^{31}P NMR spectroscopy has become a common tool in recent years for studying the structural and electronic properties of organometallic complexes containing phosphine ligands. Direct information about the tensor properties of the chemical shift is not available from solution spectra but can be regained from solid-state spectra under either non-spinning conditions or with magic-angle spinning, where the well-known "powder pattern" is replaced by a sharp isotropic peak surrounded by spinning side bands and the chemical shift tensor information can be recovered from the relative intensities of the spinning side-band manifolds at low spinning speeds (1). This is desirable because the components of the chemical shift tensor provide more information than do the isotropic chemical shifts.

Theoretical methods, particularly Density Functional Theory (DFT) approaches, are now capable of calculating the chemical shift tensors of molecules containing "heavy" nuclei (2), and the purpose of the present study was to determine the chemical shift tensor components for a series of phosphine-substituted group 6 metal pentacarbonyl complexes of the form $M(CO)_5PR_3$ (M = Cr, Mo, W and R = Me, Ph) and to compare these values with the results of the DFT predictions of Kaupp (3) and of Ruiz-Morales and Ziegler (4). The known trend (5) of the ^{31}P isotropic chemical shifts in the direction of increased shielding on going from chromium to tungsten was interpreted by Kaupp as arising from changes in the perpendicular components of the shift tensor. Supporting evidence for this has been reported recently for Group 6 metal pentacarbonyl complexes with the ligand 5-phenyldibenzophosphole (PhDBP) (5). Wasylishen and co-workers (6, 7) have suggested that PhDBP resembles triphenylphosphine as a ligand except that two of the phenyl groups are constrained to one plane and the ^{31}P chemical shift anisotropy reflects this difference in local symmetry. We have examined the ^{31}P chemical shift anisotropies of the triphenylphosphine complexes for

comparison with the PhDBP results and the calculations of Ruiz-Morales and Ziegler (4).

Experimental

The complexes $M(CO)_5PPh_3$ (M = Cr, Mo, W) were prepared by the trimethylamine – N-oxide promoted substitution of the triphenylphosphine on the metal hexacarbonyl (8), and purified by recrystallization from a 2:1 ethanol–chloroform mixture. The trimethylphosphine complexes were prepared by displacement of the bromide ion from the tetraethylammonium bromopentacarbonylmetallate salt (9, 10) using trimethylphosphine – silver iodide adduct as the source of phosphine (11, 12). These complexes were purified by repeated sublimations or by crystallization from hexane solution at –20°C, the isolation of the compounds being complicated by their low melting points and tendency to form oils. Infrared and solution ^{31}P and ^1H nmr spectroscopy were used to confirm the identity and purity of the products by comparison with the literature spectra (5, 13, 14).

CP-MAS nmr spectra were recorded on a Chemagnetics CMX-300 spectrometer operating at 121.279 MHz, using high-power proton decoupling, contact times of 2 ms, and recycle delays of 2–180 s, depending on the complex studied. Samples were packed into 7.5 mm bullet-type zirconia rotors. Different spinning rates, ranging from 0.3 to 2.5 kHz, were used to locate isotropic peaks and the chemical shifts were referenced to 85% H_3PO_4. Line broadenings of between 0 and 25 Hz were applied to the spectra. The spectra were curve-fitted using the program Peakfit (Jandel Scientific) and the chemical shift tensor components were calculated from the spinning side-band intensities using the Herzfeld–Berger Analysis program of Eichele and Wasylishen (15).

Results and discussion

The phosphine complexes of the Group 6 metals are especially easy to study via ^{31}P NMR because, while each metal has nmr-active isotopes, none are present in a natural abundance large enough to seriously complicate the ^{31}P spectra with scalar coupling or quadrupole–dipole effects. The chemical shift tensor values, isotropic chemical shifts, and coupling constants for the six complexes studied are presented in Table 1, together with the calculated shift tensor values (3, 4) and the results reported for the PhDBP and MeDBP complexes (6, 7). The standard deviations in the δ_{ii} values, from the measurements at different spinning rates, were ±2 ppm.

The CP-MAS spectra showed only one chemical shift for all compounds except the trimethylphosphine(pentacarbonyl)molybdenum complex, where two shifts were observed separated by about 2 ppm. This difference is probably due to the presence of two crystallographically nonequivalent phosphorus atoms in the asymmetric unit cell, although the reported X-ray crystal structure (16) indicated only one molecule in the asymmetric unit. Unfortunately,

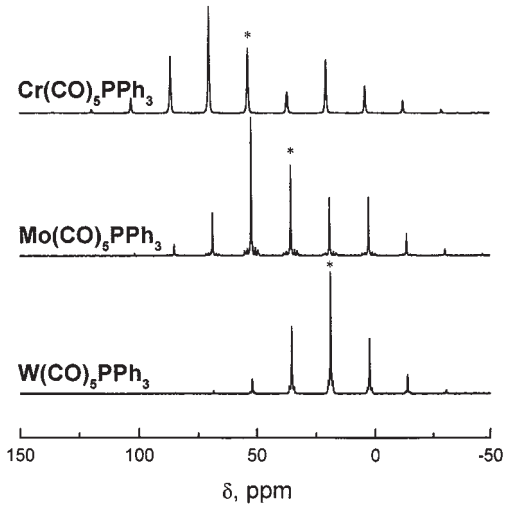
Fig. 1. ^{31}P CP-MAS spectra of the triphenylphosphine complexes of Group 6 metal pentacarbonyls. Spinning speed: 1600 Hz for all spectra. Asterisks indicate the isotropic shift position.



decomposition of the sample prevented the determination of the crystal structure of this polymorph.

The molybdenum and tungsten complexes showed additional splittings due to couplings from the isotopes with spin, ^{95}Mo (15.7%, I = 5/2), ^{97}Mo (9.46%, I = 5/2), and ^{183}W (14.4%, I = 1/2), but no splitting from ^{53}Cr (9.55%, I = 3/2) was observed in the spectra of either of the chromium complexes. The solid state value for ^{1}J(P–W) in the tungsten triphenylphosphine complex was slightly lower than the value in solution (17).

Couplings to quadrupolar nuclei are not always observed in solution state spectra, due to rapid relaxation, but can be observed in solid state spectra under magic-angle-spinning conditions (18). There is an additional line displacement that depends upon the residual dipole–quadrupole coupling interaction, d, given by eq. [1].

$$[1] \qquad d = -(3\chi D'/20\nu_s)(3\cos^2\beta - 1 + \eta \sin^2\beta \cos(2\alpha))$$

where $D' = (D - \Delta J/3)$, D is the dipolar coupling constant, $-(\mu_0/4\pi)\gamma_I\gamma_S h/(2\pi r^3)$, ΔJ is the anisotropy in the spin coupling, χ is the nuclear quadrupole coupling constant, and η is the asymmetry in the electric field gradient. The angles β and α are the polar and azimuthal angles relating the internuclear vector and the principal axes of the electric field gradient. The local symmetry around the metal–phosphorus bond is such that η is assumed to be zero and β and α are taken to be 0° and 90°, respectively, and eq. [1] is much simplified. The two molybdenum isotopes have very similar magnetogyric ratios and, therefore, have spin–spin coupling constants that cannot be easily distinguished, but the nuclear quadrupole moment of ^{97}Mo is much greater, 0.255×10^{-28} m^2 versus -0.022×10^{-28} m^2 for ^{95}Mo, and so, in principle, the second-order splittings can be analysed to give the quadrupole coupling constants and the anisotropy in J. The direct dipole coupling constants, calculated using a bond length of 2.508 Å (16), are –202 and –206 Hz for ^{97}Mo and ^{95}Mo, respectively. The quadrupole coupling constants of triphenylphosphine(pentacarbonyl)molybdenum have been measured (19) to be 1.972 MHz and 22.783 MHz for ^{95}Mo and ^{97}Mo, respectively, and the former is probably negative in sign (20). These values were obtained at 77 K and the room temperature quadrupole coupling constants would be lower in frequency. Thus, neglecting ΔJ and using the low-temperature χ values, the calculated second-order splittings would be –70 and 6.1 Hz for ^{97}Mo and ^{95}Mo, respectively, compared with the experimental values of –55 and 4.5 Hz. The differences could be due to the lower quadrupole coupling constants at high temperature and a finite anisotropy in the spin–spin coupling constant. The splittings in the spectra of the trimethylphosphine complex were not sufficiently well resolved for a full analysis and only the J value could be determined.

The experimentally determined chemical shift tensors for the trimethylphosphine complexes show near-axial symmetry ($\delta_{11} \approx \delta_{22}$), the deviations being attributable to solid state effects, and the values are in quite good agreement with the theoretical predictions (3) if the δ_{11} and δ_{22} values are averaged and compared with the calculated perpendicular component. The lack of agreement for the tungsten complex is not unexpected and was attributed by Kaupp to the neglect of spin-orbit contributions in the calculations (3). The agreement between the observed and calculated shift tensor components confirms the assignment of δ_{33} as lying along the bond direction in both the trimethyl- and triphenylphosphine complexes. The chemical shift tensors of the triphenylphosphine compounds deviate from axial symmetry, in contrast to free triphenylphosphine, which has an axially symmetric chemical shift tensor (21, 22). This asymmetry is attributed to the breakdown in local symmetry caused by the different torsional angles of the phenyl rings. For the chromium and molybdenum complexes, the δ_{22} component shows the largest difference between experimental and calculated values (4) but the spans and shift anisotropies, $\Delta\delta$, are in good agreement.

The influence of the metal atom on the phosphorus chemical shift anisotropy can be clearly seen in Table 1 and Fig. 1. The most noticeable trend is the marked decrease in the spans, $(\delta_{11} - \delta_{33})$, and anisotropies of the chemical shift tensors on moving from chromium to tungsten. This decrease is due almost entirely to changes in δ_{11} and δ_{22}. For example, in the trimethylphosphine complexes, where δ_{11} and δ_{22} change by nearly 70 ppm, δ_{33} varies by only 14 ppm. For the triphenylphosphine series, δ_{11} and δ_{22} decrease by about 20 ppm from Cr to Mo and by about 30 ppm from Mo to W. In contrast, δ_{33} for these complexes remains almost constant at –17 ± 3 ppm. It is this behaviour which results in the increased shielding observed for the solution chemical shift on going from chromium to tungsten. The DFT calculations of the shift tensor components for the series of trimethyl- and triphenylphosphine pentacarbonyl complexes the Group 6 metals showed good agreement with experiment, a result that should encourage further work, both experimental and theoretical.

Wasylishen and co-workers (6, 7) have suggested that the PhDBP ligand is analogous to triphenylphosphine and we are now able to compare the ^{31}P chemical shift tensor components of both ligands when bonded to the Group 6 metal carbonyls, Table 1. The changes in the δ_{ii} values are almost constant (within 5 ppm, and close to the experimental error) regardless of the metal atom; for PhDBP, the δ_{11} value is less

© 1998 NRC Canada

shielded by 23 ppm and the δ_{22} and δ_{33} values more shielded by 30 and 19 ppm, respectively, than in the triphenylphosphine complexes.

Ketonization of (*Z*)-2-methoxy-1,2-diphenylvinyl alcohol. Quantitative evaluation of the remarkable kinetic stability of this enol

E.A. Jefferson, A.J. Kresge, L. Matthew, and Z. Wu

Abstract: Rates of ketonization of (*Z*)-2-methoxy-1,2-diphenylvinyl alcohol were measured in aqueous perchloric acid and sodium hydroxide solutions as well as in formic acid and ammonium ion buffers, and the results were used to construct a rate profile for this reaction. These data show this substance to be a remarkably stable enol with a lifetime of 3.6 h at the bottom of its rate profile and a hydrogen ion catalytic coefficient 660 000 times less than that for the enol of acetophenone. Comparison with simple models allows partition of this rate factor into a 440-fold retardation for the β-phenyl substituent and a 1500-fold retardation for the β-methoxy substituent. A global rate of enolization of the keto isomer producing both *Z* and *E* enol isomers was also measured, and this leads to $pK_E > 5.4$ as the lower limit of the keto–enol equilibrium constant for the *Z* enol. This result could be dissected into an enol-content enhancing effect of $\delta\ pK_E = 3.2$ for the β-phenyl group and a surprising enol-content diminishing effect of $\delta\ pK_E > 0.6$ for the β-methoxy group.

Key words: enol ketonization, enol stability, keto–enol equilibrium, β-phenyl and β-methoxy substituent effects in keto–enol systems.

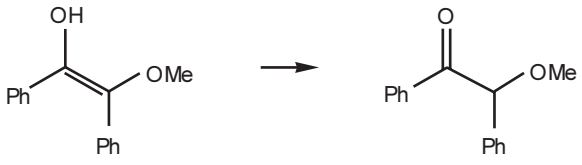
Résumé : Opérant en solutions aqueuses d'acide perchlorique et d'hydroxyde de sodium ainsi que dans l'acide formique et des tampons d'ion ammonium, on a mesuré les vitesses de cétonisation de l'alcool (*Z*)-2-méthoxy-1,2-diphénylvinylique et on a utilisé les résultats pour édifier un profil de vitesses de cette réaction. Ces données montrent que cette substance est un énol remarquablement stable dont le temps de vie est de 3,6 h au fond de son profil de vitesse et pour lequel le coefficient catalytique de l'ion hydrogène est 660 000 fois plus faible que dans le cas de l'énol de l'acétophénone. Une comparaison avec des modèles simples permet de diviser ce facteur de vitesse en un facteur retardant de 440 attribuable au substituant phényle en β et un facteur retardant de 1500 pour le substituant β-méthoxy. On a aussi mesuré une vitesse globale d'énolisation de l'isomère cétonique conduisant aux isomères *E* et *Z* de l'énol; elle permet d'établir à 5,4 la valeur inférieure limite du pK_E de la constante d'équilibre céto–énolique de l'énol *Z*. On peut disséquer ce résultat en un effet, $\delta\ pK_E > 0{,}6$ du groupe β-méthoxy, qui d'une façon surprenant diminue le contenu en énol.

Mots clés : cétonisation d'un énol, stabilité d'un énol, équilibre céto–énolique, effets des substituants β-phényle et β-méthoxy sur les systèmes céto–énoliques.

[Traduit par la Rédaction]

Most thermodynamically unstable enols are also unstable kinetically and cannot be isolated, let alone characterized by standard methods commonly used for stable substances. A notable exception is (*Z*)-2-methoxy-1,2-diphenylvinyl alcohol, **1**, which reverts to its more stable keto isomer, 2-methoxy-1,2-diphenylethanone, **2**, eq. [1], so slowly that its structure could even be determined by X-ray crystallography (1).

[1]



1 **2**

This enol was prepared (1) by treating 1,2-diphenyldiazoethanone, **3**, with sulfuric acid in methanol solution. Under these conditions, solvolysis of the diazo compound occurred through rapid pre-equilibrium protonation on carbonyl oxygen followed by rate-determining loss of nitrogen, eq. [2]; this generated a vinyl cation, **4**, which was captured by solvent on its less hindered side to give the methoxy enol, **1**, eq. [3].

Cooling the reaction mixture caused the enol to separate in crystalline form, and this solid was then characterized by its spectra and reactions in the usual way, and its *cis*-phenyl geometry was established by X-ray diffraction.[2]

To provide a quantitative assessment of the remarkable stability of this enol we have measured rates of its ketonization in aqueous solution and have used the results to construct a reaction rate profile. We have also measured rates of enolization of the keto isomer, **2**, in order to obtain an estimate of the keto–enol equilibrium constant for this system.

Experimental section

Materials

1,2-Diphenyldiazoethanone was prepared by mercuric oxide oxidation of benzil hydrazone (3). All other materials were best available commercial grades.

Kinetics, ketonization

Rates of ketonization of (*Z*)-2-methoxy-1,2-diphenylvinyl alcohol were measured by monitoring the increase in product ketone absorbance at λ = 250 nm using a Cary 2200 spectrometer with sample compartment thermostatted at 25.0 ± 0.05°C. Reactions were initiated by adding aliquots of methanol stock solution of enol to reaction media that had come to temperature equilibrium with the spectrometer cell compartment. The enol stock solutions were made just before use by allowing 1,2-diphenyldiazoethanone to solvolyze at room temperature in methanol containing 0.1 M perchloric acid. It was found that 12 min was the optimum time for this solvolysis to take place: enol formation was nearly complete but subsequent ketonization of the enol, which was ca. 20 times slower under these conditions, had not yet occurred to any appreciable extent. Five μL aliquots of these freshly prepared enol stock solutions were then added to 3.0 mL portions of reaction media; final concentrations of enol in the solutions upon which the kinetic measurements were made were ca. 3×10^{-5} M. The enol is easily oxidized by atmospheric oxygen (1), and all solutions were therefore purged with argon. Ionic strength was maintained at 0.10 M by adding sodium perchlorate as required. The kinetic data fit the first-order rate law well, and observed first-order rate constants were obtained by least-squares fitting of an exponential function.

Kinetics, enolization

Rates of enolization of 2-methoxy-1,2-diphenylethanone were measured in aqueous sodium hydroxide solutions by using bromine to scavenge the enol as it formed. In basic solutions, bromine reacts with hydroxide ion according to eq. [4] and consequently exists as hypobromite ion; reactions were therefore followed by monitoring the absorbance of this ion at λ = 330 nm.

[4] $$Br_2 + 2HO^- \rightarrow BrO^- + H_2O + Br^-$$

Measurements were made with a Cary 2200 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.05°C. In a typical experiment, 20 μL of saturated aqueous bromine solution was added to 10 mL of sodium hydroxide solution, whose ionic strength had been adjusted to 0.10 M by adding sodium bromide as required. Each of two 3.0 mL quartz cuvettes was then filled with this solution, and the absorbance of one was recorded at λ = 330 nm; this reading was later employed to calculate the hypobromite ion concentration, using ε_{330} = 300 M^{-1} cm^{-1} (4), in order to convert stoichiometric into actual sodium hydroxide concentrations according to the relationship of eq. [4]. The second cuvette was then placed in the reference compartment of the spectrometer and bromination was initiated by adding 5 μL of an acetonitrile stock solution of ketone to the first cuvette. Such double-beam operation minimized base-line drifting, which was prevalent without the use of a reference sample. Ketone concentrations in the reaction solutions were 4×10^{-4} M, and hypobromite concentrations were 1×10^{-3} M. The kinetic data conformed to the first-order rate law well, and observed first-order rate constants were obtained by least-squares fitting of an exponential function.

Results

Ketonization

Rates of ketonization of 2-methoxy-1,2-diphenylvinyl alcohol were measured in aqueous perchloric acid solutions at 10 different concentrations over the range $[HClO_4]$ = 0.001–0.1 M and in aqueous sodium hydroxide solutions at seven different concentrations over the range [NaOH] = 0.0005–0.05 M. Replicate measurements were made at each concentration. The data so obtained have been deposited and are summarized in Tables S1 and S2.[3]

[2] Sterically hindered enols for which access to the vinyl group is inhibited by bulky substituents are also remarkably stable (2).

[3] Tables S1–S4 may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2.

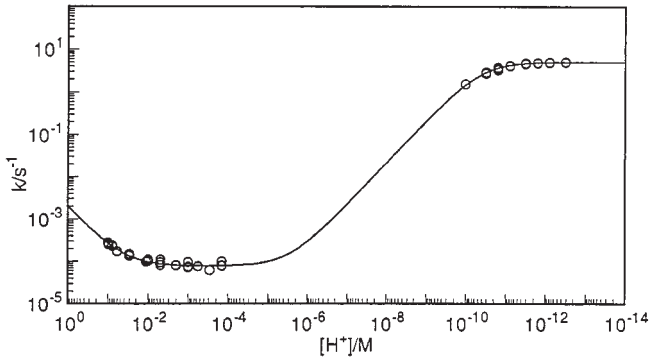
Fig. 1. Rate profile for the ketonization of 2-methoxy-1,2-diphenylvinyl alcohol in aqueous solution at 25°C.



Rates of ketonization of 2-methoxy-1,2-diphenylvinyl alcohol were also measured in formic acid and ammonium ion buffers. Series of buffer solutions of constant buffer ratio and constant ionic strength (0.10 M), and therefore constant hydrogen ion concentration, but different buffer concentrations were used. Buffer concentrations were varied by a factor of five, and replicate measurements were made at each concentration. The data so obtained are summarized in Table S3 of the depository.[3]

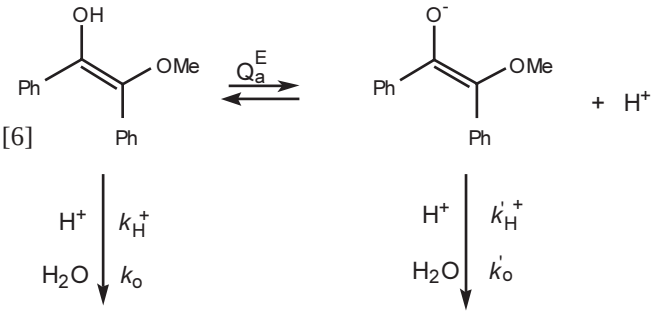
Observed first-order rate constants measured in these buffer solutions proved to be accurately proportional to buffer concentration, and the data were therefore analyzed by least-squares fitting of eq. [5].

$$[5] \qquad k_{obs} = k_o + k_{cat}[\text{buffer}]$$

The zero-buffer-concentration intercepts, k_o, obtained in this way were then used, together with the rate constants measured in perchloric acid and sodium hydroxide solutions, to construct the rate profile shown in Fig. 1. Hydrogen ion concentrations of the buffer solutions needed for this purpose were obtained by calculation, using literature values of the buffer acid dissociation constants and activity coefficients recommended by Bates (5).

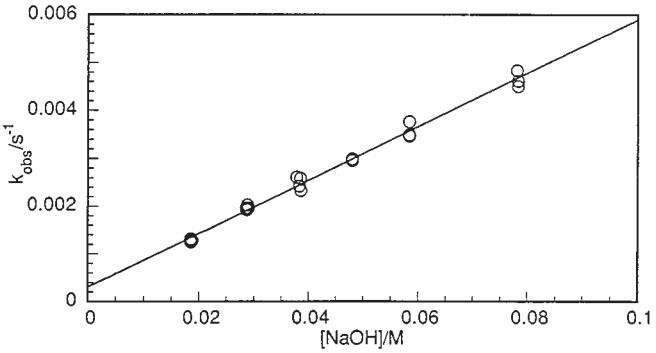
Rate profiles such as that of Fig. 1 are a characteristic feature of enol ketonization reactions (6). They reflect a reaction mechanism consisting of rate-determining protonation on β-carbon of either the enol or the enolate ion, as shown in eq. [6].

[6]



The acid-catalyzed portion at the extreme left of the profile represents carbon protonation of the enol by hydrogen ion,

Fig. 2. Relationship between hydroxide ion concentration and observed rate constants for the enolization of 2-methoxy-1,2-diphenylethanone in aqueous solution at 25°C.



and the uncatalyzed portion adjoining that represents either protonation of enol by solvent water or ionization of enol to the much more reactive enolate ion followed by carbon protonation of that by hydrogen ion. Following this uncatalyzed region is a segment of apparent hydroxide ion catalysis produced by ionization of enol to enolate followed by carbon protonation of that by water, and saturation of this catalysis, which occurs when the position of the ionization equilibrium shifts from enol to enolate, gives the second uncatalyzed region at the very right of the profile.

The rate law that describes this reaction scheme is shown in eq. [7],

$$[7] \qquad K_{obs} = k_{H^+}[H^+] + k_{UC} + k'_o\, Q_a^E/(Q_a^E + [H^+])$$

whose symbols are defined by eq. [5] with k_{UC} = either k_o or $k'_{H^+}\, Q_a^E$. Least-squares fitting of this expression gave the following results: k_{H^+} = (1.89 ± 0.06) × 10^{-3} M^{-1} s^{-1}, k_{UC} = (7.71 ± 0.13) × 10^{-5} s^{-1}, k'_o = (4.99 ± 0.10) s^{-1}, and Q_a^E = (4.22 ± 0.34) × 10^{-11} M, pQ_a^E = 10.38 ± 0.04.[4]

Enolization

Rates of enolization of 2-methoxy-1,2-diphenylethanone were measured in aqueous sodium hydroxide solutions at six different concentrations over the range [NaOH] = 0.02–0.08 M. Replicate measurements were made at each concentration. The data so obtained are summarized in Table S4 of the depository.[3]

Observed first-order rate constants determined in these solutions proved to be accurately proportional to sodium hydroxide concentration (see Fig. 2), and linear least-squares analysis gave k_{HO^-} = (5.59 ± 0.12) × 10^{-2} as the hydroxide ion catalytic coefficient for the enolization reaction.

Discussion

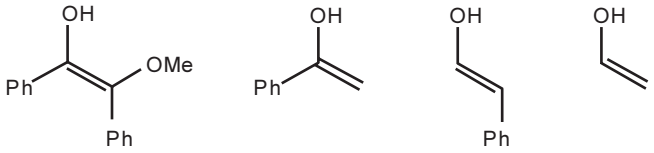
Reaction identification

2-Methoxy-1,2-diphenylvinyl alcohol is a vinyl ether as well as an enol, and, in view of the fact that vinyl ethers are subject to facile acid-catalyzed hydrolysis (7), this substance might have undergone that reaction, as shown in eq. [8], rather than the intended ketonization. It is known, however, that acid-catalyzed ketonization of enols is at least an order

[4] This acidity constant is a concentration quotient applicable at ionic strength equal to 0.10 M.

© 1998 NRC Canada

[8] 
[9] 
[10] 
of magnitude more rapid than the hydrolysis of the corresponding methyl vinyl ethers (6). The ketonization of enols, moreover, is strongly catalyzed by bases as well as by acids, whereas the hydrolysis of vinyl ethers is catalyzed only by acids. This, plus the fact that 2-methoxy-1,2-diphenylethanone, **2**, is the only product formed (1), would appear to make it safe to conclude that the process under observation here is in fact the intended ketonization reaction.



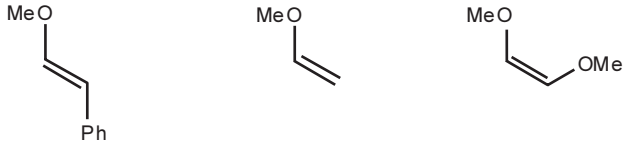
1 **5** **6** **7**

Reactivity

The lifetime of 2-methoxy-1,2-diphenylvinyl alcohol, **1**, at the bottom of its rate profile (Fig. 1) is $\tau = 3.6$ h. This contrasts sharply with the lifetime of the enol of acetophenone, **5**, in the corresponding region, $\tau = 6$ s (8), and shows that the additional β-methoxy and β-phenyl substituents in **1** have a very strong stabilizing effect.

Because the ketonization of enols at the bottom of their rate profiles can occur by either of two mechanisms (vide supra), a better assessment of the β-methoxy and β-phenyl group effects may be made using rate constants from a different region of the profile. Use of the acid-catalyzed region, moreover, allows comparison with vinyl ether hydrolysis; this is useful because acid catalysis of both ketonization and vinyl ether hydrolysis occurs by the same reaction mechanism, i.e., simple rate-determining proton transfer to the substrates's β-carbon atom. Combination of $k_{H^+} = 1.25 \times 10^3$ M^{-1} s^{-1} for acetophenone enol (9) with the presently determined value for 2-methoxy-1,2-diphenylvinyl alcohol then gives a rate factor of 660 000, which is equivalent to a difference in free energy of activation of $\delta\Delta G^{\ddagger} = 7.9$ kcal mol^{-1}.

This rate factor may be separated into effects of β-phenyl and β-methoxy by using rates of ketonization of the *trans*-enol of phenylacetaldehyde, **6**, $k_{H^+} = 7.45 \times 10^{-2}$ M^{-1} s^{-1} (10), and of vinyl alcohol, **7**, $k_{H^+} = 3.30 \times 10^1$ M^{-1} s^{-1} (11), to estimate retardation by a β-phenyl group. The result, a factor of 440, then leaves 1500 as the β-methoxy group effect. Similarly large rate retardations by β-phenyl and β-methoxy groups occur in vinyl ether hyrolysis; for example, k_{H^+} for *trans*-β-methoxystyrene (12), **8**, is 1100 times less than that for methyl vinyl ether (13), **9**, and k_{H^+} for *cis*-1,2-dimethoxyethene (14), **10**, is 13 000 times less than that for methyl vinyl ether. These retardations in rates of vinyl ether hydrolysis are believed to be the result of initial-state free-energy lowering by the well-known double-bond stabilizing effects of phenyl and methoxyl groups (15), which are partially lost in the reactions' transition states. A similar explanation can be advanced for the effect of these groups on enol ketonization reactions, and the greater velocities of the ketonizations over the vinyl ether hydrolyses, and their consequent earlier and more reactant-like transition states, can be invoked to rationalize the somewhat smaller size of the effects in ketonization than in vinyl ether hydrolysis.



8 **9** **10**

Keto–enol equilibrium

Keto–enol equilibrium constants have traditionally been determined by the halogen titration method invented nearly

© 1998 NRC Canada

a century ago (16). This method, unfortunately, fails when enol contents are as low as is commonly the case for simple aldehydes and ketones (17), and in that situation it is useful to employ a kinetic method where the keto–enol equilibrium constant is determined as the ratio of enolization to ketonization rate constants: $K_E = k_E/k_K$.

The presently determined ketonization rate constants, of course, refer only to the *Z* enol isomer, but the enolization rate constants are global values referring to the production of both *Z* and *E* enols, as shown in eq. [9]. Simply taking the ratio of the enolization to ketonization rate constants determined here will therefore not produce a proper keto–enol equilibrium constant: the global rate constants should be separated into values for production of the individual isomers, but that cannot be done because the method of analysis used, bromination, does not distinguish between the isomers. A simple ratio of presently determined rate constants does, however, provide an upper limit to K_E for the *Z* isomer, and that is enough to produce an interesting result.

The keto–enol equilibrium involving the *Z* isomer promoted by hydroxide ion may be represented as shown in eq. [10], and the equilibrium constant for this representation is given by eq. [11].

$$[11] \qquad K_E = \frac{f k_E^{gl}}{k'_o} \frac{Q_w}{Q_a^E}$$

In the latter expression, *f* is the (unknown) fraction of the global enolization rate constant, k_E^{gl}, that refers to production of the *Z* isomer only, Q_w is the autoprotolysis constant of water, and the remaining symbols are as defined by eq. [6]. Insertion of numerical values into this expression then leads to $K_E = (f)\ (4.22 \times 10^{-6})$. Since *f* is a fraction less than one, K_E must be less than 4.22×10^{-6} with $pK_E > 5.38$ as a lower limit.

Comparison of this result with $pK_E = 7.96$ for acetophenone (18) shows that β-phenyl and β-methoxy substituents introduced together increase enol content, and since $pK_E = 5.38$ is a lower limit, the combined effect of these groups can be no greater than 7.96 – 5.38 = 2.58 p*K* units. The effect of a β-phenyl substituent introduced alone may be estimated as $\delta\Delta pK_E = 3.16$, by comparing $pK_E = 3.07$ for the *trans*-enol of phenylacetaldehyde, (10), **6**, with $pK_E = 6.23$ for acetaldehyde (11), **7**. This difference is greater than the upper limit of 2.58 p*K* units estimated above for the combined effect of β-phenyl and β-methoxy substituents, which means that the effect of β-methoxy alone must be in the opposite direction, i.e., the effect of this group must be to lower rather than to raise enol content, and its magnitude must be greater than 3.16 – 2.58 = 0.58 p*K* units.

This is a surprising result. It implies that β-methoxy substituents destabilize enols thermodynamically,[5] in contrast to the kinetic stabilization shown by their marked retarding effect on rates of enol ketonization (vide supra). It is possible, however, that the various comparisons made leading to this result are not entirely valid, inasmuch as they were made using models containing only single phenyl substituents in which steric crowding interfered little, if at all, with substituent-functional group interaction. The enol investigated, 2-methoxy-1,2-diphenylvinyl alcohol, on the other hand, is a sterically congested molecule, as shown by the fact that its phenyl groups are twisted out of the vinyl plane by some 47° (1).

[5] It is likely that β-substituents influence the position of keto–enol equilibria largely by altering the energy of the enol rather than that of the keto isomer, because in the enol the substituent is placed directly on the functional group, whereas in the keto isomer it is insulated from the functional group by a saturated carbon atom.

Structure reassignment of the major isomer from the Diels–Alder reaction of acryloyl chloride and 4,5,6,6a-tetrahydropentalene

M. Parvez, A. Rauk, T.S. Sorensen, and F. Sun

Abstract: After hydrogenation and hydrolysis, the two adducts formed from the Diels–Alder reaction of acryloyl chloride and 4,5,6,6a-tetrahydropentalene were originally assigned 7-*exo*- and 7-*endo*-carboxylic acid structures **3** and **4**. Based on unexpected results in using these acids as starting materials for a superacid carbocation study, a reinvestigation of these structural assignments was carried out. From an extensive series of 2D NMR experiments, we conclude that **4** is correctly assigned, but that the other isomer is the 9-*endo* carboxylic acid **8**. The formation of these two isomers (out of eight possible modes of addition) can be rationalized. Finally, an X-ray study of **8** was carried out as a final proof of structure.

Key words: Diels–Alder reaction, facial selectivity, regioselectivity, X-ray structure, MO calculation.

Résumé : La réaction de Diels–Alder entre le chlorure d'acryloyle et le 4,5,6,6a-tétrahydropentalène conduit à deux adduits; on a originalement attribué les structures **3** et **4**, acides carboxyliques 7-*exo* et 7-*endo*-, aux produits obtenus après hydrogénation et hydrolyse. En se basant sur des résultats inattendus obtenus lorsque nous avons essayé d'utiliser ces acides comme produits de départ pour une étude de carbocations obtenus à l'aide de superacides, on a réexaminé les attributions de structure faites originalement. Après une série extensive d'études RMN en 2D, on en conclut que la structure **4** a été attribuée correctement, mais que l'autre isomère est plutôt l'acide carboxylique 9-*endo*, **8**. On peut rationaliser la formation de ces deux isomères (parmi les huit modes possibles d'addition). Enfin, comme preuve finale de sa structure, on a effectué une étude par diffraction des rayons X du composé **8**.

[Traduit par la Rédaction]

Introduction

Acryloyl chloride **1** and the tetrahydropentalene **2** undergo a low temperature (–30°C) Diels–Alder (D–A) reaction in which, after hydrolysis of the acid chloride and hydrogenation of the double bond, two isomeric carboxylic acid adducts were obtained in a ratio of about 2:1 (eq. [1]) (1). Other dienophiles have also been used with **2** or related dihydropentalenes (2–5).

In the experimental procedure communicated by Holm,[2] the major and minor adducts were assigned to an *exo–endo* pair of 7-COOH epimers **3** and **4**, and then the carboxyl group was replaced with hydrogen, and a single hydrocarbon was formed from the mixture. Our interest in this tricyclic skeleton was concerned with mechanistic studies of the "adamantaneland" rearrangements (as were Holm and coworkers (1)) but we were directly studying the carbocations

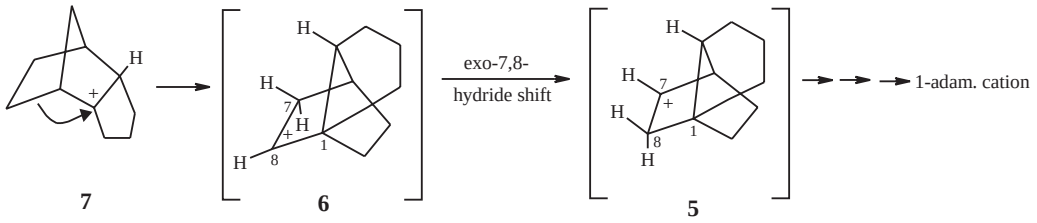
involved, rather than focusing on the hydrocarbons themselves. Cation **5** was expected to be a key structure in the overall rearrangement of the tetrahydrodicyclopentadiene skeleton into adamantane. The hydride shift **6** → **5** in the already high-energy intermediate **6** was in fact a prime candidate for the "watershed" transition state on the overall potential energy surface. The generation of cation **6** under non-steady-state conditions was expected to produce only **7** as the observable species, while **5** proceeded along the pathway towards the 1-adamantyl cation (6). Our intent therefore was to prepare a suitable precursor of cation **5** to try and verify the above postulate. In this course of this work it became necessary to reassign the structure of **3**, which is the subject of this paper.



7 6 5

Results and discussion

Based on the original assignments for **3** – **4**, a modified Hunsdiecker reaction was performed on the mixture of **3** and **4**, obtaining two chlorides in approximately the same ratios as for **3** – **4**, and assignable as a C7 *exo–endo* mixture (6). When this chloride mixture was added to the superacid SbF_5/SO_2ClF, the transient cation **5** was expected to be formed and, as explained in the Introduction, this was expected to proceed toward the 1-adamantyl cation. To our surprise we obtained a mixture of two cations, which included the one expected for the forward rearrangement process. However, the major cation was **7**. This result led us to reconsider the structure assignments shown for **3** and **4**, and by implication the structures of the original Diels–Alder adducts.

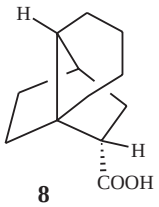
From the binary acid mixture, a sample of the pure major isomer can be readily obtained by crystallization. Analysis of the minor isomer was carried out on a mixed sample enriched in this acid.

NMR analysis of the major and minor carboxylic acid isomers

At first glance the original assignment as **3** seems compatible with the d,d,d pattern for the $>C<^{COOH}_{H}$ peak (coupling to *exo* and *endo* H8 and to H6). The same proton in the minor isomer is even more complex, again consistent with an extra W coupling to *exo* H10 in the assignment **4**. Furthermore, the chemical shift of H7 in each isomer is quite consistent with expectations for the **3** – **4** structures, δ 2.74 in the major isomer, 3.26 in the minor, this ca. 0.5 ppm difference being typical for *exo* and *endo* hydrogens in a norbornyl-type skeleton, with the *endo* H at higher field.

Only when one looks in detail at the coupling interactions of the $>C<^{H}_{COOH}$ hydrogen in the major isomer does one find fatal inconsistencies with structure **3**. Three of the ten skeletal ^{13}C peaks are CH, and a HETCOR 2-D spectrum locates the three ^1H peaks, which except for $>C<^{H}_{COOH}$ are located in overlapped regions. The COSY spectrum locates the hydrogens coupling to $>C<^{H}_{COOH}$ (which are again in overlapped regions) and one can clearly deduce that a methine hydrogen is not one of these coupling hydrogens, as would be required for structure **3**.

There are eight possible Diels–Alder adducts from the reaction of **1** and **2**, and eight possible hydrogenated products. The -COOH group can be located at C7, C8, C9, or C10, and can be either *exo* or *endo* in each case. If the -COOH is located at C10, one has the same inconsistent coupling behavior as with a C7 location, i.e., expected (but not observed) coupling between H-10 and H-6. This puts the -COOH group at C8 or C9, and requires an *endo* -COOH position so that the $>C<^{H}_{COOH}$ hydrogen will have two vicinal and one W couplings. Finally, the C9 position (structure **8**) became favored because of a NOESY cross-peak between H5 and hydrogens on C7 and C8, and another NOESY interaction between H9 and a proton assigned by HETCOR and COSY spectra as one of H2 or H3.



8

Analysis of the minor carboxylic acid isomer using HETCOR, COSY, HMBC, and NOESY spectra led to the conclusion that structure **4** was correct for this compound. In particular, a NOESY interaction between the $>C<^{H}_{COOH}$ hydrogen and the bridgehead H5 hydrogen placed the -COOH group in an *endo* position at C7 or C8. However, a C8 placement would lead to only three coupling interactions for the $>C<^{H}_{COOH}$ hydrogen, in conflict with the experimental spectrum.

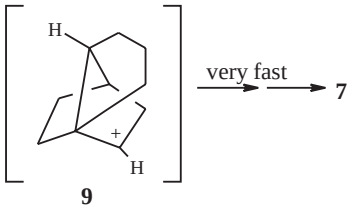
The assignment of structure for the major isomer was subsequently verified by means of a single crystal X-ray diffraction study. Compound **8** crystallizes in a primitive tetragonal cell of space group $P4_2/n$ (no. 86). A total of 1888 unique reflections were collected and the structure was solved by direct methods (*R*-factor of 4.4%). There are eight molecules of **8** in the unit cell, arranged as four hydrogen-bonded dimers. The packing diagram is shown in Fig. 1. An ORTEP

© 1998 NRC Canada

plot of a single molecule is shown in Fig. 2. Details concerning the X-ray structure are provided as supplementary material.[3]

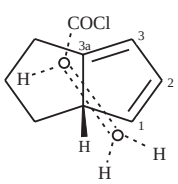
There have been two previous X-ray studies involving a substituted tricyclo[4.2.2.0^{1,5}] decane ring system (8, 9).

It should be mentioned that carbocation **9**, expected from a C9 chloride (via **8**), would rearrange rapidly to cation **7**, and so the mystery of how **7** was being formed in our initial experiments is now explained. Furthermore, since all of the possible Diels–Alder adducts of **1** and **2** (eight possible isomers) have the tricyclo[4.2.2.0^{1,5}] decane framework, the results of ref. 1 are easily accounted for.

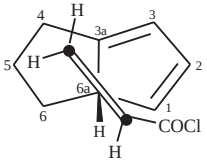


9

It is interesting to compare the contrasting diene–dienophile geometries that lead to the two D–A adducts. These are shown below:



A (major)

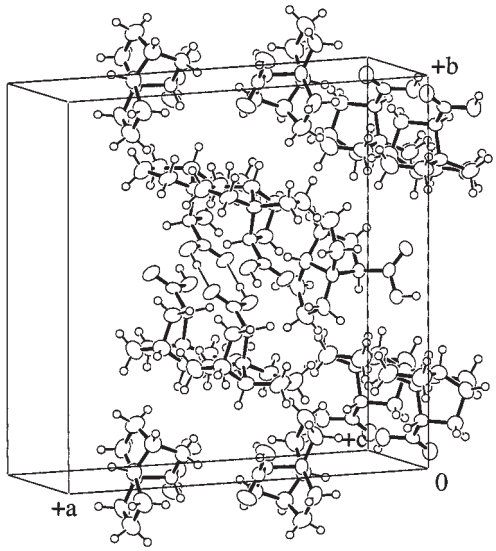


B (minor)

Molecular orbital calculations (B3LYP/6-31G*) of **2** result in a geometry where the diene part is very close to planar. However, the C3a—C4 bond is not colinear with the diene unit, leading to a somewhat curved overall geometry, with the C6a hydrogen on the convex surface.

The LUMO orbital of an acrylic dienophile is well known to have the larger coefficient on the terminal $=CH_2$ carbon, and the initial bonding interaction with the diene should be stronger at this centre (9). Experimentally, there is only a very small preference for the **A** transition state but the choice of only these two geometries (**A** and **B**) can be rationalized by noting that the C3a centre is already slightly sp^3 hybridized (4-3a-6a-1 dihedral angle of –162.6°) and to complete this rehybridization, one requires the dienophile addition geometry as shown in **B**. Conversely, dienophile addition from the concave surface of the diene could be disfavored at C3a by this same geometry. A careful examination of the HOMO p_z orbital on C3a shows that this orbital is not much affected by the ring distortion, but the concave-side lobe is very marginally smaller than the convex surface counterpart, so that both steric and orbital overlap considerations may disfavor C3a.

Fig. 1. Packing diagram for crystalline **8**. Note the existence of four hydrogen-bonded dimers in each unit cell.



This analysis does not of course explain why one gets this almost equal bifacial attack, but given the latter, the regiochemical choices of **A** and **B** seem reasonable. A recent theoretical study by Poirier, Burnell, and co-workers (10) on the facial selectivity of D–A reactions involving 5-substituted cyclopentadienes found 20% *syn*, 80% *anti* for the 5-methylcyclopentadiene case, a compound bearing some resemblance to **2**. Using this model, transition state **A** would be equivalent to *syn* attack.

The *endo* geometry in both **A** and **B** transition states is a normal expectation, contrary to the situation that existed in the structure originally assigned for **8**, i.e., **3**.

Experimental

NMR spectra were obtained on a Bruker AM-400 spectrometer. Carbon multiplicities were determined from DEPT 135 spectra. ^1H–^{13}C correlations were obtained from normal HETCOR. Longer range correlations were made using the inverse HMBC method. Proton–proton coupled networks were determined from COSY or long-range COSY 2D spectra. NOESY 2D spectra were used to assign NOE-related protons.

The preparation of the acids **8** and **4** has been reported, as has the purification of **8** by recrystallization (1). For **8**, ^1H NMR (400 MHz, $CDCl_3$), δ: 2.74 (d,d,d, H9), 2.4–2.15 (2H, H3), 2.1–1.95 (5H, complex, H7, H5, H10, H4, H6), 1.97–1.87 (1H, H10), 1.78–1.68 (d,d,d, 1H, H7), 1.57–1.42 (3H, complex, H2, *endo*-H8, H4), 1.4–1.23 (2H, complex, H2, *exo*-H8). ^{13}C NMR (100 MHz, $CDCl_3$), δ: 182.0 (C=O),

63.9 (q, C1), 63.2 (C5), 47.0 (C9), 36.8 (C7), 36.2 (C6), 30.8 (C10), 29.8 (C3), 28.2 (C4), 27.6 (C8), 20.9 (C2). The data for **4** were obtained from spectra of the **8**–**4** mixture. ^{1}H NMR (400 MHz, partial spectrum; $CDCl_3$), δ: 3.26 (1H, complex, H7), 2.42 (1H, t, H6), 1.91 (H5). ^{13}C NMR (100 MHz, $CDCl_3$), δ: 180.8 (C=O), 61.1 (C5), 58.8 (q, C1), 52.9 (C7), 41.25 (C6), 34.25, 32.0, 29.6, 28.7, 24.4 and 21.3 (all CH_2). ^{13}C assignments for the C2–C4 group in each isomer are somewhat tentative.

Computational details

The structure of dihydropentalene **2** was optimized by standard ab initio molecular orbital calculations at the B3LYP/6-31G* level of theory using the Gaussian 94 suite of programs (11) (E = –310.827 8214 hartrees).

X-ray crystallography

Data collection

A colorless needle crystal of compound **8**, $C_{11}H_{16}O_2$, having approximate dimensions of 0.25 × 0.30 × 0.50 mm was mounted on a glass fiber. All measurements were made on a Rigaku AFC6S diffractometer with graphite-monochromated Mo-Kα radiation.

Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 17 carefully centered reflections in the range 24.20° < 2θ < 37.71° corresponded to a primitive tetragonal cell (Laue class: $4/m$) with dimensions a = 17.589(1) Å, c = 6.276(2) Å, V = 1941.6(7) Å^3. For Z = 8 and F.W. = 180.25, the calculated density is 1.23 g/cm^3. The systematic absences of $hk0$: $H + K \neq 2n$ and $00l$: $L \neq 2n$ uniquely determine the space group to be $P4_2/n$ (no. 86).

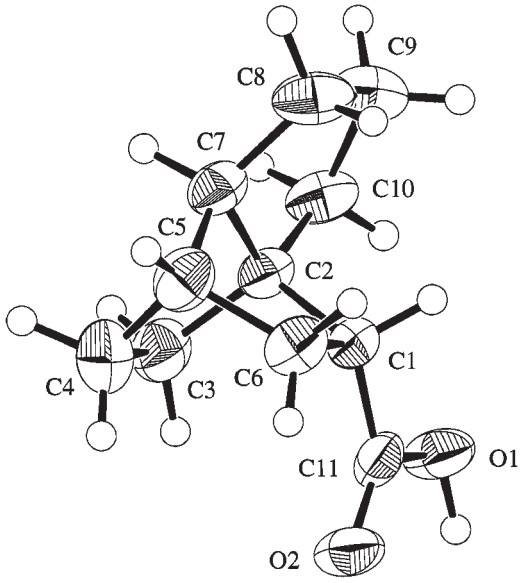
The data were collected at a temperature of 23 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 50.0°. ω-Scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.36° with a take-off angle of 6.0°. Scans of (1.52 + 0.35 tan θ)° were made at a speed of 4.0°/min (in ω). The weak reflections ($I > 10.0\sigma(I)$) were rescanned (maximum of three rescans) and the counts were accumulated to ensure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The diameter of the incident beam collimator was 0.5 mm and the crystal-to-detector distance was 400 mm.

Data reduction

Of the 2017 reflections that were collected, 1888 were unique (R_{int} = 0.045). The intensities of three representative reflections were measured after every 200 reflections. Over the course of data collection, the standards decreased by 1.4%. A linear correction factor was applied to the data to account for this phenomenon.

The linear absorption coefficient, μ, for Mo-Kα radiation is 0.078 mm^{-1}. An empirical absorption correction based on azimuthal scans of several reflections was applied; this resulted in transmission factors ranging from 0.96 to 1.00. The data were corrected for Lorentz and polarization effects. A correction for secondary extinction was applied (coefficient = 2.56519 × 10^{-7}).

Fig. 2. ORTEP plot of the X-ray structure of **8** using a crystallographic numbering scheme.



Structure solution and refinement

The structure was solved by direct methods (12) and expanded using Fourier techniques (13). The non-hydrogen atoms were refined anisotropically. The hydrogen atom coordinates were refined but their isotropic B's were held fixed. The final cycle of full-matrix least-squares refinement was based on 995 observed reflections ($I > 3.00\ \sigma\ (I)$) and 167 variable parameters and converged (largest parameter shift was 0.00 times its esd) with unweighted and weighted agreement factors of

$$R = \Sigma\ ||F_o| - |F_c||\Sigma\ |F_o| = 0.044$$

and

$$R\omega = ([\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega F_o^2)])^{1/2} = 0.019$$

The standard deviation of an observation of unit weight was 2.91. The weighting scheme was based on counting statistics and included a factor (p = 0.001) to downweight the intense reflections. Plots of $\Sigma\omega(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, sin θ/λ, and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.17 and –0.15 e$^-$/ Å^3, respectively.

Neutral atom scattering factors were taken from Cromer and Waber (14). Anomalous dispersion effects were included in Fcalc (15); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (16). The values for the mass attenuation coefficients are those of Creagh and Hubbel (17). All calculations were performed using the teXsan crystallographic software package of the Molecular Structure Corporation (18).

Calculation of octanol–water partition coefficients of organic solutes from their molecular volumes

John T. Edward

Abstract: Bodor and Buchwald (8) have produced a two-parameter equation for calculating the logarithm of the partition coefficient (log *P*) of an organic solute between *n*-octanol and water. They computed the first parameter, a van der Waals volume of the of the solute molecule, using an algorithm combining analytical and numerical techniques. This parameter can be obtained more simply by addition of increments for the various atoms making up the molecule. The second parameter *N*, an integer, is obtained by summation of the integral *N* values associated with the different polar groups present in the molecule, as long as these polar groups are not too close to each other. The *N* term results in a decrease in log *P*. The *N* parameter is thought to measure the total number of H-bonds between the hydrogen of water and H-acceptor bonding sites of the various polar groups of the solute molecule. The detailed nature of the hydrogen bonds between a polar group and water can be elucidated by calculations involving *N* and $\overline{V}^0$, the partial molal volume in water of a solute molecule containing this group.

Key words: partition coefficient, molecular volume, hydrogen bonding, van der Waals volume.

Résumé : Bodor et Buchwald (8) ont proposé une équation à deux paramètres pour calculer le logarithme du coefficient de partage (log *P*) d'un soluté organique entre l'octanol et l'eau. Ils ont calculé le premier paramètre, un volume de van der Waals de la molécule de soluté, en utilisant un algorithme combinant des techniques analytiques et numériques. On peut déterminer ce paramètre d'une façon plus simple par l'addition de valeurs différentielles pour les divers atomes formant la molécule. On obtient le deuxième paramètre, *N*, un nombre entier, en faisant la somme des valeurs de *N* associées aux divers groupes polaires présents dans la molécule, à la condition que ces groupes polaires ne soient pas trop près les uns des autres. Le terme *N* provoque une diminution du log *P*. On croit que le paramètre *N* est une mesure du nombre total de liaisons hydrogènes entre l'hydrogène de l'eau et les sites de liaison pouvant accepter un H des divers groupes polaires de la molécule de soluté. On a déterminé la nature exacte des liaisons hydrogènes entre un groupe polaire et l'eau à l'aide de calculs impliquant *N* et $\overline{V}^0$, le volume molal partiel dans l'eau d'une molécule de soluté contenant ce groupe.

Mots clés : coefficient de partage, volume moléculaire, liaison hydrogène, volume de van der Waals.

[Traduit par la Rédaction]

Introduction

Hansch (1, 2) proposed that the *n*-octanol–water partition coefficient *P* of an organic solute be adopted as a quantitative measure of its lipophilic–hydrophilic character. His proposal has been generally accepted, and log *P* thus defined has found wide use in quantitative structure–activity relationships (QSAR) in pharmacology, physiology, biochemistry, toxicology and environmental sciences; a recent book (3) gives hundreds of references to papers in these different fields.

Many methods for calculating log *P* have been developed (3–7). Those most generally used start by dissecting the structural formula of a molecule into its component fragments (-CH_3, -$CONH_2$, etc.) or atoms, for which fragmental constants have been determined. The value log *P* is then obtained by summation of these fragmental constants, with correction factors for any special features (e.g., intramolecular hydrogen bonding) present in the molecule. A cumbrous array of fragmental constants and correction factors is required. Recently, Bodor and Buchwald (8) showed that for more than 700 organic compounds (including about 80 large pharmaceutically active molecules) log *P* was given with acceptable accuracy by a surprisingly simple equation:

$$\log P = 0.032 v_{BB} - 0.723N \quad [1]$$

where v_{BB} (my notation) represents the Bodor and Buchwald version of the van der Waals volume (*V* in their notation; in $Å^3$) of the individual molecule (further discussed below) and *N* is a positive integer, obtained by adding up the integers characteristic of each hydrophilic group in the molecule. Simple polar atoms or groups (-OH, -O-, -NH_2, -NH-, >N-, -CN, -NO_2, -CO-, -CO_2H, -COO-, -CH=NOH, -N=N-) have *N* = 2; -CON < and -CONH- have *N* = 4. However,

Table 1. The van der Waals increments (in Å^3) of atoms.

Atom	Increment	Atom	Increment	Atom	Increment
>C<	5.6	F-(ar)[b]	8.9	$^-$O-	10.1
>C=	8.1	Cl-(alk)[a]	19.0	-S-	17.9
=C=	11.6	Cl-(ar)[b]	25.8	S=	20.1
-C≡	13.4	Br-(alk)[a]	26.9	>N-	7.2
H-(C)	5.5	Br-(ar)[b]	35.1	-N=	8.6
H-(N)	5.2	I-(alk)[a]	39.8	>N$^+$=	6.7
H-(O)	7.2	I-(ar)[b]	52.1	>N$^+$<	4.6
H-(S)	6.6	-O-	6.2	N≡	8.0
F-(alk)[a]	9.5	O=	11.3	>Si<	18.5

[a]Joined to alkene, alkane, or alkyne carbon.
[b] Joined to aromatic carbon.

when the polar atom or group is attached to an aromatic ring, as in Ar-OH, Ar-O-, Ar-NO_2, Ar-CN, and Ar-CO_2H, *N* equals to 1, although for Ar-NH_2, Ar-NH-, and Ar-COO- *N* remains 2; Ar-CONH- has $N = 3$, and Ar-SO_2NH_2 has $N = 4$.

Equation [1] is based on the generally accepted model of the partition process. The transfer of an organic molecule from water to the *n*-octanol layer is favoured by the greater energy required to create a cavity for the molecule in water, the more highly cohesive solvent. This energy is proportional to the size of the solute molecule, and accounts for the first term (positive) on the RHS of eq. [1]. On the other hand, the volume effect of a polar, hydrophilic group in the solute molecule will be more than compensated by its stronger hydrogen bonding to water than to *n*-octanol; this will favour transfer of the solute from *n*-octanol to the water layer, and accounts for the second term (negative) on the RHS of eq. [1]. In theory, the energy required to form a cavity in solvent should be proportional to the surface area, and not to the volume of the solute molecule, but Bodor and Buchwald found that the experimental evidence favoured (albeit only slightly) the reverse.

Calculation of molecular volumes

While eq. [1], with only two parameters, offers an apparently simple method for calculating log *P*, the calculation of the first parameter by the Bodor and Buchwald method is far from simple. In this calculation each atom is represented by a sphere centred at equilibrium position of the atomic nucleus and having a radius equal to its reported van der Waals radius (but see below). The exterior surfaces of all the spheres define the van der Waals surface of the molecule, which encloses its van der Waals volume. The van der Waals volumes and surface areas were computed with a novel algorithm developed by combining analytical and numerical techniques reported in the literature, with particular attention to the overlaps between spheres joined to a common sphere, and between spheres joined into rings. A complete program for the algorithm was developed.

In applying this program, Bodor and Buchwald adopted atomic radii r_{BB} for the common atoms (C, H, O, N) about 10% smaller than the van der Waals radii r_W adopted by Bondi (9), which since 1964 have been accepted, with small or negligible changes, by most chemists (e.g., Gavezotti (10)). Bodor and Buchwald also reduced the Bondi radii for other atoms, but by varying amounts: F, by 10%; Si, 19%; P, 3%; S, 6%; Cl, 9%; Br, 3%. The radius r_{BB} of I was increased by 4%. Furthermore, the radii r_{BB} of Cl, Br, and I attached to aromatic rings were increased over the Bondi r_W values by the following amounts: Cl, 3%; Br, 8%; I, 9%. The reasons behind these changes are discussed below.

Using these r_{BB} values and known bond lengths and angles, Bodor and Buchwald calculated v_{BB} of more than 700 molecules of which 149 are reported in Table 1 and eight in Chart 1 of their paper.

In 1964 Bondi (9; cf. also 11, 12) described a very much simpler method for obtaining the van der Waals volume v_W of a molecule, by addition of the volume increments of the constituent atoms. The increments were calculated from the bond lengths between atoms and from their van der Waals radii r_W, as estimated by a careful analysis of X-ray crystallographic data. The volume increments for a particular atom varied depending on the other atoms to which it was bonded. Thus Bondi found the increment for the ether oxygen atom -O- to vary from 5.3 to 8.6 Å^3, depending on whether the oxygen was present in a cyclic or acyclic aliphatic or an aromatic ether. In 1970 I adopted a compromise value of 6.2 Å^3 for -O- in ethers, and also in alcohols, carboxylic acids, and esters (12).[2] The same averaging procedure was applied to the Bondi increments for the other common atoms, and the 1970 values thus adopted are reproduced in Table 1, except for -H, -Cl, -Br, -I and ≡N. In the case of -H attached to C, the increment (5.5 Å^3) now given in Table 1 lies between the values reported in 1970 for -H attached to alkane, alkene, and alkyne carbon (5.7 Å^3) and to aromatic carbon (5.3 Å^3).

Increments for the common groups (-CH_3, -OH, -NH-, etc.), based on the atomic increments in Table 1, are given in Table 2. Using atomic and group increments, the calculation of v_W is simple, as illustrated in the case of benzylpenicillin in Fig. 1.

How much is lost by using the summation of the Bondi increments in place of the Bodor and Buchwald computer algorithm to find the volume of a molecule? If we compare v_{BB} and v_W of compounds containing only C, H, O, and N (111 out of 149 compounds in Table 1 of Bodor and

[2] Since in most organic molecules 80–90% of the volume is made up by contributions from C and H, the errors introduced by this averaging are not serious, particularly when the parameter sought is $r_w \equiv (3v_W/4\pi)1/3$ (cf. refs. 13–20), varying as the cube root of v_W.

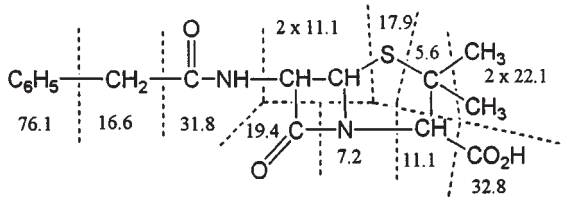
Table 2. The van der Waals increments (in Å^3) of groups.

Group	Increment	Group	Increment	Group	Increment
-CH_3	22.1	-NH_2	17.6	-NO_2	28.1
-CH_2-	16.6	-NH-	12.4	-CO-O-	25.6
>CH-	11.1	-OH	13.4	-CO-OH	32.8
-C_6H_5	76.1	>C=O	19.4	-CO-NH_2	37.0
-C_6H_4-	70.6	-SO_2-	32.3	-CO-NH-	31.8

Fig. 1. Calculation of van der Waals volume v_W (in Å^3) of benzylpenicillin by addition of atomic (Table 1) or group increments (Table 2): v_W = 76.1 + 16.6 + 31.8 + 22.2 + 17.9 + 5.6 + 44.2 + 32.8 + 11.1 + 7.2 + 19.4 = 284.9 Å^3.



Buchwald (8)), we find that essentially nothing is lost, v_{BB} being related to v_W by the linear equation

[2] $$v_{BB} = 0.838v_w$$

with a correlation coefficient r of about 0.999. However, for the 27 other compounds in Table 1 of Bodor and Buchwald (8) containing ≡N or halogen, the correlation is poorer. This is to be expected: while Bodor and Buchwald made r_{BB} about 10% smaller than r_W for C, H, O, and N, they made it smaller or larger by varying amounts for the halogens (as discussed above) in order to bring log P calculated by eq. [1] into agreement with experiment. I have followed this policy and altered the atomic increments for -F, -Cl, -Br, -I, and ≡N from their 1970 values (12) to those now given in Table 1. With these revised increments, eq. [2] now applies to 145 out of the 149 compounds listed by Bodor and Buchwald in their Table 1 (8).[3] (The four compounds not considered, ampyzine, myleran, methopromazine, and cyanamphenicol, had structures that could not be found in the pharmacopoeias consulted, and have been ignored). The 145 compounds range from methylamine (v_{BB} 35.27 Å^3) and acetonitrile (v_{BB} 36.16 Å^3) to fluocinonide (v_{BB} 358.75 Å^3) and betamethasone-17,21-dipropionate (v_{BB} 384.97 Å^3). The excellence of the correlation is shown in Fig. 2 (slope 0.838; r = 0.99916), and further in Table 3 in which v_{BB} of eight compounds listed by Bodor and Buchwald in Chart 1 of their paper is compared with $0.838v_W$. Both measures of molecular volume prove to be essentially identical, and both equally suitable for calculating log P by eq. [1]. Accordingly, this equation may be recast as

[1*a*] $$\log P = 0.027v_w - 0.723N$$

Testing eq. [1*a*] or [3*a*] with two further data sets

Equation [1*a*] accommodates Bodor and Buchwald's data set of log P values for more than 700 compounds; we now consider how well it accommodates another data set of 187 compounds listed by Sangster (4), and a set of 37 compounds (22) containing one or another of two polar groups not listed by Bodor and Buchwald.

The 187 compounds listed by Sangster (4),[3,4] comprise a great variety of types, including 14 alkanes ranging from methane to methylcyclohexane. Bodor and Buchwald (8) showed that for alkanes eq. [1] must be expanded to

[3] $$\log P = 0.032v_{BB} - 0.723N + 0.010v_{BB}I$$

where I is a simple indicator variable, equal to 1 for alkanes and zero for other compounds. Substituting $0.838v_W$ for v_{BB} gives

[3*a*] $$\log P = 0.027v_w - 0.723N + 0.008v_wI$$

This equation with I = 1 yields values of log P in good agreement with experiment for the alkanes of Table 2S,[3] but also, surprisingly, for five perhaloalkanes in Table 4; the exception (tetrafluoromethane, no. 4) should perhaps be reinvestigated.

For the remaining 167 of the 187 compounds listed by Sangster I = 0. Using values of N given by Bodor and Buchwald's rules (except for 11 "special cases" discussed below) eq. [3*a*] gives values of log P_{calc} in good agreement with experiment. This is shown in Fig. 3, an error histogram (estimation error Δ = log P_{calc} – log P_{expt}) for the data set of 187 compounds; 52% have an error of 0.20 or less, and 98% an error of 0.80 or less, about equal to the performance of the AFC method of Meylan and Howard (23) for a data set of 8406 compounds. However, this is not a fair comparison: the data set used by Meylan and Howard is vastly greater, and the calculations were carried out by computer (no human intervention), while N for the 11 aberrant compounds in my data set were chosen to optimize agreement between experimental and calculated values of log P. Still, it shows the

[3] Table 1S giving v_W, $0.838v_W$, and v_{BB} of the 145 compounds is available as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2. (Also available from this source is Table 2S, mentioned later.) The v_W values of ring compounds (e.g., benzylpenicillin in Fig. 1) were obtained by summation of increments without applying corrections for ring formation (21); these corrections resulted in a poorer correlation of v_W with v_{BB}.

[4] Table 2S, available as supplementary material,[3] lists the 187 compounds with an identifying number, formula, name, v_W, N, I, log P_{calc} by eq. [3*a*], log P_{expt}, and estimation error Δ (≡ log P_{calc} – log P_{expt}). Sangster listed 210 compounds (ref. 4, pp. 157–161); the 23 compounds omitted from consideration were amino acid zwitterions (structures contain charged groups not included in Table 2), compounds identified by trade names, not chemical names, and compounds whose structures included atoms or groups not included in Tables 1 and 2.

24	CCl_3–CCl_3	4.14	3.38	–0.76	4.88	0.24

[a]Number of compound as listed in Table 2S.
[b] From Sangster (4, pp. 157–158).
[c] $\Delta \equiv$ log P_{calc} – log P_{expt}.
[d] I = 1 in eq. [3*a*].

potential of eq. [3*a*] if the difficulties with N can be surmounted: it is vastly more simple than present computerized methods (cf. AFC method of Meylan and Howard, which uses 130 atom/fragment contribution values and 235 correction factors). At present it works well for compounds that contain no polar groups, one polar group, or two or more polar groups sufficiently separated from each other. This can be seen by scanning Table 2S,[3] which contains mostly simple compounds.

The larger errors shown in Fig. 3 (e.g., for hexachlorocyclopentadiene, ethylene diamine) may in fact be due to errors in reported values of log P_{expt}; these

Fig. 3. Error histogram for the 187 compounds listed by Sangster (4) showing the number N of compounds having estimation errors Δ (= log P_{calc} – log P_{expt}) in the intervals –0.99 to –0.90, ... –0.09 to 0, 0.01 to 0.10, etc.

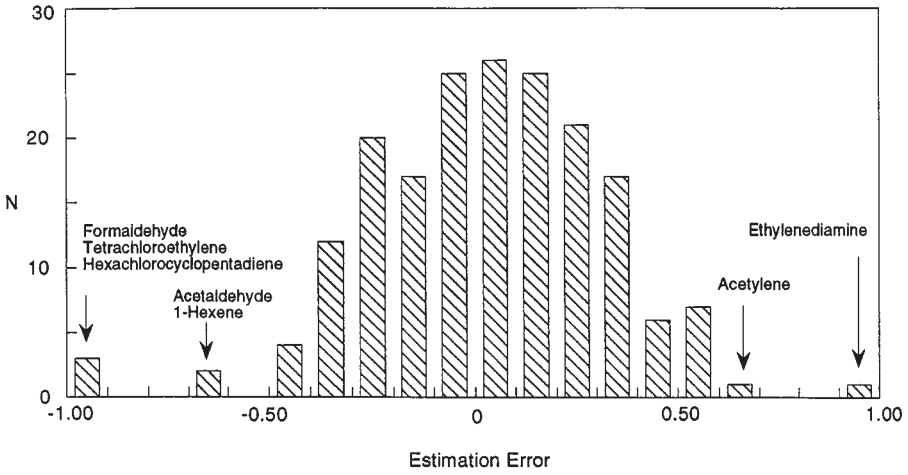

Fig. 4. General structures **1** (the 100 series), **2** (200 series), and **3** (300 series) of the iron-chelating compounds of Table 5.

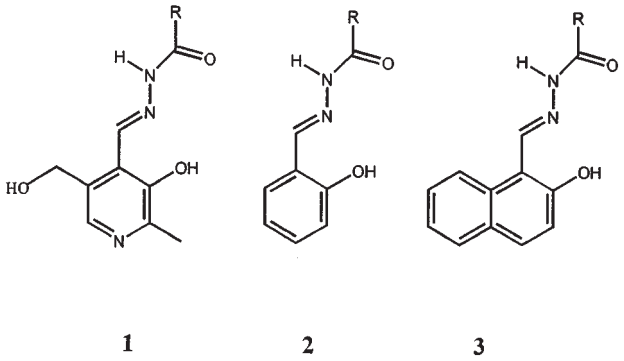

compounds should be reinvestigated. The error of –0.91 for tetrachloroethylene comes from accepting log P_{expt} = 3.40 given by Sangster (4); accepting log P_{expt} = 2.60 given by Bodor and Buchwald (8) reduces the error to –0.11.[5]

The estimation errors of –0.98 for formaldehyde and –0.63 for acetaldehyde shown in Fig. 3 are not real, log P_{calc} being based on the assumption that in water these compounds have the structures $CH_2{=}O$ and $CH_3CH{=}O$. This is almost completely false for formaldehyde (no. 12, Table 2S[3]), more than 99% of which exists in the hydrated form $CH_2(OH)_2$, and partly false for acetaldehyde (no. 38), about 55% of which exists in water in the hydrated form $CH_3CH(OH)_2$ and 45% in the unhydrated form $CH_3CH{=}O$ (24). For hydrated formaldehyde eq. [3*a*] with N = 1 (see below) gives log P_{calc} = 0.45, in good agreement (Δ = 0.10) with log P_{expt} = 0.35 (4). Accepting N = 1 for the hydrated form of acetaldehyde also, the log P_{expt} of 0.45 (4) for acetaldehyde (no. 38) is compatible with a mixture of 58% $CH_3CH(OH)_2$ and 42% $CH_3CH{=}O$, close to the proportions indicated by other properties (24) and reported above. Similarly, the log P_{expt} of 0.59 for propanal (no. 65) corresponds to a mixture of 30% $CH_3CH_2CH(OH)_2$ and 70% $CH_3CH_2CH{=}O$; the proportions in water previously reported (24) are 42:58. However, acetone (no. 64), shown to be about 99.8% in the unhydrated form in water (24), has an estimation error Δ of 0.50; a confirmation of log P_{expt} would be desirable. Furfural (no. 110) and benzaldehyde (no. 180), which undergo negligible hydration, have N = 2, like acetophenone (8), and only small errors in log P_{calc}.

The error of –0.60 for 1-hexene (Fig. 2) is reduced to +0.23 if I in eq. [3*a*] is set at 1, not zero; i.e., if 1-hexene is regarded as behaving more as an alkane than an alkene. Data for other long-chain alkenes would be interesting.

Choice of *N* values for 11 special cases

For most of the 187 compounds listed by Sangster the value of N to be used in eq. [3*a*] presented no problems. Thus for the hydroxyl group, N = 2, so that for ethanol (no. 45 in Table 2S) N = 2, for ethylene glycol (no. 47) N = 4, and for glycerol (no. 79) N = 6. In the polyhydroxy compounds each hydroxyl is separated by at least two carbon atoms from its neighbour. However, as we saw above, in order to calculate a reasonable log P for $CH_2(OH)_2$ in which the hydroxyls are separated by a single carbon atom, it was necessary to set N = 1, not 4. This is an example of the general rule: in a molecule containing several polar groups, the value of N for the molecule is the sum of the N values for the individual polar groups only if the groups are sufficiently separated from each other; otherwise the value for N of the molecule may become less than this sum (the "proximity" effect). This effect has been known for a long time (7), but is not invoked by Bodor and Buchwald for any of the 157 compounds in their paper to which they assign N values. However, it seems to show up in the N value which they assign to benzylpenicillin (Fig. 1), which contains a carboxyl group (N = 2) and two amide groups (N = 4) separated by single carbon atoms. According to simple additivity this should lead to N = 4 + 4 + 2 = 10, but Bodor and

[5] Of 187 compounds listed by Sangster in Table 2S,[3] 34 are also listed in Bodor and Buchwald's paper (8). For 31 of these compounds, log P_{expt} values reported by Sangster (4) and by Bodor and Buchwald are the same or almost the same; for only three compounds log P_{expt} values differ by more than 0.20: tetrachloroethylene (see above), ethylene glycol (–1.65 (8), –1.36 (4); 2,3-dimethylbutane (3.85 (8), 3.42 (4)).

Buchwald assign to the compound $N = 8$ (without comment).

Several other examples of the proximity effect become apparent on examining Table 2S. Thus when two ether oxygen atoms ($N = 2$) are separated by at least two carbon atoms, as in 1,4-dioxane (no. 82), $N = 4$; when they are separated by one carbon atom, as in methylal (dimethoxymethane, no. 76) and 1,3-dioxalane (no. 67), N for the molecule is 3. Similarly, 1,3,5-trioxane (no. 70) has three ether oxygen atoms separated by single carbon atoms in a ring, and has $N = 3$, not 6.

Even more than proximity, juxtaposition of polar groups can reduce N. This is already apparent in the N values assigned by Bodor and Buchwald to composite polar groups. Thus -O-, -OH, and -CO- all have $N = 2$, but the composite groups -CO-O- and -CO-OH also have $N = 2$, rather than $N = 4$ expected by simple additivity. Consequently, it comes as no surprise that on the basis of their log P_{expt} values carbon dioxide O=C=O (no. 5) must have $N = 0$, urea (no. 19: H_2N-, $N = 2$, and -$CONH_2$, $N = 4$) must have $N = 5$, and theophylline (no. 183), a bicyclic compound containing one imidazole ring ($N = 2$) and a second ring containing two -CONH- groups ($N = 2 \times 4$), must have $N = 6$, not 10. At present, it is necessary (in the absence of any theory) to determine experimentally the N value for each case of juxtaposed polar groups.

Electronic or steric effects can also reduce N. Bodor and Buchwald noted that while nitrobenzene has $N = 1$, and aniline $N = 2$, *p*-nitroaniline has $N = 2$, not 3, because the electron-withdrawing effect of the nitro group reduces the N value of the amino group. The same effect may be operating progressively in the ethanolamines (nos. 51, 108, and 174 in Table 2S), as shown by their pK^{BH+} values. Monoethanolamine (no. 51; pK^{BH+} 9.98 (25)) has $N = 4$, and diethanolamine (no. 108, pK^{BH+} 8.97 (25)) has $N = 6$, as expected; triethanolamine (no. 174, pK^{BH+} 7.92 (25)) has $N = 7$, not 8. Reduced base strength and (or) steric hindrance may be responsible. *N*-Nitrosodimethylamine (no. 44) and *N*-nitrosodiethylamine (no. 97) have $N = 3$, but *N*-nitrosodipropylamine (no. 169) has $N = 2$. Steric effects may be involved here and in the case of some of the phenols which follow. Thus phenol and 2,3,4,5-tetrachlorophenol (no. 133), which has only one chlorine atom *ortho* to the hydroxyl group, have $N = 1$, but 2,3,4,6-tetrachlorophenol (no. 134) and pentachlorophenol (no. 129), which have two chlorine atoms *ortho* to the hydroxyl group, have $N = 0$. On the other hand, 2,6-dichlorophenol (no. 144, two *ortho* chlorine atoms) has $N = 1$; a buttressing effect may be missing in this molecule. Tetrachloro-4-methoxyphenol (no. 175, two chlorine atoms *ortho* to both -OH ($N = 1$) and -OCH_3 ($N = 1$)) has $N = 1$.

The N values of the 11 compounds discussed above are marked with asterisks in Table 2S[3] to show that they have been assigned on the basis of log P_{expt} values (i.e., to minimize Δ). This "fudging" reduces the overall error for the 187 compounds and narrows the spread in Fig. 3, but not by very much; the assignment of N to the other 176 compounds followed automatically from Bodor and Buchwald's rules. More experimental data for marginal compounds are required before we can discover if it is possible to extend Bodor and Buchwald's rules to accommodate them.

A second data set

The second data set for testing eq. [3*a*] consists of 37 iron-chelating compounds having the general structures **1** (the 100 series), **2** (200 series), and **3** (300 series) shown in Fig. 4; detailed structures are indicated in Table 5. These compounds all contain the composite polar group -CH=N-NHCO-, except for two (113 and 213 in Table 5), which contain instead the composite group -CH= N-NH-. The log P_{expt} values of these compounds have recently been reported (22), but Bodor and Buchwald do not give an N value for either composite group.

The experimental data under **4** in Fig. 5 require $N = 4$ for -CH=N-. Bodor and Buchwald report $N = 3$ for aromatic -NHCO-, in agreement with the log P_{expt} for **5** (Fig. 5), and in the absence of a juxtaposition effect the value of N for -CH=N-NHCO- would be 4 + 3 = 7. In fact, log P_{expt} for the compound **6** in Fig. 4 requires $N = 4$ for this grouping.

The introduction of an aromatic -OH group into an organic molecule increases N by one unit, but this is usually cancelled out when it is introduced *ortho* to a group to which it can hydrogen bond, as in *ortho*-hydroxybenzoic acid (8). Hydrogen bonding would also be expected to occur when -OH is introduced *ortho* to the >C=N- group of **6**, so that **2** would be expected to have $N = 4$. This is found to be true: compounds of the general structures **2** and **3** in which the substituent R does not have a polar group (e.g., compounds 201, 203, 206, 208, 209, 210, 212, 214, 215, 309, 310, 314 in Table 5) all have $N = 4$. When the R group contains a polar substituent (-OH in 202 and 302; -NO_2 in 204; -NH_2 in 205 and 305; pyridinyl N in 211) it should be sufficiently distant from the other polar groups to make its usual contribution to the N value of the molecule. This is what happens.

Compounds of the 100 series (Table 5) have, in addition to the polar groups found in **2** and **3** which account for $N = 4$, a -CH_2OH group ($N = 2$) and a pyridine nitrogen ($N = 2$), adding up to $N = 8$ for the simple structure (with no polar group in R). In fact, $N = 6$ is required to accommodate the experimental data for compounds 101, 102, 106, 108, 109, 110, 112, 114, and 115 in Table 5. Polar groups in R make their usual contrbutions to N of compounds 102, 104, 105, 107 and 110 in Table 5.

Compounds 113 and 213 have -CH=N-NH- in place of -CH=N-NHCO- in **1** and **2**, and R is 2-pyridinyl ($N = 2$). For these molecules the experimental data require $N = 3$ (see Table 5), a large reduction from the sum of the N values of the separate groups: CH=N- ($N = 4$), -NH- ($N = 2$), and 2-pyridinyl ($N = 2$).

If ever N can be estimated with confidence, eq. [3*a*] may prove to be one of the more accurate methods for calculating log *P*. This is shown by comparing its performance with that of the three computerized methods considered most reliable by Sangster (4), and listed in Table 6, in calculating log *P* of the 35 compounds in Table 5 (omitting the compounds 113 and 213 of different structure). A quantitative measure of performance is given by fitting calculated log *P* values to the experimental data in Table 5 according to the equation

$$[4] \qquad \log P_{calc} = a + b \log P_{expt}$$

© 1998 NRC Canada

Table 6. Comparison of four methods for calculating partition coefficients: statistical data from fitting log P_{calc} values to eq. [4] by linear regression, using experimental data (log P_{expt}) from Table 5.

Calculation method for log P_{calc}	n	a	b	r
Eq. 1[a], this paper	35	0.13	0.93	0.940
CLOGP 1.0.0 for Windows	35	–0.95	0.97	0.920
KOWWIN 1.54	37	–1.98	1.31	0.952
ACD/Log P1.0	37	–2.38	1.51	0.913

by linear regression. For a perfect correlation, $a = 0$, $b = 1$, and the correlation coefficient $r = 1.000$. The results in Table 6 show that eq. [3*a*] performs very well. A strict comparison with the results for the computerized methods would not be fair, because their parameters are based on data sets of many thousands of compounds, while the parameter N used in eq. [3*a*] was chosen to give the best possible correlation of log P_{expt} with log P_{calc} for this very limited data set of 35 compounds. Still, it shows the potential of eq. [3*a*] if the problems of estimating the parameter N can be resolved.

The value *N* and types of hydrogen bonding

Insight into the different ways in which a polar group forms H-bonds to water comes from combining information from N and from $\bar{V}^0$, the partial molal volumes of compounds containing this group.

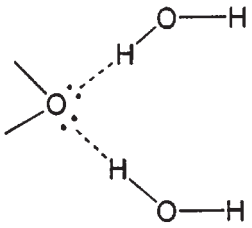
Polar groups G: with unshared pairs of electrons such as -O-, >C=O, and >C=N- can form only one type of hydrogen bond, G:---H-OH or G:---H-OR, to the acidic hydrogen of water or *n*-octanol. We designate these as type I bonds. Polar groups -G-H containing labile hydrogen, such as -OH, -NH-, -CO_2H, and -CO-NH-, can form both type I and type II bonds, in the latter case the H of -G-H bonding to the unshared electron pairs of water and *n*-octanol: -G-H---OH_2 or -G-H---OHR.

Bodor and Buchwald (8) assert that N measures only type I bonds: *n*-octanol and water have nearly equal solvent β-strengths (26–28), and hence type II bonds by G-H to the oxygen of either *n*-octanol or water will have about equal strengths, and so will not affect the partition process. Since -O- and -N < have different numbers of unshared pairs of electrons, but both have $N = 2$, it seems plausible that they form H-bonds of different character, as shown in **7** and **8** (Fig. 6), >N- bonding a linked pair of water molecules because of its superior basicity.

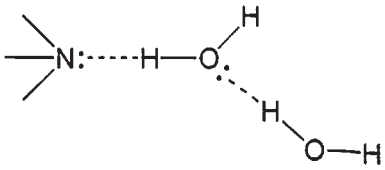
Information on the total number N_H (= $N_I + N_{II}$) of hydrogen bonds formed by a polar group in water comes from $\bar{V}^0$ of organic solutes in water (21, 29–31).The value $\bar{V}^0$ is made up of the individual volume contributions $\bar{v}^0$(= $\bar{V}^0/N_a$) of N_a molecules, N_a being the Avogadro number. The contribution $\bar{v}^0$ of a single molecule can be considered to be made up of its van der Waals volume v_W plus the average void or empty volume (32) associated with it. For spherical molecules the empty volume is given by an enclosing spherical shell of thickness Δ, so that

$$[5] \qquad \bar{v}^0 = 4\pi(r_w + \Delta)^3/3$$

Fig. 6. Possible modes of H-bonding of water molecules to ether oxygen **7** and to amine nitrogen **8**.



7



8

where $r_W = (3v_W/4\pi)^{1/3}$ and Δ = 0.57 Å for approximately spherical molecules (21, 29). For cylindrical molecules an alternative equation (also involving v_W) is required (21, 30, 33).

Equation [5] appears to be applicable to molecules that do not hydrogen bond appreciably to water. When hydrogen bonding groups G or G-H are present on the surface of the molecule, $\bar{v}^0$ is decreased according to the equation

$$[6] \qquad \bar{v}^0 = 4\pi(r_w + \Delta)^3/3 - \Sigma n_i\sigma_i$$

where n_i is the number of polar groups of type i in the molecule and σ_i is the volume decrement associated with type i (30). This equation gives fairly accurate estimates (usually to within 1–2%) of the partial molal volumes of a wide variety of compounds, ranging from methane to oligosaccharides (31). Values of σ_i determined by experiment for different polar groups are given in Table 7.

With the assumption that the formation of each hydrogen bond leads to a contraction of 1.8 Å^3 in $\bar{v}^0$ (about the estimate of Bondi (9)), the σ_i values lead to the estimates of N_H given in Table 7 (compare σ_i(expt) with σ_i(calc)). Simple arguments from structure lead to the division of N_H into numbers of H-bonds of type I (N_I) and type II (N_{II}) given in the table.

For a given group, values of N_I should correspond to Bodor and Buchwald's N. This is found to be true for the hydroxyl, primary amino, secondary amino, tertiary amino, and amide groups, but not for ketone or ester carbonyl oxygen ($N_I > N$) or for ether oxygen ($N_I = 0$, Bodor and Buchwald's $N = 2$). In the last case, n_i was assumed to be zero in order to derive the value of 0.57 Å for the fundamental parameter Δ (21); all the values of σ_i and thence N_I in Table 7 are dependent on this assumption. By assuming for ethers that $N_I = 2$ and $\sigma = 3.6$ Å^3, it is possible to recalculate Δ = 0.59 Å. This leads to larger values of σ_i for the other groups in Table 7, and to unrealistically large values of N_H.

Table 7. Hydrogen bonding of polar groups to water as calculated from σ values (ref. 29) and from Bodor and Buchwald *N* values (ref. 8).

	σ_i (eq. [8])		H-bonds			Bodor and Buchwald
Group	Expt.[a]	Calc.[b]	N_H[c]	N_{II}	N_I	N[d]
-N=	3.6	3.6	2	0	2	2
>N-H	7.2	7.2	4	2	2	2
$-NH_2$	10.8	10.8	6	4	2	2
>C=O	8.0	7.2	4	0	4	2
>C=S	0	0	0	0	0	-
-O-C(=O)-	8.0	7.2	4	0	4	2
H_2N-C(=O)-	18.8	18.0	10	6	4	4
-O-	0	0	0	0	0	2
-S-	0	0	0	0	0	0 or 1[e]
-O-H	9.8	10.8	6	4	2	2

[a] From ref. 29.
[b] Assuming $\sigma_i = 1.8\ N_H$.
[c] Chosen to make σ(calc) ~ σ(expt).
[d] From ref. 8.
[e] Bodor and Buchwald (ref. 8) report $N = 1$ for ethyl sulfide and $N = 0$ for thiophenol.

It is possible that H-bonding of pure water (the solvent for $\bar{V}^0$ studies) to ether or ketone oxygen is different from H-bonding of water saturated with *n*-octanol to these groups. Further work is needed.

Conclusions

Because of its simplicity, Bodor and Buchwald's two parameter equation has great promise. As shown in this paper, the first parameter is easily obtained from atomic increments. The second parameter (*N*) can be assigned without difficulty, following Bodor and Buchwald's rules, for compounds without a polar group, with a single polar group, or with two or more polar groups sufficiently separated from each other. However, the rules for *N* fail when two or more polar groups are too close to each other: when, for example, two ether oxygens are separated by a single carbon atom. This particular case may be due to the anomeric effect (34); other cases may involve other electronic or steric effects. Further work is required to discover whether Bodor and Buchwald's rules for *N* can be expanded to cover these special cases.

Acknowledgments

I am grateful to Professor D.F.R. Gilson for bringing ref. 8 to my attention and for counsel over many years, to Dr. J. Sangster for advice and for his invaluable book, to Professor R.B. Lennox for hospitality in his laboratory, to Dr. F.L. Chubb for drawing figures, to two anonymous referees for helpful criticism, to my son Jeremy for much help in computations and in drawing Fig. 2, and to my son Valentine for typing this paper.

A practical and efficient enantioselective synthesis of (2*S*)-3-(*tert*-butylsulfonyl)-2-benzylpropionic acid, a useful chiral building block for renin inhibitors

Yoshifumi Yuasa, Yoko Yuasa, and Haruki Tsuruta

Abstract: (2*S*)-3-(*tert*-Butylsulfonyl)-2-benzylpropionic acid **1**, which is used as the *N*-terminal chiral building block of renin inhibitors, is synthesized from (*Z*)-2-(*tert*-butylsulfonylmethyl)-3-phenyl-2-propenoic acid **6** by enantioselective hydrogenation using Ru–BINAP complexes in the presence of triethylamine with 84% ee. The enantioselective hydrogenation of a substrate with sulfone functionality is first reported.

Key words: hydrogenation, enantioselectivity, Ru–BINAP, oxidation, renin inhibitor.

Résumé : Faisant appel à une hydrogénation sélective catalysée par des complexes de Ru–BINAP en présence de triéthylamine, on a synthétisé l'acide (2*S*)-3-(*tert*-butylsulfonyl)-2-benzylpropionique, **1**, (ee de 84%) à partir de l'acide (*Z*)-2-(*tert*-butylsulfonylméthyl)-3-phénylprop-2-énoïque, **6**. Il s'agit du premier cas d'hydrogénation énantiosélective d'un substrat comportant une fonction sulfone.

Mots clés : hydrogénation, énantiosélectivity, Ru–BINAP, oxydation, inhibiteur de la rénine.

Introduction

(2*S*)-3-(*tert*-Butylsulfonyl)-2-benzylpropionic acid **1** (Fig. 1) has become of interest because it serves as the *N*-terminal position of many renin inhibitors (1, 2). Several preparations of **1** are known: (*i*) resolution by its diastereomeric salt with (+)-dehydroabiethylamine (2), (*ii*) enzymatic hydrolysis of the ester of racemic **1** (3), and (*iii*) synthesis from a chiral oxazoline derivative (4).

In addition, different synthetic approaches are reported for compounds related to **1** (5, 6).

On the other hand, enantioselective hydrogenation with Ru–BINAP complex catalyst is one of the most powerful tools for the synthesis of optically active compounds (for a review, see ref. 7). In particular, enantioselective hydrogenation of 3-substituted-2-propenoic acids and substituted alkylidenesuccinic acids are well known (7*a*, 8, 9). The enantioselective hydrogenation of a 2-sulfur substituted-3-naphthyl-2-propenoic acid has been reported (10, 11), however, that of 2-sulfonyl substituted propenoic acid is unknown.

We have studied the enantioselective hydrogenation of 2-sulfonyl substituted propenoic acid in order to develop a practical synthesis of **1**. We report an efficient synthesis of **1** from (*Z*)-2-(*tert*-butylsulfonylmethyl)-3-phenyl-2-propenoic acid **6** via enantioselective hydrogenation using an Ru–BINAP complex catalyst.

Results and discussion

The starting substrates, (*Z*)-2-(*tert*-butylthiomethyl)-3-phenyl-2-propenoic acid **5** and (*Z*)-2-(*tert*-butylsulfonylmethyl)-3-phenyl-2-propenoic acid **6** were synthesized from ethyl (*Z*)-2-(chloromethyl)-3-phenyl-2-propenate **3** (12, 13). Treatment of **3** with *tert*-BuSH at room temperature for 18 h gave ethyl (*Z*)-2-(*tert*-butylthiomethyl)-3-phenyl-2-propenate **4** in 87% yield. Sulfide **4** was hydrolyzed with 1 N NaOH and a catalytic amount of benzyltriethylammonium chloride (BTEAC) at reflux (rfx) for 5 h to afford sulfide acid **5** in 88% yield. Sulfide acid **5** was oxidized with 30% H_2O_2 in the presence of a catalytic amount of Na_2WO_4 at 60°C for 3 h to provide sulfone acid **6** in 96% yield (Scheme 1).

We next investigated the enantioselective hydrogenation of sulfone acid **6** using Ru-*p*-tolyl-BINAP (*p*-tolyl-BINAP = 2,2′-bis(di-*p*-tolyl-phosphino)-1,1′-binaphtyl; see ref. 14). Sulfone acid **6** in a methanol–H_2O mixture solvent was hydrogenated using $Ru_2Cl_4[(-)$-*p*-tolyl-BINAP$]_2Et_3N$ (14) to give **1** in 84% ee (Scheme 2). Recently, Jendralla et al. (10, 11) reported the hydrogenation of the naphthyl analog of sulfide acid **5** using Ru[(–)-BINAP]$(OAc)_2$ in methanol; however, they have not reported the enantioselective hydro-

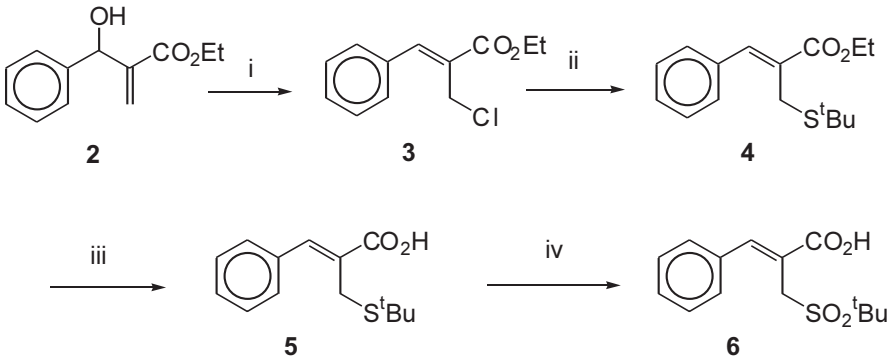
Scheme 1. Synthesis of **5** and **6**; (*i*) conc. HCl – conc. H_2SO_4, rt, 18 h (78%); (*ii*) *t*-BuSH, K_2CO_3, CH_3CN, rt, 18 h, (87%); (*iii*) 1 N NaOH, BTEAC, rfx, 5 h, then 6 N HCl (88%); (*iv*) 30% H_2O_2, Na_2WO_4, MeOH, 60°C, 2 h (96%).



Scheme 2. Enantioselective hydrogenation of **5** and **6**; (*i*) H_2, 40 atm, Ru-*p*-tolyl-BINAP, MeOH–H_2O, as required Et_3N, 80°C, 16 h.

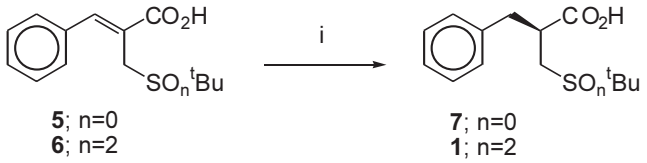


Fig. 1. (2*S*)-3-(*tert*-Butylsulfonyl)-2-benzylpropionic acid.

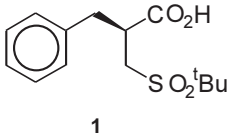

genation of sulfone acid. When sulfide acid **5** was hydrogenated using Ru_2Cl_4[(+)-*p*-tolyl-BINAP]$_2Et_3N$ as catalyst, (2*S*)-3-(*tert*-butylthio)-2-benzylpropionic acid **7** of 78% ee was produced. Enantioselectivity in the hydrogenation of sulfide **5** was lower than the reaction with sulfone **6**. The hydrogenation results using various Ru–BINAP complexes are listed in Table 1. We found that the addition of 10 wt.% H_2O to MeOH, as solvent, increased the conversion. The use of only MeOH resulted in lower conversion. The addition of a catalytic amount of triethylamine incremented the enantioselectivity of the hydrogenation to provide **1**. On the other hand, triethylamine had no effect on the enantioselectivity to provide **7**. This additional catalytic amount of triethylamine represents a new technical improvement on the hydrogenation procedure of sulfone acid. High reaction temperature (>100°C) caused decomposition of substrate. The enantiomeric purity of the target compound **1** could be enriched to 98% ee by recrystallization of its cyclohexylammonium salt.

The enantiomeric purity of **1** and **7** was determined by NMR and (or) HPLC analysis after conversion to the corresponding (*R*)-1-(1-naphthyl)ethylamides (see Experimental section). The absolute configuration of **7** was determined by oxidation to **1** under conditions similar to those previously described for the synthesis of **6** from **5**.

In conclusion, we have described a practical and efficient synthesis of a building block for renin inhibitor. (2*S*)-3-(*tert*-Butylsulfonyl)-2-benzylpropionic acid **1** was produced via an enantioselective hydrogenation of (*Z*)-2-(*tert*-butylsulfonylmethyl)-3-phenyl-2-propenoic acid **6** in an overall yield of 35% from propenate **3**.

Experimental section

All reagents and solvents were obtained from commercial sources and used without further purification. Melting points were measured using a Yanagimoto micromelting apparatus and are uncorrected. Boiling points are uncorrected. The IR spectra were recorded on a Jasco IR-810 instrument (ν in cm^{-1}). Optical rotations were measured on a Jasco DIP-4 digital polarimeter. Mass spectra (electronic impact) and high-resolution mass (HRMS) spectra were obtained using a Hitachi M-80A mass spectrometer. The ^{1}H NMR and ^{13}C NMR spectra (TMS as internal standard) were recorded on a Bruker AM-400 (400 MHz and 100 MHz). The GLC were performed using a Shimadzu GC-9A with an FID detector (column: PEG-HT (df = 0.15 μm, 0.25 mm ID × 25 m); at 100–200°C, +4.0°/min; carrier gas N_2, 1.0 kg/cm^2); HPLC were performed on a Hitachi L-6000 with a L-4000 UV as a detector (column: Inertsil ODS-2 (5 μm, 4.6 mm × 250 mm) using an eluent of CH_3CN/H_2O, 7:3 (pH 2.3; adjusted by

using H_3PO_4), and a flow rate of 0.6 mL/min with UV detection at 210 nm or 254 nm).

Ethyl (*Z*)-2-(*tert*-butylthiomethyl)-3-phenyl-2-propenate 4

To ethyl (*Z*)-2-(chloromethyl)-3-phenyl-2-propenate **3** (12, 13) (44.9 g, 0.2 mol) in acetonitrile (200 mL) were added K_2CO_3 (29 g, 0.21 mol) and *tert*-BuSH (25 mL, 0.22 mol) at room temperature. The reaction mixture was stirred at room temperature for 18 h. The insoluble solid was filtered off, and the filtrate was concentrated. To the residue, AcOEt was added, and the organic layer was separated, washed with brine, dried with $MgSO_4$, and concentrated in vacuo. The residue was distilled under reduced pressure to give **4** (48.4 g, 87% yield) as an oil; bp 142–145°C (0.5 torr); IR (neat): 1715, 1635, 1580 cm^{-1}; ^1H NMR ($CDCl_3$), δ: 1.35 (t, J = 7.1 Hz, 3H, CH_3), 1.36 (s, 9H, *t*-C_4H_9), 3.67 (s, 2H, SCH_2), 4.30 (q, J = 7.1 Hz, 2H, CH_2), 7.35–7.43 (m, 3H, Harom), 7.61–7.63 (m, 2H, Harom), 7.72 (s, 1H, CH=); ^{13}C NMR ($CDCl_3$), δ: 14.27 (CH_3), 25.92 (CH_2), 30.61 (C(**C**H_3)$_3$), 43.21 (**C**$(CH_3)_3$), 61.12 (CH_2S), 128.39 (2 X CH, Ar), 128.54 (C, Ar), 128.74 (CH, Ar), 129.63 (2 X CH, Ar), 135.09 (C=), 140.78 (CH=), 167.36 (CO); MS (EI, 70 eV), *m*/*z*: 278 (M^+, 41), 222 (45), 176 (94), 115 (100), 57 (63). HRMS calcd. for $C_{16}H_{22}O_2S$: 278.1339; found: 278.1337.

(*Z*)-2-(*tert*-Butylthiomethyl)-3-phenyl-2-propenoic acid 5

To ethyl (*Z*)-2-(*tert*-butylthiomethyl)-3-phenyl-2-propenate **4** (36.3 g, 0.13 mol) were added 1 N NaOH (240 mL) and benzyltriethylammonium chloride (BTEAC) (0.36 g). After heated to a reflux for 5 h, the reaction mixture was cooled to room temperature and adjusted to pH 2 with 6 N HCl. After extraction with AcOEt, the organic layer was washed with brine, dried with $MgSO_4$, and concentrated in vacuo to give **5** (28.6 g, 88% yield) as a white solid; mp 86–88°C; IR ($CHCl_3$): 1690, 1625, 1580 cm^{-1}; ^1H NMR ($CDCl_3$), δ: 1.39 (s, 9H, *t*-C_4H_9), 3.69 (s, 2H, SCH_2), 7.38–7.46 (m, 3H, Harom), 7.66–7.68 (m, 2H, Harom), 7.87 (s, 1H, CH=); ^{13}C NMR ($CDCl_3$), δ: 25.58 (SCH_2), 30.64 (C(**C**H_3)$_3$), 43.36 (**C**$(CH_3)_3$), 127.73 (C, Ar), 128.63 (2 X CH, Ar), 129.37 (CH, Ar), 129.90 (2 X CH, Ar), 134.22 (C=), 143.22 (CH=), 172.78 (CO); MS (EI, 70 eV), *m*/*z*: 250 (M^+, 32), 194 (65), 176 (36), 161 (61), 115 (81), 57 (100). Anal. calcd. for $C_{14}H_{18}O_2S$: C 67.17, H 7.25, S 12.81; found: C 67.20, H 7.26, S 12.89.

(*Z*)-2-(*tert*-Butylsulfonylmethyl)-3-phenyl-2-propenoic acid 6

To (*Z*)-2-(*tert*-butylthiomethyl)-3-phenyl-2-propenoic acid **5** (20 g, 80 mmol) in MeOH (250 mL), Na_2WO_4 (0.2 g, 0.6 mmol) and 2 N H_2SO_4 (10 mL) were added. The mixture was heated to 60°C and 30% H_2O_2 (40 mL) was added dropwise over a period of 1 h. The reaction mixture was stirred at 60°C for 2 h and cooled to room temperature. Ten percent aqueous $Na_2S_2O_3$ solution (100 mL) was added and concentrated in vacuo. To the residue, AcOEt was added, and the organic layer was separated, washed with brine, and dried with $MgSO_4$. The solvent was concentrated in vacuo to give a solid. The solid was recrystallized from AcOEt–*n*-hexane to give **6** (21.6 g, 96% yield) as a white solid; mp 187–188°C; IR ($CHCl_3$): 1690, 1625, 1580 cm^{-1}; ^1H NMR ($CDCl_3$), δ: 1.48 (s, 9H, *t*-C_4H_9), 4.32 (s, 2H, SO_2CH_2), 7.43–7.46 (s, 3H, Harom), 7.73–7.75 (m, 2H, Harom), 8.23 (s, 1H, PhCH=); ^{13}C NMR ($CDCl_3$), δ: 23.43 (C(**C**H_3)$_3$), 45.19 (SO_2CH_2), 60.52 (**C**$(CH_3)_3$), 119.36 (C, Ar), 128.83 (2 X CH, Ar), 129.49 (2 X CH, Ar), 130.11 (C, Ar), 133.76 (C=), 148.36 (CH=), 171.71 (CO); MS (EI, 70 eV), *m*/*z*: 282 (M^+, 3), 162 (100), 133 (27), 115 (93), 57 (100). Anal. calcd. for $C_{14}H_{18}O_4S$: C 59.55, H 6.43, S 11.35; found: C 59.59, H 6.44, S 11.30.

Hydrogenation procedure

All hydrogenations were carried out in a 100 mL stainless-steel autoclave. Under N_2, catalyst (0.028 mmol), substrate **5** or **6** (28 mmol), as required, Et_3N (6.4 μL), and the solvent MeOH–H_2O (10/1, 41.8 mL) were added. The atmosphere was then replaced with H_2 (40 atm), and the reaction mixture was stirred at 80°C for 16 h. Upon completion of the reaction, the solvent was removed under reduced pressure. The residue was dissolved in 1 N NaOH and washed twice with Et_2O. The aqueous layer was acidified with 2 N HCl and extracted with AcOEt. The extract was dried with $MgSO_4$ and concentrated in vacuo to give a crude product **7** (6.3 g, 89% yield, 78% ee by ^1H NMR) or **1** (7.41 g, 93% yield, 84% ee by HPLC). For determination of enantiomeric purity by ^1H NMR or HPLC, sulfide acid **7** and sulfone acid **1** were derivatized to the (*R*)-1-(1-naphthyl)ethylamides. To a CH_2Cl_2 solution containing crude **7** or **1** (10 mmol), (*R*)-1-(1-naphthyl)ethylamine (10 mmol), *N*,*N*′-dicyclohexylcarbodiimide (11 mmol) and 4-dimethylaminopyridine (20 mg) were added, and the mixture was stirred at room temperature for 6 h. The mixture was washed with 1 N HCl, 5% Na_2CO_3 solution, brine, and dried with $MgSO_4$. The solvent was evaporated and analyzed by ^1H NMR or HPLC. ^1H NMR (*S*,*R*)-amide of **7**, δ: 1.61 (d, J = 6.7 Hz, CH_3), 5.65 (d, J = 8 Hz, C<u>H</u>CON), 5.87(m, NC<u>H</u>CH_3); (*R*,*R*)-amide of **7**, δ: 1.36 (d, J = 6.7 Hz, CH_3), 5.44 (d, J = 8 Hz, C<u>H</u>CON), 5.76 (m, NC<u>H</u>CH_3). HPLC (t_{ret}: (*S*,*R*)-amide of **1**, 12.2 min; (*R*,*R*)-amide of **1**, 13.1 min).

(2*S*)-3-(*tert*-Butylthio)-2-benzylpropionic acid 7

To 6.3 g of crude **7**, which was previously described in the hydrogen procedure, diethyl ether – *n*-hexane mixture (1/2, 30 mL) was added, and an insoluble solid was filtered off and mother liquid was concentrated in vacuo to give 3.5 g (49% yield) of **7** as a viscous oil. The enantiomeric purity was 98% ee by ^1H NMR. $[\alpha]_D^{24}$ +7.6 (*c* 1.0, CH_2Cl_2); IR ($CHCl_3$): 1710, 1605 cm^{-1}; ^1H NMR ($CDCl_3$), δ: 1.27 (s, 9H, *t*-C_4H_9), 2.64 (dd, J = 5.7, 12.2 Hz, 1H, $PhCH_2$), 2.79 (dd, J = 7.4, 12.2 Hz, 1H, $PhCH_2$), 2.87–2.96 (m, 2H, SCH_2), 3.01–3.05 (m, 1H, $CHCO_2$), 7.20–7.29 (m, 5H, Harom); ^{13}C NMR ($CDCl_3$), δ: 29.04 (SCH_2), 30.82 (C(**C**H_3)$_3$), 37.27 ($PhCH_2$), 42.56 (**C**$(CH_3)_3$), 47.99 (CH), 126.64 (CH, Ar), 128.43 (2 X CH, Ar), 129.00 (2 X CH, Ar), 138.26 (C, Ar), 180.18 (CO); MS (EI, 70 eV), *m*/*z*: 252 (M^+, 4), 210 (11), 176 (20), 117 (30), 91 (23), 71 (7), 57 (100); HRMS calcd. for $C_{14}H_{20}O_2S$: 252.1182; found: 252.1180.

(2*S*)-3-(*tert*-Butylsulfonyl)-2-benzylpropionic acid 1

In this preparation, 7.42 g of the crude solid **1**, which was described in previous hydrogen procedure, was dissolved in 50 mL of EtOH, and then 2.78 g of cyclohexylamine was

© 1998 NRC Canada

added. The reaction mixture was cooled at 5°C, and the precipitated crystalline was filtered off and washed with 2-propanol (30 mL) to give 6.23 g of a cyclohexylamine salt of **1**. The cyclohexylamine salt was treated with 1 N HCl, and the aqueous mixture was extracted with AcOEt. After drying with $MgSO_4$, the evaporation of the solvent in vacuo gave 3.78 g (51% yield) of **1** as a white solid. The enantiomeric purity was 98% ee by HPLC (15); mp 98–99°C; lit. (4) mp 99–101°C; $[\alpha]_D^{24}$ +10.58 (*c* 1.0, CH_2Cl_2), lit. (4) $[\alpha]_D^{24}$ +10.9 (*c* 1.0, CH_2Cl_2); IR ($CHCl_3$): 1710, 1600, 1300, 1110 cm^{-1}; ^1H NMR ($CDCl_3$), δ: 1.36 (s, 9H, *t*-C_4H_9), 2.98 (dd, *J* = 3.4, 12 Hz, 1H, $CHCO_2$), 3.04 (dd, *J* = 7.1, 13.8 Hz, 1H, $PhCH_2$), 3.22 (dd, *J* = 6.1, 13.8 Hz, 1H, $PhCH_2$), 3.42 (m, 2H, SO_2CH_2), 7.23–7.33 (m, 5H, Harom); ^{13}C NMR ($CDCl_3$), δ: 23.23 (C(**C**$H_3)_3$), 37.47($PhCH_2$), 40.04 (CH), 45.52 (SO_2CH_2), 59.58 (**C**$(CH_3)_3$), 127.22 (CH, Ar), 128.79 (2 X CH, Ar), 129.24 (2 X CH, Ar), 136.75 (C, Ar), 177.22 (CO); MS (EI, 70 eV), *m*/*z*: 284 (M^+, 4), 238 (8), 164 (40), 117 (59), 91 (65), 73 (55), 57 (100). HRMS calcd. for $C_{14}H_{20}O_4S$: 284.3696; found: 284.3712.

Observations on the stereochemistry of reduction of 2,6-dimethylcyclohexanones

Thomas E. Goodwin, Jennifer M. Meacham, and Mark E. Smith

Abstract: The reduction of *cis*-2,6-dimethylcyclohexanone with $NaBH_4$ in methanol is shown to produce predominantly the axial alcohol, an unexpected result based upon prior reports and current paradigms for similar cyclohexanone reductions. This finding prompted a careful and systematic investigation of the $NaBH_4$ and $LiAlH_4$ reductions of *cis*- and *trans*-2,6-dimethylcyclohexanones in various solvents, with additional results contrary to literature reports. Possible explanations for these discrepancies are given, an unusual solvent effect is noted, the rate of epimerization versus reduction is examined, molecular modeling results are reported, and an important caveat is offered for future stereochemical studies of this nature.

Key words: cyclic ketone reduction, stereochemistry, molecular modeling.

Résumé : On démontre que la réduction de la *cis*-2,6-diméthylcyclohexanone par le $NaBH_4$ dans le méthanol conduit d'une façon prépondérante à l'alcool axial; ce résultat est inattendu sur l'on se base sur les rapports antérieurs et sur les paradigmes actuels proposés pour les réductions de cyclohexanones semblables. Cette observation nous a amenés à réexaminer d'une façon soignée et systématique les réductions des *cis*- et *trans*-2,6-diméthylcyclohexanones par le $NaBH_4$ et le $LiAlH_4$ dans divers solvants; on a obtenu d'autres résultats sont contraires à ceux rapportés antérieurement. On présente diverses propositions pour expliquer ces différences; on note un effet de solvant inhabituel, on a examiné la vitesse d'épimérisation par rapport à la vitesse de réduction, on rapporte des résultats de modélisation moléculaire et on présente une mise en garde pour les futures études stéréochimiques de cette nature.

Mots clés : réduction de cétone cyclique, stéréochimie, modélisation moléculaire.

Introduction

The stereochemical course of the reduction of cyclic ketones, especially cyclohexanones, has been a topic of intense theoretical and practical interest for decades (for a convenient tabular listing of examples, see ref. 1). In general, sterically undemanding reducing agents such as $LiAlH_4$ and $NaBH_4$ are known to approach simple cyclic ketones preferentially along what is apparently the more hindered axial trajectory, thus leading to the equatorial alcohol as the major reaction product. This tendency can be reversed by using reagents or substrates that are more sterically demanding. Reduction of *cis*-2,6-dimethylcyclohexanone (**1**) can yield two diastereomeric alcohols (**2** and **3**). The *trans* isomer (**4**) provides diastereomers **5** and **6**, which are easily interconverted by a ring flip, thus yielding for all practical purposes only the more stable conformer **5**. In a seminal paper, Wigfield and Phelps (2) reported that reduction of the *cis* isomer **1** with $NaBH_4$ in 2-propanol gave a **2**:**3** alcohol ratio of 62:38. Assignment of equatorial alcohol **2** as the major product was based on relative GC retention times and analysis of 60 MHz NMR spectra. Garner (3) found that reduction of **1** with $NaBH_4$ in methanol yielded two alcohols in a ratio of 68:32; by analogy to the earlier work, the major isomer was assumed to be equatorial alcohol **2** (see Scheme 1).

When we repeated the reduction of *cis*-2,6-dimethylcyclohexanone with $NaBH_4$ in methanol, the axial alcohol **3** was clearly the major product, an unexpected result based upon prior reports and current paradigms for similar cyclohexanone reductions (see Discussion). We have carefully and systematically reexamined the $NaBH_4$ and $LiAlH_4$ reductions of *cis*- and *trans*-2,6-dimethylcyclohexanones and report herein additional results that are not entirely in accord with prior reports. Possible explanations for the discordances are given, an unusual solvent effect is noted, the rate of epimerization versus reduction is examined, molecular modeling results are reported, and an important caveat is offered for other stereochemical studies of this nature.

Results

The reduction of a mixture of *cis*- and *trans*-2,6-dimethylcyclohexanones was performed using $LiAlH_4$ in both diethyl ether and THF, as well as with $NaBH_4$ in both methanol and 2-propanol.[2] As much as possible, reaction conditions were standardized (see Experimental). The product mixtures were directly analyzed by GC–MS before any solvent evaporation, since we experienced product loss with

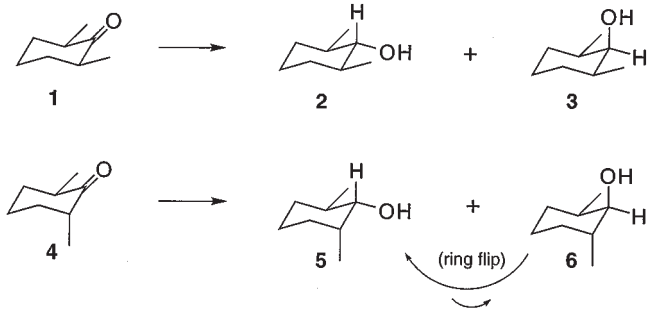
Scheme 1. Reduction products from 2,6-dimethylcyclohexanones.



use of a rotary evaporator. Product mixtures were also analyzed by ^{1}H NMR spectroscopy. Before preparation of NMR samples, the dried product solutions were placed in a hood to allow selective solvent evaporation at the ambient temperature.

Table 1 shows the ratio of products from reduction of *cis*-2,6-dimethylcyclohexanone as determined by both GC–MS and NMR.[3] Very little stereoselectivity is evident for reduction of the *cis* ketone with the notable exception of the $NaBH_4$ reduction in methanol for which our ratios are similar to those reported by Garner (3). In contrast, however, to the earlier assumption for this reductant–solvent combination, it is clear that the axial alcohol **3** predominates over the equatorial alcohol **2** in the product mixture as shown by 300 MHz ^{1}H NMR spectral analysis and integration. Specifically, the HCOH methine hydrogen for isomer **2** appears as a triplet (J = 9.6 Hz) at δ 2.70, while that for isomer **3** appears as a broad singlet at δ 3.53, thus they are easily distinguished. The analogous hydrogen for alcohol **5** appears as a doublet of doublets (J = 7.7, 4.1 Hz) at δ 3.32).[4]

There is less consonance between our ratios for reduction of the *cis* isomer with $NaBH_4$ in 2-propanol and the 62:38 ratio reported previously (2). This reaction was run again in our laboratories under the more dilute conditions and longer reaction time used in the former work (5), to provide a **2**:**3** ratio of 49:51 as determined by GC–MS.[5] In view of the product loss in this reaction when using a rotary evaporator, it is possible that differential evaporation of isomers **2** and **3** gave rise to the apparent predominance of **2** reported by earlier workers. Support for this conclusion is evidenced in entry D of Table 1, which reports essentially no selectivity by GC–MS, but a slight excess of alcohol **2** by NMR integration after solvent evaporation, a result more in line with the prior report (2).

Table 1. Relative percent of reduction products from 2,6-dimethylcyclohexanones.

		Compound no.	
Reagent–solvent	Method	**2**:**3**	(**2** + **3**):**5**
A. LAH–THF	GC–MS	49:51	80:20
	NMR	49:51	79:21
B. LAH–Et_2O	GC–MS	53:47	80:20
	NMR	54:46	79:21
C. $NaBH_4$–MeOH	GC–MS	29:71	80:20
	NMR	33:67	79:21
D. $NaBH_4$–*i*-PrOH	GC–MS	50:50	75:25
	NMR	54:46	71:29

Our $LiAlH_4$ data disagree with a tabulated **2**:**3** ratio of 62:38 in the literature (6), although the origin of that ratio is not clear and may be a mistaken citation of the Wigfield and Phelps data (2) using $NaBH_4$ in 2-propanol.[6] Our results are, however, in line with those of Boone and Ashby (7), who observed that $LiAlH_4$ reduction of the closely related *cis*,*cis*-4-*tert*-butyl-2,6-dimethylcyclohexanone in THF gave 53% of the equatorial alcohol (axial hydride addition).

The table also lists the ratio of products (**2** + **3**) derived from reduction of *cis*-2,6-dimethylcyclohexanone to that (product **5**) from the *trans* isomer. This ratio is of interest when compared to the ratio of reactant ketones (see footnote 2). The GC–MS and ^{1}H NMR spectral analyses reveal a constant ratio for entries A, B, and C, suggesting little if any epimerization of the reactant ketones before reduction. The exception is entry D ($NaBH_4$ in 2-propanol), where the proportion of alcohol **5** in the product mixture is higher than that of ketone **4** in the reactant mix. This phenomenon has been noted previously (2*a*). This discrepancy was found to be even more pronounced in a more dilute solution of 2-propanol (see footnote 5) where a (**2** + **3**):**5** ratio of 84:16 was determined by GC–MS, although the **2**:**3** ratio was essentially unchanged relative to entry D in Table 1. The $NaBH_4$ reduction of 2,6-dimethylcyclohexanones in 2-propanol is apparently significantly slower than for the other three reductant–solvent combinations, a difference which becomes even more pronounced upon dilution. This rate decrease then allows epimerization to take place prior to reduction, giving rise to variable results.

Discussion

Boone and Ashby (7) have presented clear evidence that equatorial α-methyl substituents on a cyclohexanone ring

[2] The mixture of *cis*- and *trans*-2,6-dimethylcyclohexanones was obtained from Aldrich and was labeled as 98% pure. By GC–MS, a *cis*:*trans* ratio of 80:20 was found, remarkably close to the 81:19 ratio reported by Garner (3) in 1993. A ratio of 79:21 by integration of the ^{1}H NMR spectrum of a $CDCl_3$ solution was also observed. As the results in Table 1 and discussion in the text reveal, minor ratio discrepancies of this sort are common, and thus are at least partly related to idiosyncrasies of the two measurement techniques.

[3] The values in Table 1 represent an average of duplicate, simultaneous reactions. The NMR ratios for the two LAH–THF reactions were 51:49 and 48:52. Otherwise, agreement was excellent between duplicate runs, with differences in relative product percentages between each pair of reactions averaging 0.4 for GC–MS analysis and 0.7 for NMR analysis.

[4] A similar chemical-shift trend and coupling pattern was reported for the analogous acetates (4*a*). Coupling constants for the HCOH methine hydrogen were calculated on MMX-minimized structures using PCMODEL (Serena Software) and are in good agreement with experimental values: **2** (t, J = 10.1 Hz), **3** (t, J = 1.8 Hz), and **5** (dd, J = 10.1, 4.6 Hz). The ^{1}H NMR calculation using PCMODEL is based on a modified Karplus algorithm (4*b*). The ^{13}C NMR spectral assignments for alcohols **2**, **3**, and **5** have been reported (4*c*).

[5] The ketone mix (89 μL) and $NaBH_4$ (29 mg) were reacted in 3.2 mL of 2-propanol for 23 h.

retard axial approach of $LiAlH_4$. A simple, yet compelling steric rationalization for this trend is that with each additional equatorial α-alkyl group, a new 1,3-diaxial-type interaction exists between the incoming axial nucleophile and a C—H bond on a rotamer of the alkyl group, thus disfavoring this approach trajectory (e.g., for *cis*-2,6-dimethylcyclohexanone, four such interactions would exist: one from each axial hydrogen on carbons 3 and 5, and one from each α-methyl). When the "nonbonded" electron isodensity surface (the molecule's "electron cloud") from 3-21G(*) ab initio calculations is examined, an increasing steric bias against axial approach of a nucleophile is observed as α-substitution increases.[7]

An explanation for the usual avoidance of equatorial approach of a small nucleophile to the carbonyl carbon of an unhindered cyclic ketone invokes torsional strain with neighboring axial α-hydrogens (8). Anh (9*a*) has proposed that axial approach of the nucleophile is most favorable when the axial α-hydrogens are closer to being perpendicular to the plane of the carbonyl group (the "flattening rule"), thus maximizing the n-σ^* interaction between the unshared electron pair of the nucleophile and the antibonding orbital of each axial α-C—H bond (the "antiperiplanar effect").[8]

To examine flattening in the present case, the dihedral angle has been determined between an axial α-hydrogen and the carbonyl for cyclohexanone, 2-methylcyclohexanone, and *cis*-2,6-dimethylcyclohexanone on structures generated by geometry optimization using AM 1 semi-empirical calculations, followed by single-point 3-21G(*) ab initio calculations. The angles are 105.1°, 111.0°, and 113.1°, respectively, thus leading to a correct prediction of an increased equatorial approach of the nucleophile with α-substitution based on Anh's flattening rule.

Nucleophilic additions to carbonyl groups are often considered to result from an interaction between the HOMO of the nucleophile and the LUMO of the carbonyl group. It is of interest to note that the absolute value of the LUMO[7] for cyclohexanone, 2-methylcyclohexanone, and *cis*-2,6-dimethylcyclohexanone is greater on the face of the ring corresponding to axial approach of the nucleophile, thus suggesting preferred nucleophilic approach from that direction. As α-substitution increases, however, steric factors may become more decisive than these orbital interactions. Notably, when the 2,6-dimethylcyclohexanone mixture was reduced with the bulky reducing agent $Li(s\text{-}Bu)_3BH$ in THF, none of product **2** could be detected, thus demonstrating that axial bond formation on ketone **1** is sterically disfavored.[9]

Conclusions

For reduction of *cis*-2,6-dimethylcyclohexanone with $LiAlH_4$ in diethyl ether or THF, or with $NaBH_4$ in 2-propanol, there is apparently a very close balance between factors that hinder and (or) encourage axial and equatorial hydride addition thus leading to little stereoselectivity. With $NaBH_4$ in methanol, however, formation of the axial alcohol **3** predominates. In an earlier mechanistic study on ketone reductions with $NaBH_4$ in a protic solvent, Wigfield and Gowland (12) found a kinetic order of 1.5 with respect to 2-propanol. Therefore, solvent clearly can play a role in the $NaBH_4$ reduction mechanism. Perhaps interaction of *cis*-2,6-dimethylcyclohexanone with methanol results in a subtle conformational shift, which increases the dihedral angle between the axial α-hydrogens and the carbonyl, thus leading to increased equatorial approach of the reducing agent. Whatever the reason, the solvent-dependent stereoselectivity reported herein provides further evidence of the important role that the solvent plays in $NaBH_4$ reductions. Finally, a caveat is proffered: our experience suggests that similar studies of reduction stereochemistry should analyze isomer ratios before solvent evaporation is attempted, to avoid possible alteration of product ratios through differential rates of evaporation.

Experimental

All reductions were run in duplicate for 1 h on 89 μL (82.3 mg; 0.652 mmol) of a commercial mixture (Aldrich) of *cis*- and *trans*-2,6-dimethylcyclohexanones (see footnote 2) and an excess of the reducing agent (0.738 mmol of $LiAlH_4$ or 0.714 mmol of $NaBH_4$) with stirring in 1 mL of solvent. In all cases, the ketones were added with caution to a stirring mixture of the reducing agent in the chosen solvent at the ambient temperature (approx. 20°C). The $NaBH_4$ reductions were cautiously quenched with 3 M HCl (1 mL), diluted with saturated NaCl solution (1 mL), and extracted with diethyl ether (3 × 1 mL). The $LiAlH_4$ reactions were cautiously quenched with H_2O (two drops), aqueous NaOH solution (15%; six drops), and again with H_2O (two drops), then filtered over Celite, which was rinsed with diethyl ether (4 mL). Ether solutions were dried over anhydrous Na_2SO_4.

The GC–MS analysis was carried out using a Hewlett Packard 5890 Series II chromatograph with an HP 5971A mass selective detector. The capillary column was an HP-5 (cross-linked 5% phenyl methyl silicone) with a length of 30 m, an inner diameter of 0.25 mm, and a film thickness of 0.25 μm. Baseline separation was achieved for all three alcohol products with an initial temperature of 60°C (hold 0.5 min), followed by a 4°C/min ramp to 90°C (hold 0.5 min), then a 10°C/min ramp to 100°C. The starting ketones were not detected in any of the product mixtures. The

[7] All ab initio calculations were carried out using MacSpartan Plus from Wavefunction, Inc.

[8] Another popular and useful hypothesis proposed by Cieplak (10*a*) assumes an electron-poor transition state for nucleophilic addition to a carbonyl, thence leading to reaction preferentially antiperiplanar to the best electron-donating vicinal bond. (For a review of arguments for and against the Cieplak model, see ref. 10*b*; for a cogent commentary and new data, see ref. 10*c*.).

[9] Throughout Discussion, an assumption has been made that the reduction of the cyclic ketones proceeds via the more stable chair conformers, yet it is possible that the less populous chair conformer is reduced more rapidly (cf. ref. 11). Examination of the nonbonded electron isodensity surface from 3-21G(*) calculations for the less stable chairs of 2-methylcyclohexanone, and *cis*-2,6-dimethylcyclohexanone reveals a clear steric preference for formation of the equatorial alcohol (axial approach of the nucleophile), which upon chair flip to the more stable conformer provides the axial alcohol. This is the same major product that would be expected from reduction of the more stable ketone conformer if the reaction outcome is controlled primarily by steric factors.

Solubility of fluoranthene in organic nonelectrolyte solvents. Comparison of observed versus predicted values based upon Mobile Order theory

Carmen E. Hernández and William E. Acree, Jr.

Abstract: Experimental solubilities are reported at 25.0°C for fluoranthene dissolved in 36 different organic nonelectrolyte solvents containing ester, ether, hydroxy, chloro, methyl, and *tert*-butyl functional groups. Results of these measurements are used to test the applications and limitations of expressions derived from Mobile Order theory. For the 28 solvents for which predictions could be made, computations show that Mobile Order theory does provide fairly reasonable estimates of the saturation mole fraction solubilities. Average absolute deviation between predicted and observed values is 53%. In comparison, the average absolute deviation is 1574% when ideal solution behavior is assumed.

Key words: fluoranthene solubilities, organic nonelectrolyte solvents, solubility predictions.

Résumé : On a déterminé les solubilités expérimentales, à 25°C, du fluoranthène dissous dans 36 solvants organiques non électrolytes contenant des groupes fonctionnels ester, éther, hydroxyle, chloro, méthyle et *tert*-butyle. On a utilisé les résultats de ces mesures pour vérifier les applications et les limitations d'expressions dérivées de la théorie de l'ordre mobile. Dans le cas des 28 solvants pour lesquels il a été possible de faire des calculs, ceux-ci montrent que la théorie de l'ordre mobile conduit à des évaluations assez raisonnables des solubilités de saturation exprimées en fraction molaire. La déviation moyenne absolue entre les valeurs calculées et observées est de 53%. En comparaison, la déviation moyenne absolue est de 1574% lorsqu'on fait l'hypothèse que la solution se comporte de façon idéale.

Mots clés : solubilités du fluoranthène, solvants organiques non électrolytes, prédictions de solubilité.

[Traduit par la Rédaction]

Introduction

Solid–liquid equilibrium data for organic nonelectrolyte systems are becoming increasingly important in the petroleum industry, particularly in light of present trends towards heavier feedstocks and known carcinogenicity/mutagenicity of many of the larger polycyclic aromatic compounds. Solubility data for a number of polycyclic aromatic hydrocarbons (e.g., anthracene and pyrene) and hetero-atom polynuclear aromatics (e.g., carbazole, dibenzothiophene, and xanthene) have been published in the recent chemical literature (for listing of references see Acree (1–3)). Despite efforts by experimentalists and scientific organizations, both in terms of new experimental measurements and critically evaluated data compilations, there still exist numerous systems for which solubility data are not readily available.

To address this problem, researchers have turned to group contribution methods and semiempirical expressions to predict desired quantities. Group contribution methods have proved fairly successful in estimating solid solubility in pure and binary solvent mixtures from structural information (4–11). Practical application, however, is limited to systems for which all group interaction parameters are known. Interaction parameters can be evaluated from liquid–vapor, liquid–liquid, and solid–liquid equilibria data. It is important that the data base contain as many different functional groups as possible, preferably with adequate representation from both mono- and multi-functional solute/solvent molecules to permit evaluation of potential synergistic effects. The data base should contain sufficient experimental values near infinite dilution in the event that one wishes to determine separate interaction parameters for finite concentration and infinite dilution activity coefficient predictions.

Abraham et al. (12, 13) recently developed a general solvation equation that can be used in the correlation and understanding of physicochemical and biochemical phenomena. Physical properties that have been correlated include gas–solvent partition coefficients (as log L)

$$[1] \qquad \log L = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + d\log L^{16}$$

and water–solvent partition coefficients (as log P)

$$[2] \qquad \log P = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + vV_x$$

Received March 25, 1998.

© 1998 NRC Canada

where R_2 and V_x refer to the molar refraction and McGowan volume of the solute, respectively, π_2^H is the solute dipolarity/polarizability descriptor, and $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ are measures of the hydrogen-bond acidity and hydrogen-bond basicity of the solute. For any given solvent, numerical values of the curve-fit coefficients (*c*, *r*, s, *a*, *b*, *d*, and *v*) are deduced by regressing experimental partition coefficient data in accordance with eqs. [1] and [2]. The input partition coefficients were sometimes calculated as the ratio of the solute molar solubilities in the organic solvent and water, $P = C_A^{org}/C_A^{aq}$, and as the ratio of the solute molar solubility in the organic solvent and vapor concentration, $L = C_A^{org}/C_A^{gas}$. Published papers have reported curve-fit coefficients for water (12, 13) and a few select organic solvents (13).

To increase the solubility database available for developing group contribution methods and general solvation correlations, we are in the process of measuring solubility data for polycyclic aromatic hydrocarbons (PAHs) and polycyclic aromatic nitrogen heteroatoms (PANHs). In the present communication, we report fluoranthene solubilities in 36 different organic solvents. Functional groups represented include ethers, esters, hydroxy, chloro, aromatic, and saturated hydrocarbons. Results of these measurements are used to further test the applications and limitations of predictive expressions derived from Mobile Order theory.

Materials and methods

Fluoranthene (Aldrich, 98%) was recrystallized several times from methanol. *n*-Hexane (Aldrich, 99%), *n*-heptane (Aldrich, HPLC), *n*-octane (Aldrich, 99+%, anhydrous), *n*-nonane (TCI, 99+%), *n*-decane (TCI, 99+%), *n*-hexadecane (Aldrich, 99%), cyclohexane (Aldrich, HPLC), methylcyclohexane (Aldrich, 99+%, anhydrous), cyclooctane (Aldrich, 99+%), 2,2,4-trimethylpentane (Aldrich, HPLC), *tert*-butylcyclohexane (Aldrich, 99+%), dibutyl ether (Aldrich, 99%), methyl *tert*-butyl ether (Arco, 99.9+%), butyl acetate (Aldrich, 99.7%), ethyl acetate (Aldrich, HPLC, 99.9%), 1-chlorobutane (Sigma-Aldrich, HPLC, 99.5+%), 1-chlorooctane (Aldrich, 99%), chlorocyclohexane (Aldrich, 99%), methanol (Aldrich, 99.9+%), ethanol (Aaper Alcohol and Chemical Company, absolute), 1-propanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich HPLC, 99.8+%), 2-butanol (Aldrich, 99+%, anhydrous), 1-pentanol (Aldrich, 99+%), 2-pentanol (Acros 99+%), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), 2-methyl-2-butanol (Acros, 99+%), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 3-methyl-1-butanol (Aldrich, 99+%, anhydrous), 1-octanol (Aldrich, 99+%, anhydrous), 4-methyl-2-pentanol (Acros, 99+%), 2-ethyl-1-hexanol (Aldrich, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), and cyclopentanol (Aldrich, 99%) were stored over molecular sieves before use. Gas chromatographic analysis showed solvent purities to be 99.7 mol% or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1°C for at least 3 days (often longer). Attainment of equilibrium was verified both by repetitive measurements after several additional days and by approaching equilibrium from supersaturation by preequilibrating the solutions at a higher temperature. Aliquots of saturated fluoranthene solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample, and were diluted quantitatively with methanol for spectrophotometric analysis at 357 nm on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance versus concentration working curve for nine standard solutions. The concentration of fluoranthene in the standard solutions varied from 6.55×10^{-5} M to 2.18×10^{-4} M. The calculated molar absorptivity of the standard solutions varied slightly over the concentration range, from $\varepsilon \approx 8260$ L mol^{-1} cm^{-1} (6.55×10^{-5} M) to $\varepsilon \approx 7915$ L mol^{-1} cm^{-1} (2.18×10^{-4} M). Experimental molar concentrations were converted to (mass/mass) solubility fractions by multiplying by the molar mass of fluoranthene, volume(s) of volumetric

flask(s) used, and any dilutions required to place the measured absorbances on the Beer–Lambert law absorbance versus concentration working curve, and then dividing by the mass of the saturated solution analyzed. Mole fraction solubilities were computed from (mass/mass) solubility fractions using the molar masses of the solute and solvent. Experimental fluoranthene solubilities, X_A^{sat}, in the 36 organic solvents studied are listed in Table 1. Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±1.5%.

Results and discussion

Solubility data for fluoranthene are available in the chemical literature for only 2 of the 36 solvents listed in Table 1. McLaughlin and Zainal (14) previously reported the solubility of fluoranthene in cyclohexane as a function of temperature. The five temperatures studied by the authors ranged from 301.8 K to 344.2 K, and did not include 298.15 K. The mole fraction solubility at 298.15 K can be obtained by curve-fitting the experimental data to

$$[3] \qquad \ln x_A^{sat} = 60.6443 - 35{,}702/T + 4{,}896{,}935/T^2$$

a $1/T$ polynomial. Three terms were needed to accurately describe the experimental values. Using the above mathematical representation, we calculate a mole fraction solubility of x_A^{sat} = 0.018 05 at 298.15 K, which is in excellent agreement with our measured value of x_A^{sat} = 0.018 07.

Two literature values were found for the solubility of fluoranthene in 1-octanol. Pinal et al. (15) determined a molar solubility of C_A^{sat} = 0.198 at 296.15 K, whereas Miller et al. (16) measured a significantly smaller solubility of C_A^{sat} = 0.1726 at 298.15 K. Both values were determined using well-established analytical methodologies. There is no reason for us to select one value over the other. Molar solubilities can be converted to mole fractions using $V_{octanol}$ = 158.30 cm^3 mol^{-1} and $V_{fluoran}$ = 162.0 cm^3 mol^{-1} (estimated using the group contribution method of Shahidi et al. (17)), and by assuming that the excess volume of mixing is negligible. Performing this computation, mole fraction solubilities of x_A^{sat} = 0.0314 and x_A^{sat} = 0.027 34 were calculated for fluoranthene dissolved in 1-octanol, compared to our measured solubility of x_A^{sat} = 0.031 25.

The solvents listed in Table 1 include both noncomplexing alkanes and self-associating alcohols. Of the many solution models proposed in recent years, Mobile Order theory is perhaps the only one that is capable of describing solute behavior over such a wide range of solvent mixtures. The basic model (18–25) assumes that all molecular groups perpetually move, and that neighbors of a given kind of external atom in a molecule constantly change identity. All molecules of a given kind dispose of the same volume, equal to the total volume V of the liquid divided by the number N_A of molecules of the same kind, i.e., Dom A = V/N_A. The center of this domain perpetually moves. The highest mobile disorder is achieved whenever groups visit all parts of their domain without preference. Preferential contacts lead to deviations with respect to this "random" visiting. This is especially true in the case of hydrogen bonding as specific interactions result in a specific orientation of the "donor" molecule with respect to an adjacent "acceptor" molecule.

In the case of an inert crystalline solute dissolved in a self-associating solvent, Mobile Order theory expresses the volume fraction saturation solubility, ϕ_A^{sat}, as

$$[4] \qquad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\,\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2\, V_A(\delta'_A - \delta'_{solvent})^2 (RT)^{-1} - r_{solvent}(V_A/V_{solvent})\,\phi_{solvent}$$

where the $r_{solvent}\,(V_A/V_{solvent})\,\phi_{solvent}$ term represents the contributions resulting from hydrogen-bond formation between the solvent molecules. For most of the published applications, $r_{solvent}$ was assumed to be unity for strongly associated solvents with single hydrogen-bonded chains such as monofunctional alcohols, to be two for water or diols, and to equal zero for nonassociated solvents such as saturated hydrocarbons. A more exact value for alcoholic solvents can be calculated based upon

$$[5] \qquad r_{solvent} = (K_{solvent}\,\phi_{solvent}/V_{solvent})/(1 + K_{solvent}\,\phi_{solvent}/V_{solvent})$$

with a numerical value of $K_{solvent}$ = 5000 cm^3 mol^{-1} assumed for all monofunctional alcohols.

If complexation does occur between the crystalline solute and solvent

$$[6] \qquad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\,\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2\, V_A(\delta'_A - \delta'_{solvent})^2 (RT)^{-1} + \ln [1 + \phi_{solvent}(K_{ASolvent}/V_{solvent})]$$

then an additional term involving the solute–solvent equilibrium constant, $K_{ASolvent}$, must be introduced to describe the solubility enhancement that arises as a result of specific interactions. A slightly more complex expression applies in the case of solute complexation with a self-associating solvent. The symbols δ'_A and $\delta'_{solvent}$ denote the modified solubility parameters of the solute and solvent, respectively, V_i is the molar volume, and a_A^{solid} is the activity of the solid solute. This latter quantity is defined as the ratio of the fugacity of the solid to the fugacity of the pure hypothetical supercooled liquid. The numerical value of a_a^{solid} can be computed from

$$[7] \qquad \ln a_A^{solid} = -\Delta H_A^{fus}(T_{mp} - T)/(RTT_{mp})$$

where ΔH_A^{fus} is the solute's molar enthalpy of fusion at the normal melting point temperature, T_{mp}. Contributions from nonspecific interaction are incorporated into Mobile Order theory through the $\phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2 (RT)^{-1}$ term. Ruelle et al. (21–25) have presented an impressive set of comparisons between experimental and predicted values for anthracene, naphthalene, pyrene, biphenyl, carbazole, benzil, *p*-benzoquinone, tricosane, octacosane, 10-nonadecanone, 11-heneicosanone, and 12-tricosanone solubilities in a wide range of both noncomplexing and complexing solvents to document the predictive ability of Mobile Order theory.

Fluoranthene [b]	162.0 [c]	20.80 [d]

[a]Tabulated values are taken from a compilation given in Ruelle et al. (21, 22, 24, 25).

[b]The numerical value of a_A^{solid} = 0.1912 was calculated from the molar enthalpy of fusion, ΔH_A^{fus} = 18,870 J mol^{-1} (26), at the normal melting point temperature of the solute, T_{mp} = 380.95 K.

[c]Numerical value of $V_{fluoran}$ = 162 cm^3 mol^{-1} was calculated using the group contribution method proposed by Shahidi et al. (17).

[d]Numerical value was calculated using the measured fluoranthene mole fraction solubilities in *n*-hexane, *n*-heptane, and *n*-octane, in accordance with eqs. [4] and [6]; with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ =0.

Predictive application of eqs. [4] and [6] is relatively straightforward. First, an average numerical value of $\delta'_{fluoran}$ = 20.80 $MPa^{1/2}$ is computed by requiring that each equation (with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0) perfectly describes fluoranthene mole fraction solubility data in *n*-hexane ($\delta'_{fluoran}$ = 20.95 $MPa^{1/2}$), *n*-heptane ($\delta'_{fluoran}$ = 20.75 $MPa^{1/2}$), and *n*-octane ($\delta'_{fluoran}$ = 20.70 $MPa^{1/2}$). The numerical value of a_A^{solid} = 0.1912 is calculated using eq. [7] with ΔH_A^{fus} = 18,870 J mol^{-1} (26) and T_{mp} = 380.95 K. A numerical value of $V_{fluoran}$ = 162 cm^3 mol^{-1} was used for the molar volume of the hypothetical subcooled liquid solute.

Table 1 summarizes the predictive ability of Mobile Order theory for the 28 different organic solvents for which both fluoranthene solubility data and modified solubility parameters could be found. Solvent molar volumes and modified solubility parameters are listed in Table 2. The modified solubility parameters account for only nonspecific interactions, and in the case of the alcoholic solvents the hydrogen-bonding contributions have been removed. Numerical values of $\delta'_{solvent}$ were obtained from published compilations (21, 22, 24, 25), and were either deduced by regressing actual solubility data of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (27) or estimated using known values for similar organic solvents. Examination of the entries in Table 1 reveals that Mobile Order theory does provide fairly reasonable estimates of the solubility behavior of fluoranthene in a wide range of organic solvents. Average absolute deviation between predicted and observed values is 53%. Readers are reminded that in evaluating the applicability of Mobile Order theory one must realize that many of these particular systems are highly nonideal, and that the experimental solubility data cover over a 50-fold range in mole fraction. Had an ideal solution been assumed, then the predicted mole fraction solubility would be $X_A^{sat} = a_A^{solid}$ = 0.1912 for each solvent. The ideal solution approximation corresponds to a considerably larger average absolute deviation of 1574% between predicted and observed values.

Formation of mixed-ligand fluoroboron cations involving C=N donors. A ^{19}F and ^{11}B NMR study

J. Stephen Hartman, Elizabeth I. Ilnicki, James A. W. Shoemaker, Wojciech R. Szerminski, and Zheng Yuan

Abstract: Mixed-donor difluoroboron and chlorofluoroboron cations $DD'BF_2^+$ and $DD'BFCl^+$ involving at least one C=N donor molecule can be formed by Cl^- displacement from the mixed boron trihalide adducts $D\cdot BF_2Cl$ and $D\cdot BFCl_2$, provided that the steric hindrance of D′ and especially D is not too great. The $DD'BF_2^+$ cations can also be formed by selective displacement of one donor molecule in certain $D_2BF_2^+$ cations, present in acetone as their PF_6^- salts, allowing isolation of the first salt of a mixed-donor difluoroboron cation, (quinuclidine)(pyridine)$BF_2^+\cdot PF_6^-$. In less favourable cases, however, either no reaction occurs or the reaction continues to give $D'_2BF_2^+$. Reactivities and ^{19}F and ^{11}B NMR parameters of mixed boron trihalide adducts and fluoroboron cations of a number of C=N donors are reported.

Key words: fluoroboron cations, mixed-ligand, fluorine-19 NMR, boron-11 NMR, oxazolines, thiazolines, C=N donors.

Résumé : À la condition que l'empêchement stérique des donneurs D′ et D ne sont pas trop important, on peut former des cations difluorobore et chlorofluorobore à donneurs mixtes $DD'BF_2^+$ et $DD'BCl^+$ impliquant au moins une molécule donneur C=N par déplacement du Cl^- à partir d'adduits mixtes trihalogénés du bore. On peut aussi former les cations $DD'BF_2^+$ par déplacement sélectif d'une molécule de donneur de certains cations $D_2BF_2^+$ présents dans l'acétone sous la forme de leurs sels de PF_6^-; cette technique a permis d'isoler le premier sel d'un cation difluorobore à donneurs mixtes, (quinuclidine)(pyridine)$BF_2^+\cdot PF_6^-$. Toutefois, dans les cas moins favorables, il n'y a pas de réaction ou celle-ci se poursuit pour donner des $D'_2BF_2^+$. On a déterminé les réactivités et les paramètres de RMN du ^{19}F et du ^{11}B d'adduits mixtes trihalogénés du bore et des cations difluorobore d'un certain nombre de donneurs C=N.

Mots clés : cations difluorobore, ligands mixtes, RMN du fluor-19, RMN du bore-11, oxazolines, thiazolines, donneurs C=N.

[Traduit par la Rédaction]

Introduction

Our studies of the formation of haloboron cations, by reaction of mixed boron trihalide adducts with nitrogen-donor Lewis bases, have shown that tertiary aliphatic amines (1, 2), pyridines (3), and amidines (4) are successively more effective in generating four-coordinate fluoroboron cations by selective displacement of the heavy halide ion from the mixed-halogen adducts. Whereas tertiary aliphatic amines only form $D_2BF_2^+$ and $DD'BF_2^+$ from $D\cdot BF_2X$ (X = Cl, Br; eq. [1]), and even then only when the amine steric hindrance is low, pyridines and amidines form $D_2BF_2^+$ and $DD'BF_2^+$

$$D\cdot BF_2X + D' \rightarrow DD'BF_2^+ + X^- \quad [1]$$

much more rapidly and also form D_2BFCl^+, D_2BFBr^+, and D_3BF^{2+} by heavy halide ion displacement from $D\cdot BFX_2$ (3, 4) (eq. [2]). These reactions allow the attacking donor D′ to be different from D, and many mixed-donor difluoroboron cations involving tertiary amines and pyridines as donors have been detected by NMR (1–3), as well as a few

$$\begin{array}{c} D\cdot BFX_2 + D' \rightarrow DD'BFX^+ + X^- \\ \downarrow \\ DD'_2BF^{2+} + X^- \end{array} \quad [2]$$

chlorofluoroboron cations (3). We here explore the formation of further mixed-ligand difluoroboron and chlorofluoroboron cations involving C=N donors according to eqs. [1] and [2], and show that these can also be prepared by ligand substitution reactions of $D_2BF_2^+$, present as its PF_6^- salt (eq. [3]).

$$D_2BF_2^+ + D' \rightarrow DD'BF_2^+ + D \quad [3]$$

To increase our range of C=N donors we have studied the formation of mixed boron trihalide adducts and fluoroboron cations of the oxazoline and thiazoline bases 2-methyl-2-oxazoline (MOZ), 2-ethyl-2-oxazoline (EOZ), 2-methyl-2-thiazoline (MTZ), and 2-(methylthio)-2-thiazoline (MTTZ). The coordination chemistry of oxazolines has recently become important in the field of enantioselective transition metal catalysis (5), and thiazolines also have an extensive

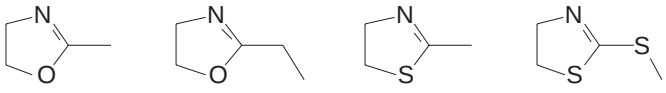
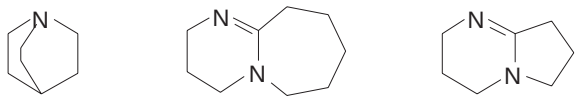
coordination chemistry (6), but their coordination to the boron trihalides has apparently not been reported. We also report some adducts and fluoroboron cations of *N*-(*n*-propyl)dimethylketimine and *N*,*N*,*N*′,*N*′-tetramethylguanidine



(TMG), and have investigated the formation of mixed-donor fluoroboron cations involving our new C=N donors and our previously studied (1–4) bases quinuclidine (Q; 1-azabicyclo-[2.2.2]octane), pyridine, and the amidines 1,8-diazabicyclo-[5,4,0]undec-7-ene (DBU) and 1,5-diazabicyclo[4,3,0]non-5-ene (DBN).



Experimental

Materials

Materials were handled with standard inert-atmosphere Schlenk line and glove bag techniques. Solvents were carefully dried: hexane with sodium wire, and $CDCl_3$ over Lindé 3 Å or 5 Å molecular sieves that had been heated in a muffle furnace at 400°C for more than 3 h and cooled over a period of 0.5 h in a vacuum desiccator. Boron trifluoride and boron trichloride were handled as described previously (4), and quinuclidine, DBU, DBN, and pyridines were obtained as described previously (3, 4). 2-Methyl-2-oxazoline (MOZ; Aldrich, 98%), 2-ethyl-2-oxazoline (EOZ; Aldrich, 99%), 2-methyl-2-thiazoline (MTZ; Aldrich, 99%), and 2-(methylthio)-2-thiazoline (MTTZ; Aldrich, 98%) were stored over Lindé 3 Å molecular sieves and used without further purification. 1,1,3,3-Tetramethylguanidine (Aldrich, 97%) was stored over Lindé 5 Å molecular sieves. *N*-(*n*-Propyl)dimethylketimine was synthesized by reacting 11.9 g of *n*-propylamine with 6.1 g of acetone over a large excess of activated Lindé 5 Å molecular sieves. The product was fractionally distilled in vacuum to give a clear oil that was stored over Lindé 3 Å molecular sieves until use.[3]

The BF_nCl_{3-n} (n = 0–3) adducts and difluoroboron cations of the various bases were prepared in $CDCl_3$ solution as for the analogous amidine complexes (4), and $DD'BF_2^+$ and $DD'BFCl^+$ cations were prepared by reacting D′ with the BF_2Cl and $BFCl_2$ adducts, respectively, of a different donor D, in $CDCl_3$ solution as in previous work (3). Optimum formation of $DD'BF_2^+$ requires optimizing the amount of $D{\cdot}BF_2Cl$ in solution (F:Cl ratio of 1:0.8), while optimum formation of $DD'BFCl^+$ requires optimizing the amount of $D{\cdot}BFCl_2$ in solution (F:Cl ratio of 1:1.2 to 1:1.5).

Reactions of $D_2BF_2^+{\cdot}PF_6^-$ salts with a second donor D′ were carried out in acetone due to the insolubility of the salts in $CDCl_3$ (2–4).

Isolation of (quinuclidine)(pyridine)difluoroboron hexafluorophosphate

In a typical ligand substitution reaction, excess solid quinuclidine was added to 33 mg of $pyr_2BF_2^+{\cdot}PF_6^-$ in 0.5 mL of acetone in a 5 mm NMR tube. On allowing this capped tube to stand in a 50°C oil bath for 1 h, the reaction went to completion with only $(Q)(pyr)BF_2^+$ being produced, as shown by ^{19}F NMR. The solvent was allowed to evaporate on standing, and the residues were washed with two portions of $CHCl_3$ to remove uncomplexed pyridine and quinuclidine. The remaining precipitate was recrystallized from 1:1 acetone/EtOH. Positive ion FAB spectrum, *m*/*z*: 623 $[\{(QpyrBF_2^+)_2PF_6^-\}^+]$, 239 $[(QpyrBF_2)^+]$ (100%), 160 $[QBF_2^+]$, and 112 $[pyrBF_2^+]$. Elemental analysis, found: C 37.56, 37.86; H 4.83, 4.73; N 7.13, 7.16; calculated: C 37.50, H 4.72, N 7.29.

Instrumentation

Most ^{19}F and ^{11}B NMR spectra were obtained on a Bruker AC-200 4.7 tesla multinuclear Fourier transform NMR spectrometer operating at 188.31 MHz (^{19}F) and 64.20 MHz (^{11}B), using 5 mm NMR tubes. The ^{19}F spectra were obtained with 16K FID's, spectral windows of up to 35 000 Hz, with between 200 and 2000 30° pulses and a relaxation delay of 1.0 s. The 90° pulse durations were 6.6 μs (^{19}F) and 17.1 μs (^{11}B). The ^{19}F chemical shifts are accurate to ±0.1 ppm and were internally referenced to C_6F_6 as a secondary standard (–162.7 ppm from $CFC1_3$), and are reported in ppm from $CFC1_3$. The ^{11}B spectra were obtained with 8K FID's and spectral windows of up to 2000 Hz. However, the narrow range of ^{11}B chemical shifts led to such severe overlap of multiplets arising from ^{11}B–^{19}F coupling, that 4.7 tesla ^{11}B spectra were not routinely obtained.

Some ^{19}F, ^{11}B, and $^{11}B\{^{19}F\}$ NMR spectra were obtained at 30°C on a Bruker DRX-500 11.7 tesla multinuclear Fourier transform NMR spectrometer (McMaster University) operating at 470.53 MHz (^{19}F) and 160.46 MHz (^{11}B) using between 40 and 128 30° pulses with 32K FID's. The 90° pulse durations were 7.5 μs (^{19}F) and 15.0 μs (^{11}B). Spectral windows of 42 016 Hz (^{19}F) and 40 000 Hz (^{11}B) were used.

Initial positive-ion fast atom bombardment mass spectra (FAB spectra) were obtained on an AEI MS-30 (Kratos Ltd., Manchester) double-beam mass spectrometer coupled to a saddle-field atom gun (Ion Tech Ltd, Teddington, U.K.), retrofitted with a Kratos FAB source in beam 1. The accelerating voltage was 4 kV. 3-Nitrobenzyl alcohol (NBA) was used as a liquid matrix. Data were collected on a DS-55 Kratos data system. A Hewlett–Packard 2631G printer was used to plot the spectra and mass-intensity data. Signals from the matrix were subtracted automatically in the computer system in most situations. The BMASROS program was utilized for interpretation of isotope patterns. More recently positive ion FAB spectra were obtained on a Concept 1S double beam mass spectrometer, with 8 kV accelerating voltage using Xe collision gas at 7.5 W power. Data were

collected on a Kratos DART data system with SUN Spectrostation 10, using XMACH3 software.

Results

(*a*) BF_nCl_{3-n} adducts and fluoroboron cations of new C=N donor molecules

The BF_nCl_{3-n} adducts, and $D_2BF_2^+$ and D_2BFCl^+ cations, of the oxazoline and thiazoline bases and of further C=N donors form readily under standard conditions, (2–4, 7) and are readily detected by ^{19}F and ^{11}B NMR. Their NMR parameters (Table 1) are typical of fluoroboron cations and $D{\cdot}BF_nCl_{3-n}$ adducts (1–4, 7, 8) except that the $D_2BF_2^+$ ^{19}F signals of MOZ and EOZ occur well to low frequency (high field) of $D{\cdot}BF_3$. The ^{11}B multiplets of the BF_nCl_{3-n} adducts and $D_2BF_2^+$ cations overlap so badly at 4.7 tesla that many spectra could not be interpreted; much better ^{11}B spectra were obtained at 11.7 tesla.

The BF_nCl_{3-n} adduct system of MTTZ gives very small additional ^{19}F 1:1:1:1 quartets arising from $BFCl_3^-$ and $BF_2Cl_2^-$ (9) (Fig. 1), which along with BF_3Cl^- are formed in much larger amounts in the corresponding amidine adduct systems (4) but do not appear at all in the adduct systems of most bases. Similarly, the *N*-(*n*-propyl)dimethylketimine–BF_nCl_{3-n} system gave a ^{19}F peak arising from $BFCl_3^-$.[3] These anions apparently form by the mechanism we proposed for amidine adduct systems, involving carbene intermediates generated from the $CDCl_3$ solvent (4). Additional fluorine-containing species, apparently related to the presence of the reactive N-H proton, arise in the $TMG{\cdot}BF_nCl_{3-n}$ system; addition of excess tetramethylguanidine eliminates the ^{19}F signals of the BF_2Cl and $BFCl_2$ adducts and gives broad ^{19}F signals at –143.0 and –169.8 ppm. We have confirmed the identity of $(TMG)_2BF_2^+$ by observing its ^{11}B 1:2:1 triplet and its positive ion FAB peak at *m*/*z* 279 with the expected isotope pattern. Further studies of TMG and its adducts were not carried out because of complications introduced by the high reactivity of the N-H proton.

The D_2BFCl^+ cations of the oxazoline and thiazoline bases form more slowly than the $D_2BF_2^+$ cations, as in the analogous systems with pyridine (3) and amidine (4) donors. However, while pyridine- and amidine-system D_2BFCl^+ cations undergo further chloride ion displacement to give the

[c] Poor resolution.

D_3BF^{2+} cations under forcing conditions, a D_3BF^{2+} cation could be detected only with MOZ. In the other oxazoline and thiazoline systems, standing with excess donor at 40–50°C led only to decomposition of the already-present adducts and cations and the appearance of new ^{19}F signals without splittings due to $^{11}B–^{19}F$ coupling.

Only with MOZ as donor does a broad ^{19}F signal appear at –146.0 ppm where the D_3BF^{2+} signal was expected by analogy with the pyridine and amidine systems. This signal did not show splittings due to $^{11}B–^{19}F$ coupling on the 4.7 tesla instrument. Such splittings are not present, or if present are not well resolved, in the 4.7 tesla ^{19}F signals of confirmed D_3BF^{2+} cations, and this is attributed to slower tumbling and more efficient ^{11}B quadrupole relaxation when boron has three bulky substituents (4). Further evidence for the presence of $(MOZ)_3BF^{2+}$ comes from the 11.7 tesla ^{11}B spectrum, which includes a 1:1 doublet at 2.5 ppm with $J(^{11}B–^{19}F)$ = 51.0 Hz. The DBN system (4), which gives fluoroboron adduct and cation ^{19}F NMR parameters very similar to their MOZ-system analogs, has a well-established $(DBN)_3BF^{2+}$ cation with ^{19}F chemical shift –143.4 ppm and ^{11}B chemical shift 2.2 ppm but with no splittings due to $^{11}B–^{19}F$ coupling detectable on the 4.7 tesla NMR instrument (4). We have recently detected splittings due to $^{11}B–^{19}F$ coupling in the 11.7 tesla ^{11}B and ^{19}F spectra of this species: J = 48.6 Hz. These similarities to the NMR parameters of the species formed in the MOZ system supports the existence of the analogous $(MOZ)_3BF^{2+}$ cation.

(*b*) Mixed-ligand fluoroboron cations from $D{\cdot}BF_2Cl$ and $D{\cdot}BFCl_2$

General

Mixed-ligand fluoroboron cations form in a manner very similar to the unmixed-ligand cations described above, but D′ for D exchange in the BF_3 adduct competes with Cl^- displacement by D′. The DD′BF_2^+ cations form readily at room temperature in $CDCl_3$ giving distinctive ^{19}F and ^{11}B NMR signals. The entire series of adducts $D{\cdot}BF_nCl_{3-n}$ (n = 0–3) is present in these solutions but as in previous work (3) the $D{\cdot}BF_2Cl$ adduct always reacts first. Following its disappearance, the $D{\cdot}BFCl_2$ adduct reacts slowly with D′ to give DD′$BFCl^+$. The NMR parameters of the difluoroboron and chlorofluoroboron cations are given in Tables 2 and 3, respectively. The ^{11}B chemical shifts show little variation in these series, and only a few were determined.

Reactions of DBU·BF_nCl_{3-n} with D′

D′ = quinuclidine: The ^{19}F NMR monitoring of the formation of $(DBU)(Q)BF_2^+$ from $DBU{\cdot}BF_2Cl$ is shown in Fig. 2. In amidine–BF_nCl_{3-n} systems all ionic and neutral adduct species and the mixed chlorofluoroborate anions are observed, the latter apparently arising from attack of the strongly basic amidines on $CDCl_3$ (4). Introduction of successive portions of quinuclidine led to rapid reaction of quinuclidine with the anions and neutral adducts. The intensity of the $DBU{\cdot}BF_2Cl$ ^{19}F resonance decreased regularly as the resonance assigned to $(DBU)(Q)BF_2^+$ (intermediate in chemical shift and coupling constant values between $(DBU)_2BF_2^+$ and $Q_2BF_2^+$) increased by similar amounts, confirming that $(DBU)(Q)BF_2^+$ forms from $DBU{\cdot}BF_2Cl$. Interestingly the reaction does not proceed further to give the well-known (1, 2) $Q_2BF_2^+$. The initially present ^{19}F signals of the mixed chlorofluoroborate anions diminished while the

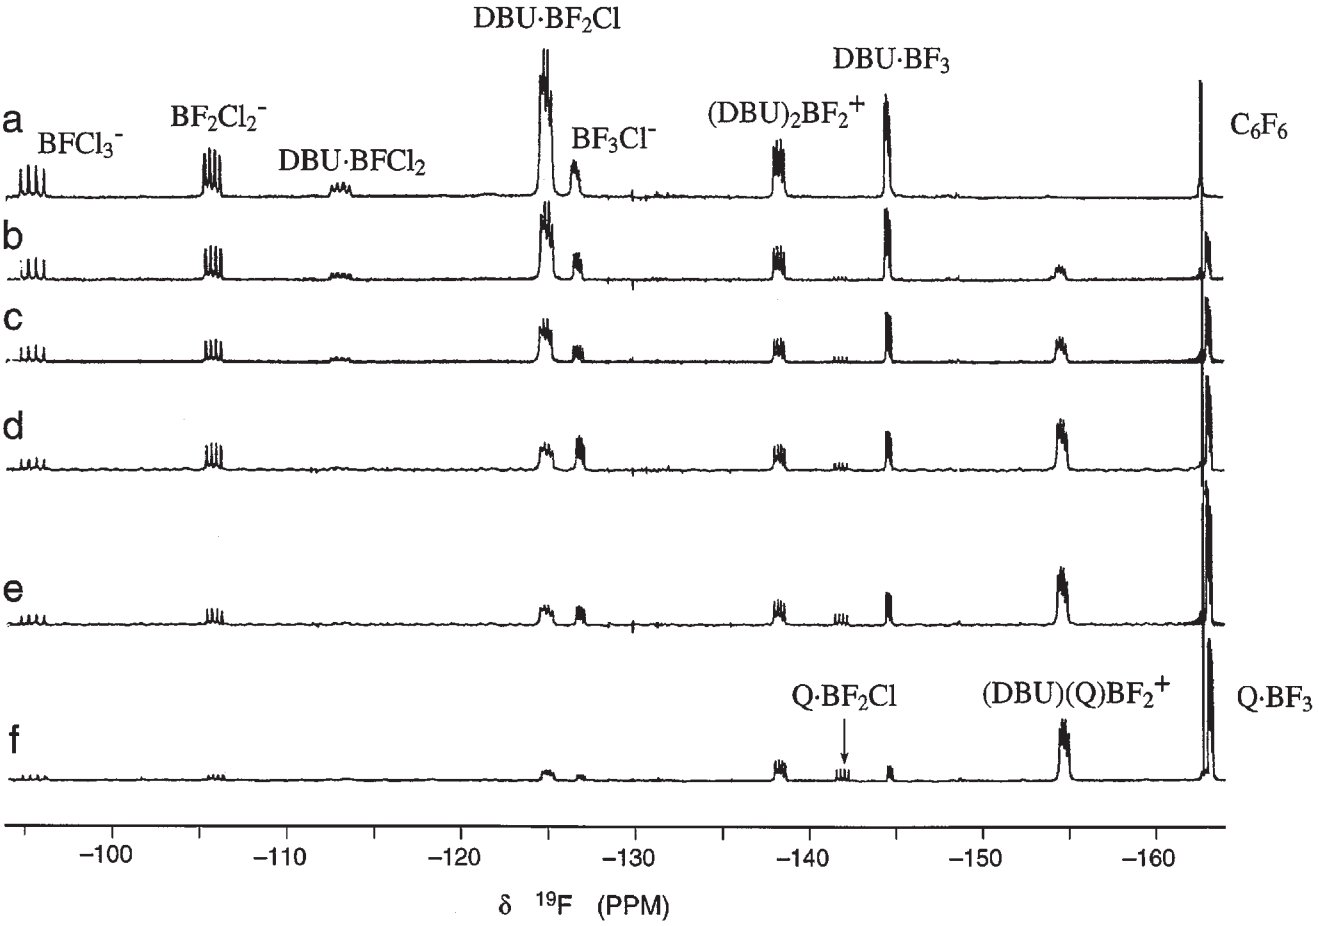
Fig. 2. 188.31 MHz ^{19}F NMR monitoring of the titration of a DBU·BF_nCl_{3-n} solution in $CDCl_3$ (0.2 mmol DBU; mole ratio DBU:BF_3:BCl_3 = 2:1:1) with quinuclidine. Amount of quinuclidine (mmol) added: (*a*) 0; (*b*) 0.02; (*c*) 0.04; (*d*) 0.06; (*e*) 0.08; (*f*) 0.10.



signals of the BF_3 and BF_2Cl adducts of quinuclidine increased, consistent with quinuclidine attacking these anions and driving off Cl^-. No signal appeared that would be consistent with formation of $(DBU)(Q)BFCl^+$.

D′ = DBN: The DBN readily displaces Cl^- from DBU·BF_2Cl to give $(DBU)(DBN)BF_2^+$ but $(DBU)(DBN)BFCl^+$ does not form from DBU·$BFCl_2$, nor does DBN displace DBU from its BF_3 adduct.

D′ = pyridine: Pyridine readily forms $(DBU)(pyr)BF_2^+$ from (DBU)·BF_2Cl, but $(DBU)(pyr)BFCl^+$ was observed to form from (DBU)·$BFCl_2$ only in samples in which Cl is enriched compared to F (BCl_3:BF_3 = 1.5:1 rather than 1:1). High-field ^{11}B NMR monitoring of a titration of the DBU·BF_nCl_{3-n} system with pyridine showed the formation of large amounts of pyr·BF_3 (Fig. 3 and Table 4). This no doubt forms partly by displacement of Cl^- from BF_3Cl^-, but BF_3Cl^- is a minor species so direct displacement of DBU from DBU·BF_3 must be the main source.

D′ = oxazolines: MOZ and EOZ displace Cl^- from DBU·BF_2Cl to form $(DBU)(MOZ)BF_2^+$ and $(DBU)(EOZ)BF_2^+$, but the corresponding $BFCl^+$ species do not form. Oxazolines do displace DBU from DBU·BF_3.

Reactions of DBN·BF_nCl_{3-n} with D′

The DBN·BF_nCl_{3-n} adduct system reacts similarly to the corresponding DBU·BF_nCl_{3-n} adduct system, i.e., the mixed-donor BF_2^+ and $BFCl^+$ cations form from DBN·BF_2Cl and DBN·$BFCl_2$, respectively, on reaction with quinuclidine, pyridine, oxazolines, and thiazolines. The DBN adduct system forms the mixed-donor BF_2^+ cation, but not the $BFCl^+$ cation, with DBU. DBN is displaced from its BF_3 adduct by quinuclidine, pyridine, oxazolines, and thiazolines, but not by DBU, to form D′·BF_3.

Reactions of D·BF_nCl_{3-n} (D = oxazolines and thiazolines) with D′

All of the donors studied (DBN, DBU, other oxazolines and thiazolines, pyridine, and quinuclidine) can displace Cl^- from oxazoline·BF_2Cl and thiazoline·BF_2Cl to give DD′BF_2^+, and from oxazoline·$BFCl_2$ and thiazoline·$BFCl_2$ to give DD′$BFCl^+$. The ^{19}F chemical shift of $(MOZ)(pyr)BF_2^+$ is unusual in being slightly outside the range of the corresponding unmixed-donor cations. All of these donors also displace oxazolines and thiazolines from their BF_3 adducts.

Reactions of pyr·BF_nCl_{3-n} with D′

Most of the donors studied (DBN, DBU, MTZ, and quinuclidine) give (pyr)(D′)BF_2^+ and (pyr)(D′)$BFCl^+$ species by Cl^- displacement from pyr·BF_2Cl and pyr·$BFCl_2$. Note

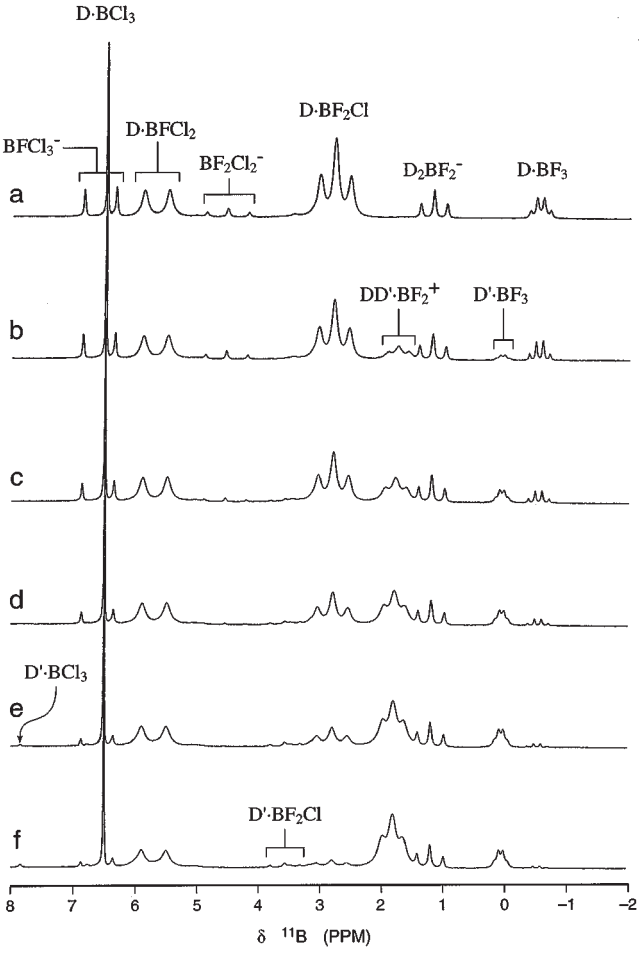
Fig. 3. 160.46 MHz ^{11}B NMR monitoring of the titration of a $DBU{\cdot}BF_nCl_{3-n}$ solution in $CDCl_3$ (0.2 mmol DBU; mole ratio $DBU:BF_3:BCl_3$ = 2:1:1) with pyridine. Amount of pyridine (mmol) added: (*a*) 0; (*b*) 0.02; (*c*) 0.04; (*d*) 0.06; (*e*) 0.08; (*f*) 0.10. D = DBU; D′ = pyridine.



that (pyr)(Q)BF_2^+ and (pyr)(Q)$BFCl^+$ are both reported in Table 1 of ref. 2. Our early studies of the quinuclidine–pyridine system alerted us to the importance of the low steric hindrance of pyridines, compared to R_3N donors, in increasing the range of accessible fluoroboron cations (1, 2). In all of these cases, and with MOZ as donor, pyridine is displaced from its BF_3 adduct by the second donor D′. Surprisingly however, MOZ is unable to displace chloride to give (MOZ)(pyr)BF_2^+ or (MOZ)(pyr)$BFCl^+$.

Reactions of $Q{\cdot}BF_nCl_{3-n}$ with D′

No mixed difluoroboron or chlorofluoroboron cations could be formed by chloride displacement from $Q{\cdot}BF_2Cl$ or $Q{\cdot}BFCl_2$ by any of the amidine, oxazoline, thiazoline, or pyridine bases, and none of these bases are able to displace quinuclidine from its BF_3 adduct.

(*c*) $DD'BF_2^+$ formed from $D_2BF_2^+{\cdot}PF_6^-$ and D′

With many combinations of D and D′, reaction [3] either does not proceed at all or it continues past the mixed-donor cation stage to give $D'_2BF_2^+$. In the most favourable cases only one D′ substitutes, giving $DD'BF_2^+$ uncontaminated by $D_2BF_2^+$ or $D'_2BF_2^+$. Because of the insolubility of the $D_2BF_2^+{\cdot}PF_6^-$ salts in $CDCl_3$ (2–4) these reactions were carried out in acetone where the ^{19}F chemical shifts of the fluoroboron cations differ by up to 3 ppm from their values (as primarily halide salts) in $CDCl_3$.

Reactions of $pyr_2BF_2^+{\cdot}PF_6^-$

$Pyr_2BF_2^+{\cdot}PF_6^-$ (3) reacts with quinuclidine in acetone to give (Q)(pyr)BF_2^+ by ligand displacement, as shown by ^{19}F NMR (Fig. 4). The identity of the mixed-donor cation was confirmed by positive-ion FAB. It is the first mixed-ligand difluoroboron cation salt to be isolated (as its PF_6^- salt). There is no further substitution of quinuclidine to give the well-known $Q_2BF_2^+$, which would give an easily-detected ^{19}F 1:1:1:1 quartet near its $CDCl_3$ chemical shift of –161.5 ppm (1, 2).

The much stronger Lewis bases DBN, DBU, and TMG react immediately with $pyr_2BF_2^+{\cdot}PF_6^-$ in acetone and give a series of fluorine- and boron-containing products in solution, as well as some precipitate that is very air-sensitive. Figure 5, obtained after DBN addition, is a typical spectrum. The major 1:1:1:1 quartet at δ –146.6 ppm, (J = 31.5 Hz) can be assigned to $(DBN)_2BF_2^+$ (lit. –149.4 ppm, J = 31.6 Hz in $CDCl_3$ (4)); its presence was confirmed by its positive-ion FAB peak at m/z 297. The small quartet labelled J in Fig. 5 (δ –150.5 ppm, J = 27.6 Hz) probably arises from (pyr)(DBN)BF_2^+ (see Table 2), and the singlet labelled I (δ –150.2 ppm) probably arises from BF_4^-. Further species giving signals in Fig. 5[4] remain to be identified. The reactivity of the donors with $pyr_2BF_2^+$ is in the order DBN > DBU > TMG > > quinuclidine.

Reactions of $Q_2BF_2^+{\cdot}PF_6^-$

The compound $Q_2BF_2^+{\cdot}PF_6^-$ (2) does not react with any of the bases 4-methylpyridine, DBN, or TMG in acetone to give a mixed-donor cation, even on prolonged standing at 50°C.

Reactions of $(DBU)_2BF_2^+$

This cation readily undergoes complex reactions of the coordinated DBU ligand in the presence of water and alcohol, which prevented isolation of the PF_6^- salt by our usual method (4). Its reactions are the subject of a separate study (10).

(*d*) Attempted formation of mixed-donor cations from $(DBU)_3BF^{2+}{\cdot}(PF_6^-)_2$

The compound $[(DBU)_3BF^{2+}](PF_6^-)_2$ (4) is stable indefinitely in acetone at 50°C and is resistant to attack by strong organic bases at ambient temperature, but decomposes on standing for 24 h in acetone at 50°C with an excess of DBN, TMG, or quinuclidine. Although a number of new ^{19}F NMR signals appear, some of which show splittings due to ^{11}B–^{19}F coupling, we have as yet no clear evidence of formation of

[4] A, δ –135.1 ppm; B, δ –137.2 ppm; C, δ –137.8 ppm; D, δ –140.6 ppm, J = 30.8 Hz; E, δ –142.4 ppm, J = 30.4 Hz; F, δ –143.3 ppm, J = 12.8 Hz; G, δ –145.5 pm, J = 25.2 Hz; H, δ –146.2 ppm, J = ~16 Hz; K, δ –152.0 ppm.

the hoped-for mixed-donor cations $(DBU)_2D'BF^{2+}$ or $(DBU)D'_2BF^{2+}$.

Discussion

Reaction of every $D\cdot BF_2Cl$ and $D\cdot BFCl_2$ adduct need not occur with every potential donor D′; thus tertiary amines R_3N generally displace Cl^- only very slowly if at all, with D′ steric hindrance the crucial factor (2). The low steric hindrance of the two-coordinate C=N nitrogen donor sites greatly facilitates reactions [1] and [2] (3, 4), and reactivity is further supplemented by the high base strength of amidines (4). The trends that appear in the present study are summarized in Table 5 and are consistent with our previous work (1–4) in demonstrating the predominant effects of D and D′ steric hindrance on reactivity in the formation of fluoroboron cations, supplemented by basicity effects.

In addition the original donor is in most cases displaced by D′ from its BF_3 adduct during the above reactions. Susceptibility to D displacement in $D\cdot BF_3$ closely parallels susceptibility to Cl^- displacement in $D\cdot BF_2Cl$ (Table 5). The displaced D then tends to displace chloride from the chlorofluoroborate anions if these are present, to form additional amounts of various already-present D-containing species. Only when both D and D′ are amidines, or when D is R_3N, does D′ displacement of D not occur in $D\cdot BF_3$ (Table 5). Similar D′ displacement in $D\cdot BF_3$ occurs regardless of whether only the $D\cdot BF_3$ adduct, or the full $D\cdot BF_nCl_{3-n}$ (n = 0–3) adduct system is present. The mixed-halogen adducts are however not susceptible to D′ displacement of D and undergo Cl^- displacement instead, while the $D\cdot BCl_3$ adducts are inert under our conditions.

Base strength certainly plays a role. (pK_b values (11, 11*b* for DBU, 11*c* for DBN) are included in Table 5.) Pyridine, MOZ, and DBU do not displace the very highly basic DBN from $D\cdot BF_3$, but DBU, DBN, and pyridine do displace the less basic MOZ. The basicity of the already-attached D is

Table 5. Substitution patterns for Cl^- displacement by D′ to form $DD'BF_2^+$ from $D \cdot BF_2Cl$, and D displacement by D′ to form $D' \cdot BF_3$ from $D \cdot BF_3$.

		D′				
D	pK_b	Amidines	Pyridine	Quinuclidine	Oxazolines	Thiazolines
Amidines	0.5–1.1	[a]	Yes	Yes	Yes	Yes
Pyridine	8.8	Yes		Yes	[b]	Yes
Quinuclidine	2.9	No	No		No	No
Oxazolines	8.5	Yes	Yes	Yes	Yes	Yes
Thiazolines		Yes	Yes	Yes	Yes	Yes

[a] Forms $(DBU)(DBN)BF_2^+$ from $DBN \cdot BF_2Cl$ or $DBU \cdot BF_2Cl$, but amidines do not displace each other to form $D' \cdot BF_3$ from $D \cdot BF_3$.

[b] Does not form $(pyr)(oxazoline)BF_2^+$ from $pyr \cdot BF_2Cl$, but oxazoline does displace pyr from $pyr \cdot BF_3$ to form $oxazoline \cdot BF_3$.

not important in displacement of halide in reactions [1] and [2] (Table 5). Thus MOZ readily displaces Cl^- from adducts of the highly basic DBU to give $(DBU)(MOZ)BF_2^+$ and $(DBU)(MOZ)BFCl^+$ (but cannot displace DBU to give $(MOZ)_2BF_2^+$), just as Q readily displaces Cl^- from adducts of the much less basic pyridine. Nor does basicity have much effect on displacement of D from its BF_3 adduct by D′ (Table 5).

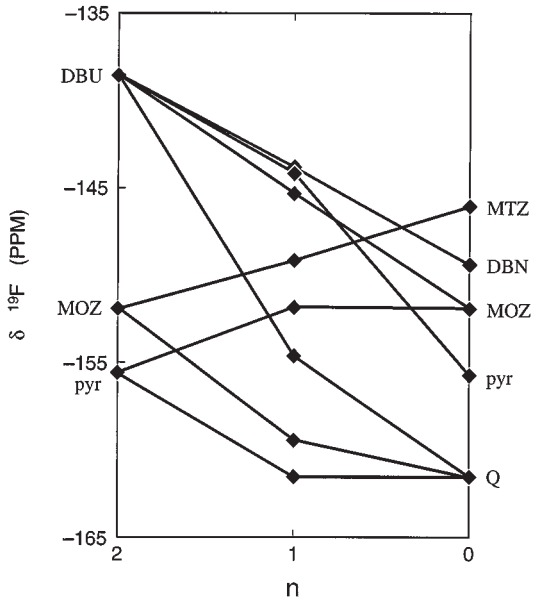
Formation of $DD'BFCl^+$ by Cl^- displacement from $D \cdot BFCl_2$ proceeds much less readily than the analogous formation of $DD'BF_2^+$ from $D \cdot BF_2Cl$, and is prevented by D and D′ steric effects in several cases where the analogous $DD'BF_2^+$ species do form. Thus we could not form $(DBN)(DBU)BFCl^+$ or $(DBU)(Q)BFCl^+$, and could form $(DBN)(Q)BFCl^+$ only from attack of Q on $DBN \cdot BFCl_2$ and not from attack of DBN on $Q \cdot BFCl_2$.

Displacement of D by D′ in $D_2BF_2^+ \cdot PF_6^-$, reported here for the first time, follows the same trends as displacement of Cl^- from a mixed-halogen adduct, or D from $D \cdot BF_3$. Thus the bulky quinuclidine can replace only one pyridine from $pyr_2BF_2^+ \cdot PF_6^-$, giving the first isolated mixed-donor difluoroboron cation, whereas the less bulky C=N donors tend to replace both pyridines. Similarly $(DBU)(Q)BF_2^+$, formed in $CDCl_3$ solution from $DBU \cdot BF_2Cl$ and quinuclidine, does not react further to give the well-known (1, 2) $Q_2BF_2^+$ by displacement of DBU.

In previous work we have explained reactivity trends in terms of stabilization of the S_N2 transition state by π bonding to boron from nitrogen donors that remain attached throughout the reaction (2–4). Tertiary amines such as quinuclidine cannot participate in π bonding and hence cannot stabilize the transition state, so that reactions involving Q, which remains attached to boron should occur less readily, in keeping with the observed lower reactivity when Q is already present. Reactivities are apparently determined by a complex interplay of steric effects, ligand basicity effects, and differential stabilization of the transition state by π bonding effects. Thus, in addition to the increased steric hindrance on forming $Q_2BF_2^+$, the transition state for the reaction would be less favourable because no DBU molecule

© 1998 NRC Canada

Fig. 6. Variation of ^{19}F chemical shift with *n* in several series of difluoroboron cations $D_nD'_{2-n}BF_2^+$ (*n* = 2–0).



would remain to participate in π bonding. Similarly the inertness of $Q_2BF_2^+ \cdot PF_6^-$ to substitution by D′, regardless of the base strength of D′, can be attributed to the high steric hindrance imparted by the two bulky quinuclidine ligands, supplemented by a very unfavourable transition state in which neither already-attached donor molecule could participate in π bonding.

In the $D \cdot BF_nCl_{3-n}$ adduct systems with many species present and many possible redistribution reactions, chloride displacement by D′ is by far the fastest reaction. Interestingly, high-field ^{11}B NMR confirms that the total amounts of BF_3, BF_2, BF, and non-fluorinated B species do not change appreciably during chloride ion displacement in titrations of D′ into a $D \cdot BF_nCl_{3-n}$ adduct system. Table 4 shows typical results where D = DBU and D′ = pyr. Before the titration, the total amounts of BF_3, BF_2, BF, and non-fluorinated B species are present in the ratio 8:58:19:10, while after the titration, with very different species present, the ratio is unchanged within experimental error: 8:59:20:12. Prolonged standing in the capped NMR tube, however, gives a very different product distribution: the mixed-donor difluoroboron cation is no longer the major species, and the total amounts of BF_3, BF_2, BF, and non-fluorinated B species are now present in the very different ratio 26:53:15:6. (right-hand column of Table 4). The entire system appears to have moved closer to equilibrium as a number of much slower reactions proceed, which involve donor-for-fluorine and chlorine-for-fluorine exchange. It is of particular interest that the neutral adducts of both donors become predominant at the expense of the fluoroboron cations. This is reasonable on steric grounds, since the donor molecules are bulkier than the halogens, and in the adducts each boron is bonded to only one donor molecule.

However more than donor-for-fluorine and chlorine-for-fluorine rearrangement reactions must be occurring on prolonged standing. A comparison of the ratios of BF_3, BF_2, BF, and non-fluorinated B species before and after standing for two weeks, as determined from the ^{11}B peak intensity data of Table 4, indicates a 60% increase in the number of fluorines per boron for the sample as a whole. Since no precipitate formed we can exclude formation of insoluble boron–oxygen materials, which would be likely to appear if there were appreciable hydrolysis by moisture diffusing through the NMR tube cap. No new peaks in addition to those of Table 4 appeared on standing. Loss of a volatile boron species from the capped NMR tube cannot be ruled out but would be surprising in excess-donor samples. Furthermore, a sealed sample behaves similarly to a tightly capped sample except that it does not lose any $CDCl_3$ solvent by evaporation, while an uncapped sample behaves very differently, with BF_4^- becoming the predominant fluorine-containing species over the two-week period. BF_4^-, indicative of contamination by moisture, is undetectable in either the sealed or the capped sample after two weeks. We conclude that we can adequately monitor these reactions in tightly capped NMR tubes without appreciable contamination by moisture.

The mixed-donor difluoroboron cations have ^{19}F chemical shifts very close to the mean of the corresponding $D_2BF_2^+$ and $D'_2BF_2^+$ species when D and D′ are similar donors, which is how we first demonstrated the existence of $DD'BF_2^+$ ions: with (tetramethylurea)(dimethylacetamide)BF_2^+ (12), and when D and D′ were different benzoate esters (13). The pairs of donors DBU–DBN, DBU–MOZ, and MOZ–MTZ closely fit this pattern (Fig. 6). However a linear variation in chemical shift across the series need not occur when different classes of donors such as MOZ–pyridine and pyridine–quinuclidine are involved. Pyridine tends to allow the other base to determine the chemical shift of the mixed difluoroboron cation, the extreme case being MOZ–pyridine ($(MOZ)_2BF_2^+$, –151.9 ppm; $(MOZ)(pyr) \cdot BF_2^+$, –151.8 ppm; $(pyr)_2BF_2^+$, –155.6 ppm), while quinuclidine tends to influence the mixed-donor cation chemical shift towards the $Q_2BF_2^+$ value. "Pairwise interaction" NMR parameters (2, 3, 14) can be useful in calculating chemical shifts in situations in which chemical shifts vary in a non-linear fashion on successive substitution of one substituent by another.

All of the C=N donor $D \cdot BF_3$ adducts have ^{19}F chemical shifts in a narrow range, between 3,5-Me_2pyr$\cdot BF_3$ at δ –152.2 ppm and DBU$\cdot BF_3$ at δ –144.3 ppm, well to high frequency (low field) of simple tertiary-amine$\cdot BF_3$ adducts except when extreme steric hindrance is present (7). The ^{19}F shifts of adducts and cations of C=N donors, like those of R_3N donors, move to higher frequency with increasing donor steric hindrance.

Conclusions

Ligand displacement from $D_2BF_2^+$, in solution as its PF_6^- salt, can be just as selective as halide ion displacement from $D \cdot BF_2X$ in forming only the mixed-donor difluoroboron cation $DD'BF_2^+$. However, in many less favourable cases, either there is no reaction or the reaction goes further to give $D'_2BF_2^+$ and (or) additional products. The D and D′ steric hindrance, D′ base strength, and π-bonding stabilization of the transition state all apparently contribute to the large variations in reactivity, as in the displacement of Cl^- by D′ to form $DD'BF_2^+$ from $D \cdot BF_2Cl$, and $DD'BFCl^+$ from $D \cdot BFCl_2$.

© 1998 NRC Canada

D′ displacement of D from $D{\cdot}BF_3$ occurs widely, provided that the steric hindrance of D is not too high. We are exploring pyridine displacement from $pyr_2BF_2^+{\cdot}PF_6^-$ as a route to synthesis of previously inaccessible (15) chelating-donor fluoroboron cations.

Acknowledgments

We are indebted to the late Mel Farquharson for preparing $pyr_2BF_2^+{\cdot}PF_6^-$ and $(quinuclidine)_2BF_2^+{\cdot}PF_6^-$. We also thank Tim Jones for assistance with the instrumentation, Prof. Alex F. Janzen (University of Manitoba) for helpful discussions, Brian Sayer and Dr. Don Hughes (McMaster University) for assistance in using the 11.7 tesla NMR instrument, and the Natural Sciences and Engineering Research Council of Canada for financial support.

1997 Alfred Bader Award Lecture Reactivities of arylnitrenium ions with guanine derivatives and other nucleophiles[1]

Robert A. McClelland, Timothy A. Gadosy, and Daniel Ren

Abstract: The carcinogens 4-aminobiphenyl and 2-aminofluorene are metabolized to hydroxylamine esters that undergo N-O heterolysis to produce arylnitrenium ions that react with DNA, especially at guanine residues. These nitrenium ions and a number of their derivatives have been studied by the laser flash photolysis technique, to provide direct kinetic information about the lifetimes of the electrophiles in water and their reactivities with added nucleophiles. Arylnitrenium ions $ArNH^+$ are longer-lived in water than arylcarbenium analogs $ArCH_2^+$, in some cases significantly longer-lived. The nitrenium ions do react with azide ion at the diffusion limit (providing the cation is not highly stabilized). This behaviour completely parallels that of carbenium ions. The biphenylyl- and fluorenylnitrenium ions react with guanine derivatives such as 2′-deoxyguanosine (dG) with rate constants that are close to or at the diffusion limit (2×10^9 M^{-1} s^{-1}) for the more reactive cations. Thus, in spite of cation lifetimes of the order of 100 ns to a millisecond in water, dG effectively competes with the solvent. The product is a C8 adduct, the same adduct observed with carcinogenic arylamines and DNA. With delocalized carbenium ions that have similar lifetimes, guanine derivatives compete very poorly with water. Thus, arylnitrenium ions have high dG:water selectivities; arylcarbenium ions have low selectivities. Nitrenium ions and carbenium ions do have parallel reactivities with primary alkyl amines. More reactive cations show a greater reactivity with less basic amines and the rate constants level below the diffusion limit. This can be explained by hydrogen bonding of the amine lone pair. Using the NH_2 group of the alkyl amines as a model for the C_2-NH_2 group of guanine shows why nitrenium ions show no detectable reactivity at this site. The rate constant for the nitrenium–guanine reaction that forms the C8 adduct is at least an order of magnitude greater than that of a nitrenium–NH_2 reaction. Nitrenium ions do form a guanine–NH_2 adduct in DNA, suggesting that incorporation into the polymer changes reactivity patterns. With imidazoles, nitrenium ions show reactivity trends that parallel the nitrenium–dG reaction, with rate constants levelling at the 2×10^9 limit for the more reactive cations. Imidazole itself and 1-methylimidazole are generally less reactive than dG, while 2-methylimidazole and 1,2-dimethylimidazole are very similar. A Brönsted-like plot incorporating points for dG, primary amines and imidazoles shows no correlation of nitrenium rate constants with nitrogen basicity. This is true even if only dG and imidazoles are considered. Thus a previous correlation of nitrenium reactivity with purine N7 basicity is suspect. The conclusion is that there is some feature of guanine that makes its reaction with nitrenium ions unusually fast. The reasons for this are not immediately apparent, especially since there is conflicting evidence as to the detailed nature of the mechanism of the reaction that forms the C8 adduct.

Key words: nitrenium, aryl azide, guanine, DNA, carcinogen.

Résumé : Le métabolisme des 4-aminobiphényle et 2-aminotoluène, des cancérigènes, conduit à des esters d'hydroxylamine; ceux-ci subissent une hétérolyse N-O conduisant à des ions arylnitrénium qui réagissent avec l'ADN, particulièrement avec les résidus de guanine. On a étudié ces ions nitrénium et un certain nombre de leurs dérivés à l'aide de la technique de la photolyse éclair au laser afin d'obtenir des données cinétiques directes relatives aux temps de vie des électrophiles dans l'eau et à leurs réactivités avec des nucléophiles ajoutés. Dans l'eau, les ions arylnitrénium, $ArNH^+$, ont des temps de vie plus longs que leurs analogues arylcarbénium, $ArCH_2^+$, et, dans quelques cas, les différences sont importantes. Les ions nitrénium réagissent avec l'ion azoture à une vitesse correspondant à la limite de diffusion (à la condition que le cation ne soit pas stabilisé). Ce comportement est tout à fait parallèle à celui des ions carbénium. Les ions biphénylyl- et fluorénylnitrénium réagissent avec les dérivés de la guanine, tel que la 2′-désoxyguanosine (dG); dans les cas des cations les plus réactifs, les constantes de vitesse se rapprochent ou sont égales à la limite de diffusion (2×10^9 M^{-1} s^{-1}). Donc, malgré des temps de vie de l'ordre de 100 ns à une milliseconde dans

l'eau, la dG entre avec succès en compétition le solvant. Le produit est un adduit C8, le même adduit que celui observé lors de la réaction d'arylamines cancérigènes avec l'ADN. Avec des ions carbénium délocalisés qui ont des temps de vie semblables, les dérivés de la guanine ne compétitionnent pas bien avec l'eau. Ainsi, les ions arylnitrénium présentent des sélectivités dG:eau élevées; les ions arylcarbénium présentent de faibles sélectivités. Les réactivités des ions nitrénium et des ions carbénium vis-à-vis des alkylamines primaires sont parallèles. Les cations plus réactifs présentent une plus grande réactivité avec les amines moins basiques et les constantes de vitesse sont inférieures à la limite de diffusion. On peut probablement expliquer ce résultat par la formation d'une liaison hydrogène avec la paire d'électrons non partagée de l'azote. Utilisant le groupe NH_2 des alkylamines comme modèle du groupe C_2NH_2 de la guanine, on peut montrer pourquoi les ions nitrénium ne présentent aucune réactivité détectable à ce site. La constante de vitesse pour la réaction nitrénium–guanine conduisant à la formation de l'adduit C8 est au moins un ordre de grandeur supérieure à celle de la réaction nitrénium–NH_2. Les ions nitrénium forment un adduit guanine–NH_2 dans l'ADN; ceci suggère que l'incorporation dans un polymère provoque un changement dans les patrons réactionnels. Avec les imidazoles, les ions nitrénium présentent une tendance de réactivité qui est parallèle à celle de la réaction nitrénium–dG; pour les cations les plus réactifs, les constantes de vitesses atteignent la limite de 2×10^9. L'imidazole et le 1-méthylimidazole sont généralement moins réactifs que le dG alors que le 2-méthylimidazole et le 1,2-diméthylamidazole sont très semblables. Une courbe de type Brönsted incorporant des points pour dG, des amines primaires et des imidazoles ne permet d'observer aucune corrélation entre les constantes de vitesse des nitrénium et la basicité de l'azote. Ceci est vrai même si l'on ne considère que dG et les imidazoles. On peut donc considérer comme suspecte une corrélation proposée antérieurement pour relier la réactivité des nitrénium et la basicité du N7 de la purine. On peut conclure qu'il existe une caractéristique de la guanine qui fait que sa réaction avec les ions nitrénium est exceptionnellement rapide. Les raisons ne sont pas immédiatement apparentes, particulièrement si l'on considère qu'il existe des données contradictoires concernant la nature exacte du mécanisme de la réaction conduisant à la formation de l'adduit C8.

Mots clés : nitrénium, azidoaryle, guanine, ADN, cancérigène.

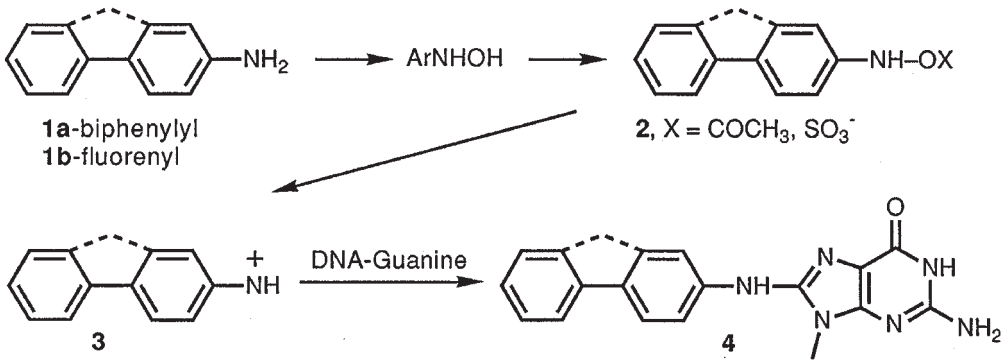
Scheme 1.

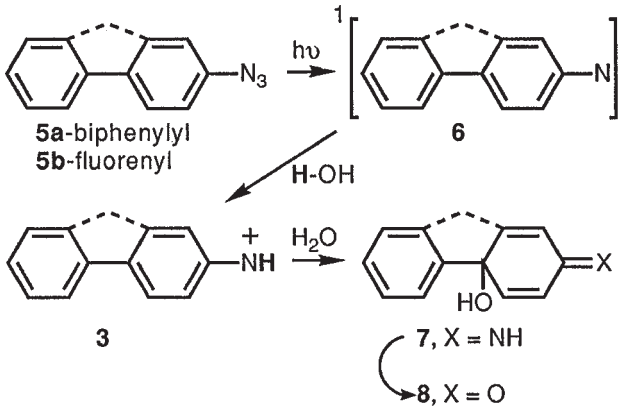


Many aromatic amines are long established carcinogens in animal models (1) and are suspect or known carcinogens in man (2). Well studied examples are 4-aminobiphenyl **1a**, a component of cigarette smoke (3–5), and 2-aminofluorene **1b**, found in diesel exhaust (6) (Scheme 1). These compounds require metabolic activation to an ultimate carcinogen, an *N*-arylhydroxylamine ester **2** (2, 7, 8). This occurs in two steps, oxidation to the hydroxylamine and then esterification with either a sulfotransferase or an acetyl transferase. There have also been indications that acetates **2** can form by N-O acetyl transfer in a hydroxamic acid (9, 10). The esters **2** are unstable in aqueous solution and undergo N-O heterolysis to an electrophilic intermediate, a nitrenium ion. This reacts with DNA to form covalent adducts (7, 8, 11–13), the most abundant being the C8 adduct **4** at guanine residues. The formation of these adducts has been correlated with the carcinogenic effects of the amines (8, 13, 14). Although there have been suggestions of the involvement of S_N2 mechanisms (15–17), there is now excellent evidence that nitrenium ions do form in aqueous solutions (18–22), and that these are the species responsible for the guanine C8 adducts (23, 24).

Arylnitrenium ions are the nitrogen analogs of arylcarbenium ions. Unlike the latter, a nitrenium ion can have either a singlet or triplet electronic configuration. While the parent NH_2^+ is a ground state triplet (25, 26), phenyl substitution stabilizes the singlet relative to the triplet, and phenylnitrenium ion is calculated to be a ground state singlet, by ~20 kcal/mol (27). Until recently, nitrenium ions had been studied experimentally as steady-state intermediates of ground state reactions, usually S_N1 solvolysis reactions. Compared to carbocations, there had been very little direct study. Examples bearing strongly stabilizing substituents had been observed in acetonitrile following electrochemical oxidation of the amine (28–30), but no arylnitrenium ion has been characterized in superacids (31, 32).

© 1998 NRC Canada

Scheme 2.



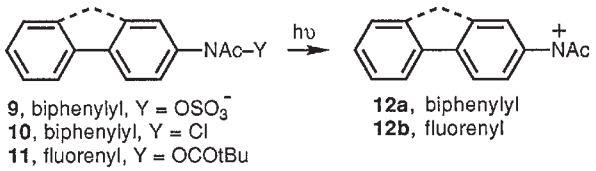
For some time now our group at the University of Toronto has been using laser flash photolysis (LFP) for the observation of carbocations in aqueous and alcoholic solvents (33). With LFP, the cation is generated photochemically by a short pulse of laser light, and is observed by fast time-resolved spectroscopic methods, in our case by UV-visible absorption spectroscopy. In addition to characterizing the cation in a solvent where it is typically found as a reactive intermediate, this approach supplies direct kinetic information about the lifetime of the cation in the solvent, and its reactions with added nucleophiles. Within the past few years, we have turned out attention to the arylnitrenium class, with a particular emphasis on the biphenylyl and fluorenyl systems. This paper summarizes our findings with these compounds. We in particular present new kinetic data on the reactions of the nitrenium ions with guanine derivatives, imidazoles, and primary amines. Also of interest is the comparison of nitrenium ions with corresponding carbenium ions.

Flash photolysis generation of 4-biphenylyl and 2-fluorenylnitrenium ions

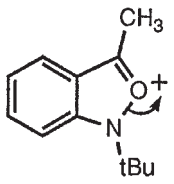
The LFP method requires a photochemical reaction to generate the reactive intermediate of interest. As illustrated in Scheme 2, the nitrenium ions **3a** and **3b** are obtained on irradiation of the azides **5a** and **5b** in aqueous solution (34, 35). The key step is protonation of the singlet nitrene **6** by a solvent water molecule. This occurs very rapidly (35), before the unstable nitrene can undergo one of its other decay processes (36). There are several more recent examples of nitrene protonation (37–39), although in some cases the addition of strong acids is required.

The LFP studies of *N*-acetyl analogs **12** have also been performed (40), the cations being formed upon heterolytic cleavage of an N—O or N—Cl bond of precursors **9–11** (eq. [1]).

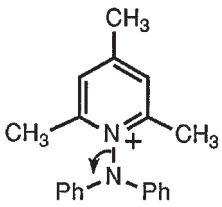
[1]



Each of these two methods has precedence in the study of carbocations by LFP. Certain carbenes can be trapped by protonation, forming secondary carbocations $R_1R_2CH^+$ (41–44). Photoheterolysis of C—Y bonds is probably the most widely used method for the study of carbocations (33) (although the actual photochemical route by which the cation eventually forms is still open to question (45–47). Photoheterolysis with neutral leaving groups has been employed by the Falvey group for the LFP investigations of nitrenium ions (48–51). The cations **13** and **14**, for example, provide nitrenium ions upon irradiation in acetonitrile.



13



14

Characterization of nitrenium ions and trapping by azide anions

Since nitrenium ions have not been characterized under super acid conditions, the assignment of a nitrenium structure to the transients observed in LFP experiments is based on indirect methods. Nevertheless the evidence is strong. To start with, products of irradiation are exactly those expected of a nitrenium ion intermediate. As one example, irradiation of 4-azidobiphenyl **5a** in 10% acetonitrile gives a 90% yield of the ketone **8** (35), the product that results from water capture of a nitrenium ion intermediate (19). Such a compound would not form in any of the other normal reactions of a nitrene (36). Both the yield of **8**, and the intensity of the transient decrease as the acetonitrile content of the medium increases (35). This solvent dependence reflects the requirement that water trap the nitrene. The parallel behaviour indicates that the LFP transient is the precursor of the product. The quenching behaviour of the nitrenium transient is also characteristic. Oxygen, a quencher of radicals and triplet excited states, has no effect, but nucleophiles do react.

Particularly compelling evidence is supplied with azide ion as the quencher. Novak and co-workers have investigated ground state solvolysis reactions in the presence of this nucleophile (19–21), for example, employing the pivalate **15** as a precursor to the nitrenium ion **3a** (19). As azide is added, there are increasing amounts of an azide-incorporated product at the expense of products derived from solvent (e.g., **16** versus **8**). At the same time, there is no change in the rate constant for the reaction, a clear indicator of an S_N1 reaction proceeding through rate-limiting ionization. Quantitative analysis of the product ratios provides the rate constant ratio $k_{Az}:k_w$. With LFP the absolute values for these two constants are directly measured, k_w as the first-order rate constant for the decay in the solvent alone, and k_{Az} as the slope of the linear plot of k_{decay} versus $[N_3^-]$. In the cases where both have been determined, the ratio from LFP is exactly the same as the ratio from solvolysis, for example $(2.8 \pm 0.1) \times 10^3$ (LFP, ref. 35) versus (2.9 ±

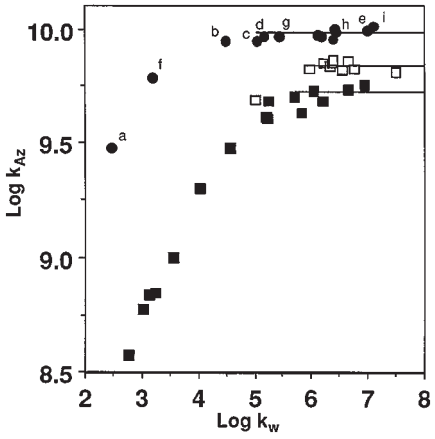
0.2) × 10^3 (competition, ref. 19) for the system of Scheme 3. Such observations not only provide evidence that the transient is a nitrenium ion, but they also establish the transient as a ground state nitrenium ion, identical with one formed in a solvolysis reaction.

The azide-clock method converts selectivities measured in a ground state solvolysis into absolute rate constants, through the assumption that the azide reaction occurs at the encounter limit, so that k_{Az} = 5 × 10^9 M^{-1} s^{-1} (52, 53). The LFP provides a way of verifying this, since it supplies absolute rate constants. The situation with arylnitrenium ions and two series of carbenium ions is illustrated in Fig. 1. With the more stable ions in each series, structural changes that increase k_w also increase k_{Az}. A break is then observed, with k_{Az} being effectively constant for the more reactive cations. The limiting rate constants are of the order of magnitude associated with an encounter-controlled process, although the

Fig. 1. Variation of log k_{Az} with log k_w for carbenium and nitrenium ions showing leveling of k_{Az} for more reactive cations. Closed squares, triarylmethyl carbocations (56); open squares, diarylmethyl carbocations (56); closed circles, nitrenium ions (*a*, 4-(*N*-methyl-*N*-acetylamino)phenylnitrenium (57); *b*, 2-fluorenylnitrenium (**3b**) (35); *c*, *N*-acetyl-2-fluorenylnitrenium (**12b**) (40); *d*, 3,5-dimethyl-4-biphenylylnitrenium (58); *e*, *N*-acetyl-4-biphenylylnitrenium (**12a**) (40); others are 3′- or 4′-substituted-4-biphenylylnitrenium ions (55), e.g., *f*, 4′-methoxy; *g*, 4′-methyl; *h*, parent (**3a**); *i*, 3′-chloro). Rate constants are at 20°C, zero ionic strength, and 20% acetonitrile (nitrenium and diarylmethyl ions) or 33% acetonitrile (triarylmethyl). Units of k_{Az} are M^{-1} s^{-1}; k_w, s^{-1}. The lines drawn with each set represent the limiting rate constant, 1 × 10^{10} M^{-1} s^{-1} for the nitrenium ions, 7 × 10^9 M^{-1} s^{-1} for the diarylmethyl ions, and 5 × 10^9 M^{-1} s^{-1} for the triarylmethyl ions.



limits do depend on the type of cation. We have previously explained the difference in the carbocation series in terms of a steric effect (56), more nonproductive encounters occurring in the case of the more bulky triaryl system. The slightly higher limit with the nitrenium series would suggest that this is less sterically congested. The conclusion is that the azide-clock approach is valid for both nitrenium ions and carbenium ions, at least for more reactive cations. A second conclusion is that arylcarbenium ions and arylnitrenium ions behave in an essentially identical fashion in their reaction with azide ion. This is perhaps not surprising. The nitrenium ions react with azide ion at one of the ring carbons, that is, through a carbocation resonance contributor.

Lifetimes of nitrenium ions in water

Despite the positive charge formally sitting on a more electronegative atom, arylnitrenium ions are longer-lived than arylcarbenium analogs (Table 1). Thus the parent phenylnitrenium ion **17**, though short-lived does have a lifetime in water. There would be questions as to the existence of the parent benzyl cation (65); the diphenylmethyl cation **18**, with two stabilizing phenyl groups, has about the same lifetime as **17**. The 4-methoxyphenylnitrenium ion **19** is two orders of magnitude longer-lived than its benzyl analog **21**. In the fluorenyl system, the difference between the NH^+ and CH_2^+ ions is even greater; the carbenium ion **22** with an extra phenyl is already three orders of magnitude more reac-

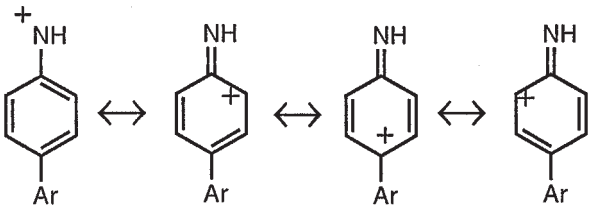
© 1998 NRC Canada

tive than **3b**. With 2-imidazoyl, the difference between $ArNH^+$ and $ArCH_2^+$ (**23** versus **25**) is almost a million.

This relative kinetic stabilization of nitrenium ions is likely a reflection of their reaction with water at a ring carbon (see Schemes 2 and 3). The immediate product of hydration is therefore not aromatic. Arylcarbenium ions in general react at the external carbon, so that the product is aromatic. We would argue that this provides a driving force lowering the barrier for the carbocation hydration.

The structural representation with the positive charge on nitrogen (e.g., **26a**) is actually a minor resonance contributor. Several pieces of evidence suggest that the cation is better regarded as a delocalized cyclohexadienyl cation, comprising the resonance structures **26b**–**26d**. For example, biphenylyl derivatives $Ar\text{-}C_6H_4NH^+$ show pronounced effects of substituents in Ar, with linear free energy correlations suggesting that the interaction is more like that in a benzylic cation, e.g., as if the structure were **26c** (55). Perhaps most convincing is a recent flash photolysis study of the precursor **14** employing IR detection. The stretching frequency of the C—N bond moves towards that of an imine when the nitrenium ion Ph_2N^+ forms (66).

The importance of the carbenium ion resonance contributors is likely the reason that rate constants for simple nitrenium ions $4\text{-}XC_6H_4NH^+$ produce a highly scattered Hammett plot using the σ^+ values for X. This feature of nitrenium ion

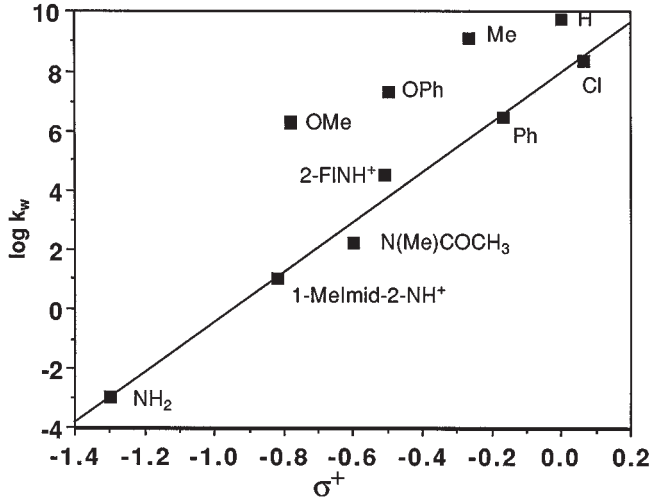


chemistry was first noted by the Novak group using k_w values obtained by the clock method (20); a more extended version of the plot is shown in Fig. 2. Lifetimes span a range of almost 13 log units from the parent $PhNH^+$ to the 4-amino derivative. There is however a very poor correlation. The data appear to separate into two families, although this is probably not real, since there is no obvious structural feature that distinguishes the two. The scatter is also quite large. The 4-methoxy derivative, for example, is four orders of magnitude more reactive than 4-NMeAc, despite the fact that 4-MeO is more stabilizing according to its σ^+ value.

Reactivity with guanine derivatives

While an ion like the 2-fluorenylnitrenium ion does have a lifetime in water, it is still a short-lived species, surviving for less than 100 μs in the solvent alone. Considering this, the guanine ring is a very effective trap. This was first seen by the Novak group in solvolysis reactions run under competition conditions (23, 24). Low concentrations of 2′-deoxyguanosine (dG) result in the formation of the C8-adduct at the expense of the water products (Scheme 4), with no change in rate constant. Selectivities k_{dG}:k_w are high

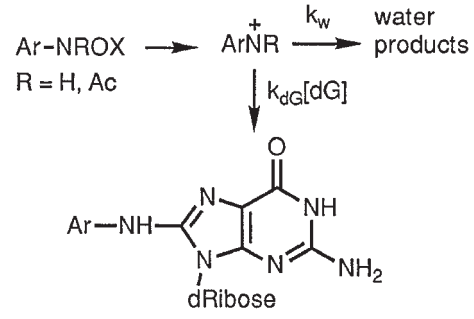
Fig. 2. Hammett plot for the hydration of arylnitrenium ions $4\text{-}XC_6H_4NH^+$. Data for H (59), 4-Me (21), and 4-Cl (21) are based on a clock method. All other rate constants are directly measured: 4-Ph (35), 2-fluorenyl (35), 4-MeO (60), 4-PhO (Ramlall and McClelland, unpublished), $4\text{-}NMeCOCH_3$ (57), 1-methyl-2-imidazoyl (62), $4\text{-}NH_2$ (monoprotonated benzoquinone bis-imine) (67). The σ^+ values for 2-fluorenyl (20) and 1-methyl-2-imidazoyl (68) are values for the entire group. The line has been drawn for the bottom six points and has a slope of +9.



(Table 2). The dG reaction was suggested to be occurring at or near the encounter limit (24).

The nucleoside is a very effective quencher in LFP studies. Moreover, k_{dG}:k_w ratios based on the absolute rate constants are in complete agreement with Novak's competition results (Table 2). This is an important result since it conclusively establishes that these nitrenium ions do react with guanine forming the C8 adduct. As further corroboration of the photochemical system, products were analyzed following irradiation of 4-azidobiphenyl and 2-azidofluorene in an aqueous solution containing 10 mM 2′-deoxyguanosine. There is one product derived from the nucleoside, and it is the C8 adduct, as proven by isolation from scaled-up photolyses. In both cases the yield of this adduct at high concentrations of dG is 80–85%, close to the maximum yield of

Scheme 4.



nitrenium ion (35). For the 2-fluorenyl system, the variation in yield was determined at lower concentrations, furnishing a k_{dG}:k_w ratio that is in excellent agreement with the LFP one (Table 2).

Table 3. Second-order rate constants (M^{-1} s^{-1}) for the trapping of nitrenium ions by nucleosides and nucleotides (conditions: 20°C, 20% acetonitrile, ionic strength = 0.1 ($NACLO_4$), pH 7 phosphate buffer.)

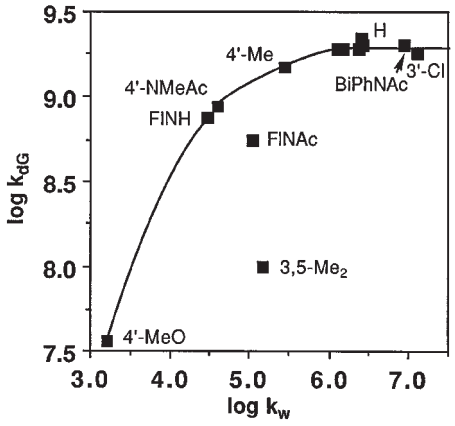
Nucleophile	4-BiPhNH+	2-FlNAc+	2-FlNH+
2′-Deoxyguanosine	2.0×10^9	4.1×10^8	7.6×10^8
Guanosine		4.3×10^8	7.2×10^8
2′-Deoxyguanosine 5′-phosphate	1.9×10^9	4.5×10^8	9.2×10^8
Guanosine 5′-phosphate	2.4×10^9	4.9×10^8	9.3×10^8
2′-Deoxyinosine		1.8×10^6	9×10^5
2′-Deoxyadenosine		3.2×10^6	

As shown in Table 3, other guanine derivatives react with rate constants very similar to dG. The nucleosides 2′-deoxyadenosine and 2′-deoxyinosine on the other hand are less effective quenchers, as has been noted by the Novak group (24).

Table 4 lists values of k_{dG} for a series of 4-biphenylylnitrenium ions, and Fig. 3 plots the dependence of log k_{dG} on log k_w. With a couple of exceptions, this figure shows a smooth curve of the same form as the azide dependencies of Fig. 1. In particular the more reactive nitrenium ions show no dependence of k_{dG} on structure, all reacting at $(2 \pm 0.2) \times 10^9$ M^{-1} s^{-1}. This can be argued to represent the diffusion limit. The value is five times smaller than the limit for azide ion with the same cations. This is the difference between a cation–neutral encounter and a cation–anion encounter. The latter pair benefits from an electrostatic attraction that increases the rate of encounter (compare $Ar_2CH^+ + N_3^-$ (54) with $Ar_2CH^+ + RNH_2$ (69)).

The two points that fall off the curve in Fig. 2 are the *N*-acetyl-2-fluorenylnitrenium ion **12b** and the 3,5-dimethyl- 4-biphenylylnitrenium ion **27**. The latter has methyl groups *ortho* to the reacting nitrogen, so that its deviation is likely due to a steric effect. The deviation with the former may indicate that *N*-acetyl derivatives do not fall on the same curve as the NH cations. (The only other *N*-acetyl derivative studied thus far, cation **12a**, is very reactive and may have reached its limit). Interestingly **12b** is less reactive towards dG than its NH analog **3b**, while the order is reversed with

Fig. 3. Variation of log k_{dG} with log k_w.



water as the nucleophile. One explanation is that with the *N*-acetylnitrenium ion, the electron withdrawing acetyl group has reduced the positive charge even more on the external nitrogen, the reacting site in the dG reaction.

In contrast to nitrenium ions, it is difficult to observe dG quenching of carbocations in LFP experiments. For example, cations **22** and **28** (70) show no change in decay rate constant in 20% acetonitrile in changing from 0 to 15 mM dG, about the maximum concentration attainable. Since an increase of 10% would be detectable, this places upper limits on k_{dG} as given in Table 5. Quenching can be observed in trifluoroethanol, where the background decay is suppressed because of the weaker solvent nucleophilicity. In TFE the cations **22** and **29** react with dG with rate constants of 10^6–10^7 M^{-1} s^{-1}. If these rate constants are applied to an aqueous solution, in 1 M dG only 22% (for **22**) and 7% (for **29**) of the products would be derived from the nucleoside.

One aspect of the comparison of nitrenium ions and carbenium ions that is important to note is that the site of reaction in guanine is different. With the 4-biphenylyl- and 2-fluorenyl nitrenium ions the only product with 2′-deoxyguanosine in water is the C8 adduct (23, 24). With carbon electrophiles on the other hand, there is no instance of reaction at C8, and the delocalized carbocations of Table 5 would be expected to react at the NH_2 group (13). It is

also interesting to speculate why the carbocations show such a low dG:water selectivity as compared to nitrenium ions. This is likely related to a combination of an enhanced guanine reactivity for the nitrenium ion, coupled with an unusually low water reactivity. We discussed the latter previously in comparing lifetimes of nitrenium and carbenium ions. The reactivities with imidazoles and amines to be presented in the next section point to the unusually high guanine reactivity.

Whatever the explanation, guanine monomers are capable of competing very effectively with solvent water molecules for the nitrenium ions derived from the carcinogens 2-aminofluorene and 4-aminobiphenyl. This contrasts with the situation for a fully-formed carbocation of a similar lifetime, where the competition strongly favors the solvent. In fact under conditions where the nitrenium ion is predominantly trapped by the guanine, there would be little if any guanine reaction with the carbocation.

Reactivity with imidazole derivatives and primary amines

The rate constants for four imidazoles reacting with nitrenium ions are given in Table 4. It can be seen that methyl substitution at N1 has only a minor effect, while methyl substitution at C2 has a more pronounced effect. Taking one member from each pair, plots of log k_{imid} vs. log k_w have been constructed and are shown in Fig. 4. The 2-methylimidazoles behave in a similar manner to 2′-deoxyguanosine. In particular the rate constants have become effectively constant for the more reactive ions. The limits are $(2.3 \pm 0.4) \times 10^9$ M^{-1} s^{-1} for 1-methylimidazole

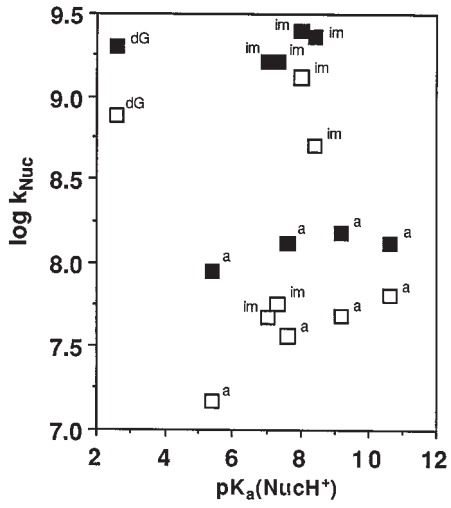
and $(2.2 \pm 0.2) \times 10^9$ M^{-1} s^{-1} for 1,2-dimethylimidazole. These numbers are very similar (if not indistinguishable considering experimental uncertainty) to the limit for 2′-deoxyguanosine. The plots for imidazole and 1-methylimidazole are also curved. However, in contrast to the 2-methylimidazoles and dG, the $\sim 2 \times 10^9$ limit is just being reached for the most reactive ion. The other nitrenium ions react below this limit, and show a dependence of rate constant on cation structure.

Data for four primary amines of varying basicity are provided in Table 6. The behaviour here is the same as previously seen for the same series of amines reacting with diarylmethyl carbocations (69). Brönsted-like plots (Fig. 5) are curved. The more reactive ions show an inversion of reactivity and basicity; i.e., 1-butylamine is less reactive than less basic analogs. Finally, as seen in Fig. 4, the limiting k_{amine} appears to fall below the 2×10^9 number associated with diffusion control. This behaviour is explained (69, 71, 72) by recognizing that the nucleophilic site is involved in a hydrogen bond with a solvent water molecule (RH_2N:----H—OH). This must be broken at some stage when the nitrogen bonds with an electrophile. For highly reactive electrophiles, breaking the hydrogen bond becomes more important than actual N–electrophile bond formation. Thus more basic amines with stronger hydrogen bonds are actually less reactive. The limiting rate constants are also less than diffusion control, since the hydrogen bond must always be broken.

If the NH_2 group of the alkyl amine is employed as a model for the C_2-NH_2 group of guanine, it is apparent from Fig. 4 why there is little reaction of the nitrenium ions at this site. Whatever the structures of amine and nitrenium ion, the dG reaction forming the C8 adduct is at least a factor of 10 faster than the amine reaction. In fact the difference is likely

Fig. 6. Failure of nitrenium ion reactivity to correlate with nitrogen basicity. Closed squares, 4-biphenylylnitrenium ion; open squares, 2-fluorenylnitrenium ion; dG, 2′-deoxyguanosine; *a*, primary amine; im, imidazole. The pK_a for dG is that for N7 protonation.



greater than this, since the NH_2 group of guanine is considerably less basic than even $CF_3CH_2NH_2$, the least basic of the alkyl amines.

It is also apparent that if 2′-deoxyguanosine and the imidazoles are included, there is absolutely no correlation of nitrogen basicity with reactivity towards nitrenium ions (Fig. 6). The imidazoles and 2′-deoxyguanosine might be considered as a series since protonation involves the same type of nitrogen, but even here there is no correlation. The

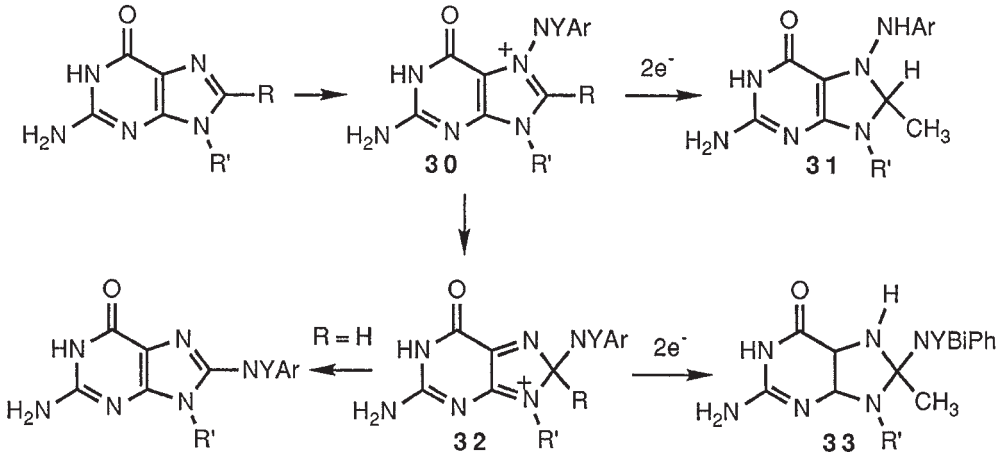
Scheme 5.



nucleoside has about the same reactivity as the 2-methylimidazoles, but is more reactive than imidazole and 1-methylimidazole, compounds that are 4–5 log units more basic. These conclusions should be regarded as preliminary since the products with the amines and imidazoles have not been determined. Such studies are in progress.

Questions regarding nitrenium-guanine chemistry

There are still several unanswered questions regarding the nitrenium–guanine reaction — why is it so fast, what is the mechanism for the formation of the C8 adduct, and are there differences between monomeric guanine and the guanine residues of DNA? With respect to the mechanism, there are conflicting reports regarding the exact details. Humphreys et al. (73) have suggested that the initial site of reaction is N7, to give intermediate **30**. This was based on experiments with an 8-methylguanine derivative and the 2-fluorenylnitrenium ion. With both NMR and MS, structures were assigned to both the unstable **30** and its reduction product **31**. The Novak group have also looked at the 8-methyl system, in their case with the biphenylylnitrenium ions **3a** and **12a**. They however assign C8 adduct structures **32** and **33** to an intermediate and its reduction product. Nevertheless they still propose that N7 is the initial site of attack, based on a correlation of reactivity with the N7 basicity. That correlation obviously breaks down if imidazoles are included, as we have just discussed. Very recent flash photolysis experiments in our group have shown that the decay of a nitrenium ion in the presence of 2′-deoxyguanosine is accompanied by the formation of an intermediate absorbing in the range 300–400 nm. Several pieces of evidence suggest that that species is the C8 adduct **32**, with R = H. In particular the decay of that intermediate exhibits a very large primary isotope effect when comparing guanine C8-H and C8-D (Scheme 5).

The situation with guanine in DNA is also an interesting one. Novak and Kennedy (74) have performed experiments that show that a double-stranded DNA hexamer containing one dG does not quench the nitrenium ion **12b**. The single-stranded form does, but on a per guanine basis, only a quarter as effectively as 2′-deoxyguanosine. Other studies have however shown an opposite behaviour, with DNA giving more adducts than monomeric guanine (see for example, ref. 75). There are also a number of reports that suggest that carbenium ions can form adducts with DNA–guanine (13, 76), despite our failure to see quenching with the monomer. As has been pointed out by Novak (24, 75), the reactivity pattern in guanine DNA is also different. Whereas the monomer studies show only the C8 adduct, with guanine in DNA there is usually a small fraction of adduct where the guanine NH_2 group has joined with one of the ring carbons of the nitrenium ion (13). Thus, the electrophile is behaving as a carbenium ion, doing typical carbenium chemistry.

Thus, there is uncertainty as to whether the results obtained with monomeric guanine derivatives can be extended to DNA. With the availability of both flash photolysis precursors and solvolytic precursors, it should be possible to examine this question in detail.

Experimental section

Precursors for the flash photolysis generation of the nitrenium and carbenium ions whose data appear in Tables 1–6 have been presented in previous publications (35, 40, 54, 55, 70). Flash photolysis experiments were conducted with 308 nm irradiation, and detection at the λ_{max} of the electrophile (35, 40, 54, 55, 70). The solutions contained 20% by volume acetonitrile in water, and the temperature was 20°C. Five to seven concentrations of the quenching nucleophile were employed, chosen such that the most concentrated solution had a rate acceleration at least a factor of ten greater than solvent alone. The exceptions to this were the 3′-chlorobiphenylylnitrenium ion and the *N*-acetyl-4-biphenylylnitrenium ion, where smaller rate accelerations were necessary because of the very fast background rate. All solutions gave excellent exponential decay traces. First-order rate constants *k*(decay) were obtained by nonlinear regression of the expression for single exponential decay. Plots of *k*(decay) versus the concentration of the quencher were excellently linear. The second-order rate constant for the quencher was determined from the slope of this line by linear regression. In general the standard deviation in this value was in the range 2–4%, except for the two more reactive ions (see above) where the errors are larger.

Diastereoselective alkoxymethylation of aromatic aldehydes with chiral lithiomethyl ethers. Synthesis of optically active monoprotected glycols

Viviana L. Ponzo and Teodoro S. Kaufman

Abstract: The synthesis of optically active α-alkoxymethyl benzyl alcohols by reaction of polysubstituted benzaldehydes with chiral α-alkoxymethyllithiums, easily obtained by transmetallation of the corresponding α-alkoxystannanes with *n*-butyllithium, is reported. Chemical yields of the transformation are good while low asymmetric induction (<1.6:1) is obtained.

Key words: diastereoselective synthesis, monoprotected glycols, chiral alkoxymethyllithiums, addition to aldehydes, optically active alcohols.

Résumé : On a réalisé la synthèse d'alcools α-alkoxyméthylbenzyliques optiquement actifs par réaction de benzaldéhydes polysubstitués avec des α-alkoxyméthyllithiens chiraux facilement obtenus par transmétallation des α-alkoxystannanes avec du butyllithium. Les rendements chimiques de la transformation sont bons et on obtient de faibles inductions asymétriques (<1,6:1).

Mots clés : synthèse diastéréosélective, glycols monoprotégés, alkoxyméthyllithiens chiraux, addition à des aldéhydes, alcools optiquement actifs.

[Traduit par la Rédaction]

The preparation of enantiomerically pure compounds is one of the most challenging problems in organic chemistry; therefore, much effort is being devoted to the development of efficient methods for the accomplishment of this objective. Among them, the enantioselective reactions of the carbonyl group involving reductions with modified boron and aluminum hydrides or nucleophilic additions of chelated organometallics have received considerable attention for a long time (for reviews, see ref. 1).

During our work on the synthesis of bioactive tetrahydroisoquinolines, we have elaborated and employed α-alkoxymethyl benzyl alcohols as key intermediates, both as racemates (2) and in their optically active form (3). We observed that, in contrast with the abundant literature on the synthesis of chiral benzylic alcohols by reduction of prochiral ketones or addition of alkylzinc derivatives to aromatic aldehydes (1), the direct enantio- and diastereoselective alkoxymethylation of the latter have been scarcely studied (4).

The extended use of this kind of compounds and the previously reported syntheses of racemic monoprotected glycols by addition of organotin derived α-alkoxymethyllithiums to aldehydes (5), prompted us to evaluate the use of our recently developed one-pot synthesis of chiral α-alkoxymethyl organostannanes (6) as an easy, convenient, and inexpensive entry to these chiral glycol monoethers.

Herein we report the synthesis of optically active α-alkoxymethyl benzyl alcohols by reaction of aromatic aldehydes with chiral lithiomethyl ethers. For the purposes of this study, test aldehydes **1**–**6** and chiral organostannanes **7a**–**9a** derived from (+)-isopinocampheol, (–)-8-phenylmenthol, and the natural (–)-menthol, respectively, were employed.

When the aromatic aldehydes were added to THF solutions of the chiral α-alkoxymethyllithium (for examples of transmetallation of α-alkoxymethyltins and related species, see ref. 7) reagents **7b**–**9b** derived from stannanes **7a**–**9a** at –78°C, it was observed an almost immediate formation of the corresponding alkoxymethylated products (Scheme 1), very slightly contaminated with the alcohols originated in the *n*-butyllithium addition to the carbonyls (5*b*, 5*c*).

In a preliminary exploration, the nucleophiles derived from chiral stannanes **7a**–**9a** were tested against the same aldehyde, as exemplified in entries 1–3 of Table 1. Interestingly, it was observed that the products resulting from the use of **7a** could not be separated, while employing **8a** gave rise to a mixture of alcohols, the diastereoisomeric excess (de) of which was not different from that obtained when its less bulkier and less expensive congener **9a** was used; therefore the latter was selected for further experiments.

The TLC and ^{1}H NMR analysis revealed that the reactions proceeded in good yield, but with low diastereoselectivity (Table 1). Although the components of the diastereoisomeric mixture exhibited similar R_f values, careful flash chromatography of the crudes allowed the isolation of pure diastereoisomers in most of the cases, when benzene–EtOAc was employed as eluent.

The low diastereoselectivity observed can be explained taking into account the high reactivity of the α-alkoxymethyllithium intermediates, which are known to add to aldehydes at rates comparable to those of *n*-butyllithium even at low temperature (5*a*), preventing the differentiation of both prochiral faces of the electrophile (8). On the other hand, being the chiral moiety of the nucleophile far from its carbanionic centre, the proper transmission of the chiral information to the newly generated asymmetric carbon becames difficult (8*b*); this effect was also noticed by Colombo et al. (9) during their study on asymmetric induction in the α-lithioacetal and α-lithiooxazolidine series.

Noteworthy, a Lewis acid-mediated reaction of a chiral α-alkoxyorganolead compound with benzaldehyde giving a chiral glycol monoether, has been recently reported (10). Lacking the above drawbacks, this transformation demonstrated to be highly diastereoselective. In our hands, however, no reaction was observed when a mixture of stannane **9a**, and aldehyde **1** was treated with $BF_3{\cdot}Et_2O$ (2–4 equiv.) under the most different conditions (–78°C to RT and 1 h to 2 days). Presumably, this unsuccessful outcome is a consequence of the fact that tin forms stronger bonds with carbon than does lead (10*b*).

The use of an oxazaborolidine-mediated reduction of carbonyls (CBS process) was employed to obtain information about the absolute configuration of the newly formed chiral centre of the diatereoisomeric monoprotected glycols, on the basis that the mechanism of the CBS reduction with oxazaborolidine **(*S*)-18** derived from (–)-diphenylprolinol has been extensively studied (11) and shown to occur by way of a transition state assembly which allows the correct prediction of the absolute configuration of the product (12).

Thus, the mixture of **12a** and **12b** was subjected to a Swern oxidation (Scheme 2), affording ketone **19** in 91%

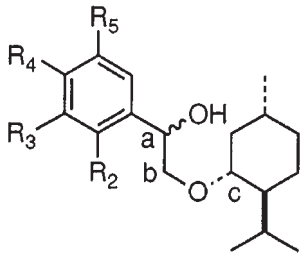
Table 2. Chromatographic behaviour, specific rotation data, and selected ^{13}C NMR resonances of α-menthyloxymethyl benzyl alcohols.



Compound	R_f	$[\alpha]^{25}_D$	δ_a	δ_b	δ_c
12a	0.69	–8.40	68.52	73.11	79.91
12b	0.65	–84.30	68.13	73.02	79.44
13a	0.74	–21.70	67.87	72.22	79.97
13b	0.64	–63.09	67.78	72.10	79.57
14a	0.72	–10.50	68.49	72.66	79.86
14b	0.66	–64.80	68.33	72.45	79.41
15a	0.62	–16.10	73.42	74.14	79.96
15b	0.57	–82.50	72.93	73.77	79.51
16a	0.60	–17.34	68.67	73.05	79.74
16b	0.58	–21.83	68.00	72.48	78.91

yield, while subsequent submission of **19** to the CBS reduction protocol (for a review about reductions in the presence of oxazaborolidines, see ref. 13) under **(*S*)-18** catalysis, furnished 97% of the less polar diastereoisomer **12a** (>98% de), to which benzylic centre was assigned the ***S*** configuration, on the basis of the reaction mechanism and literature precedents (1*b*, 13, 14).

Analysis of the ^{13}C NMR spectra of the (–)-menthyloxy derivatives **12**–**16** revealed interesting correlations between the chemical shifts of the alicyclic carbon atoms attached to oxygen of the diastereoisomers, their chromatographic behaviour and the corresponding specific rotations. As shown in Table 2, the less polar diastereoisomers exhibited higher $[\alpha]^{25}_D$ values and more deprotected oxygen-bonded alicyclic carbons than their more polar epimers. The above correlations probably indicate that the absolute configuration of the benzylic centre of all the less polar alcohols should be the same, and opposite to that of their more polar diastereoisomers.

In conclusion, the addition of chiral α-alkoxymethyllithium reagents to aromatic aldehydes as prochiral electrophiles gives good yields of optically active α-alkoxymethyl benzyl alcohols, which can be isolated in enantiomerically pure form. Asymmetric induction, however, is low.

Experimental section

Melting points were measured on an Ernst Leitz hot-stage microscope apparatus and are uncorrected. The IR spectra were taken on a Bruker IFS 25 spectrometer with solid samples as KBr pellets and liquid samples as films. The ^1H and ^{13}C NMR spectra were recorded in deuteriochloroform, on a Bruker AC-200E instrument at 200.13 and 50.33 MHz, respectively, with tetramethylsilane as the internal standard. The ^{13}C NMR resonances corresponding to two carbon atoms are designated with an asterisk. Optical rotation data were obtained employing a Jasco DIP 1000 electronic photopolarimeter. High-resolution mass spectra were obtained from UMYMFOR (Buenos Aires). Measurement of the diastereoisomeric excess of the oxazaborolidine-mediated reduction products was carried out employing a Gilson HPLC system equipped with a Chiralcel OD column, employing hexane-2-propanol (95:5) as the mobile phase at a rate of 0.5 mL/min and UV detection at 254 nm. Starting aromatic aldehydes were commercially available, and chiral α-alkoxymethyl tributyl stannanes were prepared from the corresponding chloromethyl ethers following our recently reported one-pot procedure (6). All reactions were carried out in a dry oxygen-free argon atmosphere. Reactions were monitored by thin layer chromatography on Merck's precoated silica gel 60 F_{254} TLC plates developed in benzene–EtOAc 8:2 and detected by examination under UV light, and by spraying with 2% *p*-anisaldehyde – sulfuric acid reagent in ethanol. Careful heating improved the sensitivity of the detection. All new compunds gave a single spot by TLC. The R_f values (TLC) were determined employing benzene–EtOAc 8:2 as mobile phase. Flash chromatography was carried out on Merck Kieselgel 60 (0.04–0.063 mm), packed in benzene; elution was done with mixtures of benzene–EtOAc, using gradient techniques. Compounds were preadsorbed from diethyl ether or dichloromethane solutions onto the adsorbent before column chromatography.

General procedure for the preparation of chiral α-alkoxymethyllithiums and their addition to aromatic aldehydes

A solution of *n*-butyllithium in hexanes (0.28 mL, 0.58 mmol) was added dropwise to a stirred solution of the starting chiral α-alkoxymethyl tributylstannane (0.60 mmol) in dry THF (1 mL) at –78°C. After 5 min, a solution of the aldehyde (0.5 mmol) in THF (1 mL) was incorporated to the thus formed α-alkoxymethyllithium derivative at the same temperature and stirring continued for an additional 10 min period. The reaction mixture was then quenched with saturated ammonium chloride solution (5 mL), warmed to room temperature, and extracted with EtOAc (3 × 20 mL). The combined organic extracts were dried (Na_2SO_4), concentrated in vacuo and chromatographed.

1-(2′′,3′′-Dimethoxyphenyl)-2-[(1′*S*, 2′*R*, 3′*R*, 5′*S*)-2′,6′,6′-triethylbicyclo[3.1.1]hept-3′-yloxymethyl]-ethanol (10a and 10b)

Unseparable mixture of diastereoisomers: R_f = 0.67; IR (neat): 3460, 2940, 1590, 1485, and 1290 cm^{-1}; HREIMS calcd. for $C_{20}H_{30}O_4$: 334.2144; found: 334.2155. Characteristic signals, major diastereoisomer: ^{1}H NMR, δ: 3.36 (dd, *J* = 9.9, 9.9 Hz, 1H) and 3.69 (dt, *J* = 3.2, 9.9 Hz, 1H); ^{13}C NMR, δ: 68.08, 73.53, and 79.75; minor diastereoisomer: ^{1}H NMR, δ: 3.42 (dd, *J* = 10.1, 10.1 Hz, 1H) and 3.73 (dt, *J* = 3.2, 10.1 Hz, 1H); ^{13}C NMR, δ: 67.72, 73.27, and 79.23.

1-(2′′,3′′-Dimethoxyphenyl)-2-[(1′*R*, 2′*S*, 5′*R*)-5′-methyl-2′-(1-methyl-1-phenylethyl)-cyclohexyloxy]-ethanol (11a and 11b)

*First diastereoisomer (**11a**)*: R_f = 0.64; $[\alpha]^{25}_D$ = +16.1 (*c* = 0.60, $CHCl_3$); IR (neat): 3450, 2954, 2868, 1586, 1478, 1370, 1278, 1222, 1052, 808, 752 and 702 cm^{-1}; ^{1}H NMR, δ: 0.80–1.12 (m, 3H), 0.88 (d, *J* = 6.5 Hz, 3H), 1.20–1.33 (m, 1H), 1.24 (s, 3H), 1.40 (s, 3H), 1.55–1.70 (m, 2H), 1.88–2.11 (m, 2H), 2.16 (d, *J* = 2.5 Hz, 1H), 3.06 (dd, *J* = 9.1, 9.1 Hz, 1H), 3.16 (dt, *J* = 4.1, 10.4 Hz, 1H), 3.63 (dd, *J* = 2.9, 9.1 Hz, 1H), 3.80 (s, 3H), 3.83 (s, 3H), 4.83 (ddd, *J* = 2.5, 2.9, 9.1 Hz, 1H), 6.81 (dd, *J* = 2.7, 7.9 Hz, 1H), 7.01 (dd, *J* = 7.5, 7.9 Hz, 1H), 7.02 (dd, *J* = 2.7, 7.5 Hz, 1H), and 7.08–7.40 (m, 5H); ^{13}C NMR, δ: 21.96, 26.11, 26.95, 28.01, 31.42, 34.97, 39.98, 40.65, 51.46, 55.70, 60.62, 68.60, 72.57, 80.84, 111.70, 118.92, 123.89, 124.92, 125.26,* 127.86,* 134.09, 146.11, 152.26, and 152.31; HREIMS calcd. for $C_{26}H_{36}O_4$: 412.2614; found: 412.2623.

Synthesis and oxazaborolidine-mediated reduction of 2′′,3′′-dimethoxyphenyl-[(1′*R*, 2′*S*, 5′*R*)-2′-isopropyl-5′-methylcyclohexyloxy]-ketone (19)

A CH_2Cl_2 solution of dimethyl sulfoxide (1.2 mL, 2.55 mmol) was added dropwise in 2 min to a stirred solution of trifluoroacetic anhydride (2.04 mmol) in the same solvent (1.8 mL) cooled to –60°C. Stirring continued for 7 min, when a solution containing alcohols **12a** and **12b** (172 mg, 0.51 mmol) in CH_2Cl_2 (1 mL) was incorporated dropwise. After a 20 min reaction period, triethylamine (0.43 mL, 3.1 mmol) was added and left to react for 20 min at –60°C and for 20 min at room temperature. The reaction was quenched with brine (10 mL), and the product was extracted with EtOAc (3 × 25 mL). The extracts were combined, dried over sodium sulfate, concentrated under reduced pressure, and chromatographed to furnish ketone **19** (145 mg, 91%) as an oil; R_f = 0.88; $[\alpha]^{25}_D$ = –66.2 (c = 0.61, $CHCl_3$); IR (neat): 2952, 2868, 1694, 1582, 1478, 1312, 1268, 1132, 1090, 1004, and 748 cm^{-1}; ^{1}H NMR, δ: 0.78 (d, J = 6.9 Hz, 3H), 0.80–1.11 (m, 3H), 0.89 (d, J = 7.1 Hz, 3H), 0.91 (d, J = 6.4 Hz, 3H), 1.18–1.50 (m, 2H), 1.58–1.70 (m, 2H), 2.03–2.40 (m, 2H), 3.19 (dt, J = 4.2, 10.5 Hz, 1H), 3.89 (s, 3H), 3.91 (s, 3H), 4.66 (d, J = 18.0 Hz, 1H), 4.77 (d, J = 18.0 Hz, 1H), 7.05 (dd, J = 2.3, 7.8 Hz, 1H), 7.09 (dd, J = 7.1, 7.8 Hz, 1H) and 7.26 (dd, J = 2.3, 7.1 Hz, 1H); ^{13}C NMR, δ: 16.10, 20.88, 22.17, 23.17, 25.34, 31.47, 34.35, 40.17, 48.11, 55.92, 61.24, 74.47, 80.02, 115.90, 120.92, 124.11, 131.46, 148.35, 152.70, and 199.32.

Without further treatment, a solution of ketone **19** (40 mg, 0.12 mmol) in anhydrous toluene (1.5 mL) was added at room temperature over 90 min to a stirred mixture of oxazaborolidine **(*S*)-18** (0.024 mmol) and borane – methyl sulfide (0.24 mL, 0.24 mmol) in dry toluene (1.5 mL). After the addition was completed the reaction mixture was further stirred for 15 min and quenched with MeOH (0.1 mL). Stirring continued for another 30 min, when the reaction was diluted with EtOAc (20 mL) and the organic phase washed with brine (2 × 5 mL). Drying, concentration in vacuo, and chromatography of the organic phase furnished a solid (39 mg, 97%) which melting point, $[\alpha]^{25}_D$, spectral data, as well as its chromatographic behaviour (TLC and HPLC), were in complete agreement with those recorded for **12a**. The HPLC of the crude reaction mixture indicated a diastereoisomeric excess greater than 98%.

Reaction of carbanions generated from arylmethylphosphonates with cyclic enones. Regio- and stereoselectivity of addition

Agnes M. Modro, Tom A. Modro, Malose J. Mphahlele, Wieslawa Perlikowska, André Pienaar, Marcelo Sales, and Petrus H. van Rooyen

Abstract: α-Lithiated benzylphosphonate esters, $XC_6H_4CH(Li)PO_3Et_2$, add regioselectively to cyclohex-2-enone at the carbonyl group; higher reaction temperatures lead to the reversal to the starting materials, and not to the 1,4-addition. Relative configuration of the C(1) and C_α centers in the 1,2-adducts was determined from the ^{13}C NMR spectra. For 2-methylcyclohex-2-enone the regioselectivity of the addition is decreased. The lithioderivative of diethyl 1-naphthylmethylphosphonate, $C_{10}H_7CH(Li)PO_3Et_2$, shows reverse regioselectivity yielding the 1,4-, but not the 1,2-addition product. The crystal and molecular structure of that 1,4-adduct has been determined and demonstrates that the conformation about the C(1)—C_α bond is close to that existing in solution, deduced from the value of the ^1H NMR $^3J_{HH}$ vicinal coupling constant of the H(1)-C(1)-C_α-H hydrogens. The same conformation was also confirmed as the most stable by molecular modeling.

Key words: α-lithiated arylmethylphosphonates, 1,2- vs. 1,4-addition to cyclic enones, steric effects of the cyclohex-2-enone, molecular structure and molecular modelling of the 1,4-adduct of 1-naphthylmethylphosphonate to cyclohex-2-enone.

Résumé : Les esters benzylphosphonates α-lithiés, $XC_6H_4CH(Li)PO_3Et_2$, s'additionnent régiosélectivement au groupe carbonyle de la cyclohex-2-énone; des températures plus élevées conduisent à un retour vers les produits de départ et, non pas, à une addition-1,4. On a fait appel à la RMN du ^{13}C pour déterminer les configurations relatives au niveau des centres C(1) et C_α des adduits-1,2. Avec la 2-méthylcyclohex-2-énone, la régiosélectivité de l'addition diminue. Le dérivé lithié du 1-naphtylméthylphosphonate de diéthyle, $C_{10}H_7CH(Li)PO_3Et_2$, provoque une régiosélectivité inversée conduisant au produit d'addition-1,4 et non pas 1,2. On a déterminé la structure cristalline et moléculaire de l'adduit-1,4 et elle démontre que la conformation autour de la liaison C(1)—C_α ressemble à celle qui existe en solution et qui a été déduite de la valeur de la constante de couplage $^3J_{HH}$ observée en RMN du ^1H pour les hydrogènes H(1)-C(1)-C_α-H. La modélisation moléculaire a permis de confirmer que cette même conformation est la plus stable.

Mots clés : arylméthylphosphonates α-lithiés, additions-1,2 vs. -1,4 à des énones cycliques, effets stériques de la cyclohex-2-énone, structure moléculaire et modélisation moléculaire de l'adduit-1,4 du 1-naphtylmétylphosphonate sur la cyclohex-2-énone.

[Traduit par la Rédaction]

Introduction

Nucleophilic addition to the α,β-unsaturated carbonyl compounds is one of the general methods of synthesis (1). The same can be said about the reactions of phosphorus-stabilized carbanions with electrophilic acceptors (2). In spite of this, reactions between the latter nucleophiles and enones has attracted little attention. Reference 1 does not list phosphorus-stabilized carbanions in the review of the nucleophilic reagents used in conjugate addition. There is also no mention of that reaction in ref. 2*b*, and only isolated cases are reported in ref. 2*a* (3). We have recently reported our first results on the reaction of the α-lithiated phosphonates (Wadsworth–Emmons reagents) with cyclic enones (4). It was found that the reaction outcome depends on the nature of the nucleophilic reagent ("localized," derived from an alkylphosphonate, or "delocalized," derived from an alk-2-enylphosphonate), as well as on the substitution pattern on the enone, and that the reaction can follow different mechanisms (1,2-addition, 1,4-addition, addition-elimination) with a large degree of selectivity. In this work we have extended our study on the reaction of cyclic enones with α-lithiated

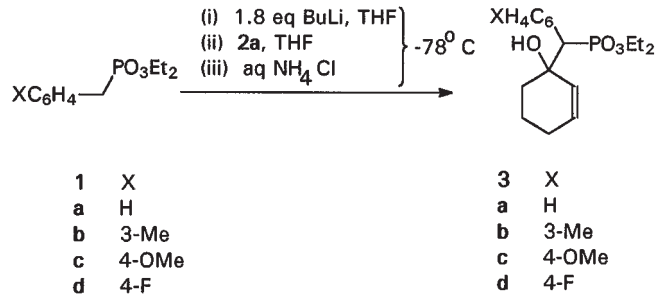
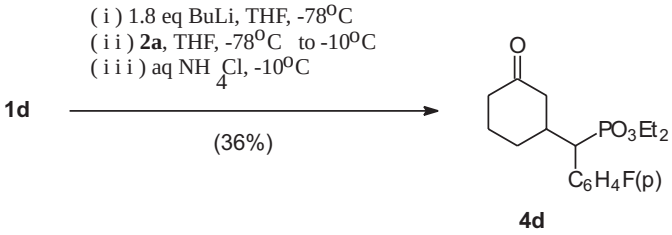


Scheme 2.



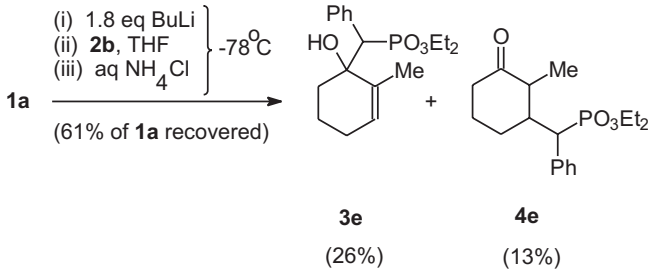
arylmethylphosphonates, and we demonstrate that the nature of the aryl group can dramatically change the regioselectivity of the addition.

Results and discussion

Petrova and co-workers studied the reactions of the carbanions derived from diethyl arylmethylphosphonates with unconjugated aldehydes and ketones (5). They concluded that the addition to the carbonyl group is reversible, which seriously reduces the yields of the olefination step and leads to the recovery of substrates upon longer reaction times. Reaction of heteroatom- (but not phosphorus-)stabilized carbanions with α,β-unsaturated carbonyl substrates has received considerable attention during the past three decades (for example, see ref. 6), and Schultz and Yee recognized that the direct addition of ester enolates to 2-cyclohexen-1-one is reversible at higher temperatures, and that the structural modifications of the nucleophile have a strong effect on the selectivity (7).

The reversibility of the 1,2-addition and steric acceleration of the reverse step was confirmed in further work on the addition of other, non-phosphorus heteroatom-stabilized carbanions with enones (for example, see ref. 8). The important conclusion on the regioselectivity was reached by Heathcock and co-workers in their extensive work on the Michael addition (9). They found that ketone enolates give 1,4-addition even at low temperatures (1,2-adducts are transient, but unstable intermediates), but for ester enolates, the 1,2-adducts can be obtained and can be rearranged to the 1,4-adducts upon warming. Thus, small differences in the nature and resultant stability of the nucleophile may have a powerful effect on the rate of the reverse of the carbonyl addition step.

Scheme 3.



Reactions of five diethyl arylmethylphosphonates **1a**–**1e** with 2-cyclohex-1-one (**2a**) and its 2-methyl (**2b**) and 3-methyl (**2c**) derivatives were studied in this work. With **2a**, all carbanions derived from benzylphosphonic esters (**1a**–**1d**) reacted exclusively according to the 1,2-addition pattern (Scheme 1), and no reversibility was observed at –78°C. In each case two diastereomeric alcohols **3** were obtained (major and minor), which were separated by column chromatography. Attempts to change the reaction course to the conjugate addition by raising the temperature of the reaction failed, as only starting materials were recovered under those conditions. This result shows that the conjugate base of **3** is only stable at low temperature, and that upon warming it undergoes fragmentation to the starting materials, but not to the possible products of the subsequent olefination step.[2] For **1d** we were able to find an intermediate temperature at which 1,4-addition successfully competed with the carbonyl addition (Scheme 2), albeit with low yield because of the still predominant reverse reaction. It seems that at temperatures higher than –78°C the rate of the retro-1,2-addition is too fast for any of the conjugate base of **3** to accumulate in the reaction medium. Since **4d** could be prepared at –10°C, but not at room temperature, it follows that the 1,4-addition step does occur at higher temperatures, but the retro-1,4-addition step also becomes too fast to allow accumulation of the conjugate base of **4**. It also follows that at room temperature the couple: lithiated **1** + **2a** (substrates) is thermodynamically more stable than either of the Li salts of the oxyanions derived from **3** or **4**.[3] Indeed, when alcohols **3a**–**d** and ketone **4d** were treated with BuLi in THF at –78°C, and the solutions were warmed to room temperature, kept at that temperature for 24 h, and subjected to aqueous work-up, only starting materials **1a**–**d** and **2a** were recovered. It shows that the oxyanions derived from **3**, and the enolate of **4d** undergo fragmentation back to **2a** and the lithiated **1**. This result contrasts with the reported thermal stability of the adducts of sulfur-stabilized organolithium compounds with **2a** (10), shedding some light on the relative stability of the P- or S-stabilized carbanions (substrates) vs. the corresponding oxyanions (products).

With 2-methyl-2-cyclohex-1-one (**2b**) the 1,2-addition was sufficiently slowed down (and its reversal accelerated) relative to the 1,4-addition by the steric effect of the 2-Me group, so that even at –78°C the reaction showed low selectivity (Scheme 3). The observed high proportion of the start-

[2] In no case was any fragmentation of the 1,2-addition product to diethylphosphate anion and the corresponding diene observed.

[3] Spectroscopic studies suggest similar stabilization of an adjacent carbanion by the P=O and the C=O groups (2*a*). In our case additional stabilization by the Ar group seems to favor the carbanion of **1** relative to the conjugate base of a tertiary alcohol (**3**) or a simple ketone enolate (**4**).

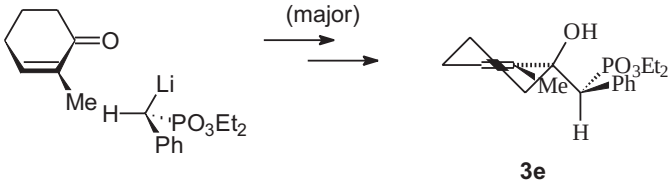
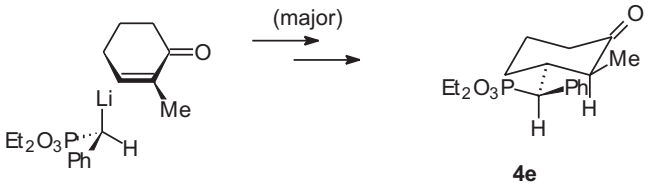
Scheme 5.



Scheme 6.



ing materials supports the conclusion on steric acceleration of the retro-addition step (for example, see ref. 8), and again indicates thermodynamic stability of the lithiated arylmethylphosphonate system relative to the corresponding oxyanions. When warmed to room temperature before the aqueous work-up, the mixture given in Scheme 3 reversed exclusively to the starting materials.

Scheme 1 shows that under "kinetic" conditions alcohols **3a**–**d** can be obtained with high yields and free of the 1,4-adducts. The diastereomeric mixtures of the 1,2-adducts were separated into individual stereoisomers, and in some cases ^{13}C NMR analysis allowed us to determine the relative configuration of the products. For example, for **3a**, **3c**, and **3d** the major stereoisomers gave rise to the ^{13}C NMR spectra from which the $^3J_{CP}$ coupling between the olefinic (C2) and the aliphatic (C6) carbons of the cyclohexene ring and the P atom could be determined as $^3J_{(C2)P}$ = 4.6, $^3J_{(C6)P}$ = 11.0 Hz for **3a** and **3c**, as well as $^3J_{(C2)P}$ = 4.4, $^3J_{(C6)P}$ = 11.3 Hz for **3d**. For **3b**, it was the minor stereoisomer that provided us with the values of $^3J_{(C2)P}$ = 10.0 and $^3J_{(C6)P}$ = 6.3 Hz. The angular dependence of the $^3J_{CP}$ values can be used to determine the configuration (and conformation) of organophosphorus compounds (11). The empirical relationship developed for the 2-phosphorylated-2-hydroxycamphane system gives the calculated values of the $^3J_{CP}$ coupling constants of 2.8 and 18.9 Hz for the *gauche* and for the *trans* orientation of the carbon and the phosphorus atoms of the C-C-C-PO_3R_2 skeleton (12). Our spectroscopic results show that alcohols **3** experience a high degree of restricted rotation about the C_α—C_1 bond and that the most populated conformation of the major stereoisomer can be represented as shown in Scheme 4, indicating spatial preference of the approach of the lithiated **1** to the enone function in **2a**. The stereochemistry of the 1,2-addition is reversed for **2b**, where the major stereoisomer of **3e** (after isolation and purification) gave rise to the $^3J_{CP}$ values of 13.2 and 5.1 Hz for C2 and C6 atoms, respectively. According to those values, the preferred conformation of the major stereoisomer of **3e** is as shown in Scheme 5; the geometry is most likely the consequence of the reluctance of the bulky PO_3Et_2 group[4] to be located in the vicinity of the 2-Me group in the transition state of the 1,2-addition.

For the 1,4-adduct **4d** we were not able to separate the product into two stereoisomers, but for the major isomer both $^3J_{CP}$ constants for both aliphatic carbons of the cyclohexanone ring (C2 and C4) could be determined as 8.2 and 9.4 Hz. It is clear that in the absence of the intramolecular hydrogen bonding between the OH and the phosphoryl group, which stabilizes the conformers in case of the 2-hydroxyalkylphosphonates **3** (14), there is a high degree of free rotation about the C_α—C_3 bond in **4d**. Finally, the 1,4-adduct **4e**, formed as a minor product in the reaction between **1a** and **2b** (Scheme 3) exists as a mixture of three streoisomers from which the major was successfully separated from the other two isomers formed in very small quantities. In contrast to **4d**, free rotation about the C_α—C_3 bond is in this case severely restricted, leading to very different values of the $^3J_{CP}$ coupling constants (14.6 and 2.2 Hz for C2 and C4, respectively). Obviously, the methyl group at C2 introduces enough steric hinderance to the PO_3Et_2 group in the condensation step to give high stereoselectivity of the reaction and is also responsible for the restriction of the free rotation (Scheme 6). Spectroscopic analysis of adducts **3** leads to a conclusion about the order of steric hinderance offered by C2 and C6 centers in the 2-cyclo-hexen-1-one system with respect to the approach of the α-PO_3Et_2 substituted carbanionic carbon to the carbonyl group during the 1,2-addition process (Schemes 4 and 5). The repulsion increases in the following order of the substitution pattern of the carbons adjacent to the carbonyl group: =C(H)- < -CH_2- < =C(Me)-.

The next carbanion studied in the addition to **2a**, derived from diethyl 1-naphthylmethylphosphonate **1e**, behaved in a unique fashion. The difference in the aromatic skeleton led to a totally different outcome of the reaction. At –78°C no reaction could be observed, and the aqueous work-up led to full recovery of substrates. The absence of the reaction (or the complete reversal of the addition) may result from either the increased steric effect of the $C_{10}H_7$ group (relative to the XC_6H_4 group) on the rate of the 1,2-addition, or from the increased resonance stabilization of the carbanion by that group that reduces its nucleophilic reactivity and disfavors the product formation. However, when the reaction mixture

[4] The steric substituent constant for the PO_3Et_2 is not available, but the $-E_S$ constant for CEt_3 substituent is 10 times larger than that of the Ph group (13).

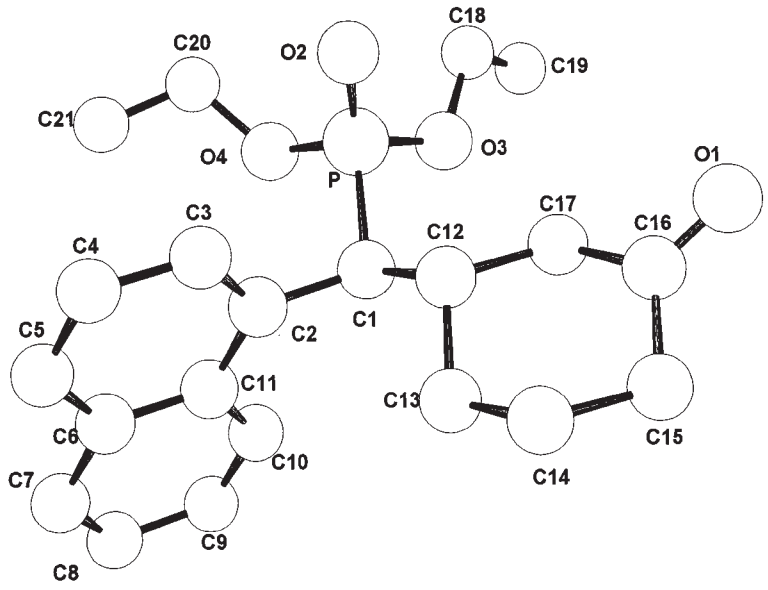
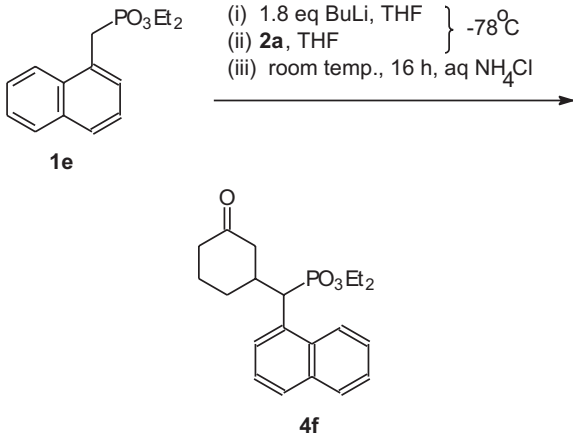


Scheme 7.



was warmed to room temperature after the addition of **2a** and left overnight, we obtained exclusively (in addition to the unreacted substrates) the product of the conjugate addition (**4f**), isolated in 55% yield (Scheme 7). As expected, **1e** failed to give any addition product with **2c**, either at –78°C or at room temperature. The 1,4-adduct **4f** was formed as a mixture of two diastereomers (ca. 1.5:1), and the major isomer was isolated in pure state by column chromatography and fractional crystallization. The $^3J_{CP}$ values for the coupling of the cyclohexanone carbon atoms C2 and C4 were found for the major isomer to be 0.64 and 10.8 Hz, respectively, indicating severe restriction of the rotation about the C_α—C_3 bond. The vicinal $^3J_{HH}$ constant involving the C_α-H and C_3-H protons was found to be 8.3 Hz, which corresponds to an average spatial orientation of those hydrogens not far from *trans* (ca. 162°). The structure of the major stereoisomer of **4f** was then determined by X-ray diffraction. The structure was solved by Patterson and direct methods (15, 16). Refinement by full-matrix least-squares methods was based on *F* (16). All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in idealized positions and included in the refinement with common isotropic thermal parameters that were also refined as indicated in Table 1. Atomic scattering factors were taken from the literature (17). Atomic coordinates, bond lengths and angles, anisotropic thermal parameters, and hydrogen atom coordinates have been deposited as supplementary material.[5] A perspective view of the molecule, prepared with ORTEP (18), is represented in Fig. 1, illustrating the molecular conformation and the crystallographic numbering schemes used. It can be seen that in order to minimize repulsive interactions between two bulky substituents (naphthyl and PO_3Et_2), the H atoms at C1 and C12 (C_α and C_3) are indeed oriented *trans* (the torsion angle H(1)-C(1)-C(12)-H(12) = 176.3°). The C(17)-C(12)-C(1)-P and the C(13)-C(12)-C(1)-P torsion angles were obtained from the crystal structure as 62.5 and 177.4°, respectively. Substituting those values to the Karplus equation (19) we obtained the calculated $^3J_{CP}$ values of 0.6 and 11.6 Hz, respectively. They remain in good agreement with the experimental coupling constants and suggest close correspondence of the solid-state conformation of **4f** to its preferred conformation in solution.

The correlation between the solid-state geometry and the spectroscopic (NMR) data obtained in solution prompted us to also include in the comparison the molecular dynamics (MD) method. The method known as simulated annealing was used to identify the low-energy conformations of **4f** with respect to the rotation about the C(1)—C(12) bond (20). From the plot of the potential energy (PE) vs. H(1)-C(1)-C(12)-H(12) torsion angle (Fig. 2*a*) it can be deduced

that during the simulation the barriers between all torsion angles were successfully traversed when the PE was greater than 200 kcal mol^{-1}, indicating a true Boltzmann distribution of conformers. The plot of the torsion angles H(1)-C(1)-C(12)-H(12) vs. the PE of the annealed low-energy conformers resulting from 50 cycles is given in Fig. 2*b*. Analogous plots were obtained when the conformers *b* and *c* were used as starting conformers for annealing experiments, showing that the conformers distribution is independent of the starting conformation. The conformer *a* shown in Fig. 2*b* underwent full minimalization and the resulting structure is given in Fig. 2*c*; the resemblance to the crystal structure of **4f** is evident. If the population distribution of the final annealed rotors reflects the population distribution of the rotors in solution, the calculated vicinal coupling between protons H(1) and H(12) (C_α-H and C_1-H) should agree with the experimental coupling of 8.3 Hz. The Haasnoot equation predicts that the vicinal coupling constant between these protons is a consequence of the population distribution of the rotors of **4f** defined by the H(1)-C(1)-C(12)-H(12) torsion (21). The torsion angles H(1)-C(1)-C(12)-H(12) for the fully minimized conformers *a*, *b*, and *c* were calculated as 164.2, 56.5, and –58.9°, respectively, and the populations of those conformers, calculated from their relative energies, were 60, 22, and 18%, respectively. The theoretical value of the vicinal $^3J_{HH}$ constant, obtained from the calculated fractions of the populations of the conformers and the theoretical coupling constants, is $^3J_{H(1)H(12)}$ = 9.2 Hz. The agreement with the experimental value of 8.3 Hz is reasonable, indicating that the conformational energy barriers present in the gas phase affect the population distribution of the final annealed structures to a similar degree as these barriers affect the population of the conformers in solution.

Experimental section

Solvents and commercially available reagents were purified by conventional methods before use. Reactions involving organolithium reagents were carried out in an atmosphere of dry nitrogen using flame-dried glassware. Melting points are uncorrected. For column chromatography, Merck Kieselgel 60 (0.063–0.200 mm) was used as a stationary phase. Unless otherwise stated, ethyl acetate was used as eluent. Mass spectra were recorded at an ionization potential of 70 eV. The NMR spectra were recorded as ca. 0.2 M solutions in $CDCl_3$. The ^{1}H and ^{13}C chemical shifts are given relative to the solvent ($CDCl_3$; ^{1}H: 7.24 ppm; ^{13}C: 77.0 ppm). The ^{31}P NMR chemical shifts are given relative to 85% H_3PO_4 as external standard, and ^{19}F NMR chemical shifts are given relative to $CFCl_3$ as external standard. The IR spectra were recorded as ca. 0.2 M solutions in $CHCl_3$.

Diethyl benzylphosphonate **1a** (Aldrich) was distilled before use; bp 100–101°C (0.7 mm). Diethyl arylmethylphosphonates **1b**–**1e** were prepared from triethyl phosphite, and the corresponding arylmethyl chloride or bromide according to the literature procedure for the Arbuzov reaction (22); **1b** (88%): bp 120–122°C (0.5 mm), n_D^{20} 1.4448 (lit. (23) bp 126–127°C (0.7 mm), n_D^{20} 1.4450); **1c** (83%): bp 175–180°C (0.5 mm), n_D^{20} 1.5035 (lit. (23) bp 176–178°C (0.21 mm), n_D^{20} 1.5040); **1d** (80%): bp 126–128°C (0.5 mm), n_D^{20} 1.4775 (lit. (23) bp 148–150°C (6 mm), n_D^{20} 1.478); **1e** (96%): purified by bulb-to-bulb distillation, oven temp. 220°C (0.5 mm), n_D^{20} 1.5630 (lit. (23) bp 202–205°C (0.2 mm), n_D^{25} 1.5610).

Reactions of diethyl arylmethylphosphonates 1 with cyclic enones 2. General procedure

N-Butyllithium (1.6 M solution in hexane, 1.8–2.0 mol equiv.[6]) was diluted with THF (3 mL per mmol of **1**). To this solution, cooled to –78°C, was added dropwise with stirring a solution of **1** (1 mol equiv., typically 8 mmol) in THF

[6] Any decrease in the excess of BuLi below 1.8 mol equiv. resulted in a serious decrease of the yield.

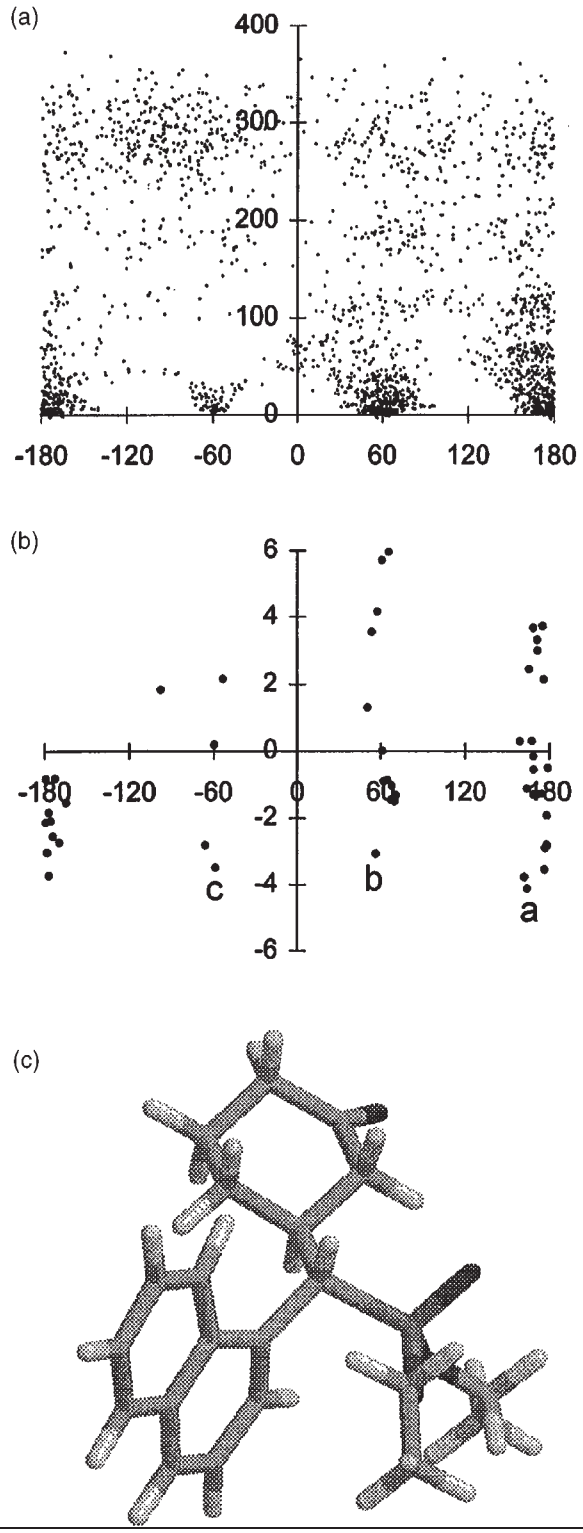
Fig. 2. (*a*) The plot of PE (kcal mol^{-1}) vs. torsion angle H(1)-C(1)-C(12)-H(12) (deg) for **4f**. (*b*) The plot of PE (kcal mol^{-1}) vs. torsion angle H(1)-C(1)-C(12)-H(12) (deg) for the low-energy conformers of **4f**. (*c*) Fully minimized structure of the conformer *a* of **4f**.



(1 mL per mmol of **1**) and the solution was stirred at that temperature for 1 h. A solution of enone **2** (1.2 mol equiv.) in THF (1 mL per mmol of **2**) was then added, and the reaction mixture was stirred at –78°C for 2 h. Saturated aq. NH_4Cl was then added at –78°C, and the solution was allowed to warm to room temperature. The mixture was extracted with ether (3 × 20 mL) after which the combined etheral layers were dried ($MgSO_4$), filtered, and evaporated under reduced pressure. The products were purified and identified as indicated for individual compounds.

In an alternative procedure, after the addition of **2** and stirring at –78°C for 2 h, the mixture was allowed to warm to a temperature indicated for individual compounds, before the aqueous work-up. Separation and purification procedure was then followed up as above. The following products **3** and **4** were prepared.[7]

*Diethyl (1-hydroxycyclohex-2-enyl)(phenyl)methylphosphonate **3a***

(All steps at –78°C.) Purified by column chromatography (99%): MS, *m*/*z*: 306 ($M^+ - H_2O$, 26%), 228 (100), 168 (55), 91 (51), 79 (7), 29 (15); IR: ν_{PO} 1231, ν_{OH} 3489. Anal. calcd. for $C_{17}H_{25}O_4P$: C 62.95, H 7.77; found: C 62.92, H 7.87. Separated by column chromatography to two isomers. Major isomer (79%), δ_H: 1.50 (2H, m), 1.61–2.00 (4H, m), 3.27 (1H, d, J_{HP} 23.7), 4.48 (1H, br s), 5.71 (1H, dt, J_{HH} 6.3, 9.8), 6.00 (1H, dd, J_{HP} 1.9, J_{HH} 10.2), 7.25 (3H, m), 7.43 (2H, m); proton-decoupled δ_C: 18.5, 24.6, 33.9 (d, J_{CP} 11.2), 53.5 (d, J_{CP} 132.4), 71.1, 127.0, 128.0, 128.1, 130.5, 132.6 (d, J_{CP} 4.6), 134.0; δ_P: 28.6. Minor isomer (20%), δ_H: 1.50 (2H, m), 1.61–2.00 (4H, m), 3.22 (1H, d, J_{HP} 22.9), 4.32 (1H, br s), 5.71 (1H, dt, J_{HH} 6.3, 9.8), 6.00 (1H, dd, J_{HP} 1.9, 10.3), 7.25 (3H, m), 7.45 (2H, m); proton-decoupled δ_C: 18.5, 24.5, 33.9 (d, J_{CP} 11.2), 54.8 (d, J_{CP} 127.9), 71.1, 127.1, 128.0, 128.1, 130.4, 132.7 (d, J_{CP} 4.6), 133.9; δ_P: 27.8.

*Diethyl (1-hydroxycyclohex-2-enyl)(3-methylphenyl)methylphosphonate **3b***

(All steps at –78°C.) Purified by column chromatography (55%): MS, *m*/*z*: 320 ($M^+ - H_2O$, 26%), 182 (9), 105 (100), 79 (13), 29 (18); IR: ν_{PO} 1209, ν_{OH} 3417. Anal. calcd. for $C_{18}H_{27}O_4P$: C 63.90, H 7.99; found: C 63.81, H 8.15. Separated by column chromatography to two isomers. Major isomer (39%), δ_H: 1.49–1.70 (4H, m), 1.83–1.99 (2H, m), 2.30 (3H, s), 3.23 (1H, d, J_{HP} 23.7), 4.51 (1H, br s), 5.70 (1H, dt, J_{HH} 3.6, 10.2), 6.00 (1H, d, J_{HH} = 10.2 Hz), 7.04 (1H, s), 7.19 (3H, m); proton-decoupled δ_C: 18.7, 21.4, 24.7, 33.0, (d, J_{CP} 11.3), 53.7 (d, J_{CP} 131.8), 70.2, 127.7 (d, J_{CP} 6.7), 128.0, 128.1, 131.2 (d, J_{CP} 7.5), 137.7 (d, J_{CP} 4.9), 141.6; δ_P: 28.7. Minor isomer (16%), δ_H: 1.49–1.66 (4H, m), 1.77–1.93 (2H, m), 2.30 (s), 3.18 (1H, d, J_{HP} 23.0), 4.50 (1H, br s), 5.62 (1H, d, J_{HH} 11.1), 5.75 (1H, m), 7.04 (1H, m), 7.19 (3H, m); proton-decoupled δ_C: 18.7, 21.4, 24.8, 36.5 (d, J_{CP} 6.3), 54.9 (d, J_{CP} 130.5), 71.1, 127.8, 127.9, 128.2, 130.2 (d, J_{CP} 10.0), 130.6, 131.3 (d, J_{CP} 4.2), 134.0, 137.6; δ_P: 28.0.

[7] All products **3** and **4** are diethyl esters of phosphonic acids. For the sake of brevity, the ^1H and ^{13}C NMR signals of the POEt ester groups are not included in the spectroscopic data of individual products. In all cases those groups gave rise to the following signals: δ_H: 1.15–1.30 (6H, t, J_{HH} 7.0–7.1), 3.95–4.15 (4H, dq, J_{HP} ca. 11, J_{HH} ca. 7); proton-decoupled δ_C: ca. 16 (d, J_{CP} ca. 5.5), ca. 62 (d, J_{CP} ca. 7). In case of diastereomeric mixtures, pairs of the corresponding signals were obtained.

Minor isomer (26%), δ_H: 1.51 (2H, m), 1.74–2.01 (4H, m), 3.21 (d, J_{HP} 23.0), 4.23 (1H, br s), 5.58 (1H, d, J_{HH} 10.4), 5.79 (1H, m), 6.96 (2H, dd, J_{HF} 8.6, J_{HH} 8.7 Hz), 7.40 (2H, m); proton-decoupled δ_C: 18.3, 24.4, 36.0 (d, J_{CP} 6.3), 53.7 (d, J_{CP} 132.1), 70.7, 114.7 (d, J_{CP} 21.4), 128.1, 129.8 (d, J_{CP} 9.4), 130.4, 131.9, 161.8 (d, J_{CF} 246.4); δ_P: 27.5 (d, J_{PF} 3.9); δ_F: –115.6.

*Diethyl (3-oxocyclohexyl)(4-fluorophenyl)methylphosphonate **4d***

(Aqueous work-up step after warming to –10°C). Isolated by column chromatography as a mixture of two stereoisomers (36%): MS, *m/z*: 342 (M^+, 2%), 246 (100), 204 (16), 109 (43), 81 (5), 29 (8); IR: ν_{PO} 1220, ν_{CO} 1707. Anal. calcd. for $C_{17}H_{24}FO_4P$: C 59.65, H 7.02; found: C 59.20, H 7.35. δ_H: 1.34–1.47 (1H, m), 1.86–1.92 (2H, m), 2.01–2.09 (1H, m), 2.22 (1H, m), 2.37 (2H, m), 2.56 (1H, m), 2.80 (1H, m), 3.00 (1H, d, J_{HP} 21.4), 6.91 (2H, m), 7.20 (2H, m); proton-decoupled δ_C: 24.6, 28.8 (d, J_{CP} 9.4), 39.6, 40.8, 47.1 (d, J_{CP} 8.2), 49.2 (d, J_{CP} 138.9), 115.3 (d, J_{CP} 19.0), 130.3, 131.2 (dd, J_{CP} 6.6, J_{CF} 6.7), 161.9 (dd, J_{CP} 20.5, J_{CF} 247.8), 210.3; δ_P: 27.1 (d, J_{PF} 3.3), 27.2 (d, J_{PF} 4.4); δ_F: –115.3 (major), –116.4 (minor).

*Diethyl (1-hydroxy-2-methylcyclohex-2-enyl)(phenyl)methylphosphonate **3e***

(Aqueous work-up after warming to –40°C and stirring at that temperature for 2 h.) Isolated from the reaction mixture and separated to two stereoisomers by column chromatography (hexane/AcOEt, 3:2, v/v). Major isomer (18%), δ_H: 1.59–1.71 (5H, m), 1.82–1.92 (2H, m), 2.12–2.22 (2H, m), 3.59 (1H, d, J_{HP} 25.0), 5.45 (1H, m), 7.23 (3H, m), 7.38 (2H, m); proton-decoupled δ_C: 17.9, 18.4, 24.7, 35.1 (d, J_{CP} 5.1), 52.9 (d, J_{CP} 130.6), 73.6, 126.8, 127.4, 127.5, 130.5 (d, J_{CP} 6.0), 133.6, 135.3; δ_P: 28.7; MS, *m/z*: 320 ($M^+ - H_2O$, 10%), 228 (100), 172 (66), 91 (77), 79 (8), 29 (13). Anal. calcd. for $C_{18}H_{27}O_4P$: C 63.90, H 7.99; found: C 63.55, H 8.01. Minor isomer (8%), δ_H: 1.26 (3H, s), 1.70 (3H, m), 2.01 (2H, m), 2.48 (1H, m), 3.49 (1H, d, J_{HP} 22.6), 5.41 (1H, m), 7.27 (3H, m), 7.46 (2H, m); proton-decoupled δ_C: 18.5, 18.9, 24.4, 36.3, 51.8 (d, J_{CP} 131.5), 73.6, 125.4, 127.0, 127.7, 131.2 (d, J_{CP} 8.1), 133.7, 137.8; δ_P: 27.2; MS, *m/z*: 320 ($M^+ - H_2O$, 8%), 228 (100), 172 (54), 91 (68), 79 (5), 29 (11). Anal. found: C 63.60, H 7.58.

*Diethyl (2-methyl-3-oxocyclohexyl)(phenyl)methylphosphonate **4e***

Formed together with **3e** and isolated from the reaction mixture by column chromatography (hexane/AcOEt, 3:2, v/v) as the last fraction, following the unreacted **1a** and both stereoisomers of **3e** (13%), δ_H: 1.11 (3H, d, J_{HH} 6.5), 1.46–1.55 (2H, m), 1.94–2.55 (6H, m), 3.32 (1H, d, J_{HP} 26.3), 7.28 (3H, m), 7.42 (2H, m); proton-decoupled δ_C: 11.9, 24.8, 27.2 (d, J_{CP} 2.2), 41.0, 44.9 (d, J_{CP} 139.5), 45.2, 47.0 (d, J_{CP} 14.6), 127.0, 127.9, 130.9, 132.2; δ_P: 28.6; MS, *m/z*: 338 (M^+, 3%), 228 (100), 200 (73), 172 (63), 91 (78), 79 (6), 29 (14). Anal. found: C 63.75, H 8.00.

*Diethyl (3-oxocyclohexyl)(1-naphthyl)methylphosphonate **4f***

(Aqueous work-up carried out after warming the reaction mixture to room temperature and stirring for 16 h.) Purified by bulb-to-bulb distillation, oven temp. 250°C (0.5 mm); oil, mixture of two stereoisomers (55%), δ_H: 1.29 (1H, m), 1.50 (1H, m), 1.87 (2H, m), 2.11–2.32 (3H, m), 2.68 (1H, m), 2.87 (1H, m), 3.91 (1H, dd, J_{HH} 8.2, J_{HP} 23.6), 7.49 (3H, m), 7.82 (3H, m), 8.00 (1H, d, J_{HH} 8.1); proton-decoupled δ_C: 24.6, 29.2 (d, J_{CP} 10.8), 40.9, 41.1, 43.1 (d, J_{CP} 138.3), 49.6 (d, J_{CP} 6.4), 122.7, 125.2, 125.6, 126.5, 127.0 (d, J_{CP} 6.2), 127.9 (d, J_{CP} 2.2), 129.1, 131.2 (d, J_{CP} 4.6), 132.6 (d, J_{CP} 8.5), 133.9, 210.4; δ_P: 27.56 (major),[8] 27.64 (minor); IR: ν_{PO} 1221, ν_{CO} 1707; MS, *m/z*: 374 (M^+, 16%), 278 (100), 141 (77), 81 (7), 29 (8). Anal. calcd. for $C_{21}H_{27}O_4P$: C 67.38, H 7.22; found: C 67.12, H 7.15.

Reversibility of addition

A sample of pure alcohol **3a**–**d** or ketone **4d** (typically 1–2 mmol) was dissolved in THF (1 mL per mmol of substrate), the solution was cooled to –78°C and *n*-butyllithium (1.6 M solution in hexane, 1.2 mol equiv.) was added. The

[8] According to the integrated ^{31}P NMR spectrum of **4f**, it consisted of ca. 1.5:1 mixture of diastereomers. In the ^1H and ^{13}C NMR spectra the signals of the major stereoisomer were accompanied by less intense signals derived from the minor isomer. Only the signals derived from the major isomer are given for the ^1H and ^{13}C NMR spectra.

© 1998 NRC Canada

solution was allowed to warm to room temperature, kept for 24 h, and subjected to the usual aqueous work-up. The product obtained after the evaporation of ether was examined by NMR (^{1}H and ^{13}C) spectroscopy and thin layer chromatography using authentic samples of **2a** and the corresponding phosphonate **1** as standards. Only the starting materials for the addition reactions (**1a–d**, together with **2a**), were observed.

Molecular modeling

The calculations were performed with the default values of the TRIPOS (24) (SYBYL program version 6.2 released by TRIPOS Inc.). The electrostatic point charges of the atoms were calculated with the Gasteiger–Hückel method. All minimisations were carried out using the Powell method (25) up to a gradient of 0.05 kcal mol^{-1} Å^{-1}. The default setup for simulated annealing, which applied a constant temperature algorythm based on the method of Berendsen et al. (26) and the rate for decreasing the temperature of 0.5 K fs^{-1}, was used. The thermal bath coupling constant and the integration time step were 5.0 fs and 0.5 fs, respectively. The model of **4f** was built to resemble the conformation found in the crystal structure and then minimized. The minimized structure was subjected to 50 cycles of simulated annealing using distance dependant relative permitivity and a cut-off radius of 9 Å for nonbonded interactions in vacuo. Each cycle that consisted of 12 000 fs was sampled every 50 fs.

Crystal structure determination

The major steroisomer of **4f** was isolated by dissolving the diastereomeric mixture in anhydrous ether and allowing slow evaporation of the solution.. The major stereoisomer (δ_P 27.56) separated as colourless crystals, mp 142.5°C. Crystals suitable for X-ray diffractions were obtained by dissolving the compound in a minimum volume of dichloromethane and placing the solution in a larger, closed container with anhydrous ether. Diffusion of the ether vapours to the dichloromethane solution resulted in slow formation of crystals. X-ray diffraction data were measured on an Enraf Nonius CAD4 diffractometer with MoK_α radiation (graphite monochromator, λ = 0.7107 Å) and were collected at room temperature. Accurate unit cell parameters were obtained by least-squares methods from the position of 25 carefully selected centred reflections. During data collection three reference reflections were measured periodically to check crystal stability. There was no significant crystal decay, and intensities were corrected for absorption, as well as for Lorentz and polarization effects. Crystal data and structural refinement parameters are given in Table 1.

Synthesis and comparative study of three monomeric boronates by spectroscopic methods and X-ray crystallography[1]

Herbert Höpfl, Mario Sánchez, Norberto Farfán, and Victor Barba

Abstract: Three boronates have been synthesized by reaction of tridentate azomethine ligands derived from salicylaldehyde with phenylboronic acid. The [5.4.0], [4.4.0], and [4.3.0]heterobicyclic structures obtained have been characterized by NMR spectroscopy and X-ray crystallography, whereby it could be proved that the [4.4.0]heterobicycle is the most stable one. Unexpectedly the salicylideneaminoethanol derivative does not lead to a macrocyclic structure, although molecular modeling reveals high ring strain for the monomeric product that is actually obtained.

Key words: boronates, boron complexes, tridentate azomethine ligands, phenylboronic acid, X-ray crystallography.

Résumé : On a synthétisé trois boronates par réaction de l'acide phénylboronique avec des ligands azométhines tridentates dérivés du salicylaldéhyde. On a caractérisé les structures hétérobicycliques [5.4.0], [4.4.0], et [4.3.0] par spectroscopie RMN et par diffraction des rayons X; on a ainsi pu prouver que l'hétérobicycle [4.4.0] est le plus stable. D'une manière inattendue, le dérivé salicylidèneaminoéthanol ne conduit pas à une structure macrocyclique, même si la modélisation moléculaire indique l'existence d'une forte tension de cycle pour le produit monomère qui est en fait obtenu.

Mots clés : boronates, complexes du bore, ligands azométhines tridentates, acide phénylboronique, diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

During our studies of boron complexes with a coordinative N→B bond (1–10), we recently discovered the synthesis of two new macrocyclic structures that consist of a dimeric and a tetrameric boronate ring system of 20 and 10 members, respectively (**1** and **2a** in Fig. 1) (11). Both molecules are stable in the air and are obtained in high yields in one-step syntheses between the corresponding tridentate ligands and phenylboronic acid. The molecular structures of both macrocycles have been studied in detail by X-ray crystallography (11), and it could be shown that monomeric systems would be more strained due to the tetrahedral geometry at the boron atom and its small atomic radius. A detailed study of how different substituents in salicylideneaminoethanol influence the formation of monomeric or dimeric boronates with phenylboronic acid was also reported (12). Thereby, it was shown that the dimeric structure type **2** is preferred over the [4.3.0]heterobicyclic type **3** in the absence of steric effects that preclude formation of the macrocycle (Fig. 1). This is the case in compounds **3a** and **3b**, where two methyl groups on the carbon atom adjacent to the nitrogen inhibit the dimer formation (compare also to **2d**).

In search of new tridentate ligands that could be probable promoters of macrocycle formation with phenylboronic acid it was considered promising to fix the carbon–carbon bond of the 2-ethanolamine group in the ligand by a double bond using 2-aminophenol.

Experimental

Instrumentation

The NMR studies were performed with the following spectrometers: Jeol GSX 270 and Eclipse +400. Special techniques (COSY, HETCOR) were applied when necessary to assign the spectra adequately. Standards were TMS (^{1}H, ^{13}C) and $BF_3 \cdot OEt_2$ (^{11}B). Chemical shifts are stated in ppm; they are positive, when the signal is shifted to higher frequencies than the standard. The IR spectra have been recorded with a Perkin Elmer 16F-PC FT-IR spectrophotometer. Mass spectra were obtained with an HP 5989 A equipment. Melting points were determined with a Gallenkamp MFB-595 apparatus and have not been corrected.

	R^1	R^2
3a	H	Me
3b	Me	Me

X-ray diffraction studies of monocrystals were determined on an Enraf–Nonius CAD4 diffractometer ($\lambda_{MoK\alpha}$ = 0.71069 Å, monochromator: graphite, T = 293 K for **5a** and **5c**, T = 193 K for **5b**, ω–2θ scan). Crystals were mounted in LINDEMAN tubes. Cell parameters were determined by least-squares refinement on diffractometer angles for 24 automatically centered reflections in the θ range of 10–11°. Crystals of compound **5a** diffracted only weakly so that reflections were only collected up to θ = 24°. Absorption correction was not necessary, corrections were made for Lorentz and polarization effects. Solution and refinement: direct methods (SHELXS-86) for structure solution and the CRYSTALS (version 9, 1994) software package for refinement and data output. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were determined by difference Fourier maps, and their positions as well as one overall isotropic thermal parameter were refined; $I > 3\sigma(I)$; ($R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2}$. In all cases only independent reflections on the basis of Friedel's law have been collected and a reflection–parameter ratio >5 has been considered sufficient for the type of structural studies performed here.

Reagents

All starting materials were commercial. Solvents were used without further purification, but monocrystals were grown from spectrophotometric grade solvents.

General procedure for the preparation of ligands 4a–4c

To prepare the tridentate ligands **4a–4c**, equimolar quantities of the corresponding aminophenol or aminoalcohol and salicylaldehyde were refluxed in benzene for 30 min. The solvent and the water formed during the reaction were then removed by a Dean Stark trap to yield an oil or a solid that was washed with chloroform and used without further purification. The preparation and spectroscopic data of **4a** have already been published (13–17).

2-[[(2-Hydroxyphenyl)imino]methyl]phenol (4a)

Compound **4a** was prepared from 0.90 g (8.19 mmol) of 2-aminophenol and 1.00 g (8.19 mmol) of salicylaldehyde. The product obtained is a yellow solid (1.63 g, 7.65 mmol); mp 189–191°C; yield 93%.

2-[[(2-Hydroxyphenyl)methylene]imino]benzenemethanol (4b)

Compound **4b** was prepared from 1.00 g (8.13 mmol) of 2-aminobenzyl alcohol and 1.00 g (8.19 mmol) of salicylaldehyde. The product obtained is an orange solid (1.63 g, 7.65 mmol); mp 138–140°C; yield 76%. ^{1}H NMR (270 MHz, $CDCl_3$), δ (ppm): 4.82 (2H, AB, OCH_2), 6.91–7.51 (8H, m, aromat.), 8.57 (1H, s, H-7); ^{13}C NMR (67.8 MHz, $CDCl_3$), δ (ppm): 61.8 (OCH_2), 117.3, 118.0, 119.2 (C-3, C-5, C-6′), 118.1 (C-1), 127.1, 128.3, 128.8 (C-3′, C-4′, C-5′), 132.4, 133.4 (C-4, C-6), 134.5 (C-2′), 146.6 (C-1′), 161.0 (C-2), 163.1 (C-7). Infrared (KBr): 3260 (br, m), 2912 (m), 2862 (m), 1618 (s), 1594 (w), 1576 (m), 1570 (m), 1560 (m), 1505 (w), 1498 (w), 1432 (m), 1456 (m), 1368 (w), 1280 (m), 1230 (w), 1202 (m), 1178 (m), 1162 (w), 1150 (w), 1114 (w), 1106 (w), 1032 (s) cm^{-1}.

2-[[(2-Hydroxyphenyl)methylene]amino]benzeneethanol (4c)

Compound **4c** was prepared from 0.90 g (7.32 mmol) of 2-aminophenethyl alcohol and 0.90 g (7.32 mmol) of salicylaldehyde. The product obtained is an orange oil (1.64 g, 6.81 mmol); yield 93%. ^{1}H NMR (270 MHz, $CDCl_3$), δ (ppm): 2.95 (2H, t, J = 7 Hz, OCH_2CH_2), 3.73 (2H, t, J = 7 Hz, OCH_2), 6.83–7.30 (8H, m, aromat.), 8.42 (1H, s, H-7); ^{13}C NMR (67.8 MHz, $CDCl_3$), δ (ppm): 35.3 (OCH_2CH_2), 62.3 (OCH_2), 117.0, 117.9, 118.9 (C-3, C-5, C-6′), 119.1 (C-1), 126.8, 127.5, 130.6 (C-3′, C-4′, C-5′), 132.6 (C-2′), 132.1, 133.0 (C-4, C-6), 147.0 (C-1′), 160.9 (C-2), 162.5 (C-7). Infrared (NaCl): 3396 (br, s), 3060 (w), 3024 (w), 2932 (w), 2878 (w), 1616 (s), 1594 (m), 1570 (m), 1498 (w), 1482 (m), 1456 (w), 1404 (w), 1364 (w), 1278 (m), 1200 (w), 1178 (m), 1150 (m), 1106 (w), 1046 (w), 910 (m) cm^{-1}. EI mass spectrum (70 eV), m/z: 241 (100%, M), 222 (47%), 210 (39%), 130 (26%), 117 (35%), 91 (43%), 77 (26%), 65 (44%), 31 (25%).

General method for the preparation of compounds 5a–5c

An equimolar amount of phenylboronic acid was added to a solution of the tridentate ligand in benzene (usually about 10 mL for 2–3 mmol). The mixture was refluxed for 30 min and quantified by water and solvent separation with a Dean

Stark trap. The solid obtained was collected by filtration under vacuum and washed with small amounts of benzene and hexane.

*2-Phenyldibenzo[*d,h*]-6-aza-1,3,2-dioxaboracyclonon-6-ene (**5a**)*

Compound **5a** was prepared from 0.50 g (2.34 mmol) of **4a** and 0.28 g (2.34 mmol) of phenylboronic acid. The product obtained is a yellow solid (0.61 g, 2.04 mmol) that is slightly soluble in chloroform, dichloromethane, methanol, and DMSO. Crystals suitable for X-ray diffraction were obtained, when the reaction was performed in dichloromethane at room temperature without stirring; mp 229–231°C; yield 87%. ^{1}H NMR (270 MHz, $CDCl_3$), δ (ppm): 6.90, (1H, t, J = 8 Hz, H-4′), 6.94 (1H, t, J = 8 Hz, H-5), 7.10 (1H, d, J = 8 Hz, H-6′), 7.12 (1H, t, J = 8 Hz, *p*-BC_6H_5), 7.15 (2H, m, *m*-BC_6H_5), 7.21 (1H, d, J = 8 Hz, H-3), 7.31 (2H, d, J = 7 Hz, *o*-BC_6H_5), 7.38 (3H, m, H-6, H-3′, H-5′), 7.54 (1H, t, J = 7 Hz, H-4), 8.32 (1H, s, H-7); ^{13}C NMR (67.8 MHz, $CDCl_3$), δ (ppm): 115.0 (C-3′), 115.2 (C-6′), 119.3 (C-1, C-4′), 120.3 (C-3, C-5), 127.4 (*m*-BC_6H_5), 127.8 (*p*-BC_6H_5), 131.2 (C-1′, *o*-BC_6H_5), 131.3, 132.5 (C-6, C-5′), 137.9 (C-4), 148.7 (C-7), 157.5, 158.7 (C-2, C-2′); ^{11}B NMR (86.6 MHz, $CDCl_3$), δ (ppm): 8 ($h_{1/2}$ = 120 Hz). Infrared (KBr): 3066 (w), 3040 (w), 2930 (w), 1628 (s), 1608 (m), 1576 (w), 1570 (w), 1558 (m), 1550 (m), 1540 (m), 1534 (m), 1522 (w), 1506 (w), 1472 (m), 1466 (s), 1458 (m), 1452 (w), 1436 (w), 1430 (w), 1380 (m), 1326 (m), 1314 (m), 1284 (m), 1256 (w), 1240 (w), 1226 (m), 1190 (s), 1182 (s), 1154 (s), 1122 (m), 1044 (w), 1032 (w), 1012 (s), 954 (s) cm^{-1}. EI mass spectrum (70 eV, DIP), *m*/*z*: 299 (14%, M), 222 (100%, M – C_6H_5), 193 (2%), 151 (1%), 102 (2%), 77 (26%, $C_6H_5^+$), 51 (15%), 39 (3%). Results and discussion

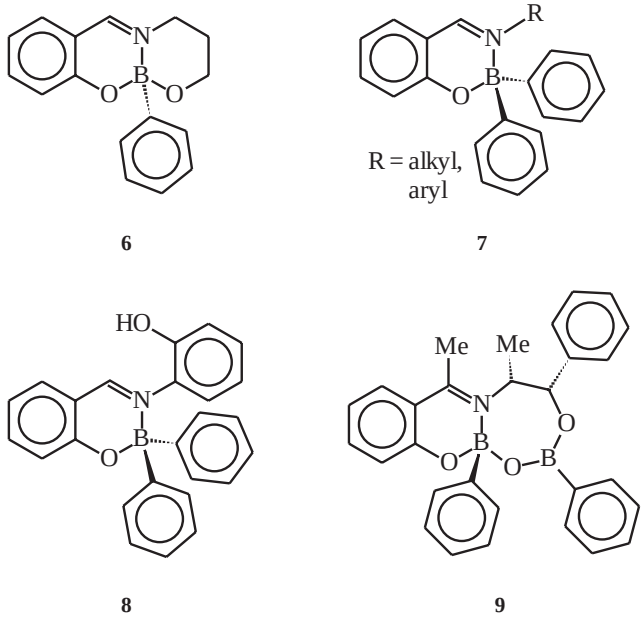
Although a high ring strain can be predicted from molecular modeling for the monomeric structure, the reaction between ligand **4a** and phenylboronic acid leads to compound **5a** (Scheme 1). For comparison compounds **5b** and **5c** have been synthesized, too. The formula of the three heterobicyclic compounds are proved by mass spectrometry. In all molecules the molecular ion is detected. Due to the easy loss of a phenyl radical the base peak corresponds to the $[M - C_6H_5]^+$ ion (18–21), where the boron atom is bound to two oxygens and a nitrogen atom.

The C=N stretching band in the IR spectra is shifted to higher wave numbers after the complex formation in the case of **5b** (1618 cm^{-1} for **4b** and 1624 cm^{-1} for **5b**) and **5c** (1616 cm^{-1} for **4c** and 1622 cm^{-1} for **5c**), as it has been observed already for other boron chelates (22–23), while it is shifted to lower wave numbers in the case of **5a** (1636 cm^{-1} for **4a** and 1628 cm^{-1} for **5a**).

The ^{1}H, ^{13}C, and ^{11}B NMR data of the monomeric boronates **5a–5c** and their corresponding ligands **4a–4c** are listed in Tables 1 and 2. A comparison of the ^{1}H NMR spectra shows that the azomethine hydrogen atom H-7 is shifted to higher field for **5a** and **5c** with N→B coordination (Δδ = 0.65 and 0.26 ppm), while it is not significantly displaced in **5b** (Δδ = 0.02 ppm). The resonances of the OCH_2 groups in **5b** and **5c** are detected downfield as diastereotopic signals (Δδ = 0.10 ppm and 0.34 ppm). The OCH_2CH_2 methylene hydrogens in the seven-membered heterocycle of compound **5c** are also diastereotopic (Δδ = 0.30 ppm), indicating a fixed configuration of the complex in solution.

Fig. 2. Structures of compounds **6**–**9**.



6 **7** **8** **9**

From the ^{13}C NMR spectra the most interesting observation is the extreme high field shift of the azomethine carbon atom in compound **5a** after the chelate formation (δ = 161.6 ppm ↔ δ = 148.7 ppm). The correct assignment has

[a]Temperature 293 K for **5a** and **5c**, 193 K for **5b**, Enraf Nonius CAD4 diffractometer, MoK_α (λ = 0.71069) radiation, graphite monochromator, $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2}$, where $w = 1/\sigma^2$. Values given for *R*, R_w, and gof are based on those reflections with $I > 3\sigma(I)$.

been evidenced by a HETCOR experiment. This difference diminishes in compound **5b** (δ = 163.1 ppm ↔ δ = 156.7 ppm) and changes its sign in **5c** (δ = 162.5 ppm ↔ δ = 164.9 ppm). In the similar six-membered diphenylboron chelate **6** (Fig. 2) only a small high field shift could be detected (17). The downfield shift of 5–6 ppm for the C-4 carbon atom is characteristic for the formation of a boron complex and has been already reported for other boronates with a similar structure (12). It seems therefore to be a typical indicator for the N→B bond coordination in salicylideneamino chelates. The OCH_2 carbon atom in the boronates is found at lower field for **5b** (Δδ = 2.1 ppm) and at higher field for **5c** (Δδ = 2.7 ppm).

The ^{11}B NMR spectra of the boron complexes **5a–5c** specify tetracoordinated boron atoms (24). The chemical shifts indicate the weakest coordination for the [4.3.0]heterobicycle **5a** (δ = 8 ppm) and the strongest coordination for the [4.4.0]heterobicycle **5b** (δ = 5 ppm), although the difference is not very striking. The ^{11}B NMR signal for the [5.4.0]heterobicycle **5c** is detected at δ = 6 ppm.

The ^{13}C NMR spectroscopic data indicate effects in the structures of **5a–5c**, that vary the chemical shifts of the azomethine group so distinctly. To obtain more structural information an X-ray crystallographic study of the three boronates **5a–5c** was undertaken (Tables 3–6). Crystal data, atomic coordinates, anisotropic thermal parameters, bond angles and distances, and torsion angles have been deposited.[3] The molecular structures of **5a–5c** are shown in Figs. 3–5.

Table 3 shows that the asymmetric unit of **5a** contains two independent molecules.[4] The structures are not significantly different with respect to bond lengths and bond angles, but

[3] Supplementary material may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2. With the exception of anisotropic thermal parameters and torsion angles, these have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[4] The independency has been confirmed on basis of the correlation coefficients, which do not indicate a systematic correlation between the two molecules.

[a]The mean plane is calculated for C(5) to C(10) and additionally for C(55) to C(60) in the case of **5a**.
[b]Equations of the planes: $-3.99642X - 16.62096Y + 2.31592Z = -3.807$; $-8.19089X - 0.86122Y + 10.97109Z = -7.409$.
[c]Equation of the plane: $-6.53926X + 6.24804Y - 5.74052Z = -1.148$.
[d]Equation of the plane: $-5.60300X + 6.35883Y - 6.37166Z = -2.668$.
X, Y, Z are orthogonal coordinates w.r.t. axes a, b, c^*; Δ is the deviation from the mean plane.

vary in the deviation of the boron atom from the boronate mean plane (Table 5) and the orientation of the B-phenyl ring. This differences are probably due to crystal packing effects.

The N→B bond lengths are 1.613 (5) Å for **5a**, 1.615 (7) Å for **5b**, and 1.635 (4) Å for **5c** (Table 4), somewhat longer than for the monomeric structures **3b** and **7** (Figs. 1 and 2), where a value of 1.601 Å has been determined for both molecules (12).

Fig. 4. Molecular structure of compound **5b**. The thermal ellipsoid probability level is 25%.

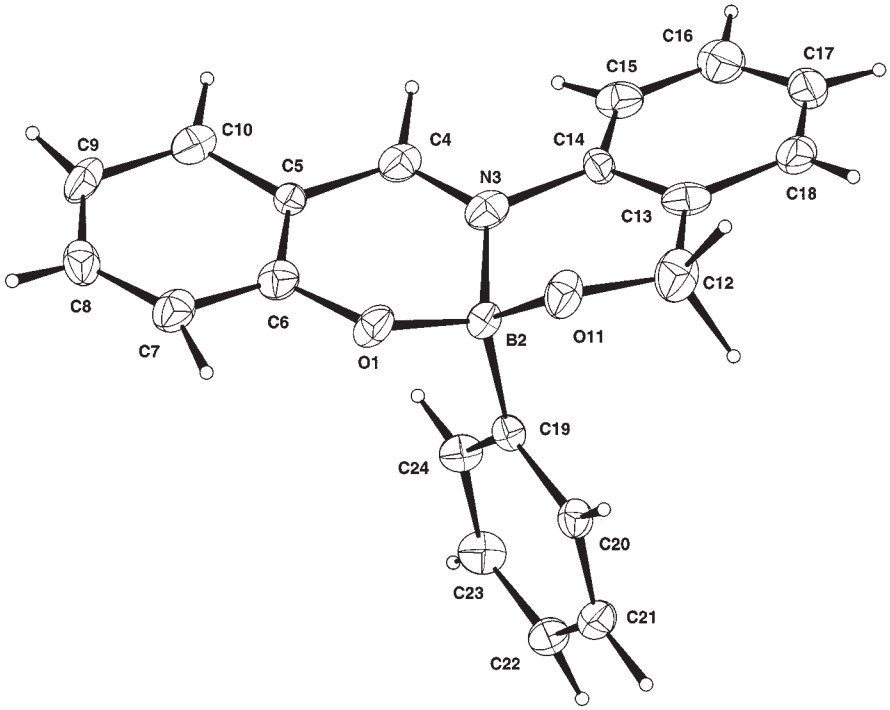

Fig. 5. Molecular structure of compound **5c**. The thermal ellipsoid probability level is 25%.

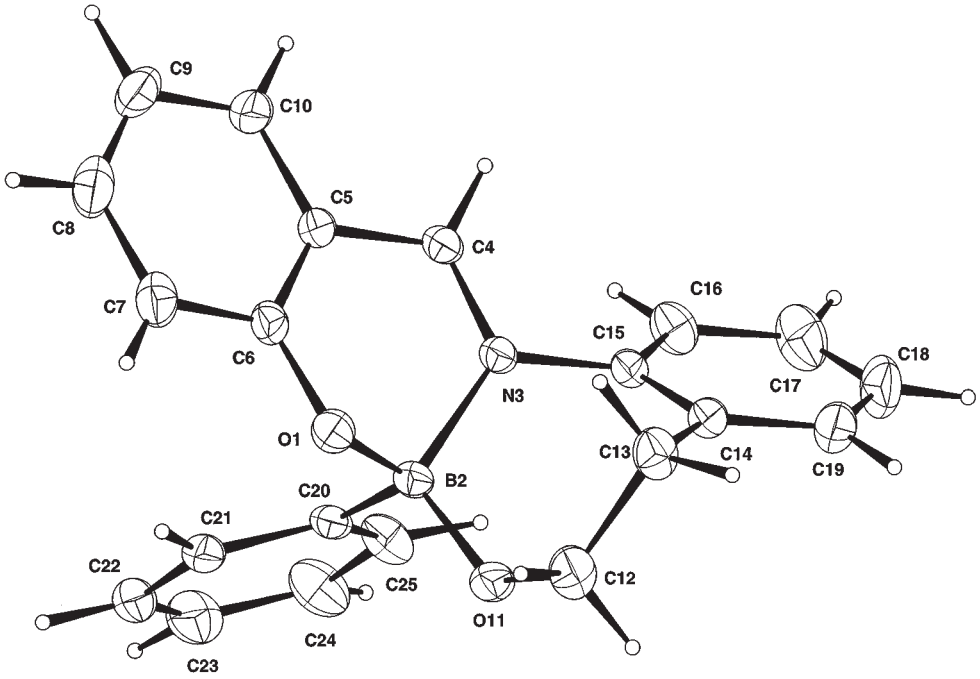

One of the interests of the crystallographic study was to investigate which one of the three heterobicycles is the most stable one. From molecular modeling it is expected that it is the [4.4.0]heterobicycle **5b**, but the N→B bond length seems to favor also the [4.3.0]heterobicycle **5a**. However, the deviation of the boron atom from the boronate mean plane (Table 5) is lowest for compound **5b** (Δ = 0.284 Å), while for **5a** and **5c** values of Δ = 0.520 and 0.585 Å are calculated. Additional evidence for the proposed relative stabilities of **5a–5c** is provided by the sum of bond lengths at the boron atom. This sum tends to be constant for a given set of bonded atoms (O_2NC) for **5a–5c**, and it has been shown that

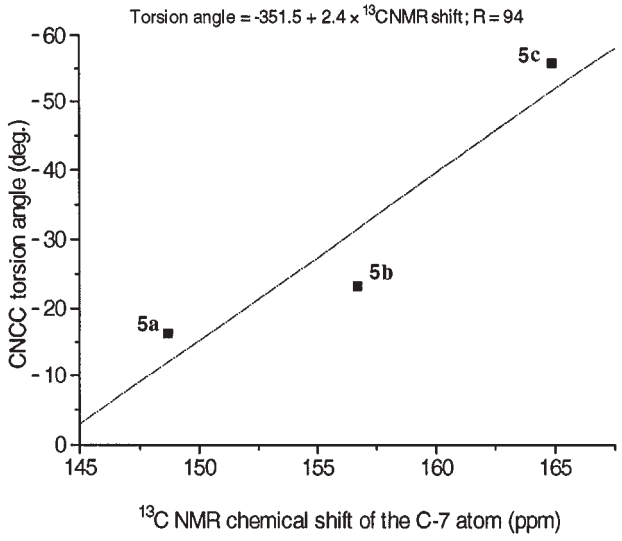
Fig. 6. Correlation between the ^{13}C NMR chemical shift of the azomethine carbon atom and the CNCC torsion angle for compounds **5a**–**5c**.

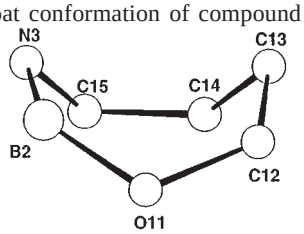


the strain at the boron center is related to the magnitude of this sum (25). The sums are 6.182, 6.124, and 6.140 Å for **5a–5c**, respectively.

The mean value of bond angles in the heterocycles (Table 6) can be added as further proof that the stability of the bicyclic boronates decreases in the following order: [4.4.0] >> [5.4.0], [4.3.0].

For **5b** mean values of 119.0(5) and 115.5(5)° for the six- and five-membered rings are calculated, while the corresponding values for **5a** are 117.0(3) and 107.2(3)° and for **5c** are 116.5(3) and 117.1(1)°. The ring strains of the three compounds are perhaps best expressed by the torsion angles summarized in Table 6. The ideal values for the O(11)-B(2)-N(3)-C(13, 14, 15) and C_{Ph}-B(2)-N(3)-C(13, 14, 15) dihedral angles are 60°, and it can be seen that both compounds **5a** and **5c** are far away from it. A zero degree value of the C(4)-N(3)-C(13)-C(14) torsion angle would correspond to a perfect π-delocalization between the two aromatic rings that are connected by the imino group. This dihedral angle is increasing from compound **5a** to **5c** (16.2 → 23.2 → 55.7°), so that the π-delocalization is strongest in **5a**, while it is practically lost in **5c** in favor of one gauche interaction less. This observation may be the explanation for the unusual high

Fig. 7. Twisted boat conformation of compound **5c**.



field shift of the azomethine signals in the ^{13}C NMR spectra of **5a** and **5b** and as can be seen from Fig. 6 there exists a correlation between the ^{13}C NMR shifts of C-7 and the corresponding torsion angles. It should be noted that the phenolic B(2)—O(11) bond in compound **5a** is significantly longer than the alkanolic B(2)—O(11) bond in compounds **5b** and **5c** (1.503 (5), 1.435 (6), and 1.416 (3) Å, respectively).

The N(3)—C(4) bond length is significantly shorter in **5a** and **5b** when compared to **5c** (1.249 (4), 1.235 (6), and 1.292 (3) Å, respectively). A longer bond length (1.297 (5) Å) has been reported also for the molecular structure of the diphenylboron chelate **8** (Fig. 2), where the phenol group is also twisted out of the mean plane (16).

The seven-membered heterocycle in the boronate **5c** presents a twisted boat conformation (26) with N(3) and C(13) above the plane (Fig. 7). In comparison to the [5.4.0]heterobicycle **9** (Fig. 2) with a planar B–O–B moiety the geometry is rather different (12). Nonetheless, the average values of the bond angles in the seven-membered ring are practically identical (117.1 (3) and 117.3 (3)° for **5c** and **9**, respectively). The same is true for the N→B bond lengths (1.635 (4) and 1.629 (5) Å for **5c** and **9**, respectively). But, the deviation of the boron atom from the boronate mean plane is lower in **5c** (0.585 for **5c** ↔ 0.714 Å for **9**). The resonances in the ^{11}B NMR spectra are identical for both compounds (δ = 6 ppm).

Conclusions

From the present study it can be concluded that the tridentate azomethine ligand **4a** does not lead to the formation of a macrocyclic structure, although the monomeric species **5a** is highly strained. There exist various possible explanations for this observation. From molecular modeling it can be seen that one may be the loss of coplanarity between the two aromatic systems and the imino group upon

© 1998 NRC Canada

dimer formation, and another explanation may be the introduction of additional strain in a dimeric structure due to the planarity of the 2-aminophenoxy group. It has also to be considered that **4a** is a planar ligand that favors the formation of a monomeric structure.

The comparative study of **5a–5c** has shown that in the present case the boronates with a [4.4.0] heterobicyclic structure are less strained than the corresponding [4.3.0] and [5.4.0] heterobicycles. The conjugation between the two aromatic rings and the imino group is lost, when the number of members in the second heterocyclic ring is increased. The loss of conjugation can be detected by the ^{13}C NMR chemical shifts of the carbon atoms that are in correlation with the corresponding CNCC torsion angles.

Surface studies of nano-dimensional particle size iron–manganese spinel mixed oxides

Ellie L. Uzunova, Dimitar G. Klissurski, and Stella D. Nemska

Abstract: Monophase binary iron–manganese spinel oxides of high dispersity are prepared by thermal decomposition of carbonate precursors in the limits $0.33 \leq Fe/Mn \leq 2$, at temperatures 570–770 K. Interparticle *meso*- and macropores contribute to the surface morphology of the spinel oxides, composed from spherical-shaped particles with diameters in the range 7–12 nm. The cation distribution of manganese ferrite corresponds to $Mn_{0.85}Fe_{0.15}[Mn_{0.14}Fe_{1.86}]O_{4+\delta}$. Surface analysis by ESCA reveals high concentration of nonstoichiometric oxygen and presence of Mn(III) and Mn(IV) is indicated in the X-ray photoelectron spectra. Reduction with hydrogen proceeds in two steps and is shifted to higher temperatures with increasing the iron content.

Key words: ferrite, spinel, Fe, Mn.

Résumé : Les oxydes binaires monophases de Fe et Mn de type spinel avec une dispersion très haute sont preparés par une décomposition thermique des carbonates comme précurseurs dans les limites des rapports $0.33 \leq Fe/Mn \leq 2$ à température 570–770 K. La morphologie des oxydes est formeé, par des particules sphériques au diamètre 7–12 nm et des *meso*- et macro-pores interparticulaires. La distribution des cations correspond à la formule $Mn_{0.85}Fe_{0.15}[Mn_{0.14}Fe_{1.86}]O_{4+\delta}$. Une haute concentration d'oxygène non-stoichiométrique à la surface a été etablie par ESCA. Les spectres XPS indiquent aussi une présence de Mn(III) et Mn(IV). La réduction par l'hydrogène est effectuée en deux étapes et exige une plus haute température avec l'augmentation du contenu du fer.

Mots clés : ferrite, spinel, Fe, Mn.

Introduction

Spinel oxides, containing manganese and iron, are interesting as magnetic materials and are also acknowledged for their catalytic properties. Binary spinel oxides, containing transition metal cations in higher oxidation state, are very active combustion catalysts for CO and hydrocarbons (1–3). Catalysts in the Fischer–Tropsch synthesis are developed on the basis of different iron–manganese oxide compositions (4). For all these applications, low particle dimensions of the oxide phase is essential, and it is usually achieved by the "soft chemistry" synthesis methods in the low-temperature range of thermal decomposition and the choice of an appropriate precursor compound, containing all metal cations in a single crystalline phase (5–11). The precursor route may direct the synthesis towards particular chemical architecture (11). Nitrate salt decomposition favours higher oxidation states of the metal cations in the final product, due to the oxidative media, created during the thermolysis (5). Oxalates form mixed crystals with a number of transition metal cations and are often employed as precursors, but their thermal decomposition should be performed with care to avoid reduction (6). Transition-metal binary oxides and particularly those, containing manganese, exist in a broad range of structure types, depending on the composition and the oxidation state of the cations. Their reactivity in oxidation reactions is governed by the particular forms of adsorbed oxygen and the surface oxygen concentration. Cation-deficient oxides of high-dispersity and with Lewis-base properties are generally obtained by the thermal decomposition of basic carbonates (8, 9).

The present study reports on the structure and morphology of high-dispersity iron–manganese binary spinel oxides. The relation between surface composition, metal cation oxidation states, and oxidation reactivity is discussed.

Experimental

The iron–manganese spinel oxides were synthesised by thermal decomposition of calcite-like carbonate precursors at temperatures in the range 570–870 K. The carbonates were coprecipitated from a solution of Fe(II) and Mn(II) chlorides, taken in a desired molar ratio and total Me(II) concentration 0.6 mol/dm^3 with a sodium carbonate solution at pH 9. The iron and manganese content was determined by X-ray fluorescence analysis. The XRD analysis was performed on a diffractometer with CuK_α monochromatized radiation. Moessbauer spectra were recorded in constant acceleration mode at room temperature. The source used was a ^{57}Co/(Cr matrix), and the isomer shifts were referred to α-Fe. Full-sorption nitrogen isotherms at 77 K were re-

corded on a Omnisorp 100 equipment in a continuous flow regime. Particle dimensions were determined by transmission electron microscopy. X-ray photoelectron spectra (XPS) were registered on a ESCALAB MkII spectrometer with AlK_α radiation (1486.6 eV). Temperature-programmed reduction with hydrogen (TPR) was performed in a flow system with 5% H_2 in helium at flow rate 40 mL/min and heating rate 20 K/min.

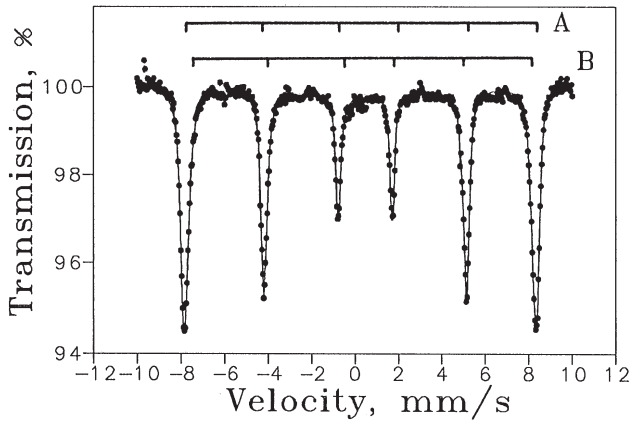
Results and discussion

Structure and cation distribution

The samples with Fe/Mn ratios in the range $0.33 \leq Fe/Mn \leq 2$, decomposed at 670 K are with spinel structure, the first two being tetragonal (Table 1). The slight decrease of unit-cell parameters for samples with higher Fe/Mn ratio is consistent with the hypothesis of Mn(III)–Fe(III) substitution on octahedral sites. Comparison of the effective high-spin octahedral ionic radii (Mn^{3+} = 0.645 Å, Fe^{3+} = 0.645 Å) (12) does not support directly this statement; however, in iron-rich samples the cooperative effect of Jahn–Teller Mn^{3+}–$[O^{2-}]_6$ local distortions is diminished, leading to a regular cubic spinel structure and smaller unit-cell size (8, 9). At temperatures above 770 K, the spinel oxides undergo phase segregation to the individual oxides: manganese oxides (MnO and Mn_2O_3) from the manganese rich spinels and α-Fe_2O_3 from the spinels with Fe/Mn > 2. Manganese ferrite is of relatively higher thermal stability and remains as a single phase spinel up to 870 K. A stable manganese ferrite phase is obtained also at temperatures above 1300 K, while in the temperature range 870–1200 K a mixture of spinel and α-phase exist.

