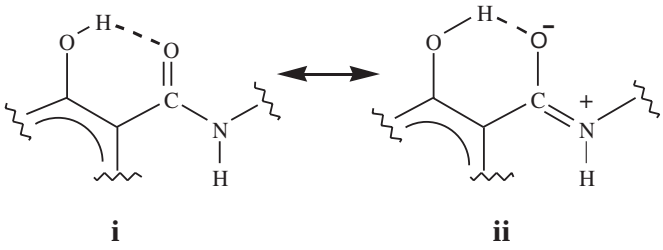
A noteworthy detail in the solid state H-bonding network present in H_3PICTAME is the variation in the H-bond distances (and angles) of the two-center O—H···O (Table 5). Thus, whereas O(6)—H(3)···O(5) constitutes a symmetrical H-bonding site, the other two analogous H-bonds are asymmetric and, accordingly, the corresponding H···O distances are significantly longer. The most interesting aspect about the geometry of the symmetrical site is that, as a result of its perfect linearity (within experimental error), an unseemly angle of 87(2)° is imposed upon the C(20)-O(6)-H(3) bond — in contrast to 105(2)° for the other two analogous angles (Fig. 3). In spite of this anomalous bond angle, however, the symmetrical disposition of the H3, with respect to the two adjacent oxygens (O6 and O5), is corroborated by the significant lengthening of the respective C(18)—O(5) bond to 1.254 Å, (C(4)—O(1) = 1.245 Å, C(11)—O(3) = 1.243 Å) and a decrease in the C(18)—N(5) bond to 1.324 Å (C(4)—N(1) = 1.327 Å, C(11)—N(3) = 1.333 Å). This observation would be expected if the amide resonance structure **ii** (Fig. 4) were more predominant; the more the type **ii** resonance contributes to the overall resonance hybrid structure, the better the H-bonding acceptor ability of that amidic oxygen. The structural data summarized above clearly reflect this fact: the concomitant increase in C═O and decrease in C—N bond lengths is paralleled by a shortening of the H-bond distance. Thus, not too surprisingly, the longest C═O bond length, C(18)—O(5), corresponds to the shortest H-bond (1.28(5) Å, O(5)···H(3)).

Fig. 4. The amide resonance and H-bonding (see text).



General characterization

The preorganization of a multidentate ligand is governed by two factors, each capable of diminishing the entropic penalty attendant upon metal ion complexation: (*i*) the conformation of each metal binding moiety in the molecule; (*ii*) the conformation of the "arms" (containing the binding moiety) with respect to each other. The first factor determines, for instance, the ease with which a chelate ring will form, while the second factor contributes to the complete encapsulation of the metal ion. Based on the solid state structure of H_3PICTAME, it is evident that although the structure is preorganized in the first sense, the three arms are not favorably disposed to define the cavity necessary for the coordination of a group 13 metal ion in a hexacoordinate octahedral polyhedron. In fact, in solution, as evinced by ^{1}H NMR spectroscopy, one set of signals is observed for the tripodal arylamides prepared, indicating that each arm rotates freely. The exceptions to this finding are, of course, H_3PICSPERM and H_3NICSPERM, which are asymmetric by virtue of their spermidine backbones. Therefore, for the purposes of solution coordination chemistry, the latter facet of preorganization is of no relevance in the case of the arylamides.

In considering the local conformation of each individual metal binding moiety, it is possible to predict which conformer is preferred (Fig. 5) by comparing the strengths of the hydrogen bonds available to the two forms. The strength of an H-bond (A—H···B) is known to depend on the relative acidity of A and the basicity of B; the strength of the H-bond should increase as the acid becomes more acidic and the base more basic (39). Since the phenolic hydrogens (pK_a ca. 10) (40) are more acidic than the amide (pK_a ca. 15) (41), the strongest H-bonds ought to occur in conformations **1a** and **2a** (Fig. 5). The ^{1}H NMR and IR spectroscopic results, although not unequivocally conclusive, appear to be in accord with the qualitative prediction that conformers **1a** and **2a** are prevalent in solution.

The ^{1}H NMR chemical shifts of the phenolic hydrogens of the arylamides show extensive downfield shifts (ca. 12 ppm in DMSO-d_6) indicative of H-bonding. The same observation was found to hold true in the less polar solvent $CDCl_3$, in the case of the picolinic amides; the nicotinic derivatives were not soluble enough in chloroform to allow for ^{1}H NMR spectroscopy (vide infra). On the other hand, the IR spectrum of H_3PICTAME in CCl_4 shows a broad band ranging from ca. 3200 to 2700 cm^{-1} characteristic of an intramolecular chelated phenolic OH stretching frequency (42). In the solid state IR spectrum of H_3PICTAME (KBr pellet), however, the phenolic stretching frequency ranges over a greater span from ca. 3600

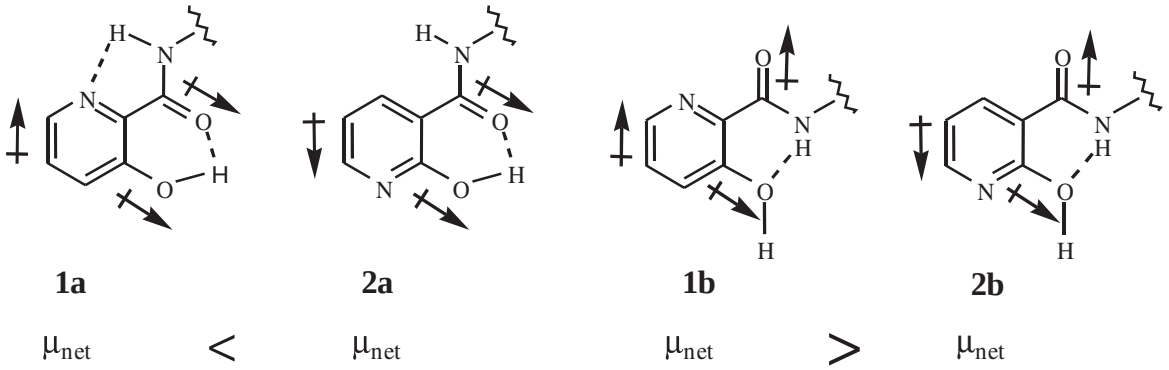
Fig. 5. The two conformers of 3-hydroxypicolinyl (**1a**, **1b**) and 2-hydroxynicotinyl amide derivatives (**2a**, **2b**). (The dipole moments are depicted merely in a qualitative sense; they are not drawn to scale).



to 2700 cm^{-1}, in agreement with the solid state structure provided by X-ray crystallography wherein both intra- and intermolecular H-bonds are found to exist (the intermolecularly H-bonded OH stretching frequencies are found in the 3550–3450 cm^{-1} range) (42).

It is worthwhile to reflect on the significant solubility difference between the 2-hydroxynicotinyl and the 3-hydroxypicolinyl amide derivatives. The water solubility (at neutral pH) of the 3-hydroxypicolinyl amide derivatives is typically on the order of tens of μM as opposed to the 2-hydroxynictonyl counterparts that are soluble to the extent of ca. 0.5 mM, which is in accord with the polarity differences expected based on a qualitative consideration of dipole moments. In calculating the dipole moments of the molecule (μ_{net}) it is convenient to employ the moments of groups of atoms (amide, pyridine, OH) as an approximation (43) as shown in Fig. 5, where the magnitude of the three group moments are taken to be the same. It is clear that *only* type **a** conformers (Fig. 5) corroborate the observed water solubility trend.

The fact that 2-hydroxynicotinic amides adopt the type **2a** conformation is unexpected from the point of view of the electroneutrality principle (ref. 35, pp. 172 and 273), which would favor a conformation with a smaller electric dipole moment, i.e., the **2b** conformer. The reason for this conformational preference lies in H-bonding (cf. Fig. 5): the H-bonding in **2a** is more fortified, as discussed previously. Thus, the O—H···O hydrogen bond should still be stronger than N—H···O in water, even though this effect is mitigated in the presence of such a polar solvent; the H-bond energy decreases in more polar environments, since the H-bond has a substantial electrostatic component. Based on the evidence discussed here, the 2-hydroxynicotinic and the 3-hydroxypicolinic arylamides display an intramolecular H-bonding network that is sustained in water. Therefore, it can be concluded that these arylamide ligands are significantly partially preorganized for metal ion chelation.

Ligand deprotonation constants

The deprotonation constants[4] were obtained on the basis of a three- or four-proton model for H_3NICTAME and H_3NICTREN, respectively, in the pH 2.2–11.5 region at 25°C and in 0.16 M NaCl. The deprotonation constants thus obtained appear in Table 6, and correspond to the successive deprotonation equilibria of the three phenols (pK_{a1}, pK_{a2}, pK_{a3}) and, in the case of H_3NICTREN, the deprotonation of the protonated apical nitrogen. The pK_a values of the pyridine ring nitrogens are too low to be measured in the pH range examined, while those of the amides fall outside the upper pH limit of the measurements. The water solubility of H_3PICTAME and H_3PICTREN was too low for potentiometric measurements.

It is appropriate to compare the pK_a's of H_3NICTAME and H_3NICTREN with those of the parent acids and some related aminephenol ligands (Table 6). The phenolic pK_a's of H_3NICTAME, H_3NICTREN, H_2nic, and H_2pic are particularly high. This would be anticipated for H_3NICTAME on the basis of its crystal structure, where all three phenol groups are involved in hydrogen bonding with the adjacent amide carbonyl oxygen. A similar explanation would account for the phenolic pK_a's of H_3NICTREN, and the high pK_{a1} of H_2nic and H_2pic is consistent with the presence of a six-membered H-bond ring involving the phenolic group and the deprotonated carboxylate oxygen of these ligands. These arguments are reinforced with the observation that for the aminephenols H_6TRNS and H_6TAMS, the phenolic pK_a's are much lower as there is no possibility of hydrogen bonding for the protonated phenol. In fact, the deprotonated phenolate oxygen may H-bond with an adjacent ammonium group, which would tend to favour deprotonation of the phenol and a low pK_a.

Concluding remarks

A series of potentially polydentate arylamide ligands have been synthesized from the coupling of several tripodal amines with nicotinic and picolinic acids and their derivatives. Two synthetic procedures were utilized in this study but the HOSuNic method was not favoured due to the difficulty of separating the DCU side product from the activated ester. Hence, the CDI method was used in the synthesis of the compounds in this work.

The X-ray crystal structure of H_3PICTAME revealed extensive hydrogen bonding, with eight intra- and one

[4] The acid dissociation constant, K_a, is defined as:
$H_nL^{m+} \rightleftharpoons H_{n-1}L^{(m-1)+} + H^+$
$K_{an} = ([H_{n-1}L^{(m-1)+}]\,[H^+]) / [H_nL^{m+}]$
$pK_a = -\log K_a$

intermolecular H-bonds per molecule. In solution each arm of the tripodal arylamides rotates freely. Nevertheless, the NMR, IR, and solubility results indicate that the intramolecular H-bonding network of these arylamides is sustained in solution and, thus, these ligands are partially preorganized for the complexation of metal ions.

Structure and dynamics of azapropazone derivatives studied by crystallography and nuclear magnetic resonance

Theresa Fauconnier, Alex D. Bain, Paul Hazendonk, R.A. Bell, and Colin J.L. Lock

Abstract: The X-ray crystal structure of a derivative of the nonsteroidal anti-inflammatory drug, azapropazone, has been determined using a data set obtained from a charge-coupled device (CCD) area detector. Azapropazone itself, 5-(dimethylamino)-9-methyl-2-propyl-1*H*-pyrazolo[1,2-*a*][1,2,4]benzotriazine-1,3(2*H*)-dione, has previously been shown to be nonplanar, probably due to steric interactions between the pyrazolidine ring and the exocyclic dimethylamino group. The derivative studied in this work, 3-dimethylamino-7-methyl-1,2,4-benzotriazine, does not have the pyrazolidine ring and is shown here to be strictly planar. There is also a significant difference in the kinetics of restricted rotation around the bond joining the dimethylamino group to the triazine ring, as measured by NMR. Both the enthalpy and entropy of activation are quite different. For the chemical exchange of the two methyl groups in azapropazone, $\Delta H^{\ddagger} = 36 \pm 0.5$ kJ mol^{-1}, and $\Delta S^{\ddagger} = -34 \pm 2$ J K^{-1}. For the derivative, $\Delta H^{\ddagger} = 48 \pm 0.4$ kJ mol^{-1}, and $\Delta S^{\ddagger} = -12 \pm 2$ J K^{-1}. This is rationalized by assuming the equilibrium state of the derivative is planar, and this defines the potential energy curve. The ground state of azapropazone is relatively destabilized, and somewhat disordered, by the steric interaction. Therefore, azapropazone has a small barrier to surmount, and the entropy of activation should be negative.

Key words: NMR, chemical exchange, entropy, barriers to rotation, crystal structure.

Résumé : Utilisant un ensemble de données obtenues à l'aide d'un dispositif à couplage de charge (DCC) comme détecteur de surface, on a déterminé la structure cristalline aux rayons X d'un dérivé d'un médicament anti-inflammatoire non stéroïdal. Il a été démontré antérieurement que l'azapropazone de base, 5-(diméthylamino)-9-méthyl-2-propyl-1*H*-pyrazolo[1,2-*a*][1,2,4]benzotriazine-1,3(2*H*)-dione, n'est pas planaire, probablement à cause d'interactions stériques entre le noyau pyrazolidine et le groupe diméthylamino exocyclique. Le dérivé examiné dans ce travail, la 3-diméthylamino-7-méthyl-1,2,4-benzotriazine, ne comporte pas de noyau pyrazolidine et on démontre qu'il est strictement planaire. Sur la base de mesures RMN, il existe aussi des différences importantes dans la cinétique de la rotation empêchée autour de la liaison reliant le groupe diméthylamino et le noyau triazine. Tant l'enthalpie que l'entropie d'activation sont très différentes. Pour l'échange chimique des deux groupes méthyles de l'azapropazone, $\Delta H^{\ddagger} = 36 \pm 0{,}5$ kJ mol^{-1} et $\Delta S^{\ddagger} = -34 \pm 2$ J K^{-1}. Pour le dérivé, $\Delta H^{\ddagger} = 48 \pm 0{,}4$ kJ mol^{-1} et $\Delta S^{\ddagger} = -12 \pm 2$ J K^{-1}. On rationalise ces résultats en suggérant, pour le dérivé, un état d'équilibre plan qui définit la courbe de l'énergie potentielle. L'état fondamental de l'azapropazone est relativement déstabilisé et assez désordonné à cause de l'interaction stérique. Il en découle que l'azapropazone comporte une faible barrière qu'il lui faut surmonter et il en découle que l'entropie d'activation devrait être négative.

Mots clés : RMN, échange chimique, entropie, barrières à la rotation, structure cristalline.

[Traduit par la rédaction]

Introduction

Azapropazone, or 5-(dimethylamino)-9-methyl-2-propyl-1*H*-pyrazolo[1,2-*a*][1,2,4]benzotriazine-1,3(2*H*)-dione (**1**), is one of a class of nonsteroidal anti-inflammatory drugs (1, 2) and is used to treat various forms of arthritis. The determination of the structure of a drug is invaluable for its characterization, but it can also be used to investigate the action of the drug at the molecular level. Rapid developments in structural biology and computational chemistry have helped determine what a molecule recognizes as a receptor in the body. For azapropazone, there has been some controversy in the literature over its structure (3): in particular, over the planarity of the ring and the positions of the hydrogens. Recent crystal structures (3) of azapropazone (Fig. 1) and one of its derivatives resolved these questions. For instance, the structure in the Merck Index (4) (called apazone there) is incorrect in that a proton is in the wrong position. The drug exists as a zwitterion, and the tricyclic part of the molecule is distinctly nonplanar.

A related observation was that at low temperature, the two methyls in the dimethylamino group in azapropazone were nonequivalent in the NMR spectrum below 220 K (3). There

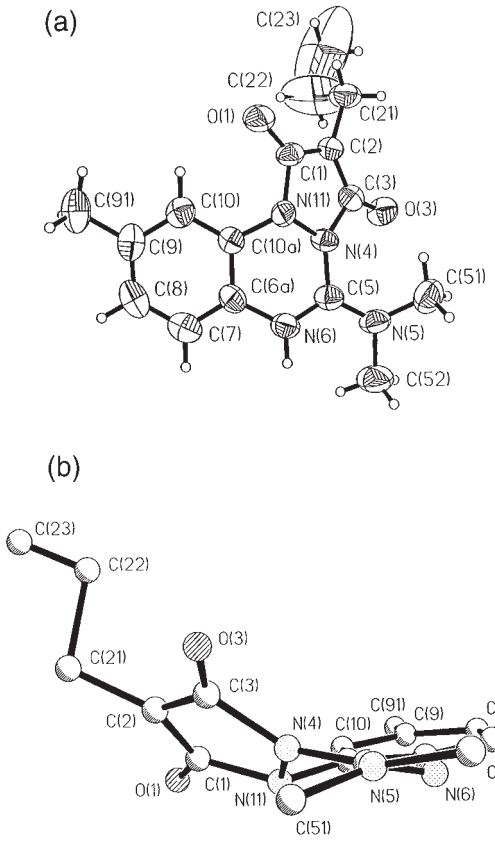
Fig. 1. Structure of azapropazone (**1**) (*a*) and view of azapropazone along the C(5)—N(5) bond (*b*), showing how the dimethylamino group is not in the plane of the triazine ring. Structure taken from (3).



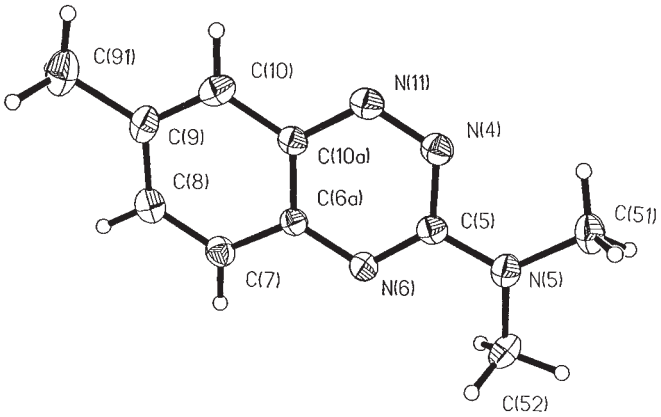
is sufficient steric crowding between the pyrazolidine ring and the dimethylamino group so that they cannot be coplanar. The rotation about the bond joining the dimethlyamino group to the triazine ring is restricted in some way.

The molecule in Fig. 2, 3-dimethylamino-7-methyl-1,2,4-benzotriazine (**2**), could help to understand these observations, since the pyrazolidine ring in azapropazone is absent and there are no steric interactions. This molecule is also an azapropazone derivative and has been identified as a photodegradation product of azapropazone, responsible for the photodermatitis that sometimes occurs to patients taking the drug (5). In this paper we present a crystal structure of **2**, derived from a data set obtained on a CCD detector. We also present a more detailed analysis of the dynamic NMR spectra of the dimethylamino group in the two molecules, using a powerful combination of NMR experiments (6). From these data, reliable values of both the enthalpy and entropy of activation for each molecule are derived.

Experimental

Azapropazone (**1**) was kindly provided as a yellow powder by Siegfried Pharma AG, Zotingen, Switzerland. To prepare 3-dimethylamino-7-methyl-1,2,4-benzotriazine (**2**), crude azapropazone (2 g) was dissolved in 1 M NaOH (20 mL). The reaction mixture was cooled in an ice bath while 30% H_2O_2 was added dropwise. The dark orange solution was allowed to

Fig. 2. Structure of 3-dimethylamino-7-methyl-1,2,4-benzotriazine (**2**), with the atoms numbered by analogy to **1**. Note the absence of the pyrazolidine ring (compare Fig. 1) at N(4)–N(11). The molecule is essentially planar.



cool. The solution sat open to the air for three days, whereupon bright orange parallelepiped crystals appeared (mp 58–61°C, lit. (1) 61–63°C). ^{1}H NMR (200 MHz in $CDCl_3$ at 300 K) δ: 2.48 (3H, s, aromatic CH_3), 3.39 (6H, s, collapsed N-$(CH_3)_2$), 7.24 (1H, d, aromatic H(7)), 7.50 (1H, d, aromatic H(8)), 7.96 (1H, s, aromatic H(10)). ^{13}C NMR (125 MHz, 500 MHz for ^{1}H, in DMSO-d_6 at 300 K) δ: 20.68 (aromatic CH_3), 36.74 (N-$(CH_3)_2$), 125.8 (aromatic C(7)), 127.41 (aromatic C(8)), 134.66 (aromatic C(9)), 138.26 (aromatic C(10)), 140.23 (aromatic C(6-*a*)), 141.47 (aromatic C(10-*a*)), 158.83 (C-5). EI-MS *m*/*z*(%): 188 (20, M^+), 160 (70), 145 (100, $M - NC_2H_6$).

For the structure determination, a crystal was selected after examination for clarity and sharp extinction in a polarizing microscope. The crystal was soluble in all solvents and adhesives used to try to mount the crystal. Instead a glass capillary was drawn out over a Bunsen burner and broken off at the top, so the crystal could sit in the top. The bottom of the capillary was glued to a brass pin. Unit cell determination and intensity data collection were performed on a Siemans SMART Platform CCD 3-circle diffractometer with monochromatized MoK_α (λ = 0.71073 Å). An initial set of cell constants was calculated from reflections harvested from three sets of 30 frames. This produced orientation matrices determined from 46 reflections. Final cell constants were calculated from a set of 2079 strong reflections from the actual data collection. A semiempirical ψ-scan absorption correction was applied. The structure was solved by direct methods and refined on F^2 by full-matrix least squares. The details of data acquisition and treatment are given in Table 1. The atomic coordinates and isotropic temperature factors are in Table 2, and the interatomic distances and angles are given in Table 3. The molecule is shown in Fig. 2, and the packing diagrams in Fig. 3.

For the exchange measurements, an approximately 2% solution of **2** in acetone-d_6 was made up. Proton NMR spectra were obtained at 300 MHz on a Bruker AC300 spectrometer equipped with a 5 mm 4-nucleus probe and a BVT 2000 variable temperature unit. The 90° pulse width was 9.0 μs. The number of points in the FID was 64 k words, and the sweep width used was 5208 Hz. After acquisition, data were transferred to Silicon Graphics Indy workstation and processed

using Bruker's XWINNMR program. Lineshapes in the intermediate exchange regime were calculated using the program MEX (available from ADB) (7) and compared with experimental data using the dual display routine of XWINNMR. Figure 4 shows the match between simulated and experimental lineshapes, and the decomposition of the lineshape into individual transitions. For fast exchange, T_2 measurements using the offset saturation experiment provided the rate information (8). For slow exchange, selective inversion experiments were used (9).

Fig. 4. Experimental (top) and simulated lineshapes for the two methyl signals of the dimethylamino group in **2** at 253 K. The bottom trace shows the decomposition of the lineshape into individual transitions.

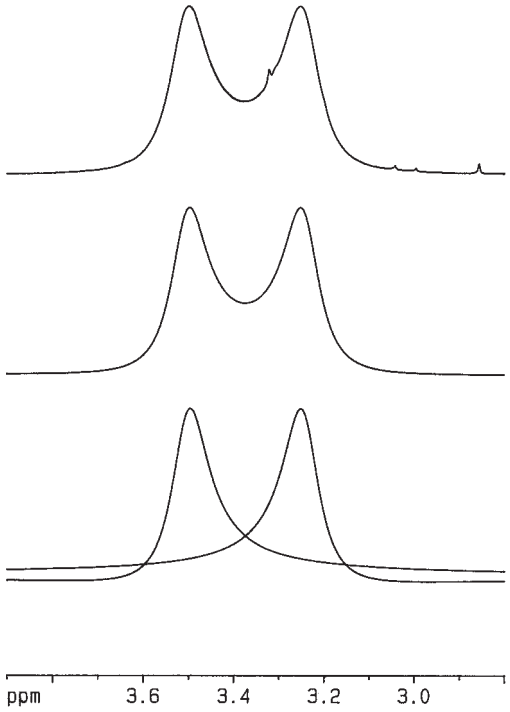

Fig. 5. Eyring plot of log(rate/*T*) versus 1/*T* for the exchange rates of the dimethylamino group in azapropazone (**1**) and its derivative (**2**). The intercept with the axis at $1/T = 0$ is shown to indicate the entropy of activation for the reaction.

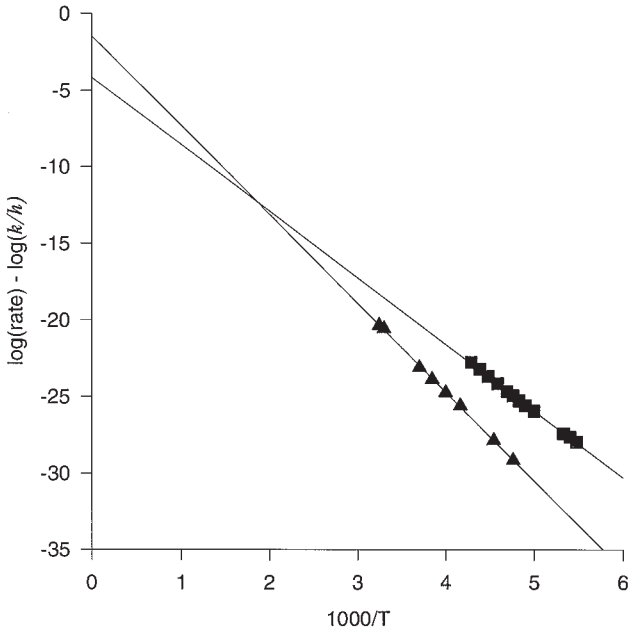
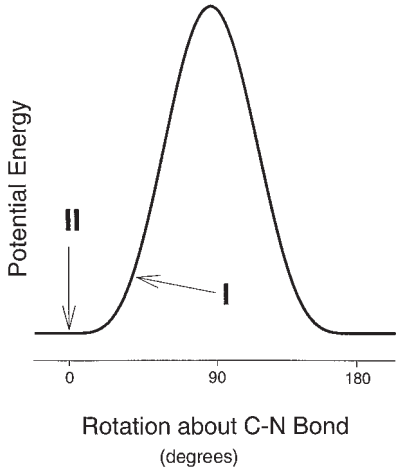


The activation parameters were estimated from a linear regression on an Eyring plot of log(rate/*T*) versus 1/T. The error in $\Delta H^{\ddagger}$ was taken directly from the error in the slope, and the error in $\Delta S^{\ddagger}$ was calculated from the combined effect of the error in the intercept and the extrapolation error due to the error in the slope.

Fig. 6. Schematic potential energy diagram for the rotation about the C—N bond joining the dimethylamino group to the triazine ring.



Discussion

The molecule is planar (maximum deviation, C(51), 0.077 Å). There appears to be considerable delocalization through the N(5)–C(5)–N(6)–C(6*a*) system (N(5)—C(5), 1.353(4) Å; C(5)—N(6), 1.339(4) Å; N(6)—C(6*a*), 1.356(4) Å) and less delocalization around the N(4)—N(11) double bond (N(4)—N(11), 1.296(4) Å; N(4)—C(10*a*), 1.377(4) Å; N(11)—C(5), 1.375(4) Å). The dihedral angle between the best planes of the benzene and triazine ring is 1.2°, and the dihedral angle between the dimethylamino group, C(51)-N(5)-C(52) and the plane of N(4)-C(5)-N(6) is 2.8°. For azapropazone itself, the corresponding angle that the dimethylamino groups make with the ring is 24.1(8)°.

The crystal packing of **2**, shown in Fig. 3, consists of spiral chains along the *b* and *c* direction. In the *a* direction, translationally equivalent molecules are stacked 3.5 Å apart, indicating some π–π interaction. The interactions between the chains appear to be van der Waals type.

For **2**, exchange of the two methyl groups simply involves a rotation about the bond joining the dimethylamino group to the triazine ring. However, azapropazone (**1**) is chiral, since it is not planar (Fig. 1). Exchange of the two methyl groups involves not only bond rotation, but also inversion at N(11), the junction of the triazine and pyrazolidine rings. Figure 5 shows an Eyring plot of log(*k*/*T*) vs. 1/*T* for the exchange rates, *k*, for both azapropazone and its derivative, II. It is clear from this plot that both the enthalpy and entropy of activation for the exchange process are significantly different in the two molecules. For the drug itself, $\Delta H = 36 \pm 0.5$ kJ mol^{-1}, and $\Delta S = -34 \pm 2$ J K^{-1}, and for the derivative $\Delta H = 48 \pm 0.4$ kJ mol^{-1}, and $\Delta S = -12 \pm 2$ J K^{-1}. We interpret these parameters as follows.

Figure 6 shows schematically the potential energy of the molecule as a function of the angle between the plane of the dimethylamino group and the triazine ring in the derivative (**2**). The molecule is planar, so the energy is a minimum when the angle is zero, and the transition state is at 90°. For **2**, the

© 1998 NRC Canada

behaviour is as might be expected: there is a barrier of about 48 kJ mol^{-1}, and the entropy of activation is close to zero, since the ground and transition states are both quite symmetrical. There are few reports of barriers to rotation in closely related compounds (10, 11), but the value is well within the normal range for dimethylamino groups attached to aromatic rings (12).

However, azapropazone (**1**) is nonplanar, so the dimethylamino group cannot correspond to the bottom of the curve in Fig. 6. The ground state for azapropazone is part way up the curve, so the barrier to exchange is lower. Also, the ground state is considerably less symmetrical than the postulated transition state with the dimethylamino group perpendicular to the ring. This would lead to a decrease in entropy on going to the transition state. The observed entropy of activation in azapropazone is significantly more negative than in its planar derivative, **2**.

The lower barrier in azapropazone is perhaps surprising in other contexts. The C(5)—N(5) bond, about which rotation occurs, is significantly shorter in azapropazone (1.313(7) Å) than in **2** (1.353(4) Å). Also, the exchange of the two methyl groups in azapropazone involves inversion at N(11) as well as bond rotation. An alternative explanation for the different barriers is that perhaps the transition states are different. The transition state for **2** presumably has the dimethylamino group perpendicular to the plane of the molecule. Another possible transition state for azapropazone is that the whole molecule is planar, including the dimethylamino group. That would mean that the exchange occurs by inversion at N(11), and the methyl group slides by the pyrazolidine ring, rather than rotating through a large angle and a perpendicular orientation. However, since the ground state of azapropazone is significantly distorted from planarity, we feel that the steric interactions in a completely planar transition state would preclude this mechanism.

Conclusions

The crystal structure of 3-dimethylamino-7-methyl-1,2,4-benzotriazine (**2**) is quite different from the parent compound, azapropazone (**1**). Removal of the pyrazolidine ring from **1** allows the molecule to become planar, since it removes the steric interaction with the exocyclic dimethylamino group. This change also has a dramatic effect on the rate of chemical exchange between the nonequivalent methyl groups in the dimethylamino moiety. In azapropazone, the enthalpy of activation is 36 kJ mol^{-1}, and the entropy of activation is significantly negative. In **2**, the enthalpy of activation is 48 kJ mol^{-1}, and the entropy is close to zero. We interpret these results to indicate that since the dimethylamino group in **1** cannot lie flat, it is trapped partway up a potential energy barrier. This means that it will take less energy to surmount the barrier. The entropy of activation for a unimolecular chemical exchange process is normally expected to be small. However, the ground state in azapropazone is nonplanar, and relatively disordered compared to a postulated transition state in which the tricyclic ring structure is planar and the dimethylamino group is perpendicular to the plane.

Acknowledgments

We would like to thank Victor Young of the X-ray Crystallographic Laboratory at the University of Minnesota, Twin Cities Campus, for obtaining the data and Dr. K.D. Rainsford of the University of Sheffield for samples of azapropazone. We would also like to thank the Natural Sciences and Engineering Research Council of Canada for financial support.

Synthesis and evaluation of a bicyclic deoxymannojirimycin derivative as a potential glycosidase inhibitor

Kelly S.E. Tanaka and Andrew J. Bennet

Abstract: A bicyclo[2.2.2] analogue of the glycosidase inhibitor 1-deoxynojirimycin, 2,6-anhydro-1-deoxymannojirimycin (**6**), has been synthesized in nine steps from 1,5-anhydro-D-glucitol. This conformationally restricted aza-sugar has been shown to inhibit, albeit weakly, several glycosidase enzymes.

Key words: glycosidase, inhibitor, bicyclic, deoxymannojirimycin, deoxynojirimycin.

Résumé : Utilisant le 1,5-anhydro-D-glucitol comme produit de départ, on a réalisé une synthèse en neuf étapes de la 2,6-anhydro-1-désoxymannojirimycine (**6**), un analogue bicyclo[2.2.2] de la 1-désoxynojirimyrine, un inhibiteur de glycosidase. Il a été démontré que cet aza-sucre conformationnellement restreint inhibe plusieurs enzymes glycosidase, même si ce n'est que faiblement.

Mots clés : glycosidase, inhibiteur, bicyclique, désoxymannojirimycine, désoxynojirimycine.

Introduction

Recent advances in the understanding of the diverse biological function of carbohydrates have led to a renewed interest in carbohydrate-processing enzymes (for recent examples of the use of carbohydrate-processing enzymes for synthesis, see ref. 1). These enzymes can be classified as either (*a*) glycosyl transferases, enzymes that are involved in the construction of oligosaccharides, or (*b*) glycosidases, enzymes that hydrolyze glycosidic linkages. Of particular interest in recent years is the design and synthesis of glycosidase inhibitors. In addition to providing insight into the hydrolytic mechanism of glycosidases (2), these inhibitors have potential therapeutic value in the treatment of metabolic disorders (3), tumor metastasis (4), and viral infections (5). A large class of glycosidase inhibitors are aza-sugars, compounds where a nitrogen atom has replaced the endocyclic oxygen atom of the corresponding carbohydrate. The most noted example is 1-deoxynojirimycin (**1**), an aza-sugar with the same hydroxyl configuration as 1-deoxyglucose (6). These aza-sugars are good inhibitors of glycosidases since the basic nitrogen atom is protonated at physiological pH, and the resultant positive charge is believed to mimic an enzyme-catalyzed transition state (TS). For retaining glycosidase enzymes, the reaction occurs through a double displacement mechanism that was first proposed by Koshland in 1953 (2, 7). In this mechanism, both the glycosylation and deglycosylation steps are believed to occur through TSs containing a distorted glycone ring that has significant oxocarbenium ion character (Fig. 1) (2*a*, 2*c*). Thus, the N-protonated forms of **1** (6) and its C-2 epimer **2** (8) inhibit glucosidases and mannosidases, respectively. Similarly, the glucosidase inhibitor castanospermine (**3**), is a bicyclic molecule that is locked in a $^4C_1$ conformation, and possesses a basic endocyclic nitrogen atom that is protonated at physiological pH (9). Another class of bicyclic glycosidase inhibitors is the calystegines (10), for example, calystegine B_2 (**4**), a molecule that possessess a basic nitrogen atom and is locked in a $^4C_1$ conformation (11). On the other hand, it is believed that the neutral compound nojiritetrazole **5** is a glucosidase inhibitor because the tetrazole ring distorts the glycosyl ring from the $^4C_1$ to the $^4H_3$ conformation (12).

From these studies it is evident that, in addition to the relative configuration of the hydroxyl groups, conformation and charge are two important factors in the design and synthesis of potential glycosidase inhibitors. The relative importance of these two factors in determining the potency of glycosidase inhibitors remains an active area of research (for example, see two recent sialidase inhibitor studies, ref. 13).

With regard to structure, there are four possible ring conformations a glycopyranosyl oxocarbenium ion intermediate can adopt (Fig. 2) and the thermodynamically most favourable $^4H_3$ has been the structural motif used in the design of many glycosidase inhibitors (2*b*, 12, 14). Variability in the inhibitory potency of these compounds suggests that this may not be the TS conformation of the substrate during the hydrolysis reaction catalyzed by all glycosidase enzymes. In 1985 Hosie and Sinnott proposed that yeast α-glucosidase-catalyzed hydrolysis of α-D-glucopyranosyl 4-bromoisoquinolinium bromide proceeded via a $^{2,5}B$ TS conformation (15). The two key results in this study that led to this hypothesis were (*a*) the measured β-secondary kinetic isotope effect for hydrolysis of α-D-glucopyranosyl 4-bromoisoquinolinium bromide (15) and (*b*) the inability of the conformationally rigid castanospermine to inhibit this α-glucosidase enzyme (9).

To further probe possible inhibitor conformations it was decided to synthesize nojirimycin analogues that are forced to adopt a boat-like conformation. Specifically, the target

Results and discussion

The symmetry of the bicyclic target **6** allows four possible synthetic pathways (**a**–**d**) for the cyclization reaction using carbohydrate-based precursors (Scheme 1). It was anticipated that an efficient cyclization would occur via route **a** using a 2-amino-1,2-dideoxymannose precursor. Synthesis of the 2-*O*-methanesulfonate ester **8**, in five steps from D-glucose, was completed using a combination of literature procedures (16). Using a slightly modified procedure, the yield for the selective mesylation of the 2-OH group of 1,5-anhydro-4,6-*O*-benzylidene-D-glucitol **7** was modestly improved from 53% (16*d*) to 60% by increasing the reaction time at –40°C from 1 h to 10 h (Scheme 2). Nucleophilic displacement of the 2-*O*-methanesulfonate group in **8** with azide introduced the required nitrogen atom at the C-2 position, with the appropriate stereochemistry for the subsequent cyclization reaction (Scheme 2). Protection of the 3-*O* hydroxyl group, by benzylation, was necessary at this stage because cyclization of **13.2** led to formation of a [3.2.1] bicyclic product. The benzylation reaction was carried out to afford the 3-*O*-benzyl ether **10**, in good yield (89%) (Scheme 2).

Removal of the 4,6-*O*-benzylidene group followed by controlled hydrogenation resulted in the formation of the 2-amino-3-*O*-benzyl-2-deoxy compound **12** in a combined crude yield of 78% (Scheme 3). In a single step, ditosylation of the 6-OH and the 2-NH_2 groups efficiently introduced a leaving group and acidified the remaining nitrogen-bound hydrogen (TsCl, pyridine 77%; Scheme 3). Ditosylate **13** was efficiently cyclized using a hydroxide-promoted reaction to give **14** in 94% yield (Scheme 4). Simultaneous deprotection of the 4-*O*-benzyl ether and the *N*-toluenesulfonamido groups[2] was readily accomplished to give **6** in an unoptimized yield after recrystallization of 35% (Na, NH_3; Scheme 4). Confirmation that the final product **6** had the required [2.2.2]-bicyclic ring structure was accomplished by ^1H NMR spectroscopy using the measured ^1H coupling constants and the observed nOe contacts (Fig. 3).

Inhibition of four commercial glycosidases by **6** was measured using standard kinetic techniques (see experimental section for details). The kinetic data were fit, using a nonlinear least-squares routine, to a standard competitive-inhibitor rate equation because the corresponding Lineweaver–Burke plots (not shown) displayed the expected behaviour for a competitive inhibitor. Listed in Table 1 are the calculated inhibition constants (K_i) for **6** with these glycosidases. Although these measured K_i values are relatively high, this is the first demonstration that a [2.2.2]-bicyclic aza-sugar analogue can bind to the active site of glycosidases. This observation is particularly noteworthy since this inhibitor (**6**) lacks both the 2- and the 6-hydroxyl groups found in deoxynojirimycin. These hydroxyl groups can form H-bonds, and these interactions are known to be important in glycosidase-catalyzed hydrolysis reactions (17).

In conclusion, a novel, conformationally restricted, aza-sugar **6** has been synthesized (20% yield from **8**) and has been shown to inhibit, albeit weakly, several glycosidase enzymes.

Experimental

Thin-layer chromatography (TLC) was performed on analytical plates of aluminum precoated with Merck Silica Gel 60 F_{254}. Compounds were visualized on developed plates by UV light and (or) charring with 10% H_2SO_4 in methanol. Flash column chromatography was performed using Merck Silica Gel 60 (230–400 mesh). Melting point values are uncorrected. THF was distilled from the sodium ketyl of benzophenone, pyridine was distilled from CaH_2, and DMSO and DMF were distilled from CaH_2 at reduced pressure. All other reagents were used as purchased. Reactions using moisture-sensitive reagents were carried out under a nitrogen atmosphere using oven-dried glassware. Solutions of methanolic HCl (1% w/v) were prepared by the in situ reaction of acetyl chloride with methanol. NMR spectra were recorded on a Bruker AMX-400 NMR spectrometer operating at 400.13 MHz and 100.61 MHz for ^1H and ^{13}C, respectively. Chemical shifts (δ) for all compounds are listed in ppm downfield from TMS using residual $CHCl_3$ (δ 7.24 ppm) or HDO (δ 4.63 ppm) as the internal reference for ^1H spectra and $CDCl_3$ (δ 77.0 ppm) as the internal reference for ^{13}C spectra. Characterization of all new compounds included ^1H and $^{13}C\{^1H\}$ NMR spectra. The observed resonances in the NMR spectra were fully assigned using

[2] The numbering system of compound **5** is derived on the basis that the molecule is a derivative of 1-deoxymannojirimycin.

1,5-Anhydro-4,6-*O*-benzylidene-2-*O*-methanesulfonyl-D-glucitol (8)

A solution of 1,5-anhydro-4,6-*O*-benzylidene-D-glucitol **(7)** (16*a*–*c*) (3.00 g, 11.9 mmol) in dry pyridine (10 mL) was cooled to –40°C (Dry Ice – acetone) after which methanesulfonyl chloride (1.5 mL, 1.1 equiv.) was added dropwise over a period of 60 min. The resulting yellow solution was stirred at –40°C for a further 10 h and allowed to warm to –20°C overnight. After the reaction was quenched by the addition of cold H_2O–ice (100 mL), stirring was continued for 1 h and the product was extracted with EtOAc (3 × 75 mL). The organic extracts were combined, washed with cold 10% (v/v) H_2SO_4 (3 × 100 mL), saturated aqueous $NaHCO_3$ (100 mL), brine (100 mL), and dried (Na_2SO_4). After filtration the solvent was removed at reduced pressure to give a pale-yellow solid. The crude product was purified by flash column chromatography (toluene/EtOAc 9:1) to yield **8** (2.36 g, 60%) as a colourless solid: mp 149–150°C; $[\alpha]_D^{22}$ –12 (*c* 1.0, $CHCl_3$) (lit. (16*d*) mp 155–157°C; $[\alpha]_D^{22}$ –10.6 (*c* 1.1, $CHCl_3$)); R_f 0.48 (EtOAc/toluene 1:3); IR (cm^{-1}): 1182 S(═O)$_2$, 1348 S(═O)$_2$, 3434 (OH); ^{1}H NMR ($CDCl_3$) δ: 3.16 (s, 3 H, SO_2CH_3), 3.39 (dt, 1 H, $J_{4,5} + J_{5,6a}$ = 19.4 Hz, $J_{5,6e}$ = 5.0 Hz, H-5), 3.45–3.52 (m, 2 H, H-1a, H-4), 3.69 (t, 1 H, $J_{5,6a} + J_{6a,6e}$ = 20.5 Hz, H-6a), 3.94 (t, 1 H, $J_{2,3} + J_{3,4}$ = 18.2 Hz, H-3), 4.21 (dd, 1 H, $J_{1e,2}$ = 6.0 Hz, $J_{1e,1a}$ = 11.5 Hz, H-1e), 4.34 (dd, 1 H, $J_{6e,6a}$ = 10.5 Hz, H-6e), 4.59 (ddd, 1 H, $J_{2,3}$ = 8.7 Hz, $J_{1a,2}$ = 10.6 Hz, H-2), 5.52 (s, 1 H, CHC_6H_5), 7.35–7.41 (m, 3 H, CHC_6H_5), 7.45–7.50 (m, 2 H, CHC_6H_5); ^{13}C NMR (CDCl) δ: 38.3 (SO_2CH_3), 68.2 (C-6), 68.6 (C-1), 70.9 (C-5), 72.9 (C-3), 78.1 (C-4), 81.1 (C-2), 102.1 (Ar), 126.3 (Ar), 128.4 (Ar), 129.5 (Ar), 136.8 (Ar). 1,5-Anhydro-2-azido-2-deoxy-4,6-*O*-benzylidene-D-mannitol (9)

A stirred solution of **8** (1.16 g, 3.52 mmol) and sodium azide (0.915 g, 4.0 equiv.) in dry DMSO (5 mL) was heated to 85°C (oil bath) for 2 days. After the addition of H_2O–ice (50 mL) the product was extracted with EtOAc (3 × 50 mL). The organic extracts were combined and washed with cold H_2O (100 mL) and brine (100 mL), then dried (Na_2SO_4) and filtered. After removing the solvent at reduced pressure, the crude yellow solid was purified by flash column chromatography (EtOAc/hexane 1:3) to give **9** (0.864 g, 89%) as a colourless solid; R_f 0.49 (EtOAc/hexane 1:2); mp 80–81°C; $[\alpha]_D^{22}$ –66 (*c* 0.89, $CHCl_3$); IR (cm^{-1}): 2102 (N_3), 3445 (OH); ^{1}H NMR ($CDCl_3$) δ: 2.82 (d, 1 H, *J* = 4.0 Hz, 3-OH), 3.35 (ddd, 1 H, $J_{5,6e}$ = 5.0 Hz, $J_{5,6a}$ = 9.5 Hz, $J_{4,5}$ = 14.4 Hz, H-5), 3.68 (dd, 1 H, $J_{1e,2}$ = 1.7 Hz, $J_{1e,1a}$ = 12.7 Hz, H-1e), 3.77 (t, 1 H, H-6a), 3.90 (t, 1 H, $J_{3,4} + J_{4,5}$ = 18.8 Hz, H-4), 4.00 (m, 1 H, H-1a), 4.03–4.08 (m, 2 H, H-2, H-3), 4.29 (dd, 1 H, $J_{6a,6e}$ = 10.4 Hz, H-6e), 5.52

1,5-Anhydro-2-azido-3-*O*-benzyl-4,6-*O*-benzylidene-2-deoxy-D-mannitol (10)

A suspension of sodium hydride (0.54 g, 13.4 mmol) and **9** (3.11 g, 11.2 mmol) in dry THF (50 mL) was stirred at room temperature (RT) for 30 min. Benzyl bromide (1.1 equiv., 1.47 mL) and tetrabutylammonium iodide (0.1 equiv., 42 mg) were added to this suspension and the resulting mixture was stirred at RT for 12 h. After the solvent was removed at reduced pressure the residue was suspended in brine (20 mL), and the product was extracted with ether (3 × 50 mL). The combined organic extracts were concentrated at reduced pressure to give a pale-yellow oil that, after purification by flash column chromatography (EtOAc/hexane 2:1), yielded **10** (3.75 g, 91%) as a colourless oil: $[\alpha]_D^{22}$ –50 (*c* 0.98, $CHCl_3$); R_f 0.45 (EtOAc/hexane 1:2); IR (cm^{-1}): 1124, 2105 (N_3); ^{1}H NMR ($CDCl_3$) δ: 3.33 (ddd, 1 H, $J_{5,6e}$ = 5.0 Hz, $J_{4,5}$ = 9.4 Hz, $J_{5,6a}$ = 10.1 Hz, H-5), 3.59 (dd, 1 H, $J_{1e,2}$ = 1.5 Hz, $J_{1e,1a}$ = 12.5 Hz, H-1e), 3.80 (t, 1 H, H-6a), 3.85 (dd, 1 H, $J_{2,3}$ = 3.9 Hz, $J_{3,4}$ = 9.4 Hz, H-3), 3.93 (m, 1 H, H-2), 3.98 (dd, 1 H, $J_{1a,2}$ = 1.9 Hz, H-1a), 4.11 (t, 1 H, $J_{3,4}+J_{4,5}$ = 18.6 Hz, H-4), 4.28 (dd, 1 H, $J_{6e,6a}$ = 10.1 Hz, H-6e), 4.77 (d, 1 H, $J_{A,B}$ = 12.5 Hz, CH_AH$_B$C$_6$H$_5$), 4.91 (d, 1 H, CH$_A$*H*$_B$C$_6$H$_5$), 5.64 (s, 1 H, C*H*C$_6$H$_5$), 7.30–7.40 (m, 8 H, Ar), 7.45–7.50 (m, 2 H, Ar); ^{13}C NMR ($CDCl_3$) δ: 61.0 (C-2), 68.5 (C-6), 69.3 (C-1), 72.5 (C-5), 73.1 (*C*H$_2$C$_6$H$_5$), 78.1 (C-3), 79.4 (C-4), 101.6 (*C*HC$_6$H$_5$), 126.1 (Ar), 127.7 (Ar), 127.8 (Ar), 128.2 (Ar), 128.5 (Ar), 128.9 (Ar), 137.5 (Ar), 138.1 (Ar). Anal. calcd. for $C_{20}H_{21}O_4N_3$: C 65.38, H 5.76, N 11.44; found: C 65.21, H 5.71, N 11.46.

1,5-Anhydro-2-azido-3-*O*-benzyl-2-deoxy-D-mannitol (11)

A solution of **10** (1.14 g, 3.11 mmol) in MeOH (25 mL) containing 1% HCl (w/v) was stirred at RT for 1.5 h, after which analysis by TLC (R_f 0.21, EtOAc/hexane 2:1 for **10**) indicated that the deprotection was complete. The solution was neutralized by stirring with Amberlite resin (IRA-400L, $^-$OH form). The resin was removed and the solution was concentrated at reduced pressure to give **11** (0.84 g, 97%) as a colourless solid. An analytically pure sample of **11** was obtained by recrystallization from EtOAc/ether/hexane (5:1:1): mp 98–99°C; $[\alpha]_D^{22}$ –86 (*c* 0.94, $CHCl_3$); IR (cm^{-1}): 1120, 2100 (N_3), 3450 (OH); ^{1}H NMR ($CDCl_3$) δ: 2.03 (brd, 1 H, *J* = 5.8 Hz, 6-O*H*), 2.44 (d, 1 H, *J* = 2.6 Hz, 4-O*H*), 3.26 (ddd, 1 H, $J_{5,6A}$ = 3.3 Hz, $J_{5,6B}$ = 5.3 Hz, $J_{4,5}$ = 9.4 Hz, H-5), 3.55 (dd, 1 H, $J_{1e,2}$ = 1.5 Hz, $J_{1e,1a}$ = 12.6 Hz, H-1e), 3.59 (dd, 1 H, $J_{3,2}$ = 3.7 Hz, $J_{3,4}$ = 9.2 Hz, H-3), 3.70 (dd, 1 H, $J_{6A,6B}$ = 11.9 Hz, H-6$_A$), 3.75 (dd, 1 H, H-6$_B$), 3.86–3.92 (m, 2 H, H-2, H-4), 4.01 (dd, 1 H, $J_{1a,2}$ = 2.0 Hz, H-1a), 4.60 (d, 1 H, $J_{A,B}$ = 11.6 Hz, C*H*$_A$H$_B$C6H5), 4.80 (d, 1 H, CH$_A$*H*$_B$C$_6$H$_5$), 7.32–7.40 (m, 5 H, Ar); ^{13}C NMR ($CDCl_3$) δ: 58.5 (C-2), 62.9 (C-6), 67.7 (C-4), 68.2 (C-1), 72.1 (*C*H$_2$C$_6$H$_5$), 80.3 (C-5), 82.4 (C-3), 128.0 (Ar), 128.3 (Ar), 128.7 (Ar), 137.3 (Ar). Anal. calcd. for $C_{13}H_{17}O_4N_3$: C 55.91, H 6.14, N 15.05; found: C 55.80, H 6.17, N 15.11.

