

[1] $\text{R-N=N-R} \xrightarrow{k_i} 2\text{R}\cdot + \text{N}_2$, rate $= R_i$

Propagation:

[2] $\text{R}\cdot + \text{O}_2 \xrightarrow{\text{fast}} \text{ROO}\cdot$

[3] $\text{ROO} + \text{RH (substrate)} \xrightarrow{k_p} \text{ROOH} + \text{R}\cdot$

Termination:

[4] $\text{ROO}\cdot + \text{ROO}\cdot \xrightarrow{2k_t}$ nonradical products $+ \text{O}_2$

The rate law for this mechanism is given in eq. [5], where k_p is the propagation rate constant, $2k_t$, the termination rate constant, [RH], the substrate concentration, and R_i, the rate of chain initiation.

[5] $$-\text{d}[\text{O}_2]/\text{d}t = k_p/2k_t^{1/2}[\text{RH}]R_i^{1/2}$$

The quantitative kinetic method employs azo initiators with known rate constants of decomposition, k_i, and efficiency, e, of initiation, so that R_i is controlled, as shown in eq. [6].

[6] $$R_i = 2ek_i\,[\text{R-N=N-R}]$$

During inhibited oxidation by a phenolic antioxidant (ArOH), efficient antioxidants can trap two peroxyl radicals, as represented by eqs. [7] and [8].

[7] $\text{ArOH} + \text{ROO}\cdot \xrightarrow{k_{inh}} \text{ArO}\cdot + \text{ROOH}$

[8] $\text{ArO}\cdot + \text{ROO}\cdot \rightarrow \text{ArOROO}$

During this inhibition, oxygen uptake is suppressed until the antioxidant is consumed. The inhibition period, τ, has a simple relationship to R_i, which can be measured using eq. [9] where n is the stoichiometric factor, the number of peroxyl radicals trapped per antioxidant molecule.

[9] $$R_i = n\,[\text{ArOH}]/\tau$$

Using a steady stable approximation, the rate law during suppressed oxidation can be expressed in terms of R_i, the concentrations of substrate and antioxidant, and the rate constants for propagation, k_p, and inhibition, k_{inh}, according to eq. [10]:

[10] $$-\text{d}[\text{O}_2]/\text{d}t = (k_p/k_{inh}\,[\text{RH}]R_i)/n[\text{ArOH}]$$

These quantitative kinetic methods have been applied as models of biological systems to determine activities of antioxidants in heterogeneous systems such as lipids in aqueous micelles (6–13). In this paper we report on (*i*) the antioxidant activities (k_{inh} of eq. [7]) of catechols **1**, **2**, and **3** during inhibited peroxidation of styrene in solution and of methyl linoleate and in 0.50 M sodium dodecyl sulphate (SDS), (*ii*) direct and azo-initiated oxidation of **3**, and (*iii*) the effect of ascorbate, ascorbyl palmitate, homocysteine, and a polythiol[2] both alone and in combinations of ascorbate + thiol as inhibitors of azo-initiated thermal peroxidation. Reactions in styrene solution were initiated by azobisisobutyrylnitrile (AIBN) where R_i is measured using 2,2,5,7,8-pentamethyl-4-hydroxylchroman (PMHC). Reactions in aqueous SDS micelles are initiated by di-*tert*-butylhyponitrite (DBHN) or azobis(amidinopropane hydrochloride) (ABAP), and the R_i is measured using 2-carboxy-2,5,7,8-tetramethyl-4-hyroxychroman (Trolox).

Results

1. The antioxidant activities of catechols 1–3 and their stoichiometric factors (*n*)

The antioxidant activities of **1**, **2**, and **3** were determined by measurements of the oxygen uptake during the course of the inhibition period, referred to herein as the IOU method. The integrated form of the equation for inhibition, eq. [11], was used as before (7), and k_{inh} was obtained from a plot of the linear equation, $\Delta[\text{O}_2]_t$ versus $-\ln(1 - t/\tau)$, where the slope is equal to $k_p[\text{RH}]/k_{inh.}$

[11] $$\Delta[\text{O}_2]_t = (-k_p/k_{inh}) \times [\text{RH}]\ln(1 - t/\tau)$$

Values of k_p determined separately in styrene (41.0 M s^{-1}) (14) and for linoleate in 0.50 M SDS (37.0 M s^{-1}) (15) under these conditions were used in the calculations.

The stoichiometric factor, n, was determined relative to the value of $n = 2$, which we used for the model compound PMHC (16),[3] by determination of R_i employing PMHC (eq. [9]) and measurements of the induction periods for known amounts of **1**, **2**, and **3** under the same conditions. The n factor for **1**, **2**, and **3** are then calculated using eq. [12].

[2] Polythiol prepared from polyethylene glycol and thiolactic acid, referred to as PEG 3400, was kindly provided by Dr. J.K.S. Wan of the Department of Chemistry, Queen's University, Kingston, Ont.

[3] The actual value for PMHC under these conditions was found to be $n = 1.89$, relative to $n = 2.00$ for α-tocopherol (16).

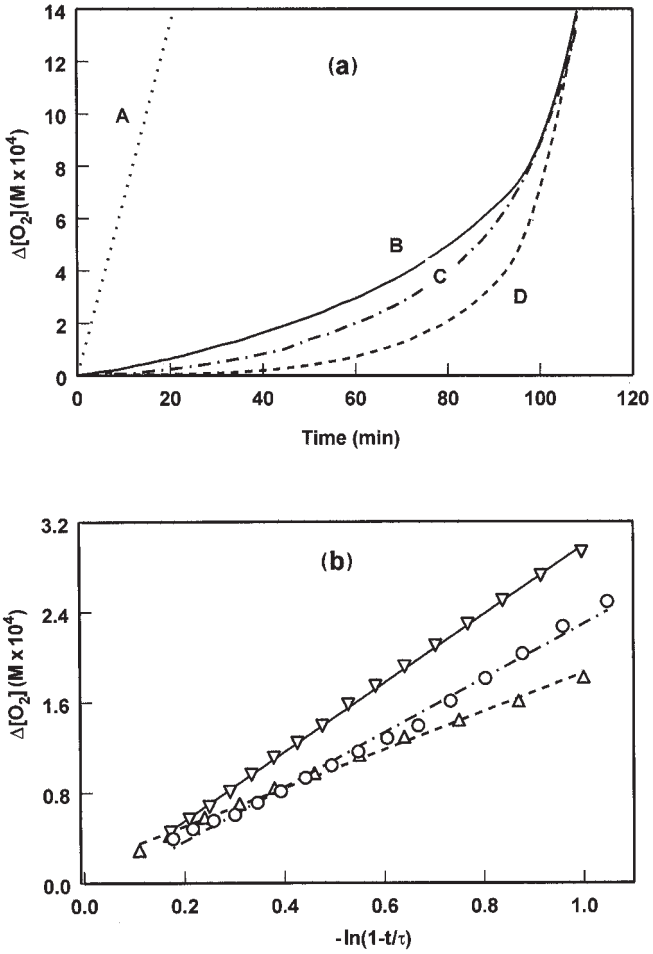
Fig. 1. Autoxidation of styrene (4.37 M) in chlorobenzene initiated by AIBN (1.85×10^{-2} M) at 30°C. (*a*) *A*, uninhibited reaction; *B*, inhibited by catechol (5.16×10^{-6} M); *C*, inhibited by 4-*tert*-butylcatechol (5.70×10^{-6} M); *D*, inhibited by 3,5-di-*tert*-butylcatechol (5.16×10^{-6} M); $R_i = 2.27 \times 10^{-9}$ M s^{-1}. (*b*) Plots of oxygen consumed versus $-\ln(1 - t/\tau)$ for peroxidation of styrene in chlorobenzene initiated by AIBN; ∇, inhibited by catechol; ○, inhibited by 4-*tert*-butylcatechol; Δ, inhibited by 3,5-di-*tert*-butylcatechol. Amounts are given in Table 1. The antioxidant activities, k_{inh}, are obtained from the slopes which equal $k_p/k_{inh} \times$ [R-H] (see text).

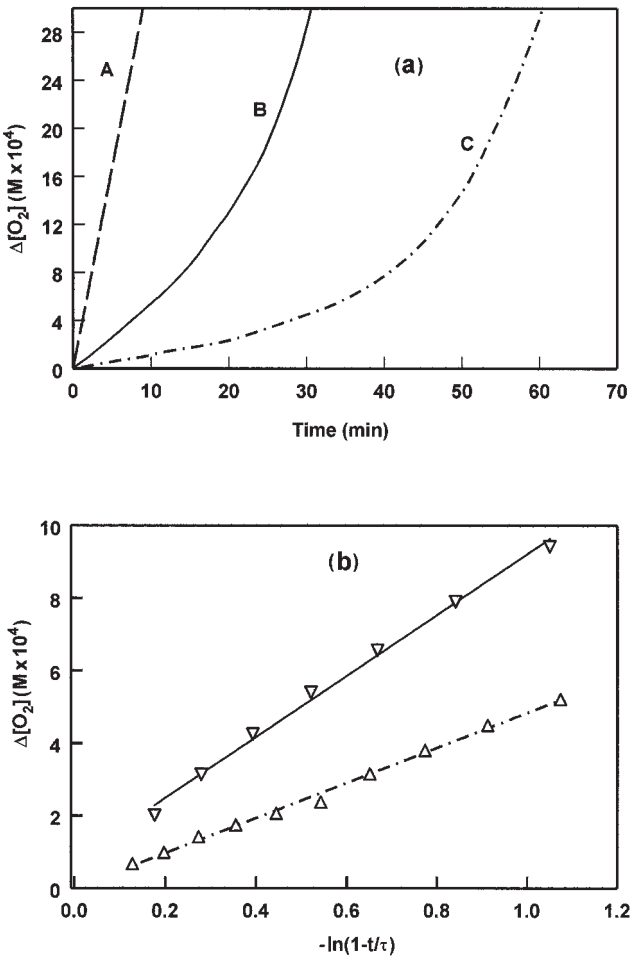


[12] $n = R_i \times \tau/[\text{ArOH}]$

(a) Antioxidant activities in homogeneous solution

Initial experiments on the effects of catechols were conducted in homogeneous solution during inhibited oxidative polymerization of styrene initiated by AIBN, since reliable data on various phenolic antioxidants are available in the literature (16, 17). The experimental profiles of inhibition by **1**, **2**, and **3** (shown in Fig. 1*a*) indicate that they possess antioxidant properties. Their antioxidant activities k_{inh} are determined by the plot of oxygen uptake during inhibition periods versus $-\ln(1 - t/\tau)$ (Fig. 1*b*). The values are in the order **3** > **2** > **1** (Table 1). The disubstituted catechol **3** exhibits significant antioxidant activity, since its $k_{inh} = 149 \times 10^4$ M^{-1} s^{-1} is approximately half that of α-tocopherol (vitamin E), one of the most active natural chain-breaking antioxidants (17).

Fig. 2. Autoxidation of methyl linoleate (see Table 2 for amount) in 3.00 mL 0.50 M SDS – phosphate buffer (pH 7) at 37°C. (a) *A*, initiated by DBHN (2.38×10^{-5} mol), uninhibited reaction; *B*, initiated by DBHN (3.14×10^{-5} mol), inhibited by 3,5-di-*tert*-butylcatechol (2.40×10^{-8} mol), $R_i = 3.47 \times 10^{-7}$ M s^{-1}; *C*, initiated by ABAP (2.5×10^{-5} mol), inhibited by 3,5-di-*tert*-butylcatechol (3.16×10^{-8} mol), $R_i = 3.90 \times 10^{-9}$ M s^{-1}. (*b*) Plots of oxygen consumed versus $\ln(1 - t/\tau)$ for peroxidation of methyl linoleate in SDS micelles, inhibited by 3,5 di-*tert*-butylcatechol; ∇, initiated by DBHN; Δ, initiated by ABAP. Amounts are given in Table 2. The antioxidant activities, k_{inh}, are obtained from the slopes which equal $k_p/k_{inh} \times$ [R-H] (see text).



(b) In aqueous SDS micelles

The typical profiles of DBHN- and ABAP-initiated peroxidations of methyl linoleate in aqueous micelles showing the effect of **3** are illustrated in Fig. 2*a*. Linear plots for the integrated expression obtained for **3** are given in Fig. 2*b*. The data of measurements are given in Table 2. The antioxidant activity of **3**, $k_{inh} = (3.31–2.32) \times 10^4$ M^{-1} s^{-1}, dropped 45- to 64-fold in micelles, compared with k_{inh} in homogeneous solution (see Table 1).

Solutions of DTBC in 0.50 M SDS were found to undergo oxidation directly at 37°C. After 2 h, which is the average time for most inhibition periods for azo-initiated experiments, approximately 3% of **3** was consumed according to oxygen-uptake studies and measurement of the amount of quinone, **4**, formed by determination of the absorbance at 412 nm.

[a] 70 μL methyl linoleate in 3 mL 0.50 M SDS micelles was used in DBHN-initiated peroxidation; 50 μL methyl linoleate in 3.00 mL 0.5 M SDS micelles was used in ABAP-initiated peroxidation.

[b] Concentrations of DBHN and DTBC are mol/L of micelles, using a calculated volume of 3.75×10^{-4} L for 3.00 mL of 0.50 M SDS (see ref. 11); amounts of DBHN were measured spectrally; concentration of ABAP is mol/L of the bulk phase, 2.00 mL.

[c] The rate of chain initiation was measured with Trolox; see eq. [9] in text.

[d] Inhibition rate constants were determined from the slope of the plot of $\Delta[O_2]_t$ versus $-\ln(1 - t/\tau)$; see text.

2. Cooperative effects of ascorbate and thiols on the inhibited peroxidation by DTBC

(a) In homogenous solution

A number of experiments were carried out to determine the cooperative inhibiting effects of ascorbyl palmitate and polythiol with DTBC on peroxidation of styrene, a phenomenon observed previously with ascorbate and α-tocopherol and its analogues (11, 18–23). The results show that induction periods for combinations of ascorbyl palmitate with DTBC are longer than that for DTBC alone, as illustrated in Fig. 3, although the induction periods for the combination ($\tau_{DTBC+AP}$) are less than the sum of separate induction periods ($\tau_{DTBC} + \tau_{AP}$) by DTBC and ascorbyl palmitate. The combination of polythiol with DTBC resulted in the same effect (not shown). The data of cooperative inhibiting activities are given in Table 3. The extensions of induction periods are indicative of regeneration of DTBC from its phenoxyl free radical by ascorbyl palmitate and polythiol. The product of the extension, τ_{ext}, and the rate of chain initiation, R_i, is a measure of the stoichiometric factor for regeneration of DTBC by ascorbyl palmitate or polythiol as shown in eq. [13].

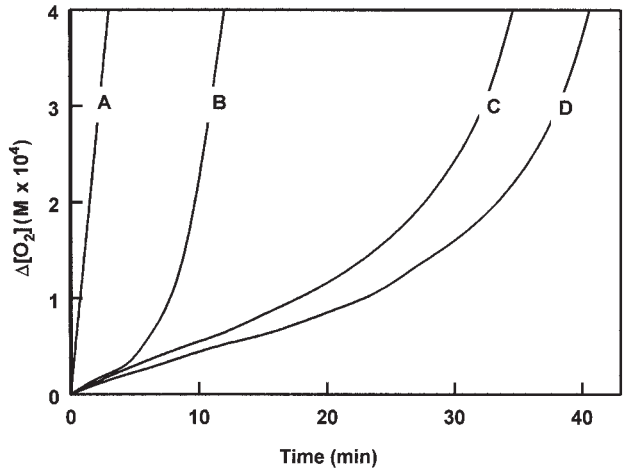
Fig. 3. Autoxidation of styrene (7.77 M) in tetrachloroethane (2.25 mL), thermally initiated by AIBN (3.71×10^{-2} M) at 30 °C. *A*, uninhibited reaction; *B*, inhibited by ascorbyl palmitate (5.01×10^{-6} M); *C*, inhibited by 3,5-di-*tert*-butylcatechol (5.01×10^{-6} M); *D*, inhibited by 3,5-di-*tert*-butylcatechol (5.01×10^{-6} M) and ascorbyl palmitate (5.01×10^{-6} M); $R_i = 4.17 \times 10^{-9}$ M s^{-1}.



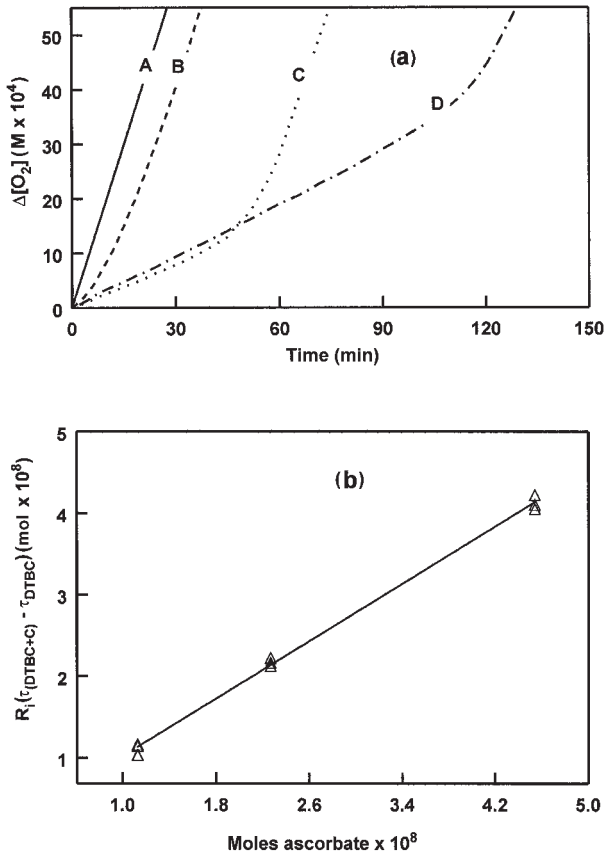
[13] $n = R_i\,[\tau_{DTBC+AP(thiol)} - \tau_{DTBC}]/AP(thiol)$

The value of *n* obtained under these conditions is 0.22 for ascorbyl palmitate and 0.19 for polythiol, assuming that both of the -SH groups of polythiol are involved. The stoichiometric factor is very low. This is probably due to autoxidation of ascorbyl palmitate and polythiol in the presence of oxygen under these conditions.

(b) In aqueous SDS micelles

The relative cooperative antioxidant effects of ascorbate, homocysteine, and polythiol with DTBC during peroxidation of methyl linoleate initiated by DBHN were determined by experiments conducted in 0.50 M SDS. Some typical profiles of oxygen uptake are illustrated in Fig. 4 to show the effect of ascorbate and DTBC, separately and in combination. The data are summarized in Tables 4 and 5. As can be seen in Fig. 4*a*, ascorbate when used alone was a rather poor inhibitor of autoxidation of methyl linoleate in SDS micelles. These results are in agreement with those of earlier studies (8). The combination of ascorbate with DTBC alone was found to greatly extend the inhibition period. The data in Table 4 show that the lengths of induction periods obtained by combinations of ascorbate and DTBC ($\tau_{(C+DTBC)}$) are longer than the sum of the separate induction periods using the same amounts of ascorbate and DTBC. The amount of synergism observed varies from 23 to 57%, depending on the ratio of ascorbate/DTBC. The quantitative studies on the effects of different ratios of ascorbate/DTBC on the length of induction periods give further insight into the efficiency with which ascorbate in the aqueous phase regenerates DTBC in the micellar phase. The extension $\tau_{(C+DTBC)} - \tau_{DTBC}$ (see column 6 in Table 5) can be taken as an indication of the amount of DTBC regenerated for a particular rate of chain initiation, R_i. Thus, the product $R_i \times (\tau_{(C+DTBC)} - \tau_{DTBC})$ is a measure of the amount of radicals trapped by ascorbate, and the product is divided by the number of moles of ascorbate to obtain the stoichiometric factor (*n*) of ascorbate, i.e., the amount of DTBC regenerated per mole of

Fig. 4. Autoxidation of methyl linoleate (5.43×10^{-5} mol) in 2.00 mL 0.50 M SDS – phosphate buffer (pH 7), initiated by DBHN (5.75×10^{-6} mol) at 37°C. (*a*) *A*, uninhibited reaction; *B*, inhibited by ascorbic acid (4.54×10^{-8} mol); *C*, inhibited by 3,5-di-*tert*-butylcatechol (4.54×10^{-8} mol); *D*, inhibited by 3,5-di-*tert*-butylcatechol (4.54×10^{-8} mol) and ascorbic acid (4.54×10^{-8} mol); $R_i = 1.08 \times 10^{-11}$ mol s^{-1}. (*b*) Plot of extension of the induction period $\times R_i$ versus moles of ascorbate (see text and Table 5).



ascorbate. The stoichiometric factor for this interaction was found to drop as the ratio of ascorbate/DTBC was varied from 0.25 to 2. At low concentrations of added ascorbate, the value of *n* was found to be approximately 1, while at higher combination ratio the value dropped to 0.68, probably due to significant loss of ascorbate via its own autoxidation. A plot of the product $R_i \times (\tau_{(C+DTBC)} - \tau_{DTBC})$ versus the moles of ascorbate added to the reaction system is drawn as shown in Fig. 4*b*. The slope of the plot gives a value of $n = 0.71$ up to 9.08×10^{-8} mol ascorbate. Similar synergetic inhibiting effects on peroxidation of methyl linoleate resulted from combinations of DTBC with homocysteine and polythiol, as shown in Figs. 5*a* and *b*. The data are summarized in Table 6. Again, the induction periods for the combinations are longer than the sum of induction periods by DTBC, homocysteine, and polythiol, separately. The value of the stoichiometric factor is 0.46 for homocysteine, 0.51 for polythiol. The degradation of polythiol was determined under the experimental conditions described above. Figure 5*b* shows that in the case of the combination of DTBC and polythiol (curve C) the rate of uptake does not return to the uninhibited rate at the end of the induction period. We find by

thiol analysis that this is due to residual polythiol after the break in the inhibition period. This polythiol alone does not give a definite inhibition period but only causes a reduction in the rate of oxygen uptake.

Experiments were carried out to determine if combinations of homocysteine and polythiol further enhance cooperative inhibition effects of DTBC and ascorbate on DBHN-initiated peroxidation of linoleate in micelles. A typical trace shown in Fig. 6 indicates that a thiol does afford additional cooperative antioxidation activities when used with DTBC and ascorbate. The results are summarized in Table 7.

3. Regeneration of DTBC, 3, by ascorbates and thiols and of ascorbate by homocysteine and polythiol

*(a) Regeneration of DTBC, **3**, from di-*tert*-butyl-ortho-quinone (DTBQ) with ascorbate and thiols in organic solvent or in SDS micelles*

Experiments were carried out by uv measurement to determine the effects of ascorbate, homocysteine, and polythiol on the oxidation product, DTBQ, of DTBC. Results of these experiments are illustrated in Fig. 7. Ascorbyl palmitate took 2 h to regenerate 43% of DTBC when a ratio of ascorbyl palmitate/DTBQ of 1 in tetrachloroethane was used. On the other hand, either ascorbyl palmitate or ascorbate regenerated DTBC *rapidly* in SDS micelles. Homocysteine and polythiol are somewhat slower to regenerate DTBC in SDS micelles than ascorbate, however, they regenerate 87% and 93% DTBC, respectively, within 60 min.

(b) Regeneration of ascorbate from dehydroascorbic acid with homocysteine or polythiol in SDS micelles

It is reported that homocysteine is able to regenerate ascorbate from its oxidation product, dehydroascorbic acid, in aqueous buffer. In this study, we find that either homocysteine or polythiol acts on dehydroascorbic acid to regenerate ascorbic acid, as previously mentioned (6), measured by analysis using potassium ferricyanide.

(c) Regeneration of DTBC, ***3,*** *from DTBQ during peroxidation in organic solvent or in SDS micelles*

To determine the effect of ascorbate on DTBQ during peroxidations of styrene and of methyl linoleate, experiments were conducted on regeneration of DTBC by ascorbyl palmitate, under conditions of AIBN-initiated peroxidation, using styrene as a substrate in 1,1,2,2-tetrachloroethane (TEC), and by ascorbate during DBHN-initiated or ABAP-initiated peroxidation of methyl linoleate in SDS micelles. The results are illustrated in Figs. 8*a* and *b*. As can be seen, the inhibition periods ($\tau_{AP+DTBQ}$), when ascorbyl palmitate is used along with 3,5-di-*tert*-butyl-*ortho*-quinone (DTBQ), are longer than those (τ_{AP}) when ascorbyl palmitate is used alone. The extended inhibition periods ($\tau_{AP+DTBQ} - \tau_{AP}$), which are attributed to regenerated DTBC, were divided by the inhibition periods by the same amounts of DTBC to give the percentage of regeneration of DTBC from DTBQ. The results show that ascorbyl palmitate does not efficiently regenerate DTBC in a nonprotic solvent. A combination of DTBQ and ascorbyl palmitate at ratio of 1 only regenerated 9% DTBC. In micelles, however, a ratio of ascorbate/DTBQ of 1 regenerated 100% DTBC during either DBHN-initiated or ABAP-initiated peroxidation as shown in Fig. 8*b* during initiation by DBHN.

4. Observation on the di-*tert*-butylsemiquinone radical (5)

The di-*tert*-butylsemiquinone radical (**5**) was observed in pulse radiolysis studies (5), but there are no reports that we are aware of on its esr spectra. Because **5** appears to be an important intermediate in our inhibition studies (vide infra), we conducted a few esr experiments on its formation and quenching by ascorbate and the polythiol. The esr spectra of other *ortho*-semiquinone radicals have been studied in some detail by different groups (24–27). The spectra can be complicated due to intramolecular and intermolecular chemical exchanges which in turn are subject to solvent effects (26). Nevertheless, we can assign a 16-line spectrum formed during photolysis with

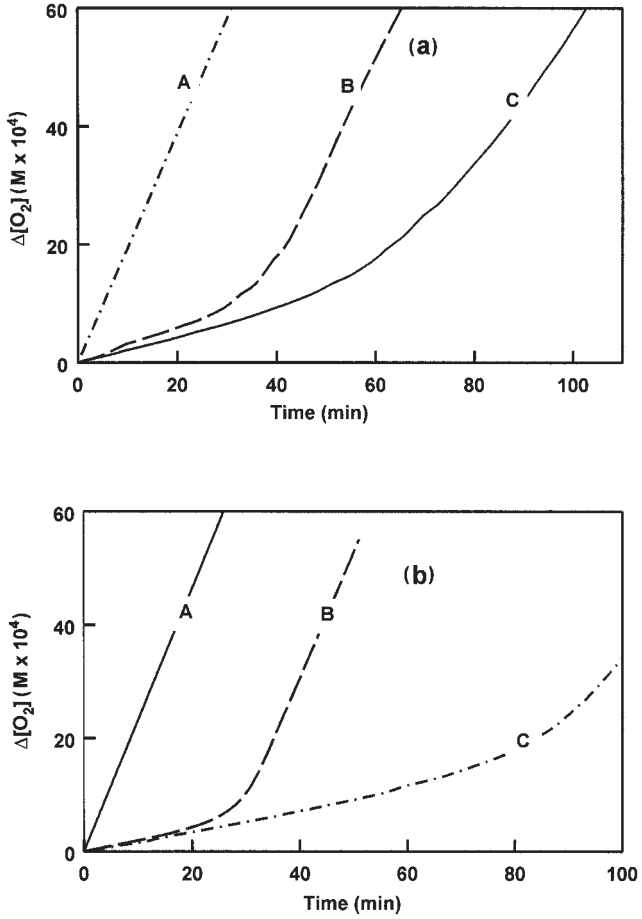
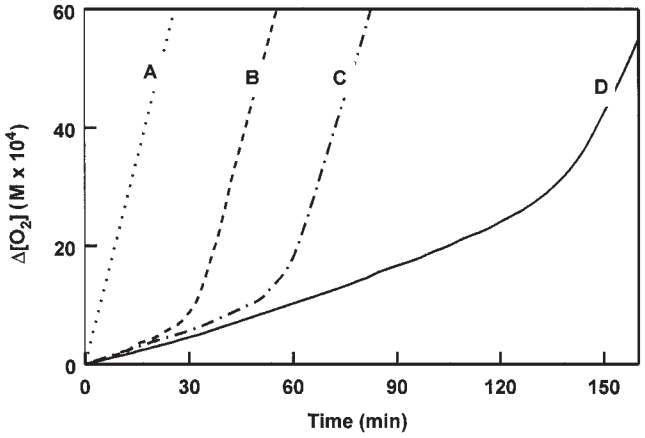
Fig. 5. Autoxidation of methyl linoleate (5.43×10^{-5} mol) in 2.00 mL 0.50 M SDS – phosphate buffer (pH 7), initiated by DBHN (8.68×10^{-6} mol) at 37°C. (*a*) *A*, uninhibited reaction; *B*, inhibited by 3,5-di-*tert*-butylcatechol (5.01×10^{-8} mol); *C*, inhibited by 3,5-di-*tert*- butylcatechol (5.01×10^{-8} mol) and homocysteine (12.04×10^{-8} mol); $R_i = 1.08 \times 10^{-11}$ mol s^{-1}. (*b*) *A*, uninhibited reaction; *B*, inhibited by 3,5-di-*tert*-butylcatechol (4.85×10^{-8} mol); *C*, inhibited by 3,5-di-*tert*-butylcatechol (4.85×10^{-8} mol) and polythiol (12.50×10^{-6} mol); $R_i = 1.21\text{x } 10^{-11}$ mol s^{-1}.



di-*tert*-butylperoxide in hexane to the di-*tert*-butylsemiquinone radical, **5** (Fig. 9*a*). This radical was remarkably persistent and the signal remained strong after several hours at room temperature. The signals were rapidly quenched on addition of polythiol (Fig. 9*b*). It was interesting to discover that this persistent spectrum was also observed (not shown) on mixing equimolar amounts of DTBC (**3**) and the DTBQ (**4**) in hexane; that is, the same semiquinone radical forms on spontaneous hydrogen abstraction from the catechol by *ortho*-quinone in laboratory light. The photolysis of **3** in methanol and di-*tert*-butylperoxide followed by the addition of ascorbic acid in methanol quenched the signal of the semiquinone radical, and there remains a doublet, $a_H = 1.86$ G, assigned to the ascorbyl radical (28) (Fig. 9*c*). On the other hand, we did not observe the semiquinone radical during the rapid reduction of DTBQ by ascorbic acid directly in the esr probe. Evidently, the conversion of DTBQ to DTBC is rapid under these conditions such that the intermediate radical is not observed.

Fig. 6. Autoxidation of methyl linoleate (5.43×10^{-5} mol) in 2.00 mL 0.50 M SDS – phosphate buffer (pH 7), initiated by DBHN (9.14×10^{-6} mol) at 37°C. *A*, uninhibited reaction; *B*, inhibited by 3,5-di-*tert*-butylcatechol (4.06×10^{-8} mol); *C*, inhibited by 3,5-di-*tert*-butylcatechol (4.06×10^{-8} mol) and ascorbic acid (4.06×10^{-8} mol); *D*, inhibited by 3,5-di-*tert*-butylcatechol (4.06×10^{-8} mol), ascorbic acid (4.06×10^{-8} mol), and polythiol (12.04×10^{-6} mol); $R_i = 2.14 \times 10^{-11}$ mol s^{-1}.



Discussion

1. The antioxidant activities of catechols

The catechol structural unit appears in nature in a wide variety of sources and has attracted a remarkable interest because of the antioxidant property it imparts to the more complex structure containing this simple system. For example, polyphenolic compounds known as flavonoids and caffeic acid, which are commonly found in fruits and vegetables, were reported frequently to possess antioxidant activity (29–33). In animals the catechol structure appears in arylethylamines (catechol amines) and in steroidal compounds (e.g., catechol estrogens), and both classes of compounds have been reported to be antioxidants. For example, L-dopa and dopamine were reported to have both toxic and antioxidant effects on animal cell cultures (34, 35), and such effects of these compounds may be significant in neural diseases (36). Catechol steroids such as 2-hydroxyestradiol and 2-hydroxyestrone were reported earlier to possess high antioxidant activity in liposomes even compared to vitamin E (37), and these compounds were reported more recently to be effective antioxidants during peroxidation of lipoproteins (38, 39) and rat liver microsomes (40, 41).

Unfortunately, these studies on antioxidant effects of natural compounds containing the catechol unit involved initiation in the presence of heavy-metal ions. Consequently, catechols could act both as *preventative* antioxidants by complexation of the metal ions as well as *chain-breaking* antioxidants. Under these conditions, it is difficult to evaluate their activities as peroxyl radical chain-breaking antioxidants.

We believe that the present inhibited oxygen-uptake procedure provides the best method to evaluate antioxidant activities of various catechols. Our results provide the first unambiguous determinations of the peroxyl-radical trapping activities of simple catechols. Two main factors appear to account for the activities of catechols **1**, **2**, and **3**: (*i*) intramolecular hydrogen bonding in the aryloxyl radical semiquinone formed in the

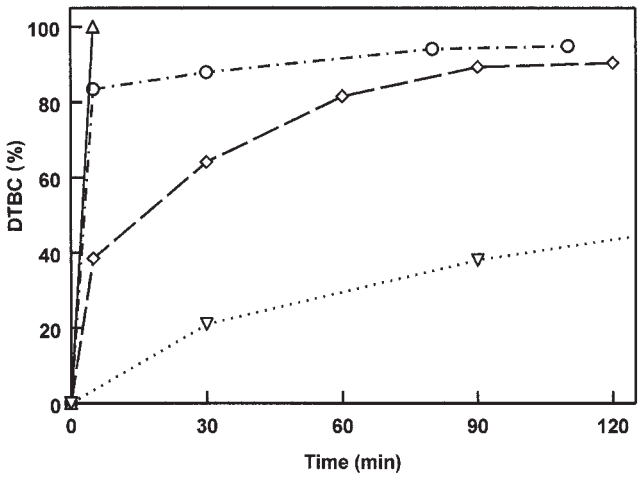
rate-determining inhibition step (eq. [7]), and (*ii*) stabilization of the radical by the inductive effects of the *tert*-butyl group(s). Hydrogen bonding of the intermediate semiquinone radical is probably the more significant effect because we find that **3** is nearly 50 times more active than propylguaiacol, where this factor is blocked by the *ortho*-methoxyl group (42). In this regard, it is interesting to note that even the unsubstituted catechol, **1**, is more active than the simple polyalkyl phenols (17). Additional activity is attributed to the inductive effect of a *tert*-butyl operating *para* (17) or *meta* to the incipient phenoxyl radical, so that the relative ratios of the k_{inh} values of **2**/**1** and **3**/**2** are 1.60 and 1.64, respectively. The stoichiometric factors, *n*, of the three catechols in homogeneous nonprotic solvent were in the range of 2.1–2.3. Details of the partial peroxyl-radical trapping by catechols is under study to clarify the factors determining *n* values. These could involve contributions of both the phenolic hydroxyls and the recombination step (eq. [8]).

The antioxidant activity of **3** dropped dramatically in the aqueous SDS micelles system by an average of approximately 50-fold. Effects of aqueous media on antioxidant activities of phenols have been the subject of considerable interest and debate (10, 15, 43, 44). In these catechols we interpret the decrease of activity in terms of a combination of H-bonding effects by water, namely, (*i*) the effect of H-bonding by water on the catechol antioxidant, which hinders abstraction of a phenolic hydrogen by peroxyl radicals, and (*ii*) *intermolecular* H-bonding between the phenolic hydroxyl in the semiquinone radical and water. The latter effect is expected to inhibit the main factor that controls the activity of **3**, i.e., *intramolecular* H-bonding in the semiquinone radical at least in nonprotic solvents.

The drop in the stoichiometric factor for **3** found in aqueous SDS micelles, by a factor of 1.7 during initiation by DBHN or by 2.2 during initiation by ABAP (Table 2), when compared to results in chlorobenzene–styrene (Table 1) contrasts with earlier results for some monohydroxyphenols, where about the same values for *n* were found in 0.50 M SDS as in solution (7). This overall decreased efficiency in the antioxidant effect of **3** in aqueous SDS is in part attributed to oxidation of **3** in this medium. Solutions in SDS were found to become yellow whereas they are stable for days in an organic solvent. Hydrogen bonding by water of the semiquinone radical may also contribute to lowering the *n* factor by inhibiting the second hydrogen from effective reaction with peroxyl radicals.

Fig. 7. Plots of regeneration of 3,5-di-*tert*-butylcatechol from 3,5-di-*tert*-butylquinone (2.03×10^{-5} M); ∇, by equimolar AP in tetrachloroethane; Δ , by equimolar AP or C in 0.50 M SDS micelles; ○, by equimolar polythiol in SDS micelles; ◇, by equimolar homocysteine in 0.50 M SDS micelles.



2. Cooperative antioxidant effects of ascorbate and thiols with di-*tert*-butylcatechol: the di-*tert* -butylsemiquinone radical

The results on cooperative effects between antioxidants in these experiments illustrate the very significant control that a

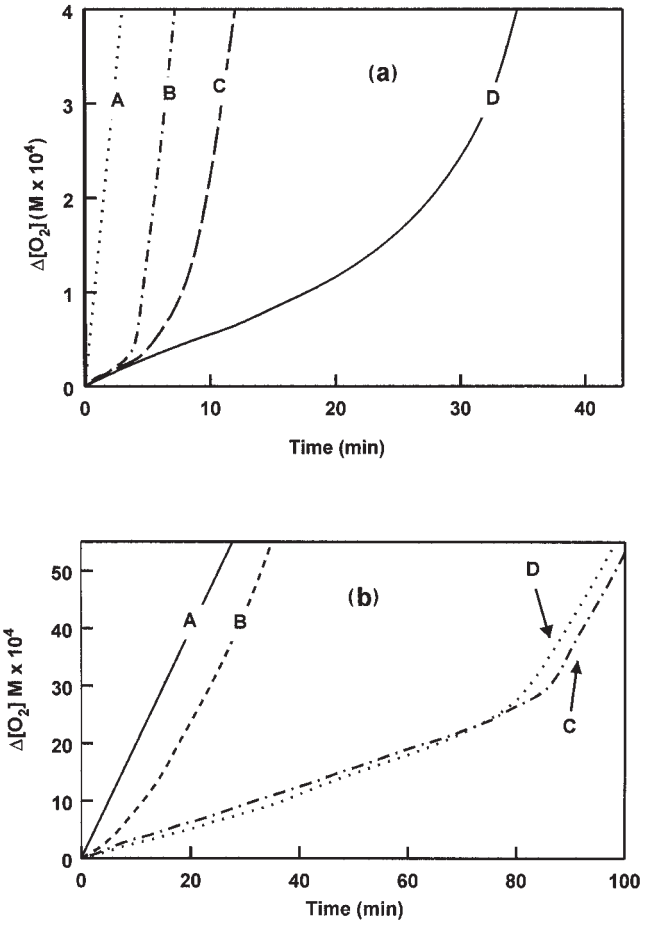
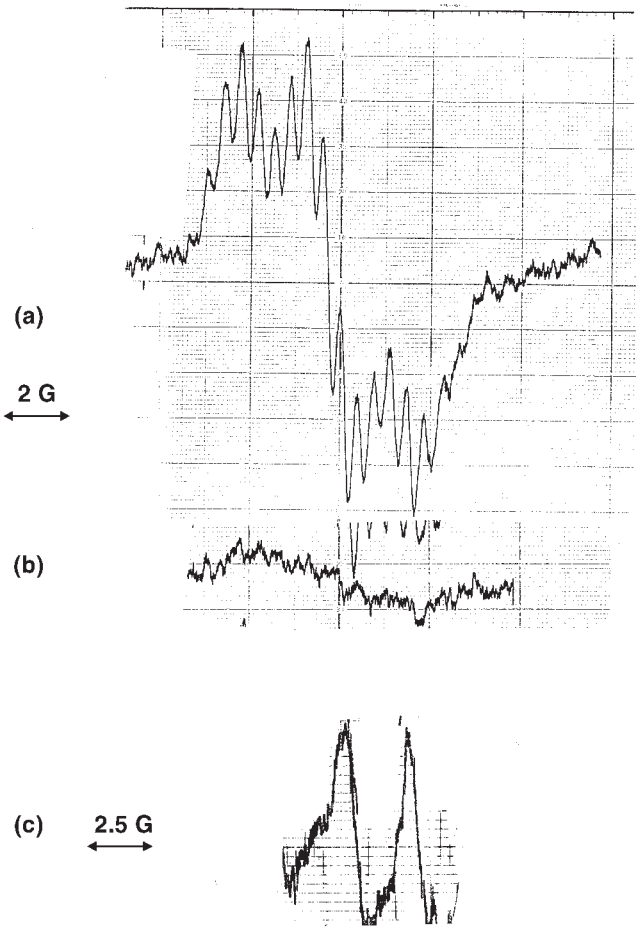
Fig. 8. (*a*) Autoxidation of styrene (6.46 M) initiated by AIBN (4.04×10^{-2} mol) in tetrachloroethane. *A*, uninhibited reaction; *B*, inhibited by ascorbyl palmitate (1.01×10^{-5} M); *C*, inhibited by 3,5-di-*tert*-butylquinone (1.02×10^{-5} M) and ascorbyl palmitate (1.01×10^{-5} M); *D*, inhibited by 3,5-di-*tert*-butylcatechol (1.02×10^{-5} M). (*b*) Autoxidation of methyl linoleate (5.43×10^{-5} mol), initiated by DBHN (5.86×10^{-5} mol) in 0.50 M SDS – phosphate buffer (pH 7). *A*, uninhibited reaction; *B*, inhibited by ascorbic acid (8.78×10^{-8} mol); *C*, inhibited by 3,5-di-*tert*-butylquinone (8.78×10^{-8} mol) and ascorbyl palmitate (8.78×10^{-8} mol); *D*, inhibited by 3,5-di-*tert*- butylcatechol (8.78×10^{-8} mol).



biphasic system like SDS micelles exerts on interaction between water- and lipid-soluble antioxidants. In homogeneous solution, combinations of ascorbyl palmitate or of polythiol with DTBC gave additive effects whereby the induction periods of DTBC were extended. In contrast, such combinations of vitamin C or polythiol with DTBC in 0.50 M SDS resulted in synergistic interactions. The amount of synergism, represented by the difference $\tau_{(C+DTBC)} - (\tau_{DTBC} + \tau_C)$ in Table 4 was in the range of 23–57%. The results are complicated by the oxidation of vitamin C, which is well known to occur readily in water (6), however, a detailed study employing various concentrations of ascorbate (e.g., Fig. 4*b*) shows that it can regenerate a mole of DTBC per mole of ascorbate. These results employing micelles resemble synergistic effects observed for the interaction of vitamin C with α-tocopherol or of Trolox reported earlier in micelles (11) and in phospholipid bilayers (18).

The observed cooperative antioxidant effects for

Fig. 9. The esr spectra. (*a*) Di-*tert*-butylsemiquinone radical, **5**, formed by photolysis of di-*tert*-butylcatechol, **3**, with di-*tert*-butyl peroxide in hexane. (*b*) Scan from (*a*) immediately after addition of polythiol in hexane. (*c*) Spectrum assigned to ascorbyl radical after quenching of **5** by addition of ascorbic acid in methanol. Concentrations are in the range of 10–50 mM.



combinations of homocysteine or of polythiol with the catechol DTBC (Table 6) imply regeneration of DTBC from the intermediate semiquinone radical (**5**) by hydrogen transfer from the thiols. This mechanism is supported by the observed rapid quenching of the otherwise persistent radical upon addition of polythiol in solution (Figs. 9*a*, *b*). While this appears to be a novel thiol mediated regeneration of a catechol from its semiquinone radical, regenerations of phenols from phenoxyl radicals by thiols are known to be facile (45–47), including repair of the galvinoxyl (48) and Trolox C radical (49) by thiols and of the vitamin E radical during inhibition of free-radical peroxidation of phosphatidylcholine liposomes by combinations of vitamin E and cysteine (50).

It is of particular interest to find that *combinations* of three inhibitors, DTBC, vitamin C, and a thiol provided additional cooperative inhibition effects. As shown in Table 7, homocysteine or polythiol gave additional *cooperative extensions* of induction periods provided by the cooperative effects of DTBC + ascorbate. A typical trace of such effects is shown in Fig. 6. The mechanism of such "combination effects" is a matter of some speculation. Nevertheless, it is probable that the

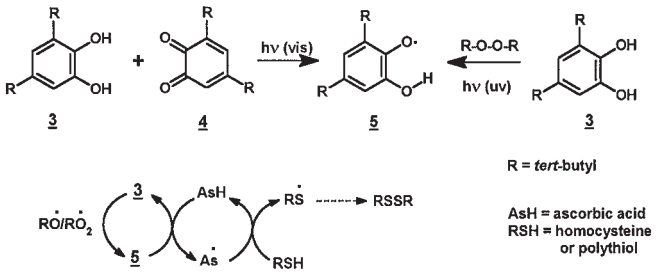
© 1998 NRC Canada

thiols act to regenerate the vitamin C from the ascorbyl radical and (or) from dehydroascorbate. The latter regeneration was observed earlier to be facile in aqueous SDS micelles (6), and the thiols and ascorbate are in the same (aqueous) phase in these current studies.

The quinone, **4**, was shown earlier (5) to convert to the catechol **3** by reduction with ascorbate in aqueous methanol. Our results using the quinone combined with ascorbate added to peroxidizing methyl linoleate in SDS micelles demonstrate that this reduction occurs efficiently in the presence of a radical chain reaction. This result, together with the rapid reduction of the quinone to the catechol in SDS micelles at pH 7, indicates that rapid electron transfer from ionized ascorbate ($pK_1 = 4.2$) (28) is probably the initial step in this reduction. The much faster conversion of DTBQ to DTBC in aqueous SDS (pH 7) by ascorbate compared to the conversion in a nonprotic solvent (tetrachloroethane) is expected, considering the known effects of polar protic solvents on electron transfer reactions (51).

The relationships between compounds **3**, **4**, and intermediate **5** are outlined in Scheme 1. The observations on the cooperative and synergistic effects involving regeneration of DTBC by ascorbate and the combination effect with a thiol and ascorbate are accounted for by indicating that the processes are mediated via the intermediate semiquinone radical, **5**. Our results on the significant antioxidant activity of catechols, the persistent semiquinone radical, facile reduction of the quinone (**4**) to the catechol (**3**), and synergistic interactions of ascorbate and thiols with the catechol in an aqueous system have significant implications for the antioxidant activity of various natural antioxidants and their interactions in natural systems. For example, the antioxidant activity of the polyhydroxy flavonoids, currently receiving considerable attention, is probably due to the catechol group, as suggested in recent calculations (24). Persistent semiquinone radicals could be responsible for the persistent "residual phenoxy structures formed" in CTMP and TMP papers (4), which are significant in the yellowing process. In this regard, the combination effects of inhibitors we found is expected to play an important role in the prevention of yellowing. In human systems, it now seems probable that ascorbate and natural thiols play very important roles to maintain molecules such as catechol amines and steroidal catechols in their reduced forms (34–41).

Scheme 1



Experimental

Materials and preparations

The solvents used, chlorobenzene, 1,1,2,2-tetrachloroethane (TCE), methanol, and water, were of HPLC grade. Styrene was purchased from the Aldrich Chemical Co. and was passed through a packed column prior to using to remove the inhibitor. Methyl linoleate was purchased from Nuchek Prep, Inc. AIBN and ABAP were obtained from Polysciences Inc. DBHN was prepared by a known method (52). Catechol, 4-*tert*-butylcatechol, DTBC, ascorbic acid, and 5-5'-dithiobis(2-nitrobenzoic acid) (DTNB) were purchased from Aldrich Chemical Co., and dehydroascorbic acid from Pfaltz and Bauer, Inc. Polythiol was a gift from Dr. J.K.S. Wan from Queen's University, Kingston, Ont., and Trolox, a gift from Hoffman–LaRoche, Nutley, New Jersey. Di-*tert*-butyl-*ortho*-quinone (DTBQ) was prepared using a known method (53). Potassium ferricyanide was obtained from Fisher Scientific Co. Phosphate buffer (pH 7) was prepared from 0.05 M each of NaH_2PO_4 and Na_2HPO_4 in glass-distilled water containing 1×10^{-4} M EDTA and adjusted to the desired pH with NaOH. Immediately before use, this solution was passed through a Chelex-100 column (Bio-Rad 50–100 mesh) to remove traces of heavy metals. Electrophoresis pure sodium dodecyl sulfate (SDS) was purchased from Bio-Rad Laboratories. Stock solutions of 0.50 M SDS were prepared in the 0.10 M phosphate buffer (pH 7) described above.

Autoxidation procedure

Autoxidations and inhibition studies of oxygen uptake were carried out at 30 or 37°C (760 Torr) (1 Torr = 133.3 Pa) under oxygen in a sensitive dual-channel calibrated pressure transducer system that is described elsewhere (54, 55). For AIBN-initiated autoxidations, a known amount of styrene diluted to 2 mL with chlorobenzene or tetrachloroethane was shaken in a calibrated cell on the pressure transducer until a steady base line on a recorder was established. After constant oxygen uptake started by injecting a known amount of AIBN, the uninhibited autoxidation was measured, followed by injection of a known amount of inhibitor to measure induction periods and determine its antioxidant activity. The R_i was determined by injecting a known amount of PMHC and measuring the time until the rate returned to the uninhibited rate of oxygen uptake. For DBHN-initiated autoxidation, a 2.00 mL sample of DBHN in 0.50 M SDS was added to a sample cell, followed by a known amount of methyl linoleate; the rate of constant oxygen uptake was measured, followed by injection of the antioxidants in buffered SDS and determination of the inhibition periods. For ABAP-initiated autoxidation, typically 50 μL of methyl linoleate was added to 2.00 mL of 0.50 M SDS in a calibrated cell. This mixture was shaken to establish a steady base line followed by injection of 100 μL of 0.50 M ABAP in buffer to start the reaction. Known amounts of the antioxidants in SDS were then injected into the cell and inhibition periods were measured as before.

Analyses

Thiol analysis was performed by the Ellman method (56) using the reaction with DTNB and measuring the absorption of the reaction mixture at 412 nm. Ascorbic acid was determined by its reaction of potassium ferricyanide, the latter forming a bright-yellow solution in phosphate buffer that absorbs at 420 nm (6). DTBC and DTBQ were analysed by measuring the absorption at 281 and 412 nm, respectively.

Electron-spin resonance measurements were made directly

in the probe of a Varian E–3 bench-top spectrometer at room temperature. Photolysis experiments using an Oriel 200 W super pressure Hg arc on DTBC in hexane containing di-*tert*-butylperoxide (Pfaltz and Bauer) or experiments on combinations of DTBC and DTBQ were conducted in quartz tubes under argon. Due to solubility limits, experiments using ascorbic acid were carried out in methanol under argon in flat esr tubes or capillaries. Concentations of compounds used were generally in the range of 10–50 mM.

Acknowledgements

Support of this research by the Mechanical and Chemimechanical Wood-Pulps Network, part of Canada's Network of Centres of Excellence, is gratefully acknowledged. We thank Roger Smith and Allister MacDonald for construction of the sensitive pressure – transducer – oxygen-uptake apparatus required for this research and Krista McLeod for prepartion of di-*tert*-butylhyponitrite.

Dynamics of silicate exchange in highly alkaline potassium silicate solutions

Eva Vallazza, Alex D. Bain, and Thomas W. Swaddle

Abstract: The problem of measuring the kinetics of Si exchange between aqueous silicate species by ^{29}Si NMR has been revisited, using highly alkaline KOH solutions (2.8 mol Si^{IV} per kg solvent, $[Si^{IV}]/K_2O = 0.43$) at 60–90°C to minimize the number of silicate species present. Longitudinal ^{29}Si relaxation times T_1 and apparent rate constants estimated from line-shape analysis (LSA) varied markedly with the degree of purity of the KOH used, but rate constants k obtained by selective inversion–recovery (SIR) using the CIFIT data-fitting program were independent of the source of KOH and were smaller than those obtained from LSA by at least an order of magnitude. Although only four kinetically significant silicate anions (monomer M, dimer D, linear trimer L, and cyclic trimer C) were present, overlap of the D and L resonances prevented complete analysis of the SIR data. True rate constants could therefore be obtained only for the M–D exchange (for formation of D, k_1 (90°C) = 0.13 ± 0.01 kg mol $^{-1}$ s^{-1}, $\Delta H_1^{\ddagger}$ = 67.4 kJ mol^{-1}, $\Delta S_1^{\ddagger}$ = –78 J K^{-1} mol^{-1}; for dissociation of D, k_{-1} (90°C) = 1.4 ± 0.1 s^{-1}, $\Delta H_{-1}^{\ddagger}$ = 64.7 kJ mol^{-1}, and $\Delta S_1^{\ddagger}$ = –66 J K^{-1} mol^{-1}). Models that included L as the precursor of C (MDLC mechanism) showed, within the limitations imposed by D–L band overlap, that the reactivities of M, D, L, and C in Si-O-Si link formation or dissociation were all roughly comparable. Good fits of the experimental data, however, and equally reliable rate constants for the M–D exchange, could be obtained with models that ignored the presence of L entirely (MDC mechanism). The simple MDC model also provides consistent apparent rate constants k_C and k_{-C} for the *overall* formation of C from M + D and the reverse process, respectively, by SIR of either M or C ($\Delta H_C^{\ddagger}$ = 76.5 kJ mol^{-1}, $\Delta S_C^{\ddagger}$ = –57 J K^{-1} mol^{-1}; $\Delta H_{-C}^{\ddagger}$ = 88.6 kJ mol^{-1}, and $\Delta S_{-C}^{\ddagger}$ = –7 J K^{-1} mol^{-1}).

Key words: kinetics, silicates, ^{29}Si NMR.

Résumé : On a réexaminé le problème associé à la mesure de la cinétique de l'échange du Si entre des espèces silicates aqueuses à l'aide de la RMN du ^{29}Si; à cette fin, opérant à des températures allant de 60 à 90°C, on a utilisé des solutions extrêmement alcalines de KOH (contenant 2,8 mol Si^{IV} par kg de solvant, $[Si^{IV}]/K_2O = 0,43$) afin de minimiser le nombre d'espèces de silicate. Les temps de relaxation longitudinale du ^{29}Si, T_1, ainsi que les constantes apparentes de vitesse évaluées sur la base d'une analyse de la forme de la raie («LSA») varient beaucoup avec le degré de pureté du KOH utilisé; toutefois, les constantes de vitesse k, obtenues par une récupération sélective de l'inversion («SIR») en utilisant le programme «CIFIT» d'ajustement des données, sont indépendantes de la source de KOH et elles sont au moins 10 fois plus faibles que celles obtenues par la méthode de «LSA». Même si seulement quatre anions silicates (monomère, M; dimère, D; trimère linéaire, L; trimère cyclique, C) cinétiquement significatifs sont présents, le recouvrement des résonances des entités D et L rend impossible l'analyse complète des données «SIR». On n'a donc pu obtenir les vraies constantes de vitesse que pour l'échange M–D (pour la formation de D, k_1 (90°C) = 0,013 ± 0,01 kg mol^{-1} s^{-1}, $\Delta H_1^{\ddagger}$ = 67,4 kJ mol^{-1} et $\Delta S_1^{\ddagger}$ = –78 J K^{-1} mol^{-1}; pour la dissociation de D, k_{-1} (90°C) = 1,3 ± 0,1 s^{-1}, $\Delta H_{-1}^{\ddagger}$ = 64,7 kJ mol^{-1} et $\Delta S_{-1}^{\ddagger}$ = –66 J K^{-1} mol^{-1}). Les modèles qui incluent L comme précurseur de C (mécanisme MDLC) démontrent, sujet aux limitations imposées par le recouvrement des bandes D–L, que les réactivités de M, D, L et C sont assez semblables pour la formation et la dissociation de la liaison Si-O-Si. Toutefois, de bons accords avec les données expérimentales et des constantes de vitesse également fiables pour l'échange M–D pourraient aussi être obtenus à l'aide de modèles qui ignoreraient complètement la présence de L (mécanisme MDC). Le modèle MDC simple fournit aussi des constantes de vitesse apparentes k_C et k_{-C} cohérentes respectivement pour la formation *globale* de C à partir des entités M + D ainsi que pour le processus inverse, par «SIR» des entités soit M ou C ($\Delta H_C^{\ddagger}$ = 76,5 kJ mol^{-1} et $\Delta S_C^{\ddagger}$ = –57 J K^{-1} mol^{-1}; $\Delta H_{-C}^{\ddagger}$ = 88,6 kJ mol^{-1} et $\Delta S_{-C}^{\ddagger}$ = –7 J K^{-1} mol^{-1}).

Introduction

Aqueous solutions of silicates and aluminosilicates are important in a wide variety of technological, geological, and biomedical contexts, as noted in a recent review (1). Silicate anions occur in alkaline aqueous solution in at least 25 oligomeric forms, in addition to the orthosilicate monomer $(HO)_{4-z}SiO_z^{z-}$. In their pioneering studies, Harris et al. (2–5) identified most of these oligomers by ^{29}Si NMR spectroscopy, a technique that, along with ^{17}O NMR, also reveals that the oligomers (other than special cases such as the cubic cage species $Si_8O_{20}^{8-}$ (6)) undergo rapid intermolecular Si–Si site exchange (7–13).

It has proved difficult, however, to obtain reliable rate constants for exchange between specific silicate species in typical solutions with pH around 11, where the average charge per Si atom is about –1, because of the excessive number of species present. The number of detectable oligomeric species diminishes as the pH and temperature are raised (14), whereas the rates of Si site exchange increase with rising temperature but decrease with rising pH (10). Thus, the most favorable conditions for the quantitative study of Si–Si exchange kinetics by NMR are high pH and elevated temperatures — conditions that have some intrinsic technological interest in relation to the synthesis of zeolite catalysts and the carryover of silicate in the Bayer process for bauxite refining (1). An added complication, however, is that traditional NMR line-shape analysis (LSA) methods of determining exchange rates are subject to error because of nonkinetic contributions to the line widths, particularly line broadening by adventitious paramagnetic contaminants (8, 10), and this problem can be expected to worsen with the addition of high concentrations of alkalis that inevitably contain traces of paramagnetic substances (15).

Fortunately, the kinetics of Si–Si chemical exchange can be studied without these complications by the technique of *selective inversion–recovery* (SIR) (8, 10, 12), in which the magnetization of the population of one exchanging species is inverted and the propagation of the magnetic perturbation to the other species through chemical exchange is monitored. The rate of disappearance of the imposed perturbation of magnetization is then a function of the chemical exchange rates and nuclear spin-lattice relaxation times T_1 of the species involved in exchange, and numerical analysis can, in principle, separate these parameters to yield unambiguous chemical exchange rate constants. Rigorous analysis of the evolution of the observed spectral changes with time t is not trivial, particularly for intermolecular processes such as silicate–silicate exchange, and was not attempted in our previous report on this topic (10). The original ^{29}Si SIR study by Harris and co-workers (8) gave rate constants only for the dimerization of orthosilicate (0.21 and 1.06 kg mol^{-1} s^{-1} at 83 and 107°C, respectively) in a solution of 2.8 mol kg^{-1} SiO_2 in aqueous KOH (K:Si = 3.8:1). Bell and co-workers (12) considered the interconversion of the monomer M, the dimer D, and the cyclic trimer C (Fig. 1) in SIR experiments on solutions of 3 mol% SiO_2 in 10 mol% aqueous KOH, but only for a single unspecified temperature, and the possible involvement of other oligomers was not taken into account. Thus, there is need for a reexamination of the problem of silicate exchange kinetics.

The present article describes an attempt to extract reliable rate constants k by the SIR and LSA methods for silicate exchange at 60–90°C in highly alkaline potassium silicate solutions, in which the only detectable silicate species present were the monomer $(HO)_{4-z}SiO_z^{z-}$ (M), the dimer $(HO)_{6-z}(Si_2O)O_z^{z-}$ (D), the "linear" or acyclic trimer $(HO)_{8-z}(Si_3O_2)O_z^{z-}$ (L), the cyclic trimer $(HO)_{6-z}(Si_3O_3)O_z^{z-}$ (C), and the branched tetramer $(HO)_{8-z}(Si_4O_4)O_z^{z-}$ (B) (Fig. 1). We focus upon results from two particular samples, called I and II, that were almost identical except for the source of the KOH used. Numerical analysis of SIR data was carried out using the CIFIT program (16–18), which is based on Muhandiram and McClung's SIFIT procedure (19). The rate constants so obtained are subject to uncertainties arising from the irreducible chemical complexity of the exchanging silicate system, but nevertheless the results present a more complete picture than previously published studies (8, 10, 12). Comparison is made with rate constants estimated from complete line-shape analyses. In particular, it is shown that trace impurities in the alkali lead to substantially shortened longitudinal relaxation times T_1 and to apparent rate constants for Si–Si exchange from LSA that are too large.

Experimental

Materials

All alkaline solutions were prepared in Teflon–FEP containers, which were soaked successively in dilute solutions of HCl, HNO_3, and Na_2H_2EDTA prior to use. Amorphous silica was prepared by dropwise hydrolysis of freshly distilled silicon tetrachloride (Fisher, technical grade) in water. The resulting gel was dried, crushed, and washed with water. Potassium hydroxide solutions were prepared by dissolving solid KOH (BDH ACS grade for sample I, or Alfa Aesar, 99.995% pure on the basis of metals content, for sample II) in freshly boiled solvent consisting of approximately 75% D_2O (Aldrich, 99.9 at.% D) and 25% deionized distilled H_2O.

Sample preparation

Samples were prepared directly in Teflon–FEP NMR tube liners by dissolving a known quantity of silica (dried at 250°C) in a weighed portion of KOH solution that had been standardized with potassium hydrogen phthalate. Dissolved oxygen was purged from the sample with N_2, then the tube was closed with a Teflon stopper and sealed with Parafilm. The compositions of samples I and II are given in Table 1 in various ways to facilitate comparison with other published work.

NMR measurements

Silicon-29 spectra were obtained at 59.624 MHz on a Bruker AMX2-300 spectrometer using a 10 mm probehead with spin rate of 10 Hz. The glass coil supports of the probe and the NMR glass tube gave rise to a broad signal centered around –40 ppm relative to the orthosilicate resonance. Spectra were

recorded over a temperature range from 4.5 to 90°C. Temperature calibration was carried out using the proton spectra of neat ethylene glycol (Fisher, ACS Certified) (20).

The ^{29}Si 90° pulse width was determined for each temperature and was between 22 μs (at 4.5°C) and 45 μs (at 90°C). Longitudinal relaxation times T_1 (Table 2) were estimated by nonselective inversion–recovery measurements (180°–τ–90°–FID–t_d), and pulse intervals were chosen to be greater than 5 times the maximum measured T_1, i.e., intervals of 30–75 s for sample I and 75–300 s for sample II. Selective inversion–recovery (SIR) experiments were conducted as described by Morris and Freeman (21). A DANTE sequence of 18 pulses of 5 μs with 0.4–0.7 ms interpulse delay was used to invert selectively the Q^0 Si spins[2] of the monomeric silicate anion M, the Q^1 spins of Si of the dimer D and linear trimer L (overlapping bands), or the Q^2 Si spins in three-membered rings of cyclic trimer C and branched tetramer B (overlapping bands). Results of M-, (D + L)-, and C-SIR experiments on sample I at 90°C, and sample II at 60 and 90°C, have been deposited as supplementary material.[3]

Calculations

Complete line-shape analyses (LSA) were carried out using the Fortran program GNMR derived from the exchange-modified Bloch equations (10). For each sample, the low-temperature (4.5°C) unbroadened spectrum was simulated manually by iterating the positions, line widths, and areas of five computer-generated Lorentzian peaks. Reaction models were tested to find appropriate sets of rate equations (kinetic matrices (22)) that would replicate the observed line broadening.

SIR curves were calculated using the C program CIFIT (16, 17), designed to fit data from SIR experiments of systems undergoing slow chemical exchange. CIFIT searches for the set of parameters (rate constants k, relaxation times T_1, and initial and equilibrium band intensities M_0 and M_∞) that best fits the experimental data. Since the three observed peaks have different line widths, peak areas were used to describe changes in z-magnetizations. They were calculated by integrating the simulated peaks obtained by deconvoluting spectra processed with an artificial line broadening of 1 Hz using the Bruker WINFIT program. For each SIR experiment the normalized peak areas were fitted optimally using the CIFIT program with various mechanistic models. Since the number of parameters was large, it was generally necessary to allow only the M_0 and M_∞ values and limited sets of k and T_1 to vary in a given computation; the best-fit values of k and T_1 and the associated uncertainties were then determined by manual iteration (18). In cases where the propagated SIR effect on a particular peak was weak, k and T_1 values determined for that peak by its direct inversion were inserted as fixed parameters.

[2] The connectivity n of a silicon center is denoted as Q^n ; thus, the connectivity of a terminal SiO_4 unit is Q^1, and that of the Si centers in the cubic octamer $Si_8O_{20}^{8-}$ is Q^3.

[3] Tables S1–S9 (10 pages), giving integrated signal intensities as functions of delay time for M-, (D + L)-, and C-SIR experiments on sample I at 90°C, and on sample II at 60 and 90°C, may be purchased from: the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Table 2. Longitudinal ^{29}Si relaxation times from nonselective inversion–recovery.

Sample	Temp./°C	Longitudinal relaxation times T_1/s		
		M peak	Combined D/L band	Combined C/B band
I	90	7	6	6
II	90	20	21	17
II	60	16	9	13

Results

It can be inferred immediately from the experimental spectra shown in Figs. 2 and 3 that there is a much larger intrinsic line broadening for sample I (that with the less pure KOH) than for sample II, and hence that line-shape analysis for sample I is likely to overestimate the chemical exchange rates. Furthermore, although the spectra at 90°C (the optimum temperature for SIR experiments on the samples used in this study) for both samples show a single band at chemical shift $\delta \approx -7.0$ ppm, it is clear from the low-temperature spectra that this feature includes intensity from the minor but not negligible band at $\delta \approx -6.9$ ppm due to the Q^2 silicons of the linear trimer L, as well as from the dimer D. Extrapolation from spectra run at lower temperatures indicated that the band comprised 80% D with 20% L at 60°C, and 82% D with 18% L at 90°C. These and other relative integrated band intensities allowed calculation of the actual concentrations of M, D, L, and C in the two samples at 60 and 90°C (Table 1).

On the other hand, the resonance expected for the Q^2 silicon of L at $\delta \approx -16.6$ ppm (14) was not observable (probably because of strong kinetic line broadening) and was of necessity neglected. The small feature discernible at $\delta \approx -9.5$ ppm, attributable to the branched tetramer B, remained distinct from 4.5 to 90°C for sample II at least, and therefore corresponded to exchange processes slow enough to be disregarded in calculating the integrated C signal intensity.

Longitudinal ^{29}Si relaxation times T_1 calculated from nonselective inversion experiments are listed in Table 2. Values of T_1 obtained at 90°C may be partly averaged by chemical exchange (23); Kinrade et al. (15) report that onset of averaging of T_1 occurred above 50°C for a sample containing 2.2 mol kg^{-1} of each of NaOH and SiO_2 but, in the present study

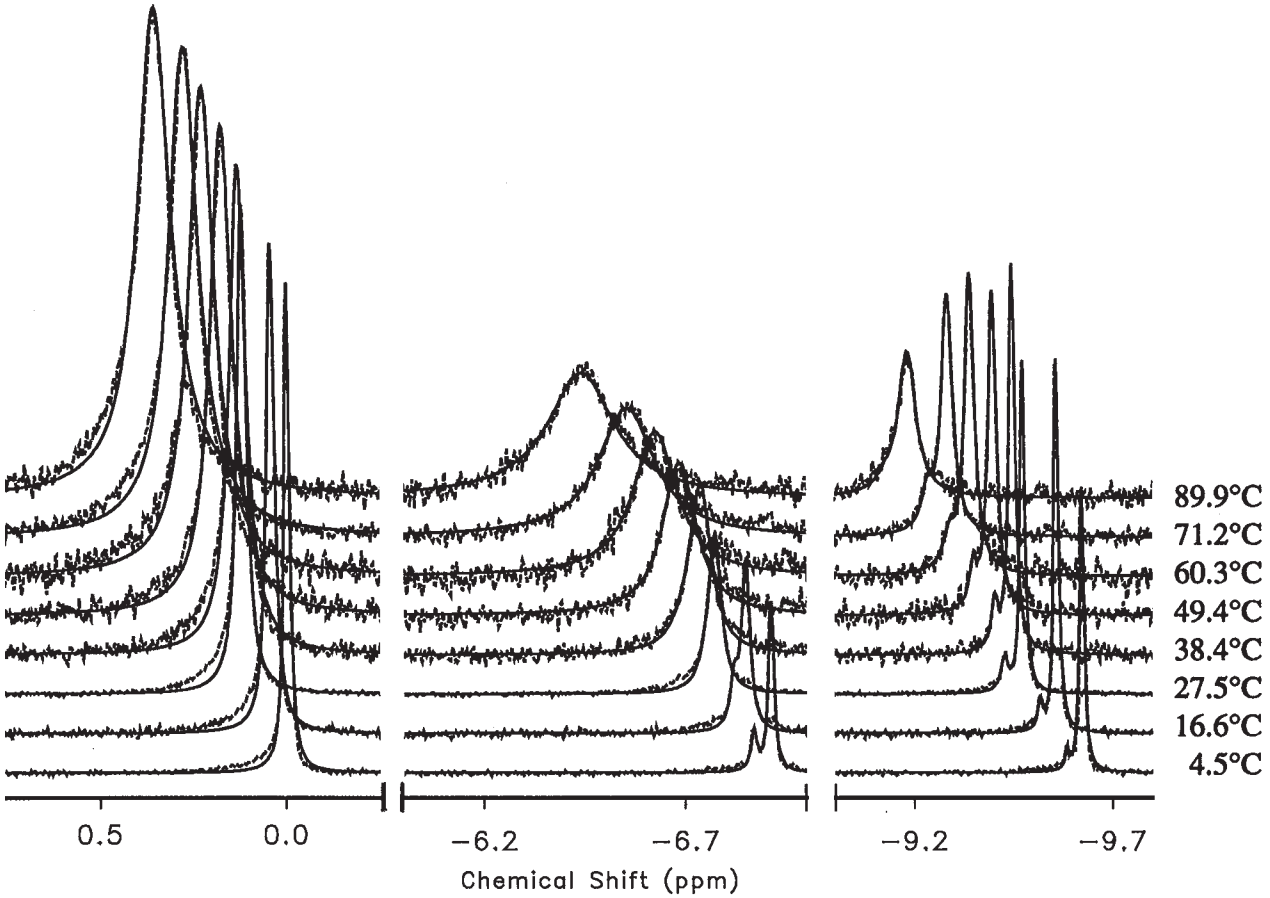
Fig. 2. Comparison of experimental (dotted lines) and simulated (solid lines) spectra for sample I at various temperatures. The simulations are based on the assumption that the spectrum at 4.5°C shows no chemical exchange. Small variations in resonance frequencies caused by phenomena other than spin–site exchange, as well as shifts in population equilibria, were corrected manually. The branched tetramer peak at about –9.5 ppm was neglected in line-shape analyses and in the interpretation of selective inversion–recovery experiments.



with higher alkalinity and consequently slower chemical exchange, T_1 data obtained at 60°C should be reasonably close to the values for independent silicate centers.

When fitting the data in both line-shape analysis and selective inversion–recovery, two main mechanisms were considered:

MDC mechanism:

[1] $M + M \underset{k_{-D}}{\overset{k_D}{\rightleftharpoons}} D$

$k_D' = k_D[M] = k_{-D}[D]/[M]$; $K_D = k_D/k_{-D} = [D]/[M]^2$

[2] $M + D \underset{k_{-C}}{\overset{k_C}{\rightleftharpoons}} C$

$k_C' = k_C[D] = k_{-C}[C]/[M]$; $K_C = k_C/k_{-C} = [C]/[D][M]$

MDLC mechanism:

[3] $M + M \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} D$

$k_1' = k_1[M] = k_{-1}[D]/[M]$; $K_1 = k_1/k_{-1} = [D]/[M]^2 = K_D$

[4] $M + D \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} L$

$k_2' = k_2[D] = k_{-2}[L]/[M]$; $K_2 = k_2/k_{-2} = [L]/[D][M]$

Table 3. Equilibrium constants, and associated enthalpies and entropies of reaction, for the MDLC reaction scheme under the

Parameter	$i = 1$	$i = 2$	$i = 3$
K_i (60°C)	0.088[a]	0.117[a]	1.64
K_i (90°C)	0.096[a]	0.103[a]	1.30_5
ΔH_i/kJ mol^{-1}	+2.7	–4.4	–7.7
ΔS_i/J K^{-1} mol^{-1}	–12	–31	–19

[a] Units: kg mol^{-1}.

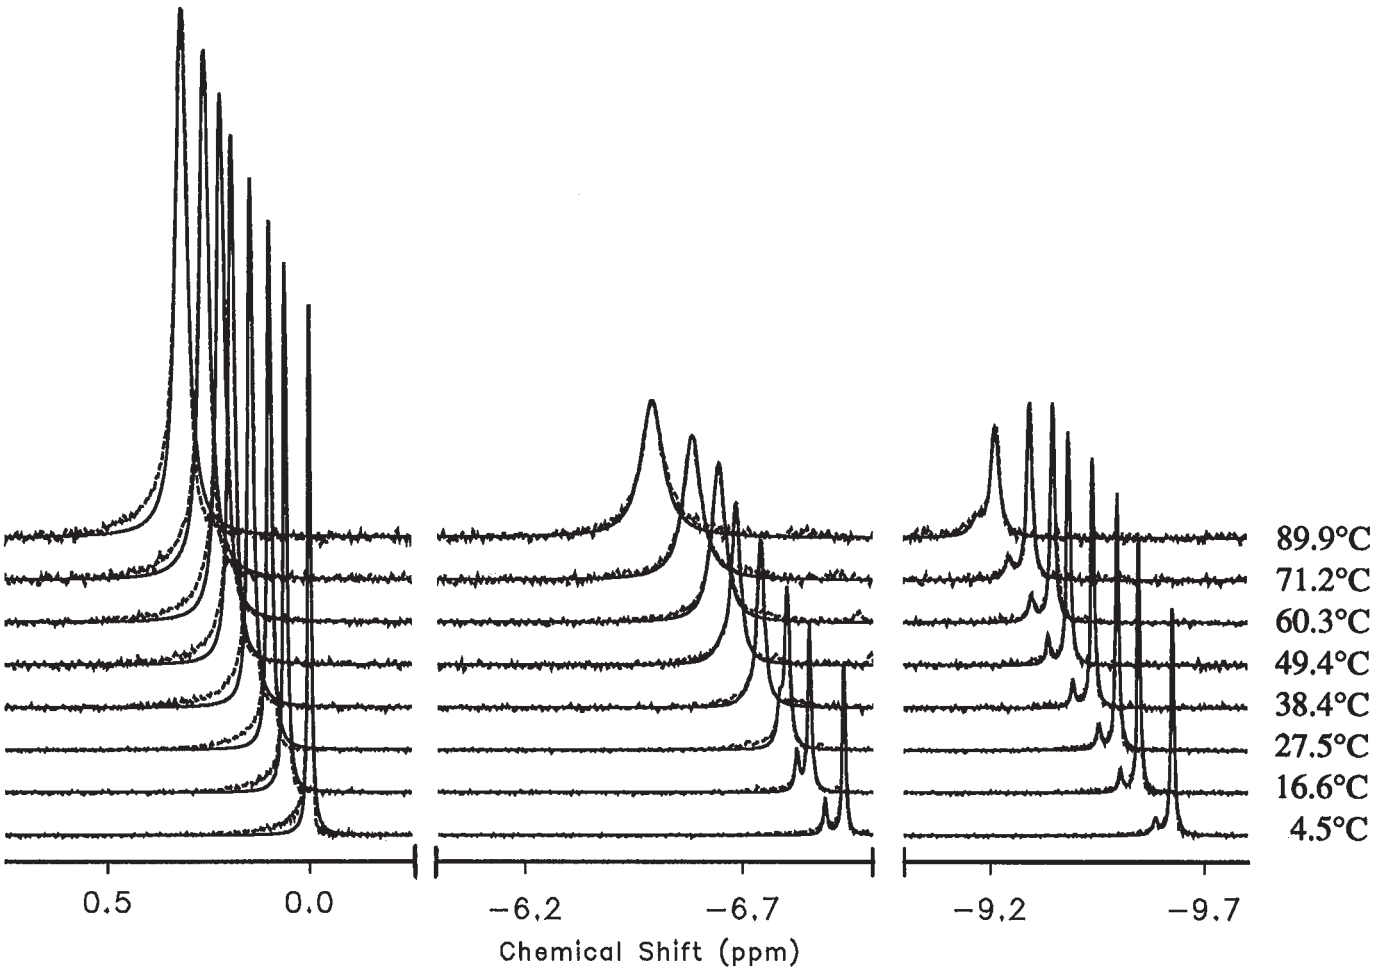
[5] $L \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} C$

$k_3 = k_{-3}[C]/[L]$; $K_3 = k_3/k_{-3} = [C]/[L]$; $K_2K_3 = K_C$.

Here, the various k_i are rate constants and the K_i are equilibrium constants. Values of K_i and the associated enthalpies (ΔH_i) and entropies (ΔS_i) estimated from the data of Table 1 and cognate data for lower temperatures are given in Table 3. The MDC mechanism differs from the MDLC mechanism in that participation of the linear trimer L in the exchange processes is discounted, i.e., either addition of monomer to dimer and subsequent ring closure to form the trimer can be

© 1998 NRC Canada

Fig. 3. Comparison of experimental (dotted lines) and simulated (solid lines) spectra for sample II at various temperatures. Details as for Fig. 2.



represented by a single rate constant k_C or, contrary to chemical intuition, L is not an intermediate in the D–C exchange process.

Selective inversion–recovery analysis

As is shown in the Appendix, the kinetic equation for the MDC mechanism is

$$[6]\quad \frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} M \\ D \\ C \end{bmatrix} = k_D'\begin{bmatrix} -1 & \frac{M_\infty}{D_\infty} \\ 1 & -\frac{M_\infty}{D_\infty} \end{bmatrix}\begin{bmatrix} M \\ D \end{bmatrix} + k_C'\begin{bmatrix} -1 & 0 & \frac{M_\infty}{C_\infty} \\ 0 & -2\frac{M_\infty}{D_\infty} & 2\frac{M_\infty}{C_\infty} \\ 1 & 2\frac{M_\infty}{D_\infty} & -3\frac{M_\infty}{C_\infty} \end{bmatrix}\begin{bmatrix} M \\ D \\ C \end{bmatrix}$$

where the italicized quantities M, D, and C are the magnetizations of the monomer M, dimer D, and cyclic trimer C, respectively. The subscripts ∞ indicate equilibrium values, and these are proportional to the corresponding concentrations multiplied by the number of nuclei per molecule of the particular kind observed. The branched tetramer was excluded and the area of the peak at –9.7 ppm was attributed to the cyclic trimer alone. If the participation of the linear trimer as the precursor of the cyclic trimer in the exchange processes is included (MDLC mechanism), and it is assumed that all three Si nuclei in L were represented in the (D + L) band, the kinetic equation becomes

© 1998 NRC Canada

$$[7]\quad \frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} M \\ D \\ L \\ C \end{bmatrix} = k_1'\begin{bmatrix} -1 & \frac{M_\infty}{D_\infty} \\ 1 & -\frac{M_\infty}{D_\infty} \end{bmatrix}\begin{bmatrix} M \\ D \end{bmatrix} + k_2'\begin{bmatrix} -1 & 0 & \frac{M_\infty}{L_\infty} \\ 0 & -2\frac{M_\infty}{D_\infty} & 2\frac{M_\infty}{L_\infty} \\ 1 & 2\frac{M_\infty}{D_\infty} & -3\frac{M_\infty}{L_\infty} \end{bmatrix}\begin{bmatrix} -1 & \frac{L_\infty}{C_\infty} \\ 1 & -\frac{L_\infty}{C_\infty} \end{bmatrix}\begin{bmatrix} L \\ C \end{bmatrix}$$

In fact, only the two Q^1 nuclei in L are expected to contribute to the intensity of the (D + L) band, but for computational purposes the signal of the unobservable third (Q^2) nucleus had to be assumed to be included to conserve the number of NMR-active sites in eqs. [4] and [5]. It should be noted that, while reaction [5] involves three NMR-active nuclei, it is also mechanistically triply degenerate, i.e., any of the three Si-O-Si links in C may be broken to form L.

Because the overlap of the D and L resonances prevents rigorous numerical analysis of the SIR data, several approximate approaches with more or less faulty assumptions were tried with the object of producing consistent, accurate fits of the experimental results in terms of a mechanistic picture, as well as meaningful rate constants for those reaction steps for which these could be defined.

Model (i)

The (D + L) band was assumed to represent the major component D alone, and the MDC model was applied; that is, we feigned ignorance of the composite character of this band for expediency in computation (the true concentrations of D and L were, however, used in calculating K_C, K_D, k_{-C}, and k_{-D}). Separate experiments involving, respectively, selective inversion of the M, (D + L), and C bands can be accommodated by the CIFIT program for the MDC mechanism (Figs. 4–7).

Model (ii)

The minor component L of the (D + L) band was assumed to be inactive in Si exchange on the time scale of the M–D and D–C exchanges; the MDC model was then applied to data sets in which the integrated ($D + L$) signal intensities were uniformly reduced by an amount L_∞ corresponding to the stoichiometric concentration of Q^1 L nuclei. The M-SIR data of sample I are well represented by this approach, but the assumption that L is inactive cannot be correct since no sharp resonance corresponding to the Q^2 nucleus of L was detectable and no inverted signal corresponding to the L component persisted in SIR of the combined (D + L) band.

Model (iii)

As a variant of (*ii*), the MDC mechanism was applied with all ($D + L$) signal intensities reduced by a factor of $L_\infty/(D_\infty + L_\infty)$. This implies that the time dependence of L follows that of D, as could happen if equilibration of L with D + M were rapid on a time scale on which the formation of C is slow.

Model (iv)

D–C exchange was assumed to proceed through L as an intermediate, and the MDLC mechanism was invoked. To achieve this in an approximate way, the integrated ($D + L$) band intensity was divided proportionally into magnetizations D and L, as in model (*iii*), on the basis of the *known* equilibrium concentrations of D and L (Table 1). This dissection is exact for the equilibrium magnetizations D_∞ and L_∞ that appear in the CIFIT matrices of eq. [7] and is accurate enough for the zero-time magnetizations required by the CIFIT program, but it is unlikely to reflect accurately the evolutions of D and L over time during spin inversion–recovery unless they are fortuitously similar. This assumption is reasonable, however, since the pseudo-first-order reactions of M with another M and with D are likely to be mechanistically similar and, besides, the change in the intensity of the L signal with time will be small relative to the concurrent changes in M, D, and C. Since the CIFIT program cannot handle SIR of the (D + L) band if it is divided into two contributions, only M-SIR and C-SIR data can be analyzed with this model. To reduce the number of parameters, a reasonable approximation, viz., that T_1 values for the Q^1 silicons of D and L are the same, was made. Typical results of this approach are shown in Figs. 8 (sample II) and 9 (sample I, with scales expanded to show detail).

Model (v)

The fraction of the (D + L) band allocated to L as in model *(iv)* was augmented by 50% to represent a contribution from the missing Q^2 resonance of L, and the MDLC mechanism was applied. The kinetic and NMR parameters so obtained for a given sample and temperature were essentially the same as those obtained in model (*iv*); thus, the numerical analysis of the SIR results was insensitive to the number of active nuclei assigned to the L resonance when preparing the data files.

The numerical results of the various SIR analyses are collected in Tables 4 and 5. Adopted (in most cases, averaged) values of the kinetic parameters are listed in Table 6. The inconsistency of rate constants derived from D-SIR reflects the composite nature of the (D + L) band.

Line-shape simulations

Line-shape simulations were carried out for spectra acquired from 4.5 to 90°C, with the assumption that there was no observable chemical exchange at 4.5°C and therefore the line widths at this low temperature represent natural line widths. Line positions, populations, and rate constants were adjusted manually to describe the experimental spectra. It became evident that the apparent rate constants for LSA were much greater than for SIR, but also that no self-consistent set of rate constants corresponding to the MDC or MDLC mechanisms could be derived. The monomer and dimer peaks could not both be accurately reproduced simultaneously unless an additional line- broadening factor for the monomer was arbitrarily included. This excess broadening of the M signal was more evident in sample I than in sample II, and experiments with samples not described in Table 1 showed that the broadening

Fig. 4. M-SIR of sample I at 90°C, MDC model. (●): M signal; (▼): (D + L) signal; (▲): C signal. Fitted curves yield T_1^{-1} =0.101, 0.25, and 0.14 s^{-1} for M, (D + L), and C, respectively; $k_D' = 0.282$ s^{-1}, and $k_C' = 0.037$ s^{-1}.

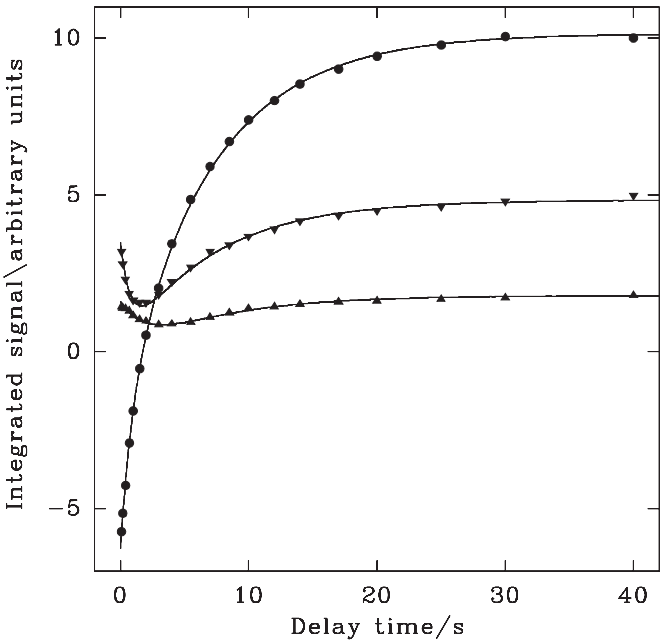

Fig. 5. M-SIR of sample II at 90°C, MDC model. Legend as for Fig. 4. Fitted curves yield T_1^{-1} = 0.035, 0.080, and 0.024 s^{-1} for M, (D + L), and C, respectively; $k_D' = 0.31$ s^{-1}, and $k_C' = 0.029$ s^{-1}.

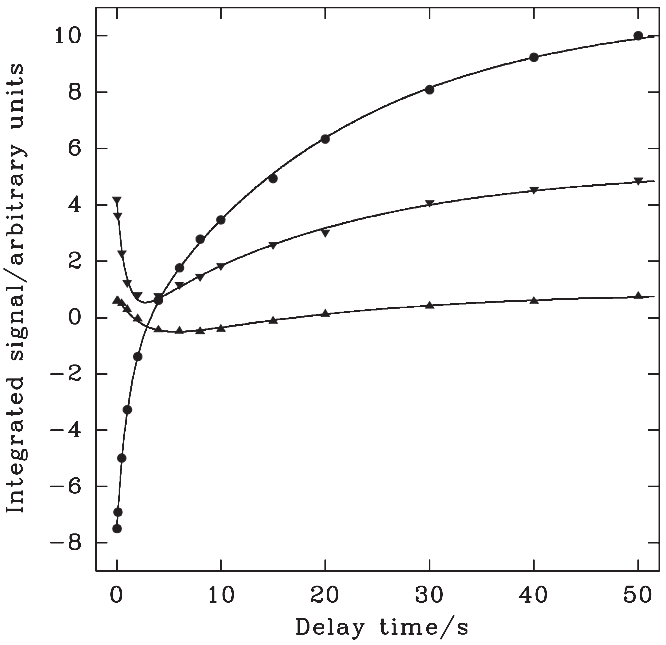

was greater the more ACS Reagent-grade alkali that was present, despite the fact that increasing [OH^-] is known to retard the Si–Si exchange rate (10). The excess broadening was arbitrarily expressed as an apparent rate constant k_{corr}, which may represent a process, other than simple silicate–silicate exchange, in which the monomer interacts preferentially with

Fig. 6. D-SIR of sample II at 90°C, MDC model. Legend as for Fig. 4. Fitted curves correspond to T_1^{-1} = 0.037, 0.080, and 0.035 s^{-1} for M, (D + L), and C, respectively; $k_D' = 0.28$ s^{-1}, and $k_C' = 0.25$ s^{-1}.

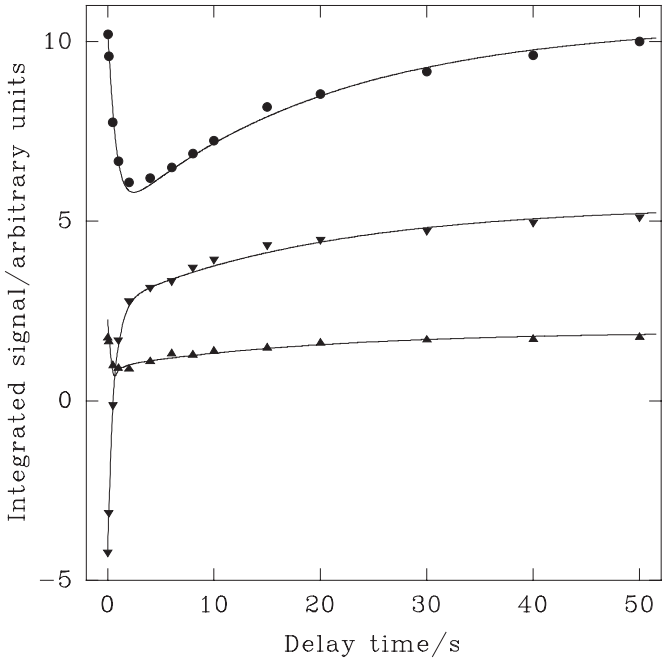

Fig. 7. C-SIR of sample II at 90°C, MDC model. Legend as for Fig. 4. The broken curves represent best fits and yield T_1^{-1} = 0.016, 0.084, and 0.044 s^{-1} for M, (D + L), and C, respectively, k_D' 0.034 s^{-1}, and $k_C' = 0.044$ s^{-1}. The solid curves are constructed with fixed parameters derived in other calculations: T_1^{-1} = 0.037, 0.080, and 0.044 s^{-1} for M, (D + L), and C, respectively, and $k_D' = 0.28$ s^{-1}; these give $k_C' = 0.040$ s^{-1}.

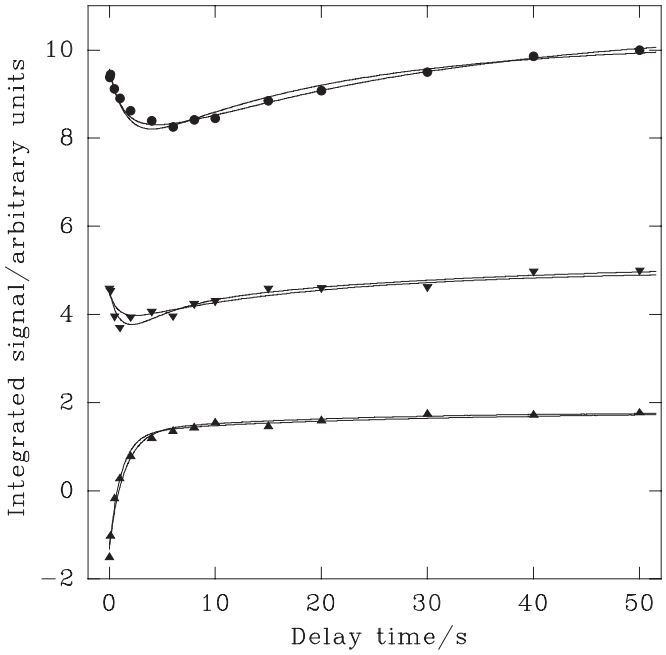

paramagnetic impurities brought in with the alkali. To facilitate LSA simulations based on the MDLC mechanism for the

Fitted curves correspond to $T_1^{-1} = 0.036$, 0.070, 0.070, and 0.053 s^{-1} for M, D, L, and C, respectively; $k_1' = 0.26$ s^{-1}, $k_2' = 0.089$ s^{-1}, and $k_3' = 1.4$ s^{-1}. The dimer signal intensities have been increased by 1.0 unit for clarity.

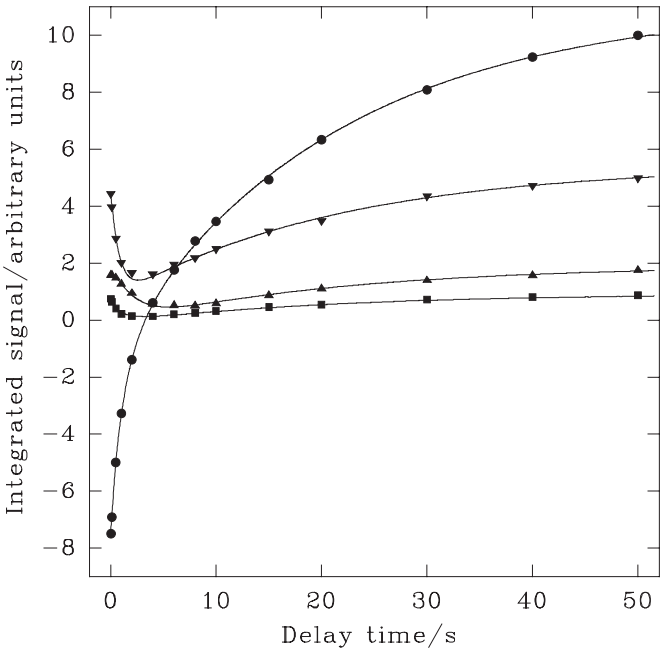

Fig. 9. Early stages of M-SIR for sample I at 90°C, MDLC model (*iv*). Legend as for Fig. 8. Fitted curves correspond to $T_1^{-1} = 0.101$, 0.29, 0.29, and 0.084 s^{-1} for M, D, L, and C, respectively; $k_1' = 0.24$ s^{-1}, $k_2' = 0.097$ s^{-1}, and $k_3' = 1.5$ s^{-1}.

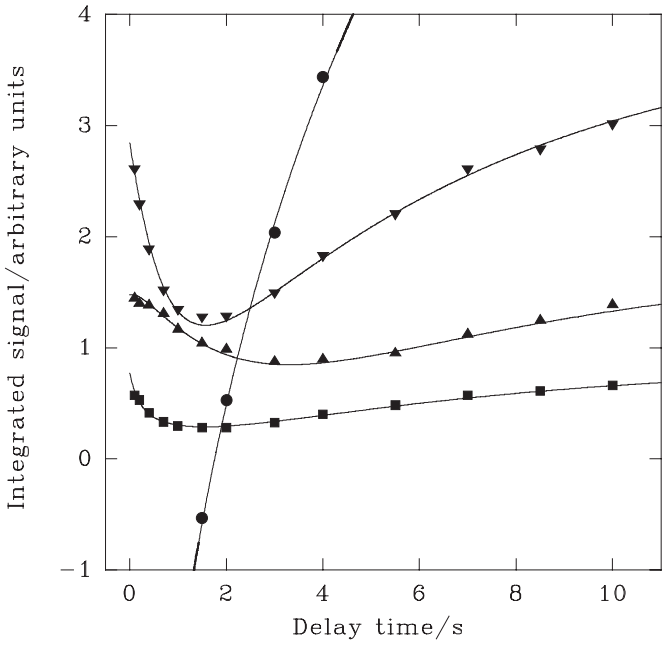

sake of order-of-magnitude comparison with the SIR results, $k_1'$was set equal to k_2', giving the approximate data of Table 7.

Discussion

The conditional ΔH_i values of Table 3 illustrate the general observation (14) that, at a given [OH^-], higher temperatures disfavor the larger oligomers; the monomer–dimer equilibrium, however, is almost thermoneutral. It is not possible at present to apportion contributions to the thermodynamic parameters between proton ionization of Si-O-H groups (relatively few of which should remain in the highly alkaline solutions used in this study) and Si-O-Si bonding changes.

A salient feature of the SIR results is that T_1 values for the various ^{29}Si nuclei are in reasonable agreement between different experiments for a particular sample and temperature but are about three times as long for sample II as for sample I, as may be seen in the nonselective inversion results of Table 2 as well as in the SIR data of Tables 4 and 5 and by visual inspection of Figs. 4 and 5 (noting the different time scales). Since samples I and II differ significantly only in the source of KOH used, we may conclude that paramagnetic contaminants are present in sufficiently high levels in typical concentrated aqueous KOH solutions to exert important influences on the ^{29}Si NMR spectra of silicates. These observations are consistent with those of Creswell et al. (8) and Kinrade et al. (15).

Consequently, rate constants for Si exchange in alkaline solution estimated by line-shape analyses will almost inevitably be too large. This is borne out by the SIR results, which gave rate constants an order of magnitude lower than did LSA even for sample II (that with the purer KOH). Furthermore, it proved impossible to obtain accurate LSA fits for all the major bands simultaneously on the basis of silicate–silicate exchange alone; excess broadening of the monomer band may represent a preferentially rapid interaction of the monomer with some impurity.

In the SIR analyses, selective inversion of the strong M band gave much more reliable SIR data than did inversion of the (D + L) band (which is composite as well as much weaker than the M signal) or of the C band (the weakest; the C-SIR spectra of sample I were of especially poor quality, and those of sample II could not be analyzed unambiguously, as shown in Fig. 7). Unfortunately, complications due to the overlap of the D and L signals could not be avoided, and the results of the computations, summarized in Tables 4–6, are therefore necessarily tentative. Furthermore, our failure to observe the Q^2 center of L serves as a warning that other undetected Si centers could have contributed to the dynamics of a network of Si–Si exchanges. Nevertheless, there is encouraging consistency in the rate constants for M–D exchange (±10% of the average in Table 6) for the two samples and different modes of analysis. Clearly, k_D and k_{-D} are identical with k_1 and k_{-1}, respectively, and are the true reaction rate constants governing monomer–dimer exchange under the given conditions. Thus, at 90°C, $k_1 = 0.13 \pm 0.01$ kg mol s^{-1} and $k_{-1} = 1.4 \pm 0.1$ s^{-1}, with corresponding activation parameters $\Delta H_1^{\ddagger} = 67.4$ kJ mol^{-1}, $\Delta S_1^{\ddagger} = -78$ J K^{-1} mol^{-1}, $\Delta H_{-1}^{\ddagger} = 64.7$ kJ mol^{-1}, and $\Delta S_{-1}^{\ddagger} = -66$ J K^{-1} mol^{-1}.

Creswell et al. (8) reported first-order rate constants k_D of 0.21 and 1.06 kg mol^{-1} s^{-1} at 83 and 107°C, respectively, obtained with an MDC model for a solution containing 2.8 mol kg^{-1} SiO_2 with K/Si = 3.8. These values are 2.6–2.9 times faster than calculated for these temperatures from our activation parameters, in accordance with the general observation that Si exchange rates become slower with rising alkalinity. If each Si center is associated with two negative charges, as is

likely at such high pH, then the concentration of free OH^- was about 5.4 mol kg^{-1} in our samples I and II, as compared with 3.0 mol kg^{-1} in the solutions of Creswell et al. (8), but no simple relationship between k_1 and stoichiometric [OH^-] can be expected in these highly concentrated solutions in which interionic interactions will be strong and the activity of solvent water will be far removed from unity. McCormick et al. (12) used an MDC model to obtain $k_D = 0.05–0.1$ L mol^{-1} s^{-1} and $k_C = 0.1–0.2$ L mol^{-1} s^{-1} (see Appendix) for a solution containing 3 mol% SiO_2 with $SiO_2/K_2O = 0.6$, but the temperature was not reported; very short (<1 s) T_1 values suggest the presence of substantial concentrations of paramagnetic solutes in their solutions.

The agreement between values of the overall rate constant k_C for the formation of the cyclic trimer from D and M obtained by C-SIR (Table 6) and those from M-SIR is good, considering the roughness of the C-SIR data and the oversimplification inherent in the MDC model. Values of k_C are reproduced by $\Delta H_C^{\ddagger} = 76.5$ kJ mol^{-1} and $\Delta S_C^{\ddagger} = -57$ J K^{-1} mol^{-1}, and k_{-C} by $\Delta H_{-C}^{\ddagger} = 88.6$ kJ mol^{-1} and $\Delta S_{-C}^{\ddagger} = -7$ J K^{-1} mol^{-1}.

The rate constants k_2, k_3, and their reverse counterparts from the MDLC model (Table 6) are in some measure fictitious because of the arbitrariness of the assumptions about the role of L. The quality of fits of the data using model (*iv*), however, suggests that the implicit scenario of the formation of D from 2M and of L from M + D followed by a ring-closure step to form C, all at comparable rates, is realistic. Values of k_2 are less than twice k_1, implying similar reactivities of M and D toward attack by M, although this may be an artifact of the assumptions of model (*iv*). Close scrutiny of the early stages of M-SIR (see Figs. 4–8 and especially Fig. 9) suggests that transfer of magnetization from D and L into C is somewhat slower, particularly in the first few hundred milliseconds. This effect is not easy to quantify, since k_2 and k_3 are of different kinetic orders and therefore not directly comparable, but clearly (and perhaps contrary to naive expectations) ring closure of L to form C is not significantly faster than other Si-O-Si link-forming processes. As for the reverse processes, the pseudo-first-order reverse rate constants k_{-D}, k_{-C}, k_{-1}, k_{-2}, and k_{-3}, all of which refer to the breaking of a Si-O-Si link, span only a narrow range. This suggests that Si-O-Si bond cleavage rates are not strongly affected by the intramolecular environment in small silicate oligomers.

In conclusion, this study shows that rate constants for sili-

cate monomer–dimer exchange in aqueous alkaline solution can be obtained with a reproducibility of better than ±10% from selective inversion–recovery ^{29}Si NMR by use of the CIFIT program. Furthermore, these SIR rate constants are unaffected by trace (presumably paramagnetic) contaminants, inevitably introduced with the alkali, that accelerate both longitudinal and transverse magnetic relaxation and invalidate rate constants estimated from NMR line-shape analysis; in the very highly alkaline solutions of this study, such rate constants were too large by an order of magnitude even when the purest commercial KOH was used, although apparent rate constants reported in other LSA studies in which the alkalinity was relatively low should still be at least qualitatively useful. Unfortunately, the overlapping of NMR resonances, particularly those of the centrally important dimer and linear trimer, invalidate the use of SIR of those resonances and prohibit a full quantitative analysis of the exchange kinetics of silicate oligomers, even when the number of such oligomers is minimized by use of elevated temperatures and very high alkalinity. Models that attempt to recognize the mechanistic participation of the linear trimer can represent the experimental data well, but the simple MDC model (*i*) based on eqs. [1] and [2] suffices to describe the experimental data from M-, D-, or C-SIR consistently and accurately, and to give meaningful values of the rate constants for monomer–dimer and overall dimer – cyclic trimer exchanges. Definitive rate constants for the D–L and L–C steps of the MDLC model cannot be obtained, but the reactivities of Si centers in formation and cleavage of Si-O-Si links, including the cyclization of L, are evidently rather similar for the silicate species considered in this study under the conditions of high pH and [Si].

Appendix: Derivation of eqs. [6] and [7]

Since the NMR-active ^{29}Si isotope is present only at natural (i.e., low) abundance, we may consider the exchange of a single spin-inverted ^{29}Si center (a) between monomer (A), dimer (AA), and cyclic trimer (*c*-AAA) sites, as in eqs. [8]–[11]. In the derivation of eq. [6], the possible intermediacy of the linear trimer in eqs. [9]–[11] is ignored (MDC model). We may also disregard degenerate exchange processes such as [12], since such processes may be assumed to occur through intermediates of increased or reduced connectivity (reactions [8]–[11]). All three pathways [9]–[11] must be included, even though the products *c*-aAA, *c*-AAa, and *c*-AaA are indistinguishable.

[8] $\mathrm{a + A} \underset{k_{-D}}{\overset{k_D}{\rightleftharpoons}} \mathrm{aA}$

[9] $\mathrm{a + AA} \underset{k_{-C}}{\overset{k_C}{\rightleftharpoons}} \mathit{c}\text{–aAA}$

[10] $\mathrm{A + Aa} \underset{k_{-C}}{\overset{k_C}{\rightleftharpoons}} \mathit{c}\text{–AAa}$

[11] $\mathrm{Aa + A} \underset{k_{-C}}{\overset{k_C}{\rightleftharpoons}} \mathit{c}\text{–AaA}$

[12] $\mathrm{a + AA} \rightleftharpoons \mathrm{aA + A}$

The kinetic equations for the chemical exchange processes [8]–[11] are then as follows.

[13] $\mathrm{d[a]}/dt = -k_D\mathrm{[a][A]} - k_C\mathrm{[a][AA]} + k_{-D}\mathrm{[aA]} + k_{-C}[c\text{-aAA}]$

[14] $\mathrm{d[aA]}/dt = k_D\mathrm{[a][A]} + 2k_{-C}[c\text{-aAA}] - k_{-D}\mathrm{[aA]} - 2k_C\mathrm{[A][aA]}$

[15] $\mathrm{d[aAA]}/dt = k_C\mathrm{[a][AA]} + k_C\mathrm{[aA][A]} - 2k_{-C}[c\text{-aAA}]$

The *observed* time-dependent magnetizations M, D, and C and their equilibrium values M_∞, D_∞, and C_∞, however, arise from all nuclei at sites of a given kind, and so we have:

$[\mathrm{a}] \propto M; [\mathrm{aA}] \propto D/2; [c\text{-aAA}] \propto C/3$

$[\mathrm{A}] = [\mathrm{M}] \propto M_\infty; [\mathrm{AA}] = [\mathrm{D}] \propto D_\infty/2; [c\text{-AAA}] = [\mathrm{C}] \propto C_\infty/3$

The kinetic equation is then

$$[15]\quad \frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} M \\ D \\ C \end{bmatrix} = \begin{bmatrix} -k_D\mathrm{[M]} - k_C\mathrm{[D]} & k_{-D}/2 & k_{-C}/3 \\ k_D\mathrm{[M]} & -(k_{-D}/2) - k_C\mathrm{[M]} & 2k_{-C}/3 \\ k_C\mathrm{[D]} & k_C\mathrm{[M]}/2 & -k_{-C} \end{bmatrix}\begin{bmatrix} M \\ D \\ C \end{bmatrix}$$

Incorporating the equilibrium relationships given with eqs. [1] and [2], we obtain:

$$[16]\quad \frac{\mathrm{d}}{\mathrm{d}t}\begin{bmatrix} M \\ D \\ C \end{bmatrix} = \begin{bmatrix} -k_D\mathrm{[M]} - k_C\mathrm{[D]} & k_D\dfrac{\mathrm{[M]^2}}{2\mathrm{[D]}} & k_C\dfrac{\mathrm{[M][D]}}{3\mathrm{[C]}} \\ k_D\mathrm{[M]} & -k_D\dfrac{\mathrm{[M]^2}}{2\mathrm{[D]}} - k_c\mathrm{[M]} & 2k_C\dfrac{\mathrm{[M][D]}}{3\mathrm{[C]}} \\ k_C\mathrm{[D]} & k_C\mathrm{[M]} & -k_{-C}\dfrac{\mathrm{[M][D]}}{\mathrm{[C]}} \end{bmatrix}\begin{bmatrix} M \\ D \\ C \end{bmatrix}$$

$$= k_D\mathrm{[M]}\begin{bmatrix} -1 & \dfrac{M_\infty}{D_\infty} \\ 1 & -\dfrac{M_\infty}{D_\infty} \end{bmatrix}\begin{bmatrix} M \\ D \end{bmatrix} + k_C\mathrm{[D]}\begin{bmatrix} -1 & 0 & \dfrac{M_\infty}{C_\infty} \\ 0 & -2\dfrac{M_\infty}{D_\infty} & 2\dfrac{M_\infty}{C_\infty} \\ 1 & 2\dfrac{M_\infty}{D_\infty} & -3\dfrac{M_\infty}{C_\infty} \end{bmatrix}\begin{bmatrix} M \\ D \\ C \end{bmatrix}$$

On writing $k_D\mathrm{[M]} = k_D'$ and $k_C\mathrm{[D]} = k_C'$, this becomes eq. [6]. Equation [16] is essentially that used by McCormick et al. (12) except that the k_1 defined by them corresponds to $k_D/2$ (as a result of counting path [8] twice). Equation [7] may be derived in a similar fashion, with the assumption that the magnetizations L^t and L^c of the terminal and central Si sites in the species L (aAA and AaA; $L^c = L^t/2 = L/3$) can be taken in combination. In practice, neither L^t nor L^c can be independently observed at temperatures at which chemical exchange rates can be reliably measured by ^{29}Si NMR. For the same reason, the full 5×5 kinetic matrix that includes L^t and L^c was not considered in this work.

Control of relative migration of small inorganic and organic anions with cyclodextrins in capillary electrophoresis (CE)

Costas Stathakis and Richard M. Cassidy

Abstract: The capillary electrophoretic separation of iodide, nitrate, perchlorate, thiocyanate, bromate, iodate, and ethane-, butane-, pentane-, and octanesulphonate was examined in sodium chromate or potassium hydrogen phthalate electrolytes and in the presence of α-, γ-, (0–40 mmol/L) and β-cyclodextrin (0–10 mmol/L). Largest decreases in electrophoretic mobility were observed for iodide, perchlorate, and thiocyanate, probably due to inclusion of these anions in the cyclodextrin (CD) cavity. Changes in migration patterns and electroosmotic flow were observed, which depended on cyclodextrin type and concentration and on electrolyte–cyclodextrin interactions. Thus for larger cavity cyclodextrins (β- or γ- cyclodextrin) or in the presence of chromate, relatively small decreases in electrophoretic mobilities for all the anions were observed, indicating that a good match between analyte and cavity size and minimal cyclodextrin affinity for electrolyte ions are essential for different migration patterns. Separation efficiencies were between 50 000 and 400 000 theoretical plates, and calibration plots for iodide and octanesulphonate were linear; $R^2 = 0.998$ and 0.9999, respectively, in the concentration range (5×10^{-5})–(5×10^{-3}) mol/L.

Key words: capillary electrophoresis, inorganic and organic anions, cyclodextrins, inclusion complex, electroosmotic flow control.

Résumé : Opérant dans des électrolytes de chromate de sodium ou de phtalate acide de potassium, en présence d'α-, γ- (0–40 mmol/L) et β-cyclodextrines (0–10 mmol/L), on a étudié la séparation par électrophorèse capillaire des ions iodure, nitrate, perchlorate, thiocyanate, bromate, iodate et éthane-, butane-, pentane- et octanesulfonate. Les diminutions les plus importantes dans la mobilité électrophorétique ont été observées avec les ions iodure, perchlorate et thiocyanate, probablement à cause d'une inclusion de ces anions dans la cavité de la cyclodextrine (CD). Des changements dans les patrons de migration et dans l'écoulement électroosmotique ont été observés; ils dépendent du type de cyclodextrine, de la concentration et des interactions électrolyte–cyclodextrine. Ainsi, avec tous les anions et les cyclodextrines de cavité plus grande (β- ou γ-cyclodextrine) ou en présence de chromate, on a observé des diminutions relativement faibles des mobilités électrophorétiques; ces résultats indiquent qu'une bonne correspondance entre les analytes et la taille de la cavité ainsi qu'une affinité minimale de la cyclodextrine pour les ions électrolytes sont essentiels pour différents patrons de migration. Les efficacités de séparation s'établissent entre 50 000 et 400 000 plateaux théoriques et les courbes de calibration pour les ions iodure et octanesulfonate sont linéaires; $R^2 = 0{,}998$ et 0,9999 respectivement pour la plage de concentration allant de (5×10^{-5}) à (5×10^{-3}) mol/L.

Mots clés : électrophorèse capillaire, anions inorganiques et organiques, cyclodextrines, complexe d'inclusion, contrôle de l'écoulement électroosmotique.

[Traduit par la rédaction]

Introduction

In recent years capillary electrophoresis (CE) has emerged as a viable alternative to ion chromatography for the separation and quantitation of small inorganic and organic ions (1–5). Optimization of CE separations requires control of electroosmotic flow (EOF) and of analyte relative migration, which can be accomplished via incorporation of additives (e.g., cationic surfactants (1), polyelectrolytes (6), complexing agents (3)) capable of wall and analyte interactions. However, with surfactant additives a number of difficulties have been reported for the analysis of hydrophobic ("structure breaking") inorganic anions (e.g., iodide, perchlorate, and thiocyanate) and with some surfactant species. Weakly hydrated inorganic anions form strong ion pairs with cationic surfactants, resulting in decreased efficiencies (2), whereas alkyl sulphonate species with chain lengths greater than C_5 interact strongly with surfactant additives and co-migrate with the neutral marker (3). Although some of these difficulties are circumvented with polyelectrolytes, alternative means for controlling analyte migration may be desirable in some analytical situations. One alternative may be hydrophobic inclusion of small inorganic and organic anions with cyclodextrins (CDs). CDs have been

used for control of relative migration in the separation of neutral (7, 8) or charged (9–11) aromatic species, and such interactions have also been modelled theoretically (12–15). CD affinity for inorganic anions has not been explored for optimization of CE separations, although physicochemical studies (16–18) indicate that interactions of CDs with anions such as iodide, thiocyanate, and perchlorate are possible and the extent of CD–analyte interaction correlates with the relative hydrophobicities of these anions. It should be possible to control analyte–CD interactions, and thus analyte relative migration patterns, via choice of CD concentration, cavity size, and the nature of the electrolyte anion. In addition, native CDs are neutral, a feature that should allow for changes in CD concentration without compromising efficiency and resolution because of Joule heating.

This paper examines the potential of cyclodextrins for control of relative migration of small anion separations in CE. The analytes examined included iodide, nitrate, thiocyanate, perchlorate, and ethane-, butane-, pentane-, and octanesulphonate. The choice of these anions was based on their differing hydrophobicities (and presumably their CD affinities), and because of the difficulties associated with the CE separation of some of these ions (e.g., octanesulphonate) in the presence of cationic surfactants. Chromate and phthalate electrolytes were chosen because they are expected to interact to a different extent with the cyclodextrins, and these interactions should have different effects on CD–analyte complexation and thus analyte migration.

Materials and methods

Instrumentation

The capillary electrophoretic (CE) instrument used was a Quanta 4000 (Waters, Milford, Mass.) equipped with a pen-ray lamp-detector cell assembly and forced-air cooling. Detection was indirect at 254 nm (Hg lamp). The CE unit was interfaced to a NEC APC IV personal computer (DX286, 12 MHz). Data acquisition was done via a Maxima 820 chromatography workstation (version 3.30, Dynamic Solutions, Sykesville, Md.) at data acquisition rates ranging from 1 to 25 Hz. All pH measurements were done with a model 805 MP Accumet pH meter (Fisher Scientific, Edmonton, Alta.) equipped with a Ag/AgCl reference electrode. An AE163 digital balance (Mettler Instrument, Greifensee, Switzerland) was used to weigh out all stock solutions used to prepare standards and separation electrolytes.

Capillary preparation

Fused silica capillaries (Polymicro Technologies, Phoenix, Ariz.) had an inner diameter (i.d. = 75 μm) and an outside diameter (o.d. = 365 μm). Capillary end-to-end length was 60 cm and end-to-detection window was 52 cm. Prior to the first run the capillary was conditioned with the separation medium for periods ranging from 15 to 30 min. In between runs, the capillary was rinsed with the separation medium for about 2 min using a vacuum (15 mm Hg) (1 mm Hg = 133.3 Pa) or a syringe. When separation electrolytes were changed, the capillary was purged with deionized distilled water (DDW) then 0.1 mol/L NaOH, followed by a purge with DDW. Overnight conditioning of capillaries was done by rinsing with DDW using gravity flow.

Reagents and analyte standards

All standard, sample, and separation electrolyte stock solutions were prepared in distilled deionized water (Corning, Mega-Pure, MP-6A & D2, Elmira, N.Y.) and were introduced into the capillary via hydrostatic injection for 15 s (10^{-4} mol/L) from a height of 10 cm. Reagents, such as separation electrolytes, polymers, and analyte standards, were used as obtained from the manufacturer without further purification. Separation electrolytes were filtered by passing through a Nylon filter (0.2 μm pore, Cole-Palmer,Chicago, Ill.) to remove any particulate matter. The cationic polyelectrolyte, poly(1,1-dimethyl-3,5-dimethylenepiperidinium chloride) (PDDPiCl, MW 200 000 g/mol), available as 20% solids in water, was purchased from Polysciences Inc. (Warrington, Pa.) and converted to the chromate and phthalate form as outlined elsewhere (6). The cyclodextrins were purchased from Aldrich (Milwaukee, Wis.) Sodium chromate tetrahydrate (99+%) was purchased from Aldrich, and potassium hydrogen phthalate was acquired from BDH Chemicals (Toronto, Ont.) All analyte standards were analytical grade and were prepared in deionized distilled water as 0.02 mol/L stock solutions. Adjustment of pH was done with chromium(VI) oxide (chromic acid; 99.9%; Aldrich) and phthalic acid (BDH).

Calculations

The rate of electroosmosis was monitored via measurement of the neutral marker (water) migration time at the tip of the peak. Electroosmotic mobility (μ_{eo}) was calculated from

$$[1] \quad \mu_{eo} = \frac{l \times L}{V \times t_{eo}}$$

where V is the separation voltage (V), L is the capillary length (cm), l is the injection-to-detection window length (cm), and t_{eo} is the migration time of the neutral marker (s). Observed migration mobility (μ) for analyte species was calculated from

$$[2] \quad \mu = \frac{l \times L}{V \times t}$$

where t is the analyte migration time (s). Analyte electrophoretic mobility (μ_{ep}) was calculated from

$$[3] \quad \mu_{ep} = \mu - \mu_{eo}$$

Points of μ_{ep} or μ_{eo} versus polyelectrolyte concentration on the various plots are connected with lines for clarity only, and regions in between points do not represent data measured. The error associated with each point is <1% (RSD).

The number of theoretical plates (N) was calculated from

$$[4] \quad N = 5.54 \times \left(\frac{t}{w_{0.5}} \right)^2$$

where t is the zone *net* migration time (s) and $w_{0.5}$ is the width (in time units) at 50% of the peak height. Efficiencies were calculated from electropherograms sampled at 10 points/s.

Results and discussion

Electroosmotic flow studies

A small amount of polyelectrolyte PDDPiCr or PDDPiPh (0.002% w/v) was incorporated to assure stable and anodal EOF, based on our previous studies with cationic polymers (6). A study was then conducted on the effects of cyclodextrin type and concentration in 5 mmol/L sodium chromate plus 0.002% (w/v) PDDPiCr at pH 8 and in 5 mmol/L potassium hydrogen phthalate (KHP) plus 0.002% (w/v) PDDPiPh at pH 6.4. The difference in pH for the two separation media does not influence analyte or CD speciation to any significant extent. Polyelectrolyte–CD interactions are generally weak and not expected to influence EOF magnitude. This is in contrast to surfactant–CD interactions where the surfactant tail has a high affinity for the CD cavity, a process that may compete not only with surfactant wall adsorption (and thus EOF reversal) but also with analyte inclusion. However, as indicated in Fig. 1 for the chromate system, small decreases in EOF were observed as a function of cyclodextrin type and concentration. Decreasing EOF rates were observed along the series γ- > β- > α-, which are in the same order as increasing viscosity values for separation electrolyte in the presence of equimolar amounts of the three different CDs (15, 19). EOF reproducibility was 0.96–2.6% (RSD) over a 2.5 h period.

Selectivity control studies

Migration patterns were found to depend on CD type and concentration and on the electrolyte co-ion. As indicated in Fig. 2 for the chromate system, the largest decreases in electrophoretic mobility were observed for the more hydrophobic anions iodide, perchlorate, and thiocyanate. The ability to preferentially slow down perchlorate and thiocyanate via CD complexation is useful in changing analyte migration order. Over the concentration range 0–20 mmol/L there were several changes in migration order of the inorganic anions, but the sulphonate surfactants migrated in order of increasing chain length. Typical electropherograms demonstrating migration-order dependence on CD type for the inorganic anions are shown in Fig. 3 (20 mmol/L α-CD) and Fig. 4 (12 mmol/L γ-CD). For the surfactant species, improved resolution was observed, especially between ethane- and butanesulfonate; the results in Fig. 2 suggest that ethanesulfonate does not interact appreciably with α-CD. With β-CD (Fig. 5), decreasing electrophoretic mobilities were also observed, but were relatively small likely due to the fact that β-CD has a larger cavity than α-cyclodextrin (by a factor of 1.25 (20)), which does not allow for strong inclusion of the anions. As a result, the anions migrate close to their free-zone electrophoretic mobilities, and incomplete resolution between thiocyanate and perchlorate was observed. With γ-CD, which has an even larger cavity, fairly constant electrophoretic mobility versus CD concentration profiles where observed for all anions including the alkyl sulphonates. Although it has been reported that a number of long-chain surfactants (e.g., sodium dodecyl sulfate) have a high affinity for the CD cavity (21), such an effect is presumably smaller for these lower chain surfactants. Inclusion of chromate by the CDs is not expected to influence CD–analyte interactions significantly, since isotachophoretic data indicates that chromate interacts weakly with α-, β-, and γ-CD, compared to perchlorate or thiocyanate (22).

With a phthalate electrolyte (Fig. 6), changes in mobility were larger compared to chromate electrolytes. This indicates that chromate probably interacts with the CD cavity to a larger extent than phthalate. This observation is in agreement with data indicating that *charged* aromatic species have CD association constants that are smaller by a factor of 10–20 compared to their neutral counterparts (23). In both chromate and phthalate electrolytes and in the case of β-CD, analyte electrophoretic mobilities were constant to within a few percent, presumably due to an analyte size – CD cavity mismatch, which does not favour analyte inclusion. Separation efficiencies in chromate and phthalate electrolytes were between 50 000 and

400 000 theoretical plates, which indicate rapid and reversible analyte inclusion in the CD cavity.

The migration orders observed for the inorganic anions in the presence of CDs are different to the orders seen for a number of surfactants and other electrolyte systems. Kaneta et al. (24) studied the separation of iodide, nitrate, bromate, and iodate in 0.2–25 mmol/L cetyltrimethylammonium chloride (CTAC). Selectivities reflected the relative affinity of these anions for the micellar core, and the orders of migration for the anions were nitrate, bromate, iodate, and iodide (1.0 mmol/L CTAC) and iodate, bromate, nitrate, and iodide (25 mmol/L CTAC). In the presence of cyclodextrins, the order of migration was either iodide, nitrate, bromate, and iodate or nitrate, iodide, bromate, and iodate. Jimidard and Massart (25) studied the separation of a series of inorganic anions in 0.45 mmol/L CTAB. The order of migration they observed was nitrate, iodide, and iodate. Separation efficiency for iodide, however, was quite low (12 000 theoretical plates), possibly due to strong ion-pairing interactions with CTAB. Similarly, Jones and Jandik (26) reported the separation of iodide, nitrate, and perchlorate in 0.3 mmol/L OFM, with the migration order iodide, nitrate, and perchlorate. In their

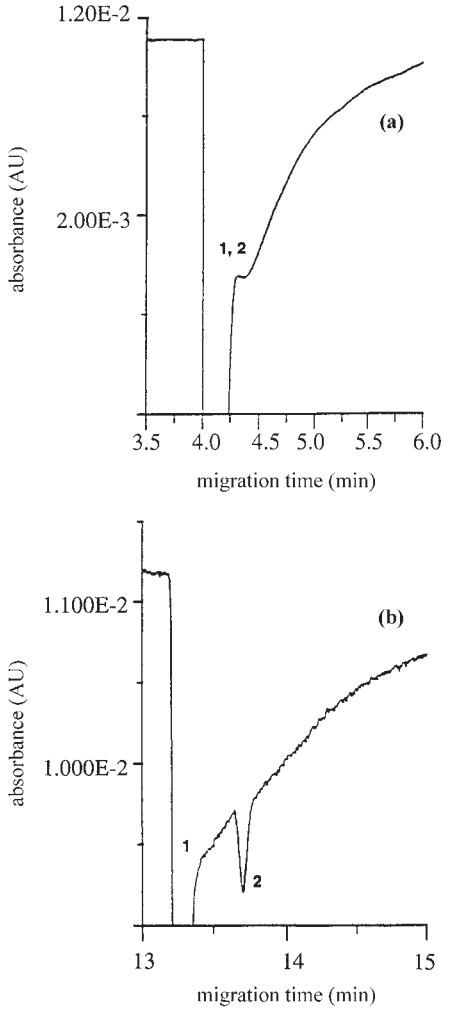
Fig. 7. Electropherogram of 1×10^{-4} mol/L chloride plus 4×10^{-3} mol/L iodide in 5 mmol/L sodium chromate at pH 7.9 with no α-CD (*a*) and with 17 mmol/L α-CD (*b*). **1**, chloride; **2**, iodide; hydrostatic injection for 10 s from a height of 10 cm; field strength, 333 V/cm.



electropherograms, chloride was only partially resolved from iodide; Fig. 7 shows the improvement in resolution of chloride in the presence of a 40-fold excess of iodide when α-CD is used. Similarly, Buchberger and Haddad (27) reported co-migration of iodide and bromide in 0.5 mmol/L OFM plus 30% v/v methanol. Both these anions were well resolved in 10 mmol/L β-CD (data not shown in Fig. 5). Hauser et al. (28) described the separation of nitrate, iodide, and perchlorate in 10 mmol/L acetic acid and sodium acetate buffer (pH 5.0) under counter-electroosmotic conditions. Although all anions are well resolved, analysis times are relatively long (11 min) and peaks for perchlorate and iodide exhibit tailing. Thus for some analytical situations the application of CD additives may prove useful in controlling relative migration.