The Moessbauer spectra of samples, synthesised at 670 K contain a central doublet, resulting from small particle superparamagnetism. This effect may be produced also by the presence of tetrahedral site cation vacancies (8).The doublet remains even at sintering temperatures of 870 K, except in the case of manganese ferrite, where a typical sextet is registered (Fig. 1). The spectrum was computer fitted, assuming two components that are due to iron cations on tetrahedral (A) and octahedral (B) positions in the spinel structure (13). The Moessbauer parameters are presented in Table 2. The isomer shifts of the components correspond to iron(III) cations in cubic spinels, with zero quadrupole splittings. The cation distribution, deduced from the ratio of the areas of the two components and based on chemical analysis data can be written as $Mn_{0.85}Fe_{0.15}[Mn_{0.14}Fe_{1.86}]O_{4+\delta}$. This formula composition is consistent with the low affinity of Mn(II) and the preference of Mn(III) for octahedral coordination, evidenced by the value of the crystal field stabilization energy (14). The effective hyperfine magnetic field at Fe^{57} in both tetrahedral and octahedral sites is stronger, compared to the one reported by Sawatsky et al. (13) for high-temperature syntheses. We have observed a similar effect with cobalt ferrite, where the samples, synthesised at low temperature (670 K) possess higher internal magnetic field (15). This result indicates, that the presence of cation vacancies (8, 9) is rather a surface phenomenon and does not interfere with the A–A, B–B and A–B iron cation interactions.

Fig. 1. Moessbauer spectrum of manganese ferrite, synthesized at 870 K.



Morphology and pore distribution study

The full-sorption isotherms of all samples suggest presence of *meso*- and macropores (16). While the major contribution in pore volume for samples MF31 and MF21 comes from pores of radii 100–300 Å, the iron-rich samples contain predominantly smaller pores of radii 20–40 Å (Table 3). For all samples, the pore distribution is rather broad, and there is a significant part of macropores of radii above 250 Å. The particles are of spherical shape, and their effective diameters are within 70–120 Å, measured by TEM. Surface area increases with the Fe/Mn ratio due to both the smaller particle size of the ferrite samples and to the more developed mesopore structure.

Surface analysis

The electron binding energies are summarized in Table 4 and compared to reference measurements, reported for similar oxides. The peak position of Mn $2p_{3/2}$ is shifted towards higher binding energy, and the peak maxima correspond to a value within the range for MnO_2 and Mn_2O_3, rather than MnO (17). The Fe $2p_{3/2}$ and O1*s* peak maxima are in agreement with the values, reported earlier for ferrites (15, 17). Considerable broadening is observed for Mn $2p_{3/2}$ and Fe $2p_{3/2}$, but all peaks are symmetric in shape, Fig. 2.

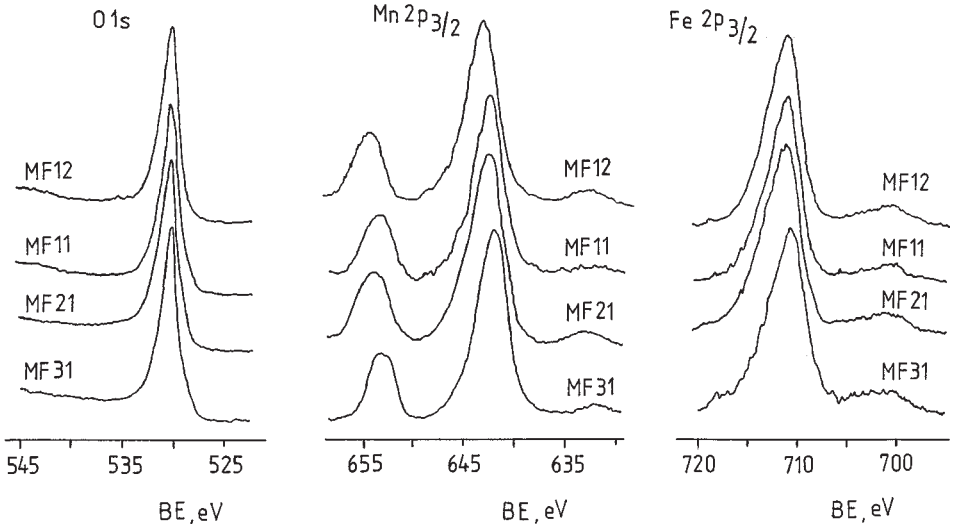
Fig. 2. The Mn $2p_{3/2}$, Fe $2p_{3/2}$, and O1*s* spectra of iron–manganese spinel oxides, synthesized at 670 K.



The oxygen-to-metal cation ratio on the surface slightly increases with the iron bulk concentration, Fig. 3. The non-stoichiometric surface oxygen exceeds the quantity expected for spinel oxides M_3O_4, where both divalent and trivalent cations take place in the structure; sesquioxides M_2O_3, where all cations are in the trivalent state; and even the oxygen content for $M(IV)O_2$. The very high oxygen-to-metal cation ratio on the surface, together with the shift to higher binding energies in the Mn $2p_{3/2}$ spectra can be interpreted by suggesting presence of manganese in a higher oxidation state: Mn(III) and Mn(IV). The surface cation distribution in terms of iron/manganese ratio corresponds to the bulk stoichiometry in the range $0.33 \leq Fe/Mn \leq 1$, Fig. 4. Iron-dominated compositions MF12 and MF13 possess manganese-enriched surface, suggesting that the occurrence of surface cation vacancies is mainly on behalf of the Fe(III) cations.

Temperature-programmed reduction

Two peaks are registered in the TPR spectra of iron–manganese spinel oxides, Fig. 5. The first one does not change significantly with sample composition and corresponds to reduction of nonstoichiometric surface oxygen. The second peak covers a broad temperature range and shifts to higher temperature for the iron-rich samples, $Fe/Mn \geq 1$. The trivalent cations of manganese and iron are less stable and are easily reduced to the divalent oxidation state, followed by the reduction steps Fe(II) → Fe and Mn(II) → Mn. These processes give rise to a single broad peak in the TPR pat-

Fig. 3. Oxygen to metal cation surface ratio as a function of bulk iron/manganese ratio.

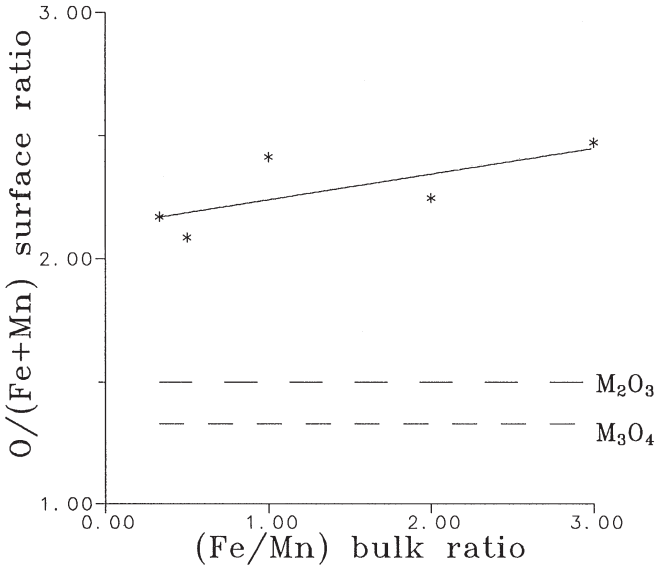

Fig. 4. Surface iron/manganese ratio as a function of the bulk one.

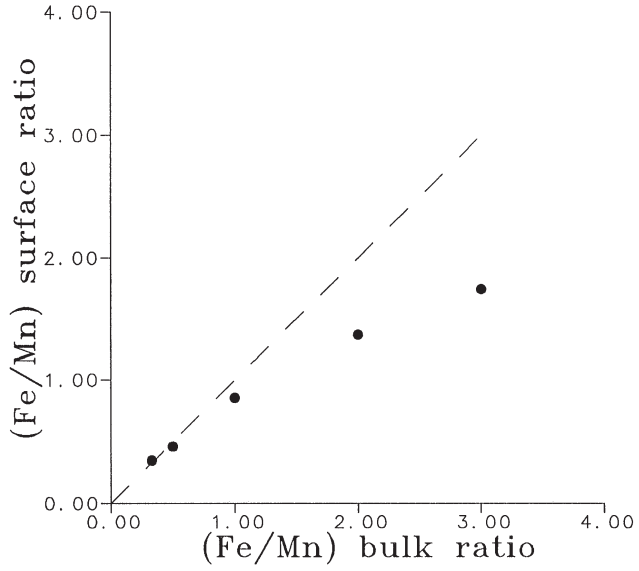

terns, and the individual steps cannot be distinguished. The resistance of manganese ferrite towards reduction is governed by two factors: the higher thermal stability of the ferrite spinel phase and the fact that reduction of divalent manganese is energetically least favoured.

Conclusions

The high-dispersity spinel iron–manganese oxides, synthesized from carbonate precursors, contain a large excess of surface oxygen, related to surface cation deficiency and presence of manganese cations in a higher oxidation state: Mn(III) and Mn(IV). Reduction with hydrogen proceeds in two steps and very high temperature is needed for the complete reduction of iron-rich compositions.

Spectroscopic and differential scanning calorimetric studies of the phase transitions in oxanorbornane

Ralph M. Paroli, Denis F.R. Gilson, and Ian S. Butler

Abstract: Oxanorbornane (7-oxabicyclo[2.2.1]heptane, $C_6H_{10}O$) resembles other bicycloheptane-like molecules by exhibiting order–disorder transitions in the solid state. Differential scanning calorimetric studies show that five different phases may occur, with hysteresis in the transition temperatures. The vibrational spectra have been examined, and a factor group analysis of the vibrational splittings indicates that the crystal structure of the ordered phase has D_{2d} symmetry. Activation energies for molecular motions were derived from proton spin-lattice relaxation time measurements.

Key words: oxanorbornane, order–disorder, phase transitions.

Résumé : L'oxanorbornane (7-oxabicyclo[2.2.1]heptane, $C_6H_{10}O$) ressemble à d'autres molécules de type bicycloheptane qui présentent des transitions ordre–désordre dans l'état solide. Des études de calorimétrie à balayage différenciel montrent qu'il peut se produire cinq phases différentes avec une hystérèse dans les températures de transition. On a étudié les spectres de vibration et une analyse factorielle de groupe des dédoublements des vibrations indique que la structure cristalline de la phase ordonnée possède une symétrie D_{2d}. On a déterminé les énergies d'activation des mouvements moléculaires à partir de mesures de temps de relaxation spin-réseau du proton.

Mots clés : oxanorbornane, ordre–désordre, transitions de phase.

[Traduit par la Rédaction]

Introduction

The bicyclo[2.2.1]heptane series of rigid hydrocarbons is well known to have order–disorder phase transitions in the solid state (1, 2). These materials are characterized by low entropies of melting and extensive molecular motions in the disordered phase. An interesting difference between this series and other disordered materials is that the high-temperature phases tend to be hexagonal-close-packed structures instead of the more usual face-centered-cubic (3). Norbornane has a second transition, with very low entropy, from the hcp to fcc structure. Oxanorbornane (7-oxabicyclo-[2.2.1]heptane, $C_6H_{10}O$) has a similar molecular structure except that the bridging methylene group is replaced by an oxygen atom, resulting in a larger dipole moment, and the possibility that disordered phases exist for this compound seemed worth exploring.

The structures of the ordered phases at low temperature are seldom known, but information can be obtained from the splittings that occur in the vibrational spectra as a result of the change in site or factor group symmetries, and we have investigated the transitions for norbornane, norbornene, norbornadiene, and quadricyclane by examining the effects of both temperature and pressure on their vibrational spectra (4–8). We report here on the differential scanning calorimetry, the temperature dependence of the infrared and Raman spectra, and the proton spin-lattice relaxation times of oxanorbornane.

Experimental

Oxanorbornane was obtained from Aldrich Chemical Co. and was purified by double distillation over calcium hydride. The DSC experiments were performed on a Perkin–Elmer DSC-7 calorimeter calibrated for both temperature and enthalpy scales using the melting and phase transitions of cyclohexane. Samples were scanned at 5 K min^{-1}. Infrared spectra were measured using an Analect AQS-18 spectrometer equipped with a KBr beam splitter and triglycine (TGS) detector. The temperature was varied using an evacuated cryostat cooled with liquid nitrogen and controlled with heaters attached to the liquid sample cell holder. Raman spectra were obtained using an Instruments S.A. spectrometer with a Jobin–Yvon U-1000, 1.0 m double monochromator. The 514.5 nm line of a Spectra-Physics model 164 argon-ion laser was used for excitation with a laser power of 100 mW at the sample. The sample was contained in a glass capillary tube attached with indium foil to the cold finger of a Cryodyne Model 21 Cryocooler. The resolution was 4 cm^{-1} for infrared spectra and between 1 and 3 cm^{-1} for the Raman spectra.

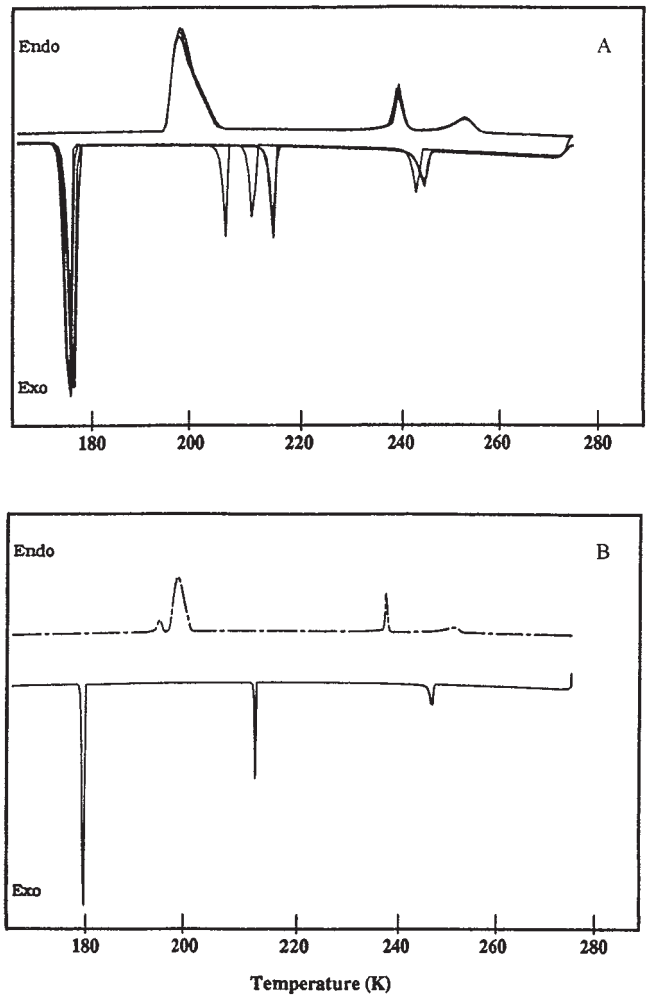
Fig. 1. (*a*) The DSC thermograms during repeated scanning at 20 K min^{-1}; (*b*) thermograms after cycling.



Proton spin-lattice relaxation times were measured by the inversion recovery method using a SpinLock CPS2 spectrometer at a resonance frequency of 33 MHz. Delays between measurements were at least $5T_1$. The temperature was controlled by a stream of cold nitrogen gas and measured with a copper-constantan thermocouple.

Results and discussion

DSC results

No exotherms on heating were observed, and so no glassy states were formed. On first cooling, the melting transition was observed at 244 K, followed by two other transitions at 206 and 170 K. On heating, the transition temperatures occurred at 191 and 231 K and melting at 243 K. Thus there is considerable hysteresis associated with the two solid-state transitions. The major transition was much broader on heating than on cooling. Additional DSC experiments were performed in which the sample was repeatedly scanned, Fig. 1(*a*), at a much faster rate of 20 K min^{-1}. Remarkably, the three transitions showed little change in transition temperature for the heating direction, but on cooling the higher temperature transition fluctuated for the first four cycles and then remained unchanged. A single scan, at 5 K min^{-1}, performed after the cycling procedure, showed that the lower temperature transition, which previously was rather broad, now consisted of two sharp transitions, Fig 1(*b*). Thus five possible different phases exist.

The entropies are given in Table 1, where they are compared with other members of the bicyloheptyl series. The entropy of fusion of oxanorbornane is very low, the lowest of this series of molecules, and typical of materials that melt from a disordered phase. Oxanorbornane resembles norbornane in that a low entropy transition occurred between the major transition and the melting point but the transition entropy of 4.53 J K^{-1} mol^{-1} was much higher than that of norbornane (0.3 J K^{-1} mol^{-1}), indicating that this phase might be partially ordered in oxanorbornane. The sum of the two solid-phase transitions for these two compounds is about the same but much lower than the entropies for the single transition in norbornadiene and quadricyclane. The transition in norbornylene is not directly comparable, since the symmetry of the molecule is lower. The hysteresis observed for these order–disorder transitions is attributable to lattice strain arising from the difficulty of nucleating the new crystal structure within the old. This is often associated with a large volume difference between the phases, which, in turn, can make a significant contribution to the entropy of transition (9).

Vibrational spectra

The vibrational spectra at different temperatures are shown in Figs. 2 and 3 and the frequencies listed in Table 2. The spectra of the liquid and disordered phases were very similar, and the Raman spectrum of the lattice region showed only a broadened Rayleigh line. This is the typical behaviour of disordered solid phases. In the intermediate phase, four lattice modes were observed, which confirms the DSC result that this phase is at least partly crystalline, and in the low-temperature phase there were seven lattice modes. The most pronounced changes occurred in the C–H stretching region of the Raman spectrum, where five broad peaks occurred in the disordered phase, increasing to 15 relatively sharp peaks at the first transition and then 21 sharp bands in the lowest temperature phase. Additional splittings were observed for other regions of the spectrum. For example, the peak at 888 cm^{-1} occurred as a broad singlet, which first sharpened and then split into a triplet as the temperature was decreased through the phase transitions. The peak at 938 cm^{-1} changed from a singlet at 240 K to a sharp doublet at 150 K. In the infrared spectrum, similar changes occurred for the C–H stretching modes, where four very broad bands with two shoulders at 240 K changed to 11 peaks and shoulders at 100 K. Many of the remaining peaks split into two components except for the peak at 1262 cm^{-1}, which split into four peaks on going from the intermediate to the low-temperature phase.

The point group symmetry of oxanorbornane is C_{2v}, and the representation of the 45 possible normal modes reduces to $G_{vib} = 13a_1 + 10a_2 + 12b_1 + 10b_2$. All modes are Raman active and the a_1, b_1, and b_2 modes are infrared active. There are numerous cases where the vibrations are coincident in both the infrared and Raman spectra, and therefore, the unit cell cannot be centrosymmetric. The site symmetry in the lattice must be equal or lower than the molecular symmetry, i.e., C_{2v}, C_2, C_s or C_1, and there are three different possible

types of site and factor group combinations; (*i*) a D_2 crystal with a C_2 site or a C_{2v} crystal with either a C_2 or C_s site, (*ii*) a D_{2d} crystal with a C_s site, or (*iii*) an S_4 or C_4 crystal with a C_1 site. In the first case, some ir peaks should become doublets, and all Raman active peaks should be doublets. Since a number of Raman active peaks split into triplets, this possible crystal symmetry is unlikely. For the D_{2d} crystal, some infrared peaks should double, while Raman peaks should split into two or three peaks, and for the S_4 or C_4 crystal all the infrared peaks should double, and all Raman peaks should triple. Since seven lattice modes were observed in the Raman spectrum there are at least two molecules in the unit cell. From the observed splittings, the D_{2d} structure appears to be the most likely, i.e., a monoclinic crystal, C_s, or an orthorhombic crystal, D_2 or C_{2v}, both with two molecules per unit cell, or a tetragonal crystal, D_{2d} with $Z = 4$.

Spin-lattice relaxation time measurements

The dependence of the spin-lattice relaxation times is shown in Fig. 4. The phase transitions and the hysteresis are clearly apparent. The slopes of the ln (T_1) versus reciprocal temperature plots gave the activation energies for each re-

gion. In the high-temperature region, the barrier to rotation was 7.8 ± 0.5 kJ mol^{-1}, which is less than the value for the liquid phase of 9.8 ± 1.8 kJ mol^{-1}. This is unusual but has been observed previously for *t*-butyl compounds (10). In the intermediate phase the barrier was 12.5 ± 0.5 kJ mol^{-1}, rising to 17.5 ± 1.4 kJ mol^{-1} in the low-temperature phase. These energies are similar to those reported (11) for the other bicyclic compounds where, for their disordered phases, both norbornane and norbornylene showed nonlinear T_1 plots with slopes ranging from 5.4 to 8.8 kJ mol^{-1}, and 6.3 to 10.5 kJ mol^{-1}, respectively, and in norbornadiene the activation energy was 8.0 kJ mol^{-1}.

The supramolecular architecture of 4-aminoacetophenone (1-(4-fluorophenyl)ethylidene)hydrazone hydrate. Double T-contacts and extremely low-density water layers in a mixed azine[1,2]

Michael Lewis, Charles L. Barnes, and Rainer Glaser

Abstract: The crystal structure of unsymmetrical azine 4-aminoacetophenone (1-(4-fluorophenyl)ethylidene)hydrazone hydrate, **1**·H_2O, was determined. Comparison to the X-ray structures of the symmetrical 4-fluoro- and 4-aminoacetophenone azines, **2** and **3**, respectively, reinforces the view of the azine bridge as a conjugation stopper. The focus of the analysis lies with the supramolecular architecture. The structure demonstrates azines as double T-contact synthons and suggests that novel L-type arene–arene contacts also might play a significant role in the supramolecular architecture. The absence of inter-water hydrogen bonding in an extremely low-density water layer is one of the surprising and unique features of the solid-state structure of the title compound. The water layers connect azine layers through a hydrogen bonded network which is described by graph set analysis.

Key words: arene–arene interaction, hydrogen bonding, graph set analysis, azine, supramolecular synthon, low density water monolayer.

Résumé : On a déterminé la structure cristalline de l'hydrate de la 4-aminacétophénone (1-(4-fluorophényl)éthylidène)hydrazone (**1**·H_2O) (dérivé asymétrique de l'azine de l'acétophénone). Une comparaison de celle-ci avec les structures cristallines des azines symétriques 4-fluoro- et 4-aminoacétophénone-azines, respectivement **2** et **3**, confirme le fait que le pont azine arrête la conjugaison. L'analyse se concentre sur l'architecture supramoléculaire. La structure démontre que les azines agissent comme synthons à doubles contacts-T et elle suggère la possibilité que de nouveaux contacts arène-arène de type-L puissent jouer un rôle significatif dans l'architecture supramoléculaire. L'absence de liaison hydrogène entre molécules d'eau dans une couche aqueuse de densité extrêmement faible est l'une des caractéristiques surprenantes et uniques de la structure à l'état solide du composé mentionné dans le titre. Les couches d'eau connectent les couches d'azines par le biais d'un réseau de liaisons hydrogènes que l'on décrit à l'aide d'une analyse d'un ensemble de graphes.

Mots clés : interaction arène–arène, liaison hydrogène, analyse d'un ensemble de graphes, azine, synthon supramoléculaire, monocouche d'eau de faible densit.

Introduction

We have been interested in the linear and nonlinear optical properties of *N*-perturbed donor–acceptor asymmetrized conjugated systems of the azine type. As a first step toward the elucidation of the underlying electronic structures and properties, we have systematically studied the crystal structures and the packing of symmetric (1, 2) and unsymmetric (3–5) acetophenone azines. These acetophenone azines have the general formula X-Ph-C(Me)=N-N=C(Me)-Ph-Y, and they are called symmetric if X = Y and unsymmetric in the case X ≠ Y(see Appendix). Our studies have resulted in the first realization of two prototypes of molecular organic materials with near-perfect dipole parallel-alignment in the pure crystal of the mixed azines 4-bromo- and 4-chloro-acetophenone (1-(4-methoxyphenyl)ethylidene)hydrazone (3, 4)[4,5].

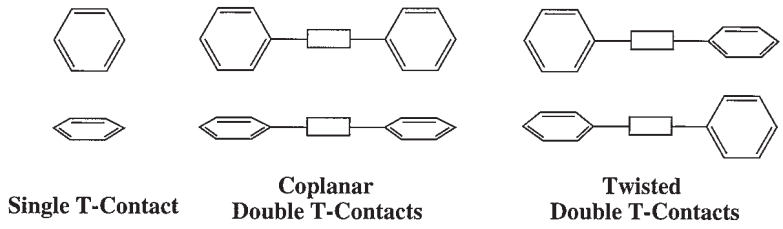

Fig. 1. ORTEP II drawing of mixed azine **1**. Major bond lengths in angstroms are F1—C5 = 1.3605(25), C2—C1 = 1.480(3), C1=N1 = 1.286(3), N1—N2 = 1.4140(23), C9—N2 = 1.293(3), C9—C10 = 1.480(3), and C13—N3 = 1.374(3).

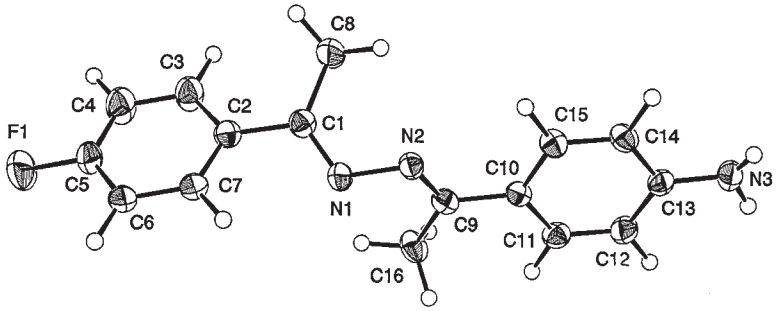
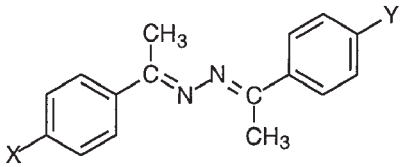


Non-centrosymmetry is a necessary requirement for all types of polar effects of crystals (6) (nonlinear optical (NLO) activity, piezo- and pyroelectric effects, and many others) but it is not a sufficient requirement. Many organic compounds crystallize in chiral space groups (7) without realizing any significant macroscopic polar effects (8, 9). The proper alignment of the polar building blocks is the pertinent issue, and the creation of large crystal polarizations remains a challenge beyond the simple quest for non-centrosymmetry. The de novo design of crystals is an undertaking of extraordinary difficulty since the lattice architecture results from the optimization of a large number of weak intermolecular interactions. These interactions are far too complex to trace and, thus, also far to complex to create by pure design. Olson (10) recently pointed out that the simplifying methods of scientific analysis can contribute to meeting this challenge when such analyses are pursued within the systems approach of engineering. Central to the systems approach is the sequential, deep and rigorous scientific analysis of a small number of prototypes. It is the goal of the prototype analysis to recognize significant intermolecular interactions. Molecular fragments capable of binding with certain other atoms or functional groups with high selectivity and high affinity are referred to as synthons (11, 12). The crystal structures of the prototypes of the ferroelectric azines show pairs of perfectly parallel aligned unsymmetrical azine molecules with two T-contact arene–arene interactions. The azine spacer is special in that its conformational flexibility (13) allows for near-orthogonality between the two benzenes in the same azine. The Ph-CR=N-N=CR-Ph system thus constitutes a "double T-contact synthon" and we believe this motif to be key to understanding the suprastructures of the prototypes. Double T-contacts occur when the arene rings of two compounds containing two arene groups each stack in such a way that two edge-to-face arene–arene contacts are realized. Scheme 1 illustrates the two possibilities for double T-contacts.

Coplanar double T-contacts result when the arene rings of each bisarene compound are (more or less) in the same plane. Thus, if the spacer between the two aromatic rings is unsaturated, there exists the possiblity of conjugation. Twisted double T-contacts require the arene rings of each bisarenes to be (more or less) orthogonal. This situation can only occur through a twisting of the spacer between the arene rings, and therefore one would not expect any conjugation between the arene rings.

As part of our studies of unsymmetric acetophenone azines we have now prepared the mixed azine 4-aminoacetophenone (1-(4-fluorophenyl)ethylidene)hydrazone (**1**, Fig. 1), and here we report the crystal structure of its hydrate,



1: X=F, Y=NH_2
2: X=Y=F
3: X=Y=NH_2

1·H_2O. We have previously reported the solid-state structures of the respective symmetrical azines **2** (X = Y = F) and **3** (X = Y = NH_2) (2), and these data present the best possible reference to discuss the structural effects of asymmetrization. The structure of **1** demonstrates the importance of the double T-contact synthon. The superstructure of the title compound also is unique in two further respects. First, the supramolecular architecture of **1** features not only T-type arene–arene interactions but also exhibits highly perturbed T-contacts that can be described as L-type van-der-Waals arene–arene interactions. The other interesting feature relates to the occurrence of water layers which are exceptional in that there is no hydrogen bonding between the intra-layer water molecules.

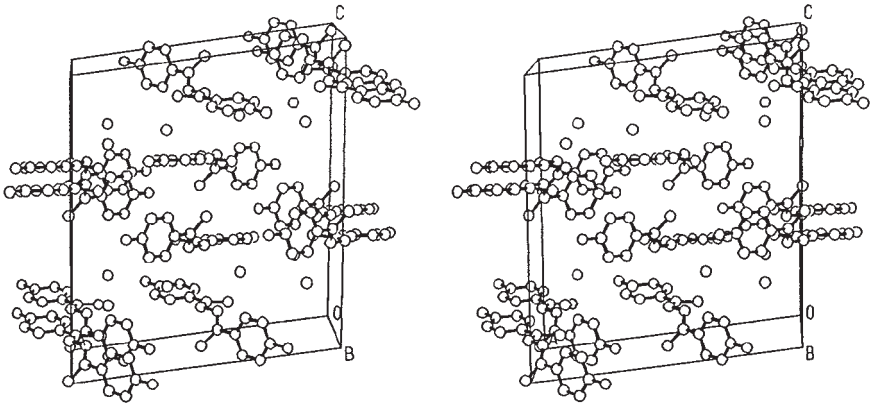
Fig. 2. Packing of azine hydrate **1**·H_2O.



Results and discussion

Structural effects of asymmetrization and the question of π-conjugation

The ORTEP II diagram of **1** is shown in Fig. 1, and a view of the packing of **1**·H_2O is shown in Fig. 2. The crystallographic data for **1**·H_2O is presented in Tables 1–3. At first glance the title compound **1** appears to be a classical example of a donor–acceptor molecule which allows for donation of electron density from the amino-substituted phenyl ring into the fluoro-substituted phenyl ring. However, Fig. 1 reveals that mixed azine **1** is not planar, but rather the >C=N-N=C< bridge assumes a *gauche* conformation (τ = 56.4°) and the phenyl rings both are twisted more or less out of the conformation that would be best for conjugation. The amino-substituted phenyl ring is twisted only slightly by ϕ_1 = 8.4° out of the plane defined by the *ipso*-carbon and the atoms of the C9=N2 imine bond and still allows for through conjugation from the amino group to the imine functionality. Conversely, the fluoro-substituted phenyl ring is twisted by ϕ_2 = 31.2° out of the plane defined by the *ipso*-carbon and the C1=N1 imine bond, eliminating all possibilities for through-conjugation. Since the C2—C1, N1—N2, and C9—C10 bonds in **1** are almost parallel, the sum of τ, ϕ_1, and ϕ_2 provides an excellent approximation for the angle ω between the best planes through the benzene rings. Recognizing that τ and ϕ_i all serve to increase ω, this approximation gives $\omega \approx 96.0°$ and leaves the benzenes nearly orthogonal. Rather than considering the azine spacer a conjugating bridge in an extended donor–acceptor system, the azine bridge in **1** acts more like a "conjugation stopper," a term we introduced earlier to describe the electronics of asymmetric acetophenone azines. In this model the azine bridge is viewed as two oppositely oriented imine acceptors. The azine **1** should thus present itself as a system with a dipolar donor–acceptor half with an NH_2-donor and a C9=N2 imine bond acceptor, and an essentially quadrupolar half, where both the F and the C1=N1 imine bond are acceptors. Comparison with the symmetrically substituted azines **2** and **3** reinforces the view for the azine bridge as a conjugation stopper. The NH_2-half of **1** is perturbed very little as compared to the NH_2-halves for the symmetrical azine **3**. The average C_{ipso}—NH_2, C9—C10, and N2—C9 bond lengths in **3** are 1.38, 1.48, and 1.29 Å, respectively. These bond lengths are identical to the corresponding C9—C10 and N2—C9 bond lengths in **1**. The C_{ipso}—NH_2 is marginally less for **1** at 1.37 Å and a small discrepancy is to be expected since **1** crystallizes into a different H-bonded network than **3**. The same trend is present when comparing the F-half of **1** with azine **2**. The average C_{ipso}—F bond length is 1.36 Å for **2**, while the bond lengths that correspond to C2—C1, and C1—N1 are 1.48 and 1.28 Å, respectively. These bond lengths are identical to the corresponding bond lengths in **1**, except for C1—N1 which is 1.29 Å long.[6] Once again, a small variation is to be expected since **1** and **3** are in different crystal environments. Thus, the six bond lengths that would be affected most by through conjugation in fact remain almost unperturbed.

Double T-contacts in the van der Waals bonded azine layers

The crystal lattice (Fig. 2) of **1**·H_2O contains alternating layers of azines and water molecules stacked in the direction of the *c*-axis. Each azine layer is rotated by 90° from the azine layer below or above it and consists of inversion-symmetric pairs of dipole antiparallel-aligned azines with N–N *gauche* conformations (Fig. 3*a*). In the *P*/*M* nomenclature for the chirality of conformational isomers (14), the top structure of the azine pair depicted in Fig. 3*a* has *M* helicity, while the bottom structure has *P* stereochemistry. The azine pairs in Fig. 2 are characterized by two identical intermolecular arene–arene T-contacts (15, 16) that can best be described as twisted double T-contacts (Scheme 1). The near perpendicular phenyl arrangement ($\omega \approx 96.0°$) in **1** might be adopted to take full advantage of these intermolecular double T-contacts. A priori there is a choice as to which of the substituted benzenes serves as the vertex or the head of the T-contact. In the crystal structure of **1**, we find that the F-substituted benzenes always serve as the vertices. It is possible that polymorphs might exist with the opposite arrangement. The contact distance between the two phenyl rings ranges from 3.6 to over 4.1 Å (Fig. 3*b*). Alternatively, the layering of **1** along the direction of the *c*-axis can be described as involving two azine monolayers between water

[6] The estimated standard deviations (esd's) for the bond distances discussed in this section are on the order of thousandths of angstroms. Since we only cite the bond distances to hundredths of angstroms, these very small esd's strengthen our arguments.

layers and from this vantage point the T-contacts are responsible for the cohesion between the azine monolayers. Each of these azine monolayers is completely dipole aligned but in opposite directions.

The inter-pair packing between azines in each respective layer also occurs via arene–arene interactions. These contacts are highly distorted T-contacts, and they might also be described as L-type arene–arene interactions (Fig. 3*c*). Arene–arene interactions have been studied extensively by ab initio (15, 17), Monte Carlo (18), and molecular mechanics (19) theoretical methods, using Raman (20), NMR (21), and mass selective hole-burning (22) spectroscopic techniques and also by solid-state X-ray crystallography (23). These studies produced a vast body of evidence for the significance of face-to-face and T-contacts, however there is no evidence for T-contacts perturbations that lead to L-contacts. There are many examples of perturbed T-contacts of the herringbone motif (15–17*a*) which are the result of non-orthogonal (and slipped) vertices. The L-contact exhibited in **1** is the result of a strong perturbation of the T-contact with the rings remaining perpendicular (Fig. 3*d*). Since the C_j—C_l bond is coplanar with the benzene ring shown on the

right (containing C_k), and since the atoms C_i, C_j, and C_k lie in a plane that is almost perpendicular to the molecular planes of both phenyl rings, the angle (C_i, C_j, C_k) = 89.8° shows that the benzene planes are essentially perpendicular. It is for these reasons that we refer to this arrangement as an L-contact. As was the case for the intra-pair packing, the F-substituted phenyl rings serve as the vertices in the inter-pair arene–arene interactions. The distance between the L-packed arene rings ranges from 3.556 to 4.142 Å (Fig. 3*d*) for the edge-to-edge contacts illustrated in Fig. 3*c*. Note that the realization of the L-contacts requires a translation of neighboring azines within each monolayer along their long molecular axis such that an X-substituted benzene interacts with a Y-substituted benzene. In the absence of such a translation, the packing might benefit from face-to-face stacking of the F-substituted arenes but the amino-substituted benzenes would not be in any favorable position. It has been noted that benzene aggregates do not assume one rigid structure (24) but instead there are a variety of geometries that can be adopted (15). Thus, the formation of the L-contact should not be an entirely surprising result, as the intermolecular forces that govern arene–arene interactions are weak and could be overcome with relative ease due to a variety of competing non-covalent interactions.

Graph set analysis of the hydrogen bonding and low-density water layers

As illustrated in Fig. 2, the azine layers in **1** are held together by layers of water molecules. The positions of the water H-atoms were determined, and the water molecules do not engage in any water–water hydrogen bonding. The water molecules all are aligned such that their molecular planes are nearly parallel with the *ac*-plane, and all of the water dipole moments are nearly colinear with the crystallographic *a*-axis. Each water participates in four hydrogen bonds with

four separate azines (Fig. 4). The hydrogen bonding network is best revealed via the graph set theoretical description proposed by Bernstein and Davis (25). Using their notation, the H_a- and H_b-bonds have unitary graph set notation N_1 = DD, indicating that each hydrogen bond H_a and H_b is finite. These two hydrogen bonds are formed between a water acting as a H-donor and an azine N-atom. The system of Bernstein and Davis also allows for more complex graph sets. A binary graph set describes a pattern in which only two types of hydrogen bonds are present, whereas systems with more than two hydrogen bonds can be described by complex basis sets. The hydrogen bonded pattern produced by H_a and H_b has a binary graph set of $N_2(a,b) = C_2^2(5)$ and a complex graph set of $N_2(a,b) = R_4^4(10)$ (Fig. 4*a*). We exemplify the meaning of the binary graph set for $N_2(a,b) = C_2^2(5)$. The term $N_2(a,b)$ denotes a graph set with two types of hydrogen bonds, H_a and H_b. $C_2^2(5)$ indicates a chain (C) which contains two hydrogen bond acceptors (superscript) and two hydrogen bond donors (subscript) and covers five atoms linked by either covalent or hydrogen bonds. Similarly, the complex graph set R denotes a ring pattern consisting of four donor and four acceptor sites in a 10-membered ring. The other types of hydrogen bonds H_c and H_d both involve water as the hydrogen bond acceptor and the amino groups are the hydrogen bond donors (Fig. 4*b*). The amino groups are slightly pyramidalized (sum of angles at *N* = 354.2°) and the direction of pyramidalization is such as to suggest optimization of the hydrogen-bonding interactions. The bonds H_c and H_d can be described by a unitary graph set, N_1 = DD, and a binary graph, $N_2(c,d) = C_2^1(4)$. In this case, however, there is no complex graph set that relates H_c and H_d. Finally, there also exists two complex graph sets that describe the patterns created by H_a, H_c, and H_d and by all four hydrogen bonds. The pattern produced by H_a, H_c, and H_d has the complex graph set $N_3(a,c,d) = R_4^3(14)$ and is illustrated in Fig. 4*c* by the thick broken lines. The pattern relating all four hydrogen bonds can loosely be described by the complex graph set $N_4(a,b,c,d) = R_8^7(24)$. This description does not strictly adhere to the notation of Bernstein and Davis because the pattern created by all four hydrogen bonds is not a ring. Instead, a spiro motif exists where the

ring created by the graph set $N_3(a,c,d) = R_4^3(14)$ shares a common oxygen with the ring created by the graph set $N_2(a,b) = R_4^4(10)$ (the latter ring is shown in Fig. 4*c* by the thin broken lines). This spiral pattern of hydrogen bonds reveals the infinite two-dimensional layer which acts as the glue that holds the layers of azine pairs together. It appears that the water layer in **1** represents the least dense arrangement of water molecules in the solid state observed to date. The O—O distances of 4.81 and 5.90 Å correspond to a density of approximately one half that of ice I and II (average O—O distance of 2.79 Å (26)). This extreme low density is attributed to the absence of inter-water H-bonding. The unique arrangement of water molecules in $1\cdot H_2O$ represents a first for infinite water layers, and it is attributed to the presence of a strong H-bond acceptor in the form of the amino-N atom. The literature on hydrates shows structures of two general classes. The first family of hydrates realizes crystal lattices in which the water molecules hydrogen bond with each other (27) and the other class contains water molecules that are interspersed throughout the crystal lattice (28). Neither of these classes of hydrates show any water aggregates with cavities. It appears that the infinitely ordered water sheet of the kind demonstrated by $\mathbf{1}\cdot H_2O$ is entirely unprecedented.

Experimental

Synthesis and recrystallization

Mixed azine **1** was prepared via hydrazono-de-oxo-bisubstitution (29). Hydrazine hydrate was added to *p*-aminoacetophenone in ethanol to yield the corresponding hydrazone. Reaction of the hydrazone with *p*-fluoroacetophenone in ethanol in the presence a few drops of glacial acetic acid afforded the azine which was purified by column chromatography (hexane–ethylacetate gradient elution). Crystals of the hydrate $\mathbf{1}\cdot H_2O$ were grown by slow diffusion of hexane into a solution of **1** in chloroform.

Crystal structure determination

A single crystal X-ray analysis was performed on the hydrate ($C_{16}H_{16}N_3F\cdot H_2O$, M_r = 287.33). The compound $\mathbf{1}\cdot H_2O$

Fig. 4. All distances are in angstroms. (*a*) The water H atoms act as the hydrogen bond donors, while the azine-N atoms are the acceptors. By only considering the two unique hydrogen bonds H_a and H_b, the binary basis set $N_2(a,b) = C_2^2(5)$ is realized. The complex basis set $N_2(a,b) = R_4^4(10)$ is a result of two binary sets forming a circle. (*b*) The amino-H atoms act as hydrogen bond donors, and the water-O atoms are the acceptors. The two unique H-bonds H_c and H_d can be described by the binary basis set $N_2(c,d) = C_2^2(4)$. There is no complex basis set relating H_c and H_d. (*c*) The complex basis set $N_4(a,c,d) = R_4^4(14)$ is obtained by considering the hydrogen bonded system described by the thick broken lines. All four hydrogen bonds are related by the spiral motif created by the graph sets $N_2(a,b) = R_4^4(10)$ and $N_4(a,c,d) = R_4^4(14)$.

Appendix

Nomenclature of azines: azines are 2,3-diazabutadienes, they are characterized by the functional group >C=N-N=C<, and they formally are the products of condensation between hydrazine and two carbonyl compounds. Symmetrical or unsymmetrical (or mixed) azines are formed, respectively, if the two carbonyl compounds are the same or different. Azines have the general formula RR′C=N-N=CRR′, and they are named substitutively as an assembly of identical units using the prefix "azino-." According to functional class nomenclature, they may be named by adding the class name "azine" as a separate word after the name of the corresponding aldehyde or ketone. Hence, Me_2C=N-N=CMe_2 is called azinoacetone or, more frequently, acetone azine (see http://www.acdlabs.com/iupac/nomenclature/93/r93_469.htm). In the IUPAC nomenclature, the unsymmetrical azines RR′C=N-N=CR′′R′′′ are named as alkylidenehydrazones. Hence, Me_2C=N-N=CH_2 can be called formaldehyde (isopropylidene) hydrazone or acetone (methylidene) hydrazone.

[7] Supplementary material and the results of the crystal structure analysis may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2. With the exception of isotropic and anisotropic thermal parameters, these and the crystal structure (in CIF format) have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Synthesis and characterization of homoleptic ruthenium(II) imidazole complexes, and a carbonyl species derived by CO abstraction from DMF

Ian R. Baird, Steven J. Rettig, Brian R. James, and Kirsten A. Skov

Abstract: $[Ru(II)(L)_6]^{2+}$ complexes were synthesized from $[Ru(DMF)_6][CF_3SO_3]_3$; DMF = dimethylformamide, L = imidazole (Im), *N*-methylimidazole (NMeIm) and 5-methylimidazole (5MeIm). The 2-methylimidazole complex *trans*-$[Ru(CO)(DMF)(2MeIm)_4][CF_3SO_3]_2$ (**4**) was also synthesized via a reaction involving abstraction of CO from DMF; **4** loses CO reversibly at ambient temperature to form $[Ru(DMF)(2MeIm)_4][CF_3SO_3]_2$ (**5**), and the DMF can be removed to generate a $[Ru(CF_3SO_3)_x(2MeIm)_4][CF_3SO_3]_y$ species ($x = 2$, $y = 0$, or $x = 1 = y$), containing coordinated triflate. The complexes were characterized by elemental analysis, conductivity, UV-vis, NMR, and IR spectroscopies. The structures of $[Ru(Im)_6][CF_3SO_3]_2$ (**1**), $[Ru(NMeIm)_6][CF_3SO_3]_2$ (**2**), and $[Ru(5MeIm)_6][CF_3SO_3]_2$ (**3**) were established by X-ray crystallographic analyses. Crystals of **1**, are triclinic, $a = 7.4010(6)$, $b = 9.9846(15)$, $c = 11.275(2)$ Å, $\alpha = 113.469(5)$, $\beta = 92.419(2)$, $\gamma = 94.737(2)°$, $Z = 1$, space group $P\bar{1}$; those of **2**, are trigonal, $a = 11.558(2)$, $c = 8.109(3)$ Å, $Z = 1$, space group $P\bar{3}$; and those of **3**, are trigonal, $a = 12.6547(4)$, $c = 20.4078(12)$ Å, $Z = 3$, space group $R\bar{3}$. The structures were solved by Patterson methods and refined by full-matrix least-squares procedures to $R(F) = 0.029$, 0.034, and 0.034 ($R_w(F^2) = 0.055$, $R_w(F) = 0.031$, and $R_w(F^2) = 0.058$), respectively.

Key words: hexakis(imidazole)ruthenium(II) triflates, crystal structures, CO abstraction.

Résumé : On a synthétisé les complexes $[Ru(II)(L)_6]^{2+}$ à partir du $[Ru(DMF)_6][CF_3SO_3]_3$ dans lesquels DMF = diméthylformamide, L = imidazole (Im), *N*-méthylimidazole (NMeIm) et 5-méthylimidazole (5MeIm). On a aussi synthétisé le complexe dérivé du 2-méthylimidazole, *trans*-$[Ru(CO)(DMF)(2MeIm)_4][CF_3SO_3]_2$ (**4**), par le biais d'une réaction impliquant l'enlèvement de CO à partir du DMF; à la température ambiante, le composé **4** perd du CO d'une façon réversible pour conduire au $[Ru(DMF)(2MeIm)_4][CF_3SO_3]_2$ (**5**) et on peut enlever le DMF pour générer une espèce $[Ru(CF_3SO_3)_x(2MeIm)_4][CF_3SO_3]_y$ ($x = 2$, $y = 0$ ou $x = 1 = y$) comportant un triflate coordonné. On a caractérisé les complexes par analyse élémentaire, conductivité, spectroscopies UV-vis, IR et RMN. On a aussi déterminé les structures des composés $[Ru(Im)_6][CF_3SO_3]_2$ (**1**), $[Ru(NMeIm)_6][CF_3SO_3]_2$ (**2**), et $[Ru(5MeIm)_6][CF_3SO_3]_2$ (**3**), par diffraction des rayons X. Les cristaux du composé **1** sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 7{,}4010(6)$, $b = 9{,}9846(15)$ et $c = 11{,}275(2)$ Å, $\alpha = 113{,}469(5)$, $\beta = 92{,}419(2)$ et $\gamma = 94{,}737(2)°$ et $Z = 1$; ceux du composé **2** sont trigonaux, groupe d'espace $P\bar{3}$, avec $a = 11{,}558(2)$ et $c = 8{,}109(3)$ Å et $Z = 1$ et ceux du composé **3** sont trigonaux, groupe d'espace $R\bar{3}$, avec $a = 12{,}6547(4)$ et $c = 20{,}4078(12)$ Å et $Z = 3$. On a résolu les structures par les méthodes de Patterson et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de $R(F) = 0{,}029$, 0,034 et 0,034 et ($R_w(F^2) = 0{,}055$, $R_w(F) = 0{,}031$ et $R_w(F^2) = 0{,}058$) respectivement.

Mots clés : triflates d'hexakis(imidazole)ruthénium, structures cristallines, enlèvement de CO.

Introduction

Ruthenium imidazole complexes as chemotherapeutic agents show less cytotoxicity than their platinum counterparts (1, 2). These Ru complexes are of interest for their antitumor activity (3), for their ability to ligate radiosensitizing agents to DNA (4), as models for the bonding of Ru to nucleic acids (occurring most frequently on the imidazole ring of guanine (5–7)), and as a new class of compounds that, in the low nanomolar range, specifically inhibit the proliferation of human *T*-lymphocytes in vitro (2, 8). The interaction of Ru complexes with biomolecules has been studied extensively (9), and the form of the complex surviving to coordinate the biomolecules usually differs from that originally introduced into the organism. This is especially true for Ru(III) complexes which are transformed by an in vivo reduction to Ru(II), a more active species toward DNA bind-

ing, as reduction accelerates substitution reactions at the metal center (10).

Ruthenium(III) imidazole complexes such as $[ImH]_2[RuCl_5(Im)]$ (11) and *trans*-$[ImH][RuCl_4(Im)_2]$ (6, 12–14) have been synthesized and characterized, and their solution chemistry and antitumor activity thoroughly investigated. Ruthenium(II) imidazole complexes, however, are less common and, during our studies of such species, the two homoleptic species $[Ru(Im)_6]CO_3\cdot 5H_2O$ (14) and $[Ru(NMeIm)_6]Cl_2\cdot 2H_2O$ (3) were reported; X-ray structures were presented but no spectroscopic data, and indeed synthetic procedures for these complexes have not been reported, at least in the open literature. Crystals of the $(NMeIm)_6$ complex were a gift from a drug company (3), while those of the $(Im)_6$ complex grew in an NMR-tube after several weeks from a solution containing $[ImH]_2[RuCl_5(Im)]$ and excess Im (14). Several Ru(II)-imidazole species have been reported to show immunosuppression activity (15). Here we report the synthesis and structural characterization of the complexes $[RuL_6][CF_3SO_3]_2$, where L = imidazole (Im) (**1**), *N*-methylimidazole (NMeIm) (**2**), and 5-methylimidazole (5MeIm) (**3**),[2] as well as NMR, IR, and UV-vis data. The synthesis and characterization of the complex $[Ru(CO)(DMF)(2MeIm)_4][CF_3SO_3]_2$ (**4**), resulting from the decarbonylation of DMF, are also reported.

Experimental

Chemicals

Im, 2-methylimidazole (2MeIm), and 4(5)MeIm (Aldrich products) and NMeIm (from Merck) were used as received. Reagent grade DMF (Fisher) was distilled and dried over molecular sieves, and MeCN (anhydrous, Aldrich) was used as received. Other solvents were dried using the appropriate drying agent: MeOH (Mg), acetone (K_2CO_3), and CH_2Cl_2 (CaH_2). The precursor complexes $[Ru(DMF)_6][CF_3SO_3]_3$ and $[Ru(DMF)_6][CF_3SO_3]_2$ were synthesized according to literature procedures (16,17) from $RuCl_3\cdot 3H_2O$ and $Pb(CF_3SO_3)_2$ (the latter being synthesized from $PbCl_2$ and Aldrich, reagent grade CF_3SO_3H).

Physical techniques and methods

UV-vis absorption spectra were recorded on an HP 8452A diode array spectrophotometer and are given as λ_{max} (nm), [ε_{max} (M^{-1} cm^{-1})], sh = shoulder. IR spectra (as KBr pellets) were recorded on an ATI Mattson Genesis FTIR spectrophotometer (only the relatively intense bands are reported), and ^1H and $^{19}F\{^1H\}$ NMR spectra were recorded on a Bruker AC200F spectrometer. ^1H shifts are referenced to the residual proton shift of the internal deuterated solvent, and ^{19}F shifts are referenced to trifluoroacetic acid. GC analysis was done on an HP 5890A instrument using a 30 kPa He flow at 75°C with an HP-17 50% phenyl, 50% methyl, polysiloxane intermediate polarity column with a flame ionization detector and an HP 3392A Integrator. Electrochemistry was performed on 10^{-3} M solutions (MeCN) in 0.1 M TBAP (tetrabutylammonium perchlorate) on a Pine Biopotentiostat Model AFCBP1; the working and counter electrodes were Pt plates (6 mm^2) and the reference electrode was Pt wire (reduction potentials are reported vs. Ag/AgCl, the values being determined by reference to a measured ferrocene/ferrocenium couple). Conductivity measurements were made on a 10^{-3} M solution of the complex at room temperature (r.t.) using a Serfass conductance bridge model RCM15B1 (Arthur H. Thomas Co. Ltd.) connected to a 3404 cell from the Yellow Springs Instrument Co., and are reported as Λ_M (ohm^{-1} cm^2 mol^{-1}). TLC was run on precoated (0.2 mm) silica gel 60 F_{254} plates (E.M. Laboratories, Inc). Elemental analyses were performed in the UBC chemistry department by Mr. P. Borda.

Complexes

*$[Ru(Im)_6][CF_3SO_3]_2$ (**1**)*

In a 100 mL Schlenk tube $[Ru(DMF)_6][CF_3SO_3]_3$ (0.362 g, 0.367 mmol) was dissolved in MeOH (20 mL) under N_2 to yield a bright yellow solution. Finely ground Im (0.189 g, 2.78 mmol), dissolved in hot MeOH (5 mL), was then added via syringe. The reaction mixture was stirred at 70°C for 5 h over which time the solution went through orange to become dark green; however, the reaction remained incomplete according to TLC. The solution was thus stirred at 40°C for an additional 8 h. The MeOH was removed in vacuo leaving a dark green gum that contained DMF. Acetone (5 mL) was then added, followed by CH_2Cl_2 (~30 mL) which resulted in a green microcrystalline precipitate. This was collected, washed with warm CH_2Cl_2 (6 × 5 mL, to ensure removal of any excess Im) and dried in vacuo at 80°C for 2 days (yield 0.236 g, 80%). Dark green, X-ray quality crystals resulted from slow evaporation of a MeOH solution of **1**. ^1H NMR (r.t., d_6-DMSO), δ: 12.47 (s, 1H, Im-H_1), 7.23 (s, 1H, Im-H_5), 6.88 (br.s, 1H, Im-H_2), 6.22 (s, 1H, Im-H_4). ^{19}F NMR (r.t., d_6-DMSO), δ: –1.20 (s, $CF_3SO_3^-$). Anal. calcd. for $C_{20}H_{24}N_{12}F_6S_2O_6Ru$: C 29.74, H 3.00, N 20.81; found: C 29.87, H 2.87, N 20.45. UV-vis (MeOH): 218 (12 250), 288 (7590), 642 (33); for free Im, 216 (1640). Infrared (KBr), cm^{-1}: 3329, 3145, 2966, 2864, 1253, 1226(sh), 1173, 1068, 1027, 766, 636. $E°$ = 246 ± 2 mV.

*$[Ru(NMeIm)_6][CF_3SO_3]_2$ (**2**)*

In a double-neck, 25 mL flask, equipped with a reflux condenser, $[Ru(DMF)_6][CF_3SO_3]_3$ (0.088 g, 0.089 mmol) was dissolved in neat NMeIm (8 mL) under N_2 to give a bright yellow solution. The reaction mixture was stirred at 70°C. After 2 h the solution became pale green and slowly became darker with time. After 20 h, at which time the solution had become orange–brown, the mixture was immersed in an ice-bath; addition of toluene (10 mL) resulted in a creamy white precipitate, that was collected, washed with Et_2O (4 × 5 mL) and dried in vacuo at 80°C for 3 days (yield 0.0691 g, 87%). Bright yellow crystals suitable for X-ray analysis formed from slow cooling of a hot MeOH solution of **2**. ^1H NMR (r.t., d_6-DMSO), δ: 7.28 (s, 1H, Im-H_5), 7.20 (s, 1H, Im-H_2), 6.31 (s, 1H, Im-H_4), 3.68 (s, 3H, Im-*NMe*). ^{19}F NMR (r.t., d_6-DMSO), δ: –1.21 (s,$CF_3SO_3^-$).

[2] In complex **3**, the noncoordinated N-atom (with the H-atom) is defined as N(1), and the coordinated N-atom is defined as N(3); note that within the atomic labelling of Fig. 3, these N-atoms are arbitrarily labelled as N(2) and N(1), respectively.

Anal. calcd. for $C_{26}H_{36}N_{12}F_6S_2O_6Ru$: C 35.02, H 4.07, N 18.85; found: C 35.13, H 3.95, N 18.93. UV-vis (MeOH): 224 (12 080), 298 (10 200); for free NMeIm, 220 (1320). Infrared (KBr), ν cm^{-1}: 3131, 2967, 2926, 1533, 1270, 1226(sh), 1151, 1094, 1033, 637. $E°$ = 271 ± 3 mV.

*[Ru(5MeIm)$_6$][CF$_3$SO$_3$]$_2$ (**3**)*

In a 100 mL Schlenk tube $[Ru(DMF)_6][CF_3SO_3]_3$ (0.352 g, 0.357 mmol) was dissolved in MeOH (15 mL) under N_2 to give a bright yellow solution. 4(5)MeIm (0.240 g, 2.92 mmol) dissolved in hot MeOH (5 mL) was then added via syringe, when the solution became orange. After being stirred at 70°C for 4 h, the solution became dark brown–green. The MeOH was removed in vacuo leaving a dark brown gum. Acetone and CH_2Cl_2 were added (~5 mL each) to yield a brown–green solution which upon addition of Et_2O gave a yellow precipitate (yield 0.210 g, 66%). Bright yellow crystals suitable for X-ray diffraction formed from slow cooling of a hot MeOH solution of **3**. ^{1}H NMR (r.t., d_6-DMSO, for isolated crystals), δ: 12.09 (br.s, 1H, Im-H_1), 6.85 (s, 1H, Im-H_2), 6.03 (s, 1H, Im-H_4), 2.40 (s, 3H, Im-*5Me*); (for yellow precipitate) δ 12.10 (br.s, 12H, Im-H_1), 6.95 and 6.85 (overlapping singlets, 12H, Im-H_2), 6.60 (s, 1H, Im-H_5), 6.28 (s, 5H, Im-H_4), 6.03 (s, 6H, Im-H_4), 2.40 (s, 36H, Im-*5Me* + Im-*4Me* (buried)). ^{19}F NMR (r.t., d_6-DMSO), δ: –1.22 (s, C$F_3SO_3^-$). Anal. calcd. for $C_{26}H_{36}N_{12}F_6S_2O_6Ru$: C 35.02, H 4.07, N 18.85; found: C 35.07, H 4.09, N 18.77. UV-Vis (MeOH): 228 (12140), 292 (5620), 366 (sh); for free 4(5)MeIm, 220 (2715). Infrared (KBr), ν cm^{-1}: 3267, 3187, 3016, 2903, 1599, 1263, 1225(sh), 1170, 1099, 1030, 820, 637. $E°$ = 174 ± 3 mV.

N.B.: Pure complexes **1**–**3** were also synthesized from $[Ru(DMF)_6][CF_3SO_3]_2$ and the appropriate imidazole in MeOH. The reaction times were considerably shorter (2 h maximum) than those described in the above syntheses, and the yields were similar from the Ru(III) precursor.

trans-*[Ru(CO)(DMF)(2MeIm)$_4$][CF$_3$SO$_3$]$_2$ (**4**), [Ru(DMF)(2MeIm)$_4$][CF$_3$SO$_3$]$_2$ (**5**), and [Ru(CF$_3$SO$_3$)$_x$(2MeIm)$_4$][CF$_3$SO$_3$]$_y$ (x = 2, y = 0, or x = 1 = y) (**6**)*

The procedure used was identical to that used for the synthesis of **1,** but using $[Ru(DMF)_6][CF_3SO_3]_3$ (0.208 g, 0.211 mmol) and 2MeIm (0.123 g, 1.49 mmol); colour changes similar to those noted for the Im system were seen. For the work-up procedure, the MeOH volume was reduced to ~5 mL and then Et_2O (20 mL) was added slowly. The green solution became cloudy and storage at 0°C for 16 h resulted in a green crystalline solid (**4**), which was collected, washed with Et_2O (3 × 5 mL) and dried in vacuo at r.t. During pumping the green solid started to turn brown and after 4 h was a dark brown solid formulated as $[Ru(DMF)(2MeIm)_4][CF_3SO_3]_2$ (**5**). ^{1}H NMR (r.t., d_6-acetone), δ: 11.91 (br. s, 4H, Im-H_1), 8.40 (s, 1H, DMF-*H*), 6.77 (s, 4H, Im-H_5), 6.61 (s, 4H, Im-H_4), 3.22 (s, 3H, DMF-*Me*), 3.10 (s, 3H, DMF-*Me*), 2.45 (s, 12H, Im-*2Me*). ^{19}F NMR (r.t., d_6-acetone), δ: –1.21 (s, C$F_3SO_3^-$). If acetone is added to the NMR sample, a new peak appears at δ 2.14 (s, coord. $Me_2C{=}O$), slightly downfield of the free acetone peak (δ 2.04). If the brown solid was pumped on at 80°C, it turned black, being converted to $[Ru(CF_3SO_3)_x(2MeIm)_4][CF_3SO_3]_y$ (**6**). ^{1}H NMR (r.t., d_6-DMSO), δ: 12.11 (br. s, 1H, Im-H_1), 7.24 (s, 1H, Im-H_5), 7.03 (s, 1H, Im-H_4), 2.07 (s, 3H, Im-*2Me*). ^{19}F NMR (r.t., d_6-DMSO), δ: –1.21 (s, C$F_3SO_3^-$). Anal. calcd. for $C_{18}H_{24}N_8F_6S_2O_6Ru$: C 29.71, H 3.32, N 15.40; (for $C_{18}H_{24}N_8F_6S_2O_6Ru{\cdot}H_2O$ (and **6** was extremely hygroscopic): C 29.00, H 3.51, N 15.03); found: C 29.05, H 3.52, N 14.73. Infrared (KBr), ν cm^{-1}: (**4**) 3257, 3134, 2933, 2861, 2103 (C≡O), 1654 ($C{=}O_{DMF}$), 1572, 1283, 1249, 1167, 1030, 749, 638; (**5**) 3256, 3129, 2929, 2857, 1648 ($C{=}O_{DMF}$), 1572, 1284, 1248, 1167, 1030, 749, 638; (**6**) 3249, 3127, 2926, 2850, 1572, 1280, 1251, 1169, 1031, 754, 639. Conductivity of **6** (MeOH): Λ_M 115 (1 min) [1:1 electrolyte], becoming 165 after 3 h [2:1 electrolyte]. GC data: retention times for MeOH (5.26 min) and dry dimethylamine (5.06 min) match those found in the headspace of the sealed reaction vessel used for the synthesis of **4** (5.29 and 5.05 min).

*X-ray crystallographic analyses of **1**, **2**, and **3***

Crystallographic data appear in Table 1, and the respective structures are shown in Figs. 1–3. The final unit-cell parameters were obtained by least-squares on the setting angles for 5877 reflections with 2θ = 4.0–60.1° for **1**, 25 reflections with 2θ = 22.8–29.0° for **2**, and 6933 reflections with 2θ = 4.0–60.1° for **3**. The intensities of three standard reflections, measured every 200 reflections throughout the data collection for **2**, showed only small random fluctuations. The data were processed (18), corrected for Lorentz and polarization effects, and absorption (based on analysis of symmetry equivalent data for **1** and **3** and azimuthal scans for **2**).

The structures were solved by Patterson methods, all three analyses being initiated in the centrosymmetric space groups on the basis of *E*-statistics. The cation of **1** lies on a centre of symmetry, and those of **2** and **3** on points of S_6 symmetry. The triflate anion of **2** is massively disordered about the threefold axis, while that of **3** lies on a threefold axis. The triflate disorder in **2** was modeled by assigning the largest peaks in the region to partially occupied S, F, O, or C sites. Population parameters for the disordered atoms were adjusted to give roughly equivalent isotropic thermal parameters. There was some divergence in the thermal parameters when the S, F, and O sites were refined anisotropically. No attempt was made to obtain realistic triflate geometry, but care was taken to insure that the appropriate number of electrons was modeled and that the density in this region was accounted for. Geometrical parameters for the anion of **2** are very unreliable and are not given. All non-hydrogen atoms except C(5) and C(6) (the triflate carbons) for **2** were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and $B_H = 1.2B_{\text{bonded atom}}$. A correction for secondary extinction was applied for **1** (Zachariasen type, isotropic, Gaussian), the final value of the extinction coefficient being 6.2(2) × 10^{-6}. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from standard tables (19). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and bond angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion an-

All data used in the refinement.

[b]Temperature 294 K, Rigaku AFC6S diffractometer, Mo K_α radiation (λ = 0.71069 Å), graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1), $\sigma^2(F^2) = [S^2(C + 4B)]/Lp^2$ (S = scan rate, C = scan count, B = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$. Residuals and gof based on data with $I \geq 3\sigma(I)$.

[c]Includes crystal decay, absorption, and scaling corrections.

gles, intermolecular contacts, and least squares planes are included as supplementary material.[3]

Results and discussion

Preparation and characterization of hexakisimidazole Ru(II) complexes

Availability of the starting complexes $[Ru(DMF)_6][CF_3SO_3]_x$, where x = 2 or 3 (16), provides a useful general method for access to the homoleptic hexa-coordinate Ru(II) imidazole complexes $[Ru(L)_6][CF_3SO_3]_2$ (L = Im (**1**), NMeIm (**2**), and 5MeIm (**3**)). The DMF-containing precursors provide a useful alternative to the commercially available $RuCl_3 \cdot 3H_2O$ which is of variable composition. The cations of **1** and **2** have been previously reported with X-ray structural data, but with CO_3^{2-} and $[Cl^-]_2$ as their respective anions (3, 14) and, as mentioned in Introduction, syntheses of these compounds were not reported. Further, no other characterization data were reported for $[Ru(Im)_6][CO_3] \cdot 5H_2O$, which was insoluble in common solvents (14), or $[Ru(NMeIm)_6]Cl_2 \cdot 2H_2O$

[3] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Tables of hydrogen atom coordinates and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

Fig. 1. An ORTEP view of $Ru(Im)_6^{2+}$ (**1**); 50% probability thermal ellipsoids are shown.

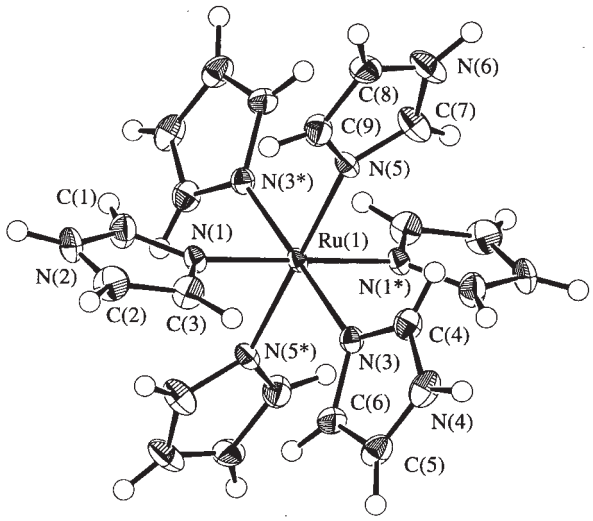

Fig. 2. An ORTEP view of $Ru(NMeIm)_6^{2+}$ (**2**); 33% probability thermal ellipsoids are shown.

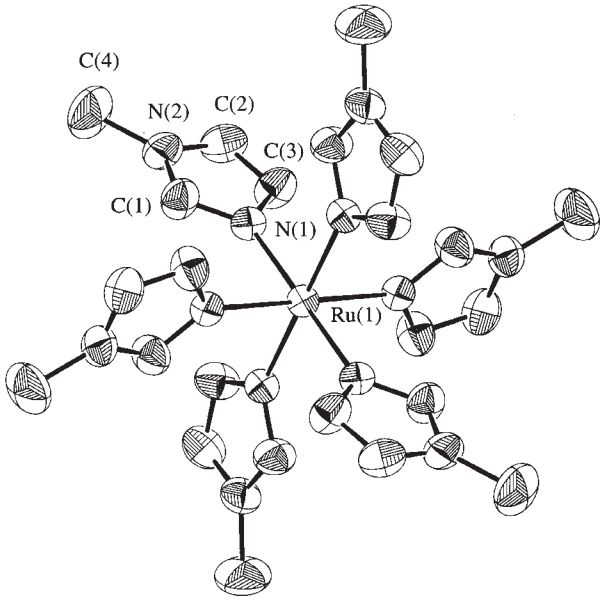

Fig. 3. An ORTEP view of $Ru(5MeIm)_6^{2+}$ (**3**); 50% probability thermal ellipsoids are shown.

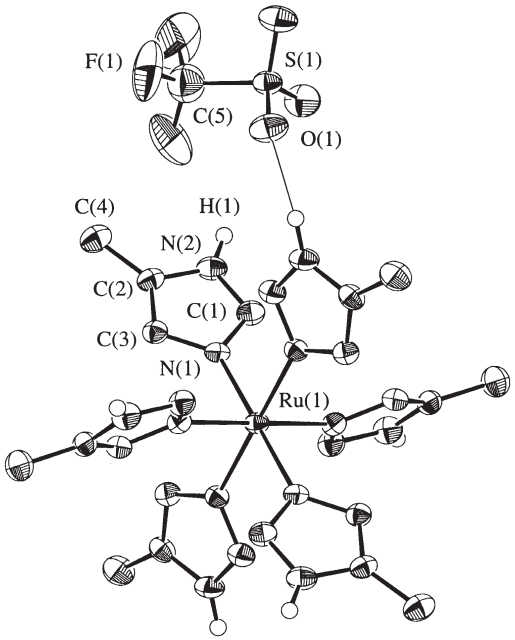

(3); CV data have been given for $[Ru(Im)_6][ClO_4]_3$ and $[Ru(NMeIm)_6][PF_6]_3$ (3).

Complexes **1**–**3**, which contain no waters of crystallization, can be obtained by simple exchange of the DMF ligands of $[Ru(DMF)_6]^{2+}$ by the imidazole. However, this Ru(II) precursor is moderately air-sensitive, and it is more convenient to use the air-stable $[Ru(DMF)_6][CF_3SO_3]_3$ precursor, although longer reaction times are needed, presumably (at least in part) because of the reduction of Ru(III) to Ru(II). There is literature precedence for both MeOH (20) and imidazoles (14, 21) acting as reductants of transition metal species, including those of Ru(III) which we have observed also in analogous nitroimidazole systems.[4] Substitution reactions at Ru(II) centres are typically faster than those at corresponding Ru(III) centres (22), and the longer Ru—O bond in $[Ru(DMF)_6]^{2+}$ vs. $[Ru(DMF)_6]^{3+}$ is consistent with such a reactivity trend (16).

Structural data on the cations within **1** and **2** have been reported previously within the structures of $[Ru(Im)_6]CO_3 \cdot 5H_2O$ (**1′**) (14) and $[Ru(NMeIm)_6]Cl_2 \cdot 2H_2O$ (**2′**) (3), respectively. The corresponding pairs of crystal structures, however, are quite different. Complex **1** crystallizes in the triclinic space group $P\bar{1}$ with the Ru atom situated on an inversion centre with the three unique Ru—N distances averaging 2.099(2) Å; crystals of **1′** are hexagonal with the Ru atom located at a point of S_6 symmetry with six equivalent Ru—N bonds of 2.102(2) Å. Complex **2** crystallizes in a trigonal space group with (like **1′**) the Ru atom at a point of S_6 symmetry and Ru—N bond lengths of 2.100(2) Å, while **2′** forms monoclinic crystals in which the Ru atom lies on a centre of symmetry (like **1**) with the three independent Ru—N distances averaging 2.106(8) Å. (Complex **3**, the $(5MeIm)_6$ species, is similar to **2** in being trigonal, with the Ru being at an S_6 site and the Ru—N length being 2.093(2) Å.) The Ru—N distances are significantly less than that reported for $Ru(NH_3)_6^{2+}$, 2.144(4) Å (23); this could result from a combination of some degree of π-backbonding from the Ru(II) to the imidazole ligands, and σ-hybridization

effects (a trigonal planar nitrogen has a slightly shorter bond radius than a tetrahedral nitrogen). Clarke et al. (3) have misquoted this Ru^{II}—NH_3 bond length as 2.114(4) Å, and reached a different conclusion.

The N-Ru-N angles for all of the complexes mentioned above are essentially orthogonal, and the basic geometries of the imidazoles (Im, NMeIm, 5MeIm) are very similar. Hydrogen bonding is evident between the triflate oxygens and the H-atoms of the nonbonded N-atoms of the coordinated imidazoles (e.g., in Fig. 3, N(2)...O(1) = 2.885(3) Å, with N(2)-H...O(1) = 163.5°).

The ^{1}H nmr spectra for **1**–**3** reveal sharp, well defined peaks with δ values near those of the free ligands, consistent with imidazoles bonded to a diamagnetic Ru(II) centre; in d_6-DMSO, the N-H_1 signal is readily detected. Paramagnetic shifts diagnostic of analogous Ru(III) complexes (3, 14, 24) are not seen. Free Im has signals at δ 12.02 (H_1), 7.63 (H_2), and 7.00 (H_4 and H_5, these being equivalent due to tautomerization in solution); within complex **1**, H_1 shifts downfield to δ 12.47, H_2 upfield to δ 6.88, and H_4 and H_5 split into separate resonances at 6.22 and 7.23, respectively. The proximity of the H to Ru(II), a strong π-donor, determines whether the signal will be shifted upfield (as for H_2 and H_4), or downfield (as for H_5 and H_1). The ^{1}H spectrum for **2** shows the same trend, with H_5 shifting from δ 7.08 to 7.28, and H_2 and H_4 shifting upfield from δ 7.60 and 6.92 to 7.20 and 6.31, respectively; the N-Me signal shifts slightly downfield from δ 3.61 to 3.68. The resonances of the X-ray sample of complex **3** also followed the same trend: H_1 (δ 11.89 → 12.09), H_2 (δ 7.51 → 6.85), H_4 (δ 6.69 → 6.03), and 5Me (δ 2.16 → 2.40). Of note, the ^{1}H NMR data for the initially precipitated **3** (resonances for both H_4, H_5, and H_2 (overlapping), as well as overlapping Me resonances) most likely imply the presence of a 1:1 mixture of $[Ru(5MeIm)_6]^{2+}$ and $[Ru(5MeIm)_5(4MeIm)]^{2+}$ species; X-ray results show that $[Ru(5MeIm)_6]^{2+}$ preferentially crystallizes out. Clarke et al. (3) have noted similarly formation of complexes $[Ru(NH_3)_5(5MeIm)]Cl_3$ and $[Ru(NH_3)_5(4MeIm)]Cl_3$ in a 20:1 ratio from reaction of $[Ru(NH_3)_5(H_2O)]Cl_2$ with 4(5)MeIm in air. Our results also imply that there is a preference for formation of the less sterically demanding species, $[Ru(5MeIm)_6]^{2+}$.

Complexes **1–3** in MeOH show two UV bands: the higher energy absorbances come at 218, 224, and 228 nm, respectively, slightly higher wavelengths than those of the $\pi \rightarrow \pi^*$ transitions of the free ligands, but the ε values within the complexes are an order of magnitude greater than those of the free ligands. The lower energy UV maxima in **1**–**3** have ε values of (5.6–10.2) × 10^3 M^{-1} cm^{-1} and presumably correspond to an LMCT band (25, 26). Only complex **1** (which has a crystallographic centre of symmetry) has a band in the visible region (642 nm, ε = 33) typical of a *d–d* transition which is formally Laporte forbidden for an octahedral complex; however, in the presence of unsymmetrical vibrations the centre of symmetry can be destroyed, and vibronic transitions can be observed (25). Solutions of complexes **2** and **3** (which have crystallographic S_6 symmetry) do not exhibit an absorption maximum in the visible region.

The CV data for the Ru^{III}/Ru^{II} reduction potentials for **1** ($E°$ = 246 mV vs, Ag/AgCl) and **2** ($E°$ = 271 mV) in MeCN/TBAP compare with the values of 295 and 283 mV reported by Clarke et al. (3) for the Ru(III) salts $[Ru(Im)_6][ClO_4]_3$ and $[Ru(NMeIm)_6][PF_6]_3$, respectively, in aqueous chloride media. Our $E°$ value of 174 mV for **3**, the $(5MeIm)_6$ species, shows a relative stabilization of the Ru(III) state for this system.

Reaction of $[Ru(DMF)_6][CF_3SO_3]_3$ with 2MeIm

The reaction of 2MeIm, a more sterically demanding ligand than Im, NMeIm, and 5MeIm, with $[Ru(DMF)_6][CF_3SO_3]_3$ led to the isolation of a green solid (**4**), similar in appearance to complex **1**. However, **4** is formulated as *trans*-$[Ru(CO)(DMF)(2MeIm)_4][CF_3SO_3]_2$. The CO results from the decarbonylation of DMF, and the required co-product, dimethylamine, was detected. Such decarbonylation of DMF to generate metal carbonyls is well documented (27). An example analogous to that seen here is shown in eq. [1] (porp = porphyrin dianion) (28). It has

[1] $$Ru(porp)(DMF)_2 \rightarrow Ru(porp)(CO)(DMF) + Me_2NH$$

not been possible to obtain good elemental analysis or definitive NMR data for **4** because during attempts to remove associated DMF by pumping, the CO is removed to generate the brown complex $[Ru(DMF)(2MeIm)_4][CF_3SO_3]_2$ (**5**) and, of note, **4** can be regenerated by exposing solid **5** to 1 atm CO (see Scheme 1).

Complex **4** shows υ_{CO} bands in the IR at 2103 and 1654 cm^{-1} attributed to the CO and DMF ligands, respec-

tively (for free CO and DMF, these bands appear at 2143 and 1673 cm^{-1}). More typically, υ_{CO} values for Ru(II)-N donor systems are in the range ~ 2010–1920 cm^{-1} (29, 30), and it should be recalled that the υ_{CO} value is dependent on the medium used for measurement (for example, υ_{CO} values for $[Ru(NH_3)_5CO]^{2+}$ vary from 1993 to 1923 cm^{-1} depending on the associated anion and the medium) (29). A υ_{CO} value of 2008 cm^{-1} is seen for a *trans*-Ru(porp)$(CO)_2$ species; the mutually *trans*-π-acceptor carbonyls expectedly lead to a high υ_{CO} and a relatively labile CO ligand (30). For *tcc*-$RuCl_2(CO)_2(PPh_3)_2$, the *cis*-carbonyls are each trans to the π-acceptor phosphines and υ_{CO} values of 2059 and 1995 cm^{-1} are recorded (31). The π-electron density available from the Ru(II) for back-bonding to the CO of **4** must be minimal, resulting in the remarkably high υ_{CO} value of 2103 cm^{-1}, a weak Ru—CO bond, and high lability of the CO. We did consider that the 2103 cm^{-1} band might result from "occluded" rather than coordinated CO; however, we have been

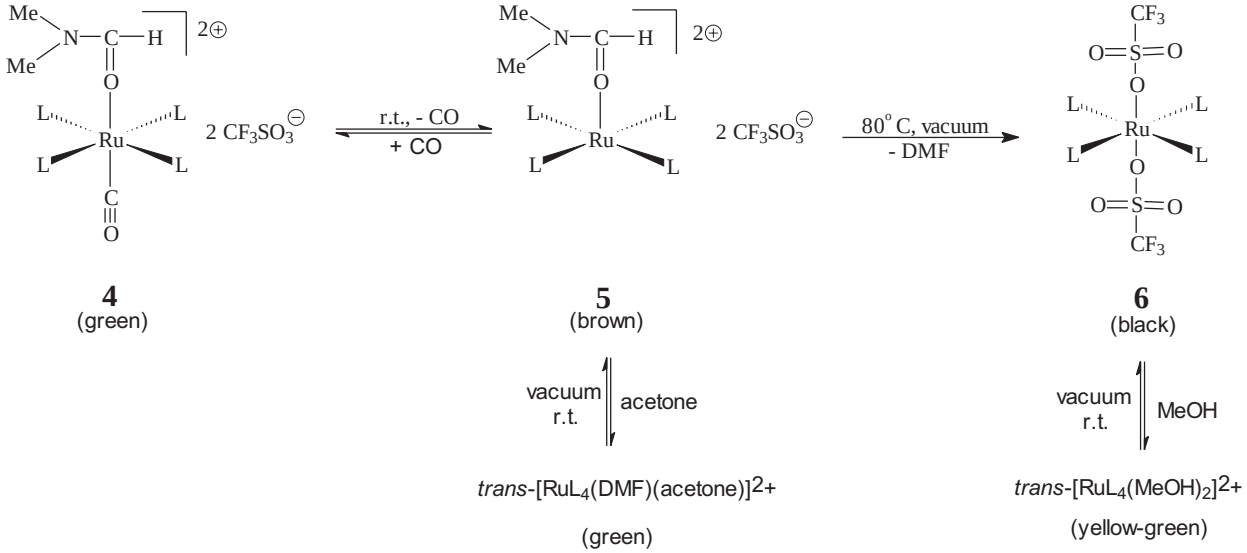
Scheme 1. Conversion of **4** → **5** → **6**, with suggested formulations (L = 2MeIm).



unable to find experimental evidence for this. The υ_{CO} value for the DMF in **4** is some 20 cm^{-1} below that of free DMF (υ_{CO} 1673 cm^{-1}), while that for $Ru(DMF)_6^{2+}$ is 1635 cm^{-1}. The IR spectrum of **5** is essentially identical to that of **4**, except the υ_{CO} for the CO has disappeared and υ_{CO} (DMF) has shifted to 1648 cm^{-1}, consistent with somewhat more π-back bonding available from Ru(II) to the carbonyl of DMF.

We have been unable to isolate an analytically pure sample of **5**, as its generation from **4** always leads to contamination by $[Ru(CF_3SO_3)_x(2MeIm)_4][CF_3SO_3]_y$ (**6**) (see below) which is formed from **5** by removing the coordinated DMF under vacuum (Scheme 1). Nevertheless, ^1H NMR data for samples of **5** reveal the existence of one coordinated DMF with inequivalent Me resonances at δ 3.22 and 3.10, and the formyl proton seen at δ 8.40 (these signals are downfield from those of free DMF and are comparable to those found for $[Ru(DMF)_6]^{2+}$) (16). The brown **5** reacts with acetone to give a green solution, and a singlet at δ 2.14 (downfield from that of free acetone, δ 2.04) is assigned to coordinated acetone; the acetone can be removed in vacuo to regenerate **5** (Scheme 1).

Complex **6** (Scheme 1) is obtained as an analytically pure solid; the black colour is unusual and we originally thought the complex might be $[Ru(2MeIm)_4][CF_3SO_3]_2$ containing tetrahedrally coordinated Ru. However, the NMR data and an Evan's method magnetic moment measurement (32) illustrate the diamagnetic character of **6**. On dissolution in MeOH, species **6** shows an immediate conductivity corresponding to a 1:1 electrolyte, but this increases over 3 h to a maximum Λ_M typical of a 2:1 electrolyte (33); during the conductivity measurements, the original black solution fades to a final yellow–green colouration, presumably due to *trans*-$[Ru(2MeIm)_4(MeOH)_2]^{2+}$. The data cannot distinguish between (*i*) **6** being a neutral, six-coordinate species with *trans*-triflate ligands, which on dissolution in MeOH immediately dissociates one triflate ligand, and then the second one is slowly displaced, and (*ii*) **6** being a five-coordinate species $[Ru(CF_3SO_3)(2MeIm)_4][CF_3SO_3]$ that in MeOH slowly loses the coordinated triflate. Of note, the measured υ_{SO} values for the triflate anion within $[Ru(DMF)_6][CF_3SO_3]_3$ and the $[RuL_6][CF_3SO_3]_2$ complexes **1**– **3** are seen at 1255, 1253, 1270, and 1263 cm^{-1}, respectively; in **6,** two IR bands are seen at 1280 and 1251 cm^{-1}, and such splitting could be consistent with the presence of coordinated triflate (34). Contrary to such reasoning, however, complexes **4** and **5** also show "split" bands in this region of the IR spectrum (1283 and 1249, and 1284 and 1248 cm^{-1}, respectively). Complex **5** could be reformulated as the six-coordinate species $[Ru(CF_3SO_3)(DMF)(2MeIm)_4][CF_3SO_3]$, but **4** cannot contain coordinated triflate. The measured υ_{CF3} values for **1**–**3** are seen at 1173, 1151, and 1170 cm^{-1}, while those for **4**–**6** were observed at 1167, 1167, and 1169 cm^{-1}, respectively, suggesting this IR band cannot be used as a diagnostic tool for the presence of absence of coordinated triflate. More definite evidence is needed to identify unambiguously species **4**–**6**. The incorporation of the sterically hindered 2MeIm ligand certainly enriches the chemistry of these Ru(II)-imidazole species.

Molecular modelling studies of a nerve growth factor receptor

Igor L. Shamovsky, Gregory M. Ross, Richard J. Riopelle, and Donald F. Weaver

Abstract: Using computer simulations, a geometry for the receptor binding site for nerve growth factor (NGF) has been proposed. Variable basis Monte Carlo simulated annealing calculations have been used to ascertain the structures of the complexes of four fully active NGF analogues with the second leucine-rich motif (LRM-2) of trkA, a putative binding site for NGF. The previously suggested bioactive conformation of the amino and carboxyl termini of NGF docks favourably with the receptor defined by the LRM-2 of trkA: only minor conformational changes take place in the NGF analogues upon docking. Extensive intermolecular van der Waals contacts arise from the geometric fit of the NGF binding domain to the LRM-2. Within this receptor environment, five distinct binding areas reveal a highly selective multiple-point NGF–trkA recognition based on hydrophobic, ionic, hydrogen bonding, and van der Waals interactions. Binding specificity is determined primarily by residues Lys^{100}, Asp^{109}, and Phe^{113} of trkA which bind to conserved NGF residues Asp^{16}, Arg^{114}, Lys^{115}, and Phe^{7}. An explicit atom-level model of the high-affinity NGF receptor is thus developed.

Key words: NGF, trkA, leucine-rich motif, protein docking, Alzheimer's disease.

Résumé : Utilisant les résultats de simulations par ordinateur, on propose une géométrie pour le site de liaison du récepteur pour le facteur de croissance des nerfs (FCN). On a utilisé des calculs de Monte Carlo à base variable pour évaluer les structures des complexes de quatre analogues actifs du FCN avec le deuxième motif riche en leucine («LRM-2») du trkA, a site de liaison putatif du FCN. La conformation bioactive proposée antérieurement pour les extrémités amino et carboxyle du FCN s'adapte favorablement au récepteur défini par le «LRM-2» du trkA: lors de la jonction, il ne se produit que de faibles changements conformationnels. Sur la base de l'ajustement géométrique du domaine de fixation du FCN au «LRM-2», il se développe d'important contacts de van der Waals intermoléculaires. Dans le cadre de l'environnement de ce récepteur, on observe que cinq portions distinctes de fixation donnent lieu à une reconnaissance FCN–trkA en plusieurs points et hautement sélective découlant d'interactions hydrophobes, ioniques, de liaisons hydrogènes et de van der Waals. La spécificité de la liaison est déterminée principalement par les résidus Lys^{100}, Asp^{109}, et Phe^{113} du trkA qui se lie aux résidus Asp^{16}, Arg^{114} et Phe^{7} préservés du FCN. On a ainsi développé un modèle explicite au niveau atomique du récepteur à grande affinité du FCN.

Mots clés : FCN, trkA, motif riche en leucine, jonction de protéines, maladie d'Alzheimer.

[Traduit par la Rédaction]

1. Introduction

Nerve growth factor (NGF), a protein involved in the pathogenesis of diverse neurological disorders, is the prototypical member of the neurotrophin family, which also includes brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4/5). Neurotrophins transduce intracellular signalling through the activation of a class of transmembrane tyrosine kinase receptor proteins (trkA, trkB, and trkC). Specificity of action of neurotrophins results from their selective interactions with members of the trk family of receptors: NGF–trkA, BDNF–trkB, NT-4/5–trkB, and NT-3–trkC, particularly when the trk's are coexpressed with the common neurotrophin receptor $p75^{NTR}$ (1–5). Explicit modelling of these receptors will be critical to the rational design of neurotrophin based drugs.

The NGF displays high and low affinity binding sites in sensory and sympathetic neurons and in pheochromocytoma PC12 cells (6–8). The coexpression of the common neurotrophin receptor $p75^{NTR}$ with trkA is required to form the high affinity binding site (9–12). Several models of the trkA–$p75^{NTR}$ interaction have been proposed to explain high

affinity NGF binding (12–17). These models differ with respect to direct (conformational model) or indirect (ligand-presentation model) interaction of $p75^{NTR}$ with trkA. Direct trkA–$p75^{NTR}$ interaction is consistent with much of the existing experimental data (12, 17).

While several regions of NGF participate in the NGF–trkA interaction (3–5, 18, 19), mutation studies suggest that relatively few key residues, namely those located in the NGF amino and carboxyl termini, are required for high affinity binding (1, 19–37). The amino and carboxyl terminal regions therefore represent a "functional epitope" which contains relatively few contact residues mediating high affinity binding. The ability of a small number of residues to cause high affinity binding has previously been demonstrated and may represent a general property of protein–protein interface (38). Although a crystallographic structure of NGF has been reported (39, 40), geometry of the important amino (residues 1–11) and carboxyl (residues 112–118) termini remain unresolved. Because of high flexibility of the NGF termini, it is difficult to determine *experimentally* their bioactive conformations, particularly since transition metal cations commonly used in X-ray crystallography (39, 40) have high affinity for His residues (41) and thus may affect conformation of the NGF amino terminus. Indeed, conformational alterations within the receptor binding domains of NGF caused by transition metal cations Zn^{2+}, Cu^{2+}, and Pd^{2+} (leading to inactivation of NGF) have been described recently (42, Ross et al., submitted). A bioactive conformation of the NGF termini has been obtained *theoretically* using variable basis Monte Carlo simulated annealing (VBMC) computations (43), providing a structure compatible with experimental observations.

The location of the binding site for NGF within the trkA receptor is the subject of debate (44). Based upon published data, there is reason to believe that two trkA interactive motifs in NGF may conform to two putative NGF binding sites on the trkA protein: the "second immunoglobulin-like domain" (IgC2, residues Trp^{299}–Asn^{365}) and the "second leucine-rich motif" (LRM-2, residues Thr^{97}–Leu^{120}) (18, 37, 44–49). The LRM containing proteins represent a diverse group of molecules with different functions and cellular locations, and are known to mediate strong and selective protein–protein interactions (50–52). The amino acid sequence of a LRM is characterized by conserved hydrophobic consensus residues (45, 50–53). Typically, LRMs exist as repetitive cassettes, with an individual LRM representing a right-handed β-α hairpin unit (50–52). Recent crystallographic studies on porcine ribonuclease inhibitor indicate that the side chains of the consensus residues form the hydrophobic core of the LRM modules, thereby determining their geometric features (50).

In this study we report an explicit atom-level model of the trkA receptor site for NGF. To deduce this model, we have investigated the interaction of the bioactive conformation of the NGF amino and carboxyl termini region with the LRM-2 binding site of trkA. A series of four active NGF analogues, namely human NGF (hNGF) (23, 32), mouse NGF (mNGF) (23, 28), the 3-9 deletion of mNGF (mNGFΔ3-9) (28) and the hNGF:NT-4/5 heterodimer (35), have been docked to the LRM-2 of rat trkA. For all four NGF molecules studied, a stereochemical fit of the LRM-2 to the amino and carboxyl region was demonstrated. These results suggest that the bioactive conformation of the NGF termini represent a functional epitope which mediates high affinity binding via an interaction with the LRM-2 of trkA.

2. Methods

A sequence of three logical steps has been used to deduce a model of the interaction of NGF with its trkA receptor binding site. *Step 1*: the bioactive conformations of the amino and carboxyl termini of NGF analogues were determined; *Step 2*: the residues of the trkA protein which form a potential binding site for NGF were identified; *Step 3*: the interaction of the bioactive conformation of the NGF amino and carboxyl termini with the trkA binding site was modeled computationally. Finally, the predicted features of the NGF–trkA interaction model were validated against available experimental data. For this study, residues of the first NGF monomer are designated 1 to 118, those of the second monomer are designated 1′ to 118′; the LRM-2 residues have double-primed numbering.

2.1. Step 1: revealing the bioactive conformation of the NGF termini

The most energetically favoured conformations of the amino and carboxyl termini of NGF analogues have been obtained by VBMC computations and have been reported previously (43). Since three-dimensional structures of the termini of fully active NGF molecules were different from those of trkA-inactive analogues, these conformations were predicted to be "bioactive" for trkA-mediated activity of NGF. This implies that those geometric features, which are exclusively inherent in active NGF molecules, are anticipated to be compatible with the structure of the trkA binding site for NGF.

2.2. Step 2: selection of the LRM-2 boundaries within the trkA receptor

Since there is controversy in the literature regarding the actual boundaries of LRMs (45, 48–53), the following experimental background (Fig. 1) was used to define boundaries for this computational study. According to Schneider and colleagues (45, 53), the LRM domains of trkA begin with $Leu^{68''}$, $Leu^{93''}$, and $Leu^{117''}$, whereas those boundaries are slightly shifted in the crystallographic studies of Kobe and Deisenhofer (50). Furthermore, the boundaries of the "minimal" LRM module of trkA (designated B4 in Fig. 1), which demonstrates the same NGF binding affinity as wild type trkA, is substantially shifted towards the carboxyl terminus (48, 49) with respect to those suggested by Schneider and colleagues (45, 53). However, a comparison of active (B1 and B4) and inactive (N4) LRM domains indicates that the presence of the minimal amino acid sequence (B4) does not ensure NGF binding. Understanding those factors which maintain the essential features of the LRM geometry in segments B1 and B4, but which destroy them in N4, is of fundamental relevance to the correct assignment of the LRM boundaries.

β-Strand motifs exist in proteins only if hydrogen bonded (H-bonded) to other β-strands; otherwise their structure is unstable (51). Tandems of LRMs represent a prominent ex-

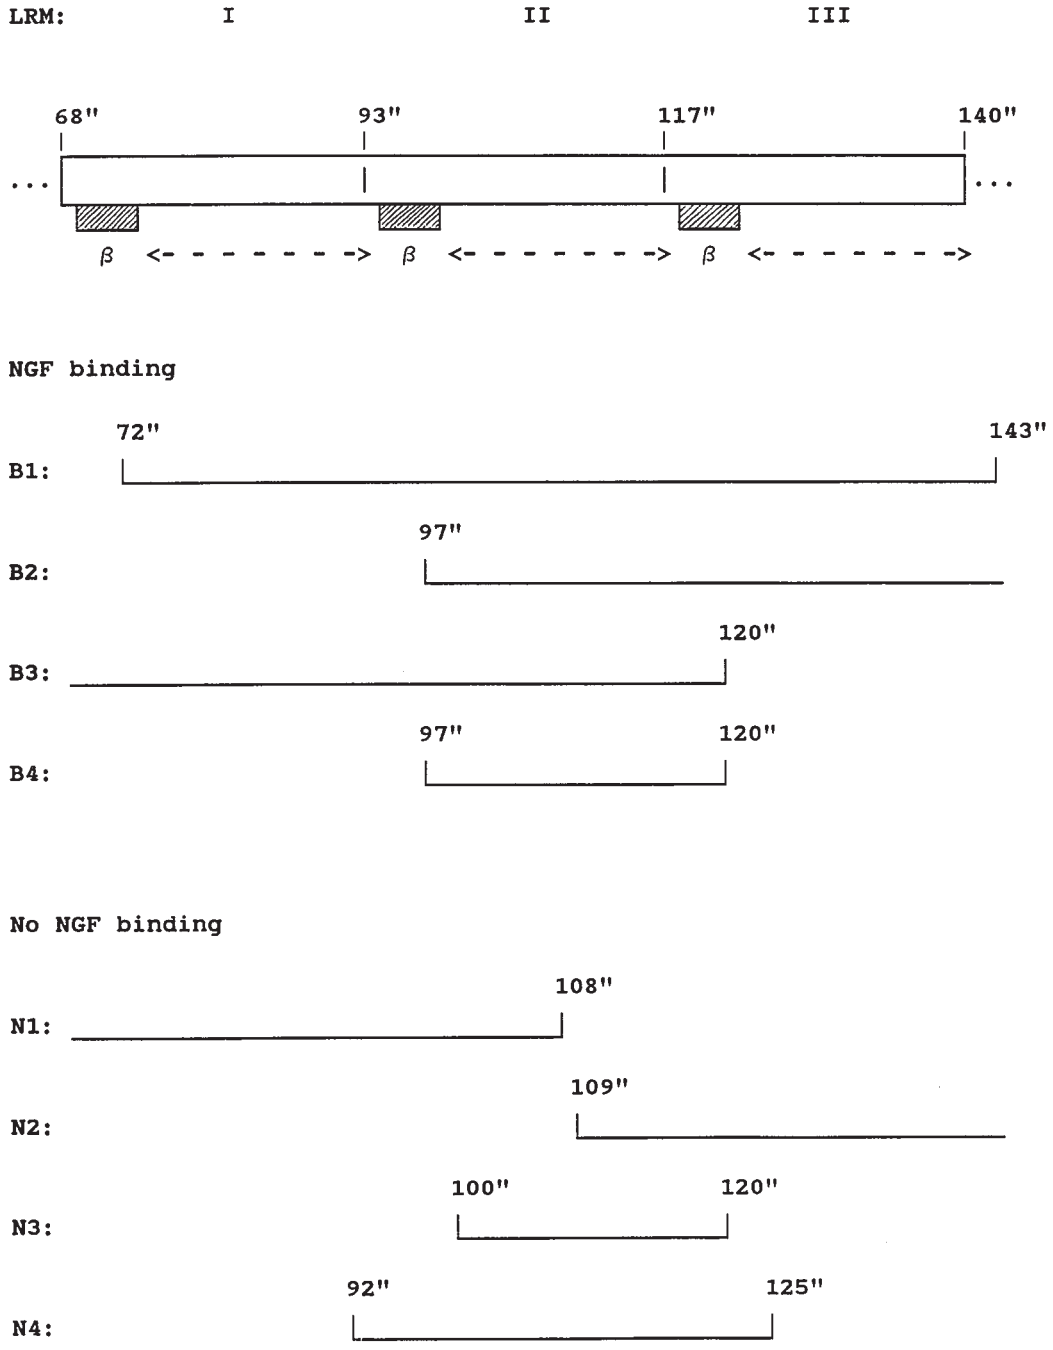
Fig. 1. The trkA leucine-rich motifs. Locations of parallel β-strands are illustrated by the shaded areas designated by symbol β. Fragments B1–B4 demonstrate NGF binding affinity, while N1–N4 do not (48, 49).



ample of H-bonded parallel β-strand motifs. The general location of the β-strand motifs in the LRM according to X-ray data is illustrated in Fig. 1; however, in a single LRM their particular geometry is destroyed (50–52). Consequently, disruption of the inter-strand H-bonding between β-strand motifs results in dramatic conformational changes, and the only way to preserve a characteristic geometry of a protein domain is to exclude those motifs. Accordingly, both boundaries of segment B4 are located in the middle of the β-strand regions of the adjacent LRMs such that this segment appears to be free of any β-strand. Nevertheless, the β-strand motif is a characteristic structural unit of LRMs, and thus it is likely that this unit is also involved in the NGF–trkA recognition process. Additionally, a short exposed β-strand motif has been detected in the bioactive conformation of the NGF termini (43). The incorporation of the β-strand regions at both sides of the B4 segment (as in N4) results in cooperative H-bonding between these β-strands and a complete loss of NGF binding, which indicates that accessibility of the β-strand motif for intermolecular contacts is essential. On the other hand, the separation of the entire LRM segment from the adjacent LRMs within the B1 molecule as a result of conformational kinking is likely to be energetically more favourable, since the entire LRM module has the internal sta-

© 1998 NRC Canada

bilizing factors. Moreover, kinking between the adjacent LRMs within the LRM tandem does not disrupt the structure of their β-strand motifs (since they remain H-bonded with their opposite sides), but makes them accessible for molecular recognition processes.

Accordingly, in the present study we used the conventional boundaries of the LRMs of trkA (45, 53), which keep the β-strand motif in the LRM, and we explicitly arranged H-bonding of this unit with the parallel β-strand motif of the NGF amino terminus (43) to preserve it from conformational reorganizations. Thus, the trkA segment between residues $Leu^{93''}$ and $Leu^{117''}$ was designated the LRM-2 of trkA.

2.3. Step 3: computational simulation of the NGF–trkA interaction

The docking interaction between the NGF termini (from Step 1) and the trkA receptor fragment (from Step 2) was simulated using a combined VBMC/CHARMM approach. VBMC is an algorithm which permits a search of conformational space (43); CHARMM is a force field which defines conformational energy (54). The goal of Step 3 was to investigate the stereochemical fit of the predicted bioactive conformation of the NGF binding determinant (43) to a putative trkA receptor binding site for NGF (48, 49) rather than to comprehensively explore the whole configurational space of the ligand–receptor complexes.

The VBMC algorithm performs conformational and orientational space searches of a complicated molecular system with the aim of finding the structure which corresponds to the global minimum on the potential energy E_{tot} surface. Periodical rotation of a basis of configurational variables in the framework of the VBMC algorithm results in directing individual Monte Carlo moves along the soft modes of a molecular system, which accelerates molecular motions and conformational transitions (43).

$$[1] \qquad E_{tot} = E_t + E_w + E_e + E_{hb} + E_{qq} + E_{hy} + E_c$$

The following potential energy terms have been considered in the framework of the united atom CHARMM force field (54; the force field parameters have been extracted from CHARMM version 23.1, Molecular Simulations Inc., San Diego, Calif.): torsional distortion E_t, van der Waals interactions E_w, electrostatic interactions E_e, and hydrogen bonding E_{hb}. Since the united atom approach is not appropriate to treat rigorously the quadrupole–quadrupole interactions of benzene rings (which are important for determining their mutual orientations in proteins (55, 56), single quadrupoles have been placed at the centers of the benzene rings of phenylalanine and tryptophan, and the energy of the quadrupole–quadrupole interactions, E_{qq}, has been calculated as suggested by Schauer and Bernstein (57). (The potential energy function of two interacting benzene molecules comprised of the E_{qq} and E_w terms has stationary points corresponding to both known electrostatically favourable "edge-to-face" and "offset stacked" orientations with the dimerization energy of 1.94 kcal/mol agreeing well with ab initio quantum mechanical calculations (58).) In addition, the conformationally dependent free energy of hydration, E_{hy}, has been calculated according to the hydration shell model including both nonspecific and specific hydration terms (59, 60). A dielectric constant equal to the interatomic separation in angstroms has been used to implicitly simulate solvation effects (61).

The E_c term represents the distance constraints which maintain the H-bonding pattern of residues Glu^{11}, His^{8}, and $Arg^{118'}$ inherent in the bioactive conformation of the NGF termini (three H-bonds; ref. 43). In addition, two intermolecular H-bonds, arising from the alignment of complementary parallel β-strand motifs of NGF and LRM-2, are also constrained and contribute to E_c. In the Monte Carlo conformational space search, E_c is defined as follows:

$$[2] \qquad E_c = 10 \times \sum_{AB} (d_{AB} - 1.8)^2$$

where d_{AB} is the distance in angstroms between selected atoms A and B which are to be H-bonded (the sum includes only five additives). The E_c term is neglected when performing final energy minimization following the VBMC simulated annealing. In addition, this term has not been utilized when studying the mNGFΔ3-9/LRM-2 complex. Since the mNGFΔ3-9 deletion mutant does not have a β-strand region (43), the geometry of its LRM-2 counterpart, namely $Leu^{93''}$-$Ile^{98''}$, has been kept fixed in the crystallographic conformation (50) during Monte Carlo simulations. The E_c term, being "soft," does not preclude conformational and orientational changes to occur during Monte Carlo simulations. This term increases rigidity of the bioactive conformation of the ligand, which allows us to utilize the knowledge obtained at Step 1 instead of explicit considerations of inactive NGF analogues in Step 3. In addition, this term keeps conformations of the β-strands of both ligand and binding site from destruction, and thereby allows us to avoid an explicit consideration of the adjacent first LRM of trkA. Furthermore, this term maintains the known orientation of the parallel β-strand motifs.

The amino acid sequences of the binding determinants of the NGF molecules under study are presented in Fig. 2. The conformational space of the NGF analogues consists of torsional angles determining geometry of the amino terminus of one monomer (residues 1–11) and the carboxyl terminus of the other (residues 112′–118′), while keeping the rest of the dimers in the experimental geometry of mNGF (39). The conformational space of the trkA LRM-2 consists of torsional angles representing fragment $Arg^{94''}$-$Leu^{117''}$. Covalent bond lengths and bond angles have been kept fixed. The geometry of each i-th residue is determined only by flexible torsional angles of the backbone (ϕ_i and ψ_i) and the side chain ($\chi_i 1$, $\chi_i 2$, ...). All torsional angles for prolines, except ψ_i have been fixed. Torsional angles describing structural motifs with planar geometries (such as peptide bonds or conjugated regions in side chains) were fixed. Likewise, the configurations of the sp^3-carbons were fixed. In addition to the conformational variables, the six orientational variables (three Euler angles and three translations along the coordinate axes) were used to describe the NGF/LRM-2 mutual orientations.

In accord with the simulated annealing approach (62–67), the molecular systems were kept at a constant temperature of 800 K for 2×10^6 Monte Carlo moves before the initiation of "cooling." The temperature was then decreased at every Monte Carlo move by a small increment such that after 2

$\times 10^6$ Monte Carlo moves it reached 120 K; at this time, a local energy refinement was performed to identify the nearest stationary point on the potential energy surface. According to the VBMC algorithm, the basis of independent structural parameters was recalculated after every 7×10^4 Monte Carlo moves to direct them along the valleys of the potential energy surface, thereby accelerating conformational and orientational changes (43).

All calculations were performed on an Indigo-2 Silicon Graphics workstation and an 8-node IBM Scalable POWERparallel 2 [SP2] high performance computer.

3. Results and discussion

3.1. Conformational flexibility within receptor environment

Five independent VBMC simulations from different initial configurations were performed for each of the four molecular complexes under study. Geometries of the NGF analogues consistent with their predicted bioactive conformations (43) were the same in all of these initial configurations. The initial three-dimensional structure of the peptide backbone of the LRM-2 was the same in the independent runs being consistent with the observed geometry of the LRM domains in porcine ribonuclease inhibitor (50), whereas initial conformations of the LRM-2 amino acid side chains were random. The elimination of the distance constraints after the stationary point was reached did not result in any noticeable conformational changes within the complexes. Although independent VBMC simulations did not always converge to the same geometry for the same molecule, the final structures differed insignificantly; i.e., the conformations of the peptide backbones remained unchanged with the exception of residues 1–3 of the NGF amino terminus and the terminal residue $Leu^{117''}$ of the LRM-2. The differences between the VBMC generated structures were located in side-chain conformations of a limited number of residues, specifically Ser^{1}, $Val^{117'}$ ($Thr^{117'}$ in mNGF), $Thr^{97''}$, and $Ser^{101''}$. These residues are not involved in intermolecular or intramolecular interactions, and do not affect the overall structures of the complexes.

A grid search of the internal space of the complexes using a "water molecule" spherical probe with 1.4 Å radius (68), as incorporated into the QUANTA program (QUANTA version 4.1, Molecular Simulations Inc., San Diego, Calif.) shows that there is no internal cavity available for a solvent molecule in the hNGF/LRM-2 complex. This explains the rigidity of the complex and demonstrates the optimum stereochemical fit of the hNGF amino-carboxyl termini complex to the LRM-2.

3.2. Specific binding areas within receptor environment

Comparison of the most stable structures of the different complexes (Fig. 3) shows their striking conformational similarity. In all molecules, ligand–receptor binding is caused by similar hydrophobic, ionic, H-bonding, and van der Waals interactions. There are five distinct areas (A–E) within the NGF/LRM-2 fit: areas A and B have hydrophobic interactions, areas C and D have ionic H-bonding, and area E has the cooperative H-bonding between parallel β-strand motifs.

Area A represents the hydrophobic region at which residue $Phe^{105''}$ interacts with $Trp^{76'}$, which in turn forms hydrophobic contacts with Phe^{12} and $Leu^{112'}$. The aromatic rings of Phe^{12}, $Trp^{76'}$ and $Phe^{105''}$ are approximately perpendicular to each other, which is energetically favourable (55, 56, 58). This particular geometry would create a hole within the

complex, if it was not filled by hydrophobic residue Leu$^{112'}$. In area B, Phe^{7} of NGF is placed within the hydrophobic core of the LRM-2, created by the consensus residues (45, 50–53). Similar to the favourable orientation of the aromatic residues in area A, the aromatic rings of Phe$^{111''}$ and Phe$^{113''}$ are perpendicular to that of Phe^{7}. On the other hand, residues Phe$^{111''}$ and Phe$^{113''}$ are not perpendicular to each other; their orientation instead resembles the favourable offset stacked geometry described by Hunter and others (55, 56, 58). As in area A, a hole created by the three neighbouring favourably oriented aromatic rings is filled by the fourth residue, Thr$^{114''}$. Interactions between aromatic rings in proteins are very common and represent an important conformational driving force for folding and molecular recognition processes (56, 69). Consequently, the fact that all three phenylalanine residues of the LRM-2 find their counterparts within the NGF binding domain supports the structure of the NGF/LRM-2 complex.

In ionic binding area C, the negatively charged residue Asp$^{109''}$ exerts a central role. It is surrounded by the three positively charged amino acids His$^{112''}$, Arg$^{114'}$, and Lys$^{115'}$ in hNGF, mNGF and mNGFΔ3-9, and by His$^{112''}$, Arg$^{115'}$, and Arg^{9} in hNGF:NT-4/5. Residue His$^{112''}$ plays a secondary role: it creates the electrostatic dipole Asp$^{109''}$→His$^{112''}$ in the LRM-2, which imposes constraints to the spatial positions of the recognized positively charged residues of NGF, thereby reinforcing geometric selectivity in this area. Although the hNGF:NT-4/5 heterodimer has two substitutions in the C-area segment of the NT-4/5 carboxyl terminus, namely R114S and K115R, the geometry of the C area remains qualitatively the same, since residues Arg^{9} and Arg$^{115'}$ of hNGF:NT-4/5 functionally replace the absent Lys$^{115'}$ and Arg$^{114'}$ amino acids, respectively. Although Arg^{9} also exists in the hNGF homodimer, it is not involved in the ionic binding in this molecule, since it is separated from area C due to electrostatic repulsions. Similarly, the charged amino end of mNGFΔ3-9, which functionally replaces Arg^{9} (43), is also separated from area C. There is no place for the fourth positively charged residue in area C. Thus, in all molecules under study the two positively charged amino acids of the ligand saturate the coordination possibilities of the receptor residue Asp$^{109''}$.

Area C is partially isolated from its surrounding environment by flanking hydrophobic residues Val$^{106''}$ and Pro$^{115''}$. Similarly, the principal charged residues of NGF, namely His^{8}, Glu^{11}, and Arg$^{118'}$ (43), are located between hydrophobic residues Ile^{6} (Val^{6} in mNGF), Val$^{111'}$ (Leu$^{113'}$ in hNGF:NT-4/5), and Val$^{99''}$ within the complexes. Thus, residues Val$^{99''}$, Val$^{106''}$, and Pro$^{115''}$ of the LRM-2 participate in "compartmentalization" of the principal ionic interactions of the complexes, thereby shielding them from the destructive influence of solvation.

The organization of ionic binding area D is similar to that of area C. Positively charged residues Arg^{59} and Arg^{69} are located in the vicinity of negatively charged Asp^{16} within the NGF structure (4, 39) such that the coordination of the latter is not full. The third positively charged residue, Lys$^{100''}$, comes from the LRM-2 to complete the Asp^{16} coordination. In addition to the ionic binding, residue Lys$^{100''}$ forms a H-bond with the Ser^{13} side chain.

Area E consists of the H-bonded parallel β-strand motifs of the LRM-2 and NGF (Fig. 3*b*, *c*, and *e*), each of them consisting of three peptide bonds. The LRM-2 β-strand motif is located between the α-carbon atoms of Asn$^{95''}$ and Ile$^{98''}$ whereas the NGF β-strand is situated between the α-carbons of the sixth and ninth residues. The locations of the β-strand regions in the uncomplexed LRM (50) and NGF (43) resemble those in the complexes considered. In the complexed LRM-2, the β-strand motif is shortened by one peptide bond at the amino end to accommodate the His^{4} side chain of NGF. On the other hand, the two peptide bond β-strand of the uncomplexed NGF is lengthened by one peptide bond at its amino end in the complexes.

3.3. Ligand–receptor interaction energy

Table 1 presents the components of the intermolecular energies of the NGF–trkA complexes. Stability of the NGF/LRM-2 complexes is primarily caused by attractive electrostatic and van der Waals interactions, with intermolecular H-bonding playing a secondary role. It should be noted, however, that in the framework of the molecular mechanics approach, the H-bonding energy is partially incorporated into the electrostatic interaction energy term, so the tabulated E_{hb} values reflect only part of H-bonding energy. Accordingly, intermolecular H-bonding is more important for the NGF/LRM-2 interaction than it appears in Table 1. On the other hand, the intermolecular component of the E_{qq} term seems to be insignificant. The reason for the latter is that the aromatic moieties of Phe^{7}, Trp$^{76'}$, Phe$^{105''}$, Phe$^{111''}$, and Phe$^{113''}$ are "preorganized" for intermolecular contacts with their counterparts in the complexes in electrostatically attractive geometry in which the quadrupole–quadrupole interaction energy term is not significant. In addition, hydrophobic ligand–receptor interaction energy is presumably extremely important for the NGF/LRM-2 complexation, but rigorous quantitative evaluation is currently not possible.

Since neither electrostatic interactions nor hydrogen bonding can significantly stabilize the ligand–receptor complex in a water environment, the stability of the complex is generally caused by van der Waals and hydrophobic interactions (38). Considerable contribution of intermolecular van der Waals interaction energy E_w (Table 1) arises from the geometric complementarity of the NGF binding domain and the trkA recognition site, such that the high value of the E_w term is due to the large number of intermolecular van der Waals contacts. This complementarity is a consequence of the right-handed twists of both the NGF amino-carboxyl termini complex and the LRM-2, since this geometric feature is characteristic for each of these domains in both uncomplexed (43, 50) and complexed conformations. Thus,

purely geometric ligand–receptor compatibility together with the distinct hydrophobic contacts play a crucial role in the NGF–trkA recognition, while attractive electrostatic interactions and H-bonding further reinforce specificity of binding, which is in agreement with generalizations made by Clackson and Wells (38).

3.4. Induced conformational changes

Conformations of the NGF amino and carboxyl termini remain almost the same after complexation with the LRM-2 (compare Fig. 3*a* with Fig. 3*b–e*). A few local conformational changes occur in the $Arg^{114'}$ and the $Lys^{115'}$ side chains, and in the backbones of residues Ser^{2} and Phe^{7}. As demonstrated previously (43), conserved charged residues $Arg^{114'}$ and $Lys^{115'}$ do not participate in principal intermolecular interactions within the NGF termini but are expected to form ionic intermolecular contacts with the trkA binding site. Indeed, these are the intermolecular ionic NGF/LRM-2 interactions in area C, which change considerably the side-chain conformations of $Arg^{114'}$ and $Lys^{115'}$ while keeping their backbone geometry intact. The LRM-2-induced conformational changes in residue Phe^{7} are caused by the intermolecular H-bonding in area E while the geometry of Ser^{2} is slightly changed to accommodate the LRM-2 residue $Thr^{114''}$. The rest of the structure of the LRM-2-complexed NGF termini retains the minimal energy conformation of the uncomplexed molecules because it is controlled by multiple intramolecular H-bonds (43). Consequently, the geometry of the NGF termini is "preorganized" for complexation with the LRM-2, and only local conformational changes, primarily in residues $Arg^{114'}$ and $Lys^{115'}$, occur upon complexation. Geometric "preorganization" of the NGF termini as a ligand for binding to a leucine-rich motif is consistent with X-ray studies of Kobe and Deisenhofer (52), who have demonstrated that ribonuclease A maintains a fixed geometry upon binding to the LRMs of ribonuclease inhibitor.

Figure 4 illustrates the isolated structure of the LRM-2 from the hNGF/LRM-2 complex. As seen, the side chains of the general consensus residues, $Leu^{93''}$, $Leu^{96''}$, $Ile^{98''}$, $Leu^{103''}$, and $Phe^{111''}$ (45, 53), form the hydrophobic core, similarly to their conformations in intact leucine-rich repeats (50). Terminal consensus residue $Leu^{117''}$ is solvent-exposed due to a boundary effect. Amino acids $Ala^{107''}$, $Pro^{108''}$, $Ala^{110''}$, and $Phe^{113''}$ are also incorporated into the LRM-2 hydrophobic core. On the other hand, residues $Val^{99''}$, $Phe^{105''}$, $Val^{106''}$, and $Pro^{115''}$ are not involved in hydrophobic interaction with the core, and seem to have their specific roles in the trkA recognition site. The most hydrophilic residues of the LRM-2, namely $Arg^{94''}$, $Lys^{100''}$, $Arg^{104''}$, $Asp^{109''}$, $His^{112''}$, and $Arg^{116''}$ are exposed from the hydrophobic core in the complexes. Amino acids $Lys^{100''}$, $Asp^{109''}$, and $His^{112''}$ participate in specific intermolecular interactions while the other three are solvent-exposed. The reasonable location of the hydrophobic and hydrophilic residues of the

LRM binding sites			**A**									**C**	**C**			

LRM-2 within the NGF/LRM-2 complexes with respect to water environment supports their structures.

The NGF/LRM-2 binding spans almost the whole LRM-2 domain, i.e., the residues between $Leu^{94''}$ and $Pro^{115''}$ which is comprised of three distinct regions: the β-strand, the α-helix, and the loop connecting the carboxyl terminus of the β-strand and the amino terminus of the α-helix (49–51). This is in agreement with recent crystallographic studies on the ribonuclease A – porcine ribonuclease inhibitor complex (52) in which these particular regions of leucine-rich repeats of ribonuclease inhibitor are also involved in the molecular recognition process. While the β-strand structure exists in the complexed LRM-2, the α-helix motif is destroyed by intermolecular interactions with NGF. Accordingly, the LRM-2 β-strand determines the proper orientation of the ligand with respect to the trkA recognition site but does not undergo noticeable conformational changes. Consequently, the cooperative ligand–receptor H-bonding in area E cannot directly mediate those changes in the receptor conformation which trigger receptor phosphorylation processes. Available experimental data confirm this point. First, the mNGFΔ3-9 deletion mutant, which does not have the β-strand motif (43), and consequently, cannot specifically bind area E, is as active as wild type mNGF (28). Second, the 24-residue LRM fragment $Thr^{97''}$-$Leu^{120''}$ lacking the β-strand region (50), demonstrates the same kinetics of binding to NGF as wild type trkA (48, 49).

3.5. Principal amino acids involved in NGF–trkA recognition

The amino acids of NGF which are primarily responsible for maintaining bioactive conformations (39, 43) or which directly participate in the NGF–trkA recognition are specified in Fig. 5. Almost all residues of the amino and carboxyl termini of NGF as well as the $His^{75'}$-$Asn^{77'}$ region are involved in specific intra- or intermolecular interactions. Only five amino acids of the 30-residue binding domain of NGF do not seem to be essential for either maintaining its bioactive conformation or binding to the trkA recognition site. These include Ser^{1}, Ser^{2}, Ser^{3}, $Ala^{116'}$, and $Val^{117'}$.

The observation that the important amino acids of the NGF binding domain are conserved across all species while the unnecessary five residues are variable (Fig. 5) (39) supports the particular structural features of the NGF/LRM-2 complexes. There are, however, exceptions which require explanation. In most cases principal amino acids of NGF molecules derived from different species appear to be substituted by similar residues, e.g., I6V, F7L, L112I, S113T, or R114K; in some special cases the substituent is quite different but the particular substitution is still consistent with the present model, e.g., R9M, R9L, or R118Q (39, 43); in the case of the H8N substitution (39), histidine and asparagine have the same topology with respect to H-bonding to the Glu^{11} carboxyl oxygen (43). The structure of snake NGF (sNGF) requires special consideration. Principal hydropho-

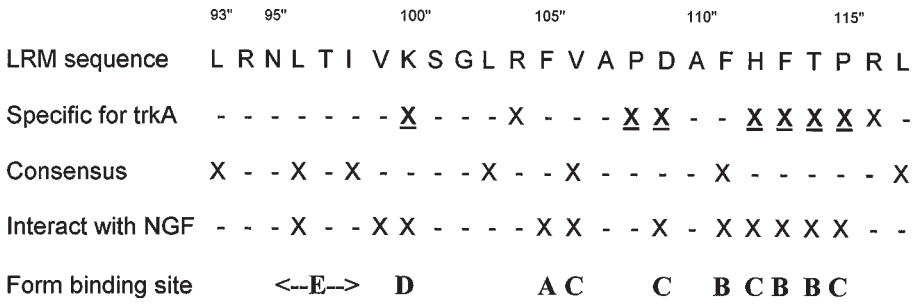
Fig. 6. Principal residues of the LRM-2 of trkA. The residues which are specific for trkA (48, 49) and critical for the present model are designated by X and **X**, respectively.



bic residues Phe[7] and Phe[12] are replaced by histidine residues in sNGF. Although these mutations could be accompanied by structural differences in snake trkA, they are consistent with the present model. According to the survey of Warme and Morgan (69), side-chain interactions of histidine with tryptophan or threonine are very common in natural proteins, which implies the existence of specific inter-residue affinities. This being the case, attractive interactions His[7]···Thr[114″] and His[12]···Trp[76′] in areas B and A, respectively, may replace corresponding hydrophobic interactions with Phe[7] and Phe[12].

The principal residues of the LRM-2 are shown in Fig. 6. The general consensus residues (45, 53) maintain the specific geometry of the LRM (50–52). The amino acids which form the distinct binding areas are involved in specific intermolecular interactions with the NGF binding domain. Since NGF does not activate the trkB receptor, those residues which are specific for the trkA receptor have been postulated to be directly involved in the NGF/LRM-2 recognition (48, 49). As seen, the LRM-2 segment has nine specific residues, seven of them directly participating in the NGF/LRM-2 recognition in the framework of the present model. Thus, Lys[100″] binds Asp[16] in area D, Pro[108″] is completely buried inside the NGF/LRM-2 complexes, residues Asp[109″], His[112″], and Pro[115″] form binding area C, and residues Phe[113″] and Thr[114″] are involved in forming area B. The other specific residues, Arg[104″] and Arg[116″], do not seem to be required for specific NGF/LRM-2 interactions. It is seen, furthermore, that binding areas A and E are not specific for the trkA recognition site, which unequivocally indicates that binding specificity of the LRM-2 is determined by Lys[100″], Asp[109″], and Phe[113″]. The fact that these particular amino acids are replaced in the trkB recognition site by residues of a different chemical nature, namely Asp[100″], Lys[109″], and Lys[113″], respectively (48, 49), which makes corresponding NGF–trkB binding absolutely impossible, supports the predicted details of the NGF/LRM-2 recognition. Principal residue Phe[105″], although being common both to trkA and trkB recognition sites (48, 49), is also important for the NGF–trkA recognition process, since oxidation of its counterpart, Trp[76], results in a complete loss of the receptor binding (70).

3.6. Explanation for structure–activity relationships

The trkA mediated activity has been evaluated for 27 point and deletion mutants of the trkA binding domain of NGF: hNGF (23, 32), mNGF (23, 28), mNGFΔ3-9 (28), (1-120)hNGF (71), (1-120)mNGF (25), (1-117)hNGF (71), and hNGF:NT-4/5 (35) retain full activity; mNGFΔ2-8, mNGFΔ61-66 (28), hNGF-R9A, hNGFΔ1-5, and hNGF-P5A (32) demonstrate intermediate potency; hNGFΔ1-9 (23–25, 28, 32, 34), mNGFΔ1-8 (22, 23), mNGFΔ1-9, mNGFΔ9-13 (36), mNGFΔ3-8, mNGFΔ3-11, mNGFΔ3-12, mNGFΔ3-13, mNGFΔ3-14, mNGFΔ9-14, mNGFΔ112-118 (28), hNGF-H4A, hNGF-H4D (32), BDNF (26), and NT-4/5 (35) are almost or completely inactive. The present model of the NGF/LRM-2 recognition enables a comprehensive explanation for the structure-activity relationships.

As demonstrated, fully active hNGF, mNGF, and hNGF:NT-4/5 fit perfectly to the five binding areas A–E of the trkA recognition site, while the mNGFΔ3-9 deletion mutant fits only to A, C, and D, without any specific binding taking place in areas B or E. Therefore, there are three common geometric features of the four fully active molecules which distinguish them from the less active analogues. *First*, conformations of the amino and carboxyl termini of these NGF analogues are "preorganized" for binding to the principal LRM-2 binding areas A, C, and D. *Second*, there is no stereochemical incompatibility in the binding areas B and E. *Third*, there is no hole inside the NGF/LRM-2 complexes.

The structures of the other three fully active NGF analogues, (1-120)hNGF, (1-120)mNGF, and (1-117)hNGF, are consistent with the above criteria. Indeed, since the NGF carboxyl end is located on the surface of the NGF/LRM-2 complexes (Fig. 3) and does not directly participate in principal intermolecular interactions, the lengthening of the NGF carboxyl terminus by the two amino acids does not explicitly affect the NGF/LRM-2 compatibility. As far as the (1-117)hNGF molecule is concerned, terminal residue Arg[118′] of NGF has been shown to form the inter-chain ionic H-bonds with Glu[11] (43), and, hence, seems to be important in maintaining the structure of the NGF bioactive conformation. On the other hand, there is the second factor stabilizing the bioactive conformation of the hNGF termini, namely inter-chain H-bonding of residue Arg[9] (43). Because of the latter binding, the above criteria are still fulfilled for (1-117)hNGF.

The deletion of the principal residue Phe[12] participating in hydrophobic interactions in area A results in a substantial loss of trkA mediated activity of the mNGFΔ3-12, mNGFΔ3-13, mNGFΔ3-14, and mNGFΔ9-14 deletion mutants (28). Likewise, the absence of the principal residues Arg[114′] and Lys[115′] essential for the ionic binding in area C is the reason for the dramatic loss of bioactivity of mNGFΔ112-118 (28). Similarly, geometric perturbations of the essential residues Arg[59] and Arg[69] in the mNGFΔ61-66 deletion mutant results in the incomplete NGF/LRM-2 com-

© 1998 NRC Canada

patibility in area D and, accordingly, a considerable loss of activity.

The specific location of the NGF ninth amino acid side chain in the "hollow" existing on the surface of the NGF rigid region has been predicted to be critical for high trkA mediated activity (43). The present study provides a detailed explanation for this prediction. Indeed, the hollow is buried inside the NGF/LRM-2 complexes, and a moiety located in this hollow fills the cavity which otherwise would exist inside the complexes and destroy the NGF/LRM-2 compatibility. Since this moiety is therefore located in the internal cavity of the complexes (Fig. 3), very severe limitations are imposed on its size. Accordingly, a short side chain does not fill this cavity; therefore, the hNGF-R9A mutant demonstrates noticeably diminished activity (32). This cavity should be filled either by a bulky amino acid side chain, such as arginine (e.g., hNGF), methionine (e.g., mNGF) or leucine (sNGF), or by the two residue peptide backbone (mNGFΔ3-9 or mNGFΔ2-8) (43). A longer amino terminus tail (e.g., in mNGFΔ3-8, mNGFΔ9-13 or mNGFΔ1-5) cannot be accommodated in the internal hole of the NGF/LRM-2 complex, and hence, interferes with binding areas B and E. In this case, most deletion or point mutations of the NGF amino terminus destroy the exposed β-strand motif Phe^7-Arg^9 and change the proper orientation of the Phe^7 side chain, thereby affecting the NGF/LRM-2 compatibility in areas B and E. Thus, incorporation of a negatively charged residue into the relatively long NGF amino terminus, as in hNGF-H4D, BDNF, NT-3, and NT-4/5, or substitution H8R, which is characteristic for BDNF and NT-4/5, has been demonstrated to cause dramatic conformational changes in the complex of the amino-carboxyl termini (43), which makes it inconsistent with the LRM-2. This is the stereochemical incompatibility of the geometry of the NGF amino terminus with binding areas B and E of the LRM-2, which is the reason for the partial or complete loss of the trkA related activity of mNGFΔ3-8, mNGFΔ1-5, hNGF-P5A, hNGF-H4A, hNGF-H4D, mNGFΔ1-8, hNGFΔ1-9, mNGFΔ1-9, mNGFΔ9-13, mNGFΔ3-11, BDNF, and NT-4/5.

As demonstrated, both NGF monomers are directly involved in specific ligand–receptor interactions, i.e., the first monomer binds areas B, D, and E, whereas the second one binds A and C. Consequently, the dimeric structure of NGF is necessary to retain high biological activity, which is consistent with experimental data (72).

In addition to the described structure–activity relationships, new data have been recently reported. The importance of residues Phe^7 (73), Leu^{112}, Arg^{114}, and Lys^{115} (74) for trkA mediated activity of NGF has been experimentally established, which is consistent with their participation in the specific NGF/LRM-2 binding in the framework of the present model.

3.7. Explanation for the NGF–trkA receptor binding kinetics

The results presented permit a plausible explanation for the kinetic properties of the NGF–trkA binding in the framework of the conformational model of the trkA–$p75^{NTR}$ interaction (11, 12). The low and high affinity binding sites of trkA are characterized by the same dissociation, but different association kinetics of NGF binding such that the latter binds NGF with a 25-fold higher rate of association k_{+1} (11). This observation invokes a hypothesis that the different NGF–trkA association kinetics might be caused by the same trkA module (48, 49), which is considerably more accessible when trkA and $p75^{NTR}$ receptors are coexpressed. In accord with this, since the LRM-2 of trkA is flanked by the adjacent LRMs in the LRM_3 cassette (45, 48, 49) and taking into account the tight packing of adjacent LRMs within LRM tandems (50–52), we would conclude that the trkA LRM-2 when not coexpressed with $p75^{NTR}$ is less accessible for direct intermolecular interactions with the NGF binding domain. On the other hand, interactions between trkA and $p75^{NTR}$ (15–17) could result in kinking between the second and the third LRMs of trkA, making the LRM-2 more accessible for NGF binding as manifest by a more rapid rate of association. This being the case, the LRM-2 with the predicted geometric features could represent one of the high affinity binding sites of trkA for NGF consistent with experimental data of Windisch and colleagues (48, 49).

4. Conclusions

The complexes of the amino and carboxyl termini of the four fully active NGF analogues with the second leucine-rich motif of trkA were obtained using variable basis Monte Carlo simulated annealing calculations. The structural features of the resulting NGF–trkA binding are supported by the following: (*i*) geometric and electronic complementarity of the binding domains of NGF and trkA without considerable conformational changes; (*ii*) appropriate environments for hydrophobic and hydrophilic residues within the complexes; (*iii*) analysis of structural variability of both binding domains; (*iv*) comprehensive explanation of currently published structure–activity relationships. Within these complexes, NGF–trkA molecular recognition is based upon multiple-point intermolecular interactions of hydrophobic, van der Waals, ionic, and hydrogen bonding origin. Extensive intermolecular van der Waals contacts arise from complementarity of the NGF binding domain and the trkA recognition site in size and shape. In addition, there are five specific binding areas within the receptor model: hydrophobic A and B, ionic C and D, and cooperative hydrogen bonding E. The NGF–trkA stereochemical compatibility in areas A, C, and D are essential for trkA receptor activation whereas areas B and E reinforce binding specificity, which makes the NGF molecule a very sophisticated key triggering the chain of biological events following receptor phosphorylation. The three-dimensional structures of the binding domains of the fully active NGF analogues are preorganized for stereochemical fit to the second leucine-rich motif of trkA. The predicted mechanism of high affinity NGF–trkA binding is consistent with the conformational model of trkA–$p75^{NTR}$ interactions (12).

Supporting information available: The full three-dimensional coordinates (in PDB format) of the complexes under study, and the optimized torsional angles of free and complexed NGF termini (Table 1S) and the complexed LRM-2 (Table 2S) are available on the WWW site: http://www.chem.queensu.ca/faculty/weaver/weaverpub.html.

Temperature dependence of self-entanglements in protein backones near the glass-like transition

Gustavo A. Arteca and Denise I. Caughill

Abstract: Many proteins undergo a phase change whereby catalytic activity is switched on at a glass-transition temperature T^* ~ 200 K. Over T^*, large anharmonic motions dominate, most particularly on atoms coupled to the hydration layer. These changes are detectable in the positional disorder, e.g., in the Debye–Waller thermal *B*-factors. Yet, the glass transition is not detected in descriptors of backbone mean shape, e.g., the molecular size. In this work, we show that other descriptors of mean shape may be better at detecting the transition. We suggest that a property that uses the equilibrium geometry *and* the backbone connectivity can exhibit larger variations with thermal fluctuations. In particular, we contrast the effects of bond length fluctuations on the mean number of overcrossings and the radius of gyration. Using the glass transition of ribonuclease-A as a test example, we show that the change in Debye–Waller factors is also reflected in the mean overcrossing numbers computed with the backbones. The approach can be used to follow other configurational transitions and to assess the effect of various external perturbations.

Key words: Molecular shape fluctuations, isotropic temperature factors, anharmonic vibrations, glass phase transition, flexible molecular chains.

Résumé : Quelques protéines montrent une transition de phase de verre où l'activité catalytique émerge après une température T^* ~ 200 K. Au-dessus T^*, les mouvements sont principalement anharmoniques, spécialement chez les atomes couplés à la couche d'hydration. Ces changements sont détectables dans le désordre positionnel avec les facteurs de Debye–Waller. Par contre, la transition n'est pas visible avec des descripteurs de la forme moyenne, p. ex., la taille. Ici nous montrons que d'autres mesures de la forme moyenne offrent une meilleure alternative pour détecter la transition. On propose qu'une propriété qui dépend de la géométrie *et* de la connectivité de la chaîne peut varier trop avec les fluctuations thermiques. En particulier, nous étudions l'effet des fluctuations sur le rayon de gravité et les enchevêtrements. En suivant la transition chez la ribonuclease-A, on voit que le changement des facteurs de Debye–Waller est accompagné par un saut dans le nombre moyen des croissements. La méthode est applicable à l'étude d'autres transitions configurationnelles et à la mesure de l'effet des perturbations extérieures sur une protéine.

Mots clés : fluctuations de la forme moléculaire, facteurs de témperature isotrope, vibrations anharmoniques, transition de phase de verre, chaînes moléculaires flexibles.

[Traduit par la Rédaction]

Introduction

Proteins exhibit a wide scale of atomic motions (1–4). The flexibility of a protein is manifested in motions ranging from localized vibrations (with $\bar{\nu}$ ~ 2000 cm^{-1} as typical wave numbers) up to extended vibrational modes affecting the folding of entire domains (whose wave numbers are $\bar{\nu}$ < 30 cm^{-1}) (4, 5). These motions play an important role in various aspects of protein function. Large amplitude rearrangements are known to accompany the binding of some substrates or inhibitors at room temperature (6, 7). As the temperature changes, however, the range of accessible motions is greatly affected (8–14). The effect is especially strong on localized small amplitude vibrations (11–13). In this work, we deal with the characterization of the extent of these motions. In particular, we study whether the effect of temperature on the large-scale protein shape can be extracted by using *descriptors of the mean shape of the backbone*.

Classic experiments on myoglobin using Mössbauer spectroscopy (15,16) and elastic incoherent neutron scattering (11, 12) show the existence of a phase transition at T^* ~ 200 K, below which the enzymatic activity is suppressed. A similar phenomenon is found in other proteins (13, 17–19). This transition is accompanied by a shift in the amplitude of the atomic motions. At low temperature ($T < T^*$), the protein exhibits localized *harmonic* vibrations, whereas extended *anharmonic* vibrations are found at $T > T^*$. This change (sometimes referred to as "dynamical transition") is analogous to a *glass transition*. Below T^*, the structure is locked in conformationally frustrated local energy minina; over T^*,

the structure has a larger degree of conformational flexibility and a liquid-like behaviour.

This single-molecule "phase transition" can be recognized as a biphasic behaviour in descriptors of positional disorder, e.g., the isotropic (or Debye–Waller) temperature *B*-factors. (These are proportional to mean-squared displacements, $B = 8\pi^2\langle\langle(\Delta r)^2\rangle\rangle$, where $\langle\langle\ \ \rangle\rangle$ indicates an average over all nuclei.) These parameters can be evaluated experimentally (11–13) and in computer simulations (20). (For a comparison between the results derived by the two approaches, see ref. 19.) The experiments show that *B* rises rapidly when $T > T^*$ (13). Consistently, molecular dynamics simulations indicate a rapid change in the average number of conformational "jumps" among dihedral torsions (20). These jumps are virtually absent for $T < T^*$, but they increase exponentially for temperatures over T^*.

The above descriptors measure *fluctuations* about an equilibrium geometry at a given temperature. However, they provide little information as to the extent of any reorganizations in the *average three-dimensional (3D) equilibrium geometry.* Whereas it is clear that temperature effects can be extracted from dynamic information or thermal noise, detecting these transitions with standard backbone shape descriptors seems elusive (13, 20, 21). Here we address the question: *Is there an alternative 3D descriptor of average molecular folding that exhibits a change at the glass transition similar to that in the* B-*factors*?

To address this question, we must pay attention to the effect of temperature on various atomic positions. Fluctuations appear to be particularly large within the hydration layer. A biphasic behaviour is also observed in the $\langle\langle(\Delta r)^2\rangle\rangle$ values for side-chain atoms and, to a smaller extent, in main-chain atoms (13). However, the size of the protein (as measured by the backbone radius of gyration, R_G) shows typically a *smooth* marginal swelling of ca. 3% over the temperature range 100–300 K. In other words, the glass transition at $T^* \sim$ 200 K is not reflected in R_G. This is not unexpected since R_G depends only on *mean* positions, and these may be little affected by thermal fluctuations or "breathing" modes of the protein. However, there are other descriptors of mean shape that contain more information than R_G, and these can potentially exhibit larger variations near the glass transition.

In this work, we deal with the temperature effect on shape descriptors that depend on *both* atomic positions and backbone connectivity. In particular, we use a measure of "self-entanglements" in protein backbones, the *mean overcrossing number* $\overline{N}$ (or average crossing number) (22–24). Qualitatively, this descriptor can be thought as the extension to single chains of the notion of entanglements in a polymer melt. In our case, we regard a single polymer conformation (e.g., the protein backbone) as a chain immersed in a "virtual," highly viscous medium. Here, over a period of time, the chain's dynamical and structural properties will be determined by the instantaneous entanglements among its own loops. Quantitatively, $\overline{N}$ is simply the number of bond–bond intersections ("double points" or "overcrossings") in a planar projection of the polymer chain, averaged over all planes in three-space. (The symbol $\bar{a}$ indicates that the property "*a*" is averaged over all projections.) The resulting number $\overline{N}$ is a *geometrical* descriptor of global molecular shape: rod-like chains exhibit $\overline{N} = 0$, whereas $\overline{N}$ is maximized in "collapsed" (or "poor-solvent") chain configurations.

The scaling behaviour of $\overline{N}$ as a function of the monomer number has been discussed in the literature for random polymers (25–28) and proteins (25, 29). Using these results, it is possible to view $\overline{N}$ (and also the related maximum overcrossing probability) as an order parameter to compare the folding features of different polymers (30). Recently, the time-averaged values of $\overline{N}$ (computed from molecular dynamics trajectories) have been used to monitor premelting transitions in alkanes (31) and the shape stability of short helical peptides (32, 33). The results indicate that the mean overcrossing number can provide information about the onset of conformational transitions. Here, we employ $\overline{N}$ to study how thermal fluctuations affect the mean shape of protein native states.

The work is organized as follows. In the next section, we discuss some analytical properties of $\overline{N}$ for simple chains. Some of these properties suggest that $\overline{N}$ should indeed be more sensitive than R_G to thermal fluctuations or breathing modes. In a following section, we apply these ideas to the glass transition in bovine pancreatic ribonuclease-A. As far as we know, this protein is the only example in the Brookhaven Protein Data Bank (PDB) where several X-ray structures are available over an extended temperature range. The section compares the thermal behaviours of R_G and $\overline{N}$ for ribonuclease-A. We conclude with possible extensions of our method to analyze the effect of external perturbations (e.g., temperature, pH, ionic force) on proteins and their hydration layer.

Measure of self-entanglements in polymer chains with fluctuating bond lengths

The mean overcrossing number $\overline{N}$ is a geometrical descriptor of polymer shape (24). It can be defined for single polymers with arbitrary architecture (34) and also for a network of polymer chains (35). There is a great deal of interest on overcrossing numbers and related properties (e.g., the *writhe* of a curve) as descriptors of complexity in entangled polymers. Although these geometrical measures are not topological invariants, they discriminate between some polymer topologies. For example, it has recently been shown that the mean overcrossing number of the "ideal" conformation of variously knotted DNA strands correlates with diffusion velocities in gel electrophoresis (36, 37). (An ideal conformation is that of a knotted tube with maximum diameter to length ratio.) To some extent, $\overline{N}$ (or its time average, $\langle\overline{N}\rangle$) behaves as a "weak" topological invariant that can be used for knot classification (36–38). Similar correlations between knot complexity and the writhe have also been discussed in the literature (39). In our case, we deal with the extension of these descriptors to a single open polymer chain. In this case, the chain can be *thought of as "dynamically" entangled with itself*. Such a chain does not form knots, yet when studied with molecular dynamics, it behaves as if it were entangled within its own loops over a period of time.

From the computational viewpoint, $\overline{N}$ can easily be evaluated numerically (24). The simplest approach is to enclose the polymer by the smallest sphere (centred at its geometri-

© 1998 NRC Canada

cal centre) and then project the chain to randomly chosen planes tangent to the sphere. On each projected image, we compute a number of bond–bond overcrossings (N). Finally, for a linear chain with n identical monomers ("beads"), the mean overcrossing number is simply:

$$[1] \qquad \overline{N} = \lim_{m\to\infty} \sum_{N=0}^{(n-2)(n-3)/2} N\,\frac{m_N}{m}$$

where m_N is the number of projections (over a total of m) that exhibit N overcrossings. In practice, configurations show a number of overcrossings much smaller than the maximum possible (i.e., $(n-2)(n-3)/2$). In an actual calculation of $\overline{N}$, accurate results can typically be obtained with $m \sim 10^4$ random projections (24).

Note that the evaluation of $\overline{N}$ uses not only the nuclear geometry (as does R_G) but also the information on chain connectivity. It is the special arrangement and distribution of *all* bonds in space what confers a protein a particular folding feature. As such, $\overline{N}$ is a *global shape descriptor*, involving *all possible bond–bond crossings*, regardless of the internuclear distances (24). However, bonds that are far away from each other *contribute less* to the mean overcrossing number than bonds close to each other. (This is due to the fact that there will be fewer "viewing directions" that produce a crossing between bonds separated by a great distance.) As a consequence, the $\overline{N}$ descriptor takes *naturally* into account the intuitive notion that bond–bond crossings by neighbouring bonds should be "physically" more important than others. Therefore, there is no need to add a cut-off distance to "weigh" the overcrossings according to the backbone geometry. As we show in more detail below, this feature is already incorporated into the theory.

The above approach (eq. [1]) produces good numerical results but few insights on exact properties. To study the general effect of temperature on $\overline{N}$, we need an *analytical* formula. Here, we use a recently developed path-integral approach to $\overline{N}$ in order to compare the behaviour of $\overline{N}$ and R_G under thermal fluctuations.

The use of analytical descriptors of entanglement is well established in polymer theory. Path-integral representation of the Gauss linking number (40, 41) and writhe (42) have long been used to describe topological constraints on closed (linked or knotted) polymer loops (43–48). These descriptors convey the geometrical configurations of knots, links, or polymer networks by using line integrals instead of algebraic descriptors.

Using the Gauss "looping" integral (41, 42) and spherical mappings (49), one can derive a similar path-integral representation for the mean overcrossing number of *closed loops* (50–52). This approach has recently been used to study the relation between the $\overline{N}$ value and knot energies in knotted polymer rings (51–54). The same formulation can be generalized to the case of *open* chains (27, 28) and general networks,[2] instead of loops. Recently (27, 28), the path-integral representation of $\overline{N}$ has been used to explain the observed scaling behaviour with the number of monomers (25, 26). In this section, we will simply adapt some of the recent approaches (27, 50, 53) to our present objective, namely, studying the effect of bond length fluctuations on chain self-entanglements. (A more detailed analysis appears elsewhere.)[2]

Consider a *linear* (nonbranched) polymer chain, comprising a series of connected segments. These "segments" can be curved. Let n be the number of monomers, each one represented by a single (identical) bead with position vector $\mathbf{r}_i$, $i = 1, 2, ..., n$. The "segment" joining monomers i and $i+1$ will be a curve denoted by $\gamma_i (i \le n-1)$. Each of these segments can be regarded as a parametrized path over the unit interval $I = [0, 1]$:

$$[2] \qquad \gamma_i : I \to \mathcal{R}^3, \quad \gamma_i(0) = \mathbf{r}_i,\ \gamma_i(1) = \mathbf{r}_{i+1}$$

whose continuous parametric derivatives $\dot{\gamma}_i(s) = \partial\ \gamma_i(s)/\partial s$ exist for all $s \in I$, and satisfy:

$$[3] \qquad \dot{\gamma}_i(0) = \lim_{s\downarrow 0} \dot{\gamma}_i(s), \quad \dot{\gamma}_i(1) = \lim_{s\uparrow 1} \dot{\gamma}_i(s)$$

The set of all points in the segment (i.e., the image of the map γ_i) will be indicated by G_i:

$$[4] \qquad G_i = \{\gamma_i(s) \in \mathcal{R}^3, \quad s \in I\ \}$$

In the special case of straight-line segments (e.g., a polymer or protein backbone) we will use C_i instead of G_i, that is,

$$[5] \qquad C_i = \{\gamma_i(s) \in \mathcal{R}^3 : \gamma_i(s) = \mathbf{r}_i + s(\mathbf{r}_{i+1} - \mathbf{r}_i), \quad s \in I\}$$

With this notation, we can now introduce the mean number of "bond–bond" crossings associated *exclusively* with the projections where the segments G_i and G_j overcross (i.e., $\overline{N}(G_i, G_j)$). The result is given by coupled line integrals over the curves $\gamma_i(s)$ and $\gamma_j(t)$ (50, 53):

$$[6] \qquad \overline{N}(G_i, G_j) = \frac{1}{4\pi} \int_0^1 \int_0^1 \frac{|(\dot{\gamma}_i(s) \times \dot{\gamma}_j(t)) \cdot (\gamma_i(s) - \gamma_j(t))|}{\|\gamma_i(s) - \gamma_j(t)\|^3} \mathrm{d}s\ \mathrm{d}t$$

This formula describes only the overcrossings between two curves, seen as distinct "isolated" entities. When the entire polymer chain is considered, represented by the ensemble $G = \bigcup_{i=1}^{n-1} G_i$, the total mean number of overcrossings $\overline{N}(G, G)$ will involve all possible combinations of segment–segment overcrossings $\overline{N}(G_i, G_j)$, that is:

$$[7] \qquad \overline{N}(G, G) = 2\sum_{i=1}^{n-2} \sum_{j=i+1}^{n-1} \overline{N}(G_i, G_j) + \sum_{i=1}^{n-1} \overline{N}(G_i, G_i)$$

where the diagonal terms $\overline{N}(G_i, G_i)$ represent overcrossings *within* a given segment. Now, straight-line segments cannot overcross with themselves or with their connected (adjacent) neighbours. In this case, the diagonal terms in eq. [7] vanish, as well as the contributions of the form $\overline{N}(G_i, G_{i+1})$. The resulting mean number of overcrossings $\overline{N}(C, C)$ will be denoted as simply $\overline{N}_{\text{chain}}$. Using eqs. [6] and [7] we get:

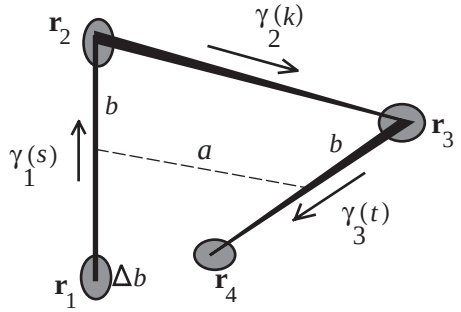
Fig. 1. Minimal chain used for the exact computation of the mean overcrossing number. (Note that only the segments γ_1 and γ_3 can overcross. These two segments are chosen perpendicular, at a distance a, and of equal length b. The bond fluctuations Δb are indicated as thermal ellipsoids.)



$$[8]\qquad \bar{N}_{\text{chain}} = \frac{1}{2\pi}\sum_{i=1}^{n-3}\sum_{j=i+2}^{n-1}\int_0^1\int_0^1 \frac{|(\dot{\gamma}_i(s)\times\dot{\gamma}_j(t))\cdot(\gamma_i(s)-\gamma_j(t))|}{||\gamma_i(s)-\gamma_j(t)||^3}\,\mathrm{d}s\,\mathrm{d}t$$

Equation [8] provides an analytical representation that is convenient to study the effect of thermal fluctuations on self-entanglements. To illustrate this notion, we shall apply eq. [8] to a simple "toy" chain.

Consider the simple "tetramer chain" in Fig. 1. It consists of three straight-line segments (indicated by γ_1, γ_2, γ_3). For a simpler analysis, we choose the segments γ_1 and γ_3 to be perpendicular and of equal length. These segments generate the only nonzero contributions to overcrossings, since connected straight-line segments do not overcross.

Let b be the length of each segment, and a the distance between the centres of the segments γ_1 and γ_3. The full chain is defined by the four points: $\mathbf{r}_1 = (0, 0, 0)$, $\mathbf{r}_2 = (0, 0, b)$, $\mathbf{r}_3 = (a, -b/2, b/2)$, $\mathbf{r}_4 = (a, b/2, b/2)$. Hence, the radius of gyration is given by

$$[9]\qquad R_G = \frac{1}{2}(a^2+b^2)^{1/2}$$

and it coincides with the distance from a point $\mathbf{r}_i$ to the geometrical centre of the chain. Using eq. [5], the overcrossing segments follow:

$$[10]\qquad \gamma_1(s) = \mathbf{r}_1 + s(\mathbf{r}_2 - \mathbf{r}_1) = (0,\ 0,\ sb)$$

$$[11]\qquad \gamma_3(t) = \mathbf{r}_3 + t(\mathbf{r}_4 - \mathbf{r}_3) = (a,\ b(t-1/2),\ b/2)$$

with parametric derivatives: $\dot{\gamma}_1 = (0, 0, b)$, $\dot{\gamma}_3 = (0, b, 0)$. In addition, we obtain:

$$[12]\qquad |(\dot{\gamma}_1\times\dot{\gamma}_3)\cdot(\gamma_1-\gamma_3)| = ab^2$$

$$[13]\qquad ||\gamma_1-\gamma_3||^3 = b^3[a'^2+(t-\frac{1}{2})^2+(s-\frac{1}{2})^2]^{3/2}$$

where $a' = a/b$. With these results we compute the mean overcrossing number (eq. [8]):

$$[14]\qquad \bar{N} = \bar{N}_{\text{chain}} = \frac{1}{2\pi}\int_0^1\int_0^1 \frac{|(\dot{\gamma}_1(s)\times\dot{\gamma}_3(t))\cdot(\gamma_1(s)-\gamma_3(t))|}{||\gamma_1(s)-\gamma_3(t)||^3}\,\mathrm{d}s\,\mathrm{d}t = \frac{1}{2\pi a'^2}\int_0^1\int_0^1 [1+(\frac{t-1/2}{a'})^2+(\frac{s-1/2}{a'})^2]^{-3/2}\,\mathrm{d}s\,\mathrm{d}t$$

Evaluation of the integral [14] produces a simple closed-form expression for $\bar{N}$ (55):

$$[15]\qquad \bar{N} = \frac{2}{\pi}\arctan\left(\frac{2^{1/2}}{4a'(1+2a'^2)^{1/2}}\right)$$

In principle, we expect that $\bar{N}$ may convey different shape features than a descriptor of molecular size such as R_G. We can now quantify this conjecture by using the example in Fig. 1. Firstly, note that $\bar{N}$ and R_G follow different asymptotics when the chain is squished. When $a << b$, a simple calculation from eqs. [9] and [15] gives:

$$[16]\qquad R_G/b = \frac{1}{2}+\frac{a'^2}{4}-\frac{a'^4}{16}+O(a'^6)$$

$$[17]\qquad \bar{N} = 1-\frac{2^{5/2}a'}{\pi}+\frac{a'^3}{\pi}(\frac{2^{1/2}}{3}-2^{5/2})+O(a'^5)$$

These results suggest that the effect of moving apart the segments γ_1 and γ_3 is *an order of magnitude larger* in $\bar{N}$ than in R_G. (We also note, in passing, that according to eq. [15] the mean overcrossing number *vanishes* when $a'\to\infty$. In other words, as already pointed out in the introduction, two bonds far away from each other contribute little indeed to the entanglement descriptor $\bar{N}$.)

We can now estimate the variation in shape descriptors produced by a *systematic change* in the molecular geometry (e.g., a "breathing mode" in the molecule). In Fig. 1, such a change can be represented by (*i*) a variation in the bond lengths b, or (*ii*) a change in the bond–bond distance a. Let us suppose that, for the sake of simplicity, thermal fluctuations produce an *identical* variation Δb in each of the bonds. We can regard Δb as a fluctuation that swells the entire polymer, as it is expected in a protein as temperature increases (13). This value can be estimated in terms of the Debye–Waller factors as $\Delta b^2 \approx B/8\pi^2$. This "swelling," or Δb-fluctuation, will produce fluctuations in the shape descriptors, denoted by $\Delta\bar{N}$ and ΔR_G. The effect of temperature can then be expressed in terms of the relative variations per bond fluctuation. Using eqs. [9] and [15], we obtain:

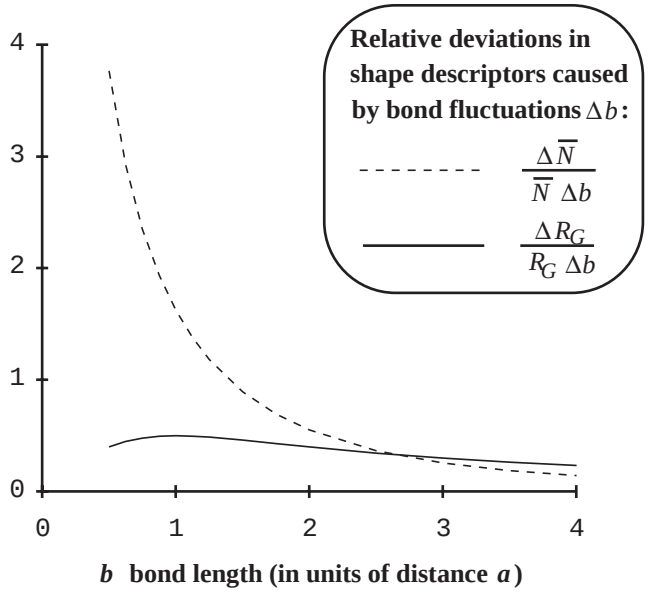
$$[18]\qquad \frac{\Delta R_G}{R_G\Delta b} = \frac{b}{(a^2+b^2)}$$

$$[19]\qquad \frac{\Delta\bar{N}}{\bar{N}\Delta b} = \frac{2^{3/2}ab}{(4a^2+b^2)(2a^2+b^2)^{1/2}}[\arctan(\frac{2^{1/2}b^2}{4a(b^2+2a^2)^{1/2}})]^{-1}$$

These two equations are compared in Fig. 2. The figure shows the relative importance of the fluctuations over a range bond length values b (measured in units of $a = 1$).

© 1998 NRC Canada

Fig. 2. Relative deviations in the molecular size and chain self-entanglement descriptors for the model "polymer" in Fig. 1. (The results given per unit of bond fluctuation Δb, over a range of possible b values. The figure shows the results corresponding to the case $a = 1$.)



When $b > 2.5a$, a Δb-fluctuation affects the molecular size and the mean overcrossing number to the same extent. However, the effect is very different for smaller bond lengths. According to Fig. 2, we expect the effect of bond fluctuations on $\bar{N}$ to be approximately five times larger than that for R_G in compact chains, where $b \sim a$. A more conservative bound can be estimated by considering equal-length bonds in Fig. 1. (The condition $a = 1$ requires $b = 2^{1/2}$ to produce three equal length segments in Fig. 1.) Even in this case, as Fig. 2 shows, the effect of a Δb-fluctuation on $\bar{N}$ will still be more than twice that on R_G.

We arrive to a similar conclusion if the breathing mode is represented by a variation in a. Using eq. [15], a Δa-fluctuation produces the following effect in the mean overcrossing numbers:

$$[20] \quad \left|\frac{\Delta\bar{N}}{\bar{N}\Delta a}\right| = \frac{2^{3/2}b^2}{(4a^2+b^2)(2a^2+b^2)^{1/2}}\left[\arctan\left(\frac{2^{1/2}b^2}{4a(b^2+2a^2)^{1/2}}\right)\right]^{-1}$$

When this fluctuation is analyzed over a variation in bond length b, the effect is even larger than the one observed in eq. [19].

We can rationalize all these observations as follows. The radius of gyration depends only on individual nuclear positions and not on their connectivity. Therefore, a fluctuation in the position of one atom affects only slightly the contribution to R_G of all others. (The only effect is due to a small shift in the centre of mass.) The situation is very different for the mean number of overcrossings. Note that $\bar{N}$ takes into consideration the *entire* path connecting two atoms and *not* only the position of the terminal points. Moreover, the resulting overcrossings depend on relations between all pairs of paths. Consequently, a Δb- or Δa-fluctuation will affect the path lengths and their relative positions, which in turn will have an effect on how each path overcrosses all others. Clearly, the net result of a thermal fluctuation will be a strong modulation of the global overcrossing pattern throughout the polymer chain. As a result, we expect $\bar{N}$ to be always more sensitive than R_G over the whole range of nuclear motions. (It should be noted that fluctuations that leave the *mean* equilibrium geometry invariant may give rise to a large $\Delta\bar{N}$ fluctuation, while leaving the mean $\bar{N}$ value constant. On the other hand, fluctuations that *shift* the equilibrium geometry will change both $\bar{N}$ *and* $\Delta\bar{N}$. As discussed before, fluctuations in bonds far away will always have a smaller effect on the $\bar{N}$ value than fluctuations in bonds closer to each other.)

In real polymer chains, the distribution of segments is complicated and $\bar{N}$ cannot be computed in closed form by using eq. [8]. However, the overcrossing pattern of all three-segment sections should not be too different from that described by eq. [15]. We would still expect $\bar{N}$ to exhibit larger variations during thermal fluctuations when compared to R_G. In the next section, we test these ideas by studying similar effects in an actual protein.

Variation of mean overcrossing numbers during the glass transition of ribonuclease-A

The best studied examples of protein glass transitions are myoglobin (9, 10–12, 20) (a mostly α-helical protein) and ribonuclease-A (13, 19) (a primarily β-sheet protein). We shall discuss here the case of bovine pancreatic ribonuclease-A, as it is the only example in the Brookhaven PDB with a large number of available X-ray structures as a function of T.

Ribonuclease-A is a small monomeric protein ($n = 124$). Its catalytic function is to hydrolyze single-stranded RNA by binding it in a deeply buried active site. The catalytic activity and structures of this protein have been studied over a range of temperatures. Nine X-ray structures are available, with PDB codes *p*RAT ($p = 1, 2, ..., 9$), corresponding to temperatures $T = 98, 130, 160, 180, 220, 240, 260, 300, 320$ K, respectively.

The overall thermal effect on this protein is small and subtle (13). The larger changes appear at loops and α-helices, whereas the inner β-sheet core is less affected (13). Experiments (13) and computer simulations (20) indicate a mean-squared deviation of $\langle\langle(\Delta r)^2\rangle\rangle^{1/2} \approx 0.4$ Å for an *inner* residue. Considering the distances between α-carbon atoms in a protein backbone, this amounts to a bond-length fluctuation $\Delta b \approx 0.1b$.

For each of the nine structures, we have computed molecular size and self-entanglements. To monitor thermal effects with increasing resolution, we have considered two models of the chain. Firstly, we represent the chain by using only α-carbon atoms (the "C_α-skeleton"). Then, we enlarge the chain by taking into consideration all main-chain atoms (the "N-C_α-C-skeleton"). (Only fluctuations in backbone atoms can modify the value of the entanglement descriptor. As be-

Fig. 3. Variation in molecular size as a function of temperature, for two models of the protein backbone of bovine pancreatic ribonuclease-A. (The glass transition is indicated by T^*. Note that there is no clear systematic change in R_G values accompanying this transition.)

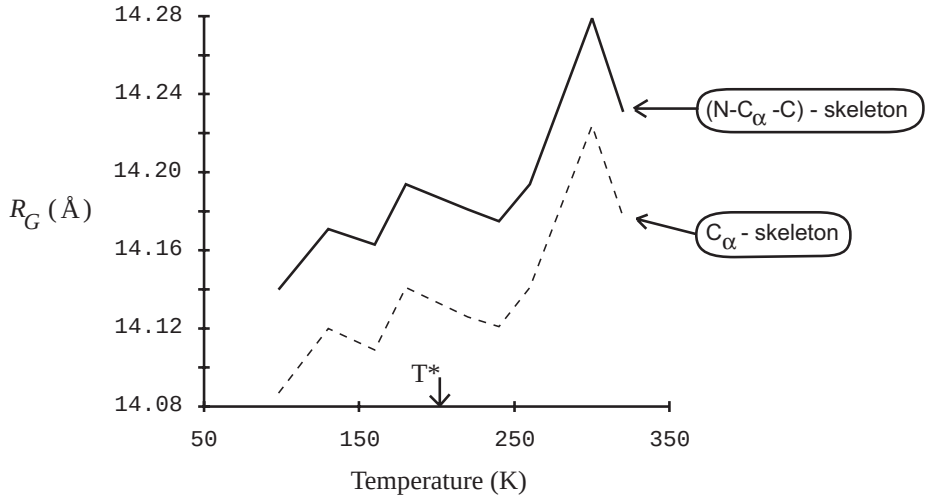

Fig. 4. Variation in chain self-entanglements as a function of temperature, for two models of the protein backbone of bovine pancreatic ribonuclease-A. (The glass transition is indicated by T^*. The boxes indicate the numerical errors in the computation of overcrossings. Note that there is a clear change in $\overline{N}$ values accompanying the transition. The extent of the transition appears to grow as the resolution of the protein backbone is increased by adding main-chain atoms.)

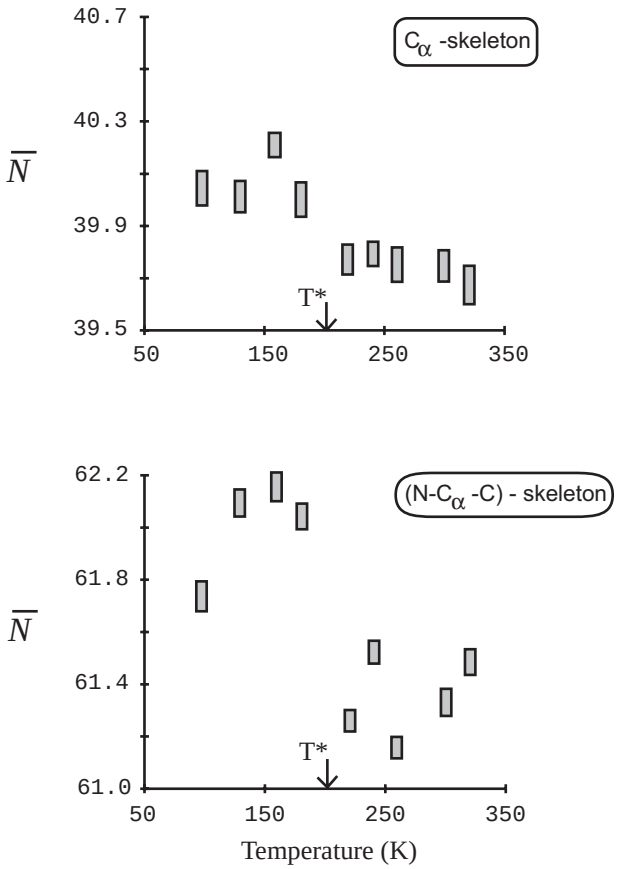

fore, fluctuations in atoms separated by large distances will affect little the global mean overcrossing number.)

For the computation of the mean overcrossing number $\overline{N}$, we follow the numerical approach indicated by eq. [1]. For each chain model, we have produced 10 independent estimations of $\overline{N}$, each one of them consisting of 5×10^5 randomized projections on the surface of a sphere enclosing the backbone (24). The final estimation is made by averaging the 10 series, with error bars expressed as standard deviations. This procedure typically generates $\overline{N}$ values with at least three significant figures.

The R_G values for each backbone model are displayed in Fig. 3. As expected, the results show that R_G does not uncover any new features as the "resolution" of the backbone increases. The overall result is a small, irregular swelling of the backbone with no particular change at the glass-transition temperature (indicated by T^*). The picture obtained is consistent with the observations in ref. 13.

These results can be contrasted with the behaviour of the mean overcrossing numbers, displayed in Fig. 4. Firstly, the $\overline{N}$ values increase markedly as more atoms are added to the backbone. For the two chain models, $\overline{N}$ shows a clear *jump* from high to low values at the glass transition temperature T^*. The *qualitative* variation in $\overline{N}$ is consistent with the behaviour of the molecular size, because larger overcrossing numbers are normally found in more compact configurations (i.e., a decrease in $\overline{N}$ indicates that the backbone becomes partially "open" as T increases). However, the *quantitative* change in $\overline{N}$ indicates two clear domains, whereby $\overline{N}$ remains relatively constant for $T > T^*$. (Of course, this conclusion is valid for temperatures *moderately* higher than T^*. We would expect other shape transitions at higher temperatures as the protein unfolds or denatures.)

In the case of the mean overcrossing number, we find evidence that a *shape transition* (31–33) in the backbone takes place at T^*. At the glass-transition, there seems to be not only a fast change in Debye–Waller B-factors but also in backbone entanglements.

The effect is small, but still noticeable, in the C_α-skeleton, which exhibits the largest "bond" distances. In contrast,

© 1998 NRC Canada

there is a remarkable shape transition when considering the N-C_α-C-skeleton. This backbone involves shorter bonds with similar lengths (i.e., the N—C_α, C_α—C, and C—N bonds), a feature that magnifies the effect of thermal fluctuations on the atomic positions. Whereas in the C_α-skeleton the jump in $\overline{N}$ values at T^* is rather marginal (only two standard deviations within the confidence of our calculations), random variations can be ruled out in the case of the N-C_α-C-skeleton.

The results for the glass-transition in ribonuclease-A are consistent with the analysis for the toy chain in the previous section. Our findings suggest that we *can* extract important information on the thermal behaviour of a macromolecule by monitoring shape features other than the molecular size. It will be important to test whether a similar behaviour is found during the glass transitions of other proteins.

Further comments and conclusions

In conclusion, we have found that transitions in the average backbone shape can be "recovered" by monitoring chain self-entanglements, even when the molecular size shows no remarkable change. The results indicate that the mean number of overcrossings $\overline{N}$ can be a more sensitive shape descriptor than R_G. By construction, $\overline{N}$ "magnifies" the effect of *thermal fluctuations on the backbone bonds*. Fluctuations in other atoms, or in backbone atoms far away from each other, have a smaller effect on $\overline{N}$.

We believe that the observation that a backbone *shape transition* may accompany the glass transition in a protein can be quite useful. Up to now, glass transitions have been monitored by using mean-squared deviations from a reference equilibrium position. However, these quantities are characterized by an error much larger than the uncertainty in the atomic positions. In fact, it is difficult to give an unambiguous interpretation to the Debye–Waller *B*-factors (8, 13). These factors depend on lattice fluctuations, protein packing in the crystal, in addition to inter- and intramolecular fluctuations. The consensus is that the thermal variation of *B*-factors during the glass transition stems mostly from *intramolecular* motions (8). However, it is hard to assess the relative importance of the other factors. In this work, we have shown that the standard analysis can be complemented by studying the chain self-entanglements. This property can be unambiguously interpreted in terms of the backbone of a single macromolecule. Therefore, a coincidence between a fast change in *B*-factors and a fast change in $\overline{N}$ would provide a stronger argument for the occurrence of an *intramolecular glass transition* (i.e., one characterized by the access to intramolecular motions of large amplitude whenever $T > T^*$).

Our analysis can be extended to the study of *all* atoms involved in the glass transition. By using the definition of overcrossings in a network (35), we can apply the present procedure to the study of fluctuations in the transient patterns of a hydrogen-bonded network. Moreover, the present technique is not restricted to the analysis of shape transitions triggered by temperature changes. In the future, we will explore whether transitions in entanglements are found when other external perturbations are applied to a protein, e.g., variations in pH, pressure, and ionic force.

Acknowledgment

G.A.A. would like to thank R. Cachau (NCI, Structural Biochemistry Lab, Frederick, Md.), L. Massa (CUNY, New York), J. Karle (Naval Research Lab, Washington, D.C.), and A. Grosberg (MIT, Cambridge, Mass.) for fruitful discussions and pointing out some useful references. The authors thank also A. Kholodenko (Clemson University, S.C.) for sending ref. 28 prior to publication and N. Grant (Sudbury) for her comments on the manuscript. General base-catalyzed hydrolysis and carbonyl-^{18}O exchange of *N*-(4-nitrobenzoyl)pyrrole

Laurence J. Beach, Raymond J. Batchelor, Frederick W.B. Einstein, and Andrew J. Bennet

Abstract: Base-promoted hydrolysis kinetics for *N*-(4-nitrobenzoyl)pyrrole (**1**) have been measured as a function of buffer concentration at several pH values at 25°C. In addition carbonyl-^{18}O exchange kinetics have been determined at a single pH value (9.48) as a function of 1,4-diazobicyclo[2.2.2]octane (DABCO) concentration. At zero buffer concentration the measured ratio of ^{18}O exchange to hydrolysis (k_{ex}/k_{hyd}) is approximately 0.04, and this value increases and finally levels off at about 0.23 as the DABCO concentration is increased. These observations are consistent with the buffer acting as a general-base to catalyze both the attack of water to generate an anionic tetrahedral intermediate (T_{O^-}) and the breakdown of T_{O^-} to give hydrolysis products.

Key words: amide, hydrolysis, catalysis, general-base, tetrahedral intermediate.

Résumé : Opérant à 25°C, à plusieurs valeurs de pH, on a mesuré la cinétique de l'hydrolyse catalysée par les bases du *N*-(4-nitrobenzoyl)pyrrole (**1**) en fonction de la concentration du tampon. De plus, opérant à une seule valeur de pH (9,48), on a déterminé la cinétique d'échange du ^{18}O en fonction de la concentration du 1,4-diazobicyclo[2.2.2]octane (DABCO). À une concentration nulle de tampon, le rapport des vitesses d'échange du ^{18}O et d'hydrolyse (k_{ec}/k_{hyd}) est approximativement égal à 0,04; lorsqu'on augmente la concentration du DABCO, cette valeur augmente pour atteindre une valeur limite d'environ 0,23. Ces observations sont en accord avec l'hypothèse selon laquelle le tampon agit comme une base générale qui catalyse aussi bien l'attaque de l'eau qui génère l'intermédiaire anionique tétraédrique (T_{O^-}) que la rupture de T_{O^-} qui conduit aux produits d'hydrolyse.

Mots clés : amide, hydrolyse, catalyse, basique générale, intermédiaire tétraédrique.

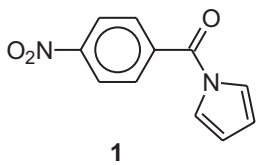
[Traduit par la Rédaction]

Introduction

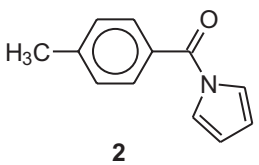
The amide C—N bond is one of the main structural units in biological chemistry, and as such hydrolysis of this linkage has been widely studied (1). Scheme 1 shows the generally accepted mechanism for hydrolysis of amides in basic nonbuffered solutions. These hydrolysis reactions involve reversible formation of an anionic tetrahedral intermediate (T_{O^-}) followed by subsequent breakdown to generate amine and carboxylate anion.

Whether these base-promoted hydrolysis reactions exhibit a second-order domain in their pH–rate profiles depends on the basicity of the amine leaving group (2). For example, simple amides such as benzamides (3) and simple aliphatic amides (1*c*, 4) only show first-order terms in [HO^-] during hydrolysis (i.e., $k_2 >> k_3[OH^-]$). In these cases the tetrahedral intermediate T_{O^-} (Scheme 1) is sufficiently reactive to break down to products without the assistance of a second hydroxide ion. In contrast, hydroxide-catalyzed breakdown of T_{O^-} has been reported to occur during the hydrolysis of amides that contain less basic amines, for example acetanilides (5), formanilides (6), trifluoroacetanilides (7), and *N*-acyl pyrroles (8). Furthermore, during the base-promoted hydrolysis of trifluoro- and trichloroacetanilide general base-catalysis has been observed for the breakdown of T_{O^-} (9).

Menger and Donahue (8*a*) reported that the hydrolysis of *N*-(4-nitrobenzoyl)pyrrole (**1**) was catalyzed by buffers, such as 1,4-diazobicyclo[2.2.2]octane (DABCO) and trimethylamine (TMA). In contrast, Slebocka-Tilk et al. (2*c*) reported that neither hydrolysis nor ^{18}O-*carbonyl* exchange of the structurally similar amide *N*-toluoyl pyrrole (**2**) was catalyzed by added buffers.



1



2

Menger and Donahue (8*a*) analyzed the observed effects of added buffer on the rate of hydrolysis of **1** as a buffer-assisted attack of water on the carbonyl group to generate the anionic tetrahedral intermediate T_{O^-}, i.e., general base-catalysis. However, given that the structurally similar amide **2** undergoes a hydroxide-catalyzed breakdown of T_{O^-} it is possible that the observed general base-catalyzed hydrolysis of **1** may involve catalysis of the breakdown rather than (or

in addition to) the formation of the anionic tetrahedral intermediate.

The present report contains the details of a kinetic study on the rates of *carbonyl*-^{18}O exchange and hydrolysis for *N*-(4-nitrobenzoyl)pyrrole (**1**) as a function of buffer concentration with the aim of elucidating the mechanism of general catalysis. In addition, the measured solvent deuterium kinetic isotope effect (SDKIE) on the hydroxide-promoted rate of hydrolysis is included in this report, as is the solid state structure of *N*-(4-nitrobenzoyl)pyrrole (**1**).

Results

The experimental conditions employed in the present study to elucidate the mechanism of buffer-catalyzed hydrolysis of **1** were modified from those used by Menger and Donahue (8*a*) so that ionic strength was kept constant. Tables S1 and S2 (supplementary material)[2] list the complete rate constant data (k_{hyd}) measured for the hydrolysis of **1** at various pH values and buffer concentrations (μ = 1.0, KCl; T = 25°C). The corresponding plots of k_{hyd} versus buffer concentration are shown in Figs. 1 and 2. To determine the active component of the buffer, second-order rate constants (k_{BT}) for the TMA-catalyzed reaction were calculated using a linear fit of the data from Table S1.[3]

Figure 3 illustrates the calculated second-order rate constants (k_{BT}) versus the fraction of base (X_B) for the TMA-catalyzed hydrolysis of **1**, also included in the plot is the best linear fit to this data.

Fig. 2. Plot of k_{obs} versus [DABCO] for **1**, T = 25°C, μ = 1.0 (KCl).

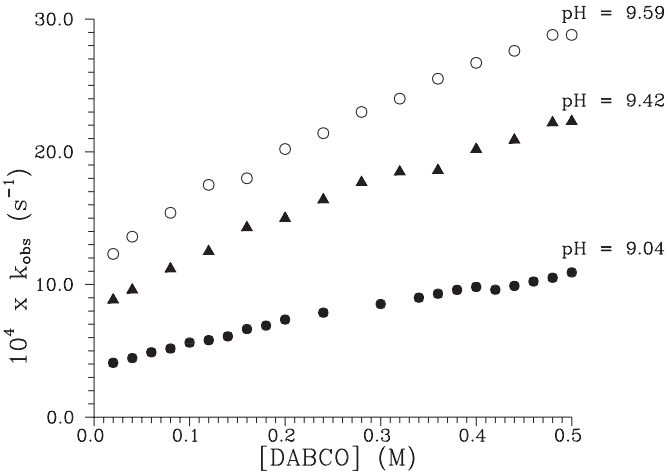

Fig. 3. Plot of k_{BT} versus fraction of base (X_B) for DABCO-catalyzed hydrolysis of **1**, T = 25°C, μ = 1.0 (KCl). Line drawn through the points is the best linear fit to the data.

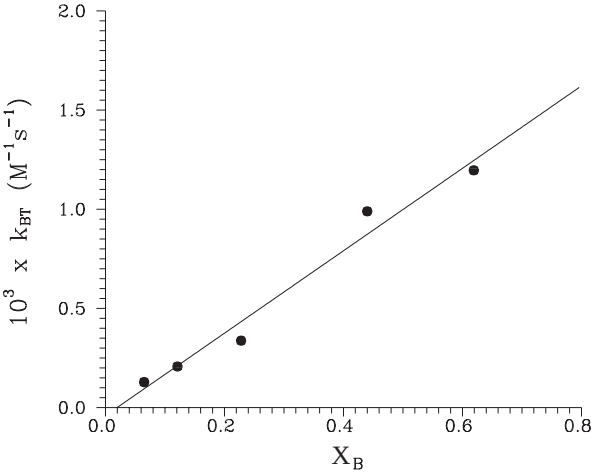

Rate constants for the hydroxide-promoted hydrolysis of **1**, at low pH values, were determined by extrapolating the measured rate constants in the presence of buffers to zero buffer concentration. The derived values (k_{calc}) are compiled in Table 1. Using the data from Table 1, for pH values <10, the calculated second-order rate constant for the hydroxide-promoted hydrolysis of **1** is 31.5 ± 2.7 M^{-1} s^{-1}.

At high pH values (12–14) the rate of hydrolysis of **1** at varying [OH^-] and [OD^-] was measured directly, and the obtained pseudo-first-order rate constants are listed in Table 2.

The second-order rate constant for hydroxide- and deuteroxide-promoted hydrolysis of **1** at high pH were calculated to be 35.2 ± 1.5 and 39.4 ± 1.4 M^{-1} s^{-1}, respectively. Thus, the SDKIE (k_{H_2O}/k_{D_2O}) for this base-promoted hydrolysis reaction is 0.89 ± 0.05 (25°C). To determine partitioning of tetrahedral intermediates formed during the hydrolysis of **1**

the ratio of *carbonyl*-^{18}O exchange to hydrolysis was measured as a function of buffer concentration at a single pH value. In an initial set of experiments (pH = 9.0) *carbonyl*-^{18}O labelled amide was subjected to the hydrolysis conditions for one half-time of hydrolysis. After reisolation of the labelled amide remaining and determination of the percentage of ^{18}O present estimates for the ratio k_{ex}/k_{hyd} were made using eq. [1].

$$[1] \qquad \frac{k_{ex}}{k_{hyd}} = \frac{\ln\left(^{18}O_0 / ^{18}O_t\right)}{\ln(2)}$$

Table 3. Observed pseudo-first-order rate constants for *carbonyl*-^{18}O exchange and hydrolysis of **1** in the presence of added DABCO, pH = 9.48, T = 25°C, μ = 1.00 (KCl).

[a]Exchange rate constant calculated according to ref. 10, p. 150, from the data given in Tables S4–S6.

[b]Mean value of three independent kinetic runs; quoted error = σ_{n-1}.

[c]Errors calculated according to ref. 10.

[d]Additional estimate for the pseudo-first-order rate constant k_{ex} using data from Table S6 is 0.55 ± 0.25 × 10^{-4} s^{-1}.

[e]Extrapolated value from data with [DABCO] ≤ 0.1 M.

[f]Value interpolated from the data given in Table 1 is 9.55 × 10^{-4} s^{-1}.

[g]Additional estimate using data from Table S6 is k_{ex}/k_{hyd} = 0.057 ± 0.026.

Given in Table S3 are the measured values for $^{18}O_t$ (percentage ^{18}O at time = $t_{1/2hyd}$) and the calculated rate constant ratios k_{ex}/k_{hyd}. This tabulated data suggests that the ratio k_{ex}/k_{hyd} varies as a function of buffer concentration however, the reproducibility of the measured $^{18}O_t$ values was generally worse at higher buffer concentrations, a possible consequence of the required acid quench. Therefore, it was decided to follow *carbonyl*-^{18}O exchange and hydrolysis at a higher pH value using a flow system where the rapid acid quenching of large volumes of DABCO buffers could be avoided (see experimental section).

The measured rate constants for hydrolysis, *carbonyl*-^{18}O exchange and their ratio (k_{ex}/k_{hyd}) at a pH of 9.48 using the flow system are given in Table 3 (10), and the corresponding plot of k_{ex}/k_{hyd} versus buffer concentration is shown in Fig. 4. In addition, the measured ^{16}O:^{18}O ratios for reisolated **1** are given in Tables S4, S5, and S6 (supplementary material).[2]

A single crystal diffraction study was undertaken on **1** to examine possible structural differences between **1** and **2**. Crystallographic details are summarized in Table 4. The final fractional atomic coordinates for the non-hydrogen atoms are listed in Table S7 (supplementary material).[2] The observed bond lengths and those calculated after a rigid body analysis (see experimental section) for **1** are included in Table 5, and the important bond angles are given in Table 6. Figure 5 presents an ORTEP diagram of the so obtained structure for amide **1**.

Given in Table 7 is a comparison of the C—N and C—O amide bond lengths for amides **1** and **2** (11). Also included in Table 7 are the calculated Dunitz parameters (χ_C and χ_N) for these two amides (12).

Discussion

(*i*) Hydrolysis of 1 in the absence of buffers

The reported hydrolysis mechanism for *N*-toluoylpyrrole (**2**) includes a hydroxide-catalyzed term for breakdown of the anionic tetrahedral intermediate (T_{O^-}) to generate carboxylate and pyrrole anions (2*c*). The derived expressions of the rate constants for hydrolysis (k_{hyd}), exchange (k_{ex}), and their ratio (k_{ex}/k_{hyd}) from the mechanism shown in Scheme 1 are given by eqs. [2]–[4] where $k_2' = k_2/k_{-1}$ and $k_3' = k_3/k_{-1}$. The factor of two in eqs. [3] and [4] arises from the necessary assumption that one-half of T_{O^-} reversal to regenerate amide leads to *carbonyl*-^{18}O exchange, i.e., the two oxygen atoms in the tetrahedral intermediate are protonically equilibrated. This assumption has been shown to be valid for T_{O^-} formed during the hydrolysis of **2** (2*c*).

$$[2] \qquad k_{hyd} = \frac{k_1[OH^-](k_2' + k_3'[OH^-])}{1 + k_2' + k_3'[OH^-]}$$

Table 7. Comparison of the structural parameters for the amides **1** and **2**.

Parameter	**1**[a]	**2**
r(C—O) (Å)	1.220	1.211
r(C—N) (Å)	1.388	1.409
χ_C (°)	1.1	0.0
χ_N (°)	1.0	10.1

[a]Bond distances corrected for rigid-body thermal motion (see Table 5).

$$[3] \qquad k_{ex} = \frac{k_1[OH^-]}{2(1 + k_2' + k_3'[OH^-])}$$

$$[4] \qquad \frac{k_{ex}}{k_{hyd}} = \frac{1}{2(k_2' + k_3'[OH^-])}$$

An indication that a similar pathway exists for the hydrolysis of **1** in the absence of buffers is shown by the difference in the calculated second-order rate constants at high and low pH values in the absence of added buffers (2*c*). In the low pH domain, $k_3'[OH^-] << k_2'$, the value for $k_{hyd}/[OH^-]$ of 31.5 ± 2.7 M^{-1} s^{-1} is equal to $k_1k_2'/(1 + k_2')$, while in the high pH domain, $k_3'[OH^-] >> k_2'$, the value for $k_{hyd}/[OH^-]$ of 35.2 ± 1.5 M^{-1} s^{-1} is equal to k_1. Using these two values an estimate of 0.12 ± 0.11 can be computed for the uncatalyzed partitioning (k_{-1}/k_2) of the anionic tetrahedral intermediate T_{O^-} between regeneration (k_{-1}) and hydrolysis (k_2) of the amide. Although, this calculated partitioning ratio contains a large associated error, a second estimate of this quantity can be made from the rate of *carbonyl*-^{18}O exchange (k_{ex}) relative to hydrolysis (k_{hyd}). Where in the absence of buffers and at a pH value of 9.48, assuming $k_3'[OH^-] << k_2'$, the measured value for k_{ex}/k_{hyd} (Table 3) of 0.037 ± 0.02 (repeat value 0.06 ± 0.03) generates an estimated value for k_{-1}/k_2 of 0.07 ± 0.04. That the observed value for k_{ex}/k_{hyd} (0.04–0.06) for the base-promoted hydrolysis of **1**, at low pH measurements, is less than that reported (k_{ex}/k_{hyd} = 0.24) for the corresponding reaction of **2** (2*c*) requires that T_{O^-} partitioning to products is favoured to a greater extent by the electron-withdrawing nitro group (**1**) than by the electron-donating methyl group (**2**). This difference corresponds to a relative reduction in the kinetic barrier (k_2) for product formation from amide **1** compared to amide **2** of approximately 3–4 kJ mol^{-1}. The anionic intermediate T_{O^-} formed during the reactions of **1** will be more stable than the corresponding intermediate formed from **2** because of the electron-withdrawing nitro group. Therefore, it can be safely assumed that the two oxygens in the intermediate (T_{O^-}) formed from **1** are protonically equilibrated and that the change in the k_{ex}/k_{hyd} ratio, in the absence of buffer, indicates a greater tendency for the unimolecular ejection of the pyrrole anion, relative to hydroxide ion, from the more stable tetrahedral intermediate. The origin of this effect could be the formation of a hydrogen bond, at the transition state for pyrrole anion ejection, between the anionic tetrahedral intermediate's O–H group and a solvating water molecule.

(*ii*) Mechanism of buffer catalysis

The intercept with the *y*-axis (X_B = 0, Fig. 3) for the second-order rate constants for buffer-catalyzed hydrolysis of **1** is, within experimental error, zero. Therefore, the basic form of the buffer is the active species for the general-catalyzed hydrolysis of **1**. Shown in Scheme 2 is the modified mechanism for hydrolysis of **1**, where the basic form of the buffer can catalyze the formation (k_{BF}) and (or) the breakdown (k_{BP}) of T_{O^-}. The principal of microscopic reversibility requires that if general base-catalysis for the formation of T_{O^-} occurs then reversal to generate starting material must also occur with general acid-catalysis.

The derived expressions of the rate constants for hydrolysis (k_{hyd}), exchange (k_{ex}), and their ratio (k_{ex}/k_{hyd}) from the mechanism shown in Scheme 2 are given by eqs. [5]–[7] where $k_{BF}' = k_{BF}/k_{-1}$, $k_{BH}' = k_{BH}/k_{-1}$, and $k_{BP}' = k_{BP}/k_{-1}$.

$$[5] \qquad k_{hyd} = \frac{(k_1[OH^-] + k_{BF}[B])(k_2' + k_{BP}'[B] + k_3'[OH^-])}{1 + k_{BH}'[BH^+] + k_2' + k_{BP}'[B] + k_3'[OH^-]}$$

$$[6] \qquad k_{ex} = \frac{(k_1[OH^-] + k_{BF}[B])(1 + k_{BH}'[BH^+])}{2(1 + k_{BH}'[BH^+] + k_2' + k_{BP}'[B] + k_3'[OH^-])}$$

$$[7] \qquad \frac{k_{ex}}{k_{hyd}} = \frac{1 + k_{BH}'[BH^+]}{2(k_2' + k_{BP}'[B] + k_3'[OH^-])}$$

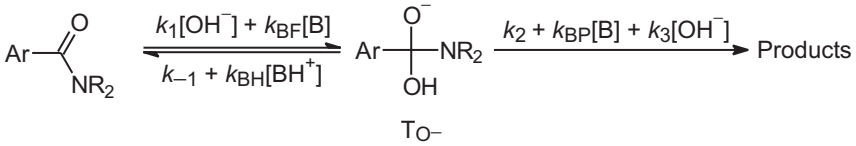
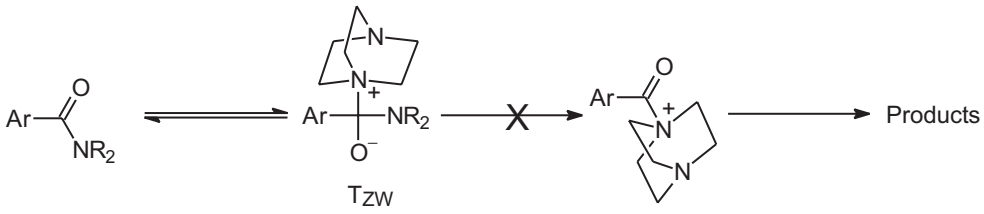
Scheme 2.



Scheme 3.



Three immediate conclusions can be drawn from the data shown in Figs. 1 and 2, and given in Table 3, namely, (*i*) the hydrolysis reactions of **1** are buffer-catalyzed; (*ii*) since $k_{ex}/k_{hyd} << 1$, at low pH and in the absence of buffer, the rate-limiting step for the hydroxide-promoted hydrolysis must be formation of T_{O^-}; and (*iii*) buffer accelerates the slow step of the hydrolysis reaction, i.e., T_{O^-} formation. However, if the buffer only catalyzed the formation of the tetrahedral intermediate ($k_{BP}' = 0$, eq. [7]) then at a constant pH value the ratio k_{ex}/k_{hyd} should increase in a linear fashion when the buffer concentration is increased. The observation that the k_{ex}/k_{hyd} ratio increases with buffer concentration and levels off at high concentration provides convincing evidence that both the attack of water on the amide to generate T_{O^-} and the breakdown of T_{O^-} to generate the hydrolysis products are catalyzed by buffer. At high buffer concentration, i.e., when $k_{BP}'[B] >> k_2' + k_3'[OH^-]$ and $k_{BH}'[BH^+] >> 1$, the derived expression for k_{ex}/k_{hyd} (eq. [7]) simplifies to eq. [8].

$$[8] \qquad \frac{k_{ex}}{k_{hyd}} = \frac{k_{BH}'[BH^+]}{2k_{BP}'[B]}$$

In DABCO buffer at a pH value of 9.48 where $(k_{ex}/k_{hyd})_{limit} \approx 0.23$ and $[B]/[BH^+] = 2.13$ substitution of these values into eq. [8] gives a ratio for k_{BH}'/k_{BP}' of approximately 1 ($0.23 \times 2 \times 2.13 = 0.98$).

Since the kinetic expression for buffer-catalyzed hydrolysis of **1** contains several variables estimation of the two parameters k_{BF} and k_{BP}' for the DABCO-catalyzed formation and breakdown of T_{O^-} were made using a constrained nonlinear least-squares fit of all the DABCO-catalyzed hydrolysis data (Tables S2 and 3) to eq. [5]. The constraints used in the nonlinear fit were as follows: $k_{BP}' = k_{BH}'$, $k_1 = 35.2\ M^{-1}\ s^{-1}$, and $k_3'[OH^-] \approx 0$. The calculated rate constants and standard errors that were derived using the program SYSTAT are $k_{BF} = 0.0066 \pm 0.0003\ M^{-1}\ s^{-1}$, $k_{BP}' = 29 \pm 6\ M^{-1}\ s^{-1}$, and $k_2' = 11.2 \pm 0.02$. Although, the complexity of eq. [5] means that these derived values are correlated the estimated value for k_2' is consistent with that obtained from the ratio of exchange to hydrolysis at zero buffer concentration (Table 3), i.e., $k_{ex}/k_{hyd} \approx 1/2k_2'$. Implicit in the above arguments is that the buffer acts as a general base rather than as a nucleophile during the catalytic reaction. If the buffer nucleophilically attacked the carbonyl carbon to generate an intermediate such as T_{ZW} then the ratio of k_{ex}/k_{hyd} should drop to zero, since no *carbonyl*-^{18}O exchange into the starting amide is possible from T_{ZW}. Therefore, if any nucleophilic attack by DABCO occurred the intermediate T_{ZW} must always revert to starting amide (Scheme 3).

From the above analysis it must be concluded that the observed DABCO-catalyzed breakdown of T_{O^-} to give hydrolysis products is an example of general base-catalysis. Consequently, the ejection of the pyrrole anion from the anionic tetrahedral intermediate must occur simultaneously with, and not subsequent to, proton removal. This conclusion is in contrast to the proposal of Menger and Donahue (8*a*).

(*iii*) Solvent deuterium kinetic isotope effect

The measured values for the SDKIE of 0.89 ± 0.05 for the hydroxide attack at the carbonyl carbon is similar to the reported value for **2** (2*c*) and is consistent with the transition state for this step involving direct attack of a partially desolvated hydroxide ion on the carbonyl carbon (2).

(*iv*) Structural comparison of amides 1 and 2

The data reported in Table 7 shows that in the solid state both amide linkages in **1** and **2** have similar structural parameters. Consequently, no information is obtained that can explain either the absence of buffer-catalysis during the hydrolysis of **2**, or the presence of this type of catalysis in the case of **1**.

Conclusions

In conclusion, replacement of the 4-methyl group in pyrrole amide **2** with a 4-nitro group (amide **1**) activates the amide linkage sufficiently that general-base-catalyzed attack of water on the carbonyl group becomes a viable mechanism. In addition, although the nitro group unquestionably increases the lifetime of the anionic tetrahedral intermediate (T_{O^-}), via inductive withdrawal, the uncatalyzed breakdown of T_{O^-} favours ejection of the pyrrole anion over hydroxide ion ($k_{ex}/k_{hyd} = 0.04–0.06$) to a greater extent than does the tetrahedral intermediate formed during the hydrolysis of **2** ($k_{ex}/k_{hyd} = 0.24$). This effect might be caused by the differences in acidity of the two respective tetrahedral intermediates. Thus, in compound **1** the electron-withdrawing nitro

© 1998 NRC Canada

group should result in the development of a stronger hydrogen bond at the transition state (k_2) for product formation.

Experimental

The following materials were purchased and used as received unless stated otherwise: pyrrole (Aldrich), 4-nitrobenzoyl chloride (Lancaster), potassium metal and thionyl chloride (Anachemia), $H_2{}^{18}O$ (Isotec, 98.5 atom % ^{18}O, lot no. DU2255), trimethylamine hydrochloride (SIGMA, TMA-HCl), deuterium oxide (Isotec, 99.9 atom % D), and potassium chloride (BDH). DABCO (1,4-diazabicyclo[2.2.2]octane; Aldrich, 98%) was recrystallized from pet ether for the ^{18}O-oxygen exchange experiments. Reagent grade tetrahydrofuran (BDH, THF) was distilled from its sodium benzophenone ketal, and reagent grade toluene (BDH) was distilled from calcium hydride. NMR spectra were acquired using a Brucker AMX400 NMR spectrophotometer operating at frequencies of 400.1 and 100.6 MHz for ^1H and ^{13}C, respectively. Mass spectra were obtained using a direct insertion probe and electron impact ionization (70 eV) on a Hewlett Packard 5985 mass spectrometer. Melting points are uncorrected.

N-(4-Nitrobenzoyl)pyrrole (1)

Under a dry nitrogen atmosphere potassium metal (0.9 g, 23.1 mmol) was added in small portions to a solution containing freshly distilled pyrrole (1.6 mL, 23.1 mmol) in anhydrous THF (20 mL). After the addition was complete the resulting solution was heated to reflux until the potassium had complete reacted. After cooling to ambient temperature anhydrous toluene (70 mL) was added followed by the dropwise addition of a solution containing 4-nitrobenzoyl chloride (4.29 g, 23.1 mmol) in anhydrous toluene (200 mL). The resulting solution was heated to reflux for 24 h, and after cooling to ambient temperature a mixture of 1:1 ice-cold water – diethyl ether (total volume 100 mL) was added. The diethyl ether layer was separated and washed with ice-cold water (50 mL). The two aqueous layers were combined and washed with diethyl ether (50 mL), after the two layers were separated the organic layers were combined and volatile materials were removed under reduced pressure. The resulting black residue was sublimed (100°C; 0.25 mTorr) onto a cold finger, and the resulting product was further purified by recrystallization from hexane:2-butanol to give an analytically pure sample of **1** (1.25 g; 25%): mp 128.5–130.0°C (lit. (8) mp 127–128°C); ir (KBr pellet), ν: 3155 (w), 3107 (w), 1692 (s), 1601 (m), 1519 (s), 1474 (s), 1409 (s), 1332 (s), 1256 (w), 1189 (w), 1112 (w), 1091 (m), 1075 (m), 1037 (w), 1012 (m), 972 (m), 884 (m), 865 (m), 844 (s), 747 (s), 730 (s) 712 (s); ^1H NMR (400 MHz; CD_3COCD_3), δ: 6.40 (2H, *app* dd), 7.29 (2H, *app* dd), 8.04 (2H, m), 8.43 (2H, m); ^{13}C NMR (100 MHz; CD_3COCD_3), δ: 166.6, 150.9, 140.0, 124.6, 122.0, 114.5; EI–MS, *m*/*z*: 216(M^+, 65), 150(100), 120(20), 104(25), 92(21), and 76(23). Anal. calcd. for $C_{11}H_8N_2O_3$: C 61.11, H 3.73, N 12.95; found: C 61.30, H 3.69, N 12.97.

N-(4-Nitro-*carbonyl*-^{18}O-benzoyl)pyrrole

To a solution of freshly distilled 4-nitrobenzoyl chloride (1.33 g, 7.2 mmol) in anhydrous THF (15 mL) was added ^{18}O-water (129 mL, 6.5 mmol) under a nitrogen atmosphere. After this solution had been stirred at ambient temperature for 24 h the volatile materials were removed under reduced pressure. To the resulting residue anhydrous toluene (15 mL) was added, followed by the dropwise addition of thionyl chloride (1.04 mL, 14.3 mmol), and the reaction mixture was heated to reflux for 18 h. After the volatile materials were removed under reduced pressure the resulting 4-nitro-*carbonyl*-^{18}O-benzoyl chloride was purified by vacuum distillation (125°C; 5 mTorr). The ^{18}O-labelled acid chloride was used to prepare *N*-(4-nitro-*carbonyl*-^{18}O-benzol)pyrrole in an analogous fashion to the preparation of unlabelled **1**. The overall yield for the synthesis of ^{18}O-labelled **1** from 4-nitrobenzoyl chloride was 21%; ir (KBr pellet), ν: 3155 (w), 3107 (w), 1692 (s), 1660 (s), 1601 (m), 1519 (s), 1474 (s), 1409 (s), 1332 (s), 1256 (w), 1189 (w), 1112 (w), 1091 (m), 1075 (m), 1037 (w), 1012 (m), 972 (m), 884 (m), 865 (m), 844 (s), 747 (s), 730 (s) 712 (s); EI–MS, *m*/*z*: 218(^{18}O-M^+, 59), 216(^{16}O-M^+, 72), 152(68), 150(100), 122(11), 120(11), 106(21), 104(30), 94(16), 92(17), and 76(44).

Hydrolysis kinetics

Hydrolysis of **1** was monitored by measuring the change in absorbance at either 240 nm (trimethylamine buffers) or 278 nm (OH^- solutions or DABCO buffers) using either a Cary-3E UV-vis spectrophotometer equipped with the Cary six cell Peltier constant temperature accessory or a DURRUM 110 stopped-flow apparatus thermostatted with a Lauda RM6 circulating water bath. The slower reactions were initiated by injection of a stock solution of **1** in DME (20–50 mL; 18.5 mM) into a equilibrated solvent mixture (3 mL; 30 min), whereas for the stopped-flow reactions an equal volume of a solution of **1** (0.4 mM) in 10^{-4} M HCl (μ = 1, KCl) was mixed with NaOH. Rate constants in deuterated solvents were measured in an analogous fashion using D_2O solutions.

Exchange kinetics

^{18}O-*Carbonyl* exchange of labelled-**1** in the presence of DABCO buffers was monitored utilizing a fluid flow system identical to that reported earlier (2*c*) except that the reaction was quenched by utilizing a pH-stat assembly consisting of Radiometer TTT80 titrator, ABU80 autoburette, a PHM82 standard pH meter, and a Broadley–James combination electrode (silver/silver chloride reference) to maintain the quenching solution at a pH of 4. The rate of ^{18}O-*carbonyl* exchange in the absence of buffer was measured using the pH-stat assembly to maintain a constant pH for a time equal to one or two times the half-time for hydrolysis of **1**. The labelled-**1** remaining in the hydrolysis medium was isolated by extracting the aqueous solution with freshly distilled CH_2Cl_2 (4 × 2 mL), and the combined organic layers were washed with a saturated $NaHCO_3$ solution (2 × 4 mL) and water (2 mL). The dichloromethane layer was dried ($MgSO_4$), filtered, and evaporated onto a small dry lint-free tissue. The tissue was inserted into a melting point tube and the ^{18}O-content of the sample was determined by mass spectroscopy. In a typical determination 20 separate scans of the M^+ and the $M^+ + 2$ ions in the mass spectrum were used to estimate the ^{18}O-content of the sample and its associated standard error. The rate constant for exchange was calculated using eq. [9] where $^{18}O_0$ is the ^{18}O-content of the start-

© 1998 NRC Canada

ing amide and $^{18}O_t$ is the ^{18}O-content of the amide reisolated from the reaction medium at time t.[4]

$$[9] \qquad k_{ex} = \frac{-\ln (^{18}O_t / ^{18}O_0)}{t}$$

Structure determination

A single colourless needle-shaped crystal of **1**, obtained from the slow evaporation of a solution of **1** in 1:1 v/v 2-butanol:hexane, was cleaved and fragments of a suitable size and shape were mounted on glass fibres using epoxy adhesive. Data were recorded at 205 K with an Enraf Nonius CAD4F diffractometer equipped with an in-house modified low-temperature attachment and using graphite monochromatized Mo K_α radiation. Two fragments of the same crystal, having comparable size and shape, were used because the first fragment became dislodged during an interruption of the cooling caused by ice build-up in the low-temperature apparatus. The same two intensity standard reflections were measured every hour of exposure time for both crystal fragments and, in either case, fluctuated by ±2.5% during the course of the measurements. No corrections for absorption were deemed necessary. Data reduction included corrections for intensity scale variations and for Lorentz and polarization effects.

The structure was solved using direct methods. All hydrogen atoms were located from an electron density difference map. All atomic coordinates, anisotropic thermal parameters for the non-hydrogen atoms and isotropic thermal parameters for the hydrogen atoms were refined.

An extinction parameter was refined (13). A weighting scheme, based on counting statistics, was used such that $\langle w(|F_o| - |F_c|)^2 \rangle$ was near constant as a function of both $|F_o|$ and sin θ/λ. Final full matrix least-squares refinement of 178 parameters for 1142 data ($I_o > 2.5\sigma(I_o)$) converged at R = 0.034 with a maximum |shift/error| of 0.001.

The programs used for data reduction, structure solution, refinement, and plot generation were from the NRCVAX crystal structure system (14). The programs suite CRYSTALS (15) was employed for analysis of structure factors and thermal parameters. Complex scattering factors for neutral atoms (16) were used in the calculation of structure factors. Computations were carried out on MicroVAX-II and 80486 computers.

Rigid body analysis (17) of the anisotropic thermal parameters of the molecule yielded R = 0.176 for the agreement between observed and calculated U_{ij} and an rms discrepancy of 0.0058 Å^2. In particular the oxygen atoms of the NO_2-group showed excess motion. Analysis of internal motion of the molecule in terms of a segmented rigid body (18) in which the NO_2 group was allowed libration about the C(14)—N(2) bond axis gave R = 0.089 and an rms discrepancy of 0.0023 Å^2.

DISQUAC structure-dependent interaction parameters for mixtures containing *sec*-alkanols and benzene, toluene, or *n*-alkanones

Juan Antonio González, I. García de la Fuente, and J.C. Cobos

Abstract: Mixtures containing *sec*-alkanols and benzene, toluene, or *n*-alkanones are characterized in terms of DISQUAC by means of structure-dependent interaction parameters. The quasichemical (QUAC) interchange coefficients are independent of the size alcohol for a given organic solvent; while the dispersive (DIS) ones change with the size of the alcohol. This behaviour has been found for other many alcoholic solutions. DISQUAC represents well the thermodynamic properties of these mixtures: vapor-liquid equilibria, VLE, molar excess Gibbs energies, G^E, and molar excess enthalpies, H^E. So, the mean deviations between experimental and calculated results are about 2% for pressure, and 8% for H^E. A short comparison between DISQUAC results and those given by the Dortmund version of UNIFAC, the UNIQUAC association theory and other similar model is also presented. In the case of the Dortmund version of UNIFAC, poorer predictions are obtained for H^E, as this property is more sensitive to molecular structure. Association theories provide better results because are used as correlation equations.

Key words: thermodynamics, 2-alkanols, group contributions, interactions.

Résumé : On a caractérisé des mélanges contenant des alcanols secondaires et du benzène, du toluène ou des alcanones en termes de «DISQUAC» à l'aide de paramètres d'interaction dépendants de la structure. Pour un solvant organique donné, les coefficients d'échange quasichimique («QUAC») sont indépendants de la taille de l'alcool alors que les coefficients dispersifs («DIS») varient avec la taille de l'alcool. On a aussi observé ce comportement avec plusieurs solutions alcooliques. Les «DISQUAC» permettent de donner une bonne représentation des propriétés thermodynamiques de ces mélanges: équilibre vapeur-liquide, «VLE», énergies molaires de Gibbs en excès, G^E, et enthalpies molaires en excès, H^E. Il en résulte que les déviations moyennes entre les résultats expérimentaux et les résultats calculés sont d'environ 2% pour la pression et de 8% pour H^E. On présente aussi une courte comparaison entre les résultats «DISQUAC» et ceux donnés par la version de Dortmound d'«UNIFAC», la théorie d'association «UNIQUAC» et d'autres modèles semblables. Dans le cas de la version de Dortmound d'«UNIFAC», on obtient de moins bonnes prédictions pour le H^E parce que cette propriété dépend fortement de la structure moléculaire. Les théories d'association conduisent à de meilleurs résultats parce qu'elles sont utilisées comme équations de corrélation.

Mots clés : thermodynamiques, alcanols secondaires, contributions de groupes, interactions.

[Traduit par la Rédaction]

1. Introduction

The theoretical treatment of alcoholic solutions is a very interesting matter due to the number of factors which contribute to the values of their thermodynamic properties: (*i*) self-association of the alcohols, which seems to be more important in other than in primary alkanols (1); (*ii*) change in the extent and strength of the hydrogen bonding when the mixture is formed (2, 3); (*iii*) physical contributions; (*iv*) structural effects (4). The values of the excess properties result from balances between these contributions, and their relative importance depends on the property under consideration (2–4). So, in mixtures with *n*-alkanes, there is an increase in magnitude of H^E in the sequence: primary alkanol < secondary alkanol < tertiary alkanol; whereas the variation of G^E is produced in the inverse sequence (4, 5). In systems including water, there are miscibility gaps for those with 1-butanol, *iso*-butanol, and 2-butanol, while no miscibility gap is observed for *tert*-butanol.

Group contribution methods are a common tool to predict thermodynamic properties using a low number of interaction parameters obtained from a limited data base. However, there are weaknesess related with the solution of groups concept when a very low number of interaction parameters is fitted because then some important effects are removed, e.g., isomeric effects. These ones are taken into account in different ways, depending on the model applied. Particularly for alcohols, in the framework of the Dortmund version of UNIFAC (6) (hereafter, merely UNIFAC), the hydroxyl group in primary, secondary, and tertiary alkanols is assumed to have different geometrical parameters but identical group energy-interaction parameters (except methanol). In

terms of DISQUAC (7, 8), the geometrical parameters of the hydroxyl group are assumed to be independent of its environment, but interaction parameters are different for 1-alkanols, *sec*-alkanols and *tert*-alkanols.

Association theories are other approach to treat alcoholic solutions. They are based on the existence in the mixture of polymeric species formed by hydrogen bonding. Actually, the model more widely applied, with excellent results, is the UNIQUAC association theory (9–13).

Under the basic assumption of structure-dependent interaction parameters (see below), we have shown that DISQUAC is a reliable method to represent thermodynamic properties, VLE, liquid–liquid (LLE), or solid–liquid equilibria, G^E, H^E, and excess heat capacities at constant pressure of alcoholic solutions. Up to now, the following classes of mixtures have been successfully characterized: 1-alkanols + *n*-alkanes (14–16), + cyclohexane (17, 18), + benzene or + toluene (19, 20), + CCl_4 (18, 21), + 1-alkanols (22, 23), + linear monocarboxylic acids (24), + propanal (25), or + *n*-alkanones (26); *tert*-alkanols (27), *sec*-alkanols (28) or cycloalkanols (29) + *n*-alkanes or cycloalkanes; and phenol + several organic solvents (30).

The purpose of the present article is to continue this previous work, extending DISQUAC to mixtures containing *sec*-alkanols and organic solvents such as benzene, toluene, or *n*-alkanones. At this end, we report the needed interaction parameters.

A short comparison between DISQUAC results and those given by UNIFAC, the UNIQUAC association model and other similar association model (see below) is also included.

2. The models

2.1. DISQUAC

2.1.1. Main features

DISQUAC is a purely physical model based on the rigid lattice theory developed by Guggenheim (31) for liquid mixtures. Some of its main features are: (*i*) the partition function is factorized into two terms, in such way that the excess functions are calculated as the sum of two contributions: a dispersive term which represents the contribution from dispersive forces, and a quasichemical term which arises from the anisotropy of the field forces created by the solution molecules; in the case of G^E, the combinatorial entropy is represented by the Flory–Huggins equation (32); (*ii*) the interaction parameters are assumed to be structure dependent; (*iii*) mixtures are studied systematically in order of increasing complexity of molecular structure and intermolecular interactions.

The fact that the coordination number, *z*, is assumed to be the same for all the contacts, is one of the more important shortcomings of DISQUAC, and can be partially removed via the hypothesis of considering structure-dependent interaction parameters. Although this means to leaving the classical concept of group contribution, it is essential for practical purposes. It leads to improved predictions, mainly in the case of branched and cyclic molecules, and for the first members of an homologous series.

2.1.2. Assessment of geometrical parameters

In the framework of DISQUAC, mixtures of *sec*-alkanols with benzene, toluene, or *n*-alkanones are regarded as possessing three types of surface: (*i*) type a, aliphatic (CH_3, CH_2, or CH in *sec*-alkanols, *n*-alkanones, or toluene); (*ii*) type h, hydroxyl (OH in *sec*-alkanols); (*iii*) type s, s = b or p, aromatic (C_6H_6 or C_6H_5 in toluene, respectively); s = k, carbonyl (CO in *n*-alkanones).

When DISQUAC is applied, the total relative molecular volumes, r_i, surfaces, q_i, and the molecular surface fractions, α_{si}, of the compounds present in the mixture are usually calculated additively on the basis of the group volumes V_G and surfaces A_G, recommended by Bondi (1968) (33). As volume and surface units, the volume V_{CH_4} and surface A_{CH_4} of methane are taken arbitrarily (32). The geometrical parameters for the groups referred to in this work are given elsewhere (28, 32, 34). They are assumed to be identical for the OH group in primary, secondary, and tertiary alkanols.

2.1.3. Equations

The equations used to calculate G^E and H^E are the same as in other applications (14). As coordination number, the reference value was chosen, that is, $z = 4$.

The temperature dependence of the interaction parameters g_{st}, h_{st}, and c_{pst} has been expressed in terms of the DIS and (or) QUAC interchange coefficients $C_{st,l}^{DIS}$ and $C_{st,l}^{QUAC}$, where s, t = a, b, k, or h, and $l = 1$ (Gibbs energy; $C_{st,l}^{DIS/QUAC} = g_{st}^{DIS/QUAC}(T_O)/RT_O$); $l = 2$ (enthalpy; $C_{st,2}^{DIS/QUAC} = h_{st}^{DIS/QUAC}(T_O)/RT_O$); and $l = 3$ (heat capacity; $C_{st,3}^{DIS/QUAC} = c_{pst}^{DIS/QUAC}(T_O)/R$); $T_O = 298.15$ K is the scaling temperature. This temperature dependence is as follows:

$$[1]\quad g_{st}^{DIS/QUAC}(T)/RT = C_{st,1}^{DIS/QUAC} + C_{st,2}^{DIS/QUAC}[(T_O/T) - 1] + C_{st,3}^{DIS/QUAC}[\ln(T_O/T) - (T_O/T) + 1]$$

where T is the system temperature. Accordingly,

$$[2]\quad h_{st}^{DIS/QUAC}(T)/RT = C_{st,2}^{DIS/QUAC}(T_O/T) - C_{st,3}^{DIS/QUAC}[(T_O/T) - 1]$$

and

$$[3]\quad C_{pst}^{DIS/QUAC}(T)/R = C_{st,3}^{DIS/QUAC}$$

2.2. Modified UNIFAC (Dortmund version)

The modified UNIFAC (6) differs from the original UNIFAC (35) by the combinatorial term and the temperature dependence of the group interaction parameters. This dependence is as follows:

$$[4]\quad \psi_{nm} = \exp\,[-(a_{nm} + b_{nm}T + c_{nm}T^2)/T]$$

The equations used to calculate G^E and H^E are obtained from the fundamental equation for the activity coefficient γ_i of component *i*:

© 1998 NRC Canada

[5] $$\ln \gamma_i = \ln \gamma_i^{COMB} + \ln \gamma_i^{RES}$$

where $\ln \gamma_i^{COMB}$ is the combinatorial term, which takes into account differences in size and shape, and $\ln \gamma_i^{RES}$ is the residual term, essentially due to energy interactions.

2.2.1. Assessment of geometrical parameters

In modified UNIFAC, alcohols are characterized by several different groups. Alkanols are represented by two main groups CH_3OH and OH; the main group CH_3OH is a group itself which characterizes methanol. The main group OH is subdivided in three subgroups, OH(p) for primary alkanols; OH(s) for secondary alkanols, and OH(t) for tertiary alkanols. Aromatic compounds are represented by two main groups ACH and $ACCH_2$, subdivided in two, ACH and AC, and three subgroups, $ACCH_3$, $ACCH_2$, and ACCH, respectively. Ketones are represented by the main group CH_2CO subdivided in two subgroups CH_3CO and CH_2CO. The subgroups have different geometrical parameters, but the subgroups within the same main group are assumed to have identical group energy-interaction parameters. The geometrical parameters, the relative van der Waals volumes and the relative van der Waals surfaces of the different subgroups are not calculated from molecular parameters like in the original UNIFAC but fit together with the interaction parameters (a_{nm}, b_{nm}, c_{nm}) to the experimental values of the thermodynamic properties considered. The geometrical and interaction parameters are taken from ref. (6) and used without modifications.

2.3. Association models

In these models, the factorization of the partition function into two terms leads to both physical and chemical contributions to the excess functions. The former can be calculated by an equation of state (EOS), e.g., the Flory EOS (36) in the ERAS model (37), or by the Scatchard–Hildebrand equation (38), NRTL (39) or UNIQUAC (40) equations in other continuous linear association models. The physical term plays an essential role when predicting LLE since the type of association normally observed is not sufficient, by itself, to produce phase separation (41). It is also important to describe H^E of ternary mixtures involving one alkanol (42). The chemical contribution is calculated assuming that the specific interactions lead to the formation of different associated species according to a well-defined set of chemical reactions of the Kretschmer and Wiebe type (43), each characterized by an equilibrium constant. The problem is to elucidate which polymeric species are present in the mixture, because the treatment and results depend on this point.

For the models considered here, the chemical contribution is similar: includes four association constants for open-chain and cyclic hydrogen-bonded groups and a solvation constant between the terminal hydroxyl group of the alcohol chain and a solvating molecule (9, 44, 45). However the physical term is different: Model I (44, 45) uses the NRTL equation and Model II (9) the UNIQUAC equation.

3. The interaction parameters

The general procedure used by us in the fitting of any interaction parameters has been described in detail elsewhere (14, 22) and will not be repeated here.

The three types of surface generate three pairs of contacts: (a, h); (a, s) and (h, s) where s = b, p, or k.

2-Propanol or 2-butanol + benzene or + toluene mixtures

These systems are characterized by three types of contact (a, h), (a, s), and (h, s) where s = b or p. The nonpolar (a, b) or (a, p) interactions are represented by DIS parameters calculated on the basis of properties of benzene or toluene + *n*-alkanes mixtures, respectively (46). In these systems, the experimental H^E values are larger than the calculated values for the higher *n*-alkanes (10 or more carbon atoms). It has been attributed to conformational and (or) short-range orientational changes when *n*-alkanes are mixed with globular molecules (Patterson's effect) (8, 46). As consequence, the interaction parameters depend on *n*, the number of carbon atoms in the *n*-alkane. However, for simplicity we have used the values corresponding to mixtures with *n*-heptane (Table 1), e.g., average values. The polar (a, h) contacts are represented by DIS and QUAC interchange coefficients (28) (Table 1). Being known the (a, b), or (a, p) and (a, h) parameters, those for the (h, s) contacts are obtained straightforward on the basis of the G^E and H^E data available (Table 2).

2-Propanol or 2-butanol + *n*-alkanones mixtures

These systems are characterized by three types of contact: (a, k), (a, h), and (h, k). The (a, k) polar interactions are represented by DIS and QUAC interchange coefficients, previously determined (47) (Table 1). Being known the (a, k) and (a, h) parameters, those for the (k, h) contacts are obtained straightforward (Table 2) using the G^E and H^E data available.

We note that, for a given solvent, the QUAC parameters are independent of the alcohol size, i.e., there is no steric effect on these parameters. This is an important result, also encountered in other many alcoholic solutions investigated in terms of DISQUAC: 1-alkanols + C_6H_6, + C_7H_8, + CCl_4, + *n*-alkanones or + propanal; cycloalkanols or phenol + alkanes. Nevertheless, some exceptions exist; e.g., in *sec*-alkanols + *n*-alkanes mixtures, the QUAC coefficients for l = 1 and l = 3 can be also kept constant, while for l = 2, one must distinguish two ensembles, depending on the situation of the OH group (2-alkanols and 3-alkanols), each characterized by different enthalpic QUAC interaction parameters (Table 1). The constancy of the QUAC parameters is probably a general characteristic of the model, very useful in absence of appropiate VLE data which can be used in the fitting of the first DIS and QUAC interchange coefficients. The latter are needed to estimate the QUAC enthalpic parameters because the quasichemical contribution to H^E depends not only on such parameters, but also on the first QUAC Gibbs energy parameters via the surface fractions and Boltzmann's factor (eqs. 40, 66, and 68 in ref. 32).

From the $C_{hk,l}^{DIS/QUAC}$ coefficients of 2-propanol or 2-butanol + *n*-alkanones, it is noted that its structure dependence is similar to that of 1-alkanols + *n*-alkanones (26). Estimation of interaction parameters for mixtures with higher *sec*-alkanols can be done easily. Such estimation is more difficult for mixtures with benzene or toluene due to the few experimental data available. It can be done assuming that only an inductive effect exists on the DIS coefficients, i.e.,

increase with the size of the alcohol while the the QUAC ones remain constant (see above).

4. Results

4.1. Comparison of DISQUAC results with experiment

Tables 3–5 and Figs. 1–5 show numerical and graphical comparisons, respectively, between experimental data and DISQUAC results. For the sake of major clarity deviations in pressure, P, and in H^E defined as

$$[6] \qquad \sigma_r(P) = \{1/N \Sigma [(P_{exp} - P_{calc})/P_{exp}]^2\}^{1/2}$$

$$[7] \qquad dev(H^E) = [1/N \Sigma (H^E_{exp} - H^E_{calc})^2]^{1/2}/H^E_{exp}(x = 0.5)$$

are also included in Tables 3 and 5, respectively. In eqs. [6] and [7], N stands for the number of data points of each system. Pressures are calculated at a given temperature and at different values of the mole fraction in the liquid state (isothermal VLE of the P–x type). The mean deviations between experimental and calculated results are about 2% for pressure, 4.9% for G^E at equimolar composition, and 8% for H^E. Note the good results obtained for azeotropes coordinates. In conclusion, DISQUAC provides a good representation of VLE, G^E and H^E. Even results for H^E of the 2-propanol + 2-propanone system at the higher temperatures are still acceptable (Table 5). An improvement could be obtained by using $C^{DIS}_{hk,3}$ = –2.00 and $C^{QUAC}_{hk,3}$ = –4.00. Then, the deviations (eq. [7]) for H^E at 283.15, 323.15, 343.15, and 363.15 K are respectively: 0.093, 0.025, 0.037, and 0.039.

On the other hand, it should be remarked that preliminary calculations show that it is possible to predict thermodynamic properties, VLE and H^E, of ternary systems including 2-alkanols and two of the organic solvents considered here on the basis of binary parameters only, that is, by neglecting ternary interactions. So, for VLE at 318.15 K of the 2-propanol + cyclohexane + toluene system (48), we obtain $\sigma_r(P)$ = 0.023 (N = 23), and for H^E at 298.15 K of the 2-propanol + benzene + cyclohexane (49), we found that $\sigma_r(H^E)$, defined similarly to eq. [6], is 0.044 (N = 67). These results are similar to those obtained for other ternary alcoholic solutions previously investigated in terms of DISQUAC (22, 50, 51).

4.2. Comparison with other models

Results obtained using UNIFAC for G^E and H^E at equimolar composition are collected in Tables 3 and 5, respectively. In the case of H^E, dev(H^E) as defined by eq. [7] is also given (Table 5). The mean deviations between UNIFAC results and experimental values are 11.6% for G^E (DISQUAC: 4.6%) at equimolar composition, and 27% for H^E (DISQUAC: 8%).

The poorer results are obtained for mixtures with toluene, when the number of needed interaction parameters is maximum (up 30), as the presence of the main group $ACCH_2$ in toluene increases the number of contacts. The good predictions obtained for the 2-propanol + 2-propanone system over a rather wide range of temperature are remarkable (Table 5).

The main advantage of UNIFAC is the large available matrix of interaction parameters, which can be used for predic-

[a]Estimated value.

tion purposes. However the main groups have to be subdivided to accommodate adjacent molecular structure of the components; in this way a molecular family is represented by one or several main groups subdivided in subgroups. As consequence, the interaction parameters between two main groups are constant but some isomers can no be distinguish from each other. On the other hand, proximity effects or cyclization are not considered properly (52). In this work, results for G^E are better than for H^E as this property is more sensitive to molecular structure. For 1-alkanols + linear oxaalkanes, a similar result is encountered (53).

The regular change of the DISQUAC parameters with molecular structure allows to estimate with confidence unavailable parameters, being the calculated properties in good agreement with the measured values.

Regarding the association models considered, they provide better results than DISQUAC (Table 6), because are used as methods of correlation of binary data in such way that each mixture has its own set of adjustable parameters, two for VLE and four for H^E. So, even the same mixture at different temperatures needs different adjustable parameters to reproduce VLE and H^E. An additional complication is that many sets of association constants must be tested to represent accurately the thermodynamic data over the whole concentration range (9, 44, 45).

5. Discussion

As already mentioned, the thermodynamic properties of alcoholic solutions are the result of several contributions (1–4; see Introduction).

At a given temperature, H^E of mixtures containing alcohols and organic solvents increases in the sequence: ketones > aromatic compounds > alkanes. This behaviour is independent of the isomeric alcohol considered (linear or branched). Moreover, for a given solvent, systems with 1-alkanols present lower H^E values than those with 2-alkanols. Such results may be interpreted in terms of the effective polarity of alcohols in liquid phase. In fact, this quantity is reasonably correlated by the dimensionless ratio (54, 55):

[a]The abbreviations used are the following: 2-PrOH, 2-propanol; 2-BuOH, 2-butanol; 1CO1, 2-propanone; 1CO2, 2-butanone.

[b]Obtained using an equation of the Redlich–Kister type to represent G^E.

[c]System used in the estimation of the interchange coefficients.

$$[8] \qquad \bar{\mu} = [\mu^2/4\pi\varepsilon_O\sigma^3 k_B T]^{1/2}$$

or equivalently, by virtue of the corresponding states principle by

$$[9] \qquad \bar{\mu} = [\mu^2 N_A/4\pi\varepsilon_O V_c k_B T]^{1/2}$$

where $\bar{\mu}$ is the effective dipole moment in liquid phase, μ is the dipole moment in the gas phase, ε_O the permittivity of the vacuum, σ an appropiate molecular size parameter, say the effective hard sphere diameter, N_A the Avogadro's constant, k_B the Boltzmann's constant, and V_C the critical molar volume.

It is noteworthy that, μ, of 1-alkanols in is practically the same (1.7, 1.8, and 1.8 D (56) for methanol, 1-butanol, or 1-decanol), $\bar{\mu}$ decreases with the aliphatic chain length of the alcohol (the respective values are: 0.60, 0.41, and 0.18), indicating that the alkanol–alkanol interactions in the condensed phase decrease in the sequence methanol > 1-butanol > ... 1-decanol.

For 1-propanol, 2-propanol, 1-butanol, and 2-butanol, not only the μ values are constant, 1.7, 1.7, 1.8, and 1.7 D (56), respectively, but also their $\bar{\mu}$ values have close values: 0.44, 0.44, 0.41, and 0.40, in the same order as above. This means that H^E(2-alkanols) > H^E(1-alkanols) may be well due to steric hindrance to H-bond formation, in such way that, at a given alcohol concentration, fewer hydrogen bonds would be formed in, e.g., 2-butanol (or *ter*-butanol) than in 1-butanol. This implies that more bonds are also broken in 2-alkanols than in 1-alkanols, leading to a higher value of H^E.

If the solvent is a polar compound, or a non-polar but active component, other effects come into play. Mainly, these are strong solvent-to-solvent and hydroxyl group-to-solvent interactions (2). When the solvent is a ketone, the latter produce a larger number of broken alkanol—alkanol bonds, and

Fig. 1. VLE for 2-alkanols(1) + toluene(2) mixtures at different temperatures. Solid lines, DISQUAC calculations; points, experimental values: ●, 2-propanol (61), 298.15 K; ■, 2-butanol (64), 333.31 K.

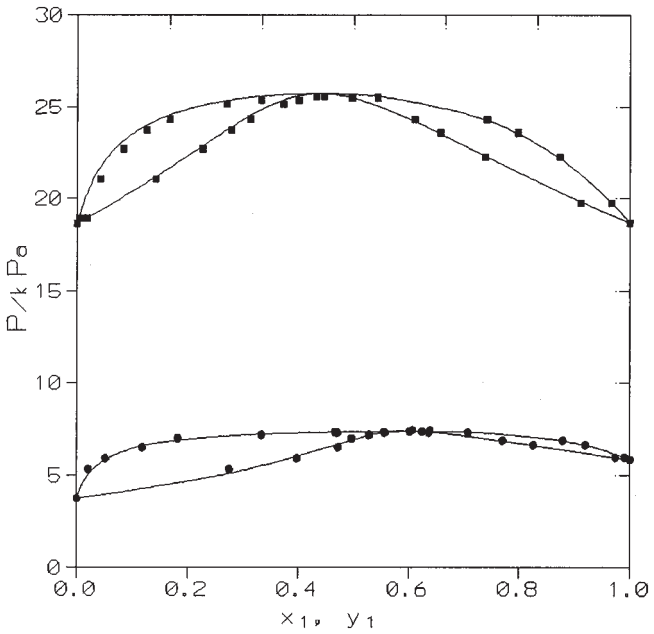

Fig. 2. H^E values for 2-propanol(1) + benzene(2) mixtures at different temperatures. Solid lines, DISQUAC calculations; points, experimental results (75): ●, 298.15 K; ■, 308.15 K; ▲, 318.15 K.

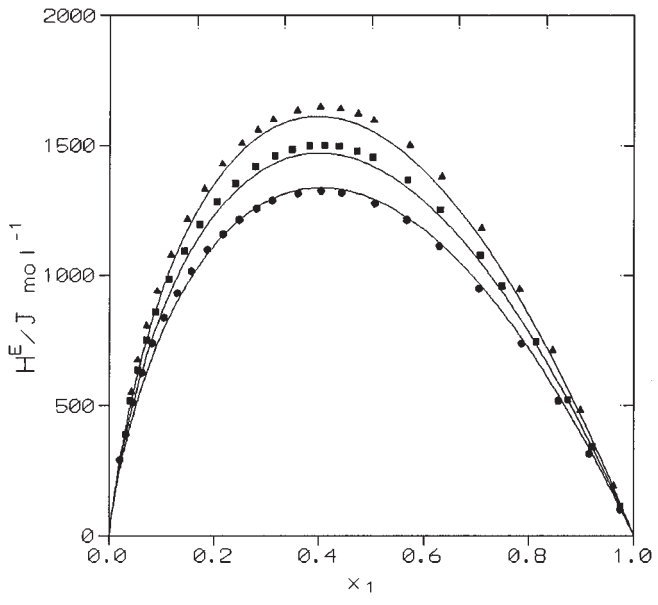

the formation of O—H---O=C bonds. Both effects decrease with the chain length of the alcohol. So, the increasing of H^E with the size of the alcohol for a given ketone is probably due to physical interactions between equal molecules.

DISQUAC describes fairly well this complex behaviour using structure-dependent interaction parameters, which follows rather simple rules. It is interesting to remark that our QUAC parameters follow the trend pointed out by Brown et al. (2) in an earlier work on alcoholic solutions. They explained the thermodynamic properties of mixtures of alcohols and *n*-alkanes by means of an idealized model in which the only exchange energies contributing to the mixture properties were the Gibbs energy, *w*, and the enthalpy, h, associated with the breaking of the hydrogen bonds. They assumed

that h was independent of the alcohol and that the number of broken alkanol–alkanol bonds was a function of w/k_BT. By comparing the hydroxyl group contribution to standard enthalpies of pure alcohols, they concluded that w(2-propanol) < w(1-propanol) (or w(*tert*-butanol) < w(2-butanol) < w(1-butanol)), and from here that H^E changes in the inverse sequence.

In terms of DISQUAC, we note that the first QUAC coefficients are lower for 2-alkanols than for 1-alkanols. The same occurs for the second QUAC coefficients. Probably,

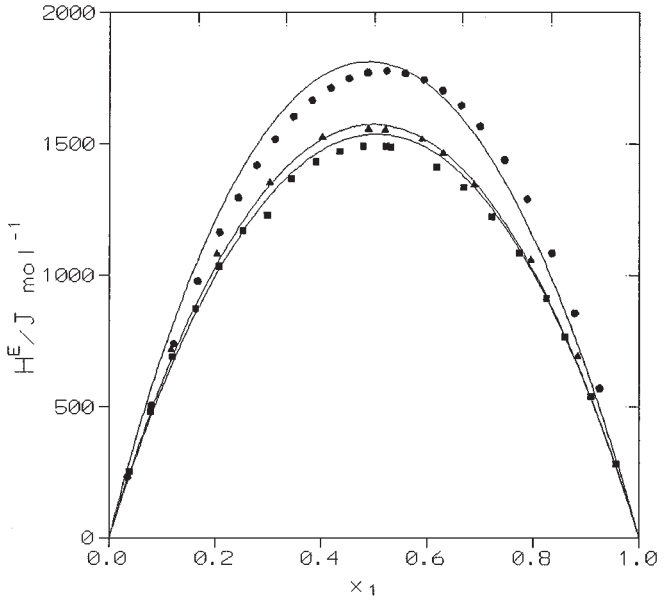
Fig. 5. H^E values of 2-alkanols(1) + 2-butanone(2) mixtures at different temperatures. Solid lines, DISQUAC calculations; points, experimental results: ■, 298.15 K and ▲, 318.15 K, 2-propanol (84); ●, 2-butanol (87), 298.15 K.



this is due to the existence of other effects, such steric hindrance, do not taken into account by Brown et al. (2).

6. Conclusions

The main conclusion is referred to the evolution of the structure-dependent interaction parameters: no steric effect is encountered in the QUAC interchange coefficients (they are independent of the compounds in the mixture for a given series), while an increasing inductive effect is observed in the DIS interchange coefficients. Using the reported interaction parameters, DISQUAC describes well a whole set of thermodynamic properties: VLE, G^E, or H^E.

Synthesis of a new class of difunctional tetraphenylene crown ethers

Harry W. Gibson, Devdatt S. Nagvekar, Yadollah Delaviz, and William S. Bryant

Abstract: Three new substituted tetraphenylene crown ethers have been made. Bis(5-carbomethoxy-1,3-phenylene)-bis(*p*-phenylene)-(3*x* + 6)-crown-*x*, where *x* = 12, 16, and 20 (**11b**–**11d**) were synthesized via [1 + 1] cyclization of methyl 3,5-bis[ω-chloro(oligoethyleneoxy)]benzoates (**13b**–**3d**) with methyl 3,5-bis[ω-(*p*-hydroxyphenoxy)(oligoethyleneoxy)]benzoates (**16b**–**6d**) using K_2CO_3 as base and tetrabutylammonium iodide as a phase transfer agent in dimethylformamide (DMF). The corresponding 30-membered (*x* = 8) macrocycle **11a** could not be made by this approach; only the elimination product, 3,5-bis(vinyloxy)benzoic acid (**19**), was isolated. **16a**–**16d** were made via alkylation of *p*-benzyloxyphenol (**14**) with **13a**–**13d**, respectively, followed by hydrogenolysis with Pd/C as catalyst. No complexation of these macrocycles with dibenzylammonium ions was detected by NMR spectroscopy, but weak complexation of **11d** with a paraquat derivative was observed.

Key words: crown ethers, cyclization, macrocycles.

Résumé : On a préparé trois nouveaux éthers couronnes de type tétraphénylène substitué. On a synthétisé les bis(5-carbométhoxy-1,3-phénylène)-bis(*p*-phénylène)-(3*x* + 6)-couronnes-*x*, dans lesquelles *x* = 12, 16 et 20 (**11b**–**11d**) par le biais d'une cyclisation [1 + 1] des 3,5-bis[ω-chloro(oligoéthylèneoxy)]benzoates de méthyle (**13b**–**13d**) avec les 3,5-bis[ω-(*p*-hydroxyphénoxy)(oligoéthylèneoxy)]benzoates de méthyle (**16b**–**16d**) dans le diméthylformamide (DMF), en présence de K_2CO_3 agissant comme base et d'iodure de tétrabutylammonium agissant comme agent de transfert de phase. Utilisant cette méthode, il n'a pas été possible de préparer le macrocycle correspondant à trente chaînons (*x* = 8) (**11a**); on n'a isolé que le produit d'élimination, l'acide 3,5-bis(vinyloxy)benzoïque (**19**). On a préparé les produits **16a**–**16d** par le biais d'alkylations du *p*-benzylphénol (**14**) avec les esters **13a**–**13d**, suivies d'une hydrogénolyse avec du Pd/C comme catalyseur. Par spectroscopie RMN, on n'a pas pu détecter de complexation de ces macrocycles avec les ions dibenzylammonium; on a toutefois observé une faible complexation du composé **11d** avec un dérivé du paraquat.

Mots clés : éthers couronnes, cyclisation, macrocycles.

[Traduit par la Rédaction]

Introduction

Crown ethers are an interesting class of molecules which are known for their ability to complex with a wide variety of cations, including metal and organic species (1). We are interested in macrocyclic polyethers which are semi-flexible in nature and have the ability to undergo complexation with linear molecules to form pseudorotaxanes, rotaxanes, and polyrotaxanes (see reviews in ref. 2*a*–*f*) of various types. A number of bisphenylene crown ethers with ring sizes from 24–34 atoms have been synthesized previously in our laboratory (3–5) for these purposes (2*a*, *b*, *g*–*o*; for poly(urethane crown ether rotaxane)s see ref. 2*g*; for poly(ester crown ether rotaxane)s see refs. 2*h* and *i*; for poly(methacrylate crown ether side chain rotaxane)s see ref. 2*j*; for self-assembled supramolecular structures see refs. 2*k*–*o*).

Larger macrocycles are also of interest for these and related applications. Bis(*p*-phenylene)-bis(*m*-phenylene)-66-crown-20 (**1b**) was isolated in 11% yield (6) as a [2 + 2] by-product from the [1 + 1] synthesis of *p*-phenylene-*m*-phenylene-33-crown-10 (**1a**) (7). Cyclization of resorcinol with tetra(ethylene glycol) ditosylate generated [1 + 1], [2 + 2], and [3 + 3] products, *m*-phenylene-16-crown-5 (**2a**), bis-*m*-phenylene-32-crown-10 (**2b**), and tris(*m*-phenylene)-48-crown-15 (**2c**) in 54, 8.4, and 1.7% yields, respectively (8). Tris(*p*-phenylene)-51-crown-15 (**3b)** and tetrakis(*p*-phenylene)-68-crown-20 (**3c**) have been reported (9) and shown to act as templates for paraquat units (**5**) in catenane syntheses and as hosts for dibenzylammonium ion (**6**), forming pseudorotaxanes with varying stoichiometries (10*a*). And recently the corresponding analogous 1,5-dioxynaphthalene family of crown ethers was expanded to include the bis-, tris-, and tetrakis- species **4a**–**4c**; these hosts were used in catenane syntheses using cyclobis(paraquat-arylene)s (10*b*). These reports have prompted us to describe our efforts with bis(5-carbomethoxy-1,3-phenylene)-bis(*p*-phenylene)-(3*x* + 6)-crown-*x* (**11a**–**11d**) systems, which began in 1990.

Our ongoing efforts led us to focus our attention on tetraphenylene macrocycles with ring sizes between 42 and 66 atoms.

Results and discussion

1. The [2 + 2] cyclization approaches

Although it is well known that multistep methods are more efficient for large oligomeric macrocycles than direct [*n* + *n*] approaches (11, 12), the latter have the appeal of using simple starting materials in a one-step procedure reaction sequence. Thus, we initially attempted the synthesis of tetraphenylene crown ethers in this way.

The generic [2 + 2] route to bis(5-carbomethoxy-1,3-phenylene)-bis(*p*-phenylene)-(3*x* + 6)-crown-*x* (**11**) (Schemes 1 and 2) involves preparation of bis[ω-chloro(oligoethyleneoxy)] derivatives (**9**) of hydroquinone and their condensations with methyl 3,5-dihydroxybenzoate (**10**).

This route to bis(5-carbomethoxy-1,3-phenylene)-bis(*p*-phenylene)-30-crown-8 (**11a**) was explored via synthesis of diol **8a** and its conversion to the corresponding dichloride **9a**, both in good yields. However, from the attempted cyclization of **9a** with **10** we were unable to isolate the desired **11a**.

The larger bis(5-carbomethoxy-1,3-phenylene)-bis(*p*-phenylene)-42-crown-12 (**11b**) was approached in an analogous manner. Hydroquinone was alkylated with 2-[2′-(2′′-chloroethoxy)ethoxy]tetrahydropyran (**7b**), and the resultant THP ether was deprotected to afford *p*-bis[2-(2′-hydroxyethoxy)ethoxy]benzene (**8b**). Treatment of **8b** with thionyl chloride produced *p*-bis[2-(2′-chloroethoxy)ethoxy]benzene (**9b**). Attempts to isolate macrocycle **11b** from condensation of bisphenol **10** and **9b** were fruitless.

2. The [1 + 1] cyclization approaches

The more efficient [1 + 1] cyclization approaches to higher cyclic oligomers requires the syntheses of larger building blocks, but allows the more effective use of pseudo-high dilution (syringe pump addition) techniques (11, 12). Tetraphenylene crown ethers **11** were approached by the method depicted in Scheme 3.

*(a) Dihalide intermediates **13***

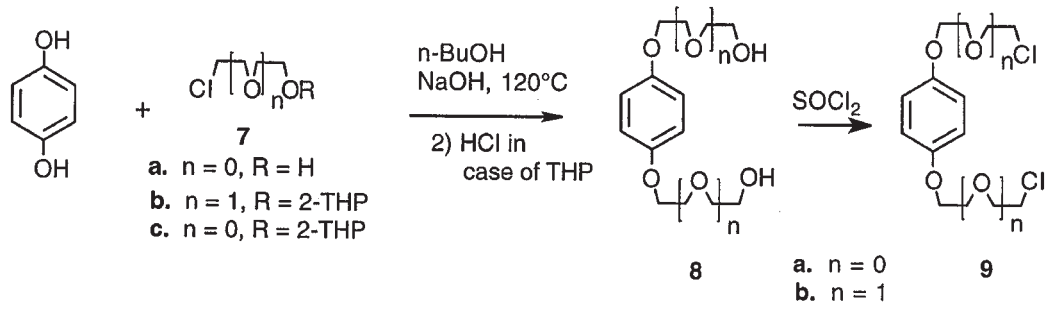
Methyl 3,5-bis(5-chloro-3-oxapentyloxy)benzoate (**13b**), methyl 3,5-bis(8-chloro-3,6-dioxaoctyloxy)benzoate (**13c**), and methyl 3,5-bis(11-chloro-3,6,9-trioxaundecyloxy)benzoate (**13d**) were each synthesized in one step by reacting large excesses of di-, tri-, and tetra-(ethylene glycol) dichlorides (**12b**–**12d**), respectively, with the disodium salt of methyl 3,5-dihydroxybenzoate (**10**) (Scheme 3), as previously reported (3, 4).

A one-pot synthesis of methyl 3,5-bis(2-chloroethoxy)benzoate (**13a**) was also attempted by reacting a suspension of the disodium salt of methyl 3,5-dihydroxybenzoate (**10**) with a large excess of dichloroethane (**12a**) in DMF. Thin layer chromatography (TLC) indicated a considerable amount of starting benzoate **10** along with the desired product **13a**, which was obtained (10%) upon Soxhlet extraction. Even at longer reaction times considerable amounts of starting material were found.

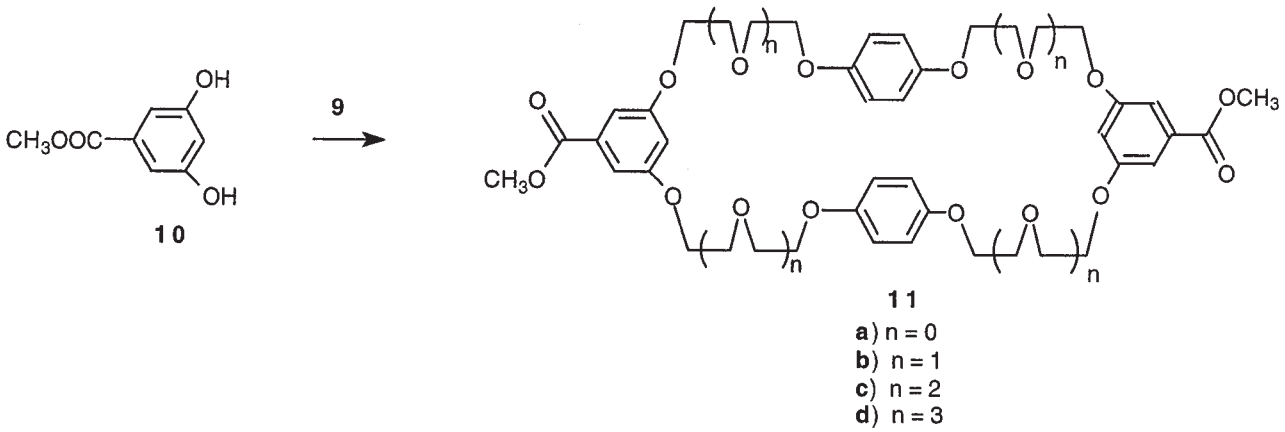
To synthesize methyl 3,5-bis(2-hydroxyethoxy)benzoate as a precursor to **13a**, the dianion of methyl 3,5-dihydroxybenzoate (**10**), generated in situ with potassium carbonate, was reacted with chloroethanol (**7a**) at 70°C for three days.

© 1998 NRC Canada

Scheme 1.



Scheme 2.



Less than a 10% yield of pure product was obtained. The use of THP protected chloroethanol (**7c**) was then examined. Treatment of methyl 3,5dihydroxybenzoate (**10**) with sodium hydride in DMF followed by reaction with **7c** gave (77%) after deprotection the desired intermediate methyl 3,5-bis(2-hydroxyethoxy)benzoate. After work-up this compound was without purification converted (88%) to the corresponding dichloride **13a** with thionyl chloride and pyridine in benzene.

*(b) Bisphenols **16***

The synthesis of the second fragment for cyclization to **11a**, methyl 3,5-bis[2-(*p*-hydroxyphenoxy)ethoxy]benzoate (**16a**), was initiated via reaction of *p*-benzyloxyphenol (**14**) with methyl 3,5-bis(2-chloroethoxy)benzoate (**13a**) using sodium hydride as base (Scheme 3), but this did not result in the formation of product **15a**. A three-step approach to **15a** was then evaluated (Scheme 4). Reaction of THP protected chloroethanol (**7c**) with *p*-benzyloxyphenol (**14**) and subsequent deprotection gave *p*-(2-hydroxyethoxy)benzyloxybenzene (**17**) in quantitative yield. The compound **17** was converted to the chloro derivative **18** with thionyl chloride and pyridine. Reaction of methyl 3,5-dihydroxybenzoate (**10**) with **18** using sodium hydride as base gave (60%) the desired product, methyl 3,5-bis[2(*p*-benzyloxyphenoxy)ethoxy]benzoate (**15a**).

Methyl 3,5-bis{[*p*-(benzyloxy)phenoxy]oligoethyleneoxybenzoates (**15b**–**15d**) were produced via reaction of *p*-benzyloxyphenol (**14**) with dichlorides **13b**–**13d** using sodium hydride as the base (Scheme 3). These intermediates were purified via flash silica gel chromatography and characterized by NMR and FAB MS.

Removal of the benzyl groups from **15a**–**15d** via hydrogenolysis with palladium on carbon as catalyst gave the desired bisphenols **16a**–**16d** in 90–99% yields (Scheme 3).

*(c) Cyclization reactions to form macrocycles **11***

Our previous cyclization studies showed that the yields were either higher (20- and 26-membered) (5) or almost identical (32-membered) (3, 4) with potassium salts, as compared to the more expensive cesium salts. Thus, we used potassium carbonate as the base in the [1 + 1] cyclization of the bisphenols **16b**–**16d** with dichlorides **13b**–**13d** in DMF at 110°C (Scheme 3). This method provided macrocycles **11b**–**11d** in 17–24% yields.

The cyclization of methyl 3,5-bis[2-(*p*-hydroxyphenoxy)ethoxy]benzoate (**16a**) with methyl 3,5-bis(2-chloroethoxy)benzoate (**13a**) under these conditions was not successful. Therefore, cyclization was attempted at 85°C using sodium hydride as base in DMF via the syringe pump technique. Sodium was used as the metal ion to match the small cavity size of 30-membered **11a**. However, we were able to isolate only (19%) 3,5-bis(vinyloxy)benzoic acid (**19**), the product of two elimination reactions.

*(d) Attempted complexation with dibenzylammonium salt **6***

Bis(*o*- and *p*-phenylene) crown ethers are known to complex strongly with secondary ammonium ions, such as dibenzylammonium hexafluorophosphate (**6**), yielding pseudorotaxanes (2*c*, *e*, *f*, 10*a*, 13) In the present work, in the ^{1}H NMR spectra of $CDCl_3$ solutions of **11b**–**11d** (individually) in the presence of solid ammonium salt **6** there were no indi-

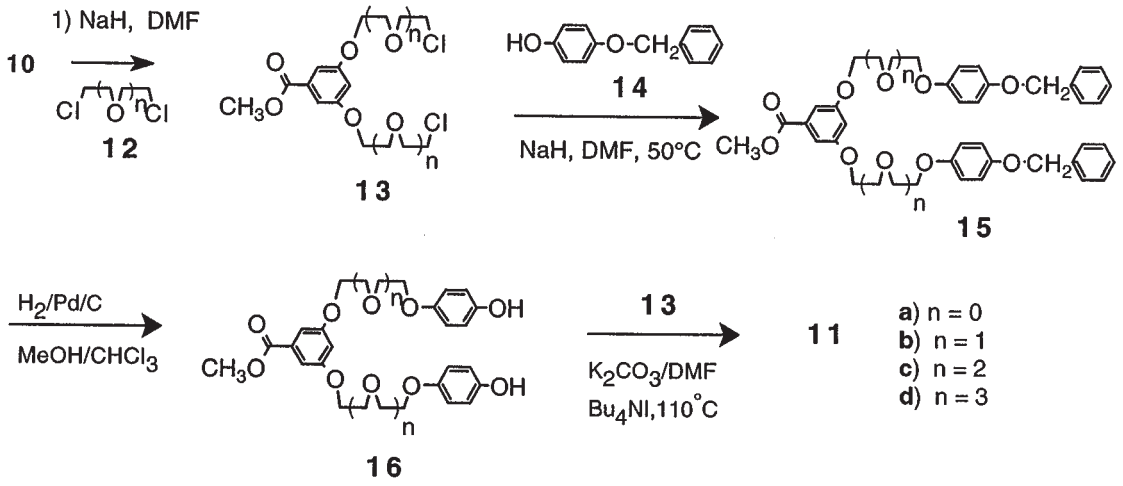
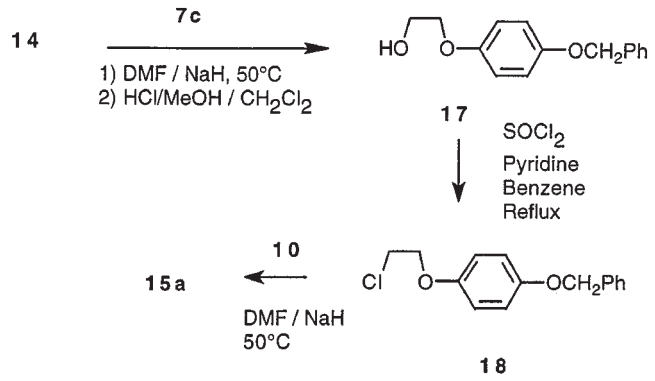


Scheme 4.



cations of complexation, i.e., no changes of chemical shifts of the proton signals; furthermore, the ammonium salt did not dissolve in $CDCl_3$ solutions of the crown ethers, a good qualitative test for complex formation.

The inclusion complexation of secondary ammonium ions such as **6** by crown ethers appears to be relatively facile based on the isolation of pseudorotaxanes of various stoichiometries for benzo and *p*-phenylene macrocycles ranging from dibenzo-24-crown-8 to tetrakis(*p*-phenylene)-68-crown-20 (**3d**) (10*a*, 13). As deduced from single crystal X-ray structures, the N-H—O bonds in these complexes involve both the phenolic and ethyleneoxy oxygen atoms, as do the benzylic C-H—O bonds, in some cases augmented by π–π interactions. However, we have found that bis(*m*-phenylene) crown ethers complex either very weakly or not at all with secondary ammonium ions (14). Bis(*m*-phenylene)-26-crown-8, in spite of its homology with dibenzo-24-crown-8, which efficiently yields a pseudorotaxane (13), does not give any indication of complexation with **6** by NMR spectroscopy. The larger bis(*m*-phenylene)-32-crown-10 (**2b**), like its 34-membered *p*-analog **3b** (13), gives [3]pseudorotaxanes with two ammmonium ions as guests, but its association constants are quite low (<10 M^{-1}) (14). X-ray analysis of the crystalline [3]pseudorotaxane **2b**:(**6**)$_2$ revealed that the structure and attractive forces are very similar to those reported for **3b**:(**6**)$_2$ (13, 14). The difference in the association constants, therefore, must be a result of poorer preorganization in the case of **2b**. In **11b**–**11d** the electron-withdrawing carbomethoxy groups on the *m*-phenylene units further decrease the tendency for the *m*-phenylene moieties to undergo complexation. However, the hydroquinol ether linkages were expected to provide suitable sites. The only explanation for the lack of complexation of secondary ammonium ions by **11b**–**11d** seems to be that the conformational properties imbued by the *m*-phenylene units are such that complexation is entropically unfavorable.

*(e) Complexation with paraquat diol **5b***

The complexation of paraquat (**5a**) with bis(*m*-phenylene)-32-crown-10 and bis(*p*-phenylene)-34-crown-10 is driven primarily by hydrogen bonding of the α-protons of the bipyridinium units with the ether oxygen atoms, but also involves donor–acceptor, π-stacking, and dipole–dipole attractions (15). It has been deduced that, because four ethyleneoxy units serve to maximize the association constants, hydrogen bonding of the central oxygen atom in the tetra(ethyleneoxy) segment is most important, but that the next nearest oxygen atom plays a role by an allosteric effect (16). X-ray crystallographic results show that both of these interactions are in force in the solid state (6, 9, 15).

Upon mixing solutions of **11d** with **5b** a pale yellow–orange color indicative of charge transfer was observed; in the ^{1}H NMR spectra shifts of the signals for the hydroquinol unit proton, the intra-annular aromatic proton of the *m*-phenylene unit and the CH_2O group adjacent to the hydroquinol unit were observed. Although we have not yet determined the stoichiometry of this complex, it is clear that some relatively weak complexation takes place. Studies with crown ethers containing *m*-phenylene linkages in comparison to their *p*-linked counterparts, e.g., **2b** vs. **3b**, and internally in catenanes derived from **1a**, have demonstrated the preference of paraquat (**5a**) complexation centered on the *p*-phenylene units (6). Thus, we hypothesize that the hydroquinol units of **11d** are the active sites, especially since we have shown that the electron-withdrawing carbomethoxy groups in bis(5-carbomethoxy-1,3-phenylene)-32-crown-10

© 1998 NRC Canada

are detrimental for complexation of paraquats.[2]

Current work is aimed at determining the stoichiometry of the complex of **11d** with **5b**, so that its association constant can be measured, and, hopefully, obtaining crystals suitable for X-ray analysis.

Experimental

Materials

Unless specified otherwise, reagent grade reactants and solvents were used as received from chemical suppliers. The compounds **5b** (17), **6** (13), **7b** (18), **7c** (19), **10** (20), **13b** (3), **13c** (3), and **13d** (4) were synthesized according to literature procedures.

Instrumentation and techniques

Melting points were taken in capillary tubes and have been corrected. The ^{1}H and ^{13}C NMR spectra were obtained at room temperature (RT) on a 400 MHz spectrometer using $CDCl_3$ as solvent with $SiMe_4$ (δ = 0) as internal standard, except as noted. The MS was carried out in house, at the Washington University Mass Spectrometry Resource and at the Nebraska Center for Mass Spectrometry using the FAB technique in 3-nitrobenzyl alcohol matrices (HR = high resolution). A syringe infusion pump was used to control the addition rates in the cyclization reactions.

p-Bis(2-hydroxyethoxy)benzene (8a)

A solution of **7c** (52.5 g, 320 mmol) in *n*-BuOH (150 mL) was added dropwise to a refluxing solution of hydroquinone (11.0 g, 101 mmol), NaOH (8.20 g, 200 mmol), sodium dithionite (40 mg), and *n*-BuOH (300 mL). The solution was refluxed for 15 h under N_2, and more NaOH (2.90 g, 72.5 mmol) was added and refluxing was continued for 15 h. The reaction mixture was cooled, filtered, and concentrated in vacuo to remove solvent and excess **7c**. The residue was dissolved in MeOH:CH_2Cl_2 (1:1 v:v, 500 mL), treated with conc. HCl (5 mL) and stirred for 4 h at RT to hydrolyze the THP ether. The solution was neutralized with $NaHCO_3$. The organic layer was dried (Na_2SO_4) and evaporated to give the crude product (17.0 g, 85%), which was recrystallized from EtOAc: mp 105–107°C; this compound is commercially available.

p-Bis[2-(2′-hydroxyethoxy)ethoxy]benzene (8b)

Application of the above procedure using **7b** on twice the scale afforded 43.6 g (76%) of colorless solid after recrystallization from EtOAc: mp 74.5–75.5°C. ^{1}H NMR, δ (ppm): 2.75 (s, 2H), 3.6–4.4 (m, 16H), 6.85 (s, 4H). Anal. calcd. for $C_{14}H_{22}O_6$: C 58.72, H 7.75; found: C 58.64, H 7.78.

p-Bis(2-chloroethoxy)benzene (9a)

The compound $SOCl_2$ (223.0 g, 1.874 mol) was added very slowly to a solution of **8a** (148.66 g, 750 mmol), pyridine (150 mL), and toluene (450 mL). The solution was refluxed for 24 h, cooled, and the precipitate was extracted with toluene (2 × 150 mL). The extract was washed with H_2O (200 mL), dried (Na_2SO_4), and evaporated to produce 149.5 g (79%) of crude product, which was recrystallized from EtOAc: mp 102–103°C, lit. (21) oil. ^{1}H NMR, δ (ppm): 3.79 (t, J = 7 Hz, 4H), 4.19 (t, J = 7 Hz, 4H), 6.87 (s, 4H). MS (EI), m/z: 238 [(M $^{37}Cl_2)^+$, 10%], 236 [(M ^{37}Cl $^{35}Cl)^+$, 67%], 234 [(M $^{35}Cl_2)^+$, 100%], 171 [(M $^{35}Cl_2$ – CH_2CH_2Cl), 90%], 109 [(M – 2(CH_2CH_2Cl)), 100%].

p-Bis[2-(2′-chloroethoxy)ethoxy]benzene (9b)

Application of the above procedure to **8b** produced (85%) crude **9b**, which was recrystallized from EtOAc: mp 62.2–64.0°C, lit. (21) oil. ^{1}H NMR, δ (ppm): 3.6–4.2 (m, 16H), 6.85 (s, 4H). MS (EI), m/z: 324 [(M ^{37}Cl $^{35}Cl)^+$, 24%], 322 [(M $^{35}Cl_2)^+$, 35%], 113 (100%). Anal. calcd. for $C_{14}H_{20}Cl_2O_4$: C 52.02, H 6.24; found: C 51.88, H 6.25.

Methyl 3,5-bis(2-hydroxyethoxy)benzoate

NaH (5.14 g, 128 mmol, 60% in mineral oil) was added to a solution of **10** (10.05 g, 59.77 mmol) in 100 mL of DMF, and the mixture was heated at 110°C for 2 h, cooled to 50°C, and **7c** (22.29 g, 135.4 mmol) was added while stirring. After 5 days the mixture was cooled to RT, filtered through Celite, and concentrated in vacuo. The resulting brown oil was extracted with MeOH:CH_2Cl_2 (70:30, 250 mL) containing 20 mL of conc. HCl. After concentration the mixture was diluted with H_2O (250 mL) and treated with satd. aq. $NaHCO_3$. After extraction with EtOAc (3 × 100 mL), the organic layer was washed with H_2O and satd. aq. NaCl. The brown oil (11.85 g, 77%) was used for the next step without further purification. ^{1}H NMR, δ (ppm): 3.89 (s, 3H), 3.96 (t, J = 4.4 Hz, 4H), 4.07 (t, J = 4.4 Hz, 4H), 6.65 (t, J = 2.2 Hz, 1H), and 7.17 (d, J = 2.2 Hz, 2H). ^{13}C NMR, δ (ppm): 52.30, 61.16, 69.48, 106.86, 107.98, 131.90, 159.56, and 166.72 (8 peaks as required).

Methyl 3,5-bis(2-chloroethoxy)benzoate (13a)

A solution of methyl 3,5-bis(2-hydroxyethoxy)benzoate (10.98 g, 42.85 mmol) in C_6H_6 (275 mL) was refluxed for 30 min using a Dean–Stark apparatus. At RT pyridine (7.0 mL, 87 mmol, 2.0 equiv.) was added along with $SOCl_2$ (6.4 mL, 88 mmol) over 1 h. After 48 h at reflux, the mixture was cooled to RT and the salt removed by decantation, washed with C_6H_6, and the organic layers were combined and then washed sequentially with H_2O, dil. HCl, and satd. aq. NaCl. Evaporation resulted in an oil; passage through a short SiO_2 column using $CHCl_3$:EtOAc (20:1) gave **13a** (11.10 g, 88%), an oil, which crystallized: mp 68.2–69.4°C. ^{1}H NMR, δ (ppm): 3.82 (t, J = 5.8 Hz, 4H), 3.90 (s, 3H), 4.25 (t, J = 5.8 Hz, 4H), 6.70 (t, J = 2.4 Hz, 1H), and 7.21 (d, J = 2.4 Hz, 2H). ^{13}C NMR, δ (ppm): 41.70, 52.26, 68.23, 107.06, 108.33, 132.20, 159.18, 166.37 (8 peaks as required). Anal. calc. for $C_{12}H_{14}Cl_2O_4$: C 49.16, H 4.81; found: C 49.48, H 4.77.

p-(2-Hydroxyethoxy)benzyloxybenzene (17)

NaH (1.84 g, 46.0 mmol, 60% in mineral oil) was added to a solution of **14** (8.02 g, 40.1 mmol) in DMF (60 mL). At 50°C, **7c** (7.45 g, 45.3 mmol) was added, and the mixture was stirred for 30 h at 50°C. After filtration, DMF was evaporated, and the oil was diluted with MeOH:CH_2Cl_2 (6:2,

[2] P.B. Balanda and H.W. Gibson. Unpublished results.

150 mL) containing conc. HCl (5 mL). After 6 h, the solvent was removed, and the mixture was diluted with H_2O. The EtOAc extract was dried (Na_2SO_4) and evaporated to give a white solid, which was recrystallized from EtOH to give **17** (10.02 g, 100%), a white solid: mp 104.2–106.0°C, lit. (22) mp 103.5–104.5. ^{1}H NMR, δ (ppm): 3.90 (m, 2H), 4.00 (t, J = 4.4 Hz, 2H), 5.00 (s, 2H), 6.86 (AB q, J = 9.2 Hz, 4H), and 7.36 (m, 5H). ^{13}C NMR, δ (ppm): 61.45, 69.80, 70.59, 115.49, 115.81, 127.40, 127.83, 128.48, 137.14, 152.88, and 153.20 (11 peaks as required).

p-(2-Chloroethoxy)benzyloxybenzene (18)

Pyridine (7.6 mL, 94 mmol) and then $SOCl_2$ (6.9 mL, 95 mmol) were added to a solution of **17** (9.53 g, 39.0 mmol) in C_6H_6 (150 mL). After 48 h at reflux, the mixture was cooled to RT, and salt was removed by decantation, washed with C_6H_6, and the organic layers were combined, washed with H_2O, dil. HCl, and satd. aq. NaCl. Evaporation gave a light yellow solid, which was recrystallized from EtOH to give **18** (8.38 g, 82%), a white solid: mp 69.7–71.2°C. ^{1}H NMR, δ (ppm): 3.75 (t, J = 5.8 Hz, 2H), 4.14 (t, J = 5.8 Hz, 2H), 4.99 (s, 2H), 6.87 (AB q, J = 9.2 Hz, 4H), and 7.37 (m, 5H). ^{13}C NMR, δ (ppm): 41.97, 68.79, 70.57, 115.83, 115.89, 127.40, 127.86, 128.49, 137.12, 152.44, and 153.46 (11 peaks as required). Anal. calc. for $C_{15}H_{15}ClO_2$: C 68.57, H 5.75; found: C 68.66, H 5.78.

Methyl 3,5-bis[2-(*p*-benzyloxyphenoxyethoxy]benzoate (15a)

Method A: NaH (316 mg, 13.2 mmol,) was added to a solution of **10** (1.02 g, 6.07 mmol) in DMF (60 mL), and the solution was stirred for 1 h at 110°C. At 65°C, **18** (3.30 g, 12.6 mmol) was added as a solid, and the mixture was stirred for 48 h. After filtration, DMF was evaporated, and the oil was subjected to column chromatography (SiO_2) with $CHCl_3$:EtOAc (20:1). The resultant oil upon trituration with hexane gave **15a**, a white solid (2.27 g, 60%): mp 79.4–81.7°C. ^{1}H NMR, δ (ppm): 3.90 (s, 3H), 4.28 (m, 8H), 5.02 (s, 4H), 6.76 (brs, 1H), 6.90 (AB q, 8H, J = 9.2 Hz, 8H), 7.25 (d, J = 2.0 Hz, 2H), and 7.37 (m, 1 OH). ^{13}C NMR, δ (ppm): 52.25, 66.95, 67.11, 70.66, 107.15, 108.22, 115.78, 115.86, 127.44, 127.87, 128.52, 132.02, 137.19, 152.878, 153.33, 159.66, and 166.69 (17 peaks as required). Anal. calc. for $C_{38}H_{36}O_8$: C 73.53, H 5.85; found: C 73.14, H 6.13.

Method B: The same except using 1.82 g (13.2 mmol) of K_2CO_3 instead of NaH at 80°C; 3.03 g (80%) of **15a**.

Methyl 3,5-bis[5-(*p*-benzyloxyphenoxy)-3-oxapentyloxy]benzoate (15b)

NaH (680 mg, 17 mmol, 60% in mineral oil) was added to a stirred solution of **14** (3.24 g, 16.2 mmol) in DMF (50 mL). After 30 min a solution of **13b** (2.95 g, 7.74 mmol) in DMF (20 mL) was added, and the mixture was stirred for 2 days at RT, filtered, and concentrated to give an oil, which was purified via flash SiO_2 chromatography using Et_2O to give 3.38 g (62%) of **15b**, a white solid, which was recrystallized from EtOAc:pet. ether (bp 39–59°C): mp 60.9–62.4°C. ^{1}H NMR, δ (ppm): 3.88 (s, 3H), 3.90 (m, 8H), 4.10 (t, J = 4.8 Hz, 4H), 4.16 (t, J = 4.8 Hz, 4H), 5.00 (s, 4H), 6.71 (t, J = 2.4 Hz, 1H), 6.87 (AB q, J = 9.2 Hz, 8H), 7.20 (d, J = 2.4 Hz, 2H), and 7.37 (m, 10H). ^{13}C NMR, δ (ppm): 52.22, 67.79, 68.13, 69.76, 70.06, 70.64, 106.93, 108.12, 115.65, 115.77, 127.46, 127.86, 128.52, 131.90, 137.25, 153.06, 153.15, 159.72, and 166.74 (19 peaks as required). MS (FAB), m/z (rel. int.): 708 [M^+, 100%], 677 [$(M - OCH_3)^+$, 76%], and 586 [$(M - OCH_3 - CH_2C_6H_5)^+$, 12%]. HRFAB, m/z, calcd. for $C_{42}H_{44}O_{10}$ [$M]^+$: 708.2934; found: 708.2955 (error 2.8 ppm).

Methyl 3,5-bis[8-(*p*-benzyloxyphenoxy)-3,6-dioxaoctyloxy]benzoate (15c)

A procedure similar to that used for **15b** was utilized to prepare **15c** (63%), which crystallized slowly to give a light yellow solid: mp 61–63°C. ^{1}H NMR, δ (ppm): 3.74 (m, 8H), 3.84 (m, 8H), 3.87 (s, 3H), 4.07 (t, J = 4.8 Hz, 4H), 4.13 (t, J = 4.8 Hz, 4H), 6.69 (s, 4H), 6.70 (t, J = 2.2 Hz, 1H), 6.86 (AB q, J = 9.2 Hz, 8H), 7.19 (d, J = 2.2 Hz, 2H), and 7.35 (m, 10H). ^{13}C NMR, δ (ppm): 52.16, 67.68, 68.00, 69.58, 69.86, 70.58, 70.79, 70.84, 106.86, 107.99, 115.71, 115.56, 127.42, 127.81, 128.48, 131.84, 137.22, 153.05, 153.08, 159.71, and 166.70 (21 peaks as required). MS (FAB), m/z (rel. int.): 819.4 [$(M + Na)^+$, 5%], 796.4 (M^+, 85%), 765.4 [$(M - OCH_3)^+$, 42%], 706.4 [$(M - COOCH_3)^+$, 8%], and 674 [$(M - OCH_3 - CH_2C_6H_5)^+$, 5%], 76 [100%]. HRFAB, m/z, calcd. for $C_{46}H_{52}O_{12}$ [$M]^+$: 796.3459; found: 796.3476 (error 2.2 ppm). Anal. calc. for $C_{46}H_{52}O_{12}$: C 69.33, H 6.58; found: C 69.48, H 6.63.

Methyl 3,5-bis[11-(*p*-benzyloxyphenoxy)-3,6,9-oxaundecyloxy]benzoate (15d)

A procedure similar to that used for **15b** was utilized to prepare **15d** (64%), an oil. ^{1}H NMR, δ (ppm): 3.70 (m, 16H), 3.82 (m, 8H), 3.87 (s, 3H), 4.06 (t, J = 4.8 Hz, 4H), 4.12 (t, J = 4.8 Hz, 4H), 4.99 (s, 4H), 6.68 (t, J = 2.4 Hz, 1H), 6.86 (AB q, J = 9.2 Hz, 8H), 7.19 (d, J = 2.4 Hz, 2H), and 7.36 (m, 10H). ^{13}C NMR (ppm): 52.19, 67.68, 67.98, 69.54, 69.80, 70.59, 70.63, 70.74, 70.79, 106.84, 107.97, 115.54, 115.71, 127.43, 127.82, 128.48, 131.82, 137.22, 153.03, 153.08, 159.70, and 166.72 (22 peaks; theory 23). MS (FAB), m/z (rel. int.): 907 [$(M + Na)^+$, 2%], 884 [M^+, 41%], 853 [$(M - OCH_3)^+$ 32%], and 762 [$(M - C_8H_{10}O)^+$, 3%], 225 (56%), 200 (100%); HRFAB, m/z, calcd. for $C_{50}H_{60}O_{14}$ [$M]^+$: 884.3983, found: 884.3982 (error 0.1 ppm).

Methyl 3,5-bis[2-(*p*-hydroxyphenoxy)ethoxy]benzoate (16a)

A solution of **15a** (1.08 g, 1.74 mmol) in $CHCl_3$:MeOH (1:1, 40 mL) containing Pd/C (100 mg) was subjected to hydrogenolysis at 60 psi for 48 h, filtered, and concentrated to give an oil, which was purified by SiO_2 column chromatography. Addition of $CHCl_3$ to the resulting oil gave **16a** (0.96 g, 90%), a white solid: mp 130.3–131.9°C. ^{1}H NMR, δ (ppm): 3.84 (s, 3H), 4.20 (m, 4H), 4.32 (m, 4H), 6.76 (AB q, J = 9.2 Hz, 8H), 6.90 (t, J = 2.2 Hz, 1H), 7.12 (d, J = 2.2 Hz, 2H), and 8.95 (s, 2H). ^{13}C NMR, δ (ppm): 52.32, 66.67, 66.98, 106.30, 107.58, 115.50, 115.74, 131.65, 151.04, 151.38, 159.61, and 165.83 (12 peaks, as required). Anal. calc. for $C_{24}H_{24}O_8 \cdot H_2O$: C 62.87, H 5.72; found: C 62.72, H 5.36.

Methyl 3,5-bis[5-(*p*-hydroxyphenoxy)-3-oxapentyloxy]benzoate (16b)

A solution of **15b** (2.58 g, 3.64 mmol) in $CHCl_3$:EtOAc (1:1, 30 mL) was subjected to hydrogenolysis (60 psi) at RT

© 1998 NRC Canada

in the presence of 10% Pd/C (150 mg) for 10 h, filtered, and concentrated in vacuo to give **16b** (1.9 g, 98%), an oil. ^{1}H NMR, δ (ppm): 3.87 (m, 11 H), 4.07 (m, 8H), 6.55 (t, *J* = 2.2 Hz, 1 H), 6.72 (s, 8H), and 7.15 (d, *J* = 2.2 Hz, 2H). ^{13}C NMR, δ (ppm): 52.33, 67.59, 68.09, 69.63, 69.98, 107.06, 108.02, 115.85, 116.07, 131.60, 150.05, 152.36, 159.53, and 167.04 (14 peaks as required). MS (FAB), *m*/*z* (rel. int.): 528 [M^+, 100%], 497 [$(M - OCH_3)^+$, 49%], and 420 ($M^+ - CH_3 - C_6H_4OH$, 16%); HRFAB, *m*/*z*, calcd. for $C_{28}H_{32}O_{10}$ $[M]^+$: 528.1995, found: 528.1981 (error 2.7 ppm).

Methyl 3,5-bis[8-(*p*-hydroxyphenoxy)-3-,6-dioxaoctyloxy]benzoate (16c)

A procedure similar to that used for **16b** was utilized to prepare **16c**, an oil (99%). ^{1}H NMR (DMSO), δ (ppm): 3.58 (m, 8H), 3.68 (t, *J* = 4.6 Hz, 4H), 3.73 (t, *J* = 4.6 Hz, 4H), 3.81 (s, 3H), 3.94 (t, *J* = 4.6 Hz, 4H), 4.12 (t, *J* = 4.6 Hz, 4H), 6.68 (AB q, *J* = 9.2 Hz, 8H), 6.80 (t, *J* = 2.2 Hz, 1 H), 7.05 (d, *J* = 2.2 Hz, 2H), and 8.89 (s, 2H). ^{13}C NMR (DMSO), δ (ppm): 52.28, 67.51, 67.60, 68.82, 69.12, 69.90, 69.95, 106.15, 107.45, 115.36, 115.69, 131.57, 151.20, 151.24, 159.69, and 165.87 (16 peaks as required). MS (FAB), *m*/*z* (rel. int.): 639 [$(M + Na)^+$, 5%], 616 [M^+, 34%], and 585 [$(M - OCH_3)^+$, 20%), 163 (100%); HRFAB, *m*/*z*, calcd. for $C_{32}H_{40}O_{12}$ $[M]^+$: 616.2520, found: 616.2511 (error 1.4 ppm).

Methyl 3,5-bis[11-(*p*-hydroxyphenoxy)-3,6,9-oxaundecyloxy]benzoate (16d)

A procedure similar to that used for **16b** was utilized to prepare **16d**, an oil (98%). ^{1}H NMR, δ (ppm): 3.69 (m, 16H), 3.79 (m, 8H), 3.87 (s, 3H), 3.96 (t, *J* = 4.8 Hz, 4H), 4.00 (t, *J* = 4.8 Hz, 4H), 6.56 (t, *J* = 2.4 Hz, 1 H), 6.65 (s, 2H), 6.69 (AB q, *J* = 9.2 Hz, 8H), 7.13 (d, *J* = 2.4 Hz, 2H). ^{13}C NMR, δ (ppm): 52.29, 67.50, 67.99, 69.57, 69.78, 70.52, 70.56, 106.644, 108.06, 115.67, 116.06, 131.62, 150.36, 152.28, 159.61, and 167.04 (16 peaks; theory 18). MS (FAB), *m*/*z* (rel. int.): 704 [$(M + Na)^+$, 8%], 391 [$(M - COOCH_3 - 2HOC_6H_4 - OCH_2CH_2)^+$, 80%], 167 (100%); HRFAB, *m*/*z*, calcd. for $C_{34}H_{48}O_{14}$ $[M + Na]^+$: 703.2941, found: 703.2952 (error 1.4 ppm).

3,5-Bis(vinyloxy)benzoic acid (19) from attempted synthesis of 11a

A solution of **13a** (814.1 mg, 2.780 mmol) and **16a** (1.16 g, 2.63 mmol) in DMF (total volume = 12 mL) was added via a syringe pump at 2.0 mL/h to a suspension of NaH (1.2 g, 30 mmol, 60% in mineral oil) in DMF (175 mL) at 110°C. After addition, the mixture was stirred at 85°C for 4 days, cooled, evaporated, treated with $CHCl_3$, and filtered. Removal of $CHCl_3$ followed by flash SiO_2 column chromatography eluting with $CHCl_3$:EtOAc (20:1) gave pure **19** (110 mg, 19%): mp 115.7–117.5°C. ^{1}H NMR, δ (ppm): 4.57 (dd, *J* = 6.0 and 2.4 Hz, 1H), 4.87 (dd, *J* = 13.6 and 2.0 Hz, 1H), 6.66 (dd, *J* = 13.6 and 2.0 Hz, 1H), 6.91 (t, *J* = 2.2 Hz, 1H), and 7.46 (d, *J* = 2.2 Hz, 2H). ^{13}C NMR, δ (ppm): 97.04, 111.42, 112.75, 131.66, 147.09, 157.86, and 170.71 (7 peaks as required). Anal. calc. for $C_{11}H_{10}O_4 \cdot 1/4\ H_2O$: C 62.70, H 5.02; found: C 62.80, H 4.93.

Bis(5-carbomethoxy-1,3-phenylene)-bis(*p*-phenylene)-42-crown-12 (11b)

A solution of **16b** (1.91 g, 3.61 mmol) and **13b** (1.38 g, 3.62 mmol) in DMF (total volume 20 mL) was added via a syringe pump at 1.5 mL/h to a suspension of K_2CO_3 (5.20 g, 37.6 mmol) and tetra(*n*-butyl)ammonium iodide (20 mg) in DMF (175 mL) at 110°C. After complete addition, the mixture was stirred vigorously at 110°C for 5 days, cooled, and evaporated. The residue was dissolved in CH_2Cl_2 and filtered. Removal of CH_2Cl_2 followed by flash column (SiO_2) chromatography eluting with Et_2O gave pure **11b** (700 mg, 23%): mp 140–142°C. ^{1}H NMR, δ (ppm): 3.89 (m, 22H), 4.08 (t, *J* = 4.6 Hz, 8H), 4.14 (t, *J* = 4.6 Hz, 8H), 6.71 (t, *J* = 2.2 Hz, 2H), 6.82 (s, 8H), and 7.19 (d, *J* = 2.2 Hz, 4H). ^{13}C NMR, δ (ppm): 52.19, 67.84, 68.16, 69.65, 69.97, 107.18, 108.09, 115.64, 131.81, 153.05, 159.70, and 166.72 (12 peaks as required). MS (FAB), *m*/*z* (rel. int.): 859.1 [$(M + Na)^+$, 14%], 836.1 (M^+, 100%), and 805.1 [$(M - OCH_3)^+$, 16%]; HRFAB, *m*/*z*, calcd. for $C_{44}H_{52}O_{16}$ [M^+]: 836.3255, found 836.3286 (error 3.6 ppm).

Bis(5-carbomethoxy-1,3-phenylene)-bis(*p*-phenylene)-54-crown-16 (11c)

A procedure similar to that used for **11b** was utilized to prepare **11c** (18%), a white solid: mp 102.9–104.3°C. ^{1}H NMR, δ (ppm): 3.73 (m, 16H), 3.83 (m, 8H), 3.89 (s, 6H), 4.05 (t, *J* = 4.8 Hz, 8H), 4.12 (t, *J* = 4.8 Hz, 8H), 6.70 (t, *J* = 2.2 Hz, 2H), 6.81 (s, 8H), and 7.18 (d, *J* = 2.2 Hz, 4H). ^{13}C NMR, δ (ppm): 52.19, 67.76, 68.07, 69.60, 69.87, 70.83, 70.91, 106.92, 108.06, 115.58, 131.84, 153.05, 159.74, and 166.72 (14 peaks as required). MS (FAB), *m*/*z* (rel. int.): 1012.9 (M^+, 100%), 981.9 [$(M - OCH_3)^+$, 15%], and 950.9 [$(M - 2OCH_3)^+$, 12%]; HRFAB, *m*/*z*, calcd. for $C_{52}H_{69}O_{20}$ $[M + H]^+$ 1013.4382; found 1013.4399 (error 1.6 ppm).

Bis(5-carbomethoxy-1,3-phenylene)-bis(*p*-phenylene)-66-crown-20 (11d)

A procedure similar to that used for **11b** was utilized to prepare **11d** (19%), a white solid: mp 77.5–79.5°C. ^{1}H NMR, δ (ppm): 3.69 (m, 32H), 3.82 (m, 16H), 3.88 (s, 6H), 4.04 (t, *J* = 4.8 Hz, 8H), 4.12 (t, *J* = 4.8 Hz, 8H), 6.69 (t, *J* = 2.2 Hz, 2H), 6.81 (s, 8H), and 7.18 (d, *J* = 2.2 Hz, 4H). ^{13}C NMR, δ (ppm): 52.17, 69.72, 68.00, 69.51, 69.77, 70.64, 70.74, 70.80, 106.86, 107.98, 115.51, 131.81, 153.01, 159.71, and 166.70 (15 peaks; theory 16). MS (FAB), *m*/*z* (rel. int.): 1211 [$(M + Na)^+$, 1%], 1188.4 (M^+, 100%), 1173.3 [$(M - CH_3)^+$, 5%], and 1157.4 [$(M - OCH_3)^+$, 16%], 1125 [$(M - 2OCH_3)^+$, 8%]; HRFAB, *m*/*z*, calcd. for $C_{60}H_{85}O_{24}$ $[M + H]^+$: 1189.5431; found 1189.5440 (error 0.8 ppm).

Conclusions

We have synthesized three new functionalized cyclic tetraphenylene polyethers, namely bis(5-carbomethoxy-1,3-phenylene)-bis(*p*-phenylene)-(3*x* + 6)crown-*x*, where *x* = 12, 16, and 20 (**11b**–**11d**) with ring sizes of 42, 54, and 66 atoms in 17–24% yields by [1 + 1] condensations of dichlorides **13b**–**13d** with the corresponding bisphenols **16b**–**16d**. These macrocycles do not complex with second-

© 1998 NRC Canada

ary ammonium ions, but in at least in one case, **11d**, do complex with paraquats such as **5b**.

Chemical kinetics and thermodynamics of tin ionization in H_2-O_2-N_2 flames and the proton affinity of SnO

John M. Goodings and QingFeng Chen

Abstract: A small amount ($\leq 10^{-6}$ mol fraction) of tin was introduced into five, fuel-rich, H_2-O_2-N_2 flames in the temperature range 1820–2400 K at atmospheric pressure. Ions in a flame were observed by sampling the flame along its axis through a nozzle into a mass spectrometer. The major neutral tin species in these flames were SnO (>97%) and Sn (<3%). The principal tin ions observed were $SnOH^+$ and Sn^+. Thermodynamic functions for $SnOH^+$, Sn^+, SnO, and Sn were calculated by statistical mechanics using published data from ab initio calculations and spectroscopy. The $SnOH^+$ ion was formed initially by proton transfer to SnO by H_3O^+, a natural flame ion, with which it is in equilibrium. It was also produced by chemi-ionization of SnO reacting with H; $SnOH^+$ rapidly equilibrates with Sn^+. Ion ratio measurements of $SnOH^+/H_3O^+$ led to the proton affinity PA°_{298} (SnO) = 911 ± 21 kJ mol $^{-1}$ (218 ± 5 kcal mol^{-1}). A calculated equilibrium constant provided the $SnOH^+/Sn^+$ ion ratio. When electron-ion recombination of $SnOH^+$ with free electrons was made dominant by the addition of CH_4 and K, the measured recombination coefficient of $SnOH^+$ was $(0.116 \pm 0.065)T^{-(1.66\pm0.16)}$ cm^3 $molecule^{-1}$ s^{-1}; the temperature dependence is in good agreement with the $T^{-1.5}$ dependence predicted by simple theory. The rate constant for chemi-ionization could not be measured due to impurity ions from potassium and sodium, but the equilibrium constant for chemi-ionization/recombination was calculated to be 0.004 863 exp (–52 070/*T*). Assuming detailed balance and the experimental recombination coefficient, the relatively small rate constant for chemi-ionization was given by 3.27×10^{-10} exp (–48 630/*T*) cm^3 $molecule^{-1}$ s^{-1}. Finally, calculated values were obtained for the bond energy D°_0(HO—Sn^+) = 408 ± 21 kJ mol^{-1}, and the standard zero-point enthalpy of formation $\Delta_f H^\circ_0(SnOH^+)$ = 637 ± 21 kJ mol^{-1}.

Key words: flame ionization, chemi-ionization, proton affinity, mass spectrometry, tin.

Résumé : On a introduit de faibles quantités (fraction molaire $\leq 10^{-6}$) d'étain dans cinq flammes de H_2-O_2-N_2 riches en combustible, à des températures allant de 1820 à 2400 K et à la pression ambiante. On a observé les ions dans les flammes en procédant à un échantillonnage de la flamme le long de son axe à l'aide d'une canule de spectromètre de masse. L'espèce principale d'étain dans ces flammes est le SnO (>97%) accompagnée de Sn (<3%). Les ions principaux observés sont le $SnOH^+$ et le Sn^+. Faisant appel à des méthodes de mécanique statistique et utilisant des données publiées de calculs ab initio et de spectroscopie, on a calculé les fonctions thermodynamiques du $SnOH^+$, Sn^+, SnO et Sn. L'ion $SnOH^+$ se forme initialement par un transfert de proton de H_3O^+ à SnO, un ion naturel de la flamme avec lequel il est en équilibre. Il se forme aussi par chimi-ionisation du SnO réagissant avec H; le $SnOH^+$ s'équilibre rapidement avec le Sn^+. Des mesures de rapports ioniques $SnOH^+/H_3O^+$ permettent de déterminer l'affinité protonique PA°_{298}(SnO) = 911 ± 21 kJ mol^{-1} (218 ± 5 kcal mol^{-1}). On a obtenu un rapport ionique $SnOH^+$ à l'aide de la constante d'équilibre calculée. Lorsque l'addition de CH_4 et de K fait que la recombinaison électron-ion du $SnOH^+$ avec des électrons libres devient la réaction dominante, le coefficient de recombinaison mesuré du $SnOH^+$ est égal à (0,116 ± 0,065) $T^{(-1,66\pm0,16)}$ cm^3 $molécule^{-1}$ s^{-1}; la relation avec la température est en bon accord avec la dépendance $T^{-1,5}$ qui est prédite par la théorie simple. Il n'a pas été possible de mesurer la constante de vitesse de la réaction de chimi-ionisation à cause de la présence d'ions de potassium et de sodium à l'état d'impuretés; on a toutefois calculé que la constante d'équilibre chimi-ionisation/recombinaison est égale à 0,004 863 exp (–52 070/*T*). Si l'on fait l'hypothèse qu'il existe une balance détaillée et que l'on utilise le coefficient de recombinaison expérimental, on peut établir que la relativement faible constante de vitesse de la réaction de chimi-ionisation est donnée par l'équation $3,27 \times 10^{-10}$ exp (–48 630/*T*) *T* cm^3 $molécule^{-1}$ s^{-1}. Finalement, on a obtenu des valeurs calculées pour l'énergie de liaison, D°_0(HO—Sn^+) = 408 ± 21 kJ mol^{-1}, et l'enthalpie de formation au point zéro standard, $\Delta_f H^\circ_0(SnOH^+)$ = 637 ± 21 kJ mol^{-1}.

Mots clés : ionisation de flamme, chimi-ionisation, affinité protonique, spectrométrie de masse, étain.

1. Introduction

In a short note in 1969, Jensen (1) reported on the formation of tin ions when 10^{-3}–10^{-4} mol fraction of $Sn(CH_3)_4$, a rather high concentration, was introduced into a pair of H_2-O_2-N_2 flames at 2020 and 2475 K and atmospheric pressure. Using a microwave cavity resonator to measure the free electron concentration [e^-] and a mass spectrometer to sample the ions, he first showed that the $SnOH^+$ and Sn^+ ions observed were linked by a balanced (equilibrated) reaction. Further experiments indicated that the rather strongly endothermic chemi-ionization reaction of SnO with H to form $SnOH^+$ was not equilibrated in these flames. Aided by statistical thermodynamic calculations, values were obtained for the zero-point standard energy change $\Delta E_0^\circ (= \Delta H_0^\circ)$ for both reactions and the standard internal energy of formation $\Delta_f E_0^\circ(SnOH^+)$.

Very recently, Hopkinson and co-workers (2) carried out ab initio calculations of the group 14 monoxides for C, Si, Ge, and Sn to obtain their proton affinities. For tin, these were conducted at the B3LYP level of theory with wave functions optimised using density functional theory. In particular, two calculations designated A (B3LYP/DZVP) and B (B3YP/Sadlej) each provided a set of rotational and vibrational temperatures for $SnOH^+$ for statistical thermodynamic calculations. Combined with the thermodynamic data and tables for SnO from Pedley and Marshall (3) and the spectroscopic data for Sn and Sn^+ from Moore (4), this provided us with the impetus to re-examine the ionization of tin in flames.

The objectives of this study were to measure the proton affinity PA of SnO, the electron-ion recombination coefficient for $SnOH^+$ and the rate constant for chemi-ionization of SnO reacting with H using our flame-ion mass spectrometer to sample flames in the temperature range 1820–2400 K. Experimental values for PA°(SnO) by proton transfer with H_3O^+ and the recombination coefficient were obtained. For the very fast equilibrated reaction linking $SnOH^+$ and Sn^+, ion ratio measurements were falsified by cooling of the sample in the nozzle of the mass spectrometer but the equilibrium constant was calculated by statistical methods. Direct measurements of the relatively weak chemi-ionization reaction were compromised by the presence of K^+ and Na^+ impurity ions. However, values of the rate constant were obtained by calculating the equilibrium constant for chemi-ionization/recombination and multiplying it by the experimental recombination coefficient with the assumption of detailed balance.

2. Experimental

Five premixed, laminar, H_2-O_2-N_2 flames of fuel-rich composition (equivalence ratio $\phi = 1.5$) at atmospheric pressure were employed for this work spanning a temperature range 1820–2400 K. Their properties, including the calculated compositions of the equilibrium burnt gas based on the JANAF tables (5), are given in Table 1. These flames have been used extensively by Hayhurst and Kittelson who have measured their temperatures, rise velocities and free-radical compositions (6). The concentrations of free radicals overshoot their equilibrium values in the flame reaction zone and then decay downstream towards equilibrium in the burnt gas. The actual concentration is obtained using Sugden's disequilibrium parameter γ (7), defined as the ratio of the local concentration of a radical at a given position in the flame to its final equilibrium value given in Table 1; γ can achieve large values (>100) close to the reaction zone of the cooler flames before decaying downstream in the burnt gas towards unity. For fuel-rich flames where H_2O and H_2 are major product species, $\gamma_H = \gamma_{OH} \equiv \gamma$ and $\gamma_O = \gamma^2$. Plots of γ versus axial distance z are available (6) for the five fuel-rich flames listed in Table 1; thus, the radical concentrations are known at all points in the flames. These pseudo-one-dimensional (flat) flames were stabilized on a water-cooled brass burner previously described (8), consisting basically of a circular bundle of 151 stainless-steel hypodermic needle tubes. The fuel-rich flames in plug flow were cylindrical in shape with a diameter of about 12 mm.

Tin was introduced into the flames by spraying an aqueous solution of $SnCl_4 \cdot 5H_2O$ (Aldrich, 98+%) as an aerosol derived from an atomizer described previously (9) into the nitrogen supply of the premixed flame gas. This salt contained very small amounts of potassium and sodium as impurities. Spraying a 0.1 M solution introduced 9.5×10^{-7}

© 1998 NRC Canada

mol fraction of total tin into the unburnt flame gas. A small amount of a grey solid, presumably metallic tin, condensed onto the cooled sampling nozzle and mounting plate placed in front of the flame. The usual very pale blue colour of the flames developed a slightly stronger whitish luminosity with tin present. No evidence was observed for the formation of solid particles.

The five flames described in Table 1 exhibit only a low level of natural ionization. It was sometimes advantageous to add 0.25 mol% of CH_4 to the premixed flame gas to produce a high initial concentration of H_3O^+ ions stemming from the chemi-ionization of CH + O near the flame reaction zone; these ions subsequently decay downstream by electron-ion recombination. With the simultaneous addition of tin, H_3O^+ can produce tin ions by chemical ionization (CI) processes. The addition of CH_4 was small enough, however, so that the flame composition and temperature remained essentially unchanged. In other cases, it was occasionally desirable to add a small amount of KNO_3 to the tin solution sprayed by the atomizer to produce K^+ and free electrons e^- in the flame by collisional (thermal) ionization. By this means, the electron–ion recombination rate of the tin ions could be increased; there was no evidence for any direct reaction of K^+ with the tin ions. Thus, tin ionization could be enhanced early in the flame by methane and (or) suppressed later in the flame by potassium.

The burner is mounted horizontally on a motorized carriage with calibrated drive coupled to the *X*-axis of an *XY*-recorder. The flame axis *z* is accurately aligned with the sampling nozzle of the mass spectrometer. The apparatus has been described in detail previously (8) so only a brief description will be given here. Flame gas containing ions is sampled through an orifice in the tip of a conical nozzle protruding from a water-cooled sampling plate. The nozzles were fabricated by swaging a tiny electron microscope lens of Pt/Ir alloy into the tip of a 60° stainless-steel cone; orifice diameters of 0.17 and 0.20 mm were employed. Alternatively, a 60° electroformed nickel nozzle of diameter 0.20 mm exhibited less cooling of the sample in the boundary layer and was used when it was desired to minimize the formation of ion hydrates. The ions enter a first vacuum chamber maintained at 0.04 Pa (3×10^{-4} Torr), and are focused into a beam by an electrostatic lens. The beam then passes through a 3 mm orifice in the tip of a nose-cone into a second vacuum chamber pumped to a pressure below 0.003 Pa (2×10^{-5} Torr). The ions traverse a second ion lens into a quadrupole mass filter in which they have an axial ion energy of 15 eV. They are detected by a Faraday collector connected to a vibrating-reed electrometer having a grid-leak resistance of 10^{10} ohm; the ion signal is applied to the *Y*-axis of the *XY*-recorder. Thus, ion signal magnitudes quoted in the figures below as a voltage (in mV) refer to the collected ion current passing through 10^{10} ohm. By driving the flame towards the sampling nozzle, profiles may be obtained of an individual ion signal versus distance along the flame axis *z*. The zero on the *X*-axis distance scale ($z = 0$) is defined experimentally where the pressure abruptly rises when the sampling nozzle pokes through the flame reaction zone into the cooler unburnt gas upstream. The pressure is measured with an ionization gauge mounted on the second vacuum chamber.

As an alternative to individual ions, total positive ion (TPI) profiles can be measured by switching off the dc voltages to the quadrupole rods. Still with the dc voltages switched off and the spectrometer's mass dial set to a given mass number, all of the ions above that mass number are collected; e.g., TPI_{100} designates total positive ions above 100 u which includes just the tin ions whereas TPI_{12} includes all the ions (since no measureable flame ions occur below 12 u). This technique is useful in separating total tin ions from ions of low mass number such as H_3O^+, K^+, and Na^+ if present. However, the sensitivity of the mass spectrometer is different for individual ions and TPI because the former are measured at fairly high resolution whereas total ion collection amounts to zero resolution. The former sensitivity is approximately one half of the latter. Since a flame is a quasi-neutral plasma, $[TPI_{12}]$ is equal to $[e^-]$, the concentration of free electrons. It should be pointed out that no negative tin ions were detected in the FR flames.

A second method of measuring total ion signals was employed, which has a bearing on calibration procedures. With an appropriate voltage bias on the sampling plate, the total current of positive ions passing through the orifice was collected on the ion lens and nose-cone in the first vacuum chamber; it was measured with a sensitive picoammeter. This method is appealing when absolute ion concentrations must be measured because tuning errors and mass discrimination of individual ions are avoided. The total ion current was calibrated using the known rate for electron-ion recombination of H_3O^+ with e^-. With the atomizer turned off, 0.25 mol% of CH_4 was admitted. From the slope of a second-order recombination plot together with Butler and Hayhurst's rate coefficient $k = (3.6 \pm 0.5)\ T^{-2.1\pm0.7}$ cm^3 molecule^{-1} s^{-1} (10), a calibration factor was obtained for converting ion current (μA) into ion concentration (molecule cm^{-3}). The same procedure was employed with the mass spectrometer for calibrating ion signal (mV) in terms of ion concentration (molecule cm^{-3}). The calibration was routinely done for each flame when absolute ion densities were needed.

On occasion, it was noted that the ion signal slowly and steadily decreased over a period of several minutes. The worst cases occurred for the hot flames 2 and 25 when the burner was moved in close to the sampling nozzle; in these circumstances, the nozzle can become red hot. A possible explanation involves the formation of a thin layer of dielectric oxide which coats the orifice rim and subsequently acquires a positive charge which repels incoming positive ions as they approach the nozzle. Accordingly, the calibration procedure with CH_4 addition was carried out at the beginning and end of each set of tin experiments with each flame, and the results were accepted only if the calibration factor remained constant. Calibration procedures for the atomizer delivery of tin into the flame gas have been given previously (11, 12).

When the gas is sampled through the nozzle, it cools in two regions: in the thermal boundary layer surrounding the orifice and in the near-adiabatic expansion downstream of the nozzle throat. This can cause a shift of fast equilibrium reactions in the exothermic direction during sampling. In particular, ion hydrates can be enhanced with respect to the parent ion. These sampling problems have been discussed in

	989.66	1039.94
	5427.05	5521.94

considerable detail (13–15). In general, if the relaxation time τ of an equilibrium reaction is greater than the sampling time of roughly 1 μs, it may be assumed that the reaction does not shift during sampling. In the present study, the problem arising from hydrates of the tin ions, such as $SnOH^+ \cdot H_2O$ and $Sn^+ \cdot H_2O$ which are probably not genuine flame ions, is obviated by measuring TPI_{100} such that hydrate contributions are included with the $SnOH^+$ and Sn^+ parent ion signals. At the other extreme, consider for example flame 3 in Table 1 with a rise velocity in the burnt gas of 15.6 m s^{-1}. Appreciable air entrainment is minimal for approximately the first 2.5 flame diameters downstream of the reaction zone; i.e., 30 mm, equivalent to a time of 1.9 ms. For a reaction to reach equilibrium within the time-scale of the flame, clearly τ must be small compared with 1.9 ms.

3. Statistical thermodynamic calculations

For some of the reactions involving tin, some of their properties could not be measured experimentally. Tables of thermodynamic data for many of the ancilliary species involved are listed in the JANAF tables over a wide temperature range (5); for SnO, the free-energy function $-(G_T^\circ - H_{298}^\circ)/T$ and enthalpy function $(H_T^\circ - H_{298}^\circ)$ are tabulated by Pedley and Marshall (3) up to 4000 K. Such data are not available for Sn, Sn^+, and $SnOH^+$, and it was necessary to calculate third-law absolute entropies S_T°, free energy, and enthalpy functions for some of these species by standard statistical methods. A good summary of the relevant formulae is given in the introduction to the JANAF tables (5). For the Sn neutral atom, Moore (4) lists three low-lying electronic states below 10 000 cm^{-1} with corresponding electronic temperatures θ_e (and degeneracies, g values) of 2002.5 K ($g_1 = 3$), 4931.7 K ($g_2 = 5$), and 12 392.3 K ($g_3 = 5$); for the ground state, $g_0 = 1$. For Sn^+ (4), $g_0 = 2$, and there is one low-lying state with $\theta_e = 6116.9$ K ($g_1 = 4$).

The calculation of thermodynamic functions for $SnOH^+$ was made possible by the ab initio calculations of Rodriquez et al. (2). Two of the calculations designated here as A (B3LYP/DZVP) and B (B3YP/Sadlej) each provided a set of rotational and vibrational temperatures, and also structural parameters given in Table 2. Both calculations depict $SnOH^+$ as a bent asymmetric-top molecule with one low vibrational temperature and two very low, nearly equal, rotational temperatures; conceivably, an even higher level calculation might indicate that $SnOH^+$ is linear.[2] The ground electronic state is nondegenerate, and there is no evidence of a low-lying excited state. For calculations A and B, the sum of the rotational and vibrational contributions to the thermodynamic functions had very similar magnitudes. Since there was no reason to prefer one calculation over the other, the results of the two calculations were simply averaged. Largely for reasons of conformity with the JANAF tables (5), a standard state for pressure of 0.1 MPa rather than 1 atm, designated by ° on thermodynamic quantities, was employed for the statistical calculations. Any differences, which only arise for functions involving the entropy, are small and well within the error limits.

4. Composition of neutral tin species in flames

Available spectroscopic evidence indicates that tin is present in flames only as Sn and SnO; the total concentration of tin ions is negligible in comparison. The percentage of each neutral species was found by calculating the equilibrium constant K_1 for the reaction

[1] $\quad Sn + H_2O = SnO + H_2$

The free energy function $-(G_T^\circ - H_{298}^\circ)/T$ over a wide temperature range is available for H_2O and H_2 from the JANAF tables (5) and for SnO from the tables of Pedley and Marshall (3). At any temperature T, K_1 is obtained from $\Delta G_T^\circ[1] = -RT \ln K_1$ with $\Delta G_T^\circ = \Delta H_{298}^\circ - T\Delta\{-(G_T^\circ - H_{298}^\circ)/T\}$ for reaction [1]; $\Delta H_{298}^\circ[1] = -D_{298}^\circ(SnO) + D_{298}^\circ(OH) + D_{298}^\circ(H\text{-}OH) - D_{298}^\circ(H_2) = -42.2$ kJ mol^{-1} (16) based on $D_0^\circ(SnO) = 528 \pm 13$ kJ mol^{-1} (3). A plot of $\ln K_1$ versus $1/T$ gives a very good straight line over the whole temperature range 298.15–2500 K, yielding $K_1 = 1.665 \exp(5140/T)$ from a least-squares fit; specifically over the temperature range 1820–2400 K of the five flames, $K_1 = 1.015 \exp(6064/T)$. The percentage SnO/Sn ratio for the five flames is given in Table 1; in all cases, SnO > 96.9% of the total tin present and SnOH is negligible.

5. Results and discussion

The tin atom has 10 stable isotopes (16) with mass numbers u and natural abundances (%) of 112 (0.97), 114 (0.65), 115 (0.36), 116 (14.53), 117 (7.68), 118 (24.22), 119 (8.58),120 (32.59), 122 (4.63), and 124 (5.79). With the atomizer spraying a 0.1 M aqueous solution of $SnCl_4 \cdot 5H_2O$ into flame 3, a mass spectrum measured at high resolution showing all of the tin ions present downstream at $z = 30$ mm is given in Fig. 1. With increasing mass number, these include H_3O^+, Na^+, a hydrate contribution from $H_5O_2^+$, $^{39}K^+$, $^{41}K^+$, and three groups of isotopic tin peaks above 100 u involving Sn^+, $SnOH^+$ (including a small contribution from $Sn^+ \cdot H_2O$), and $SnOH^+ \cdot H_2O$; sodium and potassium are present in the tin salt as impurities.

It is probably helpful to list all of the ionic reactions relevant to this paper in one place. These include

[2] $\quad H + H + OH \Leftrightarrow H_3O^+ + e^-$

[5] $SnOH^+ + H = Sn^+ + H_2O$

[6] $Sn^+ + e^- + M \rightarrow Sn + M$

[7] $K + M \rightarrow K^+ + e^- + M$

[8] $Na + M \rightarrow Na^+ + e^- + M$

[9] $H_3O^+ + K \Leftrightarrow K^+ + H_2O + H$

[10] $H_3O^+ + Na \Leftrightarrow Na^+ + H_2O + H$

where M is a third body. Here, the = sign refers to a fast balanced reaction at equilibrium whereas $\Leftrightarrow$ refers to a reaction proceeding in both directions which is not necessarily balanced. From this list, it is clear how the ions observed in the mass spectrum arise. The ion hydrates are not included, since they are assumed to form during sampling and are not genuine flame ions.

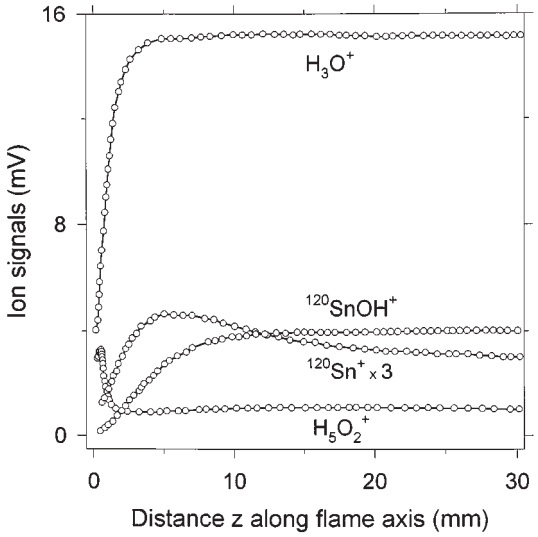
5.1 The $SnOH^+/H_3O^+$ equilibrium

In H_2-O_2-N_2 flames, the degree of natural ionization is measureable but small, produced by the chemi-ionization reaction [2] with a rate coefficient $k_2 = (3.3 \pm 1.6) \times 10^{-36}$ exp $(-13\,800/T)$ cm^6 molecule^{-2} s^{-1} (17) and a reverse recombination coefficient already given as $k_{-2} = (3.6 \pm 0.5)T^{-2.1\pm0.7}$ cm^3 molecule^{-1} s^{-1} (10). With the atomizer spraying distilled water (or turned off — the same signal is measured) in each of the five flames, an H_3O^+ profile is obtained (not shown; see (6)) which rises rapidly near the flame reaction zone to a constant plateau value that persists downstream; the magnitude increases with increasing flame temperature. The rapid rise reflects the γ^3-dependence of the three radical concentrations in reaction [2]. When tin is added to a flame, $SnOH^+$ is produced from H_3O^+ by the chemical ionization (CI) reaction [3] involving fast proton transfer, supplemented by the chemi-ionization reaction [4]. Atomic Sn^+ ions are also formed immediately by the fast balanced reaction [5].

Figure 2 presents profiles for the individual ions in flame 3 measured at low resolution with the atomizer spraying a 0.1 M solution of $SnCl_4 \cdot 5H_2O$. For a given tin ion, low resolution effectively blended all the tin isotopes into a single peak and yielded higher sensitivity. The total positive ions TPI_{12} and the total tin ions TPI_{100} are also shown; the difference of these two profiles is the sum of the H_3O^+, Na^+, $H_5O_2^+$, and K^+ profiles. The important point at issue is that, downstream near z = 30 mm, the $SnOH^+$ (+ hydrate) and H_3O^+ profiles are constant, indicative of equilibrium for the fast proton transfer reaction [3] between SnO and H_2O. Even

© 1998 NRC Canada

Fig. 3. Ion profiles measured at high resolution in flame 2 with the atomizer spraying a 0.01 M solution of $SnCl_4 \cdot 5H_2O$. The flame reaction zone is located near $z = 0$.

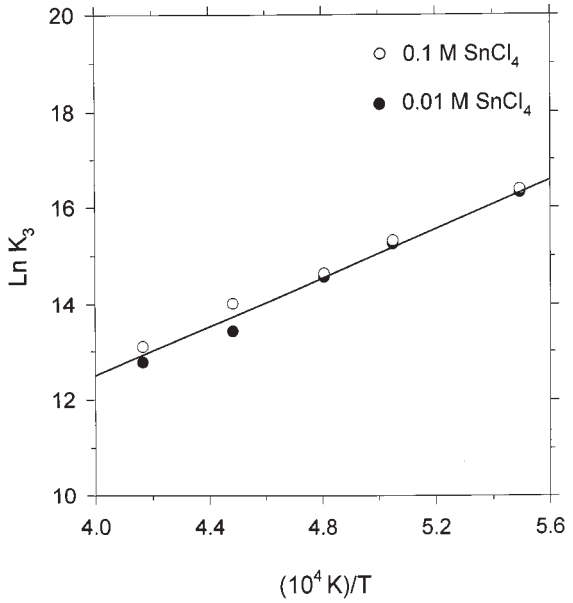


though the reaction is strongly exoergic, the large concentration ratio $[H_2O]/[SnO] \approx 3 \times 10^5$ can still bring the H_3O^+ and $SnOH^+$ ions into equilibrium in flames. Furthermore, the relaxation time $\tau_3 = 1/(k_3[SnO] + k_{-3}[H_2O])$ is of the order of 100 μs, appreciably greater than the sampling time of roughly 1 μs, such that the equilibrium reaction [3] does not shift during sampling. For this estimate, a typical value of k_3 for a proton transfer reaction of the order of 10^{-9} cm^3 $molecule^{-1}$ s^{-1} was assumed (k_3 would be somewhat higher at flame temperature than room temperature). A value for k_{-3} for the reverse reaction was estimated to be that for k_3 reduced by an exponential factor corresponding to the approximate endothermicity of the back reaction.

The objective of this aspect of the study was to measure the ion ratio $[SnOH^+]/[H_3O^+]$ to get the equilibrium constant K_3 giving $\Delta H°[3]$ from the slope of a van't Hoff plot of ln K_3 versus $1/T$ where $\Delta H°[3] = PA°(H_2O) - PA°(SnO)$, the difference of the proton affinities. There is another important feature of this method involving the measurement of K_3 in five flames spanning nearly 600 K. Suppose the two ion signals are subject to mass discrimination leading to an incorrect value of $K_3' = f \times K_3$ where f is a constant factor which is independent of temperature. The slope of the van't Hoff plot will still yield the correct value of $\Delta H°[3]$ although the intercept will be $(\Delta S°[3]/R + \ln f)$. It will be shown in the next section that reaction [5] producing Sn^+ shifts to the right during sampling such that measured values of $[SnOH^+]$ are slightly small by a nearly constant factor f which is only very weakly dependent on temperature. This is similar to the case of mass discrimination, and good values of $\Delta H°[3]$ are still obtained.

By way of contrast, the profiles in Fig. 3 were measured at high resolution in the hot flame 2 with the atomizer spraying a 0.01 M solution of $SnCl_4 \cdot 5H_2O$. Again, the $SnOH^+$ and H_3O^+ profiles are constant downstream, indicative of equilibrium. In this case, only the single biggest isotopic peak

Fig. 4. Van't Hoff plot for the equilibrium constant of the proton transfer reaction [3] involving H_3O^+ and $SnOH^+$ measured in five flames over the temperature range 1820–2400 K with the atomizer spraying aqueous solutions of $SnCl_4 \cdot 5H_2O$ of concentrations 0.1 M (open circles) and 0.01 M (closed circles).



$^{120}SnOH^+$ was measured, and $[H_3O^+] > [^{120}SnOH^+]$ at the lower tin concentration. For plotting purposes, the ^{120}Sn isotopic signals were multiplied by 100/32.59 to give 100% Sn signals. Figure 4 presents a van't Hoff plot of ln K_3 versus $1/T$ for the two runs with the 0.1 and 0.01 M solutions sprayed into five flames. From the slope of the straight line fitted by least squares, $\Delta H°_{2100}[3] = -218.0 \pm 10.5$ (standard deviation) kJ mol^{-1} over the flame temperature range 1820–2400 K centred on the average temperature of 2100 K.

To obtain $PA°_{298}(SnO) = PA°_{298}(H_2O) - \Delta H°_{298}[3]$, the reaction enthalpy at 298.15 K is required, derived from $\Delta H°_{298} = \Delta H°_{2100} - \Delta (H°_{2100} - H°_{298})$ where the standard enthalpy function $(H°_{2100} - H°_{298})$ is available for H_3O^+, H_2O (5), and SnO (3) but not for $SnOH^+$. Accordingly, it was calculated by statistical methods at the average flame temperature of 2100 K. For reaction [3], the temperature correction is small; $\Delta(H°_{2100} - H°_{298}) = 1.82$ kJ mol^{-1} giving $\Delta H°_{298}[3] = -219.8 \pm 10.5$ kJ mol^{-1}. Based on the current value of $PA°_{298}(H_2O) = 691.0$ kJ mol^{-1},[3] the proton affinity of SnO has a value $PA°_{298}(SnO) = 911 \pm 21$ kJ $mol^{-1} = 218 \pm 5$ kcal mol^{-1}, in excellent agreement with the calculated value of 215.6 kcal mol^{-1} obtained by Rodriquez et al. (2).

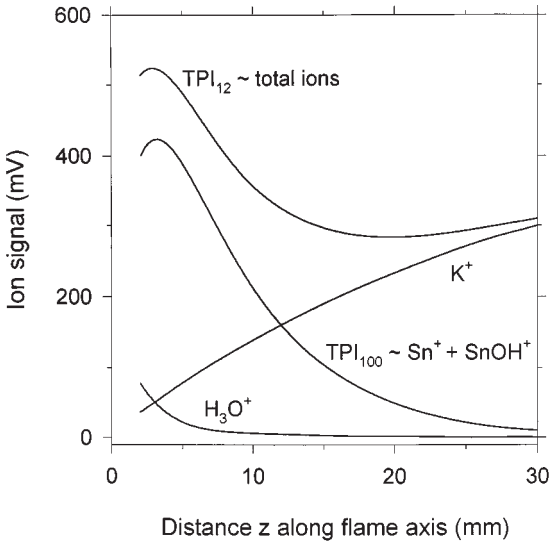
5.2 The $SnOH^+/Sn^+$ equilibrium

The equilibration of $SnOH^+$ and Sn^+ by reaction [5] is rapid in flames. If $k_5 = 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1} is assumed with k_{-5} reduced by a factor corresponding to the endothermicity of the back reaction (approximately 100 kJ mol^{-1}), the relaxation time $\tau_5 \approx 0.1$ μs. This means that the reaction will shift to the right in the exothermic direction during sampling, and measured $[SnOH^+]/[Sn^+]$ ratios will be too small.

[3] E.P. Hunter and S.G. Lias. NIST Standard Database Number 69. March 1998 release. http://webbook.nist.gov/chemistry/form-ser.html/

© 1998 NRC Canada

Fig. 5. Ion profiles measured in flame 3 with 0.25 mol% of added CH_4 and the atomizer spraying a mixed solution of 0.098 M $SnCl_4 \cdot 5H_2O$ and 0.001 M KNO_3 such that electron–ion recombination of $SnOH^+$ is the dominant process downstream; TPI_{12} denotes total positive ions and TPI_{100} is total ions of tin. The flame reaction zone is located near $z = 0$.



Since absolute $SnOH^+$ concentrations were needed for the recombination studies described below, it was necessary to calculate the equilibrium constant K_5 as a function of temperature. In this way, total tin ion signals [TPI_{100}] could be measured and true [$SnOH^+$] determined using K_5.

The free energy function $-(G_T^\circ - H_{298}^\circ)/T$ was calculated by statistical methods for $SnOH^+$ and Sn^+ at many temperatures up to 2500 K and combined with corresponding values from the JANAF tables (5) for H and H_2O to obtain $\Delta G_T^\circ - \Delta H_{298}^\circ$ for reaction [5]. Using all values at 298.15 K (16) and our value of $PA_{298}^\circ(SnO) = 910.8$ kJ mol^{-1}, ΔH_{298}°[5] = PA°(SnO) – IE°(H) + D°(SnO) + IE°(Sn) – D°(OH) – D°(H-OH) = –86.3 kJ mol^{-1}, giving ΔG_T° and thus K_5. A plot of ln K_5 versus $1/T$ gives a very good straight line over the range of flame temperatures 1820–2400 K with a least-squares fit represented by $K_5 = 0.077\,38 \exp(11\,450/T)$. In fact, a good straight line is obtained over the whole temperature range of 298–2500 K fitted by $K_5 = 0.1115 \exp(10\,890/T)$. The entropy change of reaction [5] was calculated to be $\Delta S_{2100}^\circ = -21.2$ and $\Delta S_{298}^\circ = -6.4$ J mol^{-1} K^{-1}. The reaction enthalpy has a value $\Delta H_{2100}^\circ = -94.8$ kJ mol^{-1} at the average flame temperature with $\Delta H_0^\circ = -84.3 \pm 20.9$ kJ mol^{-1} ($= \Delta E_0^\circ$), in reasonable agreement with the value arrived at by Jensen (1). He quotes a value ΔE_0°[5] = –100 ± 20 kJ mol^{-1} based on mass-spectrometric measurements of the [$SnOH^+$]/[Sn^+] ratio at two flame temperatures and a rough statistical calculation with vibrational temperatures estimated from those of the alkaline earth metals. His ion ratio measurements may not have been shifted appreciably by sampling cooling because, to the best of our knowledge, he was employing low-pressure flames (P = 1–10 Torr) in his mass spectrometer (18); since the relaxation time $\tau \propto 1/P$, its magnitude in his experiment may have exceeded the sampling time of approximately 1 μs.

5.3 Recombination of $SnOH^+$ with electrons

These hydrogen flames contain a small amount of H_3O^+ natural ionization formed by the chemi-ionization reaction [2], and $SnOH^+$ is formed by chemical ionization (CI) of SnO by H_3O^+ via the proton transfer reaction [3]. A further possible source of $SnOH^+$ is the chemi-ionization reaction [4]. To study the recombination reaction [–4], the objectives were to form a relatively high concentration of $SnOH^+$ rapidly near the flame reaction zone and then to assure that recombination was dominant downstream in the burnt gas. These conditions were achieved, first by adding 0.25 mol% of CH_4 to produce a superequilibrium level of H_3O^+ for CI by reaction [3]. Then, a small amount of potassium as KNO_3 was added to the atomizer solution to raise the concentration of free electrons in the flame, thereby enhancing the rate of recombination of $SnOH^+$ by reaction [–4]. Potassium atoms are chemically ionized initially by H_3O^+ to some extent by reaction [9] (19) but progressively ionize further downstream by collisional (thermal) ionization via reaction [7] (20). There is no evidence that potassium interacts with tin by any process other than its effect on recombination through [e^-]. It was necessary to adjust the relative concentrations of both $SnCl_4 \cdot 5H_2O$ and KNO_3 in the atomizer solution rather carefully so that (*i*) H_3O^+ disappears quite rapidly downstream to maximize the region in which $SnOH^+$ recombination is dominant, and (*ii*) [$SnOH^+$] falls to a value near zero at z = 30 mm downstream indicating that $SnOH^+$ ion production by the chemi-ionization reaction [4] was negligible.

Figure 5 presents profiles for flame 3 with added CH_4 and with the atomizer spraying a mixed aqueous solution of 0.098 M $SnCl_4 \cdot 5H_2O$ and 0.001 M KNO_3. At these concentrations, the profiles fulfil the conditions outlined in (*i*) and (*ii*) above. The TPI_{100} signal includes $SnOH^+$, Sn^+, and any hydrates formed during sampling. Since negative ions were not detected in these flames, the TPI_{12} profile which measures the sum of all positive ions gives [e^-] because a flame is a quasi-neutral plasma. From reaction [–4], $-d[SnOH^+]/dt = k_{-4}[SnOH^+][e^-]$ – (ion production term) with $v = dz/dt = 15.6$ m s^{-1} from Table 1. Differentiation of [TPI_{100}] gives the kinetic expression $-d[TPI_{100}]/dt = -d[SnOH^+]/dt - d[Sn^+]/dt = k_{-4}[SnOH^+][e^-] + k_6[Sn^+][e^-] - k_4[SnO][H]_{eq}\gamma$ in which the equilibrated reaction [5] does not appear. The assumptions are made that three-body recombination of atomic Sn^+ in reaction [6] is negligible compared with reaction [–4], and that the production term from reaction [4] can be ignored because of the experimental conditions set up; also, reaction [3] does not contribute downstream where [H_3O^+] ≈ 0. Since [$SnOH^+$] = $[TPI_{100}]/(1 + K_5[H]_{eq}\gamma/[H_2O])$, the kinetic expression reduces to $-v(d[TPI_{100}]/dz)(1 + K_5[H]_{eq}\gamma/[H_2O]) = k_{-4}[TPI_{100}][TPI_{12}]$. Note that the factor $(1 + K_5[H]_{eq}\gamma/[H_2O])$, which has been multiplied across to the left-hand side, is equivalent to $(1 + [Sn^+]/[SnOH^+])$; the ion ratio is small compared with unity, varying from 0.13 in flame 2 to 0.06 in flame 5.

For the final kinetic expression, Fig. 6 presents a plot for flame 3 of the left-hand side versus $[TPI_{100}][TPI_{12}]$ in the range z = 15–30 mm where [H_3O^+] ≈ 0. The slope of the plot gives the recombination coefficient $k_{-4} = 3.6 \times 10^{-7}$ cm^3 molecule^{-1} s^{-1} in this particular case. The small negative in-

Fig. 6. Plot involving the kinetic expression for $SnOH^+$ ion loss by electron–ion recombination by reaction [–4] for the range z = 15–30 mm downstream in flame 3 using the ion profiles presented in Fig. 5, where the slope yields the recombination coefficient k_{-4}.