1,5-Anhydro-3-*O*-benzyl-2-deoxy-2-*N*-toluenesulfonamido-6-*O*-toluenesulfonyl-D-mannitol (13)

A suspension of **11** (0.296 g, 1.06 mmol) and 10% Pd–C (0.15 g) in MeOH (15 mL) was stirred under a H_2 atmosphere (6 psi; 1 psi = 6.9 kPa) at RT for 45 min. After the suspension was filtered through a Celite pad and the pad was washed thoroughly with MeOH, the filtrate and washings were concentrated at reduced pressure and dried under high vacuum (0.01 Torr; 1 Torr = 133.3 Pa) to give crude 2-amino-1,5-anhydro-3-*O*-benzyl-2-deoxy-D-mannitol (**12**) (0.268 g, 100%) as a colourless oil: IR (cm^{-1}): 3364 (OH). Crude **12** (1.48 g, 5.84 mmol) was added to a solution containing *p*-toluenesulfonyl chloride (1.5 equiv., 1.6 g) in dry pyridine (30 mL) and the resulting mixture was stirred at RT. After 20 min a second aliquot of *p*-toluenesulfonyl chloride (1.3 equiv., 1.4 g) was added and the resulting mixture was stirred at RT for a further 12 h. The reaction mixture was diluted by the addition of H_2O–ice (50 mL) and the product was extracted with EtOAc (3 × 50 mL). The combined organic extracts were washed with cold 20% H_2SO_4 (50 mL), saturated aqueous $NaHCO_3$ (50 mL), H_2O (50 mL), brine (40 mL), and dried (Na_2SO_4). The resulting solution was filtered and concentrated at reduced pressure to give a pale-yellow solid. Purification of the solid by flash column chromatography (EtOAc/hexane 1:1) gave **13** (2.52 g, 77%) as a colourless solid. In addition the 2-*N*-monotosylated compound **13.1**, was obtained as a colourless solid (0.26 g, 8%; R_f 0.41, EtOAc/hexane 3:1). For compound **13**; mp 68–70°C; $[\alpha]_D^{22}$ –59 (*c* 0.97, $CHCl_3$); IR (cm^{-1}): 1160, 1174 S(═ O)$_2$, 1191 S(═ O)$_2$, 1349 S(═ O)$_2$, 3450 (OH); ^{1}H NMR ($CDCl_3$) δ: 2.35 (d, 1 H, *J* = 2.6, 4-O*H*), 2.39 (s, 3 H, Me), 2.45 (s, 3 H, Me), 3.25–3.32 (m, 2 H, H-1a, H-5), 3.36

Table 1. Binding constants for compounds **1**, **2**, and **6**, and the corresponding 4-nitrophenyl glycosides.

			K_i [a] (mM) for competitve inhibition		
Enzyme	K_m (mM)	pH	1	2	6
α-Glucosidase (yeast)	0.210 ±.008	6.8	0.015 ± 0.001[b]	ND	7.0 ± 1.0
α-Glucosidase (rice)[c]	0.73 ± 0.07[d]	5.0	$(2.4 \pm 0.4) \times 10^{-6}$ [e]	ND	0.8 ± 0.2
β-Glucosidase (almonds)	2.39 ± 0.07	6.8	0.018 ± 0.001[f]	ND	1.01 ± 0.06
α-Mannosidase (almonds)	2.6 ± 0.2	5.0	ND[g]	0.24 ± 0.05[h]	15 ± 2[i]

[a] Data were analysed using nonlinear least-squares regression; estimate of standard error in brackets
[b] Reference 8 lists $K_i = 0.013$ mM at a pH of 6.8.
[c] Slow onset to inhibition was observed for this enzyme.
[d] Substrate used was α-D-glucopyranosyl 4-bromoisoquinolinium bromide.
[e] Reference 17*a* lists $K_i = 1.0 \times 10^{-5}$ mM at a pH of 6.0.
[f] Reference 17*d* lists $K_i = 0.029$ mM at a pH of 6.2.
[g] ND (not determined).
[h] Reference 8 lists $K_i = 0.11$ mM at a pH of 4.5.
[i] Value estimated using data acquired at two inhibitor concentrations (1.65 and 3.30 mM).

(dd, 1 H, $J_{2,3}$ = 6.4 Hz, $J_{3,4}$ = 9.5 Hz, H-3), 3.58 (dt, 1 H, $J_{4,5}$ = 9.5 Hz, H-4), 3.77 (m, 1 H, H-2), 3.82 (dd, 1 H, $J_{1e,2}$ = 1.9 Hz, $J_{1e,1a}$ = 12.4 Hz, H-1e), 4.18 (dd, 1 H, $J_{5,6A}$ = 5.5 Hz, $J_{6A,6B}$ = 11.1 Hz, H-6_A), 4.19 (d, 1 H, $J_{A,B}$ = 11.4 Hz, CH_AH$_B$C$_6$H$_5$), 4.31 (dd, 1 H, $J_{5,6B}$ = 2.0 Hz, H-6_B), 4.47 (d, 1 H, CH$_A$$H_BC_6H_5$), 4.93 (d, 1 H, $J_{NH,2}$ = 7.1 Hz, TsN*H*), 7.19–7.28 (m, 5 H, CH$_2$C$_6$$H_5$), 7.30–7.36 (m, 4 H, *Ar*), 7.77 (d, 2 H, *J* = 8.5 Hz, *Ar*), 7.79 (d, 2 H, *Ar*); ^{13}C NMR (CDCl$_3$) δ: 21.5 (*C*H$_3$Ar), 21.6 (*C*H$_3$Ar), 50.7 (C-2), 66.4 (C-4), 68.6 (C-1), 68.8 (C-6), 70.9 (*C*H$_2$C$_6$H$_5$), 78.0 (C-5), 79.5 (C-3), 127.1 (Ar), 127.9 (Ar), 128.0 (Ar), 128.2 (Ar), 128.6 (Ar), 129.7 (Ar), 129.8 (Ar), 133.2 (Ar), 137.0 (Ar), 137.9 (Ar), 143.6 (Ar), 144.9 (Ar). 1,5:2,6-Dianhydro-3-*O*-benzyl-2-deoxy-2-*N*-toluenesulfonamido-D-mannitol (14)

A solution of **13** (2.52 g, 4.49 mmol) in DMSO (70 mL) and H$_2$O (50 mL) containing NaOH (1 equiv.) was stirred at RT for 24 h. After the removal of the solvent at reduced pressure the residue was purified by flash column chromatography (EtOAc/hexane 1:1) to give **14** (1.64 g, 94%) as a colourless solid: mp 113–115°C; $[\alpha]_D^{22}$ –79 (*c* 1.2, CHCl$_3$); R_f 0.43 (EtOAc/hexane 2:1); IR (cm^{-1}): 1163, 1192 S(═ O)$_2$, 1345 S(═ O)$_2$, 3446 (OH); ^{1}H NMR (CDCl$_3$) δ: 2.24 (d, 1 H, *J* = 8.1, 4-O*H*), 2.40 (s, 3 H, Me), 3.40 (dd, 1 H, $J_{5,6A}$ = 1.7 Hz, $J_{6A,6B}$ = 10.7 Hz, H-6_A), 3.59 (m, 1 H, H-3), 3.69 (dd, 1 H, $J_{5,6B}$ = 3.3 Hz, H-6_B), 3.77 (dd, 1 H, $J_{1A,2}$ = 1.58 Hz, $J_{1A,1B}$ = 10.0 Hz, H-1_A), 3.81 (brd, 1 H, H-4), 3.89 (m, 1 H, H-5), 3.90 (dd, 1 H, $J_{1B,2}$ = 2.4 Hz, H-1_B), 4.21 (m, 1 H, H-2), 4.51 (d, 1 H, $J_{A,B}$ = 11.6 Hz, CH_AH$_B$C6H5), 4.75 (d, 1 H, CH$_A$$H_BC_6H_5$), 7.21 (d, 2 H, *J* = 8.52 Hz, Ar), 7.36–7.40 (m, 5 H, Ar), 7.73 (d, 2 H, Ar); ^{13}C NMR (CDCl$_3$) δ: 21.5 (*C*H$_3$Ar), 47.2 (C-6), 50.0 (C-2), 67.4 (C-1), 70.4 (C-5), 70.8 (*C*H$_2$C$_6$H$_5$), 75.6 (C-4), 83.1 (C-3), 127.4 (Ar), 127.8 (Ar), 128.0 (Ar), 128.4 (Ar), 129.6 (Ar), 136.4 (Ar), 137.6 (Ar), 143.5 (Ar). Anal. calcd. for $C_{20}H_{23}NO_5S$: C 61.68, H 5.95, N 3.60; found: C 61.53, H 5.85, N 3.46.

2,6-Anhydro-1-deoxymannojirimycin (6)

A solution of **14** (0.380 g, 0.976 mmol) in dry THF (5 mL) was cooled to –78°C (Dry Ice – acetone) in a three-neck flask fitted with a cold finger. After approximately 15 mL of ammonia was condensed in the flask, Na (0.11 g, 5 equiv.) was added to the suspension and the resulting mixture was stirred at –78°C for 30 min after a persistent blue colour was observed. The reaction was quenched by the addition of MeOH (30 mL) followed by evaporation to dryness. The crude product was dissolved in MeOH and again evaporated to dryness. The crude product was recrystallized from EtOH–ether–HCl to give the HCl salt of **6** as a colourless solid (62 mg, 35%): mp 227–230°C: $[\alpha]_D^{22}$ –44 (*c* 1.2, H$_2$O); ^{1}H NMR (D$_2$O) δ: 3.13 (dd, 1 H, $J_{1R,2}$ = 1.2 Hz, $J_{1R,1S}$ = 13.2 Hz, H-1_R), 3.66 (dd, 1 H, $J_{1S,2}$ = 3.6 Hz, H-1_S), 3.71 (m, 1 H, H-5), 3.82 (m, 1 H, H-3), 3.95 (dd, 1 H, $J_{6R,5}$ = 1.6 Hz, $J_{6R,6S}$ = 11.6 Hz, H-6_R), 4.02–4.06 (m, 2 H, H-2, H-4), 4.20 (dd, 1 H, $J_{6S,5}$ = 2.4 Hz, H-6_S); ^{13}C NMR (D$_2$O) δ: 46.0 (C-1), 53.2 (C-5), 64.5 (C-6), 69.9 (C-2), 74.0 (C-4), 76.7 (C-3). Anal. calcd. for $C_6H_{12}NO_3Cl$: C 39.68, H 6.66, N 7.71; found: C 39.46, H 6.76, N 7.52.

Enzyme kinetics

Yeast α-glucosidase (G-7256), rice α-glucosidase (G-9259), almond β-glucosidase (G-0395), and almond α-mannosidase (M-1266) were purchased from Sigma. Ammonium sulfate was removed from the stock yeast enzyme solution by washing through a Centricon-30 filter with 50 mM phosphate buffer (3 × 100 μL, pH 6.8), and diluting the final suspension 10-fold with 50 mM phosphate buffer (pH 6.8, 0.1% w/v BSA). All other enzymes were used as purchased. Inhibitor **1** was synthesized using a combination of literature procedures (20) and **2** was purchased from Sigma. Inhibition constants (K_i) of glycosidase-catalyzed hydrolyses were measured using a range of inhibitor concentrations (typically five concentrations) encompassing the K_i value, and a range of six substrate concentrations surrounding the Michaelis–Menton constant (K_m). The total volume for all assays was 350 μL. All assays were carried out using reaction times where less than 10% of the total amount of substrate was hydrolyzed. The K_m and the K_i values were calculated using nonlinear least-squares regression analysis of the data to a standard competitive-inhibition equation. The hydrolysis kinetics were followed using a CARY-3E UV–Vis spectrophotometer equipped with a Cary six-cell Peltier constant-temperature controller.

Yeast α-glucosidase and almond β-glucosidase kinetics

© 1998 NRC Canada

were carried out at 25°C in 50 mM phosphate buffer (0.1% w/v BSA) at pH 6.8 using 4-nitrophenyl α-(or β-)D-glucopyranoside as the substrate. The increase in absorbance due to the liberation of 4-nitrophenol was monitored at 400 nm and was linear with respect to time over the course of the measurements (1–3 min). The slope of the line was taken as the velocity for the hydrolysis of the substrate. A typical assay involved the incubation of the substrate (S) and inhibitor (I) for 10 min prior to the addition of enzyme (E).

The rice α-glucosidase kinetics were carried out at 37°C in 50 mM acetate buffer (0.1% w/v BSA) at pH 5.0 using α-D-glucopyranosyl 4-bromoisoquinolinium bromide as the substrate. The increase in absorbance due to the liberation of 4-bromoisoquinoline was monitored at 345 nm and was linear with respect to time over the course of the measurements (1–3 min). Due to the slow onset of inhibitor binding with this enzyme, assays were carried out where the inhibitor and glycosidase were preincubated together for 15 min before the addition of the substrate. Due to substrate inhibition, the substrate concentrations used did not exceed more than two times K_m.

Almond α-mannosidase kinetics were carried out at 25°C in 50 mM acetate buffer at pH 5.0 using 4-nitrophenyl α-D-mannopyranoside as the substrate. The increase in absorbance due to the liberation of 4-nitrophenol was monitored at 343 nm and was linear with respect to time for the duration of the measurements (10 min). The 4-nitrophenyl α-D-mannopyranoside and inhibitor were incubated together for 10 min prior to the addition of enzyme.

Acknowledgments

The authors are grateful to the Natural Sciences and Engineering Research Council of Canada, the British Columbia Health Research Foundation, and Simon Fraser University for financial support. In addition, the authors would like to thank M.K. Yang for carrying out the elemental analyses and M.M. Tracey for the acquisition of numerous NMR spectra.

Thermodynamics of dissolving gaseous argon in different solvents

Giuseppe Graziano

Abstract: The solvation of argon in 10 different solvents at room temperature is analysed in terms of the theoretical framework developed by Lee. In order to perform calculations, we used the approach devised by Pierotti and firmly validated by Lee's theory. The fair agreement between the experimental and the calculated values of $\Delta G^{\bullet}$, $\Delta H^{\bullet}$, and $\Delta S^{\bullet}$ is carefully analysed. It proves that the excluded volume effect, due to cavity creation in the solvent, opposes the solubility process. This effect in water is exaggerated by the small size of the water molecules and is the cause of hydrophobicity. The qualitative difference between water and hydrazine with regard to the solvation enthalpy and entropy changes is rationalized on the basis of the contributions arising from the structural reorganization in the two solvents on solute insertion.

Key words: hydrophobic hydration, cavity creation, structural solvent reorganization.

Résumé : On utilise une approche théorique développée par Lee pour faire l'analyse de la solvatation de l'argon dans 10 solvants différents, à la température ambiante. Afin d'effectuer ces calculs, on a utilisé l'approche développée par Pierotti pour bien valider la théorie de Lee. On a fait une analyse approfondie du bon accord entre les valeurs expérimentales des $\Delta G^{\bullet}$, $\Delta H^{\bullet}$, et $\Delta S^{\bullet}$ et les valeurs calculées correspondantes. Il démontre que l'effet de volume exclu, provoqué par la création d'une cavité dans le solvant, s'oppose au processus de solubilité. Dans l'eau, cet effet est exagéré par la faible taille des molécules d'eau et elle est la cause du caractère hydrophobe. La différence qualitative entre l'eau et l'hydrazine concernant l'enthalpie et l'entropie de solvatation peut s'expliquer sur la base des contributions provenant de la réorganisation structurale dans les deux solvants lors de l'insertion du soluté.

Mots clés : hydratation hydrophobe, création de cavité, réorganisation structurale du solvant.

[Traduit par la rédaction]

Introduction

Hydrophobicity is a well-known natural phenomenon, but the actual cause of the low solubility of hydrocarbons in water is not yet completely understood (1). The importance of the topic is readily recognized, being mindful of its correlation with the formation and stability of micelles, double-layer membranes, and globular proteins (2). The most intriguing feature of hydrophobicity is the fact that, at room temperature, it arises from a negative entropy change. This experimental evidence has been difficult to reconcile with basic mixing thermodynamic theories, but in 1945 Frank and Evans suggested that the entropy decrease was due to "iceberg" formation around the nonpolar molecules (3). Water molecules, in order to avoid the waste of hydrogen bonds and to minimize the perturbation caused by the hydrocarbon moiety, reorganize themselves to give rise to an ordered structure, similar to the arrangement found in ice. The original idea of an enhancement of water structure around a nonpolar solute was largely accepted by the scientific community and reformulated in more sophisticated approaches by various authors (4, 5). It was also the basis for the introduction by Kauzmann of the concept of hydrophobic interaction, which should play a major role in determining the stability of globular proteins (6). However, thermodynamic investigations over large temperature ranges have shown that this simple picture is unable to explain satisfactorily all the details of the phenomenon (7, 8). The enthalpy and entropy changes associated with the transfer of nonpolar solutes from gas phase or organic liquid into water are strongly temperature dependent: at 25°C they are negative, pass through zero at a certain temperature, and then become positive. Around room temperature hydrophobicity would be caused by entropy, whereas at higher temperatures it would be governed by enthalpy (9). This finding is difficult to rationalize in terms of iceberg formation. The temperature dependence originates from the large positive heat capacity change (10) that is generally ascribed to the gradual melting of the structure formed. The heat capacity change, however, is large positive even beyond 100°C, where the iceberg would be melted (11–14). Finally, the Gibbs transfer energy change is little affected by temperature, being always positive and showing a very broad maximum around 100°C (7). This means that the temperature-dependent changes in enthalpy and entropy are large in magnitude, but largely compensate one another (15). These experimental results point out the inherent limitations of the structure-formation hypothesis to explain hydrophobicity. Moreover, many computer simulation studies have made clear that there is no iceberg formation around nonpolar moieties in water at room temperature (16). In addition, recent neutron-scattering measurements have shown that the structure of water in the hydration shell of a

nonpolar group is by no means more ordered than that of bulk water (17). This indicates that there is one molecular mechanism that determines hydrophobicity and is little dependent on temperature.

To study the solvation process it is necessary to consider the transfer of a molecule from a fixed position in the ideal gas phase to a fixed position in a liquid phase. The thermodynamic quantities of this process do not contain the effects associated with the difference in volume of the two phases. The thermodynamics of solvation processes were analysed in detail by Ben-Naim (18), who showed that the effects of volume and translational motion can be excluded by using the molar concentration scale. The thermodynamic quantities reported in the literature are usually defined using a mole-fraction-based standard state. Therefore they have to be corrected for the Ben-Naim standard state. The relationships required to pass from the conventional standard to the Ben-Naim standard are the following:

$$[1] \quad \Delta G^{\bullet} = \Delta G^{\circ} - RT \ln (RT/p^{\circ}v^{\circ}_1)$$

$$[2] \quad \Delta H^{\bullet} = \Delta H^{\circ} + RT(1 - \alpha^{\circ}_1 T)$$

$$[3] \quad \Delta S^{\bullet} = (\Delta H^{\bullet} - \Delta G^{\bullet})/T$$

$$[4] \quad \Delta C_p^{\bullet} = \Delta C_p^{\circ} + R\,[1 - 2\alpha^{\circ}_1 T - (\alpha^{\circ}_1)' T^2]$$

where $p^{\circ} = 1$ atm, v°_1 is the molar volume of the solvent, α°_1 is the thermal expansion coefficient of the solvent, $(\alpha^{\circ}_1)'$ is the corresponding temperature derivative, and the filled circle denotes the Ben-Naim standard.

In this paper, first the theory developed by Lee (19–22), to analyse and interpret the solvation process of nonpolar gases, is reexamined because, in our opinion, it seems the most reliable, proposed so far, from a physico-chemical point of view. Then, the solvation process of argon at room temperature in 10 different solvents is analysed, using the simple approach devised by Pierotti (23, 24), grounded on Scaled Particle Theory, SPT (25), and strongly validated by Lee's theory. The calculated values of $\Delta G^{\bullet}$, $\Delta H^{\bullet}$, and $\Delta S^{\bullet}$ are in satisfactory agreement with the experimental values. On this basis, the physical origin of hydrophobicity, or better, of solvophobicity, and the contribution arising from structural solvent reorganization upon solute insertion are rediscussed. Finally, an in-depth comparison between the transfer thermodynamics of He, Ar, and N_2 in water and hydrazine is carried out. Hydrazine shows slightly larger values of $\Delta G^{\bullet}$ than does water, but qualitatively different values of $\Delta H^{\bullet}$. Lumry and co-workers (26) used these experimental findings to propose a drastic reexamination of the origin of hydrophobicity. Actually, SPT calculations are also able to reproduce the values of thermodynamic quantities for hydrazine, and allow us to clarify the physical origin of the different behaviour of N_2H_4 and H_2O for the enthalpy changes. This fact lends further support to the physical interpretation of the low solubility of nonpolar gases in liquids arising from Lee's theory.

Lee s theory

From a microscopic point of view, according to the liquid perturbation theory (27), the process of inserting a solute molecule at a fixed point in a solvent can be dissected into two steps: (*a*) creation, in the solvent, of a cavity of suitable size to accommodate the solute molecule; (*b*) introduction, into the cavity, of the solute molecule, which then interacts with the solvent according to some potential law. Thus, the Gibbs energy change upon transferring the solute from the gas phase to a liquid phase is given by

$$[5] \quad \Delta G^{\bullet} = \Delta G_c + \Delta G_a$$

where ΔG_c is the reversible work to create a mole of cavities in the solvent, and ΔG_a is the Gibbs energy change associated with the turning on of solute–solvent interactions.

Lee pointed out that ΔG_c can be calculated from the following exact relationship of statistical mechanics (20, 28):

$$[6] \quad \Delta G_c = -RT \ln P_0 = RT\nu$$

where P_0 is the fraction of pure solvent molecular configurations that have a cavity of desired dimension at the point considered, and ν is a dimensionless number that has to be considered an effective solvation number of the solute. Unfortunately, this exact formula is not directly applicable, because it would require knowledge of the molecular distribution function of pure solvent, a system with a very large number of interacting particles. Actually, in recent years, eq. [6] has been used by performing computer simulations of the liquid phase and counting those instances possessing the desired cavity (29, 30). Additionally, eq. [6] demonstrates that ΔG_c arises from a purely entropic contribution, since it measures the fraction of molecular configurations of the pure solvent that become inaccessible to solvent molecules upon creation of the cavity (19, 20). Lee, by using fundamental relations of equilibrium thermodynamics, showed that the purely structural solvent reorganization associated with cavity creation is a compensating process, i.e., it does not affect the net Gibbs energy change because the enthalpic contribution exactly cancels the entropic one. In fact, it is

$$[7] \quad \Delta H_c = -RT^2 (\partial\nu/\partial T)_p$$

$$[8] \quad T{\cdot}\Delta S_c = -RT\nu - RT^2 (\partial\nu/\partial T)_p$$

The purely structural solvent reorganization is proportional to the temperature derivative of the effective solvation number. From a microscopic point of view, it can be stated that the enthalpy change due to the rupture of non-covalent interactions among solvent molecules exactly matches the entropy change associated with the gain of degrees of freedom upon breakage of the solvent–solvent interactions.

For the Gibbs energy change upon turning on the solute–solvent interactions, Lee (21, 22) pointed out that, on the basis of the potential distribution theorem of Widom (31), it can be expressed as

$$[9] \quad \Delta G_a = -RT \ln \langle \exp(-\psi_a/RT) \rangle$$

where ψ_a is the potential energy describing the solute–solvent interactions, and the brackets represent the ensemble average over the solvent molecular configurations containing the cavity. The enthalpy change is

$$[10] \quad \Delta H_a = \langle \psi_a \rangle + \Delta H_{ra}$$

where $\langle \psi_a \rangle$ is the ensemble average of the interaction energy and ΔH_{ra} represents the contribution of the structural solvent reorganization upon turning on the solute–solvent interactions. Lee (21, 22), exploiting an inversion relationship demonstrated

© 1998 NRC Canada

by Widom (31), showed that, when the fluctuations in the value of $< \psi_a >$ are small, the entropy change is

[11] $T \cdot \Delta S_a \approx \Delta H_{ra}$

On the basis of calculations by several authors (32), the condition of small fluctuations in the value of $< \psi_a >$ is valid for the interaction of nonpolar molecules with water. Therefore, the structural solvent reorganization associated with the process of turning on the attractive potential ψ_a around the cavity is a compensating process, because the entropy change cancels the enthalpy change. The net Gibbs energy change is due to a purely enthalpic contribution arising from the establishment of attractive interactions between the solute molecule in the cavity and all the surrounding solvent molecules, i.e., $\Delta G_a \approx < \psi_a >$.

In conclusion, the overall Gibbs energy change upon transferring the solute from gas phase to liquid phase is given by

[12] $\Delta G^\bullet = \Delta G_c + \Delta G_a = RT\nu + < \psi_a >$

This formula exactly matches that first proposed and used by Pierotti in the middle sixties (23). On the basis of this theoretical validation, we used Pierotti's approach, which is briefly outlined in the following section, to perform a series of calculations.

Pierotti s approach

Pierotti (23, 24) evaluated the Gibbs energy change to create a cavity in a solvent using the following theoretical equation derived from Scaled Particle Theory, SPT (25):

[13] $\Delta G_c = RT[K_0 + K_1(\sigma_2/\sigma_1) + K_2(\sigma_2/\sigma_1)^2 + K_3(\sigma_2/\sigma_1)^3]$

where $K_0 = -\ln(1-\xi)$; $K_1 = u = 3\xi/(1-\xi)$; $K_2 = u(u+2)/2$; $K_3 = \xi \cdot p v^\circ_1/RT$.

In these relations R is the gas constant; ξ is the volume packing density of pure solvent, which is defined as the ratio of the physical volume of a mole of solvent molecules over the molar volume of the solvent, v°_1 (i.e., $\xi = \pi \cdot \sigma_1^3 \cdot N_{Av}/6 \cdot v^\circ$); p is the hydrostatic pressure over the liquid; σ_1 and σ_2 are the hard-sphere diameters of the solvent and solute molecules, respectively. The temperature dependence of ΔG_c is due to the solvent packing density, which is a function of volume, which in turn depends on the temperature. The slight temperature dependence of molecular diameters is not considered in this work. The enthalpy change is calculated from the appropriate temperature derivative:

[14] $\Delta H_c = [\xi \alpha^\circ_1 \cdot RT^2/(1-\xi)^3]\,[(1-\xi)^2 + 3(1-\xi)(\sigma_2/\sigma_1) + 3(1+2\xi)(\sigma_2/\sigma_1)^2] + \xi p v^\circ_1 (\sigma_2/\sigma_1)^3$

where α°_1 is the thermal expansion coefficient of the solvent. The entropy change is

[15] $\Delta S_c = (\Delta H_c - \Delta G_c)/T$

Pierotti calculated the Gibbs energy change needed to turn on the attractive interactions between solute and solvent molecules, using the Lennard-Jones 6-12 potential, and a permanent dipole-inductive dipole term, integrated over the solvent molecules. In addition, he assumed that the solvent structure around the solute is uniform with the density equal to that of pure solvent. The resulting expression is

[16] $\Delta G_a = -(64/3) \cdot \xi \cdot \varepsilon_{12} \cdot (\sigma_{12}/\sigma_1)^3 - (8 \cdot \xi \cdot \mu_1^2 \cdot \alpha_2)/(\sigma_1 \cdot \sigma_{12})^3$

Table 1. Gibbs energy, enthalpy, and entropy changes associated with the dissolution of argon in several solvents at 298.15 K, according to the Ben-Naim standard state. For each solvent the experimental values are given in the first line, while the values calculated using Pierotti's procedure are given in the second line.

[e] EG stands for ethylene glycol; ref. 36.

where μ_1 is the dipole moment of the solvent molecule, α_2 is the polarizability of the solute molecule, $\sigma_{12} = (\sigma_1 + \sigma_2)/2$, and $\varepsilon_{12} = (\varepsilon_1 \varepsilon_2)^{1/2}$, where ε_1 and ε_2 are the Lennard-Jones potential parameters for the solvent and solute, respectively, measuring the magnitude of the maximum attractive potential energy. Pierotti considered ΔG_a purely enthalpic, $\Delta G_a = \Delta H_a$ (i.e., the interaction term has no entropic contribution), and independent of temperature. Therefore, in Pierotti's approach, the overall enthalpy and entropy changes are given by

[17] $\Delta H^\bullet = \Delta H_c + \Delta G_a$ and $\Delta S^\bullet = \Delta S_c$

The solvation of argon

The experimental values of the change in Gibbs energy, enthalpy, and entropy, corrected for the Ben-Naim standard state, associated with the dissolution of argon in several solvents at 25°C, are collected in Table 1 (8, 33–36). It is readily recognized that the values of $\Delta G^\bullet$ are always positive, also for nonpolar solvents such as *n*-hexane and CCl_4. The solvation process for argon at 25°C is not thermodynamically favoured under Ben-Naim standard state conditions, regardless of the physico-chemical properties of the solvent. Furthermore, this solvation process is strongly exothermic only in H_2O and D_2O, is slightly exothermic in *n*-hexane and ethylene glycol, slightly endothermic in all other solvents except hydrazine, where it is

strongly endothermic. Therefore, there are large differences among the solvents for the values of $\Delta H^\bullet$. The entropy change is negative for all the solvents, but is very large only in H_2O and D_2O. It is useful to test whether Pierotti's approach is able to reproduce these experimental findings. The molecular parameters and physical properties, at 25°C, of the compounds considered in this work are collected in Table 2 (19, 23, 24, 37–40). The calculated values of ΔG_c, ΔG_a, and ΔH_c for all the solvents are reported in Table 3. The comparison between the experimental and calculated values of $\Delta G^\bullet$, $\Delta H^\bullet$, and $\Delta S^\bullet$ is made in Table 1. It is readily recognized that the agreement is satisfactory, in view of the physical features of the considered solvents, most of them being extensively hydrogen bonded.

The $\Delta G^\bullet$ values are reproduced quite well, as expected from Lee's theoretical analysis. The calculated values of $\Delta H^\bullet$ and $\Delta S^\bullet$ do not agree so well with the experimental values, as expected in view of the assumptions made by Pierotti. In any case the overall agreement is satisfactory, considering that no explicit information about the solvent structure has been introduced into the calculations. The success of SPT in reproducing the experimental data of the solvation process for nonpolar gases, first pointed out by Pierotti (22) and confirmed by several authors (1, 41), is striking and cannot be disregarded. Therefore, let us analyse the calculated values in detail.

The term ΔG_a is negative and little affected by the solvent considered, as can be seen from the values reported in Table 3. This finding is strongly validated by the theoretical calculations of dispersive interactions carried out by various authors

Table 3. Cavity and attractive terms contributing to the thermodynamics of dissolution of argon in several solvents. All values are calculated at 298.15 K, using Pierotti's procedure.

	ΔG_c J mol^{-1}	ΔG_a J mol^{-1}	ΔH_c J mol^{-1}

EG	17 222	–9 536	8 721

(32). In addition, measurements of surface tension suggest that dispersive interactions between alkanes, and between alkanes and water, are very similar (42). Therefore, the term ΔG_a cannot be the cause of the low solubility of nonpolar gases in water. On the contrary, the term ΔG_c is large positive and strongly affected by the solvent considered: $\Delta G_c = 11\,929$ J mol^{-1} in *n*-hexane, 15 358 J mol^{-1} in benzene, 18 460 J mol^{-1} in water, and 21 193 J mol^{-1} in hydrazine. Equation [13] indicates that ΔG_c, for a fixed cavity size, is strongly dependent on the size of solvent molecules and on the solvent packing density. The Gibbs energy cost to create a cavity of a given radius is larger when the solvent molecules are smaller and the solvent packing density is higher. In other words, it is more difficult to create a cavity in a liquid of high packing density and constituted by small molecules, because the cavity does affect a larger number of solvent configurations. Water has the smallest molecular size among all other solvents (i.e., it corresponds roughly to the size of an oxygen atom), and this raises the value of ΔG_c. On the other hand, water also has a very low value of packing density because there are three-dimensional networks of H-bonds and this lowers the value of ΔG_c. Actually, the size effect in the case of water prevails, rendering ΔG_c very large. For the organic solvents the size effect prevails again but, in view of their large molecular diameters, the ΔG_c term is substantially lower than in water (see Table 3). Therefore, as stressed by Lucas (43) and mainly by Lee (19, 21), the origin of hydrophobicity is in the small size of the water molecules through an amplification of the excluded volume effect associated with the cavity creation (i.e., restriction of the translational degrees of freedom of the solvent molecules due to the cavity creation).

It is worth noting that SPT calculations also reproduce the experimental finding that argon is slightly more soluble in D_2O than in H_2O. The increase in solubility arises from the lower packing density of heavy water with respect to water ($\xi = 0.361$ for D_2O against 0.363 for H_2O), which renders the Gibbs energy cost to create the cavity smaller, as already pointed out by Jolicoeur and co-workers (44).

The overall enthalpy change represents the sum of two terms: (*i*) ΔG_a, which is negative and more or less similar for all the solvents (see above); (*ii*) ΔH_c, which is positive and strongly dependent on the solvent considered. Indeed, ΔH_c is a function of σ_1, ξ, and α°_1. Actually, it is directly proportional to α°_1, the thermal expansion coefficient of the solvent. It is

© 1998 NRC Canada

well known that the value of α°_1 for water and heavy water is abnormally small with respect to all other solvents at room temperature. As a consequence, the values of ΔH_c in H_2O and D_2O are the lowest among all other solvents, and the total enthalpy change, dominated by the ΔG_a term, proves to be large negative. In addition, the process is slightly more exothermic in D_2O than in H_2O, because α°_1 is lower for heavy water than for water. For the other solvents, except for hydrazine (see next section), the ΔH_c term is almost equal to ΔG_a but of opposite sign, and the solvation process proves to be very slightly endothermic or exothermic.

In Pierotti's approach, the overall entropy change takes into account only the entropy change associated with cavity creation, since ΔG_a is considered purely enthalpic. The entropy of cavity creation, according to eq. [8], is given by the sum of two terms: the first represents the contribution from the excluded volume effect (i.e., the exclusion of solvent molecules from the space occupied by the solute molecule) and has a negative sign; the second term represents the structural solvent reorganization as a response to volume exclusion (i.e., the breakage of some non-covalent interactions among solvent molecules) and has a positive sign. The contribution from the excluded volume effect is the prevailing one, and the calculated values of $\Delta S^\bullet$ are negative for all solvents, as can be seen in Table 1.

It is worth noting that, although the calculated values of $\Delta G^\bullet$ in some cases are very close to the experimental ones, Pierotti's approach does not really constitute a method for the prediction of $\Delta G^\bullet$ values. It strongly depends on the value of σ_1, which is determined from experimental solubility data (37), as already stressed by several authors (45). In this respect, it is not obvious that molecules such as water, *n*-hexane, and benzene can be described accurately as impenetrable spheres with a defined hard-sphere diameter. Indeed, Madan and Lee (30) emphasized that there are two sizes associated with water: the commonly used hard-sphere diameter, 2.75 Å, close to the first peak of the radial oxygen–oxygen distribution function, and the Lennard-Jones size parameter, which ranges from 2.96 to 3.24 Å for the different water models (46). Furthermore, experimentally known properties of the solvent, such as v°_1 and α°_1, are used in the application of SPT. These quantities serve to preserve as much information as possible about the real attractive interactions among the solvent molecules (i.e., H-bonds play important roles in determining the unusually small values for the molar volume and thermal expansion coefficient of water).

In any case, the success of Pierotti's approach in the case of water is a strong validation of Lee's theory, since in SPT the water molecules do not have orientational degrees of freedom. The work of cavity formation depends on the ability of the solvent to spontaneously generate atomic-sized cavities (20, 25, 29, 47). SPT indicates that the frequency of occurrence of atomic-sized cavities is low in water compared to that in common organic solvents, because the size of a water molecule is small and, consequently, the free volume in water is distributed in smaller packets. Computer simulations on water models with and without H-bonding potential (29, 30, 48) have confirmed that the Gibbs energy cost to create a cavity in water does not depend on the presence of H-bonds. This means that the purely structural reorganization of H-bonds is a compensating process that does not affect the Gibbs energy change. Recently, various authors (49–51), by using different theoretical approaches, concluded that the solvent reorganization contributions to the enthalpy and the entropy exactly cancel one another. The possibility of neglecting the solvent reorganization in calculating the hydration Gibbs energies also explains the success of the integral equation theory of Pratt and Chandler (52), because an essential ingredient of the theory is the assumption that water does not reorganize itself around nonpolar solutes. Finally, de Souza and Ben-Amotz (53) showed that large positive solvation Gibbs energies in water can be accounted for by a hard-sphere model, which has no orientational order, as a consequence of entropy changes associated with the repulsive translational constraints imposed on water molecules by a solute. Therefore, the analysis performed leads to the conclusion, with Lucas, Lee, and Ben-Amotz, that the low solubility of nonpolar gases in water is determined by the small size of water molecules, which amplifies the excluded volume effect due to cavity creation.

Hydrazine versus water behaviour

The dissolution of helium, argon, and nitrogen in water and hydrazine at room temperature has the following thermodynamic features (see Table 4): (*i*) $\Delta G^\bullet$ is large positive in both H_2O and N_2H_4; (*ii*) $\Delta H^\bullet$ is large negative in H_2O, but large positive in N_2H_4 (this is not true for He because it has very small values of both the polarizability and the Lennard-Jones parameter); (*iii*) $\Delta S^\bullet$ is large negative in H_2O and small negative in N_2H_4; (*iv*) $\Delta C_p{}^\bullet$ is large positive in H_2O and equal to zero in N_2H_4. On the basis of the experimental values collected in Table 4, the solvation process in water at 25°C seems to be dominated by entropy, whereas the solvation process in hydrazine at 25°C seems to be dominated by enthalpy. However, as well emphasized by the calculated values of ΔG_c and ΔG_a (see Table 5), it is always the excluded volume effect associated with cavity creation that plays the fundamental role in the transfer process. For the sake of clarity, in the following, we restrict our attention to the solvation of argon, but the conclusions are valid also for helium and nitrogen.

The values of ΔG_a are practically identical in the two solvents: $\Delta G_a = -10\,929$ J mol^{-1} in H_2O and $-10\,527$ J mol^{-1} in N_2H_4. On the contrary, $\Delta G_c = 18\,460$ J mol^{-1} in H_2O and 21 193 J mol^{-1} in N_2H_4. The reversible work necessary to create a suitable cavity for accommodating argon is larger in hydrazine than in water because, even though the water molecule is smaller ($\sigma_1 = 2.75$ Å for H_2O against 3.62 Å for N_2H_4), liquid hydrazine has a packing density greater than that of water ($\xi = 0.468$ for N_2H_4 against 0.363 for H_2O). For the pair H_2O–N_2H_4 the effect of the solvent packing density on ΔG_c prevails over the effect of the molecular dimension and argon is less soluble in hydrazine than in water. It has to be stressed that this experimental finding emerges directly from SPT calculations, which reproduce well the measured values of $\Delta G^\bullet$. According to Lee's theory, the substantial difference between N_2H_4 and H_2O for the value and sign of $\Delta H^\bullet$ and the value of $\Delta S^\bullet$ must be due to the purely structural reorganization process of solvent molecules upon cavity creation and turning on of solute–solvent interactions. Pierotti's approach allows us to estimate only the structural reorganization upon cavity creation and so the agreement between the calculated and the experimental values of $\Delta H^\bullet$ and $\Delta S^\bullet$ is expected to be less

Table 5. Cavity and attractive terms contributing to the thermodynamics of dissolution of helium, argon, and nitrogen in water (first line) and hydrazine (second line). All values are calculated at 298.15 K, using Pierotti's procedure.

	ΔG_c	ΔG_a	ΔH_c
	J mol^{-1}	J mol^{-1}	J mol^{-1}
Helium	12 361	–1 666	1 845
	14 327	–1 639	9 247
Argon	18 460	–10 929	2 843
	21 193	–10 527	14 238
Nitrogen	21 051	–10 819	3 270
	24 105	–10 338	16 375

satisfactory. In any case, ΔH_c = 2843 J mol^{-1}, $\Delta H^\bullet$ = –8086 J mol^{-1}, and $\Delta S^\bullet$ = –52.38 J K^{-1} mol^{-1} in H_2O, whereas ΔH_c = 14 238 J mol^{-1}, $\Delta H^\bullet$ = 3711 J mol^{-1}, and $\Delta S^\bullet$ = –23.33 J K^{-1} mol^{-1} in N_2H_4. It is worth noting that the calculations indicate, without any special assumptions, that the solvation of argon is strongly exothermic in water and endothermic in hydrazine. This striking difference requires an explanation.

The importance of the comparison between the two liquids was first recognized by Bernal and Fowler in their pioneering work of 1933 (54). Many of the physical properties of water and hydrazine are almost identical. Melting points, boiling points, heats and entropies of vaporization, densities, surface tensions, dipole moments, and viscosities are very similar. In all probability, the existence in both liquids of a three-dimensional network of H-bonds is the origin of the similarities (26). The two liquids, however, differ in those properties that are attributed to the unique structural features of water. Hydrazine does not expand upon freezing, exhibits no liquid density maximum, has a remarkably lower dielectric constant, and a heat capacity per atom lower than that of water (26). Indeed, one essential difference between H_2O and N_2H_4 that is readily recognized is their difference in functionality. Water is almost unique in being 2–2 functional, so that there is an exact matching. In addition, these functions exert their maximum action along the tetrahedral directions that are equivalent in each function. Thus a variety of three-dimensional structures possessing similar connectivity are favoured, and external perturbations do not cause drastic alterations (i.e., the number of H-bonds is very little affected). Hydrazine is 2–4 functional, with an excess of hydrogens over lone-pairs, and is involved in a conformational equilibrium between the *gauche* and *cis* rotamers, which are separated by an energy barrier. Therefore, hydrazine would be a model of inhibited water, a liquid with a connectivity system similar to that of water, but free of the fluctuational processes responsible for the anomalous behaviour of water (26). These features of N_2H_4 significantly affect the purely structural reorganization of solvent molecules upon solute insertion. In all probability, ΔH_c is large positive in N_2H_4 because hydrazine is forced to sacrifice some H-bonds in the reorganization upon cavity creation, due to its molecular structure. The loss of H-bonds, in view of their strength, gives a large positive contribution to the enthalpy change, overwhelming the negative contribution arising from the solute–solvent interactions. From this analysis, the large positive value of $\Delta H^\bullet$ found for solvation in N_2H_4 is understandable. At the same time, the breakage of H-bonds gives a large positive contribution to the entropy change, partially compensating for the large negative contribution arising from the excluded volume effect associated with cavity creation. Therefore, $\Delta S^\bullet$ in N_2H_4 is negative, but lower than in H_2O. In addition, the experimental evidence that the transfer heat capacity change is zero demonstrates the absence of significant enthalpy fluctuations in liquid hydrazine.

In water the molecules are capable of assuming a variety of three-dimensional structures without sacrificing H-bonds, in view of the 2–2 tetrahedral functionality. Therefore, the structural reorganization process associated with solute insertion does not significantly affect the number of H-bonds and $\Delta H^\bullet$ is dominated by the negative contribution of solute–solvent interactions, while $\Delta G^\bullet$ is dominated by the excluded volume effect. Indeed, for H_2O, $\Delta H^\bullet$ and $\Delta S^\bullet$ are both large negative. It has to be stressed that the purely structural reorganization process of water molecules can be described, in thermodynamic terms, with the simple two-state model developed by Muller (55), and later modified by Lee and Graziano (56) to render it compensating, as required by the theory. This model reproduces well the large positive heat capacity change associated with the transfer into water of nonpolar solutes and its temperature dependence.

The analysis performed shows that the striking difference between H_2O and N_2H_4 for the values of $\Delta H^\bullet$ and $\Delta S^\bullet$ is perfectly understandable within Lee's theory. Indeed, the calculations performed following Pierotti's procedure are in qualitative agreement with experimental values. The existence of a very poor (unfavourable) reaction field between water and nonpolar solutes, giving rise to a positive contribution to the

© 1998 NRC Canada

enthalpy change, and masked by the negative contribution arising from the relaxation process of water clusters as inferred by Lumry and co-workers (26) on the basis of the experimental values of $\Delta H^{\bullet}$ in hydrazine, is not justified. All theoretical calculations, both ab initio and semi-empirical, performed so far to characterize the interaction of water with nonpolar molecules, have shown the existence of a net attractive reaction field (32). Therefore, the reexamination of the origin of hydrophobicity carried out by Lumry and co-workers, being grounded in a physically incorrect idea, is simply wrong.

Appendix

It may be useful to verify how small changes in the parameter values can affect the results of Pierotti's approach. By fixing σ_1 = 2.80 Å (ξ = 0.383) for water, ΔG_c = 20043 J mol^{-1} and ΔH_c

© 1998 NRC Canada

= 3226 J mol^{-1}: the cavity terms are sensitive to small variations in the value of the hard-sphere diameter. Furthermore, by using $\mu_1 = 2.45$ D, the dipole moment of a water molecule in liquid water, in connection with $\sigma_1 = 2.80$ Å, $\Delta G_a = -12\,313$ J mol^{-1}. The corresponding thermodynamic functions calculated for the hydration of argon at 25°C are $\Delta G^\bullet = 7730$ J mol^{-1}, $\Delta H^\bullet = -9087$ J mol^{-1}, and $\Delta S^\bullet = -56.40$ J K^{-1} mol^{-1}. Such figures are in slightly better agreement with the experimental values than those calculated with $\sigma_1 = 2.75$ Å and $\mu_1 = 1.84$ D (see Table 1). The aim of the work, however, is not the optimization of the values calculated by means of Pierotti's approach. The purpose is to show that the excluded volume effect, the fundamental ingredient of SPT, plays the dominant role in determining solvophobicity.

Syntheses and Fe(II)/Fe(III) equilibria of the new multidentate ligands pyridine-2-phosphonic-6-carboxylic acid and 2,6-pyridinediphosphonic acid for the use of their iron chelates as catalysts for the oxidation of H_2S to S_8 by air

Dian Chen, Arthur E. Martell, Ramunas J. Motekaitis, and Derek McManus

Abstract: The syntheses of two terdentate chelating agents, pyridine-2-phosphonic-6-carboxylic acid (2PP6C) and 2,6-pyridinediphosphonic acid (2,6PDPA), are described. The stepwise stability constants for the ferric complexes at 25.0°C and $\mu = 0.100$ M (KNO_3) are log $K_{ML} = 15.97$ and log $K_{ML_2} = 9.50$ for 2PP6C, and log $K_{ML} = 20.87$ and log $K_{ML_2} = 7.81$ for 2,6PDPA. Under the same conditions the stepwise formation constants for the ferrous chelates are log $K_{ML} = 8.70$ and log $K_{ML_2} = 5.10$ for 2PP6C, and log $K_{ML} = 10.12$ and log $K_{ML_2} = 5.33$ for 2,6PDPA. The stabilities of the Fe(III) and Fe(II) chelates are high enough to prevent precipitation of $Fe(OH)_3$ and FeS, respectively, from solutions having pH as high as 10.0. The rates of oxidative degradation of these ligands are very slow when the iron chelates are used as redox catalysts for the oxidation of H_2S to S_8 by air. The rates of oxidative degradation are immeasurably slow when the iron chelates are used with sodium thiosulfate as a radical scavenger.

Key words: 2,6-pyridinediphosphonic acid, pyridine-2-phosphonic-6-carboxylic acid, hydrogen sulfide oxidation, oxidative degradation, nitrilotriacetic acid.

Résumé : On décrit les synthèses de deux agents chélatants terdentates, l'acide pyridine-2-phosphonique-6-carboxylique (2PP6C) et l'acide pyridine-2,6-diphosphonique (2,6PDPA). Les constantes de stabilité progressives pour les complexes ferriques à 25°C et à $\mu = 0{,}100$ M (KNO_3) sont log $K_{ML} = 15{,}97$ et log $K_{ML_2} = 9{,}50$ pour le 2PP6C et log $K_{ML} = 20{,}87$ et log $K_{ML_2} = 7{,}81$ pour le 2,6PDPA. Dans les mêmes conditions, les constantes de formation progressives pour les chélates ferreux sont log $K_{ML} = 8{,}70$ et log $K_{ML_2} = 5{,}10$ pour le 2PP6C et log $K_{ML} = 10{,}12$ et log $K_{ML_2} = 5{,}33$ pour le 2,6PDPA. Les stabilités des chélates Fe(III) et Fe(II) sont suffisamment élevées pour empêcher la précipitation respectivement du $Fe(OH)_3$ et du FeS à partir de solutions ayant des pH allant jusqu'à 10,0. Les vitesses de dégradation oxydantes de ces ligands sont extrêmement lentes lorsqu'on utilise des chélates de fer comme catalyseurs redox pour l'oxydation du H_2S en S_8 par l'air. Les vitesses de dégradations oxydantes sont extrêmement lentes lorsqu'on utilise les chélates de fer avec du thiosulfate de sodium comme piège à radicaux.

Mots clés : acide pyridine-2,6-diphosphonique, acide pyridine-2-phosphonique-6-carboxylique, oxydation du sulfure d'hydrogène, dégradation oxydante, acide nitrilotriacétique.

[Traduit par la rédaction]

Introduction

In industrial, chelated iron sulfur recovery processes, which generally operate within a pH range of 7.0–8.5, NTA, EDTA, and HEDTA are typically used as the primary iron(III) chelators (1–4). In some cases the iron sequestering ability of the solution is increased by addition of compounds such as hexitols that form stable, soluble iron(III) complexes at high pH. High stability of the Fe(III) chelate is an important requirement for catalysts that are effective for the conversion of H_2S to S_8, since the acidic gas H_2S is best absorbed in a mildly alkaline solution in which HS^- is formed and is oxidized under these conditions to S_8. In this pH range the precipitation of $Fe(OH)_3$ must be prevented by using chelates of sufficiently high stability.

The Fe(III) chelates of dipicolinic acid (pyridine-2,6-dicarboxylic acid, PDCA) are less stable than those of NTA and EDTA (5, 6), and Fe(III) PDCA cannot be used as a catalyst above pH about 6.0 without the precipitation of $Fe(OH)_3$. This is highly unsatisfactory, since the low solubility of H_2S at this pH would require both a larger absorber vessel and a catalyst solution volume. One advantage of PDCA, however, is the

very slow rate of oxidative degradation of the ligand, relative to aminocarboxylates, in the reoxidation by air of the ferrous chelate to the ferric form. With EDTA, NTA, and other aminocarboxylates, the rate of oxidative degradation of the ligand in the reoxidation step, even in the presence of free-radical scavengers such as thiosulfate, is appreciable (2, 3) and generally requires continuous replenishment of the chelating ligand in an amount equivalent to that lost by oxidative degradation. The replenishment of the chelating ligand increases the operating cost and is a significant factor in generally limiting the capacity of the plant.