Application of this separation methodology was briefly examined for the determination of iodide and octanesulphonate ((1×10^{-5})–(1×10^{-3}) mol/L; five concentration points) in a series of simulated samples. Analysis of iodide is of interest to the food and fertilizer industries, whereas the determination of octanesulphonate is important to detergent and emulsifier manufacturers. Calibration plots for iodide and octanesulphonate were linear; $R^2 = 0.998$ and 0.9999, respectively, with sensitivity plots constant to ±8%, only in the range (1×10^{-4})–(1×10^{-3}) mol/L, and to ±20% for iodide in the concentration range (5×10^{-5})–(1×10^{-3}) mol/L.

Synthesis of *trans*-2,3-dimethoxy-3-(phenylamino)flavanones and related compounds[1]

Surya K. De, Mrinal G. Dhara, and Asok K. Mallik

Abstract: *trans*-2,3-Dimethoxy-3-(phenylamino)flavanones **(2)**, a new type of flavanone derivatives, are synthesized from flavanones or 2′-hydroxychalcones in two steps, the first one being a condensation with nitrosobenzenes (Ehrlich–Sachs reaction) and the second an oxidation with (diacetoxyiodo)benzene in methanol. Nitrone formation, an important side reaction of the Ehrlich–Sachs reaction, has also been exploited to synthesize **2** simply by use of an excess of nitrosobenzene in aqueous methanol. Syntheses of several analogues of **2** are also reported.

Key words: *trans*-2,3-dimethoxy-3-(phenylamino)flavanones, 2′-hydroxychalcones, nitrosobenzenes, 3-(phenylamino)flavones, (diacetoxyiodo)benzene.

Résumé : On a réalisé la synthèse de *trans*-2,3-diméthoxy-3-(phénylamino)flavones (**2**), un nouveau type de dérivés des flavones; cette synthèse fait appel à l'utilisation des flavanones ou 2'-hydroxychalcones comme produits de départ et elle implique deux étapes, la première étant une condensation avec des nitrosobenzènes (réaction d'Ehrlich–Sachs) et la deuxième une oxydation à l'aide de (diacétoxyiodo)benzène dans le méthanol. On a aussi exploité la formation de nitrone, une réaction secondaire importante dans la réaction d'Ehrlich–Sachs, pour réaliser une synthèse simple du composé **2** en utilisant un excès de nitrosobenzène dans du méthanol aqueux. On rapporte aussi les synthèses de plusieurs analogues du composé **2.**

Mots clés : *trans*-2,3-diméthoxy-3-(phénylamino)flavones, 2'-hydroxychalcones, nitrosobenzènes, 3-(phénylamino)flavones, (diacétoxyiodo)benzène.

[Traduit par la rédaction]

Introduction

Recently, we reported (1) the formation of *trans*-2,3-dimethoxy-3-(*p*-formylphenylamino)-4′-nitroflavanones **(1)** during the alkali-catalysed condensation of *o*-hydroxyacetophenones with *p*-nitrobenzaldehyde. This is a novel reaction and the products are a new type of flavanone derivatives. Subjecting equimolar mixtures of 2′-hydroxy-4-nitrochalcones and *p*-nitrobenzaldehyde to similar reaction conditions, **1** could be obtained in 45–52% yield. However, attempted general synthesis of *trans*-2,3-dimethoxy-3-(phenylamino)flavanones **(2)** by variation of one or both of the 2′-hydroxychalcone and nitroarene components did not meet with success (1). From a consideration of potential biological activities (2, 3) of this new class of compounds we undertook a general synthesis of **2**. In this study we could develop two synthetic methods; one involves condensation of flavanones **(4)** or 2′-hydroxychalcones **(5)** with nitrosobenzenes followed by hypervalent iodine oxidation of the condensates (3-(phenylamino)flavones **(3)**) in methanol, and the other involves reaction of **4** or **5** with excess nitrosobenzenes in aqueous methanolic alkali. Several analogues of **2** have also been synthesized. An account of these studies is presented herein.

Results and discussion

The target compounds **(2)** have structural similarity with 2,3-dimethoxy-3 hydroxyflavanones **(6)**. A number of methods for the synthesis of **6** involve oxidation of flavonols **(7)** in methanol (4–10). This prompted us to start from 3-(phenylamino)flavones **(3)** for synthesis of **2**. The hypervalent iodine reagent (diacetoxyiodo)benzene (DAIB), recently applied by us for some other reactions (11, 12), was chosen to effect the oxidation. Thus, six 3-(phenylamino)flavones **(3a–f)** prepared by condensing flavanones **(4)** or 2′-hydroxychalcones **(5)** with nitrosobenzenes (equimolar amount, Method I) (13, 14) were first reacted with DAIB in methanol. For **3a–e** the desired products **(2a–e)** were obtained in good yields (Table 1) (plausible mechanism given in Scheme 1). However, in the case of **3f**, the methanolic solution turned violet immediately on addition of DAIB and neither a crystalline product nor the starting material could be obtained from the reaction mixture. This is possibly due to formation of a radical through homolysis of the N—I bond of **8** (15, 16), and its subsequent reactions. The products **2a–e** were characterized by their spectral data. The

most conspicuous feature in the ^1H NMR spectra of **1a**–**c** (appearance of broad signal for the B-ring protons (1) owing to slow rotation of this ring at ambient temperature) was also present in those of **2a–e**. The positions of the ^1H NMR signals for 2-OMe and 3-OMe in **2a–e** (one at δ 2.90–2.99 and the other at δ 3.09–3.10) were very close to those in **1a–c** (1). Moreover, the last step in the proposed mechanism for formation of **2a–e** (Scheme 1) is similar to that in the case of **1a–c**. Based on these similarities, the *trans* configuration has been assigned.

The only previously known 3-(phenylamino)flavone **3f** was reported (13, 14) to be formed by alkali-catalysed condensation of flavanone and *p*-nitroso-*N,N*-dimethylaniline in aqueous ethanol. But in neither of the two reports of its synthesis was the yield mentioned. Applying the same method, we could obtain **3a–f** in only moderate (30–47%) yield. A study of the Ehrlich–Sachs reaction (17, 18) revealed that nitrone formation (through oxidation of the intermediate **10** with a second molecule of nitrosobenzene) is an important side reaction (Scheme 2). Moreover, the reacting nitrosobenzene can undergo reduction with alcoholic alkali (ref. 17, p. 261). We suggested the intermediacy of nitrones (1) in the formation of **1**. Thus, we envisaged that if nitrones of type **11** are generated in an alkaline reaction medium containing methanol then there is scope for formation of the target compounds in the same step. Although the factors determining the relative amounts of imines and nitrones are not well understood (17, 18), in considering the requirements of the reaction leading to nitrones we decided to use excess nitrosobenzene. Moreover, since 2′-

hydroxychalcones (**5**) are known to equilibriate with flavanones (**4**) in alkali, we simplified our methodology further by starting from **5**. Thus, we carried out reactions of flavanones or 2′-hydroxychalcones with excess nitrosobenzene (2.5 mol) in aqueous methanolic alkali (Method II) and obtained the

desired compounds in moderate yields (Table 2) along with 3-(phenylamino)flavones (yield: 0–10%). Further increase of the amount of nitrosobenzene did not give **2** in significantly greater yield, but in some cases made product purification more difficult owing to formation of greater amounts of azo- and azoxy-benzenes through reduction (ref. 17, p. 261). On the other hand, several samples of **2** could be obtained even by using a molar proportion of nitrosobenzene.

Thus, we could develop two methodologies for general synthesis of **2**, of which the latter appears more attractive because of its simplicity. However, its main drawback is that the reaction is not very reproducible under similar conditions. This is not at all unexpected (17, 18). Each of the yields recorded in Table 2 is the best result obtained from a group of three analogous experiments.

Effort was then given to synthesis of some analogues of **2**. The heterocyclic analogues **16** and **17** were synthesized by Method II simply by starting from **12** and **13**, respectively

Scheme 2.

11

(yields: 39 and 34%). When compounds **14** and **15** were subjected to such reaction conditions, **20** and **21** (yields : 45 and 42%), respectively, were obtained, but no trace of analogues of **2**. DAIB oxidation of **20** in methanol afforded **18** (yield: 74%). It may be noted that the styryl double bond of **20** remains unattacked. DAIB oxidation of **21** in methanol yielded **22** (62%), but not an analogue of **2**, possibly due to inhibition of methanol addition to the imino moiety by an unfavourable steric effect. The ethoxy analogue of **2a**, not formed by treatment of **4a** with excess nitrosobenzene in aqueous ethanolic alkali, was obtained by oxidation of **3a** with DAIB in ethanol. Here, at room temperature the reaction was very slow (yield: 15%, after 60 h) while at reflux temperature no **19** could be isolated from the resulting black gummy material obtained after disappearance of **3a**.

Experimental

Melting points (mps) were recorded in a Köfler block and are uncorrected. IR spectra were recorded in Nujol on a Perkin–Elmer 297 spectrophotometer. ^{1}H NMR spectra were recorded in $CDCl_3$ on Varian EM 360 (60 MHz), Hitachi R-600 (60 MHz), JEOL FX 100 (100 MHz), Bruker AC-200 (200 MHz), Bruker AM-300L (300 MHz), and Bruker AMX-500 (500 MHz) spectrometers. The ^{13}C NMR spectrum was recorded in $CDCl_3$ on a Bruker AMX-500 (125 MHz) spectrometer. Mass spectra were recorded on a Shimadju QP-1000 spectrometer.

Analytical samples were routinely dried in vacuo at room temperature. Column and thin-layer chromatographies were carried out using neutral alumina (S.D. Fine Chem.) and alumina for TLC (SRL), respectively.

p-Nitroso-*N,N*-dimethylaniline was prepared through nitrosation of *N,N*-dimethylaniline while the other nitrosobenzenes were prepared from the corresponding nitrobenzene through Zn–NH_4Cl reduction followed by $Na_2Cr_2O_7$–H_2SO_4 oxidation (19). The 2′-hydroxychalcones (**5**) and flavanones (**4**) used were known compounds (20).

General procedure for reaction of flavanones (4) or 2′-hydroxychalcones (5) with nitrosobenzenes

(a) By using equimolar amounts of the reactants

To a mixture of **4** or **5** (1 mmol) and nitrosobenzene (1 mmol)

© 1998 NRC Canada

in ethanol or methanol (10 mL) was added potassium hydroxide solution (20%, 2 mL) and the solution was stirred at room temperature for 10 h. The reaction mixture was then diluted with water and extracted with ether (4 × 25 mL). The ether extract was concentrated and the residue was chromatographed. Pure 3-(phenylamino)flavone (**3**) thus obtained (yellow to red solid) was crystallized from chloroform–petrol. Yield (%): **3a**, 47; **3b**, 38; **3c**, 45; **3d**, 39; **3e**, 42; **3f**, 30.

(b) By using excess nitrosobenzene in aqueous methanolic solution

A mixture of **4** or **5** (1 mmol) and nitrosobenzene (2.5 mmol) in methanol was treated with potassium hydroxide solution by the aforesaid procedure. After the usual work-up, the resulting material was chromatographed. *trans*-2,3-Dimethoxy-3-(phenylamino)flavanone (**2**) (colourless solid) was eluted first and then 3-(phenylamino)flavone (**3**), if any. Finally **2** was crystallized from chloroform–petrol.

General procedure for DAIB oxidation of 3-(phenylamino)flavones (3) in methanol

DAIB (1 mmol) was added in four portions at 5 min intervals to a solution of **3** (1 mmol) in dry methanol (10 mL) and the mixture was stirred at room temperature. After disappearance of the starting material (within ca. 6 h) the solvent was removed from the reaction mixture and the concentrate was chromatographed. Pure **2** thus obtained was crystallized.

Syntheses of **16–19** and **22** were achieved by following experimental procedures analogous to those mentioned above. The melting points and analytical and spectral data of the different compounds were as follows.

3a: mp 166–167°C; IR: 3335 (N-H) and 1620 (C=O) cm^{-1}; ^1H NMR (100 MHz) δ: 6.24 (1H, br s, N-H), 6.60–6.82 (3H, m, H-2″, 4″, 6″), 6.94–7.14 (2H, m, H-3″, 5″), 7.30–7.84 (5H, m, H-6, 8, 3′, 4′, 5′), 7.74 (1H, ddd, J = 8.5, 7, and 1.8 Hz, H-7), 7.90–8.08 (2H, m, H-2′, 6′), and 8.32 (1H, dd, J = 8.5 and 1.8 Hz, H-5). Crystal structure, spectroscopic and magnetic studies, and antioxidative properties of catena-[diaqua(dihydro-orotato)manganese(II)]

Paule Castan, Christine Viala, Paul-Louis Fabre, Françoise Nepveu, Jean-Pierre Souchard, and Gérald Bernardinelli

Abstract: The polynuclear manganese(II) complex of L-dihydroorotic acid has been synthesized and characterized by X-ray crystallography, UV–visible spectroscopy, and magnetic susceptibility measurements. Crystal data: triclinic, space group $P\bar{1}$, $a = 4.7239(5)$ Å, $b = 7.902(1)$ Å, $c = 10.552(2)$ Å, $\alpha = 105.80(1)°$, $\beta = 98.864(7)°$, $\gamma = 104.69(1)°$, $V = 355.9(1)$ Å^3, $Z = 1$, $R = 0.035$, $Rw = 0.028$. This complex consists of polymer chains of manganese atoms that are bound together via carboxylate bridges with a Mn···Mn distance in the chain of 4.724 Å. The radical scavenging properties of the complex have been evaluated by ESR spectroscopy and cyclic voltammetry methods and compared to those of vitamin E and BHT (2,6-di-*tert*-butyl-4-methylphenol).

Key words: orotic acid, L-dihydroorotic acid, manganese(II) complex, antioxidative properties.

Résumé : Le complexe du manganèse(II) et de l'acide L-dihydroorotique a été synthétisé et caractérisé par spectroscopie UV–visible, susceptibilité magnétique et par diffraction des rayons X. Données cristallographiques : triclinique, groupe d'espace $P\bar{1}$, $a = 4.7239(5)$ Å, $b = 7.902(1)$ Å, $c = 10.552(2)$ Å, $\alpha = 105.80(1)°$, $\beta = 98.864(7)°$, $\gamma = 104.69(1)°$, $V = 355.9(1)$ Å^3, $Z = 1$, $R = 0.035$, $Rw = 0.028$. Ce complexe se présente comme une chaine polymérique d'atomes de manganèse liés entre eux par des ponts carboxylate, la distance Mn···Mn étant de 4.724 Å. Les propriétés antioxydantes de ce composé ont été évaluées par RPE et voltammétrie cyclique et comparées à celles de la vitamine E et du BHT (2,6-di-*tert*-butyl-4-methylphenol).

Mots clés : acide orotique, acide L-dihydroorotique, complexe du manganèse(II), propriétés antioxydantes.

Introduction

Orotic acid[2] (6-carboxyuracil, 1,2,3,6-tetrahydro-2,6-dioxo-4-pyrimidinecarboxylic acid, $OrotH_3$), being closely related to the biologically important pyrimidine bases, plays a significant role in many biological processes (1, 2). Moreover, it has been extensively used in medicine in the form of metal complexes, its therapeutical action depending on the nature of the complexed metal (3). We recently obtained the complex of 3-methylorotate with palladium(II), which displays a significant antitumor activity comparable to *cisplatin* (4, 5).In addition to its biological importance, orotic acid and its substituted derivatives (which may be viewed as substituted uracils) are also interesting ligands since they are potentially multidentate (the coordination may occur through the two N atoms of the pyrimidine ring, the two carbonyl oxygens, and the carboxylic group) and the metal complexes of orotic (4, 6–13) and isoorotic (14–16) acids have been the subject of a number of solution, spectral, and structural studies. However, studies on its coordination properties in solution and in the solid state show that orotic acid coordinates mainly via N1 and one oxygen atom of the carboxylato group. The only exceptions known so far are the copper(II) complex of 5-nitroorotic acid, which coordinates via the N1 and N3 nitrogen atoms (9), and the uranium complex of orotic acid, which coordinates only by one oxygen of the carboxylato group (17). Orotic acid does not enter the inner coordination sphere of the metal in zinc and magnesium compounds (18, 19).

As part of a program aimed at evaluating the antioxidative properties of small molecular weight metal complexes and in accordance with the reported superoxide radical scavenging activity of the Mn^{2+} ion in a number of in vitro and in vivo systems (20, 21), we studied the variation of this activity in manganese complexes with weak ligands such as carboxylic acids (22, 23). We recently described the quantitative analysis of such properties by ESR spectroscopy (24). Both the biological role and the nature of these substituted carboxylic acids prompted us to investigate the radical scavenging properties of Mn(lI) complexes of orotic acid and of some of its derivatives. Preliminary steps in this program have been to investigate the molecular structures and the physical properties of orotato complexes with manganese and we have recently reported on polynuclear manganese(II) complexes of orotic acid and of some of its derivatives (25).

$R^1 = COOH$, $R^2 = R^3 = H$, Dihydroorotic acid

The present work reports the structural, spectral, and magnetic properties of the manganese(II) complex with dihydroorotic acid together with its SOD (superoxide dismutase)-like activities evaluated by ESR spectroscopy and cyclic voltammetry methods. This ligand, unlike orotic acid, presents a nonaromatic pyrimidine ring. The aim of this work was to study a possible modification of the coordinating and antioxidative properties of the resulting manganese(II) complex, associated with the structural difference arising from this loss of aromaticity.

Experimental

Materials

L-Dihydroorotic acid, 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO), diethylenetriaminepentaacetic acid (DTPA), and dimethylaminoethylamine (DMAEA) were purchased from Aldrich Chemical Co. All other chemicals and solvents were of reagent grade.

Synthesis of $[Mn(C_5H_6N_2O_4)_2 \cdot (H_2O)_2]_n$

An aqueous solution of manganese(II) acetate (1 mmol, 5 mL) is added to a solution of L-dihydroorotic acid (1 mmol) in water–acetonitrile (80/20). The pH is adjusted to 7 by adding an ammoniacal solution and, after stirring for 2 h, the mixture is filtered off. After the filtrate has been allowed to stand for 3 weeks in a closed flask, at room temperature, pale tan crystals are formed. Anal. calcd. for $C_{10}H_{l4}MnN_4O_{10}$: Mn 13.56, C 29.64, H 3.48, N 13.82; found: Mn 13.3, C 29.25, H 3.4, N 13.7.

Physical measurements

Elemental analyses were carried out at Service Interuniversitaire de Microanalyse, Toulouse. UV spectra were recorded on a SECOMAM S 1000 spectrometer in aqueous solutions. IR spectra were recorded on a Perkin–Elmer 983 G spectrometer coupled with a Perkin–Elmer infrared data station. Samples were run in the solid state (KBr pellets).

Variable-temperature magnetic susceptibility data were collected on powdered samples of the title compound with the use of a SQUID-based sample magnetometer on a Quantum Design model MPMS instrument. All data were corrected for diamagnetism of the ligand estimated from Pascal's constants (26). ESR spectra in the solid state (300 and 120 K) and as water or water – ethylene glycol glasses at 100 K were recorded on a Bruker ESP 300E spectrometer. Acidity constants were determined through acid–base titrations by means of a METHROM autoburette.

Antioxidative properties

To study the superoxide scavenging properties, the ESR spectra were recorded on a Bruker ER 200 D spectrometer at room temperature by starting a 3 min scan after adding acetaldehyde (AC). Recording conditions were as follows: central field, 3500 G; scan range field, 200 G; microwave frequency, 9.71 GHz; frequency modulation, 70 kHz; field modulation intensity, 1 G; time constant, 0.5 s; scan speed, 24 G min^{-1}. A 1 mL sample of solution was prepared in a glass tube by adding the reagents in the following order: DMPO (50 mmol L^{-1}), xanthine oxidase (XOD) (0.018 U mL^{-1}), tested compound (x mmol L^{-1}), and acetaldehyde (60 mmol L^{-1}) in phosphate or DMAEA buffers (pH 7.4) containing 15 mM DTPA. For each concentration of compound tested, the percentage of inhibition of the ESR signal compared to the signal of the blank was calculated by adding the height of the sextet peaks of the $O_2^{\bullet -}$ dependent AC–XOD carbon-centered signal (the AC–XOD system with DMPO in phosphate or DMAEA buffers produced a sextet ESR signal resulting from the presence of the $O_2^{\bullet -}$ anion in the medium (27)). The $O_2^{\bullet -}$ scavenging activity was quantified by the compound concentration inducing a 50% decrease in the control ESR signal intensity (IC50).

Electrochemical measurements were carried out by cyclic voltammetry with a homemade potentiostat driven by a PC computer. The electrochemical cell was a conventional three-electrode configuration: working electrode, gold disk (diameter l mm); reference electrode, SCE; counter electrode, Pt wire. Experiments were carried out at room temperature in oxygenated dimethylformamide (DMF) with Bu_4NClO_4 as supporting electrolyte. The cyclic voltammetry method is based on the electrochemical properties of the redox couple, which appears to be quasi-reversible at a gold electrode in DMF. When an $O_2^{\bullet -}$ scavenger is added, the cyclic voltammogram is modified according to the kinetics of the $O_2^{\bullet -}$ deactivation. On the backward sweep, the anodic peak current, Ip_{ox}, which corresponds to $O_2^{\bullet -}$ oxidation, is lower than the initial cathodic peak current Ip_{red} of the reduction of O_2 into $O_2^{\bullet -}$ during the forward sweep. The analysis of the peak current ratio RIp (= Ip_{OX}/Ip_{red}) as a function of the potential scan speed and of the concentration of the drug tested allows the determination of the kinetic constants. The method has been standardized with vitamin E and BHT (2,6-di-*tert*-butyl-4-methylphenol).

© 1998 NRC Canada

To compare the results obtained from the two methods, radical scavenging activities are expressed as vitamin E equivalents.

X-ray crystal structure determination

Crystal data, measurement of intensities, and structure refinement are summarized in Table 1. Unit cell parameters and diffracted intensities were measured at room temperature on a STOE-STADI 4 diffractometer using graphite monochromated MoKα radiation. Data were corrected for Lorentz and polarization effects and for absorption. The structure was solved by direct methods (MULTRAN87) (28) and refined by the XTAL 3.2 program (29). Atomic scattering factors and anomalous dispersion terms are taken from ref. 30. All H-atom coordinates were observed and refined. Selected positional and isotropic displacement parameters for non-hydrogen atoms are listed in Table 2, and interatomic distances and angles in Table 3. Complete crystal data and final fractional atomic coordinates with estimated standard deviations have been deposited as supplementary material.[3]

Results and discussion

Description of the structure

Bearing in mind the number of potential coordination sites of L-dihydroorotic acid, polymeric chains may be expected. However, very few polymeric complexes have been observed with orotic acid itself. In polymeric Co(III) and Ni(II) complexes of orotic acid, metal atoms are hexacoordinated to one orotato anion at the N1 ring nitrogen and at the adjacent carboxylate oxygen and to another orotato anion at the exocyclic keto oxygen O4. Thus in these complexes orotic acid acts as a tridentate ligand and bridges metal ions, forming polymer chains.

The Mn(II) complexes of orotic acid, 5-nitroorotic acid, and 3-methylorotic acid that we recently reported (25) consist of polymer chains in which the manganese atom is bonded to the orotato anion at the ring nitrogen N1 and at the adjacent carboxylate group. The anions are associated to form chains, the carboxylato group acting as a bridge between the metal ions, and thus the orotato group is tridentate (N1 and two oxygens of the carboxylate group). By contrast, in the isoorotic acid Mn(II) complex (15), the metal is bonded to the isoorotato anion at one oxygen of the carboxylate group and at the adjacent oxygen atom of the ring.

An ORTEP drawing of the diaqua(dihydroorotato)manganese(II) complex along with the labelling scheme is shown in Fig. 2. Selected interatomic distances and angles are listed in Table 3. This complex consists of polymer chains of manganese that are bound together via carboxylate bridges. The manganese(II) ion is situated at an inversion center (1/2, 1/2, 0) and is involved in a hexa coordination, which is the most common coordination of manganese(II). Each dihydroorotato anion is bidentate by the two oxygen atoms of the carboxylate group and thus bridges two metal ions, which are bound in the chain by two -O-C-O- bridges. Four types of carboxylate bridges have been identified in the literature; only the *syn–syn* configuration brings the metal atoms close enough to form a clustered structure. In this structure two carboxylates of two ligand molecules bridge the metal atoms by two *anti–syn* types

of carboxylate bridges forming a polymeric stack parallel to the (011) plane. Carboxylate bridging between transition-metal atoms such as copper(II) acetate hydrate (31, 32) and its analogues with other metal ions is well known. The hexa coordination around a metal atom is provided by four oxygens of four orotato anions and two water molecules (O1, O2, O′1, O′2, O01, and O′01). The octahedron has deviated from D_3 symmetry and four shorter and two longer metal–ligand bond lengths are observed. The Mn—O distances of 2.135(2), 2.163(2), and 2.235(2) Å (for Mn—O2) plainly indicate this distortion. However, the two carboxylate bond lengths are almost identical, i.e., C5—O1 = 1.249(3) and C5—O2 = 1.247(3) Å. In all structures known to date where the orotate is complexed to a metal, it acts as a dianionic ligand (13), the only exception being a uranium(VI) complex where the ligand is mono-deprotonated at the carboxylic function and monodentate (17). In the present structure both nitrogens are protonated and the dihydroorotato entity is only deprotonated at the carboxylate function.

Since the crystal structure of the dihydroorotic acid itself has not been determined, structural parameters for the dihydroorotato anion may be tentatively compared to those of orotic acid monohydrate (33). The deviation of the ring from planarity is very important; it is correlated with loss of the aromatic properties of the pyrimidine ring by addition of two hydrogen atoms on the C1—C2 bond. The dihedral angles C4-N2-C1-C2 and C2-C1-C5-O2 are 40.6(3)º and 59.8(3)°, respectively. As expected, the N2—C4, C4—N1, and N1—C3 bond lengths are slightly different than those observed for orotic acid but the bond lengths C2—C3 (1.493(4) Å), C1—C2 (1.511(4) Å), and C1—C5 (1.524(4) Å) are longer according to their single bond character. In the same way the bond distance C1—N2 (1.459(3) Å) is significantly longer than in orotic acid complexes (mean value 1.36 Å). The two carbonyl bond lengths, C3—O3 and C4—O4 at 1.226(3) and 1.231(3) Å, respectively, are in good agreement with those found in orotic acid itself (33).

Magnetic susceptibility

The magnetic susceptibility for the complex has been measured from 290 K to 5 K. At room temperature, the complex has an effective magnetic moment per manganese(II) ion of 5.83 BM, indicating the high-spin nature of the manganese ion.

The effective magnetic moment per manganese(II) decreases slowly from 5.93 to 5.02 until 20 K. The decrease is more pronounced below 20 K and the magnetic moment reaches 3.17 BM/Mn at 5 K. The results of the X-ray crystal structure determination indicate a chain structure with an *anti–syn* configuration and a Mn···Mn distance of 4.723 Å inside the chain. This distance suggests that spin–spin magnetic interactions are unlikely to occur between the manganese ions of neighbouring chains or inside the chain, since to achieve

substantial cooperative effects in physical properties, metal ions must be brought close together by bridging in the *syn–syn* configuration. However, the distortion of the manganese coordination octahedron is large enough to result in a zero-field splitting of the manganese(II) ground state and to afford a small lowering of the magnetic moment at low temperature as was previously observed for some manganese(II) complexes (34).

The complex exhibits powder X-band EPR spectra characterized by a broad resonance near $g \approx 2$ that does not show appreciable temperature dependence. However, frozen solution spectra obtained from water – ethylene glycol glasses at 95 K exhibit a central allowed hyperfine sextet typical for a Mn^{2+} ion with a fine-structure pattern similar to those observed for electronically isolated manganese species. This indicates that no interactions between the manganese atoms are involved.

Solution studies

Linear free energy relationships for proton dissociation and metal complexation have been evidenced for the pyrimidine–acid systems (35) and have also been reported in the literature for various aromatic or aliphatic systems. In water, the acidity constants of orotic acid are $pK_1 = 2.07$ and $pK_2 = 9.45$ with pK_1 corresponding to COOH and pK_2 to NH deprotonations. The acidity constants of 5-nitroorotic acid are $pK_1 = 1.5$ and $pK_2 = 4.94$, proton dissociation being considerably enhanced by the electron withdrawal groups. For L-dihydroorotic acid, only the first acid dissociation constant ($pK_1 = 3$) can be determined in H_2O (in this case, NH is less acid than H_2O). The second proton dissociation constant, which may occur from a

NH dissociation, was observed to occur in a pH region greater than 12. Taking into account these results, one might expect that, even in the presence of a metal atom, the deprotonation at one of the nitrogen atoms does not occur and that the metal atom may only coordinate to the carboxylic function.

In the same way, perturbation of the π system, which was found to have a pronounced effect on the dissociation constants determined potentiometrically, also induces considerable modification of the UV spectra. Thus, at the same acidic pH (pH = 3), the orotic acid exhibits a band at 285 nm, while L-dihydroorotic acid shows two bands at 198 and 216 nm. These two bands may be attributed to the two independent π systems, the carboxylic group (216 nm) and the ring (198 nm). Moreover, no shift is observed when the pH is increased to 12. This may be related to the fact that even at high pH values only the carboxylic function is deprotonated.

Relationships between complexation sites of pyrimidine derivatives and UV data have been reported in the past and one may note that the UV spectra predict the sites of deprotonation and then those of coordination (35–37); this was the case with copper and nickel complexes of orotic acid (38) for which the complexation induced a significant bathochromic shift of the ligand absorption band (λ_{max} = 316 nm versus 285 nm for the free ligand) correlated to complexation at the carboxylic group and adjacent endocyclic nitrogen atom.

In an attempt to elucidate the metal–ligand binding mode of manganese(II) towards L-dihydroorotic acid, UV absorption spectra of the free ligand, of the isolated Mn(II) complex, and of ligand–Mn(II) salt mixtures in different ratios were recorded and compared. For the isolated complex, any shift in the maximum absorbance wavelength (λ_{max} = 216 nm) with respect to the free anion was observed in aqueous solution. Moreover, addition of manganese(II) salt to a solution of L-dihydroorotic acid does not induce a significant bathochromic shift even with a large metal salt excess (1:50). These results indicate that the complex dissociates in aqueous solution and has a low stability since no complexation is observed even in the presence of a large excess of metal salt. We have already remarked upon (25) a quite similar behaviour for orotic acid itself in the presence of manganese salt.

Antioxidative properties

The antioxidative properties of this compound have been evaluated and compared to those of known antioxidants (vitamin E, BHT) and to those of manganese complexes of orotic acid derivatives that we have already described (39). The results are expressed with reference to vitamin E used as standard. A logarithmic scale is used to present ESR results.

Figure 4 shows cyclic voltammograms of the dioxygen system in DMF at a gold electrode. When no Mn complex is added, the electrochemical system of dioxygen is quasi-reversible (40, 41): the backward peak current is equal to the forward one. When the complex is added, the backward peak current decreases as for an EC process. The decrease of the backward peak current is enhanced when the complex concentration is increased. This can be schematized by:

$$O_2 + e \rightleftharpoons O_2^{\bullet -}$$

$$O_2^{\bullet -} + X \rightarrow \text{products } O_2^{\bullet -} + X \rightarrow \text{products}$$

By comparison of the peak ratio (backward peak current/forward peak current) for the complex with that of BHT or vitamin E, the radical scavenging activity is given in terms of a BHT or vitamin E equivalent. The complex presents a superoxide scavenging activity of 0.6 mol vitamin E/mol. Figure 5A represents the radical scavenging activities of the different Mn complexes. The activity observed for the complex of dihydroorotic acid is of the same order of magnitude as those of the Mn(orotate) complex or of the Mn(II) ion in the same buffer. However, this activity is far below that of the Mn(5-nitroorotate) complex. This low activity can be attributed to their low stability, as was the case for the complex of orotic acid.

ESR measurements give similar results, except that a logarithmic scale was used (Fig. 5B). This difference is because of the solvents used for the measurements, DMF for cyclic voltammetry and water for ESR. As the superoxide radical scavenging goes through an acid–base reaction that allows superoxide disproportionation, the radical scavenging activities (by ESR) appear higher in water than in DMF and have to be related to the acidic properties.

Conclusion

In a recent paper we emphasized that the major binding mode of the Mn(II) ion with orotic acid and some of its derivatives (where the aromatic structure of the pyrimidine ring is preserved) remains the N1 and carboxylate sites in the solid state as well as in solution. This is not the case for dihydroorotic acid, for which only the carboxylate group is involved in the metal coordination. Moreover, UV absorption spectra offer a good indication of the behaviour of these complexes in solution. In the course of our studies concerning the antioxidative properties of manganese(II) complexes of orotic acid derivatives, three types of behaviour have been found: unstable and labile complexes such as those of orotic (**a**) or dihydroorotic (**d**) acids for which no antioxidative properties were found (the activity lies in the same range that of $MnCl_2$ itself); the unstable but inert complex of 3-methylorotic acid (**b**) for which antioxidative properties are significant; and the stable and inert complex of 5-nitroorotic acid (**c**) for which very high antioxidative properties was found.

The reactions of a 1-alkenesulfenate anion with TMS-X reagents; a variable temperature NMR study

Mitchell D. Refvik and Adrian L. Schwan

Abstract: Lithium (*E*)-1-hexenesulfenate (**5a**) was treated with a number of TMS-X (TMS = trimethylsilyl) reagents to afford *N,N*-bis(trimethylsilyl)-(*E*)-1-hexenesulfenamide (**7a**) and (or) di((*E*)-1 hexenyl) disulfide (**8**), usually in low yield. The cleanest reactions, those from use of TMS-Cl (to afford **7a**) and TMS-CN (which yields **8**) were analyzed by variable temperature NMR. It was found that the low-temperature silylation reaction using TMS-Cl affords **7a** and thiosulfinate **12** as initial products. Warming the mixture coerces the decomposition of **12**. Treatment of **5a** with TMS-CN also yields thiosulfinate **12** which is reduced to disulfide **8** as the temperature warms, possibly by action of cyanide ion. Evidence is presented that allows a confident structural assignment of the transient thiosulfinate **12**, and mechanisms are suggested for the formation of **12**. The study also led to the NMR observation of (*E*)-1-hexenesulfenate (**5a**).

Key words: sulfenate, thiosulfinate, variable temperature NMR (VT NMR), silylation.

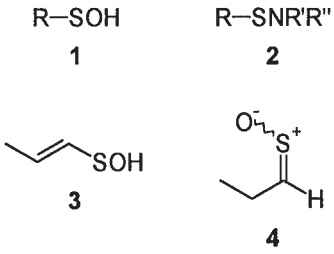
Résumé : Le traitement du (*E*)-1-hexènesulfénate de lithium (**5a**) avec un certain nombre de réactifs du type TMS-X (TMS = triméthylsilyle) conduit au *N,N*-bis(triméthylsilyl)-(*E*)-1-hexènesulfénamide (**7a**) et (ou) au disulfure de di((*E*)-1-hexényle) (**8**), généralement avec de faibles rendements. Les réactions les plus propres, celles impliquant le TMS-Cl (conduisant au produit **7a**) et le TMS-CN (conduisant au produit **8**), ont été analysées par RMN à température variable. On a observé que la silylation à basse température, à l'aide de TMS-Cl, conduit initialement au produit **7a** et au thiosulfinate **12**. Par réchauffement du mélange, il s'opère une décomposition du produit **12**. Le traitement du produit **5a** par du TMS-CN conduit aussi au thiosulfinate **12** qui, par élévation de la température, est réduit en disulfure **8** possiblement par l'action de l'ion cyanure. On présente des données qui permettent d'attribuer avec confiance une structure au thiosulfinate transitoire **12** et on suggère des mécanismes pour la formation du produit **12**. L'étude a aussi permis d'observer le (*E*)-1-hexènesulfénate (**5a**) par RMN.

Mots clés : sulfénate, thiosulfinate, RMN à température variable (RMN TV), silylation.

[Traduit par la rédaction]

There is persistent interest in the chemistry of sulfenic acids and their derivatives for a variety of reasons (1–4). Sulfenic acids (**1**) themselves are recognized primarily for their role in biological processes (2, 5). Despite their notorious instability (1), some sulfenic acids can be isolated and characterized, but only when they are generated in atypical steric (6) or electronic environments (7). Sulfenic acid amides (**2**), considerably more stable than their corresponding acids, often demonstrate chiroptical properties about the S—N bond (8).

Unsaturated sulfenic acid derivatives are the most important contributors to the flavour and lachrymatory properties of onions, garlic, and related *Allium* plants (2). Specifically, 1-propenesulfenic acid (**3**) has been shown to be the precursor of (*Z*)- and (*E*)-propanethial *S*-oxides (**4**), the familiar lachrymatory factor of onions (9). Unsaturated sulfenic acid amides have demonstrated usefulness in synthesis (10–12).



1-Alkenesulfenate anions (**5**) can be generated through the regiospecific deprotonation and stereoselective ring opening of thiirane *S*-oxides (**6**) (13) and are captured with reactive alkyl halides; the overall result is a useful preparation of *E*-1-alkenyl sulfoxides. Treatment of the 1-alkenesulfenates with trimethylsilyl chloride (TMS-Cl) resulted in the recovery of *N,N*-bis(trimethylsilyl)-1-alkenesulfenamides (**7**) which have served as a general source of other 1-alkenesulfenamides and also 1-alkenesulfonamides (14, 15).

The mechanism for the conversion of the sulfenate, nucleophilic at sulfur, to the sulfenamide, which is electrophilic at

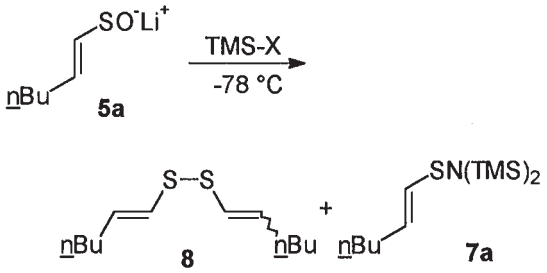
sulfur, is not well understood. Hence a study of the reactions of 1-alkenesulfenate anions with a collection of TMS-X reagents was undertaken, and in this paper, we report a number of variable temperature NMR (VT NMR) experiments that provide insight into some of the transformations taking place.

Results and discussion

As part of our investigation into the role played by the TMS-Cl during the conversion of sulfenate to sulfenamide, (*E*)-1-hexenesulfenate (**5a**) was treated with a number of different TMS-X reagents. The products are shown in reaction [1], and

[1]



the quantitation of those products is outlined in Table 1. Since early experiments in the area were associated with the silylation reaction presented in Scheme 1 (15), recovery of sulfenamide **7a** as the major product was predicted. Surprisingly, disulfide **8** was a significant component of several of the reaction mixtures, and it was the lone product in the reaction of the TMS-CN with sulfenate **5a**. Further analysis of the mixtures revealed significant nonvolatile oligomeric material that would not pass through a GC or flash-chromatography column (silica gel). Its presence could be confirmed by conglomerations of peaks in the ^{1}H NMR spectrum at δ 0.9–1.2 ppm and in the ^{13}C NMR spectrum at δ 20–30 ppm. Other TMS-X reagents were employed, but TMS-OAc, TMS-$OC(O)CF_3$, TMS-OTf, and TMS-OSO_2Ph afforded negligible isolable products.

Any mechanism put forth to account for the formation of the products obtained must address the following facets of Table 1. Most important is that identity of the leaving group in the silylation reactions plays a key role in the chemistry perhaps by influencing the initial point of silylation and (or) by participating directly in subsequent chemistry. The proposed mechanism must also account for the fact that the hexenyl portion of **8** is prone to isomerization, while the (*E*)-hexenyl geometry of **7a** is preserved. The ensuing discussion focuses primarily on the chemistry induced by TMS-Cl and TMS-CN, since their reactions represent each extreme of the observed reactivity modes.

Scheme 2 offers a series of reactions that could account for the observed products, based on precedented or generally accepted chemistry (16–21). Variable temperature NMR was utilized to analyze some of the reactions of Scheme 2, with the hope of determining the exact processes occurring. To maintain consistency with prior preparative sulfenate chemistry (13), THF-d_8 was utilized as the solvent for the NMR experiments. LiHMDS·Et_2O (22), a white solid, was used instead of the commercially available THF solution of LiHMDS in order to reduce solvent interference in the NMR spectra. Control experiments indicated that the etherate behaved in a manner comparable to the commercial THF solutions of LiHMDS. The olefinic region of the VT NMR spectrum was our principal focus. Indeed, it proved to be the least cluttered and the most diagnostic region. Little information could be gleaned in the upfield portion of the spectrum.

A logical starting point for the study was the ^{1}H NMR spectrum of 1-alkenesulfenate anion **5a** in solution. This species was generated on a small scale in THF-d_8, and the solution was transferred to an NMR tube while maintaining a cold solution (23). The ^{1}H NMR spectrum obtained (Fig. 1*a*) shows a doublet at δ 6.30 ppm corresponding to the vinyl proton adjacent to the sulfur, and a doublet of triplets at δ 4.94 assigned as the vinyl proton β to the sulfur, each consistent with the electron distribution within **5a**. Another set of peaks present in this spectrum was tentatively assigned to be thiosulfinate **12**; further evidence for this assignment was found later in this study (vide infra). The small doublet at δ 6.06 ppm and the doublet of triplets at δ 5.88 ppm are due to disulfide **8**.

Prior to introduction into the NMR tube, the mixture had been spiked with a known amount of benzene, which allowed for calculation of approximate yields of identifiable compounds.[3] It must be noted that the amounts utilized were small, and consequently an inescapable margin of error accompanies the quantitation of this and other mixtures. Alkenesulfenate **5a** was present in approximately 70% yield, while thiosulfinate **12** was present in approximately 20% yield. When preparative sulfenate mixtures are quenched with a reactive alkyl halide, vinyl sulfoxide is obtained usually in ca. 70% yield, in accord with the sulfenate concentration in the NMR tube mixture.

Sulfenate **5a** was regenerated under identical circumstances, and the new sample was treated with TMS-Cl. The ^{1}H NMR spectrum recorded at –60°C (Fig. 1*b*) shows resonances consistent with sulfenamide **7a** and another major product. The vinyl hydrogens of **7a** exhibit a doublet at δ 6.36 ppm for the hydrogen adjacent to the sulfur, and a doublet of triplets at 5.29 ppm for the other vinyl hydrogen. These peaks persist in the ^{1}H NMR spectrum up to room temperature and indefinitely thereafter, as would be expected for a stable compound. The other product possesses a doublet at 6.64 ppm and may be responsible for other peaks in the spectrum, all of which are noticeably similar to those already tentatively assigned to **12**.

[3] Integration was employed for quantitation, but it has been left off of the NMR spectra presented herein.

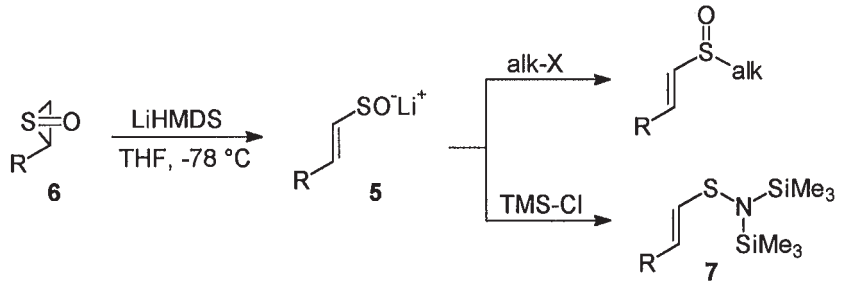
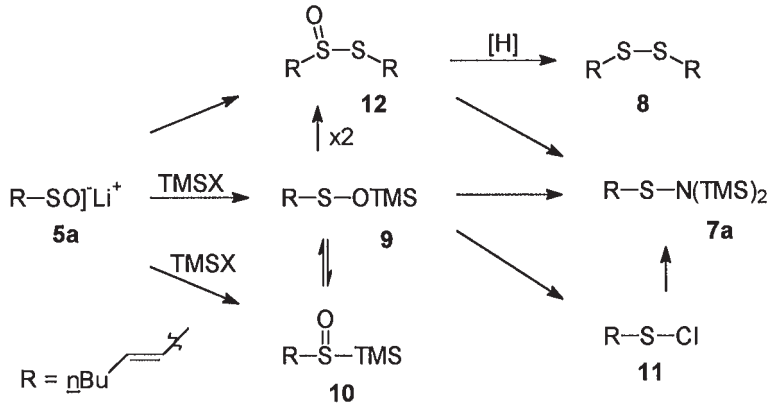
Scheme 1.

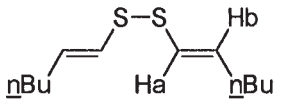


Scheme 2.

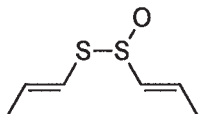


Given this assignment, a **12**:**7a** ratio of 1:1 can be measured in the mixture. Hence, for every molecule of sulfenate that proceeds to sulfenamide, two molecules combine to form thiosulfinate.

To confirm that the unknown was indeed thiosulfinate **12** an attempt was made to prepare it independently through oxidation of the corresponding disulfide **8**. The literature suggested that such a conversion to the thiosulfinate would be a facile process (24). Indeed, thiosulfinate **12** could be generated by the *m*-CPBA oxidation of **8** in $CDCl_3$ at –60°C. The ^{1}H NMR spectrum was recorded after introduction of the precooled (to –60°C) sample into the probe (Fig. 1*d*). The vinyl hydrogens of **12** form a conglomeration of peaks at δ 6.34–6.62. This data compares favourably with the ^{1}H NMR spectrum of (*E*)-1-propenyl (*E*)-1-propenethiosulfinate (**13**), which exhibits vinyl hydrogens at δ 6.30–6.65 (24). Furthermore, the remainder of the ^{1}H NMR spectrum of **12** exhibited the predicted multiplets.



8



13

The ^{1}H NMR spectrum of **12** in $CDCl_3$ bears little resemblance to the ^{1}H NMR spectrum of **12** in THF-d_8. To overcome this difficulty, the two NMR solutions were mixed, and the ^{1}H NMR of the mixture was rapidly recorded at 0°C (Fig. 1*c*). The resulting spectrum indicates the presence of **7a** and a more intense, different, but not additional collection of new peaks now representing the spectrum of **12** in the $CDCl_3$–THF-d_8 solvent system. The ratio of **12** to **7a** is much higher than in the original solution, providing evidence that thiosulfinate **12** was present in each solution. Allowing the solution to warm to room temperature resulted in the disappearance of the signals from **12**, characterizing it as a species only stable up to approximately 0°C. Furthermore, the decomposition of **12** is consistent with the low yields of recoverable material obtained from other silicon electrophile quenching reactions (Table 1) (24, 25).[4]

The most convincing evidence for the presence of **12** in these mixtures came when another reaction of **5a** with TMS-Cl was conducted, and both the ^{1}H NMR and ^{13}C NMR spectra were recorded at –78°C (Figs. 2 and 3). As expected, sulfenamide **7a** (ca. 35%) and **12** (ca. 46%) were present. The ^{13}C NMR spectrum showed seven lines in the vinylic region: one for the benzene additive, two for sulfenamide **7a**, and four lines that were assigned to **12**. After warming to room temperature and the concomitant decomposition of **12**, each of the spectra were recorded again (Figs. 2*b* and 3*b*). Four lines in the vinylic region of the ^{13}C NMR disappeared, thereby designating the peaks attributable to **12**. Of the four resonances that were lost, two are particularly supportive of the structure **12**. A peak at δ 148.7 ppm is characteristic of a vinylic carbon beside a sulfinyl functionality, while the 116.6 ppm line can be assigned to a vinylic carbon β to a divalent sulfur. All four of these vinylic ^{13}C NMR resonances (148.7, 140.4, 132.7, 116.6) are consistent with those exhibited for **13** (145.4, 136.4, 130.7, 115.6) (24).

In the context of chemistry, the information gained on

[4] Compound **13** and its geometric relatives rearrange to bicyclic compounds (24); we were unable to find any evidence for a similar transformation of **12**. Highly substituted 1-alkenyl 1-alkenethiosulfinates are stable at ambient temperature and can be fully characterized (25).

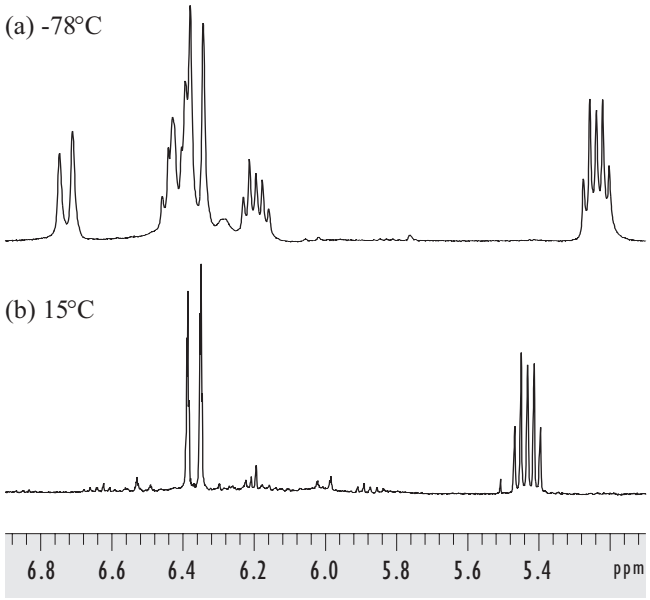

Fig. 3. [13]C NMR spectra of reaction mixture of **5a** and TMS-Cl at (*a*) –78°C; (*b*) 15°C.

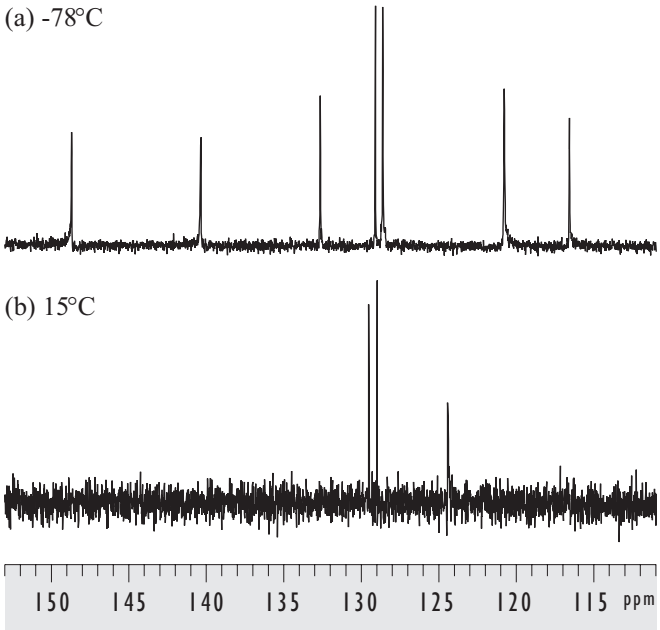


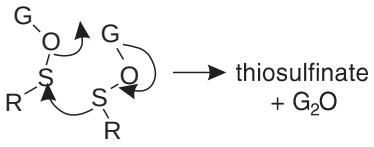
warming the solution was also quite informative. Sulfenamide was determined to still be present in 35% yield, pointing out that thiosulfinate **12** *does not* suffer the fate of a nucleophilic substitution reaction with hexamethyldisilazane to produce sulfenamide **7a** under these conditions. Otherwise the yield of sulfenamide **7a** should have increased as **12** was depleting.

Examination of the mechanism proposed in Scheme 2 suggests that **7a** must be formed through the nucleophilic reaction of hexamethyldisilazane on some species. It follows that increasing the nucleophilicity of the amine may result in an improved yield of **7a**. Towards this end, sulfenate **5a** was generated using 2 equiv. of LiHMDS. The result, as analyzed by [1]H NMR, was the formation of sulfenamide **7a** in approximately 50% yield, thiosulfinate **12** (ca. 7%) and disulfide **8** (10%). The high yield of **7a** has significant ramifications for the synthetic utility of this procedure. Indeed, the published procedure for the preparation of sulfenamides **7** utilizes 2 equiv. of hexamethyldisilazide. The observation of increased amounts of **8** is also in accord with previous preparative chemistry (15).

The observation of thiosulfinate **12** accompanying **7a** is worthy of further discussion. The usual fate of sulfenic acids (2, 17, 26) is dimerization with loss of H_2O (Fig. 4(*i*)), and this process could create some **12** through the presence of adventitious water. In the TMS-Cl quenched reaction, a similar

© 1998 NRC Canada

Fig. 4. Possible modes of thiosulfinate formation from (*i*) sulfenic acids as proposed earlier, G = H; (*ii*) from silyl sulfenate esters, G = Me_3Si.



mechanism can be proposed whereby trimethylsilyl group replaces the H (Fig. 4(*ii*)). Hence some of the silyl sulfenates **9** are captured by hexamethyldisilazane to afford sulfenamide while dimerization of **9** with loss of TMS-O-TMS competes. The experiment employing 2 equiv. of LiHMDS supports this hypothesis: a stronger nucleophile, present in a greater concentration would be expected to capture **9** more readily and other fates of **9** are reduced. Accordingly, sulfenamide **7a** was obtained in higher yield in that experiment.

Having completed an investigation of the reaction of TMS-Cl with **5a** the focus became the reaction involving TMS-CN. The techniques utilized previously were also applicable to the study of the reaction of TMS-CN. Thus 0.8 equiv. of TMS-CN was added to a THF-d_8 solution of **5a**, and a ^{1}H NMR spectrum was obtained (Fig. 5*a*). At –78°C the solution was found to contain **12** in about 35% yield and unreacted **5a** (35%). The probe was then allowed to warm, and spectra were recorded at approximately 10° intervals. At –30°C disulfide **8** was present in about 15% yield (Fig. 5*b*) while thiosulfinate (**12**) concentration fell to about 15% yield. Hence formation of **8** was probably occurring at the expense of **12** as proposed in Scheme 2. Finally in the room temperature sample, **8** was quantitated to be about 38% yield while **12** had disappeared entirely (Fig. 5*c*). This is strong evidence for the formation of **8** through deoxygenation of **12** by some mechanism, possibly that proposed by Oae and co-workers (19).[5] (*E*)-1-Hexenesulfenate (**5a**) concentration was determined to be steady at 35% throughout the temperature range.

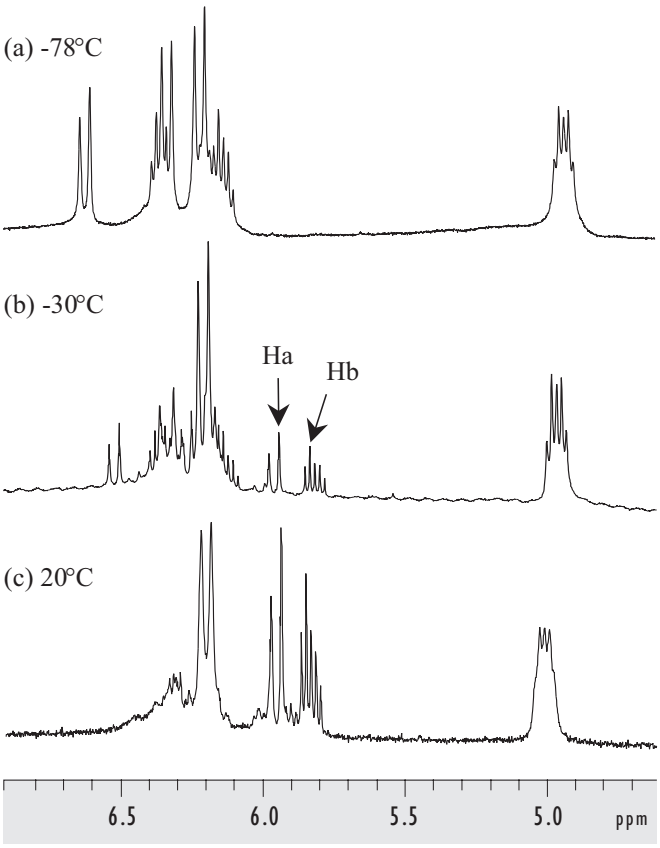
The proposed mechanisms also accommodate an explanation for the observation of some (*E,Z*)-dihexenyl disulfide. In an attempted synthesis of certain geometrically pure 1-alkenyl thiosulfinates (24), it was observed that both *E* and *Z* isomers were always present. It has been submitted that compounds such as **12**, possessing an RCH═CHSS(O)- unit, have the opportunity to undergo a 2,3-sigmatropic shift, similar to that observed for allylic sulfoxides (i.e., a sulfenate–sulfoxide rearrangement), and upon reversion of such a shift, either geometric isomer may result.[6] The general mechanism demands that other counterions of the TMS-X reagents (e.g., Br^-, I^-, N_3^-) also possess the ability to effect deoxygenation, albeit with significantly less efficiency. Hence some of **12** has the opportunity to rearrange before its reduction to **8** or to an isomer of **8** (before its decomposition).

A final set of experiments were performed in order to examine the possibility of *S*-silylation of the sulfenates, which may occur upon sulfenate quench with TMS-CN. To probe the possibility of this particular reaction, sulfinyl silane **10** became

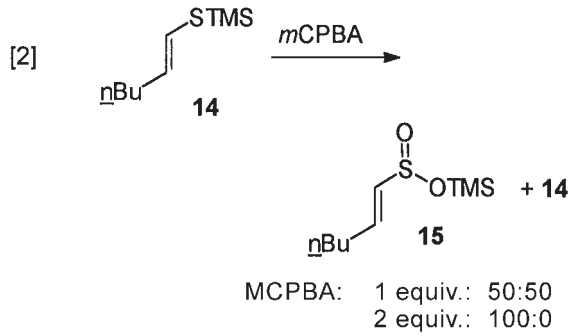
[5] Addition of commercial LiCN–DMF to mixtures containing **12** afforded small amounts of disulfide **8** upon warming.

[6] For a suitable reaction scheme the reader is referred to refs. 2 and (or) 24.

Fig. 5. ^{1}H NMR spectra of reaction mixture of **5a** and TMS-CN at (*a*) –78°C; (*b*) –30°C; (*c*) 20°C. Note appearance of vinylic peaks (Ha, Hb) of **8** in spectra (*b*) and (*c*).



a target for an independent preparation. One could conceive of the synthesis of **10** through simple oxidation of the corresponding thioether **14** (27). The oxidation of **14** with 1 equiv. of MCPBA in an NMR tube ($CDCl_3$) provided a 50:50 mixture of starting material and a product assigned to be trimethylsilyl 1-hexenesulfinate (**15**) (see reaction [2]). Complete isolation



and characterization of sulfinate **15** was not feasible due its decomposition and the presence of an accompanying by-product, *m*-chlorobenzoic acid. Nevertheless, GC/MS and ^{1}H NMR data were consistent with the assigned structure. The use of 2 equiv. of oxidant under similar conditions resulted in the complete conversion to **15** with no detectable **14**. These results are in agreement with those of Davis et al. (18) who found that the oxidation of silyl thioethers with oxaziridines afforded trialkylsilyl benzenesulfinates in good yields.

© 1998 NRC Canada

The oxidation probably occurs by initial formation of sulfoxide **10**, which rapidly tautomerizes to **9**. Compared to silyl thioether **14**, sulfenate **9** is then more susceptible to oxidation, due to the α-effect (18). This chemistry lends support to the proposal that **9** and **10** are in equilibrium (Scheme 2), with sulfenate **9** as the preferred tautomer. Hence, any evidence in support of the direct formation of **10** as shown in Scheme 2 would be fleeting. Likewise, if **10** were formed, its participation in any other chemistry is unlikely, due to its propensity to convert to **9**.

It would appear that our inability to gain any spectral evidence for **9** in the sulfenate quenching mixtures is due to the reactive nucleophiles (sulfenate and amine[7]) present under the conditions for its generation. However, of the stable trimethylsilyl alkane- and arenesulfenates known (18, 28), the arenesulfenates were prepared in the presence of hexamethyldisilazane (18). Our lab has already demonstrated that *N*-(1-alkenylthio)phthalimides, a family of unsaturated sulfenic acid amides, are more electrophilic at sulfur than their saturated counterparts. It follows here that sulfenates such as **9** are also more electrophilic at sulfur compared to the known stable analogs. In accord with our results, it has recently been communicated that trimethylsilyl 1,2-di(4-methoxyphenyl)-ethenesulfenate also has limited stability and readily reacts with amines and nucleophilic sulfur compounds (29).

An unresolved question remains: why is there significant sulfenamide formation when TMS-Cl is the quenching electrophile and virtually no formation when TMS-CN is employed? *S*-Silylation is not the solution to this problem. However, a feasible explanation may be based on the relative rates of reaction of **5a** with TMS-Cl and TMS-CN. Based on HSAB theory, one may expect the *O*-silylation of sulfenate **5a** with TMS-Cl to be rapid and complete upon addition of the chloride. Then sulfenate **9** is available for subsequent (slower) reaction with disilazane. On the other hand, based on HSAB, the *O*-silylation of **5a** with TMS-CN is predicted to be slower. As that substitution proceeds at its sluggish pace, the remaining unreacted **5a** may effect a substitution on newly created **9**, a reaction that is not possible when TMS-Cl is the electrophile, since it will rapidly functionalize *all* of the sulfenate (**5a**). The by-product of the reaction of **5a** and **9** is $^{-}$OTMS, which would probably be converted to TMS-O-TMS by reaction with TMS-CN. The resulting cyanide would then be available for the deoxygenation reaction. Support for this particular proposal was found when a model reaction was performed between $TMSO^{-}Li^{+}$ and TMS-CN in THF. Upon warming the solution from –78°C to rt, TMS-O-TMS was definitely formed in >90% yield (by NMR and GC analysis). Finally, since the sulfenate and the $^{-}$OTMS are both contributing to the consumption of the TMS-CN reagent, a rationale has been found for the observation of unreacted **5a** in Fig. 5.

Experimental

General

The *m*-CPBA was purchased from Aldrich Chemical Co. and was standardized by oxidation of benzyl sulfide prior to use. Where necessary, flasks were predried by vacuum flame drying, and syringes were dried by oven storage at 110 ºC followed by cooling in a desiccator. Air-sensitive reactions were performed under a positive pressure of dry nitrogen.

The VT NMR experiments were performed on the Varian Unity spectrometer operating at 400 MHz for ^{1}H NMR spectra and at 100.6 MHz for ^{13}C NMR spectra. The ^{1}H NMR spectra recorded in THF-d_8 were referenced to the residual protons on the carbons adjacent to the oxygen in THF-d_8 (δ = 3.58 ppm) while ^{13}C spectra were referenced to the quintet at δ = 67.4 ppm, due to the carbons adjacent to the oxygen in THF. The THF-d_8 was purchased from Aldrich Chemical Co. and was stored under nitrogen over oven-activated 4 Å molecular sieves at 3°C. Glassware utilized for the transfer of solutions in the VT NMR experiments was oven dried at 110°C, cooled in a desiccator, and stored on dry ice prior to use. The characterization of **7a** has been presented elsewhere (15).

Reactions of 1-alkenesulfenate 5a with TMS-X reagents

*Reaction of **5a** with TMS-Cl*

Compound **6a** (50.0 mg, 0.378 mmol) in cold dry THF (2 mL) was added to a solution of LiHMDS (0.42 mL, 0.42 mmol) in dry THF (10 mL) at –78°C. After 0.5 h cyclohexene (1 mL) was added followed by TMS-Cl (41.0 mg, 0.378 mmol). The mixture was allowed to warm to room temperature over 2 h and was then stirred for 16 h at ambient temperature. The solution was combined with saturated ammonium chloride (50 mL) and was extracted with ethyl acetate (3 × 15 mL). Extracts were washed with water (3 × 25 mL), brine (1 × 25 mL), then dried over anhydrous sodium sulfate and concentrated to yield crude **7a** (26.3 mg, 0.0954 mmol, 25%).

*Reaction of **5a** with TMS-CN*

Compound **6a** (50.0 mg, 0.378 mmol) was reacted as above with LiHMDS (0.42 mL, 0.42 mmol) in dry THF (12 mL) at –78°C. After 0.5 h cyclohexene (1 mL) was added followed by TMS-CN (38.0 mg, 0.378 mmol). The mixture was allowed to stir and was worked up as above. Concentration followed by chromatography yielded pure bis((*E*)-1-hexenyl) disulfide **8** (20.9 mg, 0.0902 mmol, 48%) as a colourless oil. Spectral data for **8**: ^{1}H NMR (200 MHz) δ: 6.08–5.92 (m, 4H), 2.11 (q, J = 6.0 Hz, 2H), 1.54–1.25 (m, 6H), 0.89 (t, J = 7.0 Hz, 3H); ^{13}C NMR (50.3 MHz) δ: 136.02, 123.35, 32.20, 30.98, 21.92, 13.65; IR (neat) cm^{-1}: 3018, 2927, 2856, 1638, 1445, 1433, 1333, 1135, 1013, 916; MS *m*/*z* (%): 230 (M^{+}, 100), 154 (34), 116 (27), 115 (59), 112 (20), 111 (47), 97 (29), 85 (32), 83 (25), 81 (54), 73 (94), 60 (20), 55 (54); HRMS (*m*/*z*): calcd. for $C_{12}H_{22}S_2$: 230.1163; found: 230.1160.

*General procedure for the reaction of **5a** with TMS-X reagents*

(*E*)-1-Alkenesulfenate **5a** was generated at a concentration of 0.1 M in dry THF at –78°C using the methodology outlined above. After 0.5 h the TMS-X reagent was introduced in dry THF or dry dichloromethane (0.5 mL). The mixture was allowed to warm to room temperature over 2 h and was then stirred at ambient temperature for 16 h. The mixture was then diluted with water (25 mL) and extracted into ethyl acetate (3 × 10 mL). The extracts were washed with water (3 × 10 mL), brine (1 × 10 mL),

[7] Use of a carbon base rather than an amide would preclude the presence of the amine after sulfenate formation. However, our experiments and those of others (see ref. 13 and citations therein) have shown that desulfurization of the thiirane *S*-oxide is the dominating reaction when carbon bases are employed.

© 1998 NRC Canada

and dried over anhydrous Na_2SO_4. Naphthalene (15–20 mg, 0.12–0.16 mmol) was added to the solution, and a sample was introduced into the gas chromatograph. Comparison of the peak areas resulted in the yields listed in Table 1.

Variable temperature NMR experiments

*General procedure for the formation and reactions of **5a***
Solid LiHMDS etherate (94.4–218 mg, 0.391–0.905 mmol) was introduced into a flame-dried flask (10 mL) followed by purging with nitrogen. THF-d_8 (0.40–0.60 mL) and benzene (2.0–3.0 μL), if used, was introduced, and the solution was cooled to –78°C. Compound **6a** (46.9–59.8 mg, 0.355–0.452 mmol) in THF-d_8 (0.20–0.30 mL) was introduced and the mixture was allowed to stir for 0.5 h. If utilized, the TMS-X reagent was introduced neat, and the solution was allowed to stir a further 5 min followed by transfer to a precooled NMR tube and temporary storage at –78°C.

*Synthesis and observation of **5a***
Following the above procedure, LiHMDS etherate (105 mg, 0.433 mmol), **6a** (52.1 mg, 0.394 mmol), and benzene (2.0 μL) were combined. The spectrum (Fig. 1*a*) was recorded at –78°C, and comparison of the integration indicated the presence of **5a** (70%) and **12** (20%) as well as some **8**.

*Reaction of **5a** with TMS-Cl and combination with **12***
Following the above procedure, LiHMDS etherate (94.4 mg, 0.433 mmol) and **6a** (46.9 mg, 0.355 mmol) were combined followed by the addition of TMS-Cl (30.9 mg, 0.284 mmol). The ^{1}H NMR spectrum (Fig. 1*b*) was recorded at –60°C and indicated the presence of **7a** and **12**. This solution was combined with the $CDCl_3$ solution of **12** produced as described below and the ^{1}H NMR spectrum was recorded at 0°C (Fig. 1*c*).

*Oxidation of **8** with* m-*CPBA*
To a solution of **8** (35.2 mg, 0.153 mmol) in $CDCl_3$ (1.5 mL) at –60°C was added *m*-CPBA (38.0 mg, 0.153 mmol). The reaction was stirred for 10 min at –60°C and was then suction-filtered through three grams of crushed anhydrous potassium carbonate into a flask maintained at –60°C. A sample of the solution was transferred to an NMR tube, and the ^{1}H NMR spectrum was obtained. δ (ppm): 6.64–6.32 (m, 2H), 2.30 (m, 1H), 2.21 (m, 1H), 1.47–1.21 (m, 4H), 0.85 (m, 3H); see also Fig. 1*d*.

*Reaction of **5a** with TMS-Cl*
Following the above procedure, LiHMDS etherate (115 mg, 0.477 mmol), **6a** (57.3 mg, 0.433 mmol), and benzene (3.0 μL) were combined followed by the addition of TMS-Cl (37.7 mg, 0.347 mmol). The ^{1}H NMR spectra was recorded at –78°C to show **7a** (35%) and **12** (46%). The spectra were then recorded at ambient temperature to show only **7a** (35%).

*Reaction of **5a** with TMS-Cl and LiHMDS*
Following the above procedure, LiHMDS etherate (218 mg, 0.905 mmol), **6a** (59.8 mg, 0.452 mmol), and benzene (3.0 μL) were combined followed by the addition of TMS-Cl (39.3 mg, 0.362 mmol). The ^{1}H NMR spectrum was recorded at –78°C to show **7a** (50%), **12** (7%), and **8** (10%). A second spectrum, recorded at ambient temperature, showed **7a** (58%) and **8** (10%).

*Reaction of **5a** with TMS-CN*
Following the above procedure, LiHMDS etherate (115 mg, 0.475 mmol), **6a** (59.8 mg, 0.452 mmol), and benzene (3.0 μL) were combined followed by the addition of TMS-CN (36.0 mg, 0.362 mmol). The spectrum (Fig. 5*a*) was recorded at –78°C to show **5a** (35%) and **12** (35%). A second spectrum, recorded at –30°C, showed **8** (15%), **12** (15%), and **5a** (35%) (Fig. 5*b*). A final spectrum recorded at ambient temperature showed **8** (38%) and **5a** (35%) (Fig. 5*c*).

*Reaction of **14** with 1 equiv. of* m-*CPBA*
Utilizing the procedure adopted for the oxidation of **8** above, **14** (68.4 mg, 0.363 mmol) and *m*-CPBA (89.5 mg, 0.363 mmol) were combined in $CDCl_3$ (1.5 mL) at –60°C. After suction filtration, a sample of the solution was transferred to an NMR tube, and the ^{1}H NMR spectrum was obtained. Examination of the crude spectrum showed **14** and **15** in a 1:1 ratio and *m*-chlorobenzoic acid. Crude spectral data for compound **15**: ^{1}H NMR (400 MHz) δ: 6.29–6.15 (m, 2H), 2.03 (q, J = 7.0 Hz, 2H), 1.32–1.08 (m, 4H), 0.80 (t, J = 7.1 Hz, 3H), 0.07 (s, 9H); GC/MS *m*/*z* (%): 220 (M^+, 18), 157 (15), 141 (17), 129 (24), 122 (16), 75 (27), 73 (100), 59 (14), 55 (21).

*Reaction of **14** with 2 equiv. of* m-*CPBA*
The above procedure was followed utilizing **14** (129 mg, 0.689 mmol) in $CDCl_3$ (1.5 mL) and *m*-CPBA (339 mg, 1.37 mmol) in $CDCl_3$ (1.5 mL). Examination of the crude spectrum indicated the presence of **15** and *m*-chlorobenzoic acid.

Acknowledgements

The authors wish to thank the Natural Sciences and Engineering Research Council (NSERC) of Canada for generously supporting this research and Prof. R.T. Oakley for alerting us to the usefulness of LiHMDS etherate and for donating a sample of it. The valuable technical assistance of Dr. Yvonne Lear and Ms. Laura McConachie is gratefully acknowledged. The Schwan group also thanks Dr. Sriram Naganathan for kindly providing a copy of his PhD thesis and for his helpful comments pertaining to this manuscript.

A search for an inexpensive calculational method for the reliable prediction of the first adiabatic and vertical ionization potentials of carbenes. Photoelectron spectra of two stable carbenes

Heidi M. Muchall, Nick H. Werstiuk, and Biswajit Choudhury

Abstract: Photoelectron (PE) spectra of two stable carbenes **7** and **8** have been recorded and the spectra have been interpreted with the aid of eigenvalues and eigenvectors taken from Becke3LYP calculations. For the carbene series **6**–**8**, the lone pair on the carbene carbon atom is the HOMO. The first adiabatic ionization potential (IP) of eight electronically quite different carbenes has been calculated using semiempirical PM3 and ab initio HF, Becke3LYP, and Becke3PW91 methods (3-21G(*) and 6-31+G* basis sets) as well as the CBS-4 model. For the first vertical IP, the HAM/3, Becke3LYP, and Becke3PW91 methods have been employed. CBS-4 and DFT calculations show excellent agreement with experimental values. Considering both accuracy and speed, the method of choice for the prediction of first ionization potentials of carbenes seems to be Becke3LYP/6-31+G*//Becke3LYP/3-21G(*).

Key words: carbenes, electronic structure, first ionization potential, photoelectron spectroscopy, quantum chemical calculations.

Résumé : On a déterminé les spectres photoélectroniques (PE) des deux carbènes stables **7** et **8** et on en a fait l'interprétation à l'aide des valeurs et des vecteurs propres obtenus à partir de calculs Becke3LYP. Pour les séries de carbènes **6**–**8**, la paire d'électron non partagée qui se trouve sur l'atome de carbone du carbène est la HOMO. En utilisant des calculs semi-empiriques PM3 et ab initio HF, les méthodes Becke3LYP et Becke3PW91 (ensembles de base 3-21G(*) et 6-31+G*) ainsi le modèle CBS-4, on a calculé le premier potentiel d'ionisation adiabatique (PI) de huit carbènes assez différents d'un point de vue électronique. Pour le premier PI vertical, on a utilisé les méthodes HAM/3, Becke3LYP et Becke3PW91. Les résultats des calculs CBS-4 et DFT présentent un excellent accord avec les valeurs expérimentales. Considérant l'exactitude et la vitesse, la méthode de choix pour prédire les premiers potentiels d'ionisation de carbène semble être la méthode Becke3LYP/6-31+G*//Becke3LYP/3-21G(*).

Mots clés : carbènes, structure électronique, premier potentiel d'ionisation, spectroscopie photoélectronique, calculs de chimie quantique.

[Traduit par la rédaction]

Introduction

Photoelectron (PE) spectroscopy gives information on electronic structure and binding that can be obtained by no other technique. For PE spectroscopic studies, carbenes have been generated in the gas phase from suitable precursors by techniques such as pyrolysis (1, 2) and microwave discharge (3).[2] Usually, carbenes are more or less short-lived reactive intermediates. To be detected, they must be sufficiently long lived to be ionized. Both the precursor and the lifetime of a carbene can present difficulties to a PE spectroscopic study. First, if the conversion of the precursor is not complete, ionization bands of the starting compound will still be present in the PE spectrum and possibly overlap with those of the carbene in crucial regions. And, as the carbene is not the only product formed from the starting compound, possible overlap with bands from the other primary products must be taken into account. Second, even if the carbene is generated close to the ionization beam of the spectrometer, rearrangement, fragmentation, and dimerization of the carbene can lead to secondary products whose bands can further complicate the PE spectrum.

When a carbene is to be generated explicitly, at least problems arising from the precursor can be overcome by simply choosing the most suitable one. When, on the other hand, the carbene is one possible product in a pyrolysis study, all of the items mentioned above are likely to produce a complex PE spectrum. In this case, and especially when the PE spectrum of the carbene is unknown, it is imperative to have a procedure that allows easy, accurate prediction of the first ionization of the carbene, as this is the most likely not to be covered by other ionizations.

Interpretation of the PE spectrum of a molecule is usually achieved via Koopmans' theorem (5), which equates the ionization potential (IP) in question with the negative orbital energy of the respective molecular orbital taken from quantum chemical calculations. While this method often works well when several ionizations can be attributed to one molecule and relative energy differences can be taken as additional information, absolute orbital energies are usually systematically off, sometimes by as much as several electron volts, depending on the calculational method used. This approach is therefore not particularly suited for the prediction of the first ionization.

Yet the first ionization potential is easily accessible by computing the energy difference between the neutral molecule (*N* electrons) and its radical cation (*N*–1 electrons). The geometry of the radical cation can be quite different from that of the neutral, which leads to an energetic separation between the adiabatic and vertical IPs. While the energy difference based on a full geometry optimization of both species gives the adiabatic (IP_a), ignoring the geometry change upon ionization (which is achieved through a single-point energy calculation on the geometrical structure of the neutral for (*N*–1) electrons) gives the vertical (IP_v) ionization potential. These calculated values are compared to those taken from the PE spectra to evaluate their quality. In recent years, models have been developed that give accurate energies and are therefore well suited to predict IPs (6). These models, like the G2 (7) and CBS (8) series, are very costly in terms of computational resources and can only be applied to molecules having a small number of heavy atoms (8).

Our goal was to find a method that can provide us with good predictions for first IPs of even relatively large carbenes in a reasonably short time. For future work, such a method could then be applied to the detection of unstable carbenes in our pyrolytic studies. In this paper, we present semiempirical and ab initio calculations of the first IP_a and IP_v of carbenes **1**–**5** as well as of "stable" carbenes **6**–**8**. Experimental values for **1**–**6** are taken from the literature (1–3, 9–11); He(I) PE spectra of **7** and **8** are presented here for the first time.

Experimental

HF (12), CBS-4 (8), Becke3LYP (13*a*,13*b*), and Becke3PW91 (13*b*, 13*c*) calculations were carried out on IBM RS/6000 model 39H, 350, and 530 computers with GAUSSIAN 94 (14). Semiempirical PM3 (15) calculations were performed with the MOPAC (16) program package (version 6.00) on an IBM RS/6000 model 320H computer. All semiempirical geometry optimizations used the keyword PRECISE to tighten the convergence criteria. The equilibrium geometries obtained with PM3 were used in the HAM/3 (17) calculations on the IBM RS/6000 model 320H computer. Graphical representations of the calculationally determined eigenvectors (PM3//Becke3LYP/6-31+G*; these were checked against Becke3LYP/6-31+G*// Becke3LYP/6-31+G* eigenvectors and were found to compare well) were plotted from HyperChem 5.[3]

PE spectra were measured with a locally built instrument (18) by signal averaging 12 scans with nitrogen (15.6 eV) as the calibrant. Linearity of the scale was ensured through calibrations with methyl iodide (9.54 and 10.16 eV) and O_2 (12.30 eV) performed prior to the experiments.

1,3-Diethyl-4,5-dimethylimidazol-2-ylidene (**7**) and 1,3-diisopropyl-4,5-dimethylimidazol-2-ylidene (**8**) were prepared according to the literature (19).

Results and discussion

Photoelectron spectra of stable carbenes 6–8

Ultraviolet PE spectra of carbenes **7** and **8** are depicted in Fig. 1. The spectra show great similarity with the He(I) PE spectrum of **6** (9): all three spectra exhibit two low-energy bands well separated from the main group of σ bands, which has a shoulder on the low-energy side, and the first band in each of the spectra is made up of two ionizations. The first four ionizations of **7** and **8** ($IP_{exp.}$) are listed in Table 1 along with those reported for **6** (9). While for the *tert*-butyl substituted carbene **6** the separation of the first two ionizations is large

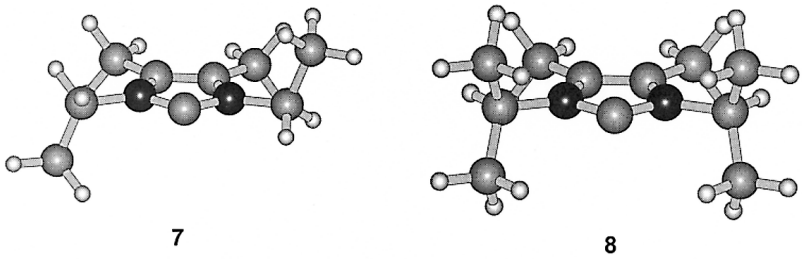
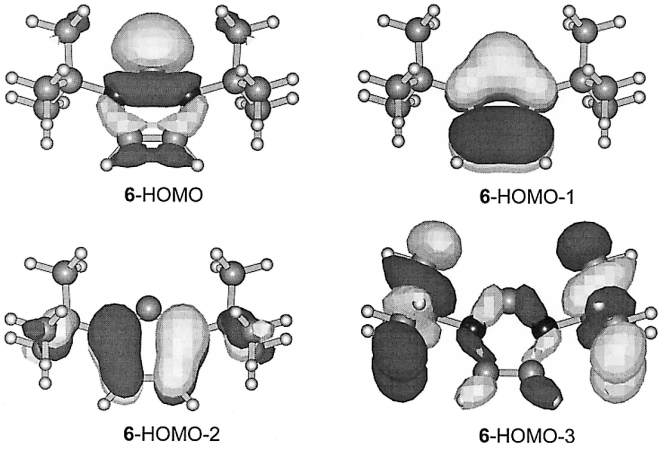
Fig. 2. Most stable conformations for carbenes **7** (Becke3LYP/6-31+G*) and **8** (Becke3LYP/3-21G*).



enough to give rise to two discrete maxima, for the ethyl and isopropyl analogues **7** and **8**, respectively, this difference is smaller and thus leads to one broad band for which only one maximum can be given. As can be seen in Table 1, Becke3LYP/6-31+G*//Becke3LYP/3-21G orbital energies ε for **6**–**8** (the lowest energy conformation for **7** and **8** is given in Fig. 2) mirror the experimental relative energy differences perfectly (the absolute deviation between –ε and $IP_{exp.}$ is about 2 eV, a value not unusual for Becke3LYP calculations). While on going from **6** to **7** there is little change in the HOMO energy, HOMO-1 is destabilized by 0.4 eV. This fact confirms the character of HOMO and HOMO-1 of carbene **6** as given by Arduengo et al. (9). The HOMO is the in-plane lone pair on the carbene carbon n_C rather than a ring π orbital (as suggested for the unsubstituted parent carbene (20)): in the sequence **6**–**7**, a π orbital would exhibit a destabilization due to methyl substitution on the ring, a behavior that is observed for HOMO-1 (π_3). Methyl substitution affects HOMO-2 (π_2) in the same way as HOMO-1 whereas HOMO-3 (mostly σ-type electron density on nitrogen substituents) is stabilized when *tert*-butyl groups are exchanged for ethyl groups. So the orbital sequence in carbenes **6**–**8**, in accord with Arduengo et al. (9), is $n_C > \pi_3 > \pi_2 > \sigma$, which is confirmed by the PE spectra.

The semiempirical HAM/3 method gives ionization potentials directly. In Table 1 IP_v's are given for PM3 optimized geometries. For **6** and **7** these geometries do not differ significantly from those obtained with ab initio methods; for **8** the methine hydrogens are twisted 47° out of the plane with PM3 (the in-plane ab initio conformation for **8** is shown in Fig. 2, yet this does not much affect the calculated ionization potentials). HAM/3 IPs show a very good correlation with the experimental data.



Calculation of the first adiabatic ionization potential

The limitation for the number of carbenes studied in this work is the number of carbene PE spectra available. We took PE spectroscopic literature values for the first adiabatic ionization potentials of singlet (21) carbenes **2**–**5** (1–3). To include a triplet carbene, the IP_a of the parent methylene (**1**) determined from a mass spectrometric experiment (10.35 eV) (11) as well as from the Rydberg series in its VUV spectrum (10.40 eV) (10) was also considered. For these carbenes, we performed calculations for first IP_a's using the compound computational model CBS-4. While being the smallest — and fastest — model in the CBS/PNO (complete basis set/pair natural orbitals) series, this model still gives accurate molecular energies on a UHF/3-21G(*) optimized geometry (the mean absolute deviation from experimental IPs for the G2 test set (22) is 2.2 kcal mol^{-1} or 0.1 eV; the maximum error is 6.1 kcal mol^{-1} or 0.3 eV for hydrogen fluoride) (8). Total energies from which IP_a's are computed are listed in Table 2. As can be seen in Table 3, CBS-4 values for carbenes **1**–**3** and **5** differ from experiment by less than 0.2 eV; the difference for **4** is only slightly larger. The mean absolute deviation is 0.13 eV, a figure against which other calculational methods can be evaluated.

There have been previous attempts at calculating first adiabatic IPs of carbenes in the literature. Using an electron propagator method (MCSTEP), Nichols et al. (23) in 1994 applied adiabatic corrections to calculated vertical ionization potentials of **1**. Rodriquez, Bohme, and Hopkinson (24) in 1996 employed fourth-order Møller–Plesset theory and QCISD(T) to obtain enthalpies of formation for **1** and **3** and from these deduce IP_a's. In 1989, Wong and Radom (25) used the CISD/6-31G* level of theory to predict the, at that time unknown, IP_a of **4** to be 8.8 eV, a value that is still 0.35 eV off. Russo, Sicilia, and Toscano (26) in 1992 used a density functional approach (LCGTO-LSD/NLC) to the IP_a's of **1**–**3**. They report 10.69 eV for **1**, 11.56 eV for **2**, and 9.55 eV for **3**, which, compared to the experimental data stated in this paper, give differences of 0.29, 0.14, and 0.28 eV, respectively. These values seem to suggest that density functional theory is suitable for our purpose.

Tables 2 and 3 give results from semiempirical PM3 and ab initio HF, Becke3LYP, and Becke3PW91 methods. PM3 IP_a's (Table 3) for difluoro carbene (**2**), dichloro carbene (**3**), and propadienylidene (**5**) are unacceptably low and even though those of methylene (**1**) and cyclopropenylidene (**4**) are very close to the experimental values, PM3 cannot be used for our

purpose. HF with a 6-31+G* basis set performs much worse; all IP_a's are prohibitively low. Becke3LYP, on the other hand, with as small a basis set as 3-21G, gives very good agreement with experiment, the only exception being for dichloro carbene (**3**). This is obviously due to the presence of third-row chlorine atoms and is corrected by including polarization functions in the basis set (Table 3). The resulting mean absolute deviation is an amazing 0.13 eV, the same value that we obtained using CBS-4. With the 6-31+G* basis set it even drops to 0.04 eV for this set of five carbenes, which is considerably better than the CBS-4 value.

For Becke3LYP calculations we omitted corrections for zero-point vibrational energies (ZPVEs) as we expected their influence to be small. A check with unscaled ZPVEs (the

[i]The carbene was not optimized at this level of theory.

factor for Becke3LYP/6-31G* is 0.98 (6), which is close enough to 1.0; we assumed the same to be true for the 6-31+G* basis) on Becke3LYP/6-31+G* total energies confirmed this (Tables 2 and 3).

Although the number of carbenes studied is small, electronically **1**–**5** are quite different. That Becke3LYP did an excellent job of predicting all first IP_a's was promising for an extension of the study to the so-called "stable" carbenes **6**–**8**. Carbenes **6**–**8** have considerably more heavy atoms than carbenes **1**–**5** and obtaining optimized geometries of their radical cations using Becke3LYP/6-31+G* is still computationally demanding. We therefore checked the possibility of doing single-point energy calculations at this level of theory using the Becke3LYP/3-21G(*) optimized geometries. The result is a mean absolute deviation of 0.06 eV; calculated IP_a's can be seen in Table 3. So this is probably the method of choice for calculating the first IP_a of carbenes of all sizes.

For a further comparison,[4] we repeated the above DFT calculations using the PW91 correlation functional (Tables 2 and 3). While Becke3PW91 performs slightly better than Becke3LYP with the 3-21G(*) basis set, it is definitely worse when the 6-31+G* basis set is employed.

Experimental IP_a's of carbenes **6**–**8** as given in Table 3 were estimated from their PE spectra (onset of the first band). The calculational data (Tables 3 and 4) for these stable carbenes confirm the previous findings for the ordinary carbenes: Becke3LYP/6-31+G*//Becke3LYP/3-21G(*) gives excellent results.

Calculation of the first vertical ionization potential

Experimental first vertical IPs of carbenes **2**–**8** are listed in Table 5. As there are no reported IP_v's for carbenes **3**–**5**, we estimated them from their PE spectra (maximum of the band) (1, 2). For carbenes **6**–**8** we have shown that IP_v's calculated with the semiempirical HAM/3 method are in very good agreement with experiment (see above). This statement was based on a total of 12 IPs for the three compounds. Yet, if only the first IP_v of a carbene is considered, deviations from the experimental value can be rather large (Table 5).

A calculation of the first IP_v differs from a calculation of the first IP_a: while the IP_a requires optimized geometries for both the carbene *and* its radical cation (relaxation), for the IP_v

[4] We thank A.D. Becke for suggesting this comparison.

[a]The carbene was not optimized at this level of theory.

the energy of the radical cation is calculated on the geometry of the neutral carbene (no relaxation). As for the first IP_a, there have been attempts at calculating first vertical IPs of carbenes. In 1985, Nguyen et al. (27) performed HF, MP2, MP3, and MP4SDQ (6-31G** basis) single-point energy calculations on the HF/3-21G* geometry for **3** and obtained IP_v's of 9.45, 9.73, 9.86, and 9.75 eV, respectively, which shows the level of theory necessary to get close to the estimated value of 9.8 eV given in Table 5. Bauschlicher and Taylor (28) in 1987 published full CI benchmark calculations for IP_v's of **1** to which other high-level calculations were compared (X.-C. Wang and K.F. Freed in 1989 (29), Nichols et al. (23)). The work of Wong and Radom (25) includes the predicted IP_v of **4**. The reported value of 9.0 eV using CISD/6-31G* differs from the value in Table 5 by 0.4 eV. Russo, Sicilia, and Toscano (26) give LCGTO-LSD/NLC IP_v's for **1** (10.73 eV), **2** (12.09 eV), and **3** (10.30 eV).

Table 5 shows the Becke3LYP/6-31+G* IP_v's (total energies for the radical cations are given in Table 6) from this work for carbenes **1**–**7**. For **1**, there is no IP_v available, but our calculations suggest that it should be close to its IP_a of 10.4 eV. IP_v's for **2** and **4**–**7** are very close to the experimental values with the largest difference of 0.12 eV for **6**. The difference for **3** with 0.38 eV is somewhat large; this might be partially due to an uncertainty in our estimation of the experimental first IP_v. As can be seen in Table 5, good results are obtained with Becke3LYP/6-31+G*//Becke3LYP/3-21G(*) for **1**–**8**, especially for carbenes with more heavy atoms. Except for dihalo carbenes **2** and **3** with a difference of 0.33 and 0.63 eV (the latter value could be smaller, see above), respectively, IP_v's differ by less than 0.22 eV. Becke3PW91 values for the first vertical IP, in contrast to values obtained for the first adiabatic IP, are comparable to those obtained with Becke3LYP (Table 5).

Conclusions

Recorded PE spectra of stable carbenes **7** and **8** resemble that of the *tert*-butyl substituted carbene **6**. An interpretation of the change in ionization potentials on going from **6** to **7** together with orbital energies taken from Becke3LYP/6-31+G* calculations and the effect of methyl substitution on the ring gave the character of the four highest occupied molecular orbitals for **6**–**8** as $n_C > \pi_3 > \pi_2 > \sigma$.

The Becke3LYP method was employed in the calculation of first adiabatic and vertical ionization potentials of carbenes **1**–**8**. For the IP_a's of the small carbenes **1**–**5**, a mean absolute deviation of 0.04 eV was achieved with Becke3LYP/6-31+G*; this was found to be substantially better than even the CBS-4 performance (mean absolute deviation of 0.13 eV) for this set of molecules. The Becke3LYP/6-31+G*//Becke3LYP/3-21G(*) level of theory was also tested and found to be sufficiently accurate (the largest absolute error was 0.14 eV for **7**, which could be due to an uncertainty in our location of the experimental IP_a). While semiempirical PM3 and ab initio HF/6-31+G* calculations gave unsatisfactory values for the adiabatic IP, those obtained with the Becke3PW91 method were found to be only slightly worse than Becke3LYP results.

Calculated Becke3LYP/6-31+G* first IP_v's of carbenes **2**–**7** are very close to the experimental values (less than 0.13 eV difference) with the exception of dichloro carbene (**3**) (the difference of 0.38 eV could again be attributed to an error in our prediction of the experimental IP_v). Becke3LYP/6-31+G*//Becke3LYP/3-21G(*) gave similar results with a slight loss of accuracy. For IP_v's, Becke3PW91 performs about as well as Becke3LYP.

This study has provided us with a calculational method, Becke3LYP/6-31+G*, that gives accurate first adiabatic and vertical ionization potentials for carbenes without being computationally too demanding. Depending on the size of the carbene, 3-21G(*) or 6-31+G* basis sets can be employed in geometry optimizations. In future gas phase pyrolysis studies, this can aid in the interpretation of PE spectra with regard to the possible presence of carbenes.

Photochemical reduction of CO_2 using Cu-loaded silicate rock powder suspended in water

Kiyohisa Ohta, Youko Ueda, Satoshi Nakaguchi, and Takayuki Mizuno

Abstract: The photocatalytic reduction of CO_2 using copper-loaded silicate rocks has been reported. The Cu–silicate rock powders suspended in the solution were illuminated with sunlight. Amphibolite, gneiss, granite, granodiorite, phyllite, quartzdiorite, and shale, which are quite ordinary rocks, were tested as substrates (silicate rock) of the catalyst. These catalysts were specific for the formation of formic acid. The effects of amounts of copper, illumination time, and temperature were investigated on photoreduction of CO_2. The 30% Cu-loaded quartzdiorite (0.3 g/g) in these Cu rocks was the best catalyst. The formation of formic acid on the Cu–silicate rock increased with time up to 10 h after which the formation decreased, and then became constant. The formic acid formation decreased with temperature for 10 h sunlight illumination. For the photochemical reduction of CO_2, a relatively low temperature was suitable. With photochemical reduction, the maximum yield of formic acid was 54 nmol/g under optimum experimental conditions. The carbon dioxide reduction system developed might well become of practical interest for the photochemical production of raw materials for the photochemical industry.

Key words: photocatalytic reduction of carbon dioxide, formic acid, copper-loaded silicate rocks, temperature effect, illumination time.

Résumé : On a réalisé la réduction photocatalytique du CO_2 à l'aide de roches de silicate enduites de cuivre. Les roches de silicate enduites de cuivre, réduites en poudre, ont été mises en suspension dans des solvants et irradiés par de la lumière solaire. Des roches ordinaires d'amphibolite, gneiss, granit, granodiorite, phyllite, quartzdiorite et de schiste ont été évaluées comme substrats (roches de silicate) pour le catalyseur. Ces catalyseurs sont spécifiques pour la formation d'acide formique. On a étudié l'influence des quantités de cuivre, des temps d'illumination et de la température sur la photoréduction du CO_2. La quartzdiorite portant 30% de cuivre (0,3 g/g) est le meilleur catalyseur. La formation d'acide formique sur des roches de silicate enduites de cuivre augmente avec le temps, jusqu'à 10 h; toutefois, au-delà de ce temps, la formation diminue et devient constante. Jusqu'à 10 h d'illumination, la formation d'acide formique diminue avec la température. Pour la réduction photochimique du CO_2, des températures relativement faibles. Dans des conditions expérimentales optimales, le rendement maximal d'acide formique par réduction photochimique est de 54 nmol/g. Le système de réduction du dioxyde de carbone qui a été développé pourrait avoir un intérêt pratique pour la production photochimique de produits de base pour l'industrie photochimique.

Mots clés : réduction photocatalytique du dioxyde de carbone, acide formique, roches enduites de cuivre, effet de la température, temps d'illumination.

[Traduit par la rédaction]

The establishment of techniques for the removal of CO_2 and its conversion into organic raw materials is of interest because of the approaching exhaustion of petroleum deposits and the greenhouse effect of the increase of CO_2 in the atmosphere. Therefore, many methods for the fixation and removal of CO_2 have been reported (1–7). In these studies, photocatalytic reduction of CO_2 (1, 3, 5, 6, 8–12) is drawing worldwide attention because of simplicity and easy control of the system, specificity for the formations of fuel and organic raw materials, and low cost. Fujishima and co-workers (8) showed that CO_2 in water was reduced to formic acid, formaldehyde, and methanol, using photosensitive semiconductor powders such as WO_3, TiO_2, ZnO, CdS, GaP, and SiC. Halmann (5) and Halmann and Aurian-Blajeni (9) have reported CO_2 reduction of aqueous suspensions of WO_3, TiO_2, ZnO, Fe_2O_3, or nontronite by irradiation with sunlight or an Hg lamp. Thampi et al. (10) examined methanation and photomethanation of CO_2 at room temperature and atmospheric pressure, using TiO_2-loaded Ru/RuO_x. Rophael and Malati (11) described photocatalyzed reduction of aqueous sodium carbonate to carbon using platinized titania. Hirano et al. (12) studied photocatalyzed reduction of CO_2 to methanol, formaldehyde, and formic acid in aqueous TiO_2 suspension mixed with copper powder. However, these catalysts are artificial and expensive. To develop a low cost catalyst for CO_2 reduction, quite ordinary rocks need to be investigated. In a previous study (13), it was found that

water decomposed to hydrogen and oxygen on silicate rock powders under sunlight illumination. Furthermore, since copper was useful for the photoreduction, as Hirano et al. (12) reported, copper-loaded rocks were prepared as the catalysts. However, there is little information on the photoreduction of CO_2 using copper-loaded silicate rock powders under sunlight.

In this report, a photocatalytic reduction of CO_2 using copper-loaded silicate rock powders at ambient temperature is described. The Cu–silicate rock powders suspended in the solution were illuminated with sunlight.

Experimental

Preparation of Cu-loaded silicate rock powders

The substrates of the photocatalyst used were silicate rocks. The rocks were amphibolite, gneiss, granite, granodiorite, phyllite, quartzdiorite, and shale. These are quite ordinary rocks that were collected from a river beach and a mountain of middle Japan.

The rocks were pulverized in an iron mortar and then were sieved by 30-mesh stainless sieves. The diameter of the powder particulates was about 0.85 mm, and the surface area was 0.25–0.30 m^2/g by BET adsorption method. After washing with 1 M nitric acid and distilled deionized water to wash down metals from the surface of the rock powders, the sample was prepared by heating to dry for 8 h at 150°C in an oven to sterilize microorganisms. After drying, the powders were placed in copper chloride solution with optional concentration (0.11–1.4 g/mL) and stirred sufficiently. The silicate rock powders were dried, after recovery by filtration, at 150°C for 4 h in an oven and heated in a hydrogen gas stream at 400°C for 2 h to reduce $CuCl_2$ to metallic copper. After being cooled in nitrogen atmosphere, the powders were weighed to calculate the amount of Cu loaded.

Procedures

The Cu–silicate rock powders were accurately weighed (about 5 g) and placed in a Pyrex glass photocell reported in a previous paper (13). After the addition of fresh water (5 mL), highly purified carbon dioxide gas (99.9999% purity) was bubbled for 10 min at a rate of 2 mL/s. The pH of the solution was 4.96. The vessel was stopped with a silicon rubber stopper to prevent loss of carbon dioxide and evaporation of water. The powders in the vessel were illuminated by sunlight (about 31 600 lux, corresponding to 284 W/m^2). In this case, the short ultraviolet radiation ($\lambda < 310$ nm) was removed by the vessel wall. The intensity of sunlight was measured by a Koito radiometer (IKS-35) and a lumeter (Tokyo Photoelectric, Type ANA-500). For X-ray analysis of the catalyst, a Rigaku L114-1 X-ray diffraction apparatus equipped with a Cu anode and a proportional detector was used. Scanning electron micrographs (SEM) were measured with a Hitachi HHS-2X scanning electron microscope.

Product analysis

Gaseous products by the photocatalytic reduction of carbon dioxide were analyzed by gas chromatography (Porapak Q and molecular sieve 5A columns) using high-purity helium gas as carrier gas. However, gaseous product such as methane was not detected. The products dissolved in water were analyzed by liquid chromatography (Hitachi L600) with an Ionpak KC-811 and KC-810P. The identification of formic acid was performed by analysis of standard high-purity formic acid.

Results and discussion

A Cu electrode has been used for electrochemical reduction of CO_2 to hydrocarbons (2, 4). Hirano et al. (12) reported that methanol, formaldehyde, methane, and carbon monoxide were formed in CO_2-saturated aqueous solution containing powdered suspensions of TiO_2 and Cu. Therefore, a photocatalytic effect of Cu-loaded silicate rock powders on the reduction of CO_2 was examined.

Effect of amounts of Cu on photoreduction of CO_2

The effect of amounts of loaded Cu on photoreduction of CO_2 at ambient temperature was evaluated under 10 h illuminations. The amounts of Cu loaded were 0.05, 0.1, 0.3, 0.5, and 0.7 g per 1 g rock powders (5, 10, 30, 50, and 70 wt.%). In the present work, the main product formed on the Cu rocks was formic acid. Methane, ethylene, ethane, hydrogen, methanol, and formaldehyde were not detected. No product was formed from carbon dioxide by photocatalytic reduction in the dark. The formic acid formations for the amounts of loaded Cu are shown in Figs. 1 and 2. Formic acid formations on Cu: amphibolite (Fig. 1), gneiss (Fig. 1), granodiorite (Fig. 2), quartzdiorite (Fig. 2), and shale (Fig. 2) increased with an increase of Cu up to 0.3 g/g of Cu; and the maximum amounts of formic acid were 35, 32, 33, 54, and 29 nmol/g, respectively. The formation amounts on Cu rocks over 0.4 g/g of Cu decreased dramatically. The formic acid formations on Cu–granite and Cu–phyllite were maximum at 0.1–0.5 g/g of Cu, as shown in Figs. 1 and 2. The largest quantity of formic acid was obtained on Cu (30%) – quartzdiorite. Since the amount of formic acids formed on the Cu–silicate rock powders was larger than that obtained with only silicate rock powders (13), it was found that Cu loading was useful to formic acid production. However, the reason for maximum formation of formic acid on Cu 30 wt.% rocks is not clear.

Surfaces of Cu–silicates were observed by a scanning electron microscope. Typical scanning electron micrographs of Cu–silicate rock (quartzdiorite) are shown in Fig. 3. Before hydrogen reduction, small anisotropic crystals of copper chloride can be visually observed on Cu (30%) – silicate rock (Fig. 3*a*), and surfaces of Cu (70%) – silicate rock are covered with the crystals (Fig. 3*d*). Metal copper (0.3–0.7 mm) on Cu (5–30%) – silicate rock substrates becomes apparent in the SEM photographs of Cu (5–30%) – silicate rocks after hydrogen reduction (Fig. 3*b*). The Cu (70%) – silicate rock is coated

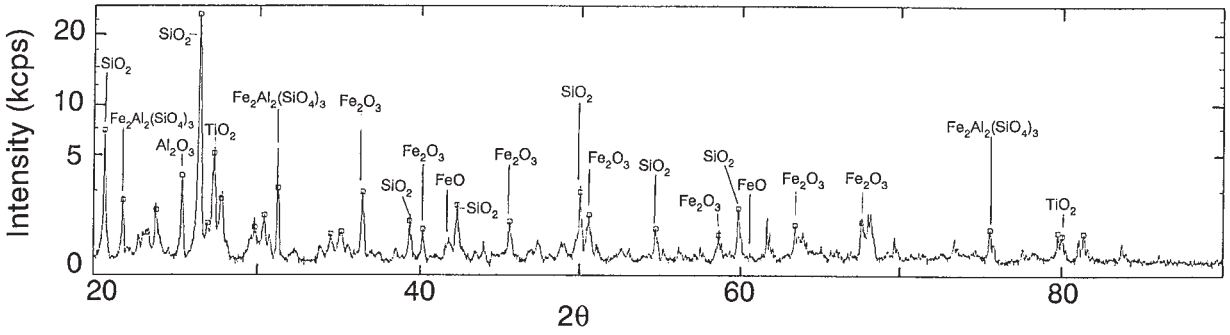
Fig. 7. X-ray diffraction pattern for quartz diorite.



with flakes (plate copper metals) produced by hydrogen reduction, as shown in Fig. 3*e*. After sunlight illumination, the crystals of rock substrate in Cu (30%) – rock catalysts changed to rounding crystals (Fig. 3*c*), but the surface of Cu (70%) – silicate rock did not change compared with that of the rock after hydrogen reduction (Fig. 3*f*). The phenomenon of Cu (30%) – silicate rocks is probably due to the higher yield of formic acid.

Since TiO_2 and Fe^{2+} salts in tested rocks are well known as a photocatalyst and an electron carrier (14, 15), respectively, a relationship between the composition of these compounds and the maximum amount of formic acid obtained on Cu (30%) rock powders was investigated. A graph of FeO content vs. the maximum amount of formic acid produced was examined because these rocks contained similar amounts of $Ti0_2$ (0.34–0.94%). Formic acid formation is significant for FeO contents of <6% in these rocks, as shown in Fig. 4.

Effect of illumination time

The effect of illumination time on photoreduction of CO_2 was investigated by use of a Cu-loaded quartzdiorite catalyst (0.3 g/g of Cu), which was the best catalyst in the Cu rocks. The results at ambient temperature are shown in Fig. 5. Formic acid on the Cu-loaded quartzdiorite increased with time up to 10 h, but over the time the formations of formic acid decreased, and then became constant. The phenomenon may be due to the decomposition of formic acid. Consequently, the maximum yield of formic acid was 54 nmol/g on Cu–quartzdiorite powders over 10 h.

Effect of temperature

The effect of temperature on the photochemical reduction of CO_2 was evaluated by use of Cu–quartzdiorite powders. The results under 10 h sunlight illumination are shown in Fig. 6. The formic acid formation decreased with temperature. A reason for the phenomenon seems to be the lower solubility of CO_2 in higher temperature water. For the photochemical reduction of CO_2, lower temperature was suitable.

Reduction process

To reveal the reduction process, X-ray diffraction patterns were measured for silicate rocks used as a catalyst. The typical pattern is shown in Fig. 7. All of these rocks contained small amounts of TiO_2 (0.34–0.94%) and Fe^{2+} salts (2.0–9.84%), which are known as a photocatalyst and an electron carrier (14, 15), respectively. From the results, the detection of oxygen emission in the present study, and the literature cited above (8, 10, 12, 13), the formic acid formation process by CO_2 reduction on Cu–silicate rocks is suggested to be as follows:

$$\text{Cu rock} + h\nu \rightarrow \text{Cu rock}^{*}(\, e^{-}_{cond} + h^{+}_{val}\,)$$

For an oxidation:

$$H_2O \xrightarrow[\text{Cu / } TiO_2\text{, Fe salts / } SiO_2]{h\nu} 2H^{+} + 1/2\ O_2$$

For a reduction:

$$CO_2 \xrightarrow[\text{Cu / } TiO_2\text{, Fe salts / } SiO_2]{e^{-},\ h\nu} \cdot CO_2^{-} \xrightarrow[\text{Cu / } TiO_2\text{, Fe salts / } SiO_2]{H^{+} + e^{-}} HCOO^{-}$$

In conclusion, formic acid was specifically produced on the photocatalyst Cu (30 wt.%) – silicate rock powders in the present work. The amounts of formic acids formed with the Cu–silicate rock powders were larger than that obtained with only silicate rock powders (13). Since the Cu-loaded silicate rock powders catalysts are relatively easy to make and inexpensive, the CO_2 reduction system developed may be economically feasible in large-scale formic acid productions. In other words, the system might well become of practical interest for photochemical fuel production, storage of solar energy, and organic raw material production. However, it has some disadvantages: low yield and necessity of large area for the plant.

Influence des ultrasons sur la diastéréosélectivité. Synthèse d'imidazolidine-4-one chirales

Cathy Hubert et Bernard Garrigues

Résumé : La synthèse d'imidazolidine-4-one a pu être réalisée en trois étapes. Lors de la dernière étape de réduction d'une fonction cétonique, le dithionite de sodium s'est révélé un excellent agent réducteur. La réaction est lente sous chauffage classique et conduit à une faible diastéréosélectivité. Sous irradiation ultrasonore, nous avons pu observer une importante sélectivité avec un bon rendement. Le dithionite de sodium permet de travailler dans l'eau et évite l'utilisation d'agent réducteur comme les hydrures.

Mots clés : dithionite de sodium, ultrasons, imidazolidine-4-one.

Abstract: A three-step synthesis of imidazolidine-4-one has been realized. Sodium dithionite was a very efficient reagent for the last step, the reduction of a ketone. The reaction is slow under the normal conditions of heating and its diastereoselectivity is poor. Under the influence of ultrasound, the selectivity and the yield are very good. The use of sodium dithionite makes it possible to work in water and to avoid the use of hydrides.

Key words: sodium dithionite, ultrasound, imidazolidine-4-one.

[Journal translation]

Introduction

Devant certaines difficultés expérimentales les chimistes ont été incités à rechercher des méthodes d'activation susceptibles d'augmenter d'une part la vitesse et le rendement, d'autre part la régio- et la stéréosélectivité. Parmi ces méthodes, les ultrasons jouent un rôle important.

Il existe à ce jour peu d'exemples dans lesquels les ultrasons ont pu modifier la stéréochimie et la sélectivité de certaines réactions.

Une isomérisation *Z*/*E* a pu être mise en évidence, sous ultrasons, dans le cas de maléate (1), de cinnamonitrile (2), d'hydantoines (3) et de phosphines vinyliques (4).

D'autre part Ando et al. (5) a observé que la sonication permet d'éviter l'utilisation de la catalyse par transfert de phase dans l'oxydation des alcools avec le permanganate de potassium. Cette méthode est très sélective car une double liaison reste intacte sous ultrasons en milieu apolaire, et seule la fonction alcool est oxydée, ce qui n'est pas le cas en milieu polaire.

Dans le cas de la réaction de Diels–Alder entre des styrènes et des 1,4-benzoquinones sous ultrasons, les dérivés phénanthréniques sont obtenus avec une régiosélectivité importante (6).

Nous nous proposons dans ce travail d'étudier l'influence des ultrasons sur la diastéréosélectivité lors de la synthèse d'imidazolidinones chirales, obtenues par réduction sonochimique de cétones en alcool.

Les exemples de réduction sonochimique de cétones sont peu nombreux. On citera la réduction de cétones aromatiques en alcool par le lithium, en présence de 4,4′-di-(*tert*-butyl) biphényl (7–9), la réduction de la cyclohexanone en présence d'halogénures d'alkyle et de lithium (10, 11) et de benzophénone avec l'aluminium dans NH_3 à 25°C sous ultrasons (12). Dans aucune des trois méthodes une modification de la sélectivité n'a été observée.

Partie experimentale

Généralités

Ultrasons : les réactions que nous avons décrites ont été réalisées avec un générateur Bioblock Scientific et une sonde de 13 mm de diamètre dans un réacteur thermostaté double paroi.

Spectres RMN ^{1}H : déplacements chimiques en ppm par rapport au TMS; constantes de couplage en Hz; appareil Bruker AC 80.

Spectres RMN ^{13}C : déplacements chimiques en ppm par rapport au TMS; appareil Bruker AC 250.

Spectres IR : entre lames KBr; enregistrés sur un spectromètre Perkin–Elmer 257.

Les analyses élémentaires ont été effectuées par le service de Microanalyse de l'École nationale supérieure de chimie de Toulouse. Tous les produits nouveaux donnent des analyses satisfaisantes C ± 0,48, H ± 0,4, N ± 0,53. La purification des produits sur colonne est effectuée avec de la silice (230–400 mesh).

Points de fusion, non corrigés en capillaires appareil (Tottoli, Büchi).

À 1/100 de mole de (5*S*) : **2a–2d** en solution dans 35 mL de dioxanne, à 85°C, on ajoute 35 mL d'eau à 85°C contenant 5,5 g de $NaHCO_3$, dans un récipient thermostaté à 85°C sous argon. On rajoute ensuite 2,5 g de dithionite de sodium (Merck, LAB, réf. 6507). Trois autres additions successives de 2,5 g de $Na_2S_2O_4$ sont effectuées au bout de 5, 10, 15 min. La réaction est arrêtée, soit après 30 min d'irradiation ultrasonore à 85°C, soit au bout de 4 h de chauffage dans le réacteur à 85°C. On ajoute de l'eau jusqu'à ce que la solution devienne claire, puis on extrait à l'éther (3 × 50 mL). La phase organique est séchée sur $MgSO_4$. Le produit recherché est isolé après séparation sur colonne de silice (éluant : acétate d'éthyle). Les rendements et le rapport entre les diastéréoisomères **3**/**4** sont indiqués dans le tableau 1. La reproductibilité de la méthode a été vérifiée.

RØsultats et discussion

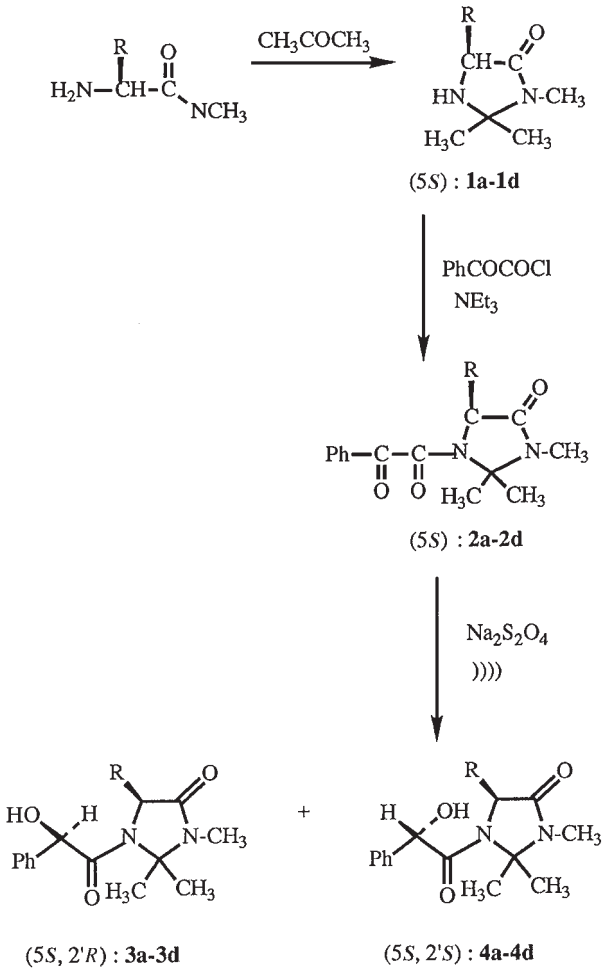
Nous avons étudié la réduction d'α-oxo amide (5*S*) : **2a–2d** dérivant d'acide phényl-glyoxilique contenant un auxiliaire chiral : (5*S*)-5-alkyl-2,2,3 triméthylimidazolidine-4-one ((5*S*) : **1a–1d**). Cet auxiliaire chiral a été utilisé pour la première fois lors de la réduction d'α-oxo amides avec le $NaBH_4$ dans le cas du composé **2d** (14).

Les imidazolidines-4-one (5*S*) : **1a–1d** ont été préparées en faisant réagir les N-méthyl amides d'amino-acides dans l'acétone 24 h au reflux (14) (schéma 1).

L'étape suivante consiste en une N-acylation de **1a–1d** à partir de PhCOCOCl; elle conduit aux α-oxo-amides chirales **2a–2d**, de configuration *S*.

Nous avons choisi lors de la dernière étape comme agent réducteur le dithionite de sodium ($Na_2S_2O_4$) car d'une part, il ne réduit pas les amides et d'autre part, il a été montré dans la littérature que les réactions mettant en jeu un transfert monoélectronique sont accélérées sous ultrasons (15–19). Deux hypothèses ont été avancées pour expliquer le mécanisme de la réduction de la fonction carbonyle par la dithionite de sodium (20). La première met en jeu un transfert d'électrons. Le radical anion sulfoxylate formé au cours de l'homolyse de la liaison S—S est à l'origine de ce transfert d'électron (21, 22) :

Schéma 1.



a : R = CH_3
b : R = $CH_2CH(CH_3)_2$
c : R = Ph
d : R = CH_2Ph

© 1997 NRC Canada

$S_2O_4^{2-} \leftrightharpoons 2SO_2^-$. Ce radical a pu être détecté par RPE (23–25). La deuxième hypothèse fait appel à une addition nucléophile sur le groupement carbonyle (20).

Enfin, dans un cas, il a été mis en évidence lors d'une réduction de la fonction carbonyle, que l'addition nucléophile peut être éliminée au profit d'un seul mécanisme faisant appel à un transfert d'électron (26).

Nous avons comparé dans les mêmes conditions expérimentales la réduction par chauffage classique et sous irradiation ultrasonore à l'aide d'une sonde plongeante à 85°C dans un réacteur thermostaté. Nous avons vérifié qu'en dessous de cette température, on n'observe pas de réaction (27). On opère dans un mélange eau–dioxanne (50/50) pour augmenter la solubilité du produit organique **2a–2d**. On doit d'une part opérer sous argon pour éviter l'oxydation du dithionite de sodium (28), d'autre part ajouter $Na_2S_2O_4$ en petites quantités pour éviter une décomposition spontanée en solution aqueuse en thiosulfate et sulfite (29, 30) et enfin travailler en milieu basique ($NaHCO_3$) pour éviter la rapide décomposition de $Na_2S_2O_4$.

Comme on peut le voir dans le tableau 1, la réaction, par chauffage classique, conduit au bout de 4 h à un rendement compris entre seulement 27% (pour R = Ph) et 42% (pour $R = CH_2CH(CH_3)_2$). Le rapport entre les deux diastéréoisomères (5*S*, 2'*R*) : **3a** et (5*S*-2'*S*) : **4a** est compris entre 70/30 ($R = CH_3$) et 85/15 (R = Ph). Dans les mêmes conditions de concentration et de température (85°C), sous irradiation ultrasonore au bout de seulement 30 min, le rendement est compris entre 76% ($R = CH_3$) et 94% (R = Ph). Cette réaction sous ultrasons conduit à une importante diastéréosélectivité : le diastéréoisomère (5*S*, 2'*R*) : **3** est très majoritaire, son pourcentage varie entre 90% ($R = CH_3$) et 98% $R = CH(CH_3)_2$.

Les deux diastéréoisomères ont été séparés sur colonne de silice. Pour déterminer la configuration absolue de **3a–3d**, nous avons utilisé la méthode déjà utilisée dans la littérature (14) qui consiste à préparer un échantillon authentique de (5*S*, 2'*R*) : **3a–3d** en deux étapes. Dans la première, (R)-$PhCH(OH)CO_2H$ (1 équiv.) réagit avec $(COCl)_2$ (1 équiv.) dans CH_2Cl_2 1 h à 25°C; on rajoute ensuite (5*S*) : **1a–1d** (1 équiv.) et de la triéthylamine (2 équiv.) dans CH_2Cl_2 à 0°C. L'échantillon observé correspond au diastéréoisomère majoritaire (5*S*, 2'*R*) : **3a–3d** obtenu lors de la réduction par le dithionite de sodium.

En conclusion, la synthèse d'imidazolidine-4-one a pu être réalisée en trois étapes. Lors de la dernière étape de réduction d'une fonction cétonique, le dithionite de sodium s'est révélé un excellent agent réducteur. La réaction est lente sous chauffage classique et conduit à une faible diastéréosélectivité. Sous irradiation ultrasonore, nous avons pu observer une importante sélectivité avec un bon rendement. Le dithionite de sodium permet de travailler dans l'eau et évite l'utilisation d'agent réducteur comme les hydrures.

Remerciements

Nous remercions Madame A. Colomer pour l'enregistrement des spectres IR.

Thermolysis of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline studied with photoelectron spectroscopy. He(I) photoelectron spectrum of dimethoxycarbene

H.M. Muchall, N.H. Werstiuk, B. Choudhury, J. Ma, J. Warkentin, and J.P. Pezacki

Abstract: Gas phase thermolysis of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**) in an ultraviolet photoelectron spectrometer by means of a CW CO_2 laser as directed heat source at 26 W gave a complex PE spectrum that included ionization bands belonging to acetone, tetramethoxyethylene (**3**), and dimethyl oxalate (**4**). Subtraction of the spectra of acetone, **3**, and **4** from the pyrolysis spectrum of **1** left a simple PE spectrum that is attributed to dimethoxycarbene (**2**) along with some ethane. Becke3LYP/6-31+G* calculations gave first adiabatic and vertical ionization potentials of **2** as well as orbital energies that are in perfect agreement with experimental values. From the available experimental and calculational data, **2** is assumed to adopt a *w* conformation.

Key words: dimethoxycarbene, 2,2-dimethoxy-Δ^3-1,3,4-oxadiazoline, tetramethoxyethylene, He(I) photoelectron spectroscopy, thermolysis.

Résumé : La thermolyse en phase gazeuse de la 2,2-diméthoxy-5,5-diméthyl-Δ^3-1,3,4-oxadiazoline (**1**) dans un spectromètre photoélectronique ultraviolet, à l'aide d'un laser à CO_2 CW utilisé comme source dirigée de chaleur à 26 W, conduit à un spectre PE complexe comportant des bandes d'ionisation appartenant à l'acétone, au tétraméthoxyéthylène (**3**) et à l'oxalate de diméthyle (**4**). Si l'on soustrait les spectres de l'acétone et ceux des composés **3** et **4** du spectre de pyrolyse du composé **1**, on obtient un spectre PE résiduel qui a été attribué au diméthoxycarbène (**2**) en présence de faibles quantités d'éthane. Des calculs de Becke3LYP/6-31+G* ont permis d'obtenir les premiers potentiels d'ionisation adiabatique et verticale de l'entité **2** ainsi que des énergies d'orbitales qui sont en parfait accord avec les valeurs expérimentales. Sur la base des données expérimentales et résultats des calculs, on peut faire l'hypothèse que l'entité **2** adopte une conformation *w*.

Mots clés : diméthoxycarbène, 2,2-diméthoxy-Δ^3-1,3,4-oxadiazoline, tétraméthoxyéthylène, spectroscopie photoélectronique He(I), thermolyse.

[Traduit par la rédaction]

The combination of photoelectron (PE) spectroscopy with quantum chemical calculations of molecular orbital eigenvalues and eigenvectors gives information about the electronic structure and bonding of stable as well as transient species that is provided by no other technique. PE spectra of transient carbenes are very rare (1) due to the high reactivity of these species, which requires special instrumentation. Usually, reactive intermediates are generated pyrolytically from thermally labile precursors using electrically heated furnaces that are several centimeters in length (2). Yet carbenes have to be generated close to the ionization beam to minimize the incursion of reactions like rearrangement, fragmentation, or dimerization. Our unique ultraviolet PE spectrometer – CW CO_2 laser apparatus (3) allows us to use the laser as a directed heat source to produce a hot zone as short as 1 mm in length on the tip of a quartz tube positioned at about 1 cm from the point of intersection with the ionization beam. We used this setup successfully to obtain PE spectra of short-lived reactive species such as benzazete and *o*-benzyne (4), 1,2-cyclohexadiene (5), 1-(2-thiaindane)ketene and benzocyclobutenethione (6), as well as *p*-substituted phenylketenes (7) through pyrolyses of suitable precursors (Scheme 1).

We decided to study the thermal gas phase decomposition of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**) (8), because thermolysis in solution had shown formation of

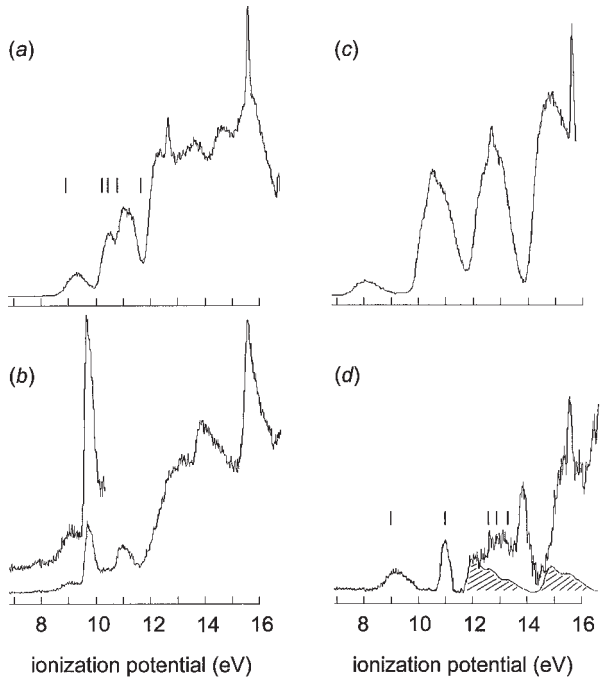
Uniformly shifted calculated eigenvalues (Becke3LYP/6-31+G*) are given as vertical bars in (*a*) and (*d*).



tetramethoxyethylene (**3**) (9) and preliminary flash vacuum pyrolysis experiments on **1** gave dimethyl oxalate (**4**), both of which could arise from a common precursor, dimethoxycarbene (**2**). Our recent computational study on the first adiabatic and vertical ionization potentials of carbenes (10) provided us with a calculational method (Becke3LYP/6-31+G* (11)) for the reliable prediction of these values. Applying these calculations to dimethoxycarbene (**2**), we expected to identify **2** through its ionization potentials if its spectrum actually was present in the pyrolysis spectrum of **1**, and possibly to establish its conformation. The particular choice of oxadiazoline **1** for this study was made because (*a*) it is a source of **2**; (*b*) it gave

us the additional opportunity to compare the mode of its decomposition (on a different path **1** can also yield nitrogen, dimethylcarbene, and dimethyl carbonate) in the gas phase to that in solution (9); and (*c*) it is the first member in a series of similar oxadiazolines that could be used as possible precursors of O,S- and O,N-substituted carbenes in the gas phase. In this communication, we report the results of a He(I) PE spectroscopic study of the thermolysis of oxadiazoline **1** along with ab initio (Gaussian 94 (12)) calculational data on **1** and two of its pyrolysis products, dimethoxycarbene (**2**) and tetramethoxyethylene (**3**). PE spectra for **2** and **3** are presented for the first time.