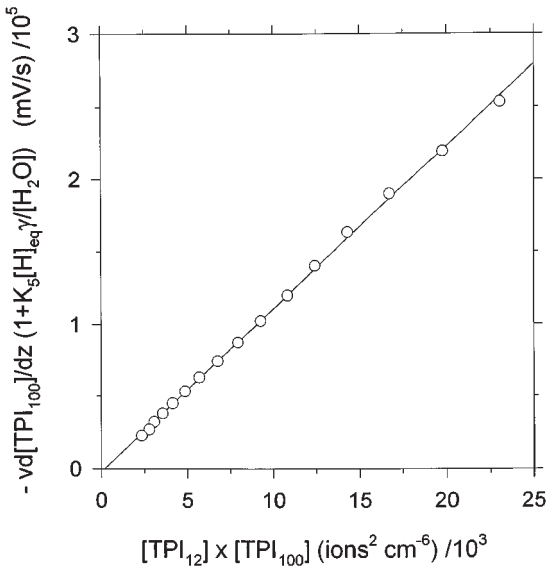

Fig. 7. Logarithmic plot of the recombination coefficient k_{-4} versus temperature T in the range 1820–2400 K. The best-fit solid line exhibits a $T^{-1.7}$ dependence, for comparison with the broken line giving the $T^{-1.5}$ dependence expected from simple theory.

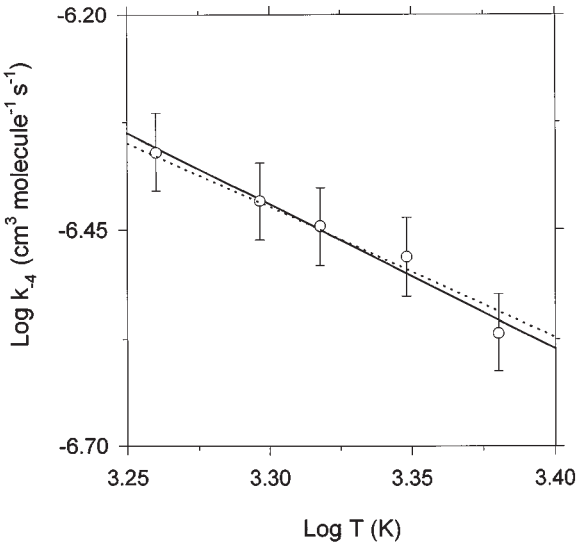

tercept shows that ion production is small and can safely be ignored. Similar profiles were measured and plots made to evaluate k_{-4} in all five flames. The results over the temperature range 1820–2400 K are given in Fig. 7 as a plot of log k_{-4} versus log T. A straight line fitted by least squares gives the temperature variation as $k_{-4} = (0.116 \pm 0.065)T^{-(1.66\pm0.16)}$ cm^3 molecule^{-1} s^{-1}. A discussion of the temperature dependence of electron-ion recombination coefficients in flames has been given by Butler and Hayhurst (10). Simple theory indicates a $T^{-1.5}$ dependence with which our value is in good agreement.

5.4 Chemi-ionization of SnO + H

Repeated attempts were made to measure the rate constant of the chemi-ionization reaction [4] directly but were frustrated by the presence of tiny amounts of potassium and sodium in the salt sample of $SnCl_4 \cdot 5H_2O$. These impurities give rise to the K^+ and Na^+ peaks visible in the mass spectrum shown in Fig. 1 which arise initially upstream by the electron transfer reactions [9] and [10] (19), and further downstream by the collisional (thermal) ionization reactions [7] and [8] (20). The initial rise of the $SnOH^+$ profile in Fig. 2 stems from proton transfer by reaction [3]. This means that the growth of the $SnOH^+$ profile in the upstream region cannot be analysed for k_4. Figure 2 also shows how the K^+ and Na^+ signals grow downstream by thermal ionization to increase [e^-]. Furthermore, k_4 cannot be readily evaluated from the constant $SnOH^+$ profile downstream near z = 30 mm because reaction [4] is not at equilibrium. The relaxation time is given by $\tau_4 = \{\ln(2e-1)\}/2(k_4 k_{-4}[SnO][[H])^{1/2}$ which has a value of the order of 10 ms for a 0.1 M solution of $SnCl_4 \cdot 5H_2O$ sprayed by the atomizer and $k_4 \approx 10^{-20}$ cm^3 molecule^{-1} s^{-1} at 2100 K (derived below); equilibrium cannot be achieved in the time of approximately 2 ms corresponding to 30 mm of flame. The same conclusion was reached by Jensen (1). A final consideration is that the rate of collisional (thermal) ionization $R_7 \approx 10^8$ ions cm^{-3} s^{-1} even for a tiny (unknown) potassium impurity concentration of 10^{-7} M in the atomizer solution (20); the rate R_4 for the chemi-ionization of tin is very comparable, and certainly not dominant. Although the experiments were not successful, these considerations seemed worthy of discussion because they indicate the complete ionization picture and may apply to other metals with small rate coefficients for chemi-ionization.

Accordingly, the equilibrium constant K_4 for reaction [4] was obtained by statistical methods, again involving the free energy function $-(G_T^\circ - H_{298}^\circ)/T$ calculated for $SnOH^+$ and available for SnO (3), H and e^- (5). At any temperature T, this gives $\Delta\{-(G_T^\circ - H_{298}^\circ)/T\} = R \ln K_4 + \Delta H_{298}^\circ/T$ with $\Delta H_{298}^\circ[4] = -PA_{298}^\circ(SnO) + IE_{298}^\circ(H) = 407.4$ kJ mol^{-1}. Over the temperature range 1820–2400 K of the five flames, a plot of ln K_4 versus $1/T$ gave a very good straight line from which $K_4 = 0.004\,868 \exp(-52\,070/T)$. Over the whole temperature range 298.15–2500 K, a similar plot gave a good straight line yielding $K_4 = 0.001\,324 \exp(-49\,710/T)$.

For reaction [4], other channels in both the forward and reverse directions are unlikely, and the assumption of detailed balance is reasonable. Using K_4 in the range of flame temperatures, the rate constant for chemi-ionization is obtained from $k_4 = k_{-4}K_4$. When combined with the experimental values of k_{-4} in the five flames, values of k_4 are obtained ranging from 5.03×10^{-19} in flame 2 at 2400 K to 8.07×10^{-22} cm^3 molecule^{-1} s^{-1} in flame 5 at 1820 K. A plot of ln k_4 versus $1/T$ is shown in Fig. 8. A good straight line fitted by least squares through the data points gives $k_4 = 3.27 \times 10^{-10} \exp(-48\,630/T)$ cm^3 molecule^{-1} s^{-1} for the temperature range 1820–2400 K. Even at flame temperatures, the values of the rate constant are small but should have been measureable experimentally were it not for the presence of potassium and sodium as impurities.

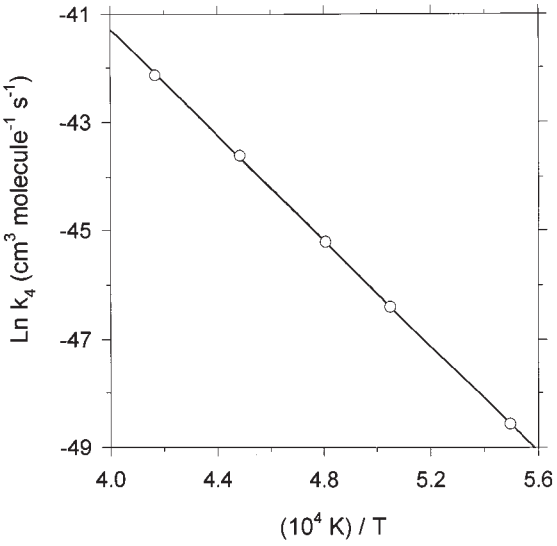
Fig. 8. Semi-logarithmic plot giving the temperature variation of the rate constant as ln k_4 versus $1/T$ for the chemi-ionization reaction [4] in the range 1820–2400 K.



5.5 Bond energy D_0°(HO-Sn$^+$) and $\Delta_f H_0^\circ$(SnOH$^+$)

The standard Sn—O bond dissociation energy for the $SnOH^+$ ion can be found from the calculated change in the enthalpy function for the dissociation reaction

[11] $SnOH^+ \rightarrow Sn^+ + OH$

with reference to reaction [5]; i.e., $\Delta\{H_{298}^\circ - H_0^\circ\}[11] = 3.49$ kJ mol^{-1} = $\Delta H_{298}^\circ[11] - \Delta H_0^\circ[11] = \Delta H_{298}^\circ[5] + D_{298}^\circ$(H—OH) – D_0°(HO—Sn$^+$). This gives a value for the bond energy D_0°(HO—Sn$^+$) = 408 ± 21 kJ mol^{-1} (98 ± 5 kcal mol^{-1}). Finally, the standard zero-point enthalpy of formation $\Delta_f H_0^\circ(SnOH^+)$ can be obtained from $\Delta H_0^\circ[5] = -84.3$ kJ mol^{-1} with $\Delta_f H_0^\circ(Sn^+) = 1010.6$ (21), $\Delta_f H_0^\circ(H_2O) = -238.9$ and $\Delta_f H_0^\circ(H) = 216.0$ kJ mol^{-1} (5). The value is $\Delta_f H_0^\circ(SnOH^+)$ = 640 ± 21 kJ mol^{-1} (153 ± 5 kcal mol^{-1}); at room temperature, $\Delta_f H_{298}^\circ(SnOH^+)$ = 637 ± 21 kJ mol^{-1}. It is in good agreement with Jensen's value stated as the equivalent function $\Delta_f E_0^\circ(SnOH^+)$ = 655 ± 27 kJ mol^{-1} estimated nearly 30 years ago from a crude statistical model.

6. Summary and conclusions

The ionization of tin was investigated in H_2-O_2-N_2 flames in the range 1820–2400 K by mass-spectrometric sampling. The study was greatly aided by data for rotational and vibrational temperatures of the $SnOH^+$ ion from ab initio calculations (2) so that thermodynamic functions could be calculated by statistical mechanics. If total tin is present only as SnO and Sn, SnO > 97% in these fuel-rich flames. The flame conditions are such that $SnOH^+$ can be measured in equilibrium with H_3O^+, leading to the proton affinity PA°(SnO) relative to that of H_2O. The rapid equilibration of $SnOH^+$ with Sn^+ cannot be measured because it is shifted to a lower unknown temperature during sampling, but its equilibrium constant could be determined by a statistical thermodynamic calculation. This provided correct values of the $SnOH^+$ concentration for the experimental measurement of the electron-ion recombination coefficient of $SnOH^+$ as a function of temperature. Its $T^{-1.7}$ temperature dependence is close to the $T^{-1.5}$ dependence predicted by simple theory. The recombination reaction is the backward direction of the chemi-ionization reaction of SnO + H. Its relatively small rate coefficient could not be measured experimentally due to the ionization of potassium and sodium present as impurities in the tin salt. However, the equilibrium constant for chemi-ionization/recombination could be calculated by statistical methods. Assuming detailed balance, the rate coefficient for chemi-ionization as a function of temperature was obtained as the product of the experimental recombination coefficient and calculated equilibrium constant. Finally, the bond strength D_0°(HO—Sn$^+$) could be calculated, and also the standard zero-point enthalpy of formation $\Delta_f H_0^\circ(SnOH^+)$. This study combines experiment with theoretical calculations to give a fairly complete analysis of tin ionization.

Application of [Ru((*R*)-BINAP)(MeCN)(1-3:5,6-η-C_8H_{11})](BF_4) as a catalyst precursor for enantioselective hydrogenations

Christopher J.A. Daley, Jason A. Wiles, and Steven H. Bergens

Abstract: A catalyst system employing [Ru((*R*)-BINAP)(MeCN)(1-3:5,6-η-C_8H_{11})](BF_4) as catalyst precursor was evaluated using the enantioselective hydrogenations of tiglic acid, α-acetamidocinnamic acid, itaconic acid, methyl tiglate, dimethyl itaconate, geraniol, ethyl acetoacetate, and dimethyl oxaloacetate as a series of typical substrates. Acetone and MeOH were used as model aprotic and protic solvents, respectively. The hydrogenation of substrates containing an α,β-unsaturated carboxylic acid functionality required stoichiometric quantities of NEt_3 to occur at reasonable rates in acetone solution, while in MeOH solution it did not. The enantioselectivities were typically higher in acetone than in MeOH. This catalyst system is among the more enantioselective ruthenium–BINAP type systems reported for the catalytic hydrogenation of substrates containing an α,β-unsaturated acid or ester functionality. The enantioselectivities for the hydrogenation of ketones ranged from poor (15%) to moderate (74%). 1,4-Dicarboxylate substrates with the prochiral olefin or ketone at the 2-position were all hydrogenated in good to high ee with the same enantioface selectivity both with our system and other catalysts reported in the literature. This raised the possibility that these substrates were hydrogenated through intermediates with similar structural features.

Key words: ruthenium, BINAP, enantioselective, hydrogenation, catalysis.

Résumé : Utilisant les hydrogénations énantiosélectives des acides tiglique, α-acétamidocinnamique et itaconique, du tiglate de méthyle, de l'itaconate de diméthyle, du géraniol, de l'acétoacétate d'éthyle et de l'oxaloacétate de diméthyle comme substrats typiques, on a évalué un système de catalyseur faisant appel au [Ru((*R*)-BINAP)(MeCN)(1,3,5,6-η-C_8H_{11})](BF_4) comme précurseur du catalyseur. On a utilisé l'acétone et le méthanol comme modèles de solvant respectivement aprotique et protique. Les énantiosélectivités sont généralement plus élevées dans l'acétone que dans le méthanol. Pour réaliser l'hydrogénation d'acides carboxyliques insaturés à une vitesse raisonnable dans l'acétone, il est nécessaire d'utiliser des quantités stoechiométriques de triéthylamine; ce n'est pas le cas dans le méthanol. Pour l'hydrogénation catalytique d'acides et d'esters α,β-insaturés, ce système de catalyseur se trouve parmi les systèmes de type ruthénium–BINAP les plus énantiosélectifs. Les énantiosélectivités pour l'hydrogénation des cétones vont de mauvaises (15%) à modérées (74%). Avec les substrats portant des 1,4-dicarboxylates et une oléfine ou une cétone prochirale en position 2, les hydrogénations conduisent à des ee allant de bons à élevés; notre système et les autres catalyseurs proposés antérieurement dans la littérature ont les mêmes sélectivités et ceci suggère que les hydrogénations de ces substrats se produisent par des intermédiaires possédant des caractéristiques structurales semblables.

Mots clés : ruthénium, BINAP, énantiosélectif, hydrogénation, catalyse.

[Traduit par la Rédaction]

Introduction

Asymmetric catalysis by chiral transition metal complexes is among the most successful methods to synthesize optically active organic compounds. Of the hundreds of chiral ligands reported, 2,2′-bis(diphenylphosphino)-1,1′-binaphthyl (BINAP) is one of the most successful (for recent reviews on the use of BINAP in enantioselective catalysis, see ref. 1). While rhodium–BINAP systems are highly enantioselective catalysts for the hydrogenation of certain prochiral olefins (2), ruthenium–BINAP systems hydrogenate a much wider range of prochiral olefins and ketones with high enantioselectivities (3; for earlier references see 1*d*, *f*, and refs. cited therein).

We previously reported the synthesis of [Ru((*R*)-BINAP)(MeCN)(1-3:5,6-η-C_8H_{11})](BF_4) (**I**) and its use as a catalyst precursor for several catalytic processes (4). Compound **I** reacts with H_2 in acetone, THF, or MeOH solution to generate [Ru((*R*)-BINAP)(H)$(MeCN)_n(Sol)_{3-n}$](BF_4) (**II,** Sol = acetone, THF, or MeOH; n = 0–3), which we believe is the active catalyst for the described reactions.

The catalyst system **II** is distinguished from other ruthenium–BINAP catalysts by the combination of the following three features. First, it is reasonably well-defined. Second, the active catalyst is generated in high concentrations under

mild conditions. In acetone, THF, or MeOH solution, the catalyst precursor **I** reacts under 1–2 atm of H_2 at room temperature to generate complex **II** in minutes. Third, the system has at least two readily available coordination sites (occupied by labile solvento ligands) to allow easy access by substrate molecules to the ruthenium centre. This feature is essential for the study of substrate–catalyst interactions.

We now report the use of **II** as a catalyst system for the enantioselective catalytic hydrogenation of a representative series of prochiral substrates. This work will define the utility of **II** as a catalyst system relative to the other ruthenium–BINAP catalyst systems reported in the literature, and it will explore any possible general trends in enantioselectivity by such catalysts. It is only through such trends that the general components of enantioselectivity (if they exist) by ruthenium–BINAP catalysts can be established.

Results and discussion

The nature of II

The MeCN ligand is rapidly exchanged between all the available vacant coordination sites in acetone solutions of **II** at room temperature. This exchange halts upon cooling to –80°C to give a static mixture of eight hydrides ranging from [Ru((*R*)-BINAP)(H)(acetone)$_3$](BF$_4$) to [Ru((*R*)-BINAP)(H)-(MeCN)$_3$](BF$_4$). These compounds all contain the hydride ligand in a coordination site *cis* to both phosphorus centres. This mutually *cis* disposition of the coordinated hydride and phosphorus centres presumably results from the high *trans influence* commonly observed for both of these types of ligands (5). In THF solution, the system exists mainly (~85%) as one diastereomer of the mono-MeCN complex [Ru((*R*)-(BINAP)(H)(MeCN)(THF)$_2$](BF$_4$). In MeCN solution, it exists solely as [Ru((*R*)-(BINAP)(H)(MeCN)$_3$](BF$_4$). To a first approximation, the system can be regarded as a source of the catalyst fragment "[Ru((*R*)-(BINAP)(H)]$^+$." For example, the solvento and MeCN ligands can all be displaced by arene donors to generate the corresponding [Ru((*R*)-(BINAP)(H)(η^6-arene)](BF$_4$) complexes (6).

Hydrogenations using II as catalyst

Figure 1 shows the representative substrates we hydrogenated using **I** as the catalyst precursor. Figure 1 also shows the major enantiomer of the hydrogenation products. Tables 1, 2, and 4 summarize our results.

Substrates containing an α,β-unsaturated acid or ester functionality

Hydrogenations were performed in MeOH as a model protic solvent. The hydrogenation of tiglic acid (**1a**) (Table 1, entry 1) was quantitative under mild conditions, giving 2-methylbutyric acid (**1c**) in high ee (90% (*R*)). The ee decreased to 72% (*R*) when the initial pressure of H_2 was increased from 3 to 55 atm (Table 1, entry 2). Attempts to hydrogenate methyl tiglate (**1b**) were unsuccessful under 3 atm of H_2 (Table 1, entry 3). This difference in reactivity between tiglic acid and methyl tiglate has been previously reported for another ruthenium–BINAP catalyst system (7).

We previously reported (4) that hydrogenation of (*Z*)-methyl α-acetamidocinnamate (MAC, **2b**) to *N*-acetylphenylalanine methyl ester (**2d**) in MeOH goes to completion in high ee (86% (*R*)) under mild conditions. This result is included for comparative purposes (Table 1, entry 6). Surprisingly, hydrogenation of the corresponding acid (α-acetamidocinnamic acid (**2a**)) under similar conditions proceeds much more slowly, with only 10% conversion after 94 h (Table 1, entry 4). To obtain complete conversion it was necessary to increase the pressure of H_2 to 100 atm, resulting in 46% ee (*R*) (Table 1, entry 5).

The hydrogenation of itaconic acid (**3a**) (Table 1, entry 7) proceeded smoothly under mild conditions giving methylsuccinic acid (**3c**) in 90% ee (*S*). The corresponding hydrogenation of dimethyl itaconate (**3b**) (Table 1, entry 8) under similar conditions was more successful, yielding dimethyl methylsuccinate (**3d**) in 95% ee (*S*). We note that the net enantioface selection by the catalyst for substrates **3a** and **3b** is the same as that for the structurally related substrates **2a** and **2b**.

To investigate the use of an aprotic solvent, the hydrogenations were carried out in acetone. The results of these reactions are reported in Table 2. As we previously reported (8), the hydrogenation of **2b** proceeds smoothly under mild conditions to give **2d** in higher ee (92% (*R*)) than does the hydrogenation in MeOH (86% (*R*)). This result is included for comparative purposes (Table 2, entry 6). The hydrogenation of **3b** also proceeded under mild conditions in acetone (Table 2, entry 10) to yield **3d** in similar ee to that obtained from the hydrogenation in MeOH (95% ee (*S*)). As was the case in MeOH, **1b** did not undergo hydrogenation in acetone (Table 2, entry 3). The hydrogenations of **1a**, **2a**, and **3a** were extremely slow under these conditions (4 atm H_2, 25°C, acetone), giving low to moderate conversions ranging from <10% to ~55% (Table 2, entries 1, 4, and 7, respectively). Even at 50°C and 4 atm of H_2 the hydrogenation of **3a** proceeded to a maximum of ~65% conversion (Table 2, entry 8). It is well known that addition of an equivalent of base (e.g., amines) for every acid unit in the substrate often (but not always) yields higher ee and rates for the hydrogenation of acid substrates using both ruthenium and rhodium catalyst systems (9). We examined this effect on the hydrogenations of the acids (**1a**, **2a**, and **3a**) in acetone. The hydrogenations of **1a** and **3a** (Table 2, entries 2 and 9, respectively) proceeded to completion under mild conditions in the presence of 1 equiv. of NEt_3 per acid group. Further, the ee improved from 90% (*R*) for **1a** and 90% (*S*) for **3a** in the absence of added base in MeOH to 95% ee (*R*) and 95% ee (*S*) with added base in acetone. The addition of 1 equiv. of NEt_3 did not enhance the rate of hydrogenation of **2a** (Table 2, entry 5).

Table 3 compares our results to the best results reported in the literature for other ruthenium–BINAP systems we are aware of. Apart from the hydrogenation of **2b**,[2] all the literature examples reported in Table 3 were performed in pure alcohol or binary alcohol–solvent solutions (solvent = THF or CH_2Cl_2), under mild temperatures (20–50°C), and under low to moderate pressures of H_2 (1–5 atm). The results obtained

[2] This is the only literature example we are aware of where **2b** is hydrogenated using a ruthenium–BINAP catalyst.

with complex **I** as the catalyst precursor show it to be among the better ruthenium–BINAP systems examined to date for the hydrogenation of these substrates.

Inspection of Table 3 shows no real trends in the absolute configuration of the major enantiomer produced by hydrogenation of tiglic acid (**1a**) using ruthenium–BINAP catalyst systems. That methyl tiglate (**1b**) does not undergo hydrogenation but tiglic acid does suggests that substrates with one ester group that are not easily supported by chelation upon coordination to ruthenium will not undergo hydrogenation. Indeed, we observed no evidence of interaction between the active catalyst species **II** and an up to 100-fold excess of

[a] Reaction performed under 100 atm of H_2.

methyl tiglate in acetone solution.[3] The acids and other esters studied in this report all react stoichiometrically (1:1) with **II** to generate a variety of products. The structures of these ruthenium–substrate compounds are under investigation in our laboratories.

Substrates **2a**, **2b**, **3a**, and **3b** are hydrogenated with good to excellent ee and with the same enantioface selectivity. Figure 2 shows that these substrates all contain the same basic framework, a 1,4-dicarbonyl unit with the prochiral functionality at the 2-position (**7**). That hydrogenation of **2a**, **2b**, **3a**, and **3b** all proceed with the same face selectivity for most, if not all reported ruthenium–BINAP systems (Table 3) under similar conditions, raises the possibility that they proceed through structurally related intermediates. Figure 2 illustrates one possible structure type for such a species (**8**). We suggest this structure based on the recently

[3] $[Ru((R)\text{-BINAP})(H)(MeCN)_n(acetone)_{3-n}](BF_4)$ (n = 0–3) was the only species detected by ^{31}P NMR spectroscopy.

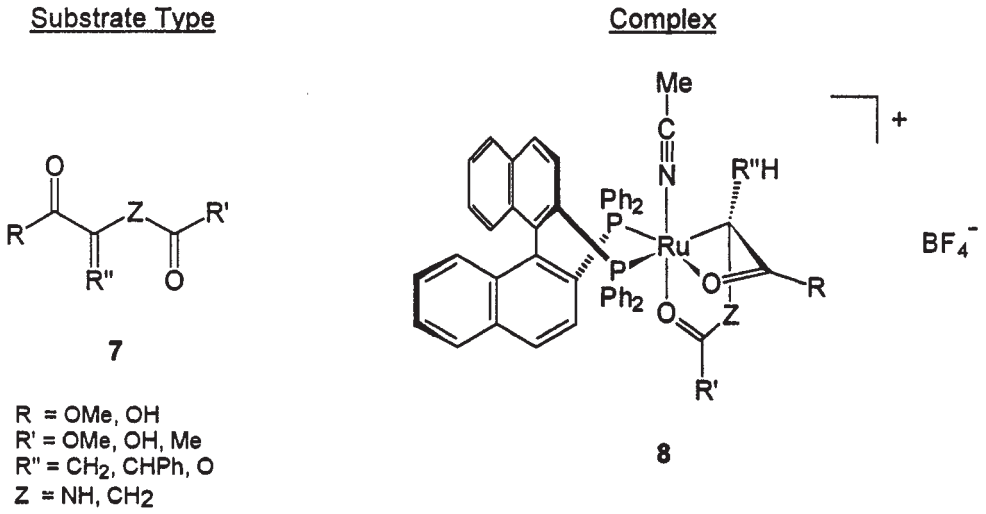
Fig. 2. Model for a possible common intermediate structure type.



reported (6) crystallographically characterized compound we isolated from the reaction of MAC (**2b**) with **II** (Fig. 2, **8**, R = OMe, R′ = Me, R′′ = CHPh, Z = NH). If such species form with these and other related substrates, and if these species contribute to the enantioselection by the catalytic hydrogenation must be investigated by experiment.

The role of NEt_3 as promoter for the hydrogenation of tiglic acid and itaconic acid in acetone is unknown. We have found, however, that reaction of tiglic acid with **II** in acetone results in immediate protonolysis of the Ru—H bond to generate a Ru-tiglato complex (eq. [1]). Reaction of Ru—D (formed by deuteration of **I** with D_2) resulted in the formation of the Ru-tiglato complex and concomitant formation of HD. We were unable to identify the absolute configuration of the tiglato complex about the ruthenium centre. We postulate that it is the Δ configuration on the basis of the arguments previously reported for the related complex Ru((*R*)-BINAP)($O_2CCMe{=}CHMe)_2$ (17). Two possible roles of the NEt_3 as promoter for hydrogenations of unsaturated acids may therefore be to enhance the rate of carboxylate exchange on such complexes, or to prevent protonolysis of the Ru—H bond by deprotonating the acid substrate. King and others have reported that NEt_3 decomposes (perhaps via a β-hydride elimination (18)) upon reaction with $[RuCl_2(COD)]_n$ and (*R*)-BINAP, or similar bis(phosphines), from 110 to 140°C to generate $[Et_2NH_2](Ru_2Cl_5((R)\text{-}(BINAP)_2)$ (19). It seems unlikely, however, that such a process occurs under H_2 at 25°C using **II** as catalyst (Table 2, entries 2, 5, and 9). The reasons why NEt_3 is not required to promote these hydrogenations in MeOH is unknown.

Geraniol

We found that the enantioselectivity for the hydrogenation of geraniol (**4a**) using **II** as catalyst was inversely dependent on the pressure of H_2. The sense of the enantioselectivity inverted and its magnitude increased when the pressure of H_2 was increased from 1 atm (Table 4, entries 1–3). The maximum ee, 86% (*S*), was obtained at 100 atm of H_2. Noyori and co-workers (20) reported increases in ee from 70 to 98% (*S*) when the pressure of H_2 was increased from 4 to 100 atm using Ru((*R*)-BINAP)($O_2CMe)_2$ as catalyst precursor. Sowa and co-workers (21) found that the isomerization of geraniol to γ-geraniol occurs at a rate comparable to that of hydrogenation using $[Et_2NH_2](Ru_2Cl_5((S)\text{-Tol-BINAP})_2)$ (Tol-BINAP = (di-*p*-tolylphosphino)-1,1′-binaphthyl) as catalyst precursor. The enantioselectivity for the direct hydrogenation of geraniol was found to be opposite to that for the direct hydrogenation of γ-geraniol, resulting in an inversion of enantioselectivity over the course of the catalytic hydrogenation. Our results indicate that use of **II** as catalyst results in similar behaviour. We report, however, that reaction of **II** with geraniol in the absence of H_2 results in a complex mixture of olefin isomerization products, not just formation of γ-geraniol.

[c]Reaction done in acetone.

α- and β-Keto esters

The hydrogenation of ethyl acetoacetate (**5a**) to ethyl 3-hydroxybutyrate (**5b**) (Table 4, entry 4) proceeded in a quantitative fashion, but in low ee (15% (*S*)). Takaya and coworkers (22) reported that addition of 2 equiv. of HX (e.g., X = Cl, Br) to Ru((*R*)-BINAP)$(O_2CMe)_2$ followed by removal of all volatiles in vacuo gave rise to highly efficient catalysts which hydrogenate various β-keto esters with greater than 98% ee. The addition of 10 equiv. of LiCl to **I** (Table 4, entry 5) increased the ee, but only to 20% and in the opposite absolute configuration (*R*). The role of LiCl is unclear but the enantioselectivity of complex **II** remains poor compared to other reported ruthenium–BINAP systems which often yield enantiomeric excesses greater than 95% for the hydrogenation of such substrates (23).

Examining the structural framework of the model substrates for our catalyst system (Fig. 2, **7**) led to our use of dimethyl oxaloacetate (**6a**). Dimethyl oxaloacetate has similar structural characteristics to dimethyl itaconate (**3b**) where the olefinic bond is replaced by a carbonyl functionality. The hydrogenation of **6a** proceeded to completion (100 atm H_2, 50°C, acetone, Table 4, entry 6) yielding dimethyl hydroxysuccinate (**6b**) in 74% ee (*S*). Although the ee is moderate, it is a substantial increase from the hydrogenation of ethyl acetoacetate. Further, the hydrogenation product (**6b**) resulted from the same enantioface selection as those for the hydrogenations of **2b** and **3b**. These findings support the possibility that substrates with similar structural features proceed through structurally related intermediates (Fig. 2).

Conclusions

Complex **II** is among the more effective ruthenium–BINAP catalysts reported for the asymmetric hydrogenation of substrates containing an α,β-unsaturated carboxylic acid or ester functionality. Its success in the asymmetric reduction of ketones is only moderate. Prochiral substrates with the general structure **7** shown in Fig. 2 are hydrogenated with the same enantioface selection. Extrapolations of these results from mechanistic investigations of one combination of substrate, catalyst, and reaction conditions are precarious in their nature because of the large number of variables involved in such reactions. That substrates of the general structure **7** are hydrogenated with the same enantioface selection raises the possibility that a general trend may exist in these catalyst systems. Further investigations into the true significance of this apparent general trend in enantioselection by ruthenium–BINAP catalysts are underway in our laboratories.

Experimental

Materials and methods

All operations were performed under an Ar atmosphere using standard Schlenk techniques. The solvents were dried and distilled under an Ar atmosphere before use by standard methods (24). The Ar (Praxair, 99.998%) was passed through a drying train containing 3 Å molecular sieves and P_4O_{10} before use. Trace quantities of oxygen were removed from the H_2 (Praxair, 99.99%) by passage through an Alltech Oxy-Trap. All commercial reagents (Aldrich or Fluka) were recrystallized or distilled under an Ar atmosphere before use. [Ru((*R*)-BINAP)-(MeCN)(1-3:5,6-η-C_8H_{11})](BF_4) (4), (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetylchloride (25), [Rh(η^4-norbornadiene)(DIPHOS)](ClO_4) (26), and dimethyl oxaloacetate (27) were prepared using established procedures.

Unless stated otherwise, all ^1H, ^{13}C, and ^{31}P NMR spectra were measured with a Bruker AM-400 spectrometer operating at 400.1 MHz, 100.6 MHz, and 161.9 MHz, respectively. ^1H and ^{13}C NMR chemical shifts are reported in ppm (δ) relative to TMS, using the solvent as an internal reference. ^{31}P NMR chemical shifts are reported in ppm (δ) relative to an 85% H_3PO_4 external reference. Mass spectra were measured using a Kratos MS50 spectrometer. Microanalyses were performed at the University of Alberta Microanalysis Laboratory. Optical rotations were measured with a Perkin–Elmer 241 polarimeter at 589 nm using 1.0 dm cells. Specific rotations, $[\alpha]_D$, are reported in degrees per decimeter at 25°C, and the concentration (*c*) is given in grams per 100 mL.

Hydrogenation procedure

A glass pressure reactor (Lab Glass) was employed for hydrogenation reactions where the pressure of H_2 was ≤ 4 atm. For reactions requiring elevated pressures, a Parr cell-disruption bomb was used. A typical hydrogenation procedure is described below.

Under an Ar atmosphere, the catalyst precursor (**I**) (0.010 mmol), substrate (1.0 mmol), and NEt_3 (1 equiv. per acid unit as required, Table 2), were introduced into the reactor. The dry, deoxygenated solvent (MeOH or acetone) was then added (3.8 mL), and the solution was stirred for 5 min. The atmosphere was then replaced by H_2, and the solution was allowed to react under the prescribed conditions (Tables 1, 2, and 4). On completion of the reaction, the sol-

© 1998 NRC Canada

vent was removed under reduced pressure, and the products were worked up as detailed below. Complete conversion and identification of the products were confirmed by CIMS and (or) ^{1}H NMR analyses.

*Tiglic acid (**1a**)*

The product residue from the hydrogenation in MeOH was dissolved in CH_2Cl_2 and passed through a Florisil plug to remove the catalyst. The solvent was then removed under reduced pressure, and the residue was converted to the corresponding diastereomeric amides of (*S*)-(–)-α-methylbenzylamine (28). The ee and absolute configuration were determined by comparison of the ^{1}H NMR spectrum of the derivatized residue to that of the corresponding amide derivatives prepared from (±)-2-methylbutyric acid and authentic (*S*)-(+)-2-methylbutyric acid, respectively.

To the acetone–NEt_3 product residue was added 10% aq. HCl (10 mL). The solution was filtered, and the filtrate extracted with Et_2O (5 × 40 mL). The combined organic layers were washed with 5% aq. HCl (3 × 8 mL), dried over $MgSO_4$, filtered, and concentrated under reduced pressure to give 2-methylbutyric acid. The ee and absolute configuration were then determined as described above. NMR data for the (*S*, *S*) diastereomer: ^{1}H (400.1 MHz, $CDCl_3$), δ: 0.84 (t, *J* = 7.4 Hz, 3H), 1.13 (d, *J* = 6.9 Hz, 3H), 1.39 (m, 1H), 1.46 (d, *J* = 6.9 Hz, 3H), 1.64 (m, 1H), 2.10 (apparent sextet, *J* = 6.9 Hz, 1H), 5.14 (apparent quintet, *J* = 7.2 Hz, 1H), 5.89 (br s, 1H), 7.15–7.40 (aromatic, 5H); NMR data for (*R*, *S*) diastereomer: ^{1}H (400.1 MHz, $CDCl_3$), δ: 0.92 (t, *J* = 7.4 Hz, 3H), 1.10 (d, *J* = 6.9 Hz, 3H), 1.38 (m, 1H, overlapped with (*S*, *S*) diastereomer), 1.47 (d, *J* = 6.9 Hz, 3H), 1.64 (m, 1H, overlapped with (*S*, *S*) diastereomer), 2.09 (apparent sextet, *J* = 6.9 Hz, 1H, overlapped with (*S*, *S*) diastereomer), 5.13 (apparent quintet, *J* = 7.2 Hz, 1H, overlapped with (*S*, *S*) diastereomer), 5.89 (br s, 1H, overlapped with (*S*, *S*) diastereomer), 7.15–7.40 (m, 5H, aromatic, overlapped with (*S*, *S*) diastereomer).

*α-Acetamidocinnamic acid (**2a**)*

The product residue was converted to the corresponding diastereomeric amides of (*S*)-(–)-α-methylbenzylamine (28). The absolute configuration of the product was determined by comparison of its optical rotation to that of the reported optical rotation of (*R*)-(–)-*N*-acetylphenylalanine (**2b**) ($[\alpha]^{27}_D$ = –40.3°, *c* = 1.0, MeOH) (29). The ee was determined by ^{1}H NMR analysis (400 MHz, $CDCl_3$) of the resulting diastereomeric amides.[4] NMR data of the diastereomeric amides: ^{1}H (400.1 MHz, $CDCl_3$), δ: 1.21 (d, *J* = 7.0 Hz, 3H; (*R*, *R*) diastereomer), 1.40 (d, *J* = 7.0 Hz, 3H; (*R*, *S*) diastereomer), 1.88 (s, 3H; (*R*, *R*) diastereomer), 1.95 (s, 3H; (*R*, *S*) diastereomer), 2.92 (m, 2H; (*R*, *S*) diastereomer), 2.97 (dd, *J* = 13.4, 8.8 Hz, 1H; (*R*, *R*) diastereomer), 3.10 (dd, *J* = 13.4, 6.1 Hz, 1H; (*R*, *R*) diastereomer), 4.70 (m, 2H), 4.91 (apparent quintet, *J* = 7.0 Hz, 1H; (*R*, *R*) diastereomer), 4.97 (apparent quintet, *J* = 7.0 Hz, 1H; (*R*, *S*) diastereomer), 6.49 (d, *J* = 7.7 Hz, 1H), 6.72 (m, 3H), 7.00–7.45 (m, 20H). N*H* signals not observed.

*Itaconic acid (**3a**)*

The product residue was converted directly to the dimethyl ester with CH_2N_2 (30), whereas the acetone–NEt_3 product was first worked up in a manner similar to that described for tiglic acid (**2a**), and then treated with CH_2N_2. The product was then dissolved in CH_2Cl_2 and passed through a Florisil plug to remove the catalyst. The solvent was removed under reduced pressure to yield dimethyl methylsuccinate. The ee and absolute configuration were then determined as described in the dimethyl itaconate (**3b**) hydrogenation work-up.

*Dimethyl itaconate (**3b**)*

The products of the MeOH and acetone reactions were treated in a similar manner. The product residue was dissolved in CH_2Cl_2 and passed through a Florisil plug to remove the catalyst. The solvent was removed under reduced pressure, yielding dimethyl methylsuccinate. The ee was spectroscopically determined (^{1}H NMR, CD_2Cl_2) upon addition of chiral lanthanide shift reagent ((+)-Eu(tfc)$_3$))[5] (31). The absolute configuration of the product was determined by comparison of its optical rotation to that of authentic (*R*)-dimethyl methylsuccinate ($[\alpha]^{25}_D$ = +4.8°, *c* = 4.0, $CHCl_3$).

*Geraniol (**4a**)*

The product residue was purified by flash distillation and reacted with (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetylchloride (25). The ee was determined by ^{1}H NMR spectroscopy of the diastereomeric esters.[6] The absolute configuration of the product was determined by comparison of its rotation with the reported optical rotation of (*R*)-citronellol ($[\alpha]^{25}_D$ = +5.12°, *c* = 21.0, $CHCl_3$) (32). NMR data for the diastereomeric esters: ^{1}H (400.1 MHz, $CDCl_3$), δ: 0.90 (d, *J* = 6.3 Hz, 3H; (*R*, *S*) diastereomer), 0.91 (d, *J* = 6.3 Hz, 3H; (*R*, *R*) diastereomer), 1.19 (m, 2H), 1.33 (m, 2H), 1.51 (m, 4H), 1.59 (s, 6H), 1.68 (s, 6H), 1.74 (m, 2H), 1.95 (m, 4H), 3.50 (br s, 3H; (*R*, *S*) diastereomer), 3.56 (br s, 3H; (*R*, *R*) diastereomer), 4.37 (m, 4H), 5.06 (m, 2H), 7.35–7.70 (m, 10H, aromatic). ^{1}H NMR signals for individual diastereomers were assigned when overlap did not occur.

*Ethyl acetoacetate (**5a**)*

The product residue was purified by flash distillation and reacted with (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetylchloride (25). The ee and absolute configuration were determined by comparison of the ^{1}H NMR of the derivatized residue to that of the diastereomeric Mosher's esters of (±)-3-hydroxybutyrate and authentic ethyl (*R*)-(–)-3-hydroxybutyrate, respectively. NMR data for the diastereomeric esters: ^{1}H NMR (400.1 MHz, $CDCl_3$): (*R*, *R*) diastereomer, δ: 1.23 (t, *J* = 7.1 Hz, 3H), 1.34 (d, *J* = 6.3 Hz, 3H), 2.57 (dd, *J* = 16.0, 4.7 Hz, 1H), 2.72 (dd, *J* = 16.0,

[4] The ratio of the acyl peaks at δ = 1.94 (s, CH_3, *S*) and δ = 1.78 (s, CH_3, *R*) were used to determine the ee. The ratio of these peaks was 1:1 for racemic *N*-acetyl phenylalanine.

[5] The ratio of the methoxy signals (ca. 4 ppm) were used to determine the ee. The ratio of these peaks was 1:1 for racemic dimethyl methylsuccinate.

[6] The ratio of the methyl peaks at δ = 0.91 (d, *J* = 6.4 Hz, CH_3, *R*) and δ = 0.90 (d, *J* = 6.4 Hz, CH_3, *S*) were used to determine the ee. The ratio of these peaks was 1:1 for racemic β-citronellol.

8.5 Hz, 1H), 3.49 (br s, 3H), 4.13 (qd, J = 7.1, 1.3 Hz, 2H), 5.57 (m, 1H), 7.3–7.7 (m, 5H, aromatic); (*R*, *S*) diastereomer, δ: 1.19 (t, J = 7.1 Hz, 3H), 1.43 (d, J = 6.3 Hz, 3H), 2.53 (dd, J = 16.0, 5.0 Hz, 1H), 2.68 (dd, J = 16.0, 8.3 Hz, 1H), 3.55 (br s, 3H), 4.06 (q, J = 7.1 Hz, 2H), 5.57 (m, 1H), 7.3–7.7 (m, 5H, aromatic).

*Dimethyl oxaloacetate (**6a**)*

The product residue was dissolved in CH_2Cl_2 and passed through a Florisil plug to remove the catalyst. The solvent was removed under reduced pressure, and the residue was reacted with (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetylchloride (25). The ee was determined by comparison of the ^{1}H NMR spectrum of the derivatized residue to that of the Mosher's esters of (±)-dimethyl hydroxysuccinate (see achiral hydrogenation for NMR data). The absolute configuration was determined by comparison with the optical rotation of authentic (*S*)-(–)-dimethyl hydroxysuccinate ($[\alpha]^{25}_D$ = –8.85°, c = 5.2, MeOH).

Achiral hydrogenation of dimethyl oxaloacetate

A stainless-steel autoclave was charged with [Rh(η^4-norbornadiene)(DIPHOS)](ClO_4) (6.9 mg, 0.01 mmol), dimethyl oxaloacetate (160.0 mg, 1.0 mmol), and acetone (3.8 mL). The solution was stirred for 5 min, and the atmosphere was then replaced with H_2. The solution was allowed to react for 75 h at 50°C and 100 atm H_2. The product was worked up as described for the hydrogenation of dimethyl oxaloacetate with **I** as catalyst precursor and reacted with (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetylchloride (25). NMR spectroscopic data: ^{1}H (300.1 MHz, $CDCl_3$): (*R*, *R*) diastereomer, δ: 2.88 (dd, J = 16.7, 8.4 Hz, 1H), 2.96 (dd, J = 16.7, 5.0 Hz, 1H), 3.60 (s, 3H), 3.63 (br s, 3H), 3.81 (s, 3H), 5.72 (dd, J = 8.4, 5.0 Hz, 1H), 7.42 (m, 3H), 7.60 (m, 2H); (*R*, *S*) diastereomer, δ: 2.92 (dd, J = 16.9, 8.9 Hz, 1H), 3.02 (dd, J = 16.9, 4.0 Hz, 1H), 3.55 (br s, 3H), 3.70 (s, 3H), 3.76 (s, 3H), 5.71 (dd, J = 8.9, 4.0 Hz, 1H), 7.42 (m, 3H), 7.60 (m, 2H).

Hydrogenation of [Ru((*R*)-BINAP)(1-3:5,6-η-C_8H_{11})(MeCN)](BF_4) (I) in acetone-d_6

Compound **I** (19.5 mg, 2.03×10^{-5} mol) was partially dissolved in acetone-d_6 (0.6 mL) in an NMR tube under an Ar atmosphere. At room temperature, the tube was flushed with H_2, pressurized (1–2 atm), and shaken until a deep orange–yellow solution was generated (~5 min). The H_2 atmosphere was replaced by Ar, and the resulting solution was analyzed by ^{1}H and ^{31}P NMR spectroscopy at –80°C. NMR spectroscopic analysis indicated a mixture of eight ruthenium-hydrido species ([Ru((*R*)-BINAP)(H)$(MeCN)_n((CD_3)_2CO)_{3-n}$]($BF_4$), where n = 0–3) and cyclooctane were present. At –80°C, D_2 (5.0 mL) was injected into the headspace of the tube. The tube was removed from the cooling bath, shaken for ~15 s, and then immediately placed in a precooled (–80°C) NMR probe. The ^{31}P NMR spectrum at –80°C remained unchanged, while the ^{1}H NMR spectrum indicated that exchange of all ruthenium-hydrido species with D_2 (to form ruthenium-deutero species) had occurred with concomitant formation of HD. NMR spectroscopic data of the hydrides (A-H): ^{1}H (400.1 MHz, $(CD_3)_2CO$, –80°C), δ: –19.87 (br, A), –19.60 (apparent t, $^2J_{H-P}$ = 30 Hz, B), –19.45 (br, C), –19.26 (apparent t, $^2J_{H-P}$ = 30 Hz, D), –13.50 (apparent t, $^2J_{H-P}$ = 25 Hz, E), –13.20 (apparent t, $^2J_{H-P}$ = 25 Hz, F), –13.15 (dd, $^2J_{H-P}$ = 28 Hz, $^2J_{H-P}$ = 24 Hz, G), –12.88 (apparent t, $^2J_{H-P}$ = 27 Hz, H), 1.65–2.35 (12 s, Ru-NCCH_3), 6.00–8.50 (aromatic); ^{31}P{^{1}H} (161.9 MHz, $(CD_3)_2CO$), δ: 59.4 (d, $^2J_{P-P}$ = 43.0 Hz, A), 60.8 (d, $^2J_{P-P}$ = 46.4 Hz, B), 63.2 (d, $^2J_{P-P}$ = 44.2 Hz, F), 63.6 (d, $^2J_{P-P}$ = 40.6 Hz, E), 66.0 (d, $^2J_{P-P}$ = 43.0 Hz, A), 68.2 (d, $^2J_{P-P}$ = 46.0 Hz, C),[7] 69.6 (d, $^2J_{P-P}$ = 40.6 Hz, E), 71.2 (d, $^2J_{P-P}$ = 49.6 Hz, D), 71.5 (d, $^2J_{P-P}$ = 42.9 Hz, G), 74.2 (d, $^2J_{P-P}$ = 47.0 Hz, H), 75.4 (d, $^2J_{P-P}$ = 42.9 Hz, G), 76.5 (d, $^2J_{P-P}$ = 46.4 Hz, B), 79.3 (d, $^2J_{P-P}$ = 49.6 Hz, D), 80.3 (d, $^2J_{P-P}$ = 44.2 Hz, F), 82.7 (d, $^2J_{P-P}$ = 47.0 Hz, H). Approximate percentages of hydrido species present: A(3), B(14), C(5), D(22), E(15), F(15), G(11), H(15). Although we were unable to assign individual structures for each hydride, we have independently prepared *fac*-[Ru((*R*)-BINAP)(H)$(MeCN)_3$](BF_4) which corresponded to hydride E.

Stoichiometric reaction of [Ru((*R*)-BINAP)(H)$(MeCN)_n(Sol)_{3-n}$](BF_4) (II, n = 0–3) with tiglic acid in acetone

A Schlenk flask was charged with **I** (40.0 mg, 4.18×10^{-5} mol), tiglic acid (4.2 mg, 4.18×10^{-5} mol), and acetone (4.0 mL) under an Ar atmosphere. At room temperature, the flask was flushed with H_2, pressurized (1–2 atm), and shaken until a deep orange–yellow solution was generated (~5 min). The H_2 atmosphere was then replaced by Ar. To this solution was added MeCN (2.6 mL, 4.98×10^{-5} mol), and the flask was shaken (~5 min) to ensure complete reaction. The solvent was removed under reduced pressure, and the remaining orange solid was washed with hexanes (3 × 5 mL). The isolated solid was stored under an Ar atmosphere at –30°C. The product readily loses MeCN in vacuo. NMR spectroscopic data of the complex: ^{1}H (400.1 MHz, $(CD_3)_2CO$), δ: 1.45 (apparent t, $CH_3CHC(CH_3)CO_2Ru$, $^4J_{H-H}$ = 1.5 Hz, $^5J_{H-H}$ = 1.2 Hz), 1.56 (dd, $CH_3CHC(CH_3).CO_2Ru$, $^3J_{H-H}$ = 7.2 Hz, $^5J_{H-H}$ = 1.2 Hz), 2.01 (s, CH_3CN), 2.03 (s, CH_3CN), 6.45 (dq, $CH_3CHC(CH_3)CO_2Ru$, $^3J_{H-H}$ = 7.2 Hz, $^4J_{H-H}$ = 1.5 Hz), 6.58–7.89 (m, 32H, BINAP). ^{31}P{^{1}H} (161.9 MHz, $(CD_3)_2CO$), δ: 52.6 (dd, $^2J_{P-P}$ = 37.5 Hz), 56.9 (d, $^2J_{P-P}$ = 37.5 Hz). ^{13}C{^{1}H} (100.6 MHz, $(CD_3)_2CO$), δ: 2.4 (CH_3CN), 4.65 (CH_3CN), 10.72 and 13.90 ($CH_3CHC(CH_3)CO_2Ru$), 123.99 (CH_3CN), 124.14 (CH_3CN), 124.42–141.45 (BINAP and $CH_3CHC(CH_3)CO_2Ru$), 185.46 ($CH_3CHC(CH_3)CO_2Ru$).

Stoichiometric reaction of [Ru((*R*)-BINAP)(D)$(MeCN)_n(Sol)_{3-n}$](BF_4) (II, n = 0–3) with tiglic acid in acetone-d_6

Compound **I** (13.5 mg, 1.41×10^{-5} mol) was partially dissolved in acetone-d_6 (~0.8 mL) in an NMR tube under an Ar atmosphere. At room temperature, the tube was flushed with D_2, pressurized (1–2 atm), and shaken until a deep orange–yellow solution was generated (~5 min). The D_2 atmosphere was replaced by Ar, and the solution was then transferred to an NMR tube containing tiglic acid (1.41 mg, 1.41×10^{-5}

[7] The corresponding ^{31}P{^{1}H} NMR signal was obscured by resonances attributed to hydrides D and G ca. 71.3 ppm.

mol) under an Ar atmosphere. To this solution was added excess CD_3CN (2.0 μL, 3.83×10^{-5} mol) via a gas-tight syringe. The solution was immediately analyzed by ^1H NMR. The product was exclusively formed with concomitant formation of HD. ^1H (400.1 MHz, $(CD_3)_2CO$), δ: 1.45 (apparent t, $CH_3CHC(CH_3)CO_2Ru$, $^4J_{H-H}$ = 1.5 Hz, $^5J_{H-H}$ = 1.1 Hz), 1.46–1.52 (br m, partially deuterated cyclooctane), 1.56 (dd, $CH_3CHC(CH_3)CO_2Ru$, $^3J_{H-H}$ = 7.2 Hz, $^5J_{H-H}$ = 1.1 Hz), 1.99 (s, CH_3CN), 3.26 (br t, HD, $^1J_{H-D}$ = 240 Hz), 6.45 (dq, $CH_3CHC(CH_3)CO_2Ru$, $^3J_{H-H}$ = 7.2 Hz, $^4J_{H-H}$ = 1.6 Hz), 6.58–7.89 (m, 32H, BINAP). $^{31}P\{^1H\}$ (161.9 MHz, $(CD_3)_2CO$), δ: 52.6 (dd, $^2J_{P-P}$ = 37.5 Hz), 56.9 (d, $^2J_{P-P}$ = 37.5 Hz).

A combined QM/MM study of ligand substitution enthalpies in the $L_2Fe(CO)_3$, $RuCpL_2Cl$, and $RuCp^*L_2Cl$ systems

Luigi Cavallo, Tom K. Woo, and Tom Ziegler

Abstract: A combined density functional and molecular mechanics approach (QM/MM) has been validated in a study of the substitution reactions: (*i*) $(PH_3)_2Fe(CO)_3 + 2ER_3 \leftrightarrow (ER_3)_2Fe(CO)_3 + 2PH_3$ (ER_3 = PMe_3, PEt_3, $PMePh_2$, PPh_3, $PCyPh_2$, P^iPr_3, PBz_3, PCy_3, $AsEt_3$, $AsPh_3$); and (*ii*) $Cp'Ru(PH_3)_2Cl + 2ER_3 \leftrightarrow Cp'Ru(ER_3)_2Cl + 2PH_3$ (Cp' = C_5H_5, $C_5(CH_3)_5$; ER_3 = PMe_3, PEt_3, P^nBu_3, PMe_2Ph, $PMePh_2$, PPh_3, $AsEt_3$, $P(OMe)_3$, $P(OPh)_3$, $P(OCH_2)_3CEt$). The steric influence of the R substituents on the substitution enthalpies correlates well with experimental data. The combined QM/MM approach is also able to afford molecular structures in good accord with experimental estimates.

Key words: combined QM/MM, ligand substitutions, organometallic complexes.

Résumé : On a validé une approche combinée de densité fonctionnelle et de mécanique moléculaire (QM/MM) à l'aide d'une étude des réactions de substitution suivantes: (*i*) $(PH_3)_2Fe(CO)_3 + 2ER_3 \leftrightarrow (ER_3)_2Fe(CO)_3 + 2PH_3$ (ER_3 = PMe_3, PEt_3, $PMePh_2$, PPh_3, $PCyPh_2$, $P(iPr)_3$, PBz_3, PCy_3, $AsEt_3$, $AsPH_3$) et (*ii*) $Cp'Ru(PH_3)_2Cl + 2ER_3 \leftrightarrow Cp'Ru(ER_3)_2Cl + 2PH_3$ (Cp' = C_5H_5, $C_5(CH_3)_5$; ER_3 = PM_3, PEt_3, PBu_3, PMe_2Ph, $PMePh_2$, PPh_3, $AsEt_3$, $P(OMe)_3$, $P(OPh)_3$, $P(OCH_2)_3CEt$). Il existe une bonne corrélation entre l'influence stérique des substituants R sur les enthalpies de substitution et les données expérimentales. L'approche combinée QM/MM permet aussi d'obtenir des structures moléculaires qui sont en bon accord avec les valeurs expérimentales.

Mots clés : approche combinée de densité fonctionnelle et de mécanique moléculaire (QM/MM), substitutions de ligands, complexes organométalliques.

[Traduit par la Rédaction]

1. Introduction

Phosphine ligands play an important role in transition-metal chemistry, since their great variability in terms of steric bulk and electronic properties make it possible to fine-tune the reactivity of the metal center to which they are coordinated. The steric influence of phosphines was first studied experimentally by Tolman (1) who introduced the concept of the "cone angle" as a measure for the bulkiness of a specific ligand. Their electronic abilities as σ-donors and π-acceptors have been analyzed in a parallel series of experimental studies (2). Recently, Nolan (3–6) and co-workers have investigated how steric and electronic changes in the ER_3 ligand influence the overall reaction enthalpy of the substitution processes:

[1] $$(BDA)_2Fe(CO)_3 + 2ER_3 \leftrightarrow (ER_3)_2Fe(CO)_3 + BDA$$

[2] $$CpRu(COD)Cl + 2ER_3 \leftrightarrow CpRu(ER_3)_2Cl + COD$$

Received April 13, 1998.

[3] $$Cp^*Ru(COD)Cl + 2ER_3 \leftrightarrow Cp^*Ru(ER_3)_2Cl + COD$$

where BDA = PhCH=CHCOMe; COD = cyclooctadiene; Cp = η^5-C_5H_5; Cp* = η^5-C_5Me_5; ER_3 = tertiary phosphine, arsine, phosphite. Theoretical investigations to date on phosphine complexes have either focused on the steric aspects with the help of pure molecular mechanics (MM) calculations (7) or the electronic properties based on full quantum mechanical (QM) calculations (8).

In recent years attempts have been made to combine MM and QM calculations (QM/MM) in order to study chemical problems where both steric bulk and electronic effects are of importance at the same time, as in the case of the phosphine ligands. Work in this direction has been pioneered by Warshel and Karplus (9), Karplus and co-workers (10), Singh and Kollmann (11), as well as Morokuma and co-workers (12). The combined QM/MM approach has been applied to a few organometallic systems (13, 14). However, more systematic investigations are required to validate the QM/MM approach in the field of coordination chemistry. We have to this end conducted a QM/MM study of the ligand substitution reactions:

[4] $$(PH_3)_2Fe(CO)_3 + 2ER_3 \leftrightarrow (ER_3)_2Fe(CO)_3 + 2PH_3$$

where ER_3 = PMe_3, PEt_3, $PMePh_2$, PPh_3, $PCyPh_2$, P^iPr_3, PBz_3, PCy_3, $AsEt_3$, $AsPh_3$, and

© 1998 NRC Canada

[5] $CpRu(PH_3)Cl + 2ER_3 \leftrightarrow CpRu(ER_3)_2Cl + PH_3$

[6] $Cp^*Ru(PH_3)Cl + 2ER_3 \leftrightarrow Cp^*Ru(ER_3)_2Cl + PH_3$

where ER_3 = PMe_3, PEt_3, P^nBu_3, PMe_2Ph, $PMePh_2$, PPh_3, $AsEt_3$, $P(OMe)_3$, $P(OPh)_3$, $P(OCH_2)_3CEt$. We note that changes in the reaction enthalpy of the processes [4]–[6] can be compared to the corresponding differences in reactions [1]–[3] from the experimental studies of Nolan and co-workers (3–6). In the following, references to relative experimental M–ER_3 bond energies are taken from the work of Nolan and co-workers (3–6).

The PH_3 ligand has been chosen as reference in the theoretical studies due to the fact that this ligand represents the phosphine with the smallest possible steric requirements. The presence of two metal centers with different coordination geometry allows us further to study complexes where the degree of steric interaction between the ER_3 groups is quite different. Thus, the iron systems have a trigonal bipyramidal geometry with the ER_3 ligands well separated in trans-axial positions, whereas the ruthenium complexes are roughly tetrahedral with the ER_3 groups in much closer contact.

2. Computational details

All reported quantum-mechanical calculations were performed by means of the Amsterdam Density Functional (ADF) program system, developed by Baerends et al. (15, 16), and vectorized by Ravenek (17). The numerical integration scheme applied for the calculations was developed by te Velde and Baerends (18). The geometry-optimization procedure was based on the method by Versluis and Ziegler (19). The electronic configurations of the molecular systems were described by a triple-ζ basis set (20, 21) on the metal centers for the *ns*, *np*, *nd*, (*n* + 1)*s* and (*n* + 1)*p* valence shells. A double-ζ STO basis set was used for carbon (2*s*, 2*p*), hydrogen (1*s*), chlorine (3*s*, 3*p*), and phosphorus (3*s*, 3*p*), augmented with a single 3*d* polarization function, except for hydrogen where a 2*p* function was used. The inner shells on the metals, as well as carbon, oxygen, phosphorus, and chlorine, were treated within the frozen core approximation. A set of auxiliary s, *p*, *d*, *f*, and *g* STO functions (22), centered on all nuclei, was used in order to fit the molecular density and present Coulomb and exchange potentials accurately in each SCF cycle. Energy differences were calculated by augmenting the local exchange-correlation potential by Vosko et al. (23) with the nonlocal exchange of corrections of Becke (24) and the nonlocal correlation corrections of Perdew (25, 26).

The molecular mechanics force field was of the form

[7] $E_{MM} = E_{str} + E_{bend} + E_{tors} + E_{ofpl} + E_{vdw_i}$

where

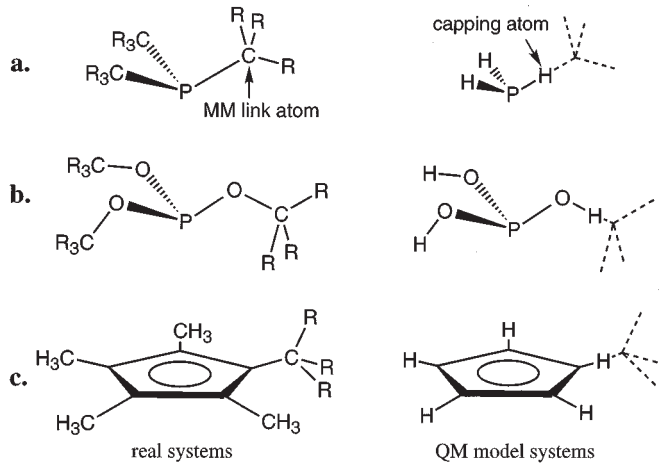
[8*a*] $E_{str} = 1/2K_{str}(R - R_0)^2$

[8*b*] $E_{bend} = 1/2K_{bend}(\theta - \theta_0)^2$

[8*c*] $E_{tors} = 1/2K_{tors}(1 + \cos(n\phi - \phi_0))$

[8*d*] $E_{ofpl} = 1/2K_{ofpl}(1 - \cos(n\tau - \tau_0))$

Scheme 1.



[8*e*] $E_{vdw_1} = \varepsilon_{min}[(d_{min}/d)^{12} - 2(d_{min}/d)^6]$

[8*f*] $E_{vdw_2} = D_0 \exp(\gamma(1 - d/d_0))$

For the nonbonded interactions two energy expressions have been implemented. The first, E_{vdw_1} of eq. [8*e*], employs the standard attractive–repulsive (attr–rep) 6-12 Lennard–Jones potential. The second, E_{vdw_2} of eq. [8*f*], uses an exponential expression fitted to the repulsive part of the attr–rep Lennard–Jones potential. This second approach has been adopted to eliminate spurious stabilizations from the long-range attractive part of E_{vdw_1} (7, 27), as discussed in previous applications (7, 28). The force constants were taken from the AMBER force field (29), except for the iron, ruthenium, and arsenic atoms for which we used the van der Waals parameters of the universal force field of Rappé et al. (30).

The combined QM/MM approach of Maseras and Morokuma (12) as implemented within the ADF density functional package (31) was utilized. In the combined QM/MM method, the molecular system is partitioned into QM and MM regions. Resultingly, the total molecular potential is a hybrid of a QM potential determined from an electronic structure calculation and a MM potential determined from a force-field calculation. The electronic system of the QM region is truncated with so-called "capping atoms" (11) (often hydrogen atoms), which are not part of the "real" molecular system. The capping atoms serve to allow a standard electronic structure calculation to be performed on what is termed the QM model system. Take the example illustrated in Scheme 1*a* in which a phosphine ligand, $P(CR_3)_3$, is partitioned into QM and MM regions across the three P—C bonds. Here, the electronic structure calculation would be performed on the PH_3 fragment, and a molecular mechanics potential would be used to represent the remainder of the system. In the real system, the capping atoms of the QM model system are replaced by "MM-link" atoms, which are constrained to lie along the vector of the capping atom bond.

In this study, only the bulky "R" substituents in the phosphine (PR_3), arsine (AsR_3), and phosphite ($P(OR)_3$) fragments, and the methyl groups in the Cp* groups are treated by a molecular mechanics potential. The transition-metal

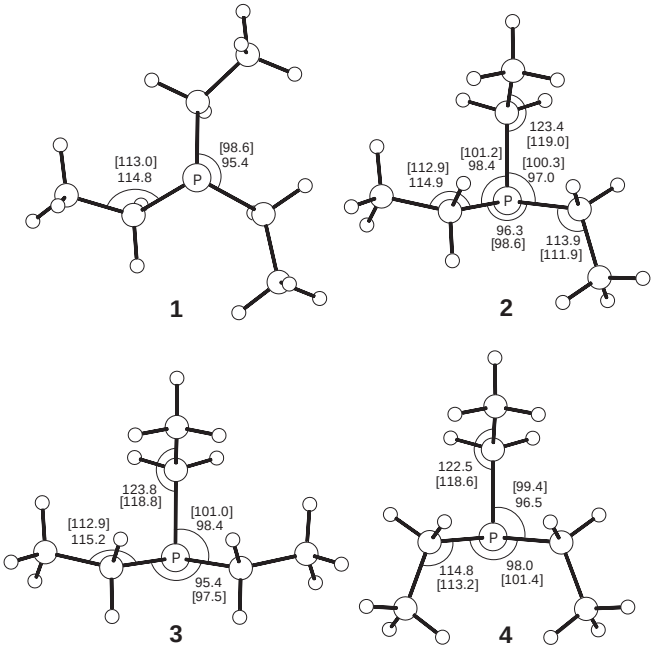
Fig. 1. Optimized pure QM geometries for four conformations of the PEt_3 phosphine ligand. The corresponding geometrical parameters obtained from the QM/MM method based on the purely repulsive nonbonded energy expression E_{vdw_2} are in parentheses.



center and all other ancillary ligands are delegated to the QM region. Scheme 1 shows the real and QM model systems for the phosphines (and arsines), the phosphites, and the Cp* group that were used. The difference, ΔR, between the bond distance of the capping atom and the corresponding bond distance of the MM link atom is fixed. For sp^3 and sp^2 carbon atoms we adopted ΔR = 0.415 and 0.400 Å, respectively. This approach approximates the distances P—C (alkyl), P—C (aryl), As—C (alkyl), As—C (aryl), O—C (alkyl), O—C (aryl), and C (cyclopentadienyl)—C (methyl) to roughly 1.845, 1.830, 1.950, 1.935, 1.450, 1.435, and 1.450 Å , respectively.

The enthalpies for the substitution reactions studied by Nolan and co-workers (3–6):

[9*a*] (complex with ER_3) + BDA or COD

$$\leftrightarrow \text{(complex with BDA or COD)} + 2ER_3$$

and the substitution processes studied here:

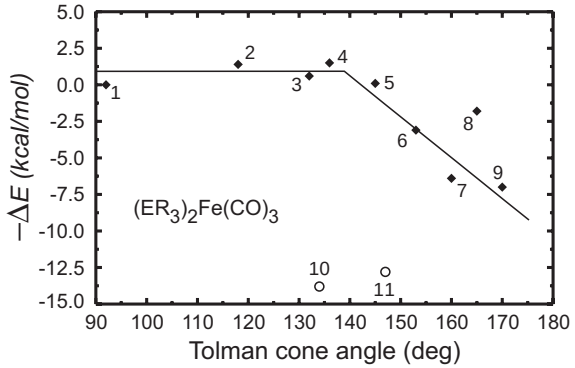
[9*b*] (complex with ER_3) + PH_3

$$\leftrightarrow \text{(complex with } PH_3\text{)} + ER_3$$

differ only by a constant. Thus, it is possible to directly compare experimental trends from eq. [9*a*] with calculated trends from eq. [9*b*]. The reaction enthalpy for the substitution processes, eq. [9*b*], have been calculated according to the formula:

$$[10] \quad -\Delta E_{Tot} = E(\text{complex with } PH_3) + 2E(ER_3) - E(\text{complex with } ER_3) - 2E(PH_3)$$

Fig. 2. Enthalpy of ligand substitution $-\Delta E_{Tot}$ vs. Tolman cone angle for the $L_2Fe(CO)_3$ systems. The plotted $-\Delta E_{Tot}$ values are based on E_{vdw_2}. Diamonds and hollow circles represent phosphines and arsines, respectively. The ligand numbering scheme is reported in column 1 of Table 1.



3. Results and discussion

The PEt_3 system

The first problem we have considered is the ability of the QM/MM methodology to describe properly the geometries and relative energies of different conformations for the same phosphine. We take PEt_3 as an example. We performed complete optimizations by treating PEt_3 with a pure QM method as well as the combined QM/MM approach. In the latter case the QM part of PEt_3 is represented by PH_3 whereas the ethyl groups constitute the MM component. In the QM/MM optimizations, both of the expressions for the nonbonded energy term e_{vdw_i} (i = 1, 2) of eq. [8] have been explored. The four geometries considered are reported in Fig. 1. They differ essentially in the relative orientation of the ethyl groups. Structure **1** of C_3 symmetry is the most stable independently of the computational method. Two other considered structures, **2** and **3** of C_1 and C_s symmetry, respectively, are of similar energy. According to the pure QM calculations they are 0.87 and 0.82 kcal/mol higher in energy compared to structure **1**. With the combined approach, these energy values are 1.51 and 1.52 kcal/mol, respectively, for e_{vdw_1} compared to 1.85 and 1.97 kcal/mol, respectively, in the case of e_{vdw_2}. Finally, structure **4**, was found to be 1.60 kcal/mol higher in energy than **1** according to the pure QM method, compared to 2.03 and 2.30 kcal/mol for the combined QM/MM scheme with e_{vdw_1} and e_{vdw_2}, respectively. Although the agreement is less than perfect, the relative order of stability calculated by the QM scheme is seen to be well reproduced by the QM/MM approach. We note that the steric differentiation between the conformations, as expected, is largest in the case of the purely repulsive nonbonded energy expression e_{vdw_2}.

Turning to a comparison of the optimized geometries, the main differences between QM and QM/MM structural parameters are in the C-P-C angles, which are underestimated by QM/MM. Apparently, the H–P–H force constant from the QM treatment in the QM/MM approach is too stiff to represent the electronic part of the C–P–C force constant in the PR_3 ligand and open up the C-P-C angle sufficiently. As a result, steric interaction between the different R substituents

[a]Energies calculated during geometry optimizations with the modified purely repulsive nonbonded functional.
[b]E = P or As.
[c]The QM region is fixed with the geometry taken from the optimized structure using the purely repulsive van der Waals potential E_{vdw_2} of eq. [8*f*]. The MM region of the complex is reoptimized using the attr–rep 6-12 Lennard–Jones potential E_{vdw_1} of eq. [8*e*].

are overestimated, and the sterically determined energy differences between conformations **1**–**4** exaggerated by QM/MM compared to QM.

$L_2Fe(CO)_3$ systems

Figure 2 plots the reaction enthalpies, $-\Delta E_{Tot}$ of eq. [10], for the ligand substitution reaction [9*b*] as a function of the Tolman cone angle Θ. Increasingly negative values for $-\Delta E_{Tot}$ indicate that the substitution of ER_3 by the small PH_3 ligand becomes more and more favorable. All energy calculations were based on e_{vdw_2} of eq. [8*f*].

It is quite clear from Fig. 2 that a steric threshold angle Θ_0 is present beyond which the steric bulk of ER_3 suddenly destabilizes the M—ER_3 bond compared to the M—PH_3 linkage. This threshold angle is not yet reached for PMe_3 and PEt_3 with numerically small substitution enthalpies and cone angles equal to 118 and 132°, respectively. The presence of a steric threshold angle, and the calculated value for this angle, are in excellent agreement with the QALE treatment (quantitative analysis of ligand effects) (2, 32) performed by Stevens and Nolan (3). According to his analysis, a steric threshold of 135° is present for the $L_2Fe(CO)_3$ systems.

For bulkier ligands than PMe_3 and PEt_3 a destabilization of the M—ER_3 bond compared to PH_3 is evident. A linear fit ($y = -ax + b$) of $-\Delta E_{Tot}$ as a function of the cone angle gives a value of $a = 0.28 \pm 0.04$ kcal mol^{-1} deg^{-1}. This value is in reasonable agreement with the estimate of 0.46 kcal mol^{-1} deg^{-1} proposed by Stevens and Nolan (3) on the basis of a QALE treatment. In the linear fit, the PBz_3 phosphine was not included. As already remarked by Giering and coworkers (2) and Stevens and Nolan (3), this phosphine ligand usually proves to be a problem in such analyses (33) and is often not included.

The electronic, $-\Delta E_{QM}$, and steric, $-\Delta E_{MM}$, contributions to the total reaction enthalpy, $-\Delta E_{Tot}$, are reported in Table 1 for both e_{vdw_1} of eq. [8*e*] and e_{vdw_2} of eq. [8*f*]. We shall in the following discussions of $L_2Fe(CO)_3$, $RuCpL_2Cl$, and $RuCp^*L_2Cl$ concentrate on the results based on e_{vdw_2} and defer comments on the use of e_{vdw_1} to the end of the discussion section.

In the decomposition of $-\Delta E_{Tot}$ a negative value for $-\Delta E_{MM}$ indicates that the M—ER_3 bond has been destabilized by steric factors. Positive values in the electronic QM contribution, $-\Delta E_{QM}$, come from the fact that the H-P-H angle in the PH_3 ligand is distorted on coordination from 92 to 98°. The other phosphines already have angles close to 98° in the free state and are not distorted much further in the complex. Thus, a positive value for the QM contribution, $-\Delta E_{QM}$, stems from the fact that it takes more energy to prepare (distort) PH_3 to become as a ligand than any of the other ER_3 species.

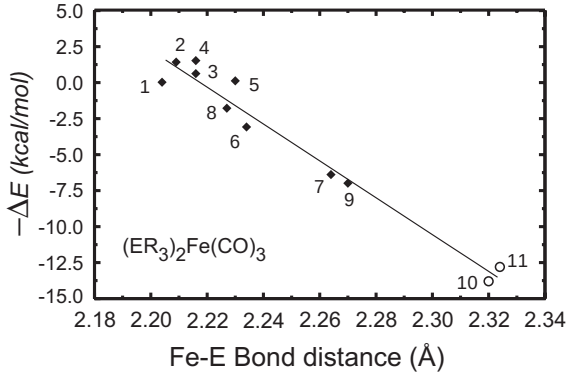
Figure 3 plots the calculated enthalpies of reaction versus the Fe—P bond distance. A linear bond strength – bond length relationship is clearly present. For the systems with phosphines having cone angles smaller than 135°, the Fe—P bond distances are practically the same. On the other hand, for the more weakly bound and more encumbered phosphines the Fe—P bond distance increases from 2.20 up to 2.27 Å, in going from the PH_3 to the PCy_3 complex. For the correlation in Fig. 3 PBz_3 is in line with the other phosphines.

We have taken a detailed look at the deformations of the PBz_3 ligand after coordination in order to rationalize the special behavior of PBz_3 in the QALE treatment. The most noticeable change is a rotation around the C_{sp^3}—C_{s^2} bond from 107° in free PBz_3 to 92° in coordinated PBz_3. The rotation increases the contact distance between phenyl carbons and the carbon on CO from 3.1 to 3.4 Å. The deformation amounts to only 0.3 kcal/mol in the free ligand and greatly reduces the steric interaction in the complex along with the cone angle of PBz_3. It is clear that for phosphines with a flexible structure, the cone angle calculated for the uncoordinated phosphine is probably only a rough approximation to the "real" value assumed in encumbered complexes. In such cases, as suggested by several authors, use should be made of cone angles obtained from X-ray structures of the coordinates phosphine.

Figure 4 reports the optimized structure for the $Fe(PCyPh_2)_2(CO)_3$ complex with experimental values in parentheses. The overall agreement between the calculated and the experimentally observed structures is reasonably good.

© 1998 NRC Canada

Fig. 3. Enthalpy of ligand substitution vs. the average Fe—E (E = P, As) bond distance for the $L_2Fe(CO)_3$ systems. The plotted $-\Delta E_{Tot}$ values are based on E_{vdw_2}. Diamonds and hollow circles represent phosphines and arsines, respectively. The ligand numbering scheme is reported in column 1 of Table 1.



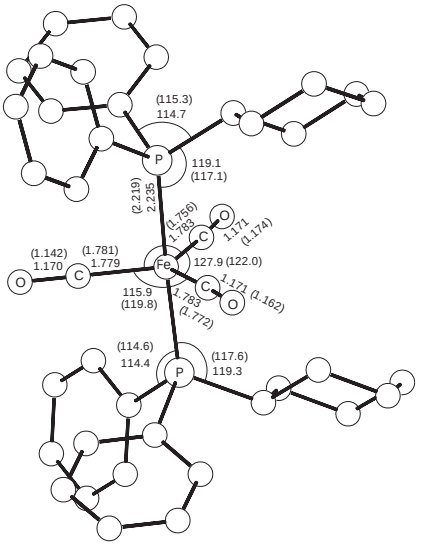
The calculated P-Fe-P angle is 178°, while the C-Fe-C angle that encloses the Cy substituents is forced by the presence of the bulky Cy rings to 128°. In the experimentally determined structure, these angles assume values of 178 and 122°, respectively.

Compared to the corresponding phosphines, the arsine ligands $AsEt_3$ and $AsPh_3$ are calculated to form bonds to iron that are weaker by 14.4 and 12.9 kcal/mol, respectively. The corresponding experimental values are 17.9 and 16.7 kcal/mol, respectively (3). For the two arsines considered, steric effects are almost insignificant. This can be explained by the larger covalent radius of the arsenic atom compared to phosporous, which keeps the R substituents further apart. This observation is reflected in the MM energy contribution due to the interaction of the arsines with the other ligands. On a per arsine basis, the MM interaction energies of the arsine with the other ligands are 0.4 and 0.7 kcal/mol in the $AsEt_3$ and $AsPh_3$ containing complexes whereas in the corresponding phosphine complexes these MM energies are 0.8 and 1.4 kcal/mol, respectively. Finally, the Fe—As bond distances in the two considered arsines are practically the same (0.004 Å longer in the $AsPh_3$ complex) whereas the Fe—P distance in the PPh_3 complex is 0.014 Å larger than in the PEt_3 system.

$RuCpL_2Cl$ systems

Table 2 displays the calculated substitution enthalpies $-\Delta E_{Tot}$ for eq. [5] decomposed into its steric, $-\Delta E_{MM}$, and electronic, $-\Delta E_{QM}$, components. The steric contribution is obtained using the purely repulsive van der Waals potential of eq. [8*f*]. Negative values indicate a destabilization compared to the PH_3 ligand. Figure 5 plots the enthalpies of ligand substitution as a function of the Tolman cone angle for the $RuCpL_2Cl$ systems. These systems have the phosphine ligands close together compared to $L_2Fe(CO)_3$, and a steric destabilization of 1.4 kcal/mol is present even for PMe_3, which is the substituted phosphine with the smallest cone angle. A linear fit of the type $y = -ax + b$ for $-\Delta E_{Tot}$ with respect to the cone angle affords a value of $a = 0.23 \pm 0.09$ in the case of the phosphine systems. This value should be compared to the corresponding estimate of $a = 0.50 \pm 0.13$ from the experimental data of Nolan and co-workers

Fig. 4. Optimized QM/MM geometry of the $Fe(PCyPh_2)_2(CO)_3$ complex based on E_{vdw_2}. Parenthetic values refer to the same geometric parameters found in the crystalline structure.



(4). Our theoretical QM/MM model takes only steric factors into account and neglects the decline in σ-donicity with the cone angles described by Nolan and co-workers (4) in their QALE analysis. That is, $-\Delta E_{MM}$ might have the right trend whereas the variation in $-\Delta E_{QM}$ is too small, since PH_3 is used to describe the electronic part for all phosphines. Thus, it is understandable that the *a* factor is underestimated by the current QM/MM approach, since a positive electronic contribution from $-\Delta E_{QM}$ is missing.

The QM/MM study of the phosphites was carried out with $P(OH)_3$ representing the QM region. We find that the coordination of $P(OCH_2)_3CEt$ and $P(OPh)_3$ are, respectively, 6.9 and 10.1 kcal/mol less favorable than the coordination of $P(OMe)_3$. These values are in a reasonable agreement with the experimental estimates of 5.9 and 7.7 kcal/mol, respectively. For $P(OPh)_3$ the weaker coordination is due to the steric bulk, $-\Delta E_{MM}$, whereas the poor coordination of $P(OCH_2)_3CEt$ with a small cone angle is electronic, $-\Delta E_{QM}$, in nature. Our analysis of the bonding orbitals suggests this is caused by the almost *trans* conformation assumed by the Ru-P-O-H torsional angles, which stabilize the σ-donor orbital and affords a poor σ-donicity of the $P(OCH_2)_3CEt$ ligand. The σ-donor orbital stabilization in the caged phosphite is due to a decrease of antibonding interactions between the O and P lone pair orbitals. It is interesting that this electronic effect, $-\Delta E_{QM}$, is represented well by the QM model ligand $P(OH)_3$ as it is forced to a *trans* conformation of the Ru-P-O-H torsional angle by the $(CH_2)_3CEt$ MM framework. A comparison between phosphites and phosphines, in particular $P(OMe)_3$ vs. PMe_3, indicates that the phosphite coordinates better by 19.7 kcal/mol. This value compares poorly with the experimental estimate of 3.4 kcal/mol. A better agreement would require PH_3 to be modeled by PMe_3 as the QM ligand. For the single arsine treated here, $AsEt_3$, the coordination is weaker by 11.3 kcal/mol compared to PEt_3. The corresponding experimental value is 15.1 kcal/mol (4).

Fig. 5. Enthalpy of ligand substitution vs. Tolman cone angle for the $RuCpL_2Cl$ systems. The plotted $-\Delta E_{Tot}$ values are based on E_{vdw_2}. Diamonds, hollow circles, and stars represent phosphines, arsines, and phosphites, respectively. The ligands numbering scheme is reported in column 1 of Table 2.

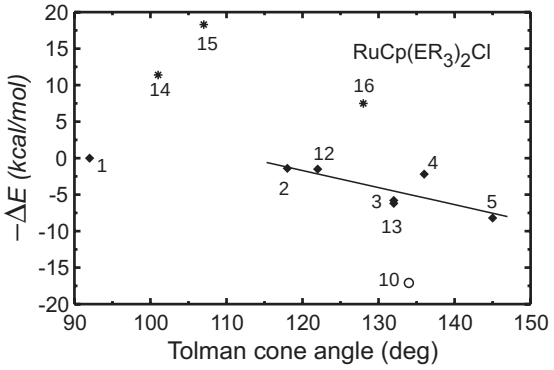

Fig. 6. Enthalpy of ligand substitution vs. the average Ru—E (E = P, As) bond distance for the $RuCpL_2Cl$ systems. The plotted $-\Delta E_{Tot}$ values are based on E_{vdw_2}. Diamonds, hollow circles, and stars represent phosphines, arsines, and phosphites, respectively. The ligands numbering scheme is reported in column 1 of Table 2.

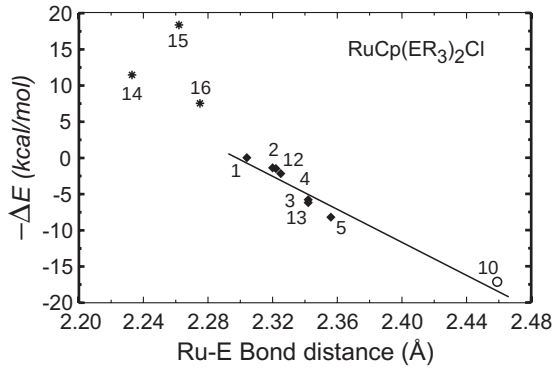

Figure 6 plots the calculated enthalpies of reaction versus the Ru—P bond distance. A linear fit, with all phosphines included, provides a slope of –112 vs. –140 kcal mol^{-1} $Å^{-1}$ determined by Nolan. Also given in the plot are the phosphites at shorter Ru—E distances and the arsine at longer Ru—E distance. As one would expect, it is not possible to extend the linear plot of the phosphines to include other types of ligands.

Figure 7 reports the optimized structure of the $RuCp(PEt_3)_2Cl$ complex. The corresponding experimental data are reported in parentheses. The overall agreement between the calculated and the experimentally observed structure is reasonably good. In particular, the steric requirements of the system open the P-Ru-P and P-Ru-Cl angles from 91° and 82° calculated for the $RuCp(PH_3)_2Cl$ complex to 96° and 88° calculated for the $RuCp(PEt_3)_2Cl$ complex. These values are to be compared with the experimental estimates of 95° and 90° obtained by Nolan in the $RuCp(PEt_3)_2Cl$ complex.

$RuCp^*L_2Cl$ systems

Figure 8 plots the enthalpies of ligand substitution as a function of the Tolman cone angle for the $RuCp^*L_2Cl$ systems based on e_{vdw_2} of eq. [8*f*]. For these species, steric effects are even more important than in the corresponding $RuCpL_2Cl$ compounds due to the bulk of Cp*. The PMe_3 complex is already destabilized by 3.6 kcal/mol with respect to the naked PH_3 complex. A linear fit, $y = -ax + b$, of $-\Delta E_{Tot}$ against the cone angle of the phosphines affords a value of $a = 0.58 \pm 0.24$. This value has to be compared with the estimate of 0.47 obtained by using the data due to Nolan and co-workers (5). Our results, as already suggested by Nolan and co-workers (5), indicate that the behavior of the permethylated ruthenium complexes is essentially determined by steric effects. The various steric, $-\Delta E_{MM}$, and electronic, $-\Delta E_{QM}$, contributions to $-\Delta E_{Tot}$ are reported in Table 3. Enthalpy data for the substitution of L by PMe_3 in $L_2Fe(CO)_3$, $RuCpL_2Cl$, and $RuCp^*L_2Cl$ are found in Table 4.

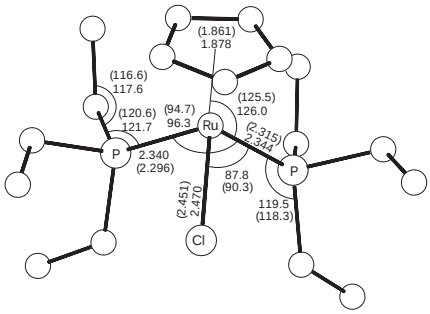
[a] Energies calculated during geometry optimizations with the modified purely repulsive nonbonded functional.
[b] E = P or As.
[c] The QM region is fixed with the geometry taken from the optimized structure using the purely repulsive van der Waals potential E_{vdw_2} of eq. [8*f*]. The MM region of the complex is reoptimized using the attr–rep 6-12 Lennard–Jones potential E_{vdw_1} of eq. [8*e*].

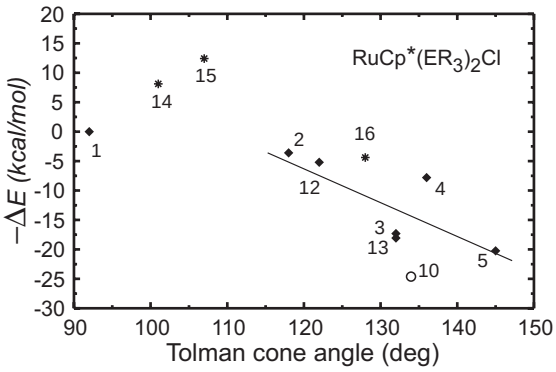
Fig. 7. Optimized QM/MM geometry of the $RuCp(PEt_3)_2Cl$ complex based on E_{vdw_2}. Experimental data in parentheses.



For the remaining ligand types, the phosphites are seen to bind stronger to ruthenium than the phosphines whereas $AsEt_3$ binds more weakly. Also, $P(OMe)_3$ coordinates stronger than either $P(OCH_2)_3CEt$ or $P(OPh)_3$, Fig. 3. These trends are in good agreement with experiment and were already noted (and rationalized) in the connected discussion of the $RuCpL_2Cl$ systems. Figure 9 plots the calculated enthalpies of reaction versus the Ru—E bond distances. For the phosphines we obtain a good linear bond strength – bond length relationship with a slope of –124.

Figure 10 reports the optimized structure of the $RuCp^*(P(OCH_2)_3CEt)_2Cl$ complex, with experimental numbers in parentheses. The overall agreement between the calculated and the experimentally observed structure is reasonably good. A comparison between the calculated geometries for the $RuCp^*(P(OCH_2)_3CEt)_2Cl$ and $RuCp^*(P(OMe)_3)_2Cl$ compounds indicates that for the complex with the caged phosphite the P—Ru bond distance is slightly shorter (2.238 vs. 2.274 Å). A similar trend was observed for the systems with the unsubstituted Cp ligand. Finally, in the complexes based on the caged phosphite the O-P-O angle is on average 3.5° larger than in the complexes based on the trimethyl phosphite. This value can be compared with the value of 3° found by Nolan and co-workers (6).

Fig. 8. Enthalpy of ligand substitution vs. Tolman cone angle for the $RuCp^*L_2Cl$ systems. The plotted $-\Delta E_{Tot}$ values are based on E_{vdw_2}. Diamonds, hollow circles, and stars represent phosphines, arsines, and phosphites, respectively. The ligands numbering scheme is reported in column 1 of Table 3.



A comparison between $RuCpL_2Cl$ and $RuCp^*L_2Cl$ systems

To compare the role played by steric effects in the $RuCpL_2Cl$ and $RuCp^*L_2Cl$ systems, we calculated the enthalpies of the following reaction:

[11] $Cp^*Ru(COD)_2Cl + CpRu(ER_3)_2Cl \leftrightarrow Cp^*Ru(ER_3)_2Cl + CpRu(COD)_2Cl$

The mean value we obtained for the above reaction is 2.7 kcal/mol, which is in a reasonable agreement with the experimental value of 5.1 kcal/mol obtained from the experimental data due to Nolan and co-workers. In agreement with the experimental results, the largest values are calculated for the complexes based on PEt_3 and P^nBu_3. The theoretical values for these two ligands are 6.7 and 7.1 kcal/mol whereas the corresponding experimental estimates are 7.3 and 9.4 kcal/mol, respectively. Our results are in agreement with the hypothesis suggested by Nolan and co-workers (6) that steric effects only partially contribute to the different behavior of the Cp and Cp* systems. The comparison between the

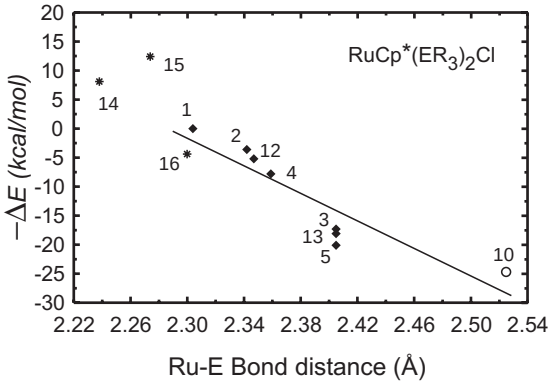
Fig. 9. Enthalpy of ligand substitution vs. the average Ru—E (E = P, As) bond distance for the $RuCp^*L_2Cl$ systems. The plotted $-\Delta E_{Tot}$ values are based on E_{vdw_2}. Diamonds, hollow circles, and stars represent phosphines, arsines, and phosphites, respectively. The ligands numbering scheme is reported in column 1 of Table 3.



calculated and experimental geometries also supports the buildup of steric pressure in the permethylated systems. In fact, the calculated Ru–P and Ru–Cp (centroid) distances are ca. 0.063 and 0.015 Å longer in the Cp* complexes based on the PEt_3 and P^nBu_3 phosphines, with respect to the analogous complexes based on the unsubstituted Cp ring. These bond stretches have to be compared with elongations of 0.033 and 0.015 Å observed for the same distances when comparing the X-ray structures of the $CpRu(PEt_3)_2Cl$ (4) and $Cp^*Ru(P^nBu_3)_2Cl$[2] complexes. Finally, in the Cp* complexes the calculated P-Ru-Cl angles is on average 3.6° smaller than in the corresponding Cp complexes. This value can be compared with the experimentally observed reduction of 2.6° of the P-Ru-Cl angle in going from the $CpRu(PEt_3)_2Cl$ (4) to the $Cp^*Ru(PBu_3)_2Cl$ (32) complex.

Using the standard attractive–repulsive Lennard–Jones potential

We have up to now discussed reaction enthalpies, $-\Delta E_{Tot}$, for eq. [9*b*] based on the totally repulsive nonbonding energy term E_{vdw_2} of eq. [8*f*]. Tables 1–3 also contain reaction enthalpies based on the regular attractive–repulsive Lennard–Jones potential E_{vdw_1} of eq. [8*e*]. Figure 11 plots the values of the enthalpies of ligand substitution for all the considered systems obtained using the standard attr–rep Lennard–Jones potential as a function of the cone angle. The scattered patterns obtained would prevent any linear correlation. Moreover, the plot of $-\Delta E_{Tot}$ as a function for the cone angle is qualitatively incorrect for systems such as $L_2Fe(CO)_3$ with a great number of atoms and a modest steric pressure. That is, the more stable complexes correspond to systems based on phosphines with large cone angles. This behavior is due to the long-range attractive tails of the standard 6-12 Lennard–Jones potential (7, 27, 28). For the class of reactions here considered, that is, ligands substitution reactions, the attrac-

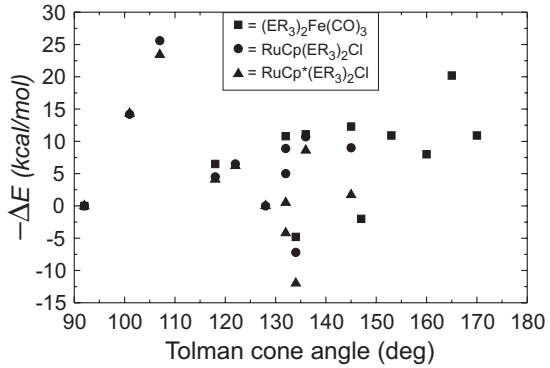
Fig. 11. Enthalpy of ligand substitution vs. Tolman cone angle for the $L_2Fe(CO)_3$, $RuCpL_2Cl$, and $RuCp^*L_2Cl$ systems. The plotted $-\Delta E_{Tot}$ values are based on E_{vdw_1}. Squares, circles, and triangles represent $L_2Fe(CO)_3$, $RuCpL_2Cl$, and $RuCp^*L_2Cl$ systems, respectively.



tive tails give a stabilizing contribution to the total energy that is proportional to the total number of atoms present in the molecule. However, this is a spurious effect due to the fact that our models simulate gas-phase reactions. In fact, in the presence of a solvent, these stabilizing long-range Lennard–Jones interactions occur as well with solvent molecules.

4. Concluding remarks

The combined QM/MM method has considerable potential in allowing for efficient computational modeling steric effects in coordination chemistry. However, to date, there have been only a few applications of the method to coordination compounds (13, 14). In the present investigation, we attempt to validate the approach, which so far has been lacking, by comparing theoretical results obtained by the QM/MM method with the rich source of experimental data generated by Nolan and co-workers (3–6) in their experimental studies of the substitution reactions [1]–[3].

The present QM/MM scheme is able to reproduce the gross features of the QALE analysis on the substitution reactions [1]–[3] provided by Nolan and co-workers (3–6). It can in addition provide geometrical parameters for some of the complexes involved in reactions [1]–[3] that are in good agreement with experimental structures.

Our investigation also points to a number of problems with the present QM/MM approach. First, the regular attractive–repulsive Lennard–Jones potential, E_{vdw_1} of eq. [8*e*], is inadequate for coordination compounds and provides relationships between substitution enthalpies and cone angles that are contrary to the experimental QALE analysis (3). The additive nature of the MM van der Waals potentials, leads to the large bulky ligands being bound more strongly than the smaller ligands, simply due to the sheer number of atoms associated with the larger ligands. To rectify this problem we have utilized a purely repulsive potential, E_{vdw_2} of eq. [8*f*], in accordance with previous works (7, 28). Although the purely repulsive van der Waals potential provides reasonable results, further work is required in order to generate an adequate nonbonded interaction potential.

The use of the minimal quantum mechanical units PH_3 and AsH_3 to describe the electronic properties of all phosphines and arsines, respectively, has proven to be inadequate. For phosphites, the use of $P(OH)_3$ as the quantum mechanical unit is capable of representing a broad range of phosphites. This is because the dominant electronic effect in phosphites is due to the oxygen atoms. It is evident that even for substitution reactions in which sterics are thought to dominate the substitution energies, the electronic characteristics of the ligands, which are not captured by the QM/MM method, play a substantial role. Large absolute deviations are present for some of these reactions. Thus, future work will concentrate on larger and more realistic quantum mechanical units for the various categories of ER_3 units that more effectively capture the electronic effects.

Oxidation of 2-methylpyrroles with perchlorinated iron(III) metalloporphyrin catalysts: a versatile synthesis of symmetric and asymmetric dipyrromethanes

Veranja Karunaratne and David Dolphin

Abstract: A variety of substituted 2-methylpyrroles (**3**–**8**) were oxidized using the metalloporphyrin catalysts iron(III) *meso*-tetra(2,6-dichloro-3-sulphonatophenyl)-β-octachloroporphyrin chloride **1** and iron(III) *meso*-tetra(2,6-dichlorophenyl)-β-octachloroporphyrin chloride **2** under very mild conditions. Treatment of the resulting allylic alcohols **3a**–**8a** with α-free pyrroles **9** and **10** resulted in a very efficient synthesis of the corresponding dipyrromethanes **3b**–**8b** and **3c**–**8c**. Furthermore, the above allylic alcohols when treated with furfurylamine produced the novel (2-furylmethyl)-2-pyrrolylmethylamines **3d**–**8d**.

Key words: catalytic oxidation, metalloporphyrins, pyrroles, dipyrromethanes, polyhalogenated porphyrins.

Résumé : Opérant dans des conditions très douces, on a oxydé divers 2-méthylpyrroles substitués (**3**–**8**) à l'aide de catalyseurs métalloporphyrines, le chlorure de la *méso*-tétra(2,6-dichloro-3-sulfonatophényl)-β-octachloroporphyrine fer(III), **1** et le chlorure de la *méso*-tétra(2,6-dichlorophényl)-β-octachloroporphyrine fer(III), **2**. Le traitement des alcools allyliques obtenus (**3a**–**8a**) avec les pyrroles **9** et **10** dont les positions α sont libres permet de réaliser une synthèse très efficace des dipyrrométhanes correspondants, **3b**–**8b** et **3c**–**8c**. De plus, la réaction de ces alcools allyliques avec de la furfurylamine conduit à de nouvelles (2-furfurylméthyl)-2-pyrrolylméthylamines **3d**–**8d**.

Mots clés : oxydation catalytique, métalloporphyrines, pyrroles, dipyrrométhanes, porphyrines polyhalogénées.

[Traduit par la Rédaction]

Some of the most interesting and widely studied heme proteins are cytochromes P-450 (1). Activation of dioxygen by such monooxygenase enzymes involves insertion of one of the atoms of O_2 into the organic substrate while the other is reduced to water in the presence of an electron donor. Studies to unravel the cytochrome P-450 monooxygenase activity are complicated by the protein. Since much of the oxidation chemistry occurs at the iron porphyrin, in vitro biomimetic studies have been focused on synthetic metalloporphyrins. As such, *meso*-tetraphenylporphyrins (2), which are readily synthesized, are commonly used as mimics of the natural systems.

In 1979, Groves et al. (3) first reported the cytochrome P-450 monooxygenase-like activity in a model system using iron(III) *meso*-tetraphenylporphyrin and iodosylbenzene (PhIO) as a co-oxidant. Several other metalloporphyrins were also shown to catalyze both alkene epoxidations (4) and hydroxylation of unactivated hydrocarbons (1, 5) mimicking the natural system. However, the utility of these catalysts in organic synthesis has been limited. While the first-generation

8	R = Et	R_1 = Me	R_2 = ME

catalysts qualitatively exhibited cytochrome P-450 reactions, their catalytic activity was rapidly lost by destruction of the metalloporphyrin. Firstly, these catalysts were improved by introduction of halogens at the *ortho*-positions of the phenyl groups (6). Halogenation imparts steric protection and electronic activation of the metalloporphyrin. Secondly, further halogenation of the β-positions has given the full benefit of such a dual effect, producing more robust catalysts with additional resistance to oxidative catalyst destruction (7). For example, Mansuy and Battioni (8) have shown that when iron(III) *meso*-tetra(2,6-dichlorophenyl)-β-octachloroporphyrin chloride (**2**) ($ClFeTPPCl_8\beta Cl_8$) and the corresponding β-octabromo substituted porphyrin catalyst, iron(III) *meso*-tetra(2,6-dichlorophenyl)-β-octabromoporphyrin chloride (**2a**) ($ClFeTPPBr_8\beta Br_8$), were used in the hydroxylation of heptane the total yield of heptanols produced was increased. Furthermore, the polyhalometalloporphyrin catalysts showed greater chemoselectivity for alkane hydroxylation over alkene epoxidation. Such perhalogenated metalloporphyrins can be rendered water soluble by sulphonation of the *meta*-positions of the phenyl ring (9). All of the available evidence from model studies suggest the $O{=}Fe^{IV}Por^{+\cdot}$ (porphyrin π-cation radical) (9) formulation for the oxidizing intermediate, although the exact nature of this high-valent oxo-metal complex will depend on both the metalloporphyrin and the co-oxidant.

In continuation of our efforts in the area of polyhaloporphyrin catalysts (10), we report herein a straightforward and efficient oxidation of substituted 2-methylpyrroles (for a preliminary account of the work described see ref. 11) using both iron(III) *meso*-tetra(2,6-dichloro-3-sulphonatophenyl)-β-octachloroporphyrin chloride (**1**) ($ClFeTPPCl_8S_4\beta Cl_8$) and iron(III) *meso*-tetra(2,6-dichlorophenyl)-β-octachloroporphyrin chloride (**2**) ($ClFeTPPCl_8\beta Cl_8$).

Specifically, when a cold (0°C) solution of 2-methylpyrrole (**3**, 0.2 mmol) in 3 mL of $HCl–CH_3CN$ (1:1 v/v) containing a catalytic amount of the catalyst **1** (0.0009 mmol) in the presence of PhIO (1 equiv.) was allowed to react for 10 min, the crude allylic alcohol **3a** was obtained (Scheme 1). The ^1H NMR spectrum of crude **3a** was clean with no trace of starting material and showed a singlet (2H) at δ 4.58 corresponding to the allylic methylene group. The ^1H NMR and the high resolution mass spectra of **3a** were in full accord with the assigned structure. Purification of this compound was not attempted due to its known instability. Furthermore, its IR spectrum exhibited an absorption at 3300 cm^{-1} due to the allylic alcohol moiety while the low-resolution mass spectrum gave a peak at m/z 225 ($M^+ - H_2O$). Importantly, compound **3a** underwent coupling to the α-free pyrrole, 2-benzyloxycarbonyl-3,4-dimethylpyrrole (**9**) under very mild

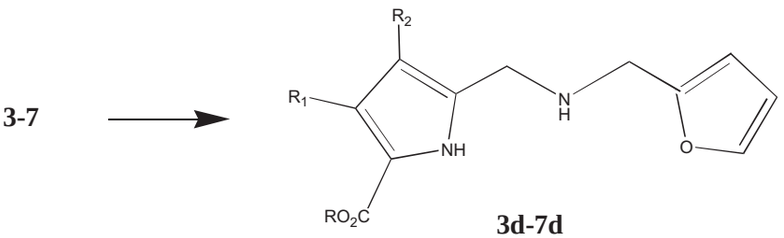
Scheme 2.



3d-7d

conditions (CH_2Cl_2, rt) to provide the dipyrromethane **3b** in 42% yield (from **3**). In a similar fashion pyrroles **4**–**8** were oxidized and coupled as before to provide the dipyrromethanes **4b**–**8b**. In a control experiment, a solution (HCl–CH_3CN, 1:1 v/v) of pyrrole **3** was treated with PhIO in the absence of the catalyst **1**, and the resulting crude mixture was treated with 2-benzyloxycarbonyl-3,4-dimethylpyrrole. The yield of the dipyrromethane **3b** isolated varied between 5–15%. Upon further investigation of the effect of PhIO alone on several other 2-methylpyrroles, it became evident that the yields of the dipyrromethanes produced were without exception substantially lower than in the presence of the catalyst. Interestingly, the HCl–CH_3CN combination was found to be crucial for the effective oxidation of the substrates. For example, the oxidation in the H_2O–CH_3CN medium was very sluggish, clearly indicating the necessity of an acidic medium for the success of the reaction.

Next, we turned our attention to the utilization of catalyst **2** in the same oxidation reaction. More explicitly, when a TFA–CH_2Cl_2 (1:9) solution of pyrrole **3** (0.194 mmol) was treated with the catalyst **2** (0.0015 mmol) and PhIO (1 equiv.), oxidation of the 2-methyl group occurred within 5 min. As was the case with the catalyst **1**, an acidic medium was also found to be necessary for clean and effective oxidation with the catalyst **2**. Neither *p*-toluenesulphonic acid nor acetic acid were suitable for this purpose, presumably due to the acids themselves undergoing oxidation along with the substrates. However, trifluoroacetic acid proved to be an excellent reagent. Thus, addition of 2-benzyloxycarbonyl-3,4-dimethylpyrrole (**9**) into the same reaction mixture resulted in an in situ coupling to provide (after neutralization of the mixture with $NaHCO_3$ followed by chromatography) the corresponding dipyrromethane **3b** in 62% yield. In a different run, when 2-ethoxycarbonyl-4-ethyl-3-methylpyrrole (**10**) was added to the reaction mixture obtained after the initial oxidation, the dipyrromethane **3c** was obtained in 60% yield. In a similar fashion, the dipyrromethanes **4c**–**8c** were prepared from pyrroles **4**–**8**. Thus, by using the appropriate monopyrrole unit it is possible to synthesize 1,9-dioxycarbonyldipyrromethanes with either symmetric (**8b**, **3c**, **6c**) or asymmetric (**3b**–**7b**, **4c**, **5c**, **7c**, **8c**) substitution patterns. To the best of our knowledge, this is the first report of a one-pot synthesis of dipyrromethanes starting from the corresponding monopyrrole units. Catalyst **1**, due its insolubility in organic solvents, is not suitable for use under these conditions. On the other hand, when the same one-pot procedure was attempted with catalyst **1** in aqueous acidic medium (HCl–CH_3CN), the reaction was less clean, and the yields of the dipyrromethanes obtained were substantially lower than with catalyst **2**.

In contrast to $Pb(OAc)_4$ which is the only other reliable oxidant of 2-methylpyrroles, the ease of oxidation with both catalysts **1** and **2** stands out as a clear advantage. Furthermore, the sequence of $Pb(OAc)_4$ oxidation(HOAc, Ac_2O, 80°C, 24h) followed by dipyrromethane formation (conc. HCl, reflux) employs considerably harsher conditions and longer reaction times and leads only to symmetric dipyrromethanes. To assess the coupling ability of 2-acetoxypyrroles with an α-free pyrrole under our reaction conditions, 2-acetoxymethyl-5-benzyloxycarbonyl-3-ethyl-4-methylpyrrole was treated overnight at room temperature with 2-benzyloxycarbonyl-3,5-dimethylpyrrole in CH_2Cl_2. The ^1H NMR spectrum of the crude reaction mixture indicated only 15% conversion to the dipyrromethane **4b**. On the other hand, direct generation of allylic alcohols by our method allows ready manipulation of pyrrole units with diverse substitution patterns and facile generation of synthetically and biosynthetically important dipyrromethane units.

As a further example of the applicability of our oxidation protocol, the reaction of allylic alcohols (**3a**–**7a**) with furfurylamine was examined. Thus, when a solution of compound **3a** in CH_2Cl_2 was allowed to react with an excess of furfurylamine, the novel (2-furylmethyl)-2-pyrrolylmethylamine (**3d**) was obtained in 36% yield (from **3**). Similarly, the furan derivatives **4d**–**7d** were prepared from their corresponding allylic alcohols (Scheme 2).

Aromatic macrocyclic molecules capable of absorbing in the far red or near infrared region are now finding applications in biomedical research, specifically as photosensitizers for use in photodynamic therapy (PDT) of hyperproliferative diseases such as cancer and psoriasis (12, 13). Substituted dipyrromethanes which are functionalized with 1,9-diester groups are precursors in the preparation of the corresponding 1,9-dicyanodipyrromethanes (14). These dicyano compounds have been successfully employed in the synthesis of porphocyanins, a new class of expanded porphyrins (15, 16). These compounds due to their long wavelength absorptions in the visible-near infrared region, and their ability to make singlet oxygen makes them potential candidates for PDT. Thus, the methodology described above provides access to a large library of symmetrical and unsymmetrical 1,9-diacyldipyrromethanes as key intermediates in the synthesis of porphocyanins and other polypyrrolic macrocyclic systems.

Experimental

Proton nuclear magnetic resonance (^1H NMR) spectra were obtained from samples dissolved in $CDCl_3$ on a Bruker AC-200 (200 MHz) or a Bruker WH-400 (400 MHz). Low- and high-resolution electron impact (EI) mass spectra were

recorded on a Kratos/AEI MS-902 spectrometer. Microanalyses was carried out using a Carlo Erba Elemental Analyzer 1106. Flash chromatography was performed on silica gel 60 (70–230 mesh supplied by E. Merck Co.). All chemical and solvents were reagent grade.

Oxidation of 2-methylpyrroles with PhIO/ClFeTPPCl$_8$S$_4$βCl$_8$ (1). General procedure A

To a cold (0°C) solution of the pyrrole in CH_3CN – 3 N HCl (1:1, v/v, 2.5 mL/mmol) was added the catalyst **1** (0.0009 mmol) in one portion. To the resulting light yellow–brown solution was added PhIO (1 equiv.) in one portion. After stirring the resulting mixture (all of the PhIO dissolves rapidly) at 0°C for 10 min, CH_2Cl_2 (10 mL/mmol) was added followed by water (5 mL/mmol). The layers were separated, and the organic layer was dried ($MgSO_4$) and evaporated to provide the corresponding allylic alcohol as a yellow oily substance which was used immediately in the next step.

Coupling of 2-benzyloxycarbonyl-3,4-dimethyl pyrrole with the allylic alcohols 3a–8a. General procedure B

To a solution of the allylic alcohol obtained in the above reaction in CH_2Cl_2 (2 mL/mmol) was added 2-benzyloxycarbonyl-3,4-dimethylpyrrole (**9**) or 2-ethoxycarbonyl-4-ethyl-3-methylpyrrole (**10**) (1.5 equiv.) The resulting mixture was stirred at rt for 3 h. The solvent was evaporated, and the resulting yellow oil was subjected to column chromatography on silica gel to afford the pure dipyrromethane.

Preparation of 2(furylmethyl)-2-pyrrolylmethylamines 3c–7c. General procedure C

To a solution of the crude allylic alcohol (obtained in the general procedure A) in CH_2Cl_2 (3 mL/mmol) was added furfurylamine (3 mmol) in one portion. The resultant solution was stirred at rt for 6 h. Evaporation of the solvent afforded the crude product as a yellow oil. Flash chromatography of the crude material on silica gel afforded the pure 2(furylmethyl)-2-pyrrolylmethylamines.

Oxidation of 2-methylpyrroles with PhIO/ClFeTPPCl$_8$βCl$_8$ (2). One-pot synthesis of dipyrromethanes. General procedure D

To a cold (0°C) solution of the pyrrole in CH_2Cl_2–TFA (9:1, v/v, 1.5 mL/mmol) containing the catalyst **2** (0.0009 mmol) was added PhIO (1 equiv.) in one portion. After ~5 min (when all the solids had dissolved) was added the appropriate α-free pyrrole (1.5 equiv.). The slightly reddish-orange solution obtained was stirred at 0°C for 1.5 h. Water (5 mL/mmol) was added and the layers were separated. The organic phase was washed with saturated $NaHCO_3$ until the aqueous phase was basic to litmus. The organic layer was separated, dried ($MgSO_4$), and evaporated to afford the crude dipyrromethane as a yellow oil. The crude material was separated by flash chromatography on silica gel to afford the pure dipyrromethane.

Allylic alcohol 3a

The pyrrole **3** (0.05 g, 0.193 mmol) was converted into the allylic alcohol **3a** according to the general procedure A, by treatment with PhIO (0.042 g, 0.193 mmol) and the catalyst **1** (0.0015 g, 0.0009 mmol). The crude material isolated exhibited ^{1}H NMR (200 MHz), δ: 1.10 (t, 3H, J = 7.5 Hz), 2.30 (s, 3H), 2.44 (q, 2H, J = 7.5 Hz), 4.58 (s, 2H), 5.30 (s, 2H), 7.20–7.41 (m, 5H), 9.00 (br s, 1H); LREIMS (m/z): 255 (M^+ – 18).

2-[(5-Benzyloxycarbonyl-3,4-dimethylpyrrole-2-yl)methyl]-5′-benzyloxycarbonyl-3′-ethyl-4′-methylpyrrole (3b)

The crude material obtained from the above reaction was treated with the pyrrole (general procedure B) to provide the crude dipyrromethane **3a**. This material was flash chromatographed on silica gel (1 g, CH_2Cl_2) to provide the pure compound (0.039 g, 42% from pyrrole **3**) as a pale white solid which exhibited ^{1}H NMR (400 MHz), δ: 1.04 (t, 3H, J = 8 Hz), 1.95 (s, 3H), 2.24 (s, 3H), 2.29 (s, 3H), 2.40 (q, 2H, J = 8 Hz), 3.80 (s, 2H), 5.25 (s, 4H), 7.23–7.45 (m, 10H), 8.95, 8.97 (pair of overlapping s, 1H each). Exact mass calcd. for $C_{30}H_{32}O_4N_2$: 484.2362; found: 484.2359.

Allylic alcohol 4a

This material was prepared according to the general procedure A, by treatment of the pyrrole **4** (0.05 g, 0.158 mmol) with PhIO (0.34 g, 0.158 mmol) and the catalyst **1** (0.0015 g, 0.0009 mmol). The crude substance **4a** obtained showed ^{1}H NMR (200 MHz), δ: 2.29 (s, 3H), 2.50 (t, 2H, J = 6 Hz), 2.78 (t, 2H, J = 6 Hz), 3.68 (s, 3H), 4.63 (s, 2H), 5.30 (s, 2H), 7.22–7.43 (m, 5H), 8.98 (br s, 1H); LRFABMS (m/z): 314 ($M^+ - H_2O + H$).

2-[(5-Benzyloxycarbonyl-3,4-dimethylpyrrole-2-yl)methyl]-5′-benzyloxycarbonyl-3′(carbomethoxyeth-2-yl)-4′-methylpyrrole 4b

The crude material obtained from the above reaction was treated with 2-benzyloxycarbonyl-3,4-dimethylpyrrole (**9**) (general procedure B) to provide the crude dipyrromethane **4b**. This material was flash chromatographed on silica gel (1 g, CH_2Cl_2/EtOAc, 95:5) to provide the pure compound (0.033 g, 38% from pyrrole **5**) as a white solid ; ^{1}H NMR (400 MHz), δ: 2.00 (s, 3H), 2.25 (s, 3H), 2.27 (s, 3H), 2.45 (t, 2H, J = 7.5 Hz), 2.72 (t, 2H, J = 7.5 Hz), 3.57 (s, 3H), 3.90 (s, 2H), 5.25 (s, 2H), 5.27 (s, 2H), 7.27–7.40 (m, 10H), 8.55 (s, 1H), 9.08 (s, 1H). Exact mass calcd. for $C_{32}H_{34}O_6N_2$: 542.2417; found: 542.2427.

Allylic alcohol 5a

This compound was obtained according to the procedure A, by treatment of the pyrrole **5** (0.05 g, 0.146 mmol) with PhIO (0.032 g, 0.146 mmol) and the catalyst **1** (0.0015 g, 0.0009 mmol). The crude material exhibited ^{1}H NMR (200 MHz), δ: 0.89 (br t, 3H, J = ~7 Hz), 1.40–1.50 (m, 10H), 2.30 (s, 3H), 2.40 (t, 2H, J = 8 Hz), 4.50 (s, 2H), 5.30 (s, 2H), 7.20–7.50 (m, 5H), 9.30 (br s, 1H); LREIMS (m/e): 339 (M^+ – 18).

2-[(5-Benzyloxycarbonyl-3,4-dimethylpyrrole-2-yl)methyl]-5′-benzyloxycarbonyl-3′-octyl-4′-methylpyrrole (5b)

The crude material obtained from the above reaction was treated with 2-benzyloxycarbonyl-3,4-dimethylpyrrole (**9**) (general procedure B) to provide the crude dipyrromethane

5b. This material was flash chromatographed on silica gel (1 g, CH_2Cl_2) to provide the pure compound (0.033 g, 40% from pyrrole **5**) as a white solid; ^{1}H NMR (400 MHz), δ: 0.87 (t, 3H, *J* = 8 Hz), 1.10–1.40 (m, 10H), 1.93 (s, 3H), 2.25 (s, 3H), 2.27 (s, 3H), 2.33 (t, 2H, *J* = 8 Hz), 3.30 (s, 2H), 5.25 (s, 4H), 7.25–7.40 (m, 10H), 8.25, 8.28 (pair of overlapping s, 1H each). Exact mass calcd. for $C_{36}H_{44}O_4N_2$: 568.3300; found: 568.3309.

Allylic alcohol 6a

The pyrrole **6** (0.05 g, 0.256 mmol) was treated with PhIO (0.056 g, 0.256 mmol) and the catalyst **1** (0.0015 g, 0.0009 mmol), according to the general procedure A, to yield the crude compound; ^{1}H NMR (200 MHz), δ: 1.00 (t, 3H, *J* = 8 Hz), 1.22 (t, 3H, *J* = 8 Hz), 2.00 (s, 3H), 2.40 (q, 2H, *J* = 8 Hz), 4.22 (q, 2H, *J* = 8 Hz), 4.45 (s, 2H), 8.80 (br s, 1H); LREIMS (*m*/*e*): 193 (M^+ – 18).

2-[(5-Benzyloxycarbonyl-3,4-dimethylpyrrole-2-yl)methyl]-5′-ethoxycarbonyl-3′-ethyl-4′-methylpyrrole (6b)

The crude material obtained from the above reaction was treated with 2-benzyloxycarbonyl-3,4-dimethylpyrrole (**9**) (general procedure B) to provide the crude dipyrromethane **6b**. This material was flash chromatographed on silica gel (1 g, CH_2Cl_2/EtOAc, 95:5) to provide the pure compound (0.035 g, 32% from pyrrole **6**) as a white solid; ^{1}H NMR (400 MHz), δ: 1.01 (t, 3H, *J* = 8 Hz), 1.29 (t, 3H, *J* = 8 Hz), 1.95 (s, 3H), 2.24 (s, 3H), 2.26 (s, 3H), 2.40 (q, 2H, *J* = 8 Hz), 3.32 (s, 2H), 4.22 (q, 2H, *J* = 8 Hz), 5.24 (s, 2H), 7.24–7.34 (m, 5H), 9.15, 9.17 (pair of overlapping s, 1H each). Exact mass calcd. for $C_{25}H_{30}O_4N_2$: 422.2205; found: 422.2206. Anal. calcd. for $C_{25}H_{30}O_4N_2$: C 71.11, H 7.15, N 6.63; found: C 71.15, H 7.19, N 6.59.

Allylic alcohol 7a

This material was prepared according to the general procedure A, by treatment of the pyrrole **7** (0.05 g, 0.239 mmol) with PhIO (0.052 g, 0.239 mmol) and the catalyst **1** (0.0015 g, 0.0009 mmol). The crude material obtained showed ^{1}H NMR (200 MHz), δ: 1.00–1.20 (two overlapped q, 6H, *J* = 8 Hz each), 1.32 (t, 3H, *J* = 8 Hz), 2.41 (q, 2H, *J* = 8 Hz), 2.68 (q, 2H, *J* = 8 Hz), 4.25 (q, 2H, *J* = 8 Hz), 4.60 (s, 2H), 9.00 (br s, 1H); LREIMS (*m*/*e*): 207 (M^+ – 18).

2-[(5-Benzyloxycarbonyl-3,4-dimethylpyrrole-2-yl)methyl]-5′-ethoxycarbonyl-3′,4′-diethylpyrrole (7b)

The crude material obtained from the above reaction was treated with 2-benzyloxycarbonyl-3,4-dimethylpyrrole (**9**) (general procedure B) to provide the crude dipyrromethane **7b**. This material was flash chromatographed on silica gel (1 g, CH_2Cl_2/EtOAc, 95:5) to provide the pure compound (0.036 g, 35% from pyrrole **7**) as a white solid; ^{1}H NMR (400 MHz), δ: 1.05 (t, 3H, *J* = 8 Hz), 1.14 (t, 3H, *J* = 8 Hz), 1.29 (t, 3H, *J* = 7.5 Hz), 1.95 (s, 3H), 2.25 (s, 3H), 2.41 (q, 2H, *J* = 8 Hz), 2.71 (q, 2H, *J* = 8 Hz), 3.34 (s, 2H), 4.25 (q, 2H, *J* = 7.5 Hz), 5.26 (s, 2H), 7.27–7.38 (m, 5H), 8.78 (br s, 2H). Exact mass calcd. for $C_{26}H_{32}O_4N_2$: 436.2362; found: 436.2371.

Allylic alcohol 8a

This substance was prepared according to the procedure A, by treatment of the pyrrole (0.05 g, 0.276 mmol) with PhIO (0.06 g, 0.276 mmol) and the catalyst **1** (0.0015 g, 0.0009 mmol). The crude material obtained exhibited ^{1}H NMR (200 MHz), δ: 1.25 (t, 3H, *J* = 8 Hz), 2.20 (s, 3H), 2.22 (s, 3H), 4.24 (q, 2H, *J* = 8 Hz), 4.40 (s, 2H), 8.83 (br s, 1H); LREIMS (*m*/*e*): 179 (M^+ – 18).

2-[(5-Benzyloxycarbonyl-3,4-dimethylpyrrole-2-yl)methyl]-5′-ethoxycarbonyl-3′,4′-dimethylpyrrole (8b)

The crude material obtained from the above reaction was treated with the pyrrole (general procedure B) to provide the crude dipyrromethane **8b**. This material was flash chromatographed on silica gel (1 g, CH_2Cl_2/EtOAc, 95:5) to provide the pure compound (0.029 g, 25% from pyrrole **8**) as a white solid; ^{1}H NMR (400 MHz) δ: 1.31 (t, 3H, *J* = 8 Hz), 1.92 (s, 3H), 1.94 (s, 3H), 2.22 (s, 3H), 2.25 (s, 3H), 3.32 (s, 2H), 4.25 (q, 2H, *J* = 8 Hz), 5.25 (s, 2H), 7.30–7.41 (m, 5H), 8.65 (br s, 2H). Exact mass calcd. for $C_{24}H_{28}O_4N_2$: 408.2449; found: 408.2049. Anal. calcd. for $C_{24}H_{28}O_4N_2$: C 70.60, H 6.91, N 6.86; found: C 70.66, H 6.95, N 6.84.

2-(Furylmethyl)-2(5-benzyloxycarbonyl-3-ethyl-4-methyl)pyrrolylmethylamine (3d)

The pyrrole **3** (0.05 g, 0.194 mmol) was transformed into compound **3d** by treatment with furfurylamine (0.05 g, 0.582 mmol) (general procedure C). The crude product was purified by flash chromatography on silica gel (1 g, CH_2Cl_2) and yielded the pure compound (0.025 g, 36% from pyrrole **3**) as a colorless oil; ^{1}H NMR (400 MHz) δ: 1.02 (t, 3H, *J* = 7.5 Hz), 2.29 (s, 3H), 2.36 (q, 2H, *J* = 7.5 Hz), 3.71 (s, 2H), 3.75 (s, 2H), 5.30 (s, 2H), 6.15 (d, 1H, *J* = ~2 Hz), 6.31 (d, 1H, *J* = ~2 Hz), 7.30–7.45 (m, 6H), 9.07 (br s, 1H). Exact mass calcd. for $C_{21}H_{24}O_3N_2$: 352.1786; found: 352.1795.

2-(Furylmethyl)-2[5-benzyloxycarbonyl-3(carbomethoxyeth-2-yl)]4-methyl)pyrroloylmethylamine (4d)

The pyrrole **4** (0.05 g, 0.158 mmol) was transformed into compound **4d** by treatment with furfurylamine (0.045 g, 0.474 mmol) (general procedure C). The crude product, purified by flash chromatography on silica gel (1 g, CH_2Cl_2), yielded the pure compound (0.21 g, 32% from pyrrole **4**) as a colorless oil; ^{1}H NMR (400 MHz), δ: 2.44 (s, 3H), 2.58 (t, 2H, *J* = 6.5 Hz), 2.85 (t, 2H, *J* = 6.5 Hz), 3.79 (s, 3H), 3.89 (s, 2H), 3.91 (s, 2H), 5.45 (s, 2H), 6.33 (d, 1H, *J* = ~2 Hz), 6.74 (d, 1H, *J* = ~2 Hz), 7.46–7.60 (m, 6H), 9.30 (br s, 1H). Exact mass calcd. for $C_{22}H_{26}O_5N_2$: 410.1841; found: 410.1839. Anal. calcd. for $C_{23}H_{26}O_5N_2$: C 67.34, H 6.38, N 6.82; found: C 67.38, H 6.41, N 6.79.

2-(Furylmethyl)-2-(5-benzyloxycarbonyl-4-methyl-3-octyl) pyrrolylmethylamine (5d)

The pyrrole **5** (0.05 g, 0.146 mmol) was transformed into compound **5d** by treatment with furfurylamine (0.042 g, 0.438 mmol) (general procedure C). The crude product, purified by flash chromatography on silica gel (1 g, CH_2Cl_2), yielded the pure compound (0.019 g, 30%) as a colorless oil; ^{1}H NMR (400 MHz), δ: 0.79 (t, 3H, *J* = 7 Hz), 1.10–1.32 (m, 12H), 2.19 (s, 3H), 2.25 (t, 2H, *J* = 7 Hz), 3.63 (s, 2H),

3.68 (s, 2H), 5.21 (s, 2H), 6.09 (d, 1H, J = ~2 Hz), 6.23 (d, 1H, J = ~2 Hz), 7.23–7.36 (m, 6H), 9.00 (br s, 1H). Exact mass calcd. for $C_{27}H_{36}O_3N_2$: 436.2725; found: 436.2717.

2-(Furylmethyl)-2-(5-ethoxycarbonyl-3-ethyl-4-methyl) pyrrolylmethylamine (6d)

The pyrrole **6** (0.05 g, 0.256 mmol) was transformed into compound **6d** by treatment with furfurylamine (0.074 g, 0.768 mmol) (general procedure C). The crude product purified by flash chromatography on silica gel (1 g, CH_2Cl_2) yielded the pure compound (0.021 g, 28%) as a colorless oil; ^{1}H NMR (400 MHz) δ: 1.03 (t, 3H, J = 7 Hz), 1.35 (t, 3H, J = 7.5 Hz), 2.28 (s, 3H), 2.37 (q, 2H, J = 7 Hz), 3.22 (s, 2H), 3.28 (s, 2H), 4.29 (q, 2H, J = 7.5 Hz), 6.18 (d, 1H, J = ~2 Hz), 6.34 (d, 1H, J = ~2, Hz), 7.39 (d, 1H, J = 1 Hz), 8.96 (br s, 1H). Exact mass calcd. for $C_{16}H_{22}O_3N_2$: 290.1630; found: 290.1659.

2-(Furylmethyl)-2-(5-ethoxycarbonyl-3,4-diethyl) pyrrolylmethylamine (7d)

The pyrrole **7** (0.05 g, 0.239 mmol) was transformed into compound **7d** by treatment with furfurylamine (0.069 g, 0.717 mmol) (general procedure C). The crude product was purified by flash chromatography on silica gel (1 g, CH_2Cl_2) and yielded the pure compound (0.023 g, 32%) as a colorless oil; ^{1}H NMR (400 MHz), δ: 1.21 (t, 3H, J = 7 Hz), 1.33 (t, 3H, J = 8 Hz), 1.53 (t, 3H, J = 7.5 Hz), 2.55 (q, 2H, J = 7 Hz), 2.90 (q, 2H, J = 8 Hz), 3.91 (s, 2H), 3.95 (s, 2H), 3.47 (q, 2H, J = 7.5 Hz), 6.37 (d, 1H, J = ~2 Hz), 6.51 (d, 1H, J = 2. Hz), 7.58 (d, 1H, J = 1 Hz), 9.21 (br s, 1H). Exact mass calcd. for $C_{17}H_{24}O_3N_2$: 304.1768; found: 304.1786. Anal. calcd. for $C_{17}H_{24}O_3N_2$: C 67.12, H 7.94, N 9.20; found: C 67.15, H 7.98, N 8.89.

2-[(5′-Ethoxycarbonyl-3′-ethyl-4′-methylpyrrole-2-yl)methyl-5-benzyloxycarbonyl-3-ethyl-4-methylpyrrole (3c)

The pyrrole **3** (0.05 g, 0.194 mmol) was converted into the dipyrromethane **3c** according to the general D by treatment with PhIO (0.42 g, 1 equiv.), the catalyst **2** (0.002 g, 0.0015 mmol), and 2-ethoxycarbonyl-4-ethyl-3-methyl-pyrrole (**10**). Flash chromatography of the crude material on silica gel (1 g, CH_2Cl_2/EtOAc 95:5) provided the dipyrromethane (0.05 g, 60%) as a pale white solid; ^{1}H NMR (400 MHz), δ: 1.02 (pair of overlapping t, 3H each, J = ~7 Hz each), 1.27 (t, 3H, J = 7.5 Hz), 2.25 (s, 3H), 2.26 (partially buried q, 2H, J = ~7 Hz), 2.28 (s, 3H), 2.41 (q, 2H, J = 7 Hz), 3.84 (s, 2H), 4.20 (q, 2H, J = 7.5 Hz), 5.20 (s, 2H), 7.24–7.35 (m, 5H), 8.98, 9.00 (pair of overlapping s, 1H each). Exact mass calcd. for $C_{26}H_{32}O_4N_2$: 436.2362; found: 436.2378.

2-[(5-Benzyloxycarbonyl-3(carbomethoxyeth-2-yl)-4-methylpyrrole-2-yl)methyl]-5′-ethoxycarbonyl-3′-ethyl-4′-methylpyrrole (4c)

The pyrrole **4** (0.05 g, 0.158 mmol) was converted into the dipyrromethane **4c** according to the general procedure D by treatment with PhIO (0.34 g, 1 equiv.), catalyst **2** (0.002 g, 0.0015 mmol), and 2-ethoxycarbonyl-4-ethyl-3-methyl-pyrrole (**10**). Flash chromatography of the crude material on silica gel (1 g, CH_2Cl_2/EtOAc 90:10) provided the dipyrromethane (0.038 g, 48%) as a white solid; ^{1}H NMR (400 MHz), δ: 1.05 (t, 3H, J = 7 Hz), 1.30 (t, 3H, J = 7.5 Hz), 2.27 (s, 6H), 2.43 (partially buried t, 2H, J = 6.5 Hz), 2.46 (overlapping q, 2H, J = 7 Hz), 2.23 (q, 2H, J = 6.5), 3.67 (s, 3H), 3.91 (s, 2H), 4.25 (q, 2H, J = 7.5 Hz), 5.24 (s, 2H), 7.28–7.39 (m, 5H), 8.68 (br s, 1H), 9.08 (br s, 1H). Exact mass calcd. for $C_{28}H_{34}O_6N_2$: 294.5929; found: 494.5932. Anal. calcd. for $C_{28}H_{34}O_6N_2$: C 67.99, H 6.92, N 5.66; found: C 68.02, H 6.96, N 5.61.

2-[(5-Benzyloxycarbonyl-4-methyl-3-octylylpyrrole-2-yl)methyl]-5′-ethoxycarbonyl-3′-ethyl-4′-methylpyrrole (5c)

The pyrrole **5** (0.05 g, 0.146 mmol) was converted into the dipyrromethane **5c** according to the general procedure D by treatment with PhIO (0.032 g, 1 equiv.), the catalyst **2** (0.002 g, 0.0015 mmol) and 2-ethoxycarbonyl-4-ethyl-3-methyl-pyrrole (**10**). Flash chromatography of the crude material on silica gel (1 g, CH_2Cl_2/EtOAc 95:5) provided the dipyrromethane (0.042 g, 55%) as a white solid; ^{1}H NMR (400 MHz), δ: 0.88 (t, 3H, J = 6.5 Hz), 1.03 (t, 3H, J = 7.5 Hz), 1.20–1.36 (m, 17H), 2.25 (s, 6H), 2.37 (t, 2H, J = 6.5 Hz), 3.83 (s, 2H), 4.24 (q, 2H, J = 7.5 Hz), 5.25 (s, 2H), 7.28–7.40 (m, 5H), 8.74, 8.80 (pair of overlapping s, 1H each). Exact mass calcd. for $C_{32}H_{44}O_4N_2$: 520.3300; found: 520.3304.

2-[(5-Ethoxycarbonyl-3-ethyl-4-methylpyrrole-2-yl)methyl]-5′-ethoxycarbonyl-3′-ethyl-4′-methylpyrrole (6c)

The pyrrole **6** (0.05 g, 0.256 mmol) was converted into the dipyrromethane **6c** according to the general procedure D by treatment with PhIO (0.056 g, 1 equiv.), the catalyst **1** (0.002 g, 0.0015 mmol) 3-ethoxycarbonyl-3-ethyl-4-methyl-pyrrole (**10**). Flash chromatography of the crude material on silica gel (1 g, CH_2Cl_2/EtOAc 95:5) provided the dipyrromethane (0.042 g, 44%) as a white solid; ^{1}H NMR (400 MHz), δ: 1.04 (t, 6H, J = 8 Hz), 1.32 (t, 6H, J = 8 Hz), 2.28 (s, 6H), 2.41 (q, 4H, J = 8 Hz), 3.86 (s, 2H), 4.27 (q, 4H, J = 8 Hz), 8.61 (br s, 2H). Exact mass calcd. for $C_{21}H_{30}O_4N_2$: 374.4842; found: 374.4851. Anal. calcd. for $C_{21}H_{30}O_4N_2$: C 67.35, H 8.07; N 7.47; found: C 67.38, H 8.09, N 7.42.

2-[(5-Ethoxycarbonyl-3,4-diethylpyrrole-2-yl)methyl]-5′-ethoxycarbonyl-3′-ethyl-4′-methylpyrrole (7c)

The pyrrole **7** (0.05 g, 0.293 mmol) was converted into the dipyrromethane **7c** according to the general procedure D by treatment with PhIO (0.052 g, 1 equiv.), the catalyst **1** (0.002 g, 0.0015 mmol), and 2-ethoxycarbonyl-4-ethyl-3-methyl-pyrrole (**10**). Flash chromatography of the crude material on silica gel (1 g, CH_2Cl_2/EtOAc 95:5) provided the dipyrromethane (0.048 g, 52%) as a white solid; ^{1}H NMR (400 MHz), δ: 1.02, 1.05 (pair of overlapping t, 3H, J = ~7 Hz each), 1.15 (t, 3H, J = 7.5 Hz), 1.30 (t, 6H, J = 8 Hz), 2.25 (s, 3H), 2.38–2.47 (m, 4H), 2.70 (q, 2H, J = 7.5 Hz), 3.78 (s, 2H), 4.24 (q, 4H, J = 8 Hz), 8.90 (br s, 2H). Exact mass calcd. for $C_{22}H_{32}O_4N_2$: 388.2362; found: 388.2359.

2-[(5-Ethoxycarbonyl-3,4-dimethylpyrrole-2-yl)methyl]-5′-ethoxycarbonyl-3′-ethyl-4′-methylpyrrole (8c)

The pyrrole **8** (0.05 g, 0.276 mmol) was converted into the dipyrromethane **8c** according to the general procedure D by treatment with PhIO (0.060 g, 1 equiv.), the catalyst **1**

The absolute kinetics for radical addition and electronic energy transfer to [1.1.1]propellane

P.F. McGarry and J.C. Scaiano

Abstract: Free radicals react more readily with [1.1.1]propellane, **1**, than with styrene. For example $Et_3Si\cdot$ reacts with **1** and styrene with rate constants of 6×10^8 M^{-1} s^{-1} and 2×10^8 M^{-1} s^{-1}, respectively. Fluorenone, phenanthrene, triphenylene, benzophenone, and pyrene transfer electronic energy to **1** with rate constants well below the diffusion-controlled limit. For example, triplet benzophenone is quenched by **1** with a bimolecular rate constant of 9.9×10^6 M^{-1} s^{-1}. A linear dependence of the log of the quenching rate constants, log k_q, upon the excited-state energy of the donors is found.

Key words: propellane, laser flash photolysis, free radicals, triplet states.

Résumé : Les radicaux libres réagissent plus facilement avec le [1.1.1]propellane, **1**, qu'avec le styrène. Par exemple, les constantes de vitesse de réaction du $Et_3Si\cdot$ avec **1** et avec le styrène sont respectivement de 6×10^8 M^{-1} s^{-1} et 2×10^8 M^{-1} s^{-1}. Le transfert d'énergie électronique de la fluorénone, du phénanthrène, du triphénylène, de la benzophénone et du pyrène vers **1** se fait à des constantes de vitesse de beaucoup inférieure à la limite contrôlée par la diffusion. Par exemple, le triplet de la benzophénone est désactivé par **1** avec une constante bimoléculaire de $9{,}9 \times 10^6$ M^{-1} s^{-1}. On a observé qu'il existe une relation linéaire entre le logarithme des constantes de vitesse de désactivation, log k_q, et l'énergie de l'état excité des donneurs.

Mots clés : propellane, photolyse laser éclair, radicaux libres, états triplets.

[Traduit par la Rédaction]

Introduction

Since Von Baeyer's works in the 1880's the effect of angle strain upon molecular reactivity has been of interest to organic chemists (1). In this respect [1.1.1]propellane is abnormally stable despite a high strain energy content in the molecule (2). The accepted rationalization used to explain the experimentally observed stability is that the lowest energy pathway to reactivity, breakage of the central bond, releases little strain energy (3, 4). Work on the free-radical reactions of [1.1.1]propellane, **1**, by a number of groups has been reviewed by Wiberg et al. (5, 6). Three general rules regarding the free-radical reactions of [1.1.1]propellane can be distilled from these summaries and some more recent contributions (7):

(*i*) Free radicals react with **1** solely by addition reactions in which the central bridgehead–bridgehead bond is cleaved via an S_H2 mechanism (excepting perhaps one instance reported by Zefirov et al. (8) for addition of chlorine atoms).

(*ii*) The new nonplanar carbon-centered radical is an unusually reactive species which exhibits nucleophilic character.

Received May 29, 1998.

[2]Author to whom correspondence may be addressed. Telephone 613-562-5896. Fax: (613) 562-5633.

(*iii*) The resulting bicyclo[1.1.1]pent-1-yl radicals do not rearrange except in the cases of excited states or carbenes (9).

Despite definitive works probing the qualitative reactivity of **1** (4, 10–12), measurements of the absolute rate constants for the radical reactions of **1** have been mostly absent from the literature (13). A few values of absolute rate constants for carbene additions to **1** have been published (9, 14). We report here on our nanosecond laser flash photolysis measurements of the absolute rate constants for the free-radical addition reactions of **1** shown in Scheme 1.

Whereas the mechanisms of free-radical reactions of **1** are well established the electronic excited states of **1** and the chemistry ensuing from them are not. The lowest triplet and singlet excited-state energies and geometries of **1** have been the subject of theoretical studies (15–21). Only recently, however, have experimental values have been reported (22). In light of the continuing interest in the abnormal properties of **1** we undertook the study of electronic energy transfer to [1.1.1]propellane. Thus we report our findings concerning the rate constants and mechanisms for electronic energy transfer to **1** and on possible mechanisms for electronic relaxation of excited **1**.

Experimental section

Materials

The solvents used were of the highest quality commercially available and were generally used as received. In some cases, however, it was found that best results for flash photolysis studies were obtained when the solvents were purified just prior to use. These special cases are described be-

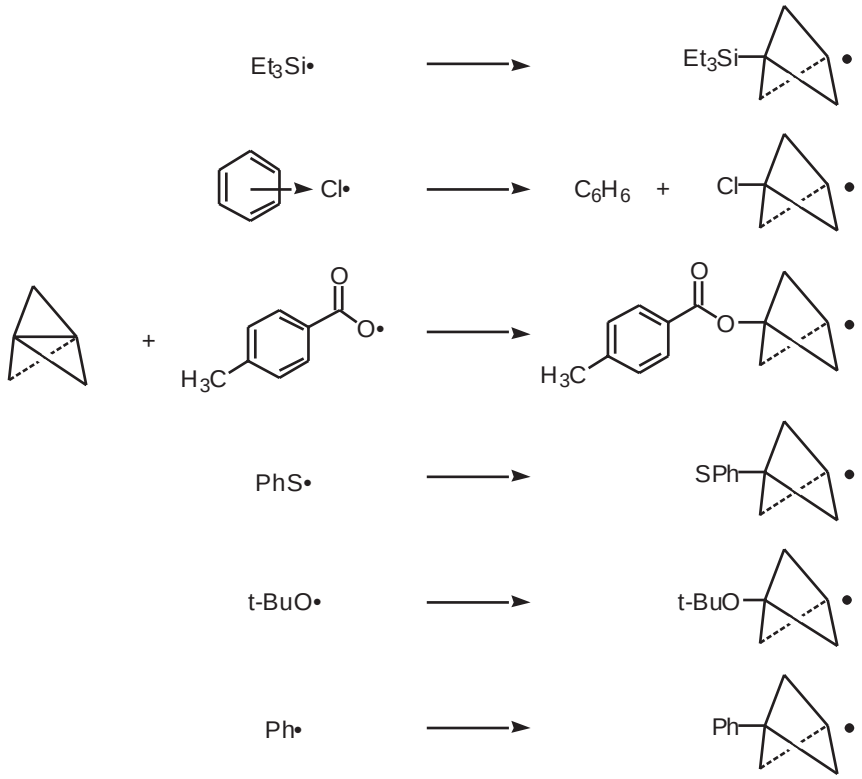
Scheme 1.



low. Di-*tert*-butylperoxide was passed over alumina just prior to use to remove traces of hydroperoxide. Benzene was washed with dilute sulfuric acid (10%) and water. It was dried with $MgSO_4$ and distilled from calcium hydride.

Synthesis of [1.1.1]propellane

The method of Szeimies and co-workers (23) was used. The dilute mixture of propellane in ether obtained from this synthesis was tediously purified by preparative gas chromatography (vide infra). Thus we modified the method by reducing the solvent volume by one half prior to reaction (many attempts to exchange the methyllithium solvent from ether to a less volatile one such as triglyme resulted in a dismal yield of propellane) thus affording a propellane–ether solution of twice the propellane concentration and reducing the prep GC time by half. Pure, neat [1.1.1]propellane polymerizes spontaneously at room temperature (24). It is essential for kinetic measurements of propellane reactivity that solutions of **1** contain no reactive impurities. Thus for most experiments the outlet gas mixture from the prep GC was fed through gas-tight tubing equipped with a three-way valve. Ether and methyl bromide were passed through to a –78°C trap and discarded. Propellane was diverted through to a needle submerged in the inert solvent of choice at –15 to –20°C to trap the propellane more efficiently and to reduce the likelihood of polymerization. Solutions up to 2.0 M in **1** could be prepared in this way. The concentrations were checked using ^{1}H NMR.

Apparatus

Laser photolysis experiments were carried out using either a Lumonics EX 530 XeCl excimer laser (λ = 308 nm, 6–8 ns pulse duration, <20 mJ/pulse) or a Molectron UV-24 nitrogen laser (λ = 337 nm, 8 ns pulse duration, <10 mJ/pulse). Further details of the laser flash photolysis instrument have been published previously (25, 26).

Fluorescence spectra were recorded with a Perkin–Elmer LS5 spectrofluorimeter equipped with a PE data station. Fluorescence lifetimes were recorded with a PRA single photon counting instrument.

Results

Free-radical reactions

t-*Butoxyl radical addition*

A 1:1 benzene/di-*tert*-butyl peroxide mixture (v/v) was irradiated with a pulse from a nitrogen laser (λ = 337 nm). Neither the *tert*-butoxyl radical nor the adduct radical formed by reaction of *t*-butoxyl with **1** have appreciable absorptions in the region of the UV-vis spectrum available to us (300–800 nm). Thus we employed diphenylmethanol as a kinetic probe (27). The ketyl radical produced by reaction of this substrate with *t*-butoxyl radicals (the same as that produced in the photoreduction of benzophenone) has a characteristic absorption at λ = 535 nm. The proposed mechanism for this system is summarized by the following equations:

© 1998 NRC Canada

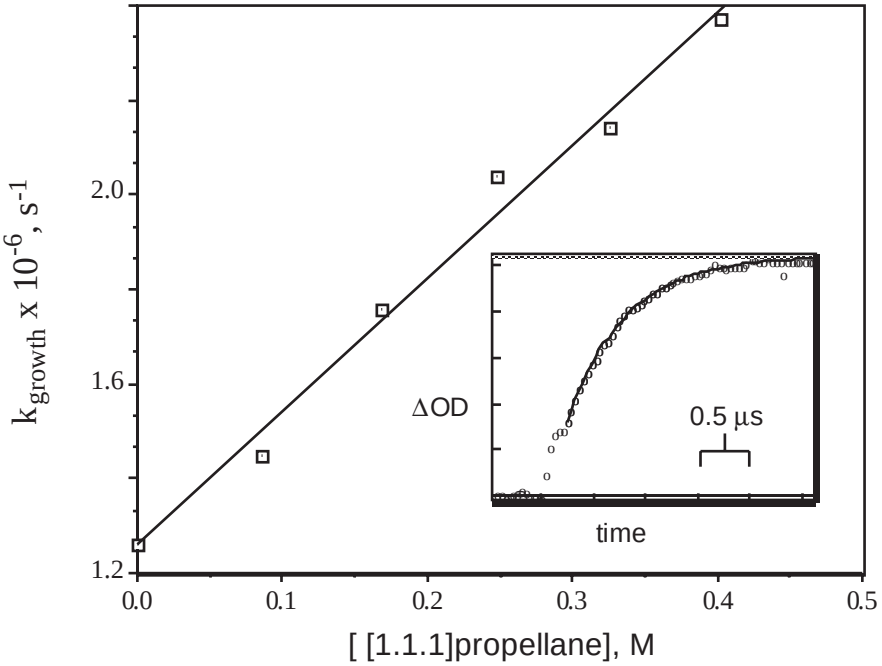
[1] t-BuOO(t-Bu) ⟶ 2 t-BuO•

[2] -BuO• t ⟶ First order decay

[3] t-BuO• + Ph_2CHOH ⟶ t-BuOH + $Ph_2\dot{C}OH$

[4] t-BuO• +  ⟶ 
1

Fig. 1. Plot according to eq. [5] for [Ph_2CHOH] = 69 mM. *Insert:* Transient absorption trace showing the buildup of ketyl signal at 535 nm for 85 mM [1.1.1]propellane.



The buildup of the ketyl radical signal at 535 nm according to eq. [3] follows clean first-order kinetics (see insert in Fig. 1); a monoexponential fit of the signal growth leads to k_{growth}, which is related to the rate constants of interest according to:

[5] $k_{growth} = k_2 + k_3[Ph_2CHOH] + k_4[propellane]$

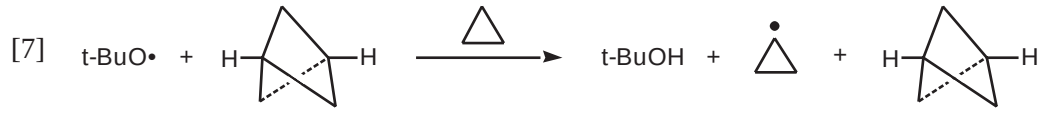
Thus, a plot of k_{growth} against the concentration of [1.1.1]propellane at constant diphenylmethanol concentration yields from the slope the value of k_4. The plot of Fig. 1 leads to $k_4 = (2.8 \pm 0.3) \times 10^6$ M^{-1} s^{-1}. This is a remarkably fast reaction for *t*-butoxyl radical addition to unsaturated systems (28, 29).

The kinetic probe technique cannot be used to determine the mechanism of reaction (30). For the mechanistic details we turned to precedence in the literature (4, 31) and to our own product studies. For instance it has been shown (4) that *t*-butyl hypochlorite gives addition products with **1** which are consistent with a free-radical S_H2 addition to the central bond in **1** by *t*-butoxyl radical:

[6] t-BuOCl ⟶ 
1

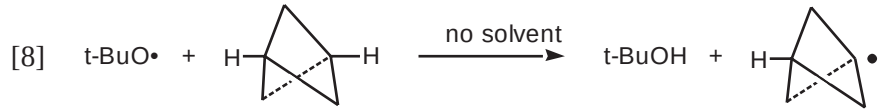
© 1998 NRC Canada

That *t*-butoxyl radicals add to the central bond in **1** rather than abstract a hydrogen atom from one of the methylene groups is also consistent with observations by Maillard and Walton (31) who studied the ESR spectrum of the bicyclo[1.1.1]pent-1-yl radical. Cyclopropane is often used as the solvent for such studies because its C—H bonds are relatively impervious to radical abstraction reactions. It was found, however, when cyclopropane was used as solvent for **2** in the presence of *t*-butoxyl radical the main species observed was the cyclopropyl radical. When no solvent was employed H-abstraction preferentially gave the cyclopent-1-yl, **3**, and no cyclopent-2-yl radical (reactions [7] and [8]):



2

(reaction only with cyclopropane solvent)



3

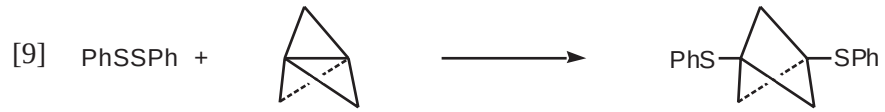
The results of Maillard and Walton (31) clearly demonstrate that the methylene hydrogens of the bicyclopentane ring system are extraordinarily unreactive towards H-atom abstraction.

Despite the compelling evidence in favour of S_H2 addition by *t*-butoxyl to **1** given above we carried out product studies of our own because under the conditions of laser flash photolysis of the peroxide in the presence of **1** there was no possibility for a chain reaction. Thus mixtures of **1** in 1:1 benzene/cyclohexane (v/v) were exposed to either thermal or photochemical sources of *t*-butoxyl radical (di-*t*-butyl hyponitrite or di-*t*-butyl peroxide, respectively). In both cases the solutions became opaque shortly after initiation of the reactions due to the precipitation of flocculant white material. The cyclohexane cosolvent was used in the hope that the adduct radical formed by addition of *t*-butoxyl radical to **1** could be trapped if it abstracted hydrogen from this solvent. Following removal of the insolubles, GC–MS of the supernatant reaction mixture indicated several products which incorporated both *t*-butoxyl and [1.1.1]bicyclopentane substructures as determined from the MS fragmentation patterns (vide infra). Unfortunately the nature of the *t*-butoxyl extension of the oligomers of **1** can be expected to result in facile fragmentation of the molecular ion. Indeed for all peaks observed in the GC trace no molecular ion peaks could be found in the corresponding GC–MS analysis.

Several features of the fragmentation pattern are worth noting. No molecular ion peak is observed. Differences in *m*/*e* between important peaks frequently correspond to the mass of propellane moiety (66). The propellane plus hydrogen peak of *m*/*e* = 67 is relatively important (the intermediacy of a bridgehead bicyclo[1.1.1]pentane carbocation has been reported in the reaction of electrophiles with [1.1.1]propellane) (32). Thus we concluded (14) that addition of *t*-butoxyl initiates polymerization of **1** resulting in oligomers which are similar to those already characterized by Michl et al. (33, 34).

Addition of thiophenoxyl radical

Thiophenoxyl radicals, which have a characteristic absorption with λ_{max} at 440 nm (35), were readily generated by laser irradiation (308 nm) of diphenyl disulfide. Experiments in deaerated cyclohexane showed that the radicals decayed by second-order kinetics, presumably to regenerate the starting material (Fig. 2). When [1.1.1]propellane was added, little or no effect on the rate of thiophenoxyl radical decay was observed, despite the fact that Wiberg et al. (4) have clearly shown that the disulfide adds across the central bond to give **4**, reaction [9].



4

This situation is not uncommon for resonance stabilized radicals and reflects the fact that additions of PhS· are frequently reversible. Ito and Matsuda (35) have demonstrated that oxygen can be employed to trap carbon-centered radicals produced by reaction of thiophenoxy radicals with styrenes (vide infra) and that under these conditions it is possible to prevent the back reaction. In our case we observe that in the presence of air or oxygen [1.1.1]propellane does quench thiophenoxy radicals and that under these conditions the thiophenoxy radicals decay by pseudo-first-order kinetics; however, the bimolecular rate constant, k_{exptl}, obtained from a plot of k_{decay} vs. the propellane concentration (Fig. 3) is a function of the oxygen concentration (e.g., $(6.4 \pm 0.6) \times 10^6$ M^{-1} s^{-1} under air), suggesting that oxygen trapping is not quantitative. Reactions [10]–[13] show the mechanism proposed and is similar to that for thiophenoxyl addition to alkenes.

Oxygen is known to scavenge quite readily carbon-centered radicals, with rate constants that normally exceed 10^9 M^{-1} s^{-1} in fluid solution (31). In this system oxygen inhibits the regeneration of PhS·, which we suggest occurs via back reaction [12]. In principle, the regeneration of PhS· could have two different origins: (*a*) reaction [12] may be reversible, as already indi-

[12] PhS• +  ⇌ 
[13]  + O_2 ⟶

5

cated (by analogy with the case of olefins) (36, 37), or (*b*) radical **5** may react with the disulfide to yield another PhS· radical. The kinetic analysis that follows is independent of which mechanism is followed for the regeneration of PhS·. We believe that (*a*) is the correct explanation (vide infra). The values of k_{exptl} can be related with the rate constants of interest according to eq. [14]; the derivation of this expression can be found in the literature (13, 35).

$$[14] \quad \frac{1}{k_{apparent}} = \frac{1}{k_{12}} + \frac{k_{-12}}{k_{12}k_{13}[O_2]}$$

Thus, if the oxygen concentration is sufficiently high, the value of $k_{apparent}$ corresponds directly to k_{12}. Unfortunately, in our case saturation with oxygen in cyclohexane was not sufficient to meet this criterion. In our studies of $1/k_{apparent}$ vs. the reciprocal oxygen concentration, the intercepts of plots according to eq. [14] were always too small to allow a meaningful determination of anything other than an upper limit of 5×10^{-8} Ms. This establishes a lower limit of 2×10^7 M^{-1} s^{-1} for k_{12} in cyclohexane. However, in the case of Freon-113 as a solvent (where the oxygen solubility is much higher than in cyclohexane) (38),we were able to obtain significantly better data. Weighted least-squares analysis according to eq. [14] (Fig. 4) gives an intercept which, in spite of the large error, is significantly different from zero and leads to a k_{12} value of $(6.2 \pm 2.0) \times 10^7$ M^{-1} s^{-1}. Combining this with the slope leads to $k_{13}/k_{-12} \approx 59$ M^{-1}. Further, examination of reported absolute rate constants for radical reactions with oxygen suggest that the value of k_{13} should be in the neighborhood of 4×10^9 M^{-1} s^{-1} (31); combining this estimate with the slope from eq. [14] we estimate $k_{-12} \approx 6.8 \times 10^7$ s^{-1} in Freon-113. This is a remarkably fast rate, and may suggest that the addition of PhS· to propellane is thermoneutral, or slightly exothermic. Wiberg and Waddell (39) noted that the adduct of [1.1.1]propellane and PhSSPh can revert back to [1.1.1]propellane by reaction with diaryl lithium radical anion. Related examples of central bond formation via radical reactions have recently been reported (40).

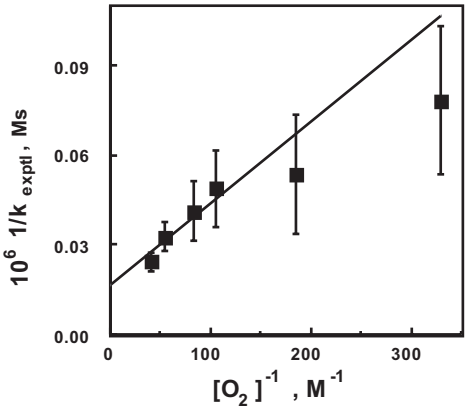
Fig. 4. Plot according to eq. [14] for the reaction of PhS· with [1.1.1]propellane. The error bars are based on the dispersion of the data obtained for the decay of PhS· as a function of [**1**] for each oxygen concentration.

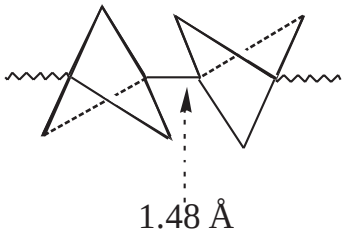


We wished to show independently that the composite thiyl-propellane radical, **5**, does dissociate to yield thiyl radical and propellane. Thus 1-(thiophenoxy)bicyclo-[1.1.1]pentane, **6** (reaction [15]), in 33% di-*tert*-butyl peroxide in benzene (v/v) solution was irradiated with an excimer laser pulse (λ = 308 nm). No growth of phenylthiyl radical at 440 nm was observed. Addition of varying amounts of **6** had no effect on the *t*-butoxyl radical lifetime (investigated using the benzhydrol kinetic probe) which indicated the inability of *t*-butoxyl to abstract the bridgehead hydrogen from **6** as shown in eq. [15].

[15] t-BuO• + PhS—H ⟶ no reaction

6

We also investigated the reactivity of **6** towards benzophenone triplet. Thiyl radical was observed at 440 nm. It must have arisen from energy transfer from benzophenone triplet to **6** rather than H-abstraction, since the absorption expected at 535 nm (indicating the presence of benzophenone ketyl radical) was absent. The fact that the bridgehead hydrogen of **6** is not easily abstracted is not unexpected, since crystal structures of the oligomers of **1** indicate that the corresponding C—C bond is short (1.48 Å) (34) and thus strong.



We also measured a rate constant for the addition of thiophenoxy radical to styrene to be 2.2×10^7 M^{-1} s^{-1}, in excellent agreement with the reported value of 2.0×10^7 M^{-1} s^{-1} (35). That phenylthiyl addition to propellane is faster than addition to styrene attests to the high reactivity of inverted structures at carbon towards addition reactions.

Triethylsilyl radical addition

Silyl radicals have been the subject of several extensive flash photolysis studies (41, 42). One convenient method for generation of silyl radicals is borrowed from successful studies of the triethylsilyl radicals by ESR spectroscopy (41, 43). This involves the photodecomposition of di-*tert*-butyl peroxide in the presence of triethylsilane. In this way a sufficient concentration of silyl radical can be obtained such that their further reactions may be studied.

[16] $t\text{-BuO}\cdot + Et_3SiH \rightarrow t\text{-BuOH} + Et_3Si\cdot$

The concentration of triethylsilane used is about 3.0 M. This concentration combined with the rate constant for hydrogen abstraction from triethylsilane by *t*-butoxyl radical of 6×10^6 M^{-1} s^{-1} gives an estimated lifetime for the grow-in of silyl radicals to be ≈53 ns (44). On the other hand, at the highest concentration of **1** employed, 2.3 mM, <<1% of the *t*-butoxyl radicals are trapped by propellane.

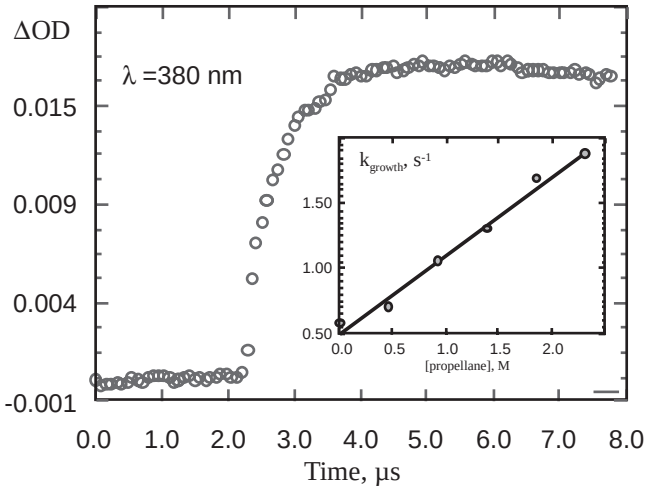
Fig. 5. Transient absorption trace showing the buildup of the adduct radical, **23**, at 380 nm, for 1.4 mM [1.1.1]propellane and 0.4 mM benzil. *Insert*: Plot according to eq. [20] for the reaction of $Et_3Si\cdot$ with [1.1.1]propellane with [benzil] = 0.4 mM. The slope yields a rate constant for addition of (6.0 ± 0.7) × 10^8 M^{-1} s^{-1}.



The triethylsilyl–propellane adduct radical **8**, does not show any significant absorptions above λ > 300 nm, and triethylsilyl radical itself absorbs only weakly below 340 nm (44, 45). Therefore we resorted to the use of benzil to probe the kinetics of the reaction between trethylsilyl radical and [1.1.1]propellane, **1** (41). This probe method takes advantage of the well known addition of silyl radicals to the oxygen of a carbonyl group (43) to give the carbon-centered adduct radical, **7**, as summarized in eq. [18]. The silyl radicals were generated by laser photolysis of di-*tert*-butyl peroxide at 337 nm in 1:1 triethylsilane/di-*tert*-butyl peroxide mixture (v/v). The generation of silyl radicals under these conditions was quite fast (vide supra), and in the presence of 0.4 mM benzil led to the grow-in of a strong absorption centered at ~380 nm, corresponding to the adduct radical **7** (eq. [18]). Reactions [17]–[19] show the mechanism proposed for reaction of triethylsilyl radical with **1**.

[17] $Et_3Si\bullet$ ⟶ First order decay

[18] $Et_3Si\bullet$ +  →

7

[19] $Et_3Si\bullet$ +  →

8

The signal monitored at 380 nm exhibits smooth monoexponential growth kinetics; a first-order fit of the data leads to k_{growth}. By analogy with eq. [5], the rate constant of reaction of triethylsilyl radical with the substrate of interest is related to k_{growth}, for the triethylsilyl–benzil adduct by the following equation.

[20] $k_{growth} = k_{17} + k_{18}[\text{benzil}] + k_{19}[\text{propellane}]$

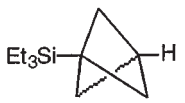
When the concentration of benzil is held constant a plot of k_{growth} vs. [**1**] yields a straight-line plot whose slope is equated to k_{19}, the rate constant for reaction of triethylsilyl radical with **1**.

Figure 5 shows a plot of k_{growth} vs. [propellane]. The slope of the best line fit to the data represents the rate constant for addition of the triethylsilyl radical to **1** and was found to be k_{19} = (6.0 ± 0.7) × 10^8 M^{-1} s^{-1}. The rate constant for addition of triethylsilyl radical to [1.1.1]propellane compares favorably to that for addition to styrene (2 × 10^8 M^{-1} s^{-1}) and is much faster than the rate constant for addition to 1-hexene (5 × 10^6 M^{-1} s^{-1}) (46). That **1** is more reactive than styrene with triethylsilyl radical probably reflects the localized charge density at the bridgehead carbons in **1** and the electrophilic nature of $Et_3Si\cdot$ (4, 46).

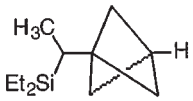
The mechanism of addition of triethylsilyl radical is clearly established by Wiberg et al. (5) as being one of S_H2 attack at one of the bridgehead sites of **1** to cleave the central bond (reaction [19]), ultimately leading to **8**. In his study Wiberg also

© 1998 NRC Canada

noted that the triethylsilane–propellane adduct **10** was formed.



9



10

11

This clearly implicates radical **11** as an important species in their free-radical chain process. This radical plays no role in our kinetic studies (43, 44), given that the probe (benzil) is not expected to react significantly with it.

Benzene – chlorine atom π-complex reaction

Absolute rate constants for reaction of "free" chlorine atoms have been measured using laser flash photolysis (47–49). The techniques used are not practical for measuring a rate constant for the reaction between Cl· and **1** because they frequently employ Cl_2 as the chlorine atom precursor with which [1.1.1]propellane reacts spontaneously. One alternative is to investigate the rate of reaction of the chlorine atom – benzene π-complex (50). This species (51–53) has been extensively and thoroughly characterized by laser flash photolysis (47). Of five methods for generating the chlorine atom by flash photolysis only photolysis (47) of α-chloroacetophenone is suitable for study with **1**, since reaction between this chlorine atom precursor and **1** is unlikely.

Presumably the photolysis of α-chloroacetophenone in benzene produces the triplet state of this molecule which has, as the principal route of decay, β-cleavage to give a chlorine atom. The lifetime of the triplet and thus the growth of the benzene π-Cl· complex was estimated to be about 50 ns (47). The proposed mechanism is shown in eqs. [21] and [22].

[21] 
[22] 
π-complex

This source of chlorine atom – benzene π-complex is limited by the lifetime of the precursor excited states (47, 54). Because the production of benzene-Cl· is limited by the lifetime of the triplet precursor the production of the complex is not quite "instantaneous." Thus in our investigations we were limited to conditions where the lifetime of the complex is greater than 200 ns.

Laser excitation (λ = 337 nm) of α-chloroacetophenone in benzene gave a strong absorption at 490 nm in deoxygenated benzene at 293 K. Upon addition of small amounts of [1.1.1]propellane the kinetics of decay changed from predominantly second order to predominantly first order. To help reduce error due to second-order radical–radical interactions the nitrogen laser beam was attenuated to 40% of its full power by use of a neutral density filter. The clean monoexponential decay traces were fit to first-order kinetics to yield k_{decay} of the complex in the presence of various concentrations of **1**. The rate constant for addition of π-complexed chlorine atom to **1** was then determined by plotting k_{decay} against the propellane concentration according to eq. [23].

$$[23] \quad k_{decay} = \tau^{-1} + k_{24}[\text{propellane}]$$

where τ^{-1} is the rate constant for decay of the complex by any first- or pseudo-first-order processes in the absence of **1**, and k_{24} is the rate constant for addition of π-Cl· to **1** according to eq. [24].

[24]

The rate constant for addition of the benzene – chlorine atom π-complex to [1.1.1]propellane, k_{24} is obtained from the slope of the line to be $(3.1 \pm 0.5) \times 10^9$ M^{-1} s^{-1}. This rate constant is close to the diffusion-controlled limit and indicates an exothermic reaction. It implies that the complex is reacting directly with **1** and is not just the source of free chlorine atom in equilibrium with the complex. The rate of addition of "free" chlorine atoms with **1** must be diffusion-controlled as these radicals are more reactive than the complexed ones (51).

© 1998 NRC Canada

The products of the reaction of halogen atoms with [1.1.1]propellane has been unambiguously established by Zefirov et al. (8). The principal mode of addition is S_H2 displacement of the central bond at one of the bridgehead carbons to ultimately give the 1,3-disubstituted bicyclo[1.1.1]pentane in a radical chain reaction as summarized in reactions [25] to [27].

[25] $Cl_2 \xrightarrow{h\nu} 2\ Cl\bullet$

[26] $Cl\bullet$ + $\longrightarrow C_6H_6$ + 
[27]  + Cl_2 $\longrightarrow$  + $Cl\bullet$

Addition of p-*methoxybenzoyloxyl*

Benzoyloxyl radicals have been studied by laser photolysis techniques (42, 55) and by time resolved ESR spectroscopy (56, 57). While these radicals are known to undergo facile decarboxylation, by use of time resolved techniques it was possible to investigate other reactions which competed with their unimolecular decomposition. Equations [28]–[32] show the proposed mechanism for the photolysis of a bis(aroyloxyl) peroxide in the presence of [1.1.1]propellane.

[28]  $\xrightarrow{h\nu}$ 2 
[29]  $\longrightarrow$ Ar• + CO_2

[30]  + RH $\longrightarrow$ $ArCO_2H$ + R• (or addition)

[31]  +  $\longrightarrow$ Products

[32]  + $\longrightarrow$ 
Thus aryloxyl radicals may decarboxylate, react with the solvent, with the peroxide precursor, or some added substrate possibly by hydrogen atom abstraction or by addition. We chose to study the reaction of *p*-methoxybenzoyloxy radical with **1**, since this is the longest lived of the known aroyloxyl radicals (55, 58). It undergoes decarboxylation in CCl_4, slowly giving it a lifetime of about 2 μs and decarboxylates even slower ($\tau > 50$ μms) in acetonitrile. The decreased rate for decarboxylation is attributed to a stabilization of the *p*-methoxybenzoyloxy radical by this solvent (42).

The decay of *p*-methoxybenzoyloxy radical was monitored at 720 nm, at room temperature (20°C) in aerated acetonitrile. It exhibited a ~5 μs lifetime showing first-order decay kinetics, following laser excitation (308 nm) of bis-(4-methoxybenzoyloxyl) peroxide. Since no radical scavengers were present, and the radical does not react with this solvent or oxygen, the principal mode of decay was taken to be reaction with the peroxide precursor whose concentration was ≈10 mM (42). Upon addition of [1.1.1]propellane to the system the observed rate of decay of the radical increased. Thus the rate constant for addition of the benzoyloxyl radical to **1**, k_{32}, is related to the experimentally observed decay rate constant, k_{decay}, according to eq. [33].

Table 1. Summary of room-temperature-solution rate constants for addition of various radicals to [1.1.1]propellane and comparison to styrene rate constants where applicable.

Radical	Propellane (M^{-1} s^{-1})	Styrene (M^{-1} s^{-1})	Ratio *P*/*S*
t-Butoxy	2.8×10^6	0.91×10^6	3.0
Thiophenoxy	6.2×10^7	2.2×10^7	2.8
Triethylsilyl	6.0×10^8	2.0×10^8	3.0
Benzene – chlorine atom π-complex	3.1×10^9	—	—
p-Methoxybenzoyloxyl	1.0×10^7	5.5×10^6	1.8

Table 2. Rate constants for electronic energy transfer to [1.1.1]propellane.

Sensitizer	Excited state	Energy (kcal mol^{-1})[a]	$k_q/10^6$ (M^{-1} s^{-1})	Solvent
Triphenylene	$^3(\pi,\pi^*)$	67	6.8	Benzene
Benzophenone	$^3(n,\pi^*)$	69	9.9	Benzene
Benzophenone	$^3(n,\pi^*)$	69	7.6	Acetonitrile
Phenanthrene	$^3(\pi,\pi^*)$	62	0.92	Benzene
Fluorenone	$^3(\pi,\pi^*)$	53	0.063	Benzene
Pyrene	$^1(\pi,\pi^*)$	77	140	Benzene

[a]Values from ref. 61.

[33] $$k_{decay} = k_0 + k_{32}[\text{propellane}]$$

where k_0 incorporates all pseudo-first- or first-order modes of decay that are independent of the propellane concentration, such as reactions [29]–[31]. This yields a rate constant for addition of *p*-methoxybenzoyloxyl to [1.1.1]propellane of $(1.0 \pm 0.1) \times 10^7$ M^{-1} s^{-1}.

Thus, *p*-methoxybenzoyloxy radicals are about as reactive as *t*-butoxyl radicals in hydrogen atom abstractions but far more reactive in additions to multiple bonds. This was of interest, since in reaction with [1.1.1]propellane we could expect a faster addition rate across the central bond than that for *t*-butoxy. As expected we measured a larger rate constant of addition then that for *t*-butoxyl radical addition to **1**. How does this compare to *p*-methoxybenzoyloxy addition to styrene? It is slower than the rate measured by Chateauneuf et al. (70) (5.5×10^7 M^{-1} s^{-1}) but their measurement was carried out using CCl_4 as the solvent. Since they noted a consistent reduction in rates on changing solvent from CCl_4 to acetonitrile we can assume that the rate constants for addition of *p*-methoxybenzoyloxyl to styrene and to **1** are roughly equal. The rate constants for radical substitution of **1** are summarized in Table 1.

Interaction of [1.1.1]propellane with excited molecules

Triplet excited states and [1.1.1]propellane

The rate constants for the deactivation of the first triplet states of benzophenone, triphenylene, phenanthrene, and fluorenone by [1.1.1]propellane have been measured. The method for determining the rate constants was almost identical for each of the four triplet donors. Thus a detailed description of the experiment for benzophenone which is provided below is representative for all the measurements.

An oxygen-free solution of benzophenone in benzene (5 mM) was excited with the pulses of a nitrogen laser (337.1 nm, ~8 ns, <10 mJ/pulse). The transient absorption of benzophenone triplet may be monitored in the 500–600 nm region. We chose to monitor this triplet at 600 nm in order to avoid contributions from possible ketyl radical absorption at 540 nm (59). The triplet lifetime, τ_o, in benzene in the absence of **1** was usually 2–3 μs. Longer lifetimes could undoubtedly be obtained by exhaustive purification of the solvent, but this would not give an improvement in our results and could even introduce errors due to triplet–triplet annihilation processes.

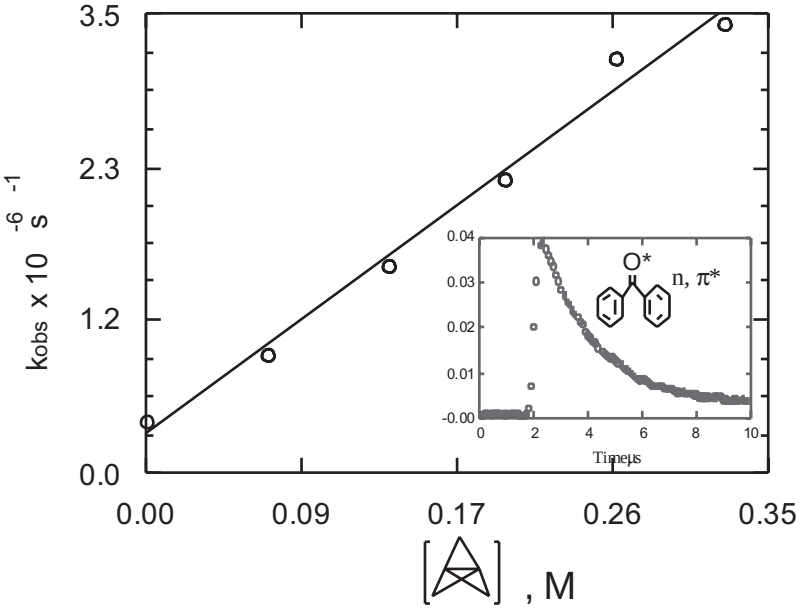
The rate constant for quenching of benzophenone triplet by propellane may be related to the observed rate constant, k_{obs}, obtained by monoexponential fitting of the experimental decay, by the following expression, eq. [34].

[34] $$k_{obs} = \frac{1}{\tau_o} + k_q[\text{propellane}]$$

Thus, a plot of the observed rate constant against the concentration of **1** lead to a straight line whose slope represents the bimolecular rate constant of interest. This plot is shown in Fig. 6, and from the slope the value of k_q has been determined to be $(9.9 \pm 1.1) \times 10^6$ M^{-1} s^{-1}. Similar experiments for triplet triphenylene, triplet fluorenone, and triplet phenanthrene were analyzed in the same manner to yield the rate constants summarized in Table 2.

© 1998 NRC Canada

Fig. 6. Plot of k_{obs} vs. [**1**] for the benzophenone–propellane system. The slope yields a bimolecular rate constant of (9.9 ± 1.1) × 10^6 M^{-1} s^{-1}. *Insert*: Decay trace for benzophenone triplet monitored at 600 nm. The concentration of **1** is 0.39 M in benzene at 21°C.



Pyrene fluorescence quenching by [1.1.1]propellane

The rate constant for quenching of pyrene fluorescence by **1** was measured via Stern–Volmer analysis (60). The proposed mechanism following excitation of pyrene to its excited singlet state and deactivation by **1**, as shown below (Py = pyrene).

[35] $Py^* \xrightarrow{k_e} Py + h\nu$

[36] $Py^* \xrightarrow{k_d} Py$

[37] $Py^* +$ $\xrightarrow{k_q} Py +$

The Stern–Volmer equation relates the relative fluorescence efficiency to the rate constant for fluorescence quenching by **1** as shown in eq. [38].

$$[38] \quad \frac{\Phi_e^o}{\Phi_e} = 1 + k_q \tau_{Py}[\text{propellane}]$$

where τ_{Py} is the lifetime of the pyrene singlet state in the absence of quenchers. Thus, a plot of the ratio of the efficiencies, $\Phi_e°/\Phi_e$, of pyrene in the presence and absence of **1** versus the concentration of **1** yields a straight line whose slope is equated to $k_q\tau_{Py}$ with an intercept of 1. The fluorescence lifetime of pyrene under the experimental conditions was measured by single photon counting to be 382 ns, in good agreement with the literature value (61). Combining τ_{Py} with the value of the Stern–Volmer slope lead to k_q = (1.42 ± 0.13) × 10^8 M^{-1} s^{-1}.

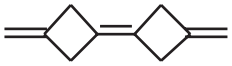
Product and steady-state photolysis studies for excited-state quenching

Analysis of the samples used in the kinetic studies by GC and GC–MS showed no new products corresponding to 1:1 adducts of **1** and pyrene, benzophenone, triphenylene, phenanthrene, or fluorenone. In the benzophenone–propellane system polymerization was evident. In acetonitrile a cloudy white precipitate was formed, and when benzene was used as solvent a sharp increase in viscosity followed irradiation, indicative of polymer formation. Several lower molecular weight products (m/e < 182, i.e., less than the molecular weight of benzophenone) were detected. These corresponded to propellane dimerization and addition to solvent (acetonitrile). Except for the dimer of **1** (**13**) they were not considered important, as they also arose in the absence of irradiation. The order of magnitude measurements for the quantum yield for propellane dimer production and sensitizer consumption were measured using steady-state photolysis and valerophenone as an actinometer in a few cases (62). The results are summarized in Table 3.

© 1998 NRC Canada

Table 3. Quantum yields for the dimerization of **1**.

Sensitizer	Φ consumption	Φ dimerization
Benzophenone	0.130	0.072
Triphenylene	0.003	0.062



13

Table 4. Comparison of *t*-butoxyl addition rate constants.

Hydrocarbon	k (M^{-1} s^{-1})
Cyclopentene	0.64×10^{6a}
Cyclopentadiene	4.06×10^{6a}
Norbornene	1.00×10^{6a}
Norbornadiene	3.22×10^{6a}
Styrene	9.1×10^{5b}
[1.1.1]Propellane	2.80×10^{6}

[a]The rate constants have been taken from ref. 29 and converted from composite (addition + abstraction) rate constants to addition rate constants by employing the measured *t*-butanol quantum yields which were used as a measure of H-abstraction. These rate constants have been calculated for reactions occurring at 293 K by using the reported activation parameters in order that they match the temperature at which the rate constant for addition to propellane was measured.

[b]Rate constant taken from ref. 70 was measured in CCl_4 as solvent at 21°C.

Discussion

Free-radical addition rate constants

We have compared, whenever possible, our measured rates of radical reactions with **1** to rates of additions of the same radicals with olefins (styrene in particular) which have been measured with a similar methodology. We feel this is more useful than comparison with rates of addition to other inverted geometries at carbon because (*i*) there is only one other example at present (63) and (*ii*) most chemists already have an appreciation for the reactivity of carbon–carbon π-bonds. In fact S_H2 reactions at carbon centers are so uncommon (64) that one has no choice but to compare them with the next closest option, addition to C—C double bonds. Thus it is felt that the radical addition reactions to olefins in general and to styrene in particular supply the ruler by which we can measure the reactivity of the inverted geometry in [1.1.1]propellane. Our discussion begins with the relative reactivity of propellane with respect to *t*-butoxyl radical addition to it and to several mono- and dienes and subsequently several rate constants involving radical additions to styrene.

Of the radical additions studied *t*-butoxyl is the one for which the most information is available regarding its reactivity with a number of olefins (29). For example, when given a choice between addition or of H-atom abstraction on the same hydrocarbon the latter is clearly preferred, especially in the cases where olefins bear allylic hydrogens. In the case of **1** addition is the only mode of attack. This indicates that the methylene hydrogens in **1** are unreactive towards H atom abstraction (vide infra). Some rates for addition of *t*-butoxyl to unsaturated systems are reproduced in Table 4 for comparison to the measured rate of addition to [1.1.1]propellane. One will note that Table 4 shows that the rate of addition of *t*-butoxyl to **1** is fast and intermediate between the rate constants for addition to mono- and dienes.

[1.1.1]Propellane may be compared most consistently with styrene, however, when considering it as a reactive substrate, since there are addition rate constants available for styrene for most of the radicals studied here. The rate constants are summarized in Table 1. For all but one case **1** reacts more rapidly with a given radical than does styrene. The exception is for the *p*-methoxybenzoyloxyl radical. It is instructive to note, however, that the two reported rate constants for this radical were measured in different solvents (acetonitrile for **1** and carbon tetrachloride for styrene). A consistent reduction in rate of reaction has been demonstrated for most additions of *p*-methoxybenzoyloxyl radical in acetonitrile compared with CCl_4 due to a strong stabilizing effect by the former solvent compared to the latter. The overall conclusion is that the central carbon–carbon single bond of [1.1.1]propellane is more reactive towards radical addition reactions than most hydrocarbons containing double bonds. A result which underlines the unique properties of the inverted structure within **1**.

Discussion of the interaction of electronic excited states with [1.1.1]propellane

The quenching of the triplet states of fluorenone, phenanthrene, triphenylene, and benzophenone by **1** must occur by the electron exchange mechanism. Several mechanisms can be proposed for this interaction. In the case of all the triplets a two-step exchange mechanism via radical ion pair intermediates is unlikely, since there was no enhancement in the quenching rate constant when acetonitrile, a more polar solvent, was employed. For the π,π* triplet states, fluorenone, phenanthrene, and triphenylene, the covalent bonding mechanism at the bridgehead is probably not operational, since biradical intermediates were not observed for these systems. To observe the biradical intermediate, a high concentration of propellane is employed which rapidly and quantitatively quenches all triplet states present. Possible biradical intermediates, such as that illustrated below for benzophenone (**14**), if generated rapidly in good yields, should be easily detectable by their unique UV-vis absorption spectra. The new intermediate should exhibit growth kinetics coincident with the decay kinetics of the precursor triplet state. A successful example of this experiment is the observation of the propellane – triplet diphenylcarbene adduct biradical (14). For the excited states described here, all such experiments yielded no detectable transient signals and thus biradical intermediates are unlikely. Thus triplet–triplet energy transfer to give triplet **1** by the concerted electron exchange mechanism is likely for π,π* triplet quenching by [1.1.1]propellane.

© 1998 NRC Canada

Fig. 7. Qualitative illustration of the transitions involved in triplet excitation transfer to **1**. Note that we have assumed a bound triplet state, but with a significantly longer C—C distance. The triplet is likely to have a more shallow surface.

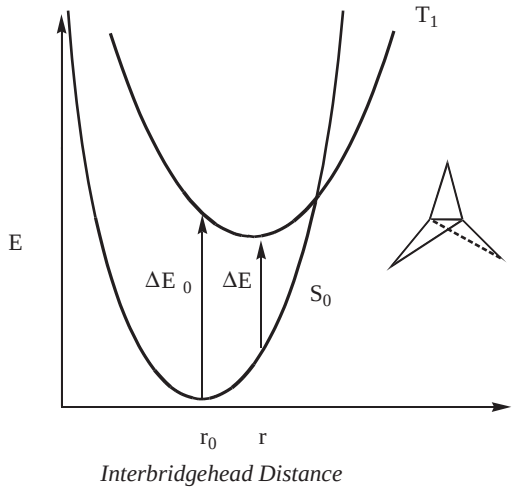


Fig. 8. Dependence of log (k_q) in benzene on the excited-state energy of the sensitizer. The slope of the best line is 0.14 mol/kcal.

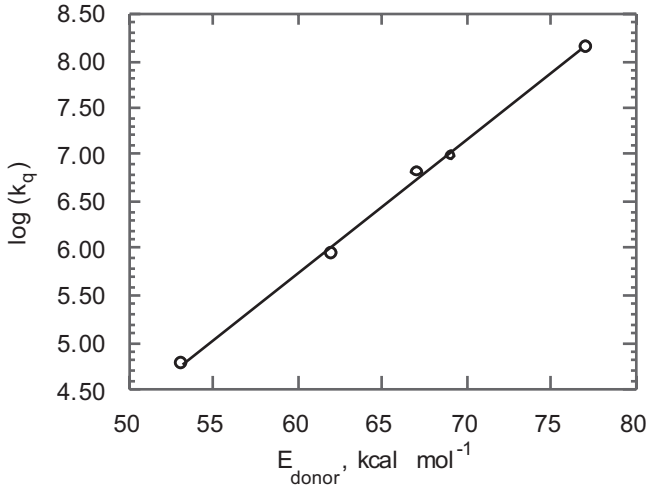
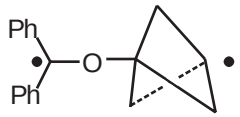


Discerning the operating mechanism by which triplet benzophenone is quenched by **1** is not as easy as in the π,π* case. Since the triplet *n*,π* state of benzophenone is radical-like, one might expect it to behave similarly to the *t*-butoxyl radical and add across the central bond of **1** to form biradical **14**. At short triplet lifetimes, corresponding to high quenching concentrations of **1**, no new transients such as **14** could be detected in our laser flash photolysis experiments. No 1:1 benzophenone/propellane adduct was detectable in product studies. Thus the possibility that the quenching of benzophenone triplet by **1** occurs by concerted electron exchange rather than the covalent bonding mechanism must be considered. There is, however, evidence of polymerization of **1** possibly initiated by benzophenone.

The benzophenone system differs in that polymerization of propellane is detectable, much greater than for the other triplet π,π* systems, and that the sensitizer is partially consumed. The benzophenone system is similar to the others in that most en-



14

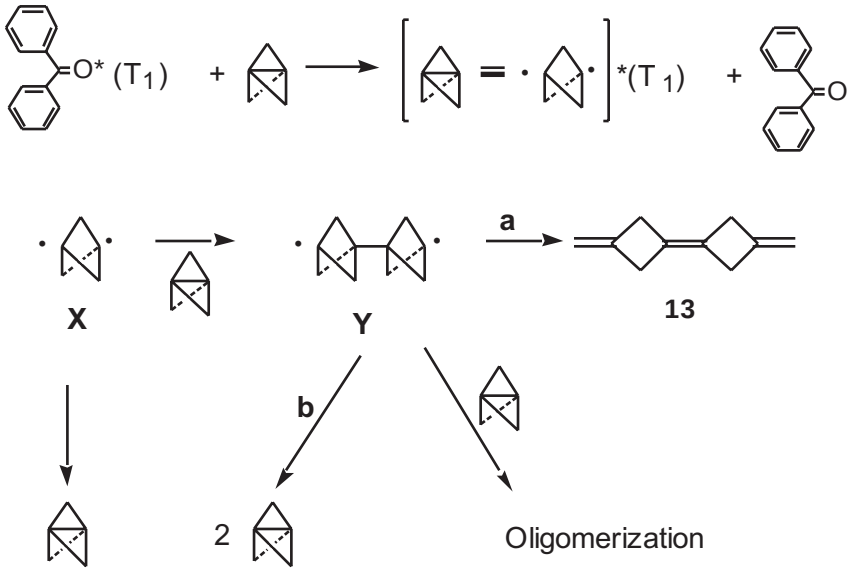
counters between benzophenone triplet and **1** generate ground-state benzophenone, as evidenced by the modest quantum efficiency of consumption of benzophenone in steady-state product studies. One possible mechanism which can explain these observations is that triplet benzophenone covalently bonds to **1** to form the biradical **14**, but the reaction is reversible and yields benzophenone unchanged in 9 cases out of 10. The tenth would, presumably, yield polymeric material by further reaction of **14** with propellane monomers.

The quenching rate constants for all the sensitizers are smaller than that expected for a diffusion-controlled process. This may reflect a large Frank–Condon S_0–T_1 or S_0–S_1 energy gap from the zero vibrational level in S_0. In fact the energies of the vertical transitions have been measured recently by low energy electron impact excitation (22). The estimates for the vertical energy gaps from S_0 to S_1 and from S_0 to T_1 are 167 and 108 kcal/mol, respectively. The difference between the electronic energies of the donor states which are quenched by **1** and the energy reported for the vertical transition must lie in the steepness of the excited-state surface at the ground-state interbridgehead distance as shown in Fig. 7. For example one may see that the vertical transition energy required to reach T_1 at r_0 on Fig. 7 is much greater than that at *r*. This results in energy transfer requiring an activation energy. This is illustrated by the approximately linear relationship which is found between the logarithm of k_q and the energy of the electronic energy donor (see Fig. 8). This type of behavior has been observed before (65–68), particularly for singlet and triplet energy transfer to molecules containing dissociative S_1 or T_1 states as in the case for di-*tert*-butylperoxide (67, 68).

In the case of [1.1.1]propellane the S_1 and T_1 states should be dissociative due to rupture of the weak central bond (15, 16). The bridgehead carbons cannot separate completely, however, since three bridging methylene groups between the bridgehead carbons hold them together. Thus the lowest excited states of propellane should have Morse-like potential energy curves. The correlation of log (k_q) with E_{donor} for energy transfer to **1** may be explained in the same way as for peroxides because the equilibrium bridghead–bridgehead distance in the excited state is larger than in the ground state (the difference in r_0 for S_0 and r_0 for S_1 is about 0.2 Å) (69).

© 1998 NRC Canada

Scheme 2.



From the plot of log (k_q) vs. E_{donor} (Fig. 8) we can draw a number of conclusions about the mechanism of energy transfer to [1.1.1]propellane. First, the principal factor which controls the rate of energy transfer to **1** is the excited-state energy of the donor and not the type (π,π^* or n,π^*) nor the multiplicity (S_1 or T_1). This implies that either the mechanism of electronic excited-state quenching by **1** is the same for all the electronic energy donors studied or that the rate of quenching is independent of the energy transfer mechanism. Secondly, the value of the slope from Fig. 8 (0.14 mol/kcal) is larger than that observed for energy transfer to di-*tert*-butyl peroxide (0.072 mol/kcal) (67) but smaller than that for triplet energy transfer to bound excited states (0.733 mol/kcal) (65). If the slope of an upper potential curve is inherently steeper when the state is more bound, then the excited state of propellane might be considered as intermediate in nature between the two extremes of dissociative and bound excited states.

Thus the results obtained for excited-state quenching by [1.1.1]propellane can be explained by a mechanism where thermally excited propellane molecules (ones that have greater bridghead–bridgehead bond lengths than the equilibrium value) are responsible for quenching excited states whose energies are less than the vertical energy gap of equilibrium S_0 T_1 or S_1 transition in propellane.

Bis(1,1′-methylenecyclobutylidene): the dimer of [1.1.1]propellane

From the apparent quantum yield of dimer production at 350 nm in benzene under sensitized conditions (energy transfer from either benzophenone or triphenylene, see Table 3) it is obvious that if dimer is a result of [1.1.1]propellane excited state that it is an inefficient process. Most propellane excited states must revert to propellane ground state with only a small fraction forming dimer. The existence of excited states of propellane, however, have not been proven by our studies but are merely implied. Thus any mechanism described by us where the dimer of propellane arises from excited singlet or triplet propellane must be considered entirely speculative.

Nevertheless, the dimer of **1** is formed in substantially enhanced yields under conditions of triplet–triplet sensitization. It has been shown from a number of theoretical studies that the lowest excited triplet state of **1** is the biradical formed by dissociation of the central bond in **1**. Thus, we tentatively suggest that the propellane dimer **13** is formed by the mechanism of Scheme 2.

Conclusion

Several radical addition reactions of [1.1.1]propellane are studied and the absolute bimolecular rate constants for the reactions are measured and compared to those for unsaturated hydrocarbons and, in particular, styrene. The rate constants range from $<1 \times 10^5$ to 3.1×10^9 M^{-1} s^{-1} (benzyl and benzene – chlorine atom π-complex radicals, respectively). In most cases the central single carbon–carbon bond reacts more readily with radicals than the carbon–carbon double bond of styrene. Thus a remarkable reactivity towards S_H2 radical additions, unparalleled in any carbon–carbon single bonds of more "normal" hydrocarbons, is displayed by the inverted geometry of the central bond in [1.1.1]propellane.

Uniaxial deformation of nylon-6 and nylon-11: changes in orientation and crystal phase

Sonia Moffatt, Abdellah Ajji, Bernard Lotz, and Josée Brisson

Abstract: The effect of uniaxial drawing on orientation of the crystalline fraction of two polymers forming hydrogen bonds, nylon-6 and nylon-11, has been investigated using X-ray diffraction. These two polymers have similar crystal phases, although their hydrogen bond density differs. For both polymers, the deformation occurs in two steps, the first being a plastic deformation of the α-phase spherulites. This leads to two populations of crystals, one with the chain axis oriented parallel to the draw direction, the second with the *a* axis (hydrogen bond direction) aligned along the draw direction. In the second step, the *a*-axis aligned population gradually tilts, leading to a uniaxial orientation of the samples with chain axis aligned along the draw direction. For nylon-11, the onset of this step corresponds to the emergence of crystals of the γ phase, which rapidly becomes the major phase. It reaches a higher orientation than the α phase, and stems from crystallization upon tension of the polymer. For nylon-6, although the γ phase also appears during drawing, at the maximum draw ratio only a small fraction is present. This difference is attributed to the relative stability of the two phases, which is different for nylon-6 than for nylon-11.

Key words: orientation, X-ray diffraction, nylon, hydrogen bonds.

Résumé : L'effet d'un étirement uniaxial sur l'orientation des cristaux de deux polymères formant des liaisons hydrogène, soit le nylon-6 et le nylon-11, a été étudié par diffraction des rayons X. Ces deux polymères possèdent des phases cristallines semblables, bien que la densité de liaisons hydrogène diffère. Pour les deux polymères, la déformation se produit en deux étapes, la première étant une déformation plastique des sphérolites de la forme α. Ceci conduit à l'existence de deux populations de cristaux, un orientée avec l'axe de chaîne parallèle à la direction d'étirement, l'autre avec l'axe *a* (direction des liaisons hydrogène) parallèle à cette même direction. Dans le second stade, il y a bascul des cristaux ayant l'axe *a* orienté avec l'axe d'étirement, résultant en une orientation uniaxe où l'axe de chaîne est orienté avec la direction d'étirement. Pour le nylon-11, ce stade correspond à l'apparition de la phase γ, qui devient rapidement majoritaire. Celle-ci est plus orientée que la phase α, et son apparition est attribuée principalement à la cristallisation sous tension du polymère. Pour le nylon-6, la phase γ apparaît aussi en cours d'étirement, mais elle reste minoritaire. Cette différence est attribuée à la stabilité relative de ces deux phases, qui est différente pour le nylon-6 et pour le nylon-11.

Mots clés : orientation, diffraction des rayons X, nylon, liaisons hydrogène.

Introduction

Polymers have become some of the most widely used materials in industry. They were first used as cheap substitution materials for more noble substances, but they are now firmly entrenched in high-technology applications. One way of modifying the properties of these materials is via orientation. The polymer chains, when submitted to an external force or when in a liquid-crystalline state, will change directions. The final morphology can be characterized in terms of orientation of the chain axis along the draw direction(s). Classical orientation techniques, such as drawing or compression, lead to limited orientation as compared to the theoretical maximum values. Specific techniques such as gel (1) and liquid-crystalline spinning (2), ram extrusion (3), and solid-state roll-drawing (4) from the melt–gel or rubbery state have been developed to overcome such limitations. These lead to ultra-high orientation in polymers that have Young moduli close to theoretical values along the direction of the chain axis (close to that of steel for polyethylene).

Even when the orientation is more moderate, mechanical properties become anisotropic. Orientation is detrimental in the case of injection-moulded parts where preferred orientation in one direction leads to weaknesses in other directions. Orientation is, however, desirable in fibres and films, and post-extrusion drawing in one or many directions is standard procedure to achieve optimal properties for these samples. Film blowing is also used to produce biaxial orientation,

which leads to superior mechanical properties. Other properties, such as gas permeability, impact strength, barrier, shrinkage, optical properties, and so forth, can also be modified when inducing orientation in a polymer sample.

Previous work by some members of our group has focussed on the effect of hydrogen bonds on orientation of amorphous polymers (5, 6). In the present work, hydrogen-bond-forming semicrystalline polymers will be studied. The orientation of semicrystalline polymers is governed mainly by crystal fracture and transformation mechanisms, leading to a fibrillar structure (7).

The two polymers chosen for this study, nylon-6 and nylon-11, are both commercial polyamides that differ by the length of their aliphatic segment, and therefore by the density of hydrogen bonds vs. van der Waals interactions. This has a profound influence on various properties of the polymer, in particular the melting temperature and water absorption, which are lower for the polymer having the lowest density of hydrogen bonds, nylon-11. What influence this may have on orientation at relatively low deformation rates is unknown, and will be the focus of this article.

Structurally, these polymers adopt similar crystal packings, the so-called α and γ phases being the most documented, although many variations have been reported. Nylon-6 has been studied throughly in this respect, and reviews of the various crystal forms proposed are available in the literature (8, 9). The α phase is characterized by an all-*trans* fully extended conformation of the chains. This crystal structure was first resolved for nylon-6 by Holmes, Bunn and Smith (10). Aélion proposed the first crystal structure for nylon-11 (11), but many alternate structures were proposed later (12, 13), and no clear consensus exists as to which better describes the actual experimental data.

The γ phase can be obtained by treatment of nylon-6 with KI–I_2 (14), by annealing (15) or by melt spinning at very high speeds (16). This structure is a twisted or pleated-chain conformation, which exhibits a repeat distance shorter than that of the all-*trans* α phase. The aliphatic segment itself is in an all-*trans* conformation, the twist being located between the amide group and the aliphatic segment. This conformational change was confirmed by the frequency shift of the amide V vibration (17, 18).

In the case of nylon-11, it has been shown that converting the α form into the γ form was possible at elevated temperatures or pressures (19) or by chemical treatment (20). At 95°C and 1 atm (= 101.3 kPa), the γ form was observed, whereas at room temperature and pressure, it is the α form that is usually obtained.

It is well known that changes in crystallinity and crystal structure are liable to occur during deformation of a crystalline sample. In the case of PBT (21), this change has been shown to be reversible, the β phase being obtained only as long as an extensional force is applied on the fibers. Upon removal of this force, the structure reverts to the more stable α phase. In other cases, such as PET, crystallization is induced during deformation.

In the present study, the evolution of orientation of various diffraction planes of nylon-6 and nylon-11 will be followed with respect to crystal phases present and draw ratio. Because of the industrial importance of nylon-6, countless papers dealing with almost every aspect of this polymer have been published. Orientation is no exception, and will not be reviewed fully here. The reader is referred to the review by Perkings and Porter (22) on solid-state deformation, by Peterlin (23) on drawing and extrusion of semicrystalline polymers, and on more recent work on nylon-6 by Galeski, Argon, and Cohen (24) for a brief overview of the orientation studies published in the literature concerning nylon-6. Nylon-11 has, however, been studied very little in these respects. It must therefore be stressed that although the behavior of nylon-6 has already been studied throughly by previous authors, it is reported here, processed under the same conditions as nylon-11, as a comparison point to nylon-11 and to highlight differences related to changes in the hydrogen bond content. This will allow a better understanding of the characteristics of these hydrogen-bond-forming polymers.

Experimental

Polymers used in this study

Nylon-6 used for this study was Zytel Z11 NC010 from Du Pont (melting temperature T_m = 220°C, glass transition temperature T_g = 50°C). For nylon-11, Elf Atochem Besno was used (T_m = 180°C, T_g = 46°C). The polymer granules were first dried under vacuum at 95°C during 24 h. Films were prepared using a Carver press at T = 230°C for nylon-6 and 200°C for nylon-11, which was followed by a slow cooling in order to relax the compression-induced orientation and to allow optimal crystallization of the polymer. Film dimensions prior to stretching were 10 mm in width, 65 mm in length, and 0.5 mm in thickness.

These films were stretched at a constant speed of 5 mm/min on an Instron machine. Stretching temperature was 80°C for both nylons. Samples were air-quenched after stretching, to limit orientation relaxation immediately after cessation of deformation.

An amorphous sample of nylon-6 was obtained by rapid cooling of a pressed sample. The diffraction spectrum was registered immediately in the case of this sample, in order to avoid any recrystallization.

Electron diffraction

Samples for electron diffraction were obtained by epitaxial crystallization on benzoic acid, hydroxyquinone, and polytetrafluoroethylene following the technique described in ref. 25. The substrate was placed on a glass slide, the polymer deposited in the form of solutions in trifluoroacetic acid, and a second glass slide deposited over the polymer. Samples were heated above melt temperature and cooled slowly. A few samples were subjected to annealing at 150°C followed by slow cooling. Samples were deposited on carbon-coated electron diffraction grids and observed under low-dose conditions on a Philips CM12 transmission electron microscope functioning at 120 kV, resulting in a wavelength of approximately 0.03 Å for the electron beam.

X-ray diffraction

X-ray diffraction of the stretched polymers was performed using a Rigaku RU200 B rotating anode generator functioning at 55 kV and 190 mA with copper Kα Ni-filtered radiation and equipped with a scintillation counter. The θ–2θ geometry was used for both 2θ scans and for orientation

© 1998 NRC Canada

scans, θ being the diffraction or Bragg angle and 2θ the angle between the diffracted beam and the direct beam. For orientation scans, the sample and detector were fixed at the θ–2θ geometry corresponding to a given diffraction plane, and the sample was slowly rotated about the normal to its surface from χ = 0°(equator position) to χ = 90° (meridian position). The χ value thus experimentally obtained corresponds to the angle between the normal to the lattice plane considered and the machine direction.

Calculation of the orientation function $\langle P_n \rangle$

The orientation function $\langle P_n(\cos\chi)\rangle$ was calculated using various diffraction planes by fitting the observed azimuthal intensity of a given diffraction plane to a Legendre polynomial series $P_n \cos\chi$. In all cases, the value is reported for the orientation of a given diffraction plane with respect to the draw or machine direction. The observed coefficients are first calculated for a given reflection using the following equation:

$$[1] \qquad \langle P_n(\cos\chi)\rangle_{obs} = \frac{\int_0^{180} I(\chi)\, P_n(\cos\chi)\, \sin(\chi)\, d\chi}{\int_0^{180} I(\chi)\, \sin(\chi)\, d\chi}$$

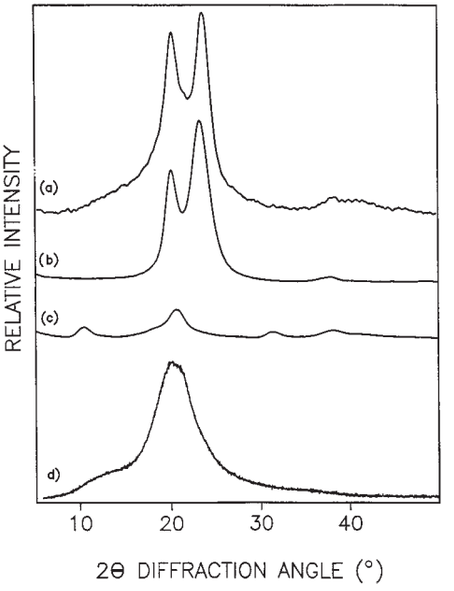
$I(\chi)$ is corrected for background scattering prior to calculation of $\langle P_n(\cos\chi)\rangle_{obs}$ by determining the baseline by linear interpolation of the intensity on the θ–2θ scan before and after the maximum of the peak under consideration.

When samples exhibit uniaxial symmetry, it is customary to report the orientation of the chain axis with respect to the draw direction. When the peak used for the calculation in a uniaxially oriented sample is centered at the meridian (which corresponds to an azimuthal value of 90°), the $\langle P_n(\cos\chi)\rangle_{obs}$ values correspond directly to the orientation functions along the chain axis, $\langle P_n(\cos\chi)\rangle_{chain}$. If this is not the case, the following relationship first proposed by Lovell and Mitchell (26) can be used to derive $\langle P_n(\cos\chi)\rangle_{chain}$ values for uniaxially oriented samples:

$$[2] \qquad \langle P_n(\cos\chi)\rangle_{chain} = \frac{(-1)^n\, 2^{2n}\, (n!)^2\, \langle P_n(\cos\chi)\rangle_{obs}}{(2n)!}$$

The $\langle P_n(\cos\chi)\rangle_{chain}$ values are used to compare orientation of different systems and will be abbreviated $\langle P_n\rangle$. Although X-ray diffraction gives access to the whole range of $\langle P_n\rangle$ values (values for $\langle P_2\rangle$ to $\langle P_{32}\rangle$ have been reported for polyethylene), for samples that do not exhibit ultra-high orientation, the use of the second moment of the orientation function $\langle P_2\rangle$ is sufficient, and will be the only orientation factor reported in this study. This value corresponds to Herman's orientation factor. $\langle P_2\rangle$ values range from 1.0 for a perfect orientation of the chain axis along the draw direction to –0.5 for a perfect orientation with chain axis perpendicular to the draw direction, while an isotropic sample yields a value of zero.

Fig. 1. X-ray diffraction scans of nylon-6: (*a*) unoriented sample; (*b*) oriented sample (λ = 3.0), equatorial scan (χ = 0°); (*c*) oriented sample (λ = 3.0), meridional scan (χ = 90°); (*d*) unoriented amorphous sample.



Results and discussion

Choice of conditions for deformation and orientation measurements

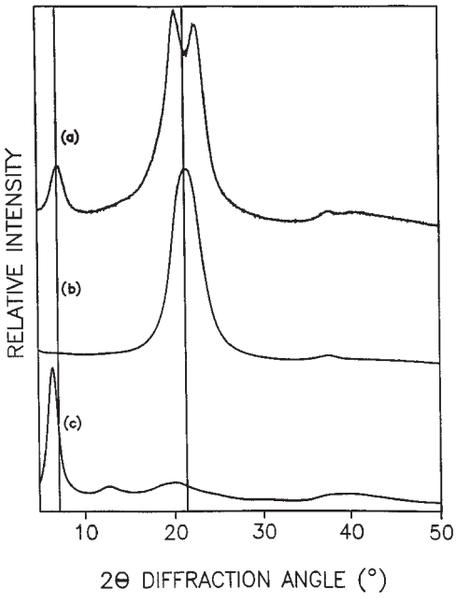
Draw conditions influence markedly the final morphology and orientation of the samples. A single draw temperature was chosen for both polymers in this study (80°C, which is 30°C above T_g for nylon-6 and 34°C above T_g for nylon-11). When comparing the orientation of amorphous polymers, it is customary to report the deformation temperature with respect to T_g. The choice of a unique draw temperature, in this case, was prompted by the desire to avoid necking, which would preclude studies at low deformation. For the same reason, a slow deformation speed, 5 mm/min, was chosen. This value is the same as was used in a previous study by Peterlin (28). In all cases, the samples studied did not exhibit any detectable necking.

As reported in previous work on nylon-6 (29) and on other semicrystalline polymers (30), at low deformation ratios there is a certain degree of biaxiality in the deformation process in spite of the fact that the force is applied uniaxially. This disappears at higher deformation ratios, where true uniaxial symmetry becomes apparent This has been linked to a morphology-related deformation mechanism in semicrystalline polymers (30). It was therefore decided to follow the orientation of reflections pertaining to different axes of the unit cell. It was also necessary to verify which crystal form was present in both the initial nonoriented samples and in the final oriented samples since, as mentioned in the introduction, both nylon-6 and nylon-11 can exhibit polymorphism.

As can be seen from Fig. 1, for nylon-6, no change in the diffraction spectra (other than changes in relative intensity)

© 1998 NRC Canada

Fig. 2. X-ray diffraction scans of nylon-11: (*a*) unoriented sample; (*b*) oriented sample (λ = 3.0), equatorial scan (χ = 0°); (*c*) oriented sample (λ = 3.0), meridional scan (χ = 90°).



was seen between the unoriented sample and the sample with a draw ratio λ of 3.0. The presence of two intense peaks on the equator (spectrum taken at χ = 0°) at 20.3° (*d* spacing = 4.37 Å) and 23.4° (*d* spacing = 3.80 Å) is a clear indication that the α form dominates. The γ form, when present, yields a single intense peak at an intermediate position of 21.5° (*d* spacing = 4.13 Å) on the equator, as well as a medium-intensity peak on the meridian, at a position of 10.6° (*d* spacing = 8.35 Å). To ascertain whether this crystal phase is present or not, the latter peak is the most useful. A weak peak can be observed at this position on the meridional scan (spectrum taken at χ = 90°), indicating that a small amount of the γ form has indeed appeared during stretching. Changes from the α to the γ form have been reported previously, for instance in the study by Stepaniak, Garton, Carlsson, and Wiles (31) on extrusion combined with in-line drawing. This phase can, however, be detected only at relatively high draw ratio (from λ = 3.0 and higher), and only in small quantity, which makes the characterization of its orientation difficult. It has therefore not been studied in the present work.

The unit cell proposed by Holmes, Bunn, and Smith was used for indexation of the diffraction peaks of the nylon-6 α form (monoclinic, *a* = 9.56 Å, *b* = 17.24 Å (chain axis), *c* = 8.01 Å, β = 67.5°). The peak positioned at 20.3°, which is assigned to the 200 plane of the α form, is almost perfectly superimposed with the amorphous phase scattering halo, which would definitely cause an important underestimation of the orientation function. It was, however, used to follow qualitatively the evolution of orientation for the *a* axis of the unit cell, which is parallel to the direction of the hydrogen bonds. The peak at 2θ = 23.4° is due mostly to the 002 plane of the α phase, although the 202 plane also contributes to a much smaller extent to its intensity (32). It is the most intense peak of the spectra and is only slightly superimposed with that of the amorphous halo. It was therefore used to ascertain the relative orientation of the *c* axis. This crystallographic axis is roughly perpendicular to the hydrogen-bonded sheets of molecules. Finally, the 0 14 0 peak, positioned at 2θ = 77.4° (*d* spacing = 1.23 Å), will be used to follow the orientation changes along the chain or *b* axis. Although it has a relatively low intensity and is situated at a high 2θ position, at which broadening due to crystal defects and crystal size is often quite important, it offers the advantage of being characteristic of the α phase and of not being superimposed with peaks of the amorphous halo.

In the case of nylon-11, as can be seen from Fig. 2, it soon became evident that the orientation behaviour would be less straightforward, but also more interesting to study. The sample showed two intense peaks at 2θ = 20.5° and 23.5° prior to orientation, characteristic of the α phase, as expected. Upon orientation, only one intense peak remained on the equatorial scan (χ = 0°), at an intermediate angle of 21.5° (*d* spacing = 4.13 Å), which is typical of the γ phase. At the same time, the small peak observed at 7.0° (*d* spacing = 12.63 Å) for the unoriented sample is gradually superseded by a medium-intensity peak at 6.3° (*d* spacing = 14.0 Å) on the meridian spectrum (χ = 90°). At the end of the stretching procedure, the γ phase clearly forms the major phase in the samples. It is striking that under the same processing conditions, the γ form is much more favoured for nylon-11 than for nylon-6, which may be related to the relative stability afforded to the γ phase by van der Waals interactions for longer aliphatic segments. Newman, Sham, and Pae (19) showed that, for nylon-11, a reversible phase transition occurs from the α to the γ phase at 95°C, a temperature only slightly above that used for drawing in the present work (80°C). Under drawing conditions, the transition temperature may become lower, which would explain the predominance of the γ form in our samples. The transition, in this case, may not have been reversible because of the quenching procedure used to limit relaxation.

Since it was evident that the γ crystal phase becomes predominant upon orientation, it was imperative to follow the orientation of this phase for nylon-11. Positions for the maximum intensity of various diffraction planes of each of the two phases were selected. It was impossible to choose a position where no superimposition was present because of the intrinsic width of the diffraction peaks for polymers, of the presence of a large amorphous halo centred around 20°, and because of the proximity of most peaks in the diffraction spectra. For the α phase, peaks centred at 7.0°, 20.5°, and 23.5° were selected, which correspond to the 001 (chain axis), 120 (direction of hydrogen bonds), and 020 + 220 (which should correspond, by analogy to nylon-6, to the direction perpendicular to the hydrogen bonds) diffraction planes in the unit cell proposed by Hasegawa, Kimoto, Chatani, Tadokoro, and Sekiguchi (33) (triclinic, *a* = 9.5 Å, *b* = 10.0 Å, *c* = 15.0 Å, α = 60°, β = 90°, γ = 67°). This unit cell gave the best fit with our experimental data, especially in the case of the 7.0° diffraction peak. For the γ phase, the unit cell selected to represent the data is that proposed by Kawagushi, Ikawa, Fujiwara, Tabuchi, and Monobe (34) (*a* = 9.48 Å, *b* = 29.4 Å, *c* = 4.51Å, β = 118.5°). The peaks centred at 6.3° and 21.5°, corresponding to the 020 (chain axis) and 200 diffraction planes (attributed to the direction

of hydrogen bonds by analogy to nylon-6), were used for estimation of the orientation.

Qualitative description of the orientation changes upon deformation

Using the 2θ peak positions selected in the previous section, orientation scans were measured and are grouped according to direction in the unit cell. Figure 3 contains spectra related to chain axis orientation, Fig. 4 to orientation perpendicular to the hydrogen bond direction, and Fig. 5 to orientation parallel to the hydrogen bonds. In all of these spectra, it must be emphasized that the baseline does not correspond to the position at which the minimum intensity occurs: baseline is considerably lower for low-draw ratio samples, corresponding to the fact that, at the low orientation achieved in these samples, a small number of crystals segregate to a preferred orientation, the rest remaining dispersed along all azimuthal angles. Peak areas are therefore insufficient to quantitatively compare the orientation, and spectra are only reported to compare the deformation behaviour at low orientation.

As can be seen in Fig. 3, for nylon-6 and both phases of nylon-11, the chain axis orientation evolves in a constant fashion, with the appearance of a maximum in intensity at χ = 90°, as expected. At very low orientation (λ = 1.25), one can barely distinguish two maxima centred at 60° and 120° for the nylon-6 and 70° and 110° for the nylon-11 α forms. The γ form differs, the orientation always being along the chain axis and χ remaining, within experimental error, centred at 90°. This indicates that, as previously reported for nylon-6 by Galeski, Argon and Cohen (29), for the α phase of both nylon-6 and nylon-11, at the beginning of stretching, orientation does not occur only along the chain direction. For nylon-11, the small fraction of γ phase at λ = 1.25 and the low intensity of this peak do not allow us, with any certainty, to draw conclusions on the deformation mechanism from the data presented here.

The peaks corresponding to the orientation perpendicular to the hydrogen bonds are presented in Fig. 4. Orientation evolves in a continuous and very comparable fashion for nylon-6 and both forms of nylon-11. Orientation is easier to detect on the λ = 1.25 spectra than in the case of the chain axis, an indication that orientation is stronger in this direction, giving rise to a broad peak centred around 25° and 155°. As the stretching proceeds further, this maximum shifts towards the final position of 0° and 180° for this peak maximum.

Orientation scans parallel to the hydrogen bonds are reported in Fig. 5. The information is unavailable for the nylon-11 γ form, since no peaks with sufficient intensity have been isolated in this case. Nylon-6 and nylon-11 (α form) behave similarly, albeit in a completely different manner than that depicted for the planes perpendicular to the hydrogen bonds. Orientation first proceeds along χ = 90° at low draw ratio with an intensity similar to that of the direction perpendicular to the hydrogen bonds and, again, much larger than that along the chain axis direction. As the draw ratio is increased, a second population appears centred around 0° for nylon-6 and 30° for nylon-11. The population of crystals with planes parallel to the draw direction decreases as orientation proceeds, whereas the reverse is true for the second

Fig. 3. Chain axis orientation scans: (*a*) nylon-6, (0 14 0) diffraction plane (2θ = 77.4°); (*b*) nylon-11, α phase, (0 0 1) diffraction plane (2θ = 7.0°); (*c*) nylon-11, γ phase, (0 2 0) diffraction plane (2θ = 6.3°).

Fig. 4. Orientation scans of planes perpendicular to hydrogen bonds: (*a*) nylon-6, (0 0 2) diffraction plane (2θ = 23.5°); (*b*) nylon-11, α phase, (0 2 0) + (2 2 0) diffraction planes (2θ = 23.5°); (*c*) nylon-11, γ phase, (2 0 0) diffraction plane (2θ = 21.5°).

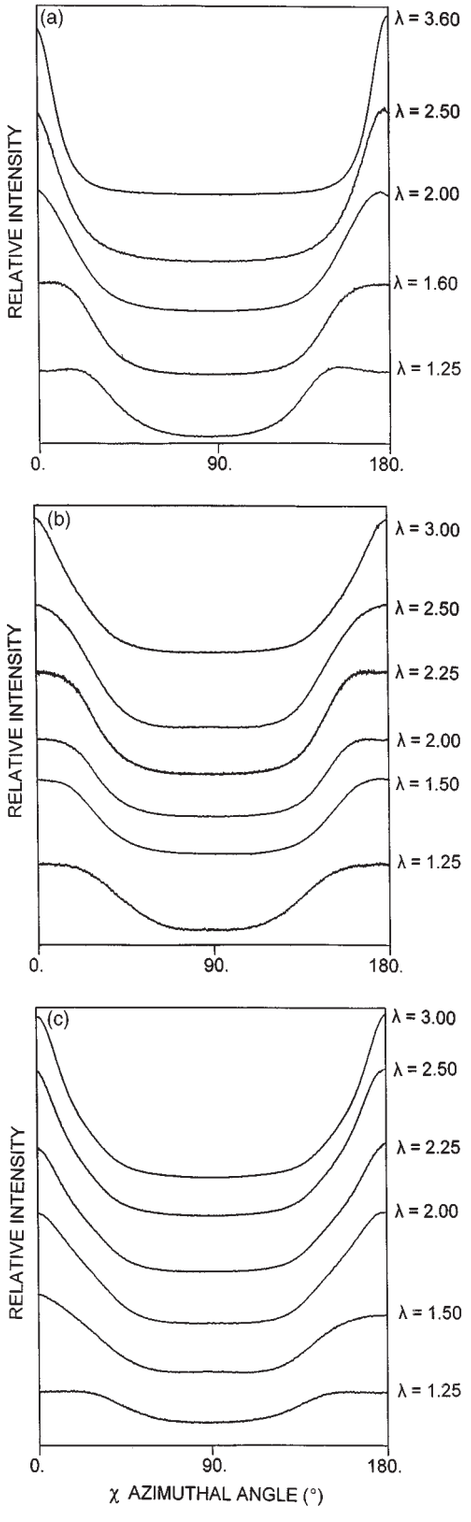

Fig. 5. Orientation scans of planes parallel to the hydrogen bonds: (*a*) nylon-6, (2 0 0) diffraction plane (2θ = 20.1°); (*b*) nylon-11, α phase, (1 2 0) diffraction plane (2θ = 20.3°).

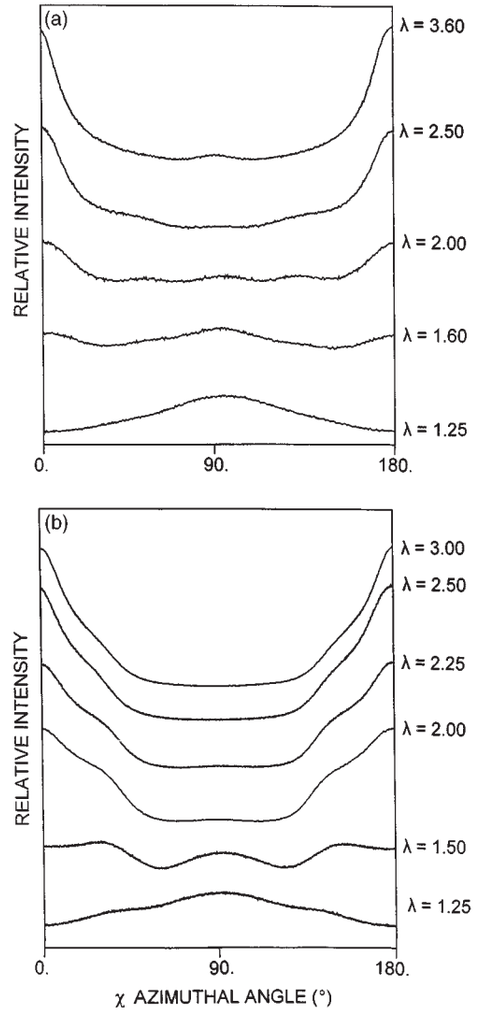
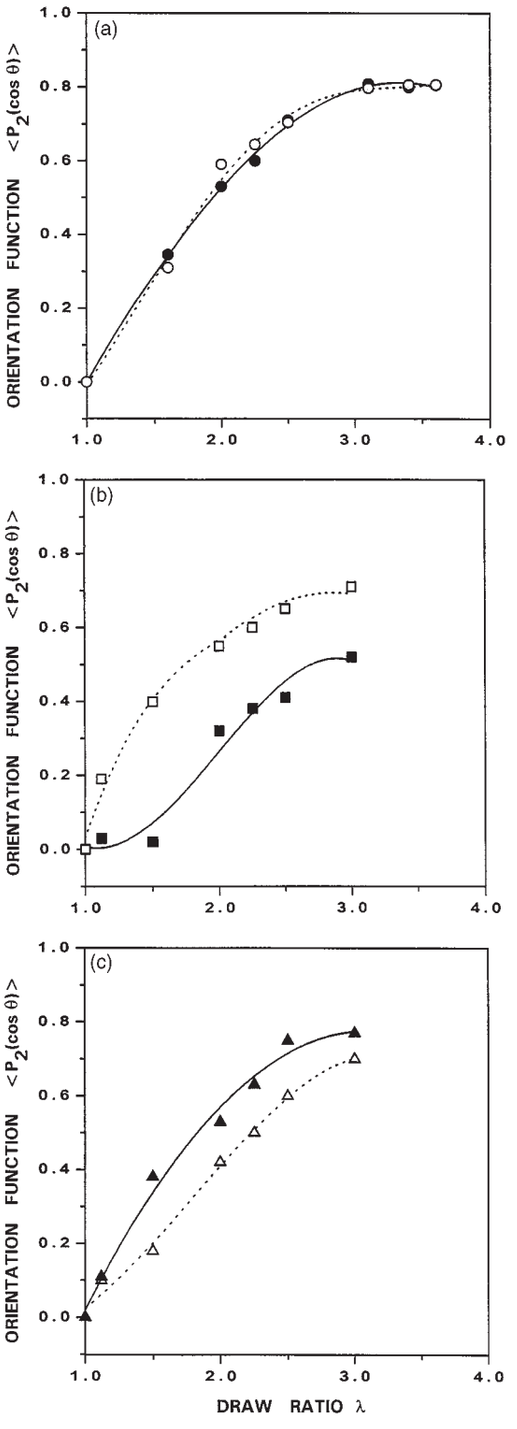


population whose planes are perpendicular to the draw direction. In the case of nylon-11, a third population appears near λ = 2, centred at χ = 0°, and supersedes the two previous ones. At maximum draw ratio, for nylon-6, there remains only a small peak at χ = 90°, but it is unclear whether this is due to a separate diffraction peak or to residual crystals in the first population. For nylon-11, on the other hand, no peak remains at χ = 0°, but a strong shoulder is seen at χ = 25°.This shoulder is attributed to the 210 reflection, and, accordingly, will alter the value obtained for $\langle P_2 \rangle$ unless it is removed prior to calculations. Therefore, this peak position has not been used for quantitative evaluation of the orientation function.

A full description of the deformation mechanism at low deformation would require acquisition of pole figures (which have already been reported in the case of nylon-6 by Galeski, Argon, and Cohen (29)), and is not the aim of this article. Furthermore, at low deformation, the orientation mechanism strongly depends on the initial morphology of the samples (35), the complexitiy of which has been fully

© 1998 NRC Canada

Fig. 6. Evolution of orientation with draw ratio λ (filled symbol = chain axis, open symbol = perpendicular to hydrogen bonds): (*a*) nylon-6; (*b*) nylon-11, α phase; (*c*) nylon-11, γ-phase.



demonstrated (36). Nevertheless, one of the main observations stemming from this work, and one that was possible because the drawing and measurement conditions are the same for both polymers, is the striking similarity in behaviour of the α phase of both nylon-6 and nylon-11, as can be seen in Figs. 3–5. It is also interesting to note that, at low deformation, the axis parallel to the hydrogen bonds and, to a much smaller extent, the chain axis show a tendency to align along the machine or draw direction. The direction perpendicular to the hydrogen bonds remains resolutely perpendicular to the draw direction throughout the drawing process. The fact that the two long axes of the crystallites, the directions parallel and perpendicular to the hydrogen bonds, are those that yield the highest orientation function, points to a deformation mechanism in which the hydrogen-bonded platelets act as the structural rigid unit. These deform along the draw direction, leading to a morphology reminiscent of the cross-β texture observed for fibrous proteins (37). Spherulite deformation modes have been discussed in detail by Samuels (30), and have been shown for polypropylene to yield, through intraspherulite rearrangements, two crystal populations. Similar rearrangements could explain the chain axis orientation and the appearance of peaks off the equatorial and meridian in the first deformation stage.

At higher deformation, crystals deform or tilt and the hydrogen bond direction aligns along the equatorial, the chain axis becoming more and more oriented in the stretching direction, yielding a typical uniaxial orientation. This behaviour corresponds well with the orientation model proposed by Peterlin (38). The first step is a plastic deformation of spherulites, which occurs for nylon-6 below λ = 2 according to this author (28). In the second step, the lamellae stacks are destroyed and unravel to form microfibrils, with the chain axis orienting in the draw direction. In the case of the polymers studied here, the first step would correspond to the initial stage where both the chain axis and the hydrogen bond direction orient along the draw direction.

The present data concerning the appearance of the γ phase confirm a previous pole figure study of nylon-6 by Galeski, Argon, and Cohen (29). However, the morphology they report is much closer to uniaxial than that observed here. This may be due to the higher draw ratio of the samples they have studied (λ = 2.16), which lies, for nylon-6 (28), near the limit for the first step of the mechanism proposed by Peterlin. Differences in initial morphology of the samples may also cause discrepancies between their observations and the present work.

For the γ form of nylon-11, it is not possible to draw conclusions about the exact mechanism of deformation at low draw ratio, due to the uncertainty of the assignment of the 21.3° peak and to the low intensity of the peak used to follow chain axis orientation.

Quantitative description of the orientation changes upon deformation

Using the various diffraction scans studied, the orientation function $\langle P_2 \rangle$ was evaluated quantitatively. Two peaks can be used to quantify the orientation for nylon-6: the 0 14 0 peak and the 002 peak. The 200 peak is superimposed with the amorphous phase in such a way that all attempts to use this peak quantitatively failed. Results for these two peaks appear in Fig. 6*a* and yield, within experimental error, the same $\langle P_2 \rangle$ values. The maximum $\langle P_2 \rangle$ value achieved, 0.81, is relatively low for a crystalline phase, and considerably lower than those reported for nylon-6 in the literature, which are closer to the ideal value of 1.0. For example, Sakaoku,

Fig. 7. Comparison between orientation changes and draw ratio λ for nylon-6 and nylon-11 (○, nylon-6, perpendicular to hydrogen bonds; □, nylon-11, α phase, perpendicular to hydrogen bonds, ▲, nylon-11, γ phase, chain axis).

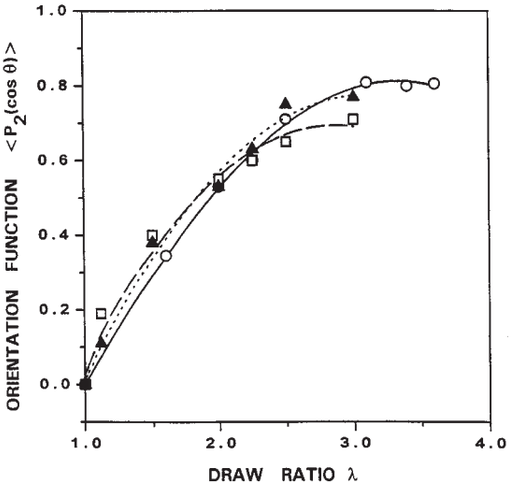

Fig. 8. Changes in the relative intensity of the α-phase diffraction plane and of the γ-phase diffraction plane upon deformation for nylon-11 (■, α form, ▲, γ form).

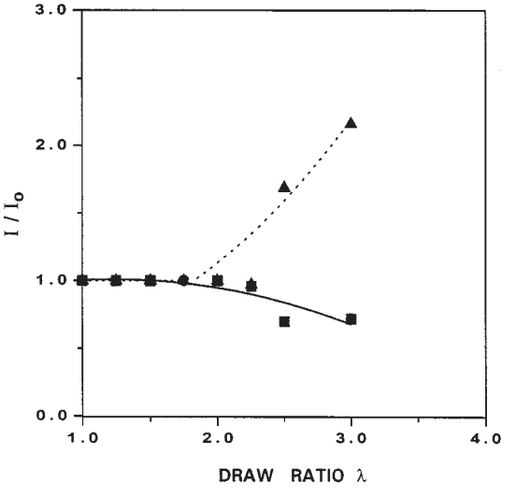

Morosoff, and Peterlin (39) report a value of 0.97 for λ = 5. The lower value we obtain is proposed to stem from differences in the processing conditions, and in particular to the fact that no annealing was performed in the present work after drawing.

Orientation functions for nylon-11 are reported in Figs. 6*b* (α phase) and 6*c* (γ phase). In these cases, considerable variations result from the use of different diffraction peaks for the same phase. For the α phase, orientation reaches a maximum value of 0.73 for the second moment of the orientation function $\langle P_2 \rangle$ when measured using the 020 peak at 23.4°, whereas a much lower value of 0.52 is obtained when calculating, using the diffraction peak on the meridian. It is proposed that this lower value is due to a slight shift of the ideal position of the peaks at 7.0° with respect to the azimuthal angle. Although the experimental value is positioned at 90°, calculations using previously proposed unit cells yield an azimuthal angle of 75°. The use of a wrong χ angle causes an underestimation of the orientation function, which could be corrected using the equation of Mitchell and Lovell. Therefore, correct $\langle P_2 \rangle$ values should be obtained using the 23.4° reflection.

For the γ phase, the reverse is observed. The maximum value of 0.77 is obtained when using the 6.3° meridional diffraction peak. In this case, this is attributed to an important overlap with the amorphous phase at approximately 21.4°, leading to a lower calculated value of 0.70. Since it is well known that the amorphous phase is less oriented than its crystalline counterpart, this superimposition leads to an underestimation of the actual orientation of the crystalline phase. For this phase, the correct $\langle P_2 \rangle$ values are therefore obtained using the 6.3° reflection.

A comparison of the orientation functions obtained for nylon-6 (23.4° peak), nylon-11 α phase (23.4° peak), and nylon-11 γ phase (6.3° peak) is shown in Fig. 7. As can be seen, although the maximum draw ratio is lower for nylon-11 than for nylon-6, the maximum orientation is comparable, being slightly lower (0.73 vs. 0.77) for the nylon-11 α phase. At low orientation, the α phase of nylon-6 shows a tendency to orient more rapidly than both nylon-11 and the nylon-11 γ form, although this may simply be related to differences in orientation mechanism at the stretching onset.

It is interesting to note that, for nylon-11, a higher orientation is achieved for the γ phase than the α phase. To determine the significance of this observation in terms of deformation mechanism, it is necessary to determine whether the γ phase observed comes only from the crystalline transformation from the α to the γ phase, or whether it can also be attributed to recrystallization of amorphous domains.

Evaluation of the crystal phase change upon orientation

During orientation, the relative proportion of amorphous, crystalline α, and crystalline γ phases also varies, as was observed qualitatively in Fig. 2. Because of severe overlaps, it is difficult to precisely quantify these changes. This is particularly true of the region between 20° and 24°, where peaks stemming from the amorphous phase and the crystalline α and γ phases overlap extensively. Although it is possible to conduct a deconvolution, it was preferred in the present work to rely on the less overlapped region between 6° and 8°, which is amenable to semiquantitative evaluation. The values obtained are fraught with intrinsic error, as differences in width and therefore perfection or size of crystals between the two crystal forms are not taken into account. A further limitation is that the total intensity of the peak is assumed proportional to that of a single χ angle position, which would be true only if no change in crystal size or perfection occurred during drawing, a factor that has not been evaluated quantitatively in the present work. These approximations are expected to have only a small impact on the actual values in this case, since the starting material is crystalline, and since changes in peak width were not observed for this spectral region, as can be verified in Fig. 2. The intensity I of the 020 and 001 peaks was integrated along the χ angle at a fixed 2θ angle (6.3° and 7°, respectively) and compared to the intensity measured for an unoriented sample I_o. The I/I_o ratio is reported with respect to the draw

Fig. 9. Electron diffraction pattern of nylon-11, α-phase, epitaxially grown on benzoic acid.

ratio in Fig. 8, and measures the relative increase in intensity of each peak. As can be seen, the proportion of α and γ phases does not vary, within experimental error, until a draw ratio of 2.25 is reached. Once this value is passed, however, the intensity of the γ phase clearly increases, reaching a value of 2.2 at λ = 3. The fraction of γ phase present has therefore more than doubled. Meanwhile, this ratio decreases only slightly for the α phase, going down to a value of 0.7. Although the relative intensity of the γ-phase peak is intrinsically larger than that of the α-phase peak, as seen in Fig. 2, crystallization of the α phase is still not sufficient to explain such a large increase in γ phase. It is therefore proposed that the appearance of the γ phase is due in large part to conversion of amorphous or interfacial domains in this new crystalline form, whereas a certain amount of α phase is also converted during deformation to the γ phase.

Epitaxial crystallization was performed on various substrates for nylon-11, using a crystallization temperature close to that used for drawing, in an attempt to obtain more information on the unit cell of nylon-11 for both the α and the γ phases. A typical photograph of diffraction patterns obtained in this way is presented in Fig. 9. Only few diffraction spots are present on the equator, which excludes a fiber-type orientation. Only the 6th and 12th strata appear with good intensity, and meridian or quasi-meridian reflections appear at 1.13 Å, a distance characteristic of a projection of the carbon–carbon bond distance upon the chain axis. Tilting of the samples results in the appearance of equator diffraction spots with *d*-spacings of 4.40 and 3.73 Å. These observations are consistent with a superimposition of two distinct orientations of the α phase. In the first, the hydrogen-bonded sheets are parallel to the substrate, giving rise to a typical *hk*0 diffraction pattern similar to that observed for polyglycine (40) (*c* being taken as the chain axis). Additional reflections are observed and were attributed, again by comparison with polyglycine, to crystals tilted by 90° from this orientation. This is typical of two *hk*0-twinned unit cells, one growing on the crystal surface of the epitaxic substrate, the second growing on the edges of the crystal substrate, the "*a*" direction being common to the two and acting as the growth direction for crystals.

Various attempts were made to obtain the γ phase, including annealing at various temperatures from 80 to 170°C, followed by rapid quenching. In all cases, only the α phase was observed in the final samples. This again confirms that, whether the γ phase emerges because of temperature-driven phase transition or not, drawing is essential to its stabilization in melt-processed samples and to its consequent observation at room temperature. This does not exclude the possibility that draw temperatures play a role in the relative proportions of the α and γ phases.

Most γ-phase crystals are proposed to stem from draw-induced crystallization. Since, as mentioned previously, the γ phase is more oriented than the α phase, it is concluded that, in this case, stress-induced crystallization yields a higher orientation than deformation of existing crystals. This is in agreement with observations made on nylon-6 by McKerron (41).

Conclusions

Comparison of two hydrogen-bond forming polymers, nylon-6 and nylon-11, which differ mainly by the length of the aliphatic segment and by the relative density of hydrogen bonds, shows that these factors have little effect on the deformation mode in the first deformation stage (up to approximately λ = 2). Orientation proceeds in a remarkably similar fashion. Deformation mechanisms strongly depend on the initial morphology of the sample and deformation conditions. In terms of morphology, for the two polymers studied, this study shows the importance of the initial crystal phase, in terms of chain packing and organization of hydrogen-bonded sheets.

Maximum orientation is also similar, although a slightly smaller maximum draw ratio was achieved for nylon-11. The main difference in the behaviour of these polymers upon orientation lies in the relative amount of the γ phase that appears during crystallization. The onset of crystallization appears clearly around λ = 2 for nylon-11, therefore at the end of the first plastic deformation stage and at the onset of crystal unravelling to form the microfibrillar morphology. The γ phase soon supersedes the initial α phase for nylon-11, partly by the occurrence of stress-induced crystallization. The initial α phase decreases, indicating that some of the γ crystals are obtained by a solid-state phase transition at the draw temperature. In the case of nylon-6, as previously

© 1998 NRC Canada

reported in the literature (29), only a small fraction of the γ phase appears at higher draw ratios. These differences in crystallization are attributed to the relative stability of each phase and are believed to be related to the hydrogen and van der Waals interaction energies, which are different for the two polymers.

Acknowledgements

This work was made possible through the financial contribution of the Natural Sciences and Engineering Research Council of Canada (NSERCC) and the Fonds pour la formation des chercheurs et l'aide à la recherche (FCAR) of the government of Québec. The authors would also like to thank Annette Thierry for her help in technical aspects of sample preparation for electron microscopy.

Phase behaviour of model stratum corneum lipid mixtures: an infrared spectroscopy investigation

Michel Lafleur

Abstract: The stratum corneum, the top layer of the epidermis, is the material that constitutes the membrane enveloping our body. The lipids that are present are responsible for the permeability properties of the skin and, as a consequence, are essential to maintain the hydration of the internal components and to protect our body from external agents. In the present work, the mixing and the structural properties of model mixtures formed by the main lipids of the stratum corneum have been examined by infrared spectroscopy. The model is formed by an equimolar mixture of ceramides (type III), cholesterol, and perdeuterated palmitic acid. Binary mixtures as well as mixtures for which the ceramides were substituted by sphingomyelin, a ceramide precursor, have also been studied. The results indicate that the stratum corneum model mixture exhibits a rich polymorphism, ranging from crystalline domains with heterogeneous lipid composition and orthorhombic chain packing, to a fluid and homogeneous phase. To obtain this particular behaviour, the three components are essential and the specific role of each species is discussed. In addition, the results reveal that the homogeneous lipid distribution observed for temperatures higher than 70°C can be maintained at low temperatures, leading to the formation of a metastable phase. Several weeks are needed to obtain the thermodynamically stable phase if the sample is incubated at 5°C. However, it is rapidly induced by annealing the sample at 40°C.

Key words: stratum corneum, lipid, infrared spectroscopy, ceramide.

Résumé : Le stratum corneum, la couche supérieure de l'épiderme, est le matériau constituant la membrane enveloppant notre corps. Les lipides qu'on y retrouve sont responsables des propriétés de perméabilité de la peau et, en conséquence, sont nécessaires au maintien de l'hydratation des composantes internes et à la protection du corps contre les agents externes. Dans le présent travail, les propriétés de mélange et structurales de mélanges modèles constitués des principaux lipides du stratum corneum ont été examinées par spectroscopie infrarouge. Le modèle utilisé est constitué d'un mélange équimolaire de céramides (de type III), de cholestérol et d'acide palmitique perdeutéré. Des mélanges binaires ainsi que des mélanges pour lesquels les céramides sont replacés par la sphingomyéline, un précurseur des céramides, ont été aussi étudiés. Les résultats montrent que le mélange modèle du stratum corneum montre un riche polymorphisme, allant de domaines cristallins hétérogènes du point de vue de leur composition en lipide et où les chaînes possèdent un empilement orthorhombique, à une phase fluide homogène. Pour obtenir ce comportement, les trois composantes sont essentielles et le rôle spécifique de chaque espèce est discuté. De plus, les résultats révèlent que la distribution homogène des lipides obtenue à des températures supérieures à 70°C peut être maintenue à basses températures, conduisant à la formation d'une phase métastable. Plusieurs semaines sont nécessaires pour obtenir la phase thermodynamiquement stable si l'échantillon est maintenu à 5°C. Cependant, celle-ci est rapidement induite par un recuit à 40°C.

Mots clés : stratum corneum, lipide, spectroscopie infrarouge, céramide.

Introduction

The stratum corneum (SC),[2] the top layer of the epidermis, is a material with vital functions since it constitutes the envelope around our body (a membrane of about 20 000 cm^2 for an adult) that tightly controls exchanges with the external world (1–4). It is of particular importance in the case of water, contributing to the preservation of adequate hydration of the internal components, and as protection from the toxins of the external world. The selective permeability of this

biomaterial also represents a permanent challenge in the development of transdermal drug delivery. These physiological functions of the SC make it the main constituent of the *skin barrier*. The SC is formed by the stacking of dead skin cells filled with fibrous proteins and called corneocytes, embedded within a lipid matrix (5, 6). The unique permeability properties of SC have been intimately related to its lipidic portion (2, 7, 8). The organization of the SC has been depicted by the brick (the corneocytes) and mortar (the lipids) model. However, it is now established that the lipidic portion is not an "isotropic mortar" but presents defined structures. To understand the molecular basis of the properties of this material, considerable effort has been devoted to determining the organization of the SC lipids. A significant proportion of the lipids has been found to exist in crystalline domains with an orthorhombic and hexagonal packing (9–12). It has been proposed that these domains would have a crucial impact on the SC permeability (13). The SC lipids undergo a transition from an ordered to a disordered phase between 60 and 80°C (4, 8, 14–16). This transition has considerable impact on the permeability properties: the permeability of the disordered phase is generally greater than that of the ordered one (4, 7, 8) (e.g., a 1000-fold increase for the hydrocortisone permeability is observed upon heating the SC above its transition). Therefore, a lipidic organization appears to be crucial for the permeability properties of the SC.

The lipid composition of SC is peculiar. It essentially comprises a mixture of ceramides (CER), cholesterol (chol) and some derivatives, and free fatty acids (5, 17–19). The ceramides are *N*-acyl-sphingosine, the acyl chain being linked to the head group by an amide group. In vivo, they are partly derived from the sphingomyelin (SPM), which exists in the deeper layers of the skin and which is hydrolysed by a sphingomyelinase during the migration towards the surface (20). The enzymatic cleavage of the phosphorylcholine group, replaced by a hydroxyl, leads to a lipid with a relatively small head group. The free fatty acids constitute about 20% of the lipid composition. They are mainly saturated, ranging from 14 to 20 carbon atoms in length, C_{16} and C_{18} being the most abundant (5, 18).

Because the lipid composition of the SC is complex, model systems have often been used to investigate the molecular details of lipid behaviour. Several studies have used model mixtures that include ceramide, cholesterol, and fatty acid, the three main components of SC (21–26). The ceramide that has often been used is ceramide III extracted from bovine brain because of its similarity to SC ceramides and its commercial availability. Stearic (octadecanoic) and nervonic (15-tetracosenoic) acyl chains are the most abundant in these derived ceramides (26). Despite the simplification, the model reproduces several features of the SC. A transition from an ordered to a disordered lipid phase has been observed in the model mixtures (21–25); as well, the presence of crystalline or solid regions has been reported. In an equimolar mixture of CER–chol – palmitic acid (PA), it has been shown that a large proportion of the cholesterol and the fatty acids exists in a solid form below 40°C (23, 24). Recently it was found, in a similar mixture, that PA and ceramide independently form crystalline domains (25).

In the present paper, the mixing properties of ceramide with cholesterol and PA were investigated, and the conditions for which lipid crystallization occurs were examined. The behaviour of binary mixtures was also investigated to gain a deeper understanding of the role played by the different components in the ternary mixture. The thermotropism of the investigated mixtures was compared with that of equivalent systems for which CER had been replaced by SPM; this latter lipid displays a simpler behaviour, as will be discussed, and the comparison highlights the importance of the sphingolipid head group in the SC structure. Infrared (IR) spectroscopy is a powerful technique for investigating the structure of such systems because several vibrations give rise to bands that constitute local probes of the organization. This technique has already been used to characterize the phase transitions of the SC (4, 7–8, 14, 18, 27) and of related model systems (22, 25). These transitions were detected by the shift of the methylene stretching bands since their positions are sensitive to the conformational order of the lipid acyl chains (25, 28). In the present work, the C–H and the C–D stretching modes were used to characterize independently the behaviour of the sphingolipid and the deuterated fatty acid, respectively, in SC models. IR spectroscopy also provides valuable tools for investigating crystalline phase formation. The intermolecular vibrational coupling in a crystal can give rise to a factor group splitting of certain bands. This phenomenon has been observed, at the acyl chain level, for the scissoring (29, 30) and the rocking (25, 31) modes of the methylenes. A recent study has taken advantage of these spectral features to identify the formation of orthorhombic structures in an SC model mixture (25). Recently, a similar splitting was proposed for the Amide I band of the ceramide (32). The Amide I band as well as the C=O stretching ($\nu_{C=O}$) of the carboxylic group of the fatty acid were also examined as IR probes to investigate the interface. Preliminary results were obtained in a buffer made with H_2O (33). However, in the present work, D_2O-based buffer was used to avoid the overlap of the H_2O deformation band at 1640 cm^{-1} with the lipid bands in this region.

Material and methods

Sphingomyelin from bovine brain, derived ceramide III, and cholesterol were purchased from Sigma Chemical Co (St. Louis, Mo., U.S.A.). The ceramide was prepared from the SPM, using phospholipase C. Therefore the two lipids are different at the head-group level but the acyl chain composition is the same. The perdeuterated palmitic acid (PA-d_{31}) was obtained from the deuteration of palmitic acid (Sigma) according to a procedure described elsewhere (34). The deuterated acid was recrystallized in hexanes. Palmitic acid bearing a ^{13}C-labelled carboxylic group (^{13}C-PA) was purchased from CDN Isotopes (Pointe-Claire, Québec).

To obtain lipid mixtures, a stock solution of each lipid was prepared in a benzene/MeOH 92/8 (v/v) mixture. Aliquots of these solutions were mixed together to provide the desired composition. The organic solutions were then freeze-dried. The solid lipids were hydrated with a 100 mM Mes buffer, containing 100 mM NaCl, 5 mM EDTA, in D_2O, at pH 5.2 (corresponding to a pD of 5.6 (35)); this pH is in the range of the recognized physiological pH of the SC layer (36, 37). The final lipid concentration was about 20 (w/v)% for the samples containing SPM. For the samples

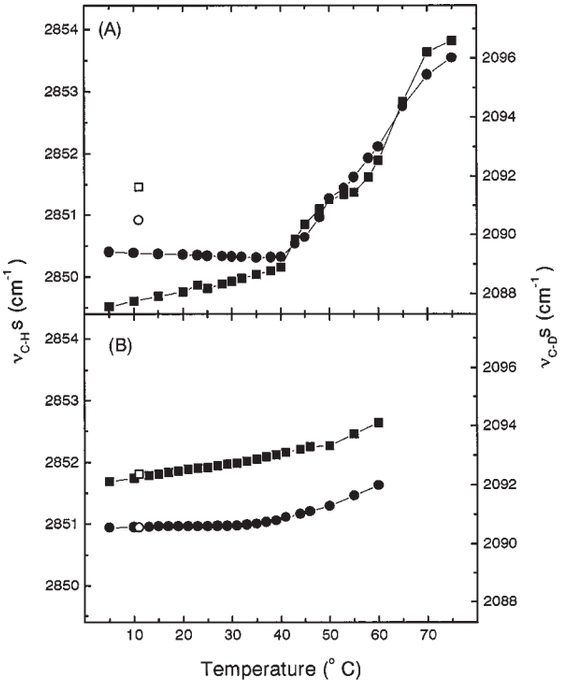
Fig. 1. Thermotropism of (*A*) CER–PA-d_{31}–chol and (*B*) SPM–PA-d_{31}–chol equimolar mixtures as probed by the shift of the (■) ν_{C-H}s and (●) ν_{C-D}s bands. The relative position and amplitude of the two *y* axes were determined to obtain the overlap of the transition of SPM and PA-d_{31} in the binary mixture (see Fig. 6) and the same scales were kept for this figure. The empty symbols represent the positions of the bands when the samples were quenched from high temperature down to 11°C.



containing ceramides, a large excess of buffer was used during the incubation (≈3 (w/v)% in lipid). The samples were incubated for three 10 min periods at 80°C for the mixtures containing CER or at 70°C for the mixtures containing SPM. Between incubation periods, the samples were cooled down to room temperature. The samples containing ceramides were finally incubated at 40°C for 15 min, prior to recording the spectra; the importance of this step in the incubation procedure is discussed below. During the incubations, the samples were periodically vortexed. Other incubation procedures were used and they are explicitly described in the text.

An aliquot of the sample was transferred between two CaF_2 windows, and the sample thickness was controlled by a 5 μm thick Teflon ring. The cell was mounted in a brass sample holder whose temperature is regulated by thermopumps. The infrared spectra were recorded on a FTS-25 Bio-Rad spectrometer equipped with a water-cooled globar source and a medium-band mercury – cadmium telluride detector. For each spectrum, 100 scans with a resolution of 2 cm^{-1} were coadded, and were Fourier transformed using a triangular apodization function. The spectra were recorded as a function of increasing temperature. Subsequently a spectrum was measured at 11°C to examine the reversibility of the transition; it took about 10 min to cool the sample from 75 to 11°C. The contribution of the O–D stretching band at 2500 cm^{-1} has been corrected for in the C–H and C–D stretching regions by subtracting a least-squares-fitted polynomial simulating the edge of the water band. The band positions reported in this paper correspond to the centers of gravity of the top 5% of the bands.

Results

The thermotropism of the model SC lipid mixture (CER–PA-d_{31}–chol in equimolar proportion) as well as the analogous mixture in which ceramide was replaced by SPM is presented in Fig. 1. The thermal evolution of the sphingolipid was probed by the symmetric C–H stretching of the lipid methylene groups (ν_{C-H}s) (the contribution of cholesterol in this region is considered to be constant) whereas the band assigned to the symmetric C–D stretching of the methylene groups (ν_{C-D}s) is associated with PA-d_{31}. The behaviour of the SPM–PA-d_{31}–chol mixture is relatively simple. Both the ν_{C-H}s and ν_{C-D}s frequencies show a progressive increase upon heating. Pure SPM undergoes a gel-to-liquid crystalline phase transition at a temperature (T_m) of 35°C (38, 39). For the ν_{C-H}s band, the values obtained below the T_m of the pure SPM are higher than those observed for pure SPM (2851 cm^{-1}) whereas they are smaller than those of the pure SPM for temperatures higher than the T_m of pure SPM (2853.2 cm^{-1}). These spectral features indicate that cholesterol disorders the lipid gel phase whereas it orders the liquid crystalline phase.

The thermotropism of the CER–PA-d_{31}–chol mixture is drastically different. First of all, a significant increase in frequency is observed as a function of increasing temperature for both the ν_{C-H}s and ν_{C-D}s band positions. In the case of the ν_{C-H}s band, the frequency has a value lower than 2850 cm^{-1} at low temperature, a value typical of a very ordered phase (ref. 25, for example). It increases by about 1.5 cm^{-1} between 40 and 50°C. Between 55 and 70°C, there is a second increase, by about 2 cm^{-1}, the frequency reaching the values observed for a lipid in the fluid phase (Fig. 6 of this work, and refs. 25 and 28, for example). This behaviour contrasts with that of the pure ceramide, which remains very ordered over this temperature range (32). The variation of the position of the ν_{C-D}s band as a function of temperature is also reported. The value between 5 and 40°C is constant and indicative of an ordered phase. Between 40 and 60°C, the band shifts continuously up to 2096 cm^{-1}; an inflection is observed around 55°C. The ν_{C-D}s profile is somewhat different than that derived from the asymmetric C–D methylene stretching (ν_{C-D}a) (data not shown). The ν_{C-D}a band experiences an abrupt shift by 3 cm^{-1} during the first transition (between 40 and 47°C) to reach about 2196 cm^{-1} and increases by less than 1 cm^{-1} between 50 and 70°C. This illustrates that the ν_{C-D}a and the ν_{C-D}s bands are not sensitive, to the same extent, to certain molecular changes. The variation of ν_{C-D}s displays a thermal profile similar to that reported by the first moment of the ^{2}H NMR spectrum of an equivalent mixture (23). As seen on the curves, the transition is not readily reversible since the positions of both ν_{C-H}s and ν_{C-D}s bands are shifted when quenching the sample at 11°C (open symbols) towards frequencies higher than those observed at the beginning of the experiment (i.e., after incubation at 40°C).

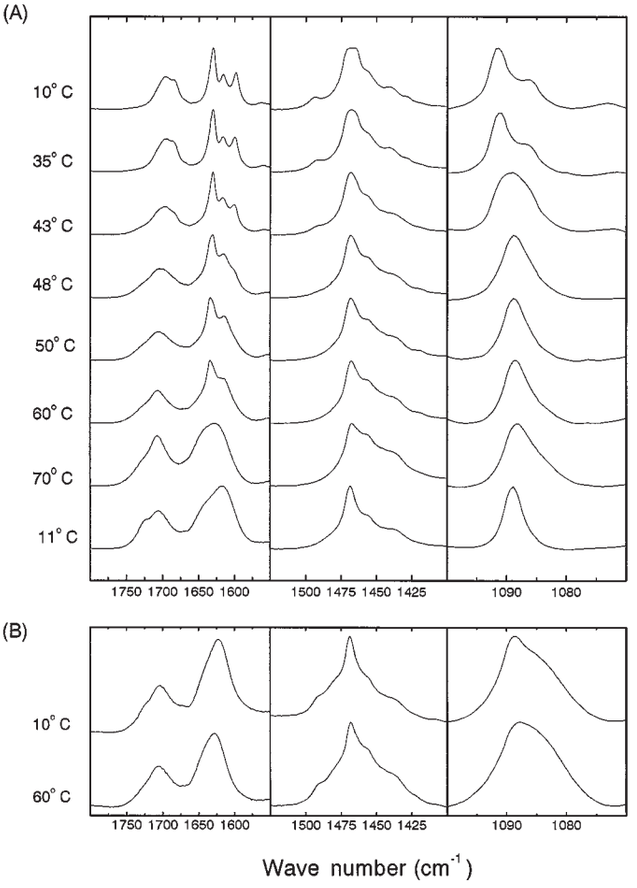
Fig. 2. Infrared spectra in the Amide I′ and $\nu_{C=O}$ (1800–1550 cm^{-1}), the δ_{CH_2} (1525–1400 cm^{-1}), and the δ_{CD_2} (1100–1070 cm^{-1}) regions for (*A*) CER–PA-d_{31}–chol and (*B*) SPM–PA-d_{31}–chol equimolar mixtures. The temperatures are indicated on the left side.



The Amide I′, the CH_2, and CD_2 scissoring (δ_{CH_2} and δ_{CD_2}) regions have also been examined (Fig. 2). The prime (′) of the Amide I′ band indicates that the amide bond is deuterated as a consequence of the use of a D_2O-based buffer. The H–D exchange of the amide protons is indicated by the absence of the Amide II band, which would appear around 1550 cm^{-1} for the hydrogenated amide bond whereas it is shifted to 1450 cm^{-1} upon deuteration. In the 1800–1550 cm^{-1} region, two broad features are observed for the SPM–PA-d_{31}–chol mixture. The Amide I′ appears at about 1623 and 1627 cm^{-1} at 10 and 60°C, respectively, similar to its position for pure SPM (data not shown). It is lower than 1651 cm^{-1}, the value measured for the non-hydrogen-bonded SPM amide in $CHCl_3$ (data not shown). It is concluded that the SPM carbonyls participate in hydrogen bonding but there is no formation of crystalline structure as inferred from the broadness of the band. The second feature shows two components at 1724 and 1702 cm^{-1}, assigned to the carbonyl stretching ($\nu_{C=O}$) of the carboxylic group of the fatty acid (40), indicating that the fatty acid exists in the protonated form at pH = 5.2. The frequency values are lower than that measured for the non-hydrogen-bonded C=O in a dilute solution of PA-d_{31} in $CHCl_3$, appearing at 1745 cm^{-1} (data not shown). It can be concluded that both SPM and PA-d_{31} participate in hydrogen bonding in this mixture. Between 1525 and 1400 cm^{-1}, the main component (1468 cm^{-1}) corresponds to the acyl chain δ_{CH_2} band (29, 30). This region is cluttered with the contribution of the Amide II′ band but the maximum of the δ_{CH_2} band is well defined and its position is indicative of a hexagonal chain packing or a fluid phase (29, 30). In the region between 1100 and 1170 cm^{-1}, the CD_2 scissoring (δ_{CD_2}) band is a single component at about 1088 cm^{-1}, superimposed on the antisymmetric PO_4^- band at about 1085 cm^{-1} (28). There is no important spectral change in these areas between 10 and 60°C.

The CER–PA-d_{31}–chol mixture shows a different profile in these regions. At 10°C, three components are observed, at 1630, 1615, and 1597 $cm^{-1,}$ for the Amide I′ band; these three frequencies are significantly lower than that for the non-hydrogen-bonded amide carbonyl (1652 cm^{-1}). The first two peaks are similar to those observed in the pure ceramide spectra (32). It is proposed that the low-frequency component be attributed to a strongly hydrogen-bonded amide carbonyl, as will be discussed later. The band associated with the $\nu_{C=O}$ of the palmitic acid shows at least two components, at 1694 and 1683 cm^{-1}. These values are close to that measured for solid PA-d_{31} in a KBr pellet where a peak at 1698 cm^{-1} is observed (data not shown), suggesting that the carbonyls participate in hydrogen bonding comparable to those in the solid fatty acid. At 10°C, the δ_{CH_2} band is broad

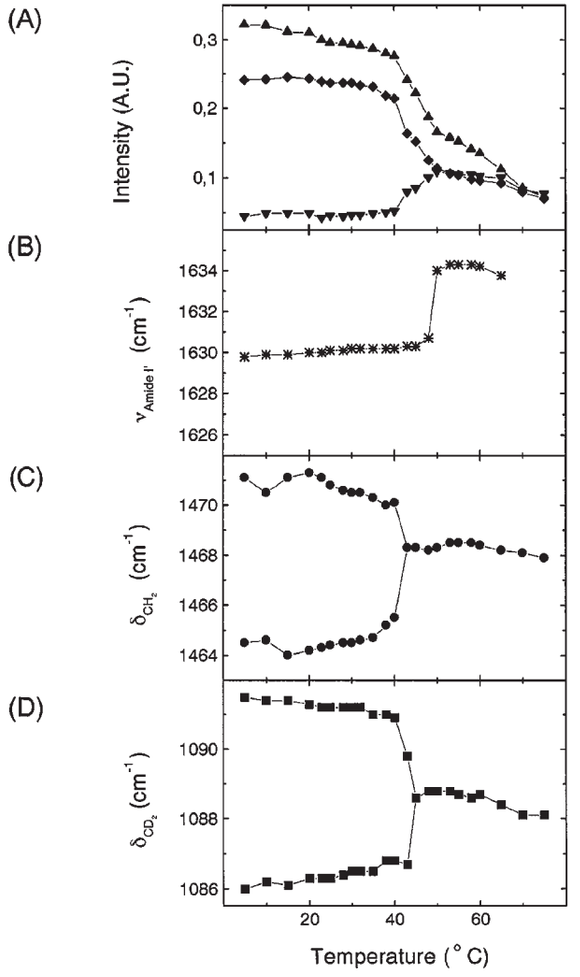
Fig. 3. Variations of selected spectral features as a function of temperature for the CER–PA-d_{31}–chol equimolar mixture. (*A*) Variation of the intensity at (▲) 1600, (◆) 1683, and (▼) 1726 cm^{-1}. (*B*) Position of the maximum of Amide I′ component at about 1630 cm^{-1}: for $T > 60°C$, a single broad component is observed at about 1620 cm^{-1}. (*C*) Splitting of the δ_{CH_2} band. (*D*) Splitting of the δ_{CD_2} band.



and Fourier self-deconvolution reveals two components at 1471 and 1464 cm^{-1}, a splitting similar to that observed for pure ceramide (32). This splitting is indicative of molecules packed in an orthorhombic subcell (29, 30). The δ_{CD_2} band is also split and the two components appear at 1091 and 1086 cm^{-1}, in agreement with previous results (25). This splitting has also been associated with the formation of domains with orthorhombic chain packing (41, 42). At 35°C, the three regions are similar to those recorded at 10°C. Upon increasing temperature, several spectral features change (Figs. 2 and 3). At about 43°C, the CH_2 and CD_2 scissoring band splittings collapse and a single component is obtained at 1468 and 1089 cm^{-1} for the CH_2 and CD_2 scissoring bands, respectively. Between 55 and 70°C, this latter band shifts slightly to 1088 cm^{-1}. In parallel, the components of the $\nu_{C=O}$ band of the palmitic acid are upshifted to 1726 and 1707 cm^{-1} between 40 and 50°C. This shift is due to a transition involving two defined species as indicated by two isosbestic points observed when the spectra are stacked. Therefore, it is concluded that the fatty acid undergoes a transition from a state in which the chains are highly ordered and the head groups participate in strong intermolecular H-bonding to a structure in which the chains are more disordered and which involves weaker intermolecular hydrogen bonds between the head groups or with water molecules, similar to those formed by PA-d_{31} mixed with SPM. This thermally induced change is concomitant with changes in the Amide I′ region. First, there is the disappearance of the component at 1597 cm^{-1}. Second, the other two components shift from 1630 and 1616 cm^{-1} at 40°C to 1634 and 1615 cm^{-1} at 50°C. When the temperature is increased above 70°C, a broad and asymmetric feature with a maximum around 1620 cm^{-1} is observed in the Amide I′ region. It must be added that the three regions investigated indicate, according to the position of the methylene stretching bands, that the thermally induced transition is not readily reversible: when quenched at 11°C, the Amide I′ band remains broad, and the CH_2 and CD_2 scissoring regions do not show the initial splittings.

To confirm the band assignment in the $\nu_{C=O}$ region, particularly that of the component at 1597 cm^{-1}, spectra were obtained from a ternary mixture prepared using ^{13}C-PA (Fig. 4). The Amide I′ region shows the three components at 1630, 1614, and 1597 cm^{-1}, as previously observed for the mixture prepared with the deuterated acid (Fig. 2). Conversely, the band associated with the carboxylic acid is shifted to 1650 cm^{-1}, as expected from the isotopic effect and in agreement with a previous report (43). These results reinforce the proposition that the component at 1597 cm^{-1} be attributed to the Amide group. Upon heating, changes similar to those observed with the mixture prepared with the deuterated fatty acid are obtained. Between 40 and 50°C, there is the disappearance of the 1597 cm^{-1} component, and the shift of the most intense Amide I′ component from 1630 to 1634 cm^{-1}, as well as that of the $\nu_{C=O}$ of the carboxylic acid towards higher frequencies (from 1651 to 1665 cm^{-1} in the case of ^{13}C-PA). Above 65°C, a broad feature is observed, the bands from the ceramide amide and the acid carboxylic group no longer being resolved. As already shown, the temperature-induced transition is not readily reversible.

The literature reports that low-temperature incubation is necessary to obtain the solid phase (24). To estimate the kinetics of the formation of the solid phases in fully hydrated samples and to identify the sequence of appearance of the spectral features associated with these, samples that had been incubated at 75°C for three 10 min periods were quenched at 5°C and spectra were acquired as function of time (Fig. 5*A*). The appearance of the spectral features associated with solid phases can be roughly divided into two categories. First, the appearance of the $\nu_{C=O}$ bands of PA-d_{31} at 1694 and 1683 cm^{-1}, the splitting of the Amide I′ band giving rise to the two components at 1630 and 1615 cm^{-1}, as well as the splitting of the δ_{CD_2} band are observable after 9 days of incubation at 5°C and evolve up to 50 days of incubation. The second category includes the splitting of the δ_{CH_2} band and the appearance of the 1597 cm^{-1} component, which require more than 90 days of incubation at 5°C to become apparent. Figure 5*B* shows the same type of experiment but this time

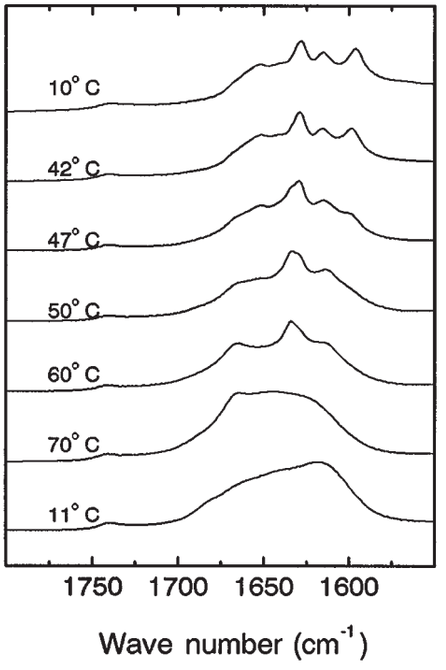
Fig. 4. Infrared spectra in the Amide I′ and $\nu_{C=O}$ (1800–1550 cm^{-1}) region for CER–^{13}C-PA–chol equimolar mixtures. The temperatures are indicated on the left side.



the incubation temperature is 40°C. In this case, all the features of the solid domains are already observed after 10 min. It is concluded that heating the sample leads to an annealing during which the ordering occurs.

To obtain more insight into the role of the different constituents in our model system, binary mixtures of PA-d_{31} with ceramide or SPM were prepared. The addition of palmitic acid to SPM and to ceramide has a different effect on their thermotropism. In the case of sphingomyelin (Fig. 6*B*), the gel-to-liquid crystalline transition of SPM, as probed by the ν_{C-H}s frequency, is shifted towards higher temperatures; the abrupt change in frequency is observed at about 60°C for the SPM–PA-d_{31} mixture. A similar shift is observed for the ν_{C-D}s mode at the same temperature. The results show that the disordering of the two lipid species occurs in a concomitant manner, indicating that SPM and PA-d_{31} form a homogeneous mixture. The incorporation of the fatty acid in the SPM bilayers leads to an increase in the T_m of SPM, going from about 35°C for the pure lipid (38, 39) to 60°C for the equimolar mixture with palmitic acid. A SPM–PA-$d_3$1 2:1 mixture (in mol) exhibits a T_m of about 50°C (33), indicating a progressive shift of the gel-to-liquid crystalline phase transition.

The behaviour of the CER–PA-d_{31} mixture is different (Fig. 6*A*). The ν_{C-D}s region indicates that the fatty acid is ordered at low temperature and experiences a very cooperative transition towards a disordered phase at about 52°C. The thermal changes associated with ceramide, as reported by the ν_{C-H}s mode, are different. At low temperatures, the ceramide exists in a very ordered form. Around 55°C, there is a small shift of the ν_{C-H}s frequency by about 0.5 cm^{-1} towards higher values. At 68°C, the shift becomes more abrupt, and the ν_{C-H}s frequency reaches 2853 cm^{-1} at 75°C, a value close to those measured for a disordered phase. The other regions investigated also reveal the presence of a transition (Figs. 7 and 8). At low temperature (T < 52°C), the spectral regions indicate that this binary lipid mixture forms solid domains. The $\nu_{C=O}$ band components of PA-d_{31} are observed at 1694 and 1683 cm^{-1}, the Amide I′ shows two components at 1635 and 1614 cm^{-1}, and the scissoring bands show a splitting at 1465 and 1471 cm^{-1} for the δ_{CH_2} mode and at 1086 and 1091 cm^{-1} for the δ_{CD_2} mode. The two components in the Amide I′ regions are present over the whole temperature range investigated (10–75°C). It is noted that the low-frequency component at 1598 cm^{-1} is not observed for this mixture. Conversely, the two components of the δ_{CH_2} band merge at about 50°C. Those of the δ_{CD_2} band merge at 53°C, simultaneously with the main transition observed from the ν_{C-D}s band position. During this transition, the $\nu_{C=O}$ bands of the acid also shift toward high frequencies, to 1726 and 1707 cm^{-1}. It is inferred from these results that the acid undergoes a transition at 54°C, from an ordered phase with the characteristics of a solid to a disordered phase, whereas ceramide remains ordered up to 65°C. If the sample is heated at 90°C outside the cell (this temperature is practically inaccessible with the setup used in these experiments), the spectra at temperatures below 40°C consist of broad bands in the Amide I′, δ_{CH_2}, and δ_{CD_2} regions (data not shown). In this case, the frequencies of the ν_{C-H} and ν_{C-D} bands are also significantly higher than those reported in Fig. 6.

Discussion

It is established that the chemical transformation of SPM into ceramide leads to drastic changes in their polymorphism. The particular ceramide head group provides a high stability of the lipid packing as illustrated by the formation of an orthorhombic chain packing and an ordered to a fluid phase transition at about 80°C (32). In contrast, SPM undergoes a gel-to-liquid crystalline phase transition at about 35°C (38, 39). In the present work, it is shown that the different head-group structure of the ceramide and the SPM has a drastic impact on the organization of the binary and ternary mixtures. In the case of SPM mixed in equimolar proportion with cholesterol and palmitic acid, the gel-to-liquid crystalline transition of SPM is no longer observed, as inferred from progressive changes in the methylene stretching band positions. The abolition of gel-to-liquid crystalline transition is also observed in the SPM–chol equimolar mixture (data not shown). This abolition was previously observed for similar binary mixtures (38, 44). For the ternary mixture, cholesterol induces an increase of chain order in the gel phase whereas it leads to a decrease of order in the fluid phase, similar to the behavior of SPM–chol mixtures (38). This behaviour, also observed for various phosphatidylcholines and phosphatidylethanolamine in the presence of cholesterol (28, 45–47), is likely associated with the formation of a liquid-ordered phase in which the lipid diffusion is similar to that observed in a fluid phase but the lipid acyl chains are ordered. The abolition of the gel-to-liquid crystalline phase transition suggests that a considerable proportion of cholesterol is present in the lipid bilayers. The ν_{C-D}s frequency

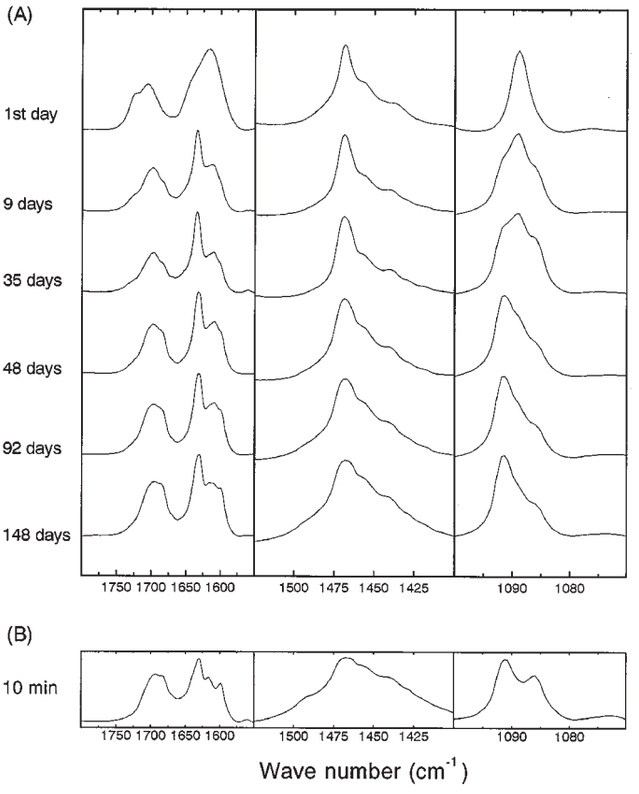
Fig. 5. Infrared spectra in the Amide I′ and $\nu_{C=O}$ (1800–1550 cm^{-1}), the δ_{CH_2} (1525–1400 cm^{-1}), and the δ_{CD_2} (1100–1070 cm^{-1}) regions for CER–PA-d_{31}–chol equimolar mixture incubated at (*A*) 5°C and (*B*) 40°C, after three 10 min periods of incubation at 70°C. The time was set to 0 at the end of the high-temperature incubation.



variation as a function of temperature also displays a monotonic increase, indicating that the palmitic acid is inserted in the liquid-ordered matrix. This conclusion is in agreement with previous ^2H NMR results (23) showing that PA-d_{31} in a similar ternary mixture displays a spectrum typical of a liquid-ordered phase. Our results show that SPM is also involved in the liquid-ordered phase in the ternary mixture, suggesting that this mixture is homogeneous.

If SPM is replaced by ceramide in the ternary mixture, a completely different behaviour is observed. At low temperatures (between 5 and 40°C), several spectral features indicate the formation of a highly ordered structure. Both the CH_2 and the CD_2 scissoring modes indicate that the ceramide and the fatty acid exist in an orthorhombic subcell. Because the observed splittings are due to short-range interchain couplings and occur only if the vibrations of the adjacent groups have a similar frequency (i.e., the vibrational coupling between hydrogenated and deuterated chains is negligible), their presence in mixtures containing chains of both types is an indication of lipid demixing (41, 42). In the SC model lipid mixture, the splittings of the methylene scissoring bands are similar to those observed in the pure lipids (ceramide and PA-d_{31}), suggesting extensive lipid demixing. The splitting of the δ_{CH_2} band ($\Delta\nu$ = 6.5 cm^{-1}) is smaller than that measured for long-chain phosphatidylcholine at 0°C (e.g., $\Delta\nu$ = 12 cm^{-1} for dibehenoylphosphatidylcholine (DBPC), (C_{22})) (30), but this difference is likely associated with the chain heterogeneity of the ceramide sample. The formation of orthorhombic crystalline domains was previously reported for a similar mixture, based on the analysis of the δ_{CD_2} and the CH_2 rocking modes (25). The present work provides additional spectral indications of the very ordered structure. The carboxylic $\nu_{C=O}$ band indicates that the carbonyl is involved in strong hydrogen bonding, comparable to the crystalline fatty acid. The presence of this band also confirms that the palmitic acid in this ternary mixture exists in the protonated form. The amide I′ region is also indicative of high order since the two components corresponding to pure ceramide are observed. The presence of solid PA-d_{31} has been also reported for a ternary mixture with the same lipid composition, in ^2H NMR studies (23, 24).

The crystalline domains undergo a transition towards a disordered phase upon heating. It was reported (25) that PA and ceramide experience separate conformational disordering of the chains, centered at 50 and 67°C, respectively. In the present system, a different thermal evolution is observed for the CER–PA-d_{31}–chol mixture since both ceramide and fatty acid are involved in both transitions. The transition at around 40–50°C is related to the solid–fluid transition of PA (23, 25), confirmed by the collapse of the δ_{CD_2} band splitting and the shift of the $\nu_{C=O}$ band. In the present work, it is shown that the ceramide is involved in this transition. First, the ceramide population associated with the low-frequency component of the Amide I′ region of the ternary mixture (made up with PA-d_{31} or ^{13}C-PA) vanishes during the transition associated with the PA-d_{31} crystalline domains. Its

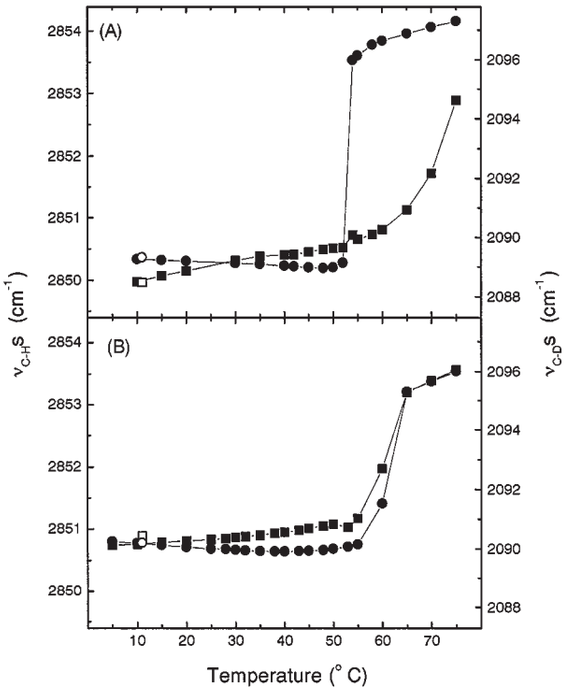
Fig. 6. Thermotropism of (*A*) CER–PA-d_{31} and (*B*) SPM–PA-d_{31} equimolar mixtures as probed by the shift of the (■) ν_{C-H}s and (●) ν_{C-D}s bands. The empty symbols represent the position of the band when the samples were quenched from high temperature down to 11°C.



position suggests that the carbonyl is involved in very strong hydrogen bonding or that the amide bond has an unusual conformation. This ceramide fraction likely involves interactions with both PA and cholesterol since the band is absent from the spectra of the pure ceramide or the binary mixtures of ceramide with PA-d_{31} or with cholesterol (data not shown). Second, the positions of the two other Amide I′ components are shifted between 40 and 50°C. Third, this phase transition of PA-d_{31} occurs at a relatively low temperature and implies interactions with the other components. PA-d_{31} by itself is insoluble in aqueous media and has a melting temperature of 59°C. When the fatty acid is in equimolar mixture with only ceramide or only cholesterol, the transition probed by the ν_{C-D} shift occurs at about 53–54°C (data not shown). The presence of both ceramide and cholesterol is necessary to observe the transition at around 45°C, suggesting that a certain proportion of ceramide and cholesterol is involved in this transition. Fourth, the participation of ceramide in the PA-d_{31} domain transition is also supported by the concurrent occurrence of the ν_{C-H}s frequency shift. The participation of ceramide is in agreement with a previous NMR study (48) where the transition at about 40°C in a CER–PA-d_{31}–chol equimolar mixture was detected as a variation of the second moments of both the ^{2}H NMR (associated with the deuterated acid) and the ^{1}H NMR (whose variations are associated with the ceramide) signals. It is proposed that a limited proportion of ceramide participates in the transition since most of the ceramide appears to remain ordered, as illustrated by the presence of the two components of the Amide I′ band at 1634 and 1615 cm^{-1}. At this point, it is not possible to determine whether the ceramides participating in the transition are present in the PA crystalline phase, the fluid phase, or in both. It may be tempting to suggest that the low-frequency component of the Amide I′ is associated with ceramide strongly H-bonded to crystalline PA. However, it is clear that if some ceramide is present in the crystalline PA, it is in limited amount since the δ_{CD_2} splitting is not significantly affected (only about 10% of hydrogenated species can be introduced into a *n*-$C_{36}D_{74}$ matrix without significantly affecting the δ_{CD_2} splitting (41)). It is also proposed that this transition corresponds to the introduction of cholesterol into the fluid PA matrix (25). This is supported by the shift of the ν_{C-D}s band to an intermediate value close to that measured in the SPM–PA-d_{31}–chol mixture, and is also in good agreement with previous ^{2}H NMR studies (23, 48) in which PA-d_{31}, under similar conditions, led to a spectrum of a fluid but ordered phase.

The second transition, occurring between 55 and 70°C, is associated with the transition of the ordered ceramide domains towards a disordered phase (25) as supported by the increase of the ν_{C-H}s frequency to a value typical of a disordered chain, and by the disappearance of the narrow Amide I′ components. The present work highlights the participation of the fatty acid in this transition. First, the shift of the ν_{C-D}s band indicates further disordering of the fatty acid. Second, fluid spectral features related to the ceramide are not observed for the pure spingolipid, or for CER–PA-d_{31} or CER–chol mixtures at temperatures below 75°C. This finding is also supported by the drastic profile change in the ^{2}H NMR spectrum of PA-d_{31} in the equivalent ternary mixture, going from a fluid powder pattern to an isotropic line (23). This transition was also detected as a variation of the second moments of both the ^{2}H NMR (associated with the deuterated acid) and the ^{1}H NMR (whose variations are associated with the ceramide) signals (48). It is proposed that this second transition corresponds to the formation of a homogeneous fluid mixture by the three components, giving rise to a liquid-like phase.

It is concluded from ref. 25 and this work that, at low temperatures, there is an extensive or complete phase separation leading to the formation of crystalline domains with orthorhombic chain packing. The homogenization of the ternary mixture and the formation of a fluid phase at high temperatures are also proposed. It appears that the participation of the lipidic species in the transitions between these two states may vary and this phenomenon can have several origins. A recent study on SC lipids in monolayers (26) provides a possible explanation. It has been proposed that, in a monolayer, the mixture of ceramides (also ceramides III from Sigma), cholesterol, and free palmitic acid form domains. The short-chain ceramides (such as those bearing a C_{16} chain) mix with cholesterol and PA whereas the long-chain ceramides (such as those bearing a C_{24} chain) form domains on their own. The different chain composition of the ceramides can be at the origin of the difference between the results obtained by Moore et al. (25) and in this work, and the effect of acyl chain length on the mixing properties should therefore be carefully examined. The influence of other factors such as pH or incubation protocol should also be taken into consideration.

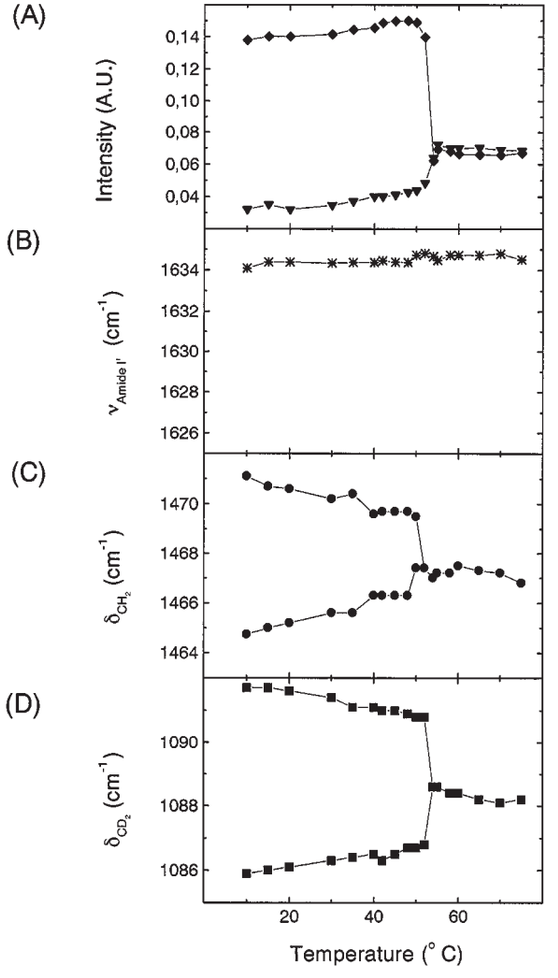
(*B*) Position of the maximum of Amide I′ component at about 1630 cm^{-1}. (*C*) Splitting of the δ_{CH_2} band. (*D*) Splitting of the δ_{CD_2} band.



The present study shows that the homogenous distribution of ceramide, cholesterol, and PA-d_{31} obtained above 65°C can be quenched at lower temperatures. If the homogenous sample at high temperature is rapidly cooled to 10°C, the lipids form an ordered phase but no crystalline structures. This is illustrated by the ν_{C-H}s and ν_{C-D}s frequencies, which decrease upon cooling but not down to the values obtained when solid domains exist in the mixture. In addition, there is no sign of splitting for the scissoring CH_2 and CD_2 modes or for the Amide I′ band. The $\nu_{C=O}$ band shows also that the hydrogen bonds are not as strong as in the crystalline domains. Actually, all the regions investigated are very similar to those obtained for the homogeneous SPM–PA-d_{31}–chol mixture, suggesting that the homogeneous distribution obtained at high temperatures can be quenched in a metastable state and that the slow diffusion or molecular reorientation rate of the lipids at low temperatures prevents the rapid formation of the crystalline domains. Such a time-dependent phenomenon is a parameter that should be examined during the lipid migration through the SC. The results also indicate that the kinetics of the crystallization and the segregation are strongly temperature dependent. The thermodynamically stable state, where lipid demixing and crystallization have occurred, can be easily obtained by annealing at 40°C whereas it takes several weeks when the incubation is done at 5°C. The identification of this behaviour is critical to studying the mixtures in a reproducible and thermodynamically stable macroorganization.

It is interesting to examine the influence of palmitic acid on the sphingolipid polymorphism, in order to highlight the role of the components in the ternary mixture. In the case of the SPM–PA-d_{31} mixture, a gel-to-liquid phase transition that involves both lipids is observed at about 60°C, suggesting the formation of a homogeneous phase. The transition is shifted towards a higher temperature than that observed for pure SPM. This phenomenon is rationalized by the small polar head-group size of the fatty acid, leading to a tighter lipid packing and therefore a higher temperature for the gel-to-liquid phase transition. Similar behaviour was also observed when saturated fatty acids were introduced into phosphatidylcholine (43, 49, 50).

The CER–PA-d_{31} mixture has again different lipid mixing properties. At temperatures below 55°C, both lipids exist in separate crystalline domains with orthorhombic chain packing. This is inferred from the low ν_{C-H}s and ν_{C-D}s band

frequencies, the splitting of the methylene scissoring modes, and the narrow components of the Amide I′ band. Conversely to the ternary mixture that includes cholesterol, the ceramide and the fatty acid undergo a transition at a different temperature: the PA molecules experience the transition towards a fluid phase at 53°C, whereas the disordering of the ceramide acyl chains occurs above 65°C. The transition of PA-d_{31} is in agreement with a previous ^{2}H NMR study on a similar mixture (23) showing that PA-d_{31} exists in a solid form below 50°C and forms a phase that gives rise to an isotropic line at higher temperature. The present study reveals that the participation of the ceramide in this transition is very limited and that the lipid demixing is practically complete in the binary mixture. The comparison between this behaviour and that observed for the ternary mixture suggests that cholesterol plays a crucial role in the mixing properties of the SC lipids. The temperature at which there is the formation of a homogeneous mixture supports this proposition. The homogeneous mixing is observed at a lower temperature in the presence of the sterol (for $T > 70$°C) than in absence of the sterol (not determined precisely but for $T > 75$°C). The sterol appears to favour the mixing of the PA-d_{31} and the ceramide. Cholesterol was previously shown to act as a homogenizing agent in some lipid mixtures with limited miscibility (51, 52).

In the present work, the importance of the head group in the mixing properties of the SC lipids is highlighted. While the SPM forms a homogeneous liquid ordered mixture with cholesterol and the fatty acid, the CER–PA-d_{31}–chol mixture exhibits a rich polymorphism. The particular thermotropism of the CER–PA-d_{31}–chol mixture requires the three components. The ceramide, because of the strong intermolecular interactions, provides a stable crystalline structure. This structure is a direct consequence of the enzymatic cleavage of the SPM head group since the SPM appears incapable of forming crystalline phases in an aqueous environment. PA-d_{31} acts as an enhancer of fluid structures since the PA-d_{31} crystalline domains are the first to undergo a transition toward a fluid phase, and because the fatty acid reduces the temperature at which ceramide becomes fluid. Finally, cholesterol promotes the lipid mixing. As a consequence, this composite biomaterial displays a unique polymorphic behaviour that includes different structures, going from lipid demixing and the formation of orthorhombic crystalline domains at low temperatures, to a homogeneous fluid phase at high temperatures. The structural information is very much in agreement with the suggestion that the SC is organized as a domain mosaic model (13). It is found here that the domain mosaic can be modulated by temperature or, more physiologically relevant, by lipid composition or time, if the metastable state is involved.

Despite the simplicity of the model used in the present study, the behaviour reported for the SC lipid model mixture shows striking similarities to that of the real SC. In the case of mouse (9, 11) and human (12) SC, an orthorhombic lateral packing is observed at low temperatures. Between 40 and 45°C, this packing disappears, leading to the formation of a hexagonal packing and, at 80°C, the lipids show only a fluid structure. In addition, a splitting of the δ_{CH_2} band observed on porcine SC (16) suggests the formation of orthorhombic domains. The thermotropic features that are common to the SC and the model mixture may have similar molecular origin, and the present work suggests details of the lipid organization and the conditions under which such structures may be obtained.

^{2}H NMR studies of dipalmitoylphosphatidylcholine and dipalmitoylphosphatidylcholine–cholesterol bilayers at high pressure

Boyan B. Bonev and Michael R. Morrow

Abstract: Wideline deuterium nuclear magnetic resonance was used to investigate the phase behaviour of bilayer dispersions of chain-perdeuterated dipalmitoylphosphatidylcholine (DPPC-d_{62}) and DPPC-d_{62} containing 28.5 mol% cholesterol for temperatures between 0°C and 90°C and pressures from ambient to 270 MPa. Spectra were obtained over a range of temperature at ambient pressure, 100 MPa, and 210 MPa and over a range of pressure at fixed temperatures of 0°C and 45°C (40°C for the sample containing cholesterol). The combination of complementary isobaric and isothermal scans produced observations that suggest two possible refinements to previously reported DPPC-d_{62} pressure–temperature phase diagrams. In contrast to DPPC-d_{62}, which displays at least three transitions as temperature is lowered from 90°C to 0°C at a fixed pressure of 210 MPa, the sample containing 28.5 mol% cholesterol displayed a continuous change from fluid to ordered over a wide temperature range for 210 MPa and below. These observations suggest that pressure does not induce any substantial repositioning of cholesterol in the bilayer over the range of conditions studied and that cholesterol reduces the sensitivity of bilayer properties to pressure.

Key words: deuterium nuclear magnetic resonance, model membrane, high pressure, cholesterol, phase transition.

Résumé : Opérant à des températures allant de 0° à 90°C et à des pressions allant de la pression ambiante à 270 MPa et faisant appel à la résonance magnétique nucléaire du deutérium à bande large, on a étudié comportement de phase de dispersions en bicouches de chaînes perdeutérées de dipalmitoylphosphatidylcholine (DPPC-d_{62}) et de DPPC-d_{62} contenant 28,5 mol% de cholestérol. Les spectres ont été obtenus à diverses températures à la pression ambiante, à 100 MPa et à 210 MPa et à diverses pressions à des températures fixes de 0° et de 45°C (40°C pour l'échantillon contenant du cholestérol). La combinaison de balayages complémentaires isobares et isothermes a permis d'obtenir des observations supplémentaires qui suggèrent deux raffinements possibles pour les diagrammes de phase pression–température rapportés antérieurement pour le DPPC-d_{62}. Par opposition avec le DPPC-d_{62} qui présente au moins trois transitions lorsqu'on abaisse la température de 90° à 0°C, à pression fixe de 210 MPa, l'échantillon contenant 28,5 mol% de cholestérol présente un changement continue de fluide à ordonné sur une gamme importante de température à des pressions allant jusqu'à 210 MPa. Ces observations suggèrent que, dans le domaine des conditions étudiées, la pression n'induit pas de repositionnement important du cholestérol dans la bicouche et que le cholestérol réduit la sensibilité des propriétés de la bicouche à la pression.

Mots clés : résonance magnétique nucléaire du deutérium, membrane modèle, pression élevée, cholestérol, transition de phase.

Introduction

Natural membranes consist of lipid bilayers, which typically comprise a complex mixture of phospholipids, glycolipids, and sterols, along with embedded or surface-associated proteins. The lipid bilayer acts as the structural base for the membrane and defines the physical environment in which membrane proteins function. Lipid bilayers are also remarkable examples of self-assembling soft material with a rich array of physical properties that are largely determined by interactions between bilayer components. The dynamic and anisotropic aspects of the bilayer mechanical properties in a natural membrane exert a substantial influence on processes that occur at and in the membrane. Studying lipid bilayers can yield information about the relationship between structure and function in natural membranes and, at the same time, provide insights into the range of properties accessible in self-assembled soft materials.

Cholesterol is an important component of animal cell membranes. Because it can significantly modify bilayer physical properties such as acyl chain orientational order,

model membranes containing cholesterol have been studied extensively. Effects of cholesterol on membrane properties have been reviewed by Presti (1) and Yeagle (2). Magnetic resonance experiments indicate that cholesterol in a liquid crystalline bilayer increases the orientational order of the lipid acyl chains without substantially restricting the translational diffusion or the axially symmetric nature of acyl chain segmental reorientation in the liquid crystalline phase (3–10). Cholesterol, in effect, thickens a liquid crystalline bilayer and increases the packing density of lipid acyl chains in the plane of the bilayer in a way that has been referred to as a condensing effect (4).

A number of studies have focussed on the temperature–composition phase diagram of phospholipid bilayers containing cholesterol. Some of these studies have used deuterium spectral differences to obtain the end points of tie lines in two-phase coexistence regions where the spectra obtained from chain-perdeuterated lipid samples are superpositions of characteristic gel and liquid crystalline phase spectra with proportions determined by the lever rule (9, 11, 12). Studies based on this approach have tended to yield phospholipid–cholesterol phase diagrams displaying a eutectic point. At low cholesterol concentration, the low-temperature phase, which is essentially the phospholipid gel phase, is often referred to as the *solid-ordered (so)* phase. Above the phospholipid main transition temperature, for low cholesterol concentration, the bilayer is in a liquid crystalline phase that, on phospholipid–cholesterol phase diagrams, is often labelled as the *liquid-disordered (ld)* phase. Most phospholipid–cholesterol phase diagrams obtained in this way display a region of *so–ld* two-phase coexistence in a narrow temperature range close to the pure phospholipid main transition temperature. This region of two-phase coexistence ends at a eutectic point between 5 mol% cholesterol and 10 mol% cholesterol. For cholesterol concentrations above about 20 mol%, the bilayers are generally found in a phase that displays a high degree of acyl chain orientational order along with fast, axially symmetric, chain segment reorientation. This phase, often referred to as the *liquid-ordered (lo)* phase, extends over a wide temperature range. Its properties have been examined in detail by Reinl et al. (13) using a range of physical techniques. At intermediate cholesterol concentrations, the *so* and *lo* phases coexist at low temperature and the *ld* and *lo* phases coexist at higher temperature. These two-phase coexistence regions in the binary phase diagram are separated by a three-phase coexistence line close to the pure phospholipid main transition temperature. It should be noted that aspects of this phase diagram, such as the existence of a eutectic point, are still debated (14, 15).

Hydrostatic pressure also affects a number of bilayer properties. Comparing the response of bilayer properties to the application of pressure with the response to other perturbations can provide general insights into bilayer properties at ambient pressure. Early studies of the effect of pressure on bilayer phase behaviour, compressibility, and chain order made use of volumetric measurements (16, 17), calorimetry (18), neutron scattering (19–21), and vibrational spectroscopy (22–25). More recently, NMR has been used to examine the effect of pressure on bilayer properties including phase behaviour (26–30) and headgroup orientation (31, 32). One reason that pressure is a particularly interesting variable for bilayer studies is that the response of a phospholipid bilayer to the application of pressure, like its response to temperature, is anisotropic. In the liquid crystalline phase, the application of pressure increases bilayer thickness and reduces area per lipid (20, 21).

The present study is focussed on the effect of hydrostatic pressure on dipalmitoylphosphatidylcholine (DPPC) bilayers and DPPC bilayers containing 28.5 mol% cholesterol. As pressure is increased isothermally, DPPC bilayers pass through a series of ordered phases (23, 25) including one that is reported to be a chain-interdigitated phase (19, 21, 25). Recently, Jonas and co-workers have studied the pressure–temperature phase diagram of DPPC bilayers using ^{2}H NMR spectroscopy, on bilayers of chain-perdeuterated DPPC (27) and selectively labelled DPPC (33), and ^{31}P NMR spectroscopy (31). They estimated the location of phase boundaries in the pressure–temperature diagram by examining spectra obtained while scanning pressure at a number of fixed temperatures. While DPPC-d_{62} results reported in the present study are primarily intended to provide a context in which to discuss the behaviour of bilayers containing cholesterol, they do provide some additional insights into the DPPC-d_{62} pressure–temperature diagram. The DPPC-d_{62} results presented here were obtained while scanning temperature under isobaric conditions of ambient pressure, 100 MPa, and 210 MPa as well as while scanning pressure under isothermal conditions. As such, they complement previous explorations of this pressure–temperature diagram. Spectra of DPPC-d_{62} bilayers containing 28.5 mol% cholesterol have been obtained under similar conditions. At ambient pressure, DPPC-d_{62} bilayers with this cholesterol concentration are in the *lo* phase over a wide temperature range straddling the pure lipid transition temperature. The responses to pressure of DPPC-d_{62} bilayers with and without cholesterol present are compared. One issue of particular interest in this study is whether there is any evidence of a pressure-induced change in the location of cholesterol molecules in the bilayer. Cholesterol-containing bilayers have previously been studied at high pressure using neutron scattering (20) and Fourier transform infrared spectroscopy (34, 35).

Methods and materials

DPPC-d_{62} was synthesized by acylation of glycerophosphocholine (Sigma, St. Louis, Mo.) with chain-perdeuterated palmitic anhydride using the method of Gupta et al. (36). Perdeuterated palmitic acid was prepared by the method of Hsiao et al. (37). The final product was purified on a 1.5 m Sephadex LH-20 liquid chromatography column (Pharmacia Biotech, Baie d'Urfe, Que.) and eluted with 100% ethanol, which was redistilled before use. Using thin-layer chromatography, the product was found to migrate as a single spot.

Samples of 28.5 mol% cholesterol in DPPC-d_{62} were prepared by mixing the two components in chloroform solution and then removing the solvent under dry nitrogen flow after which the mixture was vacuum-dried for approximately 5 h. Both DPPC-d_{62} and DPPC-d_{62}–cholesterol samples were hydrated in excess 0.1 M phosphate buffer (pH 7.2). The buffer to lipid ratio was about 2:1 by weight. Suspensions of multilamellar vesicles were prepared by stirring thoroughly with a

© 1998 NRC Canada

fine glass rod. The suspended samples were transferred to thin-walled polyethylene tubes, which then were heat-sealed.

Deuterium NMR was carried out in a 3.5 T superconducting solenoid (Nalorac Cryogenics, Martinez, Calif.) using a probe capable of operating at applied hydrostatic pressures up to 2.7 kbar and temperatures ranging from –20°C to 80°C (38). The coil and the tube containing the sample are both contained within a beryllium–copper cell that was pressurized with hydraulic oil (AW ISO grade 32). Pressure in the cell was measured using a Bourdon tube pressure gauge, which was calibrated using a dead-weight gauge. To maintain isobaric conditions while varying sample temperature, the pressure cell in the NMR probe was connected to a temperature-controlled external vessel of approximately twice the volume.

Spectra were obtained using a quadrupole echo sequence (39) with $\pi/2$ pulses of between 2.35 and 2.55 μs and a pulse separation of 35 μs. For each spectrum, between 8000 and 72 000 transients were averaged. Free induction decays were digitized at 2 μs per point in the liquid crystalline phase and 1 μs per point in the gel and ordered phases. Oversampling (40) by a factor of two was used to obtain effective digitizer dwell times of 4 μs and 2 μs in the liquid crystalline and ordered phases, respectively.

The weighted mean splitting of the ^{2}H NMR spectrum can be obtained by calculating the first spectral moment over half of the spectrum using (41)

$$M_1 = \frac{\int_0^\infty \omega f(\omega) d\omega}{\int_0^\infty f(\omega) d\omega}$$

where $f(\omega)$ is the spectrum. For a chain-perdeuterated lipid in the liquid crystalline phase, M_1 is proportional to the average, over all deuterons on the chain, of the orientational order parameter,

$$S_{CD} = \frac{1}{2} + \left\langle 3\cos^2 \theta_{CD} - 1 \right\rangle$$

where θ_{CD} is the instantaneous angle between a given carbon–deuterium bond and the axis of rotational symmetry of the molecules.

Results and discussion

By varying the pressure at fixed temperature, Driscoll et al. (27) used ^{2}H NMR to partially locate boundaries between ordered phases in the pressure–temperature phase diagram of DPPC-d_{62}. Complementary phase diagram information can be obtained from similar experiments in which temperature is scanned with the hydrostatic pressure fixed. Figure 1 shows the ^{2}H NMR spectra of DPPC-d_{62} for a series of temperatures at ambient pressure, 100 MPa, and 210 MPa. Above the transition, the spectra at ambient pressure and 100 MPa are superpositions of Pake doublets characteristic of axially symmetric reorientation. Below the transition, the spectra reflect slower axially asymmetric motions characteristic of the gel phase. It is difficult to distinguish the L_β and P_β' phases using ^{2}H NMR and we do not distinguish those phases here. Selected ordered-phase spectra obtained at 210 MPa are shown in Fig. 1*c*. The temperature dependence of the first spectral moment, M_1, at ambient pressure, 100 MPa, and 210 MPa is shown in Fig. 2.

As can be seen from the spectra of Fig. 1, the main transitions at ambient pressure and at 100 MPa are from the liquid crystalline phase to the normal gel phase. While the temperature dependence of M_1 at 210 MPa shows a similar jump at the main transition, it is clear from the spectra of Fig. 1*c* that the ordered phase just below the transition is not the gel phase seen at ambient pressure. This is consistent with the phase diagram presented by Driscoll et al. (27) who show the liquid crystal to gel transition being replaced by a liquid crystal to interdigitated gel transition near 200 MPa and 80°C. Interdigitation has been reported under similar conditions by workers using a variety of techniques including neutron diffraction (19, 21), Fourier-transform infrared spectroscopy (24, 25), and deuterium NMR on specifically labelled lipid (33).

The isobaric series of spectra shown in Fig. 1*c* provide some insight into the location of boundaries between ordered phases at 210 MPa. The shape of the spectrum evolves continuously from 81°C to 38°C. Between 38°C and 36°C there is a subtle but distinct change in the spectrum, which begins to display a shoulder near ±40 kHz in addition to the shoulder near ±20 kHz. In Fig. 2, this transition can also be seen as a slight break in M_1 versus T results for 210 MPa. The phase below this transition is identified as GIII on the basis of a comparison with results of Driscoll et al. (27) that show a DPPC-d_{62} spectrum displaying similar shoulders situated within this region of the pressure–temperature phase diagram. Peng et al. (33) display ^{2}H NMR spectra of selectively chain-deuterated DPPC in several ordered phases at high pressure. In the GIII phase, deuterons at the C13 position give rise to a prominent doublet with peaks at about ±40 kHz. If deuterons on neighbouring carbons display similar spectra, their superposition could account for the shoulders that seem to be characteristic of the DPPC-d_{62} GIII spectrum.

Structures of the ordered phases, including GII and GIII, have been described by Wong et al. (25). In both GII and GIII, chains are extended and tilted with respect to the bilayer normal. While the degree of interchain ordering is higher in GIII than in GII, neither phase is entirely static on the NMR time scale. As discussed below, the GII phase can be identified with one of the ordered bilayer phases observable at ambient pressure. The current measurements at 210 MPa do not display a region of GII around 40°C but the selective label studies of Peng et al. (33) suggest that the distinction between GII and GIII is most apparent in the spectra of deuterons near the methyl end of the acyl chain. The GII and GIII phases may thus be difficult to distinguish with perdeuterated samples.

While the phase existing between 38°C and 26°C corresponds to the GIII phase described by Jonas and co-workers (27, 33), the width of this region seems to be substantially smaller than indicated in their phase diagram. At 24°C and below, the major component of the spectrum is axially symmetric with a splitting corresponding to the full quadrupole interaction. The central component, due to the methyl deuterons, is narrowed by rotation about the symmetry axis of

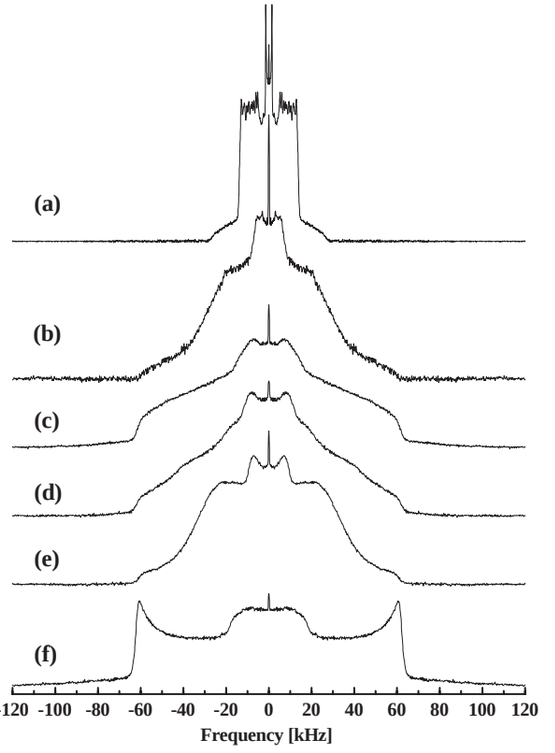
the methyl group. This phase, in which the chains appear to be rigid, has been labelled phase X by Driscoll et al. (27).

One interesting question that requires comment is the relationship between the ordered phases identified at high pressure and the subgel or L_C phase that has been reported for a variety of phospholipid systems at ambient pressure and high pressure (29, 42–45). In some cases, formation of this phase requires incubation of the sample at a temperature that is low enough for the ordered phase to be stable but high enough that molecular rearrangement into the more ordered phase is not frozen out. For some unsaturated lipids (45) or saturated lipids at elevated pressure (29), this temperature range can be limited to a few degrees.

The formation of the subgel phase of DPPC-d_{62} near 0°C is barely discernable in the temperature dependence of ambient pressure first and second spectral moments presented by Davis (46). Results obtained with different effective cooling

Fig. 3. ^{2}H NMR spectra of DPPC-d_{62} at selected pressures and temperatures representing phases encountered in these experiments: (*a*) L_α at 40°C, ambient pressure; (*b*) P_β' (GI) at 32°C, ambient pressure; (*c*) L_C (subgel) at 0°C, ambient pressure; (*d*) GIII at 0°C, 100 MPa; (*e*) Gi (interdigitated gel) at 50°C, 270 MPa; (*f*) *X* at 0°C, 270 MPa.



rates have sometimes fortuitously displayed a clearer transition near 0°C (47). Given that there is a transition from a gel phase to a more ordered phase near 0°C at ambient pressure,

the low-pressure, low-temperature region of the phase diagram presented by Driscoll et al. (27) is presumably incomplete since the GII to GIII and GIII to X boundaries both extrapolate to ambient pressure at temperatures below 0°C. Wong et al. (25) have pointed out, however, that pressure can hinder the molecular reorientations required to bring about the transition into or out of the subgel phase and make the phase transformation effectively unobservable.

Because the subgel phase falls outside of the naming convention used by Driscoll et al. (27), it is helpful to make note of Luzatti's naming convention (48) in which the liquid crystalline phase is L_α, the tilted gel phase just below the transition is P_β', the gel phase below the pretransition is L_β, and the subgel phase is L_C. Figure 3 shows representative spectra for these ambient pressure phases plus the phases observed at high pressure. The L_β and P_β' spectra are similar except for some rounding of the shoulders in the former phase. The difference between the L_C and GIII spectra near the transition is subtle but distinct and it is clear that these phases can be distinguished by ^{2}H NMR if conditions permit formation of the subgel phase.

Figure 4 shows spectra for series of decreasing pressures at 0°C and 45°C. At 45°C, the change in spectral shape from the interdigitated phase to the GI (or P_β') phase seems to occur between 121 and 55 MPa. At 0°C, the spectra evolve from the rigid lattice spectrum characteristic of the *X* phase to spectra characteristic of the GIII phase between 270 and 143 MPa. The spectra for 121–55 MPa are characteristic of the GIII phase. The spectra are characteristic of the L_C phase for 44 MPa and below. It is interesting to note that the spectra at 22 and 132 MPa are strikingly similar, which reinforces the point that the difference between the L_C and GIII phases is subtle. The pressure dependence of M_1 for 0°C, shown in Fig. 5, confirms the existence of three pressure ranges in which the spectra appear to display distinct behaviours. These transition pressures are close to those indicated in the phase diagram of Driscoll et al. (27) but the lowest pressure phase is L_C rather than GII (or L_β). This implies a nearly vertical boundary, in the pressure–temperature diagram, between the L_C and GII (or L_β) phases. To be consistent with the results presented by Driscoll et al. (27), this boundary must presumably terminate at a L_C–GII–GIII triple point in the neighbourhood of 50 MPa and at a temperature slightly above 0°C.

Except for the two points noted above, the present observations are consistent with the DPPC-d_{62} pressure–temperature phase diagram presented by Driscoll et al. (27). At ambient pressure, the accessible phases are the liquid crystalline phase, L_α, the gel phases, P_β' and L_β, and the subgel phase, L_C. At 210 MPa, the phases observed are the liquid

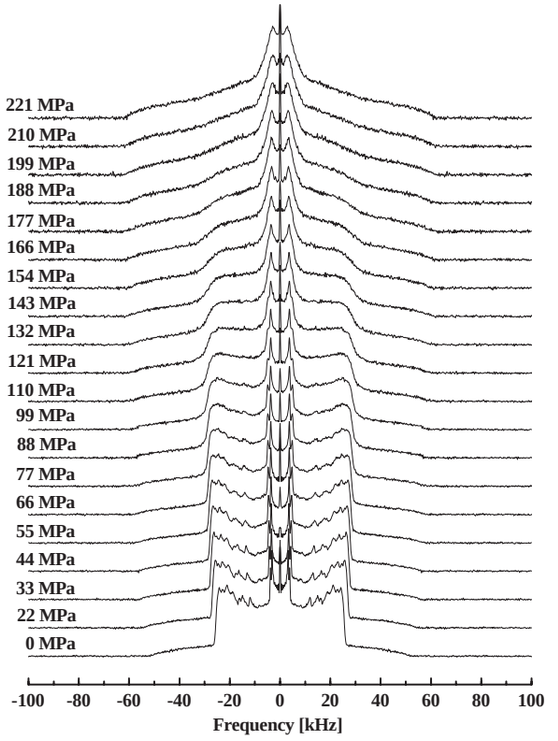
crystalline phase, the interdigitated gel phase, the GIII phase, and the nearly rigid lattice *X* phase. Knowledge of this phase diagram provides a background from which to consider the effect of pressure on the interaction of cholesterol with DPPC and, in particular, to address the question of whether pressure alters the location of cholesterol within the bilayer.

For concentrations above 25 mol% cholesterol in DPPC, at ambient pressure, the bilayer is in the liquid-ordered (*lo*) phase (13). Within this region of the temperature–composition phase diagram, the bilayer changes continuously from a relatively ordered lipid phase at low temperature to a more fluid phase at higher temperature with no crossings of phase boundaries (9). Similar results have been observed for other cholesterol–phospholipid systems (11, 12) although it must be noted that other phase diagrams have been proposed (14, 15). Figure 6 shows ^{2}H NMR spectra of DPPC-d_{62} containing 28.5 mol% cholesterol for a series of temperatures at ambient pressure, 100 MPa, and 210 MPa. At 50°C, the ambient pressure spectrum is a superposition of Pake doublets, characteristic of fast axially symmetric motion, but with significantly larger splittings than would be seen in the liquid crystalline phase of the pure lipid. The larger splittings reflect the ordering effect of cholesterol on the lipid acyl chains. At 0°C, the ambient pressure spectrum is broader and no longer characteristic of fast axially symmetric reorientation. Between these two temperatures, however, the evolution of spectral shape is continuous and there is no change that can be identified as a phase transition. The spectra retain the sharp features characteristic of a fluid phase down to at least 20° below the transition temperature of pure DPPC-d_{62}. Figures 6*b* and 6*c* show spectra obtained from the same sample for a series of temperatures at 100 MPa and a series of temperatures at 210 MPa. At both 100 and 210 MPa, the spectra again display large splittings but remain characteristic of a fluid phase to well below the DPPC-d_{62} transition temperature at that pressure. For 210 MPa, the collection of spectra was continued to nearly 40° below the DPPC-d_{62} transition temperature at that pressure. While the spectra evolved into a shape that increasingly departed from that characteristic of fast axially symmetric reorientation, there was again no clear transition. Figure 7 shows spectra of the cholesterol-containing sample for a series of pressures at 40°C. Continuous evolution of the spectrum through a range of spectral shape is again observed. While the spectra around 40°C and 210 MPa display some resemblance to gel phase spectra that are characteristic of slow, axially asymmetric, reorientation, the prominence of the central doublet suggests that enough motion persists for there to be a significant variation of quadrupole echo decay time along the chain. Similarly distorted spectra have been observed in mixtures of unsaturated lipid and cholesterol, which also order continuously with decreasing temperature (45).

Figure 8 shows the temperature dependence of M_1 for DPPC-d_{62} and DPPC-d_{62} containing 28.5 mol% cholesterol at ambient pressure, 100 MPa, and 210 MPa. Except for a pressure-induced shift in temperature, the behaviour of M_1 is similar for all three cases. This is particularly interesting at 210 MPa where the transition in the pure DPPC-d_{62} system is from the liquid crystalline phase to an interdigitated phase. There was no evidence in these results of the formation of an interdigitated phase in the cholesterol-containing sample. Indeed, the behaviour of the cholesterol-containing sample at high pressure appears to be analogous to that observed in the liquid-ordered (*lo*) phase at ambient pressure. In essence, cholesterol modifies the response of the bilayer phase behaviour to applied pressure. For all three pressures, the spectrum of the cholesterol-containing sample was characteristic of a fluid phase at the temperature corresponding to the pure lipid transition for that pressure. The first moments of these spectra, however, were close to those observed in the ambient-pressure gel phase of DPPC-d_{62}. Bearing in mind that increased chain order generally corresponds to increased bilayer thickness, this observation suggests that, for a given

© 1998 NRC Canada

Fig. 7. ^{2}H NMR spectra of DPPC-d_{62} plus 28.5 mol% cholesterol at selected pressures for 40°C.

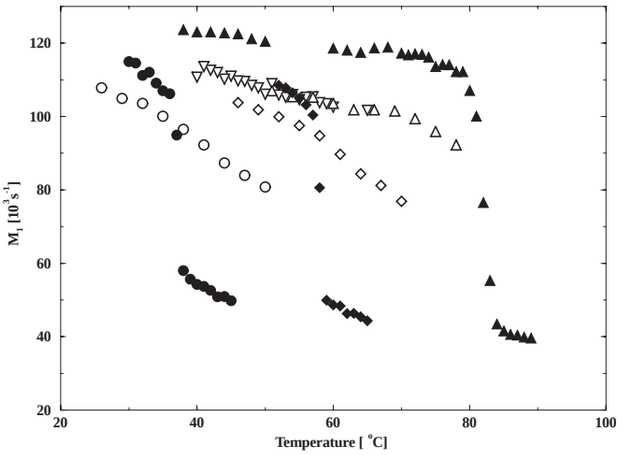


temperature, the presence of cholesterol may substantially diminish the effect of pressure on the thickness of fluid bilayers. Reis et al. (35) have drawn a similar conclusion from Fourier transform infrared studies of internal chain motions in DPPC–cholesterol bilayers at high pressure. The observation that the temperature dependence of M_1 does not change with increased pressure, aside from an overall shift, is indirect evidence that pressure does not substantially alter the interaction of cholesterol with the bilayer and thus that the location of cholesterol within the bilayer is not changed by the application of pressure despite the anisotropic response of the bilayer to applied pressure.

Conclusions

The pressure and temperature dependences of ^{2}H NMR spectra reported here are consistent with the DPPC-d_{62} phase diagram reported by Driscoll et al. (27) with the exceptions of the position of the boundary between the GIII and *X* phases and the presence of the L_C phase at low pressure and temperature. Near 200 MPa, DPPC-d_{62} passes through a variety of phases including the liquid crystalline phase, an interdigitated phase, the GIII phase, and the *X* phase as temperature is lowered from 80 to 0°C. Under the same conditions, the sample containing 28.5 mol% cholesterol changes continuously from fluid to ordered without passing through this series of phases. The behaviour at high pressure thus appears to be analogous with that observed at ambient pressure where DPPC bilayers containing this concentration of cholesterol remain in the liquid-ordered (*lo*) phase over a wide temperature range. The presence of cholesterol also reduces

Fig. 8. Inverted and upright open triangles represent two separate runs on the same sample.



the sensitivity of bilayer thickness to pressure. These observations provide an example of how the response of bilayer properties to pressure can be substantially altered by addition of a second amphiphilic component. This point is particularly interesting in light of the complexity of natural membranes that have evolved under the influence of various stresses.

Evidence for room temperature mesomorphism in a mixed-valent diruthenium(II,III) quintapalmitoleate polymer

Jennifer F. Caplan, Christopher A. Murphy, Susan Swansburg, Robert P. Lemieux, T. Stanley Cameron, and Manuel A.S. Aquino

Abstract: The synthesis of $Ru_2(\mu\text{-}O_2CR)_4(\mu'\text{-}O_2CR)$ **(1)**, R = $\text{-}CH_2(CH_2)_6CH{=}{=}CH(CH_2)_5CH_3$, has been achieved and characterization using elemental analysis and FTIR and UV–Vis spectroscopies undertaken. Strong evidence for a hexagonal discotic mesophase has been found using differential scanning calorimetry, variable-temperature polarizing optical microscopy, and X-ray powder diffraction. A solid to liquid crystal transition was found upon heating at 128°C and the mesophase is found to persist to room temperature upon cooling from 150°C. This is the first report of room temperature mesomorphism in a mixed-valent metallomesogen.

Key words: ruthenium carboxylate, liquid crystal, metallomesogen, mixed valence, polymer.

Résumé : On a effectué la synthèse du complexe $Ru_2(\mu\text{-}O_2CR)_4(\mu'\text{-}O_2CR)$ (**1**) [R = $\text{-}CH_2(CH_2)_6CH{=}CH(CH_2)_5CH_3$] et on l'a caractérisé par analyse élémentaire et par spectroscopies IR par TF et UV–Vis. Faisant appel à la calorimétrie à balayage différentiel, à la microscopie optique polarisante à température variable et à la diffraction des rayons X, on a obtenu de fortes indications suggérant l'existence d'une mésophase discotique hexagonale. Par chauffage à 128°C, on a établi la présence d'une transition de solide à cristal liquide et on a observé que, lors de son refroidissement de 150°C à la température ambiante, la mésophase persiste. Il s'agirait du premier cas de mésomorphie à température ambiante pour un métallomésogène à valence mixte.

Mots clés : carboxylate de ruthénium, cristal liquide, métallomésogène, valence mixte, polymère.

[Traduit par la Rédaction]

Introduction

The synthesis of transition metal containing liquid crystals (metallomesogens) is one of the fastest growing areas of inorganic materials science, and stresses the importance of coordination chemistry in inorganic materials design (1). In contrast to their organic cousins, few metallomesogens display liquid crystalline behaviour at room temperature. Metallomesogens derived from homovalent dinuclear metal carboxylates, $M_2(\mu\text{-}O_2CR)_4L_2$ (M = Cr, Mo, W, Rh, Ru, and Cu), have proven to be some of the most interesting systems (2–5). These compounds offer much flexibility in that the metal and R (often a long-chain alkyl group) can be varied to elicit desired electronic, magnetic, and (or) mesogenic properties.

Ruthenium carboxylates are the only examples in which both homovalent Ru_2(II,II) and mixed-valent Ru_2(II,III) systems have been studied (2*a*, 4*b*, 5, 6). The homovalent $Ru_2(\mu\text{-}O_2CR)_4$ systems, despite their inherent air sensitivity, have received more attention. Their structure consists of chains of dimer units linked by intermolecular Ru···O bonds (Fig. 1*a*). Mesophases are observed with linear, saturated R = $n\text{-}C_4H_9$ chains that have a transition temperature of 151°C. These values drop as the chain length increases, and plateau at ~ 100°C for R = $n\text{-}C_8H_{17}$ to $n\text{-}C_{19}H_{39}$ chains (5*b*). A later study found that by introducing branching or unsaturation into the side-chain R groups a drop in the transition temperature could be achieved. In the 11-undecenoic acid derivative of Ru_2(II,II) the transition was found to drop to 53°C, compared to 103°C in the saturated linear analogue (2*a*). The mixed-valent diruthenium carboxylates are of great interest because of their significantly greater air stability and their unique magnetic and electronic properties. (Each dimer has three unpaired electrons due to an accidental degeneracy of the π^* and δ^* orbitals) (7). The $Ru_2(\mu\text{-}O_2CR)_4(\mu'\text{-}O_2CR)$ complexes (where R = $n\text{-}C_8H_{17}$ and $n\text{-}C_{11}H_{23}$) were the first reported examples of mixed-valent metallomesogens (6). Both derivatives displayed a transition temperature of 149°C (with ΔH = 15 and 66 kJ mol^{-1}, respectively). They contain five bridging linear-chain carboxylic acids, four *intra*dimer and one *inter*dimer (see Fig. 1*b*).

We wish to report here the first example of a mixed-valent metallomesogen, $Ru_2(\mu\text{-}O_2CR)_4(\mu'\text{-}O_2CR)$ **(1)**, incorporating

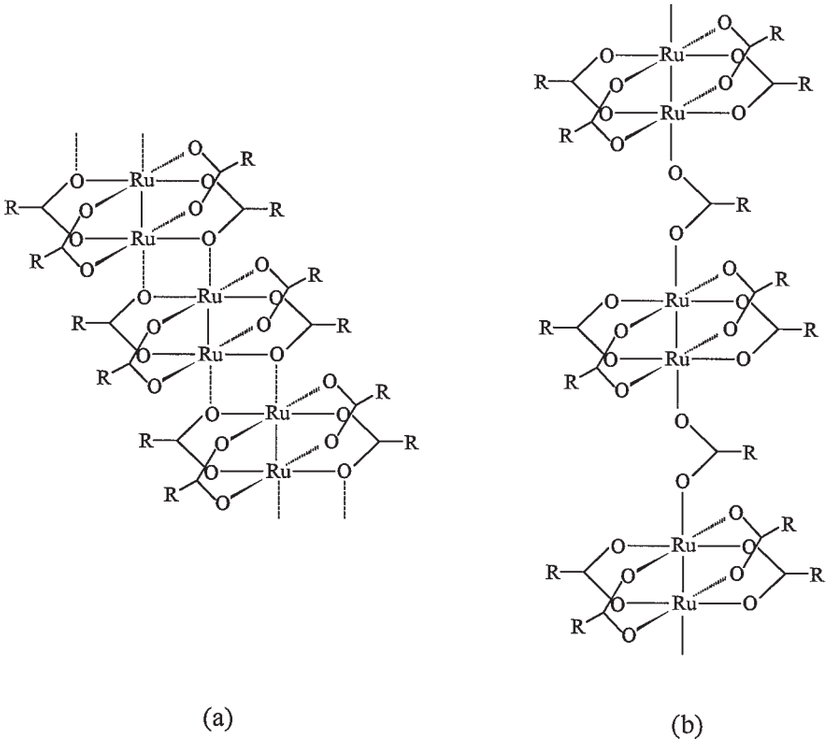
Fig. 1. Proposed structure of (*a*) homovalent $Ru_2(\mu\text{-}O_2CR)_4$ chains and (*b*) mixed-valent $Ru_2(\mu\text{-}O_2CR)_4(\mu'\text{-}O_2CR)$ chains.



an unsaturated side chain derived from palmitoleic acid (*cis*-9-hexadecenoic acid), i.e., R = $-CH_2(CH_2)_6CH{=}CH(CH_2)_5CH_3$, that displays liquid crystal behaviour at room temperature.