In this paper two ligands are described, pyridine-2-phosphonic-6-carboxylic acid (2PP6C) and 2,6-pyridinediphosphonic acid (2,6PDPA) (7), which form stable Fe(III,II) chelates and are effective catalysts for the oxidation of H_2S to S_8. As shown by molecular mechanics the replacement of a carboxylate in PDCA by a phosphonate donor group produces a ligand with dimensions more suitable for coordinating iron(III) (8). Moreover these phosphonates resemble PDCA in that they undergo negligible degradation when the ferrous chelate is oxidized to the ferric form. The ligand 2PP6C was first described by Boduszek (9). The disphosphonic acid 2,6PDPA is apparently a new compound. Syntheses and iron(II,III) equilibria of 2PP6C and 2,6PDPA have been deposited as supplementary material.[2]

Experimental

Materials and reagents

The following are the sources of reagents and starting materials used in synthesis: butyllithium (10.0 M solution in hexane, Aldrich Co.); picolinic acid (99%, Aldrich Co.); HAc (GR, Glacial, EM Sciences, a Division of EM Industries, Inc.); H_2O_2 (30% aqueous solution EM Sciences); Me_2SO_4 (99%, Aldrich Co.); CH_2Cl_2 (Reagent ACS, Fisher Scientific Co.); pyridine-*N*-oxide (98%, Janssen Chimica); $Fe(NO)_3{\cdot}9H_2O$ (certified ACS, Fisher Scientific Co.); $Na_2S_2O_3$ (GR, EM Sciences); $CuCl_2{\cdot}2H_2O$ (Baker analyzed reagent); MeOH (HPLC grade, EM Sciences); H_2S (99.5%, Gas Analytical Service); hexadecyltrimethylammonium bromide (99%, Sigma); EDTA (ACS, Aldrich Co.); KNO_3 (ACS, Aldrich Co.). *Standard KOH*: a carbonate-free solution of the titrant, KOH, was prepared by dilution of analytical concentrate "Dilut-It" (J.T. Baker Chemical Co.) with double-distilled water under a stream of purified Ar gas. The solution was standardized by titration with primary standard potassium acid phthalate.

Synthesis of pyridine-2-phosphonic-6-carboxylic acid (2PP6C)

Pyridine-2-carboxylic acid N-*oxide*, **1**. Picolinic acid (20.0 g) was treated with 125 mL glacial acetic acid and 22 mL of 30% H_2O_2, and the reaction mixture was heated to 70–80°C for 3 h. Another 11 mL of 30% H_2O_2 was then added, and the temperature was maintained at 70°C for 18 h. The solvent was removed by vacuum evaporation. Compound **1** was obtained as a white solid and was used directly in the next step.

Ethyl pyridine-N-*oxide-2-carboxylate,* **2**. To compound **1** 130 mL of EtOH was added, and the mixture was treated with HCl gas for 30 min. Then the solution was heated to reflux for 30 min. The solvent was removed by evaporation under reduced pressure. To the residue, 130 mL of EtOH was then added, and the above procedure was repeated twice. Compound **2** was obtained as a white solid and was used directly in the next step.

Ethyl N-*methoxypyridinium-2-carboxylate methyl sulfate*, **3**. Dimethyl sulfate (19.5 mL) was slowly added to compound **2**, prepared in the previous step, over a 30 min period. The reaction mixture was then heated at 85°C for 3 h to ensure complete reaction. Compound **3** was obtained as a yellow oil and was used directly in the next step.

Triethyl pyridine-2-phosphate-6-carboxylate, **4**. *n*-Butyllithium (20.0 mL of 10.0 M solution in hexane) was added dropwise to 30.0 g of diethyl phosphite at –40 to –35°C over a 2 h period. (This procedure was first described by Redmore (10).) To the resulting solution of lithium diethyl phosphite, compound **3** (obtained above) in diethyl phosphite (40 mL) was added in 1 h at –25 to –30°C. The reaction mixture was stirred at room temperature for 16 h and heated at 70°C for 2 h. After the mixture was cooled to room temperature, 140 mL of water was added. The mixture was extracted three times with 75 mL CH_2Cl_2. The organic extracts were combined and were extracted with 4 M HCl (100 mL). The organic solvent was removed by evaporation under vacuum. The residue (yellow oil) was chromatographed on silica gel. Compound **4** was eluted with CH_2Cl_2. After the solvent was removed, a viscous oil was obtained (53 g, yield 88%).

Pyridine-2-phosphonic-6-carboxylic acid, **5**. This compound was synthesized by a modification of the method of Redmore (10). Compound **4** (53 g) was heated under reflux with 150 mL conc. HCl for 16 h. After the mixture was cooled to room temperature, the solution was extracted four times with 50 mL CH_2Cl_2, and the organic extracts were discarded. The aqueous acid solution was evaporated, treated with a small amount of mixed solvent (CH_2Cl_2:MeOH = 4:1), and the white solid formed was filtered off. The residue was washed with the same mixed solvent several times. The product, **5**, was dried under vacuum at 60°C for 4 h (10.3 g, yield 58.1%). The overall yield based on picolinic acid was 31.2%.

Proton NMR (in D_2O): 8.42 (m, 1H, pyridine), 8.26 (d, 1H, pyridine), 8.18 (t, 1H, pyridine). ^{13}C NMR: 165.4 (COOH), 156.8 (C-$PO(OH)_2$), 146.3 (C-COOH), 143.1, 128.6, 124.8 (pyridine). ^{31}P NMR: 0.46 (s, 1P, $PO(OH)_2$). λ_{max} = 273 nm, $\varepsilon = 8.49 \times 10^3$; MS gave the molecular ion 202 $(M - H)^-$. Anal. calcd. for $C_6H_6NPO_5$: C 35.48, H 2.98, N 6.90, P 15.26; found: C 35.31, H 3.33, N 7.01, P 15.66.

Synthesis of 2,6-pyridinediphosphonic acid (2,6PDPA, 10)

Diethylpyridine-2-phosphate, **6**. This compound was prepared by a modification of the method of Redmore (10). *n*-Butyllithium (10.0 M in hexane) 31.5 mL (0.315 mol) was added dropwise to 12.5 g (0.090 mol) of diethyl phosphite at –20.0 to –30.0°C over a 2 h period. To the resulting solution of lithium diethyl phosphite, a solution of *N*-methoxypyridiniummethylsulfate, (from 7.15 g (0.075 mol) pyridine *N*-oxide, **2**, and 9.5 g (0.075 mol) of dimethyl sulfate in diethyl phosphite (20 mL) was added at –15.0°C in 1 h. The reaction mixture was stirred at room temperature for 16 h, then 50 mL of water was added. The mixture was extracted with $CHCl_3$ (3/38 mL),

[2] Supplementary material may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2.

and the organic extracts were combined and extracted with 4 N HCl, neutralized with base, and re-extracted with $CHCl_3$. From this $CHCl_3$ solution after distillation 10.8 g of product, **6**, was obtained: yield 71%.

Diethylpyridine-N-*oxide-2-phosphate*, **7**. Compound **6** (10.8 g), 36 mL of glacial acetic acid, and 6 mL of 30% H_2O_2 were mixed, and the reaction mixture was heated to 70.0–80.0°C for 3 h. Another 3 mL of 30% H_2O_2 was added, and the temperature was maintained at 70.0°C for 16 h. The solvent was removed by rotovaporation. To the residue, 100 mL of $CHCl_3$ was added, the organic phase was washed with concentrated sodium carbonate solution and was then dried with magnesium sulfate for 16 h. After the solvent was removed, 7.9 g of the product, **7**, was obtained: yield 68%.

Diethyl-N-*methoxypyridinium-2-phosphonate methyl sulfate*, **8**. Dimethyl sulfate (4.3 g) was slowly added to 7.9 g of compound **7** within 30 min. This reaction mixture was heated with a steam bath for 2 h to ensure complete reaction. The compound was purified by silica gel, with a mixed solvent of CH_2Cl_2 and MeOH used as eluant. After the solvents were removed, 8.4 g of compound **8** was obtained: yield 69%.

Pyridine-bis(2,6-diethylphosphonate), **9**. The same procedure as in the preparation of compound **4** was used: yield 72%.

2,6-Pyridinediphosphonic acid, **10**. Compound **9** (3.0 g) was heated under reflux with 30 mL of 6 M HCl for 12 h. The solvent was removed by evaporation under reduced pressure, and a yellow oil was obtained. Addition of methanol yielded a yellow solid, which was then recrystallized three times from methanol. The sample of pure product 2,6-pyridinediphosphonic acid, **10**, amounted to 0.95 g: yield 40%. Proton NMR (in D_2O): 8.7 (m, 1H, pyridine-4); 8.4 (t, 2H, pyridine-3,5). ^{31}P NMR (in D_2O): –2.0 (s, 2P, $-PO(OH)_2$). ^{13}C NMR (D_2O): 153.6, 150.1 (C-$PO(OH)_2$), 146.8, 130.3 (pyridine) λ_{max} = 272 nm, $\varepsilon = 6.62 \times 10^3$. Anal. calcd. for $C_5H_7NP_2O_6$: C 25.10, H 2.95, N 5.86, P 25.94; found: C 24.98, H 3.06, N 5.69, P 26.56. MS gave the molecular ion 240 ($239 + H^+$).

Quantitative analysis of 2PP6C

Preparation of iron-free sample. To 4.0 mL of solution taken from the continuous reactor (1), 100 mg of NaOH in 20 mL water was added dropwise with stirring. The mixture was heated to 70–80°C for 30 min. The $Fe(OH)_3$ that precipitated was filtered off carefully and was washed several times with water. The filtrate was combined with the washings and was transferred to a 50 mL volumetric flask. The pH of the solution was adjusted with acid to 4.2 and then diluted with distilled water to 50 mL.

Operating conditions. Analytical column: IBM-SIL 5 C8, reverse phase 4.5 × 150 mm; column temperature: ambient; mobile phase flow rate: 1.5 mL/min; detector: UV at 275 nm, 0.20 AUFS; sample volume: 20 μL; recorder: 10 mV full-scale; chart speed: 0.5 cm/min. The mobile phase contained: 0.0010 M Cu(II), 60:40 H_2O:MeOH, 2% HAc, 0.2% $CH_3(CH_2)_{15}(CH_3)_3NBr$, adjusted to pH 4.2 with NaOH solution.

The calibration of the HPLC analysis of 2PP6C by this method results in a linear correlation between the peak height and concentration up to 5×10^{-4} M.

Quantitative determination of 2,6PDPA

The compound 2,6PDPA was measured quantitatively by its absorption spectrum. To 1.000 mL of solution taken from the continuous reactor, 150 mg of NaOH in 15 mL water was added with stirring. The mixture was heated with a steam bath for 2 h, then it was allowed to stand at room temperature for 2 h. The $Fe(OH)_3$ that precipitated was filtered off carefully and was washed several times with water. The filtrate, combined with the washings, was transferred to a 50 mL volumetric flask and then diluted with distilled water to 50 mL. A 5 mL sample of solution was taken from the volumetric flask and placed in a 10 mL volumetric flask and was diluted to 10 mL with 6 N HCl. This solution was ready for UV-vis spectrophotometric analysis. The calibration of the UV-vis analysis of 2,6PDPA by this method results in Beer's Law behavior up to 2×10^{-4} M.

Potentiometric titrations

Potentiometric measurements were conducted in a jacketed cell thermostated at 25 ± 0.1°C and under an inert atmosphere of purified Ar. A Corning Model 350 pH meter fitted with glass and calomel reference electrodes was used. The apparatus was calibrated in terms of $-\log[H^+]$, designated as pH, by titration of a small quantity of dilute HCl at 0.10 M ionic strength and 25.0°C, followed by adjustment of the meter so as to minimize the calculated pH versus observed values. Log K_w for the system, defined in terms of $\log[H^+][OH^-]$, was found to be –13.78 at the ionic strength employed (11) and was maintained fixed during refinements.

Potentiometric measurements of solutions containing ligand or equimolar amounts of ligand and metal ion were made at concentrations of approximately 2.0×10^{-3} M and ionic strength $m = 0.10$ M. Each titration produced at least 10 points per neutralization of a hydrogen ion, equivalent with titrations being repeated until satisfactory agreement was obtained. A minimum of three sets of data were used in each case to calculate the overall stability constants. The range of accurate pH measurement was considered to be 2–12. Equilibrium constants and species distribution diagrams were calculated using the programs BEST and SPE, respectively (11).

Degradation studies

Preparation of iron(III) chelate solution. The chelated metal catalyst solution is prepared by dissolving 0.018 mol $Fe(NO)_3 \cdot H_2O$ in about 200 mL water, separately dissolving 0.036 mol chelating agent (2,6PDPA or 2PP6C) in about 300 mL water and mixing the two solutions together. The pH is adjusted to 8.5 by NaOH solution, and the mixture is diluted to 1 L with water. This solution is ready for the following degradation study.

Oxidative degradation of chelating agents was carried out in the manner previously described (1) in a 1 L glass apparatus designed to simulate industrial conditions. The pH was continually monitored and kept close to 8.5. The H_2S was introduced into the absorber at the rate of 2.0 mL/min, and air was introduced into the oxidizer at the rate of 1.0 L/min. Both the absorber and oxidizer, as part of the glass apparatus, were operated at room temperature. The ligand 2PP6C was measured as a function of time by HPLC, as described above, while 2,6PDPA was measured quantitatively, as described above, from its UV-visible absorbance.

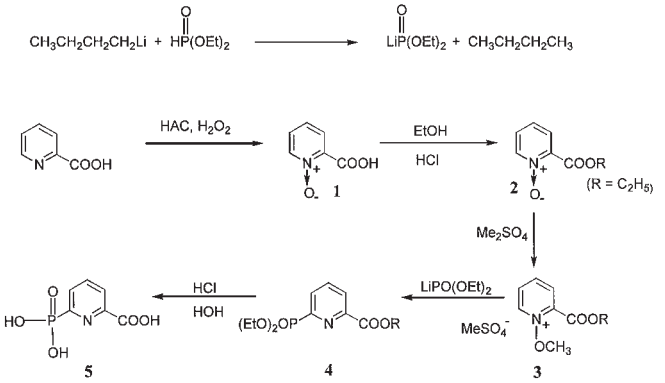
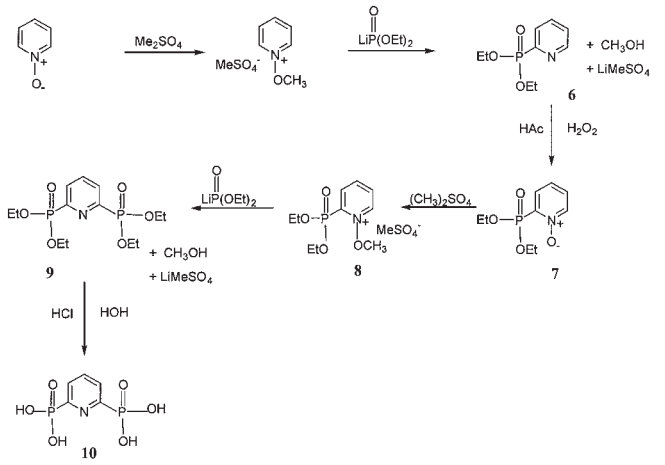


Scheme 2. Outline of the synthesis of 2,6PDPA.



Results and discussion

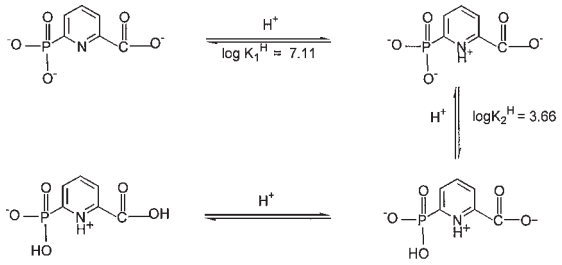
Synthesis

The reaction sequences by which the phosphonate ligands 2PP6C and 2,6PDPA were synthesized are given in outline form in Schemes 1 and 2. In these syntheses the pyridine is activated toward nucleophilic substitution by formation of the *N*-oxide as an intermediate before the substitution reaction. The many steps required in these synthetic schemes drive down the overall yield. Thus, while the individual steps in the synthesis of 2,6PDPA are reasonable to good, the overall yield based on starting material was less than 10%. Caution should be exercised in the use of dimethyl sulfate, which is known to be very toxic. It is also probable that the mono methyl sulfate intermediates and by-products shown in Schemes 1 and 2 are also very toxic.

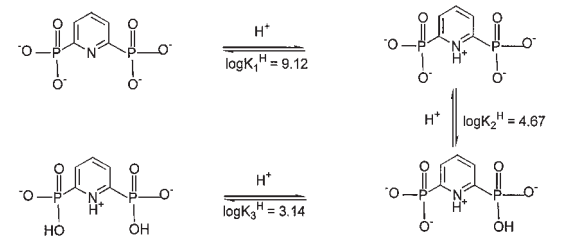
Thermodynamic stabilities

Protonation constants. The protonation constants of 2PP6C and of 2,6PDPA were determined by direct potentiometric titration and are listed in Table 2. The values of K_3^H for 2PP6C and K_4^H for 2,6PDPA are too low to be measured potentiometrically. Protonation sequences for 2PP6C and 2,6PDPA are illustrated by Schemes 3 and 4, respectively. The most basic group is the pyridine nitrogen (12). The higher basicity of the first phosphonate in 2,6PDPA over the phosphonate group in 2PP6C is due to the greater electronic withdrawing effect of a

Scheme 3. Protonation of 2PP6C.



Scheme 4. Protonation of 2,6PDPA.



phosphonate relative to a carboxylate group transmitted through the pyridine ring. The phosphonate is probably the next lower in basicity, and it is therefore shown to become protonated after the pyridine nitrogen becomes protonated. The carboxylate group is considered to have the lowest basicity and is shown in Scheme 3 to be the last to be protonated. These assignments are in accordance with the p*K*s of several related compounds described by Redmore (12).

The equilibrium constants for the Fe(III)–2PP6C and the Fe(III)–PDPA chelate systems

It was found that the 1:1 complexes of Fe(III)–2PP6C and Fe(III)–2,6PDPA are completely formed at pH 2.0, and their stability constants could not be determined potentiometrically by direct titration. The formation constants of these complexes were therefore determined by competition with EDTA. In these systems at low pH, the Fe(III)–EDTA chelate is completely formed, but as the pH is raised this chelate is completely converted to the Fe(III)–2PP6C and Fe(III)–2,6PDPA chelates. The formation constants of these complexes were calculated from the degree of formation of the complex in competition with EDTA and all other known data (6), such as the protonation constants of EDTA and the phosphonates, and the stability constant of the Fe(III)–EDTA chelate.

In the competition solution with EDTA present, equilibrium took place rapidly enough to be investigated by direct potentiometric titration. Therefore the mixed ligand Fe(III) systems containing EDTA and 2PP6C or EDTA and 2,6PDPA were subjected to standard titration from pH 2 to 10 by the incremental addition of standard KOH solution.

The equilibrium constants involving metal chelate hydrolysis (hydroxo complex formation) and protonation were calculated from direct potentiometric titration of the phosphonic acids and Fe(III) without EDTA (11). Because of the very slow equilibrium for the direct titration, a batch method (13) was used. The pH of each point was read 8 and 10 days after preparation of the solution. Identical readings after this length of time confirmed that equilibrium had been reached.

[c] Reference 6.

Fe(III)–2,6PDPA systems are shown in Table 1. The species distribution curves of the 1:2 Fe(III)–2PP6C and Fe(III)–2,6PDPA systems calculated from the data in Table 1 are shown in Figs. 1*a* and *b*. It is seen that the 1:2 chelates are the major species over the pH range from 3 to 9 for the 2PP6C system and from 4.5 to 9.5 for the 2,6PDPA system, reaching a maximum of about 95% in both cases.

Because complexes of 2:1 stoichiometry of 2PP6C and 2,6PDPA with Fe(III) are formed, the systems are concentration dependent. At higher concentration the relative concentration of the 2:1 chelate is increased. The 2:1 complexes of 2PP6C and 2,6PDPA with Fe(III) under these conditions predominate over a larger pH range.

The hydroxo complexes listed in Table 1 of the 1:1 ligand:metal complexes are expected, since combination of Fe(III) with a terdentate ligand results in three or more water molecules in the coordination sphere, giving rise to mono- and dihydroxo complexes at high pH. The protonated complexes are probably formed because of the presence of the uncoordinated phosphonate oxygens as protonation sites.

The equilibrium constants for the Fe(II)–2PP6C and the Fe(II)–PDPA chelate systems

Potentiometric determination of the stability constants of Fe(II)–2PP6C and Fe(II)–2,6PDPA system requires special precautions to prevent the oxidation of the ferrous chelate by oxygen of air. In this work the dry, weighed solid $FeSO_4 \cdot 7H_2O$ was kept separated for 1 h from the gently stirred 2PP6C solution by placing the weighed salt on a small ceramic boat kept afloat over the prepurified solution in the sealed titration cell (4). The Ar purging was continued during the 1 h period. At the end of 1 h the ferrous salt was tipped into the solution through agitation. The ferrous salt was considered dissolved (within a few minutes) after the pH meter reading stabilized (4).

The equilibrium constants for the Fe(II)–2PP6C and Fe(II)–2,6PDPA systems are shown in Table 1. From calculations based on these equilibrium data it is seen that the 1:1 complex is formed at low pH for both of the above systems and predominates between pH 3.5 and 9.0, reaching a maximum of 99.4% for the Fe(II)–2PP6C, and from pH 4.5 to 9.5, reaching a maximum and 99.5% for the Fe(II)–2,6PDPA system. At low pH the MHL species is formed and is the major species over the pH range 2–3.5, reaching a maximum of about 70% for the Fe(II)–2PP6C system. The MH_2L species is also formed in addition to the MHL species for the Fe(II)–2,6PDPA system. At high pH the hydroxo chelate M(OH)L is formed at pH about 7, and $M(OH)_2L$ is formed at about pH 9 for the Fe(II)–2PP6C system. Above pH 8 the hydroxo chelates M(OH)L and $M(OH)_2L$ begin to form and are the dominant species above pH 9.5 for the Fe(II)–2,6PDPA system. The solution of the Fe(II)–2,6PDPA system is yellow in color at pH about 2.0 and above. More than 50% ferrous chelates, initially in the protonated species, are formed at pH 2.0 and above. The protonated and nonprotonated ferrous chelates are probably responsible for the yellow color of the solution.

The species distribution curves of the 2:1 Fe(II)–2PP6C and Fe(II)–2,6PDPA systems are shown in Figs. 2 and 3. It is seen that the 2:1 chelate is formed about at pH 4 and is the major species over the pH range 4.4–10.5, reaching a maximum of about 93% at pH 8 for the Fe(II)–2PP6C system. In the Fe(II)–2,6PDPA system the 2:1 chelate is formed at about pH 5 and is the major species over the pH range 7.0–11.5, reaching a maximum of about 93.1% at pH 9.4. At low pH MHL_2 and MH_2L_2 form in addition to MHL for the Fe(II)–2PP6C system. In the Fe(II)–2,6PDPA system the species MHL_2, MH_2L_2, MH_3L_2, and MH_4L_2 form besides MHL and MH_2L. At 10 times the concentration of Fe(II) and ligand the concentration of the 2:1 chelates are increased relative to the concentration of species found in the more dilute solution. Thus the maximum concentration of MHL_2 is increased from 39.2% to 57.5%, that of MH_2L_2 is increased from 34.0% to

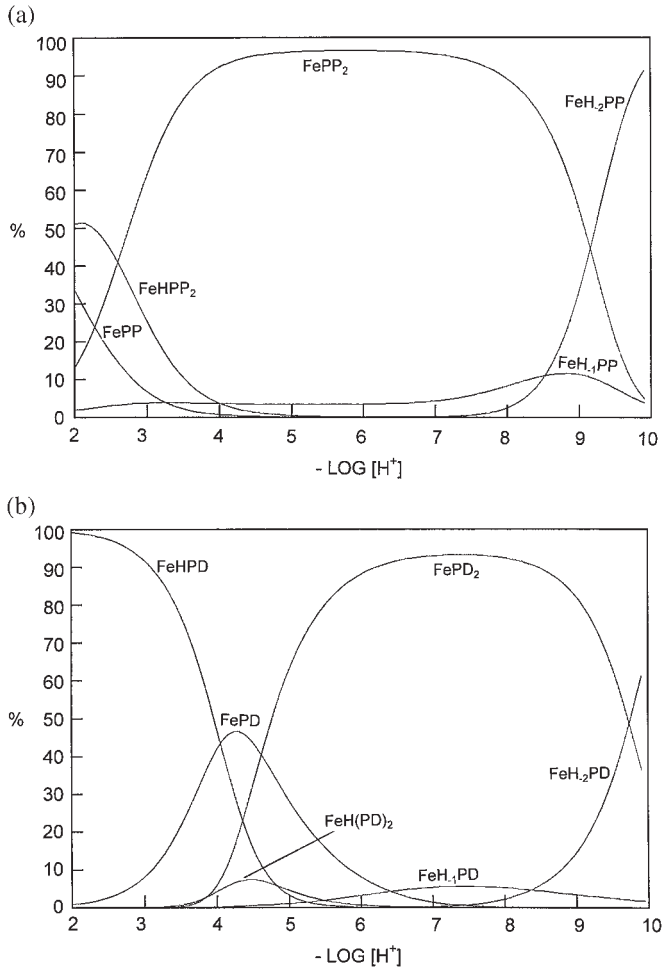
Fig. 1. (*a*) Species distribution curves of 1:2 Fe(III)–2PP6C; μ = 0.100 M (KNO_3), t = 25.0°C, [2PP6C] = 4.55×10^{-3} M, 1:2 [Fe(III)] = 2.27×10^{-3} M. H_{-n} represents $(OH)_n$; PP = 2PP6C. (*b*) Species distribution curves of Fe(III)–2,6PDPA; μ = 0.100 M (KNO_3), t = 25.0°C, [2,6PDPA] = 4.00×10^{-3} M, [Fe(III)] = 2.00×10^{-3} M. H_{-n} represents $(OH)_n$; PD = 2,6PDPA.



62.8% and that of ML_2 is increased from 93.1% to 97.7% for the Fe(II)–2PP6C system. In the Fe(II)–2,6PDPA system the maximum concentration of ML_2 is increased from 93.1% to 97.7%, that of MHL_2 is increased from 32.0% to 58.3%, that of MH_2L_2 is increased from 16.0% to 33.9%, and MH_3L_2 is increased from 14.9% to 32.8%, and MH_4L_2 is increased from 17.9% to 48.1%.

In the 2:1 system, because of formation of the more stable 2:1 chelate, the concentration of M(OH)L is decreased from 76.2% (in the 1:1 system) to 21.6% when the molar ratio of ligand to metal ion is 2:1. Its relative concentration is further decreased to 9.0% in the system in which the metal ion and ligand concentrations are 10 times higher for the Fe(II)–2PP6C system. Similar phenomena were also observed in the Fe(II)–2,6PDPA system.

A comparison of log stability constants of the ferric complexes of 2,6-pyridinedicarboxylic acid (PDCA), 2PP6C, 2,6PDPA, and NTA is indicated in Table 1, together with the corresponding protonation constants of each ligand. The data show that among the four ligands compared, the ferric complex of 2,6PDPA is the most stable. The stability constant of Fe(III)–2,6PDPA (1:1) is about 5 log units higher than that of Fe(III)–2PP6C and 10 log units higher than that of Fe(III)–PDCA. This difference indicates that $-PO(O^-)_2$ is a much more powerful coordinating group for Fe(III) ion than is COO^-. As expected, the stability constant of Fe(III)–2PP6C is between those of Fe(III)–PDCA and Fe(III)–PDPA, because the ligand 2PP6C contains one strong coordinating group, $PO(O^-)_2$, and a weaker donor, COO^-. The stability constant sequence for the above four ferric chelates (2:1) is as follows: 2,6PDPA > 2PP6C > NTA > PDCA. The same sequence applies to the ferrous chelates (2:1).

Fig. 2. Species distribution curves of the 1:2 Fe(II)–2PP6C; μ = 0.100 M (KNO_3), t = 25.0°C, [2PP6C] = 3.95×10^{-3} M, [Fe(II)] = 1.97×10^{-3} M. H_{-n} represents $(OH)_n$; PP = 2PP6C.

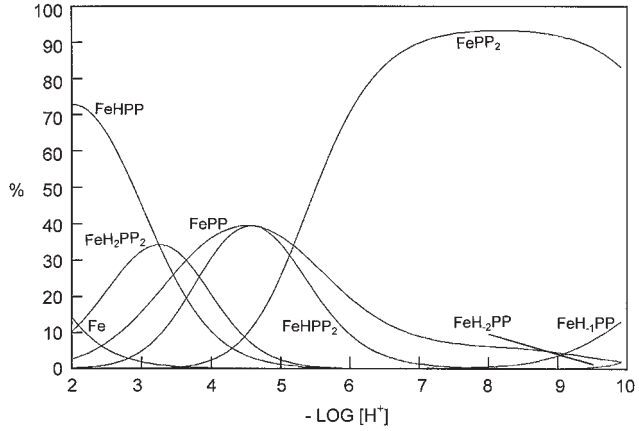


Fig. 3. Species distribution curves of the 1:2 Fe(II)–2,6PDPA, μ = 0.100 M (KNO_3), t = 25.0°C, [2,6PDPA] = 4.00×10^{-3} M, [Fe(II)] = 2.00×10^{-3} M. H_{-n} represents $(OH)_n$; PD = 2,6PDPA.

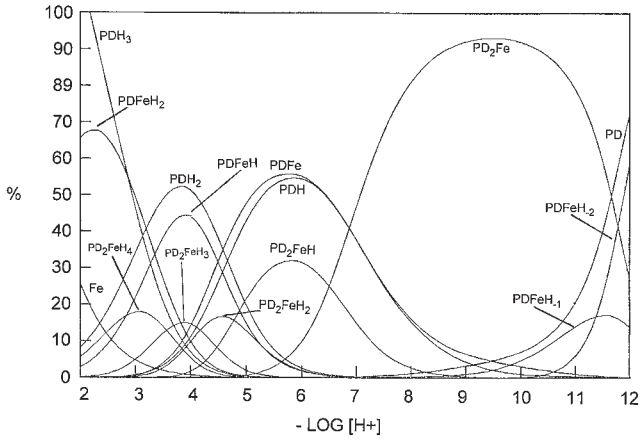

Calculation of reduction potential *E*(Fe(III) chelate→Fe(II) chelate) and K_c (conditional stability constants) for the oxidation of H_2S to S and pM values of Fe(II) and Fe(III) for the Fe(II)–2PP6C, Fe(III)–2PP6C, Fe(II)–2,6PDPA, and Fe(III)–2,6PDPA systems

The calculated pM of Fe(II) and Fe(III), E and log K_c (3) for the above two systems are shown in Table 2. The data show that the conditional constants (log K_c) of both Fe(III)–2PP6C

Table 2. The pM of Fe(II) and Fe(III), E, and log K_c.

	pM[a]				
	Fe(II)	Fe(III)	Δ pM	E[b]	log K_c[c]
NTA	8.0	20.8	12.8	0.013	7.98
2PP6C	12.3	24.0	11.7	0.080	10.26
2,6PDPA	12.6	25.9	13.3	–0.015	7.06

[a] The pM for Fe(II)–NTA and Fe(III)–NTA, taken from ref. 5, and for 100% excess ligand, 10^{-2} M metal chelate.

[b] E for reduction of ferric to ferrous ions, taken from pM values of the metal ions and the equation: $E = 0.770 - 0.059\log([Fe(II)]/[Fe(III)])$.

[c] K_c conditonal constants for the reaction: $2Fe(III)L + HS^- \rightarrow 2Fe(II)L + H^+ + S_{(s)}$ at pH 8.5 and $[HS^-]$ taken as 10^{-3} M.

and Fe(III)–2,6PDPA systems are sufficiently high for the oxidation of H_2S to S (3). The conditional constant sequence for the above three systems is as follows: 2PP6C > NTA > 2,6PDPA.

Oxidative degradation of Fe(III)–2PP6C at pH 8.5

The concentration of 2PP6C was analyzed by HPLC by the method described in Experimental. After the redox reaction was carried out for 100 h, about 20% of the 2PP6C was lost, presumably by hydroxylation of the pyridine ring (1, 2).

The experimental run on the degradation of the 2:1 chelate of 2-phosphonopyridine-6-carboxylate and Fe(III) was also carried out in the presence of 5% sodium thiosulfate. After the redox reaction was continued for 100 h, no significant degradation of 2PP6C was observed. The HPLC analysis of the degradation of 2PP6C shows that in the presence of 5% $Na_2S_2O_3$, the hydroxyl radical does not oxidize this ligand at a measurable rate, and this ligand can therefore be used over a long time period without significant degradation. The stabilizing effect of $Na_2S_2O_3$ (14) seems to be much more efficient in preventing free-radical oxidation of 2PP6C than for NTA. The action of thiosulfate has been explained as follows (15):

Radical scavenger:

$$S_2O_3^{2-} + \cdot OH \rightarrow \cdot S_2O_3^- + OH^-$$

Regeneration:

$$\cdot S_2O_3^- + Fe(II)NTA^- \rightarrow S_2O_3^{2-} + Fe(III)NTA$$

The use of 2PP6C as the redox catalyst has additional advantages in that no FeS or $Fe(OH)_3$ precipitate was formed in the process, and the sulfur was easily filtered off during the reaction.

Because the stabilities of the Fe(III)–2PP6C chelates are higher than those formed in the NTA system (4) (see Table 1), the redox reaction for the Fe(III)–2PP6C system can be carried out at pH 9.0 (no $Fe(OH)_3$ precipitate appears). The Fe(II)–2PP6C system is also more stable than the corresponding Fe(II)–NTA system (see Table 1) thus the FeS does not precipitate at pH as high as 9.0. The difference in the stabilities of the Fe(III) and Fe(II) chelates at higher pH is still large enough to oxidize H_2S to S_8. The use of higher pH has the advantage that absorption of H_2S is more rapid. Industrially this means that a smaller and less expensive absorber may be used. A further advantage is that the degradation of the ligand decreases as the pH is increased (1), so that the oxidation of H_2S to S may be carried out with even less degradation of the catalyst.

Degradation of Fe(III)–2,6PDPA at pH 8.5 (Fe(III) 0.0090 M, 2,6PDPA 0.018 M)

The concentration of 2,6PDPA was analyzed with its UV-vis spectrum by the method described in Experimental. The spectral analysis of the degradation of 2,6PDPA shows that the degradation of 2,6PDPA is less than 5% over a 100 h period. When the degradation run was repeated in the presence of 5% sodium thiosulfate, no degradation of 2,6PDPA was detected over a 100 h period. Thus 2,6PDPA forms a 2:1 iron(III) chelate that seems to survive as long as the iron(III) chelate of 2PP6C as a catalyst for the oxidation of H_2S to S_8 by air. Previously it was found that the iron chelate of pyridine-2-phosphonic acid undergoes facile oxidative degradation when used as a catalyst for the oxidation of H_2S to S_8 by air.[3] Apparently when a second phosphonic acid or a carboxylic acid function is substituted at the other alpha position of the pyridine ring, the new ligands, 2PP6C and 2,6PDPA, form iron(III) chelates that are much more resistant to oxidative degradation than are the iron(III) chelates of the parent ligand. This interesting phenomenon was also observed for pyridinedicarboxylic acid, PDCA, the iron chelate of which is much more resistant to oxidative degradation than is pyridine-2-carboxylic acid (picolinic acid).

Étude d'ions négatifs préparés « in situ » dans un piège ionique quadripolaire

Sébastien Gregoire, Jean-Charles Mathurin, Raymond E. March et Jean-Claude Tabet

Résumé : Le piège ionique quadripolaire constitue un appareil d'analyse de grand intérêt en spectrométrie de masse. Pourtant, dans sa configuration à ionisation interne (les ions sont formés au sein du piège), l'étude des ions négatifs est difficile. L'objet de ce travail est de déterminer les problèmes rencontrés lors d'analyse en mode négatif sur un piège ionique quadripolaire à ionisation interne. La première difficulté, due à la détection simultanée des ions positifs et des ions négatifs, s'explique par la grande énergie cinétique des ions éjectés. De plus, la formation des ions négatifs, par capture électronique, est fortement limitée en raison de la forte accélération des électrons par le champ quadripolaire, limitant le nombre d'électrons d'énergie thermique nécessaire au processus de capture électronique. Enfin, le confinement simultané des ions positifs et des ions négatifs perturbe fortement les spectres de masse enregistrés. Les potentiels de charge d'espace qui règnent au sein du piège (due aux conditions d'ionisation nécessaires à la détection d'ions négatifs) déstabilisent les ions positifs de hauts rapports *m/z*, tandis que les ions négatifs stabilisés sont observés. De plus, des pertes de résolution et de décalibration peuvent survenir, dans certains cas, pour les ions négatifs, lorsque ces derniers sont éjectés en présence d'ions positifs de plus hauts rapports *m/z*. Enfin, les interactions ion–ion semblent limiter l'observation des ions négatifs au sein du piège. La compréhension de tous ces phénomènes, détection, formation et confinement simultané, permettra de proposer des solutions possibles aux problèmes rencontrés pour la production d'ions négatifs dans les pièges ioniques quadripolaires à ionisation interne.

Mots clés : spectrométrie de masse, piège ionique quadripolaire, ion négatif, perfluorotributylamine, charge d'espace.

Abstract: The quadrupole ion trap mass spectrometer is of great interest for chemical analysis. Nevertheless, negative ion studies using in situ ionization (negative ions created inside the ion trap) are difficult and limited. This paper describes the difficulties that occurred during negative ion analysis when using a commercial gas chromatography quadrupole ion trap mass spectrometer (GC/MS) system. Detection problems, due to simultaneous trapping of both positive and negative ions, are explained by the large kinetic energies of the ejected ions. Negative ion formation, produced by electron capture, is limited by the fundamental RF field, which imparts high kinetic energy to the electrons, precluding the possibility that the electrons will reach the thermal energies needed for electron capture processes. In addition, simultaneous confinement of negative and positive ions affects the recorded mass spectra. Space charge potentials that exist inside the ion trap (due to the ionization conditions necessary to detect negative ions) induce the destabilization of positive ions at higher *m/z* ratios, while negative ions in the same *m/z* range are stabilized. Moreover, loss of resolution and decalibration could occur for negative ions when they are ejected in the presence of positive ions with higher *m/z* ratios. At the very least, ion–ion reactions could limit the observation of negative ions. The understanding of these phenomena, viz. detection, formation, and simultaneous confinement, will permit the proposal of solutions for negative ion analysis with quadrupole ion trap mass spectrometers using in situ ionization.

Key words: mass spectrometry, quadrupole ion trap, negative ion, perfluorotributylamine, space charge.

Introduction

La « préhistoire » du piège ionique quadripolaire débute en 1953 avec les travaux de Paul et Steinwedel sur les champs électriques de nature alternative; ces derniers conduisirent à la réalisation du premier analyseur de masse de type quadripolaire (filtre de Paul) et au dispositif à piégeage d'ions appelé piège de Paul (1). Par la suite le développement de ce dernier s'effectua avec les travaux de Fisher en spectrométrie de masse (2) et par Dehmelt (3, 4) dans le domaine de spectroscopie d'ions confinés. Le prix Nobel de physique de 1989 fut d'ailleurs attribué à Paul pour l'invention du piège ionique qui porte son nom et à Dehmelt pour l'utilisation de ce dernier en spectroscopie atomique.

Les temps modernes de ces spectromètres de masse débutent dans les années 80 avec les travaux des ingénieurs de la société Finnigan (5), qui conduisent à la commercialisation d'un GC/MS (Gas Chromatograph/Mass Spectrometer) : l'ITD™ (Ion Trap Detector), suivi peu après par une version améliorée : l'ITMS™ (Ion Trap Mass Spectrometrer) en 1985. Le piège ionique quadripolaire entre alors dans le domaine de l'analyse, notamment avec la possibilité d'obtenir aisément

des spectres de masse grâce à la technique de l'instabilité axiale (6), ainsi qu'à l'apport d'un bain d'hélium (6, 7) qui augmente la sensibilité et la résolution. Deux autres fonctions améliorent les performances de l'appareil : la modulation axiale (8) qui améliore la résolution, et l'AGC (Automatic Gain Control) (9) qui permet de calculer le temps d'ionisation optimal de façon à donner le signal d'intensité maximum sans conduire à une perte de résolution par effet de charge d'espace (dû à des densités de charge suffisamment importantes pour perturber le champ quadripolaire).

Il s'avère alors que le piège de Paul est un instrument de choix dans des champs d'investigation très variés, dont celui de l'environnement, pour la détection de traces (10), en raison de sa sensibilité (11) et des possibilités de $(MS)^n$ en routine (12). Les potentiels affichés par cet appareil, que constituent l'accès à des ions de masse relativement élevée (13) ou à la très haute résolution (14), laissent présager un avenir grandissant. Enfin la pluralité des couplages réalisables (15) (Matrix Assisted Laser Desorption and Ionization (MALDI) (16), Electrospray Ionization (ESI) (17),...) associée à une résolution moyenne de $\Delta m/z = 0{,}2$ Th[3] et à l'accès aux hautes masses (= 6000 Th) augmente l'attrait analytique pour cet instrument. Ce dernier type de couplage fait actuellement l'objet d'un effort considérable de la part des constructeurs avec la mise sur le marché d'appareils du type ESI-Trap (l'Esquire™ de Brüker ou le LCQ™ de Finnigan).

Il faut toutefois relativiser ces particularités. Actuellement, le parc mondial de pièges ioniques quadripolaires commerciaux est principalement constitué de GC/MS, où l'introduction des échantillons se fait par l'intermédiaire d'un chromatographe en phase gazeuse, et l'ionisation est dite « interne » (création des ions dans le piège). Cette approche permet de limiter les pertes de sensibilité qui se produiraient en utilisant une source externe, les ions étant créés au sein même du piège, où se feront les étapes ultérieures (manipulation et analyse en masse). Néanmoins, la gamme de rapport m/z est limitée à 650 Th avec un pouvoir de résolution unitaire. Ce type d'appareil a montré des capacités pour l'analyse en ionisation chimique positive (18, 19), sans pouvoir utiliser des hautes pressions en gaz réactif (utile à des fins de stabilisation d'ions adduits non covalents).

D'un autre côté, la formation d'ions négatifs par capture électronique (20) donne accès à une meilleure sensibilité, ceci étant en partie dû à la faible proportion de fragmentation et à la forte section efficace de capture électronique (21). En outre, ce même mode d'ionisation présente une bonne sélectivité. Il est ainsi possible de détecter des composés à forte affinité électronique à l'état de trace dans des mélanges complexes (21).

De ce point de vue, le potentiel analytique du piège ionique quadripolaire allié aux spécificités de la capture électronique laisse présager de bonnes perspectives. Malheureusement, il s'avère que le piège quadripolaire à ionisation interne ne permet pas de former efficacement des ions négatifs. La principale raison avancée concerne la difficulté d'avoir des électrons thermiques donc de faible énergie cinétique nécessaires à la création d'ions négatifs; mais il est également impossible d'avoir recours à des pressions partielles élevées en gaz tampon nécessaires à leur formation en forte abondance, sous peine d'une forte perte de signal. De telles conditions sont habituellement utilisées dans les sources haute pression des spectromètres de masse conventionnels pour produire des ions négatifs (22).

Ces points expliquent le faible engouement pour l'étude des ions négatifs sur ce type d'appareil. La première étude faite par Schermann et Major décrit le confinement d'ions iodure (I^-) formés par photodissociation de l'iodure de thallium (23). Plus tard, Hughes observe des ions négatifs dans des spectres d'impact électronique de petites molécules (24). En 1987, McLuckey et Glish (25) mirent en évidence la possibilité de confiner des ions négatifs formés par ionisation chimique, utilisant des ions négatifs réactifs OH^- et $O^{\bullet -}$ créés au sein du piège. En 1994, Berberich et Yost ont étudié les paramètres d'ionisation influençant l'efficacité de formation des ions négatifs (26). Plus récemment, quelques exemples d'applications analytiques pour des composés à forte affinité électronique (composés polychlorés) ont été reportés (27, 28).

Dans cette étude, les raisons pour lesquelles le piège quadripolaire se prête difficilement aux applications analytiques des ions négatifs, seront discutées. Après une description sommaire du principe de fonctionnement de cet instrument, la détection des ions négatifs, qui constitue une difficulté sérieuse, sera décrite. Il s'avère que le piège possède un comportement particulier nécessitant une bonne compréhension des processus de piègeage et de détection. Les moyens disponibles pour identifier la charge d'un ion seront décrits, d'autant plus que les ions négatifs et positifs créés dans le piège pendant l'ionisation sont détectés simultanément; d'où l'intérêt porté aux méthodes d'identification de la polarité des ions. Puis le rôle joué par l'énergie des électrons de capture sur la limitation de la formation des ions négatifs sera étudié. Enfin, la conséquence directe du confinement simultané des ions positifs et négatifs est la création d'importants potentiels de charge d'espace affectant la stabilité des ions positifs et des ions négatifs. Un autre aspect de ce confinement simultané concerne la résolution des ions positifs comme celle des ions négatifs éjectés en présence d'ions de polarité opposée. Enfin, des indices concernant les interactions possibles entre les ions positifs et les ions négatifs, second facteur limitant l'utilisation analytique des ions négatifs dans le piège, seront aussi présentés.

Partie expérimentale

Toutes les expériences ont été réalisées sur un piège ionique quadripolaire Varian Saturn III™ qui possède une géométrie « étirée ». Une jauge de pression Penning (CF2P, Alcatel) a été installée sur la partie inférieure de l'enceinte de l'appareil qui a été modifiée. La jauge n'ayant pas été calibrée, les valeurs de pression données ne sont donc pas corrigées.

L'hélium est introduit dans la cavité du spectromètre de masse par l'intermédiaire du chromatographe en phase gazeuse (Varian Star 3400 CX™). La pression en gaz tampon (hélium) est d'environ 10^{-3} Torr (pression réelle) (1 Torr = 133,3 Pa). La perfluorotributylamine (FC43) (purifiée par Aldrich) employée dans ces expériences pénètre en continu dans le piège par l'intermédiaire d'une vanne aiguille à une pression partielle lue de $(1–2) \times 10^{-5}$ mbar. L'enceinte de l'appareil est maintenue à une température de 170°C. L'acquisition des spectres de masse est réalisée à la vitesse de balayage de

3. Le Thomson (Th) est défini comme le rapport entre la masse exprimée en unité de masse atomique (u) et le nombre de charges.

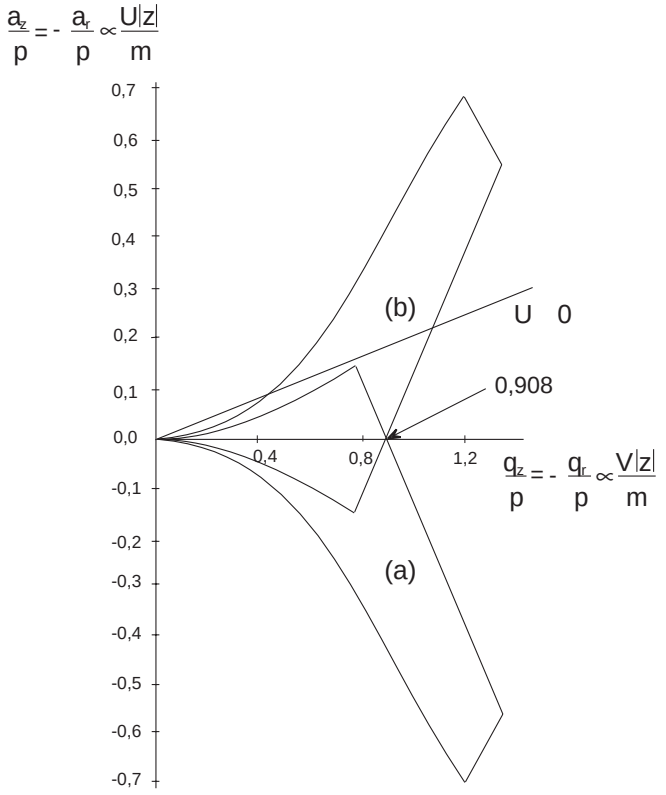
Fig. 1. Diagramme de stabilité décrivant les différences entre les ions positifs (*a*) et négatifs (*b*). La zone de recouvrement dénote une stabilité simultanée des ions positifs et négatifs. Les axes choisis nécessitent une pondération des paramètres de stabilité par la polarité, a_u/p, q_u/p. La droite de fonctionnement représentée correspond à l'application d'une tension continue négative permettant l'isolement des ions négatifs (vide supra).



5555 Th/s, avec une segmentation standard entre 25 et 650 Th (29) et correspondant à la moyenne d'une centaine de balayages.

Les conditions d'ionisation en mode positif sont standards. Le niveau RF d'ionisation (LMCO) est de 50 Th (pendant l'ionisation, seule une tension RF d'amplitude constante, exprimée comme la limite de basse masse, est appliquée à l'électrode circulaire). Le courant d'émission du filament (FEC) est relativement faible (10 µA), tandis que le temps d'ionisation est ajusté de façon à conserver une résolution unitaire tout en optimisant l'intensité du signal (typiquement un temps d'ionisation de 300 µs pour la pression partielle en échantillon utilisée).

Il a été au préalable nécessaire d'équiper l'appareil d'un système de détection modifié afin de détecter les ions négatifs. Ce dernier est constitué d'un channeltron classique devant lequel est placée une dynode de conversion de géométrie du type « Venetian Blind » (Torn Emi, Fairfield, Conn., U.S.A.). L'alimentation de la dynode est comprise entre +5 kV et –5 kV.

La formation des ions négatifs étant défavorisée, il est nécessaire d'utiliser un temps d'ionisation de 25 ms (valeur maximale) et un FEC intense (typiquement compris entre 40 et 80 µA), de façon à augmenter la probabilité de formation des ions négatifs. Enfin, le LMCO est classiquement de 10 Th. Les expériences portant sur l'effet du niveau RF d'ionisation utilisent un FEC de 50 µA. L'étude des effets du FEC (cf. les figures 7 et 8) a été effectuée à un LMCO de 35 Th (pour pouvoir confiner simultanément des ions positifs et négatifs ayants des rapports *m*/*z* proches) avec une variation du FEC comprise entre 10 et 50 µA avec un incrément de 1 µA.