The PE spectrum of **1** is shown in Fig. 1*a*. Three bands belonging to four ionizations (at 9.30, 10.49, 11.00, and 11.22 eV) are separated from the main group of bands with its first band at about 12.1 eV. The sharp peak at 12.63 eV belongs to traces of water. Vertical bars in Fig. 1*a* give negative Becke3LYP/6-31+G* orbital energies (–ε 6.81, 8.11, 8.33, 8.74, and 9.49 eV), which are shifted so that the HOMO energy equals that of the calculated first vertical ionization potential IP_v (8.89 eV; total energies are given in Table 1). Support for applying a Koopmans' Theorem-like interpretation of orbital energies at the DFT level of theory in PE spectroscopic studies has been provided by Arduengo et al. (1*d*). The most stable conformation of **1**, with methoxy groups "sickle" as shown in Fig. 2*a*, was used in these calculations.

© 1998 NRC Canada

The PE spectrum of the pyrolysate of **1** taken at a laser power level of 26 W, which corresponds to a temperature of 500 ± 50°C (3), is given in Fig. 1*b*. Besides nitrogen (sharp peak at 15.60 eV), the complex spectrum shows the prominent band of acetone (9.70 eV) (13). On its low-energy side, two bands of low intensity with maxima at 8.0 and 9.0 eV can be attributed to further pyrolysis products. One path of decomposition of oxadiazoline **1** is given in Scheme 1. If nitrogen and acetone are two products, the remaining PE spectrum must be partially due to dimethoxycarbene (**2**) or to products arising from **2**. When tetramethoxyethylene (**3**), the product of dimerization of **2**, was prepared (14) and its PE spectrum (Fig. 1*c*) recorded, the first low-intensity band in the pyrolysis spectrum of **1** could be assigned to **3** (first IP at 8.0, shoulder at 10.1, and maximum of the second band at 10.5 eV). Interesting is the very broad first band of **3**: its IP_a (first adiabatic ionization potential) is at 7.1 eV. Calculated Becke3LYP/6-31+G* first adiabatic and vertical IPs (Table 1) of the all-*anti* conformer, which is the global minimum according to HF/3-21G calculations, match experimental values and confirm the energy difference between IP_a and IP_v found in the spectrum. Upon opening the fast-pumping valve on the spectrometer in the thermolysis of **1**, the band at 8.0 eV disappeared, which is proof that **3** is formed through dimerization of **2**. To know whether **3** is stable at the thermolysis temperature (its thermal decomposition has been reported (15)), it was pyrolyzed in an independent experiment. The PE spectrum of the pyrolysate of **3** (not given) obtained at a laser power level of 26 W seems to be exclusively that of dimethyl oxalate (**4**) (16): IPs of bands are the same as those in a spectrum of an authentic sample of **4** taken with our spectrometer. The peak for the methyl radical (the literature value (17) is 9.84 eV) cannot be identified with certainty; it might be present on the low-energy side of the first band of **4**.

When the PE spectra of acetone, tetramethoxyethylene (**3**), and dimethyl oxalate (**4**) were subtracted from the pyrolysis spectrum of **1**, a simple spectrum remained. There are two bands of comparable intensity at 9.0 (onset at 8.4 eV) and 11.0 eV, followed by an unstructured region with its first band at 12.0 eV and a further maximum at 13.8 eV. These ionizations, except for the band at 12.0 eV, are reproduced nicely by Becke3LYP/6-31+G* calculations on dimethoxycarbene (**2**): for the *w* conformer given in Fig. 2(*b*), which is more stable than the *sk* conformer by 7.67 kJ mol^{-1} (or 7.64 kJ mol^{-1} when zero-point vibrational energies are included), IP_a and IP_v are 8.29 and 9.01 eV, respectively, and if orbital energies (–ε 6.36, 8.39, 9.97, and 10.34 eV) are shifted uniformly as explained above, the correlation is ideal (Fig. 1*d*). While data for the *sk* conformer are not too different, IP_a 8.11 eV, IP_v 9.01 eV, –ε 6.36, 8.71, 9.80, and 10.30 eV, a distinction between **2***w* and **2***sk* is possible by means of the second IP. The additional band at 12.0 eV is the only obvious ionization not arising from **2**. The facts that there are no bands unaccounted for in the low-energy region of the spectrum and that methyl radicals are being formed in the thermolysis of **3** led us to assign this band to ethane (literature (13) IP is 11.99 eV). Additional support for this is supplied by subtraction of the PE spectrum of **4** from the pyrolysis spectrum of **3**, which leaves a spectrum that has the features of that of ethane (13).

Neither were the products of a second possible path of decomposition of **1**, dimethylcarbene (and from it propene) and dimethyl carbonate, detected in the pyrolysis PE spectrum, in agreement with results reported for the thermolysis of **1** in solution (9).

A benzo-fused oxapenem from a β-lactam-4-ylidene

Philippe Couture and John Warkentin

Abstract: Spiro-fused β-lactam oxadiazoline **2a** was prepared from acetone semicarbazone in five steps. Thermolysis of **2a** at 100°C in benzene led to carbene **3a**, which cyclized to the benzo-fused oxapenem derivative **4** via intramolecular OH insertion. Compound **10**, with a β-lactam ring linked to an azetidinedione ring, was a minor product.

Key words: benzoxapenem, carbene, β-lactam-4-ylidene, OH insertion.

Résumé : Utilisant la semicarbazone de l'acétone comme produit de départ, on a préparé l'oxadiazoline **2a**, une spiro β-lactame, en cinq étapes. La thermolyse du produit **2a** à 100°C, dans le benzène, conduit au carbène **3a** qui, par cyclisation par le biais d'une insertion intramoléculaire, donne le dérivé benzooxapénème **4**. On retrouve aussi le composé **10**, comportant un cycle β-lactame lié à un cycle azétidinedione, comme produit mineur.

Mots clés : benzoxapénème, carbène, β-lactam-4-ylidène, insertion de OH.

[Traduit par la rédaction]

Studies of the chemistry of β-lactam-4-ylidenes, generated by thermolysis of spiro-fused β-lactam oxadiazolines (**1**) (1), have recently been reported. This work demonstrated that those carbenes undergo both inter- and intramolecular reactions in fair to excellent yields, including cyclopropanation with styrene, insertion into the OH bond of methanol, and insertion into a tethered OH group (1*a*) to afford the oxapenam nucleus, Scheme 1.[2] β-Lactams have been prepared by a large number of methods[3] including a carbene-based approach to the four-membered ring from a diazoamide (3). Oxapenams, oxapenems, and other bicyclic β-lactam systems are also well known (4) and a carbene approach to the oxapenam ring, by CH insertion into a CH_2 group of the five-membered ring system, was successful, Scheme 2 (5). Benzo-fused oxapenems appear to be unreported, possibly because they are not expected to be biologically active. Many β-lactams that have well-established antibiotic activity bear acetic acid functionality at N (6). Nevertheless the synthesis of a simple benzo-fused oxapenem was of interest as a test of the β-lactam-4-ylidene approach, which could become useful for compounds bearing other functionality.

Results and discussion

Benzoxapenem **4**, from the ylidene **3a**, required oxadiazoline precursor **2a** (Scheme 3), which had been reported (1*a*), but without the phenolic OH group. That group could be incorporated by introducing the protection/deprotection methods shown in Scheme 4.[4] Semicarbazone **5** was prepared by transamination of acetone semicarbazone with 2-aminophenol in refluxing toluene. Protection of the phenol as the TBDMS ether was followed by oxidative cyclization with $PhI(OAc)_2$, which afforded imino oxadiazoline **6**. The β-lactam ring of **7** was then constructed by means of the ketene-plus-imine approach (2*d*, 7), by treating **6** with diphenylacetyl chloride (1.2 equiv.) in the presence of triethylamine (2.5 equiv.) at –23°C. Subsequent deprotection of the phenolic group with nBu_4NF (8) gave the desired **2a**.

Thermolysis (100°C, 24 h) of **2a** as a 14 mM solution in benzene generated β-lactam-4-ylidene **3a**, which, as anticipated on the basis of analogy (9), underwent intramolecular O-H insertion to yield benzoxapenem **4** in 53% yield (Scheme 3). The mechanism may involve attack of the hydroxyl oxygen at the carbene carbon (ylide formation), rather than proton transfer to that carbon, because a β-lactam-4-ylidene is appreciably electrophilic, as implied from its cyclopropanation reaction with 4-bromo-1-butene (1*e*). Compound **10** was also formed, as a minor product isolated in 7% yield,[5] as well as several very minor products that were not identified. One possible multistep mechanism that could account for **10** is illustrated in Scheme 5. It involves, as a competing pathway, 1,3-dipolar cycloreversion of the oxadiazoline ring to 2-diazopropane and a 2,4-azetidinedione (**8**). The 2-diazopropane thus generated reacts with the starting material, phenol **2a**, to give ether **2c**. Predominant 1,3-dipolar cycloreversion of the latter generates carbene **3c**, which undergoes an intermolecular C-H insertion reaction with **2a** to give **9**. Finally, fragmentation of the oxadiazoline moiety of **9** by the competing pathway (loss of 2-diazopropane) yields **10**. This sequence, involving the "minor" cycloreversion twice, requires that the process should occur in ca. 30% yield ($0.3 \times 0.3 = 0.09$; 7% found), assuming

Reagents and conditions: i. toluene, reflux; ii. NEt_3, TBDMSCl, CH_2Cl_2, 0°C; iii. $PhI(OAc)_2$, CH_2Cl_2, 0°C to rt; iv. NEt_3, $Ph_2CHCOCl$, CH_2Cl_2, –23°C; v. nBu_4NF, THF, –23°C to rt.

that cycloreversion to diazopropane is equally likely in **2a** and **9**. Formation of **12** from **11** is a precedent for such a cycloreversion, Scheme 6 (10). Another way of generating the azetidinedione would involve fragmentation of a carbonyl ylide intermediate (11) to that dione and propylidene as shown in Scheme 7 for the known case **13**→**14** (12). Although 2-propylidene also could isopropylate the phenolic OH group, the known fast 1,2 H-migration in that carbene (13) makes that pathway unlikely.

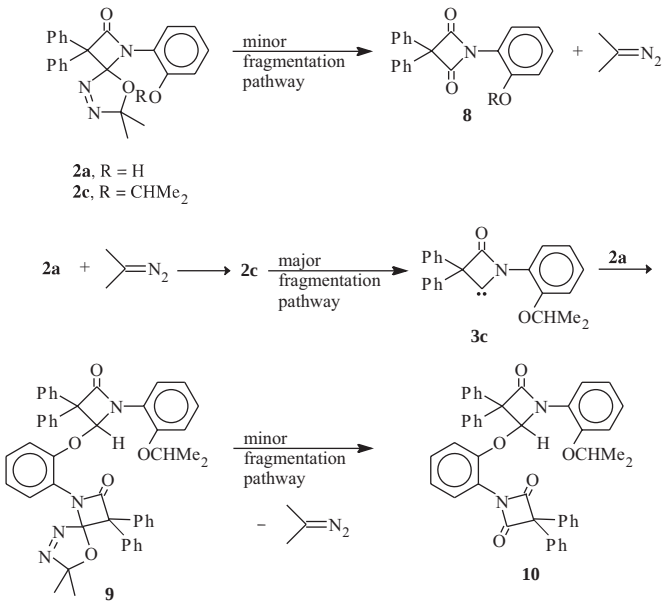
In summary, β-lactam-4-ylidene **3a** inserts effectively into the tethered phenolic OH group, as expected, to afford the apparently new, tricyclic, benzo-fused oxapenem system **4**, 2,3-benz-6,6-diphenyl-4-oxa-1-azabicyclo[3.2.0]hept-2-en-7-one.

Experimental

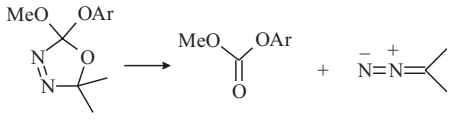
Preparation of 5

A solution of acetone semicarbazone (2.88 g, 25 mmol) and 2-aminophenol (2.88 g, 26 mmol) in toluene (9 mL) was heated to reflux for 8.5 h. The product, precipitated from the

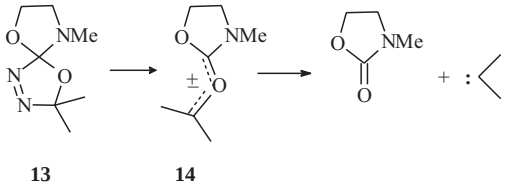
Scheme 5.



Scheme 6.



Scheme 7.



cooled solution, was triturated with diethyl ether and obtained as a white solid in 59% yield. It could be recrystallized from ethanol–ether, but with some decomposition; mp 165–166°C (turns orange at ca. 140°C); IR (KBr) cm^{-1}: 3500–2500 (OH, NH), 1654 (C═O), 1558; ^1H NMR (300 MHz, $CDCl_3$): 1.91 (s, 3H), 2.05 (s, 3H), 6.60–7.20 (m, 4H), 8.27 (br s, 1H), 8.61 (br s, 1H), 9.57 (br s, 1H); ^{13}C NMR (75 MHz, C_6D_6): 16.14, 24.66, 120.18, 120.22, 122.40, 126.03, 126.39, ca. 128 (overlap with solvent signal), 149.72, 156.06; MS (EI) *m/z*: 207 (M^+, 21%), 135 (6), 109 (100), 99 (23), 79 (23), 72 (35); MS (CI, NH_3) *m/z*: 208 $(M+H)^+$; HRMS *m/z* calcd. for $C_{10}H_{13}N_3O_2$ (M^+): 207.1008; found: 207.1008.

Protection of the OH group of 5

Semicarbazone **5** (3.40 g, 16 mmol) was dissolved in CH_2Cl_2 (100 mL) to which triethylamine (3.00 g, 30 mmol) was added. A solution of *tert*-$BuSiMe_2Cl$ (3.71 g, 25 mmol, in 35 mL of CH_2Cl_2) was then added dropwise to the ice-cold semicarbazone solution. The solution was kept at 0°C for a further 5 h before it was allowed to warm to room temperature overnight. The solid recovered after evaporation of the solvent was washed with water (to remove $Et_3NH^+Cl^-$) and recrystallized from toluene. Beige solid (43% yield), mp 170–171°C; IR (CCl_4) cm^{-1}: 3387 (NH), 3207 (NH), 1688 (C═O), 1534; ^1H NMR (300 MHz, $CDCl_3$): 0.29 (s, 6H), 1.05 (s, 9H), 1.92 (s, 3H), 2.03 (s, 3H), 6.80–7.00 (m, 3H), 8.10 (br s, 1H), 8.28 (dd, ^4J = 1.8 Hz, ^3J = 7.8 Hz), 8.69 (br s, 1H); ^{13}C NMR (75 MHz, C_6D_6): –4.28, 16.54, 18.22, 24.98, 25.85, 117.52, 119.35, 121.47, 122.17, 130.09, 144.14, 147.31, 153.54; MS (EI) *m/z*: 321 (M^+, 8%), 264 (M – ^{t}Bu, 100), 208 (10), 166 (57), 150 (46), 135 (26), 99 (22), 73 (61), 56 (29); MS (CI, NH_3) *m/z*: 322 $(M+H)^+$; HRMS *m/z* calcd. for $C_{16}H_{27}N_3O_2Si$ (M^+): 321.1873; found: 321.1868.

Preparation of 6

A solution of $PhI(OAc)_2$ (3.75 g, 12 mmol, in 75 mL of CH_2Cl_2) was added over 1 h to the protected semicarbazone (3.00 g, 9.3 mmol, in 75 mL of CH_2Cl_2) at 0°C under N_2. The solution was allowed to warm to room temperature overnight. After washing with aqueous $NaHCO_3$ (5%) and water, the organic phase was dried ($MgSO_4$), and the solvent was evaporated in vacuo. Separation of the product mixture by column chromatography on silica, eluting first with hexane and then with 5% ethyl acetate in hexane, gave 1.55 g (52%) of **6** (*Z* isomer assumed to be the major component) as a dark yellow solid that melted over the range ca. 52–60°C; IR (KBr) cm^{-1}: 1717 (C═N), 1481, 1265, 1107, 927, 842; ^1H NMR (200 MHz, $CDCl_3$): 0.21 (s, 6H), 0.99 (s, 9H), 1.63 (s, 6H), 6.88–7.02 (m, 2H), 7.02–7.14 (m, 1H), 7.23–7.33 (m, 1H); ^{13}C NMR (50 MHz, $CDCl_3$): –4.35, 18.34, 23.54, 25.70, 121.11, 121.32, 121.72, 122.86, 126.76, 135.21, 149.04, 159.63; MS (EI) *m/z*: 262 (M – ^{t}Bu, 14%), 206 (16), 192 (81), 176 (68), 164 (23), 150 (6), 135 (6), 100 (14), 84 (39), 74 (18), 47 (100); MS (CI, NH_3) *m/z*: 320 $(M+H)^+$.

Preparation of 7

This was carried out essentially as described by Zoghbi and Warkentin (1*d*) for related compounds. To a solution of **6** (0.82 g, 2.6 mmol) and triethylamine (0.66 g, 6.5 mmol) in CH_2Cl_2 (25 mL) at –23°C, diphenylacetyl chloride (0.74 g, 3.2 mmol, in 13 mL of CH_2Cl_2) was added over about 30 min. The solution was kept in the cold bath for an additional 1 h, and was then allowed to warm to room temperature overnight. After washing with aqueous $NaHCO_3$ (5%) and brine, and drying over $MgSO_4$, the solvent was evaporated. The product was obtained as a white solid in 85% yield following purification by radial chromatography (5–10% ethyl acetate in hexane); mp ca. 118–120°C (dec.); IR (CCl_4) cm^{-1}: 1786 (C═O), 1501; ^1H NMR (200 MHz, $CDCl_3$): 0.16 (s, 3H), 0.17 (s, 3H), 0.83 (s, 9H), 1.14 (s, 3H), 1.58 (s, 3H), 6.79–6.93 (m, 2H), 7.08–7.60 (m, 12H); ^{13}C NMR (50 MHz, $CDCl_3$): –4.16, 18.21, 24.26, 24.73, 25.57, 74.42, 119.49, 120.69, 122.20, 122.64, 125.43, 127.44, 127.90, 128.17, 128.29, 128.38, 130.19, 135.99, 137.21, 153.01, 166.87; MS (EI) *m/z*: 514 (M^+, 3%), 457 (M – ^{t}Bu, 10), 444 (M – diazopropane, 9), 428 (M – N_2–Me_2CO, 34), 400 (100), 387 (14), 358 (26), 342 (96), 265 (16), 249 (43), 234 (23), 194 ($[Ph_2C{=}C{=}O]^+$, 70), 165 (69), 117 (13), 73 (47); MS (CI, NH_3) *m/z*: 514 $(M+H)^+$.

Preparation of 2a

A solution of the protected oxadiazoline (0.66 g, 1.3 mmol) in dry THF (3.0 mL) was placed in a flask fitted with a septum. After flushing with dry N_2, the flask was immersed in an ice bath for several minutes, before adding 1.75 mL of nBu_4NF (1.0 M in THF, 1.75 mmol) by syringe, over about 15 min. The sample was kept in ice for an additional 20–30 min, and was then left to reach room temperature during 2 h. After evaporation of the solvent, a mixture of 15 mL of CH_2Cl_2 + 6 mL of 0.1 N HCl was added to the crude product mixture. After separation of the two layers, the aqueous phase was extracted with CH_2Cl_2, and the combined organic fractions were washed with aqueous $NaHCO_3$ (5%) and water. Slightly impure **2a**, obtained after chromatography on silica using 10–40% ethyl acetate in hexane as elution solvent, was recrystallized from ethyl acetate – hexane to afford a white solid in 77% yield; mp ca. 120–150°C (dec.); IR (CCl_4) cm^{-1}: 3600–3000 br (OH), 1745 (C═O), 1497; ^1H NMR (300 MHz, $CDCl_3$): 1.43 (s, 3H), 1.49 (s, 3H), 6.79–6.93 (m, 2H), 7.01–7.12 (m, 2H), 7.17–7.26 (m, 1H), 7.28–7.50 (m, 10H); ^{13}C NMR (75 MHz, $CDCl_3$, some signals overlap): 24.17, 24.22, 74.77, 119.07, 120.72, 120.95, 123.36, 124.52, 128.07, 128.39, 128.44, 128.67, 129.98, 133.97, 135.74, 151.29, 163.53; MS (EI) *m/z*: 285 (13%), 254 (4), 208 (5), 194 ($[Ph_2C{=}C{=}O]^+$, 89), 177 (9), 165 (100), 152 (7), 135 (23), 115 (7), 84 (10), 77 (7), 63 (10), 45 (46); MS (CI, NH_3) *m/z*: 417 $(M+NH_4)^+$, 400 $(M+H)^+$. Anal. calcd. for $C_{24}H_{21}N_3O_3$: C 72.17, H 5.30, N 10.52; found: C 72.45, H 5.00, N 10.55.

Preparation of 4 and 10

A sample of **2a** (285 mg, 0.71 mmol), dissolved in benzene (50 mL), was heated at 100°C for 24 h. The thermolysis products were separated by radial chromatography with solutions of ethyl acetate and hexane in various proportions.

Compound **4** was obtained as a white solid, mp 157–158°C (sample recrystallized from ethyl acetate – hexane); IR (CCl_4) cm^{-1}: 1801 (C═O), 1473, 1274; ^1H NMR (200 MHz, $CDCl_3$): 6.46 (s, 1H), 6.77–7.12 (m, 3H), 7.20–7.50 (m, 11H); ^{13}C NMR (50 MHz, $CDCl_3$): 76.59, 97.08, 109.73, 117.49, 121.76, 126.49, 126.87, 127.68, 128.00, 128.06, 128.41, 129.11, 130.31, 135.06, 138.20, 155.71, 177.19; MS (EI) *m/z*: 194 ($[Ph_2C{=}C{=}O]^+$, 32%), 165 (100), 139 (11), 115 (4), 86 (6), 74 (4), 63 (6), 51 (6); MS (CI, NH_3) *m/z*: 331 $(M+NH_4)^+$, 314 $(M+H)^+$. Anal. calcd. for $C_{21}H_{15}NO_2$: C 80.49, H 4.82, N 4.47; found: C 80.59, H 4.87, N 4.39.

Product **10** was also a white solid, mp 176–177°C (from ethyl acetate – hexane); IR (CCl_4) cm^{-1}: 1771 (C═O), 1754 (C═O), 1501, 1382; ^1H NMR (200 MHz, $CDCl_3$): 1.01 (d, ^3J = 6.0 Hz, 3H), 1.24 (d, ^3J = 6.0 Hz, 3H), 4.54 (septet, ^3J = 6.0 Hz, 1H), 6.7–7.7 (m, 29H); ^{13}C NMR (50 MHz, $CDCl_3$): 21.63, 22.01, 70.00, 73.25, 74.51, 89.80, 112.93, 114.21, 119.63, 120.30, 121.85, 123.46, 125.26, 126.78, 127.28, 127.51, 127.66, 127.79, 127.91, 128.24, 128.78, 128.92, 130.09, 134.84, 135.19, 138.10, 150.07, 150.87, 167.02, 168.08; MS (EI) *m/z*: 684 (M^+, 2%), 507 (12), 490 (6), 356 (41), 328 (100), 314 (20), 286 (91), 194 ($[Ph_2C{=}C{=}O]^+$, 65),

Synthesis, spectroscopy, and structures of the seven-coordinate complexes $(CH_3)_2AsC(CF_3)$═$C(CF_3)As(CH_3)_2W(CO)_2I_2P(OC_6H_5)_3$ and $[(CH_3)_2AsC(CF_3)$═$C(CF_3)As(CH_3)_2]_2W(CO)Br_2$ and spectroscopy of related seven-coordinate complexes

Richard J. Barton, Sushil K. Manocha, Beverly E. Robertson, and Lynn M. Mihichuk

Abstract: (L-L)$W(CO)_3I_2$ (L-L = $(CH_3)_2AsC(CF_3)$═$C(CF_3)As(CH_3)_2$) reacts with the monodentate phosphite $P(OC_6H_5)_3$ and (L-L)$W(CO)_3Br_2$ reacts with L-L to form new seven-coordinate complexes (L-L)$W(CO)_2I_2P(OC_6H_5)_3$ and (L-L)$_2W(CO)Br_2$. Low-temperature X-ray diffraction analyses show the tungsten atom to be seven coordinate in both complexes, with the geometry most closely approximated by a monocapped octahedral environment, the capping group being a carbonyl in the dicarbonyl complex; the geometry is most closely approximated by a pentagonal bipyramidal environment in the monocarbonyl complex. The ^1H, ^{13}C, and ^{19}F NMR data indicate that the dicarbonyl complex is stereochemically nonrigid at 298 K and rigid at lower temperatures, while the monocarbonyl is nonrigid both at 298 K and at lower temperatures. $\Delta G^{\neq}$ values calculated at coalescence temperatures are consistent with an intramolecular rearrangement process for both complexes. The ^{13}C chemical shifts and $^2J(^{13}C\text{-}^{31}P)$ values provide important structural considerations in the assignment of a seven-coordinate geometry. Spectroscopic properties for the related seven-coordinate dicarbonyl complexes (L-L)$W(CO)_2PX_2$ (P = $P(OC_6H_5)_3$; X = Br; P = $P(OCH_3)_3$, $P(C_6H_5)_3$; X = Br, I) and monocarbonyl complexes (L-L)$_2W(CO)I_2$ and (L-L)$W(CO)X_2[P(OCH_3)_3]_2$ (X = Br, I) are presented and compared to those of the two title complexes.

Key words: seven-coordination, X-ray, NMR analysis.

Résumé : Le (L-L)$W(CO)_3I_2$ (L-L = $(CH_3)_2AsC(CF_3)$═$C(CF_3)As(CH_3)_2$) réagit avec le phosphite monodentate $P(OC_6H_5)_3$ alors que (L-L)$W(CO_3)Br_2$ réagit avec L-L pour former respectivement les nouveaux complexes heptacoordinés (L-L)$W(CO)_2I_2P(OC_6H_5)_3$ et (L-L)$_2W(CO)Br_2$. Des analyses de diffraction des rayons X à basse température ont permis de montrer que l'atome de tungstène est heptacoordiné dans les deux complexes: dans le complexe dicarbonyle, sa géométrie peut être décrite approximativement par un environnement octaédrique à cap unique qui est le dicarbonyle; dans le complexe monocarbonyle, la géométrie peut être décrite approximativement par un environnement bipyramidal pentagonal. Les données de RMN du ^1H, du ^{13}C et du ^{19}F indiquent que le complexe dicarbonyle est stéréochimiquement non rigide à 298 K mais qu'il est rigide à des températures inférieures; par ailleurs, le complexe monocarbonyle n'est pas rigide ni à 298 K ni à des températures inférieures. Pour chacun de ces complexes, les valeurs de $\Delta G^{\neq}$ calculées à partir des températures de coalescence sont en accord avec un processus de réarrangement intramoléculaire. Les valeurs des déplacements chimiques en ^{13}C ainsi que celles des $^2J(^{13}C\text{-}^{31}P)$ fournissent des considérations structurales importantes dans l'attribution de la géométrie heptacoordinée. On rapporte les propriétés spectroscopiques des complexes dicarbonyles heptacoordinés apparentés (L-L)$W(CO)_2PX_2$ (P = $P(OC_6H_5)_3$; X = Br; P = $P(OCH_3)_3$ ou $P(C_6H_5)_3$; X = Br, I) et des complexes monocarbonyles (L-L)$_2W(CO)I_2$ et (L-L)$W(CO)X_2[P(OCH_3)_3]_2$ (X = Br, I) et on les compare à celles des deux complexes mentionnés dans le titre.

Mots clés : heptacoordination, rayons X, analyse par RMN.

[Traduit par la rédaction]

Introduction

In the area of seven coordination the relevant polytopal polyhedra are the pentagonal bipyramid, the monocapped octahedron, and the quadrilaterally monocapped trigonal prism. X-ray crystallographic studies of seven-coordinate transition metal carbonyl complexes have shown the latter two types of geometry to predominate (1–12). However, the actual structures seldom match the ideal polyhedral arrangements, and

various criteria have been proposed to aid in the assignment of the most appropriate description to an experimentally determined polyhedron (13–15).

We have been interested in the seven-coordinate chemistry of group six metal (Mo, W) carbonyl complexes from the point of view of structure and dynamic behaviour (10–12, 16). Structural studies have been restricted to the tungsten analogues because the corresponding molybdenum complexes decompose in the X-ray beam during X-ray analysis, preventing the collection of useful structural data. In addition the 14.4% spin one-half ^{183}W atom provides important coupling parameters not present in the molybdenum series. The molybdenum and tungsten complexes nevertheless show similar properties and are assumed to behave in a similar manner with regard to fluxionality and reactivity. Our present study, which includes a detailed spectroscopic investigation of tungsten complexes containing one bidentate ligand and extends into a study of corresponding complexes incorporating two bidentate ligands, allows for a greater understanding of structural features in terms of a predominant geometry and fluxional behaviour.

Seven-coordinate carbonyl complexes also exhibit fluxionality in solution, resulting in room-temperature NMR spectra often not being consistent with the X-ray crystal structure. The reason for this behaviour is thought to be due to the small energy barriers between stereochemical isomers. To explain the mechanisms of these dynamic processes both intramolecular and (or) intermolecular pathways are possible (14, 16–18), and no typical mechanism is responsible for these processes although most are described as intramolecular rearrangements. We are compiling structural and solution NMR data in order to better understand the dynamic behaviour and elucidate the mechanism of the ligand motion.

In this paper we describe the synthesis, X-ray structure, spectroscopic properties, and fluxional behaviour of the seven-coordinate complexes $(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2$-$W(CO)_2I_2P(OC_6H_5)_3$ and $[(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2]_2$-$W(CO)Br_2$ and spectroscopic properties of related seven-coordinate complexes.

Experimental section

General considerations

All reactions were carried out under an argon atmosphere using standard Schlenk tube techniques. Solvents were dried and purified by known procedures and distilled under nitrogen prior to use. The ligand *cis*-2,3-bis(dimethylarsino)-1,1,1,4,4,4-hexafluorobut-2-ene(L-L) (19, 20) and the starting complexes (L-L)$W(CO)_3I_2$ and (L-L)$W(CO)_3Br_2$ were prepared as previously described (16).

All seven-coordinate dicarbonyl complexes for which spectroscopic data are presented were prepared in a similar manner to that of (L-L)$W(CO)_2I_2P(OC_6H_5)_3$, discussed below. Specifically, the preparation of (L-L)$W(CO)_2I_2P(OCH_3)_3$ (11) and (L-L)$W(CO)_2Br_2P(C_6H_5)_3$ (12) have been previously described. The synthesis of the seven-coordinate monocarbonyl complex (L-L)$W(CO)Br_2[P(OCH_3)_3]_2$ has been previously described (10), and the iodo analogue was prepared in a similar manner to that of (L-L)$_2W(CO)Br_2$, discussed below, as was (L-L)$_2W(CO)I_2$.

The ^1H, ^{31}P-{^1H}, ^{19}F-{^1H}, and ^{13}C NMR data were recorded on a Bruker AC 200 QNP NMR spectrometer (^1H, 200.13 MHz; ^{31}P, 81.02 MHz; ^{19}F, 188.31 MHz; ^{13}C, 50.3 MHz). Chemical shifts are expressed in parts per million, downfield from $Si(CH_3)_4$ (^1H, ^{13}C), downfield (positive) or upfield (negative) from 85% H_3PO_4(^{31}P) and upfield (negative) from $CFCl_3$(^{19}F).

Infrared spectra were recorded on a Perkin–Elmer 1600 FT instrument in dichloromethane and are reported in cm^{-1}. Elemental analyses were measured using a Perkin–Elmer 2400 CHN elemental analyzer.

Preparation of (L-L)$W(CO)_2I_2P(OC_6H_5)_3$

The (L-L)$W(CO)_3I_2$ (0.25 g, 0.28 mmol) and $P(OC_6H_5)_3$ (0.12 g, 0.32 mmol) were refluxed in 50 mL of benzene for 17 h. The infrared spectra indicated complete conversion of the tricarbonyl complex to the dicarbonyl complex. The solvent was removed in vacuo, and the resulting yellow solid was washed with *n*-hexane to remove any unreacted $P(OC_6H_5)_3$ and was then recrystallized from a dichloromethane hexane mixture at –20°C to give 0.25 g (75%) of (L-L)$W(CO)_2I_2P(OC_6H_5)_3$. ^1H NMR ($CDCl_3$): 2.01 (s, 12H, $As(CH_3)_2$), 7.27 (m, 15H, $P(OC_6H_5)_3$); ^{31}P-{^1H}NMR ($CDCl_3$): 90.7 (s, W-P, $J(^{183}W$-$^{31}P) = 403$ Hz); ^{19}F-{^1H}NMR ($CDCl_3$): –53.1 (s, CF_3). Anal. calcd. for $C_{28}H_{27}As_2F_6I_2O_5PW$: C 28.57, H 2.30, I 21.60; found: C 28.90, H 2.29, I 21.77.

Preparation of (L-L)$_2W(CO)Br_2$

The (L-L)$W(CO)_3Br_2$ (0.25 g, 0.31 mmol) and (L-L) (0.25 g, 0.67 mmol) were refluxed in 50 mL of toluene for 22 h. The colour of the reaction mixture changed from yellow to orange to dark brown. Infrared spectroscopy indicated complete conversion of the tricarbonyl complex to the monocarbonyl complex. The solvent was removed in vacuo, and the resulting brown–black solid was recrystallized from a toluene–hexane mixture at –20°C to give 0.23 g (65%) of (L-L)$_2W(CO)Br_2$. ^1H NMR (CD_2Cl_2): 2.05 (s, $As(CH_3)_2$); ^{19}F-{^1H}NMR ($CDCl_3$): –50.6 (s, CF_3). Anal. calcd. for $C_{17}H_{24}As_4Br_2F_{12}OW$: C 18.29, H 2.15, Br 14.34; found: C 17.93, H 2.08, Br 14.81.

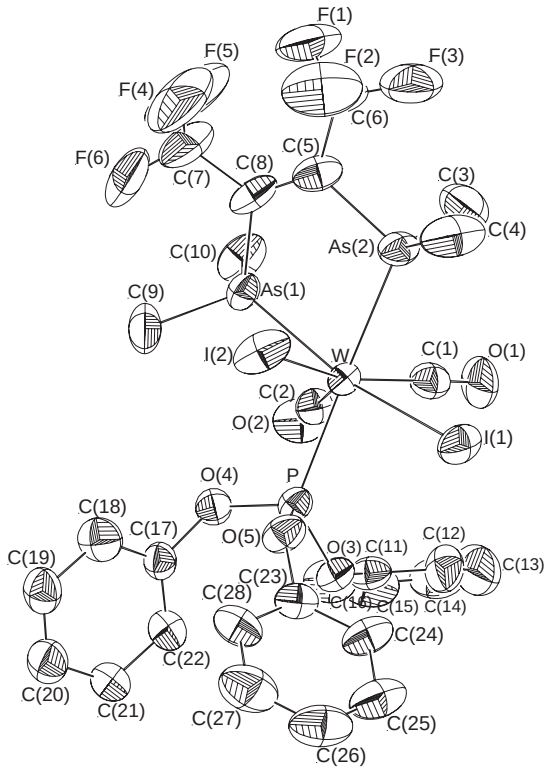
Fig. 1. ORTEP diagram for (L-L)W(CO)$_2$I$_2$P(OC$_6$H$_5$)$_3$ showing the atomic labelling scheme with 50% probability thermal ellipsoids.



Crystallographic characterization of (L-L)W(CO)$_2$I$_2$P(OC$_6$H$_5$)$_3$

A yellow–orange crystal with approximate dimensions 0.41 × 0.44 × 0.45 mm was selected and coated with collodion. Preliminary investigation of the precession photographs showed symmetry and systematic extinction conditions (*hkl*: $h + k = 2n$; *h*01: h, $l = 2n$; and 0*k*0: $k = 2n$) indicative of the space group *C*2/*c* or *Cc*. The accurate unit cell parameters were obtained from the least-squares refinement of 24 reflections and their Friedel pairs in the 2θ range 35–45°, as observed on a modified Picker FACS-1 four-circle diffractometer. The intensity data were collected at 218 ± 4 K using an Enraf–Nonius Universal low-temperature device. Three standard reflections were measured after every 47 reflections. No significant decay was observed during data collection.

The intensities of 8291 independent reflections were measured for 2θ values between 3° and 55° of which 6663 were considered to be observed with $I \geq 2\sigma(I)$. Absorption corrections were applied using the Gaussian integration method. The crystal data are given in Table 1. The intensity statistics indicated the centrosymmetric space group *C*2/*c*. The structure was solved by combined direct methods and Fourier syntheses. All non-hydrogen atoms were refined anisotropically by the full-matrix least-squares method. Weights were assigned according to the REGWT program with $w = (\sigma_c^2 + \sigma_m^2)^{-1}$, where σ_c^2 is the variance and σ_m^2 is the term calculated by REGWT using iterative methods to remove the systematic trends with respect to *F* and sin θ/λ in the residuals of the structure factors (21). Several cycles of least-squares refinement were performed to achieve a convergence with a conventional *R* value of 0.047 and a weighted *R* value of 0.063. The maximum and average shift/esd of the least-squares parameters were 1.8×10^{-3} and 1.1×10^{-4}, respectively. In the final Fourier difference map a peak corresponding to 1.71 e Å^{-3} was located approximately 1.07 Å from the center of the W atom. The residual density near the heavy transition metal is not unexpected in light of the approximations used in the absorption corrections. All calculations were carried out using the XTAL 2.4 system of programs (22). Important bond lengths and bond angles are given in Table 2.[2] An ORTEP drawing showing the atomic labelling scheme is given in Fig. 1, and a schematic diagram showing the torsional angles in the five-membered ring of the chelate ligand for (L-L)W(CO)$_2$I$_2$P(OC$_6$H$_5$)$_3$ and (L-L)W(CO)$_2$I$_2$P(OCH$_3$)$_3$ is given in Fig. 2.

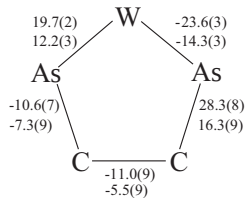
Fig. 2. Schematic diagram showing the torsional angles in the five-membered ring of the chelate ligand for $(L\text{-}L)W(CO)_2I_2P(OC_6H_5)_3$ (top numbers) and the related complex $(L\text{-}L)W(CO)_2I_2P(OCH_3)_3$ (bottom numbers).



mixture at –20°C under an inert atmosphere. A hexagonal plate with approximate dimensions 0.39 × 0.22 × 0.19 mm was selected and coated with collodion. Precession photographs showed systematic extinction conditions ($h0l$: $l = 2n$; $0k0$: $k = 2n$) and symmetry indicative of the space group $P2_1/c$. The accurate unit cell parameters were obtained from the least-squares refinement of 36 reflections in the 2θ range 25–45°, observed as for the previous compound. The data were collected at 203 ± 4 K. The intensities of three standard reflections, measured after every 47 data points, showed an average decay of 20% over the period of the data collection.

The intensities of 7611 reflections were measured (hkl, $hk\bar{l}$ for 2θ values in the range 3–45°) of which 5364 were considered to be observed with $I \geq 2\sigma(I)$. The data were corrected for the decay in the standard reflections, and absorption corrections were applied as for the previous compound. Faces of the crystal were not well defined and were approximated. The crystal data are given in Table 1. The structure has two independent molecules in the unit cell. The structure was solved by the heavy-atom method, using direct methods to confirm the positions of the two tungsten atoms. The remaining non-hydrogen atoms were found from successive Fourier maps. The positions of the hydrogen atoms were not apparent on the difference maps. The structure was refined by full-matrix least squares, treating the tungsten, arsenic, bromine, and fluorine atoms anisotropically and the carbon and oxygen atoms isotropically. Weights were assigned as $w = \sigma_c^{-2}$, where σ_c^2 is the variance in F as calculated from counting statistics and the instability factor.

The refinement converged to a conventional R value of 0.073 and a weighted R value of 0.10. These high values reflect the decay of the sample during data collection and the poor quality of the sample as manifested by a large number of weak reflections. The maximum and average shift/esd were 1.2×10^{-3} and 3.1×10^{-5}, respectively, at the end of refinement. The coordinates of the two independent molecules were approximately related by the operator $1/2 + x$, $1/2 - y$, z. If this relation were exact, reflections $h0l$ would be absent. The data showed that these reflections were weak but not absent. Further examination showed that they were not due to multiple scattering. Therefore, the apparent symmetry is only approximate. Pairs of residual electron-density peaks, with a maximum height of 3.6 e Å^{-3}, were observed near each of the tungsten, bromine, and arsenic atoms, reflecting the limitations in the approximate absorption corrections.

All calculations were carried out using the XTAL 2.4 system of programs (22). Important bond lengths and angles are given in Table 3. The labelling for the two molecules are

identical except that the chemical symbols for one are primed. An ORTEP drawing showing the labelling scheme for the unprimed molecule is given in Fig. 3.

Results and discussion

Synthesis of the seven-coordinate complexes

The dicarbonyl complexes containing a monodentate phosphine or phosphite ligand were readily synthesized from the corresponding tricarbonyl complexes in refluxing benzene. More vigorous conditions (refluxing toluene) were necessary to form the monocarbonyl complexes; attempts yielded only $(L\text{-}L)_2W(CO)X_2$ and $(L\text{-}L)W(CO)X_2[P(OCH_3)_3]_2$ (X = Br, I). Presumably there is congestion around the tungsten atom with ligands such as $P(C_6H_5)_3$, $P(OC_6H_5)_3$, $P(OC_2H_5)_3$, and $P(C_4H_9)_3$.

Crystal structure of $(L\text{-}L)W(CO)_2I_2P(OC_6H_5)_3$

The tungsten atom is seven-coordinate with the coordination sphere containing the two arsenic atoms of the L-L ligand, two iodine atoms, two carbon atoms of the carbonyl groups, and the phosphorus atom of the triphenylphosphite group. To determine the stereochemistry of the title compound we have used the δ parameters of Porai–Koshits and Aslanov (23), as calculated by Muetterties and Guggenberger (13). The δ parameter values (21°, 17°, 6°), when compared with the idealized monocapped octahedron (24.2°, 24.2°, 24.2°) and the idealized monocapped trigonal prism (0°, 0°, 41.5°), indicate the geometry to be closer to a monocapped octahedron. For this geometry the capping atom is the C(2) carbonyl group with the capped face containing the As(1), C(1), and P atoms. Kepert (24) has shown that seven-coordinate complexes containing one bidentate ligand with a normalized *bite* (defined as the distance between points representing the donor atoms of the bidentate ligands on a sphere of unit radius and with the same angles subtended at the center as in the real coordination polyhedron) less than 1.11 would be expected to exhibit pentagonal–bipyramidal geometry, and those with a normalized *bite* greater than 1.11 would be expected to exhibit either monocapped octahedral or monocapped trigonal prismatic geometry. The observed geometry of the tungsten complex with a normalized *bite* of 1.24 for the L-L ligand is in accord with Kepert's (24) conclusions. A similar geometry is observed for the related complex $(L\text{-}L)W(CO)_2I_2P(OCH_3)_3$ with an L-L normalized *bite* of 1.23 (11). Both complexes also exhibit other features associated with a monocapped octahedral geometry. The mean $C_c\text{-}W\text{-}A_c$ and $C_c\text{-}W\text{-}A_u$ angles (C_c is a capping atom, A_c is an atom in the capped face, and A_u is an atom in the uncapped face) are 73.4° and 127.3° for the triphenylphosphite compound and 72.7° and 127.8° for the trimethyl phosphite complex (11), respectively, with corresponding angles for an ideal monocapped octahedron being 74.1° and 125.5° (25). The other feature is that the unique capping atom has very close contacts with the three atoms in the capped face. Thus in the triphenylphosphite complex the capping carbon is 2.27, 2.69, and 2.77 Å from the C, As, and P atoms, respectively, in the capped face and in the related trimethyl phosphite complex 2.28, 2.71, and 2.69 Å from these atoms (11).

The five-membered ring of the chelate ligand shows a moderate degree of puckering in both the triphenylphosphite and trimethyl phosphite complexes. The torsional angles for both complexes are shown in Fig. 2. The ring-puckering parameters, according to the method of Cremer and Pople (26) are $q = 0.42$ and $\phi = 14°$ for $(L\text{-}L)W(CO)_2I_2P(OC_6H_5)_3$ and $q = 0.26$ and $\phi = 10.1°$ for $(L\text{-}L)W(CO)_2I_2P(OCH_3)_3$ (11), indicating a moderate degree of puckering, intermediate between a twist and envelope conformation. The greater degree of puckering in the triphenylphosphite complex is primarily due to the presence of the bulky phenyl rings compared to the methyl groups. The tetrahedral coordination of the arsenic atoms is also distorted by the contacts.

The two carbon monoxide ligands are in a *cis* arrangement to each other (71.2°), the arrangement required in order to minimize competition for dπ electron density from the d^4 tungsten atom. The lengths of the two W—As bonds are significantly different from each other at 2.5603(7) and 2.6004(7) Å, which can be explained by a consideration of their respective *trans* ligands. The I(1) atom *trans* to As(1) is not as strong an acceptor as the P atom *trans* to As(2), resulting in greater back donation to As(1). This results in a shortening of the W—As(1) bond compared to the W—As(2) bond, the difference being 0.04(1) Å. The average W—I bond length of 2.87 Å in this complex is close to the average of 2.85 Å reported for similar complexes (27, 28). The W—P bond length of 2.457(2) Å is similar to that in $(L\text{-}L)W(CO)_2I_2P(OCH_3)_2$ (2.466(3) Å) (11) but considerably shorter as compared to $(L\text{-}L)W(CO)_2Br_2P(C_6H_5)_3$ (2.548(2) Å) (12). This difference may reflect both the steric restrictions of the greater bulk of the $P(C_6H_5)_3$ groups and the presence of more double-bond character through back donation from the tungsten in $(L\text{-}L)W(CO)_2I_2P(OC_6H_5)_3$. These results are in accord with differences in the π-acceptor ability of the phosphorus ligands.

Crystal structure of $(L\text{-}L)_2W(CO)Br_2$

The structure contains two crystallographically independent

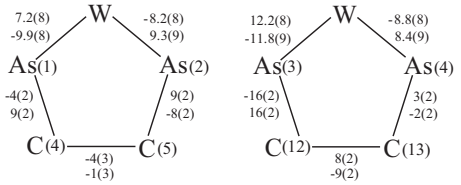
Fig. 4. Schematic diagram showing the torsional angles in the two five-membered rings of the chelate ligands for $(L\text{-}L)_2W(CO)Br_2$. As(1) and As(2) occupy equatorial and axial positions, respectively; As(3) and As(4), equatorial positions. The top numbers refer to each ring of the unprimed molecule and the bottom numbers to each corresponding ring of the primed molecule.



molecules that are related as near enantiomers. They are chemically equivalent; equivalent metal—ligand bond distances differ by less than 0.02 Å, equivalent interligand distances differ by an average of 0.04 Å, and intramolecular bond angles agree within 2.5°. In both molecules the two L-L ligands chelate the metal to form a seven-coordinate tungsten (II) complex with the two bromine atoms and the carbonyl group. The tungsten atom has a slightly distorted pentagonal bipyramidal geometry. The δ parameters of Porai–Koshits and Aslanov (23) are 37° and 52°. In the pentagonal bipyramid the third δ parameter represents an interatomic vector internal to the polyhedron. The δ values for an ideal pentagonal bipyramid with identical ligands are both 54.4°. The equatorial plane of the pyramid is occupied by an L-L ligand, the two bromine atoms, and one arsenic atom of the other L-L ligand, leaving the second arsenic atom and the carbonyl group to fill the apical positions. The tungsten atom is displaced from the average plane of the pentagonal ring by 0.0144(2) Å. Thus this less symmetric pentagonal bipyramid has fewer steric constraints than the more symmetric one with both L-L ligands in the pentagonal plane, with repulsions between the methyl groups on adjacent arsenic atoms.

This type of geometry is rare (29, 30) for seven-coordinate carbonyl complexes of the type $MX_2(CO)_nL_{5-n}$ (M = Mo, W; n = 1–3). The tungsten—carbon bond is unique, being extremely short (1.78(2) Å) compared to a related monocarbonyl complex (10) containing two monodentate $P(OCH_3)_3$ ligands (1.86(3) Å) and the related dicarbonyl complexes (11, 12) (average 1.94 Å). The relative shortness of the tungsten—carbon bond here represents considerable double-bond character arising from back donation of π electrons from tungsten.

The four five-membered rings of the chelate ligands in the two independent molecules of $(L\text{-}L)_2W(CO)Br_2$ show a variation in conformation. Their torsional angles are shown in Fig. 4. One of the two chelates in each independent molecule has a *bite* that spans from the equatorial plane of the pentagonal bipyramid to one of the axial vertices (equatorial–axial), involving the atoms As(1) and As(2). The other chelate in each molecule has a *bite* that forms an edge of the equatorial plane (equatorial–equatorial), involving the atoms As(3) and As(4).

Because of the approximate enantiomorphic relation between the two independent molecules, the torsional angles of their equatorial–equatorial five-membered rings have similar torsional angle magnitudes but with opposite signs. This is further illustrated by the ring-puckering parameters of Cremer and Pople (26), which show similar puckering amplitudes (0.20 for each) and puckering phase angles different by approximately 180° (200° in one molecule and 22° in the other molecule). These phase angles correspond to the twist conformation of a five-membered ring. The equatorial–axial chelates are less similar, with puckering amplitudes of 0.15 and 0.18, and the respective puckering phase angles of 168° and 1°. These phase angles correspond to an intermediate twist-boat conformation and a boat conformation, respectively. In this case, four of the torsional angles show opposite signs, with the fifth small and negative in both cases.

$(L\text{-}L)_2W(CO)Br_2$	1809	260.5(s)	

[a] Spectra were recorded in CH_2Cl_2; vs = very strong, s = strong.

[b] Spectra were recorded in CD_2Cl_2 at 200 K in the presence of a trace amount of [Cr(acac)$_3$]; s = singlet, d = doublet, dd = doublet of doublets.

Spectroscopic properties of $(L\text{-}L)W(CO)_2I_2P(OC_6H_5)_3$ and related seven-coordinate dicarbonyl complexes

Table 4 lists carbonyl IR stretching frequencies and ^{13}C NMR data, and Table 5 lists $^{19}F\text{-}\{^1H\}$ and $^{31}P\text{-}\{^1H\}$ NMR data for all the seven-coordinate complexes under study. The observation of a single As–CH_3 resonance in the ^1H NMR spectrum (297 K) and a single CF_3 resonance in the $^{19}F\text{-}\{^1H\}$ NMR spectrum of $(L\text{-}L)W(CO)_2I_2P(OC_6H_5)_3$ are not consistent with the molecule having a static solution structure equivalent to that determined from the X-ray determination. The static structure consistent with the solid-state structure is frozen out at 200 K. Thus, As–CH_3 resonances are found at 1.50, 1.84, 2.51, two CF_3 quartets at –52.2 and –53.8, and two ^{13}C doublets (carbonyl region) at 212.4 and 240.4. It is assumed that accidental degeneracy may have caused the 1:2:1 As–CH_3 triplet, since all other related complexes exhibited four equal-area As–CH_3 resonances. The dicarbonyl complexes are related as shown by the similarity of carbonyl stretching frequencies, chemical shifts, coupling constants, and variable temperature ^1H and $^{19}F\text{-}\{^1H\}$ NMR data. As the temperature is increased, four As–CH_3 peaks (three for the title compound) indicative of the low-temperature slow-exchange limiting spectra coalesce into two peaks. The line broadening continues until an averaged

[a] Spectra were recorded in CD_2Cl_2; s = singlet, q = quartet, m = A_3B_3 multiplet.
[b] Each resonance (297 K) appeared as a singlet with ^{183}W satellites except for (L-L)W(CO)X$_2$[P(OCH$_3$)$_3$]$_2$ (X = Br, I) for which each resonance (210 K) appeared as a doublet with ^{183}W satellites.

single As–CH_3 resonance is observed, indicative of the high-temperature fast-exchange limiting spectra.

The ^{13}C chemical shifts (carbonyl region), carbonyl stretching frequencies, and $J(^{31}P\text{-}^{183}W)$ values are consistent with the electronic differences of the three phosphorus monodentate ligands in which P(C$_6$H$_5$)$_3$ is a better net donor: P(OC$_6$H$_5$)$_3$, P(OCH$_3$)$_3$, P(C$_6$H$_5$)$_3$. An examination of the low-temperature ^{13}C chemical shifts in Table 4 shows two unique resonances for the dicarbonyl complexes, one that is approximately 30 ppm downfield from the other. For the title dicarbonyl complex the downfield resonance is assigned to the unique capping carbonyl group consistent with the work of Colton and Kevekordes (31), where they assigned the low field carbonyl chemical shift absorption to the capping carbon in a structure best described as a monocapped octahedron. Another unique feature of the ^{13}C NMR data is the large differences in $^{2}J(^{13}C\text{-}^{31}P)$ values that are consistent with *cis* coupling. Previous work has shown an average $^{2}J(^{13}C\text{-}^{31}P)$ value of 32 Hz for angles subtended at tungsten by the phosphorus and carbonyl carbon in the range of 72–78° and a $^{2}J(^{13}C\text{-}^{31}P)$ value of 6 Hz for a corresponding angle of 95° (25, 32–34). On this basis the larger $^{2}J(^{13}C\text{-}^{31}P)$ value could be assigned to the carbonyl with a P-W-C angle in the range 70–80° and the lower $^{2}J(^{13}C\text{-}^{31}P)$ value to the carbonyl with a P-W-C angle above 100°. For the title dicarbonyl complex, the capping carbonyl (<P-W-C = 77.2°) is assigned the resonance with $^{2}J(^{13}C\text{-}^{31}P)$ = 39.9 Hz, and the noncapping carbonyl (<P-W-C = 110.7°) the resonance with $^{2}J(^{13}C\text{-}^{31}P)$ = 9.3 Hz. These assignments are compatible with the earlier assignments made for the carbonyl group chemical shift on the basis of the unique capping position.

In view of the difficulty in assigning a configuration for seven-coordinate complexes based on multinuclear NMR data, we believe ^{13}C chemical shifts and $^{2}J(^{13}C\text{-}^{31}P)$ values provide important insights in elucidating structural considerations.

There have been many possible pathways suggested to explain the fluxional behaviour in seven-coordinate compounds involving dissociative processes and intramolecular rearrangements. Dissociative processes such as phosphite or phosphine dissociation or carbonyl dissociation for the dicarbonyl complexes can be eliminated by the fact that the ^{31}P-{^{1}H} fast-exchange limiting NMR spectra exhibited $^{31}P\text{-}^{183}W$ coupling, and ^{13}C fast-exchange limiting NMR spectra exhibited both $^{13}C\text{-}^{183}W$ and $^{13}C\text{-}^{31}P$ coupling. Dissociation of one end of the chelated ligand would probably require a much higher barrier than that which is observed ($\Delta G^{\neq}$ values in the range 45.1–54.0 kJ/mol).

The activation energy barriers $\Delta G^{\neq}$ for methyl group exchange (calculated from the Eyring equation (35) at the coalescence temperature) show an increase, with an increase in the size of the halide and the bulk of the phosphorus ligand, consistent with an intramolecular process (36) in which the tungsten—halide and tungsten—phosphorus bonds are retained throughout the dynamic process.

To explain the dynamic behaviour of the title compound an exchange process can be envisaged, which itself varies over a narrow temperature range. The process might begin with random scrambling of the atoms I(1), C(1), and P, leaving the atom I(2) rigidly held in the "pocket" of the chelate ring. This would equilibrate the atoms C(4) and C(9) as one pair, and the atoms C(3) and C(10) as the other pair. As the temperature is raised further the atom I(2) is gradually added to the random scrambling motion, causing coalescence to a single peak. The $\Delta G^{\neq}$ value associated with the lower temperature part of the process is 51.7(2) kJ/mol and with the higher temperature part of the process is 54.0(2) kJ/mol. The similarity of these two values supports the description of the phenomenon responsible for the coalescence as being one process.

Spectroscopic properties of (L-L)$_2$W(CO)Br$_2$ and related seven-coordinate monocarbonyl complexes

As with the previous complex, the observations of a single As–CH_3 resonance in the ^{1}H NMR spectrum (297 K) and a

single CF_3 resonance in the $^{19}F\text{-}\{^1H\}$NMR spectrum of $(L\text{-}L)_2W(CO)Br_2$ are not consistent with the X-ray crystal structure, suggesting dynamic behaviour. Lowering the temperature to 180 K produced two As–CH_3 resonances at 1.76 and 2.15 and a complex CF_3 multiplet centred at –51.0. Further lowering of the temperature to 170 K (lowest attainable due to solvent limitations) caused the low field As–CH_3 resonance to broaden. Thus it was not possible to obtain a low-temperature slow-exchange limiting spectrum indicative of the solid-state X-ray crystal structure. The $\Delta G^{\neq}$ value of 43.5 kJ/mol is comparatively low for a complex containing two bidentate ligands relative to the dicarbonyl complexes; perhaps the small *bite* of the two L-L ligands provides extra space around the tungsten centre for other ligands, thus enhancing the possibility for rearrangements.

A nondissociative mechanism consistent with the NMR data could involve a concerted rearrangement in which the roles of the two bidentate L-L ligands are reversed, and the environments of their methyl groups are also equilibrated. An intermediate polyhedron between the two pentagonal bipyramidal geometries is a monocapped trigonal prism, with the carbonyl ligand capping the quadrilateral face formed by the four arsenic atoms as illustrated in Fig. 5. Then the polyhedron found in the crystal can be generated from it by moving any one of the four As atoms through the Br- -Br edge of that polyhedron to become the apical polyhedron of the pentagonal bipyramid, leaving its ligand mate near the pentagonal plane between the two Br atoms.

If the pentagonal symmetry is not fully formed, as is seen in the crystal structure, then there will be a tendency for relaxation back to the monocapped trigonal prism intermediate polyhedron to proceed along the same route as that by which the pentagonal bipyramid was formed. This would then leave two broad peaks, corresponding to the As–CH_3 resonances for the CH_3 on the two sides of the plane of the intermediate. The deviations from the full symmetry of the pentagonal bipyramid are associated with the puckering of the plane of the bidentate ligand. However, if the full symmetry of the pentagonal bipyramid is formed at higher temperature, then relaxation back to the intermediate polyhedron may take place with equal probability for the apical As to arrive back in the monocapped trigonal pyramid sharing an edge with Br(1) or with Br(2). Then all eight As–CH_3 resonances would be equilibrated.

Attempts to produce other related monocarbonyl complexes have only yielded $(L\text{-}L)W(CO)X_2[P(OCH_3)_3]_2$ (X = Br, I). We have previously published the X-ray crystal structure of $(L\text{-}L)W(CO)Br_2[P(OCH_3)_3]_2$ (10) and have included extensive spectroscopic data in the present paper. Low-temperature NMR studies of the trimethylphosphite monocarbonyl complex suggest a static structure consistent with the X-ray crystal structure (best described as a monocapped trigonal prism with a Br in the capping position and two As atoms, a P, and a Br atom in the quadrilateral capped face; four ^1H As-CH_3 singlets; and two $^{31}P\text{-}\{^1H\}$doublets). As the temperature is increased the four As–CH_3 resonances coalesce into two and then into an averaged As–CH_3 resonance. Similarly, the two $^{31}P\text{-}\{^1H\}$doublets coalesce into a single resonance with ^{183}W satellites. The $\Delta G^{\neq}$ values (51.3 and 69.7 kJ/mol) are considerably higher than the previously discussed monocarbonyl containing the two bidentate L-L ligands, reflecting a greater steric hindrance exerted by the bulkier $P(OCH_3)_3$ monodentate ligands. The equilibration of four As–CH_3 resonances into two and two ^{31}P resonances into one can be rationalized by the dynamic behaviour illustrated in Fig. 6, producing a pentagonal bipyramidal intermediate with $As_1As_2Br_2P_1P_2$ in the equatorial plane. This would equilibrate the As–CH_3 groups above the pentagonal plane as one set and As–CH_3 groups below the pentagonal plane as the other set as well as equilibrating the two ^{31}P environments of the trimethylphosphite ligands. The equilibration of two As–CH_3 resonances into one at a coalescence temperature of 348 K occurs with a higher activation energy than that for the first process (69.7 vs. 51.3 kJ/mol), suggesting either a dissociative process or a high-energy random scrambling process. The possibility of phosphorus dissociation can be eliminated on the basis of the retention of $J(^{31}P\text{-}^{183}W)$ coupling in the high-temperature fast-exchange limiting spectra.

Finally, the low-temperature ^{13}C NMR data (carbonyl

© 1998 NRC Canada

region) are consistent with *cis* coupling on the basis of $^2J(^{13}C-^{31}P)$ values (Table 4), and the values of 34.8 and 36.0 Hz for the bromomonocarbonyl are consistent with the angles subtended at tungsten by the phosphorus and carbonyl carbon atoms (71° and 76°) (10), a correlation previously discussed for the dicarbonyl complexes.

To determine the influence of the bidentate ligand and to provide additional ^{31}P NMR parameters that were lacking in this study further work is continuing in the area of seven coordination incorporating the ligands $(C_6H_5)_2PCH_2P(C_6H_5)_2$, $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$, and *cis*-$(C_6H_5)_2PCH{=}CHP(C_6H_5)_2$. This work is aimed at the study of monocarbonyl complexes containing two identical bidentate ligands and two different bidentate ligands. In addition the potential use of ^{183}W NMR is being investigated.

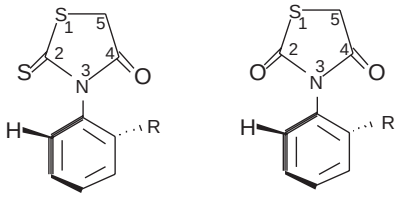
Chiral *N*-(*o*-aryl)-thiazolidinediones: synthesis from rhodanines and investigation on rotational enantiomers by NMR spectroscopy

Mehmet Karataş, Serap Koni, and İlknur Doğan

Abstract: Sterically hindered *N*-(*o*-aryl)-rhodanines (**a**) (*N*-(*o*-aryl)-2-thioxo-4-thiazolidinones) have been synthesized and the *N*-(*o*-tolyl) and *N*-(*o*-chlorophenyl) derivatives have been converted to their dioxo analogs (**b**) (*N*-(*o*-aryl)-2,4-thiazolidinediones). The chirality of the compounds in their conformational ground states was proved by detection of the diastereotopic protons or methyl groups at C-5 of the heteroring using ^{1}H and ^{13}C NMR spectroscopy. In the presence of the optically active auxiliary (*S*)-(+)-1-(9-anthryl)-2,2,2-trifluoroethanol the enantiomers of the racemic mixtures formed diastereomeric association complexes via H-bonding.

Key words: chirality, chiral auxiliary, rotational isomerism, *N*-(*o*-aryl)-rhodanines, *N*-(*o*-aryl)-2,4-thiazolidinediones, ^{1}H and ^{13}C NMR.



Résumé : On a synthétisé les *N*-(*o*-aryl)-rhodanines (**a**) stériquement empêchées (*N*-(*o*-aryl)-2-thioxo-4-thiazolidinones) et on a transformé les dérivés *N*-(*o*-tolyle) et *N*-(*o*-chlorophényle) en leurs analogues dioxo (**b**) (*N*-(*o*-aryl)-2,4-thiazolidine-2,4-diones). Faisant appel à la RMN du ^{1}H et du ^{13}C, on a déterminé la chiralité des composés dans leurs états conformationnels fondamentaux par détection des protons ou des groupes méthyles diastéréotopiques en C-5 de l'hétérocycle. En présence de l'auxiliaire optiquement actif (*S*)-(+)-1-(9-anthryl)-2,2,2-trifluoroéthanol, les énantiomères présents dans les mélanges racémiques forment des complexes d'association diastéréomères par le biais de liaisons hydrogènes.

Mots clés : chiralité, auxiliaire de chiralité, isomérie rotationnelle, *N*-(*o*-aryl)-rhodanines, *N*-(*o*-aryl)-thiazolidine-2,4-diones, RMN du ^{1}H et du ^{13}C.

[Traduit par la rédaction]

Introduction

Conformational isomerism in *N*-*o*-aryl substituted heterocyclic compounds has attracted considerable attention (1–5) because of their analogy to sterically hindered biphenyls. Experimental (6–12) as well as theoretical (13) studies have been reported concerning the enantiomeric and diastereomeric rotational isomers resulting from restricted internal rotation around the $C_{(aryl)}$—$N_{(heterocyclic)}$ bond. In a previous study, *N*-*o*-aryl substituted 2-thioxo-4-oxazolidinones and rhodanines were synthesized (14), their chirality was proven (14), and their enantiomers were preparatively enriched on cellulose triacetate (15). Barriers to racemization have also been determined experimentally (16–19). The present work is about the synthesis of *N*-*o*-aryl substituted 2,4-thiazolidinediones from rhodanines (Table 1) and (or) from the reaction of isocyanates with ethyl thioglycolate and the study of rotational isomerism in these molecules. Their enantiomers are detected by ^{1}H NMR in the presence of an optically active auxiliary compound.

Results and discussion

Racemic mixtures of *N*-(*o*-aryl)-rhodanines have been synthesized either from the reaction of isothiocyanates with ethyl thioglycolate or from α-halo carboxylic acid salts with

ammonium *o*-aryldithiocarbamate (obtained from carbon disulfide and *ortho*-substituted aniline in 25% ammonia solution (20)). The yields were found to be much higher for the former (61% vs. 5–15%). Conversion of the synthesized rhodanines (Table 1) to the corresponding thiazolidinediones was attempted by the reaction with bromine in acetic acid. *N*-*o*-tolyl- and *N*-*o*-chlorophenyl substituted rhodanines were successfully converted to the diones in 31–56% yield (Scheme 1). However, the reaction failed with sterically more hindered rhodanines such as *N*-(*o*-bromophenyl) and *N*-(α-naphthyl)-rhodanines. The thiazolidinediones were also synthesized independently, from the reaction of aryl isocyanates with ethyl thioglycolate.

The 200 MHz ^{1}H or ^{13}C NMR spectra of the synthesized compounds (Table 1) showed the presence of diastereotopic protons or methyl groups. Thus, in ^{1}H NMR, AB coupling patterns were observed for the protons on C-5 of the heteroring (Fig. 1). The two methyl groups bonded to C-5 were observed as separate singlets in the ^{1}H NMR spectrum and as different signals in the ^{13}C NMR spectrum.

The chemical shift differences of the AB protons ranged from 0.18 to 0.01 ppm, the differences being solvent dependent. The shift differences were found to be largest in hexadeuterobenzene. The coupling constants ranged from 17.5 to 18.3 Hz. The ^{1}H and ^{13}C NMR results are summarized in Tables 1 and 2, respectively. All proton-bearing phenyl and naphthyl carbons were found to resonate in the relatively narrow region between 121 and 134 ppm in the ^{13}C NMR spectra.

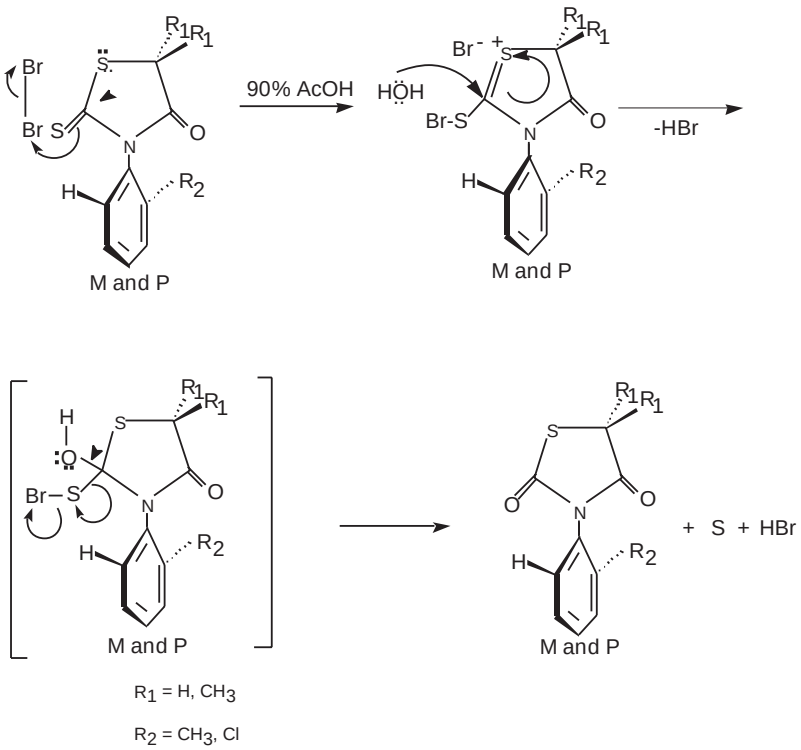
Scheme 1.



Although unambigious assignments could not be made for some of the carbons on a one-to-one basis, the values for most carbons were assigned based on chemical shift criteria (Table 2).

The presence of the AB quartets and observation of different signals for methyl groups at C-5 showed the presence of a large rotational barrier in the molecules, resulting in a slow conformational interconversion on the NMR time scale. Otherwise, the groups attached to this carbon would have been isochronous. Thus the thiazolidinediones studied here were found to be mixtures of two slowly interconverting enantiomers.This is consistent with the earlier observations (14, 21) that steric interactions within these molecules are caused by the presence of an *o*-aryl substituent and the oxo and (or) thioxo groups on the heteroring. As the *ortho* substituents become bulkier, the barrier to interconversion between the enantiomers should increase. Of the compounds studied, the largest AB splitting was observed for the C-5 protons of *N*-(*o*-bromophenyl)-rhodanine, which is expected to be the sterically most hindered one, namely, to have a lowest energy conformation with the largest dihedral angle. In fact, coalescence of the AB signals of even *N*-(*o*-chlorophenyl)-2,4-thiazolidinedione and *N*-(α-naphthyl)-2,4-thiazolidinedione was not observed by ^{1}H NMR at 90°C in pyridine. This shows that the activation energy for rotation for these molecules should be higher than 100 kJ/mol, which means that they could be resolved at room temperature. Especially if the *o*-bromoaryl derivatives, which are expected to have the largest barriers due to the size of the bromo substituent, were resolved, the chiral enantiomers could be used in further chemical reactions, without being racemized, at suitably chosen temperatures and reaction times determined mainly by the energy barrier. Conversion of the chiral rhodanine to the corresponding chiral thiazolidinedione might have been interesting for the correlation of configurations (12) of the two structurally related compounds. However, attempts to convert the racemic rhodanines to thiazolidinediones at room temperatures failed.

Since both enantiomers of the compounds were found to be separated by a racemization barrier high enough for the process to be slow on the NMR time scale, addition of a chiral auxiliary compound should split some of their signals via formation of diastereomeric association complexes. Pirkle's alcohol, *S*-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol (*S*-(+)-TFAE), was used for this purpose. The chiral auxiliary is expected to be associated with the compounds studied through H-bonding. π–π Interactions between the aryl or naphthyl groups and the anthryl group of the (*S*)-(+)-TFAE may also be important (14, 21) in forming the diastereomeric complexes. In fact, upfield shifts of 0.01–0.2 ppm for the 5-CH_2 protons accompanied by signal splittings of the AB quartets and 0.03–0.05 ppm upfield shifts for *ortho* CH_3 protons were observed. It turned out that, for these compounds, the 5-CH_2 group is a better probe in studying the hindered rotation than is the *ortho* CH_3 group. The latter split only in the case of compound **5,** by a chemical shift difference of 0.02 ppm. Two signals that had been observed for the diastereotopic methyl groups at C-5 did not split further in the presence of (*S*)-(+)-TFAE. Best results were obtained when 8 equiv. of the chiral auxiliary was used (see Table 1, compound **3**). Proton NMR results in the presence of the chiral auxiliary are given in Table 1.

IR spectra of the compounds were especially useful in following the conversion reactions. The only structural difference between the rhodanines and 2,4-thiazolidinediones is the replacement of the carbonyl group at position 2 by a thiocarbonyl. The C═S group of the rhodanines showed stretching

vibrations at 1250, 1210, and 1168 cm^{-1} that were found to disappear upon conversion to 2,4-thiazolidinediones.

Experimental

Proton NMR spectra were recorded on a Varian T-60A (60 MHz, $T = 24°C$), or on a Bruker AC-200 (200 MHz, $T = 23°C$) spectrometer. Carbon-13 NMR spectra were recorded on a Bruker AC-200 spectrometer (200 MHz, $T = 23°C$). The IR spectra were recorded on a Perkin Elmer 1600 FT-IR or Mattson 1000 FT-IR spectrometer using KBr discs. Melting points were determined using an Electrothermal 9100 melting point apparatus. Ultraviolet spectra were obtained in ethanol on a Unicam UV2-100 spectrophotometer. Elemental analyses were obtained on a Carlo Erba 1100 instrument.

Materials

Arylisocyanates were prepared from the corresponding commercially available acid chloride derivatives and sodium azide in toluene. α-Naphthyl chloride was synthesized from the corresponding commercially available α-naphthoic acid and thionyl chloride. *N*-(*o*-Tolyl)-isothiocyanate was prepared from *o*-toluidene and carbon disulfide with lead(II) nitrate, as described in the literature (20). *N*-(*o*-Bromophenyl)- and *N*-(α-naphthyl)-isothiocyanates (purity >98%) and (*S*)-(+)-1-(9-anthryl)-2,2,2-trifluoroethanol were purchased from Aldrich.

The synthesis of *N*-(*o*-aryl)-rhodanines

Two different methods of synthesis were undertaken for the preparation of *N*-(*o*-aryl)-rhodanines.

Method A (ref.14)
Arylisothiocyanate (0.025 mol) and ethyl thioglycolate (0.025 mol) were mixed in 25 mL of toluene, and metallic sodium (0.0025 mol) was added in small pieces. The reaction mixture was refluxed for 5 h. Toluene was distilled off and the remaining crude product was purified by recrystallizing twice from ethanol.

Method B (ref.14)
The reaction of ammonium *o*-aryldithiocarbamate (obtained from CS_2 and *ortho*-substituted aniline in 25% ammonia solution (20)) with the α-halo carboxylic acid salt was carried out in aqueous alkaline solution at room temperature. After 1 h stirring, the mixture was acidified with concentrated HCl (pH = 5–5.5) and warmed on a water bath for 2 h. The crude product was extracted from the reaction mixture by a suitable solvent (e.g., benzene or carbon tetrachloride). The white crystals that appeared after awhile were discarded by vacuum filtration and the solvent was distilled off. The remaining crude product was purified by recrystallizing from ethanol.

The synthesis of *N*-(*o*-aryl)-2,4-thiazolidinediones

Two different methods of synthesis were undertaken for the preparation of *N*-(*o*-aryl)-2,4-thiazolidinediones.

Method A′
o-Arylisocyanate (0.02 mol) and ethyl thioglycolate (0.02 mol) were mixed in 15 mL of toluene. Metallic sodium (0.05–0.1 g) was added in small pieces. After the addition of sodium the reaction mixture was heated at 80 °C for 10 h. Then

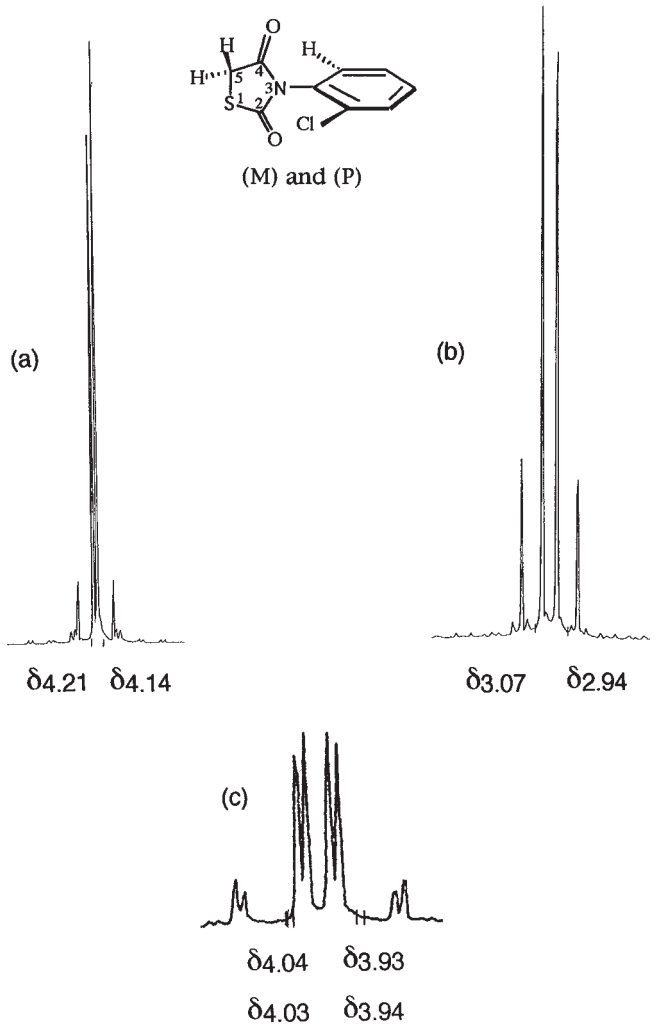
Fig. 1. The 200 MHz ^{1}H NMR signals of C-5 methylene protons of **2** at room temperature (*a*) in $CDCl_3$, (*b*) in C_6D_6, and (*c*) in $CDCl_3$ in the presence of 4 equiv. of (*S*)-(+)-TFAE.



the temperature was raised to 100–110 °C for 1 h. The toluene was distilled off, and the *N*-(*o*-aryl)-2,4-thiazolidinedione left in the flask was purified through recrystallization from ethanol.

Method B′

General procedure for the conversion of *N*-(*o*-aryl)-rhodanine to *N*-(*o*-aryl)-2,4-thiazolidinedione (22): 1 mmol *N*-(*o*-aryl)-rhodanine was dissolved in 90% acetic acid solution at reflux temperature (95°C). Bromine (2 mmol) was introduced dropwise into the flask with stirring. The reaction mixture was heated under reflux and monitored by thin-layer chromatography (TLC) on silica with a chloroform:toluene mixture (15:3) as eluent. When the reaction was completed, the reaction mixture was treated with charcoal and filtered. Acetic acid solution was distilled off by vacuum distillation. The residue was lixiviated with chloroform. After distillation of the chloroform, the remaining crude product was purified by recrystallization (three times) from ethanol.

N-*(*o-*Tolyl)-2,4-thiazolidinedione,* **1**

Synthesized according to the general procedure described in method A′ or method B′. Yields: 19% and 32%, respectively; mp 120–122°C; UV (ethanol), λ_{max}: 221 nm (ε 7.41×10^3 cm^{-1} M^{-1}), 263 nm (ε 5.62×10^2 cm^{-1} M^{-1}), 463 nm(ε 4.17×10^1 cm^{-1} M^{-1}), 530 nm (ε 4.17×10^1 cm^{-1} M^{-1}), 570 nm (ε 3.1×10^1 cm^{-1} M^{-1}); ^{1}H NMR ($CDCl_3$) δ: 2.18 (3H, s), 4.14 (2H, s), 7.10–7.47 (4H, m); ^{1}H NMR (C_6D_6) δ: 1.92 (3H, s), δ_A: 2.96, δ_B: 2.92 (2H, B). Anal. calcd. for $C_{10}H_9NO_2S$: C 57.97, H 4.34, N 6.76%; found: C 57.91, H 4.28, N 6.71%.

N-*(*o-*Chlorophenyl)-2,4-thiazolidinedione,* **2**

Synthesized according to the general procedure described in method A′ or method B′. Yields: 19% and 31%, respectively; mp 137–139°C; UV (ethanol), λ_{max}: 219 nm (ε 8.13×10^3 cm^{-1} M^{-1}), 265 nm (ε 6.17×10^2 cm^{-1} M^{-1}), 463 nm (ε 5.13×10^2 cm^{-1} M^{-1}), 530 nm (ε 5.13×10^2 cm^{-1} M^{-1}), 571 nm (ε 3.39×10^1 cm^{-1} M^{-1}); ^{1}H NMR ($CDCl_3$) δ_A: 4.21, δ_B: 4.14 (2H,B, J_{AB} = 17.5 Hz), δ: 7.59–7.24 (4H, m); ^{1}H NMR (C_6D_6) δ_A: 3.07, δ_B: 2.94 (2H, AB). Anal. calcd. for $C_9H_6NO_2SCl$: C 47.49, H 2.64, N 6.15%; found: C 47.40, H 2.59, N 5.96%.

N-*(*α-*Naphthyl)-2,4-thiazolidinedione,* **3**

Synthesized according to the general procedure described in method A′. Yield: 7%; mp 155–157°C; UV (ethanol), λ_{max}: 222 nm (ε 1.38×10^4 cm^{-1} M^{-1}), 269 nm (ε 1.29×10^3 cm^{-1} M^{-1}), 281 nm (ε 1.35×10^3 cm^{-1} M^{-1}), 463 nm (ε 4.90×10^1 cm^{-1} M^{-1}), 528 nm (ε 4.90×10^1 cm^{-1} M^{-1}), 571 nm (ε 3.63×10^1 cm^{-1} M^{-1}); ^{1}H NMR ($CDCl_3$) δ_A : 4.29, δ_B: 4.22 (2H, AB, J_{AB} = 17.6 Hz), δ: 7.25–8.01 (7H, m); ^{1}H NMR (C_6D_6) δ_A: 3.05, δ_B: 2.98 (2H, AB). Anal. calcd. for $C_{13}H_9NO_2S$: C 64.19, H 3.70, N 5.76%; found: C 63.11, H 3.63, N 5.69%.

N-*(*o-*Tolyl)-rhodanine,* **4**

Synthesized according to the general procedure described in method A or method B. Yields: 61% and 5%, respectively; mp 110°C; UV (ethanol), λ_{max}: 256 nm (ε 1.26×10^4 cm^{-1} M^{-1}), 295 nm (ε 1.41×10^4 cm^{-1} M^{-1}), 388 nm (ε 6.61×10^1 cm^{-1} M^{-1}); ^{1}H NMR ($CDCl_3$) δ: 2.20 (3H, s), 4.28 (2H, s), 7.47–6.87 (4H, m).

N-*(*o-*Tolyl)-thiohydantoin,* **5**

Obtained by the reaction of o-tolyl isothiocyanate and glycine in ethanol. The reaction was carried out in aqueous NaOH solution. After the mixture was heated for 2 h under reflux, excess alcohol was distilled off. Later, dilute HCl was added to the mixture and the mixture was evaporated to dryness. The residue was recrystallized from ethanol. Yield: 30%; mp 145°C; ^{1}H NMR ($CDCl_3$) δ: 2.2 (3H, s), δ_A: 4.28, δ_B: 4.25 (2H, AB, J_{AB} = 24.7 Hz), 7.68–7.13 (4H, m); ^{1}H NMR (C_6D_6) δ: 2.08 (3H, s), δ_A: 2.93, δ_B: 2.86 (2H, AB). Anal. calcd. for $C_{10}H_{10}N_2OS$: C 58.25, H 4.85, N 13.59%; found: C 58.21, H 4.80, N 13.51%.

N-*(*o-*Bromophenyl)-rhodanine,* **6**

Synthesized according to the general procedure described in method A. Yield: 60%; mp 144–145°C; UV (ethanol), λ_{max}: 202 nm (ε 1.55×10^4 cm^{-1} M^{-1}), 253 nm (ε 1.07×10^4 cm^{-1} M^{-1}), 294 nm (ε 1.10×10^4 cm^{-1} M^{-1}), 395 nm (ε 7.94×10^1 cm^{-1} M^{-1}); ^{1}H NMR ($CDCl_3$) δ_A: 4.28, δ_B: 4.21 (2H,,AB, J_{AB} = 18.29 Hz), δ: 7.77–7.22 (4H, m); ^{1}H NMR (C_6D_6) δ_A: 3.10, δ_B: 2.92 (2H, AB, J_{AB} = 18.29 Hz). Anal. calcd. for

Oxidation of olefins catalyzed by iron complexes of bleomycin model compounds bearing a hydrophobic or hydrophilic steric factor

Kazuo Shinozuka, Junya Kohda, and Hiroaki Sawai

Abstract: The bleomycin (BLM) model iron complexes bearing either a hydrophobic or hydrophilic steric factor around the sixth coordination sphere exhibited considerable substrate specificity and stereoselectivity in the oxidation of *cis*- and *trans*-olefins in a methanol solution in the presence of H_2O_2. The catalytic efficiency of the complexes was somehow correlated with the nature of the steric factor rather than with their oxygen-activating ability. In a benzene–phosphate buffer (micelle-forming condition), on the other hand, only the complex having micelle-forming ability exhibited the epoxidation of the substrates.

Key words: bleomycin model compound, steric factor, substrate specificity, asymmetric oxidation, oxidation in micelle.

Résumé : Lors de l'oxydation d'oléfines *cis* ou *trans* en solution dans le méthanol, en présence de H_2O_2, les complexes de fer, modèles de la bléomycine, qui portent un facteur stérique hydrophobe ou hydrophile autour de la sixième sphère de coordination présentent une spécificité et une stéréosélectivité importante par rapport au substrat. Il existe une légère corrélation entre l'efficacité catalytique des complexes et la nature du facteur stérique plutôt qu'avec leur habilité à activer l'oxygène. Par ailleurs, dans un tampon de benzène–phosphate (un condition de former une micelle), seul le complexe ayant la possibilité de former une micelle permet d'effectuer l'époxydation des substrats.

Mots clés : composé modèle de la bléomycine, facteur stérique, spécificité par rapport au substrat, oxydation asymétrique, oxydation dans une micelle.

[Traduit par la rédaction]

Introduction

The antitumor antibiotic bleomycin (BLM) is a member of a family of glycopeptides isolated as a Cu(II) complex from a culture of *Streptomyces veticillus* (1). In living tissue, BLM forms an Fe(II) complex and activates molecular oxygen, thereby inducing the oxidative cleavage of DNA (2). It has been shown that the active species responsible for the oxidative reaction is related to the transient BLM–Fe(III)–OOH complex (3). In addition to the DNA cleaving activity, the BLM–Fe complex exhibits catalytic oxidation of olefinic substrates such as stilbene, styrene, and β-methylstyrene in the presence of O_2, H_2O_2, PhIO, or $KHSO_2$ (4, 5*a*, *c*). In the reaction, the BLM–Fe complex was found to oxidize *cis*-olefinic substrates more efficiently than the corresponding *trans*-olefinic substrates (4*a–c*, *e*, 5*a*, *c*). An asymmetric oxidation was, however, observed only in the oxidation of *cis*-β-methylstyrene with the BLM–Fe–H_2O_2 system (5*c*).

Meanwhile, a number of studies have been reported on the synthesis and properties of model compounds, which simplified the metal coordination site of BLM. Thus, the oxidation of *cis*- and *trans*-β-methylstyrene and stilbene by Fe complexes of several BLM model compounds were reported by Ohno and co-workers (5*a*, *c*, *d*) and Mascharak and co-workers (5*e*, *f*). The reaction using these model complexes with H_2O_2 as the oxidant seems to proceed stereoselectively, in general. Some of these complexes also exhibited substrate selectivity between the *cis*- and *trans*-olefinic substrates in the reaction like the BLM–Fe complex (5*a*, *c*, *e*, *f*). However, very limited work has been done on the asymmetric oxidation of the olefinic substrates using the model complexes (5*c, d*). Furthermore, the effect of the steric factor of the BLM model compounds in place of the disaccharide moiety of the BLM on the efficiency and the stereoselectivity of the oxidation remains uncertain.

Previously, we have reported the synthesis of simple BLM model compounds bearing a hydrophobic or hydrophilic steric factor around the sixth coordination sphere in place of the disaccharide moiety of the BLM, namely, the model compound **I** bearing a long alkyl chain (lauryl group), the model compound **II** bearing a *tert*-butyl group, and the model compound **III** bearing a trishydroxymethyl group (Fig. 1) (6, 7). The steric factor in the models is introduced in a chiral-specific manner at the carboxy residue of L-histidine through an amide linkage instead of the position of the hydroxy residue of *erythro*-β-hydroxy-L-histidine through an ether linkage, as in the case of BLM or the models reported by Ohno and co-workers (1, 5*a–d*). The iron complexes of **I**, **II**, and **III** have exhibited significantly high oxygen activation ability (6, 7). The compound **I** has also shown micelle-forming ability (6).

II	$-C(CH_3)_3$
III	$-C(CH_2OH)_3$

To examine the effects of the steric factor around the sixth coordination sphere and the formation ofa micelle on the oxidation reaction, we carried out the oxidation of olefinic compounds using the iron complexes of **I**, **II** and **III** in a methanol solution and in a micelle-forming condition (benzene buffer).

Results and discussion

Oxidation of olefin in a solution

The oxidation reaction by the Fe(III) complex system of the compound **I**, **II**, or **III** with H_2O_2 in solution was carried out as follows. A solution of the model Fe(III) complex, H_2O_2 (50 equiv. to the complex), and substrate (50 equiv. to the complex) in degassed methanol was stirred under argon atmosphere at room temperature. After the addition of dichloromethane and brine, the mixture was partitioned and the organic layer was isolated. The solution was directly analyzed by gas chromatography. The products were identified by comparing their retention time with those of the authentic racemic samples. The absolute stereochemistry and enantiomeric excess (ee) of the epoxides were determined, based on the ^{1}H NMR measurement (8, 5*d*). The details of these are described in the experimental section.

In methanol solution, the Fe(III)–H_2O_2 systems of **I**, **II**, and **III** exhibited catalytic oxidation of the substrates, giving the corresponding epoxides as the major products as shown in Table 1. The results also clearly demonstrate that the reaction proceeds stereoselectively. Thus, *cis*-olefin afforded *cis*-epoxides and *trans*-olefin gave *trans*-epoxides with concomitant formation of benzaldehyde. Small amounts of *trans*-epoxides were formed with the *cis*-olefin oxidation while the oxidation of *trans*-olefin gave *trans*-epoxides exclusively. The results are in agreement with the previous reports using the BLM–Fe complex and the simplified model complexes of BLM (4, 5*a*, *d–f*).

The extent of the oxidation of *cis*-stilbene was much more pronounced than that of *trans*- stilbene, as observed in the case of BLM–Fe(III) mediated reaction (4*a–c*, *e*, 5*c*). The observed substrate discrimination ability could be derived from the fact that the stereochemical environment around the oxygen coordination site (catalytic site) of the current model complexes is highly crowded to achieve the stereochemical discrimination between the isomers, as was discussed previously in the oxidation by BLM–Fe(III) (5*a*, *c*). Another interesting feature in the current results is that the catalytic efficiency of the complexes was not proportional to their oxygen-activating ability (5*a*) but to the nature of the steric factor. Our previous estimation of oxygen-activating ability based on the EPR spin-trapping experiment for the model Fe complexes **I**, **II**, and **III** is 58, 52, and 74% of that of the BLM standard, respectively (Table 2) (6, 7). The model complex **III**–Fe(III) (7) having a hydrophilic steric factor, however, exhibited the lowest catalytic efficiency among the complexes. A high degree of asymmetric induction was also observed in the oxidation of *cis*-olefins. For example, 1,2-dihydronaphthalene was epoxidized to the corresponding (–)-*cis*-epoxide in about 36 and 49% of enantiomeric excess (ee) with **I–**Fe(III) and **II–**Fe(III), respectively. In general, **II**–Fe(III) exhibited slightly higher enantioselective efficiency to the substrates tested than **I–**Fe(III), as indicated in Table 1.

These results suggest that oxygen is bound tightly to the central iron at the sixth coordination site of the model complexes, and the stereochemical environment around the iron–oxygen center may influence the transition state of the oxidation reaction. Furthermore, the fact that the model complexes bearing hydrophobic steric factor (**I**–Fe and **II**–Fe) exhibited higher degree of catalytic efficiency as well as the asymmetric induction in epoxidation compared with the complex bearing a hydrophilic steric factor (**III–**Fe) suggest that a kind of direct interaction, such as hydrophobic interaction or CH–π interaction (9), between the phenyl group of the substrates and the steric factor of **I**–Fe and **II**–Fe may exist. Such interaction would help to arrange the spatial direction of the interaction between the substrate and the complex more stringently than the simple steric repulsion between the substrates and the steric factor.

Oxidation of olefin in a micelle-forming condition

As was reported previously, the model compound **I** and its metal complex have micelle-forming abilities (6). Thus, we first attempted to determine the critical micelle concentration (cmc) of **I** using a Cu(II) complex of I. Measurement of cmc was performed by the UV turbidity method (Fig. 2) (10). To a solution of **I**–Cu(II) complex (0.01–0.16 mM) in Tris-HCl buffer (100 mM, pH 7.2) was added chloroform. After the sonication of the mixture, the UV transmittance (T'/T) of the resulting mixture was measured (10), where T' is the transmittance of the mixture after the sonication, and T is the transmittance of the corresponding aqueous solution. The value of cmc determined by the method was 0.09 mM.

The oxidation reaction by the Fe(III)–H_2O_2 system of **I** or **II** in a micelle-forming condition was carried out in the same manner as the reaction in solution conditions, except that the solvent methanol was replaced with a benzene–phosphate buffer (1/10, v/v, pH 7.2). Under these conditions, the formation of the micelle was observed for the case of the **I–**Fe(III) complex at the concentration higher than ≈0.075 mM but not for the case of the **II**–Fe(III) complex. Table 3 shows the results of oxidation in the micelle-forming conditions with the model complexes **I**–Fe(III) and **II–**Fe(III). Contrary to the reaction carried out in methanol, only the **I**–Fe(III) complex exhibited the epoxidation of the substrates. The reactions of the **I**–Fe(III) complex with *cis*-β-methylstyrene and 1,2-dihydronaphthalene gave *cis*-β-methylstyrene oxide and 1,2-dihydronaphthalene oxide, respectively. The efficiency of the reaction was, however, found to depend on the concentration of the complex. Thus, the yield of the products was almost zero below 0.05 mM of the complex, and it increased with increasing concentration of the complex, reaching a plateau over the cmc (Fig. 3). The catalytic efficiency was, however, substantially suppressed compared with the solution condition. These

Model **III**	74

[a] Oxygen-activating ability was estimated by EPR spin-trapping experiment (5, 6).

results strongly suggest that the oxidation reaction proceeds inside the micelle and, therefore, the resulted epoxides stay inside the micelle.

Interestingly, the enantioselectivity of **I**–Fe(III) in the oxidation of dihydronaphthalene was also substantially decreased compared with that of the reaction in methanol. This may be due to the fact that in the micelle-forming condition, the arrangement of the spatial interaction between the substrate and the complex is rather disturbed compared to homogeneous-solution condition. It should be noted that, although **I**–Fe(III) failed to show high catalytic efficiency and enantioselectivity in the micelle-forming condition, this is the first example of olefin oxidation mediated by BLM model complexes under these conditions.

Concluding remarks

The results presented here demonstrated that iron complexes of simple compounds **I**, **II**, and **III**, mimicking the metal coordination of BLM, exhibit properties that resemble those characteristic of the parent BLM–Fe complex in the oxidation reaction of olefinic substrates in a methanol solution. The complexes showed considerable substrate discrimination ability and stereoselectivity in the reaction, which may reflect the fact that oxygen is bound tightly to the central iron at the sixth coordination site of the model complexes and that the stereochemical environment around the iron–oxygen center is very

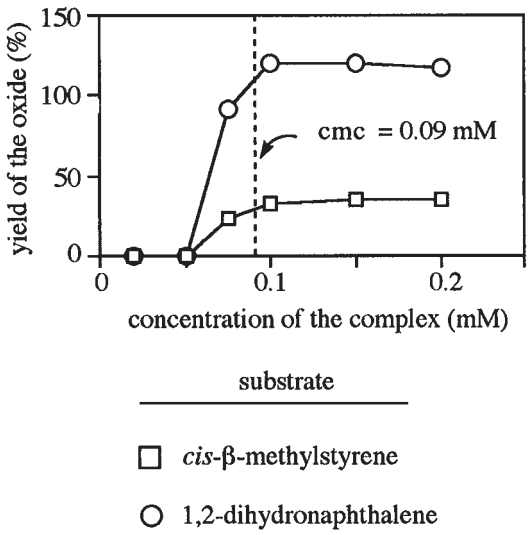
Fig. 3. Dependence of the oxidation on the concentration of **I**–Fe complex in a micelle-forming condition. Conditions: **I**–Fe complex, 0.02–0.2 mM; substrate, 50 equiv. to the complex; H_2O_2, 50 equiv. to the complex; solvent, phosphate buffer (2–20 mM, pH 7.2)/benzene, 10/1 (v/v). The reactions were carried out at room temperature for 1 h. The yields are based on Fe(III).



close to that of BLM–Fe. The higher catalytic efficiency and the asymmetric induction in epoxidation observed for the complexes **I** and **II**, both bearing the hydrophobic functional group as the steric factor, seem to suggest that these features are rather correlated with the hydrophobic nature of the steric factor than with their oxygen-activating ability. Thus, the interaction between the steric factor of the complexes and the substrates in addition to the stereochemical environment around the iron–oxygen center of the complex may play an important role in the reaction. Also, we could successfully demonstrate the first example of olefin oxidation mediated by BLM model complex **I** in a micelle-forming condition. Although the catalytic efficiency and the enantioselectivity exhibited by **I**–Fe(III) under these conditions were not very high, the results may provide useful information towards development of a new type of oxidizing agent that is capable of oxidizing substrates in the micelle.

Experimental

General

The synthesis and the physical properties of the model compounds **I**, **II**, and **III** were reported previously (6, 7).

Detection of the oxidation products was done by gas chromatography using a Shimadzu GC-14A equipped with a flame ionization detector (J & W Scientific Fused Silica capillary column, 30 m × 0.25 mm i.d., 0.25 μm film, He as a carrier gas). Identification of the reaction products was performed by injection of the standard materials to compare their retention time. Reagents and solvent were purified by standard procedures. *n*-Octadecane (99.5%) was purchased from Tokyo Kasei and used without further purification. Methanol used for the oxidation reaction was distilled and degassed immediately before use.

Oxidation of olefin using Fe complex of the model compounds I, II, and III and hydrogen peroxide in a methanol solution

The oxidation reaction and the analysis of the products were carried out by a similar procedure reported previously with slight modification (4*b*, 5*d*). The reaction was carried out under argon atmosphere at 25°C. A solution containing 0.48 μmol of an iron complex (formed by admixture of 0.53 μmol of a model ligand and 0.48 μmol of $Fe(ClO_4)_3 \cdot 6H_2O$ in 2.7 mL of MeOH) was combined with a solution containing 24 μmol of olefin in 0.48 mL of methanol. Hydrogen peroxide (1.2 M solution, 20 μL, 24 μmol) was added dropwise. After being stirred for 30 min, CH_2Cl_2 (10 mL) and satd. NaCl (10 mL) was added to the mixture. The mixture was partitioned and the CH_2Cl_2 layer was collected. The aqueous layer was further extracted with CH_2Cl_2. The organic layer was combined, and a small amount of insoluble material was removed by filtration. The volume of the organic layer was standardized to 25 mL by addition of extra CH_2Cl_2 and the internal standard (*n*-octadecane, 0.48 μmol), and the solution was directly analyzed by gas chromatography. Calibration curves were prepared and the products were quantified by area normalization of the peak for the internal standard.

The enantiomeric excess (ee) of the oxide was determined as follows. A solution containing 4.8 μmol of an iron complex (formed by admixture of 5.3 μmol of model ligand and

© 1998 NRC Canada

4.8 μmol of $Fe(ClO_4)_3 \cdot 6H_2O$ in 13 mL of MeOH) was combined with a solution containing 240 μmol of olefin in 2.4 mL of methanol. Hydrogen peroxide (1.2 M solution, 200 μL, 240 μmol) was added dropwise. After being stirred at room temperature for 30 min, the reaction mixture was extracted with CH_2Cl_2, as described above. The obtained organic layer was dried over Na_2SO_4 and concentrated at a temperature below 25°C. Olefin oxide was isolated by applying the residue on a silica-gel column chromatography (eluted with hexane followed by CH_2Cl_2:hexane of 1:10). The ee of the oxide was determined by ^1H NMR measurement using tris[3-(heptafluoropropylhydroxymethylene)-(+)-camphorato] europium(III) as a chiral shift agent (5*d*, 8).

Oxidation of olefin using Fe complex of the model compounds I and II and hydrogen peroxide in a micelle-forming condition

The reaction was carried out in the same manner as above except that the solvent methanol was replaced with a benzene–phosphate buffer (1/10, v/v, pH 7.2). A solution containing 0.48 μmol of iron complex (formed by admixture of 0.53 μmol of model ligand and 0.48 μmol of $Fe(ClO_4)_3 \cdot 6H_2O$ in 2.9 mL of phosphate buffer) was combined with a solution containing 24 μmol of olefin in 0.29 mL of benzene. Hydrogen peroxide (1.2 M solution, 20 μL, 24 μmol) was added dropwise under argon atmosphere. After the mixture was stirred at room temperature for 1 h, a solution obtained by the extractive workup was analyzed by gas chromatography as described above.

The ee of the oxide was determined as follows. A solution containing 4.8 μmol of an iron complex (formed by admixture of 5.3 μmol of model ligand and 4.8 μmol of $Fe(ClO_4)_3 \cdot 6H_2O$ in 13 mL of MeOH) was combined with a solution containing 240 μmol of olefin in 1.3 mL of benzene. Hydrogen peroxide (1.2 M solution, 200 μL, 240 μmol) was added dropwise. After being stirred at room temperature for 1 h, the reaction mixture was extracted with CH_2Cl_2. The obtained organic layer was dried over Na_2SO_4 and concentrated at a temperature below 25°C. Olefin oxide was isolated by silica-gel column chromatography (eluted with hexane followed by CH_2Cl_2:hexane of 1:10) and ee of the oxide was determined as above.

Concentration dependence of the oxidation in a micelle-forming condition using I–Fe complex

The reaction was carried out in the same manner as above except that the concentration of the complex varied from 0.02 to 0.2 mM. Also, the amount of hydrogen peroxide and the substrate used for the reaction was adjusted to 50 equiv. to the complex.

Measurement of the critical micelle concentration (cmc)

The critical concentration was measured according to the published procedure (10) using Cu(II) complex of **I** (6). In brief, to a solution of **I**–Cu(II) complex (0.01–0.16 mM in 100 mM Tris-HCl buffer, pH 7.2, 100 μL) placed in a UV cuvette (1 mm path length) was added chloroform (10 μL), and the mixture was sonicated for 180 s at 25°C. The UV transmittance of the resulted turbid mixture was measured at 220 and 270 nm, which corresponds to the absorption maxima of the complex. Relative transmittance (T'/T), where T' is the transmittance of the aqueous solution after sonication under the presence of chloroform and the T is transmittance of the aqueous solution, is plotted against concentration.

Surface plasmon resonance sensors using molecularly imprinted polymers for sorbent assay of theophylline, caffeine, and xanthine

Edward P.C. Lai, Ania Fafara, Victoria A. VanderNoot, Mari Kono, and Brandee Polsky

Abstract: A sensor system based on the optical phenomenon of surface plasmon resonance (SPR), which employs either photothermal deflection spectroscopy (PDS) or a photodiode array (PDA) for detection, was developed to use molecularly imprinted (MI) polymethacrylic acid – ethylene glycol dimethacrylates (PMAA–EDMA) as the sensing element. The MI polymers were first processed by Soxhlet extraction to remove the print molecules (theophylline, caffeine, and xanthine), yielding the specific *anti*-polymers. Each *anti*-polymer was layered over a silver film to serve as the analysis surface for the molecularly imprinted sorbent assay (MIA) of one target drug. This surface was exposed for 60 min to an aqueous standard drug solution, dried in air, and the uptake of the print molecule into the *anti*-polymer was monitored by shifts in the SPR angle θ_r (and hence the SPR–PDS signal measured at constant θ). The linear dynamic range of the MIA was found to extend up to 6 mg/mL, with a concentration detection limit estimated at 0.4 mg/mL for theophylline in aqueous solution. A cross-reactivity study of the *anti*-theophylline and *anti*-caffeine polymers, using eight other drugs structurally similar to theophylline and caffeine, showed none or very slight shifts in θ_r. This implies that the *anti*-polymers were selective only for their original print molecules and had no affinity for the other drug molecules. Similar molecular recognition characteristics were observed for the *anti*-xanthine polymer.

Key words: surface plasmon resonance, molecular imprinting, theophylline, caffeine, xanthine, sensor.

Résumé : Dans le but d'utiliser un mélange d'acide polyméthacrylique – diméthylacrylates d'éthylèneglycol (APMA–DMAE) moléculairement imprimés (MI) comme élément senseur, on a développé un système basé sur le phénomène optique de la résonance plasmonique de surface (RPS) et qui fait appel à une détection par spectroscopie de déflexion photothermique (SDP) ou un arrangement de photodiode (APD). Dans une première étape, les polymères MI ont été soumis à une extraction au Soxhlet pour enlever les molécules imprimer (théophylline, caféine et xanthine) afin d'obtenir des anti-polymères spécifiques. On a placé une couche de chacun des anti-polymères sur un film d'argent pour servir de surface d'analyse pour dosage d'un adsorbant moléculairement imprimé (AMI) d'un médicament choisi. On a exposé cette surface à une solution aqueuse de médicament de référence pendant 60 min, on l'a séchée à l'air et on a déterminé l'adsorption de la molécule imprimée dans l'anti-polymère grâce aux déplacements de l'angle θ_r dans la RPS (et, par conséquent, par le biais du signal de RPS–SDP à valeur constante de θ). On a trouvé que la plage dynamique linéaire d'AMI va jusqu'à 6 mg/mL, on évalue que la concentration limite de détection de la théophylline en solution aqueuse est de 0,4 mg/mL. Une étude de réactivité croisée des polymères des *anti*-théophylline et *anti*-caféine, faisant appel à huit autres médicaments structuralement apparentés à la théophylline et à la caféine, a permis de montrer que les déplacements dans la valeur de θ_r sont nuls ou très faibles. Ce résultat implique que les *anti*-polymères ne sont sélectifs que pour les molécules imprimées originales et qu'ils n'ont aucune affinité pour les autres molécules de médicaments. Des caractéristiques de reconnaissance semblables ont aussi été observées avec le polymère de l'*anti*-xanthine.

Mots clés : résonance plasmonique de surface, impression moléculaire, théophylline, caféine, xanthine, senseur.

Introduction

Sensor devices for the detection of different analytes have great significance in medicine, pharmaceutics, and environmental toxicology. One of the driving forces in chemical-sensing research is for ways to incorporate the inherent specificity of binding and recognition methods to the high sensitivity of instrumental techniques (1). Due to its specificity and high sensitivity, immunoassay is often the method of choice for trace analyses of clinically important compounds contained in complex biological matrices. A wide range of radioisotopic, enzymatic, fluorescent, chemiluminescent, IR-active and redox labels or markers have played an important role in the development of immunoassay in the last two decades. Although these labels certainly have their own specific advantages, they also have characteristics that limit their usefulness

in assaying biochemical molecules from both commercial and practical viewpoints (2). Since the success of an immunoassay depends critically on the specific antibody, the making of proprietary antibodies and field analytical test kits based on immunology technology has been monopolized by a handful of manufacturers (e.g., RISc® test kits of EnSys, EnviroGard[7] test kits of Millipore, etc.) Test tubes provided with the kit (package) come precoated with antibodies. However, shelf life is at the maximum extended to three months when stored at room temperature without refrigeration. There is a continuing effort to develop synthetic immunoanalytical reagents that are more stable, particularly utilizing the technique of molecular imprinting.

Two decades ago, Wulff et al. (3) first reported a novel template polymerization called molecular imprinting (MI) by which polymers could be prepared with high selectivity for the template compounds (or print molecules). The MI involves the preparation of a polymer cast by reacting functional monomers in the presence of a print molecule. When the print molecule is removed by extraction, sites are left behind in the polymer that complement the template in shape and positioning of chemical functionality. A stationary phase prepared by template polymerization was applied to the enantio-separation of amino acid derivatives by Mosbach and co-workers (4). Continuous rods of MI polymers were prepared by Matsui et al. (5) for separating positional isomers of diaminonaphthalene and resolving enantiomers of phenylalanine anilide. In 1993, Mosbach and co-workers (6) used the MI technique to create selective recognition sites in polymers that functioned as well as antibodies in ligand-binding assays for two drugs, theophylline and diazepam. This important contribution demonstrated that a completely synthetic approach to the creation of functional binding sites could produce selectivities and binding constants typically in the range from 10^4 to 10^7 M^{-1}, which are comparable to those found in biological systems. Although the molecularly imprinted sorbent assay (MIA) method involved an extra step (extraction) compared with antibody-based methods, the synthetic approach offered several advantages. First, MI is an alternative to the use of laboratory animals to produce receptors, in the form of *anti*-polymers. Second, *anti*-polymers are easier to prepare and cheaper to manufacture than natural antibodies. Third, these polymers are stable enough to be stored in the dry state at ambient temperature for years without loss of recognition capability. Last, it has been confirmed that they are stable in acid, base, organic solvents, high temperatures (e.g., autoclave) and pressure conditions that antibodies could not withstand (7). To date, MI polymers for over 20 classes of compounds have been made (8). Stable MI polymers specific for several nucleotides, amino acids, and herbicides were synthesized for possible use in sensor devices (9). However, they have not extensively been applied on a detector surface to create optical sensors, except the fibre-optic sensing device recently reported for the determination of derivatized amino acids (9), fiber-optic fluorescence of dansyl-L-phenylalanine (10), as well as optical fluorescence of sialic acid (11).

Surface plasmon resonance (SPR) is an optical phenomenon that has been used as a standard approach for the detection of small quantities of organics at a conductive interface. In the Kretschman geometry, incident light is coupled via total internal reflection in a glass prism to the charge density waves (or plasmons) present on the surface of a thin metal film under appropriate conditions of resonance (a simultaneous match of both frequency and wave vector) (12). The SPR has a variety of applications: surface plasmon microscopy (SPM) for high-contrast imaging of thin dielectric films (13), surface-enhanced Raman scattering (SERS), and coherent anti-Stokes Raman scattering (CARS) (14), SPR enhanced laser desorption (15), immunoassay (16), and fibre-optic chemical sensing (17). The SPR chemical sensing depends on the sensitivity of resonance condition to changes in dielectric permittivity very close to the sensor surface. Any changes to the dielectric function of the sample medium in contact with the silver film, during for instance the binding between an immobilized antibody and the antigen, will shift the resonant angle of incidence. Changes in the resonance condition have traditionally been probed by measuring a loss in reflectance (18). Alternatively, Inagaki et al. (19) employed photoacoustic spectrometry to probe the radiationless processes associated with SPR. Our laboratory took advantage of photothermal deflection spectrometry (PDS) to successfully detect SPR (20). The SPR–PDS technique could determine submonolayer quantities (2×10^{-7} g) of anti-human immunoglobulin G (a-IgG). Using a monolayer of a-IgG to act as the sensing surface, a detection limit of 100 parts per billion has been achieved for immunoglobulin G (IgG). These sensor results were linear over concentration ranges encountered in standard immunoassays and therapeutic monitoring. Recently, a SPR biosensor with cavity-enhanced photothermal spectroscopy detection was developed (21), and a sensitivity analysis showed that high signal-to-noise ratios are possible (22). The present work reports the development of both the SPR–PDS sensor system and another SPR system based on a photodiode array (PDA) detector to make use of MI polymers as the sensing surface material. Specifically, three *anti*-polymers that can recognize theophylline, caffeine, and xanthine drug molecules are examined. The *anti*-caffeine and *anti*-xanthine polymers are newly synthesized in our laboratory and reported here for the first time.

Experimental

Molecular imprinting

The MI polymers containing theophylline, caffeine, and xanthine were prepared according to the procedure outlined previously (6). To 25 mL of chloroform contained in a 100 mL flask was added 0.47 g of theophylline, 0.9 g of methacrylic acid (MAA), 9.4 g of ethylene glycol dimethacrylate (EDMA), and 0.12 g of 2,2′-azobis(2-methylproprionitrile) initiator (AIBN). The mixture was degassed in a sonicating bath under vacuum and flushed with nitrogen for 5 min. Polymerization began within 1 h at 60°C inside a thermostatted water jacket and was continued for 24 h. The resultant polymer was ground with a mortar and pestle to produce a fine powder.

Extraction of print molecule

To produce *anti*-theophylline polymer, the print molecule (theophylline) was removed from the polymer powder (0.5 g) by Soxhlet extraction using 150 mL of methanol – acetic acid (9:1 v/v) over 24 h (7). Alternatively, dynamic supercritical fluid extraction (SFE) was carried out on a Suprex SFE/50 supercritical fluid extractor (Pittsburgh, Pa.), using CO_2 at 400

© 1998 NRC Canada

atm (1 atm = 101.3 kPa) and 40°C (density = 0.96–0.99 g mL^{-1}) with a flow rate of 0.5 mL min^{-1} over 60 min. The theophylline extracted from the polymer was collected by passing the supercritical fluid effluent through three glass collection vials, each containing 4 mL of methanol. The SFE was repeated using first CO_2 with 5% (or 9 mL/180 mL) methanol as a modifier under the same conditions as above and next N_2O at 300 atm and 50°C with a flow rate of 0.5 mL min^{-1} over 60 min. In each case, the percent recovery was determined by UV spectrophotometry at 210 and 270 nm, GC-FID (Varian 3400, DB-5 30 m × 0.25 mm column at 150°C, hydrogen gas flow rate = 30 cm/s, retention time = 7.2 min), and HPLC (Varian 9010 solvent delivery system, 100% methanol, Zorbax ODS reverse phase 25 cm × 4.6 mm column, 9050 variable wavelength UV-visible detector set at 270 nm, retention time = 2.5 min).

Anti-polymer overlayer

Silver films for SPR were prepared by Interoptics Ltd. (Ottawa, Ont.) on 1 in. × 1 in. (1 in. = 24.4 mm) glass slides by depositing 57 ± 1 nm of silver at a rate of 1 nm/s on top of a 150 nm in thickness aluminum oxide layer. The aluminum oxide was laid down first to improve adhesion to silver. The silver films on glass slides were wrapped in a special oven-dried paper to prevent contamination of the film surfaces; they were stored under vacuum till needed.

Thin overlayers of *anti*-polymers were coated onto silver films by evaporation, over 60 min, from 100 μL of a 0.1–1.0 mg/mL solution in acetonitrile – acetic acid (99:1 v/v) spotted with a micropipet on approximately 6 cm^2 of silver film surface. The solid *anti*-polymer overlayers were rinsed with water to remove any residual acetic acid and dried in air for 24 h.

MIA

The SPR angular profiles were first recorded for the dry *anti*-polymer overlayers. The overlayers were then exposed to 60 μL of either water or 1–6 mg/mL standard aqueous solutions of theophylline, caffeine, or xanthine, which spread over an area of 1 cm^2. After incubation for 60 min, the *anti*-polymer overlayers were rinsed with water and allowed to dry in air overnight. New SPR angular profiles were measured on the next day either by PDS or with a PDA. Special efforts were made to fix the silver films in exactly the same position on the prism for all SPR analyses.

Cross-reactivity

A set of eight different drugs with similar structures to theophylline and caffeine were obtained from Health Canada (Ottawa, Ont.) for cross-reactivity tests. They included acetaminophen, dyphylline, hydrochlorothiazide, β-hydroxyethyl theophylline, nicotinic acid, phenyl butazone, and theobromine. These drugs were dissolved in water to make up 6 mg/mL solutions, except for hydrochlorothiazide, phenyl butazone, and theobromine, which were hard to dissolve beyond 1–2 mg/mL. After exposure of *anti*-theophylline, *anti*-caffeine, or *anti*-xanthine polymer overlayers to the drug solutions separately, their angular SPR profiles were obtained to determine if any drug had bound to the *anti*-polymers.

The SPR–PDS and SPR–PDA sensor systems

The SPR–PDS sensor system shown in Fig. 1 has been described previously (20). An argon-ion-pumped dye laser provided the excitation beam (λ = 590 nm, irradiated power = 100 mW), which was chopped at 200 Hz and focused through a glass prism (base angle = 45°, refractive index = 1.517 ± 0.001 at 590 nm) on the microscope slide – silver film interface at an angle of incidence θ (analysis area = 0.01–0.04 mm^2). The pump beam was polarized in the plane of incidence, and dibutyl phthalate was used for the optical coupling between the glass prism and the microscope slide. When resonance condition (θ_r) was attained, energy was transferred from the laser beam to excite the surface plasmons on the silver film surface. As the plasmons relaxed nonradiatively, heat was released from the silver film to the surroundings, producing a refractive index gradient in the air medium outside the silver film. A collimated probe beam from a He–Ne laser (output power = 1 mW) passing through this gradient would be deflected. As a result of deflection, the beam intensity at a particular area in space was changed, and a photodiode with a pin hole was used as a detector to generate a PDS signal. The signal amplitude was recorded by a lock-in amplifier, at regular θ intervals over the range of 42–50° to generate an SPR angular profile for θ_r determination.

In the SPR–PDA sensor system, a diode laser (Applied Laser Systems, Grants Pass, Oreg.) with an output power of 10 mW at 670 nm was used as the light source for SPR because of its small dimensions and plane-polarized output (Fig. 2). After the intensity of the laser beam was reduced by a set of neutral density filters of 4.4 OD (optical density), it was focused by a plano-convex lens through the glass prism onto the silver film at the analysis area. The diverging reflected beam was passed through a cylindrical lens and a slit to produce a line image on a PDA (Princeton Instruments, Trenton, N.J.). Each ray of the focused beam had a different angle of incidence θ and would be reflected orderly to fall onto a different photodiode of the array. The PDA was useful for monitoring the angular intensity profile of the line image. Its output signals from 1024 diodes were acquired by a Princeton Instruments model ST120 controller and processed by an ST1000 MSMA computer program for display on the monitor screen. The diode numbers along the *x*-scale corresponded to a range of angles of incidence, which could be calibrated in degree units by placing the arm of a goniometer over the prism at a specified angle and dropping a thin wire from the arm perpendicularly into the incident beam. This thin wire produced a dark line image on the PDA, and hence a sharp dip would be displayed in the angular profile on the screen display. Five different angles of incidence were chosen for the calibration, to cover the entire angular intensity profile of the focused beam. After calibration, any change in SPR angle resulting from a MIA experiment would be observed as a shift to a larger θ value.

Results and discussion

Preparation of *anti*-polymers by MI

Theophylline, caffeine, or xanthine was reacted with MAA and EDMA in the presence of AIBN initiator. Complementary interactions were developed and noncovalent linkages were formed between the print molecule and MAA monomers.

© 1998 NRC Canada

Fig. 1. Schematic diagram of the SPR–PDS sensor system.

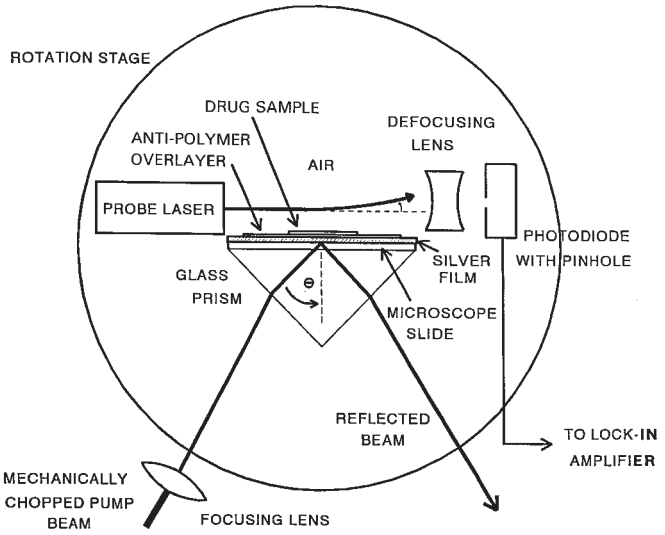

Fig. 2. Schematic diagram of the SPR–PDA sensor system based on a laser diode.

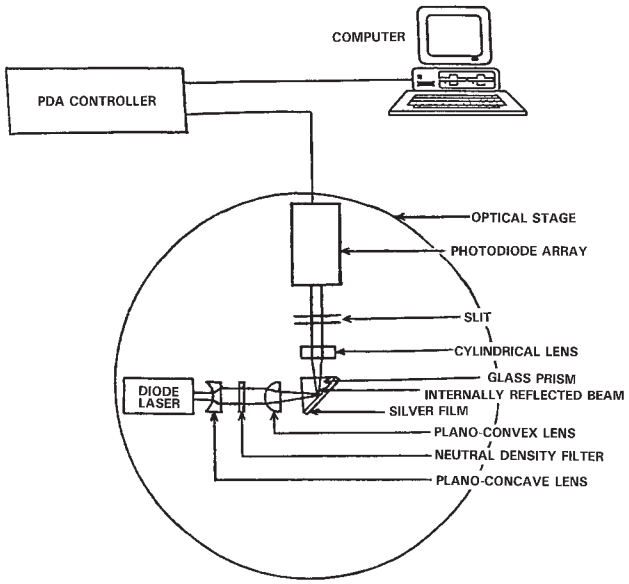

Thermal initiation of the polymerization in the presence of EDMA created a three-dimensional network, cross-linking the MAA monomers to form the MI polymer. After the polymer was isolated and ground, the print molecule could be extracted from the MAA–EDMA matrix as detailed below. This produced an *anti*-polymer with cavities containing sorbent sites that complement the original print molecule in shape and chemical functionality. These sites had an affinity for the print molecule, and molecular recognition would occur when the *anti*-polymer was later exposed to a sample solution containing the print molecule in MIA.

Extraction of print molecule

Soxhlet extraction with methanol – acetic acid (9:1 v/v) over 24 h resulted in near quantitative removal of all three print molecules from their respective MI polymers (see Table 1). Unlike organic networks where open structures from which guest molecules can be removed completely cannot yet be made (23), the cross-linked matrix in MI polymers apparently could engage in dynamic motions that opened up channels for the ready escape of desorbed print molecules.

Although Soxhlet extraction was able to remove nearly all (88–104%) of the theophylline present in the MI polymer powder (at 4.3 wt.%), the process was lengthy and consumed much of the solvent. The SFE was next attempted as a potentially fast, efficient extraction technique. Successful application of SFE to polymers has been reported before. For example, Hirata and Okamato (24) used CO_2 to obtain complete extraction of additives in polyethylene films in under 2 h, compared with 24 h for a Soxhlet extraction. Our use of supercritical CO_2 fluid, however, could recover only 5% of the theophylline from the MI polymer in 1 h. Since theophylline is a polar molecule, the extraction rate might be limited by solubility in the nonpolar supercritical CO_2 fluid. Addition of 5 mol% methanol, which increased the polarity and hence solvent power of CO_2, improved the extraction efficiency to 10%. Further attempt using polar N_2O SFE at 50°C yielded only a modest 9% recovery. The amount of theophylline that could be extracted from PMAA–EDMA by SFE was considerably less than that achieved by Soxhlet extraction. It seems that most of the print molecules were locked into the polymer matrix and not accessible to SFE. For SFE to be successful, the solute must, firstly, be sufficiently soluble in the supercritical fluid and, secondly, be transported sufficiently rapid (by diffusion or otherwise) from the core of the polymeric particles to the surface. Apparently, the rate-determining step was molecular diffusion in the polymer particles when these two SFE experiments were carried out at a temperature of 40–50°C, which was lower than the operating temperature of the Soxhlet extraction. The solvents used for Soxhlet extraction of polymers are normally good swelling agents for the polymer. Since the present MI polymer has an extensive cross-linked matrix structure, its glass transition temperature is ill defined and was experimentally undeterminable by differential scanning calorimetry up to its degradation at 189°C (according to thermogravimetric measurement in our laboratory). It is therefore hard to say whether the SFEs were performed at sufficiently high temperatures so that the polymer was swollen to release the print molecules.