The synthesis of **1** was carried out in aqueous solution using a carboxylate exchange reaction (2*a*) in which the bridging acetates of $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]^+$ (generated in situ by prior dechlorination of $Ru_2(\mu\text{-}O_2CCH_3)_4Cl$ with Ag_2SO_4) are replaced by palmitoleic acid by vigorous stirring at room temperature for 1 week.

$$[1]\quad Ru_2(\mu\text{-}O_2CCH_3)_4Cl + Ag^+ + 2\,H_2O \rightarrow [Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]^+ + AgCl$$

$$[2]\quad [Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]^+ + 5RCOO^- \rightarrow Ru_2(\mu\text{-}O_2CR)_4(\mu'\text{-}O_2CR) + 2H_2O + 4CH_3COO^-$$

Subsequent extraction of the resulting dark brown oil with heptane and precipitation with cold acetone gave the product **(1)** in 22% yield. (Anal. calcd. for $C_{80}H_{145}O_{10}Ru_2$: C 65.40, H 9.95, Ru 13.76; found: C 65.04, H 9.85, Ru 13.89.) The product is insoluble in most solvents but slightly soluble in dichloromethane, dichloroethane, and longer chain hydrocarbons such as heptane.

Elemental analysis (C, H, and Ru) is consistent with five carboxylates per diruthenium unit. The infrared spectrum shows strong bands at 2925 and 2850 cm^{-1} due to C–H stretching. $\nu_{sym}(OCO)$ and $\nu_{asym}(OCO)$ at 1416 and 1455 cm^{-1}, respectively, are characteristic of the four intradimer bridging carboxylates (8), a strong band at 1524 cm^{-1} being diagnostic of the $\nu_{asym}(OCO)$ for the interdimer bridging carboxylate (9). The total absence of a band at ~1720 cm^{-1} indicates that there is no free acid present. A UV–visible spectrum in dichloromethane shows the characteristic $\pi^*(Ru_2) \leftarrow \pi(RuO, Ru_2)$ transition at 429 nm (ε = 2270 M^{-1} cm^{-1}). Typically these bands lie around 425 nm (7) with molar absorptivities in the range 500–800 M^{-1} cm^{-1} for non-polymeric species. The extinction coefficient is higher, possibly due to the polymeric nature of the complex. It has been found that π interactions with *inter*dimer bridging ligands cause the $\pi^*(Ru_2)$ orbital to have more ligand character therefore making the $\pi^*(Ru_2) \leftarrow \pi(RuO, Ru_2)$ transition less forbidden (10). In addition, preliminary gel permeation chromatography (GPC) measurements in dichloroethane indicate an average $M_w = 2 \times 10^5$.

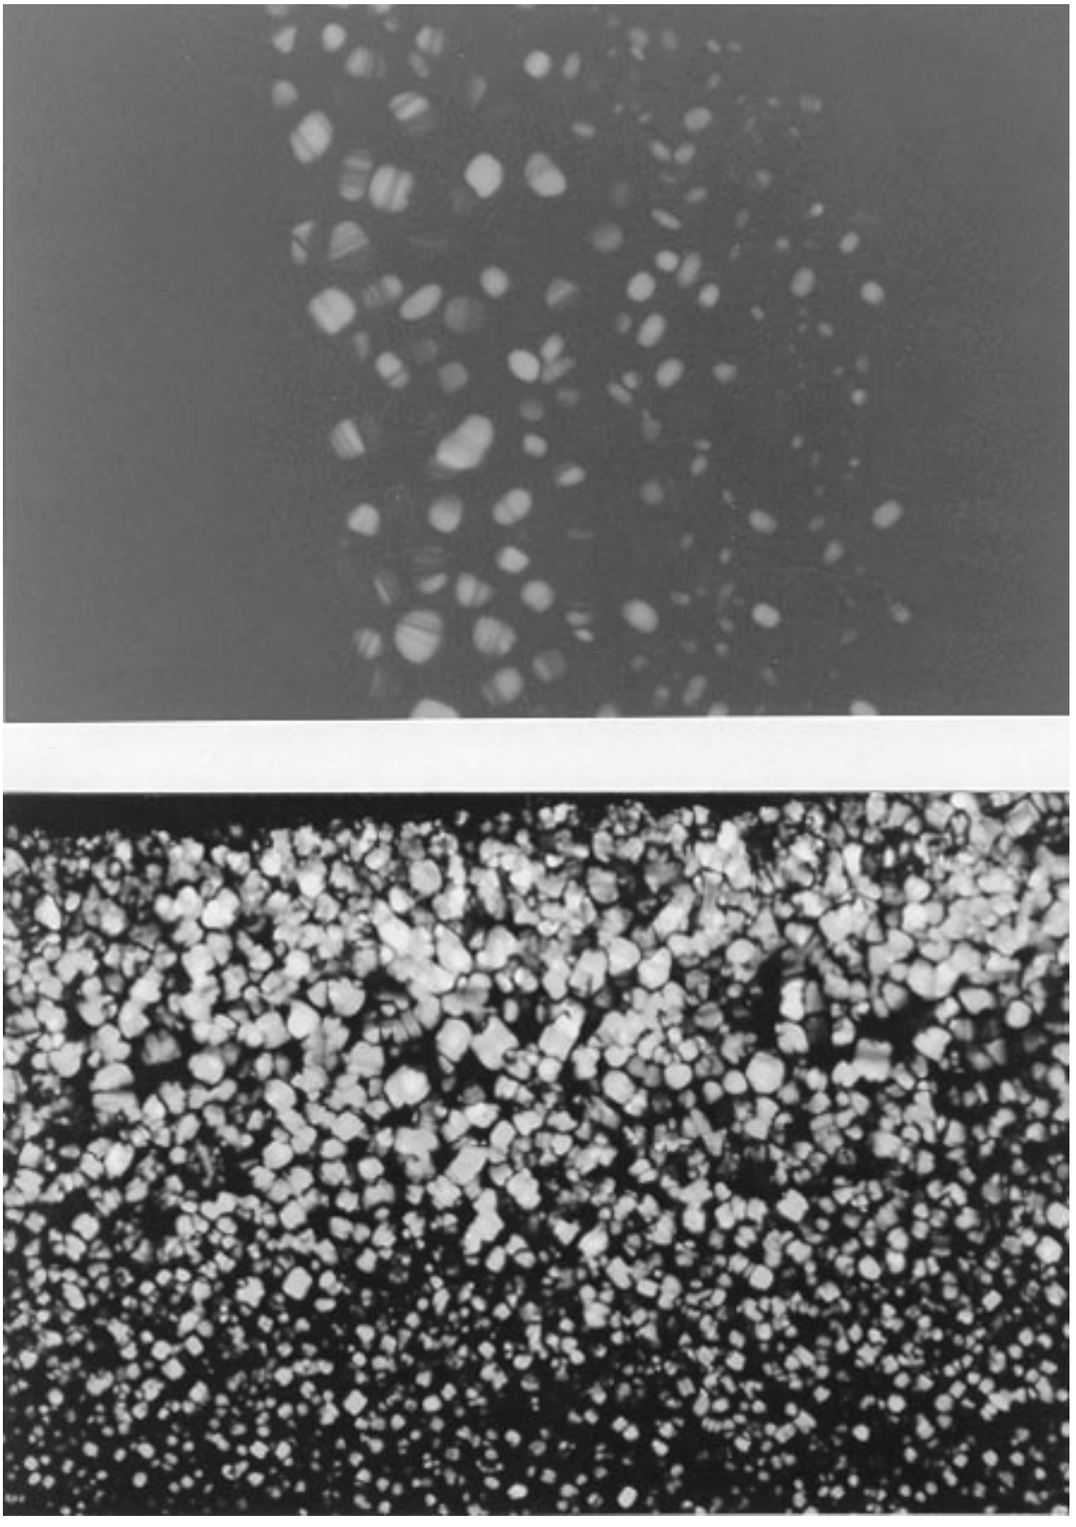
The stoichiometry revealed by the elemental analysis, the presence of the distinct *inter*dimer carboxylate stretch in the infrared spectra and the absence of any free acid carbonyl, the higher than usual molar absorptivities in the electronic spectra, and the limited solubility of this complex, together with the GPC results, lead us to postulate a polymeric structure (Fig. 1*b*).

Using differential scanning calorimetry (DSC), variable-temperature polarizing optical microscopy, and X-ray powder diffraction, we have been able to provide strong evidence that compound **1** exhibits room-temperature liquid-crystalline behaviour.

Heating and cooling cycles were performed and, upon heating, the compound displays an endotherm with a transition temperature of 128°C (ΔH = 9.6 kJ mol^{-1}) corresponding to a solid-to-liquid crystal transition. However, upon subsequent cooling from 160°C no peaks are observed down to room temperature. A second cycle yields a flat line for

© 1998 NRC Canada

Fig. 2. Optical texture of the mesophase for **1** obtained upon cooling from 150°C. Top: 100°C, bottom: 50°C.



both heating and cooling. Scans to higher temperatures reveal decomposition at >300°C. There is no evidence of clearing to an isotropic liquid. The transition temperature is 20°C less than those observed by Cukiernik et al. (6) for the mixed-valent, $Ru_2(\mu\text{-}O_2C\text{-}n\text{-}C_8H_{17})_4(\mu'\text{-}O_2C\text{-}n\text{-}C_8H_{17})$, and $Ru_2(\mu\text{-}O_2C\text{-}n\text{-}C_{11}H_{23})_4(\mu'\text{-}O_2C\text{-}n\text{-}C_{11}H_{23})$ species with saturated side chains but even more dramatic is the substantial drop in the ΔH value. It has generally been observed for the

© 1998 NRC Canada

homovalent Ru_2(II,II) complexes with the saturated side chains that ΔH increases with increasing length of the side chain (although the dependence is by no means linear) from 20 kJ mol^{-1} in $Ru_2(\mu\text{-}O_2C\text{-}n\text{-}C_4H_9)_4$ to 155 kJ mol^{-1} in $Ru_2(\mu\text{-}O_2C\text{-}n\text{-}C_{19}H_{39})_4$ (5*b*). Introduction of unsaturation and branching does serve to lower the ΔH values over the saturated analogues. $Ru_2(\mu\text{-}O_2C(CH_2)_8CH{=}CH_2)_4$ has ΔH = 32 kJ mol^{-1} versus 78 kJ mol^{-1} for the saturated derivative (2*a*). In our case the value of 9.6 kJ mol^{-1} is significantly smaller than the value for any of the Ru_2(II,II) complexes of comparable chain length and, more importantly, less than the 15 kJ mol^{-1} reported for the mixed-valent $Ru_2(\mu\text{-}O_2C\text{-}n\text{-}C_8H_{17})_4$ (μ'-O_2C-*n*-C_8H_{17}), which has only half the side-chain length!

Polarizing optical microscopy reveals a liquid crystal phase for **1** at slightly above 100°C upon cooling the sample from 150°C. As shown in Figs. 2*a* and 2*b*, cooling results in the appearance of small fan-like domains from a homeotropic domain, which merge on further cooling into a mosaic texture that persists to room temperature. The texture is consistent with a monotropic columnar hexagonal discotic phase, D_H, (11), which has been observed for other metal carboxylate mesogens. The absence of any visible birefringence upon heating is due to the fact that uniaxial phases such as hexagonal discotics tend to form large homeotropic domains with the column axis perpendicular to the glass.

The X-ray diffraction pattern obtained for **1** at room temperature before heating shows a broad peak at 4.4 Å, most likely due to the stacking period of the binuclear ruthenium core along the column axis (5*b*). After heating the sample past the transition temperature to 140°C, a series of sharp peaks appear with *d*-spacings of 6.8, 7.8, 10.3, and 11.6 Å, in addition to the broad peak at 4.4 Å. These peaks persist virtually unshifted when subsequent scans are taken upon cooling to 60°C and room temperature. Scans taken 24 h later at room temperature on the same sample still show evidence of these same peaks although their intensities have diminished. This behaviour parallels nicely the DSC and optical microscopy measurements and the new peaks are assigned to the appearance of the mesophase. Due to instrument limitations, the intercolumnar *d*-spacing (assuming a columnar structure) in the liquid-crystal phase, which would be predicted to lie higher than 17.6 Å (the *d*-spacing limit corresponding to $2\theta = 5°$) is not seen (5*b*, 6) and no direct ratio comparisons could be made to the peaks that do appear. However, the reciprocal spacings of the peaks that are observed are very close to the $3^{1/2} : 4^{1/2} : 7^{1/2} : 9^{1/2}$ ratio predicted for an hexagonal discotic phase (4*a*, 5*b*).

It is probably not appropriate to compare our mixed-valent system with the homovalent Ru_2(II,II) complexes; the structures are different (compare Figs. 1*a* and 1*b*), but it is clear that even a small degree of unsaturation lowers the transition temperature somewhat and ΔH substantially. When unsaturation is present, particularly near the middle of the side chain, the packing of these chains will be less efficient since there is less flexibility and the result is a less stable crystalline phase. It will require less energy and lower temperatures to undergo the transition to the mesophase. Despite the still relatively high transition temperature, persistence of a mesophase to room temperature for a mixed-valent system is, as far as we know, unprecedented. Since this occurs after only one heating cycle it may be due to a supercooling effect. The material eventually (2–3 days) reproduces the original IR and DSC measurements albeit with some decomposition. Supercooling has been seen in *homovalent* Cu_2(II,II) tetraoleates and tetracitronellates (2*a*). Further insight into this interesting effect will hopefully be gained by increasing the degree of unsaturation as well as by studying the effect of branching in the side chain in a series of analogous compounds. Studies in this direction are currently underway.

Synthesis and properties of a sterically encumbered poly(thienylene vinylene): poly[*E*-1,2-(4,4′-dihexyl-2,2′-dithienyl)ethylene]

Jimmy Lowe, Carl Bartels, and Steven Holdcroft

Abstract : Electrically conducting poly[*E*-1,2-(4,4′-dihexyl-2,2′-dithienyl)ethylene] was synthesized and structurally characterized by UV–visible, ^{1}H NMR, and FTIR spectroscopy. The head-to-head arrangement of the alkylthiophene dyads directly affects the UV–visible, photoluminescence, and electroluminescence maxima of the polymer. The conductivity of the doped polymer was measured to be ~2 S cm^{-1} and the stability of the oxidized polymer possessing various dopants was compared. UV–visible irradiation of PDHDTE rendered the films insoluble and photolithography was used to produce micron-size images. FTIR was used to monitor the photoproducts during photolysis of PDHDTE. Mechanisms of photooxidation were proposed, based on the photoproducts observed.

Key words: polythiophene derivative, head-to-head dyad, photolithography, photooxidation, electroluminescence.

Résumé : On a synthétisé le poly[*E*-1,2-(4,4′-dihexyl-2,2′-dithiényl)éthylène] qui conduit l'électricité et on a caractérisé sa structure par spectroscopies UV–visible, IR à TF et RMN du ^{1}H. L'arrangement tête-à-tête des diades alkylthiophènes affecte directement les maxima du polymère dans les spectres UV–visible, la photoluminescence et l'électroluminescence. On a mesuré que la conductivité du polymère dopé est approximativement égale à 2 S cm^{-1} et on a comparé la stabilité du polymère oxydé comportant divers dopants. L'irradiation UV–visible du PDHDTE rend les films insolubles et on a fait appel à la photolithographie pour produire des images de la taille du micron. On a utilisé l'IR à TF pour détecter les photoproduits obtenus par photolyse de PDHDTE. On propose des mécanismes de photooxydation qui tiennent compte des photoproduits observés.

[Traduit par la Rédaction]

Introduction

The growing interest in conjugated polymers for applications in devices such as light-emitting diodes (LEDs), electrical conductors, and electrochromic displays has led to the design of many new materials. Much work has recently been devoted to the synthesis of polymers containing vinylene linkages, e.g., poly(phenylene vinylene) (PPV) and poly(thienylene vinylene) (PTV), because regioregular copolymers can be made with new or enhanced properties (1–3). Unsubstituted PPV and PTV polymers are insoluble, infusible, and therefore difficult to process. To overcome these difficulties they are often prepared via a soluble precursor polymer. More recently, this problem has been overcome by the attachment of flexible side chains on the polymeric backbone, which confers solubility on the polymer.

An alternative route to PTV and its derivatives has been achieved through organometallic chemistry (4–6). These polymers contain repeat thienylenevinylene or (2,2′-dithienyl-5,5′-vinylene) units and are soluble due to the presence of alkyl or alkoxy substituents. For example, Catellani et al. have synthesized regioregular poly[*E*-1,2-(3,3′-dialkyl-2,2′-dithienyl)ethylenes] (Fig. 1) where the repeat unit is thienylene–vinylene–thienylene (TVT) in which 3-alkylated thiophene dyads are linked via a tail-to-tail (TT) configuration (5). These materials display low band gaps, ~1.7 eV, and are transparent in the doped state. Poly(3,4-dibutoxythiophenevinylene) and poly[bis(3,4-dibutoxythienylene)vinylene] have been synthesized using nickel-catalyzed Grignard coupling reactions with *trans*-1,2-dichloroethene (6). The polymers were reported to possess absorption maxima of 607 and 527 nm, respectively, and conductivities in the range of 0.03 –1 S cm^{-1} using ferric chloride as a dopant.

Previous work in our group has shown that the quantum yield of photoluminescence in poly(3-alkylthiophenes) films increases with both the alkyl chain length and the head-to-head (HH) content (7, 8). We were therefore interested to learn what effect the regioregularity had on the properties of alkylated PTVs. This paper reports the synthesis and properties of poly[*E*-1,2-(4,4′-dihexyl-2,2′-dithienyl)ethylene] (PDHDTE) (Fig. 1) in which the thiophene dyads are linked via a HH configuration. The polymer, made by oxidative coupling of the oligomer, is soluble in common organic solvents due to the presence of the side chains. Our research group has an ongoing interest in the photochemistry and photolithography of conjugated materials. We therefore describe preliminary work on the photolithography of this material and discuss

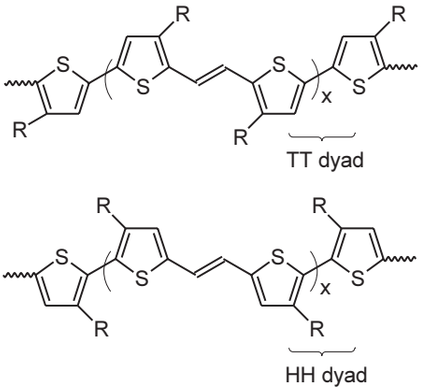
Fig. 1. Structure of poly[*E*-1,2-(3,3′-dialkyl-2,2′-dithienyl)-ethylene] (top) and poly[*E*-1,2-(4,4′-dialkyl-2,2′-dithienyl)ethylenes] (bottom). R = alkyl.



mechanisms of its photooxidation. The conductivity and half-life of PDHDTE possessing various dopants were measured.

Experimental section

Chemicals

A hexane solution of *n*-butyllithium (2.5 M), magnesium bromide diethyl etherate ($MgBr_2 \cdot Et_2O$), *trans*-1,2-dichloroethene (Aldrich), 1,3-bis(diphenylphosphino)propane nickel(II) chloride ($NiCl_2$dppp, Stern Chemicals), and $FeCl_3$ (BDH) were used as received. $CHCl_3$ (BDH) and diethyl ether (Anachemia) were dried over Na and freshly distilled under N_2 before use. 3-Hexylthiophene was synthesized according to the procedure outlined by Kumada and co-workers (9).

Synthesis of *E*-1,2-(4,4′-dihexyl-2,2′-dithienyl)ethylene (DHDTE) (Scheme 1)

This procedure was adopted from Blohm et al. (6). A 250 mL round-bottom flask fitted with a nitrogen inlet and a condenser was charged with 3-hexylthiophene (3.355 g, 19.93 mmol). Freshly distilled ether (90 mL) was added, followed by the addition of 2.5 M *n*-butyllithium in hexanes (7.97 mL, 19.93 mmol) at 0°C. After stirring for 40 min, crushed $MgBr_2 \cdot Et_2O$ was added to the yellow solution and the mixture was stirred for 2 h. *trans*-1,2-Dichloroethene was injected by syringe (0.78 mL, 9.96 mmol) into the suspension at 0°C. Upon addition of the catalyst, $NiCl_2$dppp, the mixture turned orange in colour. The suspension was gently refluxed for 24 h. The reaction mixture was worked up by extraction with diethyl ether and washed with saturated NH_4Cl solution and saturated NaCl solution. The organic layer was dried over anhydrous $MgSO_4$ and concentrated to yield yellow crystals. The crystals were recrystallized from hexanes, collected by suction filtration, and washed with ice-cold heptane. The yield of the recrystallized product was 25%; mp 68–69°C. FTIR (KBr) cm^{-1}: 3075, 3013, 2955, 2921, 2849, 1545, 1466, 1372, 1272, 1200, 1177, 1139, 937, 853, 831, 746, 720, 662. UV–vis ($CHCl_3$), λ_{max}: 350 nm. 1H NMR (400 MHz, $CDCl_3$), δ: 6.95 (2H, -CH=*CH*-), 6.86 (2H, ring, H-5), 6.75 (2H, ring, H-3), 2.54 (4H, t, J = 8 Hz, α-CH_2-ring), 1.51 (4H, dt, J = 8 Hz, β-CH_2-), 1.28 (12H, m, -$(CH_2)_3$-), 0.89 (6H, t, J = 8 Hz, -CH_3). Anal. calcd. for $C_{22}H_{32}S_2$: C 73.33, H 8.89; found: C 73.12, H 9.10.

Synthesis of poly[*E*-1,2-(4,4′-dihexyl-2,2′-dithienyl)ethylene] (PDHDTE)

A round-bottom flask was charged with anhydrous $FeCl_3$ (1.011 g, 6.32 mmol) in $CHCl_3$ (25 mL) and cooled in an ice bath. *E*-1,2-(4,4′-Dihexylthienyl)ethylene (0.5021 g, 1.39 mmol) was dissolved in $CHCl_3$ (10 mL) and added dropwise to the stirred mixture. The addition of the monomer formed a dark purple colour and an hour later a dark blue precipitate was observed. After 4 h, the polymer was precipitated in methanol (75 mL) and stirred overnight. The precipitate was collected and washed with triethylamine followed by acidified methanol. The orange precipitate was extracted via Soxhlet with methanol and pumped dry. Yield: 73%. FTIR (KBr) cm^{-1}: 3075, 3016, 2954, 2925, 2854, 1684, 1652, 1559, 1541, 1457, 1377, 934, 833, 722. UV–vis ($CHCl_3$), λ_{max}: 422 nm. ^{1}H NMR (400 MHz, $CDCl_3$), δ: 6.94 (2H, -*CH*=*CH*-), 6.90 (2H, ring, H-3), 2.51 (4H, br, α-CH_2-ring), 1.54 (4H, br, β-CH_2-), 1.28 (12H, m, -$(CH_2)_3$-), 0.89 (6H, t, J = 8 Hz, -CH_3).

Characterization

^{1}H NMR spectra were recorded on a 400 MHz Bruker AMX400 in $CDCl_3$. Molecular weight distribution curves of polymers were determined by gel permeation chromatography (GPC) using 10^5, 10^4, 10^3 Å μ-Styragel columns at 25°C. Polymers were eluted with tetrahydrofuran (BDH, HPLC grade) and detected using a UV–visible spectrophotometer (Spectra-Physics, model SP8000) and a refractive index detector (Waters, model R400). Data were acquired, stored, and analyzed using an IBM personal computer and custom-written software. Polystyrene (PS) standards (Polymer Labs. Inc.) of molecular weights ranging from 233 000 to 750 Da were used for calibrating GPC columns for hydrodynamic volume versus elution volume. The PS calibration curve was converted to a poly(3-hexylthiophene) (P3HT) based calibration using the following Mark–Houwink constants: for P3HT, $K = 2.28 \times 10^{-3}$ cm^3/g and $a = 0.96$; for PS, $K = 1.29 \times 10^{-2}$ cm^3/g and $a = 0.713$ (10, 11). Infrared spectra were recorded on a Bomem Michelson FTIR (120 series) spectrometer. UV–visible absorption spectra were recorded on a Perkin–Elmer Lambda 3A UV–vis spectrophotometer at 25°C.

For measurements of conductivity, chloroform solutions of polymer were spin-cast on to glass slides. The polymers were oxidized to their electronically conductive form by submersion of the polymer/substrate into an anhydrous 0.1 M solution of gold trichloride in acetonitrile, ferric chloride in nitromethane, or exposed to I_2 vapour. Electronic conductivities were measured using the four-point probe technique.

Photolysis and photolithography

Polymer films were spin-cast from chloroform solution on glass slides. The optical density of the films at λ_{max} was 0.5–0.8. The illumination source was a 200 W high-pressure mercury lamp (Illumination Industries Ltd.). The wavelength of incident light was >300 nm due to the presence of a 300 nm cutoff filter and the light was focused to a diameter of 3 cm. Thin films of PDHDTE were solvent evaporated

onto KBr disks and the FTIR recorded before and during irradiation for various time intervals. To obtain photoimages, polymers were spin-cast onto glass or silicon. The films were irradiated for 3 min through a photomask and an image was obtained upon dissolution of the unexposed polymer in chloroform. All experiments were performed using front-face irradiation of films in ambient air at 25°C.

Electroluminescence of PDHDTE

Steady state luminescence and electroluminescence were measured on an LS-100 spectrofluorometer (Photon Technology International Inc.). For construction of the light-emitting diode (LED), indium tin oxide coated glass slides (ITO) were used as the hole injecting contact. A solution of PDHDTE was used to spin-coat a film of thickness 125 nm. Aluminum (99.999%, Aldrich) was deposited on top of the polymer by vapour deposition to act as the electron-injecting contact.

Results and discussion

The oligomer synthesized possesses a thienylene–vinylene–thienylene (TVT) sequence with the hexyl chains in the 4-position of the thiophene rings. Addition of *n*-butyllithium at 0°C to 3-hexylthiophene favourably lithiates the 5-position due to the presence of the large alkyl group in the 3-position (12). Grignard formation occurs upon addition of $MgBr_2 \cdot Et_2O$. Two equivalents of the Grignard reagent are coupled to *trans*-1,2-dichloroethene using $NiCl_2$(dppp) catalyst. Polymers prepared from *E*-1,2-(3,3′-disubsituted-2,2′-dithienyl) ethylenes have previously been synthesized by chemical polymerization with $FeCl_3$ with retention of the vinyl double bond (4–6). Poly[*E*-1,2-(4,4′-dihexyl-2,2′-dithienyl)ethylene] (PDHDTE) prepared in this work is expected to have the thienyl groups coupled in a head-to-head (HH) dyad and this is confirmed spectroscopically (see below).

Spectroscopic analysis

The polymer is soluble in organic solvents such as chloroform and tetrahydrofuran due to the presence of the pendent hexyl side chains. The number average molecular weight of the polymer was 2500 and the molecular weight distribution was 2.3. M_n is similar to values determined by Toyoshima et al. for poly[*E*-1,2-(dihexyl-2,2′-dithienyl)ethylene] prepared under similar reaction conditions (13).

The infrared spectrum of PDHDTE shows absorptions that are characteristic of alkyl-substituted polydithienylethylenes. The peak assignments were based on FTIR data of similar TVT oligomers and polymers (5, 14). The *trans* geometry of the vinylic double bond is detected by the out-of-plane bending of the C—H bond at 934 cm^{-1} and its C–H stretch at 3016 cm^{-1}. The band at 1457 cm^{-1} is due to the stretching mode of the thiophene ring, which overlaps with the CH_2 and CH_3 deformations. Also, the peak at 833 cm^{-1} is due to the thiophene ring C–H out-of-plane bend.

^{1}H NMR provided more structural information on the oligomer and polymer. The α-protons of thiophene in DHDTE are observed at 6.86 ppm but are not present in the spectrum of the polymer, indicating a predominantly α–α′ coupling of the oligomer. Two signals in the aromatic region of the polymer correspond to the thienyl ring and vinylene protons. Integration of the aromatic signals is equivalent to the integrated signal obtained for the α-methylene of PDHDTE. A peak is observed at 2.51 ppm for the α-methylene. This is taken as evidence for HH linkages in chemically polymerized PDHDTE and is consistent with the spectrum of poly(3,3′-dihexyl-2,2′-bithiophene) where only one α-methylene signal was observed at 2.51 ppm (15). Poly[*E*-1,2-(3,3′-dialkyl-2,2′-dithienyl)ethylene] also gives one α-methylene signal, at 2.66 ppm, showing that this isomer has a different chemical shift than PDHDTE (5). Collectively, the ^{1}H NMR spectra indicate that an HH configuration of hexylthiophene dyads is obtained in the repeating unit (TVT sequence) of the polymer.

UV–visible spectra of solutions and films of PDHDTE exhibit broad maxima due to the π–π* absorption transition. The solutions are yellow and exhibit a λ_{max} of 422 nm. λ_{max} for films is 426 nm, which indicates that a significant degree of twist exists between thiophene–thiophene linkages in the solid state; that is, there is very little difference in coplanarity of the polymer chains for polymers in solution and in the solid state. This twisting is attributed to the HH dyad linkage associated with the hexylthiophene units. PDHDTE is blue-shifted in the solid state by 153 nm compared to the analogous polymer, poly[*E*-1,2-(3,3′-dioctyl-2,2′-dithienyl)-ethylene] (PDODTE, λ_{max} = 577 nm), which is reported to contain tail-to-tail (TT) octylthiophene dyad couplings (5). Furthermore, PDODTE displays a relatively large red shift of 32 nm between $CHCl_3$ solutions and films. It is interesting to note that poly(3,3′-dihexyl-2,2′-bithiophene) exhibits an absorption maximum that is blue-shifted by 112 nm compared to poly(3-hexylthiophene) containing 100% HT links (i.e., 398 vs. 510 nm for films) (15, 16). The presence of the vinylene group along the polymer backbone provides a 24 nm red shift in λ_{max} when compared with poly(3,3′-dihexyl-2,2′-bithiophene) solutions, presumably because it facilitates π-conjugation. Table 1 shows a comparison of photoluminescence maxima for derivatives of polythiophene and poly(dithienyl ethylene) found in the literature.

Conductivity

To obtain comparative results for the conductivity and relative stabilities of the polymer, we used thin spin-coated films that possessed an average thickness of 75 nm. The

conductivity of doped PDHDTE was measured by the four-point probe technique. The doped films were exposed to ambient light at 25°C. Films doped with $AuCl_3$ and $FeCl_3$ were bluish-gray in colour while films doped with I_2 vapour were golden brown. Doping the polymer with $AuCl_3$ decreases the absorption intensity at 426 nm and new maxima form at 910 nm and 1560 nm, indicating the formation of polaronic and bipolaronic charge carriers. Similar spectra were obtained for films doped with $FeCl_3$ and I_2. The measured conductivities (0.1–2 S cm^{-1}) are of the same magnitude as literature values for alkyl-substituted (5, 13) and alkoxy-substituted (3, 6) poly[*E*-1,2-(2,2′-dithienyl)ethylene]'s. This indicates that the HH thiophene dyad does not adversely affect the conductivity when compared to polymers possessing TVT sequences coupled via the TT configuration.

The stability of doped films in ambient atmosphere was monitored in the presence and absence of light. A plot of log (σ/σ_o) versus time confirms that PDHDTE is very sensitive to the combined effects of light and air. Exposed films that were doped with $AuCl_3$ ($t_{1/2}$ = 35 h) provide a greater stability than $FeCl_3$ ($t_{1/2}$ = 4 h) and I_2 doped films ($t_{1/2}$ = 0.2 h). For films stored in the dark, the respective half-lifetimes for $AuCl_3$ and $FeCl_3$ were 75 and 28 h. For comparison, $t_{1/2}$ values determined for $FeCl_3$-doped and $AuCl_3$-doped poly(3-hexylthiophene) were 8 h and several months, respectively (20). It is important to stress that thin films of conjugated polymers dedope much more rapidly than thicker films. Therefore, thicker films were substantially more stable in the oxidized state.

Photochemistry and photolithography

PTV and its derivatives are being investigated as potential materials for electrooptical and optoelectronic devices. It is therefore useful to examine the stability of these films upon exposure to light. With a better understanding of the photodegradation of these materials, their stability and performance can perhaps be improved. The photoproducts of PDHDTE films exposed to UV–visible irradiation in ambient atmosphere were examined by FTIR. Figure 2 shows the FTIR of the polymer film before and after photolysis with polychromatic light (>300 nm) for various times. The spectra show the growth of peaks in the regions of 3400–3080, 1717–1650, and 1300–1090 cm^{-1}. Previous work has shown that residual Fe salts from the chemical polymerization reaction generate free radicals upon exposure to light (21, 22). Consequently, these radicals abstract H-atoms from the α-methylene of the alkyl thiophene, which in the presence of O_2 leads to the formation of -OOH and -OH (3600–3080 cm^{-1}) (23, 24). The polymer-bound radicals have also been postulated to undergo various other reactions: by reacting with another α-methylene of a neighbouring polymer chain, C-O-C linkages (1230 cm^{-1}) are formed leading to crosslinking and insolubilization of the polymer; the radical can undergo β-scission to yield an aldehyde (1717 cm^{-1}) or abstract a H atom to yield a secondary hydroxyl group (3400 cm^{-1}). Thiophene oligomers and polymers have also been shown to be $^1O_2$ photosensitizers (25–29). Photogenerated $^1O_2$ is known to react via a 1,4-Diels–Alder addition to thiophene, producing carbonyl groups (1710 cm^{-1}) and sulfines (1230 cm^{-1}). These reactions destroy the conjugation along the polymer and thus films are photobleached during irradiation. The growth of FTIR peaks is consistent with the photochemistry of both poly(3-hexylthiophene) in solution and in the solid state (21, 22). This suggests that the degradation and crosslinking mechanism of PDHDTE has similarities to that found for poly(3-alkylthiophenes).

During irradiation the FTIR also shows a simultaneous decrease in the peaks at 3016 and 934 cm^{-1}, and an increase in the peaks at ~2927 cm^{-1}. These regions are assigned to the vinyl C–H stretch, the out-of-plane bending of the *trans* vinyl group, and the aliphatic C–H stretching, respectively. Apparently singlet oxygen not only targets thiophenes but

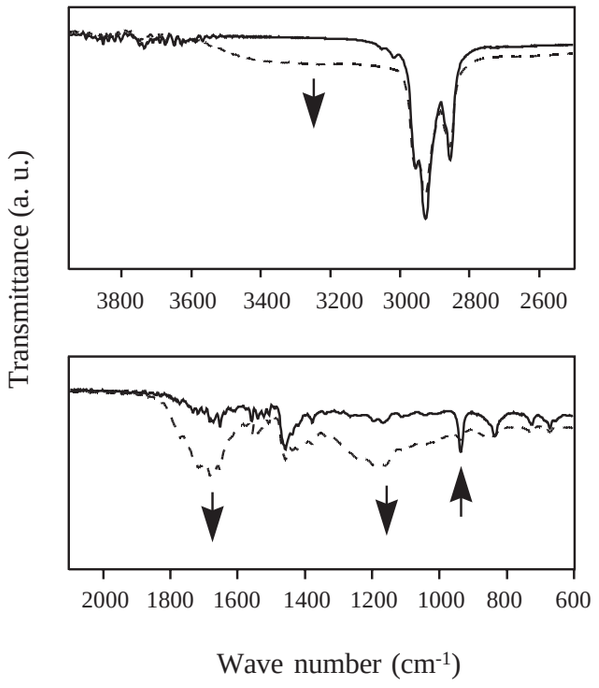
Fig. 2. FTIR of PDHDTE (——) and after photolysis for 30 min (- - -). Arrows show the growth and decrease of various peaks. Film thickness ~100 nm.



the vinylene backbone is also susceptible to attack. This confirms a previous report in which $^1O_2$ is shown to be the reactive intermediate in the photodegradation of poly(2,5-(bis(cholestanoxy)-1,4-phenylene vinylene) (BCHA-PPV) (30). BCHA-PPV irradiated in dry air results in the formation of ester and aldehyde species (30, 31). IR reflection absorption spectra of BCHA-PPV films show a decrease of the *trans* vinyl C–H wagging at 975 cm^{-1} and the concurrent growth of a C=O peak at 1723 cm^{-1} (31). A mechanism was proposed that claimed the initial point of photooxidation was the 1,2-cycloaddition of singlet oxygen to a vinylene unit, resulting in the formation of a biradical (30, 31). This would account for the decrease of the *trans* vinyl peak of PDHDTE following irradiation as observed in the present study.

In the construction of conjugated polymer devices it is desirable to find techniques to deposit the material with well-defined structure and architecture. Several studies have been reported in which photolithography is employed to achieve patterned images of alkyl- (22, 32), methacryloyl- (33), and water-soluble (34) polythiophenes. Irradiation of PDHDTE renders the films insoluble in organic solvents, showing that such polymers can be photochemically imaged. Using conventional photolithography, we were able to obtain patterned images of the polymer. The spin-cast film (125 nm thick) was irradiated for 3 min through a mask and developed in $CHCl_3$ to produce images with resolution of 15 μm for the smallest image (Fig. 3). The images appeared yellow under the microscope, indicating that π-conjugation is not visibly destroyed by the cross-linking processes under the low irradiation doses employed for imaging.

Photoluminescence and electroluminescence of PDHDTE

An ITO anode/PDHDTE (195 nm)/Al electroluminescence device was constructed. Figure 4 shows the normalized photoluminescence (PL) and electroluminescence (EL) spectra of the device. The respective λ_{max} were 576 nm (2.15 eV), using a excitation wavelength of 426 nm and ~610 nm (2.03 eV) for the LED. The colour output of the LED was observed to be green-blue. The photoluminescence and electroluminescence spectra are similar although the EL is slightly red-shifted. Inganas and co-workers observed green electroluminescence from poly(3-cyclohexylthiophene) based LEDs (35). The absorbance and PL spectra are similar in wavelength to those of the polymer investigated in this study. In the case of poly(3-cyclohexylthiophene), steric hindrance resulting from the cyclohexyl side chain forces the main chain out of coplanarity. This results in the blue shift of the absorption and emission spectra compared to polythiophene polymers in which steric hindrance is absent. This effect of sterically encumbering poly(thienylene vinylene) polymers is therefore also demonstrated in PDHDTE by the incorporation of HH dyads.

Conclusions

Poly[*E*-1,2-(4,4′-dihexyl-2,2′-dithienyl)ethylene] (PDHDTE) has been prepared in which the hexylthiophene dyads are configured in a head-to-head (HH) arrangement. Interestingly, the conductivity of this polymer is of the same magnitude as that of poly[*E*-1,2-(3,3′-dialkyl-2,2′-dithienyl)ethylene], which consists of tail-to-tail (TT) thiophene dyads. The differences between these two polymer isomers are clearly indicated by their ^1H NMR and UV–visible spectra. The steric interaction of the HH thiophene dyads results in similar absorption spectra for the polymer in solution and in the solid state, whereas the TT isomer, poly[*E*-1,2-(3,3′-dialkyl-2,2′-dithienyl)ethylene] (5), displays a 32 nm difference in λ_{max} between polymer solutions and polymer films. Upon irradiation, PDHDTE films become insoluble due to photo-cross-linking. FTIR identifies the formation of OH, C-O-C, and OOH functional groups due to the reaction of oxygen with the polymer. The mechanisms of photooxidation and photo-cross-linking are similar to those observed for poly(3-alkylthiophenes) with the addition that the vinylic functionality also participates in photodegradation. Photo-cross-linking enables these materials to be imaged photolithographically. Images of micron (μm) resolution were achieved for which π-conjugation of the polymer was retained. A LED device based on this polymer gives emission of blue-green light. This is of higher energy than regioregular poly(3-alkylthiophenes) incorporating linear side chains, due to the twisted nature of the PDHDTE polymer chains, and results from the incorporation of sterically encumbered HH thiophene dyads.

Surface functionalization of cadmium sulfide quantum-confined nanoclusters. 4. Formation and reactivity of an aniline surface quantum dot[1]

Jonathan G.C. Veinot, Josie Galloro, Linda Pugliese, Valerie Bell, Robert Pestrin, and William J. Pietro

Abstract: The preparation, characterization, properties, and reactivity of a novel quantum-confined CdS nanocluster containing a chemically active aniline surface are described, along with three general methods for the covalent attachment of a wide scope of molecular moieties to the cluster surface. The formation of facile covalent linkages via DCC mediated amidization, secondary amine formation, and thiourea condensation is discussed and, as the introduction of surface functionality is crucial for the eventual realization of molecular electronic devices fabricated from such nanoclusters, several derivatized nanoclusters bearing interesting chromophoric, fluorescent, electroactive, and chiroptical tethered species are described. All three derivatization techniques occur under very mild conditions that have been demonstrated not to disturb the integrity of the nanocluster core.

Key words: quantum dot, nanocluster, semiconductor, surface-functionalized, nanostructured.

Résumé : On décrit la préparation, la caractérisation, les propriétés et la réactivité d'un nouveau nanoagrégat de CdS, confiné d'un point de vue quantique et contenant une surface d'aniline chimiquement active; on décrit aussi trois méthodes générales pour attacher d'une façon covalente un grand nombre de parties de molécules à la surface de l'agrégat. On discute de la formation facile de liaisons covalentes par le biais d'une amidisation facilitée par le DCC, la formation d'amine secondaire et la condensation de la thiourée et, comme l'introduction d'une fonctionnalité à la surface est cruciale à la réalisation de dispositifs électroniques moléculaires à partir de tels nanoagrégats, on décrit plusieurs dérivés de nanoagrégats portant des espèces chromophores, fluorescentes, électroactives et chiroptiques. Les trois techniques de transformations en dérivés peuvent être réalisées dans des conditions très douces et il a été démontré qu'elles ne provoquent pas de modifications à l'intégrité du noyau du nanoagrégat.

Mots clés : point quantique, nanoagrégat, semiconducteur, surface fonctionnalisée, nanostructuré.

[Traduit par la Rédaction]

Introduction

Much recent intensive research has focused on the formation of particles of metallic or semiconducting materials having nanometer dimensionality (for recent reviews, see ref. 1). These interesting systems, commonly referred to as quantum-confined nanoclusters or quantum dots, exhibit electronic and optical properties significantly different from their bulk counterparts. Such differences arise from the confinement of conduction electrons within regions smaller than the Bohr radius of the material's exciton (2). The so-called quantum confinement effect may give rise to the fabrication of electronic devices possessing properties heretofore unheard of in conventional semiconductor electronics, such as dynamically tunable light-emitting diodes, unusual nonlinear optical materials, and coulomb blockade devices such as single-electron diodes and transistors.[3] The realization of such devices may well occur via covalent or coordinative coupling to the surface of chemically activated nanoclusters. Thus, the creation of a few surface-functionalized semiconductor nanocrystallites has recently been reported, along with the use of the surface functionalities to assemble macromolecular aggregates of discrete semiconductor nanoclusters (4). We have previously reported the synthesis and physical and chemical properties of a variety of cadmium sulfide quantum-confined nanoclusters bearing chemically active

surfaces. We have also demonstrated that these surface-activated nanoclusters can participate in a number of subsequent reactions capable of coupling a wide range of interesting optical, chromophoric, luminescent, and electroactive species to the surface without disrupting the integrity of the nanocluster core (5). We now report the formation of a cadmium sulfide quantum dot having a chemically active aniline surface, and describe three methods for covalently coupling a wide scope of molecular moieties to the nanocluster surface.

Experimental section

Chemicals

Reagent grade acetonitrile and dimethylformamide (DMF) were dried over 4 Å molecular sieves and filtered prior to use. Methanol and acetic acid were obtained reagent grade from Caledon Laboratories and used without further purification. Water was first deionized by passage through a Sybron–Barnstead D8902 mixed-bed ion-exchange column and then freed from organic impurities using a Sybron–Barnstead D8204 activated charcoal filter. All deuterated solvents used for ^{1}H NMR spectroscopy were purchased in sealed ampules from Cambridge Isotope Laboratories (Andover, Mass.) and used immediately upon opening the ampule. Cadmium acetate (Aldrich reagent grade) was recrystallized once from glacial acetic acid and dried at 100°C in vacuo. Sodium sulfide nonahydrate, dicyclohexylcarbodiimide (DCC), benzyl chloroformate, and ferrocene carboxylic acid were purchased reagent grade from Aldrich and used without further purification. Fluorescein (Aldrich) was obtained as the sodium salt and converted to the acid form with 1 M HCl. Erythrosin B isothiocyanate (Aldrich, 99%) was recrystallized from acetone prior to use. 4-Mercaptoaniline (Aldrich reagent grade) was purified by sublimation at 60°C and 100 mTorr (1 Torr = 133.3 Pa), and stored under dry N_2 at temperatures below 18°C. *l*-Histidine was purchased from BDH and purified by successive free-base – acid precipitation cycles, then recrystallized as the hydrochloride from absolute ethanol. 8-Hydroxyquinoline (Aldrich) was recrystallized from methanol. Chlorotriphenylmethane was purchased 98% from Aldrich and purified by precipitation from benzene (containing 0.1% v/v acetyl chloride) upon addition of petroleum ether.

Preparation of aniline surface CdS quantum dots ($QDNH_2$, 1)

The preparation of the aniline surface CdS nanoclusters ($QDNH_2$) followed a modification of a known kinetic trapping technique (5, 6). All procedures were carried out under subdued light and under N_2, and all solutions were thoroughly N_2 deoxygenated. A solution containing 2.53 g (11 mmol) of $Na_2S{\cdot}9H_2O$ and 4.96 g (40 mmol) of 4-mercaptoaniline in 125 mL of a 1:1:2 (v/v/v) CH_3OH–CH_3CN–H_2O solvent mixture was added with rapid stirring to a solution of 5.00 g (22 mmol) of cadmium acetate in the same solvent mixture, producing an immediate bright yellow precipitate. The reaction mixture was stirred at room temperature for 1 h, then concentrated at room temperature under reduced pressure to two thirds of its volume using a rotary evaporator. The precipitate was isolated by centrifugation, washed with water, and resuspended by sonication in DMF. Bulk solid particulate was removed from the DMF suspension by centrifugation at 4400 × *g* in a Baxter Biofuge 17R refrigerated centrifuge, and the quantum dots were subsequently precipitated by doubling the volume of the DMF suspension with water. The quantum dots were further purified by repeated sequential sonication–centrifugation cycles in water, methanol, acetone, and diethyl ether until no aromatic signal could be detected in the ^{1}H NMR of the concentrated washings. The yellowish white solid was then dried for 18 h at 85°C in high vacuum (~10^{-4} Torr), pulverized, then dried for an additional 18 h at 85°C in high vacuum in a drying pistol (charged with solid KOH), and stored in a vacuum desiccator in darkness for no longer than 3 days before use. Yield: 2.49 g.

5-Chloromethyl-8-hydroxyquinoline

8-Hydroxyquinoline was 5-chloromethylated via a modification of a literature procedure (7). A solution containing 50.6 g (0.35 mol) of 8-hydroxyquinoline, 125 mL of 37% aqueous formaldehyde, and 125 mL of concentrated hydrochloric acid was bubbled with anhydrous HCl for 6 h and allowed to stand overnight. The bright yellow precipitate was washed repeatedly with diethyl ether and dried in vacuo at 65ºC over KOH in a drying pistol. Yield: 42.0 g (62%), mp 280–283ºC. ^{1}H NMR (400 MHz, DMSO-d_6) δ (ppm): 5.32 (s, 2H, -CH_2Cl), 7.52 (d, 1H, $|J_{H-H}|$ = 8 Hz, C7-H), 7.86 (d, 1H, $|J_{H-H}|$ = 8 Hz, C6-H), 8.08 (m, 1H, C3-H), 9.11 (d, 1H, $|J_{H-H}|$ = 5 Hz, C4-H), 9.21 (d, 1H, $|J_{H-H}|$ = 8 Hz, C2-H).

N-*Carbobenzoxy*-l-*histidine hydrochloride*

l-Histidine was N-protected using a modification of the method of Patchornik et al. (8). Benzyl chloroformate (17 mL, 0.12 mol) was added in 1 mL portions to a cooled, stirring solution of 10.5 g of *l*-histidine hydrochloride (55 mmol) in 50 mL of 2 M NaOH. After each addition the mixture was allowed to stir for 5 min, after which time the solution was readjusted to pH 9 with 2 M NaOH. Following the last addition the reaction mixture was allowed to stir for 20 min and the pH was adjusted to 2.4 using 6 M HCl. The resulting precipitate was recrystallized from methanol and dried in vacuo for 3 h. Yield: 11.4 g (45%), mp 127–130°C (lit. (8) mp ~107°C); $[\alpha]_D^{20}$ +15.3º (DSMO); ^{1}H NMR (D_2O) δ (ppm): 2.89 (m, 1H, α-CH), 3.23 (m, 2H, Im-CH_2-), 3.93 (br, 1H, ImN-H), 4.20 (br, 1H, amide NH), 4.92 (m, 2H, ϕ-CH_2-OC(O)-), 7.07 (s, 1H, ImC4-H), 7.22 (m, 5H, arom), 8.31 (d, 1H, ImC2-H).

Amidization of $QDNH_2$ via DCC mediated coupling of carboxylic acids (method 1)

All amidization reactions of **1** followed the same procedure; the formation of the acetamide (QDNHAc, **2a**) will be described as a representative example. All procedures were carried out under dry N_2 in subdued light. **1** (1.63 g) was suspended in 15 mL of dry, deoxygenated DMF, sonicated, and centrifuged to yield a clear, non-opalescent suspension. A solution of 0.64 mL (11.3 mmol) of glacial acetic acid and 2.3 g of DCC (11.1 mmol) in 20 mL of dry deoxygenated DMF was stirred at room temperature for 20 min, then added to the $QDNH_2$ suspension. This reaction mixture was stirred for 24 h. The white precipitate of dicyclohexylurea

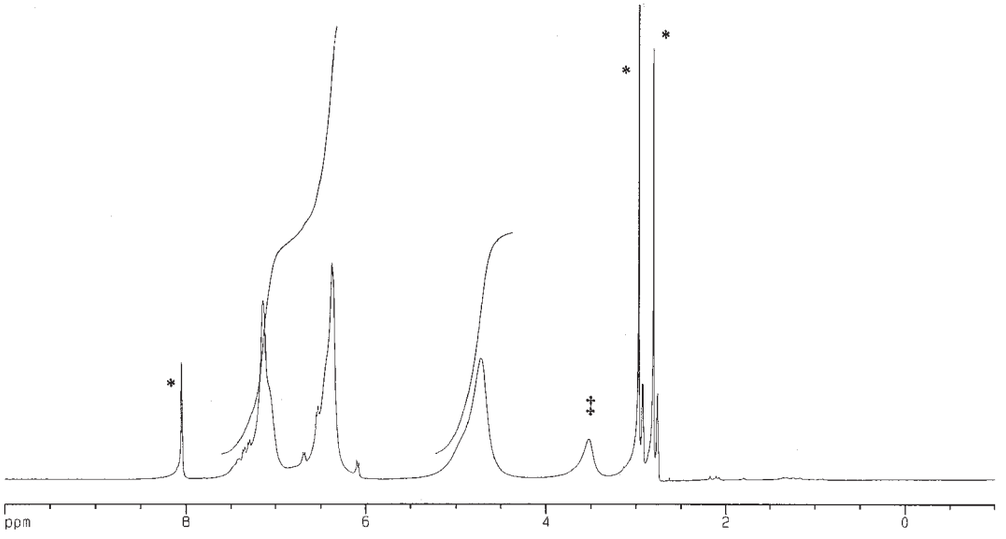
Fig. 1. 400 MHz ^{1}H NMR spectrum of the underivatized $QDNH_2$ CdS nanocluster, **1**, in DMF-d_7. * indicates DMF residual signals and ‡ indicates water.



was removed by filtration and 35 mL of water was added to the filtrate. The resulting yellowish white precipitate was washed by repeated sonication–centrifugation cycles using water, acetonitrile, acetone, and finally diethyl ether. The solid was dried for 12 h at 85°C under high vacuum (~10^{-4} Torr). Yield: 1.27 g.

Coupling via secondary amine formation (method 2)

All procedures were carried out under dry N_2 in subdued light. **1** (0.5 g) was suspended in 25 mL of dry DMF, sonicated, and centrifuged to produce a clear, non-opalescent suspension. 5-Chloromethyl-8-hydroxyquinoline (0.67 g) was added to the suspension and stirred at room temperature to dissolve. Triethylamine (0.5 mL) was then added and the reaction mixture was stirred for 1 h. The reaction was quenched with water and the resulting yellow precipitate was collected and washed by repeated sonication–centrifugation cycles with, sequentially, water, ethanol, and acetone until no aromatic signal could be detected in the ^{1}H NMR of the concentrated washings, then dried overnight at 85°C in high vacuum. Yield: 0.32 g.

Coupling via thiourea formation (method 3)

The general procedure for modification of the $QDNH_2$ surface via thiourea formation is a modification of the method of Castro et al. (9); the phenylurea derivatization will be described as a representative example. All procedures were carried out under dry N_2 in subdued light. **1** (0.3 g) was suspended in 100 mL of dry, deoxygenated DMF, sonicated, and centrifuged to yield a clear, non-opalescent suspension. Phenyl isothiocyanate (34 mL) was added with rapid stirring, and the reaction mixture was stirred for 12 h at room temperature. The reaction mixture was added to 200 mL of water and the yellow precipitate was separated by centrifugation. The solid was washed by repeated sonication–centrifugation cycles using water, acetonitrile, acetone, and diethyl ether until no aromatic signal could be detected in the ^{1}H NMR of the concentrated washings, then dried in high vacuum (~10^{-4} Torr) at 85°C for 24 h. Yield: 0.22 g.

Spectroscopy

Infrared spectra were recorded as KBr (Aldrich FT-IR grade KBr) pellets with a Mattson 3000 Fourier transform infrared spectrometer. ^{1}H NMR spectra were obtained on a Brucker ARX 400 MHz Fourier transform nuclear magnetic resonance spectrometer using DMSO-d_6 or DMF-d_7 as solvent. Electronic spectroscopy on $QDNH_2$ and all of its amides was performed in DMF in 1 cm quartz cuvettes using a Hewlett–Packard 8452 diode array spectrophotometer. Optical rotation measurements were carried out on a Perkin–Elmer 241 polarimeter in a 10.002 cm quartz cell using 1 s integration time. Fluorescence measurements were made in 1 cm quartz cuvettes using a Shimadzu RF-551 spectrofluorometric detector driven by PC-551 software.

Electron microscopy

Transmission electron microscopy (TEM) was performed using a Philips EM-301 transmission electron microscope. Nanocluster samples for TEM analysis were prepared by applying a few drops of a freshly sonicated and centrifuged DMF suspension of the nanocluster (2.5 mg of nanocluster to 3 mL of solvent) onto J. B. EM Services (Pointe Claire, Dorval, Que.) JBS-183 300 mesh carbon-coated copper grids (cleaned in acetone, then chloroform, then acetone, and air-dried). The solvent was absorbed through the grid by a layer of filter paper, leaving aggregates as well as individual nanoclusters adhering to the grid wires. The grids were then air-dried at room temperature. Size calibration was performed using a precision silicon grid of 21 600 lines per cm.

Results and discussion

Cadmium sulfide nanoclusters prepared via the kinetic trapping method afford a convenient starting point for the eventual fabrication of nanocluster-based molecular electronic

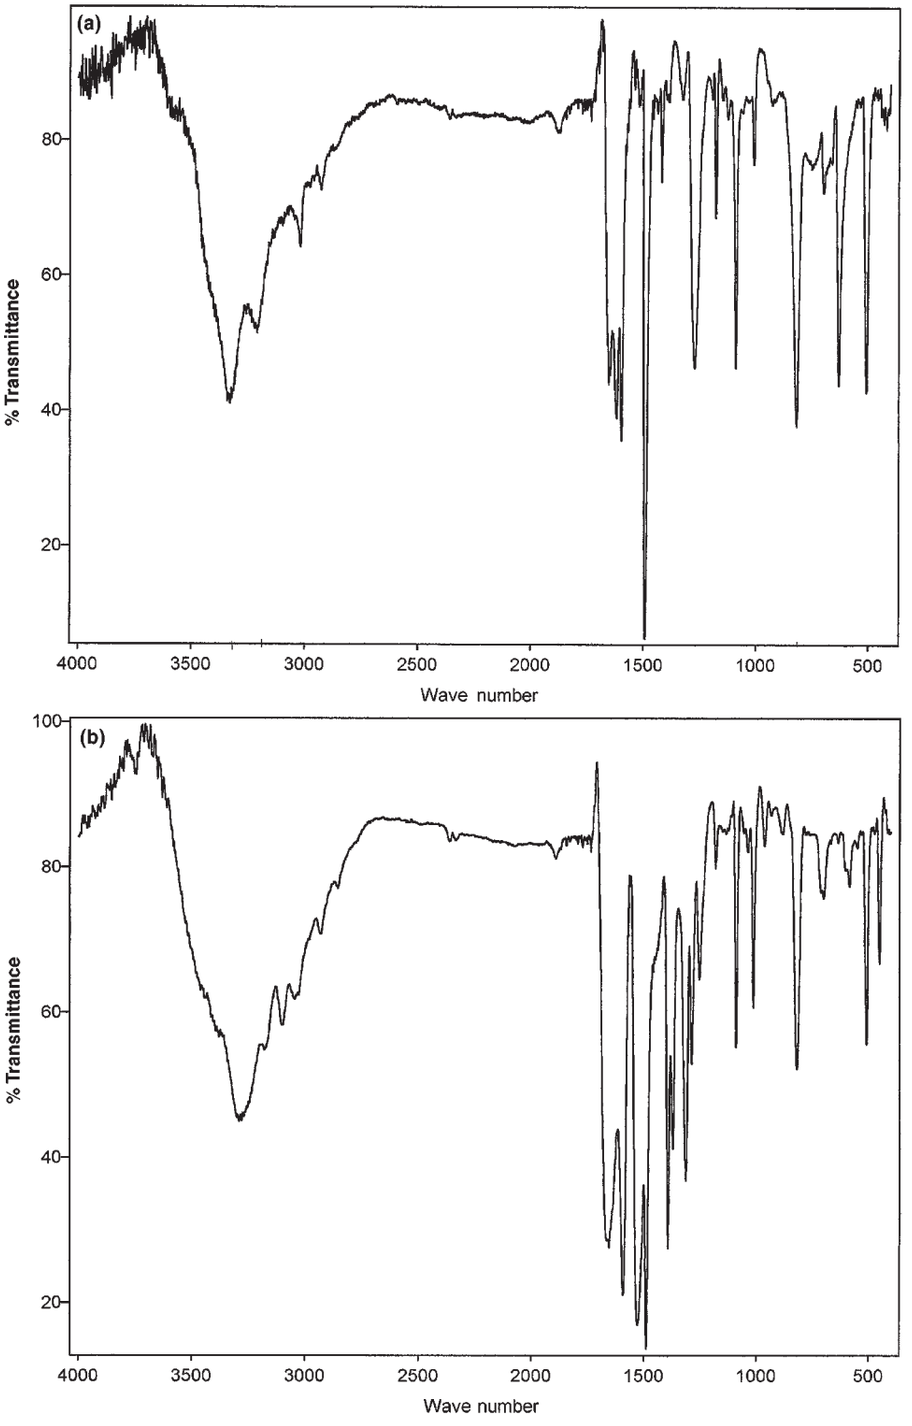
Fig. 2. Infrared absorption spectrum of the $QDNH_2$ CdS nanocluster, **1**, in KBr (*a*) before and (*b*) after amidization with DCC activated acetic acid.



devices. Not only does the surface organic layer prevent coalescence into bulk (6), but also provides a platform for linking chemically active functionalites (5). The covalent attachment of molecular moieties such as chromophores, luminophores, redox centers, or quantum wires to the surface of semiconductor nanoclusters is a likely necessary step towards the realization of quantum dot based molecular electronic or optoelectronic devices. However, once a chemically active functional group has been introduced on the surface of a II–VI semiconductor nanocluster, the problem of lability of the cluster core towards a variety of common organic reaction conditions (acidic, basic, oxidizing, reducing, nucleophilic,

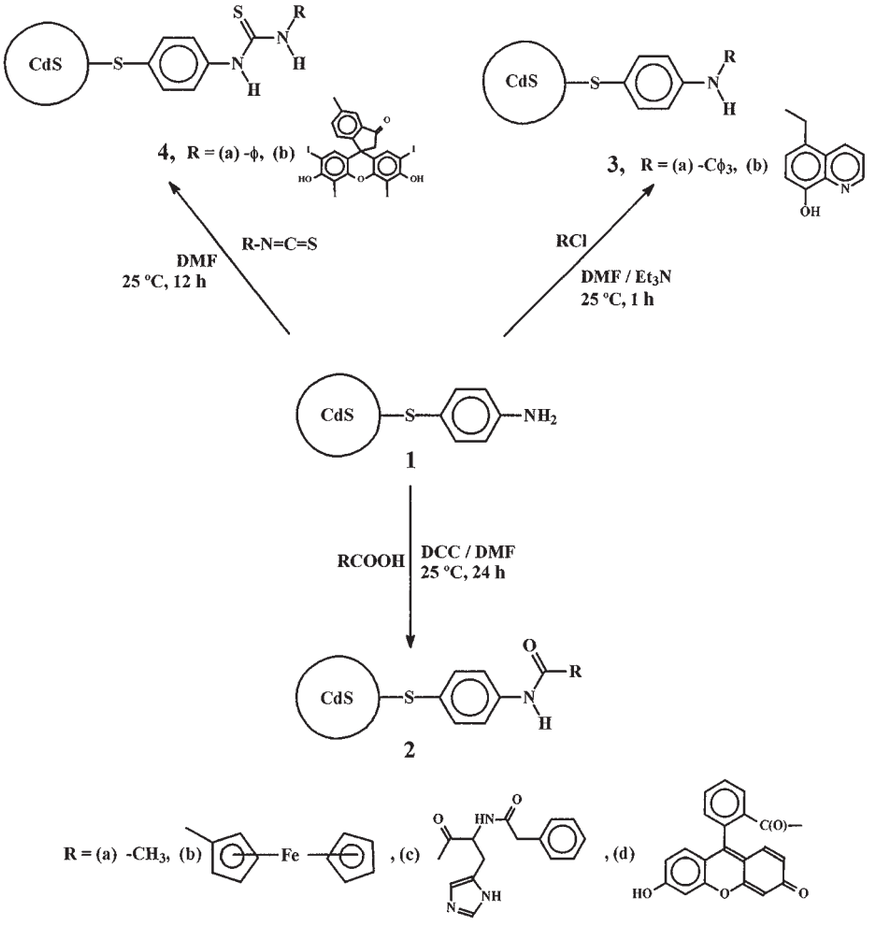
Scheme 1.



or electrophilic) can still pose a major obstacle towards the attachment of other molecular species via the surface functionality. Moreover, electrophilic reagents intended for the functionality may instead attack the thiol sulfur. For example, aniline surface CdS nanoclusters would certainly not survive the conditions employed in conventional amidization reactions, i.e., from acids, acid anhydrides, or acyl chlorides.

The introduction of an aniline surface to CdS quantum dots ($QDNH_2$, **1**) has been accomplished here by the precipitation of CdS in the presence of 4-mercaptoaniline, in an analogous fashion to the formation of phenolic surface CdS nanoclusters (5*c*). The ^1H NMR spectrum of **1**, presented in Fig. 1, is clearly indicative of binding to the cluster through sulfur. The characteristic ϕ-SH singlet at δ 3.79 ppm of 4-mercaptoaniline is completely absent in the cluster, while the ϕ-NH_2 and aromatic proton resonances remain intact and integrate to exactly 1:2, respectively. As is generally observed with thiophenolate-capped nanoclusters, all ^1H NMR signals appear homogeneously broadened, and, as has been previously observed with phenolic surface CdS nanoclusters (5*c*), the aromatic and ϕ-NH_2 signals are superimposed with structure, indicative of ring and amino protons in multiple environments. The infrared spectrum of **1** (Fig. 2*a*) shows the expected strong benzene ring C=C vibration at 1484 cm^{-1} as well as weak overtone and combination bands between 1700 and 1900 cm^{-1} and a sharp C–H out-of-plane wag at 816 cm^{-1} characteristic of 1,4-disubstitution. The strong N–H stretching absorption is quite broad, ranging from about 2600 to 3600 cm^{-1}, and splits at its peak into two bands corresponding to the NH_2 symmetric (3184 cm^{-1}) and antisymmetric (3316 cm^{-1}) motions. The broadness of this band is again indicative of the amino group existing on the surface in multiple environments. Superimposed on the N–H band is a sharp ring C–H stretch at 3020 cm^{-1}.

Our strategies for coupling molecular moieties to the quantum dot surface are summarized in Scheme 1. Methods, starting reagents, reaction conditions, and percent conversion data for $QDNH_2$ and all derivatives are presented in Table 1. All CdS nanoclusters prepared in this contribution form transparent, non-opalescent suspensions in DMF and DMSO that do not settle and cannot be centrifuged at conventional speeds, but exhibit pronounced Tyndall effects under the direct illumination of a He–Ne laser. In most cases, ^1H NMR spectra reveal residual -NH_2, along with -C(O)NH-, -NH-C(S)-NH-, or -NHR signals, enabling percent conversions to be calculated. Where separate amine vs. amide proton signals were not discernable (as in the case of the fluorescein derivative, **2d**), integration of aliphatic proton signals from the tethered group were used to obtain conversion ratios. ^1H NMR data for **1** and all derivatives appear in

Table 2. Coupling via amide linkages involves the action of a DCC activated acid on the $QDNH_2$ amino group. Equimolar quantities of acid and DCC are first allowed to react in DMF, then added to a DMF suspension of **1**. The reaction proceeds smoothly over 24 h with near quantitative amidization for low molecular weight acids (i.e., acetyl) but typically amidizing less than 50% of the surface amino groups in the case of sterically bulkier moieties, as determined by ^{1}H NMR integration ratios. By-product cyclohexylurea precipitates as a crystalline solid that can be removed from the nanocluster suspension by conventional filtration or low-field centrifugation. ^{1}H NMR spectra for the amide derivatives of **1** are straightforward, appearing as a superposition of the tethered group and thiophenolate sig-

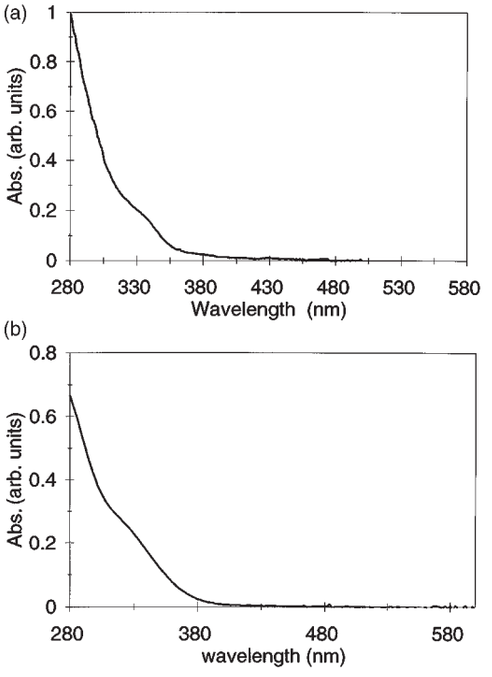
nals. Most characteristic, however, is the appearance of a -C(O)NHϕ resonance at ca. δ 9.6–9.8 ppm, located significantly downfield from the underivatized ϕ-NH_2 protons (ca. δ 4.6–4.8 ppm). Infrared absorption peak assignments for $QDNH_2$ and its amide derivatives are collected in Table 3. The infrared spectra for all amide-linked CdS quantum dots exhibit the characteristic amide I carbonyl and amide II C–N stretching vibrations at ca. 1660 and 1590 cm^{-1}, respectively, as illustrated by the spectrum of a representative amidized surface in Fig. 2*b*. These systems also show a sharp characteristic absorption at ca. 1250 cm^{-1}, indicative of a *trans* -NH-CO- amide linkage. The broad N–H stretching band is also present between 2800 and 3800 cm^{-1}. In the case of the acetamide quantum dot, this band exhibits one peak at 3290 cm^{-1} instead of the split two-peak pattern (characteristic of -NH_2), providing further evidence of quantitative conversion in this case. The absorption bands and overtones indicative of 1,4-disubstituted phenyl also remain discernable. The scope of the reaction is quite wide; Table 1 summarizes some of the CdS nanoclusters prepared by this method. Of particular interest is **2c**, which bears a chiral surface induced by amide linkages to N-protected *l*-histidine. These clusters are optically active with a specific rotation significantly higher than the pure untethered enantiomer

© 1998 NRC Canada

Fig. 3. Optical absorption stpectum of a 10^{-4} M $QDNH_2$ nanocluster suspension in DMF (1 cm path length) (*a*) before and (*b*) after amidization with DCC activated ferrocene carboxylic acid.



($[\alpha]_D^{20}$ –106.8° for the cluster vs. $[\alpha]_D^{20}$ +15.3° for the protected *l*-histidine). Studies are presently underway in our laboratories to determine the extent to which the surface chirality of this species and other amino acid functionalized quantum dots affects the optical and possibly electronic properties of the semiconductor core.

Another useful class of reagents for extending the functionality of the aniline surface quantum dot are the isothiocyanates, RNCS, which couple molecular moieties to the nanocluster via thiourea linkages, also shown in Scheme 1. The reaction conditions are gentle, proceeding in DMF suspension at room temperature for ca. 12 h. ^{1}H NMR analysis indicates again that surface conversion is not complete and, for sterically large groups, the percent conversion is quite small (4% for erythrosin B isothiocyanate), as summarized in Table 1. Nevertheless, the reagents do not appear to disrupt the integrity of the nanocluster in any detectable manner. The IR spectrum for the phenylthiourea derivative, **4a**, exhibits a strong, sharp absorption at 1534 cm^{-1} and a broad, structured band between 1182 and 1305 cm^{-1}, both characteristic of a thiourea linkage. In addition, the N–H stretching region has considerably broadened, as expected of a mixture of -NH_2 and thioamide -NH- groups. The ring C=C and ϕ-S bands appear nearly unchanged relative to their $QDNH_2$ counterparts. Table 3 summarizes the IR peak assignments for thiourea linked nanoclusters.

The aniline N-protons are also active towards direct substitution (Scheme 1). Hence, treatment of a sonicated DMF suspension of $QDNH_2$ with 5-chloromethyl-8-hydroxyquinoline in the presence of triethylamine resulted in 77% conversion of the aniline amino groups to the corresponding *N*-methyl-8-hydroxyquinoline derivative. Both the protons α to the quinoline nitrogen and on the 4-carbon in the same ring are clearly visible in the ^{1}H NMR spectrum at δ 8.8 and 8.5 ppm, respectively (this is an area of the NMR spectrum distinct from the thiophenolate aromatic region). These protons appear shifted somewhat upfield from their counterparts in unbound 5-chloromethyl-8-hydroxyquinoline (δ 9.2 and 9.1 ppm, respectively). A very broad -OH proton signal is also observed for the cluster at ca. δ 12.5 ppm; its significant downfield location is indicative of intramolecular hydrogen bonding with the quinoline nitrogen. Although the resonances are broad, the aromatic region between δ 6.2 and 7.6 ppm is sufficiently structured to enable the three remaining quinoline ring protons to be distinguished from the four thiophenolate ring protons. The integration ratio of the entire aromatic region between δ 6.2 and 7.6 ppm and the two signals between δ 8.5 and 8.8 ppm is close to 4:1, as expected. These data are collected in Table 2. The methylene proton signal appears at δ 4.3 ppm in the cluster, shifted upfield from the corresponding chemical shift of 5.3 ppm in the unbound 5-chloromethyl-8-hydroxyquinoline. Accordingly, an upfield shift of approximately 0.8 ppm for the methylene protons is expected upon substitution of a chlorine with an amino nitrogen. Both primary and secondary amine protons (at δ 4.5 and 5.2 ppm, respectively) are observed with an integration ratio of 0.59, indicating that 77% of the surface amino groups have been substituted. Similar treatment of $QDNH_2$ with chlorotriphenylmethane resulted in conversion of 46% of the aniline amino groups to the corresponding *N*-triphenylmethyl derivative.

The electronic absorption spectra of **1** and all derivatives prepared in this contribution are typical of thiolate-capped CdS quantum-confined nanloclusters (6), with the onset of band-to-band absorption at ca. 380 nm (Fig. 3*a*), affording a bandgap energy of 3.27 eV. The difference of 0.74 eV between the bandgap of the $QDNH_2$ nanocluster and that of bulk CdS (E_g = 2.53 eV) arises from carrier quantum-confinement effects and can be used to estimate a diameter of

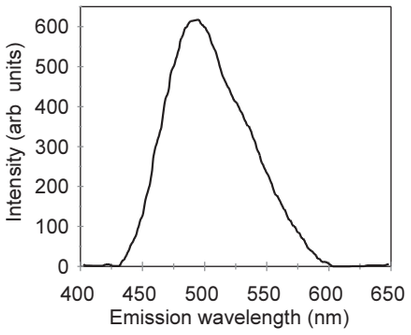
Fig. 4. Fluorescence spectrum for the 5-methylene-8-hydroxyquinoline derivatized $QDNH_2$ CdS nanocluster, **3b**, in DMF. $\lambda_{ex.}$ = 325 nm.



approximately 21 Å for the $QDNH_2$ cluster, in accordance with tight-binding band analysis (10). Upon derivatization using any of the methods described herein the cluster diameters do not change significantly, nor do the CdS core excitonic absorption wavelengths (see Fig. 3*b*), providing further indication that the core integrity is not disrupted. These diameters are in good agreement with the unfunctionalized diameters and a variety of other functionalized CdS nanoclusters prepared under similar conditions (ca. 20–30 Å) (4–6). Tight-binding band calculated diameters for the $QDNH_2$ derivatives are collected in Table 4. The electronic absorption spectrum for **3b** shows, in addition to the CdS excitonic band, an absorption due to 8-hydroxyquinoline. Interestingly, however, this band, assigned in the free compound as π–π* (11), is significantly red-shifted with respect to free 8-hydroxyquinoline (λ_{max} = 314 nm). Moreover, the intensity of the π–π* absorption in free 8-hydroxyquinoline is far too weak to give rise to the moderately intense band in the derivatized nanocluster. Upon deprotonation of the phenolic group, however, the 8-hydroxyquinoline π–π* band is known to red-shift to 400 nm and dramatically increase in intensity (11), and is reassigned as *n*–π* (12). Our ^1H NMR and FT IR data, however, indicate intact -OH. We therefore conclude that a small fraction of the tethered moiety exists in a deprotonated or, perhaps more likely, cadmium-complexed form. This is confirmed by the fluorescence spectrum of **3b,** which exhibits a strong broad emission centered at 495 nm (Fig. 4), consistent with previously measured emission wavelengths for the free anion (13) as well as a number of M^{2+} and M^{3+} 8-hydroxyquinoline complexes (11, 14). Investigations concerning the coordination chemistry and photophysical properties of **3c** are currently underway in our laboratories.

Transmission electron microscopy (TEM) of **1** and all derivatives studied in this work demonstrates that the nanoclusters tend to agglomerate into larger spheroids of various sizes embedded in fields of individual nanoclusters, behavior that we have observed in our previous studies concerning phenolic surface CdS quantum dots (5*c*). Histogram analyses (see Figs. 5 and 6 for a typical TEM picture and histogram, respectively) indicate that all systems are fairly monodisperse in diameter, as presented in Table 4, and agree well with nanocluster diameters calculated from tight-binding band treatment of the optical absorption data. TEM confirms

Fig. 5. Computer-enhanced transmission electron micrograph of the fluorescene derivatized $QDNH_2$ CdS nanocluster, **2d**. Magnification: ×370 000 (1 cm = 27 nm).

that derivatization of the aniline surface affects neither the size nor size distribution of the nanoclusters, further evidence that the CdS core integrity is not disrupted.

Conclusions

The realization of novel molecular electronic or optoelectronic devices fabricated from semiconductor quantum-confined nanoclusters, or quantum dots, will necessarily involve the formation of covalent linkages to the cluster surfaces. We have been investigating the chemical activation of the surfaces of cadmium sulfide quantum dots with such purpose in mind, and have previously demonstrated that the introduction of pyridyl (5*a*, 5*b*) and hydroxy (5*c*) functional groups enables CdS nanoclusters to participate in a wide scope of surface-extending reactions, resulting in a variety of interesting new materials. We demonstrate here that CdS

© 1998 NRC Canada

nanoclusters bearing an aniline surface can provide a wide range of new quantum dots, including nanoclusters with unusual fluorescent and chiroptical properties. We present three types of surface-extending reactions that can be employed to conveniently tether interesting molecular moieties to the nanocluster surface without disrupting the integrity of the CdS core.

Acknowledgment

The authors wish to thank Professor A.B.P. Lever, Leah Veinot, Robert Metcalfe, and Dr. Abdiaziz Farah for their helpful suggestions and input, and Karen Rethoret for assistance with the electron microscopy. Phonon dispersion and defect energies for rubidium chloride, bromide, iodide, and sulphide

Patrick W.M. Jacobs and Marcia L. Vernon

Abstract: New crystal potentials have been developed for rubidium chloride, bromide, iodide, and sulphide, and also strontium chloride, by first calculating the pair-interactions in the electron-gas approximation and then refitting the potential parameters to available crystal properties. These potentials were then further tested by calculating the phonon dispersion in these materials along principal symmetry directions, with generally good agreement with experiment (except for rubidium sulphide for which no experimental neutron scattering data are available). The potentials were then used in the HADES computer code to calculate the energies of formation and migration of point defects in these materials. Our calculations indicate that several transport mechanisms may be important in the Rb halides and this has been verified in the case of RbCl by a recent very detailed analysis of the ionic conductivity of pure and doped RbCl.

Key words: rubidium halides, defect energies, ionic transport, phonon dispersion, strontium chloride, rubidium sulphide.

Résumé : On a développé de nouveaux potentiels cristallins pour les chlorure, bromure, iodure et sulfure de rubidium ainsi que pour le chlorure de strontium en calculant les interactions de paires à l'aide de l'approximation gaz-électron et en les affinant ensuite les paramètres de potentiel avec les propriétés cristallines disponibles. On a alors revérifié ces potentiels en calculant la dispersion phonique dans ces matériaux le long des principales directions de symétrie; il y a généralement un bon accord entre ces valeurs et les données expérimentales (excepté dans le cas du sulfure de rubidium pour lequel il n'existe aucune donnée expérimentale de dispersion des neutrons). On a ensuite utilisé les potentiels dans le code « HADES » d'ordinateur pour calculer les énergies de formation et de migration des défauts ponctuels dans ces matériaux. Nos calculs indiquent que plusieurs mécanismes de transport peuvent jouer un rôle important dans les halogénures de Rb et cette hypothèse a été vérifiée dans le cas du RbCl grâce à l'analyse détaillée de la conductivité ionique du RbCl, pur et dopé, rapportée récemment.

Mots clés : halogénures de rubidium, énergies de défauts, transport ionique, dispersion phonique, chlorure de strontium, sulfure de rubidium.

[Traduit par la Rédaction]

Introduction

There have been several previous calculations of defect energies for the rubidium halides RbCl, RbBr, RbI (1–6) but because of differing crystal potentials and the conditions under which the calculations were carried out, there are considerable variations in the results. For example the calculated energy to form a Schottky defect (that is, a vacant site on each of the cation and anion sub-lattices) varies from 2.16 to 2.52 eV (1–6) for RbCl, while the calculated activation energy for the migration of cation vacancies in RbCl varies from 0.63 to 0.80 eV (2–5). Similar variations exist for the calculated anion vacancy migration energy in RbCl and for calculated defect energies for RbBr and RbI. This paper reports a new study of defect properties of RbCl, RbBr, and RbI, and also of Rb_2S for which no previous calculations have been published. Particular attention has been paid to the development of new crystal potentials and the agreement between calculated perfect-crystal properties and experimental data, including phonon dispersion. A necessary feature of this work was the development of a new interatomic pair-potential for the Cl^-–Cl^- interaction, and so we took advantage of this to recalculate the phonon dispersion and defect properties of $SrCl_2$, which had been the subject of a previous investigation in this laboratory (7). Sr^{2+}–Rb^+ and S^{2-}–Cl^- potentials were also calculated in order to investigate the properties of doped RbCl. The availability of recent ionic conductivity measurements for pure and doped RbCl from this laboratory meant that a particularly careful comparison with experiment could be made for this material.

The calculations

The method of calculation adopted was that based on the two-region strategy of Mott and Littleton (8) as implemented in the computer codes HADES (9) and CASCADE (10). The theoretical basis of the Mott–Littleton method has been described in the literature (11, 12) and the results obtained for various classes of compounds have been assessed (12–14). It is therefore only necessary to state the region

© 1998 NRC Canada

sizes and to discuss the crystal potentials employed. In our calculations the inner region consisted of approximately 100 ions. (It is essential that the inner region contain complete symmetry classes and therefore the precise number of ions in region I may vary slightly with defect symmetry.) The adjacent region IIa, which separates region I from the outer region IIb (which in the Mott–Littleton method is treated as a dielectric continuum), consisted of 1000–1500 ions. These region sizes are sufficient to ensure adequate convergence of the defect energies. As is invariably so in applying this method, the calculations were done with constant lattice parameter and since no calculations were done at elevated pressures, the results are indistinguishable from defect energies at constant volume. The errors involved in comparing such constant-volume energies with experimental enthalpies determined at constant pressure at elevated temperatures can be expected to be no more than about 2% (12, 15).

Any defect-energy simulation of an ionic crystal involves the calculation of the self-consistent energy of interaction between the ions in their fully relaxed positions. At long range this interaction is dominated by Coulombic forces but, as ionic separations decrease, dispersion forces become significant. These forces arise from the interaction of mutually induced multipoles, the strongest being the dipole–dipole interaction $\phi^{DD}(r)$. At even closer separations the ionic charge densities overlap and a strong closed-shell repulsion results. This overlap repulsion energy $\phi^{R}(r)$ is commonly described by a Born–Mayer exponential term. If many-body effects and angle-dependent forces are neglected, which is a reasonable approximation for alkali halide crystals (12), the short-range interaction can be described by the pair-potential

$$[1] \qquad \phi^{SR}(r) = \phi^{R}(r) + \phi^{DD}(r) = A_{ij} \exp\left(-\frac{r}{\rho_{ij}}\right) + \phi^{DD}(r)$$

where A_{ij} is the repulsive parameter and ρ_{ij} the hardness parameter (for ions of species i and j). Traditionally, ϕ^{DD} has been represented by $-C_{ij}r^{-6}$ and the resulting potential [1] is then called a Buckingham potential. A_{ij} and ρ_{ij} must be found either by fitting crystal properties (12, 16) or determined by calculation. Because of the difficulties involved in doing a quantum-mechanical calculation of the short-range energy in a realistic crystal environment (17, 18), the method of choice (12) has frequently been some variant of what have come to be called "electron-gas calculations" (19, 20). These involve the HFSCF calculation of single-ion charge densities (ρ_i, ρ_j), followed by a calculation of the interaction energy between a pair of ions of species i and j in the Thomas–Fermi–Dirac approximation in which the kinetic and exchange contributions are taken to be those of a uniform free-electron gas of density $\rho = \rho_i + \rho_j$. One worries about the accuracy of this *conserved density approximation* (12) and that is why it is best to test the results of electron-gas calculations by calculating known properties of perfect crystals and modifying the hardness and repulsive parameters where necessary to obtain the best possible fit to the lattice constant and elastic constants, and this has been done in this work. Estimates of C may be obtained from the Slater–Kirkwood formula (18, 21, 22) and refined by fitting.

Nearly all calculations of defect energies use the shell model to simulate the polarizability of an ion and the shell-model charges Y_i, Y_j, and the force constants K_i, K_j are adjusted to fit the relative permittivities ϵ_s, ϵ_∞, anion polarizability, and the zone-centre frequency of the transverse optic mode. Some hints on fitting procedures are given in ref. 12. Generally, we prefer to reserve the calculation of the phonon dispersion in the principal symmetry directions in the Brillouin zone as a final test of the crystal potential.

Table 1. Potential parameters for RbCl, RbBr, and RbI.

Interaction	A_{ij}/eV	ρ_{ij}/Å	C_{ij}/eV Å^6	r_m/Å
RbCl				
Cl^-–Cl^-	596.54	0.380	170.06	4.0
Rb^+–Cl^-	2 050.94	0.348	108.87	4.1
Rb^+–Rb^+	4 959.53	0.286	68.31	3.8
RbBr				
Br^-–Br^-	1 445.89	0.361	127.59	4.3
Rb^+–Br^-	5 800.44	0.319	85.00	4.5
Rb^+–Rb^+	5 020.49	0.285	70.02	3.8
RbI				
I^-–I^-	1 833.12	0.369	115.53	4.9
Rb^+–I^-	29 540.18	0.287	27.00	5.6
Rb^+–Rb^+	5 080.49	0.285	70.02	3.8

Our potentials differ from those commonly employed in one significant respect, namely, the insertion of a damping coefficient $\chi(r)$ so that

$$[2] \qquad \phi^{DD}(r) = -\chi(r)\, C_{ij}/r^6$$

where (23, 24)

$$[3] \qquad \chi(r) = \exp[-((1.28\, r_m/r) - 1)^2]; \quad r < 1.28\, r_m$$
$$\chi(r) = 1; \quad r \geq 1.28\, r_m$$

r_m being the ionic separation at the potential minimum. The inclusion of $\chi(r)$ reduces the undamped energies in the charge-overlap region. r_m is a scaling factor and the number 1.28 comes from extensive tests using experimental data (23).

Theoretical formulae for damping coefficients have been given by Pyper (17) but, in our experience (24), eq. [3] is a simple but effective method of removing the unphysical net attraction in the Buckingham potential at small r. For some impurity potentials, fitting is not possible because of lack of data and in these instances the calculated electron-gas potentials were employed without further refinement.

Results

Crystal potentials

Pair-potentials for the three rubidium halides are given in Table 1 and shell-model parameters in Table 2. Calculated perfect-crystal properties are compared with experimental values in Table 3. In these calculations the lattice constants a_o were taken to be the experimental values at 0 K. Any deviation from the minimum in the calculated cohesive energy as a function of a_o would then appear as a bulk lattice strain. In all our calculations the calculated bulk lattice strains were extremely small (about 0.0001). This is equivalent to saying that the structure and lattice constant are fitted almost exactly. The experimental cohesive energy u_c elastic constants

Table 2. Shell model parameters for RbCl, RbBr, and RbI.

Ion	Y/eV	K/eV Å^{-2}
Cl^-	–2.485	29.5
Rb^+ (in RbCl)	5.000	171.0
Br^-	–3.205	34.7
Rb^+ (in RbBr)	5.000	175.0
I^-	–4.087	36.9
Rb^+ (in RbI)	5.000	185.0

and relative permittivities are the 0 K values but the experimental frequencies of the longitudinal (LO) and transverse (TO) optic modes come from experimental measurements at 80 K. There were insufficient experimental data to extrapolate these quantities to 0 K. The overall agreement with experiment is very good for this type of work. Since we are using pair-potentials and every ion is at a centre of cubic symmetry, our calculated values of the elastic constants c_{12} and c_{44} satisfy the Cauchy relation $c_{12} = c_{44}$. The modest failure of this relation for experimental values of the elastic constants indicates small contributions from many-body interactions. These are clearly much smaller than in the silver halides, for example (25), and we believe that the contributions from many-body forces will have only a relatively small effect on the calculated defect energies (compare ref. 16). Calculated phonon dispersion curves are compared with experiment in Figs. 1–3. Agreement for acoustic modes is uniformly excellent. For RbI the agreement between calculated and experimental optic modes is also excellent. For RbBr the calculated TO mode lies slightly below the experimental data, while from RbCl the calculated TO and LO modes are both somewhat low. This is a result of the relatively poor fitting of the zone-centre transverse optic mode frequency ω_{TO}, coupled with the excellent fitting of the high- and low-frequency permittivities, which will inevitably drag the LO mode down as well. The fitting of crystal potentials is always a compromise between various considerations. Here we adopted as an article of faith the principle that the shell parameters for Rb^+ should be, as far as practicable, transferable between the three halides, with only minor variations permitted in the spring-constant K to allow for the different crystal environments. The same principle was applied to the Rb^+–Rb^+ Buckingham potential and the success of these two assumptions may be seen in Tables 2 and 3. We feel that this principle is basically sound, though the constraints that it implies in practice may have been a little too severe, with some minor repercussions in the RbCl potential. In assessing the phonon dispersion curves, it is important to recall that only one point, the ω_{TO} frequency at Γ, is used in fitting the rock-salt structured rubidium halides. Although ω_{LO} appears in the tables because it helps to give an idea of the quality of the fitting achieved to the experimental data, it is not an independent point because of the Lydane–Sachs–Teller relation and the fact that the static and high-frequency permittivities are also fitted properties. In the fluorite-structured Rb_2S and $SrCl_2$ the Raman frequency is an independent parameter and it is therefore included in the fitting. So the calculated phonon dispersion curves involve only one (or two) fitted points and the rather good overall agreement with experiment in Figs. 1–3 and 5 should be seen in that light.

The alkali chalcogenides have not been investigated as thoroughly as the alkali halides. In fact the only available crystal data for Rb_2S are the lattice constant, cohesive energy, and refractive index n, from which the high-frequency permittivity may be calculated using the relation $\epsilon_\infty = n^2$. Potential parameters for Rb_2S are given in Table 4 and calculated and available experimental values of crystal properties are in Table 5. Potential parameters for $SrCl_2$ are given in Table 6 and the comparison of calculated and experimental properties in Table 7. The difference between this and the previous work on $SrCl_2$ (7) is that the hardness parameter ρ_{ij} and van der Waals coefficient C_{ij} for the Cl^-–Cl^- interaction were fixed at the values found for RbCl and only the Cl^-–Cl^- repulsive parameter and the Sr^{2+}–Cl^- and Sr^{2+}–Sr^{2+} parameters were allowed to vary during fitting. The overall agreement with experiment in Table 7 shows some improvement over previous work, although the difficulty in fitting the elastic constants c_{12} and c_{44} has not been resolved completely.

Fig. 1. Calculated phonon dispersion for RbCl compared with experiment (∇) (26).

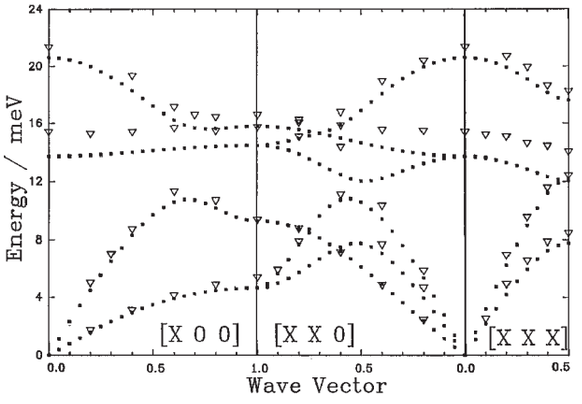

Fig. 2. Calculated phonon dispersion for RbBr compared with experiment (∇) (27).

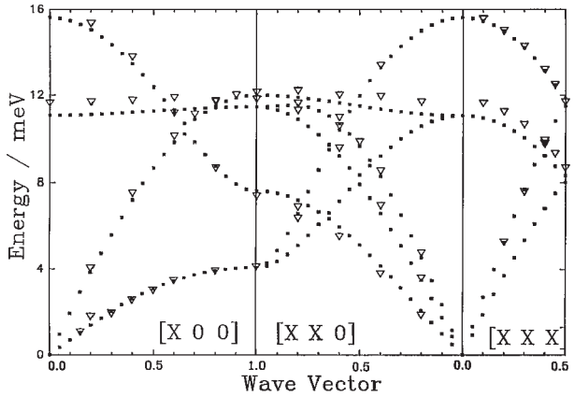

The calculated phonon dispersion for Rb_2S and $SrCl_2$ is shown in Figs. 4 and 5. There are no experimental data for Rb_2S but the general form of the dispersion curves (for example, the very flat Raman branch along ΓX) resembles that of other fluorite-structured ionic crystals, such as Na_2S, for which there are experimental data (7), $SrCl_2$ (Fig. 5), and Li_2O (30). The remarkable feature of these crystals is the minimum in the LO mode and the corresponding maximum in the transverse Raman (TR) mode, which occur at the same q-point, [q_1 q_1 0] with q_1 about 0.66. This behaviour is very marked in Na_2S and Li_2O (7, 26). In $SrCl_2$ the LO minimum appears in the calculated curves and there is a strong hint of a Raman peak in the experimental data that, however, is not reproduced in our calculations. In Rb_2S the TR and LO modes meet at this point (q_1 = 0.65), strongly suggesting that the same type of cooperative dynamical motion that exists in Li_2O (30) might be operative also in the formation of Rb^+ interstitials in Rb_2S. In Rb_2S the TO and TR modes are well separated at Γ but in $SrCl_2$ they are much closer and in Na_2S they are almost degenerate, no doubt a consequence of differing atomic masses and crystal potentials.

Two additional potentials Sr^{2+} – Rb^+ and S^{2-} – Cl^- were needed for defect calculations on doped crystals and these were calculated by fitting results of electron-gas calculations to the Born–Mayer repulsion. No fitting to crystal properties is possible in these cases. The results of these calculations

Fig. 3. Calculated phonon dispersion for RbI compared with experiment (∇) (28).

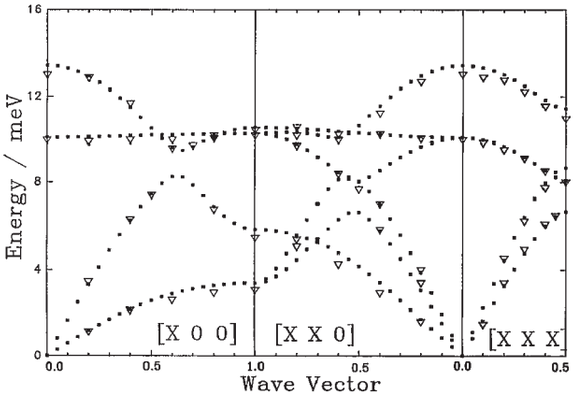

Table 4. Potential parameters for Rb_2S.

Interaction	A_{ij} /eV	ρ_{ij} /Å	C_{ij} /eV Å^6	r_m/Å
S^{2-}–S^{2-}	73.38	0.627	0.00	—
Rb^+–S^{2-}	1419.00	0.397	194.48	4.9

are given in Table 8. Shell-model parameters for the individual impurity ions S^{2-} and Sr^{2+} were taken to be the same as in the pure crystals Rb_2S and $SrCl_2$ (Tables 4, 6).

Defect energies

In this work defect formation energies are calculated using the convention that the final state of an ion removed from the lattice to form a vacancy is at rest at infinity and similarly the initial state of an ion that ends up in an interstitial site is the ion at rest at infinity. Consequently the energy required to form a Frenkel defect (u_F) is the sum of vacancy and interstitial formation energies for ions from the appropriate sub-lattice, indicated by subscripts c for cation and a for anion. The energy to form a Schottky defect (u_S) is the sum of cation and anion vacancy formation energies required to make up the stoichiometric unit (MX, M_2X, or MX_2) minus the cohesive energy of the crystal. The vacancy migration energy is the energy required for an ion to jump from a nearest neighbour (nn) sub-lattice site into the vacancy (v) along a direct path. Interstitials in the rock-salt structure can jump into a nn interstitial site by one of three mechanisms: along a direct path (id), by a collinear interstitialcy mechanism (ic), or by a non-collinear interstitialcy mechanism (inc). In the fluorite structure only the inc mechanism is possible. Migration energies are indicated in the tables by the symbol Δu with appropriate subscripts to show the sub-lattice (c or a), the defect (v or i), and the interstitial mechanism. The vacancy pair-formation energy (u_p) is the energy to form a pair of vacancies on nn sites from two isolated vacancies in the crystal, and Δu_{cp}, Δu_{ap} are the energies required for a nn cation or anion to hop into a vacancy pair.

Association energies u_1, u_2 are the energy to form nn or next nn (nnn) complexes between a divalent impurity ion and a vacancy on the same sub-lattice (Fig. 6). The various possible jumps of a vacancy in a complex are designated w_1, w_2, w_3, and w_4 and these are defined in Fig. 6. Corresponding migration energies are designated Δu_1 through Δu_4.

The contribution of a particular defect species to ionic transport in a material can be assessed from its Arrhenius energy designated by E, with a superscript showing the defect type (S or F or p) and a subscript that indicates the migration mechanism. Thus, for example,

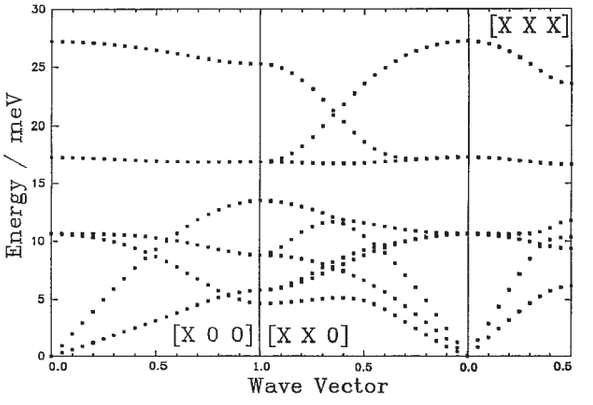

Fig. 5. Calculated phonon dispersion for $SrCl_2$ compared with experiment (∇) (29).

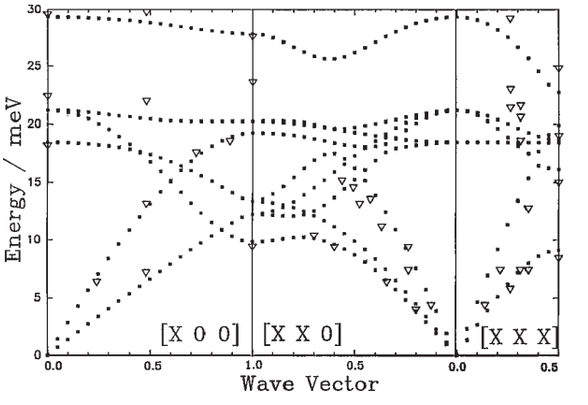

$$[4]\quad E^{F}_{cv} = (u_{Fc}/2) + \Delta u_{cv}\ ;\ E^{F}_{cic} = (u_{Fc}/2) + \Delta u_{cic}$$
$$E^{S}_{av} = (u_S/2) + \Delta u_{av}\ ;\ E^{p}_{ap} = u_S + u_p + \Delta u_{ap}$$

Calculated defect energies for RbCl, RbBr, and RbI are given in Table 9, using the symbols already defined in the text. We have already remarked that the results of previous calculations (1–6) are spread over quite wide ranges because of the various potentials and calculation parameters employed. Even when the same models and potentials were employed discrepancies arise; for example, the calculations of Rowell and Sangster (5) were intended to supplement those of Uppal et al. (3) but the calculated energies in the two sets differ by up to 0.2 eV, which the former authors attribute to a difference in the short-range potential cutoff used. We standardized this parameter at 1.5 × the nn distance a_o so that first and second neighbours were always included in the short-range contribution (16).

Table 10 shows the binding energies for nn and nnn complexes in RbCl and also the vacancy jump energies. These are important parameters in discussions of diffusion and dielectric loss in doped crystals (31). Atom transport in doped crystals depends on the five jump frequencies w_1, w_2, w_3, w_4, and w_0, which is that of a free vacancy. These jump frequencies involve the corresponding entropies as well, and these

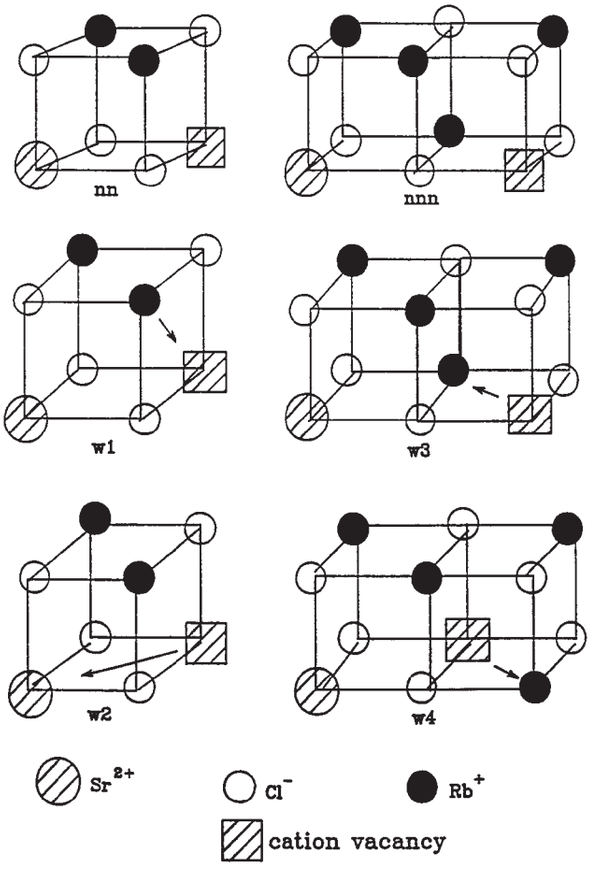
Fig. 6. RbCl:Sr^{2+} nn and nnn complexes and vacancy jumps in these complexes.



elusive quantities are much more difficult to calculate than defect energies (32). However, in divalent-cation doped crystals the calculated migration energies Δu_1, Δu_3, Δu_4 are often quite similar to Δu_{cv}, while Δu_2 is very different (13). Hence the five-frequency model can often be approximated by a two-frequency model. From the results in Table 10 this appears to be a reasonable first approximation for RbCl:Sr^{2+} but not for RbCl:S^{2-}. The binding energies of nn and nnn complexes in RbCl:Sr^{2+} are similar, which is quite often the case (13) except when the substitutional ion is larger than the host-lattice ion it replaces, when the nn complex becomes more favoured. These ion-size effects are apparent in the results for RbCl:S^{2-}. Calculated defect energies for Rb_2S are given in Table 11. Since there are no other calculated or experimental values to compare with these, we include the corresponding values for Na_2S from ref. 7. The trends are similar, with quantitative differences probably due to the greater ion polarizability of Rb^+. One can safely predict cation interstitial disorder in Rb_2S with vacancy motion along ⟨100⟩ predominating but with some contribution from interstitials.

The best test of theoretical calculations of defect energies is with experiment. We have recently published (33) a thorough analysis of the ionic conductivity of pure and doped crystals of RbCl. Ionic transport data are usually represented as plots of log σT vs. T^{-1} or log D vs. T^{-1} (σ = ionic conductivity, D = diffusivity) and consequently the gradients of these plots, when multiplied by 2.3026 k_B, are called Arrhenius energies. Arrhenius energies for RbCl, RbBr, and RbI (calculated from equations like [4]) are given in Table 11. This contains important information about transport mechanisms. We can expect both cv and av to contribute significantly to ionic transport in all three of the Rb halides, with the majority of these vacancies coming from Schottky rather than Frenkel defects. We must also expect substantial contributions from interstitials resulting from cation and anion Frenkel defects. Vacancy pairs will also contribute significantly to diffusion, though anion diffusion will be dominated by anion interstitials from Frenkel defects and anion vacancies from Schottky defects. Cation interstitials can be expected to dominate cation diffusion with smaller contributions form cation vacancies and pairs. These expectations may undergo some modifications in practice because the rate of transport depends on defect Gibbs energies rather than just enthalpies. Nevertheless defect energy calculations are a very useful guide in the analysis of transport data (33–35). It is the multiplicity of transport mechanisms in alkali halides that makes ionic conductivity data on pure crystals so difficult to analyze without additional data on σ for doped crystals and (or) diffusion. The above predicitions were substantially verified for RbCl and especially by the predictions of diffusion coefficients from defect parameters that resulted from analysis of conductivity data (see Fig. 11 of ref. 33).

E_{a}^{p}	2.39	2.41	2.43

Table 12 shows a comparison of values of defect enthalpies determined from ionic conductivity of RbCl with the calculated defect energies. The agreement is very close for cation parameters and somewhat less so for anion parameters. This is not too suprising because of the limited solubility of S^{2-} (and other divalent anions) in RbCl. The calculations for impurities also involve pair-potentials that could not be checked independently.

The ionic conductivity of RbBr and the diffusion of Rb^+ in RbBr have been measured by Downing and Friauf (36). They found Arrhenius energies of 2.01 and 1.99 eV for diffusion of Rb and Br and a value of 2.017 eV from conductivity. Since they considered only cation and anion vacancies and vacancy pairs, the implication is that the migration enthalpies for cv and av are very similar. However, an Arrhenius plot of conductivity data showed signficant curvature that our results (Table 11) indicate to be due to contributions from interstitials. Conductivity measurements on divalent cation- and anion-doped crystals are needed to permit a detailed analysis of the transport data for RbBr.

The ionic conductivity of pure RbI and RbI:Sr^{2+} has been measured by Chandra and Rolfe (37) and their Schottky defect formation enthalpy of 2.1 eV agrees well with our calculated energy. Unfortunately the conductivity of divalent anion-doped RbI could not be measured due to the low solubility of $RbCO_3$ in RbI, and consequently anion parameters could not be determined accurately. As for RbBr and RbCl, our calculations show that multiple transport mechanisms can be expected. Interstitials and vacancy pairs certainly should be considered in all three Rb halides.

Conclusions

The generally good agreement with experiment when such comparisons are possible supports the reliability of the pair potentials and defect energies reported in this paper. Such calculations make an invaluable contribution to our understanding of transport processes in ionic materials. They distinguish between possible transport mechanisms and are a useful guide in the analysis of transport data. Specifically, these results were indispensable in the analysis of ionic conductivity data for RbCl. They also suggest the models that should be used in the analysis of transport data for RbBr and RbI when further experimental data become available. The support received for these potentials indicates that the relatively straightforward hybrid method employed (namely, electron-gas calculations, supplemented by fitting of potential parameters to crystal data) is a reliable and useful method. The use of some form of dispersion damping in the charge overlap region is recommended both in potential fitting and in defect calculations. These calculations also provide further support (12, 13) for the reliablity of the Mott–Littleton method and of the HADES code.

Table 12. Defect enthalpies determined from ionic conductivity measurements on RbCl in the temperature range 520–960 K (29). Values quoted are the means from the computer-analysis of nine runs on pure RbCl, RbCl:Sr^{2+}, and RbCl:S^{2-}. Subscripts have the same meaning as in Tables 9 and 10. Frenkel defect formation enthalpies and interstitial migration enthalpies were held constant during nonlinear least-squares fitting of the data, so although their values do not provide an independent check on the calculations one can at least say that the calculated values are consistent with experiment. h_{1c} and h_{1a} are the nn association enthalpies determined from three runs each on RbCl:Sr^{2+} and RbCl:S^{2-}. Corresponding defect energies are reproduced from Tables 9 and 10 to facilitate comparison.

	Experimental (33) defect enthalpy/eV		Calculated defect energy/eV
h_s	2.520	u_s	2.52
Δh_{cv}	0.661	Δu_{cv}	0.66
Δh_{av}	0.720	Δu_{av}	0.67
h_{1c}	–0.592	u_1	–0.60
h_{1a}	–0.878	u_1	–0.65

A serious effort was made to see if a single set of Rb^+ shell parameters and Rb^+–Rb^+ Buckingham parameters could be established. However, it was found impossible to achieve this kind of accuracy in fitting properties without including some substance-dependent effects. As Table 1 shows, when Y for Rb^+ was held fixed, the variation in K was $\leq \pm 5\%$, while for the Buckingham parameters: ϱ /Å = 0.2853 ± 0.2%, A /eV = 5020.17 ± 1.2%, C /eV Å^6 = 69.45 ± 1.6%. These seem to be the limits to which a single transferable set can be developed for the Rb halides. Until such time as the calculation of ab initio potentials becomes a routine procedure, the present hybrid method can be recommended as a useful and relatively straightforward procedure.

Computer simulation of time correlation functions and matter transport coefficients for a model order–disorder alloy

Ziqiang Qin, Alan R. Allnatt, and E. Loftus Allnatt

Abstract: The time correlation functions associated with the Onsager phenomenological coefficients for isothermal matter transport have been calculated by Monte Carlo simulation for a binary system (A,B) at the equiatomic composition according to the Kikuchi–Sato model of an order–disorder alloy with vacancy transport mechanism. The diagonal (AA) time correlation functions are positive, decay monotonically to zero, and exhibit a long time tail where they vary as t^{-n} where t is time; the exponent n varies weakly with temperature at high temperatures and more rapidly as the temperature is lowered through the order–disorder transition temperature. In the region of short-range order the off-diagonal (AB) time correlation function is negative but otherwise shows similar behaviour to the diagonal one, although as the transition temperature is approached n varies more rapidly. At the transition temperature and below, the off-diagonal time correlation function increases from an initial negative value to a maximum where it is positive and then, at later times, decreases to zero. The implications of these observations for approximate theoretical calculations of the phenomenological coefficients are briefly indicated.

Key words: diffusion, non-equilibrium phenomena, statistical mechanics, transport properties.

Résumé : On a calculé les fonctions de corrélation de temps associées aux coefficients phénoménologiques d'Onsager pour le transport isotherme de la matière en utilisant une simulation de Monte Carlo pour un système binaire (A,B) à composition équiatomique, dans le modèle de Kikuchi–Sato d'un alliage en ordre–désordre et suivant le mécanisme de transports des lacunes. Les fonctions de corrélation de temps diagonales (AA) sont positives, elles donnent une décroissance monotone vers zéro et elles présentent une longue traitée en fonction du temps qui varie selon la fonction t^{-n} dans laquelle t est le temps; à température élevée, l'exposant n varie faiblement avec la température et il varie plus rapidement lorsqu'on abaisse la température et qu'elle croise la température de transition ordre–désordre. Dans la région d'ordre à courte distance, la fonction de corrélation de temps hors diagonale (AB) est négative, mais elle présente autrement un comportement similaire à celui de la diagonale même si, lorsqu'on approche la température de transition, elle varie plus rapidement. Jusqu'à la température de transition, la fonction de corrélation de temps hors diagonale augmente en passant d'une valeur initiale négative jusqu'à un maximum qui est positif avant de redescendre avec le temps jusqu'à zéro. On indique brièvement les implications de ces observations pour les calculs théoriques approximatifs des coefficients phénoménologiques.

Mots clés : diffusion, phénomène de non équilibre, mécanique statistique, propriétés de transport

[Traduit par la Rédaction]

1. Introduction

The transport of matter through solids underlies a great range of the phenomena of concern in materials science and in solid state physics and chemistry. In this context linear non-equilibrium thermodynamics provides an economical unifying theoretical framework (1) that has been increasingly adopted (2, 3); at its heart is the symmetric matrix of phenomenological coefficients, L_{ij}. For an isothermal system L_{ij} denotes the coefficient of proportionality between the flux of atoms of species i and the thermodynamic force acting on species j. Measured matter transport properties can all be expressed as functions of the L coefficients. It is important to recognize that in many practical cases, such as the annealing of radiation damage, the demixing of materials in externally maintained chemical potential gradients and even for simpler properties such as the intrinsic diffusion coefficients, both the diagonal and off-diagonal elements of the L matrix are significant (2, 3). Furthermore, the L coefficients for the major chemical components, with which we are concerned in this paper, cannot necessarily be expressed in terms of the more easily measured tracer diffusion coefficients of these components, although there is evidence that approximate relationships may hold in some circumstances (3, 4). These considerations, coupled with the difficulty of measuring the individual L coefficients experimentally, mean that it is invaluable to have statistical mechanical theories of these

coefficients for molecular models whose parameters are energies of interaction between atoms and between the various lattice defects, as well as the jump frequencies of atomic jumps between lattice sites in various local environments. For dilute alloys there are well-established and routine methods (3) for such calculations of the L coefficients for the main vacancy and interstitial migration mechanisms of atom transport but for concentrated alloys and highly defective systems this is far from being the case. The present paper is concerned with the L coefficients for a model of concentrated alloys with matter transport by a small concentration of vacancies.

The interacting lattice gas model with nearest-neighbour interactions between atoms (the Ising model (5)) has provided the basis for much of our understanding of the equilibrium properties of concentrated alloys. To describe matter transport this model must be supplemented with a consistent recipe for the jump frequencies; that due to Kikuchi and Sato (6) has been almost universally used and is the only one considered in this paper. The Kikuchi (7) path probability method has been used to calculate approximate expressions for the L coefficients of this model and later applications of this method have been reviewed (8). Apart from a recent work (27) described below, there appear to be no other kinetic theories of the non-tracer L coefficients of the Kikuchi–Sato model with which this paper is concerned, although there are interesting adaptations (9) of ideas, from the Manning theory (10) of the random alloy model to calculations of the tracer diffusion coefficients. (In the random alloy model all configurations have the same energy and each atom–vacancy exchange frequency depends only on the species of the jumping atom and is independent of the species of nearby atoms.) In principle, the L coefficients of the major chemical components could therefore be calculated by coupling these tracer diffusion coefficient expressions (9) with the approximate relationships (4) already referred to, but we shall not investigate this alternative route here.

In recent years Monte Carlo simulation results have been obtained for the L coefficients of the Kikuchi–Sato model of binary alloys with a very small vacancy content, mainly for the order–disorder case (11) but also for the strictly regular solution case (12). There are also results for the important extension of the order–disorder model to a wide range of vacancy concentrations (13). All these simulations are based on an exact linear response formula for the L coefficients written in a form that is a generalization of the familiar Einstein expression for tracer diffusion coefficients (3, 14). Two recent approaches have emphasized the utility of carrying out simulations on alloy models, which, unlike the Einstein method, provide additional kinetic data that can be associated with particular analytical approaches, thus providing additional tests and insights for approximate analytical theories. In one method (15), based on a decomposition of the Einstein type of formula and closely related to random walk methods that are well established for analyses of dilute alloys, attention is focused on averages of certain "collective" cosines of the angle between successive atom jumps. The method has so far been applied to the random alloy model. In this paper we concentrate on the second method, which simulates time correlation functions from which the L coefficients can be found by an integration over time. It has the advantage that, for analytical work, one can draw on adaptations of the Mori memory function formalism (16) for time correlation functions, which has proved so useful in the theory of the transport coefficients of fluids (17). A widely used method in the latter field has been to construct approximations to the time correlation functions from a knowledge of their lowest order moments (essentially, the coefficients of the Taylor expansion in powers of time of the time correlation functions). We have applied a scheme of this kind to the L coefficients of the random alloy and a two-sublattice generalization of that model (18). Recently we extended such calculations to the Kikuchi–Sato model of a simple cubic binary alloy with short-range order and a low vacancy content (27). The complexity of the moment calculations restricted these new results to an approximation for the time correlation functions that is expected to be good only at short times. In the present paper we summarize some features of new Monte Carlo simulations for such a system at the equiatomic composition as a function of temperature. These allow us to characterize the longer time behaviour of the time correlation functions and define more closely the structure needed for further development of the theory. Although we are primarily concerned with the region of short-range order covered by the recent theory, these simulations overlap the high-temperature end of the region with long-range order.

2. Model and simulation method

The model adopted is the same as that described and used in simulations by Murch and co-workers (11, 19) for order–disorder alloys. It is a rigid lattice model of a simple cubic alloy with nearest neighbour interaction energies E_{AA}, E_{BB}, and E_{AB} between atomic components A and B. These energies enter the partition function through the parameter

$$E = E_{AA} + E_{BB} - 2E_{AB} \quad [1]$$

For $E > 0$ there is a phase with long-range order at low temperatures. It exists within a boundary symmetric about the equiatomic composition, at which the transition temperature is given by $E/kT_c = 0.887$.

An atom can migrate by exchanging with a nearest neighbour vacancy. It is assumed that the vacancies are single and at such low concentration that they affect the bulk thermodynamic properties negligibly. The Kikuchi–Sato expression for the exchange frequency of an A atom with a nearest neighbour vacancy is

$$w_A^\alpha = \nu_A \exp(-U_A/kT) \exp([z_A^\alpha E_{AA} + z_B^\alpha E_{AB}]/kT) \quad [2]$$

and there is a similar expression for B. Here ν_A, the attempt frequency, and U_A, the energy of the jumping atom at the saddle point, are both taken as independent of the configuration α of the surroundings. The energy in the second exponential is that of the jumping atom before its jump, and z_A^α and z_B^α are the numbers of A and of B atoms, respectively, that are nearest neighbors to the jumping A atom before its jump. Following the practice in the earlier simulations on the order–disorder model (11) we shall set the quantities ν_i and $\exp(-U_i/kT)$ equal to unity in the simulation.

The linear response expression (3) for a phenomenological coefficient L_{ij} is the sum of a so-called uncorrelated part, $L_{ij}^{(0)}$, which is the value calculated neglecting correlations between successive molecular states and a term, $L_{ij}^{(1)}$, which contains such correlations and can be expressed in terms of a time correlation function. For the vacancy mechanism the off-diagonal ($i \neq j$) uncorrelated parts are zero. It has become conventional (3) to express theoretical results for the correlated parts in terms of correlation functions $f_{ij}^{(j)}$ defined as

$$[3] \qquad f_{ij}^{(j)} = \frac{L_{ij}}{L_{jj}^{(0)}}$$

where we drop the superscript j when $i = j$. The order of subscripts in $f_{ij}^{(j)}$ is immaterial because of the Onsager relation $L_{ij} = L_{ji}$. Using the linear response expression for the L coefficients this definition yields (20), for a simple cubic lattice, the equation

$$[4] \qquad f_{ij}^{(j)} = \delta_{ij} - \frac{2}{r_j}\int_0^\infty C_{ij}(t)\,\mathrm{d}t$$

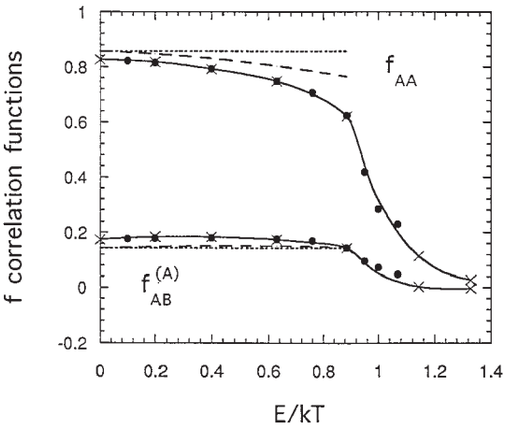
Here δ_{ij} is a Kroenecker delta, r_j is the mean number of j atom jumps per unit time, and $C_{ij}(t)$ is a time correlation function which can be expressed as

$$[5] \qquad C_{ij}(t) = \left\langle \boldsymbol{V}_i(t) \cdot \boldsymbol{V}_j(0) \right\rangle$$

where the angular brackets denote an equilibrium average. For a given configuration of atoms at time t the quantity $\boldsymbol{V}_i(t)$ is the jump frequency multiplied by a unit vector in the direction moved by the jumping atom added up for all possible i atom jumps that can occur in that configuration. $\boldsymbol{V}_i$ is a stochastic analogue of the collective velocity of the i atoms. The matrix of the time correlation functions is symmetric, $C_{ij}(t) = C_{ji}(t)$. The uncorrelated part $L_{jj}^{(0)}$ is proportional to the mean jump rate r_j calculated in the simulations (20); these quantities will not be discussed here since they pose a problem in equilibrium statistical mechanics that is relatively straightforward. Our interest in this paper is mainly in the structure of the time correlation functions, i.e., in the truly kinetic (non-equilibrium) part of the problem. It should be noted that despite the naming of the $f_{ij}^{(j)}$ as correlation functions it is $f_{ij}^{(j)} - \delta_{ij}$ which is a measure of the size of the correlation effects.

Calculations were made for a 20 × 20 × 20 simple cubic lattice with periodic boundary conditions. As in earlier simulations for this model (11, 19), an equilibrium system was first generated by conducting a grand canonical ensemble Monte Carlo simulation exactly as described in ref. 19*a* using a fully ordered initial state without vacancies. After 8×10^6 states a vacancy was introduced by removing a randomly chosen atom and the kinetic simulation was started. The latter followed the method already described for the random alloy (20) and for a random model with two sublattices (21). With the system in a known configuration at time t, the waiting time in that state was calculated and the next jump of the vacancy was selected by the procedure described in more detail by Reed and Ehrlich (22). This required calculating the exchange frequencies of the vacancy for the six possible jumps out of its current site and then forming the sum w_T of these frequencies. The waiting time t_W in the current state was then set equal to $-(\ln R)/w_T$, where R is a random number in the interval from 0 to 1 and the actual jump to be made was selected in accord with the relative probabilities of the six possible jumps using a further random number. The next configuration was then set up by moving the vacancy to the selected nearest neighbour site and the time counter was increased from t to $t + t_W$. A long sequence of configurations was generated in this way and the velocity vectors $\boldsymbol{V}_A$ and $\boldsymbol{V}_B$ were determined at equally spaced intervals Δt of time. The time correlation functions $C_{ij}(t)$ were calculated from the average of the scalar product of the appropriate velocity vectors each measured at an interval apart of time t. The correlation functions $f_{ij}^{(j)}$ were calculated by time integration of the time correlation functions using Simpson's rule. Runs were made until significant changes in the results of interest were no longer apparent. This required 40 to 60 million vacancy jumps (although longer runs were sometimes made) and took several hours on a Cray J90se computer.

Fig. 1. The f correlation functions (f_{AA} and $f_{AB}^{(A)}$) (as functions of E/kT: (●) present Monte Carlo simulation points; (— × —) simulation points by Einstein method (11) with a smooth line added; (– – –) Mori-type theory (27); (-----) path probability theory (23).



Results in this paper all refer to the equiatomic concentration with $E_{AA} = E_{BB}$. The zero of energy was chosen as $E_{AA} = 0$ for convenience. At the chosen composition one expects that $f_{AA} = f_{BB}$, and $f_{AB}^{(A)} = f_{AB}^{(B)}$; this was verified to high accuracy in all the simulations.

3. Results and discussion

Our results for the correlation functions f_{AA} and $f_{AB}^{(A)}$ as functions of E/kT are shown in Fig. 1 for five temperatures in the "high temperature" region above T_c and also at T_c and three lower temperatures. Points calculated by Murch and co-workers (11) by the Einstein method, plus the exact theoretical values at $E/kT = 0$, are also shown with a smooth curve drawn between them. Agreement is excellent in the high-temperature region but there are small discrepancies below T_c where slow convergence can be a problem in both methods.

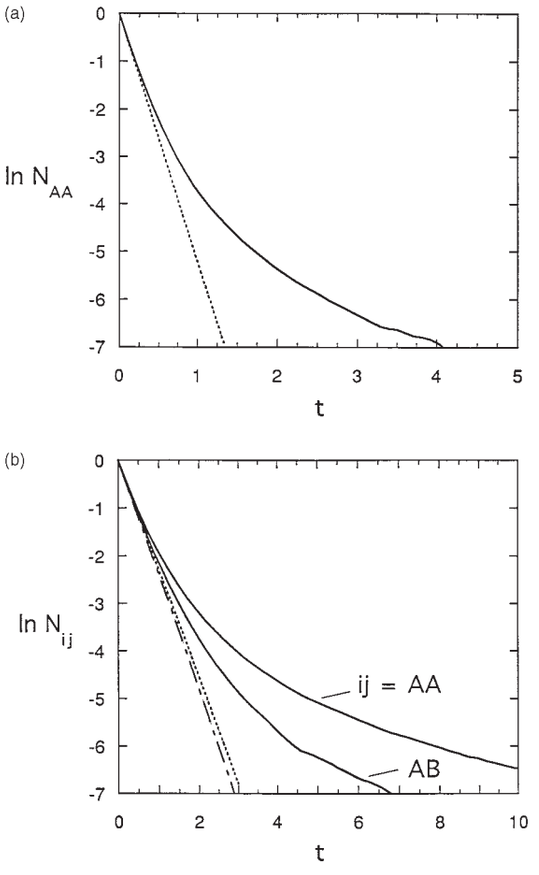
Fig. 2. Logarithm of the normalized time correlation function N_{ij} as a function of the reduced time t: (——) interpolated line through Monte Carlo simulation points taken at intervals in t of 0.014 in (*a*) and 0.03 in *(b)*; (-----) Mori-type theory for N_{AA} (27); (— - —) Mori-type theory for N_{AB}. (*a*) N_{AA} for E/kT = 0.2; (*b*) N_{AA} and N_{AB} for E/kT = 0.76.

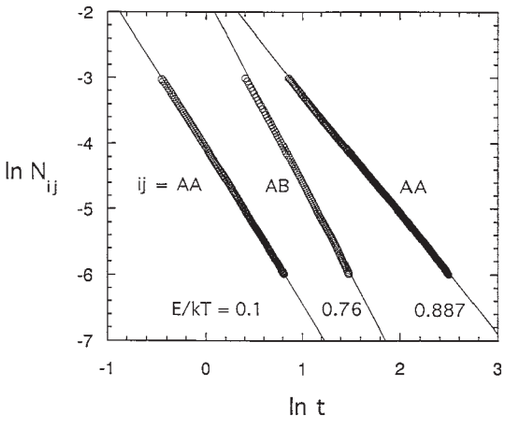


The results in Fig. 1 also show that the predictions from our recent theory based on the Mori formalism for the system with short-range order underestimate the correlation effects but are a useful guide to the correct results. For f_{AA} our predictions are slightly more successful than those that are shown from the path probability method (23), but for $f_{AB}^{(A)}$ there is little difference. References to later versions of the path probability method than the version employed in ref. 23 can be found in the review (8) cited earlier, but these have not so far been applied in detail to the model of interest here.

Our theory uses approximate expressions for the two lowest order moments of each of the time correlation functions and a truncation of the Mori continued fractions for the time correlation functions. It is expected to supply a correct short-time approximation to the time correlation functions. This is verified at all the temperatures by plots of ln N_{ij} versus t, where we employ the normalized time correlation function defined by

$$[6] \qquad N_{ij}(t) = C_{ij}(t)/C_{ij}(0)$$

Fig. 3. Log–log plots of normalized time correlation functions N_{ij} as functions of reduced time t at three values of E/kT: (○) Monte Carlo simulation points for $-6 < \ln N_{ij} < -3$; (——) linear least- squares fit. For the two N_{AA} plots all the points shown are fitted but for N_{AB} only $-6 < \ln N_{AB} < -4$ is used.



Examples are shown in Fig. 2 for temperatures towards the high- and low-temperature ends of the short-range order region. In the former case (E/kT = 0.2) $N_{AA}(t)$ and $N_{AB}(t)$ would be almost indistinguishable on the plot shown in Fig. 2(*a*) but for the latter case (E/kT = 0.76) the two functions are, as shown in Fig. 2(*b*), appreciably different. We should note that $C_{ij}(0)$ is always positive for ij = AA and always negative for ij = AB, and that the difference between $C_{AA}(t)$ and $C_{BB}(t)$ in the simulation results is negligible. The reduced time t in the figures is a dimensionless quantitity that is the actual time in units of $(\nu_i \exp(-U_i/kT))^{-1}$. (As noted earlier, $\nu_i \exp(-U_i/kT)$ has been set equal to 1 for i = A, B.)

Since the discrepancy between the theory and simulations is at long times we turn to the characterization of the long-time behaviour of the simulated time correlation functions. Examination of plots of ln N_{AA} versus ln t shows a linear relation at the largest times. Noise in the plots is greater the larger the value of t and can be decreased only by longer simulation runs. It was concluded that for the data presented here no values of $N_{AA}(t)$ smaller than 0.002 should be considered in any numerical analysis. With this limitation one finds that the linear regions extend over about the last three decades in t; examples are shown in Fig. 3 at the highest temperature simulated (E/kT = 0.1) and at the transition temperature (E/kT = 0.887). We find from least-squares fitting that $N_{AA}(t)$ varies as $t^{-n_{AA}}$ where, in the high-temperature region, n_{AA} decreases with increasing E/kT, as shown in Fig. 4. This figure includes a theoretical value of n_{AA} = 2.5 at E/kT = 0, which is consistent with the simulation data. The origin of this theoretical result is as follows.

At the high-temperature limit (E/kT = 0) the model is equivalent to the random alloy model at the equiatomic composition for two components with equal jump frequencies. It was shown earlier (20), both theoretically and in simulation, that the normalized time correlation function for the latter system is the same as that for a tracer atom migrating in a pure crystal with the host atom and tracer atom jump frequencies equal; an analysis of the asymptotic form of the

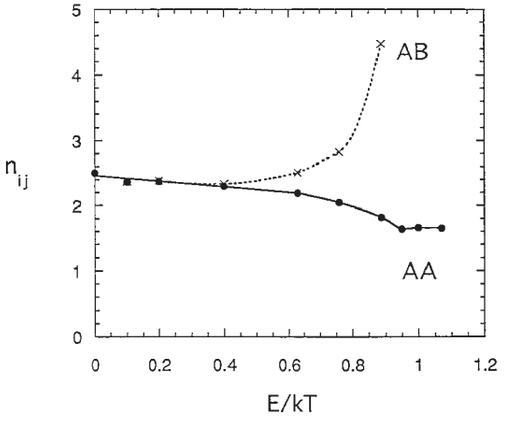
Fig. 4. The exponents n_{ij} for the power law tails of the time correlation functions as functions of E/kT: (●) for n_{AA}, (×) for n_{AB}; lines have been added to guide the eye. Values are determined from plots in Fig. 3 plus similar plots for other values of E/kT. For $E/kT = 0.887$, n_{AB} refers to the approach to the minimum where $N_{AB}(t) > 0$ and not to the tail at longer times where $N_{AB}(t) < 0$, see Fig. 5.

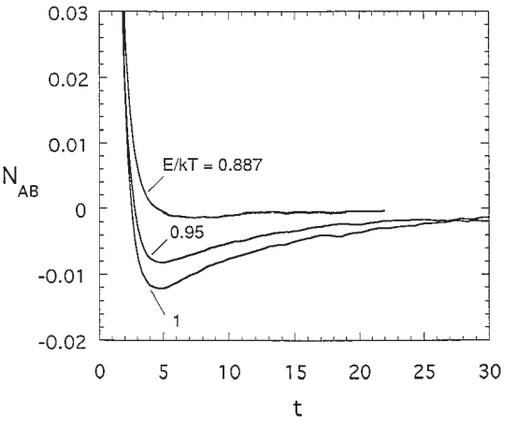


theoretical expression for this time correlation function (24) shows that the tail decays as t^{-n} with $n = 2.5$. The same result is also obtained (25) from an analysis of the tracer system based on an adaptation of mode coupling ideas, more usually formulated for Hamiltonian models (17*b*), to the domain of hopping models. The compatibility of the trend of our simulated results at finite temperatures with this limiting theoretical value therefore suggests that the tail behaviour we have found lies within the region accessible to mode coupling methods, although we know of no such analysis for the model studied here.

Referring again to Fig. 4 we note that n_{AA} drops more rapidly with decreasing temperature in the neighbourhood of T_c than at higher temperatures. It falls to 1.86 at the transition temperature, $E/kT_c = 0.887$. At the three temperatures below the transition that we have studied it is in the range 1.65–1.68.

At the highest temperature studied ($E/kT = 0.1$) $N_{AB}(t)$ is essentially indistinguishable from $N_{AA}(t)$ but as the temperature is lowered N_{AB} is found to decay as a function of time more rapidly than N_{AA} and, as shown in Fig. 3, the linear portion of the log–log plot for $N_{AB}(t)$ shrinks to about two decades in t at $E/kT = 0.76$. As shown in Fig. 4, n_{AB} (from fits of $N_{AB}(t)$ to $t^{-n_{AB}}$) is therefore equal to n_{AA} at the highest temperature simulated, but at $E/kT = 0.63$ and lower temperatures the two quantities diverge in value as the transition temperature is approached, with n_{AB} increasing as T is decreased (in contrast to n_{AA}). Whereas $N_{AA}(t)$ at all temperatures and $N_{AB}(t)$ at temperatures above T_c both decrease monotonically to zero, we find that at T_c and lower temperatures $N_{AB}(t)$ decreases to a minimum where it is negative and then, at later times, increases to zero. As shown in Fig. 5, in the limited range studied here the well depth increases as T is decreased. The long-time tail at the temperatures below T_c, where $N_{AB}(t)$ is negative at the longest times, is large enough to be quite significant in calculating $f_{AB}^{(A)}$. Unfortunately, the noise level is too large to determine

Fig. 5. Normalized time correlation functions N_{AB} as functions of reduced time t in the region of the minimum in N_{AB} at the transition temperature and below for values of E/kT as marked. Interpolated curves are shown because of the high density of sample points used.



whether the tail of N_{AB} accurately obeys a power law decay to zero in this region. (We should remark that the AB time correlation function decreases in magnitude compared with the AA time correlation function as T is lowered. The ratio $-C_{AB}(0)/C_{AA}(0)$ decreases from 0.99 at $E/kT = 0$ to 0.54 at T_c, and decreases from 0.37 to 0.28 as T is lowered from $E/kT = 0.95$ to $E/kT = 1.07$. In practice, the length of simulation used here is quite adequate to allow characterization of the tail of C_{AA} but not of C_{AB} at the transition temperature and below.)

4. Concluding remarks

The simulation results described show that the time correlation functions associated with the phenomenological coefficients for the Kikuchi–Sato model of a binary alloy with a low vacancy content show a slow decay at long times. As already indicated, a possible route to understanding the change with temperature of the time dependence of this decay is through mode coupling methods that have so far been worked out only for tracer mixtures (25). In addition, an improved approach to the theory of approximate analytical formulae for the L coefficients may be made through the inclusion of mode coupling ideas in the calculation of time correlation functions and their associated memory functions within the framework of the projection operator formalism; in effect, one can seek to build on our recent theory, which employs just low-order moments within this framework. Earlier examples of such procedures in the theory of transport in fluids (17*b*, 26) provide indications of the techniques possible in this context. As a preliminary, we have recently investigated, in the context of the Mori (16) type of theory, the use of projection operator methods for time correlation functions that, as here, are based on a discrete master equation (3) rather than the Liouville equation description employed for fluids (Qin and Allnatt, in preparation).

A second striking feature of the simulation results is the occurrence of a sign reversal at intermediate times in the off-diagonal time correlation function but not in the diagonal

© 1998 NRC Canada

one when there is long-range order. We hesitate to attempt a quick physical interpretation of this result, in part because it is not clear to us whether it is connected with the occurrence of cycles of vacancy jumps recently found to be significant in recent simulations (26) of two models of ordered alloys.

Composite poly(*p*-phenylenevinylene)–Nafion thin films

Troy A.E. Loss, Cerrie W. Rogers, and Michael O. Wolf

Abstract: Composite thin films of poly(*p*-phenylenevinylene) and the polyelectrolyte Nafion have been prepared by the polymerization of 1,1′-[(*p*-phenylene)bis(methylene)bis[tetrahydrothiophenium] dichloride electrostatically bound to Nafion. The composite films are strongly fluorescent. The absorption and photoluminescence spectra of the films have been measured and are similar to those of poly(*p*-phenylenevinylene). X-ray microanalysis and weight gain experiments performed on the films suggest that the dicationic monomer occupies less than 15% of the cation exchanging sites in the Nafion, leaving sites available for binding of additional small cations.

Key words: thin films, conducting polymers, poly(*p*-phenylenevinylene), polyelectrolyte, photoluminescence.

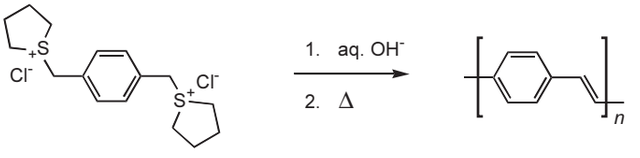
Résumé : Des films composites minces de poly(*p*-phénylènevinylène) et de polyélectrolyte Nafion ont été préparés par polymérisation de dichlorure de 1,1′-[(*p*-phénylène)bis(méthylène)-bis(tétrahydrothiophénium)] électrostatiquement lié au Nafion. Ces films composites fluorescent fortement. Leur spectres d'absorbance et de photoluminescence ont été mesurés et sont comparable à ceux du poly(*p*-phénylvinylène). Le taux d'occupation des sites par les dications monomères est de moins de 15%, mesuré par microanalyses rayons X et gain de poids. Il reste de nombreux sites disponibles capable d'accepter de petits cations.

Mots clés : films minces, polymères conducteurs, poly(*p*-phénylènevinylène), polyélectrolyte, photoluminescence.

Introduction

In the past several years, the efforts of many materials scientists have been focused on developing highly luminescent, conducting polymers for use in polymer-based light-emitting diodes (LEDs). LEDs are devices that emit light when electrons and holes injected into a layer of emissive material recombine and release energy. Emissive polymers open the door to low-cost, flexible, large-area colour displays because of their enhanced processibility and structural variety (1). Polymer LEDs were first prepared by Friend and co-workers in 1990 using poly(*p*-phenylenevinylene) (PPV) **1** sandwiched between indium tin oxide and Al electrodes (2). One method of synthesizing PPV is by polymerization of 1,1′-[(*p*-phenylene)bis(methylene)-bis[tetrahydrothiophenium] dichloride **2** (3).

Much work has been devoted to improving the overall efficiency of polymer LEDs (4). Chemical modifications of the PPV framework have led to both easier polymer processing and tuning of the colour of the emitted light (5). Since the mobility of charge carriers (electrons and holes) is critical to the functioning of polymer LEDs, conducting polymers have been coupled with other materials in order to develop systems that exhibit high charge mobility. Progress has been made using multicomponent systems, typically multilayer devices that incorporate hole-injecting and electron-injecting layers, as well as a variety of electrode-polymer combinations (5).



2 **1**

Composites of polyelectrolytes and conducting polymers have been the subject of much interest recently (6–12). Polyelectrolytes, such as poly(styrenesulfonate) and Nafion,[2] function as ion exchange polymers through which charged species can readily migrate. They are therefore ideal hosts for conducting polymers such as polythiophene, polypyrrole, and polyaniline because these heterocyclic polymers are readily electropolymerized, a process that requires mobile charges. By first embedding the appropriate monomer into the polyelectrolyte, this electropolymerization can be carried out in situ. The properties of the resulting composite materials are often different from those of the pure conducting polymer. Although the conductivity of such composites has been extensively studied (6–12), there are only a few studies of

the electroluminesence of composite materials containing conducting polymers and polyelectrolytes (13–21).

LEDs in which the emitting layer is a composite of PPV and a polyelectrolyte have been shown to perform efficiently because the device functions as a solid state electrochemical cell (13–21). We are developing polymer LEDs based on composite materials formed by polymerizing PPV within a polyelectrolyte matrix. In this paper, we describe the preparation and properties of such composites of PPV and the polyelectrolyte Nafion. Our approach is novel in that the dicationic PPV monomer is exchanged into a Nafion film, followed by in situ chemical polymerization of the PPV. Figure 1 schematically illustrates the sequence of steps used to prepare the PPV–Nafion composite material.

Results and discussion

Film preparation

Nafion **3** is a perfluorinated polymer containing sulfonated side chains (22) that is used as an ion-exchange matrix (23). Cations are strongly absorbed by Nafion films, and composite cation–polyelectrolyte materials have been used in a variety of applications. High-quality Nafion films can readily be prepared by evaporating solutions of the polymer onto a surface. Such films adhere to glass surfaces; however, we find that Nafion films cast on glass peel easily upon immersion into aqueous solutions, even for short immersion times.

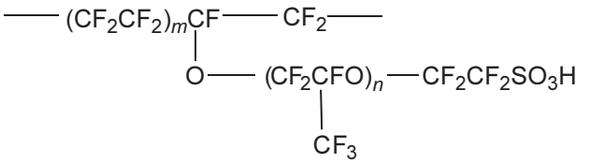
Since the PPV monomer **2** polymerizes in aqueous base, it was necessary to find a surface treatment that would prevent peeling of the Nafion film in base solutions. This was accomplished by pretreating the glass surface overnight with neat 3-aminopropyltriethoxysilane. Organosilanes are well known to behave as adhesion promoters for polymers on glass surfaces (24, 25). Nafion films cast onto such pretreated surfaces are more durable in base than those cast onto untreated surfaces; however, extended immersion in base still causes peeling of the films. Adhesion of the Nafion is likely enhanced by the aminosilane treatment because of protonation of the surface amino groups by the free-acid form of Nafion, resulting in electrostatic binding of the Nafion to the surface. In neutral aqueous solutions, such films on aminosilanized glass are stable; however, in basic solution, deprotonation of the surface ammonium groups results in eventual cleavage due to removal of the electrostatic stabilization.

The monomer **2** is incorporated into the Nafion matrix by immersion of prepared films in a dilute aqueous solution of **2** for 10 min (Fig. 1B). Subsequent immersion into a solution of the highly coloured tris(2,2′-bipyridyl)ruthenium(II) dication ($Ru(bpy)_3^{2+}$) does not result in any colour change in the film, suggesting that most of the binding sites in the film that are available to large cations are occupied by **2.** In comparison, immersion of a pristine Nafion film in a solution of

© 1998 NRC Canada

$Ru(bpy)_3^{2+}$ results in a rapid colour change from colourless to deep orange.

Weight gain experiments to determine monomer loading show that monomer **2** occupies a small fraction of the total available ion exchange sites in the Nafion film.[3] Based on the ion exchange capacity of Nafion (equiv. wt. 1100), occupation of all sites by **2** would result in mass increase of 16%,



3

assuming one monomer per two sulfonate groups. However, the observed mass increase is negligible, which corresponds to occupation of fewer than 15% of the sites by **2**.

The Nafion films treated with **2** are polymerized by immersion in 1 M KOH for 2 min (Fig. 1C). Extended immersion in base results in peeling of the films, and even with the surface pretreatment it has not been possible to obtain completely uniform, well-bonded films. After base treatment, the films are heated to promote the thermal elimination of tetrahydrothiophene that produces the conjugated PPV structure (Fig. 1D). During heating, the films become yellow and fluoresce strongly under UV light (366 nm). Visually, the films are smooth and uniformly coloured.

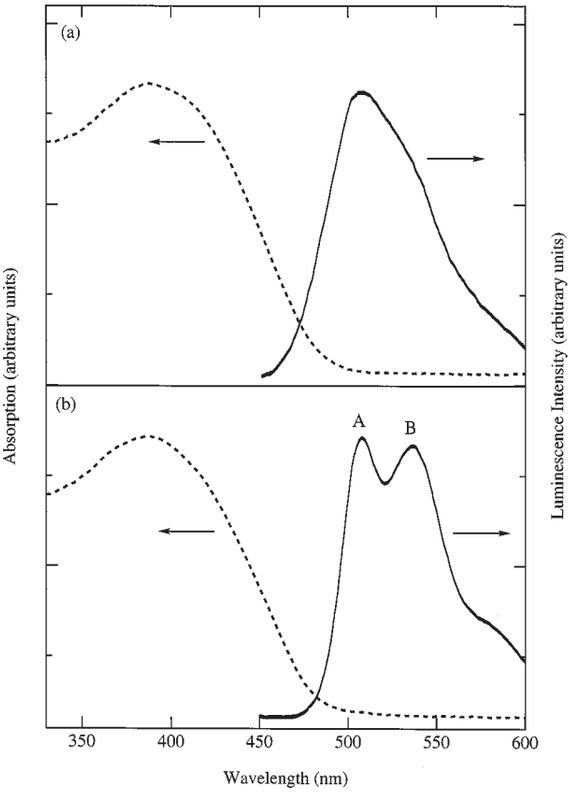
Absorption and photoluminescence spectra

The absorption and photoluminescence spectra of the PPV–Nafion composite at 25°C are shown in Fig. 2*a*. The absorption spectrum is nearly identical to that observed for PPV prepared by thermal treatment of base-polymerized **2** (Fig. 2*b*), the absorption maximum falling in the visible region at approximately 390 nm. The similarity of the two absorption spectra suggests that the conjugation length in the two materials is comparable.

The PPV–Nafion films are highly fluorescent, emitting in the green region as do PPV films. The photoluminescence spectrum of the composite has one band (λ_{max} = 510 nm) with a small low-energy shoulder. The spectrum of the composite is, however, significantly different from that observed for PPV (Fig. 2*b*), in which two well-defined bands are observed (A: λ_{max} = 510 nm; B: λ_{max} = 540 nm) plus a low-energy shoulder. These bands are due to coupling of the electronic transitions to vibrational modes; band A corresponds to the 0–0 transition, band B corresponds to the 0–1 transition. Resolved vibrational structure is typically observed for samples with a high degree of intrachain order (26), and the relative intensities of the transitions vary with temperature (26). In the spectrum of the composite film, the vibrational structure is not resolved, which suggests that the constrained environment of the Nafion host gives rise to PPV that is more disordered than conventional PPV.

It is conceivable that limited polymerization may have occurred within the Nafion matrix, yielding oligomeric PPV. PPV oligomers exhibit blue-shifted emission but retain the same spectral shape as long-chain PPV, with the energy of oligomer emission converging to that of the polymer for chains containing over six monomer units (27). Based on the observed emission spectrum of the composite film (Fig. 2*a*), if limited polymerization has occurred, the oligomers must be over six monomer units long. This is consistent with the absorption spectrum as noted above.

Fig. 2. Absorption (---) and photoluminesence (——) spectra of (*a*) a PPV–Nafion composite film and (*b*) a PPV film. Photoluminescence spectra were obtained using excitation at 420 nm.



X-ray microanalysis

The films were characterized by energy-dispersive X-ray microanalysis (EDX) in order to determine elemental content. We analyzed samples corresponding to the four stages of film preparation as depicted in Fig. 1A–D. The data indicate that all samples contain approximately the same percentage of sulfur, consistent with only a small percentage of the available ion exchange sites being occupied by **2** (vide supra). Interestingly, the composite films contain a significant amount of potassium (~20%) after base treatment (Fig. 1C). The potassium is not removed by rinsing with water and is therefore presumed to be electrostatically bound to the Nafion. Thus, the large fraction of sites inaccessible to **2** may be occupied by K^+ ions. This is likely due to the large differences in size and shape between **2** (effective radius ~ 10 Å) and K^+ (1.37 Å) (28).

[3] Number of ion exchange sites calculated as follows: 1000 × (equiv. wt.)$^{-1}$ = mequiv./g Nafion.

© 1998 NRC Canada

Recent investigations of Nafion film microstructure (29–32) have shown that the films consist of hydrophilic pores containing clusters of $-SO_3^-$ groups dispersed in a hydrophobic fluorocarbon matrix. These ionic clusters range from 30 to 100 Å in diameter. Monomer **2** is sufficiently large that it may be difficult to exchange it into the smaller hydrophilic clusters in the Nafion film, leaving the smaller pores to exchange K^+ ions upon base treatment of the film. Also, the rodlike monomer molecules may "plug" the smaller pores if their orientation is correct; this would prevent further incorporation of monomer (32). The variation in pore size and the "plugging effect" may account for the low monomer loading observed. The clustered nature of the ionophores in Nafion may also influence the morphology of the PPV that is produced within this matrix, perhaps inducing decreased conformational order as is suggested by the fluorescence spectrum of the PPV–Nafion composite.

Conclusions

The PPV–Nafion composite has several properties that suggest it will be an interesting material for use in LED devices. The absorption and fluorescence spectra indicate that PPV is formed, although it appears to be more disordered than conventionally prepared PPV. The incorporation of K^+ ions into the composite indicates that binding additional small cations is possible. These sites may be useful for binding additional lumophores. Further investigations into the properties of the composite are underway.

Experimental section

Materials

Nafion (free acid form, 5 wt.% solution in a mixture of lower aliphatic alcohols) and 3-aminopropyltriethoxysilane (98%) were used as received from Aldrich. Tris(2,2′-bipyridyl)ruthenium(II) chloride trihydrate (>98%) was used as received from Strem Chemical. 1,1′-[(*p*-Phenylene)bis(methylene)bis(tetrahydrothiophenium)] dichloride was prepared as described in the literature (3).

Film preparation

Glass surfaces were cleaned by sonicating for 10 min in soapy water, rinsing with distilled water, sonicating 10 min each in methanol and acetone, and air-drying. The clean surfaces were then immersed overnight in neat 3-aminopropyltriethoxysilane, rinsed with acetone, and dried in air. Nafion films were cast onto the treated surfaces and the solvent was allowed to evaporate completely. To incorporate monomer, Nafion films were immersed in 3 mM aqueous **2** for 10 min, rinsed with distilled water, and air-dried. Polymerization was carried out in the Nafion matrix by immersing prepared films in 1 M KOH for 1–2 min, followed by rinsing with distilled water. The PPV-precursor polymer within the resulting polyelectrolyte composite was thermally converted to PPV by heating to >250°C with a heat gun until the film became visibly yellow-green. Reference PPV films were prepared similarly from dilute methanolic solutions of base-polymerized **2** cast directly onto clean glass surfaces.

Film characterization

UV–vis absorption and fluorescence spectra of the films were measured on a UNICAM UV2 UV–vis spectrometer and a Perkin–Elmer LS-5B photoluminescence spectrometer, respectively. EDX microanalysis was carried out using a Hitachi S-2300 scanning electron microscope coupled with a Kevex 8000 (with quantum window) microanalyzer system. Weight gain upon monomer incorporation was determined by weighing dry Nafion films before and after treatment with aqueous monomer **2**.

Acknowledgements

We would like to thank Dr. L. Burtnick for the use of the photoluminescence spectrometer and Mary Major (Dept. of Metals and Materials Engineering, UBC) for assistance with the EDX measurements. We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for funding in the form of a research grant to M.O.W. and a postgraduate fellowship to C.W.R.

The adsorption of bis(hexafluoroacetylacetonato)zinc(II) on Si(111)-7×7

J. Hugh Horton, Johann Rasmusson, Joseph G. Shapter, and Peter R. Norton

Abstract: The adsorption of the organometallic compounds bis(hexafluoroacetylacetonato)zinc(II) ($Zn(hfac)_2$) and bis(hexafluoroacetylacetonato)nickel(II) ($Ni(hfac)_2$) on the surface of Si(111)-7×7 were studied by a combination of scanning tunnelling microscopy (STM) and X-ray photoelectron spectroscopy (XPS). These compounds are analogues of the compound bis(hexafluoroacetylacetonato)copper(II), which is an important precursor for the chemical vapour deposition of copper that we have previously studied. Both XPS and STM results indicate that the $Zn(hfac)_2$ is adsorbed intact on the surface, and remains intact on the surface at temperatures up to 300 K. The XPS shows a transition from a physisorbed state to a chemisorbed state at temperatures between 160 and 300 K. At higher temperatures $Zn(hfac)_2$ decomposed to form Zn and fluorocarbon fragments. The metal component diffused into the substrate. The $Ni(hfac)_2$ complex could not be successfully adsorbed on the Si surface: it was shown that this was due to decomposition of the molecule in the vapour phase, probably due to the higher temperatures needed to evaporate this relatively involatile compound.

Key words: scanning tunnelling microscopy, chemical vapour deposition, zinc, copper.

Résumé : Faisant appel à une combinaison de microscopie tunnel à balayage (« STM ») et de spectroscopie photoélectronique par rayons X (SPX), on a étudié l'adsorption des composés bis(hexafluoroacétylacétonato)zinc(II) ($Zn(hfac)_2$) et bis(hexafluoroacétylacétonato)nickel(II) ($Ni(hfac)_2$) sur la surface de Si(111)-7×7. Ces composés sont analogues au composé bis(hexafluoroacétylacétonato)cuivre(II) qui est un précurseur important pour la déposition chimique de vapeurs de cuivre que nous avons étudié antérieurement. Les résultats tant de SPX que de STM indiquent que le $Zn(hfac)_2$ est absorbé d'une façon intacte sur la surface et qu'il reste dans cet état sur la surface à des températures allant jusqu'à 300K. Les données de SPX montrent que, à des températures entre 160 et 300 K, il se produit une transition d'un état physisorbé à un état chimisorbé. Aux températures plus élevées, le $Zn(hfac)_2$ se décompose pour former du Zn et des fragments fluorocarbonés. Le composant métallique diffuse dans le substrat. Il n'a pas été possible d'adsorber correctement le complexe de $Ni(hfac)_2$ sur la surface Si : il a été démontré que cette situation résulte d'une décomposition de la molécule en phase vapeur qui est probablement due aux températures plus élevées nécessaires pour évaporer ce composé qui est relativement peu volatil.

Mots clés : microscopie tunnel à balayage, déposition chimique de vapeurs, zinc, cuivre.

Introduction

Organometallic chemical vapour deposition (OMCVD) from chemical precursors containing the hexafluoroacetylacetonato ligand, $[CF_3COCHCOCF_3]^-$, or $hfac^-$, has attracted considerable interest of late (1). The most widely studied of these compounds contain copper, and include such compounds as $Cu(hfac)_2$ and Cu(hfac)X where X can be a number of neutral ligands including cyclooctadiene or vinyltrimethylsilane. These copper compounds have shown considerable promise in the OMCVD of copper for use in microelectronics applications (2). This is because Cu is a potentially good interconnect metal due to its high conductivity and resistance to electromigration. OMCVD is also promising because deposition also takes place at relatively low temperatures (200–300°C) under low-vacuum conditions. Cu OMCVD from these compounds is also selective: that is, it will nucleate and grow films preferentially on some surfaces (3).

To understand the initial nucleation of copper during the OMCVD process we recently undertook a study of the deposition of $Cu(hfac)_2$ on the surface of Si(111)-7×7 (4). The initial deposition was examined using a combination of scanning tunnelling microscopy (STM), X-ray and ultraviolet photoelectron spectroscopy (XPS, UPS), and Rutherford backscattering (RBS). It was found that $Cu(hfac)_2$ decomposed on the surface even at temperatures of about 160 K to

Table 1. Binding energies, kinetic energies, and Auger parameters of Zn and F photoelectron spectra observed for the adsorption of $Zn(hfac)_2$ on Si(111)-7×7.

	Temperature		
Transition	160 K	300 K	600 K
Zn $2p_{3/2}$ B.E.	1 024.2	1 023.6	1 022.5
Zn $L_3M_{4.5}M_{4.5}$ K.E.	984.6	987.4	Not observed
Zn α	2 009.3	2 011.8	Not observed
F 1*s* B.E.	689.5	688.9	687.4
F $KL_{2.3}L_{2.3}$	651.9	652.2	653.3
F α	1 341.4	1 341.1	1 340.7

form metallic Cu and free $hfac^-$ ligand. STM and RBS investigations at 300 K showed that the Cu nucleated as small clusters of about 10 atoms on the surface and, furthermore, that the cluster size was invariant with Cu coverage, at least over the range studied, which was from a Cu to Si surface atom ratio (Cu/Si) of ~0.001 to ~0.2–0.3. This remarkable effect is not understood, but we suggested that it could be related to a change in reactivity of existing clusters on the surface towards the addition of Cu atoms once the cluster contained 8–10 atoms; this could be due to a "magic number" effect, in which addition of Cu atoms costs energy. Alternatively, the clusters might be terminated with hfac ligands at this critical cluster size and hence become unreactive, although why this should occur at 8–10 atoms is not clear, unless the cluster reactivity decreases as it becomes "three-dimensional"; i.e., second and third layer growth occurs. Certainly the STM images and the measured average cluster size were consistent with a pyramid of Cu atoms with three layers.

We therefore decided to examine the reactivity of similar organometallic compounds on Si(111)-7×7, in order to discover whether other metals showed behaviour analogous to copper on the surface. A number of $M(hfac)_2$ compounds are commercially available, including those in which M = Pt, Ni, and Zn. We have examined the latter two, $Ni(hfac)_2$ and $Zn(hfac)_2$, adsorbed on Si(111)-7×7, by means of both XPS and STM.

Experimental

These experiments were conducted using two UHV chambers. Each chamber had a base pressure $<1 \times 10^{-10}$ Torr (1 Torr = 133.3 Pa) and has been described in detail previously (4–6). Samples were prepared in both the STM and the XPS chambers. The 0.5 cm × 1.7 cm, 0.3 Ω cm Si samples (Virginia Semiconductors) are prepared by outgassing at 600°C for at least 6 h followed by repeated flashing to ~1100°C. In the case of the STM, the microscope was used to check the surface after this preparation. An excellent 7×7 reconstruction is observed with fewer than 1% defects. LEED was used to compare the extent and quality of the reconstruction in each chamber.

The CVD precursor was dosed using two home-built dosers designed for dosing solids into the vacuum environment (7). The two dosers (one on the STM chamber and the other on the XPS chamber) are similar in design in that they both have heatable, differentially pumped reservoirs for the solid precursors and allow a directed flow of the precursor to the sample. Both dosers were mounted on linear transfers that allowed them to be moved close to the samples during dosing, and hence, even for very low vapour pressure precursors, a reasonable flux of adsorbate reaches the surface. All coverages were controlled via the *apparent* exposure, that is, by measuring the rise in background pressure during gas dosing, which was between 5×10^{-10} and 2×10^{-9} Torr. This provides a reproducible method of controlling the organometallic precursor dose.

All the organometallic compounds used here were obtained commercially and used without subsequent purification. $Zn(hfac)_2$ (Aldrich, 98%) was deposited by heating the doser reservoir to 35°C, while attempts to deposit $Ni(hfac)_2$ (Aldrich, 98%) were run with the reservoir temperature at up to 150°C. In both cases the compounds were pumped for 24 h at a pressure of 1×10^{-7} Torr to remove any residual water in the sample. In the case of $Zn(hfac)_2$, contamination by residual $Cu(hfac)_2$ in the doser from previous experiments proved to be a problem. This difficulty was solved by differentially pumping the empty doser at 150°C for several hours before adding the $Zn(hfac)_2$.

Results

In Figs. 1*a*–1*c* we show constant current STM images of a Si(111)-7×7 surface that has been exposed to 0.02 L of $Zn(hfac)_2$ at 300 K. The images are each 40 nm × 40 nm in size and are taken at tip bias voltages of –1.5, –0.5, and +1.5 V, respectively. Several points are immediately apparent. First, the surface consists of a standard Si(111)-7×7 pattern overlaid with small irregular patches some 1–3 nm across. As the tip bias voltage is changed the underlying Si substrate pattern changes in the manner expected for clean Si(111)-7×7 (8). The small irregular patches, however, appear in bright contrast with respect to the substrate in Figs. 1*a* and 1*c* (–1.5 and +1.5 V) but appear in dark contrast at a bias voltage of –0.5 V.

Zn $2p_{3/2}$ XPS and $L_3M_{4,5}M_{4,5}$ X-ray induced Auger spectra (XAES) are presented in Figs. 2*a* and 2*b*, respectively. In this case, the spectra were initially taken of 0.02 L of $Zn(hfac)_2$ adsorbed on the Si(111)-7×7 substrate held at a temperature of 140 K. The substrate was subsequently allowed to warm to 300 K (i.e., room temperature) for the second set of spectra and a third set were then taken after annealing the substrate to 600 K. Other than a decrease in intensity, there is little change in peak shape among the three sets of spectra. However, in both cases a drift to lower binding energy (higher kinetic energy) can be observed. This is summarized in Table 1, which also contains values for the Auger parameter, α, where α is defined as

$$\alpha = \text{B.E.} + \text{K.E.(Auger)}$$

where B.E. is the binding energy of the photoelectron, and K.E. is the kinetic energy of the main Auger peak. The signal intensity of the Zn Auger transition was quite weak, and thus a peak position and Auger parameter for the 600 K annealed sample could not be obtained.

Figure 3 shows the C 1*s* XP spectrum for $Zn(hfac)_2$ deposited on the Si(111)-7×7 surface. The spectra were taken

Fig. 1. STM images of 0.02 Langmuir $Zn(hfac)_2$ adsorbed on Si(111)-7×7 at 300 K. All images are 40 nm × 40 nm. The tunnelling current was 0.2 nA and the tip bias voltages were (*a*) –1.5 V, (*b*) –0.5 V, and (*c*) +1.5 V.

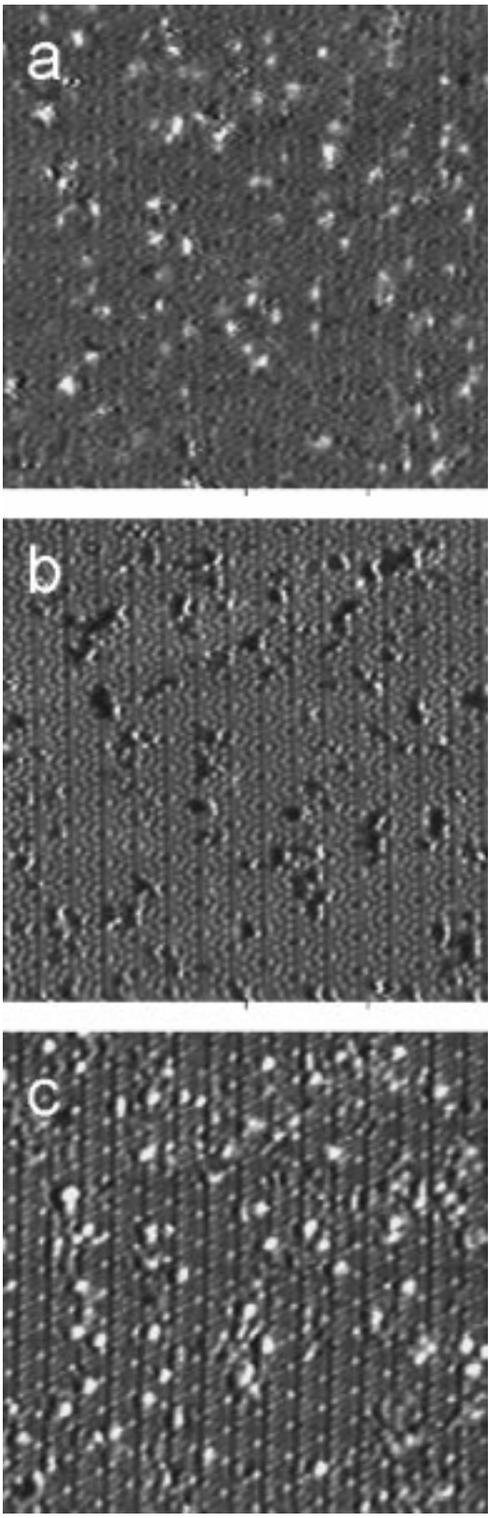

Fig. 2. (*a*) Zn $2p_{3/2}$ XPS spectra and (*b*) Zn $L_3M_{4,5}M_{4,5}$ X-ray excited Auger spectra of 0.02 Langmuir $Zn(hfac)_2$ molecule adsorbed on Si(111)-7×7 at various temperatures. The exciting radiation was Al Kα (1486.6 eV).

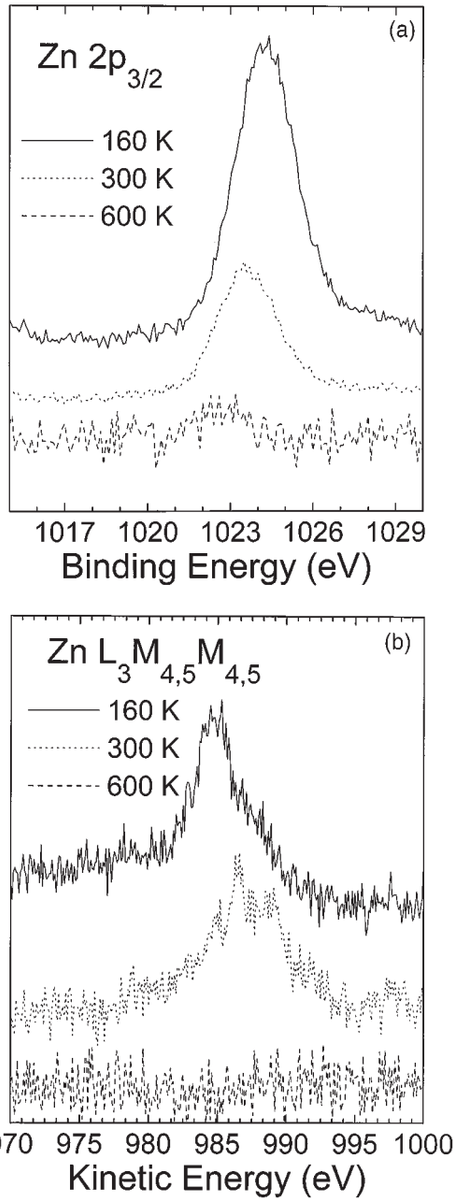
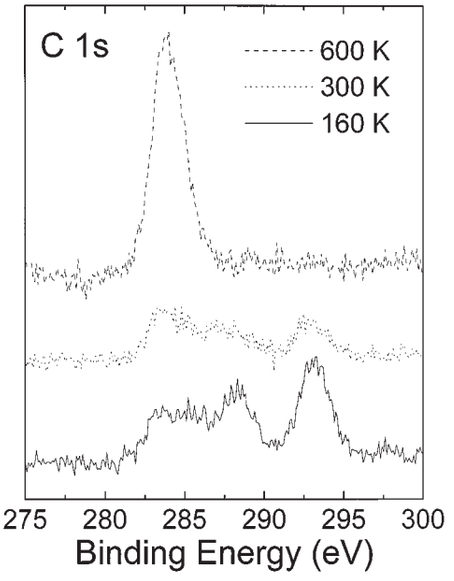


under identical conditions to those described for the Zn data. In the 140 K spectrum three peaks can be seen at binding energies of 283.8, 288.0, and 292.8 eV. A similar spectrum is observed at 300 K, although the 283.8 eV peak has grown in intensity relative to the other two. At 600 K, only the 283.8 eV peak remains: it has grown considerably in intensity compared with those for the spectra taken at lower temperatures.

We also acquired the F 1*s* and F Auger spectra under the same conditions as those above. Chemical shift and Auger parameter data for these peaks are also included in Table 1.

© 1998 NRC Canada

Fig. 3. C 1*s* XPS spectra of 0.02 Langmuir $Zn(hfac)_2$ molecule adsorbed on Si(111)-7×7 at various temperatures. The exciting radiation was Al Kα (1486.6 eV).



Attempts were also made to use XPS to analyse the adsorption of $Ni(hfac)_2$ on a Si(111)-7×7 surface. In this case, O, F, and C 1*s* XPS spectra indicated the presence of intact hfac ligand on the surface, but no Ni signals were observed. No Ni deposition was observed even when the doser reservoir temperature was increased to 150°C.

Discussion

One important difference between $Cu(hfac)_2$ and the two compounds examined here is the higher vapour pressure associated with the Cu compound. In our previous work, $Cu(hfac)_2$ could be introduced into the UHV system without any heating of the doser reservoir. This is not surprising since at room temperature the vapour pressure of $Cu(hfac)_2$ is ~30 mTorr (9). While the vapour pressure of $Zn(hfac)_2$ does not appear to have been measured, it has a melting point of 155°C, which is somewhat higher than that of $Cu(hfac)_2$ at 130°C. It is thus not surprising that it required a heated sample reservoir in order to deposit $Zn(hfac)_2$ on the Si surface. $Ni(hfac)_2$ has a melting point of 213°C, considerably higher than either of the Zn or Cu compounds. When attempts were made to deposit $Ni(hfac)_2$ on the surface, C, O, and F XPS signals, which had magnitudes similar to those obtained when $Zn(hfac)_2$ was deposited on the surface, were obtained. Since the Ni $2p_{3/2}$ X-ray absorption cross section is not greatly different from that for Zn $2p_{3/2}$ (10), it seems likely that very little Ni was present on the surface, certainly less than 0.1 monolayer. While we cannot rule out the presence of trace amounts of Ni on the surface, these results suggest that the higher temperatures required to evaporate the $Ni(hfac)_2$ led to the decomposition of the molecule before it reached the surface. The most likely reaction would be similar to that obtained in a CVD process

$$Ni(hfac)_2 + H_2, H_2O \rightarrow hfacH + Ni, NiO$$

where hfacH is the protonated $hfac^-$ ligand, and residual water and (or) hydrogen in the gas doser act as reducing agents, resulting in the deposition of Ni or NiO on the walls of the gas doser. Another path would involve the heterogeneous decomposition on the walls of the doser, perhaps even catalyzed by Ni first deposited by a homogenous process.

Since it did not prove possible to adsorb significant amounts of $Ni(hfac)_2$ on the Si surface, further (and more difficult) STM experiments were not attempted with this compound. However, XPS shows that it is indeed possible to adsorb $Zn(hfac)_2$ on the surface. The STM images shown in Fig. 1 demonstrate that there is only one type of feature associated with the adsorption of $Zn(hfac)_2$. The appearance of the feature is sensitive to tip bias voltage: at $|V_{tip}| > 0.5$ V the $Zn(hfac)_2$ feature is bright, while for $|V_{tip}| \leq 0.5$ V the features are dark. This is in considerable contrast to the case of $Cu(hfac)_2$ where we found two distinct features present on the surface upon adsorption of the organometallic complex. In that case, areas of bright contrast were associated with clusters of Cu atoms, while regions of dark contrast were found to correspond to hfac ligand adsorbed on the surface. Since we know that the hfac ligand gives rise to dark areas at tip biases of –1.5 V (4), the images demonstrate that there is no free hfac ligand on the surface when $Zn(hfac)_2$ is adsorbed at 300 K. Thus, the $Zn(hfac)_2$ molecule must remain intact upon adsorption at this temperature. A $Zn(hfac)_2$ molecule has dimensions of about 0.65 × 1.0 nm, while the features observed in the STM images are rather larger than this (1–3 nm) and also irregular in shape. This suggests that what we are observing is small clusters of anywhere from one to four $Zn(hfac)_2$ molecules adsorbed on the surface.

The Zn XPS spectra tend to support the hypothesis of intact $Zn(hfac)_2$ molecules adsorbed on the surface. In Fig. 2 and Table 1 we have an overview of the Zn chemical shifts and Auger parameters under various conditions. Unlike some other first-row transition elements, Zn XPS spectra generally do not contain any strong satellites due to shake-up or shake-off transitions and, more importantly, the chemical shift is reasonably insensitive to chemical environment. This is because the chemical shift, $\Delta\zeta$, is a function of both the core hole binding energy shift, $\Delta\varepsilon$, and extra-atomic relaxation energy ΔR^{ea} (i.e., polarizability of the environment of the X-ray excited atom) (11). These two effects are often opposed to one another, resulting in little or no net chemical shift in the XPS peak. However, it has been shown that the Auger parameter, defined above, is a sensitive measure of the extra-atomic relaxation effect (11). If both the XPS and XAES transitions used involve core electrons only, it can be shown that $\Delta\alpha = 2\Delta R^{ea}$. In the case of the Zn Auger parameters measured here and generally quoted in the literature this relationship does not strictly hold, since the most intense Auger transition, and hence most widely measured, $L_3M_{4,5}M_{4,5}$, involves valence band electrons. Nonetheless, since the Auger parameter is defined by taking the *difference* in energy of two peak positions, any instrumental calibration errors of the binding or kinetic energies tend to cancel out and Auger parameters obtained from different laboratories can be compared with considerable confidence.

We first consider the XP and XAE spectra acquired at sample temperatures of 160 K and 300 K. The Zn Auger parameter at 160 K is 2009.3 eV. This is quite similar to that

© 1998 NRC Canada

measured for ZnO of 2009.8 eV (12), suggesting that the Zn atom is in a similar environment in the two compounds. Since in the $Zn(hfac)_2$ molecule Zn is coordinated through four Zn—O bonds, this indicates that at 160 K, at least, the molecule lies intact on the surface. Upon warming the sample to 300 K, several changes are noted in the Zn spectra. First, the 2*p* binding energy decreases while the Auger kinetic energy is increased. The Auger parameter shifts to 2011.8 eV. At the same time, the Zn peak intensity falls to about one-half its initial value. This decrease in Zn signal intensity could have two explanations. At 300 K, Zn has either diffused into the bulk of the substrate, or a physisorbed overlayer of $Zn(hfac)_2$ has been desorbed from the surface. Since the former possibility requires the $Zn(hfac)_2$ to have decomposed at this temperature and this is not borne out in the STM results, the desorption model is more appropriate. The fact that only half of the Zn intensity is lost suggests a very thin overlayer in which XPS can detect molecules in all layers. Second, the observation that the Auger parameter for Zn at 160 K is consistent with *all* the Zn being present in the complex suggests that the molecules in the first layer (next to the Si) and in the second (physisorbed) layer, are very similar. Upon warming to 300 K, the Auger parameter shifts by +2.5 eV to 2011.8 eV. This value is intermediate to those observed for ZnO, 2009.8 eV, and for metallic Zn, 2013.8 eV (13). These observations together suggest that two phenomena occur upon warming from 160 to 300 K: desorption of physically adsorbed precursor and reaction of the remainder to form a new chemisorbed state. The Auger parameter measured at 300 K indicates that Zn does not appear to exist in the metallic state on the surface; the change in is more probably associated with a shift to a more polarizable environment with the $Zn(hfac)_2$ bound directly to Si substrate. When coupled with the STM results, this indicates that, in contrast to the case of $Cu(hfac)_2$, the Zn analogue does not form metal clusters on the surface.

The C 1*s* spectra presented in Fig. 3 also tend to support the above conclusions. The spectra taken at 160 K and 300 K are both consistent with those previously obtained for intact hfac ligand, both adsorbed directly on the surface and bound to a metal centre in $Cu(hfac)_2$. The peaks at 292.8, 288.0, and 283.8 eV correspond to C in CF_3, C=O, and C-H sites in the ligand, respectively. At 300 K the spectral intensity has decreased compared to that at 160 K, again demonstrating partial desorption of the $Zn(hfac)_2$ complex. By 600 K, C XPS indicates that the hfac ligand has completely decomposed on the surface, as the single, much more intense peak at 283.8 eV is typical of graphitic carbon on the surface. The increase in signal intensity suggests that some background carbon contamination has occurred by this point in the experiment. At the same time, the Zn 2*p* intensity has also decreased, suggesting that the zinc released during the process has probably diffused into the bulk, similar to the behaviour of Cu at these temperatures.

Finally, in the F 1*s* spectra, we note trends similar to those above. As the substrate annealing temperature is increased, the signal intensity decreases, particularly between 160 and 300 K, demonstrating desorption from the surface. At the same time there is a downward shift in the F 1*s* binding energy, consistent with chemisorption of $Zn(hfac)_2$ to the electron-donating substrate at higher temperatures. The small shift in F Auger parameter is more difficult to interpret, especially as few data seem available in the literature, but it is not inconsistent with a shift to a more polarizable environment at higher temperatures.

Conclusions

We have examined the adsorption of $Zn(hfac)_2$ on the Si(111)-7×7 surface by means of XPS and STM. The behaviour of this organometallic molecule differs considerably from that shown by its copper analogue, $Cu(hfac)_2$. Examination of the C and Zn XPS chemical shift and Auger parameter data indicates that molecules adsorbed at 160 K remain intact, and are physisorbed on the surface. In further contrast to $Cu(hfac)_2$, the zinc organometallic complex remains intact on the surface upon adsorption at 300 K or on warming from 160 to 300 K. This warming is accompanied by desorption of about half of the physisorbed complex, but the Zn Auger parameter shift at this temperature indicates a change in the bonding of the remaining $Zn(hfac)_2$ to the surface, while the C and F 1*s* XPS data indicate that the molecule remains intact. STM indicates that direct chemisorption in clusters of one to four molecules occurs at 300 K. There was no evidence either for the formation of metallic Zn clusters similar to those observed during $Cu(hfac)_2$ adsorption on the surface, or for the formation of clusters of hfac ligand.

Three-dimensional H-bonded supramolecular complexes. Synthesis and crystal structures of $[Mn(\mu\text{-bpe})(H_2O)_4](ClO_4)_2\cdot 4(bpe)\cdot 2H_2O$ and $[M(\mu\text{-bpe})(bpe)_2(H_2O)_2](ClO_4)_2\cdot bpe\cdot H_2O$, where M = Zn, Ni and bpe = 1,2-bis(4-pyridyl)ethane

Fernande D. Rochon, Marius Andruh, and Robert Melanson

Abstract: The reaction of Mn(II), Zn(II), and Ni(II) perchlorate with 1,2-bis(4-pyridyl)ethane (*bpe*) was studied and the products were characterized by IR spectroscopy and X-ray diffraction methods. The zinc and nickel compounds are isomorphous with a metal–*bpe* molar ratio of 1:4, while the manganese compound is quite different with a Mn–*bpe* ratio of 1:5. $[Mn(\mu\text{-bpe})(H_2O)_4](ClO_4)_2\cdot 4(bpe)\cdot 2H_2O$ (**1**) is monoclinic, *C*2/*c*, with a = 30.141(7), b = 13.993(4), c = 19.765(4) Å, β = 129.41(1)°, and R = 0.059. The Mn atom is located on an inversion centre and forms an infinite chain with the bridged *bpe* ligand. The four other *bpe* molecules are hydrogen-bonded to the aqua ligands and form an extensive H-bonded interpenetrating 3D network. The bonds Mn—N = 2.316(3) Å and Mn—OH_2 = 2.148(4) and 2.178(3) Å. $[Zn(\mu\text{-bpe})(bpe)_2(H_2O)_2](ClO_4)_2\cdot bpe\cdot H_2O$ (**2**) crystallized in the $P2_1/c$ space group, with a = 14.609(4), b = 21.164(5), c = 16.482(5) Å, β = 114.69(2)°, and R = 0.058. For $[Ni(\mu\text{-bpe})(bpe)_2(H_2O)_2](ClO_4)_2\cdot bpe\cdot H_2O$ (**3**), a = 14.511(6), b = 21.216(7), c = 16.467(7) Å, β = 114.76(3)°, and R = 0.065. The aqua ligands are located *trans* to each other. The bridged *bpe* ligands form an infinite chain with the metal atoms. Two other terminal *bpe* ligands are coordinated to the metal in *trans* positions to each other. These ligands form H-bonds with the aqua ligands of other chains resulting in an H-bonded 3D network. The Zn—N distances vary from 2.151(3) to 2.185(4) Å while the Ni—N bonds are between 2.098(10) and 2.126(11) Å. The bonds Zn—OH_2 = 2.125(4), 2.161(4) Å and Ni—OH_2 = 2.077(11), 2.110(11) Å.

Key words: crystal structure, manganese complex, zinc complex, nickel complex, 1,2-bis(4-pyridyl)ethane.

Résumé : La réaction des perchlorates de Mn(II), Zn(II) et Ni(II) avec 1,2-bis(4-pyridyl)ethane (*bpe*) a été étudiée et les produits ont été caractérisés par spectroscopie IR et par diffraction des rayons- X. Les composés du zinc et du nickel sont isomorphes et la proportion metal–*bpe* est 1 : 4, tandis que le composé de manganèse est différent avec une proportion molaire métal–*bpe* de 1 : 5. $[Mn(\mu\text{-bpe})(H_2O)_4](ClO_4)_2\cdot 4(bpe)\cdot 2H_2O$ (**1**) est monoclinique, *C*2/*c* avec a = 30,141(7), b = 13,993(4), c = 19,765(4) Å, β = 129,41(1)° et R = 0,059. L'atome de Mn est situé sur un centre d'inversion et forme une chaîne infinie avec les ligands *bpe* pontés. Les quatre autres molécules *bpe* sont liées par ponts-hydrogène aux ligands aqua et forment un réseau étendu entrecroisé tridimensionnel. Les distances Mn—N = 2,316(3) Å et Mn—OH_2 = 2,148(4) et 2,178(3) Å. $[Zn(\mu\text{-bpe})(bpe)_2(H_2O)_2](ClO_4)_2\cdot bpe\cdot H_2O$ (**2**) cristallise dans le système monoclinique $P2_1/c$, avec a = 14,609(4), b = 21,164(5), c = 16,482(5) Å, β = 114,69(2)° et R = 0,058. Pour $[Ni(\mu\text{-bpe})(bpe)_2(H_2O)_2](ClO_4)_2\cdot bpe\cdot H_2O$ (**3**), a = 14,511(6), b = 21,216(7), c = 16,467(7) Å, β = 114,76(3)° et R = 0,065. Les ligands aqua sont localisés en position *trans*. Les ligands pontants *bpe* forment une chaîne infinie avec les atomes métalliques. Deux autres ligands *bpe* terminaux situés en position *trans* sont coordinés au métal. Ces derniers sont liés par des ponts-hydrogène avec les ligands aqua d'autres chaînes, formant un réseau tri-dimensionnel. Les distances Zn—N varient de 2,151(3) à 2,185(4) Å, et les liens Ni—N sont entre 2,098(10) et 2,126(11) Å. Les liaisons Zn—OH_2 = 2,125(4), 2,161(4) Å et Ni—OH_2 = 2,077(11), 2,110(11) Å.

Introduction

In recent years, considerable progress has been achieved in the field of crystal engineering. Several remarkable compounds illustrating predictions of the crystal structures have recently been reported (1–5). However, the design of crystalline materials with specific functions and properties still remains a target difficult to attain. The well-planned design of

organic or inorganic crystals is possible only by understanding the interplay of the noncovalent interactions, as well as their role in the self-assembly process. At this stage, new examples of structurally characterized compounds are needed and the subsequent retrospective analysis of these will further inform researchers about the factors governing the interactions at the supramolecular level.

A key point in this field is the search for versatile building blocks, able to generate materials with extended structures. e*xo*-Bidentate ligands, such as pyrazine and 4,4′-bipyridine, are classical building blocks for the design of coordination compounds with extended structures. A 1:1 ligand-to-metal molar ratio usually leads to either linear or zigzag chains (6–9). In a few cases, interesting tetranuclear complexes forming molecular boxes have been synthesized from *cis*-dichloro complexes of Pd(II) or Pt(II) with 4,4′-bipyridine (10, 11). A change in the stoichiometry, namely, an increase in the ligand-to-metal molar ratio, led to the formation of elegant 2D and 3D solid-state architectures. Diamondlike or interpenetrating diamondlike networks (12–14), square grid sheets (15, 16) or interpenetrating square grid sheets (17), honeycomb (13) or fully interlocked honeycomb networks (13, 18), and 2D waferlike polymers (19) have been recently synthesized by the self assembly of different metal ions with pyrazine or 4,4′-bipyridine. Several novel supramolecular architectures have been reported using a rigid, rodlike building block, namely, *trans*-1,2-bis(4-pyridyl)ethylene (20), or a conformationally flexible bridging ligand such as *N*,*N*′-*p*-phenylene-dimethylene-bis(pyridine-4-one) (21, 22).

In addition to the clever choice of the building blocks, the synthetic strategies leading to one-, two-, or three-dimensional arrays are usually based on the ingenious use of directional hydrogen bonds, π–π stacking interactions, and metal coordination. These factors are very efficient organizing forces in the self-assembly process (23–29). The coordination algorithm of the metal atoms plays a crucial role in the type of long-range order that will be formed.

To test the ability of another 4-pyridyl-containing building block to generate extended structures, we have studied the reaction of some transition metal(II) compounds with the flexible, potentially bridging, ligand 1,2-bis(4-pyridyl)ethane (*bpe*). A few compounds with this ligand have been reported (30, 31). Because of the different conformations exhibited by this type of ligand, as well as its capability of forming hydrogen bonds, it was anticipated that the products would present interesting and outstanding structural features. We report in this paper the synthesis and characterization of some H-bonded supramolecular complexes of Mn(II), Zn(II), and Ni(II). The synthetic approach is based on a metal-to-ligand starting molar ratio of 1:4.

Experimental

The chemicals were purchased from Aldrich and were used as received. The IR spectra (KBr pellets) were measured on a Perkin–Elmer 783 spectrophotometer.

Synthesis

The three compounds were prepared following the same general procedure. An ethanolic solution (5 mL) containing 2 mmol of 1,2-bis(4-pyridyl)ethane (*bpe*) was added with stirring to an aqueous solution (15 mL) containing the manganese(II), zinc(II), or nickel(II) perchlorate (0.5 mmol). The slow evaporation of the resulting mixtures obtained from the reactions of the Mn(II) and Ni(II) compounds produced highly crystalline materials, while the Zn(II) compound precipitated immediately as a white microcrystalline powder. Single crystals of the Zn(II) product were obtained by recrystallization from a water–acetonitrile 1:2 mixture. ***Caution!*** No problems were encountered during the preparation of the perchlorate derivatives described above. However, suitable care and precautions must be taken when handling potentially explosive compounds.

[Mn(μ-*bpe*)$(H_2O)_4$]$(ClO_4)_2$·4(*bpe*)·2H_2O (**1**): Yield: 58%, white-yellowish crystals. IR data (cm^{-1}): 3600w, 3540w, 3040m, 2830m, 1610s, 1560m, 1505w, 1420m, 1220w, 1090vs, 1010m, 825m, 810m, 620m, 550m, 530w, 500w.

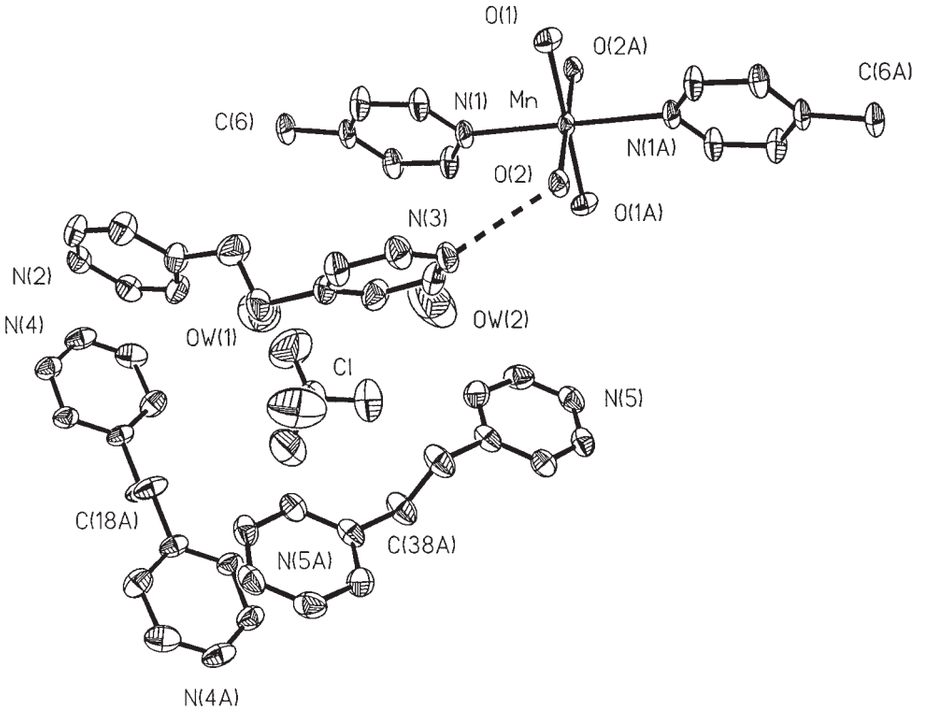
Fig. 1. Labelled diagram of $[Mn(\mu\text{-}bpe)(H_2O)_4](ClO_4)_2\cdot 4(bpe)\cdot 2H_2O$ (**1**).



$[Zn(\mu\text{-}bpe)(bpe)_2(H_2O)_2](ClO_4)_2\cdot bpe\cdot H_2O$ (**2**): Yield: 64%, white crystals. IR data (cm^{-1}): 3400m, 3040m, 2860m, 1640s, 1620s, 1600s, 1560m, 1500w, 1460w, 1430m, 1220w, 1100vs, 1020m, 980m, 830s, 810m, 625s, 550s.

$[Ni(\mu\text{-}bpe)(bpe)_2(H_2O)_2](ClO_4)_2\cdot bpe\cdot H_2O$ (**3**): Yield: 77%, light blue crystals. IR data (cm^{-1}): 3300m, 3060m, 2970m, 1640s, 1620s, 1560m, 1500w, 1430m, 1230w, 1100vs, 1020m, 1000m, 930w, 880w, 830s, 810m, 620s, 550s.

X-ray structure determination and refinement

The crystals were selected after examination for homogeneity under a polarizing microscope. The data collections were made at room temperature on a Siemens P4 diffractometer with graphite-monochromatized MoKα radiation (λ = 0.71073 Å). The XSCANS program was used for the data collection. The unit cell parameters were obtained by least-squares refinement of the angles 2θ (16°–30°), ω, and χ for about 30 well-centered reflections. The coordinates of the heavy atoms were determined from direct methods and the positions of all the other non-hydrogen atoms were found by the usual Fourier methods. The O atoms in the perchlorate ions in **1** were found to be disordered on three positions (occupation factors of component a: 0.54, b: 0.33, and c: 0.13). The refinement of the structures was done by full-matrix least-squares analysis. The H atoms, except those of the water molecules and a few methylene H atoms in *bpe*, which were located and refined, were fixed at their calculated positions (riding model). The H atoms on OW1 in crystal **1** could not be located. The calculations were done on a SHELXTL system.[2] The scattering factors and other pertinent crystallographic information were taken from the *International tables for X-ray crystallography* (32). The crystal data are summarized in Table 1. The experimental details of the crystallographic studies and the coordinates of the atoms are available as supplementary material.[3]

Results and discussion

The three coordination compounds, $[Mn(\mu\text{-}bpe)(H_2O)_4](ClO_4)_2\cdot 4(bpe)\cdot 2H_2O$(1), $[Zn(\mu\text{-}bpe)(bpe)_2(H_2O)_2]$ $(ClO_4)_2\cdot bpe\cdot H_2O$ (**2**), and $[Ni(\mu\text{-}bpe)(bpe)_2(H_2O)_2](ClO_4)_2\cdot bpe\cdot H_2O$ (**3**), were prepared by simply mixing an aqueous solution of the metal(II) perchlorate with an ethanolic solution of the *bpe* ligand in a metal(II):*bpe* molar ratio of 1:4. The starting molar ratio was recovered in crystals **2** and **3**, whereas in the case of manganese, the product that crystallized had a molar ratio of 1:5. The supramolecular order on the nanometer scale in the crystalline state of these compounds is created by the interplay of metal coordination, hydrogen bonding, and π–π interactions as described below.

The first compounds that we prepared and characterized were the manganese(II) (**1**) and the zinc(II) (**2**) derivatives.

The two compounds have different stoichiometries, although the starting metal:ligand molar ratio was the same, 1:4. In both compounds the metal ions exhibit pseudo-octahedral geometries and only one *bpe* molecule acts as a genuine bridging ligand, forming infinite linear chains. The very different and unpredictible packing patterns for crystals **1** and **2** prompted us to pursue the investigation. Since the geometry around the metals in the two compounds is essentially octahedral and since both compounds have been obtained under the same conditions, the following question was raised: which structure will select, under the same conditions, another metal ion with a marked preference for octahedral stereochemistry, for instance, nickel(II)? Consequently, we have studied a similar reaction with nickel perchlorate and characterized its product (**3**). The crystallographic results have shown that **3** is isomorphous with the zinc derivative (**2**).

The structural investigation of [Mn(μ-*bpe*)(H_2O)$_4$] (ClO_4)$_2$ ·4(*bpe*)·2H_2O (**1**) has shown that the manganese atoms are bridged by one *bpe* molecule, resulting in infinite chains parallel to the *b* axis. The manganese atom is located on an inversion center and is hexacoordinated by two nitrogen atoms arising from two bridging *bpe* molecules, disposed *trans* to each other, and by four aqua ligands. The local symmetry of the manganese(II) atoms is therefore approximately D_{4h}. The labelling scheme is shown in Fig. 1. Selected bond distances and angles are collected in Table 2. The Mn—N distances (2.316(3) Å) are slightly longer than those found in polymeric Mn(II)-4,4′-bipyridine systems (e.g., 2.265 Å (7), 2.278 Å (8)). The metal–aqua bonds Mn—O(1) and Mn—O(2) are 2.148(4) and 2.178(3) Å, respectively. The distance between the manganese atoms within the chain corresponds to the *b* axis, 13.993(4) Å.

The other four *bpe* molecules are not coordinated to the metal atoms, but they are involved in an interesting extensive hydrogen-bonding system. Each aqua ligand is hydrogen-bonded to two nitrogen atoms arising from the organic molecules. There are intra- and inter-chain hydrogen bonds, which present the most intriguing feature of the crystal structure of this compound. Two *trans* aqua ligands (O(2)) from one manganese atom are "bridged" through intra-chain

Fig. 2. Infinite triple chain parallel to the *b* axis in crystal **1**.

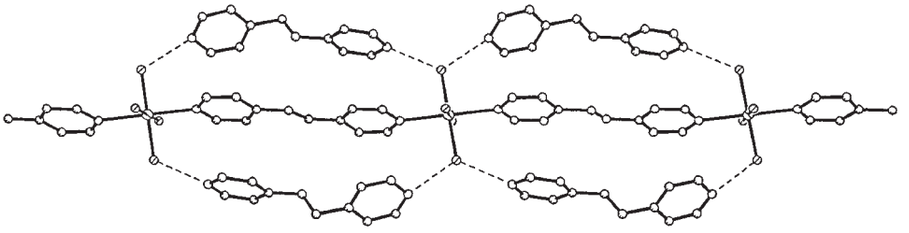

Fig. 3. Diagram of the packing in crystal **1** (*b* axis horizontal, *a* axis vertical). The ClO_4^- ions and the free H_2O molecules have been omitted. The *bpe* molecules and ligands are shown as straight lines between the two N atoms.

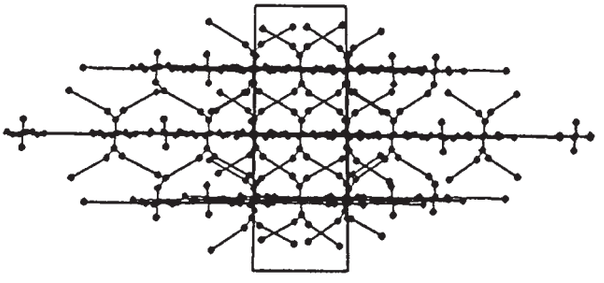

hydrogen bonds, by two *bpe* molecules, to the equivalent aqua ligands on the next manganese atom along the chain. The O(2)···N(2) and O(2)···N(3) distances are 2.828 and 2.811 Å, respectively. The angles are Mn—O(2)···N(2) = 123.2° and Mn—O(2)···N(3) = 116.2°. These two *bpe* molecules together with the main *bpe*-bridged manganese(II) chain form infinite triple chains running along the crystallographic *b* axis (Fig. 2). The angle around the H-bonded aqua ligand N(2)···O(2)···N(3) is 118.1°.

The other two aqua ligands (O(1)) are then inter-chain hydrogen-bonded, via the fourth and fifth *bpe* molecules (containing N(4) and N(5), respectively), resulting in two equivalent interpenetrating infinite 2D chicken-wire sheets (Fig. 3). The O(1)···N(4) and O(1)···N(5) distances are 2.771 and 2.737 Å, respectively. The angles are Mn—O(1)···N(4) = 119.8° and Mn— O(1)···N(5) = 118.2°, while the angle around the H-bonded aqua ligand N(4)···O(1)···N(5) is 121.8°. According to the classification of such networks (33), compound **1** belongs approximately to class II-*h*, where the interpenetration of 2D infinite nets of hexagonal (*h*) meshes occurs in (approximately) mutually perpendicular directions, forming a 3D network. The hexagonal meshes have two short and four long edges: the short ones (4.297 Å) represent the O(1)—Mn—O(1′) distance, while each of the four long edges (14.650 and 14.755 Å) is formed by one *bpe* molecule that is hydrogen-bonded to two aqua ligands (O(1) belonging to two different Mn—μ-*bpe*–Mn—μ-*bpe* chains. A layer is made up of edge-sharing hexagons, with O(1) at each corner, and a manganese(II) atom in the centre of the short edges. The separation between the parallel layers is about 12.6 Å. The stacking of these layers generates large hexagonal channels perpendicular to the *b* axis. The center of each channel is occupied by a Mn—μ-*bpe*–Mn—μ-*bpe* chain belonging to the other equivalent 2D chicken-wire sheet. The dihedral angle between the two interlocking sheets was calculated approximately as 52°. Another example of meshed honeycomb hydrogen-bonded 2D networks is the solid-state structure of 1,3,5-benzenetricarboxylic acid (34).

The bond distances and angles in the bonded and nonbonded *bpe* ligands are identical as shown in Table 2. It is interesting to note that the angles in the pyridine rings are not all identical. The C-N-C angles are significantly smaller (avg. 116.2(4)°) than the *ortho* N-C-C angles (avg. 123.9(6)°). The average *meta* C-C-C angle is 119.7(7)°, while the average *para* angle is smaller, 116.9(5)°.

The O atoms of the perchlorate ions are disordered on three positions. The compound crystallized with two molecules of water located in the lattice on twofold axes. These molecules are extensively hydrogen-bonded to the perchlorate ions. The Ow···O (perchlorate) distances vary between 2.706 and 2.925 Å.

The main differences between compounds **1** and $[Zn(\mu\text{-}bpe)(bpe)_2(H_2O)_2](ClO_4)_2\cdot bpe\cdot H_2O$ (**2**) arise from their stoichiometry and from the coordination spheres of Mn(II) (MnN_2O_4) and Zn(II) (ZnN_4O_2). As already mentioned, the nickel derivative, **3**, is isomorphous with compound **2**. Three *bpe* molecules are directly coordinated to the Zn(II) or the Ni(II) atoms. Again, only one *bpe* ligand is bridged between the metallic centres forming a chain parallel to the *a* direction. The distance between the metal atoms in the chain is 13.494 Å for **2** and 13.406 Å for **3**. The other two *bpe* ligands act as terminal ligands and are located in *trans* positions to each other. The metal centres exhibit a pseudo-octahedral geometry (Fig. 4). Selected bond distances and angles are collected in Table 2. As expected, the Zn—N distances (avg. 2.167(4) Å) are shorter than those found in compound **1**, and slightly longer than the ones reported for Zn(II)-4,4′-bipy complexes (15, 17). The Ni—N bonds are even shorter and vary between 2.098(10) and 2.127(11) Å. The bond distances M—N(1) and M—N(2) (avg. 2.154(3) Å for Zn and 2.105(10) Å for Ni) located in the M—μ-*bpe*—Mn chain seem slightly shorter (≈0.025 Å) than the M— N(3) and M—N(4) bonds (avg. 2.180(4) Å for Zn and 2.127(11) Å for Ni) of the terminal ligands. The difference is significant for the Zn complex, but not for the Ni compound because of the high esd's obtained for crystal **3**. The Zn—O bond distances are 2.125(4) and 2.161(4) Å, while the Ni —O bonds are also shorter, 2.077(11) and 2.110(11) Å.

The bridged (N(1)——N(2)) and one terminal *bpe* (N(3)——N(5)) ligands in crystals **2** and **3** exhibit, as in compound **1**, the more stable *antiperiplanar* conformation. Interestingly, the second terminal *bpe* ligand (N(4)——N(6)) is frozen into the *gauche* conformation. The latter conforma-

Fig. 4. Diagram of $[Zn(\mu\text{-}bpe)(bpe)_2(H_2O)_2](ClO_4)_2 \cdot bpe \cdot H_2O$ (**2**) The ClO_4^- ions and the molecule of H_2O are not shown for clarity. (The same diagram can be applied for **3**).

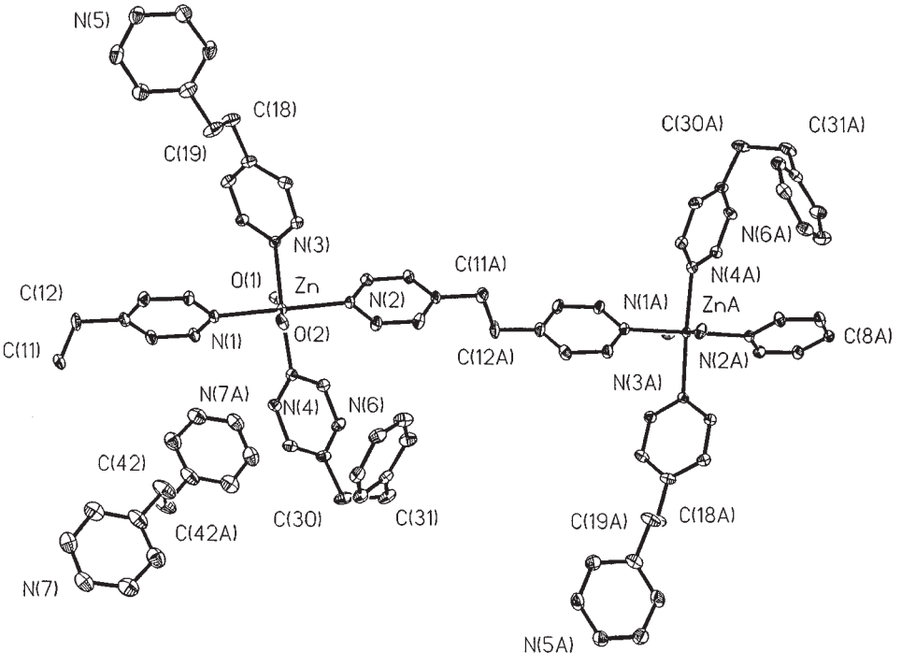

Fig. 5. Packing in $[Zn(\mu\text{-}bpe)(bpe)_2(H_2O)_2](ClO_4)_2 \cdot bpe \cdot H_2O$ (**2**) (*b* axis horizontal, *a* axis vertical). The *bpe* ligands are shown as straight lines between the two N atoms. The perchlorate ions and the unbonded *bpe* and H_2O molecules are not shown.

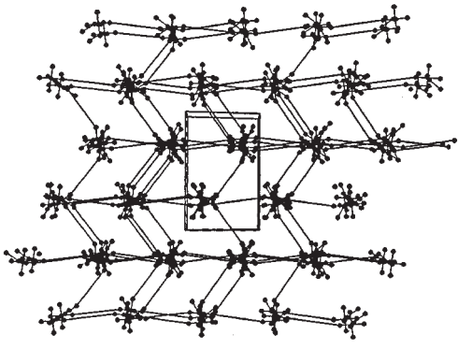

tion is chiral and seems to influence very strongly the directional properties of the inter-chain hydrogen-bonding system. The different stoichiometry, the presence of two terminal *bpe* molecules, and the *gauche* conformation of one of them generate a hydrogen-bonding network pattern, which is very different from the one observed in crystal **1**. In compounds **2** and **3**, the centre of the bridging *bpe* ligand is located on an inversion center. Consequently, the *gauche pbe* ligands have alternate chiralities along the infinite chain. Each *gauche bpe* molecule of one chain is hydrogen-bonded (through N(6)) to the aqua ligand (O(1)) from the metal atoms of a second chain located at a distance of $c/2$ Å. The distances are O(1)···N(6) = 2.757 Å and 2.772 Å and the angles M—O(1)···N(6) = 125.5° and 126.1° for Zn and Ni, respectively. The second chain is further connected in the same way to a third chain in the *c* direction, and so on, resulting in infinite layers parallel to the *ac* plane. Due to this particular conformation of the terminal *bpe* ligand, the distance between the metal atoms of two different chains, H-bonded through the *gauche bpe* molecules, is much shorter (8.321 Å for **2** and 8.320 Å for **3**) than the distance between the metal atoms within a chain. *Gauche bpe* molecules have also been observed in a few Co(II) (31) and Cd(II) (30) compounds.

Each layer is then connected on both sides to the adjacent layers in the *b* direction, through hydrogen bonds established between the *antiperiplanar bpe* terminal ligand from one layer and one aqua ligand from another layer and vice versa with distances O(2)···N(5) = 2.776 and 2.778 Å and with angles M—O(2)···N(5) = 126.8° and 127.5° for Zn and Ni, respectively. The H-bonded sheets that are parallel to the *ac* plane can be observed in Fig. 5. The metal–metal distance M—N(3)——N(5)···H_2O(2)—M is the largest, 14.991 and 14.921 Å for **2** and **3**, respectively. An H-bonded three-dimensional network results, with large channels occupied by the water molecules, the perchlorate anions, as well as by the fourth nonbonded *bpe* molecule. The latter is hydrogen-bonded to the water molecule with N(7)···Ow = 2.747 Å for **2** and 2.703 Å for **3**. The water molecule is further hydrogen-bonded to the perchlorate ions with Ow···O(7) = 2.884 Å for **2** and 2.968 Å for **3**. The aqua ligands are also hydrogen-bonded to the water molecule with O(1)···Ow = 2.813 and 2.807 Å and angles M—O(1)···Ow = 126.0° and 128.1° for **2** and **3**, respectively. The second aqua ligand is also hydrogen-bonded to the water molecule with O(2)···Ow distances = 2.733 and 2.734 Å and angles M—O(2)···Ow = 129.8° and 131.0° for **2** and **3,** respectively. This water molecule acts as a hydrogen-bond donor to the free *bpe* molecule (N(7)) and the perchlorate ions with an angle O(7)···Ow···N(7) = 120.4° and 119.6° for**2** and **3**, respec-

© 1998 NRC Canada

tively, and as a hydrogen-bond acceptor towards the two aqua ligands.

Interestingly, the M—O(1) bond distances, where the aqua ligand is H-bonded to the *gauche bpe* ligand seems slightly shorter (by ≈0.035 Å) than the M—O(2) bonds. The latter aqua ligand is H-bonded to the *antiperiplanar bpe* terminal ligand.

The minor differences between compounds **2** and **3** arise from the slightly smaller ionic radius of nickel(II) (d^8 configuration with the paired electrons in the low energy t_{2g} orbitals) in comparison with zinc(II) (d^{10}) (Table 2). The crystallographic results are much better for the Zn compound. The standard deviations obtained on the Ni compound are quite high, since all the crystals were small. Therefore, the number of observed reflections (1988) was rather low for the number of parameters varied (600).

Stacking of the aromatic rings seems also to play a stabilizing role in the crystal packing, especially between the chains, which are H-bonded by the *gauche bpe* ligands. This type of π–π interaction seems quite general in this type of crystals and is an important factor in the synthetic strategies leading to the synthesis of specifically designed supramolecular materials.

Magnetic measurements of compound **3** were made, but the results were not reproducible. This was attributed to anisotropy. The sample is a light fluffy powder and was probably moving as the measurements were being taken. Compacting the powder would stop the realignment but usually a preferred orientation is obtained. Therefore, the magnetic measurements of an anisotropic compound are difficult to interpret, since it is not possible to know what is really being measured.

The structures reported in this paper illustrate the ability of a flexible ligand such as 1,2-bis(4-pyridyl)ethane to generate novel supramolecular complexes through simultaneous metal coordination, hydrogen-bond interactions, and π–π stacking. It is difficult, at this stage, to rationalize our results to other species. However, the three examples described here, as well as the isomorphism of compounds **2** and **3,** have shown that this class of materials could be extended with other new metal compounds. Further work in this area is in progress.

Optical and electrical properties of fluorene-based π-conjugated polymers

Maxime Ranger and Mario Leclerc

Abstract: Electroactive and photoactive copolymers derived from fluorenes have been prepared from palladium-catalyzed Suzuki couplings. For instance, poly((4,4′-biphenylene)-2,7-(9,9-dioctylfluorene)) and poly((2,5-thienylene)-2,7-(9,9-dioctylfluorene)) exhibit strong emission in the blue region (406 nm, ϕ_{fl} = 0.72) and in the green region (496 nm, ϕ_{fl} = 0.49), respectively. These fluorene-based π-conjugated polymers also show reversible electroactivity upon reduction and oxidation. The good electrical transport of both *p*-type and *n*-type charge carriers combined with excellent luminescent properties should lead to the development of efficient light-emitting devices.

Key words: polyfluorenes, Suzuki couplings, luminescence, electrochromism, *n* and *p* doping.

Résumé : Une série de copolymères électroactifs et photoactifs possèdant des unités fluorène a été préparée par couplages de type Suzuki (catalyse au palladium). Parmi ces polymères, le poly((4,4′-biphenylene)-2,7-(9,9-dioctylfluorene)) et le poly((2,5-thienylene)-2,7-(9,9-dioctylfluorene)) montrent, par exemple, des propriétés intéressantes de fluorescence dans la région du bleu (406 nm, ϕ_{fl} = 0.72) et dans la région du vert (496 nm, ϕ_{fl} = 0.49), respectivement. Ces polymères π-conjugués dérivés du fluorène montrent également une électroactivité réversible en réduction et en oxydation. Ce bon transport de porteurs de charge de types *p* et *n* combiné aux excellentes propriétés de luminescence devrait permettre le développement de diodes électroluminescentes efficaces.

Mots clés : polyfluorenes, couplages de type Suzuki, luminescence, électrochromisme, dopage *n* et *p*.

Introduction

Conjugated polymers (poly(phenylene vinylene)s, polythiophenes, polyphenylenes, polyfluorenes, etc.) show unusual and interesting properties for the development of different electrical and (or) optical devices such as lightweight batteries, electrochromic display devices, light- emitting diodes, optical switches, etc. (1–19). Among these properties, electroluminescent polymers have recently attracted great attention due to their possible utilization in flat display devices (1–6). In particular, there is presently great interest in developing efficient and stable blue-light- emitting materials to get access to the three primary colors. Along these lines, several authors, such as Pei and Yang (14) and Yoshino and co-workers (15, 16), have reported blue- light-emitting diodes using polyfluorene derivatives. Moreover, Reynolds and co-workers (17) recently reported the utilization of polyfluorene derivatives in electrochromic display devices while some polyfluorene derivatives have also shown interesting liquid crystalline (18) and lasing properties (19). From all these results, it is then clear that polyfluorenes are particularly promising for various optical applications.

On the other hand, light-emitting diodes need also a good and balanced transport of both injected electrons and holes to permit an efficient recombination of these electrical charges in the luminescent chromophores (1–6, 14–16). In this regard, it has been shown that copolymers containing alternating donor and acceptor (push–pull structure) π-conjugated units exhibit reduced band gaps and, by this fact, allow both n-*type* (reduced) and p-*type* (oxidized) electrical transport (20). Therefore, on the basis of these recent results, the development of well-defined alternating copolymers derived from fluorenes should lead to tunable electrochromic, electrochemical, and photophysical properties and should combine, in principle, in one material the required optical and electrical properties for the development of efficient light-emitting diodes. For all these reasons, we report here the preparation, from Suzuki couplings (11, 21–24), of alternating conjugated copolymers, namely, poly((1,4-phenylene)-2,7-(9, 9-dioctylfluorene)) (**PPF**),poly((4,4′-biphenylene)-2,7-(9,9-dioctylfluorene)) (**PBPF**), poly-((2,5-thienylene)-2,7-(9,9-dioctylfluorene)) (**PTF**), and poly((2,2′-bithienylene)-2,7-(9,9-dioctylfluorene)) (**PBTF**) (see Chart 1). Their electrical, electrochemical, and optical properties have been characterized and show promising features for various electrooptical applications.

Experimental part

Material

Fluorene, 2,5-dibromothiophene, 1,4-dibromobenzene, 2,2′-bithiophene, and 4,4′-dibromo-1,1′-biphenyl were obtained from the Aldrich Co. Tetrakis(triphenylphosphine)-palla-

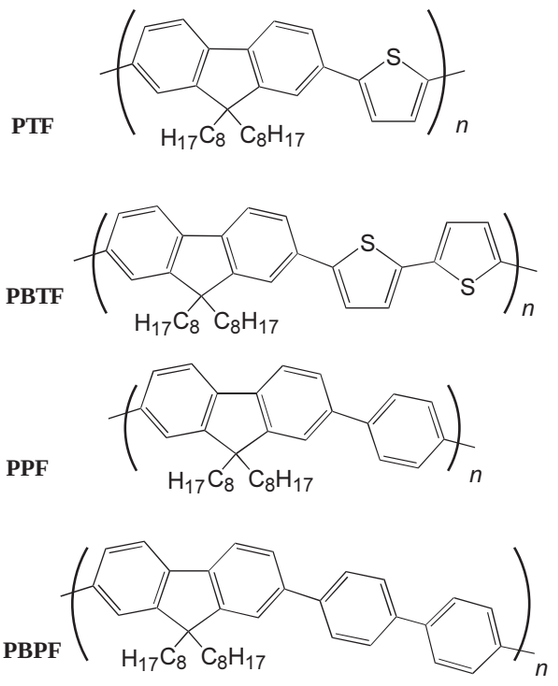
Chart 1.



dium(0) was synthesized following a procedure reported in the literature (25). Acetonitrile (Aldrich) was dried on CaH_2 under inert atmosphere (Ar) during 24 h. Tetraethylammonium tetrafluoroborate ($TEABF_4$, Aldrich) was recrystallized in a 60/40 mixture of methanol/water and dried at 100°C under reduced pressure (1 Torr (= 133.3 Pa)).

Instrumentation

^1H and ^{13}C NMR spectra were recorded on a Bruker AMX300 or AMX400 apparatus in deuterated chloroform solutions at 298 K. Number-average (M_n) and weight-average (M_w) molecular weights were determined by size exclusion chromatography (SEC) with an HPLC Waters 510 pump using a Waters 410 differential refractometer. The calibration was made with a series of monodispersed polystyrene standards in THF (HPLC grade, Aldrich) at 308 K.

Fluorescence measurements were carried out with a Spex Fluorolog 1681 spectrometer. For fluorescence analysis in solution, the polymer concentration was about 10^{-6} M (on the basis of one repeat unit), giving absorbances always less than 0.06 to avoid any inner filter effect. The quantum yields of fluorescence were determined in argon-saturated solutions at 298 K in chloroform against 9,10-diphenylanthracene (Aldrich) in cyclohexane (ϕ_F = 0.90) (26) or 3″,4‴-didecyl-2,2′;5′,2″;5″,2‴;5‴,2⁗;5⁗,2⁗′-sexithiophene in $CHCl_3$ (ϕ_F = 0.24) (27), as standards. For fluorescence analysis in the solid state, the polymer was applied on a quartz plate and was disposed at 45° of the incident beam. All corrected fluorescence excitation spectra were found to be equivalent to their respective absorption spectra. UV–visible absorption spectra were recorded on a Hewlett–Packard diode-array spectrophotometer (model 8452A).

All electrochemical analyses were done with a Solartron and an EG&G Princeton Applied Research model 273 potentiostat/galvanostat. Electrochemical experiments were carried out in 1 M $TEABF_4$ – acetonitrile solution, under inert and anhydrous atmosphere. The working electrode was a platinum disc with a diameter of 0.8 cm and platinum sheet (1.4 cm^2) was used as counter electrode. The reference electrode was Ag/AgNO3 0.0998 M in acetonitrile (0.287 V vs. SCE). The deposition of polymers on the electrode was done by the evaporation of a dilute chloroform solution.

In situ electrical conductivities were obtained with a platinum two-band microelectrode (a separation of 60 mm between the bands) according to a procedure described elsewhere (28). Determination of the electrical conductivity was carried out by the two-probe technique with this two-band microelectrode. Spectroelectrochemical analyses were carried out with an indium tin oxide (ITO) coated glass electrode as working electrode, platinum counter electrode (sheet) and a silver wire as quasi-reference electrode in 0.1 M $TEABF_4$ – MeCN (0.30 V vs. Ag/Ag^+).

Synthesis

*9,9-Dioctylfluorene (**1**) (ref. 29)*

To a solution of 16.96 g (102.2 mmol) of fluorene (Aldrich) in THF (210 mL) at –78°C was added, dropwise, 85.84 mL (214.6 mmol) of *n*-butyllithium (2.5 M in hexane, Aldrich). The mixture was stirred at –78°C for 45 min and 45.40 g (235.06 mmol) of octyl bromide (Aldrich) in THF (40 mL) was added dropwise to the mixture. The solution was allowed to warm to room temperature and was stirred for 3 h. The mixture was poured into water and extracted with ether. The organic extracts were washed with brine and dried over magnesium sulfate. The solvent was removed under reduced pressure. Excess of octyl bromide was removed by distillation (44°C/0.3 Torr) to give 39.50 g of 9,9-dioctylfluorene (99%). (R_f: 0.87, silica TLC in hexane). Pale-brown powder; mp 34–37°C. ^1H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.82 (dd, 2H, *J* = 4.3 Hz), 7.42 (m, 6H), 2.12 (m, 4H, *J* = 3.8 Hz), 1.35–1.24 (m, 20H), 0.96 (t, 6H, *J* = 7.1 Hz), 0.79 (m, 4H, *J* = 3.8 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 150.63, 141.15, 126.98, 126.70, 122.78, 119.64, 55.01, 40.46, 31.84, 30.11, 29.26, 29.05, 23.77, 22.64, 14.09. HRMS calcd. for $C_{29}H_{42:}$ 390.651; found: 390.598.

*2,7-Dibromo-9,9-dioctylfluorene (**2**) (ref. 30)*

To a solution of 9,9-dioctylfluorene (**1**) (18.01 g, 46.10 mmol) in $CHCl_3$ (70 mL) at 0°C were added 115.2 mg (0.706 mmol) of ferric chloride and 4.97 mL (96.62 mmol) of bromine. It is important that the reaction proceeds in the dark to avoid any bromination of the aliphatic part of the molecule. The solution was warmed to room temperature and was stirred for 3 h. The resulting slurry was poured into water and washed with sodium thiosulfate until the red color disappeared. The aqueous layer was extracted with $CHCl_3$ (×2), and the combined organic layers were dried over magnesium sulfate to afford 25.28 g (99%) of the title product as a pale-brown solid. (R_f: 0.85, silica TLC in hexane); mp 44–47°C. ^1H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.53 (d, 2H, *J* = 7.7 Hz), 7.46 (d, 2H, *J* = 1.8 Hz), 7.44 (d, 2H, *J* = 1.1 Hz), 1.91 (m, 4H, *J* = 3.7 Hz), 1.26–1.05 (m, 20H), 0.83 (t, 6H, *J* = 3.6 Hz), 0.58 (m, 4H, *J* = 3.5 Hz). ^{13}C NMR

(75 MHz, $CDCl_3$) δ (ppm): 152.44, 138.94, 130.04, 126.07, 121.38, 120.96, 55.56, 40.02, 31.63, 29.78, 29.04, 29.01, 23.51, 22.47, 13.94. HRMS calcd. for $C_{29}H_{40}{}^{79}Br_2$: 546.150; found: 546.149.

2,7-Dibromofluorene ***(3)*** *(ref. 30)*

Same procedure as for 2,7-dibromo-9,9-dioctylfluorene (**2**). Yield 97%. Recrystallization was made from a THF–ethanol mixture to yield pale-yellow crystals; mp 159–161°C (lit. (22) mp 160–161°C). ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.67 (2H, d, *J* = 1 Hz), 7.61 (2H, d, *J* = 8 Hz), 7.51 (2H, dd, *J* = 8 Hz), 3.87 (2H, s). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 144.65, 139.55, 130.01, 128.16, 121.04, 120.82, 36.43. HRMS calcd. for $C_{13}H_8{}^{79}Br_2$: 321.898; found: 321.899.

2,7-Bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene ***(4)*** *(refs. 29, 31)*

To a solution of 2,7-dibromo-9,9-dioctylfluorene (**2**, 5.00 g, 9.1 mmol) in THF (70 mL) at –78°C was added, by syringe, 7.64 mL (19.11 mmol) of *n*-butyllithium (2.5 M in hexanes, Aldrich). The mixture was stirred at –78°C, warmed to 0°C for 15 min, and cooled again at –78°C for 15 min. 2-Isopropoxy-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (4.00 g, 21.5 mmol, Aldrich) was added rapidly to the solution, warmed to room temperature, and stirred for 24 h. The mixture was poured into water and extracted with ether. The organic extracts were washed with brine and dried over magnesium sulfate. The solvent was removed by rotary evaporation, and the residue was purified by column chromatography (silica gel, 7% ethyl acetate in hexane, R_f: 0.20) to provide 3.80 g (65%) of the title product as a pale-yellow solid. ^{1}H NMR (300 MHz, $CDCl_3$) δ (ppm): 7.84 (d, 2H, *J* = 7.6 Hz), 7.78 (s, 2H), 7.75 (d, 2H, *J* = 7.6 Hz), 2.03 (m, 4H, *J* = 3.4 Hz), 1.43 (s, 24H), 1.26–1.04 (m, 20H), 0.83 (t, 6H, *J* = 6.6 Hz), 0.58 (m, 4H). ^{13}C NMR (75 MHz, $CDCl_3$) δ (ppm): 150.31, 143.78, 133.54, 128.77, 119.23, 83.54, 55.03, 39.36, 31.65, 29.79, 29.05, 29.00, 24.80, 23.44, 22.45, 13.94. HRMS calcd. for $C_{41}H_{64}O_4{}^{11}B_2$: 642.499; found: 642.497.

2,2′-Dibromo-5,5′-bithiophene ***(5)***

Synthesized by the method reported in literature (32, 33).

Polymerization

Carefully purified dibromo derivatives (1.00 equiv.), 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)-9,9-dioctylfluorene (1.00 equiv.), and $(PPh_3)_4Pd(0)$ (0.5–1.5 mol%) were dissolved in a mixture of THF ([monomer] = 0.4 M) and aqueous 2 M K_2CO_3 (1:1.5 THF). The solution was first put under argon atmosphere and was refluxed with vigorous stirring for 48 h. The whole mixture was then poured into methanol (150 mL). The precipitated material was recovered by filtration with a Büchner funnel and washed with a dilute HCl solution. The solid material was washed for 24 h in a Soxhlet apparatus using acetone to remove oligomers and catalyst residues. The resulting polymers were soluble in THF and $CHCl_3$. Yields ~86–95%.

Results and discussion

Synthesis and characterization of polymers

As illustrated in Scheme 1, palladium-catalyzed Suzuki couplings have allowed the easy preparation of well-defined alternating conjugated polyfluorene derivatives. The utilization of 2,7-bis(4,4,5,5-tetramethyl-1,3,2-dioxaboron-2-yl)-9 ,9-dioctylfluorene simplified the purification of this monomeric precursor combined with a protective effect (1,1,2,2-tetramethylethylene glycol) of the boronic acid moieties. During the polymerization, the presence of such protective groups as ethylene glycol did not affect the yield of the couplings (34), because a hydroxylation deprotection reaction is also

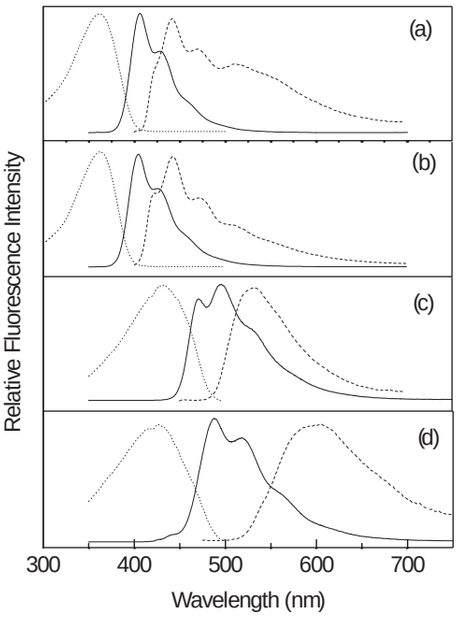
taking place during the polymerization process. Tetrahydrofuran (THF) was used to increase the solubility of the growing polymeric chains. Indeed, **PPF** has a higher molecular weight (M_n: 12000) when prepared in a polymerization mixture of THF–water than our first attempt (M_n: 4600) performed in a toluene–water mixture (22). All polymers are completely soluble in $CHCl_3$ and THF. Most polymers exhibit a relatively high molecular weight with a polydispersity index (M_w/M_n) around 2 (Table 1). These polydispersity indexes are consistent with a polycondensation reaction.

UV–visible and fluorescence measurements

In all cases, excitation spectra were found to be similar to the corresponding absorption spectra. Moreover, the absorption spectra for solutions and cast films were almost identical, indicating little structural rearrangement in the condensed phase (19). These optical properties of the fluorene-based π-conjugated polymers are presented in Table 2. By incorporating thiophene units in the polymer, the backbone conformation should be more planar since the energy barrier for the *thienyl–phenyl* rotation is lower than for the *phenyl–phenyl* rotation (35, 36). This can partially explain the fact that the absorption maxima of **PPF** and **PBPF** are blue-shifted by about 65 nm compared to **PBTF** and **PTF**. Furthermore, all these copolymers are strongly luminescent in chloroform solution. Not surprisingly, **PTF** and **PBTF** show lower quantum yield of fluorescence than **PPF** and **PBPF**, the sulfur atom being well known to quench the excited state by the heavy-atom effect. All Stokes shifts are lower than 2800 cm^{-1} (in solution), which can be related to the rigidity of the fluorene moiety that contributes to a fast emission with very similar molecular geometries in both the ground and the excited states. In the solid state, the emission maxima of **PPF** and **PBPF** are red-shifted by about 40 nm compared to those obtained in solution (Figs. 1*a* and 1*b*). These results could be explained by a more delocalized excited state in the condensed phase while **PPF** even shows an additional emission maximum around 510 nm possibly associated with the formation of an excimer (14, 19, 37, 38). The emission in solution and in the solid state of **PPF** and **PBPF** shows a vibronic structure associated with coupling of a C=C vibration mode (around 1500–1600 cm^{-1}).

Fig. 1. Fluorescence spectra (—-) in the solid state, excitation spectra (·····), and fluorescence spectra (——) in chloroform solution for (*a*) **PPF**; (*b*) **PBPF**; (*c*) **PTF**; (*d*) **PBTF**.



The emission spectra of **PTF** and **PBTF** exhibit a similar vibronic structure in solution. However, in contrast to **PPF**, **PBPF**, and **PTF** (Figs. 1*a*–1*c*), the emission spectrum of **PBTF** in the solid state is remarkably different from that observed in solution (Fig. 1*d*). From these preliminary results, it is supposed that an excimer is also formed in **PBTF** in the solid state but it is clear that further measurements will be necessary to get a clear understanding of the photophysical processes involved in these polymeric materials. Nevertheless, it is already evident that it is possible to modulate the maximum emission wavelength by incorporating different aromatic units in a fluorene-based conjugated polymer while keeping relatively high fluorescence quantum yields.

Electrochemical measurements

As shown in Figs. 2 and 3 (and summarized in Table 3), all copolymers also exhibit some electroactivity upon reduction and oxidation. This is not the case for most homopolymers derived from fluorenes or thiophenes. By alternating thiophene (or phenylene) and fluorene moieties, the reduction potential of the resulting copolymers appears around –2.7 V vs. Ag/Ag^+. It is now well established that the alternation of aromatic units with different electronic properties (push–pull structure) leads to conjugated polymers with lower band gaps and accessible *p*- and *n*-doping reactions (20, 39). Although all cyclic voltammograms seem to indicate a low reversibility of the redox processes, most of the electrochemical charges are slowly recovered in the backward processes (see Table 3), indicating some kinetic

problems in ejecting the counterions inserted during the oxidation or reduction of these copolymers. It is also worth noting that the oxidation potential decreases with the presence of thiophene or bithiophene units (compared to phenyl or biphenyl moieties) in the copolymers, whereas the reduction potential remains almost constant for these four different copolymers. These latter results could indicate that the energy of the LUMO level is almost the same in all these copolymers and would be mainly driven by the nature of the fluorene units. In contrast, the energy of the HOMO level would be more sensitive to the presence of thiophene units.

Interestingly, in situ conductivity measurements have revealed similar electrical conductivities for both reduced and oxidized forms (Fig. 4). The thickness of the films cast onto the microelectrode was difficult to measure with great precision but electrical conductivities up to 10^{-4} S cm^{-1} have been calculated for these polymers in the doped state. These values are in agreement with previous results reported for polyfluorene derivatives (17). The relatively low conductivity levels of these conjugated polymers could be related to important interchain distances caused by the presence of two alkyl side chains (neccessary to keep the solubility of the co-

polymers) onto the fluorene unit (40). Higher electrical conductivities are expected with the incorporation of a double bond at the 9-position bearing two flexible alkyl chains; such new monomers are being currently developed in our laboratory. Nevertheless, the present combination of luminescence properties with a good and comparable electrical transport for both positive and negative charge carriers should be particularly useful for the development of efficient light-emitting diodes (41).

Spectroelectrochemical measurements

These polymers not only possess interesting fluorescence and electrochemical properties but also show reversible electrochromism upon reduction and oxidation. By synthesizing a series of copolymers as presented in this paper, it is possible to modulate the absorption maximum from 364 to 660 nm in the solid state. For instance, upon oxidation, **PTF** exhibits a new absorption band around 660 nm while the intensity of the 438 nm band (related to the neutral form) decreases (Fig 5). This new absorption band is related to the formation of positive charge carriers, probably dications (bipolarons) in the present case. **PTF** absorbs in practically the same region in its reduced form (formation of dianions). In Fig. 6, the oxidation of **PPF** shows the appearance of a band at 530 nm and the beginning of another band in the near-infrared (NIR) range. In Fig. 7, the absorption maximum of the reduced form of **PBPF** shifts to 485 nm and a

new band appears at the beginning of NIR range. **PBTF** shows similar electrochromic properties, which are consistent with those previously reported by Reynolds and co-workers (17) for oxidized **PBTF**. However, in our study, a vibronic structure is presumably associated with a well-defined structure. **PBTF** synthetized by electrochemical polymerization (17) could have some defects causing by irregular couplings.

Conclusions

The incorporation of alternating thiophene or phenyl moieties in fluorene-based π-conjugated polymers has permitted the preparation of processable, tunable, electroactive, and photoactive materials. **PPF** and **PBPF** exhibit emissive properties in the blue area, an important feature for the development of full-color flat display devices. With an electrical conductivity around 10^{-4} S cm^{-1}, the combination of a good electrical transport for both *n*- and *p*-type charge carriers and a high fluorescence quantum yield for these copolymers may lead to the development of well-defined and efficient light-emitting devices, electrochromic display devices, and electrochemical cells. All these electrooptical devices should be fabricated and tested in the near future.

A simple method for the generation of negative pressure in liquids

William D. Machin

Abstract: A new technique for the generation of negative pressure in liquids is described, based on the pressure difference that exists across a curved liquid–vapour interface. Menisci in pores having very small radii may induce large negative pressures, or tensions, within the liquid phase. The magnitude of this tension is readily controlled through the pressure of the external vapour phase. Liquid butane when contained in hollow capsules, or Bertholet tubes, with walls formed from Vycor porous glass (pore radius ca. 5 nm) has developed negative pressures as large as –4 MPa for brief periods and lesser tensions for much longer times. This tension approaches the theoretical limit (ca. –6 MPa) calculated from the Laplace equation. Maximum possible tensions based on the theory of homogenous nucleation and on spinodal decomposition are much larger and, in principle, may be reached by reducing the pore size. Our unsuccessful attempts to do so are described.

Key words: Bertholet tube, liquid, negative pressure, nucleation.

Résumé : On décrit une nouvelle technique permettant de générer une pression négative dans des liquides; elle est basée sur la différence de pression qui existe à travers une interface liquide–vapeur courbe. Les ménisques des pores possédant de très faibles rayons peuvent induire de grandes pressions négatives (ou tensions) dans la phase liquide. L'amplitude de cette tension est rapidement contrôlée par la pression de la phase vapeur externe. Lorsqu'on enferme du butane liquide dans des capsules creuses (ou des tubes de Bertholet) dont les parois sont faites de verre poreux, de type Vycor (avec des rayons de pores d'environ 5 nm), il développe des pressions négatives allant jusqu'à –4 MPa pour de faibles périodes et des tensions plus faibles pour des temps beaucoup plus longs. Cette tension s'approche de la limite théorique (environ –6 MPa) calculée d'après l'équation de Laplace. Les tensions maximales possibles sur la base de la théorie de nucléation homogène et sur une décomposition spinodale sont beaucoup plus importantes et, en principe, on peut les atteindre en réduisant la taille des pores. On décrit nos efforts infructueux de la faire.

Mots clés : tube de Bertholet, liquide, pression négative, nucléation.

Introduction

While a variety of methods have been used to generate negative pressures in liquids (1), the Bertholet method is most often used to generate static negative pressures. This method employs a sealed container of fixed volume completely filled with liquid at a given temperature and then slowly cooled. Since the thermal expansivity of the liquid is much larger than that of the container the pressure within the liquid decreases rapidly with temperature. Ohde et al. (2), using a metal Bertholet tube, reported negative pressures as great as –20 MPa for several organic liquids while Henderson and Speedy (3) obtained similar tensions with water in a glass tube. More recently Zheng et al. (4), using an inclusion synthesis technique whereby microscopic volumes of water are trapped in fissures within various crystals, obtained tensions of ca. –140 MPa, close to the homogenous nucleation limit of liquid water. Our interest in liquids at negative pressure stems from our work on capillary-condensed liquids. For example, we have found that the equation of state proposed by Speedy (5) provides an excellent description of water at negative pressures, when condensed in a microporous silica gel (6). From a theoretical point of view, however, it is better to study macroscopic volumes of liquid.

Tensions observed in macroscopic Bertholet tubes are usually much less than those predicted from theoretical considerations. As Ohde et al. (7) have pointed out, this may be due to the presence in the system of potential nuclei such as minute or nascent air bubbles, surface impurities that foster heterogenous (surface) nucleation, or microscopic crevices holding minute amounts of trapped air. Some of these contaminants originate with the method of filling the apparatus, where the tube is almost completely filled with liquid, then sealed. The small bubble of air is removed by warming the tube and as the liquid expands to fill the entire tube the air dissolves in the liquid. Subsequent cooling induces negative pressure in the liquid along a given isochore if vapour phase (bubble) nucleation is absent. To obtain data for different isochores it is necessary to reopen the tube and change the amount of liquid. This is not only inconvenient and time consuming but also provides opportunity for further contamination of the liquid. In this work we describe a Bertholet

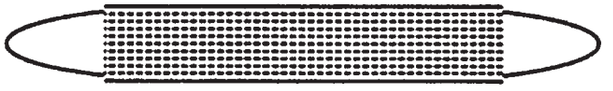
Fig. 1. Bertholet tube. Stippled region corresponds to Vycor porous glass tubing (ca. 5 mm diameter) and the sealed ends are essentially nonporous silica.



tube that avoids many of these problems and we present some results for liquid butane. The method is based on the development of a large pressure difference across a highly curved liquid–vapour interface and is similar, in principle, to the method developed by Marinho (8) to study capillary suction in soils.

Experimental

The cell, shown in Fig. 1, is a section of Vycor porous glass tubing (ca. 5 mm diameter) sealed at both ends. While the ends are nonporous vitreous silica, the walls of the tube contain many submicroscopic pores (diameter 2–6 nm) that pass through the cell walls (9). The cell is mounted in an apparatus (Fig. 2) where it can be baked out under vacuum. Butane, stored in the reservoir, is degassed by several freeze–thaw cycles, then condensed around the cell at ice temperature so that the cell is completely covered. The liquid slowly flows through the pores until the cell is filled. This may take several days but the process may be accelerated if condensed butane extends into warmer ambient temperatures as shown in Fig. 2 (inset A). Cells that fill rapidly are usually defective. Once the cell is filled, excess butane, external to the cell, is slowly (without boiling) returned to the reservoir. After all the external liquid has evaporated (Fig. 1, inset B) further removal of vapour reduces the pressure in the vapour phase, P_{vap}, below the saturation vapour pressure of butane, P^{o}_{vap}. This causes the formation of hemispherical menisci within the pores in the cell walls. The capillary pressure difference, ΔP_c, across the curved liquid–vapour interface is given by the Laplace equation,

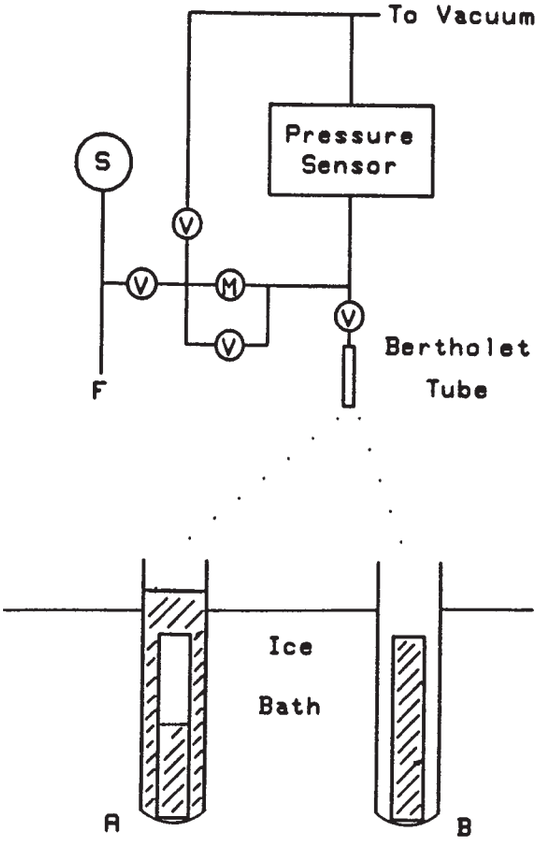
$$[1] \qquad \Delta P_c = P_{vap} - P_{liq} = 2\gamma/r$$

where γ is the surface tension of the liquid, P_{liq} is the pressure within the liquid, and r is the radius of curvature of the meniscus. If r is very small P_{liq} may be negative. It is readily shown (10) that

$$[2] \qquad \Delta P_c = -(RT/V_{liq}) \ln (P_{vap}/P^{o}_{vap})$$

where V_{liq} is the liquid molar volume. For our present purposes only a small error is introduced if the liquid is assumed to be incompressible, but at large negative pressures, close to the spinodal limit, this assumption will not be valid (6). When the relative pressure, P_{vap}/P^{o}_{vap}, is less than unity and the cell remains filled with (metastable) liquid, P_{liq} is readily calculated. Further removal of vapour results in the evaporation of some of the liquid through the porous cell walls and an increase in ΔP, i.e., P_{liq} becomes more negative. This process can be continued until a bubble forms within the liquid, at which point the liquid evaporates and the vapour phase pressure rapidly increases to the saturation vapour pressure. Two runs are shown as examples in Fig. 3.

Fig. 2. Apparatus for filling and testing Bertholet tubes (schematic). S is a 2 L storage bulb and F is a freeze-out for degassing the butane. V are stainless steel bellows-seal valves and M is a similar metering valve. The pressure sensor (MKS Baratron) reads to 1000 Torr (1 Torr = 133.3 Pa) with an accuracy of at least 0.1%. Inset A shows an expanded view of a partially filled tube submerged in liquid butane while inset B shows the tube filled with the external excess butane removed.



Discussion

There are four possible mechanisms for the formation of a bubble within the liquid: (*i*) heterogenous nucleation at the inner surface of the cell; (*ii*) homogenous nucleation within the liquid; (*iii*) spinodal failure of the liquid, and (*iv*) penetration of the external vapour phase through the porous cell wall. The latter will occur when the radius of curvature of the liquid–vapour interface (eq. [1]) becomes less than the radius of at least one pore connecting the internal liquid phase with the external vapour phase, i.e., when $r < r_p - t$, where r_p is the pore radius and t is the thickness of the adsorbed layer on the pore walls (10). The pressure at which homogenous nucleation occurs is calculated from the equation given by Fisher (11),

$$[3] \qquad \Delta P_{hn} = [16\pi\gamma^3/3kT \ln (nkT/h)]^{1/2}$$

where k and h are the Boltzmann and Planck constants and n is the number of molecules in the liquid. Spinodal

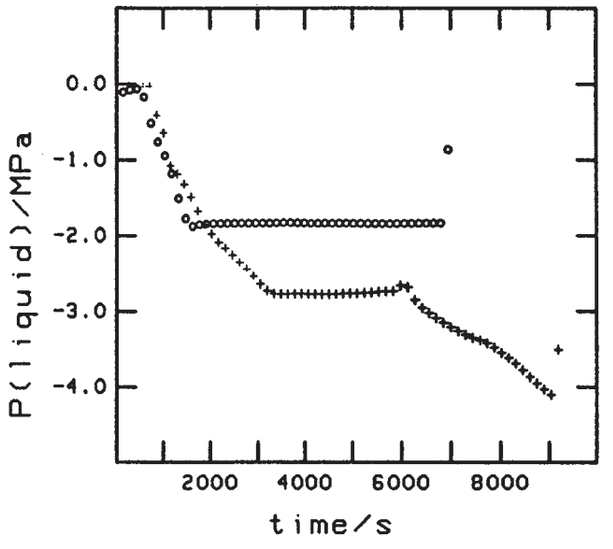
Fig. 3. Example runs. Curve A (circles): at t < ca. 1000 s a small amount of liquid remains outside the Bertholet tube. This establishes the baseline saturation pressure P^{o}_{vap}. Between 1000 and 2000 s all of the excess liquid and some of the residual vapour is slowly removed to establish a tension of ca. –1.8 MPa within the liquid ($P_{vap} < P^{o}_{vap}$, see eq. [2]). Nucleation occurs at ca. 7000 s. Curve B (crosses): as for curve A but after 3000 s a plateau is established at ca. –2.7 MPa. Continued slow removal of vapour after 6000 s leads to nucleation at ca. –4 MPa. The maximum possible tension, imposed by the pore size in the Bertholet tube, is estimated to be –5.9 MPa (see text).



decomposition occurs when the negative pressure is sufficiently large that the liquid passes from a metastable to an unstable state. The pressure, ΔP_{sp}, at which this occurs can be estimated from the hard-sphere equation of state with an attractive van der Waals tail as given by Ben-Amotz and Herschbach (12). In general $\Delta P_{sp} > \Delta P_{hn}$, i.e., homogenous nucleation will occur before spinodal decomposition (4), but the relative magnitude of ΔP_{hn} and ΔP_{c} (eq. [1]) will depend on the radius of the pores in the cell walls. Heterogenous nucleation occurs at relatively small negative pressures when the liquid does not completely wet the walls of the tube (13). For butane at the ice point $\Delta P_{sp} \cong 20$ MPa, $\Delta P_{hn} = 13.6$ MPa, and, for pores of radius 5.0 nm (14), $\Delta P_{c} = 5.9$ MPa.

Typical behaviour of the liquid at negative pressure is shown in Fig. 3. Curve A in this figure is characteristic of several runs at constant negative pressure. Metastable liquid can persist for long periods (up to 2×10^4 s) but eventually bubble formation occurs. A light blow or tap on the external supporting tube (Fig. 2) may be sufficient to initiate nucleation. When the external vapour pressure is slowly decreased (curve B) the liquid fails at ca. –4 MPa, which is comparable to the pressure limit imposed by the pore size ($\Delta P_{c} \cong 5.9$ MPa).

This method offers an advantage over other types of Bertholet tubes in that the tube can be filled with degassed, microfiltered liquid in a closed system. For volatile liquids it also has the major advantage that P_{liq} can be controlled through the external pressure, P_{vap} (eq. [2]), and that P_{liq} can be changed isothermally. In principle, with tubes having sufficiently small pore radii, it should also be possible to distinguish between homogenous nucleation and spinodal decomposition. The latter should be accompanied by divergence of the isothermal compressibility as the spinodal limit is approached. This would be noted as a marked diminution in the liquid density, observed as a decrease in the overall mass of the liquid in the tube.

Unfortunately, these tubes are difficult to make and, in some respects, are relatively fragile. For example, they cannot be abruptly immersed in liquids, especially those having high surface tension such as water. They often fail in use, tending to form a ring crack near the boundary between the nonporous (fused) end and the main porous (unfused) wall of the tube. In an attempt to circumvent this problem several tubes were sealed with epoxy resin but this material appeared to serve as a nucleating surface and only insignificant negative pressures could be developed. In an attempt to decrease the pore size and hence extend the range of ΔP_{c}, other tubes were immersed in a water–TMOS (tetramethyl orthosilicate) solution but all cracked after short exposure to the solution. Vapour phase adsorption of water on the pore walls, followed by vapour phase adsorption – reaction with TMOS proved similarly unsuccessful. In principle, this type of Bertholet tube offers significant advantages over other types, especially for volatile liquids. However, the tubes are difficult to make and have a short lifetime.

Acknowledgements

Mr. G. Lewis carried out many of the runs, such as those shown in Fig. 3, and Professor P.D. Golding provided useful discussion. This work was supported by the Natural Sciences and Engineering Research Council of Canada. The author thanks one of the referees for pointing out ref. 8.

An ab initio and neutron diffraction study of ammonium chloride

A. Alavi, R.M. Lynden-Bell, P.A. Willis, I.P. Swainson, and R.J.C. Brown

Abstract: Ab initio density functional calculations have been carried out on the ordered phase of ammonium chloride and the results compared with experimental data. Powder neutron diffraction measurements have been carried out on $^{14}ND_4Cl$ and $^{15}ND_4Cl$ at a temperature of 5 K; the lattice parameter is 3.8224(4) Å and the N—D bond length is 1.0318(8) Å. Calculated structural and spectroscopic quantities agree well with the results of the neutron diffraction refinements, and with measured spectroscopic data. The calculated barrier to reorientation of the ammonium ion about the fourfold axis is 29 kJ mol^{-1}, and the calculated compressibility is 3.78×10^{-11} Pa^{-1}. The octopole moment of the ammonium ion in the crystal has been estimated from the calculated electron density, and is about 10–20% greater than for the free ion. The octopole moment does not vary appreciably with the orientation of the ammonium ion in the lattice. There is no evidence of any covalent interaction between the ammonium and chloride ions.

Key words: ammonium chloride, density functional theory, neutron diffraction, ab initio calculations.

Résumé : On a effectué des calculs ab initio de densité fonctionnelle sur la phase ordonnée du chlorure d'ammonium et on a comparé les résultats avec les données expérimentales. On a effectué des mesures de diffraction de neutrons par des poudres de $^{14}ND_4Cl$ et $^{15}ND_4Cl$ à 5 K; le paramètre de réseau est égal à 3,8224(4) Å et la longueur de la liaison N—D est égale à 1,0318(8) Å. Les valeurs structurales et spectroscopiques calculées sont en bon accord avec les résultats de l'affinement de la diffusion de neutrons et les données spectroscopiques mesurées. La barrière calculée pour la réorientation de l'ion ammonium autour de l'axe quaternaire est de 29 kJ mol^{-1} et la compressibilité calculée est de $3,78 \times 10)^{11}$ $Pa)^{1}$. On a évalué le moment octapolaire de l'ion ammonium dans le cristal à partir de la densité électronique calculée et elle est environ de 10 à 20% plus élevée que celle de l'ion libre. Le moment octapolaire ne varie pas beaucoup avec l'orientation de l'ion ammonium dans le réseau. On n'a relevé aucune indication de présence d'interactions covalentes entre les ions ammonium et chlorure.

Mots clés : chlorure d'ammonium, théorie fonctionnelle, diffraction de neutrons, calculs ab initio.

[Traduit par la Rédaction]

Introduction

The ammonium ion is singly charged, small, and approximately spherical. It forms ionic crystals, which have many similarities to those of the alkali metals. However, because it has additional orientational degrees of freedom, these crystals have a range of structures and phase transitions that have no counterparts in the salts of the alkali metals. The ammonium ion is also a potential hydrogen bond donor, but the extent to which this occurs in halide crystals has been a matter of discussion. In this work we combine an accurate determination of the crystal structure of the low-temperature ordered phase of ammonium chloride with an ab initio quantum calculation of the electronic energy and density in this structure.

At room temperature ammonium chloride (NH_4Cl) forms an ionic crystal in which there is orientational disorder of the ammonium ions. The discovery of the order–disorder phase transition in 1922 (1) was followed by extensive spectroscopic, thermodynamic, and other studies (2). At temperatures below 457.6 K ammonium chloride crystallizes in the CsCl structure. In the ordered phase below 242.5 K the space group is $P\bar{4}3m$ and the ammonium ions are aligned parallel to each other with bonds along four of the [111] directions. At temperatures between 242.5 and 457.6 K the space group is $Pm3m$ and the crystal is orientationally disordered with equal populations of the two possible orientations. In the deuterated salt ND_4Cl, the order–disorder phase transition takes place at 249.7 K. The order–disorder phase transition is first order at atmospheric pressure, but becomes second order at a tricritical point at a pressure of approximately 100 MPa. The structures of these two phases have been established by neutron diffraction (3, 4).

Many of the interesting spectroscopic and thermodynamic properties of ammonium chloride are related to motion of the ammonium ion. The potential energy surface for the ammonium ion has been discussed by many authors (5–11), usually on the basis of either an electrostatic or atom–atom

potential expressed in terms of a symmetry-adapted expansion of the potential function. In some cases an empirical potential function is fitted to such measured data as librational frequencies. Smith has recently reviewed potential functions for ammonium ions in crystalline salts (12).

Classical molecular dynamics calculations based on these potential functions have been carried out by several groups and used to study the ammonium ion dynamics and the nature of the phase transition in solid NH_4Cl (13–15) and in $(NH_4Cl)_n$ clusters (16).

In recent years there has been a great increase in the availability of ab initio methods suitable for solid state problems. The innovation that has been particularly appropriate for the solid state is the use of density functional theory, with modern density functionals that have been used successfully for semiconductor, metallic, and ionic systems (see, for example, the website http://gserv1.dl.ac.uk/TCSC/HCM/PSIK/main.html). The main results of such calculations are the energy and electron density as functions of nuclear positions. These can be used to obtain a better understanding of the electron distribution and hence of the bonding in the material under study. In this work we use such a calculation to study the low-temperature ordered phase of ammonium chloride. The results of the calculation are compared with the structural parameters of ammonium chloride at low temperature determined by neutron diffraction. Our interest in this substance is informed by our earlier attempts to model orientationally disordered phases containing molecular ions (17). We address the question of how far the ammonium ion can be described as a distinct molecule interacting weakly with the other ions, or whether there is a high degree of covalency. How much hydrogen bonding is present and how much does the electronic structure change as the ammonium ions are rotated relative to the chloride lattice? How adequate is a classical model with fixed charges on atomic sites? While answering these questions we also obtain values for the bond length, lattice parameter, compressibility, and vibrational frequencies for the model.

The structure of the paper is as follows. The following two sections report the methods used for the ab initio calculations and the neutron diffraction experiment. Then the results of the calulations are compared with the structural properties determined experimentally and with published spectroscopic data. Finally, the electronic structure of the ammonium ion in this crystal is discussed and compared with the results of other calculations.

Ab initio calculations — method

The method we use is Alavi's FEMD method (18–20) in which the free energy functional of Mermin (21) is minimized. In fact, as the gap between the highest occupied and lowest unoccupied orbitals is large, the use of this method rather than a more standard total energy method such as Car–Parrinello (22) or other density functional total energy methods is immaterial. We used the local density approximation with gradient corrections (23, 24). The electronic orbitals were expanded in plane-wave basis set up to a cutoff of 73.2 Ry, corresponding to approximately 16 500 plane waves. We used the pseudopotential method to obviate the need to explicitly include core electrons. Troullier–Martins pseudopotentials (25) in the Kleinman–Bylander form (26) using *s* and *d* non-locality for Cl and N were employed. The pseudopotentials were generated using core radii of 1.4 a.u. for the valence states of both N and Cl. The above cutoff was sufficient to give well-converged results. Calculations were done on a single unit cell of NH_4Cl with periodic boundary conditions. Given this unit cell, we found it essential to construct the density from orbitals that sample adequately the Brillouin zone. For this purpose we used a $4 \times 4 \times 4$ Monkhorst–Pack k-point mesh. Using fewer k points gave rise to large errors, including for example a 30% error in the lattice spacing. For the calculation of the compressibility the number of plane waves was fixed at 16 494, to eliminate the discontinuities that arise from changes in the number of the plane waves as the cell dimensions are varied.

Calculations were performed with a number of lattice parameters and a number of N—H bond lengths to find the energy minimum. These results also gave the compressibility and the N–H symmetrical stretching frequency. The transverse optical frequency was calculated by displacing the chloride ions from their lattice positions and calculating the corresponding force constant. The energy was then mapped out by keeping the lattice parameter and bond length constant and rotating the ammonium ions around (in turn) twofold and threefold ion symmetry axes. Electron distributions were compared in the extremes of these orientations. Following Klein et al. (13), we shall refer to the orientation with the ion rotated by 45° about one of its C_2 (or S_4) symmetry axes as the D_{2d} orientation and the orientation with the ion rotated by 60° about an N—H bond or C_3 symmetry axis as the C_{3v} orientation.

Neutron diffraction — methods

Structural data for ammonium chloride were determined by powder neutron diffraction measurements on ND_4Cl and on $^{15}ND_4Cl$. The objective of using two samples with different nitrogen isotopes was to test the validity of the N—H bond length and the torsional thermal parameters by independent refinement of data for two samples with identical moments of inertia for the ammonium ion, but different neutron scattering properties. Powdered $^{14}ND_4Cl$ (99.3% D) and $^{15}ND_4Cl$ (99.2% D, 99% ^{15}N) supplied by Isotech Inc. (Miamisburg, Ohio) were examined at five temperatures from 5 K to ambient temperature. The materials were checked initially by X-ray diffraction and were used as supplied. The powder samples were contained in vanadium tubes of 5 mm inside diameter and wall thickness 0.18 mm, which were filled with helium exchange gas. The samples were rotated about one axis throughout data collection to improve averaging over crystallite orientation.

The experiment was done on the C2 Dualspec high-resolution powder diffractometer at the NRU reactor at Chalk River, and data were collected from 5° to 120° with a step size of 0.025°. The monochromator was Si (531) and the take-off angle was $2\theta = 110.05°$. The neutron wavelength of 1.50443(3) Å was calibrated using a separate Si powder standard. Sample temperature was controlled by a helium cryostat, with separate thermocouples for the measurement and control of temperature. Structure refinement was carried out using the GSAS Rietveld refinement code (27). Rigid

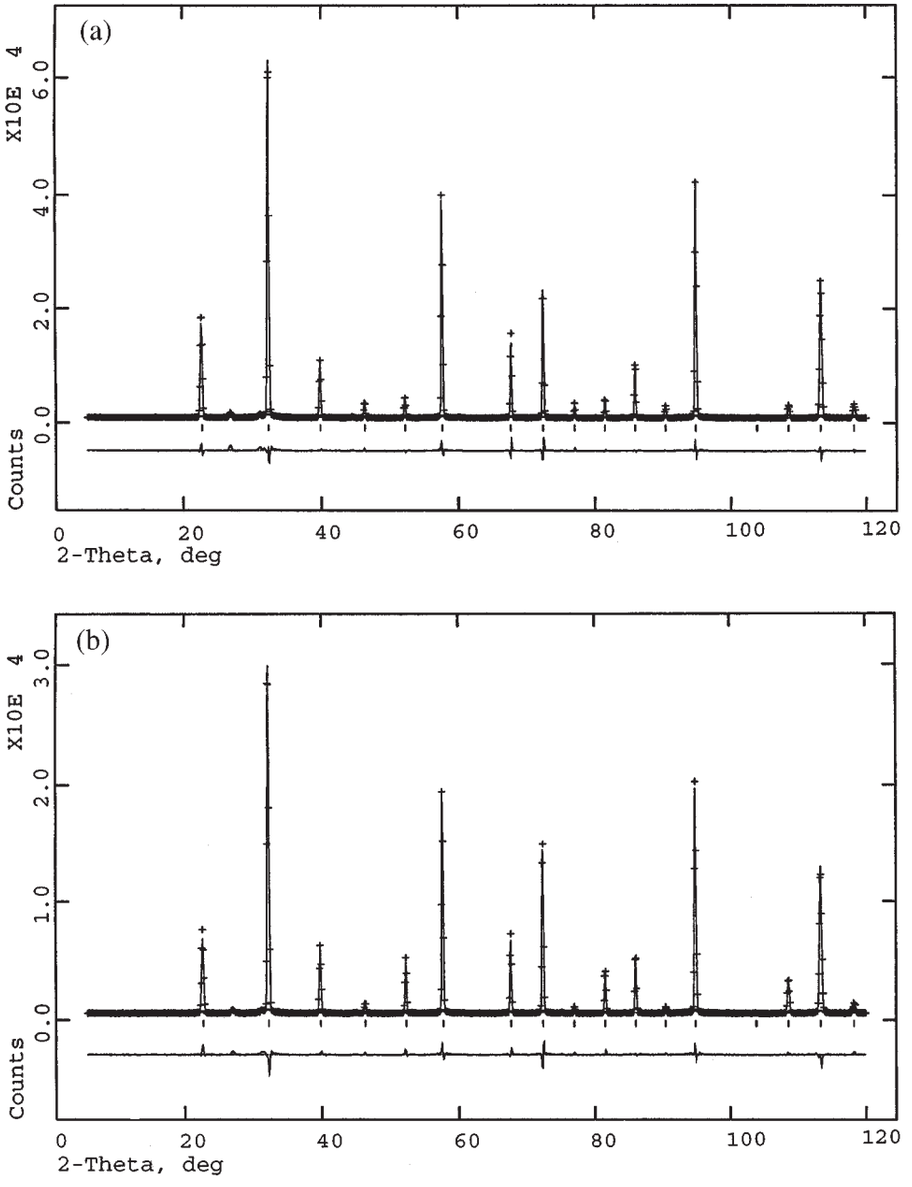
Fig. 1. Neutron diffraction intensity profiles and calculated fits for ammonium chloride at 5 K. (*a*) $^{14}ND_4Cl$; (*b*) $^{15}ND_4Cl$. In each case the upper part of the diagram shows the observed and calculated profiles, and the lower part of the diagram shows the difference between observed and calculated profiles.



body constraints were used to define the ammonium ion as a regular tetrahedron, and the thermal parameters for the ammonium ion were expressed in the TLS format. The profiles were corrected for absorption before refinement with an overall absorption factor for the unit cell. Figure 1 shows the observed and calculated powder patterns for the two sets of data.

Neutron diffraction — results

The results of the refinements are summarized in Table 1. The unit cell parameters of the two samples do not agree as well as might be expected based on the indicated statistical precision. This effect has been noted before for independent experiments (28), and is thought to be due to nonreproducibility in the sample position. The average value for the cell parameter is 3.8224(4) Å. The bond lengths for the ammonium ion derived from the two samples agree satisfactorily and the average bond length is 1.0318(8) Å. This bond length is longer than that found in ND_4ReO_4 at 20 K, 1.025(1) Å (29), but shorter than the bond lengths in NH_4F at 77 K, which are 1.035(8) Å and 1.045(6) Å (30). The thermal parameters for the ammonium ion agree well between the two samples, and indicate an r.m.s. torsional amplitude of 6.6°.

Ab initio calculations — results

The results of the calculations are summarized in Table 2. In comparing the calculated structural parameters with the

Compressibility	3.78 × 10^{-11} Pa^{-1}	3.73 × 10^{-11} Pa^{-1} (37)
Rotational barrier	29 kJ mol^{-1} [b]	27.2 kJ mol^{-1} (38–41)

[a] This work.

[b] The calculated barrier is for simultaneous rotation of all ammonium ions (see text).

neutron diffraction results, it should be kept in mind that the calculations refer to the protonated salt, NH_4Cl, but do not include any averaging over vibrational motion; the neutron diffraction results refer to the actual deuterated salt ND_4Cl including zero point motion and residual thermal motion at a temperature of 5 K. The calculated vibrational frequencies in the table refer to NH_4Cl.

The calculated lattice parameter and equilibrium bond length are in reasonable agreement with experiment. It was found that the calculated lattice parameter was sensitive to the number of k-points included in the calculations and to the cutoff. The lattice parameter is about 2% larger than the measured value, but the N—H bond length is in good agreement with the neutron diffraction results.

The vibrational spectra of both protonated and deuterated ammonium chloride were reported by Schumaker and Garland (31). The dispersion curves of the external modes have been determined in a neutron scattering study of ND_4Cl by Teh and Brockhouse (32, 33). The calculated and experimental spectroscopic results listed in Table 2 all pertain to the zone centre vibrational modes in which the displacement in every unit cell is identical. The calculated symmetrical stretching frequency of the ammonium ion is larger than the measured frequency by about 3%. In the calculation all three translational optic modes (in which the chloride and ammonium ions move in opposite directions) are degenerate. This frequency gives the predicted transverse optic mode frequency; the longitudinal optic mode has a higher frequency due to the interaction of the local oscillating dipole moment with the electric field. The calculated transverse optical frequency agrees satisfactorily with experiment; the longitudinal optical frequency was calculated from the calculated transverse optical frequency using the ratio of dielectric constants at low and high frequencies, namely $\varepsilon_s/\varepsilon_\infty = 2.17$, and the Lyddane–Sachs–Teller relation (34, 35), following Teh and Brockhouse (32).

The compressibility was calculated by fitting a parabola to the calculated total energy as a function of lattice parameter, and comparing with the strain energy for a cubic crystal (36). The estimated experimental value is based upon the ultrasonic measurements of Garland and Renard (37). Their measured values of the isentropic elastic constants c_{11} and $C' = (c_{11} - c_{12})/2$ as a function of temperature were extrapolated to absolute zero, at which temperature the difference between the isentropic and isothermal elastic constants is zero. The estimated experimental compressibility was then calculated from the formula $\kappa^{-1} = c_{11} - 4C'/3$ (36). The agreement between the calculated and experimental values is very good.

Figure 2 shows the variation of energy with rotation of the ammonium ion in the ordered phase. In these calculations all the ammonium ions in the crystal are rotated in phase about either a C_3 symmetry axis (dotted line, period 120°) or an S_4 symmetry axis (full line, period 90°). The curvature around the T_d orientation is identical for both displacements as the librations of the ammonium ion at the G point are all degenerate. As the energy curves are very close to sinusoidal, it follows that the lowest barrier is for the rotation with the smallest angular period. At the barrier for rotation about an S_4 axis the ions are in the D_{2d} orientation; the bonds are still equivalent but the bond angles need no longer be equal. At the barrier for rotation about a C_3 axis, the bonds are no longer even equivalent. In our calculations the internal geometry of the ion is fixed at the equilibrium tetrahedral geometry. If this restriction were relaxed one would expect a slight lowering of the barriers. The calculated barriers are 29 kJ mol^{-1} for simultaneous rotation of all molecules about parallel S_4 axes and 35.5 kJ mol^{-1} for rotation about parallel C_3 axes; rotation about the S_4 axis is preferred.

Experimental values for the barrier to rotation are based primarily upon NMR determinations of the activation energy for rotation from relaxation time measurements (38–40) and quasi-elastic neutron scattering (41). Mandema and Trappeniers (38) give the activation energy in the ordered phase as 21.2 kJ mol^{-1}, while Woessner and Snowden (39) and Sharp and Pintar (40) both give 19.7 kJ mol^{-1}. Töpler et al. give the activation energy for reorientation about the S_4 axis as 20.4 kJ mol^{-1} (41). The average of these values, 20.2

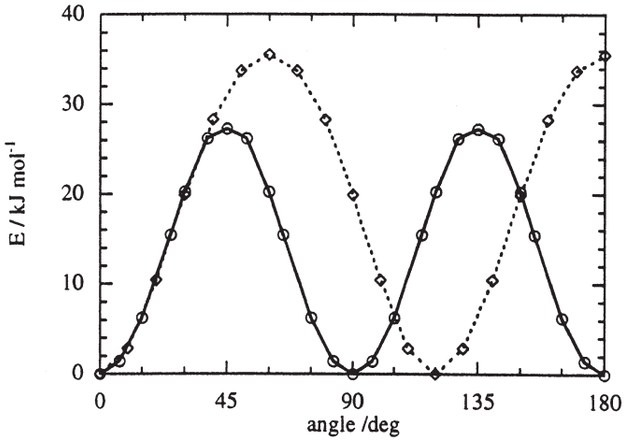
Fig. 2. Energy as function of angle of rotation of the ammonium ions about their S_4 axes (solid line) and their C_3 axes (dotted line). The barriers to rotation are 29 kJ mol^{-1} for the S_4 rotation and 35.5 kJ mol^{-1} for the C_3 rotation.



kJ mol^{-1}, has been used in the following. The barrier height is the sum of the activation energy and the zero point energy for the triply degenerate librational mode with an experimental frequency of 389 cm^{-1} (Table 2). The result is 27.2 kJ mol^{-1}, which agrees well with the calculation, and confirms the earlier conclusion (9, 15) that reorientation takes place about the S_4 rather than the C_3 axis of the ammonium ion. The main difference between the calculated and experimental barrier height is probably due to the fact that the calculated result is for the simultaneous rotation of every ammonium ion in the crystal while the experimental result is for the reorientation of a single ion.

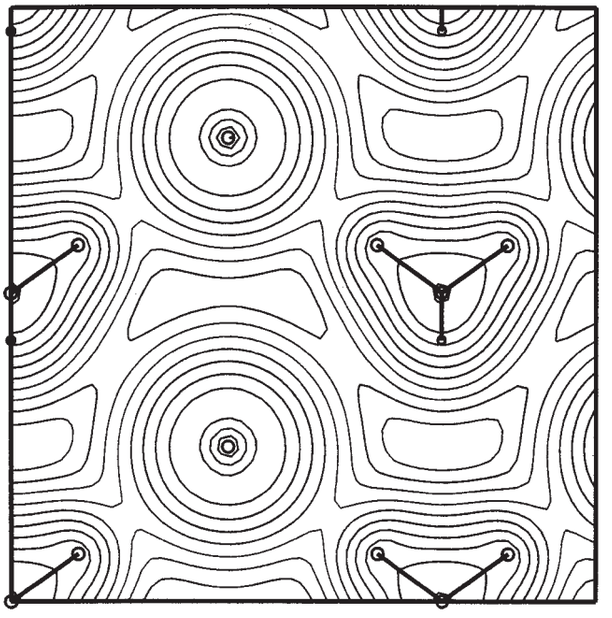
We conclude that the ab initio calculations give results that agree with the experimental quantities within about 5% or better for most quantities.

Electronic structure of the ions

Figure 3 shows electron density contours with the ammonium ion in its most stable T_d orientation. The electron density has been computed in a (110) plane through the lattice, containing two N—H bonds (long bold lines) in each ammonium ion, and the adjacent chloride ions to which they point. The shorter bold lines are the projections of the out-of-plane N—H bonds, while the chloride ions are at the centres of circles. Figure 4 shows electron density contours in the (110) plane with the ammonium ion in the C_{3v} orientation. The plane of the diagram contains chloride ions and two N—H bonds. One of the two in-plane N—H bonds lies along the N—H···Cl axis about which the 60° rotation has taken place, and the other in-plane N—H bond points between chloride ions. Figure 5 shows electron density contours in the (100) plane through the nitrogen atom with the ammonium ion in the D_{2d} orientation. In this orientation none of the N—H bonds point at a chloride ion.

In each of these figures the contours are plotted at logarithmic intervals so that low-lying contours are at very low values of the electron density. Note that the use of a pseudopotential gives a distorted electron density near the Cl and N cores. Comparing these three plots we see that the contours

Fig. 3. Contour plot of the electron density in ammonium chloride with the cation in the most stable (T_d) orientation. The plot shows the electron density in a (110) plane passing through the nitrogen atoms. This plane contains two N—H bonds (long bold lines) that point at chloride ions (circles). The two shorter bold lines show the other N—H bonds projected onto this plane.



near both the chloride ions and the ammonium ions are very similar in all configurations. It is only for electron densities of 0.03 electrons per cubic bohr and lower that we see any differences between the configurations. This is consistent with the idea that the molecules and ions remain distinct with little or no covalent interactions. There is also little evidence for induced moments in the ions. The chloride ion, for example, remains spherical rather than being distorted. The concentric equally spaced circles around these atoms show that the electron density falls off exponentially and that there is little distortion of the electron density by the ammonium ion.

The minimum electron density along the N—H···Cl vector in both the lowest energy T_d orientation (Fig. 3) and in the C_{3v} orientation (Fig. 4) is about 0.026 electrons per cubic bohr, which is about twice as high as the minimum electron density (0.011 electrons per cubic bohr) along the N···Cl direction when the ammonium ion is in the D_{2d} orientation (Fig. 5) and there is no hydrogen atom close to a chloride ion. This may be interpreted as being due to the overlap of the tails of the molecular electron distributions, which gives a repulsive contribution, or may be a sign of very weak covalency, which would give part of the attractive force and contribute to the formation of a weak hydrogen bond. In density functional theory, the local energy contains a repulsive part that increases as the electron density increases, and an electrostatic part, which contains the stabilization due to the mutual attraction of the nuclei and the electrons, and it is not possible to distinguish between these possibilities.

Fig. 4. Contour plot of the electron density in ammonium chloride with the cation rotated by 60° about an N—H bond into the C_{3v} orientation. The plot shows the same (110) plane as in Fig. 3. There are two N—H bonds per cation in this plane; only one N—H bond points at a chloride ion, and the other lies midway between two chloride ions.

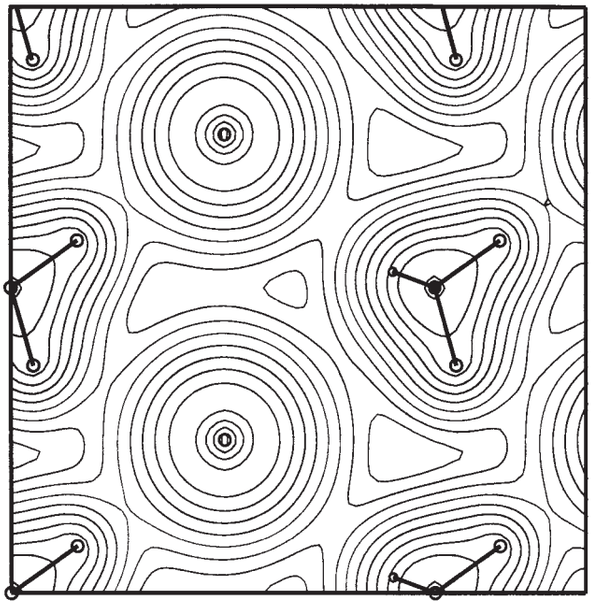

Fig. 5. Contour plot of the electron density in ammonium chloride with the cation rotated by 90° about an S_4 axis into the D_{2d} orientation. The plot shows a (100) plane passing through the nitrogen atom containing two N—H bonds; all the N—H bonds lie midway between chloride ions, all of which lie outside this plane.

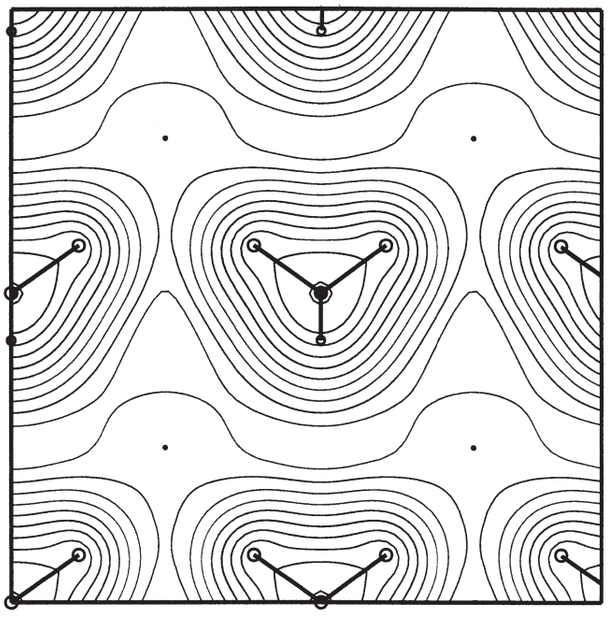

Electrical properties of the ammonium ion

In classical simulations of ammonium salts (13–17) it has been usual to model the ammonium ion by a tetrahedron with interaction sites on the nuclei. A very important parameter for the simulation is the value of the partial charge on each site, and Table 3 lists some of the charge distributions that have been used in previous work. The unit of electrical charge is the magnitude of the electronic charge.

The lowest multipole moment of a tetrahedral ion is the octopole moment. In molecule- based coordinates with the C_2 axes parallel to the Cartesian axes there is only one non-zero component, namely the *xyz* component

$$\Omega_{xyz} = 2.5\int xyz\rho(x, y, z)\mathrm{d}s\ \mathrm{d}y\ \mathrm{d}z$$

where the integral is taken over the molecule with the N atom at the origin, and includes the nuclear charges. In a model with partial charges of $+q_H$ on the protons the octopole moment is $10/(3(3)^{1/2})q_H r^3$ where r is the bond length. Brown and Lynden-Bell (16) chose the hydrogen charge q_H to fit the octopole moment calculated by Fowler et al. (43). Once q_H is fixed, the higher multipole moments of the model ion are completely determined.

We have attempted to evaluate the octopole moment of the ammonium ion in its surroundings from our ab initio calculations. The octopole moment is difficult to calculate accurately because the integral is heavily weighted towards large values of *r.* Furthermore, it is difficult to define the outer limit of a molecule in a crystal because the electron density is continuous. To estimate the octopole moment we evaluated the integral over a sphere centred on the nitrogen atom containing exactly eight electrons. The radius of this sphere is 1.8 Å and corresponds closely to the saddle point between the hydrogen and chlorine atoms shown in Fig. 3. Adding the positive contribution from the four protons to the value of the octopole integral over this sphere gives an octopole moment Ω = 8.0 atomic units. This is higher than the value of 6.48 a.u. calculated for a free ammonium ion by Fowler et al. (43). If the octopole were modelled by placing a charge on each hydrogen atom site with a net cation charge of +1, then one would need an effective charge q_H = +0.56 rather than +0.469.

An alternative method is to calculate the dipole moment of each of the eight octants and to take the differences between octants containing bonds and empty octants. As this calculation weights the positions by distance rather than by the cube of the distance, it may be more accurate. Applying this method we obtain an estimate of the octopole of 7.4 a.u., which corresponds to a charge of +0.52 on each proton.

The calculation of octopole moment was repeated in all three orientations of the ammonium ion (T_d, C_{3v}, and D_{2d}). The striking result of these calculations is that the variation found between the three orientations is only about 1%. This shows that the molecular ion is not significantly polarized during reorientation. It is probable that the increase in the octopole in the crystal compared to the free ion, which results from the lowering of the magnitude of the electronic contribution, is due to the compression of the electron density in the outer parts of the ion.

+1	+0.35	13, 15
+0.8	+0.5	14
+1	+0.469	16

Discussion and conclusions

In this study we have performed accurate ab initio calculations on the ordered phase of ammonium chloride, and neutron diffraction measurements of the structural parameters of the same material. The results of the calculation have also been compared with experimental data for spectroscopic and thermodynamic quantities. Calculation and experiment agree well in spite of various approximations inherent in ab initio methods. From the calculations we conclude that the electron distribution in the ammonium ion does not vary significantly with orientation and that the electrostatic intermolecular forces should be described by an octopole moment that is 10–20% greater than for the free ion. We recommend a value for the octopole moment of about 7.4 a.u., which corresponds to $q = +0.52$ on each hydrogen atom and $q = -1.08$ on the nitrogen atom. We find no evidence of any covalent interaction between the ammonium and the chloride ions, which is consistent with previous speculation about participation of ammonium ions in hydrogen bonding (44).

Ternary cobalt germanium pnictides $CoGe_xPn_{1-x}$ (*Pn* = P, As, Sb) and the structure of Co_3Ge_2Sb, an intermetallic compound with stuffed Sb_2 pairs

Allison M. Mills, Robert Lam, and Arthur Mar

Abstract: The ternary cobalt germanium pnictide systems $CoGe_xPn_{1-x}$ (*Pn* = P, As, Sb; $0 < x < 1$) were investigated. The ternary phosphides $CoGe_xP_{1-x}$ and arsenides $CoGe_xAs_{1-x}$ adopt the MnP structure (*Pnma*) in the range $0 < x < 0.8$, with Ge and *Pn* (*Pn* = P, As) disordering over the anion sites. Reactions in the antimonide system $CoGe_xSb_{1-x}$ result in a mixture of ternary phases, one with the NiAs structure ($P6_3/mmc$) in which Ge and Sb disorder over the anion sites, and another that is a new intermetallic compound, Co_3Ge_2Sb. Single-crystal X-ray diffraction reveals that Co_3Ge_2Sb crystallizes in the hexagonal space group $P6/mmm$ with $a = 8.9128(13)$ Å, $c = 7.6312(8)$ Å, and $Z = 6$ ($T = 22$°C). The structure of Co_3Ge_2Sb comprises alternating kagomé nets of Co atoms and 6^3 nets of Ge atoms, with Sb_2 pairs stuffed along the centres of the concentric hexagons of these nets. Co_3Ge_2Sb may be regarded as an intermediate structure that is distorted from the limiting CoSn and $CaCu_5$ structures.

Key words: cobalt, germanium, antimony, pnictide, crystal structure.

Résumé : On a étudié les systèmes ternaires de pnictures de germanium et de cobalt, $CoGe_xPn_{1-x}$ (*Pn* = P, As, Sb; $0 < x < 1$). Dans la plage de valeurs $0 < x < 0{,}8$, les phosphorures $CoGe_xP_{1-x}$ et les arséniures $CoGe_xAs_{1-x}$ ternaires adoptent la structure MnP (*Pnma*) alors que le Ge et le *Pn* (*Pn* = P, As) se répartissent dans le désordre sur les sites anioniques. Les réactions dans le système antimoniure $CoGe_xSb_{1-x}$ provoquent un mélange des phases ternaires; une possède une structure NiAs ($P6_3/mmc$) dans laquelle le Ge et le Sb se répartissent dans le désordre sur les sites anioniques et une autre correspond à un nouveau composé intermétallique, Co_3Ge_2Sb. La diffraction des rayons X par un cristal unique de Co_3Ge_2Sb révèle qu'il cristallise dans le groupe d'espace $P6/mmm$ avec $a = 8{,}9128(13)$ et $c = 7{,}6312(8)$ Å et $Z = 6$ ($T = 22$°C). La structure de Co_3Ge_2Sb comporte des réseaux «kagomé» alternants d'atomes de Co et des réseaux 6^3 d'atomes de Ge avec des paires de Sb_2 insérés le long des centres des hexagones concentriques de ces réseaux. On peut considérer le Co_3Ge_2Sb comme une structure intermédiaire qui est déformée par rapport aux structures limites du CoSn et du $CaCu_5$.

Mots clés : cobalt, germanium, antimoine, pnicture, structure cristalline.

[Traduit par la Rédaction]

Introduction

Ternary pnictides have long merited investigation because they exhibit a wide array of useful electrical and magnetic properties. Most of these studies have focused on mixed-metal systems, in which the effect of differing proportions of transition metals on these properties has been measured. For instance, mixed-metal monopnictides $M_xM'_{1-x}Pn$ (*M*, *M′* = first-row transition metals; *Pn* = P, As, Sb; $0 < x < 1$) (1–8) have been prepared with an aim towards modifying the unusual magnetic properties found in such binaries as FeP (9) or CoAs (10), and to understand the effect of electron count on the transitions between the MnP or NiAs structures that these binaries typically adopt (11–13). However, given that the parent NiAs structure is prevalent not only in transition-metal pnictides, but also in chalcogenides and germanides, it is surprising that relatively little has been done in mixed-anion systems. Investigations in the cobalt-containing Co/Si/P (1), Co/B/P (1), Co/As/Sb (6), Co/Sn/As (14), and Co/Sn/Sb (14) systems have been reported. We present here structural studies on the cobalt germanium pnictides, $CoGe_xPn_{1-x}$ (*Pn* = P, As, Sb; $0 < x < 1$) and the regions of their phase stability. In addition, we describe the structure of a new intermetallic compound, Co_3Ge_2Sb, and draw attention to the close relationship between this structure and those of CoSn and $CaCu_5$. Reasons are suggested for the adoption of different structures for these cobalt germanium phosphides and arsenides on the one hand, and for the antimonides on the other.

Experimental section

Synthesis

Reagents used were the elemental powders: Co, 99.8% (Cerac); Ge, 99.999% (Cerac); P, 99.995% (Cerac); As, 99.99%

(Alfa-Aesar); Sb, 99.995% (Aldrich). Reactions were generally carried out on a 0.250–0.500 g scale in evacuated fused-silica tubes (8 cm length, 10 mm i.d.). Elemental compositions were determined by EDX (energy-dispersive X-ray) analysis on a Hitachi F2700 scanning electron microscope. X-ray powder patterns were obtained on an Enraf–Nonius FR552 Guinier camera (Cu$K\alpha_1$ radiation; Si standard).

Co_3Ge_2Sb was originally identified in a reaction of Co, Ge, and Sb in a 1:1:3 ratio, heated at 570°C for 1 day and then at 950°C for 4 days, cooled to 500°C over 4 days, and finally cooled to 20°C over 12 h. The product consisted of a shiny grey regulus, which was crushed to reveal short hexagonal prismatic crystals within. Anal. (mol%): Co 50(2), Ge, 37(2), Sb 13(1) (average of 4 analyses). One of these crystals was subsequently selected for the structure determination. Although this synthesis is reproducible, it is not ideal as the products contain significant amounts of impurities, including $CoSb_3$ and Sb.

Phase-pure samples of Co_3Ge_2Sb are difficult to prepare. While Co_3Ge_2Sb can be obtained by arc-melting a pellet of the elements combined in the stoichiometric ratio, the resulting product is contaminated with binary impurities, suggesting that this phase is incongruently melting. Moreover, stoichiometric reactions performed at increasingly higher temperatures (from 500° to 900°C) show that a greater proportion of the product (~15% at 900°C) consists of a ternary phase with the NiAs structure, in addition to the major phase, Co_3Ge_2Sb. At lower temperatures (< 600°C), other unidentified impurities appear. The phase transition from the Co_3Ge_2Sb structure (*P6/mmm*) to the NiAs structure (*P6$_3$/mmc*) (which is usually characterized as a high-temperature phase) is thus a sluggish one. For the purposes of physical property measurements, pure samples of Co_3Ge_2Sb can be obtained by manually separating these crystals on the basis of their different habits. Reaction at 900/800°C with the addition of a few grains of I_2 as a mineralizer affords masses of short, shiny, hexagonal prismatic crystals of the Co_3Ge_2Sb phase, which are easily distinguished from the longer, dull, acicular crystals of the NiAs phase.

To investigate the regions of phase stability in the Co*Pn*–CoGe (*Pn* = P, As, Sb) quasibinary systems, the series of reactions with the loading stoichiometry $CoGe_xPn_{1-x}$ ($0 < x < 1$) were prepared at 700°C. X-ray powder patterns were analyzed with the FilmScan and Jade 3.0 software packages (15). The cell parameters were refined with the use of the program POLSQ (16), and are listed in Tables S1 and S2.[2] The observed and calculated interplanar distances of Co_3Ge_2Sb, as well as the intensities determined with the program LAZY-PULVERIX (17), are listed in Table S3.[2]

We attempted to prepare substitutional analogues of Co_3Ge_2Sb (replacing Co by other transition metals, and Ge and Sb by congeneric elements), but so far without success. Substitutional studies in the P and As systems indicate that Fe can replace Co, but with a more limited range of phase stability.

Structure determination of Co_3Ge_2Sb

Weissenberg photographs reveal hexagonal Laue symmetry *6/mmm*; in particular, upper-level photographs clearly display sixfold rotational symmetry, ruling out trigonal space groups. Moreover, long-exposure photographs show weak but observable intensities for reflections with odd *l*, establishing the presence of superstructure along *c*. Final cell parameters were determined from a least-squares analysis of the setting angles of 24 reflections in the range 20° ≤ 2θ(Mo$K\alpha$) ≤ 30° centred on an Enraf–Nonius CAD4 diffractometer. Intensity data were collected at 22°C with the θ–2θ scan technique in the range 2° ≤ 2θ(Mo$K\alpha$) ≤ 70°. Crystal data and further details of the data collection are given in Tables 1 and S4.[2]

Calculations were carried out with the use of the SHELXTL (Version 5.0) package (18). Conventional atomic scattering factors and anomalous dispersion corrections were used (19). Intensity data were reduced and averaged, and face-indexed Gaussian-type absorption corrections were applied in XPREP. The centrosymmetric space group *P6/mmm* was chosen on the basis of intensity statistics and the successful structure solution. The higher symmetry space group *P6$_3$/mmc*, which would lead to an undistorted structure, was definitively ruled out because of widespread violations of the systematic extinction (*hh*2*hl*, *l* = 2*n* + 1) required for a *c*-glide plane. Out of 384 such data, 176 had $I > 3\sigma(I)$, and the

[2] Tables S1–S6 (comprising cell parameters, X-ray powder diffraction data, crystallographic data, anisotropic displacement parameters, and selected interatomic distances and angles) are available as supplementary material, which may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. With the exception of the anisotropic displacement parameters, these tables have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

peak profiles of some of these reflections were individually scanned to confirm their presence. The initial positions of all atoms were found by direct methods, and the structure was then refined by least-squares methods. The displacement parameter for Sb(1) was somewhat higher than the others, and as nonstoichiometry is a common feature of solid state compounds, refinements were performed in which the occupancies of successive atoms were allowed to vary. These refinements resulted in essentially 100% occupancy for all atoms except for Sb(1), which is partially occupied at 92(1)% and whose displacement parameter is now similar to the others. For simplicity, we retain the formulation "Co_3Ge_2Sb" in referring to this structure. The atomic positions were standardized with the program STRUCTURE TIDY (20). The final cycle of least-squares refinement on F_o^2 of 27 variables (including anisotropic displacement parameters and an isotropic extinction parameter) and 513 averaged reflections (including those having $F_o^2 < 0$) converged to residuals of $R_w(F_o^2)$ of 0.094 and $R(F)$ (for $F_o^2 > 2\sigma(F_o^2)$) of 0.039. The final difference electron density map shows no features with a height greater than 2% that of an Sb atom. Final values of the positional and displacement parameters are given in Table 2, anisotropic displacement parameters in Table S5, interatomic distances in Table 3, and angles in Table S6.[2] Final structure amplitudes are available from A.M.

Results and discussion

Description of the Co_3Ge_2Sb structure

A view of the structure of Co_3Ge_2Sb perpendicular to the *bc* plane is shown in Fig. 1. Although bonding interactions extend in all three dimensions, it is convenient to describe this intermetallic structure as a stacking of nets along the *c* axis, alternating in composition from Co to Ge, as shown in Fig. 2. Then, Sb_2 pairs are viewed as being stuffed into the open sites within the structure. At $z \approx$ ¼ and ¾, the Co(1) and Co(2) atoms form a ruffled 3636 (kagomé) net (Fig. 2*b*). At z = ½, the Ge(1) atoms form a 6^3 net, distorted to present six-membered Ge_6 rings (Fig. 2*a*). At z = 0, the Ge(2) atoms form a similar 6^3 net, but they segregate into short and long Ge–Ge pairwise interactions (Fig. 2*c*). If the kagomé nets are denoted by α and the 6^3 nets by **a**, Co_3Ge_2Sb is described as a four-layer structure, **aαaα**, in which a superstructure of the simpler α**a** stacking arises because of the slightly different arrangement of Ge atoms in the **a** nets. Slight displacement of the Sb atoms above or below the centres of each hexagon in the Co kagomé nets results in Sb_2 pairs that are twice as dense in the Ge(1) layer as in the Ge(2) layer.

The coordination around each atom may be examined. The Co(1) and Co(2) atoms reside in similar coordination environments with CN10. Each Co atom has four other Co neighbours at 2.5752(7)–2.5782(13) Å and two Sb neighbours at 2.5981(4)–2.6198(13) Å in the same plane, and four Ge neighbours at 2.4178(7)–2.4357(11) Å above or below the plane. These correspond to reasonable bonding distances, as may be compared to the Co—Co distances in elemental *hcp*-Co (2.497–2.507 Å) (21) or CoGe (2.47(2)–2.57(2) Å) (22), the Co—Sb distances in CoSb (2.59 Å) (23) or $CoSb_3$ (2.5287(3) Å) (24), and the Co—Ge distances in CoGe (2.38(2)–2.58(1) Å) (22), respectively. The Ge(1) and Ge(2) atoms are each coordinated in a trigonal prismatic fashion by triangles of Co atoms above and below. There is further coordination to neighbouring Ge atoms within the same plane. The Ge(1) atoms clustered into six-membered rings contain Ge–Ge interactions at 2.8185(11) Å; the inter-ring Ge—Ge distances of 3.276(2) Å are too long to be significant. The Ge(2) atoms are paired at a short distance of 2.717(2) Å, with longer distances occurring at 3.098(2) Å. These distances are longer than the full Ge—Ge bonds in the isolated

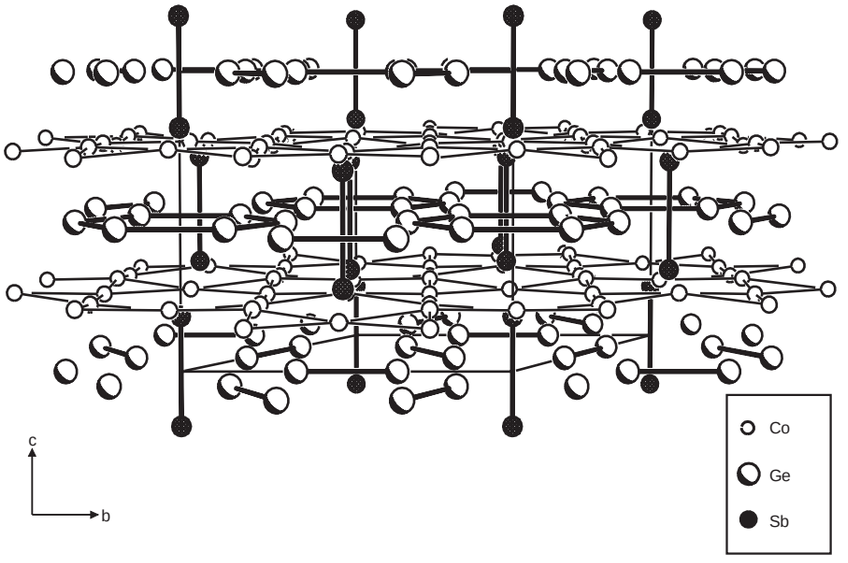
Fig. 1. View of Co_3Ge_2Sb perpendicular to the *bc* plane, showing the stacking of the nets. The small open circles are Co atoms, the partly-shaded circles are Ge atoms, and the filled circles are Sb atoms.



Ge_6 units found in Ge_6Ph_{12} (~2.46 Å) (25) and $Ba_{10}Ge_7O_3$ (2.475 Å) (26). However, longer Ge–Ge interactions indicative of weak bonding can also be found in CoGe (2.77(2) Å is the shortest such distance) and the Zintl ion Ge_9^{3-} (2.494(7)–3.324(8) Å) (27). If Pauling's bond-order relation ($D_n = D_1 - 0.71 \log n$) is applied and a single Ge—Ge bond is assumed to be 2.44 Å (28), a Ge–Ge distance of ~2.8 Å corresponds to a bond order of 0.31. Lastly, the Sb(1) and Sb(2) atoms are each arranged in Sb_2 pairs (2.829(2)–2.884(2) Å) in addition to being coordinated to a hexagon of Co atoms. These Sb–Sb distances indicate strong interactions, when compared to those found in elemental α-Sb (2.908 Å) (21) or in the Sb_4 squares in $CoSb_3$ (2.8540(6)–2.9760(6) Å) (24).

It is useful to search for structural relationships between Co_3Ge_2Sb and other known intermetallic structure types. While Co_3Ge_2Sb can be described as a distortion of the CoSn structure, it also serves as an intermediate structure that draws attention to the close relationship between the rare CoSn structure type (29) (with only 11 known examples (30)) and the much more prevalent $CaCu_5$ structure type (31) (with well over 200 examples (30)). As shown in Fig. 3, the CoSn, Co_3Ge_2Sb, and $CaCu_5$ structures are composed of alternating 3636 and 6^3 nets. They differ in the placement of the remaining large atom that must fit into the structure. In CoSn, the Sn(1) atoms reside at the centres of large hexagons within the 3636 Co nets (Fig. 3*a*). In $CaCu_5$, the Ca atoms reside at the centres of large hexagons within the 6^3 Cu(1) nets (Fig. 3*c*). Compared to Sn(1) atoms in CoSn, the Sb atoms in Co_3Ge_2Sb are displaced ~0.5 Å above or below the centres of the hexagons of the 3636 Co nets (Fig. 3*b*). Alternatively, Co_3Ge_2Sb can be viewed as a variant of the $CaCu_5$ structure, if some of the Ca atoms are replaced by Sb_2 *pairs*, leaving other Ca atoms to be replaced by vacancies. In both viewpoints, the resulting skewers of short–long Sb–Sb distances, which are aligned along the axes of concentric hexagons, are ordered in such a fashion so as to double the *c* parameter and triple the area $\vec{a} \cdot \vec{b}$.

Phase stability in $CoGe_xSb_{1-x}$

Reactions at 700°C with loading stoichiometries $CoGe_xSb_{1-x}$ ($0 < x < 1$) result in a mixture of ternary compounds, the dominant phase with the new Co_3Ge_2Sb-structure ($P6/mmm$) and a minor phase with the simpler NiAs-structure ($P6_3/mmc$). Crystals of the latter phase obtained as a side product in the preparation of Co_3Ge_2Sb crystals were confirmed by EDX measurements to contain all three elements, and the cell parameters from Weissenberg analysis are consistent with the NiAs structure. The powder pattern of this component matches with the NiAs structure in which Ge and Sb are presumed to be disordered over the anion sites. The cell parameters of these two phases, which will be referred to as the Co_3Ge_2Sb and NiAs phases, are plotted as a function of *x* in Fig. 4. Although the compositions cannot be directly related to the loading stoichiometries because the products are not single phase, some useful conclusions can still be drawn from these data.

The cell parameters of the Co_3Ge_2Sb phase (Fig. 4*a*) vary as *x* is decreased from 0.9 to 0.7, at which point limiting values are reached as suggested by the plateaus below $x = 0.7$. This implies that "$CoGe_{0.7}Sb_{0.3}$" represents a limiting composition, which is consistent with that determined from the crystal structure, "Co_3Ge_2Sb." There is also evidence from the single-crystal data that the Co_3Ge_2Sb structure is subject to Sb deficiencies. If the reaction conditions do not supply sufficient Sb (e.g., at $x = 0.9$), the cell volume is smaller because of these vacancies. As more Sb becomes available, the contraction in *c* suggests that bonding is strengthened along the axes of the Sb_2 pairs, while the expansion in *a* suggests that the structure is spread apart within the Co and Ge nets.

The variation in the cell parameters of the minor NiAs phase is more difficult to interpret. Presumably this phase adopts whatever composition remains after the Co_3Ge_2Sb phase is accounted for. Starting with the binary CoSb, which adopts the NiAs structure, replacement of Sb with the smaller Ge atom should result in a reduction of cell volume. As Fig. 4*b* shows, while an abrupt decrease in cell vol-

Fig. 2. View down the *c* axis of Co_3Ge_2Sb showing the composition of the individual nets at (*a*) *z* = ½, (*b*) *z* = ¼, ¾, and (*c*) *z* = 0. The unit cell is outlined.

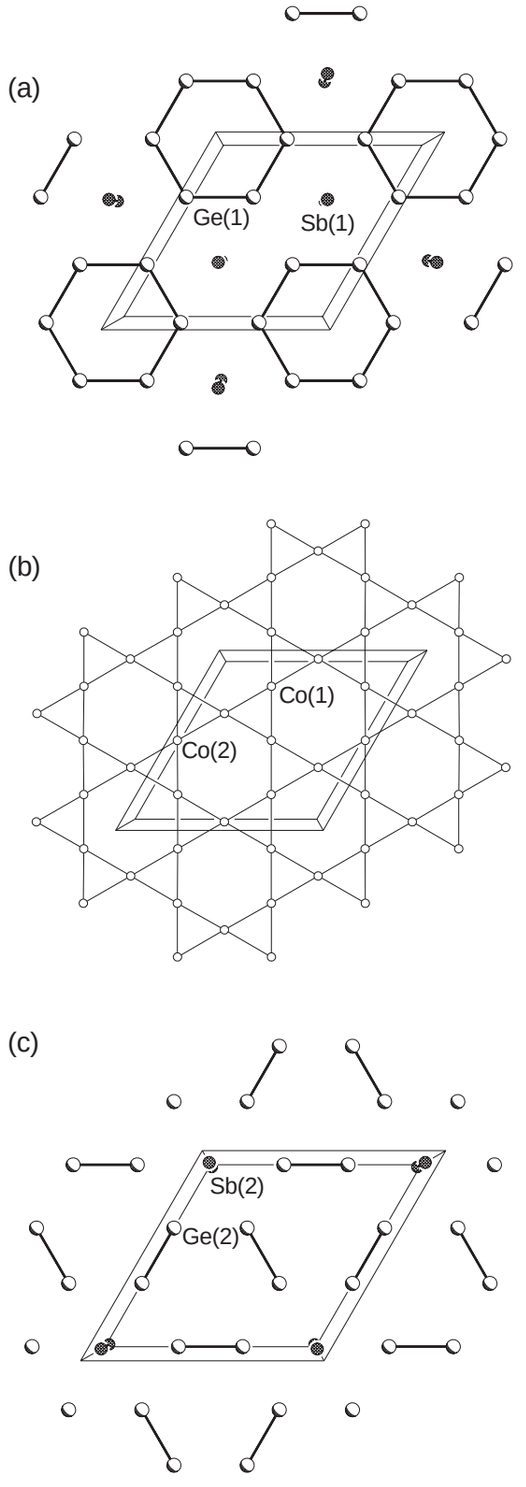

Fig. 3. Comparison of the closely related (*a*) CoSn, (*b*) Co_3Ge_2Sb, and (*c*) $CaCu_5$ structures, all in space group *P6/mmm*. The views are perpendicular to the (110) plane of the CoSn and $CaCu_5$ unit cells, and perpendicular to the (010) plane of the larger Co_3Ge_2Sb unit cell.

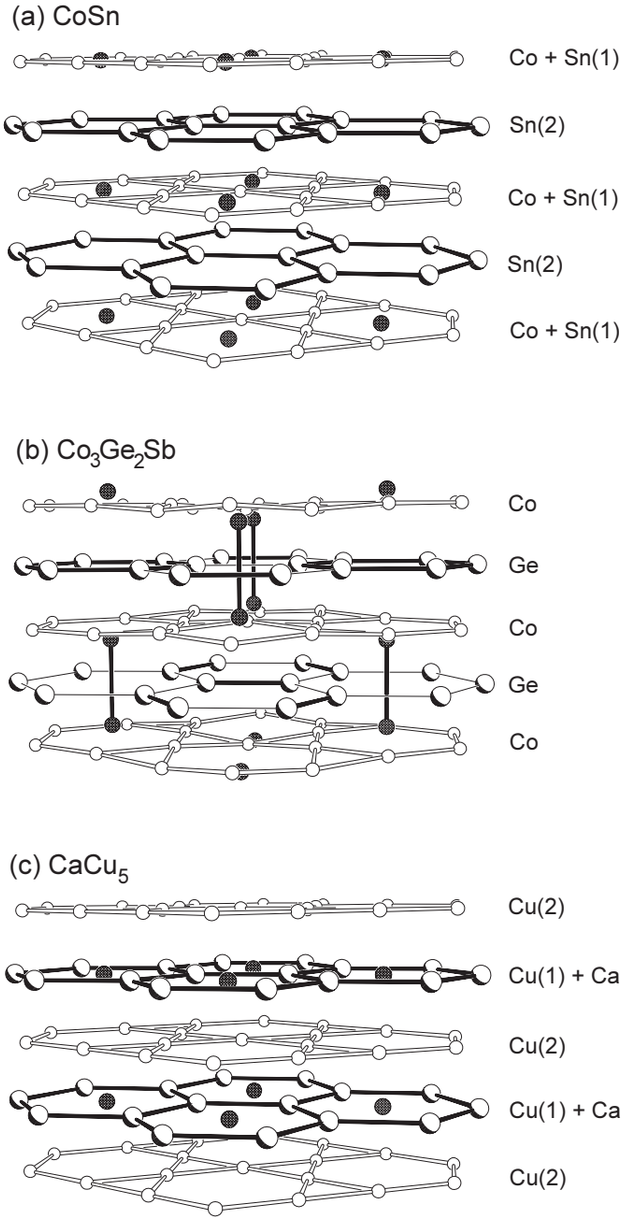

ume does occur initially as *x* is increased, the competition between the formation of the NiAs and Co_3Ge_2Sb phases complicates the interpretation until *x* reaches 0.6–0.7. Beyond this point, there is an excess of Ge that can now enter into the NiAs structure and disorders over the anion sites to cause a more pronounced cell volume contraction.

$CoGe_xP_{1-x}$ and $CoGe_xAs_{1-x}$

Reactions at 700°C with loading stoichiometries in the range $0 < x < 0.8$ result in a single phase whose powder pattern is consistent with the orthorhombic MnP structure

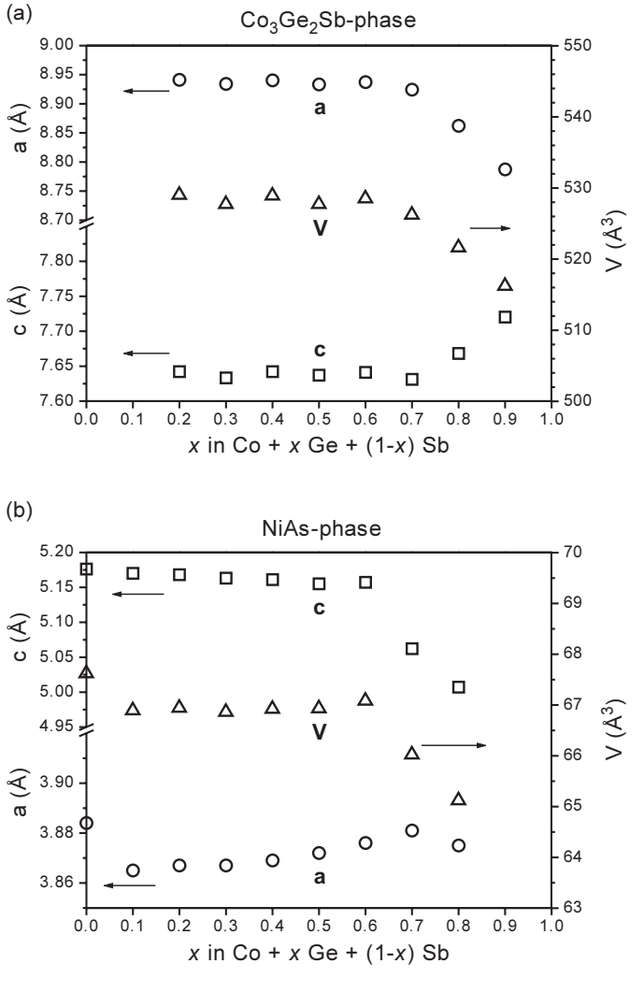
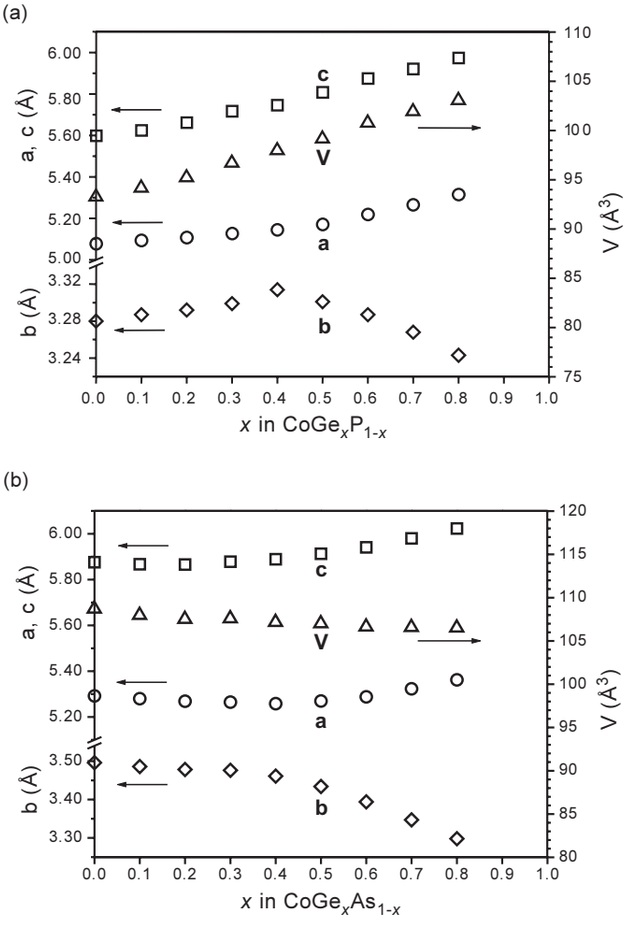
Fig. 4. Plots of cell parameters of phases with (*a*) the Co_3Ge_2Sb structure ($P6/mmm$) and (*b*) the NiAs structure ($P6_3/mmc$) obtained as products from reactions Co + *x* Ge + (1–*x*) Sb ($0 < x < 1$). The values of *x* merely indicate the loading stoichiometry in the reactions and cannot be directly related to the composition of these phases.



(*Pnma*) in which the germanium and pnicogen atoms are disordered over the anion sites. The cell parameters are plotted as a function of *x* in Fig. 5. The MnP structure is a distortion of the NiAs structure, in which zigzag chains of metal atoms are aligned along the *a* direction, and similar chains of nonmetal atoms are aligned along the *b* direction (1). (The *c* direction is a less useful indicator because both types of zigzag chains have components along it.) Figure 5*a* shows that the cell volume in $CoGe_xP_{1-x}$ increases monotonically as more of the larger Ge atoms are substituted for the P atoms in CoP. This occurs in conjunction with an initial weakening of both the metal–metal bonds and anion–anion bonds, up to $x = 0.4$, at which point the anion–anion bonds actually strengthen. In contrast, the variation in cell parameters in $CoGe_xAs_{1-x}$ is generally less pronounced given the more similar size of Ge and As atoms. Figure 5*b*

Fig. 5. Plots of cell parameters of ternary (*a*) $CoGe_xP_{1-x}$ and (*b*) $CoGe_xAs_{1-x}$ phases with the MnP structure (*Pnma*) obtained from reactions Co + *x* Ge + (1–*x*) *Pn* ($0 < x < 1$). The products are single-phase, so the loading stoichiometry can be directly related to their composition.



shows that the cell volume in $CoGe_xAs_{1-x}$ decreases slightly as more Ge is substituted for As in CoAs. This contraction is dominated by the strengthening of the anion–anion bonds along the *b* direction, at the expense of metal–metal bonding along the *a* direction. These variations are probably controlled to a greater extent by size and orbital differences than by electron count.

Bonding

Several models have been developed to account for structural variations in the transition metal monopnictides M*Pn* (or mixed-metal solid solutions thereof), which commonly take on the related NiAs, MnP, or NiP structures (1, 3, 11–13, 32, 33). Partial substitution of the pnicogen *Pn* with another nonmetal introduces changes that are more drastic than would be possible in the mixed-metal systems, so it is of interest to see if the same bonding models are applicable.

In the most general case, Mooser–Pearson plots show regions of phase stability as a function of the average principal quantum number of the valence shell, $\bar{n}$, and the difference in electronegativities of cation and anion, $\Delta\chi$ (32, 33). The

© 1998 NRC Canada

binary pnictides CoP ($\bar{n}$ = 3.5, $\Delta\chi$ = 0.4), CoAs ($\bar{n}$ = 4.0, $\Delta\chi$ = 0.3), and CoSb ($\bar{n}$ = 4.5, $\Delta\chi$ = 0.1) segregate clearly into the MnP region for the first two and the NiAs region for the last. Substitution of Ge for P or As has as its main effect a reduction in the average electronegativity difference, $\Delta\chi$, placing all members of the $CoGe_xP_{1-x}$ and $CoGe_xAs_{1-x}$ ($0 < x < 0.8$) series still within the MnP region. In contrast, substitution of Ge for Sb reduces $\bar{n}$ in the $CoGe_xSb_{1-x}$ system, which straddles the boundary between the MnP and NiAs structural regions. With its high symmetry and high coordination for all atoms (nondirectional bonding), the NiAs structure is typically adopted by many intermetallic compounds such as CoSb where the electronegativity difference is low. Rather than undergoing a simple distortion of the NiAs structure to form the MnP structure, with its zigzag chains of metal–metal and nonmetal–nonmetal bonds, the $CoGe_xSb_{1-x}$ system responds instead by going to a different structure, that of Co_3Ge_2Sb, in which anion *pairs* (Sb–Sb and Ge–Ge) form.

Alternatively, it has been noted that the transition between the NiAs, MnP, and NiP structures correlates with electron count, the MnP structure being stable in the range from 10 or 11 to 14 valence electrons per formula unit (3, 13). All members of the $CoGe_xP_{1-x}$ and $CoGe_xAs_{1-x}$ ($0 < x < 0.8$) systems fall within this range (13.2–14 e^-), consistent with their adopting the MnP structure. For the antimonides, this rule no longer applies (binary metal antimonides invariably adopt the NiAs structure (13, 32)), probably because the lower electronegativity differences make them less prone to the distortions that accompany the formation of the MnP structure. One would predict, therefore, that $FeGe_xP_{1-x}$ and $FeGe_xAs_{1-x}$ (12–13 e^-) should adopt the MnP structure, while $NiGe_xP_{1-x}$ and $NiGe_xAs_{1-x}$ (14–15 e^-) will not, and we have evidence for both. Equally, "Fe_3Ge_2Sb" is a compound worth targeting.

On a firmer basis, band structure calculations show that the occupation of metal–metal bonding levels favours the MnP structure at precisely the electron counts mentioned above (13), and this should apply to $CoGe_xP_{1-x}$ and $CoGe_xAs_{1-x}$ as well. However, Co_3Ge_2Sb presents an unrelated structure, and a calculation comparing the CoSn and Co_3Ge_2Sb is a more natural one to perform that may provide insight into the different kinds of distortion that occur here. Although size effects introduced by substitution of the larger Sb atom cannot be discounted, the displacement of Sb atoms to form pairs indicates that Sb—Sb bonding is an important component of the stability of this structure. Finally, given that kagomé nets in Co_3Ge_2Sb are a feature that has been associated with magnetically frustrated spin systems (34, 35), we anticipate interesting magnetic properties for this compound.

Engineering of magnetic properties using ultrathin metallic structures prepared by Molecular Beam Epitaxy

B. Heinrich, M. Kowalewski, and J.F. Cochran

Abstract: The interface magnetic energy in fcc Cu/Co/Cu(001) and Pd/Co/Pd(001) and the interlayer exchange coupling in bcc Fe/Cu/Fe(001) will be discussed and compared to recent theoretical models. The effect of interface magnetostriction and interface magnetic anisotropy will be described using a model proposed by Victora and MacClaren. The Victora–MacLaren theory of magnetic anisotropies is based on a generalized Néel pair interaction model that allows one to express the total interface energy in terms of the interface anisotropy and interface magnetoelastic contributions. It will be argued that the change in the sign of the interface anisotropy K_s as a result of replacing Cu atoms by Pd atoms is caused primarily by the enhanced role of the spin-orbit interaction in the Co–Pd pair interaction and in the tendency of Pd to acquire a significant magnetic moment in the proximity of ferromagnetic atoms. It will be shown that the interface lattice separations play an important role and the balance between these two magnetoelastic terms determines the total magnetoelastic contribution to the interface energy. The magnetoelastic interface contributions to K_s are +0.08 ergs/cm^2 and +0.17 ergs/cm^2 for the fcc Cu/Co/Cu(001) and Pd/Co/Pd(001) structures, respectively. The interlayer exchange coupling has been investigated in bcc trilayer structures Fe/Cu/X_cCu_{1-c}/Cu/Fe where X_cCu_{1-c} represents an alloyed atomic layer with X = Fe, Cr, Ag. The purpose of these studies was to determine the effect of foreign atoms inside a nonmagnetic spacer on the direct interlayer exchange coupling between the outside Fe layers mediated by the valence electrons of the Cu spacer. The experimental results will be compared with recent first principles calculations using the Layer Korringa–Kohn–Rostoker (LKKR) method. It will be shown that the local electron potential of the foreign atoms affects the spin transport across the spacer and is chiefly responsible for the observed behavior of the interlayer exchange coupling in Fe/Cu/X_cCu_{1-c}/Cu/Fe. The interlayer exchange coupling depends very strongly on the magnetic state of the foreign atoms within the spacer. For foreign atoms with no long-range ferromagnetic order the exchange coupling is mainly affected by the 3*d* valence band electrons. Foreign atoms that are isoelectronic with the spacer atoms modify the strength of the exchange coupling only due to lattice relaxations that are associated with their atomic size.

Key words: ultrathin metallic magnetic films, magnetic anisotropy, exchange interaction, Molecular Beam Epitaxy.

Résumé : On discute de l'énergie magnétique interfaciale dans le Cu/Co/Cu(001) et le Pd/Co/Pd(001) ainsi que le couplage d'échange intercouche dans le Fe/Cu(Fe(001) et on les compare aux valeurs obtenues à l'aide de modèles théoriques récents. On décrit l'effet de la magnétostriction interfaciale et de l'anisotropie magnétique interfaciale à l'aide d'un modèle proposé par Victora et MacClaren. La théorie des anisotropies magnétiques de Victora–MacClaren est basée sur un modèle généralisée de l'interaction de paires de Néel qui permet d'exprimer l'énergie interfaciale totale en termes de l'anisotropie interfaciale et de contributions magnétolastiques interfaciales. On suggère que le changement de signe de l'anisotropie d'interface K_s, qui accompagne le remplacement d'atomes de Cu par des atomes de Pd, est provoqué principalement par une augmentation du rôle de l'interaction spin-orbite dans l'interaction de la paire Co–Pd et par la tendance du Pd d'acquérir un moment magnétique significatif lorsqu'ils sont à proximité d'atomes ferromagnétiques. On démontre que les séparations dans l'interface du réseau jouent un rôle important et que la balance entre ces deux termes magnétolastiques détermine la contribution magnétolastique totale à l'énergie interfaciale. Les contributions magnétolastiques interfaciales à la valeur K_s sont de +0,08 ergs/cm^2 et +0,17 ergs/cm^2 respectivement pour les structures de Cu/Co/Cu(001) et Pd/Co/Pd(001). On a étudié le couplage d'échange intercouche dans les structures à trois couches Fe/Cu/X_cCu_{1-c} /Cu/Fe dans lesquelles X_cCu_{1-c} correspond à une couche atomique d'alliage avec X = Fe, Cr et Ag. Le but de ces études était de déterminer l'effet d'atomes étrangers dans un espaceur non magnétique sur couplage d'échange intercouche direct entre des couches de Fe extérieures facilité par les électrons de valence du Cu intercalé. On compare les résultats expérimentaux avec des calculs récents basés sur des principes fondamentaux en utilisant la méthode de la couche de Korringa–Kohn–Rostoker (LKKR). On

démontre que le potentiel de l'électron local des atomes étrangers affecte le transport de spin à travers l'atome intercalé et qu'il est le principal responsable du comportement observé pour le couplage d'échange intercouche dans le $Fe/Cu/X_cCu_{1-c}/Cu/Fe$. Le couplage d'échange intercouche dépend très fortement de l'état magnétique des atomes étrangers présents dans l'espaceur. Pour des atomes étrangers ne possédant pas d'ordre ferromagnétique à longue distance, le couplage s'effectue principalement par les électrons de la bande de valence 3*d*. Les atomes étrangers qui sont isoélectroniques avec les atomes intercalés ne modifient la force du couplage d'échange que par des relaxations du réseau associées à leur taille atomique.

Mots clés : films magnétiques métalliques ultraminces, anisotropie magnétique, interaction d'échange, épitaxie du faisceau moléculaire.

Introduction

Ultrathin magnetic metallic films have been intensely investigated and have resulted in a wide range of exciting studies that are attractive to scientists working on basic aspects of low dimensional systems and to materials scientists interested in nanostructures and nanostructure devices. The applied aspects of magnetic metallic ultrathin structures have been pursued in parallel and have provided needed inspiration and excitement. The success of this field has been based on the ability to create new structures in which the interfaces play a crucial role. In-plane lattice matching of an epitaxial layer to the substrate template allows one, for the correct growth conditions, to create atomic structures having very sharp interfaces. The magnetic properties of interface atoms are often very different from those in the bulk. Ultrathin films behave like giant magnetic molecules characterized by novel magnetic properties: these novel magnetic properties depend upon the presence of a large fraction of interface atoms. Three major phenomena have strongly affected progress in the development of new magnetic materials based on ultrathin metallic structures: (*a*) interface magnetic anisotropies; (*b*) interlayer exchange coupling; and (*c*) magneto-electron transport. The ability to admix interface and bulk magnetic properties allows one to engineer new materials whose properties are different from standard magnetic materials. The individual magnetic atoms are replaced by ultrathin films that act as giant magnetic molecules having unique magnetic properties, and the magnetic exchange coupling between layers can be controlled by nonmagnetic interlayers separating the ultrathin magnetic films. The magnetic interface and strain energies can be used to control the overall magnetic anisotropies, allowing one to obtain magnetic moments of the ultrathin films oriented either parallel or perpendicular to the film surface. For example, metallic ferromagnetic iron films separated by suitable thicknesses of copper spacer layers can be used to produce an intrinsic antiferromagnet in which the magnetizations of successive iron layers are oriented antiparallel. One can go even further. Multilayers can be grown in which ferromagnetic thin films are separated by nonmagnetic spacer layers. By adjusting the thicknesses of the spacer layers, and by controlling the widths of the interface atomic terraces, one can adjust the angle between the magnetizations on adjacent magnetic films (giant magnetic molecules) to lie at any angle between 0° and 180°. Using atomic engineering one is able to create materials that do not have any equivalents occurring in natural form. Truly new magnetic materials can be manufactured that do not exist in nature and that can only be grown by these artificial means. Magnetoresistance (GMR) in spin valves, and tunneling magnetoresistance (TMR) have provided enormous opportunities in the development of a new generation of magnetic technologies that are based on nanoscale systems. The GMR and spin-valve effects have very quickly found their place in device applications, magnetic sensors, and spin-valve magnetic read and write memories (MRAM). Spin-polarized FET and hybrid ferromagnet–semiconductor nonvolatile gates have become a part of very active applied research programs and provide a solid basis for the future generation of nonvolatile magnetoelectronics.

The future success of this field will depend very strongly on our ability to improve our understanding of underlying physical concepts and on our capability to control the quality of interfaces. In this article we will describe our recent studies of the role of atomic interfaces on fundamental magnetic properties, interface magnetic energies, and exchange coupling.

Interface magnetic energy

Epitaxial structures are most often affected by lattice strains. The in-plane lattice spacing of the template is usually somewhat larger than that of the epitaxial overlayer grown on it. Typical examples are fcc Cu/Co/Cu(001) and Pd/Co/Pd(001) structures. Metastable fcc Co(001) structures have been grown on bulk Cu(001) substrates. LEED and Thermal-Energy Atomic Scattering studies by de Miguel et al. (1) have shown that for the first 10 ML the fcc Co structures grown on Cu(001) substrates are characterized by a $p(1\times1)$ symmetry with the cobalt lattice expanded in the plane of the surface. Detailed LEED investigations in combination with dynamical scattering calculations revealed a change in the average tetragonal distortion for films 3 ML and thinner (2). The vertical lattice compression in films more than 5 ML thick is more or less constant, and amounts to ~3%, corresponding to a ratio $c/a = 0.96$. A homogeneous and constant strain due to the lattice mismatch between Co(001) and Cu(001) is expected for samples between 5 and 10 ML, $e_{xx} = e_{yy} = e_{\|} = +0.019$ and a vertical contraction $e_{zz} = e_{\perp} = -0.025$. The measured strains in fcc Pd/Co/(001) structures having a Co thickness less than 10 ML are even bigger, $e_{\|} = +0.08$, $e_{\perp} = -0.096$ (3, 4) based on an unstrained fcc Co cubic primitive cell 3.545 Å on a side. We have used a coordinate system in which the *z*-axis is directed along the film normal.

The contribution to the volume anisotropy energy due to magnetoelastic energy can be estimated for a tetragonally distorted cubic crystal by means of the expression quoted by Chikazumi (5):

$$[1] \qquad E_{me} = B_1[e_{xx}(\alpha_1^2 - 1/3) + e_{yy}(\alpha_2^2 - 1/3) + e_{zz}(\alpha_3^2 - 1/3)]$$

where the e_{ii} are strain components and α_1, α_2, α_3 are direction cosines of the magnetization vector. But if $e_{xx} = e_{yy}$, and using $\alpha_1^2 + \alpha_2^2 = 1 - \alpha_3^2$, this expression can be written in the form (neglecting terms independent of magnetization direction)

$$[2] \qquad E_{me} = B_1(e_{zz} - e_{xx}) \cos^2(\vartheta)$$

where

$$[3] \qquad B_1 = -(3/2)\, \lambda_{100}(C_{11} - C_{12})$$

λ_{100} is the usual magnetostrictive coefficient for a cubic magnetic material (5), and ϑ is the angle of the saturation magnetization with respect to the surface normal.