Enfin les simulations ont été effectuées avec le logiciel ITSIM™ (30). Celles-ci utilisent un piège avec une géométrie étirée, comme celle employée dans ce travail. Toutefois, aucune contribution des champs d'ordre élevé n'est considérée (ceux-ci n'introduisent qu'une faible dispersion des trajectoires et ne modifient pas l'énergie cinétique maximale des électrons) : le champ quadripolaire est donc pur. De plus, aucun ion n'est supposé présent au sein du piège; le potentiel de charge d'espace est négligé. Les collisions des électrons avec l'hélium ne sont pas prises en compte (en effet, le temps de résidence des électrons est au maximum de 20 ns, alors que le temps moyen entre deux collisions est au minimum de 1 µs, estimé à partir du modèle de Langevin (31) en supposant des électrons thermiques). Seule une tension RF de fréquence fixe 1,05 MHz et d'amplitude constante 114 $V_{0\text{-}p}$ (LMCO = 10 Th) est appliquée à l'électrode circulaire. Chaque simulation considère 100 électrons créés simultanément à un angle de phase RF donné. Les électrons pénètrent dans le piège par l'électrode chapeau supérieure, avec une distribution uniforme de 2 mm de large suivant les directions *x* et *y* et centrée sur l'axe *z*. La vitesse de chaque électron est axiale et sans composante radiale, et correspond à une valeur fixe d'énergie cinétique de 12,5 eV (tension du filament conseillée par défaut pour le Saturn™).

Partie théorique

Le mode de fonctionnement des pièges ioniques quadripolaires a été amplement décrit dans la littérature (32). Le diagramme de stabilité permet de déterminer si un ion est stable ou non au sein du piège. Il est typiquement représenté en coordonnée a_u et q_u connues sous le nom de paramètres de stabilité :

$$[1] \qquad a_z = -2a_r = -\frac{16zeU}{m(r_o^2 + 2z_o^2)\Omega^2}$$

$$[2] \qquad q_z = -2q_r = -\frac{8zeV}{m(r_o^2 + 2z_o^2)\Omega^2}$$

où *u* représente les coordonnées (*r* et *z*); *m* est la masse de l'ion et *z* son nombre de charges; *V* représente l'amplitude zéro à crête de la tension radiofréquence (RF) de pulsation Ω et *U* est l'amplitude de la tension continue (DC) appliquées toutes deux à l'électrode circulaire de rayon r_0 ; z_0 décrit la distance entre les électrodes chapeaux.

Dans le cas présent, les paramètres de stabilité a_u et q_u sont pondérés par la polarité *p* de l'ion considéré (avec $z = p|z|$ et $p = \pm 1$) de façon à différencier le diagramme de stabilité des ions négatifs de celui des ions positifs. Le diagramme de stabilité de ces derniers est le symétrique par rapport à l'axe q_u/p de celui des ions négatifs (figure 1). Toutefois, la pondération des paramètres de stabilité par la polarité n'est généralement pas prise en compte dans la représentation des diagrammes de stabilité des ions positifs et négatifs.

Cette figure présente une zone commune aux ions positifs et négatifs, notamment pour le mode de fonctionnement classique ($a_u/p = 0$). Ainsi, dans ces conditions il y a confinement

© 1998 NRC Canada

simultané. Il est toutefois possible d'isoler sélectivement des ions négatifs et positifs, en travaillant sur l'axe a_u/p ($U \neq 0$).

Il reste à déterminer la stabilité relative d'un ion par rapport à un autre, ou d'un ion en fonction des tensions U et V employées. Il faut savoir que la détermination de l'allure d'une trajectoire est une approche complexe. Différentes méthodes ont été mises au point pour étudier le mouvement des ions piégés dans un champ quadripolaire (33–35). Plus récemment, de nombreux auteurs ont étudié, à l'aide de simulations (ITSIM™ (30), SIS™ (31)), l'influence de différents paramètres sur les conditions de piégeage : effet de l'hélium (31), de l'instabilité axiale (30), de l'excitation résonnante (36) ou des phénomènes de charge d'espace (37, 38). Malgré les promesses engendrées par ces méthodes, les moyens mis en oeuvre sont difficiles (logiciel et traitement informatique complexes). Toutefois un traitement beaucoup plus accessible, mais moins rigoureux, a été développé par Major et Dehmelt (33). Il permet d'avoir une idée de la stabilité relative d'un ion donné dans des conditions opératoires données (paramètres a_u et q_u fixés). Ce traitement conçoit le mouvement d'un ion comme un simple mouvement oscillatoire à la fréquence séculaire selon une direction u, ω_u (cette dernière est liée au facteur m/z de la façon suivante, $\omega_u = \beta_u\Omega/2$) dans un puits de pseudo-potentiel de profondeur $\overline{D}_u$. Ce modèle n'est cependant quantitativement valable que pour des valeurs de q_u inférieures à 0,4 où $\beta_u = \sqrt{a_u + q_u^2/2}$. Si l'on considère que seule une tension RF est appliquée à l'électrode circulaire ($a_u = 0$), on a :

$$[3] \qquad \overline{D}_u = \frac{mq_u^2\Omega^2}{16ze}u_0^2$$

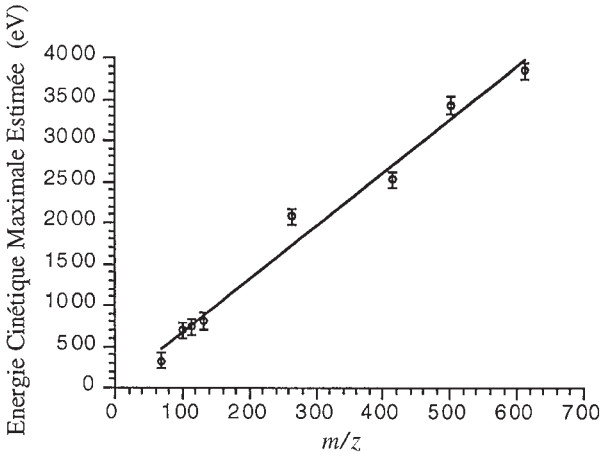
En considérant la relation $r_0^2 = 2z_0^2$, on a $\overline{D}_z = 2\overline{D}_r$. Un ion est donc d'autant plus stable que sa valeur de q_z est élevée et que son rapport m/z est faible.

Détection et identification des ions négatifs

La détection d'ions négatifs implique un détecteur approprié (39). La difficulté à les détecter est liée au principe même du fonctionnement des détecteurs conventionnels en mode analogique (channeltron, galettes de microcanaux ou multiplicateur d'électrons). Un ion incident entre en collision avec le haut du détecteur, ce qui induit la production d'électrons secondaires en cascades depuis le site d'impact porté à un potentiel négatif vers le collecteur porté à la masse.

Dans les générations précédentes de spectromètres à faisceau d'ions de hautes énergies, l'ion négatif incident possède une énergie cinétique suffisante pour passer la barrière de potentiel imposée par un détecteur conventionnel. Ainsi un ion négatif peut être détecté malgré le fait que le détecteur soit porté à un potentiel négatif (40). Dans un cadre plus général, pour détecter des ions négatifs, il faut les accélérer vers le détecteur au moyen d'un potentiel positif; il est alors nécessaire d'avoir un collecteur porté à un haut potentiel positif (41). Cependant, cela pose des difficultés technologiques importantes en détection analogique. La deuxième solution plus couramment utilisée depuis une vingtaine d'années sur les spectromètres de masse conventionnels utilise une dynode de conversion (42, 43). Les ions négatifs sont accélérés vers une surface métallique portée à un haut potentiel positif de plusieurs kV. De la collision sur surface, résultent des espèces

Fig. 2. Dépendance linéaire liant l'énergie cinétique (en eV) maximale estimée (obtenue au travers de la mesure du seuil de disparition du signal d'un ion donné par variation du potentiel positif appliqué à la dynode) au rapport m/z des ions du FC43 (les conditions opératoires étant des conditions d'impact électronique standard : FEC = 10 μA, LMCO = 35 Th, TI = 300 μs).



secondaires positives qui dans un second temps seront détectées par un channeltron classique. L'utilisation d'un « Venetian Blind » comme dynode de conversion permet une émission des espèces secondaires suivant le même axe que les ions incidents. Le gain de place ainsi occasionné permet d'utiliser ce système sur des pièges ioniques commerciaux avec peu de soucis technologiques.

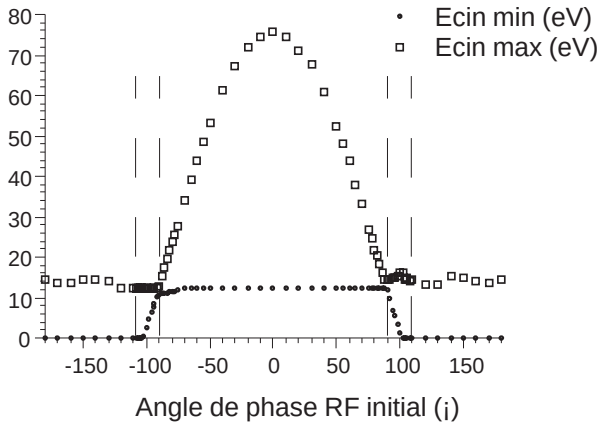
En 1980, Mather et Todd (44) ont reporté la détection simultanée d'ions positifs et d'ions négatifs. Pour cela, il faut que les ions négatifs possèdent une énergie cinétique suffisante pour passer la barrière de potentiel imposée par le détecteur. Cooks et coll. (45) ont précédemment déterminé expérimentalement la distribution d'énergie cinétique des ions éjectés sous instabilité axiale. Il apparaît selon cette étude que les ions sont éjectés à vitesse constante; autrement dit, l'énergie cinétique des ions éjectés augmente linéairement avec le rapport m/z.

Les résultats présentés dans ce travail montrent que le signal des ions positifs décroît avec l'augmentation de la tension positive appliquée au Venetian Blind. Cette diminution résulte de deux facteurs : premièrement les ions positifs sont ralentis et l'efficacité de conversion diminue, celle-ci étant fonction de l'énergie des ions incidents (46); deuxièmement la décroissance reflète la distribution d'énergie cinétique (normalement accessible en effectuant la dérivée de la courbe du signal en fonction du potentiel retardateur). L'efficacité de conversion étant une inconnue, seule une estimation de l'énergie cinétique maximale peut être faite. Cette dernière correspond à la tension seuil appliquée à la dynode pour laquelle le signal des ions positifs détectés disparaît. L'utilisation du Venetian Blind permet de confirmer la détection simultanée au travers de la grande énergie cinétique caractérisant les ions positifs et négatifs. La figure 2 montre la corrélation liant l'énergie cinétique maximum estimée d'un ion donné en fonction de son rapport masse sur charge. Cette dépendance linéaire est proche de $E_{cin_{max}} = [27{,}15+6{,}44m/z]$ eV selon un coefficient de corrélation de 0,9913.

Cependant, la détection simultanée ne résulte pas uniquement de l'énergie cinétique des ions éjectés; il existe, comme

© 1998 NRC Canada

Fig. 3. Résultats de la simulation de la variation des énergies cinétiques (en eV) maximale et minimale des électrons en fonction de l'angle phase RF initial (E_{init} = 12,5 eV, V = 114 $V_{0\text{-}p}$ soit 10 Th et $\Omega/2\pi$ = 1,05 MHz).



cela a été précédemment montré, la possibilité de conversion par collision sur l'électrode chapeau supérieure (47). En effet, les ions négatifs, ne possédant pas suffisamment d'énergie cinétique pour passer la barrière de potentiel imposé par le détecteur, sont repoussés vers l'électrode chapeau inférieure. La collision sur surface qui en résulte libère des espèces positives secondaires, qui peuvent être détectées.

La détection simultanée des ions positifs et des ions négatifs repose sur le principe de fonctionnement du piège quadripolaire. Cependant, à partir du moment où l'on peut détecter des ions de polarité différente sans aucun moyen d'identification, des confusions peuvent être faites. Différentes méthodes sont à notre disposition pour passer outre ce problème. La première solution utilise le fait même que les ions éjectés possèdent une grande énergie cinétique. Suivant la polarité de l'ion étudié, l'évolution de son signal en fonction de la tension appliquée à la dynode sera différente. Il est possible aussi de s'affranchir de ces difficultés causées, premièrement par l'énergie cinétique à l'éjection en utilisant une dynode de conversion située hors de l'axe z et portée à un très haut potentiel (jusqu'à ±15 kV), avec les difficultés technologiques que comportent l'utilisation de très hautes tensions ainsi que le volume occupé par le détecteur, deuxièmement en insérant un isolant derrière l'électrode chapeau et devant le système de détection (pour s'affranchir de la conversion par collision sur l'électrode chapeau, et éviter une perturbation éventuelle du champ quadripolaire par le potentiel élevé appliqué à la dynode). La société Finnigan sur le GCQ™ et le LCQ™ et la société Brüker sur l'Esquire™ proposent des systèmes, brevetés, de détection analogues.

Récemment, une étude a confirmé la polarité des ions négatifs à m/z 452, m/z 595 et m/z 633 étudiés dans le présent travail (27), en utilisant la solution la plus courante : l'application à l'électrode circulaire d'une tension continue U. Comme il l'a été montré précédemment, le diagramme de stabilité des ions négatifs présente certaines parties communes avec celui des ions positifs. Par contre, dans les parties indépendantes, il est possible de confiner sélectivement soit des ions positifs soit des ions négatifs. Ainsi en appliquant une combinaison d'une tension RF et d'une tension continue positive appropriée (a_u/p <0) à l'électrode circulaire, la droite de fonctionnement (sur laquelle se positionnent les points de fonctionnement (a_u/p, q_u/p) des ions négatifs et positifs) est hors des limites du diagramme de stabilité des ions négatifs. Les ions positifs sont alors piégés sélectivement. Inversement, avec une tension continue négative, les ions négatifs sont isolés. Sur la figure 1, décrivant les diagrammes de stabilité des ions négatifs et des ions positifs avec la représentation a_u/p, q_u/p, est reportée la droite de fonctionnement pour une tension continue négative. Pour avoir un isolement en l'absence de tout ion positif, la droite de fonctionnement doit passer au delà de l'extrémité supérieure du diagramme de stabilité des ions positifs. Dans ces conditions, la gamme de masse d'ions négatifs isolés se réduit, puisque certains ions négatifs de hauts rapports m/z ($m/z > M$) sont situés au-delà de la limite de stabilité $\beta_z = 0$. Afin d'isoler les ions négatifs de rapports m/z supérieurs à M, les tensions U et V sont modifiées (tout en les maintenant dans un rapport constant) de façon à ce que le point de fonctionnement de l'ion de masse M se retrouve à la place de celui de l'ion de masse m. Ceci permet d'isoler des ions négatifs de plus hauts rapports m/z, et déplace la limite de haute masse à une valeur plus élevée.[4] Ainsi, si l'on veut enregistrer un spectre de masse d'ions négatifs en l'absence de tout ion positif, il convient d'utiliser six séquences différentes correspondant à six combinaisons de tension U et V. Ceci présente alors un net désavantage d'un point de vue analytique, puisque dans un pic chromatographique il faut enregistrer cinq balayages différents pour avoir le spectre de masse des ions négatifs sur toute la gamme de masse.

Marquette et Wang (48) ont proposé une solution permettant de s'affranchir de la tension continue. L'utilisation d'une tension RF dipolaire, à la même fréquence que celle du champ de piégeage Ω, appliquée aux électrodes chapeaux permet l'éjection unidirectionnelle des ions confinés. Dans le cas d'ions négatifs et positifs confinés simultanément, chacun d'entre eux sera alors éjecté suivant des directions opposées, et donc pourra être analysé séparément.

La formation des ions négatifs

Trois types de réactions sont invoquées sous le terme générique de capture électronique (49). La première est la capture résonnante d'électron (réaction [4]), la seconde la capture d'électron dissociative (réaction [5]), la troisième enfin est la formation de paire d'ions (réaction [6]).

[4] $A + e^- \rightarrow A^{\bullet -}$

[5] $A + e^- \rightarrow [A^{\bullet -}]^* \rightarrow F^- + N$

[6] $AB + e^- \rightarrow A^- + B^+ + e^-$

Quelle que soit la réaction envisagée, l'énergie cinétique des électrons ionisants doit être faible. Or l'électron, compte tenu de son rapport m/z, est instable au sein du piège et est fortement accéléré par le champ quadripolaire, limitant ainsi les processus de capture.

4. En pratique, la gamme de masse est plus restreinte. La limite de basse masse m est située à l'aplomb de la limite de stabilité à q_z = 0,908, à cause de la séquence d'isolement utilisée : la tension RF est augmentée jusqu'à une valeur, correspondant à un seuil de basse masse de m, puis est appliquée la tension DC, déplaçant le point de fonctionnement de cet ion m à la verticale de la limite à q_z = 0,908.

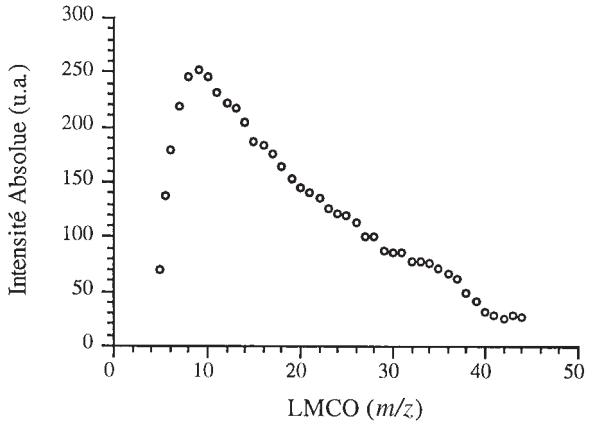
Fig. 4. Variation expérimentale de l'intensité absolue du signal de l'ion négatif *m*/*z* 452 du FC43 en fonction du niveau RF d'ionisation, exprimé en *m*/*z* (TI = 25ms, FEC = 50 μA).



L'utilisation du programme de simulation ITSIM™ a permis de déterminer l'influence de l'angle de phase RF initial $2\xi_0$ de la tension RF (autrement dit la tension $V \cos 2\xi_0$), appliquée à l'électrode circulaire lors de la période d'ionisation, sur la trajectoire des électrons. La figure 3 reporte l'évolution de l'énergie cinétique maximale et minimale des électrons, au cours de la trajectoire, en fonction de l'angle de phase RF initial. Les électrons sont injectés par l'électrode chapeau supérieure avec une vitesse correspondant à une énergie cinétique de 12,5 eV (la vitesse est supposée sans composante radiale). Les résultats obtenus sont comparables à ceux de Pedder et al. (50).

Cette courbe peut être découpée en trois zones distinctes. La zone I correspond aux angles de phase RF initiaux pour lesquels le potentiel $V \cos 2\xi_0$ est supérieur à –25 eV (soit $2\xi_0$ = 102.7° et –102.7°). Dans ces conditions, les électrons traversent le piège de part en part et viennent frapper l'électrode chapeau inférieure. Lorsque le potentiel $V \cos 2\xi_0$ augmente, leurs énergies cinétiques maximales croient jusqu'à un maximum à $2\xi_0 = 0°$; parallèlement leurs temps de résidence diminuent. La variation de l'énergie cinétique maximale suit la relation suivante :

$$[7] \qquad E_{e^-}(\max) = 0{,}5V \cos 2\xi_0 + E_{\text{init}}$$

Cette relation est différente de celle donnée par Pedder et al. (50). Ceci est dû aux conditions de simulation utilisées, où la vitesse est supposée sans composante radiale. Les électrons passent donc au centre du piège, où le potentiel est de $0{,}5V \cos 2\xi_0$ (32). L'énergie cinétique maximale suit, dans ce cas particulier, la relation [7].

La zone II correspond à une période de transition. Elle est centrée sur une valeur d'angle de phase où $V \cos 2\xi_0 = -2E_{\text{init}}$. Cette zone caractérise le passage des trajectoires de type I (associées à la zone qui les caractérise) à des trajectoires de type III. Les électrons vont voir leur temps de confinement progressivement augmenter, et leur énergie cinétique minimale diminuer. Lorsque l'électron passe au centre du piège, son énergie cinétique atteint un minimum. À ce moment, le potentiel est légèrement supérieur à $-2E_{\text{init}}$. Le potentiel RF devient plus négatif et l'électron ne traverse plus le piège de part en part. Il pénètre alors celui-ci plus ou moins profondément, selon la valeur de $V \cos 2\xi_0$, puis est repoussé vers l'électrode chapeau supérieure. L'énergie cinétique minimale est nulle, lorsque l'électron a effectué son incursion maximale au sein du piège. Cette zone II correspond aux électrons ayant une faible énergie cinétique (proche de zéro) lorsqu'ils sont au centre du piège. Ceux-ci sont très probablement à l'origine des interactions électron–molécule nécessaires à la formation des ions négatifs, car ils possèdent une faible énergie cinétique nécessaire au processus de capture.

Durant la troisième période (zone III), les électrons sont repoussés vers l'électrode chapeau supérieure. L'incursion axiale décroît lorsque le potentiel $V \cos 2\xi_0$ devient plus négatif, et le temps de résidence décroît aussi. L'énergie cinétique maximale garde une valeur constante égale à l'énergie cinétique initiale.

Le même raisonnement peut être tenu avec les électrons secondaires issus de l'impact électronique (équation [8]). Ceux-ci créés au centre du piège avec une énergie thermique initiale ont des temps de confinement bien plus longs, et interviennent donc fort probablement dans les processus de capture (51). Toutefois, ces simulations montrent aussi le rôle joué par les électrons primaires issus du filament. Il est cependant très difficile de faire la part des choses entre ces deux origines.

$$[8] \qquad \mathrm{M} + e^-_{\text{prim}} \rightarrow M^{\bullet +} + \mathrm{e}^{\prime -}_{\text{prim}} + \mathrm{e}^-_{\text{sec}}$$

D'après l'équation [8], l'énergie cinétique maximale des électrons est affectée par la tension RF d'ionisation *V*. La figure 4 reporte le signal de l'ion négatif *m*/*z* 452 en fonction du niveau RF d'ionisation (noté LMCO). Les courbes pour les autres ions négatifs à *m*/*z* 595 et *m*/*z* 633 ont une évolution similaire.

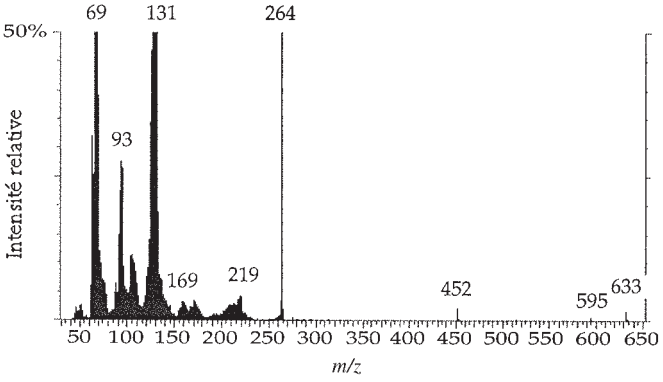
Ce paramètre affecte le courant ionique selon deux facteurs : (*i*) le paramètre de stabilité q_u de chaque ion confiné selon son rapport *m*/*z*, ce qui affecte par la même la stabilité des ions piégés, estimée selon le modèle du puits de pseudo-potentiel de Dehmelt (équation [3]) et (*ii*) l'énergie cinétique et la trajectoire des électrons primaires issus du filament et des électrons secondaires. Ces deux points conduisent à une dépendance caractérisée par la présence d'un maximum du courant ionique, et illustrent deux effets antagonistes. Lorsque le LMCO augmente, l'efficacité d'ionisation diminue, car l'énergie cinétique des électrons croît; parallèlement le puits de pseudo-potentiel est plus profond et l'ion *m*/*z* 452 est d'autant plus stable. La figure 4 présente certaines particularités propres au fait qu'elle caractérise un ion négatif : l'optimum se situe autour du rapport 10 *m*/*z* suivi d'une diminution monotone pour atteindre une faible valeur vers *m*/*z* 45, alors que pour un ion positif ayant un rapport *m*/*z* équivalent (*m*/*z* 464) le maximum se situe autour de la valeur de 25 Th suivi d'une lente décroissance (50). La formation des ions négatifs nécessitant des électrons de faible énergie cinétique, le LMCO joue donc un rôle particulièrement néfaste sur le courant de ces ions.

La présence d'ions négatifs ayant des rapports *m*/*z* élevés (*m*/*z* 633, *m*/*z* 595,...) à de faibles LMCO est remarquable, or dans ces conditions la valeur du D_z est très faible (eq. [3]) : D_z = 0,225 V pour l'ion à *m*/*z* 633 avec une tension RF d'ionisation de 114 $V_{0\text{-}p}$ (LMCO = 10 Th). Par contre, l'ion positif à *m*/*z* 614 avec un seuil de basse masse analogue présente une intensité très faible, car cet ion n'est pas suffisamment stable au sein du piège. Cet aspect résulte des conditions d'ionisation particulières utilisées et sera discuté plus en détail.

Le recours à des pressions partielles élevées en gaz tampon

© 1998 NRC Canada

Fig. 5. Spectre de masse d'ions négatifs du FC43 (TI = 25 ms, FEC = 80 μA, LMCO = 10 Th). Il apparaît une forte abondance d'ions positifs de faible rapport *m*/*z* et corrélativement la disparition des ions de hauts rapports *m*/*z*, ainsi que l'apparition d'ions négatifs de hauts rapports *m*/*z* avec des signaux bien résolus.



(22) est la solution couramment employée pour limiter les problèmes de reproductibilité qui se posent lorsqu'on étudie les ions négatifs (52). Ce gaz tampon permet de thermaliser les électrons et donc de favoriser les processus de capture, mais aussi il stabilise les ions négatifs et limite les pertes de signal qui surviennent par autodétachement (49). Sears et Grimsrud ont comparé les sensibilités relatives de détection d'ion négatif moléculaire du nitrobenzène avec différents gaz tampons à la même pression (53). Avec CO_2 et CH_4, des sensibilités similaires ont été obtenues, alors qu'avec l'azote ou l'argon les sensibilités sont plus faibles d'un facteur 30, tandis qu'avec l'hélium la sensibilité est plus faible d'un facteur 100. Malheureusement, dans les pièges ioniques quadripolaires, les gaz les plus performants (CO_2, CH_4) induisent des diminutions de l'intensité du signal (54), tandis que l'hélium, qui améliore la sensibilité dans le piège (7), donne des résultats plus modestes. Il n'est donc pas possible de bénéficier de l'avantage de ces gaz tampons dans les pièges ioniques quadripolaires, même si ces derniers sont présents en mélange avec l'hélium (55).

Influence des ions positifs sur les ions négatifs

Comme cela vient d'être décrit, la principale raison pour laquelle les ions négatifs sont peu étudiés est due à la faible probabilité de les créer. Il est alors nécessaire d'utiliser des conditions d'ionisation extrêmes de façon à favoriser l'observation de ces espèces. Le temps d'ionisation utilisé est donc maximal, ainsi que le courant d'émission du filament. Enfin, il est préférable d'avoir des quantités importantes d'échantillon. Étant donné que seule une tension RF est appliquée à l'électrode circulaire pendant l'ionisation, les ions positifs et les ions négatifs créés au cours de cette période sont confinés simultanément. De plus, la formation d'ions positifs est beaucoup plus probable (56). Aussi pendant l'ionisation, une quantité considérable d'ions positifs est produite, ce qui induit des potentiels de charge d'espace particulièrement intenses. Il faut préciser que lorsque le piège ionique est utilisé en condition normale d'étude des ions positifs (avec contrôle du nombre d'ions formés par l'AGC (9)) la quantité d'ions négatifs simultanément formée est trop faible pour perturber l'enregistrement des spectres de masse.

L'effet de l'environnement subi par les ions négatifs est dû à la présence d'un grand nombre d'ions positifs, et cet effet a été très peu étudié (32, 47). Pourtant, compte tenu de l'allure des spectres de masse enregistrés, l'influence des ions positifs est loin d'être négligeable. La figure 5 représente un spectre de masse du FC43 comportant des ions négatifs obtenus pour le FC43 (TI = 25 ms, FEC = 60 μA, LMCO = 35 Th).

Ce spectre de masse présente plusieurs particularités, dont la première est la détection simultanée, dont les raisons ont été déjà discutées, d'ions positifs et des trois ions négatifs de haute masse à *m*/*z* 633, *m*/*z* 595 et *m*/*z* 452 (détectés avec la dynode de conversion portée à un potentiel de –3 kV). Les autres points sont imputables au potentiel de charge d'espace. Ainsi, les profils des ions positifs de faibles rapports *m*/*z* sont fortement perturbés : décalibration accompagnée d'un élargissement des signaux.

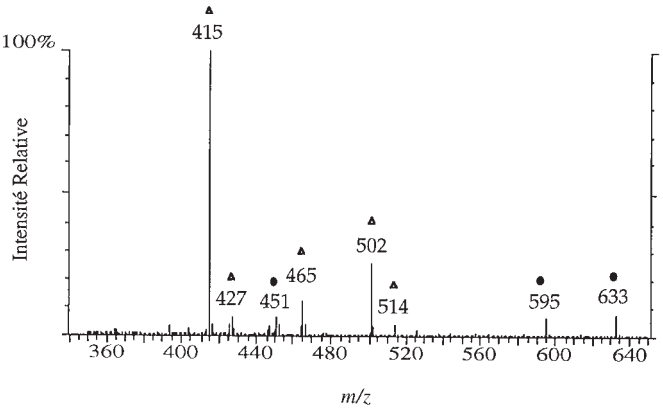
Ces perturbations sont dues aux interactions coulombiennes répulsives entre espèces chargées de même polarité. À cet égard, la prédominance des ions positifs de faibles rapports *m*/*z* par rapport aux ions négatifs permet en première approximation de négliger les éventuelles perturbations induites par ces derniers. Lorsque la quantité d'ions positifs présents au sein du piège, lors de l'éjection d'ions positifs de rapport *m*/*z* donné par instabilité sélective en masse, est importante, le profil des ions éjectés est déplacé vers les hauts rapports *m*/*z* et sa largeur à mi-hauteur augmente (57). Étant donné que cette perte de résolution (élargissement et déplacement des pics vers les hautes valeurs de *m*/*z*) est fonction du nombre d'ions, ceux de plus faible rapport *m*/*z* seront les plus affectés. En effet, le capital d'ions formés et piégés pendant l'ionisation, dont les rapports *m*/*z* sont supérieurs au seuil de basse masse, diminue par éjection, lors du balayage de la tension RF, depuis les ions de bas rapports *m*/*z* vers ceux de hauts rapports *m*/*z*. La deuxième conséquence du potentiel de charge d'espace porte sur la déstabilisation des ions positifs de hauts rapports *m*/*z* (58). Ainsi, le spectre reporté figure 5 ne présente aucun ion positif ayant un rapport *m*/*z* supérieur à 270 Th, le signal à *m*/*z* 264 a donc une résolution unitaire. Il n'est pas possible d'éviter ces perturbations rencontrées au cours de l'étude des ions négatifs à l'aide d'algorithme permettant de contrôler le temps d'ionisation tel que l'AGC. En effet, les ions négatifs étant formés en beaucoup plus faible proportion que les ions positifs, une diminution trop importante de la période d'ionisation pour limiter le nombre d'ions positifs créés empêcherait l'observation d'ions négatifs.

Déstabilisation des ions positifs et stabilisation des ions négatifs

La déstabilisation des ions positifs survient pendant l'ionisation, au cours de laquelle la population d'ions positifs peut être modifiée. Les répulsions coulombiennes entre les ions positifs déstabilisent les ions positifs les moins stables au sein du piège, qui sont d'après le modèle du puits de pseudo-potentiel les ions de hauts rapports *m*/*z*. Ainsi, par augmentation progressive de la quantité d'ions et donc du potentiel de charge d'espace, les ions positifs sont éjectés selon les rapports *m*/*z* décroissants. Si le nuage d'ions est majoritairement constitué d'ions positifs de hauts rapports *m*/*z*, ceux-ci ne seront pas forcément éjectés,

© 1998 NRC Canada

Fig. 6. Spectre du FC43 montrant la présence simultanée d'ions positifs de hauts rapports *m*/*z* ▲ (*m*/*z* 414, *m*/*z* 464 et *m*/*z* 502) et d'ions négatifs ● (*m*/*z* 452, *m*/*z* 595 et *m*/*z* 633). Le profil des ions *m*/*z* 452, éjectés en présence d'ions positifs (*m*/*z* 464 et *m*/*z* 502), est déplacé vers les faibles rapports *m*/*z* (*m*/*z* 451) (TI = 25 ms, LMCO = 35 Th, FEC = 20 μA).



mais leurs abondances relatives pourront être modifiées. Ces résultats ont fait l'objet d'une publication (58), dont les résultats majeurs sont résumés ci-dessous.

Le modèle employé pour interpréter la déstabilisation des ions positifs est basé sur le modèle du puits de pseudo-potentiel. Le potentiel de charge d'espace induit par les ions de faibles rapports *m*/*z* va compenser le potentiel de piègeage des ions de hauts rapports *m*/*z* conduisant à une déstabilisation de ces derniers. Les ions de hauts rapports *m*/*z* étant d'autant moins stables que leur rapport *m*/*z* est élevé, ceux-ci seront déstabilisés suivant leur rapport *m*/*z* décroissant (c'est à dire, dans le cas de la figure 5, depuis *m*/*z* 614 jusqu'à *m*/*z* 300).

Cette déstabilisation des ions positifs s'accompagne d'une déformation du diagramme de stabilité. Des mesures expérimentales de déformation du diagramme de stabilité ont été précédemment reportées qui confirment ces résultats (59).

Intuitivement, il est probable qu'il en va différemment pour des ions de charge opposés. En effet, la figure 5 montre la présence indiscutable d'ions négatifs de hauts rapports *m*/*z*. Ceux-ci ne sont donc pas déstabilisés par le potentiel de charge d'espace dû aux ions positifs de faibles rapports *m*/*z* en quantité abondante; ils sont au contraire stabilisés (58). En fait, le diagramme de stabilité des ions négatifs en présence d'ions positifs subit une déformation inverse de celui des ions positifs (59), confirmant aussi l'effet de stabilisation des ions négatifs par le potentiel de charge d'espace dû aux ions positifs.

Décalibration des ions positifs par les ions négatifs et réciproquement

L'hypothèse faite au préalable sur l'influence négligeable des ions négatifs peut s'avérer dans certains cas hasardeuse. Sur le spectre de masse reporté figure 6, le signal des ions négatifs est bien résolu; en effet, il a été dit précédemment que la résolution du signal d'ions donnés est affectée par la quantité d'ions présents lors de l'éjection de ces derniers. Pour les conditions utilisées dans la figure 5, lors de leur éjection, les ions négatifs ne sont pas perturbés par d'éventuels ions positifs, car ceux de hauts rapports *m*/*z* ont déjà été déstabilisés par le potentiel de charge d'espace tandis que ceux de faibles rapports *m*/*z* ont été éjectés au préalable par balayage de la tension RF, ni par les ions négatifs eux-mêmes, car ils sont en quantité trop faible pour induire un potentiel de charge d'espace.

Toutefois, les ions négatifs peuvent être dans certains cas en quantité suffisamment abondante pour induire des pertes de résolution, déplaçant leurs profils vers de hauts rapports *m*/*z* (60), comme c'est le cas pour les ions positifs (57). À cet égard, il est difficile d'estimer la quantité d'ions négatifs présents au sein du piège, bien que celle-ci soit probablement plus faible que celle des ions positifs, mais tout de même suffisante pour induire un potentiel de charge d'espace. De plus, il est difficile de comparer les intensités relatives des ions positifs et des ions négatifs, les efficacités de détection n'étant pas identiques.

Parallèlement, il est possible d'observer, dans certaines conditions, la présence simultanée d'ions négatifs et d'ions positifs de plus haut rapport *m*/*z*. La figure 6 est obtenue dans des conditions similaires à celle de la figure 5, mais avec un FEC plus faible, de 20 μA, de façon à limiter l'éjection des ions positifs de hauts rapports *m*/*z* en réduisant le potentiel de charge d'espace. La résolution du signal d'ions de rapport *m*/*z* donné est affectée par la quantité d'ions ayant des rapports *m*/*z* plus élevés. Aucun ion positif ayant un rapport *m*/*z* supérieur à 526 n'est détecté. Le pic à *m*/*z* 502 est bien résolu, tandis que celui à *m*/*z* 464 est déplacé vers *m*/*z* 465, car les ions à *m*/*z* 464 subissent un potentiel de charge d'espace induit par leur propre densité ainsi que celle des ions à *m*/*z* 502. De même, les ions avec des rapports *m*/*z* plus faibles sont aussi décalibrés : *m*/*z* 426 à *m*/*z* 427, *m*/*z* 414 à *m*/*z* 415. Concernant les ions négatifs, ceux à *m*/*z* 633 et *m*/*z* 595 ne sont pas éjectés en présence d'ions positifs de plus haut rapport *m*/*z*, car ces derniers sont déstabilisés par le potentiel de charge d'espace, de plus ils ne sont pas en quantité suffisamment abondante pour affecter leurs résolutions. Par contre, les ions négatifs à *m*/*z* 452 sont éjectés en présence d'ions positifs à *m*/*z* 464 et *m*/*z* 502. Leur profil est alors déplacé vers de plus faibles rapports *m*/*z* (massif à *m*/*z* 451).

Inversement, il est fort probable que le signal d'ions positifs soit déplacé vers de plus faible rapport *m*/*z*, lorsque ces derniers sont éjectés en présence d'ions négatifs abondants. La figure 7*a* montre le profil des ions à *m*/*z* 414 en fonction de la valeur du FEC dans des conditions d'ions négatifs (TI = 25 ms, LMCO = 35 Th; ce profil a été enregistré dans des conditions de pression en FC43 légèrement différentes de celles utilisées pour les figures 5 et 6). À de faibles FEC (≤ 12 μA), le profil de ces ions est très large, dû à la présence d'ions positifs en très fortes abondances lors de l'éjection de ce dernier. À de telles valeurs de FEC, le signal semble plus faible car le courant ionique des ions à *m*/*z* 414 se répartit sur plusieurs masses. Par augmentation du FEC, le potentiel de charge d'espace est plus intense, conduisant à la déstabilisation d'ions positifs de hauts rapports *m*/*z*. Ainsi, la résolution s'améliore lorsque le FEC augmente; le profil est moins large. La figure 7*b* montre le profil de ces ions pour des valeurs de FEC comprises entre 14 et 20 μA. Quant la valeur du FEC est de 14 μA, le pic à *m*/*z* 414 est déplacé à *m*/*z* 415. À 15 μA, le nombre total d'ions à *m*/*z* 414 a légèrement diminué; le potentiel de charge d'espace subi par ces ions lors de leur éjection est plus faible et leur profil est alors redéplacé vers *m*/*z* 414 (bien que dans ces conditions, le signal ne soit pas parfaitement résolu). À 16 μA, le nombre d'ions à *m*/*z* 414 a considérablement diminué, le profil

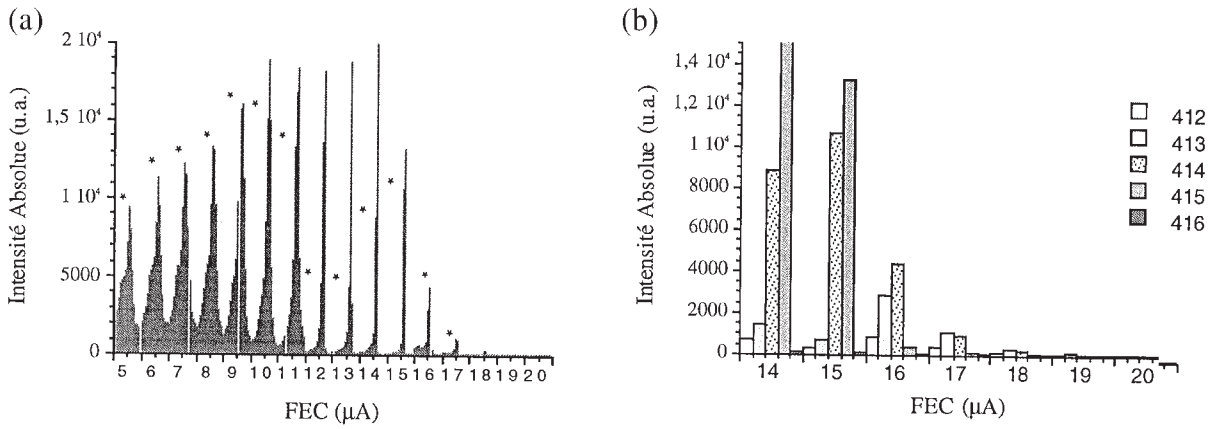
Fig. 7. (*a*) Profil des ions positifs à *m*/*z* 414 en fonction de la valeur du FEC. La perte de signal est due au potentiel de charge d'espace. Lorsque le signal est suffisamment faible, et que la quantité d'ions négatifs est assez importante, le profil des ions positifs à *m*/*z* 414 est décalibré vers les bas rapports *m*/*z*, avant de disparaître. Le signal au rapport *m*/*z* 414 est indiqué par *. Agrandissement du profil de cet ion positif pour des valeurs de FEC comprise entre 14 et 20 μA (*b*).



de ces ions se déplace à des rapports *m*/*z* inférieurs à *m*/*z* 414. À une telle valeur de FEC, des ions négatifs intenses à *m*/*z* 452, *m*/*z* 595 et *m*/*z* 633 sont présents, de telle façon que le potentiel de charge d'espace induit par ces ions déplace le profil des ions positifs à *m*/*z* 414 à de faibles rapports *m*/*z*. À des valeurs de FEC plus élevées, le déplacement se confirme, tandis que le signal de ces ions continue à décroître jusqu'à sa disparition totale à 20 μA.

Ainsi le suivi rigoureux du profil des ions positifs à *m*/*z* 414 en fonction du FEC montre l'effet des ions négatifs de hauts rapports *m*/*z* (*m*/*z* 452, *m*/*z* 595 et *m*/*z* 633) sur la résolution des pic des ions positifs.

Des réactions insolites : les interactions ion–ion

L'influence du confinement simultané des ions positifs et des ions négatifs ne se limite pas à des effets de charge d'espace. En effet, il a été envisagé la possibilité de réaction ion–ion pouvant limiter l'observation des ions négatifs (26) sans en spécifier la nature. Cependant, McLuckey et coll. (61) ont reporté récemment l'observation effective de transfert de proton entre des ions négatifs multichargés et une base forte protonnée, la pyridine. La réaction conduit à un ion négatif ayant perdu un état de charge. Ce type de réaction peut être utilisé pour améliorer les limites de détection en électrospray (62). Dans le cas d'interactions entre deux ions de même état de charge, mais de polarité opposée, il se produit une neutralisation (63). Deux types de réactions sont possibles (64).

[9] $A^+ + B^- \rightarrow A + B$

[10] $A^+ + B^- \rightarrow C + D$

La première possibilité consiste en une neutralisation par transfert d'électron, conduisant aux neutres de mêmes structures que les ions de départ (réaction [9]). Le deuxième cas concerne la formation de neutres de structures différentes (réaction [10]). La réaction chimique placée sous le label de « neutralisation » peut prendre différentes orientations : transfert d'électron, de proton, d'hydrure et autres, ou attachement,... Tout dépendra du comportement chimique des deux ions réactifs. La difficulté concernant l'étude de ces réactions réside dans l'identification des produits finaux (64). Cependant, quelle que soit la nature de la réaction, ces interactions ion–ion sont caractérisées par de fortes sections efficaces (10^{-7} cm^3 s^{-1}) (65), plus grandes que celles des réactions ion–molécule classiques (66). Ainsi la probabilité d'avoir ce type de réaction est grande. C'est pourquoi ces réactions ne peuvent être négligées au sein du nuage constitué des ions positifs et des ions négatifs piégés.

Dans le cas du FC43, des indices indirects ont montré la possibilité de rencontrer ce type de réaction. Ainsi l'évolution du signal des ions négatifs (figure 8*a*) et celle du signal des ions positifs de hauts rapports *m*/*z* (figure 8*b*) en fonction du FEC montrent une complémentarité frappante.

L'observation des ions négatifs (à *m*/*z* 452, *m*/*z* 595 et *m*/*z* 633) n'est possible qu'à partir du moment où la quantité d'ions positifs ayant des rapports *m*/*z* proches (614, 576, 502, 464, 414,...) diminue sous l'effet de déstabilisation dû au potentiel de charge d'espace (la contribution éventuelle apportée par les interactions ion–ion à la diminution du signal des ions positifs est supposée négligeable, compte tenu de la faible proportion des ions négatifs). En outre, l'évolution du courant des ions négatifs en fonction du FEC (figure 8*b*) montre deux droites de pentes différentes, ce qui semble caractériser deux types de processus. Dans un premier temps, le signal augmente grâce à une diminution des neutralisations; puis après déstabilisation des ions positifs de rapports *m*/*z* proches, l'augmentation du FEC assure seul la croissance du signal des ions négatifs. Un indice allant dans ce sens est l'extrapolation de cette deuxième droite qui passe près de l'origine, ce qui indiquerait que les interactions ion–ion empêcheraient la détection des ions négatifs entre 0 et 16 μA. Cet aspect mérite une étude plus approfondie. Notamment il faut déterminer l'impact des différents ions positifs sur les neutralisations (dans l'explication rapportée ici, les ions positifs de bas rapports *m*/*z* ne semblent avoir aucun effet).

S'il semble que les interactions ion–ion aient un effet non négligeable sur la faibles quantité d'ions négatifs présents au sein du piège, ce n'est pas la principale raison avancée. En effet, cette dernière est l'énergie des électrons nécessaire à la capture électronique.

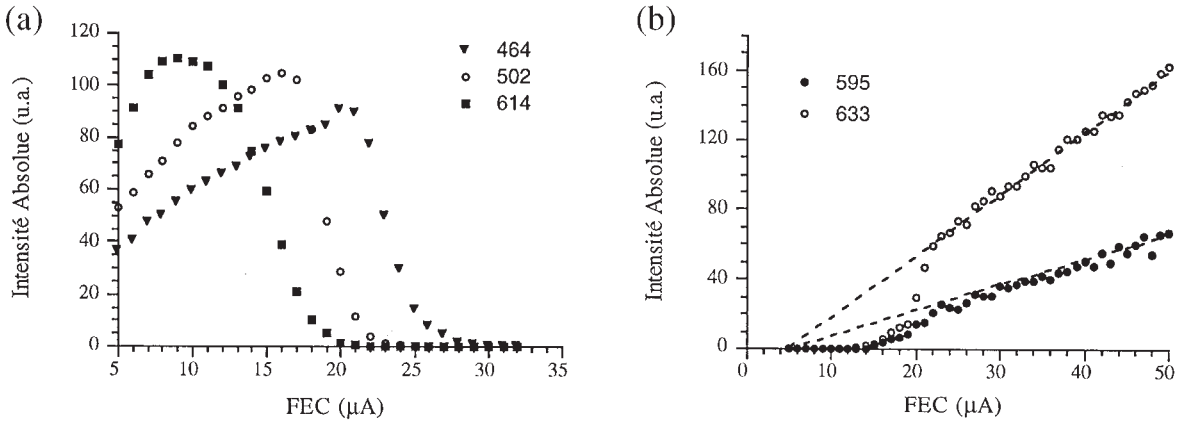
Fig. 8. Évolution de l'intensité du signal des ions positifs à *m/z* 464, *m/z* 502 et *m/z* 614 en fonction de la valeur du FEC (*a*). Les ions positifs disparaissent suivant leur rapport *m/z* décroissant dû à l'augmentation du potentiel de charge d'espace avec le FEC. L'évolution de l'abondance des ions négatifs à *m/z* 595 et *m/z* 633



Conclusion

Ce travail a permis de dégager les difficultés relatives à l'étude des ions négatifs générés dans un piège ionique quadripolaire. Il a été montré que de tels ions peuvent être observés avec des GC/MS commerciaux, comme ceux du type Saturn™, sans aucune modification instrumentale, avec cependant quelques limitations. En effet, la détection simultanée des ions positifs et des ions négatifs, rendue possible par la forte énergie cinétique des ions lors de leur éjection analytique, peut conduire à des ambiguités d'attribution de la polarité des ions détectés, si l'on n'a pas recours à un isolement RF/DC ou à un détecteur modifié. En outre, la gamme de masse d'ions négatifs qui peut être détectée est alors restreinte, car seul les ions négatifs de plus hauts rapports *m/z* peuvent être détectés. L'utilisation d'un système de détection comportant une dynode de conversion peut être une alternative intéressante.

L'efficacité de formation des ions négatifs reste un problème plus épineux. Sa résolution doit permettre de favoriser l'abondance des électrons thermiques, nécessaires au processus de capture électronique, au sein du piège. Deux solutions sont envisageables. La première concerne l'utilisation d'une vanne pulsée, qui injecterait pendant la période d'ionisation une forte quantité de gaz, autre que l'hélium (ce dernier n'apportant pas de gain de sensibilité significatif pour la formation des ions négatifs), favorisant la thermalisation des électrons. Les vannes pulsées sont d'ores et déjà utilisées pour améliorer l'efficacité d'injection des ions à partir d'une source externe (67), ou pour améliorer l'efficacité des processus de CID (dissociations induites par collision) (68), ou encore pour limiter les réactions ion–molécule parasites (69). La deuxième solution serait de pulser la tension RF pendant l'ionisation. La formation des ions négatifs serait favorisée au cours de la période sans RF, où les électrons ne sont plus accélérés, le pulse RF assurant alors le confinement des ions négatifs créés. Des simulations de ce type de séquence sont en cours d'étude.

Il reste malgré tout une difficulté majeure : le confinement simultané des ions négatifs et des ions positifs. Celui-ci conduit à des potentiels de charge d'espace, qui se présentent comme un avantage. En effet, ces derniers déstabilisent les ions positifs de hauts rapports *m/z*, permettant ainsi l'observation des ions négatifs dans cette même gamme de rapports *m/z,* et stabilisent les ions négatifs permettant l'utilisation de faible niveaux RF d'ionisation plus favorable à la formation de ces derniers. Cependant, ce confinement simultané peut induire des pertes de résolution pour des ions négatifs, lorsque ceux-ci sont détectés en présence d'ions positifs de plus hauts rapports *m/z*. En outre, des réactions ion–ion semblent contribuer à la limitation de la quantité d'ions négatifs détectables. La solution à ce confinement simultané est l'emploi d'un isolement RF/DC qui fait suite à l'ionisation, mais en limitant la gamme de masse d'ions négatifs isolables.

L'étude des ions négatifs avec un piège ionique quadripolaire à ionisation interne devrait rester sporadique et n'être utile que pour des applications bien particulières. Par contre le développement de couplage permettant d'injecter des ions négatifs préparés dans une source externe (70) devrait favoriser l'étude et l'emploi des ions négatifs, si l'on parvient à maitriser les problèmes d'éfficacité d'injection et de discrimination en masse que l'on peut rencontrer avec ces appareils. Une solution alternative est d'utiliser une source externe qui se limite à produire des ions réactifs injectés par la suite dans le piège (71). Les échantillons arrivent par l'intermédiaire du chromatographe en phase gazeuse dans le piège, les réactions ion–molécule conduisant à la formation des ions négatifs se produisant alors au sein de celui-ci. Une telle solution permet de s'affranchir des pertes de signal des ions négatifs de l'échantillon à l'injection ainsi que des discriminations en masse. En outre, les ions produits par ionisation chimique sont bien contrôlés au moyen d'un isolement préalable des ions réactifs injectés.