The low proportion of print molecules extractable by SFE is worth some investigation. A hot-ball model has previously been proposed by Bartle et al. (25) for the study of continuous SFE of powdered matrices. Their model assumes that the matrix particles are spheres, that the initial distribution of the solute within the spheres is uniform, and that the flow rate is high enough for the concentration of the solute in the supercritical fluid to be considered effectively zero. Theoretically, 37% of the solute is extracted during an initial period of $0.25t_c$, where t_c is a characteristic time for the extraction defined by $t_c = 4r^2/\pi^2 D$ with D being the diffusion coefficient. The time required to extract 99% of the solute is $4.4t_c$, i.e., 17 times the time needed to extract the first 37%. Thus, it can be calculated how many hours would be required to extract 99% of the solute if the value for D is known. Bartle et al. (25) estimated that, for example, the extraction of 2,6-di-*tert*-butyl-4-methylphenol (BHT) from polypropylene pellets (3 mm in diameter) would take 80 h to obtain a 99% recovery. Temperature is a

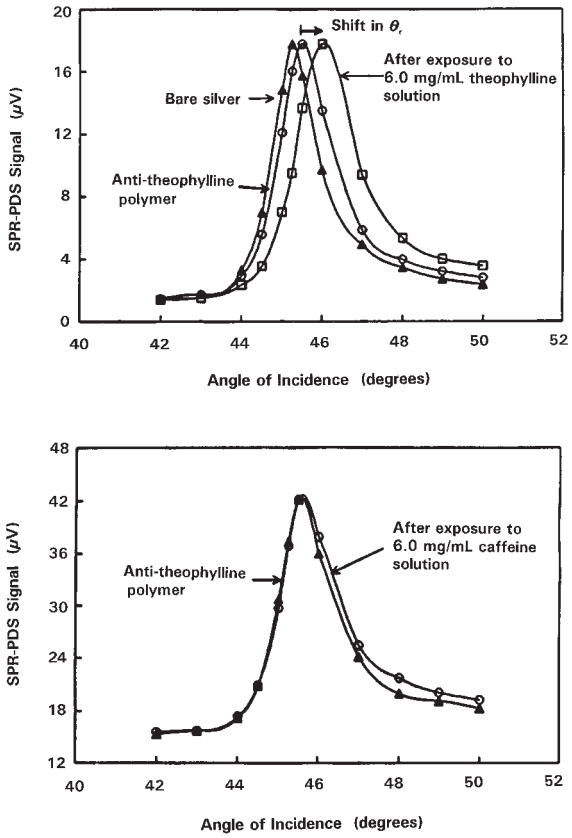
very effective parameter for enhancing diffusion and shortening the time required for mass transfer from the core of the polymer particles to the surface. Elevated temperatures will also improve the extraction efficiency by increasing the solubility of the solute in the supercritical fluid. Consequently, significant improvements in SFE of print molecules from MI polymers would only be possible by using higher temperatures, longer extraction times, and supercritical fluids that are both good swelling agents for the polymer and good solvents for the analytes (26).

Anti-polymer overlayer

For a bare silver film 56 nm in thickness, the SPR angular profile was recorded to determine a resonance angle of θ_r = 45.3 ± 0.1° in the prism (see Fig. 3). When an overlayer of the *anti*-polymer was coated on the silver film, θ_r adopted a new value ranging from 45.5 ± 0.2° to 48.6 ± 0.1°. The amount of θ_r shift depends on the thickness of the *anti*-polymer overlayer. From the angular SPR data, the thickness of the *anti*-polymer layer is estimated at 5–10 nm. Note that the depth of penetration for the SPR evanescent field (i.e., the distance at which the light intensity falls to l/e of its initial value) from glass of refractive index n_1 into the medium of lesser refractive index n_2 is given by $dp = \lambda/2\pi(n_1^2\sin^2\theta_1 - n_2^2)^{1/2}$. Typical penetration depths are 100–200 nm (27). Consequently, a thicker *anti*-polymer layer can accommodate more analytes, resulting in a larger SPR response. An optimum thickness, which balances the two effects, exists. It was found that the MIA sensitivity for an *anti*-theophylline polymer overlayer prepared from a 0.04 mg/mL solution was 0.065 normalized unit, which is greater than the sensitivity of 0.055 normalized unit for another overlayer prepared from a 0.10 mg/mL solution. Apparently, the thinner *anti*-polymer overlayer (prepared from the 0.04 mg/mL solution) allowed faster diffusion of theophylline molecules from the external sample solution to the silver–polymer interface where dielectric constant changes were sensed by SPR. Thinner overlayers also generate sharper SPR angular profiles for more sensitive PDS measurements at constant θ. One limitation existed in the preparation of *anti*-polymer overlayers by spotting: the dried overlayer might not be very uniform across the silver film surface. This affected both the position and magnitude of the SPR dip, and reproducibility of results might suffer greatly. The technique of spin coating was attempted, but the problem was not totally resolved. Spraying techniques are being investigated for their usefulness in the preparation of uniform, ultrathin *anti*-polymer overlayers.

Fig. 3. The SPR–PDS angular profiles of bare silver film, silver film with an overlayer of *anti*-theophylline polymer, *anti*-theophylline polymer overlayer after exposure to 6.0 mg/mL of theophylline in water, and *anti*-theophylline polymer overlayer after exposure to 6.0 mg/mL of caffeine in water.

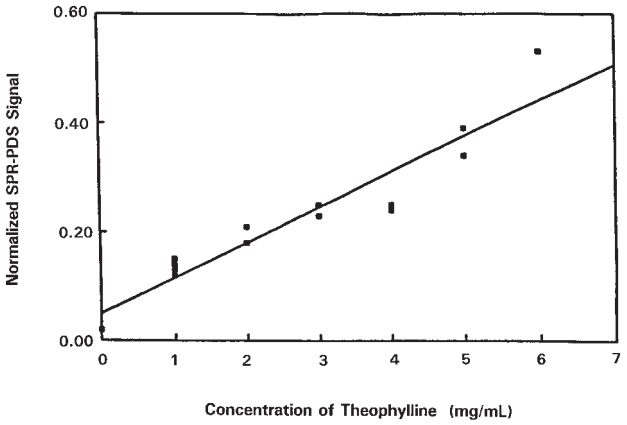


MIA

The capability of the *anti*-theophylline polymer to bind the target molecule selectively was evaluated. Using a bare silver film on the SPR sensor, the PDS signals yielded an angular profile with the peak maximum (or θ_r) at 45.3° as shown in Fig. 3. A thin overlayer of *anti*-theophylline polymer coated onto the silver film from a 0.04 mg/mL polymer solution gave a small θ_r shift of 0.2°. After a 1 h exposure of the *anti*-polymer overlayer to a blank solution containing no theophylline, no

© 1998 NRC Canada

Fig. 4. Standard calibration graph for MIA of theophylline by SPR–PDS.



further shift in θ_r was observed. This *anti*-theophylline polymer overlayer was next used as the analysis surface for the MIA of theophylline in water. After the overlayer was exposed to a sample solution of 6.0 mg/mL theophylline for 1 h, the angular SPR profile (or θ_r) shifted further. Clearly, the uptake of theophylline molecules into the sorbent sites of the *anti*-polymer caused sufficient change in the dielectric constant of the overlayer to be monitored via a measurable shift in θ_r. A standard calibration curve was obtained by measuring the SPR–PDS signal amplitudes at a constant $\theta = 46.5°$ for several theophylline concentrations in the range from 0.0 to 6.0 mg/mL. As expected, the higher the concentration of theophylline, the greater the θ_r shift toward larger θ values and hence the stronger the PDS signal amplitude at constant 46.5°. Since the SPR–PDS signal was recorded on a different spot in replicate measurements, and the *anti*-polymer overlayer might not be uniform in thickness, the raw SPR–PDS calibration data were not highly reproducible or perfectly linear. For this reason, the SPR–PDS signals were normalized by calculating the relative deviation of the after-exposure signal from the pre-exposure signal measured at 46.5°. As shown in Fig. 4, the linearity (with a correlation coefficient of 0.97) of standard calibration demonstrates that the SPR–PDS sensor system can be used with MI polymers to determine their complementary print molecules fairly accurately. The signal changes are small enough to assume that the slope of the PDS response is linear. For theophylline in aqueous solution, the concentration detection limit is estimated at 0.4 mg/mL. This analytical sensitivity is modest mainly because the specific recognition of print molecules by their *anti*-polymers is generally most favoured in the same or similar solvent to that originally used for the polymer synthesis (28). Here, theophylline binding to the *anti*-polymer is the most efficient in chloroform. This specific binding can be compromised in aqueous medium where water effectively competes for the hydrogen bonding interactions (29). Similar findings have been evidenced in our recent investigation using the *anti*-polymer as a solid stationary phase in a HPLC column for the separation of theophylline from caffeine and xanthine in chloroform or water as the mobile phase.[2] Extraction of theophyline in blood serum with chloroform can potentially eliminate proteins, increase the analyte concentration,

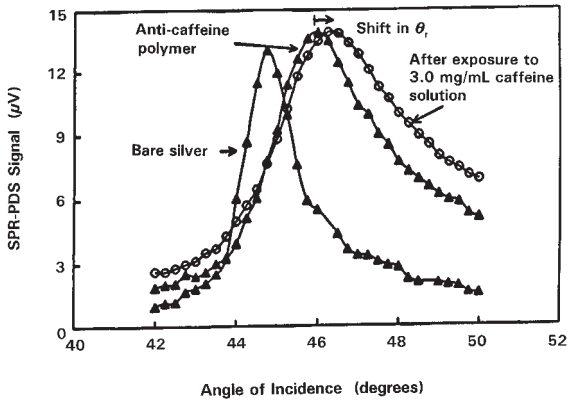
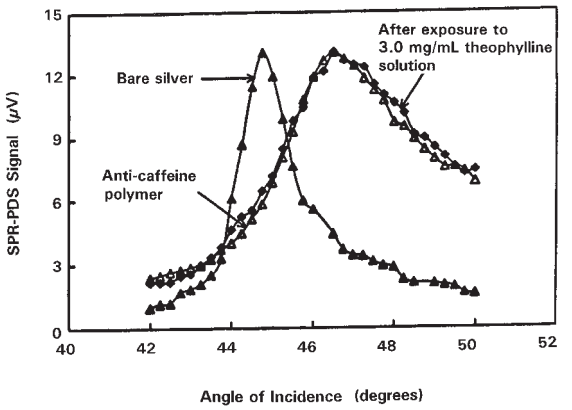
Fig. 5. The SPR–PDS angular profiles of bare silver film, silver film with an overlayer of *anti*-caffeine polymer, silver film with an overlayer of *anti*-caffeine polymer after exposure to 3.0 mg/mL of caffeine in water, and after exposure of *anti*-caffeine polymer overlayer to 3.0 mg/mL of theophylline in water.





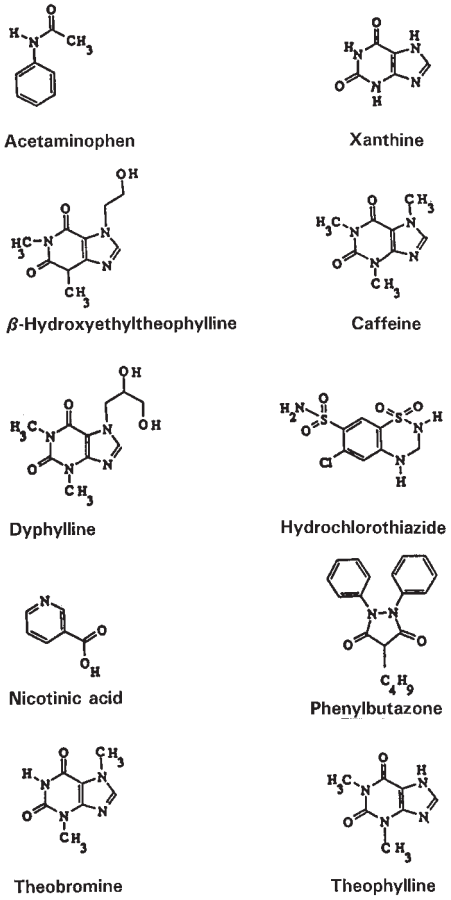
and afford a higher partition coefficient value for better MIA–SPR–PDS sensitivity than measurements in water.

It was proven to be true that print molecules having different shapes can produce cavities of different micro-architectures and functionalities. When our new *anti*-caffeine polymer was exposed to a sample solution of 3.0 mg/mL caffeine, there was a change in θ_r of 0.5° as can be seen in Fig. 5. The same *anti*-caffeine polymer exposed to 3.0 mg/mL theophylline exhibited no change in θ_r and hence showed no significant affinity for this different print molecule at the concentration specified. Thus, it can be concluded that the cavities formed in the caffeine-imprinted PMAA–EDMA during template polymerization possessed a shape and arrangement of functional groups, which corresponded to that of the caffeine molecule mainly. In another study, the print molecule was xanthine, which is the skeleton of theophylline and caffeine. The molecular recognition capability of the *anti*-xanthine polymer was tested by a cross-reaction with theophylline, which has two methyl groups added to the xanthine structure. After exposure of an *anti*-xanthine overlayer to a theophylline sample solution, there was no observable shift in θ_r. It can be concluded again that the *anti*-xanthine polymer had an affinity for its print molecule without the ability to take up theophylline in an amount sufficient to generate a SPR–PDS signal. To the best of our knowledge, this is the first report of *anti*-caffeine

© 1998 NRC Canada

and *anti*-xanthine polymers. Our work has extended and generalized the previous observations by Vlatakis et al. (6) that polymeric matrices formed by the MI technique could recognize their original print molecules. It demonstrates the great potential of MI polymer synthesis as an alternative approach to producing selective receptors for drug immunoassay. Lately, there has been a strong interest in automated analysis (under 6 min per sample) of caffeine and its metabolites (including theophylline and *p*-xanthine) in human plasma using high-performance liquid chromatography with dialysis (30). It would be interesting to see if SPR–PDS using *anti*-polymers could be developed to carry out this specific and other clinically important analyses without the cumbersome deproteination dialysis or plasma heparinization.

Fig. 6. Molecular structures of drugs used to test the selectivity of *anti*-polymers.



Selectivity of *anti*-polymers

Cross-reactivity of the *anti*-polymers with eight other drugs, several of which are of similar structures to the print molecules (Fig. 6), was studied to test their analytical selectivity. Acetaminophen, dyphylline, hydrochlorothiazide, β-hydroxyethyl theophylline, nicotinic acid, and phenyl butazone all produced no shift in θ_r when their solutions were tested on *anti*-theophylline overlayers. Only theobromine produced a slight shift of 0.2° and would cause minor interferences with the MIA of theophylline if it were present at concentrations above 1 mg/mL. Thus, it can be concluded that the *anti*-theophylline polymer has affinity only for its print molecule theophylline, but not for the other drugs studied in this work. It appears that the print molecule created, during the MI polymerization, a unique PMAA–EDMA architecture of cavities to which only it could recombine to. Although several of these other drugs are similarly shaped and contain many of the same functional groups, MI has shaped a microenvironment (shape and arrangement of functional groups) in those cavities that would not bind them in significant amounts.

Stability

A silver film exposed to the atmosphere was found by SPR analysis to be stable for one day, after which θ_r shifted by approximately 0.10° per day. This was expected, as silver is not stable in the atmosphere. A silver film coated with an *anti*-theophylline polymer overlayer, when exposed to the lab atmosphere, was found to be stable for three days. It generated SPR angular profiles at essentially the same θ_r position. After three days, there was a change in θ_r by 0.15° per day. A similar silver film coated with an *anti*-theophylline polymer overlayer, when kept inside a box, was found to be stable for three days. After that time, θ_r shifted by 0.10° per day. A third silver film coated with an *anti*-theophylline polymer overlayer, when kept under vacuum, was stable for five days. Afterwards only a slight shift in θ_r was observed, by 0.05° per day. Similarly, a silver film coated with an *anti*-xanthine polymer overlayer and kept under vacuum was stable for five days. After that, small shifts in θ_r were observed. These results show that the stability of silver films depends on such factors as room temperature, humidity, etc. If an *anti*-polymer overlayer was applied, it protected the silver film surface and retarded the deterioration. Actual data of use of an *anti*-theophylline polymer column that has been aged over one year in dry storage for the HPLC separation of theophylline from caffeine and xanthine is definitive evidence for the stability of the *anti*-polymer itself.[2]

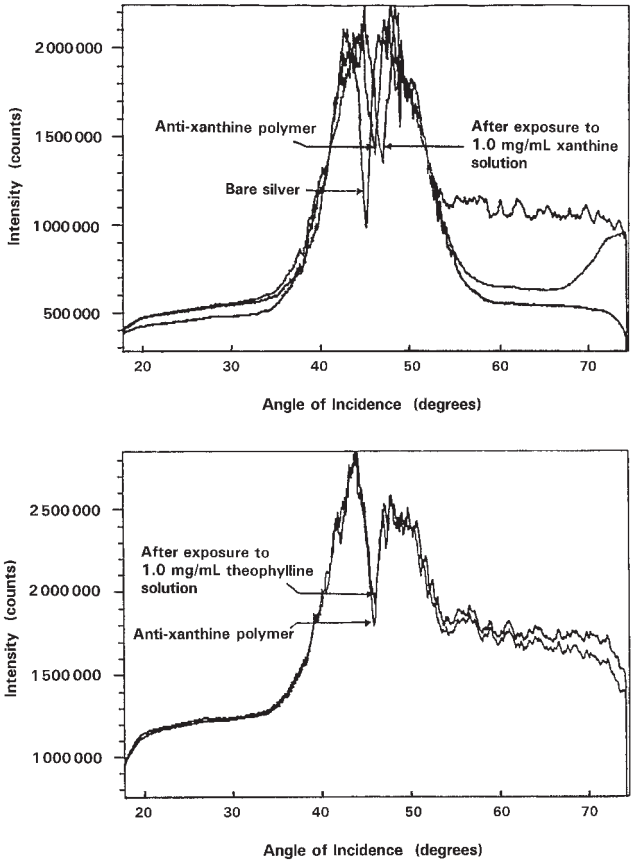
The practical implication of silver film deterioration is that a differential θ_r measurement must always be made between two regions of the same *anti*-polymer overlayer, one having been exposed to a drug sample solution and the other to a blank only. Nevertheless, accompanying the shifts in θ_r was a broadening of the SPR angular profile, which reduced the steepness of the side slopes and hence decreased the analytical sensitivity in PDS measurements. For future development of SPR–MIA of drugs, it would be greatly beneficial to find a metal that is more stable in the atmosphere. A systematic study of gold films over an extended time period is already under way in order to achieve a longer shelf life for the MIA analysis surface.

The SPR–photodiode array sensor system

While the SPR–PDS sensor system was designed for maximal analytical sensitivity, it is limited to sequential angular measurements. Repeated measurements with increasing θs were required in order to obtain the entire SPR angular profile for a determination of θ_r. This could take some 30 min to complete a range from 42 to 50° if an angular resolution of 0.1° is desirable. A technically simpler and faster SPR sensor system was next developed by using a compact laser diode with convergent light incidence through a glass prism on the silver film and multichannel angular detection of the divergent reflected laser beam with a photodiode array (PDA). The SPR–PDA system

© 1998 NRC Canada

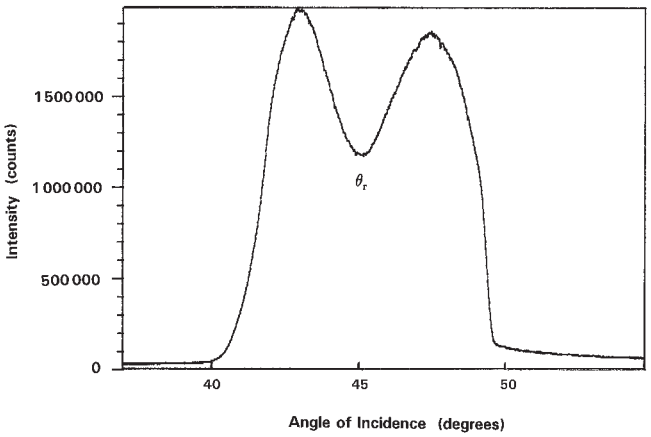
Fig. 7. The SPR–PDA angular intensity profiles for bare silver film, silver film with an overlayer of *anti*-xanthine polymer, *anti*-xanthine polymer overlayer after exposure to 1.0 mg/mL of xanthine in water, and *anti*-xanthine polymer overlayer after exposure to 1.0 mg/mL of theophylline in water.



generated a complete angular profile instantly when the reflected beam intensities were monitored simultaneously on many diodes in the array to correspond with various θs at the silver film. Since the incident light was coupled to the surface plasmons, the reflected beam would be diminished in intensity to exhibit a dip in the SPR angular profile. It is obvious from Fig. 7 that the convergent laser beam covered a sufficiently large range of θ to encompass the full width of the SPR dip, with an angular resolution of 0.055°. For a bare silver film, θ_r could be determined as 45.3 ± 0.1° at which the dip minimum occurred. With an *anti*-xanthine polymer overlayer prepared on the silver film from a 0.06 mg/mL solution, θ_r changed to 46.2 ± 0.1°. After the overlayer was exposed to a 1.0 mg/mL xanthine solution, a further shift in θ_r to 47.2 ± 0.1° was observed. Once again, the molecular recognition capability of *anti*-xanthine polymer was proven when the overlayer was exposed to a 1.0 mg/mL theophylline solution, and no shift in θ_r was observed. The faster analysis speeds and good precision of the SPR–PDA sensor system offer several advantages, including shorter method development time and more analyses completed in less time. These could be of great benefits, for example, to the determination of xanthine among nucleosides and bases in biochemical samples.

One drawback of the SPR–PDA sensor system based on a laser diode was the appearance of noise spikes on the angular

Fig. 8. The SPR–PDA angular intensity profiles for a bare silver film, using a planar LED as the light source.



profiles. A better light source would be a planar light-emitting diode (LED) with a spatially uniform output (31). The result in Fig. 8 shows that a very smooth SPR angular profile can be obtained using the LED source, which allows a more precise determination of θ_r. However, curve fitting of a theoretical SPR equation to experimental data is more difficult to perform because of the spatial incoherence and angular divergence of the LED light.

Conclusions

Vlatakis et al. (6) first showed in 1993 that polymeric matrices could be formed by the MI technique to contain cavities that could hold print molecules. Our work has extended their synthetic method to the creation of two new *anti*-polymers with specific binding capacities for caffeine and xanthine. More importantly, an optical sensor system based on SPR has been developed with the use of either PDS or a PDA for the direct determination of drug molecules without prior separation. The PDS offers good sensitivity for the detection of small shifts in θ_r and hence SPR–PDS signal at constant θ during immunoassay. The concentration detection limit is estimated at 0.4 mg/mL of theophylline in aqueous solution. On the other hand, PDA provides a simple and fast acquisition of an entire SPR angular profile for the easy characterization of *anti*-polymers. Results obtained from both SPR–PDS and SPR–PDA have proven that new *anti*-caffeine and *anti*-xanthine polymers can be formed by the MI technique, to hold cavities and sites that have a selective affinity for the original print molecules but do not recognize other structurally similar drugs. Eventually, extension of the MI technique to nucleotide bases such as adenine and guanine (which have similar structures to xanthine) will be of high significance in biochemical analysis. Application of chemically selective *anti*-polymers in SPR sensors has one limitation in terms of the 60 min incubation step. Future work of SPR–MIA based on *anti*-polymers will need to investigate the binding kinetics for rapid sorption of print molecules in different solvents and buffers. The response time and degree of reversibility will determine if thin polymer overlayers can be used as the sensing element of a SPR sensor for continuous monitoring applications in flow injection analysis,

A conformational study of (1*S*, 2*R*, 5*S*)-(+)-menthol using vibrational circular dichroism spectroscopy

Jennifer L. McCann, Arvi Rauk, and Hal Wieser

Abstract: We report the experimental and predicted absorption and vibrational circular dichroism (VCD) spectra of (1*S*, 2*R*, 5*S*)-(+)-menthol. The harmonic force fields and atomic polar tensors (APTs) were obtained for 10 conformers using density functional theory (DFT) with the Becke3LYP functional and the 6-31G** basis set. The atomic axial tensors (AATs) were obtained with restricted Hartree–Fock (RHF) theory and a 6-31G basis set. VCD intensities were predicted from vibronic coupling theory (VCT). The predicted absorption and VCD spectra based on an equilibrium mixture of conformers corresponded well with the experimental spectra, indicating a reasonable geometry and frequency analysis for each of the conformers. The largest contributions towards the equilibrium population derive from conformers in which the cyclohexane ring occupies a chair conformation, the isopropyl group is directed away from the hydroxyl group, and only the hydroxyl group assumes different conformations.

Key words: vibrational circular dichroism (VCD), menthol, conformational analysis.

Résumé : On rapporte les valeurs expérimentales et calculées pour les spectres d'absorption et de dichroïsme circulaire vibrationnel (DCV) du (1*S*,2*R*,5*S*)-(+)-menthol. On a déterminé les champs de force harmonique et les tenseurs atomiques polaires (TAP) de 10 conformères en utilisant la théorie de la densité fonctionnelle (TDF) avec la fonction Becke3LYP et l'ensemble de base 6-31G**. On a obtenu les tenseurs atomiques axiaux (TAA) à l'aide de la théorie de Hartree–Fock restreinte (HFR) et un ensemble de base 6-31G. Les intensités du DCV ont été calculées à partir de la théorie du couplage vibronique (TCV). Les valeurs prédites pour l'absorption et les spectres de DCV, telles que basées sur un mélange à l'équilibre de conformères, correspondent bien aux spectres expérimentaux; ceci indique que la géométrie utilisée et l'analyse de fréquence pour chacun des conformères sont raisonnables. Les contributions les plus importantes à la population à l'équilibre proviennent des conformères dans lesquels le noyau cyclohexane est en conformation chaise, le groupe isopropyle est orienté en direction opposée au groupe hydroxyle et que seul le groupe hydroxyle prend diverses conformations.

Mots clés : dichroïsme circulaire vibrationnel (DCV), menthol, analyse conformationnelle.

[Traduit par la rédaction]

Introduction

Within the framework of structural analysis, vibrational circular dichroism (VCD) spectroscopy (for a general review see ref. 1) has been proven a valuable technique for elucidating the molecular structure of chiral molecules in solution. Even a cursory glance at the VCD spectra of a series of chiral molecules indicates that VCD is remarkably sensitive to small changes in molecular structure, particularly in comparison to conventional absorption spectroscopy. In conjunction with theoretical models, VCD is capable of determining the conformation and absolute configuration of existing or newly discovered chiral molecules. The ability to determine the total molecular structure directly for a wide range of molecules has allowed VCD to create its own niche within the field of conformational analysis and stereochemical determination (for example, see ref. 2).

We have chosen to examine the conformational structure of menthol and its diastereomeric isomers as part of a spectroscopic study on the chiroptical properties of optically active polymers having a chiral substituent, specifically, menthol, isomenthol, or neomenthol (3). Principally, we are interested in the conformation of the menthol moiety and its interaction with the polymer component of the system. The present study was initiated to better understand how the conformation of the menthol moiety is characterized in the VCD spectra, and to relate the VCD spectrum of the menthol pendant to the VCD spectrum of the corresponding polymer.

A second motivation for the current study stems from the fact that menthol plays a central role in many biological and chemical asymmetric reactions, the bulk of which occur in solution. The principle approach in understanding the role of menthol in stereochemical applications involves obtaining explicit knowledge of the molecular structure in solution. The structure of menthol and (or) its derivatives has previously been examined by various techniques including VCD spectroscopy (4), Raman optical activity (ROA) spectroscopy (5), matrix isolation Fourier transform (MI-FT) spectroscopy (6),

optical rotation (7), as well as common techniques such as X-ray diffraction (for example, ref. 8), NMR (9), and IR spectroscopy (10). However, in none of these cases has it been possible to probe satisfactorily the conformation of the hydroxyl group.

In this paper we present the experimental and predicted IR absorption and VCD spectra of (1*S*, 2*R*, 5*S*)-(+)-menthol. IR and VCD spectra are predicted by ab initio computations. The results from experiment and computation are compared and discussed, with emphasis on the conformation of the hydroxyl and isopropyl groups.

Experimental

(1*S*,2*R*,5*S*)-(+)-Menthol was purchased from Aldrich and was used without further purification. Infrared absorption and VCD spectra were recorded at 4 cm^{-1} resolution on a modified Bomem FT-IR spectrometer (11). The spectra are displayed from 830 to 1550 cm^{-1}. Samples for both IR and VCD spectra were prepared as 0.4 M CCl_4 solutions and measured in a 0.15 mm KBr liquid cell. VCD spectral acquisition involved collecting a block of 500 dc scans, immediately followed by the collection of a block of 5000 ac scans. The raw VCD spectrum was corrected for artifacts by subtracting the VCD spectrum of the opposite enantiomer, and then calibrated in the usual fashion (12). Experimental IR and VCD spectra were analyzed using the Labcalc software (13).[2]

Computations

Computation of the VCD spectra was performed in two stages. In the first stage optimized equilibrium geometries, energies, harmonic force fields, and atomic polar tensors (for absorption intensities) were obtained for 10 conformers via density functional theory (DFT) with the Gaussian94 (14) program using a combination of Becke's three-parameter hybrid method (15) and the correlation functional of Lee, Yang, and Parr (16, 17) (i.e., Becke3LYP), with the 6-31G** basis set. The choice of Becke's hybrid density functional is based on the claim for superior agreement between experiment and theory during the harmonic vibrational analyses of a number of small chiral molecules (18, 19). In the second stage, VCD intensities were calculated with the same equilibrium geometries, harmonic force fields, and atomic polar tensors, and with atomic axial tensors generated at the RHF level and 6-31G basis set in the distributed origin gauge using vibronic coupling theory (VCT) (20–23).

Predicted spectra are displayed as Lorentzian band shapes

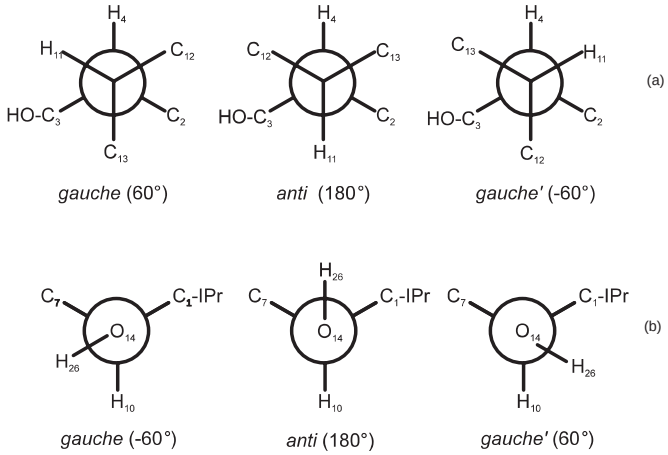
Fig. 2. Newman projections of the rotamers of (*a*) the isopropyl group about the C_5—C_1 bond and (*b*) the hydroxyl group about the O_{14}—C_3 bond. Torsion angles (in parentheses) are defined as the angle between H_{11} and H_4 along the C_5—C_1 bond for the isopropyl group, and between H_{26} and H_{10} along the O_{14}—C_3 bond for the hydroxyl group.



with half-width at half-height of 5 cm^{-1}. Calculated frequencies were uniformly scaled by 0.985 to provide a closer match to experiment. The structural formula and atom numbering used for calculations are given in Fig. 1.

Results and discussion

Conformational and normal mode analyses

Menthol presents a computational challenge as it has a relatively large formula weight and considerable conformational flexibility. The input geometry of menthol used in the present calculations is based on the more stable chair conformation of the cyclohexane ring. The conformational flexibility arises from the possibility of ring inversion and rotation of the isopropyl and hydroxyl groups. For both groups there are 3 possible staggered rotational isomers, comprising a total of 9 rotamers if all substituents are equatorial, or 18 if both equatorial and axial positions are considered for the chair conformation. The energies for 10 of these isomers were calculated, namely, the 9 for which all substituents are equatorial, and 1 conformer in which all substituents are axial. In the conformational and vibrational analyses to follow, the conformation in which all substituents occupy an axial position will not be discussed, other than to obtain the relative energy and molecular populations.

The nomenclature used below to define the conformers is based on the conventional *gauche* (*g*), *anti* (*a*), and *gauche′* (*g′*) designations, which correspond to torsion angles $\tau(H_{11}\text{-}C_1\text{-}C_5\text{-}H_4)$ of 60°, 180°, and –60°, respectively, for the isopropyl group, or torsion angles $\tau(H_{26}\text{-}O_{14}\text{-}C_3\text{-}H_{10})$ of –60°, 180°, and 60°, respectively, for the hydroxyl group (Fig. 2). The nine conformers defined in terms of the torsion angles of the isopropyl and hydroxyl substituents are listed in Table 1, along with the corresponding Becke3LYP/6-31G** energies. In each case the starting geometry was a reasonable structure based on ideal staggered conformations that was then further optimized.

In conformers **1**, **2**, and **4** the isopropyl group occupies an almost perfectly staggered *gauche* conformation, with torsion angles $\tau(H_{11}\text{-}C_5\text{-}C_1\text{-}H_4)$ of 68.85°, 65.53°, and 63.15°, respectively. In the *gauche′* conformation, the isopropyl group is distorted from the perfectly staggered position by ~20°, with torsion angles $\tau(H_{11}\text{-}C_5\text{-}C_1\text{-}H_4)$ of –78.33°, –82.04°, and –81.87° for conformers **3**, **5**, and **7**, respectively. The *anti* conformations of the isopropyl group are also distorted from the perfectly staggered position by ~20°. When the hydroxyl proton is *anti* or *gauche*, the proton of the isopropyl group is directed toward the OH group with torsion angles $\tau(H_{11}\text{-}C_5\text{-}C_1\text{-}H_4)$ corresponding to 163.42° and 154.85°, respectively. When the hydroxyl proton is *gauche′*, i.e., pointing towards the isopropyl group, the environment is more crowded and the proton of the isopropyl group is oriented away from the hydroxyl group with a torsion angle of –160.24°. Rotamers of the hydroxyl group are almost perfectly staggered for the *gauche* and *anti* conformers, with torsion angles, $\tau(H_{26}\text{-}O_{14}\text{-}C_3\text{-}H_{10})$, of –62.24±0.44° and –178.67±1.17° (mean±s.d.), respectively. The more sterically hindered *gauche′* conformation of the hydroxyl group has a more distorted torsion angle of 47.50±2.83°.

Bond distances, angles, and torsion angles averaged over the first nine conformers are listed in Table 2. The average C—C bond distances are reasonable, although more elongated in the crowded environment around C_1. Within the cyclohexane ring, the average C-C-C bond angle is greater than 109° and the average C-C-C-C torsion angle is less than 60°, indicating that the ring is flatter than the normal cyclohexane geometry. The greatest standard deviation of geometrical parameters among the isomers occurs in the vicinity of the isopropyl and hydroxyl groups, while the rest of the ring remains reasonably constant.

The relative energies (including the zero point energy) that were obtained from the Becke3LYP/6-31G** computations were used to estimate the population of conformers from the Boltzmann distribution law. It predicts that only 2 of the 10 isomers will contribute significantly to the population, namely, conformers **1** and **2** (Fig. 1), which account for 37.7% and 24.9%, respectively. In general, the lowest energy conformers are those in which the isopropyl group occupies a *gauche* position, whereas an *anti* position of the isopropyl group is associated with higher energy. The next highest energy conformers are those that have undergone ring inversion, followed by the boat conformations of the cyclohexane ring, the latter of which was calculated using the MM3 force field of Macromodel (24).

A set of non-redundant internal coordinates (local symmetry coordinates, LSCs) was defined following the recommendations of Fogarasi and Pulay (25) (available from the authors). Potential energy distributions (PEDs) calculated at the Becke3LYP/6-31G** level are shown in Table 3 for ν_{67}–ν_{23} for the two lowest energy conformers. PED contributions less than about 10% are not included, with the exception of contributions from O–H bending that have been included for ν_{44}. The vibrations are generally highly coupled, with the descriptions listed in Table 3 accounting for about 11% of a normal mode at worst and 90% at best.

in Fig. 3*a* as a CCl_4 solution and in Fig. 3*b* as a KBr pellet. Figure 3*c* is a composite spectrum that represents the superposition of the predicted spectra of conformers **1**–**9** weighted by Boltzmann distribution (Table 1). Most bands in the composite spectrum arise from the predicted spectrum of one of the two lowest energy conformers (**1** or **2** shown in Fig. 3*d* and 3*e*, respectively), thus permitting the assignment of each band in the composite spectrum to one or more normal modes of **1** or **2**. The analysis performed in this paper involved assigning the experimental bands (numbered 1–32 from low to high frequency, Fig. 3*a*), followed by comparison to bands in the composite spectrum (numbered 1–32 correspondingly, Fig. 3*c*). The experimental bands could then be interpreted in terms of the normal modes of **1** or **2** (numbered 23–67, Fig. 3*d* and 3*e*, respectively). Overall, the theoretical and experimental spectra are in excellent agreement.

Bands 1–9 of the composite spectrum correspond to ν_{23}–ν_{31} for both **1** and **2**, generally agreeing to within a few wave numbers with experiment (Table 3). Although bands 10–15 also tend to agree with experiment, better correspondence could be obtained by small intensity changes and (or) frequency shifts. The larger discrepancies in this region affect bands arising from modes with C–O stretching character, namely bands 10, 11, 12, and 15. In the composite spectrum band 10 is predicted to be too low in intensity, while bands 11 and 12 are predicted to be too high. A slight shift to higher frequency of the calculated band 14, and to lower frequency of band 15, would improve the correspondence with the

[a]Calculated at the DFT/Becke3LYP/6-31G** level of theory.
[b]Units of frequency are wave number (cm^{-1}).
[c]Units of dipole strength (D) are 10^{-40} (esu·cm)^2.
[d]Units of rotational strength (R) are 10^{-45} (esu cm)^2.
[e]Frequencies are scaled by 0.985.
[f]Only PED with a contribution greater than about ~10% are shown.
[g]Numbers in parentheses correspond to the peak position (cm^{-1}) of the VCD peak.
Symbols: Ipr = isopropyl group; sym = symmetric, asym = asymmetric; i/p = in plane; o/p = out of plane; i/ph = in phase; o/ph = out of phase; def = deformation

experimental spectrum. The bands arising from OH bending, namely 16, 21, and 23, are also closely reproduced in frequency, albeit at a significantly lower intensity. The lower than predicted intensity of these modes is attributed to intermolecular hydrogen bonding. Additional disparities arising from variations in intensity and frequency occur in the regions of methyl symmetric and asymmetric deformations, but are difficult to determine specifically due to the large number of overlapping bands. The most obvious inaccuracy is the failure to predict the characteristic doublet of the isopropyl group that is usually observed at 1385/1370 cm^{-1}. In particular, the in- and out-of-phase asymmetric deformations are predicted to be too close together in frequency.

VCD spectra

The experimental and composite VCD spectra are shown in Fig. 4*a* and 4*b*, respectively. The spectra of the two lowest energy conformers (**1** and **2**) and the corresponding normal modes are shown in Fig. 4*c* and 4*d*. The numbered bands of the experimental and composite spectra correspond to the same transitions observed in absorption. The correspondence between experiment and theory for VCD is even more remarkable than for the absorbance spectra, although the intensities are appreciably underestimated.

Bands 1 and 2 in the composite spectrum are too weak to be observed in the experimental spectrum. Bands 3–9 are reproduced very well in the composite spectrum. Band 10 has a strong negative signal arising from ν_{32} of both **1** and **2**. Band 11 of the composite spectrum is predicted to be negative,

Fig. 3. Absorption spectra of (1*S*, 2*R*, 5*S*)-(+)-menthol from 1550 to 830 cm^{-1}: (*a*) 0.4 M CCl_4 solution; (*b*) KBr pellet; (*c*) a composite of conformers **1**–**9** weighted by Boltzmann distribution; (*d*) conformer **1**; (*e*) conformer **2**. Fig. 4. VCD spectra of (1*S*, 2*R*, 5*S*)-(+)-menthol from 1550 to 830 cm^{-1}: (*a*) 0.4 M CCl_4 solution; (*b*) a composite of conformers **1**–**9** weighted by Boltzmann distribution; (*c*) conformer **1**; (*d*) conformer **2**. Numbering for (*c*) and (*d*) corresponds to the actual normal modes and is arbitrary for (*a*) and (*b*). The arbitrary assignment of numbers in (*a*) and (*b*) corresponds to the numbering used in the absorption spectra (Fig. 3).

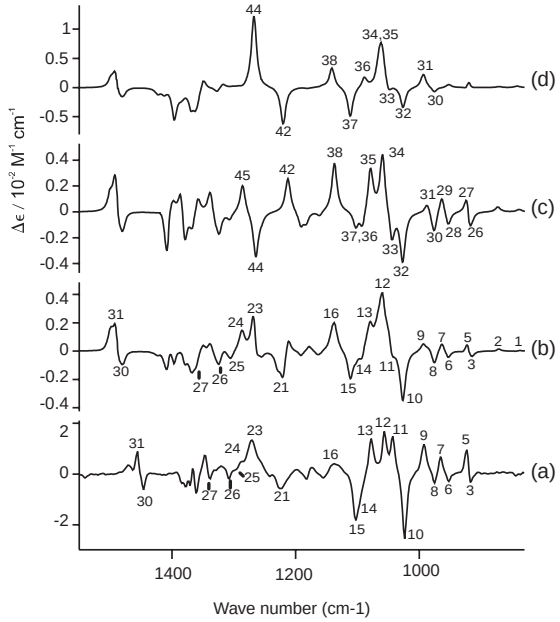

Fig. 5. Simulated absorption spectra of the nine conformers of (+)-menthol listed in Table 1.

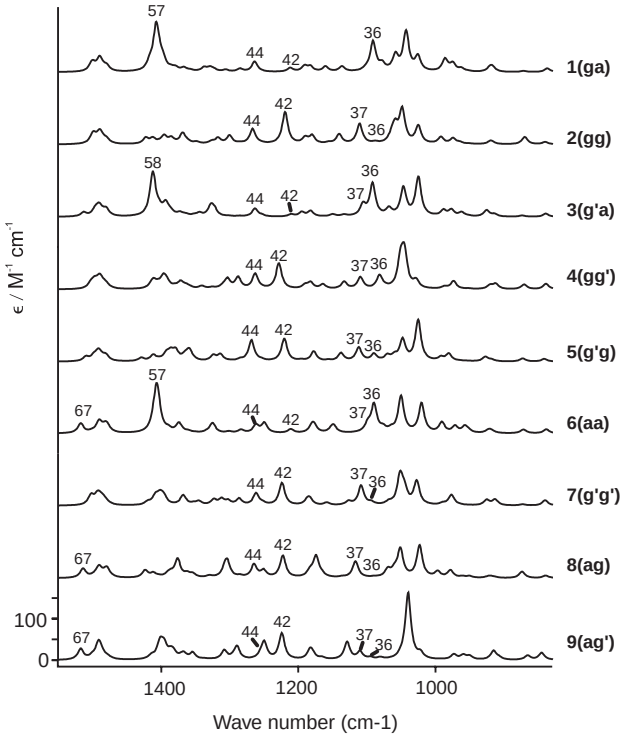


whereas the experimental spectrum exhibits a strong positive feature at the same frequency. Band 12 of the composite spectrum (1062 cm^{-1}) has positive intensity contributions from ν_{34} of **1**, and ν_{34} and ν_{35} of **2**, and is predicted to be too high in intensity. This can be rationalized as follows. If ν_{34} for either **1** and (or) **2** were calculated 10–12 cm^{-1} lower, then the large positive signal for ν_{34} would cancel out the smaller negative signal for ν_{33} occurring at the same frequency, thereby reproducing the characteristic triplet pattern of the experimental spectrum. In the absorption spectrum the intensity of band 12 would be reduced and the peak position of 11 would be shifted to lower frequency while only slightly increasing the intensity of the latter. Accordingly, peak 11 in the experimental VCD spectrum is thought to arise from ν_{34} of **1** and (or) **2**, band 12 is assigned to ν_{35} of **2**, band 13 to ν_{35} of **1**, band 14 to ν_{36} and (or) ν_{37} of **1**, and band 15 to ν_{37} of **2**. Similar to the absorption spectrum, the experimental VCD bands with significant OH bending character are expected to have larger band widths and lower intensities than predicted due to intermolecular hydrogen bonding. The bands arising from OH bending occur at 16, 21, and 23. Band 23 originates from ν_{44} of **2**, while the small negative shoulder at lower frequency originates from the same mode (ν_{44}) of **1**. Similarly, band 21 originates from ν_{42} of **2**, whereas the small positive peak at lower frequency originates from the same mode of **1**. The assignment of band 21 demonstrates the potential of VCD for conformational analysis, where the simple rotation of a ring substituent may change the sign of a signal arising from the same normal mode. In general, the assignment of VCD spectra provides another dimension to spectroscopic analysis, which invariably helps in assigning the vibrational spectra more definitively. Specifically, the analysis of the VCD spectrum has permitted the assignment of a large portion of the experimental absorption spectrum of menthol, a task which would be difficult based on the absorption spectrum alone.

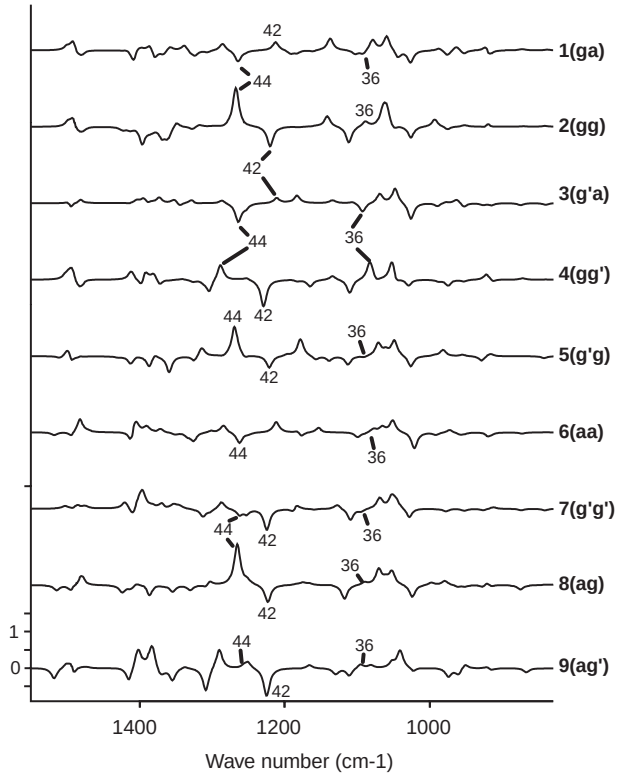
General trends

The computed absorption spectra of the nine conformers of (+)-menthol are displayed in Fig. 5 and the corresponding VCD spectra in Fig. 6. Overall, the absorption and VCD spectra predicted for each rotational isomer are unique, providing a "fingerprint" for each isomer. There are, however, certain trends that can be identified. In particular, the isopropyl and hydroxyl groups have localized vibrations corresponding to the methyl deformations and O–H bending, respectively.

The isopropyl group is characterized by the isopropyl in- or out-of-phase asymmetric deformations coupled with CH_2 scissoring at C_2, C_6, C_7 (1470–1520 cm^{-1}). Thus this region can serve in principle as a conformational probe of the isopropyl group, provided the skeleton of the ring remains the same. The absorption spectrum is noticeably overlapped when the isopropyl group occupies a *gauche* position, more separated for a *gauche´* position, and highly separated for an *anti* position. Specifically, ν_{67}, which consists largely of the isopropyl in-phase asymmetric deformation, is at a much higher frequency for the *anti* conformation. The VCD spectra in Fig. 6 reinforce the generalizations for the absorption spectra. The *gauche* conformers exhibit a very characteristic –/+ bisignate pattern (bands 30/31 from Fig. 4), in contrast to the more sterically hindered *gauche´* or *anti* arrangements where the VCD patterns become more complex and difficult to classify unambiguously. Both the highly overlapped absorption bands and –/+ bisignate VCD signals of the experimental spectra indicate

© 1998 NRC Canada

Fig. 6. Simulated VCD spectra of the nine conformers of (+)-menthol listed in Table 1.



that the dominant conformation of the isopropyl group is *gauche*, in agreement with the predicted populations listed in Table 1.

The bands affected by O–H bending vibrations are similarly characteristic. In absorption, an *anti* position of the hydroxyl group is characterized by a large signal associated with normal modes ν_{57}, ν_{58}, and ν_{36}, and relatively weak signals from modes ν_{37}, ν_{42}, and ν_{44} (Fig. 5). In contrast, the signal arising from ν_{37}, ν_{42}, and ν_{44} is high when the hydroxyl group occupies a *gauche* or *gauche′* position, while that from ν_{57}/ν_{58} and ν_{36} is notably smaller. In the VCD spectra (Fig. 6), the O–H bending patterns are best illustrated by ν_{42} and ν_{44}. For *gauche* conformers of the hydroxyl group, the peaks arising from ν_{42} and ν_{44} are very similar in intensity and sign, displaying strong negative and positive bands for the two modes, respectively. When the hydroxyl group occupies an *anti* conformation the situation is more complex. The largest contribution of O–H bending occurs in ν_{36} and ν_{42}, with a smaller contribution also in ν_{44} (i.e., 6–7%). Modes ν_{42} and ν_{44} appear as strong positive and negative VCD peaks, respectively, the exact opposite of those observed for the *gauche* conformer. Although mode ν_{36} is consistently negative for the *anti* conformer, it is generally lower in intensity and in a more congested region of the spectrum. When the hydroxyl group occupies a *gauche′* position, the O–H bend still contributes significantly to ν_{42} and ν_{44} (although only 4.4% for ν_{44} for conformer 10), giving rise to a strong negative peak for ν_{42} and a weak peak for ν_{44} that is either positive or negative.

The most notable findings here are that the VCD spectra change systematically with the orientation of the hydroxyl and isopropyl groups. These results confirm that VCD spectroscopy can be used as a conformational probe for substituents on the cyclohexane ring, provided the skeleton of the ring remains reasonably the same. Furthermore, if a strong, isolated band exists that is characteristic of a certain conformation, then it may be possible to ascertain the dominant conformation.

Conclusions

Ab initio calculations were performed for 10 conformers of (1*S*, 2*R*, 5*S*)-(+)-menthol. For each conformer, the geometry, force field, and atomic polar tensors necessary for the vibrational frequencies and absorption intensities were calculated at the DFT/B3LYP/6-31G** level using the Gaussian94 program. The atomic axial tensors needed for determining the rotational strengths were calculated at the HF/6-31G level of theory using the VCT90 and Gaussian90 programs, and were combined with the atomic polar tensors and force field calculated at the DFT/B3LYP/6-31G** level to predict the VCD spectra of the 10 conformers. The relative energies calculated for the 10 optimized conformers were used to determine the equilibrium mixture of isomers according to Boltzmann's distribution, from which the composite absorption and VCD spectra were generated. Accordingly, the conformational equilibrium of menthol consists primarily (70%) of contributions from two rotational isomers of the hydroxyl group with the isopropyl group in the *gauche* conformation. The calculated absorption spectrum resulting from the equilibrium mixture of these two isomers is consistent with the experimental observations.

The predicted VCD features also show remarkable agreement with the experimental spectra, despite the lower level of calculations and complexity of the molecule, further demonstrating that it is the quality of the force fields which is important in VCD computations. In fact, the ability to obtain a high correlation for this large terpene demonstrates the potential for VCD spectroscopy in structural analysis of chiral molecules with considerable flexibility and size. The results show that VCD is very sensitive to the conformation of the menthol molecule, including rotational isomers of the substituents on the cyclohexane ring.

Interdeterminancy of basin and surface properties of an open system

R.F.W. Bader and F.J. Mart n

Abstract: This paper delineates and illustrates an important physical consequence of the Heisenberg equation of motion governing the expectation value of an observable for a proper open system, one whose basin is bounded by a surface of zero flux in the gradient vector field of the electron density. For a system in a stationary state, this theorem derives from the variation of Schrödinger's energy functional over an open system. The variation demonstrates that the surface of the *open* system, as well as the wave function and energy of the *total* system, are simultaneously stationary with respect to any and all variations $\delta\psi$, corresponding to a stationarity with respect to any and all physical perturbations $-(i\varepsilon/\hbar)\hat{G}\psi$ caused by a generator $\hat{G}$. Thus the properties of a proper open system are dependent upon its surface and vice versa, the theorem equating the expectation value of the commutator of the Hamiltonian and a generator $\hat{G}$ for the open system to the flux in the current density for $\hat{G}$ through its surface. The criticisms of the interdependence of the basin and surface properties of a proper open system that appeared recently in this journal are refuted, including the argument that mutiplication of an electron density by a constant factor yields a density for a different system. The consequences of this interdependence in the construction of a polypeptide through the use of amino acid residues defined as proper open systems is discussed and illustrated through the explicit calculation of the properties of the C|N interatomic surfaces of the amidic bonds. It is demonstrated that the the degree of transferability of a residue is determined by the degree of similarity in the properties of its two bounding amidic surfaces.

Key words: electron density, transferability of density, atoms in molecules, zero flux surface.

Résumé : Dans ce travail on délimite et on illustre une conséquence physique importante de l'équation de mouvement d'Heisenberg relative à la valeur probable d'un phénomène observable d'un système ouvert propre, dont le bassin est fixé par une surface de flux zéro dans le vecteur de gradient du champ de la densité électronique. Pour un système en état stationnaire, ce théorème est dérivé à partir de la variation de la fonction d'énergie de Schrödinger sur le système ouvert. La variation démontre que la surface du système *ouvert*, de même que la fonction d'onde ainsi que l'énergie du système *total*, sont tous stationnaires simultanément par rapport à chacune et à toutes les variations $\delta\psi$; ceci correspond à un état stationnaire par rapport à chacune et à toutes les perturbations physiques $-(i\varepsilon/\hbar)\hat{G}\psi$ provoquées par un générateur $\hat{G}$. Ainsi, les propriétés d'un système ouvert dépendent de sa surface et vice versa puisque, selon le théorème, la valeur probable du commutateur de l'Hamiltonien et d'un générateur $\hat{G}$ d'un système ouvert égale le flux de la densité de courant pour $\hat{G}$ à travers sa surface. On doit donc considérer que les critiques qui ont été publiées récemment dans ce journal au sujet de l'interdépendance du bassin et des propriétés de surface d'un système ouvert propre sont réfutées, y compris l'argument que la multiplication d'une densité électronique par un facteur constant conduit à une densité pour un système différent. On discute des conséquences de cette interdépendance dans la construction d'un polypeptide par l'utilisation de résidus d'acides aminés définis comme des systèmes ouverts propres et on l'illustre par le biais de calculs explicites de propriétés de surfaces interatomiques C|N de liaisons amidiques. On démontre que le degré de transférabilité d'un résidu est déterminé par le degré de similarité dans les propriétés de ses deux surfaces amidiques limitantes.

Mots clés : densité d'électron, transférabilité de la densité, atomes dans des molécules, surface de flux zéro.

[Traduit par la rédaction]

Proper open systems

A proper open system is a region of real space bounded by a surface $S(\mathbf{r})$ through which there is a zero flux in the gradient vector field of the electron density (1–3), the "zero-flux" condition stated in eq [1]:

$$[1] \quad \nabla\rho(\mathbf{r})\cdot\mathbf{n}(\mathbf{r}) = \mathbf{0} \;\forall\; \mathbf{r} \in S(\mathbf{r})$$

where $\mathbf{n}(\mathbf{r})$ is a unit vector normal to $S(\mathbf{r})$. They are termed "proper" because they and their properties are defined by the principle of stationary action, a consequence of the imposition of eq. [1] as a constraint in the variation of the action integral operator for an open system (2–4). The principle of stationary action is a marriage of the principle of least action and Dirac's transformation theory (5). The action integral defines a bounded region of space and time, a space-time volume. The variation of the action over this space-time volume yields the (Schrödinger) equation of motion, just as the corresponding variation does in the classical principle of least action. In the principle of stationary action, however, the mathematical variations in the action at the time end points are retained rather than equated to zero as they are in the principle of least action.

© 1998 NRC Canada

When generalized to an open system, one with finite boundaries, the corresponding variations at the spatial boundaries are retained as well. It is these variations at the time end points and at the system's boundaries that are subsequently identified with the action of temporal and spatial generators of infinitesimal unitary transformations, thereby incorporating Dirac's transformation theory into the action principle (5). Thus, in addition to obtaining Schrödinger's equation describing the temporal development of the total system — the sole result in the principle of least action — one also obtains a variational derivation, unique to a proper open system, of the Heisenberg equation of motion for an observable $\hat{G}$. This operational statement of the principle of stationary action for an open system Ω is expressed as a variation in the Lagrange function operator (2–4), eq. [2*a*]:

$$[2a] \quad \delta\hat{\mathcal{L}}[\hat{\Psi},t,\Omega] = (\varepsilon/2)\{(i/\hbar) < \hat{\Psi}[\hat{H},\hat{G}]\hat{\Psi} >_{\Omega} + cc\}$$

For a proper open system, $\delta\hat{\mathcal{L}}[\hat{\Psi},t,\Omega]$ is given by eq. [2*b*]:

$$[2b] \quad \delta\hat{\mathcal{L}}[\hat{\Psi},t,\Omega] = (\varepsilon/2)\int_{\Omega} d\mathbf{r}\ \{\partial\hat{\rho}_G(\mathbf{r})/\partial t\} + (\varepsilon/2)\oint d\mathbf{S}(\mathbf{r}_S)\cdot\{\hat{\mathbf{j}}_G(\mathbf{r}_S) + cc\}$$

wherein the density operator for generator $\hat{G}$ is denoted by $\hat{\rho}_G(\mathbf{r})$, its current density by $\hat{\mathbf{j}}_G(\mathbf{r})$, and ε denotes an infinitesimal real number.

Interdeterminancy of basin and surface properties

Equation [2] demonstrates that for a system in a stationary state for which $\partial\hat{\rho}_G(\mathbf{r})/\partial t = 0$, the Heisenberg equation of motion equates the expectation value of the commutator to the flux in the associated current density through its surface. A discussion of the stationary state form of this theorem for a proper open system forms the basis of this paper and it is expressed in eq. [3], wherein we have reverted from the language of field theory to the Schrödinger representation in terms of the wave function ψ,

$$[3] \quad (1/2)\{(i/\hbar) < \psi|[\hat{H},\hat{G}(\mathbf{r})]|\psi >_{\Omega} cc\} = (1/2)\oint d\mathbf{S}(\mathbf{r})_S\cdot\{\hat{\mathbf{j}}_G(\mathbf{r}_S) + cc\}$$

where $\mathbf{j}_G(\mathbf{r})$ is the current density for $\hat{G}$

$$[4] \quad \mathbf{j}_G(\mathbf{r}) = (\hbar/2mi)\{\nabla\hat{G}(\mathbf{r}) - \hat{G}(\mathbf{r})\}\Gamma^{(1)}(\mathbf{r},\mathbf{r}')|_{\mathbf{r}=\mathbf{r}'}$$

and $\Gamma^{(1)}(\mathbf{r},\mathbf{r}')$ is the one-electron density matrix. The operator average over the open system Ω denoted by $< \psi|[H,\hat{G}(\mathbf{r})]|\psi >_{\Omega}$ implies a summation over all spins and integration over all spatial coordinates save those denoted by the position vector $\mathbf{r}$ defining the coordinates of the generator, which are integrated over the open system. This mode of integration follows directly from the field theoretic derivation of the principle of stationary action wherein the generator acts on a single field point (3). Equation [3] also applies to an isolated (that is, the total) system in which case the surface integral vanishes, a result sometimes referred to as the hypervirial theorem.

It is useful at this point to introduce the term "basin" from the topological definition of an open system, a basin being the region of space bounded by the union of some number of zero-flux surfaces (3). If the open system contains more than a single attractor (generally a nucleus), then the term basin will be used to refer collectively to the linked set of basins, the surface integrals for each neighbouring pair within the set cancelling in eq. [3].

Equation [3] has an important physical consequence unique to open systems, one that is the subject of this note, since its validity has been questioned in this journal (6). The commutator $(i/\hbar)[\hat{H},\hat{G}]$ in eq. [3] yields some observable whose average over the basin of Ω determines its expectation value for the open system. By eq. [3], this expectation value is equal to the flux in the current density of the observable $\hat{G}$ through the surface bounding the open system. For example, if $\hat{G} = -\mathbf{i}\hbar\nabla$, the electronic momentum operator, the commutator equals $-\nabla\hat{V}$, the operator that determines the force exerted on an electron by all of the remaining particles in the system. Its expectation value yields the Ehrenfest force acting on the electron density contained within the basin of the open system. Equation [3] equates this force to the surface flux in the momentum current density or, equivalently, to the flux in the quantum stress tensor, $\sigma(\mathbf{r})$. The stress tensor has the dimensions of an energy density or pressure and thus the force acting over the basin of an open system is determined in its entirety by the pressure acting on each of its surface elements $d\mathbf{S}$. A similar result is obtained for every observable $\hat{G}$ that is not a constant of the motion.

Thus the properties of an open system are a function of its surface: if the surface of an open system remains unchanged, then so do its average properties and, conversely, a change in the surface necessarily results in changes to the average properties. This property of a proper open system has important consequences in the use of such systems as building blocks in the theoretical construction of large molecules such as polypeptides (7, 8). The use of proper open systems in this manner is a result of their identification with the functional groups of chemistry, since they have been shown to account for all of the characteristic properties associated with this concept (1, 3, 9–15). In particular, atomic and group properties predicted in this manner have been shown to recover the experimentally determined contributions to the volume, energy, polarizability, and magnetic susceptibility in those cases where the group contributions are transferable, as well as additive. While perfect transferability is a theoretical impossibility, it can be approached to within experimental as well as computational accuracy. In those systems that exhibit such near-perfect transferability, the surfaces bounding the functional group in the different molecular environments and their properties are unchanged to the same degree of computational accuracy as are the basin properties, as required by the principle of stationary action. It is this interdependence of the surface and basin properties of an open system that has been challenged (6).

To place this interdependence on a firm mathematical basis, one can step back and replace the action of the infinitesimal generators on ψ with the variation of the state function in the expression for the variation of the action integral. For a

© 1998 NRC Canada

stationary state, this variation becomes a variation in Schrödinger's energy functional $G[\psi,\Omega]$ (2, 3, 16), as employed by him in the derivation of the "wave equation." The principle of stationary action for a proper open system, eq. [2], reduces in this case to

$$[5] \qquad \partial G[\psi,\Omega] = -(i\hbar/2) \oint d\mathbf{S}(\mathbf{r}_S)\cdot\delta_\psi \mathbf{J}(\mathbf{r}) + cc$$

where $\delta_\psi \mathbf{J}(\mathbf{r})$ denotes a variation in the vector current density with respect to a variation in the state vector ψ. Satisfaction of eq. [5] for all variations $\delta\psi$ or, alternatively, for the action of all infinitesimal generators $-(i\varepsilon/\hbar)\hat{G}$ on ψ, and subject to the boundary condition eq. [1], yields Schrödinger's equation $\hat{H}\psi = E\psi$ for the entire system and ensures satisfaction of eq. [3] for all observables $\hat{G}$ for the open system Ω. Equation [5] is in principle a method of minimizing the energy E and obtaining Schrödinger's equation together with all properties for a total system by restricting the variations to the basin of a proper open system interior to the total system and requiring this variation over the basin to equal the flux in the variation of the vector current through its surface. The possibility of employing eq. [5] in this manner was recently reviewed and discussed (17).

The derivation of eq. [2], the atomic statement of the principle of stationary action or its stationary state counterpart, eq. [5], entails both a variation of the surface itself, subject to the constraint expressed in eq. [1], as well as a variation of ψ in the surface (2–4, 16). Thus the generalized variation principle, eq. [5], demonstrates that a proper open system and its zero-flux surface are indeed uniquely interdependent, for it shows that the surface of the open system, as well as the wave function and energy of the total system, are stationary with respect to any and all variations $\delta\psi$, corresponding to a stationarity with respect to any and all physical perturbations $-(i\varepsilon/\hbar)\hat{G}\psi$.

Criticism of the interdeterminancy of basin and surface properties

Stefanov and Cioslowski (6) give two arguments in an attempt to dispute the conclusion that the electron density and the properties of a proper open system are uniquely related to its zero-flux surface. First they argue that this property of a proper open system "corresponds to a noninvertible $R^3 => R^2$ mapping and, therefore, is not bijective." This statement is made without reference to the principle of stationary action and its physical consequences for an open system. Equation [3] maps the properties of the basin onto those of its surface, a mathematical identity obtained from physics via the atomic statement of the principle of stationary action, eq. [5]. This result is hardly novel in physics, classical or quantal. For example, the force acting on an open portion of a system in classical continuum mechanics is determined by the pressure exerted on each of its surface elements with the local pressure being determined by the classical stress tensor, a result that parallels completely the quantum expression for a proper open system (2). It is worth noting that eq. [3] offers the possibility of equating an atomic expectation value to a sum of "bond" contributions in terms of a corresponding sum of surface integrals, there being a separate contribution to the surface integral in eq. [3] from each atom bonded to Ω (3).

In their second argument Stefanov and Cioslowski (6) state that multiplication of a density by a constant factor other than unity, while leaving the form of the gradient vector field and hence the surfaces of zero flux in $\nabla\rho(\mathbf{r})$ unchanged, would change the density within each basin by the constant factor and hence the properties of the open system. The argument is false as follows from the linearity of Schrödinger's equation. Multiplication of the state function or its derived density by a constant simply changes its normalization, but not the physical nature of the system or its properties. The state function ψ and its derived density $\rho(\mathbf{r})$ are uniquely determined by the Hamiltonian and its external potential, regardless of their normalization.

To be explicit and in anticipation of possible counter arguments, consider Schrödinger's equation,

$$[6] \qquad \hat{H}\psi = E\psi$$

which determines ψ to within a constant or a phase factor $\exp(i\phi)$. This remaining degree of freedom is generally determined by requiring that ψ be normalized to unity, thereby enabling Born's probabilistic interpretation of $\psi^*\psi\, d\tau$. The electron density $\rho(\mathbf{r})$ for a normalized ψ is defined to be

$$[7] \qquad \rho(\mathbf{r}) = N \int d\tau'\, \psi^*\psi$$

where the symbol $\int d\tau'$ implies a summation over all spins and integration over all spatial coordinates save those denoted by the position vector $\mathbf{r}$. Multiplication of ψ by a constant $\sqrt{k}$ to give ψ' will yield a density $\rho'(\mathbf{r}) = k\rho(\mathbf{r})$. However, this is not a new density describing a system of kN electrons (assuming k to be integer). It is derived from the same state function ψ, albeit with a new normalization, and determined by the same Hamiltonian. Thus $\rho'(\mathbf{r})$ is simply a density that integrates to kN electrons and its use in the determination of a property entails division by the new normalization factor. That is, for the expectation value of some operator $\hat{o}(\mathbf{r})$ one has

$$[8] \qquad <\hat{o}> = \int \hat{o}(\mathbf{r})\rho'(\mathbf{r})\, d\mathbf{r} / \int d\mathbf{r} \int d\tau'\, \psi'^*\psi'$$

the usual procedure for use of a ψ not normalized to unity.

One might attempt to argue that while the density $\rho'(\mathbf{r})$ is excluded by the linearity of Schrödinger's equation from being a new density for a different Coulombic Hamiltonian, it is a new density for kN electrons determined by some unknown non-Coulombic Hamiltonian. To counter even this argument, we shall appeal to density functional theory and in particular to the use of Levy's functional to suppress the problem of V representability (18). In Levy's functional one searches from among all those ψ which upon reduction yield the given ρ, for that one which yields the minimum value for $<\hat{H}>$. Its use thus extends the domain of variation; the only requirement remaining on $\rho(\mathbf{r})$ is that it be N representable. This latter requirement is met by demanding that the integral of $\rho(\mathbf{r})$ be finite, *but not necessarily equal to N* (19, 20). The density $\rho'(\mathbf{r}) = k\rho$, like ρ itself, must be N representable and since $\rho(\mathbf{r})$ is derivable from ψ (i.e., is N representable with respect to ψ), so is $\rho'(\mathbf{r})$, since it differs from $\rho(\mathbf{r})$ only in its normalization. If this were not the case, there is no demonstrated reason why one could not obtain a density for a non-integer number of electrons through multiplication of an N representable density by a suitable factor. Thus one would have to invoke the existence of Hamiltonians characterized not only by unknown forces but also by fractional numbers of particles. A closely related point is the demonstration that in the variation of

Table 1. Energy additivity and properties of HCH_2-CH_2B.

B	ΔE^a	$\Delta E(HCH_2\|)$	$\Delta E(\|CH_2B)$	$q(HCH_2\|)$	ρ	$\Delta\rho_b$
CH_3	–0.05	–10.8	+10.6	–0.017	0.2588	0.0001
NH_2	–0.09	–8.6	+8.1	+0.008	0.2640	0.0025
OH	–0.33	–2.6	+1.9	+0.047	0.2692	0.0020
F	–1.53	–0.3	–1.4	+0.066	0.2727	0.0028

[a]Energy changes are in kcal/mol, electron densities in atomic units (au). $\Delta E = E(HCH_2CH_2B) - (1/2)\{E(HCH_2CH_2H + E(BCH_2CH_2B)\}$ is calculated from the SCF energies.

Levy's functional the value of the undetermined multiplier μ, which is identified with the chemical potential and associated with the constraint on the normalization of ρ, is, at the point of variation, independent of this normalization (21).

In the same paper Stefanov and Cioslowski (6) compare the "shapes" of carbonyl oxygen atoms in different molecular environments. However, they do not base their study on a comparison of the C|O interatomic surfaces and their properties but rather they define "shape" in terms of a measure obtained from a "similarity index" that involves integration of ρ(**r**) over the common part of the basins of the oxygen atoms in two systems, a measure that is necessarily dominated by the maxima in the core densities that occur at the nuclear positions. Based on this study they conclude that "There is no correlation whatsoever between the shapes and the electronic properties of atoms in molecules." The statement is based on the finding that the properties of the carbonyl oxygen atom exhibit variations in the system R_1R_2CO for a wide range of substituents R_1 and R_2, a result that is in itself unsurprising. The net charges on the oxygen atom, for example, are found to vary between –1.18 e, for R_1 = OH and $R_2 = NH_2$, and –0.94 e for $R_1 = R_2$ = CN, a range of 0.24 e that is subjectively referred to as "broad" (6), but is in fact chemically anticipated.

While their study provides a useful comparison of the variation in the properties of the carbonyl oxygen atom through a series of compounds, it contributes nothing to the understanding of the physics that connects the properties of the surface of an atom to those of its basin. This is obtained through a study of the mechanics that relate the properties of the surface to those of the basin using eq. [3]. It requires the determination of the surface properties, as well as those of the basin (2, 3). The programs SURPROS and PROAIMV (22) enable one to determine the properties of both the interatomic surfaces bounding an atom and those of its basin. SURPROS determines the surface population, surface energy, surface force, and surface tension, for example, and relates each of these properties to the basin average of the associated commutator. It has recently been demonstrated that the quantum definition of pressure is determined by the virial of the force resulting from the electronic momentum flux through the surface of an open system, the surface virial being proportional to the pressure–volume product and equaling $-3pv$ (23). Clearly, the properties of the zero-flux surfaces are as important as those of the basins in determining the mechanics of an atom in a molecule, a point illustrated in the following examples.

Interdeterminancy and transferability of group properties

To illustrate the effect that the interdeterminancy of basin and surface properties required by eq. [3] has on the transferability of a group, consider the series of heteromolecules ACH_2CH_2B with A, B = H, CH_3, NH_2, OH, and F. Their energies are found to equal the arithmetic mean of the energies of the corresponding homomolecules ACH_2CH_2A and BCH_2CH_2B to within a few kcal/mol or less, computationally (see ΔE in Table 1 for the cases A = H) and experimentally. Examples from experiment are provided by A = H in the measured heats of formation of CH_3CH_2B that are found to differ from the arithmetic mean of the heats of formation of ethane and BCH_2CH_2B by +0.32, –0.53, and –0.17 kcal/mol, respectively, for B = OH, Cl, and I (24). The results reported here are obtained using a 6-311++G(3df,2p) basis set in a modified version of GAUSSIAN written by T.A. Keith that incorporates self-consistent virial scaling (SCVS) to ensure satisfaction of the virial theorem.[2] Values of 1×10^{-8} au are obtained for the |2T/V| ratios for the total system. The satisfaction of the atomic statement of the virial theorem is limited only by the accuracy of the numerical integrations, which, when summed over the atoms, yield errors in the total energies of less than 1.0 kcal/mol, as is illustrated below.

The groups $ACH_2|$ and $BCH_2|$ (the vertical bar denoting the defining zero-flux surface of the C—C bond) do undergo small changes in forming the heteromolecule, an amount of charge up to 0.07 e being transferred from one group to the other, Table 1. The electron population is necessarily conserved in forming the heteromolecule, and hence $q(BCH_2|) = -q(HCH_2|)$, but what is perhaps surprising is the extent to which other properties, such as the energy, are nearly similarly conserved. The apparent additivity of their energies is an example of compensatory transferability, the small change in the properties of one group induced by transfer being nullified by a compensatory change in its new neighbour. This behaviour has been illustrated before for the saturated hydrocarbons, which exhibit near-perfect additivity of the energy (10, 12), as exemplified here by the case A = H and B = CH_3 with an associated ΔE value of less than 0.1 kcal/mol. A methyl group $CH_3|$ from ethane withdraws 0.017 e from methylene in the $|CH_2CH_3$ group obtained from butane in their transfer to form propane and the energy of $CH_3|$ undergoes a decrease of 10.8 kcal/mol. However, the energy, as well as the electron population, of the methylene group changes by equal and opposite amounts for each methyl group attached to it, thereby yielding an apparent additivity of the group energies in the normal hydrocarbons in spite of the perturbations induced by their transfer. A methylene group bonded only to one methyl, as in butane, loses electronic charge and increases in energy by half the amount found for the single methylene group in propane. A methylene group bonded only to other methylenes, as first occurs in pentane, possesses a zero net charge and an energy equal to the additive increment for the methylene group. These values for the charge and energy changes are independent of basis set (10, 12).

The ΔE values in Table 1 are calculated from the total SCF energies while the changes in the group energies are obtained from differences of the appropriately summed atomic energies obtained by numerical integration. The small differences between the values of ΔE and the sum of the group energy changes, which have a maximum value of 0.4 kcal/mol, are a

[a]All quantities in atomic units save $\Delta\mathcal{V}_s$, which is in kcal/mol.

measure of the total error in the integration of the atomic energy contributions.

The changes to the group energies $\Delta E(H\text{-}CH_2|)$ and $\Delta E(|CH_2\text{-}B)$ decrease following B = CH_3, in spite of an increase in the transfer of electronic charge through the series. This occurs because, unlike the case B = CH_3 where almost the entire perturbation is restricted to the two carbon atoms sharing the new surface, the effect of the substitution of a more electronegative atom is increasingly transmitted to the hydrogens as well. Thus the compensatory behaviour is found within each group and dominates the change for B = F. In this case, the near-zero changes in $\Delta E(H\text{-}CH_2|)$ and $\Delta E(|CH_2\text{-}F)$ are the result of nearly equal and opposite changes in the energies of the carbon and hydrogen atoms within each group, in the amounts ±22 and ±13 kcal/mol, respectively, with the carbon being stabilized in methyl and destabilized in CH_2F.

The energy of a group is defined using the atomic statement of the virial theorem obtained from eq. [3] with $G = \mathbf{r}\cdot\mathbf{p}$ (2, 3). This theorem equates the energy of the atom to the negative of its electronic kinetic energy, $E(\Omega) = -T(\Omega)$ or to one-half of the atom's total virial, $E(\Omega) = (1/2)\mathcal{V}(\Omega)$. The total virial $\mathcal{V}(\Omega)$, is composed of two contributions, a basin virial and a surface virial,

$$[9]\qquad \mathcal{V}(\Omega) = \mathcal{V}_b(\Omega) + \mathcal{V}_s(\Omega) = -\int_\Omega \mathbf{r}\cdot\nabla\cdot\sigma(\mathbf{r})\, d\tau + \oint d\mathbf{S}(\mathbf{r}_s)\cdot\mathbf{r}_s\cdot\sigma(\mathbf{r}_s)$$

where $\mathbf{r}$ is referenced to the nucleus. $\mathcal{V}_s(\Omega)$ is the virial of the forces exerted on the surface of the atom or group, the surface energy. For systems in equilibrium geometries as considered here, the sum of the $E(\Omega)$ equals the total energy E of eq. [6]. In these examples of near-perfect additivity, one finds that the surface properties, including the surface energy, exhibit the same compensatory behaviour as do the energy and charge.

The largest perturbations incurred in the formation of ACH_2-CH_2B occur in the vicinity of the new C–C interatomic surface, the density in the surface attaining its largest value at the corresponding bond critical point, a value denoted by ρ_b. Table 1 lists the values of ρ_b for the heteromolecules with A = H, together with $\Delta\rho_b$, the latter quantity providing a measure of the extent to which the values of ρ_b differ from the mean of the homosubstituted values. These differences are small relative to the values of ρ_b and increase with the electronegativity of B. The value of $\Delta\rho_b$ for the formation of propane equals only 0.0001 au, and the new surface closely approximates the average of the two homomolecular surfaces, as reflected in the changes in the surface properties for each fragment, as listed in Table 2.

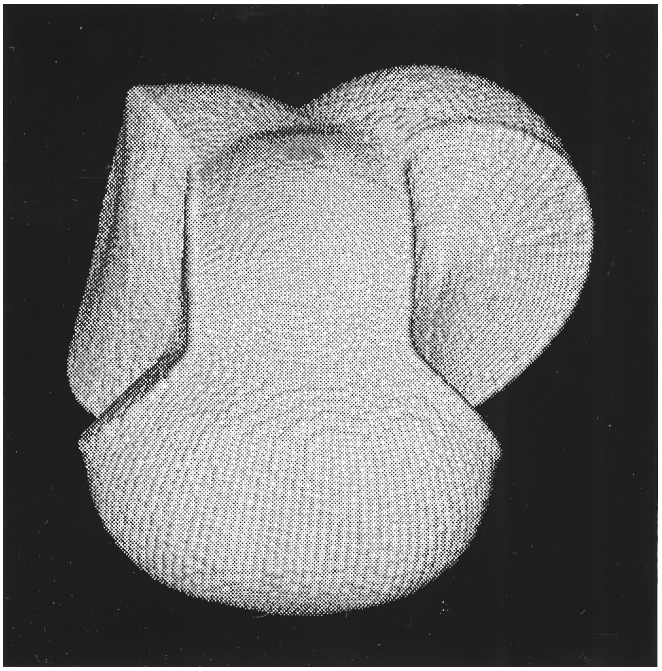
Among the properties determined in SURPROS is the surface integral of $\nabla\rho\cdot\mathbf{n}$, which should vanish for a proper open system, eq. [1]. The values obtained here are of the order of 1×10^{-4} au. The surface energy of $HCH_2|$ referenced to C, as determined by the surface virial $\mathcal{V}_s(HCH_2|)$, decreases by –0.0279 au (the quantity $\Delta\mathcal{V}_s(H)$ in Table 2) from its value in ethane upon transfer to propane, while the surface energy of $CH_3CH_2|$ referenced to the C of methylene undergoes an increase of +0.0267 au relative to its value in butane. These compensating changes result in a new surface whose energy $\mathcal{V}_s$, obtained by summing the two group contributions, differs by only –0.8 kcal/mol from the mean of the two original surface energies, the quantity $\Delta\mathcal{V}_s$ in Table 2. The addition of the two surface energies to obtain $\mathcal{V}_s$ yields the scalar product of the internuclear vector with the Ehrenfest force acting on the surface, the quantity $\mathbf{R}_{CC}\cdot\mathcal{F}_s$, the contribution of the C–C surface to the total energy of the molecule (3). Other surface properties change in a similar compensatory manner to yield small net displacements from their mean values. The integral of $\rho(\mathbf{r})$ yields $\mathcal{N}_s$, the average number of electrons per unit length, and the integral of the positive definite kinetic energy density $G(\mathbf{r})$ yields $\mathcal{G}_s$, the average electronic kinetic energy per unit length, a "kinetic force." These properties exhibit only small changes from their mean values, as listed under the headings $\Delta\mathcal{N}_s$ and $\Delta\mathcal{G}_s$, the value for $\Delta\mathcal{G}_s$ vanishing for B = CH_3. The ratio $\mathcal{G}_s/\mathcal{N}_s \sim 0.68$ au is the surface average of the kinetic energy per electron.

The data in Table 2 indicate that similar changes are found for the remaining molecules in this series, the magnitudes of $\Delta\mathcal{V}_s$, $\Delta\mathcal{N}_s$, and $\Delta\mathcal{G}_s$ increasing only slightly through the series. Such compensatory behaviour is not restricted to cases of near-perfect additivity. It suggests that a Le Chatelier-like principle underlies the observation of characteristic properties for functional groups, each group changing in response to the presence of another in such a way as to minimize the overall change. Because of the interdeterminancy imposed by eq. [3], this compensatory behaviour is observed in both the basin and surface properties. The same set of molecules, with calculations using the 6-311G** basis set, has been used to demonstrate compensatory behaviour in the source function for the density, the function that determines the contribution from a proper open system to the density at any point in space (25). The magnetic susceptibility and volumes have also been shown to be additive for this series of molecules, their values for the heteromolecule differing from the mean of the values for the homomolecules by 0.3 and 0.7% or less, respectively.

We conclude with a demonstration of how the properties of zero-flux surfaces play an important role in the synthesis of a polypeptide. Figure 1 is an example of an amino acid residue defined by its two amidic surfaces, the alanyl group $|HNC^{\alpha}H(CH_3)C(=O)|$. In general, such a residue will be denoted by |HNAC(=O)|, with A denoting the $C^{\alpha}HR$ group. Defining an amino acid residue in this manner maximizes its transferability from one polypeptide to another. The use of such fragments takes advantage of what we know to be experimentally true, that the geometries and other properties of the

© 1998 NRC Canada

Fig. 1. The alanyl group as an example of an amino acid residue prepared as a proper open system in the glycine mold. The group is represented by the 0.001 au envelope of the electron density and its intersection with the two zero-flux amidic surfaces. The methyl group and the hydrogen atom attached to C^{α} are in the foreground, the |NHA surface is on the left, and the AC(═O)| surface is on the right.



amino acid residues in general exhibit only small variations in different proteins. Knowledge of just how transferable these groups are had to await the theoretical studies (7, 8, 26), studies that demonstrated that the geometries, the electron density, and its related properties of properly defined residues are perhaps even more transferable than one might have hoped for. It was shown that glycyl and alanyl groups defined in one system were transferable without significant change, the lack of change in their properties being reflected in an almost perfect matching of their amidic surfaces in the new molecules, the predicted consequence of the interdeterminancy of basin and surface properties demanded by eq. [3].

Ideally, aside from any charge borne by the R group, an amino acid residue should be neutral if it is to represent a perfectly transferable repeating unit of a polypeptide. This limiting requirement of charge neutrality has an important consequence on the properties of its two bounding zero-flux surfaces, |NHA and AC(═O)|. Poisson's equation for the classical electrostatic potential, upon integration over an open region Ω, states that the net flux in the associated electric field **E**(**r**) through the surface must equal the contained net charge $q(\Omega)$ (27), eq. [10],

$$[10] \quad q(\Omega) = (-1/4\pi) \oint d\mathbf{S}(\mathbf{r}_s)\cdot\mathbf{E}(\mathbf{r}_s)$$

It follows from this result that if a residue possess a zero net charge even though its terminal groups |NH and C(═O)| bear net charges, then the flux of the field out of the residue through the |NHA surface will be equal and opposite to the flux into the residue through the AC(═O)| surface. The most

Fig. 2. A contour diagram of the electron density in triglycine, G′|NHCH$_2$C(═O)|G″ or G|G|G″. The bond paths and the two amidic surfaces are indicated. The symbols A′C(═O)| and *NHA denote the two sides of the amidic surface on the left of the diagram, while AC(═O)| and |NHA″ denote the two sides of the amidic surface on the right. One surface is rotated by 180° with respect to the other. The two surfaces are superimposable when rotated into alignment (as the reader can verify by making a copy and cutting the diagram). The outer contour has the value 0.001 au and the succeeding contours increase in value in the order 2×10^n, 4×10^n, and 8×10^n au with n beginning at –3 and increasing in steps of unity.

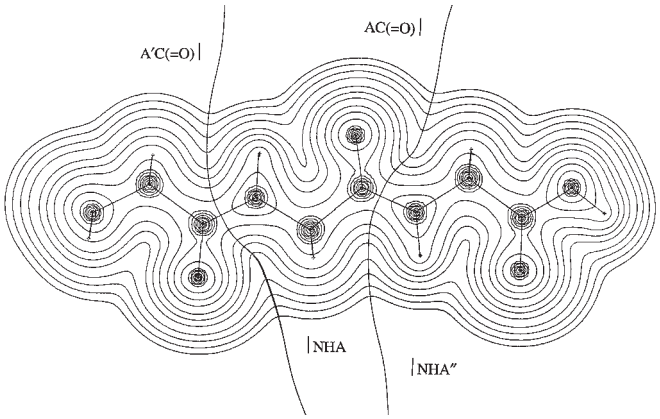


Table 3. Amidic surface properties of central glycyl group in Gly′|Gly|Gly″.[a]

direct way of meeting this requirement is for the two surfaces, each viewed with respect to their outwardly directed normal vectors, to be opposite sides of one, identical surface, one side being the template of the other, as illustrated in Fig. 2 for a glycyl residue in triglycyl. This is the very requirement needed to match the |NHA surface with the A′C(═O)| surface of the preceding residue and to match the AC(═O)| surface with the |NHA″ surface of the next residue in the chain. The molecule triglycyl is an example of the use of the "glycine mold," a tripeptide of the general form H$_2$NCH$_2$C(═O)|NHC$^{\alpha}$HRC(═O)|NHCHCO$_2$H and abbreviated to G′|NHC$^{\alpha}$HRC(═O)|G″. This mold is used to define each of the amino acid residues as a proper open system for any required set of dihedral angles ω, ϕ, and ψ (28). Aside from a reversal in the ordering of the N and C atoms sharing the surface, the two amidic surfaces bounding a given residue in the mold should exhibit identical properties if the residue is to match perfectly with its neighbouring residues upon transfer from the tripeptide to a polypeptide environment. (The two surfaces are not identical by symmetry since one faces the NH_2 terminus, while the other faces the CO_2H terminus.)

The data in Table 3 determine how closely the requirement of charge neutrality and its consequences on the amidic

© 1998 NRC Canada

surfaces is met by a glycyl residue defined in the glycine mold, Gly′|Gly|Gly″, for its "planar" minimum energy conformation (7) using a 6-311G** basis set. The net charge on the central glycyl residue, determined by numerical integration of the atoms in the residue, is –0.013 e with an integration error in the total population of the tripepetide yielding a charge of –0.0039 e. The net charge found here appears to be an upper limit for residues defined in the glycine mold, with some residues, the serinyl group for example, yielding net charges of 0.005 e. For the central residue |G| to be neutral and bounded by two identical amidic surfaces would require the two terminal groups G′| and |G″ to bear equal and opposite charges of magnitude 0.5 e. Their actual charges in the tripeptide are +0.506 e and –0.497, respectively.

The values of $\mathcal{N}_s$ for the two amidic surfaces differ by 0.002 au while the values of $\mathcal{G}_s$, the integrals of the kinetic energy density G(**r**), are identical to within the numerical accuracy, Table 3. It appears from a number of examples that the kinetic energy per electron in an amidic surface, the quantity $\mathcal{G}_s/\mathcal{N}_s$, is approximately unity, equal to 0.993 and 0.992 au in the present examples. The quantity $\mathcal{V}_s = \mathbf{R}_{CN} \cdot \mathcal{F}_s$, is a measure of the contribution of the surface energy of an amidic bond to the total energy of the tripeptide, contributions that differ by only 0.0018 au or 1.1 kcal/mol for the two amidic surfaces in triglycine, Table 3. The atomic virial theorem yields a still more stringent condition on the required similarity in the two surfaces if the central group is to be transferable without change. The condition is that the surface energy of the residue G′| referenced to the C atom in the first amidic bond equal the contribution to the surface energy of the central residue |G| referenced to the amidic carbon in the second amidic bond. Similarly, the contribution to the surface energy of the central residue |G| referenced to the N in the first amidic bond should equal the surface energy of the terminal group |G″ referenced to the N atom in the second amidic bond. The calculated differences are found to be 2.1 and –3.2 kcal/mol, Table 3, which sum to the difference in the two surface energies of –1.1 kcal/mol.

The Ehrenfest force exerted on the electron density in an atom is, as discussed above, given by the negative of the surface integral of the stress tensor. The Ehrenfest force exerted on the central residue |G| is the vector sum of the force exerted on each of its amidic surfaces S_i, denoted by $\mathbf{F}(G;S_i)$ in Table 3. Both contributions are not only of nearly equal magnitude, but both are equivalently directed, each lying along the associated C–N internuclear axes and directed into |G|. The similarities in the two amidic surfaces, as determined by a comparison of their properties including one as sensitive as the Ehrenfest force, are indeed remarkable, the differences being within or just above the present thresholds of numerical accuracy in the integrations.

Calculations are currently underway for all 20 of the amino acids clamped in the glycyl mold for conformations with the dihedral angles ψ and ϕ fixed at values characteristic of the α-helix. The determination of the surface properties for each residue determined in this manner will provide an accurate measure of its degree of transferability in terms of a matching of their respective surfaces when linked to form a polypeptide. The study of the ACH_2CH_2B systems demonstrates that the presence of a single methylene group can effectively buffer the effect of a changing substituent, the effect of the buffer being an additivity of properties and a minimization in the perturbation of the new C–C surface. A more enhanced buffering effect is operative for dampening the perturbations of the two amidic surfaces of an amino acid residue arising from changes in the side-chain R through the series of amino acids. Following glycine, the two surfaces are separated from the point of substitution by the group $||C^{\alpha}H\text{-}C^{\beta}H_2|$ in 16 of the amino acids. In two others, C^{β} is bonded to two other carbon atoms while in threonine it is linked to an oxygen. Only in proline and hydroxyproline is C^{α} linked to an atom other than hydrogen or carbon, specifically to nitrogen.

If the pairs of amidic surfaces for each residue exhibit the same degree of similarity as found for the glycyl group, then the residues defined as open systems can be combined without change and all properties of a polypeptide or a portion of it may be obtained with an acceptable accuracy by summation of the properties of each residue. One anticipates that deviations from charge neutrality, as caused by side-chain perturbations or changes in conformation, can in some instances reduce the degree of transferability, a reduction that can be quantitatively monitored by determining the degree of loss in the similarity in the two amidic surfaces. The ability to quantitatively determine this loss of similarity offers the possibility of establishing an empirical correction scheme for the transfer of a residue from the glycyl mold to its polypeptide environment.

Breneman et al. (29) also propose the construction of polyatomic molecules from fragments defined as proper open systems, fragments they label transferable atom equivalents or TAEs. They have developed an empirically based scheme for their assembly, which is done so as to allow each atom to self-consistently adjust to its new zero-flux surface in the polyatomic molecule. In this method, any adjustment of an atom to its new environment is restricted to a shift in its surface and its properties change only as a consequence of the resulting local change in the basin properties, a procedure that takes the interdeterminancy of basin and surface properties to its simplest extreme.

Conclusions

It is the physics of an atom in a molecule that provides the basis for the use of proper open systems in a theoretical synthesis of macromolecules. Stefanov and Cioslowski (6) state "Using the intuitively desirable 'building blocks of chemistry' and thus appealing in its simplicity and elegance, the aforementioned method is nevertheless theoretically flawed, as it invokes the assumption that the shape of an atom uniquely determines the electron density within its basin and consequently all of its electronic properties." This statement is made without reference to the atomic statement of the principle of stationary action, which provides the physics underlying the principle they criticize and whose existence proves their statement to be wrong. The "shape" of a proper open system is not an arbitrary quantity defined in terms of a crude similarity measurement as employed by them, but is instead precisely defined in terms of the zero-flux condition, eq. [1]. When so defined, the physics of the surface and its interrelation with the properties of the open system follows, as demonstrated here. There is nothing in the paper by Stefanov Cioslowski to dispute any of the published results regarding the use of properties of proper open systems in a theoretical synthesis of a macromolecule.

A capillary electrophoresis study of the synthesis and stability of 1,2-decanedisulfate, 1-hydroxy-2-decanesulfate, and 2-hydroxy-1-decanesulfate

Richard A. Walker, Aaron C. MacDonald, Tanya MacGillivray, D. Gerrard Marangoni, and Truis Smith-Palmer

Abstract: Capillary zone electrophoresis (CZE) was used to study the preparation of 1,2-decanedisulfate from 1,2-decanediol and determine the stability of the two-headed surfactant and the corresponding hydroxydecanesulfates under both acidic and basic conditions. The optimum buffer for the CZE determination was found to be diethylbarbiturate. Resolution of the hydroxydecanesulfate constitutional isomers was facilitated by the addition of magnesium ions. Decanedisulfate was stable in base but hydrolyzed in acid. The hydroxysulfates hydrolyzed much more rapidly, and in both acid and base. Mechanisms were postulated based on differential rates of formation and hydrolysis of the hydroxydecanesulfate constitutional isomers.

Key words: capillary zone electrophoresis, decanedisulfate, hydroxydecanesulfate, hydrolysis, surfactant.

Résumé : On a utilisé l'électrophorèse en zone de capillarité (EZC) pour étudier la préparation du décane-1,2-disulfate à partir du décane-1,2-diol et pour déterminer la stabilité de cet agent de surface à deux têtes et des hydroxydécanesulfates correspondants tant dans des conditions acides que basiques. On a déterminé que le diéthylbarbiturate est le tampon optimal pour la détermination de l'EZC. La résolution des isomères de constitution de l'hydroxysulfate est facilitée par l'addition d'ions magnésium. Le décanedisulfate est stable en milieu basique, mais il s'hydrolyse en milieu acide. Les hydroxysulfates s'hydrolysent beaucoup plus facilement, tant en milieu acide que basique. On propose des mécanismes qui tiennent compte des différences dans les vitesses de formation et d'hydrolyse des isomères de constitution de l'hydroxydécanesulfate.

Mots clés : électrophorèse en zone de capillarité, décanedisulfate, hydroxydécanesulfate, hydrolyse, agent de surface.

Introduction

Despite the large numbers of applications of surfactants in the consumer products and petroleum industries, the basic design of the surfactants used (a hydrocarbon tail and a polar head group) has remained relatively constant. The synthesis of novel detergents is important in developing improved technical processes and in academic studies of micelle formation. As part of this initiative, alkanedisulfate surfactants have been synthesized from 1,2-alkane diols (1, 2). The ease of their preparation and subsequent purification is of great interest, as is their stability in acidic and basic media. The latter is especially important in the light of previous studies on the acid hydrolysis of alkanesulfates (3–7) and disulfates (2), and the fact that the resultant alcohols would be highly surface active.

The hydrolyses of alkanesulfates have been followed using a variety of techniques, including colorimetric methods (7, 8), acid–base titrations (6), and the use of radioactively labelled sulfate (4). Recently, alkanesulfates have been analysed using capillary zone electrophoresis (CZE) (9–12). Alkanesulfates do not strongly absorb UV or visible wavelengths of light and so are most conveniently detected during CZE by indirect photometric methods. These methods require that there is an absorbing species in the buffer that can be replaced by the ion of interest. When this occurs, there is a drop in absorbance, which generates a negative peak. Indirect detection is optimum when the mobility of the analyte is close to that of the background ion (13). The electrophoretic mobilities of long-chain alkanesulfates are low because of their size, and thus they are best analysed using a positive power supply (detector at the cathode). They are carried to the detector by the electroosmotic flow, but are separated on the basis of their mobility away from the detector. Nielen (9) used 6 and 12 mM diethylbarbiturate (BARB) buffer at pH 8.6 and a voltage of + 25 kV to separate C2–C12 alkanesulfates. The limits of detection (LODs) were $(1–2) \times 10^{-5}$ M. Gibbons and Hoke quantitatively determined sodium dodecanesulfate (SDS) using 5 mM dihydroxybenzoate (DHB) at pH 8.1 (10). Chen and Pietrzyk used 5 mM salicylate in phosphate buffer at pH 7 to examine mixtures of C6–C14 alkanesulfates (11). Resolution was significantly increased by the addition of magnesium ions. The corresponding alkanesulfonates were found to give responses at similar

migration times (t_m's), and this suggests that the sodium naphthalenesulfonate – acetonitrile buffer (SNS) (pH 10) used for the separation of alkane sulfonates (14, 15) might also be used for the analysis of alkanesulfates. Nonaqueous buffers (methanol–acetonitrile and methanol–water) have also been used to separate mixtures of alkane sulfates and sulfonates (12). Although the separation times were somewhat higher, so was the separation efficiency.

In this paper, we describe our studies of alkanedisulfate surfactants and the corresponding hydroxysulfate species. CZE was used for the separation of the alkanedisulfates from the corresponding hydroxyalkanesulfates, and from inorganic anions. The constitutional isomers of the hydroxyalkanesulfates were identified by ^{13}C NMR and were separated by CZE after the addition of magnesium ions to the buffer. The stability of the compounds to acid and base hydrolysis was then investigated, as it is of great importance in determining possible future applications. It may also have a bearing on their synthesis and the subsequent work-up.

Experimental

Reagents

Acetonitrile, magnesium chloride, sodium hydroxide, and sodium carbonate were Baker Analysed, J.T. Baker Chemical Co., Phillipsburg, N.J. Sodium 2-naphthalene sulfonate (90%) and 1,2-decanediol were from Aldrich, and diethylbarbituric acid and chlorosulfonic acid were from BDH. Methanol (HPLC grade) and carbon tetrachloride (reagent grade) were from Fisher Scientific, and ethanol (absolute) was from Consolidated Alcohols. All water used was 10 MΩ cm resistivity (Millipore 4000S purification system).

Ethyl sulfate was prepared by adding 6 mL ethanol to 6.5 mL of chlorosulfonic acid, then stirring for 10 min. Additional ethanol was added and the white precipitate of ethyl sulfate was filtered off and dried.

Surfactant preparation

1,2-Decanediol (1 mol) was dissolved in the chosen solvent (usually 50 mL carbon tetrachloride), cooled in an ice bath, and the chosen volume (generally 1.2 mol) of chlorosulfonic acid was added dropwise. The reaction mixture was stirred for 10 min and in some cases an equal volume of 95% cold ethanol was added. The solution was then neutralized with 18 M aqueous sodium hydroxide or saturated aqueous sodium bicarbonate and the precipitated surfactant collected and vacuum dried. Solutions of product were prepared by dissolving 0.083 g in 25 mL water. For analysis by CE, 25 μL of these solutions was added to 0.4 mL water.

Instrumentation

CZE was carried out on a Waters Quanta 4000 capillary electrophoresis system using a 75 μm × 60 cm fused silica capillary (Polymicro Technologies Inc., Phoenix, Ariz.), hydrostatic injection mode for 30 s, a positive power supply, and indirect photometric detection at 254 nm. The data were collected using LabCalc software (Galactic, Salem, N.H.) with 1 V equal to 1 AU, and multiplied by a factor of –1 to invert the peaks. All NMR were run on a Bruker 200 MHz spectrometer. Surfactant samples were analysed using D_2O as the solvent; diol was run in $CDCl_3$.

Analyses

The buffers for the alkanesulfate analyses were prepared as follows. DHB: 2,4-Dihydroxybenzoic acid (0.0771 g) was dissolved in 15 mL methanol, 40 mL water was added, the pH was adjusted to 8.1, and the volume was made up to 100 mL (10). BARB: Diethylbarbituric acid (0.1108 g) was stirred in 60 mL water, the pH was adjusted to pH 8.6, and the volume was made up to 100 mL (9). SNS: 2-Naphthalenesulfonic acid (0.2442 g) was added to 30 mL acetonitrile, the volume was made up to 100 mL with water, and the pH was adjusted to 10 (15). The capillary was rinsed with 0.1 M NaOH (2 min), water (2 min), and buffer (2 min) prior to each run. Mg-BARB: BARB was prepared as above and $MgCl_2$ was added to 50 mL of the buffer. The pH was readjusted and the buffer filtered. The capillary was rinsed with 1 M HCl (0.5 min), water (2 min), 0.1 M NaOH (2 min), water (2 min), then buffer (2 min).

All solutions were passed through a 0.45 μm Millipore filter and sonicated for 5 min before use. LODs were determined using a k value of 3.

Hydrolyses

A 20 mL aliquot of surfactant solution was pipetted into a stoppered flask (a balloon on a syringe needle through the serum cap allowed for expansion due to temperature) in a water bath and the sample was allowed to equilibrate at the chosen temperature. An equal volume of 0.1 M H_2SO_4 or 0.1 M NaOH was added to the surfactant solution. Aliquots (20 μL) were taken and added into 0.5 mL water. These samples were then analysed by CZE using the BARB buffer as described above. All water was carbonate-free.

Results and discussion

Our initial aim was to check the purity of alkanedisulfates, which we had prepared as described in the literature (1, 2) by the reaction of diol with chlorosulfonic acid. We were interested in determining the amounts of chloride and sulfate ions that were present, and if any singly sulfated product (hydroxyalkanesulfate) had been formed. Although methods have been described for determining alkanesulfates using liquid chromatography (ref. 16, and refs. therein) and ion chromatography (17, 18), CZE is now also being used, as described in the introduction. It is much more convenient to set up a new CZE method than a new HPLC method, as the latter method could require a new column and would use much larger quantities of solvent. In addition, the times reported for the CZE analyses tended to be shorter. As an alkanedisulfate has a higher charge to mass ratio than the corresponding hydroxyalkanesulfate and thus a larger electrophoretic mobility, it would be expected that they should be easily separated by CZE. In the systems we examined, choride and sulfate anions were also present. Three different buffers were examined for the separation of 1,2-dodecanedisulfate, and the hydroxydodecanesulfates. Test samples included SDS to facilitate comparison of our results with those previously reported. We assumed that hydroxydodecanesulfate would migrate very close to SDS. Typical electropherograms are shown in Figs. 1–3. Both DHB and BARB

Fig. 1. Electropherogram of 3×10^{-5} M sodium dodecanesulfate (1), 3×10^{-5} M sodium hydroxydodecanesulfate (2), 4×10^{-6} M sodium 1,2-dodecanedisulfate (3), and 20 μg mL^{-1} sulfate (4) in 5 mM 2,4-dihydroxybenzoate in 5% v/v methanol, pH 8.1 in a 60 cm × 75 μm i.d. fused silica capillary, with 30 kV applied giving 11 μA, and indirect detection at 254 nm.

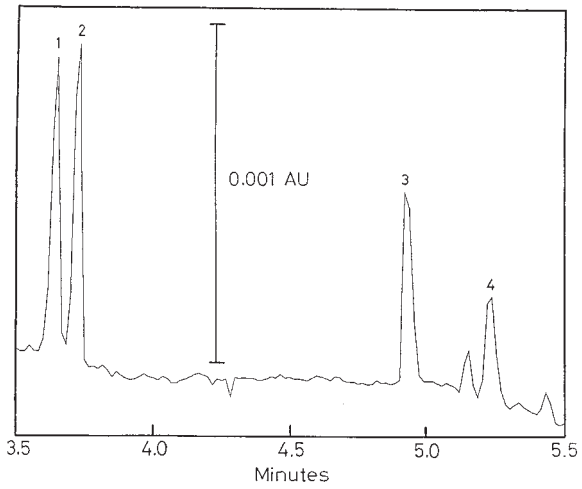

Fig. 2. Electropherogram of 3×10^{-5} M sodium dodecanesulfate (1), 3×10^{-5} M sodium hydroxydodecanesulfate (2), 4×10^{-6} M sodium 1,2-dodecanedisulfate (3), and 20 μg mL^{-1} sulfate (4) in 6 mM diethylbarbiturate, pH 8.6 in a 60 cm × 75 μm i.d. fused silica capillary, with 25 kV applied giving 8 μA, and indirect detection at 254 nm.

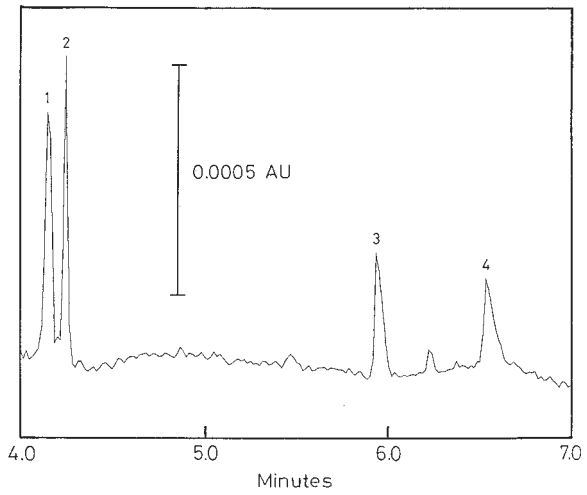

were found to be useful buffers for this separation. These buffers were easy to prepare and, providing the capillary was purged regularly with base (10), the t_m's for the compounds of interest were short and reproducible. The use of BARB as the buffer led to somewhat longer t_m's but the LODs were slightly better (4×10^{-6} M for hydroxydodecanesulfate as compared to 6×10^{-6} M in DHB, and 1×10^{-6} M for dodecanedisulfate as compared to 2×10^{-6} M in DHB). In addition, a peak due to sulfate showed in both these systems, but was cleaner and further removed from the disulfate peak when BARB was used

Ethyl sulfate			68.78	

[a] Samples run for 1000 scans

as the buffer (Fig. 2). Chloride was found to have the same migration time as sulfate in these systems. The use of SNS buffer was not as satisfactory. It was much harder to adjust the pH correctly, and the pH was not easily maintained. The t_m's were longer than those for the other two buffers and the LODs were much higher (3×10^{-5} M for hydroxydodecanesulfate and 2×10^{-5} M for dodecanedisulfate). Note that higher concentrations of surfactants were used to obtain Fig. 3 than to obtain Figs. 1 and 2; the higher concentrations were necessary in light of the poorer detection limits, especially that for the disulfate. The use of a 5 mM solution of the buffer was briefly investigated but the base line was considerably more noisy.

Analysis of a series of disulfate surfactant preparations by CZE (BARB buffer) indicated that the purity of our preparations was not consistent. The decanedisulfate (DDS) products in particular were shown to often contain hydroxydecanesulfate (HDS) in significant amounts, and thus it was the preparation of DDS that we chose to investigate further. Standard curves were prepared for DDS (t_m = 6.1 min) and HDS (t_m = 4.6 min) using peak area (A_p) divided by t_m versus concentration as μg/mL. They were fitted with the lines $A_p/t_m = 2.258e^{-4} + 3.339e^{-4}$[DDS] ($R^2$ = 0.986) and $A_p/t_m = -3.663e^{-4} + 1.858e^{-4}$[HDS] ($R^2$ = 0.998), respectively. The fact that the slope of the curve for DDS is about double that for HDS after corrections for t_m's have been made can be attributed to DDS

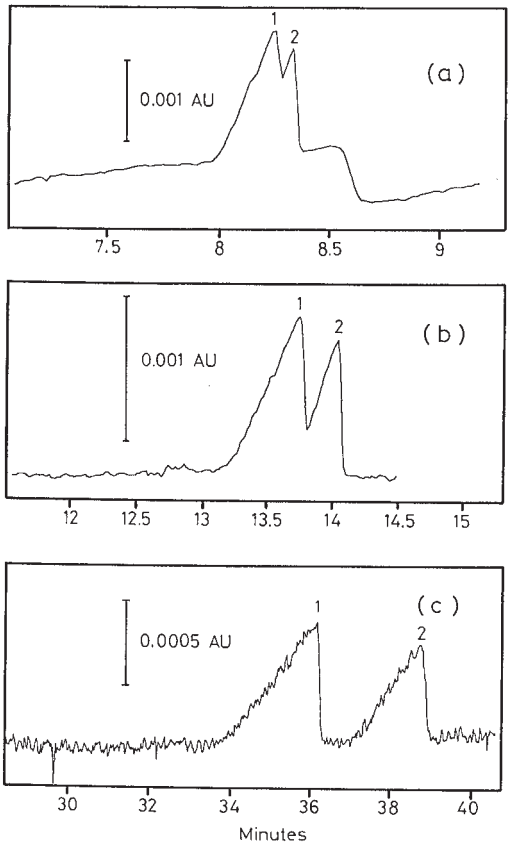

Fig. 5. Plot of migration time versus concentration of magnesium chloride added to BARB buffer for sodium 1-hydroxy-2-decanesulfate (○) and sodium 2-hydroxy-1-decanesulfate (□).

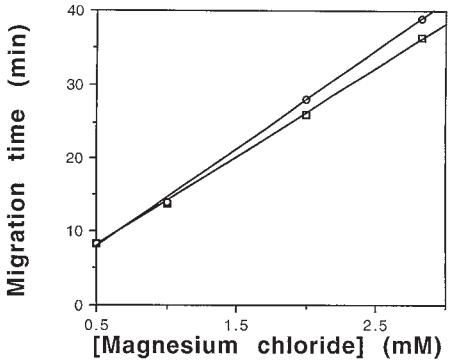

Fig. 6. Newman projections of the conformations of sodium 1-hydroxy-2-decanesulfate (*a*) and sodium 2-hydroxy-1-decanesulfate (*b*) that would lead to epoxide formation.

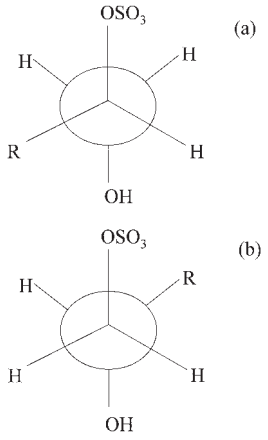

being able to replace twice the number of chromophores because of the second sulfate.

Further syntheses were then carried out under a variety of conditions (changing solvent, stirring time, ratio of chlorosulfonic acid to diol, and work-up procedure). ^{13}C NMR of the product showed the presence of two hydroxydecanesulfates in many cases. Table 1 contains the chemical shifts of the high-frequency carbons of the two isomers compared to those of the diol and the disulfate. By comparison of these shifts, 1-hydroxy-2-decanesulfate (1-OH-2-DS) could easily be distinguished from 2-hydroxy-1-decanesulfate (2-OH-1-DS). These isomers have the same charge and mass, but could be separated by CZE after the addition of magnesium ions to the BARB buffer (Fig. 4). It had been demonstrated previously by Chen and Pietrzyk (11) that addition of cations to a salicylate buffer drastically affects the electroosmotic flow. It is believed that divalent cations have a strong exchange selectivity toward silanol groups. This reduces the negative charge at the capillary wall and prevents the formation of a high concentration of hydrated positive ions at the capillary surface. As a result, the electroosmotic flow is weaker. Separation of isomers is achieved because of small changes in their electrophoretic flow due to differences in their hydrodynamic radii. At low EOF, such differences have more of an effect on a separation. Figure 4 shows three electropherograms with increasing magnesium chloride concentration. As the magnesium concentration was raised, the EOF decreased and resolution of the constitutional isomers of HDS increased. As shown in Fig. 5, there is a linear relationship between the concentration of magnesium chloride used and the migration time of the isomers. For complete resolution, run times as long as 40 min were necessary. Spiking a mixture of the constitutional HDS isomers with 2-OH-1-DS showed that 1-OH-2-DS migrated faster than its isomer. We attribute the different migration rates to differences in their shapes and thus in their hydrodynamic radii. The asymmetry of the peaks can be attributed to the differences in mobilities between the surfactant ions and the diethylbarbiturate ions (19).

In the original preparation described by El Sawy et al. (2), ethanol was used in the reaction work-up before the addition of base. This can lead to the formation of ethyl sulfate, which shows in electropherograms at 5.9 min, coming just before DDS. Ethyl sulfate is easily identified by NMR, with its distinctive downfield peak at 68.78 ppm, and is susceptible to base hydrolysis. We found that stirring a 5 mM solution of ethyl sulfate in 1 M NaOH for 2.5 h at room temperature was enough to destroy all the ethyl sulfate. Stirring in 18 M NaOH led to complete hydrolysis after 20 min.

There was often much more 1-OH-2-DS and 2-OH-1-DS mix present in the product when the ethanol was not added. Ethanol reacts with excess chlorosulfonic acid. Thus acid hydrolysis of the newly formed DDS may be prevented; neutralization with base was usually carried out slowly. In some preparations 1-OH-2-DS and 2-OH-1-DS were formed, but from other preparations we obtained only 2-OH-1-DS. One trend seemed to indicate that two isomers were most often obtained when neutralization was carried out with bicarbonate rather than hydroxide, and we felt that basic hydrolysis might also be involved.

By using CE to follow the reactions, the stability of DDS and HDS to acid and base was further assessed. Attempts to hydrolyze 5.7 mM DDS in 0.1 M NaOH over a 72 h period at 90°C were unsuccessful. This lack of reaction was attributed to the electrostatic repulsion between the charged head groups of the surfactant and the hydroxide anion. However, under the same conditions, 6.5 mM HDS was completely hydrolyzed after 2 h as indicated by the disappearance of its peak in the electropherogram. The hydrolysis of 1-OH-2-DS and 2-OH-1-DS results in the production of diol, which migrates with the water peak. Use of a Mg-BARB buffer to follow the hydrolysis indicated that there was a differential rate of hydrolysis for one isomer over the other. The 1-OH-2-DS isomer was hydrolyzed 20% more rapidly than 2-OH-1-DS. This was explained by invoking an epoxide as the intermediate, as has been done previously in sugar chemistry (20). The conformation from which the 1-OH-2-DS isomer will form an epoxide can be visualized as being more stable than the corresponding conformation of the 2-OH-1-DS isomer (Fig. 6).

Although stable in base, DDS did hydrolyze in acid. However, the hydrolysis does not occur nearly as quickly as was reported by El Sawy et al. (2). Using hours rather than minutes for the times listed by these authors would make them more realistic.

The hydroxydecanesulfates are also unstable to acid. This explains why only a very small peak appears at their characteristic t_m in the electropherograms of samples taken during the acid hydrolysis of DDS. When Mg-BARB is used as the buffer, it can be seen that both 1-OH-2-DS and 2-OH-1-DS are present, but that the 1-OH-2-DS constitutional isomer is present in a higher proportion. We would expect that hydrolysis of the primary sulfate of the DDS would be less hindered, giving 1-OH-2-DS, and for the same reason we would expect 2-OH-1-DS to be hydrolyzed more rapidly than is 1-OH-2-DS.

Conclusions

BARB was demonstrated to be the most useful CZE buffer for analysing the product mixtures. The addition of magnesium ions to the BARB buffer allowed for the separation of 1-OH-2-DS and 2-OH-1-DS, which are constitutional isomers, and thus have the same mass and charge. The amount of magnesium added determined the degree of resolution. Buffer samples containing 1.5 mM magnesium chloride gave base-line resolution.

The preparation of DDS and dodecanedisulfate often led to significant amounts of the corresponding hydroxysulfate side product, depending on the chosen reaction and work-up conditions.DDS was found to be stable in base at 90°C over several hours. However, acid hydrolysis at this temperature produced decanediol and a small amount of 1-OH-2-DS and 2-OH-1-DS, with the former isomer predominating.

1-OH-2-DS and 2-OH-1-DS were unstable in base. The former hydrolyzed more rapidly, and this was attributed to its forming an epoxide intermediate from a less sterically hindered conformation than would the latter.

Control of base in the work-up procedure seems to be a problem in view of the isomer ratios formed. The 1-OH-2-DS isomer would react most quickly and thus be removed first. In some preparations, only the 2-OH-1-DS isomer is present, but never just 1-OH-2-DS. If acid hydrolysis was occuring to any significant extent, we would expect the 1-OH-2-DS isomer to be more significant.

Competitive study of Meisenheimer rearrangement in a substrate tertiary amine with allylic and propargylic moieties

Krishna C. Majumdar and Gour H. Jana

Abstract: A number of allyl aryl propargyl amines **3a**–**3f** were synthesized in 68–82% yield. These tertiary amines were then treated with one equivalent of *m*-chloroperoxybenzoic acid (*m*-CPBA) to give products **5a–5f** in 79–90% yields arising out of the Meisenheimer rearrangement of the allyl aryl amine moiety accompanying the amine oxide rearrangement of the aryl propargyl amine moiety.

Key words: Meisenheimer rearrangement, [2,3] sigmatropic shift, amine oxide, propargyl amine, allyl amine.

Résumé : On a synthétisé un certain nombre d'allyl aryl propargylamines **3a–3f** avec des rendements allant de 68 à 82%. Par traitement de ces amines tertiaires à l'aide d'un équivalent d'acide *m*-chloroperbenzoïque (*m*-ACPB), on obtient les produits **5a–5f** avec des rendements variant de 79 à 90%; ils résultent d'un réarrangement de Meisenheimer de la portion allyl (aryl) amine qui accompagne la transposition de l'oxyde d'amine de la portion aryl (propargyl) amine.

Mots clés : réarrangement de Meisenheimer, déplacement sigmatropique [2,3], oxyde d'amine, propargylamine, allylamine.

[Traduit par la rédaction]

Introduction

[2,3] Sigmatropic rearrangements are anionic equivalents of the Cope rearrangement and, like [3,3] sigmatropic rearrangements, are not confined to carbon systems but can also involve many hetero systems. The construction of a five-membered pyrrole ring in 2,3-disubstituted indoles through rearrangement of aryl propargyl amine oxides was developed by Thyagarajan and co-workers (1). It was proposed that a [2,3] sigmatropic shift is followed by a unique Claisen rearrangement in which a [3,3] shift takes place through two heteroatoms to give indoles in almost quantitative yields. The formation of indoles occurs readily in one step by simply stirring a solution of aryl propargyl amine with one equivalent of *m*-chloroperoxybenzoic acid (*m*-CPBA) at room temperature without isolation of the labile amine oxide. The initial step in the reorganization of the aryl propargyl amine oxide is also the same [2,3] shift as in the case of the Meisenheimer rearrangement of allyl aryl amine oxides (2). Extensive studies on the Meisenheimer rearrangement have been made and accumulated knowledge suggests that formation of tertiary amine oxides of N-allyl tertiary amines prevails qualitatively in competition with the epoxidation. However, epoxidation occurred with *m*-CPBA in non-allylic systems (3). We have recently observed that the presence of *m*-chlorobenzoic acid in the reaction mixture does not interfere with the Meisenheimer rearrangement. It has also been reported (4) that the amine oxide rearrangement of *N*,*N*-bis(4-aryloxy-2- butynyl)anilines with one equivalent of *m*-CPBA furnishes only one product, 1-(4-aryloxy-2-butynyl)-2-(aryloxymethyl)-3-(*m*-chlorobenzyloxymethyl)indoles, in high yields. This observation indicates that the [2,3] shift is very specific towards one reacting propargyl moiety and the other reacting propargyl moiety is completely unaffected and is appended on the indole nitrogen. A competitive study (5) of the Claisen rearrangement of substrates containing an allyl ether and a propargyl ether moiety in the same molecule was made earlier. However, such a competitive study has not yet been reported for the case of an amine oxide rearrangement. This prompted us to undertake a study of competitive amine oxide rearrangement in a substrate tertiary amine with allylic and propargylic moieties, e.g., N-allyl, N-propargyl anilines (**3a**–**3f**). Here we report of the results of this investigation.

The starting materials (**3a**–**3f**) chosen for this study were prepared by treatment of the appropriate N-propargyl anilines(**1a–1f**) with appropriate allylic halides (**2a–2f**) in refluxing acetone in the presence of anhydrous potassium carbonate in 68–82% yields (Scheme 1). These were characterized by their elemental analyses and various spectral data.

Results and discussion

The amine oxide **4a** was prepared by slow addition of one equivalent of *m*-CPBA in chloroform to a solution of **3a** in same solvent at 0–5°C during 20 min. The formation of a highly polar amine oxide was indicated by thin-layer chromatography (TLC). A new product (a viscous oil) was obtained in 89% yield when the reaction mixture was kept at room

temperature for 8 h. The ^1H NMR spectrum of the product showed a two-proton multiplet at δ 5.20–5.22 and a one-proton multiplet at δ 5.80–6.20 due to the presence of a terminal olefin CH_2═CH function. The IR spectrum clearly indicated the absence of any carbonyl group. No change was observed when this product was refluxed in dry methanol. This product was characterized as **5a** from its elemental analysis and spectral data. It was surprising to note that there was no indication of the formation of an indole derivative such as **6a** that could have been formed by the participation of the propargyl moiety in the rearrangement. Formation of a single product encouraged us to treat each of the substrates **3b–3f** with one equivalent of *m*-CPBA and only the Meisenheimer products **5b–5f** were obtained in 79–90% yields (Scheme 2).

Formation of **5a**–**5f** from **4a**–**4f** is easily explicable by a [2,3] shift in the allyl aryl amine oxide of **4a**–**4f**. Thus, it is seen that the Meisenheimer rearrangement of the allyl aryl amine moiety is preferred over the rearrangement of the allyl propargyl amine oxide moiety. Formation of **5b** and **5f** from **3b** and **3f**, respectively, showed that the course of the reaction is independent of the substituents R^1 and R^2. Suprafacially, a five-membered transition state (6) is more favoured in the allyl system (Fig. 1) than in the propargyl system (Fig. 2) because two consecutive *sp* hybridized carbon atoms are present in the latter. Also, rotation of the C_1—C_2 single bond in the allyl

© 1998 NRC Canada

system decreases the distance between the amine oxide oxygen atom and the C_3 carbon atom, which helps to form a more favourable low-energy five-membered cyclic transition state. Such a competition was reported by Cresson and Atlani (5) for an aliphatic [3,3] sigmatropic rearrangement and the allyl vinyl ether moiety was shown to undergo [3,3] sigmatropic rearrangement in preference to the propargyl vinyl ether moiety.

From this study it is interesting to note that when both N-allyl and N-propargyl moieties are present in the same molecule of an N-alkylaniline-N-oxide, either of which can participate in the [2,3] sigmatropic rearrangement, it is the allyl group that preferentially migrates rather than the propargyl group. Such a system, where an allyl and a propargyl group can compete for the same N-oxide function, has not been studied so far. The preference exhibited by the allyl group is noteworthy. This preference is not restricted only to the [3,3] sigmatropic rearrangement (5) but is also observed in the case of a [2,3] sigmatropic rearrangement.

Experimental section

Methods and materials

UV absorption spectra ware recorded in absolute ethanol. IR spectra were run as thin films. ^{1}H NMR spectra were determined for solutions in $CDCl_3$ with $SiMe_4$ as internal standard at the Indian Institute of Chemical Biology, Calcutta. *J*-Values are given in hertz (Hz). Elemental analyses and mass spectral determinations were carried out by the Regional Sophisticated Instrumentation Centre (Central Drug Research Institute), Lucknow. Pet. ether refers to the petroleum ether of boiling range 60–80°C.

General procedure for the synthesis of tertiary amines 3a–3f

A mixture of N-propargyl anilines **3a–3f** (1.5 mmol), appropriate halides **2a–2g** (1.5 mmol), and anhydrous potassium carbonate (2 g) was refluxed in dry acetone (100 mL) for l0 h. The reaction mixture was then cooled, filtered, and the solvent was removed. The residual liquid was chromatographed over silica gel. Compounds **3a–3f** were obtained when the column was eluted with pet. ether.

Compound **3a:** yield 78%, viscous liquid; UV λ_{max}: 229 (log ε 4.21), 287 (log ε 2.03); IR (thin film): 2900, 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$, 100 MHz) δ: 3.92–4.00 (m, 4H), 4.44–4.60 (m, 4H), 5.80–5.88 (m, 2H), 6.72–7.40 (m, 13H); MS (*m*/*z*): 451, 453, 455 (M^+). Anal. calcd. for $C_{26}H_{23}Cl_2NO_2$: C 69.03, H 5.09, N 3.10%; found: C 69.41, H 5.49, N 3.21%.

General procedure for the oxidation and rearrangement of 3a–3f with *m*-CPBA

m-CPBA (1 mmol, 0.38 g, 45%) in chloroform (25 mL) was slowly added to a well-stirred solution of tertiary amines **3a–3f** (1 mmol) dissolved in chloroform (25 mL) at 0–5°C over a period of 20 min. The reaction mixture was stirred at room temperature for an additional 8 h, after which it was washed with a 10% solution of potassium carbonate (3 × 50 mL) and dried (Na_2SO_4). Removal of the solvent gave a crude mass that was purified by column chromatography over silica gel. Compounds **5a–5f** were obtained when the column was eluted with pet. ether.