The strains quoted by Navas et al. (2) for fcc Co grown on Cu(001) are a lateral expansion of 1.9% in the plane, corresponding to a ratio $e_{xx} / e_{zz} = -0.76$. The value of this ratio can be estimated from $e_{xx} / e_{zz} = (n_{100} - 1)/(2n_{100})$, where n_{100} is Poisson's ratio. Poisson's ratio is given by $n_{100} = C_{12}/(C_{11} + C_{12})$, where C_{11}, C_{12} are elastic constants. For fcc Co these constants are $C_{11} = 2.42 \times 10^{12}$ ergs/cm^3 and $C_{12} = 1.60 \times 10^{12}$ ergs/cm^3 (6) corresponding to $n_{100} = 0.40$. This value for Poisson's ratio gives $e_{xx} / e_{zz} = -0.75$, in good agreement with the observed ratio of in-plane strain to vertical strain. This agreement emphasizes the fact that linear magnetoelastic theory can be profitably applied to ultrathin structures that exhibit large lattice distortions. We have used the observed strains, along with the observed room temperature uniaxial anisotropy constant, $K_u = -10.8 \times 10^6$ ergs/cm^3 (7), to estimate the magnetostrictive constant, λ_{100}, for fcc Co from eqs.[2] and [3]: the negative sign for K_u corresponds to an easy plane. One obtains $B_1 = -2.45 \times 10^8$ ergs/cm^3 and $\lambda_{100} = 2 \times 10^{-4}$. The magnetostrictive constant deduced from measurements on fcc Co rich Co/Pd alloys is $\lambda_{100} = 1.3 \times 10^{-4}$ (8). The value of the magnetostrictive constant that is required to explain the observed bulk uniaxial anisotropy for Co(001) grown on Cu(001) is approximately 50% larger than that suggested by the alloy data.

Victora and MacClaren (9, 10) have shown that the interface energies in fcc lattices can be very well represented by a nearest neighbour pair Néel interaction model (11). The difference between their model and the original Néel idea of pair interactions (11) is that the pair interaction between magnetic and nonmagnetic atoms is included as an independent parameter. For simplicity, they also neglect any dependence of the pair interaction parameters L_{f-f}, L_{f-n} on the nearest neighbour distance. The effective pair interaction between magnetic moments can be determined by comparing the Néel uniaxial strain anisotropy with that obtained from electronic structure calculations for the interface orientation(001). The pair interaction between magnetic and nonmagnetic atoms can be obtained by fitting the Néel–Victora expression to the fcc(001) interface energy obtained using a first principles electronic structure calculation. This approach was applied to Pd/Co superlattices (9, 10) and yielded 0.67, 0.61, and 0.56 ergs/cm^2 (energies per one interface) for the [111], [011], and [001] oriented interfaces, in agreement with the experimental results obtained by Engel et al. (4). The calculations made using an unstrained structure having an (001) interface resulted in 0.4 ergs/cm^2, showing that the strain makes an important contribution to the strength of the interface energies.

It is interesting to compare the pair interaction coefficients for the Cu/Co/Cu(001) and Pd/Co/Pd(001) structures. The pair interaction can be described by simple uniaxial terms

$$[4] \qquad -L_{f-f} \cos^2(\theta),\ -L_{f-n} \cos^2(\theta)$$

where L_{f-f} and L_{f-n} describe the pair interaction coefficient between ferromagnetic–ferromagnetic atom pairs and ferromagnetic–nonferromagnetic atom pairs, and θ is the angle between the local magnetic moments and the bond direction. For the (001) orientation the uniaxial bulk anisotropy energy is given by (10)

$$[5] \qquad E_V = -[L_{f-f}(6\alpha_{f-f}^2 - 3)/V_{atom}] \cdot \cos^2(\vartheta)$$

and the surface anisotropy energy is given by

$$[6] \qquad E_S = -([2L_{f-n}(3\alpha_{f-n}^2 - 1) - L_{f-f}(3\alpha_{f-f}^2 - 1)]/S_{atom}) \cdot \cos^2(\vartheta)$$

where α_{f-f} and α_{f-n} are the cosines of the angles between the lines joining nearest neighbours and the normal to the surface, the *z*-direction. V_{atom} is the atomic volume and S_{atom} is the surface area per atom at the interface.

The above expressions for magnetic anisotropies use a minimum number of free parameters: only the two pair interaction energies L_{f-f}, L_{f-n}. Structural information is contained in the two parameters α_{f-f} and α_{f-n}. The structural information is usually obtained from X-ray diffraction studies. The use of only two structural parameters represents the simplest possible case of a constant lattice strain independent of the sample thickness. The Co/Cu(001) and Co/Pd(001) structures satisfy this requirement over the thickness range from 5 to 10 ML, and therefore one is able to calculate in a simple manner the contributions to the interface and bulk magnetic energies. The measured lattice strains give $\alpha_{f-f} = 0.691$ and $\alpha_{f-f} = 0.642$ for the Cu/Co/Cu(001) ($e_{\parallel} = +0.019$, $e_{\perp} = -0.025$ (2)) and Pd/Co/Pd(001) ($e_{\parallel} = +0.08$, $e_{\perp} = -0.096$ (3, 4)) structures, respectively. The measured values of the bulk anisotropies, K_u(Co/Cu) = -10.8×10^6 ergs/cm^3 (7), and K_u(Co/Pd) = -3.2×10^7 ergs/cm^3 (4) together with eq. [5] allow one to calculate the pair interaction coefficients. For an unstrained fcc Co lattice parameter of 3.545 Å the results are $L_{f-f} = 9.00 \times 10^{-16}$ ergs for Cu/Co/Cu(001), and $L_{f-f} = 7.12 \times 10^{-16}$ ergs for Pd/Co/Pd(001). These pair interaction coefficients are positive, which implies that the spin-orbit interaction in Co systems prefers to orient the magnetic moments along the nearest neighbour bond direction. The strength of the pair interaction is 20% stronger for the Co–Co pair bond in the Co/Cu system than for the Co–Co pair bond in the Co/Pd system. The difference in the Co–Co pair interaction parameter for the Co/Cu and the Co/Pd systems is a clear

© 1998 NRC Canada

indication that the Victora–MacLaren model is oversimplified. Probably one should take into account the dependence of the pair interaction strength on the nearest neighbour (nn) distance (11). In a strained lattice the in-plane and out-of-plane nn distances are different. For example, in the case of Co/Cu the in-plane nn distance is 2.554 Å, whereas the out-of-plane nn distance is 2.500 Å. The equivalent distances for Co/Pd are 2.708 and 2.497 Å. The original Néel theory would ascribe a different pair interaction parameter, L_{f-f}, to in-plane and out-of-plane nearest neighbours. This would, of course, complicate the model by the introduction of a new parameter, namely, dL_{f-f}/dr.

In the limit of small strains one can write

$$[7] \qquad \alpha^2_{f-f} = (1/2)[1 + e^f_\perp - e^f_\parallel]$$

Substitution of eq. [7] into eq. [5] leads to an expression similar in form to eq. [2] with $B_1 = -3L_{f-f} / V_{atom}$. Using the above values of L_{f-f} leads to B_1(Co/Cu) = -2.40×10^8 ergs/cm^3 and B_1(Co/Pd) = -1.82×10^8 ergs/cm^3. Substituting these values for B_1 into eq. [3], and using the elastic parameters for Co, $C_{11} = 2.42 \times 10^{12}$ ergs/cm^3, $C_{12} = 1.6 \times 10^{12}$ ergs/cm^3, leads to $\lambda_{100} = 2.0 \times 10^{-4}$ for the Cu/Co/Cu(001) system and $\lambda_{100} = 1.5 \times 10^{-4}$ for the Pd/Co/Pd(001) system. These values are reasonably close to the experimentally measured value, $\lambda_{100} = 1.3 \times 10^{-4}$, for fcc Co rich Co–Pd alloys (8). It is noteworthy that the λ_{100} value calculated for the Co/Pd system is closer to the experimental value $\lambda_{100} = 1.3 \times 10^{-4}$ than that calculated for the Co/Cu system even though the tetragonal distortion for the Co/Pd system ($c/a = 0.837$) is larger than that for the Co/Cu system ($c/a = 0.957$). It is likely that the introduction of the Néel parameter dL_{f-f}/dr would produce a larger correction to λ_{100} for Co/Pd than to λ_{100} for Co/Cu because the difference between out-of-plane and in-plane nn distances is greater for Co/Pd than for Co/Cu. This correction would therefore be in the wrong direction to bring the calculated values for λ_{100} into agreement with experiment. One must conclude that the pair interaction parameter L_{f-f} must be a more complex function of the electronic band structure than a simple dependence on the inter-atomic separation.

Schick et al. (12) proposed that in eq. [3] the elastic constant parameter $C_{11} - C_{12}$ should be replaced by C_{11}, because the lateral spacing of the Cu(001) lattice is clamped by the Cu spacer. However, in this case one would get values of λ_{100} considerably smaller than that determined from Co rich alloys. Probably the Cu clamping is not completely rigid and the small variations in the lateral lattice spacing required by magnetostriction are permitted.

The strength of L_{f-n} can be estimated using eq. [6]. One should point out that the surface anisotropy at the fcc (001) interface is non-zero even for $L_{f-n} = 0$. In fact, since $(3\alpha^2_{f-f} - 1)$ is positive in general, formula [6] shows that the contribution of the L_{f-f} (>0) parameter to the interface anisotropy energy is positive (leading to an easy magnetic plane, $K_s < 0$). It is the strength of the parameter L_{f-n} that decides the sign of the overall surface anisotropy. In most cases the parameter α_{f-n} is not known because one does not have available an experimental measurement of the separation between the interface magnetic and nonmagnetic layers. However, one can proceed by making the reasonable assumption that the interface spacing is given by the average of the unstrained lattice spacings of the two adjacent metals. For example, in the case of the Fe(001)/Pd system the spacing between the interface Fe and Pd layers has been measured and the result is 1.77 ± 0.1 Å (13). The layer spacings for unstrained Fe(001) and Pd(001) films are 1.433 and 1.945 Å. These give an average spacing of 1.69 Å, a value in substantial agreement with the measured interface spacing. Applying this idea to the Co/Cu system, for which the (001) interlayer spacings in the unstrained metals are 1.773 Å for fcc Co and 1.808 Å for Cu, one obtains an interface spacing 1.790 Å. The in-plane lattice spacing for the strained Co is 3.612 Å and the area per atom is $S_{atom} = 6.52 \times 10^{-16}$ cm^2. A little applied geometry gives the result $\alpha_{f-n} = 0.704$. The uniaxial interface anisotropy energy for the Co(001)/Cu system is $E_s = 0.26 \cos^2(\vartheta)$ (7) at room temperature: a comparison of this expression with eq. [6], using L_{f-f}(Co–Cu) = 9.00×10^{-16} ergs, $\alpha_{f-f} = 0.691$, and the values for α_{f-n} and S_{atom} given above, results in L_{f-n}(Co–Cu) = 2.26×10^{-16}. A similar calculation yields L_{f-n}(Co–Pd) = 6.92×10^{-16} ergs for the Co/Pd system where we have used $K_s = +0.63$ ergs/cm^2, L_{f-f}(Co–Pd) = 7.12×10^{-16} ergs, $\alpha_{f-f} = 0.642$, and 1.773 Å for the unstrained Co layer spacing and 1.945 Å for the unstrained Pd layer spacing. The latter spacings result in an average of 1.859 Å, and when this is used together with a Co in-plane strained lattice spacing of 3.829 Å one finds $\alpha_{f-n} = 0.697$. A significantly higher value of the parameter L_{f-n}(Co–Pd) compared to that of L_{f-n}(Co–Cu) is reasonable because the spin-orbit interaction in Pd is much stronger than that in Cu, and the induced magnetic moments on the Pd interface atoms are expected to be much larger than those in Cu. Therefore the observed change in the sign of the interface anisotropy as a result of replacing Cu atoms by Pd atoms is caused primarily by the enhanced role of the spin-orbit interaction in the Co–Pd interaction and in the tendency of Pd to acquire a significant magnetic moment in the proximity of ferromagnetic atoms.

The splitting of the interface energy into surface magnetic anisotropy and surface magnetoelastic contributions was introduced by O'Handley and co-workers (14). They split the interface energy into two terms; the first term represented a true interface magnetic anisotropy, and the second term was proportional to the lattice strains and therefore could be labeled an interface magnetoelastic energy. Their argument was based on the original Néel model in which only the L_{f-f} and the α_{f-f} parameters were considered. The Néel model contains only one magnetic parameter, and therefore it yields interface magnetic anisotropy and bulk magnetoelastic contributions that are related. In this respect the model used by Victora and MacLaren is more flexible because it admits of interface anisotropy and bulk magnetoelastic contributions that are independent. The expressions [5] and [6] include all the physics that is required to describe the measured anisotropies.

The expression used by MacLaren and Victora for the interface energy can be split into two parts: one part belongs to the unstrained lattice and the other part is proportional to the interface lattice strains. For this purpose it is convenient to define

$$[8] \qquad e^n_\perp - e^n_\parallel = 2\alpha^2_{f-n} - 1$$

© 1998 NRC Canada

Inserting eqs. [7] and [8] into eq. [6] and using the definition $E_s = -K_s \cos^2(\vartheta)$, one finds

$$[9] \qquad K_s = \left(\frac{\left(L_{f\text{-}n} - \frac{L_{f\text{-}f}}{2} \right)}{S_{atom}} \right) + \left(\frac{3L_{f\text{-}n}(e_{\perp}^{n} - e_{\parallel}^{n})}{S_{atom}} \right) - \left(\frac{3L_{f\text{-}f}(e_{\perp}^{f} - e_{\parallel}^{f})}{2S_{atom}} \right)$$

where $e_{\perp}^{f}$, $e_{\parallel}^{f}$ represent the vertical and in-plane strains for the interior layers of the Co film, and $e_{\perp}^{n}$ and $e_{\parallel}^{n}$ are the strains associated with the positions of the interface nonmagnetic atoms. The first term in eq. [9] represents an intrinsic contribution to the interface magnetic anisotropy. The last two terms represent magnetoelastic contributions to the interface anisotropy. The third term is the surface magnetoelastic term introduced by the O'Handley group. As was shown above, the parameter L_{f-f} can be determined from the volume anisotropy, and the measured surface anisotropy can be used to determine the parameter L_{f-n}. Using the values L_{f-f}(Co–Cu) = 9.00×10^{-16} ergs and L_{f-n}(Co–Cu) = 2.26×10^{-16} ergs, the interface anisotropy parameter for Co/Cu is calculated to be –0.34 ergs/cm^2. The second term in eq. [9] makes a negative contribution of –0.009 ergs/cm^2. The last term in eq. [9] results in an interface magnetoelastic contribution of +0.091 ergs/cm^2, resulting in an overall interface magnetoelastic contribution of +0.08 ergs/cm^2. This means that the measured interface anisotropy, –0.26 ergs/cm^2, underestimates the intrinsic value of the interface crystalline anisotropy. The surface magnetoelastic contribution favours a magnetization directed along the specimen normal. The first principles calculations (12) predicted a magnetoelastic interface contribution of +0.56 ergs/cm^2.

A similar analysis can be carried out for the Pd/Co/Pd(001) system using L_{f-f}(Co–Pd) = 7.12×10^{-16} ergs and L_{f-n}(Co–Pd) = 6.92×10^{-16} ergs. The magnetoelastic interface contributions to K_s are 0.26 and –0.08 ergs/cm^2 for the Co–Co and Co–Pd strains, respectively. The resulting total interface magnetoelastic interface contribution is +0.17 ergs/cm^2. The interface magnetoelastic energy in Pd/Co/Pd(001) prefers to orient the magnetization along the surface normal, just as it does in Cu/Co/Cu(001). The total interface magnetocrystalline surface energy parameter for Pd/Co/Pd(001) is +0.46 ergs/cm^2, which is somewhat smaller than the total measured value K_s = +0.63 ergs/cm^2.

Summary

The Victora–MacLaren model allows one to express the total interface energy in terms of interface anisotropy and interface magnetoelastic contributions. The interpretation of Co(001) ultrathin film data using Cu and Pd as growth templates shows that the Victora–MacClaren model is more complete than that based on a simple Néel model. The observed change in the sign of the interface anisotropy K_s as a result of replacing Cu atoms by Pd atoms is caused primarily by the enhanced role of the spin-orbit interaction in the Co–Pd pair interaction and in the tendency of Pd to acquire a significant magnetic moment in the proximity of ferromagnetic atoms.

The interface magnetoelastic energy does not depend only on the Co interplanar spacing. The interface lattice separations play an important role and the balance between these two magnetoelastic terms determines the total magnetoelastic contribution to the interface energy. The magnetoelastic interface contributions to K_s are +0.08 ergs/cm^2 and +0.17 ergs/cm^2 for fcc Cu/Co/Cu(001) and Pd/Co/Pd(001) structures, respectively.

Studies of interlayer exchange coupling in Fe/Ce/Fe ultrathin heterostructures

Our group has extensively studied the exchange coupling in structures consisting of two ferromagnetic iron Fe(001) layers separated by a non-ferromagnetic spacer (15–23). Such trilayer structures are the simplest systems exhibiting interlayer exchange coupling between the two ferromagnetic layers. In particular, detailed studies of the thickness dependence of the interlayer exchange coupling were performed for a pure bcc Cu(001) spacer (15, 17). Recently, we have been investigating the effect on the direct coupling between two ferromagnetic iron layers of placing foreign atoms in the copper spacer layer. The idea behind these studies is to investigate the effect of heterogeneous spacers on the exchange coupling mediated by the valence Cu electrons. The following heterostructures have been studied:

(*i*) 5.7 Fe / 5 Cu / 1 Fe_cCu_{1-c} / 5 Cu / 10 Fe
(*ii*) 5.7 Fe / 5 Cu / 1 Cr_cCu_{1-c} / 5 Cu / 10 Fe
(*iii*) 8.7 Fe / 5 Cu / 1 Ag_cCu_{1-c} / 5 Cu / 16 Fe

where X_cCu_{1-c} indicates one atomic layer (AL) of Cu atoms alloyed with foreign atoms X (Fe, ^{57}Fe, Cr, or Ag) of concentration *c*. The spacer between Fe layers is 11 AL thick in series (*i*)–(*iii*). The total thickness of the spacer was chosen such that the exchange coupling has the strongest value for pure Cu (11 AL) and is relatively insensitive to small thickness variations (15, 17).

Growth and structure

The structures were grown on single-crystal Ag(001) substrates at room temperature using Molecular Beam Epitaxy (MBE). Each structure was covered by a 20 AL thick protective layer of Au(001) before exposing it to ambient conditions. The quality of growths was monitored by observing Reflection High Energy Electron Diffraction (RHEED) patterns and RHEED intensity oscillations of the specular spot at the first anti-Bragg condition. All deposited layers were terminated at the RHEED intensity maxima, see Fig. 1. The RHEED oscillation intensities of copper were not significantly affected by the deposition of the alloyed X_c Cu_{1-c} layers, see Fig. 1, which leads us to believe that the alloyed layer followed the quasi layer-by-layer growth mode of the Cu spacer (15, 17, 24). Trilayer bcc Fe/Cu/Fe(001) structures were one of the first systems in which a long-wavelength oscillation of the exchange coupling as a function of the spacer thickness was clearly established (15), see Fig. 2. The short-wavelength oscillations (~2 ML) are not visible in Fig. 2 due to the roughness at the Fe–Cu and Cu–Fe interfaces (all elements were grown at room temperature). The growth of 5 or more AL of bcc Fe(001) on a Ag(001) substrate at room temperature yielded an average

Fig. 1. RHEED intensity oscillations of the specular spot at the first anti-Bragg condition during the growth of the Cu spacer for sample 5.7Fe/5Cu/1$Cr_{0.45}Cu_{0.55}$/5Cu/10Fe. The arrow points to the growth of the alloyed layer. Note that the growth was terminated at the RHEED intensity maximum.

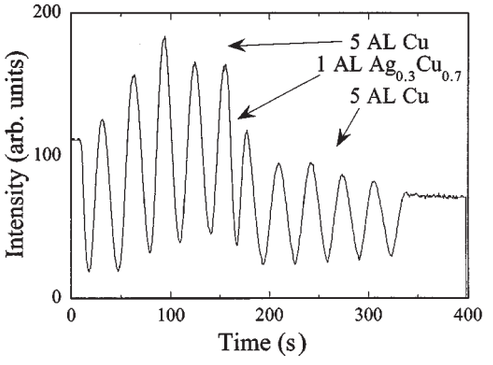

Fig. 2. Thickness dependence of the total exchange coupling, J_1–$2J_2$, through a pure Cu spacer. The Cu spacer thickness is measured in atomic layers (AL).

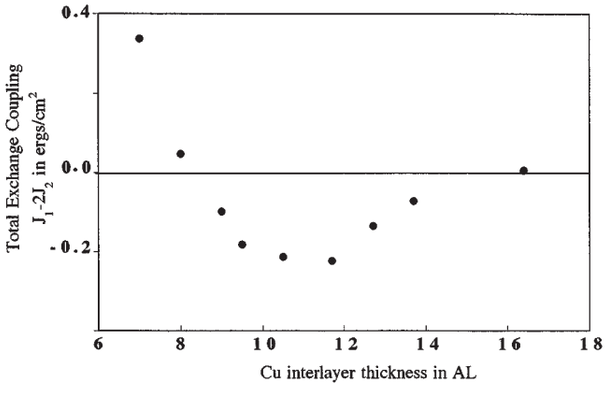

atomic terrace separation of approximately 50–60 Å (13, 17, 24). The terrace width can be increased by raising the substrate temperature during the growth of the last few atomic layers of Fe (17). In that case the short- wavelength oscillations start to be visible. However, the lack of short-wavelength oscillations was used to our advantage. We have tried to isolate the effect of placing different types of foreign atoms X within the Cu spacer. In samples having large atomic terraces, small changes in the growth conditions resulted in large variations of exchange coupling, making the systematic studies of heterogeneous spacers very difficult. It was important to eliminate unpredictable variations in the strength of the exchange coupling, and therefore all growths were performed at room temperature where the presence of short-wavelength oscillations was averaged out and the long-wavelength coupling was found to be very reproducible. The total spacer thickness of 11 AL provided a maximum antiferromagnetic coupling so that the interlayer exchange coupling was found to be relatively insensitive to small variations of spacer thickness (~0.2 ML), see Fig. 2.

The magnetic properties were measured using Ferromagnetic Resonance (FMR) (25), Magneto-Optical Kerr Effect (MOKE), and Brillouin Light Scattering (BLS) (26). The FMR measurements were carried out at temperatures of 77, 195, 273, and 373 K. BLS studies were performed at room temperature.

We found that the exchange coupling between ferromagnetic layers can be described by bilinear, J_1, and biquadratic, J_2, terms:

$$[10] \quad E = -J_1 \cos(\Theta) + J_2 \cos^2(\Theta)$$

where Θ is the angle between the magnetic moments of the two Fe layers, Fe_I and Fe_{II}. The biquadratic term is attributed to the interface roughness (16, 17, 27). The results of FMR, BLS, and MOKE at room temperature are in good agreement; the maximum variation in the strength of the exchange coupling was found to be within 20%. The FMR results are shown in Fig. 2. The magnetic anisotropies of the iron layers Fe_I and Fe_{II} were determined from the FMR absorption peak of each single Fe layer grown separately. The single and trilayer samples were grown on the same substrate using a shutter and appropriate rotations of the sample holder. Values of the total exchange coupling $J_{tot} = J_1 - 2J_2$ were obtained from the absorption FMR peak fields corresponding to acoustic and optical FMR modes, see refs. 15 and 25 for details. From the field dependence of the magnetic excitation frequencies measured by BLS, see Fig. 3, and the field positions in MOKE at which the Fe films are in the saturated and antiparallel states, see Fig. 4, values of bilinear, J_1, and biquadratic, J_2, exchange couplings were determined. The detailed analysis of MOKE and BLS measurements can be found in refs. 16, 17, and 26.

In Fig. 5 each graph shows the strength of J_{tot} as a function of concentration at four different temperatures for series (*i*)–(*iii*). Each temperature shows a similar pattern. As the concentration of the foreign atoms increases, the antiferromagnetic coupling is reduced from that of the reference, pure 11 AL Cu spacer. At lower concentrations (below 60%) Ag, Cr, and Fe atoms seem to affect the coupling in a similar manner. However, as the concentration of Ag and Cr atoms is increased the antiferromagnetic exchange coupling reaches a plateau, while in the case of Fe atoms the coupling becomes ferromagnetic (FM, $J_{tot} > 0$).

The 3*d* unfilled shells of Fe and Cr atoms can provide long-range magnetic order. In higher concentrations the magnetic moments of Fe atoms are most likely affected by some degree of ferromagnetic ordering. Since this ordering introduces a "quasi ferromagnetic layer" inside the Cu spacer, one expects an appreciable change in the exchange coupling. The magnetic behaviour of metallic Cr is different from that of Fe. The magnetic moments in metallic Cr are stabilized by the presence of a short-wavelength antiferromagnetic spin density wave in Cr (28). The Néel temperature of Cr in our samples is well below the temperature range of our measurements (29). Therefore the magnetic moments in Cr are oriented completely randomly and their direction rapidly fluctuates in time; they behave like "loose spins." Slonczewski showed (30) that loose spins can, in principle, introduce an additional exchange coupling that is absent in simple spacers having no magnetic moments. Loose spins get partly magnetized by the exchange field from the surrounding Fe layers and that in turn results in an additional energy, which depends on the orientation of the magnetic

Fig. 3. BLS peak frequencies as a function of applied magnetic field for the sample 5.7Fe/5Cu/$Cr_{0.45}Cu_{0.55}$/5Cu/10Fe. The integers represent the numbers of atomic layers. The upper and lower branches correspond to the acoustic and optical precessional modes. The solid lines represent theoretical fits using J_1 = –0.074 ergs/cm^2 and J_2 = 0.015 ergs/cm^2; $4\pi M_{eff}$ = 4.20 kOe, 13.55 kOe; $2K_1/M_s$ = 0.12 kOe, 0.30 kOe for the Fe layers 5.7 and 10 AL thick, respectively. The upper cusp corresponds to the field H_1 at which the magnetic moments start to turn away from the applied field; the lower cusp corresponds to the field H_2 at which the magnetic moments orient antiparallel.

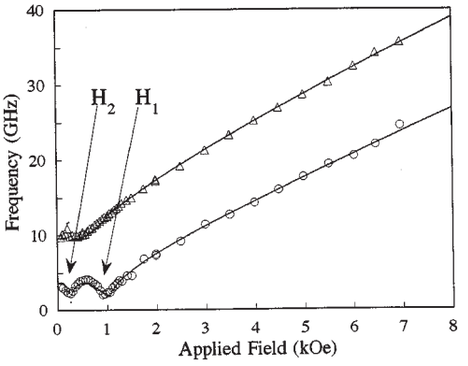

Fig. 4. The magnetization curve for the sample 8.7Fe/5Cu/$Ag_{0.30}Cu_{0.70}$/5Cu/16Fe obtained from MOKE measurements. The values J_1 = –0.172 ergs/cm^2 and J_2 = 0.015 ergs/cm^2 were obtained by fitting the positions of the critical fields H_1 (saturation state) and H_2 (antiparallel state) using $4\pi M_{eff}$ = 7.50 kOe, 16.55 kOe; $2K_1/M_s$ = 0.26 kOe, 0.40 kOe for the Fe layers 8.7 and 16 AL thick, respectively. Notice that as the field increases there is a well-defined jump at H_2 where the magnetic moments in both Fe layers start to deviate from their antiparallel orientation. This jump indicates an excellent homogeneity of the bilinear exchange coupling for this sample. The lack of a well-defined jump at H_1 is due to the presence of biquadratic exchange coupling.

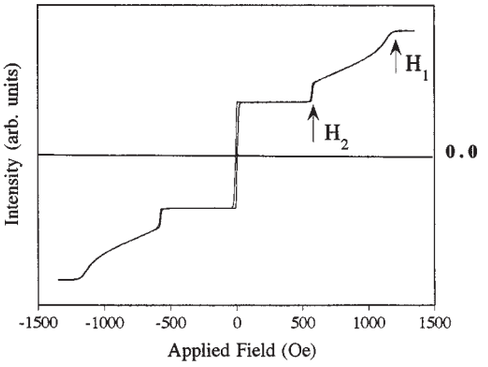

moments of the Fe layers and therefore contributes to the exchange coupling. The exchange coupling due to loose spins scales proportionally with paramagnetic susceptibility, which is inversely dependent on temperature, $1/T$. Mössbauer spectra show that the Fe foreign atoms in the low concentration limit behave definitely as loose spins (31), and yet the measured concentration and temperature dependence of the exchange coupling in series Ag_cCu_{1-c} and Cr_cCu_{1-c}, and Fe_cCu_{1-c} ($c < 0.6$), see Fig. 5, does not show any appreciably different behaviour. The difference is apparent only in a more pronounced decrease of the coupling with an increasing concentration of foreign atoms. The behavior of Ag atoms is different from that of Fe and Cr atoms. The Ag atoms are characterized by an *sp* valence band similar to that of Cu, while the Cr and Fe atoms are different from Cu and Ag due to their 3*d* valence electrons. The 3*d* unfilled states in Cr and Fe atoms perturb the electronic potential of the Cu spacer more strongly than the *sp* valence states of Ag atoms. The more pronounced decrease in the exchange coupling in the Cr_cCu_{1-c} and in the Fe_cCu_{1-c} series compared to that of the Ag_cCu_{1-c} series is most likely due to a stronger electronic perturbation of the Cu spacer for the Cr_cCu_{1-c} and the Fe_cCu_{1-c} series. In our view the contribution of loose spins to the interlayer exchange coupling as envisioned by the Slonczewski model is not observed in our samples. This conclusion is further enforced by calculations employing the loose spin model and using a reasonable estimate of the exchange coupling between the loose spins and the surrounding Fe layers. The estimate of the exchange coupling between loose spin and the surrounding Fe layers was obtained using the measured exchange coupling between Fe layers as a function of the Cu spacer thickness. The results of these calculations show that the contribution of loose spins leads to a small ferromagnetic coupling that increases with decreasing temperature as 1/T. $J_{ls}(300)$ = 0.01 and $J_{ls}(77)$ = 0.04 ergs/cm^2. These values are significantly smaller than those obtained from the FMR, MOKE, and BLS measurements. Consequently, it is the local electron potential of the foreign atoms that affects the spin transport across the spacer and is chiefly responsible for the observed behavior of the interlayer exchange coupling.

The change of the coupling from AF to FM at higher concentrations of Fe atoms is related to the magnetic state of the Fe atoms in the Cu spacer. In the sample 5.7Fe/5Cu/1^{57}Fe/5Cu/20Au, the Mössbauer studies showed a narrow Mössbauer doublet peak indicating that ^{57}Fe is in a paramagnetic state (31). However, the Mössbauer spectra in the sample 5.7Fe/5Cu/1^{57}Fe/5Cu/10Fe/20Au, with two iron layers Fe_I and Fe_{II}, showed that the foreign ^{57}Fe atoms were subjected to a non-zero hyperfine field. In this sample the Fe atoms in the alloyed layer were partially ferromagnetically ordered (31), and that ordering resulted in a ferromagnetic interlayer coupling. A relatively narrow Mössbauer doublet observed in the sample 5.7Fe/5Cu/$1^{57}Fe_{0.5}Cu_{0.5}$/5Cu/10 Fe indicated that no magnetic ordering was present, and therefore for Fe concentrations less than 60% the samples behaved like the ones that contained Cr atoms, see Fig. 5.

The MOKE and BLS room temperature measurements of bilinear and biquadratic exchange coupling showed that the decrease of the total coupling with an increasing concentration of foreign atoms is mainly due to the decrease of J_1. Furthermore, the measurement of bilinear coupling, J_1, and biquadratic coupling, J_2, by MOKE showed that the ratio J_1/J_2 was temperature independent as was observed in samples having pure Cu spacers (32).

Comparison with first principles calculations

Recently we performed first principles calculations of the interlayer exchange coupling for some of the above struc-

tures, to determine the theoretical trends in the exchange coupling due to replacing the central Cu atomic layer by an atomic layer of foreign atoms X. The first principles calculations were performed using the Layer Korringa–Kohn–Rostoker (LKKR) method. This work was carried out in cooperation with T.C. Schultess and W.H. Butler at the Oak Ridge National Laboratory using their LKKR computer codes (33). The theoretical thickness dependence of the exchange coupling between two semi-infinite Fe layers was calculated for pure Cu spacer thicknesses in the range of 1–16 AL. The effect of the foreign atoms X on the exchange coupling was investigated using a structure having a 9 AL Cu spacer as a reference sample.

Homogeneous spacer trilayers: bcc Fe/Cu/Fe(001)

The interlayer exchange coupling calculated as a function of the copper spacer thickness is shown in Fig. 6. The results were fit using two cosine functions of different amplitudes and a common $1/d^2$ thickness dependence:

$$[11] \quad \{A_1 \cos[(2\pi d/\lambda_1) - \phi_{10}] + A_2 \cos[(2\pi d/\lambda_2) - \phi_{20}]\}/d^2$$

where d is the thickness of the spacer in atomic layers (AL), A_i, ϕ_{i0}, and λ_i are the amplitude, phase, and period of oscillations (in AL), respectively, for the short- (i = 1) and the long- (i = 2) range oscillations. We used spacer thicknesses d >5 AL for which the above asymptotic formula is likely to be accurate (34). The values λ_1 = 2.1 ± 0.2 AL and λ_2 = 10.0 ± 1.0 AL found from the fit to eq. [11] are in good agreement with those predicted by Bruno for a pure bcc Cu(001) spacer using extremal spanning vectors along G–X, G, and M lines in the Fermi surface (35).

To include realistic variations of the spacer thickness due to interface roughness we simulated the interfacial roughness by averaging the coupling over several adjacent spacer thicknesses. It is reasonable to take the final thickness of the copper spacer to contain approximately 50% of the nominal thickness with some of the spacer being thinner and some thicker (17, 24). Therefore, we calculated the moving average of the earlier calculated points for a roughness confined to the three topmost layers, see Fig. 7. Comparison of the calculated results in Fig. 7 with the experimental points, Fig. 2, shows striking similarities in the behaviour of the coupling. However, there are also notable differences. The crossover from ferromagnetic to antiferromagnetic coupling occurs at ~6.5 AL in the theoretical calculation and at ~8 AL in the experimental data. Moreover, the maximum antiferromagnetic coupling in the theoretical calculation occurs at ~9 AL whereas in the experiment it occurs at ~10–11 AL. The 1–2 atomic layer shift between theory and experi-

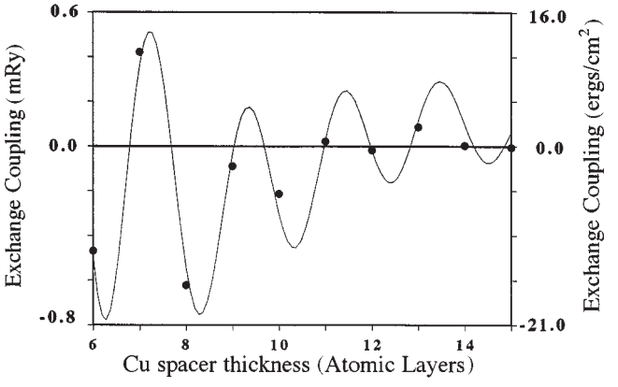
Fig. 6. Interlayer exchange coupling plotted as a function of Cu spacer thickness for atomically smooth interfaces. Our theoretically calculated points are fitted with the sum of two cosine functions of different amplitude and a common $1/d^2$ thickness dependence to determine the short- and long-period oscillations, see eq. [11] in the text. The short-period wavelength was found to be 2.1 ± 0.2 AL; the long-period wavelength was found to be 10.0 ± 1.0 AL.

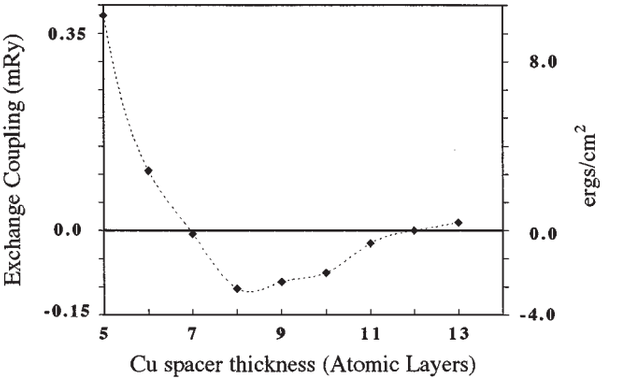


ment in both features is not surprising and can be attributed partly to the interface roughness and partly to the fact that LKKR calculations do not predict exact values for the oscillatory periods of the exchange coupling. It is also very likely that around each Fe–Cu interface up to one AL of Cu is effectively ferromagnetic and removed from the pure Cu spacer. A significant decrease in the measured coupling from that obtained from first principles calculations strongly suggests that mixed Fe–Cu interfaces also profoundly affect the strength of the coupling. Similar behaviour was observed in Fe/Cr/Fe(001) systems where interface alloying strongly reduces the strength of the interlayer coupling (22, 23).

Heterogeneous spacers: bcc Fe/Cu(4)X(1)Cu(4)/Fe(001)

The structure with pure 9 AL copper spacer was chosen as the reference sample to simplify this set of calculations. Atomically abrupt interfaces were used at both Fe–Cu and Cu–Fe interfaces as well as at the interfaces of the single foreign atomic layer X with the surrounding copper matrix. Foreign atoms of Fe, Cr, and Ag were used. Table 1 lists all the calculated values of the exchange coupling and magnetic moments of the relevant foreign atoms in the central spacer. The value of the exchange coupling for the pure 9 AL copper spacer is listed as the first entry in Table 1 for comparison. First, Fe, Cr, and Ag were placed in the unrelaxed Cu lattice and the exchange couplings calculated, see entries 2, 3, and 4, respectively, in Table 1. For Fe and Cr atoms each volume per atom in the lattice structures (and Wigner–Seitz radius) is nearly the same as that for Cu. However, the lattice constant of Ag is about 10% larger; therefore, the Cu lattice was allowed to relax in order to accommodate the Ag atoms. Silver atoms were assumed to maintain the in-plane lattice spacing of bcc Cu(001) and only the lattice spacing between the two Cu atomic layers next to silver was expanded to accommodate the correct volume per silver atom. The result of this calculation is shown as entry 5 in Table 1. The final (sixth) entry in Table 1 is the calculation of the exchange coupling for one atomic layer of Fe having fully disordered moments. The magnetic disorder was modeled by a disordered alloy consisting of equal amounts of Fe that have moments pointing in the + and – z directions, respectively. The disorder was treated within the coherent potential approximation (CPA).

Fig. 7. The calculated interlayer exchange coupling as a function of the Cu spacer thickness for simulated rough interfaces. The exchange coupling values in this graph were obtained by calculating a moving average of the couplings for pure Cu spacers having ideally smooth interfaces, Fig. 6. The interfacial roughness was simulated by averaging over values of the exchange coupling, J(N), for three adjacent pure Cu spacer thicknesses: $J_N = 0.25\ J(N-1) + 0.5J(N) + 0.25J(N+1)$, where J_N is the interlayer exchange coupling across a Cu spacer having simulated rough interfaces. The line through the points is a cubic spline fit to guide the eye. Notice that the short period oscillations are suppressed.



The results listed in Table 1 show that the foreign Fe atomic layer in the ordered magnetic state with the strongest average moment per atom affects the coupling the most. The magnetically ordered Cr atomic layer has an intermediate effect with a magnetic moment per atom an order of magnitude smaller, and Ag has the least effect with approximately zero magnetic moment per atom. The experimental Mössbauer studies of the Fe/Cu(5)/Fe(1)/Cu(5)/Fe sample indicated that the full atomic layer of Fe within the copper spacer is partially magnetically ordered (21, 31). Furthermore, similar studies of an Fe/Cu(5)/Fe(0.5)Cu(0.5)/Cu(5)/Fe sample showed that an atomic layer with 50% Fe and 50% Cu at the center of the copper spacer is magnetically disordered (21, 31). The first sample exhibited a strong ferromagnetic coupling whereas the second sample maintained antiferromagnetic coupling, similar to the homogeneous Cu spacer, but having approximately half the coupling strength. The theoretical calculation for the fully ordered and disordered Fe foreign layer, entries 2 and 6 in Table 1, confirm that the magnetic ordering of foreign atoms is the most significant factor affecting the sign and strength of the exchange coupling. A fully ordered Fe layer changes the coupling from AF to FM, similar to the behaviour observed for the partially ordered Fe atomic layer in the experiment. Additionally, the magnetically disordered model calculation for an iron atomic layer at the center of the spacer yields an antiferromagnetic coupling that is approximately half the value of the coupling across the pure Cu spacer; just this behaviour was observed experimentally for the magnetically

Table 1. Summary of results for heterogeneous Cu spacer. The interlayer exchange coupling and the magnetic moment per foreign atom for the heterogeneous spacer where the central atomic Cu layer was replaced by the atomic layer of foreign atoms of Fe, Cr, and Ag. The average magnetic moment per atom in the fully disordered Fe is zero.

Foreign atom	Exchange coupling (ergs/cm^2)	Magnetic moment (Bohr magnetons)
1. Pure Cu	–4.8	–0.004
2. Fully ordered Fe	32	2.55
3. Cr	13	0.25
4. Unrelaxed Ag	–4.6	–0.002
5. Relaxed Ag	1.9	–0.002
6. Fully disordered Fe	–2.1	±2.55

disordered iron layer, Fig. 5. These results indicate that the interlayer exchange coupling depends very strongly on the magnetic state of the atoms within the spacer. Obviously atoms within the spacer possessing some degree of magnetic ordering scatter the majority and minority valence electrons within the copper spacer in a manner that is different from that of disordered spins and this affects not only the value but also the sign of the exchange coupling. Following the Stiles (34) and Bruno (35) theories of interlayer exchange coupling, the spin asymmetry of the reflection coefficients for majority and minority spins in the quantum well of the spacer is the major variable in determining the sign and the magnitude of the coupling across homogeneous spacers. It is not surprising that placing magnetically ordered layers of atoms within the homogeneous spacer introduces further potential barriers for up and down spins of the valence electrons, thus affecting the spin reflection asymmetry and possibly even changing the sign of the coupling.

A less significant but nevertheless very visible effect on the coupling is the change of the width of the quantum well of the spacer when the lattice relaxations are included in the case of Ag, see entries 4 and 5 of Table 1. In the case of a Ag layer in an unrelaxed Cu lattice (entry 4 in Table 1) the exchange coupling was essentially the same as for pure Cu. This result is not particularly surprising since the valence band of Ag is similar to that of Cu. However, when the Cu spacer was allowed to relax around the plane of Ag atoms (entry 5 in Table 1) the coupling changed to weakly ferromagnetic. The mechanism by which the coupling is affected is now related to a change in the width of the quantum well that the Cu valence electrons are traversing.

The experimental results did not show a crossover to FM coupling for either Cr or for Ag foreign atoms deposited in the center of the Cu spacer. One has to keep in mind that the above first principles calculations were carried out for an ideal structure and for one foreign atomic layer. In these structures one should expect short-wavelength oscillations. One calculated point is certainly not enough to obtain the overall behaviour of the exchange coupling. However, one can argue that a smaller absolute value of the coupling in the Cu/Ag/Cu spacer than that in a pure Cu spacer indicates that the foreign Ag atoms weaken the overall coupling. This is in agreement with our observations. The antiferromagnetic coupling is much stronger in the Cu/Cr/Cu spacer than in Cu/Ag/Cu. However, the first principles calculations predict that the Cr atomic layer should be fully ferromagnetically ordered at $T = 0$ K. In our temperature range even a full Cr atomic layer possesses no long-range order, and therefore one should expect behaviour nearly like that of paramagnetic Fe. Indeed, the exchange coupling in the Cr_cCu_{1-c} series decreases in a manner similar to, but less than, that observed in the Fe_cCu_{1-c} series at a low concentration of Fe. The larger decrease in the coupling for the Fe_cCu_{1-c} series compared to that for the Cr_cCu_{1-c} series is due to the fact that the Cr atomic moment is smaller than the Fe atomic moment.

Summary

The strength of the exchange coupling through nonferromagnetic spacers can be controlled by the insertion of foreign atoms. The local electron potential of the foreign atoms affects the spin transport across the spacer and is chiefly responsible for the observed behaviour of the interlayer exchange coupling. The interlayer exchange coupling depends very strongly on the magnetic state of the foreign atoms within the spacer. Atoms within the spacer possessing some degree of magnetic ordering scatter the Cu majority valence electrons differently from the Cu minority valence electrons and this affects not only the value but also the sign of the exchange coupling. For foreign atoms having no long-range ferromagnetic order, the exchange coupling is mainly affected by the presence of 3*d* valence band electrons. However, the strength of this 3*d* band effect is significantly weaker than the effect of a long-range ferromagnetic order. Foreign atoms that have an atomic structure similar to that of the spacer atoms modify the strength of the exchange coupling only because of changes in the local atomic volume. Foreign atoms having the same atomic size as the spacer atoms do not affect the coupling.

Fundamentals of oxygen delignification. Part II. Functional group formation/elimination in residual kraft lignin

Faraj Asgari and Dimitris S. Argyropoulos

Abstract: The complex interaction of softwood residual kraft lignin with oxygen at elevated temperatures, pressures, and pH's was investigated by isolating and systematically oxidizing the lignin, as a function of time and temperature. The isolation of the oxidized lignin was carried out using a multistep procedure developed specifically to recover all species. Detailed quantitative ^{31}P NMR measurements provided, for the first time, three-dimensional plots describing the formation and (or) elimination of the various functional groups. Oxidative demethoxylation reactions were found to induce the formation of catechols, which are, most likely, reactive intermediates of the oxidation. The rate of carboxylic acid formation and guaiacyl phenol elimination was found to follow two distinct phases: a rapid initial phase followed by a slower phase. More specifically, the rate of carboxylic acid group formation was found to dramatically increase as the reaction temperature increased, analogous to the profiles obtained for the elimination of guaiacyl phenolic units. At reaction temperatures typical of conventional commercial oxygen delignification installations (80–100°C), only minor oxidation was found to occur within the lignin. At these temperatures, increasing the reaction time did not significantly aid the formation of carboxylic acid groups on lignin despite the idealized two-phase homogeneous conditions. The technological ramifications of these data imply that a three-phase oxygen delignification system, operating at temperatures below 100°C, causes only minor oxidative changes to the structure of the lignin in the fibre. It was also possible to isolate the effect of alkali and temperature on the structure of residual kraft lignin through experiments in which pressurized oxygen was replaced by nitrogen. These data revealed a concealed set of alkali-induced condensation and fragmentation reactions.

Key words: bleaching, catechols, carboxylic acids, delignification, guaiacyl, kinetics, oxygen, phenols, phosphorus, nuclear magnetic resonance (nmr), residual kraft lignin.

Résumé : En procédant à son isolement et son oxydation systématique en fonction du temps et de la pression, on a étudié l'interaction complexe de la lignine kraft résiduelle de bois mou avec l'oxygène à des températures, pressions et pH élevés. On a réalisé l'isolation de la lignine oxydée en appliquant une méthode en plusieurs étapes développées spécifiquement pour récupérer toutes les espèces. Des mesures quantitatives détaillées de RMN du ^{31}P ont permis d'obtenir pour la première fois des courbes tridimensionnelles décrivant la formation et (ou) l'élimination de divers groupes fonctionnels. On a trouvé que les réactions de déméthoxylation oxydante induisent la formation de catéchols qui sont vraisemblablement des intermédiaires réactifs dans l'oxydation. On a trouvé que la vitesse de formation de l'acide carboxylique et d'élimination de guaïacol phénolique suit deux phases distinctes : une phase initiale rapide suivie d'une phase plus lente. D'une façon plus spécifique, on a trouvé que la vitesse de formation d'acide carboxylique augmente d'une façon dramatique lorsqu'on élève la température; on a obtenu des profils analogues pour l'élimination des unités guaiacyles phénoliques. À des températures réactionnelles semblables à celles utilisées dans les installations commerciales conventionnelles de délignification par l'oxygène (80-100°C), on observe peu d'oxydation de la lignine. À ces températures, une augmentation du temps de réaction n'aide pas d'une façon significative à la formation d'acides carboxyliques sur la lignine malgré les conditions homogènes en deux phases idéalisées. Les ramifications technologiques de ces données impliquent qu'un système de délignification à l'oxygène en trois phases, à des températures inférieures à 100°C, ne provoque que des changements oxydants mineurs de la lignine de la fibre. Il a aussi été possible d'isoler l'effet des métaux alcalins et de la température sur la structure de la lignine kraft résiduelle en procédant à des expériences dans lesquelles l'oxygène sous pression est remplacé par de l'azote. Ces données révèlent certaines conditions induisent des réactions de condensation et de fragmentation.

Mots clés : blanchiment, catéchols, acides carboxyliques, délignification, guaiacyle, cinétique, oxygène, phénols, phosphore, résonance magnétique nucléaire, lignine kraft résiduelle.

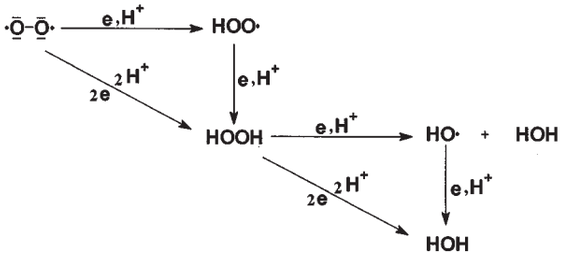
Introduction

Regulatory pressures, motivated by concerns regarding the toxicity of pulp and paper mill effluents containing chlorinated organic matter, have driven this industry to consider and (or) implement new delignification and bleaching technologies. In this context, the use of oxygen delignification is becoming of paramount global importance. The environmental, technical, and economic benefits of oxygen delignification include lower chemical requirements in the subsequent bleaching sequence, higher brightnesses with an equivalent amount of chemicals, lower amounts of rejects, and lower water consumption due to the greater recycling potential of oxygen stage effluent (1, 2). However, an oxygen delignification stage allows for limited delignification (3, 4). Beyond approximately 50% delignification, severe cellulose depolymerization takes place, causing deterioration of pulp viscosity and strength characteristics. This lack of selectivity is the main drawback of oxygen delignification (5).

The fundamental interactions of oxygen in aqueous alkali with various lignin model compounds have been the subject of various structural and kinetic enquiries (6–12). However, it should be noted that the conclusions of such studies cannot fully describe the events that occur when oxygen interacts with lignin macromolecules. The polymeric and cross-linked nature of lignin induces physical constraints that make it significantly less reactive toward oxygen than model compounds (12). It is likely that the multitude of branching and cross-linking variations that occur within lignin may cause significant accessibility variations of reactive moieties toward even the same functional groups.

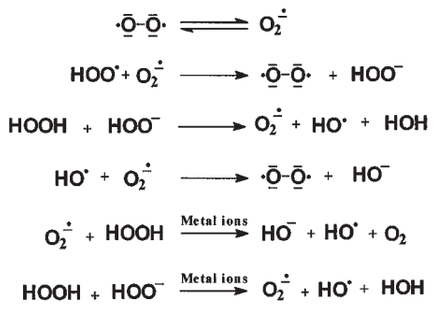
Moreover, during oxygen delignification, molecular oxygen can be transformed into a variety of species possessing different reactivities, with different lignin functional groups adding to the complexity of the process. In actual fact, the stepwise reduction of molecular oxygen can proceed via either four one-electron transfer steps or two two-electron transfer steps (Scheme 1) (9). In the course of these transformations some extremely reactive species are formed, including hydroperoxy radicals, hydroxy radicals, and hydrogen peroxide (13).

Scheme 1. The stepwise reduction of molecular oxygen (biradical) via four one-electron transfer steps and two two-electron transfer steps (9).



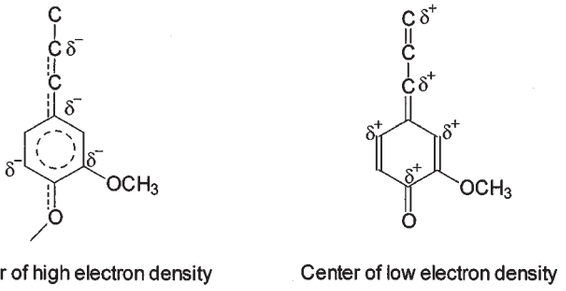
The reactions in Scheme 2, between the species produced during the stepwise reduction of oxygen depicted in Scheme 1, are also possible, both in the presence and in the absence of metal ions (14).

Scheme 2. The reactions that may occur between the species produced during the stepwise reduction of biradical oxygen in the presence and absence of metal ions (14).



The chemistry depicted in Schemes 1 and 2 clearly indicates that hydrogen peroxide is inevitably present under conditions of oxygen delignification. Therefore, both oxygen and hydrogen peroxide may cooperatively participate in defining the delignification chemistry of such systems. Gierer has classified hydroxyl radicals and the oxygen biradical as electrophilic species, while hydroperoxide anions and superoxide anion radicals are classified as nucleophilic species (14, 15). Consequently, the electrophiles will react with the centres of high electron density in lignin, while the nucleophiles will react with the centres of low electron density as shown in Scheme 3.

Scheme 3. The centres of high and low electron densities on the C_9 unit of lignin. These are the respective sites for attack by electrophiles or nucleophiles.



Numerous studies have also demonstrated that the phenolic units of lignin are amongst the most significant reaction sites for oxygen delignification (11). The primary interaction of alkali with these structures yields anions that are candidate structures for attack by oxygen and its multitude of coexisting species (16).

In an effort to provide an additional perspective on the complex interaction of kraft lignin with oxygen in alkaline media at elevated temperatures and pressures, we isolated residual softwood kraft lignin and systematically oxidized it as a function of time and temperature. This was carried out to bridge the existing knowledge gap between model compounds and actual residual kraft lignin. Detailed quantitative ^{31}P NMR measurements on the oxidized lignins provided, for the first time, the actual kinetics of formation and (or) elimination of guaiacyl phenols, carboxylic acids, catecholic phenols, and aliphatic alcohols present in residual kraft lignin.

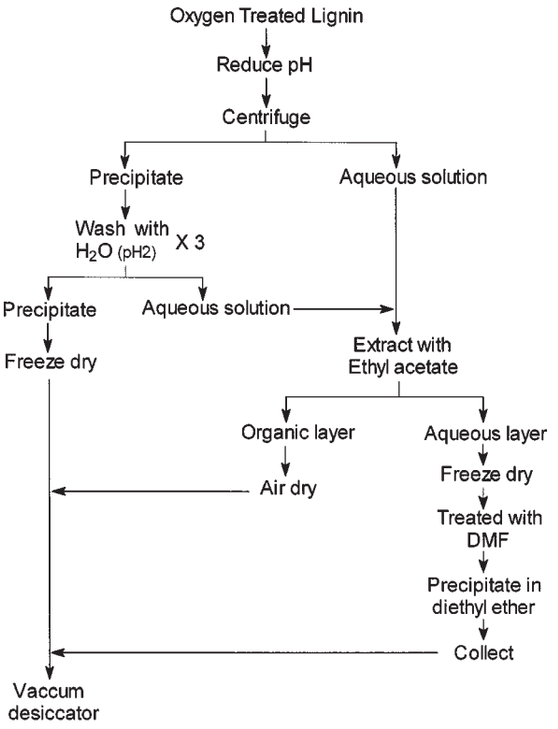
Scheme 4. Schematic representation of the recovery method developed to quantitatively isolate lignin and its fragments after oxidation with oxygen at elevated temperatures and pH's.



Experimental

Isolation of residual kraft lignin

A black spruce (*Picea mariana*) kraft pulp (kappa number 30.9) was freed from metal ions by stirring the pulp in a DTPA solution (60°C, 1 h) and, after a washing step, the pulp was treated in an acid solution (H_2SO_4 at pH 3, room temperature, 2 h), followed by thorough washing with deionized water. The residual lignin was then isolated from the pulp in several batches by using a slightly modified acidolysis procedure described elsewhere (17). The residual lignin samples were thoroughly homogenized to ensure sample uniformity. The yield of the isolation procedure varied between 35 and 45% while its purity was confirmed by UV and Klasson lignin content measurements.

Oxidation of residual kraft lignin

The residual kraft lignin was oxidized with pressurized oxygen under alkaline conditions at 80, 95, 110, 125, and 140°C for 20, 40, 60, and 80 min using a 1 L Parr reactor. To avoid metal ion contamination, all interior parts of the reactor (including cooling coils and sampling ports) were coated with Teflon. A customized glass liner was used as the actual reaction flask. The following parameters were applied to all oxidations described in this work: 560 mg of residual kraft lignin was mixed with 400 mL of deionized, distilled water. Sodium hydroxide (280 mg, which is equivalent to 2.3 wt.% based on pulp (κ no. 30.9)) was then added, causing solubilization of the lignin. The pH prior to the onset of the reaction was between 11.5 and 11.6. Prior to placing the lignin sample in the reactor, the whole system was heated to 80°C. After sealing the system, the reactor was rapidly heated to the desired temperature. It was then purged with oxygen several times prior to being subjected to a constant oxygen pressure (100 psig or 0.68 MPa) that was maintained for the duration of the oxidation.

To isolate the effect of alkalinity in the absence of oxygen, a series of samples was reacted at 140°C using 0.68 MPa of nitrogen pressure under the same conditions described above.

Quantitative recovery of oxidized and fragmented lignins

After the treatment, the sampling valve of the Parr reactor was opened and an aliquot of lignin solution was cooled to room temperature by passing it through an efficiently cooled reflux condenser. The pH of the sample was then immediately adjusted to 2, which caused the remaining polymeric fraction of the lignin to precipitate out. The precipitated lignin was then recovered by centrifugation, washed with deionized distilled water whose pH had been adjusted to 2, freeze-dried, and stored in a desiccator (see Scheme 4).

The above washings were all combined with the initial filtrate, which contained lower molecular weight lignin fractions combined with hydrophilic lignin fragments. At this point the molecules soluble in organic solvents were extracted with ethyl acetate until the organic layer was no longer coloured. The ethyl acetate extract was allowed to dry in air and stored in a desiccator.

Consequently, the remaining aqueous portion of the sample was enriched in oxidized lignin fragments. The volume of this fraction was first reduced in a rotary evaporator (set at 35–40°C) and it was freeze-dried. The collected solids were then treated with dry dimethylformamide, DMF, filtered to remove inorganic salts, and the filtrate was added dropwise in an excess of diethyl ether (400 mL), allowing the precipitation of the hydrophilic fragments and washing out excess DMF. Finally, the collected lignin fractions were combined, mixed thoroughly, and stored in a vacuum desiccator prior to ^{31}P NMR analyses.

^{31}P NMR analyses of oxidized lignins

Quantitative ^{31}P NMR analyses were carried out on the starting and the oxidized lignins using published procedures (18–20). Since oxidized lignins were found to be of limited solubility in pyridine–$CDCl_3$, a new solvent system for the acquisition of these spectra was used in this effort. Approximately 40 mg of our lignin sample was dissolved in 500 μL of deuterated DMF. A mixture of pyridine/$CDCl_3$ (300 mL, 1.6/1 v/v) was then added and the samples were phosphitylated with 100 mL of 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane, synthesized according to published procedures (21, 22). Solutions of 100 mL of cyclohexanol (1.1 mg) and chromium acetylacetonate (0.55 mg) in 10 mL of pyridine/$CDCl_3$ (1.6/1 v/v) were also added to serve as the internal standard and relaxation reagent, respectively.

The ^{31}P NMR spectra were acquired on a Varian XL-300 MHz spectrometer (operating at 121.5 MHz). The chemical shifts reported are relative to the reaction product of water with the phosphitylation reagent, which has been reported to give a sharp signal at 132.2 ppm (20, 23). For each spectrum 128

transients were acquired with a delay time of 25 s between acquisitions.

Results and discussion

The oxidation of residual kraft lignin under high pressure and alkalinity is known to partially degrade the lignin with concomitant formation of functional groups such as quinones and carboxylic acids (24), significantly altering its solubility. Since the primary objective of this work was to identify and quantify these structural changes under conditions of an oxygen delignification stage, extensive efforts were made to quantitatively isolate the lignin after the reaction.This ensured that most of the highly oxidized and low molecular weight fragments were included in the quantitative ^{31}P NMR analyses that followed. To accomplish this, a multistep procedure was developed (Scheme 4) to recover all of the species possessing different solubility characteristics in different solvents.The application of this scheme provided recovery yields between 75–95%.

Careful optimization work showed that the oxidized lignins could be divided into three distinct fractions. One fraction could easily be precipitated out of aqueous alkali by decreasing its pH to 2. More hydrophilic fractions were then recovered by extracting aqueous lignin solutions with ethyl acetate. Finally, highly oxidized lignin macromolecules and fragments were isolated by selectively dissolving them with dimethylformamide (DMF), separating them from inorganic salts. It should be noted that no attempt was made to recover

and quantify volatile by-products such as CO, CO_2, and methanol.

A series of typical quantitative ^{31}P NMR spectra of softwood residual kraft lignins obtained after phosphitylation with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane is displayed in Fig. 1. The integration ranges and signal assignment were similar to those reported by Sun and Argyropoulos (23, 25) based on previous model compound (20) and lignin studies (19). Therefore, the foundations of the following discussion belong in the quantitative ^{31}P NMR data of Table 1, which summarizes the amounts of the various hydroxyl groups present within the starting and oxidized residual kraft lignins.

The reactivity of guaiacyl phenolic units with oxygen

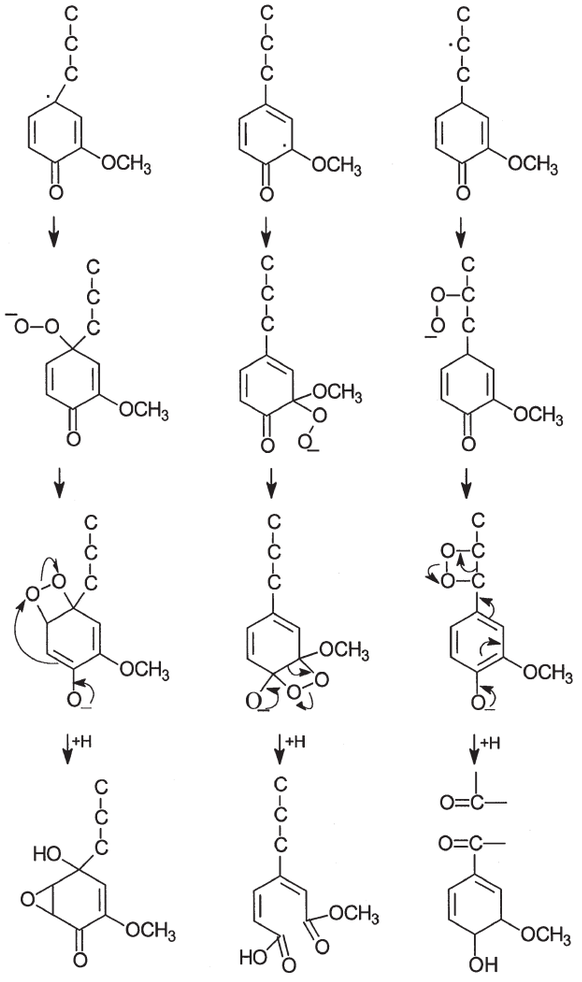
Molecular oxygen, in alkaline media at elevated temperatures, has been considered to behave as a biradical species (9, 13). Therefore, the first step in the oxidative degradation of phenolic units is thought to be the abstraction of an electron from the phenolate anion by biradical oxygen, giving the corresponding phenoxy and superoxide anion radicals (9). At the same time, the protonation of reduced oxygen gives rise to hydroperoxy radicals, which are known to behave as stronger oxidants than molecular oxygen (13), reacting faster with lignin units. As such, phenoxy radicals are attacked by hydroperoxy radicals at the centres of high electron densities as shown in Scheme 3. The reaction products are known to be the relatively unstable cyclohexadienone hydroperoxide intermediates (14–16), leading to demethoxylation, ring-opening, and side-chain elimination reactions (Schemes 5 and 6). In fact, such species have been detected, isolated, and quantified as photochemical transformation products of commercial antioxidants (26–28). The demethylation and ring-opening reactions give rise to catechols and various mono and dicarboxylic acids, such as maleic and muconic acids (Scheme 6), while the side-chain elimination reactions cause the formation of other organic acids and *para*-quinones, thus depolymerizing lignin. The outcome of all these reactions is the actual elimination of guaiacyl phenolic units.

In an attempt to shed more light in this complex series of events, the profiles of guaiacyl phenolic group elimination during the oxidation of residual kraft lignin were determined and are plotted as a function of temperature and time in Fig. 2.

It is apparent that the rate of guaiacyl phenolic unit elimination increases as the oxidation intensifies. The reaction temperature, rather than the reaction time, seems to be of primary significance in causing the elimination of these units. The rate of guaiacyl unit elimination is considerably slower at 80 and 95°C than at 110, 125, or 140°C. Furthermore, the degradation of guaiacyl units at temperatures above 100°C seems to proceed in two distinct phases: an initial rapid decrease of the guaiacyl units is observed within 20–40 min, followed by a significantly slower regime. Similarly, Lai et al. (29) claimed that 10% of these uncondensed phenolic

© 1998 NRC Canada

Scheme 6. Reactions proposed to occur under oxygen delignification conditions involving phenolic moieties and superoxide anion radicals via dioxetane intermediates (14).



units are eliminated rapidly during oxygen delignification at 100°C and 90 psi oxygen pressure (1 psi = 6.9 kPa), followed by a slow phase during which their concentrations remain relatively constant. Such behaviour is reminiscent of the kappa number reduction profiles usually encountered during oxygen delignification of kraft pulps. Physical constraints such as a diffusion-controlled reaction whose rate depends on the rate of transport of reagents from one phase to another could be responsible for stalling the reactivity in the slow phase (30). However, the data of Fig. 2 represent the oxidative elimination of guaiacyl phenolic units from within residual kraft lignin under homogeneous oxygen delignification conditions, making it likely that guaiacyl phenolic units may exist within residual kraft lignin whose reactivity toward oxidative reactions is different. Branching and cross-linking variations that occur within lignin may be responsible for the observed reactivity and (or) accessibility variations.

Fig. 2. Three-dimensional plots depicting the oxidative elimination of guaiacyl phenolic units from within residual kraft lignin under homogeneous oxygen delignification conditions.

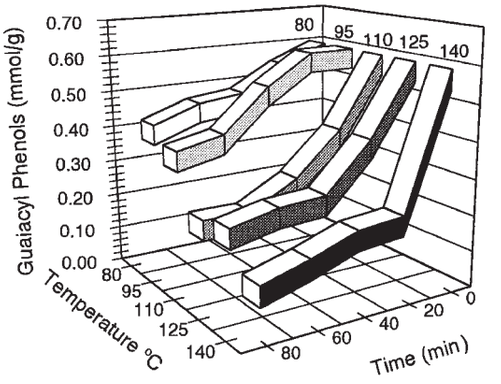


Fig. 3. Three-dimensional plots depicting the buildup of carboxylic acids within residual kraft lignin as a function of time and temperature under homogeneous oxygen delignification conditions.

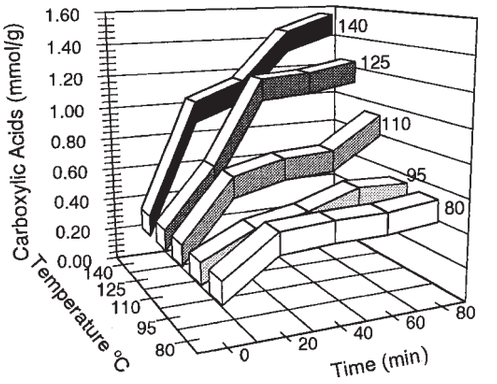

Formation of carboxylic acids within residual kraft lignin

The presence of carboxylic acid groups on the lignin macromolecule is considered to promote lignin solubilization in alkaline media during oxygen delignification (10, 23) or other bleaching stages (25). Lignin oxidation reactions may induce the formation of carboxylic acids via a number of pathways either as monomeric fragments or functional groups attached at the end of side chains of the lignin macromolecules (12, 31, 32). The most significant pathway involves side-chain elimination and ring-opening reactions in phenolic centres. Side-chain elimination reactions would form vanillin-like structures (which degrade further) while ring-opening reactions lead to moieties resembling muconic acid moieties (16). Another pathway may involve an electrophilic attack at lignin centres of high electron density, causing the formation of a four- membered cyclic peroxide intermediate termed dioxetane (14, 16, 24); (Scheme 6). This reactive species rearranges to induce efficient cleavage of C—C bonds. It should be noted that after the initial electrophilic attack, the molecule may also be attacked by external nucleophiles, but according to Gierer (14) these are only minor reactions.

Scheme 7. Possible reactions, operating on phenolic units, that may account for the formation and subsequent elimination of catechols, during the oxidation of residual kraft lignin at elevated temperatures and alkalinities.

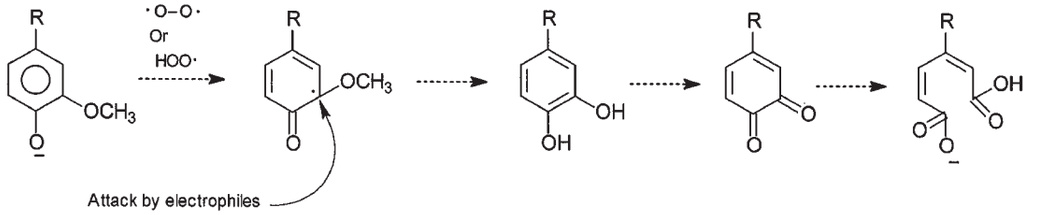

Fig. 4. Three-dimensional plots depicting the pH profiles of the medium as a function of time and temperature during the oxidation of residual kraft lignin, under homogeneous oxygen delignification conditions.

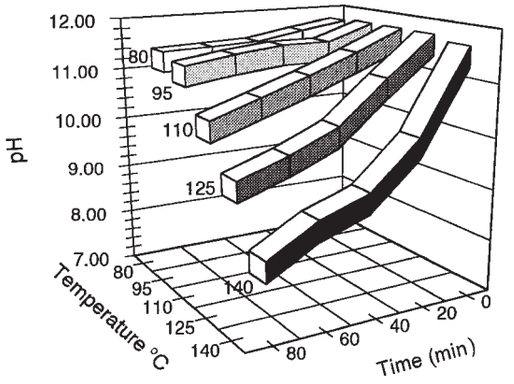

Figure 3, displaying the three-dimensional plots for the buildup of carboxylic acids within residual kraft lignin as a function of time and temperature, is very revealing. For all temperatures studied, two regimes can be distinguished describing the rate of carboxylic acid group formation: an initial rapid phase that dominates the process for the first 20 min (at all temperatures), followed by a slower one. At temperatures between 125 and 140°C, the rate of carboxylic acid group formation within the first 20 min of the process is very high. For example, the concentration of these groups after 20 min of reaction reaches and exceeds 1.0 mmol/g; while at 80–95°C, 80 min of reaction caused only a minor enrichment of the lignin structure in carboxylic acid groups (less than 0.5 mmol/g).

The rate of carboxylic acid group formation seems to dramatically increase as the reaction temperature increases, analogous to the profiles obtained for the elimination of guaiacyl phenolic units. It is interesting to observe that only minor oxidation occurs within the residual kraft lignin at reaction temperatures typical of conventional commercial oxygen delignification installations (80–100°C).

At these temperatures, increasing the reaction time does not seem to significantly aid the formation of carboxylic acid groups. Higher temperatures, however, cause the concentration of carboxylic acid groups to steadily increase as a function of treatment time. In general, the efficiency of oxidation of residual kraft lignin significantly increases above 100°C even though these experiments were conducted under idealized two-phase homogeneous conditions. The data imply that a three-phase oxygen delignification system operating at temperatures below 100°C causes only minor oxidative changes on the structure of the lignin on the fibre.

The effect of oxidation on the pH of the medium

Since pH is known to seriously affect the efficiency of an oxygen delignification stage, it was deemed appropriate to examine the dependence of pH as a function of temperature and time during the oxidation of residual kraft lignin. The amount of sodium hydroxide used in the present sequence of experiments was similar to that used during a commercial softwood oxygen delignification installation (2.3% based on oven dry fibre, see Experimental).

The data of Fig. 4 show the contribution of the oxidized groups in residual kraft lignin toward lowering the pH of the aqueous medium during oxygen delignification conditions. In a manner analogous to the formation of carboxylic acid groups (Fig. 3), the pH of the medium is practically unaffected at temperatures below 100°C. This could be significant information when one considers the design of oxygen delignification operations at temperatures above 100°C. For such a case, one should make provisions so that enough alkali is present in the medium to compensate for the greater pH losses that the oxidation of lignin will cause above 100°C. A benchmark observation guiding such a design could be that at 110°C and after 80 min of reaction, the pH of the medium was found to be slightly below 10. The trend of decreasing pH in an alkaline oxidative extraction was observed previously when the temperature was raised from 70 to 110°C, with some benefits observed by increasing the alkali charge (33).

Another interesting feature of the data of Fig. 4 is the fact that the pH profiles show two- phase reactions only at temperatures of 125 and 140°C, in contrast to the data of Fig. 3 (see relevant discussion). At lower temperatures the pH decrease is smooth throughout the examined time range.

Oxidative demethoxylation reactions

Model compound studies have shown that demethoxylation reactions may occur under oxygen delignification conditions (13). However, there has been no direct quantitative evidence for the occurrence of such reactions in residual kraft lignin during oxygen delignification. Despite the fact that the exact mechanism of demethoxylation is not known, Kratzl et al. (13) have assumed that a phenoxy radical may react with oxygen or hydroperoxy radicals, yielding cyclohexadienone hydroperoxides (Scheme 7). For these species, after demethoxylation, rearrangement and ring rearomatization yield catechols that are easily oxidized to *ortho* quinones and then to a muconic acid type of structures (13).

Fig. 5. Three-dimensional plots depicting the profile of catechol formation as a function of time and temperature during the oxidation of residual kraft lignin under homogeneous oxygen delignification conditions.

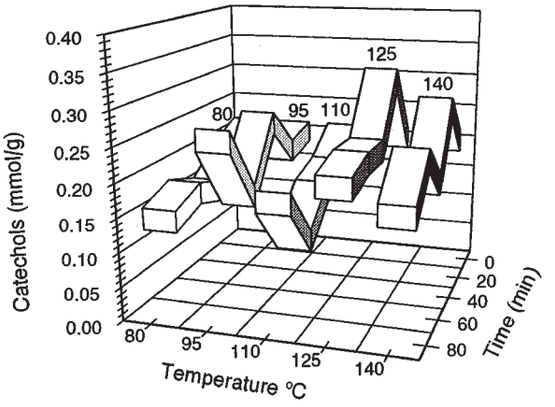

Fig. 6. A comparison of carboxylic acid group formation on residual kraft lignin in the presence and absence of oxygen at 140°C.

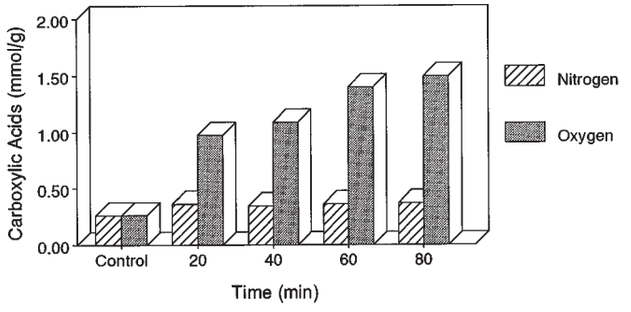
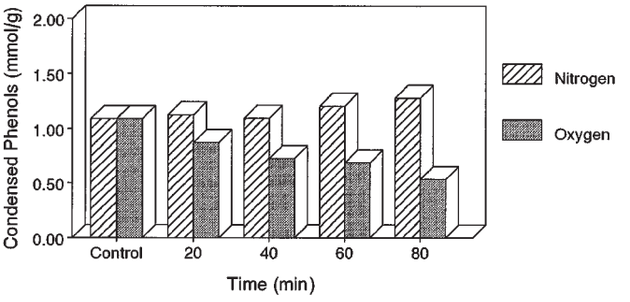


The quantitative ^{31}P NMR spectra of Fig. 1 show the characteristic signals of catechols in the region 138.6–139.1 ppm (19, 20, 23). Apparently, catechols form during the oxidation of residual kraft lignin, since these signals are not as obvious in the spectrum of the starting material (Fig. 1). Since this novel methodology allows the detection and quantification of catechols in a lignin sample, it was used to quantify them as a function of time and temperature (Fig. 5).

One can observe some minor but irregular variations in the abundance of catechols within oxidized residual kraft lignin as a function of time and temperature (Fig. 5). In general, their concentration can be considered relatively constant over the whole temperature range examined, implying that catechols are involved in the oxidation process as intermediates.Their participation in an oxygen delignification has been suggested by Gellerstedt and Lindfors (30) and Renard et al. (31, 32). It is likely that while there is a supply of guaiacyl units in the system, these intermediates would form and then be oxidized in a continuous fashion. In addition to the catechols acting as important intermediates in the oxidation process, they also increase the hydrophilicity of the lignin, augmenting its solubility in alkaline media.

Fig. 7. A comparison of condensed phenolic units on residual kraft lignin in the presence and absence of oxygen at 140°C.



The effect of alkali and temperature on the reaction pathways

During this effort we attempted to isolate the effect of alkali and temperature on the structure of residual kraft lignin by substituting pressurized oxygen with nitrogen, in otherwise identical conditions to those described so far. To emphasize the overall effects, this study was conducted at 140°C and the functional group distribution changes induced on the residual kraft lignin were compared to those in Figs. 2 and 4 obtained at 140°C.

The dramatic effect of oxygen toward inducing the formation of carboxylic acid groups within residual kraft lignin, under oxygen delignification conditions, is shown in Fig. 6. In the absence of oxygen, temperature (140°C) and alkali alone do not induce the formation of carboxylic acids in residual kraft lignin. For comparison purposes under the same conditions and in the presence of oxygen, an approximate 450% increase in carboxylic acid content was measured.

Phenolic structures that are substituted at the C5 position may be termed condensed phenols. The fate of such units, under both an oxidative and an inert atmosphere, at 140°C, is shown in Fig. 7. It appears that at 140°C the amount of condensed phenolic units decreased over 50% via oxidative degradation reactions. However, in the absence of oxygen, the condensed phenolic units increased by about 17%. It is therefore likely that this increase describes alkaline condensation reactions taking place within residual kraft lignin under the examined conditions. At elevated alkalinities and temperatures, phenoxy anions (33) may attack the α position of other C9 units and consequently, after rearrangement, new C_α–C_5 units may form, see Scheme 8 (34, 35).

In addition, any residual β-O4 units present in residual kraft lignin, albeit in minor amounts (36), may rearrange and cause the formation of minor amounts of formaldehyde. These species may then methylolate the C5 position of phenolic units, eventually creating new diphenyl methane structures (Scheme 8).The data of Fig. 7, therefore, reveal a concealed set of condensation reactions.

Figure 8 displays the changes in the actual amounts of guaiacyl phenolic units under inert and oxidative conditions. In the presence of oxygen, the amount of guaiacyl phenolic units decreases but in the absence of oxygen, the amount of guaiacyl phenolic units increased somewhat. The rationale that may be offered to explain these data is that under the examined conditions, the small amounts of β-O4 bonds that have been documented to remain on residual kraft lignin

Scheme 8. Alkaline condensation reactions that may operate on phenolic units of residual kraft lignin (34).

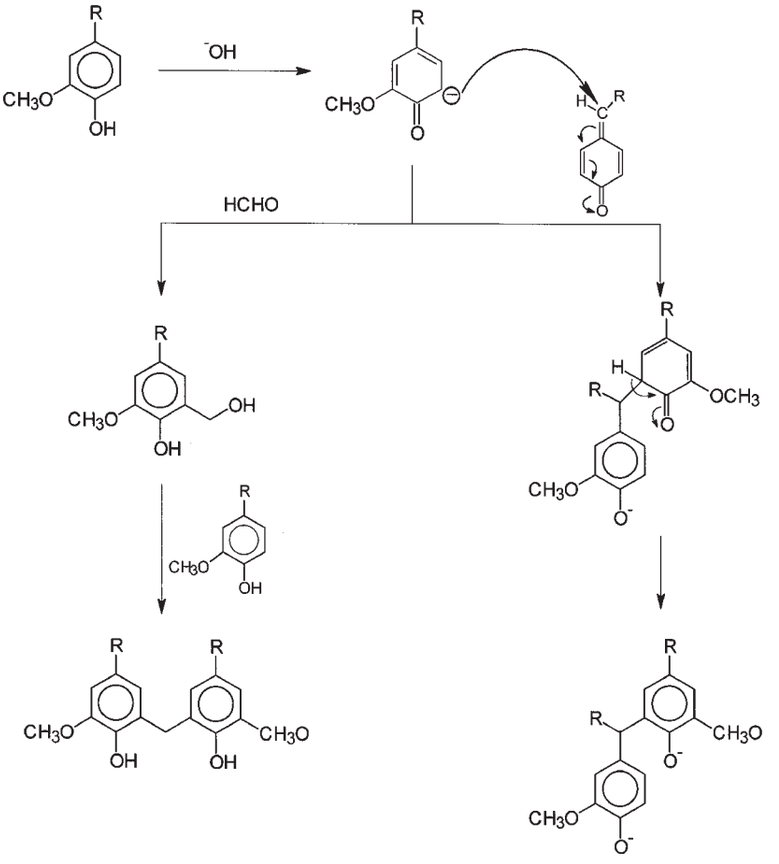

Fig. 8. A comparison of the fate of guaiacyl phenolic units present on residual kraft lignin in the presence and absence of oxygen at 140°C.

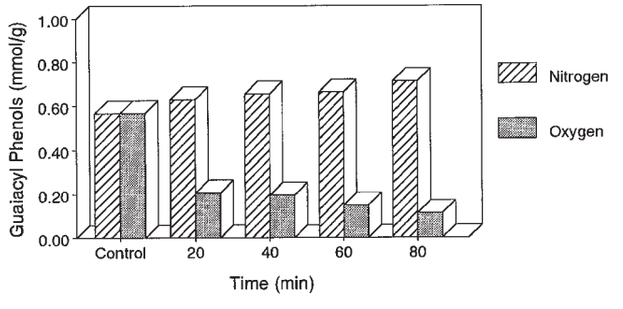

may cleave (36), and will inevitably cause the formation of new guaiacyl phenolic units.

Concluding remarks

During oxygen delignification the guaiacyl phenolic units of softwood residual kraft lignin eliminate with the concomitant formation of carboxylic acids. The rates for the elimination of phenols and the formation of acids were found to significantly increase when the reaction temperature was above 100°C. The concentration of catechols was found to be relatively constant over the whole temperature range examined, implying that catechols are involved in the oxidation process as intermediates.

In general, reaction temperatures varying between 80 and 100°C caused only minor functional group changes on softwood residual kraft lignin. The reactivity of this kraft lignin substantially increased at temperatures above 110°C. Therefore considerable oxidative delignification should be obtained at elevated temperatures. The challenge remains, however, for developing strategies that may prevent the unwanted deterioration of pulp quality.

Second-harmonic generation studies of chiral organic salts

Bozena Borecka-Bednarz, Alan V. Bree, Brian O. Patrick, John R. Scheffer, and James Trotter

Abstract: Second-harmonic generation in the solid state is restricted to materials that crystallize in non-centrosymmetric space groups. Unfortunately, the vast majority of solids crystallize in centrosymmetric space groups and are therefore SHG-inactive. The requirement for solid-state asymmetry is addressed in a new series of organic salts. The acid *p*-nitrophenylglycine, SHG-inactive due to its centrosymmetric ($P\bar{1}$) packing, was coupled to six optically pure amines to form salts and (or) complexes that, by virtue of their chiral counterion, crystallized in non-centrosymmetric space groups. The 1064 nm output from a Nd:YAG laser produced 532 nm second-harmonic generation from each of the six salts, with three of the salts producing second-harmonic intensities at least an order of magnitude greater than that of our standard, urea. X-ray crystallographic analysis was carried out on five of the six salts, and an attempt was made to rationalize the second-harmonic intensity of each of these five salts based on the orientation of its molecular charge-transfer axis in the unit cell and on its chromophore density.

Key words: second-harmonic generation, nonlinear optics, chiral organic salts, crystal structures.

Résumé : La génération de secondes harmoniques dans l'état solide est possible seulement pour les matériaux qui cristallisent dans des groupes spatiaux non-centrosymétriques. Malheureusement, la grande majorité des solides cristallisent dans un des groupes spatiaux centrosymétriques et sont, par conséquent, inactifs en ce qui concerne la génération de secondes harmoniques. Cette condition sur l'asymétrie cristalline est adressé dans une nouvelle serie de sels organiques. L'acide *p*-nitrophénylglycinique, inactive pour la génération de secondes harmoniques dû à sa cristallisation centrosymétrique ($P\bar{1}$), fut combineé avec six amines optiquement actives pour former des sels et (ou) des complèxes qui, dû à leurs contre-ions chiraux, cristallisent dans un des groupes spatiaux non-centrosymétriques. Soumis à un rayonnement lumineux de 1064 nm produit par un laser Nd:YAG (grenat d'yttrium et d'aluminium), chacun des six sels a géneré une seconde harmonique de 532 nm. Trois de ces sels ont produit des secondes harmoniques ayant des intensités d'au moins une ordre de grandeur supérieures à celle produite par notre étalon, l'urée. Cinq des six sels ont été soumis à une analyse cristallographique aux rayons X. Une tentative fut effectueé pour modeliser l'intensité de la seconde harmonique produite par chacun des cinq sels en se basant sur l'orientation de l'axe de transfert de charge dans la maille élémentaire, et sur la densité chromophorique de chacun d'entre eux.

Mots clés : génération de seconde harmonique, sels organiques chiraux, optique non-linéaire, structures cristallines.

Introduction

Over the course of the last 15 years extensive development of organic nonlinear optical (NLO) materials has led to compounds potentially suitable for application in optical telecommunication and data storage devices (1–5). Much of this research has been directed toward materials that produce second-harmonic generation (SHG), the frequency doubling of laser light. Organic materials possess several attractive properties that invite further study: they often have molecular hyperpolarizabilities (β, γ) significantly larger than inorganics that fall within the same transparency range (6, 7), while the ease with which molecules can be "designed" for efficient SHG by established synthetic methodologies is an exciting advantage for organic materials. Molecules with large hyperpolarizabilities, like *p*-nitroaniline (**PNA**), tend to contain strong electron-accepting and electron-donating groups bridged by a π-conjugated system. Several molecules bearing this type of one-dimensional charge-transfer chromophore have produced crystals that are excellent materials for SHG (8–10). Materials scientists, however, are still presented with the challenge of inducing non-centrosymmetric packing of these materials if they are to have non-zero macroscopic susceptibilities and exhibit second-order NLO properties (11, 12). Since approximately 75% of all organic materials crystallize in centrosymmetric space groups (13, 14), significant effort has been invested in developing techniques designed to force a polar alignment of chromophores, such as the various poled-polymer (15) and self-assembly techniques (16, 17). There is, however, a theoretical limit to the conversion of the molecular nonlinearity of these one-dimensional systems into crystalline nonlinearity for the SHG process. Factors such as space group and chromophore orientation

1

limit the contribution to the crystalline nonlinearity to a maximum of 38% for phase-matched SHG (18, 19).

One approach to achieving bulk asymmetry has been to introduce a resolved chiral centre in the crystal of interest. This approach is well illustrated in the case of *p*-nitrophenyl-L-prolinol (**NPP**) (8) and *N*-(5-nitropyridyl)-2-L-prolinol (**PNP**) (20), each of which is a D-π-A system like **PNA**, forced to crystallize in a non-centrosymmetric space group due to the optical purity of the material. It has been suggested that highly polar materials such as **PNA** are biased towards centrosymmetric packing, in part due to the dipolar forces that encourage neighboring molecules to pack in an anti-parallel manner. While there is some debate over what role the magnitude of the dipole moment plays in influencing molecular orientation in the crystal (21), the presence of a resolved stereogenic centre in an SHG chromophore can only ensure non-centrosymmetry. Chirality itself does little to diminish these dipolar forces. Some authors have suggested that the Coulombic interactions found in salts could overcome the dipolar forces that may be favoring the anti-parallel packing commonly found in covalent compounds of this type, by shielding adjacent dipoles from one another (2). One means of inducing an asymmetric packing arrangement that could prove advantageous for SHG materials is the *chiral ionic auxiliary* approach (22–26). In this approach an achiral acid or amine is coupled to an optically pure amine or acid to produce a salt that, by virtue of its optical purity, must crystallize in a non-centrosymmetric space group. Extended to the production of SHG materials, coupling an SHG chromophore containing acid to an optically pure amine (or a chromophore containing amine to an optically pure acid) produces a salt that, in the solid state, must reside in an asymmetric environment. As such, the chiral ionic auxiliary approach has the added advantage of employing a counterion potentially capable of separating the SHG chromophores, in addition to inducing non-centrosymmetry by virtue of its optical purity.

This paper reports the measured SHG efficiency and X-ray structural determination of a series of salts prepared using the chiral ionic auxiliary approach. Compound **1 (***p*-nitrophenylglycine), an achiral acid containing the **PNA** chromophore (Fig. 1) was synthesized. Although originally SHG-inactive, coupling of the acid to a series of optically pure amines activated the second-order NLO properties of the chromophore. The SHG intensity of each salt was measured relative to a urea standard using the Kurtz and Perry powder method (27). The theoretical macroscopic second-order susceptibilities were then estimated using an oriented gas model derived by Zyss and Oudar (18, 19), and the relative SHG intensities were rationalized on the basis of these susceptibilities.

General experimental

Reagents and general procedures

All chemicals were obtained as reagent grade materials and were used as supplied by either Aldrich, BDH, Fischer Scientific, or Sigma. Melting points (mp) were determined on a DSC 910S differential scanning calorimeter connected to the Thermal Analyst 2000 system (TA Instruments). Melting point ranges are reported as the peak of the melting endotherm. Infrared spectra (IR) were recorded from KBr pellets on a Perkin–Elmer 1710 Fourier transform infrared spectrometer. Absorption bands characteristic of amines, carboxylic acids, carboxylates, and esters are listed in reciprocal centimeters (cm^{-1}). The abbreviations used in describing the relative strength of the absorption bands are as follows: s = strong, m = medium, w = weak. Low- resolution electron impact mass spectra (EIMS) were obtained using a Kratos MS 50 mass spectrometer with 70 eV electron bombardment. Liquid secondary-ion mass spectra (LSIMS), both positive and negative, were obtained for all salts using an AEI MS 9 mass spectrometer. Each of these procedures was performed by the mass spectrometry laboratory of the University of British Columbia Chemistry Department. The mass to charge ratio (m/e) followed by the relative abundance in parentheses is given for the most abundant fragments in each spectrum. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Brüker AC-200 (200 MHz) or a Brüker WH-400 (400 MHz) spectrometer in either $CDCl_3$, CD_3OD, or acetone-d_6. Chemical shifts (δ) are given in parts per million (ppm) with the multiplicity and the number of protons in parentheses following the position. The abbreviations used in describing the signal multiplicity are as follows: s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet. UV–vis spectra were recorded on a Perkin-Elmer Lambda 4B UV/VIS spectrophotometer using a 1 cm quartz cell. HPLC grade (BDH) solvent was used without further purification. Wavelengths (λ) in nanometers (nm) are reported and the extinction coefficients (ε, M^{-1} cm^{-1}) are given in parentheses. Carbon, hydrogen, and nitrogen elemental analyses were performed by Mr. P. Borda of the microanalysis lab in the University of British Columbia Chemistry Department. A Hewlett Packard 5890A gas chromatograph fitted with a flame ionization detector, a Hewlett Packard 3392 A integrator, and a 15 m × 0.25 mm DB1 column (J & W Scientific Inc.) with helium as a gas carrier was employed for gas–liquid chromatographic analysis.

Syntheses

Synthesis of N-p-*nitrophenylglycine (1)*

Following the procedure of Lantz and Obellianne (28), 2.80 g of *p*-fluoronitrobenzene (19.8 mmol, Aldrich) was dissolved in 20 mL of ethanol. The hydrochloride salt of glycine methyl ester (2.77 g, 22.0 mmol, Sigma) and 3.99 g of $NaHCO_3$ (47.4 mmol, Aldrich) were added to a 100 mL

© 1998 NRC Canada

round-bottomed flask. The fluoronitrobenzene solution was added to the round-bottomed flask, as well as 20 mL of H_2O and several boiling chips. The flask was then equipped with a reflux condenser and the mixture was refluxed overnight, after which the now orange solution was acidified with 5 mL of 1 M HCl, causing the immediate precipitation of a yellow solid. The crude product was allowed to settle and was then vacuum filtered, dried in air, and recrystallized from methanol to afford yellow prisms (2.15 g, 11.0 mmol, 55% yield); mp > 230°C (dec.) (229°C, ref. 28); IR (KBr disc), ν (cm^{-1}): 3363 (s, N–H *str*), 1736 (s, C=O *str*), 1289 (C–O *str* / O–H *def*); UV–Vis (EtOH), λ_{max} : 363 nm (ε = 16 400 M^{-1} cm^{-1}); ^{1}H NMR (acetone-d_6, 200 MHz), δ: 2.9 (br s, 1H), 4.1 (d, 2H, *J* = 3 Hz), 6.6 (br s, 1H), 6.8 (d, 2H, *J* = 9 Hz), 8.1 (d, *J* = 9 Hz, 2H) ppm; EIMS, *m/e* (relative intensity): 196 (M, 25.7), 151 (100), 150 (67.7), 149 (34.3), 138 (28.7), 120 (54.0). Anal. calcd. for **1**, $C_8H_8N_2O_4$: C 48.98, H 4.11, N 14.28; found: C 48.75, H 4.19, N 14.50.

*Synthesis of the (1*S*, 2*S*)-(+)-pseudoephedrine salt of **1**: **1.eph***

Acid **1** (81.8 mg, 0.417 mmol) was dissolved in 150 mL of diethyl ether. The amine (1*S*, 2*S*)-(+)-pseudoephedrine (67.8 mg, 0.410 mmol, Sigma) was dissolved in 20 mL of diethyl ether and added to the solution of **1**. A light yellow precipitate formed immediately. The solution was stirred for 0.5 h, then gravity filtered and dried in air. The crude product was recovered (120.0 mg, 0.332 mmol, 81% yield) and recrystallized from ethanol; mp 178.2°C; IR (KBr disc), ν (cm^{-1}): 3377 (s, N–H *str*) 1605 (s, C–O *str*); ^{1}H NMR (CD_3OD, 400 MHz), δ: 1.09 (d, 3H, *J* = 7 Hz), 2.74 (s, 3H), 3.50 (m, 1H), 3.82 (s, 2H), 4.65 (d, 1H, *J* = 9 Hz), 6.59 (d, 2H, *J* = 9 Hz), 7.42 (m, 5H), 8.06 (d, 2H, *J* = 9 Hz) ppm; –LSIMS, *m/e* (relative intensity): 391(2 × (M^- +1), 20), 195 (M^-, 100), 179 (6.7). +LSIMS, *m/e* (relative intensity): 166 (M^+, 100), 148 (29). Anal. calcd. for **1.eph**, $C_{18}H_{23}N_3O_5$: C 59.82, H 6.41, N 11.63; found: C 59.51, H 6.48, N 11.66.

Synthesis of the S*-(–)-proline* tert*-butyl ester salt of **1**: **1.pro-but***

Acid **1** (52.1 mg, 0.266 mmol) was dissolved in 200 mL of diethyl ether with stirring. Once the solid was completely dissolved, 50 mL *S*-(–)-proline *tert*-butyl ester (50 mg, 0.292 mmol, Sigma) was added to the ether solution and stirred. The solution was concentrated to approximately 25 mL by rotary evaporation and was left to stand, stoppered, overnight. A yellow precipitate was gravity filtered, dried in air, then recrystallized from an acetone–hexane mixture (72.3 mg, 0.197 mmol, 74% yield); mp 122.3°C; IR (KBr disc), ν (cm^{-1}): 3289 (s, N–H *str*), 1726 (s, C=O *str*), 1602 (s, C–O *str*); ^{1}H NMR (CD_3OD, 400 MHz), δ: 1.5 (s, 9H), 2.0–2.4 (m, 4H), 3.35 (m, 3H), 3.78 (s, 2H), 6.61 (d, 2H, *J* = 9 Hz), 8.08 (d, 2H, *J* = 9 Hz) ppm; –LSIMS, *m/e* (relative intensity): 195 (100, M^-; +LSIMS, *m/e* (relative intensity): 172 (M^+, 91), 116 (100). Anal. calcd. for **1.pro-but**, $C_{17}H_{25}N_3O_6$: C 55.58, H 6.86, N 11.44; found: C 55.83, H 6.99, N 11.62.

Synthesis of the S*-(–)-prolinol salt of **1**: **1.pro-ol***

Acid **1** (97.6 mg, 0.498 mmol) was dissolved in 10 mL of acetone. Once the solid was completely dissolved, 50 mL of *S*-(–)-prolinol (50 mg, 0.495 mmol, Aldrich) was added to the acetone solution. This solution was stirred briefly, then concentrated to approximately 5 mL. Approximately 20 mL of diethyl ether was added to the acetone solution, immediately producing a bright yellow precipitate. The crude product was gravity filtered and dried in air, then recrystallized from a 1:1 acetone–ethanol mixture (125 mg, 0.420 mmol, 85% yield); mp 166.2°C; IR (KBr disc), ν (cm^{-1}): 3300 (s, N–H *str*), 1612 (s, C–O *str*); ^{1}H NMR (acetone-d_6, 200 MHz), δ: 1.5–2.0 (m, 4H), 2.5 (m, 1H), 3.1 (t, 2H, *J* = 9 Hz), 3.6 (m, 5H), 6.7 (d, 2H, *J* = 9 Hz), 7.1 (t, 1H, *J* = 7 Hz), 8.0 (d, 2H, *J* = 9 Hz) ppm; –LSIMS, *m/e* (relative intensity): 391 (2 × (M^- + 1), 10), 195 (M^-, 100), 179 (7.5); +LSIMS, *m/e* (relative intensity): 102 (M^+, 100). Anal. calcd. for **1.pro-ol**, $C_{13}H_{19}N_3O_5$: C 52.52, H 6.44, N 14.13; found: C 52.23, H 6.32, N 13.96.

Synthesis of the S*-(–)-prolinamide salt of **1**: **1.pro-amide***

Acid **1** (47.0 mg, 0.240 mmol) was dissolved in 125 mL of diethyl ether with stirring. The amine *S*-(–)-prolinamide (29.4 mg, 0.258 mmol, Aldrich) was added to the ether solution, immediately producing a bright yellow precipitate. The solution was stirred for 0.5 h, then gravity filtered and dried in air. The crude product (59.0 mg, 0.190 mmol, 79% yield) was recrystallized from an acetone–hexane mixture; mp 172.3°C; IR (KBr disc), ν (cm^{-1}): 3285 (s, N–H *str*), 1687 (s, C=O *str*/N–H *def*), 1600 (s, C–O *str*); ^{1}H NMR (CD_3OD, 400 MHz), δ: 2.0–2.5 (m, 4H), 3.39 (m, 3H), 3.83 (s, 2H), 6.61 (d, 2H, *J* = 9 Hz), 8.08 (d, 2H, *J* = 9 Hz) ppm; –LSIMS, *m/e* (relative intensity): 391 (2 × (M^- + 1), 17), 195 (M^-, 100), 179 (6.7); +LSIMS, *m/e* (relative intensity): 115 (M^+, 100), 70 (22). Anal. calcd. for **1.pro-amide**, $C_{13}H_{18}N_4O_5$: C 50.32, H 5.85, N 18.06; found: C 50.16, H 5.65, N 18.06.

Synthesis of the S*-(–)-proline methyl ester complex of **1**: **1.pro-meth***

The hydrochloride salt of *S*-(–)-proline methyl ester (54.4 mg, 0.329 mmol, Sigma) and 13.2 mg of NaOH (0.330 mmol, BDH) were dissolved in approximately 10 mL of ethanol, producing a cloudy precipitate (NaCl). The solution was centrifuged for 30 min, then added to a flask containing 66.2 mg of **1** (0.337 mmol) dissolved in approximately 150 mL of diethyl ether. The resultant bright yellow solution was rotary evaporated to near dryness, producing a yellow oil. Approximately 10 mL of acetone was added to the flask, then hexane was added until the solution became faintly cloudy. Over the course of several hours a light yellow solid precipitated along the walls of the flask. The crude product was recrystallized from ethanol (27.3 mg, 0.026 mmol, 15.5% yield); mp: two overlapping endotherms, the first peaking at 132.2°C, the second peaking at 138.2°C; IR (KBr disc), ν (cm^{-1}): 3377 (s, N–H *str*), 1746 (s, C=O *str*), 1607 (s, C–O *str*); ^{1}H NMR (D_2O, 400 MHz), δ: 2.0–2.5 (m, 4H), 3.4(m, 3H), 3.83 (s, 4H), 3.85 (s, 3H), 6.61 (d, 4H, *J* = 9 Hz), 8.09 (d, 4H, *J* = 9 Hz) ppm; –LSIMS, *m/e* (relative intensity): 391 (2 × (M^- + 1), 38), 195 (M^-, 100), 179 (5.6); +LSIMS, *m/e* (relative intensity): 130 (M^+, 100), 70 (24). Anal. calcd. for **1.pro-meth**, $C_{22}H_{27}N_5O_{10}$: C 50.67, H 5.22, N 13.43; found: C 50.63, H 5.17, N 13.42.

Synthesis of the S*-(–)-proline benzyl ester salt of **1**: **1.pro-benz***

The hydrochloride salt of *S*-(–)-proline benzyl ester (120.9 mg, 0.500 mmol, Sigma) and 32.4 mg of crushed KOH (0.579 mmol, Aldrich) were dissolved in 30 mL of ethanol, producing a

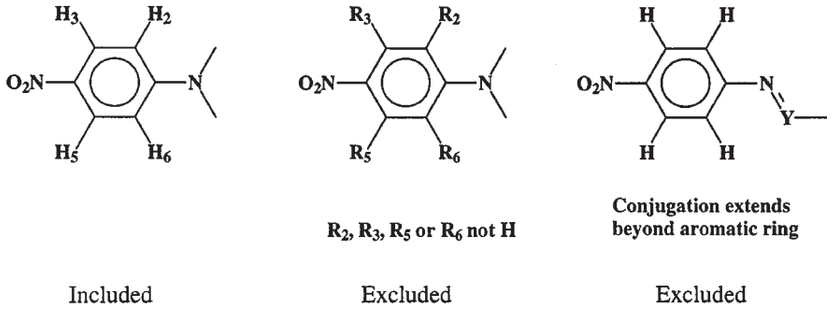
Fig. 2. Chemical structures considered in the CSD search for **PNA** analogs.



white solid precipitate (KCl). The solution was centrifuged for 10 min, after which the liquid was decanted and added to a solution of acid **1** (95.9 mg, 0.489 mmol) in 20 mL of ethanol. The resultant solution was rotary evaporated to dryness, leaving a bright yellow precipitate that was dried under vacuum. The crude product (180.6 mg, 0.450 mmol, 92% yield) was recrystallized from methanol; mp 130.5°C; IR (KBr disc), ν (cm^{-1}): 3277 (s, N–H *str*), 1732 (s, C=O *str*), 1603 (s, C–O *str*); ^{1}H NMR (CD_3OD, 400 MHz), δ: 2.0–2.5 (m, 4H), 3.4 (m, 2H), 3.83 (s, 2H), 4.5 (t, 1H, J = 9 Hz), 5.30 (m, 2H), 6.61 (d, 2H, J = 9 Hz), 7.45 (s, 5H), 8.08 (d, 2H, J = 9 Hz) ppm; –LSIMS, m/e (relative intensity): 391 (2 × (M^- + 1), 50), 195 (M^-, 100); +LSIMS, m/e (relative intensity): 206 (M^+, 100), 91 (51), 70 (24). Anal. calcd. for **1.pro-benz**, $C_{20}H_{23}N_3O_6$: C 59.84, H 5.78, N 10.47; found: C 59.60, H 5.85, N 10.54.

SHG measurements

Measurements were made using the Kurtz and Perry powder method (27). Approximately 50 mg of material were loaded into the sample cell, which was formed between two Pyrex 25 × 75 × 1 mm microscope slides (Canlab). Two strips of masking tape with a 2 cm diameter hole cut through the centre were placed 3 cm from the end of one of the slides. The circular window was filled with a thin layer of sample (~0.3 mm thick). The second microscope slide was clipped onto the first, sandwiching the sample between the slides.

The 1064 nm fundamental output from a Q-switched Nd:YAG laser (Quanta Ray) was divided by a beam splitter, where one portion of the light was directed onto a reference cell containing urea. The resultant second-harmonic signal (532 nm) was passed through a sharp-cut filter (Corning 527) designed to eliminate any stray visible light from the laser flash pump, and several neutral density filters (Wratten, 0.30 + 0.70) designed to attenuate the second-harmonic signal, before being focused onto a photomultiplier tube (RCA IP28). The second portion of the fundamental beam was directed onto a second cell containing the sample to be measured. Any second harmonic produced was passed through a series of neutral density filters (Wratten, 1.0 + 0.7), then focused into a monochromator (Beckman DU spectrophotometer, model 2400) in order to discriminate between SHG light and any stray visible light and IR light. Monochromatic 532 nm light was then directed onto a second photomultiplier (RCA IP28) for measurement. In order to measure the SHG efficiency of a given material accurately, urea was first placed in both the sample and reference cells and the relative SHG intensities were measured. The relative amounts of light directed onto the two photomultiplier tubes by the same material were then used to normalize subsequent measurements of relative intensities between a given material and urea. To gauge the accuracy of our experimental setup, the relative efficiency of **NPP** was measured. Large crystals of **NPP** and urea were crushed to a powder and passed through sieves in order to isolate the desired range of particle size. Using particles within the 125–149 μm diameter range for both urea and **NPP**, the relative SHG efficiency of 53 ± 5 for **NPP** was close to the relative efficiency of 60 previously reported (8). The SHG efficiencies of the acids, amines, and salts were first measured in the form of unsized powders. Single crystals, large enough to be crushed into a wide range of particle sizes (i.e., from ~250 μm to less than 125 μm in diameter), were grown (if possible), of any material displaying significant SHG intensity (approximately that of urea). These were then crushed and isolated on the basis of their particle size. SHG measurements were made over a series of particle size ranges in order to test for phase matchability. The SHG intensities quoted hereafter represent the measurements made with particles in the 125–149 μm diameter range.

Survey of the Cambridge Structural Database

As with all organic materials, the likelihood of a **PNA**-type molecule crystallizing in a non-centrosymmetric space group should be relatively small. While non-centrosymmetry is a prerequisite for SHG, it is insufficient by itself to ensure a strong SHG response. It is possible, for example, for chiral materials to adopt highly symmetric orientations within the crystal, and yet lack any formal centre of inversion. Materials crystallizing with their charge-transfer axes in an anti-parallel alignment adopt an orientation that is highly unfavorable for SHG. A survey of the Cambridge Structural Database (CSD) was undertaken in order to examine the packing trends of materials that are structurally similar to **PNA**. The survey was limited to materials that are unsubstituted at the 2, 3, 5, and 6 positions around the benzene ring, and whose conjugation does not extend beyond the amine nitrogen, as shown in Fig. 2.

The results of the survey, summarized in Table 1, found 119 molecules fitting the above criteria, 30 of which (25.2%) crystallized in non-centrosymmetric space groups. A further analysis of the packing geometries of the non-centrosymmetric structures was carried out by calculating the angle between the charge-transfer axes of the various symmetry-related molecules in each unit cell. Any two molecules with their charge-transfer axes separated by 175° or

Table 1. Packing trends of **PNA** analogs.[a]

Total	119		
Centrosymmetric	89		
		Achiral	Chiral
Non-centrosymmetric	30	16	14
Anti-parallel	9	2	7
Potential SHG compounds	21	14	7

[a]Results compiled from the Cambridge Structural Database (1996).

more were considered to be in an anti-parallel alignment. Of these molecules, 9 were found to be oriented in this way, leaving 21 (17.6%) as potential molecules for SHG. Of the 30 non-centrosymmetric structures found, 14 were composed of optically pure molecules and were thus forced to crystallize without a centre of inversion. Even with the addition of optical activity, half of these molecules (7) crystallized with an anti-parallel alignment of their molecular charge-transfer axes.

X-ray crystallographic analyses

General

Single crystals suitable for X-ray crystallographic analyses were grown and the structures of the materials determined for all but **1.pro-benz**. No solvent system was found in which **1.pro-benz** would recrystallize in any form other than a fine powder. Crystallographic data for **1, 1.eph, 1.pro-but, 1.pro-ol, 1.pro-amide**, and **1.pro-meth** appear in Table 2. The final unit cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 75.4°–99.9° for **1**, 2θ = 75.2°–98.8° for **1.eph**, 2θ = 55.3°–89.9° for **1.pro-but**, 2θ = 46.3°–72.1° for **1.pro-ol**, 2θ = 41.0°–67.8° for **1.pro-amide**, and 2θ = 51.3°–93.6° for **1.pro-meth**. The intensities of three standard reflections, measured every 200 reflections throughout the data collection, decayed linearly by 1.3% for **1.pro-but** and by 1.7% for **1.pro-meth**. All other crystals exhibited decay of less than 1%.

The data were processed, and corrected for Lorentz and polarization effects, decay, and absorption (based on three azimuthal scans). The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being defined from an *E*-map or from subsequent difference Fourier syntheses and refined with anisotropic thermal parameters, with the exception of the disordered *p*-nitrophenylglycinate anion of **1.eph** (see subsequent discussion). Hydrogen atoms were located either from a difference map and refined isotropically or they were fixed in calculated positions with C—H = 0.98 Å and $B_H = 1.2\ B_{\text{bonded atom}}$. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (29, 30). Final atomic coordinates and equivalent isotropic thermal parameters for all refined atoms are given in Table 3, and a summary of bond lengths and bond angles appears in Tables 4 and 5, respectively. Tables of unrefined hydrogen atom parameters, anisotropic thermal parameters, torsion angles, full bond lengths and bond angles, intermolecular contacts, and least-squares planes are available as supplementary material.[2]

Fig. 3. Crystal packing of **1**, viewed down the *b*-axis.

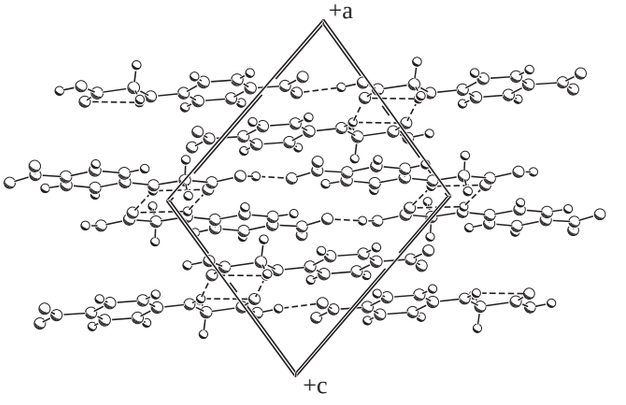

Fig. 4. ORTEP packing diagram of **1.eph** (50% probability ellipsoids). Only the major disordered fragment is shown. Hydrogens have been removed for clarity.

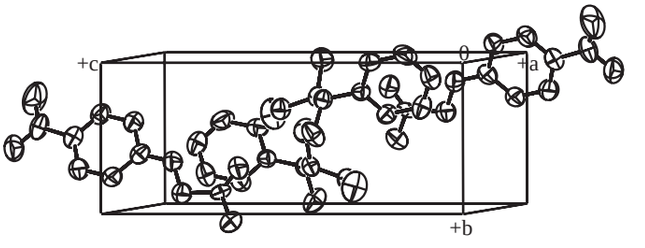

p-*Nitrophenylglycine (1)*

The SHG-inactive parent acid **(1)** crystallizes in centrosymmetric space group $P\bar{1}$. The packing of **1**, shown in Fig. 3, consists of two molecules per asymmetric unit. The carboxylic acid proton of each molecule is linked via intermolecular O—H···O hydrogen bonds to the NO_2 oxygens directly behind it. A second set of hydrogen bonds, in this case intermolecular N—H···O bonds, links each molecule to its symmetry-related neighbor, forming an infinite chain of oppositely oriented dimer pairs.

*Salt **1.eph***

The crystal packing of **1.eph** is shown in Fig. 4. The *p*-nitrophenylglycinate moiety is disordered such that it adopts two separate orientations, with the minor fragment related to the major fragment by rotating it about its charge-transfer axis by 180°. The directions of the charge-transfer axes of the major and minor fragments are then offset by approximately 16°. The orientations of both fragments are shown in Fig. 5. All of the atoms in the mi-

[a] $B_{eq} = (8/3)\pi^2\Sigma\Sigma(U_{ij}a_i^*a_j^*(\mathbf{a}_i\mathbf{a}_j))$.

nor fragment were eventually found from large peaks on the difference maps. This fragment, however, was severely distorted, particularly the aromatic ring, therefore the ring was modeled as a rigid body with idealized positions and bond lengths of 1.39 Å. The relative populations of the major and minor fragments were refined to 0.75 and 0.25, respectively. There is no evidence of disorder in the pseudoephedrinium moiety.

*Salt **1.pro-but***

The crystal packing of **1.pro-but**, shown in Fig. 6, consists of alternating layers of cations and anions stacked one upon the other along the *b*-axis of the unit cell. Each layer of

Fig. 5. Orientations of the disordered *p*-nitrophenylglycinate anion in **1.eph**. The major fragment, with labeled atoms, makes an angle of θ_{maj} = 76.7° to the *b*-axis, while the minor fragment, unlabeled, makes an angle of θ_{min} = 61.0° to the same axis.

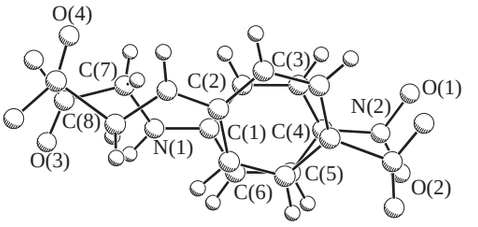

Fig. 6. ORTEP packing diagram of **1.pro-but** (50% probability ellipsoids).

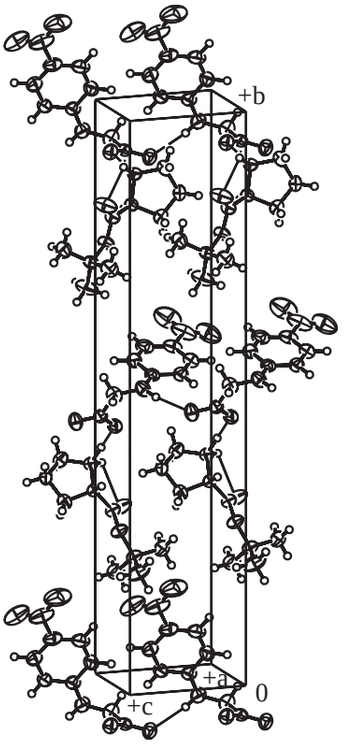

anions is an infinite chain formed by intermolecular N—H···O hydrogen-bonds between glycinate functionalities on adjacent anions. The proline *tert*-butyl ester cations comprising the cation layer are linked to each other, while the proline NH's are linked to the anion layer above, also via N—H···O hydrogen-bonds. The only disorder is found in the proline ring, which is found to adopt both of the "envelope" conformations.

*Salts **1.pro-ol** and **1.pro-amide***

Each salt packs with two formula units in the asymmetric unit, with their two *p*-nitrophenylglycinate moieties related by pseudo centres of inversion (Figs. 7 and 8). In the case of **1.pro-ol**, both *p*-nitrophenylglycinate units are linked by a pair of N—H···O hydrogen bonds between the glycine NH and carboxylate O to form a dimer. In the case of **1.pro-amide**, each prolinamide cation is bound via N—H···O hydrogen bonds to both *p*-nitrophenylglycinate

anions in the asymmetric unit, forming a dimer, while an intermolecular N—H···O hydrogen bond linking neighboring *p*-nitrophenylglycinate anions forms an infinite chain of dimers that propagate through the crystal diagonally between the *a*- and *c*-axes.

Table 6. SHG results for **1**, **NPP**, and all six salts containing the **1** chromophore.

Acid/salt			SHG vs. urea
1			0
NPP			53 ± 5
1.eph	**1** +		18 ± 2
1.pro-but	**1** +		13 ± 2
1.pro-benz	**1** +		11 ± 2
1.pro-ol	**1** +		0.010 ± 0.004
1.pro-amide	**1** +		0.012 ± 0.008
1.pro-meth	**1** +		0.022 ± 0.005

*Complex **1.pro-meth***

The **1.pro-meth** complex crystallizes with the two *p*-nitrophenylglycinate moieties oriented in an anti-parallel manner (Fig. 9). While there is no pseudo centre of inversion between the chromophores, the two charge-transfer axes are separated by almost 180°. The two *p*-nitrophenylglycine moieties share one proton via a strong N—H···O hydrogen bond between their respective carboxylate groups so that the two charge-transfer axes are anti-parallel to one another. The position of the shared proton was refined and the difference in O—H distances (1.18 Å vs. 1.39 Å) suggests that the proton is more strongly held to one oxygen than to the other. The proline ring is linked to the deprotonated carboxyl group via a strong N—H···O hydrogen bond.

Results and discussion

Macroscopic quadratic susceptibilities

Excluding the salt **1.pro-benz**, for which there is no structural information, all other salts in the series crystallize in point groups 2 or 222. According to Zyss and Oudar (18, 19), the relationship between the macroscopic quadratic susceptibility, d_{IJK}, and the molecular second-order hyperpolarizability, β_{ijk}, is given by

$$[1] \qquad d_{IJK} = N f_I^{2\omega} f_J^{\omega} f_K^{\omega} \frac{1}{n} \sum_{s=1}^{n} \sum_{ijk} \cos\ (I, i(\mathrm{s}))\ \cos\ (J, j(\mathrm{s}))\ \cos\ (K, k(\mathrm{s}))\beta_{ijk}(\mathrm{s})$$

$$[2] \qquad d_{IJK} = N f_I^{2\omega} f_J^{\omega} f_K^{\omega} b_{IJK}$$

where N is the chromophore density; f is a local-field factor used to correct for mutual polarization from neighboring molecules; n is the number of symmetry-related molecules in the unit cell (indexed by s); i, j, and k describe the direction of polarization of all the interacting electric fields in the three orthogonal directions of the molecular frame of reference, x, y and z; I, J, and K describe the direction of polarization of the interacting fields in the three orthogonal directions of the crystal frame of

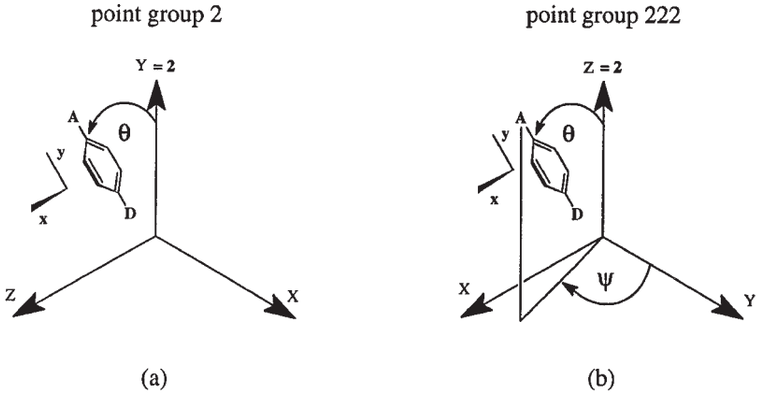

Fig. 11. UV–visible absorption spectra of **1, NPP**, and **PNA** in EtOH.

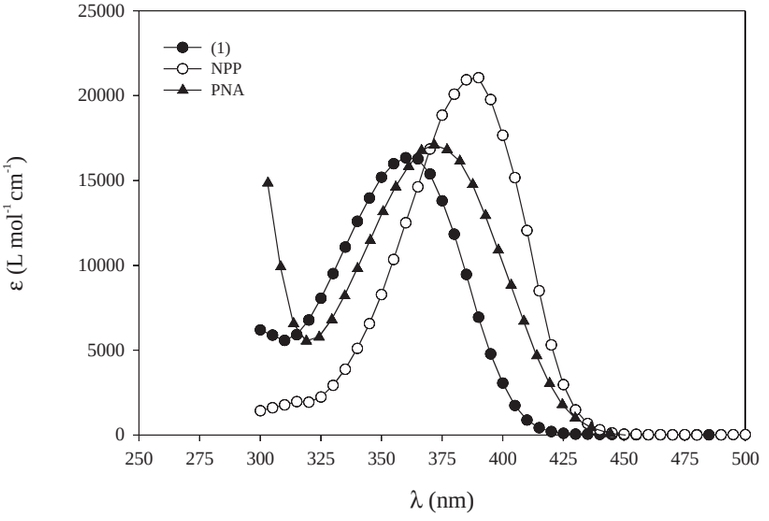

reference, *X*, *Y*, and *Z*; the cosine terms represent the rotation of the molecular reference frame from (*i*,*j*,*k*) onto the crystal reference frame (*I*,*J*,*K*); b_{IJK} in eq. [2] represents the crystalline nonlinearity per molecule. This last term can be calculated from the molecular orientations in the cell, derived from the structural data. Evaluation of the various d_{IJK} susceptibility elements requires some estimate of the local-field factors, usually taken in the Lorentz form:

$$[3] \qquad f^{\omega} = \left(\frac{n_{\omega}^2 + 2}{3} \right)$$

Assuming a one-dimensional *b* tensor (20, 31, 32) oriented in the *y*-direction defined in Fig. 1 (as is conventionally done when discussing **PNA**-type materials whose polarizability lies predominantly along the molecular charge-transfer axis) and Kleinman symmetry (33), eq. [1] reduces to

$$[4] \qquad d_{YZZ} = N f_Y^{2\omega} f_Z^{\omega} f_Z^{\omega} (\cos\theta \sin^2\theta) \beta_{yyy} \text{ [point group 2]}$$

and

$$[5] \qquad d_{XYZ} = N f_X^{2\omega} f_Y^{\omega} f_Z^{\omega} (\cos\psi \sin\psi \cos\theta \sin^2\theta) \beta_{yyy} \text{ [point group 222]}$$

where angles θ and ψ are defined as shown in Fig. 10.

SHG intensities

The measured SHG intensities of each of the six salts and of **NPP** are found in Table 6. Studies calculating and measuring the molecular hyperpolarizability of **PNA** and its derivatives have consistently shown that those with tertiary amines, such as

Table 7. Space group, chromophore density (N), and orientational parameters (θ, ψ) for **NPP** and the six salts made from **1**.

Acid/salt	Space group	N ($\times 10^{-3}$ / Å^3)	θ (°) [a]	ψ (°)
1	$P\bar{1}$	4.75	n/a [b]	n/a
NPP	$P2_1$	3.68	58.7	n/a
1.eph	$P2_1$	2.17	76.7, 61.0	n/a
1.pro-but	$P2_1$	2.17	50.3	n/a
1.pro-benz	Undetermined	—	—	—
1.pro-ol	$P2_12_12$	2.72	64.8, –117.1	80.2, –98.8
1.pro-amide	$P2_1$	2.84	47.6, –131.5	n/a
1.pro-meth	$P2_12_12_1$	3.20	–92.7, 88.9	170.7, –11.1

[a]Entries with more than one angle correspond to structures with more than one chromophore per asymmetric unit or with a disordered chromophore.
[b]n/a: not applicable.

NPP, possess molecular hyperpolarizabilities roughly comparable to or only marginally greater than **PNA** and its secondary amine derivatives, such as **1** (34–36). As a result, factors such as chromophore density and orientation should have a far greater influence on the observed SHG intensities of these salts than should their molecular hyperpolarizability, when compared with **NPP**. Assuming roughly equivalent local-field factor terms, an assumption that is consistent with their similar absorption characteristics (Fig. 11), the calculated ratio of SHG intensities between **NPP** and the salts in this study can therefore be given (9, 37) by

$$[6] \qquad \frac{I^{2\omega}(1)}{I^{2\omega}(2)} = \left(\frac{d_{IJK}(1)}{d_{IJK}(2)}\right)^2 = \left(\frac{N^{(1)}b_{IJK}^{(1)}}{N^{(2)}b_{IJK}^{(2)}}\right)^2$$

where d_{IJK} (and b_{IJK}) refers to the predominant d (and b) tensor for phase-matched SHG, d_{YZZ} for materials crystallizing in point group 2, and d_{XYZ} for those in point group 222. Included in Table 7 are the pertinent data derived for each salt whose X-ray crystal structure was determined.

*Salt **1.eph***

Although its SHG intensity is considerably weaker than that of **NPP, s**alt **1.eph** produces the greatest SHG intensity of the six salts in the series. The reduced chromophore density and unfavorable chromophore orientation, relative to **NPP**, acts to limit its phase-matching d_{YZZ} component, and consequently its SHG efficiency. The effective b_{YZZ} element for the disordered structure, taking into account the relative populations of each fragment, is

$$[7] \qquad b_{YZZ}\ (\mathbf{1.eph}) = (0.75 \cos\theta_{maj} \sin^2\theta_{maj} + 0.25 \cos\theta_{min} \sin^2\theta_{min})\ \beta_{yyy}(\mathbf{1.eph}) = 0.256\ \beta_{yyy}(\mathbf{1.eph})$$

The chromophore orientation of **NPP** leads to a near-maximized phase-matching element of: $b_{YZZ}(\mathbf{NPP}) = 0.379\beta_{yyy}(\mathbf{NPP})$.

Taking into account the different chromophore densities of the two materials and assuming roughly equivalent local-field factor correction terms, the ratio of SHG intensities between **1.eph** and **NPP** was estimated as

$$[8] \qquad \frac{I^{2\omega}(\mathbf{1.eph})}{I^{2\omega}(\mathbf{NPP})}(\text{estimated}) = \left(\frac{d_{YZZ}(\mathbf{1.eph})}{d_{YZZ}(\mathbf{NPP})}\right)^2 = 0.16$$

In fact, the measured ratio appears to be approximately twice the estimated ratio.

$$[9] \qquad \frac{I^{2\omega}(\mathbf{1.eph})}{I^{2\omega}(\mathbf{NPP})}(\text{measured}) = 0.34 \pm 0.07$$

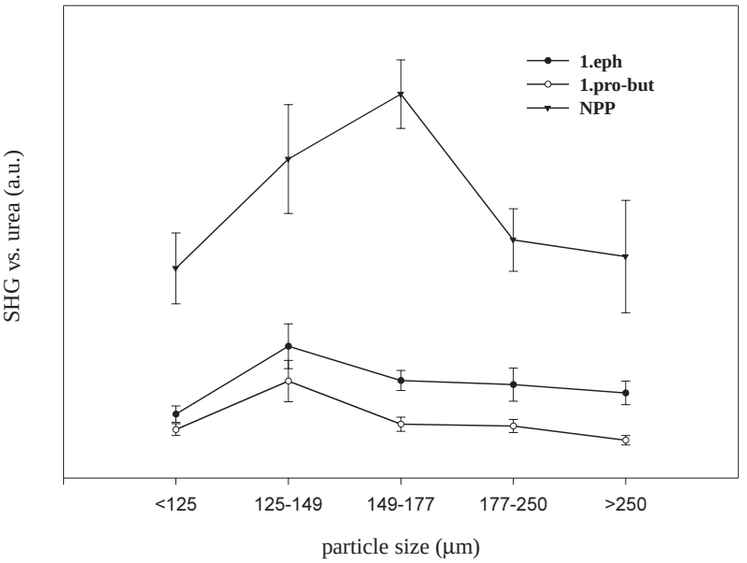
Barring the unlikely contribution to the overall molecular hyperpolarizability from the pseudoephedrinium counterion (35), the surprisingly high SHG intensity of **1.eph** relative to **NPP** may be the result of the assumptions made regarding equivalent local-field factor correction terms. These terms are intended to account for any contribution to the polarization of the chromophores from their immediate surroundings (i.e., neighboring molecules), and are assumed to be consistent throughout the crystal. The considerable fraction of disordered chromophores (25%) may have an additional influence on the refractive indices of the salt. Without direct measurement of the refractive indices for both wavelengths in question, the extent to which the disorder contributes to the increased SHG response of **1.eph** is unclear.

*Salt **1.pro-but***

The SHG-chromophore in **1.pro-but** is almost ideally oriented for phase-matched SHG. Crystallizing in space group $P2_1$, with $\theta = 50.1°$, the phase-matching element b_{YZZ} is $0.378\,\beta_{yyy}$. The decreased SHG intensity, with respect to **NPP**, appears to be the result of the significantly lower chromophore density of **1.pro-but** (2.17×10^{-3} Å^{-3} vs. 3.68×10^{-3} Å^{-3} for **NPP**), leading to an estimated SHG intensity ratio of

© 1998 NRC Canada

Fig. 12. Change in SHG intensity with particle size for **NPP**, **1.eph**, and **1.pro-but**.



$$[10]\quad \frac{I^{2\omega}(\textbf{1. pro - but})}{I^{2\omega}(\textbf{NPP})}(\text{estimated}) = \left(\frac{d_{YZZ}(\textbf{1. pro - but})}{d_{YZZ}(\textbf{NPP})}\right)^2 = 0.34$$

The observed ratio of SHG intensities is

$$[11]\quad \frac{I^{2\omega}(\textbf{1. pro - but})}{I^{2\omega}(\textbf{NPP})}(\text{measured}) = 0.25 \pm 0.05$$

*Salts **1.pro-ol** and **1.pro-amide***

Both **1.pro-ol** and **1.pro-amide** produce small but measurable amounts of SHG. The packing of each material consists of two formula units per asymmetric unit, with the two *p*-nitrophenylglycinate moieties related by a pseudo centre of inversion. In the case of **1.pro-ol**, neither chromophore in the asymmetric unit appears to be oriented to maximize its crystalline nonlinearity for materials in point group 222. In addition, the contribution from each chromophore leads to the near-complete cancellation of the overall b_{XYZ} element. This anti-parallel alignment of the two chromophores in the asymmetric unit leads to a powder SHG intensity several orders of magnitude lower than the standard, urea:

$$[12]\quad \begin{aligned} &b_{XYZ}(1) = 0.058\beta_{yyy},\ \ b_{XYZ}(2) = -0.055\beta_{yyy} \\ &b_{XYZ}(\text{tot}) = b_{XYZ}(1) + b_{XYZ}(2) = 0.003\beta_{yyy}\quad (\textbf{1. pro - ol}) \end{aligned}$$

The situation is slightly different in the case of **1.pro-amide**. Individually, each *p*-nitrophenylglycinate moiety in the asymmetric unit is favorably oriented for SHG, according to the $P2_1$ space group in which the salt crystallizes. However, addition of the two b_{YZZ} tensor elements (with $\theta(1) = 47.6°$ and $\theta(2) = -131.5°$), leads to their nearly complete cancellation, and subsequently to its weak powder SHG intensity relative to urea:

$$[13]\quad \begin{aligned} &b_{YZZ}(1) = 0.368\beta_{yyy},\quad b_{YZZ}(2) = -0.372\beta_{yyy} \\ &b_{YZZ}(\text{tot}) = b_{YZZ}(1) + b_{YZZ}(2) = -0.004\beta_{yyy}\quad (\textbf{1. pro - amide}) \end{aligned}$$

*Complex **1.pro-meth***

According to the space group in which the complex crystallizes, $P2_12_12_1$, neither of the two chromophores is favorably oriented for SHG. Addition of the two b_{XYZ} tensors gives

$$[14]\quad \begin{aligned} &b_{YXZ}(1) = 0.004\beta_{yyy},\quad b_{XYZ}(2) = -0.008\beta_{yyy} \\ &b_{XYZ}(\text{tot}) = b_{XYZ}(1) + b_{XYZ}(2) = -0.004\beta_{yyy} \end{aligned}$$

Phase-matching results

Where possible, salts displaying significant SHG activity (i.e., SHG(salt) ≥ SHG(urea)) were tested for phase matchability. Phase-matchable materials can be distinguished from non phase-matchable materials by their different behavior with increasing particle size (27, 38), with the SHG intensity of phase-matchable materials increasing to a maximum with increasing particle size before leveling off to a relatively constant intensity. In the case of **1.pro-benz**, recrystallization produced only a microcrystalline powder, therefore no test for phase matchability was carried out. The phase-matching analysis of both **1.eph** and **1.pro-but** reveals a maximum SHG intensity in the 125–149 μm range before decreasing slightly with larger particle sizes and leveling off to a constant intensity (Fig. 12). These results would appear to indicate that both are phase matchable. The behavior of **NPP**, a known phase-matchable material (39), was similar to the behavior displayed by the two salts when subjected to the same analysis. The decrease in SHG intensity for larger particle sizes is likely due to a decrease in the amount of material exposed to the incident radiation. The larger sized particles are likely to occupy the volume in the sample cell less efficiently than smaller particles, producing voids containing no sample. In addition, crystal morphology may limit the number of orientations a particle may adopt in the sample cell, possibly excluding the orientations best suited for phase matching.

Discussion

It would appear from the preceding results that the coupling of chiral ionic auxiliaries to SHG chromophores not only ensures non-centrosymmetric packing, but also significantly enhances the potential for packing that leads to large SHG efficiencies compared to achiral compounds and nonionic systems. Of the six salts prepared from the otherwise SHG-inactive parent acid **(1)**, three displayed significant SHG activity on coupling with the chiral auxiliary. While no structural information is as yet available for **1.pro-benz** (SHG vs. urea ~ 11) it seems reasonable to surmise, based on the magnitude of its SHG response, that addition of the proline benzyl ester has allowed the *p*-nitrophenylglycinate chromophore to align in a favorable orientation for SHG. Examination of all the SHG results reveals, however, that none of the salts, even those with favorably oriented chromophores, approach the SHG efficiency of **NPP**, as a result of the reduced chromophore densities associated with the salts. This is as expected since the chiral counterion is responsible only for inducing an acentric packing environment, and should have a negligible contribution to the hyperpolarizability of the salt.

Also of note is the seemingly conflicting relationship between chromophore density and SHG activity. In the case of salts with significant SHG activity (whose crystal structures were determined) both chromophore densities were ~2.2 × 10^{-3} Å^{-3}, whereas the three salts or complexes and parent acid that showed little or no SHG activity (**1.pro-ol**, **1.pro-amide**, **1.pro-meth,** and **1)** had chromophore densities of 2.7 × 10^{-3} Å^{-3} or greater. The three most strongly SHG-active salts contained the three bulkiest counterions. These bulky counterions may be more adept at separating the polar chromophores, thus diminishing the electrostatic attraction that may lead to anti-parallel packing. This, however, limits the maximum possible SHG efficiency by "diluting" the chromophore density.

Characterization of macroscopic disorder in a porous glass with NMR microimaging and scanning electron microscopy

Luc Tremblay, Serge Lacelle, and Charles G. Fry

Abstract: A study of the intensity fluctuations in one-dimensional NMR microimaging profiles of imbibed porous Pyrex glass filters is presented. An approach to characterize some aspects of the macroscopic randomness from the NMR microimaging profiles of this porous medium is developed. Statistical properties, such as the arithmetic and geometric means, of the distributions of peak separations between the intensity fluctuations are shown to reveal information about the pore size and the pore-to-pore distances in porous media. The intensity–intensity correlation functions of the one-dimensional NMR profiles display an interplay, as a function of length scale, among the dimensions of the porous network and its embedding space, and their respective dimensions in the projections. Corroboration of these NMR results are achieved with similar analysis of SEM two-dimensional images and their corresponding one-dimensional projections obtained with the same porous Pyrex glass. The approach developed to characterize the macroscopic randomness in these porous glass filters should prove generic for the study of other random materials.

Key words: NMR imaging, scanning electron microscopy, porous media, disorder, statistical characterization.

Résumé : On a réalisé une étude des fluctuations d'intensité des profils de microimagerie RMN unidimensionnelle de filtres de verre Pyrex poreux imbibés. On a développé une approche dans le but de caractériser un certain nombre d'aspects du caractère macroscopique aléatoire des profils de microimagerie RMN de ce milieu poreux. On a démontré que des propriétés statistiques, comme les moyennes arithmétiques et géométriques des distributions des séparations des pics entre les fluctuations d'intensité, fournissent de l'information relative à la taille des pores ainsi que sur les distances entre les pores du milieu poreux. Les fonctions de corrélation des profils de RMN unidimensionnelle présentent une interrelation des dimensions du réseau poreux, de la taille de son incrustation ainsi que de leurs dimensions relatives en projections en fonction de la longueur de l'échelle. On a corroboré ces résultats de la RMN à l'aide d'analyses similaires d'images bidimensionnelles microscopie électronique à balayage et des projections unidimensionnelles correspondantes obtenues avec le même verre Pyrex poreux. L'approche développée pour caractériser le caractère macroscopique aléatoire de ces filtres de verre poreux devrait s'avérer assez générale pour permettre l'étude d'autres matériaux aléatoires.

Mots clés : microimagerie RMN; microscopie électronique à balayage; milieu poreux; désordre; caractéristique statistique.

1. Introduction

A unifying theme in materials science is the relationship between microstructures and macroscopic properties of materials (1). This interplay of length scales involves a hierarchy of structures, starting from atoms and molecules to phase configurations, which are controlled through processing to yield engineered materials and products. Disorder, which appears as an integral part at all structural levels of materials, ranges from point defects, dislocation lines, grain boundaries, domain shapes, and crystal facets (2–5). The performance of materials depends to various degrees on both structures and their disorder. It is thus surprising that only in the last two decades or so has the study of disordered materials become respectable in the sense of not being denigrated, or viewing disorder solely as perturbations in ordered systems. In this paper, we characterize some aspects of the structural disorder of a macroscopically homogeneous (in a statistical sense) porous glass with nuclear magnetic resonance (NMR) microimaging and scanning electron microscopy (SEM).

Early efforts to characterize disordered materials with NMR have focused on the microscopic structural level by monitoring the dispersion of chemical environments with chemical shift measurements and local mobilities through relaxation studies. Spin-diffusion NMR methodologies have been developed and refined to probe certain aspects of domain

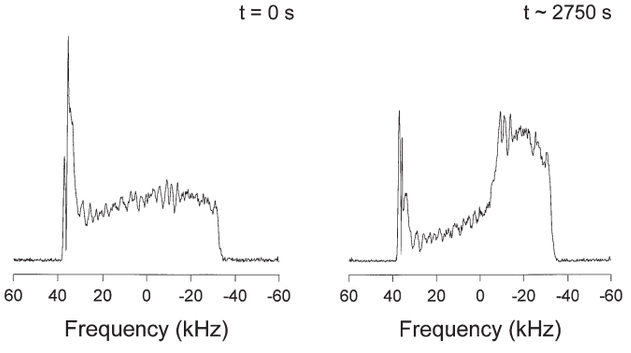
Fig. 1. Profiles of ^{1}H nuclear spin densities (intensities in arbitrary units) of the critical binary mixture, aniline–cyclohexane, in porous Pyrex glass along the gravitational (z) direction (abscissa in kHz) at t = 0 s and t = 2750 s after a thermal quench below the upper consolute solution temperature of the bulk mixture (T_c = 30°C). The bottom of the samples is in the positive frequencies; the residual binary fluid between the porous glass and the NMR tube is seen at that position.



structural disorder over ranges extending from 1 nm up to several hundred nanometers. In materials with macroscopic disorder, such as certain porous media, self-diffusion (6) and relaxation (7) NMR measurements and NMR microimaging (8) have contributed to the elucidation of structural features on length scales above tens of micrometers (μm).

For several years now, we have studied the phase separation of critical binary liquid mixtures in porous media (9, 10). To understand the role of confinement and disorder in the phase separation processes, two relevant length scales need to be examined in this problem: the correlation length of the critical composition fluctuations, ξ, and the "typical" length scale of the disorder, e.g., the average pore size L or any other moment of the pore size distribution. When $\xi > L$, the phase separation is strongly affected, as compared to the situation in the bulk (9). In the late stages of the phase separation processes, when $\xi < L$, another length scale, the so-called capillary length (arising from the competition between surface tension and gravitational stresses of interfaces between domains of different compositions and densities), becomes important when its size reaches L (10).

To probe this latter regime of phase separation in a confined space, we have measured time-dependent one-dimensional NMR microimaging profiles of the critical aniline–cyclohexane mixture in a porous Pyrex glass with $L \approx 160$ μm and $\xi \approx 50$ Å (10). Figure 1 displays the profiles of the ^{1}H nuclear spin densities of the critical binary mixture, as a function of position along the gravitational direction (z-direction) in a porous glass sample (1.5 cm in length), at t = 0 and at $t \sim 2750$ s after a thermal quench below the upper consolute solution temperature of the bulk mixture (T_c = 30°C). These results clearly indicate that phase separation has indeed occurred, and demonstrate the presence of a widespread "interface" between the two liquid phases of different densities in the porous Pyrex glass at $t \sim 2750$ s. However, some other remarkable features of such profiles are the intensity fluctuations arising from the disorder in the glass. These intensity fluctuations appear noticeably different in character from thermal noise in the NMR signal (see the signal on either side of the glass sample in Fig. 1). The specific question we address in the present work is the following: what information can be inferred about the disorder in the porous glass from such intensity fluctuations in one-dimensional NMR microimaging profiles? The interpretation of the NMR results will be compared with information gathered from analysis of SEM images of the porous glass.

In NMR imaging, as in other forms of tomography, projection profiles are extensively used to reconstruct higher dimensional images (8). Obviously, different efforts and resources are required and expended in order to obtain and analyze images of different dimensions. Advantages and disadvantages of imaging approaches are dictated by a host of factors that affect both signal-to-noise and resolution considerations (8). For example, in our time-dependent studies of binary liquid phase separation in porous Pyrex glass (10), NMR microimaging of one-dimensional projections proved to be the most convenient method at our disposal because of the time constraint imposed by the phenomenon. It is well known (11, 12) that the projection of a D-dimensional object, embedded in a d-dimensional space, onto a subspace of dimension d_s unveils some information with new perspectives. A case in point, the dimensionality of the projection D_p, is identical to d_s if $D \geq d_s$, or is equal to D if $D < d_s$. Visualization of chemical and physical processes from different perspectives appears to help to better appreciate, probe, and understand simple and complex phenomena (13). As the development of computer software and hardware evolves, it is expected that applications in the field of visualization and imaging, including projections in different dimensions, will become more common and will be used more proficiently in the study of complex disordered phenomena. It is in this sense that we present our modest contribution, to reveal and extract some features of the disorder in porous Pyrex glass, relevant to the phase separation processes of the critical binary mixture aniline–cyclohexane, from one-dimensional NMR profilometry and corroborated by SEM image analysis.

2. Experimental section

Cylindrical samples of porous Pyrex glass filters (8.97 mm in diameter and 15 mm in length) were obtained from Ace Glass Inc. (14). These filters are commercially produced by sintering small glass cylinders (see digitized SEM image, Fig. 4 in Results and discussion, Sect. 3B). The chemical composition of the glass is 81% SiO_2, 12% B_2O_3, 4.5% Na_2O, and 2.5% Al_2O (14). The cut-off particle size filtered by this porous glass is 160 ± 15 μm as determined by Ace Glass (14), by measuring the pressure necessary to force the first air bubbles through the glass when submerged in a liquid with a known surface tension. The porosity of 18% was established by analysis of SEM and optical microscopy images, and by gravimetric and NMR methods (10). The glass filters were cleaned by soaking in a large excess of deionized water for at least 24 h, followed by further soaking in ethanol for a similar duration, and finally dried in an oven at about 130°C under vacuum for at least 24 h. Prior to experiments, an extra 3 h drying period at 130°C under vacuum was allowed. Following a cooling-off period, the

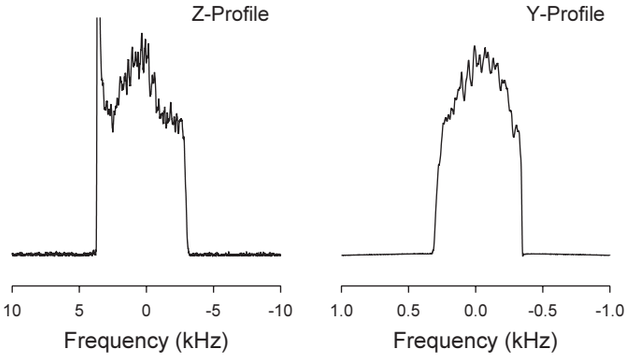
Fig. 2. Profiles of ^{1}H nuclear spin densities (intensities in arbitrary units) of cyclohexane in the porous Pyrex glass sample along the gravitational (z) direction (abscissa in kHz) and perpendicular to the gravitational directional direction (y). The cylindrical porous glass sample is 15 mm in length and 8.97 mm in diameter with its long axis oriented parallel to the z-direction. In the z-profile, the bottom of the sample is in the positive frequencies. The signal of the residual cyclohexane between the porous glass and the bottom of the NMR tube has been truncated to better observe the intensity fluctuations in the z-profile.



porous filters were subsequently inserted in flat-bottom 10 mm high-precision NMR tubes from Wilmad Inc. Spectroscopic grade cyclohexane, acquired from Sigma Chemical Company, was poured in excess over the glass. Air bubbles were then pumped out of the porous glass, and the excess cyclohexane was removed from the top of the samples.

Scanning electron microscopy (SEM) was performed with a JEOL JSM-840A instrument. To obtain SEM images, the porous glass was first injected and impregnated with a Buehler Epo-Kwick epoxy resin for 6 h. This step was necessary to reinforce the structure of the porous glass so that it could withstand the following sample preparation. After a drying period of at least 12 h, the sample was sliced in several cross sections with a diamond saw. The surface of each of these sections was polished, then covered with a 150 Å layer of Au–Pd mixture by cathodic sputtering. SEM images of these samples were obtained with a secondary electron method and with a scattered electron method at a working distance of 39 mm with a 15 kV acceleration voltage. The results were captured with a Nikkon camera on black and white TMAX 100 ASA film. These SEM images were digitized with a Hewlett–Packard ScanJet scanner with a resolution of 300 dpi; as a result, each surface pixel represents an area of 21 × 21 μm^2.

NMR experiments were performed on a Bruker MSL-300 spectrometer equipped with a microimaging unit and operating at a frequency of 300 MHz for ^{1}H. The sample temperature in the probe was controlled to ± 0.5 K with the temperature control unit supplied with the instrument. The acquisition parameters for all experiments were optimized to yield a maximum signal-to-noise ratio with a single scan. Imaging profiles in one dimension were obtained with a spin echo rf pulse sequence (8), with a typical 90° pulse width of 26 μs. Magnetic field gradient pulses were applied along the selected direction during the delay between the 90° and 180° rf pulses of the spin echo, and after the 180° pulse during the acquisition. Following the π pulse, the ensuing free induction decays (FIDs) were digitized at a rate of 250 kHz with 2048 points, providing a digital resolution of 122 Hz per point in the Fourier transformed spectra. The magnetic field gradients were 0.11 T m^{-1}, which produced a spatial resolution of 26 μm per point in the one-dimensional images along the z-direction.

The chemical composition of the glass filters and traces of residual impurities were ascertained with X-ray fluorescence using an energy dispersive Kevex 0700/8000 spectrometer. Radiation produced within the X-ray tube, by accelerating electrons with a 5 kV potential on a rhodium target in the vacuum, allowed the direct measurement of fluorescence of Na, Al, and Si. The excitation of impurities was accomplished with the secondary fluorescent source of a germanium target nominally irradiated with the X-ray tube operating at 15 kV; subsequent detection of the fluorescence identified Fe, Ni, and Cu impurities that could potentially affect the NMR results through paramagnetic relaxation as discussed in Sect. 3E.

3. Results and discussion

3A. NMR microimaging one-dimensional projection profiles

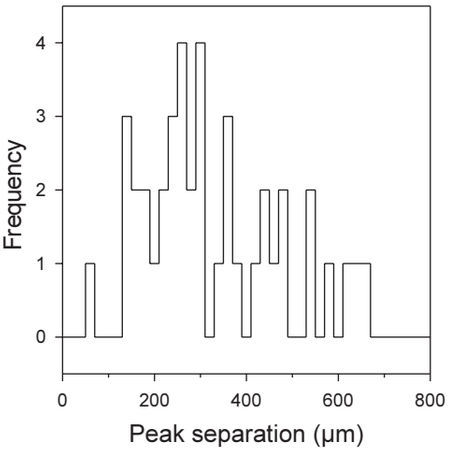
^{1}H NMR microimaging projection profiles of cyclohexane in the porous Pyrex glass parallel (z-direction along the length of the cylindrical sample) and perpendicular (y-direction) to the gravitational field (Fig. 2) clearly reveal intensity fluctuations due to the glass disorder. As the spatial resolution of these images is 26 μm per pixel, the signal intensities yield the relative number of ^{1}H nuclear spins at different positions and projected from the three-dimensional sample along a particular direction selected by the magnetic field gradients. Sample geometry and the finite radiofrequency excitation profile across the sample dictate part of the overall signal features (8, 10).

Our analysis of these NMR intensity fluctuations will proceed along two complementary avenues. First, we examine the distribution of peak separation in the NMR one-dimensional profiles. These results are compared to distributions obtained from one-dimensional projections of scanning electron microscopy images of two-dimensional slices of the porous Pyrex glass and superpositions of such SEM images. A two-dimensional chord analysis (15) of the SEM images was also performed, and the statistical characteristics of pore size distribution obtained from this analysis is contrasted to the NMR microimaging and SEM projection results. Second, from the NMR intensity profiles, intensity correlation functions are measured as a function of distance, and compared to those calculated from the distributions of one-dimensional projections of SEM images.

Figure 3 shows a histogram of the frequency of peak separations obtained from the one-dimensional profile of ^{1}H nuclear spin densities of cyclohexane in the porous Pyrex glass sample along the gravitational (z) direction from the NMR spectrum in Fig. 2. The peak separations between nearest-neighbor local intensity maxima, or peak-to-peak distances, were measured with the program Grams/32 version 4.02 from Galactic Industries Corporation. The binning of peak

© 1998 NRC Canada

Fig. 3. Histogram (frequency of occurrence) of peak separations obtained from the one-dimensional profiles of ^{1}H nuclear spin densities of cyclohexane in the porous Pyrex glass sample along the gravitational (z) direction from Fig. 2.



separations, in increments of 20 μm, corresponds approximately to the spatial resolution in the NMR microimaging experiments (26 μm) and in the projections of the digitized SEM images (21 μm). An asymmetry in the distribution appears evident in Fig. 3. In such a situation, it is often expected that the first moment, or arithmetic mean, of the distribution will be different than the most probable value, or the mode (16). A statistical measure that more accurately reflects the most probable value is the geometric mean of the distribution, defined here as $\exp\{\langle \ln(\text{peak separation})\rangle\}$, where $\langle\ \rangle$ indicates the average. The arithmetic mean of the peak separation distribution in Fig. 3 is 318 μm, and the geometric mean is 283 μm (see Table 1).

What do the arithmetic and geometric means of the distribution of peak separations in the NMR microimaging one-dimensional projections of the imbibed porous glass filters represent? The peak intensities are proportional to the number of cyclohexane ^{1}H, while the glass is "NMR-transparent" due to the lack of hydrogens in its structure. Thus, it would appear plausible that the peak separation should be sensitive to the pore size, which gives the intensities of the peaks due to the presence of cyclohexane, and to the glass region between pores, which gives the "troughs" between peaks. As these one-dimensional projections arise from a three-dimensional sample, it would be expected that the intensities and the separations of the peaks would correspond to statistical features characteristic of the three-dimensional sample. Note that no algorithm exists that could reconstruct, in a unique fashion, the three-dimensional object from a single one-dimensional projection. Hence we suggest that the peak separation in the one-dimensional NMR projections represent the pore-to-pore distance in a statistical sense. The arithmetic and geometric means of the distribution of peak separations would thus correspond to the typical pore-to-pore distance in the porous media. For wide distributions, the geometric mean would be expected to better represent the typical pore-to-pore distance.

This plausibility argument is further supported with the following mean-field approach or effective-medium treatment of the disorder in a three-dimensional porous glass. Let R be the typical pore radius. Then, for spherical pores, the typical pore volume is $(4\pi/3)\ R^3$. If the pores are homogeneously embedded, as in a cubic lattice, then for a region of space containing a single pore and the glass, the pore volume is given as $f\cdot(\langle \text{ppd}\rangle)$, where f is the porosity, and $\langle \text{ppd}\rangle$ is the average pore-to-pore distance. Equating these two typical pore volumes yields

$$\langle \text{ppd}\rangle = \left(\frac{4\pi}{3f}\right)^{1/3} R$$

For the porous Pyrex glass filters, R = 80 ± 7.5 μm (14), while f = 0.18 (10), which gives $\langle \text{ppd}\rangle$ = 210–250 μm. The most probable value of the distribution of peak separation in Fig. 3, as estimated by the geometric mean, is 283 μm, in close agreement with the predicted mean-field values.

Table 1. Geometric and arithmetic means of distributions.

Distribution	Geometric mean/μm	Arithmetic mean/μm
1-D NMR z-profile: peak separation	283	318
1-D SEM (coarse): peak separation	285	341
1-D SEM (fine): peak separation	134	178
1-D SEM superposition: peak separation	190	203
Pore chord analysis: chord length	157	227

In random systems, statistical properties of distributions are the most we can expect to measure and (or) calculate. These statistical properties are characteristic of the ensemble and do not necessarily describe the individual members of the ensemble. Our interpretation of the peak separations observed in the intensity fluctuations of the one-dimensional NMR profiles in Figs. 1 and 2 conforms to this generic outlook of disordered systems.

3B. SEM one-dimensional projection profiles

To corroborate this interpretation of the intensity fluctuations in the one-dimensional NMR profiles, scanning electron microscopy images of cross sections of the porous Pyrex glass were produced and analyzed to reveal analogous information. A digitized SEM image of a representative cross section of the porous Pyrex glass is displayed in Fig. 4. The white regions correspond to pore spaces, while the black regions depict the glass. The circle symbolizes the NMR tube. The analysis of such an image and its projection unveils rich information concerning the disorder. For example, the determination of the porosity from this image is particularly crucial, as efforts to understand mechanisms of late-stage phase separation of binary mixtures in such a confined environment (10) depend on the presence/absence of continuum percolation, or percolation path of the pore space (the volume percolation threshold is 16% in three dimensions).

Projections of the two-dimensional SEM images were obtained and the peak separation distributions inferred from

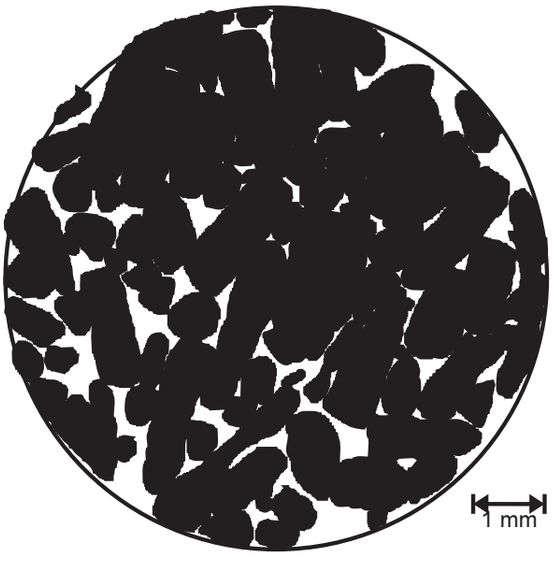
Fig. 4. Digitized SEM image of the porous glass cross section; the white regions correspond to the pore space, while the black regions represent the glass. The circle depicts the circumference of the NMR tube.



these profiles were used for direct comparison with the NMR statistical features. The projection and analysis procedure is presented in Fig. 5. The one-dimensional projection of the pore space and the porous glass is obtained by counting the respective pixels in the digitized image that contribute at a particular position along the projection. The spatial resolution of the resulting profiles is 21 μm. The intensities in the profiles therefore correspond to pore densities in the projections, and would be identical to the expected NMR signal observed in the same one-dimensional projection of the same cross section. It is noteworthy to observe the "edge effects" arising from the projection of the two-dimensional cross section "sample" in the one-dimensional profiles of the pores and glass (see right side of Fig. 5). Such effects are a simple consequence of the fact that in the one-dimensional projections, more material, i.e., glass and pores, contributes to the middle of the projections than at the edges.

A resulting one-dimensional SEM profile from such a procedure is shown in Fig. 6. This profile appears more "ragged" than the one-dimensional NMR profiles in Figs. 1 and 2 due to the small number of pixels that contribute to the SEM projection. For example, in the NMR profile along the *z*-direction, each pixel intensity would arise from the sum of all pore space pixels in a two-dimensional SEM cross section. To take into account this effect, we have used two procedures in the peak separation measurements: (*i*) direct measurements of peak separations, and (*ii*) smoothing of the SEM profile by using a running average of the intensities by 3-pixel increments followed by peak separation measurements. The first method yields "fine" resolution, while the coarse-graining procedure gives "coarse" resolution. The corresponding distributions of peak separation are displayed in Fig. 7, with fine (*A*) and coarse (*B*) resolution, while their arithmetic and geometric means are indicated in Table 1. The statistical properties of the peak separation distribution measured with the coarse resolution appear in good qualitative agreement with the NMR results. The fine resolution yields a preponderance of peak separations below 200 μm, which reduces considerably the arithmetic and geometric means.

An alternative to the heuristic smoothing method applied above consists of superposing several one-dimensional SEM profiles, each obtained by rotating a two-dimensional SEM image before the projection operation. Physically, such a procedure is closer in spirit to the projection of images of slices from *x*–*y* planes onto the *z*-axis to produce one-dimensional NMR density profiles. Figure 8 illustrates the distribution of peak separations observed by superposing the projections obtained from a single two-dimensional SEM image projected along 10 different directions; the SEM image of Fig. 4 was rotated by 18°, projected to produce one-dimensional profiles of pores, and this operation was repeated 10 times. Interestingly, the statistical properties of these superposed one-dimensional SEM profiles appear intermediate between the results of the "fine" and "coarse" method used above.

3C. SEM pore chord analysis

A chord analysis of two-dimensional SEM images of three different cross sections as in Fig. 4 was performed in order to further characterize the pore size distribution of the porous Pyrex glass filters. The arithmetic and geometric means of the pore size distributions thereby obtained were then used to calculate the average peak-to-peak distances in the NMR and SEM one-dimensional profiles with our mean-field argument of Sect. 3A.

In this method, several bundles of parallel straight lines of equal length are generated and uniformly distributed along different random directions. The histogram of the number of each intersection length inside the pores represents the pore chord distribution. In situations where pore structures can be represented by a random distribution of polydispersed spheres, the pore chord distribution can then be used to evaluate the pore size distribution (15). However, the pore network in the porous Pyrex glass appears complex, and a mathematical relationship between the distributions is certainly model dependent. A similar situation has been encountered with Vycor porous glass, which has a pore network similar in morphology to the porous Pyrex glass filters (17). Very good agreement was observed between the most probable value of the pore size obtained from the chord analysis and the average pore size measured by N_2 adsorption in Vycor porous glass. Hence we believe that the pore chord distribution should capture and represent to a good approximation some essential features of the three-dimensional structure of the pore network in the Pyrex glass filters without the need to make any assumptions about the geometry of the pores.

The pore chord distribution, obtained from the digitized two-dimensional SEM cross sections, is presented on linear and logarithmic length scales in Fig. 9. Nine different realizations of bundles of lines on the three different digitized SEM images were used to generate the distribution in Fig. 9. The large "error bars" on the small values of chord lengths arise from the digital resolution of 21 μm per pixel in the images. The geometric mean of the chord distribution is

Fig. 5. Schematic of the procedure to produce a one-dimensional projection profile of the pore density from SEM images by counting pore pixels that contribute at different positions along the projection (left side), and the resulting density profile of pores, glass, and their sum (right side). The spatial resolution of the projection is 21 μm.

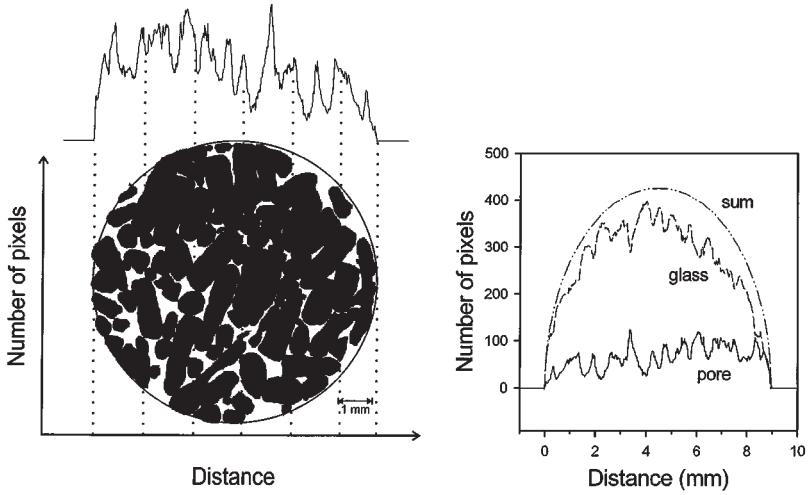

Fig. 6. One-dimensional SEM projection profile of pore density (number of pixels), obtained from Fig. 5, as a function of spatial position (mm). The spatial resolution is 21 μm.

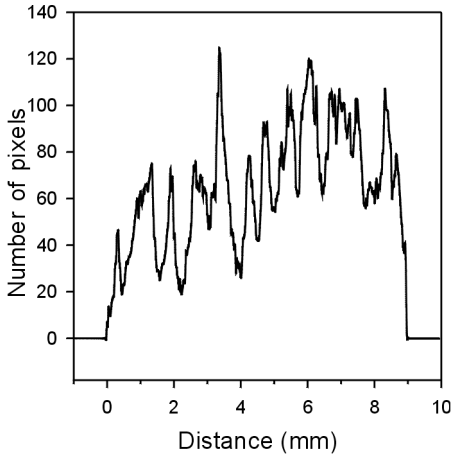

157 μm, while the arithmetic mean is 227 μm (see Table 1). The geometric mean of the chord distribution corresponds very closely to the typical pore size of 160 ± 15 μm, as observed by Ace Glass Inc. with pressure measurements (14). Thus, from these statistical features of the pore chord distribution and our mean-field model of disorder, the peak-to-peak separation in the NMR and SEM one-dimensional projection profiles would give values from 224 μm (obtained from the geometric mean) to 323 μm (obtained from the arithmetic mean). These values are in close agreement with the NMR data, and also agree with the SEM data, although in this latter case the choice of which situation is representative of the NMR microimaging results is more difficult to assess.

3D. NMR and SEM intensity correlation functions of one-dimensional projection profiles

Up to this point, we have focused exclusively on the peak separations, associated with the intensity fluctuations, in the one-dimensional NMR and SEM projection profiles of pore densities in the porous Pyrex glass. In this section, we examine the correlation of the intensity fluctuations in the same profiles. The intensity–intensity correlation function, $C(r)$, is defined as

$$[1] \qquad C(r) = \sum_{i=1}^{N} \frac{h(i)h(i+r)}{N-r} \Big/ \sum_{i=1}^{N} \frac{h(i)h(i)}{N}$$

where i is the pixel position along the projection, and $h(i)$ is the intensity at the ith pixel corresponding to the pore density at the location i in the projection. The factor $N - r$ in the numerator is necessary to normalize the contributions of $i \times (i + r)$ spatial correlations due to their different numbers along the one-dimensional projections. For example, there are $N - 1$ nearest-neighbor correlations, while there is only a single $r = N$ correlation among the two most extreme pixels in the projections.

Figure 10 displays this intensity correlation function for the NMR and SEM one-dimensional projection profiles. The same basic generic features characterize the correlation functions of these different profiles; at short distances, $C(r)$ appears to be independent of r, and then decreases rather abruptly at long r due to finite size effects. Note that the range of length scales in the SEM cross sections, or transverse images, and the longitudinal NMR profile are slightly different. However, such a difference is not significant since the statistical properties of the distributions of peak separation and the intensity–intensity correlation functions are identical for longitudinal (the analysis presented in this paper) and transverse (the analysis not presented in this paper) NMR profiles of Fig. 2. Hence the disorder in the porous Pyrex glass filters is isotropic. Furthermore, as the correlation function is normalized as explained above, one could use a reduced length scale, i.e., $0 \le r/r_{max} \le 1$; then both SEM and NMR intensity correlation functions would appear similar with identical reduced length scales. Absolute length scales were used instead in Fig. 10 simply as a matter of taste in order to stay closer and better appreciate the raw $C(r)$ data.

Fig. 7. Histograms (frequency of occurrence) of peak separations (μm) obtained from the one-dimensional SEM projection profile of pore density in Fig. 6 measured with "fine" resolution (*A*) and "coarse" resolution (*B*).

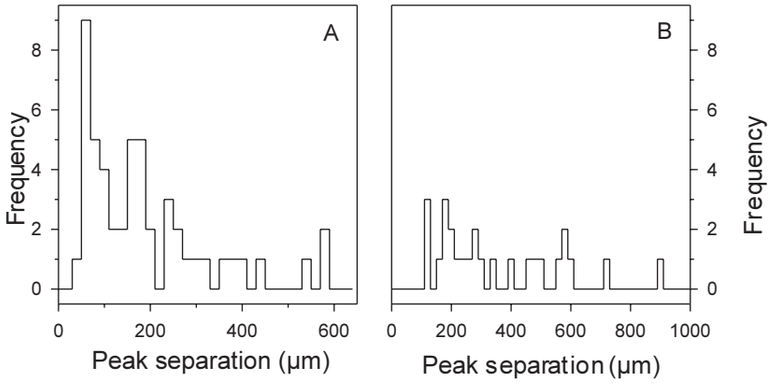

Fig. 8. Histogram (frequency of occurrence) of peak separations (μm) obtained from the superposition of 10 one-dimensional SEM projection profiles of pore space density, each produced from the two-dimensional SEM image in Fig. 4 rotated at 10 different angles (and separated by 18° increments) in the same plane.

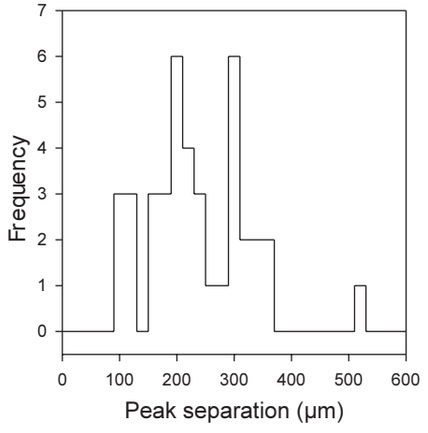

Two issues are needed to understand the behavior of $C(r)$. First, the intensities observed in the NMR and SEM one-dimensional projection profiles correspond to the number of pores that contribute at a pixel position. Hence the intensities in the projections also represent the density of pores, and $C(r)$ is thus a density–density correlation function that varies with the spatial separation along the projections. Second, for a D-dimensional object embedded in a d-dimensional space, the density–density correlation function (and also the mass–mass correlation function) scales as r^{D-d} (11, 12). As discussed in the introduction, for a projection of a D-dimensional object in a d_s subspace, the dimension of the projected object D_p depends on the relationship between D and d_s. For one-dimensional projections $d_s = 1$. If $D > d_s$, then $D_p = d_s$. The density–density correlation function of the D_p-dimensional object in the d_s-subspace, which scales as $r^{D_p - d_s}$, should therefore be independent of r when $D > d_s$. Such is the case in the present situation, and one concludes that the one-dimensional NMR and SEM projections appear to be statistically homogeneous.

3E. Influence of paramagnetic impurities on the NMR one-dimensional projection profiles

The presence of paramagnetic impurities in the glass could impose limitations, even distortions, on the statistical properties of the one-dimensional NMR microimaging profiles. With X-ray fluorescence, traces of impurities, some of which exhibit paramagnetic oxidation states, were measured in the porous Pyrex glass filters; these include Fe (208 ppm), Ni (68 ppm), and Cu (13 ppm). Due to the cleaning procedure of the glass (see Sect. 2), it is reasonable to assume that these impurities are fixed in the glass. Here, we only consider the dipolar interactions between the paramagnetic impurities and the solvent nuclei (18, 19). Since hydrogen is absent in the glass, the effects of indirect magnetization transfer to the paramagnetic impurities through spin diffusion can be safely neglected.

Static dipolar interactions between the paramagnetic forms of these impurities and the magnetic moments of solvent nuclei at the surface of the glass induce shifts of the resonance frequency of the solvent nuclei. For example, with the combination of spin and orbital moments, the effective magnetic moment of Fe(III), $\mu_{eff} \approx 6$ Bohr magneton (20), produces a local field, $H_{loc} \sim \mu_{eff} / r^3$, of roughly 56 G at 10 Å from the Fe(III) centers. This static field yields a 238 kHz frequency shift of these surface ^{1}H nuclei. Thus, a layer of tens of Å of immobilized solvent nuclei on the porous glass would not be detected due to this frequency shift. Nevertheless, such an effect would also be totally irrelevant in our experiments in view of the lower limit of spatial resolution, i.e., 26 μm, imposed by the NMR imaging experimental protocol.

However, the thermal fluctuations of dipolar interactions between the paramagnetic forms of these impurities in the glass and the solvent magnetic moments can lead to a macroscopic layer of molecules on the porous glass that relaxes rapidly, i.e., more quickly than their NMR signals can be detected. To estimate the thickness and volume of such a layer in the porous glass, we will consider a worst-case scenario in our experiments.

First, we assume that the impurities detected by X-ray fluorescence are all in their paramagnetic oxidation states, and all are found solely in the first two atomic layers of the glass. Hence, by diffusion, the solvent molecules in the neighborhood of the impurities are relaxed by the thermally

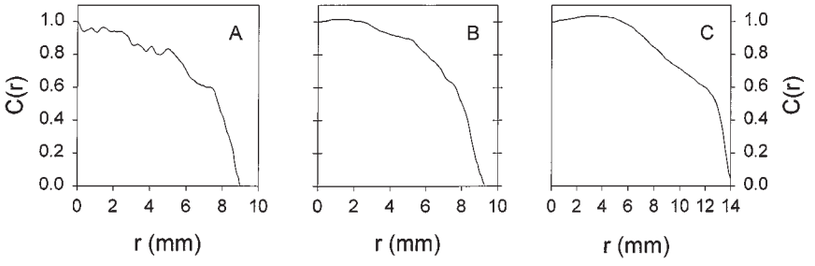
(*B*) One-dimensional SEM projection profile from the superposition of 10 one-dimensional SEM projection profiles of pore space density, each produced from the two-dimensional SEM image in Fig. 4 rotated at 10 different angles (and separated by 18° increments) in the same plane. (*C*) One-dimensional NMR projection profile of pore space density from Fig. 2*A*.



induced fluctuations of the direct dipolar interactions. In such a diffusion-limited situation, de Gennes (16) has shown that the thickness layer is given by $2(Dt/\pi)^{1/2}$, where D is here the self-diffusion of the solvent molecules, and t is the time scale of the experiment. At room temperature, $D = 1.45 \times 10^{-5}$ cm^2/s for bulk cyclohexane (21), and in our experiments the longest relevant time is 25 ms. Hence, a layer thickness of 7 μm of solvent molecules would be "transparent." Such a layer would still be much smaller than the lower limits of spatial resolution in the NMR imaging profiles.

The volume fraction of this layer over the pore volume is given by $2(Dt/\pi)^{1/2} A_v$, where A_v is the surface per unit pore volume (18). Due to the rather large pore structures of the porous Pyrex glass filters, our attempts to measure A_v with nitrogen adsorption isotherms were unsuccessful. Instead, the surface-to-volume ratio of the pores was determined from the SEM digitized image (see Fig. 4) by measuring the length of interface to surface ratio of the pores in the two-dimensional SEM cross sections. Using the arguments of dimensional properties of the projections as discussed at the end of Sect. 3D, this ratio corresponds to the surface/volume pore ratio if the dimension of the pore surface equals 2, i.e., if the surface is not fractal. Such measurements produce $A_v = 110$ cm^2/cm^3, which implies that 7.5% of pore solvent would not be detectable.

With a more realistic scenario, i.e., uniform distribution of the impurities in the glass, and considering that only a fraction of the impurities are in the paramagnetic oxidation states, we estimate that the undetectable layer thickness and volume fraction of relaxed solvent molecules in the pores would be at least one order of magnitude smaller than those calculated in the worst-case scenario presented above. Thus, the effects of paramagnetic impurities in our one-dimensional NMR microimaging profiles are well within experimental uncertainty, and should not significantly affect our results.

4. Summary

In this work, we have characterized some aspects of the macroscopic disorder in porous Pyrex glass filters with one-dimensional NMR microimaging projection profiles. It was argued and demonstrated that the intensity fluctuations in these profiles (see Figs. 1 and 2) can reveal some useful statistical information concerning the randomness in porous media. In particular, the statistical properties, such as the arithmetic and geometric means, of the distribution of peak separations between intensity fluctuations, carry information concerning the pore sizes and the pore-to-pore distances. The intensity–intensity correlation functions in the one-dimensional projections were shown to display an interplay, as a function of length scale, of the dimensions D of the porous network, d the embedding space, $d_s = 1$ for the embedding dimension of the projection, and d_p the dimension of the projected porous network. As such, *the statistical analy-*

© 1998 NRC Canada

sis of the distribution of peak separations and the intensity–intensity correlation functions represent the most information that can be extracted from intensity fluctuations in the one-dimensional NMR projection profiles of porous media. These observations were corroborated with similar analysis of the one-dimensional SEM projections obtained from the two-dimensional SEM images, and pore chord distributions derived from these same images. The approach developed in this work should prove useful and generic in studies of materials with macroscopic randomness and where only one-dimensional NMR microimaging profiles can be reliably measured.

Acknowledgments

We would like to thank Dr. F. Cau for useful discussions in the early parts of these studies, Dr. F. Gitzhofer and P. Magny for their help with the SEM, and Dr. R. Zamojska for her assistance with the X-ray fluorescence measurements. Orientation in stretched polymer-dispersed liquid crystals

Julien Brazeau, Yanick Chénard, and Yue Zhao

Abstract: The orientation behavior of liquid crystal molecules in stretched films of polymer-dispersed liquid crystals (PDLC) was investigated by means of infrared dichroism. The liquid crystal used is 4′-octyl-4-biphenyl-carbonitrile (8CN); the polymer matrices are semicrystalline poly(ε-caprolactone) (PCL) and an amorphous miscible blend of PCL with poly(vinyl chloride) (PVC). 8CN was found to have a limit of solubility below 5 wt.% in PCL. We show that an uniaxial stretching can effectively induce a macroscopic orientation of 8CN, and that this orientation can be preserved in the films after removal of the extensional force at room temperature, where 8CN is in its liquid crystalline phase. The molecular orientation is obtained even by stretching PDLC films with 8CN in the liquid state. These results suggest that an elongated polymer cavity in stretched PDLC imposes LC director fields with respect to the long axes of the droplets, which are aligned parallel to the strain direction. The experiments also reveal that the orientation of 8CN is higher in stretched PDLC with a semicrystalline matrix (PCL) than with an amorphous matrix (the PCL–PVC blend), and that the sizes of the LC droplets also have a slight effect on the induced orientation. This work represents a first step in the exploration of new electrooptical effects of PDLC through the presence of a uniform orientation of the liquid crystal molecules and modifications of the polymer cavity at the electrical field-off state.

Key words: polymer-dispersed liquid crystals, molecular orientation, infrared dichroism, electrooptical materials.

Résumé : Faisant appel au dichroïsme infrarouge, on a étudié le comportement orientationnel de molécules de cristaux liquides dans des films étirés de cristaux liquides dispersés dans un polymère (CLDP). Le cristal liquide utilisé est le 4′-octyl-4-biphénylcarbonitrile (8CN); les matrices de polymère comprennent poly(ε-caprolactone) (PCL) semicristalline et un mélange amorphe miscible de PCL et de chlorure de polyvinyle (PVC). On a trouvé que la limite de solubilité du 8CN dans le PCL est inférieure à 5% en poids. On a montré qu'une extension uniaxiale permet d'induire efficacement une orientation macroscopique du 8CN et que, à la température ambiante où le 8CN existe dans sa phase cristalline liquide, cette orientation est maintenue dans les films même après l'élimination de la force d'extension. On peut même obtenir une orientation moléculaire par extension de films de CLDP comportant du 8CN à l'état liquide. Ces résultats suggèrent qu'une cavité allongée présente dans le CLDP étiré impose des champs directeurs CL par rapport aux grands axes des gouttelettes et que ceux-ci sont parallèles à la direction d'élongation. Les expériences révèlent aussi que l'orientation du 8CN est plus importante dans le CLDP avec une matrice semicristalline de PCL que dans une matrice amorphe (mélange de PCL–PVC) et que la taille des gouttelettes de CL a aussi un léger effet sur l'orientation induite. Ce travail correspond à une première étape dans l'exploration de nouveaux effets électrooptiques des CLPD provoqués par la présence d'une orientation uniforme des molécules du cristal liquide et par des modifications de la cavité du polymère en absence d'un champ électrique.

Mots clés : cristaux liquides dispersés dans un polymère, orientation moléculaire, dichroïsme infrarouge, matériaux électrooptiques.

Introduction

Polymer-dispersed liquid crystals (PDLC) possess attractive electrooptic properties. Intensive research has been carried out since the mid-eighties in order to explore their applications, which include light shutter, display, and various photonic and optoelectronic devices (1, 2). Generally, a PDLC film contains a nematic liquid crystal that is phase separated from a polymer matrix, in the form of spherical droplets. Figure 1 sketches the basic operating principle of PDLC. The LC molecules inside the droplets can adopt different configurations (director fields) depending mainly on their interface-anchoring and elastic properties. The bipolar configuration illustrated in Fig. 1 is most often observed where the nematic director fields develop along an axis. Because of the random alignment of those droplets axes, the effective refractive index of the droplets, n_{eff}, is the mean value given by $(n_e + n_o)/2$, where n_e and n_o are the extraordinary and ordinary refractive indices associated with the long axis of the LC molecules and the other two perpendicular directions, respectively. Choosing appropriate LC and polymers, it is possible to have $n_e \approx 1.7$, $n_o \approx 1.5$, and n_p, the refractive index of the polymer matrix, also close to 1.5. Un-

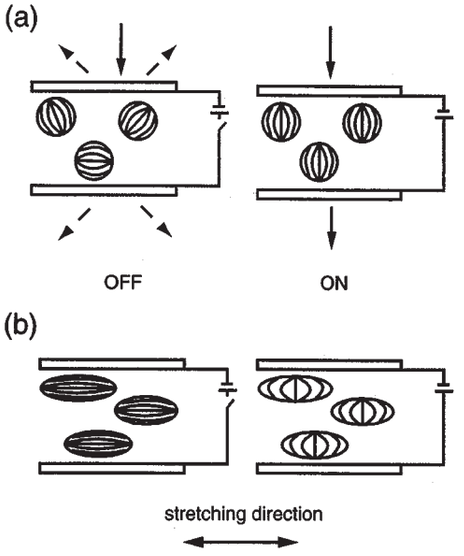
Fig. 1. Sketch of the operating principle of PDLC: (*a*) normal mode, and (*b*) stretched film.



der these conditions, n_{eff} of the LC droplets differs from n_p. When such a PDLC film is sandwiched between two transparent and conductive substrates, the system strongly scatters the incident light because of the mismatch between n_{eff} and n_p; the film appears opaque. When an electric field is applied through the film, LC molecules inside the droplets can be aligned along the field direction (the film thickness direction); the incident light now experiences n_o, which equals n_p. As a result of the matching refractive indices, the PDLC film becomes transparent. This reversible change of the film transparency under the voltage-off and voltage-on state is the basis for most applications of PDLC. The phase separation is, among other things, a key step in the fabrication of a PDLC. Generally, it can be induced by solvent evaporation, thermal effect, and polymerization from an initially homogeneous mixture of LC with polymer or polymer precursor or monomer (1–3).

A number of parameters, such as LC concentration and droplet sizes, influence the electrooptical properties of PDLC. The polymer cavity, determined by the shape of the LC droplets, is also known to play a major role (1, 2). The polymer cavity influences the anchoring of the LC molecules at the interface and, hence, the director field configuration inside the droplets. At the voltage-on state, those LC molecules anchored to the interface also behave differently from the molecules more distant from the interface. Despite the tremendous effort already dedicated to studying PDLC, it was noticed that very few studies considered stretched or sheared PDLC (1, 4), showing little interest in characterizing and relating molecular orientation of LC to the electrooptical properties. This has motivated us to undertake investigations on PDLC. Our basic idea is to introduce changes in the orientation of the LC molecules and the polymer cavity at the electrical field-off state and to study the possible new electrooptical effects.

The changes expected by stretching a PDLC film containing bipolar spherical droplets are also sketched in Fig. 1, displaying elongated LC domains and a uniform LC molecular orientation along the stretching direction. Even in this simple case, new electrooptical effects may show up. For instance, an incident light polarized parallel to the stretching (orientation) direction should see n_e at the voltage-off state and n_o at the voltage-on state. If the conditions as described above are fulfilled, the contrast of the film between opaque and transparent, which is a continuing research subject, could be improved since the refractive index mismatch at the voltage-off state is $(n_e - n_p)$, which is greater than $(n_{eff} - n_p)$ in the normal case. The approach is complementary to the existing techniques for PDLC, but it can lead to discoveries of new electrooptical effects. The possibilities exist because LC molecular orientation can be altered by different mechanical fields such as uniaxial stretching, biaxial stretching, and compression, causing different modifications of the polymer cavities. There is also the possibility of tuning the refractive indices in a specific system through the polymer matrix orientation.

To explore such an approach, some fundamental questions must be answered: can a uniform orientation of LC molecules be effectively achieved by stretching a PDLC film? and, more importantly, can the stretching-induced orientation be preserved in the deformed film once the extensional force is removed? Generally, a macroscopic orientation of LC molecules induced by an external stimulus is not thermodynamically stable, and the system tends to recover its initial state after the stimulus is removed. In the case where a liquid crystalline polymer (LCP) is dispersed in a conventional polymer matrix, the answers are yes (5). But the two systems are different in that the orientation of the mesogenic groups of LCP is frozen when the polymer is cooled below its glass transition temperature T_g. This feature obviously is not a characteristic of PDLC. In this paper, we report our very first experiments aimed at answering the above questions.

Experimental

The liquid crystal used to prepare PDLC was 4′-octyl-4-biphenyl-carbonitrile (8CN), purchased from Aldrich. It has a crystal-to-liquid-crystal transition at 24°C and a nematic-to- isotropic transition (clearing temperature) at 40°C. The choice of an appropriate polymer matrix is important, and there are several limitations. First, good PDLC films are necessary in order to perform mechanical stretching, meaning that the LC concentration generally can not exceed 40 wt.%. If the LC solubility limit in a particular polymer is substantial, that polymer cannot be used as matrix. This is known to be the case for many polymers that can solubilize LC molecules up to an LC concentration of about 30 wt.%. When we started this work, we used 30 wt.% of 8CN in several matrices including a polystyrene–poly(vinyl methyl ether) blend, a styrene–butadiene–styrene tri-block copolymer, and a couple of polyacrylates; none of those systems worked because of a high 8CN solubility in these polymers (only a few 8CN phase-separated and the rest acting as plasticizer). In other words, it is necessary to use a polymer in which 8CN has a low solubility. Secondly, on the basis of our previous studies on LCP (5), to obtain a uniform orientation it is more effective to stretch samples in their liquid

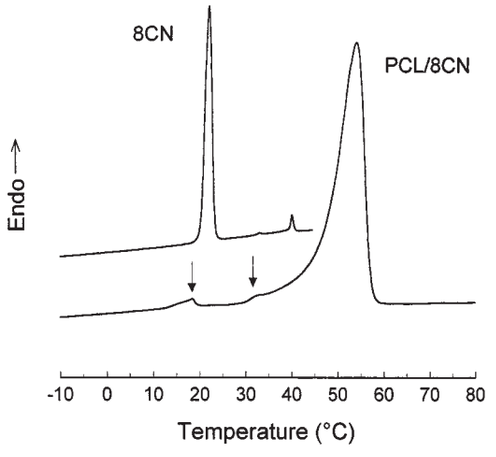
Fig. 2. DSC heating curves of 8CN and the PCL–8CN 70:30 blend.



crystalline phases. This means that the polymer matrix used for PDLC should be stretchable at temperatures below the clearing temperature of 8CN.

The matrix used in this study was poly(ε-caprolactone) (PCL), which is a semicrystalline polymer. The solubility limit of 8CN in PCL was found to be very low, probably because of the polymer crystallization. As amorphous PCL, located in the interlamellar region, has a low T_g of about –60°C, films of PCL can easily be cold-drawn at room temperature or stretched at temperatures below the crystal melting point at about 55°C. A miscible and amorphous PCL blend containing 45 wt.% of poly(vinyl chloride) (PVC) was also utilized in order to investigate the polymer matrix effects. The stretching and orientation measurements were performed on PDLC samples containing 10 and 30% of 8CN. Typically, a homogeneous solution of 8CN and the polymer was prepared using THF as solvent; then the solution-cast films were dried under vacuum at room temperature for 3 days. The film thickness was about 20–30 μm. The phase separation in the dried PDLC films is induced by solvent evaporation. Heating these PDLC films to the isotropic state, at 70°C, the mixture becomes homogeneous, but a subsequent cooling again leads to the phase-separated system, the phase separation being induced by thermal effects. The samples of PCL and PVC were also purchased from Aldrich ($M_w \approx 65\,000$ for PCL and $M_w \approx 161\,000$ for PVC).

Uniaxial stretching of the PDLC films was carried out on a laboratory-made apparatus at a rate of about 20 mm/min. In the case of PCL–8CN, the orientation of 8CN was measured on films released from the stretching machine ("relaxed films"); the deformation of the semicrystalline matrix is plastic and permanent. For stretching at temperatures above ambient, the films were cooled, under strain, to room temperature for 20 min before being removed from the stretching machine. In the case of (PCL–PVC 55:45)–8CN, the amorphous matrix has a low T_g of about –40°C; the orientation measurements were performed on films under strain in order to avoid film shrinkage.

Orientation of 8CN averaged over all molecules can be characterized by the orientation function defined as $F = (3\langle\cos^2\Theta\rangle - 1)/2$, where Θ is the angle between the long molecular axis of 8CN and the stretching direction. The value of this orientation function varies between –0.5 and unity. $F = 1$ indicates a perfect orientation parallel to the stretching direction, while $F = -0.5$ corresponds to a perfect perpendicular orientation. In PDLC, if the LC droplets are randomly aligned, the director fields of the LC molecules are randomly distributed in space; the lack of a macroscopic orientation leads to $F = 0$. Of course, F also equals zero if the LC is heated to the isotropic liquid state. In this study, infrared dichroism was used to determine the molecular orientation of 8CN in the stretched PDLC films. Using the characteristic C≡N band near 2230 cm^{-1}, the orientation function of 8CN is calculated (5) from $F = (A_\parallel / A_\perp - 1) / (A_\parallel / A_\perp + 2)$, where $A_\parallel$ and $A_\perp$ are the absorbances of the 2230 cm^{-1} band with the infrared beam polarized parallel and perpendicular to the film stretching direction, respectively. Infrared spectra of 4 cm^{-1} resolution were recorded on a Bomem MB-102 FTIR spectrometer using a wire-grid infrared polarizer placed between the sample and the DTGS detector; 50 interferograms were averaged for each spectrum. A Perkin–Elmer DSC-7 differential scanning calorimetor and a Leitz DMR-P polarizing microscope were also used for the characterizations of PDLC.

Results and discussion

For the PCL–8CN blends, the LC droplets cannot be observed with the polarizing microscope because of the rapid crystallization of PCL, giving rise to a birefringent matrix that overlaps the birefringent LC droplets. However, the phase separation is confirmed by the DSC measurements. Figure 2 shows the heating curves of pure 8CN and the PCL–8CN 70:30 blend. The large endotherm centered at 52°C for the blend is due to the PCL crystal melting; two small endothermic peaks, indicated by arrows, are noted at about 18 and 32°C and correspond to the two transitions of pure 8CN at 21 and 40°C. Such a depression of transition temperatures as well as a decrease in transition enthalpies in PDLC are a common feature, understandably resulting from interfacial interactions between the LC and the polymer matrix. For the present PDLC system, what is important is that 8CN is in its liquid crystalline phase at room temperature (about 22°C), which is necessary for LC molecular orientation under cold-drawing of the film and for any LC reorientation at the voltage-on state.

The PDLC films were stretched to various draw ratios λ, which is defined as ratio of the film length after stretching over the film length before stretching; the orientation of 8CN was measured as a function of film extension. Figure 3 presents the results obtained with samples containing 10 and 30% of 8CN by plotting the orientation function of 8CN versus the draw ratio. It is clear that a macroscopic orientation of 8CN, parallel to the strain direction, develops in the stretched films. The orientation increases continuously with the film extension up to $\lambda = 4$–5. This behavior is somewhat different from blends containing an LCP (5), whose orientation generally attains a plateau level at $\lambda = 2$–3. On the other hand, the orientation level of 8CN is similar in the two blends. This is indicative of a very low solubility of 8CN in PCL. As mentioned earlier, solubilized LC molecules act as a diluent in the polymer matrix and do not orient upon

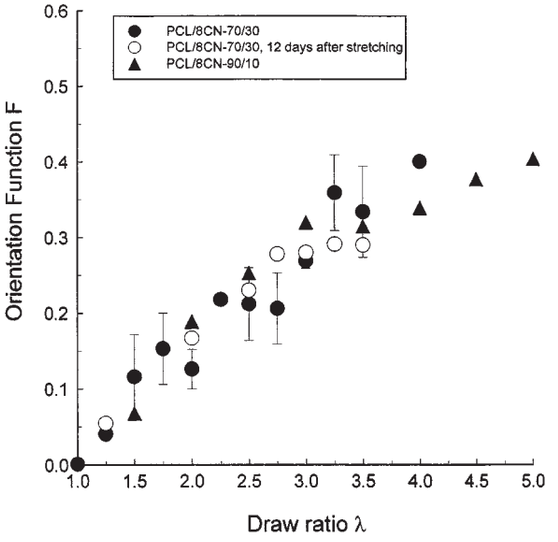

Fig. 4. Orientation function of 8CN vs. stretching temperature for PDLC films of PCL–8CN 70:30 and PCL–8CN 90:10.

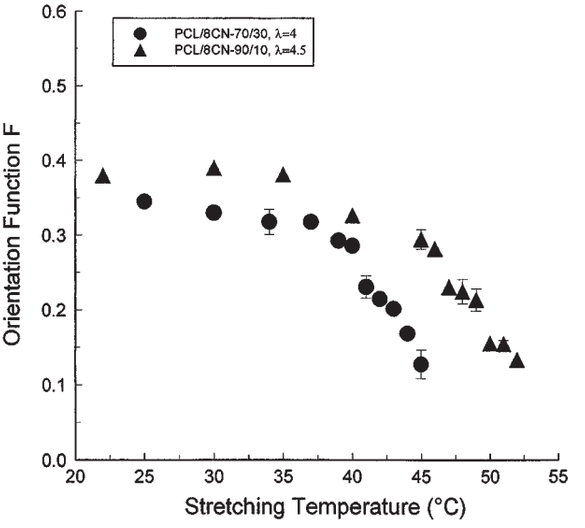

stretching. Even if the solubility limit for PCL–8CN is, for example, ca. 5%, its orientation function averaged over all molecules should be much lower in the PCL–8CN 90:10 blend than in the PCL–8CN 70:30 blend. We have made DSC measurements that confirmed this low 8CN solubility. It was found that T_g of the amorphous PCL at about –60°C, for pure PCL, is almost unchanged in blends containing 5, 10, and 30% of 8CN, indicating that the solubility limit is below 5%.

Also shown in Fig. 3 are the data obtained with the same films of the PCL–8CN 70:30 blend 12 days after stretching. During that period of time, the films were left at room temperature and allowed to relax without any constraints. No significant film shrinkage was observed and, as can be seen, the orientation of 8CN remains unchanged. The results indicate that, under the plastic deformation of PCL, the orientation of 8CN can be conserved in the stretched films after the removal of the mechanical stress. This observation is important since such a permanent LC orientation at room temperature is the basis of the approach outlined in the Introduction. At this point we can only suggest that an elongated LC droplet, and hence an elongated polymer cavity, may be responsible for retaining the LC orientation.

The influence of the stretching temperature on the LC orientation was investigated. Figure 4 shows the orientation function of 8CN versus stretching temperature. The samples containing 10% of 8CN were stretched to $\lambda = 4.5$, while those containing 30% of 8CN were stretched to $\lambda = 4$. In both cases, up to about 40°C the stretching temperature has little effect on the orientation of 8CN, but when the stretching temperature is raised further, the orientation level decreases rapidly. Considering the fact that the clearing temperature of 8CN in the blends with PCL is about 32°C (Fig. 2), the results seem to indicate that, even with 8CN in its liquid state, stretching the PDLC film can result in a uniform orientation of 8CN. Again, this feature is different from what is known for the blends containing an LCP (5), where the orientation of the mesogenic groups generally drops to zero when the stretching is performed with LCP in the isotropic state. These results are consistent with the observation of a stable 8CN orientation in relaxed films, suggesting that an elongated polymer cavity in the stretched films may be the dominant factor imposing the director fields of LC inside the droplets. The following mechanism is conceivable: Above the clearing temperature, 8CN is a liquid inside the droplets before and after the stretching, but the stretching transforms the droplets from spherical to elongated shapes; once 8CN enters into the nematic phase during the film cooling to room temperature, the polymer cavity leads to director fields aligned along the long axes of the droplets, as sketched in Fig. 1. Because of the parallel alignment of LC molecules at the interface, the symmetry axes of the elongated bipolar droplets should lie along the stretching direction in order to minimize the curvature of the director fields and the associated elastic free energy. On the other hand, if there is no coalescence of the LC droplets after the stretching, the transformation from spherical to elongated shape means an increased surface-to-volume ratio and, thus, a more important anchoring effect at the interface on the LC director fields. The severely lowered orientation of 8CN at stretching temperatures above 40°C is probably due to an enhanced miscibility between 8CN and PCL as the temperature is close to the PCL melting point. Finally, the orientation difference for the two blends is attributed to different draw ratios.

Blends of PCL with PVC are known to be miscible (6). The crystallization of PCL is slowed down by the presence of PVC because of the miscibility; having 45% of PVC in the blend, the crystallization of PCL starts about 3 h after the cooling from the liquid state. In this study, we have also investigated the orientation of 8CN dispersed in the amorphous PCL–PVC 55:45 blend. The advantages of having an amorphous matrix are (*i*) the polarizing microscope can be used to observe the LC droplets in the PDLC, and (*ii*) the LC orientation behavior can be compared to that of PDLC having the semicrystalline PCL matrix. Only one concentration of 8CN, namely 30%, was used to prepare this PDLC.

Fig. 5. Polarized photomicrographs of a PDLC film containing 30% of 8CN in the amorphous PCL–PVC 55:45 blend matrix: (*a*) 30 min and (*b*) 45 min after cooling to room temperature; (*c*) 45 min after cooling, stretched to $\lambda = 3$. Magnification: 250×.

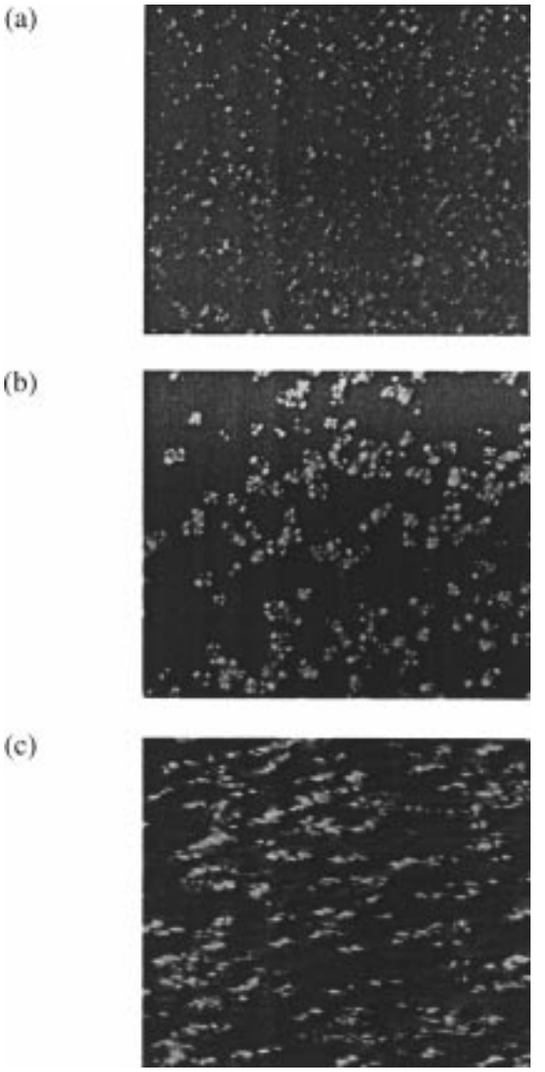

Figure 5 shows some polarized photomicrographs of this PDLC system. Two of them (5*a* and 5*b*) were taken 30 and 45 min after the film was allowed to cool from 70°C to ambient (it took several min for the sample to reach room temperature), and the third one (5*c*) was taken on the film, 45 min after the cooling, stretched to $\lambda = 3$. It is seen that the sizes of the birefringent spherical droplets in the non-stretched film grow with time. Also, the microphotographs confirm that the stretching transforms the shape of the LC droplets, and thus the polymer cavity, from spherical to elongated. The long axes of the elongated domains are aligned along the strain direction. These morphological changes in stretched PDLC films were expected, but could not be observed with the PCL–8CN films as explained above.

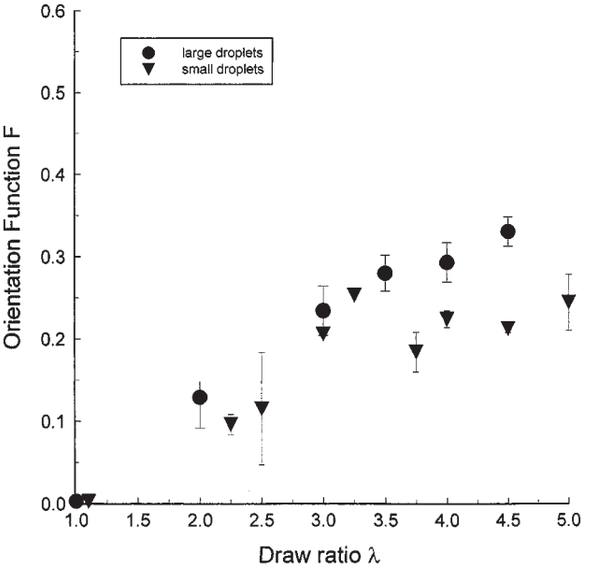
The orientation of 8CN in PDLC with the amorphous matrix was determined for samples stretched under different

Fig. 6. Orientation function of 8CN vs. draw ratio for PDLC films of (PCL–PVC)–8CN containing 30% of 8CN, films being stretched immediately (triangle) and 1 h (circle) after cooling to room temperature.



conditions. One series of the films was stretched immediately after cooling from the isotropic state, and the other films were stretched 1 h after cooling. The results are shown in Fig. 6. Several observations can be made. First, comparing the orientation of 8CN with that in the semicrystalline PCL (Fig. 3), it appears that the orientation is lower in this amorphous matrix. This apparently suggests certain effects of the matrix on the LC orientation. Secondly, the orientation in the films stretched immediately following cooling is lower than that in the films subjected to the stretching 1 h afterwards. This result seems to indicate an effect of the LC droplet size on the stretching-induced orientation; large LC droplets formed after longer times at room temperature (Fig. 5) favor the induction of a macroscopic orientation. Actually, in samples immediately after cooling, the droplets of 8CN are so small that they cannot be detected by optical microscopy (the birefringent spots were detectable 20—25 min after cooling). However, for the reasons pointed out earlier concerning the LC solubility, the results in Fig. 6 can also be explained by an increasing phase separation with time between 8CN and the matrix. As the phase separation develops, more and more molecules of 8CN are inside the droplets and contribute to the average stretching-induced orientation, which is also accompanied by a growth in size of the LC droplets.

As explained in the Introduction, this work was not aimed at studying new electrooptical effects of this particular PDLC system of PCL–8CN. Nevertheless, we have checked the reorientation of 8CN in some stretched samples having an elongated polymer cavity and a macroscopic molecular orientation. In all cases, the reorientation was observed at the electrical field-on state. When a stretched film was sandwiched between two glass plates coated with a transparent electrode of indium-tin-oxide (ITO) and placed between crossed polarizers, a decrease in the transmitted light inten-

© 1998 NRC Canada

sity occurred once the voltage was turned on, indicating the reorientation of 8CN molecules along the electrical field direction (the test voltages were 40–100 V with a 1000 Hz a.c. signal).

Conclusions

Uniaxially stretching PDLC films of PCL–8CN and (PCL–PVC 55:45)–8CN can effectively induce a macroscopic orientation of 8CN molecules parallel to the strain direction. Because of the low solubility limit of 8CN in PCL (less than 5 wt.%), the stretching-induced 8CN orientation is similar in PDLC films containing 10 and 30% of 8CN. The orientation can even be obtained by stretching PDLC at temperatures above the clearing point of 8CN. This observation suggests that elongated droplets and polymer cavity, resulting from the stretching, impose the director fields with respect to the long axes of the droplets, which are aligned parallel to the strain direction. This feature is different from orientation of liquid crystalline polymers, for which cooperative effects, characteristic of liquid crystalline phases, are important in the orientation process. For the same reason as given in connection with the elongated polymer cavity, it was found that at room temperature, where 8CN is in its liquid crystalline phase, the stretching-induced orientation of 8CN is stable in deformed PCL–8CN films after the removal of the mechanical stress. The results of this study represent a first step and the basis of an approach that explores possible new electro-optical effects of PDLC systems having a macroscopic orientation of LC molecules and modified polymer cavity at the electrical field-off state.

Irradiance and temperature dependence of photoinduced orientation in two azobenzene-based polymers

Dennis Hore, Almeria Natansohn, and Paul Rochon

Abstract: This paper concerns itself with photoinduced anisotropy in two azobenzene-functionalized polymers. A simple physical model of the process that considers only three possible states of azo chromophores is proposed. This model predicts an equilibrium level of anisotropy that depends on the pump irradiance and temperature. Each of these influences is examined in turn, with experimental illustrations from the two polymers poly[4-[2-(methacryloxy)-ethyl-ethyl]azobenzene] (pMEA) and poly[4′-[[2-(methacryloxy)ethyl]-ethyl]amino-4-nitroazobenzene] (pDR1M).

Key words: azobenzene polymers, photoinduced orientation, irradiance, temperature.

Résumé : Dans ce travail, on traite de l'anisotropie photoinduite dans deux polymères d'azobenzènes fonctionnalisés. On propose un modèle physique simple qui ne prend en considération que trois états possibles des chromophores azo. Ce modèle permet de prédire un niveau d'équilibre d'anisotropie qui dépend de l'irradiance de la pompe et de la température. On a examiné l'influence de ces divers facteurs à tour de rôle, en donnant des illustrations expérimentales à l'aide des deux polymères suivants : poly[4-[2-(méthacryloxy)éthyl]azobenzène] (pMEA) et poly[4'-[[2-(méthacryloxy)éthyl]éthyl]amino-4-nitroazobenzène] (pDR1M).

Mots clés : polymère de l'azobenzène, orientation photoinduite, irradiance, température.

Introduction

The linking of observable macroscopic properties to molecular-scale mechanisms remains one of the fundamental challenges and enticements of materials science. These properties are often geared toward engineering and technology applications and so are zealously sought. The study of the photoinduced orientation of azobenzene-based polymers represents just such an endeavour.

Anisotropy may be photoinduced in thin films of amorphous polymers containing azobenzene moieties in their side chains. This anisotropy exists well below the glass transition temperature (T_g) in an area as small as a beam can be focussed, exhibits long-range stability, and has high contrast with isotropic regions of the material. These properties make such polymers possible candidates for technologies such as reversible optical storage and waveguides.

Although the details of the orientation mechanism and underlying processes are yet to be agreed upon, a simple physical picture may be proposed. An isotropic distribution of chromophores (as present in an amorphous film) is subject to a linearly polarized pump and individual species are promoted to the lowest energy π^* excited state. One of the relaxation processes from π^* is conversion to the other geometric isomer. Since the *trans* ground state lies lower in energy than that of the *cis* isomer, any *cis* species created revert to *trans* via a thermal and (or) a photochemical route. Therefore in the presence of the pump, many *trans* $\rightarrow$ *cis* $\rightarrow$ *trans* isomerization cycles occur, resulting in orientation of the side chains. This motion may continue until the chromophores find themselves in a position where their dipole moments (along the long axis of the molecule) lie perpendicular to the polarization plane of the pump. Since there can be no further absorption in this orientation, isomerization, and therefore the accompanying side-chain motion, stops and the chromophores become "locked." Although steric interactions prohibit the complete orientation of all chromophores, at equilibrium there is a net alignment perpendicular to the pump. This anisotropy manifests itself as a measurable difference in refractive index, or birefringence.

In this study a simple model of photoinduced orientation is presented. The effect of irradiance and temperature on the order parameter is shown for two polymers whose structural units are depicted in Fig. 1. Poly[4′-[[2-(methacryloxy)ethyl]-ethyl]amino-4-nitroazobenzene] (pDR1M) belongs to the pseudo-stilbene spectral class according to Rau's classification scheme (1) since the energy ordering of the (n, π^*) and (π, π^*) states is reversed. For this polymer the bands are practically overlapping, resulting in both *trans* $\rightarrow$ *cis* and *cis* $\rightarrow$ *trans* photoisomerizations at the same excitation wavelength. Poly[4-[2-(methacryloxy)-ethyl]azobenzene] (pMEA) belongs to the azobenzene spectral class (1) with a low-intensity (n, π^*) band in the visible and a high-intensity (π, π^*) band in the UV. This results in an efficient *cis* $\rightarrow$ *trans* back-

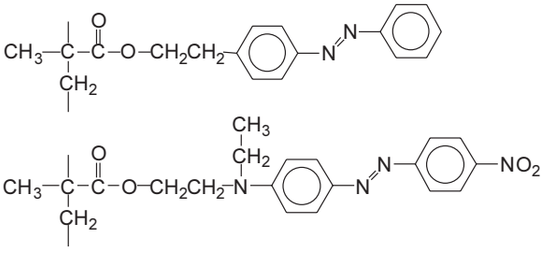
Fig. 1. The structural units of pMEA (top) and pDR1M (bottom).



isomerization at 488 nm while the *trans* → *cis* process experiences only the tail of the absorption band.

Model

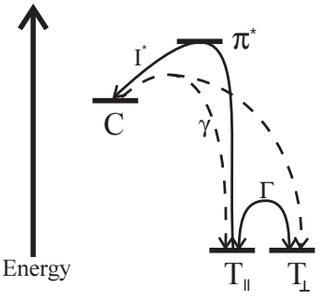
An elementary model of photoisomerization is based upon the phenomenological mechanism proposed by Sekkat and Dumont (2). There are four dominant processes that contribute to the orientation. These are (*i*) photochemical *trans* → *cis* isomerization, (*ii*) photochemical *cis* → *trans* back-isomerization, (*iii*) thermal *cis* → *trans* back-isomerization, and (*iv*) angular redistribution among species. It is assumed that only the *trans* species may contribute to the observed order parameter on account of its elongated rodlike shape. To make things even simpler, all possible angles at which the side groups can lie are reduced to two: parallel or perpendicular to the pump. As a consequence of the highly delocalized π-electron density of the azo chromophores, the probability that a species will absorb the pump radiation is proportional to $\cos^2\theta$, where θ is the angle between the electronic dipole moment and the polarization vector of the pump. Considering our two orientations, this implies complete absorption for parallel species while perpendicular groups are oblivious to the pump. An identical solution for the *photostationary* order parameter is obtained with and without the photochemical back-isomerization. Therefore, for the primary purpose of representing this equilibrium, only the thermal back-isomerization will be included in the model, keeping in mind that both occur in the actual experimental system. With these considerations in mind, three populations have to be monitored: *cis* (*C*), *trans* parallel to the pump ($T_{\|}$), and *trans* perpendicular to the pump ($T_{\perp}$). The pump I^* creates *cis* species that thermally relax back to *trans* with a reciprocal lifetime of γ. The *trans* species may flip back and forth between parallel and perpendicular orientations with a diffusion constant Γ.

The model is implemented by means of three coupled differential equations that govern the change in each population with time.

$$[1] \qquad \frac{dT_{\|}}{dt} = -I^*T_{\|} + \frac{1}{2}\gamma C - \Gamma T_{\|} + \Gamma T_{\perp}$$

In the first equation, the $T_{\|}$ population is being diminished by the pump and by rotation to the perpendicular direction, increased by *cis* → *trans* thermal relaxation and rotational diffusion from the perpendicular towards the parallel position. The thermal *cis* → *trans* process is here assumed to equally populate $T_{\|}$ and $T_{\perp}$.

Fig. 2. An energy level diagram for the three-state model of photoinduced reorientation. Here promotion to π* is shown only for the photochemical *trans* → *cis* isomerization. The *cis* species thermally relax to *trans*, and redistribution among *trans* species is also allowed to occur.



$$[2] \qquad \frac{dT_{\perp}}{dt} = +\frac{1}{2}\gamma C + \Gamma T_{\|} - \Gamma T_{\perp}$$

In the second equation, the number of $T_{\perp}$ chromophores is increased by thermal back-isomerization and is also susceptible to rotational diffusion.

$$[3] \qquad \frac{dC}{dt} = +I^*T_{\|} - \gamma C$$

In the last equation, the *cis* species is increased in number by pumping from *trans* and suffers losses to the thermal back-isomerization. An energy level diagram for such a system is shown in Fig. 2.

Experimental

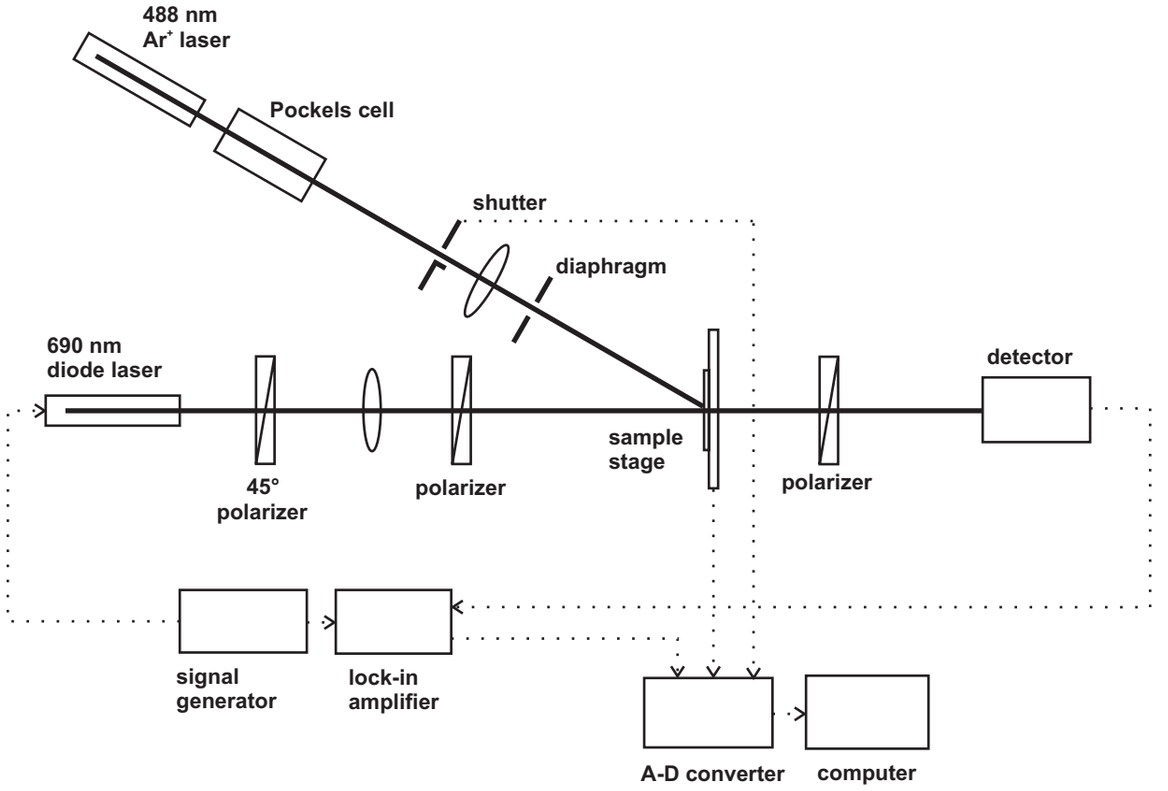
The synthesis of pMEA (3) and pDR1M (4) has been described in previous publications. The polymers were spin-cast from THF onto glass substrates and then held at their glass transition temperatures (120°C for pDR1M and 80°C for pMEA) for 1 h. This served to adhere the matrix onto the substrate, drive out solvent, and remove any anisotropy that may have been induced by spin-coating. Film thickness was measured using a Sloan Dektak II profilometer. Before beginning any of the experiments, it was necessary to choose films of an appropriate maturity to obtain reproducible rates and saturation levels, and there has been a similar report of such an age requirement in the literature (5). Consistent results were achieved with films left for 2–4 weeks at room temperature following preparation.

A schematic of the optical bench is given in Fig. 3. In the detection circuit a diode laser operating near 690 nm was incident onto a linear polarizer at 45°. The beam then passed through a focussing lens, the sample, and a crossed polarizer before reaching the detector, a photomultiplier tube. The square root of the signal from the detector is proportional to the phase lag suffered by the probe through a birefringent sample. Refractive index difference ($\Delta n = n_{\|} - n_{\perp}$) was then calculated using

$$[4] \qquad \Delta n = \frac{\sqrt{I}\,\Delta\varphi}{\sqrt{I_{\mathrm{ref}}}\,kd}$$

© 1998 NRC Canada

Fig. 3. A schematic of the optical bench used to induce and measure birefringence.



where I is the signal from the amplifier, $\Delta\varphi$ is the phase lag at reference, d is the sample thickness, $k = 2\pi / \lambda$ is the wave vector, and I_{ref} is the reference signal used in the calibration. From this, the order parameter S was obtained using

$$[5] \qquad \langle S \rangle = \frac{\Delta n}{3n_{band}}$$

where n_{band} refers to the effective isotropic index of refraction of the chromophores alone. Since the birefringence is likely the result of an anisotropic distribution of azo side groups, a measure of their orientation should include the contribution to the refractive index of just those groups. This was obtained from the (π, π^*) and (n, π^*) absorption bands using a Kramers–Kronig relation

$$[6] \qquad n_{band}(\lambda) = \int_{band} \frac{\alpha(\lambda')}{1-(\lambda'/\lambda)^2} d\lambda'$$

where $\alpha(\lambda)$ is the absorption coefficent. For pDR1M this gave a photostationary order parameter of –0.13, in agreement with that obtained by dichroic infrared (6) and transient absorption spectroscopy (7).

The 488 nm line of an Ar^+ laser was used as an excitation source, intersecting the probe beam at the sample surface. A Pockels cell was used to vary the laser polarization between linear and circular. A typical experimental protocol involved irradiating the sample for 200 s while collecting data at a rate of 1 point/s for the first 10 s, followed by 10 points/s for the remaining time. An Instec temperature controller and heating stage were used to maintain temperatures accurate to within ±0.1°C.

Results and discussion

Model predictions

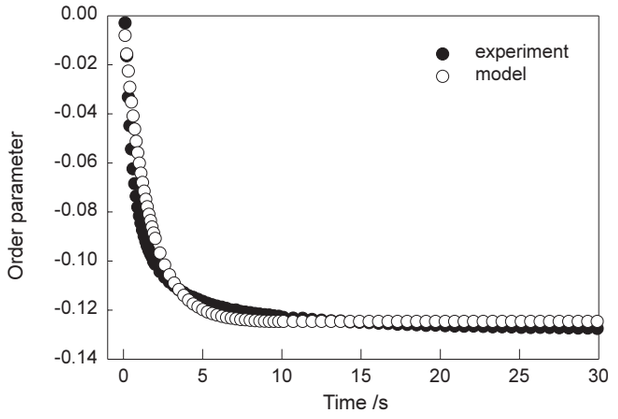
When a simulation of photo-orientation based on the above model is run, the macroscopic order parameter S reaches a saturation value, as is observed experimentally (Fig. 4). It is possible to derive an analytical expression for this saturation value by solving the linear system (eqs. [1]– [3]) with the steady-state approximation, giving

$$[7] \qquad \langle S \rangle = \frac{T_{\parallel} - T_{\perp}}{T_{\parallel} + 2T_{\perp}} = -\frac{I^*}{6\Gamma + 2I^*}$$

Although the model assumes the orientation to be two-dimensional (in the plane of the film), the order parameter must approximate a three-dimensional system to be compared with the experimental value given by eq. [5]. For the calculation of S, the total *trans* population occupies three states. Here an additional $T_{\perp}$ exists (chromophores oriented normal to the film surface and hence also perpendicular to the pump) that is, for simplicity, assumed to have the same population as the original in-plane $T_{\perp}$. The result is nearly identical to that obtained by Labarthet and Sourisseau (7) in their implementation of the model of Sekkat and Dumont (2) obtained with a more complete theory where all angular distributions are taken into account.

© 1998 NRC Canada

Fig. 4. The photostationary order parameter attained by an experimental system (pDR1M) and by simulation with the model.



The model predicts a photostationary order parameter that is independent of the reciprocal *cis* lifetime γ. The only influences that remain are the pumping rate I^* and the *trans* diffusion constant Γ. It is possible to obtain an estimate of the pumping rate based on the *trans* $\rightarrow$ *cis* quantum efficiency Φ and experimentally measurable *trans* absorption cross section σ.

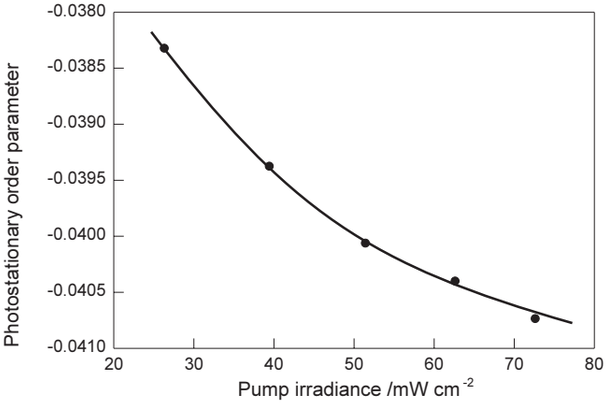
$$[8] \qquad I^* = I_{\text{pump}}\Phi\sigma$$

The likelihood of photon absorption leading to isomerization is directly related to the free volume available for such a configurational change, and so the quantum efficiency is sensitive to the polymer matrix. It has been shown to vary by more than four orders of magnitude from solution values of 0.25 (1) to 0.11 for doped systems (8) to 7.4×10^{-6} in Langmuir–Blodgett films (9). Our modelling suggests a quantum efficiency in the range 5×10^{-3} to 5×10^{-2}, which is low but reasonable, considering the inevitable crowding in a fully chromophore-loaded functionalized system. The absorption cross section was estimated based on the absorbance, film thickness, and chromophore density. Such a calculation gives a value of $\sigma = 1.3 \times 10^{-18}$ cm^2 for pMEA and $\sigma = 1.2 \times 10^{-16}$ cm^2 for pDR1M. The other parameter of interest here, the *trans* diffusion constant Γ, will be discussed along with the temperature results.

Effect of pump irradiance

It is of primary interest to compare the experimental results of the effect of pump irradiance on the photostationary order parameter with those predicted by eq. [7]. For pump irradiances in the range 13–60 mW/cm^2, the order parameter remained constant at –0.13 for pDR1M and increased in absolute value for pMEA (Fig. 5) in qualitative agreement with eq. [7]. This variation for pMEA, however, was slight (less than 5%) so the dependence is weak. Still, the adherence of pMEA to, and disagreement of pDR1M with, the predicted irradiance behaviour suggests that dipolar interactions in pDR1M may be the cause of the observed differences. This idea will be discussed further in the following section. Below 10 mW/cm^2, the absolute saturation level decreases with irradiance for both polymers. Unfortunately, the long time required to reach equilibrium at such low

Fig. 5. The variation in photostationary order parameter with pump irradiance for pMEA.



pump irradiances (ca. 4 h at 5 mW/cm^2) makes a quantitative investigation of the relationship impractical by these methods. A similar study on the same chromophore as contained in pDR1M (Disperse Red 1) doped into a poly(methyl methacrylate) matrix revealed changes in the attainable orientation when pumping below 100 mW/cm^2 (7). This larger saturation order parameter is to be expected for a doped system, due to a much lower chromophore density.

The normalized order parameter (S_n) vs. time curves at each irradiance were fitted to the biexponential equation

$$[9] \qquad S_n = A\,[1 - \exp(-k_a t)] + B\,[1 - \exp(-k_b t)]$$

where A and B represent the amplitudes of the two exponentials, k_a and k_b the rate constants. The fitting indicates that for both polymers k_a and k_b increase with increasing irradiance. This is shown for pMEA in Fig. 6 and for pDR1M in Fig. 7. The amplitude A of the term describing the fast process increases as well, slightly faster for pMEA than for pDR1M at lower irradiances (Fig. 8). Song et al. carried out similar studies on an azobenzene-functionalized polymer (5) over the same range of pump irradiances. Although there are slight differences in the fitting procedure, their results showed no change in rate constant for different pump irradiances. Their data also show that the amplitude of the exponential describing the fast process increases linearly with pump irradiance. The three values of irradiance used in that study are indicated with arrows in Fig. 8, illustrating that this region may appear to be linear for our samples as well. Measurements at lower irradiances, however, reveal that the contribution of the fast process decreases sharply in favour of the slower one.

Effect of temperature

For both pMEA and pDR1M, the photostationary order parameter increases monotonically as a function of temperature, approaching zero as the systems restore their isotropic distribution of chromophores around T_g (Fig. 9). Here the influence and temperature dependence of the *trans* rotational diffusion constant may be seen. At higher temperatures there is more redistribution and a greater tendency towards isotropy. When Γ becomes very large, eq. [7] predicts that the order parameter S tends towards zero. Examining the other limit, as $\Gamma \rightarrow 0$, $S \rightarrow -0.5$, the maximum order achievable in

theory. That this may never be fullfilled is largely the result of steric factors. The magnitude of Γ is, however, not as closely related to the absolute temperature as it is to the glass transition temperature, for it is above T_g that polymers find the maximum free volume available to redistribute their pendant chromophores. This suggests a comparison on the basis of a reduced temperature, such as $T - T_g$ (Fig. 10). Although the manner in which both polymers lose their ability to maintain ordered chromophores appears markedly different in Fig. 9 (linear in the case of pMEA, sigmoidal for pDR1M), Fig. 10 shows that for a temperature region in which both systems may be compared (55° below to 5° above their respective T_g) the behaviour is remarkably similar.

A surprising result came from fitting the normalized order parameter curves to the biexponential described by eq. [9]. For both polymers, the variation in rate constant (k_b) with temperature showed no trend for the slow process, the data being completely scattered. The rate constant (k_a) for the fast process, however, increased with increasing temperature for pMEA and decreased for pDR1M (Fig. 11). This behaviour is in contrast to the rate constant dependence on irradiance discussed in the previous section where rates for both polymers increase with increasing pump irradiance. A possible explanation might involve the larger dipole moment of the donor–acceptor substituted pDR1M (10). Large dipole–dipole interactions have been shown to give rise to cooperative effects (11) where neighbouring groups participate in orientation in an effort to minimize the electronic repulsion in energetically unfavourable chromophore alignment.

These results are best considered with the two competing processes involved in mind. On the one hand there is alignment due to the polarization of the laser; on the other there is a tendency towards disorder and restoration of the equilibrium isotropy. Larger pump irradiances would favour the orientation process and have very little effect on thermal randomization, as was demonstrated experimentally. Increasing the temperature, however, would increase the rates of both processes due to an enhanced mobility accompanying an increasing free volume. The interplay between the two processes at higher temperatures is likely sensitive to dipolar interactions, resulting in a rate constant that decreases on heating for pDR1M. Since such electronic interactions are much weaker in pMEA, the resulting behaviour is different. A separate study to verify this hypothesis, analyzing copolymers and blends with different orientations of the dipoles, is in progress.

Summary and conclusions

The photoinduced reorientation of azobenzene-based polymers is a complex phenomenon, especially in the case of functionalized polymers, since there are many possible interactions between the chromophores and the matrix. The simple model presented here accounts for experimentally observed order parameters using optical pumping and

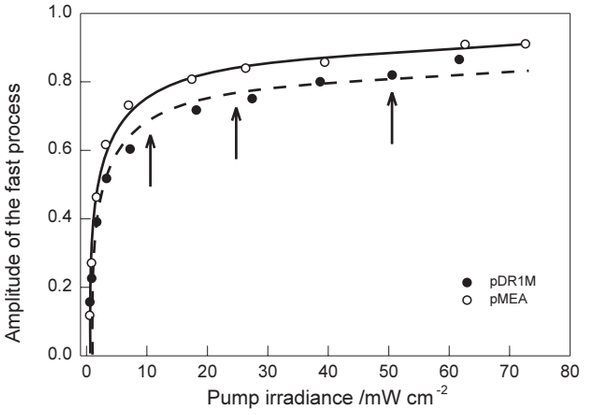

Fig. 9. The variation in photostationary order parameter for pMEA and pDR1M with increasing temperature.

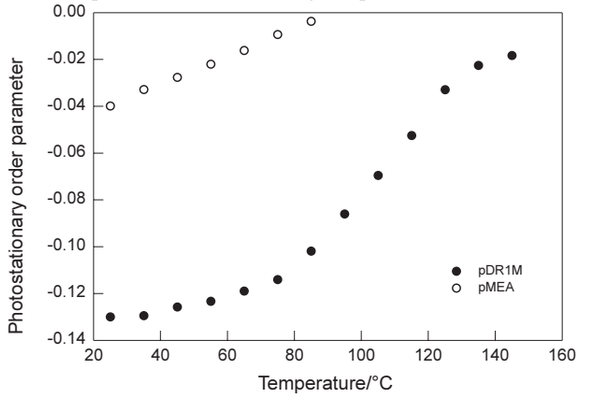

thermal redistribution. It has been used to arrive at an expression for the photostationary order parameter in terms of the pumping rate and the *trans* rotational diffusion constant. The predicted irradiance dependence of the orientation process has been qualitatively verified for pMEA, while pDR1M appears to be less dependent on the pump intensity. The rotational diffusion constant is a function of temperature and causes the photostationary order parameter to decrease at higher temperatures. For the polymer pDR1M, strong dipole–dipole interactions may be responsible for an orientation rate constant that decreases at higher temperatures. All of the experimental evidence suggests that the model of photoinduced orientation is only sufficient to describe a system such as pMEA where the lack of strong dipolar interactions allows the chromophores to be aligned independently, similar to the situation in a doped system with low chromophore density. For a system such as pDR1M, electronic effects such as dipole–dipole interactions will have to be taken into account.

The self-assembly of a layered material: metal–alkanethiolate bilayers

F. Bensebaa, T.H. Ellis, E. Kruus, R. Voicu, and Y. Zhou

Abstract: Layered materials composed of metal–alkanethiolate units have been synthesized and characterized. The self-assembly occurs at the interface between a metal-ion-containing aqueous phase and an alkanethiol-containing organic phase. Key features of the structure have been determined from X-ray diffraction and infrared spectroscopy measurements. The highly ordered bilayers are characterized by tilted, all-*trans* alkyl chains. A new model for the in-plane structure has been presented, which is based on a hexagonal arrangement of metal atoms in the central plane.

Key words: self-assembly, alkanethiolates, layered materials, vibrational spectroscopy.

Résumé : On a synthétisé et caractérisé des matériaux en couches formés d'unités alcanethiolate de métal. L'autoassemblage se produit à l'interface entre une phase aqueuse contenant l'ion métallique et une phase organique contenant l'alcanethiol. On a déterminé les caractéristiques principales de la structure par diffraction des rayons X et par spectroscopie infrarouge. Les bicouches bien ordonnées sont caractérisées par des chaînes alkyles inclinées, complètement *trans*. On propose un nouveau modèle pour la structure dans le plan; elle est basée sur un arrangement hexagonal des atomes métalliques dans le plan central.

Mots clés : autoassemblage, matériaux en couche, spectroscopie de vibration.

Introduction

Alkanethiols ($HS(CH_2)_nCH_3$) are known to react and adsorb onto the clean surfaces of coinage metals, and to self-assemble into highly ordered monolayers (1, 2). These self-assembled monolayers (SAMs) provide a means of creating well-defined surface structures whose properties can be manipulated through substitutions to the initial alkanethiol molecules (3). A wide range of surface analysis techniques has been applied to the study of alkanethiolate SAMs, yielding a wealth of information.

Less well known than SAMs are layered materials composed of metal–alkanethiolate units (4–6). These are also materials that self-assemble in solution, forming a multibilayer structure that is illustrated in Fig. 1. Such materials can be viewed as SAMs having an infinite surface-to-volume ratio. As such, we have undertaken to study these materials as model systems for SAMs. Because it is a bulk material, this greatly expands the range of measurement techniques available.

The goal of the present work is to describe the synthesis of these materials and the methods used to characterize their structure. Our preparation methods are a modification of those used for the preparation of short-chain silver–alkanthiolates (6), and we now have prepared copper–thiolate materials as well. Particular emphasis will be given to infrared spectroscopy measurements, where new information is revealed as a result of the enhanced signal from the bulk material.

Experimental section

The alkanethiols were purchased from Aldrich and used without further purification. All other reagents were acquired from general sources and used as received. Elemental analysis was performed on a Fisons Instruments model EA1108 analyser, and neutron activation analysis used the SLOWPOKE reactor at École Polytechnique de Montréal. The X-ray diffractometer is a Siemens D5000, using Co Kα radiation. Infrared spectra were recorded on a Bomem MB 100 FTIR spectrometer in transmission mode using a DTGS detector. Several drops of the metal–alkanethiolate material suspended in toluene were dropcast onto a NaCl disk and dried in air. Typically, 20 scans were co-added, and the resolution was 1 cm^{-1}.

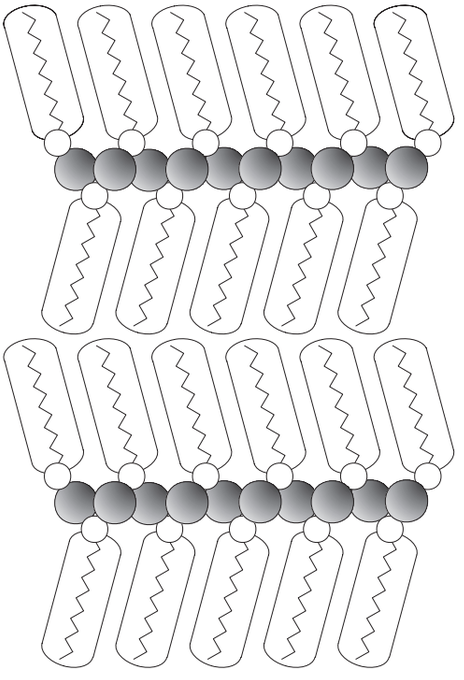
Results and discussion

The self-assembly process

The chemistry of the preparation procedure is elegant in its simplicity. The metal begins in the aqueous phase, in the

 © 1998 NRC Canada

Fig. 1. Cross-sectional view of the layered structure. Metal atoms: shaded circles; sulfur atoms: open circles; alkyl chains: rounded rectangles.



form of silver nitrate or cupric nitrate. The alkanethiol is dissolved in an organic solvent (toluene). When the two immiscible phases are brought into contact the metal–alkanethiolate material appears near the interface as a solid suspension in the organic phase. The reaction can take several hours to complete, and can be accelerated by mixing.

The reaction to form the silver–alkanethiolate material can be written as follows:

$$AgNO_3(aq) + HS(CH_2)_nCH_3(org) \Rightarrow HNO_3(aq) + AgS(CH_2)_nCH_3(org)$$

(The product will be abbreviated as AgSC(n + 1)). The exchange between the proton from the alkanethiol and the silver ion is confirmed by an analysis of the aqueous phase after the completion of the reaction: the pH of this phase is greatly diminished and no silver can be detected via precipitation with Cl^-.

The two phases are then separated, the organic phase is washed several times with water, and the suspension is collected by centrifuging. The resulting powder is washed several times with toluene and centrifuged again to purify. Analyses by elemental and neutron activation analysis (Table 1) confirm that the stoichiometry is exactly 1:1 (metal-to-alkanethiolate).

The following is an example of the synthetic conditions of AgSC12: 0.2 mL $HS(CH_2)_{11}CH_3$ (~0.84 mmol) in 15 mL toluene was added to 0.10 g $AgNO_3$ (~0.59 mmol) in 30 mL H_2O with stirring. After 1 h, the aqueous phase is clear and the measured pH is 1.5. The precipitate in the organic phase was washed three times with 50 mL H_2O, then three times with 50 mL toluene, then vacuum dried.

[c]Calulated based on a 1:1 stoichiometry.

In the case of the copper–thiolate material, the reaction is slightly more complex. Since the starting material is in the Cu(II) oxidation state, it must be reduced during the reaction. Elemental analysis (Table 1) proves that the final product has a 1:1 metal-to-thiolate stoichiometry. Our copper–thiolate material is probably similar to a precipitate that was synthesized as part of a study of multilayer films on copper (7), although the structure of that material was not determined. In that work it was suggested that copper may be reduced when two thiols react to form a disulfide. It is also possible that nitrate groups can be oxidized and liberated as gaseous products during the reaction. The overall reaction tends to be slower for copper, compared to silver, perhaps because of this extra complexity.

Both silver and copper thiolate materials have been synthesized using a variety of chain lengths. The resulting AgSC7–AgSC18 powders are pale yellow in colour. Shorter chains routinely produce bright yellow powders. Natan and co-workers have made an extensive study of butane thiolate (6), and found that powders of either colour can be produced by varying the synthesis conditions. They have labeled these materials *trans* and *gauche*, since the bright yellow *gauche* material has been found to contain *gauche* conformational defects in the alkyl chain. It was previously demonstrated that the yellow colour correlates to a trigonal sulfur-to-metal coordination, in contrast to a digonal coordination for white compounds (8). Finally, our copper material has a pale green colour (CuSC8, CuSC12, and CuSC18 have been studied to date).

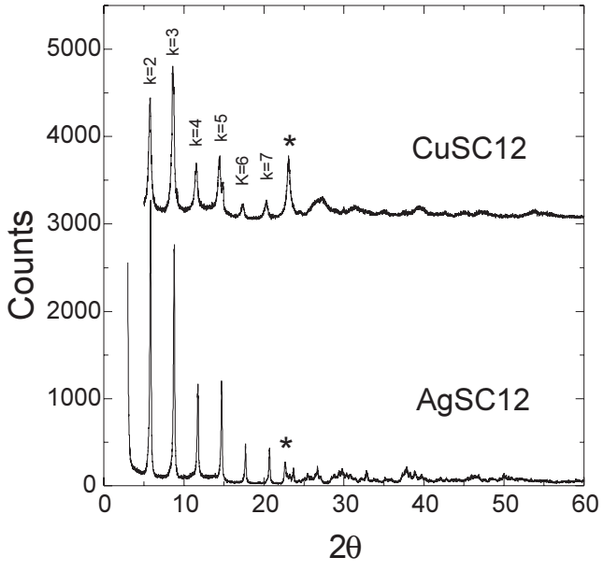
Both silver and copper materials often have the form of small, flat sheets (flakes). The largest size flakes are seen in the copper material, sometimes being several millimeters long and wide. It has also been observed that both materials can turn black, either as a result of heating or aging. Curiously, no significant change in composition or structure has been detected that correlates to this alteration.

The structure

Powder X-ray diffraction (XRD) measurements of both the Ag and Cu materials are dominated by lines that can be indexed to the interlayer spacing of the two-dimensional layered structure illustrated in Fig, 1, as shown in Fig. 2. It is worth noting that there is a complete absence of lines corresponding to the bulk (three-dimensional) metal structure. We have observed the latter in measurements of thiolate-capped metal nanoparticles, which were also produced using chemical synthesis (9, 10). Clearly, the procedures used in the present work result in a very different material.

© 1998 NRC Canada

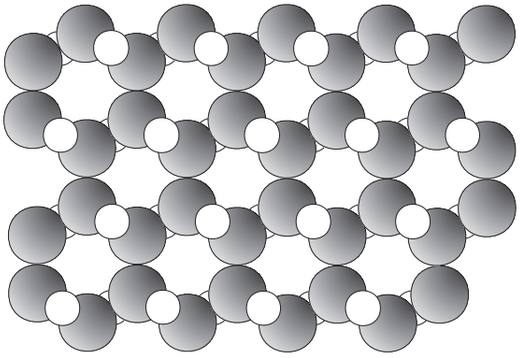
Fig. 2. XRD patterns of the CuSC12 and AgSC12 layered materials. Lines indexed to the interlayer spacing (0*k*0) are labeled. The line assigned to the in-plane structure is indicated by an asterisk.



The interlayer spacings of the Ag and Cu materials determined in this way are 35.0 ± 0.2 Å and 35.6 ± 0.2 Å, respectively. These distances are not consistent with the smaller copper radius, which could make the central layer smaller. Figure 1 indicates that the alkyl chains can be tilted with respect to the direction normal to the central plane of metal atoms. It is therefore likely that the two materials have a different chain tilt angle. A preliminary analysis of the data, for all measured chain lengths, indicates that the tilt angles with respect to the surface normal are 12 ± 3° and 10 ± 3° for Ag and Cu, respectively. It is not possible at present to determine whether the tilted chains adopt the herringbone structure shown in Fig. 1, or some other combination of positive and negative tilt angles.

The tilt angle of the silver layered materials compares well to the value of 13 ± 2° obtained by Laibinis et al. (2) for alkanethiolate SAMs on silver surfaces. Their angles were determined from a detailed modeling of the infrared spectra. For comparison, it is generally accepted that alkanethiolate SAMs on gold surfaces are more tilted, with values ranging from 26° to 34°, as determined by IR (2) and XRD (11) measurements. It is often speculated that tilting is driven by the optimization of van der Waals interactions between alkyl chains, due to the mismatch between the metal surface lattice and the close-packed spacing in bulk alkanes. However, it is worth noting that both Ag(111) and Au(111) have virtually identical lattice constants. While SAMs on Au(111) form a commensurate v3 × v3 structure, it is now known that SAMs on Ag(111) are in fact incommensurate with the underlying silver lattice (12–14). The measured overlayer lattice constant is 4.4–4.8 Å, as compared to 5.0 Å on Au(111). This would explain the smaller tilt angle observed for SAMs on Ag(111). Further, the driving forces for this incommensurate structure of these SAMs is undoubtedly related to the assembly mechanism of the layered material.

Fig. 3. Top view of the central plane. Metal atoms: shaded circles; sulfur atoms: open circles; alkyl chains: not shown. The row-to-row spacing is shown.



We can now add to this discussion the tilt angle of ~11° determined for the copper layered material. Since copper is significantly smaller than both silver and gold, it is logical to expect that the alkyl chains would be packed closer together, and there would be less of a tendency to tilt. Other factors will certainly play a role as well, such as the inherent metal–sulfur–carbon bond angle, and fine details of the alkyl chain packing.

Previous studies of silver layered materials were not able to determine the in-plane structure from XRD measurements (4, 6). A new proposal for the in-plane structure is shown in Fig. 3. It features a plane of metal atoms that adopt a hexagonal structure. By placing sulfur atoms in the digonal (twofold bridging) sites shown, they template a close-packed arrangement of the attached alkyl chains (which are not shown in this view). This is the main feature that separates this model from previous models (4, 6). A close examination of Fig. 3 shows that digonal bonded sulfur atoms appear both above and below the plane, which results in the formation of long rows composed of covalently bonded metal–sulfur units. These rows run horizontally in the drawing. The digonal bonding of the S atoms is confirmed by the pale yellow colour of the Ag material (8). Other structural features remain to be determined, such as the possible buckling of metal atoms in the central plane.

We have observed a number of XRD lines, both sharp and broad, that do not shift when the chain length is varied. They probably originate from the in-plane structure. For example, there is sharp peak at 4.55 ± 0.03 Å and 4.47 ± 0.04 Å for the Ag and Cu materials, respectively (see Fig. 2). This is much less than the difference in the size of the metal atoms (Ag is 13% larger than Cu), and indicates that chain packing plays a significant role in determining the in-plane lattice distances. The slightly smaller size of the Cu lattice is also consistent with the observed smaller tilt angle.

Vibrational spectroscopy

Previous studies of alkyl chain systems have shown that many spectral features are highly sensitive to the chain conformational order. Figure 4 shows transmission IR spectra of the AgSC12 and CuSC12 materials. It is first evident that there are a large number of sharp, well-resolved peaks. This is different from IR measurements on monolayers,

where signal levels are too low to permit detailed observation of the low-wavenumber region (2, 15). The spectra are also more detailed than those reported for thiolate capped nanoparticles (9, 10).

The degree of order can be better quantified by a detailed analysis of the peaks, whose positions are summarized in Table 2. The CH_2 stretching peaks, which can be measured with sensitivity in all alkyl chain systems, are known to shift to lower frequency with increasing conformational order. In general, antisymmetric (d^-) peaks at 2918–2920 cm^{-1} and below are typical of ordered solid systems, where all-*trans* chain conformations predominate. In liquid (disordered) systems, the peaks tend to be above 2920 cm^{-1}, indicating large percentages of *gauche* conformational defects in the chains (16–18). As seen in Table 2, the layered materials are clearly characterized by all-*trans* chain conformations. For all the chain lengths studied, values of 2915–2917 cm^{-1} and 2917–2920 cm^{-1} have been found for Ag and Cu, respectively. By comparison, well-ordered monolayers (2) on gold surfaces and thiolate-capped gold nanoparticles (9, 10) are typically characterized by d^- peak values of 2918–2920 cm^{-1}. (In all cases, the higher wavenumbers are systematically observed to occur with shorter chain lengths.) It can therefore be concluded that the layered materials are the most highly ordered (in terms of chain conformational order) of all the thiolate self-assembled systems. This is probably because in other systems the metal lattice is constrained by sub-surface metal atoms, whereas there will be more flexibility in the single layer of metal atoms in the layered materials, producing less strain in the alkyl chain structure.

A preliminary temperature-dependent study indicates that this order remains right up to the disordering transition, at about 402 K for AgSC12 and 416 K for CuSC12. This would be in contrast to temperature-dependent studies of SAMs on gold (12, 19, 20) and thiolate-capped gold nanoparticles (10), where a more continuous shift as a function of temperature is observed. Perhaps more importantly, the disordering of those systems occurred at a much lower temperature (at or below 350 K).

A second measure of order is the observation of peaks that belong to the wagging (W_x) and rocking–twisting progressions (P_x), located in the 1180–1350 cm^{-1} and 715–1030 cm^{-1} ranges, respectively. These progressions result from the coupling

© 1998 NRC Canada

of *n* identical methylene oscillators (21). They have been observed in the spectra of solid alkanes (21) and lipid bilayers (18), and they were previously used as order parameters (18). They have not been previously observed for thiolate monolayers, but they were observed, less well resolved, with thiolate-capped nanoparticles (9). Because the peaks are so clearly resolved in the present case, it has been possible to assign each indivdual peak. As seen in Table 2, both silver and copper layered materials have virtually identical peak values, indicating a similar chain conformation in both cases. Clearly, the different tilt angles do not affect the chain conformation. Once again, preliminary temperature-dependent studies indicate that a high degree of order remains right up to the phase transition that occurs above 400 K.

The peak that is labeled as δ_s in Table 2 is assigned as the CH_2 bending mode arising from the carbon atom that is bonded to S, and it is observed between 1421 and 1425 cm^{-1}. This was previously suggested by Murray and co-workers (9) based on measurements of thiolate-capped gold nanoparticles, where it is observed at 1414–1423 cm^{-1}. There is no obvious correlation to the nature of the metal atom, the tilt of the chain, or the length of the chain.

Because the spectra are composed of well-resolved peaks on a flat background, it is possible to comment on the absence of small peaks that are known to be associated with conformational defects. It has been established that peaks at 1338 cm^{-1}, 1368/1308 cm^{-1}, and 1344 cm^{-1} can be assigned to double *gauche*, internal kink, and end-*gauche* defects, respectively (22). These peaks are systematically absent from spectra of layered materials, for all chain lengths, both Ag and Cu. In contrast, some end-*gauche* defects were observed on thiolate-capped nanoparticles, where domain sizes are much smaller, and where there may be less end-to-end packing.

Information about conformational defects can also be obtained from C–C stretching peaks. In solid alkanes, these peaks form the progression labeled as R_x. The evolution of these peaks as a function of the chain length of these peaks is less systematic than the W_x and P_x series, but we have tentatively assigned three peaks in both AgSC12 and CuSC12 to this series. A detailed Raman study of this region exists for solid alkanethiols and thiolate monolayers (23). In the case of the former, three peaks are systematically observed at values close to those shown in Table 1, and all three are assigned to the *trans* conformation. One issue yet to be resolved is the fact that the peak at 1068 cm^{-1} is consistently the most intense peak in this series, and it is not clear why. Secondly, the peak at 1131 cm^{-1} is anomalously intense in the CuSC12 material, compared to all others. It is perhaps worth noting that the CuSC12 material is slightly less conformationally ordered than the AgSC12 material, as judged by peak positions and shapes.

Taking all of the above observations together, it is clear that the self-assembly process of the layered materials allows the alkyl chains to adopt an all-*trans* configuration. This will allow for the full optimization of the attractive interactions between the chains. Further, the organization of the thiolate groups appears to create a stabilization of the entire structure. In addition to the preliminary temperature-dependent studies, it should be mentioned that the short-chain materials that have been synthesized are also highly ordered. For example, the AgSC7 material has a d^- wavenumber at 2917 cm^{-1}, and 12 peaks assigned to progressions are clearly resolved. At room temperature, bulk alkanes and lipid bilayers of similar chain length are disordered. A similar stabilization of the alkyl chains occurs in other thiolate systems. Although some authors have suggested that short-chain systems are disordered at room temperature, there are now clear indications that it is indeed possible to have ordered thiolate monolayers and thiolate-capped nanoparticles with very short chains (9, 24). Combined with results from the layered materials, one can now say that self-assembled alkanethiolate systems have an inherent stabilization, with the layered materials being the most stable.

Conclusions

Layered materials composed of silver and copper thiolates have been synthesized and analyzed. They form a highly ordered bilayer structure, characterized by tilted, all-*trans* alkyl chains. A new model for the in-plane structure has been presented that is based on a hexagonal arrangement of metal atoms in the central plane. These systems lend themselves to detailed analysis by a large number of techniques, which makes them an excellent model system for other metal–thiolate materials.

A solid state ^{31}P NMR study of the synthesis of phosphorus sulfides from PCl_3 and H_2S in microporous materials[1]

Garry S. H. Lee, Christopher I. Ratcliffe, and John A. Ripmeester

Abstract: The interaction and reaction of PCl_3 and PCl_3–H_2S mixtures with the microporous materials Silicalite, ALPO-5, NaY, NaX, and NaA have been investigated, with the intention of producing phosphorus sulfide clusters in the pores. A rich chemistry was observed and monitored by solid state ^{31}P NMR. The presence of P_4S_3, α-P_4S_5, β-P_4S_6, and P_4S_7 inside the NaY α-cages was demonstrated, as well as a new species that is possibly a third geometric isomer of P_4S_4 with C_{3v} symmetry. ^{129}Xe NMR showed the exclusion of Xe from the micropores by the phosphorus sulfides. Sulfides lower than P_4S_7 are small enough that they undergo rapid pseudo-isotropic reorientation inside the NaY α-cage.

Key words: phosphorus sulfides, intrazeolitic cluster synthesis.

Résumé : On a étudié l'interaction et la réaction du PCl_3 et de mélanges de PCl_3–H_2S avec de materiaux microporeux, comme Silicalite, ALPO-5, NaY, NaX et NaA, dans le but de produire des agrégats de sulfures phosphoreux dans les pores. On a observé une chimie intéressante qui a été observée par RMN du ^{31}P à l'état solide. Dans les cages-α de NaY, on a mis en évidence la présence de P_4S_3, α-P_4S_5, β-P_4S_6 et P_4S_7 ainsi qu'une nouvelle espèce qui pourrait être un troisième isomère géométrique du P_4S_4 de symétrie C_{3v}. La RMN du ^{129}Xe montre qu'il y a exclusion du Xe des micropores par les sulfures phosphoreux. Les sulfures de formules inférieures à P_4S_7 sont suffisamment petits pour subir une réorientation pseudoisotropique à l'intérieur de la cage-α de NaY.

Mots clés : sulfures phosphoreux, synthèse d'agrégat intrazéolitique.

[Traduit par la Rédaction]

Introduction

The chemistry of the phosphorus–sulfur system is well known, having been extensively studied by crystallographic methods, NMR spectroscopy, and vibrational spectroscopy. A large number of molecules, all based on expansions of the P_4 tetrahedron of elemental white phosphorus, is now established and includes P_4S_n (n = 3–10) (1, 2). In mixtures of phosphorus and sulfur that contain between 0 and 25 at.% P, glassy materials are formed (3–5). These glasses are particularly attractive to the material sciences due to their optical and electrical properties, particularly their infrared transmitting properties (6).

The renewed interest in the study of phosphorus sulfides is based on the recent developments in solid state NMR allowing increased spectroscopic resolution of both ordered crystalline compounds and disordered systems such as the glasses (7). This permits the identification of chemical environments via chemical shift ranges and provides valuable information on the short-range order of these potentially useful materials. Currently there is also much interest in nano-clusters with properties much modified from those in the bulk material, and also for nonlinear optical and semiconductor properties. To this end zeolites and other microporous solids are being used as minireactors and templates to grow size-restricted clusters and to produce periodic arrays of clusters or nano-wires (8, 9).

With this in mind and also with a longer term interest in studying clusters and unusual entrapped species, we attempted to synthesize phosphorus–sulfur compounds within the cavities of zeolites and other microporous materials, and used ^{31}P NMR to characterize the species involved. ^{31}P NMR is perhaps the most useful tool for studying phosphorus species within zeolites, since many other techniques are hampered to some extent by the nature of the system, e.g., Raman spectroscopy suffers from problems with fluorescence, IR has problems with strong overlapping vibrational modes of the lattice, X-ray diffraction has problems with disorder, EXAFS is not so useful where numerous sites are involved. Here we describe the results of exploratory experiments on PCl_3 in microporous materials and its reactions with H_2S, focussing particularly on the behaviour with NaY zeolite.

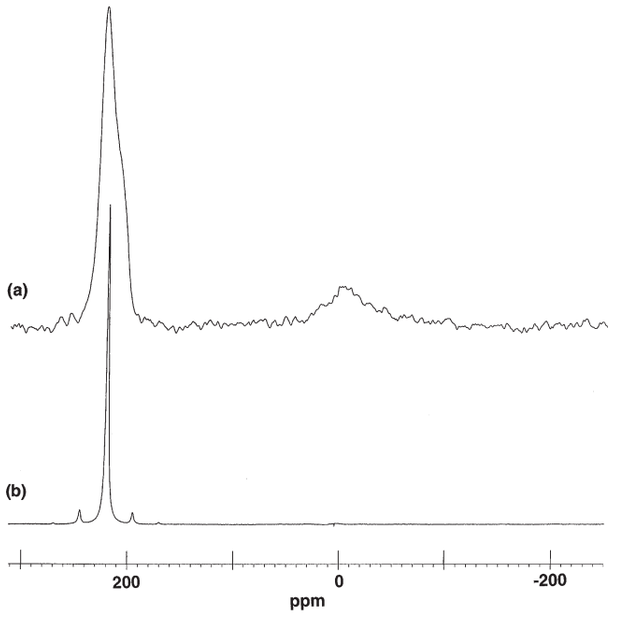
Fig. 1. ^{31}P NMR of PCl_3 in Silicalite. (*a*) Static spectrum showing chemical shift anisotropy powder pattern for PCl_3. The signal in the vicinity of 3 ppm is probably $POCl_3$ and other P/O/Cl species. (*b*) MAS spectrum of a sample with twice the loading of PCl_3, ν_r = 2.0 kHz.

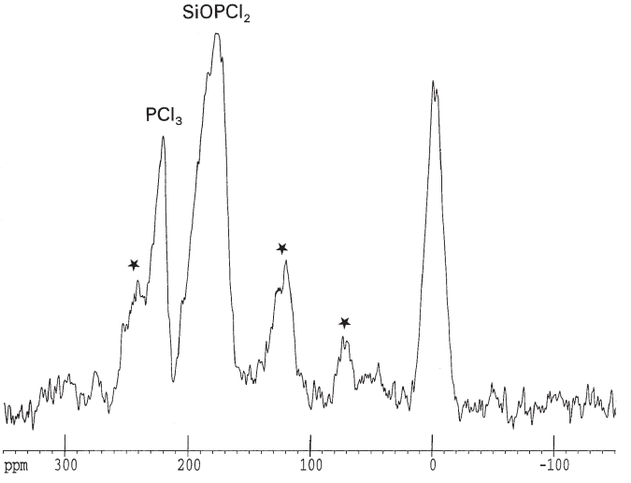


under vacuum, at progressively higher temperatures up to 450°C. All the preparative steps were carried out on a vacuum line and great care was taken to exclude all water. Measured quantities of degassed PCl_3 (liquid) were then condensed into these materials from a side arm and sealed in 5 mm o.d. tubes, allowing $4PCl_3$ per α-cage for X, Y, and A. The reactions with H_2S were carried out "in situ" after first condensing (at liquid nitrogen temperature) a known quantity of the gas onto samples of the microporous materials with PCl_3 already adsorbed (reactant ratio range used: PCl_3:H_2S = 4:3–4:10). These samples, in 5 mm o.d. tubes, were then sealed and annealed at various temperatures from 76 to 164°C. One sample was sealed after admitting a small amount of xenon gas. Solid state NMR spectra were recorded on a Bruker MSL 200 spectrometer operating at 80.962 MHz for ^{31}P and 55.321 MHz for ^{129}Xe, using a Chemagnetics magic angle spinning (MAS) pencil probe, both static and with spinning rates of 1.9–4.5 kHz. The glass sample tubes were inserted into the zirconia pencil rotors and held in place by Teflon spacer rings. Spectra were acquired using single pulses (90° pulse length 2.8–3.0 μs) with quadrature phase cycling. Positions of isotropic shifts were determined, when necessary, from MAS spectra obtained at different spinning rates. ^{31}P spectra were referenced to 85% H_3PO_4 and typically required 80 scans with recycle times of up to 100 s. The ^{129}Xe spectra were referenced to Xe gas at zero pressure.

Results and discussion

With the exception of a short note on ^{129}Xe, all the following discussion focusses on ^{31}P NMR results (Figs. 1–6, 8), which show a rich chemistry for phosphorus compounds inside zeolites. Most reactions seem to produce several products and it is a major problem to identify all of the species present. It is convenient to describe results first for the simpler systems with only PCl_3 and then with the addition of H_2S.

Fig. 2. ^{31}P NMR MAS spectrum of PCl_3 with NaY, ν_r = 4.5 kHz. Residual molecular PCl_3 shows at 220 ppm. Stars indicate spinning side bands of the line tentatively assigned to framework-attached $SiOPCl_2$.



(a) PCl_3 with microporous materials

PCl_3 is a liquid (mp –93.6°C) with a ^{31}P NMR chemical shift of 219 ppm (10). When introduced into Silicalite the spectra, Fig. 1, clearly show that the PCl_3 remains intact. However, the line indicates only a single type of PCl_3, with a small chemical shift anisotropy: δ_{iso} = 220 ± 0.4, $\delta_{11,22}$ = 227.8 ± 1.0, δ_{33} = 204.3 ± 1.0, axially symmetric within error, and there is no trace of any sharp liquid line. This anisotropy can only mean that the molecule is adsorbed in the Silicalite channels or on the surface. At the loading levels used there is not enough surface area to accommodate all the PCl_3 and consequently one must conclude that the signal most likely arises from molecules in the channels. Similar behaviour was observed with ALPO-5, which has one-dimensional channels.

With activated NaY and NaX the spectra initially show mainly the PCl_3 resonance, but with time this is very much reduced, Fig. 2, and is replaced by rather broad MAS lines with several spinning side bands that indicate considerable anisotropy. The isotropic shifts, which are at about 180–183 ppm for NaY and 153–156 ppm for NaX, can possibly be assigned to Si-O-PCl_2 and (Si-O-)$_2$PCl species (10, 11); the former were recently observed at 184 ppm in studies of PCl_3 reacting with a silica surface (10), and the latter suggested assignment of a line at 156 ppm observed by Bogatyrev et al. (11), though, ideally, further substantiation of these assignments is desirable. The presence of these chemically attached species would imply the production of NaCl (and perhaps a little HCl by reaction with any residual OH groups on the framework). Unfortunately the spectra are not good enough to determine the chemical shift anisotropies.

Fig. 3. ^{31}P NMR spectra of NaY with PCl_3–H_2S in a 4:3 ratio after heating to 76°C. (*a*) Static; (*b*) MAS, ν_r = 3.05 kHz; (*c*) 10× expansion of (*b*).

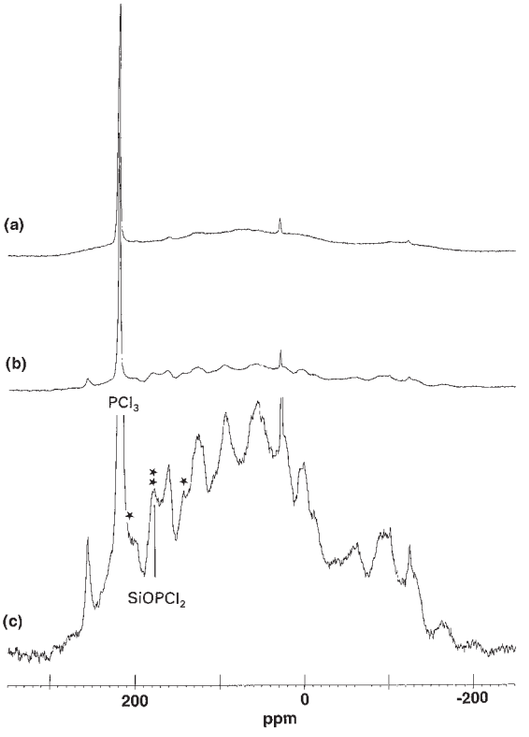

Fig. 4. ^{31}P NMR spectra of NaY with PCl_3–H_2S in a 4:3 ratio after heating to 100°C. (*a*) MAS, ν_r = 2.0 kHz; (*b*) MAS, ν_r = 2.9 kHz, 5 days after (*a*). Isotropic peaks of identified species are indicated by ○, P_4S_3; ◇, α-P_4S_5; □, β-P_4S_6.

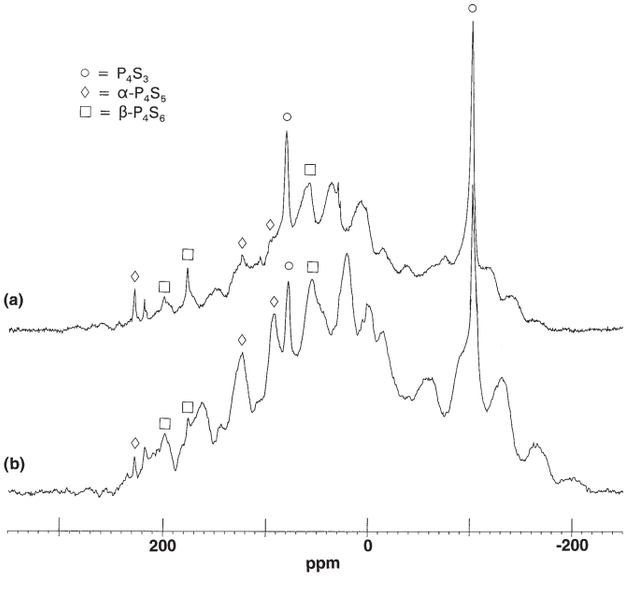
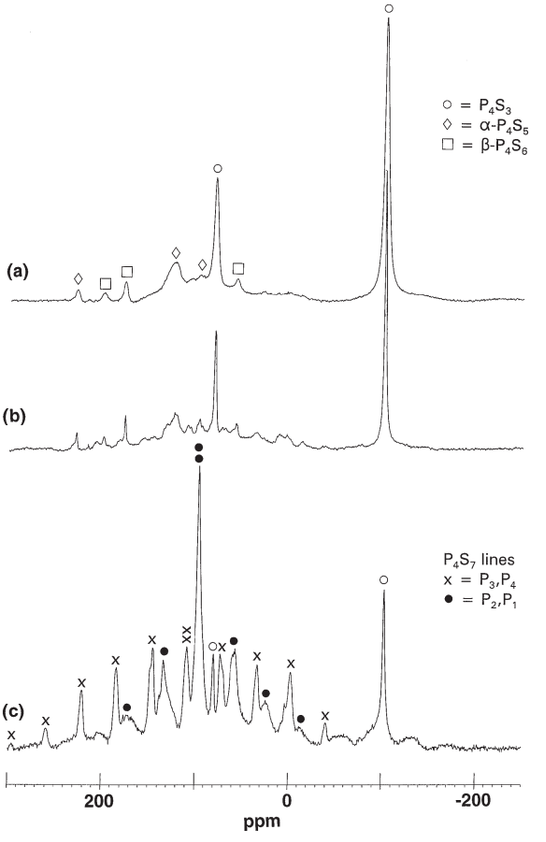


These materials also show a line in the 1.8–4.6 ppm range, which is weak in Silicalite (Fig. 1) and stronger in NaY (Fig. 2). One possible source of tis line could be $POCl_3$, a

Fig. 5. ^{31}P NMR spectra of NaY with PCl_3–H_2S in a 4:5 ratio after heating to 100°C. (*a*) Static; (*b*) MAS, ν_r = 1.95 kHz; (*c*) MAS, ν_r = 3.02 kHz, 18 days after (*a*, *b*). In (*c*) the spectrum of P_4S_7 predominates and P_4S_3 lines are much reduced. Isotropic peaks of identified species are indicated by ○, P_4S_3; ◇, α-P_4S_5; □, β-P_4S_6. The two P_4S_7 lines are indicated by × = P_3,P_4; ● = P_2,P_1. Double symbols indicate the isotropic shift.



common impurity in PCl_3 (less than 1%), which in the liquid state has a shift of 3 ppm (10). However, the intensity of the line in the NaY spectrum cannot be explained by $POCl_3$ alone, and a more likely alternative with a shift in the same range would be some other P/O/Cl or phosphorus oxy compound produced by reaction of the PCl_3 with any residual -OH groups or defect sites in the framework.

(b) PCl_3 and H_2S within microporous materials

The main phosphorus species observed in the cases of Silicalite (with a $4PCl_3$:$3H_2S$ ratio, annealed at 76°C) and ALPO-5 (with a $4PCl_3$:$5H_2S$ ratio, annealed at 80°C) was absorbed but unreacted PCl_3. In the case of Silicalite when annealed at 170°C, the main signal was still PCl_3 but several other small signals appeared, at 3.6 and 85 ppm (broad), and 48 and 55 ppm (sharp), which we have not been able to assign with any certainty.

In the reactions combining PCl_3 and H_2S (in ratios of 4:3, 4:5, and 4:10) with NaY we observe that in samples heated only to 76°C (Fig. 3), PCl_3 remains prominent in the spectra, and there is a trace of the Si-O-PCl_2 species and a strong unidentified broad signal or signals underlying the whole

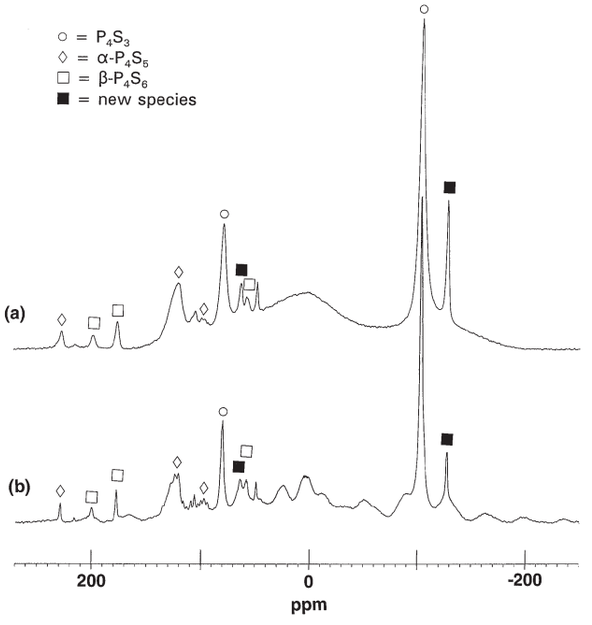
Fig. 6. ^{31}P NMR spectra of NaY with PCl_3–H_2S in a 4:10 ratio after heating to 164°C. (*a*) Static; (*b*) MAS, ν_r = 2.95 kHz. Isotropic peaks of identified species are indicated by ○, P_4S_3; ◇, α-P_4S_5; □, β-P_4S_6; ■, new species.

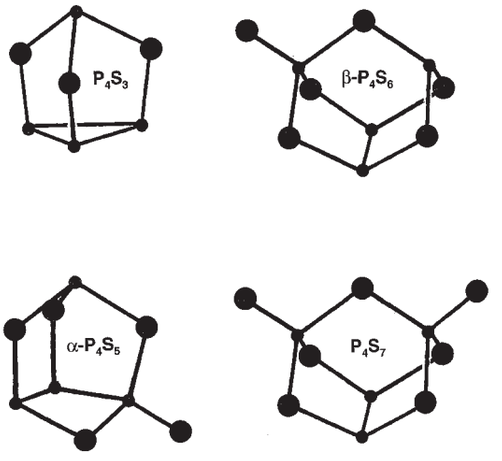


spectrum. Heating to 100°C or higher, however, initiates a complex series of reactions, and the spectra show virtually no PCl_3 and numerous new species (Figs. 4–6), which turn out to be phosphorus sulfides, as anticipated, Fig. 7. Assignments were made by comparison with known chemical shift ranges from numerous previous studies of phosphorus sulfides in solution, the melt, and the solid state, summarized in Table 1. In the early stages a major identifiable component is P_4S_3, with smaller quantities of α-P_4S_5 and β-P_4S_6. Again there are other unidentified species, which in some of the preparations have considerable intensity and large chemical shift anisotropies. The $4PCl_3$:$5H_2S$ preparation was monitored for some time after heating, and the lines of P_4S_3 were observed to diminish while those of P_4S_7 grew, Fig. 5*c*. The structures of the phosphorus sulfides identified are shown in Fig. 7.

A preparation of $4PCl_3$:$3H_2S$ with NaX zeolite showed none of the sharp phosphorus sulfide lines observed for the NaY samples. The MAS spectra showed a very broad, intense spectrum centred around 108 ppm with rather broad spinning side bands superimposed, and several sharp lines between 30 and –12 ppm, with the strongest at 2 ppm. The broader features could conceivably be phosphorus sulfides and the sharp features P/O/Cl species. The different behaviour of NaX compared to NaY is noteworthy, but any discussion of this is necessarily speculative due to the lack of any firm assignments in the NaX spectra. The higher cation content of NaX, however, means that there is also a higher Al content in the framework, and as a consequence of this there will likely be more defects where different reactions with PCl_3–H_2S and their products could occur.

A reaction with NaA with a $4PCl_3$:$7H_2S$ ratio, annealed at 80°C, was carried out with the notion that the much smaller window into the NaA large cage would prevent access even to PCl_3. The spectrum showed principally P_4S_7, again with many spinning side bands, with some P_4S_3, represented by two single lines, Fig. 8*c*. This was one of the cleanest spectra with only a trace of any other species (a broad line with several spinning side bands).

Fig. 7. Molecular structures of P_4S_3, α-P_4S_5, β-P_4S_6, and P_4S_7 (small atoms represent P).



We now proceed to a detailed discussion of the evidence for the phosphorus sulfide assignments, and whether these molecules are located inside or outside the zeolites:

P_4S_3

P_4S_3 is a globular cage molecule (Fig. 7) consisting of a triangle of three basal P_b atoms each linked via an S atom to a single apical P_a atom. The two sharp lines, which are seen in many of the current spectra at 82 ± 2 and –101 ± 2 ppm in a roughly 1:3 intensity ratio, may be assigned confidently to P_a and P_b, respectively. The low-frequency resonance is a unique characteristic of P_4S_3 that distinguishes it from the other phosphorus sulfides. There have been numerous previous studies of P_4S_3 in solution (12) and the solid state(13–18). In various solvents the P_a shift is in the range 62–79 ppm and the P_b shift is from –100 to –135 ppm (12), whereas the most recent studies of the solid give shifts of 91.0/84.5 and –87.5 ppm for the room temperature β-phase (13). (Note, in the solid, P_a appears as two lines due to crystallographically inequivalent molecules.) Clearly there is considerable variation depending on the environment, and our results fall well in the middle of the respective shift ranges.

What is most striking about the P_4S_3 resonances seen in the spectra with NaY zeolite is that the lines are isotropic, since they display no spinning side bands under MAS and remain quite sharp and featureless when static. On its own this isotropic behaviour might be taken as evidence for P_4S_3 being inside the α-cages: Within the Y zeolite α-cage a single P_4S_3 molecule would have considerable rotational freedom, and since the cage has elements of T_d symmetry the dynamic averaging of the chemical shift tensor (arising from pseudo-isotropic reorientation of the molecule) would produce an isotropic line. This is in marked contrast to the room temperature crystalline β-phase, which shows rather large chemical shift anisotropies of several hundred ppm (13).

	2	13.4		
P_4S_9	1	57.9–67.5		13, 15, 25
	3	57.8–63.6		
P_4S_{10}	4	49.7–60.1		13, 15 25

[a]Shift ranges from reported values in solution, melt, and solid phases. α's and β's in this instance refer to different molecular structural isomers (not different crystal phases).

[b]Distinct P atoms in isolated molecule.

[c]This work.

Similar anisotropies were also obtained from studies of P_4S_3 dissolved in a nematic phase (19). However, there is a second plausible explanation: Crystalline P_4S_3 is known to have a plastic phase (16, 18, 20, 21), where the molecule sits on specific lattice sites but reorients rapidly and thus gives rise to an isotropic NMR spectrum. Although the room temperature β-phase transforms to the plastic α-phase at 313.7 K, the α-phase can be supercooled to a lower limit of 259 K (20). However, it does not always have to be cooled this far down to transform back to the β-phase; for example in a T_1 study the material supercooled by about 35 degrees (21), though in a MAS study the supercooled state was only observed for a few minutes before it reconverted to the β-phase at ambient temperatures (18). Since the preparation of our zeolite / phosphorus sulfides all involved heating to 100°C or more, it is possible that the isotropic lines are from α-crystalline P_4S_3 outside the zeolite. Furthermore, resonances for the α-phase have been reported at 72 and –113 ppm (16) and, more recently, at 80.1 and –104.0 ppm (18). The latter result is very close to our results for NaY. To distinguish between these two possibilities, two of the NaY reaction samples ($4PCl_3$:$5H_2S$ and $4PCl_3$:$10H_2S$) and the NaA reaction sample were cooled to 77 K for 10 min and then allowed to warm back to room temperature; the isotropic lines were unchanged, thus demonstrating unequivocally the presence of P_4S_3 inside these zeolites.

α-P_4S_5 and β-P_4S_6

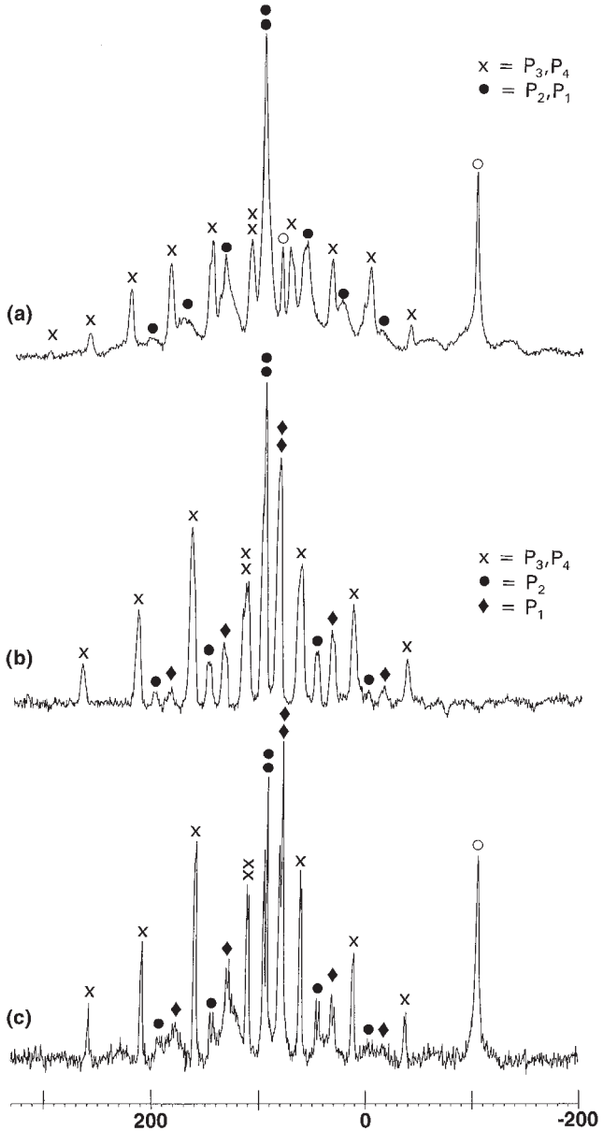
The static NMR spectra also show series of weak, sharp lines with no chemical shift anisotropy, which we assign to α-P_4S_5 and β-P_4S_6 in the zeolite α-cage, see Figs. 4–6 and Table 1. The identification of three lines for β-P_4S_6 is reasonably certain; the lines are in the correct shift regions (Table 1) and in the correct intensity ratio of 1:2:1 (2). The assignment of α-P_4S_5 must rely mainly on the unique high-frequency shift at 230 ppm (2, 13, 22), as the other expected resonances are partly obscured by other lines. Plastic (rotator) phases for α-P_4S_5 and β-P_4S_6 have not been reported and indeed, since both have a pendant S atom that makes these molecules much less globular than P_4S_3 (see Fig. 7), one would not expect them to have plastic phases. Consequently, the argument for these two products being inside the α-cages and undergoing rapid pseudo-isotropic reorientation is strong.

P_4S_7

The major product in the preparation of both NaY with $4PCl_3$:$5H_2S$, Fig. 8*a*, and NaA with $4PCl_3$:$7H_2S$, Fig. 8*c*, was P_4S_7, but this product is in two quite different states. The experiment with NaA produced crystalline α-P_4S_7, which has four resolved peaks at 82, 96, 111.5, and 113 ppm (13, 23), whereas the spectrum of NaY/P_4S_7 is definitely not that of the crystalline α-form and the isotropic shifts at 110.4

© 1998 NRC Canada

Fig. 8. ^{31}P NMR MAS spectrum of P_4S_7. (*a*) NaY/PCl_3/H_2S preparation, ν_r = 3.02 kHz; (*b*) α-crystalline preparation (no zeolite), ν_r = 4.09 kHz; (*c*) NaA/PCl_3/H_2S preparation, ν_r = 4.03 kHz. (*a*) and (*c*) both show isotropic P_4S_3 lines and traces of broader underlying resonances. (Note that spectrum (*a*) is the same as in Fig. 5*c*). × = P_3,P_4; ● = P_2; ◆ = P_1. In (*a*) P_1, P_2 overlap. Double symbols indicate the isotropic shift.



and 97.7 ppm are very similar to those observed for the amorphous form (measured by Bjorholm at 109.5 and 98 ppm (23)). In both spectra the lines show sizeable anisotropies. The molecular point group symmetry of the free P_4S_7 molecule is C_{2v}. There are two distinct pairs of equivalent P atoms and hence one expects two ^{31}P NMR resonances for the C_{2v} molecule (aside from any *J* couplings). In the solid α-phase of P_4S_7, however, the molecule is distorted because of a moderately strong and asymmetric interaction between two P atoms on one molecule and an S atom of another molecule, which makes all four P atoms inequivalent. This well-defined intermolecular interaction does not occur in the amorphous solid, which shows only two resonances, at shifts similar to those in the melt and solution. Likewise for a molecule isolated in the α-cage of NaY, only two resonances would be expected.

Table 2. ^{31}P NMR isotropic shift and principal components of the apparent [a] chemical shift tensors obtained from MAS spectra for P_4S_7 in NaY compared with crystalline α-P_4S_7.

Atom	δ_{iso}	δ_{11}	δ_{22}	δ_{33}
$P_{3,4}$ [b]	109.4	254	109	–36
$P_{1,2}$ [b]	97.8	158	92	44
P_4 [c]	113	271	124	–55
P_3 [c]	111.6	275	131	–72
P_2 [c]	96	187	85	20
		170	78	36
P_1 [c]	82	172	84	–6
		163	69	10

[a]The reader should note that these are not true chemical shift tensors, since direct and indirect coupling tensors are also involved (see ref. 13). In particular, the dipolar coupling between the directly bonded P atoms will be substantial.

[b]Data for P_4S_7 in NaY (this work).

[c]Data for crystalline α-P_4S_7 (13). The double entries for P_2 and P_1 correspond to *J*-split components.

Once again we are left with a choice between two equally plausible assignments for the NaY preparation: the amorphous solid outside the zeolite or isolated molecules inside the cages. Moreover, if the P_4S_7 molecule is inside the cages, this time it cannot be undergoing rapid reorientations because the chemical shift anisotropy is not averaged. The principal components of the chemical shift anisotropies for both resonances of NaY–P_4S_7 were determined by spinning side-band analysis at various spinning speeds using the Herzfeld–Berger method (24), which is incorporated in the Bruker software, see Table 2. From the table we note that our results, which clearly would not be expected to be the same as for crystalline α-P_4S_7 determined previously (13), nevertheless show anisotropies of similar span and skew. This rules out any question of dynamic averaging.

There are two main arguments that favour the existence of single molecules of P_4S_7 inside the cages of NaY: (*a*) There is the circumstantial evidence of the precursors being inside the cages, and several of the smaller sulfides also being formed there. (*b*) The amorphous form of P_4S_7 has only been formed previously by quenching the melt rapidly to 77 K (23), conditions quite remote from our preparation where the PCl_3 was sublimed into the zeolite and H_2S gas was added separately before annealing at 100°C.

P_4S_9 and P_4S_{10}

Since P_4S_7 appears to be static it is highly unlikely that we would see dynamic P_4S_9 and P_4S_{10}, which enables us to exclude making any assignment of sharp lines in the 50–60 ppm region to these species. Although their isotropic shifts fall in this region the static molecules have large chemical shift anisotropies (13, 15, 25).

© 1998 NRC Canada

A new P_4S_4 species in NaY ?

The $4PCl_3$:$10H_2S$ NaY preparation heated to 163°C shows three sharp lines in the static spectrum, at –126.3, 49, and 64 ppm, which do not appear for any of the other samples. Furthermore, when this material was reexamined after considerable aging, the P_4S_3 lines and the 49 ppm line had diminished considerably, and the lines due to α-P_4S_5 and β-P_4S_6 had disappeared completely, leaving a broad background centred around zero shift and more prominent lines at –126.3 and 64 ppm. The latter two lines occur in a roughly 3:1 ratio and appear to be associated with one species. The –126.3 ppm shift is very unusual, and does not appear to have been observed in the solid state before. The unique –101 ppm shift seen for P_4S_3 arises from its ring of three P atoms, so we suspect that the –126.3 ppm line may also be due to a P_3 ring, perhaps of a P_4S_3 derivative with a pendant S on the unique P atom. In this case the shift of 64 ppm for the unique P is in the region expected for $S_3P{=}S$ units. Such a P_4S_4 molecule would be a new geometric isomer with C_{3V} symmetry, and it would still have room to undergo pseudo-isotropic reorientation inside the α-cage. Why this new isomer would form in preference to the α or β forms is debatable, but it is likely influenced by the zeolite framework. A P_4S_3 molecule protonated on the unique P, $P_4S_3H^+$, is another possibility, though this has not been reported before and the S_3PH^+ unit would not be expected to have a 64 ppm shift. A chloro derivative seems much less likely since H_2S is in excess, and in fact it can be excluded, since we have observed the same two resonances in a preparation involving elemental P with H_2S in NaY annealed at 420°C (work to be reported later). One final possibility is that these resonances are from P_4S_3 in a second distinct kind of environment, though it is difficult to envisage where this might be.

^{129}Xe NMR results

The characteristic chemical shift of ^{129}Xe in pure NaY samples arises from exchange of the Xe between the zeolite cavities and the gas phase. The observed shift is a population weighted average of the shifts in the two types of situation (a high-frequency shift inside, and a low-frequency shift outside). The shifts for similar amounts of Xe in pure NaY and in an NaY with $4PCl_3$:$3H_2S$ reaction sample were 87.6 and 16.1 ppm, respectively. The much smaller shift of the Xe in the reaction sample indicates that the Xe is effectively excluded from the zeolite, implying that the cages are occupied by the phosphorus compounds. The 16.1 ppm shift, compared to that of the isolated Xe atom, indicates that the Xe is under significant pressure, the shift being caused by collisions with Xe atoms, the HCl reaction product, and any residual H_2S.

Molecular dimensions

An important consideration regarding the encapsulation of the phosphorus sulfide molecules is whether they can fit inside the zeolite cage and, if so, whether they have room to rotate. All the dimensions in the following discussion take into account the van der Waals radii of the atoms (O = 1.4, P = 1.9, S = 1.85, and Cl = 1.8 Å (29)).

NaY: The diameter of the Y zeolite α-cage, without taking into account Na^+ cations, is 11.0 Å and the diameter of the 12-ring window is 7.4 Å (30, 31).

NaA: The diameter of the A zeolite α-cage is 11.4 Å, and the diameter of the 8-ring window is only 4.1 Å (31, 32), excluding the Na^+ ions.

P_4S_3: The dimensions of P_4S_3 show a maximum diameter of 7.5 Å, and the largest diameter perpendicular to the 3-fold axis is 7.24 Å (calculated from available structural data (20, 33)). Inside the large cages of both NaY and NaA it will have considerable room. This molecule should therefore be able to go easily through the 12-ring window of NaY, but it should not be able to get through the 8-ring window of NaA zeolite.

α-P_4S_5: This is slightly smaller than β-P_4S_6 with a largest dimension of 9.3 Å (calculated from the crystal structure (34)).

β-P_4S_6: This is basically a P_4S_7 with one pendant S removed, so we have calculated its size based on the structural information for P_4S_7 (see below). Its largest dimension is 9.4 Å, and from the NMR it would appear that this is still small enough to allow rapid reorientation in the NaY cage.

P_4S_7: The smallest dimension of P_4S_7 (calculated from the crystal structure information (34–36)) is 7.7 Å and the largest is 10.2 Å.

One molecule of P_4S_7 can therefore fit inside the cage without too much trouble, but it would be difficult to get through the window. This has several implications: (*a*) The particular interactions that distort the molecules in the α-phase should not be present. (*b*) If it is inside the cage the molecule must have formed in situ from smaller precursors. (*c*) Once formed inside, the molecules will remain trapped. When the presence of Na^+ ions is also considered together with the long dimension of the molecule it is highly likely that the P_4S_7 will experience considerable hindrance to rotation, and hence the chemical shift anisotropy will not display the effects of dynamic averaging.

P_4S_9 and P_4S_{10}: Isolated P_4S_{10} is a tetrahedral molecule. The largest dimension (between two pendant S atoms) is 10.24 Å, but if the molecule were rotating pseudo-isotropically its effective diameter would be 11.71 Å (calculated from the structural data (34, 35)). P_4S_9 is structurally similar to P_4S_{10} but with one pendant S removed, hence its largest dimensions are virtually identical.

PCl_3: PCl_3 is a pyramidal molecule with dimensions (*a*) along a P—Cl bond of 5.74 Å, (*b*) along a Cl—-Cl edge of 6.73 Å, and (*c*) for the pyramid height of 4.65 Å (calculated from microwave structural data (37)). It should therefore have easy access to the NaY α-cage, and a tetrahedral cluster of four PCl_3 will just fit inside the cage. PCl_3 should not, however, be able to get through the window of the α-cage of NaA.

Other components of the spectra

We will emphasize again that the picture is incomplete as there are signals that we have been unable to assign, in particular, the broad background of signals with large chemical shift anisotropies. The MAS lines of these signals are themselves broad, whereas most crystalline materials would be expected to show sharp MAS lines. The broadening could be due to intermediate rate dynamics but a much more likely

© 1998 NRC Canada

explanation is that it is due to a distribution of species and (or) a distribution of environments for the same species.

We may be seeing impure and mixed P–S species outside the zeolite, and any species attached to the framework (inside or on the external surface) would also give broad lines with anisotropies.

Chemistry

The chemical complexity of these systems must now be quite apparent, so beyond a few obvious points our comments regarding reactions must necessarily be speculative:

1. A basic assumption is that any -SH will react with P–Cl bonds, provided the two are able to access each other, so if PCl_3 is in excess all the -SH will be depleted and there may be P/S/Cl species present, and, vice versa, in reactions where H_2S is in excess, any PCl species will disappear and there may be P/S/H species produced. The HCl by-product could itself influence further reactions.

2. We observed P_4S_3 at the early stages after heating to 100°C or more, and that this is depleted as P_4S_7 forms, suggesting a building of S onto the P_4S_3 framework.

3. It was surprising to find P_4S_3 inside NaA (demonstrated by the persistence of isotropic lines after cooling to 77 K). Since P_4S_3 cannot get through the window of NaA it must be constructed inside the cage, and yet PCl_3 is also too large to get through the window. This suggests some smaller precursor must first form at the zeolite surface and migrate into the cages, say, perhaps PCl_2^+.

4. An interesting feature of these experiments is that the zeolites seem to have a catalytic effect, enhancing the formation of the phosphorus sulfides. The thiosolvolysis reaction of PCl_3 in liquid H_2S is known to produce some P_4S_7 as part of a mixture after 60–70 h (38), while PCl_3 and H_2S in the presence of base react to give P_4S_3, among other products (1, 39). We found, however, that a yellowish white solid produced after 4 days of reaction between PCl_3 and H_2S in the absence of zeolite still showed mainly PCl_3 signals in the ^{31}P NMR (over 90% of the "observable" phosphorus), and no P_4S_7 was detected in this solid even after 3 months. The ionic nature of NaY and NaA and their microporosity probably play important roles in orchestrating the chemistry.

Conclusions

We have clear evidence for the formation of phosphorus sulfides inside the micropores; however, the chemistry is rather complicated. Moreover, with the numerous different products present, the goal of producing a regular array of identical molecules using the zeolite framework has not been realized. However, the results point the way: Perhaps this might be achievable by starting with pure P_4S_3 instead of PCl_3.

Adhesion to dentin: studies of surface chemical reactions towards the goal of improved bonding

M. Di Renzo, F. El Feninat, B. Jiménez-Esquivel, S. Poulin, M. Yavari, J. Xu, T.H. Ellis, E. Kruus, E. Sacher, and I. Stangel

Abstract: Human dentin consists of protein and mineral phases in the form of a collagen network reinforced with apatite. The bonding of materials to dentin, an important goal of dental materials research, can be achieved by the reaction of adhesion promoters with either of these phases. Our group is concerned with such bonding, and has used surface-sensitive instrumentation to elucidate the nature of a variety of surface treatments of dentin. Here, we discuss some of our findings, with particular emphasis on the kinetics of surface demineralization and deproteination, the reaction of formaldehyde with collagen, and the reaction of organophosphate with dentin apatite. The ramifications of our findings will be examined.

Key words: dentin, adhesion, vibrational spectroscopy, atomic force microscopy.

Résumé : La dentine humaine est composée de phases protéiniques et minérales formées d'un réseau de collagène renforcé par de l'apatite. Pour obtenir une liaison entre des matériaux et la dentine, un objectif important de la recherche des matériaux dentaires, on peut faire appel à la réaction de promoteurs d'adhésion avec l'une ou l'autre de ces phases. Notre groupe s'intéresse particulièrement à cette liaison et fait appel à une instrumentation sensible aux surfaces pour élucider la nature d'une variété de traitements de surface de la dentine. Dans ce travail, on discute de nos observations, en mettant l'accent sur la cinétique de la déminéralisation et de la déprotéination de la surface, la réaction du formaldéhyde avec le collagène et sur la réaction des organophosphates avec l'apatite de la dentine. On examine les ramifications de nos observations.

Mots clés : dentine, adhésion, spectroscopie de vibration, microscopie des forces atomiques.

[Traduit par la Rédaction]

Introduction

Dentin is the inner bulk structure of teeth. Human dentin is composed of about 69% (w/w) dentin apatite (i.e., a form of hydroxyapatite that contains a number of impurities, particularly carbonate), 18% proteins (90% type I collagen, the rest consisting mainly of phosphoproteins bonded to the collagen surface), and the remainder, water. The dentin is permeated by tubules 1–3 mm in diameter, which contain elongated cell bodies radiating from the dental pulp. Figure 1 shows an atomic force microscopy (AFM) view of a dentin surface, cut parallel to the occlusal plane (top surface) of the tooth and polished using an adapted metallurgical polishing protocol. A review of the composition and structure of dentin is found in ref. 1.

One of the goals of dental materials research is to develop adhesives capable of producing durable high-strength bonds to dentin. The successful adhesive retention of materials to teeth would result in minimal and less invasive operative procedures, the quality of interfaces between materials and mineralized tissues would be improved, and the cost of providing restorative care would be reduced in many cases. In contrast, dental amalgam, which does not adhere to dentin, requires the use of complex geometric designs to mechanically lock it into tooth structure. This results in the removal of otherwise healthy tissue, which unnecessarily weakens tooth structure and leads to eventual complications.

Although several polymeric dentin restorative materials are presently being used, existing materials have been shown to be less effective than amalgam in the long term (2). To improve on their durability, it is important to understand the basis of their interaction with dentin. While various theories of dentin bonding have been proposed, most rely on the extensive microscopic analysis of the resin–dentin interface. Thus, morphological, rather than molecular, information is elucidated and such theories do not generally consider chemical adhesion at the dentin–restorative interface (3).

Chemical adhesion may, in fact, occur with either phase of dentin (4, 5). Bonding to apatite may occur through complexation to the calcium ion, to the phosphate group, or by reaction with the hydroxyl group. The chemical bonding

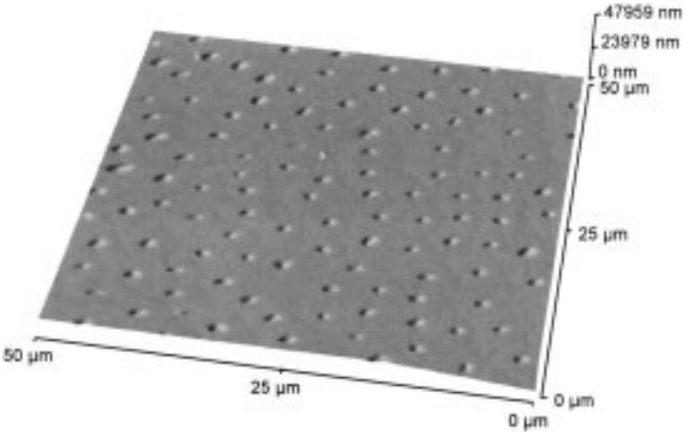
Fig. 1. AFM image of the surface of polished dentin, showing exposed tubules. The final polishing step of 0.05 μm alumina powder.



to collagen is a largely unexplored area. Reaction to the protein could occur through any exposed reactive group, provided that its concentration is high enough to give good bonding. An obvious candidate to be explored is free carboxyl, whose frequency of occurrence in collagen is about 1 in 13 residues (6). Although collagen is the predominant protein in collagen, the exact composition of the exposed surface would depend, to some extent, on whether or not phosphophoryns (the main form of phosphoproteins) are removed by pretreatments, since the relative concentrations of reactive groups on the protein surface differ significantly from phosphophoryn to collagen. Acid treatment has been found to remove at least some phosphoproteins (7).

From the onset of our studies, almost a decade ago, it was evident that two factors would be crucial for achieving a molecular-level understanding of adhesion to dentin. The first was the ability to produce conditioned, reproducible surfaces and the second, the use of highly surface-sensitive instruments and techniques capable of giving information on chemical structure at this surface. Here, we use the results of a broad range of measurements toward the goal of developing a comprehensive picture of the conditioning of the dentin surface and adhesion promotion to its components.

Experimental section

Samples for most studies were obtained from freshly extracted human molars. A diamond saw was used to prepare wafers, ~1.5 mm thick, having surfaces parallel to the occlusal plane of the tooth. The study with formaldehyde was conducted using freshly extracted bovine molars, as there was an insufficient supply of human teeth at the time of the experiment. Bovine dentin is often used a model for human dentin, due to the similarities between the two materials.

The acid etching of dentin apatite, by citric, hydrochloric, maleic, and phosphoric acids, was carried out in the pH range of 0.7–1.4. Calcium loss was detected by atomic absorption at 422.7 nm, with the output of the detector sampled by a computer interface at 0.5 s intervals. The exposed surface area of each sample was 12 mm^2, and the volume of acid solution was 100 mL.

Photoacoustic infrared spectra (PA-FTIRS) of surfaces were obtained on a Mattson RS-1 FTIR spectrometer, using an MTEC 300 photoacoustic cell. This cell measures the gas pressure change, in an enclosed volume, due to the adsorption and dissipation of infrared energy, and is, therefore, directly applicable to opaque samples. An advantage of this technique is that the major part of the signal comes from the first thermal diffusion length of the substrate, which can be shortened by increasing the modulation frequency, which, in this case, is determined by the speed of the interferometer mirror.

AFM topographic images were obtained using a TopoMetrix model 2010 Discoverer microscope (Santa Clara, Calif.). Cantilevers with nominal spring constants of 0.047 N/m and silicon carbide Supertips having radii of 10 nm were used. After storage in water, samples were imaged under ambient conditions. Excess water was removed by gentle blotting with absorbent paper.

The adhesive joint strength was measured by bonding polymer-matrix composites to both polished and acid-etched dentin using the adhesion promoters to be evaluated. After 24 h storage in water, assemblies were placed in specially designed grips in an Instron electromechanical testing device (model 4465), and tested to failure in shear, at a cross-head speed of 2 mm/min. Peak loads at failure were normalized to the surface area of the joint.

Results and discussion

Chemical conditioning of dentin

The etching kinetics of dentin apatite, irrespective of the acid used, were found to follow diffusion-controlled kinetics:

$$[1] \qquad [Ca^{2+}] = Kt^{1/2}$$

where K is a proportionality constant. As such, measurements of the amount of dissolved calcium as a function of the square root of time were found to be linear, except for a brief induction period, as seen in Fig. 2.

The rate of etching can be evaluated either by the value of K, or by measuring the total amount of calcium removed over a fixed period of time. For the latter, a period of 2 min was chosen, to reduce errors arising from the finite time required to introduce and remove the sample from the solution. We had already determined that diffusion-controlled

Fig. 2. Atomic absorption measurement of the Ca^{2+} concentration in solution, plotted as a function of the square root of acid exposure time, for HCl at pH = 1.2.

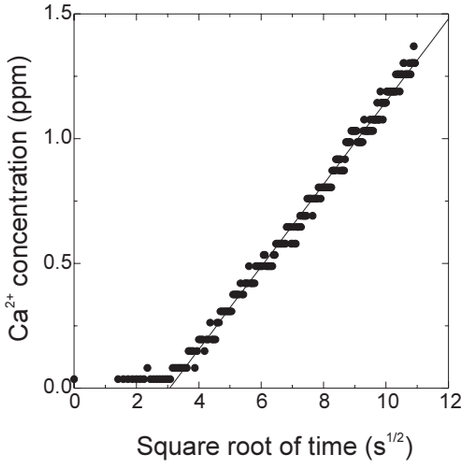

Fig. 3. PA-FTIR spectra of human dentin surfaces: (*a*) as cut; (*b*) acid etched (maleic acid, pH = 1, 2 min); (*c*) NaOCl treated (12% aqueus solution, 48 h); (*d*) acid etched as in (*b*), followed by NaOCl treatment (2 min).

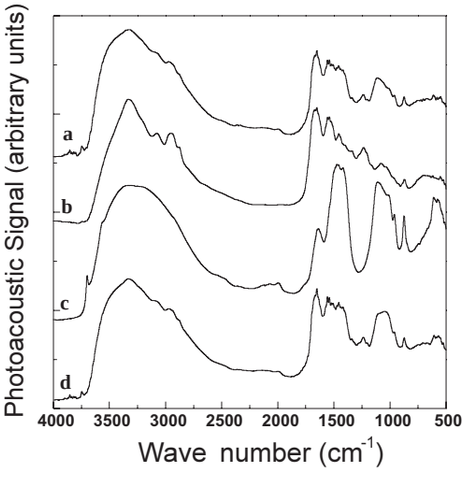

kinetics are valid for times ranging from a few seconds to several minutes. Using this procedure, a quantitative comparison was made between the rates of etching of the four different acids. For each acid, the acid concentration was adjusted until the desired pH value was obtained. By comparing different acids having the same pH values the role of the acid anions is highlighted.

The results at pH = 1.0 are shown in Table 1. Each acid should be compared to hydrochloric acid, whose anion (Cl^-) has the lowest tendency to form precipitates with calcium ions. Citric acid had the lowest etching rate, and its anion is the most likely to produce precipitates (calcium citrate tetrahydrate). The effect is the establishment of an equilibrium between the rates of etching and precipitate formation at the interface. The formation of precipitates limits access of the etchant to the surface, resulting in an etching rate lower than that which would have occurred in the absence of precipitation. Maleic and phosphoric acids had intermediate etching

Table 1. Acid etching rates at pH = 1.0.

Acid	Total calcium etched after 2 min (ppm)
Citric	0.14 ± 0.16
Phosphoric	0.74 ± 0.06
Maleic	0.91 ± 0.14
Hydrochloric	1.31 ± 0.16

rates at this pH. Additional information about acid etching was gained through a study of each acid as a function of proton concentration (8). The important conclusion from all of these studies is that, in addition to pH, acid anions play a consequential role in determining etching rates.

Our previous work on the photoacoustic IR contributions of the components of dentin demonstrated that each component contributed additively to the overall spectrum (9). A typical spectrum of human dentin is shown in Fig. 3*a*. In order to assign individual features, we also show spectra of demineralized (acid etched) and of deproteinated (NaOCl treated) dentin (Figs. 3*b* and 3*c*, respectively). A summary of peak assignments is given in Table 2. Acids preferentially remove dentin apatite, and NaOCl preferentially removes collagen. The spectrum of demineralized dentin is very similar to that of pure type I collagen (such as bovine tendon collagen). The spectrum of deproteinated dentin compares favorably to that of pure hydroxyapatite, with the exception of intense carbonate peaks in dentin apatite, these being inherent to biological apatites. The large non-hydrogen bonded O–H stretching peak from interfacial water at 3698 cm^{-1} indicates a very high surface-to-volume ratio in NaOCl-treated dentin.

PA-FTIRS probes, at most, the outer 10 μm of the surface. It was found that a 2 min acid treatment at pH = 1 was sufficient to completely demineralize the probed region, the only exception being citric acid. This slower etching by citric acid was predicted by the atomic absorption experiment.

The deproteination of dentin with NaOCl was found to differ from demineralization in a number of ways. The latter is known to be homogeneous: a demineralized zone of fairly uniform thickness is observed in TEM images of acid-etched dentin (10, 11). We have found that deproteination with NaOCl is a slower and more heterogeneous process: some collagen is observed to remain in the surface region even after the deproteination has, on average, penetrated deep into the sample. This is due to the fact that the morphology of dentin is playing a key role, and the encapsulation of collagen by apatite limits the deproteination process. On the other hand, surface collagen (i.e., collagen on the surface exposed by demineralization) was found to be removed rapidly, returning the surface to the composition of bulk dentin. This is illustrated in Fig. 3*d*, where a surface was etched for 2 min (see Fig. 3*b*) and then treated with NaOCl for 2 min, which completely removes all traces of exposed collagen. In contrast, a 2 min treatment of unetched dentin has no detectable result.

In addition to spectroscopic measurements, it is always beneficial to correlate chemical and structural information. Our group has been one of first to apply the high resolution of AFM to the study of dentin surfaces (12–14). It had already been established that the ultrastructure of collagen,

such as the characteristic 67 nm periodic banding, can be observed on isolated fibers using AFM (15, 16). It is more challenging to observe this level of structure in situ, on the surface dentin. Figure 4 shows the surface of demineralized dentin; fibers with periodic banding can be clearly seen. Two factors have been found to be crucial for this observation. First, the sample must be stored for hours to days in water after acid etching, in order to renature any denaturation induced by the acids. Second, the sample cannot be allowed to become too dry, which can lead to the permanent loss of structure. These results are of interest because any damage to the collagen layer can inhibit the penetration of resins into the demineralized zone. It will be important to find ways to renature collagen on a more practical time scale, or to reduce the degree of denaturation during demineralization.

Adhesion to the components of dentin

Surfaces prepared according to these techniques were used to study site-specific chemical reactions to the individual phases of dentin. In the case of demineralized dentin, there are a number of chemical reactions with collagen side groups that could potentially be used for the purpose of adhesion. For example, it is common practice to treat collagen with glutaraldehyde, a known fixative, prior to performing structural studies with electron microscopies. It is thought that glutaraldehyde forms chemical cross-links between collagen fibers. The reaction between amine side groups and an aldehyde would occur via the formation of a Schiff's base. To test for such reactions, demineralized bovine dentin was treated with formaldehyde, and PA-FTIRS spectra before and after treatment are shown in Fig. 5. Proof of the reaction is the appearance of a new peak at 1205 cm^{-1}, assigned to a secondary amine. The ability to observe the formation of this bond is enhanced by the fact that the peak appears in a region of the spectrum that is relatively uncongested. Although formaldehyde itself is not necessarily useful as an adhesion promoter, these results point the way to the development of adhesives that can react with collagen in a similar fashion.

An example of bonding to apatite concerns the use of alkyl phosphates (17); phosphates are capable of reacting with hydroxyl groups, even those of surface P-OH groups. In our studies, we have used derivatives of dipentaerithritol, $DP(OH)_6$, which has six reactive hydroxyl groups. Further reaction with acrylic acid gives dipentaerithritol pentaacrylate, $DP(A)_5(OH)$, having one remaining reactive hydroxyl group. This group may further react with phosphoric acid to give dipentaerithritriol pentaacrylate monophosphate, $DP(A)_5(H_2PO_4)$, a component of some commercial dental restoratives (see Scheme 1). This phosphate is capable of bonding to the hydroxyl groups of apatite (17); in doing so, it introduces to the surface strongly anchored acryloxy groups capable of further reaction with the chemically similar methacryloxy groups in the restorative resin.

In a similar fashion, $DP(A)_5(OH)$ is capable of providing hydroxyl groups for reaction with phosphate groups in apatite, and it is no surprise that this material, too, bonds to the

Table 3. Shear bond strengths at resin-dentin interface.

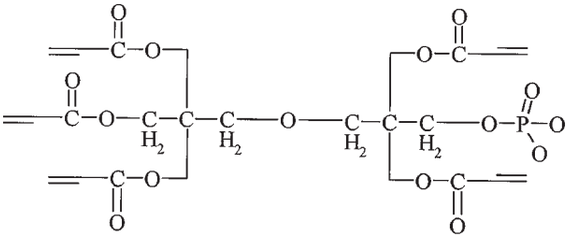
	Shear bond strength (MPa)	
Adhesive	Smeared surface	Acid etched surface
None	0.74 ± 0.56	—
$DP(A)_5(OH)$	4.2 ± 1.2	7.4 ± 2.5
$DP(A)_5(H_2PO_4)$	23.7 ± 4.3	28.0 ± 1.3

dentin surface. Similarly, phosphate can also react with groups (e.g., hydroxyl) in the exposed collagen and hydroxyl groups can react with collagenous carboxylate and partially phosphorylated serine (1) groups, creating a situation where extents of reaction are controlled by surface preparation, all potentially capable of giving strong bonds to the restorative.

The formation of such bonds can be extremely difficult to demonstrate spectroscopically, because similar bonds already exist in high concentration. Secondary evidence may sometimes be used to *infer* the existence of such bonds. Here, too, problems exist, as one may see by a consideration of bond strengths: because $DP(A)_5(OH)$ and $DP(A)_5(H_2PO_4)$ are each capable of bonding to either apatite or collagen, bond strength increases are expected in all cases.

In this regard, we consider the results of a shear bond evaluation, a technique previously described (14), which was carried out to gauge the efficiencies of $DP(A)_5(OH)$ and $DP(A)_5(H_2PO_4)$. Although it is well known that such tests are limited in their ability to simulate conditions in the oral environment, they are particularly useful for the purpose of screening candidate adhesives. As seen in Table 3, both molecules are shown to enhance resin bonding to dentin, although the $DP(A)_5(H_2PO_4)$ is by far the better. Table 3 also clearly indicates that, for this type of adhesive, the condition of the surface can be less important than the presence of the phosphate group in the adhesive. Two surface conditions were studied, one being polished (600 grit, which simulates a smear layer), and the other being acid etched (maleic acid, pH = 1.2, 30 s). Although many adhesives are thought to require a demineralized surface in order to establish a "hybrid zone" (3), this is clearly less important for the present system. Certainly, a complete understanding of bonding to dentin in only possible when both micromechanical and chemical bonding are be taken into account.

Scheme 1. Dipentaerithritriol pentaacrylate monophosphate, $DP(A)_5(H_2PO_4)$.



Conclusions and ramifications

Site-specific reactions are capable of occurring between either of the solid components of dentin and properly chosen reactants. Such reactions may form the basis of adhesion promotion to the dentin when other sites on the reactants are chosen for reaction with the (meth)acrylic groups of the resin. Adhesion promoters, having sufficiently high adhesive strength and sufficient durability in an oral environment, may potentially reduce the trauma involved in dental restorations because they eliminate the necessity of removing large amounts of tissue in order to introduce the geometrical designs necessary to fix non-adhering dental restoratives. Both spectroscopic and bond strength measurements can be valuable in providing a molecular level understanding of adhesion to dentin.

FTIR analysis of the phase content in low-density polyethylene

P. Bernazzani, V.T. Bich, H. Phuong-Nguyen, A. Haine, C. Chapados, Lê H. Dao, and G. Delmas

Abstract: The phase content of a low-density polyethylene was studied by analysis of the CH_2 rocking vibrations in non-oriented films prepared from the press (P-films) or from solution (S-films). Spectral simulations of the transmission spectra give the mass fractions of the orthorhombic phase α_{ortho} and of two noncrystalline phases (monoclinic-like and amorphous). The values of α_{ortho} (IR) are compared to α_{ortho} (*i*) where (*i*) stands for the X-ray diffraction, density, and DSC techniques. New results are obtained concerning the orthorhombic order and the change of phase content with aging. A two-phase analysis is justified for non-aged films containing a small amount of the monoclinic-like phase. The values of α_{ortho} (IR) are larger than α_{ortho} (*i*), the difference ranging between 0.12 and 0.43. The difference is a measure of the short-range order. α_{ortho} (IR) can reach 0.73 for the S-films. The stability of the short-range order phase is investigated. The sample is also analyzed using the trace of slow calorimetry. The difference between α_{ortho} by DSC and by slow calorimetry is a measure of strainable order. During aging, the variation in the phase content is large for the noncrystalline phases (in content and frequency) and small for the orthorhombic. The increase of the monoclinic-like phase during aging suggests that it is a precursor of the more stable orthorhombic organization. The quantification of two noncrystalline phases on fresh and aged films clarifies some ambiguity found in the literature about the monoclinic-like phase and the localization of bands in the rocking region for sample characterization. Analysis of other regions of the spectrum is needed to confirm the present results.

Key words: low-density PE, phase content, FTIR, network phase, slow calorimetry.

Résumé : On a étudié le contenu de la phase d'un polyéthylène de faible densité en faisant une analyse des vibrations de rotation des CH_2 dans les films non orientés préparés à l'aide d'une presse (films-P) ou d'une solution (films-S). Des simulations spectrales des spectres de transmission fournissent les fractions molaires de la phase orthorhombique, α_{ortho}, et des deux phases non cristallines (de type monoclinique et amorphe). On a comparé les valeurs α_{ortho} (IR) aux valeurs α_{ortho} (*i*) pour lesquelles (*i*) correspond à diffraction des rayons X, densité et analyse calorimétrique différentielle (ACD). On a obtenu de nouveaux résultats relatifs à l'ordre orthorhombique et le changement dans le contenu de la phase avec le vieillissement. Il est justifié d'utiliser une analyse en deux phases avec les films qui n'ont pas vieilli et qui contiennent de faibles quantités de phase de type monoclinique. Les valeurs de α_{ortho} (IR) sont plus élevées que les valeurs α_{ortho} (*i*); les différences varient entre 0,12 et 0,43. La différence est une mesure de l'ordre à faible distance. La valeur de α_{ortho} (IR) peut atteindre 0,73 pour les films-S. On a examiné la stabilité de phase d'ordre à faible distance. On a aussi étudié l'échantillon à partir d'un tracé de calorimétrie lente. La différence entre l'α_{ortho} obtenu par ACD et la calorimétrie lente est une mesure de l'ordre contraignable. Au cours du vieillissement, la variation du contenu de la phase est important pour les phases non cristallines (tant en contenu qu'en fréquence) et il est faible pour l'orthorhombique. L'augmentation de la phase de type monoclinique au cours du vieillissement suggère qu'elle est un précurseur de l'organisation orthorhombique plus stable. La quantification des deux phases non cristallines dans les films frais et vieillis clarifie des ambiguïtés retrouvées dans la littérature concernant la phase de type monoclinique et la localisation des bandes dans la région de vibration pour la caractérisation des échantillons. L'analyse d'autres régions du spectre est nécessaire pour confirmer les résultats actuels.

Mots clés : PE de faible densité, contenu de la phase, «FTIR», phase réseau, calorimétrie lente.

Introduction

In the two-phase model of semicrystalline polymers, the fraction of the long-range order phase is obtained by X-ray scattering or calorimetry and the other phase is assumed to be liquid-like. In polyethylene (PE), the presence of a third phase with mobility and order intermediate to that of the crystalline and amorphous phases has been suggested by a variety of techniques. The name and the characteristics of this third phase depend on the type of crystal growth (bulk, solution, or fiber crystals) and also on the technique used to analyze it. The chains of the third phase may be entangled chains inside the crystallites or connecting them. In consequence, this phase is heterogeneous with a range of order and tension determined by the polymerization conditions and the sample history. In NMR (1) and Raman (2–4) studies, the third phase in PE has been called interlamellar, interfacial, or interzonal, in reference to its links to the crystalline and amorphous phases. The presence of more than two phases in a semicrystalline polymer is supported by analysis of the melt. In this state, two relaxation times (5) were found by ^{13}C NMR. Bremner and Rudin (6) identified three phases by the same technique. A heterogeneous melt suggests that the solid melts in a complex mode and incompletely. From measurements such as birefringence, electron microscopy, or small-angle neutron scattering it is clear that, at the end of the endotherm of melting, a sizable amount of ordered domains remains in the melt for a long period of time. The order in the melt decreases by shear and recovers by annealing (7). The presence of a nonmeltable order is consistent with the presence of at least three phases in semicrystalline samples.

In recent studies, we have analyzed the noncrystalline phases in polyolefins (8–15). Using a sensitive calorimeter, the heat flow in the melt was analyzed. It was found that disordering of the melt can be followed if a very slow heating rate (*T*-ramp) is used. The usual fast *T*-ramp creates strain in the sample and prevents melting. The slow-melting phase has been called the network phase because the physical junctions in the network prevent normal expansion in the *T*-ramp and induce strain in the ordered regions. Another name for the network phase is the short-range order phase since the ordered CH_2 sequences are usually too short to give sharp peaks in the X-ray diffraction pattern. With samples having a large concentration of entanglements and junctions such as chemically cross-linked PE, non-orthorhombic X-ray diffraction patterns have been found in the melt.

Phase content by IR analysis

After having identified short-range order in a variety of polyolefins by slow calorimetry, we were interested in finding it by FTIR (16, 17). The advantage of the IR technique compared to calorimetry is being able to analyze the sample as it is at room temperature (RT). The inconvenience is that the vibrations of those CH_2 groups with different conformations overlap, a situation that requires spectral simulation.On the other hand, less superposition occurs in slow calorimetry because the strain generated by the expansion leads to the separation of the regions with different tension, i.e., between the different phases. An example of the range of melting typical of a semicrystalline polymer is given in Fig. 1*A*. Another drawback of transmission FTIR is the preparation of the film itself (press or solution), which brings modifications difficult to control in the morphology of the sample to be analyzed.

The elucidation of the molecular structure of PE by IR has been the subject of many articles (18–27). The assignment of the *trans–trans* and *gauche* conformations has led to the identification of ordered and less ordered regions. The ordered regions in the orthorhombic modification give a doublet in the rocking (730–720 cm^{-1}) and bending regions (1500–1400 cm^{-1}) due to the interaction between two chains in the unit cell. By analyzing the spectra of liquid, linear, and cyclic alkanes and of molten PE, information on the less ordered regions of a semicrystalline polymer has been obtained (21). The amorphous regions have been associated with peaks at 725, 720, 1078, and 1300–1368 cm^{-1}. To help resolve the active debate of the 1970's, concerning how a chain folds on itself to reenter the lamella, the conformations of the folds have been analyzed extensively, mainly on solution-grown crystals with different crystal habits. Mixtures of PE and deuterated polyethylene gave information on two- and three-dimensional order between the chains (18–20).

The characterization of the deformed crystals has also been studied extensively (18–20, 23–27). The bands associ-

ated with a monoclinic-like organization have been studied on fibers and modified samples where the orthorhombic crystals had been deformed by shaking or drawing. A singlet at 715–718 cm^{-1} appears and eventually replaces the doublet in these samples (19, 20, 26). This band can also be detected in solution-grown crystals and on annealed melt-crystallized samples by spectral subtraction. It could be detected in samples where the X-ray scattering spectra could not detect the monoclinic organization (19). In an analysis of the rocking region of linear PE, the term monoclinic-like was proposed (26). It was to take account of the fact that some samples could present monoclinic IR bands without monoclinic X-ray diffraction peaks. The range of frequency at which the monoclinic-like peak appears in the present work is another reason for using this term in the description made below of the phase content. If reference is made of large absorbance at 716–717 cm^{-1} on a drawn sample, the term monoclinic is suitable.

Evaluation of crystallinity

Analysis of the bands in the bending region was used early on to relate the X-ray or density crystallinity to the IR spectra of semicrystalline samples (22). Wedgewood and Seferis (23) analyzed the absorbance of crystalline and noncrystalline bands of well-characterized films. They found good correlation between the absorbance of the bands mentioned above and the crystallinity by density. Quantitative measurements of crystalline and noncrystalline phase orientation were also obtained. Using multiple internal reflection spectroscopy, the ratio of the absorbances of the 730 and 720 cm^{-1} bands was recently determined (25) in the characterization of the amorphous content of a commercial film and its heterogeneity as a function of penetration depth.

Several papers have remarked upon the objective difficulty of comparing the crystallinity of semicrystalline PE by different techniques. In spite of the knowledge that the vibrations are sensitive to near neighbors, i.e., to short-range order as well as long-range order, efforts were made to match the crystallinity obtained by IR and by X-ray or density measurements. The information on short-range order as seen by FTIR should complement well the short-range order as seen by slow calorimetry.

In the present work, we report the evaluation of the phase content of a low-density PE. The spectacular improvement in IR techniques during the last 10–15 years (FTIR and software), which permits calculating integrated absorbance rather than the maximum absorbance, leads to quantitative and reproducible results. During the investigation that we have been pursuing for several years on a variety of linear PE samples with different histories, we have developed confidence in the validity of the method (16, 17). The results on low-density PE seem suited to be published first since the more difficult phases to characterize, the noncrystalline phases, are the main constituents of the overall material. The first results on films made with the press showed that the fraction of orthorhombic order by IR was higher than that obtained by the other techniques. It was then decided to prepare more ordered films from solution to evaluate the limit of orthorhombic crystallinity of the sample.

To evaluate the phase content, two regions of the spectra have been analyzed, namely, those corresponding to the wagging and and to the rocking vibrations of the CH_2 groups. However, only the results for the rocking modes will be given here because the peaks of absorbance were simpler and the spectral simulation was straightforward in this region.

Experimental

Sample

Low-density PE (Union Carbide) polymerized using the high-pressure process was received already extruded and stored at RT for several years. Table 1 lists the characteristics of the sample. The columns, respectively, give the density, M_w, M_w/M_n, the intrinsic viscosity in decalin, [η], at 130°C, the number of methyls per 1000 C atoms, and the melt index. The last three columns show the values of α_{ortho} calculated by standard methods using X-ray diffraction, density, and heats of fusion from DSC measurements. In the text below, the fraction of crystallinity by FTIR will be designated as an orthorhombic crystallinity, α_{ortho} (IR). The term α_{ortho} (i) is the value obtained with the other techniques. Note that α_{ortho} (DSC) is considered as orthorhombic and comparable to the others even if it may include some non-orthorhombic order. The molecular weight distribution has been obtained by the Lower Critical Solution Temperature (LCST) technique (28).

Wide-angle X-ray scattering

Diffraction diagrams were recorded using Inel X-ray equipment operating at 40 kV and 30 mA. CuK_α1 radiation (λ = 0.15405 nm) was selected using a quartz monochromator. The values of α_{ortho} (X-ray) were determined from the ratio of the sum of the areas of all the crystalline peaks to the area of the large amorphous halo in the diffractogram.

Density measurements

The density of a liquid solution of trichlorobenzene and toluene in which the solids (film or small pellet) were equilibrated was obtained using an Anton Paar quartz densitome-

© 1998 NRC Canada

ter. The quantity α_{ortho} (d) was calculated from the density, d, using eq. [1]

$$[1] \qquad 1/d = \alpha_{ortho}/1.008 + (1 - \alpha_{ortho})/0.856$$

where 1.008 g/cm^3 is the density of the orthorhombic crystal and 0.856 g/cm^3 is the density of a fully amorphous CH_2 chain.

Calorimetry

Two significantly different calorimeters where used. In the standard DSC, a Perkin Elmer DSC7, 2–5 mg of the sample was placed in an aluminum cupola under nitrogen flow. A heating ramp of 20 K/min was used. In a special calorimeter, a C80 from Setaram (Lyon, France), 20–35 mg of the polymer was placed over 1 cm^3 Hg, in a glass tube sealed under nitrogen. The heating ramp here was extremely slow (1 K/h). The Setaram calorimeter is a very stable calorimeter that was used previously (9–12).

The absence of oxidative degradation in the slow heating was checked, as reported in previous publications. Furthermore, the high-T endotherms are seen as exotherms in slow cooling of the melt. Successive runs on the same samples confirm the findings of the first melting (9).

FTIR

A Bomem MB-series spectrometer was used in transmission mode at a resolution of 1 cm^{-1} with 25 scans.

Methods

Film preparation

Thin transparent films must be prepared for transmission measurements. Two methods were used, as reported in Table 3: (*a*) by pressing the pellets for 5 min at 130°C in a Carver press under air and a pressure of 21 metric tons (IV), and quenching, and (*b*) from solution. The 1% solution in xylene was prepared at 50°C and quenched at RT. The solvent was left to evaporate at either room temperature or 70°C. The films can be used as such (I) or pressed at different temperatures, namely, 90°C (II) and 130°C (III). The difference in phase content between the films evaporated at RT and 70°C being small, the results given have been averaged for these two treatments. The procedure was not aimed at the growth of single crystals so quenching at RT was used rather than isothermal crystallization. Probably the slower crystallization rate of this low-density PE explains the lack of sensitivity of the content of long- and short-range order in this sample to the exact conditions of crystallization. It is possible also that the two parameters that are different in these two treatments, namely, the temperature of growth of the crystals and the temperature of evaporation of the solvent, compensate each other in the final amount of total orthorhombic order. We have indications that IR measurements cannot distinguish between short- and long-range order but refined X-ray measurements should be made to confirm this observation.