Remerciements

Les auteurs remercient le Centre d'Études du Bouchet (DGA), l'Université Pierre et Marie Curie, le Centre National de la Recherche Scientifique ainsi que le Ministère de la Recherche et de l'Enseignement Supérieur pour leur support financier. La société Varian-France est remerciée pour son support technique et financier, ainsi que la société Varian Associates pour avoir fourni le logiciel QISMS™. Enfin, des remerciements

Ultrasonic velocity and volumetric properties of isomeric butanediols plus water systems

Brent Hawrylak, Kim Gracie, and R. Palepu

Abstract: Ultrasonic velocities and densities of binary aqueous solutions of isomeric butanediols were measured in the temperature range 298–318 K at 10 degree intervals over the entire composition range, and 5 degree intervals in the water-rich region. The experimental data in the dilute region, with mole fraction of water less than 0.1, was analysed to determine the partial molar volumes and adiabatic compressibilities of water at infinite dilution. The standard thermodynamic transfer functions were calculated to evaluate the environment of water at infinite dilution in these systems. From the compressibility isotherms, as a function of temperature in the water-rich region, the formation and the composition of clathrate-like structures in the liquid solutions was determined, and the nature of these structures was discussed.

Key words: ultrasonic velocity, adiabatic compressibility, density, partial molar quantities, standard thermodynamic transfer functions.

Résumé : Opérant de 298 à 318 K, à des intervalles de 10 degrés sur l'ensemble des plages de compositions et de 5 degrés dans la région riche en eau, on a mesuré les vélocités ultrasoniques et les densités de solutions aqueuses binaires des butanediols isomères. Dans le but de déterminer les volumes molaires partiels et les compressibilités adiabatiques de l'eau à dilution infinie, on a analysé les données expérimentales dans la région diluée, à des fractions molaires d'eau inférieures à 0,1. Afin d'évaluer l'environnement de l'eau à dilution infinie dans ces systèmes, on a calculé les fonctions thermodynamiques standard de transfert. Sur la base des isothermes de compressibilité en fonction de la température dans la région riche en eau, on a déterminé la formation et la composition de structures ressemblant à des clathrates en solutions liquides et on discute de la nature de ces structures.

Mots clés : vitesse ultrasonique, compressibilité adiabatique, densité, quantités molaires partielles, fonctions thermodynamiques standard de transferts.

[Traduit par la rédaction]

Introduction

The strengthening of structure of water in dilute aqueous non-polar solutes containing hydrophobic functional groups is well known in the literature (1–5). The thermodynamic properties of aqueous polar organic compounds are determined predominantly by the hydrophobic interactions. The stabilization of water structure in dilute solutions of aqueous polar organic compounds was extensively studied using ultrasonic velocity measurements (6–13). The solute molecules are expected to be accommodated in short-lived water cages of a bulky water lattice with tetrahedrally coordinated water molecules. The water lattice is similar to that of the well known solid clathrate hydrates of many organic compounds (14–17). Wagner et al. (10) provided an evidence to this clathrate-like image of the structure of dilute organic compounds.

Recently it has been concluded from the study of adiabatic compressibility isotherms, quasi clathrate-like structures exist in the dilute aqueous solutions of γ-Picoline (11, 13, 18). Studies on aqueous solutions of polyhydroxy compounds, especially those related to biological systems, have been conducted in the literature to obtain the information on the hydrophobic interactions present in these systems (19, 20).

We have undertaken a systematic investigation of isomeric butanediols (BTD) to obtain a deeper understanding of solute–solute and solute–solvent interactions in these systems and the influence of the position of the hydroxy groups on the acoustic and volumetric properties (21). In this paper we present the results dealing with standard transfer functions, to evaluate the environment of water at infinite dilution in these systems.

The standard function of transfer ($Y_s^{m\to n}$) is defined as follows:

$$[1] \qquad Y_s^{m\to n} = -Y_s^{n\to m} = Y_s^{\infty(n)} - Y_s^{\infty(m)}$$

where $Y_s^{\infty(m)}$ and $Y_s^{\infty(n)}$ are the partial molar quantities at infinite dilution of solute (s) in solvents m and n, respectively. The standard function of transfer provides valuable information on the difference in the interaction of a given solute in two different solvent systems.

Normal practice is to study the standard function of transfer of a solute molecule from an organic polar solvent to water. A study of standard function of transfer of water between two

different polar organic solvents also provides useful information in terms of coupling of water with the pure solvents. A similar environment should result in a smaller value of the function of transfer, while increasing in differences in the interactions of a water molecule with both solvents should lead to a larger value of standard function of transfer.

In the present study isomeric butanediols plus water systems were investigated using ultrasonic velocity and density measurements to calculate the function of transfer of water between different isomeric butanediols. Transfer functions reflect the differences in the surroundings of the water molecule in the corresponding isomers. Ultrasonic velocity and volumetric properties of isomeric butanediols plus water systems have been deposited.[2]

Experimental

Isomeric butanediols were obtained from Aldrich Chemical Company (>99.5%) and used without further purification. The water was nanopure quality with specific conductivity less than 2 μS cm^{-1}.

Densities of butanediol solutions were measured at five different temperatures (298–318 K) using an Anton–Paar DMA 45 vibrating tube digital densimeter operating in a static mode. The measurements obtained are accurate to 5 × 10^{-5} g cm^{-3}. The ultrasonic velocity at three different temperatures were measured at 4 MHz using a Nusonics velocimeter (Mapco model 6080) employing the sing-around technique. Rapid and accurate measurements of sound velocity as a function of butanediol concentration were made by successive additions of a known mass of diol to the thermostated beaker containing a known amount of water. The velocity measurements are accurate to ±0.1 m s^{-1}. The temperature for the density and velocity measurements was controlled to within ±0.001 K by means of a thermostatically control SODEV bath.

Results

The densities and ultrasonic velocities of pure isomers together with the literature values (21–24) are presented in Table 1. Molar volumes (V) of the solution were calculated as follows:

$$[2] \qquad V = \frac{X_1 M_1 + (1 - X_1) M_2}{\rho}$$

© 1998 NRC Canada

Fig. 1. Plot of densities of butanediols as a function of concentration at 298 K.

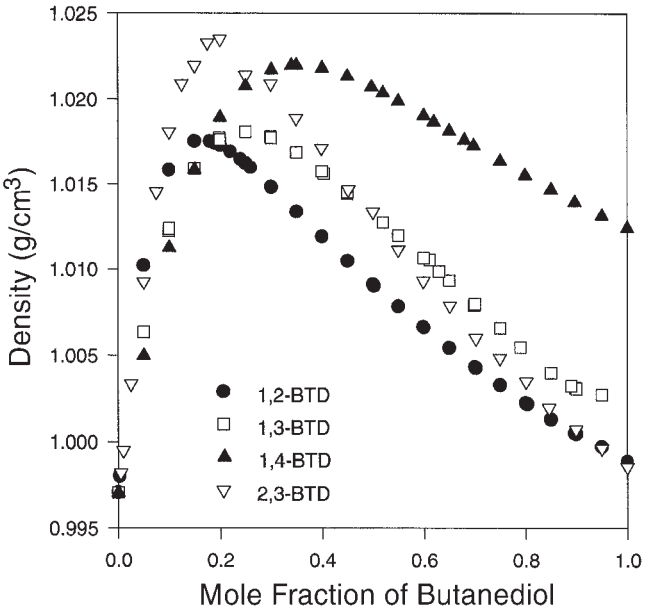

Fig. 2. Plot of adiabatic compressibilities of butanediols as a function of concentration at 298 K.

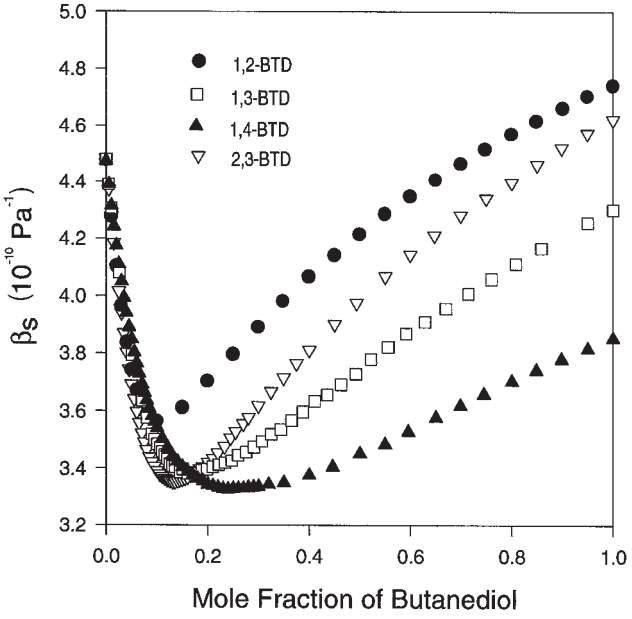

where X_1, M_1, and M_2 are mole fraction of water, molar masses of water and butanediols, respectively, and ρ is the density of the solution. Adiabatic compressibility (β_s) and molar adiabatic compressibility (K_s) were calculated using the following equations.

$$[3] \qquad \beta_s = \frac{1}{U^2\rho}, \qquad K_s = V\beta_s$$

The density and ultrasonic data in the entire composition range was reported in our previous publication (21).

The molar volumes and molar adiabatic compressibilities in the dilute region are fitted to the following equation.

$$[4] \qquad Y = a_o + a_1(1 - X)$$

The values of the coefficient a_o and a_1 were determined by least-squares method:

$$[5] \qquad Y_m = Y - (1 - X_m)\left[\frac{\partial Y}{\partial(1 - X_m)}\right]_{T,P}$$

The partial molar quantities Y_m of the mth component of a binary solution is given by the following, where $m = 1$ or 2, Y is the corresponding molar property, and X_m is the mole fraction of the mth component. From eqs. [4] and [5], one can deduce that the partial molar quantity of water at infinite dilution in the solution of butanediol is equal to the value of a_o. The partial molar quantities of water at 298, 308, and 318 K were determined at a concentration of water <0.1 and are presented in Table 2. The values of transfer functions of water $V^{m\rightarrow n}$ and $K_s^{m\rightarrow n}$ between binary isomeric butanediols were calculated from eq. [1] and presented in Table 3.

Densities and adiabatic compressibilities (β_s) at 298 K of binary aqueous mixtures of isomeric butanediols as function of composition are presented in Figs. 1 and 2, respectively. The adiabatic compressibility isotherms in the dilute aqueous solution are presented in Fig. 3. The intersection point in these isotherms was taken as the composition of quasi clathrate formation in these systems. The compositions along with the composition of density maxima and adiabatic minima are presented in Table 4.

Discussion

Transfer functions

The partial molar volumes of water at infinite dilution are smaller than the corresponding molar volume V^o values. The observation is consistent with the idea that the molar volume of pure water is a result of the sum of actual molecular volume plus empty volume that arises from the hydrogen-bonded open structure of liquid water.

Examination of Table 3 indicates that the standard transfer function of volume for water molecules from 1,2 BTD to 1,3, 1,4, and 2,3 BTD is accompanied by larger volume effects compared to the transfer of water from 1,3 to 1,4 and 2,3 or 1,4 to 2,3. The smaller values of volume for the transfer of water in 1,3, 1,4, and 2,3 indicate that the surroundings of water in these three systems are very similar at infinite dilution compared to 1,2 BTD.

The values of partial molar adiabatic compressibilities at infinite dilution are negative in all cases, indicative that water molecules are likely to fill in the intermolecular free spaces in liquid BTD or from hydrogen bonds with the neighbouring diol molecules. Both these effects will result in a decrease in the structural compressibility resulting in negative K_s. The transfer function of molar compressibilities also indicate that the nature of water in 1,3, 1,4, and 2,3 BTD is very similar and different in 1,2 BTD. Ultrasonic relaxation, calorimetric (26–28) surface tension (29), and also a complete analysis of acoustic and volumetric properties in the entire concentration range (21), indicate that 1,2 BTD molecules are more hydrophobic compared to the other isometric butanediols and differ in terms of interactions with water.

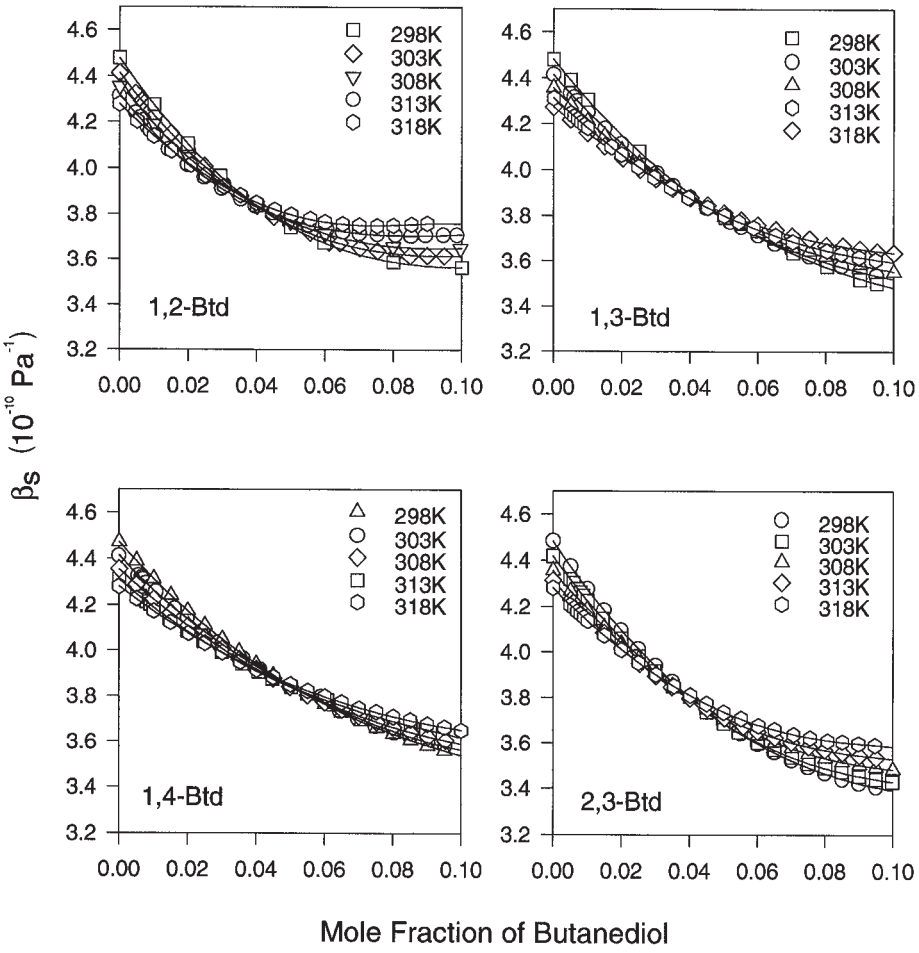
Fig. 3. Adiabatic isotherms of butanediols as a function of concentration.



Clathrate formation

Many dilute aqueous solutions of nonelectrolyte exhibited a common intersection point in adiabatic isotherms, and this phenomenon is attributed to the formation of clathrate-like structures in liquid water–organic systems. Endo (11) attributed the concentration of the zero temperature coefficient of adiabatic compressibility ($\partial\beta/\partial T$) = 0 to the composition of liquid clathrate-like hydrate, since the instantaneous compressibilities (β_∞), due to compression of molecules, intermolecular distances, as well as the structural compressibilities (β_{ST}) due to breakdown of intermolecular bonds, become simultaneously temperature independent. According to Endo (11), the cross-point concentration of solution structure corresponds either to a solid clathrate structure (**1** or **11**) or consists of polyhedra occupied by a solute molecule, and the polyhedra freely floating in water is not involved in the clathrate formation. In the present study based on the hydration numbers calculated from cross-point compositions, one can conclude that these clathrate can be viewed as clathrate **11** structure, with the larger voids (14-hedra) occupied by 1,3 and 1,4 BTD and 12-hedra occupied by 1,2 and 2,3 BTD molecules. The smaller voids are occupied by nonbonded water molecules. The stoichiometry of the clathrate-like structure formed in the solution may not correspond to the concentration of the intersection point. This can be attributed to a shift in the concentration at which $\partial\beta/\partial T = 0$ to higher value than true clathrate composition, due to the incomplete occupancy of the available empty spaces. Also, the approximation $\partial\beta/\partial T \approx \partial\beta_{ST}/\partial T$ is only applicable if $\partial\beta_\infty/\partial T \approx 0$ in the temperature range investigated.

Table 4. Concentrations of intersection points of the compressibility isotherms (X_c), compressibility minima (X_{min}), density maxima (X_{max}), and composition of the corresponding hydrates.

		X_{min}			X_{max}		
System	X_c	298 K	308 K	318 K	298 K	308 K	318 K

Conclusions

The model of aqueous solution of isomeric butanediols can be

© 1998 NRC Canada

represented as the formation of clathrate structure of type **11** arising due to hydrophobic hydration. At a higher concentration these structures gradually decay with increase in BTD content. The hydrophobic hydration is also accompanied by hydrophilic interactions through hydrogen bonding. The nature of water at infinite dilution is very similar in 1,3, 1,4, and 2,3 and different in 1,2 BTD and can be attributed to the more hydrophobic nature of 1,2 BTD compared to the other isomers of butanediols.

New heterocycles from thienopyridocinnolines

M.Z.A. Badr, A.A. Geies, M.S. Abbady, and A.A. Dahy

Abstract: 3-Cyano-4-(*p*-tolyl)pyrido[3,2-*c*]cinnolin-2(1*H*) thione **3** was reacted with α-halo ketones, esters, or amides to give the intermediates, S-alkylated products **5b**–**h**, respectively, which underwent intramolecular ring closure reactions with ethanolic sodium ethoxide to give thienopyridocinnolines **6a**–**h**. Pyrimidothienopyridocinnolines **9** and **11** were obtained by treatment of oxazino compound **8** with hydrazine hydrate and ammonium acetate. Treatment of hydrazino derivative **13** with acetylacetone, triethylorthoformate, carbon disulphide, ethyl chloroformate, and acetic anhydride afforded triazolopyrimidothienopyridocinnolines **14**–**16, 18,** and **21,** while with nitrous acid the corresponding tetrazolo compound **19** was produced.

Key words: thienopyridocinnolines; their pyrimido, triazolopyrimido, and heteroannelated systems.

Résumé : La 3-cyano-4-(*p*-tolyl)pyrido[3,2-*c*]cinnolin-2(1*H*) thione (**3**) réagit avec les α-halogéno cétones, esters ou amides pour conduire respectivement aux produits S-alkylés intermédiaires **5b**–**h** qui, sous l'influence de l'éthylate de sodium en solution dans l'éthanol, subissent des réactions de fermetures de cycle intramoléculaires fournissant les thiénopyridocinnolines **6a**–**h**. On a obtenu les pyrimidothiénopyridocinnolines **9** et **11** par traitement du composé oxazine **8** avec de l'hydrate d'hydrazine et de l'acétate d'ammonium. Le traitement du dérivé hydrazino **13** par de l'acétylacétone, de l'orthoformate d'éthyle, du disulfure de carbone, du chloroformate d'éthyle et de l'anhydride acétique conduit aux triazolopyrimidothiénopyridocinnolines **14**–**16, 18** et **21** alors que sa réaction avec l'acide nitreux conduit à la formation du composé tétrazolo correspondant **19**.

Mots clés : thiénopyridocinnolines; systèmes pyrimido, triazolopyrimido et hétérocycliques correspondants.

[Traduit par la rédaction]

Introduction

Cinnoline derivatives have been reported to constitute an important class of biologically active reagents (1). They have shown antibacterial (2), antifungal (3), and other microbicide (4) activities. Similarly, thienocinnolines and other derivatives have shown various pharmacological activities, such as acting as antihypertensive agents (5), bronchodilators (6), antioxylate drugs to improve brain functions (7), and immunostimulants (8), together with many other activities reported in the literature (9).

Results and discussion

As a continuation of our studies on the synthesis and chemistry of different new heteroannelated ring systems related to phthalazines, quinoxalines, pyrimidines, and other systems (10), we report in the present paper the synthesis and chemistry of a novel series of linear and angular tetra-, penta-, and hexaheterocyclic ring systems based on the cinnoline moiety. An approach to ring closure reactions leading to target compounds started from 4-amino-3-(*p*-methylbenzoylcinnoline **1** (11), which reacted with ethyl cyanoacetate and ammonium acetate to produce 3-cyano-4-(*p*-tolyl)pyrido[3,2-*c*]cinnolin-2(1*H*)-one **2**, which in turn, on refluxing with phosphorus pentasulphide in dry pyridine, gave the corresponding-2(1*H*)thione derivative **3**. Alkylation of **3** with alkyl (benzyl)halides or ethyl chloroformate in the presence of anhydrous sodium acetate gave the corresponding 2-alkylthio compounds **4a**–**d** (Scheme 1).

Similarly, treatment of **3** with α-halo ketones, esters, and (or) acylamides or acetanilides in basic medium gave the corresponding 2-substituted thio compounds **5b**–**h**, which in turn, as active starting materials, underwent nucleophilic ring closure reactions when treated with ethanolic sodium ethoxide solution to produce a new series of tetracyclic substituted thieno[3′,2′:5,6]pyrido[3,2-*c*]cinnolines **6b**–**h**. The corresponding **6**a isomer was produced directly from treatment of **3** with α-chloroacetone without separation of the acyclic alkylthio intermediate **5a**. 3-Amino-2-ethoxycarbonyl-4-(*p*-tolyl)thieno[3′,2′:5,6]pyrido[3,2-*c*]cinnoline **6c** was successfully used as a strategic starting material to synthesize the novel pentaheterocyclic target compound **11** together with other analogs **9** and **10** through the intermediate oxazine compound **8**.

Alkaline hydrolysis of 2-ethoxycarbonyl derivative **6c** gave the corresponding 2-carboxylic acid derivative **7**.

Ring closure reactions of the 3-amino-2-carboxylic acid compound **7** by heating with acetic anhydride gave the pentacyclic intermediate oxazino [4″,5″:4′,5′]thieno[3′,2′:5,6]-pyrido[3,2-*c*]cinnolin-11-one **8**. Refluxing of oxazino compound **8** with ammonium acetate in acetic acid produced pyrimido thienopyridocinnolin-11(10*H*)one **11**. Refluxing **8** with hydrazine hydrate in dry pyridine produced the corresponding 10-amino-11(10*H*)pyrimidone **9**, which condensed with aromatic aldehydes to give the corresponding arylideneamine derivatives **10a** and **10b.** Treatment of the 11-pyrimidone

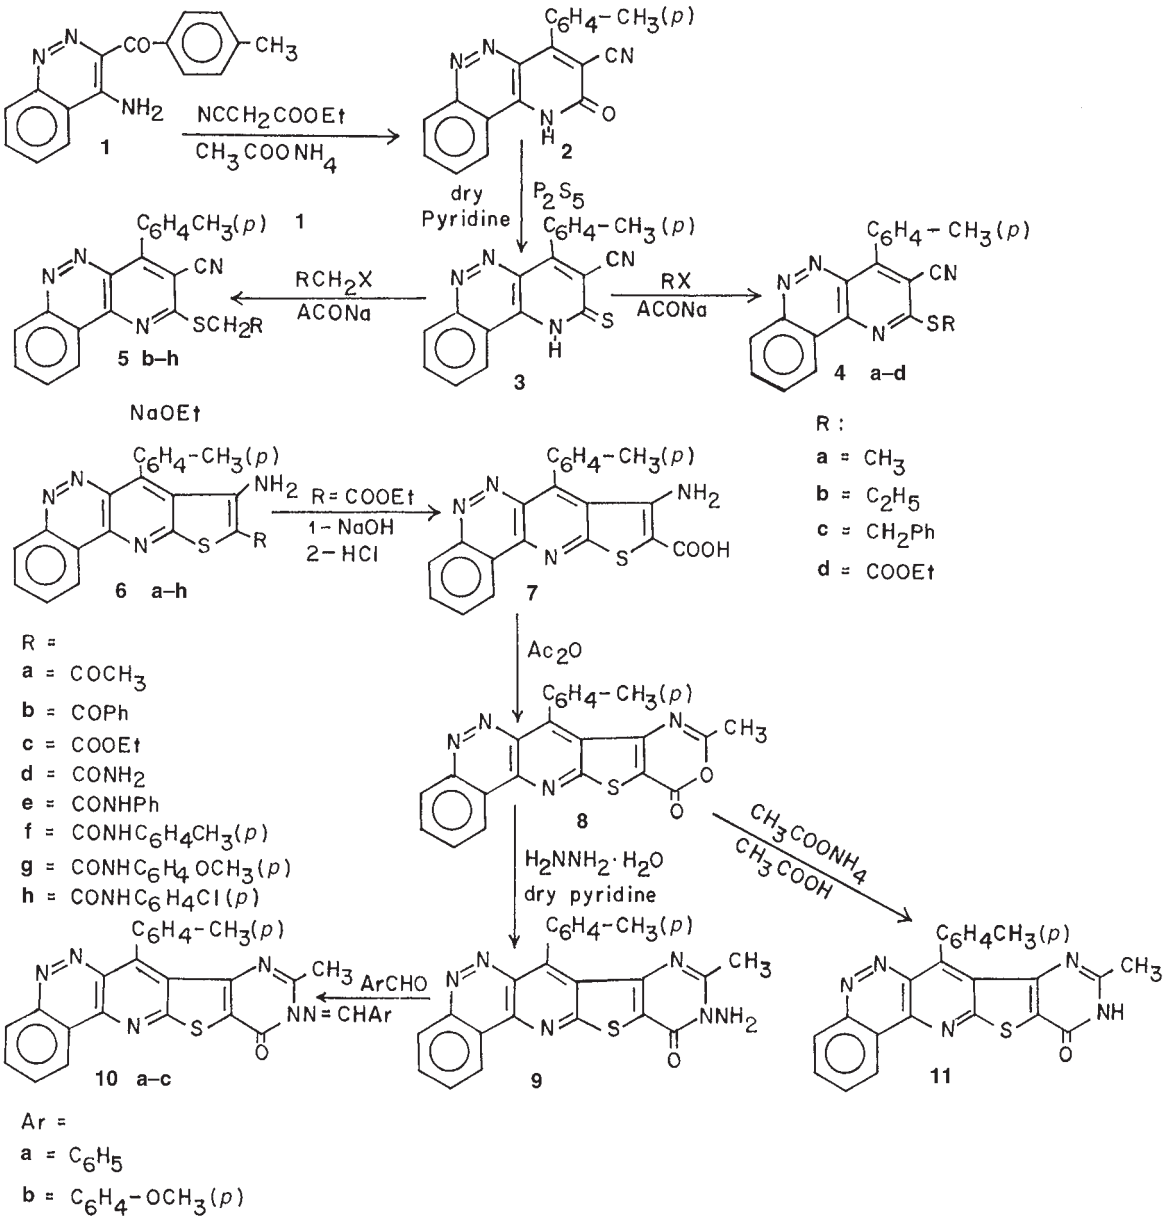
Scheme 1.



11 with phosphorus oxychloride gave the corresponding 11-chloropyrimidine derivative **12** (Scheme 2). The chlorine group of **12** underwent nucleophilic displacement by reflux with hydrazine hydrate in dioxane to produce 11-hydrazinopyrimidothienopyridocinnoline **13**, which condensed with aromatic aldehydes to give the corresponding 11-arylidinehydrazono derivatives **18a** and **18b**. Similarly, heating **13** with acetylacetone produced the corresponding 11-(3,5-dimethylpyrazolyl) derivative **14**.

The hydrazino compound **13** containing an active nitrogen nucleophile was used as strategy material and on treatment with carbonyl, thionyl, or other electrophilic reagents underwent ring closure reactions into a novel series of hexaheterocyclic target compounds. Such reactions favor the existence of the hydrazone tautomer **13** (12).

Treatment of **13** ⇌ **13′** with triethylorthoformate in acetic acid afforded 5-methyl-7-(*p*-tolyl)triazolo[3‴,4‴:1″,6″]-pyrimido[4″,5″:4′5′]thieno[3′,2′:5,6]pyrido[3,2-*c*]-cinnoline **15**. The reaction between **13** and acetic anhydride produced the corresponding 3-methyltriazolo derivative **21**.

The interaction of **13** with carbon disulphide in pyridine produced the triazolopyrimidothienopyridocinnolin-3-thione **16**. The latter interacted with ethyl chloroacetate to give the 3-ethoxycarbonylmethylthio derivative **17**. On the other hand, condensation of **13** with ethyl chloroformate led to the formation of the correspondingtriazolo-3-one compound **20**. The interaction of **13** with sodium nitrite in dilute hydrochloric acid, while cooling, afforded the corresponding tetrazolopyrimidothieno-pyridocinnoline **19**.

Experimental

All melting points are uncorrected and were determined on an electric melting point (Gallenkamp) apparatus. IR spectra were

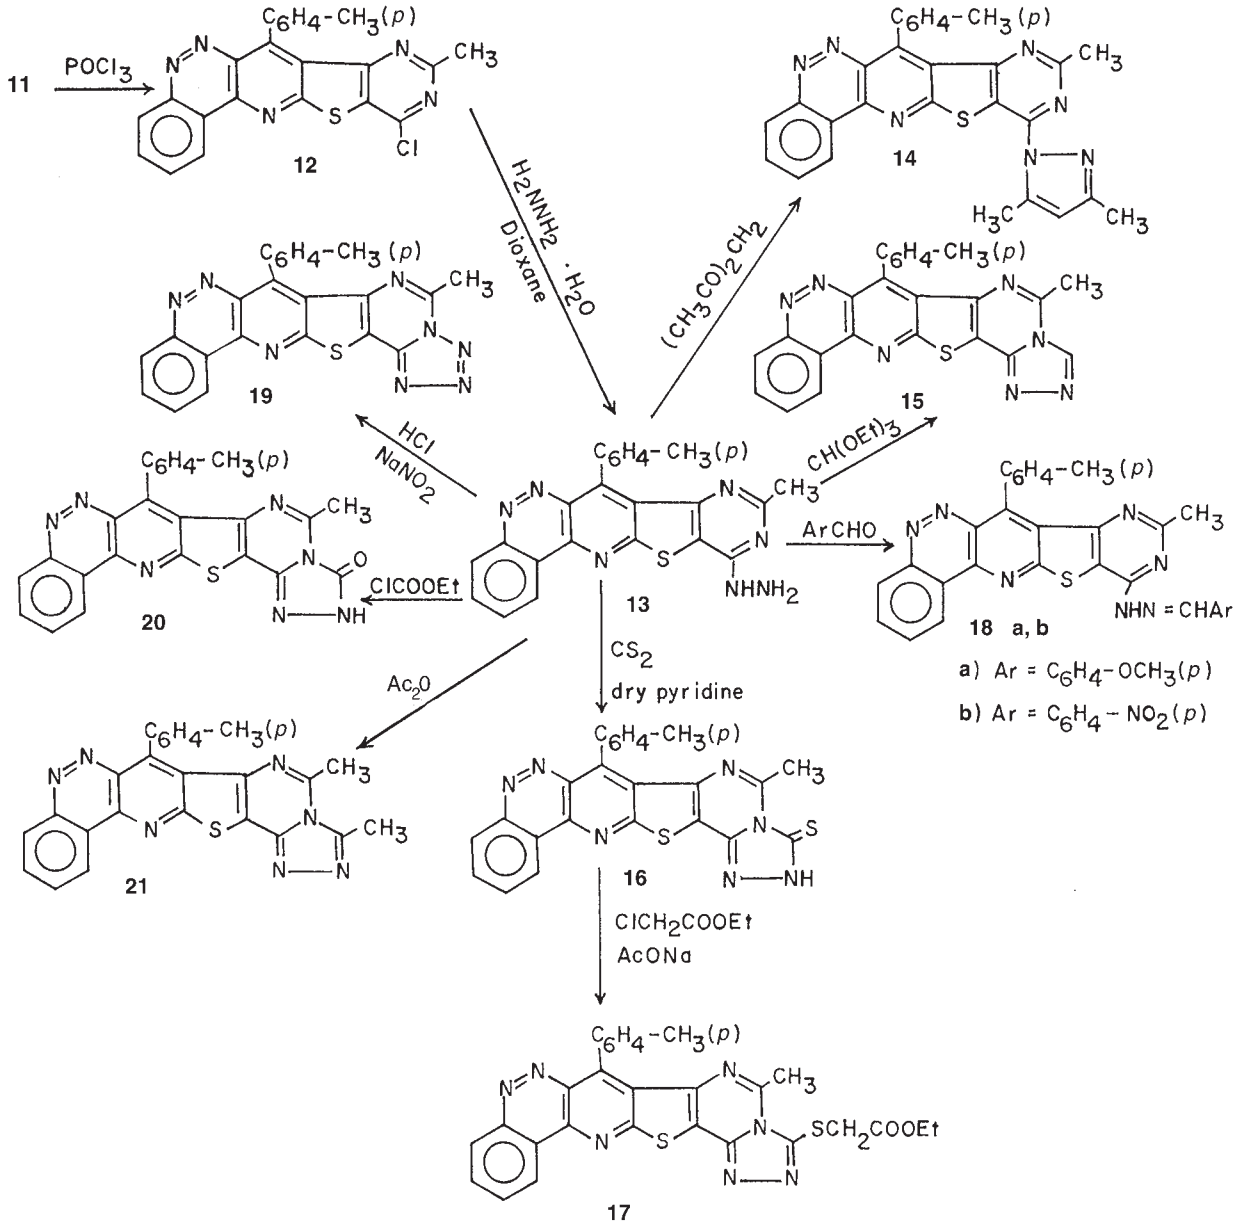
Scheme 2.



determined with a Shimadzu 470 IR spectrophotometer using KBr wafer technique. ^{1}H NMR spectra were recorded on a 90 MHz Varian EM-390 spectrometer in an appropriate solvent ($CDCl_3$, DMSO-d_6, or deuterated trifluoroacetic acid (TFA)) using TMS as internal standard. ^{1}H NMR signals for NH or NH_2 in TFA-*d* solvent were downfield. Chemical shifts are expressed in δ (ppm). Mass spectra were measured on a GC–MS QP 1000 EX spectrometer at an ionizing potential of 70 eV. Elemental analyses were carried out using a 240C Perkin Elmer analyser.

4-Amino-3-(*p*-methyl benzoyl)cinnoline (1)
A mixture of phenylhydrazonomalononitrile (0.1 mol), toluene (150 mL), and aluminium chloride (0.4 mol) was refluxed for 3 h. The separated product was crystallized from ethanol, mp 210°C (lit. (11) mp 210–212°C).

3-Cyano-4-(*p*-tolyl)pyrido[3,2-*c*]cinnolin-2(1*H*)-one (2)
A mixture of 1 (0.1 mol), ethyl cyanoacetate (0.03 mol), and ammonium acetate (0.05 mol) was heated under reflux for 3 h. After cooling, the precipitate was filtered off, washed with boiling ethanol, and recrystallized from dioxane as yellow crystals, mp >360°C, yield 56%. IR: 3100 (NH); 2200 (CN), 1650 (CO) cm^{-1}; ^{1}H NMR (DMSO) δ: 3.50 (s, 3H, CH_3) and 7.2–9.1 (m, 8H, ArH). Anal. calcd. for $C_{19}H_{12}N_4O$: C 73.07, H 3.87, N 17.94; found: C 72.92, H 3.76, N 17.62%.

3-Cyano-4-(*p*-tolyl)pyrido[3,2-*c*]cinnolin-2(1*H*)-thione (3)
A mixture of **2** (0.01 mol) and phosphorus pentasulphide (0.01 mol) in dry pyridine (20 mL) was refluxed for 4 h, then poured into ice-water. The precipitated solid was filtered, washed with water, and recrystallized from dioxane as orange crystals, mp 315–317°C, yield 86%. IR: 3280 (NH), 2200 (CN), 1250

[a] All products were recrystallized from ethanol except **4a** from acetic acid.

(C═S) cm^{-1}.^1H NMR (TFA-*d*) δ: 2.42 (s, 3H, *p*-CH_3) and 7.2–9.4 (m, 8H, ArH). Anal. calcd. for $C_{19}H_{12}N_4S$: C 69.5, H 3.68, N 17.06, S 8.76; found: C 69.65, H 3.80, N 17.12, S 8.68%.

2-Alkyl (aralkyl)thio-3-cyano-4-(*p*-tolyl)pyrido[3,2-*c*]-cinnoline (4a–d)

General procedure

A mixture of **3** (0.01 mol) and alkyl (or benzyl) halide or ethyl chloroformate (0.01mol) was refluxed in ethanol (30 mL) and anhydrous sodium acetate (2 g) for 1 h. The reaction mixture was concentrated to half volume and cooled. The precipitated solid was filtered and recrystallized from an appropriate solvent. The analytical, spectral, and physical data are summarized in Table 1.

3-Cyano-4-(*p*-tolyl)-2-substituted thiopyrido[3,2-*c*]cinnoline (5b–h)

The corresponding α-halo compound was treated with **3** following the same procedure as above. The separated solid was filtered, washed with water, and recrystallized from an appropriate solvent. The analytical, spectral, and physical data are summarized in Table 2.

3-Amino-2-substituted-4-(*p*-tolyl)thieno[3′,2′:5,6]pyrido-[3,2-*c*]cinnoline (6a–h)

General procedure

A mixture of each of the mercapto derivatives (**5b**–**h**) (0.01 mol) in ethanol (50 mL) and five drops of ethanolic sodium ethoxide was refluxed for 30 min. The solid product was filtered and recrystallized from a suitable solvent. **6a** was separated directly on treating α-chloracetone and **3** with anhydrous sodium acetate as above. The analytical, spectral, and physical data are summarized in Table 3.

2-(3-Amino-4-(*p*-tolyl)thieno[3′,2′:5,6]pyrido[3,2-*c*]-cinnolinyl)carboxylic acid (7)

A mixture of **6c** (0.01 mol) and alcoholic sodium ethoxide (30 mL, 25%) was refluxed for 3 h. Sodium salt precipitated and was filtered and acidified in water (200 mL) with dilute HCl. The solid free acid was filtered and recrystallized from acetic acid as yellow crystals, mp 330°C, yield 70%. IR: 3400, 3300 (NH_2) cm^{-1}. ^1H NMR (DMSO) δ: 2.48 (s, 3H, CH_3), 6.55 (s, 2H, NH_2), 10.20 (s, 1H, OH), both of them exchangeable with D_2O, and 7.1–9.2 (m, 8H, ArH). Anal. calcd. for $C_{21}H_{14}N_4O_2S$: C 65.27, H 3.65, N 14.50, S 8.30; found: C 65.31, H 3.87, N 14.06, S 7.97%.

9-Methyl-7-(*p*-tolyl)oxazino[4″,5″:4′,5′]thieno[3′,2′:5,6]-pyrido[3,2-*c*]cinnolin-11-one (8)

A mixture of **7** (0.01 mol) and acetic anhydride (20 mL) was refluxed for 2 h. The solid separated on cooling was filtered and recrystallized from dioxane as yellow crystals, mp 320°C, yield 74%. IR: 1750 (CO) cm^{-1}. ^1H NMR (TFA-*d*) δ: 2.58 (s, 3H, *p*-CH_3), 2.70 (s, 3H, CH_3), 7.4–9.85 (m, 8H, ArH). MS, *m*/*z* (%): 411 (M + 1, 29), 410 (M^+, 100). Anal. calcd. for $C_{23}H_{14}N_4O_2S$: C 67.3, H 3.44, N 13.65, S 7.81; found: C 66.96, H 3.89, N 13.60, S 8.00%.

10-Amino-9-methyl-7-(*p*-tolyl)pyrimido[4″,5″:4′,5′]thieno-[3′,2′:5,6]pyrido[3,2-*c*]-cinnolin-11(10*H*)-one (9)

A mixture of the oxazino compound **8** (0.01 mol) and hydrazine hydrate (0.01 mol) in dry pyridine (30 mL) was refluxed for 1 h. The solid separated on cooling was filtered and recrystallized from dioxane into yellow crystals, mp >360°C, yield 82%. IR: 3402, 3300 (NH_2), 1660 (CO) cm^{-1}. ^1H NMR (TFA-*d*) δ: 2.90 (s, 3H, *p*-CH_3), 3.18 (s, 3H, CH_3), 7.65–9.95 (m, 8H, ArH). Anal. calcd. for $C_{23}H_{16}N_6OS$: C 65.08, H 3.80, N 19.80, S 7.55; found: C 64.90, H 4.00, N 19.32, S 7.23%.

10-Arylidene amine derivatives of 9 (10a and 10b)

These were prepared by refluxing **9** (0.01 mol) with each of (*a*) benzaldehyde and (*b*) *p*-anisaldehyde (0.01 mol) in glacial acetic acid (20 mL) for 30 min. The solid product in each case

11-Chloro-9-methyl-7-(*p*-tolyl)pyrimido[4″,5″:4′,5′]thieno-[3′,2′:5,6] pyrido[3,2-*c*]-cinnoline (12)

The pyrimidinone **11** (0.01 mol) in phosphorus oxychloide (40 mL) was refluxed for 4 h. The cooled mixture was stirred in ice-water for 30 min. The solid product was filtered, washed with water, and recrystallized from dioxane as yellow crystals, mp 283°C, yield 68%. IR: both NH and CO absorptions disappeared. ^1H NMR (TFA-*d*) δ: 2.60 (s, 3H, *p*-CH_3), 2.85 (s, 3H, CH_3), 7.55–9.8 (m, 8H, ArH). Anal. calcd. for $C_{23}H_{14}N_5SCl$: C 64.56, H 3.30, N 16.37, S 7.49, Cl 8.29; found: C 64.50, H 3.60, N 16.02, S 7.60, Cl 8.58%.

11-Hydrazino-9-methyl-7-(*p*-tolyl)pyrimido[4″,5″:4′,5′]-thieno[3′,2′:5.6]pyrido[3.2-*c*]-cinnoline (13)

The chloro compound **12** (0.01 mol) and hydrazine hydrate (0.01 mol) in dioxane (30 mL) were refluxed for 30 min. The separated solid was filtered and recrystallized from dioxane as yellow crystals, mp 300°C, yield 85%. IR: 3350 (NH_2), 3200 (NH) cm^{-1}; ^1H NMR (TFA-*d*) δ: 2.69 (s, 3H, *p*-CH_3), 2.73 (s, 3H, CH_3), 7.6–9.9 (m, 8H, ArH). Generalized valence bond study of rotational singlet structures and π bond energies for systems containing C═C, Si═Si, and C═Si double bonds

Youliang Wang and Raymond A. Poirier

Abstract: Ab initio GVB(6/12)/6-31G** calculations were performed on $A_2X{=}YB_2$ (A, B = H, F; X, Y = C, Si) to obtain the optimized geometries for planar and twisted singlet structures, and to also calculate π bond energies (rotational barriers). The nature of C—C, Si—Si, and C—Si π bonds has been investigated. The results show that the C–C π bond energy (E_π(ethene) = 65.4 kcal/mol) decreases with increasing fluorine substitution. The pyramidalization at the carbon or silicon center for the twisted structures decreases the π bond energies in the substituted ethenes and their silicon counterparts. The Si—Si (E_π(disilene) = 23.2 kcal/mol) and C—Si (E_π(silaethene) = 31.6 kcal/mol) π bonds become much weaker. Fluorine substitution stabilizes both the diradical and the dipolar twisted singlet structures.

Key words: π bond energy, ab initio calculations, generalized valence bond, fluorine substitution, disilene, and silaethene.

Résumé : On a effectué des calculs ab initio au niveau GVB(6/12)/6-31G** sur des molécules du type $A_2X{=}YB_2$ (A, B = H, F; X, Y = C, Si) dans le but d'obtenir des géométries optimisées pour les structures singulets planes et déformées ainsi que pour calculer les énergies de liaison π (barrières rotationnelles). On a étudié la nature des liaisons π dans C—C, Si—Si et C—Si. Les résultats montrent que l'énergie de liaison π dans C–C (E_π(éthène) = 65,4 kcal/mol) diminue lorsqu'on augmente le nombre d'atomes de fluor comme substituants. La pyramidalisation au niveau des atomes de carbone ou de silicium pour les structures déformées diminue les énergies des liaisons π dans les éthènes substitués ainsi que dans leurs équivalents contenant du silicium. Les liaisons π dans Si—Si (E_π(disilène) = 23,2 kcal/mol) et dans C—Si (E_π(silaéthène) = 31,6 kcal/mol) deviennent beaucoup plus faibles. Une substitution par le fluor stabilise les structures tant diradicalaire que singulet déformée dipolaire.

Mots clés : énergie de liaison π, calculs ab initio, liaison de valence généralisée, substitution par le fluor, disilène, silaéthène.

[Traduit par la rédaction]

1. Introduction

Double-bond energies are often divided into σ and π contributions, but these are not directly observable quantities. Ab initio molecular orbital theory affords an excellent way to assess these components. There are two ways to obtain the π bond energies. The first procedure is to compare the bond dissociation energies of double bonds, D_e(X═Y), and single bonds, D_e(X—Y). However, the energy difference between them, D_e(X═Y) – D_e(X—Y), does not correspond to the barrier to rotation about the X═Y bond. For example, the experimental data (1) for ethene are 173.3 and 86.1 kcal/mol for D_e(X═Y) and D_e(X—Y), respectively. The difference, 87.2 kcal/mol, is far greater than the rotational barrier (65 kcal/mol) (2). Obviously, the directly deduced quantity from D_e(X═Y) – D_e(X—Y) is not the π bond energy in ethene. Schleyer and Kost (3) used isogyric reactions,

$$H_2X{=}YH_n + XH_4 + YH_{n+2} \rightarrow 2H_3X{-}YH_{n+1}$$

to compare the energies of X═Y double bonds with those of X—Y single bonds. For ethene, a π bond energy (E_π) of 69.6 kcal/mol was obtained at MP4/6-31G*//6-31G*+ZPE. Meanwhile, Schmidt et al. (4) used hydrogenation thermochemical cycles to give similar results, e.g., E_π(ethene) = 62 kcal/mol. However, there are some discrepancies between their calculated π bond energies. For instance, the calculated C═N π bond energy by Schmidt et al. (4) is 65 kcal/mol, compared to 81 kcal/mol obtained by Schleyer and Kost (3). The discrepancies are due to the use of different sets of reference species in the thermochemical cycles.

Another commonly used procedure is to equate the π bond energy with the rotational barrier (2, 4, 5), provided that the transition state has no π bond character while retaining all σ bonds. The transition state, for singlet rotation around a double bond, is the 90° twisted singlet diradical. For this diradical structure, a single determinantal wave function cannot afford

a proper description, and a multiconfiguration calculation must be used. Due to the difficulty in characterizing the twisted singlet transition state, which is very sensitive to the basis set and correlation energy, few efforts have been made to obtain the optimized geometries with extensive basis sets. Schmidt et al. (4) reported MCSCF/6-31G*//3-21G* results of the rotational barrier, or π bond energy, for ethene of 65.4 kcal/mol. Borden and co-workers (6) carried out GVB-PP(1/2)/6-31G* calculations of the rotational barrier in ethene (65.6 kcal/mol) and TCSCF (two configuration SCF) calculations of the rotational barrier in disilene (22.1 kcal/mol). Our preliminary GVB(2/4)/6-31G** calculations (7) gave a proper description of the rotation about the π bond in C_2H_4 and gave a π bond energy of 63.6 kcal/mol.

A number of ab initio (SCF (5, 8), CI (9), MCSCF (4, 6, 10), GVB (7, 11)) calculations have been performed to study the planar singlets and twisted structures triplets for ethene, silaethene, disilene, and their derivatives and isomers. However, the previous calculated geometries for the twisted singlets are far from agreement, due to the difficulty in characterizing the correct transition states, which are very sensitive to the basis set and correlation energy. For example, the MCSCF/3-21G* (4) geometry for the twisted singlet silaethene is very different from MP2/6-31G** (11*c*). As known, the twisted singlet structure is close to the twisted triplet. However, the MCSCF/3-21G* triplet (4) HSiC angle is different from Lischka's result (10*a*), i.e., 119° vs. 111.4°, while the flap angles of SiH_2 and the HCSi bond are very close to each other. The MCSCF/3-21G* and TCSCF/6-31G* (6) structures for twisted singlet disilene are also different in the flap angle of SiH_2, 17.3° vs. 47.6°. The calculated geometrical structure of disilene, especially the trans-bent angle formed by the SiH_2 plane and Si—Si bond, strongly depends on the basis sets and the electron correlation energy (11*b*). Although many studies have been done to investigate fluorine substitution effects on C═C bonding and electronic structures, no transition-state structures of fluorine substituents have been reported.

On the other hand, the early studies (11*c*–*e*) indicated that the nature of C═Si bond in silaethene is similar to that of C═C bond in ethene from their GVB orbital analysis. This may be true in the planar structure. However, the π bond energy is not only related to the planar structure, but more importantly to the transition-state structure. Most of the other experimental (12) and theoretical studies (3–5, 10*b*, 13) give a C═Si π bond energy of ~40 kcal/mol, which is only a fraction of the value in ethene.

Our objective of this study is to characterize the correct transition state for singlet rotation around the C═C, C═Si, and Si═Si double bonds. By employing GVB calculations, the π bond energies and the fluorine substitution effects are further studied.

2. Computational details

In this study, GVB(6/12)/6-31G** calculations were carried out for $A_2X{=}YB_2$ (A, B = H, F; X, Y = C, Si). The GVB(6/12) wave function includes two X—A bonds, two B—Y bonds, one X—Y σ, and one X—Y π bond, i.e.,

$$[1]\quad \Psi^{GVB}_{A_2X=YB_2} = A[\Psi_{core}\Psi_{X-Y(\sigma)}\Psi_{X-Y(\pi)}\Psi_{X-A1}\Psi_{X-A2}\Psi_{Y-B1}\Psi_{Y-B2}]$$

The planar or trans-bent structures of $A_2X{=}YB_2$ were optimized with the Davidon's optimally conditioned method (14). The singlet transition-state structures were optimized with a minimization of sum-of-squares method.[3] All equilibrium structures were characterized to have no imaginary frequency, while the transition states have only one imaginary frequency. In the transition state, the GVB CI-coefficients for π orbitals are 0.707 ± 0.005.