Compound **5a:** Yield 89%, viscous liquid; UV λ_{max}: 224 (log ε 4.32), 227 (log ε 2.75); IR (thin film): 2940 and 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$, 100 MHz) δ: 4.04–4.16 (m, 4H), 4.48–4.64 (m, 3H), 5.20–5.52 (m, 2H), 5.82–6.20 (m, 1H), 6.72–7.40 (m, 13H); MS (*m*/*z*): 467, 469, 471 (M^+). The crystal structure of 3,4,7,8-tetramethylglycoluril

Sengen Sun, James F. Britten, Christopher N. Cow, ChØrif F. Matta, and Paul H.M. Harrison

Abstract: The crystal structure of 3,4,7,8-tetramethylglycoluril (**5**) was determined by X-ray diffraction. The structure reveals a hydrogen-bonding motif in the crystal lattice that differs from that present in related glycolurils. The two sides of each molecule form part of two independent, but parallel, infinite helical chains. These chains are formed by the NH donor and C═O acceptor on one side of a glycoluril molecule, forming H-bonds to two different molecules at adjacent positions within the helix. On the other side of the same molecule, a similar motif generates another helix of opposite helicity to the first. The molecule has a crystallographic plane of symmetry through the two bridgehead carbon atoms and the two bridgehead methyl groups, which are *syn*-periplanar. Thus, **5** is similar to 3,4-dimethylglycoluril (**3**), but differs from some glycolurils, where there is a significant dihedral angle between the two bridgehead-to-bridgehead substituent bonds. Bond lengths and angles in **5** resemble those reported for **3**, but bond lengths around the bridgehead positions are slightly lengthened relative to **3**.

Key words: glycoluril, 1,2,5,8-tetramethyl-2,6,7,8-tetraazabicyclo[3.3.0]octane-3,7-dione, X-ray diffraction, crystal structure, hydrogen-bond array.

Résumé : Faisant appel à la diffraction des rayons X, on a déterminé la structure cristalline du 3,4,7,8-tétraméthylglycolurile (**5**). La structure révèle que le réseau cristallin comporte un motif de liaison hydrogène différent de celui présent dans de glycoluriles apparentés. Les deux côtés de chacune des molécules font partie de deux chaînes hélicoïdales infinies indépendantes, mais parallèles. Ces chaînes sont formées par le NH donneur et un C═O accepteur d'un côté d'une molécule de glycolurile qui créent des liaisons hydrogènes avec deux molécules différentes dans des positions adjacentes à l'intérieur de l'hélice. De l'autre côté de la même molécule, un motif similaire génère une autre hélice dont l'hélicité est inverse de celle de la première. La molécule possède un plan de symétrie cristallographique passant par les deux atomes de carbone en tête de pont et les deux groupes méthyles attachés à la tête de pont qui sont *syn*-périplanaires. Le composé **5** est donc semblable au 3,4-diméthylglycolurile (**3**), mais il diffère de quelques glycoluriles dans lesquels on retrouve un angle dièdre important entre les liaisons portées par les atomes en tête de pont. Les longueurs et les angles des liaisons du composé **5** ressemblent à ceux rapportés pour le composé **3**, mais les longueurs des liaisons autour des positions en tête de pont sont légèrement plus longues que les valeurs correspondantes du composé **3**.

Introduction

The glycolurils[2] (e.g., **1**, Fig. 1) have been extensively investigated since their discovery by Schiff (1) in 1877. Interest in these bicyclic molecules has stemmed from the potential use of **1** as a fertilizer (2); the use of nitro derivatives (e.g., **2**) as explosives (3); the psychotropic activity of alkylated glycolurils (e.g., **3**) (4); and the use of 3,4,7,8-tetraacetylglycoluril (**4**) as a bleaching activator (5, 6). A substituted glycoluril forms the basis of the IodoGen method for radio-iodination of biomolecules (7), while other derivatives form molecular clips and cages, which exhibit interesting binding features for organic molecules (8–11) as well as metal ions (9). In some cases these molecular architectures act as catalysts (9, 10), or as models for biological processes, e.g., the photosynthetic reaction centre (12). Cucurbituril provides another example of a synthetic receptor based upon the glycoluril framework (13–15). As a result of the widespread interest in the

[2] In IUPAC nomenclature, **1** is 2,4,6,8-tetraazabicyclo[3.3.0]octane-3,7-dione. Glycolurils have also been named as derivatives of perhydroimidazo[4,5-d]imidazol-2,5-dione. We have chosen to use the simpler, trivial name and used the numbering system associated therewith. Compound **5** is thus 1,6,7,8-tetramethylglycoluril, although herein we have chosen the 3,4,7,8-tetramethylglycoluril designation, since this maintains consistency with acyl derivatives of **5**, where the numbering is unambiguous.

glycolurils, a variety of crystal structures have been reported for the parent glycoluril (16, 17); for simple alkyl (4, 18–20), nitro (21), and amino (22) derivatives of the bicyclic framework; for several of the synthetic receptors (9, 11, 23); and recently for glycoluril bound to streptavidin (24). In some of these structures, a crystallographic plane of symmetry through C(7), C(8), and the two angular substituents (R_3 and R_4 in Fig. 1) is found, and R_3 and R_4 are thus *syn*-periplanar. In contrast, many other glycolurils exhibit a twist, such that the R_4-C(7)-C(8)-R_3 dihedral angle is non-zero. However, the factors leading to this twist are not entirely clear and are not solely due to the extent of substitution, since 7,8-diaminoglycoluril is twisted (22), while the highly substituted receptors exhibit variable twist (25, 26). Recently, Nolte has shown that two conformations of a synthetic receptor, which vary in their twist, can cocrystallize (27).

We have used 3,4,7,8-tetramethylglycoluril (**5**) as a template to effect intramolecular crossed-Claisen-like condensations between two acyl units (28, 29) in a manner that mimics some of the features of polyketide and fatty acid biosynthesis (Scheme 1). Template **5** can be sequentially acylated twice on the two NH sites to give, for example, acetylglycoluril **6**, then diacetylglycoluril **7**. Compound **7** undergoes an efficient

[a] Symmetry transformation used to generate equivalent atoms: $x, -y + 1/2, z$.

intramolecular rearrangement to give acetoacetylglycoluril **8**, which can be further transformed and cycled through further rounds of acylation and condensation.

To determine whether twisting of the R_4-C(7)-C(8)-R_3 dihedral angle occurs in these derivatives, and to evaluate how this dihedral angle and other molecular features affect the efficiency of the key rearrangement step (**7** to **8**), we undertook a study of the crystal structure of **5** by X-ray diffraction. These results are reported herein; the crystal structures of acetyl derivatives **6** and **7** and other related molecules will be reported shortly.[3]

Results

Glycoluril **5** was prepared, as previously described (30), and crystallized by slow cooling from ethanol. Colourless orthorhombic needles were obtained. The diffraction pattern was obtained on a Siemens SMART CCD/P4/RA diffractometer at –60°C. The structure was solved by direct methods, as implemented in the Siemens SHELXTL program. Table 1 gives crystal data and structure refinement details.

Final atomic coordinates and equivalent isotropic displacement parameters are given in Table 2*a*, while Table 2*b* gives anisotropic displacement parameters. Table 3 provides bond lengths and bond angles for **5**. Figure 2 shows ORTEP drawings of the molecule in three orthogonal views, along with the numbering scheme. A stereoview of the crystal packing is shown in Fig. 3, while Fig. 4 shows two selected views that emphasize the nearest neighbour hydrogen-bond interactions around individual glycoluril molecules.

[3] Supplementary material has been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

Discussion

The presence of multiple NH and C═O sites in glycoluril and its derivatives allows for a variety of different arrays of H-bond donor-acceptor interactions within the crystal lattices. In glycoluril **1** there are four NH donors and two carbonyl acceptors. Each NH site forms a single H-bond to the carbonyl oxygen atom of an adjacent molecule, while each C═O group forms two H-bonds, one to the NH site on *the same* adjacent molecule, thus forming an eight-membered ring comprised of two H-bonds, the other to an NH site on a different neighbour (16, 17). The overall effect is to generate extended two-dimensional nets of molecules with each molecule forming eight hydrogen bonds to four adjacent molecules within the net, although more complex arrays are also possible (16). A similar network exists in 7,8-dimethylglycoluril (**9**) (18). Substitution of alkyl groups onto the nitrogen atoms of glycoluril alters the number of NH donor sites, resulting in different hydrogen-bond arrays: 3,4-dimethylglycoluril (**3**) was cocrystallized with water, which participates in the observed three-dimensional H-bonding network (4). This network no longer involves the cyclic H-bonded structure found in **1**. In contrast, 3,4-diethylglycoluril crystallizes as a dimeric ribbon in a one-dimensional array (19). The eight-membered cyclic structure containing two H-bonds between each pair of molecules is present in 1,4-dinitroglycoluril, which thus also forms a one-dimensional H-bonded array (21). Yet more motifs are found in other disubstituted glycolurils (20), including those where both the glycoluril and the substituents participate in H-bonding (22, 23).

In contrast to the hydrogen-bonding motifs described above, 3,4,7,8-tetramethylglycoluril (**5**) forms extended two-dimensional hydrogen-bonded sheets in the crystal lattice (Fig. 4*a*). The NH of one molecule forms H-bonds to the C═O of another, the adjacent NH of which in turn H-bonds to yet another molecule. Each hydrogen bond exhibits *d*(H···O)

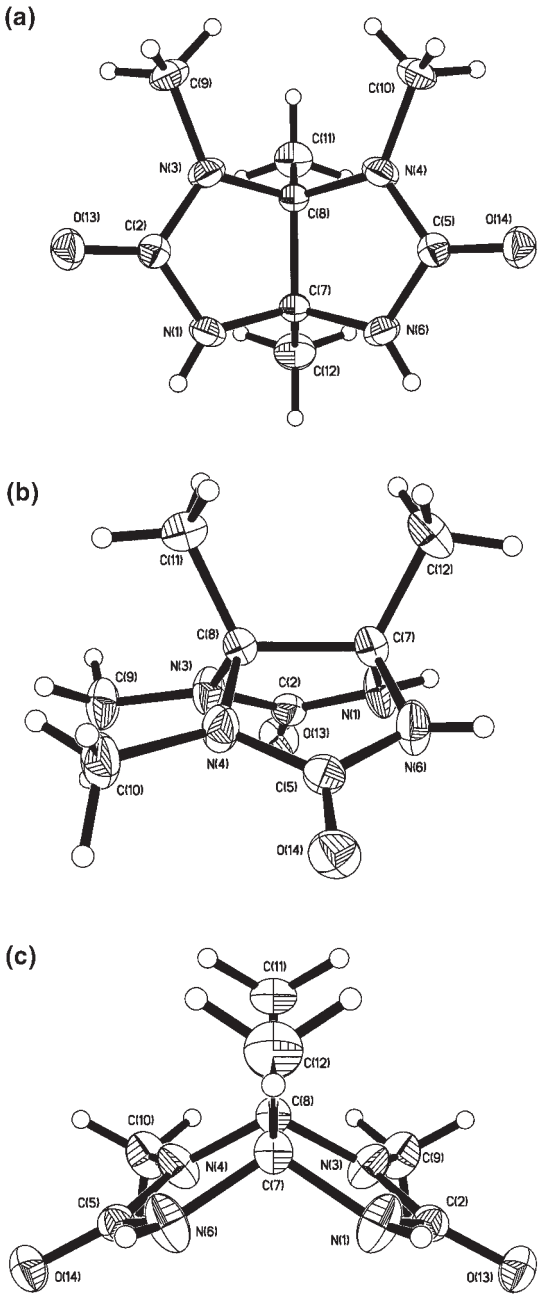
Fig. 2. Three orthogonal views of glycoluril **5**. Atoms 4, 5, 6, 10, and 14 are related by the mirror plane to atoms 3, 2, 1, 9, and 13, respectively (50% thermal ellipsoids).



2.18 Å, *d*(H-N) 0.824 Å, angle (N-H···O) 171.5°, and angle (H···O═C(2)) 135.3°. Formation of an eight-membered ring structure with two H-bonds between two molecules does not occur. The NH and C═O groups on the other side of each glycoluril molecule form a similar linear network of H-bonds parallel to the first but of opposite helicity. The net effect is to generate a two-dimensional sheet comprised of an infinite series (along the *b*-axis) of parallel helices (along the *c*-axis), with a helical pitch between molecules of 180°. A view down one such helix is shown in Fig. 4*b*. There are no H-bonding interactions in the third dimension (*a*-axis); rather, there are (probably weak) interactions between the carbonyl oxygen atoms and both the *N*-methyl (*d*(O···H) 2.41 Å) and the bridgehead methyl (*d*(O···H) 2.41 Å) hydrogen atoms. Each sheet is inverted relative to the two adjacent sheets. This structure therefore represents the first example to our knowledge of this hydrogen-bond motif within a member of the glycoluril family.

As with previously reported structures of glycolurils, **5** possesses a *cis*-fused bicyclic structure, with the two *N*-methyl groups on the same side of the molecule, in accord with the structure proposed by Biltz (30) and with our analysis of the NMR spectrum. The N-C-N bond angles are 108.6(1) and 111.8(2)° (cf. ca. 109 and 115° in **3** (4)). The five-membered ring is close to planar (mean and maximum deviations 0.013 and 0.020 Å, respectively) (cf. within 0.014 Å in **9** (18), within 0.030 Å in **3** (4)). Using the RING program (31), the puckering amplitude *Q* (32) was found to be only 0.032 Å. The angle between the mean planes of the two rings is 117.9° (cf. 121.4° in **3** (4) and 115° in **9** (18)). As with glycolurils **3** and **9**, the molecule possesses a mirror plane through the two bridgehead carbons (C(7) and C(8)) and the two attached methyl groups (C(11) and C(12)). The dihedral angle C(11)-C(8)-C(7)-C(12) is thus 0°. Therefore **5** is unlike several of the glycolurils for which X-ray data is available, where this angle reaches values as high as 22–24° (27, 33). It should be noted that all four N atoms, but no ring C atoms, have significant thermal parameters perpendicular to the respective ring planes (Fig. 2*c*). Thus the possibility that the observed structure is the average of two slightly but oppositely twisted conformations cannot be rigorously ruled out.

All the hydrogen atoms within the structure were refined from the experimental data by least-squares fitting. As in 7,8-dimethylglycoluril (**9**) (18), both sets of bridgehead methyl hydrogens are rigidly oriented *anti* and *gauche* to the bridgehead–bridgehead bond, resulting in minimal nonbonded interactions between hydrogens on these two opposing methyl groups (d(H(11A)···H(12A)) 2.41 Å); however, C(12) is relatively free to vibrate along the symmetry plane, as evidenced by the thermal ellipsoids (Fig. 2*b*), unlike C(11), which is locked in place by nonbonded interactions with methyl groups C(9), C(10), and C(12). In contrast, the *N*-methyl hydrogen atoms show disorder, and two major conformations, related by ca. 60° rotation around the N—CH_3 bond, are approximately equally populated (Table 2*a*, H(9)A,B,C where H9B eclipses the N(3)-C(8), and H(9)D,E,F where H9F eclipses the N(3)-C(2) bonds).

The bond lengths and angles for **5** are similar to **3** (4), although the bonds around and between the bridgehead carbon atoms are lengthened by 0.015–0.018 Å (2σ ca. 0.010 Å) compared to **3**. While these small differences are only marginally significant, the observation that *all* these bonds are longer than in **3** is consistent with increased steric bulk imposed by methyl substituents at the bridgehead positions compared to hydrogens. There are corresponding small decreases in the MeN-CO and C═O bond lengths, but the HN—CO bond length is unchanged. Bond angle differences between **3** and **5** correspondingly reflect these effects.

Conclusions

The crystal structure of 3,4,7,8-tetramethylglycoluril (**5**) exhibits a two-dimensional hydrogen-bonded array, which is distinct from previously reported glycoluril structures. The two

sides of the molecule each form part of two independent infinite helical chains. These chains are formed by the NH donor and C═O acceptor on each side forming H-bonds to two different molecules at adjacent positions within the helix, giving rise to this novel array within the glycolurils. The individual molecules resemble those of 7,8-dimethylglycoluril, with small differences that can be related to the effect of the additional two methyl groups at the bridgehead positions. This system provides a base structure with which to compare acyl derivatives of **5**. These results will be communicated shortly. Crystallographic data have been deposited as supplementary material.

Iodine charge-transfer salts of bis(1,2,3,5-diselenadiazolyl) diradicals; solid-state characterization of the thiophene-bridged derivative $[(Se_2N_2C)C_4H_2S(CN_2Se_2)][I]$

A. Wallace Cordes, Robert C. Haddon, Robin G. Hicks, Richard T. Oakley, and Kristen E. Vajda

Abstract: Electroreduction of the 2,5-thiophene-bridged bis(1,2,3,5-diselenadiazolylium) salt [T-2,5-Se][SbF_6]$_2$ in acetonitrile, at a Pt wire and in the presence of iodine, affords a highly conductive ($\sigma = 10^2$ S cm^{-1} at 293 K) 1:1 charge-transfer (CT) salt [T-2,5-Se][I], the crystal structure of which has been determined by single-crystal X-ray diffraction. The crystals belong to the orthorhombic space group *Fm*2*m*, $a = 3.544(2)$, $b = 10.9808(16)$, $c = 31.464(5)$ Å, $V = 1224.5(7)$ Å^3. The structure consists of perfectly superimposed π-stacks of molecular units bridged by columns of disordered iodines. This packing motif is similar to that of the related 1,3-benzene-bridged derivative [1,3-Se][I], but the lateral intermolecular Se···Se interactions linking adjacent π-stacks are considerably shorter, indicative of a more isotropic electronic structure for [T-2,5-Se][I]. Magnetic susceptibility measurements on [T-2,5-Se][I] nonetheless indicate a phase transition to a diamagnetic state near 200 K, behaviour similar to that observed for [1,3-Se][I]. The electronic structures and transport properties of the two compounds are discussed in the light of extended Hückel band-structure calculations.

Key words: diselenadiazolyl, diradical, charge-transfer salt, magnetic susceptibility, crystal structure.

Résumé : L'électroréduction du sel [T-2,5-Se][SbF_6]$_2$ [bis(1,2,3,5-disélénadiazolylium) avec pont 2,5-thiophène] en solution dans l'acétonitrile, au niveau d'un fil de Pt et en présence d'iode, conduit à un sel de transfert de charge 1:1, [T-2,5-Se][I], de conductivité élevée ($\sigma = 10^2$ S cm^{-1}, à 293 K) dont on a déterminé la structure cristalline par diffraction des rayons X par un cristal unique. Les cristaux sont orthorhombiques, groupe d'espace *Fm*2*m*, avec $a = 3{,}544(2)$ Å, $b = 10{,}9808(16)$ Å, $c = 31{,}464(5)$ Å et $V = 1224{,}5(7)$ Å^3. La structure est formée d'empilements π parfaitement superposés d'unités moléculaires pontées par des colonnes désordonnées d'iodes. Ce motif d'empilement est semblable à celui observé avec le dérivé apparenté [1,3-Se][I] comportant un pont 1,3-benzène; toutefois, les interactions latérales intermoléculaires Se···Se reliant les empilements π adjacents sont beaucoup plus courtes et ceci indique une structure électronique plus isotrope dans le cas du [T-2,5-Se][I]. Des mesures de susceptibilité magnétique effectuées avec le [T-2,5-Se][I] suggèrent toutefois la présence d'une transition de phase vers 200 K qui conduit à un état diamagnétique; ce comportement est semblable à celui observé avec le composé [1,3-Se][I]. On discute des structures électroniques et des propriétés de transport des deux composés à la lumière de calculs étendus de Hückel sur la structure de bande.

Mots clés : disélénadiazolyle, diradical, sel de transfert de charge, susceptibilité magnétique, structure cristalline.

[Traduit par la rédaction]

Introduction

The benzene-bridged bis-(1,2,3,5-dithiadiazolyl) diradicals [1,4-S] **1** and [1,3-S] **2** (E = S, Se) form highly conductive charge-transfer salts with iodine (1, 2). At room temperature the structures of these compounds consist of perfectly superimposed and evenly spaced π-stacks, interspersed by columns of disordered iodines. At lower temperatures charge-density wave (CDW) driven instabilities cause the structures to collapse into diamagnetic, semiconducting states. The susceptibility of these uniformly spaced stacks to anion-assisted (3) CDW distortions was attributed to their relatively one-dimensional electronic structures. In the case of [1,4-S][I] the nature of the charge-density state was characterized by low-temperature X-ray diffraction. From these measurements the degree of bandfilling ($f = 3/8$) was determined, and a simple model of the consequent low-temperature superlattice was proposed (2).

Our attempts to suppress the metal–insulator transition T_{MI} in these π-stacked CT salts has been based on the design of materials with more isotropic electronic structures. Towards this end we have prepared iodine CT salts of the diselenadiazolyl analogues [1,4-Se] and [1,3-Se] (**1** and **2**, E = Se), in the belief that lateral interstack interactions would be enhanced (4). However, although the crystal structures of the sulfur- and selenium-based systems [1,4-E][I] and [1,3-E][I] (E = S, Se), respectively, are similar, the selenium variants actually show *higher* T_{MI} temperatures. We have also pursued sulfur-based diradicals constructed using heterocyclic bridges such as furan **3** and pyridine **4**, but the study of these latter materials is complicated by their tendency to form CT salts with different (notably 2:1) diradical:iodine ratios (5). Herein we extend both these avenues to the thiophene-bridged bis(diselenadiazolyl) [T-2,5-Se] **5** (E = Se). The preparation and solid-state characterization of its 1:1 iodine CT salt is described, and its structure and transport properties compared to those of the closely related 1,3-benzene-bridged CT salt [1,3-Se][I].

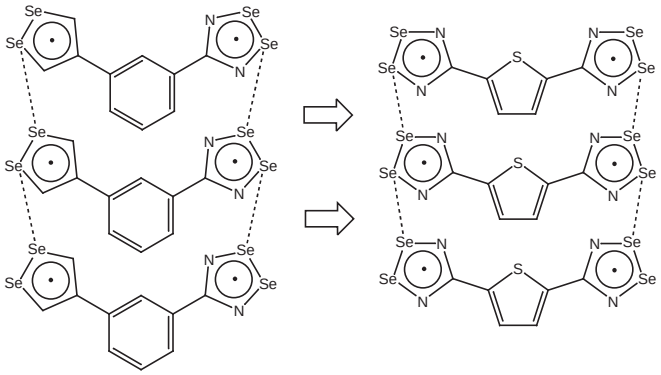
The design strategy behind this compound originated from the desire to adjust, but not alter, the "nested spoon" packing pattern exhibited by the π-stacks in [1,3-Se][I]. As illustrated in Scheme 1, the ca. 120° angle subtended between the two CN_2Se_2 rings in each molecule limits intermolecular Se···Se interactions in [1,3-Se][I]; the "bite" angle is too severe. It was hoped that replacement of a benzene ring by a thiophene heterocycle would produce a wider (>120°) "bite" angle, and hence allow for a closer approach of neighbouring CN_2Se_2 rings and enhanced lateral Se···Se contacts. If such a modification of crystal structure could be induced, then its effect on structural stability, i.e., resistance to CDW distortions, could be tested.

Results and discussion

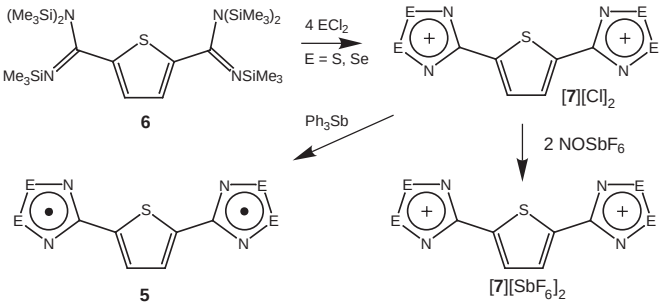
Preparation and crystal growth

We recently reported the synthesis of the thiophene-bridged bis(dithiadiazolyl) [T-2,5-S] **5** (E = S) by the condensation of the bifunctional persilylated carboxamidine **6** with SCl_2, and reduction of the corresponding bis(dithiadiazolylium) dication **7** with triphenylantimony (6). The diradical was purified by fractional sublimation in vacuo (Scheme 2). Like **1** and **2** (E = S), [T-2,5-S] reacts with iodine in hot chlorobenzene to afford a material that, on the basis of mass balance, appears to be

Scheme 1.



Scheme 2.



a 1:1 salt, i.e., [T-2,5-S][I]. Proper characterization of this compound was, however, precluded by its thermal decomposition during attempts to sublime it. The selenium analogue [T-2,5-Se] can be prepared in crude form using a similar synthetic sequence, and although the neutral material itself cannot be purified (it decomposes on sublimation), its iodine CT salt can be prepared by electroreduction of the dication [T-2,5-Se]$^{2+}$ (as its hexafluoroantimonate salt) in the presence of (excess) iodine. This technique, which we first developed for the generation of the CT salts [1,4-Se][I] and [1,3-Se][I], requires currents of <5 μA and growth periods of 10–14 days. Under these conditions, along with Pt wire electrodes, acetonitrile as solvent, no supporting electrolyte, and a strictly oxygen-free atmosphere, small needles of [T-2,5-Se][I] can be grown. This material exhibits a pressed pellet conductivity of ca. 10^2 S cm^{-1} at room temperature.

Crystal and molecular structure of [T-2,5-Se][I]

Numerous electrocrystallization experiments were performed, and many crystals of [T-2,5-Se][I] were examined; relatively few, however, were suitable for X-ray work. The structural determination reported here suffers from a paucity of data with significant intensity due to the thin dimensions of the crystals and the face-centered noncentric space group. Four data sets were collected; the data set used measured four octants of data for the face-centered orthorhombic *Fm*2*m* lattice. The nitrogen and carbon atoms were refined with isotropic displacement parameters because of the low reflection:parameter ratio, and the hydrogen atoms were constrained to idealized positions. Atomic coordinates for [T-2,5-Se][I] are listed in Table 1, and pertinent intramolecular bond distances are summarized in Table 2. Figure 1 shows an ORTEP picture of the asymmetric unit with the atom numbering scheme. All of the atoms of the

[T-2,5-Se] molecule lie on a mirror plane, and the thiophene S-atom is on the intersection of two mirror planes. The iodine atom is in a general position with an occupancy of 0.25.

From a purely molecular perspective the structural parameters of the [T-2,5-Se] molecule hold few surprises. The Se—Se distance is very similar to those reported for [1,4-Se][I] and [1,3-Se][I], and intermediate in length between those observed in fully oxidized $[RCN_2Se_2]^+$ cations (7) and reduced $[RCN_2Se_2]_2$ radical dimers (8, 9). The balance favours the neutral state nominally, suggestive of less than a full positive charge on the molecule as a whole (less than one half positive charge per CN_2Se_2 ring). While the space group of [T-2,5-Se][I] differs from that of [1,3-Se][I] (*Ima*2) the packing patterns displayed by the two structures (Fig. 2) are very similar, i.e., perfectly superimposed π-stacks with the same "nested spoon" arrangement of adjacent columns. In both cases the iodine atoms are disordered in columns that bridge neighbouring π-stacks in a head-to-head sense. This mode of ion pairing is very typical of both dithia- and diselenadiazolylium halides (1, 2, 10, 11).

When viewed from a direction perpendicular to the stacking axis (Fig. 3), the differences between the two structures become more apparent. In [T-2,5-Se][I] the molecular units are bisected by two mirror planes, so that the two CN_2Se_2 rings and the thiophene bridge are rigorously coplanar. By contrast the [1,3-Se] molecules in [1,3-Se][I] lie on a single mirror plane that bisects the benzene ring. As a whole the molecule is far from planar; the plane of the two CN_2Se_2 rings makes a dihedral angle of 16.7° with the plane of the benzene ring. Despite this difference, the π-stack repeats in [T-2,5-Se][I] (3.544(2) Å) and [1,3-Se][I] (3.543(2) Å) are virtually identical, both being longer than that found in [1,4-Se][I]

Fig. 1. ORTEP drawing of the asymmetric unit in [T-2,5-Se][I], showing atom numbering.

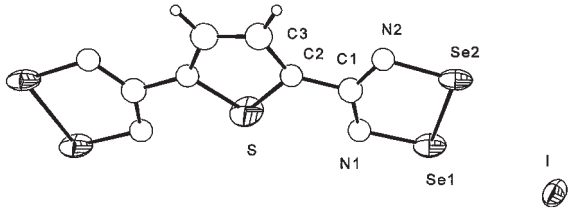

Fig. 2. Packing of [T-2,5-Se][I] (above) and [1,3-Se][I] (below), viewed down the stacking direction. Broken lines indicate lateral intermolecular Se···Se contacts.

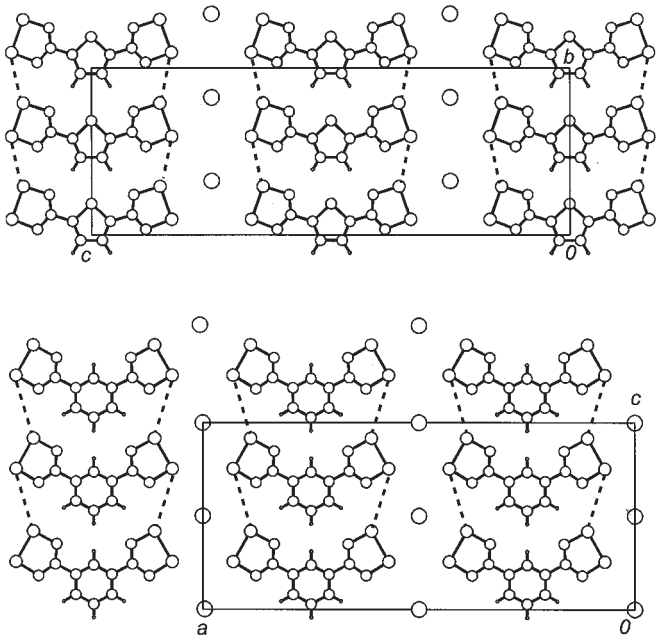

(3.5006(15) Å). Figure 2 also provides a comparison of the registry of the π-stacks. While the molecular units in adjacent columns in [1,3-Se][I] are approximately in register, those in [T-2,5-Se][I] are perfectly out of register. This difference, coupled with the tighter "nested spoon" packing found for [T-2,5-Se][I], affords shorter and more effective intercolumnar Se···Se contacts. In [1,3-Se][I], the closest Se···Se approach (4.323(6) Å), between molecules in the same "layer" of adjacent columns, is well outside of the Se···Se van der Waals separation of 3.8 Å (12). By contrast, in [T-2,5-Se][I], each selenium is laced (Fig. 2) by much shorter (3.832(7) Å) contacts to two neigbouring rings in adjacent stacks.

Magnetic measurements

Figure 4 shows the magnetic susceptibility behaviour of the [T-2,5-Se][I] as a function of temperature. The material is essentially diamagnetic at low temperatures; a Curie fit to the data below 100 K led to a value of $\chi = -249$ cgs ppm mol^{-1} for the diamagnetic term, in good agreement with estimates based on the Pascal scheme, and $\theta = 2$ K. The concentration of unpaired spins was found to be 0.05%. Paramagnetism, which can be associated with the onset of metallic conductivity (1, 2), develops near 200 K, and continues to rise up to 400 K, the limit of the experiment. Qualitatively this behaviour is very

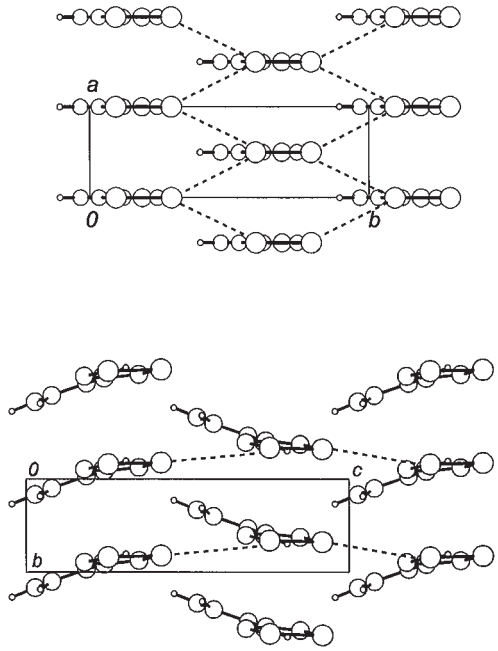
Fig. 3. Packing of [T-2,5-Se][I] (above) and [1,3-Se][I] (below), viewed perpendicular to the stacking direction. Broken lines indicate lateral intermolecular Se···Se contacts.

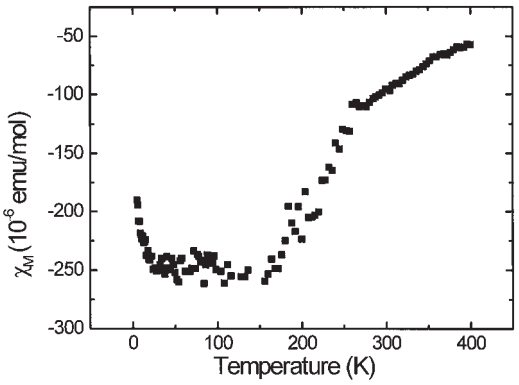


similar to that displayed by [1,3-Se][I]. It also shows a collapse from weakly paramagnetic to a diamagnetic, semiconducting state near 200 K.

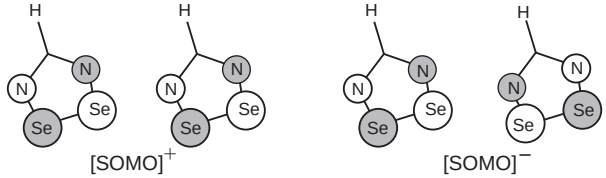
Band-structure calculations

To assess the relative magnitude of orbital interactions between the CN_2Se_2 rings along and across the stacks of [T-2,5-Se][I] and [1,3-Se][I], we have carried out a series of extended Hückel band calculations on models related to the two crystal structures. The model focusses on simplified two-dimensional unit cells consisting of two adjacent HCN_2Se_2 radicals located at positions provided by the X-ray data. The consequent crystal orbitals (COs) are accordingly grouped into pairs, the most relevant being those arising from the in-phase and out-of-phase combinations of the singly occupied molecular orbital of the radicals, i.e., $[SOMO]^+$ and $[SOMO]^-$ (Scheme 3), which form the basis for the conduction band of the solid. Figure 5 illustrates the dispersion of these two COs along a^* and b^* for [T-2,5-Se][I], and along b^* and c^* for [1,3-Se][I]. Because both cells are orthorhombic these reciprocal space directions correspond exactly to real space interactions parallel and perpendicular to the π-stacking direction. As expected, given the superimposed nature of the stacking and the nearly identical cell repeats, dispersion along the stacking direction is large, nearly 4 eV for both structures. Lateral dispersion is much smaller for both structures, again as expected, but there are now notable differences in the degree of splitting between the two COs. As a result of the greater packing efficiency found for [T-2,5-Se][I], CO dispersion approaches 0.3 eV, a value similar to that found in many classical organic conductors (13). By contrast, lateral dispersion in [1,3-Se][I] is barely 0.05 eV, reflective of the weak intermolecular interactions apparent from the X-ray structure.

Fig. 4. Magnetic susceptibility of [T-2,5-Se][I], as a function of temperature.



Scheme 3.



Summary and conclusion

Modification of the shape of the 1,3-benzene-bridged diradical [1,3-Se] by replacement of the bridging benzene ring by thiophene, to generate [T-2,5-Se], has allowed the preparation and comparison of two approximately isostructural iodine charge-transfer salts. The packing efficiency of [T-2,5-Se][I], as indicated by the size of intermolecular Se···Se interactions and the consequent degree of crystal orbital dispersion, is significantly better than that of [1,3-Se][I]. However, while lateral interactions have been improved, the structure of [T-2,5,-Se][I] is still highly one-dimensional; crystal dispersion along the stacking direction is an order of magnitude stronger. Even though a reasonable network of secondary, intercolumnar interactions, one far better than in [1,3-Se][I], has been developed, the overriding factor determining structural stability remains the highly developed interactions along the stack.

Experimental section

General procedures and starting materials

Selenium powder (Aldrich), chlorine gas (Matheson), and $NOSbF_6$ (STREM) were obtained commercially and used as received. Iodine (Fisher) was resublimed before use. The solvents acetonitrile (HPLC grade), benzonitrile, and chlorobenzene were all purified by distillation from P_2O_5. The persilylated thiophene-2,5-bis(carboxamidine) **6** was prepared as previously described (6) by the reaction of $LiN(SiMe_3)_2{\cdot}Et_2O$ (14) with 2,5-dicyanothiophene (15), followed by treatment of the intermediate bis(*N*-lithio amidinate) with chlorotrimethylsilane. Selenium tetrachloride was prepared according to a standard literature method (16). Chemical analyses were performed by MHW Laboratories, Phoenix, Ariz. Infrared spectra of the iodine CT salt could not be obtained because of excessive scattering of the incident radiation by the sample (as a nujol mull).

Preparation of [T-2,5-Se][SbF_6]$_2$

The persilyated thiophene-2,5-bis(carboxamidine) **6** (6.01 g, 10.0 mmol) was added portionwise, as a solid, to a solution of $SeCl_2$ prepared in situ by the reaction of $SeCl_4$ (4.44 g, 20.1 mmol) and elemental selenium (1.59 g, 20.1 mmol) in 100 mL CH_3CN. The resulting dark red slurry was heated under reflux for 16 h. The crude bis(diselenadiazolylium) dichloride salt was filtered off, washed with 3 × 40 mL CH_3CN, and dried in vacuo. Solid $NOSbF_6$ (5.3 g, 20.0 mmol) was added to a slurry of this crude dichloride salt in 30 mL CH_3CN. Immediate gas evolution was observed, and the solid dissolved to give a dark red solution. After 2 h the solvent was removed in vacuo, and the resulting solid mass recrystallized from chlorobenzene–benzonitrile (1:1). The burgundy-coloured crystals were filtered off and redissolved in 50 mL hot chlorobenzene–benzonitrile (1:1). Slow cooling to room temperature of this solution afforded burgundy flakes of the solvate [T-2,5-Se][SbF_6]$_2$·2PhCN (2.9 g, 2.5 mmol, 25%), dec >250°C. Anal. calcd. for $C_{20}H_{12}N_6SSe_4Sb_2F_{12}$: C 20.79, H 1.05, N 7.27; found: C 21.96, H 1.05, N 7.04.

Electrocrystallization of [T-2,5-Se][I]

Crystals of [T-2,5-Se][I] suitable for X-ray work and transport property measurements were prepared by electroreduction of 5 mM solutions of [T-2,5-Se][SbF_6]$_2$·2PhCN in acetonitrile in an H cell (17) fitted with a D porosity frit and Pt wire anode and cathode). Iodine was added to the cathode compartment to a level of 5 mM (10 mM in I). No supporting electrolyte was used. Samples for single crystal X-ray work were typically grown with a current of 3–5 μA over a period of 10–14 days. Material suitable for bulk analysis was grown at a higher current level, e.g., 5–10 μA. The dark, lustrous needles are stable in air. In view of the fact that no supporting electrolyte was used, no attempt was made to run the cells to exhaustion. Indeed, most electrodeposition experiments were halted well before 50% completion. Anal. calcd. for $C_6H_2N_4SSe_4I$: C 11.57, H 0.33, N 9.26, I 20.98; found: C 11.36, H 0.15, N 9.07, I 21.96.[2]

X-ray measurements

All X-ray data were collected on an ENRAF-Nonius CAD-4 diffractometer with monochromated Mo K_α radiation. Crystals were mounted on a glass fiber with silicone rubber. Data were collected using a θ/2θ technique. The structure was solved using direct methods and refined by full-matrix least squares, which minimized $\Sigma w(\Delta F)^2$. A summary of crystallographic data is provided in Table 3. Tables of crystal data, structure solution, and refinement parameters, bond lengths and angles, and anisotropic thermal parameters (five pages) for [T-2,5-Se][I] have been deposited.[3]

Magnetic susceptibility measurements

The magnetic susceptibility of [T-2,5-Se][I] was measured as

[2] As observed for other CT salts of this type, the iodine analysis was variable and irreproducible, as a result of interference from selenium. Repeated and consistent C, H, and N data, plus the iodine occupancy from the X-ray work, confirmed the composition.

[3] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. These data, with the exemption of anisotropic thermal parameters, have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

a function of temperature on a SQUID magnetometer operating at 1 T.

Band-structure calculations

The band-structure calculations were carried out on a Pentium 166 PC with the EHMACC suite of programs (18) using the parameters discussed previously (9, 19). The off-diagonal elements of the Hamiltonian matrix were calculated with the standard weighting formula (20). In the model two-dimensional calculations, the coordinates of the two HCN_2Se_2 radicals in the unit cell were taken directly from the X-ray data on [T-2,5-Se][I] and [1,3-Se][I].

N-Glycosyl phosphonamidates: potential transition-state analogue inhibitors of glycopeptidases

Vito Ferro, Larry Weiler, Stephen G. Withers, and Herman Ziltener

Abstract: The synthesis of *N*-glycosyl phosphonamidates has been accomplished via the coupling of peracetylated glycosylamines with an appropriate phosphonochloridate in the presence of pyridine. The resulting glycosyl phosphonamidate esters are dealkylated with bromotrimethylsilane and then deacetylated to give the target compounds, which are potential transition-state analogue inhibitors of glycopeptidases and may prove useful as haptens for generating catalytic antibodies with glycopeptidase activity.

Key words: enzyme inhibition, PNGase, phosphonamidate, amide hydrolysis.

Résumé : On a réalisé la synthèse de phosphonamidates de *N*-glycosyles par le biais du couplage de glycosylamines peracétylées avec un phosphonochloridate approprié effectué en présence de pyridine. On soumet les esters phosphonamides de glycosyles qui en résultent à une désalkylation à l'aide de bromotriméthylsilane, suivie d'une désacétylation qui conduit aux composés recherchés; ceux-ci sont des inhibiteurs d'un analogue potentiel de l'état de transition des glycopeptidases et ils peuvent s'avérer utiles comme haptènes dans la génération catalytique d'anticorps possédant une activité comme glycopeptidase.

Mots clés : inhibition d'enzyme, PNGase, phosphonamidate, hydrolyse d'amide.

[Traduit par la rédaction]

Introduction

Peptide *N*-glycosidases (PNGase) are enzymes that cleave the β-aspartylglucosylamine bond of *N*-linked glycoproteins via an amidase (amidohydrolase) mechanism (1). This family of enzymes is widely distributed in bacteria, plants, and animals, and it is speculated that PNGases may play an important role in the nonlysosomal regulation of various physiological and (or) physicochemical properties of certain target proteins involved in embryonal development (2). The enzyme from the bacterium *Flavobacterium meningosepticum* (PNGase F) (3) is probably the most widely used agent for the deglycosylation of glycoproteins (4) and is thus a valuable biochemical tool for investigating oligosaccharide structure and the biosynthesis of *N*-linked glycoproteins (5). Despite the importance of this enzyme, little is known regarding its mechanism of action and the residues involved in catalysis. The recently determined three-dimensional X-ray crystallographic structure (6) of PNGase F at 2.2 Å resolution does not identify a single active-site area but suggests three possible sites which merit further investigation. Such ambiguity could be removed by determination of the structure of a complex with an inhibitor. However no such inhibitors have been reported, with the exception of the very recently reported C-glycopeptide (7). Increased knowledge of the catalytic mechanism of PNGases should lead to a better understanding of their physiological roles and may facilitate their usage as agents of protein glycosylation by functioning in the reverse mode. Thus it is of great interest to be able to inhibit these enzymes with transition-state analogue inhibitors.

The related amidase aspartylglucosaminidase (AGA) is ubiquitously distributed in mammalian tissues where it plays a central role in the normal ordered catabolism of *N*-linked glycoproteins in lysosomes (8). A genetic deficiency of aspartylglucosaminidase gives rise to aspartylglucosaminuria, a human lysosomal storage disease in which AspNHGlcNAc accumulates (9). Recently its three-dimensional X-ray crystallographic structure has also been determined (10), and as a result a mechanism resembling that of the serine proteases has been proposed for this enzyme.

In this paper we report the first syntheses of *N*-glycosyl phosphonamidates and phosphonamidate esters. We reasoned that compounds of this type should be useful as haptens for generating catalytic antibodies capable of selectively *N*-deglycosylating proteins (or selectively glycosylating them by catalyzing the reverse reaction), an area of great current interest (11, 12). In addition, these compounds are potentially transition-state analogue inhibitors of the enzyme peptide: *N*-glycosidase (PNGase) and the related aspartylglucosaminidase (AGA).

The phosphonamidate functional group is recognized as a stable mimic of the putative transition state of amide bond

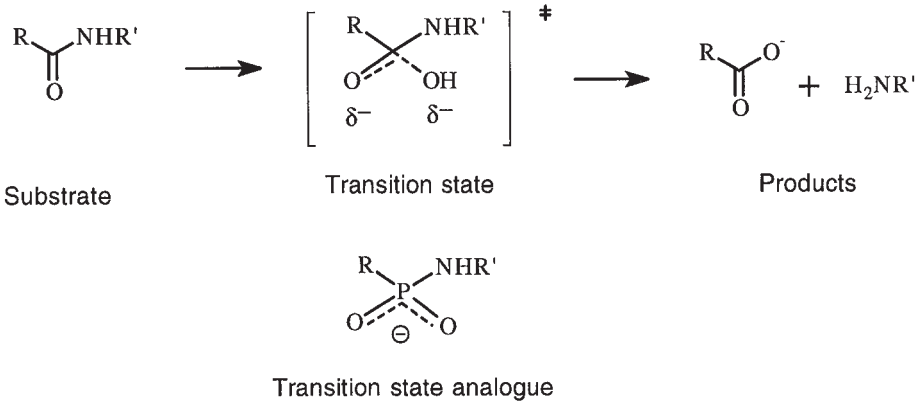
Scheme 1.



hydrolysis, with close resemblance from both a steric and electronic point of view. It possesses the hydrogen-bonding capacity, the correct overall charge and the correct geometry, shape, and size, as shown in Scheme 1. Phosphonamidates have thus been used successfully as haptens for generating catalytic antibodies with amidase (protease) or esterase activity (13, 14). Antibodies raised to phosphonamidate haptens have also been shown to catalyze the aminolysis of esters to amides (15). In addition, phosphonamidate analogues of natural peptide substrates have found great utility as potent transition-state analogue inhibitors of various proteases (16–23) and ligases (24).

Results and discussion

Phosphonamides are generally prepared by the reaction of amines with phosphonochloridates (25), which are in turn prepared by the reaction of phosphonate diesters with 1 equiv. of phosphorus pentachloride or phosphorus oxychloride. Deprotection then gives the corresponding phosphonamidates. Our approach to simple carbohydrate-derived phosphonamidates was therefore to couple the readily available protected glucosylamines **1** and **2** with an appropriate phosphonochloridate and then to remove the protecting groups.

The glucosylamines **1** and **2** were prepared, respectively, from the corresponding glucosyl azides (26, 27) by catalytic hydrogenation in ethanol with palladium on charcoal and platinum oxide as the respective catalysts. The phosphonochloridate chosen was ethyl benzylphosphonochloridate (**3**), which was readily prepared according to Morise et al. (28) by treatment of diethyl benzylphosphonate with phosphorus oxychloride. It was reacted with the glucosylamines **1** and **2** in pyridine at 0°C for 1 h and was then left overnight at room temperature. The glucosyl phosphonamides **4** and **5** were isolated in yields of 64 and 45%, respectively, following purification by flash chromatography. In the case of **1** (26), the purified (by recrystallization) amine was used in the coupling. Amine **2** (27), however, is known to be rather unstable, giving rise to dimerization products. The crude product formed from the hydrogenation of the azide precursor was therefore used immediately in the coupling step without further purification, leading to a decreased overall yield.

Compounds **4** and **5**, which gave satisfactory combustion analyses and (or) high-resolution mass spectra, were formed as mixtures of two diastereoisomers (about the chiral phosphorus atom) in ratios of approximately 1:1, as clearly evidenced by ^{31}P NMR spectroscopy (δ 26.9, 27.5 and 27.0, 28.0, respectively). Double the number of ^{13}C NMR resonances for **4** and **5** was also observed due to the presence of the additional chiral centre, and these were fully assigned. The ^{1}H NMR spectra, however, were predictably complex.

Dealkylation of the phosphonamidate ester group of **4** was achieved by treatment with bromotrimethylsilane (29) in dichloromethane at reflux followed by aqueous work-up. The product formed upon hydrolysis was the expected phosphonamide **6**, as evidenced by the NMR data of the crude product obtained in deuterochloroform. The ^{31}P NMR spectrum consisted of a singlet at δ 28.7, while the ^{1}H NMR spectrum included a broad, D_2O-exchangeable singlet at δ 6.72 assigned to the hydroxyl group on phosphorus. However, upon purification by flash chromatography, the product obtained in 83% yield as an amorphous solid was no longer compound **6**, but instead a chloroform-insoluble compound assigned the structure **7**, where M^+ is a metal cation presumably picked up from the silica gel. The NMR data, now obtained in deuterated methanol, were completely consistent with this assignment. Of particular note was the ^{31}P NMR spectrum, which showed a marked upfield shift to δ 14.7, indicative of a phosphonamidate (16). In addition, the mass spectrum of **7**, obtained in the negative-ion mode, showed the expected peak at *m/z* 500 (M, 100%). As final confirmation, treatment of **7** with acidic ion-exchange resin (Amberlite IR-120) could readily regenerate **6** (NMR). To complete the deprotection of **4**, compound **7** was treated with sodium methoxide in methanol, neutralized with Amberlite IR-120, and then dissolved in aqueous sodium bicarbonate solution to give the phosphonamidate **8**, as the sodium salt, in 54% overall yield following purification by flash chromatography. The phosphonamidate **9** was similarly obtained from **5** in an overall yield of 30%. Compounds **8** and **9** were fully characterized by ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy and mass spectrometry and were stable in neutral aqueous solution at 25°C for at least two weeks (no change in the ^{31}P NMR spectra).

Phosphonamidate esters (or so called "capped" phosphonamidates) have also been shown to inhibit proteases, with similar but reduced potency to the parent phosphonamidates (19, 21), indicating that the anionic charge of the phosphonamidate may be of lesser importance than its geometry. Therefore, the phosphonamidate esters **10** and **11** were also prepared as potential inhibitors in good yield by simple deprotection of compounds **4** and **5** with ammonia in methanol.

Our attention was next turned to preparing an *N*-glycosyl phosphonamidate hapten (to be conjugated to a carrier protein via a suitable linker) for use in generating catalytic antibodies with PNGase-like activity. To this end we required a suitably functionalized phosphonamidate for introduction of the linker. Phosphonochloridate **14** (13, 30) was therefore prepared according to the literature in good yield from diethyl 4-aminobenzylphosphonate **12**. The amino group of **12** was protected as the trifluoroacetamide by treatment with trifluoroacetic anhydride in pyridine to give the phosphonate **13**. Compound **13** was then heated in chloroform at 50°C with 1 equiv. of phosphorus pentachloride to give **14**, which was used immediately due to its instability. Both **13** and **14** were characterized extensively. The phosphonochloridate **14** was coupled with the amine **2** to give the glucosyl phosphonamide **15** as a mixture of diastereoisomers in 63% yield after flash chromatography. Selective removal of the trifluoroacetamido group of compound **15** should allow for attachment of a suitable linker (either prior to or subsequent to removal of the other protecting groups) and subsequent conjugation to a carrier protein. Details of these studies currently in progress and others directed towards the generation and characterization of catalytic antibodies derived from these haptens will be reported in due course.

Melting points (mp) were determined on a Laboratory Devices

© 1998 NRC Canada

Mel-Temp II melting point apparatus and are uncorrected. The NMR spectra were recorded on a Bruker AC 200, a Bruker WH 400, or a Varian XL 300 and are referenced to the solvent peak except when run in D_2O where they are referenced to internal acetone (δ_H 2.225, δ_C 31.0). The ^{31}P NMR spectra were recorded at 81 MHz and are referenced to external H_3PO_4 (δ 0.00). Where required, the interpretations were supported by COSY or APT NMR experiments. Mass spectra were obtained by desorption chemical ionization (DCI) on a Delsi Nermag R10-10C mass spectrometer with ammonia as the reactive gas, or by the liquid secondary ion (LSIMS) technique on a Kratos Concept mass spectrometer using thioglycerol–water as the matrix. Microanalyses were performed by Mr. Peter Borda in the microanalytical laboratory of the University of British Columbia. Solvents and reagents used were either reagent grade, certified, or spectral grade and where necessary were dried by standard procedures. Petroleum ether had a boiling range of 35–60°C. Reactions were monitored by thin layer chromatography (TLC) using Merck Kieselgel 60 F_{254} aluminium-backed sheets. Compounds were detected (where possible) under UV light or by charring with 10% sulfuric acid in MeOH or with 10% ammonium molybdate in 2 M sulfuric acid. Flash chromatography was performed on short columns (10–15 cm) of Merck Kieselgel 60 (230–400 mesh) under a positive pressure with specified eluants. Diethyl 4-aminobenzylphosphonate was purchased from Aldrich Chemical Company.

Ethyl *N*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-benzylphosphonamide (4)

A solution of ethyl benzylphosphonochloridate **3** (28) (240 mg, 1.10 mmol) in CH_2Cl_2 (1 mL) was added to a solution at 0°C of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosylamine **1** (26) (323 mg, 0.93 mmol) in 1:1 pyridine–CH_2Cl_2 (10 mL). The mixture was stirred at 0°C for 3 h and then at room temperature for 16 h. The mixture was then diluted with EtOAc and poured into water. The organic phase was separated, and the aqueous phase was extracted with EtOAc. The combined organic phases were washed successively with water and brine, dried ($MgSO_4$), filtered, and concentrated. Flash chromatography (4:1 EtOAc – petroleum ether) then gave, as a mixture of diastereoisomers, the phosphonamide **4** (317 mg, 64%) as a colourless oil; ^{31}P NMR ($CDCl_3$) δ: 26.9, 27.5; ^{13}C NMR (75 MHz, $CDCl_3$) δ: 16.1, 16.2 (2 d, J_{CCOP} 6.1 Hz, CH_2CH_3), 20.5–20.6 ($COCH_3$), 36.0, 36.9 (2 d, J_{CP} 128, 123 Hz, $PhCH_2$), 60.3, 60.4 (2 d, J_{COP} 6.7 Hz, CH_2CH_3), 61.9, 62.0 (C-6), 68.4, 68.5 (C-4), 71.3, 71.4 (2 d, J_{CCNP} 9.9, 8.9 Hz, C-2), 72.7, 72.8, 72.9 (C-3, 5), 81.7, 82.5 (C-1), 126.8–131.9 (Ph), 169.5–170.4 (C═O); DCI *m*/*z*: 530 (M + H^+, 100%); HRMS calcd. for $C_{23}H_{32}NO_{11}P$: 530.1791; found: 530.1782.

Ethyl *N*-(2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl) benzylphosphonamide (5)

A solution of 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl azide (27) (1.00 g, 2.69 mmol) in EtOH (40 mL) was hydrogenated at room temperature and pressure in the presence of platinum oxide (75 mg) for 5 h. The mixture was then filtered (Celite) and concentrated. The resultant crude 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl amine **2** (27) was dissolved in pyridine (20 mL) and cooled to 0°C. A solution of ethyl benzylphosphonochloridate (0.98 g, 4.5 mmol) in CH_2Cl_2 (5 mL) was then added, and the mixture was stirred at 0°C for 1 h and at room temperature for 16 h. Work-up as described for **4** followed by flash chromatography (1:9 MeOH–EtOAc) then gave, as a mixture of diastereoisomers, the phosphonamide **5** (0.64 g, 45%) as an amorphous solid; ^{31}P NMR ($CDCl_3$) δ: 27.0, 28.0; ^{13}C NMR (75 MHz, $CDCl_3$) δ: 16.1, 16.2 (2 d, J_{CCOP} 6.4 Hz, CH_2CH_3), 20.6–23.1 ($COCH_3$), 35.7, 36.9 (2 d, J_{CP} 128, 124 Hz, $PhCH_2$), 53.9, 54.3 (2 d, J_{CCNP} 8.6, 9.3 Hz, C-2), 60.3, 60.5 (2 d, J_{COP} 7.3, 7.1 Hz, CH_2CH_3), 62.1, 62.3 (C-6), 68.4, 68.6 (C-4), 72.8, 73.0 (C-3, 5), 82.7, 83.9 (C-1), 126.7–132.0 (Ph), 169.4–171.2 (C═O); DCI *m*/*z*: 529 (M + H^+, 90.6%). Anal. calcd. for $C_{23}H_{33}N_2O_{10}P$: C 52.27, H 6.29, N 5.30; found: C 52.11, H 6.27, N 5.14.

N-(β-D-Glucopyranosyl)benzylphosphonamidate sodium salt (8)

A solution of compound **4** (108 mg, 0.20 mmol) and bromotrimethylsilane (153 mg, 132 μL, 1.00 mmol) in CH_2Cl_2 (3 mL) was heated gently at reflux for 2 h. The mixture was concentrated, and the residue was dissolved in aqueous acetonitrile and concentrated to a yellow oil. Flash chromatography (16:4:1 EtOAc–MeOH–H_2O) gave a white amorphous solid (85 mg, 83%), with analytical data consistent with the structure **7**. ^{31}P NMR (MeOH-d_4) δ: 14.7; ^1H NMR (400 MHz, MeOH-d_4) δ: 1.95, 1.96, 1.99, 2.01 (4 s, Me), 3.02 (d, J_{PCH} 20.8 Hz, $PhCH_2$), 3.78–3.85 (bm, H-5), 4.15 (bd, $J_{6A,6B}$ 11.9 Hz, H-6A), 4.25 (bdd, $J_{5,6B}$ 4.9 Hz, H-6B), 4.67 (dd, $J_{1,2} \approx J_{1,P}$ 7.8 Hz, H-1), 4.83 (obscured by H_2O, H-2, NH), 4.99 (dd, $J_{3,4} \approx J_{4,5} = 9.7$ Hz, H-4), 5.26 (dd, $J_{2,3}$ 9.4 Hz, H-3), 7.09–7.42 (m, Ph); ^{13}C NMR (50 MHz, MeOH-d_4) δ: 20.6, 20.7, 20.9 (4 C, Me), 40.4 (d, J_{CP} 120.5 Hz, $PhCH_2$), 63.6 (C-6), 70.3 (C-4), 73.4 (d, J_{CCNP} 8.8 Hz, C-2), 73.8 (C-3), 74.9 (C-5), 84.8 (C-1), 126.6–137.8 (6 C, Ph), 171.4–172.3 (C═O); LSIMS (negative ion mode) *m*/*z*: 500 (M, 100%), 501 (M + 1, 24.7%); HRMS calcd. for $C_{21}H_{27}NO_{11}P$: 500.1322; found: 500.1327.

Treatment of a methanolic solution of **7** with Amberlite IR-120 ion-exchange resin (H^+ form) followed by filtration and concentration could regenerate compound **6** as evidenced by NMR: ^{31}P NMR ($CDCl_3$) δ: 28.7; ^1H NMR (200 MHz, $CDCl_3$) δ: 6.72 (bs, OH). Compound **7** (60 mg) was dissolved in MeOH (3 mL), and a solution of sodium methoxide in MeOH (0.5 mL of 1 M) was added. The mixture was stirred for 20 min, neutralized (Amberlite IR-120, H^+ form), and concentrated. The residue was dissolved in MeOH–H_2O (3:1, 4 mL), and solid $NaHCO_3$ (21 mg, 0.25 mmol) was added. The mixture was stirred at room temperature overnight. The mixture was then concentrated and purified by flash chromatography (7:2:1 EtOAc–MeOH–H_2O) to give a solid that was dissolved in H_2O. Filtration and lyophilization then gave the phosphonamidate **8** (23 mg, 54%) white, amorphous solid. ^{31}P NMR (D_2O) δ: 21.8; ^1H NMR (400 MHz, D_2O) δ: 3.08 (d, J_{PCH} 19.7 Hz, $PhCH_2$), 3.21 (dd, $J_{1,2} \approx J_{2,3} = 9.0$ Hz, H-2), 3.36 (dd, $J_{3,4} \approx J_{4,5}$ 9.0 Hz, H-4), 3.43 (ddd, $J_{5,6A}$ 5.7, $J_{5,6B}$ 2.1 Hz, H-5), 3.50 (dd, H-3), 3.72, 3.92 (2 dd, AB part of an ABX system, $J_{6A,6B}$ 12.2 Hz, H-6A, 6B), 4.31 (dd, J_{PNCH} 8.5 Hz, H-1), 7.23–7.46 (m, Ph); ^{13}C NMR (75 MHz, D_2O) δ: 39.2 (d, J_{CP} 117 Hz, $PhCH_2$), 61.7 (C-6), 70.7 (C-4), 74.5 (d, J_{CCNP} 8 Hz, C-2), 77.3, 77.5 (C-3, 5), 85.3 (C-1), 126.7–136.3 (Ph). LSIMS (negative ion mode) *m*/*z*: 332 (M, 25.9%); HRMS calcd. for $C_{13}H_{19}NO_7P$: 332.0899; found: 332.0900.

_N_-(2-Acetamido-2-deoxy-β-D-glucopyranosyl)benzylphosphonamidate sodium salt (9)

Compound **5** (250 mg, 0.47 mmol) was treated with bromotrimethylsilane and worked up as described for compound **4**. The crude product was subjected to flash chromatography (16:4:1 EtOAc–MeOH–H_2O) to give a pale yellow solid, which was deprotected and treated with $NaHCO_3$ as described for compound **7**. Flash chromatography (5:2:1 EtOAc–MeOH–H_2O) then gave the phosphonamidate **9** (56 mg, 30%) as a white, amorphous solid. ^{31}P NMR (D_2O) δ: 21.2; ^1H NMR (400 MHz, D_2O) δ: 2.04 (s, Me), 3.01 (m, AB part of an ABX system, $J_{A,B}$ 14.3, J_{PCH} 19.8 Hz, PhCH_2), 3.36–3.47 (m, H-4, 5), 3.54 (dd, $J_{2,3} \approx J_{3,4}$ 9.0 Hz, H-3), 3.68 (dd, $J_{1,2}$ 9.4 Hz, H-2), 3.72, 3.92 (2 dd, AB part of an ABX system, $J_{6A,6B}$ 12.0 Hz, $J_{5,6A}$ 5.2 Hz, $J_{5,6B}$ 1.0 Hz, H-6A, 6B), 4.37 (dd, J_{PNCH} 8.8 Hz, H-1), 7.25–7.48 (m, Ph); ^{13}C NMR (75 MHz, D_2O) δ 23.0 (Me), 39.0 (d, J_{CP} 119 Hz, PhCH_2), 56.9 (d, J_{CCNP} 8 Hz, C-2), 61.8 (C-6), 70.9 (C-4), 75.4 (C-3), 77.5 (C-5), 84.3 (C-1), 126.7–136.2 (Ph), 175.6 (C═O). LSIMS (negative ion mode) *m*/*z*: 373 (M, 34.8%); HRMS calcd. for $C_{15}H_{22}N_2O_7P$: 373.1165; found: 373.1160.

Ethyl _N_-(β-D-glucopyranosyl)benzylphosphonamide (10)

Compound **4** (55 mg, 0.10 mmol) was dissolved in MeOH (2 mL), and the solution was cooled to 0°C and saturated with ammonia. It was stirred at 0°C for 1 h and then at room temperature for 16 h. Concentration of the mixture followed by flash chromatography (27:2:1 EtOAc–MeOH–H_2O) gave, as a mixture of diastereoisomers, the phosphonamide **10** (35 mg, 93%) as an amorphous solid; ^{31}P NMR (D_2O) δ: 34.1; ^{13}C NMR (75 MHz, D_2O) δ: 15.8 (d, J_{CCOP} 6.0 Hz, CH_2CH_3), 35.2, 35.7 (2 d, J_{CP} 124.6, 124.2 Hz, PhCH_2), 60.9 (C-6), 62.1, 62.3 (2 d, J_{COP} 7.2 Hz, CH_2CH_3), 69.7 (C-4), 73.6, 73.7 (C-2), 76.7, 76.8, 77.2 (C-3, 5), 83.4, 83.5 (C-1), 127.4–131.8 (Ph); DCI *m*/*z*: 362 (M + H^+, 60.4%), 379 (M + NH_4^+, 100%); HRMS calcd. for $C_{15}H_{24}NO_7P$: 362.1369; found: 362.1353. Anal. calcd. for $C_{15}H_{24}NO_7P \cdot H_2O$: C 47.49, H 6.91, N 3.69; found: C 47.46, H 6.62, N 3.83.

Ethyl _N_-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-benzylphosphonamide (11)

Compound **5** (80 mg, 0.15 mmol) was dissolved in MeOH (3 mL), and the solution was cooled to 0°C and saturated with ammonia. It was stirred at 0°C for 6 h and then concentrated. Flash chromatography (16:4:1 EtOAc–MeOH–H_2O) gave, as a mixture of diastereoisomers, the phosphonamide **11** (53 mg, 87%) as an amorphous solid; ^{31}P NMR (D_2O) δ: 33.7, 33.8; ^{13}C NMR (75 MHz, D_2O) δ: 15.1 (d, J_{CCOP} 5.9 Hz, CH_2CH_3), 21.7, 21.8 ($COCH_3$), 34.1, 35.1 (2 d, J_{CP} 126, 123 Hz, PhCH_2), 55.3, 55.4 (2 d, J_{CCNP} 7.9, 7.4 Hz, C-2), 60.1 (C-6), 61.4, 61.6 (2 d, J_{COP} 7.3, 7.1 Hz, CH_2CH_3), 69.2 (C-4), 74.0, 74.1 (C-3), 76.36, 76.43 (C-5), 81.2, 81.9 (C-1), 126.7–130.9, (Ph), 174.1 (C═O); DCI *m*/*z*: 403 (M + H^+, 28.5%), 420 (M + NH_4^+, 16.2%); HRMS calcd. for $C_{17}H_{27}N_2O_7P$: 403.1634; found: 403.1630. Anal. calcd. for $C_{17}H_{27}N_2O_7P \cdot H_2O$: C 48.57, H 6.95, N 6.66; found: C 48.74, H 7.09, N 6.48.

Diethyl 4-trifluoroacetamidobenzylphosphonate (13)

Trifluoroacetic anhydride (5.19 g, 3.44 mL, 24.7 mmol) was added dropwise over 10 min to a solution at 0°C of diethyl 4-aminobenzylphosphonate **12** (5.00 g, 20.6 mmol) and pyridine (5 mL) in CH_2Cl_2 (40 mL). The mixture was stirred at 0°C for 15 min, allowed to warm to room temperature, stirred at room temperature for 1 h, and then poured into water. The organic phase was separated, and the aqueous phase was extracted with CH_2Cl_2. The combined organic phases were washed successively with 1 M HCl, water, and brine, dried ($MgSO_4$), filtered, and concentrated. The resultant solid was recrystallized from diisopropyl ether to give the phosphonate **13** (13, 30, 31) (5.76 g, 82%) as colourless prisms, mp 149–150°C; ^{31}P NMR ($CDCl_3$) δ: 25.8; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.24 (t, *J* 7.0 Hz, Me), 3.09 (d, *J* 21.5 Hz, PCH_2), 3.86–4.13 (m, 4 H, OCH_2), 7.16 (dd, 2 H, *J* 9.0, 2.5 Hz, ArH), 7.52 (d, 2 H, *J* 8.5 Hz, ArH), 10.22 (bs, NH). Anal. calcd. for $C_{13}H_{17}F_3NO_4P$: C 46.02, H 5.05, N 4.13; found: C 46.06, H 5.16, N 4.18.

Ethyl 4-trifluoroacetamidobenzylphosphonochloridate (14)

A mixture of the phosphonate **13** (339 mg, 1.00 mmol) and PCl_5 (208 mg, 1.00 mmol) in chloroform (10 mL) was heated at 50°C for 16 h. The solvent was evaporated, and petroleum ether (30 mL) was added to the residue. The resultant precipitate was collected and washed with petroleum ether to give the phosphonochloridate **14** (13, 30, 31) (300 mg, 91%) as a white solid, mp 222–224°C (dec), used immediately without further purification; ^{31}P NMR ($CDCl_3$) δ: 38.1; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.37 (t, *J* 7.1 Hz, Me), 3.37–3.63 (m, AB part of an ABX, PCH_2), 4.13–4.41 (m, OCH_2), 7.25 (dd, 2 H, *J* 8.1, 3.2 Hz, ArH), 7.54 (d, 2 H, *J* 7.3 Hz, ArH), 8.99 (bs, NH).

Ethyl _N_-(2′-acetamido-3′,4′,6′-tri-_O_-acetyl-2′-deoxy-β-D-glucopyranosyl)-4-trifluoroacetamidobenzylphosphonamide (15)

2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl azide (372 mg, 1.00 mmol) was hydrogenated as described above, and the resultant crude amine was treated with the phosphonochloridate **14** (460 mg, 1.40 mmol) analogously as described for compound **5**. Flash chromatography (EtOAc→1:9 MeOH–EtOAc) gave, as a mixture of diastereoisomers, the phosphonamide **15** (400 mg, 63%) as an amorphous solid; ^{31}P NMR (DMSO-d_6) δ: 27.0, 27.4; ^{13}C NMR (75 MHz, DMSO-d_6) δ: 16.2 (2 C, d, J_{CCOP} 5.4 Hz, CH_2CH_3), 20.4–20.5 (3 C, $COCH_3$), 22.6, 22.7 ($NHCOCH_3$), 34.6, 35.3 (2 d, J_{CP} 125, 124 Hz, PhCH_2), 53.5, 53.8 (2 d, J_{CCNP} 8.6, 10.4 Hz, C-2), 59.1 (d, J_{COP} 6.7 Hz, CH_2CH_3), 62.0, 62.2 (C-6), 68.6, 68.9 (C-4), 71.6, 71.7, 73.1, 73.2 (C-3, 5), 81.6, 82.4 (C-1), 113.9–134.5 (Ar), 154.1, 154.6 ($COCF_3$), 169.3–170.0 (C═O); DCI *m*/*z* : 640 (M + H^+, 100%). Anal. calcd. for $C_{25}H_{33}F_3N_3O_{11}P$: C 46.95, H 5.20, N 6.57; found: C 46.83, H 5.17, N 6.29.

Synthesis, spectroscopic characterization, and structural studies of organogermanium tri- and monothiocarbonates. Crystal structures of $Me_2Ge[S_2CSEt]_2$, $Ph_3Ge[SCO_2Me]$, $Ph_3Ge[SCO_2(i\text{-}Pr)]$, and $Ph_2Ge[SCO_2Me]_2$

John E. Drake and Jincai Yang

Abstract: Two series of *S*-alkyl trithiocarbonate derivatives of dimethylgermane, $Me_2Ge[S_2CSR]_2$, and halodiphenylgermane, $Ph_2GeX[S_2CSR]$, where R = Me, *i*-Pr, *n*-Pr, *n*-Bu and X = Cl, Br, and three series of *O*-alkyl monothiocarbonate derivatives of triphenylgermane, $Ph_3Ge[SCO_2R]$, diphenylgermane, $Ph_2Ge[SCO_2R]$, and trimethylgermane, $Me_3Ge[SCO_2R]$, where R = Me, *i*-Pr, and *n*-Pr, have been prepared in 73–92% yields by the reaction of the potassium or sodium salt of the appropriate tri- or monothiocarbonic acid with dichlorodimethyl-, chlorotriphenyl-, dichlorodiphenyl-, and chlorotrimethylgermane. The compounds were principally characterized by infrared, Raman, and ^1H and ^{13}C NMR spectroscopy, including some variable temperature studies, as well as by mass spectrometry. $Me_2Ge[S_2CSEt]_2$, **1**: $P2_1/m$ (No. 11) with cell parameters $a = 6.647(4)$ Å, $b = 7.423(2)$ Å, $c = 16.290(4)$ Å, $\beta = 91.07(3)°$, $V = 803.6(4)$ Å^3, $Z = 2$, $R = 0.0484$, $R_w = 0.0485$. $Ph_3Ge[SCO_2Me]$, **13**: $P\bar{1}$ (No. 2) with cell parameters $a = 9.970(4)$ Å, $b = 10.660(3)$ Å, $c = 9.853(2)$ Å, $\alpha = 101.78(2)°$, $\beta = 109.98(2)°$, $\gamma = 89.76(3)°$, $V = 961.0(5)$ Å^3, $Z = 2$, $R = 0.0534$, $R_w = 0.0451$. $Ph_3Ge[SCO_2(i\text{-}Pr)]$, **14**: $P\bar{1}$ (No. 2) with cell parameters $a = 14.386(7)$ Å, $b = 18.598(6)$ Å, $c = 9.223(3)$ Å, $\alpha = 102.85(3)°$, $\beta = 94.58(3)°$, $\gamma = 108.13(3)°$, $V = 2256(1)$ Å^3, $Z = 2$, $R = 0.0545$, $R_w = 0.0552$. $Ph_2Ge[SCO_2Me]_2$, **16**: *Cc*, (No. 9) with cell parameters $a = 11.790(4)$ Å, $b = 13.696(5)$ Å, $c = 23.232(6)$ Å, $\beta = 92.26(3)°$, $V = 3748(2)$ Å^3, $Z = 8$, $R = 0.0563$, $R_w = 0.0512$. The immediate environment about Ge is that of tetrahedral but the orientations of the thiocarbonate groups display interesting features.

Key words: structure, germanium, phenyl, methyl, thiocarbonates.

Résumé : On a préparé deux séries de dérivés trithiocarbonates de *S*-alkyle du diméthylgermane, $Me_2Ge[S_2CSR]_2$, et d'halogénodiphénylgermane, $Ph_2GeX[S_2CSR]$, dans lesquels R = Me, *i*-Pr, Pr, Bu et X = Cl, Br et trois séries de dérivés monothiocarbonates de *O*-alkyle du triphénylgermane, $Ph_3Ge[SCO_2R]$, du diphénylgermane, $Ph_2Ge[SCO_2R]$, et du triméthylgermane, $Me_3Ge[SCO_2R]$, dans lesquels R = Me, *i*-Pr et Pr, avec des rendements allant de 73 à 92% en procédant à la réaction du sel de sodium ou de potassium de l'acide tri- ou monothiocarbonique approprié avec le dichlorodiméthyl-, chlorotriphényl-, dichlorodiphényl- et le chlorotriméthylgermane. On a généralement caractérisé les composés par le biais des spectroscopies infrarouge, Raman et RMN du ^1H et du ^{13}C, y compris des études à températures variables, ainsi que par spectrométrie de masse. $Me_2Ge[S_2CSEt]_2$, **1** : $P2_1/m$ (No. 11), avec $a = 6,647(4)$, $b = 7,423(2)$ et $c = 16,290(4)$ Å, $\beta = 91,07(3)°$, $V = 803,6(4)$ Å^3, $Z = 2$, $R = 0,0484$, $R_w = 0,0485$. $Ph_3Ge[SCO_2Me]$, **13** : $P\bar{1}$ (No. 2), avec $a = 9,970(4)$, $b = 10,660(3)$ et $c = 9,853(2)$ Å, $\alpha = 101,78(2)°$, $\beta = 109,98(2)°$ et $\gamma = 89,76(3)°$, $V = 961,0(5)$ Å^3, $Z = 2$, $R = 0,0534$, $R_w = 0,0451$. $Ph_3Ge[SCO_2(i\text{-}Pr)]$, **14** :$P\bar{1}$ (No. 2), avec $a = 14,386(7)$, $b = 18,598(6)$ et $c = 9,223(3)$ Å, $\alpha = 102,85(3)°$, $\beta = 94,58(3)°$ et $\gamma = 108,13(3)°$, $V = 2256(1)$ Å^3, $Z = 2$, $R = 0,0545$, $R_w = 0,0552$. $Ph_2Ge[SCO_2Me]_2$, **16** : *Cc* (No. 9), avec $a = 11,790(4)$, $b = 13,696(5)$ et $c = 23,232(6)$ Å, $\beta = 92,26(3)°$, $V = 3748(2)$ Å^3, $Z = 8$, $R = 0,0563$, $R_w = 0,0512$. L'environnement immédiat du Ge est tétraédrique, mais les orientations des groupes thiocarbonates présentent des caractéristiques intéressantes.

Mots clés : structure, germanium, phényle, méthyle, thiocarbonates.

[Traduit par la rédaction]

Introduction

A wide variety of studies on *O*-alkyl dithiocarbonates (xanthates) have been reported but the analogous trithio- and monothiocarbonates have received considerably less attention. For trithiocarbonates, this can be attributed to the relative ease with which they undergo carbon disulfide elimination (1–3) and most reports relate to transition metal derivatives. As part of our studies on organogermanium dithio carbonates, carbamates, and phosphates (4–14), we have reported on a few

trithiocarbonate derivatives (15), and herein is reported an extension of this work involving *S*-alkyl trithiocarbonate derivatives of dimethylgermane, $Me_2Ge[S_2CSR]_2$, and halodiphenylgermane, $Ph_2GeX[S_2CSR]$, where R = Me, *i*-Pr, *n*-Pr, *n*-Bu and X = Cl, Br. Monothiocarbonate derivatives have received even less attention and again virtually all reports have involved transition metal complexes (16–20). With the exception of those on alkali metal salts (21), only one report on main group element monothiocarbonates, describing some organotellurium derivatives, has appeared (22). Three series of *O*-alkyl monothiocarbonate derivatives of triphenylgermane, $Ph_3Ge[SCO_2R]$, diphenylgermane, $Ph_2Ge[SCO_2R]_2$, and trimethylgermane, $Me_3Ge[SCO_2R]$, where R = Me, *i*-Pr, and *n*-Pr are discussed. All of the compounds described were characterized by NMR, infrared, and Raman spectroscopy, as well as by X-ray crystallography when suitable crystals were obtained.

Experimental

Materials

Me_3GeCl, Me_2GeCl_2, Ph_3GeCl, Ph_2GeCl_2, and Me_3SiBr were obtained from Aldrich and Strem Chemicals, all starting materials being used as supplied. All solvents were dried and distilled prior to use and all reactions were carried out under anhydrous conditions. The salts KS_2CSR, where R = Et, *i*-Pr, *n*-Pr, *n*-Bu, were prepared as described earlier (15) and were further purified by a method based on that described for dithiocarbonates (23). The salts $NaSCO_2R$, where R = Me, *i*-Pr, *n*-Pr, were prepared as follows. Typically, sodium metal (ca. 1.0 g) was added to dry *i*-PrOH (ca. 10 mL) in a flask under N_2 gas and the reaction allowed to proceed for 1 h, before COS gas was bubbled in for 10 min. This was followed by distillation under vacuum and pumping to dryness to give $NaSCO_2$(*i*-Pr); 5.5 g, yield 89%. IR (cm^{-1}), main features: 1550 br s, 1384 mw, 1371 m, 1186 s, 1086 br s, 973 m, 688 m; Raman (cm^{-1}): 830 (100); ^1H NMR (ppm relative to DSS): 4.83 (OC*H*, septet, 6.34 Hz), 1.21 (OCCH_3, d, 6.34 Hz); ^{13}C NMR (ppm relative to DSS): 71.12 (O*C*), 21.98 (OC*C*), 185.86 (S*C*O_2). Similarly were prepared $NaSCO_2Me$; yield 85%. IR (cm^{-1}), main features: 1592 vs, vbr, 1428 m, 1188 m, 1120 vs, br, 1040 m, 965 mw, 695 mw; Raman (cm^{-1}): 825 (100): ^1H NMR (ppm relative to DSS): 3.68 (CH_3), ^{13}C NMR (ppm relative to DSS): 54.36 (*C*H_3), 186.89 (S*C*O_2), and $NaSCO_2$(*n*-Pr); yield 92%. IR (cm^{-1}) main features: 1614 vs, br, 1432 s, 1136 s, 1098 s, 1000 m, 827 m, 668 ms; Raman (cm^{-1}): 841 (100); ^1H NMR (ppm relative to DSS): 4.01 (OCH_2, triplet, 6.6 Hz), 1.65 (OCCH_2, m), 0.94 (CH_3, triplet, 7.4 Hz); ^{13}C NMR (ppm relative to DSS): 69.34 (O*C*), 22.63(OC*C*), 10.66 (OCC*C*), 186.64 (S*C*O_2).

Synthesis of (*S*-organo trithiocarbonato) dimethylgermanes

$Me_2Ge[S_2CSEt]_2$, **1**, *$Me_2Ge[S_2CS(i\text{-}Pr)]_2$,* **2**, *$Me_2Ge[S_2CS($*n*-Pr$)]_2$,* **3**, *and $Me_2Ge[S_2CS($*n*-Bu$)]_2$,* **4**

Typically, Me_2GeCl_2 (0.10 mL, 0.87 mmol) and dried CS_2 (ca. 10 mL) were distilled onto previously degassed KS_2CSEt (0.35 g, 1.99 mmol) in a flask held at –196°C. The contents were stirred for ca. 4 h at 0°C. Unreacted KS_2CSEt and KCl were filtered off and solvent allowed to evaporate under vacuum to produce $Me_2Ge[S_2CSEt]_2$, **1**, a yellow solid (0.30 g, 0.80 mmol, yield 92%). Recrystallization from CS_2 at –15°C gave yellow crystals, mp 35°C. Prepared similarly were $Me_2Ge[S_2CS(i\text{-}Pr)]_2$, **2**, $Me_2Ge[S_2CS(n\text{-}Pr)]_2$, **3**, and $Me_2Ge[S_2CS(n\text{-}Bu)]_2$, **4**, all as yellow oils in yields of 82, 85, and 80%, respectively.

Synthesis of (*S*-organo trithiocarbonato)chloro-dimethylgermanes

$Ph_2GeCl[S_2CSEt]$, **5**, *$Ph_2GeCl[S_2CS(i\text{-}Pr)]$,* **6**, *$Ph_2GeCl[S_2CS($*n*-Pr$)]$,* **7**, *$Ph_2GeCl[S_2CS($*n*-Bu$)]$,* **8**

Typically, Ph_2GeCl_2 (0.30 g, 1.02 mmol), which was contained in a small vial, and dried KS_2CSEt (0.18 g, 1.02 mmol) were placed in a flask, which was then cooled to –196°C, degassed, and dried CS_2 (ca. 8 mL) was distilled in. The mixture was stirred for ca. 2 h at 0°C, KS_2CSEt and KCl filtered off, and the solvent allowed to evaporate under vacuum to produce $Ph_2GeCl[S_2CSEt]$, **5**, a yellow oil (0.32 g, 0.81 mmol, yield 80%). Prepared similarly were $Ph_2GeCl[S_2CS(i\text{-}Pr)]$, **6**, $Ph_2GeCl[S_2CS(n\text{-}Pr)]$, **7**, and $Ph_2GeCl[S_2CS(n\text{-}Bu)]$, **8**, all as yellow oils with yields of 80, 78, and 84%, respectively.

Synthesis of (*S*-organo trithiocarbonato)bromo-dimethylgermanes

$Ph_2GeBr[S_2CSEt]$, **9**, *$Ph_2GeBr[S_2CS(i\text{-}Pr)]$,* **10**, *$Ph_2GeBr[S_2CS($*n*-Pr$)]$,* **11**, *and $Ph_2GeBr[S_2CS($*n*-Bu$)]$,* **12**

Typically, $Ph_2GeCl[S_2CSEt]$ was prepared in situ as above from Ph_2GeCl_2 (0.31 g, 1.05 mmol) and dried KS_2CSEt (0.18 g, 1.05 mmol). The flask was recooled to –196°C, degassed again, Me_3SiBr (ca. 0.3 mL) was distilled in, and then the mixture was stirred for 2 h at 0°C, followed by evaporation under vacuum to remove Me_3SiCl and any unreacted Me_3SiBr, to produce $Ph_2GeBr[S_2CSEt]$, **9**, as a yellow oil (0.39 g, 0.88 mmol, yield 84%). Similarly were prepared $Ph_2GeBr[S_2CS(i\text{-}Pr)]$, **10**, $Ph_2GeBr[S_2CS(n\text{-}Pr)]$, **11**, and $Ph_2GeBr[S_2CS(n\text{-}Bu)]$, **12**, all as yellow oils in yields of 83, 80, and 88%, respectively. Crystallization of **2**–**12** using a variety of solvents and solvent mixtures was not successful, and attempts at obtaining boiling points resulted in the immediate release of CS_2.

Attempted preparations of halodimethylgermanium trithiocarbonates

Efforts to synthesize the species Me_2GeClL and Me_2GeBrL, where L = S_2CSR; R = Et, *i*-Pr, *n*-Pr, *n*-Bu, were not successful. The appropriate stoichiometric reactions were shown by NMR spectroscopy to always give mixtures of Me_2GeXL and Me_2GeL_2. Because of the lack of stability of these compounds, isolation by column chromatography did not give the desired compounds but only decomposition products consistent with CS_2 elimination.

Synthesis of (*O*-organo monothiocarbonato)-triphenylgermanes

$Ph_3Ge[SCO_2Me]$, **13**, *$Ph_3Ge[SCO_2(i\text{-}Pr)]$,* **14**, *and $Ph_3Ge[SCO_2($*n*-Pr$)]$,* **15**

Typically, Ph_3GeCl (0.25 g, 0.74 mmol) and excess, dried $NaSCO_2Me$ (0.09 g, 0.79 mmol) were placed in a previously evacuated flask and CH_2Cl_2 (ca. 15 mL) was distilled in at

© 1998 NRC Canada

–196°C. The mixture was stirred for 4 h at room temperature, followed by filtration and evaporation under vacuum to give $Ph_3Ge[SCO_2Me]$, **13**, a colorless solid (0.26 g, 0.66 mmol, yield 89%). Recrystallization from a CH_2Cl_2–*n*-hexane mixture gave colorless crystals, mp 101–102°C. Peaks corresponding to ^{74}Ge in a typical germanium cluster were seen at *m/z* (relative intensity): 396 ($(M)^+$, 2%), 337 ($(M - CO_2Me)^+$, 3%), 319 ($(M - Ph)^+$, 10%), 305 ($(M - SCO_2Me)^+$, 100%), 259 ($(M - PhCO_2Me)^+$, 30%), 228 ($(M - PhSCO_2Me)^+$, 30%), 183 ($(M - Ph_2CO_2Me)^+$, 5%), and 151 ($(M - Ph_2SCO_2Me)^+$, 50%). Prepared similarly was $Ph_3Ge[SCO_2(i\text{-}Pr)]$, **14**, a colorless solid (0.30 g, 0.71 mmol, yield 86%). Recrystallization from a CH_2Cl_2–*n*-hexane mixture gave colorless crystals, mp 98–99°C. Similarly was prepared $Ph_3Ge[SCO_2(n\text{-}Pr)]$, **15**, a colorless solid (0.29 g, 0.69 mmol, yield 89%), mp 91–93°C. Peaks corresponding to ^{74}Ge were seen at *m/z* (relative intensity): 305 ($(M - SCO_2C_3H_7)^+$, 100%), 287 ($(M - PhSCO)^+$, 15%), 245 ($(M - PhSCOC_3H_6)^+$, 20%), 228 ($(M - PhSCO_2C_3H_7)^+$, 38%), and 151 ($(M - Ph_2SCO_2C_3H_7)^+$, 46%). However, attempts at recrystallization failed to give crystals suitable for X-ray diffraction.

Synthesis of bis(*O*-organo monothiocarbonato)-diphenylgermanes

$Ph_2Ge[SCO_2Me]_2$, **16**, *$Ph_2Ge[SCO_2(i\text{-}Pr)]_2$,* **17**, *and $Ph_2Ge[SCO_2(n\text{-}Pr)]_2$,* **18**

Typically, Ph_2GeCl_2 (0.25 g, 0.85 mmol) in a vial and $NaSCO_2Me$ (0.25 g, 2.19 mmol) were placed in a flask and CH_2Cl_2 (ca. 15 mL) was distilled in at –196°C. Reaction and separation were carried out as for **13** to give $Ph_2Ge[SCO_2Me]_2$, **16**, as a colorless solid (0.30 g, 0.70 mmol, yield 82%). Recrystallization from a CH_2Cl_2–*n*-hexane mixture gave colorless crystals, mp 69°C. Peaks corresponding to ^{74}Ge were seen at *m/z* (relative intensity): 351 ($(M - CO_2Me)^+$, 1%), 319 ($(M - SCO_2Me)^+$, 8%), 259 ($(M - SCO_2Me(CO_2Me))^+$, 80%), 229 ($(M - SCO_2Me(SCO_2CH_2))^+$, 60%), 151 ($(M - Ph(SCO_2Me)_2)^+$, 55%), and 105 ($M - Ph_2SCO_2Me(CO_2Me))^+$, 37%), as well as 60 ($(COS)^+$, 100%). Similarly was prepared $Ph_2Ge[SCO_2(i\text{-}Pr)]_2$, **17**, as a colorless solid (yield 81%). Peaks corresponding to ^{74}Ge were seen at *m/z* (relative intensity): 469 ($(M)^+$ 5%), 347 ($M - SCO_2C_3H_7)^+$, 32%), 287 ($M - SCO_2C_3H_7(COS))^+$, 82%), 229 ($M - SCO_2C_3H_7(SCO_2C_3H_6))^+$, 100%), and 183 ($M - PhSCO_2C_3H_7(CO_2C_3H_7)^+$, 3%). Recrystallization from a CH_2Cl_2–*n*-hexane mixture gave colorless crystals, mp 95–96°C, but they were not of X-ray quality. Similarly was formed $Ph_2Ge[SCO_2(n\text{-}Pr)]_2$, **18**, as a colorless oil (yield 81%). Peaks corresponding to ^{74}Ge were seen at *m/z* (relative intensity): 347 ($(M - SCO_2C_3H_7)^+$, 22%), 304 ($(M - SCO_2C_3H_7(C_3H_7))^+$, 6%), 287 ($(M - SCO_2C_3H_7)(COS)]^+$, 48%), 259 ($(M - SCO_2C_3H_7(CO_2C_3H_7))^+$, 10%), 229 ($(M - SCO_2C_3H_7(SCO_2C_3H_6))^+$, 54%), 183 ($(M - PhSCO_2C_3H_7(CO_2C_3H_7)^+$, 23%), and 151 ($(M - Ph(SCO_2C_3H_7)_2)^+$, 28%), along with 60 ((COS)+, 67%).

Synthesis of (*O*-organo monothiocarbonato)-trimethylgermanes

$Me_3Ge[SCO_2Me]$, **19**, *$Me_3Ge[SCO_2(i\text{-}Pr)]$,* **20,** *and $Me_3Ge[SCO_2(n\text{-}Pr)]$,* **21**

Typically, Me_3GeCl (0.20 mL, 1.62 mmol) and CH_2Cl_2 (ca. 8 mL) were distilled onto $NaSCO_2Me$ (0.22 g, 1.93 mmol) at –196°C. The mixture was stirred for 4 h at room temperature, followed by filtration and evaporation under vacuum to give $Me_3Ge[SCO_2Me]$, **19**, as a colorless liquid (0.25 g, 1.20 mmol, yield 74%), bp 82–84°C. Similarly were formed $Me_3Ge[SCO_2(i\text{-}Pr)]$, **20**, a colorless liquid, yield 76%, bp 92–94°C, and $Me_3Ge[SCO_2(n\text{-}Pr)]$, **21**, a colorless liquid, yield 73%, bp 88–90°C.

Attempted preparation of halodiphenylgermanium monothiocarbonates

Attempts to isolate samples of $Ph_2GeCl[SCO_2R]$ species were not successful. Reactions with 1:1 molar ratios of Ph_2GeCl_2 and $NaSCO_2R$ always gave mixtures of the halo and bis compounds, as was confirmed from the ^1H NMR spectra.

Physical measurements

The infrared spectra were recorded on a Nicolet 5DX FT spectrometer as KBr pellets or oils smeared between KBr windows in the region 4000–400 cm^{-1}, and far infrared spectra on a Bomem DA3 infrared spectrometer between polyethylene films as oils or Nujol mulls. The Raman spectra were recorded on samples in sealed glass capillaries on a JEOL-XY Raman spectrometer using the 5145 Å exciting line of an argon ion laser. The ^1H and ^{13}C {H}NMR spectra were recorded on a Bruker 300 FT/NMR spectrometer at 300.133 and 75.471 MHz, respectively, in $CDCl_3$ using Me_4Si as internal standard. All NMR spectra were run at ambient temperature, with the exception of the routine VT NMR studies, and under standard operating conditions. The melting points were determined on a Fisher–Johns apparatus. The mass spectra were recorded on a Kratos Profile GC–MS spectrometer.

X-ray crystallographic analysis

Crystals of $Me_2Ge[S_2CSEt]_2$, **1**, were grown from carbon disulfide at –15°C and those of $Ph_3Ge[SCO_2Me]$, **13**, $Ph_3Ge[SCO_2(i\text{-}Pr)]$, **14**, and $Ph_2Ge[SCO_2Me]_2$, **16**, from CH_2Cl_2–*n*-hexane mixtures at 5°C. A yellow block crystal of **1** and colorless block crystals of **13, 14**, and **16**, of approximate dimensions $0.38 \times 0.24 \times 0.18$, $0.30 \times 0.30 \times 0.21$, $0.34 \times 0.25 \times 0.20$, and $0.35 \times 0.26 \times 0.23$ mm, respectively, were sealed in thin-walled glass capillaries and mounted on a Rigaku AFC6S diffractometer, with graphite-monochromated Mo Kα radiation.

Data collection was carried out as reported in detail earlier (10) and the important parameters are included in Table 1. Of the 1672 (**1**), 3597 (**13**), 7522 (**14**), and 3645 (**16**) reflections that were collected, 1536 (**1**), 3386 (**13**), 7178 (**14**), and 3645 (**16**) were unique. The intensities of three representative reflections measured after every 150 reflections remained constant throughout data collection, indicating crystal and electronic stability (no decay correction was applied for **1**, **13**, and **16**). However, over the course of data collection the standards decreased by 8.2% for **14**, so a linear correction factor was applied. The linear absorption coefficient for Mo Kα is 26.6 for **1**, 16.8 for **13**, 15.8 for **14**, and 18.7 cm^{-1} for **16**. An empirical absorption correction, based on azimuthal scans of several reflections, was applied that resulted in transmission factors ranging from 0.59 to 1.00 for **1**, 0.81 to 1.00 for **13**, 0.78 to 1.00 for **14**, and 0.77 to 1.00 for **16**. The data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods (24) and all

calculations were performed using the TEXSAN (25) crystallographic software package of Molecular Structure Corp. The non-hydrogen atoms were refined anisotropically and the hydrogen atoms were included in their idealized position with C—H set at 0.95 Å and with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached. The final cycle of full-matrix least-squares refinement[3] was based on 771 (**1**), 1440 (**13**), 1725 (**14**), and 1944 (**16**) observed reflections (I 3.00σ(I)) and 88 (**1**), 127 (**13**), 214 (**14**), and 225 (**16**) variable parameters and converged (largest parameter shift was 0.001 times its esd) with unweighted and weighted agreement factors of $R = \Sigma \mid |F_o| - |F_c| \mid / |F_c| =$ 0.0485 (**1**), 0.0534 (**13**), 0.0545 (**14**), and 0.0563 (**16**) and $R_w = [(\Sigma w(|F_o| - |F_c|)^2 / F_o^2)]^{1/2} = 0.0485$ (**1**), 0.0451 (**13**), 0.0552 (**14**), and 0.0512 (**16**). The standard deviation of an observation of unit weight [4] was 1.88 (**1**), 1.63 (**13**), 1.50 (**14**), and 2.06 (**16**). The refinement of **16** was carried out on both enantiomorphs by inverting the structure and the better solution chosen. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.86 and –0.62 e/Å^3, respectively, for **1**; 0.43 and –0.38 e/Å^3, respectively, for **13**; 0.57 and –0.40 e/Å^3, respectively, for **14**; and 0.63 and –0.53 e/Å^3, respectively, for **16**.

thermal parameters of non-hydrogen atoms, and fractional coordinates and thermal parameters of hydrogen atoms have been deposited.[5]

Results and discussion

The synthesis of bis(*S*-alkyl trithiocarbonato)dimethylgermanes, **1**–**4**, chloro(*S*-alkyl trithiocarbonato)diphenylgermanes, **5**–**8**, (*O*-alkyl monothiocarbonato)triphenylgermanes, **13**–**15**, bis(*O*-alkyl monothiocarbonato)diphenylgermanes, **16**–**18**, and (*O*-alkyl monothiocarbonato)trimethylgermanes, **19**–**21**, can be readily achieved in 73–90% yield by the reaction of the salt of the appropriate thiocarbonic acid in dried CS_2, CH_3Cl, or CH_2Cl_2 as solvent, or monothiocarbonic acid in dried CH_2Cl_2 as solvent with chlorotriphenylgermane, dichlorodiphenylgermane, or chlorotrimethylgermane using a standard Schlenk line in accord with eqs. [1]–[5]:

[1] $$Me_2GeCl_2 + 2KS_2CSR \rightarrow Me_2Ge[S_2CSR]_2 + 2KCl$$

[2] $$Ph_2GeCl_2 + KS_2CSR \rightarrow Ph_2GeCl[S_2CSR] + KCl$$
(R = Et, *i*-Pr, *n*-Pr, *n*-Bu)

[5] Copies of material deposited may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada. Tables of atomic coordinates have been deposited with the Cambridge Crystallographic Centre, and can be obtained on request from The Director, Cambridge Crystallographic Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K. Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

[3] $Ph_3GeCl + NaSCO_2R \rightarrow Ph_3Ge[SCO_2R] + NaCl$

[4] $Ph_2GeCl_2 + 2NaSCO_2R \rightarrow Ph_2Ge[SCO_2R]_2 + 2NaCl$

[5] $Me_3GeCl + NaSCO_2R \rightarrow Me_3Ge[SCO_2R] + NaCl$
(R = Me, *i*-Pr, *n*-Pr)

The salts are used in considerable excess relative to the stoichiometric requirements to ensure complete reaction in eqs. [1], [3], [4], and [5] and exact stoichiometric amounts in eq. [2] to favor the formation of the mixed chloro derivatives. It is essential that the trithiocarbonate salts be carefully repurified before use to avoid side reactions leading to polysulfides (23), but monothiocarbonate salts can be used as prepared provided pure dry alcohol was used in their preparation.

Chloro(*S*-alkyl trithiocarbonato)diphenylgermanes react readily in situ with bromotrimethylsilane in CS_2 or CH_2Cl_2 to give bromo(*S*-alkyl trithiocarbonato)diphenylgermanes, **9**–**12**, in accord with eq. [6]. An excess of Me_3SiBr is used as both it and Me_3SiCl are readily volatile and so are easily separated from the products.

[6] $Ph_2GeCl[S_2CSR] + Me_3SiBr \rightarrow Ph_2GeBr[S_2CSR] + Me_3SiCl$
(R = Et, *i*-Pr, *n*-Pr, *n*-Bu)

In general, all of the compounds are susceptible to moisture and air on exposure to the atmosphere, as was found for the corresponding dithiocarbonates as well as for the related trithiocarbonates reported earlier (15). This appears to be especially true for the bis-diphenyl derivatives, **16**–**18**, where the formation of crystals of $(Ph_2GeO)_3$, the ring trimer of diphenylgermanium oxide, was confirmed by X-ray crystallography (26) when solutions of $Ph_2Ge[SCO_2R]_2$ species in CH_2Cl_2 are evaporated over several days while exposed to moist air. In addition, the trithiocarbonates, **1**–**12**, characteristically readily undergo carbon disulfide elimination at room temperature in accord with eqs. [7]–[9], so that all of the compounds are stored at –15°C in sealed containers.

[7] $Ph_2GeX[S_2CSR] \rightarrow Ph_2GeX[SR] + CS_2$

[8] $Me_2Ge[S_2CSR]_2 \rightarrow Me_2Ge[S_2CSR][SR] + CS_2$

[9] $Me_2Ge[S_2CSR][SR] \rightarrow Me_2Ge[SR]_2 + CS_2$

All compounds were readily dissolved in chloroform, which was therefore used as the preferred solvent for recording NMR spectra.

Carbon disulfide elimination

In all cases, for **2**–**12**, attempts to distill the yellow oils under vacuum or to warm them to obtain their boiling points resulted in the rapid expulsion of CS_2. As found with the $Ph_3Ge[S_2CSR]$ species (15), the ^1H and ^{13}C NMR spectra of sealed samples of solutions of compounds **1**–**12** held at room temperature showed a steady decrease in intensity of the signals attributable to $Me_2Ge[S_2CSR]_2$, **1**–**4**, or $Ph_2XGe[S_2CSR]$, **5**–**12**, species. Typically, in the ^{13}C NMR spectra, a peak at 192.7 ppm, attributable to CS_2, soon appeared and steadily increased in intensity with time as the peak originally observed in the range 225.68–226.70 ppm for **1**–**4** and 217.35–224.86

ppm for **5**–**12**, attributable to the S_2CS carbon, decreased in intensity to eventually disappear. As with the $Ph_2Ge[S_2CSR]_2$ series, more complicated spectra were observed between the NMR spectra of the freshly prepared $Me_2Ge[S_2CSR]_2$ species, **1**–**4**, and the final spectra that contained only peaks attributable to CS_2 and $Me_2Ge[SR]_2$. The additional peaks were entirely consistent with the formation of the intermediate $Me_2Ge[S_2CSR][SR]$ compounds, whose relevant ^{1}H and ^{13}C NMR data are also presented in Tables 10 and 11, respectively. For the three derivatives that are oils, **2**–**4**, CS_2 elimination is complete after approximately 5 days. The halodiphenyl derivatives **5**–**12** decompose even more rapidly, the original signals attributable to $Ph_2GeX[S_2CSR]$ being totally lost in 1–2 days to be replaced by peaks attributable to the corresponding $Ph_2GeX[SR]$ compounds.

Nuclear magnetic resonance spectra

For $Me_2Ge[S_2CSR]_2$, **1**–**4**, the ^{1}H NMR chemical shifts (Table 10) of methyl attached to Ge are similar for all trithiocarbonate derivatives, being dependent on the number of groups attached to Ge rather than the alkyl group of the ligand. Thus, the chemical shifts of CH_3-Ge are at 1.42–1.43 ppm for **1**–**4** compared to 0.71–0.73 ppm for $Me_3Ge[S_2CSR]$ (15). The same phenomenon was noted for $Me_2Ge[S_2CNMe_2]_2$ and

© 1998 NRC Canada

$Me_3Ge[S_2CNMe_2]$, suggesting the group electronegativities of trithiocarbonates and dithiocarbamates are similar (6). In general, all alkyl group peaks of the ligands have the fine structure and relative intensities expected for first-order spectra, except of course for the central CH_2 groups in *n*-propyl and *n*-butyl. The phenyl signals in $Ph_2GeCl[S_2CSR]$, **5**–**8**, are very similar in appearance and position to those reported for $Ph_2Ge[S_2CSR]_2$ (15) while those of $Ph_2GeBr[S_2CSR]$, **9**–**12**, are similar to $Ph_3Ge[S_2CSR]$ derivatives (Table 12). The chemical shifts within the ligands of these halo derivatives have values that differ systematically from the bis-diphenyl compounds, the proton shifts being increasingly upfield in the order bis < Cl < Br. The similarity of all spectra suggests the trithiocarbonate groups are in identical environments in all compounds **1**–**12**.

In the ^{13}C NMR spectra (Tables 11 and 13) the chemical shifts of the alkyl groups in the ligand are relatively similar regardless of the nature (methyl or phenyl) or number of groups attached to germanium. Comparison with the corresponding S_2COR derivatives (12, 13) indicates similar values for chemical shifts of all alkyl carbon atoms except for those directly attached to the sulfur atom, the difference in shift being consistently ca. 35 ppm as illustrated by that of CH_2 in $Me_2Ge[S_2CSCH_2CH_3]_2$ (33.84) and $Me_2Ge[S_2COCH_2CH_3]_2$ (71.10 ppm) (12). In contrast, there is an upfield shift of ca. 14 ppm for the central trithiocarbonate carbon atom so that S_2CS has chemical shifts of 225.68–226.28 ppm for **1**–**4** (Table 11) compared to 207.04–212.12 ppm for S_2CO in related dithiocarbonates (12, 13). For **5**–**12** (Table 13), the chemical shifts in ligands are basically the same as in the corresponding bis compounds, while for the S_2CS carbon in $Ph_2GeCl[S_2CSR]$ the shift is downfield relative to $Ph_2Ge[S_2CSR]_2$ (15) by ca. 2 ppm, but is upfield by ca. 5 ppm for $Ph_2GeBr[S_2CSR]$. As noted for the ^1H NMR spectra, the consistencies in the ^{13}C NMR spectra point to similar trithiocarbonate environments in compounds **1**–**12**.

The ^1H and ^{13}C NMR spectral data for monothiocarbonate compounds **13**–**21** are presented in Tables 14 and 15, respectively. The ^1H NMR spectra recorded in $CDCl_3$ confirm that the products are over 98% pure relative to any hydrogen-containing impurities and integration ratios are as expected. The signals due to the phenyl groups in compounds **13**–**18** (two sets of peaks between 7.36 and 7.79 ppm) are very similar in appearance and position to those of the analogous dithiocarbonate and trithiocarbonate series (15) as well as other phenylgermanium derivatives containing Ge—S bonds, so once again the chemical shifts are dependent on the presence of the Ge—S link(s) rather than the nature of the thiocarbonate groups attached to sulfur (4–14). The monothiocarbonate ligands again give first-order spectra when expected, with chemical shifts comparable to those of the corresponding salts. The chemical shifts of hydrogen atoms on the carbon atom attached to oxygen (i.e., $OCH/OCH_2/OCH_3$) are similar for a given monothiocarbonate regardless of the number of phenyl groups attached to germanium, as was observed for the corresponding OCH_n groups in analogous dithiocarbonates and SCH_n groups in trithiocarbonates. The chemical shifts in the O-linked monothiocarbonates lie between those of the O-linked dithiocarbonates and the S-linked trithiocarbonates, suggesting that the electronegativity of the SCO_2 group lies between those of S_2CO and S_2CS. In $Me_3Ge[SCO_2R]$ species **19**–**21**, the CH_3-Ge chemical shifts hardly vary, the values being slightly less than those reported for $Me_3Ge[S_2CNMe_2]$ and the $Me_3Ge[S_2CSR]$ derivatives (15), which is consistent with the group electronegativity of monothiocarbonates being slightly larger than those of dithiocarbamates (6) and trithiocarbonates. The similarity of all of the spectra again indicates that the environments of the monothiocarbonate groups in solution are identical in **13**–**21**.

In the ^{13}C NMR spectra, the chemical shifts of monothiocarbonate alkyl groups are again similar regardless of the number or nature of groups attached to germanium. The chemical shifts for the carbon atom of the SCO_2 groups in **13**–**21** range from 167.28 to 170.80 ppm, compared to 207.04 to 212.12 ppm for a variety of S_2CO groups, and 221.36 to 226.41 ppm for the S_2CS groups in the analogous trithiocarbonates. The $(CH_3)_3Ge$ chemical shifts are similar for **19, 20**, and **21** and are close to those of the analogous dithiocarbonates (11, 12) and trithiocarbonates. The general similarity of the values of the ^{13}C NMR chemical shifts in **13**–**21** is again consistent with the presence of similar monothiocarbonate linkages in solution.

Infrared and Raman spectra

Distinctive features in the infrared and Raman spectra and their assignments are given in Table 16 for $Me_2Ge[S_2CSR]_2$, **1**–**4**, and in Table 17 for $Ph_2GeCl[S_2CSR]$, **5**–**8**, and $Ph_2GeBr[S_2CSR]$, **9**–**12**. The assignments in the tables make use of such factors as the distinctive strong methyl germanium rocking mode at approximately 850 cm^{-1} (11); the pairs of fingerprints of decreasing intensity at ca. 740 and 695 cm^{-1}, 460 and 335 cm^{-1}, and 1435 and 1095 cm^{-1} in the infrared spectra for phenyl germanes and the very intense Raman peak close to 1000 cm^{-1} (12); comparisons with the spectra of previously reported related organogermanium trithiocarbonates; comparisons with the spectra of the starting salts, KS_2CSR; and the decrease in intensity of strong bands in the spectra of all of the compounds **1**–**24** as CS_2 elimination occurs. The labelling of the phenyl modes uses the Wiffen convention (27).

Typical values for C═S and C–S stretching vibrations are 1090 and 700 cm^{-1}, respectively, so assigning four specific stretches as $\nu(S{=}CS_2)$, $\nu(S_2C{-}SR)$, $\nu(S_2CS{-}C)$, and $\nu(GeS{-}CS_2)$ is not reasonable because the average positions of $\nu(S_2CSC)_a$, $\nu(S_2CSC)_b$, $\nu(S_2CSC)_c$, and $\nu(S_2CSC)_d$ are 1069, 1044, 826, and 515 cm^{-1}, respectively. Their similarity in all derivatives suggests that all are strongly coupled in a similar fashion and all have structures similar to those of $Me_2Ge[S_2CSEt]_2$, **1**, and $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$ (15). The assignment of $\nu(S_2CSC)_d$ at ca. 515 cm^{-1} is close to that of the symmetric stretch in CS_3^{2-} (28), while the asymmetric stretch in CS_3^{2-} is typically seen in the range of 900–950 cm^{-1}, which is bracketed by the positions of $\nu(S_2CSC)_b$, and $\nu(S_2CSC)_c$. The asymmetric and symmetric Ge–C stretches are seen at ca. 626 and 580 cm^{-1} in all $Me_2Ge[S_2CSR]_2$, **1**–**4**, these values being similar to those in Me_2GeCl_2. The similarity of the position and separation between the modes indicates that **1**–**4** should have C-Ge-C angles as wide as that of 121(4)° in Me_2GeCl_2 (29). Table 6 confirms that the C-Ge-C angle in $Me_2Ge[S_2CSEt]_2$ is 128.8(6)°.

The Ge–Cl stretching vibration, $\nu(Ge{-}Cl)$, is close to 282 cm^{-1} in all $Ph_2GeCl[S_2CSR]$, **5**–**8**, compared to an average of ca. 400 cm^{-1} in Ph_2GeCl_2. A similar shift was noted for

$Me_2GeCl[S_2CNEt_2]$ where ν(Ge–Cl) was assigned at 293 cm^{-1} (8). Similarly, ν(Ge–Br), is at ca. 224 cm^{-1} in all $Ph_2GeBr[S_2CSR]$, **9**–**12**, compared to ca. 315 cm^{-1} Ph_2GeBr_2. This weakening of the Ge—X bond by the trithiocarbonate group may contribute to the difficulty of isolating the mixed $Me_2GeX[S_2CSR]$ species. A weak Ge—X bond, accompanied by less stereochemical hindrance to an incoming group with Me rather than Ph groups attached to germanium, could result in partially substituted compounds acting as reactive intermediates that could also undergo rapid exchange to the bis substituted species and dihalodimethylgermane.

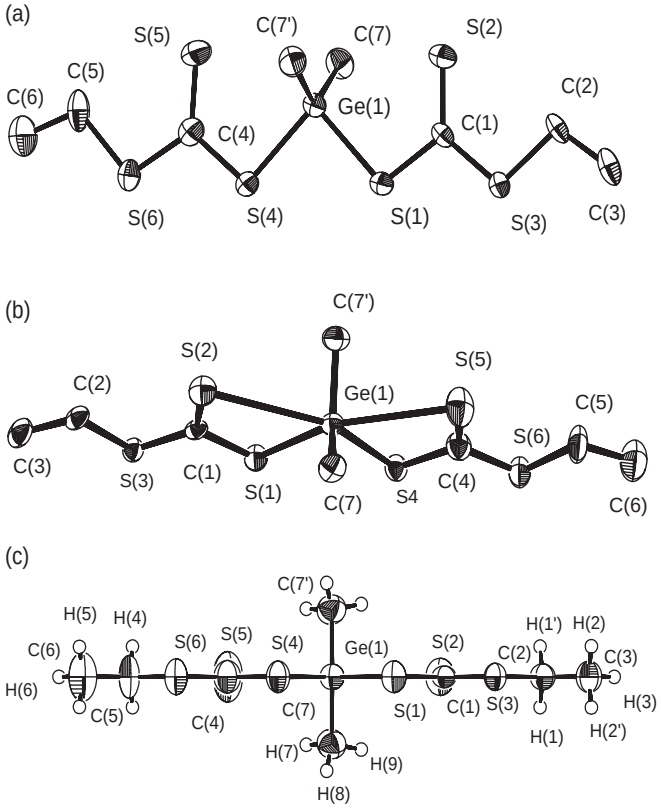
Distinctive features in the infrared and Raman spectra and their assignments are given for $Ph_3Ge[SCO_2R]$, **13**–**15**, $Ph_2Ge[SCO_2R]_2$, **16**–**18**, and $Me_3Ge[SCO_2R]$, **19**–**21**, in Tables 18–20. The assignments are based on the same factors described for the trithiocarbonates along with trends involving related dithiocarbonate species. A strong band attributable to the C═O stretching vibration, ν(C═O), which is observed at ca. 1620 cm^{-1} in the $NaSCO_2R$ salts, is shifted to higher wave number (1690–1703 cm^{-1}) in all nine compounds. This supports the presence of an essentially monodentate monothiocarbonate ligand with a very strong terminal C═O bond. The O atoms of the SCO_2C group should give rise to two intense peaks in the infrared spectra, in addition to the one at 1690–1703 cm^{-1}, and two such peaks, which are presumably primarily attributable to ν(SC–O) and ν(SCO–C), are seen in the region 1188–1066 cm^{-1} for **13**–**21,** designated $\nu(SCO_2C)_b$ and $\nu(SCO_2C)_c$, respectively. These assignments are entirely consistent with the X-ray structures of compounds **13, 14**, and **16**. Two distinctive strong peaks are also seen at ca. 840 and 670 cm^{-1}. The former can be assigned to the out-of-plane bend, $\pi(SCO_2)$, which is assigned at 830–873 cm^{-1} for $\pi(CO_3)$ in carbonate salts, suggesting similar π-electron delocalization in these planar groups. The fourth stretching vibration, $\nu(SCO_2C)_d$, presumably primarily ν(GeS–C), is assigned to 670–678 cm^{-1}, which is similar to general assignments of C—S single bonds and to the assignments reported for the corresponding dithiocarbonates.

The Ge–S vibrational modes are readily assigned within 440–400 cm^{-1} for **13**–**21** in similar positions to those in the dithiocarbamates (4–6) and Me_3GeSR (30), but at slightly higher wave number compared to those of the trithiocarbonates. This is consistent with the greater tendency for the trithiocarbonates to form anisobidentate links leading to slightly weaker Ge—S primary bonds. The Ge—S bond lengths in **13, 14**, and **16** are slightly shorter than those of $Me_2Ge[S_2CSEt]_2$, **1**, and $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$.

The crystal structure of $Me_2Ge[S_2CSEt]_2$, 1

Dimethylbis(*S*-ethyl trithiocarbonato)germane, **1**, crystallizes in the space group $P2_1/m$. The ORTEP diagram in Fig. 1(*a*) illustrates, along with Table 6, that the immediate environment about germanium is that of a distorted tetrahedron. The S-Ge-C angles have an average value of 108.8(10)° compared with 111.8(17)° for $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$ (15). By contrast, the C-Ge-C angles are very much larger than the regular tetrahedral angle: 128.8(6)° in **1** compared with 118.1(3)° in $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$. This opening up of the C-Ge-C angle in $Me_2Ge[S_2CSEt]_2$ was predicted from its vibrational spectrum. The average Ge—C bond length of 1.93(1) Å is typical for R_2GeL_2 or R_3GeL species, where L is a sulfur-bonding moiety,

Fig. 1. ORTEP plots of the molecule $Me_2Ge[S_2CSEt]_2$ (**1**) illustrating (*a*) the tetrahedral environment about germanium, (*b*) the pendant sulfur atoms acting as weak donors, and (*c*) the planarity of all non-hydrogen atoms except the carbon atoms of the ethyl groups. The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms omitted for clarity in (*a*) and (*b*).



being similar to those in $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$, $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$ (12), $Me_2Ge[S_2CNMe_2]_2$ (6), $Me_2GeCl[S_2CNMe_2]$ (5), and even in $Ph_3GeSC_6H_4(t\text{-}Bu)$ (31).

The closing down of the S-Ge-S angles to 90.0(1)° in **1** is similar to that observed in the dithiocarbamate analogues, $Ph_2Ge[S_2CNEt_2]_2$ and $Me_2Ge[S_2CNMe_2]_2$, where the S-Ge-S angles are 84.4(1)° and 87.0(1)°, respectively. These smaller angles are associated with the fact that a terminal sulfur (C═S) atom is oriented toward the germanium center (see Fig. 1) at Ge—S distances of 3.051(5) and 3.246(5) Å for $Me_2Ge[S_2CSEt]_2$, 3.078(2) and 3.158(2) Å for $Me_2Ge[S_2CNMe_2]_2$, 3.224(5) and 3.304(5) Å for $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$, and 3.183(1) Å for $Ph_2Ge[S_2CNEt_2]_2$. By contrast, in the analogous dithiocarbonate, $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$, where the terminal sulfur atom is oriented away from the germanium center (with Ge—S = 4.753(4) Å), the S-Ge-S angle is much larger at 103.2(1)° (12). Whether distances in the range of 3.05–3.3 Å, which are considerably less than the sum of the van der Waals radii of 3.75 Å, are sufficiently short to be considered as partial bonds may be questioned, but there is a relationship between these Ge—S nonbonding or anisobonding distances and the closing down of the S-Ge-S angle from the regular tetrahedral angle when the sulfur atom is oriented toward, rather than away from, germanium.

The average Ge—S bond length (2.295(1) Å) in **1** is longer than in the analogous dithiocarbonate, $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$

© 1998 NRC Canada

(2.252(3) Å) in which there are no Ge—S secondary interactions (15). However, it is similar to those in $Ph_2Ge[S_2CNEt_2]_2$, $Me_2Ge[S_2CNMe_2]_2$, and other germanium dithiocarbamates where there is the same probability of the presence of secondary bonding (6, 14). In view of the similarities noted in the spectra of the trithiocarbonates, all of these *S*-alkyl trithiocarbonate derivatives probably have the same weak anisobidentate bonding as indicated by the molecular structures of $Me_2Ge[S_2CSEt]_2$, **1**, and $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$ (15). The C═S bonds in **1**, which average 1.63(8) Å, are very slightly longer than those in $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$, 1.61(1) Å, which is again consistent with the presence of weak secondary interactions leading to the orientation of the terminal C═S rather than the CSR moiety toward the germanium centre. The average bite angle of 62.4(7)° in $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$ is essentially the same as that in $Ph_2Ge[S_2CNEt_2]_2$, where anisobidentate linkages appear to give a better overall description of the bonding of dithiocarbamates to germanium (14). There is an even larger bite angle of 65.8(1)° in **1**, which suggests an even stronger anisobidentate bond as implied by the inclusion of Ge(1)—S(2) and Ge(1)—S(4) bonds in Fig. 1(*b*).

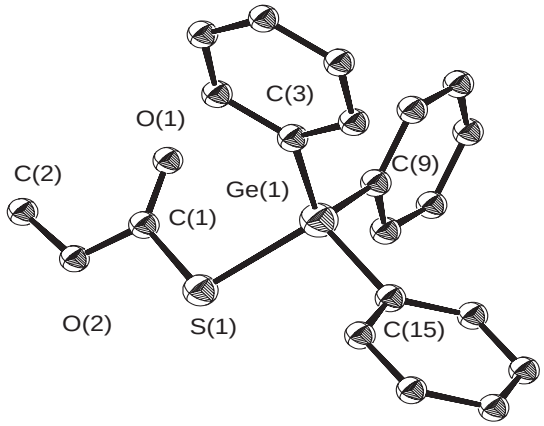
The S—CR bonds in the trithiocarbonate groups at 1.82(2) Å are essentially as expected from the sum of the covalent radii of S and C, whereas the average length of C—SGe and C—SR bonds is 1.74(2) Å, and that of the "terminal" C═S bond is 1.63(1) Å, indicating that π-electron density delocalization is not significantly extended beyond the planar groups. Nevertheless, all of the non-hydrogen atoms in both trithiocarbonate groups are coplanar, as required by the mirror plane, and the relationship between the groups is well illustrated by Fig. 1(*c*).

The crystal structures of $Ph_3Ge[SCO_2Me]$, 13, $Ph_3Ge[SCO_2(i\text{-}Pr)].0.5CH_2Cl_2$, 14, and $Ph_2Ge[SCO_2Me]_2$, 16

Triphenyl(*O*-methyl monothiocarbonato)germane, **13**, and triphenyl(*O*-isopropyl monothio-carbonato)germane, **14**, both crystallize in the space group $P\bar{1}$ (No. 2), the latter with dichloromethane in the lattice. The ORTEP diagrams in Figs. 2 and 3 illustrate, along with Tables 7 and 8, that the immediate environment about germanium in both molecules is that of a distorted tetrahedron. The average values of the C-Ge-C angles are 110.8(4)° in **13** and 111.6(16)° for the two independent molecules in **14**, while those of the S-Ge-C angles are 108(6)° in **13** and 107(5)° in **14**. It is immediately obvious that the variation in the S-Ge-C angles is larger than for the C-Ge-C angle, which arises because one S-Ge-C angle is considerably smaller (100.4(3)° in **13** and 99.4(3)° in **14**) than the other two (111.8(15)° in **13** and 110.7(27)° in **14**). All of these values are close to those found for the analogous dithiocarbonates, $Ph_3Ge[S_2COMe]$ and $Ph_3Ge[S_2CO(i\text{-}Pr)]$. The similarity extends to dithiophospates, such as $Ph_3Ge[S_2P(OMe)_2]$, where one S-Ge-C angle is again significantly smaller than the other two (4). In the dithiocarbonates and dithiophosphates, an alkoxy group is oriented towards germanium in preference to a terminal sulfur atom, whereas in **13** and **14** the alkoxy group is oriented away from germanium and the terminal oxygen atom toward germanium. Possibly, the slightly smaller range in the S-Ge-C angles in the monothiocarbonates reflects the fact that the less bulky terminal oxygen atom is more readily accommodated.

The Ge—C distances, which range from 1.931(9) to 1.950(9) Å in **13** and 1.93(1) to 1.94(1) Å in **14**, are comparable with those found in the analogous trithiocarbonates and related species as described above, and cover the same range as in the dithiophosphate, $Ph_3Ge[S_2P(OMe)_2]$, 1.930(5)–1.950(5) Å. The Ge—S bond length of 2.254(3) Å in both **13** and **14** is bracketed by those reported for the dithiocarbonates, $Ph_3Ge[S_2COMe]$ (2.249(4) Å) and $Ph_3Ge[S_2CO(i\text{-}Pr)]$ (2.272(2) Å), and slightly shorter than in the dithiophosphate, $Ph_3Ge[S_2P(OMe)_2]$ (2.285(1) Å).

Fig. 2. ORTEP plot of the molecule $Ph_3Ge[SCO_2Me]$ (**13**). The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms omitted for clarity.



As expected, the terminal C═O bond lengths of 1.19(1) and 1.20(5) Å in **13** and **14**, respectively, are much shorter than the other C—O bonds. They are also close to the expected value for a C═O double bond. The SC—O bonds, in turn, are significantly shorter than the SCO—C bonds, being similar to those reported for the two analogous dithiocarbonates (avg. 1.34(1) and 1.45(1) Å, respectively), which is consistent with the π-bond character not extending significantly beyond the planar SCO_2 core.

The terminal O atom is oriented towards germanium, with the Ge—O distance being 3.112(7) and 3.12(2) Å in **13** and **14**, respectively, which is similar to the Ge—S distances in trithiocarbonates. Thus, the intramolecular interactions, if any, must be extremely weak. However, as mentioned above, the orientations of the ligand in the dithiocarbonates and $Ph_3Ge[S_2P(OMe)_2]$ are both such as to place the (OR) groups, rather than the terminal sulfur atoms, closer to the germanium center and the Ge—OR distances in $Ph_3Ge[S_2COMe]$ (2.98(2) Å) and $Ph_3Ge[S_2CO(i\text{-}Pr)]$ (3.115(4) Å), are similar to the Ge—O(terminal) distances in **13** and **14**.

Diphenylbis(O-methyl monothiocarbonato)germane, $Ph_2Ge[SCO_2Me]_2$, **16**, crystallizes in the space group *Cc* (No. 9). The ORTEP diagram (Fig. 4) and Table 9 confirm that the immediate environment about germanium is again the expected distorted tetrahedron. The S-Ge-S angle of 93.3(7)° and C-Ge-C angle of 117.85(7)° are very close to those in the analogous dithiocarbonates, $Ph_2Ge[S_2COMe]_2$, where the corresponding angles are 93.4(2)° and 117.1(3)°) (11). The distortion from the regular tetrahedral angle is greater than was found for $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$ (12), where the corresponding angles are 103.2(1)° and 115.6(3)°, but less than that found for the trithiocarbonate, $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$, described earlier (15), where the corresponding angles are 87.3(2)° and 118.1(3)° respec-

Fig. 3. ORTEP plot of the molecule $Ph_3Ge[SCO_2(i\text{-}Pr)]$ (**14**) showing both molecules in the asymmetric unit as well as the CH_2Cl_2 trapped in the lattice. The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms omitted for clarity except for those in dichloromethane.