The term S-films is used in the text only for films prepared without press (I) and the term P-films for the films prepared without solvent (IV). Treatments II and III give results intermediate between I and IV as will be detailed in the text. The spectrum of an unaged film corresponds to that of a film whose residence time at room temperature is less than 3 days after its preparation.

Spectral simulations

The spectra were base-line corrected and the absorbance zero was put at 800 cm^{-1}. Spectral simulations of the 775–675 cm^{-1} regions in the IR spectra were then performed using the software BGRAMS/386 by Galactic industries. The simulations were performed using a Gauss + Lorenz band shape with a band width at half-height of 3.5 cm^{-1} for the orthorhombic peaks (730 and 720 cm^{-1}), 10–16 cm^{-1} for the single-chain band or amorphous region (725 cm^{-1}), and 15–19 cm^{-1} for the monoclinic-like peak (717 cm^{-1}). The abbreviation FWHM (full width at half maximum) is sometimes used. When Fourier self-deconvolution was used, the location of the peaks was found to be quite constant for the orthorhombic phase. On the other hand, the frequency of the noncrystalline phase was changing with the history of the film, i.e., the sample morphology. When three phases were introduced, the frequency of the amorphous phase was found to be constant. However, the frequency of the monoclinic-like phase was found to change with the treatment. The physical reason, we think, is the following: in a sample under stress during the IR measurements, a band is found at 715–717 cm^{-1}. The samples prepared at the press or in solution do not retain for long the tension associated with preparation, so the 717 cm^{-1} disappears to be replaced by another band described in the literature as a noncrystalline band (24). In the present work, this band is associated with the network phase. The area of the orthorhombic doublet is found easily without repeating the simulation. On the other hand, the decomposition of the non-orthorhombic phases into the amorphous and the monoclinic-like phases was more difficult until it became clear that the frequency of the monoclinic-like band was varying with the sample treatment. Details on the decomposition are given in the section on *Justification* (Sect. C, Part II, of Results and discussion).

The phase fractions were calculated from the simulated spectra using eq. [2]. The integrated absorbance of each band was ratioed against the total area of the 775–675 cm^{-1} region. The integrated absorbance of the two peaks at 730 and 720 cm^{-1}, both representing the orthorhombic fraction, were summed.

$$[2] \qquad \alpha_{,phase,(I)} = \text{Integrated area}_{phase(I)} / \text{Integrated areas}_{all\ the\ phase}$$

Extinction coefficients

The calculation of the fraction of each phase from the area of the peaks is suitable if the extinction coefficients of the different phases are the same. The extinction coefficient ε is obtained by plotting the integrated absorbance of the entire rocking region versus the film thickness for films with the same history. The value of ε has been obtained for linear and branched PE films of different densities. When the thickness is expressed in microns (μm), ε varies between 0.34 and 0.42 for $0.4 < \alpha_c (d) < 0.8$. When the value of ε is corrected by the density, the ratio ε/d is found to increase from 0.37 to 0.43 (17).This result indicates that the crystalline phase has a higher extinction coefficient than the noncrystalline phases. No correction was introduced in eq. [2] to take this

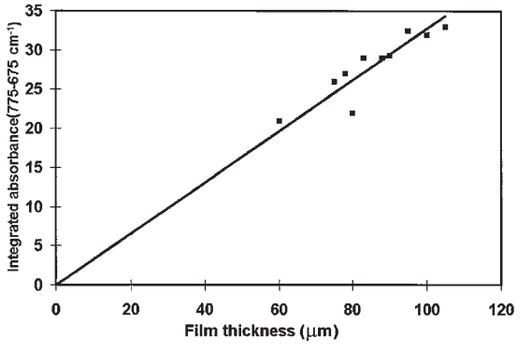
Fig. 2. Variation of the integrated absorbance in the rocking region as a function of sample thickness for P-films.



difference into account, first, because raw data are useful for other laboratories to reproduce and also because further analysis was needed to make an adequate correction. The use of the simple eq. [2] will lead to an overestimate of α_{ortho} (IR). In the rocking region, the integrated absorbance is linear with the film thickness for thicknesses up to about 100 μm. Figure 2 is such a plot for the S-films.

Results and discussion

1. Phase content by slow calorimetry

Before presenting the FTIR results, the melting trace of this sample using a very slow ramp will be given. As reported in previous work (8–12), slow calorimetry reveals endotherms not observed by fast DSC. The semi-ordered phase can melt when strain during the *T*-ramp is reduced. The rate of heating does not alter significantly the melting of the ordered chains that are not linked by entanglements. Slow calorimetry, on the other hand, allows the chains in a physical network to move during the *T*-ramp and avoids the level of strain that arrests melting in the usual rapid *T*-ramp. Figure 1*A* is an example of a melting trace of the as-received sample. The first two rows of Table 2 give the values of the enthalpies and the interval of *T* used for integration. The trace has been divided into three parts: the main sharp peak corresponds to the melting of long-range order, the medium size endotherm at low temperature is associated with crystals within the regions of the physical network that melt at low *T* because they have few entanglements. The integrated heat flow between 30 and 125°C is 142 J/g, i.e., about 60 J/g higher than in DSC. The next large endotherms have maxima at 180 and 250°C. They correspond to the melting of order within an entanglement-rich network. The total enthalpy of disordering the chains between 30 and 280°C is

$$[3] \qquad \Delta H_{total} = \Delta H_{DSC} + \Delta H_{disor.network}$$

ΔH_{DSC} is the enthalpy measured in the fast *T*-ramp. The value of ΔH_{total} is now about 400 J/g, i.e., larger than ΔH_o (293 J/g), the heat of fusion of perfect orthorhombic crystals. Discussion of this value is not suitable in the present paper on FTIR. It suffices to say here that the value of ΔH_o, obtained by different methods, corresponds to the change in enthalpy between 70°C and 145°C only. In the present technique, the change of enthalpy is followed over a larger *T*-interval and accounts for changes in enthalpy of the melt above T_m. The third and fourth rows of Table 2 give the analysis of a trace obtained at a more rapid rate of heating (12 K/h). The smaller value of ΔH_{total} is an indication that the strained network is not completely melted. Figure 1*B* is the signal for the calorimeter without the sample under the same conditions.

2. Phase content by FTIR

This part has five sections. In parts A and B the phases of fresh films (A1 and A2) and of aged films (B1 and B2) are analyzed. In part C, the justification of a three-phase decomposition is given. In part D, we compare the information on a sample provided by FTIR and by the standard techniques of analysis and, in part E, an attempt is made to relate the meltable order of a sample as given by the slow melting trace presented in Fig. 1*A* with the phase composition found by FTIR.

A. Un-aged films

A1. The orthorhombic phases: Figure 3*A* shows the IR spectra of an S-film aged at RT for less than 3 days. The spectral simulation results in four bands. The two narrow bands correspond to the well-known orthorhombic organization. The two wide bands of lower absorbance correspond to the amorphous and monoclinic-like phases. In Fig. 3*A*, the fraction of the orthorhombic phase, α_{ortho}, is 0.642, the monoclinic-like phase, α_{mono}, is 0.100, and the amorphous phase, α_{amor}, is 0.258.

Table 3 gives the values of α_{ortho} by the different techniques, for the films prepared with different histories (I–IV). The first row lists data for a short aging (3 days or less) and the second and third for longer aging times (4 and 11 months). Analyses made on some films after 17 months did not differ significantly from those at 11 months so they have not been reported. The data for α_{ortho} in these tables are averages of several films (4–7) for slightly different preparations (where the parameters were the initial concentration and the temperature of evaporation of the solvent).

The values obtained by density measurements and calorimetry for the P-samples are similar to those of the as-received sample (Table 1). As expected, the value of α_{ortho} (IR) is higher for the S-films than for the P-films. The films made using solvent and press have, after aging, values of α_{ortho} (IR) near those of the S- and P-films, respectively. The overall result is that α_{ortho} (IR) – α_{ortho} (*i*) is positive, the difference increasing with α_{ortho}. Each value of α_{ortho} (IR) – α_{ortho} (*i*) will be commented on separately.

Difference between crystallinity determined by IR and X-rays. The difference for the non-aged films is large, but larger for the S-films (0.30) than for the P-films (0.11). As the X-ray diffraction measures solely the long-range order, the origin of the difference resides in the short-range order:

$$[4] \qquad \alpha_{ortho}(\text{IR}) = \alpha_{ortho}(\text{long-range order}) + \alpha_{ortho}(\text{short-range order})$$

Obviously, there is a continuum of order in the sample but the simple separation into two types of order in eq. [4] corresponds to the limit in size, which gives a sharp X-ray diffraction pattern.

[5] α_{ortho}(short-range order)

$$= \alpha_{ortho}(\text{IR}) - \alpha_{ortho}(\text{X-ray})$$

Difference between crystallinity determined by IR and DSC.[3] The value of α_{ortho} (DSC), obtained by dividing ΔH by 293 J/g is 0.32 ± 0.04 for all the samples. The figures for the different treatments and the effect of aging for the P-films and S-films have not been reported in detail because the trends are not clear. The value of α_{ortho} (DSC) is lower than that of α_{ortho} (IR) because the latter contains some order that cannot melt because it is subject to strain ("strainable") in the *T*-ramp.

[6] $$\alpha_{ortho}(\text{strainable order}) = \alpha_{ortho}(\text{IR}) - \alpha_{ortho}(\text{DSC})$$

In the low *T*-ramp of Fig. 1*A*, 140 J/g is absorbed at low *T*, i.e., below 120°C (instead of 85 J/g in DSC). The meltable order, under these special conditions, has increased from 0.32 to 0.48 but remains lower than α_{ortho} (IR).

Difference between crystallinity determined by IR and density. The difference varies as α_{ortho} (IR) since α_{ortho} (*d*) varies little. It is smaller (0.17) for the non-aged S- and P-films. After aging, the similarity of the values of α_{ortho} (*d*) and α_{ortho} (X-ray) permits evaluation of α_{ortho} (short-range order) from the density:

[7] $$\alpha_{ortho}(\text{short-range order}) = \alpha_{ortho}(\text{IR}) - \alpha_{ortho}(d)$$

An illustration of the difference between α_{ortho} (IR) and α_{ortho} (*d*) for the different treatments is given in Fig. 4 where α_{ortho} (*d*) and α_{ortho} (IR) are plotted as abscissa and ordinate. If the two estimates of α_{ortho} were the same, the data would be on the line $x = y$. The difference between the bar and the x–y line is seen to vary with the treatment (0.16–0.25). The range of α_{ortho} (IR) is seen to be very narrow for the P-films (IV) and wide for the other treatments (I–III). The range of α_{ortho} (*d*) is narrow. This implies that movements of the chains that modify short-range order can be carried out without changing the overall density. A trace similar to Fig. 4 could have been done using the values of α_{ortho} (X-ray) for the abscissa but with a lower precision than α_{ortho} (*d*).

Solvent and vapor stability. To verify that the solvent in which the densities were taken was inert towards the low-density PE analyzed, the values of d, α_{ortho} (X-ray), and α_{ortho} (IR) were obtained after immersion in the usual solvent mixture used for density and in another mixture (ethanol–water). They were found to be the same. On the other hand, α_{ortho} (IR) can be made to increase by leaving the films to be swollen in the vapor of a solvent. After 3 days in the vapors of CCl_4 at 40°C the value of α_{ortho} (IR) increased to 0.72 for the S-films and to 0.60 for the P-films.

Order of the skin of the film. Some X-ray data have been recorded in a Siemens D-5000 reflection diffractometer the beam of which, in the actual settings, goes at a depth of a few dozen Å across the sample surface. For the P-films and the aged S-films, α_{ortho} (X-ray) has the same value as for the transmission measurements. However, for the non-aged S-films the diffractogram is diffuse and the value of value of α_{ortho} (X-ray), is found to be around 0.1. This suggests that the first few layers of the surface seen by the beam have little long-range order. The time for recovery of the usual spectra has not been measured. A similar difference has been found on thin films of amylose (Hylon VII) made from solution whose crystallinity was also measured with the two X-ray techniques.

Resistance of the orthorhombic phase to mechanical deformation. When the films made in solution are pressed at

Table 3. Values of α_{ortho} (IR), α_{ortho} (*d*), and α_{ortho} (X-ray) for treatments I–IV as a function of aging time.

Aging (months)		Sample preparation: I, solution [a] no press	II, solution [a] pressed at 90°C	III, solution [a] pressed at 130°C	IV pressed at 130°C
<0.1	α_{ortho} (IR)	0.64	0.60	0.54	0.58
4	α_{ortho} (IR)	0.59	0.51	0.46	
11	α_{ortho} (IR)	0.67	0.67	0.57	0.56
<0.1	α_{ortho} (*d*)	0.48	0.47	0.38	0.38
4	α_{ortho} (*d*)	0.50	0.47	0.40	0.40
11	α_{ortho} (*d*)	0.49	0.46	0.39	0.39
<0.1	α_{ortho} (X-ray)	0.34	—	—	0.45
4	α_{ortho} (X-ray)	—	—	—	0.45
11	α_{ortho} (X-ray)	0.50	—	0.43	0.48

[a] In xylene (1%).

Note: The values above are averages of 4–7 films for each treatment. The range of data for the same treatment is the same: α_{ortho} (*d*): 0.001–0.01, with the lower values for aged samples. α_{ortho} (IR): 0.01–0.04 with the lower values also for aged samples. α_{ortho} (X-ray) : 0.04.

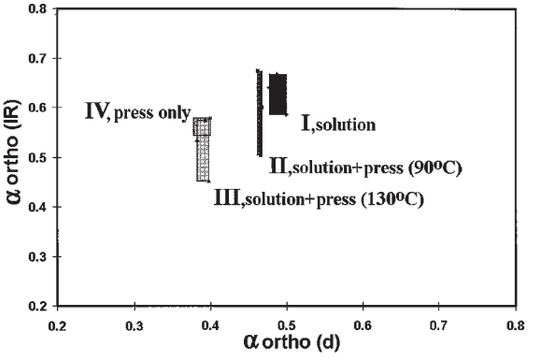
90°C they do not melt completely but deformation occurs, possibly as a consequence of a temperature gradient between the surface and the interior. As a result, the value of α_{ortho} (IR) is diminished from 0.64 to 0.60 (II in Table 3) with an increase in the amorphous and monoclinic-like phases. It is interesting to note that the density is not changed with the deformation. With time, these films recover almost to the values of the S-films. The films made in solution and pressed at 130°C have no memory of the preparation in solution, with one exception. This is the diminution of α_{mono} (IR) aged 4 months that seems to be a feature of all the films made in solution (I–III) as illustrated in Fig. 5.

A2. The non-orthorhombic phases: Table 4 gives the fractions of the non-orthorhombic phases for the films whose orthorhombic content is given in Table 3. The first two rows, labeled "two-phase decomposition," give the results of decomposition. The very small amount of monoclinic-like phase observed (0.05) implies that it can be considered a two-phase system. This occurs only for non-aged films. In the next rows one sees that the non-aged S-films have little monoclinic-like content. This will be discussed further in the following section describing the effect of aging. The data of Tables 3 and 4 have been plotted in Figs. 4 and 5. Further details on the two- and three-phase decomposition are given below under the title *Justification*.

B. Films aged or in the process of aging

According to practice and thermodynamic theory, aging at room temperature enables the lowest free energy phase, the crystalline phase, to grow within the limits imposed by the kinetics of chain reorganization in the solid state. The usual techniques of crystallinity evaluation should show an increase in crystallinity during aging. When more refined probes, such as small angle X-ray scattering (SAXS) or Raman spectroscopy (30), are used one notes that aging is a complex phenomenon that involves exchange of the CH_2 segments between the phases, widening of the distribution of the lamellar thickness, and sometimes a displacement of T_m away from the high temperature (31). In consequence, one cannot expect that aging will take place only in the orthorhombic phase, with short-range order becoming more long range with increase in aging time. The data from

Fig. 4. Correlation between α_{ortho} (IR) and α_{ortho} (*d*) for treatments I–IV. The higher values within the same treatment are for aged samples.



Figs. 5 and 6 below, show that changes in the three phases occur with time.

B1. The orthorhombic phase: The change of α_{ortho} (IR) with time is reported in Table 3 and also in Fig. 5. The ordinate of the bottom trace follows the variation of α_{ortho} (IR) with time for the different treatments. It is informative to note that α_{ortho} (IR) diminishes by 0.06–0.1 in the first months of aging, before increasing. This can be understood by the analysis made above where part of α_{ortho} (IR) does not belong to the stable long-range order but is part of the short-range orthorhombic order associated with the network phase. The movements in these chains is subordinated to those in the non-orthorhombic phases.

Table 3 shows that the change of α_{ortho} (*d*) with aging is small and difficult to interpret since a two-phase model has been used to calculate it. It is somewhat surprising that α_{ortho} (*d*) does not increase more. Linear PE, on the other hand, when submitted to a long gradual *T*-ramp up to a few degrees below T_m, reaches a value of α_{ortho} (*d*) = 0.92 (31).The authors succeeded in proving, in several year-long experiments, that regular PE could reach the same equilibrium state as high-pressure crystallized PE. Probably the low value of α_{ortho} (*d*) in the present sample that may be due to the branches could be increased by specific annealing at

[b] The two- and three-phase decompositions are similar when α_{mono} is less than 0.05, see Table 6. The ranges of data are the same as in Table 3.

higher temperature. The "long annealing" experiment showed also that no change in molecular weight occurs in well-purged samples as a consequence of the high-*T* treatment.

Correction of α_{ortho} *(d) in low-density PE*. The values of α_{ortho} (*d*) in the tables have been calculated with the data of eq. [1]. Recent X-ray scattering studies of linear low-density PE give higher cell dimensions and lower values of *d*(orthorhombic), namely, 0.9679 and 0.9820 g cm^{-3} (32, 33) for samples having, respectively, 20 and 22.7 methyls per 1000 C atoms. If an intermediate value of *d* is used, for instance, 0.975 instead of 1.008 g cm^{-3}, the α_{ortho} (*d*) values found from eq. [1] are higher than those given in Table 3. As an example, α_{ortho} (*d*) for the films formed from solution becomes 0.60, not too different from the value obtained by

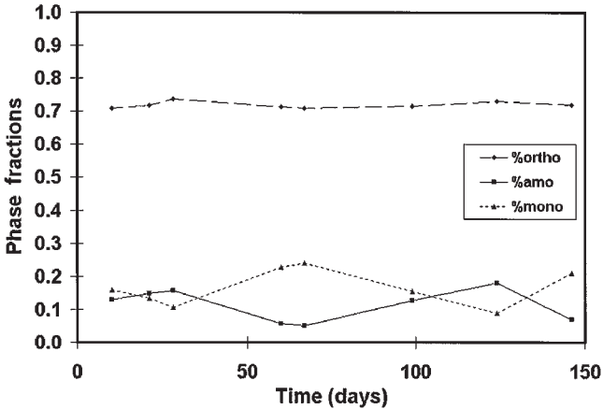
Fig.6. Phase content variation of an S-film during an aging period of 150 days.



IR (0.64). The present X-ray measurements have not been analyzed with sufficient detail to spot an eventual difference in the peak position of the S- and P-films.

The results of DSC will not be commented upon since, as said above, we were not able to see a trend in α_{ortho} (DSC) with time. After long aging, α_{ortho} (X-ray) reaches about 0.50 for the S- and P-films and the difference between them, found before aging (0.1), disappears.

B2. The non-orthorhombic phases and the overall composition: The spectrum of the S-film shown in Fig. 3*A* is given in Fig. 3*B* after it has been aged for 4 months. The monoclinic-like phase (curve 2) increases for this sample from 0.10 to 0.28 while the amorphous phase (curve 3) diminishes from 0.26 to 0.12. This suggests that the monoclinic-like organization is a necessary step for increasing long-range order. This has been reported qualitatively in the literature (18–20).

One can visualize the change in phase composition with time in Fig. 5 (I–IV) for the four treatments. The lower and upper regions represent the orthorhombic phase and the amorphous phase, respectively, while the region in between is the monoclinic-like phase. The scale for the orthorhombic values starts at 0.4 and not at 0.

As seen in the graphs (I–III) (for after 4 months), the concentration of the monoclinic-like phase increases significantly with time, reaching 0.29–0.36 at an aging time of 4 months for the S-films. After 11 months, the concentrations of the two noncrystalline phases are similar, the monoclinic-like phase being reduced to about the amount of the amorphous phase. For the P-films (with the trace shown as a dotted line because they were not analyzed after a 4 month aging), α_{mono} is still high after an 11 month aging time, an indication of incomplete aging in the non-orthorhombic phases. This interesting feature may be related to the state of the melt: more thoroughly disordered by the solvent than by the fusion under the press. We intend to obtain the spectra of the sample crystallized from the melt that has been subjected to the slow *T*-ramp in the calorimeter. It is likely that slow melting has the same effect as the solvent for increasing chain mobility in the sample after recrystallization. It is noteworthy that the non-orthorhombic phases retain a memory of the solvent history (III) even after pressing and long aging at RT. The increase of α_{mono} with time has been observed in many samples of PE with different densities.

The change of phase content with time for one sample is demonstrated in Fig. 6. Eight spectra of the same film were analyzed over a period of 150 days. For that sample, the orthothombic content (top line) fluctuates little with time (0.04 at maximum) with a small decrease at around 2 months of aging that follows the initial increase. The monoclinic-like fraction (bottom line) is seen to increase by more than a factor of 3 over the same period, the amorphous content varying in a complementary way. The fact that a maximum in α_{mono} (IR) occurs after 2 months while it occurred after 4 months for the films made and averaged in Table 3 may come from small differences in the film preparation.

Movements of methylene chains in the solid state. It was stated above that α_{ortho} (IR) could diminish during aging due to the mobility of some of the chains in this phase, since they do not belong to long-range order. Other information suggests chain mobility at RT: It was discovered quite late in the history of orthorhombic morphology, perhaps because it was counterintuitive, that chains packed in long-range order can move. The heat capacity of solid linear PE between RT and T_m has been found higher (34) than the value calculated, using a two-phase model, from its crystallinity and the known vibrations of the methylene groups in the two phases. Through modelization (34), this feature was explained by recognizing that the ordered chains in the orthorhombic crystals rotate with a high frequency, a freedom of movement unexpected for chains so close to each other. One can expect that the non-orthorhombic phases will be even more mobile, at least in the regions distant from the knots. In consequence, the change with time of the relative amounts of the phases as seen by FTIR is not unexpected. The diminution of the α_{ortho} (IR) in the first months of aging comes, in our opinion, mostly from changes in the short-range order as explained above. However, it is likely that some unfolding of the chains also takes place in the long-range order, to permit the growth of thicker lamellae.

Assuming that aging corresponds to a slow annealing, insight into aging can be obtained through studies of the change of morphology during annealing. Different techniques have been used to follow annealing, each viewing a different size or different order in the sample. One of these techniques, which measures the straight-chain lengths in PE by Raman spectroscopy, may give information relevant to the present analysis (30). The study reveals unexpected and drastic changes in straight-chain length distribution as a result of annealing. Since the frequency ν of the longitudinal acoustic mode (LAM) is related by a simple equation to L, the straight-chain length, the distribution of frequency of the LAM band permits calculation of the distribution of straight-chain lengths in the sample. Snyder et al. find that the band half-width increases from 100 to 300 Å upon annealing. They observe also that the shape of the band does not change regularly with time. Since some annealing temperatures for the LAM experiments were low (90°C), i.e., well above the value of T_m, the physical phenomena underlying the movements of the chains in the crystalline phase as seen by LAM and FTIR are likely to be similar. Again, the varia-

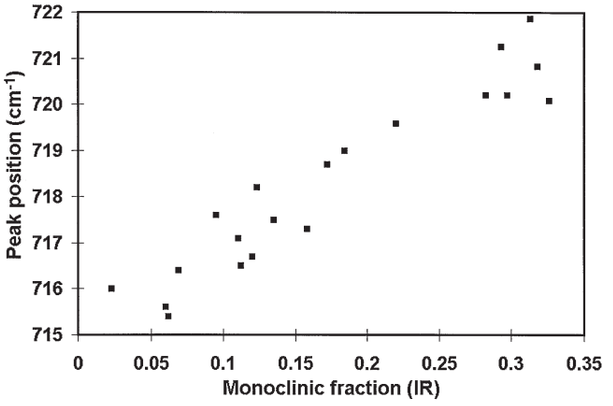
Fig. 7. Correlation between the peak position of the monoclinic-like phase and its amount in the samples. The points for $\alpha_{mono} > 0.30$ correspond to films with only two phases, the abscissa being for α_{amor} instead of α_{mono}.



tion observed, by Raman spectroscopy, in the high-density phase during aging permits us to accept that the large variations that we observe in the lower density phases by FTIR have a physical significance.

Change of frequency of the characteristic bands. The description of the phase change given in Fig. 5 is incomplete since the frequency of the noncrystalline phases changes with time. It has been observed that the frequency shift of the monoclinic-like phase is related to its concentration in the sample. Figure 7 is a plot of the frequency of the monoclinic-like phase as a function of α_{mono} (IR). The lower frequency is found in freshly prepared samples and highly deformed material but the amount of this phase is different for these two histories. The regular shift of the frequency with α_{mono} (IR) seems to indicate that the deformed phase, which is not abundant after the preparation, is replaced by a phase with specific characteristics, not closely linked with the monoclinic structure that may have existed in the fresh film. This result clarifies some ambiguity in the literature in which the monoclinic-like band had to be associated with monoclinic reflections in the X-ray pattern (18–20, 26). The points at the upper right of the graph correspond to films in which the monoclinic-like and the amorphous phases are a single phase. The frequency of the amorphous band at 725 cm^{-1} is also shifted when α_{amor} (IR) diminishes. The chains in the monoclinic phase are thought to belong to the physical network described to explain the slow calorimetry results. Phase separation between the network chains and the free chains, which favors better interactions within the same phase, may be at the origin of the shift during aging.

The frequencies of the orthorhombic bands after decomposition have not been found to change with treatment. The distance between the two peaks, 10.6 ± 0.2 cm^{-1}, is very similar to that found (10.5) for linear PE (18). The bandwidths were not found to be wider than for linear PE.

C. Justification of the decomposition of the aged films with a three-phase model

Tables 5 and 6 give, for an S-film and a P-film, details of the decomposition using either a two- or three- phase model. The corresponding spectra are given in Figs. 8 and 9. The columns give, successively, the type of simulation and the aging status of the films, the phase content, the frequencies of the bands, their width at mid-height, their shape, and the χ^2 values. The number χ^2 corresponds to the difference between the experimental and calculated absorbances over the whole band. The rows (*A*) and (*B*) are for the unaged films and (*C*) and (*D*) for the aged films. The data for a two- and three-phase decomposition of the unaged film given in (*A*) and (*B*) present the following features: (*i*) the orthorhombic phase content is the same in (*A*) and (*B*), i.e., it does not depend on the number of phases; (*ii*) neither the frequency of the amorphous band nor its shape (completely Gaussian) varies when the decomposition introduces a small amount of monoclinic-like phase (<0.05). The data in (*C*) for an aged film give a different picture: the frequency and amount of the orthorhombic phase are still independent of the number of phases but the characteristics of the amorphous phase are different. The value of ν is shifted to 720.8 cm^{-1}, the band width has increased by 3 cm^{-1} (13.7 to 16.9), and the band shape is changed from 100% to 60% Gaussian. With a three-phase simulation (*D*), the characteristics of the amorphous phase (frequency, width, and shape) are restored to the values obtained with the two-phase model (*A*). Note that the frequency of the monoclinic-like phase has increased between *C* and *D* as reported in Fig. 8. The same results are obtained in Table 6 on the S-film.

We believe that the information obtained through spectral simulation for samples with different histories as well as the consistency found between the results justify the usefulness of studying the decomposition at this stage. To our knowledge, a single technique, Raman spectroscopy, has led to the definition of four phases for linear PE (2). The conditions of the experiment (geometry of the film, temperature of crystallization, time of aging), different from the present ones, do not permit comparison of the phase content of this in-depth investigation with the present one. Combination of IR and Raman data for the same sample should permit verification of the present results. We are also planning to explore other regions of the IR spectra that could confirm the change of the relative amount of the non-orthorhombic phases with sample history.

D. Information on the sample given by the phase content obtained by FTIR

Long-range order: When precise information on a sample having undergone a specific history is required, IR by transmission with its unavoidable stage of film preparation (press or solution/crystallization) may not be the best method because the film preparation may obscure the exact properties of the sample. To overcome this problem, reflectance techniques such as internal or attenuated reflectance have been used. An advantage of these techniques is, for instance, ability to probe into the sample at different depths and reveal heterogeneity or orientation of the material (24). However, these techniques are more delicate to operate than transmission IR as they require excellent physical contact between the crystal and the sample, a requirement that is sometimes difficult to address without changing the history of the sample. If the overall crystallinity of a sample is needed (i.e., the long-range order), measurement of the density, of the X-ray

pattern, or of the heat of fusion of annealed films is, in most cases, capable of giving a good picture of the sample morphology. Data in Table 3 indicate, however, that the density is not too sensitive to sample history. The measurement of density does give other information, since it can reveal unambiguously heterogeneity in large samples crystallized with an unwanted temperature gradient (e.g., insulating material for cables).

In spite of the changes of morphology induced by film preparation, measurement of the phase content by FTIR gives sound information. Analysis of the phase content of linear PE (16, 17) gives α_{ortho} = 0.84 and 0.81 for the S- and P-films. These values are, as expected, higher than for branched PE. Furthermore, in films stabilized by their history, a controlled melting under the press does not erase the film history. Samples of linear PE have been cooled at 3 K/h to record, for instance, the different crystallization endotherms and analyze the monoclinic-like morphology induced by slow cooling. The material had to be pressed for IR measurements but it retained, in this process, a high

amount (0.25) of monoclinic-like material. The evaluation of short-range order from spectral simulations and measurement of its density or X-ray diagram (eq. [4]) represents unique information drawn from FTIR.

The non orthorhombic phases: The knowledge of the complexity of the non-orthorhombic phase obtained by our group or others (5–7) permits integration of information in the literature related to FTIR analysis and to other polymer techniques. Studies of the rocking bands made, for instance, to evaluate the sample crystallinity locate two amorphous bands at 720 and 725 cm^{-1} (25, 26). But no quantitative treatment has been done using both bands. The merit of the present study is to have detached the monoclinic-like band of that observed in deformed samples and show that it exists in most samples and allows us to characterize a distinct noncrystalline phase. This is an important result, which was made possible through the previous phase content analysis by slow calorimetry.

The variation of the non-orthorhombic phases with preparation and aging is unique information that the usual techniques measuring long-range order cannot give. The data given in Figs. 5 and 8 show large amplitude in the phase content variations with a periodicity that must depend on many parameters. The equilibrium phase content of an S-film (0.70, 0.15, 0.15 for the orthorhombic, monoclinic-like, and amorphous) is useful information to obtain. It may be related not only to the methyl content of the sample but also to the catalyst used for the polymerization.

The network phase: If the query does not concern the final crystallization but rather the morphology of the polymer itself, the IR spectra can give important information concerning the amount of network phase and its localization in the different phases. Entanglements must be distributed in all the samples but their concentration is expected to be higher in the noncrystalline phase. It was interesting to discover that half of α_{ortho} (IR) of the S-film (data obtained from α_{ortho} (IR) – α_{ortho} (DSC) did not melt in a fast *T*-ramp. This points to the fact that a fraction of short-range order is subject to strain due to its inclusion in a network. In a non-strained situation, the network content of the non-orthorhombic phases is difficult to evaluate quantitatively. An indication of the presence of the network phase in the monoclinic-like phase is that its shape and peak position change the most under strong deformation. Further work continues on the characterization of the network phase by FTIR.

E. The sum of all meltable order

We undertook this analysis to evaluate the phases that could correspond to those disordered in the trace of Fig. 1. To account for large value of ΔH (Table 1), we searched for indications of phases that could be disordered and give the endotherms found at high temperature. With the reasonable assumptions that the orthorhombic and monoclinic-like fractions can be disordered in the *T*-ramp, the sum of these two phases is about 0.8 for the P-films. The as-received sample whose melting trace is given in Fig. 1 has a morphology

similar to aged P-films. From the value of ΔH, all the phases appear to be meltable in a low *T*-ramp. The question to be asked now concerns the possibility of finding the complement (0.2) of meltable order in the third phase, i.e., the amorphous phase. It seems that the answer is positive. It has been reported in the literature that in melt-crystallized samples some of the chains fold in the 200 plane rather than the 110 plane common to single crystals (18–20). These chains are too far apart to experience field splitting so they absorb as a singlet at 725 cm^{-1} instead of the usual doublet. Due to their high fraction of *trans–trans* conformations, they have been called *trans*-planar chains (24). The *trans*-planar chains are more numerous in a low-density PE or in a deformed sample (24) than in a high-density PE. If this assumption is exact, the supplement of order needed to make consistent the slow calorimetry and FTIR analyses would be contained in the amorphous phase whose *trans*-planar chains would become disordered when the temperature is raised.

Conclusions

This investigation of the rocking regions of low-density PE has permitted the detection of three phases in films made in solution or in pressed films associated, respectively, with the orthorhombic, monoclinic-like, and amorphous morphologies. The quantitative measurement of two noncrystalline phases in non-strained samples is a new and probably general finding for semicrystalline polymers. The orthorhombic content of aged films formed in solution can reach 0.67 while the value is 0.5 by X-ray and density measurements. FTIR constitutes an unique way of detecting short-range order orthorhombic (0.2) in this highly branched PE. The fraction of meltable order by DSC is low (0.32) due to the easily strainable entangled regions. The phase with short-range order and the monoclinic-like phase are associated with the network fraction whose melting can occur under melting conditions that diminish the strain (slow calorimetry).

During aging, the concentration of the three phases changes. The monoclinic-like structure increases in size and its frequency is displaced during aging, changes associated with phase separation of free and entangled chains. The monoclinic-like phase seems to be an intermediate step to increased crystallinity. IR analysis confirms the findings of slow calorimetry but it uses a quicker and more widely available technique. The present report is not, however, definitive. We are currently analyzing other regions of the spectrum to confirm or complete the information given on this low-density PE.

Electrochemical study of the pore structure of sandstone and similar media

Jan C. Myland, Keith B. Oldham, Jörg Schiewe, and Alicia L. Taylor

Abstract: Three methods are discussed by which the internal geometry of a porous insulator may be investigated electrochemically. By adopting a simple model, the pore geometry is characterized by two parameters: the tortuosity and the porosity. In each method, a cylindrical sample of the porous medium is soaked with an aqueous electrolyte solution and its lower face is brought into contact with a mercury pool electrode. The other electrode is also a mercury pool, but in the first technique it is remote, whereas in the second and third methods it floods the upper surface of the cylindrical sample. The first technique employs a d.c. potential step, whereby the concentration of a probe ion is depleted at the lower electrode. The attempt of diffusion to replenish this surface concentration leads to a faradaic current whose time dependence is analyzed to provide estimates of the tortuosity and porosity parameters. The second method measures the frequency-dependent cell impedance. The pore structure parameters are estimated from the equivalent circuit of the cell. No faradaic process is involved in the third method, which measures the frequency-dependent conductance of the cell as a means of characterizing the pore structure. These methods are applied successfully to sandstone and fritted glass samples.

Key words: porous media, Fourier-transform methods, impedance.

Résumé : On discute de trois méthodes permettant d'étudier électrochimiquement la géométrie interne d'un isolant poreux. En adoptant un modèle simple, on caractérise la géométrie des pores à l'aide de deux paramètres, l'un de tortuosité et l'autre de porosité. Dans chaque méthode, on imbibe un échantillon cylindrique du milieu poreux à l'aide d'une solution électrolytique aqueuse et on place sa face inférieure en contact avec un réservoir de mercure servant d'électrode. L'autre électrode comporte aussi un réservoir de mercure; dans la première méthode elle est éloignée alors que, dans les deux autres techniques, elle recouvre la surface supérieure de l'échantillon cylindrique. La première technique fait appel à un régulateur de potentiel cd pendant que la concentration d'un ion sonde s'épuise à l'électrode inférieure. Les tentatives de diffusion pour régénérer la concentration de cette surface donnent lieu à un courant faradaïque dont on analyse la dépendance en fonction du temps pour obtenir des évaluations des paramètres de tortuosité et de porosité. La deuxième méthode mesure l'impédance de la cellule qui dépend de la fréquence. On évalue les paramètres de structures des pores à partir du circuit équivalent de la cellule. Il n'y a pas de procédé faradaïque d'impliquer dans la troisième méthode qui implique une mesure la conductance dépendante de la fréquence de la cellule comme moyen de caractériser la structure des pores. On a appliqué ces méthodes avec succès à des échantillons de grès et de verre fritté.

Mots clés : milieu poreux, méthodes par transformation de Fourier, impédance.

[Traduit par la Rédaction]

Introduction

Many techniques are available for studying the pore structure of a porous medium (1–3). Common methods involve forcing fluids such as air, water, or mercury through, or into, the pores. Our approach is to fill the pores with an aqueous solution containing some *probe ion* and then initiate the transport of that ion across the medium. By analyzing the rate at which the ion passes through the material, and its time or frequency dependence, we can obtain structural information about the pores.

Some of our earlier work (4–6) was successful in characterizing the properties of thin sheets of porous materials of interest as filtration media or battery separators. The present study is aimed at characterizing porous minerals. This article will discuss the theory of three methods and report experimental results obtained with sandstone and fritted glass samples. The probe ion used in much of our work is

the mercurous ion $Hg_2^{2+}(aq)$, dissolved in a mildly acidic[3] aqueous solution of high electrical conductivity.[4] The advantage of this particular probe ion is that it can be removed electrochemically from solution, via the reaction

$$[1] \qquad Hg_2^{2+}(aq) + 2e^- \rightarrow 2Hg(\ell)$$

and deposited onto mercury, which, being a liquid, can be forced into close contact with the surface of the porous matrix. Some experiments used an alternative probe ion, tetraiodomercury(II), $HgI_4^{2-}(aq)$, for which the reaction is

$$[2] \qquad HgI_4^{2-}(aq) + 2e^- \rightarrow Hg(\ell) + 4I^-(aq)$$

In experiments that employed migratory transport, all the ions present, mostly $K^+(aq)$ and $NO_3^-(aq)$, served as probes.

Three different electrochemical approaches have been employed. All these techniques, however, rely on similar physical principles. A cylindrically shaped sample of the porous medium is soaked with an aqueous electrolyte solution, containing probe ions. It is the journeying of these ions through the pores that is monitored to provide information on the characteristics (tortuosity, porosity) of the medium. In none of these techniques does the solution itself flow through the porous medium.

Model of the pore structure

The media of concern here are treated as solid rigid structures permeated by voids but without ion-exchange or other physicochemical properties. The void spaces may be interconnected pores, dead-end pores, or isolated voids. Our model involves only the pores that allow transport across the medium. For these, we adopt a "uniform tortuosity model" (4, 7), shown in Fig. 1. We assume that the pores are a collection of cylindrical tubules, all of the same length λL, where L is the thickness of the material and λ its tortuosity, and all of uniform, though not necessarily the same, cross-sectional area. We recognise that this is a simplistic model of the pore structure and have investigated models that incorporate other features, but we have found that this simple picture captures the essence of the media that we have studied.

Another characteristic of a porous material is its porosity, θ. This is the fraction of the total sample volume contributed by the pores. This parameter can be measured gravimetrically by comparing the mass, m_{dry}, of a dry cylindrical sample with that, m_{soaked}, of the same sample soaked with a liquid of known density ρ

$$[3] \qquad \theta = \frac{\text{void volume}}{\text{total volume}} = \frac{m_{soaked} - m_{dry}}{AL\rho}$$

According to the uniform tortuosity model, the total effective cross-sectional area of the pores is given by $A\theta/\lambda$. However, this is probably a poor estimate of the solution–mercury interfacial area when mercury is brought into contact with a soaked sample of porous medium. Indeed, our experiments suggest that this interfacial area is closer to the total area A.

Progressive method

In this technique, a disc of the porous material to be studied is mounted as shown in Fig. 2. The lower face of the sample sits on a mercury pool. Contact between the porous matrix and the mercury is maintained by a "head" on the mercury pool. The pores of the sample are filled with an aqueous solution of the probe ion, at concentration c^b, and a bulk supply of this solution contacts the upper face of the porous sample. Dipping into the solution is a J-tube electrode containing a small mercury pool. Anaerobic conditions were maintained in the solution during the experiment by gentle bubbling with argon. This also creates a mild stirring action that maintains a uniform bulk probe-ion concentration in the upper solution compartment. The experiment is started by the sudden imposition of an electrical potential difference, typically 190 mV, between the two mercury pools, that below the porous material being negative. The effect is to totally remove, via reaction [1] or [2], probe ions from the surface of the lower pool. Diffusion from the pores then occurs in an attempt to replenish the removed ions. At the anodic mercury pool, the reverse reaction occurs. The net result is a diffusive flow of probe ions through the porous medium. The rate at which these ions pass through the sample can conveniently be measured as a faradaic electric current. This current, initially declining but eventually settling down to a constant value, has three distinct time regimes — the early or transient current, the approach-to-steady-state current, and the final or steady-state current. These three regimes provide complementary data that, when combined

[3] To prevent hydrolysis.
[4] To ensure that transport by migration is minimized and diffusion is the dominant transport mode.

© 1998 NRC Canada

with the physical properties of the medium, can be used to characterize the pore structure.

When the potential step is applied, a concentration imbalance results that engenders motion of the probe ion. Since the experiment has been designed so that diffusion is the only operative mode of ion transport, the motion of the ion is assumed to be governed by Fick's second law for planar diffusion (8):

$$[4] \qquad \frac{\partial c}{\partial t} = -\frac{\partial}{\partial x}\left\{-D\frac{\partial c}{\partial x}\right\} = D\frac{\partial^2 c}{\partial x^2}$$

where D is the diffusivity (diffusion coefficient) of the probe ion, and c, its local concentration at position x and time t. The spatial variable x has its origin at the mercury – porous medium interface and t is measured from the instant the potential is stepped. Under the experimental conditions we have imposed and in terms of our model, Fick's second law must be solved subject to the initial condition:

$$[5] \qquad c = c^{\mathrm{b}} \text{ for } 0 < x < \lambda L, \quad t = 0$$

and the boundary conditions:

$$[6] \qquad c = 0 \text{ for } x = 0, \quad t > 0$$

and

$$[7] \qquad c = c^{\mathrm{b}} \text{ for } x = \lambda L, \quad t \geq 0$$

This third condition is maintained by gentle stirring of the solution above the porous sample, ensuring that the concentration at the end of the pores equals the original bulk value.

Subject to these conditions, Fick's second law can be solved to yield either of the following two expressions (4):

$$[8] \qquad c = c^b\left[1 - \sum_{k=0}^{\infty}\mathrm{erfc}\left\{\frac{k\lambda L + x/2}{\sqrt{Dt}}\right\} + \sum_{k=1}^{\infty}\mathrm{erfc}\left\{\frac{k\lambda L - x/2}{\sqrt{Dt}}\right\}\right]$$

where erfc{} is the error function complement (9) and

$$[9] \qquad c = c^b\left[\frac{x}{\lambda L} - \frac{2}{\pi}\sum_{k=1}^{\infty}\left\{\frac{(-)^k}{k}\right\}\sin\left\{\frac{k\pi(\lambda L - x)}{\lambda L}\right\} \times \exp\left\{\frac{-k^2\pi^2 Dt}{\lambda^2 L^2}\right\}\right]$$

Though they appear very different, these two equations describe the same dependence of concentration on time and distance but each has distinct advantages.

Fick's first law (8)

$$[10] \qquad j = -D\frac{\partial c}{\partial x}$$

relates the flux density j of a species (a measure of the amount of the species crossing unit area in unit time) to its concentration gradient. The negative sign denotes that diffusion occurs down the concentration gradient. By differentiating eqs. [8] and [9] and substituting the resulting expressions for $\partial c/\partial x$ into eq. [10] we get

$$[11] \qquad j = -c^b\sqrt{\frac{D}{\pi t}}\left[\sum_{k=0}^{\infty}\exp\left\{\frac{-(k\lambda L + x/2)^2}{Dt}\right\} + \sum_{k=1}^{\infty}\exp\left\{\frac{-(k\lambda L - x/2)^2}{Dt}\right\}\right]$$

and

$$[12] \qquad j = -c^b\frac{D}{\lambda L}\left[1 + 2\sum_{k=1}^{\infty}(-)^k\cos\left\{\frac{k\pi(\lambda L - x)}{\lambda L}\right\}\exp\left\{\frac{-k^2\pi^2 Dt}{\lambda^2 L^2}\right\}\right]$$

These expressions can be used in Faraday's law (8)

$$[13] \qquad I = nF\frac{A\theta}{\lambda}j^{\mathrm{s}}$$

which links the flux j^{s} of ions across the electrode surface (i.e., at $x = 0$) to the faradaic current, I. n is the number of electrons involved in the electrochemical reaction, 2 in this case, and F is Faraday's constant (96 485 C mol^{-1}). Setting $x = 0$ in eqs. [11] and [12] and substituting for j^{s} in eq. [13] gives

$$[14] \qquad I = -\frac{nFA\theta c^b\sqrt{D}}{\lambda\sqrt{\pi t}}\left[1 + 2\sum_{k=1}^{\infty}\exp\left\{\frac{-k^2\lambda^2 L}{Dt}\right\}\right]$$

or equivalently

$$[15] \qquad I = -\frac{nFA\theta c^b D}{\lambda^2 L}\left[1 + 2\sum_{k=1}^{\infty}\exp\left\{\frac{-k^2\pi^2 Dt}{\lambda^2 L^2}\right\}\right]$$

The significance of the negative sign is that we follow the IUPAC convention of treating current as negative if it arises from a reduction at the working electrode (8). Expressions [14] and [15] yield identical current values; however, eq. [14] is more useful at short times while eq. [15] is better at long times. Notice that both these equations show the proportionality of the current I to the *overall* effective cross-sectional area of the pores, $A\theta/\lambda$. What this implies is that our method does not provide information about individual pore sizes, just their average tortuosity and total area.

Immediately following the imposition of the potential step (i.e., at very small t), eq. [14] can be well approximated by

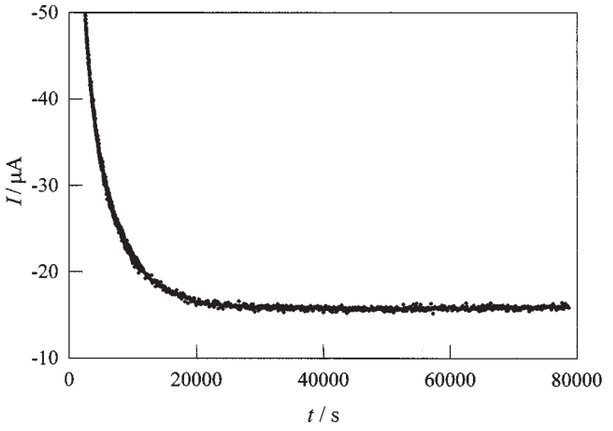
$$[16] \qquad I_0 \approx -\frac{nFA\theta c^{\mathrm{b}}}{\lambda}\sqrt{\frac{D}{\pi t}}$$

where the subscript "0" denotes initial behaviour. This equation is, as would be expected, equivalent to the Cottrell expression (10), which describes the current at a planar electrode under conditions of planar (or "linear") diffusion. Using eq. [16] we can predict that a graph of $It^{1/2}$ versus time will be horizontal during the initial stage of an experiment. This horizontal segment corresponds to

$$[17] \qquad (I\sqrt{t})_0 \approx -\frac{nFA\theta c^{\mathrm{b}}}{\lambda}\sqrt{\frac{D}{\pi}}$$

© 1998 NRC Canada

Fig. 3. Current versus time during the application of the progressive method to a sandstone sample.



At somewhat longer times we retain the first exponential term in the summation in eq. [14] and treat the higher order terms as negligible. This gives

$$[18] \quad (I\sqrt{t}) \approx (I\sqrt{t})_0\left[1 + 2\exp\left\{\frac{-\lambda^2 L^2}{Dt}\right\}\right]$$

after some rearrangement and incorporation of eq. [17]. Equation [18] can be rewritten as

$$[19] \quad \ln\left\{\frac{2(I\sqrt{t})_0}{(I\sqrt{t}) - (I\sqrt{t})_0}\right\} \approx \frac{\lambda^2 L^2}{D}\frac{1}{t}$$

Thus a plot of $\ln\{2(It^{1/2})_0/[(It^{1/2}) - (It^{1/2})_0]\}$ versus $1/t$, at short times, should be a straight line through the origin. The slope of this line, abbreviated G_1, can be used to determine the tortuosity. As eq. [19] shows, the model predicts that this slope should equal $\lambda^2 L^2/D$ and, since the two parameters L and D are known, the tortuosity λ is easily calculated.

At longer times, eq. [15] is more useful than eq. [14]. At very long times, all the exponential terms in this equation are negligible and we can write:

$$[20] \quad I_{ss} = -\frac{nFA\theta c^b D}{\lambda^2 L}$$

where the "ss" subscript denotes that this is the final, steady-state, current. At slightly shorter times, in the approach to steady state, we treat the second and higher order exponential terms as negligible and then

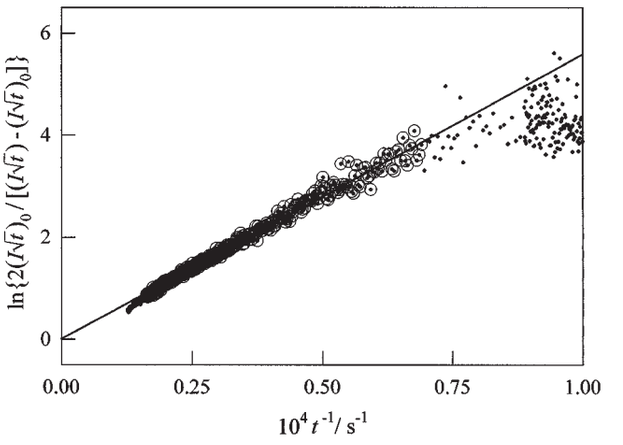
$$[21] \quad I \approx I_{ss}\left[1 + 2\exp\left\{\frac{-\pi^2 Dt}{\lambda^2 L^2}\right\}\right]$$

Rearrangement gives

$$[22] \quad \ln\left\{\frac{2I_{ss}}{I - I_{ss}}\right\} \approx \frac{\pi^2 D}{\lambda^2 L^2}t$$

from which we see that, at long times, a plot of $\ln\{2I_{ss}/(I - I_{ss})\}$ versus t should give a straight line. Tortuosity can be calculated from the slope of this line, denoted by G_2, since the model predicts that G_2 equals $\pi^2 D/\lambda^2 L^2$.

Fig. 4. "Short time" analysis of the current during a progressive experiment. Circled data points were used in the linear regression that yielded the straight line.



Yet another method of determining the tortuosity utilizes eqs. [17] and [20] combined as

$$[23] \quad \lambda = \frac{\sqrt{\pi D}}{L}\frac{(I\sqrt{t})_0}{I_{ss}}$$

The same two equations may also be combined into

$$[24] \quad \theta = \frac{\pi}{nAFc^b L}\frac{(I\sqrt{t})_0^2}{I_{ss}}$$

to provide a method of estimating the porosity of the sample.

Though we have carried out scores of such experiments on a variety of porous media, we shall report only an experiment with a sandstone disc of length L = 4.25 mm and area A = 1314 mm^2. The aqueous electrolyte solution was 2.00 M KNO_3, 10.0 mM HNO_3, 5.00 mM $Hg_2(NO_3)_2$, deoxygenated with argon and degassed prior to use. The results are shown in Figs. 3–5.

Figure 3 shows the current decline, which approaches a constant value of –15.75 μA after about 1 h. Figure 4 shows a graph of $\ln\{2(It^{1/2})_0/[(It^{1/2}) - (It^{1/2})_0]\}$ versus $1/t$, using a value of $(It^{1/2})_0$ equal to –2100 A s$^{1/2}$. The line shown has a slope of 5.58×10^4 s, from which we find a tortuosity of

[25] λ = 1.73 from eq. [19]

by using a measured value (6), $D = 9.7 \times 10^{-10}$ m^2 s^{-1}. Similarly, Fig. 5 shows a graph of $\ln\{2I_{ss}/(I - I_{ss})\}$ versus t, and from the slope, 1.75×10^{-4} s^{-1}, we calculate

[26] λ = 1.74 from eq. [22]

A third value of the tortuosity, namely,

[27] λ = 1.73 from eq. [23]

was calculated directly from the $(It^{1/2})_0$ and I_{ss} values. The agreement is gratifying. Less satisfactory, however, is the agreement between the porosity value

[28] θ = 0.163 from eq. [24]

compared with the value

Fig. 5. "Long time" analysis of the current during a progressive experiment. Circled data points were used in the linear regression that yielded the straight line.

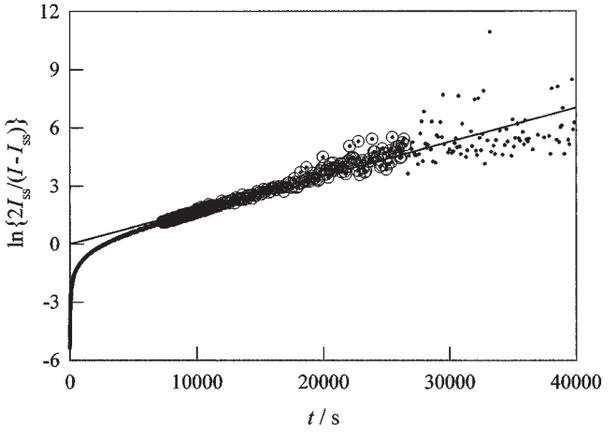

Fig. 6. Comparison of experimental data (points) with the prediction (line) of eq. [14], using $It^{½}$ = 2100 μA s^{½} and λ = 1.73, showing the inadequacy of the model at short times.

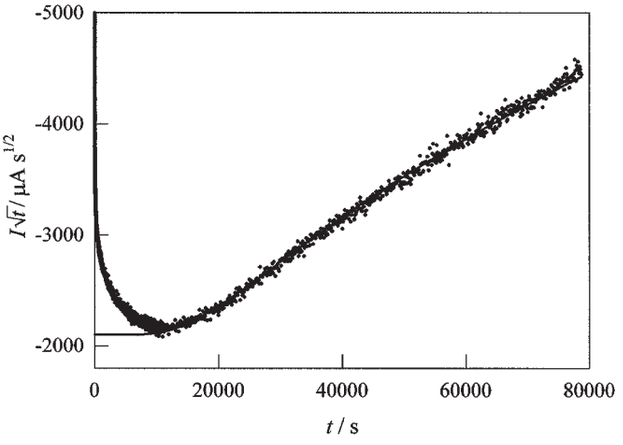

[29] θ = 0.239 by gravimetry from eq. [3]

This disagreement might have been expected from the fact that our model ignores cross-channels, which add void space but do not contribute to the current path. Note that the gravimetrically determined porosity is close to the value 0.260, appropriate to close-packed spheres (11), as might be expected for a mineral such as sandstone, composed of compacted grains.

One aspect of our experimental results that does *not* match the theory is illustrated in Fig. 6. According to the discussion surrounding eq. [17], the product $It^{½}$ should be initially constant as indicated by the line in the figure. Evidently an enhanced current flows during the first 10 000 s of electrolysis.

It is not difficult to find an explanation of this behaviour. The theory assumes that the pore structure is homogeneous right up to the junction of the mercury – porous medium, and that the area of contact between the mercury electrode and solution is the same $A\theta/\lambda$ as in the interior of the medium. There are two effects that could be imagined to augment this area and thereby lead to an elevated initial current. Firstly, one might well imagine that the pores would flare as they approach the surface. Secondly, it is not unreasonable to picture the mercury–solution interface as curved. Figure 7 is a diagram illustrating both effects.

To look further into this effect was one of the motivating reasons for evolving the second method.

Impedance method

This technique uses a disc of the porous medium sandwiched between two mercury pool electrodes. The disc was presoaked with a solution similar to that used in the progressive method, and containing the Hg_2^{2+}(aq) probe ion at a concentration of 5.00 mM, and other electrolytes. A Fourier-transform electrochemical instrument (FTEI) (12) was used to apply an alternating electrical potential between the pools and monitor the resulting current.

The signal applied by the FTEI consists of 36 superimposed sinusoidal waves, of frequencies in the 20 Hz – 30 kHz range. The amplitude of each component is in the submillivolt range and the phase angle relationships are carefully chosen so that the net voltage amplitude never exceeds 5.0 mV. The instrument has the facility to apply a simultaneous d.c. potential, and this feature was used in some experiments that are not reported here.

The program controlling the FTEI used the fast Fourier-transform algorithm to measure the real and imaginary parts of the 36 components of the current. These data are accessed as values of the real and imaginary parts, Z' and Z'' respectively, of the impedance.

The presence of an ample concentration of probe ion ensures that, provided frequencies above about 2 kHz are discounted, the a.c. current can be carried across the mercury–solution interface solely by the faradaic pathway

[30] $2Hg(\ell) \rightleftharpoons Hg_2^{2+}(aq) + 2e^-$

On the other hand, *all* the ions present will participate in carrying the a.c. current through the body of the porous medium. The equivalent circuit will therefore consist of a resistor representing the porous medium and Warburg impedances representing each electrode interface

The Warburg impedance is adequate to represent the faradaic pathway because the Hg_2^{2+}–Hg electron transfer is known to be very fast (13).

Established theory (14) predicts that the real and imaginary impedances associated with each Warburg element are

[31] $$Z_w' = -Z_w'' = \frac{RT}{8F^2ac^b\sqrt{\pi Df}}$$

where f is the frequency of the a.c. component, a is the area of the mercury exposed to solution, and other symbols have been defined previously. The resistance of the solution in the pores contributes only to the real component of the imped-

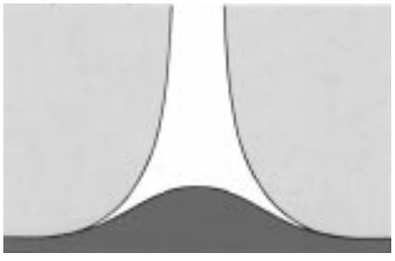
Fig. 7. Possible "flared" geometry of pore exit, with partial mercury intrusion.



ance and its contribution, according to the uniform tortuosity model is

$$[32] \quad Z_R' = \frac{\lambda^2 L}{\kappa\theta A}; \qquad Z_R'' = 0$$

where κ is the conductivity of the solution.

Experiments were carried out on a small glass frit of dimension L = 2.5 mm, A = 50.3 mm^{2,} and with a measured gravimetric porosity of 0.18. The solution conductivity was measured in a separate experiment and found to be 16.8 S m^{-1}.

Figure 8 shows experimental plots of Z' and Z'' versus $1/f^{1/2}$. These data are the averages of eight experiments. The first plot should obey the relationship

$$[33] \quad Z' = Z_R' + 2Z_W' = \frac{\lambda^2 L}{\kappa\theta A} + \frac{RT}{4F^2 a c^b \sqrt{\pi D f}}$$

and was analyzed to derive

[34] λ = 1.26

from the intercept and

[35] a = 38.5 mm^2

from the slope.

For the imaginary plot, we expect

$$[36] \quad Z'' = 2Z_W'' = \frac{-RT}{4F^2 a c^b \sqrt{\pi D f}}$$

and analysis of the lower curve in Fig. 8 leads to

[37] a = 33.7 mm^2

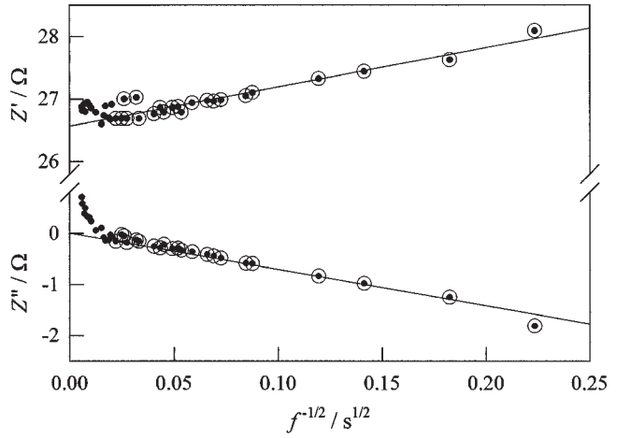
in fair agreement with result [35].

These a values, representing the area of the mercury–solution interface, are seen to be smaller than the overall geometric area A = 50.3 mm^2 but larger than the total pore cross-sectional area of $A\theta/\lambda$ = 7.1 mm^2. This is as expected for the configuration hypothesized in Fig. 7.

Migration method

The experimental arrangement for this technique is very similar to that for the impedance method. The major distinction is the absence of any deliberately added electroactive species. Instead, the aqueous soaking solution consisted of 10 mM HNO_3, 2.00 M KNO_3 of conductivity 15.8 S m^{-1}. The FTEI instrument was used again to measure the impedance by the same procedure described earlier. This time, however, the impedance was analyzed via the circuit

Fig. 8. Real and imaginary components of the impedance measured for a glass frit by the impedance method. Circled data ($f \leq$ 1.6 kHz) were included in the regression to fit eqs. [33] and [36].



in which the capacitors represent the double layer at the mercury–solution interface.

The theoretical real and imaginary components predicted by this equivalent circuit have the impedances

$$[38] \quad Z' = Z_R' = \frac{\lambda^2 L}{\kappa\theta A}$$

and

$$[39] \quad Z'' = 2Z_C'' = \frac{-1}{\pi\gamma a f}$$

where γ is the specific capacitance (F m^{-2}) of the interface.

To permit comparison with previous data, we used the same glass frit that was the subject of study by the impedance method. This time, however, the high-frequency end of the range (f >1600 Hz) of the FTEI was appropriate to use, thus avoiding any faradaic contribution resulting from adventitious electroactive impurities.

Figure 9 shows graphs of Z' and Z'' from the averages of four distinct experiments. Analysis of the upper plot in terms of eqs. [38] and [39] leads to the result

[40] λ = 1.27

which agrees well with the value 1.26 reported in eq. [34] from the impedance method. Analysis of the slope of the lower line in Fig. 9 via eq. [39] leads to a value of γ = 20.5 μF cm^{-2} when combined with the average a = 36.1 mm^2 from results [35] and [36]. This γ value is consistent with literature values (15) of specific capacitances at mercury – aqueous solution interfaces.

Summary

Three electrochemical methods of investigating porous media have been described and the results of experiments on two media have been reported. The uniform-tortuosity model is adequate to explain the behaviour of the interior of the media, but the model must be modified to represent the surface structure.

Origins of thermodynamic stability of urea:alkane inclusion compounds

Mary Anne White

Abstract: Using existing thermodynamic data, the thermodynamic stabilities of urea inclusion compounds with three different alkane guests (decane, dodecane, and hexadecane) have been determined. In all cases the inclusion compounds are found to be thermodynamically stable with respect to their component species up to their melting points. From the present analysis, the solid–solid phase transitions are found to play only a minor role in stabilization, and the thermodynamic stability is found to be predominantly enthalpically driven. At a given temperature, the stability increases in the order urea:decane < urea:dodecane < urea:hexadecane. The present analysis shows that above the melting point of the guest species the inclusion compounds become much less stable because of the competition of the liquid guest. This destabilization eventually leads to incongruent melting.

Key words: urea inclusion compounds, thermodynamic stability.

Résumé : À partir des données thermodynamiques existantes, on a déterminé les stabilités thermodynamiques des composés d'inclusion de l'urée impliquant trois alcanes différents comme molécule-hôte (décane, dodécane et hexadécane). Dans tous les cas, on a trouvé que les composés d'inclusion sont thermodynamiquement stables par rapport à leurs composants et ce jusqu'à leur point de fusion. Cette analyse révèle que les transitions de phase solide–solide jouent un faible rôle dans la stabilisation et que l'enthalpie contribue de façon prédominante à la stabilité thermodynamique. À une température donnée, la stabilité augmente dans l'ordre suivant : urée : décane < urée : dodécane < urée : hexadécane. Cette analyse révèle qu'au-dessus du point de fusion de la molécule-hôte, les composés d'inclusion deviennent moins stables en raison de la compétition de la molécule-hôte à l'état liquide. Cette déstabilisation conduit éventuellement à une fusion anormale.

Mots clés : composés d'inclusion de l'urée, stabilité thermodynamique.

[Traduit par la Rédaction]

Introduction

Inclusion compounds — materials in which one component forms a host lattice in which other components reside — are an important family of materials. They can range from clays to zeolites, clathrates to channel compounds. The confined environments provided by the host lattice can modify both chemical and physical properties of the guest species. An extensive review of inclusion compounds has been published recently (1).

One of the most studied host compounds is urea. It forms inclusion compounds with a hexagonal lattice in which guest molecules, e.g., linear hydrocarbons beyond a chain length of about six carbons (2), reside in parallel channels that have a diameter of ca. 5.5 Å. The walls of the channels are composed of urea molecules hydrogen bonded to each other. The *c*-axis periodicity of an alkane guest usually is incommensurate with that of the urea host (i.e., the guest–host repeat distance ratio is not a small-denominator rational number) and the main guest–host interaction arises from weak van der Waals forces (for a review, see ref. 3). However, some urea inclusion compounds, such as those with $(\alpha + 1),(\omega - 1)$-alkanedione guests, can form structures in which the guest and host are commensurate (see, for example, ref. 4). Most urea inclusion compounds undergo low-temperature solid–solid phase transitions involving both a change in symmetry of the host structure and a change in dynamics of the guest molecules (for a recent review, see ref. 5). The structure of pure urea is different from that of the inclusion compounds; it is tetragonal with close packing of the urea molecules (6).

World production of urea is about 10^8 ton/year, mostly for fertilizers using the tetragonal form of urea (7). However, urea inclusion compounds (UIC) also have their uses. The petroleum refining industry uses urea inclusion compounds in the separation of hydrocarbons by extractive crystallization for the production of aviation jet fuels (7). Urea is also used in dewaxing lubricant oils in the petroleum refining industry by formation of urea:alkane inclusion compounds; in a subsequent step the inclusion compound is broken down by dissolution in water, allowing recovery of the urea (7). Urea inclusion compounds are especially useful because of their selective inclusion: the chain length of the guest in the urea inclusion compound that is formed depends on the temperature in extractive crystallization (7), and petroleum feedstocks passed through fixed beds of urea take up high molecular weight *n*-alkanes in preference to lower molecular weight *n*-alkanes (8). Urea inclusion compounds also can

separate linear from branched hydrocarbons. Petroleum product purities above 99% can be obtained by separations using urea inclusion (9), and hydrocarbon separation with urea inclusion compounds remains an important processing method at present (10). Such separations must rely, at least in part, on different thermodynamic stabilities of urea inclusion compounds with different guests.

On heating, most urea inclusion compounds with hydrocarbon guests melt incongruently (11) as follows:

[1] urea·*m* guest (s) → *m* guest (l) + urea (s)

→ *m* guest (l) + urea (l)

where the second step takes place at the melting point of pure urea, T = 406 K (11); urea and its liquid guest are immiscible in this example, as is often the case for hydrocarbon guests.

Why some inclusion compounds melt congruently and others melt incongruently has been the subject of an earlier investigation (12). We have recently extended those studies to the melting behaviour of urea:hexadecane compared with hexadecane included in a similar host lattice, perhydrotriphenylene, abbreviated PHTP (13). Whereas urea:hexadecane melts incongruently to give solid urea and liquid hexadecane, PHTP:hexadecane melts congruently, i.e., giving liquid directly. Through examination of Gibbs energies, determined from adiabatic calorimetry, we concluded that both inclusion compounds are thermodynamically stable with respect to their components, and melting behaviour is dictated by the stability of the host lattice at the melting point (13).

The origins of thermodynamic stability of binary compounds relative to their components are of considerable interest, especially for urea inclusion compounds, given the relevance to petroleum separations. In the present study, we consider the thermodynamic stabilities as a function of temperature for urea inclusion compounds relative to their components for three different guests, viz. decane, dodecane, and hexadecane. All form incommensurate urea inclusion compounds, i.e., the guest and host *c*-axis repeat distances are not related by whole number ratios (14). These particular guests were chosen because the vapour pressures are low enough that only solid and liquid phases need be considered. Furthermore, all required experimental thermodynamic data were available. Through calculation of the thermodynamics of association of these urea inclusion compounds, we have looked at stability as a function of temperature from T = 0 K to the melting point, and separated out enthalpic and entropic contributions to the stability.

The purpose of this investigation was to address the following questions: How does the type of hydrocarbon guest influence the stability of urea inclusion compounds? How do enthalpic and entropic terms contribute to thermodynamic stability of urea inclusion compounds? What role do solid–solid phase transitions play in stabilizing urea inclusion compounds? Why do very short-chain hydrocarbon guests not form urea inclusion compounds? Could some urea inclusion compounds be expected to melt above the melting point of urea?

Methods and results

The thermodynamic stability of a urea inclusion compound can be considered in terms of association of the host and guest to form the inclusion compound:

[2] urea + *m* guest → urea·*m* guest (s)

where the inclusion compound is designated as urea·*m* guest, and *m* is the guest-to-urea mole ratio. From differential scanning calorimetry (11, 13), the values of *m* for urea:decane, urea:dodecane, and urea:hexadecane are 0.120, 0.103, and 0.081, respectively. The enthalpy, entropy, and Gibbs energy changes corresponding to association (eq. [2]) are designated here as $\Delta_{as}H$, $\Delta_{as}S$, and $\Delta_{as}G$.

To assess the thermodynamics of the association process, thermodynamic data for each compound are required. Using T = 0 K as the reference point, $H(T)$ for each compound, defined as

$$[3] \qquad H(T) \equiv H(T) - H(T = 0\ \mathrm{K}) = \int_{T=0}^{T} C\ \mathrm{d}T$$

and $S(T)$ for each compound, defined as

$$[4] \qquad S(T) \equiv S(T) - S(T = 0\ \mathrm{K}) = \int_{T=0}^{T} C\ \mathrm{d}\ln T$$

have been determined from experimental heat capacity data for urea (15), the urea:alkane inclusion compounds (16), and the alkanes (17). $G(T)$, also referenced to T = 0 K, for each compound was determined from

$$[5] \qquad G(T) \equiv G(T) - G(T = 0\ \mathrm{K}) = H - TS$$

The association changes are defined as

$$[6] \qquad \Delta_{as}H = H(\mathrm{UIC}) - H(\mathrm{urea}) - mH(\mathrm{guest}) + \Delta_{as}H(T = 0\ \mathrm{K})$$

$$[7] \qquad \Delta_{as}S = S(\mathrm{UIC}) - S(\mathrm{urea}) - mS(\mathrm{guest})$$

and

$$[8] \qquad \Delta_{as}G = G(\mathrm{UIC}) - mG(\mathrm{guest}) + \Delta_{as}G(T = 0\ \mathrm{K})$$

where, at T = 0 K, S(urea) = S(guest) = S(UIC) = 0 (i.e., residual entropy is assumed to be zero) and $\Delta_{as}G(T = 0\ \mathrm{K}) = \Delta_{as}H(T = 0\ \mathrm{K})$. The latter has been assessed through the thermodynamic cycle shown in Fig. 1, using literature data for heat capacities of the hydrocarbons (17), urea (15), and the urea inclusion compounds (16), and melting enthalpies of urea (11, 13), the alkanes (17), and the urea inclusion compounds (11, 13). The cycle involves a determination of the difference between two large numbers, which leads to considerable uncertainty in the result, and the calculated values for $\Delta_{as}H(T = 0\ \mathrm{K})$ for urea:decane, urea:dodecane, and urea:hexadecane are indistinguishable at –1500 J (mol urea)$^{-1}$, with an estimated uncertainty of ±1000 J (mol urea)$^{-1}$. (This uncertainty may be overestimated by about a factor of two: the present results for $\Delta_{as}H$ at 25°C for urea:decane and urea:hexadecane are 5.1 and 5.7 kJ (mol urea)$^{-1}$, respectively, which compare well with direct calorimetric determinations (18), 4.6 and 5.1 kJ (mol urea)$^{-1}$, respectively.)

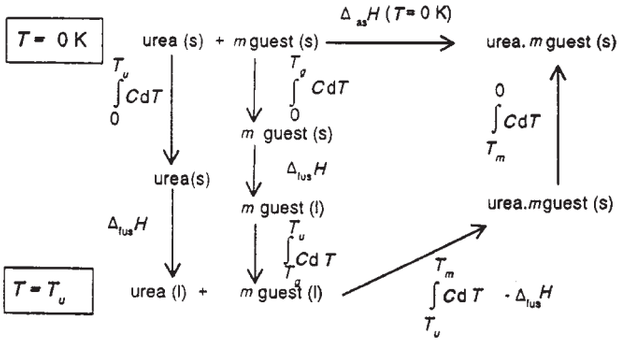
Fig. 1. The thermodynamic cycle used to determine $\Delta_{as}H$ (T = 0 K) = $\Delta_{as}G(T = 0$ K) for urea:decane, urea:dodecane, and urea:hexadecane. T_m, T_u, and T_g designate, respectively, the melting points of the inclusion compound, urea, and the guest. $\Delta_{fus}H$ is the enthalpy change on melting of the inclusion compound (total enthalpy change over two steps), urea, or the guest, depending on the process shown. Literature data were used for the heat capacity of the inclusion compound (16), urea (15), and the hydrocarbon guest (17), and for the enthalpies of fusion of the inclusion compound (11, 13), urea (11, 13), and the hydrocarbon guest (17).



$\Delta_{as}G$ and its components, $\Delta_{as}H$ and $-T\,\Delta_{as}S$, have been calculated as functions of temperature for each of the urea inclusion compounds; the results are shown in Figs. 2, 3, and 4, for urea:decane, urea:dodecane, and urea:hexadecane, respectively.

Discussion

All three urea inclusion compounds are found to be stable with respect to their components ($\Delta_{as}G < 0$ in Figs. 2, 3, and 4) from T = 0 K up to their melting points. The formation of urea:alkane inclusion complexes is known from calorimetric experiments to be exothermic (9), and this is confirmed here ($\Delta_{as}H < 0$). From the contributions to $\Delta_{as}G$, the stability is mostly a result of enthalpic interactions ($\Delta_{as}H < 0$); entropic interactions are mostly destabilizing ($-T\Delta_{as}S \geq 0$). Urea is polar and the guests are nonpolar, so there is a tendency to think of the guest–host interactions as being unfavourable in the formation of urea:alkane inclusion compounds, but the sign of $\Delta_{as}H$ indicates otherwise. Unfortunately, analysis of bulk thermodynamic data does not delineate specific interactions, and the present results do not test the theoretical finding that interaction between adjacent alkane guest molecules in urea channels is repulsive (19).

Each of the urea inclusion compounds investigated here has at least one solid–solid transformation: at 110.9 K for urea:decane, 123.2 K for urea:dodecane, and 135.3 and 151.8 K for urea:hexadecane (16). The solid–solid transitions slightly stabilize the inclusion compound further (most for urea:decane; least for urea:hexadecane) but the effect is minor and noticeable only as a slight decrease in ($d\Delta_{as}G/dT$).

The major feature common to Figs. 2, 3, and 4 is the marked decrease in stability of the inclusion compound beyond the melting point of the guest species, 243.5 K for decane, 263.6 K for dodecane, and 291.3 K for hexadecane (17). In each case the analysis shows that destabilization of

Fig. 2. Thermodynamic changes for association of urea:decane, as shown in eq. [2] with m = 0.120. $\Delta_{as}G = \Delta_{as}H - T\Delta_{as}S$. Urea:decane has a solid–solid transition at 110.9 K (16), and melts incongruently at 355 K (11). Decane melts at 243.5 K (17).

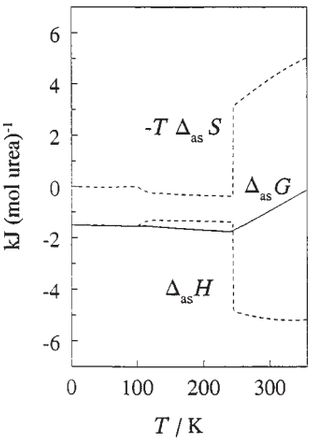


Fig. 3. Thermodynamic changes for association of urea:dodecane, as shown in eq. [2] with m = 0.103. $\Delta_{as}G = \Delta_{as}H - T\Delta_{as}S$. Urea:dodecane has a solid–solid transition at 123.2 K (16), and melts incongruently at 364 K (11). Dodecane melts at 263.6 K (17).

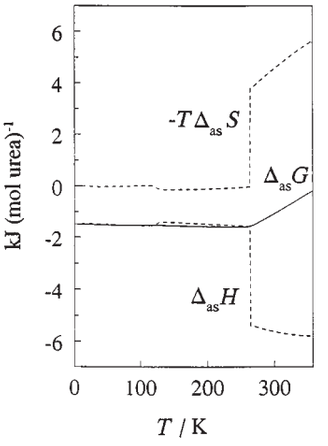
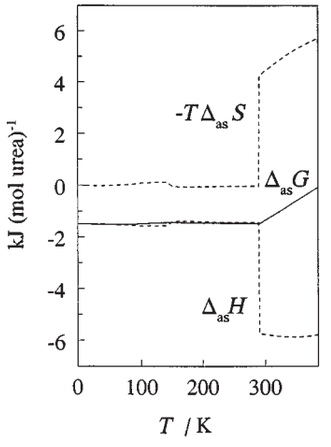


the urea inclusion compound can be considered to be driven by the high entropy of the guest species in its competing liquid phase. Ultimately it leads to $\Delta_{as}G = 0$ at the incongruent melting point of the urea inclusion compound: 355 K for urea:decane, 364 K for urea:dodecane, and 384 K for urea:hexadecane (11, 13). As these temperatures are below the melting point of pure urea (406 K), all three melt incongruently.

In the separation of alkanes on a urea bed, the capacity has been found to decrease as the temperature increases, and this was attributed to weakened interactions between the guest and the urea molecules at elevated temperatures (8). However, we can see from Figs. 2–4 that enthalpy favours UIC formation as the temperature is increased; it is the competing entropy of the liquid guest that makes the UIC less stable as the temperature is increased.

© 1998 NRC Canada

Fig. 4. Thermodynamic changes for association of urea:hexadecane, as shown in eq. [2] with $m = 0.081$. $\Delta_{as}G = \Delta_{as}H - T\Delta_{as}S$. Urea:hexadecane has solid–solid transitions at 135.3 and 151.8 K (16), and melts incongruently at 384 K (13). Hexadecane melts at 291.3 K (17).



Figures 2, 3, and 4 also indicate the trend to increased stability of urea inclusion compounds with longer alkane guests, as observed experimentally (8). For example, at T = 300 K, the values of $\Delta_{as}G$ for urea:decane, urea:dodecane, and urea:hexadecane are –0.95 kJ (mol urea)$^{-1}$, –1.06 kJ (mol urea)$^{-1}$ and –1.34 kJ (mol urea)$^{-1}$, respectively.

The main determinant in stability from one urea:alkane inclusion compound to another would appear to be the melting point of the guest (assuming that the vapour pressure plays a negligible role). Below that temperature $\Delta_{as}G$ is almost independent of guest, but above the melting point of the guest the UIC becomes dramatically destabilized with respect to its components. The correlation between stability and alkane melting point would also explain instability of urea:alkanes with very short hydrocarbon chains: their low melting points could lead to $\Delta_{as}G > 0$ at room temperature. We have recently found that urea inclusion compounds can be destabilized by photochemical means; when photoactive guests lead to fragmentation products that are too small to stabilize the inclusion compound structure, the close-packed tetragonal form of urea results (20).

The present results provide benchmarks for future theoretical investigations of stability and intermolecular forces in urea:alkane inclusion compounds. The same approach could be used to investigate other urea inclusion compounds, if experimental data were available. For example, for a given carbon chain length of guest species, the stability of urea inclusion compounds has been shown to increase in the order alkane < alcohol < amine < acid (21). It would be interesting to extend the present studies to other guests, especially to delineate the importance of commensurability of guest and host along the *c*-axis and the role of guest–host interaction in stability of urea inclusion compounds.

Characterization of deacetylated chitosan and chitosan molecular weight review

Jonathan Z. Knaul, Mohammad R. Kasaai, V. Tam Bui, and Katherine A.M. Creber

Abstract: Starting from a chitosan sample with a degree of deacetylation of 71%, three separate sample sets were generated by successive deacetylation and reacetylation processes. The degree of deacetylation of samples was determined by UV spectrometry supported by thermogravimetric analysis. The molecular weight of chitosan samples was determined in a solvent system of 0.25 M CH_3COOH/0.25 M CH_3COONa, using viscometry and gel permeation chromatography (GPC) with a TSK-gel column. The first set of samples had a similar degree of deacetylation (DDA) but differing molecular weights. The second set of samples had a similar molecular weight but differing degrees of deacetylation. The Mark–Houwink–Sakurada constants used for the determination of viscosity average molecular weight and the universal calibration of the GPC system were $K = 1.40 \times 10^{-4}$ dL/g and $a = 0.83$. Results showed that molecular weights determined from both techniques are in good accord only at lower degrees of deacetylation. This may be attributed to the fact that the chemical structure of chitosan samples could have been largely altered with increasing or decreasing degree of deacetylation. Nevertheless, the trend with which the molecular weights vary with the deacetylation time is consistent over a limited DDA range. A literature review of molecular weight analysis of chitosan is included.

Key words: chitosan, degree of deacetylation, gel permeation chromatography, molecular weight, viscometry.

Résumé : Utilisant comme produit de départ un échantillon de chitosane avec un degré de désacétylation de 71%, on a préparé trois ensembles différents d'échantillon par des processus successifs de désacétylation et de réacétylation. On a déterminé le degré de désacétylation des échantillons par spectrométrie UV associée à des analyses thermogravimétriques. On a déterminé le poids moléculaire des échantillons de chitosane par viscosimétrie et par chromatographie par perméation de gel (CPG) avec une colonne de gel de TSK, dans un système de solvant à 0,25 M CH_3COOH/0,25 M CH_3COONa. Le premier ensemble d'échantillons présentait un degré de désacétylation (DDA) semblable, mais des poids moléculaires différents. Le deuxième ensemble d'échantillons présentait des poids moléculaires semblables, mais des degrés de désacétylation différents. Les constantes de Mark–Houwink–Sakurada utilisées pour la détermination des poids moléculaires moyens par viscosité et pour la calibration universelle du système de CPG sont les suivantes : $K = 1{,}40 \times 10^{-4}$ dL/mg et $a = 0{,}83$. Les résultats montrent que les poids moléculaires déterminés par les deux techniques ne sont en bon accord qu'aux faibles degrés de désacétylation. On peut attribuer cette observation au fait que la structure chimique des échantillons de chitosane peut avoir été fortement modifiée par une augmentation ou une diminution du degré de désacétylation. Malgré tout, la tendance avec laquelle les poids moléculaires varient avec le temps de désacétylation est consistent pour un degré limité de «DDA». On a inclus une revue de la littérature relative à l'analyse des poids moléculaires des chitosanes.

Mots clés : chitosane, degré de désacétylation, chromatographie par perméation de gel, poids moléculaire, viscosimétrie.

Introduction

Chitin, a (1–4)-linked 2-acetamido-2-deoxy-β-D-glucan, is a natural polysaccharide that occurs mainly in invertebrates, fungi, and yeasts. It is the second most abundant natural polymer after cellulose (1). Chitosan, a (1–4)-linked 2-amino-2-deoxy-β-D-glucan, is the N-deacetylated derivative of chitin, although 100% N-deacetylation is almost never achieved. It is generally accepted that this biopolymer is referred to as "chitosan" if chitin is N-deacetylated to such a degree that it becomes completely soluble in dilute aqueous acidic systems (1–5% by volume aqueous acetic

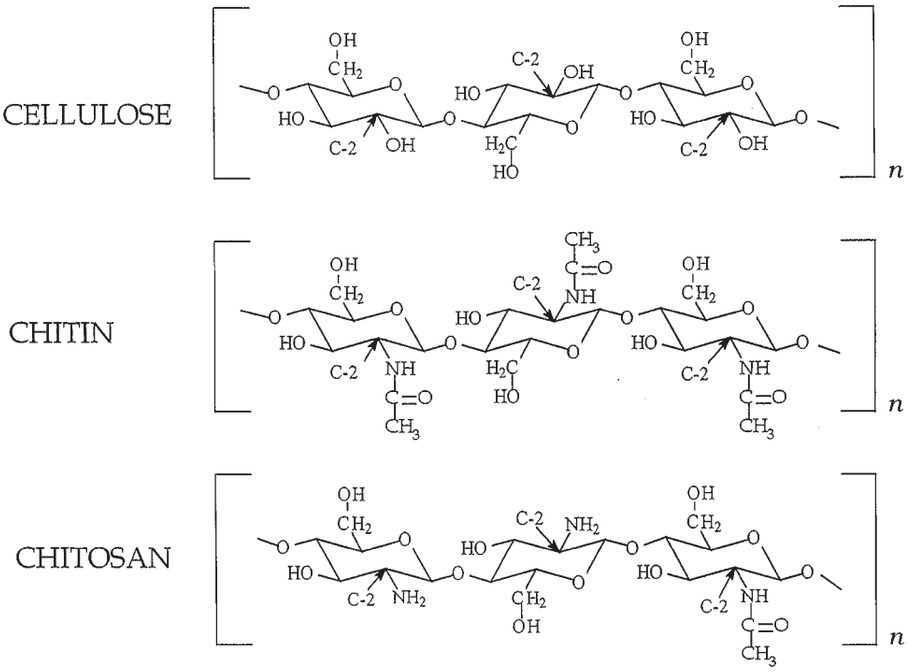
Fig. 1. Segments of cellulose, chitin, and chitosan polymers.



acid would be considered a dilute acidic medium). Structural examples of chitin, chitosan, and the structurally similar biopolymer cellulose can be found in Fig. 1. Chitosan is well known as a nontoxic and degradable polymer. It is used widely in the medical industry in products ranging from burn dressings to drug delivery capsules.

Chitosan samples can be characterized for several parameters including degree of deacetylation (DDA), turbidity, solubility, ash content, glass transition temperature, average molecular weight, and molecular weight distribution. It is known that viscometry and gel permeation chromatography (GPC) are the two most commonly used secondary methods for determining the molecular weight of polymers. They are virtually related to each other through the use of the Mark–Houwink–Sarakuda constants in both techniques (2, 3), and the reliability of these constants for a given polymer–solvent system determines the applicability of these secondary methods. As will be shown in the following section, the use of these techniques is not always straightforward, especially in the case of chitosan because of its complex hydrodynamic behaviour, which greatly depends upon its degree of deacetylation and the solvent system used.

In this study, one chitosan sample with a DDA of 71% was deacetylated and then reacetylated, providing two series of samples with either varying DDA or varying molecular weight, and one series with constant DDA and molecular weight. The samples were then characterized for the degree of deacetylation by UV spectrometry supported by thermogravimetric analysis, and for the molecular weights by viscometry and gel permeation chromatography (GPC) using a commonly used solvent system, 0.25 M CH_3COOH/0.25 M CH_3COONa. The main objective of this work is first to determine to what extent the viscometric and GPC data, based on available values of the Mark–Houwink–Sarakuda constants for the selected solvent system and for limited ranges of DDA and molecular weight, could yield reliable molecular weights of the above sets of chitosan samples, and secondly, to determine the effects of the deacetylation and reacetylation conditions, such as the reaction time and amounts of reactants used, on the properties of the chitosan samples obtained.

Literature review

Viscometric studies on chitosan

The intrinsic viscosity, [η], of a polymer solution, including nonelectrolytic and electrolytic polymers, is related to the viscosity average molecular weight, M_v, of the polymer through the Mark–Houwink–Sakurada equation (2, 3):

$$[1] \qquad [\eta] = K M_v^a$$

where K and a are constants depending on the polymer and the solvent system used, as well as the temperature. Their values are determined experimentally by evaluating the intrinsic viscosities of solutions of polymers for which the molecular weight has been determined by an independent method. Several authors have reported the K and a values for chitosan of varying DDA, in various solvent systems. Table 1 summarizes data for M_v and related the constants K and a, for different solvent systems and molecular weight ranges of chitosan. The most commonly used solvent systems are buffer solutions formed with acetic acid/sodium acetate at various concentrations. A significant result was reported by Rinauldo et al. (10): for a narrow molecular weight range, K and a were found to be nearly unchanged for three samples of DDA of 98, 88.5, and 79%, respectively. Normally, these constants have been found to vary significantly when the DDA range of 69–100% is studied over a large molecular weight range (9).

Gel permeation chromatography (GPC) studies on chitosan

The first study using a GPC system (16) was reported in 1976, using a long column packed with glass beads, and 2% aqueous acetic acid as the mobile phase. A strong absorbance peak was observed at 254 nm, which would appear to be an unusual result, as chitosan is known to absorb between 200 and 204 nm (17). The chitosan sample studied was found to have an M_n of 9.36×10^5 and an M_w of 2.05×10^6. The GPC system was calibrated based on dextran standards, but a universal calibration was not done. In a later study (18) by the same authors, it was assumed that the difference in solution behavior between chitosan and the dextran standards was negligible given their similarity in molecular structure.

The molecular weight of chitosan samples varying in degree of deacetylation between 78 and 99% was analyzed using an in-line GPC/LALLS method (19), using a solvent system of 0.2 M acetic acid/0.l M sodium acetate at 30°C. The molecular weights were found to be between 8.5×10^5 and 4.9×10^5. These values decreased with a rise in treatment temperature and with an increase in degree of deacetylation. This is in accordance with results obtained using an off-line laser light scattering method (20). Nine chitosan samples of different sources and varying molecular weights were analysed using a GPC/MALLS system (21) with dextran standards for the calibration. A dissimilarity between the hydrodynamic behaviour of dextran standards and chitosan samples was suggested as the probable cause of the overestimation of the molecular weights of chitosan samples.

In a recent study (22) using a size exclusion chromatography (SEC) system with different solvents ranging from a 0.3 M acetic acid solution to a 0.3 M acetic acid/0.2 M sodium acetate buffer, polystyrene standards were used for the calibration of the SEC system. A universal calibration was not mentioned.

Table 2. Deacetylated and reacetylated chitosan sample information.

Sample code	% DDA (±3.4%)	% Water + impurities (±1.5%)	Deacetylation/reacetylation conditions
P59a	70.8	15.4	As received from NovaChem Ltd.
Deacetylated samples:			
P59b9	87.3	12.5	P59a, 1 h, 50% $NaOH_{(aq)}$, 100°C, N_2
P59c9i	94.5	4.8	P59b9, 1 h, 50% $NaOH_{(aq)}$, 100°C, air
P59c9ii	94.9	5.9	P59b9, 2 h
P59c9iii	95.0	6.2	P59b9, 3 h,
P59c9iv	95.1	5.9	P59b9, 4 h
P59c9v	95.3	5.1	P59b9, 5 h
P59c9vi	95.3	5.3	P59b9, 5.4 h
P59c9vii	95.3	3.8	Same conditions as for P59c9ii
P59c9viii	95.1	3.2	
P59c9ix	95.4	3.0	
P59d9i	96	3	P59c9ix, 0.5 h, 50% $NaOH_{(aq)}$, 100°C, air
Reacetylated samples:			
B	90.1	4.3	P59d9i with 0.1004 g acetic anhydride
C	87.7	4.0	P59d9i withO.1236 g acetic anhydride
D	87.8	3.6	P59d9i withO.1445 g acetic anhydride
E	79.2	5.9	P59d9i withO.2845 g acetic anhydride
F	64.3	12.6	P59d9i with 0.5202 g acetic anhydride

Finally, four chitosan samples with degrees of deacetylation (23) varying between 91 and 92% were characterized using a GPC system with a series of TSK-gel columns and a mobile phase consisting of 0.3 M acetic acid/0.l M ammonium acetate buffer. This study showed that a more accurate analysis of the molecular weight distribution of chitosan samples can be made through GPC by application of the polydispersity index and the statistical skewing factor "*g*." This factor is a statistical measure of skewness of the chromatographic peaks. When $g = 0$, the peak of the sample is symmetrical. When $g > 0$, the peak has a long tail at high elution volumes and thus is skewed toward low molecular weights. When $g < 0$, the peak is skewed toward higher molecular weights. Thus *g* gives an indication of whether the polymer contains more high or low molecular weight chains. However, the chromatographic peaks are, in effect, influenced by both molecular separation and by axial dispersion as well as adsorption effects. Thus, for example, a skewed peak can result from adsorption.

The above GPC work can be summarized in the following manner. Buffer solutions of acetic acid are suitable for the mobile phase, dextran standards are commonly used for the calibration of the GPC columns, and the dissimilarity in hydrodynamic behaviour between chitosans and calibration standards should be taken into account. However, a large difficulty frequently encountered in the calibration of GPC systems arises from the fact that the hydrodynamic behaviour of chitosan in a given solvent system, indirectly represented by the Mark–Houwink–Sakurada constants, varies with its degree of deacetylation as well as with its molecular weight range.

Experimental

Materials

One chitosan sample with a degree of deacetylation of 71%, lot no. P59a, was obtained in the form of flake from Novachem Limited of Dartmouth, Nova Scotia, Canada. This is a shrimp-based product from the Gulf of St. Lawrence. The viscosity of a solution of 1% chitosan (by weight) in 1% (by volume) aqueous acetic acid was provided as 740 cP. The following chemicals were all obtained and used as reagent grade from Sigma–Aldrich Canada Ltd: sodium hydroxide, acetic acid, acetic anhydride, methanol, and sodium acetate. Chemicals used in the GPC experimentation were HPLC grade.

One set of six samples having similar degrees of deacetylation but differing molecular weights, and another set of six samples with differing degrees of deacetylation, but similar molecular weights, were prepared from the original chitosan sample according to the following deacetylation and reacetylation processes. In addition, three samples of the same DDA and molecular weight were also prepared.

Deacetylation and fragmentation

Chitosan identification codes and the particulars of deacetylation are noted in Table 2. Deacetylations were carried out by heating solutions of chitosans in aqueous NaOH solution, 50% by weight, at 100°C, for the times noted in Table 2, under a nitrogen atmosphere. The reaction product was subsequently washed in distilled water until reaching a neutral pH, and then dried in an oven at 50°C for 16 h. In the first experiment, the original chitosan, code P59a, was deacetylated for 1 h; the reaction product was code-named P59b9. All subsequent deacetylation reactions were conducted under air in order to aid in the breakup of chitosan molecules. After washing and drying, this sample, P59b9, was further reacted over the course of 6 h and one sample was removed every hour, yielding a set of chitosan samples with similar degrees of deacetylation but decreasing molecular weight. The products from this experiment were code-named P59c9(i–vi). In a second experiment, three separate samples of P59b9 were further deacetylated for 2 h under the same conditions in order to arrive at three samples with similar DDA values and molecular weights. Their code names are P59c9(vii–ix). The final DDA values, also listed in Table 2, were determined by UV spectrometry, following a reported method (17).

© 1998 NRC Canada

Reacetylation

To obtain a series of chitosan samples with similar molecular weights but varied degrees of deacetylation, a method previously described (24) was followed. The experiment used a sample of P59c9(ix) and further deacetylated it for 30 min. After washing and drying the product, it was code named P59d9(I). Five samples (2 g) of P59d9(i) were each placed into a flask containing 100 mL distilled water and stirred for 1 h before adding 100 mL of 2% aqueous acetic acid, then continuously stirred for one more hour. Methanol (200 mL) was added to each flask and stirred for a further 10 min. The final addition to each solution included 100 mL of methanol containing acetic anhydride, ranging in amount from 6.86×10^{-4} mol for sample B to 5.10×10^{-3} mol for sample F.

The solutions were then stirred for a further 16.5 h at room temperature. At the end of this period, methanolic ammonia was added to each solution in order to precipitate the chitosan. The precipitants were recovered and washed with distilled water using a sintered glass funnel under vacuum. The solids were finally dried in a convection oven at 50°C for 72 h.

Characterization

Thermogravimetric analysis

The water content of the chitosan samples, listed in Table 2, was determined using a Texas Instruments 2050 TGA thermogravimetric analyser. The sample was heated from room temperature to 300°C at 10°C per min under nitrogen. The loss in weight of a chitosan sample up to 180°C was taken to be the result of evaporation of water and volatile impurities.

Viscometry measurements

The viscosities of the chitosan samples were measured in a solvent of 0.25 M CH_3COOH/ 0.25 M CH_3COONa at 24.95 ± 0.05°C using an Ubbelohde capillary viscometer, model Cannon no. 100 E482, which yielded an average flow time of 62.29 s for the solvent system. The uncertainty in flow time was ±0.5 s, with at least three measurements for each solution. Six dilutions with the solvent were used for each chitosan sample. The flow time data were used to calculate the relative viscosity, the reduced viscosity, and then the intrinsic viscosity, [η] (by a linear regression of the reduced viscosity versus concentration). The overall error in the intrinsic viscosity, resulting mainly from the flow time and concentration uncertainties, and the temperature fluctuation, was estimated as being ±0.6 dL/g, which led to a maximum error of ±5% in the values of viscometric average molecular weight. The correlation coefficients were better than 0.950 for all chitosan samples.

Gel permeation chromatography (GPC)

GPC was carried out using the same instrumentation and method as previously described by Kasaai et al. (25). The solvent used was the same as that used in the viscosity measurements. The GPC system incorporated a Hewlett–Packard 1050 series pump. The flow rate was maintained at 0.40 mL/min under a pressure of 1.041 ± 0.021 MPa with zero attenuation. The system also included an HP 1050 series autoinjector and an HP 1047A refractive index detector. The column used was a TSK-gel GMPWXL column provided by Phenomenex with dimensions of 300 mm × 7.8 mm. The temperature of the column was maintained at 35°C. The standards used to calibrate the column were pullulan. All data provided by the GPC system were collected and analysed using the Hewlett–Packard ChemStation software package, B.02.06, 1994.

Results and discussion

Degree of deacetylation and thermogravimetric analysis

Table 2 summarizes all relevant information concerning the deacetylated and reacetylated chitosan samples obtained from the original sample, P59a. Knowledge of the water content as well as traces of volatile impurities in the chitosan samples was essential since these amounts would affect, first, the determination of their degree of deacetylation, DDA, presented in Table 2 (using data from UV spectrometry), and, secondly, the calculation of the concentration C in viscosity measurements. A typical thermogravimetric analysis (TGA) curve for chitosan samples shows a significant weight loss up to about 150°C followed by a plateau until about 250°C, and then a marked decrease in the weight of sample. It is believed that beyond 180°C all sample weight loss should be due to the thermal degradation of short and long molecular chains of chitosan. Repeated TGA runs on the same chitosan samples showed an uncertainty in water and impurities content of about 1.5%. This was the largest contributing factor to the error in the DDA determination, which was estimated as being ±3.4%. This error refers to the maximum single standard deviation after several DDA determinations performed on the same chitosan sample. The TGA results for the temperature range up to 180°C are in good agreement with those obtained by weighing chitosan samples before and after being placed in an oven at 50°C for 24 h. This TGA method for determining the water and volatile impurities content has also been successfully used by Qin (26) for the same purpose.

The deacetylation of the original chitosan sample, P59a, for 1 h in a nitrogen atmosphere increased the DDA from 70.8 to 87.3% and then up to 94.5% with one more hour of deacetylation in air. For further deacetylation times, the DDA remained nearly constant at about 95.0% while the molecular weight of samples decreased only slightly; this is shown in Table 3 and will be discussed later. It is hard to draw firm conclusions about the oxidative effect caused by oxygen in air on the deacetylation of chitosan, but it is clear that longer reaction times contribute to the chain degradation, or possibly to some branching formation of chitosan polymer molecules. Values of DDA for the reacetylation series, B–F, showed an appreciable decrease in DDA with increasing amount of acetic anhydride, which confirms the success of the reacetylation method used.

Intrinsic viscosity, [η], and viscosity average molecular weight, M_v

Reduced viscosity values for typical chitosan samples are plotted in Fig. 2 as a function of concentration. The linearity of all traces is attributed to the presence of a suitable amount of sodium acetate in the acetic acid solution. Without this salt, one would expect to observe a large depend-

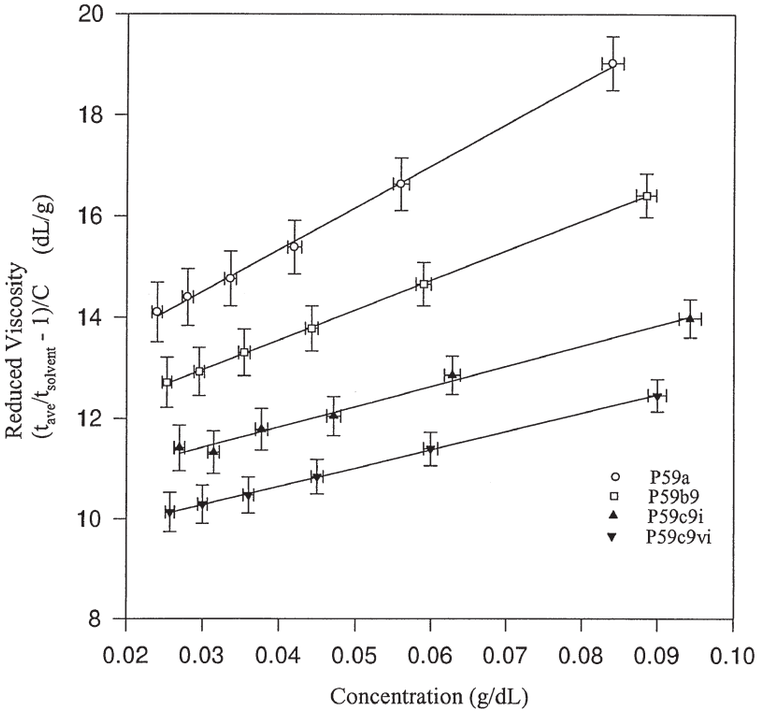
Fig. 2. Reduced viscosity versus concentration for some chitosan samples.



ence of the reduced viscosity on the concentration, most importantly in the low concentration range. This is typical for a polyelectrolyte whose molecular chains become extended as they progressively lose their charge due to the escape of some counterions from the polymer backbones, leaving the latter oppositely charged. The effect of an extended polymer molecule on the viscosity of the solution is greater than that of a random polymer chain. Consequently, if the polyelectrolyte solutions contain a sufficiently large amount of simple electrolyte, such as sodium chloride or sodium acetate, their reduced viscosity is expected to change linearly with concentration similar to that of an uncharged polymer solution.

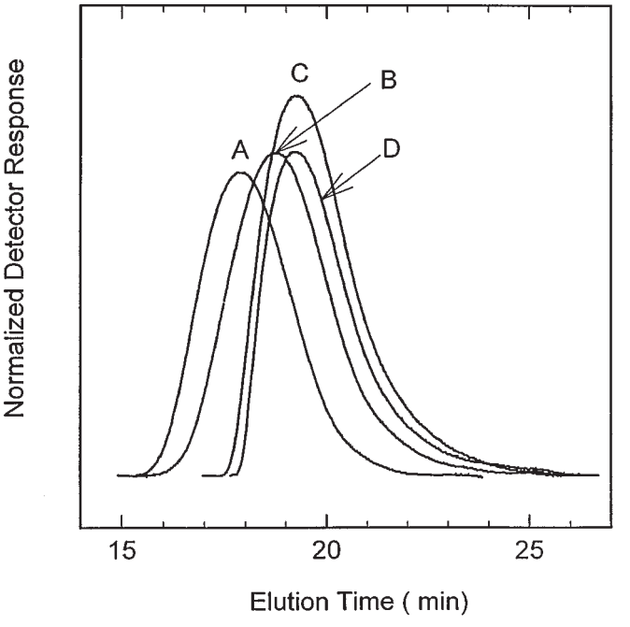
The intrinsic viscosity values, [η], and the limited value of reduced viscosity at $C = 0$, are presented in Table 3. These values allowed the calculation of the viscosity average molecular weight, M_v, also reported in Table 3, according to the following equation:

$$[\eta] = 1.40 \times 10^{-4} M_v^{0.83} \quad [2]$$

© 1998 NRC Canada

This equation for the solvent system of 0.25 M acetic acid/0.25 M sodium acetate has been developed by Kasaai et al. (25), using combined viscometry–GPC methods performed on relatively monodisperse chitosan samples, with pullulan standards used for the calibration of the GPC system where the discrepancy between the hydrodynamic behaviour of chitosan and pullulan standards was taken into account by a universal calibration method. The value of $a = 0$ means that chitosan molecules behave like random polymer chains in the given solvent system. This is supported by the results of other authors (7, 9, 10), Table 1, for similar solvent systems. As an approximation, the hydrodynamic behaviour of chitosan in the given solvent system is assumed to be nearly the same within a limited DDA range (e.g., between 71 and 95%). It is thus found that the intrinsic viscosity and then M_v largely decrease with increasing DDA, up to 2 h of reaction time, and then only slightly diminish with further reaction times. Chain scission might have occurred during the deacetylation process, and this may, to a certain degree "outweigh," but not occlude, the effect of coil expansion due to electrostatic repulsion, which closely depends on the DDA of samples. The above results do not agree with those reported by Roberts and co-workers (5, 24), where an opposite trend was observed (e.g., the intrinsic viscosity and molecular weight increased with increasing DDA). This trend was attributed (5, 24) to the fact that the cationic effect of the positively charged amine groups on the chitosan backbone plays a greater role in coil expansion than do the acetyl groups present on a more highly acetylated chitosan solution. However, the reported trend has been observed with the use of a 0.1 M acetic acid/0.2 M sodium chloride solvent system (5), which did not have the same buffer effect as the acetic acid/sodium acetate solvent systems. Consequently, it is suggested in this study that, as a result of their suitable buffer effect, the acetic acid/sodium acetate solvent systems could well minimize the difference in electrolytic effects of amine groups and acetyl groups. This, at least for a limited DDA range, leads to a lesser dependence of K and a on DDA. Furthermore, it has been proposed (9) that, with increasing DDA, chitosan chain stiffness decreases due to a decreased presence of hydrogen bonds between the monomer units of the chitin chain. In the more acetylated chitosan chain, two types of intramolecular H-bonds are available to restrict coiling of the chains: first, between the CH_2OH group and the O atom of the acetyl group of two neighbouring repeat units and, secondly, between the OH group and the β-deoxy of two neighbouring segments. Thus, by increasing the DDA, the former type of H-bonds will be reduced, leading to an increase in the coiling of chitosan chains. This H-bond effect may be a significant factor contributing to the dependence of K and a constants on the DDA of chitosan. Regarding the reacetylated sample series, the B–F samples, their intrinsic viscosity and molecular weight show only a slight decrease as the DDA greatly decreases from 96.0 to 64.3%. This may result from combined effects of, first, a possible chain scission following the reacetylation process and, secondly, changes in the conformation of chitosan chains due to differences in their electrostatic repulsion, H-bonds, and branching extent, over a large DDA range. Finally, the almost unchanged values of the intrinsic viscosity and M_v of the samples from P59c9vii to P59c9ix may lend support to the reproducibility of the deacetylation process used as well as the reliability of the DDA determination and the viscosity measurements.

Fig. 3. Size exclusion chromatograrns of initial chitosan (*A*) P59a, and three deacetylated samples: (B) P59b9, (C) P59c9i, (D) P59c9vi, respectively.



Gel permeation chromatography

The typical GPC chromatograms of some samples are presented in Fig. 3, from which the number and weight average molecular weights, M_n, M_w, and the polydispersity index were deduced, and are listed in Table 3. The original chitosan sample P59a has a relatively narrow molecular weight distribution with a polydispersity index of 1.89 and, interestingly, all deacetylated samples have even narrower molecular weight distributions with a polydispersity index of as low as 1.41. This likely resulted from the washing operation performed on deacetylated samples where relatively short chitosan chains could have been advantageously drained out. In most cases, except for samples P59a and P59b9, M_w and M_n are smaller than M_v obtained from viscosity measurements. This is typical of most polymers when applying a statistical analysis of the molecular weight distribution (25). On the other hand, results for the reacetylated samples, B–F, do not exhibit this trend, e.g., M_w becomes larger than M_v when the DDA of the samples decreases. This is likely due to the uncertainty in the use of the K and a values for the calibration of the GPC system over such a large DDA range within which the differences in the molecular conformation of chitosan such as discussed above should become overwhelming. In addition, there may be another cause, such as a greater tendency for the samples, with increasing DDA, to adhere to the column bed, thus resulting in longer elution times. Column bed – sample interaction is typically associated with an electrostatic attraction. The buffer effect of the solvent used would have suitably attenuated this interaction within a small DDA range but not completely eliminated it

© 1998 NRC Canada

over such a large DDA range. Furthermore, due to the branching conformation of chitosan (27)[2], neither the secondary viscometry nor the GPC methods used can provide accurate values of molecular weights compared to an absolute method (for example, off-line laser light scattering). Regarding the series P59c9, it was expected at the beginning that with increasing deacetylation time chitosan would reach a plateau in its DDA (27), while the molecular weight would lower significantly. This is not the case since the molecular weights change just slightly, and it is shown that 6 h of deacetylation caused virtually no reduction in molecular weight.

Conclusions

In this study, starting from one mother chitosan sample, three series of deacetylated and reacetylated samples were successfully produced: one with similar DDA values of 95% but molecular weight varying slightly from 724 000 to 637 000, another with DDA values decreasing from 90% to 61% and molecular weight varying only slightly from 586 000 to 500 000, and the last one with both DDA and molecular weight constant. The DDA of samples was determined using UV spectrometry with the help of thermogravimetric analysis, which provided the water and volatile impurities content of the samples. The reduced viscosity as well as molecular weights of samples were determined by viscometry and GPC methods using the solvent system of 0.25 M acetic acid/0.25 M sodium acetate and pullulan standards for the universal calibration of the GPC system. The difficulty with which accurate values of molecular weights could be deduced from the above methods is related to the dependence of the constants K and a, for a given solvent system, on the DDA and molecular weight ranges of the chitosan samples. Nevertheless, the results obtained did show consistent trends in variation of the intrinsic viscosity and molecular weights with the deacetylation time and with the amount of acetic anhydride used in the reacetylation process. It remains unclear whether there may be a possible oxidative effect on the deacetylation performance caused by oxygen in the air.

Gold nanoclusters reductively deposited on porous silicon: morphology and electronic structures

I. Coulthard, S. Degen, Y.-J. Zhu, and T.K. Sham

Abstract: Utilizing porous silicon as a reducing agent and a substrate, gold complex ions $[AuCl_4]^-$ were reduced from aqueous solution to produce nanoparticles of gold upon the surface of porous silicon. Scanning electron microscopy (SEM) was utilized to study the morphology of the porous silicon layers and the deposits of gold nanoparticles. It is found that preparation conditions have a profound effect on the morphology of the deposits, especially on porous silicon prepared from a p-type wafer. The gold nanoparticles, varying from micrometric aggregates of clusters of the order of 10 nm, to a distribution of nearly spherical clusters of the order of 10 nm, to strings of ~10 nm were observed and compared to bulk gold metal using X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), and X-ray absorption spectroscopy (XAS). These techniques confirm and complement the SEM findings. The potential for this reductive deposition technique is noted.

Key words: gold nanostructures, reductive deposition, porous silicon, morphology, X-ray spectroscopy.

Résumé : Utilisant de la silice poreuse comme agent de réduction et comme substrat, on a réduit des ions complexe d'or, $[AuCl_4]^-$, présents en solutions aqueuses et on a obtenu des nanoparticules d'or sur la surface de la silice poreuse. On a utilisé la microscopie électronique à balayage (MEB) pour étudier la morphologie de couches de silice poreuse et des dépôts de nanoparticules d'or. On a trouvé que les conditions de préparation ont un effet important sur la morphologie des dépôts, particulièrement sur la silice poreuse préparée à partir de plaquettes de type p. On a observé des nanoparticules d'or dont la taille varie de celle d'agrégats micrométriques de l'ordre de 10 nm, à celle d'agrégats pratiquement sphériques de l'ordre de 10 nm, à celle de chaînes d'environ 10 nm et on les a comparées à de l'or métallique à l'aide de la diffraction des rayons X (DRX), de la spectroscopie photoélectronique des rayons X (SPX) et de la spectroscopie d'absorption des rayons X (SAX). Ces techniques confirment et servent de complément aux observations faites par MEB. On note le potentiel de cette technique de dépôt par réduction.

Mots clés : nanostructures d'or, dépôt par réduction, silice poreuse, morphologie, spectroscopie des rayons X.

[Traduit par la Rédaction]

Introduction

Porous silicon (PS) is formed during the electrochemical etching of a silicon wafer in an HF solution (1). On the micro scale, the resultant porous silicon layer is a series of vertical micron-sized channels generated by current focussing during the etching process (2). At the nano scale, however, the layer is more akin to a sponge-like network of silicon containing many pillars, wires, and nodules with nanometre scale (3). The surface of freshly prepared porous silicon is passivated by hydrogen. Oxidation takes place when PS is exposed to the ambient atmosphere. Henceforth we use "ambient" to denote ambient atmosphere conditions; e.g., ambient porous silicon means porous silicon exposed to ambient air, etc. Thus the vast internal surface of a typical porous silicon sample is covered with a thin layer of silicon oxide.

An explosion of interest in porous silicon was generated when Canham (4) reported intense room temperature luminescence, from porous silicon, in the visible spectral region. This behaviour is completely unlike bulk crystalline silicon, an indirect band-gap material with a band gap of 1.1 eV. Bulk crystalline Si luminesces only very weakly in the IR region. The most widely accepted theory for the origin of the luminescence in PS is that the nano dimensions of the silicon features in porous silicon create a quantum size effect that widens the band-gap energy into the visible and relaxes the effect of momentum selection rules upon the luminescence (5, 6). Many papers on porous silicon have been published, including studies of the suitability of this material for

optoelectronic devices (7), of the insulating layer in silicon in insulator (SOI) technology (8), of the preparation of stress-free silicon nitride/oxynitride films (9), and as a chemical (10) sensor.

Although porous silicon research has received enormous attention (11), one important property, its ability to act as a modest reducing agent (12, 13), is relatively unexplored. Porous silicon can effectively reduce from solution any system with a positive half-reduction potential with respect to hydrogen (13, 14). That is, PS acts like a hydrogen electrode. It is immediately apparent that noble metals with a positive reduction potential would be ideally suited for this process. If the result of the reduction is a solid element, then porous silicon will act as both a reducing agent and a substrate for the deposition of the solid material. In solutions of noble metal ions, the ions are reduced to atoms that will diffuse to form metal clusters or aggregates onto the vast internal surface of the porous silicon (15, 16). The objective of this work is to investigate the effect of the preparation conditions upon the morphology of Au clusters on porous silicon. Based on previous studies (Pd, Ag, Pt, Au, Cu, etc. on PS) (13–16), we expect that Au nanoparticles with various dimensions will form under controlled conditions and these nano systems will generally exhibit electronic properties different from those of the bulk materials (17–19). Thus this study will have interesting implications for the fabrication of nanostructures in electronic and chemical materials applications such as interconnects and catalysis, respectively. In the latter, small particle size and increased surface area are beneficial (20).

In this report, we concentrate our study upon the reduction of $[AuCl_4]^-$ from an aqueous solution by porous silicon. This results in the deposition of Au onto the surface of porous silicon. The effects of the preparation conditions of the porous silicon, and of the conditions of deposition, upon the morphology of the Au deposits were studied. Emphasis is placed on the systematics of Au deposition on p-type based porous silicon. The structure and electronic properties of the Au deposits on porous silicon were examined with X-Ray powder Diffraction (XRD), X-ray Photoelectron Spectroscopy (XPS), and X-ray Absorption Near-Edge Structure (XANES). We will also report the effect of Au deposition on the luminescence property of porous silicon using a synchrotron light induced luminescence technique, sometimes known as XEOL (X-ray Excited Optical Luminescence) (21, 22).

Experimental

Porous silicon samples were prepared as described earlier (13) using a single electrochemical cell configuration with the silicon wafer acting as the anode and a Pt foil as the counter electrode. Both p-type (B doped) and n-type (As doped) Si (100) wafers with resistivity in the range of 1–10 Ω cm were utilized to produce porous silicon. A 1:1 mixture of 48 wt.% HF and absolute ethanol was used as the cell electrolyte. Anodization time was typically 20 min with a current density of 1–500 mA/cm^2. For p-type samples, etching is the dominant process (23) at a current density below 100 mA/cm^2 whereas for n-type samples the current density requirement is much higher (>100 mA/cm^2). The porous silicon thus prepared was left attached to the silicon substrate as a thin layer with thickness typically of 10–100 μm. The porous silicon layers, though passivated in HF by hydrogen, readily oxidize when expose to air. Samples could be *refreshed* with HF to remove the surface oxide layer.

Au was reductively deposited onto the porous silicon using aqueous solutions of $Na[AuCl_4]$. The deposition took place either by immersion of the porous silicon sample into a $Na[AuCl_4]$ solution or by the placement of a surface tension bubble of the solution on the top of the porous silicon layer. Solution concentration of $[AuCl_4]^-$ (pH = 3) was varied from 1×10^{-3} M to 1×10^{-4} M and the deposition time was varied from 15 s to 5 min. It is interesting to note that a 1 mL portion of a 1×10^{-4} M solution contains ~6×10^{16} Au atoms, which amounts to ~60 monolayers/cm^2. It was observed that oxidation in ambient air inhibited the reductive deposition, which would only take place effectively when a freshly prepared sample or an HF "refreshed" sample was utilized. During the deposition, evolution of bubbles of hydrogen is evident. Although the details of the mechanism are not clearly understood, it is known that Au is reduced from Au(III) to Au(0) and the surface hydrides of PS are oxidized to H_2 gas, leaving behind some surface Si dangling bonds that will be immediately oxidized upon exposure to the ambient atmosphere.

The morphology of the substrate and the Au deposits was investigated with a Hitachi S-4500 field emission scanning electron microscope at Surface Science Western (SSW). A voltage of 10 kV was used in the measurement. We have also carried out X-ray studies on several selected samples. X-ray powder diffraction patterns were recorded with a Rigaku Gieger Plex X-ray diffractometer using a Cu Kα source. X-ray photoelectron spectroscopy was carried out at SSW using an SSX-100 small spot spectrometer that is equipped with a monochromatic Al Kα source and a channel plate detector. X-ray absorption experiments in the soft X-ray range (Si K-edge and Au $M_{3,2}$-edge) were carried out at the Canadian Synchrotron Radiation Facility (CSRF), which is located at the Synchrotron Radiation Center, University of Wisconsin–Madison. Au $L_{3,2}$-edge measurements were made at the X11A beamline of the National Synchrotron Light Source at Brookhaven National Laboratory. Synchrotron light induced optical luminescence measurements were carried out at the Mark II grasshopper beamline at CSRF using a J-Y H10 monochromator and a Hamamatsu R943–02 PMT (photomultiplier tube).

Preparation, morphology, and structure of Au deposits on porous silicon

The chemistry of the process is clearly a redox reaction in which the surface of porous silicon is a reducing agent and the $[AuCl_4]^-$ ion is the oxidizing agent. Although the mechanism of the process is still not clearly understood, it is conceivable that the first step must be the diffusion of the complex ion to the surface, followed by adsorption and reductive detachment of the chloride ion. After that, nucleation takes place and the observed morphology results. The last step is perhaps the most complex one because it depends on the surface condition of the substrate and its history. The evolution of hydrogen gas suggests that the surface hydrides are involved in the process. This is also supported by the

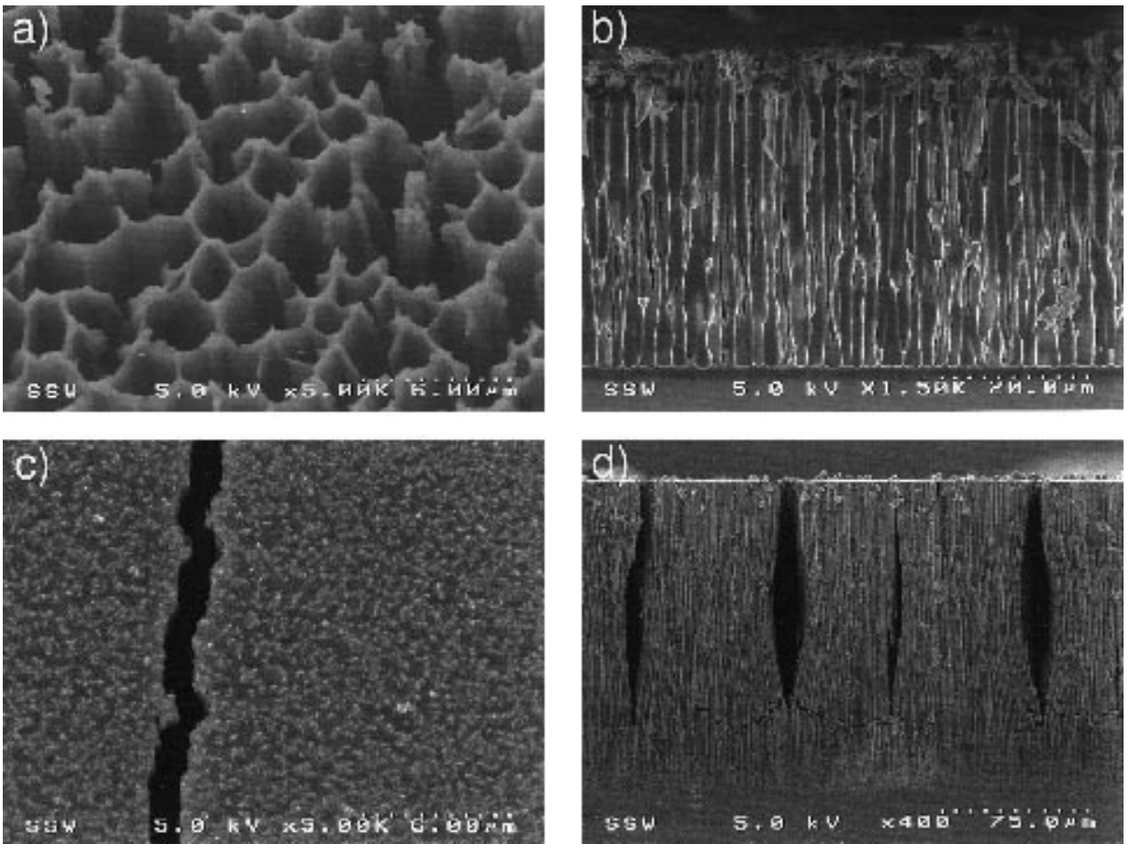
Fig 1. SEM images of two typical porous silicon samples. (*a*) Normal image, p-type (B doped) Si (100) wafer, 50 mA/cm^2, 20 min; (*b*) profile image, same sample as (*a*); (*c*) normal image, n-type (As doped) Si (100), 300 mA/cm^2, 20 min; (*d*) profile image, same sample as (*c*).



fact that Au deposition on an oxidized PS was negligible.[3] In addition, the amount of Au deposited depends on the $[AuCl_4]^-$ concentration and deposition time.[4] The process is complicated by the gas bubbles trapped inside the microchannels. In several runs we used an ultrasonic bath to minimize the effect of trapped bubbles by agitation. This process further alters the morphology of the Au aggregates. Some examples will be given. However, in this report, we remain focussed on results obtained under typical conditions. More details concerning the mechanism must await further kinetics studies and will be reported elsewhere.

Figure 1 shows the SEM micrographs, which reveal the morphology of two types of porous silicon layers. Figures 1*a* and 1*b* are SEM images (normal and cross sectional) of a sample generated using a p-type Si(100) wafer with a current density of 50 mA/cm^2 for 20 min. Figures 1*c* and 1*d* are SEM images of a sample using an n-type wafer with a current density of 300 mA/cm^2 for 20 min. These images clearly show the effect that the choice of wafer and preparation conditions can have upon the resulting morphology of the porous silicon layer. The current density utilized to generate the n-type sample is much higher due to the nature of the doping (23). Nevertheless, this difference in current density has had an effect upon the thickness and the porosity of the porous silicon layers. The images clearly show a film thickness of ~30 μm and ~120 μm for the p-type and n-type samples, respectively. In general, higher current densities produce thicker layers. For the p-type samples, there is a linear relationship between current density and thickness up to 100 mA/cm^2. The thickness for the 20 mA/cm^2 film on p-type PS that we used extensively as the substrate for Au deposition is ~10 μm. In these images, the micron-sized channels in the n-type sample appear more uniform and straight than in the p-type sample with the exception of the areas in the n-type where the thickness of the sample has caused significant stress effects as evidenced by the sample fractures deep in the layer (24).

The normal SEM images also reveal significant information. Both samples show micron-sized vertical channels; however, there is a distinct difference in channel porosity. The p-type sample shows a network of channel walls with occasional incidence of channel coalescence. Although, due to poor contrast, the n-type samples show no clearly visible channel walls as seen in the p-type PS, the dark areas are the channel

Fig. 2. SEM images of Au reductively deposited onto different porous silicon samples. (*a*)–(*c*): Au (1×10^{-3} M solution) deposited onto p-type PS (20 mA/cm^2, 20 min) with deposition time of 5 min, 1 min, and 15 s, respectively; (*d*) same as (*c*); (*e*) and (*f*): Au (4.3×10^{-5} M solution, 5 min) deposited onto p-type PS with intermittent and continuous ultrasonic agitation, respectively; (*g*) Au deposited onto n-type PS; (*h*): Au (1×10^{-4} M, 5 min, on freshly prepared p-PS); (*i*) Au (1×10^{-4} M, 1 min on freshly prepared p-PS).

openings and they are on average significantly smaller than those of the p-type PS. Thus the microchannels on n-type PS have a higher density than those of the p-type PS. It appears that increased current density has increased the porosity (hence a larger internal surface area) of the n-type sample relative to the p-type PS. This is also borne out in the reactivity of the surface towards the reduction of $[AuCl_4]^-$ ions (see below).

Figure 2 shows the SEM images of a number of porous silicon samples upon which Au has been reductively deposited. Figures 2*a*–2*c* are Au on p-type PS samples prepared with different deposition conditions (1×10^{-4} M $[AuCl_4]^-$ for 5 min, 1 min, and 15 s, respectively). They clearly show the systematics of the cluster-size dependence on deposition time. In this series of depositions, the same PS substrate and current density (20 mA/cm^2) were used. It is apparent that the 5 min deposition (Fig. 2*a*) results in clusters in the range of 30–40 nm uniformly distributed on the surface. Reducing the deposition time to 1 min yields smaller clusters (10–20 nm, Fig. 2*b*) while 15 s deposition results in very small clusters that appear as white dots. Cross-sectional SEM shows that the metal deposits generally do not penetrate the entire PS layer (25). For Au, 1–2 μm is the typical thickness. The lack of penetration depth relative to the thickness of the PS may be due to trapped gas bubbles that inhibit the diffusion of the liquid into the PS sponge. Figures 2*d*–2*f* compare the images of Au/p-type PS under three conditions: (*i*) without ultrasonic agitation, (*ii*) with intermittent agitation, and (*iii*) with constant agitation. Figure 2*d* is the same as Fig. 2*c* while Figs. 2*e* and 2*f* correspond to samples prepared with a 4.3×10^{-4} M $[AuCl]_4^-$ solution for a deposition time of 5 min. We can see that samples with agitation treatment exhibit still different patterns from those without agitation. This procedure usually increases the deposition depth into the PS layer. On the n-type samples (Fig. 2*g*), nanometre-sized clusters of gold are generally formed (bright dots and patches). These clusters seem to form nominally anywhere upon the surface of the sample and soon coalesce to form a thin but uniform layer of gold across the entire surface. This behaviour is in contrast to the p-type porous silicon where the morphology of Au deposits is much more variable depending on the preparation conditions (Figs. 2*a*–2*c*). The morphology of the deposited Au also varies somewhat depending on whether a freshly prepared or a refreshed sample is used, and upon the history of the specimen. In one example, Fig. 2*h*, the deposits of gold from freshly prepared PS are concentrated near the pores where there is a larger number of high-energy sites; smaller clusters coalesce to form a very large cluster on the order of micrometres. Grains of a size of the order of 10 nm are clearly seen. In another example, a very curious network of nanoscale strings of gold is formed on a freshly prepared PS (Fig. 2*i*).

The difference between the morphology of Au on n-type and p-type based PS seems to be related to the nature of the doping, the porosity, and the effect these have on the reductive deposition, which requires the presence of surface hydrides. The reduction is facilitated by higher porosity, which yields a larger internal surface and negative carriers in n-type PS. The p-type PS must rely more upon surface defects and other high-energy sites such as dangling bonds for initial Au nucleation, and thus many p-type samples show preferential deposition of the gold near the pores. The difference among Au/p-type PS samples is also related to the porosity of the substrate and the time of deposition. Freshly prepared samples that receive little exposure to ambient conditions tend to deposit gold preferentially near the pores as in Fig. 2*h*. Samples that are "refreshed" with HF just before deposition, on the other hand, tend to produce a more uniform distribution of Au clusters, as observed in Figs. 2*a*–2*c*.

The structure of these clusters revealed in SEM can be confirmed with X-ray powder diffraction measurements, which show diffraction patterns characteristic of fcc Au. Figure 3 shows the broadening in the Au (111) diffraction peaks as the Au cluster size decreases (Fig. 2*a* to Fig. 2*b*). The width of the diffraction line *B* can be related to the crystalline size of the cluster according to the Scherrer equation (26):

$$[1] \qquad \tau = \frac{K\lambda}{\beta_\tau \cos\theta}$$

where *K* is the shape factor and usually has a value of 0.9, λ is the wavelength of the X-rays, β_τ is given by $(B^2 - b^2)^{1/2}$ in radian units where *B* is the width at half-maximum of the observed diffraction peak (2θ) of the small crystalline clusters, *b* is the width of Au to which the contribution is mainly that of the X-ray photon width and the Darwin width of the crystal plane, and θ is the Bragg angle.

Using the values from Fig. 3 (β_τ of 1.396×10^{-2} rad and 8.56×10^{-3} rad, respectively, for the 1 min and 5 min samples), we estimated an average crystallite size of ~10 nm and ~17 nm for the Au clusters corresponding to Figs. 2*a* and 2*b*, respectively, in semiquantitative agreement with the SEM observation. These values are slightly smaller than seen in the SEM and obviously have large uncertainties since the width arises from a distribution of cluster sizes. They nevertheless represent an average of various cluster sizes. A small shift to higher 2θ value is also observed at 38.2° and 38.4° for the 5 min and 1 min samples, respectively, relative to 38.09° for Au powder. This observation indicates that the volume of the unit cell of Au in the clusters shrinks slightly (by ~1% and 1.4%, respectively) relative to bulk Au (a = 4.0786 Å). This slight compression of the Au lattice is of some interest in connection with the electronic structure of these clusters and will be discussed below.

Electronic structure from X-ray spectroscopy

The electronic structure of the Au deposits was studied by XPS, which probes the core level (4*f*) binding energies and the valence band structure of the clusters, and with Au $L_{3,2}$-

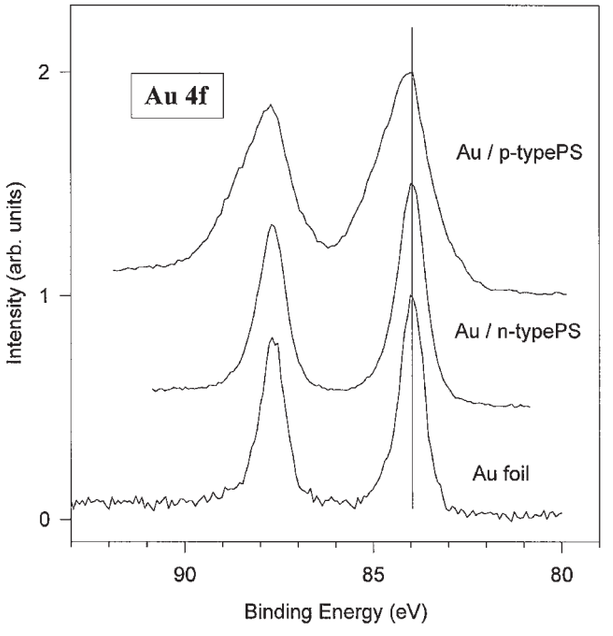
and $M_{3,2}$-edge XANES (X-ray Absorption Near Edge Structures), which probe the unoccupied densities of state of *d* character above the Fermi level. The Au 4*f* levels together with the valence band spectra can be used to identify the presence of small Au clusters. It has been shown that Au

Fig. 5. Au 4*f* for Au/p-PS, Au/n-PS, and Au metal. Charging in the spectrum for Au/p-PS has been compensated with a flood gun and the peak maximum is aligned to that of the Au metal.



clusters of ~10 nm and smaller exhibit a progressive positive 4*f* core level shift relative to that of Au in the bulk (18, 19, 27). This is due to a combination of changes in electron distribution (rehybridization), an initial state effect, and final state screening. The Au 4*f* core level shift ΔBE between Au cluster and Au metal (bulk) can be expressed as

$$[2] \qquad \Delta BE = -\Delta\epsilon_1 - \Delta\phi$$

where the initial state contribution to the binding energy, $-\Delta\epsilon_i$, is due to the difference in the one-electron energy of the 4*f* level (ϵ is a negative value) and is due primarily to the change in electronic configuration (rehybridization involving 5*d* and conduction electrons of 6*s* and 6*p* character) (28) and

$$[3] \qquad \Delta\epsilon_i = \Delta n_d F(5d,4f) + \Delta n_c F(\text{cond},4f) + \Delta S_f$$

The Δn terms in eq. [3] are changes in 5*d* and conduction electron (primarily 6*s*) counts between Au in Au cluster and in Au metal. The *F* terms are the Coulombic integral where F_d is significantly larger than F_c (28). Thus a *d* charge loss (decrease in *d* count) would contribute to a positive binding energy shift. The ΔS_f term is the difference in final state screening, which is negligible for metallic systems and becomes increasingly important as the cluster becomes smaller (18). A poorly screened atomic site would contribute to a positive binding energy shift. Finally, the $\Delta\phi$ term is the difference in work function between bulk Au and Au cluster and ϕ is not well known for a small cluster. It also depends on the surface conditions of the cluster. It has been reported that for Au clusters of less than 150 atoms, the final state screening becomes important. That is, the cluster becomes less metallic (18). The latter can account for the fact that the observed Au 4*f* shift is often larger than would be expected based on initial effect alone for pure Au. The Au 5*d* band is also informative. The Au *d* band normally exhibits a quasi

Fig. 6. Au 4*f* XPS of the strings (Fig. 2*i*), the 1 min deposition (Fig. 2*b*), and Au metal. The strings spectrum has been shifted by ~5 eV to offset charging.

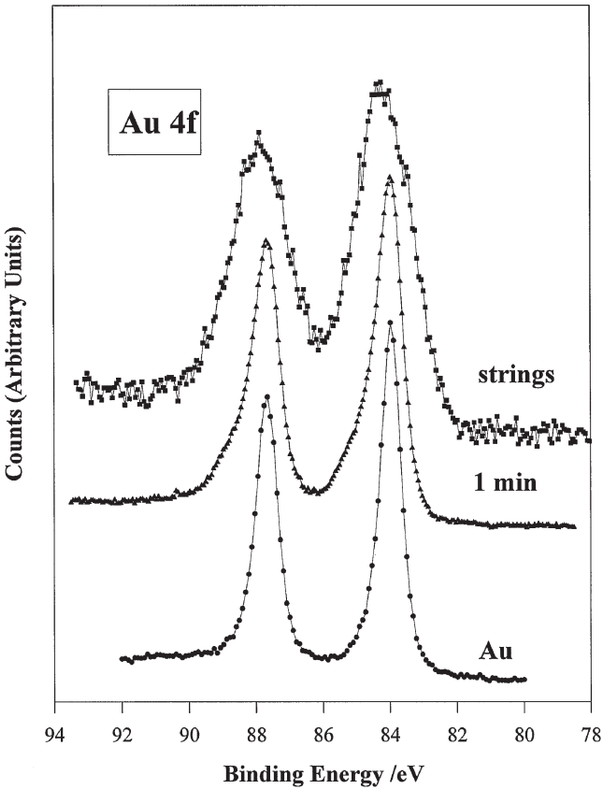

Fig. 7. Au valence band spectra for selected samples (Figs. 2*a*, 2*b*, and 2*i*) and Au metal.

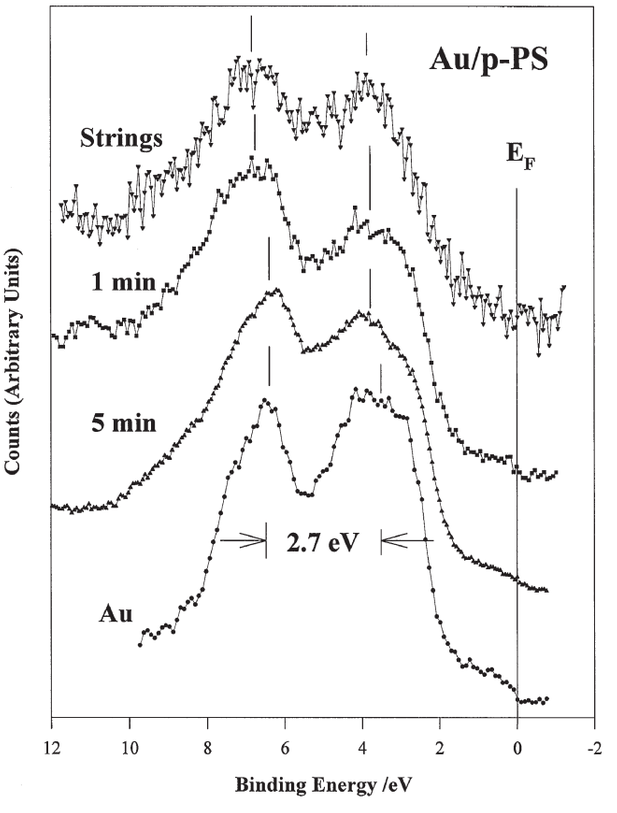

$d_{5/2}$ and $d_{3/2}$ doublet with a separation of ~2.7 eV as the result of strong spin-orbit and *d–d* interaction. This separation is considerably greater than the spin-orbit interaction, ~1.5 eV, of atomic Au. Phenomenologically, the *d* band doublet separation Δ can be expressed as the sum of contributions from the atomic spin-orbit interaction $\Delta_{s.o.}$ and a band formation term Δ_e where the latter is related to the degree of *d–d* interaction (number of like nearest neighbours: the higher the coordination number the larger the interaction) (28):

$$[4] \qquad \Delta = [\Delta_{s.o.}{}^2 + \Delta_e{}^2]^{1/2}$$

When the crystalline cluster becomes small, the number of surface atoms increases. For example, in a spherical Au cluster with a 17 nm diameter, the surface atoms constitute ~8% of the total atoms. The effect is a reduction in the coordination number of the Au atoms on average and a reduction in the doublet separation in the valence band.

Figure 4 shows the Au 4*f* core level and valence band of Au on a typical freshly prepared p-type PS substrate (Fig. 2*h*) relative to Au metal. It is interesting to note that two sets of Au 4*f* doublets appear, one at the same binding energy as that of Au metal (83.97 and 87.68 eV) and the other at several electronvolts higher binding energy. It turns out that the higher binding energy doublets are due to charging, indicating that a significant fraction of the nanocrystallites, most likely those of smaller sizes, are either becoming nonmetallic or are in poor electrical contact with the substrate. When a low-energy e-flood gun was used during XPS measurement, the charging peaks coalesce towards the higher binding energy side of the main Au peak (Fig. 5). This observation suggests that they can be attributed to smaller Au clusters since it is well known that the Au 4*f* binding energy increases as the crystallite size decreases (18, 19, 27). The Au valence band shows a similar behaviour where the *d* bands for the smaller clusters are shifted to higher binding energy. The observation of two sets of Au 4*f* peaks is common for Au on p-type PS depending on the preparation conditions (Au 4*f* for Fig. 2*a* exhibits a similar pattern). However, the higher binding energy doublet can be the sole component for samples at shorter deposition time (15 s) or with unusual dimensions (Fig. 2*i*). It is clear that the normal Au 4*f* peaks arise from the large aggregates near the micron pores where high densities of active sites (hydrides) are available for the redox reaction. The higher binding energy 4*f* peaks in Fig. 4 are attributed to the smaller clusters dispersed throughout the PS network in the near surface region. These results are in good accord with the SEM and XRD measurements.

Figure 5 shows a comparison of the Au 4*f* XPS for Au/p-type PS, Au/n-type PS, and Au metal. The effect of charging for Au/p-type PS (Fig. 4) has been removed with a low-energy electron flood gun. The high binding energy doublet seen in Fig. 4 now becomes a shoulder on the higher binding energy side of the main peaks. The broadening and the

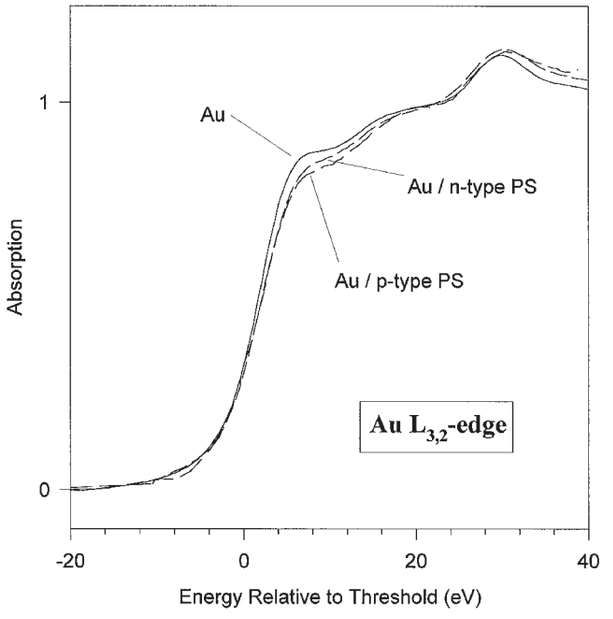

Fig. 9. Optical luminescence from ambient PS and Au deposited PS. The excitation energy of 100 eV corresponds to energy just above the PS Si $L_{3,2}$ threshold but below that of SiO_2.

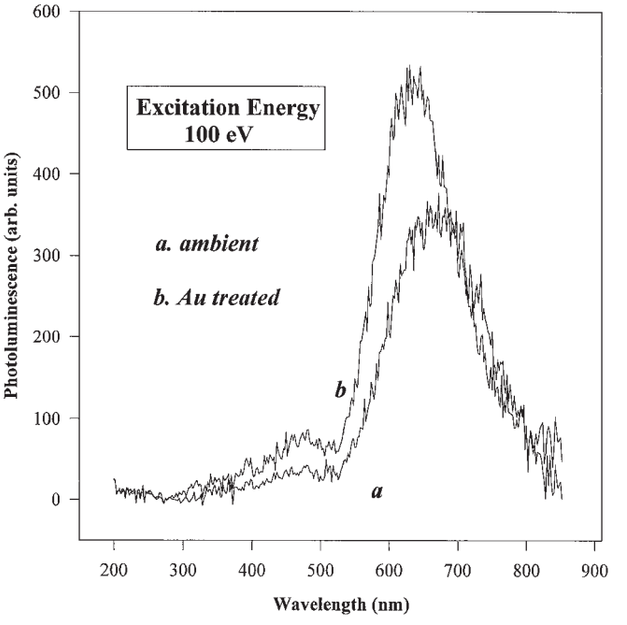

asymmetry of the peak confirms the presence of small clusters. It is interesting to note that although the effect of charging is quite common among samples of Au/p-type PS, it is hardly observed for Au/n-type PS where Au apparently wets the surface better. This is probably because Au on n-type PS tends to form more uniform films and the Au deposits are in good electrical contact with the substrate, as seen from the SEM results. This property is related to the electron-rich dopant, which possibly lowers the surface energy, and to the significantly smaller pore size and higher porosity (denser active sites) of the n-type based PS.

A comparison of the Au 4*f* linewidth is given in Fig. 6 for the 1 min deposition (Fig. 2*b*) and the strings (Fig. 2*i*) together with that of Au metal. The spectrum for the Au strings has been shifted by ~5 eV (charging) so that it aligns with that of Au metal. It is interesting to note that the Au 4*f* spectrum for the strings shows no sign of the normal Au 4*f* for large aggregates/clusters, indicating that no large clusters are formed on this surface and the Au strings are not in good electric contact with the substrate. The broadening/splitting of the Au 4*f* peaks in Au strings is due to differential charging and to a distribution of clusters with various sizes including those not readily revealed by the SEM. It is conceivable that some of the small deposits are sitting on top of an oxide layer formed after deposition and exposure to ambient air. This results in poor electrical contact. The broadening and asymmetry on the higher binding energy site of the Au 4*f* peaks of the 1 min sample again is characteristic of the presence of small clusters as described earlier (18, 19, 28).

The valence band spectra of several representative samples are shown in Fig. 7. All exhibit the characteristic Au 5*d* band. It should be noted that the Au 5*d* is the dominant signal because its photoemission cross section is significantly larger than the valence band of Si and the technique is surface sensitive. Several interesting features can be seen as the dimension of the Au deposits shrinks. First, the sharp rise of the top of the *d* band (~2 eV) in Au becomes much less steep in Au/PS as the coverage (deposition time) decreases. This behaviour is due to a reduction in coordination number and is typical of smaller cluster size as observed previously (18, 19). Second, the centre of gravity of the *d* band shifts to higher binding energy and associated with it is a slight broadening in the overall width. Since Au has the maximum coordination number of 12 in the metal and the *d*-band width is determined by the number of like nearest neighbours, it is impossible to have a Au *d* band of a cluster wider than that of the Au metal; we attribute this broadening to the overlapping of a distribution of clusters of different size, some of which exhibit a larger final state screening term, hence a higher binding energy shift of its centre of gravity despite a reduction in the doublet separation in an individual cluster (eq. [4]). The contribution of small-dimension Au deposits is also borne out in the shift of the quasi-$d_{3/2,5/2}$ peaks to higher binding energy, as previously observed (18, 19), and a negative surface atom core-level shift in Au.

The electronic structures of these Au deposits have also been investigated by X-ray Absorption Near Edge Structures (XANES). This technique measures the absorption coefficient above an absorption edge of an element in a chemical environment and permits the probing of the unoccupied densities of states just above the absorption edge. In the case of Au, the Au $L_{3,2}$-edge ($2p_{3/2,1/2}$) and $M_{3,2}$-edge ($3p_{3/2,1/2}$) are ideally suited for this investigation because we can probe the unoccupied *d* states above the Fermi level via dipole transition selection rules (29, 30). Although the *d* band in Au is nominally full, it has been shown that *d* and non-*d* (*sp*) rehybridization pushes some *d* character to above the Fermi level and the rehybridization of *d* and non-*d* electrons in Au

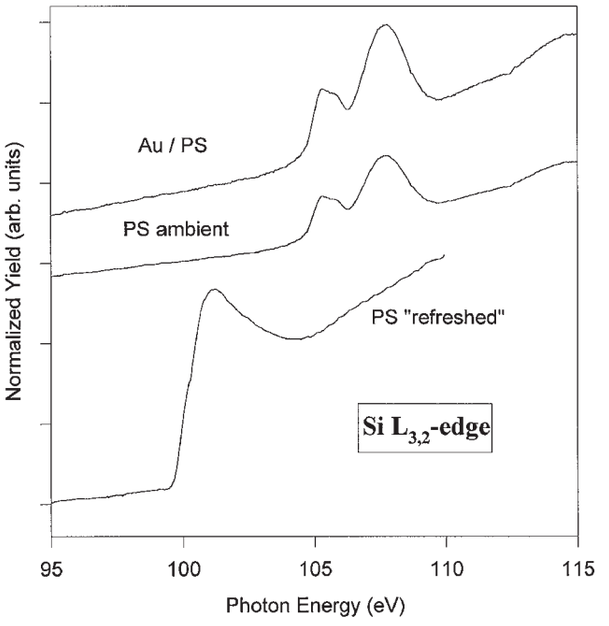
Fig. 10. Si L-edge absorption spectrum recorded in the total electron yield mode for the PS oxidized in air before and after Au deposition of which the luminescence spectra are shown in Fig. 9 together with an HF refreshed sample. Only surface oxide was detected for the ambient PS and Au/p-PS samples. After the surface oxide was removed with HF, the PS Si $L_{3,2}$-edge spectrum emerges.



has a significant and measurable effect in XPS and XANES on alloy formation (30, 31). In general, the first peak at the L_3 absorption edge is related to the unoccupied densities of *d* states associated with the absorbing atom in the materials of interest. A difference in intensity (area under the peak) reflects the change in densities of unoccupied *d* states above the Fermi level. All the resonance features above the threshold are characteristic of the extended local structure (several shells) of the absorbing atom. It has been shown with multiple scattering calculations that 5–6 shells of atoms are required for the cluster to reproduce a XANES spectrum similar to those of bulk metal (31). Thus XANES is a complimentary tool to XPS for the characterization of the structure and bonding of the specimen.

Figure 8 shows the Au $L_{3,2}$ XANES of representative Au/p-type PS and Au/n-type PS. Similar data have also been obtained at the $M_{3,2}$-edge (16). It is important to note that charging is not a problem in XANES measurements, therefore it will not induce any energy shift. From Fig. 8, we see that the Au metal spectrum exhibits a three-peak pattern within the first 40 eV above the threshold. These features are characteristic of transition and noble metals with an fcc structure except for the first peak for which the intensity varies dramatically depending on the number of *d* holes associated with the metal (30). It is evident from the spectra that Au deposits on PS have an fcc structure and generally exhibit a small but noticeable decrease in the intensity of the first peak above the edge (sometimes known as a whiteline). This indicates that, on average, small Au deposits (isolated clusters and aggregates alike) gain *d* charge (lose *d* hole count via rehybridization) relative to Au metal. This observation indicates that for small Au clusters supported on porous silicon, the *d–d* interaction is even stronger than in bulk metal. This would favour $s \rightarrow d$ rehybridization, reducing the *d* hole count. This observation is consistent with the slightly compressed lattice constant of the clusters on average as observed in XRD (Fig. 3).

We now explore further the implication of the *d* charge gain in Au clusters by considering a cluster as an intermediate between atoms and bulk metal. In transition metals in general, the electronic configuration in an atomic state is usually ns^2, $(n-1)d^m$ where *n* varies from 4 to 6 and *m* is the number of *d* electrons, which is nominally 9 for Au (31, 32). However, metals tend to adopt a configuration of ns^1, $(n-1)d^{m+1}$ or $6s^1$, $5d^{10}$ for Au. In addition, *s–d* rehybridization pushes a small amount of *d* character above the Fermi level yielding $ns^{1+\delta}$, $(n-1)d^{10-\delta}$ where δ is of the order of ~0.1 e. Thus one expects that as atoms assemble to become a cluster and then a bulk metal, the *d* configuration for Au clusters would be somewhere between d^9 and $d^{10-\delta}$. This notion, though in line with a higher binding energy Au 4*f* shift for the Au clusters due to the reduction of *d* count (*d* electrons screen the core better than the itinerant conduction electrons), does not take into account structural and surface effects and does not fit the observed XAS. Thus it is plausible that the XPS observation of higher binding energy shift for the Au clusters may be due largely to a final state effect complicated by a modified structure, surface effects, and charging. Besides, it is known that the surface atoms in Au metal exhibit a 4*f* shift to lower binding energy relative to that of the bulk (33). It appears then that although it is still useful to associate the XPS high binding energy shoulder with small Au clusters (~10 nm and smaller), as reported previously for Au clusters on graphite (18) and on pyrite (27), more work must be done on Au clusters to reveal the true origin of the shift in XPS and the behaviour of the whiteline in XAS.

The effect of Au deposition on the luminescence of porous silicon

Figure 9 shows the luminescence property of an ambient PS sample (p-type, 20 mA/cm^2, 20 min) before and after Au deposition. The Au deposit was made with 1 min deposition with $[AuCl_4]^-$, at a concentration of 1×10^{-3} M immediately after the PS was refreshed with HF. The sample was then stored in an atmospheric environment. It is obvious from Fig. 9 that Au deposition on PS enhances the luminescence intensity with the peak shifted slightly to the blue. In fact we notice visually that, in general, the luminescence becomes more uniform after reductive Au deposition. Note that the excitation energy is 100 eV, which corresponds to an energy just above the Si $L_{3,2}$ threshold. Thus absorption at this energy will enhance the luminescence from unoxidized porous silicon (see Fig. 10). The low-energy (longer wavelength) peak is due to luminescence from the "bulk" while the luminescence in the green (short wavelength) is from the Si – Si oxide surface/interface. These issues will be discussed elsewhere. The difference in the characteristics for the luminescence before and after Au deposition is likely due to subsequent oxidation of PS in the ambient and that the Au

© 1998 NRC Canada

aggregates are good light scatterers. Since Au deposition under these conditions is at least micrometres deep, the little Au mirrors will provide a more uniform luminescence. We have XAS evidence to suggest that Au deposition on p-type PS does not inhibit the oxidation of PS; in fact it facilitates the process. Figure 10 shows the Si L-edge of an ambient PS, a refreshed PS immediately after HF treatment, and the Au-deposited PS after being stored in air. In a total electron detection mode, the ambient and Au/PS samples show only SiO_2 signals, which are more intense for the Au/PS sample. The PS underneath cannot be revealed because of short electron escape depth for low-energy electrons. When the oxide is removed by HF, the spectrum of PS emerges. The oxidation of PS after Au deposition will result in smaller Si nodules and pillars, hence a blue shift in the luminescence.

Summary and conclusion

We have reported the preparation and characterization of a number of Au deposits on porous silicon. By varying the conditions in the reductive deposition technique, we have been able to prepare a variety of Au aggregates of the order of 10^2 nm and 10 nm dimensions on PS. This technique can be extended to study other metals. SEM and X-ray techniques reveal the morphology, structure, and electronic properties of these nanostructures. We show that both the chemistry and the nature of the substrate contribute to the morphology of the cluster. In turn, the ability to make clusters or aggregates of various dimensions will provide a useful testing ground for a study of the electronic property–structure relationship for materials of unusually small dimensions.

Photoinduced structural relaxation and densification in sol-gel-derived nanocomposite thin films: implications for integrated optics device fabrication

Kalaichelvi Saravanamuttu, Xin Min Du, S. Iraj Najafi, and Mark P. Andrews

Abstract: The solution sol-gel method is used to produce thin films of photosensitive hybrid organic–inorganic glass on silicon. Glasses consisted of photoinitiator, methacryloxypropyltrimethoxysilane, methacrylic acid, and zirconium oxide. Clear, low optical loss films are obtained, indicating nanophase homogeneity in the samples. The nanocomposite films are shown to be suitable for fabricating optical components such as ridge wave guides and Bragg diffraction gratings. The increase in the refractive index of the glass relative to the surrounding material during photolithographic processing is identified as a key material parameter in device fabrication. Accordingly, electronic and vibrational spectroscopy are used to provide insight into the structural changes that occur when glasses are irradiated with continuous narrow band 4.9 eV and pulsed 6.4 eV light. Arguments are advanced, linking the changes in refractive index to collateral densification leading to volume compaction of the silicate network during organic free-radical polymerization. This was shown by following the time evolution of relevant IR absorption bands. Free silanol and unreacted methoxysilane are consumed in the process. Matrix densification is indicated by shifts to low wave number in the transverse optical phonon mode associated with decreasing Si-O-Si bond angles of the antisymmetric stretching vibration (compression). Growth in the Si-O-Si framework is observed through increased intensity in this IR absorption. Similar behaviour is observed for films irradiated with 6.4 eV light from an excimer laser. A phase mask in combination with pulsed 6.4 eV light is used to inscribe a 1.5 mm, high-reflectivity polarization-independent Bragg grating into a ridge wave guide. The high reflectivity is thought to arise from a periodic modulation of the volume compaction of the matrix. Overall, the organic component of the glass confers unique properties on the material that allow it to be densified even with 4.9 eV light. By comparison, sol-gel silica with no organic component must be densified at nearly twice the photon energy.

Key words: sol-gel, wave guide, Bragg grating, photochemistry, densification, refractive index, photolithography.

Résumé : On a fait appel à la méthode de solution sol-gel pour produire des films minces de verres hybrides organiques–inorganiques sur silice photosensibles. Les verres sont formés d'un photoinitiateur, de méthacryloxypropyltriméthoxysilane, d'acide méthacrylique et d'oxyde de zirconium. On obtient des films clairs donnant de faibles pertes optiques qui indiquent l'homogénéité de la nanophase des échantillons. On a démontré que les films nanocomposites sont appropriés pour la fabrication de composantes optiques, telles que des guides à moulure et des réseaux de diffraction de Bragg. On a mis en évidence que l'augmentation de l'indice de réfraction du verre par rapport à celle du matériel avoisinant au cours du processus de photolithographie correspond au paramètre matériel clé pour la fabrication de l'appareil. En conséquence, on a utilisé les spectroscopies électronique et vibrationnelle pour obtenir des données relatives aux changements de structure qui se produisent lorsqu'on irradie des verres avec une bande de lumière étroite continue de 4,9 eV et pulsée de 6,4 eV. On apporte des arguments permettant de relier les changements d'indices de réfraction avec la densification collatérale conduisant à une compaction du réseau de silicate au cours de la polymérisation organique par radicaux libres. On a fait cette démonstration en suivant l'évolution, en fonction du temps, des bandes appropriées d'absorption IR. Le silanol libre et le méthoxysilane qui n'a pas réagi sont consommés dans ce processus. La densification de la matrice est mise en évidence par des déplacements vers les faibles nombres d'onde dans le mode de phonon optique transversal associé avec une diminution des angles de liaison Si-O-Si de la vibration d'élongation antisymétrique (compression). On observe une croissance du réseau Si-O-Si par le biais d'une augmentation de l'intensité de cette absorption IR. On a observé un comportement similaire avec les films

irradiés avec une lumière de 6,4 eV provenant d'un laser excimère. On fait appel à un masque de phase en combinaison avec la lumière pulsée de 6,4 eV pour inscrire, dans un guide d'onde à moulure, un réseau de diffraction de Bragg de 1,5 mm, de réflectivité élevée et indépendant de la polarisation. On croit que la réflectivité élevée provient d'une modulation périodique de la compaction du volume de la matrice. Dans l'ensemble, la composante organique du verre confère des propriétés uniques au matériel qui lui permettent de se densifier, même avec de la lumière de 4,9 eV. Par comparaison, il est nécessaire d'utiliser une énergie photonique double pour densifier la silice sol-gel ne comportant pas de composante organique.

Mots clés : gel-sol, guide d'onde, réseau de diffraction de Bragg, photochimie, densification, indice de réfraction, photolithographie.

[Traduit par la Rédaction]

Introduction

Photonics is concerned with optical input–output processes mediated primarily by light, rather than electrons. The chemistry of photonic materials is concerned among other things with articulating the molecular point of view on how matter acquires its suite of functional optical properties. In photonics, these properties include spatial confinement of the electromagnetic field, birefringence, photorefraction, nonlocal effects, Kerr and cascaded nonlinear responses. In turn, these properties are of significant technological and scientific interest (1, 2), which is incentive to understand how to control bulk optical properties at the molecular level. The properties of micro-optical components like silica glass wave guides and Bragg gratings are manifestations of their ramifying molecular networks. The refractive index of silica-based glasses plays a key role in defining the boundary conditions for light propagation in integrated optics components, devices, and circuits (2–7). Accordingly, the refractive index emerges as a fundamental device performance material parameter. In this regard, network relaxations that lead to densification of glass are important because the local microstructural rearrangements are often accompanied by increases in the refractive index that can be useful for fabricating optical devices. Douay et al. (8) have cogently argued this point.

Inorganic glasses can be densified not only by thermal sintering, but also by irradiation with electron beams (9–15), neutrons (16–18), ions (19), X-rays (11), γ-rays (11–16), or ultra-violet (UV) light (12, 20–23). UV-induced densification has also been studied for its relevance to optical damage in silicate glasses (20), where it has been observed that two-photon events induce elastic and inelastic densification of the structural framework. While most studies have focused on glasses derived from more or less traditional methods of high-temperature processing, a low-temperature route to glasses is attracting adherents (24). It is well known that inorganic glasses can be prepared near room temperature by solution sol-gel processing. This method can produce very pure materials by acid- or base-catalyzed hydrolysis and polycondensation of main-group and transition-metal alkoxides. A high-temperature postconsolidation step is usually required to collapse the pore structure of the gel-phase material. Reductions in porosity (internal surface area) in this case are driven by gradients in curvature. Viscous flow, surface diffusion, and evaporation–condensation usually conjoin to reduce the surface area that leads to densification in thin films (25).

High-temperature densification is a drawback if the glass must be deposited onto substrates that would be damaged above 500°C. Some effort has therefore gone into identifying methods to lower the postprocess densification temperature so that gel films might be deposited onto more fragile substrates like organic polymers, or semiconductor integrated circuits. To some extent, densification at lower temperatures can be achieved by photons having energies greater than the band gap of the oxide (though this approach is problematic for photosensitive semiconductors and organic compounds). For example, Imai et al. (22) examined the structural changes induced when sol-gel-derived silica was exposed to 9–18 eV vacuum UV (VUV) radiation. Compaction and dehydration of SiO_2 occurred to an extent similar to what was observed when gel films were sintered at 1000°C. The authors suggested that bond cleavage–formation pathways, and light-enhanced polycondensation steps were responsible for consumption of silanol Si-OH species leading to densification of the sol-gel glass (22). The findings of Imai et al. are significant for the present study. In the research described below we propose a different mechanism based on UV-light-initiated free-radical polymerization of an acrylate monomer and collateral work densification in a hybrid organic–inorganic silica glass.

In general, sol-gel processing of silica glass has been far less attractive as a route to integrated optics structures because high-temperature consolidation also carries the disadvantage of compressive interfacial stresses that cause cracking and optical-device failure. More significant perhaps is the fact that high-temperature glass integrated optics is excluded from the opportunities created by organic chemistry; and this means the exciting advances in organic small molecule and polymer optical nonlinearities. A hybrid sol-gel glass, with an appetite for both organic and inorganic phases, can rationalize the attractive features of both material regimes.

As an alternative to high-temperature gel-phase densification, we have been exploring organically modified low-temperature sol-gel glass fabrics to prepare micro-optical components and devices, including wave guides (1, 26), directional couplers (27, 28), beam splitters, and high-reflectivity Bragg gratings on ridge wave guides (2, 3, 7, 29, 30). The introduction of organic character into the silicate network offers exciting potential for the new materials field of hybrid glasses for photonics (2). This potential has been discussed elsewhere by the authors (2, 3). Our materials belong to the category of glasses, variously known as "ormocers," "ormosils," "ceramers," "polycerams," or simply hybrid sol-gel glasses (HSGGs) (31, 32). These are usu-

© 1998 NRC Canada

ally formed by acid- or base-catalyzed reactions of mixtures of organosiloxanes with tetrafunctional silicon alkoxides. The covalently bonded organic group does not normally undergo hydrolysis, and so imparts organic character to the composite. The properties of HSGGs can therefore be varied at the molecular level between those of the parent organic polymer, and those of the homogeneous inorganic glass. This is accomplished by introducing the organic component as a pendant, bridging, or polymerizable group. The latter can be polymerized sequentially or simultaneously with polycondensation of the inorganic component to provide a mutually interpenetrating network. A principal advantage of a hybrid glass is that it admits elaborate molecular-level control over macroscopic expressions of physical and chemical properties that are important for photonic devices. This gives the device designer an attractive generic silica-based medium (i.e., refractive index matched to optical fibre) that allows rapid prototyping of devices and assessment of material reliability. On the other hand, complex permutations of compositional and processing variables demand that researchers understand molecular ultrastructure and correlations with intended optical and physical properties. To this end, we have undertaken a series of spectroscopic studies to formulate a picture of how changes in the organic and inorganic network of one particular HSGG can be used to advantage to design and fabricate functional photonic devices. The ability of the HSGG material to accommodate industry standard photolithographic techniques was considered at the outset to be essential to our device agenda. Methacryloxypropyltrimethoxysilane (MAPTMS) and methacrylic acid were therefore selected as the photopolymerizable components in our glasses. Choice of the trifunctional R-$Si(OCH_3)_3$ is significant for the present work because R-group substitution at silicon reduces glass network connectivity and mechanical stiffness. Reduction in the mechanical stiffness of the network promotes capillary stress-induced collapse of the gel network during drying. This is reflected in enhanced relaxation rates and lower densification temperatures for the glasses. Choice of the vinyl ester functionality was also motivated by the large literature that has accumulated on acrylate photochemistry and photolithographic applications (33).

For acrylate hybrid glasses, UV light intervenes at the molecular level to modify the structure of the overall network, hence the refractive index, in ways that are not trivially related to radical polymerization of the organic monomer component alone. Increases in the refractive index appear to be linked both to volume compaction due to organic chain growth, and to the simultaneous onset of local relaxations and chemical condensation of siloxy species in the metastable silica network. The following is an account of our understanding of these events to date.

Experimental

Preparation of sol-gel-derived Zr HSGG

A hybrid organosilicate glass was prepared from 10:4:4 molar ratios of methacryloxypropyltrimethoxysilane:zirconium(IV)-*n*-propoxide ($Zr(OC_3H_7)_4$):methacrylic acid (MAA). Zirconium was selected as a second network former in our materials to increase mechanical stability and raise the refractive index of the composite sufficiently for waveguiding. Its careful hydrolysis in the presence of methacrylic acid is required to ensure that ZrO_2 particle diameters do not exceed 40 nm (34) and that the ZrO_2 phase is dispersed homogeneously. Methacrylic acid is therefore added to the system to regulate the hydrolysis of the zirconium alkoxide by complexation. Finally, the hydrolysis and condensation of the Zr/MAA complex is carried out in the presence of prehydrolyzed MAPTMS to avoid undesired precipitation of ZrO_2.

Accordingly, partial hydrolysis and polycondensation of MAPTMS was initiated with 0.75 equiv. of acidified H_2O (HCl, 0.05 M). Hydrolyzed zirconium propoxide was dispersed as the oxide into the host glass by addition as the MAA:$Zr(OC_3H_7)_4$ (1:1 molar ratio) complex. Hydrolysis and condensation of the remaining silicon alkoxide functionalities and the zirconium propoxide were resumed with the remaining equivalent of H_2O. A photoinitiator (1-hydroxycyclohexyl-1-phenylketone, IRGACURE-184, CIBA Geigy) was then added to the solution. The free-flowing sol was finally passed through a 0.2 μm filter before storage in the dark.

Instrumentation

A Headway photoresist spinner (EC101D & PM101D series) was used for depositing thin films. Low-energy photolyses were conducted with a mercury–xenon arc lamp having a maximum output at 4.9 eV. A 193 nm ArF excimer laser (model AQX-150, MPB Technologies) gave 60 mJ/cm^2 pulses (12–15 ns pulse width) at a repetition rate of 30 Hz for the higher energy photolysis studies. A deep UV, narrow band light illumination system and mask aligner (500 W mercury–xenon arc lamp, Oriel 87000 series, 14 W cm^{-2}) were used for photolithography. Bragg gratings were produced from the 193 nm output of the ArF laser. The gratings were written through a phase mask to give maximum reflectivity at 1.55 μm. Infrared spectra were acquired over a range of 400–5000 cm^{-1} with a Bruker IFS-48 Fourier transform infrared spectrometer. A Hewlett Packard 8452A diode array spectrophotometer was used to collect electronic absorption spectra over the range from 200 to 800 nm. GRAMS/32 software (version 4.01A, Galactic Industries, Salem, NH) was used for spectral data processing.

Preparation of films for electronic absorption spectroscopy

Thick films (5 μm) were cast onto fused silica plates (25 cm^2) by spin-coating at 3000 rpm for 40 s. Samples were dried at room temperature before being exposed to UV irradiation (2.5–5.0 eV) at a distance of 25 cm from the exit aperture of the light source. Irradiation times ranged from 0 to 60 min.

Preparation of thin films for Fourier transform infrared (FT-IR) spectroscopy

A homogeneous 5 μm film was spin-coated onto double-polished Si wafers (NOVA Electronic Materials, Texas). The film was dried at 100°C for 30 min. The wafer was then cleaved into 2 × 1 cm pieces before being irradiated. Three series of samples were prepared to cover various combinations of photon energy and irradiation times. These were as

© 1998 NRC Canada

follows: (*i*) 2.5–5.0 eV irradiation over a period of 0–60 min; (*ii*) 6.4 eV irradiation over a period of 15–300 s; (*iii*) 0.5 min of 2.5–5.0 eV irradiation followed by 6.4 eV irradiation over a period of 0–180 s. The 6.4 eV light was provided by the pulsed ArF laser having a fluence of 60 mJ/cm^2 at a 30 Hz repetition rate.

Ridge wave guide fabrication

Silicon wafer substrates with a thermally grown 2 μm thick SiO_2 layer were acquired from Nova Electronic Materials, Inc., Texas. Wafers were soaked consecutively in warm trichloroethylene, acetone, and isopropanol. They were then cleaned with distilled H_2O in an ultrasonic bath and dried under flowing N_2.

A 5 μm film of sol was spin-coated at 3000 rpm for 40 s on a 2 × 1 cm wafer fragment. The film was then dried in air at 100°C for 30 min to prevent the contact photomask from adhering to the gel film. A fused silica substrate photomask (QPS Technologies, Dorval, Que.) inscribed with an array of wave-guide openings was placed in direct contact with the film surface. The film was irradiated with 4.9 eV light from a distance of 25 cm. This corresponds to an intensity of 14 W cm^{-2}. Photolithographic elaboration of the ridge wave guides was completed by a wet-etching process described in detail elsewhere (30). In brief, the irradiated film was immersed in isopropanol to dissolve the unexposed gel regions of the film. The ridge wave guide was then heated at 120°C for 2 h.

Fabrication of Bragg gratings

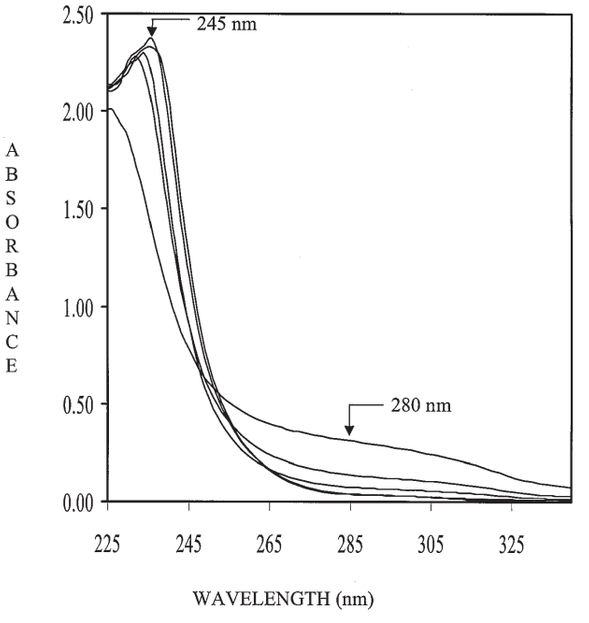
Bragg gratings of high reflectivity at 1.55 μm were photoinscribed in ridge wave guides by phase-mask processing (29). A phase mask is a binary three-dimensional quartz grating that is produced by reactive ion etching. The etch depth is optimized such that upon illumination from a UV source, light is diffracted equally into the plus/minus first orders, while energy deposited from the zero and higher orders is minimized. Interference from the diffracted first-order beams produces a near-field fringe pattern. The phase mask was provided by QPS Technologies (Dorval, Que.). The mask defined a period size (Λ) of 1055 nm, where the zero-order energy was suppressed to less than 1% for the 193 nm ArF laser line used to write the grating. The ridge wave guide was placed in direct contact with the phase mask and was aligned such that the wave-guide long axis was normal to the grooves of the mask surface relief grating. Samples were irradiated at distance of 90 cm from the exit port of the raw ArF excimer laser beam.

Results and discussion

Effects of 4. 9 eV radiation

Control experiments showed that the refractive index of the hybrid glass increased very slowly when photoinitiator was absent. The CIBA Irgacure-184 photoinitiator used in this work is in fact 1-hydroxycyclohexyl-1-phenylketone. When excited to its triplet state, the molecule undergoes α-cleavage to produce benzoyl and 1-hydroxycyclohexyl radicals. The benzoyl radical is primarily responsible for initiating polymerization of the methacryloxypropyl and methacrylic acid groups. Phan (35) has provided evidence that the 1-hydroxycyclohexyl radical also initiates acrylate chain growth.

Fig. 1. UV-vis absorption spectra of sol-gel-derived films irradiated with 4.9 eV UV light at 0, 5, 15, 30, and 60 min.



Electronic absorption spectroscopy of hybrid glass films

Figure 1 records the outcome of sequential irradiation of thin hybrid gel films over a period of 60 min. The spectral features are dominated by those belonging to the MAPTMS moiety, despite the presence of MAA and Zr(IV)propoxide in the starting materials. This was confirmed in separate experiments which showed that Zr(IV)propoxide is fully hydrolysed and that MAA is complexed with the resulting ZrO_2 (strong infrared absorption at 1550 cm^{-1}). The final products of the reaction between MAA and Zr(IV) contribute a weak absorption centred at 271 nm.

The spectrum of the film acquired prior to photolysis exhibits a prominent band peaking near 240 nm. In Mulliken notation, this transition is formally V ← N, and originates in the $\pi \rightarrow \pi^*$ excitation of the conjugated ester carbonyl of MAPTMS (36, 37). In the gel-phase host, this band is blue-shifted from its peak maximum of 282 nm for the MAPTMS molecule dissolved in dry isopropanol. A second high-energy $\pi \rightarrow \pi^*$ transition is observed at 214 nm. It too is blue-shifted from its position at 242 nm in MAPTMS–isopropanol. The localized $n \rightarrow \pi^*$ transition (i.e., Mulliken Q ← N) of the carbonyl substituent conjugated with the olefin occurs near 310 nm, but it is of very low intensity and is not visible on this scale. The $n \rightarrow \pi^*$ transition undergoes a hypsochromic shift of about 10 nm in the gel matrix relative to MAPTMS in isopropanol. The shift of the band to higher energy in the thin film suggests that the guest carbonyl is located in a more polar (hydrogen-bonding) environment, most likely containing water and silanol. In fact, this kind of behaviour for carbonyl compounds in activated silica has been noted elsewhere (38). The well known blue-shift in the $n \rightarrow \pi^*$ absorption band is the result of cooperative electro-

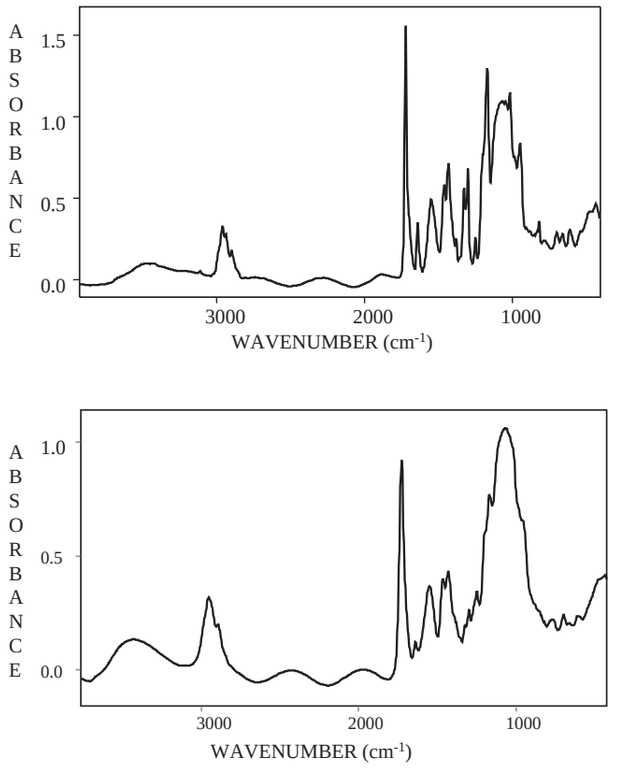
Fig. 2. FT-IR spectrum of an organically modified sol-gel thin film prior to photolysis (top) and after 25 min of photolysis (bottom).



static and hydrogen-bonding interactions with the solute propyl ester carbonyl group (39). Hydrogen bonding to the carbonyl expresses itself in infrared absorption by a shoulder at 1700 cm^{-1} adjacent to the 1722 cm^{-1} band belonging to the carbonyl stretching mode. This spectral feature is discussed later.

As the irradiation proceeded, the 240 nm band was gradually depleted, revealing an underlying absorption maximizing at 225 nm. Simultaneously, significant intensity developed at approximately 280 nm. The 280 nm band is too intense to be associated solely with the $n \rightarrow \pi^*$ transition of the carbonyl group of polymerized acrylate. Photolysis of polymer side-chain ester groups is widely documented (33), and it is well known that polyacrylates undergo main-chain and side-chain scission reactions, so that the 280 nm absorption probably contains contributions from ketone and aldehyde species, as noted elsewhere (40, 41). Further evidence of the polymerization process is presented in the following section.

Infrared spectroscopy

Photoinitiated polymerization of hybrid glass films

Infrared spectra of the gel film at various stages of photolysis are gathered in Figs. 2–5. Band assignments (42–47) are collected in Table 1. Figure 2 (bottom) emphasizes that 25 min of UV radiation causes significant changes in the vibrational spectrum, primarily in the transverse optical phonon ν_{as}(Si-O-Si) region centred at 1060 cm^{-1}. Overall, there is a substantial increase in intensity of the band. This

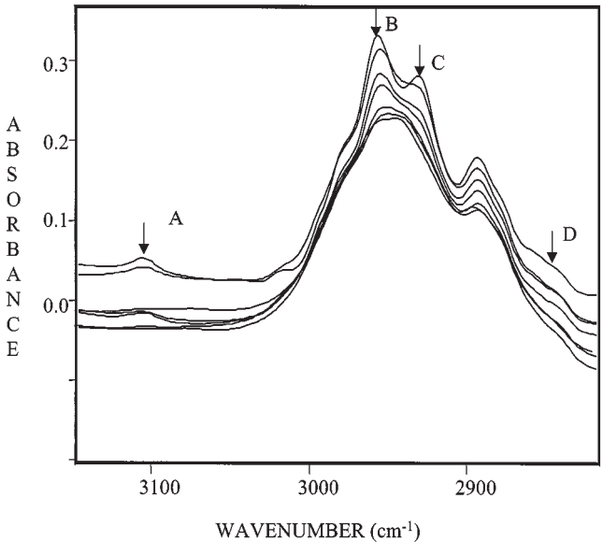
	C. Methoxy and silanol groups
472	δ_{as}(Si-O-C) of two or more -OCH_3 groups attached to Si
816	ν_s(Si-O-C) stretch
944	ν(Si-OH)
1168	-CH_3 rock of Si-OCH_3
2844	$\nu_s(CH_3)$ of Si-OCH_3
2960	ν_{as}(CH) of Si-OCH_3
3436	ν(OH) broad low band H-bonded molecular H_2O
3648	ν(OH) of hydrogen-bonded internal Si-OH

Fig. 5. Diminishing intensities of (*A*) $\nu_{as}(CH_2)$ of $=CH_2$ at 3100 cm^{-1}; (*B*) ν_{as}(CH) of Si-OCH_3 at 2960 cm^{-1}; (*C*) ν_s(CH) of $=CH_2$ at 2930 cm^{-1}; (*D*) $\nu_s(CH_3)$ of Si-OCH_3 at 2844 cm^{-1} at increasing periods of UV (4.9 eV) irradiation. Time of irradiation (min): 0, 0.5, 2, 5, 10, 15, 20, 25, 30, 35, 45, 60.



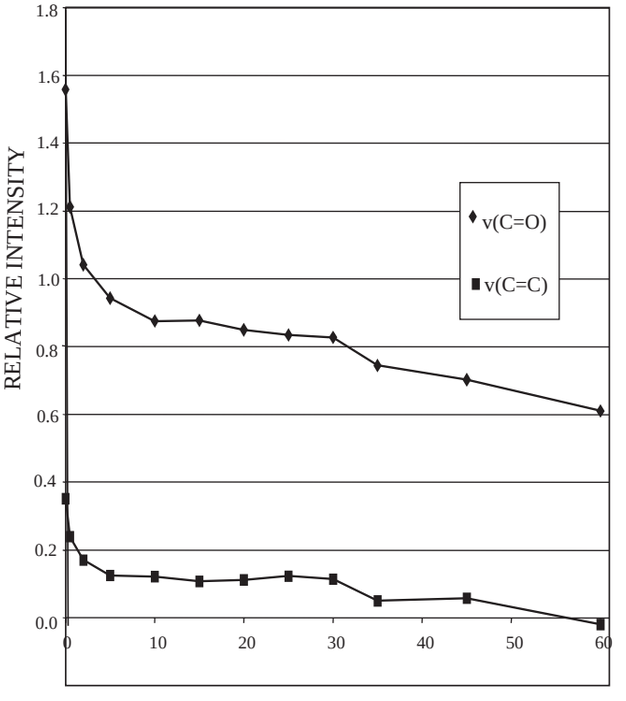
to silicon polymerize. The gross features of the spectrum are indistinguishable from those of poly(methylmethacrylate) in sol-gel-derived silica hosts (48). Additional changes in the spectra are evident in the loss of $\nu_{C=C}$ intensity at 1638 cm^{-1}, and a dimunition in contributions from the -CH_3 rocking mode (1168 cm^{-1}) of ≡Si-OCH_3.

Polymerization of the olefinic components was followed by monitoring the loss of intensity of appropriate bands in the mid-infrared region (Figs. 3–5). We focus in Fig. 3 on the vinyl group, ν(C=C) mode at 1638 cm^{-1}, the CH_2 wag, and *trans* (out-of-plane (oop)) C-H wag at 1012 and 980 cm^{-1}, respectively, and higher energy modes belonging to C-H symmetric (2930 cm^{-1}) and antisymmetric (3100 cm^{-1}) stretches. Consumption of the ν(C=C) 1638 cm^{-1} band (peak C, Fig. 3) is accompanied by a shift of the carbonyl ν(C=O) stretching mode from 1718 cm^{-1} (peak A in Fig. 3) to higher energy at 1724 cm^{-1}. The shift is typical for an ester carbonyl that is no longer conjugated with a vinyl substituent. Polymerization is indicated, since the two events are related through the isosbestic point. The shoulder at position B (1700 cm^{-1}) in Fig. 3 is evidence of hydrogen-bonded interactions between the carbonyl group and the host matrix (49–51).

The relative intensity of the acrylate ν(C=O) 1718 cm^{-1} and ν(C=C) 1638 cm^{-1} bands is plotted as a function of irradiation time in Fig. 6. Both curves show the same qualitative trends, with polymerization being most rapid within the first 10 min of irradiation. As described below, this time span coincides with the largest changes in the refractive index of the glass. This period of conversion would seem to involve acrylate groups that are sufficiently close to each other, since mass

© 1998 NRC Canada

Fig. 6. Intensity of ν(C=O) and ν(C=C) at 1718 cm^{-1} and 1638 cm^{-1}, respectively, vs. time of irradiation.



transport in the glassy host must surely be suppressed. After 10 min, the curves for these modes flatten out; there is no longer much change in the intensity of ν(C=O) and ν(C=C) bands beyond 20 min of irradiation. This effect is clearly kinetic in origin, since there can be little or no monomer diffusion in the highly crosslinked organosilicate film.

Figure 3 also indicates that additional photochemistry occurs at the longer irradiation times. This is indicated by the loss of the isosbestic point, the diminishing intensities of both the ν(C=O) and ν(C=C) bands, as well as a definite shift in the peak position of the ν(C=O) towards higher energy.

Structural changes related to increases in refractive indices

In previous publications (52, 53), we showed that low loss hybrid sol-gel glass channel wave guides for use in the key 1.55 μm telecommunications window could be deposited by UV photoinscription. Indeed, we have recently carried out an in-depth investigation of the effects of UV-light exposure on the evolution of the refractive index of hybrid glass wave guides (53, 54). This work included a systematic study of the effects of UV light on the increase in the refractive index, *n*, of MAPTMS/MAA/ZrO_2 film wave guides. For slab wave guides, increases in the refractive index were significant, as large as $\Delta n = 0.006$. The greatest increases occurred within the first 10 min of irradiation. This time frame matches the early stage of rapid consumption of the vinyl groups traced by IR spectroscopy, as described above. There were no significant changes in the refractive index of films beyond 30 min of irradiation. This observation corresponds to the flat region of the curves in Fig. 6.

Our spectroscopic evidence suggests that the changes in *n* are coupled to microstructural transformations in the glass. Close examination of Figs. 3–5 reveals features of the matrix that indicate that the photoinduced radical polymerization indeed causes a cascade of chemical reactions and structural relaxations in the matrix. Observe in the figures that there is a significant amount of residual Si-OH and alkoxy (Si-OCH_3) groups present within the film prior to photolysis. The carriers of this information are indicated in section C of Table 1. Band assignments are given in the figure captions and marked by letters on the corresponding spectra. Hydrogen bonding between the acrylate carbonyl and acidic silanol groups is indicated in Fig. 3 by the shoulder located at approximately 1700 cm^{-1}, at slightly lower energy with respect to the major ν(C=O) peak (55). Hydrogen bonding between silanol and the carbonyl oxygen of PMMA is well established (55), and it has been argued elsewhere that such interactions may be essential to control phase separation to give transparent organosilicate composites that are homogeneous on a nanometer scale (nanocomposites) (55, 56). Figure 3 shows that these hydrogen-bonded interactions are disrupted when samples containing MAPTMS are irradiated with 4.9 eV photons. Moreover, as the monomer polymerizes, the silicate network is simultaneously elaborated through further hydrolysis and polycondensation; both silanol and methoxide are lost, and there is growth in the numbers of Si-O-Si linkages, as expressed in the Si-O-Si 1063 cm^{-1} band (see also Fig. 2, bottom). These events are indicated in Fig. 4 by reductions in intensity of Si-OCH_3 and Si-OH group bands located at positions A (CH_3 rock of Si-OCH_3, 1638 cm^{-1}), D (ν(Si-OH) 944 cm^{-1}), and E (ν(Si-O-C) at 816 cm^{-1}). The decrease in absorption of the 944 cm^{-1} peak of silanol indicates loss of hydroxyl groups upon irradiation; however, the effect cannot be due to excitation of the Si-OH hydroxyl because this requires 8 eV photons (22).

Figure 5 documents the condensation of ≡Si-OCH_3 by loss of methanol. This is evidenced through loss of intensity in the $\nu_s(CH_3)$ mode of Si-OCH_3 at 2844 cm^{-1} and its asymmetric mode partner $\nu_{as}(CH_3)$ at 2960 cm^{-1}. The tell-tale band for the methanol product was detected through its Raman vibration at ~1100 cm^{-1} (mixed ν_a(C-O) + δ(COH)). This datum was obtained by launching 514.5 nm TE polarized laser light into the slab wave guide of the hybrid glass supported in a custom-built precision integrated optics spectrometer equipped with a fast imaging spectrograph and charge coupled device detector (57). The spectral data were acquired in real-time while the film was irradiated with UV light. This strategy allowed us to capture the spectrum of the methanol before the molecule diffused out of the film. Detailed results of the Raman experiments will be reported in a forthcoming publication.[2]

From the above account, we can speculate on the origin of the increase in the refractive index of this type of hybrid glass. The film is clearly metastable with respect to further polycondensation of the silicate network, and polymerization

Fig. 7. Changes in the ν(C=O) and ν(C=C) bands in thin-film hybrid glass upon ArF (6.4 eV) laser irradiation. Time of irradiation (30 Hz @ 20 mJ/cm^2): 15, 20, 60, 300 s.

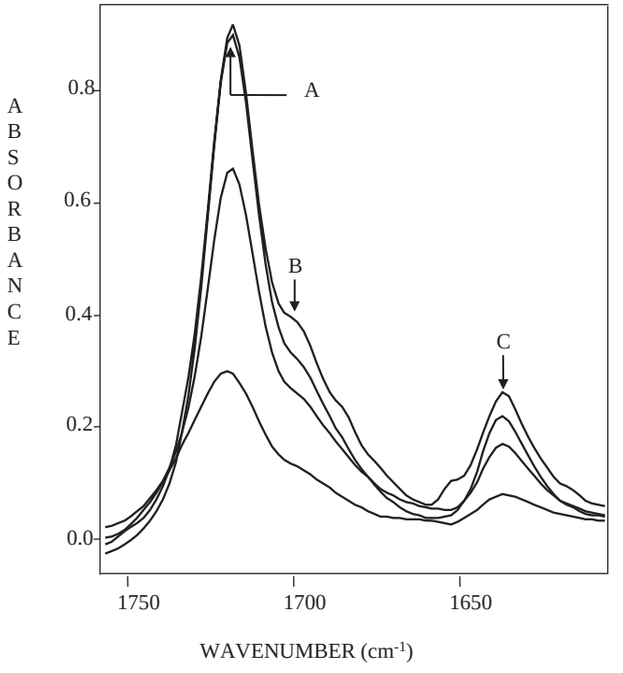

Fig. 8. Changes in the spectral features of thin films upon 6.4 eV irradiation. The line is a guide to the shifting of ν_{as}(Si-O-Si) from 1090 to 1048 cm^{-1}. The arrows mark the spectrum prior to photolysis.

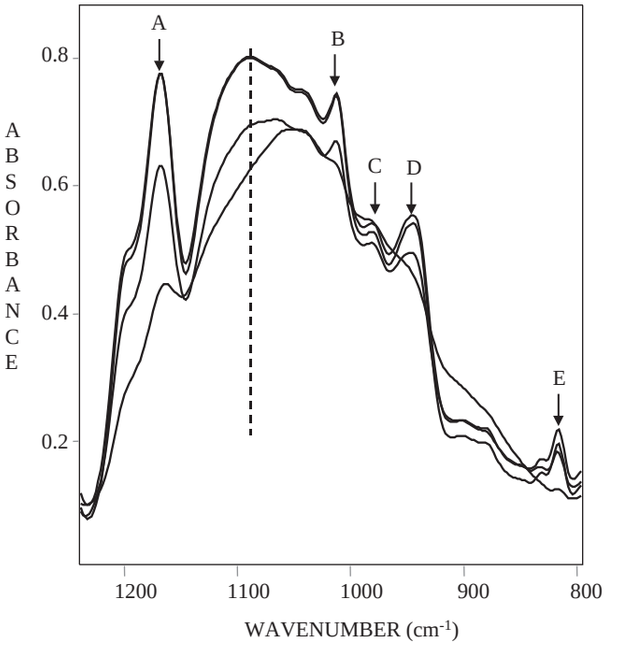

of the inorganic framework continues in concert with radical polymerization of the acrylate moieties. We suggest that a form of "photoinduced sintering" takes place in the thin film. In this view, volume compaction is initiated by molecular rearrangements associated with vinyl substituent free-radical formation, propagation and cross-linking. The latter is a standard way of increasing both the density and refractive index of polymer materials, where density and refractive index are linearly correlated (58). Network contraction during polymerization of the acrylate is caused by conversion of nonbonded distances between monomers to shorter bonding distances in polymers (59).

Volume compaction as a result of densification in this manner shows up in the Si-O-Si bond angle as an important local structural variable. In our case, UV irradiation leads to densification of hybrid glass films that is accompanied by a loss of hydroxyl groups in a manner that superficially resembles high-temperature annealing. A notable difference is that heat treatment of silica at 1000°C shifts the position of the SiO_2 ω_4-transverse optical phonon mode (60) to 1080 cm^{-1} (61). In our films this mode is peaked at 1060 cm^{-1}, with a slight shift to lower wave number after photolysis. The position of this stretching mode depends primarily on the average Si-O-Si bond angle, $\theta_{Si\text{-}O\text{-}Si}$. The decrease in energy of the peak position in our case is caused by a decrease in $\theta_{Si\text{-}O\text{-}Si}$. This band is also broadened by a distribution in the Si-O-Si angles. A shift in the IR band to lower frequency has been noted for silica films thermally grown on silicon (62). The shift to lower energy in the vibrational peak corresponded to increasing biaxial compressive stress in the thin film. In fact, increases in fictive temperature, hydrostatic pressure, or compressive stress, all cause $\theta_{Si\text{-}O\text{-}Si}$ to decrease, and the peak maximum of the TO mode to shift to lower wave number (63). We conclude that the 1060 cm^{-1} peak position for the TO phonon mode in the HSGG film also indicates an increase in density of the matrix.

In closing this section, we point out that the photoinduced densification process we have observed in the hybrid glass films is achieved at considerably lower energy than what is required to densify sol-gel-derived silica (64, 65). In the latter case, a high-energy photon (>8 eV) is involved in direct electronic excitation either of Si-OH and (or) to the conduction band of SiO_2. Bond rupture to create defects, and reassembly in the course of nonradiative decay of self-trapped excitons, could then lead to permanent atomic displacements consistent with network restructuring in SiO_2, densification, and an increase in refractive index. In contrast, the principal role of the photon in the *hybrid* glass is to decompose the photoinitiator, which in turn generates vinyl monomer free radicals. We surmise that the polymerization step precipitates the chemical and skeletal changes in the glass that are responsible for the increase in the refractive index.

Effect of 6.4 eV ArF excimer laser radiation

Bragg gratings are key building blocks of integrated optic devices (66). They are used in distributed feedback lasers, in optical-fibre amplifiers for gain flattening, and in wavelength division multiplexing. Bragg gratings can be used as mirrors to transmit light in free-space or wave guide interconnects between optical planes of photonic integrated circuits, and they have significant potential as sensing elements. Glass optical-fibre Bragg gratings have seen explosive development since the discovery (67) that periodic refractive index modulations can be written by the mutual

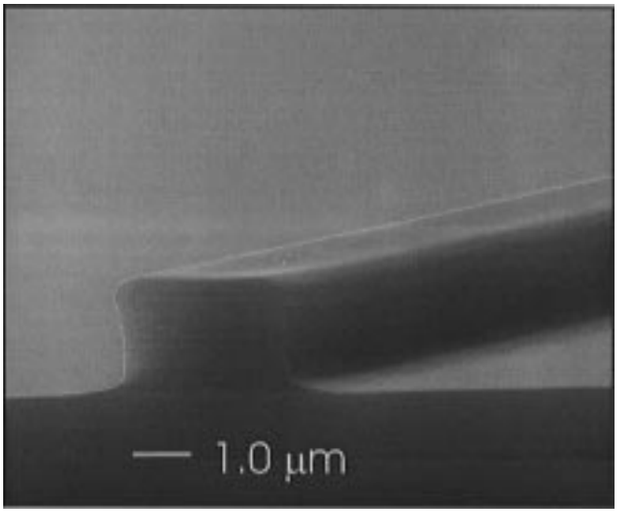

Fig. 10. Scanning electron micrograph of Bragg grating on hybrid sol-gel glass ridge wave guide. The grating is 6 μm wide by 1.5 mm long. Grating was produced by pulsed 193 nm (ArF) irradiation through a phase mask in 60 s.

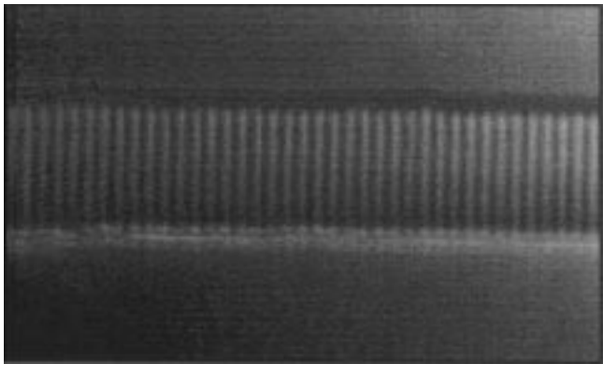
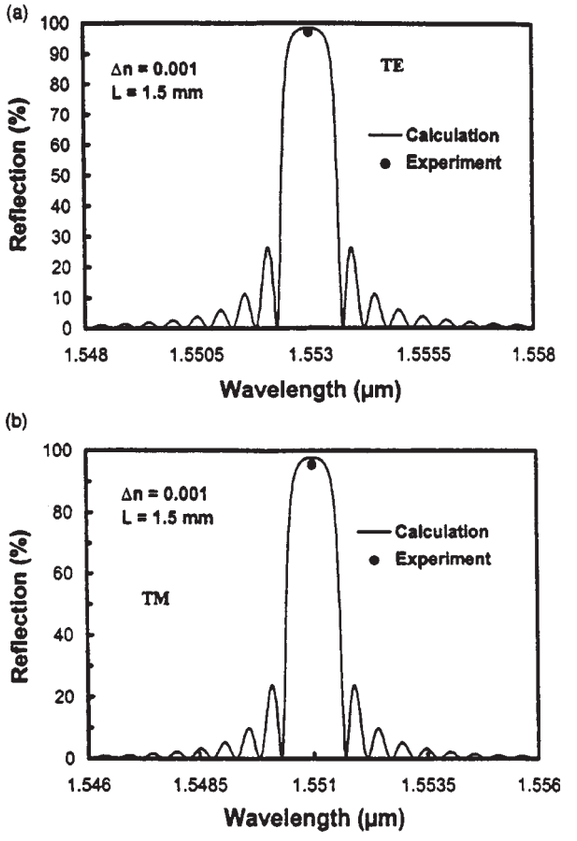


interference of counter-propagating laser beams, or by optical phase-mask technologies. It is the UV response of optical fibre that has stimulated so much recent activity into the research and technology of the photoresponse of glass (8, 68–72). The origin of the isotropic index changes in optical fibers is not still not fully understood, but it is clear that several light-activated mechanisms are involved (8, 73–77), and light-induced densification figures prominently among them (8, 78). Unfortunately, the UV-induced refractive index change in glass fibre is too small to be of practical use for making "photonic chips" the optical analogs of microelectronic integrated circuits. Among other things, this is because fibre gratings must typically be ≥1.5 cm to achieve 100% reflectivity. Recently, we reported a breakthrough in Bragg grating technology by depositing a 1.5 mm structure in a hybrid glass ridge wave guide. The grating is a factor of 10 smaller than state-of-the-art fibre gratings, and achieves

Fig. 11. Measure and calculated reflection spectra of a ridge wave guide with 6.4 eV light imprinted grating (cf. Fig. 10) for (*a*) TE and (*b*) TM modes. (Figure reproduced from ref. 54 by permission of The Society of Photo-Optical Instrumentation Engineers.)



nearly 100% reflectivity, independent of polarization. Given the importance of the Bragg grating as a micro-optical element, we chose to compare the effects of 4.9 eV irradiation with those of 6.4 eV irradiation from the ArF laser.

We observed that pulsed 6.4 eV light polymerized the acrylate component of the hybrid glass within a few seconds. Changes in the electronic absorption spectra (not shown) were indistinguishable from those caused by 4.9 eV photons, except that the changes occurred in a matter of seconds. Polymerization is confirmed in Fig. 7 by the infrared spectra acquired from the thin films exposed to 6.4 eV light for various times. There is loss of ν(C=C) intensity at 1638 cm^{-1}, while the ν(C=O) mode shifts from 1718 to 1720 cm^{-1} as conjugation with the vinyl group is relieved. The accompanying silica network polycondensation reactions are also recorded in the diminishing intensities of the Si-OCH_3 and Si-OH bands (see Fig. 8). Note that the film was not exposed to 4.9 eV light at any stage of this experiment. Figure 8 shows that the ν_{as}(Si-O-Si) stretch shifts from 1090 to 1048 cm^{-1} and broadens. By comparison, only a small shift was recorded for films irradiated with the lower energy UV lamp alone. In all other respects, the spectra show the same trends elicited by radiation from the 4.9 eV

light source. This implies that matrix densification is triggered by the ArF laser as well.

Role of photosensitivity in Bragg grating fabrication

The fabrication of ridge wave guides equipped with Bragg gratings is a multistep process that includes two different UV-radiation interventions. The wave guide is first defined as a channel by narrow band 4.9 eV UV illumination through a photomask. A propanol wet-etch step is then used to remove hybrid glass from regions of the silicon wafer not exposed to the light source. Smooth-walled rectangular prism ridge wave guides exhibiting low 0.1 dB/cm loss at 1.55 μm are produced by limiting the UV exposure time to 30 s. A scanning electron micrograph of a typical ridge wave guide is shown in Fig. 9. A Bragg grating was inscribed as a volume element by generating a plus/minus first-order 6.4 eV interference pattern in the target ridge wave guide by excimer laser illumination through a precision phase mask. The 193 nm light from an ArF laser was used to deposit the grating in the wave guide in 60 s. A scanning electron micrograph of a grating is shown in Fig. 10. The structure is 6 μm wide × 2.5 μm high and has a step refractive-index profile at 1.55 μm of 0.0585. The wave guide and grating were evaluated with an Er-doped fibre laser by measuring the reflectivity of light coupled to the fundamental mode. A polarization splitter separated the TE and TM states. The TE mode gave a reflection peak at 1.553 μm and a reflectivity of 97%. At 1.551 μm, the TM mode showed 95% reflectivity. Vectoral coupled mode theory (54) was used to simulate the reflectivity of the grating for TE and TM polarization states. Figure 11 illustrates that the theoretical and experimental values for the TE (98.4%) and TM (97%) modes agree at the peak maxima. Elsewhere (79), we have obtained agreement between the measured and predicted values over the entire wavelength range.

Because the ridge wave guide/Bragg grating construction is made with two different UV energies, we chose to simulate the procedure by irradiating a hybrid glass film on thermal oxide-on-silicon substrates under the same conditions used to make the Bragg device. The response of the hybrid glass to this radiation sequence was then monitored by infrared spectroscopy. Spectra of thin gel films exposed to 0.5 min of 4.9 eV radiation, followed by periods of 6.4 eV radiation were acquired (Figs. 12 and 13).

Spectrum (*b*) in Fig. 12 was acquired after 30 s of UV radiation from the 4.9 eV source. The film was not exposed to radiation from the excimer laser. The curve reveals, as expected, that the initial phase of irradiation to define the channel guide through the photomask stimulates radical polymerization in the matrix. Spectra (*c–g*) record the outcome of successive treatments with the ArF laser. Polymerization is indicated by the gradual loss of intensity in the 1638 cm^{-1} ν(C=C) band (position C). Clearly, the conversion of vinyl substituents occurs much more rapidly (within 3 min) under the 6.4 eV source. Comparison of Figs. 3, 7, and 12 shows that the ν(C=O) stretch near 1722 cm^{-1} undergoes the same qualitative shift to higher wave number, regardless of the photon energy or sequence of irradiation. There is no clear isosbestic point in either of Figs. 7 or 12. This suggests that 6.4 eV photons open up additional photochemical channels in the hybrid glass. Indeed, the same results are obtained when the 1-hydroxycyclohexyl-1-phenylketone photoinitiator is omitted from the glass composition. By comparing Figs. 4 and 13 (*c–g*) we confirm that polymerization of the methacryloxypropyl groups at 193 nm

© 1998 NRC Canada

elicits the same kind of activity from the silicon network: there is simultaneous polycondensation of residual silanol and alkoxy groups. These events are indicated in Fig. 13 by reductions in intensity of Si-OCH_3 and Si-OH group bands (labeled A through E) in the same manner as discussed above for ~5 eV radiation.

The TE–TM polarization insensitivity of the Bragg grating, and the very high reflectivity of the diffraction element, prove that the refractive index modulation in the ridge wave guide is a volume grating in which the refractive index is periodically modulated. Scanning electron microscopy reveals that there is also a small surface corrugation on top of the ridge guide. This is certainly evident in the optical micrograph in Fig. 10 as well. The surface texture on the wave guide might be caused by laser ablation; but we have observed elsewhere (52) that direct photoinscription of channel wave guides in hybrid glass films caused material to swell out of the plane of the film. Atomic force microscopy (79) revealed topographical relief features on the order of 40 nm. Interestingly, there is evidence (80) that swelling is somewhat suppressed when a wave guide is photoinscribed through an photoinert sol-gel overlayer into a photosensitive underlayer. Shrinkage based on oligomer cross-linking in photocurable polymer systems is well understood (81). In contrast, expansion of our photolysed sol-gel films in a direction roughly normal to the film surface is unusual when considered in a simple picture of constrained densification (82). In this view, when a densified region of glass flanked by undensified glass is allowed to relax, the densified region develops tensile stress. This tensile zone will be bounded by compressive stress in the undensified region. Densification should be greatest nearest the surface of the glass where there is least constraint, with the result that the bounding glass should pull outward on the densified glass, and a depression should appear where the sample has been irradiated through the mask. This is contrary to what we observe. On the other hand, swelling in photopolymer films has been used to define relief features (83). In this case, diffusion of monomer to the illuminated region accounts for the creation of microrelief structures due to swelling normal to the surface of the film. It is difficult to argue that mass transport in our films occurs on the scale observed in photopolymer systems. Nevertheless, given the photoinduced structural reorganization of the gel matrix, we cannot eliminate the possibility that swelling may be linked to larger scale motions of monomer whose movements show up in surface microrelief.

It is tempting to attribute the refractive index modulation in the grating to densification of the hybrid glass, although additional experiments must be performed at 6.4 eV to evaluate this notion. The mechanism of Bragg grating formation in our samples is a subject for further inquiry. The change in the refractive index of an isotropic substance undergoing densification can be associated with a change in the number of oscillators per unit volume, anisotropy in the Lorentz–Lorenz polarization under stress, and variations in atomic polarizibilities with interatomic distance. Through compaction, a fractional increase in the refractive index may be viewed as the product of reorganization of existing bond structure coupled with bond formation. This is what we have argued in this paper. But there can also be contributions to the refractive index through the products of bond scission and defect formation. Schenker (20) has reported that two 6.4 eV photons densify fused silica. He concludes, nevertheless, that there is no compelling evidence that bond rupture or defect formation is associated with densification. Although defect formation is possible in our hybrid glass composites, we believe that, should they exist, their contributions to the refractive index are small compared with the collateral densification that we observe. Future studies in this laboratory will clarify the role that 193 nm light plays in the evolution of our high-reflectivity gratings.

Conclusions

New insight was provided into how integrated optics devices like ridge wave guides and Bragg gratings are inscribed by photolithography in acrylate-rich hybrid sol-gel silica glass films on silicon substrates. Arguments were advanced linking the changes in the refractive index of the composites to chemical transformations and structural relaxation leading to densification. Electronic absorption spectroscopy indicated that the acrylate species underwent polymerization when irradiated with 4.9 eV photons. Prolonged irradiation appeared to lead to secondary photochemistry that may involve polymer chain scission. Infrared spectroscopy confirmed that photoinitiated polymerization occurs in the glass. Scrutiny of the time evolution of the IR absorption bands indicated that free-radical polymerization was accompanied by additional simultaneous polycondensation in the silica matrix. Free silanol and unreacted methoxysilane were consumed in the process. Matrix densification was indicated by shifts in the transverse optical phonon mode associated with decreases in the Si-O-Si bond angle of the antisymmetric stretching vibration. Substantial growth in the Si-O-Si framework was observed through increased intensity in this IR absorption. Similar behaviour was observed for films irradiated with 6.4 eV light from an excimer laser. A phase mask in combination with pulsed 6.4 eV light was used to write a 1.5 mm, polarization-independent high-reflectivity Bragg grating into a ridge wave guide. The high reflectivity was rationalized by postulating a periodic modulation of the volume compaction of the matrix. Overall, the organic component of the glass conferred unique properties on the material that allowed it to be densified even with 4.9 eV light. By comparison, sol-gel silica with no organic component must be densified at nearly twice the photon energy.

Acknowledgments

We gratefully acknowledge support for this research through research grants from the Natural Sciences and Engineering Research Council of Canada and the National Research Council of Canada. We thank Jean-Francois Nadeau (QPS Technologies) for instruction in the operation of the ArF laser.

Vibrational spectra and structure of tris(8-hydroxyquinoline)aluminum(III)

Mathew D. Halls and Ricardo Aroca

Abstract: The vibrational spectra of one of the most commonly used light-emitting materials for organic electroluminescence (EL) devices, tris(8-hydroxyquinoline)aluminum (Alq_3), is presented. The geometry and normal modes of *fac*-Alq_3 isomer in the ground state have been computed for the first time using ab initio methods (HF/6-31G*) to aid in discussion of normal-mode assignment. Normal inelastic scattering excited at 633 nm and low-temperature FT-Raman in addition to the infrared spectra of this material are reported. The vibrational characterization of thin solid films of the material was attempted using transmission and reflection–absorption FT-IR spectroscopy (RAIRS) on smooth silver films.

Key words: tris(8-hydroxyquinoline)aluminum, Alq_3, ab initio, assignments, infrared, Raman, thin films.

Résumé : On a déterminé le spectre de vibration du tris(8-hydroxyquinoléine)aluminium (Alq_3), l'un des produits les plus couramment utilisés comme émetteur de lumière dans des appareils d'électroluminescence (EL) organique. Utilisant des méthodes ab initio (HF/6-31G*) comme aide dans la discussion de l'attribution du mode normal, on a calculé pour la première fois la géométrie et les modes normaux de l'isomère *fac*-Alq_3 dans son état fondamental. En plus de son spectre infrarouge, on a aussi observé une diffusion inélastique normale excitée à 633 nm ainsi que le spectre Raman « FT » à basse température de ce produit. On a tenté de faire une caractérisation vibrationnelle de films solides minces de ce produit en faisant appel à la spectroscopie de transmission et de réflexion infrarouge FT (« RAIRS ») de films d'argent lisses.

Mots clés : tris(8-hydroxyquinoléine)aluminium, Alq_3, attributions ab initio, infrarouge, Raman, films minces.

[Traduit par la Rédaction]

Introduction

The properties of a class of organic materials, polymers, and metal complexes are being intensively investigated in relation to light-emitting diodes. Organic electroluminescent (EL) devices are light-emitting diodes in which the active components consist entirely of organic materials (1–3). Organic EL devices are one of the most promising next generation flat panel display systems. In the fabrication of these devices organic materials are incorporated as vacuum-deposited thin solid films. The research and development of the EL devices requires in situ characterization of the organic material in order to understand aging and other variables related to device performance. One of the objectives of the current work is to provide the reference vibrational spectra as well as the interpretation of the thin solid film spectra for these materials. One of the key materials, commonly used in quinolate organic heterojunction light emitting devices, is the electron-transporting aluminum complex tris(8-hydroxyquinoline)aluminum (Alq_3) (2, 3). The present report discusses structural and vibrational properties of Alq_3. Aided by ab initio computations, the interpretation of normal modes observed in FT-Raman spectra, at room and liquid nitrogen temperatures, and in the infrared spectra of Alq_3 in KBr matrices and thin solid films is given. The photophysics and exciton dynamics in thin solid films of Alq_3 have been recently studied (4, 5). The electronic spectroscopy of Alq_3 films has also been reported by Hopkins et al. (6). Ultraviolet photoemission spectroscopy and semiempirical molecular orbital calculations have been used to investigate the electronic structure of Alq_3 (7). Methods for the fabrication of Alq_3 films have also been discussed in the literature (8). However, the complete vibrational analysis of Alq_3 has not been reported and there are no ab initio calculations published on this molecular system. There are reports on certain aspects of the vibrational spectra of Alq_3. The infrared spectrum in the 600–250 cm^{-1} region (9) was studied to identify the isomers of Alq_3: three infrared bands at 466, 455, and 444 cm^{-1} were associated with the C_{2v} isomer, while bands at 418 and 402 cm^{-1} were assigned to the C_{3v} isomer. The SERS (Surface Enhanced Raman Spectra) of Alq_3 films on silver is the only report on the Raman spectrum of Alq_3.[2]

The interpretation of vibrational spectra collected for large molecules can be difficult due to the high density of states resulting in spectral complexity and congestion, particularly in the spectral region below 1600 cm^{-1}. In recent years, in order to complement experimental data and assist in the assignment of vibrational spectra, it has become standard to perform ab initio computations at the Hartree–Fock (HF) level to obtain normal frequencies, atomic displacement representations, and spectral intensities. The present-day application of electronic structure methods to predict vibrational properties for reasonably large molecular systems (50–100 atoms) is due to both the availability of analytic HF second derivatives since the 1980s (10) and the dramatic progress in computer technology.

Caution should be exercised when comparing calculations for molecules in gas phase and experimental data obtained for molecules in solid phase. There are several factors that could lead to considerable differences between computed and observed spectra. The computed frequencies are for the ab initio harmonic potential and the spectral intensities are computed in the double harmonic approximation (11). Also the dipole-moment derivatives and polarizability derivatives are those for the isolated molecular system. In the solid there may be a change in the shape and intensity of the vibrational bands, and each nondegenerate vibrational energy level of the free molecule in a crystal splits into as many components as there are molecules in primitive unit cell (Davydov splitting) (12). Finally, both external vibrations and internal vibrations may be observed experimentally. The comparison between the unperturbed (calculated) and the perturbed molecule is approximately valid as long as the molecular identity is retained in the solid phase.

Experimental

A sample of the purified material was provided by Dr. J. Duff of the Xerox Research Centre of Canada. The main reference in the infrared spectra is the transmission spectrum of the isotropically dispersed Alq_3 in KBr. Infrared spectra were recorded in the region of 400–4000 cm^{-1} on the Bomem DA3 FT-IR spectrometer with 1 cm^{-1} resolution. The reflection absorption infrared spectra were recorded on an in-house modified Bomem 110-E equipped with a Judson midrange (650 cm^{-1}) 1 × 1 mm MCT detector. The substrate holder consisted of a flat aluminum heating element, which was thermally controlled by a 100 V variastat. The temperature of the substrate was monitored using a thermocouple. Annealing of the sample during the RAIRS measurements was performed in situ on the heating plate.

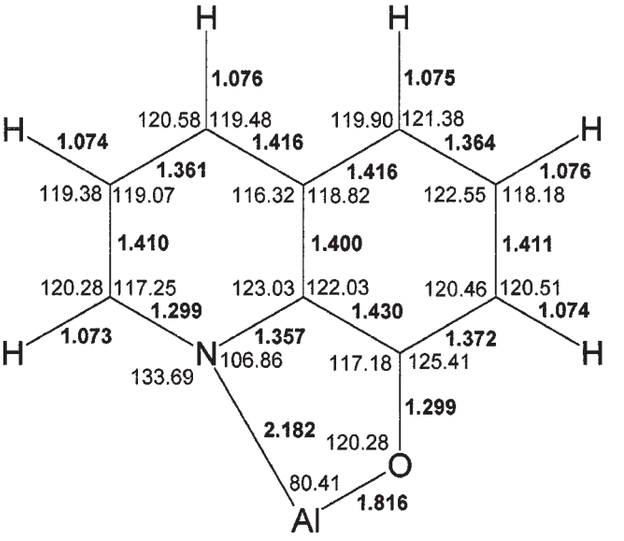
The FT-Raman spectrum of Alq_3 was recorded with a Bruker RFS100. A Nd:YAG laser (1064 nm with 60 mW at sample location) was used as the excitation source, and the spectra were collected with a 2 cm^{-1} resolution at liquid nitrogen temperature. The Raman spectra were also recorded at room temperature with 2 cm^{-1} resolution using the 633 nm laser line in a Renishaw System 2000.

Computational

Calculations were carried out at the MNDO (13) and Hartree–Fock levels of theory. Hartree–Fock calculations were performed using the standard split-valence basis set augmented with a single set of polarization functions on heavy atoms (6-31G*) (14). Computations consisted of geometry optimization followed by a subsequent harmonic frequency calculation at the same level of theory. The calculations were carried out using Gaussian 94 RevD.3 (15) running on a Cray J90 computer, requesting two processors and 381 MB of dynamic memory with total running time of 3.6 days.

Experience using HF/6-31G* to predict ground-state molecular properties is quite extensive. It is well known that ab initio computed frequencies are typically larger than the observed fundamentals. This overestimation is due to the neglect of electron correlation, basis-set truncation, and neglect of anharmonicity (16). To compensate overestimation, various scaling strategies are employed to bring the computed harmonic frequencies into better agreement with observed fundamentals (17). In the present work the simplest strategy is employed, that of homogeneous frequency scaling, using the empirical scaling factor (0.8953) determined by Scott and Radom (18). The vibrational assignments reported in this work were made using a combination of atomic displacement vector analysis, visual interpretation of normal modes, intensity pattern, and frequency matching as well as using previously reported assignments of related molecules.

Fig. 1. Computed geometric parameters for the 8-hydroxyquinoline aluminum unit at the HF/6-31G* level. Bond lengths are in boldface, interatomic angles are in regular face. The predicted quinoline ring geometry is planar.



Results and discussion

Molecular structure

The geometry of Alq_3 was calculated without symmetry constraints (C_1). Subsequent frequency calculations verified these results to be true energy minima, yielding only positive harmonic frequencies. A preliminary geometry optimization was performed using the semiempirical method MNDO for comparison with the higher level of theory. Structural parameters are shown in Fig. 1. Good agreement was found between the predicted geometries of MNDO and HF/6-31G*. Both methods predict a planar geometry for the

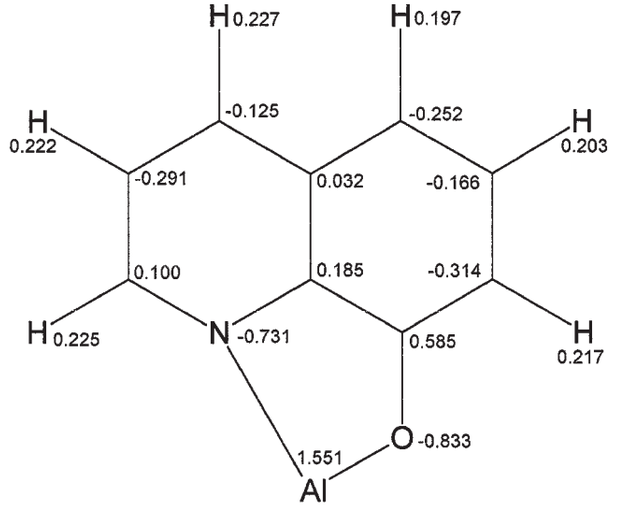
Fig. 2. Computed Mulliken atomic charges for the the 8-hydroxyquinoline aluminum unit at the HF/6-31G* level. Overall predicted dipole moment is 9.369 Debye.



quinolate ligand with negligible deviations. The oxine ligands make improper torsion angles of 13.48° and 16.22° with each other, measured with respect to the central C—C bond at the MNDO and HF levels. N-Al-N and O-Al-O bond angles are predicted to be 88.15° and 101.50°, respectively, at the MNDO level and 87.76° and 100.69° at the HF/6-31G* level.

To the best of our knowledge a detailed analysis of the crystal structure of Alq_3 has not been reported to date. In thin films Alq_3 is believed to form amorphous, monomeric films (6, 8). Several reports have been published of the crystal and molecular structures of other metalo-quinolates. Comparison between the HF/6-31G* Alq_3 geometry and reported experimental structures for Cuq_2 (19) and Znq_2 (20) show that the geometry of the quinolate ligand is largely insensitive to metal substitutions. It is reported that in both Mq_2 complexes the ligand was planar within experimental error, with the quinolate geometry having identical dimensions, although the metal centres have different electronic configurations (20). The calculations reported here support this trend of quinolate geometry conservation with Alq_3.

Frontier orbitals and charge

Atomic charges are important in considering infrared intensities, molecular packing in crystals, and are useful in molecular dynamics simulations. The most popular scheme for partitioning atomic charges is the Mulliken scheme. The Mulliken charges are shown in Fig. 2. The overall permanent dipole moment computed at the HF/6-31G* level is 9.369 Debye for the *fac*-Alq_3 isomer.

The computed highest occupied and lowest unoccupied molecular orbital energies are presented in Table 1. Frontier orbital energies for electroluminescent materials, such as Alq_3, are important in determining operating voltages and efficiency of thin film devices, since they determine barriers to carrier injection as well as emission characteristics. Numerous reports of experimental determinations of the ionization potential and frontier orbital energies by UPS and optical spectroscopies have appeared in the literature (6, 7, 21). These reports are in agreement in assigning a HOMO energy of 6.65 eV, and an ionization potential of 5.93 eV. The Hartree–Fock calculations in this work predicted a HOMO energy of 7.34 eV in good agreement with the experimental data. Analysis of the electronic structure obtained from high-level quantum chemical calculations for organic EL materials is needed to elucidate structure–property relationships and to rationalize the mobility of carriers over the molecular structure. The detailed electronic structure of Alq_3 in its neutral and ionic state will be described elsewhere.[3]

Vibrational spectra

Low frequency and M-L vibrations

The calculated Raman spectrum at HF/6-31G* level of theory is presented in Fig. 3 and can be compared with the FT-Raman spectrum of the solid at liquid nitrogen temperature. There is generally good agreement for the relative intensities of different group frequencies. The strongest Raman bands are in the 1300–1600 cm^{-1} region and correspond to the ring-stretching vibrations. The low wave number region recorded at liquid nitrogen and room temperatures is illustrated in the inset in Fig. 3. Three strong bands are observed in the low-temperature Raman spectrum at 71, 98, and 120 cm^{-1}. Two weaker bands are seen at 154 and 167 cm^{-1}. The lowest observed vibrational mode for 8-hydroxyquinoline is at 162 cm^{-1} (22) and an ab initio at HF/6-31G* level of theory gives the lowest calculated wave

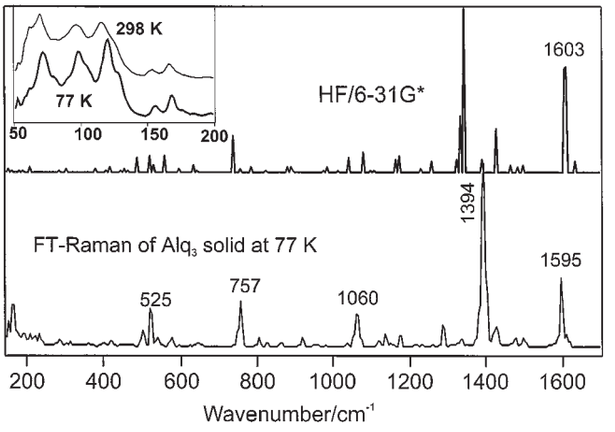
Fig. 3. Calculated Raman spectrum and FT-Raman spectrum of Alq_3. Inset contains the low spectral region recorded at two different temperatures.



number at 165 cm^{-1}. Therefore, the bands at 154 and 167 cm^{-1} are confidently assigned to ring-wagging modes of the 8-hydroxyquinoline ligands. A far-infrared spectrum recorded with the Bruker (model 113) vacuum bench FT-IR instrument gives two bands with wave numbers in the low region at 123 and 111 cm^{-1}. The FT-Raman at room temperature shows a broad band with a maximum at 117 cm^{-1} and a shoulder at 124 cm^{-1}. The calculated spectra predicts two bands at 117 cm^{-1}. It seems reasonable to assign the low-temperature band at 120 cm^{-1} to the Al–oxine deformation + Al–N stretching. The infrared band at 111 cm^{-1} is assigned to the Al–oxine deformation. The Raman band at 98 cm^{-1} in the low-temperature spectrum (broad-band centre at 97 cm^{-1} in the room-temperature spectrum) is also assigned to an Al–oxine deformation mode. Less definitive is the assignment of the lowest observed Raman band at 71 cm^{-1} (69 cm^{-1} at room temperature with a shoulder at 61 cm^{-1}). The shoulder is not observed at low temperature, and only the sharp peak at 71 cm^{-1} is seen as shown in Fig. 3. Therefore, the apparent shift could be due to less overlapping of the two bands, or to the fact that this particular mode could be an external vibration. We assumed that this band corresponds to an internal vibration.

The calculated infrared spectrum and the reflection–absorption infrared spectrum (RAIRS) of a thin solid film of Alq_3 are given in Fig. 4. It can be seen that there is good agreement between the general patterns of relative intensities. For completeness, a comparison between the FT-IR spectrum of the reference, Alq_3 dispersed in KBr, and the Raman spectrum of the powder are shown in Fig. 5. A discussion of the vibrational spectra of the ligand and references to some metallo-quinolates can be found in the report of Marchon et al. (22). Correlations of metal–oxygen vibrations in quinolate transition-metal complexes (Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cr^{2+}, Cr^{3+}, Fe^{3+}) have been collected and discussed by Shabaka et al. (23). The metal–oxygen vibration is observed with a strong relative infrared intensity in the spectral region from 487 cm^{-1} (Mn^{2+}) to 522 cm^{-1} for the Cr^{3+} complex. Similarly, the M–N stretching vibration in the complexes has been found in the 392–417 cm^{-1} infrared region. The AlO diatomic frequency is observed at 979 cm^{-1}, and the complex Al-O is expected at a lower value. The

scaled ab initio vibrational frequencies, spectral intensities, observed wave numbers, and vibrational assignments are given in Table 2. The first column has been included to indicate the accidental degeneracy (deg.) found due to characteristic frequencies of the quinoline moities. Characteristic wave numbers to be used in materials characterization applications appear in **bold** in Table 2. The units quoted for experimental integrated intensities are various. However, the unit recommended (SI) is km mol^{-1}. The calculated infrared intensities are given in km mol^{-1}. The common unit "dark" (cm $mmol^{-1}$) divided by 100 gives the intensity in km mol^{-1}. A very strong absorption band is on the order of 1000 km mol^{-1} (for example, the band at 1464 cm^{-1} has an intensity of 962 km mol^{-1}). A weak absorption band is in the order of 0.1 km mol^{-1}. The scattering coefficients are commonly given in $cm^4\ g^{-1}$ ($N \times 10^{-32}$). The calculated values are given in $Å^4$ amu^{-1} and the numerical values are identical. For instance, the scattering coefficients for the ν_1 (in CH_4) is 223 $\times 10^{-32} \times N$ ($cm^4\ g^{-1}$) = 223 $Å^4$ amu^{-1}.

Wave numbers of the oxine ligand

The $Al(C_9H_6NO)_3$ complex has 150 normal modes, and in order to discuss the vibrational spectrum, the quinolinato chelating-agent vibrations and the metal–oxygen vibrations are discussed separately. The chelating agent 8-quinolinol,

also known as 8-hydroxyquinoline or oxine (Ox) forms stable complexes with many metal cations (22).

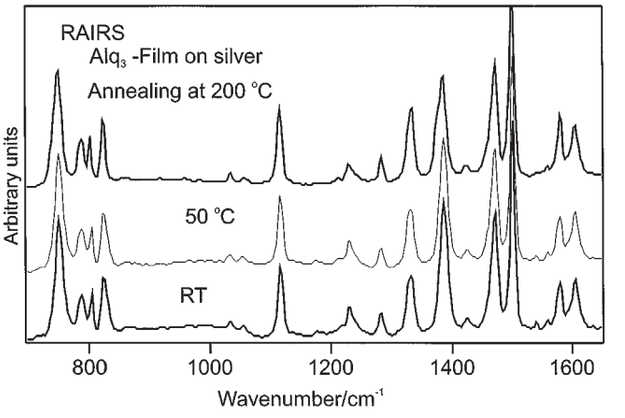
The six C–H stretching vibrations (18 internal modes) are observed in the infrared and Raman spectra forming a broad band produced by the overlapping of several components. The wave numbers reported in Table 2 correspond to the centre of the components obtained by fitting using Voigt profiles.

The oxine C–H out-of-plane bending modes are observed (22) with strong relative intensity at 742, 781, and 818 cm^{-1}. Similarly, there are three strong infrared bands in Alq_3 at 752, 789, and 825 cm^{-1}, in good agreement with the calculated spectrum, that are assigned to the C–H out-of-plane modes of the oxine moiety. The computations confirm the commonly observed fact that the C–H out-of-plane modes are strong only in the infrared spectrum. These frequencies are seen in Table 2 with an accidental degeneracy of 3, confirming their assignment as a characteristic frequency of oxine in Alq_3. The ring-breathing vibration of oxine is observed at 710 cm^{-1} with a strong Raman intensity. The calculated value for Alq_3 is 741 cm^{-1}, carrying large infrared and Raman intensities. The only strong Raman band in that region is seen at 757 cm^{-1} and is thereby assigned to the breathing mode of the oxine moiety.

Characteristic ring-stretching modes (shown in boldface in Table 2) are observed in reasonably good agreement with calculated values. The strongest Raman band in the Alq_3 spectrum is observed at 1394 cm^{-1}, in contrast to the oxine Raman spectrum (22) where three strong bands are present in this region at 1351, 1378, and 1435 cm^{-1}.

Vibrational wave numbers observed in the spectral region below 700 cm^{-1} correspond to modes that are highly coupled and their assignment is generic. The description given is from the computed spectrum. For practical applications the spectral region given in Fig. 3 is clearly the most appropriate, and the vibrational assignments for the observed wave numbers are reliable. It should be pointed out that from the low-temperature Raman spectra we could not extract conclusive information about external modes. At low temperature, band narrowing is observed; but the expected shift for external wave numbers is not evident in the observed wave numbers. The far-infrared spectrum at room temperature was also recorded, and the observed wave numbers are listed in Table 2.

Fig. 6. Reflection–absorption infrared spectra of an Alq_3 thin solid film formed by vacuum deposition onto smooth silver showing the effect of annealing.



Thin solid films

Thin solid films of 200 nm mass thickness of Alq_3 were prepared by vacuum evaporation onto KBr and smooth silver substrates. The transmission and RAIRS were recorded and compared with that of the KBr pellet (Fig. 5). All of the infrared spectra were identical. It is concluded that thin films of Alq_3 are completely amorphous. Usui et al. (8) found the same results for Alq_3 films formed using an ionization-

assisted deposition method. It is also important to establish the effect of temperature on film structure. The Alq_3 film on silver was annealed from room temperature to 200°C and monitored by collecting the RAIRS spectrum at intermediate temperatures. Figure 6 reproduces three spectra taken at room temperature, 50°C and 200°C. The spectral analysis indicates that there is no change in the film structure, and the absorbance values confirm the preservation of the integrity of the film within this range of temperature.

Conclusions

The Raman spectra of tris(8-hydroxyquinoline)aluminum recorded at room and liquid nitrogen temperatures complemented with FT-IR spectra are interpreted with the aid of a high-level ab initio calculation. The fundamental vibrational modes most suitable for materials characterization are established. Thin solid films of the Alq_3 material deposited by vacuum evaporation are amorphous and remain unchanged under thermal annealing up to 200°C.

Initial stages of cobalt-disilicide formation in mesotaxy

G.R. Carlow and M. Zinke-Allmang

Abstract: We present results on the formation of buried silicide layers at ion implantation doses in the range of 1–60% of the critical dose for formation of a uniform layer. We emphasize observations for the low-dose range of 1–5% where the precipitate density is quite dilute. The Co redistribution during post-implant annealing is measured using Rutherford backscattering techniques and secondary ion mass spectrometry. Experimental observations during post-implantation annealing at 1000°C involves (*i*) a contraction of the Co depth profile for all doses, (*ii*) shifting of the peak of the profile towards the bulk, and (*iii*) formation of a secondary Co peak near the surface. The secondary peak is only present in samples implanted to greater than 3% of the critical dose. The interpretation of the shift of the main peak and the occurrence of the secondary peak requires a model exceeding the standard ripening model used previously to describe mesotaxy. We suggest that more recent ripening-based concepts allow for a full description of these observations with a minimum of parameters, particularly not requiring interaction with the complex defect profiles formed initially during implantation. Essential for this model is a proper inclusion of precipitate–precipitate interactions and the role of diffusion screening.

Key words: silicide, Co implantation, mesotaxy, precipitate, ripening, screening.

Résumé : On a examiné l'effet, sur la formation de couche uniforme, de la formation de couches de siliciure enfouies à des implantations ioniques allant de 1 à 60% de la dose critique. On a particulièrement examiné les effets aux faibles doses allant de 1 à 5% alors que la densité du précipité est relativement diluée. On a utilisé la spectrométrie de masse des ions secondaires et des techniques de rétrodiffraction de Rutherford pour mesurer la redistribution du Co au cours de la recuisson suivant l'implantation. Les observations expérimentales faites au cours de la recuisson à 1000°C suivant l'implantation mettent en évidence: (*i*) une contraction du pic de profondeur du Co pour toutes les doses; (*ii*) un déplacement du maximum du profil vers la masse et (*iii*) la formation d'un pic secondaire près de la surface. Le pic secondaire n'est présent que dans les échantillons pour lesquels l'implantation est supérieure à 3% de la dose critique. L'interprétation du déplacement du pic principal et de la présence du pic secondaire nécessite l'utilisation d'un modèle plus important que le modèle de maturation utilisé antérieurement pour décrire la mésotaxie. On suggère l'utilisation du modèle de maturation proposé plus récemment qui est basé sur des concepts qui permettent une description complète de ces observations avec un minimum de paramètres qui ne nécessitent en particulier pas d'interaction avec les profils de défaut du complexe qui se forme initialement au cours de l'implantation. Pour ce modèle, il est essentiel d'inclure des interactions précipité–précipité correctes ainsi que le rôle d'effet d'écran de la diffusion.

Mots clés : siliciure, implantation de Co, mésotaxie, précipité, maturation, effet d'écran.

[Traduit par la Rédaction]

1. Introduction

Cobalt disilicide is one of the more promising metal silicides for use in the microelectronics industry due to its low resistivity, good thermal stability, and its good lattice match with silicon. A technique extensively studied for the formation of buried silicides in silicon is ion beam synthesis (IBS). IBS of silicides, termed "mesotaxy" (1), has been successful in achieving both high-quality buried silicide layers and silicon overlayers, although annealing temperatures above 1000°C are required, and such high temperatures are not compatible with existing Si processing in the microelectronics industry.

The standard mesotaxy process for $CoSi_2$ formation includes Co implantation into Si at about 350–400°C and results in a nominally Gaussian Co depth profile. During this step silicide precipitates nucleate in the Si matrix. The elevated temperature is beneficial, as it preserves the crystalline quality of the Si overlayer (2). Post-implantation annealing, requiring temperatures of typically 1000°C or greater, causes the Co depth profile to "collapse" from Gaussian to rectangular while forming a stoichiometric, crystalline, buried

$CoSi_2$ layer with commensurate interfaces to bulk silicon and capping layer. To achieve a continuous buried layer, a minimum implantation concentration of about 18% Co (i.e., a local stoichiometry of $Co_{0.18}Si$) is required at the peak of the as-implanted profile (3), and this requires a minimum, or critical implantation dose. This critical dose determines the thickness of the final buried layer. Just below the critical dose, pinholes result in an otherwise continuous layer while far below the critical dose, isolated $CoSi_2$ precipitates result (4).

The mesotaxy technique has been developed, following closely advances in the SIMOX technology. In SIMOX a buried insulating oxide layer is formed through IBS with an oxygen beam (5–8). Similarities of both techniques allow for better control of defect formation in the silicon matrix during mesotaxy (5) and provide a wide range of modelling efforts which can be adapted to cobalt IBS (9, 10). Of interest are particularly nonuniform structural developments, such as secondary peaks in the oxygen distribution (6). These have been associated with defect profiles in the earlier literature. However, the SIMOX layer is not crystalline, and thus strain and defect issues in both techniques may influence the morphological evolution differently.

Due to the complexity of the mesotaxial process, a complete description of the film formation process is still lacking. Reiss and Heinig (9) noted that at least five overlapping stages need to be addressed: (*i*) formation of supersaturation during implantation, (*ii*) nucleation through chemical compound formation of the implanted species and substrate atoms, (*iii*) precipitate growth at the expense of the supersaturation (possibly concurrent with continuous implantation), (*iv*) post-implantation growth of precipitates through Ostwald ripening, and (*v*) coalescence and percolation. These processes correspond to the basic stages of phase separation on surfaces for mass nonconserved systems (*i, ii, iii,* and *v*) and mass conserved systems (*iii* and *iv*) (11).

Several theoretical studies identified the ripening stage as most crucial in film formation (9, 10, 12). However, correlating the results of these studies with existing experimental data is not possible, since no single mechanism such as ripening occurs in isolation during mesotaxial formation of buried layers. The first objective of this study is to provide such experimental data. In the first section of this paper, a detailed study at dilute precipitate densities identifies specific features of the clustering process any model must reproduce.

In the second part a theoretical formulation is discussed. Starting with the well-known Ostwald ripening theory by Lifshitz and Slyozov (13, 14) a model is developed which is in agreement with the experimental data. We compare this model with computer simulations by Reiss and Heinig (9, 10) and a study by Trinkaus and Mantl (12). We show that a minimum model requires the inclusion of finite volume fraction effects of the precipitate phase (15, 16) and the screening length concept limiting dissolution of neighboring structures as proposed by Beenakker and Ross (17).

2. Ripening experiments during mesotaxy

A few experimental studies of the film formation stages of mesotaxy have been carried out by Co implantation to less than the critical dose (4, 18–20), where precipitate–precipitate distances remain sufficiently large so coalescence and percolation of precipitates do not dominate. At 10% of the critical dose (i.e., 1.8% Co peak concentration), collapse of the Co profile still occurs leading to isolated $CoSi_2$ precipitates. Concurrently the Co peak shifts toward the bulk region of the substrate with a possible smaller Co peak near the Si surface. The shifting of the main peak has not been reported for substrates implanted to the critical dose. In experiments where damage is intentionally introduced within the Co implant profile (by following the Co implant with low-temperature Si implantation) the collapse of the Co profile is centered around the damaged region (19). In has been suggested that the gettering of Co by defects is responsible for the shift of the peak towards the bulk where the end-of-range (EOR) damage caused by implantation is located. The small Co peak near the surface has received no attention.

In our study, *n*-type Si(100) wafers were implanted with 400 keV Co^+ to total doses of 15.0, 1.3, 1.0, 0.7, 0.55, and 0.30×10^{16} Co atoms/cm^2. The critical dose at 400 keV is about $2.4 \times 10^{17}/cm^2$ (3, 21), thus the implant doses represent approximately 60, 5, 4, 3, 2, and 1% of the critical dose, respectively. The samples were held at a temperature of 375°C and oriented 7° off the <100> axis during implantation to minimize channeling effects.[2] Post-implant annealing was done by rapid thermal processing in dry, flowing N_2. Samples were analyzed using Rutherford Backscattering Spectroscopy (RBS), using 3 MeV He^{++} with a backscattering angle of 170°, and Secondary Ion Mass Spectroscopy (SIMS).

Figure 1 shows the Co portion of a RBS spectrum for a sample implanted to 5% of the critical dose. The abscissa is labeled both by backscattering energy (bottom) and depth into the sample (top). Included are the Co profiles for the as-implanted sample and samples post-implant annealed at 1000°C for 1, 10, and 30 min. The as-implanted sample has a peak at a depth of about 280 nm and a full width at half maximum (FWHM) of about 270 nm. After annealing for 1 min (Fig. 1*a*), even at a lower Co dose than in earlier studies (19, 20), the Co profile narrows to a width of about 110 nm and increases in height by a factor of about 1.9 as compared to the as-implanted profile. In addition to this narrowing, the peak height position shifts about 100 nm towards the bulk, and a secondary "peak," or shoulder, forms near the surface at a depth of about 100 nm. Note that this peak does not rise above the as-implanted level. The shift of the main peak towards the bulk of the crystal is consistent with other studies (19, 20). Annealing for 10 and 30 min at 1000°C (Figs. 1*b* and *c*) results in a further small shift of the main peak towards the bulk and a slight broadening of the main peak, but very little change to the secondary peak.

The dose dependence of the Co depth profile for 1000°C annealing for 10 min is shown in Figs. 2*a–d* for the 5, 4, 3, and 1% doses, respectively. For comparison, the as-implanted profiles for each dose are shown. After annealing, the main peak for each dose narrows to about 110–150 nm and shifts about 100 nm towards the bulk, and the height of the main peak is about 1.7–2.0 times the as-implanted peak height. Note, in particular, that the secondary peak is not

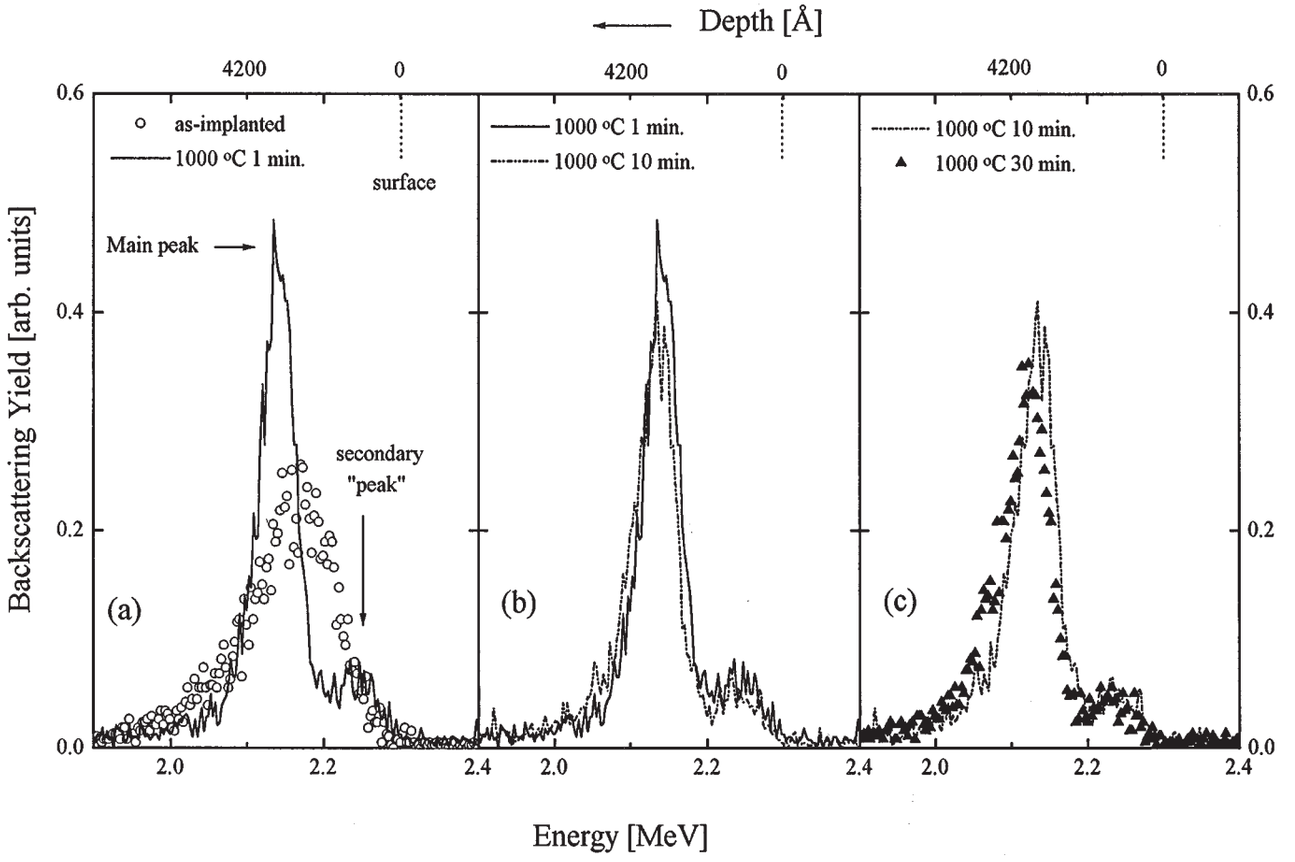
Fig. 1. Co portion of RBS spectra for a sample implanted to 5% of the critical dose. The spectra are plotted for the backscattering yield as a function of backscattering energy. Also shown is the equivalent depth using the stopping power of 25 eV/Å. (*a*) The as-implanted profile and the profile after annealing at 1000°C for 1 min. (*b*) The profiles after post-implant annealing at 1000°C for 1 and 10 min. (*c*) The profiles after post-implant annealing at 1000°C for 10 and 30 min. During annealing the main peak narrows and shifts towards the bulk.



visible for doses less than 3% of the critical dose. Due to the low RBS signal levels at these doses, this fact was verified using SIMS depth profiling. Figures 2*e* and *f* show the SIMS profiles for the 5 and 1% doses, respectively. These profiles are consistent with the profiles obtained by ion scattering (Figs. 2*a* and *d*).

Figure 3 shows the evolution of the Co profile during annealing at 1000°C for implantation to 60% of the critical dose. A shift of the main peak towards the bulk is not observed in agreement with studies at the critical dose (1, 2). However, the evolution of the profile is not symmetric about the as-implanted profile. Material accumulating in the main peak has predominantly come from the surface region of the as-implanted profile and the formation of a secondary peak, or tail, near the surface is evident after annealing for 1 min. This tail is not present after annealing for 10 min.

The details of the Co redistribution at 1000°C annealing are summarized in Table 1. Included for each dose are the main peak position relative to the surface, the main peak width (FWHM), the main peak height relative to the as-implanted peak height, and the secondary peak height. The profile for the higher dose samples tend to narrow and reach the maximum main peak height quicker than the lower dose samples. Also, once the main peak has narrowed, it subsequently tends to broaden and decrease in height with further annealing. During this broadening, the total amount of Co in the main and secondary peaks remained constant; indicating that no significant amounts of Co were diffusing away from these features deeper into the bulk of the crystal.

A secondary peak does occur in the lower dose samples, but is only detectable when annealing at lower temperatures. Figure 4*a* shows the profile for a 1% dose sample annealed at 850°C for 20 s; conditions for which a secondary peak is visible. This peak however, occurs at a depth of about 170 nm from the surface and is nearer the main peak as compared to the higher dose samples (such as the 5% dose shown in Fig. 1). Further annealing at 900°C for 20 s results in the decomposition of this peak (Fig. 4*b*).

Thus, we have established for Co depth profile redistribution during annealing for the doses in the range 1–5% of the critical dose: (*i*) the main peak initially increases in height by about a factor of 1.7–2.0 and narrows from about 270 nm to a minimum of about 110 nm. Once the main peak has reached its maximum height and corresponding minimum width, further annealing results in the main peak broadening and decreasing in height (see Table 1); (*ii*) the main peak shifts about 100 nm toward the bulk for samples; (*iii*) with 1000°C annealing the secondary peak near the surface does

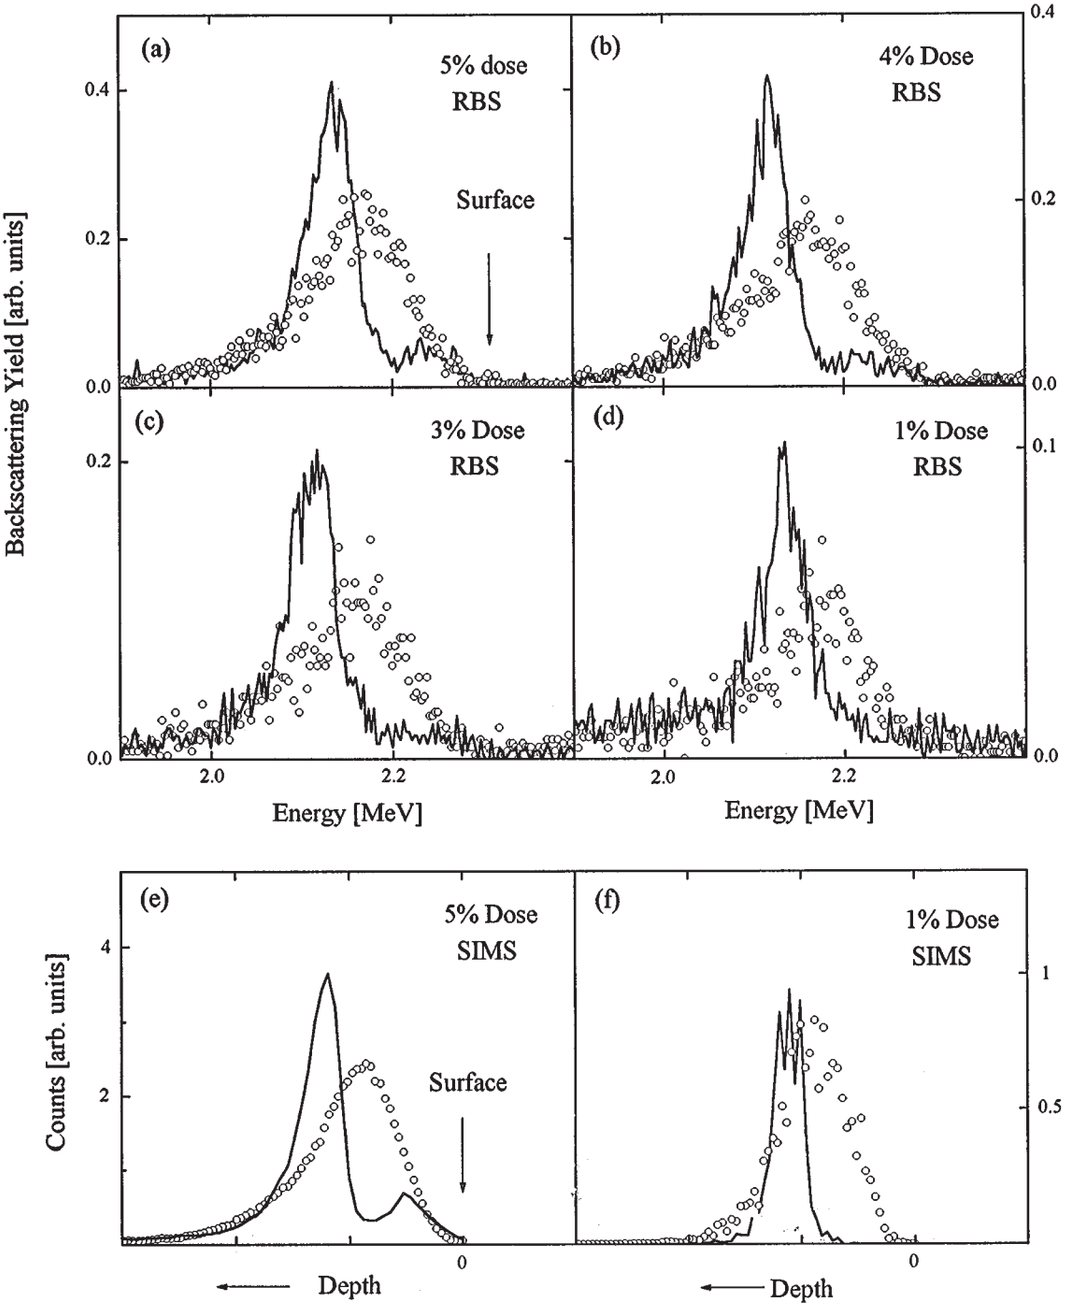
Fig. 2. Co depth profiles for different doses after implantation (○) and after post-implant annealing at 1000°C for 10 min (—). (*a*)–(*d*) The profiles from RBS for the 5, 4, 3, and 1% implant doses, respectively. The yield axes have different scales for the different doses. Note that the secondary peak is not present for doses less than 3% of the critical dose. The main peak is similar for the different doses. (*e*) and (*f*) The profiles from SIMS for the 5 and 1% doses, respectively. These profiles are similar to those obtained with RBS ((*a*) and (*d*)).



not occur in samples implanted to less than 2–3% of the critical dose. With lower temperature annealing (850°C), this secondary peak occurs in the lower dose samples (1% of the critical dose), and anneals out quickly (within 20 s) at 900°C.

At 60% of the critical dose, no shift of the main peak towards the bulk is detected. However, the evolution of the main peak is asymmetric about the as-implanted profile, and a secondary peak is present after annealing for 1 min at 1000°C. Note that for the evolution of the 60% dose, the

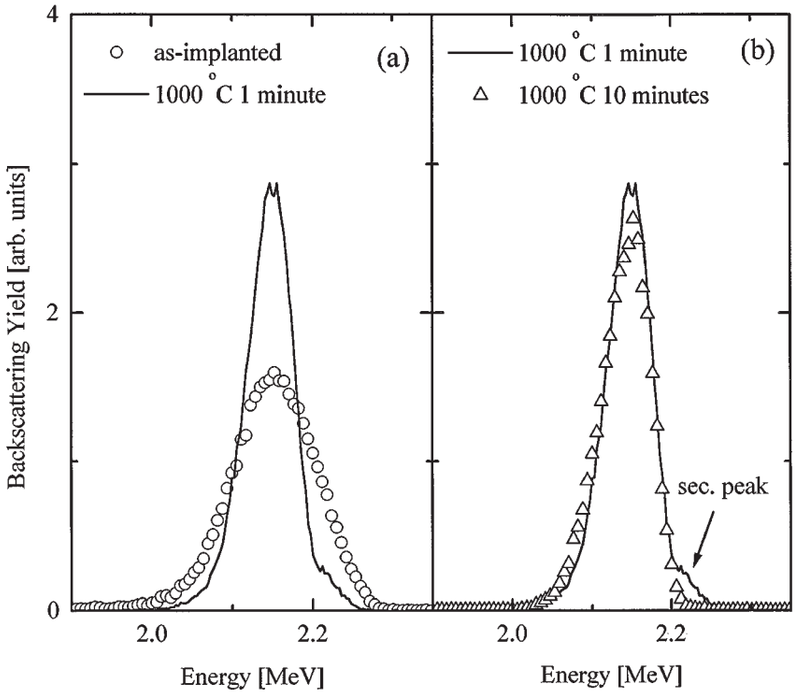
Fig. 3. Co portion of RBS spectra for a sample implanted to 60% of the critical dose. (*a*) The as-implanted profile and the profile obtained after annealing at 1000°C for 1 min. (*b*) The profiles after post-implant annealing at 1000°C for 1 and 10 min. At this relatively high dose, a secondary peak still forms near the surface, and the evolution of the Co profile is not symmetric about the as-implanted profile.



secondary peak is the last feature to disappear in the profile at 1000°C annealing temperatures.

3. Model for role of ripening during mesotaxial growth

In this section we try to develop a minimum model (model with the least parameters) which is consistent with the experimental observations in this and previous studies. Since defect profiles generated during ion implantation are highly complex, including little understood depth profiles of mono-vacancies, interstitials, and various defect conglomerates, a simple model cannot evolve if these features have to be taken into account. Therefore, the first three models discussed in section 3.1 are based on the assumption that implantation-caused defects anneal much faster at 1000°C than the observed morphological structures form and change. This assumption can be justified with observations of defect annealing after silicon self-implantation, where annealing to significantly lower temperatures is sufficient to fully recrystallize the substrate (22). In SIMOX studies, threading dislocations remain the only detectable defect structure after the annealing step (5), with typical densities of 10^5 per cm^2 and as low as 10^3 per cm^2 (23). Displacement damage did also not play a significant role in metal atom diffusion during ion implantation of cobalt and nickel at various energies (12). This assumption and a model including defect interaction are discussed more carefully in section 3.2.

3.1. Early stage mesotaxy models in a perfect matrix

In this section we present three models. The first model is based on the generally accepted mean-field analysis of Ostwald ripening by Lifshitz and Slyozov (LSW theory, refs. 13 and 14); the second model extends the LSW model to include precipitate–precipitate interactions for finite volume fractions, based on simulations by Enomoto et al. (15) and Voorhees and Glicksman (16). In the last model the diffusional screening is properly included to account for the inhomogeneous character of the system. We follow the approach proposed for open thermodynamic systems by Beenakker and Ross (17). Only the last model is not in conflict with the experimental observations.

Model 1: Mean-field Ostwald ripening model at zero volume fraction

The LSW theory is an analytical model for an infinite system. Since the model is independent of the relative precipitate positions, it does not include precipitate–precipitate interactions which have been shown to alter the evolution of the morphology at volume fractions as low as 0.1% (24). Thus, the LSW theory is only exact for zero volume fraction of the minority phase. It predicts a power law for precipitate growth with a growth rate independent of the size of the precipitate (11). Since the LSW theory predicts that all precipitates grow at the same rate, an initial profile should maintain its shape unless size variations of precipitates during nucleation or early stage growth (preceding late stage Ostwald ripening) exceed statistical size fluctuations. Standard nucleation theory (25) does not allow such an assumption, as

supersaturation levels are usually associated with variable nucleation densities and not with significant differences in the nucleus size. Early stage growth is not sufficiently investigated to make firm predictions, however, the highly local character of growth during that stage should more likely enhance statistical fluctuations as resulting from the nucleation stage rather than develop long-range size gradients (11). Thus a model based on the LSW theory does not predict a contraction of the Co depth profile. The mean field nature of this theory does further not allow for spatial inhomogeneities of the precipitate phase.

In the computer simulations by Reiss and Heinig (9, 10), growth rates of all precipitates are assumed equal and the initial size distribution is assumed uniform. Consequently, no contraction of the initial, spherical distribution of matter is observed. Trinkaus and Mantl (12) developed their model with a mean-field, zero volume fraction assumption. To achieve profile contraction, an initially nonuniform precipitate size profile is postulated.

Model 2: Ostwald ripening model with finite volume fraction

Several authors have proposed extensions of the LSW theory to include finite volume fractions of the precipitate phase (15, 16). They predict consistently that the rate of precipitate growth and the width of the precipitate size distribution increase with increasing volume fraction (24). Both of these predictions have been experimentally observed for cluster growth on surfaces for volume fractions as low as 0.1% and are associated with diffusive cluster–cluster interactions (26).

The finite volume fraction model can explain two fundamental experimental features, the significant contraction of the Co profile during ripening and the subsequent slight spreading: after implantation, the largest cobalt concentration in the peak region leads to the highest nucleation density and thus the highest volume fraction of the minority silicide phase. Likewise, the tails of the implantation profile contains a smaller volume fraction. Subsequent ripening leads to accelerated precipitate growth in the initial implantation peak region, i.e., larger precipitates are present during the late stages of the phase separation in the central region. The competition for monomers between the central section of the peak and the tail regions is decided by the Gibbs–Thomson effect (27), i.e., the capillarity effect that small precipitates have a larger chemical potential than large precipitates. The large central precipitates grow at the expense of the small precipitates in the peripheries. Material is therefore transported towards the central region and contraction of the Co profile occurs. In addition to the contraction, some spreading of the profile should occur as small precipitates in the periphery decompose and also transport material towards the bulk and surface regions. This spreading is only observed late in the annealing process (Table 1).

In the study by Trinkaus and Mantl (12), this effect has been obtained with assigning an arbitrary excess size to precipitates in the peak region. However, the collapse of the precipitate distribution is a much weaker effect in their model, as the relative size difference of precipitates does not change during ripening, leading to a fast decreasing monomer gradient toward the peak center. The collapse may even not proceed sufficiently far to reach the coalescence regime in their model if realistic fluctuations of the monomer concentration are included as the variation in supersaturation with precipitate size is a very small effect (11). The current model allows the precipitates in the denser peak region continuously to grow faster than precipitates elsewhere, thus maintaining a sufficient monomer gradient toward the peak region.

Model 3: Ostwald ripening model with finite volume fraction and screening

Model 2 does not explain several of the experimental observations, e.g., the asymmetric evolution of the profile which includes the shift of the main peak towards the bulk and the occurrence of the secondary peak near the surface. To develop the model further, the spatial inhomogeneity of the mass distribution after implantation has to be integrated. In a complete fashion, this would require adopting the actual depth profile after implantation. However, this would not only lead to a complex multiparameter system, but also confine the model to a particular system. Instead, we test a simplified model with three distinguished regions, a surface region with lower cobalt-disilicide precipitate density, the peak region with high precipitate density, and the silicon bulk free of precipitates. Focussing on the two regions near the surface first, we can use the thermodynamic open two-zone ripening model introduced by Beenakker and Ross (17). Their model is based on open mass exchange between a half-space reservoir of low monomer concentration and a region in late stage Ostwald ripening. It has been predicted and experimentally confirmed for cluster growth on surfaces (28) that the precipitates nearest to the reservoir interface screen the influence of the reservoir from the remainder of the ripening system. The reservoir then only effects the ripening system up to a characteristic screening length which is of the order of the mean precipitate spacing.

For bulk systems, this has been confirmed in computer simulations by Reiss and Heinig (9, 10). Their model involves however unrealistic assumptions preventing the prediction of the observed morphology. They assume a stable, uniform monomer concentration across a finite area. Wave-like zones of clusters, separated by a distance related to the screening length, emerge. However, fluctuations in the monomer concentration or precipitate distribution have major impact on computer simulations, as the ripening model is inherently instable against such variations as noted by Karpov (29).

The morphological evolution in model 3 allows for the decomposition of precipitates within the screening length but gives rise to a secondary peak or shoulder near the surface region when the screening length remains shorter than the peak–surface distance during the annealing. Since the screening length is larger at any given time interval for a system with larger precipitate–precipitate spacing, a lower Co implantation dose leads to dilute precipitates which can be dissolved, while a higher dose leads to a denser precipitate zone which is protected. The depleted zone should then be wider for the lower doses. This is consistent with the observation that the secondary peak completely dissolves faster for lower dose implantation. For doses less than 3% of the

© 1998 NRC Canada

critical dose, the screening length therefore extends all the way to the surface after 10 min annealing at 1000°C.

This model for the low-dose regime does not include processes such as precipitate coalescence or percolation, which occur when the spatial density of precipitates is much larger. However, at high doses, small precipitate densities should still be present in the periphery of the profile. Thus the same screening effect as in the low-dose regime should occur. This is illustrated for the 60% dose sample where similarities to the low-dose regime include an asymmetric evolution of the Co depth profile and the formation of a secondary peak near the surface region. Note that the secondary peak decomposes more quickly than in the 5% dose regime. This is associated with coalescence, percolation, and strain-induced effects that occur at the higher doses.

We note further that after post-implantation annealing at doses between 1% and 60% of the critical dose two features are identical to annealing at the critical dose. First, the peak Co concentration increases by a factor of about 1.7–2.0. This ratio is very similar to the ratio of 1.86, i.e., 33:18, that occurs at the critical dose. Secondly, the Co depth profile contracts to a minimum width of about 110 nm. This value is also very similar to the final silicide layer thickness of about 100 nm that forms at the critical dose. These similarities suggest that the same mechanisms are responsible, limiting the layer thickness at both the doses used here and the critical dose. This eliminates percolation and coalescence of precipitates as dominant mechanisms since these processes only occur at high doses, emphasizing that ripening plays a major role during mesotaxy as proposed previously.

Model 3 has one major weakness. The significant shift of the peak during annealing cannot be explained very straightforward. Without further assumptions, such a shift requires an asymmetry of the initial profile. This may be provided by the surface, which distincts the current model from SIMOX processes. Given the very shallow character of the concentration gradients within the two regions near the surface (surface peak and main peak area) and the experimentally observed minimal loss of monomers to the third region (bulk), to first order a mass redistribution toward the center of the two regions near the surface may be expected. However, this does not quantitatively agree with the experimental data.

3.2. Early stage mesotaxy model in a defective matrix

Model 3 can be extended to a defective matrix. This would strengthen the argument for the shift of the main peak toward the bulk during annealing without interfering with the arguments for the secondary peak formation in the previous section. Usually, the stopping process of implanted ions near normal incidence leads to defect structures at somewhat greater depth than the projected range of the implanted ion. This is due to a forward momentum the implanted ion carries when it interacts with nuclei of the host atoms near the EOR. If we allow for a damage zone at slightly greater depth during annealing, cobalt diffusion could be slowed down and cobalt trapping may be enhanced at this depth. This would lead to an increase of cobalt in that region. When the defects are fully decorated with cobalt, effectively larger precipitates would have emerged which would ripen more effectively than precipitates at other depths as discussed in the previous section.

Still, model 3 should not be extended to this scenario unless necessary, since the broad range of defects with variable dynamics leads to a quite complex description. Such a model would depend on many materials parameters, thus limiting the applicability of the concept. Further experimental analysis should first establish a link between the shift of the peak and other system parameters, such as the initial depth distribution and the actual monomer concentration profile.

4. Conclusions

Co was implanted into Si(100) to doses 1–60% of the critical dose required for continuous silicide layer formation. The Co depth redistribution during post implant annealing at 1000°C results in the following: (*i*) a shift of the position of the Co peak concentration towards the bulk region; (*ii*) during this shift, the Co profile narrows to a width which is typical of the width that a continuous, buried silicide layer resumes for critical dose implantation; and (*iii*) the formation of a secondary peak near the surface.

The secondary peak and the contraction can only be described with a ripening model which includes interactions between silicide precipitates (finite volume fraction effects) and diffusive screening against precipitate dissolution. Precipitate screening is the mechanism responsible for the persistence of the secondary peak at higher implant doses, i.e., a hindrance for the formation of sharp $CoSi_2$/Co-free Si interfaces toward the sample surface.

Charge-transfer phenomena in holographic recording material: dichromated poly(acrylic acid)

Christine Pizzocaro, Roger A. Lessard, and Michèle Bolte

Abstract: Dichromated poly(acrylic acid) (DCPAA) has been used as real time holographic recording material. We report here the photochemical behavior of DCPAA when irradiated under conditions representative of those used for hologram recording. Under UV–vis spectroscopy a photoredox process ($Cr^{VI} \rightarrow Cr^{III}$) was observed whose efficiency depends on the presence of dimethylformamide (DMF) used as an electron donor. ESR spectroscopy upon irradiation permits detection of the formation of Cr(V) of photochemical origin. We also identified chromium(V) of thermal origin (in the dark), organic macroradicals, and chromium(III). The formation of CO_2 and carboxylate ions was clearly shown by IR spectroscopy. The photoreaction is assumed to go through an acido–basic reaction between dichromate in the excited state and poly(acrylic acid). The resulting unstable chromium polyacrylate undergoes a redox process that gives rise to chromium(V) and a macroradical R-COO$^{\bullet}$ from which CO_2 is formed. The presence of DMF (10% by volume) makes the overall reaction faster by a factor of approximately 3.5–4. The similar shape of the curves giving chromium(V) formation as a function of irradiation time and the curves giving the diffraction efficiencies of the hologram recorded in DCPAA as a function of exposure energy, with and without DMF, strongly argues in favor of a direct involvement of chromium(V) in the quality of the resulting hologram.

Key words: holography, dichromated poly(acrylic acid), dimethylformamide, chromium.

Résumé : L'acide polyacrylique bichromaté (DCPAA) est utilisé comme matériau d'enregistrement holographique en temps réel. Nous décrivons le comportement photochimique de DCPAA sous irradiation dans des conditions représentatives de l'enregistrement holographique. Un processus de photooxydoréduction est observé; son efficacité dépend de la présence de diméthylformamide (DMF) utilisé comme donneur d'électron. Par spectroscopie RPE, nous avons pu détecter la formation de chrome(V) d'origine photochimique. Nous avons aussi identifié du chrome(V) d'origine thermique (à l'obscurité), des macroradicaux organiques et du chrome(III). La formation de CO_2 et de groupements carboxylates a été établie par spectroscopie infra-rouge. La photoréaction mettrait en jeu une réaction acide–base entre le bichromate à l'état excité et l'acide polyacrylique. Le polyacrylate de chrome résultant est instable, il subit un processus redox qui donne naissance au chrome(V) et au macroradical R-COO$^{\bullet}$ à partir duquel CO_2 est formé. La présence de DMF (10% en volume) multiplie la vitesse de la réaction par un facteur 3,5–4. La similitude des courbes donnant la formation de chrome(V) en fonction du temps d'irradiation et des courbes donnant l'efficacité de diffraction de l'hologramme enregistré dans DCPAA en fonction de l'énergie d'exposition avec et sans DMF est en faveur de l'implication du chrome(V) dans la qualité de l'hologramme.

Mots clés : holographie, l'acide polyacrylique bichromaté, diméthylformamide, chrome.

Introduction

Oxidation by chromates has been used for both preparative and analytical purposes for a long time (1–5). The reaction can be accelerated by light (6) and the process is the one involved in photosensitive dichromated materials used in holography: recording a hologram involves the illumination of the material by a pattern created by the interference of two laser beams, the object and the reference beams.

The chemical process implies the photoinduced polymerization or cross-linking of organic macromolecules such as poly(methylmethacrylate) or gelatin (7). Dichromated material such as dichromated gelatin has been used for phase holograms (8) and dyed gelatin plates (9) with electron donors (10) have been developped to form the phase gratings involving chemical development after recording the holograms.

More recently, dichromated polymer materials such as dichromated poly(vinyl alcohol) (DCPVA) and dichromated poly(acrylic acid) (DCPAA) have been employed to realize various applications in holography and, more precisely, in real time holographic recording (11). Our interest in exploiting these systems led us to the necessity of investigating the

primary photoprocess occurring upon irradiation of the polymer films at room temperature. It is known that the formation of holograms with dichromated photosensitive materials involves a reduction process giving rise to chromium(III) from the starting chromium(VI) species. Our earlier work on DCPVA permitted us to establish that the first step in such a system is electron transfer from the organic polymeric material to the cationic center, giving rise to chromium(V) and an organic macroradical (12).

In this paper, we report the primary photoprocess taking place in dichromated poly(acrylic acid) with or without dimethylformamide (DMF) used as an electron donor in order to enhance the reduction phenomenon. This work was focused on the photosensitive materials used to record holograms, which implied that the experiments be performed with DCPAA films. The work is to be correlated with our previous results concerning the quality of holograms obtained with such systems: the presence of DMF makes the diffraction efficiency of the resulting hologram higher by a factor of three (13).

To better understand the mechanism of hologram formation, three complementary techniques have been employed: (*i*) UV–visible spectroscopy to measure the quantum yield of chromium(III) formation; (*ii*) FTIR spectroscopy to monitor chromium(VI) disappearance and photoproducts formation; and (*iii*) real time electron spin resonance (ESR) technique employed to detect the intermediate paramagnetic species, sometimes unstable, formed upon irradiation.

Experimental

Materials

Ammonium dichromate $(NH_4)_2Cr_2O_7$ was of commercial origin (Fluka Purum) used without further purification. Dimethylformamide (DMF) was purchased from Aldrich (spectrometric grade). Poly(acrylic acid) (PAA) was in aqueous solution (Aldrich), 35% in water, M_w = 250 000). All the starting solutions were prepared in water purified by a Millipore Milli-Q system.

Fabrication of DCPAA films

DCPAA films were prepared by the gravity settling method. After dissolving 0.1 g of ammonium dichromate in 1 mL of water or of a water–DMF mixture, 4 mL of PAA (25%) were added and well stirred to obtain a homogeneous solution ([Cr(VI)] = 0.16 mol L^{-1}); 0.5 mL of this solution was poured onto a levelled cleaned glass substrate (2.5 × 7.5 cm^2). This was allowed to dry in a dark chamber under normal laboratory conditions for 24 h and orange-yellow clear transparent films with a thickness of 45–55 μm were obtained. The films were irradiated and analysed by UV–visible spectrometry directly on the substrate or peeled from the substrate for IR spectroscopy and finely ground for ESR experiments. Some IR experiments were performed on KBr plates.

Apparatus and procedures

A high-pressure mercury lamp with a Bausch and Lomb grating monochromator was used for irradiations at 365 nm. The light intensity was measured by ferrioxalate actinometry (14) ($I_0 \approx 2 \times 10^{15}$ photons s^{-1} cm^{-2}).

UV–visible spectra were recorded on a CARY 3 double-beam spectrophotometer. ESR spectra were recorded on a Brucker ER 200 D spectrometer at 9.30 GHz with a modulation field of 100 Hz. A Xe–Hg Hanovia lamp was used for irradiation in the ESR spectrometer cavity. When necessary, the emission was filtered at λ > 345 nm. IR spectra were recorded on a Nicolet 20SXC FT-IR spectrometer. The holographic recording was performed as previously described (13).

Results

Evolution in the dark

The DCPAA films were allowed to stand in the dark (in the absence of light at room temperature): in the absence of DMF, there was no evolution of the UV–visible spectrum of the film even after several days. In the presence of a high concentration of DMF, a darkening was observed, likely due to the formation of chromium(III) by a dark redox process. The presence of chromium(III) under these conditions was established by ESR and UV–visible spectroscopy.

The influence of DMF was also detected by measuring the formation of chromium(V) in a DCPAA film as a function of DMF concentration before irradiation. The presence of DMF made the formation of chromium(V) of thermal origin strongly decrease; a factor of 7 was observed with 10% of DMF (Table 1).

Table 1. Intensity of chromium(V) signal of thermal origin (arbitrary unit) versus DMF concentration.

DMF (vol.%)	0	2	5	10
Chromium(V) signal (arbitrary units)	20	15	13	3

Photochemical evolution

UV–visible evolution

The UV–visible spectrum of DCPAA film is represented in Fig. 1. The maximum at 350 nm and the plateau at 440 nm are characteristic of chromium(VI) as dichromate in acidic medium in film or in solution (12). Poly(acrylic acid) does not absorb significantly at a wavelength >300 nm. Upon irradiation at 365 nm, the absorbance at 350 and 440 nm decreased and the original yellow colour disappeared. For prolonged irradiations the film turned light blue: two absorption bands at 420 and 575 nm reflecting chromium(III) formation appeared. The presence of an isosbestic point at 520 nm illustrates the transformation of chromium(VI) into chromium(III). The quantum yield of chromium(III) formation was calculated from the initial slope of the curve giving the optical density at 575 nm where only chromium(III) absorbs in a significant way as a function of irradiation time.

Prior to this calculation, the molar extinction coefficients ε of the starting chromium(VI) and of the final chromium(III) in a DCPAA film have to be determined. By coating a known surface of substrate by a known amount of the mixture DCPAA, it was possible to measure ε for chromium(VI): at 350 nm it is equal to 1100 L mol^{-1} cm^{-1}. It is worth noting that the value is different from the value obtained for an aqueous solution of either DCPAA or pure dichromate in acidic medium (ε = 1600 L mol^{-1} cm^{-1}). The ε value of chromium(III) in the film was obtained by irradi-

Fig. 1. Spectral evolution of a DCPAA film upon irradiation at 365 nm.

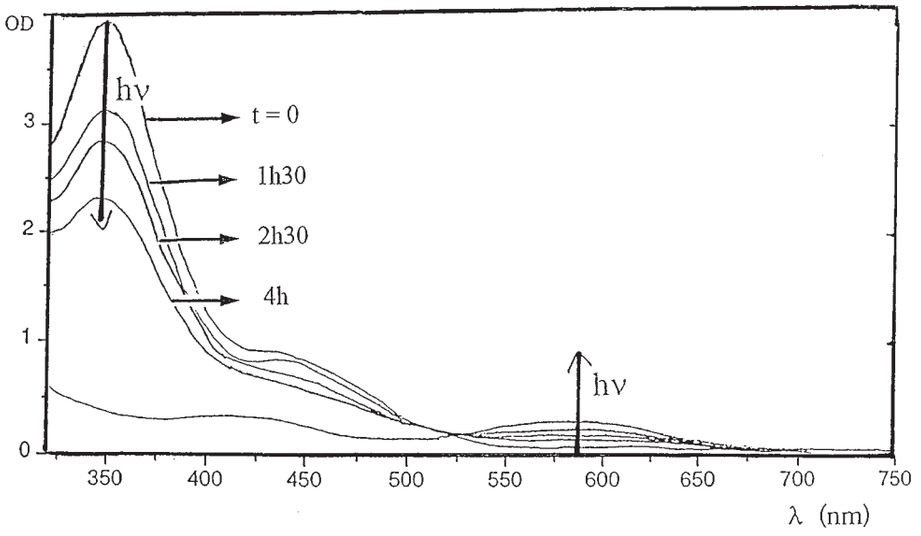

Fig. 2. Influence of DMF concentration on the formation of chromium(III) in a DCPAA film: (*a*) OD evolution (575 nm) upon irradiation (-■- 0%, -●- 5%, -▲- 10 vol.% DMF); (*b*) quantum yield evolution versus DMF percentage.

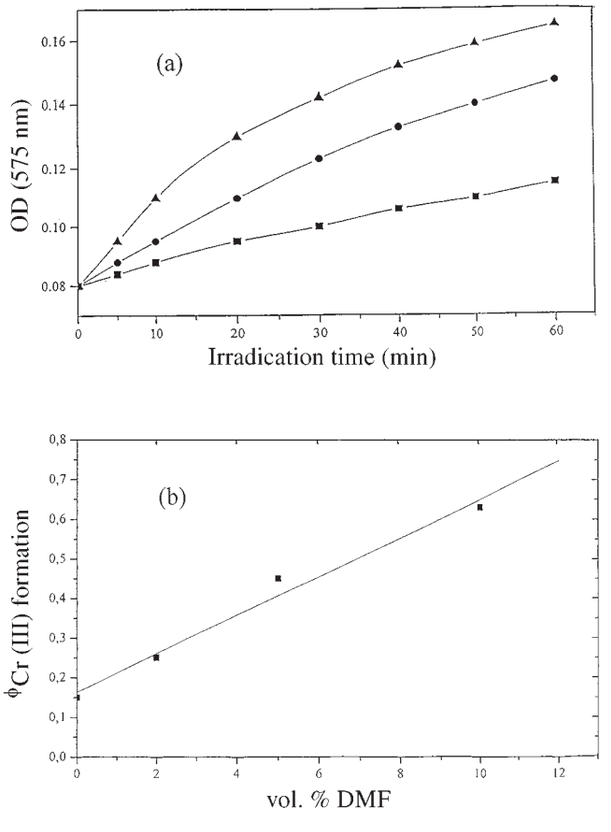


ating such a coated substrate up to complete reduction of chromium(VI) into chromium(III). A value of 45 L mol^{-1} cm^{-1} at λ = 575 nm was determined for the resulting chromium(III). These values are valid whatever the percentage of DMF in the range 0–10%. The presence of DMF does not affect the spectral evolution of a DCPAA film in the domain of wavelengths longer than 320 nm.

Table 2. Quantum yield of chromium(III) formation versus DMF concentration.

DMF (in vol.%)	0	2	5	10
$\Phi_{365\ nm}$ (Cr^{III} formation)	0.15	0.25	0.45	0.63

The experiments were performed at different concentrations of DMF (Fig. 2). We can observe a fast increase in the absorbance at 575 nm; then a plateau is reached. We observed a strong influence of the DMF on the photoreaction: the higher the concentration, the faster the formation of chromium(III) (Fig. 2*a*).

The error in the determination of the quantum yield Φ was roughly ±5% for triplicate measurements. It is noteworthy that the presence of DMF enhances the rate of the photochemical formation of chromium(III) by a factor of about 4 (Table 2).

IR analysis

In Fig. 3 is represented the FTIR spectrum of a DCPAA film upon irradiation at 365 nm. In the range 1100–700 cm^{-1} (Fig. 3*a*) the only evolution is the disappearance of the chromium(VI) bands at 903 and 950 cm^{-1} (ν CrO_3).

In the range 2500–1400 cm^{-1} (Fig. 3*b*) we can see the formation of two bands: the first one at 2338 cm^{-1} is characteristic of CO_2 coming from a decarboxylation of the polymer. The second one, at 1550 cm^{-1}, corresponds to the formation of carboxylate groups COO^-.

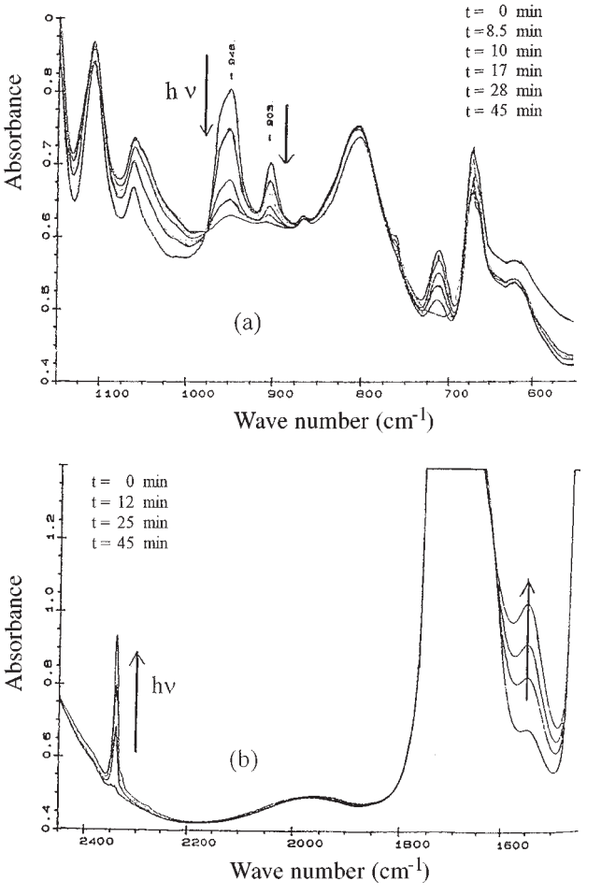
The presence of 5% by volume of DMF in a film enhances the rate of chromium(VI) disappearance and CO_2 and COO^- group formation by a factor of about 3.3.

ESR experiments

By performing ESR experiments upon irradiation on DCPAA films, we were able to detect the presence of two different signals (Fig. 4): according to previous studies in similar systems, they were both attributed to chromium(V) but from different origins (6, 12): (*i*) chromium(V) of ther-

© 1998 NRC Canada

Fig. 3. FTIR spectrum of a DCPAA film (with 5 vol.% DMF) upon irradiation at 365 nm.



mal origin (I), and (*ii*) chromium(V) of photochemical origin (II), which increased, went through a maximum, then disappeared (Fig. 4*a*), leading to the final weak and broad chromium(III) signal observed for prolonged irradiations.

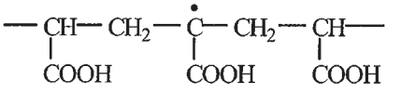
Chromium(V) formed upon irradiation was thermally unstable and disappeared, giving back the original (dark) signal (Fig. 4*b*). In the presence of DMF (10% by volume) the intensity of the signal reached a higher maximum value and the rate of chromium(V) formation is multiplied by a factor of about 30 (Fig. 5). The maximum of the chromium(V) signal intensity was reached for a longer irradiation time (25 min) in the absence of DMF.

The disappearance of chromium(V) formed upon irradiation was also followed in the dark: (*i*) in the absence of DMF, the decrease was very slow, which made a kinetic treatment of the evolution impossible; (*ii*) in the presence of DMF, a good linear relationship ($R_{corr} > 0.999$) was obtained when plotting 1/(height of the signal) as a function of irradiation time (Fig. 6).

This dependence reveals a bimolecular process of disappearance according to

[1] $2\ Cr(V) \rightarrow Cr(VI) + Cr(IV)$

The formation of a macroradical was evidenced by ESR spectroscopy upon irradiation. When PAA was directly irradiated ($\lambda > 250$ nm), a signal corresponding to an organic radical with a binomial distribution 1 4 6 4 1 was observed



(A)

(Fig. 7). This signal was also present upon irradiation of DCPAA ($\lambda > 345$ nm) but was very weak and partly obscured by the chromium(V) signal. The signal can be attributed to the macroradical (**A**) and results from the coupling of the radical with the two sets of two hydrogens on the carbons in the α position.

The high stability of the radical that makes the direct observation possible is because of its position on a tertiary carbon. This is the first time that such a stable organic signal has been reported in a dichromated polymeric system.

Discussion

Active species of chromium

In our system, chromium(VI) is the only absorbing species. In acidic aqueous solution it exists either as $HCrO_4^-$ or $Cr_2O_7^{2-}$ (15).

$$HCrO_4^- \rightleftharpoons CrO_4^{2-} + H^+ \qquad pK = 6.49$$

$$2HCrO_4^- \rightleftharpoons Cr_2O_7^{2-} + H_2O \qquad K_d = 48\ mol^{-1}\ L$$

Fig. 4. ESR signal of chromium(V) in a DCPAA film: (*a*) upon irradiation (λ > 345 nm); (*b*) thermal decay (after irradiation).

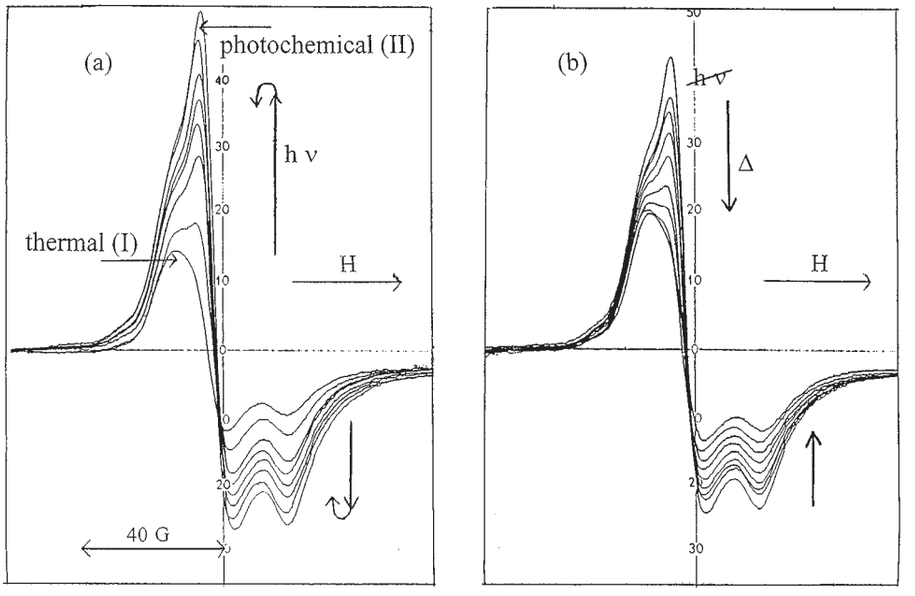

Fig. 5. Chromium(V) formation upon irradiation of DCPAA films (ESR signal intensity) (λ > 345 nm) without (-●-) DMF and with 10 vol.% DMF (-■-).

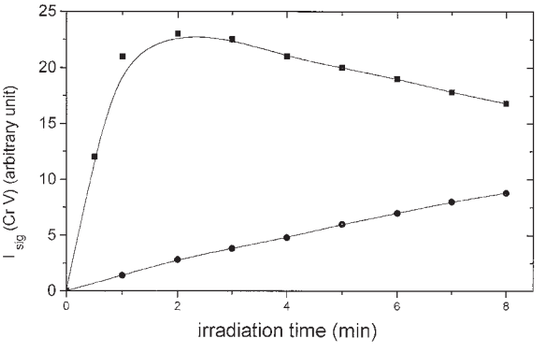

Fig. 6. Chromium(V) ESR signal evolution: (*a*) upon irradiation (λ > 345 nm); (*b*) thermal decay (after irradiation). Insert: 1/height of chromium(V) ESR signal after stopping the irradiation.

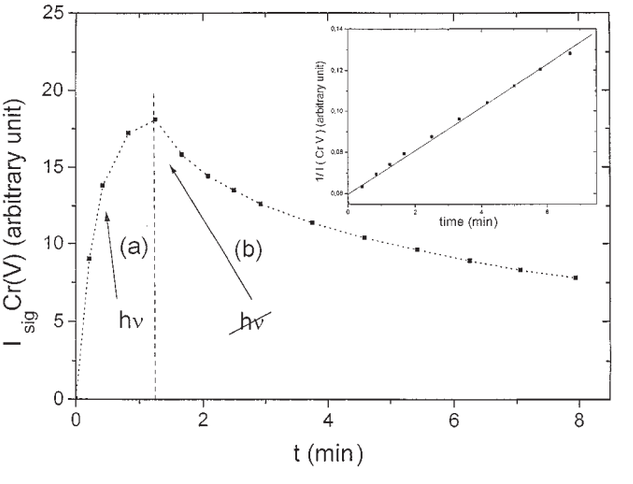

From these equations, it is possible to calculate the concentration of each species according to the concentration of dichromate in the solution (Table 3).

It is difficult to extrapolate the results obtained in solution to the films. In the films prepared from a solution 0.16 mol L^{-1} in chromium(VI), the dimer was supposed to be the predominant species, even though the monomer could be present. Because of this uncertainty, chromium(VI) will be noted Cr(VI) in the reaction mechanism without specifying the species.

Photochemical process in DCPAA

There were no detectable changes in a DCPAA film with respect to the sum of PAA and chromium(VI) spectra: there was no reaction between the two constituents. This was further confirmed by the FTIR spectrum of a DCPAA film.

Upon irradiation, the only chromium(III) formation was observed by UV–visible spectrophotometry, whereas the formation of CO_2 and carboxylate groups was established by FTIR spectrophotometry.

Such a result had already been found when studying the photochemical behaviour of the chromium(VI)–acrylic system (16). Inasmuch as there is no reaction between PAA and chromium(VI) in the ground state, this implies a quenching reaction between chromium(VI) in the excited state and PAA, leading to the formation of a chromium polyacrylate. From ESR spectroscopy measurements, it is possible to propose that a redox process by electron transfer then occurs, giving rise to Cr(V) and a macroradical that undergoes a very fast decarboxylation. Cr(V), an unstable species, is then reduced into the final chromium(III).

© 1998 NRC Canada

Fig. 7. ESR signal of PAA macroradical formed upon irradiation ($\lambda > 250$ nm).

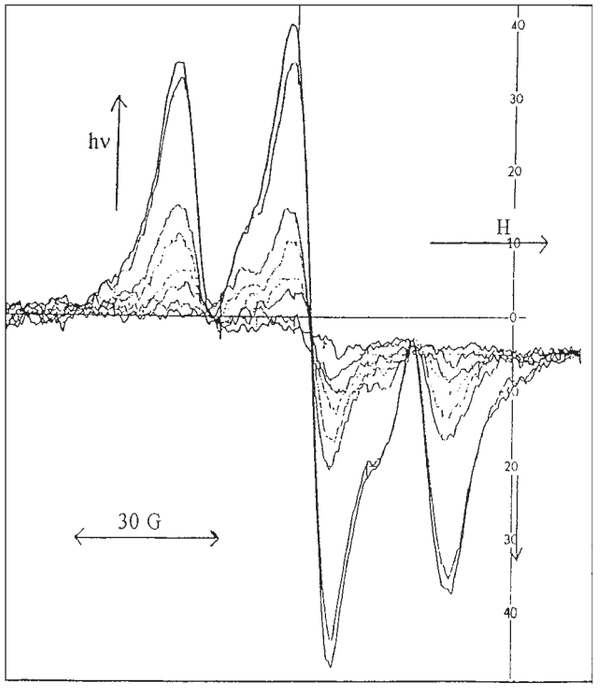

Table 3. Calculated percentage of $Cr_2O_7^{2-}$ in aqueous solution for three chromium(VI) concentrations.

Cr(VI) mol L^{-1}	% Cr(VI) as $Cr_2O_7^{2-}$
10^{-3}	10
10^{-2}	37.5
10^{-1}	72.5

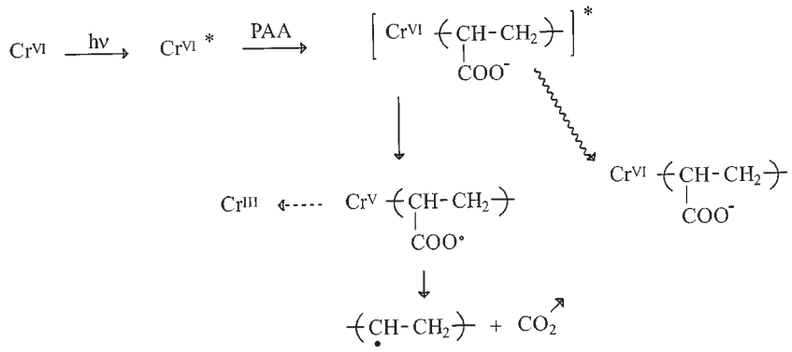
This process, involving the formation of a chromium(VI) salt by a quenching reaction between chromium(VI) in the excited state and a carboxylic acid, has already been established in the photochemical behavior of chromium(VI) – acrylic acid (16).

The redox process can also occur by hydrogen abstraction, giving rise to the stable tertiary macroradical observed by ESR spectroscopy.

The two processes are present but the second reaction seems to be a minor route. The macroradicals evolve either by mutual annihilation and (or) by a reaction with chromium(VI), which is known to be a very efficient termination agent in polymerization processes (17):

[3] $R^{\bullet} + R^{\bullet} \rightarrow$ polymer

The following mechanism can be put forward:



Effect of DMF on the photochemical behaviour

It is worth noting that there is no photoreduction of chromium(VI) in the presence of only DMF: the presence of poly(acrylic acid) appears to be necessary for the reduction of chromium(VI) to take place. The presence of DMF strongly increases the formation of chromium(V) upon irradiation, which requires the involvement of DMF in the first step of the reaction. This result, together with the linear relationship between the quantum yield of chromium(III) formation and the concentration of DMF, suggests a quenching reaction between chromium(VI) in the excited state and DMF. We checked that this increase was not due to a "diluting" effect of DMF in the film. A similar result was obtained when irradiating an aqueous solution of DCPAA with and without DMF.

The fact that the photoproducts are identical and that the only effect of DMF is the increase of the reaction rate reflects the formation of an analogous intermediate in the presence and in the absence of DMF. In addition, the factor of acceleration measured by FTIR is roughly identical for the chromium(VI) disappearance and photoproduct formation (R-COO$^{\bullet}$ and CO_2).

Thus we infer a mechanism similar to that described for DCPAA alone, in which DMF, through the eventual formation of a complex with chromium(VI) either in the ground state or in the excited state, enhances the basic character of chromium(VI), making easier the reaction with poly(acrylic acid) and the formation of chromium polyacrylate. Actually, when increasing the percentage of DMF in a chromium(VI) water–DMF solution it appeared that a complex exists in the

ground state provided the percentage of DMF is high enough (Fig. 8). The formation of the complex is not detectable with 10% DMF, which is the maximum used in this work.

As far as holography is concerned, we report in Fig. 9 the curves of diffraction efficiency as a function of exposure and the DMF effect; they closely resemble the curves of chromium(V) formation. It seems that the optimization of the quality of a hologram recorded in DCPAA requires the optimization of chromium(V) formation. It addresses the question of the extension of this conclusion to other dichromated systems. The work is in progress.

Three-dimensional magnetic resonance imaging of rigid polymeric materials using single-point ramped imaging with T_1 enhancement (SPRITE)

Christopher B. Kennedy, Bruce J. Balcom, and Igor V. Mastikhin

Abstract: A new MRI method, recently employed in porous-media studies, is introduced for the imaging of rigid polymeric materials. The method, Single-Point Ramped Imaging with T_1 Enhancement (SPRITE), is designed to spatially encode short lifetime, T_2*, signals characteristic of rigid materials. We investigate the advantages of the SPRITE technique over conventional imaging methods by comparing a 2D SPRITE image of four common polymers to a 2D spin-echo image of the same substances. We demonstrate the general applicability of SPRITE by imaging two commercial products, a stop-valve made of chlorinated polyvinyl chloride and a solid-core, multilayer golf ball, both containing synthetic materials with effective ^{1}H spin–spin relaxation times, T_2*, well under 300 μs. Three-dimensional images of millimeter resolution reveal internal physical differentiation and chemical inhomogeneities that cannot be observed using conventional MRI methods. We also consider the incorporation of active spoiler gradients in SPRITE for visualization of samples with long spin–spin relaxation times, T_2.

Key words: MRI, NMR, SPI, SPRITE, polymers, imaging.

Résumé : Une nouvelle méthode d'imagerie par résonnance magnétique (IRM), employée récemment dans les études des milieux poreux, est introduite pour obtenir l'image tridimensionnelle de polymères solides. La méthode : amplification du temps de relaxation T_1 d'image tridimensionnelle à une seule ligne de fuite (SPRITE), est désignée pour encoder la distribution spatiale des temps de vie courts T_2*, des signaux caractéristiques des matériaux rigides. Nous avons étudié les avantages de la technique SPRITE par rapport aux méthodes conventionnelles d'imagerie, en comparant les images 2D de la technique SPRITE de quatre polymères courants à l'image obtenue par écho de spin de ces mêmes substances. Nous démontrons la généralisation de cette technique en réalisant l'imagerie par résonnance magnétique de deux produits commerciaux : une valve d'arrêt faite de chlorure de polyvinyle chloré et un noyau solide, une balle de golf multicouches, ces deux produits contiennent des matériaux synthétiques ayant des temps de relaxation spin–spin du ^{1}H, T_2* bien en dessous de 300 μs. Les images 3D avec une résolution spatiale de l'ordre du millimètre révèlent une différenciation physique interne et des hétérogénéités chimiques qui ne peuvent être observées par les méthodes conventionnelles de la IRM. Nous envisageons d'incorporer un dispositif actif de gradient de champ dans la technique de SPRITE pour représenter des échantillons ayant un temps long de relaxation spin–spin T_2.

Mots clés : IRM, RMN SPI, SPRITE, polymères, imagerie.

1. Introduction

As the demand for high-performance polymers increases, so does the need for an analytical method which can provide information on the physical and chemical parameters of a species of interest (1). Despite the outstanding success of solid-state NMR (2–6) in determining polymer structure and dynamics, the methods do not permit spatial localization. This is, however, vital if one considers a real polymeric material which will be macroscopically heterogeneous, for example, due to processing, weathering, and aging. Spatial resolution requires MRI where an NMR signal is spatially encoded, usually with an applied magnetic-field gradient. Chemical and physical molecular parameters, as well as larger scale sample features such as strain, can be exploited in MRI to correlate localized inhomogeneities to material properties (7). These correlations may give information on the state of the material under investigation, such as the degree to which its molecules are oriented or its cross-link density, or they may be used as a diagnostic to observe changes in matter, such as physical aging or chain scission (7).

While the opportunities and the applications of MRI have been identified, its use in polymer and material science has been hampered by the short T_2 and T_2* values characteristic of

rigid materials (8). At present, practical MRI of polymeric materials is limited to elastomers with relaxation times which are an order of magnitude longer than more rigid solids (9).

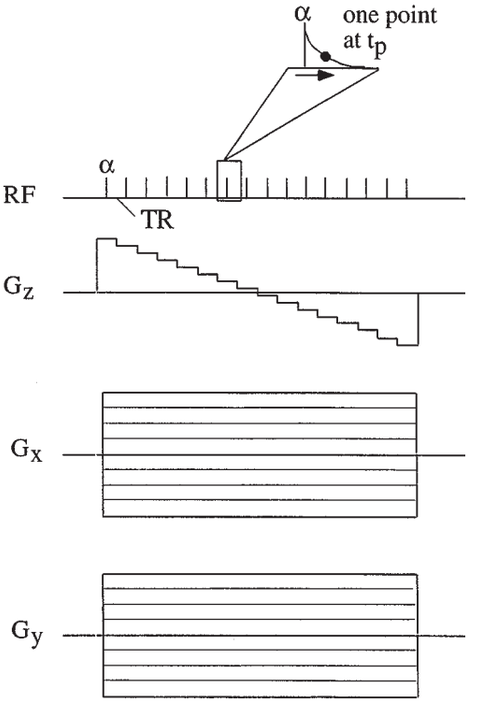
Many new MRI pulse sequences and imaging methods have been developed in an effort to overcome the interactions specific to solids. These include imaging with the use of oscillating field gradients (10), stray field imaging (STRAFI) (11), magic echo imaging (12, 13), magic angle spinning (MAS) imaging (14, 15) and single-point imaging (SPI) (16–18). While each method has been used successfully to image solid and solid-like materials, each also has major limitations ranging from prolonged gradient switching times and loss of signal, to restrictions on sample size and the number of dimensions that can be spatially encoded. To quote Bernhard Blümich "most solid-state MRI sequences introduced to date have been demonstrated on phantoms chosen to fit the method" (1).

In this paper we demonstrate the advantages of the SPRITE technique (19) over traditional MRI methods for the imaging of ^{1}H in rigid polymer materials. The imaging method has previously been applied to the study of porous materials, including concrete (20–23). In these materials the T_1 is typically <10 ms, however, in this contribution we introduce an important extension to long T_1 materials (>100 ms). The capacity of SPRITE to encode signal from species with a T_2* less than 100 μs, and its flexible contrast parameters, are revealed in a comparison between a 2D SPRITE image and a 2D spin-echo image of a phantom consisting of *cis*-polybutadiene, polyvinyl chloride, polyethylene, and plexiglass. We do not wish to demonstrate the method with "samples chosen to suit the method," therefore we have imaged two commercial, multicomponent polymeric samples to illustrate the general utility of the SPRITE method. These samples are a plastic stop-valve and a three-piece, solid-core, multilayer golf ball. Both contain short T_2* components and are difficult or impossible to image with other MRI methods. We also investigate the origin and effect of echoes on SPRITE images and discuss the mechanisms which play a role in their elimination.

2. Methods

The basic SPRITE method was developed by Balcom et al. (19) in 1996. It is a pure phase encode imaging modality based on the original single-point-imaging (SPI) sequence developed by Emid and Creyghton (16). Unlike the SPI sequence, the magnetic field gradients in the SPRITE sequence are not switched on/off for each acquisition. Instead, the primary phase encode gradient is ramped in equally spaced discrete steps. Figure 1 shows a 3D SPRITE sequence where G_z is the primary phase encode gradient and G_x and G_y are the secondary and tertiary phase encode gradients, respectively. A broad-band RF pulse with flip angle α, is applied at each step of the primary phase encode gradient. Uniform excitation of all spins requires a pulse bandwidth (1/pulse length) greater than the maximum spectral width (G_{max} × sample length). A single complex point on the free induction decay (FID) is sampled after a constant encoding time, t_p, following each α pulse. The ramped gradient greatly reduces imaging times, minimizes gradient vibration, and enables the introduction of quantitative T_1 contrast into images

Fig. 1. Schematic of a 3D SPRITE sequence. The primary phase encode gradient, $\boldsymbol{G}_z$, is stepped with the application of a RF pulse and the acquisition of a single point at each gradient level. The signal is encoded for time t_p after the pulse. The repetition time is TR. The figure shows only 16 steps, however 64 or 128 are usually applied.



(19). Unlike traditional frequency encoding methods, SPRITE images are free from distortions due to the inhomogeneity of the main magnetic field, B_0, susceptibility variations, and chemical shift.

In the following paragraphs, we outline pertinent ideas on position encoding in one dimension, *Z*. The extension to *X* and *Y* follows logically. Position is encoded in reciprocal space or *k* space as a function of the stepped phase gradient $\boldsymbol{G}_z$, where $\boldsymbol{k}_z = (1/2\pi)\gamma \boldsymbol{G}_z t_p$. The signal detected as a function of $\boldsymbol{k}_z$, $S(\boldsymbol{k}_z)$, is the sum of all signal from the sample, encoded for time t_p which incorporates relaxation weighted proton densities $\rho(\boldsymbol{z})$,

$$[1] \qquad S(\boldsymbol{k}_z) = \int_{-\infty}^{+\infty} \exp\left[-t_p/T_2^*(\boldsymbol{z})\right]\rho(\boldsymbol{z}) \exp\left[i2\pi \boldsymbol{k}_z \boldsymbol{z}\right] d\boldsymbol{z}$$

where

$$[2] \qquad \rho(\boldsymbol{z}) = R(\boldsymbol{z})\rho_0(\boldsymbol{z})$$

The variable $\rho_0(\boldsymbol{z})$ is the true proton density. A Fourier transform relationship exists between $S(\boldsymbol{k}_z)$ and $\rho(\boldsymbol{z})$, eq. [1], and a relaxation weighted image can be obtained through application of the inverse Fourier transform to the experimental $(\boldsymbol{k}_z)$ data. Our ideas on relaxation and contrast in SPRITE are more extensively outlined in Prado et al. (24) and Beyea et al. (25).

© 1998 NRC Canada

In this work we consider the relaxation weighting, $R(\boldsymbol{z})$, for the longitudinal steady-state limiting case, which results from a train of equally spaced α pulses. The expression for $R(\boldsymbol{z})$, is therefore,

$$[3] \qquad R(\boldsymbol{z}) = \left\{ \sum_{i=1}^{n} A_i \left[\frac{1 - \exp\left[-\mathrm{TR}/T_{1i}(\boldsymbol{z})\right]}{1 - \cos(\alpha) \exp\left[-\mathrm{TR}/T_{1i}(\boldsymbol{z})\right]} \right] \right\} \sin(\alpha)$$

where TR is the repetition time, constant for each step in the SPRITE ramp, α is the RF pulse flip angle, and A_i is the weighting attributed to T_{1i}. The term in square brackets is the familiar expression for steady-state longitudinal magnetization. The overall image intensity is determined by the amplitude of the *k*-space origin points. Given the pulse sequence of Fig. 1, the longitudinal steady state is usually well established before the $\boldsymbol{k_z}$ origin is acquired.

In eqs. [1] and [3] we assume a single exponential T_2* for each isochromat as well as independent T_{1i} populations. These assumptions are not universally true, however, they are reasonable approximations for this work. The selection of sequence parameters for a particular sample greatly influences the observed image. In the limit of a short t_p and a long TR and (or) small α, a true proton density, $\rho_0(\boldsymbol{z})$, image will result.

The relationship, embodied in eqs. [1]–[3], between image intensity, relaxation times, and SPRITE timing parameters, shows that to properly understand image intensity and image contrast, knowledge of the bulk relaxation times is highly advantageous.

3. Experimental

The SPRITE technique and all other MRI measurements were implemented on a Nalorac (Martinez, Calif.) 2.35 Tesla 32 cm i.d. horizontal bore superconducting magnet. The gradient set used for the spoiled SPRITE and chlorinated polyvinyl chloride (CPVC) stop-valve images was a water cooled 20 cm i.d. self-shielded gradient set (maximum gradient 10 G cm^{-1}). The gradient set used for the golf-ball images and the SPRITE–spin-echo comparison experiment was a 7.5 cm i.d. water-cooled microimaging gradient set (maximum gradient 25 G cm^{-1}). Both gradient sets were driven by Techron (Elkhart, Ind.) 7780 amplifiers except for the SPRITE–spin-echo comparison, where Techron 8710 amplifiers were used. The RF probe used for the CPVC stop-valve experiments was a commercial quadrature bird cage (Morris Instruments, Ottawa), while the RF probe used for the golf-ball image, SPRITE resolution, SPRITE spoiling, and SPRITE–spin-echo experiments was a homebuilt 32-strut bird-cage coil. Each probe had a typical 90° pulse length of 30 μs. Both RF probes were driven by a 2 MW AMT (Brea, Calif.) 3445 RF amplifier. All experiments were performed with a Tecmag (Houston, TX) Libra S-16 console at ambient temperature. Pulse programming and some image reconstruction was undertaken with MacNMR 5.4 software (Tecmag, Houston, Tex.). Most image reconstruction and display employed IDL 5.0 (Research Systems, Boulder, Colo.).

Bulk T_1 and T_2* measurements were performed on all samples. All T_1 measurements were made using basic inversion recovery methods with exponential fitting. The T_2* values were determined from the line width of the Lorentzian fit of the Fourier transform of the FID. All the polymer materials, except for the O-ring in the stop-valve and the plexiglass sample, demonstrated multiexponential T_1 relaxation parameters. The T_2* values of most polymer materials were also multiexponential, however, their short lifetimes made accurate assessments difficult and, therefore, only one approximate value for T_2* was considered for each sample.

The SPRITE–spin-echo phantom was assembled from a *cis*-polybutadiene disc cut from the core of a multilayer golf ball. The polyvinyl chloride, polyethylene, and plexiglass discs were sliced from long rods, obtained in bulk from an industrial plastics manufacturer. The CPVC stop-valve was purchased in a local hardware store, as were the multilayer golf balls.

The spin-echo sequence, SPRITE–spin-echo comparison, had an echo time, TE, of 1.28 ms, an acquisition time of 800 μs, a dwell time of 12.5 μs, and a spectral width of ±40 kHz. The phase encode gradient was applied for 435 μs, *X* axis, with a maximum strength of 1.9 G cm^{-1}. It was stepped in 64 equal intervals to –1.9 G cm^{-1}. The field of view, *X* direction, (FOV$_x$) was 7.3 cm. The read gradient, *Z* axis, was 1.9 G cm^{-1} yielding a FOV$_z$ of 7.4 cm. Thirty-two signal averages were performed for each 64-point echo acquisition, giving a total imaging time of 35 min.

The SPRITE sequence, SPRITE–spin-echo comparison, 64 × 64 points, had an α pulse of 8°, a t_p of 50 μs, and a TR of 2.2 ms. The primary phase encode gradient, *Z* axis, had a maximum value of 15.6 G cm^{-1} while the secondary phase encode gradient, *X* axis, had a maximum value of 15.9 G cm^{-1}. The field of view was therefore 7.4 × 7.4 cm. The SPRITE acquisition, total time 15 min, was signal-averaged 64 times to ensure that the low signal intensity from the plexiglass (T_2* = 38 μs) could be distinguished from background noise.

The SPRITE resolution experiments, 64 × 64 points, employed an 8° α pulse, a 2 ms TR, and a t_p of 100 μs. Four signal averages, quadrature phase cycling, were acquired. The gradients, G_x and G_y, had maximum values of 12 G cm^{-1}, which gave a 5.6 × 5.6 cm FOV in the *X* and *Y* directions with a nominal pixel resolution of 0.9 mm.

The CPVC stop-valve was imaged, 64^3 points, with an α pulse of 14°, a t_p of 100 μs, and a TR of 2.5 ms. Four signal averages were acquired, quadrature phase cycling, with a 1 s delay at the end of each cycle of the primary phase encode gradient. The overall imaging time was approximately 5.5 h. The primary phase encode gradient, *X* axis, had a maximum value of 5.2 G cm^{-1}. The FOV$_x$ was therefore 14.5 cm. The secondary and tertiary phase encode gradients, *Y* and *Z* axes, had maximum values of 4.0 and 7.1 G cm^{-1}, yielding a FOV$_y$ of 18.6 cm and a FOV$_z$ of 10.2 cm.

The multilayer golf ball was imaged, 64^3 points, with a 14° α pulse, a 50 μs t_p, and a 5 ms TR. Eight scans, quadrature phase cycling, were performed with a delay at the end of each primary phase encode gradient cycle of 0.5 s. The total imaging time was approximately 7.5 h. The gradients were set at maximum values of G_x 23.9 G cm^{-1}, G_y 21.5 G cm^{-1}, and G_z 23.9 G cm^{-1}. This produced a FOV$_x$ of 6.3 cm, a FOV$_y$ of 7.0 cm, and a FOV$_z$ of 6.3 cm.

The SPRITE spoiling experiment, 64 points, employed an α pulse of 8°, a t_p of 400 μs, and a TR of 2.8 ms. Four signal averages, quadrature phase cycling, were acquired. The G_x

gradient had a maximum value of 3.5 G cm^{-1}, giving a one-dimensional FOV$_x$ of 7.6 cm. The maximum spoiling gradient, *Z* axis, was 0.9 G cm^{-1}.

4. Results and discussion

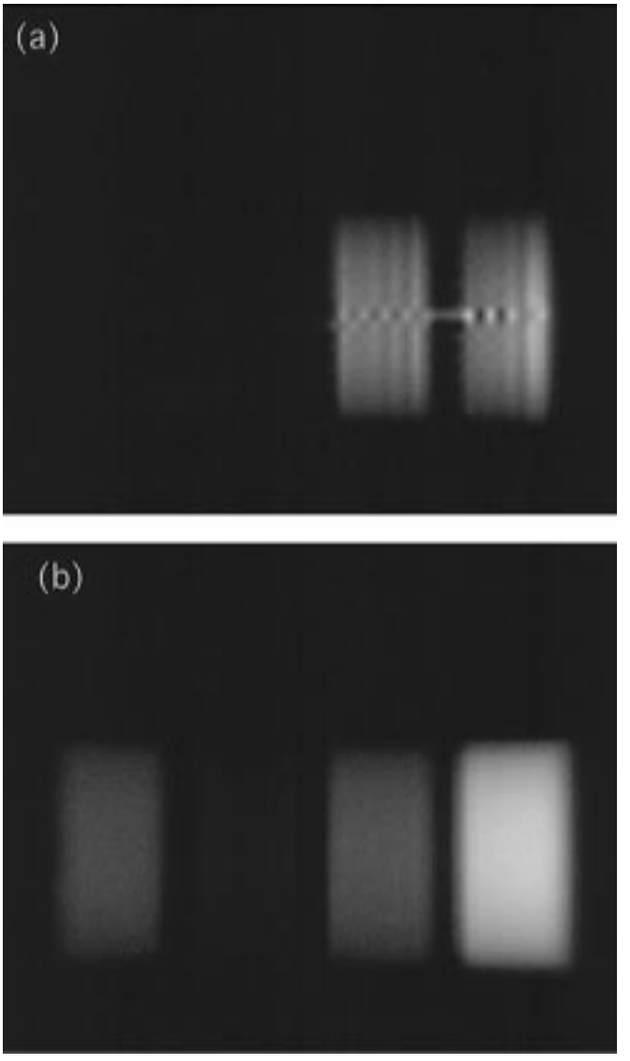
Comparison of spin-echo and SPRITE imaging methods

To illustrate the advantages of the SPRITE technique for polymer imaging we performed a simple phantom experiment with two dimensional SPRITE and spin-echo imaging methods. The spin-echo sequence is the simplest and most commonly used pulse sequence in MRI (26). It is a T_2 based imaging method which requires the formation of a spin-echo generated by a 90° excitation pulse and a 180° refocusing pulse. The time between the 90° pulse and the peak of the echo is the echo time, TE. The echo is acquired in the presence of a pulsed magnetic field gradient known as the read gradient. A series of spin-echo acquisitions, performed with a variable amplitude pulsed phase encode gradient, results in a 2D map of *k* space which can then be Fourier transformed to give an image.

The polymer phantom was a composite cylinder composed of four stacked polymer discs (2.5 cm diam. × 1.2 cm ht.). The four discs were polyethylene, plexiglass, polyvinyl chloride and *cis*-polybutadiene. Individual discs were separated by 0.3 cm teflon spacers. Bulk T_1 and T_2* relaxation times were measured for each disc individually, Table 1.

The two-dimensional, 64 × 64, SPRITE, and spin-echo phantom images are reproduced in Fig. 2. No image processing was performed, other than Fourier reconstruction of the raw *k*-space data. The grey scale images are displayed with identical windowing, the maximum intensity (white) in each image corresponding to the peak image intensity. In each image the polymer discs, rectangular projection in two dimensions, are arranged left to right: polyethylene, plexiglass, polyvinyl chloride, and *cis*-polybutadiene. The polyethylene and plexiglass phantoms are not apparent in the spin-echo image due to their short T_2 relaxation times which will attenuate the observable transverse magnetization by more than 10 and 20 exponential time constants, respectively, during the 1.28 ms echo time. Very low intensity, poor *S*/*N*, polyethylene, and plexiglass images are in fact apparent if one lowers the display window. These low-intensity images are, however, only apparent due to minor, long T_2, signal components present in each polymer.

Fig. 2. Comparison of (*a*) spin-echo and (*b*) SPRITE acquisitions on a phantom consisting of, left to right: polyethylene, plexiglass, polyvinyl chloride, and *cis*-polybutadiene. The spin-echo image has noticeable image artifacts. The short T_2* polymer components, polyethylene and plexiglass, are not detected in the spin-echo image. The image contrast and *S*/*N* differs in the spin-echo and SPRITE images.



Although intuitively appealing it is not possible to greatly reduce the echo time to regain lost signal. A typical gradient rise time, in a reasonable size gradient set is on the order of 200 μs, and a stable gradient is required as one digitizes the echo signal. Switched magnetic field gradients, before and after the 180° pulse, are required because the RF pulses must be applied in the absence of a field gradient. Since, in addition, a finite acquisition time (800 μs in this case) is required to symmetrically sample the echo, an echo time much longer than many polymer T_2 relaxation times is difficult to avoid. The *S*/*N* ratio of the polyvinyl chloride and *cis*-polybutadiene was 150 and 160, respectively, as determined from the experimental images. The *S*/*N* determination

© 1998 NRC Canada

was greatly hindered by the obvious image artifacts in the spin-echo image.

The most striking feature of Fig. 2*a*, the spin-echo image, is the zipper artifact transverse to each polymer in the image and the ripple artifact parallel to the edge of the discs. A zipper artifact in the direction of the read gradient, horizontal direction in the image, is well known to result from a residual FID generated by an imperfect 180° refocusing pulse (27). The residual FID was clearly present in the experimental *k*-space data. One of the most common methods of eliminating the residual FID artifact is to spoil transverse magnetization immediately after the 180° pulse with a set of matched spoiler sandwiching the 180° pulse (27). This solution is not possible in the present circumstances because it would have required increasing the echo time still further to accommodate switching the spoil gradient on and off twice. The ripple artifact is an unusual manifestation of a truncation artifact (27). It occurs in this instance because the transverse magnetization is rapidly changing, because of the short T_2, during the acquisition window. Very fast signal digitization would be necessary to remove this truncation artifact. Note that no such artifact is apparent in the vertical, phase encode, direction of Fig. 2*a*.

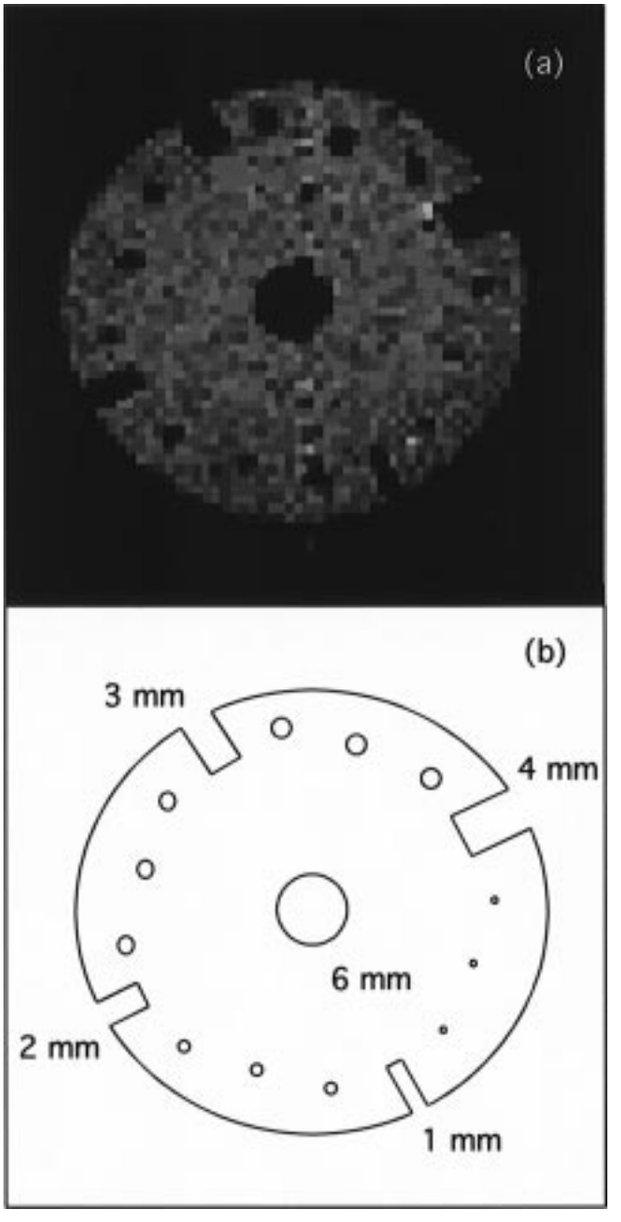
The SPRITE image, Fig. 2*b*, of the same phantom is artifact free. The nearly identical field of view and an equivalent 64 × 64 data matrix, means that *k* space has been equivalently sampled by each method, yet the SPRITE technique is clearly more robust. It has also clearly visualized the polyethylene polymer (*S*/*N* of 31) in addition to the polyvinyl chloride (*S*/*N* of 40) and *cis*-polybutadiene discs (*S*/*N* of 180). The plexiglass disc is barely visible with the default display windowing in the grey scale image, Fig. 2*b*, due to its low signal (*S*/*N* of 7).

The SPRITE image has minimal artifacts and is clearly able to visualize shorter lifetime signals because of the unique manner with which it encodes transverse magnetization. In the SPRITE sequence pulse application and signal acquisition are performed in the presence of a stable gradient (Fig. 1). This permits a greatly reduced time between signal excitation and detection which permits encoding of much shorter lifetime signals. The acquired points in SPRITE *k* space are consistently encoded at a constant t_p of 50 μs, allowing for the signal contribution from polyethylene and plexiglass to be sampled before complete dephasing occurs. We therefore observe polyethylene and plexiglass in the SPRITE image (Fig. 2*b*) despite their short signal lifetimes in the transverse plane.

Figure 2*b* also shows that *cis*-polybutadiene is visualized with better *S*/*N* than in the spin-echo image, and the image contrast between the *cis*-polybutadiene and polyvinyl chloride has radically changed. They appeared to have near identical image intensities, zero contrast, in the spin-echo image.

The T_1 and T_2* values for rigid polymer materials are typically multiexponential with the longer T_1 values ranging from 300 to 400 ms and the shortest T_2* values falling under 100 μs. Equation [3] shows that TR and α experimental parameters will manipulate the signal intensity through T_1 effects without influencing the T_2* decay contribution to the observed signal in eq. [1]. The significant difference between polymer T_1 and T_2* values thereby leads to great flexibility in SPRITE contrast. From eq. [1] we see that the observed signal in a SPRITE experiment maybe dominated by T_2* dephasing. In Fig. 2*b* the two polymers with the shortest T_2* values have the lowest image intensity.