When a doubly bonded $A_2X{=}YB_2$ molecule is rotated by 90° to the diradical transition state, the X—Y π bond is broken while retaining all σ bonds. The barrier to X═Y double-bond rotation can be defined as the π bond energy, E_π. The π bond energies reported here are not corrected for zero-point energy (ZPE).[4]

All calculations are carried out with the GVB program in the MUNGAUSS ab initio package (15),[5] which is written using the OSIPE (open structured interfaceable programming environment) tools and automatically generates reliable initial GVB orbitals leading to the proper and fast energy convergence (7).The OSIPE is an "object-oriented" approach to programming in which objects are computed dynamically.

3. Results and discussion

The computed GVB total energies for ground states and transition states, and rotational barriers are summarized in Table 1. The optimized geometrical parameters are given in Tables 2 and 3 for reactants and transition states, respectively. The results of X–Y bond order and Mulliken charges on X and Y are also listed in Table 4. The transition-state structures for ethene, silaethene, and disilene are illustrated in Fig. 1.

3.1 The C═C bond

The C═C π bond in ethene is probably the best characterized π bond, both experimentally and theoretically. A number of theoretical papers (4, 11*a*, 16) have indicated that the triplet state and the rotated singlet state (which is usually referred to as the N state) represent a violation of Hund's rule. In accordance with Hund's rule, the two unpaired π electrons should give the triplet ground state. The GVB treatments (11*a*), along with MCSCF (4), CI (16), UHF (5), predict that the lowest energy rotation path on the singlet N state potential-energy surface is entirely below the triplet surface, for ethene. In the other $A_2X{=}YB_2$ (A, B = H, F; X, Y = C, Si), the 90° twisted triplet is about 1–3 kcal/mol lower than the rotated singlets, with geometries similar to their singlets. The rotated singlets are considered as the transition states for X═Y double bond rotation in this study.

(i) Optimized geometries

For planar $H_2C{=}CH_2$, $H_2C{=}CF_2$, and $F_2C{=}CF_2$, the GVB geometries are very close to the CISD (8*d*) and MCSCF (4)

results. The C=C and C—F bond lengths decrease with increasing fluorine substitution, as observed from early Hartree–Fock calculations (8*d*).

The twisted structure of ethene is illustrated in Fig. 1*a*. For twisted $H_2C{=}CH_2$, $H_2C{=}CF_2$, and $F_2C{=}CF_2$, the GVB C—C bond lengths are 1.492, 1.490, and 1.501 Å, respectively, which are very close to Schaefer's CI C—C bond length of 1.494 Å for $H_2C{=}CH_2$ (9*a*). The C—C bond length in the twisted structure is close to the single C—C bond length of 1.531 Å in C_2H_6, obtained at full valence GVB/6-31G** (17).

The F-C-C bond angle (θ_2 in Tables 2 and 3) clearly shows that the bond at which substitution occurs (CF_2) is changed from a planar (sp^2 hybridization, ~120°) conformation to a tetrahedral (sp^3 hybridization, ~113°) conformation, indicating the pyramidalization at CF_2 in the twisted structure.

(ii) C–C π bond energies

Our GVB/6-31G** results of C–C π bond energies (E_π) are in very good agreement with the previous ab initio calculations and the available experimental results. For instance, E_π(ethene) is 65.4 kcal/mol, compared to 67.9 (Schaefer's CI (9*a*)), 65.4 (MCSCF (4)), 65.6 (GVB(1/2) (18)), and 64 kcal/mol (experiment (2)). The E_π of fluoroethene contains a contribution from pyramidalization of the CF_2 radical center. The intrinsic π bond energy is the calculated result without the pyramidalization. Constraining the CF_2 radical center to planarity in the 1,1-difluoroethene diradical results in a E_π that is higher than E_π(ethene) by 11.5 kcal/mol. The actual E_π is, however, obtained from the transition state in which pyramidalization is allowed and is lower than E_π(ethene) by 2.2 kcal/mol. Therefore, the pyramidalization at the carbon or silicon center from sp^2(120°) to sp^3(109.5°) stabilizes the diradical transition state. The value of E_π is related to the B-Y-X bond angle in the transition state, i.e., θ_2 in Table 3. For example, the θ_2 values are 121.1°, 115.2°, 113.9° for $CH_2{=}CH_2$, $CH_2{=}CF_2$, and $CF_2{=}CF_2$, respectively. Their differences from 109.5° are 10.6°, 5.7°, and 4.4°, which correlates well with the calculated E_π values of 65.4, 63.2, and 51.7 kcal/mol, respectively. With two carbon centers pyramidalized, the rotational barrier in tetrafluoroethene is much lower. The C–C π bond energy decreases with increase fluorine substitution.

For the isodesmic reaction,

$$CH_2{=}CH_2 + CF_2{=}CF_2 \rightarrow 2CH_2{=}CF_2$$

the calculated GVB reaction energy (ΔE) of –16.5 kcal/mol is in excellent agreement with the experimental value of –14.6 kcal/mol (18) of which –9.3 kcal/mol can be attributed to differences in the π bond energies. The exothermicity of this reaction can be attributed to the replacement of the homopolar σ and π C—C bonds in ethene and tetrafluoroethene with the heteropolar σ and π C—C bonds in 1,1-difluoroethene.

The C–C bond orders clearly show that the π bond is totally broken in the twisted structures, with the C–C bond order of -0.9. The C–C bond orders are 1.778, 1.738, and 1.670 for planar $CH_2{=}CH_2$, $CH_2{=}CF_2$, $CF_2{=}CF_2$, respectively, decreasing with increasing fluorine substitution. The differences in the C–C bond order between planar and transition-state

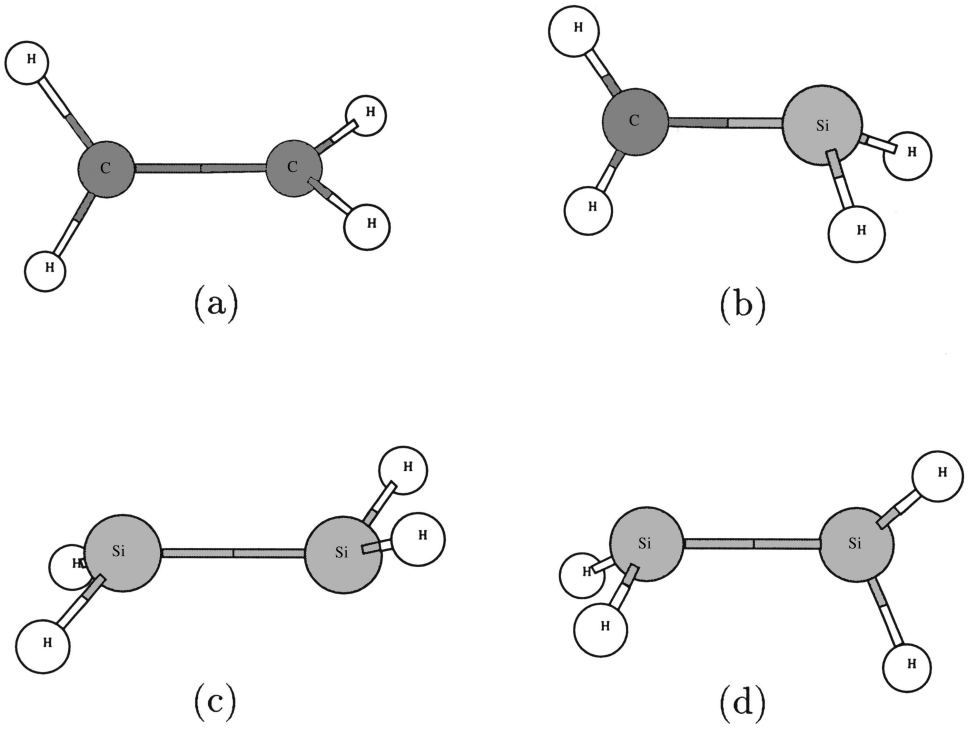
Fig. 1. The structure of $A_2X{=}YB_2$ planar and perpendicular conformation. (*a*) twisted C_2H_4; (*b*) twisted $CH_2{=}SiH_4$; (*c*) trans-bent Si_2H_4; (*d*) twisted Si_2H_4.



structures (0.812, 0.788, and 0.767, respectively), are the measure of π bond order and are related to the π bond energies. Overall, the C–C π bond energy decreases with increasing fluorine substitution, due to the strong pyramidalization of CF_2 in the twisted structures.

3.2 The C═Si bond

Silaethenes have long been implicated as reactive intermediates. 1,1-Dimethylsilaethene (DMSE) is the simplest silaethene that has been detected in the gas phase. Shin et al. (11*c*) experimentally found that silaethene is more stable than methylsilylene by 10 ± 3 kcal/mol, which is corroborated by GVB calculations. Their experimentally estimated π bond energy is 34 ± 4 kcal/mol for silaethene, which is less than the earlier estimate of 41 ± 5 kcal/mol for DMSE (12). However, their GVB calculations predicted a much higher value of 59.9 kcal/mol, since they did not allow for pyramidalization at the Si center in the twisted structure and the barrier was incorrectly calculated for a rotation from a planar singlet (two pairs GVB) to a twisted triplet (one pair GVB). The correct C–Si π bond energy can be equated to the barrier calculated by a consistent wave function for a rotation from a planar singlet to a twisted singlet with pyramidalization at the Si atom.

(i) Optimized geometries

For silaethene $H_2C{=}SiH_2$, the GVB C—Si distance is 1.734 Å, compared to 1.743 Å for MCSCF/3-21G* (4). These values are in reasonable agreement with experimental C—Si bond lengths of complex silaethenes 1.747 Å (19) and 1.702 Å (20). For planar (C_{2v}) $F_2C{=}SiH_2$ and $H_2C{=}SiF_2$, the GVB C—Si bond lengths are 1.749 and 1.688 Å, respectively. For twisted (C_s) structure, the GVB C—Si bond lengths are 1.884, 1.912, and 1.858 Å for $H_2C{=}SiH_2$, $F_2C{=}SiH_2$, and $H_2C{=}SiF_2$, respectively. From our GVB results, it can be found that a very short C—Si double bond in $H_2C{=}SiF_2$ is due to the strong dipolar (ionic) interaction between C and Si. The C—Si bond in the twisted structure is still a short single bond.

In the twisted singlet silaethene as shown in Fig. 1*b*, our GVB calculated H-Si-C bond angle (θ_2 in Table 3) is 112.1°, which is in good agreement with the H-Si-Si, H-Si-N, H-Si-P bond angle of ~110° reported by the previous MCSCF/3-21G* calculations (4). It is also in good agreement with the H-Si-C bond angle (111.4°) in the triplet structure reported by others (10*a*), supporting that the twisted singlet and triplet structures are similar. The flap angle for Si═Si transition state was incorrectly reported to be 17.6° in ref. 4. The correct value is 45.5°.

(ii) C–Si π bond energies

Our GVB calculations give a C═Si π bond energy (without pyramidalization at silicon) of 40.7 kcal/mol. Pyramidalization of the silicon center from sp^2 to sp^3 stabilizes the diradical transition state and decreases the π bond energy. Our GVB(6/12)/6-31G** E_π(silaethene) is 31.6 kcal/mol, which is close to the experimental result of 34 ± 4 kcal/mol (11*c*) and the MCSCF/6-31G*//3-21G* result of 35.6 kcal/mol (4). The E_π(silaethene) is less than the experimental estimate of 41 ± 5 kcal/mol for 1,1-dimethyl-silaethene (12). As mentioned before, the previous GVB result of 59.9 kcal/mol (11*c*) is too high, because the geometries were constrained in the twisted conformation.

The $H_2C{=}SiF_2$ bond is more stable than the $F_2C{=}SiH_2$ bond with a larger C–Si bond order in the planar structure. This large C–Si bond order is from the strong ionic interaction, so

© 1998 NRC Canada

that the bond order difference (0.89) between the transition state and the planar structure is larger than the actual C–Si π bond order. In general, the closer θ_2 is to 109.5° (sp^3) in the transition state, the smaller the π bond energy. Because of pyramidalization at silicon, the GVB H(F)-Si-C bond angles (θ_2 in Table 3) in the transition states are 112.1°, 110.8°, and 109.7° for silaethene, 2,2-difluorosilaethene, and 1,1-difluorosilaethene, respectively. Their deviations from 109.5° are 2.6°, 1.3°, and 0.2°, which correlate well with the π bond energies of 31.6, 24.6, and 21.3 kcal/mol.

In general, the pyramidalization at carbon or silicon will decrease the energy of the transition state more than that of the reactant, thus decreasing the rotational barrier. In contrast to the early suggestion (11*c–e*) that the nature of C═Si bond in silaethene is similar to that of the C═C bond in ethene, our GVB results clearly show that the C—Si π bond is very different from C—C π bond and much weaker.

3.3 The Si═Si bond

Because disilene Si_2H_4 is the simplest species with a Si—Si double bond, and its ground state shows an unusual preference for a trans-bent C_{2h} structure rather than a planar D_{2h} structure, it has been the subject of much interest experimentally and theoretically, since the isolation of tetramesityldisilene in 1981 (4, 6, 8*a,* b, 10*a*, 11*b*).

(i) Optimized geometries

The trans-bent singlet disilene, as shown in Fig. 1*c*, is more stable than the planar structure. Our GVB equilibrium geometry is very close to TCSCF/6-31G* result (6). For $H_2Si{=}SiH_2$ (C_{2h} for trans-bent structure), the Si—Si bond distance is 2.240 Å, compared to 2.160 Å (experimental observation for tetramesityldisilene (21)), 2.217 Å (MCSCF/3-21G* (4)), 2.242 Å (TCSCF/6-31G* (6)), 2.248 Å (GVB(2/4)/6-31G** (8*b*)), and 2.236 Å (CASSCF/6-31G** (8*b*)). Such a long bond length reflects the diradical character of the Si—Si bond, even though it is still shorter than that of the single bond. However, some double-bond character exists in disilene (C_{2h}) as illustrated by the Si–Si bond order of 1.380. For the twisted (C_{2h}) structure as shown in Fig. 1*d*, the Si—Si bond distance is 2.358 Å, compared to 2.351 Å (TCSCF/6-31G*), 2.355 Å (MCSCF/3-21G*), which is a single bond with a bond order of 0.863.

(ii) Si–Si π bond energies

The energetics of disilene are significantly affected by the incorporation of the electron correlation corrections. The calculated GVB barrier to rotation is 23.2 kcal/mol, which is close to 22.1 (TCSCF/6-31G* (6)), 22.7 (MCSCF/6-31G*//3-21G* (4)), and 25.0 kcal/mol (CISD/DZP (6)). The small Si–Si π bond energy is consistent with the Si–Si bond order of 1.380 in the trans-bent structure, and the difference of the Si–Si bond order between the trans-bent and twisted structures is 0.517, which is considered as the Si–Si π bond order. It is noticed that the rotation increases the positive charge at silicon in disilene, which increases the negative charge at carbon in ethene. The pyramidalization at silicon will decrease the energy of the transition state more than that of the reactant, thus decreasing the rotational barrier. The E_π(disilene) is much weaker than E_π(ethene).

For the following reaction:

$$H_2C{=}CH_2 + H_2Si{=}SiH_2 \rightarrow 2H_2C{=}SiH_2$$

the GVB reaction energy (ΔE) is 21.8 kcal/mol of which 25.4 kcal/mol can be attributed to differences in the π bond energies. For

$$H_2Si{=}SiH_2 + F_2C{=}CF_2 \rightarrow 2F_2C{=}SiH_2$$

the GVB reaction energy (ΔE) is 28.9 kcal/mol of which 25.7 kcal/mol can be attributed to differences in the π bond energies. The results show that the π bond change is the dominant contribution to the total enthalpy change in the above reactions. However, these two reactions are endothermic rather than exothermic. Because the C—C π bond is much stronger than the C—Si π bond, the breaking of C═C and Si═Si bonds to form C═Si bonds is not favoured energetically.

Conclusions

The GVB(6/12)/6-31G** study on the singlet state rotation around the double bond of $A_2X{=}YB_2$ (X, Y = C, Si and A, B = H, F), gives the twisted singlet structures and π bond energies. The X—Y π bond is essentially broken in the transition state while retaining all σ bonds. Our GVB results of C–C π bond energies (E_π(ethene) = 65.4 kcal/mol) are in very good agreement with the previous ab initio calculations and the available experimental results. The results indicate that the C–C bond energy decreases with increasing fluorine substitution. The pyramidalization at carbon or silicon decreases the energy of the transition state more than that of the reactant, thus decreasing the rotational barrier. In general, the pyramidalization at carbon or silicon center from sp^2 to sp^3 stabilizes both diradical and dipolar transition states. The closer θ_2 is to 109.5° in transition state, the smaller the π bond energy for the same type of X–Y bonding. Our GVB results show that the C—Si π bond (E_π(silaethene) = 31.6 kcal/mol) and Si—Si π bond (E_π(disilene) = 23.2 kcal/mol) are much weaker than the C═C bond.

Average energy approximations for anisotropic triple-dipole dispersion energy coefficients using three-body interactions involving O_2, NO, CO, N_2, H_2, and the rare gases as tests

Sean A.C. McDowell and W.J. Meath

Abstract: Average energy approximations for the anisotropic triple-dipole dispersion energy coefficients are tested using reliable results for these coefficients, which are available for all interactions involving the rare gases, H_2, N_2, CO, O_2, and NO. The original average energy approximation does not reproduce any of the anisotropic coefficients to within their estimated uncertainties. More recently derived average energy approximation formulae, requiring the isotropic and anisotropic polarizabilities and average energies for the interacting species as input, reproduce all but 69 of the 680 isotropic and anisotropic coefficients considered to within their estimated uncertainties.

Key words: nonadditive, three-body interactions, dispersion energies.

Résumé : On a vérifié des approximations de l'énergie moyenne pour les coefficients d'énergie de dispersion anisotrope de triples dipôles en faisant appel à des résultats fiables pour tous les coefficients disponibles pour toutes les interactions impliquant les gaz rares ainsi que H_2, N_2, CO, O_2 et NO. L'approximation originale de l'énergie moyenne ne permet pas de reproduire les coefficients anisotropes à des valeurs situées dans les limites des évaluations des incertitudes. Des formules d'approximation de l'énergie moyenne développées plus récemment, dans lesquelles il est nécessaire d'introduire des polarisabilités isotropes et anisotropes ainsi que les énergies moyennes des espèces interagissantes, permettent de reproduire l'ensemble des 680, à l'exception de 69 d'entre eux, coefficients isotropes et anisotropes à des valeurs considérées dans les limites des évaluations des incertitudes.

Mots clés : non additif, interactions entre trois corps, énergies de dispersion.

[Traduit par la rédaction]

1. Introduction

Nonadditive interaction energies are important for the understanding and the evaluation of many bulk properties of matter, ranging from third virial coefficients and absorption spectra of fluids, surface tension, binding energies of solids, molecular adsorption and interactions on surfaces, pressure–volume relations, internal energies, and structures of solids and fluids (refs. 1–9 and many refs. therein). The importance of these effects has also been stressed recently for microscopic molecular properties, namely the spectroscopy of van der Waals complexes (10–13).

Nonadditive interactions arising from dispersion forces, and for rare gas systems, are perhaps the best understood of the nonadditive interactions (however, see refs. 7, 8, 14–19), and of these the lead triple-dipole dispersion energy (20, 21), DDD, is most important. It is now well known that there are many types of nonadditive effects, which are of the same order of magnitude as DDD for interatomic or intermolecular distances of interest in rare gas or molecular systems (7, 8, 10–19). Nevertheless, the triple-dipole dispersion energy continues to play a significant role in representing nonadditive effects in both bulk and microscopic systems (1–19, 22).

Accurate results have been available, for some time, for the isotropic DDD energy for many interactions involving three rare gas atoms and (or) molecules (23–28). To date, however, the only reliable results for the anisotropic triple-dipole coefficients for interactions involving molecules are for three-body systems made up of He, Ne, Ar, Kr, Xe, H_2, N_2, CO, O_2, and NO (29). In applications these anisotropic coefficients have usually been evaluated using an average energy approximation developed by Stogryn (30), and it has recently been shown, using prototype interactions as examples, that the results so obtained can lead to poor representations of the anisotropy of

the DDD for interactions involving molecules (22, 31). Part of the purpose of this paper is to use the available reliable anisotropic DDD coefficients to explicitly test the validity of the original average energy approximation (30) for the anisotropic DDD, on a coefficient by coefficient basis, and to further test a recently derived (32) anisotropic average energy approximation for these coefficients.

The recent average energy approximations for the isotropic and anisotropic DDD coefficients are reviewed in Sect. 2.2; the corresponding average energy approximations for the isotropic and anisotropic two-body dipole–dipole dispersion energy coefficients are reviewed in Sect. 2.1. The approach is tested in Sect. 3.1 and Sect. 3.2, for all two-body and three-body interactions, respectively, involving O_2 and NO, both with each other and with the rare gases, H_2, N_2, and CO. This augments the analogous tests for all two- and three-body interactions arising from the rare gases and H_2, N_2, and CO discussed previously in this journal (32). The new tests involve 54 unique two-body dispersion energy coefficients and 394 unique three-body dispersion energy coefficients of which all but 11 and 51, respectively, are reproduced to within the recently established (29) error estimates in the reliable results for the coefficients. Requiring a 1% reproducability for all the coefficients, the criteria used in earlier tests (32), increases the number of species failing the test to 17 and 94, respectively. The earlier tests involved 66 unique two-body and 286 unique three-body coefficients of which 13 and 26, respectively, cannot be reproduced to within 1% by the new average energy approximation. Section 3.2 also contains a test of the Stogryn average energy approximation (30) for all three-body interactions arising from the rare gases, H_2, N_2, CO, O_2, and NO, where at least one species is a molecule; none of the 460 unique anisotropic DDD coefficients are reproduced within their estimated uncertainties by this original anisotropic DDD average energy approximation. Finally, Sect. 4 contains a brief discussion of some of our results, and their relevance, in the context of nonadditive interactions.

2. Average energy approximations for the anisotropic dipolar dispersion energy coefficients

Here we summarize the average energy approximations for the anisotropic dipole–dipole and triple-dipole dispersion energy coefficients to be considered later in this paper.

2.1 The dipole–dipole dispersion energy

The long range dipole–dipole dispersion energy, which depends on the relative orientations of the two linear molecules, is given by (33, 34)

$$[1]\qquad E^{ab}_{dis,R^{-1}} = -\frac{C_6(a,b)}{R^6}\left[1 + \Gamma_{ab}P_2(\cos\theta_a) + \Gamma_{ba}P_2(\cos\theta_b) + \Delta_{ab}\left(\frac{4\pi}{5}\right)\sum_{m=-2}^{m=2}(3-|m|)Y_2^m(\theta_a,\phi_a)Y_2^{-m}(\theta_b,\phi_b)\right]$$

where R is the distance between the interacting molecules, and P_2 and Y_2^m are Legendre and spherical harmonic functions of the spherical polar angles (θ_a, ϕ_a) and (θ_b, ϕ_b) specifying the relative orientations of the interactioning molecules a and b (as specified in refs. 33 and 34). The isotropic dispersion energy coeffient, $C_6(a, b)$, and the anisotropy parameters Γ_{ab}, Γ_{ba}, and Δ_{ab}, can be expressed (33–36) in terms of anisotropic dispersion energy coefficients $C^{\zeta,\zeta'}_{ab}$, ζ, $\zeta' = \parallel$ or $\perp$ (see ref. 32 for explicit expressions). Without loss of accuracy (26, 35–37), these coefficients are most easily evaluated using pseudo dipole oscillator strength distributions (DOSDs), which provide a discrete representation of the recommended original DOSDs for the molecule. Thus,

$$[2]\qquad C^{\zeta,\zeta'}_{ab} = \frac{1}{4}\sum_{k_a=1}^{N_a}\sum_{k_b=1}^{N_b}\frac{f^{\zeta}_{k_a}f^{\zeta'}_{k_b}}{E^{\zeta}_{k_a}E^{\zeta'}_{k_b}[E^{\zeta}_{k_a}+E^{\zeta'}_{k_b}]}$$

where the ζ-component of the pseudo-DOSD for molecule a, say, is given by $\{E^{\zeta}_{k_a}, f^{\zeta}_{k_a}\}$ where the $E^{\zeta}_{k_a}$ and $f^{\zeta}_{k_a}$ are the excitation energy – oscillator strength pairs defining the pseudo-DOSD for the molecule a. If one of the species is isotropic, a say, then eq. [2] is written as $C^{0,\zeta'}_{ab}$ and is given by eq. [2] with the ζ-pseudo-DOSD for molecule a replaced by the isotropic atomic DOSD (35, 36).

The Unsöld average energy approximation (38) can be applied to eq. [2] to obtain (32)

$$[3]\qquad C^{\zeta,\zeta'}_{ab} = \frac{1}{4}\alpha_a^{\zeta}\alpha_b^{\zeta'}\frac{U_a^{\zeta}U_b^{\zeta'}}{(U_a^{\zeta}+U_b^{\zeta'})}$$

where U_a^{ζ} is a molecular ($\zeta = \parallel$ or $\perp$) or an atomic ($\zeta = 0$, $U_a^0 = U_a$) average energy, which is independent of k_a, and α_a^{ζ} is either the ζ-component of the anisotropic dipole polarizability for a molecule ($\zeta = \parallel$ or $\perp$) or the isotropic dipole polarizability α_a for an atom. Using eq. [3] it can be shown that the average energies U_a and U_b for atoms a and b can be related to the isotropic $C_6(a,b)$ dispersion energy coefficient by (30, 39)

$$[4]\qquad C_6(a,b) = \frac{3}{2}\frac{U_aU_b}{(U_a+U_b)}\alpha_a\alpha_b$$

and for two like atoms this yields

$$[5]\qquad U_a = \frac{4C_6(a,a)}{3\alpha_a^2}$$

For linear molecules average energies $U_a^{\parallel}$ and $U_a^{\perp}$ can be determined from $C^{\parallel,\parallel}_{aa}$ and $C^{\perp,\perp}_{aa}$ via eq. [3],

$$[6]\qquad U_a^{\zeta} = \frac{8C^{\zeta,\zeta}_{aa}}{(\alpha_a^{\zeta})^2},\qquad \zeta = \parallel \text{ or } \perp$$

Thus average energies for each of the rare gas atoms can be evaluated from eq. [5] from reliable values (23–25) of the isotropic C_6 coefficients and isotropic dipole polarizabilities, while the parallel and perpendicular average energies $U_a^{\parallel}$ and $U_b^{\perp}$ for H_2, N_2, CO, O_2, and NO can be obtained from eq. [6] using reliable values of the anisotropic polarizabilities and the $C^{\zeta,\zeta}_{aa}$, which have been computed from molecular pseudo-DOSDs (35, 36, 40, 41). The rare gas and H_2, N_2, and CO polarizabilities, α_a^{ζ}, and average energies, U_a^{ζ}, are given in ref. 32; those for O_2 and NO are in Table 1.

2.2 The triple-dipole dispersion energy

The triple-dipole dispersion energy (DDD) for the interaction of three linear molecules can be written in the form (22, 31)

© 1998 NRC Canada

$$[7]\quad \mathrm{DDD} = \frac{(1 + 3\cos\theta_A\cos\theta_B\cos\theta_C)C_9(a,b,c)}{R_{ab}^3 R_{bc}^3 R_{ac}^3}\,\mathrm{Re}[1 - \Gamma(a)W(\theta_a, \phi_a, \theta_A, \theta_B) - \Gamma(b)W(\theta_b, \phi_b, \theta_A, \theta_B) - \Gamma(c)W(\theta_c, \phi_c, \theta_A, \theta_B) + \Gamma(a,b)W(\theta_a, \phi_a, \theta_b, \phi_b, \theta_A, \theta_B) + \Gamma(a,c)W(\theta_a, \phi_a, \theta_c, \phi_c, \theta_A, \theta_B) + \Gamma(b,c)W(\theta_b, \phi_b, \theta_c, \phi_c, \theta_A, \theta_B) - \Gamma(a,b,c)W(\theta_a, \phi_a, \theta_b, \phi_b, \theta_c, \phi_c, \theta_A, \theta_B)]$$

where Re[···] indicates the real part of [···], θ_A, θ_B, and θ_C are the internal angles of the triangle formed by the centres of mass of molecules a, b, and c, and R_{ab} represents the distance between molecules a and b. The coefficients, W, are complicated functions of the spherical polar angles, (θ_i, ϕ_i) for i = a, b, c, specifying the relative orientations of the interacting molecules; expressions for the W's and details of the coordinate system used to define eq. [7] can be found in ref. 31.

The C_9 and the Γ's occurring in eq. [7] are the isotropic and anisotropic triple-dipole dispersion energy coefficients for the a–b–c interaction and are defined in terms of individual anisotropic triple-dipole dispersion energy coefficients defined by (31)

$$[8]\quad C_{abc}^{\zeta,\zeta',\zeta''} = \frac{1}{2}\sum_{k_a=1}^{N_a}\sum_{k_b=1}^{N_b}\sum_{k_c=1}^{N_c}\frac{f_{k_a}^{\zeta} f_{k_b}^{\zeta'} f_{k_c}^{\zeta''}\,[E_{k_a}^{\zeta} + E_{k_b}^{\zeta'} + E_{k_c}^{\zeta''}]}{E_{k_a}^{\zeta} E_{k_b}^{\zeta'} E_{k_c}^{\zeta''}[E_{k_a}^{\zeta} + E_{k_b}^{\zeta'}][[E_{k_a}^{\zeta} + E_{k_c}^{\zeta''}][[E_{k_b}^{\zeta'} + E_{k_c}^{\zeta''}]}$$

where $\zeta, \zeta', \zeta'' = \parallel, \perp$. Explicit expressions for C_9 and the various Γ's occurring in eq. [7], in terms of these coefficients, are given in refs. 31 and 32.

The extension of the average energy approximation for the dipole–dipole dispersion energy, Sect. 2.1, to DDD has been discussed previously (32). Applying this approximation to eq. [8] leads to

$$[9]\quad C_{\bar{a}bc}^{\zeta,\zeta',\zeta''} = \frac{1}{2}\frac{[U_a^{\zeta} + U_b^{\zeta'} + U_c^{\zeta''}]U_a^{\zeta} U_b^{\zeta'} U_c^{\zeta''}}{[U_a^{\zeta} + U_b^{\zeta'}][U_a^{\zeta} + U_c^{\zeta''}]\,[U_b^{\zeta'} + U_c^{\zeta''}]}\alpha_a^{\zeta}\alpha_b^{\zeta'}\alpha_c^{\zeta''} = \frac{1}{2}U_{\bar{a}bc}^{\zeta,\zeta',\zeta''}\alpha_a^{\zeta}\alpha_b^{\zeta'}\alpha_c^{\zeta''}$$

For isotropic interactions the parameter $U_{\bar{a}bc}^{\zeta,\zeta',\zeta''} = U_{abc}$ is independent of ζ, ζ', ζ''. Following Stogryn (30), U_{abc} can expressed in terms of the isotropic C_9(a, b, c) and polarizabilities,

$$[10]\quad U_{abc} = \frac{2C_9(a,b,c)}{3\alpha_a\alpha_b\alpha_c}$$

which leads to an average energy, for each rare gas atom a, given by (32)

$$[11]\quad U_a = \frac{16C_9(a,a,a)}{3(\alpha_a)^3}$$

Similarly to the two-body interactions involving linear molecules discussed in Sect. 2.1, average energies $(U_a^{\parallel}, U_a^{\perp})$ for each molecule can be obtained from the anisotropic DDD coefficients defined by eq. [9] with $\zeta = \zeta' = \zeta'' = \parallel$ or $\perp$ (32);

$$[12]\quad U_a^{\zeta} = \frac{16C_{\bar{a}\bar{a}\bar{a}}^{\zeta,\zeta,\zeta}}{3(\alpha_a^{\zeta})^3}, \qquad \zeta = \parallel \text{or} \perp$$

Average energies for the rare gases can therefore be evaluated using eq. [11] and reliable values (23–25) for the like rare gas C_9 triple-dipole coefficients and rare gas polarizabilities. The molecular parallel and perpendicular average energies are obtained from eq. [12] using reliable results for the molecular anisotropic polarizabilities and the like molecule anisotropic triple-dipole coefficients $C_{\bar{a}\bar{a}\bar{a}}^{\zeta,\zeta,\zeta}$, $\zeta = \parallel$ or $\perp$, that have been computed from the pseudo-DOSDs for the molecules (35, 36, 40, 41). The rare gas and H_2, N_2, and CO results are listed in ref. 32; the average energies and polarizabilities for O_2 and NO are included in Table 1.

3. Further tests of the average energy approximations

The average energy approximations, reviewed in Sect. 2, have been tested for all pair and three-body interactions involving the rare gases, H_2, N_2, and CO previously. Here the earlier analysis is extended to include O_2 and NO. Also, an analysis of the validity of results for the DDD coefficients obtained using Stogyn's original average energy approximation (30) for all three-body interactions arising from the rare gases and H_2, N_2, CO, O_2, and NO, which include at least one molecule, is included in Sect. 3.2. It should be noted that the expressions for the anisotropic dipole–dipole and triple-dipole dispersion energies, given by eqs. [1] and [7], do not contain additional terms arising from degeneracy of the $^2\Pi$ ground state of NO (29, 41, 42). Their computation requires the separate $\Pi\rightarrow\Sigma$ and $\Pi\rightarrow\Delta$ components of the $\perp$-DOSD, which are not available (41). Indeed the extra terms have been developed only for the interaction of a Π state molecule with an S state atom, for the two-body dispersion energy, where they have been shown to be small (42).

3.1 Results for the dipole–dipole dispersion energy

To test the validity of the average energy approximation, all the two-body dispersion energy coefficients C_6(a, b), $\Gamma_{a,b}$, Γ_{ba}, and Δ_{ab} are computed, in the average energy approximation discussed in Sect. 2.1, for all two-body interactions involving O_2 and NO, both with each other and with the rare gases, H_2, N_2, and CO. The expressions for the various coefficients, in terms of the $C_{ab}^{\zeta,\zeta'}$, are given explicitly by eqs. [2]–[5] of ref. 32, and the results for the $C_{ab}^{\zeta,\zeta'}$, in the average energy approximation, are obtained from eq. [3]; the polarizabilities and dipole–dipole average energies for O_2 and NO given in Table 1, and the analogous results for the other species given in ref. 32. In all cases the average energies are obtained using the like-species interaction coefficients $C_{\bar{a}b}^{\zeta,\zeta}$, $\zeta = \parallel$ or $\perp$, and C_6(a, a). The average energy results are compared against the reliable DOSD results for the two-body dispersion energy coefficients, which are available in the literature (25, 35, 36, 40, 41).

© 1998 NRC Canada

For the interactions considered explicitly here, there are 54 unique two-body dispersion energy coefficients C_6, Γ's, and Δ's. Of these, all but 17 can be generated, within the 1% uncertainty claimed (25, 35, 36, 40, 41) for C_6(a, a), Γ_{ab}, and Γ_{ba}, by the average energy approximation discussed in Sect. 2.1. The reliable DOSD values for the 17 coeffients, together with the percent difference between them and the average energy results, are listed in Table 2. As discussed in refs. 25, 35, 36, 40, 41, the estimated uncertainties in the reliable DOSD results for the small coefficient Δ_{ab} is often ≤2%, not ≤1%, and using a greater than 2% criteria for Δ_{ab} would eliminate six entries from Table 2.

Generally the percent differences are reasonably small with, as expected, those for Δ_{ab} being largest. Relatively high discrepancies are generally due to cumulative errors arising from "summing" the individual $C_{ab}^{\zeta,\zeta'}$ to obtain the overall dispersion energy coefficients (29, 32). In general the DOSD results for the individual $C_{ab}^{\zeta,\zeta'}$ coefficients are reproduced to within ~1%. For example for O_2–O_2 the discrepancy between the average energy and DOSD results for $\Delta = 2(C^{\|,\|} + C^{\perp,\perp} - 2C^{\|,\perp})/(3C_6)$ is –12%. The errors in using the average energy approximation to evaluate the (large) individual $C^{\zeta,\zeta'}$ is ≤1%, but since $(C^{\|,\|} + C^{\perp\perp}) \sim 2C^{\|,\perp}$, the cumulative effect of these small errors is large for this small interaction coefficient.

3.2 Results for the triple-dipole dispersion energy

All the triple-dipole dispersion energy coefficients (C_9 and Γ's) for all three-body interactions involving O_2 and NO, both with each other and with the rare gases and H_2, N_2, CO, have been evaluated using the average energy approximation detailed in Sect. 2.2. The expressions for the various coefficients, in terms of the $C_{abc}^{\zeta,\zeta',\zeta''}$, are given by eqs. [14]–[18] of ref. 32, and related symmetry conditions, and the results for the $C_{abc}^{\zeta,\zeta',\zeta''}$ are obtained from eq. [9]; the polarizabilities and the triple-dipole average energies for O_2 and NO given in Table 1, and the analogous results for the other species given in ref. 32. As for the two-body case, the average energies are determined using input concerning like-species interactions only. A comparison of the average energy results, with reliable values (29) obtained by directly evaluating the C_9's and Γ's using the relevant atomic and molecular DOSDs (25, 35, 36, 40, 41), is made below.

There are 394 unique three-body triple-dipole dispersion energy coefficients for the interactions considered explicitly here. Of these there are 60 atom–atom–molecule, 170 atom–molecule–molecule, and 164 molecule–molecule–molecule coefficients, and of these, respectively, all but 10, 43, and 41 can be reproduced to within 1% by the average energy approximation outlined in Sect. 2.2. A realistic assessment of the errors in the reliable DOSD results for the triple-dipole dispersion energy coefficients for the interactions of interest has been made (29) and yields error estimates of ≤1–2% for C_9 and Γ(i), ≤2–3% for Γ(i, j), and ≤5–10% for Γ(i, j, k) with the latter probably being excessive; these estimates were not available in the context of ref. 32. Therefore to reduce the tabular data to be presented, we report, in Tables 3–5, the reliable DOSD results for the relevant coefficients, together with the percent deviation of the average energy results from the reliable values, only if the average energy values disagree by more than 1%, 1.5%, and 2% for C_9 and Γ(i), Γ(i, j), and Γ(i, j, k), respectively. This reduces the tabular entries to 29 and 25 for the atom–molecule–molecule and the molecule–molecule–molecule results, relative to the 43 and 41 entries that would have been obtained if the 1% criteria for all coefficients, used in our previous analysis (32) of the three-body interactions arising from the rare gases, H_2, N_2, and CO, had been used. Using the error estimates themselves as criteria regarding Tables 4 and 5, namely 2% and 5%, would reduce the entries in these tables only by 1, to 28, and by 12, to 13, respectively. With respect to Table 5, only one Γ(i, j, k) value is not reproduced within the estimated error of 5%, while five Γ(i, j) values are not reproduced within 2%.

Table 1. Polarizabilities (40, 41) and average energies for O_2 and NO. Two sets of average energies are provided. One, labelled U_{DD}^{ζ}, is obtained from like molecule–molecule dipole–dipole dispersion energy interaction coefficients and the other, labelled U_{DDD}^{ζ}, from like molecule–molecule–molecule triple-dipole dispersion energy interaction coefficients (see main text for definitions). All quantities are in atomic units. The analogous results for the rare gases and H_2, N_2, and CO can be found in ref. 32.

	α	$\alpha^{\|}$	$\alpha^{\perp}$	$U_{DD}^{\|}$	$U_{DD}^{\perp}$	$U_{DDD}^{\|}$	$U_{DDD}^{\perp}$
O_2	10.59	15.29	8.238	0.5605	0.9275	0.5218	0.8825
NO	11.53	15.24	9.669	0.6375	0.7544	0.6078	0.7006

Until recently (22, 31), the only available computationally viable expression for the anisotropic triple-dipole dispersion energy was that due to Stogryn (30) in an average energy approximation. Relative to the average energy approximation discussed in Sect. 2.2, Stogryn's average energy approximation for DDD assumes all average energies $U_{abc}^{\zeta,\zeta',\zeta''}$ occurring in eq. [9] are the same and given by eq. [10]. Thus in this original average energy approximation, the molecular anisotropy of the DDD coefficients $C_{abc}^{\zeta,\zeta',\zeta''}$, defined by eq. [9], are given by those of the molecular polarizabilities only. The input for the Stogryn average energy eq. [10] are the isotropic DDD coefficient and polarizabilities only.

We have evaluated the anisotropic DDD coefficients Γ for all three-body interactions involving all the rare gases and H_2, N_2, CO, O_2, and NO and at least one molecule. There are 460 such unique coefficients and none of these are reproduced, by Stogryn's average energy approximation, within the error estimates of ≤1–2% for C_9 and Γ(i), ≤2–3% for Γ(i, j), and ≤5–10% for Γ(i, j, k), for the reliable results (29) for these coefficients. The discrepancies vary from ~5.0% to –58.7% for the Γ(i), from ~10.5% to ~ –91.3% for the Γ(i, j), and from ~16.0% to ~ –105.5% for the Γ(i, j, k). With a few exceptions, namely –4.9%, –4.4%, –3.7%, –4.6%, –3.8%, -4.7%, –4.9%, –4.6%, 1.3%, and 1.0% for Γ(N_2, CO), for the Ar–N_2–CO, Kr–N_2–CO, and Xe–N_2–CO interactions, Γ(CO–NO) for the Kr–CO–NO and Xe–CO–NO interactions, Γ(CO–N_2) for the CO–CO–N_2 interaction, Γ(CO–NO) for the CO–CO–NO interaction, Γ(CO–CO–H_2), Γ(CO–CO–N_2), and Γ(CO–CO–NO), respectively, the magnitude of the discrepancies exceed 5% and are generally large, and negative, especially for interactions involving the O_2 molecule. As discussed previously for some prototype interactions (22, 31), errors of this magnitude for the individual Γ's can lead to very poor representations for

the anisotropy of the total triple-dipole dispersion energy for interactions involving molecules.

4. Discussion

Combining the results of this paper, with those of our earlier tests of the average energy approximation reviewed in Sect. 2, for all the two- and three-body interactions arising from He, Ne, Ar, Kr, Xe, H_2, N_2, CO, O_2, and NO, 120 unique two-body C_6's, Γ's, and Δ's corresponding to 55 unique two-body interactions, and 680 unique three-body C_9's and Γ's for 220 unique three-body interactions, are involved in the testing of the average energy approximation. In global summary, the average energy approximation expressions, with the provided input (Table 1 and Tables 1 and 2 of ref. 32), reproduce all but 19 of the two-body dispersion energy coefficients and all but 69 of the three-body dispersion energy coefficients to within the estimated uncertainties in the reliable results for these coefficients (25, 29, 35, 36, 40, 41). Thus a relatively small body of input data, and an average energy approximation, can be used to represent are large number of dipolar dispersion energy coefficients, especially for the triple-dipole dispersion energy interaction coefficients. Section 3.2 also contains a test of Stogryn's (30) average energy approximation for the anisotropic triple-dipole coefficients Γ. In summary, none of these 460 unique Γ's are reproduced to within their estimated uncertainties by this original DDD average energy approximation.

In general the anisotropic DDD energy will not be well represented by Stogryn's average energy approximation. However, until recently, this average energy approximation result for the anisotropic DDD energy was the only computationally viable result for this important nonadditive energy, and it has therefore been used in a variety of applications in the literature. It is also relevant to note that this average energy expression requires much less molecular input than does the exact expression for DDD or our average energy approximations. Indeed the reliable input required to evaluate the exact expression (31), of the form of eq. [7], is still only available for relatively few molecules at the present time. Thus, for example, in investigations of the effects of nonadditivity in the spectroscopy of van der Waals complexes, such as Ar_2–HF, Ar_2–HCl, and Ar_2–DCl, the anisotropic DDD energy has been evaluated in the Stogryn average energy approximation (10–13) (see also relevant discussion in ref. 22). Reliable results apparently are only available for the isotropic triple-dipole dispersion energy for interactions involving hydrogen halides (HX, X = Br, Cl, F) and one or two rare gases (25).

Table 3. Reliable anisotropic triple-dipole dispersion energy coefficients (29) for rare gas – rare gas – molecule interactions involving the rare gases, NO and O_2, evaluated using DOSDs (25, 35, 36, 40, 41), which are not reproduced to within 1% by the average energy approximation discussed in Sect. 2.2. The percentage difference, [(reliable – approximate)/reliable] × 100%, is shown in parentheses. The isotropic C_9 coefficient for He–Xe–O_2 is 148.6 (1.04%). All quantities are in atomic units.

a–b–c	
He–He–O_2	Γ(c) = 0.1428 (5.2%)
He–Ne–O_2	Γ(c) = 0.1399 (5.4%)
He–Ar–O_2	Γ(c) = 0.1514 (2.8%)
He–Kr–O_2	Γ(c) = 0.1545 (1.9%)
Ne–Ne–O_2	Γ(c) = 0.1367 (5.5%)
Ne–Ar–O_2	Γ(c) = 0.1491 (3.0%)
Ne–Kr–O_2	Γ(c) = 0.1524 (2.0%)
Ar–Ar–O_2	Γ(c) = 0.1588 (1.3%)
Xe–Xe–O_2	Γ(c) = 0.1710 (–1.04%)

As discussed in the introduction, it is clear that nonadditive energies are important for the understanding and evaluation of many properties of matter and that the triple-dipole dispersion energy is only one of several competing nonadditive interaction energies occurring in many (greater than two) body systems. It is important to quantify as many of these competing interactions as possible so that experiments can be used to study other, more difficult to compute, nonadditive energies (7, 8). Hopefully the results of this paper are a contribution to this end and will also help lead to improved average energy approximations, analogous to Stogryn's work, for the anisotropic triple-dipole energy that will be both tractable, and reliable, for a wide variety of three-body molecular interactions.

Complexes of ketodiesters and related compounds with $TiCl_4$. Attempts to use chelation to promote the simultaneous coordination of ketones by two Lewis acids

Okba Saied, Benoit Bachand, and James D. Wuest

Abstract: Carbonyl oxygen atoms have two formal lone pairs of electrons. In principle, both can be used simultaneously to form complexes with two or more Lewis acids. This multiple coordination promises to have a variety of interesting consequences; unfortunately, however, complexes of carbonyl compounds with multiple Lewis acids are extremely rare. To promote multiple coordination, we have made a series of symmetric ketodiesters and related compounds in which the carbonyl group of a ketone is flanked by two additional sites of Lewis basicity. In such compounds, the flanking bases and both lone pairs of the central ketone are available for binding two equivalents of suitable Lewis acids, thereby producing symmetric double chelates in which the central ketone interacts with two Lewis acids at the same time. As expected, treatment of 3-oxoglutarates and 4-oxopimelates with $TiCl_4$ in a 1:1 ratio yielded unsymmetric single chelates in which the carbonyl groups of the ketone and one ester bind $TiCl_4$, while the other ester remains free. Unfortunately, treatment of the same ketodiesters with $TiCl_4$ in a 1:2 ratio did not produce the desired symmetric double chelates. Instead, 2:4 complexes were formed in which the free esters of the unsymmetric single chelates bind $TiCl_4$ in the normal way, without assistance from the keto group. We attribute this observation to the inherent reluctance of ketones to bind multiple Lewis acids, as well as to unfavorable Cl···Cl interactions created in the hypothetical double chelates by the simultaneous attachment of two octahedrally coordinated atoms of titanium to a single carbonyl oxygen atom.

Key words: Lewis acids, chelation, ketodiesters, $TiCl_4$.

Résumé : Les atomes d'oxygène des groupes carbonyles possèdent formellement deux paires d'électrons non partagés. En principe, chacune peut être utilisée simultanément pour former des complexes avec deux ou plusieurs acides de Lewis. Cette coordination multiple suggère la possibilité de plusieurs conséquences intéressantes; toutefois, malheureusement, les complexes des composés carbonylés avec divers acides de Lewis sont extrêmement rares. Dans le but de promouvoir des coordinations multiples, on a préparé une série de cétoesters et de composés apparentés symétriques dans lesquels le groupe carbonyle de la cétone est entouré de deux sites additionnels de basicité de Lewis. Dans de tels composés, les bases périphériques ainsi que les deux paires d'électrons non partagés de la cétone centrale sont toutes disponibles pour se lier à deux équivalents d'acides de Lewis appropriés conduisant à la formation de chélates doubles symétriques dans lesquels la cétone centrale interagit avec deux acides de Lewis en même temps. Tel que prévu, le traitement des 3-oxoglutarate et 4-oxopimélate avec du $TiCl_4$ dans un rapport 1 : 1 conduit à des chélates simples non symétriques dans lesquels les groupes carbonyles de la cétone et d'un ester sont liés au $TiCl_4$ alors que l'autre ester reste libre. Malheureusement, le traitement des mêmes cétodiesters avec le $TiCl_4$ dans un rapport de 1 : 2 ne conduit pas aux doubles chélates symétriques désirés. Il se forme plutôt des complexes 2 : 4 dans lesquels les esters libres des chélates simples non symétriques se lient au $TiCl_4$ de façon normale, sans l'aide du groupe cétonique. On attribue cette observation à la faible disposition des groupes cétoniques à se lier à plusieurs acides de Lewis ainsi qu'aux interactions Cl···Cl non favorables qui se créeraient dans les chélates doubles hypothétiques lors de la fixation simultanée de deux atomes de titane à coordination octaédrique sur un seul atome d'oxygène d'un carbonyle.

Mots clés : acides de Lewis, chélation, cétodiesters, $TiCl_4$.

Introduction

Carbonyl oxygen atoms have two formal lone pairs of electrons in sp^2 orbitals (1), and both are potentially available for interaction with Lewis acids. Simultaneous coordination of ketones by two or more Lewis acids is therefore plausible, although ketones are among the least basic carbonyl compounds (2). Such multiple coordination can be expected to have a variety of interesting consequences (3, 4). Of particular

© 1998 NRC Canada

importance to organic chemists is the possibility that ketones interacting with multiple Lewis acids may experience an unusually high degree of electrophilic activation (3, 4). Unfortunately, complexes of this type are extremely uncommon. No complexes in which simple ketones interact *inter*molecularly with multiple Lewis acids are known, although related structures involving carbonyl compounds more basic than ketones have been characterized (3). In addition, we have established that the carbonyl oxygen atom of relatively simple ketones can form complexes **1** by interacting *intra*molecularly with two nearby sites of Lewis acidity when they are held by covalent

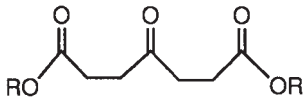
1 **2**

(LA = Lewis acid, LB = Lewis base)

bonds in a suitable orientation (5). As expected, this double coordination has marked effects on the geometry, spectroscopic properties, and reactivity of the bound carbonyl group (3–5). An even more ambitious objective is to construct related doubly coordinated complexes **2** in which the carbonyl group is flanked by two nearby sites of Lewis acidity that are held in place only by relatively weak dative bonds involving adjacent sites of Lewis basicity (6). In such complexes, the carbonyl oxygen atom of the central ketone uses both of its lone pairs in order to participate in the simultaneous formation of two chelates. Chelation is thereby used to promote the simultaneous coordination of the ketone by two Lewis acids. In this paper, we describe our efforts to prepare novel complexes of this type by treating selected ketodiesters and related compounds with $TiCl_4$.