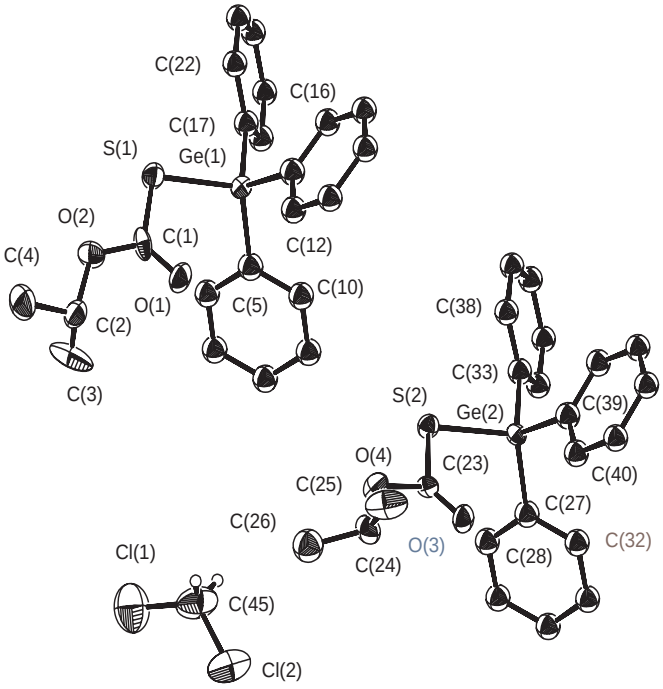

Fig. 4. ORTEP plots of the molecule $Ph_2Ge[SCO_2Me]_2$ (**16**) showing different views of the two molecules in the asymmetric unit. The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms omitted for clarity except for those in dichloromethane.

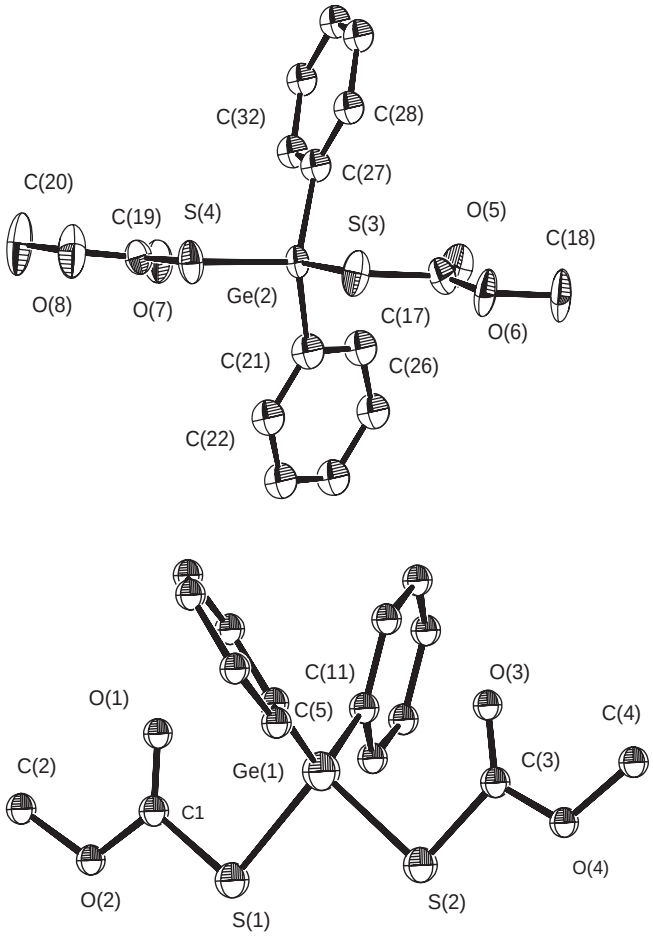

tively, or $Me_2Ge[S_2CSEt]_2$, **1**, with angles of 90.0(1)° and 128.6(6)°, respectively. The S-Ge-S angle in **16** is considerably wider than the 84.4° in $Ph_2Ge[S_2CNEt_2]_2$ (8), where the ligand was assumed to be anisobidentate.

The Ge—C bond length of 1.928(5) Å in **16** is again very similar to those reported for **13** and **14**, as well for trithiocarbonates including **1**, and the other S-linked groups mentioned earlier. The average Ge—S bond length in **16** of 2.258(4) Å brackets those observed in $Ph_2Ge[S_2COMe]_2$ (2.262(3) Å) and $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$ (2.252(1) Å) and is slightly shorter than those found for the dithiocarbamate, $Ph_2Ge[S_2CNEt_2]_2$ (2.277(2) Å) and the trithiocarbonate, $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$ (2.280(5) Å). In general, the bis compounds appear to have slightly longer Ge—S bonds than those containing only one thio ligand as in **13** and **14.**

The GeS—C average bond length in **16** of 1.77(1) Å is not significantly different from those in **13** and **14**, and is typical of values observed in $Ph_2Ge[S_2COMe]_2$, $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$, and $Ph_2Ge[S_2CNEt_2]_2$ (1.76(1) Å), as well as for $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$ (1.745(6) Å). The distances between germanium and the terminal O atom of 3.00(1) and 3.07(1) Å are similar to those in **13** and **14**, as are the S-Ge—O bite angles, which range from 57.3(3)° to 62.9(1)°, again indicating that if there is any secondary interaction between germanium and the terminal O atom, it must be very weak. The bond lengths and angles within the SCO_2C group of **16** are essentially the same as in **13** and **14**. The angles in the planar core do indeed add up to 360°, with average values in **16** being O═C-S (125.8(13)°), O═C-O (125.8(17)°), and S-C-O (108.5(13)°) compared with O═C-S (125.0(14)°), O═C-O (125.7(6)°, and S-C-O (109.3(16)° for **13** and **14**. The much larger angles involving the terminal C═O bond reflect the fact that this is the bond most strongly involved in the delocalized π-bonding. The average value of the C-O-C angle in all three molecules is 116(1)°, which is consistent with much less π-bond character in C—O bonds involved in the C-O-C link than in the SCO_2 core. The Ge-S-C angles, which ranged from 96.5(7)° to 100.5(6)°, are somewhat smaller, but essentially very similar to the corresponding angles in $Ph_2Ge[S_2COMe]_2$, 102.7(5)°, $Ph_2Ge[S_2CO(i\text{-}Pr)]_2$, 105.0(3)°, $Ph_2Ge[S_2CNEt_2]_2$, 102.1(1)°, as well as in $Ph_2Ge[S_2CS(i\text{-}Pr)]_2$, 101(1)°, indicating little or no change in the nature of this link regardless of the thio derivative attached.

Concluding comments

Previous studies of organogermanium dithiocarbonates gave a wide variety of relatively stable derivatives, some of which were tested for suitability as oil additives. Given the paucity of work on any main group monothiocarbonates, it is somewhat surprising that organogermanium monothiocarbonates have proven to be relatively easy to prepare and characterize fully by spectroscopic methods as well as by X-ray crystallography. However, the organogermanium trithiocarbonates all readily

© 1998 NRC Canada

eliminate CS_2 regardless of the nature of the organo groups or the number of groups attached to germanium. By contrast, the only sign of reductive elimination in the monothiocarbonates is the presence of the COS^+ ion in some of their mass spectra. The interpretation of the NMR and vibrational spectra is entirely consistent, with the structures found in the solid state being essentially maintained in solution. Thus, like the dithiocarbonates, there is an essentially monodentate link through sulfur. However, in all cases in the solid state, there is apparently a weak interaction with the "terminal" sulfur atom (for tri- and dithiocarbonates) and possibly even with the "terminal" oxygen atom (for monothiocarbonates) as these atoms are oriented toward the germanium center at distances well inside that of the sum of the van der Waals radii, particularly for Ge—S. In related tellurium species, we found that on occasion, as in $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, one of the OR groups was oriented toward tellurium and the pendant oxygen was possibly involved in a weak link to an adjacent tellurium center, creating a weakly bonded extended structure. There was no indication of similar behavior with germanium.

The decarbonylation of ionized β-hydroxypyruvic acid: the hydrogen-bridged radical cation $[CH_2{=}O{\cdots}H{\cdots}O{=}C\text{-}OH]^{\bullet+}$ studied by experiment and theory

Lorne M. Fell, Peter C. Burgers, Paul J.A. Ruttink, and Johan K. Terlouw

Abstract: The intriguing gas-phase ion chemistry of β-hydroxypyruvic acid (HPA), $HOCH_2C(=O)COOH$, has been investigated using tandem mass spectrometry (metastable ion (MI) and (multiple) collision-induced dissociation (CID) experiments, neutralization–reionization mass spectrometry (NRMS), ^{18}O and D isotopic labelling on both the acid and its methyl ester) in conjunction with computational chemistry (ab initio MO and density functional theories). HPA does not enolize upon evaporation, but it retains its keto structure. When ionized, decarbonylation occurs and, depending on the internal-energy content, this dissociation reaction proceeds via two distinct routes. The source-generated, high-energy ions lose the keto C═O, not via a least-motion extrusion into ionized glycolic acid, $HOCH_2COOH^{\bullet+}$, but via a rearrangement that yields the title H-bridged radical cation $CH_2{=}O{\cdots}H{\cdots}O{=}C\text{-}OH^{\bullet+}$ for which $\Delta H_f^0 = 99 \pm 3$ kcal/mol. The long-lived low-energy ions enolize prior to decarbonylation and lose the carboxyl C═O. Again, this is not a least-motion extrusion (which would produce the most stable isomer, $HOC(H){=}C(OH)_2^{\bullet+}$, $\Delta H_f^0 = 73$ kcal/mol) but a rearrangement yielding the ion–dipole complex $HOC(H)C{\equiv}C{=}O^{\bullet+}/H_2O$. The methyl ester of HPA behaves analogously, yielding $CH_2{=}O{\cdots}H{\cdots}O{=}C\text{-}OCH_3^{\bullet+}$ and $HOC(H)C{\equiv}C{=}O^{\bullet+}/CH_3OH$ upon decarbonylation of the high- and low-energy ions, respectively. Decarboxylation into the ylidion $CH_2OH_2^{\bullet+}$ characterizes the dissociation chemistry of both the title H-bridged ion and its glycolic acid isomer $HOCH_2COOH^{\bullet+}$. A computational analysis of this reaction (which satisfies the experimental observations) leads to the proposal that the decarboxylation of the acid occurs via $CH_2\text{-}O(H){\cdots}H{\cdots}O{=}C{=}O^{\bullet+}$ as the key intermediate, whereas the title H-bridged ion follows a higher energy route that involves ion–dipole rotations leading to the ionized carbene $HO(H_2)CO\text{-}C\text{-}OH^{\bullet+}$ and the distonic ion $H_2O\text{-}C(H_2)\text{-}O\text{-}C{=}O^{\bullet+}$ as key intermediates.

Key words: tandem mass spectrometry, hydrogen-bridged radical cation, hydroxypyruvic acid, ab initio calculations, keto–enol tautomerization, ^{18}O labelling.

Résumé : Faisant appel à la spectrométrie de masse en tandem (ion métastable (IM) et expériences de dissociations induites par des collisions (DIC) (multiples), spectrométrie de masse avec neutralisation et réionisation (SMNR), marquage isotopique à ^{18}O et D tant de l'acide que de l'ester méthylique) en combinaison avec des calculs théoriques (théories de OM ab initio et densité fonctionnelle), on a étudié la chimie ionique en phase gazeuse de l'acide β-hydroxypyruvique (AHP), $HOCH_2C(=O)COOH$, qui présente des caractéristiques intrigantes. L'AHP ne s'énolise pas par évaporation; elle garde sa structure cétonique. Son ionisation provoque une décarbonylation et, suivant le niveau de l'énergie interne, cette réaction se produit par le biais de deux voies distinctes. Les ions d'énergie élevée générés par la source perdent le groupe carbonyle, C═O, non pas par une extrusion de moindre mouvement conduisant à l'acide glycolique ionisé, $HOCH_2COOH^{\bullet+}$, mais par le biais d'un réarrangement conduisant au cation radical à pont hydrogène mentionné dans le titre, $CH_2{=}O{\cdots}H{\cdots}O{=}C\text{-}OH^{\bullet+}$, pour lequel le $\Delta H_f^0 = 99 \pm 3$ kcal mol)[1]. Les ions de faible énergie et de longue vie s'énolisent avant la décarbonylation et ils perdent le C═O du carboxyle. Encore une fois, il ne s'agit pas d'une extrusion par le moindre mouvement (qui produirait l'isomère le plus stable, $HOC(H){=}C(OH)_2^{\bullet+}$, $\Delta H_f^0 = 73$ kcal mol^{-1}), mais d'un réarrangement conduisant au complexe ion–dipôle $HOC(H)C{\equiv}C{=}O^{\bullet+}/H_2O$. L'ester méthylique de l'AHP se comporte de la même manière et les décarbonylations des ions à haute et à basse énergie conduisent respectivement aux ions radicaux $CH_2{=}O{\cdots}H{\cdots}O{=}C\text{-}OCH_3^{\bullet+}$ et $HOC(H)C{\equiv}C{=}O^{\bullet+}/CH_3OH$. La décarboxylation de l'ion ylure $CH_2OH_2^{\bullet+}$ caractérise la chimie de dissociation de l'ion à pont hydrogène mentionné dans le titre ainsi que son isomère de l'acide glycolique, $HOCH_2COOH^{\bullet+}$. Une analyse de cette réaction

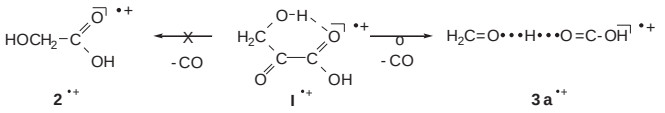
Introduction

In the context of ionic rearrangements, hydrogen-bridged radical cations (for selected reviews see ref. 1), particularly O···H···O and N···H···O bonded ions, are being proposed with increasing frequency as intermediates to rationalize the dissociation behaviour of low-energy radical cations. This growing realization (2) follows findings from both theory and experiment that such hydrogen-bridged species can be thermodynamically more stable than the nonrearranged reactant, which makes them energetically attractive intermediates. Ab initio calculations on such species do not only attest to their stability, they also confirm the intuitive expectation that the bridging H in these complexes is more closely connected to the moiety of higher proton affinity (PA). In fact, such (necessarily asymmetric) O···H···O bridged radical cations can best be described as H-bridged ion–dipole complexes of the type [M···H-R]$^{\bullet+}$ or [M-H···R]$^{\bullet+}$ (M = molecule, R = radical), where most of the stabilization energy is provided by ion–dipole interactions. As shown in recent studies on ionized ethylene glycol, $HOCH_2CH_2OH^{\bullet+}$ (3), acetol, $CH_3C(=O)CH_2OH^{\bullet+}$(4), and several related molecules (5), the O···H···O intermediates undergo a facile isomerization leading to C-H···O bridged ions, and these are the key intermediates in the low-energy dissociation reactions of the molecular ions. Such C-H···O species are not as stable as their O···H···O bonded counterparts, but calculations indicate that they can be easily formed from O···H···O bonded ions by a dipole-catalyzed proton shift (3, 4), a process that is identical to Böhme's concept of "proton-transfer catalysis" (6).[2] In a recent experimental study (7) it was observed that the isomerization $CH_3OH^{\bullet+} \rightarrow CH_2OH_2^{\bullet+}$, which does not occur unassisted, can be catalyzed by the addition of water; this constitutes a prime example of proton-transport catalysis, which has recently been confirmed and elegantly rationalized by the ab initio computational studies of Radom and co-workers (7*c–e*).

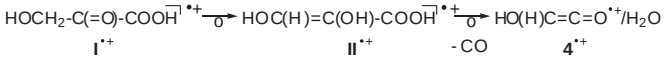
Despite their role as key intermediates in dissociation reactions, only relatively few H-bridged radical cations have been characterized as stable product ions, in part because of the experimental difficulties to differentiate such ions from their distonic counterparts (1*c*). The well characterized species include the vinyl alcohol – water and methanol ions CH_2═C(H)O···H···$OH_2^{\bullet+}$ and CH_2═C(H)O···H···$HOCH_3^{\bullet+}$ (2), the carbonic acid isomer HO···H···O═C═O$^{\bullet+}$(8), CH_3(H)O···H···O═C-H$^{\bullet+}$(9), which is also a key intermediate in the dissociation chemistry of ionized ethylene glycol (3), and most recently H_2O···H···O═C-OH$^{\bullet+}$. The latter ion was shown in a combined experimental and theoretical study to be the stable product ion formed by the consecutive loss of three CO molecules from HOOC(OH)═C(OH)COOH$^{\bullet+}$, ionized dihydroxyfumaric acid (DHF) (10).

In the present study we report on the identification of a related H-bridged radical cation, viz. CH_2═O···H···O═C-OH$^{\bullet+}$, which forms part of the $C_2H_4O_3^{\bullet+}$ (*m/z* 76) system of ions and which inter alia comprises ionized glycolic acid, $HOCH_2COOH^{\bullet+}$, and its enol HOC(H)═C(OH)$_2^{\bullet+}$ (11) as members whose neutral counterpart are molecules of conventional structure. A combination of tandem mass spectrometric techniques (metastable ion (MI), collision-induced dissociation (CID), neutralization–reionization mass spectrometry (NRMS), and MS/MS/MS experiments) and computational chemistry (using ab initio MO and density functional theories) is used to show that the decarbonylation of ionized ß-hydroxypyruvic acid (HPA), **I**$^{\bullet+}$, does *not* lead, via a least-motion extrusion, to ionized glycolic acid, **2**$^{\bullet+}$, nor to its enol, **1**$^{\bullet+}$, but rather to the H-bridged radical cation **3a**$^{\bullet+}$:



This H-bridged ion has two closely related isomers, viz. CH_2═O···H···O(H)-C═O$^{\bullet+}$, **3b**$^{\bullet+}$, and CH_2O(H)···H···O═C═O$^{\bullet+}$, **3c**$^{\bullet+}$, of which the latter, as shown in the theoretical section below, is by far the most stable. Since formation of $CH_2OH_2^{\bullet+}$ and CO_2 represents the dissociation reaction of lowest energy requirement in **3a**$^{\bullet+}$ and also in **2**$^{\bullet+}$, the participation of **3c**$^{\bullet+}$ in their isomerization cum dissociation reactions will be considered using results of ab initio MO theoretical calculations.

The above scenario refers to the decarbonylation reaction in the ion source, i.e., the loss of CO from high-energy HPA ions. Low-energy (metastable) HPA ions also lose CO but, it will be shown, from molecular ions that have isomerized into their enol counterpart, viz. ionized 1,2-dihydroxyacrylic acid, **II**$^{\bullet+}$:



The resulting product ion is not the H-bridged species **3a**$^{\bullet+}$ but the more stable ion–dipole complex **4**$^{\bullet+}$ whose dissociation chemistry is related to that of the enol ion HOC(H)═C(OH)$_2^{\bullet+}$, **1**$^{\bullet+}$, (11).

The principal precursor molecule used in this study, ß-hydroxypyruvic acid, has been the subject of numerous biochemical studies (12, 13) but, unlike pyruvic acid itself, HPA is a thermally labile compound that decomposes vigorously at

[2] For CH_3^+ shuttle see V. Baranov et al. (6).

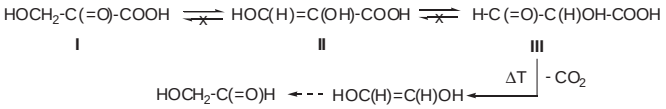
Scheme 1.



its melting point, 82°C (13*a*). This facile decomposition of the pure solid at elevated temperatures is a decarboxylation that also occurs in aqueous solutions of varying acidity at room temperature where it has been proposed (13*c*, *d*) to yield glycol aldehyde, $HOCH_2CHO$, as the final reaction product. The reaction of HPA in the solid melt may well occur analogously to that established for the decarboxylation of oxalacetic acid (14) i.e., as shown in Scheme 1.

In this context we note that the statement in entry H-0-03641 of the latest edition of *The Dictionary of Organic Compounds* (15) that HPA would consist of an equilibrium mixture of **I** with its enol 1,2-dihydroxyacrylic acid, **II**, is clearly incorrect. The IR spectroscopic findings of Bellamy and Williams (13*b*), the polarographic and UV results of Fleury and Fleury (13*e*), and also the results of our own deuterium incorporation experiments described in the experimental section leave little doubt that at room temperature solid ß-hydroxypyruvic acid and aqueous solutions thereof consist of the keto structure **I**.

Results and discussion

1. Conventional EI mass spectra of ß-hydroxypyruvic acid: thermal decarboxylation vs. electron impact induced decarbonylation

The rather striking differences between the mass spectra displayed in Figs. 1*a* and *b* illustrate how strongly the EI mass spectrum of HPA ($M = 104$) depends upon the method of sample introduction. Figure 1*a* is representative of a typical spectrum obtained from a "bulk" sample introduced at the lowest possible temperature (see Experimental for further details). The overall appearance of the spectrum obtained under these conditions remained fairly constant. The spectrum displays a molecular ion at *m*/*z* 104 and, in the absence of further information, most of the other peaks including the base peak at *m*/*z* 31, CH_2OH^+, can readily be assigned as fragment ions generated from $\mathbf{I}^{\bullet+}$.

Figure 1*b* shows the spectrum obtained from the same sample but now using a much higher source temperature, 170°C. Comparison with Fig. 1*a* shows that the relative intensity of the signals at *m*/*z* 60 and *m*/*z* 44 has greatly increased. The CID spectra of these ions were obtained (spectra not shown), and comparison with reference spectra (16*a*) shows that the *m*/*z* 60 ions are a mixture of $HOCH{=}C(H)OH^{\bullet+}$ and $HOCH_2CHO^{\bullet+}$, whereas the *m*/*z* 44 ions are $CO_2^{\bullet+}$.

Thus at elevated temperatures **I** is prone to decarboxylate, and the structure of the reaction products supports the mechanism presented in Scheme 1 of Introduction.

On the other hand, the decarbonylation responsible for the *m*/*z* 76 ions appears to be a genuine electron impact induced process. This reaction is even more prominent in the EI spectrum of the methyl ester of **I**,[3] which does not suffer from thermal decarboxylation and which is sufficiently volatile to be introduced into the ion source as a vapour at room temperature. As will be shown in detail elsewhere,[3] the molecular ions of the methyl ester decarbonylate via two distinct mechanisms, yielding product ions of a different structure (see Scheme 2): at high internal energies (source-generated ions) the product ion is the

Fig. 1. The EI mass spectrum of β-hydroxypyruvic acid (**I**): (*a*) obtained from a "bulk" sample at an ion source temperature of 110°C (see text); (*b*) obtained from a bulk sample at an ion source temperature of 110°C (see text), using an ion source temperature of 170°C; (*c*) CID mass spectrum [2ffr,O_2] of $\mathbf{I}^+$; (*d*) neutralization–reionization (NR) mass spectrum of $\mathbf{I}^+$ (S denotes the survivor ion).

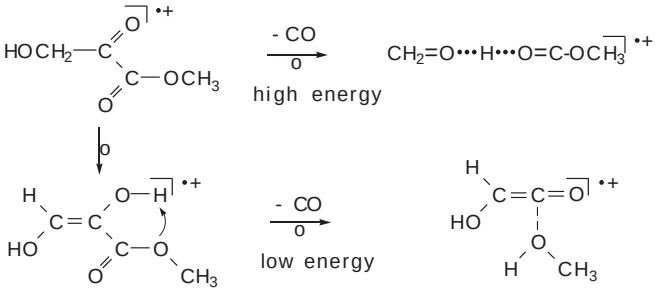
Scheme 2.



H-bridged radical cation $CH_2{=}O{\cdots}H{\cdots}O{=}C\text{-}OCH_3^{\bullet+}$ (5*a*) whereas the low-energy molecular ions (metastable ions) also produce this ion, but as further discussed in Sect. 5, these ions are produced in admixture with the more stable isomer $HO(H)C{=}C{=}O^{\bullet+}/CH_3OH$ (9). The generation of the latter ion involves a slow isomerization of the keto molecular ion into its enolic counterpart, which then loses CO via a mechanism analogous to that for the decarbonylation of ionized $CH_2{=}C(OH)COOH^{\bullet+}$, which was recently shown (14) to specifically yield $CH_2{=}C{=}O^{\bullet+}/H_2O$ and not the more stable isomer $CH_2{=}C(OH)_2^{\bullet+}$.

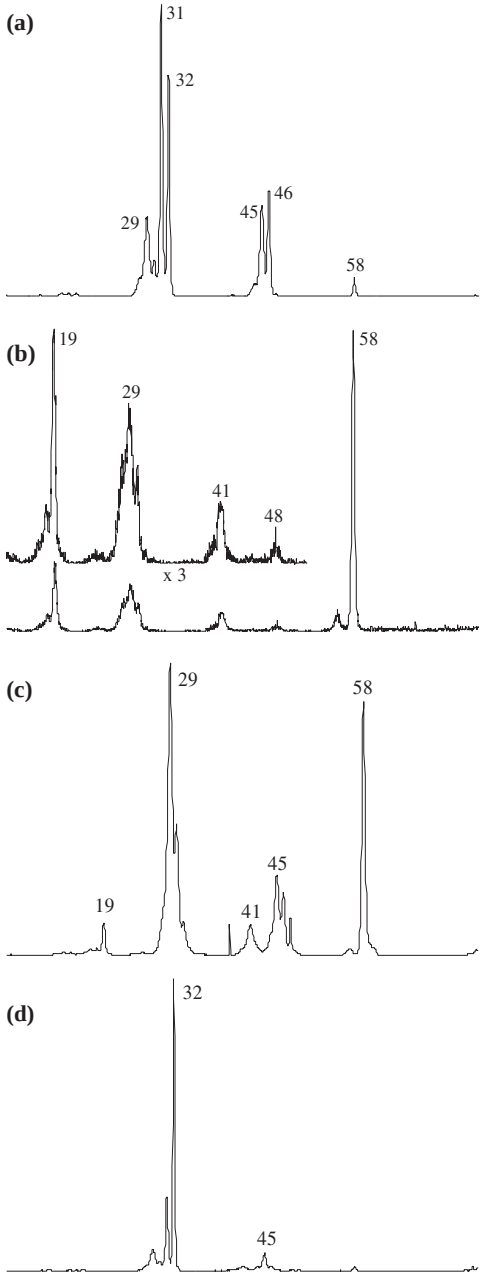
A similar situation obtains, we propose, for the parent acid **I**: Fig. 1*c* shows the CID mass spectrum of $\mathbf{I}^{\bullet+}$, and even a cursory inspection indicates that the (majority of the) HPA molecular ions must have lost their parent keto structure, as witnessed by the greatly reduced intensity of the *m/z* 31 CH_2OH^+ ion and the appearance of the prominent peak at *m/z* 58, $HO(H)C{=}C{=}O^{\bullet+}$ (structure identified from a MS/MS experiment and compared with reference spectra (9); result not shown). It will be shown in Sect. 5 that most of these long-lived ions have rearranged to the enol $HOC(H){=}C(OH)COOH^{\bullet+}$, $\mathbf{II}^{\bullet+}$.

Figure 2 shows the CID mass spectra of the source-generated *m/z* 76 $[M - CO]^{\bullet+}$ ions (part *a*) along with that of the *m/z* 76 ions found in the MI spectrum of the molecular ions (part *b*). Also given are the CID mass spectra of the isomeric ions $HOC(H){=}C(OH)_2^{\bullet+}$, $\mathbf{1}^{\bullet+}$, and $HOCH_2COOH^{\bullet+}$, $\mathbf{2}^{\bullet+}$, whose ion chemistry has been discussed in considerable detail in a previous study (11). Comparison of the four spectra shows (*i*) that the source-generated *m/z* 76 ions from HPA are neither $\mathbf{2}^{\bullet+}$ nor its enol nor a mixture thereof and (*ii*) that the structure of the low-energy *m/z* 76 ions from $\mathbf{I}^{\bullet+}$ must be different from that of the source-generated ions, and that it is akin to that of the ionized enol $\mathbf{1}^{\bullet+}$. Thus the source-generated ions and the metastably generated ions (high- and low-energy ions) appear to have different structures (and also different precursor structures), and we will therefore deal with these in different sections.

2. The decarbonylation of high-energy HPA ions: generation of the H-bridged radical cation $CH_2{=}O{\cdots}H{\cdots}O{=}C\text{-}OH^{\bullet+}$, $\mathbf{3a}^{\bullet+}$

The CID mass spectrum of the *m/z* 76 $C_2H_4O_3^{\bullet+}$ ions generated from HPA, $\mathbf{I}^{\bullet+}$, shows a tell-tale peak at *m/z* 46, $C(OH)_2^{\bullet+}$, which differentiates this spectrum from that of the two isomers of conventional structure, viz. ionized glycolic acid, $\mathbf{2}^{\bullet+}$, and its more stable enol $\mathbf{1}^{\bullet+}$. The MI spectrum of the *m/z* 76 ions is dominated by a signal at *m/z* 32 (ion structure established by a MS/MS experiment; result not shown), $CH_2OH_2^{\bullet+}$, and *m/z* 46 is completely absent. Further, the threshold energy for the most

Fig. 2. The CID mass spectra of the $[M - CO]^{\bullet+}$ ions (*m/z* 76) from ionized β-hydroxypyruvic acid, $\mathbf{I}^{\bullet+}$: (*a*) *source*-generated ions; (*b*) *metastably* generated ions; (*c*) and (*d*) represent reference spectra of ionized trihydroxyethylene, $\mathbf{1}^{\bullet+}$, and ionized glycolic acid, $\mathbf{2}^{\bullet+}$, repectively [9].



prominent dissociation taking place upon collisional activation, $76^{\bullet+} \rightarrow CH_2OH^+$ (*m/z* 31) + HOCO•, 122 kcal/mol (17), is considerably lower than that for the formation of *m/z* 46, i.e., 149 kcal/mol (17*a*) for $76^{\bullet+} \rightarrow C(OH)_2^{\bullet+} + CH_2{=}O$. That the *m/z* 46 ions are ionized dihydroxycarbene ions and not the isomeric ionized formic acid, $H\text{-}C(=O)OH^{\bullet+}$, follows from a MS/MS experiment (see Fig. 3*a*) and comparison with reference spectra of the two isomeric ions (18). Thus it is reasonable to assume that the formation of *m/z* 46, $C(OH)_2^{\bullet+}$, and $CH_2{=}O$ involves a high-energy direct bond cleavage reaction, and this

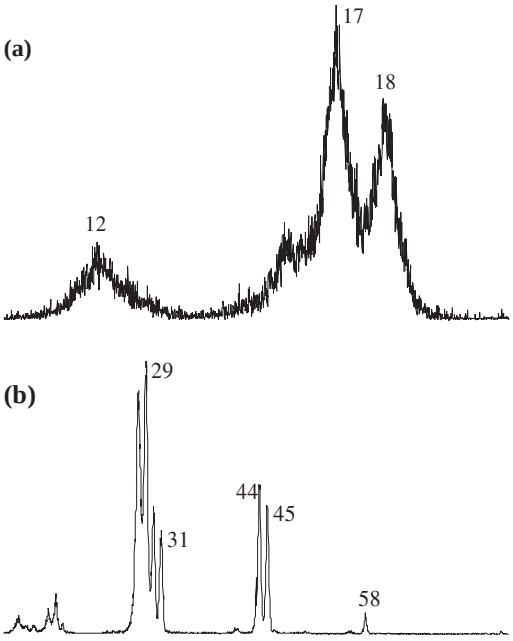
Fig. 3. (*a*) Partial CID mass spectrum [3ffr/O_2] of the m/*z* 46 ion in the CID mass spectum of Fig. 2*a*; (*b*) NR mass spectrum of the source-generated m/*z* 76 ions from β-hydroxypyruvic acid.



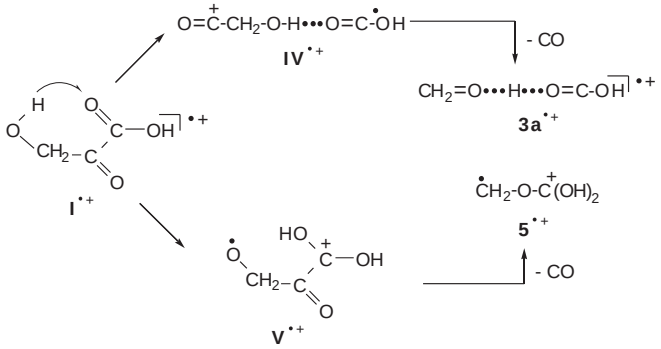
narrows down possible structures for the *m/z* 76 ions to either the H-bridged ion CH_2═O···H···O═C-$OH^{\bullet+}$, **3a**$^{\bullet+}$, or its distonic isomer $CH_2OC(OH)_2^{\bullet+}$, **5**$^{\bullet+}$. Plausible mechanisms for the generation of either ion involve a common 1,5-H transfer and the loss of the carbonyl CO group, as depicted in Scheme 3.

That the ion generated is not the distonic ion **5**$^{\bullet+}$ but rather the H-bridged ion **3a**$^{\bullet+}$ is supported by the following arguments:

(*i*) The first step in the proposed mechanism for the formation of **5**$^{\bullet+}$, an undoubtedly facile 1,5-H shift, leads to a stable intermediate, **V**$^{\bullet+}$ (see Sect. 5), which may be expected to competitively dissociate into $(HO)_2C$═C═O$^{\bullet+}$ (*m/z* 74) + CH_2═O by direct bond cleavage,[4] either in the ion source or upon collisional activation of the long-lived molecular ions. However, neither the EI spectrum of **I** nor the CID mass spectrum of **I**$^{\bullet+}$ shows a signal at *m/z* 74 indicative of this reaction. This also excludes formation of **3a**$^{\bullet+}$ via the H-bridged intermediate CH_2═O···H-O-C(OH)═C═O$^{\bullet}$.

(*ii*) The ionized methyl ester of **I**$^{\bullet+}$ (see above) also shows a prominent decarbonylation, and here the corresponding product ions would be either CH_2═O···H···O═C-$OCH_3^{\bullet+}$ or $CH_2OC(OH)(OCH_3)^{\bullet+}$. The latter ion was independently generated and examined in previous study (5a), and from a comparison of the exchange behaviour of multiple (^{13}C and D) labelled isotopomers, it follows that the methyl ester ion does not generate $CH_2OC(OH)(OCH_3)^{\bullet+}$ but rather

Scheme 3.



CH_2═O···H···O═C-$OCH_3^{\bullet+}$, and also that the two isomers do not easily communicate.[3]

(*iii*) The $CH_2OC(OH)(OCH_3)^{\bullet+}$ ion undergoes a facile reversible isomerization, via a 1,4-H shift, into $CH_3OC(=O)(OCH_3)^{\bullet+}$ (5*a*) and by analogy ion **5**$^{\bullet+}$, $CH_2OC(OH)_2^{\bullet+}$, may be expected to communicate with $CH_3OC(=O)(OH)^{\bullet+}$. However, this process leads to loss of positional identity of the C- and O-bonded H atoms, and this is not what is observed. Comparison of the CID mass spectrum of the source-generated *m/z* 78 $[M - CO]^{\bullet+}$ ions from the D-labelled HPA isotopomer $DOCH_2C(=O)COOD^{\bullet+}$ with that of the unlabelled *m/z* 76 ion, shown in Fig. 2*a*, showed that the *m/z* 31, 32, 45, and 46 ions are cleanly shifted to *m/z* 32, 34, 46, and 48, respectively, in agreement with the proposed H-bridged structure CH_2═O···D···O═C-$OD^{\bullet+}$, not $CH_2OC(OD)_2^{\bullet+}$.

Thus we propose that the parent acid **I**$^{\bullet+}$ also produces the H-bridged ion, CH_2═O···H···O═C-$OH^{\bullet+}$, **3a**$^{\bullet+}$, and that it is generated by the mechanism depicted above.

Two peaks in the CID mass spectrum of **3a**$^{\bullet+}$ deserve further comment: the signal at *m/z* 32, $CH_2OH_2^{\bullet+}$, which dominates the MI spectrum, and the peak at *m/z* 58. The latter ion, (HO)HC═C═O$^{\bullet+}$ (structure established by a MS/MS experiment; result not shown) is the principal fragment ion in the CID spectrum of the low-energy decarbonylation of **I**$^{\bullet+}$ (see Fig. 2*b*), and its presence in the spectrum of the source-generated *m/z* 76 ions most likely reflects a small contribution of the low-energy decarbonylation product ion **4**$^{\bullet+}$, which will be further discussed in Sect. 5. This may also explain the presence of the weak *m/z* 58 ion in the NR spectrum (for a recent review see ref. 20) of the [**I** – CO]$^{\bullet+}$ source-generated ions (see Fig. 3*b*). The other features of the NR spectrum are readily accommodated by the proposed **3a**$^{\bullet+}$ structure and CIDI (for a recent review see ref. 21) contributions from its metastable dissociation (responsible for the larger part of the peak at *m/z* 44, $CO_2^{\bullet+}$). The neutral counterpart of the hydrogen-bridged ion is not expected to be stable, and indeed the *m/z* 76 survivor signal is of negligible intensity. Neutralized **3a**$^{\bullet+}$ may (formally) dissociate by direct bond cleavage into HOCO$^{\bullet}$ + $CH_2OH^{\bullet}$ and (or) **:**$C(OH)_2$ + CH_2═O, and upon collisional ionization these neutrals would give rise to ions at *m/z* 45 and *m/z* 31 for the first process and *m/z* 46 and *m/z* 30 for the second, and lower mass fragment ions generated therefrom. The fact that *m/z* 46, $C(OH)_2^{\bullet+}$, ions are barely detectable in the NR spectrum is not due to the NR properties of $C(OH)_2^{\bullet+}$ (18) nor to the energetic demands of the **:**$C(OH)_2$ generation

[4] The threshold energy for this reaction is 88.6 kcal/mol, ΔH_f^{298} ($(HO)_2C$═C═O^{+}) is 114.6 kcal/mol (neutral is –76.4 kcal/mol) (G2(MP2) (19*a*, *b*, footnote 5) values, this work), and ΔH_f^{298} (CH_2═O) is –26.0 kcal/mol (18*a*). Note also that $(HO)_2C$═C═O^{+} is a prominent fragment ion in the 70 eV EI mass spectrum of mesoxalic acid, HOOCC(═O)COOH.

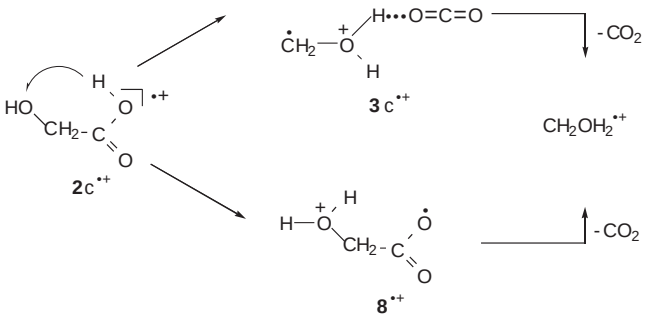
Scheme 4.



vis-à-vis that of HOCO•, but rather to the charge distribution in **3a**•+, which, as discussed below, is best represented as a CH_2OH^+ *ion* interacting via an H-bridge with a HOCO• dipole. The related H-bridged radical cation $H_2O\cdots H\cdots O{=}C\text{-}OH^{\bullet+}$ shows a similar NR behaviour (10).

The CO_2 loss, which dominates the MI but not the CID spectrum of the source-generated $[\mathbf{I} - CO]^{\bullet+}$ ions, is obviously a rearrangement reaction, since the threshold energy for the generation of $CH_2OH_2^{\bullet+} + CO_2$, 101 kcal/mol, is considerably lower than that associated with the base peak in the CID spectrum: CH_2OH^+ (*m*/*z* 31) + HOCO• = 122 kcal/mol (17). This observation further supports our proposal that the source-generated $[\mathbf{I} - CO]^{\bullet+}$ ions have structure **3a**•+ and not that of the isomeric H-bridged radical cations **3b**•+ or **3c**•+, although the latter may be involved as a stable intermediate en route to the loss of CO_2 from **3a**•+. Loss of CO_2 also dominates the MI spectrum of the isomeric glycolic acid ion **2**•+, and two mechanisms involving a 1,4-H transfer of which one involves the H-bridged ion **3c**•+ can be envisaged (see Scheme 4).

This raises the question: does the H-bridged ion **3a**•+ communicate with **2**•+ prior to the common CO_2 loss, and if not, how then does **3a**•+ isomerize to lose CO_2? Analysis of the metastable peak shapes for the two reactions rules out a facile interconversion, albeit not a communication, between **3a**•+ and **2**•+: the two isomeric ions display Gaussian shaped metastable peaks (21), but that for the loss of CO_2 from **3a**•+, $T_{0.5}$ = 43 meV, is significantly larger than that from **2**•+ whose $T_{0.5}$ value is only 21 meV (0.5 kcal/mol). Unfortunately, another valuable piece of experimental information, i.e., an accurate appearance energy (AE) for the two CO_2 losses is not available: the involatility (glycolic acid) and additional thermal lability (HPA) of the acids precludes AE measurements with the currently accessible instrumentation. In this context we also note that an AE of the *m*/*z* 76 ions from **I**•+ would not lead to an experimental heat of formation of the H-bridged ion **3a**•+ but rather to that of the low-energy isomer **4**•+.

However, the intriguing mechanistic question regarding the loss of CO_2 from **3a**•+ and its relationship with **2**•+ can be addressed computationally. This is done in Sect. 4, but first we will discuss the computational results of the $[\mathbf{I} - CO]^{\bullet+}$ isomers.

3. The structure and stability of $CH_2{=}O\cdots H\cdots O{=}C\text{-}OH^{\bullet+}$ and its principal isomers: ab initio computational results and considerations

The isomers examined are ionized trihydroxyethylene, **1**•+; ionized glycolic acid, **2**•+; the H-bridged radical cations **3a–c**•+; the hydroxyketene•+–water ion–dipole complex **4**•+; the ß-distonic ion **5**•+ of Scheme 3; $HO(H_2)CO\cdots O{=}C\text{-}OH^{\bullet+}$, **6a**•+, an ion–dipole complex derived from **3a**•+ and its carbenic conformer $HO(H_2)C\text{-}O\text{-}C\text{-}OH^{\bullet+}$, **6b**•+; the distonic ions $H_2O\text{-}C(H_2)\text{-}O\text{-}C{=}O^{\bullet+}$, **7**•+, and $H_2O\text{-}C(H_2)\text{-}C(=O)\text{-}O^{\bullet+}$, **8**•+, precursor ions for the direct loss of CO_2 discussed in the next section. Their MP2(full) optimized geometries and CCSD(T) derived relative energies[5] are presented in Fig. 4 and Table 1, respectively, along with the transition states for loss of CO_2, discussed in the next section. Geometries were also optimized using the UHF and B3LYP methodology (using standard basis sets; see theoretical section for further details), and we will refer to those results that are relevant to the discussion.

The optimized geometry for **1**•+ in Fig. 4 represents the lowest energy conformer of the ionized enol (11), which is the most stable of the isomers examined. Its G2(MP2) derived enthalpy of formation, ΔH_f^{298} = 71.6 kcal/mol (11), was chosen as the anchor point because accurate experimental data are not available for any of the isomeric ions. The energy differences between the anchor point and the experimental (thermochemical) values of the dissociation limits $CH_2OH_2^{\bullet+} + CO_2$ and $CH_2OH^+ + HOCO^\bullet$ are 29 and 52 kcal/mol, respectively (see last column of Table 1). These values are gratifyingly close to those derived from our CCSD(T) calculations, 29.8 and 53.4 kcal/mol (note that these refer to 0 K, whereas the estimated energies were evaluated at 298 K). The last column of Table 1 also lists values for those isomeric ions whose ionic enthalpy can be reliably estimated, and here, too, comparison with the calculated energy differences is satisfactory. In particular, the calculated keto ion (**2c**) – enol ion (**1**) energy difference, 35.5 kcal/mol, is close to the estimate, 34 kcal/mol, and also compatible with ionic keto–enol energy differences established in related systems (25). In view of these facts, we propose that the ΔH_f for the key H-bridged ion **3a**•+ equals 99 kcal/mol, with an estimated uncertainty of ±3 kcal/mol.

For ionized glycolic acid, **2**•+, various conformers were examined to determine the most stable conformer and to probe potential routes for the loss of CO_2. The MP2(full) calculations yielded seven stable species, represented by items **2a–e** in Fig. 4. Two of these, **2d**•+ and **2c′**•+, have a greatly elongated C—C bond, whereas optimization starting from the most stable neutral conformer (26) of glycolic acid led to a spontaneous rearrangement via a 1,4-H shift into the energetically favourable distonic ion **2e**•+. No such rearrangement occurs without electron correlation: at the Hartree–Fock (UHF/6-31G*) level of theory, structure **2e**•+ **[UHF]** (see Fig. 4) was obtained with a relative energy (37.5 kcal above ion **1**•+) in reasonable agreement with the keto–enol differences mentioned above.

In view of its stability, the distonic ion **2e**•+ may well be a principal species among the various conformers generated by the EI of glycolic acid. Nevertheless, the CID mass spectrum of **2**•+ in Fig. 2*d* clearly reveals that the structure characteristic high-energy dissociation of **2e**•+ into $C(OH)_2^{\bullet+}$ (*m*/*z* 46) and $CH_2{=}O$ is of only marginal importance, possibly because of a facile interconversion with the various conformers of **2**•+ prior to dissociation.

Ion **2a**•+ is considerably higher in energy (by ~15 kcal/mol) than **2b**•+ and **2c**•+, the other conformers of conventional C—C bond length. This is likely due to differing electronic structures, which is reflected in the geometries shown in Fig. 4. In ion **2a**•+, the charge and the radical are largely located on the

[a] Scaled by a factor of 0.9646 (see ref. 23).

[b] Using ΔH_f^{298}(**1**$^{\bullet+}$) = 71.6 kcal/mol and ΔH_f^{0}(**1**$^{\bullet+}$) = 73.4 kcal/mol as the anchor point (G2(MP2) values from ref. 11); ΔH_f^{298}(**1**) values from G2(MP2) (19*a*, *b*) and CBS-4 (19*a*, *c*) are –107.5 and –108.5 kcal/mol, respectively.

[c] Using ΔH_f(**2**) = –139.5 kcal/mol (11) and IE(**2**) = 10.6 eV; the CBS-4 value for the lowest energy conformer of **2** (the neutral counterpart of the UHF structure **2e**$^{\bullet+}$ in Fig. 4) is –137.6 kcal/mol at 298 K (this work).

[d] Using ΔH_f(**3a**$^{\bullet+}$) = 99 kcal/mol and ΔH_f(**3c**$^{\bullet+}$) = 82 kcal/mol; estimates based on the empirical relationship for O/H/O proton bound dimers: SE (kcal/mol) = 30.4 – 0.30ΔPA (23); SE = stabilization energy relative to the dissociation products of lowest combined enthalpy; PA = proton affinity; PA($CH_2{=}O$) = 170.4 kcal/mol (24*a*); PA(CO_2) = 129.4 kcal/mol (24*b*); PA($^{\bullet}CH_2OH \rightarrow CH_2OH_2^{\bullet+}$) = 166 kcal/mol; PA($^{\bullet}COOH \rightarrow C(OH)_2^{\bullet+}$) = 145 kcal/mol; from ΔH_f(COOH) = –46 kcal/mol (17*b*) and $\Delta H_f(C(OH)_2^{\bullet+})$ =175 kcal/mol (17*a*).

[e] Using the following ΔH_f^{298} values: $CH_2OH_2^{\bullet+}$ = 195 kcal/mol and CO_2 = –94 kcal/mol (17*a*).

[f] Using the following ΔH_f^{298} values: CH_2OH^+ = 169 kcal/mol and $^{\bullet}COOH$ = –46 kcal/mol (17*b*).

[g] Using $\Delta H_f^{298}(H_2O)$ = –58 kcal/mol and $\Delta H_f^{298}(HO(H)C{=}C{=}O^{\bullet+})$ = 163 kcal/mol; the latter value was obtained from a G2 calculation (19*a*, *b*) on the isodesmic reaction $HO(H)C{=}C{=}O^{\bullet+} + CH_4 \rightarrow H_2C{=}C{=}O^{\bullet+} + CH_3OH$, using $\Delta H_f^{298}(CH_3OH)$ = –48.2 kcal/mol, $\Delta H_f^{298}(CH_4)$ = –17.8 kcal/mol, and $\Delta H_f^{298}(H_2C{=}C{=}O^{\bullet+})$ = 209 kcal/mol (24*d*).

oxygen atom of the CH_2OH group, since the O—H (1.021 Å) bond is slightly shortened and the C—O (1.379 Å) bond slightly elongated, relative to the corresponding bond length in the neutral, 0.997 and 1.407 Å (26). For **2b**$^{\bullet+}$ and **2c**$^{\bullet+}$, the values are much closer to neutral CH_2OH, and moreover, their carbonyl C═O bond (1.274 and 1.269 Å) is much longer than that in **2a**$^{\bullet+}$ (1.199 Å; the corresponding neutral value is 1.211 Å (26)), indicating that the charge and radical electron are now localized in the carbonyl moiety. These proposals are confirmed by population analysis of these species. Note further that the relative energy of **2a**$^{\bullet+}$ is such that it lies above the direct bond cleavage dissociation into CH_2OH^+ (*m*/*z* 31) and HOCO$^{\bullet}$. Thus, **2a**$^{\bullet+}$ may play a significant role in the high-energy source reactions represented by the conventional 70 eV EI spectrum of **2** (where *m*/*z* 31 is the base peak) but not in the chemistry of the long-lived ions **2**$^{\bullet+}$ sampled by MI and CID experiments.

Conformers **2d**$^{\bullet+}$ and **2c′**$^{\bullet+}$ are so-called long-bonded species (3*a*) having C—C bond lengths of 1.898 and 1.990 Å, respectively (on the DFT surface; values in parentheses in Fig. 4; the effect is less pronounced). Both are low-energy species with geometrical parameters of the HOCO moiety that lie in between that of the HOCO ion and its neutral counterpart, indicating that the charge and the radical are localized in the long C—C bond. Note also that one of these conformers, **2c′**$^{\bullet+}$, along with its short-bonded counterpart, **2c**$^{\bullet+}$, has the correct orientation for a 1,4-H transfer leading to the ultimate loss of CO_2, as depicted in Scheme 4.

The H-bridged radical cations **3a**–**c**$^{\bullet+}$ are among the most stable isomers, and their calculated relative energies agree well

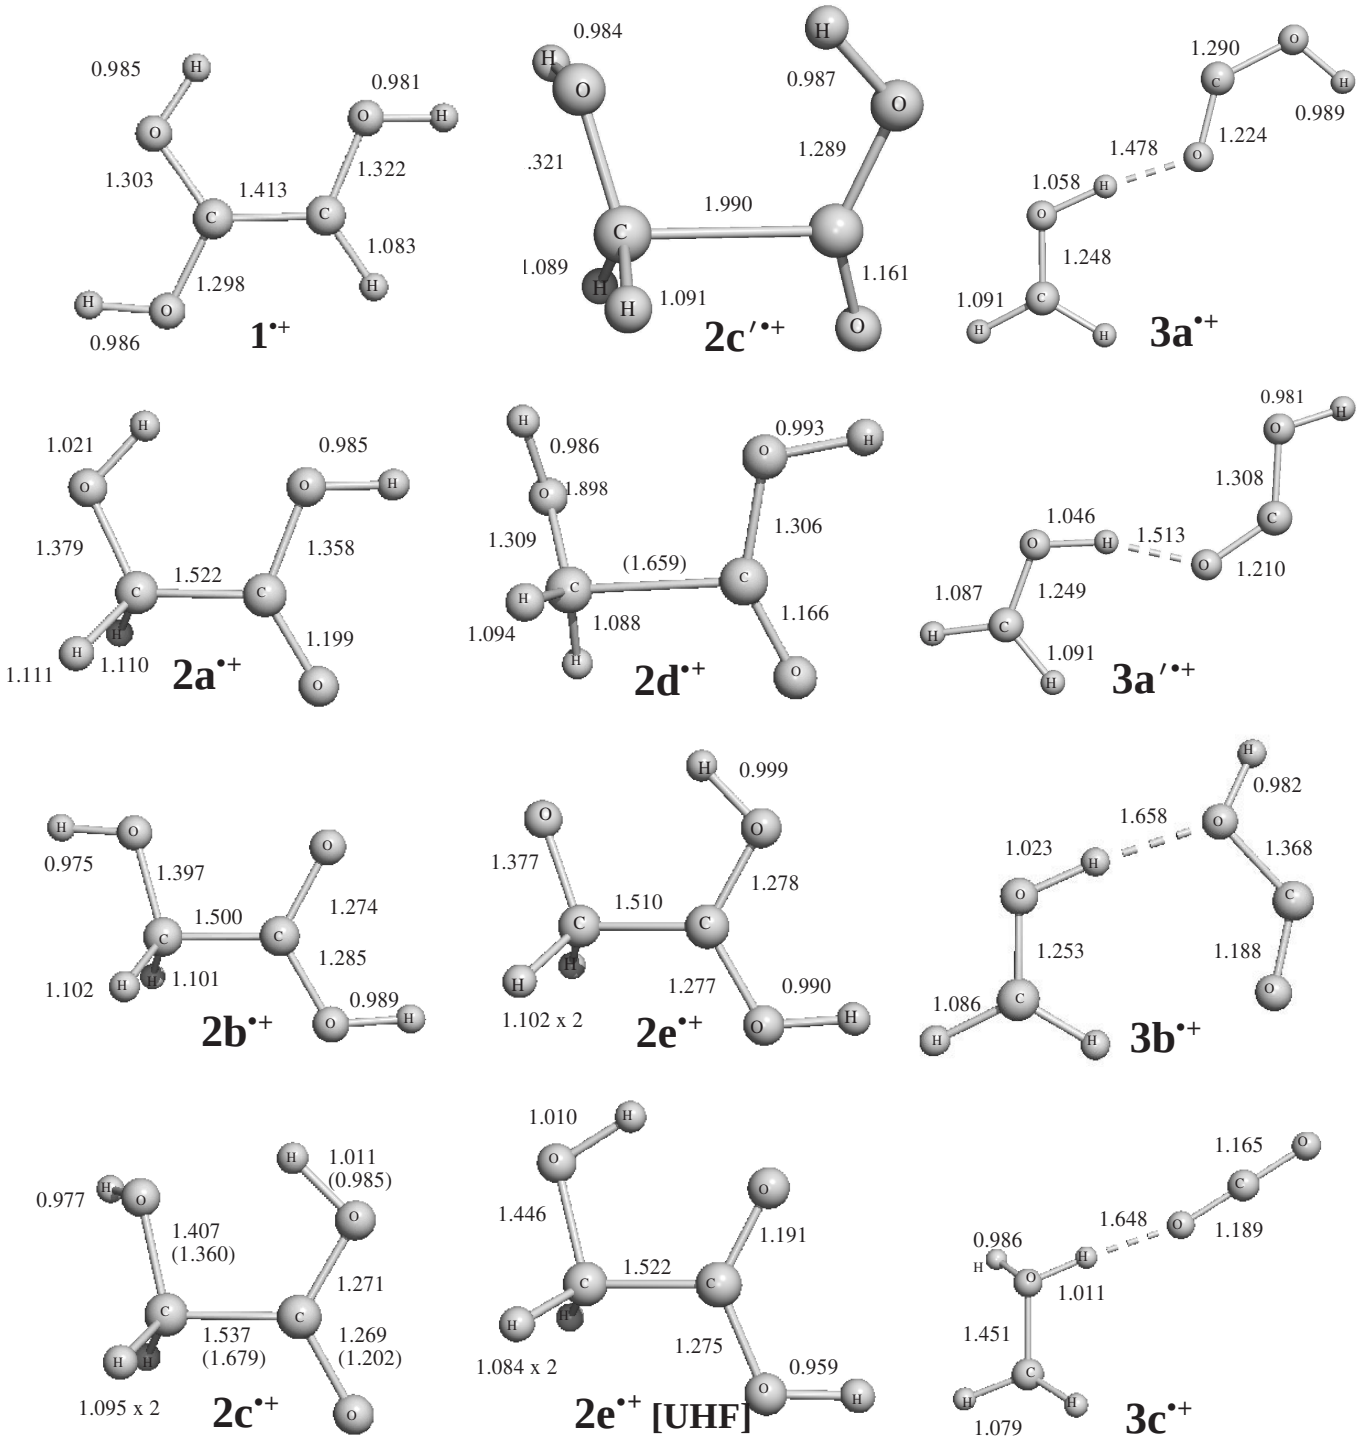
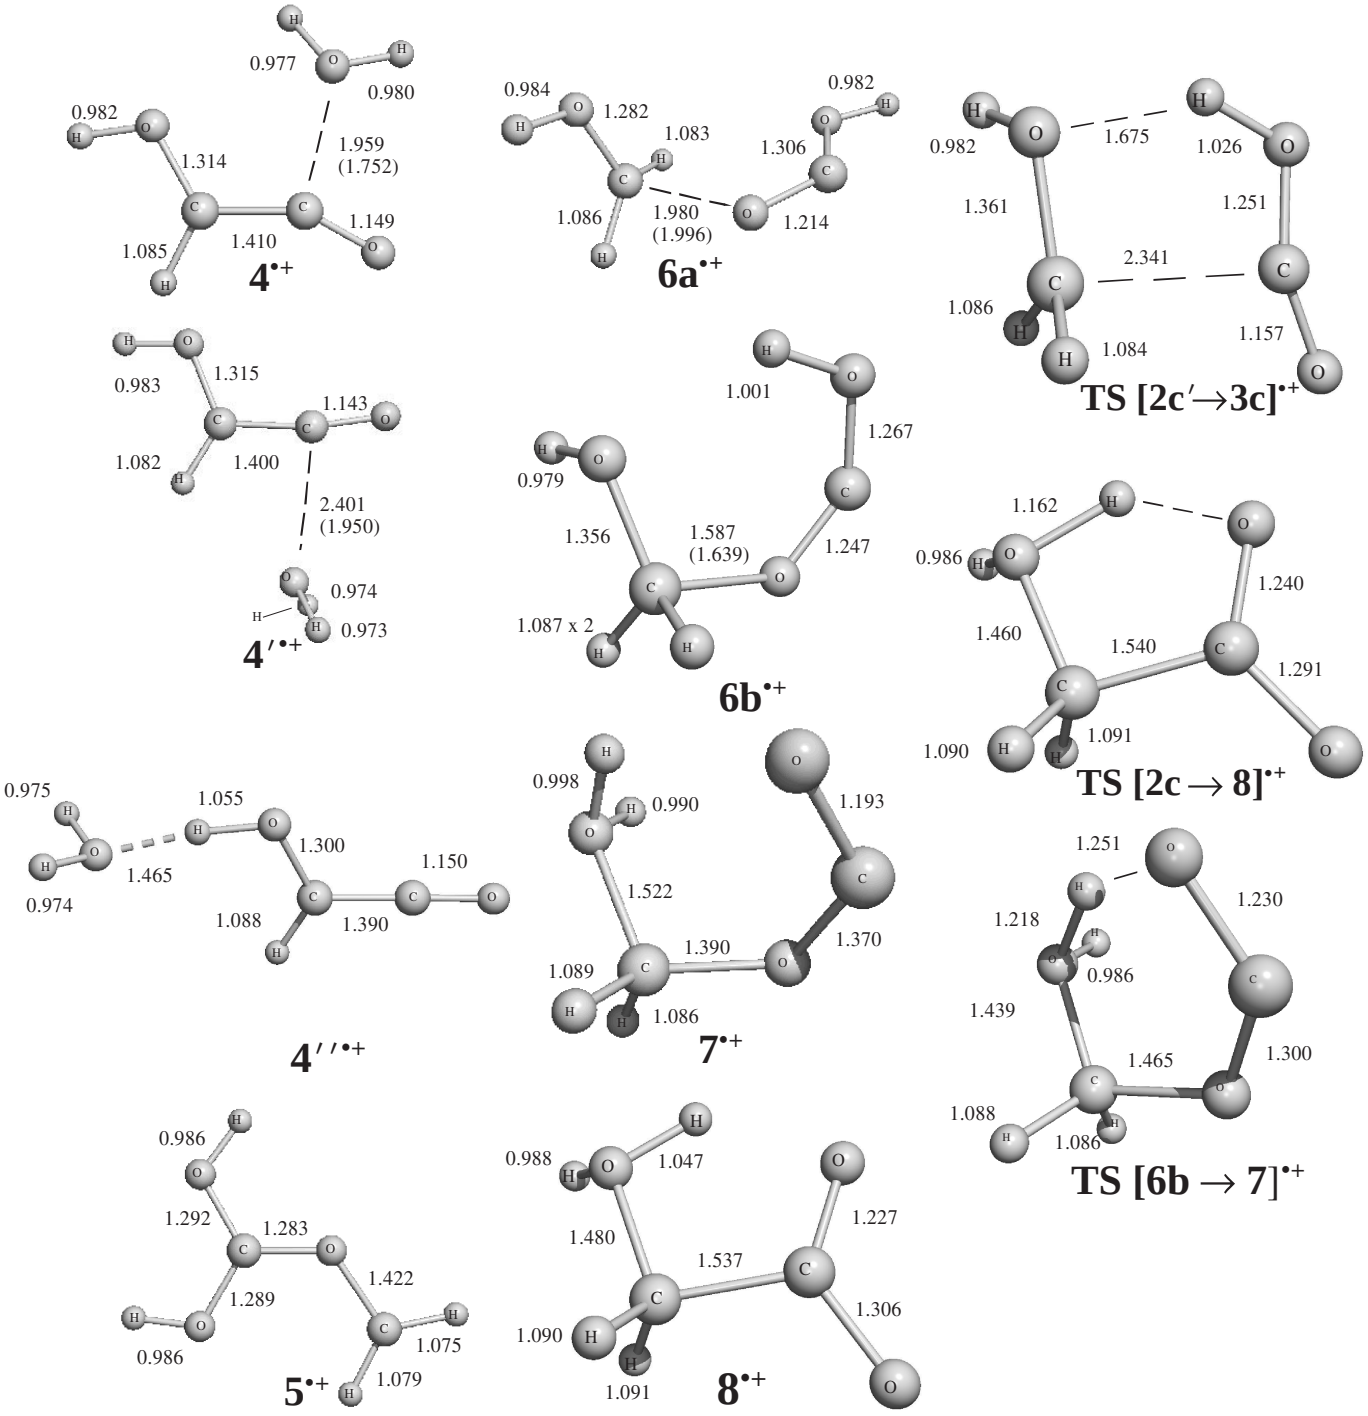
Fig. 4. The MP2(full)/6-31G* optimized geometries of various $C_2H_4O_3^{\cdot+}$ (*m*/*z* 76) isomers; values in parentheses refer to geometries optimized with B3LYP/6-31G*.



with the estimates. In all these H-bridged structures the moiety with the largest proton affinity (PA) (see footnotes in Table 1 for numerical values) covalently binds the bridging hydrogen. Thus, the best description of ions **3a**$^{\cdot+}$ and **3b**$^{\cdot+}$ is a CH_2OH^+ ion interacting with a HOCO$^{\cdot}$ dipole, that is, **3a**$^{\cdot+}$ and **3b**$^{\cdot+}$ have different connectivities but the same distribution of charge and radical, as confirmed by standard population analysis. Similarly, ion **3c**$^{\cdot+}$ represents the interaction of a CO_2 molecule with

© 1998 NRC Canada

Fig. 4. (*concluded*)



the ylid ion $CH_2OH_2^{\bullet+}$. This ion is the most stable of the H-bridged ions and a prime candidate for the dissociation reaction of lowest energy requirement, viz. loss of CO_2 by separation of the two moieties.

For the ionized hydroxyketene$^{\bullet+}$–water complex, the conformers examined (**4**$^{\bullet+}$, **4′**$^{\bullet+}$, and **4′′**$^{\bullet+}$) were the analogues of the lowest energy conformers in the ketene$^{\bullet+}$–water system (16). Conformers **4**$^{\bullet+}$ and **4′**$^{\bullet+}$ represent "pure" ion–dipole complexes with computationally derived stabilization energies (SE) of 17.3 and 18.8 kcal/mol, respectively. These SE values are in reasonable agreement with those calculated for **4**$^{\bullet+}$ and **4′**$^{\bullet+}$ from SE = 68.8μ/r^2 kcal/mol, using $\mu[H_2O]$ = 1.85 D and

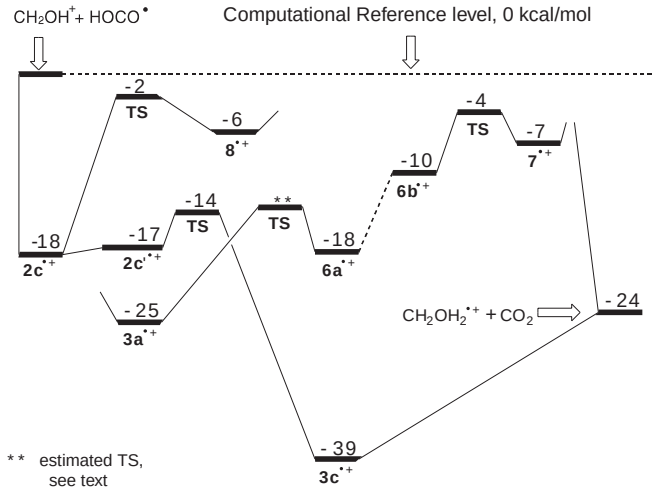
Fig. 5. Energy-level diagram for the decarboxylation of ionized glycolic acid, $\mathbf{2}^{\bullet+}$, versus that of the H-bridged radical cation, $\mathbf{3a'}^{\bullet+}$.



r values of 2.7 and 2.4 Å, derived from the optimized structures in Fig. 4 (17.5 and 22 kcal/mol). Not unexpectedly, conformer $\mathbf{4''}^{\bullet+}$ is considerably lower in energy, by ~10 kcal/mol, because it benefits from the added stabilization of the hydrogen bridge.

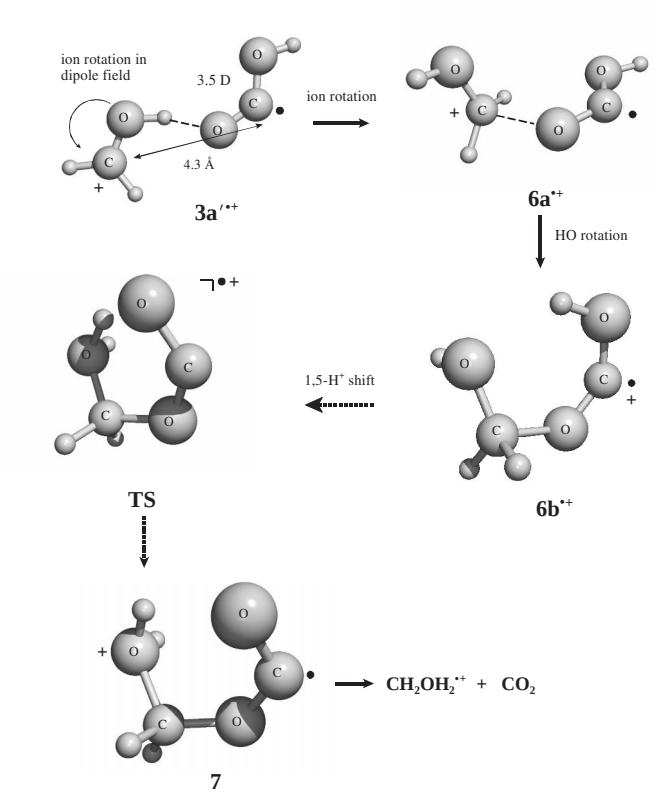
The distonic ion $\mathbf{5}^{\bullet+}$ is indeed quite a stable intermediate, as it lies 18 kcal/mol above ion $\mathbf{1}^{\bullet+}$, but as argued above, it is not generated from ionized HPA. Also presented in Table 1 and Fig. 4 are ions $\mathbf{6}^{\bullet+}$–$\mathbf{8}^{\bullet+}$, key intermediates in the decarboxylation of $\mathbf{3a}^{\bullet+}$ and $\mathbf{2}^{\bullet+}$, which will be discussed in the next section along with three strategic transition states.

4. Mechanistic proposals for the loss of CO_2 from $CH_2{=}O{\cdots}H{\cdots}O{=}C{-}OH^{\bullet+}$, $\mathbf{3a}^{\bullet+}$, participation of the stable isomer $CH_2O(H){\cdots}H{\cdots}O{=}C{=}O^{\bullet+}$, $\mathbf{3c}^{\bullet+}$?

First, we will consider how the low-energy glycolic acid ions lose CO_2. Following Scheme 4, one pathway involves isomerization into $\mathbf{3c}^{\bullet+}$, via a 1,4-H transfer and C—C bond cleavage, whereas the alternative route leads to the distonic ions $\mathbf{8}^{\bullet+}$, via a 1,4-H transfer without C—C cleavage. As discussed in the previous section, the long- and short-bonded conformers $\mathbf{2c'}^{\bullet+}$and $\mathbf{2c}^{\bullet+}$ may serve as the immediate precursors. Transition states (TS) could be located for both pathways: TS $[\mathbf{2c}{\rightarrow}\mathbf{8}]^{\bullet+}$ and TS $[\mathbf{2c'}{\rightarrow}\mathbf{3c}]^{\bullet+}$ in Fig. 4. The TS $[\mathbf{2c}{\rightarrow}\mathbf{8}]^{\bullet+}$ lies very high in energy, ca. 16 kcal/mol above $\mathbf{2c}^{\bullet+}$ and only a few kcal/mol below the direct bond cleavage dissociation limit $CH_2OH^+ + HOCO^\bullet$ (see Fig. 5). If this were the principal route by which glycolic acid ions lose CO_2, one would predict the normal mass spectrum to have a sizable molecular ion and the CID spectrum to be dominated by *m*/*z* 31 CH_2OH^+ ions. This is clearly not the case; the normal mass spectrum displays a very weak molecular ion (1 of base peak, *m*/*z* 31), while the CID mass spectrum (Fig. 2*d*) is dominated by loss of CO_2, not $HOCO^\bullet$. Thus, there must be a pathway of much lower energy, and indeed the alternative route $\mathbf{2c'}^{\bullet+} \rightarrow$ TS $[\mathbf{2c'}{\rightarrow}\mathbf{3c}]^{\bullet+} \rightarrow \mathbf{3c}^{\bullet+} \rightarrow CH_2OH_2^{\bullet+} + CO_2$ is calculated to have a critical energy of only a few kcal/mol (see Fig. 5).

Now that we have established that the majority of the low-energy ions $\mathbf{2}^{\bullet+}$ lose CO_2 via the H-bridged ion $\mathbf{3c}^{\bullet+}$, the question arises whether the CO_2 loss from ions $\mathbf{3a}^{\bullet+}$ may follow the same route, via the isomerization $\mathbf{3a}^{\bullet+}{\rightarrow}\mathbf{2}^{\bullet+}$. The one way for this to occur is that the CH_2OH^+ and $HOCO^\bullet$ moieties in $\mathbf{3a}^{\bullet+}$ separate and recombine, carbon to carbon or ion center to radical center, to form glycolic acid ions $\mathbf{2}^{\bullet+}$. However, such a recombination reaction is highly unlikely, since it requires rotation of the dipole of the $HOCO^\bullet$ moiety such that the ion–dipole stabilization is completely lost, and the moieties would fly apart, i.e., dissociation into $CH_2OH^+ + HOCO^\bullet$ would ensue. The same arguments apply to the isomerization $\mathbf{3a}^{\bullet+}{\rightarrow}\mathbf{3c}^{\bullet+}$. That the loss of CO_2 from $\mathbf{2}^{\bullet+}$ and $\mathbf{3a}^{\bullet+}$ would involve a common pathway is therefore unlikely, in agreement with the experimental observations (KER differences) discussed in Sect. 2.

Scheme 5.



How then does ion $\mathbf{3a}^{\bullet+}$ lose CO_2? Recombination of the separated moieties of $\mathbf{3a}^{\bullet+}$ such that the dipole vector remains pointed to the ionic center would allow the ion to isomerize, and this forms the basis of our mechanistic proposal presented in Scheme 5. The CH_2OH^+ group in $\mathbf{3a}^{\bullet+}$ can freely rotate in the dipole field of $HOCO^\bullet$. Such a motion sacrifices the stabilization energy (SE) of the H-bridge, but it leaves the ion–dipole stabilization intact. The SE of the H-bridged ion $\mathbf{3a'}^{\bullet+}$ is 24 kcal/mol (from data in Table 1), whereas all configurations resulting from the rotation of the CH_2OH^+ moiety about the charged carbon atom at the original ion–dipole distance (4.3 Å) retain a SE of ~13 kcal/mol, still well below the dissociation limit (denoted as ** in Fig. 5). When the rotation is coupled with a shortening of the ion–dipole distance, the SE increases, and this process may eventually lead to the formation of $\mathbf{6a}^{\bullet+}$ whose stability is close to that of ionized glycolic

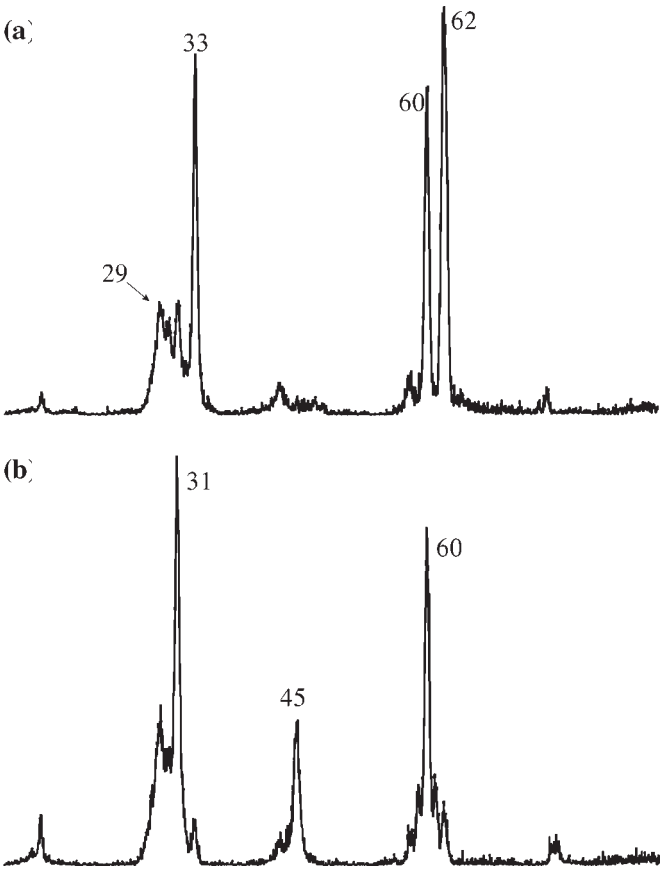
Fig. 6. The CID mass spectra of the *metastably* generated decarbonylation products from ionized O^{18} labelled methyl β-hydroxypyruvate, $HOCH_2C(=O^{18})COOCH_3$: (*a*) the spectrum of the $[M - CO^{16}]^{\bullet+}$ (*m/z* 92) ions; (*b*) the spectrum of the $[M - CO^{18}]^{\bullet+}$ (*m/z* 90) ions.

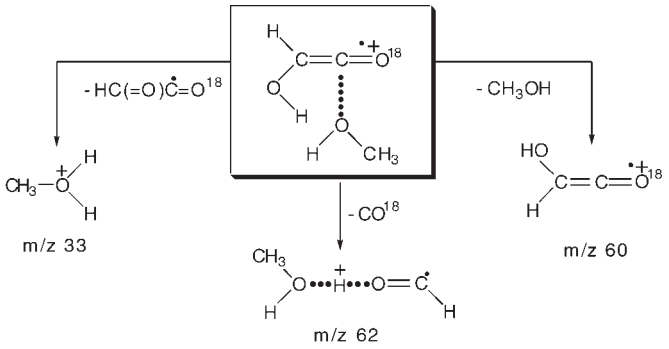


acid (Table 1). Via rotations that are not too energy demanding, **6a**$^{\bullet+}$ may convert into its "conformer" **6b**$^{\bullet+}$ (an ionized carbene). A 1,5-H^+ transfer in this ion would yield the distonic ion **7**$^{\bullet+}$, which by direct bond cleavage exothermically decarboxylates (see Scheme 5 and Fig. 5). We have located (Fig. 4 and Table 1) the key transition state **6b**$^{\bullet+}$→**7**$^{\bullet+}$ in this proposal and, as shown in Fig. 5, it indeed lies below the dissociation limit CH_2OH^+ + HOCO$^{\bullet}$. Note that our calculations predict that ions **3a**$^{\bullet+}$ should dissociate with a significantly larger KER than ions **2c**$^{\bullet+}$.

5. The decarbonylation of low-energy HPA ions I$^{\bullet+}$: isomerization into the enol II$^{\bullet+}$ and generation of the ion–dipole complex HO(H)C═C═O$^{\bullet+}$/H_2O, **4**$^{\bullet+}$ therefrom. Comparison with the behaviour of the ionized methyl ester

We will begin our discussion of the decarbonylation of the metastable HPA ions with a brief analysis of the behaviour of its methyl ester. As was mentioned in Sect. 1 the decarbonylation of the *metastable* molecular ions of the methyl ester occurs via two distinct mechanisms, yielding two different product ions i.e., the methyl(ated) analogue of the H-bridged ion **3a**$^{\bullet+}$, CH_2═O···H···O═C-$OCH_3^{\bullet+}$ (which is the sole product ion generated in the source)[3] in admixture with the more stable isomer HO(H)C═C═O$^{\bullet+}$/CH_3OH (9) (see Scheme 2). A first

Scheme 6.

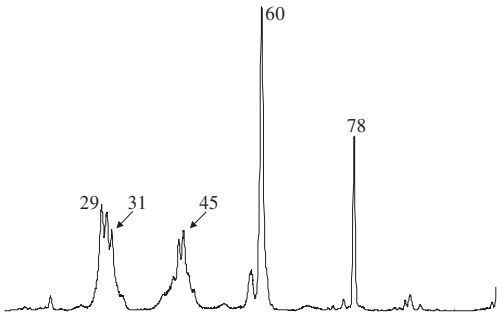


indication that we are dealing with two mechanisms comes from the observation that the metastable peak for the decarbonylation is a Gaussian shaped composite (21) whose $T_{0.5}$ value is 60 meV. Next a sample of the specifically labelled ^{18}O isotopomer $HOCH_2C(=O^{18})COOCH_3$ was prepared, and the MI spectrum of its molecular ion was examined: it displayed two noncomposite Gaussian shaped peaks, at *m/z* 92 (loss of CO^{16}) and *m/z* 90 (loss of CO^{18}) with an intensity ratio of 3:2 and $T_{0.5}$ values of 43 and 96 meV, respectively. Following the proposal in Scheme 2, it is expected that the source-generated ions exclusively lose CO^{18}, and this is substantiated by the EI mass spectrum (not shown) where [*m/z* 92] is less than 5 of I [*m/z* 90]. The CID mass spectra of the metastably generated *m/z* 92 and *m/z* 90 ions are presented in Fig. 6: it is seen that these spectra are entirely different. Loss of CO^{18} yields a spectrum dominated by peaks at *m/z* 60 (CH_3O-C-$OH^{\bullet+}$), 45 (HO-C═O^+), and 31 (CH_2OH^+), which is closely similar to that of the source-generated ions and which is entirely compatible with the formation of the H-bridged ion CH_2═O···H···O═C-$OCH_3^{\bullet+}$ (5a).[3] Loss of CO^{16} yields a spectrum dominated by ions at *m/z* 62, 60, and 33, which we assign to the ion–dipole complex HO(H)C═C═$^{18}O^{\bullet+}$/CH_3OH whose principal dissociation routes are rationalized in Scheme 6.

The proposal in Scheme 6 finds strong support from a previous study (9) on the enol of methyl glycolate ion, HOC(H)═C(OH)$OCH_3^{\bullet+}$, and several D and ^{18}O labelled isotopomers, where it was concluded that part of the low-energy enol ions slowly isomerize into the ion–dipole complex HO(H)C═C═O$^{\bullet+}$/CH_3OH prior to dissociation (see Scheme 1 in ref. 9). In this study it was also established, from an MS/MS/MS/MS experiment, that the *m/z* 62 ion is the H-bridged radical cation $CH_3O(H)$···H···O═C-H$^{\bullet+}$.

Unlike the methyl ester, the metastable peak for the decarbonylation of the low-energy ions of the parent acid, **I**$^{\bullet+}$, is a simple Gaussian ($T_{0.5}$ = 23 meV), and this suggests that we are dealing with a single mechanism. We have already noted (see Sect. 1 and Fig. 2) that the product ions generated are not **3a**$^{\bullet+}$ but rather HO(H)C═C═O$^{\bullet+}$/H_2O, **4**$^{\bullet+}$, a species akin to the enol ion HOC(H)═$C(OH)_2^{\bullet+}$, **1**$^{\bullet+}$, but nevertheless characteristically different. The spectrum of the enol ion features a unique *m/z* 46 ion (HOCOH$^{\bullet+}$ (3*a*)) whereas *m/z* 48 is absent, and the intensity of *m/z* 19 (H_3O^+) is greatly reduced. We also note that the dissociation reactions that characterize HO(H)C═C═O$^{\bullet+}$/CH_3OH (see Scheme 6 and Fig. 6*a*) are also found in the spectrum (Fig. 2*b*) of the putative ion HO(H)C═C═O$^{\bullet+}$/H_2O, **4**$^{\bullet+}$, viz. loss of H_2O yielding HO(H)C═C═O$^{\bullet+}$ (*m/z* 58), loss of CO yielding

Fig. 7. The CID mass spectrum of the molecular ion of the ^{18}O labelled β-hydroxypyruvic acid isotopomer $HOCH_2C(O^{18})COOH$.

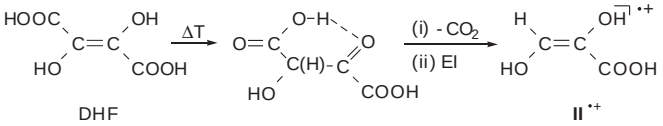


$H_2O(H)O\cdots H\cdots O{=}C\text{-}H^{\bullet+}$(27) (*m*/*z* 48), and loss of $HC(=O)C{=}O^{\bullet}$ yielding H_3O^+ (*m*/*z* 19), albeit that their relative abundances are greatly different.[6]

Analysis of a small sample of $HOCH_2C(=O^{18})COOH$, prepared under carefully controlled conditions (see Experimental) shows that the source-generated ions exclusively lose CO^{18} (providing further support for the high-energy decarbonylation mechanism in Scheme 3), whereas both the MI and the CID spectrum (see Fig. 7) of its molecular ion show a specific loss of CO^{16}. This supports our proposal that the *metastable* ions decarbonylate via a mechanism analogous to that depicted in Scheme 2 for the low-energy methyl ester ions, yielding $HOC(H){=}C{=}O^{\bullet+}/H_2O$, $\mathbf{4}^{\bullet+}$, as the product ion (Scheme 7).

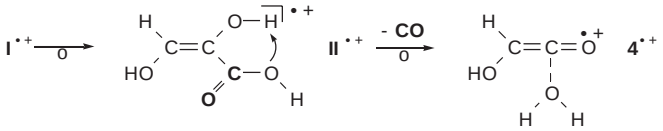
That the majority of the long-lived nondissociating HPA ions have isomerized followed already from a comparison of the CID mass spectrum of $\mathbf{I}^{\bullet+}$ with the EI mass spectrum of the acid (see Sect. 1 and Fig. 1) and also from the observation that the low-energy isomer ($\mathbf{4}^{\bullet+}$ vis à vis $\mathbf{3a}^{\bullet+}$) is not formed at high internal energies.

That it is the enol ion 1,2-dihydroxyacrylic acid, $\mathbf{II}^{\bullet+}$, that is predominantly generated comes from a comparison of the MI, CID, and NR spectra of the independently generated enol: when solid samples of dihydroxyfumaric acid (DHF) are evaporated into the ion source at elevated probe temperatures some thermal decarboxylation takes place, which, analogous to the mechanism for the loss of CO_2 from oxalacetic acid (OAA) (14), may reasonably be expected to yield the gaseous enol **II**:

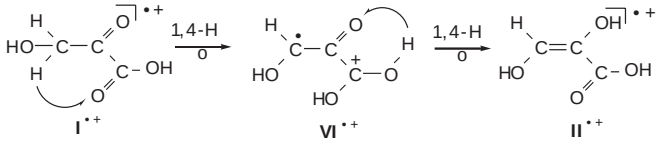


The NR mass spectrum of the *m*/*z* 104 ion generated from DHF appeared to be indistinguishable from that of HPA shown in Fig. 1*d*, whereas its CID mass spectrum was closely similar to that presented in Fig. 1*c*: the only notable difference was the reduced abundance of the *m*/*z* 42 ($CH_2{=}C{=}O^{\bullet+}$) ion. The latter ion is also present in the MI spectrum of the HPA derived ions (10 of base peak at *m*/*z* 76) but not in that of the DHF derived ion, which exclusively decarbonylates yielding *m*/*z* 76 ions whose CID mass spectrum is indistinguishable from that presented in Fig. 2*b* for HPA. Thus, we conclude that the long-lived HPA ions have largely isomerized into their enol counterpart, which may decarbonylate, as shown in Scheme 7, i.e., analogous to the decarbonylation of its lower homologue ionized α-hydroxyacrylic acid, $CH_2{=}C(OH)COOH^{\bullet+}$ (14).

Scheme 7.



Scheme 8.



A plausible mechanism for the keto–enol tautomerization of the HPA ions involves two consecutive 1,4-H shifts, with the distonic ion $\mathbf{VI}^{\bullet+}$ as the key intermediate (see Scheme 8).

Considering the size and complexity of the system, a detailed computational treatment of the mechanisms for the high- and low-energy decarbonylation reactions of HPA ions presented in Schemes 3, 7, and 8 would be a formidable task. We have therefore confined ourselves to exploratory calculations at the B3LYP/6-311+G(3df,3pd)//B3LYP/6-31G(d,p) level of theory[5] on the HPA isomers $\mathbf{I}^{\bullet+}$–$\mathbf{VI}^{\bullet+}$ that are proposed in the schemes. Figure 8 shows their optimized geometries, all of which represent stable minima on the $C_3H_4O_4^{\bullet+}$ PES. The enol ion $\mathbf{II}^{\bullet+}$ and the distonic ion $\mathbf{VI}^{\bullet+}$ are found to be considerably more stable than the keto ion $\mathbf{I}^{\bullet+}$, which is in agreement with expectation (25). More importantly, all of the proposed intermediate species are calculated to lie below the dissociation limit for the direct bond cleavage reaction of lowest energy requirement, $\mathbf{I}^{\bullet+} \rightarrow HOCH_2C{=}O^+ + {}^{\bullet}COOH$, calculated to lie 22 kcal/mol above $\mathbf{I}^{\bullet+}$.

Conclusions

Ionized ß-hydroxypyruvic acid (as well as its methyl ester) undergoes decarbonylation, and depending on the internal energy content, fragmentation occurs via two distinct mechanisms, leading to two distinct product structures (see Scheme 9).

(*i*) At high internal energies, specific elimination of the keto C=O is observed; this reaction is not a least-motion extrusion into ionized glycolic acid, $HOCH_2COOH^{\bullet+}$, but a rearrangement that produces the title H-bridged radical cation $CH_2{=}O\cdots H\cdots O{=}C\text{-}OH^{\bullet+}$.

(*ii*) By contrast, at low internal energies, it is the carboxyl C=O that is specifically lost. Comparative collision-induced dissociation experiments show that the long-lived, nondecomposing molecular ions have irreversibly rearranged to the more stable enol structure, $HOCH{=}C(OH)COOH^{\bullet+}$, which serves

[6] The combined product enthalpies for the direct bond cleavage loss of H_2O from $HO(H)C{=}C{=}O^{\bullet+}/H_2O$ and CH_3OH from $HO(H)C{=}C{=}O^{\bullet+}/CH_3OH$ are 105 and 115 kcal/mol, respectively (18*a*, footnote *g* in Table 1). For the rearrangement leading to loss of CO, the corresponding numbers are 111 (27) and 102 (11) kcal/mol. These differences in energy requirement may explain why the loss of CO from $\mathbf{4}^{\bullet+}$ is only a minor reaction, whereas it is prominent in the spectrum of $HO(H)C{=}C{=}O^{\bullet+}/CH_3OH$.

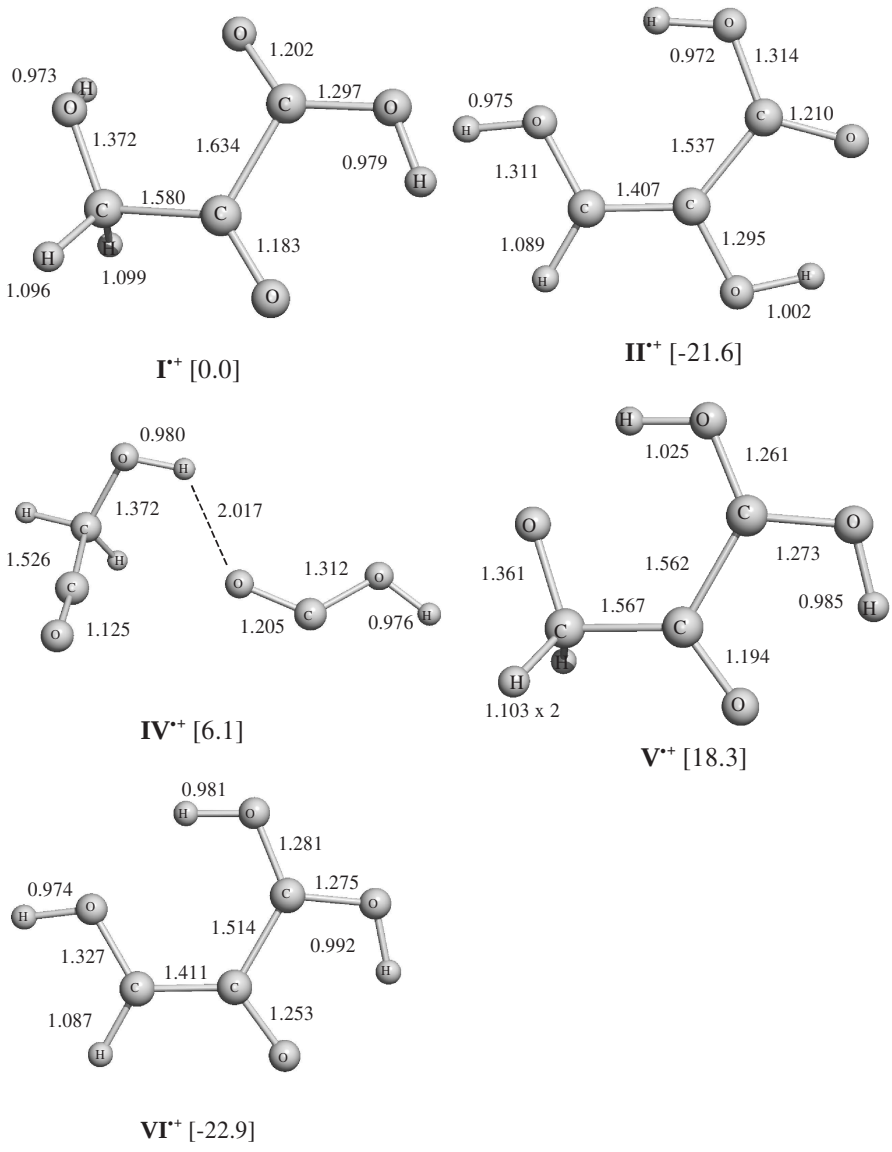
Fig. 8. The B3LYP/6-31G(d,p) optimized geometries for ionized β-hydroxypyruvic acid, $\mathbf{I}^{\bullet+}$, and selected stable isomers thereof. Values in parentheses refer to relative energies (kcal/mol) calculated at the B3LYP/6-311+G(3df,3pd) + ZPVE level of theory.



as precursor for CO loss and which contains only one C═O functionality. Again, decarbonylation is not a least-motion extrusion but a rearrangement yielding the ion–dipole complex $HOC(H)C{=}C{=}O^{\bullet+}/H_2O$, which is more stable than the above radical cation.

Hence, the more stable product ions are generated only at low internal energies, i.e., from molecular ions that dissociate slowly, whereas the lesser stable product ions are formed only at elevated energies, i.e., from molecular ions that dissociate rapidly. This is precisely what is expected as the more stable product ion can only be formed after slow isomerization of the molecular ions into the enol structure.

(*iii*) The H-bridged ion and its conventional isomer glycolic acid, $HOCH_2COOH^{\bullet+}$, both undergo decarboxylation into the ylidion $CH_2OH_2^{\bullet+}$. Ab initio calculations indicate that for the acid, stretching of the C—C bond leads eventually to proton transfer to generate the stable H-bridged radical cation CH_2-O(H)···H···O═C═$O^{\bullet+}$, which then sheds CO_2. The titled H-bridged ions dissociate via a higher energy route that involves the ionized carbene $HO(H_2)CO$-C-$OH^{\bullet+}$.

Experimental and theoretical

The ß-hydroxypyruvic acid (HPA) samples used in this study were obtained from Sigma and used without further purification. The EI mass spectrum of HPA shown in Fig. 1*a* was obtained as follows: a probe tube (glass, 15 mm, f = 1 mm) filled with tightly packed sample (~15 mg) was introduced via the direct solids insertion probe into the ion chamber such that the tip of the capillary just protruded into the source, which was kept at 110°C. The bottom part of the sample tube was kept at ambient temperature, and radiative heat transfer from the ion chamber to the sample tube caused the sample to slowly evaporate into the source, yielding a stable ion current for ca.

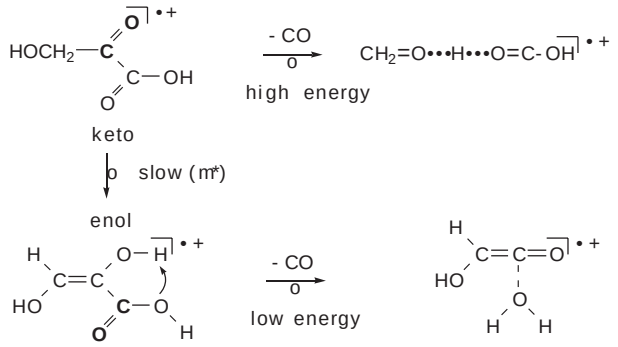
Scheme 9.



1 h. The spectrum shown in Fig. 1*b* was obtained by increasing the source temperature to 170°C. All other experiments on HPA and the samples described below were performed at a source temperature of 110°C.

Samples of the methyl ester of HPA were prepared on a milligram scale by dissolving ca. 30 mg of the acid in 150 mL of dry methanol and leaving the clear solution at room temperature. A ^{13}C NMR control experiment showed that the esterification of this rather strong acid is essentially complete in 30 min. Next, the alcohol and the water were quickly removed from the reaction mixture using a rotary pump, and the residual viscous liquid was then introduced into the ion chamber of the mass spectrometer using the all-quartz direct liquids insertion probe. The sample reservoir of this probe was kept at ambient temperature, and under these conditions the parent acid does not noticeably evaporate. The ^{18}O labelled isotopomer $HOCH_2C(=O^{18})COOCH_3$ was obtained by first preparing the methyl ester as described above and then adding 20 mL of $H_2{}^{18}O$ (90 ^{18}O, 3.7 ^{17}O) (Ventron GMBH, Karlsruhe) to allow the carbonyl oxygen to exchange (28). The mixture was left at room temperature for 10 min and was then worked up and introduced as described above. The EI mass spectra of the molecular ion region showed that only one ^{18}O atom had been incorporated in the ca. 40 enriched ester. The ^{18}O labelled isotopomer of the acid, $HOCH_2C(=O^{18})COOH$, M = 106, was prepared by dissolving ca. 30 mg of the acid in 200 mL of 3:1 mixture of CH_3OH and $H_2{}^{18}O$ and leaving the clear solution at room temperature for 10 min (at much longer reaction times and when using $H_2{}^{18}O$ only, a noticable exchange of the carboxyl group also takes place). The sample was then worked up and introduced as described above for the acid. The EI mass spectra of the molecular ion region showed that only one ^{18}O atom had been incorporated (m/z 108 is less than 5 of m/z 106) in the ca. 50 enriched ester. The D labelled HPA isotopomer $DOCH_2C(=O)COOD$ was prepared by dissolving ca. 30 mg of the acid in 150 mL of CH_3OD, followed by immediate work up as described above. The EI mass spectra of the sample showed that not more than two D atoms had been incorporated, thus showing that the acid does not equilibrate with its enol form under these conditions (see Introduction). The dihydroxyfumaric acid (DHF) sample came from Aldrich and was used without further purification. The intensity of the m/z 104 ion resulting from EI ionization of its in situ generated thermal decarboxylation product HO(H)C═C(OH)COOH, **II**, was comparable to that of the DHF molecular ion (see Experimental and Table 1 of ref. 10 for further details).

The mass spectrometric experiments were performed with the McMaster University VG Analytical (Manchester, UK) ZAB-R instrument of BE_1E_2 geometry (B, magnet; E, electric sector) (29) using an accelerating voltage of 8 or 10 keV. Metastable ion (MI) mass spectra were recorded in the second field-free region (2ffr). Collision-induced dissociation (CID) mass spectra were recorded in the 2ffr and third field-free region (3ffr), using oxygen as collision gas (transmittance T = 70). The CID mass spectra of the 2ffr metastable or CID peaks (MS/MS experiments) were obtained in the 3ffr, using O_2 as the collision gas. Neutralization–reionization (NR) spectra were recorded in the 2ffr, using , -dimethylaniline as reducing agent and oxygen gas for reionization. All spectra were recorded using a small PC-based data system developed by Mommers Technologies Inc. (Ottawa).

Standard ab initio and density functional MO calculations were performed with the Gaussian 94 suite of programs (30). Key results (transition states) were verified with the GAMESS (30) computational chemistry program using the RHF/DZP methodology (see ref. 3 for details). For the $C_2H_4O_3{}^{\bullet+}$ isomers geometry optimizations and frequency calculations were performed at the UHF/6-31G*, UB3LYP/6-31G* (31), and UMP2(full) /6-31G* levels of theory. The coupled cluster approximation (32) utilizing singles, doubles, and estimated triple excitations (CCSD(T)) was used to obtain our best relative energies on UMP2(full) /6-31G* optimized structures. The CCSD(T) calculations used the double zeta correlation consistent basis set of Dunning, cc-pVDZ (33). Scaling factors for zero-point vibrational energies (ZPVE) were HF = 0.9, B3LYP = unscaled, and MP2(full) = 0.9646 (22). All transition states had the correct number of negative eigenvalues of the corresponding Hessian matrix. The reaction pathways were verified with IRC calculations, at the same level of theory as the geometry optimizations. The HPA isomeric ions (Fig. 8) were optimized with the B3LYP/6-31G(d,p) method. The relative energies reported in Fig. 8 were generated using the same hybrid functional but with a much larger basis set, 6-311+G(3df,3pd), which reproduced typical keto(**I**)–enol(**II**) energy differences. The spin contamination of the UHF wave functions was acceptable for all species investigated, i.e., less than 10 of 0.75. The ray-traced images of the optimized structures in Figs. 4 and 8 were generated from their Gaussian output using a combination of PovChem[7] and POV-Ray.[8] Numerical values for the (dihedral) bond angles in the structures presented are available on request.

Kinetics and mechanism of hydroxylamine oxidation by $[Fe_2^{III}(\mu\text{-}O)(phen)_4(H_2O)_2]^{4+}$ in aqueous media[1]

Beauty Chaudhuri and Rupendranath Banerjee

Abstract: Equilibrium studies show that in aqueous solutions containing excess 1,10-phenanthroline (phen) in the range pH 3–9, the complex ion $[Fe_2^{III}(\mu\text{-}O)(phen)_4(H_2O)_2]^{4+}$ (**1**) undergoes rapid but partial hydrolysis and coexists with $[Fe_2^{III}(\mu\text{-}O)(phen)_3(H_2O)_4]^{4+}$ (**1d**), $[Fe_2^{III}(\mu\text{-}O)(phen)_4(H_2O)(OH)]^{3+}$ (**2**), and $[Fe_2^{III}(\mu\text{-}O)(phen)_4(OH)_2]^{2+}$ (**3**). The solution oxidizes hydroxylamine quantitatively to N_2O and is itself reduced to $[Fe(phen)_3]^{2+}$. The reactions in the range pH 3–6 are first-order in concentrations of complex and hydroxylamine but exhibits complex $[H^+]$ dependence, suggesting kinetic contributions from **1**, **1d**, and **2** but not from **3**. Rapid formation of inner-sphere adducts between NH_2OH and different $\{Fe_2O\}^{4+}$ species followed by rate-determining one-electron transfer to produce NHOH and $\{Fe_2O\}^{3+}$ is proposed. All subsequent steps are rapid. Ambient light does not affect kinetics and reaction products.

Key words: kinetics, equilibrium, oxo bridge, iron (III), hydroxylamine.

Résumé : Des études d'équilibre ont montré que, dans des solutions aqueuses contenant un excès de 1,10-phénanthroline (phen), à des pH allant de 3 à 9, l'ion complexe $[Fe_2^{III}(\mu\text{-}O)(phen)_4(H_2O)_2]^{4+}$ (**1**) subit une rapide hydrolyse partielle et qu'il coexiste avec les ions $[Fe_2^{III}(\mu\text{-}O)(phen)_3(H_2O)_4]^{4+}$ (**1d**), $[Fe_2^{III}(\mu\text{-}O)(phen)_4(H_2O)(OH)]^{3+}$ (**2**) et $[Fe_2^{III}(\mu\text{-}O)(phen)_4(OH)_2]^{2+}$ (**3**). Cette solution permet d'oxyder quantitativement l'hydroxylamine en N_2O alors qu'elle est réduite en $[Fe(phen)_3]^{2+}$. Les réactions à des pH allant de 3 à 6 sont du premier ordre en concentrations de complexe et de hydroxylamine, mais la dépendance sur la $[H^+]$ est complexe; ces résultats suggèrent la présence de contributions cinétiques des composés **1**, **1d** et **2**, mais pas du composé **3**. On suggère qu'il y a formation rapide d'adduits dans la sphère interne entre le NH_2OH et diverses espèces de $\{Fe_2O\}^{4+}$ suivie d'un transfert cinétiquement limitant d'un électron conduisant à la formation de NHOH et de $\{Fe_2O\}^{3+}$. Toutes les étapes subséquentes sont rapides. La lumière ambiante n'affecte pas la cinétique et les produits réactionnels.

Mots clés : cinétiques, équilibre, pont oxo, fer(III), hydroxylamine.

[Traduit par la rédaction]

Introduction

The μ-oxo diiron(III) unit, $\{Fe_2O\}^{4+}$, appears conspicuously in iron chemistry, both inside and outside the protein systems. Three reviews (1) emphasized the biological role of this chemical unit and amply represented the interest of inorganic chemists in the synthesis, structural characterization, and spectroscopic and magnetic properties of oxo-bridged diiron(III) complexes. However, reactivity studies appear to be occasional (2), and kinetic and mechanistic studies are extremely rare outside a protein environment (3). The situation appears somewhat surprising when one looks at the rich literature (4) on the substitution and redox kinetics of mononuclear iron(III) species. It might be mentioned at this point that proper interpretation of kinetics of mononuclear species demands detailed knowledge of the solution properties of oxo-bridged binuclear species, which are often difficult to avoid under the kinetic conditions used for mononuclear systems. On the whole, it appeared worthwhile to learn the kinetic and mechanistic features of reactions involving the $\{Fe_2O\}^{4+}$ unit.

The complex salt $[Fe_2(\mu\text{-}O)(phen)_4(H_2O)_2](NO_3)_4{\cdot}5H_2O$ (phen = 1,10-phenanthroline) can be obtained in a highly pure state and was characterized by X-ray crystallography (5). It is a Raman spectroscopic model (5) for the binuclear iron site in ribonucleotide reductase (6*a*) and *met*-hemerythrin, the oxidized form of the oxygen transport protein hemerythrin (6*b*). In solution, the complex oxidizes hydroxylamine at a moderate rate, measurable by conventional spectrophotometry. Oxidation of hydroxylamine in simple inorganic systems has been studied extensively (7–9), but no report is available on the reaction of NH_2OH with any of the different $\{Fe_2O\}^{4+}$ units.

(5). Hydroxylamine nitrate was prepared in solution by double decomposition of hydroxylamine hydrochloride (A.R., E. Merck) with barium nitrate (A.R., E. Merck) and standardized by oxidation with Fe^{III} in 1 M H_2SO_4 (eq. [1]) (9*a*). The Fe^{II} formed was titrated with standard $(NH_4)_2Ce(NO_3)_6$. We found the solution to be stable (10) for more than a week at room temperature (27°C).

[1] $2NH_2OH + 2\ Fe_2(SO_4)_3 \rightarrow N_2O + 4\ FeSO_4 + 2\ H_2SO_4 + H_2O$

Tris(phenanthroline)iron(III) nitrate (11) and tris(phenanthroline)iron(II) nitrate (12) were prepared according to the literature. The 1,10-phenanthroline was an E. Merck product and was used without further purification. Solution of recrystallized $NaNO_3$ (A.R., B.D.H.) was standardized by ion-exchange technique (13). All other reagents used were of analytical grade. Chromium(II)-scrubbed dinitrogen gas and triply distilled water were used throughout. Reported kinetic and equilibrium data are at 30.0°C and I = 1.0 M.

Physical measurements and kinetics

Equilibrium constants for equilibria [2]–[4] were evaluated spectrophotometrically. Kinetics were monitored mostly at 510 nm, the visible maximum of the reaction product, $[Fe(phen)_3]^{2+}$ (**4**). Large excess of hydroxylamine (c_R = $[NH_3OH^+] + [NH_2OH]$; 5–50 mM) over the total complex (c_{Fe} = 0.05–0.005 mM) was used, and the reactions

[2] $[Fe_2^{III}(\mu\text{-}O)(phen)_4(H_2O)_2]^{4+} + 2H_2O \overset{K_d}{\rightleftharpoons} [Fe_2^{III}(\mu\text{-}O)(phen)_3(H_2O)_4]^{4+} + phen$

[3] $[Fe_2(\mu\text{-}O)(phen)_4(H_2O)_2]^{4+} \overset{K_{a1}}{\rightleftharpoons} [Fe_2^{III}(\mu\text{-}O)(phen)_4(H_2O)(OH)]^{3+} + H^+$

[4] $[Fe_2(\mu\text{-}O)(phen)_4(H_2O)(OH)]^{3+} \overset{K_{a2}}{\rightleftharpoons} [Fe_2^{III}(\mu\text{-}O)(phen)_4(OH)_2]^{2+} + H^+$

were followed in situ in the thermoelectrically controlled (±0.1°C) cell housing (CPS-240A) of a Shimadzu spectrophotometer (UV-1601 PC). For some faster reactions, reactants were mixed in the spectrophotometer cell: 3.0 mL of the reductant solution at the required pH, buffer concentration, and ionic strength (1.0 M) was taken in a cell in the thermostated cell housing and allowed to attain temperature equilibrium. A small volume (<1% of the reductant) of the complex at the same pH, buffer concentration, and ionic strength was rapidly and directly injected into the cell so that the desired complex concentration was achieved after mixing. Recording of absorbance started almost simultaneously in the "kinetic mode" of the spectrophotometer, and the maximum initial absorbance (0.152) indicated that <15% of the initial reaction was missed during mixing. The first-order rate constants, k_o, were obtained from the slope of usual $\log(A_\infty - A_t)$ versus time (t) plots, where A_t and A_∞ are the absorbances at time t and after complete reaction.

We added no external buffer but generally used an excess 1,10-phenanthroline (c_{phen} = $[Hphen^+] + [phen]$) over c_{Fe}. The added phen and hydroxylamine successfully controlled solution pH within ± 0.01 during most of the kinetic studies, and the maximum variation observed was ± 0.03. The pH of experimental solutions were measured with an Orion (710A) pH meter, using a calibrated (13) Orion–Ross combination (model 81-02) electrode. All Y versus X data were analysed using the program package GRAPHER.[3] The reported errors are standard deviations. No attempt was made to estimate the small error propagated from k_o.

Stoichiometry

The UV-vis spectra (14) of product solutions indicate quantitative formation of **4** as a product. The reaction stoichiometry was determined by spectrophotometric titration of the oxidant complex (0.05 mM) with hydroxylamine in the presence of c_{phen} (3.0 mM) at pH 3.5. Different amounts of hydroxylamine were allowed to react with the oxidant solutions. The final absorption, corresponding to consumption of a stoichiometrically equivalent amount of the oxidant, was determined as a function of total hydroxylamine concentration, c_R. The absorbance due to unchanged complex, if any, is negligible (<3%) compared to the absorbance due to **4** formed under the reaction conditions. Stoichiometry was also measured by estimating unchanged hydroxylamine spectrophotometrically. For this purpose, the complex solution (0.02 mM) in excess phen (c_{phen} = 3 mM) was mixed with hydroxylamine (c_R = 0.05 mM). The final optical density at 510 nm indicated the formation of two moles of **4** per mole of **1**. Excess $Fe_2(SO_4)_3$ was then added to the mixture. Two parallel sets were taken. One of them was stored in the dark, the other under the conditions of normal laboratory illumination. The Fe^{2+} ion thus formed produced more of **4**, and absorption at 510 nm increased. The rise in absorption measured after 1 h was used to estimate hydroxylamine.

Since the formation and decay of HNO_2 was observed (15, 16) in some oxidation reactions of NH_2OH, we tested for the presence of any HNO_2 or NO_2^- as by-product. A 25 mL mixture having c_{Fe} = 0.10 mM, c_R = 0.10 mM, and c_{phen} = 5 mM at pH 6.1 was allowed to react completely. The product solution was eluted through a Dowex 50W X-8 cation exchanger in the Na^+ form, made up to 100 mL and subjected to the Griess–Ilsovey reaction for nitrous acid by reaction with sulfanilic acid followed by a coupling reaction with 1-napthyl amine to give an azo dye (λ_{max} = 520 nm, ε (molar extinction coefficient) = $3.3 \times 10^4\ M^{-1}cm^{-1}$). A 1% sulfanilic acid solution was prepared by dissolution of the powder in 25% acetic acid. A 0.6% solution of 1-napthylamine was also prepared in 25% acetic acid.

Results and discussion

Spectral and equilibrium studies

The complex solution is indefinitely stable in the range pH 2–10. However, its spectra change reversibly with changing c_{phen} and media pH. The most prominent spectral change occurs at 440 nm and has been displayed in Fig. 1. The change indicates protic and ligand dissociation equilibria, which can be suppressed almost completely in the presence of excess phen in the range pH 3–4. Under these conditions, **1** is the only absorbing species at λ > 400 nm. Its molar extinction coefficient is $\varepsilon_1 = 1460 \pm 5\ M^{-1}\ cm^{-1}$ at 440 nm.

The absorption versus c_{phen} (≥1.0 mM) data at pH 3.00 yield good fit to eq. [5] for $K_d = (4.97 \pm 0.08) \times 10^{-6}$ M

[3] Grapher. Golden Software Inc. 1988.

and $\varepsilon_{\mathbf{1d}} = (562 \pm 7)\ M^{-1}cm^{-1}$. Equation [5] can be derived for equilibrium [2] provided that $c_{phen} = ([Hphen^+] + [phen]) \approx [Hphen^+]$:

$$[5] \quad \frac{c_{Fe}}{(A_o - A_e)} = \frac{K_{Hphen}\, c_{phen}}{K_d[H^+](\varepsilon_{\mathbf{1}} - \varepsilon_{\mathbf{1d}})} + 1/(\varepsilon_{\mathbf{1}} - \varepsilon_{\mathbf{1d}})$$

where A_e and A_o are absorptions of the equilibrium mixture and of pure **1**, respectively; $\varepsilon_{\mathbf{1d}}$ is the molar extinction coefficient of the species **1d** and K_{Hphen} ($10^{-4.92}$) is the proton dissociation constant (17) for $Hphen^+$. This fit justifies equilibrium [2] and shows that only one phen dissociates under the reaction conditions.

One can safely assume that only equilibrium [3] is responsible for the changes in absorbance of complex solutions containing excess phen in the range pH 3.5–6.0 and thus derive eq. [6].

$$[6] \quad c_{Fe}/(A_o - A_e') = [H^+]/(\varepsilon_{\mathbf{1}} - \varepsilon_{\mathbf{2}})K_{a1} + 1/(\varepsilon_{\mathbf{1}} - \varepsilon_{\mathbf{2}})$$

where A_e' is the equilibrium absorbance in the range pH 3.5–6.0, and $\varepsilon_{\mathbf{2}}$ is the molar absorption coefficient for **2**.

Similarly, in the presence of excess phen, in the range pH 7–9, only equilibrium [4] is assumed to be the cause of change in solution absorbance, with pH in the range 7–9, whereby eq. [7] is valid.

$$[7] \quad c_{Fe}/(A_o' - A_e'') = [H^+]/K_{a2}(\varepsilon_{\mathbf{2}} - \varepsilon_{\mathbf{3}}) + 1/(\varepsilon_{\mathbf{2}} - \varepsilon_{\mathbf{3}})$$

In eq. [7], A_e'' is the equilibrium absorption in the range pH 7–9, $A_o' = \varepsilon_{\mathbf{2}} \times c_{Fe}$, and $\varepsilon_{\mathbf{3}}$ is the molar absorption coefficient for **3**. Absorbance versus pH data in the respective pH ranges were fitted to eqs. [6] and [7] to yield $K_{a1} = (3.84 \pm 0.04) \times 10^{-6}$ M, $K_{a2} = (2.52 \pm 0.08) \times 10^{-8}$ M, $\varepsilon_{\mathbf{2}} = (962 \pm 8)\ M^{-1}\ cm^{-1}$, and $\varepsilon_{\mathbf{3}} = (796 \pm 9)\ M^{-1}cm^{-1}$.

A global fit of absorbance versus $[H^+]$ data in the presence of excess phen was attempted using the $\varepsilon_{\mathbf{2}}$, $\varepsilon_{\mathbf{3}}$ values and eq. [8] for which A is the equilibrium absorption in the range pH 3.5–9.0, $A_2 = \varepsilon_{\mathbf{2}} \times c_{Fe}$, and $A_3 = \varepsilon_{\mathbf{2}} \times c_{Fe}$. A good fit is obtained with $K_{a1} = (4.03 \pm 0.05) \times 10^{-6}$ M and $K_{a2} = (2.54 \pm 0.06) \times 10^{-8}$ M.

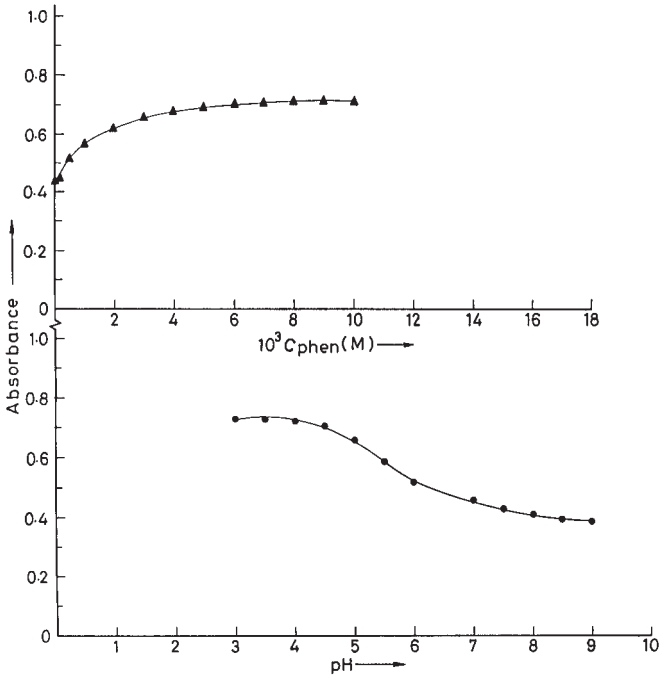
$$[8] \quad (A_o - A)[H^+]/(A - A_2) = K_{a1} + (A - A_3)K_{a1}K_{a2}/(A - A_2)[H^+]$$

The pK_{a1} (5.39 ± 0.01) and pK_{a2} (7.59 ± 0.01) values for **1** are smaller than the respective values ($pK_{a1} = 6.36$; $pK_{a2} = 9.84$) for the ruthenium(III) analogue $[Ru^{III}_2(\mu\text{-}O)(bipy)_4(H_2O)_2]^{4+}$ (**5**) (18). Greater acidity of **1** than **5** is due to smaller size of Fe^{III}. The differences ($pK_{a1} - pK_{a2}$) for the binuclear complexes **1** and **5** are comparable to those for the mononuclear Fe^{III} complexes (19) of the type $[ML_4(H_2O)_2]^{3+}$. Prominent electronic interaction of the two M^{III} centres via the oxo bridge in **1** and **5** is thus indicated and is indeed expected from the *anti* ferromagnetic coupling well known (1) in several μ-oxo-bridged complexes of Fe^{III} and Ru^{III}. Binuclear iron(III) complexes with insulating bridging groups cannot enter into such interactions, and they have small differences between pK_{a1} and pK_{a2} (19).

Stoichiometry

No nitrogen(III) product could be detected by the Griess–Ilsovey reaction at pH 6.1. Under our reaction conditions a 2×10^{-6} M $NaNO_2$ solution gave an absorbance of 0.166 per cm at 520 nm. At pH 6.1 the reaction between hydroxylamine and

Fig. 1. Change in absorbance with c_{phen} at fixed pH (3.00) (▲) and change in absorbance with pH at fixed c_{phen} (0.010 M) (●). λ, 440 nm ; c_R, 0.50 mM; I, 1.0 M; path length, 1.00 cm. The solid lines are drawn using calculated values for eqs. [8] and [5], respectively.



HONO is very slow (20*a*), as is the reaction of HONO with the diiron(III) complexes. Hence, we are confident that HONO did not form at this pH.

Stoichiometric measurements in the presence of excess phenanthroline indicated a 1:1 stoichiometry (eq. [9]) from spectrophotometric titration data and determination of unused hydroxylamine. The measured stoichiometry is independent of whether diffuse light is excluded or not.

$$[9] \quad [Fe_2(\mu\text{-}O)(phen)_4(H_2O)_2]^{4+} + NH_2OH + 2phen = 0.5N_2O + 2[Fe(phen)_3]^+ + 3.5H_2O$$

Different oxidants oxidize hydroxylamine to nitrous oxide, which seems to be the most common oxidation product. Nevertheless, other products like N_2, NO_2^-, NO_3^-, and NO have been reported (8, 20, 21). Gupta and co-workers (9*b*) studied the oxidation of hydroxylamine by iron(III) in acetate buffer, and proposed $[Fe_3O(O_2CMe)_6]^+$ to be the near exclusive iron(III) species along with a small concentration of iron(III) monomers. Complex kinetics and product inhibition by iron(II) were noted, and the initial rate method was used. They reported N_2 as the oxidation product in diffuse light, but ($N_2O + N_2$) in the dark. Butler and Gordon (9*c*) also noticed the effect of light on oxidation products of hydroxylamine with iron(III) in dilute perchloric acid media. The observations are difficult to explain, but two potent sources of complications may be considered: (*a*) auto-oxidation of iron(II) to iron(III), which further consumes hydroxylamine; effectively this implies an additional pathway in which hydroxylamine is oxidized by oxygen (22) under the aerobic conditions used, and (*b*) catalysed oxidation by trace metal ions, which were apparently not excluded. Trace catalysts strongly affect both rate

© 1998 NRC Canada

Fig. 2. Spectral changes with time for a mixture containing c_{Fe} = 0.05 mM, c_R = 0.02 M, and c_{phen} = 3 mM at pH 4.50. (*i*) Spectrum of 0.05 mM complex at the same c_{phen} and pH. and product of oxidation (23) of NH_2OH and may lead to wrong conclusions about the uncatalyzed process. Light may affect stoichiometry and kinetics by its influence on either (*a*) or (*b*). Moreover, both groups worked with complex mixtures of iron(III) species of different nuclearity, which can oxidize hydroxylamine differently.

We observed no such effect of light in our system, but note that trace metal ions should be sequestered in the presence of added phen. Also, all the oxidant species are well defined and the reaction product, $[Fe(phen)_3]^{2+}$, is stable in air.

Kinetics

During the reaction course, an isosbestic point sets up at 389 nm, and absorption at this point increases with increasing c_R. Some typical values of absorbances are 0.225, 0.246, and 0.274 at c_R = 0.02, 0.04, and 0.06 M, respectively. This strongly suggests incomplete formation of precursor complexes between hydroxylamine and the oxidants. Spectrum of the complex solution, however, does not pass through this point (Fig. 2), and we propose that the isosbestic point sets up between the precursor and the final reaction product. Non-reducing substrates (for example, NCS^-) rapidly form inner-sphere adducts with **1** (24) and analogous complexes (25). Similar adducts seem reasonable with hydroxylamine. The absorbance versus time data at 510 nm obeyed first-order kinetics at least up to 95% reaction. Table 1 shows that k_o decreases with increasing c_{phen} until a constant value is reached for c_{phen} > 1 mM. Qualitatively, the data indicate that **1d** is more reactive than 1 and that [**1d**] decreases with increasing [phen] until [**1d**] becomes kinetically negligible. The value of k_o increases linearly with c_R (≤ 0.05 M), decreases with increase in pH, but does not change (± 5%) with a ten-fold (0.05–0.005 mM) change in concentration of complex. Values of k_o also do not change (± 3%) on changing the monitoring wavelength from 510 to 365 nm, or when the reaction media were purged with dinitrogen, or when stray light was excluded. Scheme 1 seems to be a reasonable explanation for the observed kinetics and equilibria.

Scheme 1

$$\mathbf{1} \rightleftharpoons \mathbf{2} + H^+, \qquad K_{a1} = 4.0 \times 10^{-6}\ M$$

$$\mathbf{1} \rightleftharpoons \mathbf{1d} + \text{phen}, \qquad K_d = 5.0 \times 10^{-6}\ M$$

$$Hphen^+ \rightleftharpoons H^+ + \text{phen}, \qquad K_{Hphen} = 1.2 \times 10^{-5}\ M$$

$$NH_3OH^+ \rightleftharpoons H^+ + NH_2OH, \qquad K_a = 1 \times 10^{-6}\ M \text{ (23)}$$

$$\mathbf{1} + NH_2OH \overset{K_1}{\rightleftharpoons} \mathbf{I_1} \overset{k_1}{\rightarrow} \text{products}$$

$$\mathbf{2} + NH_2OH \overset{K_2}{\rightleftharpoons} \mathbf{I_2} \overset{k_2}{\rightarrow} \text{products}$$

$$\mathbf{1d} + NH_2OH \overset{K_3}{\rightleftharpoons} \mathbf{I_3} \overset{k_3}{\rightarrow} \text{products}$$

In this scheme, $\mathbf{I_1}$ is $[Fe_2(\mu\text{-}O)(phen)_4(H_2O)(NH_2OH)]^{4+}$, $\mathbf{I_2}$ is $[Fe_2(\mu\text{-}O)(phen)_4\text{-}(OH)(NH_2OH)]^{3+}$, $\mathbf{I_3}$ is $[Fe_2(\mu\text{-}O)(phen)_3(H_2O)_3(NH_2OH)]^{4+}$; **1**, **2**, and **1d** are as defined previously.

© 1998 NRC Canada

Provided $K_i[NH_2OH] << 1$ ($i = 1$–4) and $c_R >> c_{Fe}$, the scheme leads to eq. [10].

$$[10] \quad k_o\{([H^+] + K_{a1})[phen] + K_d[H^+]\}/ [NH_2OH] = (k_1K_1[H^+] + k_2K_2K_{a1})[phen] + k_3K_3K_d[H^+] = m_1[phen] + c_1 \text{ (say)}$$

The assumption, $K_i[R] << 1$ seems justified because k_o and the absorbance at the isosbestic point increase linearly with c_R. The maximum value of $[NH_2OH]$ used in kinetics is 0.015 M (pH 4.50, $c_R = 0.05$ M) up to which we observed no indication for rate saturation. Hence, an upper limit for K_i is 5 M^{-1}. Stynes and co-workers (26) noted that weakly basic amines form weak adducts with the oxo-bridged diiron complex $[Fe^{III}(dmgBF_2)_2]_2O$, ($dmgBF_2$ is difluoro(dimethylglyoximato)borate). Hydroxylamine is a weak base and hence expected to form weak adducts with **1** and its derivatives. Hydroxylamine can form O-bonded complexes, but stability constants for such complexes also are very small ($K \leq 0.1$) (21*a*). It is not possible for NH_3OH^+ to coordinate to Fe^{III} without loss of a proton first. Hence, the small values for K_i and the weak acidity of NH_3OH^+ excludes the possibility of NH_3OH^+ to act as an active reducing agent.