Fig. 3. (*a*) Two-dimensional SPRITE 64^2 image of a resolution phantom composed of a cross-linked *cis*-polybutadiene polymer with holes and slots of various dimensions. No image processing, other than Fourier reconstruction, was performed to maintain a pixel size on the order of the 1 mm holes. The dimensions of the smaller holes located on the edge of the sample are 2 mm (top), 1.5 mm (left), 1.25 mm (bottom), and 1 mm (right). (*b*) Schematic of the phantom with the slots and the central hole position and dimensions indicated.



The T_1 image contrast is governed by the *R* term of eq. [2] which may be calculated from eq. [3]. The T_1 contrast in a SPRITE image depends on the sample T_1, its weighting, A_i, the repetition time, TR, and the RF flip angle, α. The short

[a]Components listed with two T_{1i} values were fit to a double exponential.

[b]Each weighting, A_i, is associated with its adjacent counterpart in the adjacent T_{1i} column.

[c]This sample is different from the polybutadiene sample of Table 1.

T_1 component (45% of the total) of polyethylene contributes significantly to the final image intensity when a short TR, typical of SPRITE, is employed. No T_1 effects are observed in the spin-echo image because a delay of $5 \times T_1$ is maintained after each echo acquisition, allowing for full recovery of the longitudinal magnetization. It would be possible to introduce T_1 contrast in the spin-echo image, further reducing the observable signal, by implementing a repetition time which is less than $5 \times T_1$. The image in Fig. 2*a* is a purely T_2 weighted image where the relative intensity of PVC is increased in comparison to the SPRITE image. The partial saturation of longitudinal magnetization, eq. [3], diminishes the PVC signal in the SPRITE acquisition. We have proposed alternate *k*-space sampling strategies, such as centric sampling, which will change the T_1 contrast observed through the *R* parameter (28).

Gravina and Cory (17) have demonstrated that single-point methods provide better sensitivity than analogous spin-echo experiments when the sample T_2 is less than the gradient switching time. It is thus no surprise that the polyethylene and plexiglass polymers (T_2* of 98 and 38 μs) are more readily observed with the SPRITE technique. Although the SPRITE and SPI class of imaging methods suffer from low efficiency, due to the fact that only one *k*-space point is sampled for each RF excitation, they do have a clear advantage in detecting otherwise invisible short T_2* signals.

Experimental sensitivity in the SPRITE experiment, without degradation of resolution, has a complicated dependence on the sample and the sequence parameters. It is currently an active area of investigation.

SPRITE resolution

In principle pure phase encode methods, such as SPRITE, are always capable of higher resolution than frequency encode methods such as the spin-echo (17). In this relatively low resolution work, we demonstrate the millimeter resolution capabilities of SPRITE. Figure 3 is a 2D image of a *cis*-polybutadiene phantom, with holes and slots of various dimensions drilled and cut into its edges and inner surface. The hole diameters range from 6 mm at the centre to 2, 1.5,

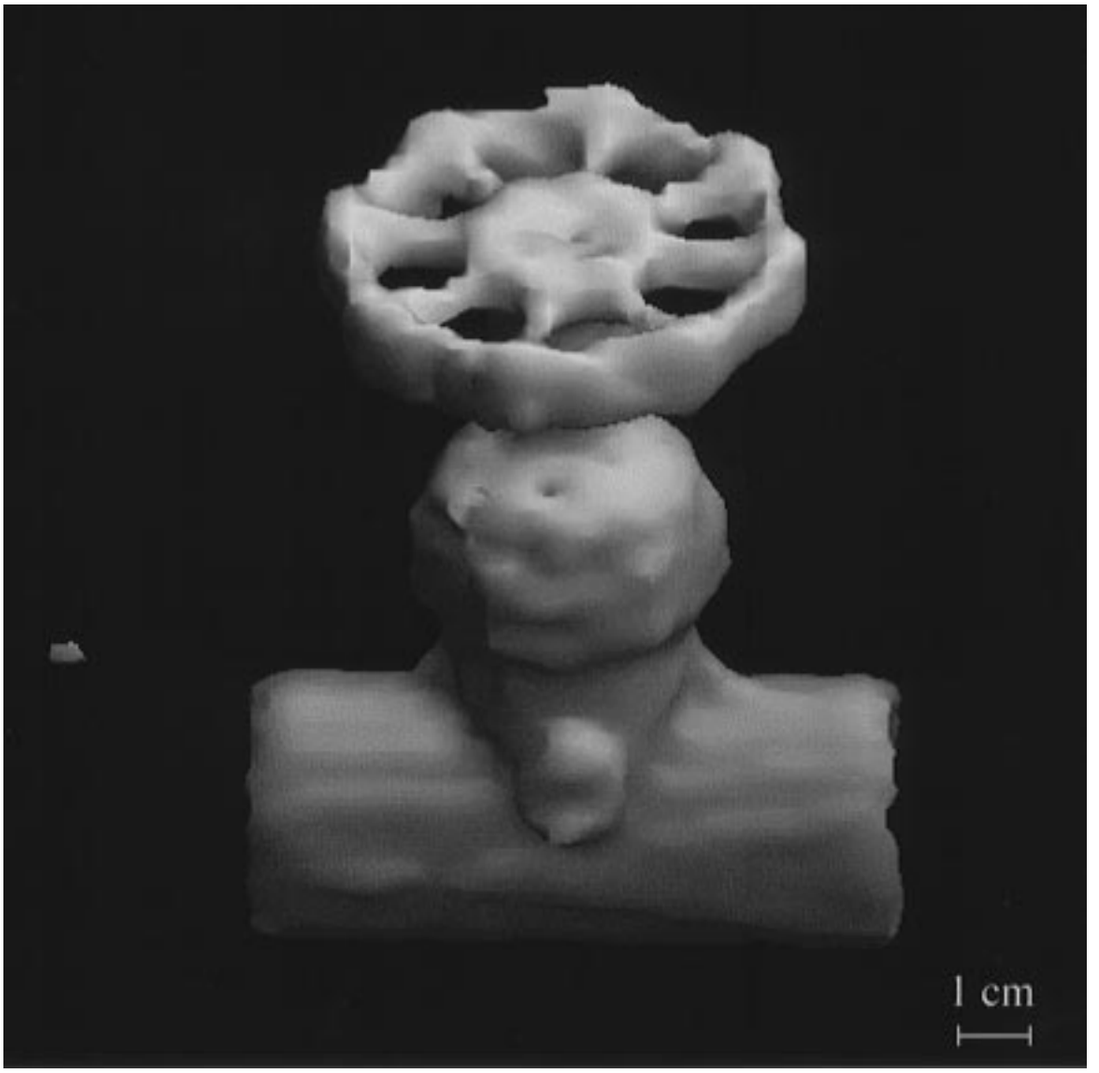
Fig. 5. Three-dimensional SPRITE 64^3 image of a CPVC stop-valve, externally rendered using IDL. The field of view was 15 × 19 × 10 cm^3. The encoding time was 100 μs and the TR was 2 ms. Total imaging time was 5.5 h. The long acquisition time ensured the gradient amplifiers did not overheat.



1.25, and 1 mm near the outer edges of the phantom. The slots cut into the edge of the phantom are 4, 3, 2, and 1 mm wide. Examination of Fig. 3 shows that under these conditions, as expected, the small 1 mm holes are discernible but not well resolved.

The protons in a solid sample experience large dipolar interactions which result in rapid dephasing of the FID (a short T_2 and T_2*) and very broad spectral line widths. This poses a major problem to conventional imaging methods, such as the spin-echo, which employ frequency encode gradients where the sample line width is the resolution limit. To remove the line width restriction on resolution, individual pixel widths (spectral width/number of points) must be larger than the sample line width. Large amplitude magnetic field gradients with attendant large spectral widths across the sample and very short dwell times (15) are therefore typically required. If, as frequently occurs, this condition cannot be achieved the result is edge degradation and blurring in the reconstructed image.

Blurring was not observed in Fig. 2*a* because both *cis*-polybutadiene and polyvinyl chloride had line widths smaller then the pixel width, while the plexiglass and polyethylene had large line widths but minimal image intensity.

Resolution in the SPRITE experiment is not limited by the sample line width. It is limited by the strength of the phase encode gradients and the encoding time, t_p, employed (17). The pixel resolution for SPRITE, Δx, also known as the sampling point spread function, is given by eq. [4] (17, 28).

$$[4] \qquad \Delta x = \frac{\mathrm{FOV}_x}{N} = \frac{1.2\pi}{\gamma G_{x,\max} t_p}$$

where γ is the gyromagnetic ratio and $G_{x,\max}$ is the maximum gradient strength. Based on eq. [4] we see that the resolution

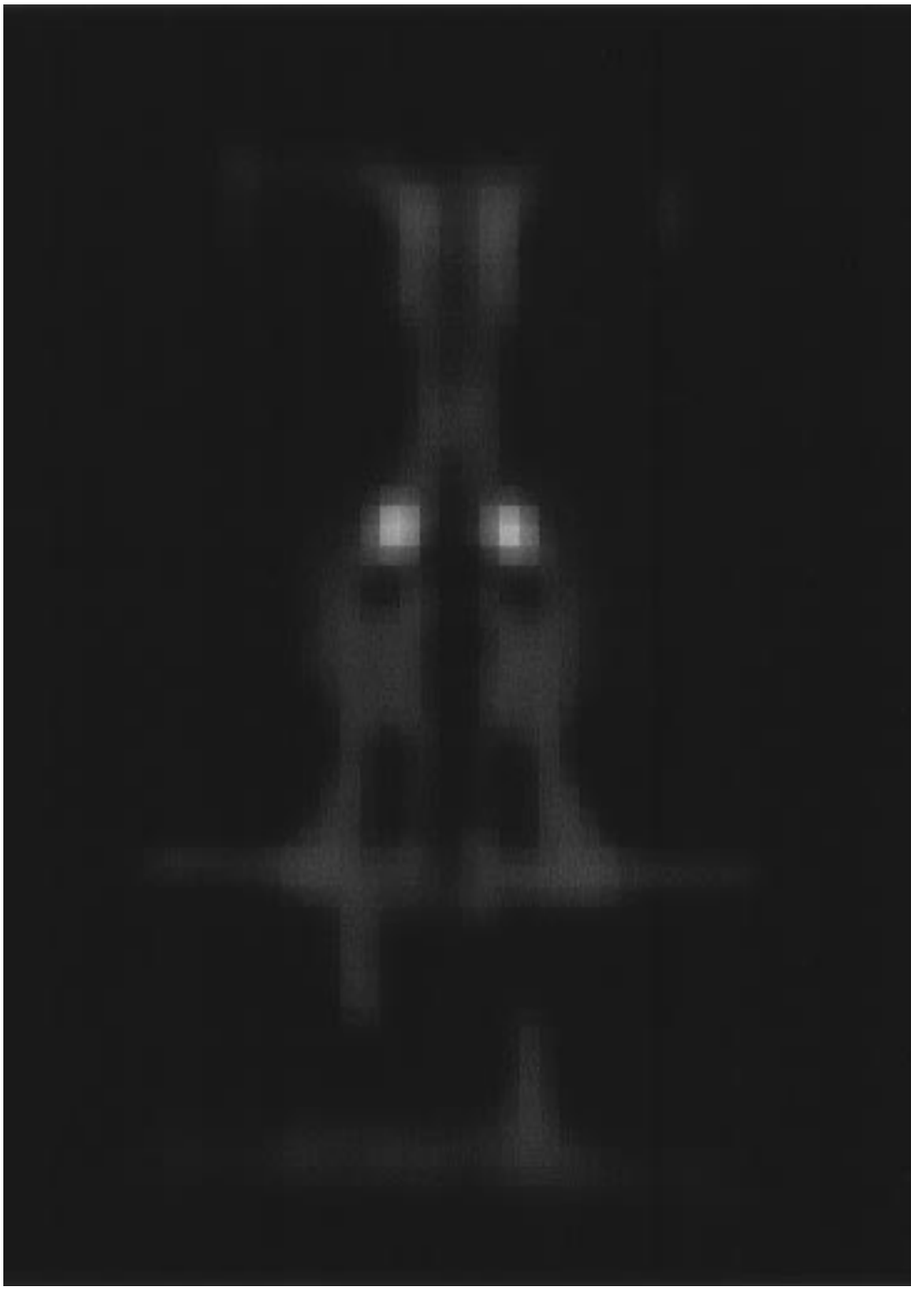
Fig. 6. Selected gray scale image of a 2D slice from the 3D data set of Fig. 5. Internal structure of the stop-valve is well defined. Signal from the CPVC is less than that of the O-ring because of saturation effects and T_2* differences.



in Fig. 3 can be greatly improved by increasing $G_{x,max}$ and acquiring more *k*-space points, *N*. This would, however, require more extensive signal averaging to achieve an adequate *S*/*N*.

Chlorinated polyvinyl chloride (CPVC) stop-valve

To explore the utility of the SPRITE method for imaging real polymeric materials we imaged in 3D a CPVC stop-valve. The valve consisted of a valve handle and T-joint, a threaded shaft, polymeric washer, and two elastomeric O-rings (Fig. 4). Bulk T_1 and T_2* measurements of the disassembled pieces, Fig. 4*b*, revealed that the longest T_1 and the shortest T_2* of the stop-valve were 221 ms and 32 μs, respectively, both resulting from signal detected from the CPVC handle (Table 2).

Given knowledge of the relaxation times of the sample a rational choice of the 3D SPRITE imaging parameters was possible. The image displayed in Fig. 5 required an overall imaging time of approximately 5 h 30 min for the entire 3D data set. The main reason for this excessively long acquisi-

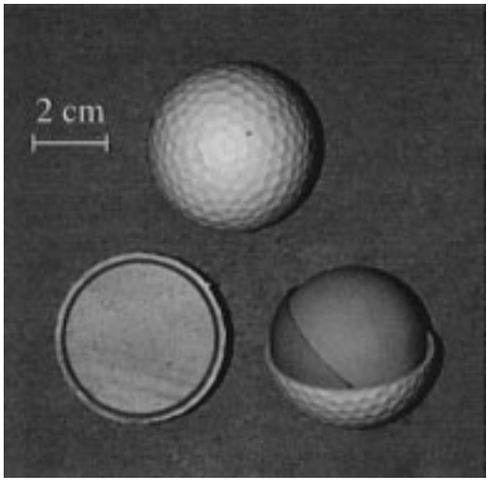
Fig. 7. Photograph of the multilayer golf ball in a variety of physical states and orientations. No voids were observed after the ball was physically cut (bottom left).



tion time is a conservative delay inserted in the pulse sequence at the end of each cycle of the primary phase encode gradient (Fig. 1). It is present to ensure that the gradient amplifiers do not overheat. Improved gradient amplifiers have reduced this restriction and should decrease the imaging time for an equivalent experiment to a more agreeable 15 min.

The 64^3 image of Fig. 5, clearly shows the ability of SPRITE to encode signal from short T_2* polymers. With a nominal pixel resolution of 2.3 mm in the *x* direction and 1.6 mm in the *z* direction, the structure of the handle and the T-joint are clearly defined. Also, note in Fig. 4 the presence of two brass screws located in the T-joint and the valve handle. While the presence of the metallic screws will distort the B_0 homogeneity, no geometrical distortions are observed in Fig. 5 because the SPRITE experiment is a pure phase encode method (17). Distortions of the main field homogeneity within a pixel decrease in the local T_2*, which may decrease the observable signal.

A two-dimensional slice taken from the 3D image data set, Fig. 6, reveals the internal structure of the stop-valve. Voids along the internal axis of the shaft and inside the T-joint are defined as well as the divisions in the pipe. Perhaps the most interesting feature of this image is the contrast observed between the O-ring and the bulk CPVC structure. Assuming a constant proton density, allowing for T_1 partial saturation effects, and estimated T_2* differences (Table 2), we predicted a factor of two difference in image intensity. The experimentally observed difference is a factor 2.4. The contrast between the two regions is primarily due to the T_2* difference.

It is clear, based on these results, that SPRITE can observe short T_2* materials such as the valve handle (Table 2 and Fig. 5), distinguish polymer materials based on image contrast, and achieve adequate resolution to observe physical differentiation within the sample (Fig. 6).

Solid-core multilayer golf ball

Our second realistic polymer test sample was a solid-core multilayer golf ball. Once more, bulk relaxation times were measured on the individual golf-ball components (Table 2). The golf ball had three distinct layers: a soft Surlyn™ cover (type 1855), a hard Surlyn™ second layer (type 1605), and an injection moulded *cis*-polybutadiene core (Fig. 7). Surlyn™, a DuPont product, is described in the patent literature as a polymeric material composed of an ionomer resin. The constituents of this resin include ethylene acid copolymers whose acid functionalities are neutralized by zinc (Zn) or sodium (Na) ions.

The initial objective of this 3D SPRITE imaging experiment was to image the outer Surlyn™ cover and discriminate it from its inner layers. Figure 8 is a 64^3 image of an intact golf ball. The raised areas on the Surlyn™ cover are signal from glue which was used to position the ball in the RF probe. The dimples on the outer cover are apparent. The internal structure is clearly revealed in a 2D slice removed from the original 3D data set shown in Fig. 9. In this 64^2 gray scale image the deviations between cover, layer, and core are clearly defined. Figure 9, also, reveals a series of signal voids in the core of the golf ball. These voids are not physical spaces in the ball, as determined by physical sectioning, but are representations of areas where the NMR signal has decayed more rapidly relative to its surroundings, probably because of a localized T_2* decrease. We hypothesize that these localized discontinuities result from an inhomogeneous distribution of additives in the golf-ball core.

It is evident that while the sensitivity and resolution of SPRITE allow each golf-ball component to be distinguished, a second, and perhaps more important, SPRITE feature is revealed. Localized chemical differences are manifest as local relaxation time differences which, as discussed above, may be manipulated to produce image contrast (Fig. 9). While the nature of the voids in the ball are not the subject of this work, it is clear that SPRITE has great potential for the noninvasive detection and investigation of a variety of polymer manufacturing defects and inhomogeneities.

5. SPRITE spoiling

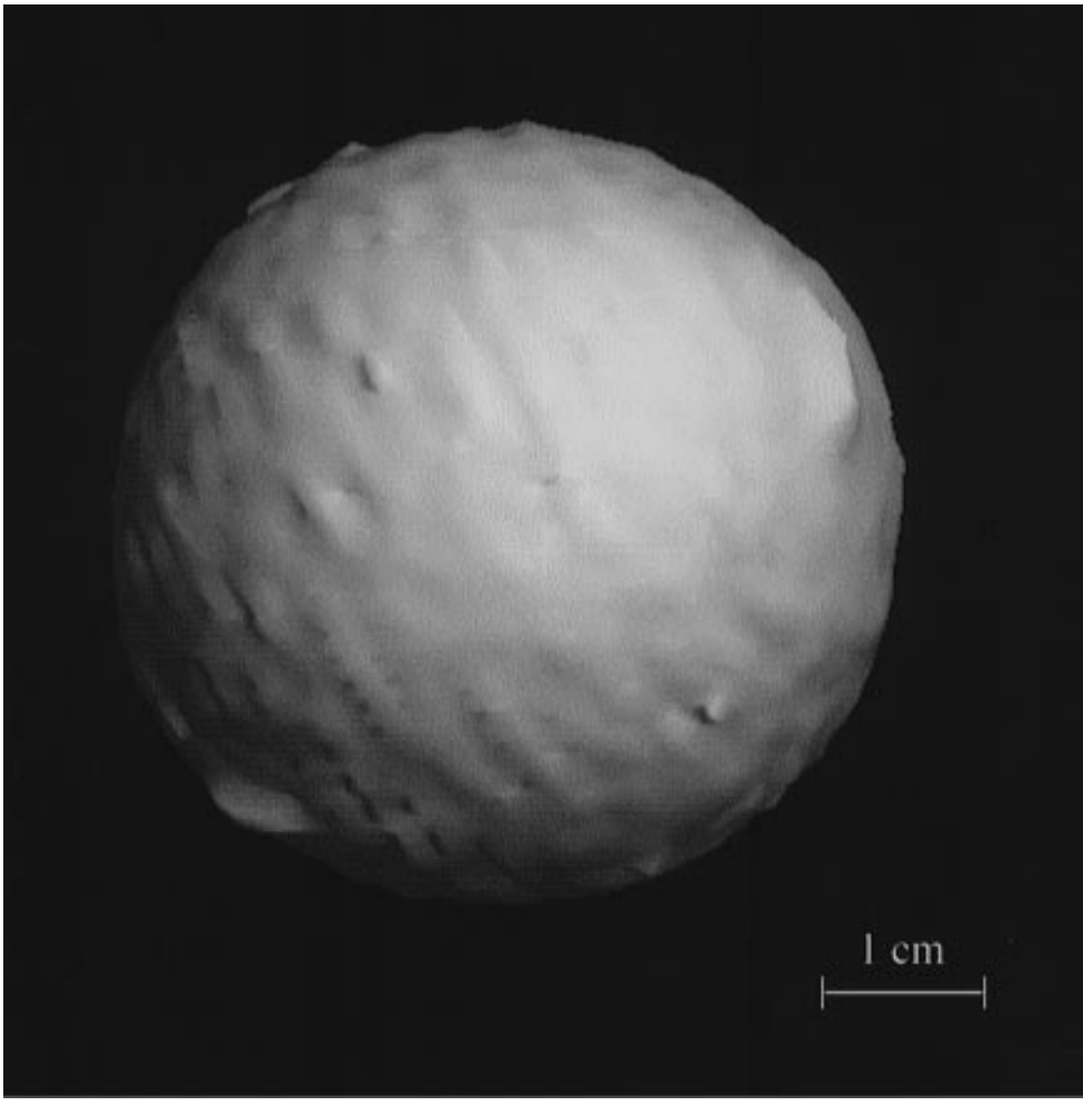
Balcom et al. (19) have observed artifacts with the SPRITE sequence from samples with spin–spin relaxation times, T_2, greater than TR. We believe that this is due to the introduction of unwanted spin and stimulated echoes during data acquisition.

In most cases SPRITE imaging of rigid polymeric materials will not require a consideration of spin-echo artifacts. The short T_2 values of these materials allow for dephasing to occur naturally and rapidly before any subsequent RF excitation pulses. One can envision, however, a variety of MRI experiments where the observation of a rigid polymer material, in the presence of a long T_2 species, is necessary, and the elimination of spin-echoes due to multiple RF pulses becomes a concern. Examples of such experimental conditions would include the presence of liquid monomers in a partially formed polymer or fluid penetration into a solid polymer.

We can discriminate between three mechanisms which would prevent unwanted echoes in a SPRITE experiment. These are an increased repetition time, TR, the passive spoiling of signal due to the primary phase encode gradient, $\boldsymbol{G_z}$, and the active spoiling of signal resulting from administered spoiling gradients, $\boldsymbol{G_{spoil}}$. We will examine each mechanism in turn.

© 1998 NRC Canada

Fig. 8. Three-dimensional SPRITE 64^3 image of a multilayer golf ball externally rendered using IDL. The field of view was 6 × 6 × 7 cm^3. The encoding time, t_p, was 50 μs and the TR was 5 ms. The dimpled Surlyn cover with a T_2* of approximately 87 μs is observed. Total imaging time was 7.5 h.



Investigating dephasing effects and echo formation in the SPRITE sequence requires consideration of the amount of transverse magnetization present immediately prior to the succeeding excitation pulse at time TR (Fig. 1). We rewrite eq. [1], substituting for $\boldsymbol{k_z}$ and exchanging t_p with TR to consider the transverse magnetization at time TR following an excitation pulse,

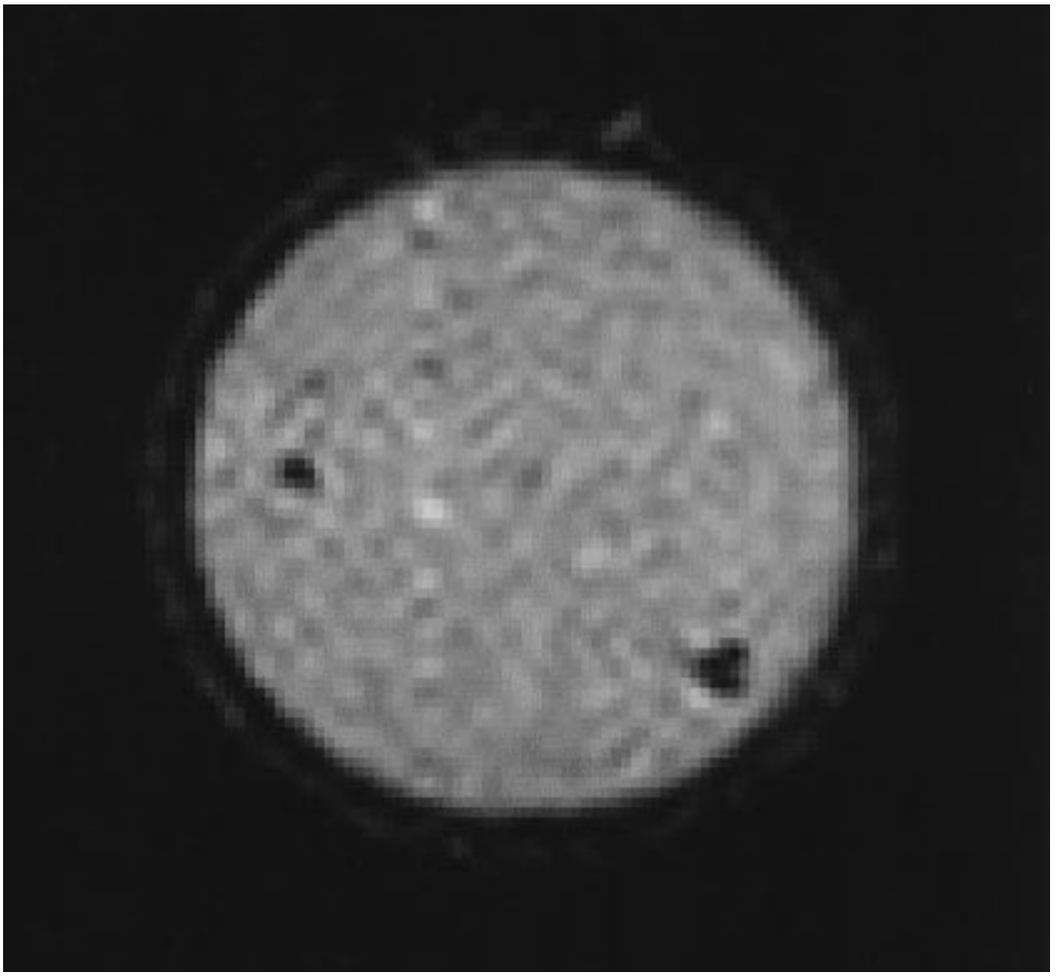
$$[5] \qquad M_{xy} \propto S(\boldsymbol{k_z}) = \int_{-\infty}^{+\infty} \exp[-\mathrm{TR}/T_2^*]\rho(\boldsymbol{z}) \exp[i\gamma \boldsymbol{G_z z}(\mathrm{TR})]\, \mathrm{d}\boldsymbol{z}$$

Spin and stimulated echoes are possible when T_2 = TR and multiple RF pulses manipulate coherent magnetization (29). Therefore one very simple and obvious method of eliminating echo artifacts is to increase TR. As TR is increased the effectiveness of the natural dephasing process is increased, which is observed as a decrease in the term, exp [–TR/T_2*] in eq. [5], and a concomitant decrease in M_{xy}. Although we discuss signal dephasing in terms of T_2* decay, our concern is primarily with T_2, the time constant which is the major culprit in echo formation. While the increase of TR is a natural solution to the elimination of echo artifacts in SPRITE, constraints must be placed on its duration to achieve adequate imaging times and to not exceed the duty cycle restrictions of the gradient coils (19) or gradient amplifiers. Therefore, as the limits of TR are reached alternative methods of ensuring signal dephasing must be considered.

If we examine eq. [5] we see that the signal from the previous pulse/encode period is really a normal FID with a weighting exp [$i\gamma \boldsymbol{G_z z}$(TR)] whose value is governed by $\boldsymbol{G_z}$. In Fig. 1, we see that for each step in the primary phase encode gradient, $\boldsymbol{G_z}$ is applied for a period TR before being

© 1998 NRC Canada

Fig. 9. Selected 2D gray scale image slice from the 3D image data set of Fig. 8. The three layers of the ball are well defined. Inhomogeneities in the core of the ball are observed.



stepped to a lower gradient level. This continuous change in gradient area is a passive dephasing condition that effectively spoils transverse magnetization. Therefore, when a large $\boldsymbol{G_z}$ is applied for the observed point at time t_p, it is evident that even if the natural dephasing process of the sample fails to eliminate M_{xy}, the passive spoiling of $\boldsymbol{G_z}$ will, as shown in eq. [5]. An exception to this condition does occur, however, at the *k*-space origin where $\boldsymbol{G_z}$ is low and echo formation can prevail.

To overcome the problems at the *k*-space origin, a rapidly switched spoiling gradient, $\boldsymbol{G_{spoil}}$, can be introduced into the SPRITE sequence (Fig. 10). Pseudo-random amplitude spoiler gradients can be applied at steps in the SPRITE sequence where little or no dephasing is otherwise achieved (i.e., where $\boldsymbol{G_z}$ is small). This SPRITE modification is very similar to spoiling in the Fast Low-Angle Shot (FLASH) imaging method (30, 31). In both sequences spoiling gradients of fixed duration but random amplitude are applied after each acquisition to actively dephase transverse magnetization before the succeeding α pulse (32). In both SPRITE and FLASH sequences we use and exploit the steady-state longitudinal magnetization but wish to remove all transverse magnetization from pulse to pulse.

This implementation of random area spoiler gradients differs greatly from the original use of spoiler gradients in spin-echo sequences such as RARE (33). As discussed earlier, this spoiling scheme will remove image artifacts which may result from transverse magnetization generated by imperfect 180° refocusing pulses (27, 33). The dephasing effects of the spoiling pulse must be balanced, however, by a matched gradient pulse prior to the 180° refocusing pulse to avoid attenuating transverse magnetization which will contribute to echo formation.

One can systematically consider the integration of passive and active spoiling in terms of an equation. An integral similar to eq. [5] could be developed to demonstrate the effects of active spoiling, where $\boldsymbol{G_z}$ is substituted for $\boldsymbol{G_{spoil}}$ and TR is replaced with the spoiling gradient application time, t_{spoil}. Alternatively, and more simply, complete signal dephasing will occur when

$$[6] \qquad \gamma \boldsymbol{G_i} \boldsymbol{L_i} t >> 2\pi$$

For spoiling in the SPRITE sequence to be effective in preventing echo formation, the product of the gradient $\boldsymbol{G_i}$, its duration, *t*, and the sample length, L, in the *i* direction, must

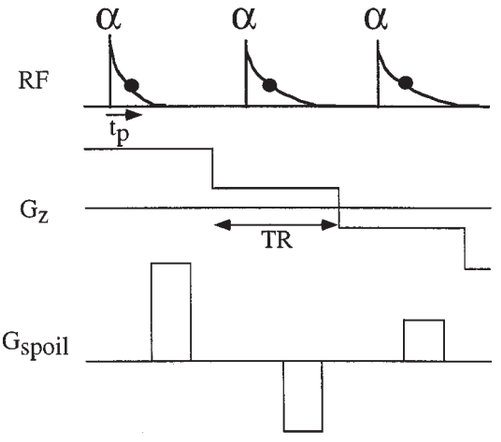
Fig. 10. Schematic of 3 pulses from a 1D SPRITE sequence with spoiler gradients. The gradients are applied with pseudo-random amplitudes in the central regions of *k* space to ensure complete dephasing of transverse magnetization. TR is the gradient step length and also the time between RF pulses.

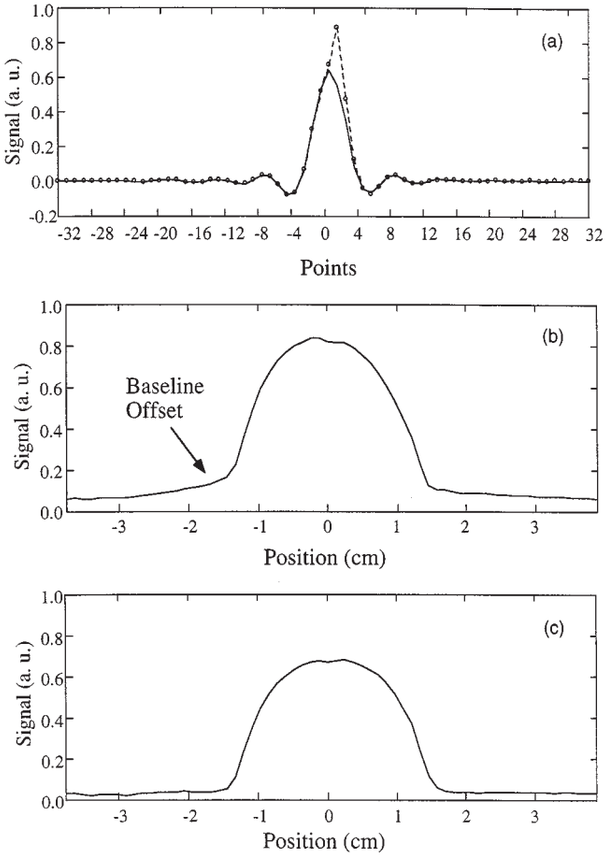


completely disperse transverse magnetization. In addition this dispersal must occur rapidly and dominate the natural dephasing processes of the sample. This condition is achieved at the extremes of *k* space where $i = z$ and t = TR and at the center of *k* space where i = spoil and $t = t_{spoil}$. Equation [6] is essentially the spoiling condition originally proposed by Hennig (34).

To illustrate the necessity of spoiling in SPRITE we have performed a simple phantom study with a uniform object where T_2^* = TR. A spin-echo artifact is observed in a 1D, 64-point SPRITE acquisition performed on a homogeneous manganese (Mn) doped 1% (wt./vol.) agarose phantom (3 cm diam. × 4 cm) (Fig. 11*a*). The T_1 and T_2^* of the phantom were determined using bulk measurements to be 87 and 2.7 ms, respectively. During the application of the SPRITE sequence the ramped phase encode gradients are at their minimum during the central *k*-space acquisitions with a zero crossing occurring at point 1. Figure 11*a* shows a signal offset in the central points of *k* space for the experiment without active spoiling.

We now consider the origin of this signal offset and show that it is due to echo formation. The evolution of transverse magnetization for the central *k*-space points in the absence of strong gradients can be considered through the application of vector product operators. We proceed with a consideration of the behaviour of one isochromat (small region of sample of a particular frequency), recognizing the fact that the sample as a whole evolves as the summation of multiple isochromats. After an interval α-TR-α-TR, it can be shown that an echo of normalized magnitude 1/2 sin α(cos α + 1) will form at point 1 in the transverse plane on the *y* axis of the rotating frame, assuming a $-x$ phase α pulse is applied. The timings of the SPRITE sequence reveal that the echo will have peaked at the exact time of application of the succeeding α pulse. Therefore, signal dephasing for time t_p from the echo peak will be mixed with the FID point sampled at point 1 leading to the observed offset (Fig. 11*b*). Also, the slight offset observed at point 0 in *k* space can be explained by some signal from the leading edge of the echo

Fig. 11. SPRITE 1D acquisition of a manganese-doped gel phantom where $T_2^* \approx$ TR, demonstrating the adverse effects of spin-echoes on *k*-space sampling and the benefits of spoiler gradients; (*a*) *k* space of signal data, real channel, with spoiling (—) and without spoiling (○); (*b*) Mn phantom profile with artifact; and (*c*) spoiled Mn phantom profile, artifact removed.



mixing with the FID signal sampled at point 0 or by an echo formed earlier in point –1.

The corruption of the image in going from reciprocal space (*k*-space) to real space can be explained using the linearity property of the Fourier transform. The addition of two functions in one domain is equivalent to the addition of the Fourier transforms of these two functions in the reciprocal domain (35). The signal offset in reciprocal space, point 1 in Fig. 11*a*, can be approximated by an impulse added to a noncorrupted, "ideal" *k*-space data set. Taking the respective FT of these two functions and moving to the spatial domain, one can see that Fig.11*b* is composed of a very low frequency wave (essentially DC) being added to a noncorrupted, ideal profile. The result of the addition is an MRI effect quite analogous to a DC offset which is frequently observed in phase-sensitive NMR experiments (36). In the later instance the DC offset in the time domain manifests itself as a spike at zero frequency in the frequency domain.

Having identified the artifact origin in Figs. 11*a* and *b* we introduced spoiling gradients into our experiment to ensure transverse magnetization is eliminated prior to successive α pulses. The spoiling gradients were applied during the nine central *k*-space acquisitions of the primary phase encode

© 1998 NRC Canada

gradient. The spoil gradients consisted of rapidly switched magnetic fields of pseudo-random amplitude on an axis perpendicular to the primary phase encode gradient. The maximum amplitude used for the spoil gradients was arbitrarily set at 1/10 the maximum level. The gradient strength could have been increased for the experiment but because 1/10 the maximum satisfied the condition put forth in eq. [6] and was experimentally successful, it was deemed unnecessary. It should be noted as well that too strong a gradient level may lead to excessive gradient vibration and noise. The gradient vibration from each set of nine spoil gradients of restricted amplitude introduces a useful audio cue to monitor the advancement of the SPRITE experiment which is otherwise silent.

The reciprocal space data from the spoiled SPRITE acquisition is shown in Fig. 11*a* as a solid line. A great improvement in the symmetry of the function relative to the nonspoiled acquisition is observed. A comparison of the spoiled profile to the nonspoiled, corrupted profile reveals a flat baseline with no DC offset (Fig. 11*c*). Thus the application of rapidly switched, low amplitude, randomized spoil gradients can be used to remove artifacts which may prevail in systems where the T_2 = TR.

6. Conclusion

SPRITE can successfully produce quantitative 2D and 3D images of polymeric materials of both variable chemical and physical composition with T_2* values <100 μs. High-resolution images of two off-the-shelf samples, a solid-core, multilayer golf ball and a CPVC stop-valve, show the flexibility and the versatility of the technique. Images of each sample reveal different levels of contrast which can be correlated to nonmolecular parameters such as $\rho_0(\boldsymbol{x})$ or molecular physical parameters such as T_2*.

The visualization of long T_2 signals in the presence of short T_2* species without echo artifacts is possible through the implementation of spoiling gradients in the SPRITE sequence.

The SPRITE sequence is rapidly developing. Improvements in hardware and software permit increased signal-to-noise and decreased imaging times. Additional contrast through NMR relaxation times such as T_1, T_2, T_2 solid echo and $T_{1\rho}$ is possible and is under active investigation. These and other developments will be the subject of subsequent publications.

Molecular self-assembly of rigid-rod alkynyl chromophores on inorganic oxide surfaces

Chi Ming Yam, Adam Dickie, Aramice Malkhasian, Ashok K. Kakkar, and M.A. Whitehead

Abstract: The hydrolysis of surface-bound basic tin-amide moieties with acidic protons of alkynyl chromophores leads to molecular self-assembly of a variety of rigid-rod alkynes on inorganic oxide surfaces such as glass, quartz, and single crystal silicon. Characterization of these newly developed thin films was achieved by contact-angle goniometry, FTIR–ATR, ellipsometry, and X-ray photoelectron spectroscopy, which indicate that these thin films are densely packed. Comparative molecular mechanics modeling studies on unbound and chemisorbed -Sn-C≡C-H monomer, dimer, trimer, and a 12 × 12 (144 molecule) model substrate, suggest that surface anchoring of Sn-alkynyl units is essential for highly ordered thin-film structures that can effect topochemical polymerization. Preliminary MO calculations on a 4 × 4 model show conjugated molecular orbitals through the system.

Key words: molecular self-assembly, rigid-rod alkynes, acid–base hydrolysis, tin-alkynyl thin films, molecular mechanics modeling studies, topochemical polymerization, molecular orbitals.

Résumé : L'hydrolyse de portions basiques d'amides d'étain liées à une surface à l'aide de protons acides de chromophores alcynyles conduit à la formation d'autoassemblages moléculaires de divers alcynes en forme de tiges rigides sur des surfaces d'oxydes inorganiques comme le verre, le quartz et des cristaux uniques de silice. On a caractérisé les films minces ainsi formés par goniométrie de l'angle de contact, «FTIR–ATR», ellipsométrie et spectroscopie photoélectronique des rayons X et les données indiquent que ces films minces sont entassés d'une façon dense. Des études comparatives de mécanique moléculaire du monomère -Sn-C≡C-H non lié et chimisorbé, du dimère, du trimère et d'un substrat modèle 12 × 12 (144 molécules) suggèrent que l'ancrage en surface des unités alcynyles d'étain est essentiel pour que les structures fortement ordonnées des films minces puissent donner lieu à une polymérisation topochimique. Des calculs préliminaires d'OM sur un modèle 4 × 4 montrent la présence d'orbitales moléculaires conjuguées à travers tout le système.

Mots clés : autoassemblage moléculaire, alcynes en forme de tiges rigides, hydrolyse acide–base, films minces d'alcynyles d'étain, études de modélisation moléculaire par mécanique moléculaire, polymérisation topochimique, orbitales moléculaires.

[Traduit par la Rédaction]

1. Introduction

Molecular self-assembly is an important and valuable technique for the construction of highly ordered interfaces which offer great potential for a variety of technological applications (1). Self-assembled monolayers (SAMs) based on long-chain alkanes can be prepared using chemisorbed processes involving trichlorosilanes on inorganic oxides, thiols on gold, and carboxylic acids on silver surfaces (2). These "first generation" thin films have been widely characterized and shown to form highly uniform and ordered systems (3). There have been a number of attempts to introduce other useful moieties into the alkanes while retaining the basic long-chain structure that leads to self-organization via van der Waals forces of attraction (4). However, investigations of the organic microstructures with extensive conjugation in the backbone which will involve purely intermolecular π–π interactions for molecular self-assembly, have just begun (5, 6). These "second-generation" SAMs offer tremendous opportunities for building thin-film devices by molecular design. We have recently developed a simple acid–base hydrolytic approach to the functionalization of inorganic oxide surfaces (6). Using this synthetic approach, a variety of thin-film structures including highly conjugated rigid-rod alkynes can be assembled on glass, quartz, and single crystal Si. We report herein our recent results on the self-organization of alkynyl chromophores on inorganic oxide surfaces including a preliminary theoretical evaluation of the behavior of conjugated organic molecules with respect to each other on interfaces. The PM3 calculations on a 4 × 4

tin-acetylene chemisorbed on silica surface show clearly the possibility of topochemical polymerization of the acetylene moieties. This 4 × 4 model is developed from initial studies by molecular mechanics and PM3 calculations of the isolated monomer, dimer, and trimer of tin-acetylene, these chemisorbed on a 12-membered silica ring, a model 12 × 12 tin-acetylene unit calculated using molecular mechanics, and a 12 × 12 tin-acetylene bonded to a 12 × 12 silica surface calculated by molecular mechanics. The 4 × 4 molecular orbitals relate to the monomer, dimer, and trimer molecular orbitals on a 12-membered silica ring. The conjugated molecular orbitals in the 4 × 4 unit presage a fully conjugated conducting band in a real system.

2. Experimental section

Materials

Phenylacetylene and 1,9-decadiyne were purchased from Aldrich and used as received. The other alkynes employed in this study were conveniently prepared using literature procedures (7). $Sn(NEt_2)_4$ was prepared from $SnCl_4$ and $LiNEt_2$ (8*c*). Toluene was distilled over sodium. The substrates were placed in a plastic carousel fitted with a magnetic stir-bar at the bottom. Thin-film depositions were performed under nitrogen in a self-assembly apparatus similar in design to a Schlenk flask but with a flat bottom.

Sample preparation and monolayer self-assembly

The glass, quartz, or Si wafers were first cleaned (*i*) by soaking in soap solution and sonocating for 1 h; (*ii*) repeated washings with deionized water; (*iii*) treatment with a solution mixture containing 70% conc. H_2SO_4 and 30% H_2O_2 (piranha solution) at 100°C for 1 h. Caution: Piranha solution is highly explosive, and care should be taken while using this mixture; (*iv*) repeated washings with deionized water; and (*v*) finally heating in oven at 150°C for 5 min and vacuum drying for 5 min to remove physisorbed water. The surface functionalization involved a two-step process of (*i*) reaction with 1% solution by volume of $Sn(NEt_2)_4$ in toluene for 18 h; followed by (*ii*) treatment with the organic chromophore in dry toluene at 80°C for 18 h.

Contact-angle measurements

The static contact angles were measured with a Rame–Hart NRL 100 goniometer using water and hexadecane as probe liquids. On average, six drops of equal volume were measured on different areas of the substrate for each sample, and the values reported are the mean values.

Fourier transform infrared spectroscopy in the attenuated total reflection mode (FTIR–ATR)

The thin films were grown on the <100> surfaces of the single side polished silicon wafers. A KRS crystal was sandwiched between the reflective faces of two silicon wafers (1.2 × 4.0 cm), and the angle of incident light was set at 45°. All spectra were run for 4000 scans at a resolution of 4 cm^{-1}, using a Bruker IFS-48 spectrometer. Spectrum of a clean silicon wafer was measured as a background correction.

Ellipsometry measurement

A Gaertner Scientific ellipsometer operating with a 633 nm He-Ne laser (λ = 6328 Å) was employed. The angle of incidence was 70°, and the compensator was set at 45°. All reported values are the average of at least six measurements taken at different locations on the sample. The thicknesses were calculated by comparing data from the same substrate before and after functionalization, and using a value of 1.46 for the refractive index.

X-ray photoelectron spectroscopy (XPS)

The XPS spectra were obtained by using a INRS 220i XL spectrometer with monochromatized AlK_α radiation source at 10^{-9} Torr pressure.

All modelling and semi-empirical calculations were performed using HyperChem™ Release 3 for Windows and Cerius 2 version 3.0/MOPAC 6. The molecular mechanics force field was MM+, and geometry optimizations were carried out using the Polak–Ribiere conjugate gradient set to terminate at an RMS gradient of 0.1 kcal/Å mol.

3. Results and discussion

3.1. Acid–base hydrolysis: in solution

The chemistry of aminostannanes, which can be conveniently prepared by the reaction of the corresponding chloride and $LiNR_2$ (8), with organic compounds containing acidic protons, is well established. For example, the compound, $(CH_3)_3Sn\text{-}NR_2$ (R = CH_3, C_2H_5), reacts with R′OH, R′SH, R′COOH (R′ = alkyl or aryl group), and alkynes (e.g., $H\text{-}C{\equiv}C\text{-}C_6H_5$) via acid–base hydrolysis to give $(CH_3)_3Sn\text{-}OR'$, $\text{-}SR'$, $\text{-}OOCR'$, and $\text{-}C{\equiv}C\text{-}C_6H_5$, respectively, in quantitative yields (eq. [1]) (8). Similarly, the reaction of 2 equiv. of $(CH_3)_3Sn\text{-}NR_2$ with $H\text{-}C{\equiv}C\text{-}R\text{-}C{\equiv}C\text{-}H$ (R = *p*-C_6H_4, *p*-C_6H_4-C_6H_4, *p*-$C_{14}H_8$, $\text{-}C{\equiv}C\text{-}C_6H_4\text{-}C{\equiv}C\text{-}$, and $(CH_2)_6$), yields the corresponding trimethyltin substituted alkynes with the elimination of diethylamine.

Evolution of this chemical methodology on inorganic oxide surfaces can lead to thin-film assemblies of molecules containing desired chemical frameworks.

3.2. On surfaces

The surfaces of inorganic oxides such as silica, glass, and quartz are acidic in nature, and contain surface hydroxyl groups (9, 10). Thus, the acid–base hydrolytic chemistry described above can be easily applied to these surfaces to give a versatile chemisorption method for a variety of organic microstructures. A general surface modification strategy is shown below in Scheme 1, which involves the chemical processes described in detail in the experimental section, and depicts a cartoon representation of the various steps involved in the thin-film construction process.

The evolution of thin-film structures was routinely monitored by surface wettability measurements, FT–IR, ellipso-

metry, X-ray photoelectron spectroscopy, etc., and the pertinent data is presented in Table 1. Surface wettability measurements have been widely used to approximate the hydrophobicity and to estimate chromophore density in thin-film assemblies (1–3). Contact-angle goniometry measures the angle that the drop of a liquid makes on a surface, and is dependent on the relative hydrophobicity or hydrophilicity of the thin-film surface and the liquid. For example, a clean and unfunctionalized glass surface produces a contact angle of ~18° with water. When a nonpolar liquid such as hexadecane is deposited onto a hydrophilic surface such as unfunctionalized glass slide, an increase in the forces of repulsion at the solid–liquid interface results in a higher contact angle (~85°). Conversely, when hexadecane is deposited onto an organic monolayer, an increase in the forces of attraction results in the lowering of the contact angle.

For long-chain alkanes deposited on the inorganic oxide or gold surfaces, contact angles of ~110° with water and 35–40° with hexadecane have been observed (2). The wetting nature of alkynyl surfaces is expected to be different than long-chain alkane self-assembled thin films, and may depend on a number of factors. The latter are currently under investigation in our laboratory. Table 1 summarizes static contact-angle data obtained from thin films of a variety of rigid-rod alkynes employed in the present study. These values that are comparable to those obtained from thio-alkynyl thin films on Au (11, 12) suggest that these thin films are densely packed.

Fourier transform infrared spectroscopy in the attenuated total reflection mode (FTIR–ATR) has been extensively used

in the characterization of thin-film structures (2). This sensitive surface technique confirms the chemical identity of the newly developed thin film. The spectra of the thin films containing alkynyl chromophores typically displayed peaks at 2097, 3260, 3033, and 1498 (br) cm^{-1}, which can be assigned to acetylene and phenyl groups of the rigid-rod structure. These values are similar to those obtained from alkynylthiols chemisorbed on Au (11).

Ellipsometry is a commonly employed technique to measure thicknesses of the molecularly self-assembled thin films (13). A detailed evaluation of this technique has been discussed elsewhere (2, 14). However, to calculate thickness of an interface one compares data from the same substrate before and after functionalization, and an assumption is made for the refractive index of the organic phase. For long-chain alkanes, a typical value of the refractive index employed for calculating thicknesses is 1.45 (13). For self-assembled alkynyl thin films reported in this study, we used a similar value (1.46). The data obtained from the functionalized silicon wafers is shown in Table 1. Calculation of the theoretical thicknesses was based on typical values of bond lengths between elements projected on the surface. There is a good agreement between calculated and experimental thicknesses of the alkynyl thin-film assemblies, and it suggests a close-packed arrangement of the rigid-rod alkynyl chromophores.

X-ray photoelectron spectroscopy is a well-known technique to determine the surface composition of the anchored species in the molecularly self-assembled thin films (2). We employed this technique for the analytical evaluation of the various alkynyl thin films on glass, and the data is presented in Table 1 that confirms the composition of the thin-film structures. A slight increase in binding energies was observed for Si 2*p*, Sn $3d_{3/2}$, and Sn $3d_{5/2}$. This increase in binding energies of the elements in chemisorbed thin films is consistent with the values expected for Si of SiO_2 and Sn of SnO_2.

4. Theoretical evaluation of alkynyl thin-film assemblies

4.1. Unbound molecules

A detailed understanding of the interactions between alkynyl molecules, and the role of the substrate in molecular self-assembly, is essential in building densely packed thin-film materials. Alkynyl moieties in supramolecular structures can be polymerized topochemically to give one-dimensional conductors and third-order nonlinear optical materials (2). An essential requirement for surface polymerization is the orientation of the alkynyl chromophores on the surface.

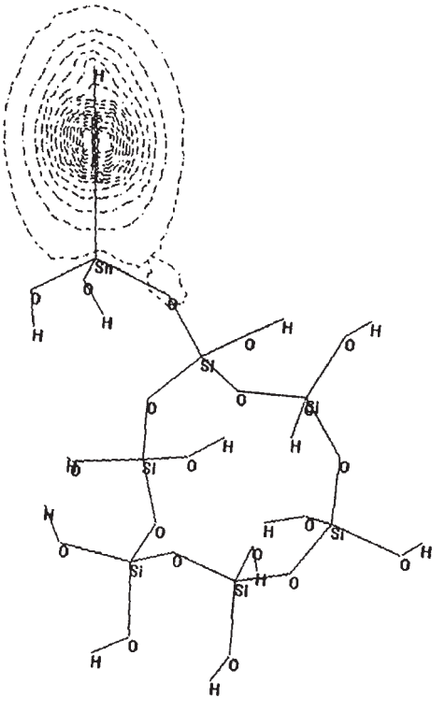
Fig. 7. Geometry-optimized Sn-C≡C-H monomer on a 12-membered ring SiO_2 by PM3 calculations showing that the C≡C molecular orbital now involves the surrounding Sn and H atoms (–30.714 69 eV).



Therefore, to get an understanding of molecular self-assembly of rigid-rod alkynes on solid substrates molecular modelling and semiempirical calculations were used. For simplicity, the Sn-C≡C-H molecule was studied which can be elaborated and provides a basis for other conjugated structures.

Molecular modelling (MM) and the MNDO and PM3 semi-empirical molecular orbital theories were first applied to the unbound tin-alkynyl molecules, the monomer (Fig. 1), dimer (Fig. 2), trimer (Fig. 3), and finally a 12 × 12 (144 molecule) structure which approximates the structure of the tin alkynyl film when surface bound to silica. The results are presented in Tables 2–4. The molecular mechanics reference binding energy of this molecule is 0.399 kcal/mol relative to the free atoms. The main contributions to the MM binding energy are the dihedral (0.998 kcal/mol) and the van der Waals (–0.599 kcal/mol) attractive forces. The C≡C bond distance is 1.20 Å, and the C-Sn-O bond angle 110°. Dimerization of the molecule, $\{O\text{-}[(HO)_2Sn\text{-}C{\equiv}C\text{-}H]_2\}$ (Fig. 2, Table 3*a* and *b*) did not change the geometry. The binding energy decreased to –1.828 kcal/mol, mainly because of the MM van der Waals attractive energy (–1.926 kcal/mol). Note the large separation (3.6 Å) between $C^1{}_a$ of the first molecule and $C^2{}_b$ of the second (Fig. 4). Topochemical polymerization on the surface requires bonding between these two carbon atoms to give a conjugated structure. Any attempt to bond this dimer results in a stable MM molecule with a 4.7 Å double bond length! The trimer, $\{(HO)(C{\equiv}C\text{-}H)Sn\text{-}[O\text{-}(HO)_2Sn\text{-}C{\equiv}C\text{-}H]_2\}$ (Fig. 3) has four equally stable conformations (Fig. 5) and is a flexible molecule. These conformations display changes in geometry from the monomer as well as the dimer (Table 4*a* and *b*). The molecules display strong MM van der Waals attractions ranging from –3.423 to –4.323 kcal/mol, and the MM binding energies for different conformers vary from –4.017 to –3.340 kcal/mol.

The MNDO and PM3 MO theories parallel molecular modelling, giving almost identical geometric structures, but show that the C≡C HOMO orbital is localized on the bond and energetically separated from the remaining molecular orbital which bonds the tin to the hydroxyls (Figs. 1–3). Therefore, it appears to be available for conjugation. The

reliability of modelling for geometric structure predictions justified approximating the formation of a Sn-C≡C-H thin film on a surface and the role of surface in molecular self-assembly by modelling a 12 × 12 layer of Sn-C≡C-H molecules with and without surface attachments (Fig. 6). For the unattached system, the MM binding energy increased dramatically to 2225.848 kcal/mol (Table 5), and the C^1_a-C^2_b chain separation covered a range of values with the attractive van der Waals energy of –444.157 kcal/mol, decreasing in importance compared to the MM bond angle bending energy of 2420.63 kcal/mol. Even by ignoring edge effects which relate to tipping of molecules near the edges away from each other, and considering a 6 × 6 spread of molecules in the centre of the monolayer as typical of the extended structure, no discernible order was observed. This suggests that binding of the alkynyl chromophore to a surface must play a significant role in molecular self-assembly of alkynes.

4.2. Surface-bound molecules: role of silica substrate

The geometry-optimized Sn-C≡C-H monomer on a 12-membered SiO_2 ring is shown in Fig. 7, and the data is given in Table 6*a* and *b*. Compared to the free monomer, the binding energy decreased to –12.442 kcal/mol with the main contribution coming from the attractive MM van der Waals energy (–13.474 kcal/mol). The C≡C bond length and the

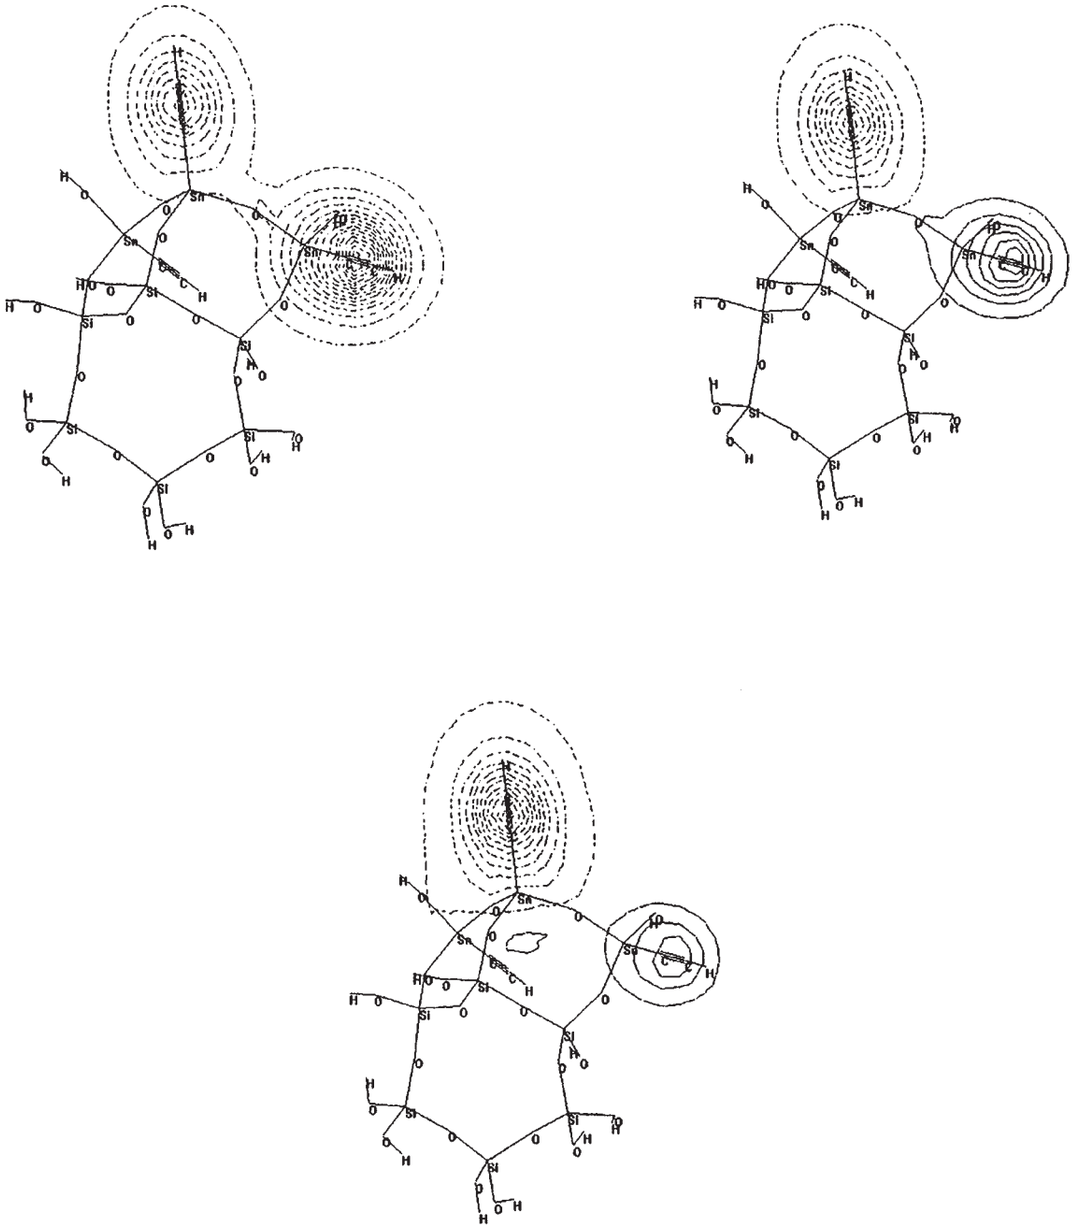
Fig. 9. Geometry-optimized Sn-C≡C-H trimer on a 12-membered ring SiO_2 by PM3 calculations showing that the three molecular orbitals are on all three C≡C and involved Sn and H (–30.683 11, –30.653 10, and –30.630 27 eV); one MO is not visible in this plane.



C-Sn-O bond angle are similar to the unbound monomer. The construction of a dimer on a 12-membered SiO_2 ring (Fig. 8) leads to interesting changes compared to the unattached dimer (Fig. 2), notably the separation between the two molecules. It has a MM van der Waals attractive energy of –14.939 kcal/mol (Table 7*b*) which indicates a possible strong π–π attraction compared to the unbound dimer (van der Waals attractive energy = –1.926 kcal/mol, Table 2*b*). The C^1_a—C^2_b chain separation increases to 7.32 Å (Table 7*a*) from 3.66 Å in the free dimer. Although, the MM binding energy decreases to –7.531 kcal/mol and the C-Sn-O bond angles remain relatively constant, the two molecules move away from each other. The addition of another molecule of Sn-C≡C-H to the silica ring leads to the trimer (Fig. 9), the MM binding energy decreases to –6.509 kcal/mol, and an increase in the π–π interaction leads to a MM van der Waals attractive energy of –15.528 kcal/mol (Table 8*b*). The alkyne-to-alkyne separation (C^1_a—C^2_b chain distance) is in the range of 6.7–7.7 Å, and the C-Sn-O angles (Table 8*a*) are the same as in the unattached trimer. Thus the alkyne molecules are bonded to the silica and through the silica to each other. By locking tin-alkynes into a fixed geometric position on a model representation of a silica surface, interactions between acetylene molecules are expected to

lead to an ordered self-assembled thin film. The MO for the single tin-alkyne on a 12-membered SiO_2 ring shows the C≡C molecular orbital covering the H and tin. It is not localized on the C≡C bond as in the free molecules. Note that the binding energies in the MM results follow the same trend as the true MO binding energies. This MO (Fig. 7) is energetically separate from all other molecular orbitals at –30.714 69 eV. When the dimer (Fig. 8) and trimer (Fig. 9) on the 12-membered SiO_2 ring are considered, the molecular orbitals are at –30.661 52, –30.634 11, –30.683 11, –30.653 10, and –30.630 27 eV.

A monolayer of Sn-C≡C-H on a 12 × 12 SiO_2 model substrate composed of interconnected 12-membered rings (Fig. 10) was calculated by molecular mechanics. The surface of SiO_2 units was frozen and held rigid, and only the $(Sn\text{-}R)_{144}$ monolayer was examined directly with molecular modelling. The 12 × 12 monolayer model substrate shows a highly ordered structure. The tipping of molecules away from the surface near edges is due to the edge effect. The latter should be ignored, since these molecules are not surrounded by a sufficient number of other molecules to experience all the necessary molecular interactions. Therefore the isolated middle 6 × 6 molecule will be discussed as free of edge effects. The binding energy of 12 574.26 kcal/mol (Table 9*a*) is mainly the MM van der Waals attractive energy (–6155.87 kcal/mol). The average of the bond angles of the

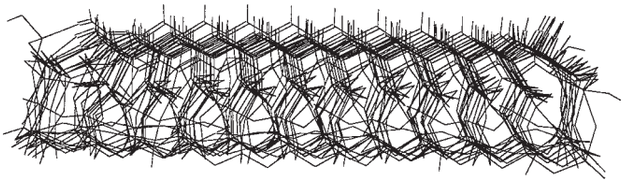

Fig. 12. The localized PM3 molecular orbital on one of the C≡C in a frozen 4 × 4 section of the 12 × 12 molecular modelling result (Fig. 10) with a different silica base to simplify the calculations. The tin-alkynyls are geometry optimized on this frozen base. This clearly shows the C≡C to be an isolated molecular orbital to the rest of the molecule and silica base. The angle is 45 ± 9° and the bond length is 1.20 Å.

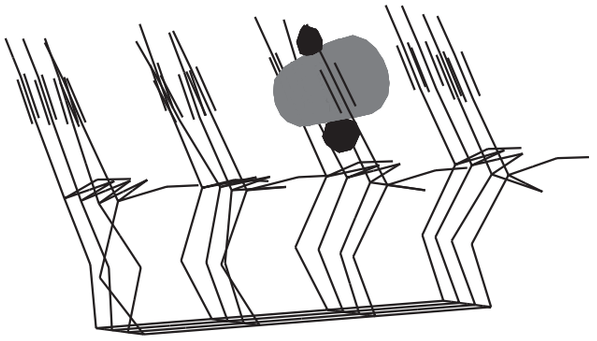

alkynyl groups is 51 ± 3° (Table 9*b*). The small variations observed reflect the underlying surface of the model SiO_2 substrate because the angles are measured against an artificial horizontal plane for convenience. The C^1_a—C^2_b chain separation decreases to 3.4 Å (Table 9*c*), suggesting that conjugation is possible, leading to surface polymerization. The MM predictions can be accepted because as shown above they parallel the MO calculations of bond lengths and angles.

Topochemical polymerization was modelled by replacing the acetylene bonds on the 12 × 12 monolayer with a $[\text{-}C_a{}^1{=}C_b{}^2\text{-}C_a{}^1{=}C_b{}^2\text{-}]$ representation of the polymer (Fig. 11) where the conjugation is easily seen at the top of the figure. Once again, only the interior 6 × 6 structure was selected for analysis. The MM binding energy increased to 49841.105 kcal/mol. The conjugated C=C and C—C bonds have identical lengths (1.50 ± 0.01 Å, Table 10*a* and *b*), suggesting a highly conjugated system, which is supported by finding the first example of a repulsive MM van der Waals

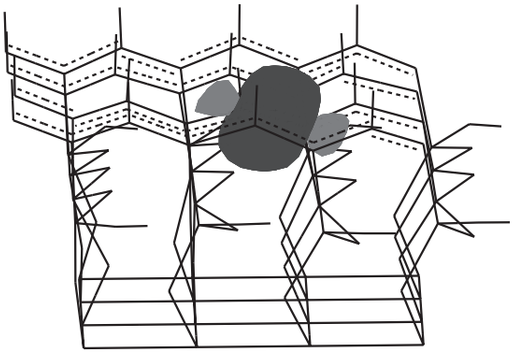
energy of +13.668 kcal/mol, when the bond angles average around 75 ± 3°. Consequently polymerization can only occur when the alkyne molecules are surface adsorbed.

Fig. 14. The localized PM3 molecular orbital on one of the conjugated C=C in a frozen 4 × 4 section. The tin-alkynyls joined from C^1_a to C^2_b were then optimized by the PM3 method to give the conjugated structure. The angle is 35 ± 6° and the bond length is 1.6 ± 0.1 Å.



Because the SiO_2 surface anchors the tin-acetylenes, it was represented by a model silica square surface (Fig. 12). This simplified MO calculation sufficiently to allow results to be obtained in a day or two per calculation. Preliminary PM3 calculations were performed on the centre 4 × 4 of the 12 × 12 molecule. The localized molecular orbitals (LMO) (Fig. 12) were found to be on the C≡C as in the free monomer (Fig. 7), small surface-bound tin-alkyne quite different from and clearly separated from all other molecular orbitals in the molecule. It is therefore free to bond when the C≡C are close enough top to tail C_a^1-C_b^2 (Fig. 4). The angles change from the MM calculations, because of the changed model surface to 45 ± 9°, and the C_a^1—C_b^2 distance reduces to 3.2 ± 0.2 Å. Bonding the C_a^1-C_b^2 head to tail in this 4 × 4 model gave delocalized MO (Fig. 13) between levels 37 and 48 at –33.256 23 to –26.175 55 eV and energetically separate as a band from the MO covering the tin and model SiO_2 surface. The preliminary localized molecular orbital (LMO) of this system is shown in Fig. 14, and it shows clearly that

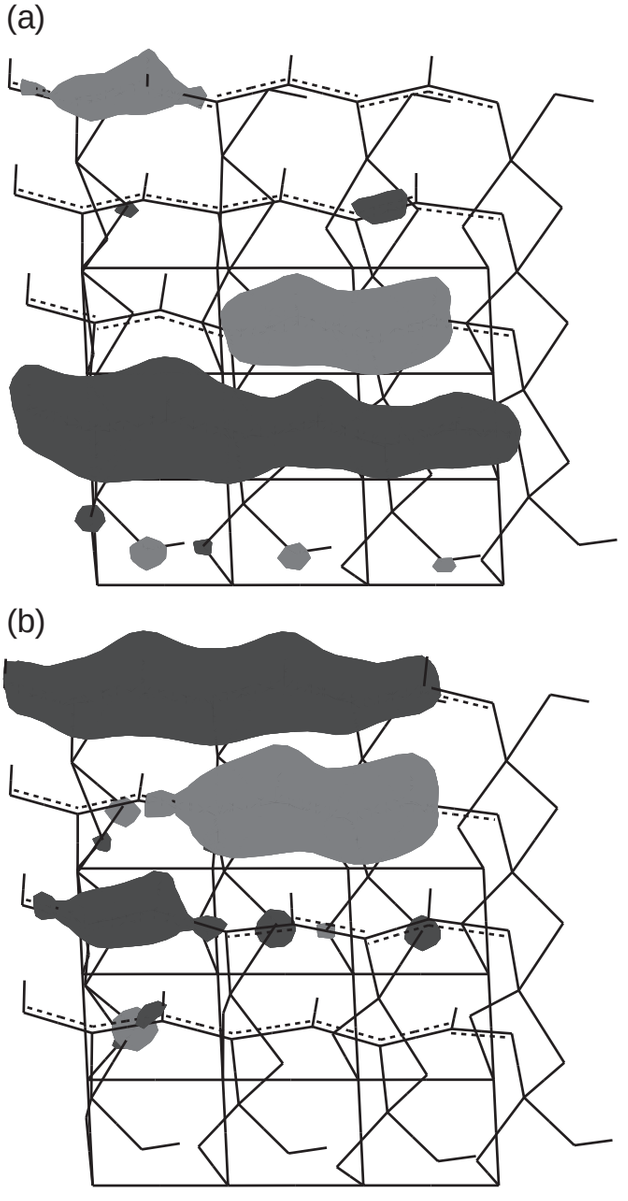
Fig. 15. Delocalized C=C-C=C to give C=C=C=C conjugation on a 4 × 4 section. PM3 geometry-optimized orbitals. Bond lengths are 1.6 ± 0.1 Å, showing that topochemical polymerization has occurred. The MO of energies (*a*) –30.642 18 eV (MO 40) and (*b*) –29.813 73 (MO 42) shown as typical of the wide range of MO in this band which is energetically separated from all other MO on the structure.



the C≡C LMO has rotated to become a C=C conjugative molecular orbital with the 178 ± 1° C≡C-H angle becoming 110 + 3° as the carbon rehybridizes from Cdidiππ (di = digonal, *sp* hybridization) to Ctrtrtrπ (tr = trigonal, sp^2 hybridization). The C-C-C angle is 138 ± 3°. The C≡C bond length of 1.20 Å becomes a conjugated C=C=C bond length of 1.6 ± 0.1 Å. The separation of the conjugated rows is 3.5 ± 0.1 Å compared to 3.3 ± 0.2 Å in the C≡C case. Thus, there is no hydrogen replacement, just rehybridization at the carbon to approximately trtrtrπ, with angles 138 ± 3°, 110 ± 3°, 112 ± 3° at all the carbons. A detailed study of the MO calculations will be published when the analysis is complete.[2] The bond lengths and bond angles essentially reflect the molecular modelling results on which the initial ideas were based.

Figure 14 and Table 11, show clearly how the C≡C level of the isolated molecule becomes the band of isolated molecular orbitals for a mere 4 × 4 silica adhered tin-acetylene structure and the change in contributions to the energy upon conjugation. These can then conjugate to give linear molecular orbitals parallel to each other. If these were extended to a true structure, this band of levels would become a conducting band similar to metal structures. The various molecular orbitals in Figs. 14 and 15 merging into a continuous band along each row of C=C=C atoms. In the real system they would generate a set of conjugated molecular orbitals, as suggested by the molecular modelling of the 12 × 12 system. The change in bond length from the C≡C (1.2 Å) and the row separation of 3.2 Å to the conjugated repetitive C=C—C=C length of 1.6 Å and the row separation of 3.5 ± 0.1 Å require a greater tilt in the angle from 45 ± 9° to 35 ± 6°. The angle change along the conjugated chain from the C≡C-H (178 ± 1°) to C=C-H of 110 + 1° show rehybridization at the carbon atoms from Cdidiππ to Ctrtrtrπ. There is no hydrogen abstraction, just rehybridization to supply three sigma and one delocalized π conjugated orbital.

Conclusions

Simple acid–base hydrolysis of surface-bound tin-amides with a variety of alkynes is a versatile approach for constructing thin films containing rigid-rod alkynes. The π–π interactions in the molecules can lead to highly ordered and densely packed thin-film structures. These results, reflected by molecular mechanics modelling studies of Sn-acetylene chromophores on a model substrate, suggest that for the formation of a highly ordered system, chemical bonding of Sn to the silica surface is essential. The C_a^1–C_b^2 interchain distance in these chemisorbed thin films is optimal for surface polymerization, leading to a highly conjugated structure. Preliminary MO calculations on a model 4 × 4 surface adhered tin-acetylene give evidence to conjugated orbitals between –32.089 11 eV and –18.865 85 eV and typical conjugated bond lengths around 1.6 ± 0.1 Å with carbon trigonal π-bonded with 138 ± 3° and two 111 ± 3° angles. This band of levels is completely separate from all other eigenvalues.

Dissolution behavior in water of a model hydrophobic alkali-swellable emulsion (HASE) polymer with $C_{20}H_{41}$ groups

Kazunaga Horiuchi, Yahya Rharbi, Ahmad Yekta, Mitchell A. Winnik, Richard D. Jenkins, and David R. Bassett

Abstract: The dissolution behavior of a hydrophobic alkali-swellable emulsion (HASE) in water was examined by dynamic light scattering and pyrene fluorescence probe experiments. The HASE polymer was obtained by the copolymerization of ethyl acrylate (EA), methacrylic acid (MAA), and a macromonomer containing a $C_{20}H_{41}$ group separated from the polymer backbone by 32 ethylene oxide units. The behavior of the copolymer was followed as a function of the neutralization degree α = [NaOH]/[COOH] of the MAA component. Particles swell with increasing α until α = 0.4 after which polymer dissolution begins. At low α, pyrene, added as a probe to the solution, dissolves in the EA–MAA copolymer phase; whereas at high α, pyrene is largely localized in $C_{20}H_{41}$ micelles. Pyrene fluorescence measurements show that the striking viscosity increase of the solution with increasing α correlates with polymer dissolution and intermolecular network formation.

Key words: associative polymer, hydrophobic substituents, polymeric micelles.

Résumé : Faisant appel à la diffusion dynamique de la lumière et à des expériences de sondes à fluorescence du pyrène, on a étudié le comportement d'une émulsion hydrophobe gonflable par les alcalis (« HASE ») lors de sa dissolution dans l'eau. On a obtenu le polymère HASE par copolymérisation de l'acrylate d'éthyle (« EA »), de l'acide méthacrylique (« MAA ») et d'un macromonomère contenant un groupe $C_{20}H_{41}$ séparé du squelette du polymère par 32 unités d'oxydes d'éthylènes. On a suivi le comportement du copolymère en fonction du degré de neutralisation, α = [NaOH]/[COOH], de la portion MAA. Les particules se gonflent avec une augmentation d'α jusqu'à α = 0,4; après la dissolution du polymère commence. À de faibles valeurs d'α, le pyrène — ajouté comme sonde à la solution — se dissout dans la phase de copolymère « EA–MAA »; toutefois, à des valeurs d'α élevées, le pyrène se localise principalement dans les micelles de $C_{20}H_{41}$. Des mesures de fluorescence du pyrène montrent la corrélation qui existe entre l'augmentation étonnante de la viscosité de la solution associée à une augmentation d'α et la dissolution du polymère et la formation d'un réseau intermoléculaire.

Mots clés : polymère associatif, substituants hydrophobes, micelles polymériques.

[Traduit par la Rédaction]

Introduction

Hydrophobically modified water-soluble polymers (1, 4) are being used in a wide range of commercial applications, particularly in paints and paper coatings. In paints, these polymers are used as thickeners ("associative thickeners" (AT)) increasing the viscosity of the formulation to prevent pigment settling during storage, and to impart an appropriate viscosity profile when the system is subjected to shear. Solutions of these polymers exhibit unusual and often very complicated rheological behavior. The type of behavior one obtains depends sensitively upon the polymer structure and the nature and location of the hydrophobic substituents.

For water-borne coatings, good performance requires the formulation to possess a viscosity low enough at high shear rates to achieve uniform coverage of the substrate, but at the same time high enough to produce a good film thickness. At low shear rates, the viscosity must be significantly higher to

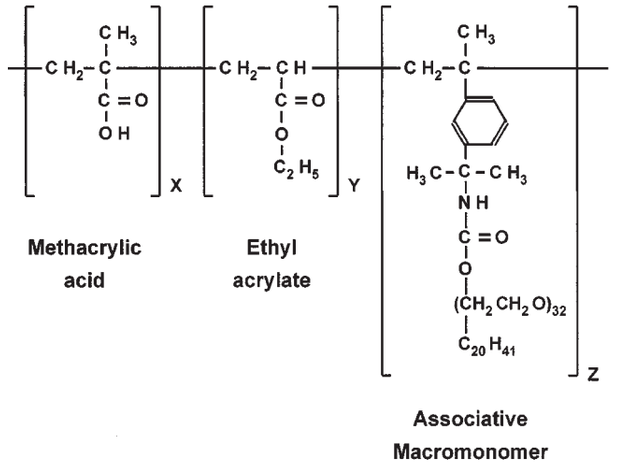
Fig. 1. Chemical structure of the model $C_{20}E_{32}$ HASE polymer, 28RDJY72–6. The name $C_{20}E_{32}$ denotes copolymer in which the associative macromonomer unit contains a $C_{20}H_{41}$ hydrophobe is attached to the polymer backbone via a linker containing 32 units of ethylene oxide. The monomer molar ratio is $X/Y/Z$ = 49.06/50.04/0.90.



prevent the paint from running, but still low enough to exhibit good flow-out and leveling on the surface. These seemingly mutually exclusive demands require the dispersion to exhibit time-dependent rheological properties specific to each particular type of application in which the viscosity changes in a controlled way with shear rate. To achieve this kind of performance, we need a much deeper understanding of the structures formed by associating polymers in aqueous solution and the response of these structures to shear and extensional stress.

One class of polymers about which our knowledge is particularly limited is the hydrophobic modified alkali-swellable emulsion (HASE) polymers (2, 3). These are long-chain acrylic polymers, typically copolymers of ethyl acrylate and methacrylic acid, containing hydrophobic pendant groups. These polymers are prepared by emulsion polymerization at low pH where they form a polyelectrolyte with hydrophobic substituents. An increase of pH results in ionization of the acid groups, leading to polymer solubility in water. The thickening efficiency in HASE polymers is achieved both by the associative mechanism as well as by expansion of the macromolecule backbone. The chain expansion has two components, the first due to particle-to-coil expansion upon dissolution, and the second due to electrostatic repulsion between the neutralized carboxylic groups. These materials are not difficult to prepare and have a striking advantage to formulate for high concentration, typically 2 wt.% for the AT applications. The dispersions in the latex formed at low pH have water-like viscosity, and raising the pH beyond 7 leads to a very large increase in viscosity and to other interesting rheological properties of the system.

These polymers, however, are significantly more complex and difficult to understand than linear water-soluble associating polymers with hydrophobic end groups. While it is fair to say that a decade ago our knowledge of all associating polymers in water was very poor, there have been over the intervening years many interesting experiments carried out on the linear associative polymers. We start to have an understanding of the origin in at least some of the globally more important properties for these telechelic polymers (4). The systems we understand best are poly(ethylene oxide) polymers with hydrophobic end groups, including the ethoxylate urethane-coupled HEUR polymers (5).

In the present paper, we examine the dissolution step of a model HASE polymer. This polymer is one of several model polymers prepared by Jenkins at Union Carbide. One of the distinguishing features of these polymer structures is that the hydrophobic substituents are separated from the polymer backbone by a polyethylene glycol (PEG) spacer chain. Recently Tirtaatmadja et al. (6, 7) and English et al. (8) reported rheological measurements on some of these polymers and discussed the striking rheological behavior observed under shear, especially strong shear, where the polymer network is imagined to be broken or rearranged. The long-term goal of our experiments is to provide a molecular-level understanding of the association mechanism in these polymers, and its connection to bulk solution rheological properties.

Materials and methods

Materials

The polymer examined in the present work is $C_{20}E_{32}$ (28RDJY72–6), shown in Fig. 1, with molar ratios *x*:*y*:*z* of 49.06:50.04:0.90. Full details of the synthesis and characterization of this and similar HASE polymers have been reported by Jenkins et al. (3*b*). In short, a macromonomer was prepared first by ethoxylation to 32 mol of the C_{20} alcohol, followed by reaction with α,α-dimethyl meta-isopropenyl benzyl isocyanate (TMI). This macromonomer was introduced into a conventional seeded semicontinuous emulsion polymerization under monomer starved conditions with appropriate amounts of methacrylic acid and ethyl acrylate. In this work, we designate this polymer $C_{20}E_{32}$. According to the structure and composition of the polymer, it contains 2.12×10^{-2} g $C_{20}H_{41}$ groups per g polymer (7.53×10^{-6} mol/g polymer).

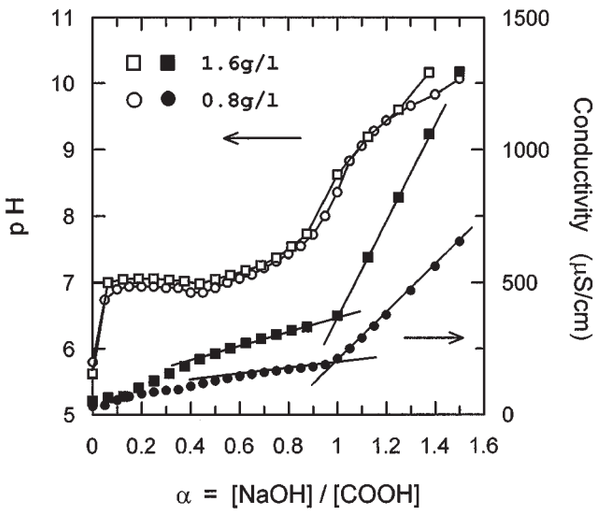
The latex emulsion was dialyzed against 3.0 L of deionized water for more than 2 weeks with a cellulose membrane, formulated to cut off from M_w 12 000 to 14 000 (Fisher Scientific). A series of different polymer concentrations was prepared by dilution of the dialyzed HASE solution with deionized water. Salt was added to give an ionic strength of 1.0 mM NaCl for viscosity and fluorescence measurements. To minimize concentration changes of the polymer solution, 1.0 M NaOH was used to neutralize the polymer.

Titration

In the titration of the HASE solution, 15 mL was placed in a 25 mL beaker equipped with magnet stirring. For forward and backward titration processes, 1.0 M NaOH and 1.0 M HCl were used, respectively. Potentiometric and conductometric signals were recorded 5 min after each dosage, using a Cole–Palmer no. 5985–80 portable pH meter and a Fisher Scientific model no. 09–326–2 portable conductivity meter.

© 1998 NRC Canada

Fig. 2. Potentiometric and conductometric titration of $C_{20}E_{32}$ for C_{pol} = 1.6 g/L and C_{pol} = 0.8 g/L, plotted as a function of degree of neutralization α = [NaOH]/[COOH].



Viscosity measurement

Relative viscosities (η/η_0) were measured using a Ubbelohde suspended-level viscometer, keeping the temperature at 25 ± 0.1°C in a temperature-controlled bath.

Dynamic light scattering measurement

Light scattering measurements were carried out on a dilute polymer solution, 0.16 g/L, to reduce multiple scattering from the latex. A series of the different neutralizations were made by adding 0.1 M NaOH with a 10 mL microsyringe. The 514.5 nm line from an Argon-ion laser (Excel 3000) was used as the excitation source, and the signal was processed in a digital correlator (Brookhaven BI-2030AT) with 136 channels. The temperature was fixed at 22.0 ± 0.1°C in a thermally stabilized container filled with a refractive-index matching liquid (toluene). The large variation of scattered intensity during the titration was compensated by adjusting the laser power without changing the pinhole and signal discriminator.

The intensity autocorrelation functions $g_2(t)$ obtained from the DLS measurements were analyzed in terms of a continuous distribution of relaxation times:

$$[1] \qquad g_1(t) = \int_0^\infty A(\tau) \exp(-t/\tau) d\tau$$

Here $g_1(t)$ is the normalized electric field autocorrelation function related to $g_2(t)$ via the so-called Siegert relation (9*a*). The REPES routine was used to obtain $A(\tau)$ without assuming a specific shape (9*b*). For converting the averaged relaxation time to a hydrodynamic radius, the Stokes–Einstein relationship for small, dilute, and noninteracting spheres was used, with η_{water} = 0.97 cP at 22°C.

Pyrene solubilization

Pyrene (Aldrich) was purified by recrystallization and twice-repeated sublimation. For pyrene solubilization into HASE solutions, a dilute acetone solution containing a known amount of pyrene was placed in a flask, and then the acetone was evaporated completely under a gentle flow of nitrogen. To equilibrate the pyrene in the HASE solution, the mixture was stirred at room temperature for 1 week. Subsequent centrifugation of the solution at 15 000 rpm for 60 min caused the insoluble pyrene crystals to sediment without affecting the dispersion or solution stability.

UV absorbance measurements

The UV absorbance of the HASE solution was measured in 10 mm quartz cuvettes using a Perkin–Elmer Lambda 6 dual-beam spectrometer. Solution turbidity was monitored at 360 nm, where there is no detectable absorption by the HASE polymer. The pyrene concentration was monitored at the strongest absorption peak at 339 nm, with a correction for the background absorption (turbidity) of the polymer.

Steady-state fluorescence measurements

A SPEX Fluorolog 2, with double-grating monochromators for both the excitation and emission, was used to observe steady-state fluorescence spectra in a right-angle geometry. The intensity ratio of the first peak to the third peak of each emission spectrum (I_1/I_3) was determined from peak heights. The excimer-to-monomer ratios (I_E/I_M) were calculated from the area integrations of the emission spectrum, from 360 to 400 nm for $I_{M,}$ and from 450 to 550 nm for I_E.

Dynamic fluorescence measurements and fluorescence-decay analysis

Fluorescence-decay profiles were measured by the single photon timing technique, using a 50 kHz D_2 lamp. The wavelengths of the excitation and emission monochromators were fixed at 339 and 371.5 nm, respectively, and a long-pass was used to prevent scattered 339 nm light from reaching the detector.

Pyrene-decay curves were fitted to the Poisson-quenching micelle model expressed by the equation (10–12):

$$[2] \qquad I(t) = I(0) \exp\{-\frac{t}{\tau} - \langle n \rangle [1 - \exp(-k\,t)]\}$$

In this equation, there are four fitting parameters, the initial intensity $I(0)$, the unquenched lifetime τ, the mean number of pyrenes per micelle $\langle n \rangle$, and the first-order rate constant k for quenching (excimer formation) in a micelle.

Results and discussions

Potentiometric and conductometric titration of $C_{20}E_{32}$ polymer solution

The titration behavior of polymer $C_{20}E_{32}$, purified by extensive dialysis, is shown for two concentrations in Fig. 2. In this figure, the relationships are plotted as a function of degree of neutralization α along the *x*-axis, where α = [NaOH]/[COOH], and the bulk concentration of COOH groups was calculated from the methacrylic acid composition of the polymer. The sharp increase in pH at small α may be due to neutralization of a small amount of $-SO_3H$ groups introduced from the initiator during the polymer synthesis. For the two concentrations examined here, C_{pol} =

Fig. 3. Optical density at 360 nm and relative viscosity (η/η_0) of $C_{20}E_{32}$ polymer for C_{pol} = 1.6 g/L, plotted as a function of the degree of neutralization α = [NaOH]/[COOH].

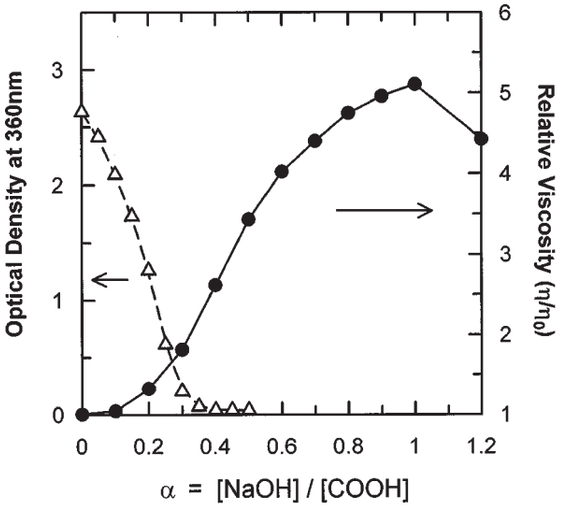

Fig. 4. Concentration dependence of the solution viscosity of $C_{20}E_{32}$ HASE polymer at α = 0.4 and at α = 1.0.

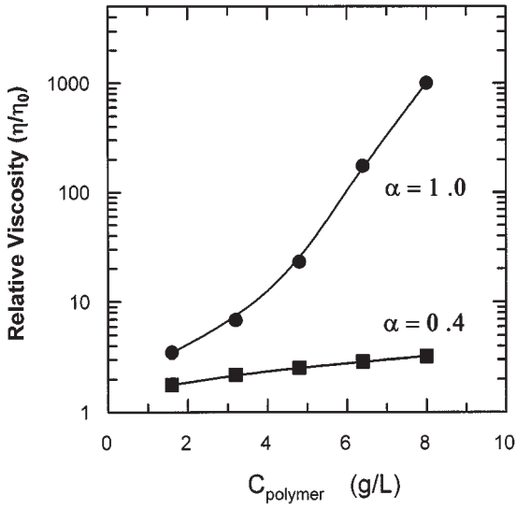
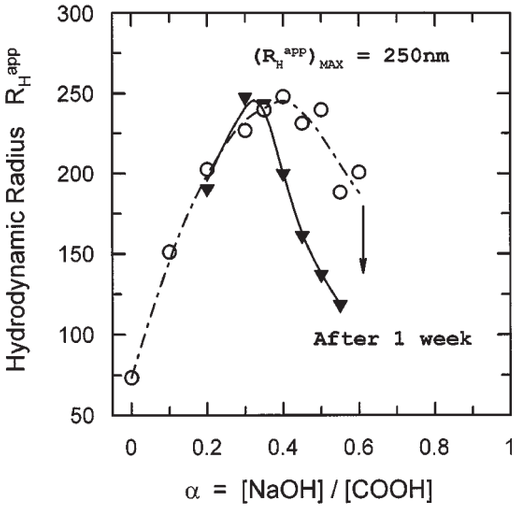


1.6 g/L and C_{pol} = 0.8 g/L, the two conductivity curves exhibit a clear inflection at approximately α = 1.0. The two potentiometric curves overlap. It could be concluded that there is no concentration dependence of α.

Note that the pH is independent of α up to about 0.4 and then begins to increase. These results serve as a reminder that because of the buffer capacity of the polymer, α provides a much better description of the state of the system than the measured pH. These potentiometric and conductometric features show good agreement with the previous results reported by Muroi et al. (13) for the titration of nonassociative alkali-swellable emulsion polymers containing copolymerized carboxylic acid. He assigned the inflection point in the conductometric titration as the point of complete neutralization of the copolymerized MAA, which is located at α = 1.0 in our HASE system.

Fig. 5. Hydrodynamic radius R_H of $C_{20}E_{32}$ HASE latex in C_{poly} = 0.16 g/L, determined by dynamic light scattering, plotted as a function of the degree of neutralization α = [NaOH]/[COOH].



Turbidity and thickening behavior in $C_{20}E_{32}$ polymer solution

As base is added to the system, the solutions become less turbid and more viscous. We quantify these results in Fig. 3, where, for a solution of $C_{20}E_{32}$ at C_{pol} = 1.6 g/L, we plot both the relative viscosity and the optical density of the solution at 360 nm vs. the degree of neutralization of the system. At this concentration, a drastic decrease in the optical density from α = 0 to 0.4 is accompanied by a remarkable increase in the solution viscosity. In other alkali-swellable systems (13*e*), optical clarity often requires higher values of α. In our system, solution viscosity reaches the maximum value α = 1.0 where the polymer is completely neutralized, and drops at α > 1.0 due to the increase of ionic strength in the solution.

The degree of neutralization has a much bigger effect at high polymer concentration on the solution viscosity, as seen in Fig. 4. At α = 0.4, the increase of polymer solution viscosity with increasing polymer concentration is relatively small. At α = 1.0, the solution exhibits a large viscosity increase. The viscosity at α = 1.0 is more than 300 times as large as the viscosity at α = 0.4 for C_{poly} = 8 g/L. Both swelling of the polymer dimensions and formation of networks with hydrophobic junctions contribute to the solution viscosity at α = 1.0.

Hydrodynamic radius (dynamic light scattering)

Some deeper insights into the origin of the viscosity changes are possible through dynamic light scattering measurements on these solutions at much lower polymer concentrations, where the behavior of individual particles can be characterized. Our results are presented in Fig. 5 for a solution at C_{poly} = 0.16 g/L. The initial latex is characterized by a hydrodynamic radius of 75 nm. The water content in a latex particle with fully protonated acid groups is roughly 30 wt.%, determined from separate experiments to check water adsorption into the dried latex film. As base is added to the

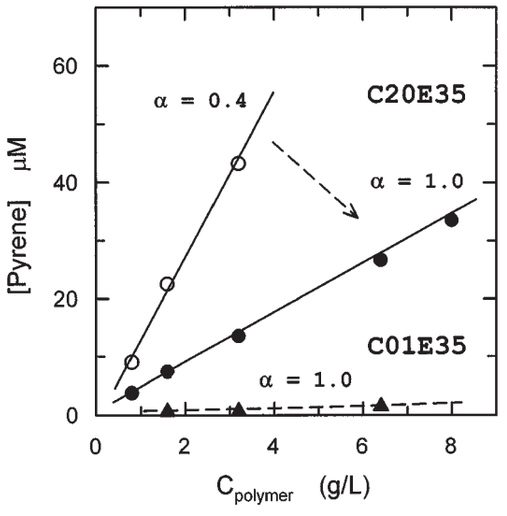
Fig. 6. Pyrene solubilization in $C_{20}E_{32}$ and C_1E_{35} HASE polymer solutions at $\alpha = 0.4$ and $\alpha = 1.0$, determined by UV absorbance measurements at 338 nm. C_1E_{35} refers to a HASE polymer with a structure analogous to that of the polymer shown in Fig. 1 in which a methyl group replaces the $C_{20}H_{41}$ group.



system, swelling of the particle occurs on the time scale of minutes. The particles double in radius at $\alpha = 0.1$ and reach a maximum radius of 250 nm at $\alpha = 0.35$–0.4. At higher degrees of neutralization, the particle size decreases, as the polymer begins to dissolve into the water phase. There is a time-dependence to the swelling and dissolution process at $\alpha > 0.3$, which is particularly pronounced at $\alpha > 0.4$.

If the system is rapidly taken to $\alpha = 0.6$, there is a large drop in signal on the time scale of minutes associated with dissolution of the latex into individual polymer molecules. At lower values of α, the particles have a much slower response, and addition of base leads to relatively small changes in the hydrodynamic radius R_H. Over time, the changes become more pronounced. One can see that for $0.4 < \alpha < 0.6$, a drop in R_H occurs when the samples are aged for 1 week. It is also noteworthy that there is no obvious angular dependence in the two series of measurements, consistent with swollen particles maintaining their spherical shape.

In calculating the data presented in Fig. 5, we used the viscosity of water to calculate hydrodynamic radius from the relaxation times in the DLS experiments. We should, in principle, consider viscosity changes in the series of samples as a function of neutralization, especially for $\alpha > 0.4$ where intermolecular networks start to form. However these are very dilute solution, and changes in bulk solution viscosity are very small. Below $\alpha = 0.4$, on the other hand, we can safely state that the estimated radii are not too far from the true radii, because there are only swollen particles, well separated from each other at $C_{poly} = 0.16$ g/L.

Solubilization of pyrene in HASE solutions

Pyrene has a solubility in water of 7×10^{-7} M at 22°C (5, 11). Water-soluble polymers with hydrophobic domains can bind or solubilize additional pyrene molecules, increasing the total solubility of pyrene in the system. To calculate the amount of pyrene dissolved in the system, one must first determine the extinction coefficients of pyrene in the polymer phase. The extinction coefficient for pyrene at 338 nm decreases from 3.7×10^4 M^{-1} cm^{-1} at $\alpha = 0.4$ to 3.2×10^4 M^{-1} cm^{-1} for $\alpha \geq 1.0$. When the limiting solubilities of pyrene are plotted vs. polymer concentration, Fig. 6, straight lines are obtained, but we note that much more pyrene is solubilized by the system at $\alpha = 0.4$ than at $\alpha = 1.0$. The polymer is fully neutralized at $\alpha = 1.0$ and is likely to exist in a highly swollen state. We anticipate that the dominant hydrophobic domains under these conditions are formed by the C_{20} hydrophobes. Under these conditions where the polymer is saturated with pyrene, there are approximately 0.05 molecules of pyrene per C_{20} hydrophobe. In terms of the liquid drop model we calculate a partition coefficient $K_v = [Py_w]/[Py_{C20}] = 2.0 \times 10^5$, where $[Py_w]$ denotes the molar concentration of pyrene in water phase and $[Py_{C20}]$ denotes the molar concentration of pyrene in the hydrocarbon phase. At $\alpha = 0.4$, approximately 60% of the MAA groups are protonated. The protonated MAA–EA copolymer is a modestly hydrophobic polymer, insoluble in water, but capable of solubilizing pyrene molecules. The difference in the behavior of the system at full and partial neutralization is that at $\alpha = 0.4$, the system contains MAA–EA domains which can solubilize additional pyrenes.

To examine whether the fully neutralized MAA–EA polymer can also solubilize pyrene, we examined pyrene solubilization in a model polymer C_1E_{35}, which has the same backbone as $C_{20}E_{32}$ polymer, containing 35 mol of ethylene oxide units with a CH_3 end group instead of $C_{20}H_{41}$. Data for this polymer are also plotted in Fig. 6. There is a small amount of pyrene solubilized in the C_1E_{35} solution at $\alpha = 1.0$. By assuming the same solubility for pyrene in the polymer backbone of $C_{20}E_{32}$, we can calculate a difference of more than 20 times for the pyrene concentration between the C_{20} hydrophobic domains and the polymer backbone. This result allows us to consider that the dominant contribution to the fluorescence spectra comes from pyrenes localized in the C_{20} hydrophobic domains.

Steady-state pyrene fluorescence in $C_{20}E_{32}$ polymer solution

Fluorescence emission spectra of pyrene (6×10^{-6} mol/L) in the presence of polymer ($C_{pol} = 1.6$ g/L) at different degrees of neutralization are plotted in Fig. 7(*a*). Pyrene, below the solubilization limit for the fully neutralized polymer, was added to the initial emulsion to prevent precipitation during the neutralization. These spectra have been normalized to the intensity of the (0,0) band (I_1) at 371.5 nm. The most obvious features of the spectra are the absence of excimer band at $\alpha < 0.4$ and the increase of the excimer band at 475 nm for $\alpha \geq 0.4$.

In a complex system like this, it is important to distinguish between static excimers formed from pyrenes, which are associated prior to absorption of light, and dynamic excimers formed through diffusion after pyrene molecules are excited. In the former case, one can expect the excitation spectrum monitored at the excimer emission at 475 nm to be significantly red-shifted compared to that of the monomer emission at 371.5 nm. In Fig. 7(*b*), we see that both excitation spectra are identical, consistent with excimers formed in a dynamic process after excitation of nonassociated pyrenes.

© 1998 NRC Canada

Fig. 7. (*a*) Fluorescence spectra of pyrene (6×10^{-6} M) in the presence of the $C_{20}E_{32}$ polymer for C_{pol} = 1.6 g/L at different degrees of neutralization. (*b*) Comparison of the excitation spectra of excimer emission monitored at 475 nm and monomer emission monitored at 371.5 nm.

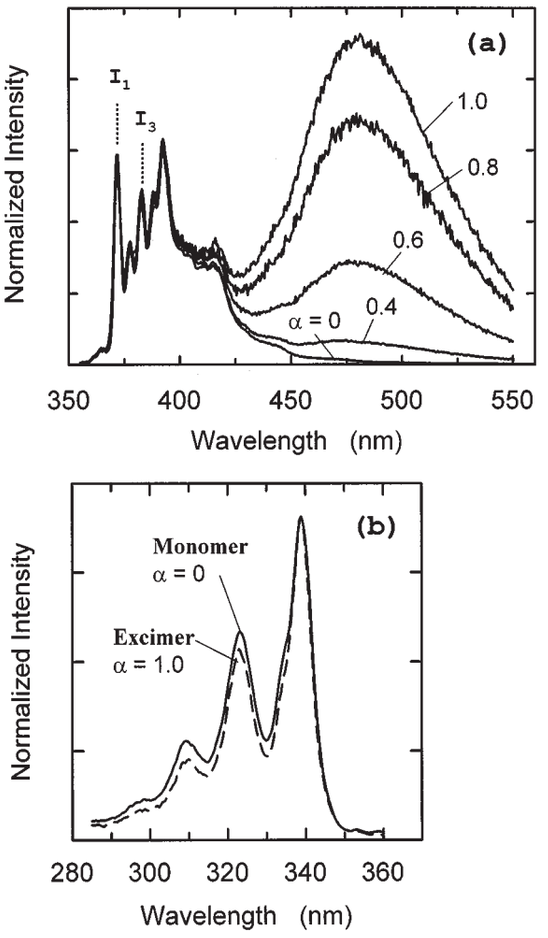


Fig. 8. (*a*) The intensity ratio I_1/I_3 of the I_3 band to the I_1 band (cf. Fig. 7) and the excimer-to-monomer intensity ratio I_E/I_M plotted as a function of degree of neutralization of the polymer. (*b*) I_1/I_3 and I_E/I_M in reacidification of the polymer solution by adding HCl.

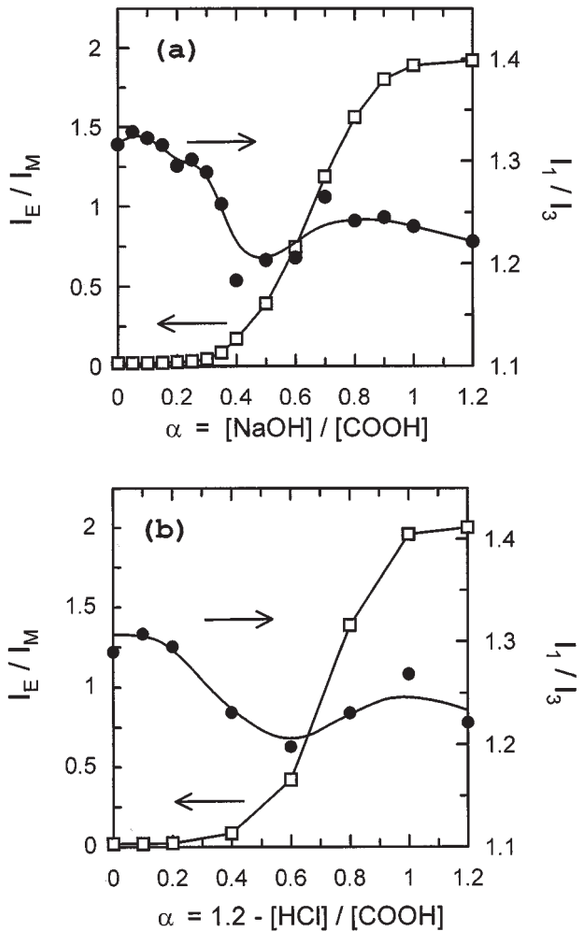

From these results, one can expect that dissolved pyrene is dispersed molecularly in the system, and that the extent of excimer formation reflects the density and mobility of pyrene in local hydrophobic domains.

There are also changes in the intensity ratio I_1/I_3 at different values in α, where I_1 and I_3 are defined in Fig. 7(*a*). The I_1/I_3 ratio is sensitive to the local environment of the pyrene in the system. Values of I_1/I_3 and of the excimer-to-monomer intensity ratio I_E/I_M, calculated from the spectra in Fig. 7(*a*), are plotted in Fig. 8(*a*). The excimer intensity is close to zero for all samples of $\alpha < 0.3$ and increases sharply between $\alpha = 0.5$ and 0.9. The I_E/I_M ratio levels off for $\alpha \geq 1.0$.

Values of I_1/I_3 are close to 1.32 at low degrees of neutralization. They decrease sharply as base is added to the system, pass through a minimum, and then level off at a value of 1.22–1.23 for $\alpha \geq 1.0$. I_1/I_3 values of 1.2 are typical for pyrene solubilized in hydrophobic micelles in water. While the values near 1.32 found at $\alpha < 0.2$ are not as large as that (1.7) of pyrene in water (14), they do indicate that the pyrenes are on average located in a more polar environment than in a hydrocarbon domain. This information, coupled with the absence of excimer emission and the increased solubility of pyrene in the system, strongly suggests that the pyrenes are simply dissolved in the EA–MAA copolymer latex at low degrees of neutralization or at low pH.

Reacidification of the polymer, by adding HCl to the system, reprotonates the polymer. This process does not reform the original latex, but it allows us to examine the effect of reprotonation. The results are plotted in Fig. 8(*b*). Except for the small shift to the acidic side, which might be explained by the increase of salt concentration resulting from acid–base reaction, both I_1/I_3 and I_E/I_M shows good correspondence to the behavior observed in the neutralization of the latex. The small minimum observed in the I_1/I_3 ratio in the region near $\alpha = 0.5$ was surprisingly reproduced in the reprotonation. We do not have a unique explanation for this effect, but it must point to a deep-seated rearrangement of the system.

While pyrene fluorescence shows good reproducibility in the cycle of base-then-acid treatment, the fully protonated polymer at the end of reacidification forms smaller particles

Fig. 9. Comparison of the I_1/I_3 behavior for $C_{20}E_{32}$ at different polymer concentrations: C_{pol} = 3.2 g/L, C_{pol} = 1.6 g/L, and C_{pol} = 0.8 g/L.

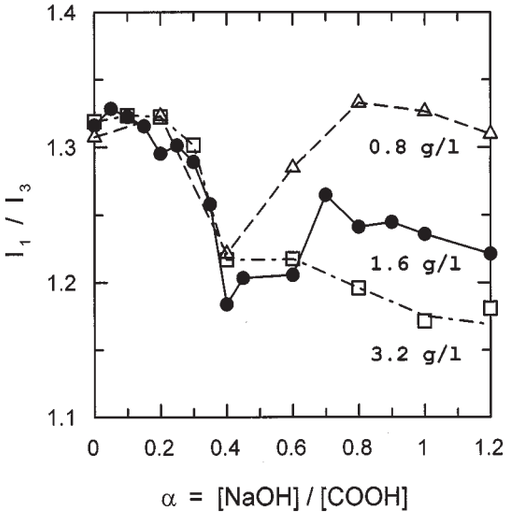

Fig. 10. Polymer concentration dependence of I_E/I_M and I_1/I_3 at α = 0.38 (*a*), at α = 1.0 (*b*).

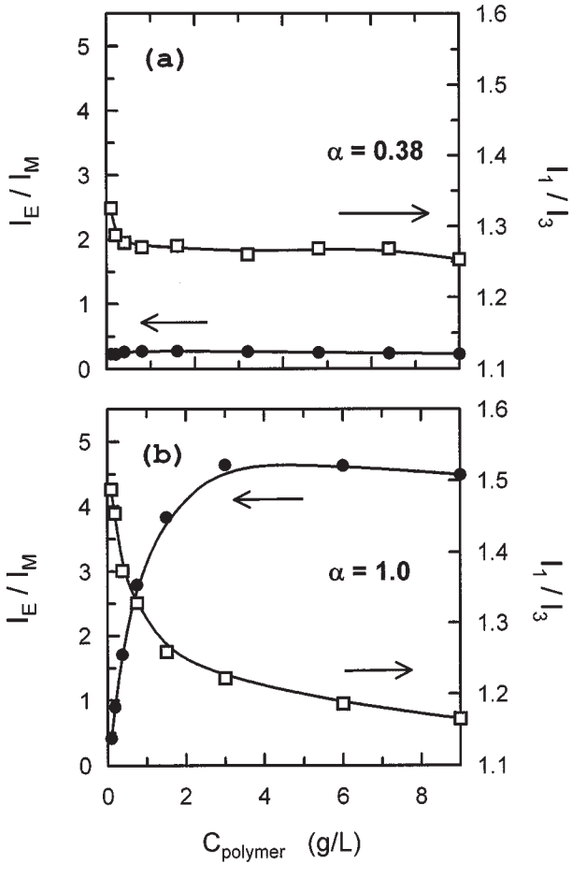
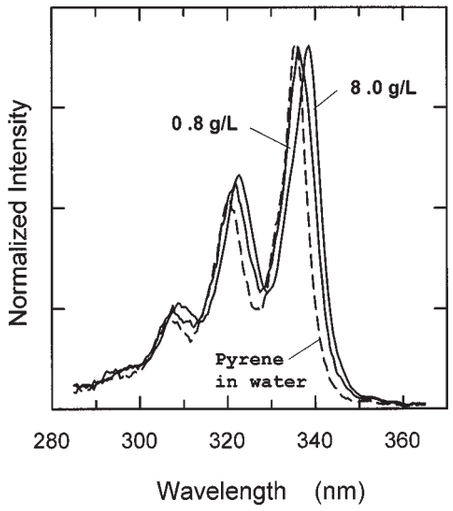


than the original latex, and the solution shows less turbidity. These results parallel those reported by Muroi (13*a*), and indicate that the polymer, once neutralized and dissolved, does not reform the initial particle, but microscopically reforms the hydrophobic domains of the EA–MAA polymer as detected by the dissolved pyrene.

Fig. 11. Comparison of the excitation spectra of the excimer emission monitored at 475 nm and monomer emission monitored at 371.5 nm for different $C_{20}E_{32}$ polymer concentrations: C_{pol} = 0.8 g/L and C_{pol} = 8.0 g/L. The broken line indicates the excitation spectrum for pyrene in water.



The complexity of the system is indicated by the influence of polymer concentration on I_1/I_3, plotted in Fig. 9, where the ratio of pyrene-to-polymer was kept constant. The I_1/I_3 values are constant at a low degree of neutralization (α < 0.2) but show a sharp decrease from α = 0.2 to 0.4 for all the concentrations. In contrast, there is considerable concentration dependence above α = 0.7, which seems to commence at α = 0.4. Our explanation for these results is that at α > 0.4, neutralization of the polymer is accompanied by a change in the partition of pyrene between the polymer and the water phase.

To obtain further information about the concentration dependence, we examined the ratio I_1/I_3 and I_E/I_M at α = 0.38 and 1.0 for a series of polymer concentrations. These results are plotted in Figs. 10(*a*) and (*b*). These experiments were carried out by preparing polymer samples of C_{pol} = 9 g/L at α = 0.4 and α = 1.0, saturated with pyrene, and examining the spectra after successive dilutions with water. Thus the ratio of pyrene-to-polymer in these experiments is kept constant. In Fig. 10(*a*) at α = 0.38, I_E/I_M values are very small and quite constant, and I_1/I_3 values are almost constant around 1.25 except at very low concentrations, below C_{pol} = 0.2 g/L. At almost all polymer concentrations, pyrene remains dissolved in the polymer phase. In Fig. 10(*b*) at α = 1.0, I_E/I_M values are very high and constant at concentrations above C_{pol} = 3 g/L. Over the same concentration range, there is a small decrease in I_1/I_3 values. The surprise occurs at lower polymer concentrations, where I_E/I_M drops sharply and approaches zero, and I_1/I_3 rises sharply to a value approaching 1.5. These results indicate that as the system is diluted, a greater fraction of the pyrene is found in the aqueous phase, where it contributes only to the monomer emission in the I_E/I_M values and to a large increase I_1/I_3 in

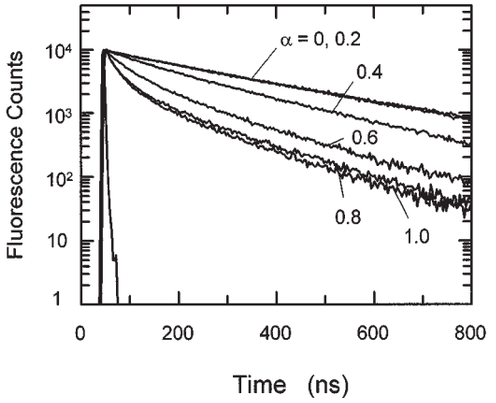
Fig. 12. Fluorescence decay profiles of pyrene (6×10^{-6} M) in the presence of $C_{20}E_{32}$ polymer for C_{pol} = 1.6 g/L at different degrees of neutralization.



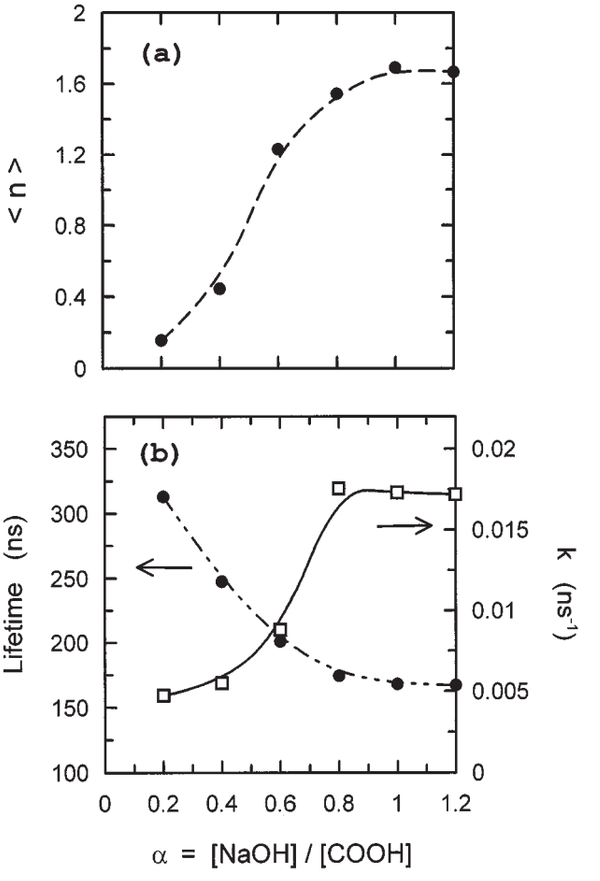
the ratios. From the data in Fig. 6 we calculate that at C_{pol} = 1.6 g/L, ca. 10% of the pyrene is in the water phase, and at C_{pol} = 0.8 g/L about 25% of the pyrene is in the water phase. To confirm this explanation, we checked the excitation spectra associated with monomer, plotted in Fig. 11. Excitation spectra associated with excimer does not change in the polymer dilution process as described in Fig. 7(*b*). However, the excitation spectra associated with monomer shows a definite blue-shift with the longest wavelength absorption maximum shifting from 339 nm at C_{pol} = 8 g/L to 337 nm at C_{pol} = 0.8 g/L.

Dynamic pyrene fluorescence in $C_{20}E_{32}$ polymer solution

In Fig. 12, we show a series of fluorescence decay profiles for pyrene at 6×10^{-6} M in a $C_{20}E_{32}$ solution of C_{pol} = 1.6 g/L. At α = 0 the decay is almost a single exponential and does not change significantly as base is added to the system until α reaches 0.4. Further neutralization leads to more rapid decays, consistent with confinement of pyrenes into smaller compartments. To get further insights into the behavior of the system, we have fitted these decays with the Poisson quenching model, eq. [2] (see above), commonly used to determine micelle aggregation numbers (6–8). As applied here, this model has four fitting parameters: the initial intensity, the unquenched pyrene lifetime τ, the rate constant *k* for excimer formation within a micelle, and the mean number of pyrene per micelle <*n*>. Equation (2) is a powerful fitting function, and it is not surprising that we get good fits to each decay curve with the four variable parameters (plus a term to correct for light scattering). The best values found for the fitting parameters are plotted in Figs. 13(*a*) and (*b*).

One sees first that *k* and <*n*> increase and τ decreases as α increases, and all the values settle above α = 0.8. The <*n*> values seem to follow the I_E/I_M values in Fig. 8(*a*). While almost all the polymer-bound pyrenes are located in a micellar phase comprised of the C_{20} hydrophobes at α = 1.0, considerable amounts of pyrenes are located in other hydrophobic domains below α = 1.0, which contain both EA and protonated MAA units. The decrease of <*n*> and I_E/I_M with

Fig. 13. (*a*) The apparent mean number <*n*> of pyrenes per micelle plotted as a function of the degree of neutralization α = [NaOH]/[COOH]. (*b*) The corresponding values of the unquenched pyrene lifetime τ and the rate constant *k* for excimer formation in a micelle obtained by fitting the fluorescence decay curves in Fig. 12 to the Poisson quenching model, eq. [2].



decrease of α is related to the dilution of pyrene into these domains, which becomes more extensive when a larger fraction of the MAA units are protonated. These explanations are consistent with the behavior of the τ values, which reflect the polarity change of hydrophobic domains. When we estimate an apparent micelle aggregation numbers from the value of <*n*> at α = 1.0, we find a value smaller than 20 C_{20} hydrophobes per micelle. We now know that this number is significantly smaller than the true aggregation number. For example, the results in Fig. 10(*b*) and Fig. 11 indicate that not all the pyrenes are in a micelle-forming environment and some pyrenes in water emit considerable amounts of fluorescence for C_{pol} = 1.6 g/L. To obtain reliable numbers, one should repeat these experiments at higher polymer concentrations, above C_{pol} = 4 g/L, to increase the fraction of pyrene in the micelles relative to that in water. Even these experiments yield complicated data. (The apparent aggregation number depends on the probe concentration and varies from 20 to 60 (15).) Further results about the determination of aggregation numbers in this system will be described in a future report.

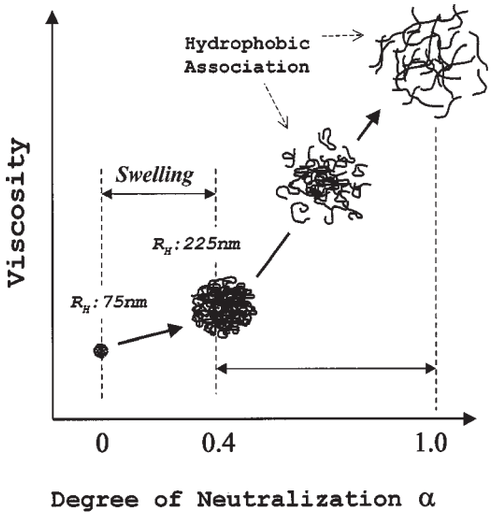
Fig. 14. A summary of our view of the response of the $C_{20}E_{32}$ polymer latex to an increasing extent of neutralization in water.



Summary

The dissolution behavior of a HASE polymer $C_{20}E_{32}$ has been examined. The results are summarized in Fig. 14. The titration behavior of this HASE polymer indicates that α = [NaOH]/[COOH] provides the best description of the degree of neutralization of the polymer MAA. The HASE particle of R_H = 75 nm at α = 0 swells gradually with neutralization by base, and the maximum swollen condition R_H = 225 nm appears at α = 0.4, as observed by dynamic light scattering. Above α = 0.4, the swollen particles disintegrate. The polymer molecules dissolve in the water phase and form hydrophobic associations, which leads to a very viscous solution. In fluorescence probe measurements, pyrene monitors the growth of the association through both I_E/I_M and I_1/I_3. At low α, the pyrene partitions into the EA–MAA copolymer, whereas at high α it is located in micelle-like domains formed by the $C_{20}H_{41}$ groups. Pyrene fluorescence decay measurements provide semi-quantitative information about the rate of excimer formation in the system.

Reaction of ketoximes with aliphatic aldehydes and diphenylborinic acid. Crystal and molecular structure of a diphenylboron chelate derived from the pivaldehyde adduct to cyclohexanone oxime[1]

Wolfgang Kliegel, Ulf Riebe, Steven J. Rettig, and James Trotter

Abstract: Various ketoximes have been reacted with aliphatic aldehydes in the presence of oxybis(diphenylborane) in order to assess the influence of increasingly bulky residues on the nature of the products. Crystals of 5-*tert*-butyl-2-cyclohexylidene-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclopentane, **4***c*, are monoclinic, a = 14.0647(9), b = 11.416(1), c = 14.756(1) Å, β = 115.696(4)°, Z = 4, space group $P2_1/c$. The structure was solved by direct methods and refined by full-matrix least-squares procedures to R = 0.038 (R_w = 0.038) for 2511 reflections with $I \geq 3\sigma(I)$. A bulky substituent at the aldehyde favors α-hydroxyalkylation at the oxime oxygen atom and subsequently leads to the formation of BOCON diphenylboron chelates, whereas formaldehyde reacts by *N*-alkylation of the oximes, resulting in COBON diphenylboron chelates.

Key words: ketoximes, organoboron compounds, crystal structure.

Résumé : Afin d'évaluer l'influence de résidus de plus en plus volumineux sur la nature des produits, on a fait réagir diverses cétoximes avec des aldéhydes aliphatiques en présence d'oxybis(diphénylborane). Les cristaux du 5-*tert*-butyl-2-cyclohexylidène-3,3-diphényl-1,4-dioxa-2-azonia-3-boratacyclopentane, **4***c*, sont monocliniques, groupe d'espace $P2_1$/c, avec a = 14,0647(9), b = 11,416(1) et c = 14,756(1)Å, β = 115,696(4)° et Z = 4. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,038 et R_w = 0,038 pour 2511 réflexions avec $I \geq 3\sigma(I)$. La présence d'un substituant volumineux dans l'aldéhyde favorise l'α-hydroxyalkylation de l'atome d'oxygène de l'oxime et conduit éventuellement à la formation de chélates diphénylbores, BOCON; par ailleurs, le formaldéhyde réagit par *N*-alkylation des oximes conduisant à la formation de chélates diphénylbores COBON.

Mots clés : cétoximes, composés organiques du bore, structure cristalline.

[Traduit par la Rédaction]

Introduction

We have previously shown that the addition of formaldehyde to ketoximes, **1**, in the presence of diphenylborinic acid (anhydride) gives five-membered boron chelates, **2** (R^3 = H) (1), Scheme 1. The heterocyclic 1,3-betaine structure was established by an X-ray crystallographic analysis of the acetone oxime derivative **2***a*, thus demonstrating the preferred *N*-alkylation of the ambident nucleophilic ketoxime by formaldehyde with subsequent trapping of the labile primary adduct as a "chelate" of the Ph_2B^+ cation. It could be assumed that higher aliphatic aldehydes would give homologous chelates **2** (R^3 = alkyl) under the same conditions. However, an *O*-alkylation of the ketoxime by the aliphatic aldehyde with subsequent formation of the isomeric boron chelate **4** had to be considered, especially since this type of compound had been formed applying trichloroacetaldehyde as a strong electrophilic carbonyl compound in the synthesis of the ketoxime derivatives **4** (R^3 = CCl_3) (1). Here we report the results of the experiments carried out with various ketoximes and aliphatic aldehydes, focusing on the influence of increasingly bulky residues.

Experimental

General procedures

All preparations and reactions were carried out under normal conditions, without protective gas atmosphere. Commercial solvents and reagents were used as supplied. Oxybis(diphenylborane) was prepared according to literature methods (2). Melting points were measured on a Linström SPA-1 apparatus and are uncorrected. Elemental analyses: (C, H, N) Carlo Erba Elemental Analyzer 1106; (B) oxidative disintegration (Schöninger) and potentiometric titration. Infrared spectra: Phillips PU 9800 FT-IR spectrometer, V 3.00 and Mattson Genesis Series FTIR Rev. I (ATI Unicam). ^{1}H nmr: Varian EM 390. ^{11}B nmr: Bruker AC 200. Mass spectra: Finnigan MAT 8430.

4-(1-Phenylethylidene)-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, 2*d*

Acetophenone oxime (0.83 g, 5.0 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and formaldehyde (1 mL 35% aqueous solution) are reacted as described in the literature for compounds **2***a–c* (1). Yield: 1.20 g (73%) of color-

less crystals; mp 137–138°C (from ethanol). Infrared (KBr, cm^{-1}): 1610, 1590 (C=N, C=C); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 2.66 (s, CH_3), 5.45 (s, N-CH_2-O), 7.10–7.80 (m, 15 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 13.0 ($W_{1/2}$ = 240 Hz) and 46.6 ($W_{1/2}$ = 300 Hz); ratio of peak areas: 10:1. Mass spectrum (EI, 70 eV, 100°C): *m*/*z* (%) = 299 (26) [$M^+ - CH_2O$], 284 (55) [$M^+ - CH_2O - CH_3$], 242 (24), 222 (21) [$M^+ - CH_2O - C_6H_5$], 181 (24) [Ph_2BO], 165 (77) [Ph_2B], 135 (14), 118 (74), 77 (100). Anal. calcd. for $C_{23}H_{26}BNO_2$: C 76.62, H 6.12, B 3.28, N 4.25; found: C 76.50, H 6.12, B 3.29, N 4.26. The product gives a blue-colored solution in ethanol upon addition of diphenylcarbazone, indicating the presence of the chelated diphenylborenium (Ph_2B^+) ion (3).

4-Diphenylmethylene-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, 2*e*

Benzophenone oxime (0.99 g, 5.0 mmol) is reacted with oxybis(diphenylborane) (0.87 g, 2.5 mmol) and formaldehyde (1 mL 35% aqueous solution) as described for **2***d*. Yield: 1.46 g (75%) of colorless crystals; mp 138–139°C (from ethanol). Infrared (KBr, cm^{-1}): 1605, 1593 (C=N, C=C); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 5.36 (s, N-CH_2-O), 7.06–8.13 (m, 20 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 13.8 ($W_{1/2}$ = 360 Hz) and 46.6 ($W_{1/2}$ = 300 Hz); ratio of peak areas: 25:1. Anal. calcd. for $C_{26}H_{22}BNO_2$: C 79.81, H 5.67, B 2.76, N 3.58; found: C 79.68, H 5.62, B 2.77, N 3.66. **2***e* gives a blue-color reaction with diphenylcarbazone as described for **2***d*.

4-Adamantylidene-2,2-diphenyl-1,3-dioxa-4-azonia-2-boratacyclopentane, 2*f*

Adamantanone oxime (0.83 g, 5.0 mmol) is reacted with oxybis(diphenylborane) (0.87 g, 2.5 mmol) and formaldehyde (1 mL 35% aqueous solution) as described for **2***d*. Yield: 1.31 g (73%) of colorless crystals; mp 157–159°C (from ethanol). Infrared (KBr, cm^{-1}): 1660 (C=N); ^1H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.50–2.23 (m, 12 aliphatic H), 2.60 and 3.80 (m_c and m_c, 2 N=C-CH), 5.40 (s, N-CH_2-O), 7.06–7.66 (m, 10 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 11.8 ($W_{1/2}$ = 260 Hz). Anal. calcd. for $C_{22}H_{26}BNO_2$: C 76.89, H 7.29, B 3.01, N 3.90; found: C 76.16, H 7.22, B 3.03, N 3.83. **2***f* gives a blue-color reaction with diphenylcarbazone as described for **2***d*.

2,5-Dimethylene-3,3,6,6-tetraphenyl-1,4-dioxa-2,5-diazonia-3,6-diboratacyclohexane, 3*a*

Method A

Formaldehyde oxime trimer hydrochloride (0.57 g, 3.3 mmol) in 10 mL of absolute ethanol is mixed with 3.3 mL of 1 N KOH solution. The precipitating KCl is filtered off, and a solution of oxybis(diphenylborane) (1.74 g, 5.0 mmol) in 10 mL of ethanol is added to the reaction mixture. After 1 min of refluxing the crystalline deposit is filtered off and washed with a small amount of cooled ethanol. Yield: 0.73 g (70%) of colorless crystals (poor solubility in methanol, ethanol, benzene, $CHCl_3$, DMSO); mp 209–210°C (decomp.); lit. (4)[3] mp 209°C (from ethyl acetate). Infrared (KBr, cm^{-1}): 1640 (C=N), 1600 (C=C); identical to the infrared spectrum of the compound prepared from dimeric *E*-(aminoxy)-diphenylborane (5) and formaldehyde by condensation (4)[3]. Mass spectrum (EI, 70 eV, 150°C): *m*/*z* (%) = 209 (48) [1/2 M^+], 181 (34) [Ph_2BO], 165 (64) [Ph_2B], 105 (71) [PhBOH], 77 (100) [C_6H_5], 51 (49) [C_4H_3]. **3***a* gives a blue-color reaction with diphenylcarbazone as described for **2***d*.

Method B

Diisopropylketone oxime[4] (0.56 g, 5.0 mmol) is reacted with oxybis(diphenylborane) (0.87 g, 2.5 mmol) and formaldehyde (1 mL 35% aqueous solution) as described for **2***d*. Yield: 0.73 g (74%) of colorless crystals; mp 209°C. Infrared (KBr): identical to **3***a*.

5-*tert*-Butyl-2-isopropylidene-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclopentane, 4*a*

Acetone oxime (0.37 g, 5.0 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and pivalaldehyde (0.43 g, 5.0 mmol) are dissolved in 5 mL of ethanol and heated briefly. If no spontaneous crystallization commences upon cooling, the solvent is removed in vacuo, and the residue taken up in chloroform. Crystallization is then induced by the addition of petroleum ether. Yield: 0.37 g (23%) of colorless crystals; mp 101–102°C (from ethanol). Infrared

Anal. calcd. for $C_{20}H_{26}BNO_2$: C 74.32, H 8.11, B 3.34, N 4.33; found: C 73.50, H 7.70, B 3.72, N 3.96. **4***a* gives a blue-color reaction with diphenylcarbazone as described for **2***d*. (See Fig. 1 for stereoview of **4***c*.)

5-*tert*-Butyl-2-cyclopentylidene-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclopentane, 4*b*

Cyclopentanone oxime (0.50 g, 5.0 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and pivalaldehyde (0.43 g, 5.0 mmol) are reacted as described above for **4***a*. Yield: 0.83 g (48%) of colorless crystals; mp 183–185°C (from ethanol). Infrared (KBr, cm^{-1}): 1688 (C=N); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.10 (s, $(CH_3)_3C$), 1.43–3.00 (m, -$(CH_2)_4$-), 5.20 (s, 60% of 1H, O-CH-O), 7.17–7.60 (m, 10 aromatic H), 9.50 (s, 40% of 1H, CH=O); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 8.2 ($W_{1/2}$ = 320 Hz). Anal. calcd. for $C_{22}H_{28}BNO_2$: C 75.65, H 8.08, B 3.10, N 4.01; found: C 75.76, H 7.99, B 3.20, N 3.93. **4***b* gives a blue-color reaction with diphenylcarbazone as described for **2***d*.

5-*tert*-Butyl-2-cyclohexylidene-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclopentane, 4*c*

Cyclohexanone oxime (0.57 g, 5.0 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and pivalaldehyde (0.43 g, 5.0 mmol) are reacted as described above for **4***a*. Yield: 1.14 g (63%) of colorless crystals; mp 148–149°C (from ethanol). Infrared (KBr, cm^{-1}): 1665 (C=N); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.10 (s, $(CH_3)_3C$), 1.25–2.90 (m, -$(CH_2)_5$-), 5.10 (s, 50% of 1H, O-CH-O), 7.14–7.66 (m, 10 aromatic H), 9.50 (s, 50% of 1H, CH=O); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 8.8 ($W_{1/2}$ = 340 Hz). Anal. calcd. for $C_{23}H_{30}BNO_2$: C 76.04, H 8.32, B 2.98, N 3.86; found: C 75.69, H 8.33, B 3.01, N 3.67. **4***c* gives a blue-color reaction with diphenylcarbazone as described for **2***d*. (See Fig. 1 for stereoview of **4***c*.)

Crystals suitable for X-ray analysis were obtained by very slow crystallization from $CHCl_3$ – petroleum ether using the liquid diffusion method (6).

2-Cyclohexylidene-5-isopropyl-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclopentane, 4*d*

Cyclohexanone oxime (0.57 g, 5.0 mmol), oxybis(diphenylborane) (0.87 g, 2.5 mmol), and isobutyraldehyde (0.36 g, 5.0 mmol) are reacted as described above for **4***a*. Yield: 1.02 g (58%) of colorless crystals; mp 164–165°C (from ethanol). Infrared (KBr, cm^{-1}): 1655 (C=N); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.07 and 1.15 (d and d, J = 4 Hz, $(CH_3)_2C$), 1.30–2.90 (m, -$(CH_2)_5$-, C-CH-C), 5.27 (d, J = 4 Hz, O-CH-O), 7.17–7.53 (m, 10 aromatic H), 9.50 (s, 50% of 1H, CH=O); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 8.4 ($W_{1/2}$ = 340 Hz). Anal. calcd. for $C_{22}H_{28}BNO_2$: C 75.65, H 8.08, B 3.10, N 4.01; found: C 75.45, H 8.30, B 3.08, N 3.89. **4***d* gives a blue-color reaction with diphenylcarbazone as described for **2***d*.

The ^{11}B nmr chemical shifts for compounds **2** and **4** are summarized in Table 1.

fluctuations. The data were processed,[5] corrected for Lorentz and polarization effects, and absorption (based on azimuthal scans).

The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and $B_H = 1.2B_{bonded\ atom}$. A correction for secondary extinction was applied (Zachariasen type, isotropic, Gaussian), the final value of the extinction coefficient being 1.18(2) × 10^{-5}. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (7). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and intra-annular torsion angles appear in Tables 3–6, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least squares planes are included as supplementary material.[6]

those observed for the diphenylboron chelates **2***a–c*. The latter had been reported (1) as a result of the same reaction using less bulky oximes (**1***a–c*). The ^{11}B nmr chemical shifts for the tetracoordinated boron nuclei of **2***d–f* between δ (Et_2OBF_3) 11.8 and 13.8 ppm[7] are similar to the values ranging from 12.1 to 12.8 ppm observed for **2***a–c* (1). The bulkier diisopropylketoxime[4] **1***g*, however, did not give the expected chelate **2***g* upon addition of formaldehyde and diphenylborinic acid, but produced instead a diphenylborinate of formaldoxime having a cyclodimeric structure **3***a*. The structure **3** has been established for several diarylborinates of aliphatic and aromatic aldoximes (11). Relatively stable dimers of type **3** are also formed by borinates of cyclic ketoximes. Noncyclic ketoxime derivatives like the acetonoxime diphenylborinate are easily converted under slight thermal stress into another type of cyclic boron compound which has been described with full structural characterization (12). In the presence of a less bulky aldehyde the bulkier ketoxime borinates (monomer or dimer) tend to exchange the carbonyl component resulting in the aldoxime derivatives **3**. A very bulky aldehyde, however, might not exchange with the ketone component of a ketoxime, as shown by the reaction with pivaldehyde. So far, no specific experiments have been carried out to investigate the extent or the equilibria of these exchange reactions. In the case of **1***g* the bulky substitution might favor the exchange of the carbonyl component in the oxime leading to the formaldoxime derivative **3***a* rather than the more sterically hindered **2***g*.

Similar "reoximations" were also observed during the reaction of the less bulky ketoximes **1***a–c* with propanal as the aldehyde component and diphenylborinic acid. In all cases the known (11) BONBON cyclodimer **3***b* was isolated. Using isobutyraldehyde in the same reaction system, **1***a* and **1***b* also gave the BONBON type cyclic dimer **3***c*. The use of cyclohexanone oxime (**1***c*) resulted in the formation of a diphenylboron chelate containing the isobutyraldehyde component, as did all three of the ketoximes **1***a–c* with pivaldehyde and diphenylborinic acid. The ^{11}B nmr signals of these diphenylboron chelates, however, have chemical shift values of about 8.5 ppm (see Table 1), distinctly different from those near 13 ppm reported for the diphenylboron chelates of type **2** (1). The similarity of these ^{11}B nmr shift values to those ranging from 8.7 to 9.5 ppm found for boron chelates formed by the trichloroacetaldehyde adducts of ketoximes (**4**, $R^3 = CCl_3$) suggests a BOCON ring system of type **4** for the pival- and isobutyraldehyde derivatives **4***a–d*, rather than a COBON chelate ring system of type **2**. Infrared and ^{1}H nmr spectra are not sufficient to discriminate between the isomeric structural types **2** and **4**. The other isomeric structures **5** and **6** containing COBON and BOCON heterocycles, respectively, in which the aldehyde and ketone functions have changed places, can be excluded on the basis of an acetalic methine proton signal (O-CH-O or O-CH-N) near δ = 5 ppm in the ^{1}H nmr spectra.[8] Compounds **5** or **6** would display an azomethine proton signal (N=CH) near 7 ppm, as observed in the ^{1}H nmr spectra of type **3** compounds (11). To verify the assumption of a BOCON ring of type **4**, containing an *O,O*-acetal function, an X-ray crystallographic analysis of **4***c* (which gave suitable crystals) was performed.

The X-ray analysis unambiguously establishes the molecular structure of **4***c*. It appears that a bulky substituent at the aldehyde (R^3-CH=O) favors the α-hydroxyalkylation at the oxime oxygen atom and subsequently leads to the formation of the diphenylboron chelates of type **4**, whereas formaldehyde (R^3 = H) reacts by *N*-alkylation of the oximes, resulting in the diphenylboron chelates of type **2** (1). Compounds **4***a–d* represent further examples of boron chelates forming a BOCON heterocycle, in addition to the previously reported trichloroacetaldehyde derivatives **4** ($R^3 = CCl_3$) (1). The controlling factor in the formation of **4***a–d* is obviously a steric effect rather than the strong electrophilicity that had been assumed to be the reason for the *O,O*-acetal formation in the case of the trichloroacetaldehyde derivatives **4** ($R^3 = CCl_3$) (1). In view of the current findings, it is likely that the bulkiness of the trichloromethyl group is the primary factor in the formation of **4** ($R^3 = CCl_3$).

The five-membered BOCON ring of **4***c* has a distorted O(2)-envelope conformation (Table 6). The B(1)-N(1)-O(1)-C(1) moiety (torsion angle = 8.7(2)°) is planar to within 0.017(1) Å, with O(2) displaced by 0.133(1) Å from the the BNOC mean plane. The moiety consisting of the ring atoms N(1), B(1), and O(1) along with the carbonyl (sp^2) carbon

[7] The weak side signals at 46.6 ppm in the spectra of **2***d* and **2***e* indicate the presence of a small quantity of a Ph_2B-O-R moiety (for examples see ref. 8), probably arising from partial ring opening at the weak oxime oxygen O—B coordinative bond and thus forming a trivalent (sp^2)-boron species. The stability of the acetophenone and benzophenone oxime derivatives **2***d* and **2***e* appears to be reduced relative to that of the adamantanonoxime derivative **2***f* and the other aliphatic ketoxime derivatives **2***a–c* (1) because of a decreased nucleophilicity of the (oxime) *N*-oxide ligand. A comparable phenomenon, additional side signals near 47 ppm, has been observed in the ^{11}B nmr spectra of similar boron chelates with reduced chelate stability (9, 10).

[8] Partial solvolysis can be seen in the ^{1}H nmr spectra of **4***a–c*, possibly a result of the very bulky aldehyde component. The acetal (O-CH-O) group is retained to an extent of 50–65% in the $CDCl_3$ solution of the ^{1}H nmr experiment, in accordance with the appearance of 50–35% of a free carbonyl (CH=O) group.

atom C(2) is planar to within 0.005(2) Å. The boron atom has a slightly distorted tetrahedral coordination geometry, bond angles at B(1) ranging from 95.4(1)° within the five-membered heterocycle (O(1)-B(1)-O(2)) to 115.5(2)° between the the *B*-phenyl groups (C(12)-B(1)-C(18)). The B—C(phenyl) distances are identical at 1.604(3) Å. The dimensions of the cyclohexanone oxime moiety in **4***c* are very similar to those of the acetone oxime moiety in **4** ($R^1 = R^2$ = Me, $R^3 = CCl_3$): C=N/N-O = 1.281(2)/1.396(2) Å for **4***c*, 1.278(3)/1.401(2) Å for **4** (1). The acetalic C—O bonds in the pivaldehyde derivative **4***c* are somewhat longer than the corresponding acetalic C—O bonds in the trichloroacetaldehyde derivative **4** ($R^3 = CCl_3$) (1): C(1)—O(1)/C(1)—O(2) = 1.468(2)/1.376(2) Å for **4***c*, 1.450(2)/1.357(2) Å for **4** ($R^1 = R^2$ = Me, $R^3 = CCl_3$) (1). This difference in the acetalic C—O bond lengths may be due to the lower electrophilicity of the pivaldehyde component in **4***c* relative to the trichloroacetaldehyde component of **4**. Consistent with the longer acetal C—O bonds in **4***c*, the O-C-O angle of 106.9(1)° is slightly compressed compared to the corresponding value of 109.1(2)° in the trichloroacetaldehyde derivative (1). The coordinative N→B bond in **4***c* (1.659(3) Å) is nearly 0.03 Å longer than that in **4** ($R^1 = R^2$ = Me, $R^3 = CCl_3$) (1.631(3) Å) (1) which indicates the weakened Lewis acid character of the diphenylborinate moiety in **4***c* compared to that for the trichloroacetaldehyde derivative. The overall geometry of the BOCON rings in **4***c* and **4** ($R^1 = R^2$ = Me, $R^3 = CCl_3$) is very similar.

The packing of **4***c* is dominated by van der Waals forces, all nonbonded intermolecular contacts between non-hydrogen atoms being greater than 3.6 Å. There is one relatively strong intramolecular C-H···O interaction that may influence the orientation of the cyclohexyl moiety: C(3)-H(3)···O(1), H···O = 2.23 Å, C···O = 2.680(3) Å, C-H···O = 107°.

SIMS studies of the effect of H at interfaces formed by oxidized zirconium

K. Shimizu, B.J. Flinn, P.C. Wong, and K.A.R. Mitchell

Abstract: Secondary ion mass spectrometry (SIMS) has been used to guide the search for an oxidation procedure that can produce a thin and relatively sharp oxide layer on macroscopic zirconium. A new preparation based on dip coating in H_2O_2 solution is indicated to be suitable for this purpose. SIMS further indicates that the oxide interface, for such a prepared sample, shows substantial degradation when it is heated in H_2 gas at 300°C. The presence of H appears to facilitate O migration into the metallic region, an observation that supplements those made previously on oxidized thin-film samples of zirconium prepared by deposition under ultrahigh-vacuum conditions.

Key words: secondary ion mass spectrometry, interfacial reactivity, oxidized zirconium.

Résumé : On a fait appel à la spectrométrie de masse des ions secondaires (SMIS) pour orienter la recherche d'une méthode d'oxydation pouvant conduire à une couche mince et relativement nette d'oxyde sur du zirconium macroscopique. Une nouvelle préparation fondée sur un revêtement par immersion dans une solution de H_2O_2 semble appropriée pour cet usage. La SMIS indique de plus que l'interface d'oxyde d'un échantillon préparé de cette manière subit une dégradation importante lorsqu'on le chauffe en présence de H_2 à l'état gazeux, à 300°C. La présence d'H semble faciliter la migration de l'O dans la région métallique; cette observation corrobore celles faites antérieurement avec des échantillons de films minces oxydés de zirconium préparés par dépôt dans des conditions de vide extrêmement élevé.

Mots clés : spectrométrie de masse d'ions secondaires, réactivité interfaciale, zirconium oxydé.

[Traduit par la Rédaction]

Introduction

The development of improved understanding of the interfacial stability of oxide on zirconium and its alloys, particularly in the presence of hydrogen, provides an interesting scientific challenge, but this is also one with high relevance to nuclear reactor technology (1). For example, knowledge is still extremely limited in relation to the mechanisms of H/D ingress through passivating oxide layers on CANDU reactor pressure tubes (Zr – 2.5 wt.% Nb), even though there is a considerable economic cost when metallic embrittlement results. A useful mechanistic description for real pressure-tube material has not yet been obtained but, in order to help establish basic principles for the chemical processes involved, we have been studying some model situations that highlight particular parts of the whole. Our previous work in this area emphasized studies of the stability and reactivity of thin metallic oxide layers (e.g., ~20 Å thick) deposited under well-controlled ultrahigh-vacuum (UHV) conditions onto gold, a relatively inert substrate (2, 3). This approach has permitted direct examination of the underlying interface with X-ray photoelectron spectroscopy (XPS), and has yielded insight into the nature and stability of the oxide–metal interfaces in the presence of hydrogen in an environment made slightly oxidizing by the trace presence of H_2O. For the case of deposited zirconium, the interface region may be expressed as $ZrO_2/ZrO_x/Zr/Au$, where ZrO_x indicates an O-deficient region between the stable bulk oxide ZrO_2 and Zr metal (4). The UHV studies show that the behaviour of ZrO_2/ZrO_x can be sensitively affected by the presence of hydrogen; indeed, observations were made of the interfacial compositions being systematically changed with temperature and exposure to H_2 and hydrogen plasmas (5).

Further study of the effect of H ingress on the Zr oxide – metal interface in real CANDU pressure-tube material, formed under working conditions, is generally hindered by the interface being sufficiently far below the surface that it is no longer accessible by such conventional non-destructive techniques as XPS or Auger electron spectroscopy. In principle, that interface is accessible by deeper probing techniques, such as depth profiling in secondary ion mass spectrometry (SIMS) (6) or with the use of high-energy beams, as for example in nuclear reaction analysis or Rutherford backscattering (7). Studies that have focussed on the depth profiling of H have generally not given much consideration to how the Zr oxide – metal interfacial region is affected by the H ingress, but the UHV studies indicate that the interfacial stoichiometry may change with the presence of hydrogen, apparently as a result of this atom facilitating O migration into the metallic region (4, 5). These effects may have relevance to stability of such materials in technological application, and therefore

Table 1. Sample treatments used in this work.

Designation	Preparation treatment
A1	Zr sample etched, washed, and dried (see text)
A2	A1 dip-coated in 30% H_2O_2 solution for 0.5 h
A3	A1 heated in air (200°C) for 0.5 h
A4	A1 exposed to cold O_2 plasma for 0.5 h
A5	A1 exposed to air plasma for 0.5 h
B1	A1
B2	A1 heated in N_2 (300°C) for 2 h
B3	A1 heated in H_2 (300°C) for 2 h
C1	A1 dip-coated in 30% H_2O_2 solution for 12.5 h with stirring
C2	C1 heated in N_2 (300°C) for 2 h
C3	C1 heated in H_2 (300°C) for 2 h

it appears important to be able to study them under reasonably realistic (i.e., non-UHV) conditions.

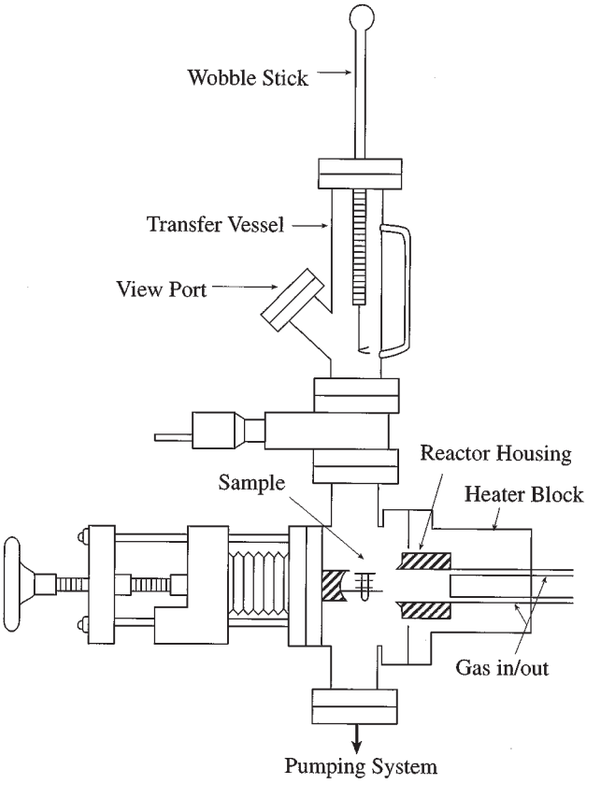
Study of chemical effects at the oxide-to-metal boundary depends fundamentally on an ability to have an accurate positioning of the interface. A complication for real industrial materials is that these interfaces are not likely to be (atomically) smooth, but the point of the work reported here was to characterize oxide-to-zirconium interfaces, prepared by different methods, with the view of searching for a procedure that allows the formation of a relatively smooth (perhaps better expressed as "less rough") interfacial region. The presence of such an interface should greatly facilitate observations of its changes as a result of H ingress, as well as help separate the changes that occur from physical variables (e.g., temperature) that also influence the H ingress.

The present work uses SIMS to probe various preparations of thin oxide layers on zirconium foil, and their subsequent changes on exposure to reactive gases including hydrogen. This study is part of a broader program whose objective is to test whether the types of H effects seen in very thin film UHV-deposited samples of zirconium (4, 5) can also be observed for oxide on bulk samples.

Experimental

SIMS characterizations were performed with a VG MM12-12S quadrupole spectrometer using a duoplasmatron source (gas 90% Ar, 10% O_2) operated at 10 kV with a current density of 12.5 μA cm^{-2} (the O_2 is filtered out before reaching the sample). The zirconium samples were cut into a suitable form (area 0.5 cm^2, thickness 0.5 mm) from polycrystalline Zr foil (99.99% pure, AESAR Chemicals), and were etched for 45 s in a solution of concentrated HF, concentrated HNO_3, and H_2O (vol. ratio 5:45:50); this was followed by a water rinse (~3 s) and drying at room temperature in a covered petri dish. This approach both limits the presence of native oxide on the surface and ensures an essentially common starting point for all samples. Subsequent treatments are listed in Table 1. Figure 1 illustrates the isolated reactor (Physical Electronics model 04-800) attached to a sample transfer vessel, which was used for the preparation of samples B2, B3, C2, and C3. This device enabled samples to be heated in a gas flow at slightly over 1 atm (101.3 kPa), followed by pump-down to around 10^{-7} Torr (1 Torr = 133.3 Pa) and transfer to the SIMS facility without atmospheric exposure. Other samples (A4 and A5) were treated by oxygen and air (cold) plasmas in a side chamber on our XPS facility as described previously (in both cases the flowing gas pressure was held at about 0.2 Torr) (4). After preparation and pump-down, these samples were also taken in the transfer vessel to the SIMS without exposure to the regular atmosphere.

Fig. 1. Schematic view of reactor/transfer device in which samples can be heated (to 600°C) in presence of gas (to ~1 atm) followed by pump-down (to ~10^{-7} Torr) and transfer to the SIMS facility without atmospheric exposure.



Results and discussion

The first comparison is made for the different preparation procedures investigated for forming the initial oxide layer (Table 1). Following Hultquist et al. (8), the oxide is characterized with SIMS by following the ZrO^+ count rate as a function of sputtering time (the initial rise reflects the effect of the inevitable contamination layer on the top of the sample). The ZrO^+ count rate directly gives insight into the distribution of O bonded to Zr below the surface. Figure 2 shows significant differences between the different preparation procedures. The etched-only sample (A1) has the thinnest oxide layer; all samples can be interpreted as having a common outermost layer that corresponds to the ZrO_2 composition. In each case this oxide is separated from the pure metal (where the ZrO^+ counts are negligible) by a transition region, which is taken to correspond to the non-stoichiometric ZrO_x-type regions identified in X-ray photoelectron spectra from samples of oxidized zirconium. It

Fig. 2. ZrO^+ depth profiles measured from oxide-covered zirconium samples prepared by five different procedures defined in Table 1: A1 (acid-etched), A2 (dip-coated in H_2O_2), A3 (heated to 200°C in air), A4 (exposed to cold O_2 plasma), and A5 (exposed to cold air plasma).

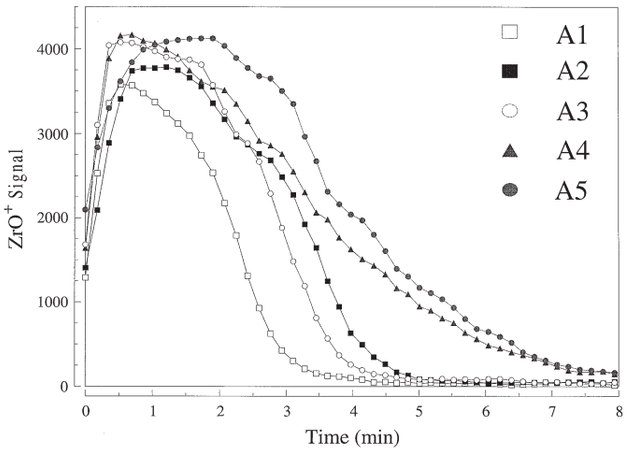

Fig. 3. ZrO^+ depth profiles measured (*a*) from three samples that do not receive an H_2O_2 treatment: B1 (acid-etched), B2 (heated in N_2), B3 (heated in H_2); and (*b*) from three samples whose preparation starts with the H_2O_2 treatment: C1, C2 (heated in N_2), C3 (heated in H_2).

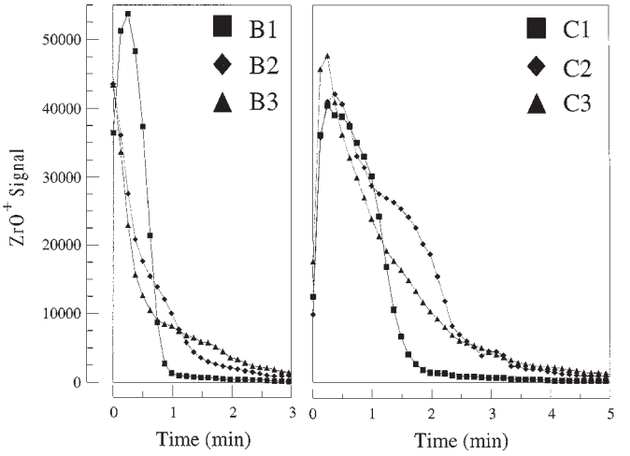

is clear that the air and O_2 plasma treatments give broader transition regions than those formed by heating in air at 200°C or by treating with 30% H_2O_2 at room temperature. The latter is indicated to give significant ZrO_2 with a relatively sharp interface region to the metal. Such features can make this approach to oxide formation particularly helpful for assessing degradation by hydrogen, and it is therefore used for some further samples tested here. Incidentally all curves in Fig. 2, except for A1, show irregularities as the depth profiling proceeds; it is believed that these are real effects that depend on the ZrO^+ ion yield increasing as the probing beam intersects grain boundaries at which oxide may be preferentially formed.

Figure 3 compares ZrO^+ depth profiles for two sets of samples that have received parallel treatments (B1 to B3 and C1 to C3 in Table 1). Samples in the B series all start with acid etching of the zirconium foil, whereas those for the C series are subsequently treated in H_2O_2. The depth profiles for both B1 (etched) and C1 (etched, followed by H_2O_2 treatment) show steep downward slopes, indicative of a similar interface region, although C1 has the thicker oxide film. When these samples are heated in H_2, to form samples B3 and C3, both interfacial regions are seriously degraded, and less negative slopes are apparent in Fig. 3; these effects result from the oxide barrier migrating toward the bulk (4, 5). However, there are two contributing factors here: (*i*) the direct effect of hydrogen, and (*ii*) the effect of the heating. To help separate these two factors, samples B2 and C2 were treated exactly similarly to B3 and C3, respectively, except that the heating was done in N_2 instead of H_2. It is clear that the O migration still occurs with the heating in N_2, consistent with sufficient thermal energy being available to surmount the activation barrier to diffusion, but in each case the migration is less than that indicated for the equivalent heating in H_2. All trends shown in Fig. 3 have been checked by working with independent samples; quite generally the effect of heating in H_2 leads to the surface oxide being more degraded, with O migrating further into the Zr sample than is the case with heating in N_2.

Concluding remarks

The observations with SIMS reported in this paper reinforce those made earlier with XPS, from atomically thin films of oxidized Zr, which showed that exposure to hydrogen can modify the oxide–metal interface, apparently by facilitating O migration into the metallic region (4, 5). This broadening to bulk samples should enable the more fundamental research to be extended to materials related to those used in engineering practice. It is well known that, at the operating temperature of the CANDU reactor (300°C), O moves readily into zirconium metal (9). Therefore, in this context, thick oxide films formed by autoclaving offer only limited possibilities for probing their interfacial chemistries using the established techniques of electron spectroscopy. However, this work has introduced a new approach to forming model oxide layers at room temperature, specifically by dipping Zr samples in H_2O_2 solution. It is anticipated that these films, by being reasonably sharp and thin, will have useful applications for designing new experiments that can help to improve our knowledge of chemical reactivity, mechanism, and passivation at their interfaces. Extensions to actual pressure-tube alloys are also planned.

Coordination complexes derived from 3,6-di(2-pyridyl)-1,4-dihydro-1,2,4,5-tetrazine (DPDHT). Synthesis and molecular structure of [(DPT)($GaMe_2$)$_2$]

Peter N. Preston, Steven J. Rettig, Alan Storr, and James Trotter

Abstract: The facile reaction of 3,6-di(2-pyridyl)-1,4-dihydro-1,2,4,5-tetrazine (DPDHT) (**1**) with trimethylgallium has resulted in the formation of the purple crystalline product, [(DPT)($GaMe_2$)$_2$] (**2**), via methane elimination. Crystals of [(DPT)($GaMe_2$)$_2$] are orthorhombic, *Pbca*, a = 15.380(2), b = 21.642(4), c = 11.355(2) Å, Z = 8. The structure was solved by heavy-atom Patterson methods and refined by full-matrix least-squares procedures to R = 0.035 for 1570 reflections with $I \geq 3\sigma(I)$ (R_w = 0.063 for all 4342 reflections). The [(DPT)($GaMe_2$)$_2$] molecule is roughly planar (apart from the four methyl groups), in contrast to the folded structure of the DPDHT molecule; molecular dimensions are normal.

Key words: methylgallium, crystal structure, dipyridyldihydrotetrazine.

Résumé : La réaction facile de la 3,6-di(2-pyridyl)-1,4-dihydro-1,2,4,5-tétrazine (DPDHT) (**1**) avec le triméthylgallium conduit à la formation du produit cristalline violet, [(DTP)($GaMe_2$)$_2$] (**2**) avec élimination de méthane. Les cristaux de [(DTP)($GaMe_2$)$_2$] sont orthorhombiques, groupe d'espace *Pbca*, avec a = 15,380(2), b = 21,642(4) et c = 11,355(2) Å, Z = 8. On a résolu la structure par la méthode des atomes lourds de Patterson et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur de R = 0,035 pour 1570 réflexions avec $I \geq 3\sigma(I)$ (R_w = 0,063 pour l'ensemble des 4342 réflexions). La molécule de [(DTP)($GaMe_2$)$_2$] est pratiquement plane (à l'exception des quatre groupes méthyles) et cette situation est en opposition à celle observée dans la molécule de DPDHT qui comporte une structure repliée; les dimensions moléculaires sont normales.

Mots clés : méthylgallium, structure cristalline, dipyridyldihydrotétrazine.

[Traduit par la Rédaction]

Introduction

We have described a number of polymeric transition metal complexes with pyrazolate (1–4) and, most recently, with imidazolate (5) ligands. The relative positions of pyrrole-type and pyridine-type nitrogen atoms in the ligand are crucial in determining the dimensionality of the ensuing polymer. Thus a three-dimensional polymetallic iron-containing imidazolate complex has proven particularly interesting, exhibiting canted spin antiferromagnetic coupling along chains of tetrahedrally coordinated iron centers with concomitant molecular magnet properties at low temperatures. We are presently extending our studies using more complex heterocycles and have included for study 3,6-di(2-pyridyl)-1,4-dihydro-1,2,4,5-tetrazine, DPDHT (**1**), deprotonation of which yields a symmetrical tetradentate ligand, DPT^{2-}, hitherto unused in coordination chemistry. In this report we illustrate the use of DPDHT in its reaction with trimethylgallium.

Experimental

Materials were handled in a conventional high-vacuum line or in a glove box under an atmosphere of oxygen-free dry dinitrogen. All solvents were dried and distilled before use. Gas volumes are at STP. Trimethylgallium was prepared, as previously described, from gallium and dimethylmercury (6). The DPDHT ligand–precursor was synthesized by a literature method (7).

Preparation of DPT·2$GaMe_2$

The orange ligand–precursor DPDHT, (**1**), (0.307 g; 1.3 mmol) was transferred to a 250 mL round-bottomed flask fitted with a break-seal side-arm. Xylene solvent (~60 mL) was added to give a pale orange solution. The reaction flask was then cooled to –196° and evacuated. Me_3Ga (0.296 g; 2.6 mmol) was vacuum-transferred into the reaction vessel which was then flame-sealed. On warming to

Chemical shift diff.	0.16	1.12	1.18	1.38						

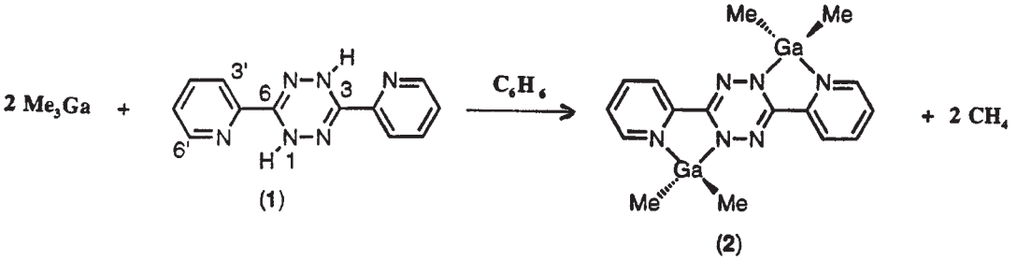
[a]Assignments for the complex (**2**) are made on the basis of decoupling experiments and the magnitude of coupling constants relative to those in the ligand (**1**).

[b]Quoted in ppm with respect to tetramethylsilane.

[c]Quoted Hz.

[d]Measured at 400 MHz in CD_2Cl_2 solvent at 25°C; the NH resonance appeared at δ 8.53.

[e]Measured at 400 MHz in C_6D_6 solvent at 25°C.



room temperature the orange solution gradually darkened through amber, golden-brown, dark brown, to deep purple. On standing overnight at room temperature the solution deposited dark purple crystals of the product [DPT·2$GaMe_2$] (**2**) in quantitative yield. The reaction flask was again cooled to –196° and the volume of methane evolved during the reaction measured using a Toepler pump (calcd. 57.8 mL; found 57.6 mL). The purple crystals were isolated in the glove box. The purple crystals were stable under a dinitrogen atmosphere but quickly turned yellow–orange on exposure to air. The infrared spectrum showed characteristic (8) Ga-C stretching frequencies ν_{asym} 590 cm^{-1} and ν_{sym} 535 cm^{-1} and was devoid of the N-H stretching frequencies observed at 3299 and 3344 cm^{-1} in the spectrum of the ligand–precursor DPDHT. The ^{1}H NMR spectrum of the complex in C_6D_6 solution showed one signal for the $GaMe_2$ groups at δ 0.20. The signals due to the protons of the pyridyl fragments of the ligand precursor, DPDHT, and the product, [DPT·2$GaMe_2$], are summarized in Table 1 and discussed below. The mass spectrum (EI) of the purple crystals displayed the expected three-line pattern for the molecular ion (M^+) and a stronger signal cluster for the M-2Me^+ ion. Anal. calcd. for [DPT·2$GaMe_2$]: C 44.1, H 4.6, N 19.3; found: C 44.4, H 4.7, N 19.2%.

X-ray crystallographic analysis

Crystallographic data appear in Table 2. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 20.3–25.2°. The intensities of three standard reflections, measured every 200 reflections throughout the data collection, decayed by 7.4%. The data were processed, corrected for Lorentz and polarization effects, and absorption (based on azimuthal scans).

The structure was solved by heavy-atom, Patterson methods. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and $B_H = 1.2B_{bonded\ atom}$. No secondary extinction correction was required. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (9). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths and angles appear in Tables 3–5, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes are included as supplementary material.[2]

Results and discussion

The reaction of group 13 trialkyls with ligands containing acidic hydrogen yields adducts which readily eliminate alkanes to produce coordinatively unsaturated intermediates (10). Coordinative saturation is usually achieved by cyclization, the degree of association being determined by a balance between steric effects, valency angle strain and entropy factors (8, 10, 11). The methane elimination reactions of trimethylgallium with pyrazoles to yield dimeric products containing central six-membered Ga_2N_4 rings are well documented (12–14). The reaction of Me_3Ga with 2-methylimidazole, on the other hand, results in the formation of tetrameric species, a consequence of the steric demands of the azolate moiety (15).

In the present study the reaction of Me_3Ga with DPDHT has been investigated to gain insights into the potential of this heterocyclic system to act as a ligand precursor in the preparation of polymeric transition metal compounds. The chemistry of DPDHT has received little attention (16). A useful aspect of its reactivity with regard to coordination chemistry, however, is sequential oxidation and alkyne dipolar cyclcoaddition which leads to substituted bis(pyridyl) pyridazines, of value as ligating heteroarenes (17). In the present study the initial adduct formation between trimethylgallium and DPDHT, probably via the lone pair on the pyridyl nitrogen atoms, places the trialkyl moieties in proximity of the N-H groups of the dihydrotetrazine ring. Facile methane elimination, at or even below room temperature, leads to the formation of the five-membered heterocyclic, GaN_2C_2, rings observed in the purple crystalline product.

The ^{1}H NMR spectrum of the ligand has been previously reported but without definitive assignments (18). In this work, long range N-H correlation experiments provided assignments of 300 (pyrimide-N), 275 (N-1), and 259 ppm (N-2), with definitive assignment of H-6′ at 8.58 ppm. (See Table 1.)

The magnitudes of coupling constants are in accord with those anticipated for substituted pyridines, a notable feature of which is the relatively low value of $J_{5'6'}$ (= 4.9 Hz) involving coupling to the proton on the carbon adjacent to the pyridine nitrogen (19). Assignments of chemical shifts in the ^{1}H NMR spectrum of the complex (**2**) were made on the basis of decoupling experiments and on the relative magnitudes of coupling constants in respect to (**1**). Complexation of the ligand causes shifts to high field for all the ring protons, but particularly (>1 ppm) for H-4′, H-5′, and H-6′. The

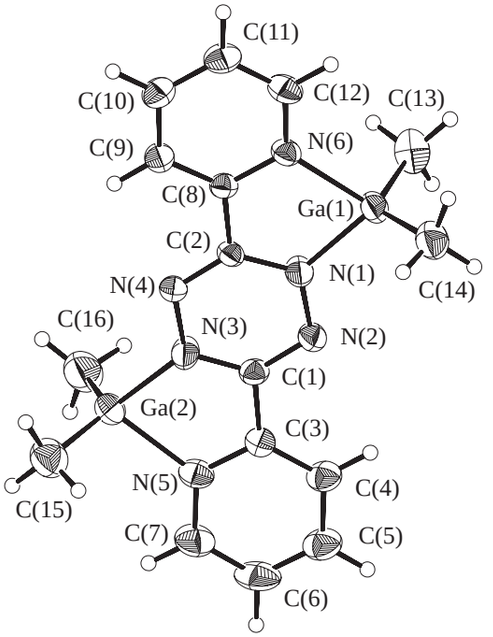
Fig. 1. View of the [(DPT)($GaMe_2$)$_2$] molecule; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.



disparity in electronic influence of the gallium moieties on chemical shifts of H-3′ vs. H-4′, 5′ and 6′ is curious, and warrants further theoretical studies of complex (**2**) and related compounds.

The X-ray analysis unambiguously establishes the molecular structure of [(DPT)($GaMe_2$)$_2$] (Fig. 1). The DPT^{2-} ligand exhibits statistically significant deviations from exact planarity, but is roughly planar (maximum displacement from mean plane = 0.192(5) Å for C(6); maximum angle between planes of the various rings = 7.0°). This is in contrast to the parent DPDHT molecule, which is folded with a boat-shaped tetrazine ring, in both the triclinic (20) and orthorhombic (21) forms. The torsion angles in the tetrazine ring of the DPDHT molecule are as high as 44°, while the corresponding angles in the DPT^{2-} ligand have a maximum of 3.0(6)°. The Ga atoms both lie 0.24 Å above the mean plane of the ligand.

Bond lengths and angles (Tables 4 and 5) are close to expected values. In particular, the C(1)—N(2) and C(2)—N(4) bond distances of the tetrazine ring (1.286(4) and 1.282(4) Å) correspond to double bonds. The Ga—N(pyridine) bonds (2.066(3) and 2.042(3) Å) are significantly longer than the Ga—N(tetrazine) bonds (1.921(3) and 1.924(3) Å); this situation has analogy in the molecular structure of Ga{2-[$NCH_2C_6H_5$]NC_5H_4}$_2$Me (cf. 2.216(3), 2.236(3) Å for Ga—N(pyridine) bonds, and 1.933(3) Å for Ga—N(amine) bonds), although it should be noted that the gallium in the latter compound is pentacoordinate (22).

The crystal packing is dominated by van der Waals forces, the shortest intermolecular contact between non-hydrogen atoms being a C···C distance of 3.28(1) Å.

Conclusions

3,6-Di(2-pyridyl)-1,4-dihydro-1,2,4,5-tetrazine (**1**) reacts readily with trimethylgallium to provide the novel pentacyclic heteroaromatic complex (**2**) in quantitative yield. Studies by X-ray crystallography and NMR spectroscopy suggest considerable bond localization in the tetrazine ring,

© 1998 NRC Canada

and marked electronic influence of the gallium moieties on chemical shift values of the pyridine protons.

A key feature to note from the work is that the known DPDHT is easily synthesized (7) in multigram quantities from commercially available materials; applications of the ligand for use in the synthesis of coordination polymers can be envisaged.

Peroxidations initiated by lignin model compounds: investigating the role of singlet oxygen in photo-yellowing

L. Ross C. Barclay, Jennifer K. Grandy, Heather D. MacKinnon, Heather C. Nichol, and Melinda R. Vinqvist

Abstract: 3,5-Di-*tert*-butyl-*ortho*-quinone, **6**, and 1-(3,4-dimethoxyphenyl–2-(2-methoxyphenoxy)-1-propanone, **7**, models for oxidized lignin and for lignin, were used as sensitizers of photo-oxidation. Product studies by HPLC from oxidation of methyl linoleate in solution sensitized by **6** or **7**, and in sodium dodecyl sulfate (SDS) sensitized by **6**, showed a product distribution of six hydroperoxides, the four conjugated 9- and 13-hydroperoxides of the geometrical isomers: *trans*-10, *cis*-12 (**2**), *cis*-9, *trans*-11 (**3**), *trans*-10, *trans*-12 (**4**), and *trans*-9, *trans*-11 (**5**)-octadecadienoates plus two nonconjugated hydroperoxides. The higher *cis*/*trans* to *trans*/*trans* (ct/tt) of geometrical isomers (**2** + **3**//**4** + **5**) compared to ct/tt from known thermal free-radical peroxidations (Type 1) indicate that singlet oxygen (Type 2) oxidation occurs in reactions sensitized by **6** or **7**. Kinetic studies by oxygen uptake are reported on oxidations of hydrocarbons 1-phenyl-2-methylpropene, **8**, and *trans*-stilbene, **9**, sensitized by the quinone, **6**, or by a dye, Rose Bengal. Quenching studies imply singlet oxygen reactions. Milled wood lignin undergoes self-initiated photo-oxidation in water, and oxygen uptake was quenched by sodium azide. Cellobiose, a cellulose model, undergoes sensitized photo-oxidation using model quinone, **6**, in a mixture of *tert*-butyl alcohol and water or using the sensitizers benzophenone or the lignin model, **7**, delivered on a solid support, silica gel, and these oxidations were quenched with sodium azide. These results implicate singlet oxygen in the photo-yellowing of high lignin content wood pulps.

Key words: lignin models, *ortho*-quinone, photo-oxidation, singlet oxygen, lignin, cellobiose.

Résumé : La 3,5-di-*tert*-butyl-*ortho*-quinone, **6**, et la 1-(3,4-diméthoxyphényl-2-(2-méthoxyphénoxy)propan-1-one, **7**, des modèles de lignine oxydée et de lignine, ont été utilisées comme sensibilisateurs de photooxydation. On a effectué l'oxydation du linoléate de méthyle, en solution sensibilisée par les produits **6** ou **7** et dans du dodécylsufate de sodium (DSS) sensibilisé par le produit **6**; la nature des produits, établie par CLHP, montre la présence de six hydroperoxydes: les quatre isomères géométriques des 9- et 13-hydroperoxydes conjugués (*trans*-10, *cis*-12 (**2**), *cis*-9, *trans*-11 (**3**), *trans*-10, *trans*-12 (**4**) et *trans*-9, *trans*-11 (**5**)-octadiénoates) en plus de deux hydroperoxydes qui ne sont pas conjugués. Le rapport plus élevé d'isomères géométriques *cis*/*trans* comparé aux isomères *trans*/*trans* (ct/tt) (**2** + **3**//**4** + **5**) observé dans ce cas par comparaison à ce qui est observé pour les peroxydations radicalaires thermiques (Type 1) indique que, dans les réactions sensibilisées par les produits **6** et **7**, il se produit une oxydation par de l'oxygène singulet (Type 2). On a aussi effectué des études cinétiques, basées sur l'absorption d'oxygène, sur les oxydations des hydrocarbures suivants: 1-phényl-2-méthylpropène, **8**, et *trans*-stilbène, **9**, sensibilisées par la quinone **6** ou par un colorant, le Rose Bengale. Des études de désactivations suggèrent que les réactions impliquent de l'oxygène singulet. La lignine de bois broyé subit une photooxydation autoinitiée dans l'eau et l'absorption d'oxygène est arrêtée par l'azoture de sodium. Le cellobiose, un modèle pour la cellulose, mis en solution dans un mélange d'alcool *tert*-butylique et d'eau, subit une photooxydation sensibilisée lorsqu'on utilise le modèle de la quinone, **6**, ou lorsqu'on utilise comme sensibilisateurs de la benzophénone ou le modèle de la lignine, **7**, livré sur un support solide, le gel de silice; ces oxydations sont arrêtées par l'azoture de sodium. Ces résultats impliquent l'oxygène à l'état de singulet dans le photojaunissement des pulpes de bois contenant des quantités importantes de lignine.

Mots clés : modèles de la lignine, *ortho*-quinone, photooxydation, oxygène singulet, lignine, cellobiose.

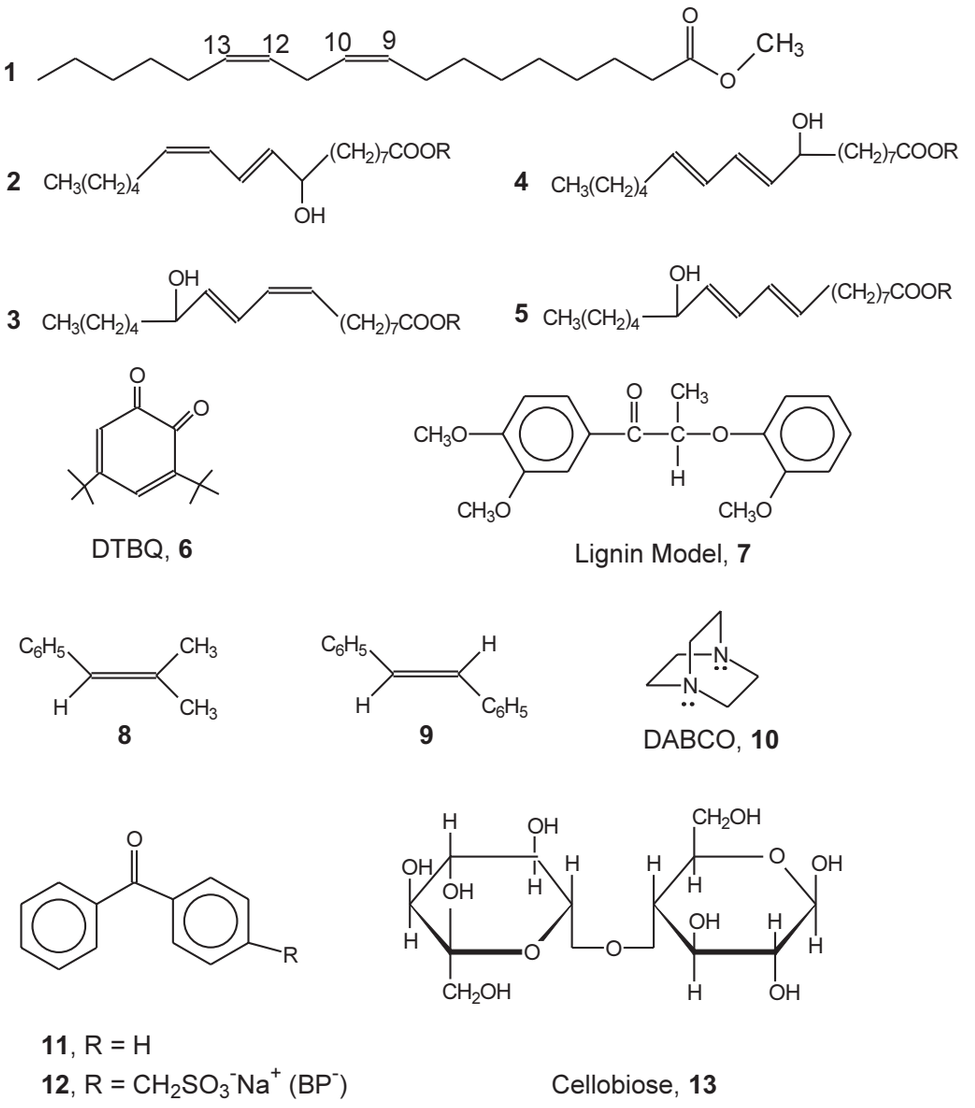
Introduction

The oxidative photo-yellowing of lignin-rich pulps and derived papers is a significant factor in limiting the full potential of mechanical pulps in Canada. Consequently the possible role of active oxygen species, such as singlet oxygen, in photo-yellowing is an important issue both from the economical and fundamental standpoint. The first excited state of molecular oxygen, $^1\Delta_g$ ($^1O_2$), has been recognized

© 1998 NRC Canada

Fig. 1. Structural formulas.



for at least six decades (1) as an important intermediate in the oxidation of a wide variety of organic substrates, and it has been the subject of many reviews (2–8), including the possible role of singlet oxygen in the oxidation of lignin (9) and its light-induced yellowing (10). Research on the possible role of singlet oxygen in photo-yellowing of pulps and papers has concentrated on the reaction of singlet oxygen *separately generated*, usually by dye-sensitization, with lignin model compounds (11–16), lignin (17), high-yield pulps (e.g., high lignin content) (12, 13, 18–20), cellobiose (21), and cellulose (22, 23).

The purpose of this current investigation is to determine if lignin model compounds, on photo-excitation in the presence of oxygen, produce singlet oxygen, and if this singlet oxygen reacts readily with organic substrates in various media and with cellobiose, a model cellulose compound. (See Fig. 1 for structural formulas.) To establish a relationship between these processes the following strategy was used. (*a*) An unsaturated lipid (methyl linoleate, 18:2) was selected as a marker for singlet oxygen, since its oxidation products are known to distinguish between classical free-radical peroxidation (Type 1 mechanism) versus that involving singlet oxygen (Type 2 mechanism) (22–27). (*b*) Comparisons were made between the product distributions resulting from dye-sensitized oxidation (e.g., singlet oxygen) of linoleate versus those from oxidation sensitized by a typical lignin model ketone, and from sensitization with a lignin model oxidation product (e.g., a quinone). Product analyses from thermal, azo-initiated, free-radical peroxidation of linoleate were compared with the above results. (*c*) Kinetic experiments employing oxygen uptake and quenching studies were conducted in solution and in aqueous heterogeneous phases. The heterogeneous systems included sodium dodecyl sulfate (SDS) micelles, and a solid support (silica

gel) containing sensitizer with the substrate (cellobiose) in the aqueous phase, to mimic a natural system.

Results

1. Peroxidation of linoleate: singlet oxygen versus free-radical oxidation

(a) Oxidations in homogeneous solution: dye-sensitized compared to thermal and photo-initiated autoxidation

Lipid peroxidation is a very useful method to distinguish between pathways involving singlet oxygen (Type 2) and free-radical autoxidation (Type 1). We used the well-known different products from peroxidation of linoleate (18:2) as an aid in distinguishing between these two types. The Type 1 reaction on linoleate normally yields a mixture of four regio-geometrical isomers: the conjugated diene 9- and 13-hydroperoxides, two having the *cis*, *trans* configuration (kinetic products) and two with the *trans*, *trans* configuration (thermodynamic products). The detailed mechanism for this Type 1 reaction has been reviewed by Porter (28) and the factors controlling the relative amounts of the isomers, e.g., the *cis*, *trans* to *trans*, *trans* ratio, such as the hydrogen atom donating ability of the system, are now well known (29). This reaction, which is initiated by hydrogen atom abstraction, proceeds through initial carbon and peroxyl radicals, and a brief outline is given in Scheme 1. In contrast the Type 2 reaction does not involve radical intermediates but proceeds directly to the hydroperoxides via a cyclic (ene) mechanism as outlined in Scheme 1. In this reaction the "kinetically controlled" 9- and 13- *cis*, *trans* hydroperoxides are accompanied by nonconjugated isomers, the hydroperoxides at positions 10 and 12 (24–27). The greater concentration observed for the 9- and 13- isomers has been attributed to internal cyclization of the initial 10 and 12 hydroperoxides (26).

We conducted some initial studies of linoleate peroxidation under conditions where the products of the different reactions give the expected typical patterns; namely, (*i*) thermal azo-initiated oxidation by 2,2-azo-bis(2,4-dimethylvaleronitrile) ADVN, (*ii*) photo-initiated oxidation by benzophenone, and (*iii*) dye-sensitized oxidation employing methylene blue. The HPLC traces of the products from typical reactions of reaction types (*i*) and (*iii*) are illustrated in Fig. 2. Both the thermal reaction initiated by peroxyl radicals derived from ADVN and the photo-initiated one employing benzophenone (type (*ii*) reaction on 5.6×10^{-2} M methyl linoleate, 1.43×10^{-6} M benzophenone initiated in octane by a Hg arc lamp gave an HPLC trace, not shown, comparable to the one shown for type (*i*) in Fig. 2*A*) gave

Fig. 2. HPLC profiles of methyl linoleate oxidation product separations at 234 nm. Peaks **3**, **5**, **2**, **4** are the 13 c,t, 13 t,t, 9 c,t, and 9 t,t products, respectively. (See Fig. 1.) (*A*) Thermally initiated oxidation of 8.6×10^{-2} M methyl linoleate using 2.0×10^{-2} M ADVN, in octane. Sample is 7.7% oxidized with a ct/tt product ratio of 0.18. Average ct/tt = 0.18 ± 0.00. (*B*) Photochemically initiated oxidation of 22.4×10^{-2} M methyl linoleate using 5.35×10^{-4} M methylene blue, irradiated using a 1000 W tungsten lamp in *tert*-butanol. Sample is 10.0% oxidized with a ct/tt product ratio of 33.3. Average ct/tt = 35.2 ± 1.5.

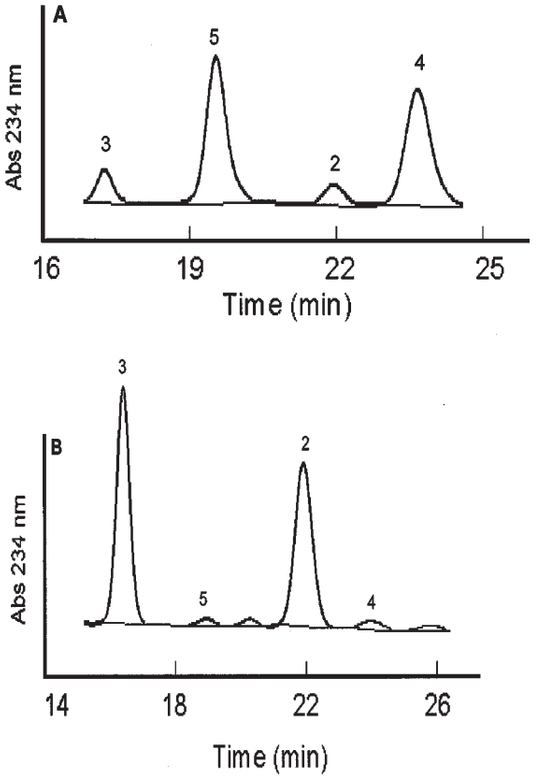

Fig. 3. HPLC profiles of methyl linoleate oxidation product separations at 234 nm. Peaks **3**, **5**, **2**, **4** are the 13 c,t, 13 t,t, 9 c,t, and 9 t,t products, respectively. (See Fig. 1.) (*A*) Photochemically initiated oxidation of 5.0×10^{-2} M methyl linoleate using 1.80×10^{-3} M **6**, irradiated using a commercial slide projector in *tert*-butanol. Sample is 6.21% oxidized with a ct/tt product ratio of 31.3. Average ct/tt = 36.2 ± 4.9. (*B*) Photochemically initiated oxidation of 22.4×10^{-2} M methyl linoleate using 9.21×10^{-4} M lignin model compound, **7**, irradiated using a 1000 W tungsten lamp in *tert*-butanol. Sample is 3.00% oxidized with a ct/tt product ratio of 7.4. Average ct/tt = 7.45 ± 0.39.

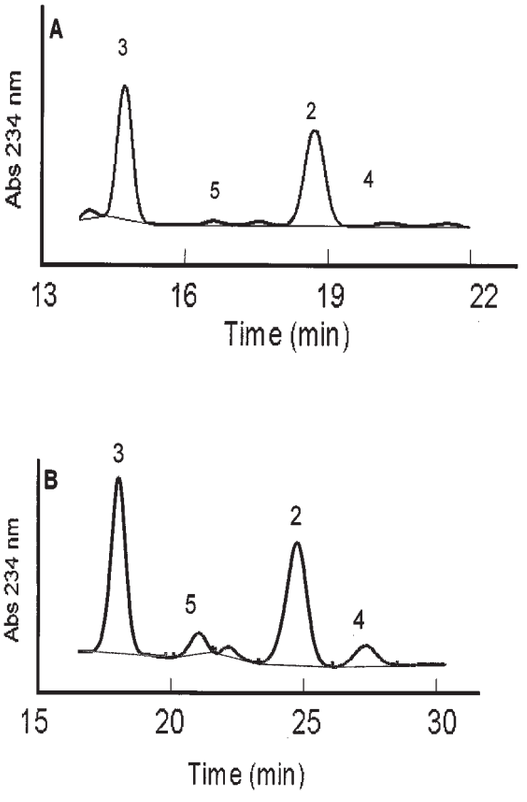

the four known (28, 29) oxidation products (e.g., **2**–**5**) and with *cis*, *trans* to *trans*, *trans* (ct/tt) ratios in the range 0.18–0.24, consistent with the free-radical (Type 1) mechanism (Scheme 1). In contrast the dye-sensitized oxidation gave a product profile of six isomers typical of the singlet oxygen reaction, where the 13- and 9-*cis*, *trans* isomers (kinetic products) are dominant and the ct/tt ratio is raised to 35. The HPLC peaks labeled **3**, **5**, **2**, and **4** in their order of elution for these four isomers (Fig. 1) were identified by comparison with thermal products using comparative HPLC traces. The additional two HPLC peaks are assigned to the nonconjugated isomers which have lower absorptivities (30).

(b) Oxidations sensitized by lignin model compounds in solution

Two model compounds were selected as potential initiators of lipid oxidation. 3,5-Di-*tert*-butylquinone (DTBQ, **6**) was used to model the oxidation products of lignin, since *ortho* quinones are known to be the major structures formed in photo-yellowing (31–33), and redox reactions of *ortho* quinones and catechols appear to be significant in the yellowing pathways (34–37). 1-(3,4-Dimethoxyphenyl)-2-(2-methoxyphenoxy)-1-propanone (**7**) was selected to model the lignin structure. Considerable information is available on the photochemistry of this and related systems (38–44), and its electronic absorption spectrum extends into the near ultraviolet range (λ_{max} 310 nm, ε = 10 000). While milled wood lignin contains carbonyl chromophores (45), we are aware of the limitations involved in the extrapolation of results using models as **6** and **7** to the more complex structure in native lignin.

First it was of interest to find that the HPLC product profiles (not shown) obtained from photo-initiation of methyl linoleate (4.3×10^{-2} to 5.0×10^{-2} M in *tert*-butanol) sensitized by the quinone, **6** (1.80×10^{-3} to 1.90×10^{-3} M), were similar whether using a simple visible projector lamp or a high intensity (1000 W) light source, although the actual ct/tt ratios varied (27 and 13, respectively). The HPLC analyses from oxidations of methyl linoleate, sensitized by **6** and

[a]Numbers 1, 4, and 5 were irradiated with a 1000 W tungsten lamp, 2 and 3 with a commercial slide projector, and 6–8 with a 200 W Hg vapor lamp.

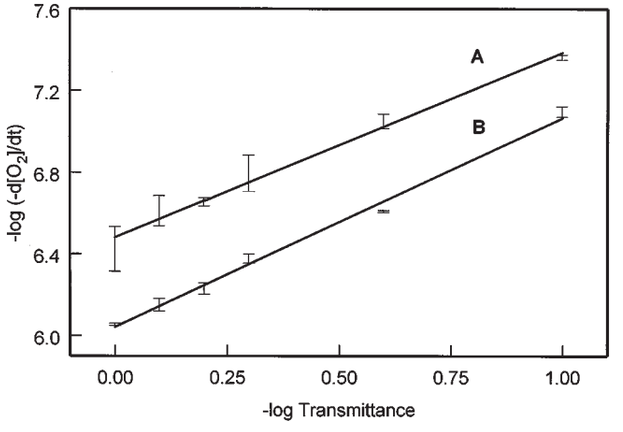
[b]MB, methylene blue.

[c]Analysis for sensitizer **6** by UV at 386 nm on aliquots during the run showed that 75% remained in expt. no. 3 and 68% in no. 4, near the end of the two runs. In the absence of substrate (projector lamp) 82% of **6** remained after 2 h irradiation.

[d]Analysis for sensitizer **7** by HPLC (retention time 33 min), along with products **2**–**5**, showed that **7** was recovered unreacted after 2 h irradiation when ct/tt = 8.4; **7** did exhibit decay on extended reaction.

[e]Rates were calculated assuming that the reactions occurred within the hydrophobic phase of the micelles or the bilayers. In nos. 6–8, amounts are given in mol due to the heterogeneous system.

Fig. 4. Plots to determine kinetic order with respect to light for the photochemically initiated oxidation of methyl linoleate in homogeneous solution. (*A*) Experiment initated with 6.17×10^{-4} M **7** oxidizing 4.27×10^{-2} M methyl linoleate in *tert*-butanol at 37°C, irradiated with a 200 W Hg arc lamp. Kinetic order = 0.91, $R^2 = 0.94$. (*B*) Experiment initiated with 1.827×10^{-3} M **6** oxidizing 4.35×10^{-2} M methyl linoleate in *tert*-butanol at 37°C, irradiated using a commercial slide projector. Kinetic order = 1.02, $R^2 = 0.99$.



7, are shown in Figs. 3*A* and *B*. The profile of products when employing **6** and a projector lamp (Fig. 3*A*) showed the pattern of six products typical of oxidation by singlet oxygen (compare Fig. 2*B*), and the ct/tt ratio increased to 36. Oxidation of linoleate to 3% conversion sensitized by **7** was observed by using a more intense 1000 W visible lamp. At this point in the oxidation, the ct/tt ratio was 7.5 (see Fig. 3*B*). The kinetic order in oxygen uptake with light intensity was determined for reactions initiated by **6** and **7**, as illustrated in Fig. 4. Both reactions showed linear plots, and the order was unity for **6** and approximately unity (0.91 ± 0.07) for initiation by **7**. Some quenching experiments were carried out for both reactions under these conditions using a singlet oxygen quencher, Dabco, and the results are shown in Table 1, nos. 2–5.

(c) Oxidations in heterogeneous systems: aqueous micelles and phospholipid bilayers

We conducted experiments employing sodium dodecyl sulfate (SDS) micelles and dilinoleoyl-phosphatidylcholine (DLPC) bilayers, expected to mimic the more complex solid–aqueous system of natural material such as lignin or wood pulp. Earlier reviews appeared on some singlet oxygen oxidations in these media (46–48), and interest in singlet oxygen oxidations in these systems continues (30, 49). For comparative purposes, we first carried out experiments in these systems using dye-sensitized oxidations. Methylene blue sensitized oxidation of methyl linoleate in SDS micelles yielded products typical of singlet oxygen oxidation (Fig. 5*A*, ct/tt = 6.7) with kinetic order in light intensity of 1.05, as did reaction sensitized by the natural dye, hematoporphyrin (not shown), with kinetic order in light intensity of 0.98. Methylene blue, 1.55 μm, sensitized oxidation of linoleate in DLPC bilayers, 44.6 μm, using a Hg arc lamp, also gave products typical of singlet oxygen oxidation with ct/tt ratio = 29 (not shown). The quinone, **6**, was an effective sensitizer for the oxidation of methyl linoleate in SDS micelles. The HPLC product analysis showed products typical of singlet oxygen oxidation of linoleate in this system (see Fig. 5*B*, ct/tt = 9.1). The results of typical quenching experiments for sensitized oxidation in SDS micelles and DLPC bilayers employing sodium azide quencher are given in Table 1, nos. 6–8. While sodium azide is a convenient quencher of singlet oxygen to use in aqueous systems, its effect can be quite ambiguous due in part to its possible quenching of the sensitizer (50) at high concentrations, and there is even some evidence that sodium azide can produce reactive peroxyl radicals (51). Therefore it was considered prudent in our experiments to use relatively small concentra-

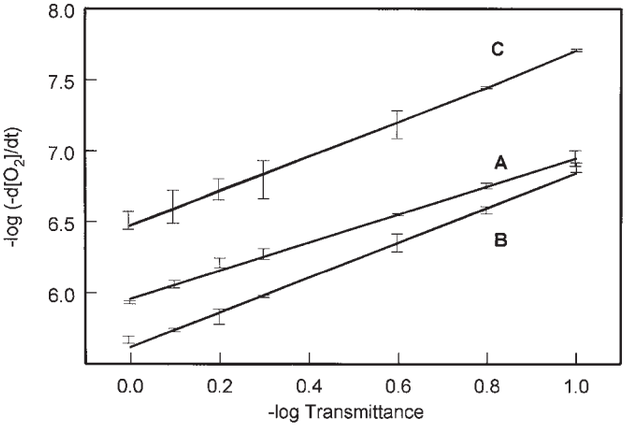
(*A*) Experiment initiated with 1.73 × 10^{-3} M **6** oxidizing 0.205 M 1-phenyl-2-methylpropene in *t*-BuOH at 30°C, irradiated using a commercial slide projector. Kinetic order = 0.99, R^2 = 0.99. (*B*) Experiment initated with 4.5 × 10^{-4} M Rose Bengal oxidizing 0.824 M *trans*-stilbene in chlorobenzene at 37°C, irradiated using a 1000 W tungsten lamp. Kinetic order = 1.23, R^2 = 0.99. (*C*) Experiment initiated with 8.7 × 10^{-4} M **6** oxidizing 0.78 M *trans*-stilbene in chlorobenzene at 37°C, irradiated using a 1000 W tungsten lamp. Kinetic order = 1.21, R^2 = 0.95.



tions of sodium azide or carry out a "quenching profile" using successive additions of this quencher, vide infra.

2. Oxidations of hydrocarbons. Sensitization by the quinone, 6, compared to that by a dye

Lignin possesses a very complex structure which contains a variety of organic functional groups attached to frameworks that include aromatic rings, and alkene connecting links among others (45). Stilbene derivatives are important structures that are formed during mechanical processing of pulp (52). In addition, stilbenes are well known to be reactive with singlet oxygen (53–57). We therefore selected two simple unsaturated hydrocarbons, 1-phenyl-2-methylpropene (**8**) and *trans*-stilbene (**9**), as substrates to test the possible effect that the lignin model quinone (**6**) might have when used as a sensitizer in their oxidation. In these experiments, oxidations initiated by the known singlet oxygen sensitizer, Rose Bengal (53), were also carried out for comparison purposes. Kinetics of oxygen uptake and quenching were used to compare the effects of the model quinone, **6**, and the dye on the photo-oxidation of these hydrocarbons. Results of these experiments are summarized in Table 2. They show that the model quinone as well as the dye initiate oxidation

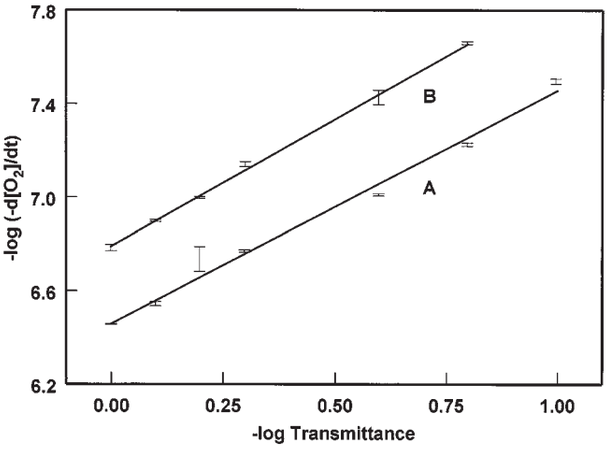
(*A*) Oxidation of 0.26 M cellobiose initiated with 1.3×10^{-6} M benzophenone derivative, **12**. Kinetic order = 1.00, $R^2 = 0.98$. (*B*) Oxidation of 0.30 M cellobiose initiated with 1.14×10^{-5} mol benzophenone coevaporated onto 200 mg silica gel. Kinetic order = 1.08, $R^2 = 0.99$.



of the hydrocarbon **8** in *tert*-butyl alcohol and **9** in chlorobenzene, and that for either system the oxygen uptake is reduced with the singlet oxygen quencher, Dabco. In addition, some experiments were conducted to determine the kinetic order in oxygen uptake with light intensity. For example, Fig. 6*A* illustrates the result for the oxidation of **8** initiated by the quinone **6.** This shows a linear plot and a kinetic order of unity. Linear plots for the order in light intensity were observed for oxidation of *trans*-stilbene initiated by Rose Bengal and by **6** as shown in Fig. 6*B* and *C*. The kinetic orders in oxygen uptake were somewhat higher in these reactions at around 1.2.

3. Applications to the oxidation of lignin and cellobiose

(a) Self-initiated oxidation and quenching of lignin

Our sensitive oxygen uptake method proved to be applicable to measure the oxidation of lignin. A small sample dispersed in SDS micelles gave measurable oxygen uptake on irradiation with a visible source, and sodium azide was an effective quencher under these conditions, as shown in Fig. 7*A*. Irradiation using an ultraviolet source (pyrex filter) of a lignin sample dispersed in water gave a much more rapid rate of oxidation as shown in Fig. 7*B*, along with a

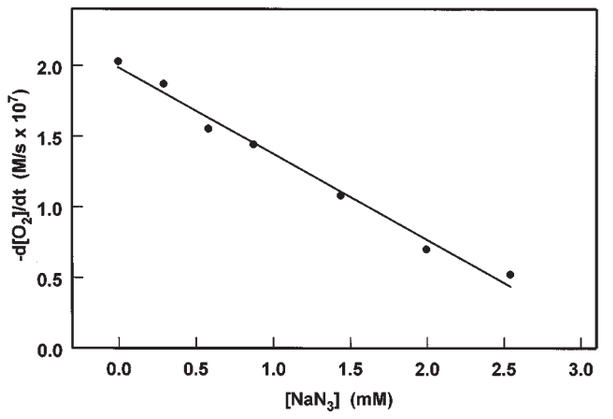
Fig. 9. Effect of increasing concentrations of NaN_3 on the rate of **12** (1.3×10^{-6} M) initiated oxidation of 0.255 M cellobiose in water at 37°C, irradiated using a 200 W Hg arc lamp.



typical partial quenching with sodium azide. Analyses for hydroperoxide buildup were carried out on aliquots taken during the experiment. The results indicate that approximately 1/4 to 1/3 of the oxygen consumed resulted in lignin hydroperoxides.

(b) Oxidation of cellobiose sensitized from solution, SDS micelles, and from a solid support

Cellulose and model compounds have long been known to be susceptible to ultraviolet light (58), and singlet oxygen reacts readily with these systems (21–23). Therefore it was of interest to conduct some experiments on the sensitized oxidation of cellobiose. For these studies we used various model systems, including initiation from the same aqueous phase employing the water-soluble benzophenone derivative, **12**, initiation from a micellar phase using the quinone, **6**, in SDS micelles and from benzophenone or the lignin model, **7**, adsorbed on a solid support, silica gel. Such solid supports have attracted considerable interest (59, 60) and should better reflect the situation in the heterogeneous lignocellulose systems. Some typical oxidation experiments on cellobiose sensitized by **6**, **7**, **12**, benzophenone, or Rose Bengal are given in Table 3. Oxygen uptake was observed in all systems on irradiation, and the rates were reduced with small amounts of sodium azide. In addition the kinetic orders in oxygen uptake were unity, determined for initiation by **12** and by benzophenone, as shown in Fig. 8*A* and *B*. A profile for the sodium azide quenching of oxidation initiated by **12** gave the linear relationship shown in Fig. 9.

Discussion

The possible role of singlet oxygen in the photo-yellowing of high-yield pulps is characterized by considerable controversy and uncertainty. Typical previous reports provide a variety of conclusions which differ remarkably; for example, singlet oxygen is stated to be "... the main actor of the discoloration process... formed by energy transfer from photoexcited lignin" (20); or "... singlet oxygen treatment had little or no effect on the brightness of the bleached TMP" (13); or "... singlet oxygen... exerts a significant *bleaching* effect on pulp sheets" (19). It is emphasized again that the significant competition which determines whether Type 1 (free radical) or Type 2 (singlet oxygen) predominates is between the selected substrate and oxygen for the excited sensitizer (5). So whether Type 1 or Type 2 predominates (or both occur) will depend on the sensitizer selected, the substrate (e.g., its H-atom donating ability) and experimental conditions such as the nature of the light source.

The linoleate lipid is a very useful substrate (marker) to test the possible role of singlet oxygen in photo-oxidation in the current research because (*i*) on the one hand, it is an effective H-atom donor so that a triplet sensitizer can readily abstract a H-atom from the substrate to permit Type 1 autoxidation over Type 2, such as with benzophenone sensitized oxidation of linoleate (61), yet (*ii*) on the other hand the products of singlet oxygen oxidation of linoleate clearly differ for this pathway compared to the Type 1 pathway (vide supra), so that product studies can serve as a test for the dominant pathway. The results of our current studies on sensitized peroxidation of linoleate are representative of a wide variety of experimental conditions so that the two pathways might be in competition.

In all cases for sensitized peroxidation of linoleate, the qualitative pattern of the HPLC analyses of oxidation products, and their high ct/tt product ratios compared to those obtained during thermal oxidation, indicate the involvement of singlet oxygen as a major pathway (see Figs. 2, 3, and 5). It is especially significant to note that this is the case for reactions sensitized by the "model" quinone, **6** (Figs. 3*A* and 5*B*), and the lignin model, **7** (Fig. 3*B*). On the other hand, the ct/tt ratios for reactions sensitized by **6** or **7** were seen to vary considerably *even for reactions under what appears to be similar conditions*. For example, this ratio for initiation employing the quinone, **6**, and a 750 W projector lamp (ct/tt = 27) is quite different from that when using a 1000 W high-intensity tungsten lamp (ct/tt = 13). In addition, the ct/tt ratio for reactions sensitized by the lignin model, **7**, are rather low (ct/tt = 7.5) compared to dye sensitized reactions or quinone sensitized reactions. We do not have a quantitative explanation for these variations but suggest that these differences reflect a competition between Type 1 and Type 2 pathways. Such a competition has been reported before in the case of the products from dye-sensitized peroxidation of linolenic ester (62). Furthermore the quinone, **6**, has been observed to abstract H from reactive donors (35), so a competition between Type 1 and Type 2 pathways may well occur with minor changes in experimental conditions. Reactions sensitized by **6** or **7** are further complicated by their consumption during experiments which were lengthy in order to obtain significant conversion of substrate (see Tables 1 and 2, footnotes *c* and *d*). Kinetic measurements of oxygen uptake were carried out during comparatively short irradiation times when conversion of **6** or **7** is small. These results contrast with earlier ones using benzophenone in photo-oxidation (Type 1), where the benzophenone was completely regenerated (61).

Quantitative kinetic studies of oxygen consumption using the sensitive pressure transducer system provide important evidence on the pathways of the peroxidation of linoleate and of the hydrocarbons **8** and **9** under various conditions. Oxygen uptake was measured by this system for these oxidations initiated by the model compounds **6** and **7** as well as

© 1998 NRC Canada

by the dyes used. Known singlet oxygen quenchers Dabco and sodium azide caused significant reductions in the rates of oxygen uptake in these experiments, as shown in Tables 1 and 2. Furthermore, we found that injections of efficient antioxidants such as 2,2,5,7,8-pentamethylhydroxychroman (PMHC) during sensitized oxidations of **8** and of linoleate in solution, or injections of 2,5,7,8-tetramethyl-6-hydroxychroman-2-carboxylate (Trolox) during oxidation of linoleate in SDS micelles, did not cause inhibition of oxidation typical of their peroxyl trapping action (e.g., did *not* produce an induction period) (61), in contrast to the earlier results for benzophenone photo-oxidation of linoleate in SDS, and had only a slight effect on the rate of oxidation. Hydroxychromans of the vitamin E class are known to act as singlet oxygen quenchers (63–66), but the observed reductions in oxidation of a substrate are quite different from the characteristic well-defined induction periods observed for Type 1 oxidations in the presence of antioxidants (61). We conclude that our sensitized reactions proceeded mainly or entirely via Type 2 pathways. The kinetic order in oxygen uptake provided a useful test of this conclusion. Photoinitiated Type 1 reactions as well as thermal-initiated ones are known to follow the classical rate law for autoxidations where the oxidation is half order in the rate of free-radical chain initiation (R_i). This was shown to be the case for benzophenone initiated oxidation of linoleate (61) where the R_i was changed by varying the light intensity through the use of filters. In contrast, the kinetic order in light intensity for reactions initiated by the quinone, **6**, or by the lignin model, **7**, in the present study were approximately unity for oxidation of methyl linoleate (Fig. 4) or for oxidation of hydrocarbon **8**. We cannot make a complete analysis from this limited kinetic data because the concentrations of substrates were not systematically varied; nevertheless, these limited results suggest a simple first-order dependence on the steady-state concentration of singlet oxygen which is expected to vary directly with light input.

Our results from photo-oxidations sensitized by the model quinone, **6**, and the lignin model, **7**, provide a very useful background for experiments on the more relevant systems containing lignin and cellobiose. The light-induced self-initiated oxidation of lignin in aqueous mixtures most certainly occurs by a singlet oxygen pathway, according to the oxygen uptake and quenching studies with sodium azide (Fig. 7). The free-radical pathway for oxidation of lignin under these conditions is not significant, since we find that the antioxidant Trolox causes only a slight reduction in oxygen uptake, and no definite "inhibition period" was observed. Excited chromophoric groups in the lignin structure must be acting to sensitize these self-initiated, singlet oxygen oxidations. We acknowledge that this is an oversimplification of a very complex system like lignin. Lignin hydroperoxides build up during the self-sensitized peroxidation, and presumably other, more complex, products form, since only 1/4 to 1/3 of the oxygen uptake is accounted for by hydroperoxide formation. We are not aware of previous use of *ortho* quinones as sensitizers in photo-oxidation. However even the simple diketene, biacetyl, when used as a model for oxidized lignin, is reported to photo-oxidize an azo dye by two "oxidizing species"; singlet oxygen and an adduct of ground-state molecular oxygen and triplet biacetyl (67). Similar conclusions were made earlier for the sensitized photo-oxidation of alkenes by benzil and biacetyl (68).

In recent years, comparatively little attention has been centered on the question of oxidation of the cellulose component of high-yield pulps. Therefore we carried out some initial studies using the readily available water-soluble model compound cellobiose. Results from studies in solution show that the water-soluble dye Rose Bengal, the benzophenone derivative **12**, and in particular the quinone, **6** (in *tert*-butanol–water), sensitize the oxidation of cellobiose (Table 3). The rates are reduced in the presence of sodium azide, indicating a singlet oxygen component to the oxidation. The oxidations sensitized using benzophenone and especially the lignin model, **7**, carried on silica gel as a solid support are of particular interest, since this heterogeneous system provides a model of the more complex situation in high-lignin pulps. While these data are somewhat preliminary, the oxidation rates and sodium azide quenching results suggest that these reactions involve singlet oxygen attack on the cellobiose structure.

Overall our results leave no doubt that singlet oxygen is indeed the main active oxygen which participates in photo-oxidations initiated by model compounds such as an *ortho* quinone (e.g., **6**) or a lignin model ketone, **7**, in homogeneous solution or in mixed phases. The initial results on lignin and cellobiose indicate that the singlet oxygen pathway must be considered when designing strategies, such as employment of quenchers and (or) sunscreens, to inhibit photo-yellowing of high lignin content pulps.

Experimental

Materials and preparations

The solvents used were of HPLC grade and were distilled before use. Phosphate buffer (pH 7.0) for use in preparation of micelles or lipid bilayers was prepared from 0.05 M each of Na_2HPO_4 and NaH_2PO_4 in distilled, deionized water containing 1×10^{-4} M EDTA. Immediately before use the buffer was passed through a Chelex-100 column (Bio-Rad 50–100 mesh) to remove traces of heavy metal ions. Electrophoresis pure sodium dodecyl sulfate (SDS) was purchased from Bio-Rad Laboratories. Dilinoleoylphosphatidylcholine (DLPC) was obtained in sealed vials from Avanti Polar Lipids and stored at –25°C. The procedure for preparation of DLPC bilayers is described elsewhere (69). Methyl linoleate was obtained from Nu-Chek-Prep in sealed vials and stored at –25°C. 3,5-Di-*tert*-butyl-*o*-quinone, **6**, was prepared by oxidation of 3,5-di-*tert*-butylcatechol (Aldrich) with lead oxide as described (70) and recrystallized from hexane in dark red needles, mp 117–119°C (lit. mp 113–114°C (70)). 1-(3,4-Dimethoxyphenyl)-2-(2-methoxyphenoxy)-1-propanone (**7**) was synthesized as described (71) and recrystallized from methanol as colorless crystals, mp 118–120°C (lit. mp 117–120°C (71)). Mass spectroscopic analysis (GC/MS) of **7** gave the theoretical parent mass at m/e = 256 and the expected ^1H and ^{13}C NMR spectra. 1-Phenyl-2-methylpropene (**8**) was obtained from Aldrich. Larger quantities were prepared by dehydration of 2-methyl-1-phenyl-2-propanol (Aldrich) in boiling xylene containing a catalytic amount of *para*-toluenesulfonic acid. The product was separated from solvent by fractional distillation. Analysis by GC/MS showed it

© 1998 NRC Canada

to be 94% of the conjugated isomer, **8**. This was confirmed ^{1}H and ^{13}C NMR in comparison with commercial **8**. 2,2-Azo-bis(2,4-dimethylvaleronitrile) (ADVN) was obtained from Polysciences, Inc. *trans*-Stilbene, 1,4-diazabicyclo-[2.2.2]octane (Dabco), benzophenone, *p*-methoxyacetophenone, heptadecane, Trolox, and cellobiose were obtained from Aldrich. *p*-(Methyl sodium sulphonate)-benzophenone (**12**) was a gift from J.C. Scaiano, University of Ottawa. Pentamethylhydroxychroman (PMHC) was synthesized as described (72). Preparations of sensitizers on silica gel were carried out by dissolving known amounts of sensitizer (**6**, **7**, or benzophenone) in methylene chloride containing a known weight of silica gel, Merck silica gel 60, 230–400 mesh. The solvent was removed under reduced pressure. The resulting solid support normally contained 1% by weight of the sensitizer. Milled wood lignin from unbleached softwood was supplied by PAPRICAN, Pointe Claire, Quebec.

Peroxidation procedures

Peroxidations and quenching studies of oxygen uptake were carried out at 30° or 37°C under oxygen at 760 Torr (1 Torr = 133.3 Pa) in a sensitive dual-channel calibrated pressure transducer system that is described elsewhere (73, 74). In the kinetic studies, each sample containing substrate, sensitizer, and solvent in a nominal 2 mL total volume was shaken under oxygen in a calibrated pyrex cell on the pressure transducer until a steady baseline was established on a recorder. Then the sample was irradiated and the oxygen uptake recorded. The light was then blocked while a known amount of quencher or antioxidant was added using a gas-tight micro syringe with an extended teflon needle. The sample was shaken again until a baseline was re-established, the light turned on again and the new oxygen uptake rate measured. This procedure is illustrated in a typical way for the oxidation and quenching of lignin in Fig. 7. The effect of light intensity was carried out by inserting a series of six neutral density filters supported on a filter wheel and measuring oxygen consumption for at least three measurements randomly positioned for each filter. Three different light sources were used. For initiations by broad-band visible light, a quartz tungsten–halogen lamp (Oriel no. 6315, 1000 W) with a photo-feedback attachment was used to ensure constant light intensity and for comparison purposes a simple commercial 750 W tungsten projector lamp was also used. Irradiations in the near UV were carried out with a mercury–xenon arc lamp (Oriel no. 6291, 200 W). In the latter case, the light intensity was monitored by sampling the light with a fibre optics cable leading to a phototube.

Analyses

Studies on product formation from methyl linoleate oxidation were conducted by HPLC. Samples of known volume were removed from an experiment at controlled intervals, and the product hydroperoxides were reduced to alcohols using an excess of triphenylphosphine (TPP) in hexane. For experiments in organic solvents, the solvent volume was reduced using a stream of argon and the sample prepared in a small volume (500 mL) of hexane. For experiments in aqueous media, TPP in methanol was used to reduce the hydroperoxides, and the product alcohols were extracted from the aqueous mixture using 2–1 mL aliquots of hexane, which were combined then condensed to 500 mL using a stream of argon. Two HPLC systems were used to determine the ct/tt product profiles: (*i*) a Varian system – Varian 9012 pump, Varian 9050 variable wavelength detector and Varian 9100 autosampler for sample introduction, with the Varian Star Chromatography workstation v.4.5 for processing results, or (*ii*) an HP system – HP1050 pump and variable wavelength detector with a manual injector and HP3365 Chemstation for processing results. Columns used were either an Apex Si 10 μ column (Jones Chromatography, 25 cm) or a Lichrosorb Si 100 10μ column (Brownlee, 25 cm). Samples were eluted with a mixture of 99.2% hexane, 0.4% isopropyl alcohol, and 0.4% acetone with a flow rate of 1 mL/min and monitored at 234 nm. Deviations of peak retention time (Figs. 2–4, 6) are due to the differences in the columns, and peak identity was confirmed by comparison of product profiles obtained from the photochemically initiated runs with product profiles from thermally initiated experiments. At least three injections were made for each sample. Some experiments used *p*-methoxy-acetophenone as an internal standard to quantify the amount of hydroperoxides being formed. Peaks eluted in the following order: *p*-methoxyacetophenone, **3**, **5**, **2**, **4**. Unconjugated products from the Type 2 pathway eluted just after **5** and after **4**. Using the same column and solvent conditions it was possible to monitor the loss of the sensitizer, **7**, which eluted after the four product alcohols, at 33 min (not shown).

Changes in concentration of the sensitizer, **6**, were monitored using a Shimadzu UV-1201 equipped with a Spectrum program pack, v.5. Samples were taken from experiments before and during irradiation and prepared to a known volume for analyses. The molar absorptivity for **6**, $\varepsilon = 2346$ at 386 nm, was calculated using a sample of **6** of known concentration.

Quantitative measurements of the formation of hydroperoxides during an experiment were made by reducing the hydroperoxides to alcohols using TPP and measuring the resultant amount of triphenylphosphine oxide (TPPO) generated, compared to an internal standard, heptadecane. Analyses were made on a Varian 3700 GC using a Durabond DB-1 fused silica megabore capillary column (1 μm film thickness, 15 m × 0.32 mm) with a flame ionization detector. The carrier gas, He, had a flow rate of 30 cm^3/min. Using a temperature program (initial temperature 130°C (held 6 min) increased 10°C/min to 220°C (held 8 min)) with fixed injector and detector temperatures of 200 and 220°C, respectively, the products separated as follows: heptadecane, 10.6 min; TPP, 15 min; TPPO, 20 min.

Mass spectra were obtained on a HP5988A GC/MS instrument using an HP5890 series 2 gas chromatograph. ^{1}H and ^{13}C NMR were measured in $CDCl_3$ (TMS internal standard) on a JEOL JNM GSX 270 FT NMR.

Cleavage of neutral alkenes and alkene radical cations; hybrid Hartree–Fock/density functional theory results

Leif A. Eriksson, C. Magnus Jansson, Donald R. Arnold, and Russell J. Boyd

Abstract: The cleavage reactions of the 1-butene and 4,4-dimethyl-1-pentene molecules and their cations, to form neutral and charged hydrocarbon products, are investigated using hybrid Hartree–Fock/density functional theory. In comparison with previous theoretical results (Du et al.), the density functional cleavage and ionization energies, including zero-point vibrational energy, lie in better agreement with experimental and thermochemical data. Assuming vertical ionization processes the mean absolute deviation (MAD) compared with experiment is 3.4 kcal/mol for the reaction sequences studied. Using adiabatic ionization processes instead gives a MAD of 5.2 kcal/mol. The largest deviation from experiment occurs for the cleavage reactions of the neutral parent molecules, where the difference between theory and experiment is up to 12.8 kcal/mol. In addition to reaction energies we also report optimized ground-state structures, and for the radicals studied, isotropic hyperfine coupling constants that are compared to experimental data. It is found that the experimental hyperfine properties of the 1-butene cation can be explained by rotational averaging caused by the flat potential surface for rotation about the C2—C3 bond.

Key words: density functional theory (DFT), alkenes, radical cations, bond cleavage, isotropic hyperfine coupling constants.

Résumé : Faisant appel à la théorie de densité fonctionnelle hybride de Hartree–Fock, on a étudié les réactions de clivage des molécules de but-1-ène et de 4,4-diméthylpent-1-ène et de leurs cations conduisant à la formation d'hydrocarbures neutres et chargés. Par comparaison avec les résultats théoriques publiés antérieurement (Du et al.), la densité fonctionnelle de clivage et les énergies d'ionisation, y compris l'énergie vibrationnelle au point zéro, sont en meilleur accord avec les données expérimentales et thermochimiques. En faisant l'hypothèse que les processus d'ionisation sont verticaux, on a déterminé que la déviation absolue moyenne (DAM) comparée à la valeur expérimentale est égale à 3,4 kcal/mol pour les séquences de réaction étudiées. Si l'on utilise plutôt des processus d'ionisation adiabatique, la valeur de DAM obtenue est égale à 5,2 kcal/mol. Les réactions de clivage des molécules parentes neutres donnent les plus grandes déviations entre les valeurs calculées et expérimentales; la différence atteint 12,8 kcal/mol. En plus des énergies de réaction, on a aussi calculé les structures optimisées des états fondamentaux et, pour les radicaux étudiés, on a aussi comparé les constantes de couplage hyperfin isotrope avec les données expérimentales. On a trouvé que les propriétés hyperfines expérimentales du cation but-1-ène peuvent être expliquées par une pondération rotationnelle moyenne provoquée par une surface de potentiel plane pour la rotation autour de la liaison C2—C3.

Mots clés : théorie de la densité fonctionnelle (DFT), alcènes, cations radicaux, clivage de liaison, constantes de couplage hyperfin isotrope.

1. Introduction

During the last few years, the new generation of methods based on density functional theory (DFT) has attracted much attention in the quantum chemical community. Today, we can find successful applications in practically every area of theoretical chemistry, traditionally focused by conventional ab initio theory. At the same time, much effort is being devoted to the development of new functional forms, fitting procedures, and hybrid methods between DFT and, e.g., ab initio theory, molecular mechanics, or molecular dynamics simulations (1–4). Of particular interest for the present work is the performance of gradient-corrected and hybrid Hartree–Fock/density functional theory (HF-DFT) methods for chemical reactivity and properties of unsaturated hydrocarbons, and the effects of photoionization of such systems.

The applicability of DFT for radical hyperfine properties is also of interest, and it has been shown (footnotes 2 and 3,

ref. 5) that the two functionals overall performing the best — often in very close agreement with highly advanced correlated ab initio methods — are the gradient-corrected DFT functional "PWP86" (6, 7) and the "B3LYP" hybrid functional (8–11), frequently reproducing experimental isotropic hyperfine coupling constants (HFCC) to 85–90% of experimental values. The density functional theories for geometric structures and radical properties of pure hydrocarbons have previously been thoroughly investigated in our laboratory (12–14). More recent applications of DFT for chemical reactivity and photoionization problems involve, e.g., the work by Wong and Radom (15) on a number of prototypical radical addition reactions, and a study of the radical cations of, e.g., silacyclobutane cations (16).

The compounds and reactions focused on in the present work serve as model systems for larger compounds and proposed reactions of interest in synthetic organic chemistry (17, 18), and where there is sufficient previous experimental and theoretical data available to enable a good evaluation of the present methods. For a more detailed survey on the more complex parent systems, we refer to ref. 17.

2. Theoretical details

All geometries, energies, and hyperfine parameters reported in the present work are computed using hybrid Hartree–Fock gradient-corrected density functional theory, as implemented in the Gaussian 94 program (19). We throughout use the B3LYP functional, i.e., Becke's three-parameter hybrid functional (8), consisting of Hartree–Fock exchange, Slater local exchange (20), Becke (B88) nonlocal exchange (10), with the Vosko–Wilk–Nusair local correlation (21), and the Lee–Yang–Parr (LYP) gradient-corrected correlation functional (11). The B3LYP functional has been previously shown to yield highly accurate geometries and hyperfine properties (footnotes 2 and 3, ref. 5). The orbital basis sets used are 6-31G(d,p) for geometry optimization and zero-point vibrational energies (ZPVE) and 6-311G(2df,p) (22) for energies and hyperfine coupling constants (HFCC). Important indirect information about the geometry and the localization of the unpaired electron in radical species can be obtained via the electron spin resonance (ESR) techniques. If the calculated HFCCs match the experimental ones, and the system does not undergo vibrational or rotational motion, one may assume the experimental and calculated structures to match. For a doublet radical the isotropic HFCC (the "Fermi contact term") of a nucleus N is obtained through the relation:

$$A_{\mathrm{iso}}^{\mathrm{N}} = \frac{8\pi}{3} C \sum_{\mu\nu} \mathrm{P}_{\mu,\nu}^{\alpha-\beta} \left\langle \phi_\mu(\vec{r}_{\mathrm{k,N}}) | \delta(\vec{r}_{\mathrm{k,N}}) | \phi_\nu(\vec{r}_{\mathrm{k,N}}) \right\rangle$$

where the constant $C = g\beta g_{\mathrm{N}}\beta_{\mathrm{N}}$, $\mathbf{P}^{\alpha-\beta}$ is the spin-density matrix, and the Dirac delta function ensures the overlap integrals to be evaluated at the position of the nucleus only. For a more detailed description of the calculation of hyperfine parameters, the reader is referred to footnote 2 and refs. 23 and 24.

3. Results

(a) Optimized geometries

The two net reactions investigated are

$$H_2C{=}CHCH_2CH_3 \rightarrow CH_2CHCH_2\cdot + CH_3^+ + e^-$$

and

$$H_2C{=}CHCH_2C(CH_3)_3 \rightarrow CH_2CHCH_2^+ + C(CH_3)_3\cdot + e^-$$

Each reaction sequence can proceed through two different pathways: an initial ionization of the neutral reactant, followed by cleavage and electron transfer, or by initial cleavage of the neutral species into two radical moieties, followed by ionization of one of them, and subsequent electron transfer. The B3LYP optimized geometries of the various reactants, intermediates, and products are shown in Figs. 1–3.

In the cleavage reaction of 1-butene, the fragmentation products are the allyl radical cation and the methyl radical cation, Figs. 3*a–d*, whereas for the 4,4-dimethyl-1-pentene system, the products of the cleavage reactions are instead the allyl and *t*-butyl radicals cations, Figs. 3*a, b, e, f*.

1-Butene conformers

For the neutral nonplanar 1-butene the highest occupied molecular orbital (HOMO) is localized to the π-bond, i.e., the C1 and C2 p_z orbitals perpendicular to the C1-C2-C3 plane. When 1-butene is ionized the HOMO (now the singly occupied molecular orbital, SOMO) changes localization to the antibonding σ*-orbital between C3 and C4, whereby the π-bond interaction between C1 and C2 is much reduced. Thus the length of the C1=C2 bond increases to above 1.40 Å, and attains a value close to that associated with a bond order of "1.5," observed in, e.g., the benzene molecule. Also the C3—C4 distance lengthens from 1.54 to 1.61.

Interestingly enough, also the local geometry of the β-carbon (C3) is strongly affected by the ionization. As seen in Figs. 1*a* and *b*, the C2—C3 bond length is markedly shortened after ionization, from 1.50 to 1.45, and the C2-C3-C4 bond angle now more resembles that of an sp^2 hybridized carbon. Furthermore the H-C3-H angle decreases by roughly 5°. All other C—H bond lengths and H-C-C bond angles remain more or less unaltered by the ionization process. The B3LYP optimized geometry of the 1-butene cation closely resembles those from previous MP2 and DFT optimizations (12, 25); the largest difference in C—C bond length between B3LYP and MP2 is 0.005 Å, and the mean deviation is 0.002 Å.

For the 1-butene radical cation three different stationary points were found, two planar (*eclipsed* and *anti*) and one nonplanar (*skewed*). The energy differences between the three forms are within 0.9 kcal/mol, with the skewed 1-butene conformer being lowest in energy. The frequency calculations showed one negative frequency for the *anti* conformer but none for the eclipsed and skewed forms. Hence, at the B3LYP level, the *anti* conformer is a transition state, not a local minimum, corresponding to out-of-plane motion connecting the two mirror images of the skewed conformer. However, after adding the ZPVE the *anti* conformer becomes the lowest in energy of the three, and the skewed con-

former the highest. The ZPVE-corrected energies are now in a range of 0.5 kcal/mol. For the neutral 1-butene the three conformers are within 2 kcal/mol of each other without ZPVE, and 1.7 kcal/mol with ZPVE included. Since the en-

ergy differences are so small we may expect substantial rotation to occur in the 1-butene both for the neutral and the cationic species. The present results are in close accord with previous MP2//UHF calculations that yielded a 1 kcal/mol energy difference between the eclipsed and anti conformer (17).

The differences in C—C bond lengths in the C1–C3 part of the three neutral conformers of 1-butene are at most 0.012 Å, and for the corresponding ions 0.009 Å. The C1-C2-C3 angle varies 1.4° among the different neutral conformers, and 2.5° among the ionic ones. The difference in methyl–allyl bond length is 0.008 Å among the neutral conformers and 0.094 Å between the ionic forms.

4,4-Dimethyl-1-pentene

When 4,4-dimethyl-1-pentene is ionized the allyl–*t*-butyl bond length increases from 1.56 to 1.90 Å, the C=C2 bond lengthens from 1.33 to 1.38 Å, the C2—C3 bond shortens from 1.51 to 1.42 Å, and the C1=C2-C3 angle decreases from 125° to 123° (Figs. 2*a* and *b*). This indicates the same type of orbital interactions for this compound as those observed for 1-butene. For computational reasons we only examined the skewed form of 4,4-dimethyl-1-pentene. The out-of-plane angle (dihedral C4-C3-C2-C1) is for this system 117.1° (neutral) and 99.8° (cation), compared with 119.9° (neutral) and 98.5° (cation) for the skewed form of 1-butene. These dihedral angles compare well with earlier findings at HF and MP2 levels (12, 17, 25).

t-*Butyl and methyl*

The *t*-butyl radical is found to be pyramidal at the present level of calculations, Fig. 3*e*, as in previous UHF and CIS calculations (26, 27). The top angle (the angle between the C—H or C—C bond and its projection in the nodal plane of the p_z orbital of the central carbon atom) is found to be 6.2°. Upon ionization, the electron is removed from the central carbon p_z orbital perpendicular to the molecular plane. The planar conformation is thereby stabilized as the possibility of gaining energy by means of a partial sp^3 type hybridization of the central carbon atom (yielding a pyramidal structure) is diminished. In the *t*-butyl cation, which is planar at the present level of calculation, all bond lengths are reduced somewhat as a result of the ionization, Fig. 3*f*, whereas for CH_3^+ we instead note an increase in the C—H bond lengths, Figs. 3*c* and *d*. The C—H bond distance for the methyl radical is in satisfactory agreement with experiment (1.082 vs. 1.079 Å). The equilibrium geometries of most of these molecules have previously been thoroughly investigated by theory as well as experiment. For both the *t*-butyl (27, 28) and methyl radicals, the potential energy surfaces are known to be very flat with respect to pyramidal motions, and it has been shown that the vibrational motion affects the hyperfine properties of the central carbon significantly (14, 27, 29–33).

Allyl

For the allyl radical, DFT calculations have previously been shown to yield too short C—C bond lengths relative to experiment (14). This is true also for the present calculations, although a minor improvement is noted. The main effect of the ionization is a decreased C1-C2-C3 bond angle (125° to 119°), whereas the C—C bond lengths are unaltered (cf. Figs. 3*a* and *b*). Minor modifications are also noted in the C—H bond lengths.

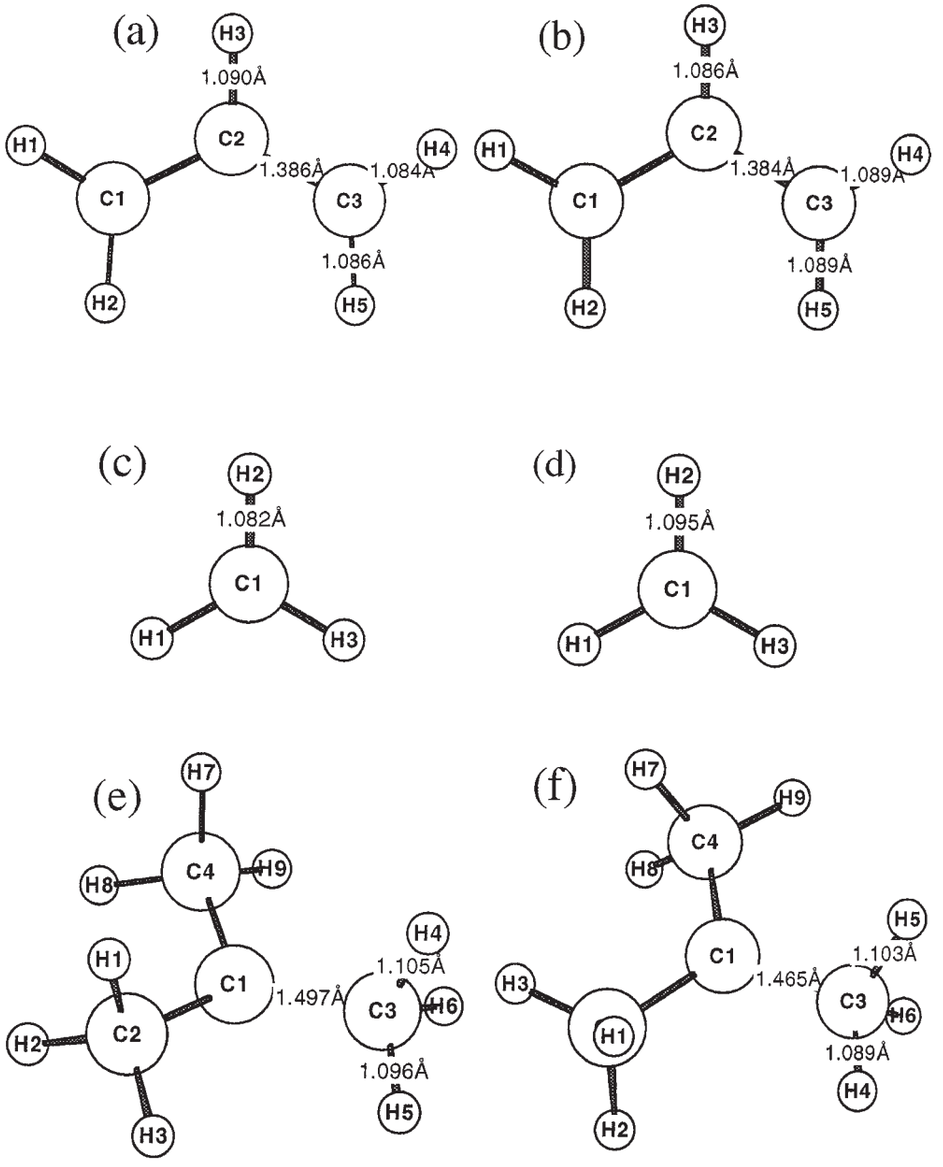
All calculations are performed using the gradient corrections and basis sets described in the text.



(b) Energetics

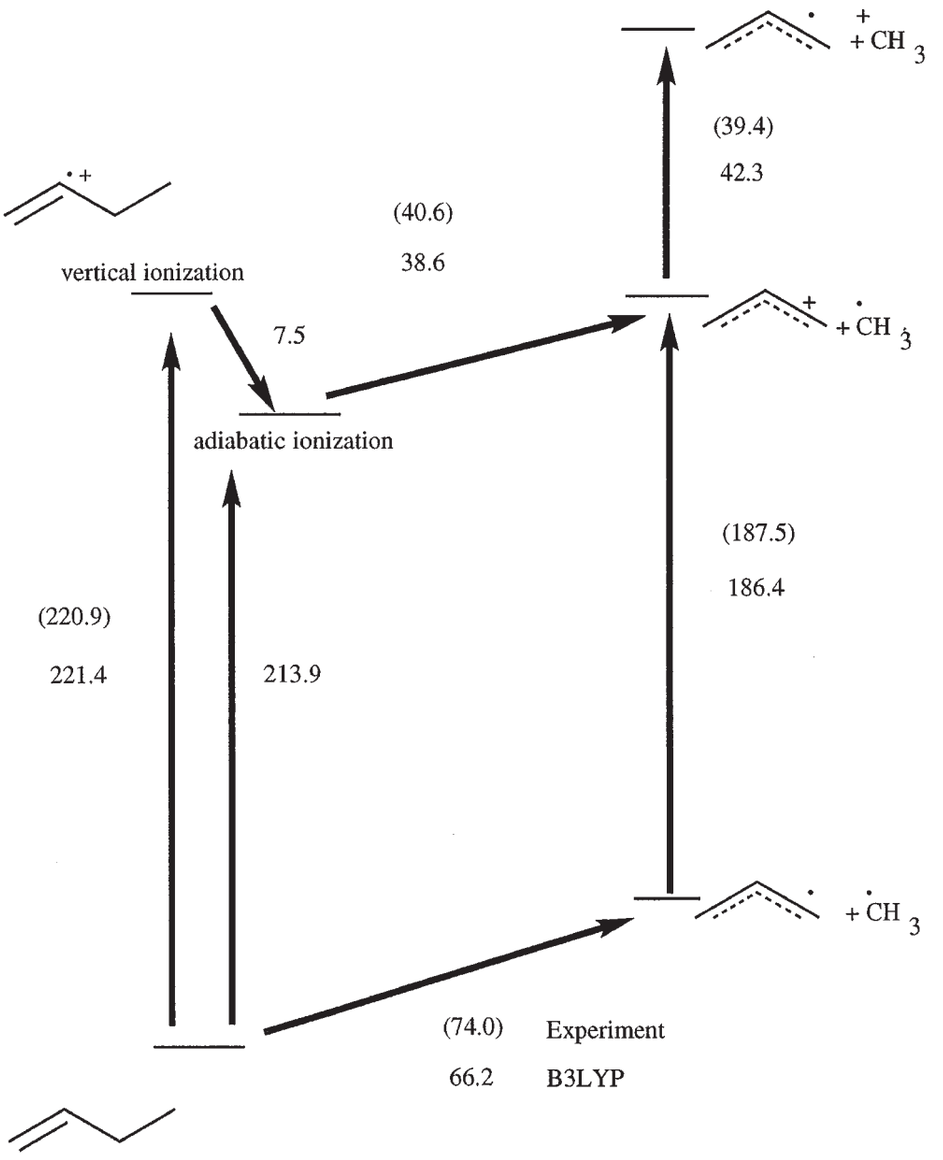
We show in Figs. 4 and 5 the energetics of the different ionization-, cleavage-, and electron-transfer reactions investigated in the present work. In Fig. 4 the reactions starting from the 1-butene molecule are displayed, and in Fig. 5 the corresponding reaction sequences for the 4,4-dimethyl-1-pentene system are presented. All energies are obtained from B3LYP/6-311G(2df,p) calculations using the corresponding B3LYP/6-31G(d,p) optimized geometries. Since the ZPVE is only well defined if the molecule is at a stationary point on its potential surface, the ZPVE correction is omitted from the energies involving the vertical ionization.

1-Butene

Following the two pathways of the 1-butene radical system (Fig. 4), we first of all note a very good overall agreement between the present DFT calculated energies and experimental data. We also note that the energetics predicted from the present DFT calculations are in far better agreement with experiment than the previous MP2//UHF data (17), with a mean absolute deviation of 3.0 kcal/mol vs. 19.7 kcal/mol (including adiabatic ionization process and without ZPVE). The main discrepancies occur for the reactions involving the neutral 1-butene. The ground state of the cation appears to be some 4.3 kcal/mol too low in energy

© 1998 NRC Canada

Fig. 4. Schematic representation of the energetics of the cleavage reactions of 1-butene. All energies (kcal/mol) have been calculated at B3LYP/6-311G(2df,p)//B3LYP/6-31G(d,p) level with ZPVE correction, except for the vertical ionization energy (see text). Experimental data (34), where available, are given in parentheses.



relative to the other reactants and products involved. The differences compared to experiment are reduced considerably if we assume vertical ionization of the neutral molecule, Table 1. For 1-butene, the vertical ionization will raise the relative position of $C_4H_8^+$ by 7.5 kcal/mol, whereby the energy difference between calculated and experimental data for this ionization process is reduced from 7.0 to 0.5 kcal/mol. As noted above, the different rotational conformers of 1-butene and 1-butene cation lie very close in energy. It is hence unlikely that the deviation is caused by different rotational structures for the neutral and cationic species. For the electron transfer process between the allyl cation – methyl radical and the allyl radical – methyl cation, there is a difference between theory and experiment of 2.9 kcal/mol.

As a comparison between the MP2 and B3LYP methods we also calculated the energies for the 1-butene reaction sequence at the HF and MP2/6-311G(2df,p) levels using the same B3LYP/6-31G(d,p) optimized geometries. This gives a MAD of 21 kcal/mol at HF and 8–10 kcal/mol at MP2 level, respectively (cf. Table 1), i.e., in worse agreement with experiment.

4,4-Dimethyl-1-pentene

For the second set of reactions, starting with the 4,4-dimethyl-1-pentene molecule, the agreement is again found to be most satisfactory. For this sequence the steps involving the ionization and electron transfer of the cleavage products allyl and *t*-butyl agree very well with experiment. We also

note the interesting fact that the energetic order between the allyl cation + *t*-butyl radical vs. allyl radical + *t*-butyl cation is reversed relative to that in Fig. 4 (allyl and methyl systems), as has also been observed experimentally (34).

The theoretical predictions, DFT as well as ab initio (17), deviate the most for the neutral 4,4-dimethyl-1-pentene system. With the present gradient-corrected DFT method, the deviation in adiabatic ionization energy towards the experimental data is 14.5 kcal/mol for the neutral molecule, including ZPVE. If we use the vertical ionization of 4,4-dimethyl-1-pentene instead of the energy for the optimized radical cations the deviation from experiment decreases from 14.5 to 2.8 kcal/mol. For the cleavage process of the neutral molecule the deviation from experiment is 12.8 kcal/mol, including ZPVE, and we have been unable to find the reason for this high deviation.

(c) Hyperfine parameters

The computation of hyperfine data has been one of many successful applications of gradient-corrected density func-

© 1998 NRC Canada

tional theory during recent years, with results often in close agreement with experimental data and highly accurate MRCI calculations (footnotes 2 and 3, ref. 5). The isotropic HFCC data of the presently studied cationic 4,4-methyl-1-pentene and 1-butene radical systems, and the neutral methyl, allyl, and *t*-butyl radicals, are listed in Table 2. For the 1-butene cation, Table 2*a*, previous CISD calculations on UHF, MP2, and semiempirical MNDO optimized geometries (25) have indicated that the radical is twisted about the weakened double bond. Geometry optimization calculations at the BP/DZP level (12) as well as the present calculations however indicate that the C=C-C (allyl) framework is planar (the C1 and C2 hydrogens remain in the plane of the C1-C2-C3 carbons). Furthermore, since the rotational barrier about the terminal C3—C4 bond, and also the middle C2—C3 bond are both very minor (17, 25), one may assume that the HFCC should be rotationally averaged with respect to C2–C3 and C3–C4 rotations. The data shown in the table are the static data (except for the rotational averaging of the terminal methyl groups), and are hence numerically larger than when averaging over a full 360° rotational motion. We note the very good agreement between the present data and that from CISD calculations on the 21° H1-C1-C2-C3 twisted structure (25). The too large H4 and H5 couplings in the present work can be ascribed to the neglect of rotational averaging. As seen from Table 2*a* the HFCC at, in particular, these positions vary markedly between the three conformers studied. Assuming a rotationally averaged set (eclipsed–skewed–*anti*–skewed), the agreement becomes much improved for all atoms, Table 2*b*. The need for rotationally averaged data also explains the poor agreement for H4-H5 also obtained at the CISD level, Table 2*a*.

For the allyl radical, the agreement between the B3LYP calculations and experiment is most satisfactory, Table 2*d*. For the two previous CIS studies (35), it seems that the one where the orbitals are obtained from preliminary MCSCF calculations render less satisfactory results relative to the more "simple" CIS(RHF) study.

For both the methyl and the *t*-butyl radical, there has been much discussion among theoreticians and experimentalists, as to the planarity/nonplanarity of the systems (for a brief summary of this, see ref. 33). The most recent conclusion in this matter, based on a collective matrix isolation ESR and theoretical picture, is that the methyl group is planar, whereas *t*-butyl carries a slight pyramidal angle as outlined above.

For methyl, previous calculations on both planar structures and those where a 5° nonplanarity is introduced (cf. Table 2*f*.) as well as coupled DFT – molecular dynamics simulations (33) indicate that the main changes occur on the central carbon. The potential surface is, however, extremely flat with respect to out-of-plane motion, and hence a vibrationally averaged HFCC is observed experimentally, rather than one arising from a static geometry (29). The effects of vibrational averaging on the HFCCs of methyl and deuterated methyl has recently been demonstrated in a hybrid B3LYP-MD simulation of CH_3 in rare gas matrices at 4 and 85 K (33). Within the static framework, i.e., subtracting the effects of vibration from the experimental data, the overall agreement seems better at the DFT level than when using the various single reference ab initio methods, Tables 2*d* and *e*.

4. Conclusions

In the present work, we have investigated the suitability of hybrid HF gradient-corrected density functional theory to predict geometries, energetics, and hyperfine properties of two sets of alkene cleavage reactions. The emphasis has been on the relative energies involved, which are found to be in close agreement with experimental data. Mean absolute deviation from experiment for the two reaction sequences studied is 3.4 kcal/mol, Table 1, which is a marked improvement over the 19.7 kcal/mol (17) for the previous study of the same process. At the MP2/6-311G(2df,p) level (this work) the mean absolute deviation for the process starting from 1-butene are considerably larger than at the corresponding B3LYP level (9.5 vs. 1.9 kcal/mol) In addition, the B3LYP/6-311G(2df,p) calculations yield HFCC in very good agreement with experimental data. The HFCCs together with calculated energies for the three 1-butene cation conformers indicate that the molecule undergoes significant rotational motion about the C2—C3 bond, leading to a rotationally averaged structure.

Spectroscopic studies of triphenyltin azide and of its adducts with *O*- and *N*-donor ligands; the crystal and molecular structures of triphenyltin azide and of azido(hexamethylphosphoramide)triphenyltin(IV)[1]

Ivor Wharf, Ryszard Wojtowski, Carol Bowes, Anne-Marie Lebuis, and Mario Onyszchuk

Abstract: Complete far-IR and Raman data (<400 cm^{-1}) are reported for triphenyltin azide (**1**) as well as for adducts $Ph_3SnN_3 \cdot L$ (L = hexamethylphosphoramide (HMPA), triphenylphosphine oxide, pyridine-*N*-oxide, 4-picoline-*N*-oxide, or pyridine). The small changes in $\nu(Sn\text{-}N_3)$ noted on going from (**1**) to the adducts, as well as solid-state ^{119}Sn nmr data, indicate that (**1**), like the adducts, has five-coordinate tin atoms. X-ray analysis shows that (**1**) crystallizes with two different chains of five-coordinate Ph_3Sn units joined by 1,3-azide bridges. In one unit, the geometry around tin is similar to that found for the monomeric HMPA adduct (**2**), which has *trans*-axial HMPA and azide ligands. The other unit in (**1**) has nonplanar -SnC_3- groups connected by less symmetric 1,3-azide bridges and thus resembles the structure of isoelectronic triphenyltin isocyanate.

Key words: triphenyltin azide, *O*- and *N*-donor adducts, far-IR/Raman, crystal structures.

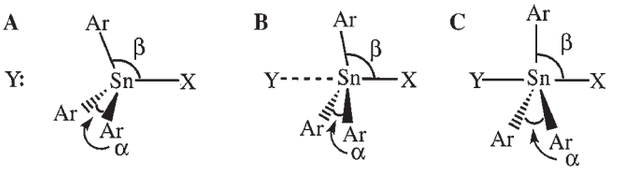
Résumé : On a enregistré les spectres Raman et IR-lointain complets (<400 cm^{-1}) de l'azoture de triphénylétain (**1**) et de ses adduits $Ph_3SnN_3 \cdot L$ (L = hexaméthylphosphoramide (HMPA), oxyde de triphénylphosphine, *N*-oxyde de pyridine, *N*-oxyde de 4-picoline ou pyridine). Les faibles changements dans les $\nu(Sn\text{-}N_3)$ observés en passant du produit **1** à ses adduits, ainsi que les données de RMN à l'état solide du ^{119}Sn, indiquent que le composé **1**, comme ses adduits, comporte des atomes d'étain pentacoordinés. Une analyse par diffraction des rayons X montre que le composé **1** cristallise avec deux chaînes différentes d'unités Ph_3Sn pentacoordinées liées par des ponts azotures-1,3. Dans l'une des unités, la géométrie autour de l'étain est semblable à celle que l'on retrouve dans l'adduit monomère du HMPA, **2**, qui comporte des ligands HMPA et azoture *trans*-axiaux. L'autre unité du composé **1** comporte des groupes -SnC_3- non planaires reliés par des ponts azotures-1,3 moins symétriques qui ressemblent donc à la structure de l'isothiocyanate de triphénylétain isoélectronique.

Mots clés : azoture de triphénylétain, adduits *O*- et *N*-donneurs, IR-lointain/Raman, structures cristallines.

[Traduit par la Rédaction]

Introduction

Triaryltin halides (Ar_3SnX, X = Cl, Br) are monomeric with four-coordinate tin (**A**) (1–6) but they form stable five-coordinate adducts ($Ar_3SnX \cdot Y$), which when X = Y have exact trigonal-bipyramidal geometry at tin with aryl groups occupying the equatorial positions (**C**) (7, 8), and almost this geometry when Y is the donor atom of a strong ligand such as a sulfoxide (9) or Ph_3PO (10, 11).



However, (**A**) and (**C**) represent extremes of a $YSnC_3X$ structural continuum (12, 13), and if Y is a weaker donor atom than X, intermediate geometries (**B**) will occur where Y is less strongly coordinated than X, and the SnC_3 moiety is nonplanar (14). With an ambidentate chalcocyanate unit anion (-X = -NCZ; Z = O, S, Se) further possibilities arise. Thus while monomeric Ar_3SnNCS (**A**) have been identified (15) and stable five-coordinate adducts ($Ar_3SnNCZ \cdot L$) (**C**) are well known (15, 16), less hindered Ph_3SnNCS is poly-

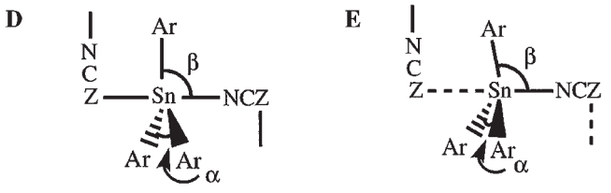
meric with a planar -SnC_3- moiety (**D**) (15, 17). In contrast, triphenyltin isocyanate has a less strongly bridged structure (**E**) (18) with a nonplanar geometry at tin.

While tin Mössbauer and NMR spectra may be used to



ascertain the degree of coordination at tin in Ar_3Sn systems, the change in ν(Sn-X) when Ph_3SnX is converted to its five-coordinate (1/1) adduct also depends on the coordination at tin in the given Ph_3SnX (16). Thus if X = Cl or Br, ν(Sn-X) decreases by ~25 or ~35%, respectively, indicative of the change from structure (**A**) to (**C**). For Ph_3SnNCS, with the same geometry at tin (**D**) as in the adducts (**C**), no change in ν(Sn-NCS) occurs on adduct formation, but with Ph_3SnNCO, the decrease by ~10% in ν(Sn-NCO) on adduct formation was considered consistent with its asymmetric five-coordinate geometry at tin (**E**) (16, 18).

Triphenyltin azide, isoelectronic with the isocyanate, was proposed on the basis of powder X-ray diffraction results (19) to be isomorphous with Ph_3SiN_3, later determined to be molecular with four-coordinate silicon (20). In contrast Mössbauer data for Ph_3SnN_3 (21) were considered more consistent with five-coordinate tin and a trigonal bipyramidal structure, as found also for the anions $Ph_3SnN_3X^-$ (X = N_3, NCS) (22) and the adduct $Ph_3SnN_3 \cdot Ph_3SnOH$ (23). Thus the question remains whether the Ph_3SnN_3 structure resembles that of Ph_3SnNCO (**E**) or that the *symmetric* azide ion forms symmetric 1,3-bridges, giving rise to a planar environment at tin (**D**). Since triphenyltin azide forms many adducts with neutral *O*- and *N*-donor ligands (24, 25), we have now extended our earlier far-infrared (far-IR) and Raman spectral studies (16) to Ph_3SnN_3 and its adducts, in order to shed more light on the structure of triphenyltin azide.

Experimental

All experimental procedures including microanalyses, and Raman (powder) and infrared (Nujol mull) spectral measurements were as described earlier (16), as were also solution tin-119 nmr studies (26). Solid-state tin-119 CPMAS nmr spectra were obtained on a Chemagnetics CMX-300 operating at 111.7 MHz. The sample was contained in a 7.5 mm rotor and spun at 3–4 kHz. The contact time and recycle delay were 3 ms and 240 s, respectively. Typically 200–300 transients were acquired. Sidebands were suppressed using a six-pulse TOSS pulse sequence. Chemical shifts were referenced to external $Sn(CH_3)_4$.

Preparations

*(a) Triphenyltin azide (**M**)*

Previously dried sodium azide (10.4 g, 0.160 mol) was added to a solution of triphenyltin chloride (30.8 g, 0.080 mol) in acetone (600 mL) and the mixture stirred, first with refluxing for 3 h, and then at room temperature for 16 h. Evaporation of the filtrate under vacuum to dryness yielded the crude *product*, which gave fine needles when recrystallized from hexane (900 mL); yield 84%; mp 113–5°C (lit. 115°C (19)); $\nu_{as}(N_3)$, IR: 2097m, 2077s, 2064s cm^{-1}.

(b) Triphenyltin azide adducts

The ligand **L** and **M** (1.00 g) were dissolved in the given solvent by heating or stirring and the clear solution then left overnight at room temperature or in the refrigerator to yield crystals of the *adduct*, $Ph_3SnN_3 \cdot L$. The adduct with HMPA was also prepared by reacting $Ph_3SnCl \cdot HMPA$ with sodium azide in acetone (24). Adding ether to the concentrated acetone solution at 0°C gave the crystals used for X-ray analysis. Complete synthesis and characterisation details are given in Table 1.

X-ray structure determinations

Crystal parameters together with data collection and structure solution details are given in Table 2. For triphenyltin azide (**1**), a crystal was selected from the bulk sample and examined using a diffractometer equipped with a CCD detector and a rotating anode source. One complete hemisphere of data was collected to better than 0.8 Å resolution; the decay correction was done by remeasuring the first 50 frames at the end of data collection, which was 99.6% complete. For the HMPA adduct (**2**) a crystal was cut from a large parallelepiped and crystal data determined from 21 reflections. Three standard reflections measured after every 250, served for decay correction (~1.2%), and absorption correction was applied (NRCVAX (28)).

Structures were solved by the Patterson method (**1**) or direct methods (**2**) (SHELXS-86)[3] and difference Fourier syntheses (SHELXL-93)[4]; all non-hydrogen atoms were anisotropic with H-atoms isotropic and calculated at idealized positions using a riding model ((**1**) *d*(C—H) 0.93 Å; (**2**) *d*(C—H) 0.93–0.96 Å); for phenyl hydrogens, U_{iso} for each H was set at 20% greater than U_{iso} for its adjacent carbon atom, while methyl U_{iso}(H) values were at 1.50 × U_{iso}(C). One phenyl ring in each structure ((**1**), ring (5); (**2**), ring (2)) exhibited considerable thermal motion which could not be effectively represented by a two-position disorder model. Neutral atom scattering factors were from the *International Tables for X-Ray Crystallography* (29). Tables ((**1**) S1–S6, (**2**) S7–S12) of atomic coordinates, anisotropic thermal parameters, full bond lengths and angles (including torsion angles), and least-squares planes data, as well as stereoviews of the unit cells, are on deposit.[5]

Results

Tables 3 and 4 list vibrational data in the skeletal region for triphenyltin azide and its (1/1) adducts with pyridine and

various *O*-donor ligands, with the assignments following the patterns established earlier (16) for their pseudohalide analogues. For the adducts $\nu(Sn—N_3)_{ave}$ = 322 cm^{-1} but two values, (**a**) 320 and (**b**) 348 cm^{-1}, were assigned for Ph_3SnN_3. Thus adduct formation causes effectively no change in (**a**) but an ~8% decrease in (**b**). This would suggest that for Ph_3SnN_3 there are at least two different five-coordinate -(Ph_3)Sn- environments in the solid state, one planar (**D**) similar to the adducts, the other resembling Ph_3SnNCO (**E**) with unequal axial Sn—N bonds.

The solid state tin-119 nmr spectrum shows two absorptions of almost equal intensity, at –128.25 and –204.5 ppm. Comparison with data for Ph_3SnN_3 in various coordinating solvents (Table 5) would suggest that one tin in the solid azide is in an environment resembling that found for Ph_3SnN_3 in acetone, a weak donor solvent, while the other tin is more like that found for Ph_3SnN_3 in the stronger donor solvent DMSO, or the adduct Ph_3SnN_3·HMPA.

Selected geometric parameters for the two independent Ph_3SnN_3 moieties, (**a**) and (**b**), in the asymmetric unit of (**1**) (Fig. 1(*a*)) listed in Table 6(*a*), clearly show the two different five-coordinate tin environments in triphenyltin azide. In (**a**) the environment around the tin with an almost *syn*-diazide grouping, (torsion angle N(2)-N(1)-N(3′)-N(2′) = 38.6(6)°) resembles one of those recently reported (32) for some bis(azido)triphenylstannate anions, with the azide ligands acting as quasi-symmetric bridges (Fig. 2 (**a**)). In (**b**), the azide ligands are in an almost *anti*-conformation, (torsion angle N(5)-N(4)-N(6′)-N(5′) = –170.7(3)°) and provide

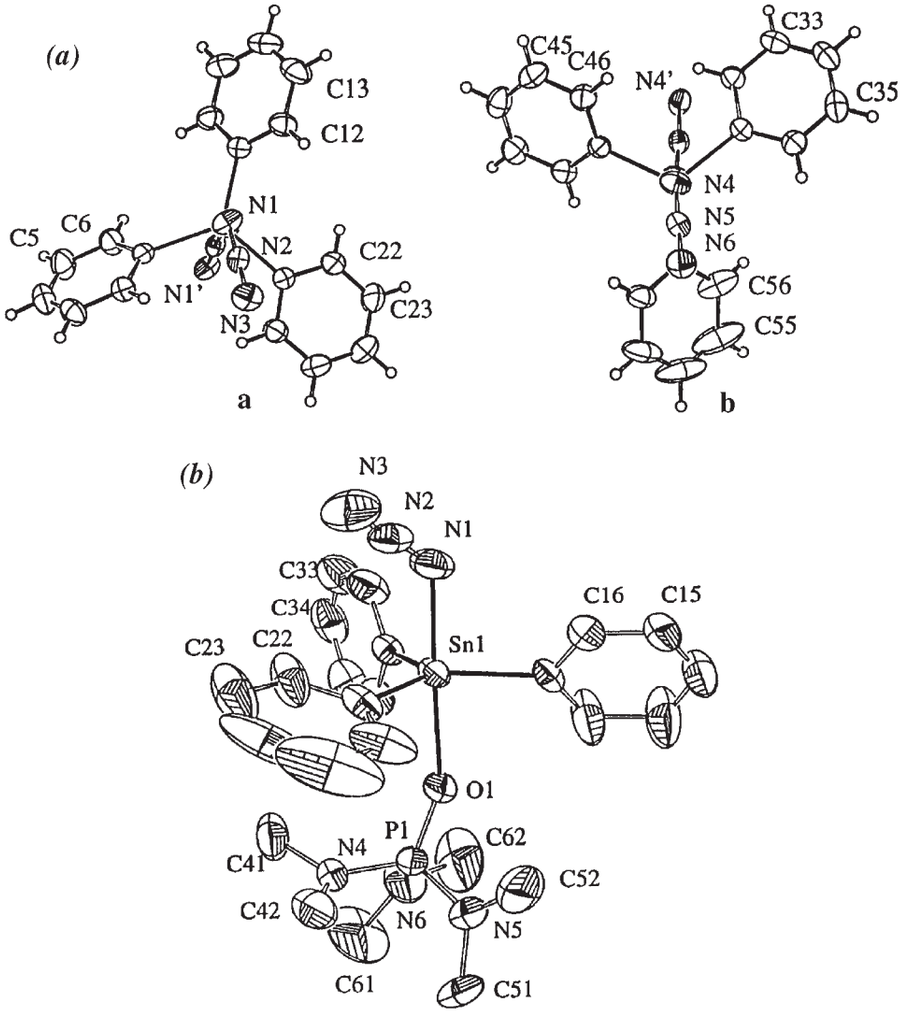
[b]Literature (31) (0.05 M): $CHCl_3$, –88.1 ppm; $(CH_3)_2CO$, –161.0 ppm.
[c]Peaks assigned to the Ph_3Sn-N_3 atom are widened by characteristic unresolved splitting, presumably due to ^{119}Sn-^{14}N coupling. This narrow, less intense absorbance is assigned to the species $Ph_3Sn[(CD_3)_2SO]_2^+$ formed by ionization of Ph_3SnN_3.

Fig. 1. (*a*) ORTEP view (40% probability) of the two independent N_3-$SnPh_3$-N_3' moieties, (**a**) and (**b**), in compound **1**, showing the differing relative orientations of the two azide groups. (*b*) ORTEP view (30% probability) of the Ph_3SnN_3·HMPA molecule.



ring (2), with thermal motion, is sandwiched by the azide group and one $(CH_3)_2N$ group of the ligand, but ring (3) is almost in line with the N-Sn-O axis, a motif noted earlier in other X-Ph_3Sn-Y systems (32). For the parent azide, dihedral angles between the phenyl rings and the SnC_3 unit for both (**a**), (0) 58.0(1), (1) 40.6(1), (2) 15.2(1)°, and (**b**), (3) 22.7(1), (4) 37.4(1), (5) 39.2(1)° indicate highly distorted propellor geometries in both cases.

Discussion

Data describing the two tin environments in (**1**) together with those for selected model systems for comparison are given in Table 7(*a*). One approach used to study the transition from four-coordinate R_3Sn-X (**A**) to *sym*-five-coordinate Y-R_3Sn-X with equivalent axial Sn—X and Sn—Y

bonds (**C**) has been to note the changes, Δd(SnX) and Δd(SnY) observed during this transition as well as the variations in the average angles $C\hat{S}nX$ and $C\hat{S}nY$ (12, 13). Thus in Table 7(*a*) there is a gradual decrease in the primary *d*(Sn—N) value in going from (**C**) $[Ph_3Sn(NCS)_2]^-$ to (**A**) $(t\text{-}C_4H_9)_3SnN_3$. However, $(CH_3)_3SnN_3$ with geometry (**C**) at tin attained by using 1,1-azide bridges (34), has *d*(Sn—N) greater than found in the model system used, $[Ph_3Sn(NCS)_2]^-$. To avoid the ambiguities involved in using axial bond-length changes, the transition from structure type (**A**) to (**C**) or (**D**) may be followed instead in terms of the changes in the angles around the tin atom, $\alpha = C\hat{S}nC_{(ave)}$ and $\beta = C\hat{S}nX_{(ave)}$ (12, 16). Thus exact trigonal-bipyramidal geometry at tin, (**C**) or (**D**), requires that $\alpha = 120°$ and $\beta = 90°$. Consideration of various Ar_3SnX (X = Cl, Br) structures (1–6) gives $\alpha = 113°$ and $\beta = 105°$ as characteristic of a monomeric four-coordinate structure (**A**). Using these criteria (Table 7(*a*)), the tin environment in unit (**a**) of Ph_3SnN_3 is like that found in $Ph_3SnNCO \cdot pyO$ rather than the HMPA adduct of (**1**) or the anion $Ph_3Sn(N_3)_2^-$. For unit (**b**) of (**1**), the structure resembles that of Ph_3SnNCO (**E**), where the tin geometry is between those of the two extreme structure types (**A**) and (**D**). Unfortunately the example for a four-coordinate R_3SnN_3, $(t\text{-}C_4H_9)_3SnN_3$ (35), has larger α and smaller β values than those specified by the model given above, presumably because of repulsions between bulky *t*-butyl groups. A "typical" monomeric R_3SnN_3 thus remains to be characterized.

The azide groups in the triorganotin azide systems listed in Table 7(*a*), show bond-length changes (Table 7(*b*)) that also correlate with the transition from structure type (**A**) to (**C**) or (**D**). The azide ion itself is symmetric (35) but covalently bound azide may be considered as a hybrid of two main resonance forms **P** and **Q**

$$\mathbf{P} \quad M\text{-}N_\alpha{=}\overset{+}{N}_\beta{=}\overset{-}{N}_\gamma \leftrightarrow M\text{-}\overset{-}{N}_\alpha\text{-}\overset{+}{N}_\beta \equiv N_\gamma \quad \mathbf{Q}$$

with the contribution of **Q** causing the azide moiety to become asymmetric (38). Thus $R = d(N_\alpha—N_\beta)/d(N_\beta{=}N_\gamma) = 1.00$ for the azide ion but for covalent HN_3, $R = 1.10$. How-

ever, R is <1.10 for $(t\text{-}C_4H_9)_3SnN_3$ and closer to 1 for the monomeric five-coordinate systems given in Table 7(*b*). This is consistent with the partial ionic character of the Sn—N_3 bond, which increases where this bond is in the axial position in a trigonal bipyramidal structure. Trends in R values also correlate with the bridging mode of the azide moiety. Thus for Ph_3SnN_3, as the geometry at tin becomes more symmetric, i.e., (**b**) and then (**a**), the 1,3-azide bridge becomes more symmetric, showing an increase in the contribution of form **P**. In contrast, the configuration of a 1,1-bridging azide, corresponding to a greater contribution of form **Q**, should resemble that found in a terminal azide by being asymmetric, and we see that the R value for polymeric $(CH_3)_3SnN_3$ is almost the same as that for its monomeric *t*-butyl analogue.

Conclusions

Our spectroscopic (far-IR/Raman and tin-119 nmr) data confirm that triphenyltin azide has five-coordinate tin in Ph_3Sn units, in agreement with earlier Mössbauer results (21). X-ray analysis shows that there are, in fact, two different five-coordinate tin environments, formed using 1,3-azide bridges, giving rise to two different $(Ph_3SnN_3)_n$ polymer chains. One has almost planar Ph_3Sn units, while the other has a geometry similar to that found for Ph_3SnNCO (18). Thus triphenyltin azide would appear to form part of a structural continuum from molecular Ph_3SiN_3 (20) to polymeric Ph_3PbN_3 (19). A reinvestigation of this series is clearly needed.

Of equal interest is the contrast between the 1,3-azide bridges in Ph_3SnN_3 and the symmetric environment around each tin found in $(CH_3)_3SnN_3$, where 1,1-azide bridges occupy the axial positions (34) and which may be due to both crystal packing and (or) electronic factors. However knowledge of a much larger number of structures of polymeric R_3SnN_3 is required before any further generalizations can be made.

Acknowledgements

The financial assistance of the Fonds FCAR (Programmes ACC, Actions spontanées) of the Government of Quebec is most gratefully acknowledged. The authorities of Dawson College, Montreal, are thanked for granting release (IW) time during which part of this research was carried out, as are Drs. Françoise Sauriol and Fred Morin of McGill University for solution and solid-state tin-119 nmr data, respectively.

Mixed anion effect in sodium thiocyanate + sodium thiosulfate + water systems

G. Kalita, N.N. Dass, and S. Mahiuddin

Abstract: Densities and viscosities of $R[x\text{NaSCN} + (1 - x)\text{Na}_2\text{S}_2\text{O}_3] + (1 - R)\text{H}_2\text{O}$ systems with R = 0.05, 0.10, 0.14, and 0.18 were measured as functions of mole fraction, x (= 0.0–1.0), and temperature ($293.15 \leq T/\text{K} \leq 323.15$). A significant mixed anion effect has been observed within the temperature range of the study. The normalized viscosity isotherms were found to detect the mixed anion effect ~1.2 to 3.7 times more than the simple viscosity isotherms. The progressive replacement of $S_2O_3^{2-}$ ions by SCN^- ions causes the systems to be less structured and $S_2O_3^{2-}$ ions polarized Na^+ ions more towards themselves than towards the SCN^- ions. Both these effects govern the variation of the viscosity with mole fraction, x. The mixed anion effect was found to vanish at around R = 0.0106.

Key words: mixed anion effect, sodium thiocyanate, sodium thiosulfate, viscosity.

Résumé : Opérant à des températures allant de 293,15 à 323,15 K et à des fractions molaires, x, allant de 0,0 à 1,0, on a mesuré les densités et les viscosités de systèmes $R[x\text{NaSCN} + (1 - x)\text{Na}_2\text{S}_2\text{O}_3] + (1 - R)\text{H}_2\text{O}$ dans lesquels R = 0,05, 0,10, 0,14 et 0,18. Dans le domaine de températures de l'étude, on a observé un effet significatif d'anion mixte. On a trouvé que les isothermes normalisées de viscosité permettent de détecter l'effet d'anion mixte d'environ 1,2 à 3,7 fois plus facilement que les isothermes de viscosité simples. Le remplacement progressif des ions $S_2O_3^{2-}$ par des ions SCN^- rend les systèmes moins structurés et fait que les ions Na^+ polarisés par les ions $S_2O_3^{2-}$ se déplacent vers ceux-ci plutôt que vers les ions SCN^-. Ces deux effets orientent la variation de la viscosité en fonction de la fraction molaire, x. On a trouvé que l'effet d'anion mixte disparaît aux environs de R = 0,0106.

Mots clés : effet d'anion mixte, thiocyanate de sodium, thiosulfate de sodium, viscosité.

[Traduit par la Rédaction]

Introduction

A pronounced deviation (either positive or negative) from linearity has been observed in the conductivity and viscosity isotherms in ternary melt or glass systems when one of the alkali ions is progressively replaced by another alkali ion in a glass or melt medium (1–6). This phenomenon is referred to as the mixed alkali effect. A similar deviation in the electrical conductivity isotherm has been reported in the mixed alkaline earth and alkali – alkaline earth systems (7). Recently, Chandra and Chandra (8) and Choi and Kim (9) have reported negative and(or) positive deviations in the electrical conductivity isotherms for systems such as $[x\text{MA} + (1 - x)\text{MA}'] + \text{PEO}$, where M is the alkali metal, A and A′ are the different anions, and PEO stands for poly(ethylene) oxide, and they suggested the deviation in the conductivity was due to the mixed anion effect. It seems that the mixed alkali or mixed anion effects are not then restricted to only the alkali ions or the anions, but are a particular example of the general phenomenon of the mixed ion or the dissimilar pair of ions effect.

To study more about the effect of anion pairs on the deviation in the transport property (viscosity and conductivity) isotherms, we report the viscosities of $R[x\text{NaSCN} + (1 - x)\text{Na}_2\text{S}_2\text{O}_3] + (1 - R)\text{H}_2\text{O}$ systems, with R = 0.05, 0.10, 0.14, and 0.18, as functions of temperature and mole fraction, x.

Experimental section

Sodium thiocyanate (Loba, 99%) was recrystallized from conductivity water and dried over P_2O_5. Sodium thiosulfate pentahydrate (E. Merck, 99.5%) was recrystallized from conductivity water, and the anhydrous sodium thiosulfate was prepared as per the reported procedure (10) and was stored in a vacuum desiccator over P_2O_5.

Densities (ρ) and viscosities (η) of $0.05[x\text{NaSCN} + (1 - x)\text{Na}_2\text{S}_2\text{O}_3] + 0.95\ \text{H}_2\text{O}$, $0.1[x\text{NaSCN} + (1 - x)\text{Na}_2\text{S}_2\text{O}_3] + 0.9\text{H}_2\text{O}$, $0.14[x\text{NaSCN} + (1 - x)\text{Na}_2\text{S}_2\text{O}_3] + 0.86\text{H}_2\text{O}$, and $0.18[x\text{NaSCN} + (1 - x)\text{Na}_2\text{S}_2\text{O}_3] + 0.82\ \text{H}_2\text{O}$ systems were measured as functions of mole fraction, x (= 0.0–1.0), and temperature ($293.15 \leq T/\text{K} \leq 323.15$). The uncertainties in densities and viscosities were found to be ±0.01% and ±0.4%, respectively. Measurement techniques were the same as described elsewhere (11). A Schott Geräte thermostat type CT-1450 was used to maintain the temperature of the study to ±0.02 K.

Results and discussion

The measured densities (ρ) for $0.05[x\text{NaSCN} + (1 - x)Na_2S_2O_3] + 0.95\ H_2O$, $0.1[x\text{NaSCN} + (1 - x)Na_2S_2O_3] + 0.9H_2O$, $0.14[x\text{NaSCN} + (1 - x)\ Na_2S_2O_3] + 0.86H_2O$, and $0.18[x\text{NaSCN} + (1 - x)Na_2S_2O_3] + 0.82H_2O$ systems are found to be a linear function of temperature and are presented in Table 1.

Viscosity values for the above systems are presented in Table 2. To examine the mixed anion effect in the present systems, the dependence of the concentration, x, on the viscosity at different temperatures has been depicted in Fig. 1. It is interesting to note that a pronounced negative deviation (~6–47% depending on the temperature) from the linearity of η vs. x plots (Fig. 1) has been observed. Such a deviation may be attributed to the onset of the mixed anion effect, which decreases from ~47% to 10% at 298.15 K (Fig. 1) as the mole fraction of water, $(1 - R)$, increases.

Dietzel (7) has suggested that the larger the difference between the cation field strength, ΔF ($\Delta F = \Delta (z/a^2)$, where z is the valency of the cation and a is the cation–anion distance in 10^{-10} m), the more pronounced is the mixed alkali effect. For example, in ternary systems containing Na^+–K^+, with $\Delta F = 0.04$ (7) either in ionic or molecular liquid medium, the deviation in viscosity and(or) conductivity isotherm was reported as ~4% (5, 6, 12). The ternary system, $0.45[x\text{LiNO}_3 + (1 - x)\text{KNO}_3] + 0.55\text{Ca}(\text{NO}_3)_2 \cdot 4.09H_2O$ with $\Delta F(Li^+–K^+) = 0.10–0.14$ (7), exhibits ~12.5% deviation in the electrical conductivity isotherm (4). A similar cation field strength difference criterion may be applied in the present system. Even though the present system contains a similar cation and different anions, cation–anion distances for Na^+–SCN^- and Na^+–$S_2O_3^{2-}$ are different, resulting in different cation field strengths, F. The crystal ionic radius for the $S_2O_3^{2-}$ ion is not available, to the best of our knowledge, and, considering that the $S_2O_3^{2-}$ ion is analogous to the SO_4^{2-} ion and the reported ionic radii of Na^+, SCN^-, and SO_4^{2-} ions (13), the difference between the cation field strength was found to be ~0.024 and would cause only ~2.4% deviation in the viscosity isotherm. In fact, we observed ~6–47% deviation in the viscosity isotherms (Fig. 1). On the other hand, the system $0.25[x\text{KSCN} + (1 - x)\text{NaSCN}] + 0.75CH_3CONH_2$ (14) showed ~27–55% deviation in the viscosity isotherms even though $\Delta F(Na^+–K^+)$ is 0.04. It seems that the field strength criterion may not be a universal parameter, particularly in liquid media with nonrigid structure, for explaining the mixed anion effect although the present system is a particular example of mixed ion systems. Therefore, the onset of the mixed anion effect in the present system may be of different origin.

The viscosities (η) of all the systems were fitted to the Vogel–Tammann–Fulcher equation of the following form:

$$[1] \qquad \eta = A \exp[B/(T - T_0)]$$

to explain the temperature dependence of the viscosity. In eq. [1] *A* and *B* are the adjustable parameters and T_0 is the ideal glass transition temperature. The T_0 values obtained by the iteration method for the systems showed an irregular trend in the variation of T_0 with composition. This is expected because, in the temperature ranges of the study, the viscosity data in the present system vary only by factors of ~1.8 to 2.0, ~1.6 to 2.2, ~1.9 to 3.8, and ~1.8 to 3.1 for $R[x\text{NaSCN} + (1 - x)Na_2S_2O_3] + (1 - R)H_2O$ systems with R = 0.05, 0.10, 0.14, and 0.18, respectively, and the computed T_0 values may not be precise. In such a situation, an alternative method suggested by Moynihan et al. (15) was adopted to estimate the T_0 values for the present systems.

The least-squares fitted values of the *A*, *B*, and T_0 parameters are listed in Table 3 and the variation of T_0 with *x* for both systems has been illustrated in Fig. 2. For x = 0.0 and 1.0 the systems represent binary systems with composition $NaSCN{\cdot}19H_2O$ (2.92 mol kg^{-1}), $Na_2S_2O_3{\cdot}19H_2O$ (2.92 mol kg^{-1}), $NaSCN{\cdot}9H_2O$ (6.168 mol kg^{-1}), $Na_2S_2O_3{\cdot}9H_2O$ (6.168 mol kg^{-1}), $NaSCN{\cdot}6.14H_2O$ (9.04 mol kg^{-1}), $Na_2S_2O_3{\cdot}6.14H_2O$ (9.04 mol kg^{-1}), $NaSCN{\cdot}4.56H_2O$ (12.18 mol kg^{-1}), and $Na_2S_2O_3{\cdot}4.56H_2O$ (12.18 mol kg^{-1}), respectively. The computed T_0 values of these binary systems are in good agreement with the reported T_0 values (16, 17) at the

corresponding composition and justify our data fitting. T_0 vs. x plots (Fig. 2) do not exhibit any mixed anion effect, unlike the case in other mixed alkali systems (18, 19).

Although the viscosity isotherms exhibit a significant mixed alkali and mixed anion effects, normalized viscosity isotherms (4) are also used to detect the mixed alkali effect. We have plotted the normalized viscosity, $F_\eta = (\eta_{x=0.0} - \eta)/(\eta_{x=0.0} - \eta_{x=1.0})$ where $\eta_{x=0.0}$ and $\eta_{x=1.0}$ are the viscosities at x = 0.0 and x = 1.0, respectively, and η is the viscosity of solution, versus mole fraction, x, in Fig. 3 at different temperatures. From Fig. 3 we note that very significant mixed anion effects with ~22–54% deviation from linearity have been observed and the normalized viscosity isotherms are ~1.2 to 3.7 times more accessible to the mixed anion effect than the simple viscosity isotherms (Fig. 1) irrespective of ΔF values.

Numerous theories have been proposed for explaining the onset of the mixed alkali effect, particularly for the system where rigid structure prevails (2). For a nonrigid system, as in the present study, an anion polarization model (20, 21) has been applied to explain the mixed alkali effect. The existence of the mixed anion effect in the present systems may be of different origin.

Earlier we reported that there are ~25 and 19 molecules of water in the primary hydration shell of sodium thiosulfate (22) and sodium thiocyanate (23) at 2.5 and 3.0 mol kg^{-1}, respectively. The system 0.05[xNaSCN + (1 – x)$Na_2S_2O_3$] + 0.95H_2O at x = 0.0 and 1.0 represents binary systems with composition $Na_2S_2O_3 \cdot 19H_2O$ (2.92 mol kg^{-1}) and $NaSCN \cdot 19H_2O$ (2.92 mol kg^{-1}), respectively. At 2.92 mol kg^{-1} there are ~24 and 19 molecules of water in the primary hydration shell of sodium thiosulfate (22) and sodium thiocyanate (23), respectively. The primary hydration shell for the $Na_2S_2O_3 \cdot 19H_2O$ system at x = 0.0 is deficient in one water molecule and becomes more structured, resulting in higher viscosity (Fig. 1) than the $NaSCN \cdot 19H_2O$, which may be due to the formation of the solvent shared ion-pair.[2] As the $S_2O_3^{2-}$ ions are progressively replaced by the SCN^- ions the system becomes less structured, resulting in lower viscosity at x = 1.0 (Fig. 1). On the other hand, $S_2O_3^{2-}$ ions polarize Na^+ ions more towards themselves than towards the SCN^- ions since the $S_2O_3^{2-}$ ion, as discussed in the preceding section, has a larger ionic radius than the SCN^- ion. Both these effects contribute towards the net deviation in the viscosity isotherms (Fig. 1). A similar inference may also be drawn for the R[xNaSCN + (1 – x)$Na_2S_2O_3$] + (1 – R)H_2O systems with R = 0.10, 0.14, and 0.18. Finally, we have plotted the percentage deviation in the viscosity isotherm obtained from Fig. 1 at x = 0.5 versus R, at 298.15 and 323.15 K, in Fig. 4. From Fig. 4 it is apparent that at R = 0.0106 the system does not exhibit any mixed anion effect within the temperature range of the study, and the higher the R value, the larger is the deviation in the viscosity isotherms (Figs. 1 and 3), which is also one of the criteria (18) for detecting the mixed ion effect.

Crystal structures of highly stabilized ylides: methyl(3-methoxy,2-methoxycarbonylbenzoyl)triphenylphosphoranylideneacetate and methyl(2-methoxycarbonyl,6-nitrobenzoyl)triphenylphosphoranylideneacetate and the salt methyl(triphenylphosphoranylidene)acetate tetrafluoroborate

Fernande D. Rochon, Robert Melanson, and Margaret M. Kayser

Abstract: At lower temperatures stabilized ylides react with unsymmetrically substituted phthalic anhydrides to give two acyclic adducts. When the reactions are allowed to proceed at higher temperature enol lactones are formed. Identification of the acyclic intermediates was necessary to understand the mechanism of these Wittig reactions. The transient species trapped in the reaction with trimethyloxonium tetrafluoroborate were unambiguously identified by crystallographic methods. The crystal structures of the tetrafluoroborate salt of methyl(triphenylphosphoranylidene)-acetate (**8**), methyl(3-methoxy,2-methoxycarbonylbenzoyl)triphenylphosphoranylideneacetate (**6**β), and methyl(2-methoxycarbonyl,6-nitrobenzoyl)triphenylphosphoranylideneacetate (**7**α) were studied by X-ray diffraction. The ionic salt (**8**) is monoclinic, $P2_1/c$, a = 12.640(5), b = 13.945(9), c = 14.825(6) Å, β = 125.32(3)°, Z = 4, and R = 0.065 ($F > 5.4\ \sigma(F)$). Crystal **6**β is monoclinic, $P2_1/c$, a = 16.391(16), b = 9.029(6), c = 19.835(19) Å, β = 116.60(6)°, Z = 4, and R = 0.070 ($F > 4.6\ \sigma(F)$), while crystal **7**α is also monoclinic, $P2_1/c$, a = 9.513(5), b = 9.361(3), c = 30.908(13) Å, β = 98.42(3)°, Z = 4, and R = 0.057 ($F > 5\sigma(F)$). In the BF_4^- salt (**12**), the four P—C distances are equal (1.791(5)–1.801(7) Å) with identical tetrahedral angles. For the two triphenylphosphoranylideneacetate compounds, the fourth P—C(1) bond is shorter (1.762(6)–1.734(5) Å) than the three P—C(Ph) bonds (avg. 1.809(5) Å). The angles C(1)-P-C(Ph) are also larger (avg. 112.9(2)° for **6**β and 111.9(2)° for **7**α) than the C(Ph)-P-C(Ph) angles (avg. 105.8(2)° for **6**β and 106.9(2)° for **7**α). These values suggest a multiple nature for the P—C(1) bond. In the nitro derivative, the nitro and the ester groups are disordered equally in positions 2 and 6.

Key words: Wittig reactions, cyclic anhydrides, stabilized ylide, phosphoranylidenes, crystal structures.

Résumé : À de faibles températures, les ylures stabilisés réagissent avec des anhydrides phtaliques substitués de façon non symétrique pour donner deux adduits acycliques. Lorsqu'on laisse les réactions se produire à des températures plus élevées, il se forme des lactones énoliques. Il a été nécessaire d'identifier les intermédiaires acycliques pour comprendre le mécanisme de ces réactions. Les espèces transitoires piégées dans la réaction du tétrafluoroborate de triméthyloxonium ont été identifiées sans ambiguïté par des méthodes cristallographiques. Faisant appel à la diffraction des rayons X, on a déterminé les structures cristallines des tétrafluoroborates de (triphényphosphoranylidène)acétate de méthyle (**8**), (3-méthoxy-2-méthoxycarbonylbenzoyl)triphénylphosphoranylidènediacétate de méthyle (**6**β) et (2-méthoxy-6-nitrobenzoyl)triphénylphosphoranylidèneacétate de méthyle (**7**α). Le sel ionique **8** est monoclinique, groupe d'espace $P2_1/c$, avec a = 12,640(5), b = 13,945(9) et c = 14,825(6) Å, β = 125,32(3)°, Z = 4 et R = 0,065 ($F > 5{,}4\ \sigma(F)$). Les cristaux de **6**β sont monocliniques, groupe d'espace $P2_1/c$, avec a = 16,391(16), b = 9,029(6) et c = 19,835(19) Å, β = 116,60(6)°, Z = 4 et R = 0,070 ($F > 4{,}6\ \sigma(F)$) alors que les cristaux de **7**α sont aussi monocliniques, groupe d'espace $P2_1/c$, avec a = 9,513(5), b = 9,361(3) et c = 30,908(13) Å, β = 98,42(3)°, Z = 4 et R = 0,057 ($F > 5\ \sigma(F)$). Dans le tétrafluoroborate **12**, les quatre distances P—C sont égales (1,791(5) à 1,801(7) Å) et les angles tétraédriques sont identiques. Pour les deux composés triphénylphosphoranylidèneacétate, la quatrième liaison P—C(1)

est plus courte (1,762(6) à 1,734(5) Å) que les trois liaisons P—C(Ph) (moyenne de 1,809(5) Å). Les angles C(1)-P-C(Ph) sont aussi plus grands (moyenne de 112,9(2)° pour le composé **6**β et de 111,9(2)° pour le composé **7**α) que les angles C(Ph)-P-C(Ph) (moyenne de 105,8(2)° pour le composé **6**β et de 106,9(2)° pour le composé **7**α). Ces valeurs suggèrent que la liaison P—C(1) adopte des natures multiples. Dans le dérivé nitré, les groupes nitro et ester des positions 2 et 6 sont également désordonnés.

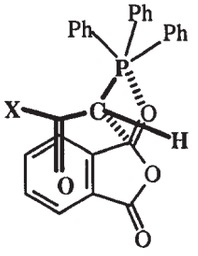
[Traduit par la Rédaction]

Introduction

The reactions of stabilized ylides with cyclic anhydrides lead to the formation of synthetically and biologically important enol-lactones (1). The condensation of phthalic anhydride with carbonyl-stabilized ylides was first studied by Chopard et al. (2), who discovered that the product enol-lactones showed a surprisingly high stereoselectivity in favor of *E* geometry (Scheme 1). Although an acyclic transition state with the COX group of the ylide in a plane parallel to the phenyl ring of phthalic anhydride (structure **2**) was proposed to account for the observed results, the mechanism of these reactions was not systematically investigated until recently (3–7). The experimental data accumulated over the years showed that the condensations with succinic and maleic anhydrides also give *E* enol-lactones as major products (8), suggesting that π-stacking was not a necessary element in the stereochemical control. Also, acyclic keto phosphoranes, such as **1**, were detected during these condensations (2, 8–10), and were generally assumed to be the intermediate species on the reaction pathway leading to enol-lactones.

Systematic investigation by ^{1}H and ^{31}P NMR and trapping



2

experiments showed that low-temperature condensations of phthalic, maleic, and succinic anhydrides with methyl (triphenylphosphoranylidene)acetate, **3**, give acyclic keto phosphoranes as the initial product and that these reactions are reversible. Subsequent studies of the condensations with unsymmetrically substituted cyclic anhydrides provided further insights into the mechanism of these reactions. One of the problems that surfaced during these studies was a failure to predict regioselectivity of the product enol-lactones on the basis of steric and electronic effects of the substituents (3–5). This was particularly evident in reactions with 3-methoxy and 3-nitrophthalic anhydrides, where experimental findings did not correspond to the regioselectivity projections based on electronic or steric effects (3). Furthermore, low-temperature NMR-monitored reactions indicated that the ratios of regioisomeric acyclic keto phosphoranes observed during the reactions were quite different from the ratios of regioisomeric enol lactones produced at the end (Schemes 2 and 3). Positive identification of the acyclic intermediates became necessary in order to trace the mechanistic path of these transformations.

Experimental

General procedure

An ylide (0.5 mmol) dissolved in $CDCl_3$ (0.5 mL) and cooled to –40°C was added to a cooled (–40°C) suspension of an anhydride (0.5 mmol) in $CDCl_3$ (0.5 mL) in an NMR tube. The mixture was shaken and the spectrum was recorded after a few minutes of equilibration at this temperature. The temperature was slowly raised while the reaction mixture was continuously monitored by ^{31}P NMR. When the maximum accumulation of the acyclic products was reached (generally at –20° to –10°C), the reaction mixture was rapidly divided, at –20°C, into two equal portions. One half was allowed to proceed to completion at higher temperature (still followed by NMR), the other half was treated with trimethyloxonium tetrafluoroborate (0.25 mmol) in $CDCl_3$ (0.5 mL), agitated for 30 min at 0°C, and analyzed by NMR. The products were isolated and purified chromatographically as described previously (3, 7). The chromatographically purified samples were crystallized from ethanol. Finally, crystals suitable for X-ray diffraction were recrystallized from methanol (crystals **8** and **6**β) or from a methanol – diethyl ether mixture (crystal **7**α).

Crystallographic measurements and structure determination

The crystals were selected after examination for homogeneity under a polarizing microscope. The unit cell parameters were obtained by least-squares refinement of the angles 2θ (11°–25°), ω, and χ for about 30 well-centered reflections on a Siemens P4 diffractometer using graphite-monochromatized MoKα radiation. The P3 program was used for the three crystals. The data collections were made at room temperature by the 2θ–θ scan technique. Crystal data and other information are summarized in Table 1. Corrections were made for Lorentz and polarization effects.

The structures were solved using direct methods.[3] Other non-H atoms were located by structure factors and Fourier-map calculations. The refinement of the structures was done using full-matrix least-squares calculations minimizing

1

$\Sigma\, w(|F_o| - |F_c|)^2$. The H atoms were fixed at their calculated positions with U_{eq} = 0.08 Å^2. The nitro and ester groups in crystal **7**α were found to be equally disordered in the two *ortho* positions. The refinement of the scale factor, coordinates, and anisotropic temperature factors of all atoms converged to R = 0.070 and R_w = 0.065 for **6**β, R = 0.057 and R_w = 0.049 for **7**α, and R = 0.065 and R_w = 0.069 for **8**. The residual peaks were less than 0.98 e/Å^3. The calculations were done on a Siemens SHELXTL system[3] and the crystallographic data were taken from the *International Tables for X-ray Crystallography* (11). The coordinates and the equivalent isotropic displacement parameters are shown in Table 2.

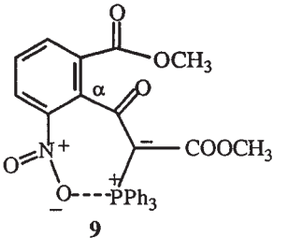
Results and discussion

In an initial effort to identify the acyclic adducts, they were trapped with diazomethane at 5°C (3-methoxy) and 15°C (3-nitro) (7). The structures were assigned on the basis of ^{13}C spectra of the isolated compounds. The assignments were tentative, since only one isomer in each pair, **6**α and β and **7**α and β, was obtained as a pure compound and the carbonyl and quarternary C signals were weak. The C–P couplings could not be unequivocally ascertained. We were not convinced that our provisionary assignment of structures was correct. In a modified series of experiments, the low temperature (–20° → –5°) reaction of ylide **3** with 3-methoxy- or 3-nitrophthalic anhydride was followed by NMR until a maximum accumulation of acyclic intermediates was reached (–5°C). At that point, one half of the reaction was allowed to proceed at higher temperature to give enol lactones, while the other half was treated with trimethyloxonium tetrafluoroborate $(CH_3)_3O^+BF_4^-$, to trap the acyclic acids as their methyl esters (Scheme 2). The trapped esters were separated by chromatography and crystallized. The *minor* regioisomer from the reaction with 3-methoxyphthalic anhydride and the *major* regioisomer from the reaction with 3-nitrophthalic anhydride were subjected to X-ray crystallographic analyses for structure determination. These compounds were identified as **6**β and **7**α, respectively. The crystal structures of the two compounds are described below.

In addition, a small quantity of another crystalline compound was isolated from the trapping experiment with 3-nitrophthalic anhydride. It was identified by crystallography as $Ph_3PCH_2COOCH_3^+BF_4^-$, **8**, the tetrafluoroborate salt of the conjugate acid of the original ylide. Its crystal structure was also determined by X-ray diffraction and the results are described below. The formation of **8** confirms that a reaction of the cyclic anhydride with a stabilized ylide is indeed an equilibrium, and that ylide **3** molecules, present at equilibrium, pick up protons from the acidic intermediates to give cationic species $Ph_3P^+CH_2COOCH_3$, which form a crystalline salt on treatment with trimethyloxonium tetrafluoroborate as shown in Scheme 4.

The advantage of having the crystal structure determinations became evident when it turned out that the initial assignment of the structure of the *major* adduct in the reaction of 3-nitrophthalic anhydride with ylide **3** was incorrect. A positive identification of the acyclic adducts leads to better understanding of the mechanism involved and allows better predictability for these reactions. The higher proportion of adducts **4**α and **5**α suggests that intrinsic electron-donating and electron-withdrawing effects of 3-methoxy and 3-nitro groups are less important than their ability to form stabilizing complexes with ylide **3**, similar to that illustrated in **2**. The particularly high stability of acyclic compound **5**α may be due to strong internal complexation between highly electron-rich oxygen of the 3-nitro substituent and the neighboring phosphorus of the ylide, as illustrated in **9**.

Labelled diagrams of the three crystals are shown in Figs. 1–3. The bond distances and angles are shown in Table 3. The crystal structure of the ionic salt



9

$PPh_3CH_2COOCH_3^+$ BF_4^- (**8**) is quite different from the other two structures. The four bonds around the P atom are of equal distances, with the three P—Ph bonds varying from 1.790(5) to 1.793(4) Å while the fourth bond is 1.801(7) Å. All the angles around the P atom are very similar with average angles C(3)-P-C(Ph) = 109.2(2)° and C(Ph)-P-C(Ph) = 109.7(2)°. The other bond distances and angles are normal. The B—F distances in the anions vary between 1.329(7) and 1.353(7) Å, while the average angle is 109.5(6)°.

In crystal **6**β, the ester group is located at the 2-position (*ortho*), while the methoxy group is in the 3-position (*meta*). The conformation of the molecule is such as to reduce the steric hindrance between the two large ester groups, which are located far from one another. In crystal **7**α, the ester and nitro groups on the phenyl ring are both located in *ortho* positions and the two groups are equally disordered on the two positions. For this reason, the bond distances in the two disordered groups are not precise. The ester group on C(1) is approximately in the center between the ester and nitro groups on the phenyl ring.

For crystals **6**β and **7**α, the P—C(phenyl) distances are normal and vary from 1.802(4) to 1.821(6) Å (**6**β), and 1.801(5) to 1.815(4) Å (**7**α), while the fourth bond P—C(1) is shorter, 1.762(6) Å (**6**β) and 1.734(5) Å (**7**α). These results are close to those obtained for similar crystal structures

Scheme 4.

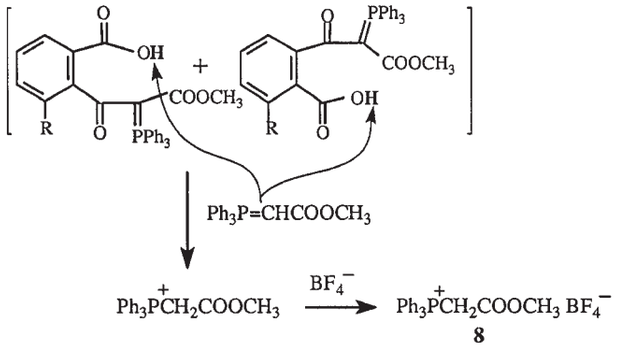

Fig. 1. Labelled diagram of the cation in the ionic salt $PPh_3CH_2COOCH_3^+$ BF_4^- (**8**).

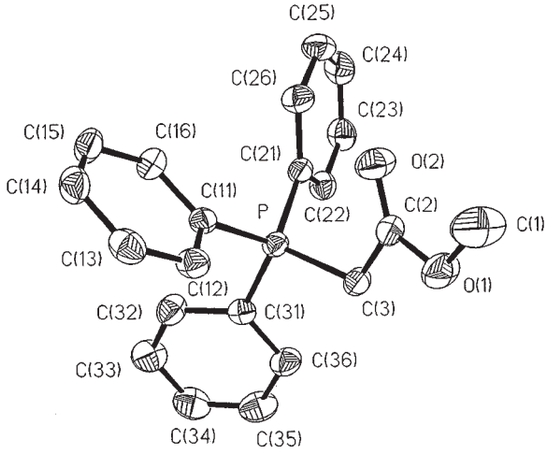

(12, 13), where the shorter distances were attributed to the multiple nature of the P—C bond. These authors have assigned the phosphorane structure in both solution and the solid state rather than the phosphonium salt. Other structures (14) have been reported showing similar results. For $Ph_3P{:}CH_2$, the P—CH_2 bond distances are much shorter, 1.662(8) and 1.659(8) Å (15).

The angles around the P atom in the two crystals are close to the tetrahedral value. The angles C(1)-P-C(Ph) are larger (avg. 112.9(2)° for **6**β and 111.9(2)° for **7**α) than the C(Ph)-P-C(Ph) values (avg. 105.8(2)° for **6**β and 106.9(2)° for **7**α), which is in agreement with the hypothesis of multiple bonding for the bond P—C(1). In crystal **6**β, the angle P-C(1)-C(2)O is much smaller (110.6(3)°) than the P-(1)-C(3)O(OCH_3) angle (126.9(5)°). The difference is significant and the values are similar to those reported by Abell et al. (12) and by Rochon et al. (13) For crystal **7**α, the two angles P-C(1)-C(2)O and P-C(1)-C(3)O(OCH_3) appear similar (120.2(3)°, 119.0(3)°). because of the disorder of the nitro and ester groups on the phenyl ring.

In crystals for **6**β and **7**α, the angle C(2)-C(1)-C(3) is 122.1(5)° and 120.8(4)°, respectively. The average value of the three angles around C(1) is consistent with an sp^2 hybridization. The two C—C bonds (C(2)—C(1) and (C(1)—C(3)) are also shorter than single bonds (1.432(8),

Fig. 2. Labelled diagram of $PPh_3C(COOCH_3)COPh(COOCH_3)(OCH_3)$ (**6**β).

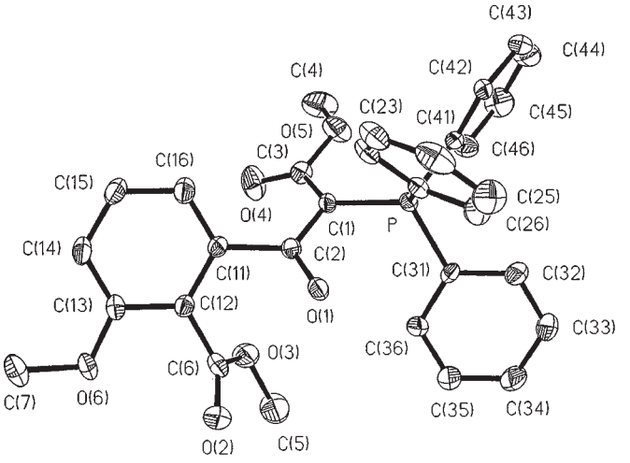

Fig. 3. Labelled diagram of $PPh_3C(COOCH_3)COPh(COOCH_3)(NO_2)$ (**7**α). (The nitro and the $COOCH_3$ groups are equally disordered in the two *ortho* positions. Only one component is shown in the drawing.)

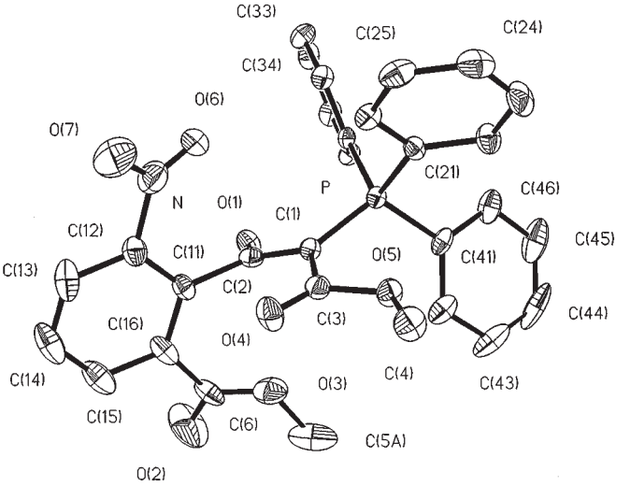

1.428(6) Å for **6**β and 1.415(6), 1.452(7) Å for **7**α), indicating that the double bond character is extended on the three bonds around C(1). The carbonyl bond C(2)—O(1) (1.237(5) Å (**6**β) and 1.234(6) Å (**7**α)) is also slightly longer than a normal double bond.

The torsion angles for crystals **6**β and **7**α have been calculated and are shown in Table 3. For crystal **6**β, the methoxy group on C(13) is in the same plane as the phenyl ring. The deviations of O(6) and C(7) from the best plane calculated through the phenyl ring are –0.034 and –0.039 Å. This planarity might extend the aromaticity of the phenyl ring. The four atoms P, C(1), C(2), and C(3) are planar. The mean deviation from the best plane calculated through the four atoms is 0.0212 Å. The dihedral angle between this plane and the phenyl ring (C(11) to C(16)) is 116.2°. For crystal **7**α, the acetyl and nitro groups located in *ortho* positions are not in the same plane as the phenyl ring. Again, the four atoms

P, C(1), C(2), and C(3) are planar with an average deviation of 0.004 Å. The dihedral angle between this plane and the phenyl ring (C(11) to C(16)) is 97.0°.

The packing diagrams of the molecules in the crystals were made. No hydrogen bond is expected in these compounds. Therefore, the molecules in crystals **6**β and **7**α are

© 1998 NRC Canada

held together only by van der Waals forces. In the ionic salt $PPh_3CH_2COOCH_3^+$ BF_4^- (**8**), the structure is further stabilized by normal electrostatic forces.

The unambiguous identification of trapped keto phosphoranes confirmed that the regioselectivity of the initial formation of these transient products differs significantly from the regioselectivity of enol lactones, as shown in Schemes 2 and 3. The crystallographic structure determination of the major keto phosphorane trapped in the reaction with 3-nitrophthalic anhydride demonstrated that previous tentative identification of that species was incorrect (7). The results of the crystallographic identification of the intermediate products favor a mechanism in which a lower energy reversible formation of acyclic adducts is affected mainly by attractive interactions between the phosphorus atom of the ylide and oxygen-rich substituents in the 3-position, while a higher energy "Wittig olefination" leading to enol-lactones is more sensitive to steric impact of these substituents. It is clear, however, that a more highly organized transition state, in which π-stacking and stabilizing complexations must play an important role, defies predictions based on the consideration of simple electronic and steric effects.

Supplementary material

The following tables have been deposited: crystal data and experimental details of the X-ray diffraction studies (S1), anisotropic thermal factors (S2), bond distances and angles (S3), and H coordinates (S4), and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. With the exception of the anisotropic thermal factors, the same tables have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K. Structure factor tables (S5) and the packing diagrams can be obtained from the authors.

Synthesis and structural characterization of (2′-hydroxyacetophenoneazine)mono(diphenylboron) chelate

Herbert Höpfl and Norberto Farfán

Abstract: Boron chelates obtained from salicylaldehyde and 2′-hydroxyacetophenone azines are colored compounds with potential applications in analytical chemistry. Up to now these complexes have not been studied by X-ray crystallography, although two structures with a six- or a seven-membered chelate ring are possible. This contribution presents the X-ray analysis of 2′-hydroxyacetophenone azine and its corresponding new mono(diphenylboron) chelate with a six-membered boron heterocyclic ring. With these data structural changes of the ligand on chelate formation and structural differences in comparison to salicylaldehyde azomethine boron chelates are discussed.

Key words: boron complex, borinate, azine, azomethine.

Résumé : Les chélates de bore obtenus à partir des salicylaldéhyde-azine et 2′-hydroxyacétophénone-azine sont des composés colorés qui peuvent avoir des applications en chimie analytique. Même si ces chélates peuvent prendre deux structures cycliques, l'une à six et l'autre à sept chaînons, ces complexes n'ont pas été étudiés par diffraction des rayons-X jusqu'à maintenant. Dans ce travail, on présente les résultats d'une analyse par rayons X de la 2′-hydroxyacétophénone-azine et de son nouveau mono(diphénylbore)chélate comportant un hétérocycle du bore à six chaînons. Sur la base de ces données, on discute des changements de structure du ligand qui se produisent lors de la formation du chélate ainsi que des différences de structure par comparaison avec celles des chélates du bore avec l'azométhine du salicylaldéhyde.

Mots clés : complexe du bore, borinate, azine, azométhine.

[Traduit par la Rédaction]

Introduction

Boron chelates of salicylaldehyde and 2′-hydroxyacetophenone azomethines (**1**) were synthesized for the first time in 1965 (1) and 1973 (2), respectively, followed by extensive spectroscopic studies of a series of derivatives in order to analyze the influence of different substituents at the imino functional group and the boron atom (Fig. 1) on the formation and stability of these compounds (3–8). The particular interest in the formation and the properties of these chelates is related to their analytical application in the separation and identification of primary alkylamines by high-performance liquid chromatography (9). Thereby, the boron chelates can be prepared in a one-step synthesis from salicylaldehyde or 2′-hydroxyacetophenone, the primary amine, and diphenylborinic acid.

Due to their color-deepening effect on chelate formation, boron complexes obtained from salicylaldehyde and 2′-hydroxyacetophenone azines (2–6, 8) as well as 2,2′-dihydroxyazobenzenes (10) could be important for the quantitative determination of chelate components. These compounds are also of interest from a structural viewpoint, because there exist four different possibilities of chelate formation, as it is illustrated by the example of 2′-hydroxyacetophenone azine (Scheme 1).

Compounds **3** and **4** are spectroscopically not clearly discernible isomers with a six- and seven-membered boron heterocyclic ring, respectively. Further reaction products with distinctly different compositions could be compound **5**, the corresponding bischelate of compound **3**, or compound **6** obtained by elimination of a benzene molecule, as it has been already observed for other diphenylboron complexes (9). Up to now it is known that compounds **5** and **6** are not formed in this reaction, even when 2 equiv. of the diphenylborinic acid are used. Between the monochelates **3** and **4** the most probable structure is **3** (3), although the formation of a seven-membered heterocycle cannot be completely excluded, since seven-membered rings are formed in the case of

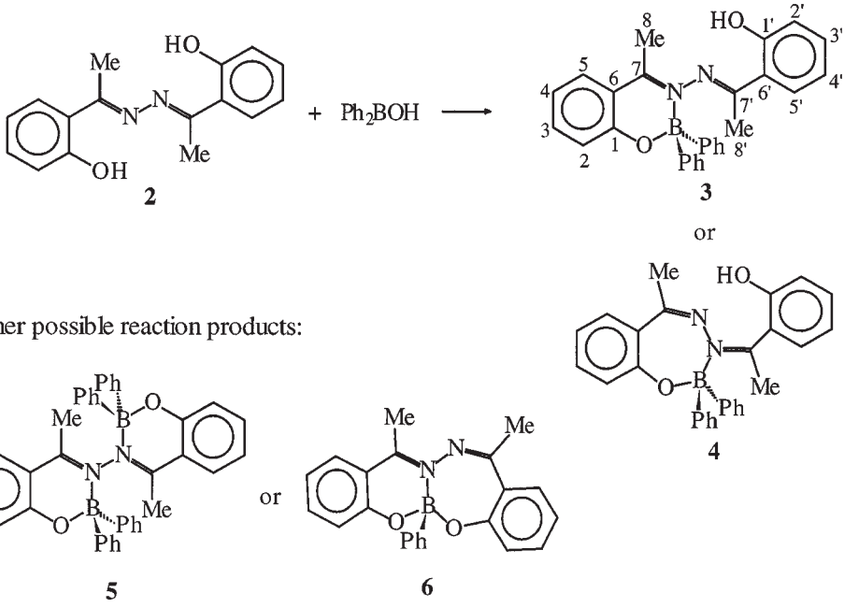

Fig. 1. Boron complexes with salicyladehyde and 2′-hydroxyacetophenone azomethines.

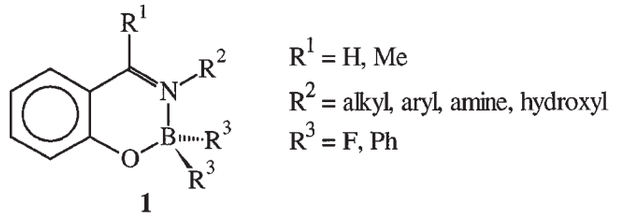

salicylaldehyde nitrones (11). It should be noted that the ^{1}H, ^{13}C, and ^{11}B NMR spectra alone do not allow an unambiguous prediction of the structure type.

Therefore, an X-ray crystallographic study was undertaken to decide between the two structures **3** and **4**. The molecular structure of the ligand was also examined, because there is some recent interest in the stereochemistry and stereoelectronics of acetophenone azines (12).

Experimental

Instrumentation

NMR studies were performed with the following spectrometers: Jeol GSX 270 and Bruker Avance 300. Standards were TMS (^{1}H, ^{13}C) and $BF_3 \cdot OEt_2$ (^{11}B). Chemical shifts are stated in ppm; they are positive, when the signal is shifted to higher frequencies than the standard.

IR spectra have been recorded with a Perkin Elmer 16F-PC FT-IR spectrophotometer. Mass spectra were obtained with an HP 5989 A equipment.

Melting points were determined with a Gallenkamp MFB-595 apparatus and have not been corrected. Elemental microanalyses were performed by Oneida Research Service., Whitesboro, N.Y.

*X-ray crystallographic study of **2** and **3***

The crystallographic studies of **2** and **3** were performed on an Enraf–Nonius CAD4 diffractometer (λ_{MoK_α} = 0.710 69 Å, monochromator: graphite, T = 293 K, ω-2θ scan). Cell parameters were determined by least-squares refinement on diffractometer angles for 24 automatically centered reflections. Absorption correction was not necessary, corrections were made for Lorentz and polarization effects. Solution and refinement: direct methods (SHELXS-86) for structure solution and the CRYSTALS (version 9, 1994) software package for refinement and data output. $I > 3\sigma(I)$. $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2]^{1/2}$. Non-hydrogen atoms were refined anisotropically and a reflections:parameter ratio >5 was considered sufficient for the studies performed in here. Hydrogen atoms have been found by difference Fourier maps, and their coordinates as well as one overall isotropic thermal parameter were refined.

Reagents

All starting materials were commercially available. Solvents were used without further purification, but monocrystals were grown from spectrophotometric grade solvents.

*2′-Hydroxyacetophenone azine (**2**)*

Compound **2** was prepared as described in the literature for salicylaldehyde azine (2, 8). A yellow solid is obtained. Crystals suitable for X-ray crystallography were obtained from THF/hexane; mp 197–199°C. Yield: 90%. Infrared (KBr): 3446 (br, w), 2918 (w), 2850 (w), 1624 (m), 1606 (s), 1590 (s), 1560 (s), 1506 (w), 1494 (m), 1438 (m), 1364 (m), 1300 (s), 1252 (m), 1160 (m) cm^{-1}. ^{1}H (300 MHz, DMSO-d_6), δ (ppm): 2.54 (3H, s, H-8), 6.96 (1H, dd, H-4), 6.98 (1H, d, H-2), 7.41 (1H, dd, H-3), 7.78 (1H, d, H-5), 12.95 (1H, s, OH); ^{13}C (75.5 MHz, $CDCl_3$), δ (ppm): 15.8 (C-8), 118.1 (C-2), 119.9 (C-4), 120.2 (C-6), 130.6 (C-5), 133.6 (C-3), 160.4 (C-1), 169.0 (C-7). EI mass spectrometry (70 eV, DIP), *m*/*z*: 268 (100%, M^+), 253 (67%), 134 (31%),

Results and discussion

The X-ray analysis (Table 1) establishes the six-membered chelate structure **3** and is thus consistent with the peak of *m*/*z* = 134 (29%) in the mass spectrum that corresponds to the C_8H_8NO fragment. Compound **3** is the first boron complex with a salicylaldehyde or 2′-hydroxyacetophenone azine characterized by X-ray crystallography. The final coordinates, selected bond lengths, and selected bond angles for compounds **2** and **3** are summarized in Tables 2–5. The molecular structures of **2** and **3** can be seen from Figs. 2 and 3. Crystal data, atomic coordinates, bond angles, interatomic distances, torsion angles, and anisotropic thermal parameters have been deposited as supplementary material.[2]

[2] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. With the exception of torsion angles and anisotropic thermal parameters these have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

The crystal structure of the 2′-hydroxyacetophenone azine **2** consists of discrete molecules with intramolecular hydrogen bonds O-H···N (1.579 Å, 141.5° for H(11)···N(10) and 1.862 Å, 155.8° for H(511)···N(60)) and an (*E*,*E*)-*trans* conformation. The value of the C=N-N=C torsion angle is 177.0° and is different in comparison to other *para*-substituted (H, F, Cl, Br, OH, etc.) acetophenone azines with values between 124.7 and 148.0° (12, 14).

The crystal structure of **3** consists of discrete molecules with a strong intramolecular hydrogen bond at the nonchelated site of the molecule (O-H···N = 1.627 Å and 149.1°). The (*E*,*E*)-*trans* conformation is lost upon chelate formation due to a steric interaction between one of the BC_6H_5 groups and the C(14) methyl group. The C=N-N=C torsion angle changes from 177.0 to 99.1°, whilst the N—N bond length remains rather constant (1.401 (5) Å for **2** and 1.408 (2) Å for **3**). The mean N—N bond length of other *para*-acetophenone azines is 1.395 (3) Å (12).

In Table 6 some interesting bond lengths of **2** and **3** are summarized and compared to the corresponding data of the salicylaldehyde azomethine boron chelates **8** (15) and **9** (7) (Fig. 4). There are significant differences in the N→B, the B—O, the C(6)—C(7)[3], and the C=N bonds, specially between the boron complexes **3** and **8**. Compound **8** shows the shortest N→B bond with a value of 1.602 (3) Å, while the N→B bonds of **3** and **9** are significantly longer, 1.651 (3) and 1.634 (6) Å, respectively. The B—O bond lengths of **8** and **9** with values of 1.513 (2) and 1.522 (6) Å are significantly longer than in **3** with only 1.477 (2) Å. The structural differences between **3**, **8**, and **9** could be explained with a compromise between the mesomeric forms I and II (Scheme 2) (16). The mean value for a single B—O bond in different 2-aminoethyl diphenylborinates is 1.477 (2) Å (17), while a coordinative O→B bond should be in the range of 1.561 (5) to 1.595 (3) Å (18–21). Although these resonance structures fit well for the differences in the N→B and B—O bond lengths in the case of **3** (I is preferred) and **8** (II is preferred), no such correlation can be found for structure **9**. There is a small, but significant difference in the C(6)—C(7)[3] and C=N bond lengths of the three molecules, however the change is not conclusive in the case of the imine bond. Instead of being shorter in compound **3** it is longer than in compound **8**. Also, the C—O and C(1)—C(6)[3] bonds are not significantly different for the three structures. Therefore, it may be more reasonable not to consider this mesomeric scheme and to state instead that a longer N→B bond results in a shorter B—O bond, and vice versa, in order to compensate the electron deficiency of the boron atom. An explanation for the longer N→B bond in the azine chelate **3** could be the presence of the second nitrogen atom that is more electronegative than a carbon atom and attracts electron density from the trivalent nitrogen atom. The competition for electron density of the two atoms should also be the reason why a bischelate with two electron-withdrawing diphenylboryl groups cannot be obtained (2).

If the bond lengths of ligand **2** are compared to the ones of chelates **3**, **8**, and **9**, there is only one striking difference and that is the C(6)—C(7)[3] bond. The mean value for five para-substituted acetophenone azines is 1.480 (4) Å (1.478 (6) Å for **2**), while the mean value of structures **3**, **8**, and **9** is 1.441 (4) Å, indicating that there exists some delocalization between the imine group and the aromatic ring on chelate formation.

[3] The numbering used here corresponds to the one shown in Schemes 1 and 2.

Fig. 3. Molecular structure of the (2′-hydroxyacetophenoneazine)mono(diphenylboron) chelate **3**. The thermal ellipsoid probability level is 25%.

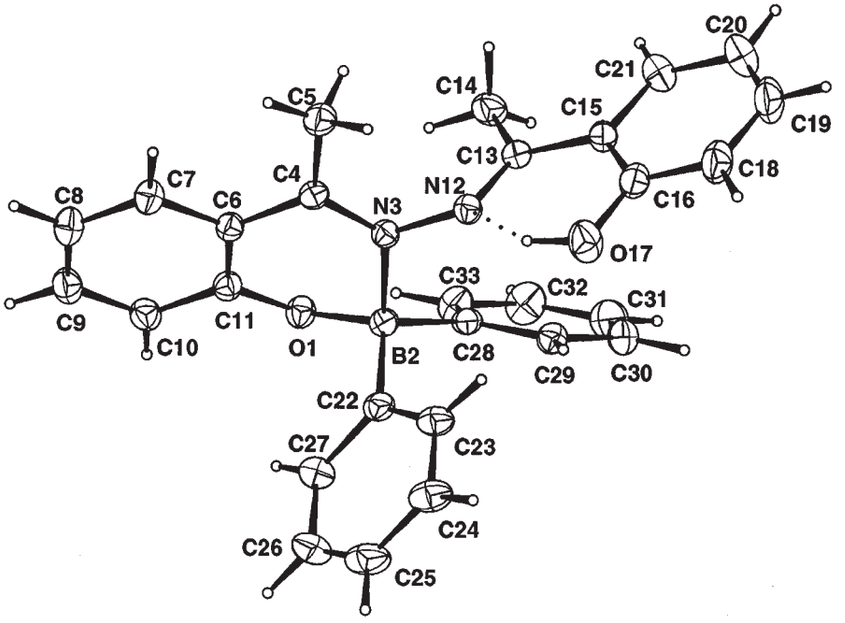

Fig. 4. Boron chelates **8** and **9**.

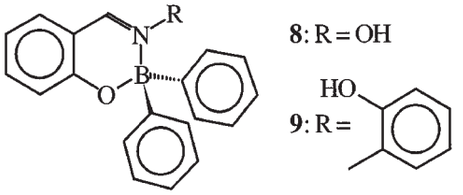
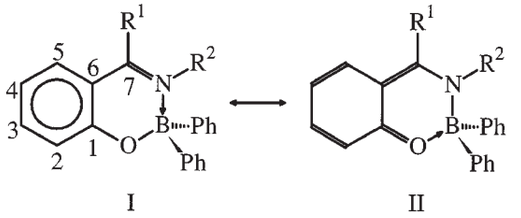


Scheme 2. Mesomeric forms of salicylaldehyde and 2′-hydroxyacetophenone diphenylboron chelates.



The mean values of the bond angles in the six-membered heterocycles of the three boron complexes are 117.5 (2) for **3**, 118.3 (1) for **8**, and 116.8 (2) for **9**. Smaller values indicate a higher ring strain (22). This is confirmed by the deviation of the boron and oxygen atoms from the borinate mean plane. The deviation of the boron atom is highest for **9**, 0.691 Å, whilst **3** and **8** present similar values, 0.481 and 0.427 Å, respectively. The deviations of the oxygen atom are 0.026 Å for **9**, 0.083 Å for **8**, and –0.144 Å for **3**. Therefore, the C_3BNO chelate rings are significantly nonplanar and may be described as either boron-envelopes (**8**, **9**) or half-chairs with boron and oxygen atoms displaced in opposite directions from the approximate plane (**3**).

Temperature dependence of the excess volumes of binary mixtures containing cyclohexane + some higher *n*-alkanes

Mohamed M. El-Banna and Mervette M. El-Batouti

Abstract: Excess molar volumes, V^E, for three binary liquid mixtures of cyclohexane + *n*-dodecane, *n*-tetradecane, and *n*-hexadecane were determined from density measurements at seven different temperatures in the range from 283.15 to 313.15 K and atmospheric pressure, over the entire range of mole fractions. The V^E values were derived and the results show a regular negative pattern of behaviour for each of the three sets of the binary system. For cyclohexane, the magnitude of V^E increases with the alkane chain length. The Prigogine–Flory–Patterson theory was applied to analyze the experimental behaviour by calculating three different contributions to V^E, i.e., interactional, free volume, and internal pressure. The theory gives a representation of the main feature of the systems studied by using a fitted parameter to describe the behaviour throughout the composition range.

Key words: excess molar volumes, binary mixtures, cyclohexane, *n*-dodecane, *n*-tetradecane, *n*-hexadecane, Prigogine–Flory–Patterson theory.

Résumé : Faisant appel à la mesure de densités à sept températures allant de 283,15 à 313,15 K, à la pression atmosphérique et à des fractions molaires couvrant l'ensemble des concentrations, on a déterminé les volumes molaires en excès, V^E, pour les mélanges liquides binaires du cyclohexane avec le dodécane, le tétradécane et l'hexadécane. Les valeurs de V^E ont été obtenues et chacun des trois ensembles de système binaire présente un patron de comportement régulièrement négatif. Pour le cyclohexane, l'amplitude de V^E augmente avec la longueur de la chaîne de l'alcane. On a appliqué la théorie de Prigogine–Flory–Patterson pour analyser le comportement expérimental; à cette fin, on a calculé trois contributions différentes à la valeur de V^E, soit celle des interactions, du volume libre et de la pression interne. Si l'on utilise un paramètre ajusté pour décrire le comportement sur l'ensemble des concentrations, la théorie donne une représentation de la principale caractéristique des systèmes étudiés.