Results and discussion

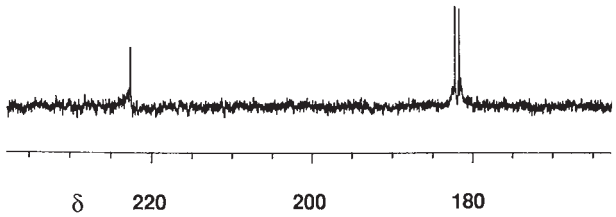
Transesterification of diethyl 4-ketopimelate provided the corresponding diphenethyl ester **3**, which forms complexes with $TiCl_4$ that proved to be soluble enough in CH_2Cl_2 to permit their ^1H and ^{13}C NMR spectra to be recorded at low temperatures. The carbonyl region of the ^{13}C NMR spectrum of ketodiester **3** ($CDCl_3$, 25°C) showed two peaks at δ 172.4 and



3 (R = CH_2CH_2Ph)

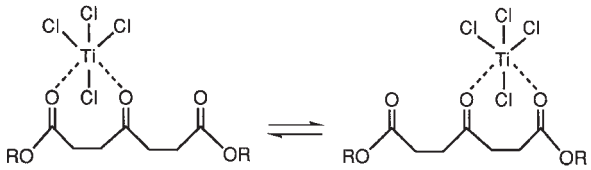
206.7, which can be assigned to the carbonyl carbon atoms of the ester and the ketone, respectively. In the ^{13}C NMR spectrum of a solution prepared by mixing ketodiester **3** and $TiCl_4$ in a 1:1 ratio (0.50 M in CD_2Cl_2, 25°C), the corresponding peaks appeared at δ 177.7 and 222.2. The pronounced downfield shifts indicate that complexation occurs, as expected, and that the ester and ketone groups must both participate. A similar spectrum recorded at –85°C revealed a total of 19 peaks, including 3 in the carbonyl region at δ 171.6, 180.9, and 225.2.

Fig. 1. The carbonyl region of the low-temperature ^{13}C NMR spectrum of a solution prepared by mixing ketodiester **3** and $TiCl_4$ in a 1:2 ratio (0.060 M in CD_2Cl_2, –65°C).



Together, these observations demonstrate that solutions prepared from equimolar amounts of ketodiester **3** and $TiCl_4$ must contain primarily a single 1:1 complex; moreover, the complex must be the unsymmetric chelate **4**, in which the carbonyl groups of the ketone and one ester are bound to $TiCl_4$ and their carbonyl carbon atoms are shifted downfield, while the other ester remains free and essentially unshifted. Analogous chelates of simple dicarbonyl compounds are well known (7).

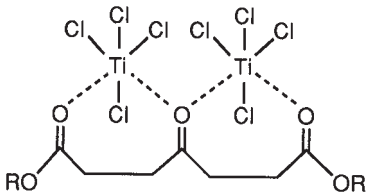
[1]



4 (R = CH_2CH_2Ph)

Symmetrization of the complex (eq. [1]) is sufficiently rapid at 25°C that the two esters can no longer be distinguished by ^{13}C NMR spectroscopy.

We hoped that the ^1H and ^{13}C NMR spectra of solutions prepared by mixing ketodiester **3** and $TiCl_4$ in a 1:2 ratio would provide evidence for the formation of the symmetric double chelate **5**. In fact, the carbonyl region of the ^{13}C NMR spectrum (0.33 M in CD_2Cl_2, 25°C) showed two peaks at δ 180.4 and 223.2, which are both farther downfield than those observed in the spectrum of the 1:1 mixture under similar conditions (δ 177.7 and 222.2). The relatively large downfield shift of the upfield carbonyl carbon atom (Δδ 2.7) indicates that both ester groups must now be bound to $TiCl_4$; however, the



5 (R = CH_2CH_2Ph)

downfield shift of the ketonic carbonyl carbon atom (Δδ 1.0) appears to be too small to be consistent with the formation of the desired symmetric double chelate **5**. Furthermore, a similar spectrum recorded at –65°C revealed three peaks in the carbonyl region at δ 181.5, 182.0, and 222.4 (Fig. 1). This confirms that addition of an equimolar amount of $TiCl_4$ to the unsymmetric single chelate **4** under these conditions does not produce the symmetric double chelate **5**. Instead, we propose that the free ester group of unsymmetric chelate **4** behaves in

6a of stoichiometry 2 **3**·4 $TiCl_4$. This hypothesis is reasonable because a wide range of simple esters are known to form structurally analogous chloride-bridged 2:2 complexes with $TiCl_4$ (8).

Direct confirmation was provided by an X-ray crystallographic study of crystals of a CH_2Cl_2 solvate of complex **6a**,

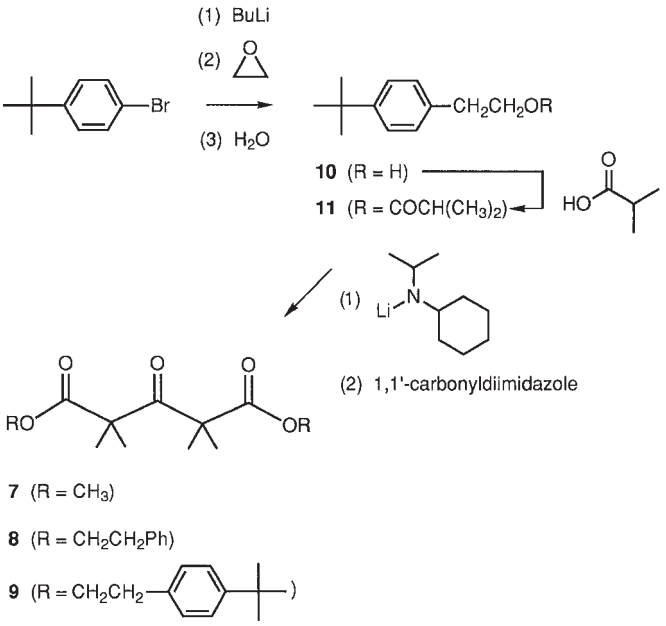
Scheme 1.

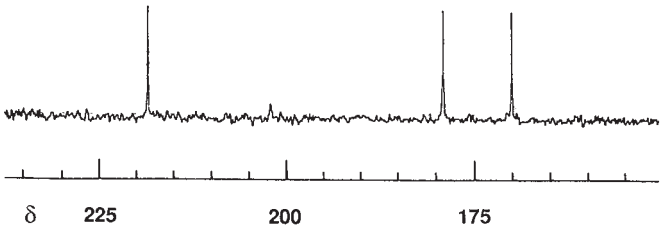


which were obtained by allowing pentane to diffuse into a solution prepared by mixing ketodiester **3** and $TiCl_4$ in CH_2Cl_2 in a 1:2 ratio. The results of this study are summarized in Fig. 2 and in Tables 1 and 2. Most of the observed bond lengths and angles are similar to those found in related structures (7, 8). For example, normal values are observed for the average lengths of Ti(1)—Cl bonds *trans* to the chelating oxygen atoms (2.226(3) Å), Ti(1)—Cl bonds *cis* to the chelating oxygen atoms (2.287(3) Å), terminal Ti(2)—Cl bonds (2.208(3) Å), bridging Ti(2)—Cl bonds (2.450(3) Å), Ti(1)···O bonds to the carbonyl groups of the chelating ester (2.076(6) Å) and ketone (2.141(6) Å), Ti(2)···O bond to the carbonyl group of the non-chelating ester (2.050(7) Å), and C = O bonds of the chelating ester (1.206(11) Å), ketone (1.242(10) Å), and non-chelating ester (1.231(11) Å). Typically large values are observed for the carbonyl C=O···Ti(1) angles involving the chelating ester (152.4(6)°) and the ketone (140.3(6)°), as well as for the carbonyl C=O···Ti(2) angles involving the non-chelating ester (153.2(8)°). In addition, both atoms of titanium have approximate octahedral coordination. As expected, the dihedral angles Ti(1)···O(4)-C(4)-C(3′) (2.0(20)°) and Ti(2)···O(1)-C(1)-C(2) (–6.0(20)°) are small, indicating that normal $\eta^1(\sigma)$ complexation is favored by the ketone and the non-chelating ester, with Ti lying close to the carbonyl plane. However, an unusual value is observed for the dihedral angle Ti(1)···O(1′)-C(1′)-C(2′) involving the chelating ester (23.0(20)°), which reveals that Ti(1) lies far from the carbonyl plane and that the interaction must therefore have important π character (9).

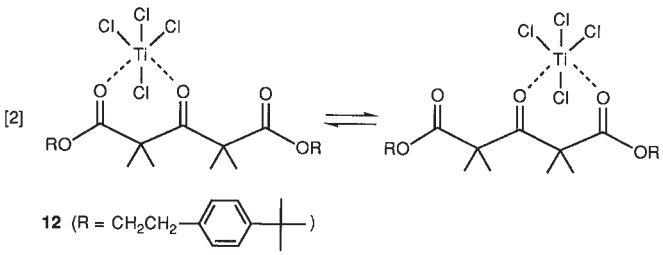
In principle, the conversion of 2:4 complex **6a** into two equivalents of symmetric double chelate **5** is entropically favorable and should be favored by dilution. Even at the lowest concentrations that could be studied, however, low-temperature ^{13}C NMR spectra of solutions prepared by mixing ketodiester **3** and $TiCl_4$ in a 1:2 ratio provided no evidence for the formation of symmetric double chelate **5**.

We reasoned that hypothetical structure **5** and other double chelates derived from 4-ketopimelates might be disfavored because they contain two seven-membered rings, so we also examined the interaction of representative 3-ketoglutarates with $TiCl_4$. Neither dimethyl 2,2,4,4-tetramethyl-3-oxopentanedioate (**7**) (10) nor the corresponding diphenethyl ester **8** formed complexes with $TiCl_4$ that were sufficiently soluble in CH_2Cl_2 at low temperatures, so we prepared derivative **9** by the route summarized in Scheme 1.[3] Lithiation of 1-bromo-4-(1,1-dimethylethyl)benzene, followed by the addition of excess ethylene oxide and then water, provided 4-(1,1-dimethylethyl)benzeneethanol (**10**) in 77% yield. Subsequent esterification then gave the corresponding 2-methylpropanoate **11** in 88% yield. Deprotonation of ester **11**, followed by treatment of the resulting enolate with 1,1′-carbonyldiimidazole, finally provided the required 3-ketoglutarate **9** in 43% yield.

Fig. 3. The carbonyl region of the low-temperature ^{13}C NMR spectrum of a solution prepared by mixing ketodiester **9** and $TiCl_4$ in a 1:1 ratio (0.064 M in CD_2Cl_2, –85°C).



The carbonyl region of the ^{13}C NMR spectrum of compound **9** (CD_2Cl_2, 25°C) showed two peaks at δ 173.6 and 205.4, which correspond to the carbonyl carbon atoms of the ester and the ketone, respectively. As expected, the low-temperature ^{13}C NMR spectrum of a solution prepared by mixing ketodiester **9** and $TiCl_4$ in a 1:1 ratio (0.064 M in CD_2Cl_2, –85°C) contained three peaks in the carbonyl region at δ 170.2, 179.1, and 218.6 (Fig. 3). This provides strong evidence for the formation of the unsymmetric single chelate **12**. Low-temperature spectra of solutions prepared by mixing ketodiester **9** and $TiCl_4$ in a 1:2 ratio were also recorded, but peaks in the carbonyl region remained too broad to permit detailed analysis; however, no conspicuous downfield shift of the carbonyl



carbon atom of the ketone was observed, so we doubt that symmetric double chelate **13** is the principal product.

Although the two ester groups of unsymmetric single chelate **12** can be distinguished by ^{13}C NMR spectroscopy at –85°C, symmetrization is nevertheless rapid (eq. [2]). Variable-temperature ^{13}C NMR spectroscopy established that coalescence of the ester peaks occurred at T_c = –35°C, enabling

[3] This synthesis resembles the one previously used to make dimethyl 2,2,4,4-tetramethyl-3-oxopentanedioate (**7**) (10).

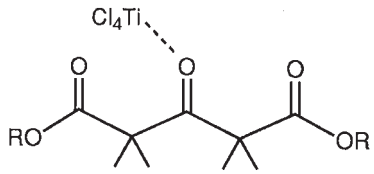
13 (R = CH_2CH_2–C$_6$H$_4$–C(CH$_3$)$_3$)

us to estimate that $\Delta G^{\ddagger} = 10.2 \pm 0.2$ kcal mol^{-1} for the symmetrization of single chelate **12** (11). In principle, this process can occur by three distinct mechanisms: (*i*) intermolecular or intramolecular attack of the free ester on chelated $TiCl_4$, with displacement of the other ester; (*ii*) complete dissociation of $TiCl_4$, followed by reassociation; or (*iii*) partial dissociation to form the ketone complex **14**, followed by rapid *syn–anti* isomerization (12) and reassociation. Because exchange in complexes of $TiCl_4$ normally occurs by dissociation (12), mechanisms (*ii*) and (*iii*) are more probable. Furthermore, the



14 (R = CH_2CH_2–C$_6$H$_4$–C(CH$_3$)$_3$)

observed $\Delta G^{\ddagger}$ is closely similar to those measured for loss of a single ligand from 1:2 complexes of simple carbonyl compounds with $TiCl_4$ (12). As a result, we propose that the symmetrizations of unsymmetric single chelates **4** and **12** both occur by dissociation of the bound ester and reassociation of the free ester.

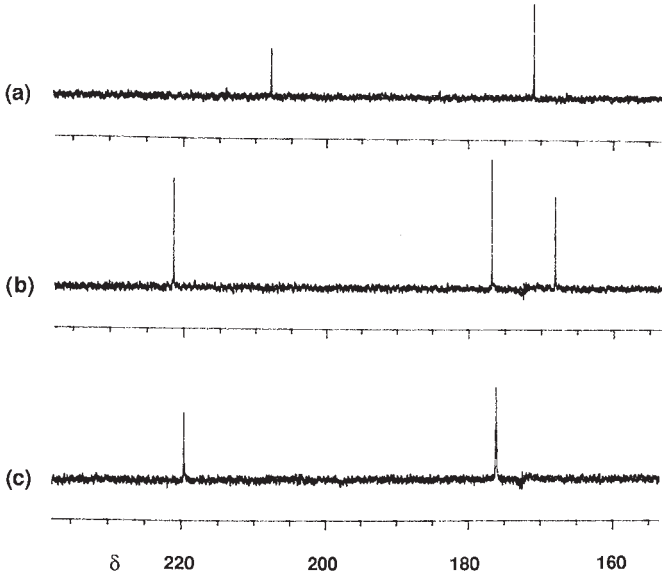
The absence of the desired double chelates **5** and **13** is noteworthy, because previous experimental and theoretical studies have suggested that the simultaneous coordination of simple ketones by two Lewis acids is enthalpically feasible (3, 5, 13, and footnote 4). Two factors may account for our failure to observe double chelates derived from 4-ketopimelates and 3-ketoglutarates:

1. Simple ketones are inherently reluctant to form complexes with multiple Lewis acids, so the formation of double chelates by the addition of $TiCl_4$ to unsymmetric single chelates **4** and **12** may not be sufficiently exothermic to compete with the formation of 2:4 complexes such as structure **6a**, even at low concentrations; moreover, ΔS for the formation of double chelates **5** and **13** is made particularly unfavorable by the conformational mobility of ketodiesters **3** and **9**.

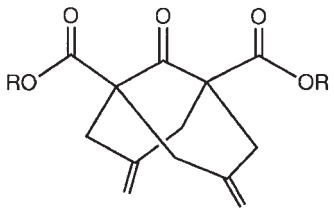
2. Careful examination of the octahedral coordination geometry of Ti in complex **6a** and other simple chelates of $TiCl_4$ (7) reveals that hypothetical double chelates **5** and **13** are likely to be destabilized by nonbonded Cl···Cl interactions created when a single carbonyl oxygen atom binds two molecules of $TiCl_4$ at the same time.

[4] P. Deschatelets and J.D. Wuest. Unpublished results.

Fig. 4. The carbonyl region of the ^{13}C NMR spectrum of (*a*) a solution of pure bicyclic ketodiester **15** (CD_2Cl_2, 25°C); (*b*) a solution prepared by mixing ketodiester **15** with $TiCl_4$ in a 1:1 ratio (0.050 M in CD_2Cl_2, –85°C); and (*c*) a solution prepared by mixing ketodiester **15** with $TiCl_4$ in a 1:2 ratio (0.050 M in CD_2Cl_2, –85°C).



To evaluate the importance of conformational mobility, we decided to study the interaction of $TiCl_4$ with bicyclic 3-ketoglutarate **15**, which is a more rigid analogue of ketodiesters **7**–**9**. Compound **15** could be made in a single step in 34% yield by treating diethyl 3-ketoglutarate with two equivalents of 3-chloro-2-(chloromethyl)-1-propene in refluxing toluene in the presence of K_2CO_3 and catalytic amounts of $(PPh_3)_2PdCl_2$ (14). The carbonyl region of the ^{13}C NMR spectrum of bicyclic



15 (R = CH_2CH_3)

ketodiester **15** (CD_2Cl_2, 25°C) showed two peaks at δ 170.7 and 207.6, which correspond to the carbonyl carbon atoms of the ester and the ketone, respectively (Fig. 4*a*). In the low-temperature ^{13}C NMR spectrum of a solution prepared by mixing bicyclic ketodiester **15** and $TiCl_4$ in a 1:1 ratio (0.050 M in CD_2Cl_2, –85°C), a total of 13 peaks appeared as anticipated, including 3 in the carbonyl region at δ 167.9, 176.6, and 221.2 (Fig. 4*b*). This provides strong evidence for the formation of the expected unsymmetric single chelate **16**. A similar low-temperature spectrum of a solution prepared by mixing bicyclic ketodiester **15** and $TiCl_4$ in a 1:2 ratio (0.050 M in CD_2Cl_2, –85°C) also consisted of 13 peaks, including 3 at δ 175.8, 175.9, and 219.3 (Fig. 4*c*). We conclude that the behavior of bicyclic ketodiester **15** resembles that of its more flexible analogues **3** and **9**, and that detectible amounts of symmetric

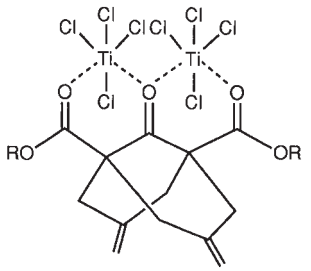
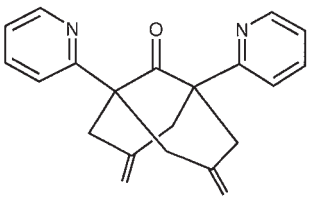
16 (R = CH_2CH_3)



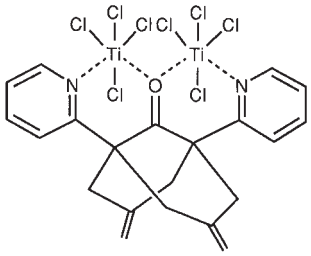
17 (R = CH_2CH_3)

double chelate **17** are not formed when compound **15** and $TiCl_4$ are mixed in a 1:2 ratio, even at the lowest accessible concentrations. Instead, the principal product must again be a 2:4 complex, presumably structure **6b**.

In a final effort to exploit the double chelation of $TiCl_4$ to promote the simultaneous coordination of a ketone by two Lewis acids, we decided to replace ketodiesters by analogues in which the ketone is flanked by stronger Lewis bases (2). In bicyclic ketone **18**, for example, the carbonyl group is flanked by two pyridines, and we hoped that strong binding of $TiCl_4$ by the pyridines would favor formation of the double chelate **19** by helping compensate for the weakly exothermic double coordination of the central carbonyl group. Compound **18** could be prepared conveniently in one step in 21% yield by treating 1,3-bis(2-pyridyl)-2-propanone (15) with 2-methylene-1,3-propanediol diacetate (16) in refluxing toluene in the presence of K_2CO_3 and catalytic amounts of $Pd(OOCCH_3)_2$ and PPh_3. The carbonyl region of the ^{13}C NMR spectrum of bicyclic dipyridylketone **18** ($CDCl_3$, 25°C) showed a single peak at δ 213.0. Unfortunately, complexes of compound **18** with $TiCl_4$ were not soluble enough in CD_2Cl_2 to allow their ^1H and ^{13}C NMR spectra to be recorded conveniently at low temperatures. However, in the ^{13}C NMR spectrum of a solution prepared by mixing bicyclic dipyridylketone **18** and $TiCl_4$ in a 1:2 ratio (0.17 M in $CDCl_3$, 25°C), the carbonyl peak appeared at δ 225.9, which corresponds to a downfield shift of Δδ 12.9. Because our previous experiments show



18



19

that similar shifts are characteristic of single chelates, we conclude that bicyclic dipyridylketone **18** resembles ketodiesters **3**, **9**, and **15** and does not yield significant amounts of a symmetric double chelate with $TiCl_4$.

Conclusions

In principle, compounds in which the carbonyl group of a simple ketone is flanked by two nearby sites of Lewis basicity are well designed to form symmetric double chelates **2**. In these hypothetical chelates, the oxygen atom of the central carbonyl group uses both of its lone pairs to bind two Lewis acids simultaneously. Unfortunately, persistent efforts to prepare such double chelates by treating ketodiesters and related compounds with two equivalents of $TiCl_4$ were unsuccessful. These instructive failures presumably result from the inherent reluctance of simple ketones to form complexes with multiple Lewis acids and from unfavorable Cl···Cl interactions that are created in the hypothetical double chelates by the simultaneous attachment of two octahedrally coordinated atoms of titanium to a single carbonyl oxygen atom. We are optimistic that double chelates can be formed when these destabilizing interactions are not present, and we are now studying the complexation of ketodiesters and related compounds with strong Lewis acids that favor non-octahedral coordination.

Experimental section

Ether and tetrahydrofuran (THF) were dried by distillation from the sodium ketyl of benzophenone, CH_2Cl_2 was dried by distillation from P_2O_5, *N*-isopropylcyclohexylamine was dried by distillation from CaH_2, ethylene oxide was dried by passage over anhydrous $CaSO_4$, and toluene was dried by distillation from sodium. $TiCl_4$ was purified by distillation, and 1,3-bis(2-pyridyl)-2-propanone (15), 2-methylene-1,3-propanediol diacetate (16), and $PdCl_2(PPh_3)_2$ (17) were made by published procedures. Other reagents were commercial products that were used without further purification. Flash chromatography was performed in the normal way (18).

Bis(2-phenylethyl) 4-oxoheptanedioate (3)

A solution of diethyl 4-oxo-heptanedioate (2.00 g, 8.69 mmol) and excess 2-phenylethanol (6.34 g, 51.9 mmol) in toluene (15 mL) was treated with a catalytic amount of concentrated H_2SO_4 (85 mg, 0.87 mmol), and the mixture was heated at reflux for 5 h in an apparatus equipped with a Dean–Stark trap. Saturated aqueous $NaHCO_3$ (100 mL) was then added, and the mixture was extracted with ether. Volatiles were removed from the combined extracts by evaporation under reduced pressure, and the residue was purified by flash chromatography (silica, toluene (80%) – ether (20%)). This yielded colorless crystals of bis(2-phenylethyl) 4-oxoheptanedioate (**3**; 3.25 g, 8.50 mmol, 98%): mp 37–38°C; IR (melt): 1735, 1714 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 2.59 (t, 4H, ^3J = 6.7 Hz), 2.73 (t, 4H, ^3J = 6.7 Hz), 2.95 (t, 4H, ^3J = 7.1 Hz), 4.30 (t, 4H, ^3J = 7.1 Hz), 7.21–7.32 (m, 10H); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 27.9, 35.0, 36.9, 65.0, 126.5, 128.4, 128.8, 137.7, 172.4, 206.7; HRMS (FAB) calcd. for $C_{23}H_{26}O_5$ + H, *m/e:* 383.1859; found, *m/e*: 383.1840. Anal. calcd. for $C_{23}H_{26}O_5$: C 72.23, H 6.85; found: C 72.52, H 6.88.

2:4 Adduct 6a of bis(2-phenylethyl) 4-oxoheptanedioate (3) and $TiCl_4$

A solution of ketodiester **3** (37.5 mg, 0.0981 mmol) in CH_2Cl_2 was stirred at 25°C under dry N_2 and treated dropwise with $TiCl_4$ (37.2 mg, 0.196 mmol). A supernatant layer of pentane (0.5 mL) was carefully added and allowed to diffuse slowly into the lower phase. This yielded yellow-orange crystals of adduct **6a** as a 1:1 CH_2Cl_2 solvate (67.2 mg, 0.0418 mmol, 85%).

© 1998 NRC Canada

X-ray crystallographic study of the CH_2Cl_2 solvate of the 2:4 adduct 6a of bis(2-phenylethyl) 4-oxoheptanedioate (3) and $TiCl_4$

Data were collected on an Enraf–Nonius CAD-4 diffractometer. Cell constants were obtained using 25 well-centered reflections ($20° \leq \theta \leq 25°$). Five standard reflections were measured every 1 h of exposure time and showed only small fluctuations. The data were corrected for absorption by Gaussian integration. The structure was solved by direct methods using SHELXS-85 (19). Full-matrix least-squares refinement on F^2 was carried out with SHELXL-93 (20). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in ideal positions and refined using a riding model with isotropic thermal parameters 1.2 times those of their carrier atoms. A detailed description of the structure determination and tables of atomic coordinates and isotropic thermal parameters, complete bond lengths and angles, anisotropic thermal parameters, hydrogen atom coordinates and thermal parameters, and distances to weighted least-squares planes are available as supplementary material.[5]

4-(1,1-Dimethylethyl)benzeneethanol (10)

A solution of 1-bromo-4-(1,1-dimethylethyl)benzene (2.46 g, 11.5 mmol) in ether (40 mL) was stirred at 0°C under dry N_2 and treated dropwise with a solution of BuLi (7.40 mL, 1.55 M in hexane, 11.5 mmol). The solution was kept at 0°C for 1 h, and then a solution of ethylene oxide (3.6 g, 82 mmol) in ether (10 mL) was added dropwise. The resulting mixture was stirred at 0°C for 2 h, treated with water, and extracted with ether. Volatiles were removed from the combined extracts by evaporation under reduced pressure, and the residue was purified by flash chromatography (silica, hexane (85%) – ethyl acetate (15%)). This yielded 4-(1,1-dimethylethyl)benzeneethanol (**10**; 1.57 g, 8.81 mmol, 77%) as a colorless oil: IR (liquid film): 3330 (br) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.32 (s, 9H), 1.43 (s, 1H), 2.85 (t, 2H, ^3J = 6.6 Hz), 3.87 (t, 2H, ^3J = 6.6 Hz), 7.18 (d, 2H, ^3J = 8.2 Hz), 7.35 (d, 2H, ^3J = 8.2 Hz); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 31.3, 34.4, 38.6, 63.6, 125.5, 128.7, 135.3, 149.3; HRMS (EI) calcd. for $C_{12}H_{18}O$, *m/e:* 173.1358; found, *m/e:* 173.1355.

2-[4-(1,1-Dimethylethyl)phenyl]ethyl 2-methylpropanoate (11)

A solution of 4-(1,1-dimethylethyl)benzeneethanol (**10**; 1.03 g, 5.78 mmol) and 2-methylpropanoic acid (0.52 g, 5.9 mmol) in benzene (10 mL) was treated with a catalytic amount of (1*S*)-10-camphorsulfonic acid (30 mg, 0.13 mmol), and the mixture was heated at reflux for 12 h in an apparatus equipped with a Dean–Stark trap. Saturated aqueous $NaHCO_3$ (10 mL) was then added, and the mixture was extracted with ether. Volatiles were removed from the combined extracts by evaporation under reduced pressure, and the residue was purified by distillation (100°C/0.3 Torr; 1 Torr = 133.3 Pa) to give 2-[4-(1,1-dimethylethyl)phenyl]ethyl 2-methylpropanoate (**11**; 1.27 g, 5.11 mmol, 88%) as a colorless liquid: IR (film): 1731 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.14 (d, 6H, ^3J = 7.0 Hz), 1.31 (s, 9H), 2.53 (septuplet, 1H, ^3J = 7.0 Hz), 2.91 (t, 2H, ^3J = 7.1 Hz), 4.27 (t, 2H, ^3J = 7.1 Hz), 7.16 (d, 2H, ^3J = 8.2 Hz), 7.33 (d, 2H, ^3J = 8.2 Hz); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 18.9, 31.3, 34.0, 34.4, 34.6, 64.7, 125.3, 128.6, 134.8, 149.3, 177.0; HRMS (EI) calcd. for $C_{16}H_{24}O_2$, *m/e:* 248.1776; found, *m/e:* 248.1756.

Bis{2-[4-(1,1-Dimethylethyl)phenyl]ethyl} 2,2,4,4-tetramethyl-3-oxopentanedioate (9)

A solution of *N*-isopropylcyclohexylamine (1.13 g, 8.00 mmol) in THF (10 mL) was stirred at –78°C under dry N_2 and treated dropwise with a solution of BuLi (5.3 mL, 1.5 M in hexane, 8.0 mmol). The solution was kept at –78°C for 40 min, and then a solution of 2-[4-(1,1-dimethylethyl)phenyl]ethyl 2-methylpropanoate (**11**; 1.98 g, 7.97 mmol) in THF (10 mL) was added dropwise. The resulting solution was kept at –78°C for 30 min and was then added dropwise to a stirred solution of 1,1′-carbonyldiimidazole (0.630 g, 3.89 mmol) in THF (10 mL) at 25°C. The mixture was kept at 25°C for 12 h, treated with water, and extracted with ether. Volatiles were removed from the combined extracts by evaporation under reduced pressure, and the residue was purified by flash chromatography (silica, hexane (95%) – ethyl acetate (5%)) to give bis{2-[4-(1,1-dimethylethyl)-phenyl]ethyl} 2,2,4,4-tetramethyl-3-oxopentanedioate (**9**; 0.882 g, 1.69 mmol, 43%) as a colorless solid. An analytically pure sample was prepared by recrystallization from hexane: mp 95–97°C; IR (melt): 1740, 1730, 1710 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.24 (s, 12H), 1.29 (s, 18H), 2.87 (t, 4H, ^3J = 6.9 Hz), 4.25 (t, 4H, ^3J = 6.9 Hz), 7.11 (d, 4H, ^3J = 8.2 Hz), 7.31 (d, 4H, ^3J = 8.2 Hz); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 23.4, 31.3, 34.2, 34.3, 55.1, 65.8, 125.4, 128.5, 134.3, 149.4, 173.3, 205.1; HRMS (FAB) calcd. for $C_{33}H_{46}O_5$ + H, *m/e:* 523.3423; found, *m/e:* 523.3465.

Diethyl 3,7-dimethylene-9-oxobicyclo[3.3.1]nonane-1,5-dicarboxylate (15)

A mixture of diethyl 3-ketoglutarate (5.04 g, 24.9 mmol), 3-chloro-2-(chloromethyl)-1-propene (6.91 g, 55.3 mmol), K_2CO_3 (15.2 g, 110 mmol), and $PdCl_2(PPh_3)_2$ (1.75 g, 2.49 mmol) in toluene (18 mL) was stirred at reflux for 36 h. The mixture was then cooled to 25°C and filtered, and volatiles were removed from the filtrate by evaporation under reduced pressure. The residue was purified by flash chromatography (silica, hexane (85%) – ethyl acetate (15%)) to give colorless crystals of diethyl 3,7-dimethylene-9-oxobicyclo-[3.3.1]nonane-1,5-dicarboxylate (**15**; 2.60 g, 8.49 mmol, 34%): mp 48–49°C; IR (melt): 1735, 1713, 1652 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.29 (t, 6H, ^3J = 7.1 Hz), 2.76 (d, 4H, ^2J = 15.4 Hz), 3.33 (d, 4H, ^2J = 15.4 Hz), 4.26 (q, 4H, ^3J = 7.1 Hz), 4.87 (t, 4H, ^4J = 2.2 Hz); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 14.1, 44.0, 56.9, 61.6, 115.0, 138.7, 170.5, 206.9; HRMS (FAB) calcd. for $C_{17}H_{22}O_5$ + H, *m/e:* 307.1545; found, *m/e:* 307.1546. Anal. calcd. for $C_{17}H_{22}O_5$: C 66.65, H 7.24; found: C 66.35, H 7.28.

3,7-Dimethylene-1,5-bis(2-pyridyl)bicyclo[3.3.1]nonan-9-one (18)

A suspension of $Pd(OOCCH_3)_2$ (0.106 g, 0.472 mmol) and PPh_3 (0.493 g, 1.88 mmol) in toluene (25 mL) was stirred at 25°C for 30 min, and then a solution of 2-methylene-1,3-propanediol diacetate (3.57 g, 20.7 mmol) in toluene (20 mL) was added, followed by a suspension of 1,3-bis(2-pyridyl)-2-propanone (2.00 g, 9.42 mmol) and K_2CO_3 (7.82 g, 56.6 mmol) in toluene (10 mL). The resulting mixture was stirred at reflux for 45 h, cooled to 25°C, and filtered. Volatiles were removed from the filtrate by evaporation under reduced pressure, and the residue was purified by flash chromatography (silica, hexane (70%) – ethyl acetate (30%)) to give a mixture of 3,7-dimethylene-1,5-bis(2-pyridyl)bicyclo[3.3.1]-nonan-9-one (**18**) and the corresponding hydrate. Dehydration was achieved by dissolving the crude product in chlorobenzene (60 mL) and removing water by azeotropic distillation (21). This provided bicyclic dipyridylketone **18** (0.621 g, 1.96 mmol, 21%) as a tan solid. Recrystallization from hexane provided an analytically pure sample: mp 115–116°C; IR (melt): 1712, 1646 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 3.11 (d, 4H, ^2J = 15.3 Hz), 3.46 (d, 4H, ^2J = 15.3 Hz), 4.96 (t, 4H, ^4J = 2.1 Hz), 7.16 (m, 2H), 7.37 (m, 2H), 7.65 (m, 2H), 8.60 (m, 2H); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 47.6, 55.4, 114.2, 121.7, 123.0, 135.6, 141.2, 148.3, 160.5, 213.0; HRMS (FAB) calcd. for $C_{21}H_{20}N_2O$ + H, *m/e:* 317.1654; found, *m/e:* 317.1665. Anal. calcd. for $C_{21}H_{20}N_2O$: C 79.72, H 6.37; found: C 76.89, H 6.38.

Acknowledgments

We are grateful to the Natural Sciences and Engineering Research Council of Canada, the Ministère de l'Éducation du Québec, and Merck Frosst for financial support. In addition, acknowledgment is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this research. We also thank Dr. Michel Simard of the Laboratoire de Diffraction des Rayons-X, Département de Chimie, Université de Montréal, for having determined the structure of complex **6a**.

1997 McBryde Medal Award Lecture Radio frequency quadrupole ion guides in modern mass spectrometry[1]

Bruce A. Thomson

Abstract: The role of RF quadrupoles in modern mass spectrometer and tandem mass spectrometer systems is described. A good deal of the success in the application of tandem quadrupole mass spectrometers and atmospheric pressure ionization mass spectrometers is due to new applications of the RF quadrupole ion guide. Developments that led from the use of very open, "transparent" electrodes in a cryopumped system to the opposite extreme of well-confined RF quadrupoles that operate advantageously at pressures of several mTorr are described. The ion containment properties of RF quadrupoles are remarkably insensitive to the accuracy of the electrode positions. This has allowed the use of novel quadrupole designs in order to provide unique solutions to instrumentational and physical-chemical problems.

Key words: quadrupole, focusing, mass spectrometer.

Résumé : On décrit le rôle des quadripôles de radiofréquence (RF) dans les spectromètres de masse modernes ainsi que ceux en tandem. Une grande partie des succès obtenus dans l'application des spectromètres de masse quadripolaires en tandem et dans les spectromètres de masse à ionisation à pression atmosphérique est due à de nouvelles applications du guide d'ion quadripolaire de RF. On décrit les développements qui ont conduit à l'utilisation d'électrodes « transparentes » très ouvertes dans un système à pompe cryogénique, à l'extrême opposé des quadripôles de RF bien confinés qui opèrent avantageusement à des pressions de plusieurs mTorr. Les propriétés de confinement des ions des quadripôles de RF sont remarquables par leur insensibilité à la précision des positions de l'électrode. Cette caractéristique a permis d'utiliser de nouveaux arrangements dans le but d'offrir des solutions uniques à des problèmes d'instrumentation et nature physicochimique.

Mots clés : quadripôle, focalisation, spectromètre de masse.

[Traduit par la rédaction]

Introduction

Quadrupole mass spectrometers have assumed a commanding place in the field of analytical mass spectrometry, due to their relatively high sensitivity, reliability, and ruggedness. As a measure of how routine they have become, the quadrupole mass spectrometer is often employed as simply another detector for a gas chromatograph. Recent developments in techniques of coupling liquid chromatography to mass spectrometry are rapidly moving the quadrupole mass spectrometer to the same level as a routine detector for a liquid chromatograph. For example, liquid chromatography, combined with tandem mass spectrometry in the form of a triple quadrupole (a technique designated as LC/MS/MS) has become the method of choice for the high-sensitivity quantitative analysis of drugs and metabolites in biological fluids. To the manufacturer, the ongoing challenge is to make the instrument ever more sensitive, selective, and cost effective (the latter factor includes price, ease of use, automation, and the ability to process more samples per unit time). This competitive challenge has resulted over the last decade in an explosion of interest directed at the quadrupole mass spectrometer, aimed at finding new ways to improve the performance or to find alternate modes of operation that improve analytical and instrumentational characteristics. As a result, new methods of using the two-dimensional and three-dimensional (i.e., ion trap) quadrupole are being discovered (1, 2) or revived (3).

However, the interesting and useful characteristics of the quadrupole are not limited to its use as a mass filter or spectrometer. The quadrupole also has the very useful property of acting as an ion guide, capable of either focusing ions or simply confining them in a beam by counteracting dispersive effects. In this mode, the strong ion containment properties of the radio-frequency (RF) quadrupole have resulted in its development as an ion storage device (a "trap") to suspend ions in space for spectroscopic measurement (4, 5), to accumulate ions from a weak beam prior to time-of-flight mass spectrometry (2) or Penning trap mass analysis (6), or to trap ions for nondestructive mass analysis using properties of ion motion in the RF field itself (7, 8). The two-dimensional RF quadrupole is used as the collision cell in triple quadrupoles (although some manufacturers prefer to use a hexapole or octapole, rather than a quadrupole), as a guide to transfer ions from the atmosphere-to-vacuum orifice of an atmospheric pressure

Fig. 1. Cross-sectional view of a conventional quadrupole with cylindrical electrodes. Opposite electrodes are connected together, with opposite phases applied to the two pairs of electrodes. The resulting equipotentials at any point in time are shown between the electrodes.

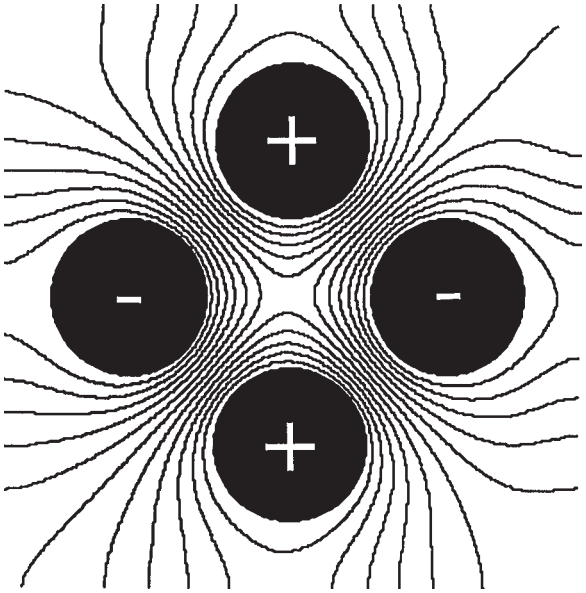

Fig. 2. The *x* and *y* components of motion of an ion inside the quadrupole at a *q* value of 0.15, with distance expressed in units of r_0, the radius of the inscribed circle between the rods. The motion consists mainly of a small "wiggle" at the RF frequency, superimposed on the higher amplitude secular motion, whose frequency is a unique function of the *q* value.

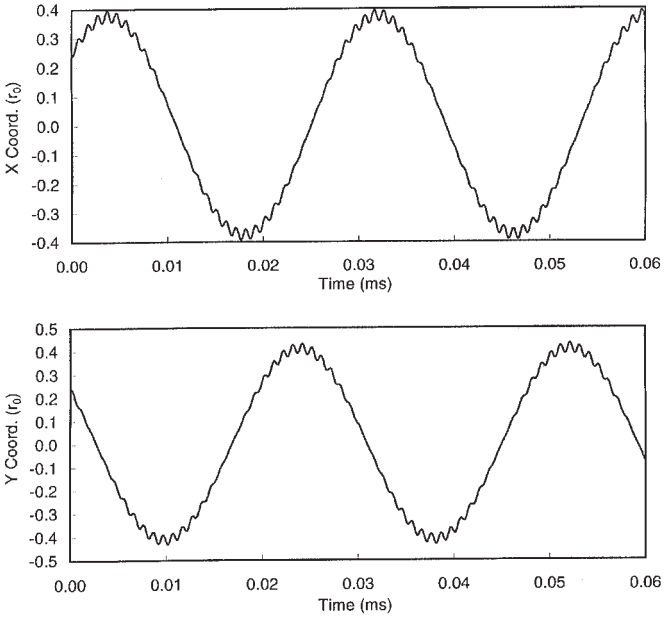


ionization (API) source (9), as the entrance optics into a mass-resolving quadrupole (a so-called Brubaker lens (10)), and as a guide from an external ion source through the strong fringing magnetic field of a Fourier-transform mass spectrometer (11).

One of the interesting things about the RF quadrupole ion guide is that, in contrast to the quadrupole mass spectrometer, the confinement characteristics are particularly insensitive to the accuracy and precision of the surrounding electrodes. While a mass filter must have electrodes that are accurately shaped and positioned to a tolerance of several parts per million (i.e., less than 1 μm), in many cases the RF-only beam guide can in principle be constructed of copper plumbing pipe without significant loss of efficiency (ignoring for the sake of this argument the fact that copper is not a suitable conductive surface for ion optical elements). Aside from the obvious benefits of cost, this factor, along with the strong containment properties, has resulted in the development of novel RF quadrupole guides that provide unique solutions or benefits in the design and performance of the triple quadrupole. The developments to be described here are the outcome of the last 15 years of research at SCIEX, and are the product of many contributing scientists in the research department. Acknowledgments for specific developments will be made at each point.

The physics of the quadrupole

The properties of quadrupole fields, along with recognition of almost all of the practical applications for operation as a mass spectrometer or ion-containment device, are found in the early papers and patents of Wolfgang Paul in Germany (12, 13), and Weurker and Langmuir in California (14, 15). For the purposes of this article, however, a thorough and comprehensive description of the development and use of multipoles (including, but not emphasizing, quadrupoles) is found in an article by Gerlich (16), following from the earlier work of Teloy and Gerlich (17) in developing the octapole beam guide for spectroscopic measurements.

The conventional RF quadrupole consists of four electrodes (usually cylindrical in shape) symmetrically disposed about a central axis, to which RF voltages are applied. The quadrupolar field results from opposite electrodes being at the same phase, and adjacent electrodes at opposite phases. Figure 1 shows the electrode arrangement, as well as the equipotentials in the *x*–*y* plane (forming rectilinear hyperbola). The equations of motion for an ion in this potential field are well known (the Mathieu equations (18)). The solution, which is a function of the ion mass (*m*), the radius of the inscribed circle between the rods (r_0), and the angular frequency and amplitude of the RF voltage applied to the electrodes (ω and *V*, respectively), is characterized by regions of stability and instability according to whether the amplitude of ion motion grows exponentially or remains bounded in space. Stability criteria can be expressed in terms of the non-dimensional parameter $q = 4eV/m\omega^2 r_0^2$; for values of $q > 0.907$, the ion motion is unstable (other, smaller regions of stability in *q*-space are ignored here).

At low values of *q* (less than approximately 0.4), the motion of an ion in the field is largely composed of a small high-frequency component (at the RF frequency), superimposed on a larger amplitude, lower frequency motion, the frequency of which is a unique function of *q*. Figure 2 shows a typical trajectory at a *q* of 0.15 (shown as the *x* and *y* components of motion, which, in a perfect quadrupolar field, are uncoupled).

An explanation of the low-frequency (so called "secular") motion is found in the mathematical derivations of the pseudopotential well model by Dehmelt (19), and the "adiabicity" model by Gerlich (16). Even though the ion motion

© 1998 NRC Canada

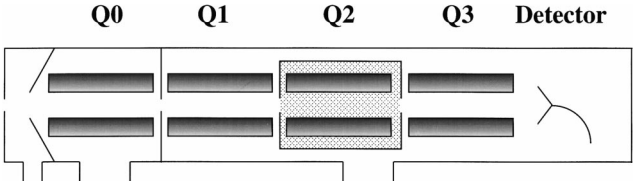
contains an infinite series of frequencies, to a very good approximation it can be treated as the secular motion with a small RF oscillation superimposed. The secular frequency can be viewed as simple harmonic motion in a pseudopotential well of depth $qV/8$. The physical justification for the concept of a potential well formed by the RF field is expressed by Gerlich (16): inhomogeneous oscillatory fields result in an average force toward the region of weakest field. In the case of a quadrupole, the region of weakest field is at the center of the rods. Thus, the RF field produces a net inward (restoring) force on every ion that is stable, resulting in oscillation about the center with an amplitude that depends on the initial position and velocity in the field. In the absence of any dissipation, the system is on average conservative, so that (on average) there is no gain or loss of kinetic energy by the ion. An ion that enters the quadrupole with a radial energy that is less than the depth of the pseudopotential well is radially confined by the field, and thus transmitted unless its amplitude of oscillation is large enough to cause it to strike a rod surface.

Applications in a triple quadrupole mass spectrometer system

The first commercial use of the RF quadrupole as an ion-containment and transport device was as a gas cell for collisionally induced dissociation in a triple quadrupole mass spectrometer (20). In a triple quadrupole (Fig. 3), ions from the source are selected by the first quadrupole, and accelerated at several tens of electron volts energy into a low-pressure gas in the center quadrupole. Fragment ions formed by collisions with the gas are mass analyzed by the third quadrupole (operated in a resolving mode). The strong containment field in the center RF quadrupole minimizes the scattering losses as ions collide with the gas molecules, allowing high sensitivity to be achieved. While the conventional RF quadrupole collision cell was a pressurized cell (a chamber with entrance and exit apertures that maintained a uniform gas density in the cell), one of the first innovations at SCIEX (by Barry French (9)) was to use a supersonic gas jet crossing the axis of the quadrupole as the collision region. This allowed the quadrupole to be closely coupled to the following mass-resolving quadrupole without an intervening aperture, and produced a well-defined collision region defined by the boundaries of the free jet. However, it required development of an RF quadrupole with electrodes that were "transparent" in order to avoid blocking or interfering with the transverse gas flow. The quadrupole was constructed of fine stainless steel wire strung between cylindrical end pieces, with the wires forming the contour of each of the four electrode surfaces (Fig. 4). Critical to the design was the use of cryopumping to condense the nitrogen or argon gas jet on a cold surface just outside of the wire quadrupole. This provided a one-pass system for the gas molecules, ensuring that no gas was scattered outside of the collision region. This wire quadrupole design was used on the SCIEX TAGA 6000 system (a triple quadrupole mass spectrometer system equipped with high-pressure ion sources), the first commercial triple quadrupole mass spectrometer to be introduced.

The concept of a "transparent" quadrupole to guide ions through a region of directed gas flow was also employed in the vacuum interface region for the TAGA 6000, which used an atmospheric pressure chemical ionization (APCI) source. Ions

Fig. 3. Schematic view of a triple quadrupole mass spectrometer system. Q1 and Q3 are mass resolving quadrupoles, while Q2 is an RF quadrupole collision cell. The Q1/Q2/Q3 configuration is generic; the use of Q0 as an ion guide in front of Q1 is usually limited to those triple quadrupole systems which use atmospheric pressure ion sources, such as electrospray.



and gas entered the chamber through a small orifice in an expanding supersonic jet. An RF quadrupole constructed of small wires outlining the electrode surfaces produced the same effect of confining the ions along the axis while allowing the gas to escape to surrounding cryosurfaces. Both of these developments demonstrated that highly efficient ion containment and transmission could be achieved with electrodes that were far from accurately defined and positioned. The same configurations were employed in the API III LC/MS/MS system several years later. The API III, based on the earlier TAGA platform, became the gold standard in the field of quantitative LC/MS/MS.

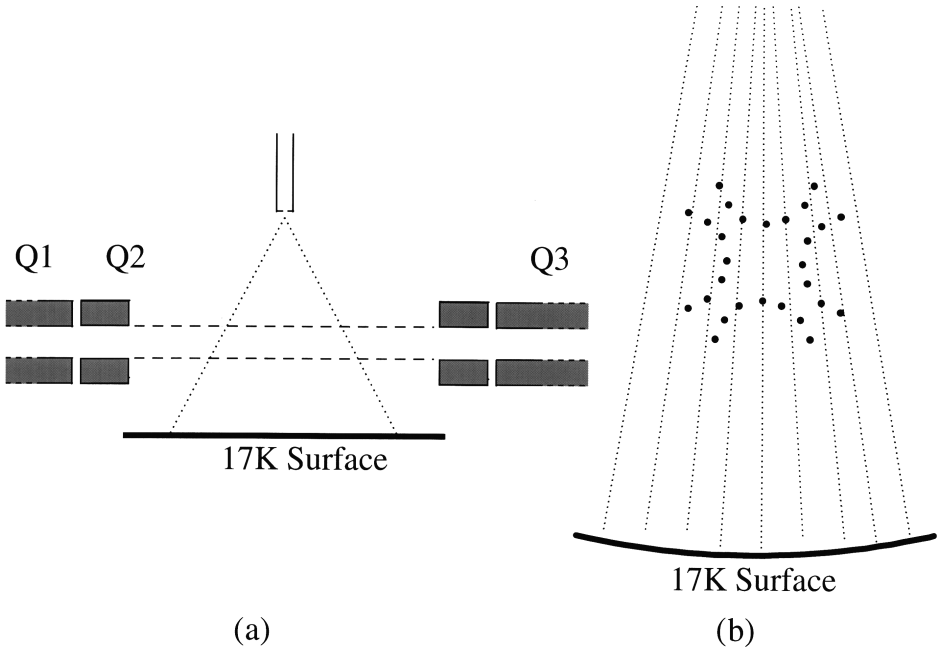
Collisional focusing in an RF quadrupole

One of the most significant breakthroughs to follow was the development of "collisional focusing" by Don Douglas and Barry French (21). The term refers to the combined effect of gas drag (due to multiple collisions between the ions and the gas) and radial containment by the RF field. The dissipative action of the collisions (damping ion motion in both the radial and axial directions) allows the ions to fall toward the centre of the potential well, thus effectively focusing the ions toward the axis. This effect can be seen in Fig. 5, which shows the results of a numerical simulation of ion motion in an RF field, including the effect of collisions with nitrogen gas at a pressure of 7×10^{-3} Torr (using a hard-sphere model) (1 Torr = 133.3 Pa). The effects are beneficial in two important regards: (*i*) gas drag in the axial direction reduces the energy spread of the ions, improving the mass resolution in the following quadrupole; (*ii*) the radial focusing improves ion transmission efficiency through a following aperture, and provides a narrower ion beam that better matches the acceptance of the following quadrupole mass filter. The use of collisional focusing was key to the design of the API 300, the triple quadrupole product that succeeded the API III and used differential pumping (with turbo pumps) rather than cryopumping. By staging the pumping so that the first ion guide (Q0) is at a pressure of about 7×10^{-3} Torr, ions that enter Q0 at an energy of several electron volts are slowed to 1–2 eV (with a spread of less than 1 eV), and are collisionally focused through an aperture of less than 2 mm diameter at the end of Q0. This provides highly efficient (greater than 50%) capture and transfer of ions from a region at moderate pressure (7×10^{-3} Torr) into a vacuum regime (10^{-5} Torr), with an ion energy spread that allows good mass resolution in the following mass-resolving quadrupole (Q1).