The k_o data at fixed pH (4.50) and c_R (0.020 M) but variable c_{phen} yielded a good fit ($r = 0.9989$; $m_1 = 8.29 \times 10^{-5}$; $c_1 = 2.92 \times 10^{-9}$) into eq. [10]. However, a better fit results ($r = 0.9997$; $m_1 = 8.43 \times 10^{-5}$; $c_1 = 1.40 \times 10^{-9}$) if k_o data at the three lowest c_{phen} (0.05, 0.10, 0.20 mM) are excluded (Fig. 3). In the presence of excess phen, [**1d**] is negligible compared to ([**1**] + [**2**]), and (K_{a1} + [H^+])[phen] is >> $K_d[H^+]$. Equation [10] may then be transformed to equation [11].

$$[11] \quad k_o([H^+] + K_{a1})([H^+] + K_a) / c_R = a[H^+]^2 + b[H^+] + c$$

where $a = k_3K_3K_dK_a/K_{Hphen}c_{phen}$, $b = (k_1K_1K_a + k_3K_3K_dK_a/c_{phen})$, and $c = k_2K_2K_{a1}K_a$. Values for k_o at different pH (≥3.5) but fixed c_{phen} and c_R were fitted into eq. [11] and yielded $a = (2.66 \pm 0.01) \times 10^{-3}$ M^{-1} s^{-1}, $b = (2.31 \pm 0.003) \times 10^{-6}$ s^{-1}, and $c = (5.46 \pm 0.03) \times 10^{-11}$ M s^{-1}. From these values, one can extract $k_1K_1 = 0.93 \pm 0.005$ M^{-1} s^{-1}, $k_2K_2 = 13.6 \pm 0.06$ M^{-1} s^{-1}, $k_3K_3 = 19.1 \pm 0.04$ M^{-1} s^{-1}. These parameters and eq. [10] generally reproduce k_o values within ± 10% (see parenthetical values in Table 1). The calculated values also follow the expected trend of variation, but they are considerably smaller than the experimental data when [phen] is very low. Trace-metal ion catalysis may become effective at low [phen] and is a probable cause for the observed deviations.

The second-order rate constants are composite constants (K_ik_i) and both K_i and k_i can control the reactivity of the intermediates. A higher value for K_3 than either K_1 or K_2 seems reasonable, since an iron(III) centre in **1d** should be more electron deficient than that in either **1** or **2**. Moreover, **1d** is structurally less rigid due to the absence of a bulky phen ligand, and can easily accommodate structural changes associated with the electron transfer step,

$$\{Fe^{III}_2O\}^{4+} \rightarrow \{Fe^{III}Fe^{II}O\}^{3+}$$

On this ground, k_3 is likely to be larger than both k_1 and k_2. The higher reactivity of $\mathbf{I_3}$ thus seems justified. It is more difficult to assess the order of reactivity of $\mathbf{I_1}$ with respect to $\mathbf{I_2}$. The water molecule in $\mathbf{I_1}$ is ≈4 times a stronger acid than NH_3OH^+. So internal proton transfer in $\mathbf{I_1}$ may weaken the adduct. This is not possible for $\mathbf{I_2}$. Thus, K_1 should be less than K_2. On the other hand, the smaller charge borne by $\mathbf{I_2}$ should render an intramolecular electron transfer less facile, and k_1 is expected to be greater than k_2. The overall effect of such opposing factors is difficult to predict.

Concentration of the dihydroxo species **3** is very small in the pH range used in kinetics. It does not contain any replaceable water molecule, and all the ligands present are held more tightly than H_2O. It should also be a weak oxidant due to the smaller positive charge on its iron(III) centres. Kinetic activity of **3** is therefore inappreciable in the range pH 3–6.

Conversion of intermediates $\mathbf{I_1}$–$\mathbf{I_3}$ to products must be multistep processes. We propose the rate-determining steps to be one-electron reduction of the intermediates to respective Fe^{II}-O-Fe^{III} dimers, which quickly collapse to Fe^{II} and Fe^{III} monomers. The iron(III) monomer $[Fe(phen)_2(H_2O)_2]^{3+}$ is further reduced to the iron(II) monomer $[Fe(phen)_2(H_2O)_2]^{2+}$, which rapidly forms **4** in the presence of phen. We have verified that $[Fe(phen)_3]^{3+}$ is reduced by hydroxylamine within the time of mixing; $[Fe(phen)_2(H_2O)_2]^{3+}$ is expected to react faster. It is also known that formation of **4** from Fe^{2+} and excess phen is a fast reaction (27) (rate constant ~10^5 s^{-1}). Inner-sphere reduction of $[Fe(phen)_3]^{3+}$ by NH_2OH should be slow since substitution on this iron(III) complex is slow. Such is not the case for the diaqua derivative. Even with $[Fe(phen)_3]^{3+}$ the outer-sphere reaction should be fast. We used simple Marcus relation to calculate the rate constant for outer-sphere oxidation of NH_2OH by $[Fe(phen)_3]^{3+}$ to be 490 $M^{-1}s^{-1}$. Consequently, even at the lowest c_R (= 0.005 M,) used in kinetics, half life for this reaction is only 0.28 s. The parameters used in this calculation are $E^0 = 1.05$ V for the couple $[Fe(phen)_3]^{3+/2+}$, its self-exchange rate constant (≈10^7 M^{-1} s^{-1}) (28), $E^0 = 0.42$ V for the couple NH_2OH^+/ NH_2OH, and its self-exchange rate constant, 5×10^{-13} M^{-1} s^{-1} (8).

Further, the oxo bridge in **1** is stable, and the complex suffers no autodecomposition within the time of kinetic studies. Martell and co-workers (29) explained that the $\{Fe_2O\}^{4+}$ core unit gains stability from superexchange of the d^5 high-spin iron(III) centres across the oxo bridge. But the high-spin Fe^{II} and Fe^{III} are probably less strongly bound to O^{2-}, since both oxidation states have two *anti* bonding electrons directed towards the formal bond axes. This would impart weaker Fe^{II}—O—Fe^{III} and Fe^{II}—O—Fe^{II} bonds, both of which should be rapidly broken by aquation. In fact the oxo bridge in the mixed valence system Fe^{II}-O-Fe^{III} is rare and in general putative outside a protein environment (1*c*). It thus appears that reduction of $\{Fe_2O\}^{4+}$ complexes by hydroxylamine involves several steps, but the rate-determining step is

$$\{Fe_2O\}^{4+} \rightarrow \{Fe_2O\}^{3+}$$

All other steps are either too fast or too slow to qualify as the rate-determining step. The immediate oxidation product of hydroxylamine should be NH_2OH^+. This is known to generate N_2O via HNO (20*a*, 23):

$$NH_2OH \rightarrow H^+ + NHOH + e^- \rightarrow H^+ + HNO + e^- \rightarrow 0.5N_2O + 0.5H_2O$$

The values for K_i could refer to outer-sphere precursor complex formation. However, hydroxylamine has a record low self-exchange rate constant, and outer-sphere reactions occur very rarely with NH_2OH in spite of its moderately low $E°$ value. We observed that **1** does not oxidize $[Fe(CN)_6]^{4-}$,

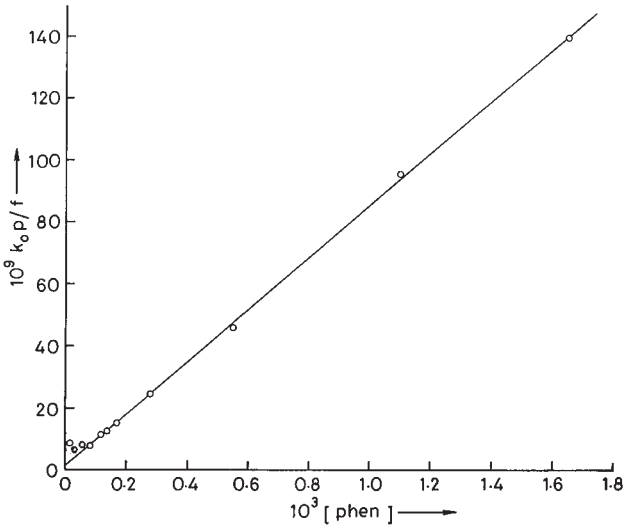
Fig. 3. Effect of phenanthroline on rate constants at a fixed pH (4.50), c_R (0.05 mM), and I (1.0 M); $p = ([H^+] + K_{a1})[phen] + K_d[H^+]$; $f = K_a c_R/(K_a + [H^+])$. The solid line is drawn using least-squares slope and intercept.



indicating for **1** a reduction potential less than that for the $[Fe(CN)_6]^{4-/3-}$ couple (0.46 V). Calculations using simple Marcus relation ($k_{12} = (k_{11}k_{22}K_{12})^{1/2}$) for outer-sphere reactions with k_iK_i used as k_{12} values imply impossibly high self-exchange rate constants ($k_{11} > 10^{10}$) for the $\{Fe_2O\}^{4+}$ complexes. The calculations refute an outer-sphere mechanism in the present system.

COMMUNICATION

Precise measurement of fluorescence from uranium taken up in sodium fluoride

Heather Marshall and Marisa A. Devine

Abstract: The fluorescence signals from replicate samples of uranium taken into fused sodium fluoride beads, read in the prescribed fashion, are not distributed normally. The signal from a single bead shows marked sinusoidal variation as the bead is rotated, and it is the superposition of this sinusoidal variation on the normal variation between beads that gives rise to a widened or even bimodal distribution among replicates. If each bead is read a second time, following a single half rotation, the average of the two readings gives the true signal underlying the sinusoidal variation; the distribution of these true signals represents simply the normal variation between replicate samples, and the precision of results is much improved.

Key words: uranium, fluorescence, fluorometry.

Résumé : Les signaux de fluorescence obtenus de façon prescrite, à partir d'échantillons subdivisés d'uranium prélevés de billes de fluorure de sodium fondues, ne donnent pas une distribution normale. Le signal obtenu à partir d'une seule bille présente une variation sinusoïdale importante lorsqu'on la fait tourner; c'est la superposition de cette variation sinusoïdale sur la variation normale entre les billes qui donne lieu à une distribution élargie ou bimodale entre les échantillons subdivisés. Si l'on effectue une deuxième mesure, après une seule demi-rotation, la moyenne des deux valeurs obtenues conduit à la valeur réelle du signal sous-jacent de la variation sinusoïdale; la distribution de ces valeurs réelles représente simplement la variation normale entre les échantillons subdivisés et il en résulte une amélioration de la précision des résultats.

Mots clés : uranium, fluorescence, fluorométrie.

Introduction

For the routine determination of uranium, fluorometry of samples taken up in fused sodium fluoride beads is a well established, robust method. The flux of choice (NaF with 2% LiF) and the optimum conditions for bead preparation are well known (1), the fluorescence intensity is proportional to the uranium content over a wide range, and the techniques to correct for possible matrix interference are those generally available for optical methods of quantitative analysis; however, we have found the uncertainty in results to be unpredictable. Close study of the observed signal reveals a corrigible fluctuation, and the precision of determinations can be improved by a simple change in the fluorescence measurement itself.

Consistency in the fusion conditions is clearly a necessity (1). In this laboratory, batches of up to 21 pellets are fused in formed platinum dishes rotating over a ring of propane-fuelled Meker burners; the pellets are heated at 500–600°C, fused at 920–940°C, and annealed at 500–600°C. The beads, in their platinum dishes, are cooled together on a perforated plate of massive aluminum for 30 min before the fluorometric measurement, and that measurement is completed within 1 h.

Although some custom instruments are still in use, most uranium fluorometry is carried out with commercial units such as the Jarrell–Ash Model 27-000 used in this laboratory. In these instruments, fused beads of about 400 mg of flux and containing nanograms of uranium are mounted facing the photomultiplier tube that is to collect the fluorescent light, and exposed to the ultraviolet light from lamps on either side of the tube. The sample holder is a shaped well in a lightproof slide, and mounting a sample bead is simply a matter of placing the bead in the well and closing the slide. The manufacturers and users emphasize the ease and rapidity with which beads can be read, and for routine work high sample throughput can be maintained.

Observations

The simplicity of mounting a bead and reading the fluorescence signal is beguiling; the observed signal is in fact complex, as the fluorescence is apparently anisotropic. If the bead is rotated in the plane of the face displayed to the photomultiplier, the output signal can be observed to have a sinusoidal

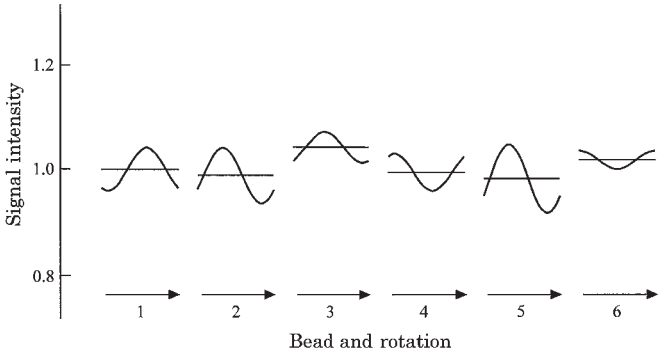
Fig. 1. Fluorescence signals from six replicate sample beads. The short horizontal lines mark the characteristic signal intensities, and the sinusoidal traces show the measured signals as the beads are rotated through 360°; the signals are plotted exactly as they were first observed, not shifted to start at zero azimuth.



perturbation; the intensity of the signal in any azimuthal orientation can be written as

$$I = C + A \sin \theta$$

where C is the characteristic signal, A is the amplitude of the perturbation, and θ is the angle of rotation from zero azimuth. As there is no visible sign on the bead to define zero azimuth for the sinusoidal perturbation, the beads cannot be mounted immediately in this desirable orientation; the intensity of the signal observed on a single reading includes the term in sin θ, and θ is unknown. The signals from six replicate beads from a single fusion batch, each rotated in this way, are shown in Fig. 1, with the perturbation plotted along a line representing the intensity of the concentration-dependent characteristic signal of each bead; the signals are plotted exactly as they were first observed, with the beads on first mounting proving to have been in orientations of –120, –30, –60, +60, –30, and +90 degrees from zero azimuth.

Discussion

When a bead is slipped into the sample holder, all azimuthal orientations are possible and equally probable. Thus, all signal intensities between $(C - A)$ and $(C + A)$ are possible; however, because sin θ changes more slowly near sin θ = 1, the extreme values are more probable, as shown in Fig. 2. While the mean of this U-shaped distribution is indeed C, a large variance is engendered by the high probability of the extreme values and the otherwise almost flat probability distribution. The superposition of this distribution on the normal distribution of uncertainty in C (the concentration-dependent characteristic signal of the beads) will obviously broaden it, as shown in Fig. 3. It is the large variance of this broadened distribution that made estimates of the precision of the technique, taken from the usual triplicate or quintuplicate measurements, erratic and apparently unrepeatable.

In our experience, the amplitude of the perturbation is about twice the standard deviation of values of C. As shown in Fig. 3*b*, the probability distribution of signal intensity under these circumstances is broad and rather trapezoidal, with an almost constant probability across the midrange. If the amplitude of the sinusoidal perturbation is somewhat larger, the extreme tendency of the perturbation predominates over the central tendency of the normal distribution, and the composite distribution broadens even further and becomes bimodal. When the amplitude of the perturbation is lower, the distribution appears to be simply a broader Gaussian, although it is in fact slightly flattened.

The amplitude of the sinusoidal perturbation is not consistently twice the standard deviation of the characteristic signals but varies, as is apparent in Fig. 1. We did not study this amplitude distribution closely, as we chose to circumvent the problem rather than make allowance for it, but the amplitude appears to be 1.8 ± 0.7 times the underlying standard deviation, which itself is generally 3% of the characteristic intensity.

The final probability distribution of signal intensities from replicate pellets, accumulating the normal distribution of the characteristic signals (which includes the uncertainty in the instrumental reading of the signal), the U-shaped distribution engendered by the azimuthal anisotropy, and the variation in the amplitude of this perturbation, is a broad and roughly normal distribution, as shown in Fig. 3*c*; the standard deviation of this cumulative distribution is about 1.8 times that of the underlying distribution of the characteristic signal. This degradation of precision by a factor of 1.8 could be corrected by taking three times as many replicate pellets, improving the precision again by a factor of $3^{1/2}$, but this would consume time and reagents, and might not even be possible, as handling three times as many pellets in one process run is often awkward with these instruments.

One could avoid dealing with the broadened distribution of signal intensity by correcting or removing the sinusoidal perturbation of the signal from each individual bead, and so dealing with only the true characteristic signals. In mechanical terms, the instrument could be adapted to rotate the bead in its holder while taking a time average of the signal. In arithmetic terms, the signal could be read in the ordinary way with the bead in several orientations, and the data fit to give the best values of the characteristic intensity and the perturbation amplitude. More simply, the signal can be read in the ordinary way, with the bead sitting at whatever the azimuthal angle happens to be, and then read again with the bead turned through exactly 180°. Since

$$\sin(\theta + 180°) = -\sin \theta$$

the average of the two readings is the underlying characteristic intensity, whatever the value of θ. (It is tempting to extend this argument to more closely-spaced readings, and to average four readings taken at 90° intervals, or even twelve readings taken at 30° intervals, but the increased tedium would not be justified; the variance of repeated readings of the signal from one bead in a single orientation is much less than the variance among replicate beads, so the improvement derived from the greater number of readings of each bead would be small.)

Conclusions

The minor added step of reading the signal from each bead a second time completely obviates the azimuthal anisotropy of the fluorescence signals, with almost no increase in analysis time or complexity. The analytical precision is improved, and the advantages of the technique can be exploited with confidence.

Additions and corrections: Transverse compression and the secondary H/D isotope effects in intramolecular S_N2 methyl-transfer reactions

Saul Wolfe, Chan-Kyung Kim, Kiyull Yang, Noham Weinberg, and Zheng Shi

Ref.: Can. J. Chem. **76**, 102–113 (1998).

This article is republished below, as parts of Figs 2–5, 8, and 13 were inadvertently deleted from the original publication. The Publisher regrets this error.

Abstract: Using ab initio molecular orbital theory mainly at the 3-21+G level, intramolecular S_N2 methyl transfer between two oxygens confined within a rigid template is found to proceed exclusively by a high energy retention mechanism when the oxygens are separated by three or four bonds, and by a high energy inversion mechanism when the oxygens are separated by six bonds. Both mechanisms exist when the oxygens are separated by five bonds. The CH_3/CD_3 kinetic isotope effects are normal (1.21–1.34) in the retention processes and inverse (0.66–0.81) in the inversion reactions. In the case of inversion, compression of C—H bonds of the transition state by structural effects in the plane perpendicular to the O-C-O plane increases the inverse isotope effect. The retention barriers are high because retention is inherently unfavorable, even when pericyclic stabilization of the transition state is possible. The inversion barriers are high because a rigid template cannot accommodate a linear O-CH_3-O structure, and the O-C-O bending vibration is stiff (the Eschenmoser effect). Using a novel design strategy, a nonrigid template has been found in which the barrier and the CH_3/CD_3 kinetic isotope effect are the same as in an intermolecular reaction.

Key words: Eschenmoser effect, isotope effect, compression, S_N2, sigmatropic rearrangement.

Résumé : En se basant sur des calculs ab initio d'orbitales moléculaires au niveau 3-21+G, on peut conclure que le transfert intramoléculaire S_N2 d'un groupe méthyle entre deux oxygènes maintenus de façon rigide dans une matrice rigide se fait avec un mécanisme de rétention de haute énergie lorsque les oxygènes sont séparés par trois ou quatre liaisons et par un mécanisme d'inversion de haute énergie lorsque les oxygènes sont séparés par six liaisons. Les deux mécanismes existent lorsque les oxygènes sont séparés par cinq liaisons. Les effets isotopiques cinétiques CH_3/CD_3 sont normaux (1,21–1,34) dans le processus avec rétention et inversés (0,66–0,81) dans les réactions de rétention. Dans le cas de l'inversion, une compression des liaisons C—H de l'état de transition résultant d'effets structuraux dans le plan perpendiculaire au plan O-C-O provoque une augmentation de l'effet isotopique inverse. Les barrières à la rétention sont élevées parce que la rétention est intrinsèquement défavorisée même quand la stabilisation péricyclique de l'état de transition est possible. Les barrières d'inversion sont élevées parce qu'une matrice rigide ne peut accommoder une structure linéaire O-CH_3-O et que la vibration de déformation O-C-O est importante (effet Eschenmoser). Utilisant une nouvelle stratégie de conception, on a développé une matrice non rigide dans laquelle la barrière ainsi que l'effet isotopique cinétique CH_3/CD_3 sont les mêmes que dans la réaction intermoléculaire.

Mots clés : effet Eschenmoser, effets isotopiques, compression, S_N2, réarrangement sigmatropique.

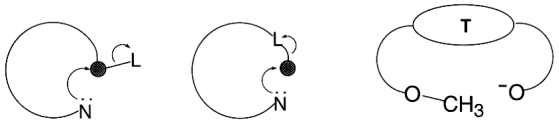
Introduction

Steric compression and the S_N2 transition state

Over half a century elapsed between Baeyer's postulate of *Spannung* (1), Kehrmann's discussion of *Raumerfüllung* (2), Meyer's *Gesetze der sterischen Behinderungen* (3), and the first attempts to quantify the concept of steric compression. Following a suggestion that the low reactivities of neopentyl halides in bimolecular substitution reactions are caused by compression of their S_N2 transition states (4), Dostrovsky, Hughes, and Ingold (5) developed a rudimentary force field to calculate this compression and to pattern reactivity trends in a series of identity reactions (eq. [1])

[1] $X^- + R\text{-}X \rightarrow X\text{-}R + X$

with R = methyl, ethyl, *n*-propyl, isopropyl, isobutyl, *t*-butyl, and neopentyl. Because the information needed to treat bond stretching and bending at the reactive carbon was not yet very accurate or complete, an idealized transition state model was



1 2 3

assumed in which the reactive carbon atom and the entering and leaving groups were collinear, with C—X bond lengths that remained constant throughout the series. Compression was then calculated by the assumption of an appropriate functional form for the van der Waals repulsions between nonbonded atoms. Although the specific choices made by these authors could be criticized (6), and later workers found the calculations to be "so cumbersome that few...have felt able to discuss the method...in any detail" (7), this daring intellectual exercise, together with an important contemporaneous suggestion by T.L. Hill (8) and Westheimer's treatment of biphenyl atropisomerism (9), are the foundations of today's sophisticated molecular mechanics procedures (10).

The force field treatment of S_N2 transition states was refined by the Ingold school (11) and then by Abraham et al. (7) and de Tar et al. (12). In the latter work, for the series X = Br and R = *n*-propyl, isobutyl, and neopentyl, increasing steric compression in the transition states was seen in a gradual increase in the C—Br bond lengths (2.22, 2.23, 2.28 Å) and a systematic decrease in the Br-C-Br bond angles (161.4, 155.3, 143.2°). These geometric trends reflect the use of a bending force constant (3×10^{-5} mdyn Å deg^{-2} molecule^{-1}) (1 dyn = 10 μN) that allows compression in the β-series to be more easily relieved by bending than by stretching (force constant 6.6×10^{-2} mdyn Å^{-1} molecule^{-1}). It is noteworthy that AM1 calculations (13, present work) (see also ref. 14) reproduce the force-field trends in the C—Br bond lengths (2.29, 2.30, and 2.31 Å, respectively), and the Br-C-Br bond angles (159.4, 155.5, and 145.3°) of the transition structures.

Longitudinal compression of the S_N2 transition state

There is an obvious relationship between the classical alkyl halide reactivity sequence (ethyl > propyl > isobutyl > neopentyl) (3, 4) and the calculated *longitudinal* compression of their S_N2 transition structures, by which we mean the compression of these structures in the X–C–X plane. Eschenmoser and co-workers (15) were the first to recognize and prove that although the formation of five- and six-membered rings by exocyclic S_N2 ring closure, i.e., **1**, is highly favored over competing intermolecular reactions (16, 17), the deceptively enticing methyl transfer depicted in **2** is so inhibited by longitudinal compression in a five- or six-membered cyclic *transition state* that only intermolecular reactions are observed. Subsequent work by King and McGarrity (18) confirmed that the "failure to observe the endocyclic reaction arises not because the intermolecular reaction is inordinately fast but simply because the intramolecular reaction is slow" and undetectable when the endocyclic transition state contains fewer than nine atoms. There are now many examples of endocyclic restriction of the S_N2 mechanism (19), and the synthetic implications of this effect have been the subject of much interest (20).

Longitudinal compression and secondary H/D isotope effects

We have recently discussed the effect of longitudinal compression on the barriers and secondary kinetic CH_3/CD_3 isotope effects (k_H/k_D) of intermolecular methyl-transfer reactions (21). The isotope effects are inverse ($k_H/k_D < 1$), primarily as a result of the increase in C-H (C-D) stretching frequencies that accompanies the tetrahedral to trigonal change in geometry of the methyl group (22).[4] Because the X-C-Y bond angles of the transition structures of such reactions are close to 180°, compression has implied a tightening (23) of C—X and C—Y bond lengths in the transition state. In both identity (X = Y) and nonidentity (X ≠ Y) reactions, this kind of compression is found to be associated with a decrease in the barrier and an

[4] Some recent discussions of this subject, referring specifically to nonidentity methyl-transfer reactions (22*a*, *b*), are flawed (*i*) by a failure to recognize that the isotope effects in such reactions are determined, inter alia, by the isotope effects of the two identity reactions and the reaction enthalpy (21*b*); (*ii*) by the contention that ion–molecule complexes do not have to be taken into account. Further discussion of this latter point can be found in footnote 81 of ref. 22*c*.

increase in k_H/k_D. We have noted that these findings create a problem for the contention (24) that k_H/k_D decreases in enzymic methyl transfer because of specific compression of the enzymic transition state and that this compression may represent the source of the enzymatic catalysis.[5]

Transverse compression

The present work was undertaken to explore the consequences of both longitudinal and transverse compression on the barriers and secondary isotope effects of intramolecular methyl-transfer reactions. By transverse compression we mean compression in the plane perpendicular to the X–C–Y plane and, specifically, compression of C—H bonds in the transition structure. It was reasoned that because the change in these bond lengths had already been found to be primarily responsible for the inverse isotope effect, any structural factor that causes additional compression of these bonds should lead to a more inverse isotope effect, and that this might be achieved with a

[5] See ref. 24*e* for more recent work on this subject, leading to the conclusion that the enzymatic and nonenzymatic transition structures are very similar.

reactant such as **3** in which **T** is a template whose dimensions are to be determined. Ideally, **T** would provide both compression of the transition structure and catalysis of the reaction.

Results and discussion

Anionic intermolecular methyl transfer between two oxygens. The optimized retention and inversion transition structures

The problem was approached in stages. In the first stage, the compression effects encountered during methyl transfer between two oxygens were examined using, as a benchmark, 3-21+G calculations[6] (25) on the reaction of eq. [2]. The calculated barrier for

[2] $CH_3O^- + CH_3\text{-}OCH_3 \rightarrow CH_3O\text{-}CH_3 + {}^-OCH_3$

intermolecular methyl transfer with inversion of configuration is 25.4 kcal/mol, and the transition structure (Fig. 1, upper) has C—O bond lengths of 1.90 Å, an O—O distance of 3.8 Å, and an O-C-O angle of 178.2°. The transition structure for intermolecular methyl transfer with retention of configuration was also found. This structure (Fig. 1, lower) has C—O bond lengths of 1.95 and 1.92 Å, an O—O distance of 2.63 Å, an O-C-O angle of 85.6°, and it is 51.2 kcal/mol less stable than the structure of Fig. 1 (upper). This energy difference is so large (26) that nucleophilic displacement at carbon with apparent retention of configuration must be regarded as definitive evidence of a multistep process that includes an even number of inversion steps (27).

In the second stage, the effect of longitudinal compression on the energetics of intramolecular methyl transfer was estimated from the O–C–O bending force constant of the inversion transition structure of Fig. 1.[7] This 3-21+G force constant is part of the Gaussian output and is calculated to be 0.2634 hartree/bohr^2 (0.0503 kcal mol^{-1} deg^{-2}). Using the harmonic approximation ΔE (kcal/mol) = $k\theta^2/2$, where θ (degrees) is the deviation of the O-C-O angle from linearity, leads to ΔE = 2.52 and 5.66 kcal/mol for θ = 10° and θ = 15°, respectively. Since two competing reactions whose activation energies differ by 2.52 and 5.66 kcal/mol will differ in reactivity by factors of 70 and 14 000, respectively, at 298 K, a compression of as little as 10° in the O-C-O angle of an inversion transition structure would be sufficient to make intramolecular methyl transfer with inversion of configuration difficult to detect with respect to a competing unconstrained intermolecular inversion process.

CH_3/CD_3 isotope effects in intramolecular methyl transfer between oxygens separated by three, four, five, and six bonds. The retention and inversion mechanisms exhibit different isotope effects

Figures 2–4 show the results of 3-21+G calculations of intramolecular methyl transfer in the β, γ, δ, and ε-methoxyalkoxides **4**–**11**. These substrates have oxygens separated by three, four, five, or six bonds, and the relative positions of the oxygens are constrained by the templates. With the exception of **5** ⇌ **6**, all of the reactions are identity methyl transfers. Table 1 gives the enthalpies of activation calculated at MP2(= FC)/6–31+G*//3-21+G, the C—H bond lengths of the transition structures, the H/D isotope effect for each hydron, and the CH_3/CD_3 isotope effects.[8]

Only the retention mechanism was found in the cases of

[6] All ab initio calculations were performed using Gaussian 92 (25*c*).

[7] For related studies, see ref. 28.

[8] Isotope effects were calculated with the Bigeleisen equation (29*a*), using methods described in refs. 29*b* and *c*.

4–**7**, and only inversion was found for **9**–**11**. Both mechanisms were seen in the case of **8**.

The isotope effects in the inversion reactions constitute evidence for the postulated transverse compression of the S_N2 transition state. As noted in several studies (21, 30), C—H bond lengths in the transition structures of intermolecular methyl-transfer reactions do not depend strongly upon the nature of the entering and leaving groups. In the inversion transition structure of Fig. 1, the average C—H bond length is 1.064 Å. In the inversion transition structure of Fig. 3, one methyl hydron (H_1) is antiperiplanar to the π-system of the cyclohexadiene template, and its C—H bond is lengthened slightly (1.076 Å). The other hydrons (H_2 and H_3) are imbedded in the π-system, and their bond lengths are compressed to 1.046 Å. The isotope effect for H_1 is normal (1.15), but for H_2 and H_3 it is inverse (0.83). The stretching and bending contributions to the overall CH_3/CD_3 isotope effect of 0.81 are 0.69 and 1.17, respectively.

In the transition structure of **9** (Fig. 4, left), one methyl hydron (H_1) is antiperiplanar to the azadecalin skeleton, and its C—H bond length (1.069 Å) is normal. The isotope effect is also normal (1.01). The side view of this transition structure shows that a second methyl hydron (H_2) is compressed, by interaction with the equatorial hydrogens adjacent to nitrogen, to a bond length of 1.051 Å. Its isotope effect is 0.86. The third methyl hydron (H_3) lies under the nitrogen lone pair, and it is compressed to a bond length of 1.041 Å. Its isotope effect is 0.80. The CH_3/CD_3 isotope effect is 0.70.

In the transition structure of **10** (Fig. 4, center), H_1 is antiperiplanar to the bicyclic template, and it has the longest bond length (1.066 Å). A second hydron, H_3, is *endo* to the bicyclic system, and it has the shortest bond length (1.049 Å). The *exo* hydron, H_2, is *syn* to the carbonyl groups, and it has a bond length of 1.059 Å. The CH_3/CD_3 isotope effect is 0.69.

In the transition structure of **11** (Fig. 4, right), H_1 is antiperiplanar to the bicyclic template, and it has the longest bond length (1.065 Å) and highest k_H/k_D (0.94). The CH_3/CD_3 isotope effect is 0.66.

There is a significant difference in the isotope effects of the retention and inversion processes. The origin of this difference is best seen by examination of the retention and inversion transition structures of Fig. 3, which have (unscaled) imaginary frequencies of 834*i* and 860*i*, respectively. In the inversion structure, the imaginary frequency is the O–C–O antisymmetric stretch. In the retention structure, the imaginary frequency is a rocking motion about the C—H_1 bond as a pivot. The isotope effects are 1.06 for H_1 and 1.12 for H_2 and H_3. The CH_3/CD_3 isotope effect of 1.34 contains a stretching component of 1.07, a bending component of 1.34, and a stretch–bend component of 0.90. The principal contribution to the bending component of the isotope effect (k_{CH_3}/k_{CD_3} = 1.22) is made by a vibration, similar to that of the imaginary frequency, which has a frequency (uncorrected) of 958 cm^{-1}. This is shown as a series of instant structures at the left of Fig. 5,[9] together with the corresponding vibration in the inversion structure, which has a frequency (unscaled) of 1159 cm^{-1}, and contributes 0.97 to the overall 0.81 CH_3/CD_3 isotope effect.

The retention mechanisms found for **4** (Fig. 2, left) and **7** (Fig. 2, right) also exhibit normal isotope effects, 1.21 in each case. For **5** ⇌ **6** (Fig. 2, center), the isotope effects are 1.29 in the exoergic direction, and 1.27 in the endoergic direction.

The difference in the retention and inversion isotope effects appears to be large enough to offer an alternative to the chiral methyl group (32) for the determination of the stereochemical course of methyl transfer (33). More importantly (34), the difference in isotope effects can allow retention and double inversion mechanisms to be distinguished.

Barriers to methyl transfer in the rigid templates 4–11

All of the activation enthalpies shown in Table 1 are much larger than the barrier for intermolecular methyl transfer with inversion of configuration (25.4 kcal/mol). This is the expected result in the case of the retention mechanisms (26). In the case of the inversion mechanism for **8**, most of the excess energy of the transition structure originates in the longitudinal compression associated with an O-C-O angle of 133°.

In the case of **9**, the barrier is more than 20 kcal/mol higher than that of an intermolecular methyl transfer. Approximately half of this increase (9 kcal/mol) can be attributed to the longitudinal compression associated with the O-C-O angle of 161°. The remainder is caused by the compression of the template itself in the formation of the transition structure. For example, as summarized in Fig. 6, reoptimization of the reactant **9r** as **9r(t)**, with the azadecalin skeleton constrained to the geometry of the transition structure **9t**, destabilizes the

[9] These structures were generated using the programme XMol (31).

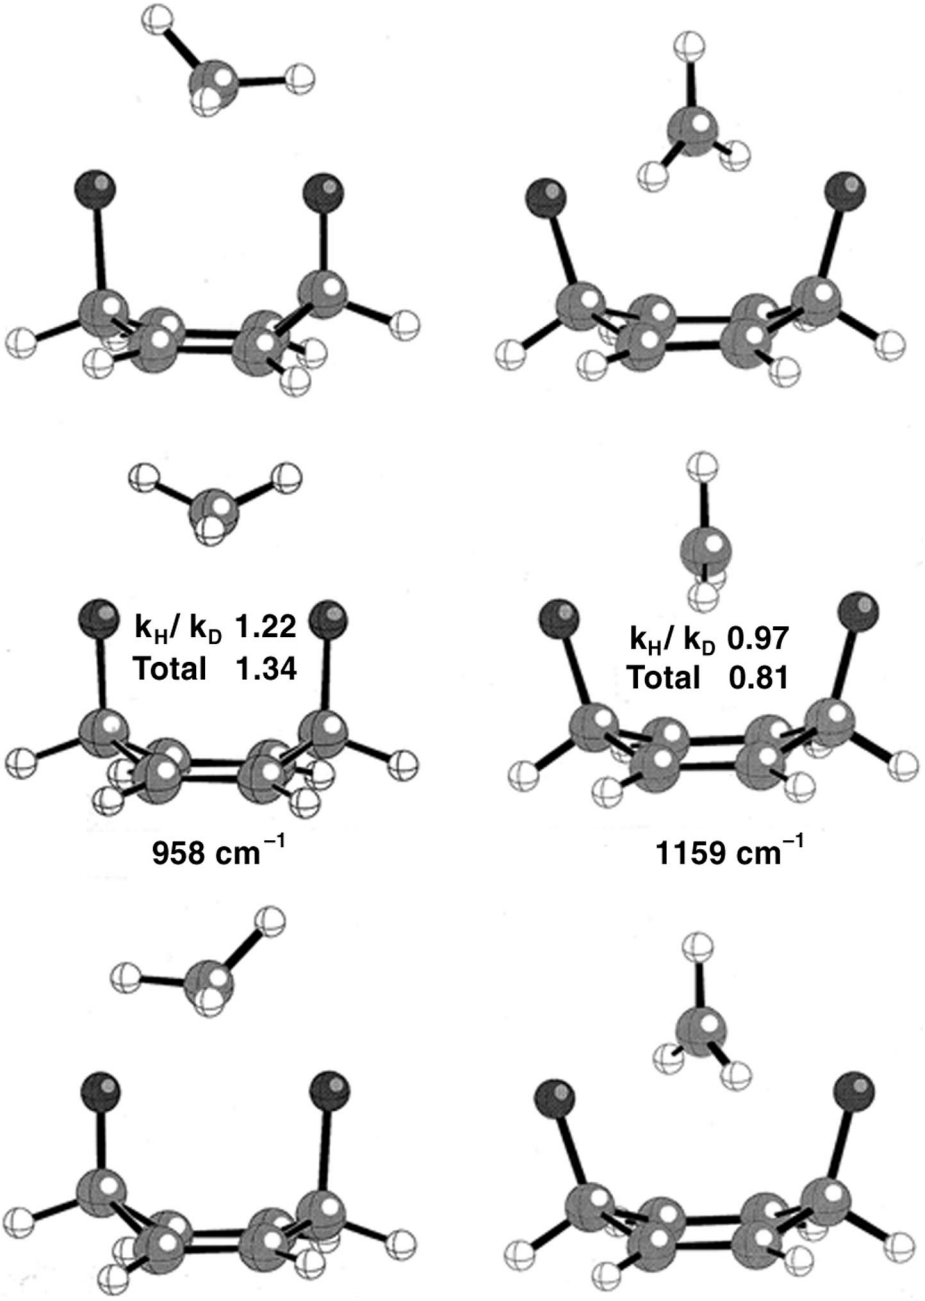
Fig. 5. A series of instant structures (top to bottom) showing the vibration that leads to the 958 cm^{-1} frequency in $\mathbf{10}_{ret}$ (left); secondary H/D isotope effects, 1.22; total, 1.34. The corresponding vibration in $\mathbf{10}_{inv}$ (right) has a frequency of 1159 cm^{-1}.



structure by 18.2 kcal/mol. Replacement of the oxygen atoms of **9r** and **9t** by hydrogens (**9r(H)** and **9t(H)**) and reoptimization with all other geometrical parameters constrained to those of **9r** and **9t**, reveals that the distortion of the azadecalin backbone amounts to 10 kcal/mol. The energy difference between **9t** and **9r(t)** is 28.8 kcal/mol, close to the 28.4 kcal/mol calculated when the carbon atoms geminal to oxygen in **9r** and **9t** are replaced by hydrogens, and the resulting structures **9rc** and **9ts** are reoptimized.

It is evident that the azadecalin backbone is too rigid, and that the geometry of **9** does not permit a linear methyl transfer. The sum of the angles at nitrogen in the transition structure **9t** is 359.1°, and in **9r** it is 344.8°. Inspection of **9r(H)** and **9t(H)** in Fig. 6 suggests that the planar configuration at nitrogen in the transition structure contributes 10 kcal/mol to the destabilization of the structure. This potential for distortion is avoided in **10** and **11**, because the bridgehead atoms are planar in both the reactant and the transition structure. Using AM1, the geometry of **12** was optimized for (*n*, *m*) = (1, 1), (1, 2), (2, 2), (2, 3), and (3, 3), and the O—O distances, O-C-O angles, and methyl-transfer barriers were examined in each case. This strategy led to the (3, 3) systems seen in **10** and **11**, in which the methyl-transfer barriers are reduced to 35.6 and 32.6 kcal/mol, respectively. However, although the longitudinal compression associated with the 170° O-C-O angle in the transition structure of **11** is estimated to be only 2.5 kcal/mol, the

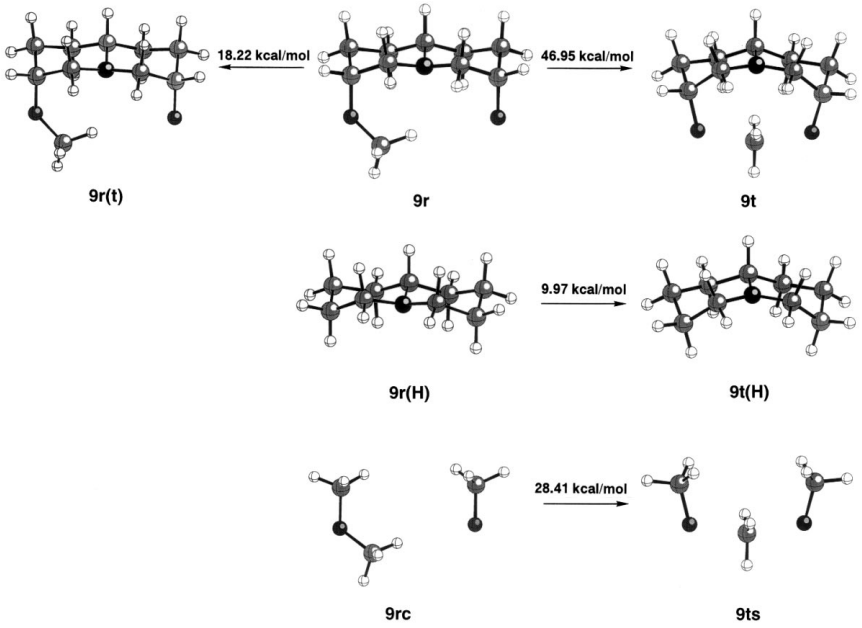

Fig. 7. Design of a flexible template for intramolecular methyl transfer.

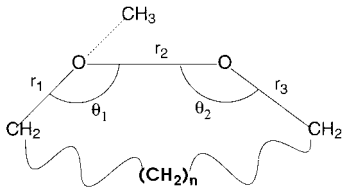

template is not entirely free of compression, and the barrier is still 7 kcal/mol higher than that of the parent intermolecular methyl-transfer reaction.

Design of a flexible template for intramolecular methyl transfer

Although transverse compression of the methyl-transfer transition state has thus been found to produce a more inverse secondary isotope effect, the additional compression introduced by the use of a rigid template overcomes any potential for catalysis of the process. It was, therefore, necessary to design an acyclic, flexible structure.

We have recently reported a novel stochastic search strategy for the conformational analysis of cyclic structures (35). Since the reactant (RC) and transition state (TS) of an intramolecular methyl transfer are pseudocyclic structures, it was possible to adapt this stochastic strategy to the search for superimposable RC and TS templates. The system was treated as an $(n + 4)$-membered ring (Fig. 7) containing an O···O "bond," with the bond lengths r_1, r_2, and r_3, and the bond angles θ_1 and θ_2 constrained to the values seen in the transition state and reactant of the intermolecular reaction. All other bond lengths and bond angles were found by MM3 minimization (36). The torsion angles of the $(CH_2)_n$ chain were obtained by random variation, as described previously (35). Using a 30° torsional increment, a total of 3733 RC rings and 3860 TS rings were produced from 10 000 randomly generated structures. Two thousand each of RC and TS rings were then minimized using MM3, with the bond lengths and bond angles at the reaction center frozen. This was achieved by the definition of atom types having $k_{stretch} = 100$ mdyn/Å (cf. $k_{CC} = 4.5$ mdyn/Å) and $k_{bend} = 10$ mdyn Å rad^{-2} (cf. $k_{CCC} = 0.67$ mdyn Å rad^{-2}). All other parameters of these atoms were taken from the values employed in MM3.

For the case of a 12-membered ring ($n = 8$), this strategy afforded 255 RC minima and 208 TS minima. These were then matched to identify structurally similar (RC, TS) pairs using the rms deviations of the torsion angles of the $(CH_2)_8$ chain as a criterion. The lowest energy pair was found to be the second lowest RC minimum (0.38 kcal/mol above the lowest minimum) and the second lowest TS minimum (0.34 kcal/mol above the lowest minimum). To complete the design process, the methyl group to be transferred was added.

Both of these structures were then subjected to 3-21+G minimization, and were optimized successfully. The results are summarized in structures **13-RC** and **13-TS** of Fig. 8, which also includes an optimized RC[10] and TS (cf. Fig. 1, upper) of the intermolecular methyl-transfer reaction.

It can be seen that the reactive centers of the two reactants and the two transition structures are virtually superimposable. The CH_3/CD_3 kinetic isotope effects calculated for RC → TS are also the same, and the free energies of activation differ by only 1.2 kcal/mol. The strategy employed to discover **13** thus appears to lead to a template for efficient intramolecular methyl transfer in the gas phase. Moreover, close examination of the CH_3 bond lengths included in Fig. 8 indicates that the methyl hydrogen that points towards the concave face of **13-TS** exhibits transverse compression. It should be possible to alter the properties of such templates by incorporation of substituents on the concave face of the chain, and initial studies

[10] This structure is not the global minimum at 3-21+G (29*b*), but it is a genuine stationary point having no imaginary frequencies.

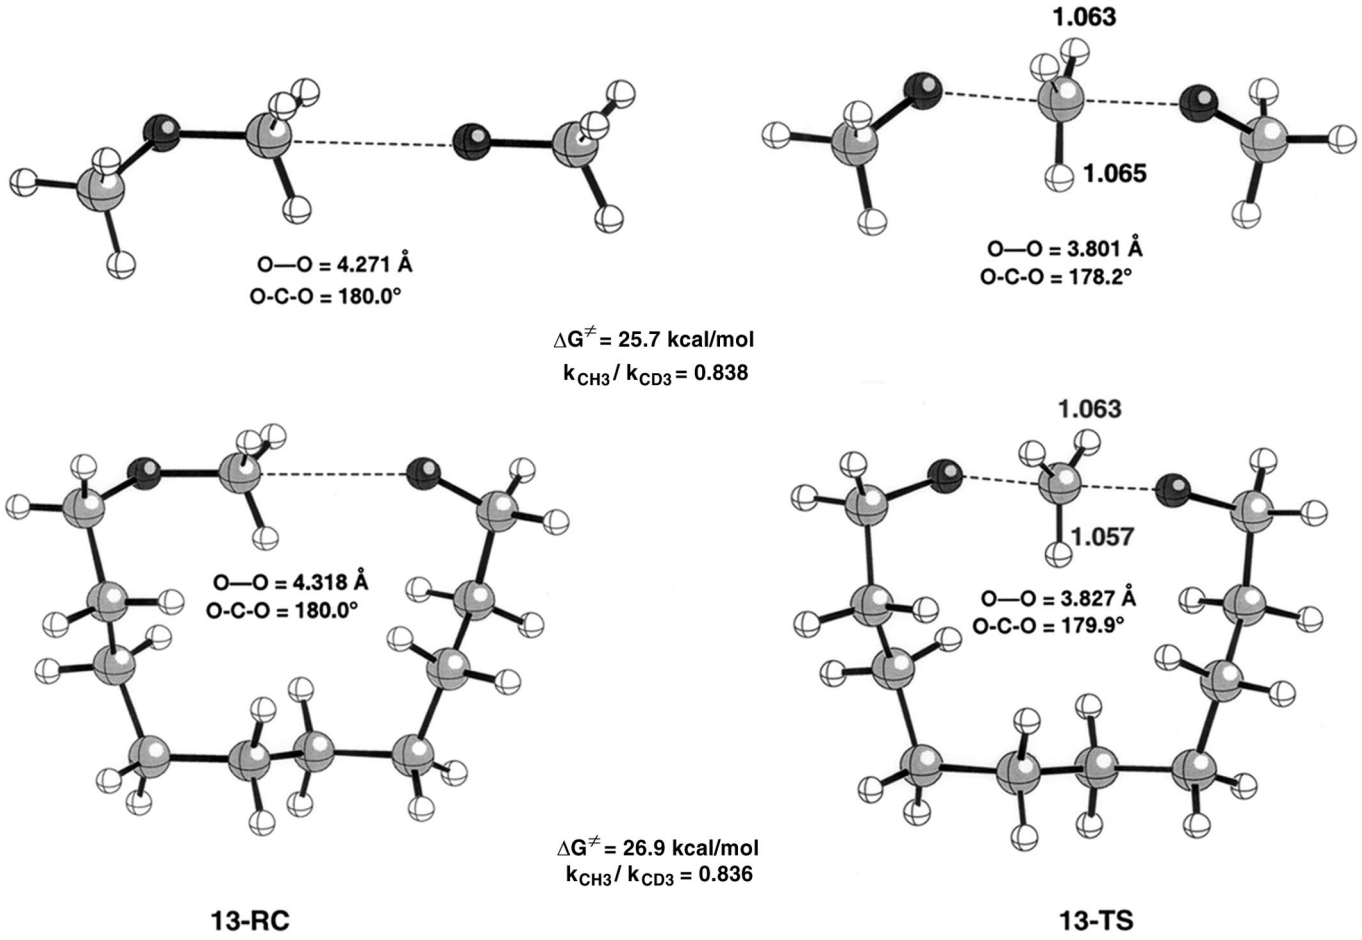
Fig. 8. Intramolecular methyl transfer with inversion of configuration in the parent system (upper) and in the flexible template **13** (lower).



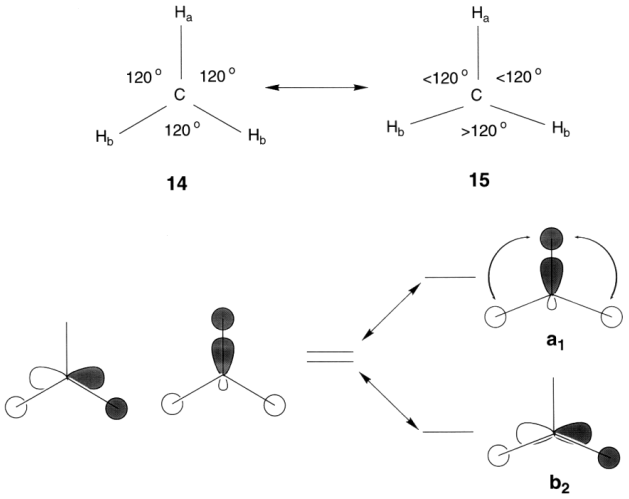
in this direction suggest that structures having $n > 8$ will be of interest.

The inversion barriers, geometrical parameters, and CH_3/CD_3 isotope effects of intramolecular methyl transfer are coupled

Figure 9 applies the Walsh–Gimarc rules (37) to the internal geometries of methyl groups having D_{3h} (**14**) and C_{2v} (**15**) symmetry. In **14**, the π-type *e* orbitals are degenerate. In **15**, the orbitals are nondegenerate; an increase in the H_b-C-H_b angle stabilizes the b_2 orbital and destabilizes the a_1 orbital. The destabilization is caused by the increased out-of-phase interaction between the 1*s* coefficients of H_b and the 1*s* coefficient of H_a, which is relieved by an increase in the C—H_a bond length.[11]

As we have seen, there is a systematic decrease in the methyl-transfer barriers in the series **8** (Fig. 3), **9**, **10**, **11** (Fig. 4), and **13** (Fig. 8), mainly because the O-C-O angles of the transition structures increase from 133.2 to 179.8°. The decrease in the barriers is accompanied by a decrease in the H_2-C-H_3 angles, from 128.5° in **8** to 119.9° in **13-TS**, leading

Fig. 9. Application of the Walsh–Gimarc rules to the frontier orbitals of methyl groups having D_{3h} (**14**) and C_{2v} (**15**) symmetries.



to an inverse relationship between the O-C-O and H_2-C-H_3 angles. This is shown in Fig. 10*a*, and is undoubtedly steric in origin. In accord with the Walsh–Gimarc rules, the decrease in the H_2-C-H_3 angle is accompanied by a decrease in the C—H_1 bond length (Fig. 10*b*), and the C—H_1 bond length

[11] These predictions have been confirmed by calculations on $CH_aH_bH_b^+$: as the H_b-C-H_b angle is increased, the C—H_a bond length is increased, the b_2 orbital is stabilized, and the a_1 orbital is destabilized.

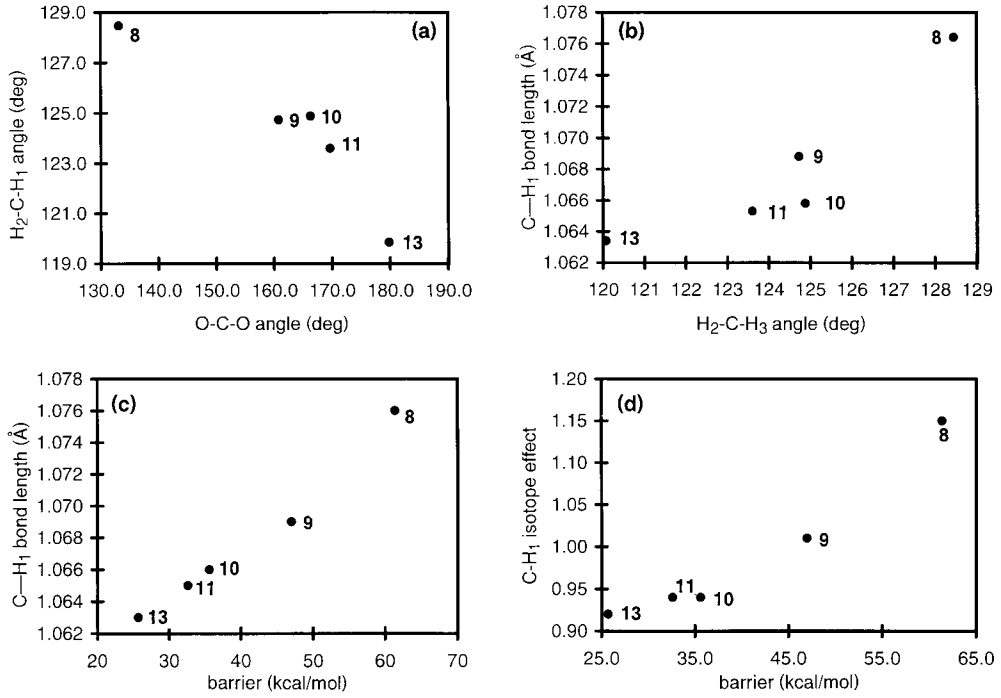
Fig. 10. (*a*) Relationship between the H_2-C-H_3 and O-C-O bond angles in the transition structures of **8**, **9**, **10**, **11,** and **13**. (*b*) Relationship between the H_2-C-H_3 bond angles and C—H_1 bond lengths in the transition structures of **8**, **9**, **10**, **11**, and **13**. (*c*) The C—H_1 bond lengths of the transition structures correlate with the barriers of methyl transfer in **8**, **9**, **10**, **11,** and **13**. (*d*) The contribution of H_1 to the CH_3/CD_3 isotope effect in templates **8**, **9**, **10**, **11**, and **13** depends on the methyl-transfer barrier.

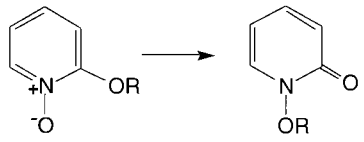


therefore decreases as the barrier decreases (Fig. 10*c*). As a result, the contribution of H_1 to the secondary CH_3/CD_3 isotope effect changes from normal to inverse as the barrier decreases (Fig. 10*d*).

The overall CH_3/CD_3 isotope effect also becomes more inverse as the barrier decreases (Fig. 11), but in the case of this property, **13** does not correlate with **8**–**11**. The reason for this is that intramolecular methyl transfer in **13** proceeds without longitudinal compression, and therefore resembles intermolecular methyl transfer, but the transverse compression of H_2 and H_3 in the transition structures of **8**–**11** causes the isotope effects to become more inverse.

Methyl transfer with retention of configuration. Can a [1*s*,4*s*] sigmatropic rearrangement be observed?

In the intramolecular methyl-transfer reactions of **4**–**8** (Figs. 2 and 3), the barrier is never less than 20 kcal/mol higher than that of an unconstrained inversion process and, in each case, the imaginary frequency of the retention transition structure is the rocking vibration discussed in Fig. 5. It is noteworthy that the transition structure of **4** (Fig. 2) exhibits no particular stabilization, because retention of configuration and a barrier less than 20 kcal/mol in the related reaction, the thermal rearrangement of 2-alkoxypyridine-1-oxides to 1-alkoxy-2-pyridones (**16** → **17**) have been thought to be consistent with a [1*s*,4*s*] sigmatropic rearrangement mechanism (38, 39). This interpretation is based on the orbital analysis shown at the top of Fig. 12, which suggests that a 1,4-suprafacial migration of a methyl group is thermally allowed. Although the HOMO of 4, also shown in Fig. 12, seems to support this interpretation, the argument does not take into account the repulsive, out-of-phase



16 **17**

relationship between the orbital of the migrating group and the orbitals at the 2- and 3-positions, which will force this group towards the nodal plane of the π-system. The situation is analogous to that encountered in the frontier molecular orbital treatment of nucleophilic addition to a carbonyl group (Fig. 12, bottom). In the latter case, the well-known (40) nonperpendicular attack of the nucleophile can be rationalized as the result of the out-of-phase relationship between the orbital of the attacking nucleophile and the *p*-orbital on oxygen (41).

Examination of a side view of the intramolecular methyl-transfer transition structure of **4** (Fig. 13, top) shows that the migrating carbon is only 6° out of the plane of the aromatic system. To check whether this is a basis set effect, the reactant and transition structure of **4** were reoptimized at MP2/6–31+G*. The out-of-plane angle of the migrating methyl group increased to 29° (Fig. 13, bottom), but the barrier remained high (51.5 kcal/mol). Thus, although the 3-21+G basis set overemphasizes the nonperpendicular character of the transition structure of an intramolecular [1*s*,4*s*] sigmatropic methyl rearrangement, it is clear that competing, intermolecular reactions will make an intramolecular reaction experimentally unobservable. The work of Hoppe and Schöllkopf (38) therefore requires reexamination and reinterpretation (34).

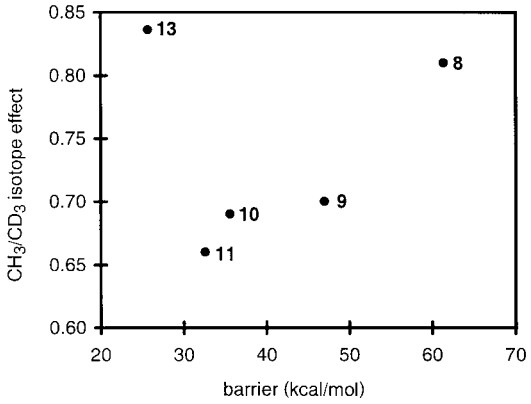

Fig. 12. Top left: orbital interaction between the HOMO of a 4π system and the LUMO of a methyl group; the phase relationship is correct for [1,4] sigmatropic rearrangement with retention of configuration, if the out-of-phase interactions (double-headed arrows) are ignored. Top right: the HOMO of **4**. Bottom: orbital interaction diagram proposed to explain nonperpendicular attack of a nucleophile on a carbonyl group.

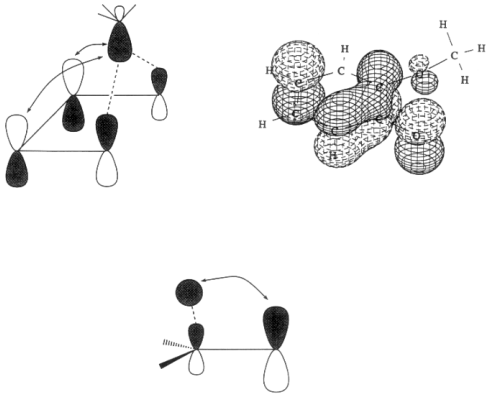

Theoretical procedures

Transition structures were located by the reaction coordinate method. The C···O bonds of the entering and leaving groups were fixed at several values near 1.9 Å, all other geometrical parameters were optimized, and the magnitudes and signs of the gradients of the two reaction coordinates were used to improve the trial values. When a structure close to the saddle point was reached, a final refinement was usually achieved using the OPT = CALCALL option of Gaussian 92 (25*c*) in which force constants are calculated in every iteration. For calculations of isotope effects, the frequencies employed as input to the Bigeleisen equation were obtained by scaling of the computed values by 0.9 (29).[12]

Summary and conclusions

Using ab initio molecular orbital theory mainly at the 3-21+G level, the CH_3/CD_3 kinetic isotope effects in intramolecular S_N2 methyl transfer between two oxygens have been found to be normal (1.21–1.34) for retention and inverse (0.66–0.81) for inversion of configuration. It is suggested that the difference in the retention and inversion isotope effects is large enough to constitute an alternative to the chiral methyl group for the determination of the stereochemical course of displacement at methyl, and to allow a genuine retention process to be distinguished from an even number of inversions.

The normal isotope effect in the retention mechanism is the result of a torsional motion about one of the C—H bonds as the methyl carbon rocks between the two oxygens. In the case of inversion, compression of C—H bonds by structural effects in the transition state, here termed transverse compression, increases the inverse isotope effect. The geometry of the methyl group is coupled to the O-C-O angle of the transition structure, so that the methyl C—H bond lengths, the O-C-O angle, the barrier, and the CH_3/CD_3 kinetic isotope effect are all coupled. A 10° deviation from linearity of the O-C-O angle of the inversion transition structure is sufficient to make an intramolecular reaction kinetically noncompetitive with respect to intermolecular processes.

For intramolecular methyl transfer within a rigid template, only a high energy retention mechanism can be found when the oxygens are separated by three or four bonds, and only inversion is seen when the oxygens are separated by six bonds. Both mechanisms exist when the oxygens are separated by five bonds. Since nonlinear methyl transfer occurs within all of the rigid templates examined so far, none of these provides catalysis of the inversion mechanism. However, treatment of the reactant and transition structure of an intramolecular methyl transfer as pseudocyclic structures, and extension to such

Fig. 13. Side view of the transition structure for intramolecular methyl transfer in **4**; the methyl carbon is not perpendicular to the aromatic ring. Upper: 3-21+G optimization. Lower: MP2/6–31+G* optimization.

structures of a recently described stochastic approach to conformational analysis, has led to the discovery of a nonrigid template that permits linear methyl transfer to take place. This template has two oxygens separated by 10 carbons, and the intramolecular methyl-transfer barrier and CH_3/CD_3 isotope effect are the same as in the intermolecular reaction.

There is no evidence for pericyclic stabilization of a [1*s*,4*s*] intramolecular sigmatropic retention process in the degenerate rearrangement of the anion of *o*-catechol *O*-methyl ether. The reason for this is that the out-of-phase interaction between the *p*-orbital of the migrating group and *p*-orbitals of the aromatic ring forces the methyl group towards the nodal plane of the π-system.

Ring-opening polymerization (ROP) of strained metallocenophanes: the discovery and development of a new route to high molecular weight poly(metallocenes)[1]

Ian Manners

Abstract: Ring-opening polymerization (ROP) of strained ring-tilted metallocenophanes can be achieved thermally, via anionic or cationic initiation, or by the use of transition-metal catalysts and provides access to a wide range of high molecular weight ($M_w = 10^5$–10^6, $M_n > 10^5$) poly(metallocenes). These materials possess a variety of interesting properties and many are very easy to prepare. This article provides an overview of our work, giving background to and an account of the initial discovery, and discusses work on the synthesis and properties of new poly(metallocenes) and related materials with particular emphasis on recent research directions.

Key words: metallocene, ring-opening polymerization, ferrocenophane, organometallic polymer.

Résumé : La polymérisation par ouverture de cycle (POC) métallocénophanes tendus à cycles inclinés peut être réalisée thermiquement, par initiation anionique ou par utilisation de catalyseurs de métaux de transition; elle donne accès à un éventail important polymétallocènes de poids moléculaires élevés ($M_w = 10^5$–10^6, $M_n > 10^5$). Ces produits possèdent une variété de propriétés intéressantes et un bon nombre peuvent être préparés facilement. Cet article présente une vue d'ensemble de nos travaux préliminaires et de nos découvertes initiales et il permet de discuter de la synthèse et des propriétés de nouveaux polymétallocènes et de produits apparentés en insistant particulièrement des directions de nos travaux récents.

Mots clés : métallocène, polymérisation par ouverture de cycle, ferrocenophane, polymère organométallique.

[Traduit par la rédaction]

Introduction

It is well established that transition-metal complexes and metal-containing solid-state materials possess a diverse array of interesting and useful redox, magnetic, optical, electrical, and catalytic properties. Polymers, on the other hand, are ubiquitous because of their tremendous processing advantages over ceramics and metals. The incorporation of transition metals into a polymer main chain therefore offers unique potential for the preparation of processable materials with properties that differ significantly from those of conventional organic polymers (1, 2). In addition, the diverse range of coordination numbers and geometries that exist for transition elements offer the possibility of accessing polymers with unusual conformational, mechanical, and morphological characteristics. Transition-metal-based polymers might also be expected to function as convenient and processable thermal or photochemical precursors to metal-containing ceramic films, fibers, and coatings with high stability and desirable and useful physical properties. However, the development of the area of transition-metal-based polymer science has been held up by considerable synthetic difficulties (2).

Much of the early work in the field in the 1950s and 1960s targeted poly(metallocenes) (3). Such efforts were encouraged by the remarkable stability and fascinating properties of monomeric and dimeric metallocenes, which were discovered by the fundamental exploratory chemistry conducted during this period. However, most of the attempted polymer syntheses utilized polycondensation reactions where either the difunctional precursors were impure or the coupling chemistry was not clean. For such step-growth processes this guaranteed the generation of low molecular weight materials ($M_n <$ ca. 3000) (4). In addition, the resulting products were often insoluble and poorly characterized. Indeed, at the end of a comprehensive review of the field of metallocene-based polymers in 1970 the authors made the critical analysis that many of the structures assigned to the polymers in the article were "hypothetical and need rigorous analytical verification, and the description of

experimental procedures and polymer properties more often than not has been superficial or has been lacking altogether" (5).

In the summer of 1990 we initiated a research program in Toronto with a major aim of exploring the use of ring-opening polymerization (ROP) as a route to polymers with metal atoms in the main chain.[3] Generally ROP processes occur via a chain-growth route, which involves a highly reactive intermediate that reacts rapidly with monomer molecules. This allows the facile formation of long polymer chains making high molecular weight polymers easily accessible (2). This is vital as high molecular weights (M_n > ca. 10 000) are required in order to realize the chain entanglement needed to access the advantageous properties of macromolecules such as ease of fabrication into films (2).

At the time we initiated our research program the only reports of the ROP of metal-containing rings involved brief communications on the polymerization of metallaphosphazene rings. In addition, very limited characterization of the resulting poly(metallaphosphazenes) was given (7). Our initial work focussed on the ROP of ferrocenophanes targeting polymers with ferrocene units in the main chain linked by spacers that should permit metal–metal interactions such as organosilane or other σ- or π-conjugated groups.

Previous work on strained [1]ferrocenophanes

The first polymers constructed from ferrocene and organosilane units were briefly described in two patents by Rosenberg and Rausch (8*a*) and Rosenberg (8*b*) in the 1960s. Polycondensation of dilithioferrocene, $fcLi_2$ (fc = $Fe(\eta\text{-}C_5H_4)_2$), with dichloroorganosilanes, R_2SiCl_2, was the reported method (eq. [1]), but the products of assigned structure **1** were black and impure, of low molecular weight (mainly M_n < 2000), and poorly characterized (8).[4]

[1] 
1

At that time [1]ferrocenophanes of any type were unknown, and although their potential presence in the reaction mixtures was considered by Rosenberg et al. (9), it was concluded that such species would be too strained to exist.[5] In 1975 Osborne and Whiteley (10) at the University of Exeter, England, reported the synthesis and characterization of the first [1]ferrocenophane, the $SiPh_2$-bridged species **2**, via the reaction of $fcLi_2$·TMEDA (TMEDA = tetramethylethylenediamine) with Ph_2SiCl_2 in nonpolar solvents (eq. [2]). These researchers showed, using single crystal X-ray diffraction, that **2** possessed a strained structure with a tilt-angle between the planes of the cyclopentadienyl ligands of ca. 19° (11). In contrast, in ferrocene the cyclopentadienyl rings are parallel.

[2] 
2

The Wrighton group (12) at M.I.T. subsequently synthesized the $SiMe_2$– and $SiCl_2$-bridged analogs in the late 1970s and showed that the methylated species undergoes stoichiometric ring-opening reactions with methanol and other reagents containing reactive -OH functionalities. This chemistry was exploited to allow the controlled derivatization of silica and other materials.

The range of [1]ferrocenophanes was extended in the early 1980s to Ge-, P-, and As-bridged species by the groups of Osborne, Seyferth, and Cullen (13–15). The stoichiometric, anionically induced ring-opening of the phosphorus-bridged [1]ferrocenophane **3** to yield **4** was also described (16) (eq. [3]).

[3] 
3 **4**

In addition, linear oligomers with between two and five repeat units (mainly the dimer and trimer) were isolated in reactions of **3** with **4** as anionic initiator (17) (eq. [4]). However, attempts to form polymers via anionic ROP of **3** using small quantities of anionic initiator were unsuccessful and afforded unreacted **3** and the same distribution of low molecular weight oligomers $\mathbf{5}_{2-5}$ (mainly $\mathbf{5}_2$ and $\mathbf{5}_3$) (17). This unsuccessful experiment, the sole attempt to polymerize ferrocenophanes via ROP reported in the literature prior to our work, was explained in terms of the propagation step being unfavourable either due to steric effects or insolubility (17).

[4] 
3 $\mathbf{5}_x$

mainly x = 2 or 3

x = 4 or 5 very small amounts

Seyferth et al. (14, 16, 17) also described the production of low molecular weight polymers **6** via the condensation polymerization of $fcLi_2$·TMEDA with $PhPCl_2$ (M_w = 8900) (17) (eq. [5]).

[3] We have also been active in the area of rings and polymers based on main group elements. For a recent review of our work see ref. 6.

[4] In one case involving the use of Ph_2SiCl_2 the resulting black polymer was reported to be only partially soluble, and the soluble fraction was shown by vapour pressure osmometry to possess M_n = ca. 7000. However, based on the insolubility of this material and on our light scattering studies of similar species it is very likely that the molecular weight is overestimated due to aggregation in solution.

[5] It is noteworthy that [2]ferrocenophanes were first prepared in the 1960s, but no studies of their ROP behavior were reported until 1993 (see ref. 52 and refs. cited therein).

© 1998 NRC Canada

[5] 
6

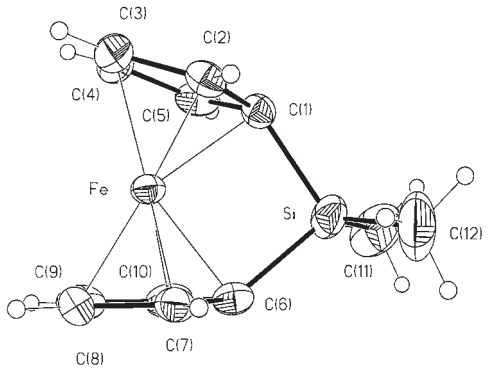
Interestingly, under certain conditions (lower temperatures, certain solvents, addition of $fcLi_2$ to $PhPCl_2$ rather than the reverse), the formation of high molecular weight polymers ($M_w > 40\,000$) was also noted (17). This would not be expected in a polycondensation reaction involving $fcLi_2$·TMEDA as a difunctional monomer, as this species is generally too impure to allow the exact stoichiometries necessary for the formation of high molecular weight materials via step-growth processes to be realized (2, 4). Our explanation of this observation was published in 1995 and was based on the advantage of hindsight gathered from our own successful studies of the anionic polymerization behavior of **3** (see below). Thus we suggested that under the specific reaction conditions reported by Seyferth, the phosphorus-bridged [1]ferrocenophane **3** probably forms in situ and then indeed undergoes anionically initiated ROP induced by $fcLi_2$ (18, 19[6]).

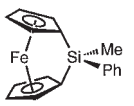
The initial discovery of the ROP of [1]ferrocenophanes

The discovery of the ROP of strained metallocenophanes in our group illustrates, once again, the key role that a combination of planned ideas, serendipity, and outstanding, inquisitive students can play in scientific developments. In addition, the crucial role played by the earlier fundamental exploratory chemistry of Osborne (and later Seyferth and Cullen), which led to the synthesis of the structurally interesting molecules that we now refer to as "[1]ferrocenophane monomers" must not be overlooked, particularly in light of the current global trend towards directed research funding.

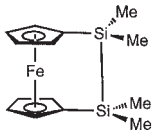
We identified silicon-bridged [1]ferrocenophanes such as **7** as potential monomers for ROP very early on (indeed, one of the author's proposed areas of research in 1989 that led to the tenure-track position at Toronto was the ROP of organometallic rings, including ferrocenophanes). However, initially we focussed on the ROP behavior of the disilane-bridged [2]ferrocenophane **8** and, unfortunately, found this species to be thermally stable to 350°C and to decompose to uncharacterized products at more elevated temperatures. Nevertheless, this disilane-bridged [2]ferrocenophane was found to exhibit some interesting Pd-catalyzed insertions of alkynes and dienes into the Si—Si bond (20).[7]

Fig. 1. Molecular structure of silicon-bridged [1]ferrocenophane **9** determined by X-ray diffraction. (Reproduced from ref. 20*b* with permission.)





7



8

Although planned very early on, our work on silicon-bridged [1]ferrocenophanes turned out to be initiated accidentally. Dan Foucher, my first graduate student (and now a scientist at Xerox Research Center of Canada, Mississauga, Ont.) was trying to make the disubstituted ferrocene derivative $fc(SiMe_2Cl)_2$ from the reaction of $fcLi_2$·TMEDA and two equiv. of Me_2SiCl_2 for possible use in Wurtz coupling polymerization reactions. However, on vacuum distillation of the product, rather than the anticipated orange distillate, he obtained an orange polymer in the distillation pot. This he had the curiousity to purify by precipitation with the help of the very able Ben Zhong Tang, a postdoc and now a chemistry professor at Hong Kong University of Science and Technology. Analysis of the polymer by ^1H NMR showed the material to possess a 1:1 rather than the 1:2 ratio of ferrocene units to $SiMe_2$ groups expected from the reaction stoichiometry. Moreover, Dan, as enthusiastic as ever, phoned me at home late at night to inform me that the molecular weight (M_w) of the material had been measured by Gel Permeation Chromatography and was well over 300 000. A discussion of the results in my office with Dan and Ben the next day quickly led us to the conclusion that the polymer could not be formed by step-growth condensation polymerization of $fcLi_2$ with $fc(SiMe_2Cl)_2$, as the molecular weight was far too high. A chain-growth reaction involving the ROP of the [1]silaferrocenophane **9** appeared to be the only logical explanation. Dan Foucher and Ben-Zhong Tang quickly performed the reaction of $fcLi_2$·TMEDA and Me_2SiCl_2 in a 1:1 ratio and isolated the

[6] The discovery that silicon-bridged [1]ferrocenophanes also undergo anionic ROP (19*a*) also led us to speculate (19*b*), again with the advantage of hindsight, that a similar situation might exist for the reported condensation route to low molecular weight poly(ferrocenylsilanes) claimed in patents by Rosenberg and Rausch (8*a*) and Rosenberg (8*b*). Indeed, a recent reinvestigation of the reactions of $fcLi_2$ and R_2SiCl_2, under conditions similar to those described in one of the Rosenberg patents (8*b*), has identified [1]silaferrocenophanes as well as poly(ferrocenylsilanes) (up to 35%) in the reaction mixture in proportions dependent on the experimental conditions. The authors suggest that the polymers reported by Rosenberg were either formed by anionic ROP or, alternatively, were actually decomposition products due to a steam distillation step (19*c*).

[7] Interestingly, [3]trithiaferrocenophanes were also identified as potential monomers for ROP. However, no work was or has been carried out in our group, in particular because of the elegant atom-abstraction polymerization of these species (which gives polymers with a two sulfur atom spacer not three) discovered by Rauchfuss that was reported in early 1992. See ref. 21.

[1]ferrocenophane **9** (Fig. 1). To our great excitement the species thermally polymerized when heated in the melt at 130°C in a sealed tube. The resulting amber, fibrous solid material **10** was readily soluble in organic solvents and possessed a molecular weight (M_w) of over 500 000. This represented the first high molecular weight poly(ferrocenylsilane), the first poly(ferrocene) that had been unequivocally formed via ROP (eq. [6]).

[6] 
9 n > 1000 **10**

We held off publishing the results for some time as we attempted to get some companies to support a patent application, although some preliminary results were reported at a conference in Vancouver in the Fall of 1991 (22). Finally, after deciding that the first publication in the area would be more useful to a tenure track faculty member and their students than the prospect of a long process of producing examples and exploring applications for a patent, we submitted and published the work in the *Journal of the American Chemical Society* in 1992 (23). Included in this communication were electrochemical studies of the poly(ferrocenylsilane) **10**, which showed that the iron atoms interact with one another. Thus a two-wave cyclic voltammogram was obtained, which was explained in terms of initial oxidation at alternating iron sites and subsequent oxidation, which is more difficult, occurring at the iron atoms in between.

Since those initial discoveries our group has devoted considerable effort towards expanding the scope of the ROP chemistry and exploration of the properties and applications of the resulting poly(ferrocene) materials. Much of the earlier work published between 1992 and 1995 has been reviewed previously (24). In this article an overview of some of our recent work is therefore provided.

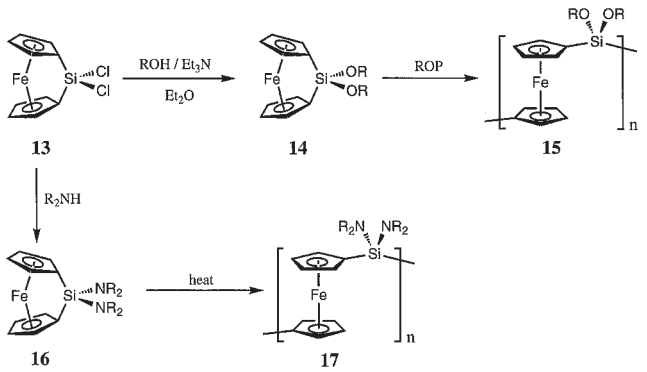
Synthesis and properties of poly(ferrocenylsilanes)

Since 1992, a wide range of silicon-bridged [1]ferrocenophanes **11** with either symmetrically or unsymmetrically alkyl or aryl substituted silicon atoms have been prepared and similarly polymerized to high molecular weight ($M_w = 10^5$–10^6, $M_n > 10^5$) poly(ferrocenylsilanes) **12** (eq. [7]). Substituents such as hydrogen, chlorine, trifluoropropyl, norbornenyl, and ferrocenyl groups have also been introduced (2, 24–26).

[7] 
11 **12**

Very recently, we have found a facile route to the first poly(ferrocenylsilanes) **15** and **17** with alkoxy, aryloxy, and amino substituents at silicon (27). These stable materials are accessible via the ROP of similarly substituted [1]silaferrocenophane precursors (**14** and **16**), which can be accessed via nucleophilic substitution reactions on the $SiCl_2$-bridged [1]ferrocenophane **13** (Scheme 1). The latter species is easily prepared in high yield via the reaction of $fcLi_2$·TMEDA with $SiCl_4$.

Scheme 1.



Considerable effort has also been directed towards investigating and understanding the properties of the resulting poly(ferrocenylsilane) materials, the vast majority of which are soluble in organic solvents, despite their very high molecular weights (24).[8] Cyclic voltammetric studies of the high polymers generally show the presence of two reversible oxidation waves in a 1:1 ratio, providing clear evidence for the existence of interactions between the iron atoms (29). The proposal that initial oxidation occurs at alternating iron sites along the main chain has been supported by recent work on model oligomers with between two and nine ferrocene units (30).

The presence of metal–metal interactions has led to studies of the charge transport properties of these materials (24). Oxidative doping of amorphous samples of poly(ferrocenyldimethylsilane) with I_2 have been shown to yield semiconducting materials (σ = ca. 10^{-7} S cm^{-1}), but much higher conductivities (up to $\sigma = 2 \times 10^{-4}$ S cm^{-1}) have recently been reported for more crystalline, oriented samples of **10** and **12** (R = R′ = *n*-Bu) (31). The latter conductivities represent a 10-order of magnitude increase over the undoped materials that are insulating (σ = ca. 10^{-14} S cm^{-1}). Charge transport properties such as hole mobility, which are important for xerography and other device applications, have also been measured and are appreciable (31). Interestingly, several years ago Garnier and co-workers (28*b*) reported that several TCNE-oxidized low molecular weight poly(ferrocenylsilanes) **12** (M_w = ca. 1500) show electron delocalization on the Mössbauer time scale (ca. 10^{-7} s) and also ferromagnetic ordering at low temperatures. However, so far, attempts to detect similar behavior with high molecular weight poly(ferrocenylsilanes) in a collaborative effort with the group of Dermot O'Hare at Oxford have been unsuccessful. Nevertheless, cooperative magnetic behavior has been noted in the case of other polymer systems such as TCNE-oxidized poly(ferrocenylethylenes) (32) (see below).

Poly(ferrocenylsilanes) also exhibit interesting morphology, and several of the symmetrically substituted derivatives will crystallize. For example, the prototypical poly(ferrocenylsilane),

[8] For the work of other groups on poly(ferrocenylsilanes) see ref. 28.

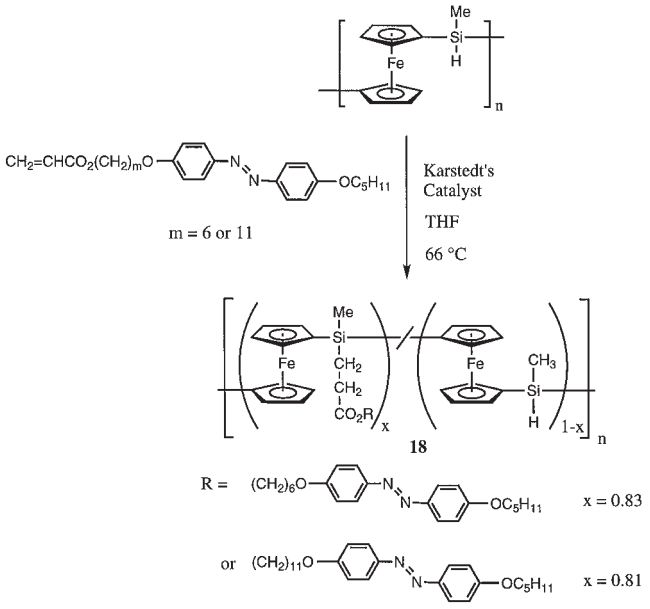
Scheme 2.



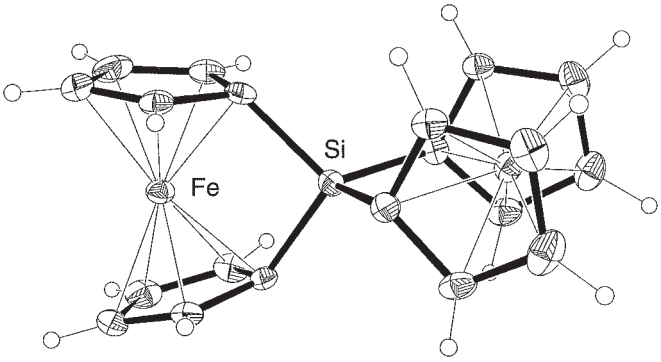
the dimethyl derivative **10**, is an amber, film-forming thermoplastic that possesses melt transitions (T_m) in the range 122–143°C and a glass transition (T_g) at 33°C. In contrast, the *n*-hexyl analogue **12** (R = R′ = *n*-hexyl) is an amber, gummy amorphous material with a T_g of –26°C (24). Alkoxy-substituted poly(ferrocenylsilanes) such as **12** (R = R′ = *n*-hexyloxy) possess T_g values down to –51°C, a remarkable testament to the flexibility of poly(ferrocene) chains, which probably arises from the freely-rotating "molecular ball bearing" nature of the ferrocene unit. It is remarkable that the incorporation of ferrocene units in the side group structure of organic polymers leads to dramatic T_g increases as the steric rigidity of this organometallic unit dominates and the free rotation is irrelevent. Thus, poly(vinylferrocene) possesses a high T_g of 184°C (33).

Recent detailed studies of the dimethyl polymer **10** by a variety of techniques including DSC, Wide Angle X-Ray Scattering (WAXS), and small angle X-ray scattering (SAXS), in collaboration with the group of Julius Vancso (at Toronto and now at U Twente, The Netherlands), suggest that the polymer adopts a similar structure in crystalline regions in the solid state to a crystallized pentamer and that the multiple melt endotherms observed by DSC are a result of the recrystallization of thin lamellae into thicker lamellae (34). The melt temperature of this prototypical poly(ferrocenylsilane) varies from 122–143°C. The equilibrium melting temperature is 143°C, as suggested by studies of a series of well-defined oligomers with between two and nine ferrocene units (30).

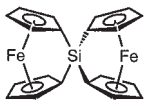
Recently, in collaboration with Duncan Bruce at the University of Exeter, England, we have prepared the first liquid crystalline poly(ferrocenylsilanes) **18** via hydrosilylation (35, 36) (Scheme 2). These materials show a nematic mesophase, and the influence of redox state on the liquid crystalline properties is of significant interest.

Many other characteristics of poly(ferrocenylsilanes) have attracted attention. The materials are electrochromic and they change color reversibly from amber to dark blue on oxidation (24, 28*c*, 37). Potential applications as thin films in sensors and

Fig. 2. Molecular structure of the spirocyclic [1]silaferrocenophane **19** determined by X-ray diffraction. (Reproduced from ref. 41 with permission.)



as variable refractive index materials have generated interest (38, 39). In addition, ferromagnetic products which contain α-Fe crystallites are generated by pyrolysis at temperatures above 500°C (40). Very recently, controlled cross-linking of poly(ferrocenylsilanes) has been achieved to yield solvent swellable, redox-active gels (41). The cross-linking can be controlled by using small amounts of the the spirocyclic [1]ferrocenophane **19** (Fig. 2) in the polymerization mixtures. This red, air-stable species is readily accessible from the reaction of $fcLi_2$·TMEDA with $SiCl_4$.



19

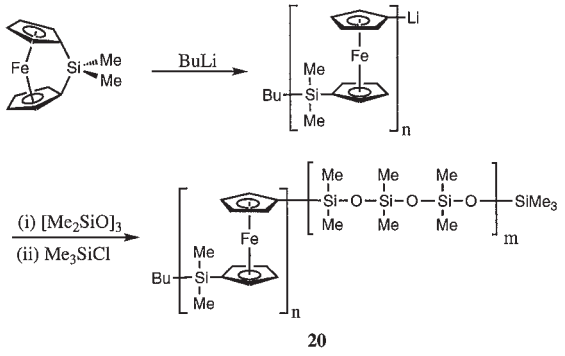
Anionic and transition-metal-catalyzed ROP of silicon-bridged [1]ferrocenophanes

Thermal copolymerization can be used to prepare random copolymers from different silicon-bridged [1]ferrocenophanes and also copolymers of ferrocenophanes and other monomers such as cyclic silanes and silicon-bridged bis(benzene)chromium complexes (2, 31). However, thermal ROP of metallocenophanes at elevated temperatures leads to virtually no control over molecular weight, and the molecular weight distribution is broad. We have shown that silicon-bridged [1]ferrocenophanes undergo living anionic ROP at 25°C using initiators such as *n*-BuLi in THF (42). This has permitted the synthesis of poly(ferrocenylsilanes) with controlled molecular weights and narrow polydispersities and has also allowed the preparation of the first block copolymers (e.g., **20**) containing skeletal transition-metal atoms (Scheme 3).

Transition-metal-catalyzed ROP of silicon-bridged [1]ferrocenophanes, which occurs in solution at room temperature, has also been reported using Pt^{II}, Pt^{0}, Rh^{I}, and Pd^{II} catalysts (43, 44). Molecular weight control can also be achieved and materials with novel architectures such as star and graft

© 1998 NRC Canada

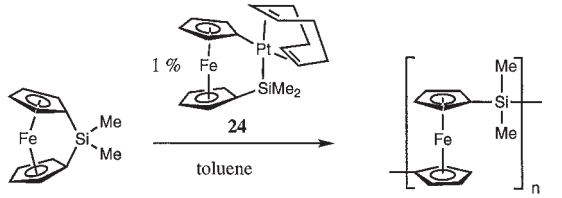
Scheme 3.



copolymers are accessible (45). Moreover, [1]silaferrocenophanes with different cyclopentadienyl rings (**21**) polymerize to yield the regioregular, crystalline poly(ferrocenylsilane) **22**, whereas thermal ROP affords a regioirregular amorphous material **23** (Scheme 4).

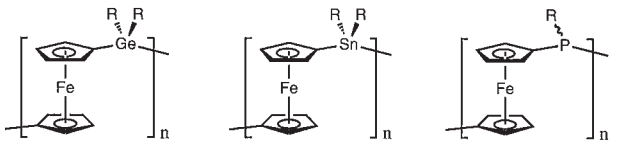
Significant understanding of the mechanism of these transition-metal-catalyzed reactions has also been forthcoming (4). The initial step is believed to be insertion of the transition metal into the strained Cp—Si bond. Indeed, species such as **24** have been prepared from exactly this type of reaction and function as ROP precatalysts, providing that weakly bound coligands (such as 1,5-cyclooctadiene) are present (46) (Fig. 3, eq. [8]). Further studies that aim to permit deeper understanding of the ROP mechanism and that target improved ROP catalysts are underway.

[8]



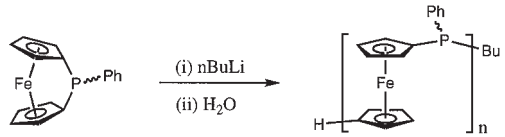
Other poly(metallocenes) via ROP: controlling interactions between metal centers

The ROP route has also been extended to the synthesis of other polymers from [1]ferrocenophane precursors. Poly(ferrocenylgermanes) **25** were first reported in 1993 and possess similar properties to their silicon analogs (47). Recently, after unsuccessful earlier attempts in the 1980s, the first tin-bridged [1]ferrocenophane was prepared. This species undergoes thermal ROP to yield a high molecular weight poly(ferrocenylstannane) **26** (48). Interestingly, this ROP reaction also occurs in solution at room temperature. Studies of this novel ROP process may provide insight into the ROP mechanism for metallocenophanes.



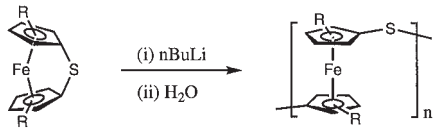
We have also shown that poly(ferrocenylphosphines) **27** are also accessible via the thermal ROP of phosphorus-bridged [1]ferrocenophanes such as **3** (49). In addition, the latter species has also been shown to undergo living anionic ROP to yield high molecular weight materials (e.g., **28**) (eq. [9]), including block copolymers (18*b*). These results contrast with those of the previous studies in the early 1980s (see above) from which it was concluded that ROP of phosphorus-bridged [1]ferrocenophane **3** does not occur and that only the formation of oligomers is possible using ring-opening methods (17).

[9]



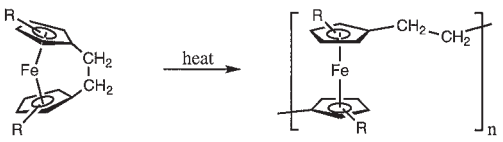
Very recently the first chalcogen-bridged [1]ferrocenophanes have been prepared. The sulfur-bridged [1]ferrocenophane **29** (R = H) is a remarkably strained species with a tilt-angle of 31° (50) (Fig. 4). This compound, and the dimethylated analog, undergo ROP to yield poly(ferrocenylsulfides), **30** (eq. [10]) (51). The iron–iron interactions in the resulting polymers are significantly greater than in the analogous poly(ferrocenylsilanes). For example, the redox coupling on the methylated poly(ferrocenylsulfide) **30** (R = Me) is 0.31–0.33 V, compared to 0.20 V for the analogous poly(dimethylferrocenyldimethylsilane) (51).

[10]



Although disilane-bridged [2]ferrocenophanes (e.g., **8**) possess very small ring-tilt angles (ca. 4–5°) and have been found to be insufficiently strained to undergo thermal ROP, hydrocarbon-bridged [2]ferrocenophanes **31** possess strained ring-tilted structures (tilt-angles = ca. 21°) as a result of the smaller atomic radius of carbon compared to silicon (52). These species have been found to yield poly(ferrocenylethylenes) **32** via ROP at 250–300°C (eq. [11]). As a consequence of the presence of a more insulating bridge, these polymers show much smaller interactions between the iron atoms (redox coupling ca. 0.09 V) compared to poly(ferrocenylsilanes). Nevertheless, in collaboration with the group of Dermot O'Hare at Oxford, we have shown that significant antiferromagnetic interactions are present in TCNE-oxidized samples of these materials (32).

[11]



The inclusion of the larger ruthenium atom into a metallocenophane structure gives rise to even more tilted and strained molecules, and hydrocarbon-bridged [2]ruthenocenophanes

(tilt angles = ca. 29–30°) undergo thermal ROP to yield poly(ruthenocenylethylenes). These materials exhibit significantly different electrochemistry from their iron analogues (53).

Very recently we prepared the first [2]thiacarboferrocenophane **33**, which possess a strained structure with a tilt-angle of ca. 18° (54). This species undergoes the first example of the cationic ROP of a metallocenophane (or any metal containing ring) with initiators such as $MeOSO_2CF_3$ or $BF_3{\cdot}OEt_2$ (eq. [12]). The resulting ring-opened polymers **34** are soluble if $M_n < 6000$ and the synthesis of soluble copolymers is in progress.

RWTH Aachen (55) (eq. [13]). This highly sensitive species possesses the highest tilt-angle (32°) for an iron group metallocenophane (Fig. 5). Attempts to polymerize this and related species to yield soluble polymers are in progress.

[13] 
35

Applications of ring-opened poly(ferrocenes) for the preparation of novel materials with nanoscale dimensions

Poly(ferrocenes) function as preceramic polymers and have been shown to yield interesting ferromagnetic Fe-containing ceramic composites at 500–1000°C (40). The use of such involatile but processable polymeric precursors to ceramics is a potentially attractive way of circumventing the difficulty of processing ceramic materials into desired shapes. In collaboration with the group of Geoff Ozin at Toronto (56) we have recently explored the pyrolysis of poly(ferrocenylsilanes) within the channels of the mesoporous silica MCM-41. The monomer **9** can be sublimed into the hexagonal mesopores at room temperature, and ROP can be induced by heating the resulting material at 140°C. Heating to 900°C generates black, nanostructured magnetic ceramic products that can be visualized in the channels by transmission electron microscopy (TEM) (Fig. 6).

Recently, in collaboration with the group of Mitch Winnik at Toronto,[9] we have shown that interesting architectures can be generated via the solution aggregation of poly(ferrocene)-based block copolymers. Thus, block copolymers such as poly(ferrocenyldimethylsilane)-*block*-poly(dimethylsiloxane) **20** (n:m = 1:2) with long polysiloxane blocks have been found to afford cylindrical, wormlike micelles in hexanes. These structures maintain their structural integrity in the solid state and can be readily visualized by tapping-mode Atomic Force Microscopy or by TEM (see Fig. 7). These cylinders consist of a wire-like core of semiconducting poly(ferrocenylsilane), surrounded by a sheath or corona of insulating poly(dimethylsiloxane). Pyrolysis of such structures, particularly if cross-linked, offers the possibility of generating magnetic wire-like structures.

Poly(ferrocene) block copolymers, like organic analogs, phase separate in the solid state. We reported the first studies of the morphology of such materials in 1996 (42). We used TEM, for example, to demonstrate that films of poly(ferrocenylsilane)-polystyrene block copolymers generate cylindrical and (or) lamellar domain structures in the solid state (Fig. 8). Future opportunities exist for the generation of highly ordered structures, which could be selectively oxidized (chemically or electrochemically e.g., by using scanning probe microscope tips) to give materials with interesting properties.[10] For example, the controlled orientation of nanoscale block copolymer spherical, cylindrical, or lamellar redox-active domains (e.g., at surfaces) might allow charge transport in certain directions or the generation of magnetic nanostructures via oxidation or pyrolysis (e.g., using lasers or ion beams). Research work in these and other areas is ongoing, in many cases in collaboration with other groups.

Summary

Ring-opening polymerization of metallocenophanes has allowed facile access to a variety of high molecular weight poly(metallocenes).[11] Much has been accomplished in terms of understanding the properties of these novel and interesting materials. Future work will be directed towards exploring the mechanisms of polymerization, developing new polymers with controlled metal–metal interactions, studying the properties of these materials in more detail and exploring applications in a variety of intriguing areas such as, for example, nanostructured materials, sensors, and charge-transport materials, and redox-active gels.

Friedel Crafts catalysis using supported reagents. Synthesis, characterization, and catalytic application of sol gel-derived silica

Jack M. Miller, David Wails, J. Stephen Hartman, Karla Schebesh, and Jennifer L. Belelie

Abstract: Novel mesoporous silicas have been prepared via a sol–gel route involving fluoride-catalyzed hydrolysis of tetraethylorthosilicate (TEOS). Incorporation of zinc chloride by sol–gel synthesis gives a range of mesoporous materials with significantly higher catalytic activity than the commercially available catalyst, Clayzic, in a model Friedel–Crafts alkylation reaction. The dependence of catalytic activity and physical structure on the amounts of solvent, water, zinc chloride, and potassium fluoride used in the preparation are explored, and the materials have been further characterized by nitrogen adsorption to determine surface areas, total pore volumes, and pore-size distributions and by ^{29}Si and ^{19}F MAS NMR spectroscopy. The most active catalysts generally have the highest total pore volumes, with pore-size distributions larger than 8 nm.

Key words: sol–gel, Friedel–Crafts, Clayzic, silica.

Résumé : On a préparé de nouvelles silices mésoporeuses par le biais d'une voie sol–gel impliquant une hydrolyse, catalysée par le fluorure, de l'orthosilicate de tétraéthyle (OSTE). L'incorporation de chlorure de zinc par la synthèse sol–gel fournit une variété de produits mésoporeux possédant, pour une réaction d'alkylation de Friedel–Crafts modèle, une activité catalytique beaucoup plus élevée que celle du catalyseur Clayzic disponible commercialement. On a étudié la relation entre l'activité catalytique ainsi que la structure physique et les quantités de solvant, d'eau, de chlorure de zinc et de fluorure de potassium utilisés dans la préparation; on a de plus caractérisé les matériaux par spectroscopie RMN du ^{29} Si et du ^{19} F ainsi que par adsorption d'azote pour déterminer les superficies des surfaces, les volumes totaux des pores et les distributions de la taille des pores. Les catalyseurs les plus actifs ont généralement les volumes totaux de pore les plus élevés et la distribution de la taille des pores est généralement supérieure à 8 nm.

Mots clés : sol–gel, Friedel–Crafts, Clayzic, silica.

Introduction

Supported metal halides, particularly zinc chloride, have been widely investigated as catalysts for Friedel–Crafts reactions in recent years (1). "Clayzic,"[2] zinc chloride supported on Montmorillonite K10 clay, was first reported in 1989 (2) and provides a useful alternative to traditional Friedel–Crafts alkylation catalysts such as $AlCl_3$ and HF, which have environmental drawbacks in addition to often poor selectivity and lack of reusability. Since the original report, this material has been widely investigated (3–10). The activity of the K10 support can be further enhanced by acid treatment, which destroys much of the original support structure and generates mesoporous materials. Pore size is critical, with the optimum diameter being 8–12 nm for maximum catalytic activity of the supported reagent (9, 10). We have recently described the synthesis of related Friedel–Crafts catalysts, based on zinc chloride incorporated into a sol–gel-derived aluminosilicate support (11).

Sol–gel methodologies offer an attractive approach to the synthesis of materials for a number of applications including ceramics, catalysts, and optical devices (12). The low-temperature sol–gel route offers a number of advantages over traditional high-temperature melt processes. Both the chemical composition of the materials and physical properties such as surface area and pore-size distribution can often be precisely controlled. The sol–gel process involves the controlled hydrolysis of suitable precursor molecules, e.g., metal alkoxides in an alcohol solvent, with acid or base catalysis (12). During hydrolysis, partially hydrolyzed metal alkoxides polymerize to give a sol, and further condensation results in gelation. This is followed by aging during which further condensation reactions may occur in the gel and drying to give the final product.

Other supports such as mesoporous silica can also be more effective than montmorillonite K10, and the pore-size characteristics appear to be the most significant factor, rather than the actual chemical nature of the support (9, 10). These studies have, however, been limited to commercially available

materials of limited pore-size distribution. In the present work, we describe the application of sol–gel methods to the synthesis of mesoporous silica-based Friedel–Crafts alkylation catalysts.

Experimental

Instrumentation

Gas chromatographic (GC) analysis was carried out using a Perkin–Elmer Sigma 3B gas chromatograph linked to a Hewlett Packard 3396 Series II integrator. Analysis was carried out with the aid of packed columns containing 3% OV-17 on Gas Chrom Q. Products were identified by GC–MS using a Carlo Erba MFC 500 GC interfaced to a Kratos Concept 1S mass spectrometer.

The NMR experiments were carried out on a Bruker DPX-300 multinuclear Fourier Transform spectrometer using a Bruker narrow bore MAS probe with 4 mm zirconia rotors. The ^{29}Si CP–MAS spectra were obtained at 59.62 MHz using cross-polarization with proton decoupling during acquisition and were referenced to external TMS. Samples were spun at 4 KHz in air. A 10 ms contact time was used with a 5 s delay between pulses, and between 5000 and 10 000 FIDs were typically accumulated over a spectral window of 18 000 Hz. The ^{19}F MAS NMR spectra were obtained at 282.88 MHz and referenced to $CFCl_3$ (0 ppm) using powdered Teflon as an external secondary standard (–123.0 ppm). The DEPTH pulse sequence was employed to remove background ^{19}F signals from the probe (13). Samples were spun at 14 KHz with air. The 256 scans were typically accumulated over a 14 KHz spectral width with a 5 s delay between pulses.

Surface area and pore-volume determinations were carried out at 77°K using a Coulter SA3100 instrument with an automated gas volumetric method employing nitrogen as the adsorbate. Surface areas were determined using the BET adsorption method (14) and pore volumes using the BJH method on the desorption branch of the isotherm (15). Samples were outgassed under high vacuum at 200°C for 1 h immediately prior to analysis.

Reagents

Benzene and ethanol were obtained from Caledon Laboratories. All other chemicals were obtained from the Aldrich Chemical Company and used as received.

Typical catalyst preparation

The TEOS (14 mL, 0.06 mol) and ethanol (20 mL) were stirred in a 100 mL teflon beaker, and a mixture of zinc chloride (2.75 g, 0.02 mol) and potassium fluoride (0.21 g, 3.6 mmol) predissolved in distilled water (4.0 mL, 0.22 mol) was added. The beaker was covered with a watch glass and the solution stirred and heated to 70°C until the contents gelled (typically 15 min). Residual solvent was then removed by heating in an oven at 100°C and finally at 225°C overnight. The yield was typically 5.75 g. The amount of TEOS was kept constant for all trials and other variables altered as detailed in the text and in Table 1; the third sample in each series in Table 1 (i.e., samples 3, 8, 13, and 18) corresponds to the basic preparation described above.

Typical catalyst testing procedure

Benzene (22.0 mL, 0.25 mol) was stirred vigorously in a 100 mL round bottomed flask and freshly dried catalyst (typically 0.50 g) added. Benzyl chloride (5.8 mL, 0.05 mol) was then added in one aliquot and the reagents stirred at room temperature for 15 min. The catalyst was filtered and the reaction mixture analyzed by GC. The percent conversion was defined as the total conversion of benzyl chloride (to diphenylmethane and the *ortho*, *meta*, and *para* isomers of dibenzylbenzene). Each series of catalysts described in Table 1 was prepared at least twice. While actual conversions varied slightly between preparations, the relative catalytic activity between each member of a series remained unchanged.

Results and discussion

General

The sol–gel synthesis of silica from tetraalkylsilicates is typically carried out under acidic (such as with HCl or HNO_3) or basic (such as NH_4OH) conditions. However, the resultant materials are ineffective as Friedel–Crafts alkylation catalysts, as tested by alkylation of benzene with benzyl chloride to give diphenylmethane, a standard model reaction with Clayzic and similar systems (2–11). Gelation at extremely low or high pH is known to give materials with microporous structures (16), which do not fit the mesoporous requirement proposed by Rhodes and Brown (9, 10) for active Friedel–Crafts catalysts.

We have recently shown that zinc chloride can be effectively incorporated into an aluminosilicate sol–gel-derived framework during preparation (11), and here we extend this approach to sol–gel-derived silica by adding zinc chloride to the sol–gel system. Although acidic and basic sol–gel synthesis conditions gave materials that were ineffective as Friedel–Crafts catalysts, the presence of fluoride leads to the formation of catalytically active materials, with potassium fluoride giving more active materials than either sodium or ammonium fluoride. Tetraethylorthosilicate was hydrolysed in ethanol with an aqueous solution containing potassium fluoride and zinc chloride. The most active catalyst prepared by this method, dried at 225°C, gave 41% conversion of benzyl chloride, whereas Clayzic (at an optimum 1 mmol g^{-1} $ZnCl_2$ loading) gave only 24% under identical conditions. The catalyst has a type IV nitrogen adsorption–desorption isotherm (Fig. 1) (17). The hysteresis associated with the adsorption–desorption branches of the isotherm suggests that the mesopores associated with the materials are in the form of interparticulate voids rather than framework mesoporosity. The corresponding Barrett–Joyner–Halenda (BJH) plot (15) derived from the desorption branch of the isotherm (Fig. 2) shows a broad, mesoporous structure with a maximum pore volume at 14 nm. The material has a surface area of 168.77 m^2 g^{-1} and a total pore volume of 0.78 cm^3 g^{-1}. Upon heating the material to 500°C, at which temperature zinc chloride is known to volatilize (11), the surface area and pore volume decrease substantially to 25.12 m^2 g^{-1} and 0.17 cm^3 g^{-1} at which point the material loses all catalytic activity.

Effect of solvent

Samples 1–5 in Table 1 detail the effect of varying the amount of ethanol on the physical properties and catalytic ability of

zinc chloride treated silicas. As the amount of solvent increases, surface areas steadily increase, although pore volumes show a maximum of 0.87 $cm^3\ g^{-1}$ with 20 mL solvent. Catalytic activity shows no clear trend with variation in solvent quantity, although it is noteworthy that highest activities are found with materials having the highest surface area or highest pore volume. Pore-size distributions are shown in Fig. 3, and it can be seen that lower volumes of solvent give materials with significantly broader distributions, whereas higher volumes give more defined structures with the maximum at a diameter of 9.15 nm (sample 5). The ^{29}Si CP–MAS NMR spectra (Fig. 4) of samples 1, 3, and 5 have two broad peaks centered at approximately –102 and –110 ppm, which may be attributed to Q^3 and Q^4 (i.e., $\underline{Si}(OSi)_3OH$ and $\underline{Si}(OSi)_4$) sites, respectively (18, 19). The Q^3 peak shifts from –102.1 ppm (sample 1) to –101.5 (sample 5), while the Q^4 peak shifts from –109.9 (sample 1) to –110.8 (sample 5), suggesting an increase in condensation reactions with an increase in the amount of solvent. The Q^3 ($\underline{Si}(OSi)_3OH$) and Q^4 ($\underline{Si}(OSi)_4$) sites both cover a range of possible environments, since the attached silicas themselves have the possibility of being further condensed to various extents, i.e., $\underline{Si}\text{-O-Si}(OSi)_m(OH)_{3-m}$ (m = 0–3), and average values of m may increase with an increase in the amount of solvent.

The sol–gel process is typically broken down into three different reactions (12):

hydrolysis,

$$\equiv Si\text{-}OC_2H_5 \rightleftharpoons \equiv Si\text{-}OH + C_2H_5OH$$

condensation, and the reverse esterification,

$$\equiv Si\text{-}OC_2H_5 + HO\text{-}Si\equiv \rightleftharpoons \equiv Si\text{-}O\text{-}Si\equiv + C_2H_5OH$$

$$\equiv Si\text{-}OH + HO\text{-}Si\equiv \rightleftharpoons \equiv Si\text{-}O\text{-}Si\equiv + H_2O$$

Since ethanol is involved in these equilibria, its function is not simply that of a solvent but of a reagent, and therefore it is not surprising that changing the amount of solvent has an effect on the silica species formed and the resulting ^{29}Si CP–MAS NMR spectra. In our products following calcination the nonbridging oxygens should be primarily -OH groups, but the presence of some residual -OEt groups has not been ruled out, and their presence could also have some effect on the ^{29}Si chemical shifts.

Effect of amount of water used

Samples 6–10 in Table 1 detail the effect of varying amounts of water on the catalyst performance and the effect on physical

© 1998 NRC Canada

Fig. 1. Catalyst nitrogen adsorption–desorption isotherm.

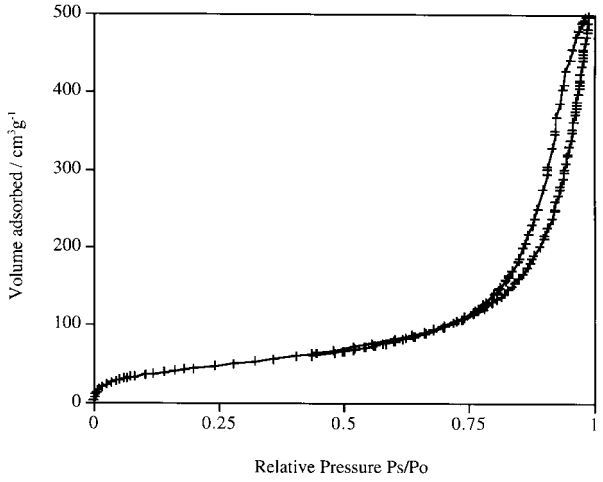

Fig. 2. Catalyst BJH pore distribution.

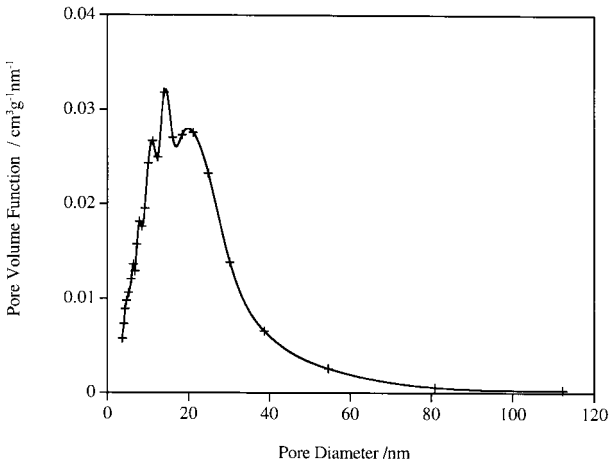

properties. Both surface area and pore volume are at a maximum (127.1 m^2 g^{-1} and 0.67 cm^3 g^{-1}) at a water:TEOS mole ratio of 3.52:1. This material (sample 8 in Table 1) shows a lower catalytic activity than sample 9, which may be anomolous. At other ratios, decreases in catalytic activity correspond to decreases in the surface area or pore volume. In materials with either low surface area or pore volume it is possible that the zinc chloride is overloaded within the pores and is behaving as crystalline zinc chloride rather than the isolated zinc chloride moieties to which the high catalytic activity of this system is attributed (9, 10). The effect on pore-size distribution is shown in Fig. 5. Increasing the amount of water dramatically increases the pore-size distribution, and although sample 7 has the optimum pore distribution as suggested by Rhodes and Brown (9, 10) for mesoporous silicas (8-10 nm), it shows only low catalytic activity. The most active material (sample 9) has an intermediate pore volume and surface area, and has a significant proportion of pore-size distribution above 10 nm. Sample 6, which shows poor activity, has the lowest surface area and pore volume, with the majority of these pores being less than 8 nm in diameter. The ^{29}Si CP–MAS spectra are shown in Fig. 6. Increasing the amount of water results in a

Fig. 3. Effect of amount of solvent on BJH pore distributions; 10 mL, sample 1 (□); 20 mL, sample 3 (◇) ; 30 mL, sample 5 (○).

broadening of the +29 Si signal of the Q^3 sites at higher water:TEOS ratios, resulting in a loss of resolution of the Q^3 and Q^4 sites and a small increase in intensity in the region associated with Q^2 (i.e., $Si(OSi)_2(OH)_2$ units) (-75 to -95 ppm), presumably as a result of the increased formation of silanol (Si–OH) groups.

Effect of zinc chloride loading

Samples 11–15 in Table 1 show no clear effect of variation of the amount of zinc chloride on the properties of the catalysts. Increasing the loading should give a steady decrease in both surface area and pore volume as the pores become gradually filled (1). In addition, once the optimum loading has been reached, catalytic activity should drop rapidly as inactive crystalline zinc chloride is formed rather than the catalytically active isolated zinc chloride molecules (9, 10). However, this does not occur here. Although maximum surface area and pore volume are associated with sample 12 (6.48 mmol g^{-1}), and further loading decreases surface area, pore volume does not decrease correspondingly. All of the materials still exhibit a mesoporous structure (Fig. 7), although at lower zinc chloride

concentrations (sample 11) the distribution is broadened considerably. From the ^{29}Si CP–MAS NMR spectra shown in Fig. 8 it is apparent that the zinc chloride is active during sol–gel synthesis and affects the relative intensities of the Q^3 and Q^4 species, although this effect is less apparent at higher zinc chloride levels. It is possible that reaction of chloride anions with the alkoxysilane gives rise to a Si–Cl group, which is then rapidly hydrolyzed to the silanol. The use of potassium chloride as a catalyst for TEOS polymerization has been reported (20). Since silanol condensation occurs more rapidly than alkoxysilane condensation, systems having more zinc chloride would be expected to show greater degrees of condensation, which would account for increased proportion of Q^4 sites in materials having higher zinc chloride loadings. It is apparent that the zinc chloride as well as the potassium fluoride is acting as a catalyst for condensation reactions in this system.

Effect of potassium fluoride

As detailed for samples 16–20 in Table 1, fluoride concentration has a significant effect on catalyst performance. Fluoride is known to react with an alkoxysilane to give a highly reactive Si—F bond, which is rapidly hydrolyzed in solution (20), although the fluoride-catalyzed TEOS polymerization has previously been reported to give microporous rather than mesoporous materials (21). Sample 16, with the lowest fluoride concentration, was completely ineffective as a catalyst. Although this material has the highest surface area, it has the lowest pore volume, and as shown in Fig. 9, a very sharp distribution centered at 5.79 nm, which is well under the optimum range required for effective Friedel–Crafts catalysis. Higher concentrations of potassium fluoride give much broader pore-size distributions. The effect of fluoride on TEOS polymerization is illustrated by the ^{29}Si CP–MAS NMR spectra (Fig. 10), which show a pronounced increase in the relative intensity of

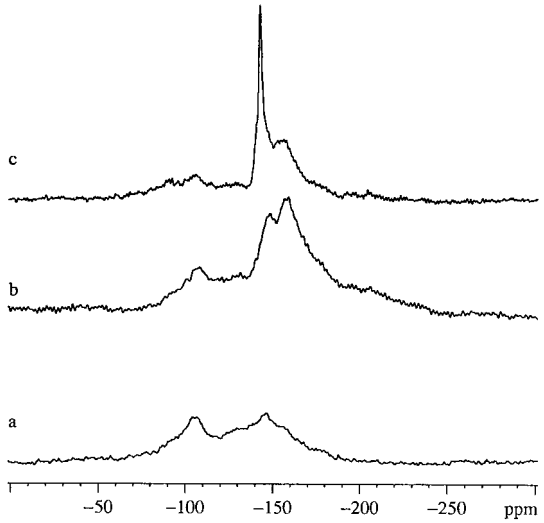
Q^4 sites over Q^3 sites, consistent with a greater degree of condensation reactions occurring at higher fluoride levels in a similar fashion to the effect of zinc chloride previously discussed. The Q^4:Q^3 ratio had recently been observed to increase with increasing amounts of fluoride in the ammonium fluoride catalyzed hydrolysis of tetramethylorthosilicate (22). The ^{19}F MAS NMR spectra (Fig. 11) show a significant broad contribution from residual probe background at low fluoride levels. At low levels, the spectra show two broad peaks centred at -104.3 and -146.4 ppm., which have been attributed to coordinated SiF_4 and SiF_6^{2-} units in a zinc fluoride supported on silica gel system (23). Considering the relative Zn^{2+} and K^+ concentration, the interaction of coordinated SiF_4 and SiF_6^{2-} groups with Zn^{2+} is not unexpected. At increasing KF concentrations, the intensity of the -104.3 ppm band decreases, and the -146.4 ppm peak becomes significantly sharper and

Fig. 11. Effect of potassium fluoride concentration on ^{19}F MAS NMR spectra; (*a*) 0.03 mol/molTEOS, sample 16; (*b*) 0.05 mol/mol TEOS, sample 18; (*c*) 0.08 mol/mol TEOS, sample 20.



increases in intensity. Increasing levels of fluoride would be expected to further fluorinate the coordinated SiF_4 units to SiF_6^{2-} groups. A third peak at -159.0 ppm, attributed to surface-adsorbed SiF_4/HF in a silica-gel supported KF system (24), also increases in intensity with increasing fluoride concentration, reflecting the increasing role of K^+ in the system.

Conclusions

Sol–gel methods may be applied to the one-step synthesis of a range of silica-based Friedel–Crafts alkylation catalysts, which show greater activity than Clayzic, the commercially available supported reagent. Careful control of preparation conditions is essential for optimum catalytic activity, including the amount of solvent, zinc chloride, potassium fluoride, and water used in the synthesis. Both zinc chloride and potassium fluoride have a catalytic effect on the sol–gel synthesis. As with previous studies, pore-volume distributions have been found to be particularly important. In particular, supported reagents having a significant proportion of pores with diameters less than 8 nm are ineffective in the model reaction. However, large total pore volumes of pores above 8 nm diameter are also an important factor for the most catalytically active materials.

Aromatic aldonitrones of 2-(hydroxyamino)benzyl alcohol and their cyclic isomers. Crystal and molecular structures of a 1-hydroxy-1,2-dihydro-4*H*-3,1-benzoxazine, a boron chelate, and its parent nitrone ligand[1]

Wolfgang Kliegel, J rg Metge, Steven J. Rettig, and James Trotter

Abstract: The synthesis of a series of *C*-aryl-*N*-[2-(hydroxymethyl)phenyl]nitrones, **5** (that can also exist under certain conditions as isomeric 1-hydroxy-2-aryl-1,2-dihydro-4*H*-3,1-benzoxazines, **8**), via 2-(hydroxyamino)benzyl alcohol, **4**, and their subsequent reactions with oxybis(diphenylborane), $(Ph_2B)_2O$, leading to the 5-(arylmethylene)-7,7-diphenyl-6,8-dioxa-5-azonia-7-borata-5*H*-6,7,8,9-tetrahydrobenzocycloheptenes **6** are described. Crystals of 1-hydroxy-2- (4-methoxyphenyl)-1,2-dihydro-4*H*-3,1-benzoxazine, **8***b*, are monoclinic, $a = 9.379(2)$, $b = 10.699(2)$, $c = 12.9392(7)$ Å, $\beta = 99.916(2)°$, $Z = 4$ (two independent molecules), space group *Pa*; those of *C*-[4-(dimethylamino)phenyl]-*N*-[(2-hydroxymethyl)phenyl]nitrone, **5***c,* are monoclinic, $a = 7.687(1)$, $b = 7.891(1)$, $c = 11.5053(9)$ Å, $\beta = 92.781(9)°$, $Z = 2$, space group $P2_1$; and those of 5-[4-(dimethylamino)phenylmethylene]-7,7-diphenyl-6,8-dioxa-5-azonia-7-borata-5*H*-6,7,8,9-tetrahydro-benzocycloheptene, **6***a*, are monoclinic, $a = 10.771(1)$, $b = 13.1057(9)$, $c = 16.8724(7)$ Å, $\beta = 90.005(5)°$, $Z = 4$, space group $P2_1/n$. The structures were solved by direct methods and refined by full-matrix least-squares procedures to $R(F^2) = 0.120$ ($R_w(F^2) = 0.135$) for all 3149 reflections ($R(F) = 0.071$, $R_w(F) = 0.063$ for 1500 reflections with $I \geq 3\sigma(I)$) for **8***b* and $R(F) = 0.035$ and 0.036 ($R_w(F) =$ 0.031 and 0.038) for 1071 and 3594 reflections with $I \geq 3\sigma(I)$, respectively, for **5***c* and **6***a*. Compound **8***b* is the first structurally characterized 1-hydroxy-1,2-dihydro-4*H*-3,1-benzoxazine derivative and **6***a* features a relatively rare seven-membered boron-containing heterocycle.

Key words: *C*-aryl-*N*-[2-(hydroxymethyl)phenyl]nitrones, 1-hydroxy-2-aryl-1,2-dihydro-4*H*-3,1-benzoxazines, organoboron compounds, crystal structures.

Résumé : On décrit la synthèse d'une série de *C*-aryl-*N*-[2-(hydroxyméthyl)phényl]nitrones, **5** (qui peuvent aussi exister dans certaines conditions sous la forme isomère 1-hydroxy-2-aryl-1,2-dihydro-4*H*-3,1-benzoxazines, **8**) par le biais de l'alcool 2-(hydroxyamino)benzylique, **4**, ainsi que leurs réactions subséquentes avec l'oxybis(diphénylborane), $(Ph_2B)_2O$, conduisant à la formation des 5-(arylméthylène)-7,7-diphényl-6,8-dioxa-5-azonia-7-borata-5*H*-6,7,8,9-tétrahydrobenzocycloheptènes, **6**. Les cristaux de la 1-hydroxy-2-(4-méthoxyphényl)-1,2-dihydro-4*H*-3,1-benzoxazine, **8***b*, sont monocliniques, groupe d'espace *Pa*, avec $a = 9,379(2)$, $b = 10,699(2)$ et $c = 12,9392(7)$ Å, $\beta = 99,916(2)°$ et $Z = 4$ (deux molécules indépendantes); ceux de la *C*-[4-(diméthylamino)phényl]-*N*-[(2-hydroxyméthyl)phényl]nitrone, **5***c*, sont monocliniques, groupe d'espace $P2_1$, avec $a = 7,687(1)$, $b = 7,891(1)$ et $c = 11,5053(9)$ Å, $\beta = 92,781(9)°$ et $Z = 2$ et ceux du 5-[4-(diméthylamino)phénylméthylène]-7,7-diphényl-6,8-dioxa-5-azonia-7-borata-5*H*-6,7,8,9-tétrahydrobenzocycloheptène, **6***a*, sont monocliniques, groupe d'espace $P2_1/n$, avec $a = 10,771(1)$, $b = 13,1057(9)$ et $c = 16,8724(7)$ Å, $\beta = 90,005(2)°$ et $Z = 4$. On a résolu les structures par des méthodes directes et on les a affinées par les méthodes des moindres carrés (matrice complète) jusqu'à des valeurs de $R(F^2) =$ 0,120 ($R_w(F^2) = 0,135$) pour l'ensemble des 3149 réflexions ($R(F) = 0,071$ et $R_w(F) = 0,063$ pour 1500 réflexions avec $I \geq 3\sigma(I)$) pour le composé **8***b* et des valeurs de $R(F) = 0,035$ et 0,036 ($R_w(F) = 0,031$ et 0,038) pour 1071 et 3594 réflexions avec $I \geq 3\sigma(I)$ pour respectivement les composés **5***c* et **6***a*. Le composé **8***b* est le premier dérivé de la 1-hydroxy-1,2-dihydro-4*H*-3,1-benzoxazine à être caractérisé et le composé **6***a* comporte un hétérocycle à sept chaînons relativement rare contenant du bore.

Mots clés : *C*-aryl-*N*-[2(-hydroxyméthyl)phénol]nitrones, 1-hydroxy-2-aryl-1,2-dihydro-4*H*-3,1-benzoxazines, composés organoborés, structures cristallines.

Introduction

As reported in the preceding paper (1), the hitherto unknown *N*-(2-hydroxyphenylmethyl)hydroxylamine **1** (Scheme 1) was trapped as various aromatic aldonitrone derivatives **2**. These nitrones could be applied as bidentate ligands for the formation of seven-membered diphenylboron chelates[3] **3**, provided that the electron density at the *N*-oxide oxygen atom of the nitrone function was sufficiently increased by electron-donating substituents, such as a *p*-dimethylamino group, at the aryl residue.

The question arose whether the nitrones **5** derived from 2-(hydroxyamino)benzyl alcohol, **4** (an isomer of **1**), would be able to serve as chelating ligands enabling the synthesis of the boron chelates **6** and, if so, would there be structural requirements similar to those for **3**? As *N*-aryl derivatives, the hydroxylamine **4** and its nitrone **5** should be weaker bases than the isomeric *N*-alkylhydroxylamine **1** and its nitrone **2**. On the other hand, the alcohol function in **4** and **5** has different ligand properties than does the phenol function in **1** and **2**, considering the higher nucleophilicity of the alcoholate anion relative to that of the phenolate anion. In this report we describe the condensation of the hydroxylamine **4** and aromatic aldehydes to achieve the synthesis of the nitrones **5** and subsequent investigations of the suitability of **5** as bidentate ligands in the formation of the seven-membered boron chelates **6**. The structures of a ring isomer, **8**, an open-chain isomer, **5**, and the product of the reaction of **5** with $(Ph_2B)_2O$, **6**, have been determined by X-ray crystallographic analysis.

Experimental

General procedures

All preparations and reactions were carried out under normal conditions, without protective gas atmosphere. Commercial solvents and reagents were used as supplied. Oxybis(diphenylborane) was prepared according to literature methods (2). Melting points were measured on a Linström SPA-1 apparatus and are uncorrected. Elemental analyses (C, H, N, O): Carlo Erba Elemental Analyzer 1106; (B): oxidative disintegration (Schöninger) and potentiometric titration. Infrared spectra: Phillips PU 9800 FT-IR spectrometer, V 3.00, and Mattson Genesis Series FTIR Rev. I (ATI Unicam). For ^{1}H nmr: Varian EM 390; ^{11}B and ^{13}C nmr: Bruker AC 200. Mass spectra: Finnigan MAT 8430.