Mots clés : volumes molaires en excès, mélanges binaires, cyclohexane, dodécane, tétradécane, hexadécane, théorie de Prigogine–Flory–Patterson.

[Traduit par la Rédaction]

Introduction

Excess thermodynamic properties of hydrocarbon-containing mixtures are currently attracting considerable interest from the viewpoint of providing information on the variation of such properties with increasing number of carbon atoms in long-chain hydrocarbons (1–8). A comparative study of the thermodynamic properties and molecular interactions based on group contribution methods in *n*-alkane mixtures has been carried out (9, 10). This study suggested a decrease of the molecular order in pure *n*-alkanes when mixed with other solvents. As a contribution to an extensive study on thermodynamic and physical properties for the pure *n*-alkane mixtures, the excess molar volumes, V^E, of binary mixtures of cyclohexane with higher *n*-alkanes (12, 14, and 16 carbon atoms) *n*-dodecane, *n*-tetradecane, and *n*-hexadecane were calculated from the experimental densities over the whole composition range at seven different temperatures in the range from 283.15 to 313.15 K and at atmospheric pressure.

The Prigogine–Flory–Patterson (PFP) theory (11) was used to calculate V^E and to derive the three different contributions considered in the theory. The results were used to calculate the different coefficients describing the variation of the V^E with isobaric change of temperature.

Prigogine–Flory–Patterson theory

The PFP theory has been described (11, 12), and can be expressed as the calculation of V^E as the sum of three contributions: the interactional contribution, which is proportional to the χ_{12} parameter; the free volume contribution, which arises from the dependence of the reduced volume on the reduced temperature as a result of the difference between the degrees of expansion of the two components; and the contribution that depends on the difference in both internal pressures and reduced volumes of the components.

The expression of V^E in terms of the three contributions is

$$[1]\quad V^{E}_{\text{interactional}}/(x_1V_1^* + x_2V_2^*) = [(\bar{v}^{1/3} - 1)\bar{v}^{2/3}\psi_1\theta_2\chi_{12}] / [(4/3)\bar{v}^{-1/3} - 1]\bar{v}$$

$$[2]\quad V^{E}_{\text{free volume}}/(x_1V_1^* + x_2V_2^*) = [(\bar{v}_1 - \bar{v}_2)^2\{(14/9)\bar{v}^{-1/3} - 1\}]\psi_1\psi_2/[(4/3)\bar{v}^{-1/3} - 1]\bar{v}$$

$$[3]\quad V^{E}_{p^*\ \text{effect}}/(x_1V_1^* + x_2V_2^*) = [(\bar{v}_1 - \bar{v}_2)\cdot(p_1^* - p_2^*)]\psi_1\psi_2/(p_1^*\psi_2 - p_2^*\psi_1)$$

The reduction parameters of the pure components (i = 1 and 2) or solutions are obtained through the relationships of the Flory model (13). Thus, the thermal expansion coefficient α_i, is used to calculate the reduced volume $\bar{v}_i$

$$[4]\quad \bar{v}_i = [1 + (\alpha_i\, T)/3(1 + \alpha_i\, T)]^3$$

and the parameters ρ_i^* are derived from experimental data of the thermal pressure coefficient γ_i:

$$[5]\quad \rho_i^* = T\gamma_i v_i^2$$

The reduced volume for the mixture $\bar{v}_i$ is obtained from the reduced equation of state given by Flory et al. (13) using the following relation for $\bar{T}$:

$$[6]\quad \bar{T} = (\psi_1\bar{T}_1 + \psi_2\bar{T}_2) / [1 - \psi_1\theta_2(\chi_{12}/p_1^*)]$$

where the contact energy fraction is obtained as

$$[7]\quad \psi_1 = (1 - \psi_2) = \phi_1 p_1^*/(\phi_1 p_1^* + \phi_2 p_2^*)$$

and the hard core volume fraction ϕ_i is defined as (14)

$$[8]\quad \phi_1 = (1 - \phi_2) = x_1V_1^*/(x_1V_1^* + x_2V_2)$$

where the volume reduction parameters V_i^* are derived from experimental molar volume values V_m, and reduced volume data $\bar{v}_i$, with the relation $V_i^* = V_m / \bar{v}_i$.

The surface or site fraction θ_i, calculated in eq. [1], is expressed as

$$[9]\quad \theta_1 = (1 - \theta_2) = \phi_1/[\phi_1 + \phi_2(s_2/s_1)]$$

where s_i is the molecular surface. The ratio s_1 / s_2 has been approximated (14) by

$$[10]\quad s_1/s_2 = (V_2^* / V_1^*)^{1/3}$$

where V_i^* is the hard core volume.

In the Flory theory of nonpolar molexules, χ_{12} is an adjustable mixing parameter and it was calculated from the experimental V^E data. χ_{12} is supposed to be a constant parameter independent of temperature.

Experimental

The pure cyclohexane and higher *n*-alkanes used in this work were obtained from Aldrich, reported purity >99.5 mol%, and were used without further purification other than storing over molecular sieve to remove any possible traces of moisture.

Density (ρ) measurements of the pure components and binary mixtures, over the complete composition range, were carried out using a Kyoto electronic vibrating tube densimeter (model DA 110) with a temperature sensor keeping the temperature within ± 0.005 K. The apparatus was calibrated several times with the well-known density values of deionized doubly distilled and degassed water, benzene, and dry air at atmospheric pressure.

The mixtures were prepared by syringe, inserting a weighed amount (Mettler A 160 range balance 0.01 mg) of the pure liquids into stoppered bottles to prevent preferential evaporation. This process was repeated four times for each measurement. The experimental technique has previously been described (15). The precision of the densities was ± 0.001 g cm^{-3} and of the mole fraction ± 0.005 mol%.

Densities of the pure liquids at the temperatures of interest in this work, together with some values from the literature, are given in Table 1.

Results and discussion

The experimental density measurements at the temperatures studied for the binary systems, at several known composition values, were used to derive the corresponding V^E values from the following equation:

$$[11]\quad V^E/\text{cm}^3\ \text{mol}^{-1} = x_1\, M_1\, (\rho_m^{-1} - \rho_1^{-1}) + x_2 M_2(\rho_m^{-1} - \rho_2^{-1})$$

where x_i, ρ_i, and M_i are the mole fraction, density, and relative molar mass of the pure components, with i = 1 for the

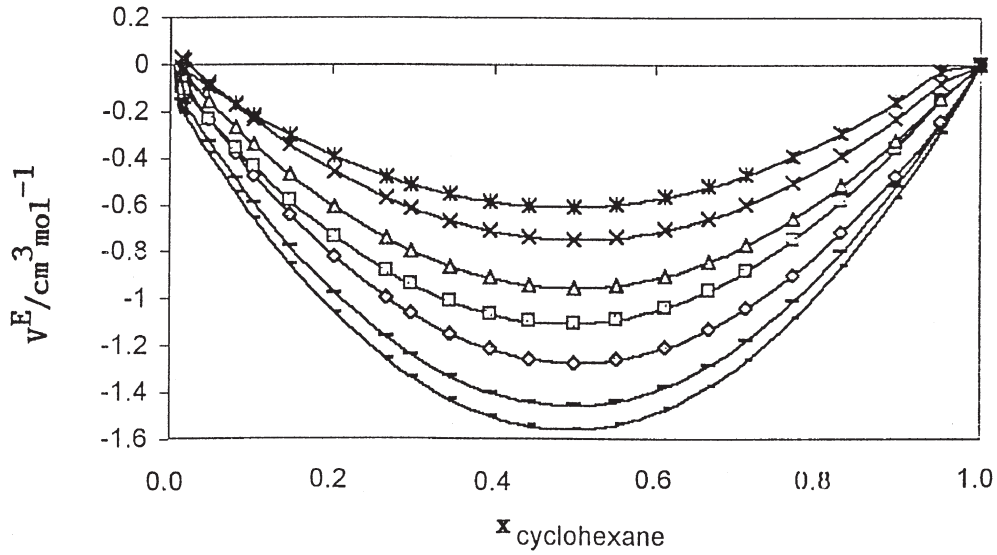
Fig. 1. Excess molar volumes vs. mole fraction of cyclohexane for (x)cyclohexane + (1 – x)n-dodecane at: 283.15 (- · -), 288.15 (– - –), 293.15 (◇), 298.15 (□), 303.15 (△), 308.15 (×), and 313.15 K (*).



cyclohexane and i = 2 for the n-alkane, and ρ_m is the density of the mixture at a given composition.

The experimental density values and the standard deviation s of each system are listed in Table 2. The derived V^E values, as a function of composition, for the three binary systems are shown in Figs. 1, 2, and 3.

The V^E values of the binary mixtures were fitted as a function of the mole fraction and temperature to a polynomial of the form:

$$[12] \quad V^E / \text{cm}^3\ \text{mol}^{-1} = x(1-x) \sum_{i=1}^{3} \sum_{j=1}^{3} B_{ij}\,(2x-1)^{i-1}\,(T-T_0)^{j-1}$$

where T is the temperature and T_0 is the reference temperature (T_0 = 278.15 K).

The coefficients B_{ij} and standard deviation s, are listed in Table 3. The V^E values for the systems (x)cyclohexane + (1 – x)n-alkane are negative; they become more negative when the temperature decreases, and are almost symmetrical with the minimum lying always near x = 0.5. The range of maximum V^E values is between –1.533 and –0.647 (Fig. 1); –1.030 and –0.555 (Fig. 2); and –0.605 and –0.035 cm^3 mol^{-1} (Fig. 3).

It was found that $V^E(x = 0.5)$ increases with increasing temperature for the same system, and increases with the n-alkane chain length in the sequence: n-hexadecane > n-tetradecane > n-dodecane. According to the above order, negative deviations occur when dispersion forces are preponderant (21).

Table 4 contains the characteristic parameters for the pure components used for the application of PFP theory. The values of the interaction parameter χ_{12} for each binary system using experimental equimolar V^E values are given in Table 5 together with equimolar values for each of the three sets of binaries at 298.15 K. It is observed that χ_{12} and the corresponding interactional contribution term are always positive

and large for the systems. This is reasonable considering the weak unlike interactional forces that are characteristic between nonpolar molecules. The free volume contribution is negative for the binary mixtures owing to the difference in free volume, or thermal expansion coefficient, eq. [4], between the corresponding cyclohexane and *n*-alkane studied. Also the contribution is larger in magnitude than the free energy term. This suggests that the repulsion forces have a predominant effect (2, 22).

Spectroelectrochemical study of the nucleophilic substitution of diacyl disulfides by 2-nitrophenyl thiolate ions in *N*,*N*-dimethylacetamide

A. Ahrika, M. Anouti, J.E. Robert, and J.L. Paris

Abstract: *S*-Aryl thiol esters RC(O)SAr and ArS_2^- ions are the end products resulting from the reactions between bis(2-nitrophenyl) disulfide Ar_2S_2 and thiocarboxylate ions $RC(O)S^-$ (R = Me, Ph) at 20°C. The apparent SNAr process in fact occurs in two steps as shown by UV–vis absorption spectrophotometry coupled with voltammetry: (*i*) formation of diacyl disulfides $[RC(O)]_2S_2$ and ArS^- ions by redox exchange; (*ii*) subsequent nucleophilic substitution of 2-nitrophenyl thiolate ions at the carbonyl carbon of diacyl disulfides.

Key words: diacyl disulfides, 2-nitrophenyldisulfide ions, *N*,*N*-dimethylacetamide, nucleophilic substitution, spectroelectrochemistry.

Résumé : Les *S*-aryl thiol esters RC(O)SAr et les ions aryldisulfures ArS_2^- sont les produits issus des réactions mises en oeuvre entre le bis (2-nitrophényl) disulfure Ar_2S_2 et les ions thiocarboxylates $RC(O)S^-$ (R = Me, Ph) à 20°C. Le processus étudié par spectrophotométrie d'absorption UV–visible couplée à la voltammétrie, est apparemment de type SNAr; il s'effectue en fait en deux étapes : (*i*) formation des diacyl disulfures $[RC(O)]_2S_2$ et des ions ArS^- par échange redox; (*ii*) substitution nucléophile ultérieure des ions 2-nitrophényl thiolates sur le groupement carbonyle des diacyl disulfures.

Mots clés : diacyl disulfures, ions 2-nitrophényldisulfures, *N*,*N*-diméthylacétamide, substitution nucléophile, spectroélectrochimie.

Introduction

Previous studies have demonstrated that electrogenerated polysulfide ions S_6^{2-} ($\rightleftharpoons S_3^{\bullet -}$) add nucleophilically to carbonyl carbons in *N*,*N*-dimethylacetamide (DMA) (1, 2), a dipolar aprotic medium. For substrates with sufficiently good leaving groups (acyl chlorides (1) and thioanhydrides (2)) evidence for two steps was obtained:

[1] $RC(O)X + S_6^{2-} \rightarrow RC(O)S^- + 5/2S_2 + X^-$

[2] $RC(O)S^- + 1/2S_2 + RC(O)X \rightarrow [RC(O)]_2S_2 + X^-$

Stable diacyl disulfides further react with S_6^{2-} ions in excess with conversion [3] into thiocarboxylate ions (1):

[3] $[RC(O)]_2S_2 + S_6^{2-} \rightarrow 2RC(O)S^- + 3S_2$

Reaction [3] can occur either as an oxidation–reduction process or as a nucleophilic substitution of $[RC(O)]_2S_2$ by the polysulfide anion. To distinguish between these two alternatives, products of reactions of diacyldisulfides $[RC(O)]_2S_2$ (for R = Me, Ph) with 2-nitrophenylthiolate ions were identified and stoichiometry found. These reactions were followed at 20°C by voltammetry coupled with UV–vis absorption spectrophotometry.

Experimental

Materials

N,*N*-Dimethylacetamide, bis(2-nitrophenyl) disulfide, acyl chlorides, and thioacids (R = Me, Ph) were obtained from Aldrich. Dibenzoyl sulfide was previously synthesized (3) by reaction of thiobenzoate ions with benzoyl chloride. Distilled DMA was stored on molecular sieves (4 Å) after addition of the supporting electrolyte, tetraethylammonium perchlorate (Fluka, 0.1 mol dm^{-3}). Acyl chlorides and thioacids were distilled just before use.

Preparation of diacyl disulfides $[PhC(O)]_2S_2$ and $[CH_3C(O)]_2S_2$

Dibenzoyl disulfide was obtained by exhaustive electrooxidation of $PhC(O)S^-$ ions, which were themselves electrogenerated by reduction of thiobenzoic acid in DMA. The reaction medium (120 cm^3) was treated as already described (1, 3). Dibenzoyl disulfide was recrystallized from 1,2-dichloroethane. Thiobenzoic acid: 1.71 g (12.4 mmol). Dibenzoyl disulfide: 1.12 g (66%), mp 135–136°C (lit. (4)

© 1998 NRC Canada

mp 136–136.5°C); δ_H: 7.53–7.75 (6H, m) and 8.13 (4H, d, *J* 7.4); direct introduction mode *m/z*: 274 (M^+, 4%), 105 (50), 77 (100), and 51 (25). Diacetyl disulfide was prepared according to Robert et al. (1), by reaction of S_4^{2-} ions on acetyl chloride in excess (overall eq. [4]):

[4] $2CH_3C(O)Cl + S_4^{2-} \rightarrow [CH_3C(O)]_2S_2 + S_2 + 2Cl^-$

S_4^{2-} ions were chemically generated (5) in DMA by heating a solution (200 cm^3) of Li_2S (Alfa, 2.32 g, 50 mmol) with a stoichiometric quantity of sulfur (4.81 g, 150 mmol S) at 50°C for 30 min. The green polysulfide ions were progressively added with acetyl chloride dissolved in 40 cm^3 of DMA up to decoloration (95 mmol $CH_3C(O)Cl$). After extraction of the crude product (1), traces of sulfur were carefully eliminated by column chromatography on silical gel (three successive times, hexane as eluent for sulfur, then hexane – diethyl ether, 70:30). Products: 3.15 g (≈42%); from GC–MS, diacetyl disulfide ((~94%) and diacetyl sulfide (~6%). Diacetyl disulfide: δ_H: 2.54 (6H, s); *m/z:* 150 (M^+, < 2%) and 43 (100). Diacetyl sulfide: δ_H: 2.52 (6H, s); *m/z:* 118 (M^+, <2%) and 43 (100).

Equipment

The solutions were transferred from the thermostatted (20 ± 0.5°C) electrolysis vessel (usable volume of 50 cm^3) to the spectrophotometric cell (1 mm pathlength) by means of PTFE tubing in a nitrogen-flushed arrangement (6), according to the flow apparatus described by Billon et al. (7). Voltammograms at a rotating gold-disc electrode (diameter = 2 mm, w = 1000 rev min^{-1}) were recorded by using a EGG-PAR 273 A potentiostat; in that case the N_2 stream was directed above the solution. The electrolyses of bis(2-nitrophenyl) disulfide (Ar_2S_2) and of $[RC(O)]_2S_2$ species leading, respectively, to ArS^- and $RC(O)S^-$ ions (c_i < 5.0 × 10^{-3} mol dm^{-3}) were carried out at a large gold grid electrode. The counter electrode was always a platinum foil, the anodic compartment being separated from the solution by a no. 4 glass frit. All potentials referred to the $Ag/AgCl_{(s)}$, KCl saturated in DMA–$N(Et)_4ClO_4$ 0.1 mol dm^{-3} electrode. Absorption spectra were obtained with a Kontron Uvikon 930 spectrophotometer. All the reactions described below were fast enough to give stable absorbances (±0.002) within 12 s after the addition of reagents, which corresponds to the dead-time of transfer and homogenization. The synthesized diacyl disulfides were analysed by ^1H (200.132 MHz) NMR spectroscopy (Bruker AC 200 spectrometer, $CDCl_3$ as solvent, *J* values in Hz) and GC–MS spectrometry (Hewlett–Packard 5989 A, EI 70 eV).

Results

Characteristics of $[RC(O)]_2S_2$/$RC(O)S_x^-$ and $(2\text{-}NO_2C_6H_4S)_2$/$2\text{-}NO_2C_6H_4S_x^-$ (x = 1, 2) species

$[RC(O)]_2S_2$/$RC(O)S_x^-$ (R = Me, Ph, x = 1, 2) and $(2\text{-}NO_2C_6H_4S)_2$/$2\text{-}NO_2C_6H_4S_x^-$ (x = 1, 2) systems will be implicated in all the processes described below. At first, their known spectroelectrochemical characteristics are reported. 2-Nitrophenyl thiolate ions (noted ArS^-) and thiocarboxylate ions $RC(O)S^-$ (R = Me, Ph) were generated by electrolysis of bis(2-nitrophenyl) disulfide (8) and of thiocarboxylic acids (3) at a controlled potential (–0.9 and –1.4 V, respectively) on the plateau of their reduction waves (eqs. [5f] and [6]):

[5] $Ar_2S_2 + 2e^- \underset{b}{\overset{f}{\rightleftharpoons}} 2ArS^-$

[6] $RC(O)SH + e^- \rightarrow RC(O)S^- + 1/2H_2$

The reduction wave of Ar_2S_2 and the oxidation waves for ArS^- and $RC(O)S^-$ ions had limiting currents, which checked the criteria of convective diffusion.

During the oxidation of $RC(O)S^-$ ions ([overall eq. [7]), the acyl thioradicals $RC(O)S^\bullet$ dimerize into diacyl disulfides without any decomposition (9):

[7] $2RC(O)S^- - 2e^- \rightarrow [RC(O)]_2S_2$

Characteristics (λ_i, ε_i, $E_{1/2}$) of Ar_2S_2, and those of $[RC(O)]_2S_2$, ArS^-, and $RC(O)S^-$ species that were previously obtained in the course of electrooxidations [5b] (8, 10) and [7] (3) are summarized in Table 1. The redox processes are highly irreversible, as shown by the reduction (R) potentials of disulfides compared with the oxidation (O) potentials of anionic species.

We reported earlier that $2\text{-}NO_2C_6H_4S^-$ and $CH_3C(O)S^-$ ions (noted RS^- in eqs. [8] and [9]) partly react with S_2 molecules (3, 8, 10) in equilibrium [10] with cyclic S_8 (6); the affinity of RS^- ions for sulfur is analogous to that of a number of "S-nucleophiles" (11) such as CN^-, SO_3^{2-}, Ar_3P...

[8] $2RS^- + S_2 \underset{b}{\overset{f}{\rightleftharpoons}} 2RS_2^-$

[9] $K_1 = [RS_2^-]^2\,[RS^-]^{-2}\,[S_2]^{-1}$

[10] $S_8 \rightleftharpoons 4S_2$

[11] $K_2\ (297\ K) = [S_2]^4\,[S_8]^{-1} = 10^{-7}\ mol^3\ dm^{-9}$

From the values of constants K_1 (10) (Table 1) and dissociation constant K_2 (6), the formation of RS_2^- ions attains 70% with R = $2\text{-}NO_2C_6H_4$ and 19% for R = $CH_3C(O)$ at initial conditions $[RS^-] = 8[S_8]_0 = 3 \times 10^{-3}$ mol dm^{-3}. In the presence of traces of sulfur the anodic wave of RS^- ions totally shifts over towards more cathodic potentials because of the electrocatalytic process [8f] + [12] already described (R = Ar (8), $CH_3C(O)$ (3)):

[12] $2RS_2^- - 2e^- \rightarrow RS_2R + S_2$

This phenomenon implies the fast formation [8f] of RS_2^- ions, followed by their electrooxidation [12] at a greater rate than that of RS^-, with recovery of sulfur.

Reactivity of $2\text{-}NO_2C_6H_4S^-$ ions with diacetyl disulfide

Figures 1 and 2 show the dependence of UV–vis spectra and voltammograms on the progressive addition of a concentrated solution of bis(2-nitrophenyl) disulfide (v_{max} = 4.5 cm^3) to an initial solution (40 cm^3) $[CH_3C(O)S^-]_0 = 2.25 \times 10^{-3}$ mol dm^{-3} at successive ratios y = $[Ar_2S_2]_{ad.}/[CH_3C(O)S^-]_0$. The fast formation of ArS_2^- ions is detected by the growths of its maximum absorptions at 681 and 362 nm up to y = 1 (Fig. 1, curves 2–6). ArS_2^- ions

[a] $\varepsilon/10^3$ dm^3 mol^{-1} cm^{-1}.

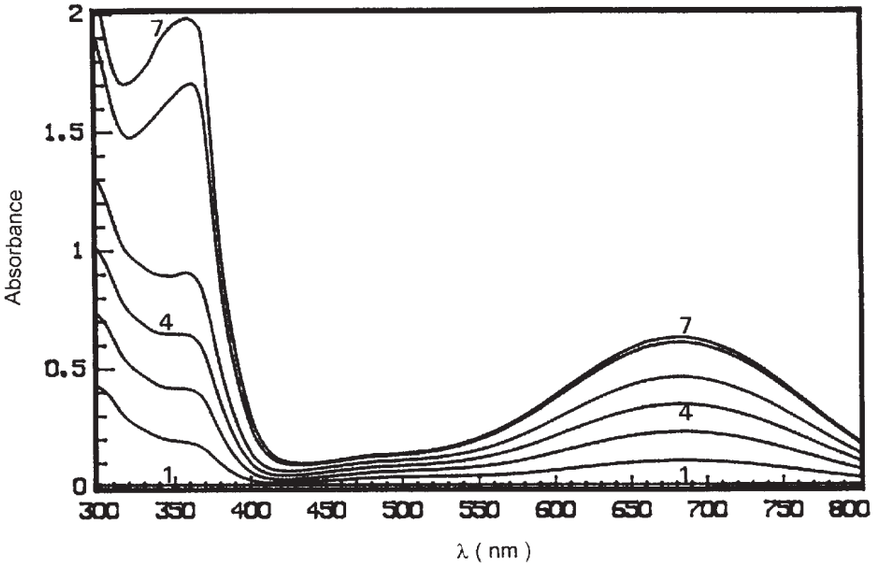
[b] At 502 nm, ε (2-NO_2PhS_2) = 350 dm^3 mol^{-1} cm^{-1}.

[c] $E_{1/2}$(O) for initial conditions $[RS^-]_0 = 8[S_8]_0$.

[d] The formation of $PhCOS_2^-$, in the diffusion layer only, gives rise to a kinetic oxidation wave (3).

[e] K_1 (293 K)/mol^{-1} dm^3.

Fig. 1. Dependence of UV–vis spectra on the addition of bis(2-nitrophenyl) disulfide to a solution $[CH_3C(O)S^-]_0 = 2.25 \times 10^{-3}$ mol dm^{-3} at ratio $y = [Ar_2S_2]_{ad.}/[CH_3C(O)S^-]_0$ = 0 (1); 0.15 (2); 0.33 (3); 0.52 (4); 0.70 (5); 0.98 (6); 1.32 (7). Thickness of the cell = 0.1 cm; scan rate 1000 nm min^{-1}.



partly dissociate into ArS^- ions (eq. (8b)) (λ_{max1} = 502 nm, λ_{max2} = 302 nm); their respective concentrations deducted from molar absorbances (Table 1) remain in a proportion close to $[ArS_2^-]/[ArS^-]$ = 70/30. The stoichiometry

$$z = \sum_{x=1,2} [ArS_x^-]/[Ar_2S_2]_{ad.} \approx 1/1$$

is in agreement with eq. [13]:

[13] $RC(O)S^- + Ar_2S_2 \rightarrow RC(O)SAr + ArS_2^-$

The cathodic wave, which increases with *y* (Fig. 2, curves 2–6) at the same time as $[ArS_x^-]$, has the characteristics of that of $CH_3C(O)SAr$, which was obtained in the course of reaction [14] going to completion ($E_{1/2}$(R) = –0.75 V, *i*(R)/*C* = 22.5 μA $mmol^{-1}$ dm^3):

[14] $ArS^- + CH_3C(O)Cl \rightarrow CH_3C(O)SAr + Cl^-$

At the end of reaction [14] the only absorption of the *S*-aryl thiol ester gives λ_{max1} [$CH_3C(O)SAr$] = 352 nm, ε_{max1} = 1200 dm^3 mol^{-1} cm^{-1}; λ_{max2} = 260 nm, ε_{max2} = 4900 dm^3 mol^{-1} cm^{-1}.

From the first addition of Ar_2S_2 (curve 2), the anodic wave of $CH_3C(O)S^-$ ($E_{1/2}$ (O) = +0.30 V) shifts to the lower oxidation potentials of ArS_2^- ($E_{1/2}$ (O) = +0.10 V) and $CH_3C(O)S_2^-$ ($E_{1/2}$ (O) = +0.12 V) ions (catalytic process described above). For *y* greater than 1 (curve 7), Ar_2S_2 in excess entails both increases of the absorbance at 360 nm (ε_{360} (Ar_2S_2) = +7.500 dm^3 mol^{-1} cm^{-1}) and of the reduction current ($E_{1/2}$ (R, Ar_2S_2) = –0.72 V). Worth noting is that eq. [13] appears to be the unlikely aromatic substitution of thiocarboxylate ions on disulfide Ar-S_2Ar. It could, instead,

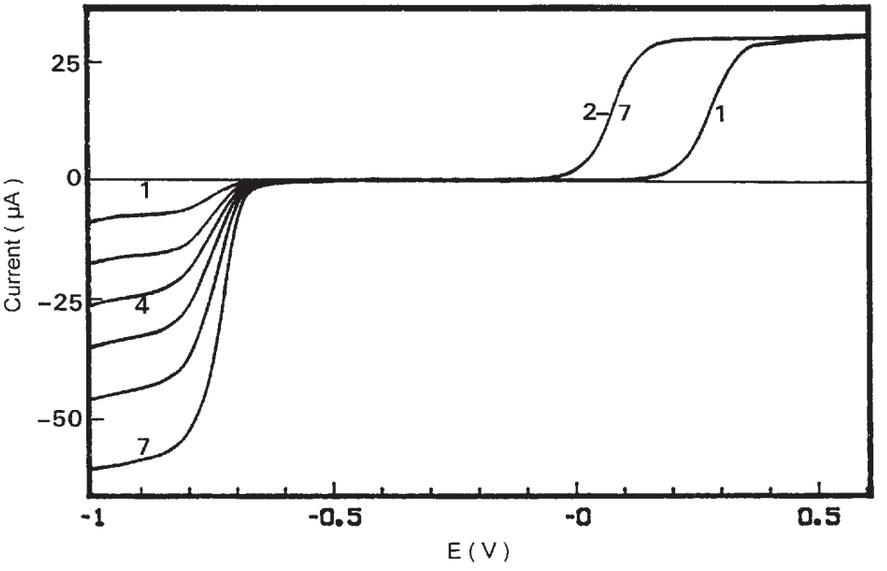
Fig. 2. Changes in voltammograms during the reaction of bis(2-nitrophenyl) disulfide with $CH_3C(O)S^-$ ions. Same conditions as for Fig. 1. Scan rate: 10 mV s^{-1}.



be initiated by the redox exchange reaction [15], with a subsequent substitution of ArS^- ions on diacyl disulfide:

[15] $2RC(O)\ S^- + Ar_2S_2 \rightarrow [CH_3C(O)]_2S_2 + 2ArS^-$

Equation [15] can also be viewed as the overall balance of "thiolate"–disulfide interchanges [16] and [17], which have been studied extensively (11):

[16] $RC(O)\ S^- + ArSSAr \rightarrow RC(O)SSAr + ArS^-$

[17] $RC(O)\ S^- + RC(O)SSAr \rightarrow [RC(O)]_2S_2 + ArS^-$

To check this assumption, diacetyl disulfide was added to a solution of 2-nitrophenyl thiolate ions $[ArS^-]_0 = 4.91 \times 10^{-3}$ mol dm^{-3} ($y = [(RCOS)_2]_{ad.}/[ArS^-]_0$), which is illustrated by the changes of spectra and voltammograms of Figs. 3*a*, 3*b*, and 4. For $0 < y < 0.5$ (Fig. 3*a*, curves 2–9) the absorption of ArS^- ions (λ_{max1} = 502 nm, λ_{max2} = 302 nm) decreases in favor of that of ArS_2^- ions (λ_{max1} = 681 nm, λ_{max2} = 362 nm) with the occurrence of three isosbestic points at λ_{is1} = 562 nm, λ_{is2} = 403 nm, and λ_{is3} = 337 nm. The consumption of ArS_x^- ions, $([ArS_x^-]_y = [ArS^-]_0 - \sum_x [ArS_x^-]_y$, agrees with eq. [18]:

[18] $2ArS^- + [RC(O)]_2S_2 \rightarrow RC(O)SAr + ArS_2^- + RC(O)S^-$

$CH_3C(O)S_2^-$ ions, which are displaced by substitution of ArS^- at the carbonyl carbon of the substrate, greatly dissociate (eq. [8b], R = $CH_3C(O)$) with a favoured formation of ArS_2^- ions (eq. [8f], R = Ar). The reduction wave of $CH_3C(O)SAr$ ($E_{1/2}$ (R) = –0.75 V) increases ($0 < y \leq 0.5$, Fig. 4, curves 2–9) with a limiting intensity in accordance with the stoichiometry $1[CH_3C(O)]_2S_2 \rightarrow 1CH_3C(O)SAr$; as soon as diacetyl disulfide is added, the anodic current of ArS^- ions (curve 1, $E_{1/2}(O)$ = +0.52 V), shifts to the lower oxidation potentials of ArS_2^- and $CH_3C(O)S_2^-$ ions (curves 2–14, $E_{1/2}(O) \sim$ +0.10 V).

ArS_2^- ions are known as better nucleophilic species than the corresponding thiolates: their reactivities compared in DMA (Ar = 2-$NO_2C_6H_4$, k_2/k_1 ratio of SN_2 or SNAr reaction rates) are $k_2/k_1 \sim 10$ towards alkyl halides (12), 18 with 2-fluoro nitrobenzene (13), and 27 with 1,2-dinitrobenzene (14). Because of this enhanced reactivity due to an "α-effect" between the unshared electron pairs on the sulfur atoms (15), the competing formations of $CH_3C(O)SAr$ (eq. [18]) and $CH_3C(O)S_2Ar$ (eq. [19]) should be observed in the course of overall reactions ArS^- + $[CH_3C(O)]_2S_2$:

[19] $ArS_2^- + [RC(O)]_2S_2 \rightarrow RC(O)S_2Ar + RC(O)S_2^-$

This is not the case, because reaction [18] is practically quantitative for $0 < y < 0.5$. Moreover, with further additions of diacetyl disulfide ($1.60 > y > 0.5$) the consumption of ArS_x^- ions (Fig. 3*b*, curves 10–14, decreases of A_{681} and A_{502}) is only observed to a low extent: as an example, $\Delta[ArS_x^-]_y / [(RCOS)_2]_{ad.} = 0.58$ for $y = 1.20$ (curve 13). This unexpected poor affinity of ArS_2^- ions for $[RC(O)]_2S_2$ can be explained by the limited redox reaction [20b] between $CH_3C(O)S_2Ar$ and $CH_3C(O)S^-$ ions in excess, since the latter are better reducing agents than ArS^- (eq. [15]):

[20] $ArS_2^- + [CH_3C(O)]_2S_2 \underset{b}{\overset{f}{\rightleftharpoons}} CH_3C(O)S_2Ar + CH_3C(O)S^- + 1/2S_2$

We previously discussed (16, 17) processes analogous to [20]: when 1,2- or 1,4-dinitrobenzenes were added to RS_2^- ions (R = 4-$CH_3C_6H_4$, 4-FC_6H_4, $C_6H_5CH_2$) evidence for two steps was found: (*i*) initial nucleophilic substitution (eq. [21]) similar to eq. [20f]:

[21] $NO_2C_6H_4NO_2 + RS_2^- \rightarrow NO_2C_6H_4S_2R + NO_2^-$

(*ii*) displacement of $NO_2C_6H_4S_2^-$ ions by redox exchange [22] similar to eq. [20b]:

[22] $NO_2C_6H_4S_2R + RS_2^- \rightarrow NO_2C_6H_4S_2^- + R_2S_2$

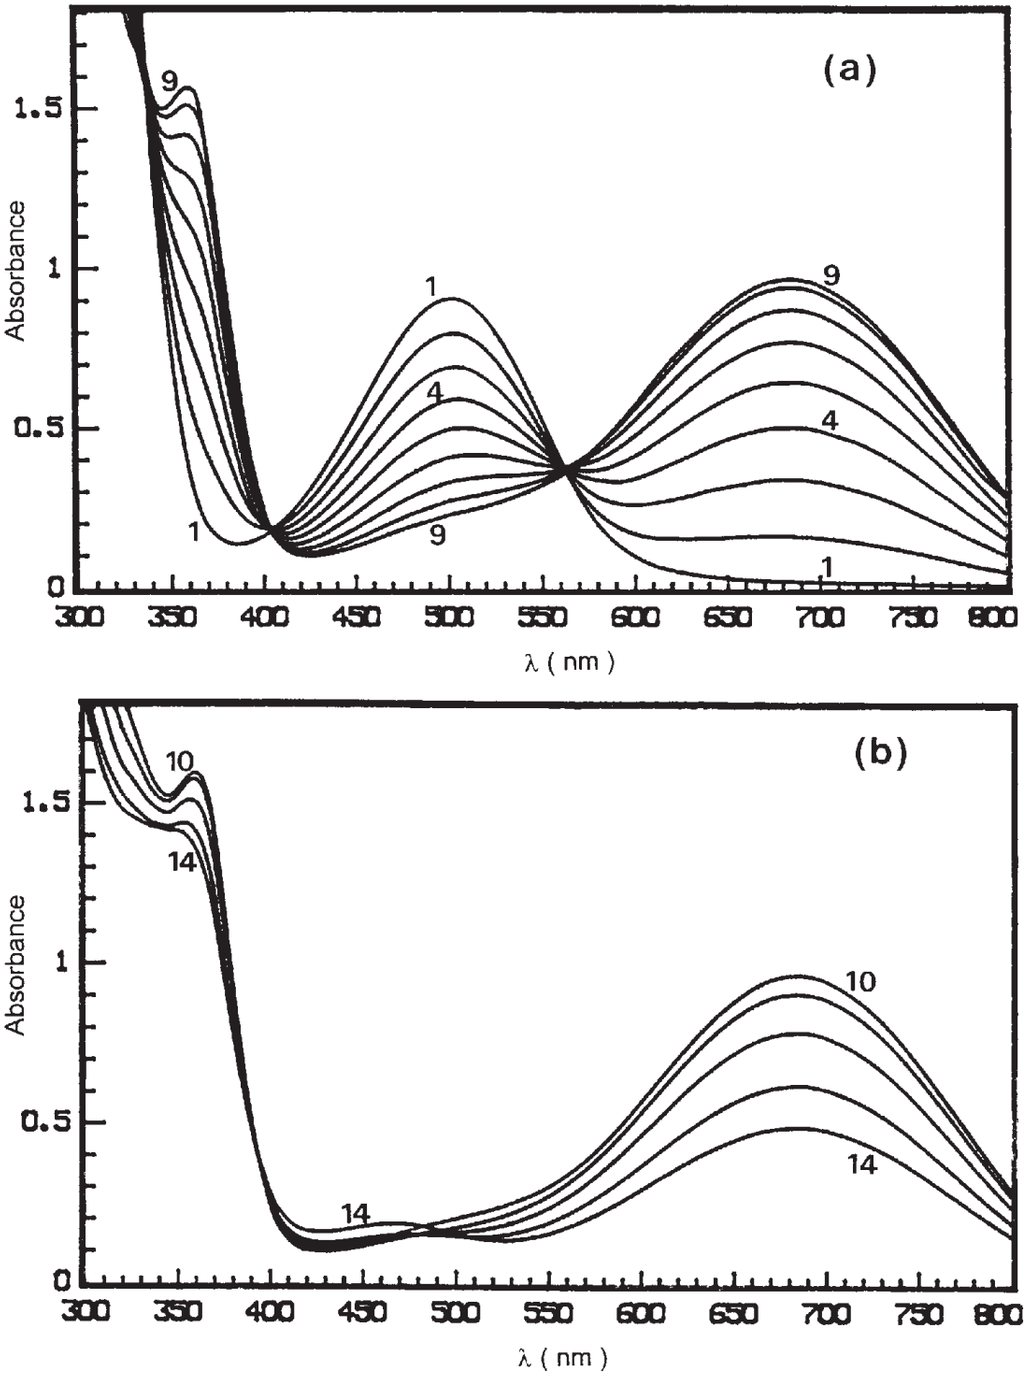
Fig. 3. (*a*) Dependence of UV–vis spectra on the addition of diacetyl disulfide to a solution $[2\text{-}NO_2PhS^-]_0 = 4.91 \times 10^{-3}$ mol dm^{-3} at ratio $y = [(CH_3COS)_2]_{ad.}/[ArS^-]_0 = 0$ (1); 0.058 (2); 0.116 (3); 0.172 (4); 0.23 (5); 0.29 (6); 0.34 (7); 0.40 (8); 0.46 (9). (*b*) $y = 0.52$ (10); 0.63 (11); 0.82 (12); 1.20 (13); 1.60 (14).



The partial generations of acyl aryl disulfide and sulfur from reaction [20f] ($y > 0.5$) are evidenced by their respective bielectronic reduction waves (Fig. 4, curves 11–13, $CH_3C(O)S_2Ar$: $E_{1/2} \approx -0.73$ V; S_8: $E_{1/2} = -0.40$ V, $S_8 + 2e^- \rightarrow S_8^{2-}$ (6)); $CH_3C(O)S_2Ar$ probably absorbs at $\lambda_{max} \approx$ 360 nm with the same characteristics (Table 1) as Ar_2S_2 ($\varepsilon_{360} = 7500$ dm^3 mol^{-1} cm^{-1}) and ArS_2^- ($\varepsilon_{362} = 7000$ dm^3 mol^{-1} cm^{-1}) since A_{360} remains constant for $y > 0.5$; $[CH_3C(O)]_2S_2$ in excess entails the growth of its cathodic current ($E_{1/2}(R) = -1.19$ V) whereas $CH_3C(O)S_2^-$ ions are detected at the greater y values (Fig. 3*b*, curves 13 and 14) by their maximal absorbance ($\lambda_{max} = 467$ nm).

Fig. 4. Changes in voltammograms during the reaction of diacetyl disulfide with 2-nitrophenyl-thiolate ions. Same conditions as for Fig. 3.

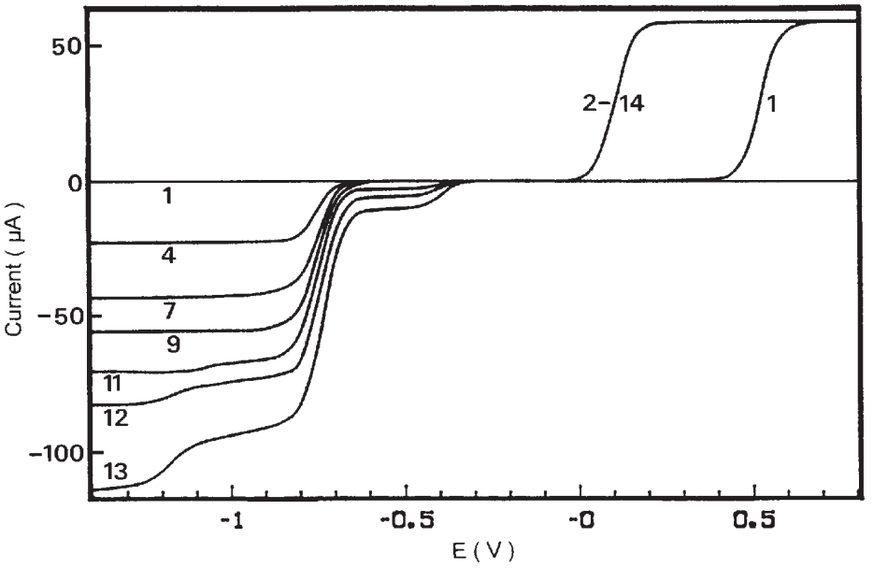

Fig. 5. Changes in voltammograms during the reaction between benzoyl chloride and a solution $[2\text{-}NO_2C_6H_4S^-]_0 = 8[S_8]_0 = 3.45 \times 10^{-3}$ mol dm^{-3}. $y = [PhC(O)Cl]_{ad.}/[ArS^-]_0 = 0$ (1); 0.11 (2); 0.33 (3); 0.56 (4); 0.78 (5); 0.98 (6).

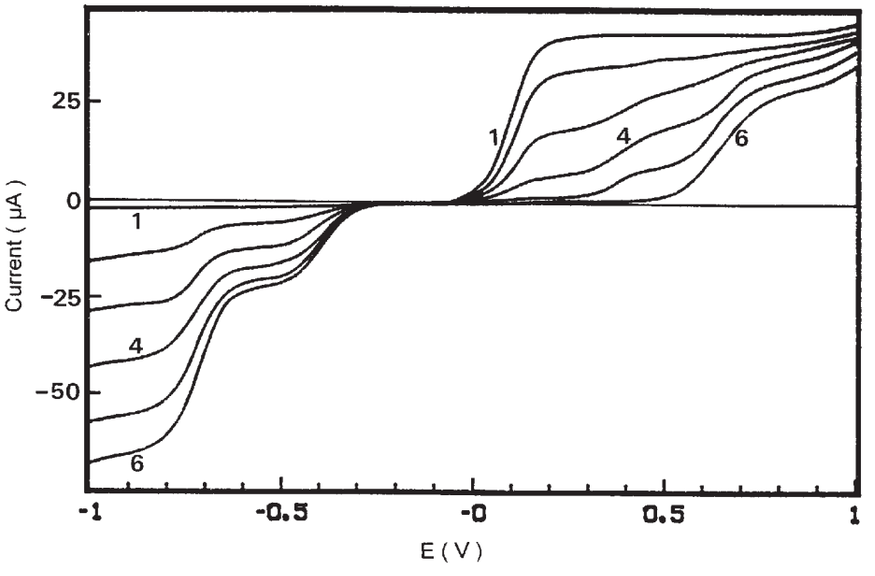

Reactivity of $NO_2C_6H_4S^-$ ions with dibenzoyl disulfide

The addition of bis(2-nitrophenyl) disulfide (Ar_2S_2) to a solution $[PhC(O)S^-]_0 = 3.0 \times 10^{-3}$ mol dm^{-3} gives the only detection of ArS_2^- and ArS^- ions on spectra (increase of A_{681}, A_{362}, and A_{502}) in a proportion $[ArS_2^-]/[ArS^-]$ 70/30 as shown with $CH_3C(O)S^-$ ions (Fig. 1). However, the overall balance, eq. [13], develops here to a moderate extent such as:

$$0.50 < \sum_{x=1,2} [ArS_x^-]/[Ar_2S_2]_{ad.} < 0.28$$

$$\text{for } 0 < [Ar_2S_2]_{ad.}/\ [PhC(O)S^-]_0 \leq 1.07$$

It can be assumed that the E^o standard potential of $[PhC(O)]_2S_2$ is a little more negative than that of Ar_2S_2; the redox initial exchange [15] is then unfavourable in spite of a fast chemical follow-up reaction analogous to eq. [18]. The addition of dibenzoyl disulfide to 2-nitrophenyl thiolate ions ($[ArS^-]_0 = 3.53 \times 10^{-3}$ mol dm^{-3}) entails changes of spectra and voltammograms similar to the diacetyl disulfide reaction. However, contrary to the reaction of $[CH_3C(O)]_2S_2$, the consumption of ArS_x^- (x = 1, 2) ions, $\Delta[ArS_x^-]_y/[(PhCOS)_2]$, remains at the greater constant value, 1.55 ± 0.05 for $0 < y = [(PhCOS)_2]_{ad.}/[ArS^-]_0 < 0.5$, and ArS_2^- ions (A_{681}, A_{362}) are here generated in solution in a lower proportion.

Table 2. Consumption of 2-$NO_2C_6H_4S_x^-$ (x = 1, 2) ions during the addition of benzoyl chloride to a solution $[ArS^-]_0 = 8[S_8]_0 = 3.45 \times 10^{-3}$ mol dm^{-3}.

$[PHC(O)Cl]_{ad.}/[ArS^-]_0$	0.11	0.22	0.33	0.44	0.56	0.67	0.78	0.89	0.98
$\Delta[ArS_x^-]/[PhC(O)Cl]_{ad.}$	1.87	1.82	1.74	1.63	1.51	1.36	1.23	1.11	1.02

The nucleophilic substitution of ArS_x^- ions on $[RC(O)]_2S_2$ giving $RC(O)S_xAr$ (x = 1, 2) is probably easier with R = Ph than with R = CH_3, but unlike R = CH_3 (see before), ArS_x^- ions could reduce $PhC(O)S_2Ar$ in agreement with $E^o((PhCOS)_2) < E^o(Ar_2S_2)$. This assumption was verified by the addition of benzoyl chloride to ArS_2^- ions coming from an initial solution $[ArS^-]_0 = 8[S_8]_0 = 3.45 \times 10^{-3}$ mol dm^{-3}, with $y = [PhC(O)Cl]_{ad.}/[ArS_x^-]_0$. Equations [23], [24], and [25] with the overall balance, eq. [26], explain the changes in spectra and voltammograms (Fig. 5):

[23] $PhC(O)Cl + ArS_2^- \rightarrow PhC(O)S_2Ar + Cl^-$

[24] $PhC(O)S_2Ar + ArS_2^- \rightarrow Ar_2S_2 + 1/2S_2 + PhC(O)S^-$

[25] $PhC(O)S^- + PhC(O)Cl \rightarrow [PhC(O)]_2S + Cl^-$

[26] $2PhC(O)Cl + 2ArS_2^- \rightarrow Ar_2S_2 + [PhC(O)]_2S + 1/2S_2 + 2Cl^-$

The variations $\Delta[ArS_x^-]/[PhC(O)Cl]_{ad.}$ as a function of y are reported in Table 2. At the lower y values ($y \leq 0.5$, curves 2, 3), ArS_2^- ions in excess preferentially react with PhC(O)Cl in a proportion close to 2/1 according to eqs. [23] + [24], similar to eqs. [21] + [22], with the appearance of sulfur ($E_{1/2}$ (R) = – 0.40V), Ar_2S_2 ($E_{1/2}$ (R) = –0.72 V), and $PhC(O)S^-$ ions ($E_{1/2}$ (O) = +0.38 V). Then concurrent substitutions of $PhC(O)S^-$ and ArS_2^- occur. At the stoichiometry 1/1 of eq. [26] (curve 6), the wave of Cl^- ions is the only anodic one ($E_{1/2} \approx$ + 0.65V, $3Cl^- \rightarrow Cl_3^- + 2e^-$), with an intensity close to that calculated after calibration with a solution of $N(CH_3)_4$ Cl; the UV spectrum and the two cathodic waves are the same as those obtained when diaryl disulfide, dibenzoyl sulfide, and sulfur are mixed at concentrations $[Ar_2S_2] = [(PhCO)_2S] = 8\ [S_8] = [ArS^-]_0/2 = 1.72 \times 10^{-3}$ mol dm^{-3} (S_8: i (–0.60 V) ≈ 23 μA; Ar_2S_2, $(PhCO)_2S$: i (–1.10 V) ≈ 70 μA, $A_{360} \approx 1.20$). So $A = f(\lambda)$ and $i = f(E)$ recordings in the course of the reaction of ArS^- ions with $[PhC(O)]_2S_2$ ($0 < y < 0.5$) are consistent with the two competing processes [27] and [28] (= [19] + [24]), which yield close concentrations of PhC(O)SAr and Ar_2S_2 species from $\Delta[ArS_x^-]_y/[(PhCOS)_2]_{ad.} = 1.55$:

[27] $2ArS^- + [PhC(O)]_2S_2 \rightarrow PhC(O)SAr + ArS_2^- + PhC(O)S^-$

[28] $2ArS_2^- + [PhC(O)]_2S_2 \rightarrow Ar_2S_2 + 2PhC(O)S^- + S_2$

Equation [28] is equivalent to the reduction of diacyl disulfide by ArS_x^- ions. ArS_2^- concentration (A_{681}) increases up to $y = 0.5$, then decreases ($0.5 \leq y \leq 1.2$) as shown with the addition of PhC(O)Cl, with release of sulfur (appearance of the reduction wave of S_8, $E_{1/2}$ (R) = –0.40 V, $i(R)/C = 30$ μA mol^{-1}), giving a limiting current in agreement with the stoichiometry of eq. [28].

Discussion

From our results, the close standard potentials of disulfides can be qualitatively classified as $E^o(Ar_2S_2) \geq E^o[(PhCOS)_2] > E^o[(CH_3COS)_2]$. However ArS_x^- ions (Ar = 2-$NO_2C_6H_4$) preferentially react with $RC(O)S_2C(O)R$ (R = CH_3, Ph) by nucleophilic substitution at the carbonyl carbon rather than by redox process (R = Ph), which would imply the cleavage of the S—S bond.

Stable polysulfide ions S_8^{2-}, S_6^{2-} ($\rightleftharpoons S_3^{\bullet -}$), S_4^{2-} can be obtained by chemical or electrochemical reduction of sulfur in dipolar aprotic media (DMA, DMF, DMSO, CH_3CN...) (6, 18). These species, which reduce "activated" diaryl disulfides Ar_2S_2 (e.g., Ar = $NO_2C_6H_4$) (8) into ArS^- ions ($E^o(S_8) < E^o(Ar_2S_2)$), entail the formation of thiocarboxylate ions from diacyl disulfides (1, 3). Similarly, $RC(O)O^-$ ions are generated from diacyl peroxides in the presence of superoxide ions (eq. [29]) (19):

[29] $[RC(O)]_2O_2 + 2O_2^{\bullet -} \rightarrow 2RC(O)O^- + 2O_2$

Both reactions [3] and [29] were encountered in the course of substitutions of acyl chlorides (1, 19*a*, 19*c*), anhydrides (2, 19*a*, 19*f*), and esters (19*b*, 19*d*, 19*g*) by S_6^{2-} or $O_2^{\bullet -}$ ions in excess. The occurrence of reaction [29] by either electron transfer ("redox," eq. [30]) or by nucleophilic displacement (eq. [31]), followed by superoxide reduction of the acyloxy or acylperoxy radicals, was thoroughly discussed (19*f*) without a convincing conclusion.

[30] $RC(O)OOC(O)R + O_2^{\bullet -} \rightarrow RC(O)O^{\bullet} + RC(O)O^- + O_2$

[31] $RC(O)OOC(O)R + O_2^{\bullet -} \rightarrow RC(O)OO^{\bullet} + RC(O)OO^-$

We conclude that overall processes [3] and [29] should proceed largely via initial nucleophilic steps, as this accommodates all of our experimental observations on the reactivity of 2-nitrophenyl thiolate ions towards diacyl disulfides.

Valorisation chimique du méthane par plasmas micro-ondes

N. Kopytko et F. Baronnet

Résumé : Opérant à des pressions allant de 4 à 28 torr, dans un réacteur tubulaire placé dans une cavité de Moreau parallépipédique, on a étudié la conversion du méthane dans un plasma à microondes direct. Le but principal de ce travail était de déterminer la nature des produits obtenus par conversion du méthane, particulièrement les hydrocarbures en C_2. On a analysé les produits de la réaction par chromatographie en phase gazeuse. On a étudié l'influence de divers paramètres réactionnels (temps de résidence, écoulement, pression, puissance...). Les résultats expérimentaux montrent que l'on peut obtenir des rendements substantiels d'hydrocarbures en C_2. On compare nos résultats expérimentaux avec ceux obtenus à l'aide de procédés différents, particulièrement le couplage oxydant et le couplage thermique ainsi que ceux obtenus par d'autres auteurs utilisant des techniques de microondes.

Mots clés : méthane, plasma micro-ondes, cavité Moreau, réactions chimiques.

Abstract: The conversion of methane in a direct microwave plasma was investigated at pressures ranging from 4 to 28 Torr in a tubular flow reactor located in a parallelepipedic Moreau cavity. The main purpose of this work was the determination of the products obtained by methane conversion, especially C_2 hydrocarbons. The reaction products were analysed by gas phase chromatography. The influence of various reaction parameters (residence time, flow, pressure, power…) was studied. The experimental results showed that substantial yields in C_2 hydrocarbons could be obtained. Our experimental results are compared to those obtained by other processes, especially oxidative coupling and thermal coupling, and also to those obtained by other authors using microwave techniques.

Key words: methane, microwave plasma, Moreau cavity, chemical reactions.

[Traduit par la Rédaction]

Introduction

En raison de la relative abondance des réserves de gaz naturel dont le méthane est le principal constituant ainsi que des difficultés et du coût liés au transport du gaz naturel, les procédés de conversion du méthane en hydrocarbures supérieurs ont fait l'objet de très nombreux travaux. Le passage par le gaz de synthèse présentant des inconvénients, dont l'endothermicité importante de l'étape de vaporéformage correspondant à une perte énergétique de l'ordre de 25 %, un effort considérable de recherche en vue d'une conversion directe du méthane, en particulier en hydrocarbures supérieurs, a été fait depuis une quinzaine d'années. Parmi les procédés étudiés, la réaction de couplage oxydant du méthane découverte en 1982 par Keller et Bhasin (1) est apparue comme une des voies les plus prometteuses. Cependant, il est apparu que, quels que soient le type de catalyseur et les conditions opératoires utilisées, le rendement en hydrocarbures supérieurs, notés C_{2+}, restait inférieur à 25 % (2) ce qui, compte tenu des recyclages en résultant, limitait sérieusement les possibilités de ce procédé. Des travaux sur cette réaction ont été conduits au laboratoire (3, 4).

La réaction dite de couplage thermique du méthane qui consiste à le faire réagir vers 1200°C en présence d'hydrogène pour limiter la formation de coke a également été étudiée au laboratoire (5, 6) mais il est certain que les niveaux thermiques nécessaires sont un inconvénient et nécessitent en particulier de réaliser le réacteur en matériaux résistant à ces températures.

Il est clair que les difficultés liées à ces différents procédés proviennent essentiellement de la relative «inertie» chimique de la molécule de méthane, plus précisément de la liaison C—H dont l'énergie de dissociation est de 104 kcal/mol; difficulté supplémentaire, les produits (éthane, éthylène, par exemple) sont moins stables que le réactif de départ dans les conditions où s'effectue la réaction, que ce soit à 1200°C (couplage thermique) ou à 800°C en présence d'oxygène (couplage oxydant).

Ceci montre donc les limites de l'amorçage thermique des réactions de conversion du méthane, puisque si de hautes températures sont nécessaires en raison de l'inertie chimique de la molécule de méthane, elles conduisent en contrepartie à la dégradation des produits formés et à des réactions secondaires indésirables; il semble donc incompatible d'obtenir en même temps une activation suffisante et une sélectivité élevée.

Une autre méthode qui pourrait éviter ces difficultés est l'activation du méthane par des plasmas micro-ondes. Il y a

de toute évidence de nombreux radicaux libres dans un plasma, ce qui permet d'obtenir une activation directe tout en restant à des températures peu élevées. Nous avions fait une première tentative dans ce sens en utilisant des décharges radiofréquences (7) mais nous avions été limités très rapidement dans la gamme des pressions utilisables. Ceci nous a conduits à nous intéresser aux plasmas micro-ondes; dans ce travail, nous avons travaillé en plasma direct contrairement à d'autres auteurs qui avaient eu recours aux plasmas différés, c'est-à-dire à la réalisation d'un plasma d'air ou d'azote avec injection de méthane dans la zone post-décharge (8). Nous comparerons les deux méthodes dans ce mémoire.

Montage expérimental

Comme nous l'avons mentionné dans ce qui précède, nous avons choisi d'exciter directement le méthane par plasma micro-ondes (plasma direct). Nous évitons ainsi les problèmes dus à l'utilisation d'un gaz plasmagène, en particulier la formation de produits indésirables.

La figure 1 donne un schéma général du montage; nous pouvons considérer qu'il se compose de trois parties successives. (*i*) Le réactif (méthane pur) est introduit dans l'installation à l'aide de RDM (régulateurs de débit massique) qui permettent à la fois la mesure du débit gazeux et son réglage à une consigne donnée (fig. 1*a*). (*ii*) Le méthane passe ensuite dans le réacteur constitué d'un tube de quartz de 20 mm de diamètre qui se trouve placé dans une cavité micro-ondes de type Moreau couplée à un magnétron par l'intermédiaire d'un guide d'ondes. L'appareillage micro-ondes est schématisé dans la figure 1*b*. (*iii*) La dernière partie du montage est constituée de la station de prélèvement des échantillons qui sont ensuite analysés par chromatographie en phase gazeuse. La figure 1*c* donne une vue plus précise de cette partie de l'installation et permet de comprendre le procédé de prélèvement : en cours d'expérience les deux vannes notées A sont ouvertes, la vanne B est fermée, le flux gazeux passe donc entre les deux vannes A. Les ampoules de prélèvement, dans lesquelles le vide a été fait au préalable, sont isolées à l'aide d'un robinet. Au moment de la prise d'échantillon les vannes sont commutées, ce qui permet d'isoler les gaz à prélever sans provoquer d'augmentation brutale de la pression dans le réacteur. Le robinet menant aux ampoules de prélèvement est ensuite ouvert.

La pression dans l'installation est réglée à l'aide d'une vanne pointeau, et une pompe à palettes placée en sortie de montage permet l'évacuation des gaz. Des capteurs de pression de type Barocell et MKS sont placés en plusieurs points de l'installation, avant et après le réacteur, ce qui a permis de vérifier que le plasma entraînait une très faible perte de charge, et au niveau de la prise d'échantillon. Enfin, un piège de laine de silice placé en sortie du réacteur permet de retenir les goudrons formés et d'éviter ainsi les problèmes d'encrassement en aval.

L'ensemble du matériel utilisé pour la production du plasma nous a été fourni par la SAIREM. Cette installation se compose d'un magnétron de Thomson CSF alimenté par un générateur haute tension de type GMP 12 KTS dont la puissance peut varier de façon continue entre 0 et 1200 W.

l'énergie le long du guide d'ondes au moyen d'une antenne d'émission.

Un wattmètre monté sur le générateur permet de connaître à tout moment la puissance incidente P_i et la puissance réfléchie P_r. La différence $P_i - P_r$ permet de connaître approximativement la puissance transmise au plasma (étant donné qu'une certaine quantité de cette puissance transmise est en fait dissipée sous forme de chaleur dans le tube à décharge).

Un circulateur refroidi à l'eau protège l'antenne des retours d'énergie micro-ondes qui peuvent se produire en cas de désadaptation.

Les ondes propagées le long du guide entrent dans une cavité résonnante parallélépipédique de type Moreau, schématisée sur la figure 2 (9). Cette cavité est limitée en amont du réacteur par un iris au travers duquel est transmise l'énergie et en aval par un piston mobile qui doit se trouver réglé de manière à ce que la longueur de la cavité corresponde à un nombre entier de demi-longueurs d'onde et permette ainsi l'instauration d'un système d'ondes résonnantes.

Le mode de résonance est un mode transverse électrique noté TE_{mnp}. Les trois indices *m*, *n* et *p* sont relatifs au nombre de demi-longueurs d'ondes établis lors de la résonance dans chacune des trois directions *xyz* repérées sur la figure 2. Le mode de résonance choisi est tel que l'axe du réacteur corresponde à un ventre des ondes électriques. Notre installation fonctionne avec un mode TE104.

Avec un tel réglage, l'oscillation du champ électrique est maximale au niveau du passage du réacteur à l'intérieur de la cavité. Elle permet de mettre en mouvement les quelques électrons libres déjà présents dans le méthane. Pour être pleinement efficace cette oscillation doit avoir lieu dans l'axe du réacteur de façon à minimiser les pertes aux parois. Dans ces conditions, les électrons accélérés rentrent en collision avec les molécules de méthane pour former soit des ions si leur énergie est suffisante, soit des espèces neutres excitées. Les électrons libérés lors de la formation d'ions vont à leur tour entrer en collision avec d'autres molécules, ce qui va entraîner une réaction en chaîne pour finalement aboutir à la création d'un plasma.

Lors de nos travaux nous nous sommes surtout attachés à l'aspect chimique du problème : dosage des produits formés, mesure de la consommation des réactifs. Il s'agissait principalement d'une recherche exploratoire destinée à déterminer l'intérêt des procédés «plasma froid» appliqués au méthane, ce qui a nécessité une mise au point relativement longue, au détriment de bilans-matière détaillés.

Résultats obtenus

Le maintien du plasma s'étant avéré relativement difficile, en particulier à cause de problèmes d'encrassement, nous avons, dans un premier temps, essayé de déterminer quelles étaient les conditions d'obtention d'un plasma stable, en fonction des principaux paramètres qui nous étaient accessibles. Nous avons ensuite plus précisément étudié l'influence sur les résultats du temps de passage, de la puissance incidente, du débit et de la pression de méthane.

Conditions d'obtention d'un plasma stable

Pour plusieurs débits, nous avons déterminé, en fonction de la pression, les puissances incidentes minimales et maximales admissibles pour obtenir un plasma stable pendant une durée de 15 min.

Il est certain que les résultats obtenus seraient modifiés en choisissant une durée plus longue de stabilité exigible pour le plasma. Mais l'intérêt présenté par ce travail est avant tout d'avoir une vue d'ensemble de l'importance d'une variation des différents paramètres.

Dans ces conditions nous avons étudié successivement les débits suivants : 15, 30, 60, 120, 160 et 240 mL/min.

Le réacteur était nettoyé à l'aide d'un plasma d'oxygène après chaque expérience. Les conditions de nettoyage ont été fixées aux normes suivantes : P_i = 300 W, P = 9 torr (1 torr = 133,3 Pa), durée 2 min. Les démontages qui ont été effectués de temps à autre ont permis de vérifier que ce nettoyage était suffisant, même dans des conditions d'encrassement important.

L'ensemble des courbes obtenues a été rassemblé sur la figure 3 où nous avons représenté, pour différents débits de méthane, les puissances incidentes minimales et maximales en fonction de la pression. Nous obtenons une forme générale «en cloche» : l'amplitude entre puissance minimale et puissance maximale diminue quand la pression augmente. D'autre part, nous remarquons qu'une augmentation du débit permet d'accéder à des domaines de pression plus importants. La pression maximale passe ainsi de 17 torr pour 15 mL/min à 28 torr pour 240 mL/min. Toutefois, il semble que le domaine de pression admissible plafonne à environ 28 torr : nous n'observons plus d'évolution notable entre 120 et 240 mL/min. Nous pouvons supposer par conséquent que 28 torr constituent une limite pour ce type de montage expérimental (guide d'onde adapté à une cavité parallélépipédique de type Moreau, réacteur de 2 cm de diamètre).

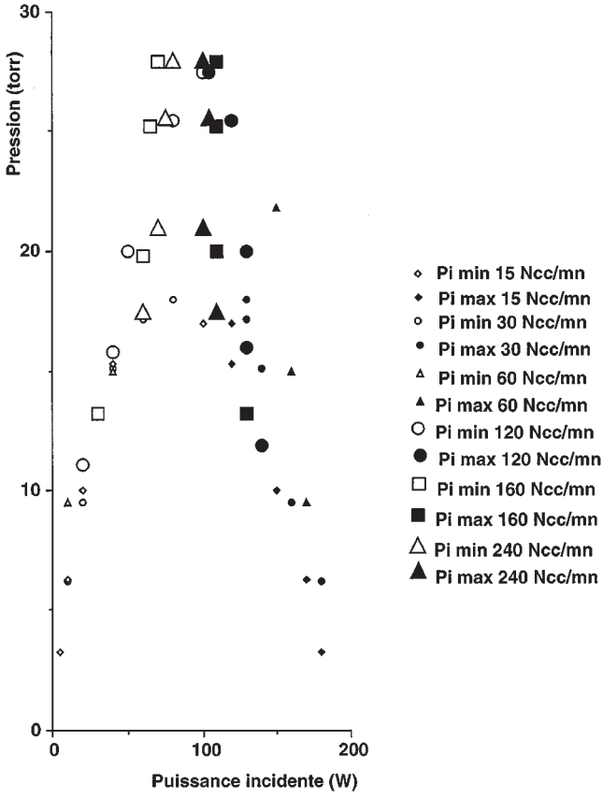
Influence du temps de passage

Le temps de passage des gaz dans le réacteur est donné par la relation

$$[1] \qquad \tau = V/QE$$

© 1998 CNRC Canada

Fig. 3. Recherche des limites de stabilité du plasma : puissances incidentes minimales et maximales admissibles en fonction des conditions de débit et de pression de méthane dans le réacteur.



avec *V,* volume du réacteur, ici pris arbitrairement comme la portion du tube en quartz passant à l'intérieur du guide d'ondes. Cette définition présente le défaut de ne guère tenir compte de la «réalité plasma», dans la mesure où la zone lumineuse n'est pas toujours la même en fonction des conditions de manipulation. Elle permet au moins d'avoir une base de calcul pour étudier ce paramètre «temps de passage». QE est le débit volumique du méthane à l'entrée du réacteur, pris à la pression d'entrée des gaz.

Nous nous sommes placés à une pression de 20 torr (pression mesurée sans plasma à l'entrée du réacteur), et avec une puissance incidente fixe de 80 W. Dans ces conditions nous avons pu faire varier le débit de méthane entre 40 et 150 NmL/min, ce qui correspondait à des temps de passage allant de 0,15 s à 0,60 s. (NmL signifie mL mesuré à 273 K, 1 atm.)

Les résultats obtenus en faisant varier le temps de passage des gaz dans le réacteur plasma sont rassemblés sur les courbes des figures 4 (pour la conversion et le rendement global en hydrocarbures en C_2) et 5 (pour les rendements respectifs en acétylène, éthylène et éthane).

La conversion du méthane croît en fonction du temps de passage de manière quasi-linéaire à partir d'une valeur de l'ordre de 0,15 s. Il n'a pas été possible de faire des points à de très faibles temps de passage, mais l'allure de la courbe laisse supposer qu'on a un «démarrage» très rapide de la réaction, ce qui semble compatible avec ce qu'on sait des milieux plasmas (milieux à forte réactivité).

Fig. 4. Conversion du méthane et rendement en hydrocarbures en C_2 en fonction du temps de passage. P = 20 torr; P_i = 80 W.

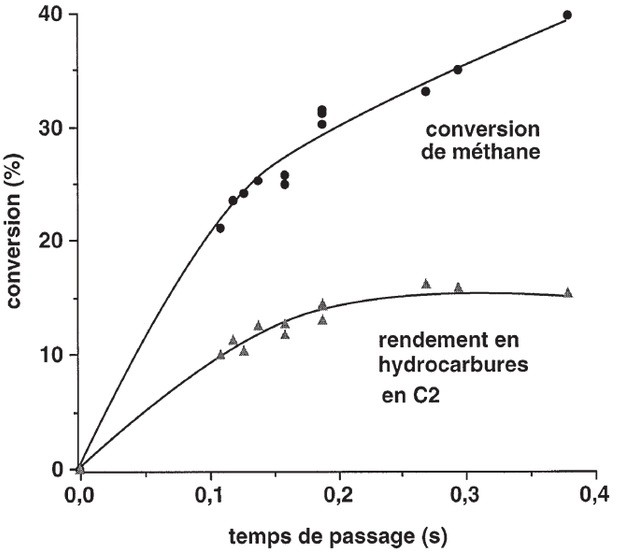


Fig. 5. Rendement en éthane, éthylène et acétylène en fonction du temps de passage. P = 20 torr; P_i = 80 W.

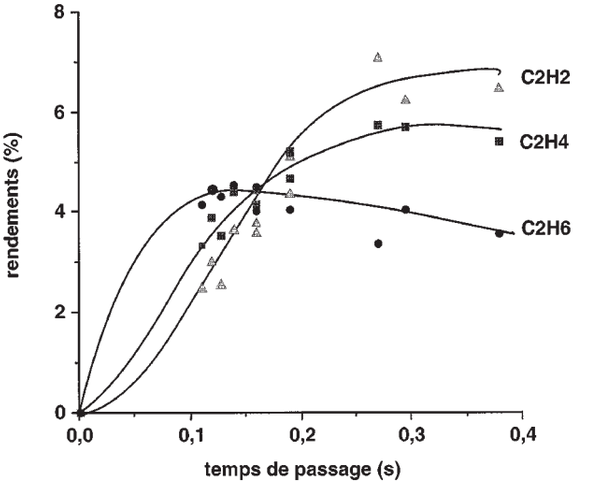

Le rendement global en hydrocarbures C_2 croît également de façon quasi-linéaire jusqu'à environ 0,2 s, puis il semble atteindre une sorte de palier. La conservation en carbone et en hydrogène est d'autant meilleure que le temps de passage est plus court. Cette évolution s'explique par la formation accrue de produits lourds (goudrons) quand le temps de passage augmente.

La figure 5 qui donne en fonction du temps de passage les rendements respectifs en acétylène, éthylène et éthane permet de voir que l'éthane est le produit majoritaire pour de faibles temps de passage, et que l'éthylène et l'acétylène deviennent ensuite prédominants. Les valeurs des pentes à l'origine paraissent a priori trop fortes pour affirmer que l'éthylène et l'acétylène sont des produits secondaires. Mais il est difficile de trancher car nous n'avons pas pu obtenir des temps de passage inférieurs à 0,1 s.

© 1998 CNRC Canada

Fig. 6. Rendement en éthane, éthylène et acétylène en fonction de la puissance incidente. P = 9,5 torr; débit = 60 mL/min.

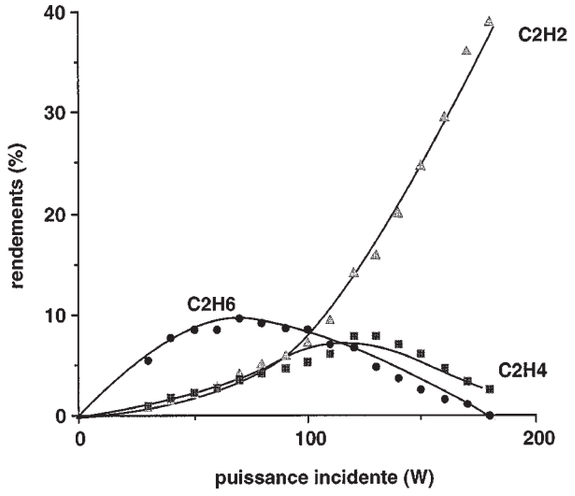

Fig. 7. Bilan en carbone : conversion du méthane, rendement en hydrogène et en acétylène en fonction de la puissance incidente. P = 9,5 torr; débit = 60 mL/min.

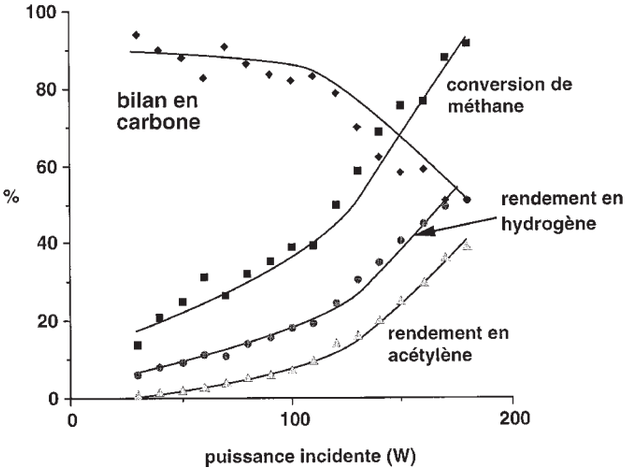

Les rendements obtenus en hydrocarbures C_2 sont de l'ordre de 14 % pour des temps de passage allant de 0,3 à 0,5 s.

Parallèlement, quelques mesures ont été faites concernant la formation d'hydrocarbures en C_3 ou en C_4. Nous avons ainsi pu constater la présence de propène, d'allène et de propyne, ainsi que des traces d'hydrocarbures en C_4. Les meilleurs rendements en hydrocarbures en C_3 (3,65 % au total) ont été obtenus dans des conditions expérimentales assez douces (P_i = 80 W, t = 0,045 s, D = 100 NmL/min). Nous pouvons supposer que dans des conditions plus dures les hydrocarbures en C_3 qui se forment sont très vite eux-mêmes polymérisés en goudrons sur les parois et n'apparaissent donc pas dans les bilans. La formation dans ce cas de figure de quantités importantes d'acétylène corrobore cette hypothèse (dans la mesure où l'acétylène peut être considéré comme un précurseur d'aromatiques).

Influence de la puissance incidente

Pour mener cette étude nous nous sommes placés dans des conditions expérimentales telles que l'amplitude de puissance accessible soit maximale. La pression choisie était de 9,5 torr et le débit de 60 NmL/min, ce qui nous permettait de faire varier la puissance incidente entre 30 et 180 W.

La figure 6 montre en fonction de la puissance incidente les rendements en hydrocarbures en C_2.

Quand nous rassemblons sur un même graphique (fig. 7) les variations de la conversion de méthane, du rendement en acétylène et en hydrogène et du bilan en élément carbone en fonction de la puissance incidente, il apparaît une variation très nette dans la pente des différentes courbes pour une puissance incidente d'environ 110 W. À partir de cette valeur nous pouvons remarquer un accroissement de la vitesse de conversion du méthane, en même temps qu'une augmentation plus rapide des quantités d'acétylène et d'hydrogène formés. Tout le méthane converti ne se transforme pas en hydrocarbures légers, ce qui explique la diminution plus rapide du pourcentage de l'élément carbone retrouvé dans le bilan de matière.

Nous pouvons en déduire que cette valeur de puissance incidente correspond, dans les conditions expérimentales choisies, à l'apparition des réactions de «troisième stade» selon Back et Back (10), c'est-à-dire à la formation de l'acétylène et des produits formés par polymérisation des hydrocarbures en C_2.

Le bilan en hydrogène est toujours meilleur que celui en carbone. Ceci est en accord avec le fait que le dépôt de goudrons formé sur les parois est beaucoup plus riche en carbone qu'en hydrogène.

Les rendements obtenus en C_2 sont très intéressants par rapport à ceux obtenus par les méthodes classiques. Nous obtenons à forte puissance plus de 40 % de rendement global en C_2, avec cette réserve qu'il y a une forte proportion d'acétylène alors qu'il serait sans doute préférable, pour une utilisation industrielle en aval, d'obtenir de l'éthylène.

Notons toutefois que ces résultats sont obtenus à relativement faible pression (9,5 torr). À titre d'exemple nous avons tracé pour chacun des hydrocarbures en C_2 les rendements en fonction de la puissance incidente pour des pressions successives de 9,5, 15,1, et 20 torr (figs. 8 à 10). Nous pouvons voir que pour C_2H_6 et C_2H_4 les rendements obtenus diminuent avec la pression, alors que le rendement en C_2H_2 est indépendant de ce paramètre, au moins dans le domaine étudié.

Les figures 9 et 10 montrent également de façon assez claire que les optima de rendements correspondent à des puissances incidentes plus élevées pour C_2H_4 que pour C_2H_6. En ce qui concerne C_2H_2 (fig. 8), l'optimum de rendement, s'il existe, n'est même pas atteint dans le cadre de nos conditions expérimentales. Ce glissement vers les fortes puissances des optima de rendement pourrait accréditer l'hypothèse d'un schéma de déshydrogénations successives du type de celui de Back et Back.

Influence de la pression et du débit de méthane

Nous nous sommes placés à une puissance incidente constante et nous avons étudié, pour 5 débits compris entre 15 et 240 NmL/min, les résultats obtenus en faisant varier la pression dans le réacteur. Le réglage de la pression s'effectuait à

© 1998 CNRC Canada

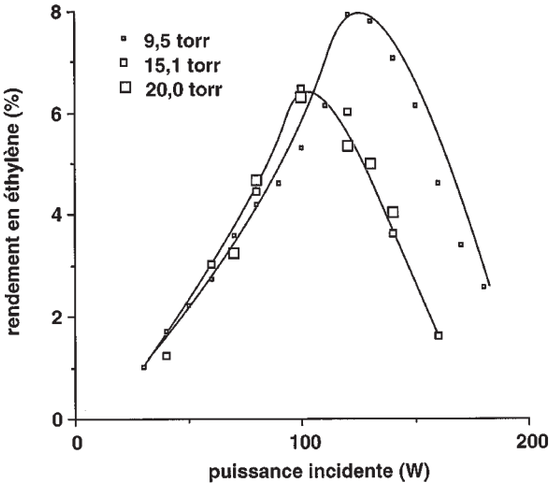

Fig. 10. Rendement en éthane en fonction de la puissance incidente pour des pressions de 9,5, 15,1 et 20 torr; débit = 60 mL/min.

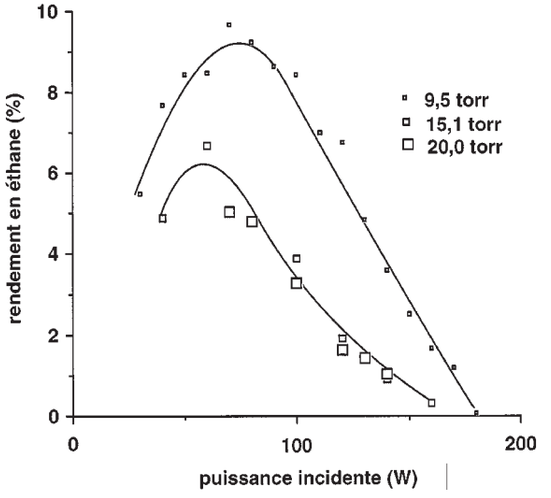

Fig. 11. Rendement en acétylène en fonction de la pression pour différents débits P_i = 80 W.

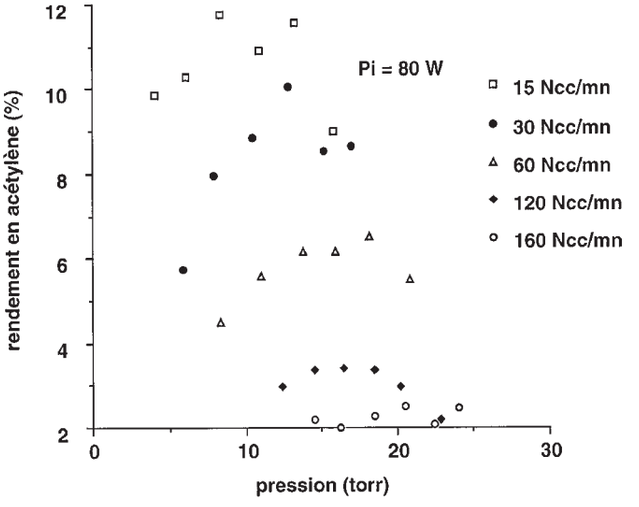

l'aide des vannes situées en aval de la section de prélèvement.

Compte tenu des résultats donnés figure 3, nous avons choisi P_i = 80 W. Cette valeur de la puissance incidente est en effet celle qui nous permettait d'étudier la plus grande amplitude de pression pour chacun des débits.

Nous avons ensuite calculé à diverses pressions les rendements obtenus pour les différents hydrocarbures en C_2 : C_2H_2 (fig. 11), C_2H_4 (fig. 12) et C_2H_6 (fig. 13).

Lorsque le débit augmente et à pression constante, les rendements en C_2H_2 et en C_2H_4 diminuent, ce qui correspond bien à l'effet produit à la fois par une diminution du temps de passage (voir la figure 5) de la puissance incidente (voir la figure 6), à condition dans ce dernier cas de se trouver pour C_2H_4 avant l'optimum de rendement. Le rendement en C_2H_6 augmente par contre légèrement. D'après les figures 5 et 6, cela veut dire que nous nous trouvons alors dans la partie descendante de la courbe, à droite de l'optimum de rendement en éthane.

Si nous nous plaçons désormais à un débit fixé, les rendements de C_2H_2 et de C_2H_4 présentent un maximum en fonction de la pression. La décroissance des rendements obtenus quand la pression augmente s'explique aisément dans la mesure où la puissance disponible restant constante, ceci correspond à une baisse de la quantité d'énergie disponible par molécule, donc à un moindre avancement de la réaction. D'autre part, la réduction du libre parcours moyen des électrons les rend moins énergétiques, ce qui contribue à réduire la constante de vitesse pour les collisions inélastiques qui sont à l'origine de la formation des radicaux libres. Il est plus délicat d'expliquer pourquoi dans un premier temps une augmentation de la pression dans le réacteur provoque une

© 1998 CNRC Canada

Fig. 12. Rendement en éthylène en fonction de la pression pour différents débits P_i = 80 W.

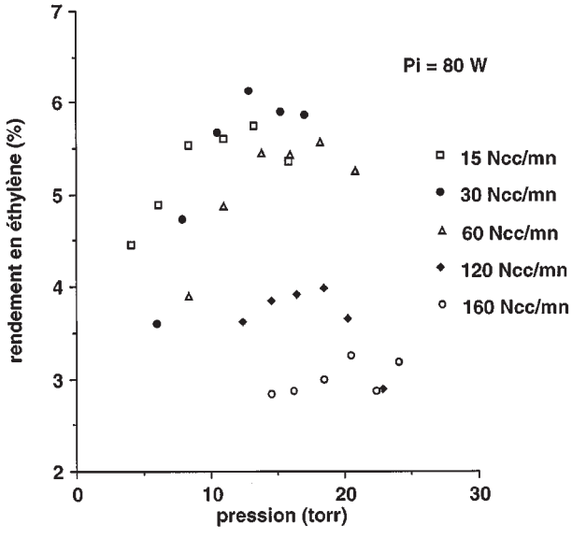

Fig. 13. Rendement en éthane en fonction de la pression pour différents débits P_i = 80 W.

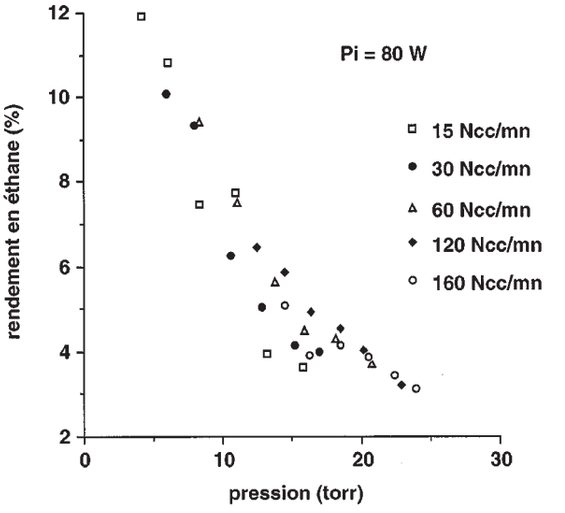

amélioration des rendements en C_2H_2 et en C_2H_4. Nous pouvons toutefois supposer que les réactions de déshydrogénation se produisent à beaucoup plus faible température et donc hors de la zone plasma. L'augmentation de la pression augmente le temps de passage et la concentration des radicaux libres dans la partie du réacteur chauffée par conduction, et donc favorise dans un premier temps la formation d'acétylène et d'éthylène. L'existence de deux effets contraires explique l'allure «en cloche» obtenue pour les tracés des rendements.

Pour les forts débits l'évolution de la pression semble être de moins en moins déterminante dans le cas de C_2H_2 et de C_2H_4. Si nous nous rapportons aux courbes donnant le rendement en fonction de la puissance incidente (fig. 6), nous constatons que pour de faibles puissances incidentes — ce qui correspond à de forts débits — la pente de la courbe obtenue est faible, ce qui est cohérent avec notre observation.

D'autre part, une augmentation de la pression pour un débit fixé se traduit par une décroissance continue du rendement en C_2H_6. L'absence d'optimum peut s'expliquer de la façon suivante : l'augmentation de la pression se traduit, comme nous l'avons déjà vu, premièrement par une diminution du libre parcours moyen des électrons et donc par une diminution de la conversion de méthane, deuxièmement par une augmentation du temps de passage des molécules dans le réacteur, défavorable à la formation d'éthane. Ainsi pouvons-nous expliquer que d'après la figure 13 le rendement en éthane soit d'autant plus élevé que la pression dans le réacteur est faible.

Interprétation mécanistique sommaire

De nombreux travaux ont déjà été réalisés concernant les mécanismes réactionnels du méthane en milieu plasma. Nous pouvons très brièvement résumer la situation en disant que la réaction du méthane en milieu plasma obéit vraisemblablement à (*i*) un mécanisme ionique en l'absence d'hydrogène (les conditions favorables se retrouvant soit au tout début de la réaction dans le cas d'un plasma de méthane pur, soit avec une forte dilution d'argon, gaz porteur de charge qui offre en plus l'avantage de favoriser ce type de réaction); (*ii*) un mécanisme radicalaire dès que la concentration d'hydrogène devient suffisamment élevée, c'est-à-dire à partir d'un certain avancement de la réaction pour un plasma de méthane pur ou dès le début dans le cas d'un plasma méthane–hydrogène (travaux de Okeke et Stori (11)).

Les travaux d'Hiraoka, Aoyama et Morise (12) qui ont été, à notre connaissance, parmi les premiers auteurs à établir un mécanisme complet concernant la réaction du méthane en milieu plasma, favorisent également l'hypothèse d'un mécanisme radicalaire. Ces auteurs ont ajouté à un plasma radio-fréquence de méthane pur successivement de l'iode (piège à radicaux) et de l'ammoniac (piège à ions). Les résultats obtenus montrent que le rendement en éthane décroît rapidement quand la quantité d'iode ajoutée dans le plasma de méthane augmente. Les rendements en éthylène et en acétylène sont par contre à peu près insensibles à l'ajout d'iode, mais les précurseurs de ces hydrocarbures sont considérés être moins sensibles à l'iode. Par contre, aucun des trois hydrocarbures éthane, éthylène ou acétylène n'est sensible à un ajout d'ammoniac, ce qui semble indiquer que le mécanisme de transformation du méthane dans un plasma froid est principalement de nature radicalaire.

Le mécanisme proposé par ces auteurs possède les caractéristiques suivantes : (*i*) les quatre radicaux formés à partir du méthane (CH_3, CH_2, CH, C) sont pris en compte, mais le radical CH_3 est considéré comme très minoritaire (13); (*ii*) nous avons toujours des déshydrogénations successives, mais elles s'opèrent ici directement à partir des radicaux libres et non de leurs produits de recombinaison, contrairement à ce qui a été établi dans le cadre du mécanisme de Back et Back.

[2] $$CH_3 \rightarrow CH_2 \rightarrow CH \rightarrow C$$

(*iii*) Les hydrocarbures en C_2 se forment ensuite par réaction des radicaux libres avec le méthane de départ. Ce sont donc

© 1998 CNRC Canada

tous des produits primaires de la réaction, au sens cinétique du terme.

Le mécanisme proposé par Hiraoka et al. pour la formation des hydrocarbures en C_2 est schématisé ci-dessous. Il est important de préciser qu'il s'agit là d'un mécanisme simplifié ne pouvant donner lieu qu'à une première approche mécanistique. Les mécanismes réels sont sûrement beaucoup plus complexes.

Initiation

Les travaux de Mahan et Mandal (14) suggèrent que CH_2 et H_2 sont les principaux produits obtenus lors de la décomposition du méthane par irradiation. Ceux de Magee (15) permettent de penser que le méthane excité se décompose en ($CH_2 + H_2$) dans 85 % des cas et en ($CH_3 + H$) dans 15 % seulement.

[3] $CH_4 = CH_3 + H$ (15%)

[4] $CH_4 = CH_2 + H_2$ (85%)

Formation de l'éthane

[5] $^1CH_2 + CH_4 = (C_2H_6)^* = 2\ CH_3$

$k = 1{,}9 \times 10^{-12}$ cm^3 molécule^{-1} s^{-1} (Laufer)

Telle qu'elle est écrite dans ce mécanisme, la formation d'une molécule d'éthane nécessite sa stabilisation par collision avec une troisième molécule. La formation d'éthane devrait donc être favorisée quand la pression d'expérience augmente, or la figure 13, que nous avons déjà commentée, montre que c'est le contraire qui se produit. Il est possible que plusieurs influences contraires s'exercent : il se forme certes davantage de molécules d'éthane grâce aux meilleures possibilités de stabilisation collisionnelle, mais des conditions plus dures règnent dans le plasma (une pression plus élevée entraîne une température plus forte, en même temps qu'un temps de passage plus long des molécules dans la zone réactive). Dans ces conditions les molécules d'éthane ont tendance à se déshydrogéner très rapidement suivant les processus classiques de Back et Back (10).

Formation de l'éthylène

[6] $CH + CH_4 = (C_2H_5)^* = C_2H_4 + H$

$= C_2H_5$

$k = 5\times10^{-11}(\exp 200/T)\text{cm}^3\,\text{molécule}^{-1}\text{s}^{-1}$(Warnatz))

Formation de l'acétylène

[7] $C + CH_4 = (C_2H_4)^* = C_2H_2 + H_2$

Qualitativement, ce mécanisme peut rendre compte de l'apparition successive des hydrocarbures en C_2 quand la puissance incidente augmente. Il permet également de justifier les paliers observés en fonction du temps de passage pour les différents rendements.

(*i*) Lorsque les conditions expérimentales (pression, puissance incidente) sont fixées, l'approximation de l'état quasi-stationnaire (AEQS), qui constitue la base des calculs de cinétique chimique, permet d'affirmer que la concentration des différentes espèces activées reste constante. Chacun des hydrocarbures en C_2 étant formé séparément par réaction d'un radical sur une molécule de méthane, nous pouvons alors comprendre la relative stabilité observée pour l'éthane, l'éthylène et l'acétylène en fonction du temps de passage (fig. 5) dans la mesure où ces molécules apparaissent et disparaissent de façon indépendante.

(*ii*) D'autre part, une augmentation de la puissance incidente se traduit par un déplacement vers la formation des radicaux les plus déshydrogénés, eux-mêmes à l'origine de la formation d'éthylène puis d'acétylène. Le mécanisme d'Hiraoka et al. permet donc également d'expliquer l'allure des courbes obtenues en fonction de P_i (fig. 6).

Il convient de noter, comme suggéré par un des rapporteurs, que le mécanisme d'Hiraoka et al. ne prend pas en compte des réactions classiques conduisant également à la formation d'hydrocarbures en C_2.

[8] $CH_3 + CH = C_2H_6$

$k = 3{,}98 \times 10^{-11}$ cm^3 molécule^{-1} s^{-1} (Baulch)

[9] $CH_3 + {}^3CH_2 = C_2H_4 + H$

$k = 7 \times 10^{-11}$ cm^3 molécule^{-1} s^{-1} (Laufer)

[10] $^3CH_2 + {}^3CH_2 = C_2H_2 + H_2$

$k = 5{,}3 \times 10^{-11}$ cm^3 molécule^{-1} s^{-1} (Laufer)

Les données partielles dont on peut disposer (cf. valeurs données ci-dessus) suggèrent que les réactions [8], [9] et [10] ont des constantes de vitesse comparables à celles des réactions [5], [6] et [7] proposées par Hiraoka et al. On tient compte pour écrire la réaction [5] du fait que dans un plasma CH_2 se trouve excité électroniquement et donc sous la forme $^1CH_2$.

Les réactions proposées par Hiraoka doivent donc être largement prépondérantes dans la mesure où la concentration en CH_4 est très supérieure dans tous les cas à celle en radicaux CH_x (puisqu'il s'agit d'un plasma froid).

Étude des ajouts

Nous nous sommes ici intéressés aux résultats obtenus en ajoutant au méthane des quantités plus ou moins importantes d'hydrogène, d'oxygène ou de dioxyde de carbone.

Les travaux déjà réalisés au laboratoire sur le couplage thermique du méthane (5) avaient montré que la dilution par l'hydrogène permettait d'accroître le rendement d'hydrocarbures en C_2 et de diminuer la formation de coke. Nous avons pu vérifier que la même influence se retrouvait en milieu plasma, et de façon d'autant plus nette que la puissance incidente était élevée. Toutefois à forte dilution nous avons observé que les rendements en hydrocarbures en C_2 diminuaient à cause de la moindre puissance micro-ondes disponible par mole de méthane.

L'ajout de faibles quantités d'oxygène dans le plasma n'a pas par contre permis de mettre en évidence un effet accélérateur important comme cela avait été le cas pour la pyrolyse d'alcanes en C_2–C_4 (16).

Les résultats les plus intéressants ont été obtenus avec des ajouts de dioxyde de carbone. Pour un mélange équimolaire CH_4–CO_2 nous avons observé à la fois une augmentation de

© 1998 CNRC Canada

la conversion du méthane et du rendement en hydrocarbures en C_2, d'autant plus marquée que la puissance incidente était élevée (avec P_i = 160 W et DCH$_4$ = 100 Ncc/min, le rendement global en hydrocarbures en C_2 était égal à 34 % avec du méthane pur et 41 % avec un mélange équimolaire CH_4–CO_2). Il est à noter que l'effet positif de ces ajouts pourrait présenter un intérêt du point de vue de l'environnement dans la mesure où les fortes quantités de dioxyde de carbone dégagées, en particulier par les combustions au niveau industriel, posent de façon de plus en plus aiguë le problème de l'effet de serre.

Discussion — comparaison avec les résultats d'autres auteurs

Dans la présente étude, les produits pris en compte dans les analyses ont été le méthane, les hydrocarbures en C_2 et l'hydrogène (avec dans certains cas particuliers la recherche d'hydrocarbures en C_3 et en C_4, qui se sont révélés être formés en faibles quantités).

Les bilans obtenus dans le cas du plasma de méthane pur pour les éléments carbone et hydrogène s'avèrent satisfaisants lorsque les conditions d'excitation du méthane sont relativement douces (faible puissance micro-ondes incidente, donc conversion limitée). Il apparaît bien que les hydrocarbures en C_2 et l'hydrogène sont les produits formés de façon majoritaire dans ces conditions expérimentales.

Par contre, pour des conditions d'excitation plus sévères, c'est-à-dire avec des conversions plus élevées, les bilans de matière deviennent de moins en moins bons, en particulier en ce qui concerne l'élément carbone. Parallèlement nous observons un accroissement de la vitesse d'encrassement du réacteur et du piège en silice par des produits solides riches en carbone (goudrons et coke).

Ces produits se forment principalement par polymérisation de l'acétylène soit en chaînes carbonées beaucoup plus longues, soit en noyaux aromatiques.

En fait, nous avons dû nous contenter d'un bilan simplifié, compte tenu de la complexité d'une analyse complète de l'ensemble des produits, y compris les difficultés liées au piégeage de certaines fractions lourdes. De plus, il faudrait inclure dans ces bilans les dépôts de carbone sur les parois du réacteur, ce qui impliquerait leur transformation en CO_2 et le dosage correspondant.

Compte tenu du caractère exploratoire de ce travail, il nous a paru prioritaire de mettre au point le montage expérimental et surtout de fixer les conditions de formation d'un plasma stable. Un autre objectif essentiel était de réaliser une étude paramétrique aussi complète que possible de manière à déterminer les conditions expérimentales permettant d'obtenir des rendements intéressants en hydrocarbures en C_2.

Il est certain également qu'une analyse plus poussée du mécanisme réactionnel serait intéressante, en particulier au niveau de l'identification des processus élémentaires et de la nature des intermédiaires réactifs. De ce point de vue, l'utilisation de méthodes spectroscopiques adaptées pourrait être un moyen intéressant d'identification de ces espèces. La connaissance suffisamment précise d'un mécanisme réactionnel est un des moyens d'amélioration d'un procédé car elle permet d'agir sur les processus importants. C'est par exemple une des approches qui a été développée dans le cas du couplage oxydant du méthane.

Un autre point que nous n'avons pas abordé dans cette étude compte tenu de l'approche plus «chimique» que nous avons retenue est la comparaison de l'efficacité de différentes cavités et c'est effectivement un aspect qui pourrait être abordé avec profit.

Au cours de cette étude, nous avons eu connaissance de travaux voisins sur la dimérisation du méthane par plasmas micro-ondes : (*i*) les travaux d'Oumghar et coll. sur l'activation du méthane à l'aide d'un plasma différé d'air ou d'azote (8, 17); (*ii*) ceux d'Huang et Suib sur la dimérisation du méthane par un plasma direct (18, 19); (*iii*) ceux de Rusanov sur la production d'hydrogène par pyrolyse de gaz naturel dans un réacteur plasma micro-ondes (20).

Travaux d'Oumghar et al. (8, 17)

Le travail effectué par A. Oumghar et al. était basé sur l'excitation du méthane à l'aide d'un plasma différé d'air ou d'azote. Le système de création du plasma est très voisin de celui que nous avons employé (applicateur micro-ondes avec cavité résonnante parallélépipédique). Toutefois la méthode d'excitation du méthane n'est pas la même.

Dans notre montage le méthane était introduit à l'entrée du réacteur pour former un plasma et nous pouvions considérer que la zone réactionnelle était constituée par la portion du tube à décharge située à l'intérieur de la cavité micro-ondes. Le domaine de puissance incidente était limité à environ 180 W dans le meilleur des cas pour éviter le cokage du réacteur et la pression de méthane pouvait varier entre 5 et 25 torr.

Dans le montage par plasma différé le méthane est introduit dans la post-décharge d'un plasma d'azote ou d'air. Le problème du cokage est éliminé car les gaz plasmagènes utilisés ne créent pas d'encrassement. La puissance plasma utilisée peut donc être beaucoup plus élevée (de l'ordre de 400 à 800 W). C'est du reste nécessaire dans la mesure où le méthane n'est excité que de manière indirecte. Les conditions de la réaction sont de toute façon beaucoup plus douces et aucune formation de produits lourds n'est observée.

Chacune des deux installations possède donc ses paramètres propres. Dans le cas du plasma différé il est possible d'étudier l'influence sur les résultats de la distance d'introduction du méthane par rapport au guide d'ondes; par contre il devient impossible de déterminer de façon exacte la zone de réaction et donc de calculer un temps de passage.

Il serait assez fastidieux de faire ici une comparaison détaillée en faisant varier les différents paramètres communs (débit de méthane, pression dans la zone réactionnelle et puissance absorbée par le gaz).

Nous pouvons toutefois retenir que l'injection de méthane en post-décharge d'un plasma d'azote conduit à des résultats voisins de ceux obtenus avec notre montage, tout en nécessitant des puissances micro-ondes fortement supérieures. Pour des pressions de l'ordre de 10 torr dans les deux cas, on obtient avec un plasma direct (P_i = 80 W) environ 20 % de rendement en hydrocarbures en C_2 pour une conversion de 40 % du méthane de départ, et en post-décharge d'un plasma d'azote (P_i = 800 W), 14 % de rendement pour une conversion de 29 %. Dans les deux cas les sélectivités obtenues en hydrocarbures en C_2 sont de l'ordre de 50 %.

© 1998 CNRC Canada

Par contre, l'injection de méthane en post-décharge d'un plasma d'air conduit à des conversions beaucoup plus fortes (de 60 à 80 %). Mais la sélectivité obtenue en hydrocarbures en C_2 est dans ce cas beaucoup plus faible (entre 16 et 34 %) car il se forme des quantités importantes de CO. Ceci nous conduit à penser que l'utilisation d'un plasma d'air pour exciter le méthane paraît être mieux adaptée à la fabrication de gaz de synthèse $CO + H_2$ et pourrait trouver des applications telles que le réformage embarqué de gaz naturel pour l'alimentation de piles à combustibles.

Il est intéressant également de considérer que la conversion de méthane varie de façon beaucoup plus nette avec la puissance absorbée dans le cas d'un plasma direct. Nous pouvons supposer que dans le cas d'un plasma différé les pertes augmentent beaucoup plus rapidement.

Travaux de Huang et Suib (18, 19)

Ces travaux se rapprochent beaucoup des nôtres puisqu'il s'agit d'une étude en plasma direct avec une puissance de 100 W à une fréquence fixe de 2,45 GHz, les pressions de méthane étant de l'ordre de 10 à 100 torr. Deux types de cavités ont été essayés : le type Beenakker (21) et le type Evenson (22). Il a été observé, en accord avec nos résultats, que le type la conversion du méthane dépend de la pression, de la puissance et du débit.

Un certain nombre d'observations se rapprochent des nôtres, y compris sur l'aspect visuel du plasma; des problèmes de cokage ont également été observés.

Cependant, les auteurs n'ont pas séparé l'éthylène de l'acétylène et il n'est donc pas possible de confirmer les observations faites sur la répartition des produits.

Des sélectivités en C_2 de l'ordre de 35 % pour des conversions de l'ordre de 25 % ont été atteintes. Les résultats obtenus suggèrent aussi aux auteurs que l'éthane serait le produit primaire et que les autres espèces en C_2 seraient de nature secondaire, alors que d'après le mécanisme de Hiraoka, Aoyama et Morise, les trois hydrocarbures en C_2 seraient de nature primaire, parce que formés par réaction entre une molécule de méthane et un radical.

Les résultats obtenus par ces auteurs suggèrent que la cavité Beenakker est la plus efficace. Des conversions de l'ordre de 90 % ont été atteintes alors que, dans notre cas (cf. fig. 4), nous nous sommes bornés à 40 % avec des rendements de l'ordre de 15 % en C_2. Huang et Suib ont atteint des sélectivités en C_2 pouvant atteindre 50 %, avec une sélectivité maximale pour une conversion du méthane de l'ordre de 20 %.

Travaux de Rusanov (20)

Ces travaux menés à l'institut Kurchatov concernent un procédé de production d'hydrogène par pyrolyse de gaz naturel dans un réacteur plasma. Un montage pilote fonctionne à ce jour sur le site et les auteurs affirment que ce procédé serait très économe en énergie (0,3 kWh (1 kWh = 3,6 MJ) par m^3 d'hydrogène), mais il se pose le problème de l'utilisation du noir de carbone ainsi formé.

Conclusion

Les résultats et comparaisons précédents montrent que le méthane peut être converti en hydrocarbures en C_2 en plasmas micro-ondes avec des rendements intéressants, comparables avec ceux obtenus par d'autres procédés. Il faut également souligner qu'à ce stade de nos recherches, nous n'avons pas cherché à optimiser la conception de la cavité résonnante. Le caractère exploratoire de notre travail a fait que nous avons surtout voulu déterminer les possibilités et les limites de l'activation par plasma froid micro-ondes.

En fait, les problèmes qui restent posés à ce stade paraissent relever de deux domaines : fondamental et appliqué.

Sur le plan fondamental, il apparaît clairement qu'il serait utile de mieux connaître le mécanisme réactionnel, en particulier la nature et l'état des espèces actives propageant la réaction, ainsi que les interactions électrons-matière. Si dans un plasma à pression réduite, la température du gaz est inférieure à celle des électrons en raison de l'état hors équilibre, il serait intéressant d'avoir une meilleure connaissance de ces paramètres. Les aspects énergétiques présenteraient également de l'intérêt.

Sur le plan appliqué, il paraît utile de comparer ce procédé aux deux procédés de conversion directe du méthane qui ont déjà été mentionnés dans l'introduction : le couplage oxydant et le couplage thermique. Comme nous l'avons rappelé, le principal inconvénient du couplage oxydant est son rendement limité à 25 % environ par passage; compte tenu des séparations et recyclages nécessaires, ce rendement est insuffisant pour permettre l'industrialisation du procédé. Il faut noter également que la formation parallèle de CO_2 est aussi un inconvénient sérieux.

Quant au couplage thermique, ses principaux inconvénients sont le niveau des températures nécessaires (1200°C) d'où des problèmes de tenue des matériaux et l'utilisation d'un ballast d'hydrogène. Par ailleurs, il se forme également du coke et de nombreux produits indésirables, dont des fractions relativement lourdes, précurseurs des suies et des dépôts carbonés.

Si l'on se reporte aux résultats obtenus dans la présente étude, l'excitation du méthane en plasma froid a permis d'obtenir des rendements atteignant 40 % d'hydrocarbures en C_2. Toutefois, les quantités de goudrons et de coke qui se forment simultanément constituent un inconvénient proche de celui mentionné pour le couplage thermique. L'acétylène qui, dans les deux cas, est un produit prépondérant de la réaction présente moins d'intérêt industriel que l'éthylène.

Il faut surtout revenir sur le problème de la pression d'expérience. Alors que dans les procédés de couplage thermique ou oxydant la réaction a lieu à pression atmosphérique (dilution par l'hydrogène dans le premier cas, par l'azote dans le second), la pression totale de méthane dans le plasma ne peut guère dépasser quelques dizaines de torr, condition sine qua non pour limiter le phénomène de cokage.

Signalons toutefois que ceci ne constitue pas un obstacle rédhibitoire, et que certains procédés industriels fonctionnent déjà sous pression réduite. Nous pouvons citer par exemple la distillation sous vide utilisée pour séparer les fractions lourdes dans les installations de raffinage.

Malgré ces limitations et réserves, la réaction de dimérisation du méthane par plasmas micro-ondes mérite d'être étudiée et développée, tant d'un point de vue fondamental que d'un point de vue plus appliqué. Les potentialités de la technique sont réelles et on peut envisager d'autres applica-

© 1998 CNRC Canada

tions. Les travaux de l'Institut Kurchatov paraissent à cet égard intéressants, d'autant qu'ils ont été étendus au traitement de l'hydrogène sulfuré (pilote de la raffinerie d'Orenburg dans l'Oural). De plus ces procédés sont facilement interruptibles et constituent un moyen intéressant d'utilisation de l'énergie électrique dans des procédés chimiques.

Remerciements

Ce travail a été financé par Electricité de France, Direction des Etudes et des Recherches. Les auteurs remercient Monsieur Joseph Chapelle, Professeur à l'Université d'Orléans (UMR 6606 CNRS) pour ses conseils et des discussions intéressantes et fructueuses.

Synthèse critique de la caractérisation électrochimique de zéolithes et d'aluminophosphates chimiquement modifiés

Lionel Roué, Emmanuel Briot et Fethi Bedioui

Résumé : L'électrochimie a montré sa capacité à nous renseigner sur le comportement rédox des zéolithes et tamis moleculaires chimiquement modifiés. Cependant, la caractérisation par voltampérométrie cyclique de ces nouveaux matériaux souffre de certaines zones d'ombre telle que l'influence de l'électrolyte support, du solvant, du mode de fixation de l'espèce électroactive et de son encombrement sur la réponse électrochimique. Aussi, avant d'entreprendre la caractérisation électrochimique de ces matériaux, il est indispensable d'analyser le processus électrochimique afin de mieux comprendre les phénomènes de compensation de charge et de transfert électronique. À cet effet, nous analyserons dans cette revue le comportement électrochimique de complexes et d'espèces électroactives se différenciant essentiellement par leur mode d'incorporation et de fixation dans le systeme microporeux des zeolithes et de certains tamis moléculaires. Bien que la nature du processus électrochimique demeure un peu confuse, il semble que les divergences d'opinion proviennent principalement du fait que les matériaux utilisés par les différentes équipes s'intéressant à ce sujet ne sont pas équivalents.

Mots clés : électrochimie, voltampérométrie cyclique, électrode modifiée, zéolithe, complexe rédox, encapsulation, tamis moléculaire, aluminophosphate.

Abstract: Zeolites that have been chemically modified by incorporating transition metal complexes in their porous network and molecular sieves chemically modified by incorporating transition metal in their framework have led to numerous applications of which the most widespread is undoubtfully catalysis. However, the catalytic activity of these inorganic compounds is still not well understood and there is a lack of evidence concerning the encapsulation efficiency of complexes within the zeolites and the location of transition metals inside the framework of molecular sieves. Numerous studies have shown that zeolite encapsulation has an influence on the redox behaviour of these complexes, such as in preventing aggregation or the dimerization process. Moreover, analysis of the electrochemical process at this type of modified electrode demonstrates solvant and electrolyte effects on the electroactivity of the encapsulated complexes. However, these different studies highlighted the unsatisfactory electrochemical accessibility of intrazeolitic or framework species. Thus, we undertake here a discussion of the different strategies reported in the literature aimed at promoting the electroactivity of these molecular materials.

Key words: electrochemistry, cyclic voltammetry, modified electrode, zeolite, redox complex, encapsulation, molecular sieve, aluminophosphate.

I. Introduction

I. 1. Généralités sur les zéolithes

Les zéolithes appartiennent à la grande famille des aluminosilicates dont font également partie les argiles. Elles sont constituées d'une structure cristalline rigide comprenant des canaux et des cavités de tailles variables. Du point de vue de la systématique, le terme de « zéolithe » ne s'applique qu'aux aluminosilicates microporeux non modifiés. En accord avec ce qui est couramment pratiqué dans la littérature, nous utiliserons le terme de « zéolithe » pour tous les aluminosilicates dont nous parlerons, qu'ils soient modifiés ou non. Nous réserverons l'utilisation du terme de « tamis moléculaire » à tous les matériaux apparentés aux zéolithes (en particulier

les aluminophosphates), dont la composition chimique est différente de celle des zéolithes. Dans le groupe de matériaux constitué par les zéolithes et les tamis moléculaires, on dénombre actuellement 40 zéolithes naturelles et environ 200 matériaux synthétiques (1–3).

La charpente des zéolithes est constituée d'un enchaînement de tétraèdres de SiO_4 et AlO_4 reliés entre eux par des sommets oxygène. Le degré formel d'oxydation des ions aluminium est de trois et leur coordinence est de quatre, ce qui implique que les tétraèdres de AlO_4 sont porteurs d'une charge négative. Pour satisfaire au principe d'électroneutralité, ces charges négatives sont compensées par des cations mobiles généralement alcalins ou alcalino-terreux. La présence de ces cations extra-réseaux confère naturellement des propriétés d'échangeur de cations à la zéolithe. La formule générale d'une zéolithe peut s'écrire de la manière suivante : $M^+{}_m\,[(AlO_2)_m(SiO_2)_n] \cdot x\,H_2O$. Dans cette formule, M^+ représente le cation extra-réseau compensateur de charge et x le nombre de molécules d'eau qui est une fonction du volume poreux de la zéolithe et de son hydrophilie. La partie entre crochet représente à proprement dit la charpente de la zéolithe. La nature du cation compensateur de charge, le rapport Si/Al, la taille des cristaux et la structure de la zéolithe sont les paramètres principaux dont dépend la stabilité de ces matériaux.

La zéolithe NaY compte parmi les plus utilisées, tant dans l'industrie que dans le cadre d'études théoriques à l'échelle du laboratoire. Sa popularité s'explique principalement par le fait que cette zéolithe a été l'une des premières à être synthétisée, et les nombreuses études qui ont été produites sur cette zéolithe ont permis d'avoir une bonne connaissance de ses propriétés physico-chimiques et de sa réactivité. De plus, les dimensions de la zéolithe NaY et notamment les diamètres d'entrée et interne de sa supercage s'accordent assez bien avec un certain nombre de complexes dont nous parlerons un peu plus loin dans ce chapitre. La figure 1 présente la structure de la zéolithe faujasite (et des zéolithes synthétiques apparentées X et Y) ainsi que quelques-unes de ses caractéristiques physico-chimiques. C'est ce matériau qui est généralement utilisé pour y incorporer des complexes de métaux de transition.

L'agencement de cette structure, comme celui de toutes les zéolithes, se fait à partir d'unités secondaires constituées d'un assemblage de polyèdres. Dans le cas de la faujasite, ces unités de base sont des cubooctaèdres (ou cage sodalite ou encore β-cage) qui sont reliés par l'intermédiaire de prismes hexagonaux. L'agencement de ces structures de base délimite un espace intérieur que l'on nomme supercage (ou α-cage) d'un diamètre interne de 13 Å et d'un diamètre d'ouverture de 7,4 Å. La maille élémentaire (ou cellule unitaire) de la zéolithe faujasite est cubique. Elle est constituée de 8 supercages et a pour formule à l'état hydraté : $Na_{56}[(AlO_2)_{56}(SiO_2)_{136}] \cdot 250\ H_2O$.

La figure 1 montre également la répartition des sites anioniques au sein de la cavité zéolithique. Certains sont localisés dans les prismes hexagonaux (SI) et d'autres au niveau des cages sodalites (SU, SI′, SII et SII′) et de la supercage (SII*, SIII, SIV et SV). Ces sites anioniques représentent bien sûr les positions privilégiées qu'occupent les cations compensateurs de charge. Cependant, l'occupation de ces sites varie en fonction de la nature du cation compensateur de charge (charge, taille), de la température et de l'état d'hydratation de la zéolithe. Les molécules polaires de petite taille telle que l'eau peuvent en effet venir se positionner à proximité de ces sites anioniques.

I. 2. Généralités sur les aluminophosphates

Historiquement, il semble que ce soit l'utilisation d'agents structurants organiques lors de la synthèse des zéolithes qui ait permis d'envisager la synthèse de tamis moléculaires dont la nature chimique et l'organisation structurale sont différentes des zéolithes classiques. L'un des groupes les plus importants de ces tamis moléculaires est sans aucun doute celui des aluminophosphates dont on dénombre une trentaine de structures différentes. C'est en 1982 que Wilson et al. (4) ont synthétisé pour la première fois un aluminophosphate microporeux et cristallin. Depuis lors, la famille des aluminophosphates (AlPO) s'est considérablement agrandie avec la synthèse de silicoaluminophosphates (notés SAPO (5)) et de métalloaluminophosphates (notés MeAPO (6)). Dans la famille des MeAPO, le métal qui substitue Al(III) ou P(V) selon les cas peut être le cobalt, le fer, le magnésium, le manganèse, le zinc, l'arsenic, le gallium, le bore, le beryllium, le germanium, le vanadium, le chrome, le lithium ou le titane, et cette liste n'est bien sûr pas exhaustive.

D'une manière similaire à ce qui existe pour les aluminosilicates, la structure des aluminophosphates est constituée de tétraèdres de AlO_4 et de PO_4 reliés entre eux par des sommets oxygène. La particularité de ces structures provient de l'exacte parité qui existe entre les ions Al(III) et les ions P(V) du réseau des AlPO. Il en résulte que la charpente de ces tamis moléculaires est neutre. De plus, les liaisons P—O—P et Al—O—Al n'existent pas dans ces matériaux. La structure des AlPO peut être appréhendée en considérant que tous les matériaux peuvent être obtenus à partir d'une construction mettant en relation des réseaux bidimensionnels (2-D), c'est à dire situés dans un plan. Ces réseaux sont bien sûr constitués de tétraèdres TO_4 dans lequel l'atome T représente indistinctement l'aluminium ou le phosphore, mais la représentation dans le plan impose de ne considérer que trois connexions.

La figure 2 représente la structure hexagonale à laquelle appartient le tamis moléculaire AlPO-5. Les atomes d'aluminium ou de phosphore se situent au niveau des sommets et les atomes d'oxygène relient entre eux ces sommets. Par soucis de clarté, les atomes d'oxygène ne sont pas représentés sur cette figure. La classification des aluminophosphates est encore plus complexe que celle des zéolithes car elle dépend de la coordinence des atomes d'aluminium. Nous ne détaillerons pas cette partie et nous retiendrons simplement que la structure AlPO-5 possède des atomes d'aluminium tétracoordonnés. Ces structures sont thermiquement très stables et peuvent résister à des températures allant jusqu'à 1000°C. La parité entre les atomes d'aluminium et de phosphore dans la structure d'AlPO-5 implique que la charpente de ce tamis est globalement neutre et qu'il ne possède donc pas de propriété d'échangeur d'ions. Les aluminophosphates possèdent donc quelques propriétés intéressantes mais ce sont les modifications apportées à ces structures qui sont à l'origine de l'engouement des chercheurs pour ces matériaux.

II. Modification chimique des zéolithes et des aluminophosphates

Malgré l'importante variété des zéolithes et des tamis moléculaires qu'il est possible de synthétiser, il arrive parfois que les caractéristiques physico-chimiques du matériau final ne correspondent pas exactement avec l'application envisagée. Pour remédier à cela, il est alors possible d'effectuer un certain nombre de modifications de ces matériaux qui peuvent intervenir pendant la synthèse ou après celle-ci.

II. 1. Modifications des zéolithes

Les modifications de la porosité, de l'acidité et de la charpente des zéolithes ont déjà été largement décrites dans la littérature (3). Notre propos s'orientera donc plus précisément vers la modification des zéolithes par incorporation de complexes de métaux de transition dans leur système poreux. En effet, dans le contexte de la catalyse, de nombreux efforts ont été fournis pour immobiliser des catalyseurs agissant habituellement en phase homogène sur des supports solides comme la silice, l'alumine ou les polymères (7, 8). Dans des conditions idéales, de tels catalyseurs hybrides combinent les avantages de la catalyse homogène (conditions douces, réactivité spécifique, etc.) et de la catalyse hétérogène tout en minimisant leurs désavantages respectifs (9). Cependant, ces catalyseurs n'ont pas toujours permis d'aboutir aux résultats escomptés, principalement à cause de leur manque de sélectivité. L'idée d'incorporer ces complexes au sein des cavités zéolithiques est donc apparue comme une solution à ce défaut de sélectivité.

Dès lors, de nombreuses équipes se sont intéressées à la modification des zéolithes par incorporation de diverses espèces telles que des cations métalliques (Ag^+, Cu^{2+}, Fe^{3+}, etc.), des clusters (Pt_5, $Pd_{10}Fe_3$, CdSe, etc.), des molécules

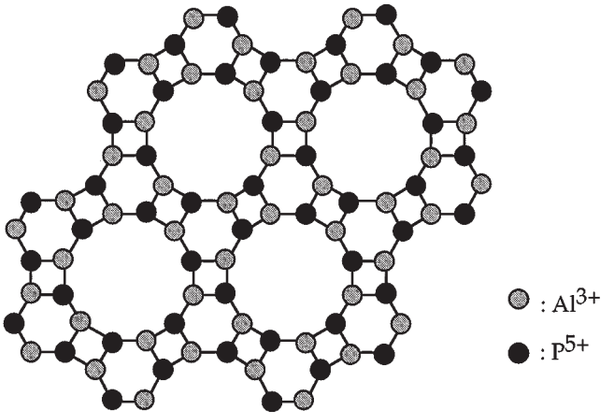
Fig. 2. Représentation de la structure hexagonale de AlPO-5. Diamètre interne des canaux : 7,4 Å. Formule d'une cellule unitaire : $Al_{12}P_{12}O_{48} \cdot qH_2O$.



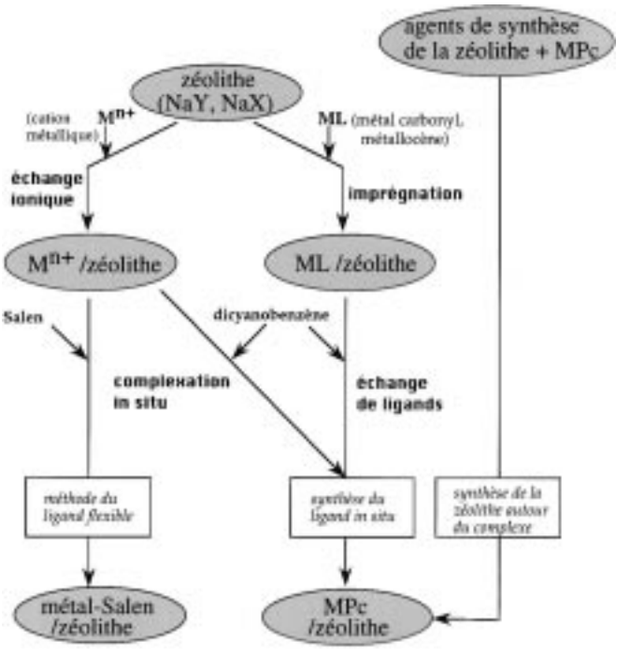
organiques (polypyrrole, méthylviologène, etc.) et des complexes organométalliques (métallocènes, métallophtalocyanines, etc.) (9–12).

Les méthodes d'incorporation des espèces au sein de la zéolithe dépendent principalement de la taille de la molécule à incorporer et de sa flexibilité. Les molécules de taille inférieure au diamètre d'ouverture des pores de la zéolithe sont incorporées par simple échange d'ions (lorsque celles-ci sont sous forme ionique) ou par adsorption en phase liquide ou gazeuse dans le cas d'espèces neutres ou lorsque la zéolithe ou le tamis moléculaire n'est pas échangeur de cation.

L'incorporation de composés dont la taille est supérieure au diamètre des ouvertures des pores de la zéolithe nécessite une méthodologie d'incorporation plus complexe que dans la cas de l'incorporation de petites molécules. Cette méthode d'incorporation est appelée « encapsulation » (néologisme inspiré de la langue anglo-saxonne et qui signifie fixation irréversible d'un complexe au sein de la cavité zéolithique). Elle a pour principe la synthèse in situ du complexe à l'intérieure des cavités de la zéolithe pour former des complexes « ship-in-a-bottle » (13). Zakharov et al. (14–17) ont été les premiers à encapsuler un complexe à base de phtalocyanine dans la zéolithe NaY en 1977. Depuis lors, de nombreuses équipes ont étudié l'encapsulation et la réactivité des complexes à base de phtalocyanines (notés Pc) et de bases de Schiff telles que le Salen (Salen = *N*,*N*′-bis(salicylaldéhyde) éthylènediimine). Les références 11 et 12 contiennent toutes les publications qui se rapportent à ce sujet et la figure 3 présente les différentes stratégies d'encapsulation. Les méthodes d'encapsulation, fonction du complexe à incorporer, peuvent être classées selon trois catégories : (*i*) la méthode dite du « ligand flexible » ; (*ii*) la méthode avec synthèse in situ du ligand; (*iii*) la synthèse de la zéolithe autour du complexe.

La méthode dite du « ligand flexible » consiste à introduire, à l'état fondu, un ligand (flexible) capable de diffuser dans le réseau poreux de la zéolithe et d'accéder aux cavités zéolithiques. Le ligand se complexe aux cations métalliques préalablement échangés avec les cations compensateurs de charge de la zéolithe. La complexation a lieu lorsque l'espace est suffisant, c'est à dire dans les grandes cavités et

Fig. 3. Les différentes stratégies d'encapsulation de complexes de métaux de transition tels que phtalocyanine (Pc) et base de Schiff (Salen = *N*,*N*′-bis(salicylaldéhyde) éthylènediimine).



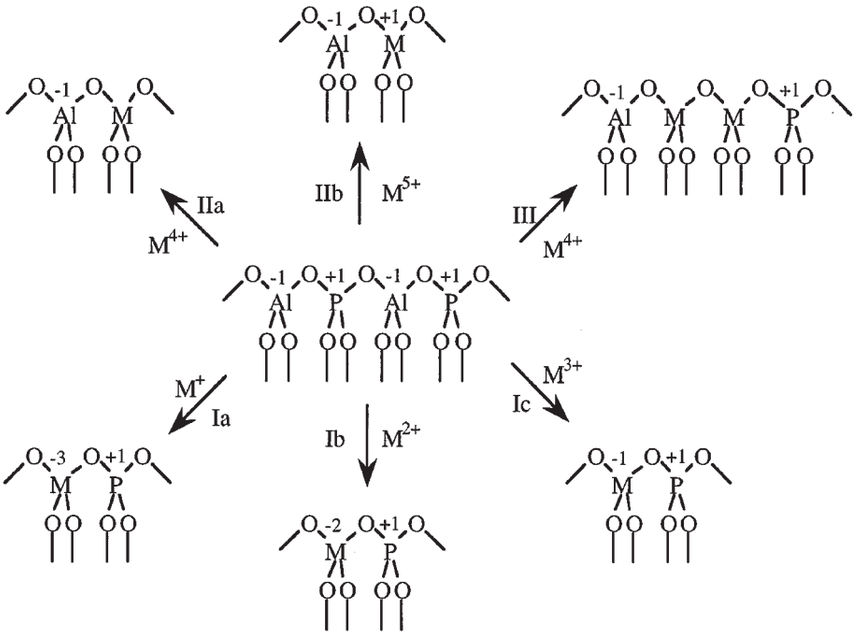
à la surface de la zéolithe. Dans la mesure où les complexes formés sont de taille supérieure au diamètre des fenêtres de ces cavités, ils sont incapables d'en sortir et se retrouvent prisonniers de la structure. Cette approche est particulièrement bien adaptée à l'encapsulation de complexes métal–Salen dans la zéolithe Y, le ligand Salen offrant la flexibilité requise. Ainsi, après coordination du métal, on obtient un complexe rigide d'une dizaine d'angström emprisonné dans des supercages d'un diamètre interne de 13 Å et dont les ouvertures ont un diamètre voisin de 7–8 Å.

La méthode avec synthèse in situ du ligand dérive de la précédente. Elle est appliquée lorsque le ligand, trop volumineux ou pas suffisamment flexible, ne peut pas pénétrer directement dans la supercage de la zéolithe. La synthèse du ligand est, dans ce cas, effectuée in situ. Cette procédure est caractéristique de l'encapsulation des métallophtalocyanines dans les zéolithes X et Y : 4 dicyanobenzènes diffusent dans la structure hôte pour se condenser autour d'un ion métallique et former le macrocycle tétradentate trop large pour sortir. La première étape, c'est à dire l'incorporation du métal au sein de la zéolithe, peut se faire soit par un simple échange ionique, soit via l'adsorption d'un métallocène ou d'un complexe métalcarbonyl. Cette étape est suivie de l'élimination des ligands (respectivement H_2O, cyclopentadiène, CO) par chauffage sous atmosphère inerte. La seconde étape consiste à additionner le dicyanobenzène à une température supérieure à sa température de fusion (140°C), l'ensemble étant agité plusieurs heures. Le dicyanobenzène diffuse dans le réseau poreux de la zéolithe pour se complexer au métal présent dans les supercages.

La méthode de synthèse de la zéolithe autour du complexe est la méthode d'encapsulation la plus récente (12). La synthèse du réseau cristallin de la zéolithe est réalisée autour du

© 1998 CNRC Canada

Fig. 4. Mécanismes de substitution isomorphe pour les structures de type AlPO-5.



complexe qui préexiste à l'état dissout dans la solution de germination. L'élaboration de cette « nouvelle » méthode d'encapsulation a été motivée par les limitations et désavantages des deux méthodes précédentes. En effet, cette méthode permet d'obtenir des complexes intra-zéolithiques parfaitement définis sans contamination du système poreux de la zéolithe par des ligands libres, par le métal non complexé ou par des oxydes métalliques. Les contraintes de taille complexe/zéolithe sont en outre moins restrictives, l'encapsulation n'étant pas limitée par des problèmes diffusionnels. Cependant, des modifications des paramètres de maille de la zéolithe paraissent inévitables. L'absence de résultats publiés sur la cristallinité de la zéolithe ne permet pas d'infirmer cette opinion. C'est également la méthode idéale pour l'encapsulation de complexes volumineux comme les métallophtalocyanines subtituées (cas des perfluorophtalocyanines de cobalt et de cuivre, incorporées dans la zéolithe X). Cependant, le complexe à encapsuler doit être suffisamment stable pour supporter les conditions opératoires de la synthèse. C'est le cas des métallophtalocyanines.

Il est important de préciser ici que quelque soit la procédure d'encapsulation choisie, il est extrêmement important de procéder à un rinçage extensif de la zéolithe modifiée afin de garantir l'absence totale de complexes formés à l'exterieur des supercages (c'est à dire à la surface de la zéolithe).

II. 2. Modifications des aluminophosphates

D'une manière similaire à ce qui a été dit dans le cas des zéolithes classiques, les tamis moléculaires peuvent subir plusieurs types de modifications pendant ou après la synthèse, entraînant des changements au niveau de leurs propriétés physico-chimiques. Nous discuterons essentiellement des modifications chimiques de ces matériaux par incorporation de cations métalliques au sein même de leur réseau, et précisément dans le cas des aluminophosphates.

Par définition, une substitution isomorphe correspond au remplacement d'un élément d'un réseau cristallin par un autre élément possédant un rayon ionique et une coordinence proche de l'élément substitué. Cette substitution est effectuée pendant la synthèse. Dans le cas des aluminophosphates, plusieurs sortes de substitutions isomorphes sont possibles. La complexité du processus provient de la présence de deux atomes différents dans le réseau et de la diversité des états de coordination possibles des atomes d'aluminium. L'aluminium et le phosphore sont en effet tous les deux susceptibles d'être substitués. Ainsi, les éléments qui se substituent à l'aluminium dans les aluminophosphates peuvent adopter la coordinence IV, V ou VI.

Les mécanismes de substitution isomorphe sont au nombre de trois et sont classés en fonction de l'atome substitué. La figure 4 résume ces trois types de mécanismes. Le mécanisme I concerne la substitution des atomes d'aluminium, le mécanisme II celle des atomes de phosphore et le mécanisme III traduit la substitution de paires adjacentes d'atomes d'aluminium et de phosphore (18, 19) et ne concerne que la substitution par le silicium. Dans le cas des aluminophosphates, c'est le degré d'oxydation formel de l'ion substituant plutôt que son rayon ionique qui détermine s'il substitue l'aluminium ou le phosphore. Les mécanismes I et II peuvent être détaillés selon la valence de l'élément introduit : monovalents (Ia), divalents (Ib), trivalents (Ic), tétravalents (IIa) et pentavalents (IIb). Aucun autre mécanisme n'est décrit dans la littérature pour la substitution des atomes d'aluminium et de phosphore dans les AlPO, car ils pourraient conduire à l'obtention d'une charpente chargée positivement ou au contraire à une densité de charge négative trop importante. Ainsi, de nombreux cations métalliques ont pu être incorporés dans la structure des AlPO et il n'existe pas

© 1998 CNRC Canada

moins de 18 éléments dont l'incorporation au sein de la structure AlPO a pu être mise en évidence : Li(I), Co(II), Fe(II), Mg(II), Mn(II), Zn(II), Be(II), Ni(II), Sn(II), B(III), Ga(III), Fe(III), Cr(III), Si(IV), Ge(IV), Ti(IV), As(V) et V(V) (18).

III. Caractérisation des zéolithes et des aluminophosphates chimiquement modifiés

Après avoir effectué la synthèse d'une zéolithe et l'encapsulation d'un complexe et avant d'envisager son utilisation, il convient de se poser plusieurs questions concernant les caractéristiques physico-chimiques du matériau :

la structure du minéral est-elle préservée après l'encapsulation?

a-t-on formé le complexe souhaité?

quelle est la répartition des complexes au sein du matériau, est-elle homogène?

existe-t-il des complexes à la surface de la zéolithe? etc.

D'une manière similaire, plusieurs questions doivent être posées après la synthèse et la modification d'un tamis moléculaire :

quelle est la structure du matériau obtenu?

quels sont la coordinence, l'état d'oxydation et la position des atomes incorporés au tamis moléculaire?

la présence des éléments substitués à l'intérieur du réseau du tamis engendre-t-elle des évolutions de la structure ou de la cristallinité du matériau?

Cette liste de questions n'est pas exhaustive et elle montre combien la tâche semble ardue pour parvenir à une connaissance approfondie du matériau. Elles peuvent être résumées par deux questions fondamentales : comment prouver l'encapsulation et comment prouver l'incorporation d'un cation métallique dans la structure d'un tamis ? Répondre à ces questions est souvent délicat et nécessite la conjonction de différentes techniques d'analyses. Le choix des techniques applicables à ce type de matériaux moléculaires est vaste : analyses chimiques élémentaires, analyses de surface, microscopie électronique à haute résolution, diffraction RX, spectroscopie infrarouge à tranformée de Fourier, spectroscopie UV–visible, résonnance paramagnétique électronique, spectroscopie Mössbauer, analyses thermiques, analyses d'adsorption, modélisation et électrochimie. À ce titre, on peut citer l'étude remarquable de Paez-Mozo et al. (20), consacrée à la pthalocyanine de cobalt encapsulée dans la zéolithe Y et rassemblant l'essentiel des techniques citées ci-dessus appliquées aux différentes étapes de la synthèse (sauf l'électrochimie). À caractère plus général, la mise au point de Balkus et Gabrielov (12) mettant à jour les différentes méthodes de caractérisation de complexes intra-zéolithiques est également intéressante.

IV. Caractérisation électrochimique des zéolithes et des aluminophosphates chimiquement modifiés

L'électrochimie peut être appliquée à la caractérisation des zéolithes et aluminophosphates chimiquement modifiés. Par rapport aux autres méthodes de caractérisation, elle a l'avantage d'être économique et rapide. En outre, l'électrochimie est particulièrement intéressante parce qu'elle intervient sur le comportement rédox des entités introduites dans le système microporeux de ces matériaux. Or les propriétés rédox de ces matériaux sont directement responsables de leur activité catalytique. Ainsi, par une technique électrochimique simple comme la voltampérométrie cyclique, on peut obtenir des informations essentielles sur leur activité rédox. Même de faibles perturbations d'ordre structural sont perceptibles par des déplacements de potentiels rédox.

Parallèlement à la caractérisation de ces matériaux, l'électrochimie appliquée aux zéolithes et aluminophosphates s'est considérablement développée durant ces dix dernières années. Il est vrai que la zéolithe offre un potentiel attractif dans le domaine des électrodes modifiées. Ses propriétés de tamis moléculaire, d'échangeur de cations, de catalyseur et de structure hôte ouvrent un large champ d'investigation aux électrochimistes. L'idée directrice est de tranférer les propriétés de la zéolithe à l'électrode (pour des soucis de simplification du texte, nous utiliserons dorénavant le terme générique « zéolithe » pour designer l'ensemble des matériaux étudiés, sauf exception mentionnée dans le texte). On peut ainsi, grâce aux propriétés de sélectivité et de préconcentration de la zéolithe, obtenir des détecteurs électrochimiques performants (21–30). On peut citer comme exemple le cas de la détection ampérométrique de glucose (27) ou de dopamine, méthylviologène, Ag^+ et Cu^{2+} (29) avec une électrode à pâte de carbone contenant la zéolithe Y et la glucose oxydase ou les zéolithes A, X et Y, respectivement. La possibilité d'incorporer dans la zéolithe des espèces électroactives a conduit à la conception de matériaux moléculaires élaborés dont l'application la plus élégante est l'étude de transferts électroniques orientés (31–33). Dans le domaine de l'électrocatalyse, l'électrode composite à base de zéolithe témoigne également d'un potentiel indéniable (34–38), comme cela a été montré dans le cas de la réduction sélective de bromure de benzyle, par rapport au bromure de triphénylméthyle, par le complexe zéro valent du nickel bis-bipyridine encapsulé dans la zéolithe Y (34). L'électrochimie peut également être un moyen d'étudier des processus fondamentaux inhérents aux zéolithes telles que les cinétiques d'échange d'ions ou la diffusion intra-zéolithique d'espèces réactives (39–42). En bref, les exemples ne manquent pas pour démontrer l'intérêt de coupler zéolithe et électrochimie.

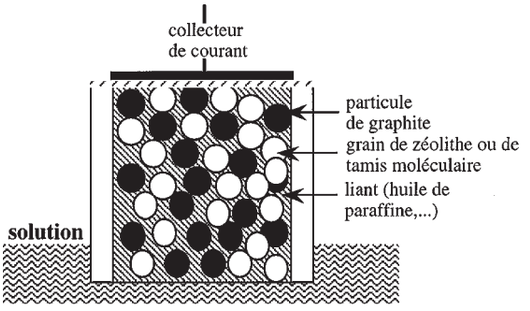
La construction d'une électrode modifiée est la première étape dans une étude électrochimique appliquée aux zéolithes. Plusieurs méthodes de modification des électrodes existent et sont reportées dans la littérature. Elles seront répertoriées ici de manière exhaustive avant d'aborder ensuite les concepts fondamentaux de l'électrochimie des zéolithes, c'est à dire les phénomènes de diffusion et de transfert électronique.

IV. 1. Fabrication de l'électrode

Le caractère isolant des zéolithes rend particulièrement délicat leur étude en électrochimie. De ce fait, le problème majeur lors de l'élaboration d'une électrode composite à base de zéolithe est d'obtenir un contact physique étroit entre le collecteur de courant et la zéolithe. La méthode la

© 1998 CNRC Canada

Fig. 5. Schéma d'une électrode du type « électrode à pâte de carbone », adapté de la reférence 46.



plus simple et la plus usuelle consiste à former une électrode en mélangeant intimement de la poudre de carbone et la zéolithe ou à fixer une couche de zéolithe à la surface d'une électrode. La multiplication des études électrochimiques portant sur les zéolithes depuis la fin des années 1980 a favorisé le développement de nouvelles techniques de fabrication. Ces différentes techniques ont fait l'objet de plusieurs mises au point (30, 43–46) d'où il est important de noter que chaque équipe de recherche a sa méthode de préparation. Ceci a le désavantage de rendre difficile la comparaison des travaux de chacun.

IV. 1. 1. Electrode à pâte de carbone

C'est une des méthodes les plus simples pour fabriquer une électrode composite à base de zéolithe. Un liant, le plus souvent de l'huile de silicone ou de paraffine, est additionné à un mélange poudre de graphite–zéolithe (contenant de 10 à 50 % de zéolithe). La pâte obtenue est incorporée dans un système à électrode à pâte de carbone conventionnel (fig. 5). Le principal avantage de ce type d'électrode est que la surface de l'électrode est facilement renouvelable par une simple élimination de la pâte contiguë à la solution. Ces électrodes présentent une bonne stabilité et les résultats obtenus sont en général reproductibles. L'inconvénient de ces électrodes est qu'elles nécessitent un liant. Ce liant engendre une chute ohmique non-négligeable surtout en milieu organique où l'utilisation de cette électrode est à proscrire (aussi à cause de la dissolution éventuelle de ce liant dans le solvant organique utilisé). De plus, la diffusion du liant de l'intérieur vers l'extérieur de l'électrode conduit à une accumulation du liant à la surface de l'électrode qui est susceptible d'altérer la réponse électrochimique (39). Par ailleurs, on peut estimer que les phénomènes observés sont principalement surfaciques (interface solution–électrode) car la diffusion au sein de l'électrode est limitée par sa compacité et par la présence du liant. La quantité de zéolithe impliquée est en conséquence faible (47). Cependant, cette remarque doit être nuancée. D'après l'étude de El Murr et al. (48) concernant le comportement rédox du Cu^{II} incorporé dans la mordenite, la quantité de cuivre réduit à l'électrode est supérieure de 600 fois (à 200 mV/s) à 2200 fois (à 10 mV/s) à la quantité de cuivre incorporé dans la première monocouche de zéolithe située à l'interface électrode–solution. En outre, Walcarius et al. (39) ont déterminé par chronocoulométrie l'épaisseur de l'électrode impliquée lors de la réduction du méthylviologène à 11 μm après 50 s d'expérience et à 84 μm après 1 h. La diffusion du méthylviologène dans l'électrode est par ailleurs limitée par l'état d'hydratation très partiel de celle-ci.

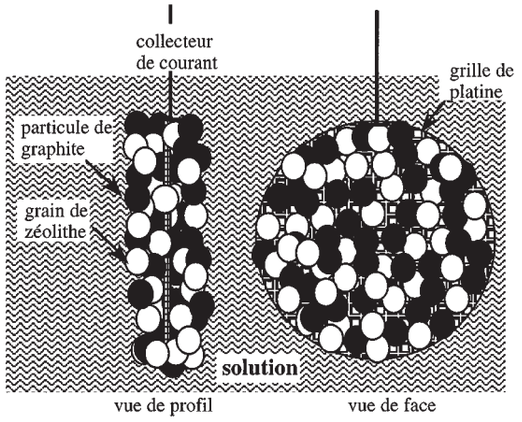
Shaw et Creasy (22) ont élaboré une électrode basée sur le principe de l'électrode à pâte de carbone mais avec un polymère comme agent liant. Ce polymère est formé à partir d'un mélange de styrène et de divinylbenzène; la polymérisation est initiée par le 2,2′-azobis(2-méthylpropionitrile). Ils obtiennent une électrode composite résistante. La surface est renouvelable par un simple polissage comme avec une électrode en carbone vitreux. Cette électrode montre une électroactivité vis à vis de la réduction de l'oxygène supérieure à celle obtenue avec l'électrode à pâte de carbone malgré une quantité de zéolithe huit fois moindre. La matrice polymérique gênerait moins que l'huile de silicone l'accès de la zéolithe aux espèces en solution. Toujours selon Shaw et Creasy (22), cette électrode est plus facile à utiliser, plus reproductible et le temps de réponse est plus rapide comparé à l'électrode du type pâte de carbone. L'amélioration de la reproductibilité est attribuée à une dispersion plus intime de la zéolithe avec le carbone mais aussi à une meilleur rigidité de l'électrode. La diminution du temps de réponse peut s'expliquer par des phénomènes observés purement surfaciques du fait d'une électrode faiblement poreuse vis à vis de la solution électrolytique.

IV. 1. 2. Electrode pressée

Également très simple à fabriquer, l'électrode du type électrode pressée peut être préparée avec ou sans poudre de graphite. Elle est pressée à 2 à 3 tonnes (1 t = 1000 kg) sous la forme d'une pastille. La comparaison des spectres RX avant et après pressage permet de s'assurer qu'il n' y a pas d'amorphisation notable des cristaux de la zéolithe et que la structure de celle-ci est bien preservée aprés l'action mécanique qui lui a été impartie. En l'absence de graphite, elle est utilisée entre autres comme électrode de batterie (49), comme membrane pour l'élaboration d'électrodes sélectives (50–52) ou bien encore comme électrolyte solide à haute température (53–55) sans que le problème posé par la probable existence de chute ohmique induite par l'absence de conducteur électronique ne soit pour autant clairement discuté. Préparée à partir d'un mélange zéolithe – poudre de graphite (1/1) pressé sur une grille d'acier inoxydable, ce type d'électrode a été utilisé pour la première fois par Pereira-Ramos et al. (56, 57) pour l'étude du comportement rédox de l'argent incorporé dans la mordenite. Les densités de courant mesurées sont importantes (jusqu'à 10 $mA/cm^{2)}$ et 75 % environ des ions Ag^+ initialement présents dans la zéolithe sont réductibles par coulométrie intentiostatique. C'est également le type d'électrode utilisé au laboratoire (34, 58–75). Son élaboration est simple : 30 mg de zéolithe sont mélangés à 30 mg de poudre de graphite, l'ensemble est pressé sous 2,5 $tonnes/cm^2$ sur une grille de platine ou d'or pendant 2–3 min (fig. 6). On obtient une pastille d'environ 12 mm de diamètre et 0,5–1 mm d'épaisseur, sa surface géométrique totale est estimée à 2 cm^2. L'avantage fondamental de cette électrode par rapport à ses concurrentes est qu'elle ne nécessite pas de liant. Les interactions solution–zéolithe ne sont donc pas modifiées par la présence d'un polymère, d'huile de silicone ou autres. Son utilisation en milieu organique est possible car sa tenue mécanique ne risque pas d'être altérée suite à la dissolution éventuelle du liant. Cependant, une dé-

© 1998 CNRC Canada

Fig. 6. Schéma d'une électrode du type « électrode pressée », adapté de la référence 46.

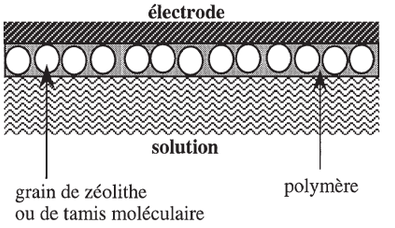


sagrégation partielle de l'électrode au cours de sa manipulation est inévitable car l'absence de liant la rend friable. De ce fait, la quantité de zéolithe à l'électrode varie d'une expérience à l'autre. Il en résulte une reproductibilité sur les intensités de courant mesurées modeste (estimée à environ ± 20 %). Néanmoins, la quantité de zéolithe impliquée dans le processus électrochimique est plus importante par rapport aux autres types d'électrodes et les densités de courant (mesurées pour un même système rédox) sont en général supérieures. On estime que l'électrolyte pénètre dans l'intégralité de l'électrode. La zone électroactive n'est donc pas limitée à la surface de l'électrode; la totalité de sa masse intervient dans la réaction électrochimique.

IV. 1. 3. Dépot d'une suspension (zéolithe + polymère)

C'est certainement le type d'électrode le plus usuel dans l'étude électrochimique des zéolithes. Une suspension de zéolithe et le polymère dissout sont déposés à la surface d'une électrode, généralement de carbone. Après évaporation du solvant, le polymère recouvre la zéolithe et la maintient à la surface de l'électrode. Le polymère universellement choisi, depuis sa première utilisation par De Vismes et al. (58), est le polystyrène et ce grâce à sa grande solubilité dans les solvants organiques tels que le dichlorométhane et le chloroforme, ce qui permet une excellente mise en oeuvre de la procédure de fabrication de l'électrode, et grâce aussi à sa porosité importante. L'inconvénient de cette électrode est la faible cohésion du dépôt. Shaw et al. (21) ont montré par microscopie électronique à balayage que le polystyrène manifeste une bonne adhérence à l'électrode mais médiocre à la surface des particules de zéolithe. Cette électrode est par conséquent mécaniquement fragile. Son utilisation dans des conditions hydrodynamiques n'est pas envisageable (contrairement à l'électrode à pâte de carbone). De plus, on observe rarement une équivalence d'un dépôt à l'autre d'où une faible reproductibilité des résultats. Shaw et al. (21) ont aussi observé une reproductibilité de ±14 %. Sauf exception (40, 76), ce type d'électrode est exclusivement exploité en milieu aqueux car on observe, dans les solvants organiques, une dissolution progressive du polymère. L'intérêt de cette électrode est qu'elle engendre des voltammogrammes bien définis du fait d'un dépot de faible épaisseur et de faible surface qui minimise les problèmes de diffusion, au sein du corps de l'électrode modifiée, et de courant capacitif. Cependant, l'électroactivité du système parait susceptible d'être faussée par une accumulation d'espèces électroactives sortantes de la zéolithe et qui se trouveraient confinées dans le film polymère ou par une entrée de l'électrolyte dans la zéolithe qui soit entravée par la présence du polymère à la surface de celle-ci.

Fig. 7. Schéma d'une électrode du type « électrode monocouche », adapté de la référence 46.



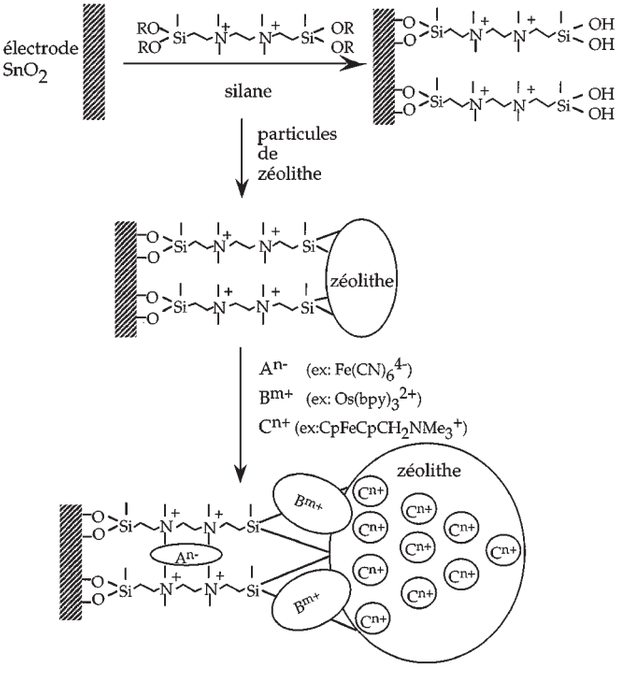
Le dépôt peut être aussi généré par électrodéposition comme l'ont démontré Rolison et coll. (25, 77). La zéolithe est mise en suspension dans une solution contenant un oxydant (par exemple, le 1,4-dinitrobenzène). Un dépôt à l'électrode se forme par la réduction répétée de l'oxydant qui s'adsorbe à la surface de l'électrode conjointement à la zéolithe. L'apport de matière est entretenu par la rotation de l'électrode. Le phénomène d'adsorption n'est observable qu'en présence de la zéolithe. Aucune explication n'a pour l'instant été donnée mais la forte nature anionique de la zéolithe doit sans doute affecter la réduction de l'oxydant. En présence de pyrrole et de zéolithe, un dépôt zéolithe–polypyrrole est formé à la surface de l'électrode par oxydation du pyrrole. Le dépôt peut être amélioré en oxydant une goutte de la solution déposée à la surface de l'électrode. La zéolithe pénètre par gravitation dans le polypyrrole naissant (25). À noter qu'il existe quelques exemples d'incorporation dans une zéolithe de polymères conducteurs tels le polypyrrole, le polyaniline, le polythiophène (78–81). Cependant, leur utilisation dans l'élaboration d'une électrode composite à base de zéolithe n'a pas pour l'instant été envisagée. Il est vrai que leur présence a le défaut d'encombrer le réseau de la zéolithe et les rares mesures de conductivité effectuées ne sont pas probantes. Aucune indication n'a été reportée dans la littérature quant à une éventuelle amélioration de la tenue mécanique de l'électrode lorsque le dépôt du film de polymère est réalisé par électrodéposition.

IV. 1. 4. Electrode type « monocouche »

La figure 7 représente une électrode type « monocouche » développée par Calzaferri et coll. (82–85). Cette électrode est en fait une évolution de l'électrode « polystyrène ». Sa fabrication consiste en un dépôt d'une suspension de zéolithe ou de tamis moléculaire suivi du dépôt de polymère qui est en général le polystyrène. D'après les travaux de Calzaferri et coll. (82–85), il est possible de réaliser un dépôt homogène d'une monocouche de zéolithe sur la surface de l'électrode. De plus, la maîtrise de la qualité du dépôt leur permet d'atteindre de bons niveaux de reproductibilité (quelques pour cent). La faible épaisseur de l'électrode (qui correspond à la taille des cristaux de zéolithe étudiés) permet de minimiser le courant capacitif et de simplifier les phénomè-

© 1998 CNRC Canada

Fig. 8. Stratégie d'élaboration d'un système trimoléculaire à partir d'une électrode fonctionnalisée.



nes de diffusion. La bonne tenue mécanique de l'électrode permet d'effectuer des études en voltampérométrie hydrodynamique mais la présence du polystyrène proscrit son utilisation dans les solvants organiques dans lesquels ce polymère est soluble. Le principal problème de cette électrode est qu'elle met en jeu de faibles quantités d'espèces électroactives lorsque le matériau étudié contient lui-même peu d'espèces électroactives.

IV. 1. 5. Electrode fonctionnalisée

Li et al. (33) ont élaboré une électrode de conception originale : un silane bifonctionnalisé est lié par une extrémité à la surface d'une électrode SnO_2 via des liaisons Sn—O—Si et par l'autre extrémité à la zéolithe Y via des liaisons Si—O—Si. Ils obtiennent un dépôt d'une monocouche de particules de zéolithe à la surface de l'électrode. Ce film est mécaniquement stable et peut fixer divers cations et anions électroactifs (fig. 8). Ainsi, il est possible de construire des « systèmes trimoléculaires» : un anion peut se lier aux sites cationiques du silane et deux cations de taille différente peuvent se fixer à la zéolithe (l'un à l'intérieur de la zéolithe, l'autre à sa surface).

IV. 1. 6. Electrode dispersée

Les surfaces des électrodes précédemment décrites sont insuffisantes pour des applications en électrosynthèse. Une solution, élaborée par Rolison et al. (37), consiste à utiliser la zéolithe à l'état dispersé et de considérer chaque particule comme une ultramicroélectrode. Pour cela, des clusters de platine sont incorporés dans et sur la zéolithe. La suspension de zéolithe modifiée est placée entre deux électrodes cylindriques de platine et un champ électrique (0–300 V/cm) est appliqué. Les électrolyses de l'eau et du mélange eau–benzène (8 : 20, v/v), en l'absence d'ajout de sel support, effectuées en présence des ultramicroélectrodes de platine supportées sur la zéolithe donnent des courants de 10 à 1000 fois supérieurs à ceux mesurés en l'absence de platine. La mise en suspension d'une zéolithe modifiée par adsorption d'une porphyrine de manganèse est une méthode qui a été également utilisée au laboratoire pour l'électrocatalyse d'oxydation de di-*tert*-butyl phénol par l'oxygène moléculaire (86). Récemment, Bessel et Rolison (87, 88) ont utilisé ce type de suspension pour l'analyse électrochimique de complexes encapsulés dans la zéolithe Y, ainsi que pour leur application en electroacatalyse préparative (cas de la carboxylation du chlorure de benzyle catalysée par le complexe CoSalen encapsulé dans la zéolithe Y).

En résumé, l'électrode idéale est une électrode suffisamment conductrice, mécaniquement stable et facile à préparer. Cette électrode n'existe pas encore. Des améliorations dans la conception d'électrodes composites à base de zéolithe doivent donc être accomplies. En fait, chaque type d'électrode décrit précédemment a ses avantages et ses inconvénients. Et selon leurs caractéristiques, elles seront mieux appropriées à une application donnée. Le tableau 1 résume les caractéristiques fondamentales de chaque type d'électrode.

IV. 2. Techniques électrochimiques

La voltampérométrie cyclique est la technique de prédilection pour étudier l'électrochimie des zéolithes. Cette suprématie se justifie avant tout par la simplicité de la méthode et son caractère usuel. C'est généralement la première technique utilisée par un électrochimiste lors de l'étude d'un nouveau système rédox. La voltampérométrie cyclique est une méthode puissante car non seulement elle permet de caractériser un système rédox mais elle rend également compte des mécanismes réactionnels mis en jeu. De plus, des paramètres cinétiques essentiels tels que les coefficients de diffusion au sein de la zéolithe peuvent être déterminés. Plus rarement utilisées, la chronoampérométrie (42, 53, 56, 58, 89), la chronopotentiométrie (54, 56, 90) et la spéctroscopie d'impédance électrochimique (45) sont généralement couplées à la voltampérométrie cyclique et s'appliquent essentiellement à une étude cinétique des phénomènes de diffusion au sein de la zéolithe. Lors d'études très spécifiques, d'autres techniques peuvent être employées. À titre d'exemple, on peut citer l'étude de la sélectivité cationique d'une membrane zéolithique par mesure de la f.é.m. de la cellule électrochimique (50–52).

IV. 3. Description des processus électrochimiques

La présence de la zéolithe à l'électrode introduit de nouvelles variables qui modifient les mécanismes électrochimiques conventionnels. Le transfert électronique entre l'électrode et l'espèce électroactive incorporée dans le système poreux de la zéolithe est de fait une opération complexe. De nombreuses mises au point récentes présentent cette complexité de manière assez détaillée (30, 43–46, 66, 87, 91, 92) et nous n'examinerons ici que les étapes-clé de la procédure d'analyse électrochimique des différentes zéolithes chimiquement modifiées recencées dans la littérature.

© 1998 CNRC Canada

Tableau 1. Avantages et inconvénients des différents types d'électrodes modifiées à base de zéolithe.

Type d'électrode	Avantages	Inconvénients	Application type
Électrode à pâte de carbone	Fabrication simple Surface renouvelable Bonne stabilité Mesures reproductibles	Nécessité d'un liant Inutilisable en milieu organique Diffusion limitée	Électroanalyse (détection)
Électrode pressée	Fabrication simple	Fragile	Électrochimie de complexes encapsulés
	Totalité de l'électrode impliquée Pas de liant Utilisable en milieu organique	Reproductibilité faible	
Dépôt à l'électrode	Courant capacitif faible	Fragile (sauf monocouche)	Étude de transferts électroniques
	Voltammogrammes bien définis	Reproductibilité faible (sauf monocouche) Peu utilisable en milieu organique Interférence possible avec le polymère	Photoélectrochimie
Électrode fonctionnalisée	Bonne stabilité	Construction complexe	Étude de systèmes trimoléculaires
Électrode dispersée	Densité de courant levée Aucune contrainte mécanique exercée sur la zéolithe		Électrosynthèse

Shaw et al. (21) proposent deux mécanismes pour décrire les processus électrochimiques à une électrode modifiée par une matrice solide poreuse contenant une espèce électroactive (zéolithe, tamis moléculaire) :

$$[1] \quad E_{(z)}^{m+} + mC_{(s)}^{+} \Leftrightarrow E_{(s)}^{m+} + mC_{(z)} + E_{(s)}^{m+} + ne^{-} \Leftrightarrow E_{(s)}^{(m-n)+}$$

$$[2] \quad E_{(z)}^{m+} + ne^{-} + nC_{(s)}^{+} \Leftrightarrow E_{(z)}^{(m-n)+} + nC_{(z)}^{+}$$

E^{m+} représente l'espèce électroactive, C^{+} le cation de l'électrolyte et les indices (z) et (s) respectivement la zéolithe et la solution.

Le mécanisme [1] ne concerne que les espèces électroactives mobiles, pouvant diffuser librement dans la structure des zéolithes ou des tamis moléculaires. Il est constitué d'une première étape qui est un échange ionique entre le cation de l'électrolyte support et l'espèce électroactive présente dans la zéolithe. Lors de la seconde étape, l'espèce électroactive subit un transfert de charge à l'extérieur de la zéolithe. Ce mécanisme est dit *extra-zéolithique*.

Le mécanisme [2] s'effectue en une seule étape dans laquelle il y a à la fois un transfert d'électrons faisant intervenir l'espèce électroactive située à l'intérieur de la zéolithe et une diffusion du cation de l'électrolyte vers l'intérieur du système poreux de la zéolithe afin de compenser la charge créée par la réaction de réduction (ou une diffusion du cation mobile compensateur de charge de la charpente zéolithique vers l'extérieur du système poreux de la zéolithe afin de compenser la charge créée par la réaction d'oxydation). Ce second mécanisme, dit *intra-zéolithique*, concerne plus particulièrement les espèces fixées irréversiblement dans la structure du matériau telles que les complexes encapsulés dans les zéolithes ou encore les cations métalliques incorporés aux réseaux des tamis moléculaires. Cependant, comme nous le verrons dans la discussion ci-après, certains auteurs pensent pouvoir attribuer à un mécanisme intra-zéolithique l'activité électrochimique observée pour de petits cations pouvant diffuser librement dans le système poreux de la zéolithe.

IV. 3. 1. Processus rédox extra-zéolithique

À ce jour, la majorité des travaux sur l'électrochimie des zéolithes implique un processus rédox extra-zéolithique. Le transfert électronique a lieu à l'extérieur de la zéolithe. Il n'est par conséquent applicable qu'aux espèces électroactives capables de diffuser hors de la zéolithe. Son mécanisme a été étudié et mis en évidence dans le cas d'espèces électroactives incorporées dans la zéolithe par simple échange ionique : Ag^{+} (54) incorporé dans la mordénite; MV^{2+} (méthylviologène) (39, 40, 76), $Ru(NH_3)_6^{3+}$ (21, 91), Cu^{2+} (21), Co^{2+} et Ag^{+} (41, 42, 59, 66, 68, 92–94) incorporés dans la zéolithe Y.

Le transfert électronique s'effectue de façon classique à la surface de la zéolithe. Il est rapide par rapport aux autres phénomènes intervenant dans le mécanisme rédox extra-zéolithique. Il ne contrôle donc pas le processus électrochimique. Aussi notre attention se focalisera sur la première étape du mécanisme extrazéolitique, c'est à dire l'échange ionique entre l'espèce électroactive intra-zéolithique et le cation de l'électrolyte support. C'est l'étape limitante du processus rédox. Les phénomènes de diffusion (diffusion de l'espèce électroactive et diffusion de l'électrolyte) ont une influence majeure sur l'électroactivité du système. Plusieurs paramètres interviennent sur les phénomènes de diffusion : la configuration de l'électrode, la structure de la zéolithe, le solvant, la température, la taille des espèces mobiles, la na-

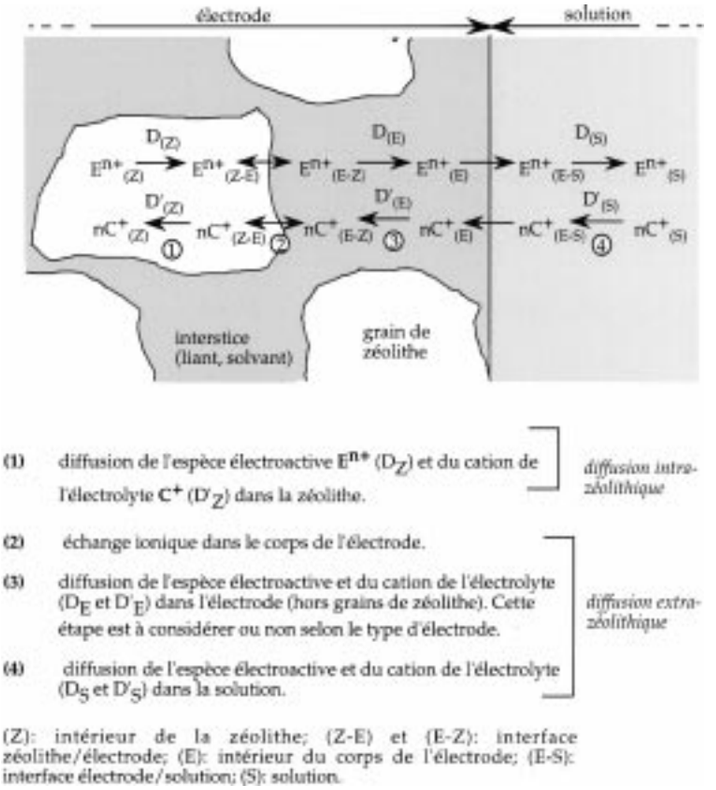
Fig. 9. Représentation des différents phénomènes diffusionnels inhérents à un processus rédox extra-zéolithique.



ture des intéractions entre les espèces mobiles et la zéolithe. La multiplicité des paramètres fait apparaître la complexité du processus. L'échange ionique pris dans sa globalité peut être subdivisé en trois processus (fig. 9) : (*i*) *diffusion intra-zéolithique* : diffusion de l'espèce électroactive et du cation de l'électrolyte dans le système poreux de la zéolithe; (*ii*) *échange ionique*; (*iii*) *diffusion extra-zéolithique* : diffusion de l'espèce électroactive et du cation de l'électrolyte dans le corps de l'électrode (hors zéolithe) et diffusion de l'espèce électroactive et du cation de l'électrolyte dans la solution.

Ces trois processus sont fortement interdépendants, il n'est donc pas aisé de les traiter séparément. Il est par exemple difficile de savoir si la taille des espèces cationiques interviendra plus particulièrement sur l'échange ionique ou sur les phénomènes de diffusion. Ou encore, lorsqu'on mesure un coefficient de diffusion, il n'est pas possible de différencier sa composante intra-zéolithique de sa composante extra-zéolithique. Toutefois, on tentera ci-après de mettre en avant les différents paramètres susceptibles d'influer sur ces différents processus.

IV. 3. 1. 1. Diffusion extra-zéolithique : (a) Diffusion dans la solution. La diffusion de l'espèce électroactive et du cation de l'électrolyte dans la solution est rapide par rapport à leur diffusion dans la zéolithe et dans l'électrode. Dès immersion de l'électrode dans la solution d'électrolyte, on observe un passage en solution de l'espèce électroactive (21, 76). Elle diffuse dans la solution en s'éloignant de l'électrode et ne participe pas au processus électrochimique. Une faible quantité est cependant susceptible d'être au contact de l'électrode et d'engendrer un courant faradique. Mais sa dilution dans la solution d'électrolyte rend ce courant insignifiant par rapport au courant engendré par l'espèce intra-zéolithique.

Afin de minimiser la perte de matière électroactive due à son passage en solution, il est profitable d'effectuer la mesure électrochimique immédiatement après contact de l'électrode avec la solution. Durant l'expérience, la perte d'espèce électroactive est inévitable. En voltampérométrie cyclique, cette perte se traduit par une décroissance, cycle après cycle, des intensités de pics (39, 66).

(*b*) *Diffusion dans l'électrode.* L'électrode à base de zéolithe est un système complexe constitué de grains de zéolithe et, selon les cas de particules de graphite, de polymère, d'huile de paraffine, etc. Ce milieu est plus ou moins poreux et doit laisser un espace suffisant pour permettre la diffusion de la solution d'électrolyte et des espèces issues de la zéolithe. On entendra par diffusion dans l'électrode les phénomènes diffusionnels propres à l'électrode mais ne concernant pas la diffusion intra-zéolithique. Selon le type d'électrode utilisé, les phénomènes de diffusion dans l'électrode sont considérés ou non. Li et Calzaferri (84) — qui utilisent une électrode modifiée par un dépôt d'une monocouche de grains de zéolithe — ne prennent pas en compte la diffusion des espèces dans l'électrode. Dans ce cas, le processus d'échange ionique est contrôlé par la diffusion des espèces dans la zéolithe. Toutefois, le polymère nécessaire à la cohésion des électrodes préparées à partir d'un dépôt est susceptible d'entraver la diffusion des espèces dans l'électrode et leur entrée dans le système poreux de la zéolithe. En effet, la

© 1998 CNRC Canada

porosité partielle du polymère, son agrégation à la surface des grains de zéolithe et son caractère hydrophobe sont des facteurs qui ne facilitent pas les phénomènes de diffusion. À ce type d'électrode, aucune étude n'a cependant montré une diffusion des espèces limitée par leur diffusion dans l'électrode. En revanche, à une électrode à pâte de carbone, Walcarius et al. (39, 40) ont montré que la diffusion des espèces dans l'électrode doit être considérée. Ils ont déterminé un coefficient de diffusion du cation méthylviologène dans l'électrode (8×10^{-11} cm^2 s^{-1}) inférieur à celui mesuré dans la zéolithe (2×10^{-8} cm^2 s^{-1}). Ce résultat est surprenant car il témoignerait de contraintes diffusionnelles beaucoup plus importantes dans le corps de l'électrode que dans la zéolithe. Le processus d'échange ionique serait donc limité par la diffusion des espèces dans l'électrode et non dans la zéolithe. La diffusion dans l'électrode peut être améliorée par son hydratation préalable. Ainsi, le coefficient de diffusion du méthylviologène dans l'électrode est multiplié par quatre lorsque celle-ci est immergée 12 h dans de l'eau hautement purifiée (39). À noter également l'importance de la vitesse de balayage et du temps d'immersion de l'électrode qui modulent l'épaisseur de l'électrode impliquée dans le phénomène de diffusion. À 1 V/s, le phénomène observé est essentiellement surfacique et dans ce cas, la diffusion des espèces dans l'électrode ne doit pas être considérée (40). En bref, si la structure de la zéolithe est toujours prise en compte lors des processus de diffusion inhérents au processus rédox, la porosité, la compacité et la mouillabilité de l'électrode sont des critères souvent sous-estimés malgré leur implication dans le phénomène observé.

IV. 3. 1. 2. L'échange ionique : L'échange ionique est ici considéré à l'équilibre. La constante d'équilibre thermodynamique de l'échange ionique entre l'espèce électroactive intra-zéolithique ($E_{(Z)}^{m+}$) et le cation monovalent de l'électrolyte support (C^+) est définie par :

$$E_{(Z)}^{m+} + mC_{(s)}^{+} \overset{K}{\Leftrightarrow} E_{(s)}^{m+} + mC_{(z)}^{+}$$

$$K = \frac{(aC_{(z)})^m \times (aE_{(s)}^{m+})}{(aC_{(s)}^{+}) \times (aE_{(z)}^{m+})}$$

L'équilibre s'établit en fonction de l'activité de chaque espèce en solution et dans la zéolithe, c'est à dire en fonction de leur concentration et de leur coefficient d'activité dans leur milieu respectif.

Au départ de l'expérience, la concentration de l'espèce électroactive dans la solution d'électrolyte est nulle, elle est par contre importante dans la zéolithe (appliquée à la zéolithe Y, la concentration est estimée à 1 M en considérant que la zéolithe contient une entité électroactive par supercage). On a donc un gradiant de concentration élevée, entre l'intérieur et l'extérieur de la zéolithe. Le passage en solution de l'espèce intra-zéolithique est en conséquence fortement favorisé. L'équilibre d'échange ionique s'établit rapidement. Ainsi, si des particules de zéolithe contenant du méthylviologène sont mises en suspension dans une solution aqueuse de NaCl 0,05 M, l'équilibre est atteint en moins d'une seconde (40).

Cependant, l'équilibre ne s'établit pas simplement en fonction de la concentration des cations dans la zéolithe et dans la solution, il faut également tenir compte de la différence d'affinité vis à vis de la zéolithe entre les deux cations. C'est à dire qu'une fois l'équilibre atteint, les deux cations ne seront pas partagés de façon identique entre la zéolithe et la solution, l'un d'eux sera en plus forte proportion que l'autre dans la zéolithe. Pour une zéolithe donnée, cette sélectivité dépend principalement de la taille et de la charge des espèces concernées mais aussi du solvant qui influe sur leur volume molaire et sur les intéractions ioniques cation–zéolithe. L'utilisation d'un cation de l'électrolyte support de grande taille peut défavoriser l'échange ionique jusqu'à l'interdire si le cation est de taille supérieure aux pores de la zéolithe. Ainsi selon Gemborys et Shaw (76), l'utilisation de l'ion tétrabutylammonium (TBA^+) ne permet pas l'échange ionique et la faible électroactivité observée a pour seule origine les espèces fixées à la surface de la zéolithe. À noter que la capacité du tétrabutylammonium à pénétrer dans le réseau poreux de la zéolithe Y est un sujet de controverse. En effet, selon les travaux effectués au laboratoire (60, 61) et ceux de Baker et al. (24, 41, 42), le cation tétrabutylammonium parait être capable de pénétrer dans la zéolithe Y. En revanche, Walcarius et al. (39) et Gemborys et Shaw (76) considérent sa pénétration dans la zéolithe Y comme incertaine. Ces résultats contradictoires témoignent du flou qui existe encore sur l'action du cation de l'électrolyte. Il est important de noter que le cation et les fenêtres d'accès de la supercage ne doivent pas être considérés comme totalement rigides, ils sont doués d'une certaine flexibilité. Ainsi, selon Barrer (95), une espèce d'un diamètre cinétique de 10 Å peut pénétrer au sein de la zéolithe Y dont le diamètre des ouvertures n'est pourtant que de 7,4 Å. En conséquence, selon ce principe, le cation tétrabutylammonium d'un diamètre cinétique compris entre 8,1 et 9 Å et dont la flexibilité est reconnue peut logiquement pénétrer au sein de la zéolithe Y. D'autre part, la pénétration du cation de l'électrolyte peut être favorisée par un déplacement de l'équilibre d'échange grâce à un effet de complexation avec l'anion de l'électrolyte. Par exemple, les courants observés lors de l'étude de l'ion Co^{2+} incorporé dans la zéolithe Y avec comme électrolyte support le cation tétrabutylammonium et l'anion I^- ou SCN^- sont supérieurs à ceux observés avec l'anion BF_4^-, l'échange ionique étant accentué par une complexation des ions cobalt avec les ions I^- et SCN^- (41). Enfin, si la taille du cation est inférieure au diamètre des pores de la zéolithe mais nécessite une perte partielle de sa sphère de solvatation lors de l'échange ionique, l'énergie de désolvatation peut être élevée et dans ce cas la réaction d'échange est énergétiquement défavorable (cas du cation Li^+ vis à vis de la zéolithe analcime (41)). Lors de la réaction d'échange, il est donc important de considérer non pas le cation seul mais le couple cation–solvant.

IV. 3. 1. 3. Diffusion intra-zéolithique : Pour être électroactive, l'espèce intra-zéolithique mais aussi le cation de l'électrolyte doivent diffuser dans le réseau poreux de la zéolithe. Pour la grande majorité des auteurs, la diffusion intra-zéolithique est considérée comme l'étape limitante du processus rédox extra-zéolithique. Par chronoampérométrie, Pereira-Ramos et al. (56) ont montré que l'électrodépôt

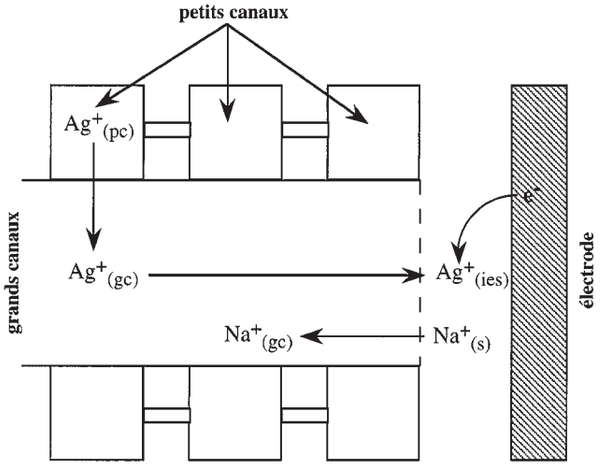
Fig. 10. Mécanisme électrochimique mis en jeu lors de la réduction des ions Ag^+ fixés dans la zéolithe $Ag_nNa_{(56-n)}Y$ avec $n < 5,9$ (d'après reférence 94). *pc* : petits canaux; *gc* **:** grands canaux; *s* **:** solution; *ies* **:** interface électrode–solution.



d'argent dans une zéolithe est contrôlé par la diffusion intra-zéolithique. Leurs résultats sont confirmés par les travaux de Baker et al. (42) qui ont par ailleurs montré la dépendance de la température sur les coefficients de diffusion. Par voltampérométrie cyclique, Shaw et Creasy (22), El Murr et al. (48) et Walcarius et al. (39) ont mesuré, avec différentes espèces électroactives, des intensités de pics proportionnelles à la racine carrée de la vitesse de balayage. Walcarius et al. (40) ont également montré que l'évolution du courant de réduction de l'ion méthylviologène incorporé dans la zéolite Y est similaire à l'évolution de la concentration en méthylviologène d'une solution contenant une suspension de zéolithe chargée en méthylviologène.

Plusieurs facteurs ont une influence sur les phénomènes de diffusion dans la zéolithe : la structure de la zéolithe bien sûr, mais aussi la taille des espèces concernées par le processus électrochimique ainsi que leur état de solvatation.

Selon la structure de la zéolithe, la diffusion des espèces impliquées dans le processus rédox sera plus ou moins facilitée. Par exemple, l'électroactivité du cuivre incorporé dans la zéolithe Y est 3,3 fois supérieure à celle du cuivre incorporé dans la zéolithe A (la zéolithe Y contenant cependant 1,6 fois plus de cuivre). Ce résultat peut être interprété par une plus grande mobilité des ions Cu^{2+} dans la zéolithe Y (21).

La taille du cation de l'électrolyte a également une incidence sur la réponse électrochimique observée. Toujours appliqué au cas du cuivre incorporé dans la zéolithe Y, le remplacement du cation Li^+ (rayon de l'ion hydraté = 5 Å) par un cation de taille inférieure tel Cs^+ (rayon de l'ion hydraté = 2,5 Å) a pour conséquence d'augmenter d'un facteur 2 l'intensité de pic correspondant à la réduction du cuivre (21). Plusieurs études ont montré une corrélation entre les intensités de pics et la taille du cation de l'électrolyte (21, 39, 41, 76, 84). En règle générale, l'électroactivité de l'espèce intra-zéolithique s'accroît avec la diminution de la taille du cation de l'électrolyte et avec l'augmentation du diamètre des pores de la zéolithe. En d'autres termes, lors d'un processus rédox extra-zéolithique, plus l'espèce électroactive et le cation de l'électrolyte sont mobiles au sein de la zéolithe, plus l'échange ionique est rapide et efficace, et plus la quantité d'espèces électroactives au contact de l'électrode est importante.

Les intéractions électrostatiques peuvent également avoir une incidence non négligeable sur la mobilité des cations dans la zéolithe (surtout dans les larges pores). Aussi, la charge de la charpente zéolithique et les propriétés diélectriques du solvant sont supposées jouer un grand rôle dans le contrôle des vitesses de diffusion intra-zéolithique. Ainsi, le caractère hydrophile de la zéolithe ralentit fortement la diffusion des cations solvatés par des solvants non-aqueux et la conductivité ionique de la zéolithe dépendra de son degré d'hydratation. Senaratne et Baker (23) ont ainsi étudié en milieu organique l'effet de trace d'eau sur l'électrochimie de l'argent incorporé dans la zéolithe A déshydratée. Ils ont obtenu une limite de détection de l'eau dans le diméthylformamide d'environ 20 ppb.

Dernièrement, Baker et al. (42, 94) ont montré la complexité des phénomènes de diffusion intra-zéolithique lors du processus rédox. Appliqué au cas de l'argent incorporé dans la zéolithe Y, ils montrent l'influence notable de la position initiale des ions Ag^+ dans le réseau poreux de la zéolithe (fonction de la quantité d'argent incorporé dans la zéolithe) sur les phénomènes de diffusion donc indirectement sur la réponse électrochimique observée. Une première distinction est faite entre les ions mobiles et les ions fixés aux sites anioniques de la charpente zéolithique. Une seconde distinction est établie entre les ions présents dans les supercages et ceux présents dans les cages sodalites et prismes hexagonaux. De fait, la diffusion intra-zéolithique doit être considérée en plusieurs étapes. Par voltampérométrie cyclique et chronoampérométrie, Baker et al. ont montré que le mécanisme de transfert de charge nécessite un échange ionique entre l'argent intra-zéolithique et le cation de l'électrolyte. Quand les supercages sont occupées par les ions Ag^+, la réaction électrochimique est contrôlée par la diffusion intra-zéolithique. En revanche, lorsque les ions Ag^+ sont exclusivement présents dans les cages sodalites et les prismes hexagonaux (c'est à dire quand la zéolithe contient peu d'argent), le processus rédox est contrôlé par la réaction d'échange intra-zéolithique (échange entre les cations de l'électrolyte présents dans les supercages et les cations Ag^+ présents dans les cages sodalites et prismes hexagonaux). La figure 10 représente le mécanisme proposé par les auteurs (94).

L'étude approfondie du comportement électrochimique du cation Cu^{2+} incorporé dans la zéolithe Y établie par Li et Calzaferri (84) a également mis en évidence l'importance des phénomènes de diffusion intra-zéolithique lors du processus rédox. Cette étude montre que plusieurs paramètres influent sur l'électroactivité du cuivre : la position de l'espèce électroactive dans la zéolithe, l'épaisseur du dépôt de zéolithe à l'électrode, la nature du cation et de l'anion de l'électrolyte support. L'étude de l'influence de la taille du cation de l'électrolyte a permis, entre autres, de démontrer que le processus rédox est limité par la diffusion intra-zéolithique du cation de l'électrolyte et non pas par la migration de l'espèce électroactive vers la surface de la zéolithe. Par ailleurs, ils estiment qu'une migration du cuivre, sous forme Cu^+ ou Cu(0), vers l'intérieur de la zéolithe

© 1998 CNRC Canada

après la réduction de Cu^{2+} à la surface de la zéolithe est possible. Une certaine ambiguïté apparaît concernant le site du transfert électronique. L'étude de l'influence de l'anion de l'électrolyte sur la réponse électrochimique montre que la réduction du cuivre ne se fait pas au sein de la zéolithe mais à l'interface zéolithe–électrode–solution. Cependant, doit-on considérer que le transfert électronique se produit exclusivement à la surface des grains de zéolithe ou bien peut-il avoir lieu dans les supercages présentes à la périphérie des grains de zéolithe? Et s'il a lieu dans les supercages, peut-on encore considérer que la réaction électrochimique s'établit selon un processus rédox extra-zéolithique. Cette ambiguïté montre qu'il est difficile de fixer une frontière bien définie entre une réaction électrochimique s'opérant selon un mécanisme rédox extra-zéolithique et celle qui s'établit selon un mécanisme rédox intra-zéolithique. Aussi, dans le cas d'espèces électroactives incorporées dans la zéolithe par un simple échange ionique, il semblerait que la mise en place d'un processus rédox extra-zéolithique n'interdise pas totalement un processus rédox intra-zéolithique. À ce titre, les travaux récents de Calzaferri et coll. (85), concernant l'étude électrochimique de l'ion Ag^+ incorporé dans la zéolithe A, démontrent que la réduction de l'argent s'effectue non seulement à la surface de la zéolithe mais aussi dans le réseau poreux de la zéolithe. À noter cependant que leur analyse n'est pas en accord avec celle de Baker et coll. (41, 92, 93) — appliquée à l'étude électrochimique de Ag^+ incorporé dans les zéolithes Y et A — qui considèrent que la réduction de l'argent ne peut se faire au sein de la zéolithe. Cependant, ils n'excluent pas une réduction de l'argent dans les supercages présentes à la surface des grains de zéolithe, supercages surfaciques qu'ils estiment représentatives de l'ensemble des supercages du réseau poreux du matériau zéolithique (93).

D'autres ions (Hg(II), Cd(II), Fe(II), etc.) dont la taille est inférieure à celle des canaux des zéolithes ont été étudiés par électrochimie mais peu de précisions ont été apportées sur le mécanisme électrochimique susceptible d'intervenir (27, 28, 89, 96, 97). Walcarius et Lamberts (98) ont étudié le comportement électrochimique des ions $Ru(NH_3)_6^{3+}$ fixés dans la zéolithe NaY en utilisant une électrode à pâte de carbone. Le système Ru(III)/Ru(II) est caractérisé par un unique couple de pics lors de l'étude du complexe $Ru(NH_3)_6^{3+}$ en solution, tandis que l'étude du même complexe fixé dans la zéolithe NaY fait apparaître un pic d'oxydation et deux pics de réduction. La représentation de l'intensité des pics de réduction n'est pas une fonction de la racine carré de la vitesse de balayage. En conséquence, les auteurs ont attribué les deux pics de réduction aux complexes $Ru(NH_3)_6^{3+}$ situés dans deux environnements différents. Afin de déterminer précisément le mécanisme mis en jeu, ils ont utilisé dans un premier temps un cation de l'électrolyte reconnu comme pouvant être exclu, du fait de sa taille, des canaux de la zéolithe Y : le cation TBA^+. Les résultats montrent clairement que le premier pic de réduction (situé au potentiel le plus positif) disparaît lors de l'utilisation de TBA^+ et les auteurs expliquent ce phénomène en considérant que ce pic est associé à un mécanisme électrochimique extra-zéolithique. En effet, la réaction de transfert de charge est dans le cas du mécanisme [1] précédée par l'échange ionique entre le cation de l'électrolyte et l'espèce électroactive. Si l'échange ionique n'a pas lieu, l'ensemble de la réaction électrochimique est bloqué. En revanche, le second pic de réduction (situé au potentiel le plus négatif) ne semble pas influencé par la nature du cation de l'électrolyte support, ce qui peut dans certains cas s'accorder avec un mécanisme électrochimique de type intra-zéolithique. D'après ces auteurs, même si le cation TBA^+ doit être considéré comme pouvant être exclu des canaux de la zéolithe Y, l'existence d'une force motrice telle que la création d'une charge négative dans le réseau de la zéolithe est en mesure de provoquer la diffusion de TBA^+ vers l'intérieur de la zéolithe. Cela permet également d'expliquer pourquoi le second pic de réduction se situe à environ 0,5 V du premier pic vers les potentiels négatifs. En effet, la surtension observée peut être due aux interactions entre le complexe et la zéolithe mais elle représente aussi l'énergie qu'il faut mettre en jeu pour imposer la pénétration du cation TBA^+ dans la zéolithe. Walcarius et Lamberts (98) ont également proposé une autre explication en ce qui concerne le second pic de réduction. Il est possible que l'électrode constituée de carbone graphite, d'huile minérale, de zéolithe et de l'espèce électroactive provoque des surtensions d'électrode suffisamment importantes pour expliquer la présence du second pic de réduction.

La majorité des travaux précédemment cités vont dans le sens d'une électroactivité s'établissant selon le processus rédox extra-zéolithique suggéré par Shaw et al. (21). Malgré la complexité du système due à l'intervention de nombreux paramètres, il en ressort que les phénomènes de diffusion intra-zéolithique ont une incidence majeure sur la réponse électrochimique observée. En règle générale, lorsque l'espèce électroactive est incorporée dans la zéolithe par un simple échange d'ions, la réaction électrochimique s'établit selon un mécanisme extra-zéolithique. Cependant, dans certains cas — l'exemple type est celui de l'argent — une réduction intra-zéolithique de l'espèce électroactive est envisagée. Il est vrai que la réduction de cations métalliques au degré d'oxydation zéro leur confère un caractère métallique donc conducteur qui est peut-être susceptible de faciliter un transfert électronique intra-zéolithique. De toute évidence, les analyses contradictoires sur l'électroactivité de certaines espèces intra-zéolithiques fait apparaître qu'il est difficile d'affirmer catégoriquement, malgré la capacité de l'espèce électroactive à diffuser à l'extérieur de la zéolithe, l'exclusivité d'un processus rédox extra-zéolithique.

IV. 3. 2. Processus rédox intra-zéolithique

Le site du transfert électronique est la différence essentielle entre un processus rédox intra-zéolithique et un processus rédox extra-zéolithique. Lors d'un processus intra-zéolithique, l'électron est transféré à une espèce présente au sein de la zéolithe. Ce processus est par conséquent applicable aux espèces prisonnières du système poreux de la zéolithe. Ainsi, l'activité électrochimique des espèces encapsulées — telles les métal–Salen, métallophtalocyanines, métal–bipyridine, métal–phénanthroline et des nickel et cobalt hexacyanoferrates incorporés dans la zéolithe Y (34, 59–74, 99) — a été considérée comme pouvant s'établir selon un processus rédox intra-zéolithique. Malgré la capacité de certaines espèces à pouvoir diffuser hors de la zéolithe, Li et coll. (31–33, 82–85) les considèrent comme pouvant être impliquées dans un processus rédox du type intra-zéolithique. De même, Senaratne et al. (92) et Bessel et Ro-

© 1998 CNRC Canada

lison (87) attribuent l'origine de l'électroactivité de leurs zéolithes chimiquement modifiées par encapsulation de Co-Salen et $(Fe(bpy)_3)^{2+}$ aux complexes immobilisés et associés à la zéolithe mais uniquement situés à la surface de celle-ci. Nous reviendrons en détail sur les travaux de chacun au cours de cette discussion.

On rappelle qu'un processus rédox intra-zéolithique s'établit selon le mécanisme :

$$E_{(z)}^{m+} + ne^- + nC_{(s)}^{+} \Leftrightarrow E_{(z)}^{(m-n)+} + nC_{(z)}^{+}$$

D'après ce mécanisme, deux conditions sont nécessaires pour observer une activité électrochimique : (*i*) un transfert électronique doit pouvoir s'établir entre l'électrode et l'espèce électroactive; (*ii*) un cation doit pouvoir entrer ou sortir de la zéolithe afin de maintenir l'électroneutralité du système.

IV. 3. 2. 1. La compensation de charge : Malgré une espèce intra-zéolithique immobilisée dans le système poreux de la zéolithe, les phénomènes de diffusion associés à un processus rédox intra-zéolithique ont autant d'importance que dans le cas d'un processus rédox extra-zéolithique. En effet, lorsqu'une espèce intra-zéolithique est oxydée ou réduite, la création de charge doit être compensée par l'entrée ou la sortie d'une espèce chargée dans la zéolithe. La zéolithe étant chargée négativement, l'entrée d'un anion dans la zéolithe n'est pas concevable. L'électroneutralité du système est en conséquence maintenue par le mouvement de cations. Ces cations mobiles peuvent être les cations compensateurs de charge de la charpente zéolithique (dans le cas d'une réaction d'oxydation) ou les cations de l'électrolyte support (dans le cas d'une réaction de réduction). Le mouvement de ces cations est indispensable au processus rédox : sans cette mobilité ionique nécessaire pour compenser la charge induite par la réaction de transfert de charge, l'électroactivité du complexe intra-zéolithique est inexistante.

Le transfert électronique étant un processus rapide par rapport au phénomène de compensation de charge, la cinétique d'un processus rédox intra-zéolithique est contrôlée par la mobilité de ces cations. Les phénomènes de diffusion ont été largement débattus lors de l'étude du processus rédox extra-zéolithique et les observations faites sont applicables à la diffusion du cation compensateur de charge lors d'un processus rédox intra-zéolithique. Nous ne reviendrons donc pas sur le sujet. On rappellera simplement que la diffusion des cations mobiles est, entre autres, influencée par leur taille, la nature du solvant, leur localisation dans la zéolithe et la morphologie de l'électrode.

IV. 3. 2. 2. Le transfert électronique : Rarement considéré comme tel, il semble pourtant opportun de faire le distinguo entre le transfert électronique électrode – complexe intra-zéolithique et le transfert électronique complexe intra-zéolithique – complexe intra-zéolithique. Le premier transfert est nécessaire pour obtenir une réponse électrochimique. En l'absence du second, une réponse électrochimique est observée mais elle est faible car seules les espèces présentes dans les cavités les plus proches de l'électrode sont électroactives.

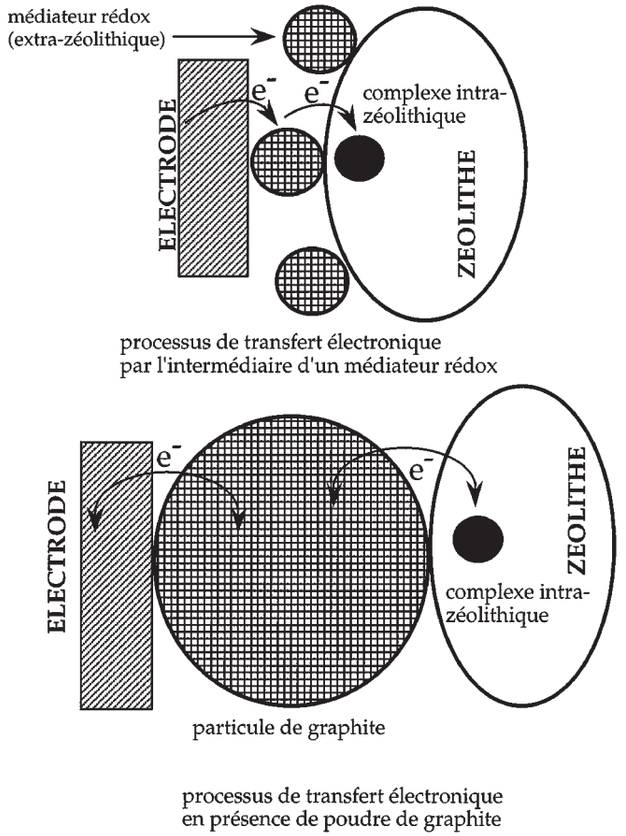
(*a*) *Transfert électrode – complexe intra-zéolithique*. Le caractère isolant de la zéolithe restreint considérablement le transfert électronique entre l'électrode et l'espèce intra-zéolithique. Ce transfert peut s'établir par un contact direct ou par l'intermédiaire d'un médiateur rédox. L'utilisation d'un médiateur rédox est spécifique aux travaux de Li et al. (31–33). Ces travaux sont basés sur le même concept : deux espèces électroactives sont fixées à une zéolithe par un simple échange d'ions. L'une est incorporée dans le réseau poreux de la zéolithe (par exemple un métallocène ou un cation viologène), l'autre est uniquement présente à la surface de la zéolithe car sa taille lui interdit de pénétrer dans la zéolithe (par exemple un métal tris(bipyridyl) ou une métalloporphyrine). L'électron est transféré de l'électrode au complexe intra-zéolithique par l'intermédiaire de l'espèce électroactive fixée à la surface de la zéolithe. Le transfert de l'électron entre ces deux espèces électroactives n'est possible que s'il est thermodynamiquement favorable. En effet, prenons l'exemple de $Ru(bipy)_3^{2+}$ fixé à la surface de la zéolithe Y et $Co(CpCOOCH_3)_2^{+}$ incorporé dans la zéolithe (31). Du fait de leur potentiel rédox respectif, la réduction du cobaltocénium par le complexe de ruthénium est envisageable mais pas la réaction inverse. Mallouk et Li (31) parlent d'un transfert électronique unidirectionnel (ou vectoriel). La possibilité de contrôler le sens du transfert de l'électron laisse présager des applications intéressantes en électrocatalyse ou en photocatalyse. La fixation d'une espèce encombrante à la surface de la zéolithe a également l'avantage d'empêcher un échange rapide des espèces présentes dans la zéolithe avec les cations de l'électrolyte support. Ainsi, la fixation de la tétrakis(*N*-méthyl-4-pyridyl)porphyrine de cobalt à la surface de la zéolithe Y joue non seulement le rôle de médiateur électronique entre l'électrode et le cation méthylviologène intra-zéolithique mais ralentirait aussi le passage de celui-ci en solution (32).

Les travaux de Li et al. (31–33) montrent de manière indéniable la réalité du transfert électronique de l'extérieur de la zéolithe vers l'intérieur des supercages situées à proximité du médiateur rédox. Cependant, dans le cas de l'étude du comportement électrochimique des métallocènes (31, 33), les complexes intra-zéolithiques peuvent diffuser librement dans la zéolithe, du fait de leur taille qui est inférieure à celle des ouvertures des cages de la zéolithe. Dans ce cas, la possible intervention d'un mécanisme de type 1 ne peut être écartée et a pour effet de partager à nouveau les opinions en ce qui concerne le mécanisme électrochimique à considérer.

Un parallèle peut être établi entre les médiateurs rédox utilisés par Mallouk et Li et les particules de graphite utilisées dans la fabrication des électrodes pressées développées au laboratoire (fig. 11). En effet, la poudre de graphite intimement mélangée aux grains de zéolithe sert de conducteur électronique entre la zéolithe et le collecteur de courant (grille métallique). Les électrons peuvent être transférés du collecteur de courant aux espèces encapsulées via les particules de graphite. Il est important de noter que seule la fraction de complexes encapsulés dans les supercages situées à la périphérie des grains de zéolithe est concernée par ce transfert électronique. Par ailleurs, des différences entre les deux types de « conducteurs » d'électrons sont à considérer. Le transfert électronique par l'intermédiaire des particules de graphite n'est pas unidirectionnel car rien n'interdit le passage de l'électron dans les deux sens (oxydation et réduction). De plus, la taille des particules de graphite est plus de

© 1998 CNRC Canada

Fig. 11. Illustration mettant en parallèle le rôle du médiateur rédox et celui de la poudre de graphite dans le mécanisme de transfert électronique.



1000 fois supérieure à celle des médiateurs rédox. Par conséquent, le contact entre les espèces intra-zéolithiques et le graphite doit être moins étroit comparé au contact établi à l'échelle moléculaire entre l'espèce intra-zéolithique et le médiateur rédox.

(*b*) *Transfert de charge intervenant dans le cas de complexes encapsulés dans les cavités zéolithiques*. L'encapsulation des complexes à l'intérieur des cavités zéolithiques devrait simplifier l'analyse de leur comportement électrochimique puisque seul le mécanisme de type intra-zéolithique (type 2) peut être avancé pour expliquer les phénomènes observés. Cependant, il n'en est rien et la nature du transfert de charge demeure un sujet très controversé. Quelques publications (66, 70, 87, 92) rendent bien compte des divergences d'avis sur ce sujet. Nous allons développer dans cette partie les arguments avancés par les partisans et les opposants du mécanisme électrochimique de type 2 et nous verrons que, là où certains croient pouvoir mettre en évidence des erreurs d'interprétation d'autres chercheurs, ils ne font que discuter de résultats qui ne sont pas comparables. En effet, la synthèse et les différentes opérations post-synthèse influencent énormément la qualité des produits obtenus et les résultats entre différentes équipes sont parfois peu comparables car les matériaux utilisés sont différents.

Dans le cadre de l'étude des complexes encapsulés dans les zéolithes, de nombreuses publications rendent compte de la possibilité d'utiliser l'électrochimie pour caractériser ces complexes (59–75, 87, 88, 92, 100). Le débat à propos du mécanisme électrochimique est dominé par l'opposition qu'il y a sur plusieurs observations. D'abord, la quantité de complexes pouvant être atteints par électrochimie est rarement supérieure à 1 % de la totalité des complexes présents dans la zéolithe. Ensuite, le comportement électrochimique des espèces encapsulées est parfois très similaire à celui observé pour le complexe en solution.

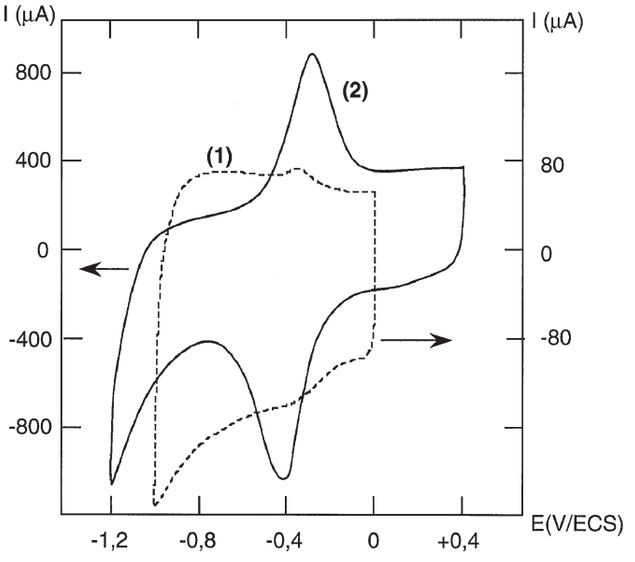
La faible électroactivité des complexes encapsulés peut s'expliquer par la configuration d'électrode utilisée. En effet, il est clair que seuls les cristaux de zéolithe placés au contact de la grille de platine ou des particules de graphite dispersées au sein de l'électrode pressée sont susceptibles de participer au processus électrochimique. Considérons tout d'abord l'électrode dans son ensemble. Les cristaux de zéolithe se trouvant éloignés de la grille de platine, ou ne se trouvant plus en contact avec les particules de graphite, n'offrent aucun complexe qui soit électroactif. Considérons maintenant les cristaux de zéolithe situés à proximité du conducteur. Trois types de cage contenant le complexe peuvent être considérés dans un cristal de zéolithe : (*i*) les cages localisées à la surface des cristaux, (*ii*) celles situées dans des défauts structuraux et (*iii*) celles présentent dans les profondeurs des cristaux. Les deux premiers types de cages sont a priori accessible par électrochimie puisque rien ne s'oppose au passage du solvant, de l'électrolyte et au transfert électronique. En revanche, le troisième type de cage peut être considéré comme inaccessible par électrochimie pour plusieurs raisons : la présence de complexes volumineux dans les cages situés à la surface des cristaux de zéolithe peut bloquer le passage du solvant et de l'électrolyte, isolant ainsi ces complexes de la solution, de plus, la présence de cages non occupées peut arrêter le processus de transmission électronique entre le collecteur de courant et les complexes encapsulés dans des cages situées dans les profondeurs des cristaux.

En tout état de cause, la voltampérométrie cyclique d'un complexe encapsulé dans la zéolithe Y est fondamentalement différente de celle du même complexe simplement adsorbé à la surface de la zéolithe. La figure 12 montre bien cette différence dans le cas du complexe $[Fe(III)Salen]^+$. Cette différence peut s'expliquer par le fait que dans le cas où le complexe est simplement adsorbé à la surface de la zéolithe, il y a perte du signal électrochimique dès immersion de l'électrode dans la solution électrolytique et ce à cause du passage en solution du complexe adsorbé par « échange ionique » avec le cation de l'électrolyte support.

Pour ce qui est des similitudes parfois rencontrées entre l'activité électrochimique des complexes encapsulés et en solution, nous pouvons avancer l'hypothèse que, bien que la charpente négative des zéolithes soit parfois considérée comme un ligand supplémentaire des complexes cationiques, il est fort possible que les complexes entourés de leurs ligands soient plus stables que les mêmes complexes, avec un ou plusieurs ligands remplacés par les charges négatives de la charpente zéolithique. Cependant, quelques études ont clairement montré que dans certains cas, les interactions entre la charpente de la zéolithe et les complexes intra-zéolithiques pouvaient être mises en avant pour expliquer leur comportement électrochimique. Par exemple, Bedioui et

© 1998 CNRC Canada

Fig. 12. Voltampérogrammes cycliques du complexe Fe(III)Salen adsorbé à la surface de la zéolithe Y (courbe 1) et du complexe Fe(III)Salen encapsulé dans la zéolithe Y (courbe 2) en milieu DMSO + $LiClO_4$, à une électrode composite (vitesse de balayage de potentiel = 10 mV/s), adaptés de la reférence 66.



al. (60) ont montré que l'activité électrochimique du complexe CoSalen encapsulé dans la zéolithe NaY montre un pic supplémentaire par rapport à l'étude du complexe en solution. De manière similaire, le système Co(II)/Co(I) est beaucoup mieux défini lors de l'étude électrochimique de perfluorophtalocyanines de cobalt encapsulées que pour le même complexe en solution (64, 66). Les auteurs ont attribué cela à un confinement du complexe au sein de la cavité zéolithique qui empêcherait les phénomènes d'aggrégation observables lorsque le complexe est en solution. En effet, les résultats reportés par Golovin et al. (101) montrent que la dissolution des complexes chloro-substitués de la Co(II)phtalocyanine dans le diméthylformamide conduit à une agrégation des complexes qui induit de nombreuses complications cinétiques ne permettant pas d'observer clairement le système Co(II)/Co(I). Le même comportement a été observé avec le complexe $Cu(II)F_{16}Pc$ qui montre un système Cu(II)/Cu(I) beaucoup mieux défini que pour le complexe en solution, lorsque celui-ci est encapsulé dans la zéolithe NaY.

Il a de plus été montré que le comportement électrochimique du complexe Fe(III)Salen encapsulé dans la zéolithe NaY se distingue de celui du complexe en solution par l'apparition d'un pic supplémentaire pour la réaction rédox Fe(III)/Fe(II) du complexe encapsulé (61). Ce pic peut être attribué à l'existence d'une coordination tétradentate et (ou) bidentate et non plane du ligand Salen au centre métallique fer à l'intérieur des cavités zéolithiques. Ces auteurs ont de plus montré que l'encapsulation du complexe MnSalen dans la zéolithe NaY permet d'éviter la formation du dimère μ-oxo ponté au cours de la réduction Mn(III)/Mn(II), alors que ce dimère se forme en solution. Le volume de la supercage de la zéolithe Y ne permettant pas au dimère du complexe MnSalen d'y tenir, l'électrochimie apporte donc ici une preuve de l'encapsulation du complexe au sein de la zéolithe. Une étude électrochimique similaire a été menée avec le complexe Rh(III)Pc encapsulé dans la zéolithe NaY (72). Ce complexe, connu pour dimériser en solution après la réduction du rhodium au degré d'oxydation II, est stable lorsqu'il est encapsulé dans la zéolithe NaY.

Rolison et coll. (87, 92) ont effectué un certain nombre d'études portant sur l'analyse du comportement électrochimique d'espèces encapsulées dans la zéolithe telles que les complexes CoSalen et $(Fe(bpy)_3)^{2+}$, en utilisant une électrode type « polystyrène » ou « monocouche ». Ils ont focalisé la première partie de leur étude sur la décroissance des intensités de pic observée lorsque plusieurs cycles de potentiel sont effectués avec une électrode contenant le complexe CoSalen encapsulé dans la zéolithe NaY. Lorsque le complexe Co(II)Salen est réduit en Co(I)Salen, il se désorbe de la surface de la zéolithe car il est chargé négativement, provoquant ainsi une perte de matière électroactive à l'électrode et donc une diminution du courant faradique observé. Ils considèrent bien sûr les complexes encapsulés comme non accessibles directement par l'électrochimie. Cette théorie est plausible mais ne corrobore pas les résultats observés par Bedioui et coll. avec des complexes du type $(Co(phen)_3)^{2+}$ (34) ou encore Mn(III)Salen et Fe(III)Salen (66) encapsulés dans la zéolithe NaY. Ces derniers observent, dans certains cas, une diminution des intensités de pics en fonction du nombre de cycles effectués et selon la nature du couple solvant + électrolyte. La figure 13 montre l'évolution des intensités des pics voltampérométrique dans les cas du complexe cationique $Ru(NH_3)_6^{3+}$ fixé par échange d'ion dans la zéolithe Y et étudié dans le DMSO + $LiBF_4$ et dans le cas du complexe Mn(III)Salen encapsulé dans la zéolithe Y et étudié dans l'acétonitrile et le DMSO en présence NBu_4BF_4. La diminution des intensités de pic dans le cas du complexe Mn(III)Salen encapsulé dans la zéolithe Y est, lorsqu'elle existe (dans DMSO), nettement inférieure à ce que Senaratne et al. (92) ont pu mettre en évidence. Bedioui et al. (66) ont interprété cette perte d'électroactivité par la création d'une gêne stérique due à la pénétration du cation de l'électrolyte suite à la réaction rédox à l'intérieur de la supercage de la zéolithe. De plus, la perte d'électroactivité semble liée au nombre de cycles effectués et non au temps d'immersion de l'électrode en solution. Il ressort de ces deux avis opposés que chacun de ces deux commentaires a des raisons d'exister et que l'analyse ne diffère que par la nature des matériaux étudiés. En effet, selon la méthode de synthèse et les procédures post-synthèse choisies, il est possible d'obtenir deux matériaux qui sont finalement peu semblables. Dans le cas des complexes encapsulés, les différences peuvent se situer au niveau du nombre de complexes par supercage, à la présence ou non de cations métalliques non complexés ou de ligands libres ou encore à la présence de complexes non encapsulés à la surface de la zéolithe. De plus, le type d'électrode utilisé peut avoir une influence notable sur la réponse électrochimique observée. Cette hypothèse est confirmée par l'allure des voltammogrammes obtenus par Senaratne et al. (92), radicalement différente de ceux obtenus par Bedioui et al. (66), pour un même complexe mais sur deux configurations d'électrode différentes.

Un point de désaccord important entre les interprétations faites par les différentes équipes travaillant sur le sujet

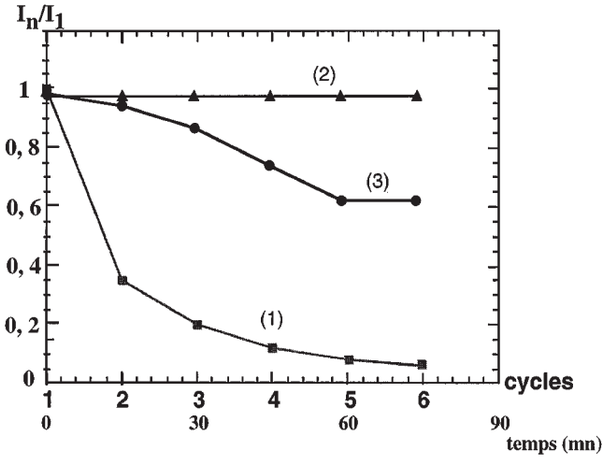
Fig. 13. Evolution du rapport I_n / I_1 (n étant le nombre de cycles de balayage de l'électrode et I_n l'intensité du pic voltampérométrique mesurée lors du nième cycle, I_1 étant l'intensité du pic lors du premier cycle de balayage) des intensités du pic anodique du couple Ru(III)/Ru(II) du complexe $Ru(NH_3)_6^{3+}$ fixé par échange d'ion dans la zéolithe Y (courbe 1, milieu DMSO + $LiBF_4$) et du couple Mn(III)/Mn(II) du complexe Mn(III)Salen encapsulé dans la zéolithe Y (courbe 2, milieu acétonitrile + NBu_4BF_4; courbe 3, milieu DMSO + NBu_4BF_4) en fonction du temps dans le cas de cycles récurrents, adapté de la reférence 66.



émane de la différence dans la fabrication des électrodes. En effet, la conception des électrodes préssées nécessite une étape dans laquelle le mélange de poudre de graphite et de zéolithe modifiée est pressé sur une grille de platine pendant 2–3 min sous une pression environ 2,5 tonnes/cm^2. D'aprés Rolison et coll. (87, 92, 102), cette étape peut engendrer une perte de cristallinité du matériau, c'est à dire créer des défauts de structure au niveau des supercages contenant les complexes encapsulés. Ainsi, quelle que soient les précautions utilisées pour désorber les complexes non encapsulés, la fabrication de l'électrode engendrerait la formation de complexes extra-zéolithiques qui seraient les seules espèces électroactives. Bessel et Rolison (87) observent par microscopie électronique à balayage une perte de cristallinité notable de la zéolithe lorsque celle-ci est broyée dans un mortier par simple action mécanique (sans pour autant préciser l'ampleur de la force exercée) pendant 10–60 min, alors que Bedioui et al. (72) montrent par diffraction X que le fait de presser la zéolithe pour préparer leur électrode de travail n'endommage pas les cristaux de la zéolithe.

Ainsi, Rolison et al. (87, 92, 102) montrent que le fait d'impartir des forces mécaniques à la zéolithe chimiquement modifiée (par simple broyage dans un mortier) engendre des voltampérogrammes avec des pics plus intenses et mieux définis que ceux obtenus sans broyage ou pression de la zéolithe. Cependant, les intensités développées par ces voltampérogrammes diminuent considérablement au cours du temps, comme nous l'avions souligné auparavant. Les auteurs interpretent l'évolution des voltampérogrammes, en fonction des forces mécaniques imposées à la zéolithe, comme étant le résultat de la déstruction des cristaux de la zéolithe qui offre ainsi la possibilité d'atteindre des complexes situés dans des cages auparavant inaccessibles. L'électroactivité ainsi observée serait celle des seuls complexes présents (à nouveau) à la surface de la zéolithe et dont l'accessibilité est maintenant assurée grâce à la fracture des cristaux de la zéolithe. La diminution rapide des intensités des pics voltampérométriques s'explique alors par la perte de matière électroactive due à son passage en solution. Notons toutefois que même si la préparation des électrodes pressées peut être fortement soupçonnée de conduire à la déstruction locale du réseau de la zéolithe, il n'a pas été reporté dans la littérature une telle évolution des voltampérogramme due à la perte visible du complexe initialement encapsulé (34, 59–75).

Au cours de leurs travaux les plus récents, Bessel et Rolison (87) ont entrepris une étude détaillée des complexes CoSalen et et $(Fe(bpy)_3)^{2+}$ encapsulés dans la zéolithe Y dans le but de mieux faire apparaitre l'effet du traitement mécanique excercé sur la zéolithe, sur la réponse électrochimique. Pour celà, les auteurs ont entrepris l'étude voltampérométrique de leurs zéolithes par la téchnique de l'électrode dispersée. L'analyse des voltampérogrammes cycliques d'une suspension de zéolithe contenant le complexe CoSalen (1 mg/1 mL) sous agitation constante, à une électrode de feutre de carbone vitreux réticulé (1 cm × 1 cm × 2,5 cm) a permis à ces auteurs d'observer deux couples rédox attribués au systèmes Co(III)/Co(II) et Co(II)/Co(I) du CoSalen. Il a été aussi noté qu'aucune évolution des voltampérogrammes cycliques n'avait eu lieu durant plus de 3 h d'expérience, ce qui laisse à penser que la réponse électrochimique observée par cette technique provient du complexe immobile et associé à la zéolithe. Il est important de rappeler ici que la zéolithe n'avait subi aucun traitement mécanique lors de la procédure de son analyse voltampérométrique, ce qui garantie l'intégrité totale de son réseau cristallin. La faible électroactivité mesurée (de l'ordre de 0.07 %) a conduit les auteurs à conclure que seules les espèces immobiles, associées et situées à la limite de la surface de la zéolithe sont électroactives. Cette interprétation est trés proche de celle donnée par Bedioui et al. (66) qui attribuent l'électroactivité observée avec les électrodes pressées à la seule fraction de complexes immobiles et encapsulés (ou associés ou figés) dans les supercages situées à la périphérie des grains de zéolithe au contact du conducteur électronique (fig. 14), comme nous l'avions précisé dans le début de cette section.

Un consensus apparaît cependant lorsqu'il s'agit d'admettre l'existence d'un mécanisme électrochimique dans le cas de l'utilisation de médiateurs rédox (31–33) ou des polymères conducteurs intra-zéolithiques (polyaniline, polypyrrole ou polythiophène) (78, 81) pour assurer le contact entre le collecteur de courant et une espèce fixée à l'intérieur des cavités zéolithiques. Mais le rôle joué par le médiateur rédox ou les polymères conducteurs n'est pas fondamentalement différent de celui joué par les particules de graphite dans les électrodes composites, c'est-à-dire d'assurer la conduction électronique du collecteur de courant (grille de platine) jusqu'aux complexes encapsulés. Cependant, la taille des particules de graphite (de l'ordre de 1 μm) n'est pas comparable à celle des médiateurs rédox (échelle moléculaire, quelques ÅngstrØm) si bien que l'amélioration de la conduction électronique est moins importante dans le cas de l'utilisation des particules de graphite que dans celui

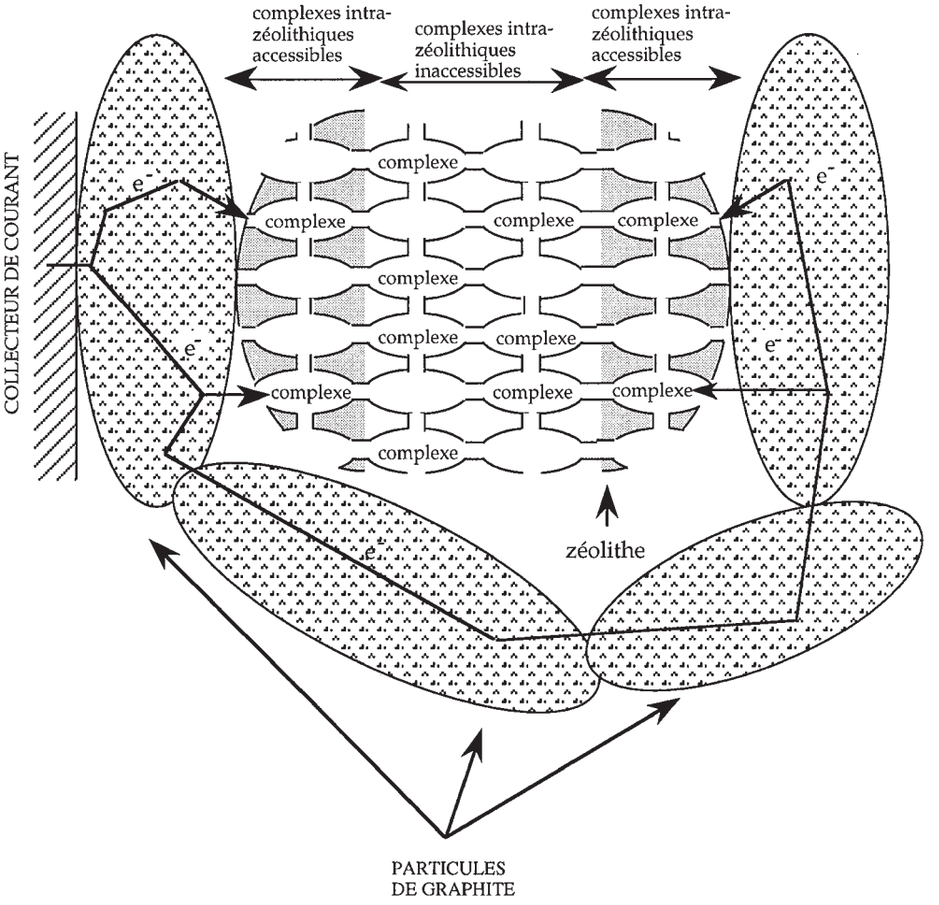
Fig. 14. Représentation schématique de l'électroactivité des complexes encapsulés en fonction de leur position dans le système microporeux de la zéolithe et dans l'électrode pressée.



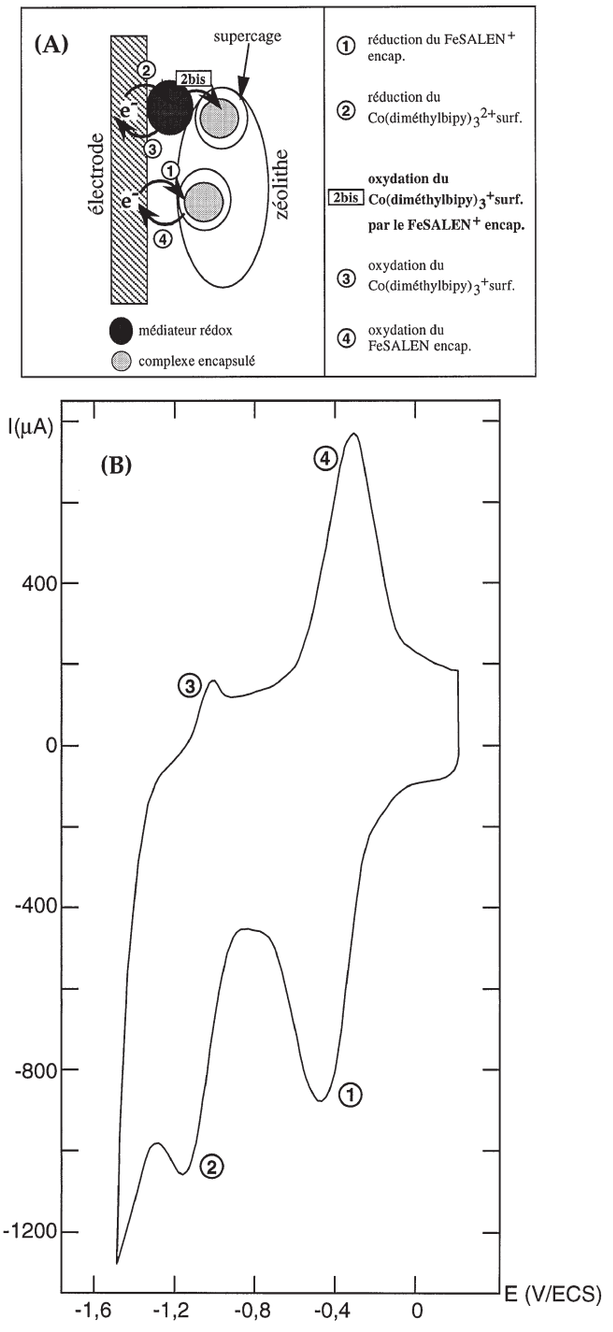
des médiateurs rédox. Dans le but de tenter d'atteindre un plus grand nombre d'espèces encapsulées, il a été développé une zéolithe bi-fonctionnelle contenant un médiateur rédox externe ($((Co(II)(dmbpy)_3)^{2+}$) et une espèce encapsulée ($((Fe(III)Salen)^{+}$) (66). Au cours de la réduction électrochimique Co(II)/Co(I), les espèces Co(I) extra-zéolithiques réduisent les espèces Fe(III) intra-zéolithiques par une réaction rédox, comme indiqué sur la fig. 15. Cette réaction est possible car la différence entre les potentiels standards apparents des couples Co(II)/Co(I) et Fe(III)/Fe(II) est de –700 mV. Le calcul de la quantité de complexes $(Fe(III)Salen)^{+}$ électroactifs suggère une augmentation de 30 % par rapport à ce qui avait été observé lors de l'étude de l'électrode sans médiateur rédox. L'augmentation du nombre de complexes accessibles par voie électrochimique a même été portée à 400 % lors de l'utilisation de particules d'argent électrogénérées au sein de la zéolithe (68).

Tous ces résultats montrent que l'une des principales sources de discorde à propos du mécanisme de transfert de charge provient des différences entre les électrodes de travail utilisées mais aussi et surtout de l'« histoire » des matériaux utilisés. En effet, les études que nous avons présentées utilisent différents échantillons, synthétisés et traités selon des voies diverses. Ainsi, les matériaux finaux sont généralement peu comparables entre eux. Dans les parties consacrées aux autres méthodes d'analyse, nous avons vu que de nombreuses études ont apporté des preuves concernant la localisation intra-zéolithique des complexes encapsulés, mais la preuve la plus évidente est apportée par les résultats obtenus en catalyse. Ils montrent en effet de très importantes différences de réactivité entre les complexes encapsulés et les même complexes simplement adsorbés à la surface de la zéolithe ou dissous en solution (34, 88). Les sélectivités par la taille et la forme des molécules, ainsi que l'accroissement de la stabilité et de l'activité des complexes, sont de bons indicateurs de leur encapsulation.

(*c*) *Transfert complexe intra-zéolithique—complexe intra-zéolithique*. Le transport d'électrons dans les polymères rédox de site rédox en site rédox par un mécanisme de saut d'électrons est un fait établi (103–105). Dans la plupart des cas, le transfert de l'électron nécessite un contact entre les centres rédox. Une certaine mobilité des centres rédox est donc nécessaire et une trop grande rigidité de la matrice peut fortement restreindre le transport électronique. Lorsque les centres rédox sont fixés au polymère par des liaisons covalentes, ils sont incapables de diffuser dans le polymère. Une concentration minimale en centres rédox est dans ce cas requise, concentration au dessous de laquelle les sites électroactifs sont si dilués que leur collision et donc le saut de l'électron est physiquement impossible. Cependant, lorsque

© 1998 CNRC Canada

Fig. 15. (*A*) Principe de fonctionnement de l'électrode composite contenant la zéolithe bifonctionnelle $Co(diméthylbipy)_3^{2+}{}_{surf}$ / $Fe(Salen)_{encap}$ /*Y*. (*B*) Voltampérogramme cyclique de la zéolithe bifonctionnelle en milieu DMSO + $LiClO_4$ (à 10 mV/s), adapté de la reférence 66.



la distance séparant deux centres rédox voisins est supérieure à la somme de leur rayon respectif, un saut d'électron « étendu » peut être considéré. Le modèle théorique établi par Fritsch-Faules et Faulkner (104) montre que deux facteurs ont une influence majeure sur un transfert d'électron « longue-distance » : la concentration des espèces rédox dans le milieu considéré et la distance séparant deux centres rédox. Ils font également intervenir deux paramètres fonction de la structure électronique des centres rédox et de la matrice. Leur modèle est en accord avec les données expérimentales appliquées aux mesures des vitesses de transfert d'électron dans les métalloprotéines.

Le mécanisme de saut d'électron « étendu » ou non est-il transposable aux systèmes intra-zéolithiques? L'étude spectroscopique du complexe $Ru(bpy)_3^{2+}$ encapsulé dans la zéolithe Y montre la nécessité d'un contact direct pour qu'un transfert de charge entre deux complexes puisse avoir lieu (106). Un mécanisme de saut d'électron intra-zéolithique semble donc possible mais il ne peut pas se faire à longue distance, c'est à dire que la présence d'une supercage vide entre deux complexes interrompt la propagation de l'électron. De fait, l'efficacité d'un processus rédox intra-zéolithique sera directement liée à l'efficacité de l'encapsulation. Par ailleurs, les mesures de la conductivité du polypyrrole (longueur des chaînes supérieure à 10 monomères) incorporé dans la zéolithe Y montrent une absence de conduction ($\sigma = 5 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$). Cette absence de conduction est interprétée par un piégeage des radicaux du polypyrrole (polarons) par les ions de la structure zéolithique (80). Aussi, lors d'un processus électrochimique, les intéractions électrostatiques entre la charpente zéolithique et les espèces électroactives ont certainement une incidence majeure sur le transport de l'électron. Ces interactions seraient-elle susceptibles de placer l'électron à un niveau d'énergie tel que sa propagation lors d'un processus rédox intra-zéolithique serait compromise voire interdite? Selon Li et Mallouk (31), 100 % des cobaltocènes intra-zéolithiques sont électroactifs (en présence de médiateur rédox) ce qui semble démontrer que le transfert électronique entre espèces intra-zéolithiques a bien lieu. Cependant leur calcul de taux d'électroactivité peut être sujet à critique car il est basé sur une quantité de zéolithe succesptible d'être sous-estimée (sur un dépôt d'une épaisseur de 60 µm, 1 µm est considéré dans le processus rédox). De plus, les cobaltocènes sont en quantité faible (environ 3 complexes pour 100 supercages) et libres de circuler dans le système poreux de la zéolithe. Aussi, le transfert électronique peut se produire après migration des cobaltocènes dans les supercages proches de la surface de la zéolithe et donc se limiter à un transfert extra–intra-zéolithe. Li et al. (85) montrent que des ions Ag^+ incorporés dans la zéolithe A sont réduits par un processus intra-zéolithique. Une propagation intra-zéolithique de l'électron semble donc tangible. La formation de clusters intra-zéolithique et le caractère fortement conducteur de l'argent réduit tendent peut-être à faciliter la propagation électronique dans la zéolithe. À noter cependant que selon Baker et al. (41, 93) et Pereira-Ramos et al. (56), la réduction de l'argent intra-zéolithique (dans la zéolithe Y et dans la mordenite) s'opère selon un processus rédox extra-zéolithique.

En définitive, si la possibilité d'un transfert électronique aux espèces intra-zéolithiques présentes dans les supercages situées à la périphérie des grains de zéolithe parait être tout à fait réalisable, et ce malgré les réticences liées à la définition exacte d'une terminologie précise de la part des differents auteurs (30, 66, 70, 87, 88, 91, 92, 100), aucune étude électrochimique ne permet de vérifier catégoriquement que

© 1998 CNRC Canada

le transfert électronique se prolonge entre espèces intra-zéolithiques. L'électroactivité observée lors de l'étude de complexes encapsulés au sein d'une zéolithe se limiterait donc aux complexes en contact direct avec le conducteur électronique (fig. 14). Le consensus vers lequel converge actuellement les différentes équipes travaillant dans ce domaine consiste à dire que l'électroactivité des complexes immobiles, associés à la zéolithe et résidant à la périphérie des pores externes est bien réelle. Il est clair que cette électroactivité est faible et ne concerne qu'une faible proportion de la population totale des espèces encapsulées.

IV.3. 3. Mécanismes électrochimiques intervenant dans le cas de cations métalliques incorporés aux réseaux de tamis moléculaires.

Par analogie avec ce que nous avons vu lors de l'étude des mécanismes électrochimiques intervenant avec les complexes encapsulés, nous pouvons considérer que l'incorporation de cations métalliques au sein du réseau des tamis moléculaires doit aboutir à des mécanismes similaires. En effet, les cations métalliques sont immobilisés au sein de la structure du tamis, ils ne peuvent donc participer qu'à un mécanisme électrochimique de nature intra-zéolithique. Les termes intra- et extra-zéolithique utilisés pour décrire les mécanismes électrochimiques sont conservés dans le cas de l'étude électrochimique des tamis moléculaires. Il y a peu d'études qui portent sur la caractérisation électrochimique des tamis moléculaires modifiés ou de matériaux s'en approchant. Cependant, quelques études électrochimiques de tamis moléculaires modifiées ont été reportées au cours des cinq dernières années.

De Guzman et al. (107) ont été les premiers à étudier l'activité électrochimique d'un tamis moléculaire contenant des cations métalliques de transition. Ils s'agit de tamis moléculaires octaédriques (OMS), ayant la structure todorokite (OMS-1) ou hollandite (OMS-2), contenant des ions Mn(II) ou Cu(II), qu'ils ont étudiés au moyen d'électrodes à pâte de carbone. Leur objectif a été de déterminer si ces ions métalliques sont mobiles et situés dans les tunnels, ou immobiles et donc incorporés au réseau du matériau. Les voltammogrammes obtenus avec OMS-1 montre un couple de pics tandis que ceux obtenus avec OMS-2 ne montrent aucun signal particulier. Ils expliquent la différence entre ces deux matériaux par la présence des ions Mn(II) dans OMS-1 alors qu'ils sont absents dans OMS-2. Des expériences conduites en RPE ont confirmé ces résultats et montré que OMS-2 contient principalement les ions Mn(III) et Mn(IV) qui ne sont pas accessibles par électrochimie dans le domaine de potentiel choisi. Les intensités de pic observées lors de l'étude de Mn–OMS-1 semblent stables alors qu'elles décroissent sensiblement avec le nombre de cycles effectués dans le cas de l'étude de Cu–OMS-1, ce qui permet aux auteurs de localiser les ions Mn(II) à l'intérieur du réseau de OMS-1 alors que les ions Cu(II) semblent occuper une position extra-réseau. Cu–OMS-2 ne montre aucune activité électrochimique particulière, ce qui est certainement dû à une ouverture de canaux trop petite (4,8 Å). D'un point de vue mécanistique, De Guzman et al. expliquent le comportement électrochimique de OMS-1 par un mécanisme intra-zéolithique. Plus précisément, ils expliquent que la conduction peut être assurée par sauts d'électrons entre les sites Mn(II) intra-réseaux. Pour ce qui est des ions Cu(II), extra-réseaux, la comparaison des voltammogrammes effectués avec Cu–OMS-1 (un couple de pics) et à partir d'une solution de Cu(II) (deux couples de pics) semble indiquer que le mécanisme électrochimique est de nature intra-zéolithique.

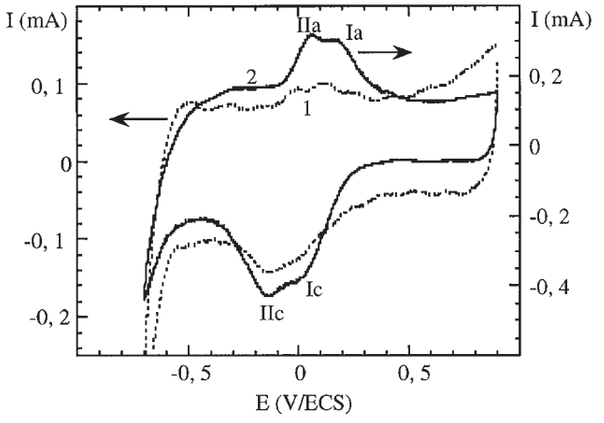
Venkatathri et al. (108) ont étudié le comportement électrochimique du tamis moléculaire VAPO-5 au moyen d'une électrode à pâte de carbone. L'étude des tamis moléculaires contenant du vanadium est rendue compliquée par les nombreux états d'oxydation et géométries que peut prendre cet élément. De plus, malgré les nombreuses méthodes d'analyse utilisées pour la caractérisation de ce type de matériau, la position intra-réseau du vanadium n'est pas encore clairement démontrée. Les voltammogrammes obtenus par Venkatathri et al. montrent deux couples de pics qu'ils attribuent aux ions vanadium (système V(V)/V(IV)) intra-réseaux situés dans deux environnements différents. Par comparaison avec les analyses effectuées en RPE et le comportement électrochimique des complexes $VO(acac)_2$ (acac = acétylacétonate) et $VO(iso\text{-}OPr_3)$ ($iso\text{-}OPr_3$ = isopropoxyde), les deux systèmes observés semblent dus aux ions vanadium situés en symétrie tétraédrique distordue et pyramide à base carré. Ils observent de plus un pic d'oxydation irréversible situé vers E_{pa} = 0,6 V/ECS, dont l'intensité diminue avec le temps d'immersion de l'électrode en solution. Ils attribuent ce pic à l'oxydation des ions VO^{2+} non incorporés au réseau pendant la synthèse.

Nous avons de notre coté montré (75) qu'il est possible d'observer l'activité électrochimique des ions vanadium situés dans les phases amorphes des échantillons VAPO-5 qui en contiennent, puis celle des ions vanadium situés au niveau du tamis moléculaire après la sédimentation. Ces derniers seraient inobservables dans les premiers temps d'expérience avec les échantillons n'ayant pas subi la sédimentation, car leur accessibilité est moins importante, donc l'activité électrochimique qu'ils engendrent est trop peu intense pour être mesurée. Cette remarque pose à nouveau le problème de la localisation des ions vanadium dans VAPO-5. Sachant que nos résultats d'analyse élémentaire nous ont montré que la quantité de vanadium présente dans les échantillons non calcinés et calcinés n'était que très faiblement supérieure à celle contenue dans les échantillons ayant subit la sédimentation, nous avons été amenés à conclure à une accessibilité beaucoup plus importante des ions vanadium localisés au niveau des phases amorphes. Quant à la localisation des ions vanadium au niveau des parties cristallines du tamis moléculaire, la stabilité des voltammogrammes obtenus après de longs temps d'immersion des électrodes en solution suggère que le vanadium se situe à l'intérieur du réseau du tamis moléculaire (fig. 16). Nous ne pouvons cependant pas exclure un mode d'incorporation des ions vanadium dans le réseau d'AlPO-5 par condensation avec les ions hydroxydes de surface.

Un dernier exemple d'utilisation de l'électrochimie pour la caractérisation des tamis moléculaires chimiquement modifiés a été développé par de Castro-Martins et al. (47, 109). Ils ont étudié le comportement électrochimique du titanosilicate TS-1 au moyen d'une électrode à pâte de carbone. Ils observent un couple de pics qu'ils attribuent au système Ti(IV)/Ti(III) d'ions titane intra-réseaux car la zéolithe ZSM-5 (isostructurale de TS-1) contenant des ions titane

© 1998 CNRC Canada

Fig. 16. Voltampérogrammes cycliques d'une électrode composite contenant VAPO-5 dans H_2O + KBF_4 après 24 h d'immersion en solution (à 10 mV/s). Courbe 1 : VAPO-5 non calciné; courbe 2 : VAPO-5 calciné, adapté de la reférence 75.



(extra-réseaux) et le composé TiO_2 ne montrent aucune activité électrochimique particulière dans les mêmes conditions. De plus, ils ont montré que le comportement électrochimique de TS-1 est très proche de celui du composé TEOT (tétraéthylorthotitanate), ce qu'ils expliquent par un environnement similaire des ions titane dans les deux matériaux, c'est-à-dire en symétrie tétraédrique. D'après ces auteurs, trois mécanismes électrochimiques sont à considérer :

1. Les ions titane, délogés du centre des tétraèdres TO_4, diffusent vers l'ouverture des canaux du tamis pour y subir le transfert d'électron.

2. Le processus électrochimique ne concerne que les ions titane situés à la frontière entre les grains de tamis et de graphite, à l'interface électrode–solution. Dans ce cas, seuls les ions titane situés à la surface du matériau sont électroactifs.

3. Le processus électrochimique n'est pas limité aux ions titane situés en surface et l'ensemble des ions titane sont impliqués dans le processus rédox. Cette possibilité implique une participation des cations de l'électrolyte pour compenser la charge créée par la réaction rédox.

Les auteurs expliquent que le premier mécanisme peut être infirmé car la diffusion des ions titane vers la solution après de longues périodes d'immersion de l'électrode en solution devrait s'accompagner d'une diminution des intensités des pics. De plus, ils n'ont pas été en mesure de détecter les ions titane en solution. Cependant, ils ne considèrent pas le fait que les ions titane peuvent quitter le tamis moléculaire sans pour autant quitter l'électrode. En revanche, l'utilisation d'un cation d'électrolyte volumineux, tel que le cation TBA^+ qui est exclu des canaux du tamis TS-1, induit la disparition des pics précédemment observés, ce qui s'accorde peu avec un mécanisme de type extra-zéolithique. Pour réfuter le second mécanisme, les auteurs considèrent qu'il n'y a pas de raison pour que les intensités de pic augmentent de manière linéaire avec le temps d'immersion de l'électrode. Cette remarque est discutable quand on sait que l'augmentation des intensités de pic peut être due au mouillage progressif de l'électrode à pâte de carbone par le solvant. La deuxième remarque permettant d'écarter le mécanisme 2 est que la taille des cristaux n'est pas reliée au courant de pic, ce qui signifie que les ions titane situés en surface ne sont pas les seuls à participer au processus électrochimique. Cependant, en se basant sur la trés faible électroactivité de ce matériau (comme unique critère), il est probable que celle-ci ne reflète que l'activité rédox des ions Ti^{4+} tétrahédriques intra-réseau mais situés à la surface du tamis moléculaire (ou à la frontière de celle-ci) sans qu'il y ait propagation électronique à travers tous les sites intra-réseau et intra-zéolithiques (110).

V. Conclusion

Malgré les intenses discussions ayant lieu actuellement concernant la caractérisation électrochimique des zéolithes et des tamis moléculaires, l'ensemble des résultats analysés ici montre tout l'intérêt de l'électrochimie comme méthode d'investigation des complexes de métaux de transition (ou des cations simples) incorporés dans ces structures. Outre sa capacité à caractériser les complexes intra-zéolithiques ou les cations rédox faisant partie intégrante du reseau de certains tamis moléculaires modifiés, l'électrochimie a montré son aptitude à témoigner de l'efficacité de l'incorporation de ces espèces, à détecter la présence de résidus mais aussi à purifier la zéolithe ou le tamis moléculaire en engendrant des phénomènes de désorption. La possibilité d'atteindre des taux d'électroactivité satisfaisants ouvrent la voie à des applications en électrocatalyse. Et dans ce domaine, de par leur structure rigide et parfaitement définie, les zéolithes et les aluminophosphates modifiés sont certainement plus sélectifs par rapport à d'autres structures minérales telles que les argiles. D'autres perspectives d'avenir existent. Ainsi, en photoélectrochimie, l'utilisation de ces matériaux offrent des avantages certains, par exemple en favorisant la séparation des espèces impliquées dans le transfert de charge ou en contrôlant la taille des semi-conducteurs intra-zéolithiques. Par ailleurs, la capacité de la zéolithe à stabiliser les étapes intermédiaires d'un processus réactionnel difficilement observables en solution a été mentionnée. La voltampérométrie peut être une méthode de caractérisation de ces états intermédiaires et permettrait ainsi l'analyse des mécanismes de réaction complexes.

VI. Remerciements

Nous tenons à remercier Dr. Jacques Devynck (Directeur de recherche au CNRS et Directeur du Laboratoire d'électrochimie et de chimie analytique) pour l'intéret qu'il a porté à ce travail et sa collaboration permanente tout au long des recherches que nous avons effectuées sur ce sujet. Nous tenons aussi à remercier Prof. Kenneth J. Balkus, Jr. (Department of Chemistry, University of Texas at Dallas) pour sa collaboration scientifique et son aide précieuse quant à la préparation de certains zéolithes et aluminophosphates chimiquements modifiés. Nous remercions aussi tous les co-auteurs dont les noms apparaissent dans nos travaux cités, ainsi que le Centre national de la recherche scientifique (France) et le National Science Foundation (U.S.A.) pour leur soutien financier.

Remarkable kinetic stability of α-thiocarbamoyl substituted 4-methoxybenzyl cations

Robert A. McClelland, Victoria E. Licence, John P. Richard, Kathleen B. Williams, and Shrong-Shi Lin

Abstract: 4-Methoxybenzyl cations bearing α-(*N*,*N*-dimethylcarbamoyl) and α-(*N*,*N*-dimethylthiocarbamoyl) substituents have been generated photochemically upon irradiation of precursors with pentafluorobenzoate or 4-methoxybenzoate leaving groups. The ions have been observed with flash photolysis in 40:60 acetonitrile:water and in 50:50 methanol:water, and rate constants were measured for their decay in solvent alone and for their capture by azide ion. The cations so studied and their lifetimes in 40% acetonitrile are **6**, $ArC^+H\text{-}CONMe_2$, 0.6 μs; **2**, $ArC^+H\text{-}CSNMe_2$, 7 ms; and **4**, $ArC^+(CH_3)\text{-}CSMe_2$, 6 ms, where Ar = 4-$MeOC_6H_4$. The cation **4** reacts with solvent by elimination of a proton from the α-methyl group, and the rate constant for solvent addition must be less than 1 s^{-1}. The $CSNMe_2$ substituted cations are 10^5–10^7-fold longer lived than analogs where the thioamide group has been replaced with an α-methyl. The UV–visible absorption spectra of these two cations also show significant differences from those of typical 4-methoxybenzyl cations. Thus, both the lifetimes and spectra point to a strong interaction of the benzylic centre with the thioamide group.

Key words: flash photolysis, thiocarbamoyl stabilized carbocation, photosolvolysis.

Résumé : L'irradiation de précurseurs appropriés portant des groupes partant pentafluorobenzoate ou 4-méthoxybenzoate permet de générer photochimiquement des cationns 4-méthoxybenzyle portant des substituants α-(*N*,*N*-diméthylcarbamoyle) et α-(*N*,*N*-diméthylthiocarbamoyle). On a observé les ions par photolyse éclair dans des mélanges 40 : 60, acétonitrile : eau et de 50 : 50, méthanol : eau et on a mesuré les constantes de décroissance dans les solvants seuls ainsi que pour leur capture par l'ion azoture. Les cations ainsi étudiés et leurs temps de vie dans l'acétonitrile à 40% sont : **6**, $ArC^+H\text{-}CONMe_2$, 0,6 μs; **2**, $ArC^+H\text{-}CSNMe_2$, 7 ms et **4**, $ArC^+CH_3\text{-}CSNMe_2$, 6 ms dans lesquels Ar = 4-$MeOC_6H_4$. Le cation **4** réagit avec le solvant pour donner une élimination de proton provenant du groupe méthyle en α et la constante de vitesse pour l'addition du solvant doit être inférieure à 1 s^{-1}. Les temps de vie des cations substitués par $CSNMe_2$ sont de 10^5–10^7 fois plus grandes que celles de leurs analogues dans lesquels le groupe thioamide a été remplacé par un α-méthyle. Les spectres d'absorption UV–visible de ces deux cations présentent des différences importantes par rapport à ceux des cations 4-méthoxybenzyles typiques. Les temps de vie et les spectres suggèrent donc tous les deux qu'il existe une forte interaction entre le centre benzylique et le groupe thioamide.

Mots clés : photolyse éclair, carbocation stabilisé par un groupe thiocarbamoyle, photosolvolyse.

[Traduit par la Rédaction]

There have been several recent studies of solvolysis reactions involving carbocations substituted at the C^+ center with a thioamide functional group such as $CSNMe_2$ (1–9). There is good evidence that the reactions do occur by a stepwise $D_N + A_N$ (S_N1) mechanism proceeding via a carbocation intermediate (2, 4, 7). Rate constants for the formation of the α-thioamido substituted cation relative to an analog with α-methyl vary. In some cases the former forms slightly more slowly, in some cases somewhat more quickly, and in some cases considerably more quickly. On the other hand, an α-$CONMe_2$ substituted cation generally forms considerably more slowly than its α-methyl analog.

Less is known about the rate constants for solvent capture of the fully formed cations. The 9-thioamidofluorenyl cation **1** has been claimed as a transient intermediate in a laser flash photolysis experiment in 2,2,2-trifluoroethanol (TFE) (6). There are, however, now serious concerns over the structural assignment in this study, since the chloro precursor that was supposedly employed decomposes instantly when dissolved in TFE (9).

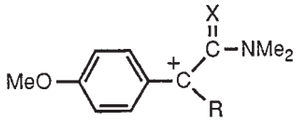
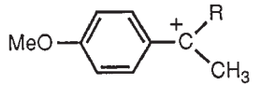
[a] Ratio obtained from analysis of products of ground state solvolysis (7).
[b] Solvent reaction is elimination. Azide reaction is sum of elimination and addition.

In a second study, competition kinetics in 50:50 methanol:water revealed that the benzylic derivative **2** has an azide:solvent selectivity k_{az}:k_s of 7 × 10^4 M^{-1} (7). This is 10^4-fold greater than the k_{az}:k_s of 7.2 M^{-1} for the 4-methoxyphenethyl cation **3** in the same solvent (7). With the assumption that the azide combination is a diffusion-limited process (10), so that k_{az} is the same for both cations (~5 × 10^9 M^{-1} s^{-1}), the lifetime ($1/k_s$) of the thioamido-substituted cation is 10 000-fold longer. Unexpected behavior is also seen with α-thioamido, α-methyl substituted cations (4, 7). The cation **4**, for example, reacts with solvent to give exclusively the alkene product derived from elimination of one of the α-protons (7). Elimination even occurs with azide although, with this ion, addition to the C^+ center also occurs. Such behavior contrasts with that of the cumyl cation analog **5**, where only nucleophilic addition is observed (e.g., less than 1% elimination in the reaction with solvent in 50:50 methanol:water) (7).



2; X = S, R = H
4; X = S, R = CH_3
6; X = O, R = H

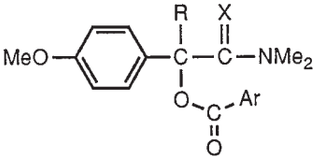


3; R = H
5; R = CH_3

As noted in the original paper (7), the large k_{az}:k_s ratio for **2** leads to concerns about the applicability of the azide clock assumption. The competing elimination/addition with **4** raises this question even more with this system. In consequence, we have performed flash photolysis experiments so as to obtain the absolute rate constants for these cations. The α-amido substituted **6** was included for comparison purposes. It transpires that these cations can be generated from the same precursors employed in the studies of the ground solvolysis. Moreover, the α-thioamido cations are remarkably long-lived.

Results

The substituted benzoates **7–9** were employed as photochemical precursors of the cations **6**, **2**, and **4**, respectively. These esters undergo ground state solvolysis with half-lives of 100 h (**7**), 130 s (**8**), and 5.2 h (**9**) in 50:50 methanol:water at 25°C (7). With **8** this meant that the flash photolysis experiments needed to be carried out immediately after preparation of the solution. It in fact proved possible to prepare the solution and irradiate within 20 s.

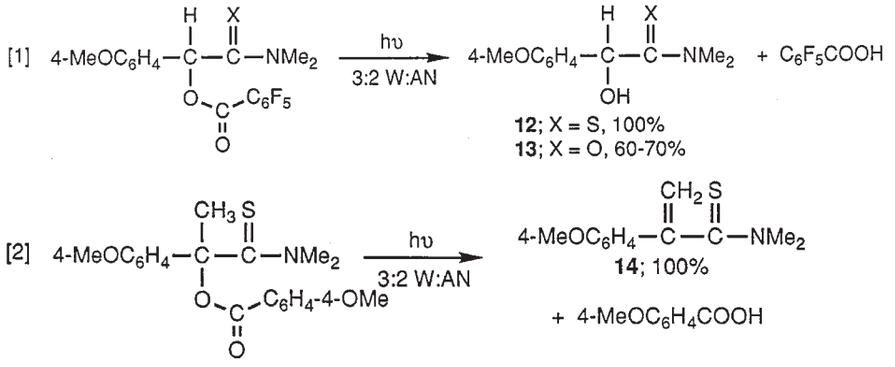


7; R = H, X = O, Ar = C_6F_5
8; R = H, X = S, Ar = C_6F_5
9; R = CH_3, X = S, Ar = 4-$CH_3OC_6H_4$

Flash photolysis spectra obtained with **7–9** in 40% acetonitrile are shown in Fig. 1. The benzoate **7** produces a transient species with λ_{max} around 350 nm, which decays over 5–10 μs to essentially zero OD. The decay is first order, with the same rate constant being obtained across the entire spectrum consistent with the presence of a single transient species. Absorbing species are also observed with **8** and **9**. However, these show no decay up to times as long as 500 μs, the longest time that can be reliably employed with the laser flash photolysis apparatus. Decay is seen, however, using a lamp photolysis apparatus. Like **7**, these decays are first order with the same rate constant throughout the spectrum. The λ_{max} of the transients with **8** and **9** lie in the range 310–325 nm, being slightly higher with **9**. There is, however, some distortion of the spectra, since the thioamido precursors absorb below 310 nm. (Note that these experiments measure a ΔOD, the OD after the laser pulse minus the OD before.) With **9**, there is a second weaker absorption with λ_{max} around 500 nm. This is due to the same transient as the absorbance at lower wavelength, since the decay here has the same rate constant. It can be noted that with **8**, aged solutions that had undergone solvolysis to the alcohol failed to produce any transient.

Azide ion accelerates the decay of all three transients, with linear plots of the observed rate constant versus azide concentration. Values of k_s, the first-order rate constant for decay in solvent alone, and k_{az}, the second-order rate constant for the quenching by azide ion, are given in Table 1. Two solvents were employed, 40:60 acetonitrile:water, and 50:50 methanol:water. The former was chosen to provide comparisons with rate constants measured by flash photolysis for other benzylic cations. The latter was the solvent

© 1998 NRC Canada



employed in the analysis of the products of the ground state solvolysis of these esters.

The final products of the irradiation were examined in 40% aqueous acetonitrile. These experiments were carried out by preparing a solution of the precursor benzoate of concentration ~100 μM, which was then split in two. One half was irradiated at 254 nm, while the other was kept in the dark under conditions sufficient for complete ground state solvolysis. The HPLC chromatograms of the two were then compared, along with the chromatograms of the authentic products of the ground state hydrolysis.

With **8**, which undergoes a relatively rapid ground state solvolysis, the solvent was cooled to 0°C before addition of the substrate. After substrate addition, half was irradiated at this temperature for 30 s, a time sufficient to remove 95% of the precursor. The other half was warmed to room temperature and allowed to stand for a total time of 1 h. (The half-life at 20°C is 4 min.) The products observed in both the excited state and ground state reactions were the alcohol **10** and pentafluorobenzoic acid (eq. [1]). Based on the relative areas of the peaks (with a small correction for remaining precursor), the yield of the the alcohol in the irradiated solution was 102% of that in ground state. Thus, within experimental error, there was quantitative formation of the same product of the ground state solvolysis.

The same conclusion was reached with **9**. Again, 30 s irradiation was sufficient to photolyze 95% of the precursor. Four hours at 50°C was required for the ground state reaction. The observed products from both were the alkene **12** and 4-methoxybenzoic acid (eq. [2]). The yield of alkene in the irradiated solution was 97% of that of the solvolyzed one.

With **9**, the situation was more complicated. The photolysis was considerably less efficient, 3 min of irradiation for example only reacting 45% of the starting material. A consequence was that the products were not stable, unlike the situation with the two thioamides, but underwent further photochemistry. The solvolysis reaction required overnight at 50°C for completion, and gave the expected alcohol **11** and pentafluorobenzoic acid (eq. [1]). These were also the major products in the irradiated solution, but their yields expressed as a percentage of reacted **7** decreased with increased irradiation time. Based on a three-point extrapolation to zero irradiation, the yield of alcohol is 60–70%. The HPLC chromatogram of the irradiated solution did have other peaks, but these were not identified.

Discussion

Identification of transients as benzylic carbocations

While there is no spectrum of an authentic cation available for comparison, there is good evidence that the transients observed with the three esters **7–9** are cations forming by photoheterolytic cleavage of the α-carbon–oxygen bond. Firstly, the stable products of irradiation are those expected of a photosolvolysis. In the case of the thioamides **8** and **9** in fact, there is a very efficient conversion to exactly the same products obtained in the ground state solvolysis reaction. Secondly, the transients are quenched by azide ion, a typical carbocation trap. More importantly, the absolute rate constants k_{az} and k_s obtained by flash photolysis give selectivities k_{az}:k_s that are essentially the same as those obtained in the ground state solvolysis (7). This comparison was made in 50:50 methanol:water and is shown in Table 1. In the case of the cations **4** and **6**, the flash photolysis ratio is slightly larger but the difference is not outside experimental error. With **2**, the flash photolysis ratio is about two thirds of that obtained in the competition experiment. The latter was, however, obtained with azide ion concentrations in the range 0.5–1.0 mM, where >95% of the products arise from azide trapping (7). This means that the amount of alcohol product being measured is quite small, creating some uncertainty in the final ratio.

Rate constants for addition and elimination in cation 4

The reaction of the cation **4** gives only alkene product in 50:50 methanol:water (7). Thus the decay of this ion observed in the flash photolysis experiments represents the reaction with solvent acting as a base, and the k_s of 210 s^{-1} is equal to k_s(B) of eq. [3]. There is less than 1% of the ether and alcohol products that would arise form nucleophilic addition of solvent. Thus k_s(Nu) < 2 s^{-1}.

With azide ion, both elimination and addition occur. The azide-catalyzed elimination is seen in the observation that the alkene:RN_3 ratio does not approach zero at high concentrations of azide, but plateaus, in fact, with a greater amount of alkene (7). The limiting [alkene]:[RN_3] is 1.69; this is equal to the ratio of rate constants for azide acting as a base and a nucleophile, k_{az}(B):k_{az}(Nu). The quenching that is observed with azide ion in the flash photolysis studies represents the sum of these two processes, i.e., k_{az}(flash photolysis) = k_{az}(B) + k_{az}(Nu). Since the ratio is known from the product analysis, the absolute values of the two can be calculated. Thus k_{az}(B) = 3.1 × 10^4 M^{-1} s^{-1} and k_{az}(Nu) =

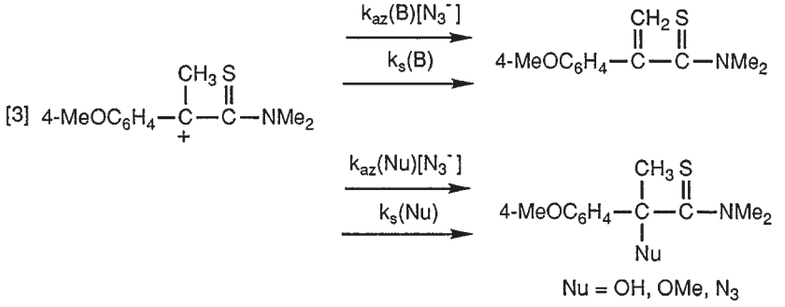
CH_3	CH_3	60 μs	25 ns	12
H	COOMe	6 μs	50 ns	13
H	$CONMe_2$		0.6 μs	This work
H	$CSNMe_2$		7 ms	This work
CH_3	$CSNMe_2$		6 ms (elim.) >1 s (add.)	This work

[a] The lifetimes of carbocations in aqueous acetonitrile solutions (0–60% acetonitrile) do not change by more than 10–20% with changing acetonitrile content (14).



1.8×10^4 M^{-1} s^{-1}. The latter is a remarkably low number for the addition of azide ion to a carbocation. Even the tris(4-methoxyphenyl)methyl cation reacts with k_{az} around 10^7 M^{-1} s^{-1} (11).

It is also worth noting that for stabilized triarylmethyl cations k_{az}:k_s is approximately constant with changing reactivity (11), although the ratio starts to sharply decrease when the azide reaction approaches the diffusion limit. For the cation **2,** where both azide and solvent react as nucleophiles, k_{az}:k_s = 4.5×10^4. If the same ratio were to apply to the nucleophilic reactions of **4**, then k_s(Nu) for this cation would be 0.4 s^{-1}, only 0.2% of the k_s(B) value.

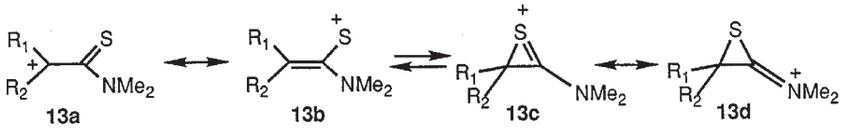
Lifetimes of 4-methoxybenzyl cations

As suspected in the earlier study (7), the assumption of diffusion control for the reactions of azide ion with the cations **2** and **4** is incorrect. The reactions with azide are considerably slower than diffusion, and the lifetimes of these two cations are substantial. A comparison with other 4-methoxybenzylic cations whose rate constants have been directly determined by flash photolysis is presented in Table 2. In the case of the parent 4-methoxybenzyl and the derivative with one α-methyl group, the lifetimes are too short in aqueous solutions for the cations to be studied by ns laser flash photolysis. These cations can, however, be observed in the less nucleophilic TFE.

As was observed previously with an α-COOMe derivative (13), the α-$CONMe_2$ cation **6** examined in this work is longer lived than its α-methyl analog. The differences, however, are not large. The amide is an order of magnitude longer lived than the ester, which in turn is probably about another order of magnitude longer lived in water than the α-methyl derivative (7, 10). These kinetic stabilizations occur in spite of the fact that the α-CO cations are much less thermodynamically stable. Such observations are also made with cations bearing α-CF_3 substituents. Explanations for this behaviour have been proposed in the literature and need not be repeated here (7, 13, 15, 16).

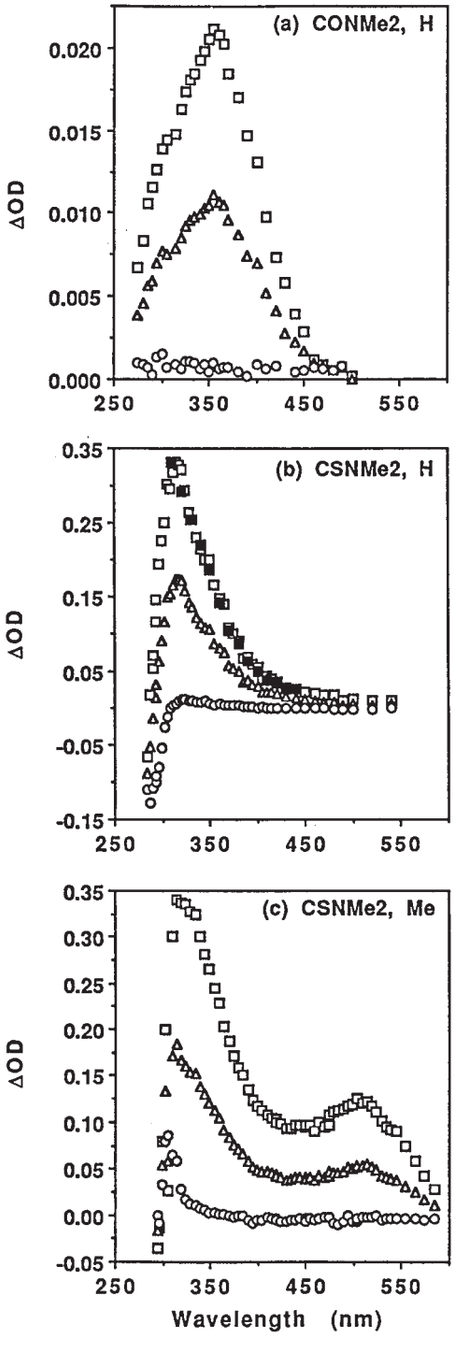
The cations bearing α-$CSNMe_2$ on the other hand are extraordinarily long-lived. The secondary ion **2**, for example, is 10^4 longer lived than its $CONMe_2$ analog and 10^6–10^7 longer lived than the 4-methoxyphenethyl cation. The tertiary **4** is 10^5 longer lived than the 4-methoxycumyl cation. If this comparison involves only solvent addition to the α-C^+ center, this factor rises to 10^7.

There are two possible interactions that could account for the stabilization. One involves a resonance interaction as shown in structure **13b** where the positive charge is delocalized to the sulfur atom. A large fraction of this interaction would be lost in the transition state for solvent capture, leading to an unusually low reactivity (15, 16). The second possibility is the formation of a bridged ion, shown as the resonance structures **13c** and **13d**.



© 1998 NRC Canada

Fig. 1. Flash photolysis spectra obtained on irradiation of **7** (*a*), **8** (*b*), and **9** (*c*) in 40:60 acetonitrile:water. Figure 1(*a*) was obtained with 248 nm laser flash photolysis; Figs. 1(*b*) and 1(*c*) were obtained with lamp flash photolysis. In each figure the uppermost spectrum is the ΔOD measured immediately after the laser or lamp flash, the middle spectrum is the ΔOD at a time corresponding to one half-life of the decay, and the bottom spectrum is the ΔOD at the completion of the decay (6–8 half-lives). The points drawn as full squares in Fig. 1(*b*) were obtained with the laser flash photolysis apparatus, and represent the ΔOD immediately after the laser flash, normalized to the same ΔOD's obtained in the lamp flash photolysis experiment.



Ab initio calculations have found that an α-thioamido cation where R_1 = H and R_2 = H is stabilized by 35.7 kcal/mol by the first interaction, but a further 47.2 kcal/mol stabilization accompanies conversion to the cyclic structure (17). The cation **13** with R_1 = H and R_2 = 3,5-bis(trifluoromethyl)phenyl reacts predominantly as a closed ion, giving 86% of a product that has arisen from reaction of solvent (acetic acid) at the thioamide carbon (2). The cation **2** of this study, however, reacts to give products of addition at the α-carbon (7). This cation of course has the strongly electron-donating 4-methoxy group, which would favour the open structure, and the contrasting behaviour with the bis-CF_3 cation implies it must be reacting through this form. There is the possibility that the open cation is a minor species in an equilibrium mixture with an unreactive closed form (7). This, however, cannot account for all of the kinetic stabilization. This conclusion is based on the measured k_{az} for **2** in aqueous acetonitrile, which is about 1% of the k_{az} of a diffusion-controlled combination (e.g., the k_{az} for **6**). Providing azide ion reacts with the open cation (as the azide product implies) there must be at least 1% of the open cation in the mixture with the closed one. A percentage less than 1% requires k_{az} to be greater than the encounter limit. This in turn means that k_w for the open cation must still be less than 10^4 s^{-1}. This is still two orders of magnitude lower than the k_w for **6** and 10^4 lower than the value for the α-methyl cation.

The UV–visible spectra observed for the three cations in this study (Fig. 1) are also interesting in the context of the structural issue. The spectrum for the α-amido cation **6** is typical of 4-methoxybenzyl cations. The 4-methoxyphenethyl and 4-methoxycumyl ions, for example, have similarly shaped absorption bands (somewhat narrower) with λ_{max} at 340 and 360 nm, respectively (12), in the same region as **6**. With this cation, therefore, there is no indication of anything highly unusual that could be attributed to a strong interaction with the α-carbonyl group.

This, however, cannot be said for the α-$CSNMe_2$ cations. With **2** the λ_{max} is shifted to a lower wavelength, perhaps not highly unusual for a benzyl cation, but there is a long tailing absorbance, and cation decay is even observed at 550 nm. The methyl cation **4** has a similar λ_{max} at the lower wavelength, and the absorbance at higher λ has now become so pronounced that there is a second band centered around 500 nm. These spectra are clearly different from the spectrum for **6**, and also from those of other benzylic derivatives. It is tempting to ascribe the high-wavelength absorption observed with **4** to increased delocalization, in other words to a strong resonance interaction of the type **13a** ↔ **13b** in an open cation. The same absorption is seen with **2**, but it is much weaker. This suggests the possibility that there is less open cation in this system, although clearly there is still some. Such conclusions are highly speculative, since there are no suitable models that allow unambiguous comparisons to be made. What can certainly be concluded is that the behaviours of the α-$CSNMe_2$ cations are unusual, and this is paralleled in both the absorption spectra and the kinetic stabilities.

Experimental section

The photochemical precursors **7–9** and the solvolysis

© 1998 NRC Canada

products **10–12** were from a previous study (7). Laser flash photolysis experiments involved ca. 20 ns pulses at 248 nm (60–120 mJ / pulse) from a Lumonics excimer laser (KrF) emission. A pulsed Xenon lamp provided monitoring light. After passing through a monochromator, the signal from the photomultiplier tube was digitized and sent to a computer for analysis. Conventional flash photolysis experiments were performed with equipment previously described (18), with the sample being irradiated with a broad-band flash lamp of ca. 100 ms duration.

The products of irradiation were determined by preparing 5 mL of a solution of **7–9** in 40% aqueous acetonitrile of concentration 100 μM. With **8**, the solvent had been cooled to 0°C in an ice bath before the substrate was added. One half (2.5 mL) of these solutions were placed in a UV cuvette, the other 2.5 mL in a capped vial wrapped in tin foil. The former were immediately irradiated at 254 nm in a spinning merry-go-round in a Rayonet reactor, then immediately analyzed by HPLC. The latter solutions were left under such conditions that no precursor remained (see Results), as shown by HPLC. Identical volumes of the irradiated and solvolyzed solutions were injected into a Waters HPLC, eluting with 60:40 water:acetonitrile through a C18 column. Products were identified by comparison with known standards. The yields of the products in the irradiated solutions were calculated from the relative peak areas of the irradiated and solvolyzed solutions.

Alumina-assisted reduction of carbonyl compounds with sodium borohydride in hexane

Shigetaka Yakabe, Masao Hirano, and Takashi Morimoto

Abstract: A broad range of aliphatic, alicyclic, and aromatic ketones and aldehydes underwent smooth reduction with a combination of common, inexpensive laboratory reagents, sodium borohydride and chromatographic neutral alumina, in hexane to afford the corresponding alcohols in a selective and high-yielding manner under mild and neutral conditions. The $NaBH_4$-based biphasic system can also successfully be used for the reduction of unsaturated substrates as well as steroidal and highly hindered ketones.

Key words: reduction, carbonyl compounds, sodium borohydride, alumina, alcohols.

Résumé : Beaucoup de cétones aliphatiques, alicycliques et aromatiques et beaucoup d'aldéhydes, peuvent être réduites dans des conditions douces en utilisant une combinaison de réactifs de laboratoires courants et peu coûteux. Par exemple la combinaison: borohydrure de sodium – alumine neutre de pureté chromatographique, dans l'hexane permet d'accéder, de manière sélective et avec des rendements élevés, aux alcools correspondants dans des conditions douces et neutres. On peut également utiliser avec succès le système hétérogène $NaBH_4$–alumine pour réduire, dans les mêmes conditions, les substrats insaturés, le groupe carbonyle des stéroïdes et également les cétones fortement encombrées.

Mots clés : réduction, composés carbonylés, borohydrure de sodium, alumine, alcools.

[Traduit par la Rédaction]

Introduction

The pioneering work of Fetizon's group on the oxidation of various functionalities with silver carbonate supported on Celite (Fetizon's reagent) in 1968 (1) was rapidly followed by rush of extensive investigations into chemistry of supported reagents and catalysts, which were reviewed in journals (2) and more recently in comprehensive books (3). These new, practically attractive reaction systems involve remarkable advantages which cannot be offered by conventional solution-phase counterparts; viz., easy reaction performance, mild conditions, modified or increased agent power, specific product selectivity, improved yield, reduced waste, etc. The last term well fits with the recent trend in environmentally compatible, clean synthesis (4). Thus the use of supported reagents and catalysts has now gained general acceptance and appears to be recognized as a promising strategy in organic synthesis (2, 3).

There have been numbers of procedures available for the preparation of supported reagents (3*a*), among which we have chosen the in situ method on the following two grounds. First, the method can instantly be performed merely by efficient stirring of a heterogeneous mixture of agent(s), substrate, and solid support in an aprotic solvent. Secondly, the method can conveniently be applied to thermally unstable solid agents, such as peroxy acid (Oxone® (5), magnesium monoperoxyphthalate (6)) and oxohalogen acid ($NaClO_2$ (7), $NaBrO_2$ (8), $Ca(OCl)_2$ (9)) derivatives, because thermal drying or activation of supported reagents can be eliminated. Since the agents we have employed are sparingly soluble in the reaction solvents, it is likely that solid supports favorably catalyze the reaction by providing an active site for them, enabling selective and rapid reactions to occur under mild conditions. Although we are mindful of a diversity of methods available for catalytic and stoichiometric reductions (10), the importance of the reaction in organic synthesis and the lack of systematic, extensive studies on this subject using supported sodium borohydride ($NaBH_4$) reagents (11) prompted us to extend TUAT[2] clean synthesis (5–9) to $NaBH_4$ reduction[3] of a wide variety of ketones and aldehydes. We would like to report here some synthetic aspects of $NaBH_4$ reduction by our in situ method using alumina as the solid catalyst (for preliminary results, see ref. 12).

Experimental

Instruments

^{1}H NMR spectra were measured with a JEOL PMX-60, JNM-FX200, or JNM-FX500 spectrometer for solutions in $CDCl_3$ using TMS as an internal standard. Analytical GC was carried out on a Shimadzu GC-14B instrument, equipped

with a FID through a 2 m × 5 mm diameter glass column packed with 5% PEG-20M on Chromosorb WAW-DMCS and interfaced with a Shimadzu Chromatopac C-R6A integrator, with temperature programming. Mass spectra were determined on a JEOL SX-102A mass spectrometer which was coupled with a Hewlett Packard GC5890 Series II GC apparatus via a heated capillary column. IR spectra were recorded for thin films (neat) or KBr disks on a JASCO A-100 spectrophotometer. Melting points were determined on a Yanagimoto MP-S3 melting point apparatus and are uncorrected.

Reagents

Hexane was dried ($CaCl_2$), distilled, and stored over molecular sieves. Commercial sodium borohydride (Yoneyama Chemical, Japan) was ground to a fine powder in a dry box and was stored in a desiccator. Ketones and aldehydes to be reduced were available from commercial sources and were used without further purification, the purities of which were checked by GC prior to use. The corresponding alcohols as reference compounds were commercially available. Addition of deionized water (0.02, 0.04, 0.11, 0.2, and 0.3 g) in portions to chromatographic neutral alumina (ICN Biomedical, alumina N, Super I; 1.0 g), which had been predried in an oven at 500°C for 6 h (dry alumina), followed by vigourous shaking of mixtures after every addition for a few minutes until free-flowing powder was obtained, afforded moist aluminas with 2, 4, 10, 17, and 23 wt.% loading of water, respectively, which were immediately employed for the reduction. Acidic and basic aluminas (ICN Biomedical, alumina A and B, respectively, Super I), silica gel (Fuji–Silysia BW-300), florisil (Kishida Chemical), Japanese acid clay (Wako), bentonite (Wako), Montmorillonite K10 (Aldrich), kaolin (Wako), and zeolites A-3 and F-9 (Wako), and calcium oxide (Kokusan Chemical Works) were predried and were then treated with deionized water as described above. Commercial Hammett indicator reagents (3*a*) were used as received.

Reduction procedure

The reduction procedure for benzophenone **1e** was representative. A 30 mL, round-bottom, two-necked flask, equipped with a 1.5 cm long Teflon-coated stirrer bar, a 25 cm long condenser, and a glass gas-inlet tubing connected to an argon-filled balloon was arranged in order to perform the reaction under a dry atmosphere by linking the top of the condenser to a liquid paraffin trap via a flexible silicone rubber tubing. The flask was charged with **1e** (1 mmol, 0.182 g), hexane (10 mL), finely ground $NaBH_4$ (0.4 mmol, 0.151 g), and freshly prepared moist alumina (0.5 g; H_2O content, 10 wt.%) and was then deaerated by passing a gentle stream of dry argon throughout the system. The flask was immersed in an oil bath and was kept at 60°C while efficient stirring of the resultant heterogeneous mixture was continued in order to ensure smooth reduction and to attain reproducible results. After 3 h, the reaction mixture was cooled rapidly to room temperature by external cooling and was then filtered through a sintered glass funnel. The filter cake was washed thoroughly with portions of dry ether (ca. 50 mL). The combined clear solvent was evaporated on a rotary evaporator under a reduced pressure to dryness to give satisfactorily pure (GC, NMR, and TLC) benzhydrol **2e** in 98% yield (0.180 g), based on the starting benzophenone (entry 26 in Table 1): mp 63.2–63.8°C, reported mp 65–67°C (13).

The recovered alumina was washed with portions of deionized water (in total 50 mL) to remove inorganic residues and then oven-dried (500°C, 3 h). After treating with deionized water as above, it was able to be used for repeat runs (Table 2).

The reductions of the other ketones and aldehydes with the $NaBH_4$ – moist alumina system were performed under conditions determined in terms of their reactivities and yields of the corresponding alcohols **2**, followed by the usual work-up as described above, affording **2**. Alcohols thus obtained were fully characterized by spectroscopic comparisons (IR, NMR, and MS) with the commercial authentic samples and were usually of satisfactory purity for a further use, for example, as substrates for the selective oxidation with chemical manganese dioxide in hexane (14).

It is noteworthy that although certain carbonyl compounds and alcohols have only limited solubilities in hexane under the conditions employed, the reductions and the work-ups of the products were achieved without any difficulty. In addition, we also encountered no difficulty upon a large-scale reduction of **1e** (40 mmol), yielding **2e** quantitatively (entry 27 in Table 1). The recovery of acetophenone **1a** and the yield of 1-phenylethanol **2a** in Tables 2 and 3 were determined by GC using biphenyl as an internal standard.

Results and discussion

Sodium borohydride has enjoyed a widespread use as a selective and mild hydride donor for a broad range of functional groups (10). Established procedures of the $NaBH_4$ reduction have been carried out in protic solvents so as to accomplish reasonably rapid reactions, and therefore an aqueous treatment during work-ups of products has been usually required. However, in order to simplify the method, to increase reagent applicability, and to eliminate aqueous wastes, our synthetic approach involves only introduction of an inorganic support material into a slurry of finely pulverized $NaBH_4$ and a carbonyl compound in an aprotic solvent, followed by the efficient stirring of the resultant heterogeneous mixture. The reduction milieu was of close resemble to supported reagent systems (2, 3) and therefore retained the practical advantage of the latter as regards facile product isolation requiring only filtration followed by evaporation of the solvent.

It is frequently observed that efficiency of supported reagents depends strongly on the choice of support materials and the presence of water (3*a*). In fact, we have experienced in the previous studies that these are decisive factors to determine the facility of the reactions, to control selectivity and yield of products (5–9). Thus, effects of supports on the reactivity of a carbonyl compound and the selectivity and the yield of the alcohol were investigated by using acetophenone **1a** as the test substrate (Table 3). The results showed an important role of a support whose absence gave no indication of the reaction in hexane (entry 1). In addition, no appreciable reaction occurred when **1a** and $NaBH_4$ were stirred with commercial or dry alumina (entries 2 and 3, respectively). There have been numbers of reports that a

small but definite amount of water is essential for supported reagents to favor their reactions (15) and, in addition, that certain reactions with solid reagents are promoted by the presence of water (16). It is a priori expedient for us to use alumina preloaded with a small amount of water so as to facilitate reactions (5–9). Thus, reactions in the presence of

[c]Entry 19 in Table 1.

water-treated alumina (moist alumina; water contents 4–17 wt.%) proceeded smoothly, achieved 100% conversion after 1 h, and gave 1-phenylethanol **2a** in quantitative yield (entries 5, 6). Consequently, it is likely that crystal lattice of $NaBH_4$ may be penetrated and then broken up by water to generate highly dispersed active species over a high-surface-area alumina, leading to increse in its accessible sites to proximal carbonyl compound.

Owing to remarkable catalysis of moist alumina in the reduction of **1a**, we looked for other efficient support materials. Comparative study carried out with a number of inorganic solid supports showed that there are appreciable differences in their efficacy (entries 6, 8–18). Clays, zeolites, and calcium oxide exhibited low activity. Aluminas, silica gel, and florisil were found to be superior to the others as solid catalysts. Sodium borohydride is insoluble and the reagent alone has no reducing capability in hexane (e.g., entry 1), and therefore the reduction must take place on support surface. No clear relationship, however, has been found between surface acidities of the supports and their efficiency (3rd column in Table 3). Since this study aimed at elucidating synthetic utility of the $NaBH_4$-based reduction, further information on physicochemical properties of the supports has not been provided; detailed characterization of the support materials and (or) the $NaBH_4$-supported reagents may offer a satisfactory explanation of the results.[4] Of the supports tested, neutral alumina was the support of choice for the present reduction in terms of ease of reaction performace and yield of the alcohol.

Encouraged by the facile and high-yielding formation of 1-phenylethanol from acetophenone, reductions of various types of ketones and aldehydes were then performed in order to examine the scope of this simple procedure (Scheme 1). Reaction conditions (concentration of $NaBH_4$, temperature, time, and quantity of moist alumina) indicated in Table 1 were optimized, under which the reduction reactions were run to 100% conversion. Simple 5–12 membered alicyclic ketones (entries 32–36), aliphatic ketones (entries 28–30), and aldehydes (entries 60–62) having medium to long alkyl chains can be readily reduced to afford the corresponding alcohols in excellent to quantitative yields. That electron-withdrawing group promotes the reduction while electron-donating group exhibits the reverse effect was suggested by the comparison of apparent reactivity of *p*-MeO- **1c** and *p*-NO_2-substituted acetophenone **1d** towards $NaBH_4$, as judged by their conversions under the same conditions (40°C, 3 h; conversions were 58 and 100%, respectively). The reaction was also sensitive to the steric bulk of substituents and (or) their positions on the cyclohexane or benzene ring. For example, independent reactions of cyclohexanone **1f**, 2-methylcyclohexanone **1g**, and 2-*t*-butylcyclohexanone **1h** under the conditions of entry 33 showed that their apparent reactivities decrease as the substituents adjacent to the carbonyls increase in size (conversions of **1f**, **1g**, and **1h** were 100, 78, and 44%, respectively). 2-Cyclohexylcyclohexanone, menthone, and camphor (entries 44, 46, and 47, respectively) also exhibited low reactivities for which higher concentration of $NaBH_4$, higher temperature, and (or) longer reaction period than those used for unhindered substrates were required in order for their reductions to proceed favorably. On the other hand, influence of side-chain α-substituents seems to be less deleterious than that of ring substituents. Indeed, conversions of benzaldehyde, acetophenone **1a**, and benzophenone were found to be 100, 90, and 83%, respectively, at 40°C for 1 h. The relatively small deference in their reactivities may not be explained on steric ground alone. Moreover, it is interesting to note that α-chloroacetophenone **1b**, which has less electron-donating but more bulky chloromethyl group as the α-substituent than methyl group of **1a**, enabled 100% conversion under the same conditions as above. Clearly, **1a** is slightly less reactive than **1b**. It appears therefore that there might be fine balance between steric and electronic factors in determining the reactivities of carbonyl compounds. Combined influence of these factors has also been suggested in the reduction of ketones with $NaBH_4$ in isopropanol (17).

The reductions in Table 1 can be run to 100% conversion in every case and no deactivation was apparent, indicating clearly that free alcohol resulting from the reduction exerts no detrimental effect on the alumina catalysis. No protic acid is added in the present reaction system, and therefore protons (or H_2O) necessary to decompose a boron complex should undoubtedly be provided from adsorbed water (18). Thus, the role of moist alumina is three-fold; it serves as an adsorption site for substrate and $NaBH_4$, a generator of active species from the latter, and a proton (or H_2O) source whose assembly enables $NaBH_4$ to be used as efficient reducing agent in hexane under mild conditions.

The present reduction is chemoselective, tolerating reducible functionalities such as nitro (entries 23–25, 54), cyano (entry 55), sulfinyl (entry 56), and ester groups (entry 58). The anhydrous conditions may favor the reduction of a carbonyl compound having the hydrolytically labile methylenedioxy linkage, **1k**, to produce piperonyl alcohol quantitatively (entry 57). Olefinic double bonds remained intact upon the reduction (entries 31, 51, 59, 63, and 64), except for a conjugated ketone, cyclohex-2-en-1-one **1j**, which underwent competitive 1,2- and 1,4-addition to afford a mixture of cyclohex-2-en-1-ol and cyclohexanol (entry 49). It is noteworthy that the reduction of *trans*-cinnamaldehyde **1l**

[4]Valuable suggestions from referees regarding various aspects of the present supported reagent system are gratefully acknowledged.

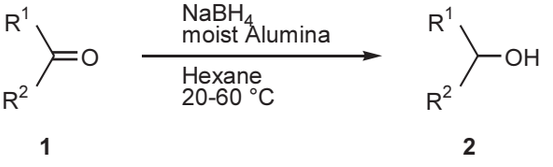
Scheme 1.



1 **2**

(entry 59) and geranial **1m** (entry 63) proceeded without any loss of the double-bond stereochemistry, giving exclusively *trans*-cinnamyl alcohol and geraniol, respectively, in excellent yields. Usefulness of the present procedure for steroidal ketones is also apparent (entries 50, 51).

About three decades ago the reduction was first reported with the use of independently prepared alumina-supported $NaBH_4$ reagents (19), and some of which are now available from commercial sources (Aldrich, Fluka, etc.). To their disadvantages, impregnation of $NaBH_4$ on supports is required a considerable preparative effort, i.e., a few hours of thorough mixing of alumina and aqueous $NaBH_4$, followed by overnight drying in vacuo (19*d*), and commercial reagents are rather expensive. It is also reported that appreciable amount of $NaBH_4$ decomposed upon the preparation (19*a*, *d*) or during storage of the supported reagent (19*a*), lowering the concentration of available $NaBH_4$, and in the latter case (19*a*), placing serious restriction on its use, since the authors themselves pointed out that a freshly prepared reagent must be employed to attain the best reaction performance. Somewhat surprisingly, the method of Santaniello et al. (19*d*) failed to reduce a highly hindered ketone such as camphor **1i** within a reasonal period of time. Of the carbonyl compounds we examined, it is indeed the least reactive substrate, but can be reduced by our in situ method within 3 h to give borneol in quasi quantitative yield (entry 47). Reductions shown in Table 1 can be readily accomplished with stoichiometric to moderate excess $NaBH_4$ (0.25–1.2 mmol of $NaBH_4$ per mmol of substrate) and can therefore be favorably compared to earlier methods by Hodosan and Serban (19*a*) (1 part of $NaBH_4$ per 2 parts of monoketone) and by Santaniello et al. (19*d*) (2.5–3 mmol of $NaBH_4$ per 1 mmol of substrate), which render the present method more economical. These observations clearly indicate that independent laborious preparation of a supported reagent is not a prerequisite for the efficient $NaBH_4$ reduction in apotic solvent. It can be further emphasized that the present reaction is clean, set-up of reaction and work-up of the product are straightforward, and from economical and environmental points of view, use of hexane as the solvent might be favorable. One additional comment should be made. Although the used alumina can safely be kept in an appropriate container and disposed according to the regional legislation, it is of practical importance to recycle the alumina in order to reduce waste and to increase the reagent utility.[4] Table 2 clearly showed that the alumina regenerated by a simple method (vide experimental section) can successfully be employed for several repeat reductions with no decrease in activity. These advantages coupled with the generality and

© 1998 NRC Canada

economic applicability could make our in situ method an attractive substitute for earlier procedures.

Conclusions

The $NaBH_4$ – moist alumina system is a mild, convenient, and efficient reducing agent, applicable to a wide range of carbonyl compounds under neutral and anhydrous conditions.

Gas-phase pyrolysis in organic synthesis. Part 2.[1] Novel rearrangement of esters and ethers into aryl ketones

Nouria A. Al-Awadi, Kamini Kaul, and Osman M.E. El-Dusouqui

Abstract: The formate ester of benzoin (**1**) and the methyl ethers of benzoin and anisoin (**2**, **3**) have been converted separately under thermal gas-phase conditions cleanly into 1,2-diarylethanone and have given, respectively, the following Arrhenius log A (s^{-1}) and E_a (kJ mol^{-1}): 10.11 and 132.0, 11.29 and 173.0, and 11.85 and 151.1. A plausible mechanism is suggested to account for these transformations based on the kinetics and products of reaction.

Key words: gas-phase, pyrolysis, kinetics, mechanism, synthesis.

Résumé : Opérant en phase gazeuse thermique, on a transformé proprement l'ester formique de la benzoïne (**1**) ainsi que les éthers méthyliques de la benzoïne et de l'anisoïne (**2** et **3**) en 1,2-diaryléthanones; les valeurs pour le log A d'Arrhenius (s^{-1}) et pour E_a (kJ mol^{-1}) sont respectivement les suivantes: 10,11 et 132,0; 11,29 et 173,0; 11,85 et 151,1. Pour expliquer ces transformations, on suggère un mécanisme plausible qui tient compte de la cinétique et de la nature des produits formés.

Mots clés : phase gazeuse, pyrolyse, cinétiques, mécanisme, synthèse.

[Traduit par la Rédaction]

Introduction

Uncatalyzed gas-phase reactions and heterogeneous processes using benign reagents and catalysts offer valuable alternatives as safe and environmentally friendly technologies in which waste is also reduced or eliminated (2, 3). The former class of reactions has the added advantage of being free of surface and media influence, hence the effects of structure on reactivity and mechanism might be deemed intrinsic.

Taylor (4) has reviewed the gas-phase pyrolysis of allyl esters of formic acid and the vinyl esters of aryl and alkyl carboxylic acids. The major pathways of these reactions lead to the formation of aldehydes and ketones, and to alkene double bonds only when the interconversions are accompanied by the formation of the stable CO_2 and CO molecular species as by-products. Taylor also speculated that when kinetic studies become available, the esters would be found to react more readily than the analogous ethers. In an earlier study, we have analyzed the structural factors which influence the thermal gas-phase reactivity of pyruvic and benzoylformic acids with reference to the elimination reactions of methyl benzoylformate and 3-hydroxy-3-methyl-2-butanone (5). The reactivity of these systems seems to be largely dependent on the magnitude of acidity of the incipient protonic hydrogen fragment. In this communication, we combine kinetic data and analysis of product of reaction with results from earlier relevant studies to elucidate the mechanism of thermal gas-phase conversion of both the aryl formate ester and the aryl methyl ether functionalities into diaryl ketones. This novel functional group transformation is an environmentally friendly chemical process. Cannizzaro-type disporportionation of benzaldehyde has been achieved over solid CaO as catalyst (6). Condensation of benzaldehyde and anisaldehyde, respectively, into benzoin and anisoin using heterogeneous catalysis instead of catalytic KCN is conceivable.

Results and discussion

Kinetics

Rates

Percent (10–20%) pyrolysis at the reaction temperature is used to evaluate the rate constant of reaction on the basis of HPLC retention data. Each recorded rate constant represents an average from at least three kinetic runs which are in agreement to within ± 2%. Rate coefficients were determined at different temperatures of 5–10°C intervals for ≥ 95% reaction. The kinetic measurements of each substrate were followed over a temperature range of 48–51 K, an experimental requirement in thermal gas-phase elimination studies. The reactions were ascertained to be homogeneous and free from surface effects and radical pathways (5, 7). Arrhenius plots of log k versus $1/T$ (K) showed strict linearity up to >90% reaction. A typical plot is shown in the Fig. 1. Kinetic data, Arrhenius parameters, and the rate coefficients of reaction at 600 K are summarized in Table 1. The

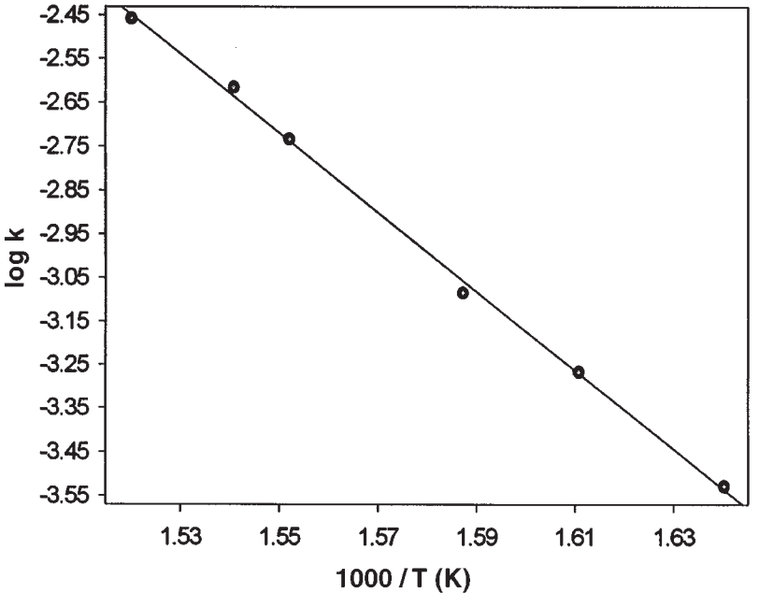
Fig. 1. Arrhenius plot for formate ester of benzoin (**1**).



rates at T = 600 K are calculated using the kinetic equation for first-order reactions: log k = log A – E_a/4.575T.

Molecular reactivity

The formate ester of benzoin (**1**) is ca. 250 times more reactive than the analogous methyl ether (**2**). The pathway of the thermal gas-phase elimination reactions of comparable substrates was found to involve a concerted cyclic six-membered transition state (5, 7, 8): Fig. 2.

The same mechanism is suggested to account for the present results. Contribution to reactivity from bond *a* depends on the relative polarity of this bond. Bond *b* exercises its effect via the lability and protophilicity of the π-electrons, and bond *c* contribution to molecular reactivity is a function of the effect of (*Z*) on the acidity of hydrogen (H) and the stability of the incipient fragment containing (*Z*) (4, 5). The structural feature which distinguishes the ester (**1**) from the ether (**2**) is the electron-withdrawing capacity of the formate carbonyl group at *Z* and the stability of its incipient CO_2 fragment.

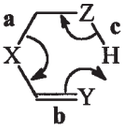
The reactivity of the anisoin ether (**3**) exceeds that of the benzoin ether (**2**) by a factor of 295. It is possible to rationalize this difference in reactivity in terms of the electron-donating mesomeric effect of the *p*-CH_3O group of the benzene ring on the relative protophilicity of the ketone carbonyl moiety: bond *b* in Fig. 2 (7).

Products and mechanism of reaction

Reaction products

The pyrolysate from each substrate was analyzed using both an online GC–MS and FT-1R pyroprobe techniques. The two ethers (**2**, **3**) and the formate ester (**1**), all gave 1,2-diarylethanone. Besides, the ethers yielded methanal and the ester produced carbon dioxide gas as the other molecular fragments of the thermal gas-phase elimination process.

Fig. 2. Concerted transition state.



Mechanism

The reaction pathways shown in Scheme 1 are compatible with both the present kinetic results and the products of pyrolysis, and follow earlier findings by us and others (9). The driving force for the pathway of reaction [1] shown in the scheme might be due to the effect that the ester carbonyl group has on the acidity of the incipient H moiety and on the stability of the departing CO_2 fragment. For substrates **2** and **3**, rate-enhancement could be explained in terms of the relative protophilicity of bond *b* which is higher for the *p*-methoxy substituted function of **3** (see reaction [2]).

Experimental

Materials

Synthesis. Benzoin and anisoin

These were prepared in 85 and 44% yield, respectively, following literature procedure (10, 11). For benzoin, 47.5 mL (0.47 mol) of benzaldehyde in 65 mL of 95% ethanol and a solution of about 5 g KCN as catalyst in 50 mL of water were used in the condensation reactions. The quantities used in the preparation of anisoin were 112 g (0.825 mol) anisaldehyde, 150 mL alcohol, 22.4 g KCN, and 90 mL water. Both benzoin and anisoin were recrystallized from alcohol.

*Benzoin formate (**1**)*

A solution of benzoin (2.4 g, 0.1 mol) in 40 mL of 96% formic acid was refluxed for 16 h, and the resulting solution was concentrated under vacuum to yield a semisolid

product. The residue was dissolved in 5 mL hot formic acid, and the mixture was cooled and filtered to remove unreacted benzoin. The mother liquor was concentrated under vacuum, and the solid residue was dissolved in ether. Any unreacted benzoin was further removed by filtration. Evaporation of ether gave a pale yellow solid, which was recrystallized repeatedly from petroleum ether to give the pure ester as a cream-coloured solid (12).

Benzoin methyl ether (2)

A solution of benzoin (2.1 g, 0.1 mol) in 140 mL of a mixture of equal volumes of methanol and dioxane was

stirred under reflux at 60–65°C. A steady stream of dry HCl was passed into the solution until saturation (2–3 h). The reaction mixture was then evaporated under vacuum, and the residue was chromotographed using petroleum ether/ethyl acetate (4:1 v/v) as eluent to give the pure ether as a white crystalline solid in 90% yield (13, 14).

*Anisoin methyl ether (**3**)*

The ether prepared from anisoin (2.7 g, 0.1 mol) using the procedure described above also gave a pale yellow compound in 40% yield (13, 15).

Characterization

Melting points were recorded on a Gallenkamp Sanyo melting point apparatus and are uncorrected (12–15). For element analysis, a LECO/CHNS-932 analyzer was used. ^{1}H NMR spectra were obtained on a Bruker AC80 spectrophotometer, and GC–MS spectral data were from a Finnigan Mat INCOSXL spectrometer.

*Benzoin formate (**1**)*: mp 72–73°C; δ_H (80 MHz; DMSO): 7.44–8.08 (5H, m, Ar), 8.18 (1H, s, HCO_{2^-}), 8.53 (1H, s, HC=O). $C_{15}H_{12}O_3$ requires C 75.00, H 5.03%; found: C 75.12, H 5.18%.

*Benzoin methyl ether (**2**)*: mp 46–47°C; δ_H (80 MHz; $CDCl_3$): 3.42 (3H, s, CH_3), 5.47 (1H, s, CH), 7.50 (5H × 2, m, Ar); ν_{max} (cm^{-1}): 1684 (s, CO). $C_{15}H_{14}O_2$ requires C 79.62, H 6.24%; found: C 79.73, H 6.26%.

*Anisoin methyl ether (**3**)*: mp 60–61°C; δ_H (80 MHz; DMSO): 3.70–3.80 (9H, s, $3CH_3$), 5.69 (1H, s, CH), 6.90–8.12 (4H, 2H, 2H, m, Ar); ν_{max} (cm^{-1}): 1682 (s, CO). $C_{17}H_{18}O_4$ requires C 71.32, H 6.30%; found: C 71.51, H 6.60%.

Kinetic procedure and product analysis

Experimental details of both kinetic and reaction product analysis have been described in an earlier communication (16). For the kinetic investigations, a custom-made chemical data pyrolysis system, HPLC (Bio-Rad model 2700), Shimadzu UV-vis detector, Bio-Rad HPLC accessories, and Comark microprocessor and platinum resistance thermometers are used. Analysis of products of reaction were carried out using both a flow technique and an online pyroprobe GC–MS (CDS Analytical Model 2000).

COMMUNICATION

A computational study on the sources of deuterium secondary kinetic isotope effects in carbocation-forming reactions

Heidi M. Muchall and Nick H. Werstiuk

Abstract: Calculations at the HF-DFT hybrid Becke3LYP level of theory have been undertaken on protonated 2-*exo*- and 2-*endo*-norbornanols as model substrates for 2-*exo*- and 2-*endo*-norbornyl brosylates to explore the source of the experimentally determined deuterium secondary kinetic isotope effects (KIEs). Calculations on protonated alcohols as models reproduce the "normal" behaviour of 2-*endo* substrate **5**. The observed *endo* γ-KIE in the 7-unsubstituted 2-*exo* system **4** is shown to arise from internal return, while those in the 7-chloro substituted 2-*exo* substrates **1** and **2** can be explained with competing 1,3 (6,2)-elimination.

Key words: deuterium secondary kinetic isotope effects, 2-norbornyl cation, Becke3LYP.

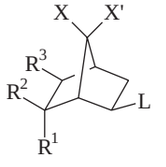
Résumé : Utilisant les formes protonées des 2-*exo*- et 2-*endo*-norbornanols comme modèles des brosylates des 2-*exo*- et 2-*endo*-norbornyles, on a effectué des calculs au niveau théorique hybride Becke3LYP HF-DFT afin d'explorer la source des effets isotopiques cinétiques (EIC) secondaires du deutérium observés expérimentalement. Les calculs sur les alcools protonés utilisés comme modèles permettent de reproduire le comportement « normal » du substrat 2-*endo* (**5**). On a démontré que l'EIC-γ *endo* observé dans le système 2-*exo* non substitué en position 7 (**4**) découle d'un retour interne alors que l'on peut expliquer ceux observés avec les substrats 2-*exo* substitués par un chlore en position 7 (**1** et **2**) en invoquant une réaction d'élimination-1,3 (6,2) compétitive.

Mots clés : effets isotopiques cinétiques secondaires du deutérium, cation 2-norbornyle, Becke3LYP.

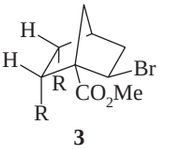
[Traduit par la Rédaction]

Deuterium secondary kinetic isotope effects (KIEs) have been used for decades to gain information on reaction intermediates and transition states, which forms the basis of widely used structure–reactivity principles. Representative of these studies is the work of Werstiuk et al. on **1-OBs** and **2-OBs** (1) and **3** (2), which was undertaken to probe the degree of C^6-C^1 participation in the cation-forming step of the solvolysis reactions in NaOAc-buffered 80:20 EtOH–H_2O.

Earlier it was shown that *exo*-2-norbornyl brosylate-*exo*-6-*d* (**4-OBs6ex**) and *exo*-2-norbornyl brosylate-*endo*-6-*d* (**4-OBs6en**) exhibit unusually large γ-KIEs (**4-OBs6ex**: 9%, **4-OBs6en**: 11%), and the results were interpreted on the basis of a C^6—C^1 bond assistance in the solvolyses (k_Δ, X = H) (3) (Scheme 1). While *endo*-2-norbornyl brosylate-*exo*-6-*d* (**5-OBs6ex**) did not exhibit a γ-KIE, that of *endo*-2-norbornyl brosylate-*endo*-6-*d* (**5-OBs6en**) was slightly inverse (3%). Similar results were obtained from acetolysis reactions (4). It was reasoned that a strong electron-withdrawing substituent at C^1 or C^7 should reduce the contribution of the k_Δ process (1), as the build up of a partial positive charge on C^1 would become less favourable.



L = OBs, OH_2^+



3

R = H, D

	R^1	R^2	R^3	X	X'
1-5ex6ex	H	D	D	Cl	H
2-5ex6ex	H	D	D	H	Cl
1-6en	D	H	H	Cl	H
2-6en	D	H	H	H	Cl

Unexpectedly, γ-KIEs in *anti*- and *syn*-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 (**1-OBs5ex6ex**: 15%, **2-OBs5ex6ex**: 12%) and *anti*- and *syn*-7-chloro-*exo*-2-norbornyl brosylate-*endo*-6-*d* (**1-OBs6en**: 12%, **2-OBs6en**: 13%) were found to be larger than those found for the parent *exo* substrate **4-OBs**. This was interpreted with a combination of ef-

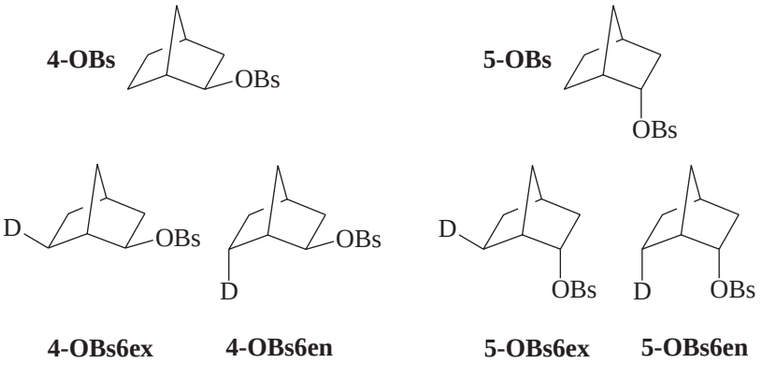
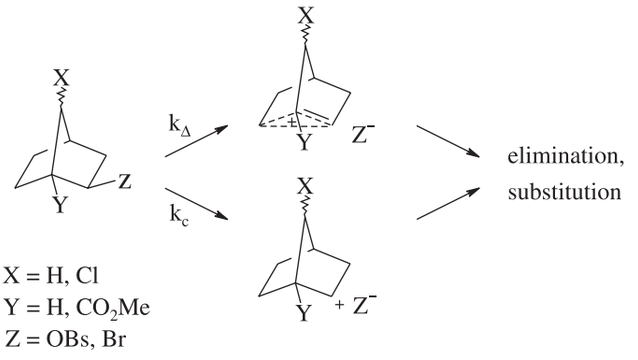


Scheme 1.



fects instead of a simple C^6—C^1 bond participation (considered were 1,3 elimination, *endo* hydrogen participation, 6,2-hydride shift, and solvent-assisted ionization), yet a final clarification was not achieved (1). Moreover, the unusually large γ-KIE found for bromoester **3** exhibited a solvent-polarity dependence (14% in 0.09 *M* NaOAc buffered 80:20 EtOH–H_2O and 20% in 0.14 *M* NaOAc buffered 80:20 EtOH–H_2O) (2). While the authors (1–4) drew conclusions from the experimental data (KIEs, products) and from analogous reactions, definitive statements could not be made at that time. Today, the full force of quantum chemical calculations can be brought to bear on problems of this type to gain fundamental information not directly accessible experimentally and, as a result, provide definitive solutions (see, for example, ref. 5). In this communication, we report the results of a computational study (using Gaussian 94 (6)) of deuterium secondary KIEs of systems **1**, **2**, **4**, and **5**.

As the brosylate systems are prohibitively large, it was necessary to find a reasonable level of theory as well as suitable model systems for substrates and solvolysis transition states. The problems in describing the 2-norbornyl cation are well known and have been confirmed by a computational study by Schleyer and co-workers (7): the classical 2-norbornyl cation (**7**) is a transition state in the rearrangement from the 2-norpinyl cation (**6**) to the — what so far has been referred to as "nonclassical" — 2-norbornyl cation (**8**); this result was achieved at the MP2(full)/6-31G(d) level of theory that was termed "adequate" because **7** was found not to be a stationary point at the HF/6-31G(d) level. In a more recent paper it is stated that a similar structure for **7** could be calculated using Becke3LYP/6-31G(d) (8). Our excellent experiences with the HF-DFT hybrid theory Becke3LYP (9) for different systems and chemical problems (10) led us to employ the computationally quite inexpensive Becke3LYP/6-31G(d,p) level of theory,[2] the inclusion of polarization functions on the hydrogen atoms being essential for the intended study of deuterium KIEs. We found that the 2-norbornyl cation can be described adequately at this level of theory: transition state **7** exhibits the one desired imaginary frequency (–266.6 cm^{-1}) and an IRC calculation links **7** to **6** and **8**. According to Becke3LYP/6-31G(d,p), **7** lies 13.17 kcal mol^{-1} above **8**,[3] which is in excellent agreement with the 13.64 kcal mol^{-1} found with MP4(sdq,fc)/6-31G (d,p)//MP2 (full)/6-31G(d) (13.1 kcal mol^{-1} with Becke 3LYP/6-311+G(d) (8)) reported by Schleyer and co-workers (7*a*). We therefore carried out geometry optimizations as well as frequency calculations using Becke3LYP/6-31G(d,p).

We assumed[4] that an optimized protonated alcohol is a good model for a reactant with the neutral leaving group water forcing the positive charge onto the hydrocarbon fragment in the transition state for dissociation. To test this approach, we calculated secondary α- and β-KIEs for a "normal" system, cyclopentyl brosylate (**9-OBs**). The KIE is computed as the ratio of the rate constant for the undeuterated (light) species over that for the deuterated (heavy) one. Secondary KIEs were determined with the program MacIEcalc[5] from masses, moments of inertia, and frequencies of light and heavy reactants as well as light and heavy transition states (TS) with the temperature set at 298.15 K if not stated otherwise. As scaling factors for Becke3LYP calculations are very close to 1.0, frequencies were not scaled (11); secondary KIEs do not require correction for a tunneling effect. A transition state for the dissociation of the protonated cyclopentanol could not be located, but computed KIEs using models for the TS, in which the C—O distance in the protonated alcohol is fixed at either 210 or 250 pm, were compared to experimental ones as determined by Stoffer and Christen (12) (KIEs in Table 1). With the 210

[2] See refs. 5*a* and *b*; in these papers, Houk and co-workers conclude that Becke3LYP calculations provide good predictions of KIEs.
[3] Zero-point energy uncorrected total energies are –273.060433 hartrees for **7** and –273.081420 for **8**.

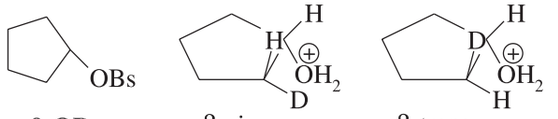
pm model, all calculated KIEs for **9** are smaller than the experimental values, while all are slightly too large at 250 pm.



9-OBs β-cis β-trans

These results suggest that the C—O distance in the TS lies between 210 and 250 pm, providing support for our choice of model.

The located transition-state geometries[6] for **4-OH$_2^+$** and **5-OH$_2^+$** resemble those reported (8), and **1-OH$_2^+$TS** is similar to **4-OH$_2^+$TS** (so far we have not been successful in locating the transition state for the *syn*-7-chloro-*exo*-2-norbornyl brosylate (**2**), but a model with the C—O distance at 290 pm was taken as an approximation to **2-OH$_2^+$TS**). The hydrocarbon fragment in each transition state is distinctly unsymmetrical as can be seen from the C^6—C^1 and C^6—C^2 distances given in Fig. 1, and even though the *exo* transition states **1-OH$_2^+$TS** and **4-OH$_2^+$TS** are closer to being symmetrical than the *endo* transition state **5-OH$_2^+$TS**, it is important to note that *all three hydrocarbon cation moieties are classical*, contrary to the interpretation of Schleyer and co-workers (8); a situation that is emphasized in Fig. 1 by means of the highlighted bond for **1-OH$_2^+$TS** and **4-OH$_2^+$TS**. The topology of the charge density of the 2-norbornyl cation that has been moved from C_S symmetry as determined in an atoms in molecules (17) study shows a (3,–1) or bond critical point only between C^6 and C^1, not between C^6 and C^2, and confirms the classical character of every struc-

[6]Zero-point energy uncorrected total energies are –809.111584 (**1-OH$_2^+$**), –809.102719 (**1-OH$_2^+$TS**), –809.129369 (**2-OH$_2^+$**), –349.527681 (**4-OH$_2^+$**), –349.518000 (**4-OH$_2^+$TS**), –349.524206 (**5**), and –349.512550 hartrees (**5-OH$_2^+$TS**).

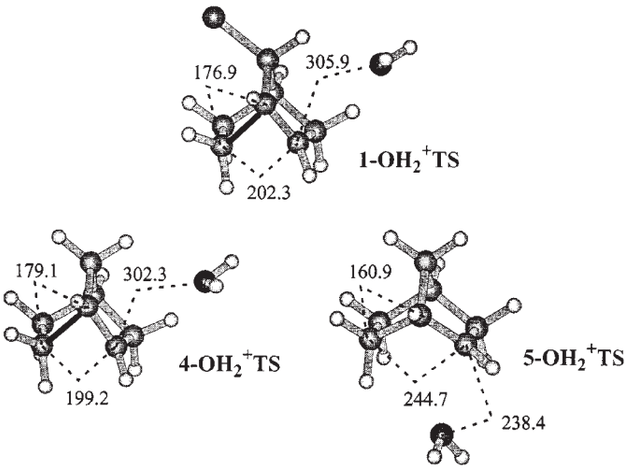
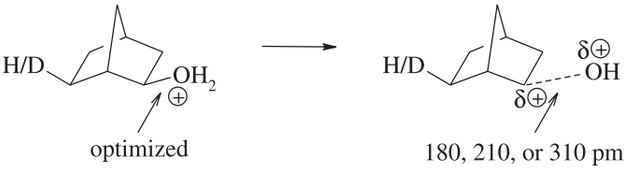
Fig. 1. Transitions states (TS) for the loss of water from protonated alcohols **1-OH$_2^+$**, **4-OH$_2^+$**, and **5-OH$_2^+$** with C—C and C—O distances in pm. See text for the highlighted bond.



Scheme 2.



ture but the C_S symmetrical one — *which is a π-complex*, as was suggested earlier by Dewar et al. (18)! A communication reporting these results has been submitted (19).

To gain some further insight into the source of the KIEs, the transition states were also modelled by fixing the C—O bond in the protonated alcohol at an appropriate value (we chose 210 pm) and optimizing the resulting system. These pseudo-transition states, just as the true gas-phase transition states, show one imaginary frequency that has the expected dispositions. Additionally, we performed calculations for 180 and 310 pm C—O distances in **4-OH$_2^+$**. The absolute value of the imaginary frequency is largest for the 210 pm model of **4-OH$_2^+$** (–120.1 cm^{-1}); it is considerably smaller for the 310 pm model (–45.7 cm^{-1}) and for **4-OH$_2^+$TS** (–51.3 cm^{-1}) and nonexistent in the 180 pm model (the lowest frequency is 91.0 cm^{-1}), Scheme 2.

Table 1 gives the computational results and comparisons to experiment for deuterated derivatives of **1**, **2**, **4**, and **5**. Five different KIEs of *endo*-2-norbornyl brosylate (**5-OBs**) can be determined with excellent accuracy in the gas phase when **5-OH$_2^+$TS** is used (entry TS in Table 1). Both normal and inverse KIEs are modelled correctly with only little overestimation. Accordingly, there are no surprises with the 210 pm model of **5**. While the calculated α-effect in **5-OH$_2^+$2ex** and the β-effect in the doubly deuterated **5-OH$_2^+$3en3ex** are slightly too small, as expected due to the 210 pm distance, which is shorter than the one in **5-OH$_2^+$TS** (Fig. 1), the experimentally observed absence of a γ-effect in **5-OBs6ex** and **5-OBs5ex6ex** is confirmed computationally, as is the modest inverse γ-effect in **5-OBs6en**. The situation is more complicated for *exo*-2-norbornyl brosylate (**4-OBs**). With **4-OH$_2^+$TS**, none of the four computed KIEs seems to show a particularly good agreement with experiment, the γ-effect in **4-OBs6ex** and **4-OBs5ex6ex** being overestimated and the β-effect in **4-OBs3en3ex** underestimated. The calculated KIE in **4-OH$_2^+$6en** seems to present the worst case. Using **4-OH$_2^+$TS** it is much too small, and calculations on the 210 pm model even predict the absence of any γ-KIE, whereas experimentally the largest KIE was found for the brosylate (11%) (1). We repeated gas-phase calculations for **4-OH$_2^+$** with C—O distances of 180 and 310 pm. As expected, a C—O distance of 180 pm is too close to the optimized C—O bond length of 163.7 pm and therefore a poor model for a transition state: the γ-effect in **4-OH$_2^+$6ex** is very small, there is no effect for **4-OH$_2^+$6en**. Going to a C—O distance of 310 pm gives rise to a significant γ-KIE in **4-OH$_2^+$6en**. These three TS models allow a step-by-step approach to the geometry change in the hydrocarbon moiety upon ionization and its effects. Figure 2 shows that the 2-norbornyl cation, which is definitely unsymmetrical at 210 pm (with distances C^6—C^1 161.8 pm and C^6—C^2 230.3 pm), is closer to being symmetrical (C^6—C^1 175.2 pm and C^6—C^2 203.7 pm) at a water distance of 310 pm where the distinction between *endo* and *exo* deuterium on C^6 is fading with beginning internal return (the structures given in Fig. 2, with one highlighted bond for the 310 pm model, represent the molecular graphs as determined in an atoms in molecules study (19)). This view finds support in the average KIE of **4-OH$_2^+$6ex** and **4-OH$_2^+$6en**, which equals 1.09 and so represents the experimental value (observed KIEs for **4-OBs6ex** and **4-OBs6en** are identical within experimental error), and also in the early acetolysis study (4), which gives initial KIEs that are in accord with those computed, i.e., a significantly smaller value for **4-OBs6en**: 1.149 ± 0.016 for **4-OBs6ex** and 1.097 ± 0.011 for **4-OBs6en**. For *exo* substrates *anti*-7-chloro **1-OBs** and *syn*-7-chloro **2-OBs**, we calculate *exo* KIEs that agree well with the observed ones whereas the *endo* KIEs, similar to **4-OH$_2^+$6en**, are too small. Yet unlike the case of **4-OBs**, major solvolysis products for

Fig. 2. Gas-phase structures of **4-OH$_2^+$** with the C—O distance at 210 and 310 pm. See text for the highlighted bond.

1-OBs6en (13%) and **2-OBs6en** (20%) are the respective chloronortricyclenes formed through a 1,3 (6,2)-elimination with the *endo* deuterium being lost preferentially (close to 80% deuterium loss) (1), and it has been shown in a steady-state treatment of a modified Winstein ion-pair scheme (2) that (and how) the isotope effects for elimination from ion pairs can contribute to k_H/k_D.

In conclusion, deuterium secondary kinetic isotope effects are computed accurately at the Becke3LYP/6-31G(d,p) level of theory when solvolysis transition states are employed. Sources for observed KIEs can be explored and resolved with Becke3LYP calculations.

Acknowledgments

We gratefully acknowledge the grant of cpu time on a CRAY T90 vector computer in the HLRZ Supercomputing Center at the Research Center Jülich, the usage of the IBM SP2 computer at Queen's University granted under the auspices of an IBM Canada – Queen's University collaborative project, as well as the usage of the SGI computing installation in the Geochemistry Labs at McMaster funded by the Natural Sciences and Engineering Research Council of Canada (NSERC). We thank Ms. O. Donini for assistance with operational aspects of parallel Gaussian 94 and NSERC for financial support.

ADDITIONS AND CORRECTIONS/AJOUTS ET CORRECTIONS

Additions and corrections: Skeletal vibrational circular dichroism of a series of bicyclic dilactones: the fingerprint region?

A. Rauk, J.L. McCann, H. Wieser, P. Bour, I.V. Vystorop, Yu.I. El'natanov, and R.G. Kostyanovsky

Ref.: Can. J. Chem. **76**, 717 (1998)

Please note that the name of author I.V. Vystorop was inadvertently omitted from the list of authors. His name and address appear correctly in the box at the bottom of the page.

Additions and corrections: Solubility of fluoranthene in organic nonelectrolyte solvents. Comparison of observed versus predicted values based upon Mobile Order theory

Carmen E. Hernández and William E. Acree, Jr.

Ref.: Can. J. Chem. **76**, 1312 (1998)

The complete title of Table 1 should read "Comparison between experimental fluoranthene mole fraction solubilities and predicted values based upon Mobile Order theory."

The mole fraction solubility of fluoranthene in 4-methyl-2-pentanol was incorrectly listed in Table 1. The listed value contained one too many zeroes. The correct value is $X_A^{sat} = 0.00948$.

ARTICLES

A.D.O. Bawagan, L. Fell, and J. Logan Time-resolved structures of electrical discharges in gases: experiment and stochastic model **1**

Françoise M. Winnik, André Morneau, Alicja M. Mika, Ronald F. Childs, Anna Roig, Elies Molins, and Ronald F. Ziolo Polyacrylic acid pore-filled microporous membranes and their use in membrane-mediated synthesis of nanocrystalline ferrihydrite **10**

Raphaël Sabbah et Maria Ermelinda da Silva Eusébio Energétique des liaisons inter- et intramoléculaires dans les trois isomères de l'aminopyridine **18**

Lee D. Wilson and Ronald E. Verrall A ^{1}H NMR study of cyclodextrin – hydrocarbon surfactant inclusion complexes in aqueous solutions **25**

Susan Swansburg, Kristin Janz, Gloria Jocys, Alexandra Pincock, and James Pincock Facial selectivity in the addition of nucleophiles to the radical cations of substituted 2-methyleneadamantanes **35**

Michael Falk, Warren Chew, John A. Walter, Witold Kwiatkowski, Katherine D. Barclay, and Gerald A. Klassen Molecular modelling and NMR studies of the caffeine dimer **48**

Marcos Loroño, J.R. Anacona, and Anibal Sierralta Coriolis coupling constants and inertial defect of B_2F_4 by ab initio calculations and the iterative method **57**

Katsuyuki Nakayama, Yuichi Kondo, and Koji Ishihara A kinetic study of the reactions of dimethyl sulfide bridged tetramethylplatinum(II) and octamethylplatinum(IV) complexes with dimethyl sulfide and bidentate ligands **62**

Yasuki Yoshimura Salt effect on the solubility of *mer*-(+)-tris(L-alaninato)cobalt(III) **71**

Daniel Ren and Robert A. McClelland Carbocation-like reactivity patterns in X′-substituted-4-biphenylylnitrenium ions **78**

Richard A. Beekman, René T. Boeré, Klaus H. Moock, and Masood Parvez Synthesis, electrochemistry, structure, and magnetic susceptibility of 5-*tert*-butyl-1,3-bis-(1,2,3,5-dithiadiazolyl)benzene. Structural effect of the bulky substituent **85**

Richard W. Friesen and Suzanne Bissada Total synthesis of (±)-9-deoxygoniopypyrone. Application of the iodocyclofunctionalization reaction of α-allenic alcohol derivatives **94**

Saul Wolfe, Chan-Kyung Kim, Kiyull Yang, Noham Weinberg, and Zheng Shi Transverse compression and the secondary H/D isotope effects in intramolecular S_N2 methyl-transfer reactions **102**

Saul Wolfe, Zheng Shi, Kiyull Yang, Stephen Ro, Noham Weinberg, and Chan-Kyung Kim Hydration of the carbonyl group. Further evidence for a cooperative mechanism from experimental and theoretical studies of the hydrations of formaldehyde, acetaldehyde, acetone, and cyclohexanone **114**

Donald L. Hooper, Ian R. Pottie, Marc Vacheresse, and Keith Vaughan 1,2-Bis(1-aryl-3-alkyltriazen-3-yl)ethanes and related compounds **125**

ADDITTIONS AND CORRECTIONS / AJOUTS ET CORRECTIONS

Philippe Couture and John Warkentin Chemistry of cyclic aminooxycarbenes **136**

Author Index / Index des auteurs **AI-1**

February / Février

ARTICLES

Sergey A. Avilov, Olga A. Drozdova, Vladimir I. Kalinin, Anatoly I. Kalinovsky, Valentin A. Stonik, Elena N. Gudimova, Ricardo Riguera, and Carlos Jiménez Frondoside C, a new nonholostane triterpene glycoside from the sea cucumber *Cucumaria frondosa*: structure and cytotoxicity of its desulfated derivative **137**

Alex B. Driega, Gerald W. Buchanan, and Corinne Bensimon Synthesis of *cis-p*-dioxano-12-crown-4 and X-ray crystallography of the (1:1) complex with lithium thiocyanate **142**

John M. McIntosh, E. Jay Kiser, and Zhigang Tian The stereochemistry of hippurate alkylation **147**

Catherine E. Drennan, Rachelle J. Hughes, Vincent C. Reinsborough, and Oladega O. Soriyan Rate enhancement of nickel(II) complexation in dilute anionic surfactant solutions **152**

Steven M. Barnett, Antonín Vlček, Jr., and Ian S. Butler Pressure-tuning infrared and Raman spectroscopic study of (2,2′-bipyridine)tetracarbonylchromium(0) **158**

James Frederick King, Gay Yuyitung, Manjinder Singh Gill, Jeffrey Charles Stewart, and Nicholas Charles Payne Stereoelectronic effects in sulfonyl compounds: axial orientation of an *N*-methyl group in a six-membered sultam **164**

Fengde Xi and L. Ross C. Barclay Cooperative antioxidant effects of ascorbate and thiols with di-*tert*-butylcatechol during inhibited peroxidation in solution and in sodium dodecyl sulfate (SDS) micelles **171**

Eva Vallazza, Alex D. Bain, and Thomas W. Swaddle Dynamics of silicate exchange in highly alkaline potassium silicate solutions **183**

Costas Stathakis and Richard M. Cassidy Control of relative migration of small inorganic and organic anions with cyclodextrins in capillary electrophoresis (CE) **194**

Surya K. De, Mrinal G. Dhara, and Asok K. Mallik Synthesis of *trans*-2,3-dimethoxy-3-(phenylamino)flavanones and related compounds **199**

Paule Castan, Christine Viala, Paul-Louis Fabre, Françoise Nepveu, Jean-Pierre Souchard, and Gérald Bernardinelli Crystal structure, spectroscopic and magnetic studies, and antioxidative properties of catena-[diaqua(dihydro-orotato)manganese(II)] **205**

Mitchell D. Refvik and Adrian L. Schwan The reactions of a 1-alkenesulfenate anion with TMS-X reagents; a variable temperature NMR study **213**

Heidi M. Muchall, Nick H. Werstiuk, and Biswajit Choudhury A search for an inexpensive calculational method for the reliable prediction of the first adiabatic and vertical ionization potentials of carbenes. Photoelectron spectra of two stable carbenes **221**

Kiyohisa Ohta, Youko Ueda, Satoshi Nakaguchi, and Takayuki Mizuno Photochemical reduction of CO_2 using Cu-loaded silicate rock powder suspended in water **228**

Cathy Hubert et Bernard Garrigues Influence des ultrasons sur la diastéréosélectivité. Synthèse d'imidazolidine-4-one chirales **234**

COMMUNICATION

H.M. Muchall, N.H. Werstiuk, B. Choudhury, J. Ma, J. Warkentin, and J.P. Pezacki Thermolysis of 2,2-dimethoxy-5,5-dimethyl-Δ^3- 1,3,4-oxadiazoline studied with photoelectron spectroscopy. He(I) photoelectron spectrum of dimethoxycarbene **238**