2-(Hydroxyamino)-benzyl alcohol, 4

With reference to the method described in the literature (3) 2-nitrobenzyl alcohol (5.10 g, 30.0 mmol) is dissolved in a mixture of 10 mL of methanol and 15 mL of water. After addition of 5 mL of 2 M NH_4Cl solution, zinc dust (8 g) is added in small portions under vigorous stirring. The temperature is kept below 65°C. Stirring is continued after the zinc addition until the temperature falls below 55°C. The warm solution is filtered off and gives small white flakes while cooling down. These crystals are carefully washed with a mimimum amount of water and dried at room temperature. Yield: 0.5 g (11%); mp 106°C (lit. (3) mp 104.2–104.7°C). Infrared (KBr, cm^{-1}): 1588 (C═C); ^{1}H nmr (400 MHz, DMSO-d_6–TMS) δ (ppm): 4.40 (d, J = 5.5 Hz, CH_2), 5.11 (t, J = 5.5 Hz, exchangeable, C-OH), 6.76 (t, J = 7 Hz, 5-H), 7.10 (d, J = 6 Hz, 3-H), 7.13 (d, J = 7 Hz, 4-H), 7.17 (d, J = 7 Hz, 6-H), 7.85 (d, J = 2 Hz, exchangeable, NH), 8.26 (d, J = 2 Hz, exchangeable, C-OH); ^{13}C nmr (100 MHz, DMSO-d_6–TMS) δ (ppm): 59.9 (C-7 "methylene"), 112.1 (C-3), 118.8 (C-5), 126.1 (C-1), 126.3 (C-6), 127.2 (C-4), 148.8 (C-2); assignment of all signals confirmed by C,H-COSY and C,H-COLOC methods; mass spectrum (EI, 70 eV) *m/z* (%): 139 (16) [M$^+$], 121 (100) [M$^+$–H_2O], 120 (85), 105 (21), 104 (23), 93 (66), 92 (61), 77 (45), 66 (58), 65 (64), 51 (24). Anal. calcd. for $C_7H_9NO_2$: C 60.42, H 6.52, N 10.07; found: C 60.53, H 6.62, N 9.88.

N-[2-(Hydroxymethyl)phenyl]-*C*-phenylnitrone, 5*a*,[4] or 1-hydroxy-2-phenyl-1,2-dihydro-4*H*-3,1-benzoxazine, 8*a*

Because of low yields of the pure crystalline 2-(hydroxyamino)-benzyl alcohol, **4**, one third of the warm filtered solution resulting from the Zn dust reduction of 2-nitrobenzyl alcohol (see above), which contains approximately 10 mmol of **4**, is mixed with benzaldehyde (1.06 g, 10.0 mmol). Crystallization commences upon cooling down to room temperature. Yield: 0.80 g (70%) of pale yellow crystals; mp 119°C. Infrared (KBr, cm^{-1}): 3443, 3347 (broadened, O-H), 1608, 1586 (C═N/C═C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS) δ (ppm): 4.55 (s, 10% of 2 H, CH_2), 4.82 and 5.06 (d and d, J = 15 Hz, AB system, 90% of 2 H, CH_2), 5.38 (s, 90% of 1 H, O-CH-N), 5.55 (s, exchangeable, OH), 6.83–7.73 (m, 9 aromatic H and 10% of 1 H, CH═N). Anal. calcd. for $C_{14}H_{13}NO_2$: C 74.00, H 5.77, N 6.16; found: C 74.08, H 5.73, N 6.15.

N-[2-(Hydroxymethyl)phenyl]-*C*-(4-methoxyphenyl)-nitrone, 5*b*,[5] or 1-hydroxy-2-(4-methoxyphenyl)-1,2-dihydro- 4*H*-3,1-benzoxazine, 8*b*

The reaction is carried out as described for **5***a* with 4-methoxybenzaldehyde (1.36 g, 10.0 mmol). Yield: 1.10 g (86%) of colorless crystals; mp 132°C. Infrared (KBr, cm^{-1}): 3474, 3362 (broadened, O-H), 1613, 1590 (C═N/C═C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS) δ (ppm): 3.80 (s, 70% of 3 H, OCH_3), 3.86 (s, 30% of 3 H, OCH_3), 4.56 (s, 30% of 2 H, CH_2), 4.83 and 5.06 (d and d, J = 15 Hz, 70% of 2 H, CH_2), 5.30 (s, 70% of 1 H, O-CH-N), 6.00 (s, exchangeable, OH), 6.80–8.40 (m, 8 aromatic H), 7.60 (s, 30% of 1 H, CH═N). Anal. calcd. for $C_{15}H_{15}NO_3$: C 70.02, H 5.88, N 5.44; found: C 70.15, H 5.86, N 5.49. Crystals suitable for X-ray analysis were obtained by very slow cooling of a solution of **5/8***b* in ethanol after repeated recrystallization.

C-[4-(Dimethylamino)phenyl]-*N*-[2-(hydroxymethyl)phenyl]-nitrone, 5*c*[6]

The reaction is carried out as described for **5***a* with 4-dimethylaminobenzaldehyde (1.49 g, 10.0 mmol). Yield: 1.05 g (78%) of yellow-brown crystals; mp 164°C (from ethanol). Infrared (KBr, cm^{-1}): 3400–2000 (very broad "curtain," peaks at 3385,

[3] Here and elsewhere in this work the term "boron chelate" refers to a nonclassical "chelate" of the Ph_2B^+ moiety. Considering the diphenylborenium moiety as a "pseudometal" explains much of the chemistry of these systems even though the bonding is (necessarily) quite different from that in true metal complexes.

[4] Alternative nomenclature: 2-(phenylmethylenamino)phenylmethanol *N*-oxide.

[5] Alternative nomenclature: 2-(4-methoxyphenylmethylenamino)-phenylmethanol *N*-oxide.

[6] Alternative nomenclature: 2-(4-dimethylamino^1-phenylmethylenamino^2)phenylmethanol N^2-oxide.

5-[4-(Dimethylamino)phenylmethylene]-7,7-diphenyl-6,8-dioxa-5-azonia-7-borata-5*H*-6,7,8,9-tetrahydrobenzocycloheptene, 6a[7]

5*c* (0.27 g, 1.0 mmol) and oxybis(diphenylborane) (0.17 g, 0.5 mmol) are dissolved in 20 mL of absolute ethanol and refluxed for 10 min. Crystallization commences during cooling to room temperature. Yield: 0.36 g (83%) of orange-colored crystals; mp 156ºC (from ethanol). Infrared (KBr, cm^{-1}): 1617 (C═N), 1603 (C═C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS) δ (ppm): 3.08 (s, $(CH_3)_2N$), 4.98 (m, CH_2), 6.48 and 7.95 (d and d, J = 9 Hz, AA′BB′ system, N-C_6H_4), 6.93–7.73 (m, 14 aromatic H), 7.70 (s, CH═N). Anal. calcd. for $C_{28}H_{27}BN_2O_2$: C 77.43, H 6.27, B 2.49, N 6.45; found: C 77.36, H 6.34, B 2.50, N 6.41. The product gives a blue-colored solution in ethanol upon addition of diphenylcarbazone, indicating the presence of the chelated diphenylborenium (Ph_2B^+) ion (4). Crystals suitable for X-ray analysis were obtained by slow crystallization from absolute ethanol.

5-[4-(Diethylamino)phenylmethylene]-7,7-diphenyl-6,8-dioxa-5-azonia-7-borata-5*H*-6,7,8,9-tetrahydrobenzocycloheptene, 6b[8]

The reaction is carried out as described for **5***a* with 4-diethylaminobenzaldehyde (1.77 g, 10.0 mmol). Since no crystallization could be achieved, the solution of the nitrone (**5***d*) was evaporated. A part of the remaining oily crude product (containing **5***d*) (0.3 g, ca. 1 mmol) and oxybis(diphenylborane) (0.17 g, 0.5 mmol) are dissolved in 20 mL of absolute ethanol and refluxed for 10 min. Cooling the solution yields 0.39 g (84%) of orange-colored crystals; mp 164°C (from ethanol). Infrared (KBr, cm^{-1}): 1617 (C═N), 1603 (C═C); ^{1}H nmr (400 MHz, $CDCl_3$–TMS) δ (ppm): 1.17 (t, J = 7 Hz, 2 CH_3), 3.37 (q, J = 7 Hz, $(CH_2)_2N$), 4.98 (m, OCH_2), 6.26–8.80 (m, 18 aromatic H and CH═N); ^{13}C nmr (100 MHz, $CDCl_3$–TMS) δ (ppm): 12.6 (2 CH_3), 44.9 (2 CH_2), 65.8 (OCH_2), 110.5, 111, 123–126.3 (aromatic C), 133.5 (C═N); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3) δ (ppm): 10.8 ($W_{1/2}$ = 364 Hz) and 47.1 ($W_{1/2}$ = 250 Hz), ratio of peak areas 20:1. Anal. calcd. for $C_{30}H_{31}BN_2O_2$: C 77.93, H 6.76, B 2.34, N 6.06; found: C 77.91, H 6.72, B 2.47, N 6.09. **6***b* gives a blue color reaction with diphenylcarbazone as described for **6***a*.

2,2′-Azoxybenzyl alcohol, 7

Pale yellow needles precipitate from the filtered solution (mother liquor) of the synthesis of **4** upon standing in air or upon concentrating the solution. Yield: 0.5 g (12%) of pale yellow needles; mp 121°C (from ethanol–water) (lit. (3) mp 123°C). Infrared (KBr, cm^{-1}): 3270–3070 (broad, OH); ^{1}H nmr (90 MHz, $CDCl_3$–TMS) δ (ppm): 3.03 (s, broad, exchangeable, 2 OH), 4.75 (s, CH_2), 4.78 (s, CH_2), 7.23–7.63 (m, 6 aromatic H), 7.76–7.93 (m, 1 aromatic H), 8.16–8.33 (m, 1 aromatic H). Anal. calcd. for $C_{14}H_{14}N_2O_3$: C 65.11, H 5.46, N 10.85; found: C 65.17, H 5.47, N 10.66. The yield of **7** is raised considerably by bubbling air through the above-mentioned solution of **4**, or by addition of small amounts of oxidants like $K_2Cr_2O_7$ or H_2O_2.

X-ray crystallographic analyses

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares employing 8737 reflections with 2θ = 4.0°–63.7º for **8***b*, 25 reflections with 2θ = 12.5°–22.3° for **5***c*, and 25 reflections with 2θ = 95.5º–107.5° for **6***a*. The intensities of three standard reflections, measured every 200 reflections throughout the data collections for **5***c* and **6***a*, decayed linearly by 5.6% for **5***c* and by 2.9% for **6***a*. The data were processed,[9] corrected for Lorentz and polarization effects, decay (**5***c* and **6***a*), and absorption (based on analysis of redundant data for **8***b* and azimuthal scans for **5***c* and **6***a*).

The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. The solution of the structure of **8***b* was initially attempted (unsuccessfully) in the centrosymmetric space group *P*2/*a* based on the *E*-statistics. Changing to the noncentrosymmetric space group *Pa* gave a solution immediately. The two independent molecules in the asymmetric unit of **8***b* are related by a pseudo-inversion centre, but it should be noted that this cannot be a true center of symmetry since the corresponding chiral carbon atoms, C(8) and C(23), both have the same chirality. The N-OH oxygen atoms of both of the two independent molecules of **8***b* were modeled as (3:1) twofold disordered, representing configurational disorder at the chiral nitrogen atoms. The geometry involving the lower-occupancy NOH oxygen atoms, as well as the anisotropic thermal parameters, in general suggests that the entire molecules of **8***b* are probably disordered with only the components of the NOH oxygen atoms separated enough to be resolved. The resulting structure of **8***b* therefore represents (except for the resolved O atoms and for each of the two independent molecules) a weighted mean of two different stereoisomers having opposite configurations at the nitrogen atom, and the accuracy of the derived parameters is likely less than that indicated by the least-squares standard deviations. For **5***c* the structure analysis was initiated in the noncentrosymmetric space group $P2_1$ on the basis of the *E*-statistics, this choice being validated by subsequent calculations. Twofold disorder (~5:1) of the aromatic -CH_2OH group of **5***c* was modeled by split-atom refinement of the oxygen atom. The site occupancy factors for the disordered oxygen atoms in **8***b* and **5***c* were adjusted as the refinement progressed to result in nearly equal equivalent isotropic thermal parameters for the two components of the disordered models. Low-occupancy oxygen atoms in **8***b* (O(2a)) and **5***c* (O(2a)) were refined with isotropic thermal parameters and all other nonhydrogen atoms were refined with anisotropic thermal parameters. The higher-occupancy NOH hydrogen atoms of **8***b* were placed in difference map positions but were not refined. The major OH hydrogen atom of **5***c* and all hydrogen atoms of **6***a* were refined with isotropic thermal parameters and the carbon-bound hydrogen atoms of **8***b* and **5***c* were fixed in calculated positions

[a]Temperature 180 K, Rigaku/ADSC CCD diffractometer, Mo K_α ($\lambda = 0.71069$ Å), graphite monochromator, takeoff angle 6.0°, aperture 94.0×94.0 mm at a distance of 39.17 mm from the crystal, $\sigma^2(F^2) = (C + B)/\mathrm{Lp}^2$ (C = scan count, B = background count), function minimized $\sum w(|F_o^2|-|F_c^2|)^2$ where $w = 1/\sigma^2(F_o^2)$, $R = \sum||F_o^2|-|F_c^2||/\sum|F_o^2|$, $R_w = (\sum w(|F_o^2|-|F_c^2|)^2 / \sum w|F_o^2|^2)^{1/2}$, and gof = $[\sum w(|F_o^2|-|F_c^2|)^2/(m-n)]^{1/2}$. Data collected to $2\theta_{max} = 60°$ (full sphere 4–40°, hemisphere 40–60°).
[b]Temperature 294 K, Rigaku AFC6S diffractometer, Mo K_α ($\lambda = 0.71069$ Å) or Cu K_α radiation ($\lambda = 1.54178$ Å), graphite monochromator, takeoff angle 6.0°, aperture 6.0×6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1), $\sigma^2(F^2) = [S^2(C + 4B)]/\mathrm{Lp}^2$ (S = scan rate, C = scan count, B = normalized background count), function minimized $\sum w(|F_o|-|F_c|)^2$ where $w = 4\,F_o^2/\sigma^2(F_o^2)$, $R = \sum||F_o|-|F_c||/\sum|F_o|$, $R_w = (\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2)^{1/2}$, and gof = $[\sum w(|F_o|-|F_c|)^2/(m-n)]^{1/2}$.
[c]Includes crystal decay, absorption, and scaling corrections

with C—H = 0.98 Å and $B_H = 1.2\ B_{\text{bonded atom}}$. The minor component OH hydrogen atoms of **8***b* and **5***c* could not be located and were excluded from the models. Corrections for secondary extinction were applied (Zachariasen type, isotropic, Gaussian), the final values of the extinction coefficients being $1.5(3) \times 10^{-6}$ for **5***c* and $1.54(2) \times 10^{-5}$ for **6***a* (no extinction correction was necessary for **8***b*). Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (5). No attempts to determine the polarity of **8***b* and the absolute configuration of **5***c* (helical chirality) were made because the data were collected with Mo radiation. Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and intra-annular torsion angles (for **8***b* and **6***a*) appear in Tables 2–5, respectively. Tables of hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes are available as supplementary material.[10]

[10] These tables may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The tables of hydrogen atom coordinates and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

Results and discussion

Synthesis and structure of the nitrones 5 and their ring isomers 8

The synthesis of the novel nitrones **5** was achieved by condensation of aromatic aldehydes and the hydroxylamine **4** (prepared as first reported in 1903 (3*a*)). The reduction of 2-nitrobenzyl alcohol with Zn dust and NH_4Cl is, however, not without problems because the isolation of the free hydroxylamine base **4** is only possible with considerable losses, if at all

(3*b*). A high solubility in most solvents (including water) as well as the competitive formation of the azoxy compound **7** (via the initially generated nitroso intermediate) reduces the yield of **4**. The yield is improved when **4** is trapped, as its nitrone **5,** directly from the solution resulting from the reduction process. In the literature the hydroxylamine **4** is mentioned only sporadically and without further details or physical data (6). In this work we present some spectroscopic data for **4** that, to the best of our knowledge, have not been previously reported.

The condensation products from **4** and aromatic aldehydes are crystalline compounds with the exception of **5***d*/**8***d*, which could not be crystallized for still unknown reasons. Considerable broadening of the O–H valence stretching bands in the solid state (KBr pellets) infrared spectra of **5**/**8***a–c* (most prominent for the 4-dimethylaminobenzaldehyde derivative) indicates an increased (associative) intra- or intermolecular O—H· · ·O interaction. The 4-dialkylamino substituted aldonitrones **5***c* and **5***d* should possess an increased basicity at the nitrone *N*-oxide function compared to the unsubstituted and 4-methoxy derivatives **5***a* and **5***b* (ref. 1, and refs. therein).

As discussed earlier for the isomeric nitrones of type **2** (1), cycloisomerization of the nitrones **5** leading to the ring tautomers **8** can be expected, at least in solution. No detectable amounts of the cyclotautomers, however, were discovered in the ^{1}H nmr spectra of **2** (1); thus it is surprising that the ^{1}H nmr spectra of **5**/**8***a* and **5**/**8***b* show signals indicating the presence of 90% and 70% of the cyclotautomers **8***a* and **8***b*, respectively, in addition to signals arising from the nitrone forms **5***a* and **5***b* in the respective ratios. In the same solvent ($CDCl_3$) the 4-dimethylaminobenzaldonitrone **5***c* does not give any signals attributable to its cyclic isomer **8***c*. The ^{1}H nmr signals used to discriminate between the isomers and to estimate their relative populations in solution are basically the same as those used for similar ring-chain isomers of nitrones (ref. 1, and refs. therein): the CH═N signal at low field for the open-chain nitrone form **5**, and the middle-field O-CH-N signal for the cyclic acetal form **8**. Additional differences are found between the benzyl-CH_2 signals that appear as a singlet for the open-chain form **5** and as an AB spin coupling pattern (quadruplet) for the cyclic form **8**, indicating the nonequivalence of the CH_2 protons in

the relatively rigid ring form. In the 4-methoxybenzaldehyde derivative **5/8***b* the 4-methoxy group serves as an additional probe for both of the isomers in that it produces singlets having different chemical shifts for ring and open-chain isomers.

The predominance of the cyclic form **8** in the ^{1}H nmr spectra of **5/8***a* and **5/8***b* induced us to attempt an X-ray crystallographic analysis of one of these derivatives. It was not possible to obtain any suitable crystals of **5/8***a,* while compound **5/8***b* gave weakly diffracting thin plates of poor quality. In spite of the shortcomings of the structure analysis that preclude any detailed discussion of molecular geometry (see Experimental), the X-ray analysis does establish the cyclic structure **8***b,* which, to the best of our knowledge, represents the first example of a 1-hydroxy-1,2-dihydro-4*H*-3,1-benzoxazine. The benzaldehyde derivative **8***a* most likely has the same ring structure. The asymmetric unit of **8***b* consists of two crystallographically independent molecules, related to one another by a pseudoinversion centre. Careful inspection of Fig. 1, however, shows that the corresponding chiral centres (N(1)/N(2) and C(8)/C(23), respectively) have the *same* absolute configurations: *S* at nitrogen and *R* at carbon. The disorder of the NOH groups (see Experimental) further complicates the issue because the minor disorder components have the opposite configuration at the chiral nitrogen atom. The crystal as a whole thus has the composition: *SR*, 37.5%, *RS*, 37.5%, *RR*, 12.5%, and *SS*, 12.5%. The six-membered heterocyclic rings in the two independent molecules of **8***b* have slightly different C(8/23)-envelope conformations (see Table 5) and the 4-methoxyphenyl groups are oriented approximately perpendicular to the mean planes of the fused-ring systems. Bond lengths and angles for **8***b* (Tables 3 and 4) are generally as expected.

An X-ray crystallographic analysis of **5***c* establishes, for the solid state, the open-chain nitrone structure (Fig. 2) indicated by ^{1}H nmr spectroscopy as the sole isomer present in solution. The increased electron density at the nitrone group, induced

by the 4-dimethylamino substituent at the benzaldehyde moiety, might prevent the cyclotautomerization that affords an electron-poor carbenium ion, and thus stabilizes the open-chain nitrone structure. Unlike the structure of the isomeric nitrone **2** (Ar = 4-$Me_2NC_6H_4$) (1), which possesses a strong intramolecular O—H· · ·O hydrogen bond connecting the phenol and nitrone groups, no such intramolecular interaction between the hydroxymethyl and nitrone groups is present in **5***c*, despite the same ring size of the potential intramolecular seven-membered proton chelate. In **5***c* intermolecular hydrogen bonds between the major component hydroxymethyl groups and the nitrone groups of neighboring molecules form helices about the twofold screw axes (O(2)—H(1)· · ·O(1): O—H = 1.05(5), H· · ·O = 1.74(5), O· · ·O = 2.787(4) Å, O—H· · ·O = 172(4)°). The minor component hydroxymethyl oxygen atom O(2a) is involved in an intermolecular C—H· · ·O interaction having geometrical parameters consistent with hydrogen bonding (7) (C(15)—H(14)· · ·O(2a): C—H = 0.98, H· · ·O = 2.35, C· · ·O = 3.32(1) Å, C—H· · ·O = 170°). The presence of this interaction may be at least partially responsible for the disordering of the hydroxymethyl group. The weaker basicity of the nitrone *N*-oxide group and the weaker acidity of the hydroxymethyl group of **5***c* compared to that of **2** (Ar = 4-$Me_2NC_6H_4$) may, in addition to other crystal packing effects, have some influence in determining whether an *intra*molecular or *inter*molecular hydrogen bond is formed between these functional groups. As noted for **2** (Ar = 4-$Me_2NC_6H_4$) (1), there is an intramolecular C—H· · ·O contact in **5***c* between the nitrone *N*-oxide oxygen atom and an *ortho* hydrogen atom of the aromatic aldehyde moiety (C(10)—H(9)· · ·O(1): H· · ·O = 2.25, C· · ·O = 2.879(3) Å, C—H· · ·O = 121°). Although this interaction does not meet the requirements for a true C—H· · ·O hydrogen bond, it can still be considered as an additional cohesive contribution to the forces determining the molecular conformation (7). As in **2** (Ar = 4-$Me_2NC_6H_4$), this contact might be favored by the approximate coplanarity of the 4-dimethylaminophenyl residue and the nitrone group as a consequence of the resonance effects within the conjugated double bond system extending from the dimethylamino group to the nitrone oxygen atom (1). In accordance with the +M effect of the 4-Me_2N substituent are the relatively short N(2)—C(12), C(10)—C(11), C(13)—C(14), and C(8)—C(9) bonds (1.357(4), 1.376(4), 1.369(4), and 1.440(4) Å, respectively), as well as the relatively longer aromatic bonds C(9)—C(14), C(12)—C(13), C(9)—C(10), and C(11)—C(12) (mean C—C = 1.405 Å). The aromatic ring at N(1), however, deviates from the planar aldonitrone moiety in **5***c*, the angle between normals to the respective mean planes being 70°. The C═N double bond (1.299(3) Å) and the N—O bond (1.312(3) Å) of the nitrone function in **5***c* are as expected for aldonitrones (ref. 1, and refs. therein).

Synthesis and structure of the boron chelates 6

The reaction of **5/8** with diphenylborinic acid anhydride gave crystalline compounds only for the *p*-dialkylaminobenzaldehyde nitrones (**5***c* and **5***d*). The derivatives **5/8***a* and **5/8***b* were recovered unchanged from the reaction mixtures in ethanol, or even in benzene under reflux conditions using a Dean–Stark

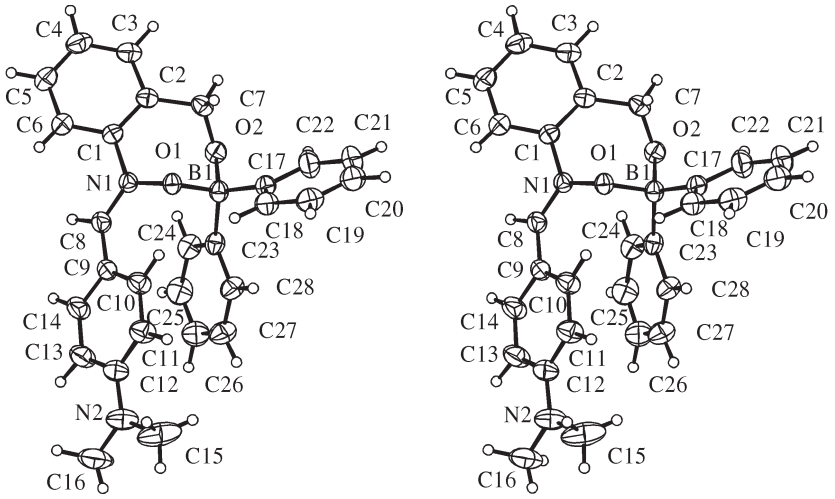
Fig. 3. Stereoview of **6***a*; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.



trap for continuous removal of water. The weaker basicity of the nitrone groups and the favored ring structure, deduced from the ^{1}H nmr spectra of **5**/**8***a* and **5**/**8***b* and the crystal structure of **8***b*, might impede the formation of stable boron chelates. The crystalline compounds obtained from **5***c* and **5***d* give elemental analyses, infrared and ^{1}H nmr spectra, and positive color reactions with diphenylcarbazone (4) corresponding to the diphenylboron chelate structure **6**. In the solid state infrared spectra (KBr pellets) of **6** there are no O–H valence stretching bands present, and the C═N absorption band of the nitrone group is found at a somewhat higher frequency (1617 cm^{-1}) than for the free ligands **5**. Similar observations have been made from the infrared spectra of other boron chelates and their nitrone ligands (ref. 1, and refs. therein).

The most striking feature in the ^{1}H nmr spectra of **6** is the signals arising from the benzylic CH_2 protons, which appear as AB quartets pointing to the magnetic inequivalence of the CH_2 protons after the incorporation of the methylene group into the chelate ring of **6**. An AB pattern like this might, however, also indicate the cyclic fixed methylene group in the isomer **9** (or its BONBON dimer). A structure such as **9**, however, can easily be excluded by the conspicuous signal of a nitrone N═CHproton and by the absence of an O-CH-N acetal methine signal in each of the ^{1}H nmr spectra. In addition, the ^{11}B nmr spectrum of **6***b*[11] shows a signal indicating a tetracoordinate boron nucleus at δ (Et_2OBF_3) = 9.2 ppm. A ^{11}B nmr signal with a shift like this cannot be expected from an isomeric compound such as **9***b*, unless it would form BONBON dimers[12] stable enough in solution to give the signals for tetracoordinate (sp^3) boron nuclei. The second ^{11}B nmr signal at 47.1 ppm, although very weak, indicates an uncoordinated Ph_2B-O-R moiety or free diphenylborinic acid, but not necessarily **9***b*. The peak could just as easily appear as a result of solvolytic removal of the coordinating nitrone ligand from the boron nucleus in **6***b,* generating the diphenylborinate of the benzyl alcohol moiety (a trivalent sp^2 boron compound) or free diphenylborinic acid. Similar solvolyses have also been noted for solutions of the diphenylboron chelates **3** (1).

An X-ray analysis of **6***a* establishes the seven-membered chelate structure (Fig. 3). Compound **6***a* is thus an isomer of the diphenylboron chelate **3** (Ar = 4-$Me_2C_6H_4$), which has also been structurally characterized by an X-ray crystallographic analysis (1). The chelate ring formation in **6***a* demonstrates that the hydroxymethyl group, *inter*molecularly hydrogen-bonded in crystalline **5***c*, may be *intra*molecularly hydrogen-bonded in solution, thus allowing the facile replacement of the "chelated" proton by a diphenylborenium (Ph_2B^+) cation.

The intramolecular C—H···O interaction found in the solid state structure of **5***c* is still present in the crystal of **6***a*, the slightly longer C···O distance in **6***a* reflecting the use of the N-oxide group as a ligand for the boron nucleus (C(10)—H(8)···O(1): H···O = 2.27(2), C···O = 2.904(2) Å, C—H···O = 119(1)°). A second weak intramolecular C—H···O interaction between one of the *B*-phenyl residues and the benzyl alcoholate oxygen is probably little more than a consequence of crystal packing forces (C(24)—H(23)···O(2): H···O = 2.47(2), C···O = 2.855(2) Å, C—H···O = 103(1)°). The intermolecular C(14)—H(11)···O(2) (1/2–*x*, 1/2 + *y*, 1/2–*z*) hydrogen bond with an angle of 158(2)° at H, H···O = 2.25(2) Å, and C···O = 3.191(2) Å, however, is most likely an additional cohesive force within the crystal lattice.

The metrical changes, going from the free nitrone ligand **5***c* to the chelate **6***a*, are essentially the same as those observed in the structural study of the ligand **2** and the chelate **3** (Ar = 4-$Me_2C_6H_4$) (1). The nitrone C═N$^+$ double bond remains practically unchanged with only a slight lengthening, whereas the N—O bond is lengthened by 0.06 Å (the corresponding difference between N—O distances in **2** and **3** is 0.05 Å) and shows the reduction of the π-bond order of the N—O bond from 0.34 in the free ligand **5***c* to 0.13 in the chelate **6***a* as estimated from plots of bond lengths vs. HMO–π-bond order (9). The changes at the 4-dimethylaminophenylmethylene moiety are similar to those noted for the isomeric ligand **2** and chelate **3** (1) with the exception of the C(12)—N(2) distance in **5***c*, which is already short compared to the corresponding distance of 1.370(2) Å in **2**. The enhanced double bond

[11] The ^{11}B nmr spectrum of **6***a* could not be obtained because of poor solubility.

[12] For more information on the BONBON dimers of *O*-borinates from hydroxylamine derivatives, see ref. 8 and literature cited therein.

character of the N(2)—C(12), C(10)—C(12), C(13)—C(14), and C(8)—C(9) bonds (1.357(4), 1.376(4), 1.369(4), and 1.440(4) Å, respectively, in **5***c*; 1.351(2), 1.355(2), 1.359(3), and 1.409(2) Å in **6***a*) reflects an increased electron donation from the *p*-dimethylamino group caused by the cooperative electron-pulling effect of the chelated diphenylborenium ion in **6***a*. The (N)O—B bond in **6***a*, coordinating the *N*-oxide group to the boron nucleus, is longer than that in the isomeric boron chelate **3** by about 0.04 Å (1.592(2) vs. 1.549(2) Å), pointing to the weaker nucleophilicity of the *N*-oxide ligand in the nitrone **5***c* and consequently in **6***a*. On the other hand, the (benzyl)O—B bond in **6***a* is about 0.04 Å shorter than the (phenyl)O—B bond in **3** (1.453(2) vs. 1.488(2) Å), indicating the stronger nucleophilicity of the alcoholate ligand in the chelate **6***a* compared to the phenolate ligand in the isomeric chelate **3**.

The (phenyl)C—B bond lengths in **6***a* (mean 1.615(1) Å) are within the range normally observed for tetracoordinate phenylboron compounds and are virtually identical to those in **3** (mean 1.615(2) Å) (1). The mean C—B/mean O—B bond length ratio of 1.060 suggests an only slightly reduced overall ligand binding strength with respect to the diphenylboron nucleus in **6***a* compared to the isomer **3** (mean C—B/mean O—B = 1.063) (1). The sum of bond lengths around the boron atom (6.275 Å) is in accordance with the same parameter in other seven-membered diphenylboron chelates (1) and confirms the observation of an essentially constant value for a given chelate ring size (10). It seems that the chelate ring of **6***a*, having the exocyclic N═C double bond fixed at the anellating benzo moiety, has a little more conformational flexibility than does that of the isomer **3**, allowing somewhat smaller ring angles. The sum of the intracyclic angles of the chelate ring in **6***a* is 806.1°, compared to corresponding values of 811.7° for **3**, and 858.4° for the less flexibile seven-membered chelate ring of the salicylaldonitrone derivative **10** (containing an endocyclic N═C bond) (ref. 1, and refs. therein). Like the seven-membered boron chelate **3**, the isomer **6** may be formally regarded as a "phenylog" (by *o*-phenyl insertion) of the five-membered boron chelate **11** (11), even though the alkylidene substituents at the nitrogen atoms of the nitrone moieties are different. The intracyclic angle in the seven-membered ring at the anellation position at C(1) in **6***a* is close to the expected value of 120° (120.9(1)°), whereas the corresponding angle in the isomer **3** is somewhat compressed (116.8(1)°). This provides evidence for the expected stronger interaction of the (sp^2) nitrogen atom of the nitrone group with the anellated benzene ring in **6***a* relative to the (sp^3) carbon atom of the methylene group at the same ring position in the isomer **3**. As noted for **3**, all of the remaining intracyclic angles in the seven-membered chelate ring of **6***a* are wider than the corresponding ring angles in **11** (11).

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada and the Fonds der Chemischen Industrie, Frankfurt am Main, for financial support. We are grateful to the Chemische Institute der Technischen Universität Braunschweig for the ^{11}B and ^{13}C nmr and mass spectra.

The reactivity of the high-energy intermediates formed in the reactions of Group 13 metal atoms and aromatic alkenes

Helen A. Joly, Maria Kepes, Natalie Roy, and Jason Prpic

Abstract: Group 13 metal atoms were reacted with aromatic alkenes in a specialized metal atom reactor known as a "rotating cryostat." The nature of the intermediates formed was deduced from a GC–MS study of their hydrolysis and deuterolysis products. The product studies suggest that 2-phenylaluminacyclopropane, *cis*- and *trans*-3,4-diphenylaluminacyclopentane, and *cis*- and *trans*- 2,4-diphenylaluminacyclopentane are formed when Al atoms react with styrene, and 2-methyl-2-phenylaluminacyclopropane and 3,4-dimethyl-3,4-diphenylaluminacyclopentane are formed when Al atoms react with α-methylstyrene. These findings are consistent with the radicals detected in the EPR spectroscopic studies of Al–alkene reaction mixtures prepared under similar conditions. Mechanisms for the formation of the organoaluminium intermediates are discussed. Analogous organogallium intermediates are formed when gallium atoms react with styrene. The reductive coupling of styrene did not occur when In and Tl atoms were used. Only trace quantities of phenylethane were detected in the hydrolyzed reaction mixture.

Key words: Group 13 metal atoms, aluminium atoms, organoaluminium intermediates, metal atom reactions.

Résumé : On a fait réagir des atomes de métaux du groupe 13 avec des alcènes aromatiques dans le réacteur à atomes de métaux connu sous le nom de « cryostat rotatif ». On a déduit la nature des intermédiaires formés en se basant sur une étude de CG–SM de leurs produits d'hydrolyse et de deutérolyse. Les études sur la nature des produits suggèrent que, lorsqu'on fait réagir des atomes d'aluminium avec le styrène, il se forme du 2-phénylaluminacyclopropane, des *cis*- et *trans*-3,4-diphénylaluminacyclopentanes et des *cis*- et *trans*-2,4-diphénylaluminacyclopentanes; lorsqu'on fait réagir des atomes d'aluminium avec l'α-méthylstyrène, il se forme du 2-méthyl-2-phénylaluminacyclopropane et du 3,4-diméthyl-3,4-diphénylaluminacyclopentane. Ces résultats sont en accord avec les radicaux détectés lors d'études RPE de mélanges provenant de réactions Al–alcènes effectuées dans des conditions semblables. On discute des mécanismes de formation des intermédiaires organoaluminium. Des intermédiaires organogallium semblables se forment lorsqu'on fait réagir des atomes de gallium avec le styrène. Le couplage réducteur du styrène ne se produit pas lorsqu'on utilise des atomes d'In et de Ti. On ne détecte que de très faibles quantités de phényléthane par hydrolyse des mélanges réactionnels.

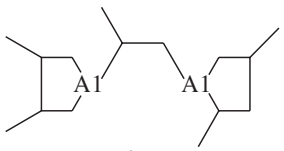
Mots clés : atomes de métaux du groupe 13, intermédiaires organoaluminium, réactions d'atomes métalliques.

[Traduit par la rédaction]

Introduction

The reactions of metal atoms with organic substrates provide interesting routes to the formation of novel organometallic intermediates. These organometallic intermediates are useful in mediating the modification of organic compounds. The reaction of Group 13 metal atoms with alkenes has been the subject of numerous investigations (1–14, and footnote 3).

Product analysis and (or) electron paramagnetic resonance (EPR) spectroscopy have been used to study the intermediates formed between Al atoms and alkenes at cryogenic temperatures. The product studies usually involve the hydrolysis or deuterolysis of the organometallic adducts formed in the metal atom reaction. The nature of the organometallic intermediate is inferred from the resulting hydrolysis products. For instance, when the organoaluminium adduct resulting from the cocondensation of Al atoms and propene (5, 6) at 77 K was subjected to deuterolysis the major products formed were deuterated propane, 2,3-dimethylbutane, 2-methylpentane, and traces of *n*-hexane. The organoaluminium intermediate most consistent with these products is **1**.



1

The reactive intermediates formed when Al atoms are reacted with propene in an adamantane matrix at 77 K have been studied by EPR spectroscopy (7, 8). Three radical species are

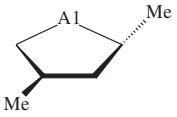
3



4

In a few cases, Al atoms react with alkenes, e.g., ethene (1–4), $CD_3CH{=}CH_2$ and $CD_3CD{=}CD_2$ (14), to form monoligand π-complexes, Al[alkene].

1,3-Butadiene reacts with Al atoms to form two major paramagnetic species detected by EPR spectroscopy (9), a σ-bonded aluminacyclopentene and aluminium-substituted allyl radicals. It would appear that conjugated systems undergo intramolecular cyclodimerization more easily than intermolecular cyclodimerization, which was observed for the simple alkenes (3, 4, 7, 8) discussed above.

Two groups of workers have investigated the interaction between Al atoms and benzene by EPR spectroscopy (10, 11) and have shown that an Al–benzene molecular complex forms. A good computer simulation of the Al–benzene species in a neon matrix (10) at 4 K was obtained, assuming an interaction between the ground state Al atom ($3s^2$, $3p^1$) and only two of the six protons of the benzene ring. This observation is consistent with the formation of a π-complex, resulting from the dative bonding of the semi-occupied Al $3p_x$ orbital with two antibonding p_π orbitals on two adjacent carbon atoms. In another study (11), the Al–benzene complex isolated in adamantane was warmed to 220 K in the cavity of the EPR spectrometer. The EPR spectrum in this case was best interpreted as the interaction of the Al atom with six equivalent hydrogen nuclei. This led Howard et al. (11) to propose the formation of an η_6-complex in which the Al atom lies along the C_{6v} axis of the benzene ring.

Often reactions of ground-state Ga atoms ($4s^2$, $4p^1$) mimic the reactions of Al atoms. For instance, Ga atoms have also been found to react with alkenes. The Ga–ethylene π-complex is the major paramagnetic species formed when Ga atoms are reacted with ethylene, in both argon (12) at 4 K and adamantane (13) at 77 K. A second paramagnetic species, detected in the Ga–ethylene reaction in adamantane (13), has been tentatively assigned to gallacyclopentane. Ga atoms react with 1,3-butadiene (9, and footnote 3) yielding 1-substituted allyl, $MCH_2CHCHCH_2$. There is no evidence for the cheleotropic addition of Ga leading to the formation of gallacyclopentene as was observed for Al atoms. An EPR study of a Ga atoms matrix isolated in benzene at 77 K (14) indicated that a trapped atom or weak Ga–benzene complex forms that is unlike the $Al[C_6H_6]$ complex found in the Al–benzene reaction. In addition, samples of Ga atoms in benzene, annealed in the cavity of the EPR spectrometer, yielded well-resolved spectra of cyclohexadienyl radicals, $C_6H_7^{\bullet}$.

Based on the studies involving the reaction of Group 13 metal atoms with alkenes, styrene presents two sites for reaction with the metal atoms, the benzene ring and the double bond. We present the results of a product study involving the Group 13 organometallic adducts formed when Group 13 metal atoms are reacted with styrene and α-methylstyrene at cryogenic temperatures.

Experimental

Preparation of the reaction mixtures

A specialized metal atom reactor known as a rotating cryostat (15) was used to prepare the reaction mixtures. The device consisted of a stainless steel drum held in the centre of a reaction chamber that was maintained at ca. 10^{-6} Torr (1 Torr = 133.3 Pa). During operation of the cryostat the liquid nitrogen filled drum rotated at 2000 rpm while the alkene and the metal vapour were introduced through portholes in the outer chamber. The metal atom vapour (generated by resistively heating Al wire, Ga, In, or Tl pellets in a tungsten basket fixed between two electrodes of a furnace), condensed on the cold surface of the rotating drum and was bombarded with the alkene at a pressure of 0.1 Torr. Reaction was believed to occur at the interface of the two reactants. After approximately 8 min, the current supplied to the furnace was decreased to 0 A and the alkene was allowed to condense onto the reaction mixture for an additional 2 min. Next, distilled water or deuterium oxide was introduced through a porthole at a pressure of 1 Torr for 3 min. The above sequence was repeated once. The reaction mixture was transferred at 77 K and under reduced pressure into a sample tube fitted with a rotoflow stopcock. The sample was slowly warmed to room temperature by keeping the sample tube in a Dewar containing liquid N_2 until the coolant had evaporated. Next, approximately 1 mL of distilled water was added to the sample tube. Samples that appeared to contain excess metal were first treated with a few drops of 5% HCl. Dichloromethane (ca. 1 mL) was added to the aqueous phase to extract the organic compounds. Molecular sieves were added to dry the dichloromethane layer, which was subsequently analyzed by gas chromatography – mass spectrometry.

Sample analysis

A Varian Saturn II gas chromatograph – mass spectrometer operating in electron impact mode at 70 eV was used to analyze the hydrolysis products. The gas chromatograph was fitted with a Varian 1093 septum-equipped programmable injector (SPI) and an SPB-1 nonpolar fused silica column (30 m × 0.25 μm film thickness, Supelco). Ultrapur helium was used as the carrier gas with a column head pressure of 12 psi (1 psi = 6.9 kPa). The SPI injector was programmed to hold at 40°C for 0.10 min at which time the temperature was ramped from 40 to 280°C at a rate of 200°C/min. After an initial 2 min hold period the column temperature was increased from 40 to 140°C at 5°C/min, then from 140 to 200°C at 2°C/min with a 5 min final hold period. The transfer line coupling the GC to the MS was maintained at 260°C whereas the temperature of the ion trap manifold was kept at 220°C. The electron impact mass spectral scans were recorded from *m*/*z* 40 to *m*/*z* 350 amu. The hydrolysis products were identified by comparing the retention times and mass spectral data to those of authentic samples.

Synthesis of standard samples

Preparation of meso- *and* dl-*2,3-diphenylbutane*

The *meso* and *dl*-2,3-diphenylbutane were synthesized by a method suggested by Kochi (16). Acetone (5 mL) in 50 mL of anhydrous diethyl ether was added dropwise to the Grignard reagent prepared from magnesium turnings (4 g, 0.16 mol) and 1-bromo-1-phenylethane (7.4 mL, 0.057 mol). The reaction mixture was next hydrolyzed and the *meso*- and *dl*-2,3-diphenylbutane recovered by ether extraction. Removal of the ether with the aid of a rotary evaporator resulted in the partial crystallization of a solid. The solid and mother liquor were separated. Recrystallization of the solid from methylcyclohexane – petroleum ether yielded 0.48 g (7%) of *meso*-2,3-diphenylbutane melting from 119 to 121°C (lit. (16) mp 124–126°C). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.19–7.35 (m, 10 H), 2.70–2.90 (m, 2 H), 1.08 (d, 6 H). GC–MS: 209 (0.1, $[M - 1]^+$), 133 (2.4, $[M - C_6H_5]^+$), 105 (100, $[C_6H_5CHCH_3]^+$), 104 (30.8), 91 (7.2), 79 (17.5), 77 (16.7), 63 (2.7), 51 (8.5).

The *dl* isomer (0.2 g, 3.5%) was recovered from the mother liquor. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.20–7.60 (m, 10 H), 3.05–3.20 (m, 2 H), 1.40 (d, 6 H). GC–MS: 209 (0.12, $[M - 1]^+$), 133 (1.4, $[M - C_6H_5]^+$), 105 (100, $[C_6H_5CHCH_3]^+$), 104 (34.0), 91 (5.1), 79 (19.0), 77 (20.1), 63 (2.9), 51 (8.9).

Preparation of 1,3-diphenylbutane (16, 17)

A mixture containing 6.30 mL (0.054 mol) of acetophenone in diethyl ether was added dropwise to a Grignard reagent prepared by adding 7.38 mL (0.054 mol) of 1-bromo-2-phenylethane in 50 mL of sodium-dried diethyl ether to 3 g (0.25 mol) of magnesium turnings. After hydrolysis with 10% H_2SO_4, 1,3-diphenyl-3-butanol was recovered from the reaction mixture by ether extraction followed by removal of the solvent on a rotary evaporator. Potassium bisulfate (14.7 g, 0.08 mol) was added to the alcohol and the mixture was heated at 160–170°C for 30 min. Distillation of the resulting liquid yielded 1,3-diphenyl-1-butene (bp 126–130°C, 3 Torr). Hydrogenation (17) of the alkene with H_2 and PtO_2 in ethanol resulted in the formation of the desired product. 1,3-Diphenylbutane (2 g, 18% yield) was collected between 115 and 120°C at 2 Torr. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.11–7.39 (m, 10 H), 2.60–2.78 (m, 1 H), 2.48–2.59 (m, 2H), 1.86–2.01 (m, 2 H), 1.30 (d, 3H). GC–MS: 210 (30.3, $[M]^+$), 133 (2.9), 119 (11.5), 106 (50.9), 105 (100), 92 (34.6), 91 (75.9), 79 (22.8), 77 (29.6), 51 (18.7).

Results and discussion

Reaction of Al atoms with styrene and α-methylstyrene

Aluminum atoms were reacted with styrene under cryogenic temperatures. The ratio of the metal:styrene was approximately 1:10. Water was added to the reaction mixture. This causes hydrolysis of the C—Al bonds and replacement of Al with a hydrogen atom. The main hydrolysis products detected by GC–MS analysis were phenylethane (EtBz), *dl*-2,3-diphenylbutane (*dl*-2,3-DPB), *meso*-2,3-diphenylbutane (*meso*-2,3-DPB), and 1,3-diphenylbutane (1,3-DPB), Table 1. Confirmation of these assignments was obtained by comparing the mass spectral data and retention times to those obtained for authentic samples.

From the entries 1, 2, and 3 in Table 1 it can be seen that the relative amount of the hydrolysis products formed varied from experiment to experiment, e.g., more phenylethane was formed in the second experiment than in the first (cf. 43% vs. 26%). However, the ratio of *dl*-2,3-, *meso*-2,3-, and 1,3-diphenylbutanes remains relatively constant for the three experiments, i.e., 11.2:4.5:1. In all cases, the relative amount of *dl*-2,3-DPB (69 ± 4%) in the mixture is greater than that of *meso*-2,3-DPB (27 ± 4%), which in turn is greater than the 1,3-DPB (6 ± 4%).

Deuterolysis of the reaction mixture, entry 4, Table 1, resulted in compounds that eluted at retention times similar to those observed for the hydrolysis products. However, in each case, the mass spectral data indicated deuterium incorporation. For instance, the *m*/*z* of the main mass spectral fragments (and the percentage abundance relative to the base peak) observed for phenylethane were 106 (27%), 91 (100%), 77 (9%), 65 (12%), and 51 (25%). The fragment at *m*/*z* 106 is the molecular ion, while the base peak with a *m*/*z* value of 91 corresponds to the $[C_7H_7]^+$ ion obtained from the rupture of the benzylic bond.

In the deuterolysis experiment, the *m*/*z* of the main mass spectral fragments for the compound eluting at a similar retention time as that of phenylethane were 108 (37%), 92 (100%), 77 (2%), 65 (7%), and 51 (4%). This is consistent with the incorporation of two deuterium atoms into the phenylethane molecule because the molecular ion has an *m*/*z* of 108 and the fragment with an *m*/*z* of 92 suggests that the $[C_7H_6D]^+$ ion formed in the fragmentation of the molecule. It has been concluded, therefore, that one of the products formed on deuterolysis of the reaction mixture is phenylethane-1,2-d_2. A similar analysis of the mass spectral data of the remaining deuterolysis products suggests that *dl*-2,3-DPB-1,4-d_2, *meso*-2,3-DPB-1,4-d_2, and 1,3-DPB-1,4-d_2 are formed. The mass spectral data of the isomeric diphenylbutanes and their deuterated analogues are presented in Table 2.

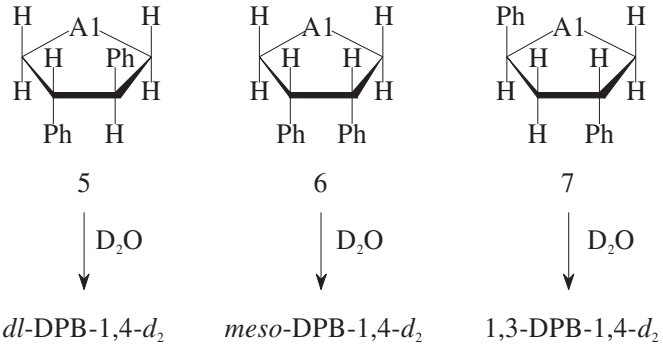
[a] The numbers in parentheses represent the relative abundance of the fragment.

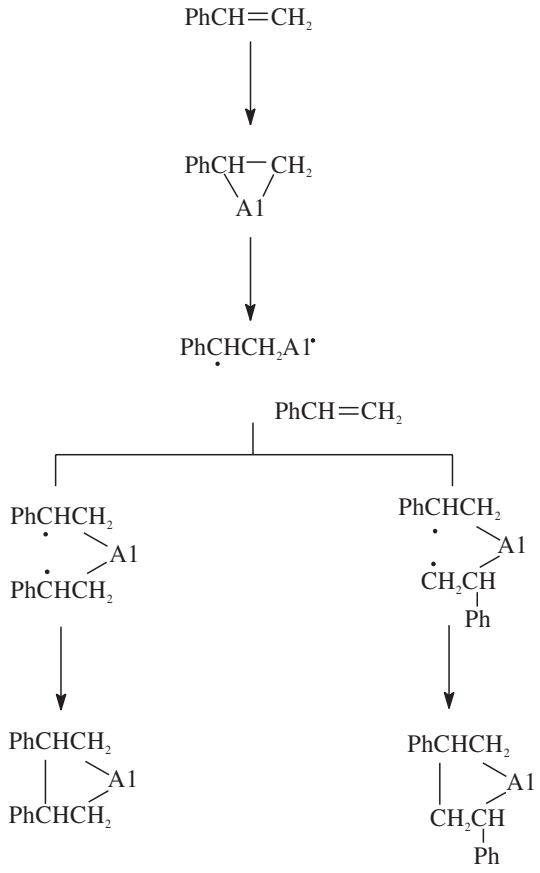
Scheme 1.



where Al was attached in the original organometallic intermediates. The formation of the dideuteriodiphenylbutanes suggests that two C—Al bonds have been ruptured and replaced in the hydrolysis process by deuterium atoms. The deuterolysis of the aluminacyclopentane intermediates **5**, **6**, and **7** would yield the dideuteriodiphenylbutanes observed in the study, Scheme 1.

Aluminacyclopentanes (3, 4, 7, 8) have been observed spectroscopically in the Al atom reactions of alkenes. In the reaction of Al atoms with ethylene (3, 4), a paramagnetic mononuclear aluminium species with EPR parameters similar to those reported for aluminacyclopentene (9) was detected. In addition, the $M_I = 1/2$ line of the organoaluminium species resolved, upon annealing the Al–ethylene sample, to give a quintet of quintets from the interaction of the unpaired electron with four equivalent hydrogen atoms with a hyperfine interaction (hfi) of 4.0 G, and with four equivalent hydrogen atoms with an hfi of 2.5 G. The two sets of four protons are consistent with aluminacyclopentane where the four protons on the two carbons adjacent to the Al have a 4 G hfi while the four protons on the β carbons have a 2.5 G hfi.

Scheme 2.

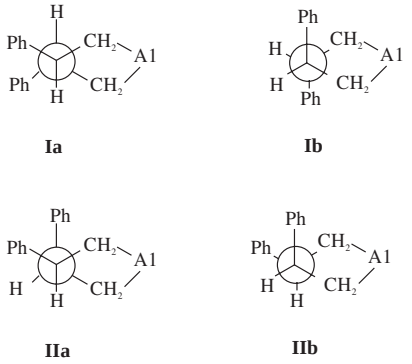


A possible mechanism for the formation of the aluminacyclopentane adducts involves the three-step process shown in Scheme 2. In the first step, Al atoms add in a concerted fashion to styrene to give 2-phenylaluminacyclopropane. The C—Al bond dissociates in a second step to give the most stable alumina–carbon radical. Then, the addition of a second molecule of styrene results in the formation of a diradical. To explain the formation of both 2,3- and 1,3-diphenylbutane, two different diradical intermediates must form, i.e., attack of the β-carbon of styrene by the β-alumina carbon radical results in the diradical that is the precursor of 2,3-diphenylbutane, whereas attack of the α-carbon of styrene results in the diradical responsible for the formation of 1,3-diphenylbutane. In the third step, a bond forms between the two radical centres to form the aluminacyclopentane intermediates. The fact that the *dl* isomer is favoured over the *meso* isomer suggests that ring closure is stereoselective. One could argue that the transition state energy for ring closure is lower when the *gauche* interactions between the phenyl groups and the CH_2 groups are minimized, as is the case for structure **Ia**, Fig. 1. As a result, it is reasonable to expect that the formation of **Ia** will be favoured kinetically and that the *dl* isomer will form more readily than the *meso* isomer.

However, there is some concern about the fact that the diradical, which is proposed to be responsible for the formation

© 1998 NRC Canada

Fig. 1. Newman projections representing conformations of the *trans* (**Ia**, **Ib**) and *cis* (**IIa**, **IIb**) 3,4-diphenylaluminacyclopentane.



of 1,3-diphenylbutane, has a primary radical centre. The relative stabilities of the primary versus the benzyl radical centre can be estimated by comparing bond dissociation energies. For instance, the bond dissociation energy of the secondary C—H bond of phenylethane (18) is 357.3 kJ/mol whereas the bond dissociation energy of the primary C—H bond of ethane (18) is 422.8 kJ/mol. The benzyl radical is therefore significantly more stable than the primary radical centre. Considering that the 1,3 isomer represents anywhere from 3.4 to 9.4% of the reaction mixture, one would expect that the difference in energies of the intermediates leading to formation of the 1,3 and 2,3 isomers would only be of the order of 4.184 kJ/mol and not of the order of 422.8 – 357.3 or 65.5 kJ/mol. Therefore, it is unlikely that the Al atom reaction of styrene proceeds via the stepwise mechanism proposed above.

Shusterman et al. (19) have suggested that dimethylgermylene produced by the thermal decomposition of 7,7-dimethyl-1,4,5,6-tetraphenyl-7-germabenzonorbornadiene adds to (*E*)-2-deuteriostyrene by a mechanism comparable to that shown in Scheme 2. These workers found that only the *cis* and *trans* isomers of 2,5-dideuterio-1,1-dimethyl-3,4-diphenylgermacyclopentane were formed. There was no evidence for the formation of 1,1-dimethyl-2,4-diphenylgermacyclopentane. In addition, unlike the Al atom reaction, the *cis* and *trans* isomers were formed in a 1:1 ratio.

Alternatively, the Al–styrene reaction could proceed by a two-atom insertion into the 2-phenylaluminacyclopropane, Scheme 3. In this process, the β-alumina radical, PhĊH-CH_2Al, is trapped by styrene in a concerted manner. The fact that three isomers of diphenylbutane were observed suggests that the radical character of the α and β carbons in the transition state is not very advanced, i.e., the transition state is early. The observation that the reaction mixtures always contain greater amounts of the *dl* isomer can be explained in terms of a steric effect. The transition state energy is lowest for the structure where the phenyl rings are *trans*. The phenylethane forms from the hydrolysis of 2-phenylaluminacyclopropane. The incorporation of two deuterium atoms into the phenylethane, at the α and β carbons, is consistent with this interpretation.

Seyferth and co-workers (20, 21) suggested that hexamethylsilirane transfers Me_2Si to styrene, giving 1,1,2,2,3,3-hexamethyl-5-phenylsilacyclopentane by a two-atom insertion comparable to that proposed for the Al–styrene reaction.

Next, Al atoms were added to α-methylstyrene. The hydrolysis of the organoaluminium intermediates gave two main products. The compound that eluted first had a retention time and mass spectrum identical to those of an authentic sample of 2-phenylpropane. The *m*/*z* values of the main mass spectral fragments (and the percentage abundance relative to the base peak) observed for the second compound were 119 (100%), 103 (7.2%), 91 (57.5%), 77 (11.9%), 65 (3.3%), and 51 (6.2%). These data are consistent with 2,3-dimethyl-2,3-diphenylbutane. The base peak has an *m*/*z* of 119 and is assigned to $[C_6H_5C(CH_3)_2]^+$. The peak at an *m*/*z* of 91 is due to $[C_7H_7]^+$ and forms as a result of the elimination of C_2H_4 from $[C_6H_5C(CH_3)_2]^+$. A molecular ion was not observed, as was the case for the symmetric compound, 2,3-diphenylbutane. The 2-phenylpropane can be explained by the hydrolysis of 2-methyl-2-phenylaluminacyclopropane, formed by the concerted addition of Al atoms to α-methylstyrene. The 2,3-dimethyl-2,3-diphenylbutane is formed upon hydrolysis of 3,4-dimethyl-3,4-diphenylaluminacyclopentane. Support for this structure comes from the deuterolysis experiments, which indicate that deuterium is incorporated in the methyl groups (at C1 and C4), Table 3. The aluminacyclopentane intermediate could form in one of at least two ways. The first reaction pathway involves the addition of the β-alumina-α-methylstyrl radical, PhĊ$(CH_3)CH_2$Al, to α-methylstyrene yielding the diradical, PhĊ$(CH_3)CH_2AlCH_2(CH_3)$Ċ Ph. The diradical ring closes in a subsequent step to give Ph$\overline{C(CH_3)CH_2AlCH_2(CH_3)C}$Ph. The

2,3-Dimethyl-2,3-DPB-1,4-d_2	120 (100, $[C_6H_5C(CH_3)(CH_2D)]^+$), 104 (5.2), 92 (32.7), 91 (64.8), 77 (15.0), 65 (4.5), 51 (9.3)

[a] The numbers in parentheses represent the relative abundance of the fragment.

β-alumina-α-methylstyrl radical could form by the ring opening of 2-methyl-2-phenylaluminacyclopropane.

Alternatively, the β-alumina-α-methylstyrl radical could insert into an α-methylstyrene molecule by a concerted two-atom insertion, as was suggested for styrene, yielding 3,4-dimethyl-3,4-diphenylaluminacyclopentane. We are not able to tell by which mechanism the reaction proceeds. However, it is interesting to note that there is no evidence for the formation of $PhC(CH_3)CH_2AlC(CH_3)PhCH_2$, suggesting that if the process were concerted the radical character of the transition state is advanced.

Reaction of other Group 13 metal atoms with styrene

The study was extended to include the reactions of several other Group 13 metal atoms, namely, Ga, In, and Tl, with styrene. In addition to phenylethane, *dl*-2,3-, *meso*-2,3-, and 1,3-DPB, hydrolysis of the Ga–styrene reaction intermediates resulted in the formation of compounds with retention times and mass spectral data identical to those of authentic samples of 1-phenylethanone and styrene oxide. A compound with mass spectral data consistent with 1-phenylethanol was also detected. (The formation of 1-phenylethanone, styrene oxide, and 1-phenylethanol will be the subject of a separate publication.) The ratio of the diphenylbutane isomers in the mixture is similar to that observed for the Al atom reaction in that the [*dl*] > [*meso*] > [1,3], Table 4. Also, the relative amounts of the *dl* and *meso* compounds are similar. However, there appears to be more of the 1,3-DPB formed in the Ga–styrene hydrolysis reaction. The deuterolysis of the Ga–styrene reaction mixture yielded phenylethane-1,2-d_2 (78%), *meso*-2,3-DPB-1,4-d_2 (13%), *dl*-2,3-DPB-1,4-d_2 (5.8%), and 1,3-DPB-1,4-d_2 (3.2%).

Phenylethane and the isomeric diphenylbutanes are the hydrolysis products of 2-phenylgallacyclopropane, *cis*- and *trans*-3,4-diphenylgallacyclopentane, and *cis*- and *trans*-2,4-diphenylgallacyclopentane. It would seem likely that the mechanism for the formation of the organogallium intermediates is comparable to that suggested for the reaction of Al atoms with styrene as the same product ratios and deuterium incorporation were observed for both cases. It is also worth noting that there is tentative EPR evidence for the formation of gallacyclopentane when Ga atoms are reacted with ethene (13).

Table 4. Relative amounts[a] of the isomeric diphenylbutanes found for the organoaluminium adducts formed in the reaction of Ga atoms with styrene at 77 K.

Entry	Relative amounts of the hydrolysis products[a]		
	2,3-DPB *dl*	2,3-DPB *meso*	1,3-DPB
1	60.8	23.1	16.1
2	67.3	21.7	11.0
3	65.8	22.1	12.1
4	67.7	21.5	10.8
5[b]	58.5	26.6	14.9
6[c]	52.5	28.5	19.9

[a] Based on $AC_i/\Sigma AC_i \times 100$ where AC_i is the area counts for product *i*, obtained from the electronic integration of the peaks in the total ion current chromatogram.

[b] D_2O was substituted for H_2O in the hydrolysis reaction.

[c] Cyclohexane was deposited as an inert matrix (vapour pressure 1 Torr) along with Ga and styrene (vapour pressure 0.1 Torr). No water was added to the reaction mixture until after the sample had been annealed to room temperature.

Indium and thallium atoms are not very reactive towards styrene. We were only able to detect traces of phenylethane in the hydrolyzed reaction mixtures. Klabunde and co-workers (22) found the reactivity order of Group 13 metal atoms/clusters for the reaction with methyl bromide to be Al > Ga > In > Tl. They argued that the reactivity displayed by the atoms would be influenced by the heats of vaporization (which are also in the order Al > Ga > In > Tl) in that the reactivity would depend on the energy put into the system during vaporization. Hauge et al. (23) have reported a similar reactivity dependency in Group 13 atom – water reactions. Whereas aluminium atoms were found to react spontaneously with water to form HAlOH, the corresponding Ga and In products were only formed after photolysis of the reaction matrix and no insertion product could be detected for the case of Tl and water.

Solvent effects on electrical conductivities of sodium tetraphenylboride in water methanol, ethanol, and 2-propanol mixed solvents

Yixing Zhao and Gordon R. Freeman

Abstract: As a foundation for a future measurement of solvated electron mobilities in alcohol–water mixed solvents, the electrical conductances of sodium tetraphenylboride (STPB) in methanol–water, ethanol–water, and 2-propanol–water were measured at different temperatures. The molar conductivity Λ_0 (10^{-4} S m^2 mol^{-1}) of STPB at 298 K is 70 in pure water and 82 in pure methanol; in methanol–water mixed solvents it passes through a minimum, the value being 45 at 70 mol% water. In 2-propanol–water Λ_0 (10^{-4} S m^2 mol^{-1}) at 298 K decreases rapidly from 70 in pure water to 22.6 in 80 mol% water, then gradually to 16.5 in pure 2-propanol. Behavior in ethanol–water is intermediate, with a minimum of 29.5 in 70 mol% water, gradually increasing to 35.5 in pure ethanol. The product of Λ_0 and the solvent viscosity η has a maximum at about 75 mol% water in methanol, 90 mol% water in ethanol, and 95 mol% water in 2-propanol. The effects are attributed to changes of solvent structure and of solvated ion radius as alcohol is added to water.

Key words: alcohol–water mixed solvents, electrical conductivity, large ions, solvent effects, activation energy.

Résumé : Dans le but de préparer le terrain pour de futures mesures des mobilités d'électrons solvatés dans des mélanges de solvants formés d'alcool et d'eau, on a mesuré les conductances du tétraphénylborure de sodium (TPBS) dans des mélanges de méthanol–eau, éthanol–eau et propan-2-ol–eau, à diverses températures. La conductivité molaire, Λ_0 (10^{-4} S m^2 mol^{-1}), du TPBS à 298 K est égale à 70 dans l'eau pure et de 82 dans le méthanol pur; dans des solvants mixtes méthanol–eau, elle passe par une valeur minimum de 45 à 70 mol% d'eau. Dans le mélange propan-2-ol–eau, la valeur de Λ_0 (10^{-4} S m^2 mol^{-1}) à 298 K diminue rapidement de 70 dans l'eau pure à 22,6 dans un mélange à 80 mol% d'eau; elle diminue ensuite graduellement jusqu'à une valeur de 16,5 dans le propan-2-ol pur. Le comportement dans des mélanges éthanol–eau est intermédiaire avec un minimum de 29,5 dans un mélange contenant 70 mol% d'eau, qui augmente graduellement jusqu'à 33,5 dans l'éthanol pur. Le produit de Λ_0 par la viscosité du solvant, η, passe par un maximum dans des mélanges à 75 mol% d'eau dans le méthanol, de 90 mol% d'eau dans l'éthanol et de 95 mol% d'eau dans le propan-2-ol. Les effets sont attribués à des changements dans la structure du solvant et dans les rayons des ions solvatés lorsqu'on ajoute de l'alcool à l'eau.

Mots clés : solvants mixtes alcool–eau, conductivité électrique, gros ions, effets de solvant, énergie d'activation.

Introduction

The study of electrical conductances of electrolytes in different solvents elucidates properties of ions and solvents (1–4), and provides reference data for solvent effects on the mobilities of solvated electrons (5–8). The electrical conductances of large-ion tetraphenylphosphonium and tetraphenylboride salts in C_1–C_4 alcohols were recently reported (2). The present paper extends the study to mixed alcohol–water solvents, as a foundation for a future measurement of solvated electron mobilities in these solvents. We have chosen sodium tetraphenylboride because its photoionization in solution would produce solvated electrons. In the solvent sequence methanol, ethanol, and 2-propanol, the molecular size increases and the molecule becomes more spherelike.

Experimental

The solute, solvents, purification method, and techniques of the conductance measurements have been reported in ref. 2.

Results and discussion

Low concentrations (0.025–0.125 mol m^{-3}) were used in the measurement of the electrical conductances of sodium tetraphenylboride (STPB) in all the solvents, and straight lines were obtained in the plots of specific conductance against solute concentration. This indicates that the ionic atmosphere effect (9) and ion association (10) were negligible.

Arrhenius plots of molar conductivities of STPB in water–methanol (Fig. 1), water–ethanol (Fig. 2), and water–2-propanol (Fig. 3) mixed solvents display considerable variation with solvent composition. Symbols used in Figs. 1–3 are listed in Table 1.

Molar conductivities of STPB

The molar conductivities Λ_0 of STPB in the three mixed solvent systems at 298 K are listed in Table 2 and plotted in Fig. 4*a* along with the viscosities η of the solvents (11, 12)

(Fig. 4*b*). The value of Λ_0 does not vary simply inversely as η in these three mixed solvent systems.

In pure ethanol at 298 K, $\Lambda_0 = 35.5$ (10^{-4} S m^2 mol^{-1}, Table 2) is preferred to the previously reported value of 35.0 (2).

Plots of $\eta\Lambda_0$ against solvent composition display a maximum at about 75 mol% water in methanol, 90 mol% water in ethanol, and 95 mol% water in 2-propanol (Fig. 5). The presence of a small amount of alcohol in water alters the solvent

structure, probably by changing the hydrogen-bond configurations toward an ice-like structure, and thereby increasing the viscosity (11). However, the shear viscosity increases more rapidly than the ion mobilities decrease, possibly because the ions disrupt the solvent structure in their vicinity.

Addition of further alcohol to the water decreases $\eta\Lambda_0$, because some of the water molecules that solvate the ions are replaced by alcohol molecules, thereby increasing the solvated ion radius. In the pure alcohols or water the radii of the solvated ions are roughly proportional to $(N + 1)^{1/2}$, where N is the number of carbon atoms in the molecule, the 1 represents the oxygen atom, and the square root represents a randomly folded chain. The values of $\eta\Lambda_0(N + 1)^{1/2}$ at 298 K are 62 in water, 65 in methanol, 68 in ethanol, 69 in 2-propanol, in satisfactory agreement with Walden's rule.

Activation energy $E_{\Lambda 0}$ and E_η

The values of $E_{\Lambda 0}$ and E_η have the same pattern (Fig. 6), and the values of $E_{\Lambda 0}$ are close to those of E_η (Table 2). In the alcohol-rich regions the values of $E_{\Lambda 0}$ are slightly lower than those of E_η, whereas in the water-rich regions $E_{\Lambda 0}$ is equal to or slightly larger than E_η. This might indicate that the ions are

less tightly solvated by alcohol molecules than by water molecules.

Conclusions

The present work provides a foundation for the measurement of solvated electron mobilities in alcohol–water mixed solvents. Values of the mobilities are needed to better understand the solvent composition dependence of reaction rate constants of solvated electrons with diverse solutes in alcohol–water mixtures (5, 6, 8, 11–14). Knowledge of the transport behavior of electrons in these molecular-scale structures (hydrogen-bonded liquids) would also provide insight into the behavior of electrons in sub-nanometer-component systems.

Mixtures of water with the sequence of alcohols CH_3OH, CH_3CH_2OH, and $(CH_3)_2CHOH$ should be extended to $(CH_3)_3COH$, to include the most globular alcohol that is completely miscible with water. Unfortunately, G.R.F. passed retirement age, the Radiation Research Centre was closed, research always opens new questions, so this last experimental article from our group is left with open circuits.

It would also be valuable to measure the change of transference numbers of $Na^+$and $(C_6H_5)_4B^-$ ions with solvent composition, to give information about selective solvation of small inorganic and large organic ions in the alcohol–water mixtures.

We hand a torch, not a baton, to the next generation.

Optical absorption spectrum of solvated electrons in pure *tert*-butanol: effect of temperature

Yixing Zhao and Gordon R. Freeman

Abstract: The energy and asymmetry of the optical absorption spectrum of solvated electrons, e_s^-, change in a nonlinear fashion on changing the solvent through the series HOH, CH_3OH, CH_3CH_3OH, $(CH_3)_2CHOH$, $(CH_3)_3COH$. The ultimate, quantum-statistical mechanical, interpretation of solvated electron spectra is needed to describe the solvent dependence. The previously reported optical spectrum of e_s^- in *tert*-butanol was somewhat inaccurate, due to a small amount of water in the alcohol and to limitations of the infrared light detector. The present note records the remeasured spectrum and its temperature dependence. The value of the energy at the absorption maximum (E_{Amax}) is 155 zJ (0.97 eV) at 299 K and 112 zJ (0.70 eV) at 338 K; the corresponding values of $G\varepsilon_{max}$ (10^{-22} m^2 aJ^{-1}) are 1.06 and 0.74. These unusually large changes are attributed to the abnormally rapid decrease of dielectric permittivity of *tert*-butanol with increasing temperature. The band asymmetry at 299 K is $W_b/W_r = 1.8$.

Key words: optical absorption spectrum, solvated electron, solvent effects, *tert*-butanol, temperature dependence.

Résumé : L'énergie et l'asymétrie des spectres d'absorption optique des électrons solvatés, e_s^-, changent d'une façon non linéaire lorsqu'on passe de l'un à l'autre des solvants suivants : HOH, CH_3OH, CH_3CH_2OH, $(CH_3)_2CHOH$, $(CH_3)_3COH$. Pour décrire l'influence du solvant, il sera nécessaire de faire appel à l'interprétation ultime des spectres des électrons solvatés, basée sur la mécanique quantique statistique. Le spectre optique de e_s^- dans le *tert*-butanol qui a été rapporté antérieurement n'était pas complètement exact à cause d'une faible quantité d'eau dans l'alcool et des limitations du détecteur de la lumière infrarouge. La présente note corrige les données relatives au spectre et à sa dépendance sur la température. La valeur de l'énergie au niveau de l'absorption maximale (E_{Amax}) est égale à 155 zJ (0,97 eV) à 299 K et de 112 zJ (0,70 eV) à 338 K; les valeurs correspondantes de $G\varepsilon_{max}$ (10^{-22} m^2 aJ^{-1}) sont égales à 1,06 et 0,74. On attribue ces changements particulièrement importants à la diminution anormalement rapide de la permittivité diélectrique du *tert*-butanol avec une augmentation de la température. L'asymétrie de la bande à 299 K est $W_b/W_r = 1,8$.

Mots clés : spectre d'absorption optique, électron solvaté, effets de solvant, *tert*-butanol, dépendance sur la température.

[Traduit par la rédaction]

Introduction

The optical absorption spectrum of solvated electrons (e_s^-) in an alcohol solvent shifts to lower energy on going from a primary to a secondary to a tertiary alcohol (1). In the isomeric butanols at 298 K the energies at the absorption maximum (E_{Amax}) were reported to be 317 zJ (1.98 eV) in 1-butanol, 254 zJ (1.59 eV) in 2-butanol, and 179 zJ (1.12 eV) in *tert*-butanol (2-methyl-2-propanol). The absorption energy in *tert*-butanol is especially sensitive to the presence of a small amount of water, so we have measured the spectrum in more thoroughly dried *tert*-butanol, and determined the temperature dependence. The solvent density and dipole correlation decrease with increasing temperature, which decreases the e_s^- optical absorption energy (ref. 2, Fig. 6 and associated discussion; each ref. no. in Fig. 6 legend should be increased by 2).

When an adequate quantum-statistical mechanical model of solvated electrons is ultimately formulated, it will accommodate the nonlinear shifts in optical absorption energy and band asymmetry on changing the solvent through the series HOH, CH_3OH, C_2H_5OH, $(CH_3)_2CHOH$, and $(CH_3)_3COH$. The present note reports e_s^- spectrum data for the last solvent in that series, *tert*-butanol; data for the spectra in the other solvents are recorded elsewhere (refs. 1, 2, and refs. therein).

In the report of solvent effects on the reactivity of e_s^- with $NO_{3,s}^-$ in C_1–C_4 alcohols (3) and in *tert*-butanol–water mixed solvents (4), an optical absorption energy E_r (halfway up the low-energy side of the band) in *tert*-butanol at 299 K was listed from unpublished work. The present note reports that work.

Experimental

The *tert*-butanol was obtained from Fluka (> 99.7%). Reference 4 reports the purification method. The water content, measured by Karl-Fisher titration, was <0.05 mol%. The freezing point of pure *tert*-butanol is 298.6 K.

The optical absorption spectrum of e_s^- was measured at 299 K, 319 K, and 338 K over the energy range 99–397 zJ (λ = 2000–500 nm). A fresh sample of purified *tert*-butanol was

used for the measurement at each temperature. The technique of the optical measurement has been reported in ref. 5.

Results and discussion

The optical absorption spectra of e_s^- in pure *tert*-butanol at 299 K, 319 K, and 338 K are shown in Fig. 1. The spectra are broad and asymmetric, skewed toward higher energies. The nonhomogeneously broadened spectrum has no fine structure (6, 7).

As the temperature was increased the magnitude of absorption decreased and the energy at the absorption maximum (E_{Amax}) shifted to a lower energy (Fig. 1). The decrease in magnitude of absorption is attributed to a decrease of free ion yield, because the value of the product of the dielectric permittivity D and the temperature T decreases with increasing temperature in *tert*-butanol (8, 9). The value of E_{Amax} decreases with increasing temperature because thermal agitation of the solvent molecular dipoles makes the electron traps more shallow (1).

The relative rate of decrease of E_{Amax} with increasing temperature, expressed as $(E_{Amax})^{-1}(-dE_{Amax}/dT) = -d(\ln E_{Amax})/dT$, is much larger in *tert*-butanol (0.0084 K^{-1}) than in water (0.0014 K^{-1}), methanol (0.0013 K^{-1}), ethanol (0.0018 K^{-1}), or 2-propanol (0.0030 K^{-1}); the values other than that for *tert*-butanol were calculated from data in ref. 1*a*, pp. 169 and 211, ref. 1*b*, Table 1, and ref. 2, Fig. 6. The relative temperature coefficient in an alcohol is larger when the alkyl group is more globular. The globular *tert*-butanol molecules are sterically hindered from strongly aligning four -O–H dipoles in the field of the electron, and the alignment is more easily disturbed by thermal agitation than appears to be the case in the other liquids. The relatively easy thermal disturbance of dipole alignment in *tert*-butanol is reflected in the relatively rapid decrease of DT with increasing T (ref. 8, Fig. 4).

Optical excitation energies of e_s^- in 1-butylamine (5) are even lower than those in *tert*-butanol, which made the amine an interesting solvent in which to study e_s^- reaction rate constants (10). Reaction rate constants of e_s^- with certain solutes are larger when the e_s^- optical absorption energies are smaller. Parameter values of the optical absorption spectrum of e_s^- in *tert*-butanol are compared with those in 1-butylamine and in water (the usual standard for comparison) in Table 1: E_{Amax}, the maximum absorption $G\varepsilon_{max}$, the energies E_r and E_b halfway up the low- (red) and high- (blue) energy sides of the band, the width of the band at half-height ($W_{1/2}$), the band asymmetry W_b/W_r, and the relative temperature dependence of the optical absorption energy $-d(\ln E_{Amax})/dT$. From the data in Table 1 one may interpolate that, at a given temperature, on going from water to *tert*-butanol to 1-butylamine the values of $G\varepsilon_{max}$ and E_{Amax} decrease, while the band asymmetry increases. The relative temperature dependence of the optical absorption is anomalously high in *tert*-butanol, due to the unusually rapid decrease of D with increasing T of that liquid (Table 1; ref. 8, Fig. 4).

The values of E_{Amax} correlate roughly with the product of D and the density d of these solvents (11).

The values of $G\varepsilon_{max}$ in these solvents correlate roughly with the product DT, due mainly to the variation of G, the free ion yield of e_s^- (9). The values of G (free ion e_s^-/16 aJ) at 298 K are 2.7 in water (2), 0.67 in *tert*-butanol (15), and about 0.27

© 1998 NRC Canada

in 1-butylamine (5), which give respective values of ε_{max} (10^{-21} m^2/e_s^-) = 3.1, 2.5, and about 5.3.

The values of the band width $W_{1/2}$ are similar in these three solvents (Table 1). We suggest that as E_{Amax} decreases, excitation to the continuum contributes an increasing portion of the total band (ref. 16, and references therein).

We await a quantum-statistical mechanical model that is consistent with these behaviors of e_s^-. The all-atom force field model (17), applied through Monte Carlo techniques to molecular reactions (18), holds promise for e_s^- properties and reactions. Polarization effects are important in low-dielectric media (19), but must also be very important in all organic liquids, including alcohols.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada for financial assistance, and the staff of the Radiation Research Center for maintaining the electronic equipment. G.R.F. is grateful to the University of Alberta for generous support of the Radiation Research Center and its personnel during three decades. The R.R.C. is now closed, and the personnel are members of the Chemistry Department.

Tripodal trisamides based on nicotinic and picolinic acid derivatives

H.R. Hoveyda, Veranja Karunaratne, Christopher J. Nichols, Steven J. Rettig, Ashley K.W. Stephens, and Chris Orvig

Abstract: A number of polydentate arylamide ligands have been prepared by coupling various acyclic tripodal or linear polyamines with derivatives of nicotinic and picolinic acids. Two synthetic procedures were utilized; tris{[(2-hydroxynicotinyl)carbonyl]-2-aminoethyl}amine (H_3NICTREN) was prepared by Method A, the HOSu/DCC method, and the other arylamides in this study were prepared by Method B, the CDI method. Method A involved the reaction of *N*-hydroxysuccinimide with 2-hydroxynicotinic acid (in the presence of dicyclohexylcarbodiimide (DCC) as a dehydrative coupling reagent) to form the succinimide ester, followed by reaction with TREN to yield H_3NICTREN. Method B involved reaction of a carboxylic acid (2-hydroxynicotinic, 3-hydroxypicolinic, nicotinic, or picolinic acids) with carbonyldiimidazole (CDI) to form the *N*-acylimidazolide, followed by reaction with the amine (TREN, TAME, spermidine, or TRPN) to yield the desired arylamide. The X-ray structure of 1,1,1-tris{[(3-hydroxypicolinyl)carbonyl]-2-aminomethyl}ethane (H_3PICTAME) was determined; crystals of H_3PICTAME are monoclinic, $a = 10.257(2)$, $b = 15.572(3)$, $c = 15.208(2)$ Å, $\beta = 96.124(15)°$, $Z = 4$, space group $P2_1/a$. The structure was solved by direct methods and refined by full-matrix least-squares procedures to $R = 0.041$ and $R_w = 0.038$ for 2506 reflections with $I \geq 3\sigma(I)$. In the solid state, H_3PICTAME contains an extensive hydrogen-bonding network, with eight intra- and one intermolecular H-bonds per molecule; the ligand is partially preorganized for metal ion chelation. The acid dissociation constants of H_3NICTREN and those of 1,1,1-tris{[(2-hydroxynicotinyl)carbonyl]-2-aminomethyl}ethane (H_3NICTAME) have been determined; $pK_{a1} = 11.2$ (10.68), $pK_{a2} = 10.7$ (10.58), $pK_{a3} = 10.0$ (9.71), and $pK_{a4} = 6.25$ for H_3NICTREN (H_3NICTAME); the high phenolic pK_a'*s* are consistent with the hydrogen bonding observed in the solid state.

Key words: arylamide, hydrogen bonding, preorganization.

Résumé : On a préparé une série de ligands arylamides polydentates en procédant au couplage de diverses polyamines linéaires ou acycliques tripodaux avec des dérivés des acides nicotinique et picolinique. On a fait appel à deux voies de synthèse : on a préparé la tris{[(2-hydroxynicotinyl)carbonyl]-2-aminoéthyl}amine (H_3NICTREN) par la méthode A, la méthode au HOSu/DCC, alors que les autres arylamides examinés dans cette étude ont été préparés par la méthode B, la méthode CDI. La méthode A implique la réaction du *N*-hydroxysuccinimide avec l'acide 2-hydroxynicotinique (en présence de dicyclohexylcarbodiimide (DCC) comme agent de couplage déshydratant) qui conduit à l'ester succinimide, suivie d'une réaction avec du « TREN » pour obtenir le H_3NICTREN. La méthode B implique la réaction d'un acide carboxylique (acides 2-hydroxynicotinique, 3-hydroxypicolinique, nicotinique ou picolinique) avec le carbonyldiimidazole (CDI) pour former le *N*-acylimidazolide, suivie d'une réaction avec l'amine (« TREN », « TAME », spermidine ou « TRPN ») conduisant à l'arylamide désiré. On a déterminé la structure cristalline du 1,1,1-tris{[(3-hydroxypicolinyl)carbonyl]-2-aminométhyl}éthane (H_3PICTAME). Les cristaux sont monocliniques, groupe d'espace $P2_1/a$, avec $a = 10{,}257(2)$, $b = 15{,}572(3)$ et $c = 15{,}208(2)$ Å, $\beta = 96{,}124(15)°$ et $Z = 4$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}041$ et $R_w = 0{,}038$ pour 2506 réflexions avec $I \geq 3\sigma(I)$. À l'état solide, le H_3PICTAME comporte un important réseau de liaisons hydrogènes, avec huit liaisons intra- et une liaison intermoléculaire par molécule; le ligand est partiellement préorganisé pour donner une chélation avec le métal. On a déterminé les constantes de dissociation acide du H_3NICTREN et du 1,1,1-tris{[(3-hydroxypicolinyl)carbonyl]-2-aminométhyl}éthane (H_3PICTAME) qui sont respectivement : $pK_{a1} = 11{,}2$ (10,68), $pK_{a2} = 10{,}7$ (10,58), $pK_{a3} = 10{,}0$ (9,71) et $pK_{a4} = 6{,}25$; les valeurs élevées du pK_a des phénols sont en accord avec les liaisons hydrogènes observées à l'état solide.

Mots clés : arylamide, liaison hydrogène, préorganisation.

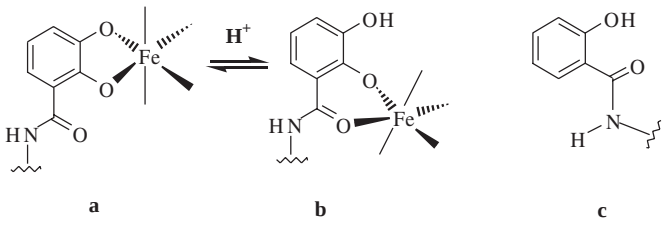
Introduction

In searching for new ligands to be used in the sequestration of trivalent metal ions (e.g., group 13 and lanthanides), much insight can be gained from an examination of naturally occurring chelating agents for trivalent iron. The physical and chemical similarities between Fe(III) and group 13 metals, especially Ga(III), are rather pronounced; they share the same charge and similar ionic radii, e.g., 0.645 Å for Fe(III) compared to 0.620 Å for Ga(III) (1). In addition, the electronic configuration of (aqueous) ferric ion is high-spin d^5, while the group 13 metal ions are diamagnetic (Al(III), d^0; Ga(III) and In(III), d^{10}), and, accordingly, none of these metal ions or the lanthanides are perturbed by crystal field effects (2). The kinship between Ga(III) and Fe(III) is nicely reflected in the kinetics of ligand exchange, for instance, the first-order water exchange rates for Ga(III) and Fe(III) (at 298 K) are 4.0×10^2 and 1.6×10^2 s^{-1}, respectively (3). Also, microorganisms and plants have evolved a host of low-molecular-weight ligands; the *siderophores* (for a general overview, see ref. 4), which show both a high affinity and a high specificity for Fe(III) (formation constants ranging from 10^{25} to 10^{49}) (5). Therefore, in a biomimetic approach, the knowledge gained from ferric ion transport can be applied, for example, to the development of ^{67}Ga radiopharmaceuticals (6, 7). Our approach in designing the ligands prepared in this paper has been biomimetic, as is outlined below.

Enterobactin forms one of the most stable Fe(III) complexes known (8), with an overall stability constant of 10^{49} (9). The backbone of this macrocyclic ligand is derived from three L-serine units, and it utilizes three catechol moieties to sequester Fe(III) in a hexadentate coordination sphere as in Fig. 1a (10–12). However, since the effective ligand is the conjugate base form (the catecholate), the coordination environment of the metal ion is a function of pH. In a series of studies (13–15), Raymond and co-workers have unequivocally established that sequential protonation of the ferric enterobactin complex (three one-proton steps) results in a concomitant shift from a "catechol binding mode" to a "salicylate binding mode" (see Fig. 1). The "arylamides" that possess the structural features depicted in Fig. 1c may thus be considered as "salicylate type"

Fig. 1. Catecholate (**a**) and salicylate (**b**) modes of bonding for the pH-dependent coordination environments of Fe(III) bound to catechoylamide ligands. Prototypical "arylamide" ligand in protonated form (**c**).

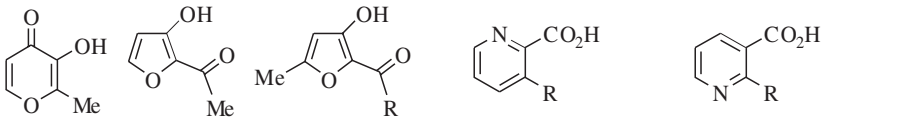


a **b** **c**

ligands, potentially capable of metal ligation via the phenolate oxygen and the amide carbonyl oxygen.

It was our interest in maltol as an effective bidentate chelating ligand for group 13 metal ions (16, 17) that instigated the investigation of its structural isomer, isomaltol, as yet another naturally occurring bidentate chelator (18). However, once it was established that isomaltol was not a good ligand for the formation of other hexadentate ligands (i.e., its denticity cannot be increased via an imine linkage), due to nucleophilic attack being favored at the C-5 carbon (19), attention was turned to using the amide linkage both as a metal binding group, as well as the "arm" to increase the denticity of the ligand. As a consequence, a bidentate analog Hahm was synthesized starting from the appropriate ethyl ester Hehm (19). In spite of the fact that Al and Ga tris(ligand) complexes could be isolated with Hahm, it was discovered that in H_2O, Hahm undergoes decomposition that is time, concentration, and pH dependent (19).

Given the fact that, in general, the half-life for hydrolysis of an amide bond (in neutral aqueous solution) is ca. 7 years (20), it is clear that replacement of the furan with another aromatic ring system would do much to alleviate the instability of these ligands, not to mention the reduction in the number of steps required for the ligand synthesis. Therefore, we have used derivatives of nicotinic and picolinic acid as (commercially available) starting materials for the formation of new arylamide ligands.



Maltol Isomaltol R = OEt (Hehm) R = N(H)Me (Hahm) R = H OH nicotinic acid 2-hydroxy-nicotinic acid (H_2nic) R = H OH picolinic acid 3-hydroxy-picolinic acid (H_2pic)

Experimental

Materials and methods

All chemicals were reagent grade and were used as received from commercial vendors (Aldrich and Sigma) unless otherwise stated. 1,1,1-Tris(azidomethyl)ethane was prepared according to a literature procedure (21). THF was distilled from Na benzophenone ketyl under Ar prior to use; 1,4-dioxane was predried over activated 4Å molecular sieves before use. Water was deionized (Barnstead D8902 and D8904 cartridges) and distilled (Corning MP-1 Megapure still). Plates used for thin-layer chromatography (TLC) were aluminum-supported 0.2 mm silica gel 60 F_{254} (EM Science). Column chromatography was carried out using 230–400 mesh size silica gel

© 1998 NRC Canada

(E. Merck, Silica Gel 60) and the "flash" technique (22), or by using lipophilic Sephadex LH-20™. All reactions were carried out under N_2 unless otherwise noted. The yields reported refer to isolated yields.

Instrumentation

NMR spectra were recorded on Bruker WH-400 (^{1}H NMR, 400 MHz), or Bruker AC-200E (^{1}H NMR, 200 MHz; ^{13}C NMR, 50 MHz) instruments. ^{1}H NMR data are reported as δ downfield from TMS (external reference) at 400 MHz in DMSO-d_6 unless otherwise noted. ^{13}C NMR data are reported as δ downfield from TMS (external reference) at 50 MHz in DMSO-d_6 unless otherwise noted. Infrared (IR) spectra were recorded as KBr disks in the range 4000–400 cm^{-1} on a Perkin Elmer PE 783 spectrophotometer and were referenced to polystyrene unless stated otherwise. Mass spectra (MS) were obtained with a Kratos MS 50 (electron-impact ionization, EI), an AEI MS 9, or a Kratos Concept IIH (fast-atom-bombardment ionization, FAB). Melting points were measured on a Mel-Temp apparatus and are uncorrected. Analyses were performed on a Carlo Erba elemental analyzer by Mr Peter Borda of this department.

Syntheses

Caution! *The handling of polyazides in large quantities may be hazardous. DCC is a severe skin irritant!*

1,1,1-Tris(aminomethyl)ethane (TAME)

TAME was prepared with some modifications to the reported method (21). To a solution of 1,1,1-tris(azidomethyl)ethane (16.8 g, 0.086 mol) in THF (200 mL) at 0°C, lithium aluminium hydride (LAH) (14.0 g, 0.364 mol) was added in small portions over 30 min. The resulting white-grey slurry was stirred at 0°C for 10 min, allowed to warm up to 20°C, and then refluxed for 24 h. The mixture was cooled to 0°C and NaOH (50 mL, 8 M) was added slowly to quench the excess LAH. To the resulting off-white slurry was added Et_2O (500 mL) and the reaction mixture was stirred for 30 min. The off-white precipitate was filtered off and washed with Et_2O. The combined filtrate and washings were dried ($MgSO_4$), and the solvent was removed on a rotary evaporator to afford TAME (8.6 g, 86%) as a pale yellow oil. ^{1}H NMR and IR spectra of the product thus obtained were identical with those previously reported (21). This product was used without any further purification.

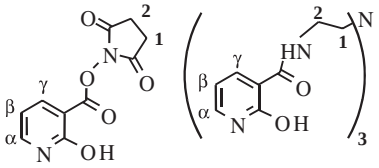
Tris(aminopropyl)amine (TRPN)

TRPN was made by reduction of nitrilotrispropionamide with LAH in THF with some modifications to the reported method (23). The intermediate trisamide was synthesized as follows. To a suspension of acrylamide (43.0 g, 0.60 mol) in H_2O (20 mL) was added 26 g of 30% NH_4OH (0.22 mol). The solution became clear in ca. 10 min, and the mixture was left stirring at 20°C for 24 h. The precipitate thus formed was filtered, washed with H_2O (3 × 10 mL), and dried in vacuo, yielding nitrilotrispropionamide (25 g, 57%). ^{1}H NMR and IR spectra of the product were identical with those previously reported.

To a suspension of the dry trisamide thus obtained (10.0 g, 0.04 mol) in 1000 mL of THF at 0°C, LAH (10.0 g, 0.26 mol) was added in small portions over 30 min. The resulting white-grey slurry was stirred at 0°C for 10 min, allowed to warm up to 20°C, and then stirred for 18 h. The mixture was then cooled to 0°C and NaOH (50 mL, 8 M) was added slowly to quench the excess LAH. To the resulting off-white slurry was added Et_2O (500 mL) and the reaction mixture was stirred for 30 min. The off-white precipitate was filtered and washed with Et_2O. The organic layer was separated, dried ($MgSO_4$), and evaporated to afford a yellow oil. The crude product was vacuum distilled (0.2 Torr; 1 Torr = 133.3 Pa) to remove the bisamine impurity (ca. 10% by ^{1}H NMR; 65°C) from the product (97–100°C), yielding 2.6 g (35%) of TRPN. ^{1}H and ^{13}C NMR spectra of TRPN thus synthesized were identical with those reported in the literature (23).

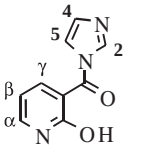
Method A: Succinimido 2-hydroxynicotinate (HOSuNic)

To a mixture of 2-hydroxynicotinic acid (1.370 g, 9.85 mmol) in THF (100 mL) was added *N*-hydroxysuccinimide (1.148 g, 9.98 mmol) and DCC (2.275 g, 11.03 mmol). The mixture was then refluxed for 20 h, whereupon it was allowed to cool to 20°C. The white precipitate was filtered, washed with CH_2Cl_2 (3 × 50 mL), and dried in vacuo. The crude product thus obtained was still contaminated with dicyclohexylurea (DCU). The product was purified via Soxhlet extraction (48 h) using CH_2Cl_2 to yield 1.02 g (42%) of HOSuNic. ^{1}H NMR: 2.98 (s, 4H^{1,2}), 6.49 (t, 1H$^{\beta}$, J = 7 Hz), 7.99 (dd, 1H$^{\gamma}$, J = 7, 2 Hz), 8.44 (dd, 1H$^{\alpha}$, J = 7, 2 Hz), 12.56 (br s, O*H*). MS (EI), *m/z*: 236 (M^+).

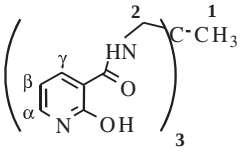


HOSuNic

H_3NICTREN



HImNic



H_3NICTAME

Tris{[((2-hydroxynicotinyl)carbonyl]-2-aminoethyl}amine (H_3NICTREN)

To a mixture of HOSuNic (1.17 g, 4.95 mmol) in THF (200 mL) was added TREN (0.240 g, 1.64 mmol) in one portion. The resultant mixture was refluxed for 18 h, whereupon it was left to cool to 20°C. The white precipitate was filtered, washed with CH_2Cl_2 and Et_2O, and dried in vacuo to afford H_3NICTREN (0.73 g, 87%), mp 242°C (dec.). IR: 3640–2600 (br, ν_{OH}), 3280 (m, ν_{NH}), 1680 (s, $\nu_{C=O}$), 1610 (m, $\nu_{C=C}$), 1560 (s, amide II (24)), 1473 (m, $\nu_{C=C}$), 1328, 1255, 1060, 980. ^{1}H NMR: 2.68 (t, 6H^1, J = 6 Hz), 3.10–3.60 (partially obscured m, 6H^2), 6.43 (t, 3H$^{\beta}$, J = 6 Hz), 7.64 (dd, 3H$^{\gamma}$, J = 6, 4 Hz), 8.28

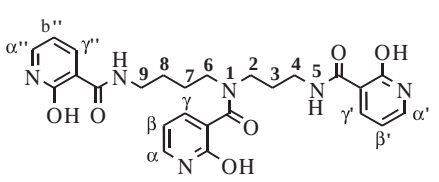
(dd, 3H$^{\alpha}$, J = 6, 4 Hz), 9.79 (t, 3H, C(O)N*H*, J = 6 Hz), 12.20 (br s, 3H, O*H*). ^{13}C NMR (DMSO-d_6): 37.42 (C*1*), 53.46 (C*2*), 106.14 (Cb), 120.63 (Cγ), 139.30 (Cα), 143.77 (Cδ), 162.32 (*C*-OH), 163.36 (*C*═O). Anal. calcd. (found) for $C_{24}H_{27}N_7O_6 \cdot 0.5H_2O$: C 55.60 (55.42), H 5.21 (5.33), N 18.90 (18.83).

Method B: N-*(2-Hydroxynicotinyl)-imidazole (HImNic)*
To a mixture of 2-hydroxynicotinic acid (5.34 g, 38.4 mmol) in THF (200 mL) was added CDI (6.43 g, 39.4 mmol) in one portion. The mixture was refluxed for 19 h. After cooling the reaction mixture to 20°C, the white precipitate was filtered, washed with Et_2O, and dried in vacuo to afford HImNic (6.65 g, 98%). ^{1}H NMR: 6.38 (t, 1H$^{\beta}$, J = 6.6 Hz), 7.05 (dd, 1H^{4}, J = 1.6, 0.8 Hz), 7.61 (t, 1H^{5}, J = 1.6 Hz), 7.74 (dd, 1H$^{\gamma}$, J = 6.3, 2.2 Hz), 7.93 (dd, 1H$^{\alpha}$, J = 6.3, 2.2 Hz), 8.16 (t, 1H^{2}, J = 0.8 Hz), 12.32 (br s, O*H*). MS (EI), *m/z*: 189 (M$^+$). Anal. calcd. (found) for $C_9H_7N_3O_2$: C 57.14 (56.95), H 3.73 (3.81), N 22.21 (22.15).

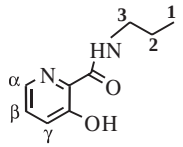
Tris{[(2-hydroxynicotinyl)carbonyl]-2-aminoethyl}amine (H$_3$NICTREN)
To a mixture of HImNic (6.30 g, 33.3 mmol) in 1,4-dioxan (400 mL) was added TREN (1.56 g, 10.67 mmol) in one portion. The resulting mixture was refluxed for 18 h. After cooling the reaction mixture to 20°C, the precipitate was filtered, washed with THF and Et_2O, and dried in vacuo to afford H_3NICTREN as a white solid (5.20 g, 95%). ^{1}H NMR, ^{13}C NMR, IR, and MS spectra were identical to those reported for the sample obtained by Method A. Anal. calcd. (found) for $C_{24}H_{27}N_7O_6 \cdot 0.25H_2O$: C 56.08 (56.15), H 5.39 (5.57), N 19.07 (19.07).

1,1,1-Tris{[(2-hydroxynicotinyl)carbonyl]-2-aminomethyl}ethane (H$_3$NICTAME)
To a mixture of HImNic (6.05 g, 32.0 mmol) in 1,4-dioxan (400 mL) was added TAME (1.10 g, 9.39 mmol) in one portion. The resulting mixture was refluxed for 19 h. After cooling the reaction mixture to 20°C, the precipitate was filtered, washed with THF and Et_2O, and dried in vacuo to afford H_3NICTAME as an off-white solid (4.22 g, 89 %), mp 270°C (dec.). IR: 3600–2600 (br, ν_{OH}), 3280 (m, ν_{NH}), 1665 (s, $\nu_{C=O}$), 1600 (m, $\nu_{C=C}$), 1562 (s, amide II), 1480 (m, $\nu_{C=C}$), 1430, 1320, 1235, 1150, 790, 770. ^{1}H NMR: 0.91 (s, 3H^{1}), 3.14–3.47 (partially obscured d, 6H^{2}, J = 6 Hz), 6.46 (t, 3H$^{\beta}$ J = 6 Hz), 7.69 (dd, 3H$^{\gamma}$, J = 8, 1.2 Hz), 8.30 (dd, 3H$^{\alpha}$, J = 8, 1.2 Hz), 10.01 (t, 3H, C(O)N*H*, J = 6 Hz), 12.38 (br s, 3H, O*H*). MS (FAB), *m/z*: 481 (M+H)$^+$. Anal. calcd. (found) for $C_{23}H_{24}N_6O_6 \cdot H_2O$: C 55.42 (55.68), H 5.22 (5.28), N 16.87 (16.55).

N^1,N^5,N^{10}-*Tris(2-hydroxynicotinyl)spermidine (H$_3$NICSPERM)*
To a suspension of HImNic (2.639 g, 13.96 mmol) in 1,4-dioxane (200 mL) was added spermidine (0.658 g, 4.53 mmol) in one portion. The resulting mixture was refluxed for 19 h. After cooling the reaction mixture to 20°C, the brown-orange precipitate was filtered, washed with Et_2O, and dried in vacuo to yield 1.611 g of the crude product; 205 mg of this was column chromatographed on lipophilic Sephadex LH-20™ (3 × 120 cm column; eluant: 50% MeOH in EtOAc) to afford pure product (150 mg, 73% recovery), equivalent to a 51% overall yield; mp 115–117°C. TLC (eluant: 50% MeOH in EtOAc) R_f = 0.3. IR: 3600–2600 (br,ν_{OH}), 3260 (m, ν_{NH}), 1675 (s, $\nu_{C=O}$), 1605 (m, $\nu_{C=C}$), 1560 (s, amide II), 1230, 775. ^{1}H NMR (δ at 200 MHz in DMSO-d_6): 1.3–1.9 (three overlapping m, 6 H^{3,7,8}), 2.9–3.6 (partially obscured overlapping m, 8H^{2,4,6,9}), 6.03–6.22 (m, 1H$^{\beta}$), 6.40–6.51 (m, 2H$^{\beta',\beta''}$), 7.24–7.45 (two overlapping m, 2H$^{\alpha,\gamma}$), 7.60–7.75 (m, 2H$^{\gamma,\gamma'}$), 8.22–8.38 (m, 2H$^{\alpha',\alpha''}$), 9.60–9.90 (m, 2H, C(O)N*H*), 11.85 (br s, 1H, O*H*), 12.45 (br s, 2H, O*H*). MS (FAB), *m/z*: 510 ± 1 (M+H)$^+$. Anal. calcd. (found) for $C_{25}H_{28}N_6O_6 \cdot H_2O$: C 57.03 (57.13), H 5.74 (5.80), N 15.96 (15.82).



H$_3$NICSPERM



HpropylPic

[(3-Hydroxypicolinyl)carbonyl]propylamine (HpropylPic)
To a mixture of 3-hydroxypicolinic acid (1.48 g, 10.6 mmol) in THF (200 mL) was added CDI (1.92 g, 11.8 mmol) in one portion. The mixture was refluxed for 2 h whereupon *n*-propylamine (10.1 g, 0.12 mol) was added and the resultant mixture was refluxed for a further 19 h. After cooling the reaction mixture to 20°C, the volatiles were removed under reduced pressure and the resultant oil was column chromatographed on silica gel (eluant: 50% pentane in Et_2O, R_f = 0.84) to afford Hpropylpic (1.40 g, 74%) as a yellow-brown liquid. IR (neat on KBr plates): 3600–2600 (br, ν_{OH}), 3380 (m, ν_{N-H}), 1650 (s, $\nu_{C=O}$), 1580 (m, $\nu_{C=C}$), 1535 (s, amide II), 1450 (m, $\nu_{C=C}$), 1340, 1295, 1255, 1195, 810, 795. ^{1}H NMR: 0.85 (t, 3H^{1}, J = 7 Hz), 1.54 (m, 2H^{2}), 3.25 (dt, 2H^{3}, J = 8, 7 Hz), 7.36 (dd, 1H$^{\gamma}$, J = 8, 0.8 Hz), 7.48 (dd, 1H$^{\beta}$, J = 8, 4 Hz), 8.12 (dd, 1H$^{\alpha}$, J = 4, 0.8 Hz), 9.14 (t, 1H, C(O)N*H*, J = 6 Hz), 12.70 (br s, O*H*). ^{13}C NMR: 11.32 (C*1*), 22.27 (C*2*), 40.05 (C*3*), 125.84 (Cγ), 128.95 (Cβ), 131.49 (Cα), 139.66 (*C*C(O)NH), 157.37 (*C*-OH), 168.70 (*C*═O). Exact Mass calcd. (found) for $C_9H_{12}N_2O_2$: 180.0904 (180.0898). Anal. calcd. (found) for $C_9H_{12}N_2O_2$: C 59.99 (59.77), H 6.71 (6.78), N 15.55 (15.50).

1,1,1-Tris{[(3-hydroxypicolinyl)carbonyl]-2-aminomethyl}-ethane (H$_3$PICTAME)
To a mixture of 3-hydroxypicolinic acid (5.34 g, 38.39 mmol) in THF (150 mL) was added CDI (6.43 g, 39.65 mmol) in one portion. The mixture was refluxed for 5 h whereupon TAME (1.50 g, 12.80 mmol) was added and the solution was refluxed for a further 26 h. After cooling the reaction mixture to 20°C, the precipitate was filtered and the filtrate was concentrated in vacuo to yield a dark reddish-brown residue. This residue was redissolved in a minimum amount of hot MeOH (ca. 40 mL), which, after cooling to room temperature, was triturated with Et_2O to yield the product as a brown solid (1.25 g, 20%), mp 165–167°C. X-ray quality crystals were obtained by slow evaporation of a MeOH:Et_2O (1:20) solution at room temperature (rt). IR: 3600–2600 (br, ν_{OH}), 3355 (m, ν_{NH}), 1650 (s, $\nu_{C=O}$), 1580 (m, $\nu_{C=C}$), 1530 (s, amide II), 1448 (m, $\nu_{C=C}$), 1355, 1315, 1295, 1245, 1200, 1160, 810, 695, 660. ^{1}H NMR:

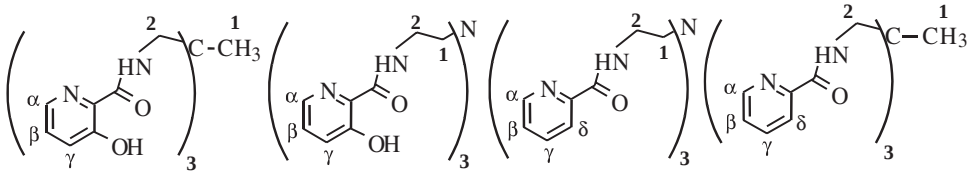
0.88 (s, 3H^{1}), 3.20–3.41 (partially obscured d, 6H^{2}, J = 6 Hz), 7.43 (dd, 3H$^{\gamma}$, J = 8, 0.8 Hz), 7.55 (dd, 3H$^{\beta}$, J = 8, 4 Hz), 8.19 (dd, 3H$^{\alpha}$, J = 4, 0.8 Hz), 9.62 (t, 3H, C(O)N*H*, J = 6 Hz), 12.46 (br s, 3H, O*H*). MS (FAB), *m/z*: 481 $(M+H)^+$. Anal. calcd. (found) for $C_{23}H_{24}N_6O_6$: C 57.50 (57.39), H 5.03 (4.90), N 17.49 (17.55).



H_3PICTAME H_3PICTREN PICTREN PICTAME

Tris{[(3-hydroxypicolinyl)carbonyl]-2-aminoethyl}amine (H_3PICTREN)

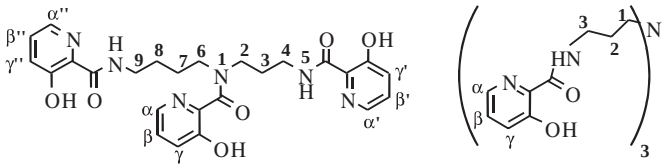
To a mixture of 3-hydroxypicolinic acid (2.52 g, 18.12 mmol) in THF (150 mL) was added CDI (3.50 g, 21.6 mmol) in one portion. The mixture was refluxed for 5 h whereupon TREN (0.883 g, 6.04 mmol) was added and the solution was refluxed for a further 18 h. After cooling the reaction mixture to 20°C, the precipitate was filtered and the filtrate was concentrated in vacuo to yield a dark reddish-brown residue. This residue was redissolved in a minimum amount of hot MeOH (ca. 20 mL), which, after cooling to rt, was triturated with Et_2O to yield the product as a light-brown solid (2.15 g, 70%), mp 156–158°C. IR: 3600–2700 (br, ν_{OH}), 3350 (m, ν_{NH}), 1640 (s, $\nu_{C=O}$), 1590 (m, $\nu_{C=C}$), 1540 (s, amide II), 1450 (m, $\nu_{C=C}$), 1300, 1240, 1200, 1180, 1150, 860, 820, 685, 665. ^{1}H NMR: 2.78 (t, 6H^{1}, J = 6 Hz), 3.36–3.47 (partially obscured m, 6H^{2}), 7.33 (dd, 3H$^{\gamma}$, J = 8, 0.8 Hz), 7.42 (dd, 3H$^{\beta}$, J = 8, 4 Hz), 7.97 (dd, 3H$^{\alpha}$, J = 4, 0.8 Hz), 8.96 (t, 3H, C(O)N*H*, J = 6 Hz), 12.52 (br s, 3H, O*H*). MS (FAB), *m/z*: 510 $(M+H)^+$. Anal. calcd. (found) for $C_{24}H_{27}N_7O_6$: C 56.58 (56.46), H 5.34 (5.41), N 19.24 (19.21).

Tris{[(picolinyl)carbonyl]-2-aminoethyl}amine (PICTREN)

To a mixture of picolinic acid (3.0 g, 24.4 mmol) in THF (200 mL) was added CDI (4.35 g, 26.8 mmol) in one portion. The resultant mixture was refluxed for 1 h whereupon TREN (1.17 g, 8.02 mmol) was added and the mixture was refluxed for a further 19 h. After cooling the reaction mixture to 20°C and removal of the solvent under reduced pressure, the dark-brown residue thus obtained was column chromatographed on lipophilic Sephadex LH-20™ (3 × 120 cm column; eluant: MeOH) to afford PICTREN (3.43 g, 93%) as a deep red-brown viscous liquid. IR (in $CHCl_3$): 3390 (m, ν_{NH}), 1665 (s, $\nu_{C=O}$). ^{1}H NMR: 2.76 (t, 6H^{1}, J = 6 Hz), 3.34–3.50 (partially obscured m, 6H^{2}), 7.49-7.56 (m, 3Hβ), 7.90–8.00 (m, 6H$^{\gamma,\delta}$), 8.43-8.47 (m, 3H$^{\alpha}$), 8.70 (t, 3H, C(O)N*H*, J = 6 Hz). MS (FAB), *m/z:* 462 $(M+H)^+$. Anal. calcd. (found) for $C_{24}H_{27}N_7O_3\cdot 0.5H_2O$: C 61.26 (60.99), H 6.00 (5.94), N 20.84 (20.92).

1,1,1-Tris{[(picolinyl)carbonyl]-2-aminomethyl}ethane (PICTAME)

To a mixture of picolinic acid (1.576 g, 12.80 mmol) in THF (150 mL) was added CDI (2.283 g, 14.08 mmol) in one portion. The resultant mixture was refluxed for 2 h whereupon TAME (0.5 g, 4.30 mmol) was added and the mixture was refluxed for a further 19 h. After cooling the reaction mixture to 20°C, and removal of the solvent under reduced pressure, the residue so obtained was column chromatographed on silica gel (eluant: 5% MeOH:45% Et_2O:50% EtOAc; R_f = 0.58) to afford PICTAME (1.30 g, 70%) as a white solid, mp 207–208°C. IR: 1670 (s, $\nu_{C=O}$), 1590 (m, $\nu_{C=C}$), 1535 (s, amide II), 1465 (m, $\nu_{C=C}$), 1435, 1335, 1000, 760, 690. ^{1}H NMR: 0.53 (s, 3H^{1}), 3.22 (d, 6H^{2}, J = 6 Hz), 7.62 (ddd, 3H$^{\beta}$, J = 8, 4, 1.2 Hz), 8.01 (dt, 3H$^{\gamma}$, J = 8, 8, 1.6 Hz), 8.06-8.16 (m, 3H$^{\delta}$), 8.66-8.74 (m, 3H$^{\alpha}$), 9.37 (t, 3H, C(O)N*H*, J = 6 Hz). MS (FAB), *m/z*: 433 $(M+H)^+$. Anal. calcd. (found) for $C_{23}H_{24}N_6O_3$: C 63.88 (63.63), H 5.59 (5.53), N 19.43 (19.20).



H_3PICSPERM H_3PICTRPN

N^1,N^5,N^{10}-*Tris(3-hydroxypicolinyl)spermidine (H_3PICSPERM)*

To a mixture of 3-hydroxypicolinic acid (2.657 g, 19.1 mmol) in THF (275 mL), CDI (3.103 g, 19.1 mmol) was added and the solution refluxed for 3 h. Spermidine (0.87 g, 5.97 mmol) was added to the mixture, which was refluxed for an additional 15 h. After cooling the reaction mixture to 20°C, the solution was filtered and the filtrate was concentrated in vacuo to a yellowish oil. The slow-moving contaminants (R_f 0.05) in the mixture were removed by column chromatography on silica gel (eluant: 5% MeOH in EtOAc). Combining the appropriate fractions and evaporating the solvent yielded a yellow oil. This material was then triturated with MeOH (ca. 50 mL) to afford H_3PICSPERM (1.31 g, 42%) as a white solid, mp 99–100°C. TLC (eluant: 5% MeOH in EtOAc) R_f = 0.48. IR: 3600–2600 (br, ν_{OH}), 3360 (m, ν_{NH}), 1650 (s, $\nu_{C=O}$), 1610 (m, $\nu_{C=C}$), 1535 (s, amide II), 1445 (m, $\nu_{C=C}$), 1610, 1390, 1190, 990, 810, 795. ^{1}H NMR (δ at 400 MHz in $CDCl_3$): 1.62–2.13 (series of overlapping m, 6H^{3,7,8}), 3.43–3.60 (m, 5H$^{4,6',9}$), 3.64, 4.04, 4.12 (three t each, 3H$^{2,6''}$, J = 6 Hz), 7.20–7.37 (m, 6H$^{\beta,\beta',\beta'',\gamma,\gamma,\gamma''}$), 7.98–8.24 (m, 3H$^{\alpha,\alpha',\alpha''}$), 8.33, 8.56 (two br s, 2H, C(O)N*H*, $W_{1/2}$ = 14 Hz), 12.2 (br s, 2H, O*H*), 12.3 (br s, 1H, O*H*). ^{13}C NMR (δ at 50 MHz in $CDCl_3$): 169.4, 169.1, 168.9, 158.8, 158.7, 157.8, 139.4, 138.8, 134.3, 131.4, 128.6,

127.4, 126.1, 102.9, 49.7, 47.8, 38.8, 36.3, 28.8, 27.6, 26.7, 24.6. MS (FAB), *m/z*: 509 $(M+H)^+$. Anal. calcd. (found) for $C_{25}H_{28}N_6O_6$: C 59.05 (59.06), H 5.55 (5.63), N 16.53 (16.60).

Tris{[(3-hydroxypicolinyl)carbonyl]-2-aminopropyl}amine (H_3PICTRPN)

To a mixture of 3-hydroxypicolinic acid (1.145 g, 8.23 mmol) in THF (120 mL) was added CDI (1.335 g, 8.23 mmol) in one portion. The mixture was refluxed for 2 h whereupon TRPN (0.5 g, 2.66 mmol) was added and the resultant mixture was refluxed for a further 19 h. After cooling the reddish-brown reaction mixture to 20°C, the solvent was removed under reduced pressure and the viscous dark-brown liquid was redissolved in a minimum amount of hot MeOH (ca.40 mL) and triturated with Et_2O to remove any unreacted starting acid (0.45 g, 39%) that precipitated. The filtrate was concentrated under reduced pressure and the brownish oil thus obtained was column chromatographed twice on lipophilic Sephadex LH-20™ (3 × 120 cm column; eluant: MeOH) and on silica gel (eluant: 10% MeOH in EtOAc, R_f = 0.13) to afford H_3PICTRPN (0.13 g, 9%) as a glassy (sticky) brown solid. IR: 3600–2600 (br, ν_{OH}), 3350 (m, ν_{NH}), 1655 (s, $\nu_{C=O}$), 1595 (m, $\nu_{C=C}$), 1540 (s, amide II), 1445 (m, $\nu_{C=C}$), 1350, 1289, 1248, 1198, 1150, 807, 695. ^{1}H NMR: 1.75 (t, 6H^1, J = 6 Hz), 2.35–2.70 (partially obscured m, 6H^2), 3.35 (dt, 6H^3, J = 8, 7 Hz), 7.38 (d, 3H$^\gamma$, J = 8 Hz), 7.48 (dd, 3H$^\beta$, J = 8, 3 Hz), 8.10 (d, 3H$^\alpha$, J = 3 Hz), 9.22 (br s, 3H, C(O)N*H*, $W_{1/2}$ = 20 Hz), 12.62 (br s, 3H, O*H*). MS (FAB), *m/z*: 552 $(M+H)^+$. Anal. calcd. (found) for $C_{27}H_{33}N_7O_6 \cdot 0.25H_2O$: C 58.32 (58.43), H 6.07 (5.90), N 17.63 (17.55).

Potentiometric equilibrium measurements

All potentiometric measurements on H_3NICTREN and H_3NICTAME were made with an automatic titrator system consisting of a Fisher model 950 digital pH meter equipped with Orion–Ross glass and calomel reference electrodes, a Metrohm Dosimat model 665 autoburet, and water-jacketed titration vessels maintained at 25.0 ± 0.1°C with a Julabo UC circulating bath (25). Both autoburet and pH meter were interfaced to an IBM-compatible PC so that the titrations were automated. During the titrations, the solutions were kept under an argon atmosphere that was first passed through 2 M NaOH solution.

The electrodes were calibrated before each titration, and often afterwards, by titrating a known amount of aqueous HCl with a known concentration of NaOH. A plot of mV (calculated) vs. pH gave a working slope and intercept so that the pH could be read directly as $-\log[H^+]$. The value of pK_w used was 13.76.

All solutions were prepared at an ionic strength of 0.16 M NaCl. Carbonate-free NaOH (~0.16 M) was prepared with deionized, distilled water that was boiled and purged with argon while cooling to ensure removal of CO_2. This solution was standardized potentiometrically with potassium hydrogen phthalate. Standard HCl solutions were prepared similarly and were standardized with the NaOH prepared above. Stock ligand solutions (~ 0.5 mM) were prepared using deionized, distilled water and were used within 3–4 days. The compounds were titrated in the pH range 2–11.5; a minimum of five titrations was performed for each compound.

Potentiometric calculations

The deprotonation constants of the ligands were calculated using the program BEST (26). The program sets up simultaneous mass-balance equations for all the components present at each addition of base and calculates the pH at each data point according to the current set of stability constants and total concentrations of each component. The stability constants are iteratively varied to minimize the sum of the square of the difference between observed (pH_{obs}) and calculated (pH_{calc}) pH values. An indication of the fit is given by σ_{fit}, where σ_{fit} is

$$\sigma_{fit} = \Sigma\,(pH_{calc} - pH_{obs})^2/(N-1)$$

and N is the total number of data points (typically ~100). In all the titrations considered, $\sigma_{fit} < 0.01$. The final calculated deprotonation constants are the average of the deprotonation constants determined from individual titrations; an estimate of the error in these values is given by one standard deviation (1σ) for these results.

X-ray crystallographic analysis of H_3PICTAME

Crystallographic data for H_3PICTAME appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 55.1°–82.4°. The intensities of three standard reflections, measured every 200 reflections throughout the data collection, showed only small random fluctuations. The data were processed,[2] corrected for Lorentz and polarization effects, and for absorption (empirical, based on azimuthal scans).

The structure was solved by direct methods. Non-hydrogen atoms were refined with anisotropic thermal parameters, the O-bound hydrogen atoms were refined with isotropic thermal parameters, and the remaining hydrogen atoms were fixed in calculated positions with N—H = 0.91 Å, C—H = 0.98 Å, and $B_H = 1.2\,B_{\text{bonded atom}}$. A correction for secondary extinction was applied (Zachariasen type, isotropic), the final value of the extinction coefficient being $5.7(3) \times 10^{-7}$. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (27). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and hydrogen bond geometry appear in Tables 2–5, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes are available as supplementary material.[3]

[a] $B_{eq} = (8/3)\pi^2\Sigma\Sigma(U_{ij}\, a_i^* a_j^* (\boldsymbol{a_i}\cdot\boldsymbol{a_j}))$.

dehydrative coupling reagent, leading to the formation of the amide bond. In the present work, however, it was important that an activated ester be isolated, as the reaction between the amines (e.g., TREN or TAME) and the pyridine carboxylic acids used was fast enough to result in the quantitative precipitation of the corresponding ammonium salt. The main drawback in using this method was the practical difficulty of purifying the activated ester from the dicyclohexylurea that formed as a side product. This problem was circumvented by adopting the more efficient CDI method.

CDI method (Method B) (31)

The advantage of method B is that it obviates the intermediacy of DCC (and hence the DCU side product). The side products formed in method B (imidazole and CO_2) are easier to remove. This method, although it involves two steps, allows for a single-step synthesis of the amide unless practical reasons call for the isolation of the intermediate imidazolide. Due to the lack of sufficient solubility in THF (bp 67°C), the *N*-acylimidazolide of 2-hydroxynicotinic acid was isolated, and the next step performed in a more suitable, i.e., more polar, solvent, dioxane. Conveniently enough, these crystalline intermediates, although highly reactive in solution towards nucleophiles such as amine nitrogen, are stable in air at room temperature for at least a week.

X-ray crystal structure of H_3PICTAME

In X-ray crystallography, the main criterion for identification of an H-bond is the distance between the hydrogen and the acceptor atom (that is, the distance H···A in B—H···A where A and B are frequently nitrogen or oxygen atoms). However, in using X-ray diffraction data to extract bond distances involving a hydrogen atom, one must be aware of the fact that such bond lengths are systematically shortened (relative to the "true" internuclear separation) since these distances are, strictly speaking, a measure of the distance between the

C(22)—C(23)	1.409(7)		

centroids of electron density of the two atoms concerned. In the case of hydrogen, this does not coincide with its nuclear position, but is displaced significantly in the direction of the covalent bond (i.e., B—H). For example, O—H and N—H covalent bond lengths, which are observed to be 0.97 and 1.03 Å by neutron diffraction, can be determined to be as short as 0.6 and 0.7 Å, respectively, by X-ray diffraction (33). Hence, in order to identify an H-bond based on X-ray diffraction data, the H···A bond length should be at least 0.09 Å (34) shorter than the sum of the van der Waals radii (35) of H and A (36). Angular orientations are also of importance, viz. the extent of deviation from linearity of the A—H···B bond. Statistical surveys of H-bond geometry in small molecules have revealed a mean value close to 180° (37), although exceptions to this finding are plentiful and are often due to the geometric constraints imposed elsewhere in the structure.

In the solid state structure, an H-bond will form whenever it can because its formation will raise the stability of a molecular crystal by a few kilocalories per mole (38). The H_3PICTAME solid state structure nicely demonstrates this observation, with eight *intra*- and one *inter*molecular H-bonds per molecule. Following the nomenclature of H-bonding geometry, two types of such interactions are present in H_3PICTAME: two-center (chelate) and three-center (bifurcated) H-bonds (Fig. 2).

The atom labelling and numbering scheme used is shown in the ORTEP diagram of the X-ray crystal structure of H_3PICTAME (Fig. 3*a*). In each arm of the molecule, the arylamide moiety is held strictly planar (Fig. 3*c*) due to the extended π network of the aromatic amide linkage. The H-bond distances and some of the relevant bond angles are listed in Table 5, a perusal of which clearly indicates that all the H-bonds identified are well within the H···A distance criterion (H···O = 2.5 Å; H···N = 2.6 Å) and, as expected, the three-center H-bonds (H(5) H-bonded to N(3), N(4), and O(5) and H(6) H-bonded to N(5), N(6), and O(1), respectively) display a greater deviation from linearity.

The molecule in the solid state lacks a C_3 axis of symmetry; the torsion angles about the apical C(2), the intervening methylene carbon, and the amidic nitrogen succinctly depict this fact (Fig. 3*b*). The apical carbon (C2) is in a staggered conformation with respect to N5; whereas the analogous torsion angles in the other two arms are roughly 60°, corresponding to a *gauche* conformation with one in a positive (clockwise) and the other in a negative (counterclockwise) sense. Since nearly all H-bond donors and acceptors are "buried" intramolecularly, preorganizing the molecule for chelation, only one *inter*molecular H-bond forms in each molecule as shown in Fig. 3. It is reasonable to conjecture, in the absence of an X-ray structure, that the structural isomer, H_3NICTAME, should show a greater propensity toward aggregation (as opposed to intramolecular H-bond formation) based merely on geometric considerations.