Recently, the same principal has been employed to

© 1998 NRC Canada

Fig. 4. The "transparent" RF quadrupole with transverse free jet (used on the TAGA 6000 and the API III triple quadrupoles). (*a*) Side view. (*b*) End view.



introduce ions into a time-of-flight mass spectrometer system (22). Even at a pressure of 7×10^{-2} Torr, ions are effectively cooled and focused into the orthogonal extraction region of the time-of-flight mass spectrometer, thereby providing the reduced spatial and energy spread required to achieve good mass resolution.

Precisely the same principles were applied to the development of a high-pressure collision cell (23). The transparent quadrupole with the transverse gas jet was replaced with an RF quadrupole in a chamber pressurized to 7×10^{-3} Torr, a pressure significantly higher than that used in earlier versions of the enclosed collision cell. The application of collisional focusing in the collision cell provided the unusual (but very desirable) benefit of simultaneously increasing both the sensitivity and the mass resolution for fragment ions. The sensitivity in an MS/MS mode was increased by a factor of 5–10 over that previously achieved with the open collision cell, while the mass resolution increased to the point of being able to distinguish the separate isotopic peaks from multiply charged ions with up to four charges. Figure 6 (reproduced, with permission, from ref. 23) shows the fragment ion spectrum from the *m*/*z* 440 quadruply charged ion of renin substrate, a peptide of MW 1758. The expanded views of several regions of the spectrum show the ability to resolve individual peaks that are separated by as little as 0.25 mass-to-charge units.

Axial electric fields in RF quadrupoles

An unwanted effect of employing collisional focusing in Q0 and in Q2 is that some ions undergo so many collisions that they are effectively brought to rest (with no average forward motion) before reaching the exit from the high-pressure region. Since in a conventional quadrupole there is no electric field in the axial direction (all of the fields being radially directed), there is nothing to force the ions toward the exit end. While all of the ions do eventually reach the exit (presumably due to diffusion and space charge forces), the significant time delay causes problems in certain modes of operation. For example, selected-reaction monitoring (SRM) is an MS/MS scan mode in which Q1 and Q3 are used to monitor several fragmentation reactions of interest by stepping several times per second between mass values corresponding to the ions of interest. If two different precursor ions happen to form the same product (fragment) ion, then ions that take longer to reach the exit of the collision cell than the measurement time being used (typically 50–200 ms) can be recorded in the wrong channel. This leads to an effect known as "cross-talk," in which some ions from one transition (*m*/*z* 500 fragmenting to *m*/*z* 230, for example) are recorded during the measurement time for the transition monitored immediately after (*m*/*z* 517 fragmenting to *m*/*z* 230). As a result, false readings can be recorded in the second channel. In another type of scan mode (the precursor ion scan mode, in which Q3 is fixed at a fragment ion of interest, and Q1 is scanned in order to reveal all of the precursors that form that fragment), the effect of time dispersion in Q2 due to the highly damped axial motion leads to a loss in mass resolution and sensitivity.

Observation of these effects stimulated the development of several methods of generating an axial field directed along the axis of the quadrupole, in order to move the ions quickly toward the exit (24). In all cases, the goal was to provide enough force on the ions to cause them to drift through the high-pressure quadrupole within much less than the typical measurement time, without inducing effects that would couple to their radial motion and reduce the collisional focusing effects.

One method involved simply dividing the RF quadrupole into several segments, and applying a different rod-offset voltage to each segment. This establishes a different dc potential within each segment, and, by arranging the voltages to decrease monotonically toward the exit, an approximately

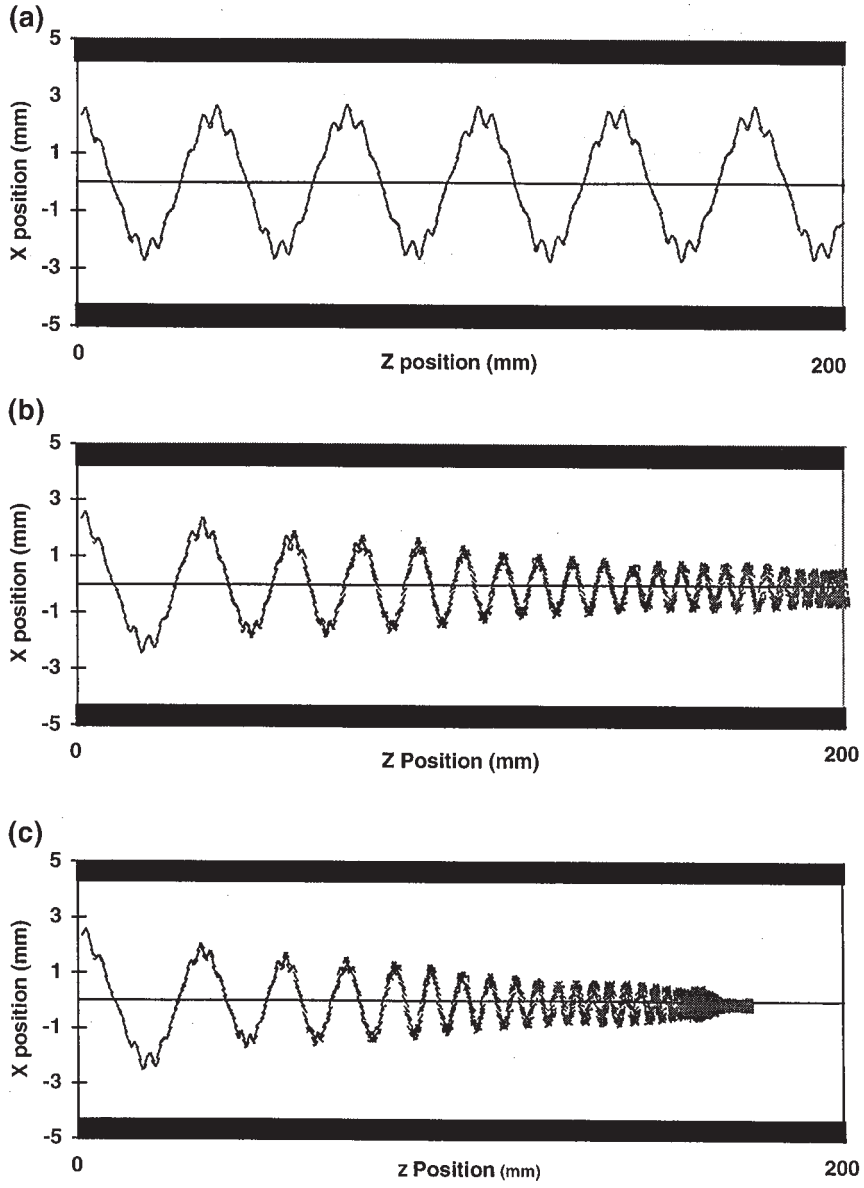
Fig. 5. Numerical simulation of an ion trajectory in a quadrupole at a pressures of (*a*) 0, (*b*) 5, and (*c*) 7 mTorr of nitrogen, showing how collisions damp the ion motion toward the centre of the quadrupole. Conditions for this simulation: *m*/*z* 1000, hard-sphere collisions with a collision cross section of 200×10^{-16} cm^2, *q*-value = 0.35. At the higher pressure, the ion does not reach the end of the quadrupole during the simulation time (0.8 ms), because neither space charge nor axial field effects have been included.



uniform dc field can be generated inside the device, parallel to the axis. This method is analogous to the use of guard rings in an ion mobility drift tube to establish a potential gradient along the axis. An RF quadrupole consisting of six separate segments, with a total potential drop of 2–3 V over the 20 cm length, was sufficient to eliminate effects produced by the loss of axial ion energy. A 20-segment RF quadrupole collision cell has also been constructed, and was used to measure the cross sections of various mass-selected ions in a triple quadrupole mass spectrometer (25). This device is described more fully in the following section.

Although the segmented quadrupole provided the desired characteristics of eliminating the problems described above, this method is mechanically complex, requiring separate connections to all 24 small rods (for 6 segments). A simpler method of generating an axial field was developed by using an asymmetric electrode geometry combined with a differential dc voltage on the two pairs of rods. Referred to as the Linac®, it has one pair of cylindrical rods tilted toward the entrance, the other pair toward the exit (Fig. 7). This configuration results in one pair of opposing rods being closer to the axis at the entrance end, and the other pair of rods being closer to the axis at the exit end. With slightly different dc voltages applied to each rod pair, an axial potential gradient (electric field) is established. This follows from the fact that the electric potential on the axis is dominated by the voltage applied to one pair of rods at the entrance, and by the voltage applied to the other pair of rods at the exit. In practice, a potential difference of

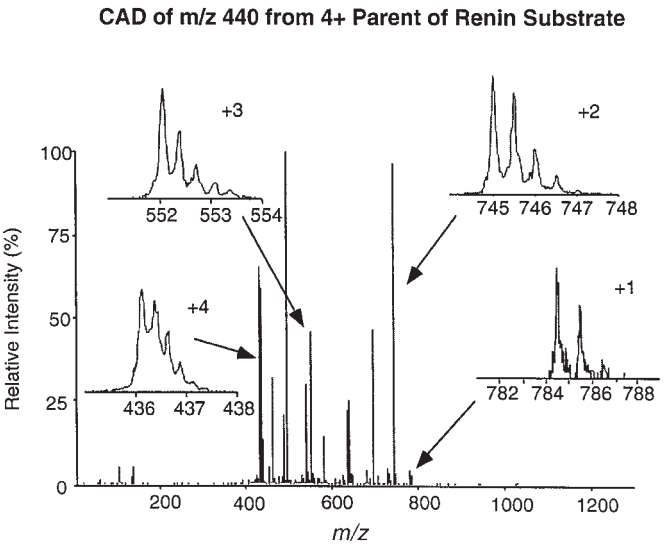
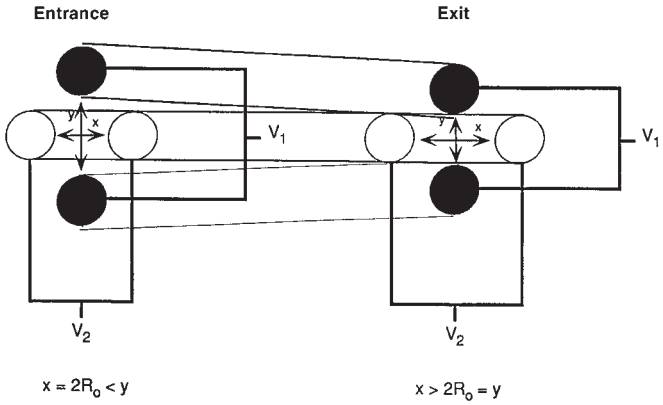
Fig. 6. Fragmentation spectrum (MS/MS) of $(M + 4H)^{4+}$ (m/z 440) from renin substrate at high fragment ion resolution, showing separation of the isotopic peaks for fragment ions with 1, 2, 3, and 4 charges (attached protons). Collision energy, 112 eV; collision gas thickness (CGT), $4 \times 10^{15}/cm^2$. Reprinted with permission from ref. 23. © 1995 American Chemical Society.



approximately 2 V between the rod pairs is sufficient to reduce or eliminate the cross-talk problem and the parent scan problems described above. Numerical modeling of the Linac electrode geometry reveals that the field gradient along the center axis due to a potential difference of 2 V is only 0.075 V cm^{-1} over the 20 cm length. This weak field is nevertheless enough to cause the ions to rapidly drift toward the exit end of the quadrupole. For example, an ion with a reduced ion mobility of 1 cm^2 V^{-1} s^{-1} would require only 2.4 ms to traverse the 20 cm length of the quadrupole at a pressure of 7 mTorr.

Other configurations that were designed to generate an axial field were also effective. These included using a segmented case surrounding the quadrupole, with different dc voltages applied to each segment, as well as using a high-resistance surface on auxiliary electrodes located between the main electrodes, with different dc potentials applied to each end of the rods to generate a continuous potential gradient. One aspect common to all geometries, however, is that in spite of using non-ideal electrode shapes and positions (far from ideal, in the case of the Linac®), in configurations that inevitably produced some non-quadrupolar radial field components in addition to the desired axial fields, the performance as an ion guide was not significantly affected. Recently, the original Linac® prototype, which used truncated conical rods rather than cylindrical rods to produce the axial field, was thoroughly investigated, both for its operational characteristics and for its function as the collision cell in a triple quadrupole. This study, conducted by B.A. Mansoori, E.W. Dyer, C.M. Lock, and R.K. Boyd of the National Research Council in Halifax, confirmed that the Linac® configuration is effective at eliminating the undesirable trapping associated with the high-pressure RF quadrupole, without affecting the transmission and focusing characteristics. (The full results of this study will soon be submitted for publication.) The conclusion supports the original contention that the confinement properties of RF quadupole

Fig. 7. The Linac® collision cell, with one set of cylindrical rods tilted toward the axis, the other set tilted away from the axis. Combined with slightly different dc voltages applied to the two sets of rods (V_1 and V_2), this produces a small axial field.



devices are very insensitive to the purity of the quadrupole field.

Cross sections of protein ions

The development of electrospray mass spectrometry has greatly expanded the range of applications to which mass spectrometry can be applied. This ionization method allows ionic and labile compounds to be easily and sensitively detected without unwanted fragmentation. Combined with MS/MS, it offers unmatched specificity and sensitivity for the analysis of biological compounds, including biopolymers such as proteins, peptides, and nucleotides. The introduction of electrospray mass spectrometry into the field of biochemistry has also led to its application for the study of the structure of proteins and biopolymers. For example, Covey and Douglas (26) used the collision cell of a triple quadrupole mass spectrometer to measure the cross section of protein ions, by measuring the rate of energy loss of ions as they experienced gas drag in traversing the cell. Herron et al. (27) have used an ion trap mass spectrometer to study ion–ion reactions of electrospray negative ions, in order to learn more about their structure and reactivity. Jarrold and co-workers (28) have combined a low-pressure drift cell with a mass spectrometer to investigate the cross section of protein ions.

The development of the axial field quadrupole described in the previous section led us to apply this device to measure the ion mobility of mass-selected ions in a segmented quadrupole collision cell (25). We replaced the conventional quadrupole collision cell in the API 300 triple quadrupole mass spectrometer with the 20-segment quadrupole described above. We were able to establish a low, uniform, electric field along the axis by applying decreasing potentials to each quadrupole segment, using a potential divider network. Using the electrospray ion source to generate multiply charged ions from proteins such as myoglobin and ubiquitin, ions were selected by Q1, allowing only one m/z value into the collision cell at one time. By gating the ions into Q2, and using a multichannel scalar to detect the ion pulse at the detector, we were able to measure the drift time of the ions. Ion mobilities were measured by varying the electric field and, from these, the ion-neutral

© 1998 NRC Canada

ollision cross sections were calculated. Results obtained with this method were in good agreement with the cross sections measured by Collings and Douglas using their energy loss method (29).

Determination of cross sections allows insight into the shape and size of large biopolymers. For example, the cross section of different charge states of apomyoglobin was observed to increase with charge state, indicating that ions with more attached charges (protons) probably exist in a more extended form (at least in the gas phase) than those with fewer charges. Holomyoglobin (myoglobin with the heme group attached) was observed to have a smaller cross section than myoglobin without the heme, supporting the view that holomyoglobin is a more compact structure than apomyoglobin (myoglobin without the heme). Douglas and others continue to use electrospray mass spectrometry to probe the structure, binding energies, and reaction kinetics of proteins.

Conclusions

Radio-frequency quadrupoles have found diverse applications in analytical mass spectrometer and tandem mass spectrometer systems where mass analysis and quantitation are the primary goals, as well as in physical chemistry applications where other properties of ions are measured while confined by an RF field. The high tolerance toward "imperfect" quadrupolar fields allows RF multipoles to be applied in unique and creative ways in order to solve problems. This tolerance has the added benefit of loosening conventional design constraints on quadrupole design, thus contributing to reduced cost and higher performance in commercial mass spectrometer systems.

On the formation of diphenylmethane structures in lignin under kraft, EMCC®, and soda pulping conditions

Behzad C. Ahvazi, Gerry Pageau, and Dimitris S. Argyropoulos

Abstract: This paper describes our efforts focused at defining the formation of diphenylmethane moieties in lignin during conventional kraft and soda pulping conditions. This objective was realized by confirming, initially, the assignment of a ^{31}P NMR signal as being due exclusively to the presence of phosphitylated diphenylmethane (DPM) phenolic hydroxyl groups. More specifically, softwood milled wood lignin (*Picea mariana*) was subjected to kraft pulping conditions in the presence and absence of varying amounts of formaldehyde. After quantitative recovery of the lignin, the ^{31}P NMR spectra were recorded and the spectra revealed selective signal growth in the region confined between 142.8 and 144.3 ppm, in accordance with previous model compound work and detailed calculations based on the Hammett principles. To further substantiate our conclusions we also carried out two series of isothermal (120°C) kraft and soda pulping experiments followed by quantitative determinations of the DPM moieties, and correlated our findings with the differences in chemistry known to occur between the two processes. Finally, diphenylmethane phenolic moieties were determined in isolated residual lignins from two western hemlock kraft pulp samples produced via an EMCC® mill protocol and a laboratory batch digester, respectively. These structures prevailed amongst the condensed phenolic units of the conventional pulp, providing additional evidence to support the fact that modern modified pulping technologies beneficially alter the structure of residual kraft lignin.

Key words: phenyl groups, kraft pulping, modified kraft process, nuclear magnetic resonance (NMR), phosphorus spectroscopy.

Résumé : Dans ce travail, on décrit nos travaux orientés vers la démonstration de conditions de formation d'entités diphénylméthane dans les conditions de fabrication de pâtes kraft et à la soude. L'objectif de ces travaux a été réalisé en confirmant initialement l'attribution d'un signal RMN du ^{31}P uniquement à la présence de groupes hydroxyles phénoliques phosphylatés du diphénylméthane. D'une façon plus précise, on a soumis de la lignine de bois mou broyé (*Picea mariana*) à des conditions de fabrication de pâte kraft, en l'absence et en présence de quantités variables de formaldéhyde. Après avoir récupéré la lignine d'une façon quantitative, on a enregistré les spectres RMN du ^{31}P qui révèlent la croissance sélective de signaux dans la région comprise entre 142,8 et 144,3 ppm, en accord avec le travail antérieur sur un composé modèle et avec des calculs détaillés basés sur les principes de Hammett. Afin de confirmer nos conclusions, on a aussi effectué deux séries d'expériences isothermes (120°C) de formation de pâte kraft et de pâte à la soude, suivies de déterminations quantitatives des portions de DPM, et on a établi une corrélation entre nos résultats et les différences bien connues dans les chimies de ces deux procédés. Enfin, on a déterminé les portions phénoliques de diphénylméthane présentes dans des lignines résiduelles isolées à partir de deux échantillons de pâte kraft de la pruche de l'ouest obtenues respectivement par le biais d'un protocole EMCC® en usine et d'un lessiveur discontinu de laboratoire. Ces structures sont prévalentes dans les unités phénoliques condensées de la pâte conventionnelle; ces résultats fournissent des preuves supplémentaires relatives au fait que les technologies modernes de fabrication de pâte altèrent de façon avantageuse la structure de la lignine kraft résiduelle.

Mots clés : groupes phényles, fabrication de pâte kraft, procédé de fabrication kraft modifié, résonance magnétique nucléaire (RMN), spectroscopie du phosphore.

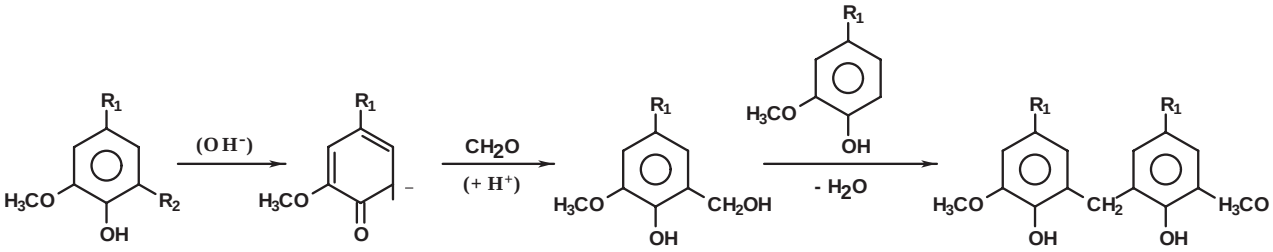
Introduction

While the ether bonds of lignin cleave efficiently under alkaline pulping conditions, the formation of condensed structures decreases its reactivity and diminishes the solubility of the residual lignin (1). This phenomenon seriously interferes with the complete removal of lignin and the rate of delignification, especially during the final stages of most pulping processes.

During the past several years a number of modifications aimed at enhancing delignification have been proposed for the conventional kraft pulping process (2–5). Rapid displacement heating (RDH) (6–9) and modified continuous cooking (MCC) (10–13) are two examples of these processes. In addition, the

© 1998 NRC Canada

Scheme 1.



use of pulping additives such as polysulphide (14–16) and anthraquinone (16–18) have also been advocated.

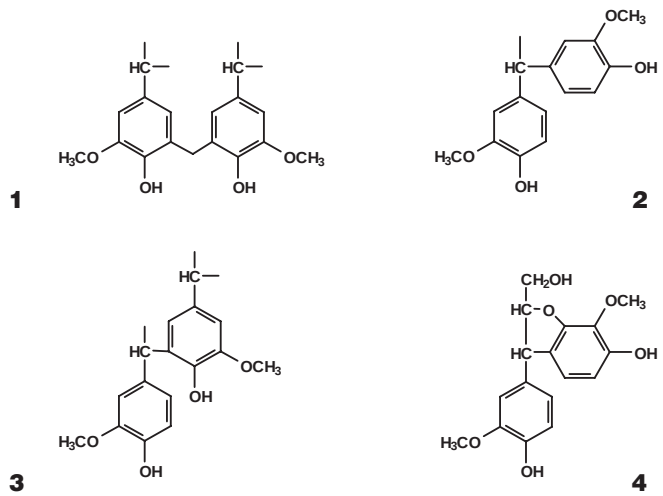
Amongst the reactions that are known to interfere with the process of alkaline delignification are those involving the formation of carbon–carbon bonds. Formaldehyde is known to be liberated (19) as early as 100°C, as a result of C_γ elimination from phenylcoumaran (20, 21) and from guaiacylglycerol-β-aryl ether structures, both abundant in native lignin (22–24). The released formaldehyde is known to cause the substitution of hydroxymethyl groups at positions *ortho* to the phenolate moieties (22). This potentially represents a very important reaction since one third of the phenolic nuclei in softwood kraft lignin (25) and about one half of the phenolic and non-phenolic units in softwood milled wood lignin contain free C5 positions (23). The methylolated phenols may undergo further reaction to yield diphenylmethane moieties (1, 26, 27) (Scheme 1).

A number of these structures (**1**–**4**) have been suggested (28–31). Another condensation reaction caused by the liberation of formaldehyde during alkaline hydrolysis is Tollen's reaction (1). This reaction involves the substitution of hydroxymethyl groups at side-chain positions provided activating carbonyl groups are present (1, 25).

Although several studies by Chiang and Funaoka (32–34) have claimed to show convincing qualitative and quantitative evidence for the presence of diphenylmethanes in residual kraft lignin, a number of questions in relation to the method of detection have recently surfaced (35). Since the development of ^{31}P NMR spectroscopy for probing lignin structure (36–40), the technique has been successfully implemented for the absolute determination of the various phenolic and non-phenolic structures in several native and technical lignins (41–44). The availability of a phosphitylating reagent (40) that permits excellent resolution and the quantitative spectroscopic detection of several phenolic moieties with varying substitution patterns (44–46) provides an excellent opportunity for systematically exploring the complex reactions that occur in lignin during alkaline pulping. For example, such an effort has already led to the definition of the fundamental thermodynamic parameters that govern the stereoselective degradation of the arylglycerol-β-aryl ether bonds in milled wood lignin under kraft pulping conditions (47).

As mills move toward elemental chlorine free bleaching (ECF), the negative impact of condensed lignin structures on the final pulp brightness ceiling provides additional incentives to minimize the possibility that condensation reactions may occur in the digester and during oxygen delignification. The precise identification of such structures and their formation kinetics could be a major step forward toward understanding and minimizing their detrimental effects.

In this paper we describe our efforts focused on defining the formation of diphenylmethane moieties in lignin during conventional kraft and soda pulping conditions. This objective was realized by initially confirming the assignment of a ^{31}P NMR signal as being due exclusively to the presence of phosphitylated diphenylmethane phenolic hydroxyl groups. The overall phosphitylation reaction of labile protons is depicted in Scheme 2. We then accumulated kinetic data for the formation of these species under soda and kraft pulping conditions and correlated this information to known chemistry.



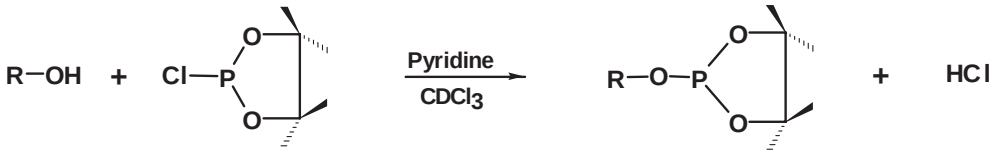
Experimental

Treatment of milled wood lignin under homogeneous kraft or soda pulping conditions

Initially, a white liquor solution containing 7.0 g of sodium hydroxide (0.175 mol NaOH) and 6.2 g of sodium sulphide (0.026 mol $Na_2S{\cdot}9H_2O$) per 100 mL deionized water was prepared. For the case of the soda "cooks" the molar amount of sodium sulphide ($Na_2S{\cdot}9H_2O$) used for the kraft pulping experiments was substituted with sodium hydroxide dissolved in 200 mL of deionized water and dioxane (1:1 v/v). This solution was then mixed with an equal volume of dioxane. During a typical experiment, 0.1 g of softwood milled wood lignin, prepared according to the Björkman procedure (47, 48) and having the following elemental composition: 60.86% carbon, 5.71% hydrogen, and 15.45% methoxy, was used. This lignin was dissolved in 1.33 g of the previously described white

© 1998 NRC Canada

Scheme 2.



liquor (the ratio of liquor to lignin was 4:1). The reaction was carried out in a 10 mL stainless steel bomb whose air was displaced by nitrogen. The kraft cooking was simulated by heating and occasionally shaking the bomb in an oil bath preheated to the desired temperature and for specific time intervals. At the end of the reaction period, the bomb was cooled with cold water and its contents were acidified to pH 2 using dilute hydrochloric acid (0.2 M HCl). The precipitate was allowed to settle overnight. It was then collected by centrifugation and washed with acidic water to remove the inorganic salts. The precipitated degraded lignin was then freeze-dried and brought to constant weight at room temperature under reduced pressure. This material accounted for approximately 80% of the initial weight of lignin used. In an effort to isolate the remaining 20%, the solution containing the water-soluble low molecular weight lignin resulting from the first aqueous acidic precipitation was allowed to dry at room temperature. The remaining low molecular weight lignin was extracted by addition of 10–15 mL high-grade tetrahydrofuran. This was followed by evaporation of the solvent to a fine viscous residue, and dropwise addition to 20 mL of diethyl ether. This step was repeated 2–3 times, allowing the collection of more lignin, free from inorganic salts. Finally, the diethyl ether was evaporated and the remaining lignin was freeze-dried. The samples, after being brought to constant weight under reduced pressure, accounted for almost 16% of the starting lignin. The two sets of degraded lignin samples collected were then mixed thoroughly prior to subsequent analyses.

Addition of formaldehyde to milled wood lignin followed by homogeneous kraft pulping

Milled wood lignin (100 mg) was placed in a 10 mL stainless steel bomb. The lignin was then dissolved by the addition of 1.33 g of white liquor solution, prepared by dissolving 7.0 g of sodium hydroxide (NaOH) and 6.2 g of sodium sulphide ($Na_2S{\cdot}9H_2O$) in a solution (200 mL) of deionized water and absolute dioxane (1:1 v/v). Two separate sets of experiments, in which the amount of formaldehyde added was varied, were carried out at 120°C. For the first series of experiments, 11.1 μL of a 30% formaldehyde solution, accounting for 50% of the total β-aryl ether bonds, was added to each sample, while for the second series, 22.2 μL (representing 100% of the total β-aryl ether bonds) was added. After replacing the air with nitrogen, each bomb was sealed. Four reaction bombs (each containing the above mixture) were then placed in a preheated oil bath and after occasional shaking they were removed after 1, 2, 3, and 4 h of treatment. The isolation and purification procedures were conducted in a manner identical to those discussed in the previous section.

Preparation of kraft pulps and residual lignin isolation

A conventional western hemlock kraft pulp was prepared at Paprican in a laboratory batch digester using conditions described previously (46). The western hemlock EMCC® (extended modified continuous cooking) pulp was supplied by a Canadian mill. The isolation of residual lignin was carried out from pre-extracted pulp meal following a procedure described previously (46).

Quantitative ^{31}P NMR spectroscopy

The derivatizing reagent 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane was synthesized (40) and used as the phosphitylation reagent. Approximately 30 mg of dry lignin was added to 800 μL of a solvent mixture containing pyridine and $CDCl_3$ at a volume ratio of 1.6:1. The mixture was stirred with a magnetic bar until the lignin was fully dissolved. This was followed by the addition of 100 μL of a solution containing both cyclohexanol (11 mg/mL) as an internal standard and chromium acetylacetonate (5 mg/mL) as a relaxation reagent. Finally, 100 μL of 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane was added and the flask was sealed and shaken to ensure thorough mixing. The ^{31}P NMR spectra were obtained by using inverse gated decoupling on a Varian XL-300 FT-NMR spectrometer at 121.5 MHz. The obtained spectra were integrated 3 times on separate occasions and the resulting data were averaged out as reported here. Further details dealing with acquisition and spectral processing have been described elsewhere (40, 49).

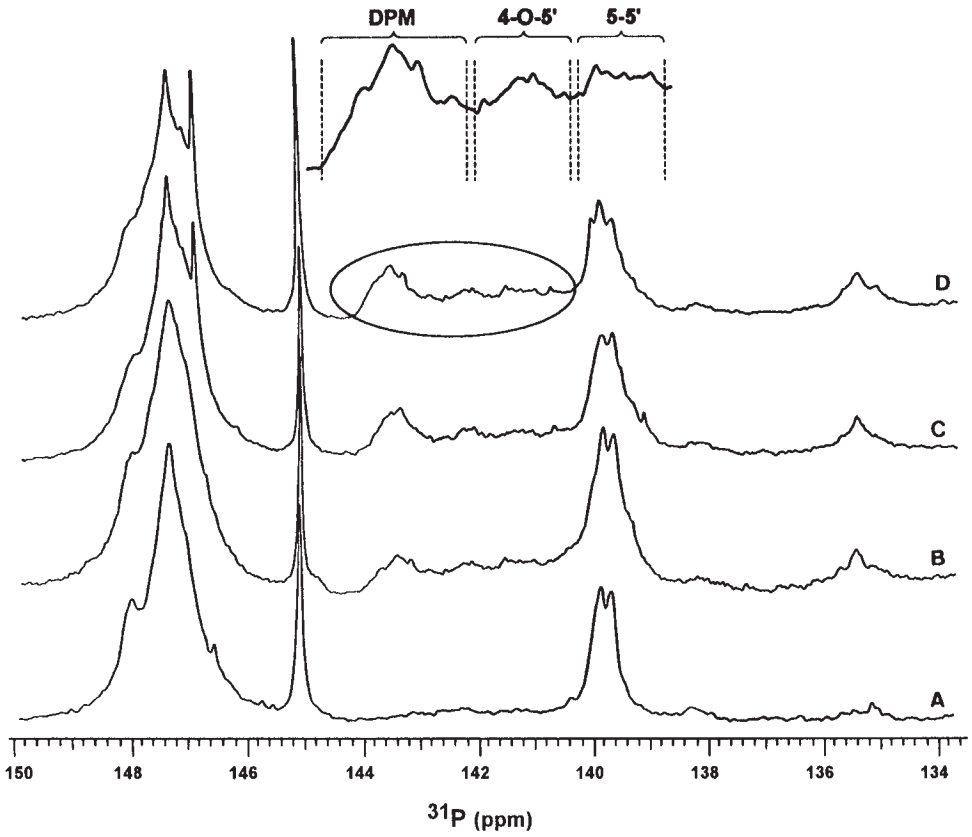
Results and discussion

In our earlier work the phosphorus NMR spectra of solubilized kraft lignin contained, among others, a signal centred around 143.5 ppm (40). On the basis of model compound work and calculations based on the Hammett principles (50), this signal was tentatively assigned to diarylmethane structures possessing free phenolic hydroxyl groups (40). In an effort to confirm the validity of our earlier work, the interaction of milled wood lignin with formaldehyde under kraft pulping conditions was clarified by conducting experiments in which different amounts of formaldehyde were introduced into the reaction mixture prior to the cook. More specifically, two different sets of experiments were carried out with four samples of milled wood lignins being subjected to kraft pulping at 120°C with the addition of formaldehyde accounting for 50 and 100% of the total aryl ether units of lignin, respectively (51). After quantitative recovery of the lignin, the ^{31}P NMR spectra were recorded and the spectra critically examined. Figure 1 shows a representative series of such spectra.

A comparison of the ^{31}P NMR spectra of milled wood lignin (*A*) to those treated under kraft pulping conditions without (*B*) and with (*C* and *D*) addition of formaldehyde reveals substantial signal growth (Table 1) at around 143.5 ppm. Indeed, the area under the broad signal (142.8–144.3 ppm), labelled DPM, was increased in spectra *C* and *D* where significant amounts of formaldehyde had been added (Table 1). In addition, the spectra of the samples to which formaldehyde was

© 1998 NRC Canada

Fig. 1. Quantitative ^{31}P NMR spectra of milled wood lignin before and after being subjected to isothermal (120°C, 3 h) homogeneous kraft pulping conditions; (*A*) blank, (*B*) control kraft pulping, (*C*) with the addition of 11 μL, and (*D*) 22 μL formaldehyde corresponding to 50% and 100% of the aryl ether structures in lignin.



added display a new signal at 147.01 ppm that appears in the aliphatic OH region. In accordance with the chemistry of the formaldehyde–phenol interaction, which is known to occur under alkaline conditions (19, 20), it is very likely that this signal is due to the aliphatic primary hydroxyl group of methylolated aromatic rings.

When the ^{31}P NMR signal in the region 142.8–144.3 ppm was integrated, the determination of the actual concentrations of diphenylmethane structures in milled wood lignin, in the presence and absence of formaldehyde under kraft pulping conditions, was made possible as a function of reaction time at 120°C (Table 1).

The quantitative data thus collected revealed that under isothermal conditions (120°C) the addition of formaldehyde to the kraft reaction medium causes the buildup of DPM structures within lignin, while in the absence of externally added formaldehyde, these structures predominate after 3–4 h of reaction. It is also interesting to note that when a large excess of formaldehyde was added (amounting to 100% of the total aryl ethers) the amount of DPM structures reached a value of 0.4 mmol/g within 60 min at 120°C, remaining approximately constant beyond this point.

In an effort to further substantiate our conclusions we then carried out two series of isothermal (120°C) kraft and soda pulping experiments followed by quantitative determinations of the DPM moieties, and correlated our findings with the differences in chemistry known to occur between the two processes.

[c] Amount of formaldehyde added, expressed as percentage of the total amount of aryl ethers present in MWL.
[d] The temperature of the kraft pulping experiment was set at 120°C.

The data of Table 2 clearly demonstrate that the formation of diphenylmethane moieties is a considerably more facile reaction under soda pulping conditions than under kraft pulping conditions. Sulphide ions present in kraft liquors are responsible for promoting and accelerating lignin fragmentation reactions as well as suppressing undesirable condensation reactions (1, 52, 53).

The presence of sulphide ions within sulfate liquors has been suggested to preclude the liberation of formaldehyde from the lignin biopolymer (19). Alternatively, the absence of sulphide, i.e., soda pulping, allows the intermediate quinone-

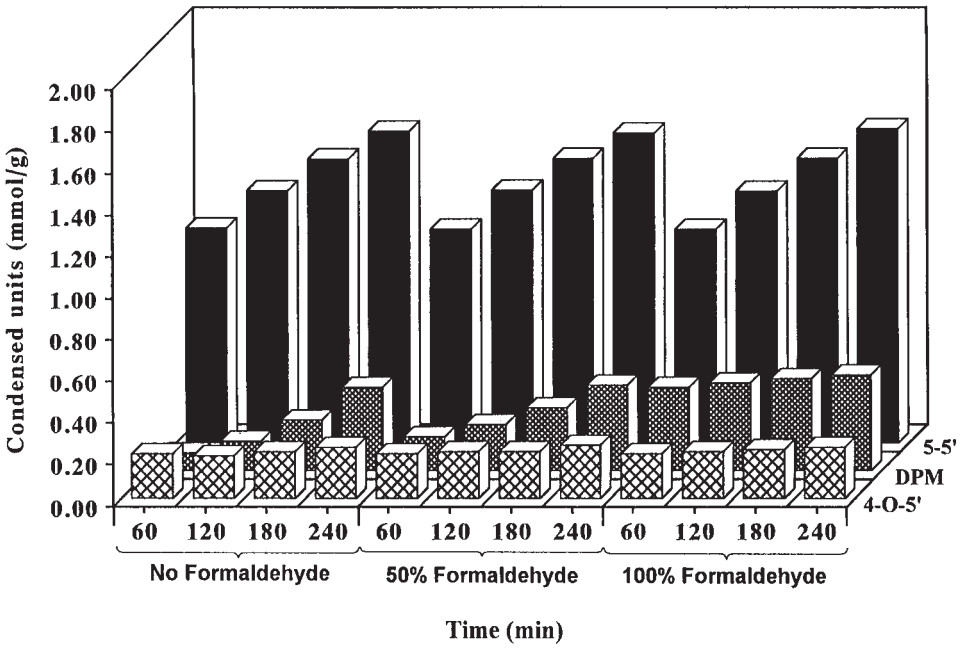
methides to lose formaldehyde, causing the formation of undesirable alkaline stable enol ethers (1, 54). The rate data of Table 2 clearly demonstrate the efficiency of formation of diphenylmethanes under soda pulping conditions, especially early in the process. Therefore, it is not surprising that bleaching a soda–AQ pulp is more difficult than bleaching a kraft pulp of a similar κ (kappa) number (55) (Scheme 3).

Among the various principles that operate during modified pulping, the control of alkalinity is of prime importance. Maintaining hydroxide concentration at a uniformly low level offers distinct advantages as far as carbohydrate degradation is concerned. In this context, maintaining a uniformly low alkalinity may also have an impact on the actual amount of diphenylmethane structures that form within the residual kraft lignin. For this reason residual lignin was isolated from two hemlock kraft pulp samples (κ number 26.0) produced via an EMCC® mill protocol and a laboratory batch digester, respectively. The data of Table 3 are in accord with the previous observations. While in the conventional kraft pulp the overall amount of C-5 substituted phenolic environments is higher by 11%, the diarylmethane structures prevail amongst them by 37%. These data, coupled with the earlier account of Froass et al. (43), provide convincing evidence supporting the fact that modern modified cooking technologies alter the structure of lignin beneficially.

The region of the ^{31}P NMR spectra assigned to the overall condensed phenolic units (140.2–144.3 ppm), in addition to the diphenylmethane moieties, also includes phenolic hydroxyl groups belonging to 4-O-5′ and 5,5′ structures. More specifically, on the basis of model compound work and detailed calculations these structures have been assigned to the signals ranging between 142.8 and 141.7 ppm and 141.7 and 140.2 ppm, respectively (40, 50) (Fig. 1). This assignment was also confirmed by the efforts of Smit et al. (44). In 1995, Brunow's group announced the discovery of the dienzodioxocin bonding patterns as being prevalent in softwoods lignins (56, 57). This involves the formation of α,β ethers on the same 5–5′ biphenyl structure. The new moiety, when subjected to soda pulping conditions, was shown to release significant amounts of structures bearing 5,5′ biphenolic hydroxyl groups (58). Therefore under kraft pulping conditions it is likely that similar reactions, releasing 5,5′ biphenolic hydroxyl groups,

© 1998 NRC Canada

Fig. 2. Kinetic data showing the development of the actual amounts of 4-*O*-5′,5,5′ biphenolic and diphenylmethane phenolic hydroxyl structures on softwood milled wood lignin under homogeneous kraft pulping conditions at 120°C in the presence and absence of formaldehyde. The amount of formaldehyde added is expressed as percentage of the total amount of aryl ethers present in MWL.



will occur. The data of Fig. 2 show that indeed such structures are released in very significant amounts after 4 h at 120°C (about 1.5 mmol/g are formed within milled wood lignin). As anticipated, the presence of formaldehyde does not seem to affect the rate of formation of 5,5′ biphenolic hydroxyl groups or the concentration of dibenzyl ether (4-O-5′) structures (Fig. 2).

Finally, the formation of diphenylmethane structures under kraft and soda pulping conditions was found to follow pseudo-first-order kinetics with rate constants $14.8 \times 10^{-5} \pm 2.2 \times 10^{-7}$ s^{-1} and $9.2 \times 10^{-5} \pm 8.8 \times 10^{-7}$ s^{-1}, respectively.

Conclusions

By using quantitative ^{31}P NMR spectroscopy it is possible to identify, quantify, and follow the formation of phenolic hydroxyl groups that belong to diphenylmethane units under kraft and soda pulping conditions. These units exhibit a ^{31}P chemical shift signal that is confined between 142.8 and 144.3 ppm. Data derived during the course of this work implied that diphenylmethanes are formed in higher quantities during a conventional pulping than are their EMCC® counterparts, at the same κ number.

The solid-state structure of bis(pentafluorophenyl)zinc

Yimin Sun, Warren E. Piers, and Masood Parvez

Abstract: Using the published method of Wiedenbruch, bis(pentafluorophenyl)zinc, **1**, was prepared from anhydrous $ZnCl_2$ and 2 equiv. of LiC_6F_5 in diethyl ether. Base-free **1** was obtained in 60–65% yield by repeated distillation of the initially formed bis(diethyl) ether adduct of **1**. The X-ray quality crystals of **1** were obtained from benzene solution. The molecular structure of **1** revealed a near linear geometry for the two-coordinate zinc center (C(1)-Zn-C(7) = 172.6(2)°), typical of monomeric ZnR_2 derivatives. In the crystal structure, stacking interactions between C_6F_5 rings on adjacent molecules is a dominant motif, with ring centroid to ring centroid distances of 3.503 and 3.563 Å observed. A weak intermolecular C-F···Zn interaction between F(2) and an adjacent zinc center, as judged by the close contact of 2.849(2) Å, also appears to be an important aspect of the crystal structure. Compound **1** is an effective but nonselective C_6F_5 transfer agent to BCl_3; **1**: monoclinic, space group $P2_1/n$, a = 11.902(2) Å, b = 7.732(2) Å, c = 13.735(2) Å, β = 110.58(1)°, V = 1183.4(4) Å^3, Z = 4, R = 0.048, R_w = 0.069.

Key words: organozinc complex, pentafluorophenyl transfer agent.

Résumé : En faisant appel à la méthode non publiée de Wiedenbruch, on a préparé le bis(pentafluorophényl)zinc, **1**, à partir du $ZnCl_2$ et de deux équivalents de LiC_6F_5 dans l'éther. On a obtenu le composé **1** sous la forme de base libre avec un rendement de 60 à 65% en procédant à la distillation répétée de l'adduit formé initialement du composé **1** avec deux molécules d'éther. À partir d'une solution de benzène, on a obtenu des cristaux de **1** pouvant être utilisés pour études par diffraction des rayons X. La structure moléculaire du composé **1** révèle que ce composée présente une géométrie pratiquement linéaire pour le zinc central bicoordiné (C(1)-Zn-C(7) = 172,62(2)°) typique de dérivés ZnR_2 monomères. Dans la structure cristalline, les interactions d'empilement entre les noyaux C_6F_5 de molécules adjacentes correspondent au motif dominant et on observe des distances 3,503 et de 3,563 Å entre les centroïdes de noyaux. Il semble qu'une faible interaction intermoléculaire C-F···Zn entre F(2) et le zinc central adjacent, détectée par un contact de 2,849(2) Å, corresponde à un aspect important de la structure. Le composé **1** est un agent de transfert efficace, mais non sélectif, de C_6F_5 vers le BCl_3. Le composé est monoclinique, groupe d'espace $P2_1/n$, avec a = 11,902(2) Å, b = 7,732(2) Å et c = 13,735(2) Å, β = 110,58(1)°, V = 1183,4(4) Å^3, Z = 4, R = 0,048 et R_w = 0,069.

Mots clés : complexe organozincique, agent de transfert de pentafluorophényle.

Introduction

The increasing commercial importance of $B(C_6F_5)_3$ (1) has stimulated interest in other perfluorinated boranes (2). The robust nature of the B—C_6F_5 bond and the heightened Lewis acidity, which the C_6F_5 group confers upon the boron center, contributes to the utility of these compounds. Increasingly, bis(pentafluorophenyl) boranes of general formula $X[B(C_6F_5)_2]_n$ are finding utility as catalysts or reagents in organic synthesis (X = OH, n = 1 (3); X = H, n = 1 (4)) and as alternative co-catalysts in homogeneous olefin polymerization (X = t-$C_4H_9CH_2CH$, n = 2 (5)).

The syntheses of such compounds is not, however, straightforward at this point. For example, the borane $HB(C_6F_5)_2$ and the boronic acid $HOB(C_6F_5)_2$ both rely on the chloroborane $ClB(C_6F_5)_2$ as a starting material. While a reliable published procedure for the preparation of this compound exists (6), it is not ideal in that it depends on the organotin compound $Me_2Sn(C_6F_5)_2$ as a reagent capable of selectively delivering two C_6F_5 groups to BCl_3. The tedious procedures necessary for separating Me_2SnCl_2 completely from the chloroborane product and concerns around the handling of this volatile organotin by-product have led us to explore other reagents for C_6F_5 transfer to boron. While testing the known compound bis(pentafluorophenyl)zinc, **1**, as a possible reagent for preparing $ClB(C_6F_5)_2$, we obtained its molecular structure, which had not previously been determined.

Results and discussion

To our knowledge, four routes to $Zn(C_6F_5)_2$, **1**, have been published (eqs. [1]–[4]). The original preparation of **1** utilized the Grignard reagent $BrMgC_6F_5$ for introducing the pentafluorophenyl groups to $ZnCl_2$, by refluxing in toluene for 2 h after an initial contact of the reagents in diethyl ether solution

© 1998 NRC Canada

[1] $$2\ BrMgC_6F_5 + ZnCl_2 \xrightarrow[2.\ \text{toluene, } 110^\circ C]{1.\ Et_2O} Zn(C_6F_5)_2\bullet(Et_2O)_2 \xrightarrow[10^{-2}\ \text{torr}]{140^\circ C} \mathbf{1}$$

[2] $$Zn(O_2C\text{-}C_6F_5)_2 \xrightarrow[-\ 2\ CO_2]{220^\circ C} Zn(C_6F_5)_2 \quad \mathbf{1}$$

[3] $$2\ IC_6F_5 + ZnEt_2 \xrightarrow[2\ L = \text{diglyme or pyridine}]{2\ L} Zn(C_6F_5)_2\bullet L_2 \not\rightarrow \mathbf{1}$$

[4] $$2\ LiC_6F_5 + ZnCl_2 \xrightarrow{-78^\circ C,\ Et_2O} Zn(C_6F_5)_2\bullet(Et_2O)_2 \xrightarrow[10^{-2}\ \text{torr}]{140^\circ C} \mathbf{1}$$

(7). The crude product mixture contained the ether adduct of **1**, which was isolated base-free by distillation of $Zn(C_6F_5)_2\cdot(Et_2O)_2$ under high vacuum at 140°C, resulting in a 15% yield of $Zn(C_6F_5)_2$. However, significant amounts of an unidentified colorless liquid by-product was also produced in this reaction.

In our hands, this procedure produced very little $Zn(C_6F_5)_2$ but large amounts of the liquid by-product, which we identified as an isomeric mixture of the Diels–Alder products formed upon reaction with tetrafluorobenzyne and toluene.[2] It is not clear which species in the reaction mixture is the source of tetrafluorobenzyne but, given the thermal stability of **1** itself, it is likely to be an intermediate in this process or perhaps $BrMgC_6F_5$. In a second route to **1**, loss of CO_2 from the dicarboxylate compound $Zn(O_2CC_6F_5)_2$ (eq. [2]) provides the driving force for relatively clean formation of **1** directly (8). Third, eq. [3] represents a relatively safe route to pentafluorophenyl zinc derivatives, but the bases employed in the published procedure (9) are not easy to remove; for our purposes, we must have base free **1**.

Despite the potential hazards associated with the more reactive reagent pentafluorophenyllithium, we turned to the fourth procedure, also developed by Weidenbruch (8), which produces **1** much more cleanly (eq. [4]). A diethyl ether solution of $ZnCl_2$ was added to in situ generated C_6F_5Li, and the resulting mixture was allowed to warm slowly to room temperature. Work-up led to base-free **1**, which gave a ^{19}F NMR spectrum essentially identical to that reported, with no trace of the Diels–Alder by-product in evidence. For larger scale preparations (>2 g), multiple distillations were required to fully remove the diethyl ether, which was judged complete when the distillate was a free-flowing powder as opposed to the oily white solid characteristic of **1** contaminated with its ether adduct.

While a few Lewis base adducts $\mathbf{1}\cdot L_2$ have been structurally characterized (L = THF (10); tetramethyltetrazene (11)), that of base free **1** has not. We therefore obtained X-ray quality crystals of **1** and evaluated its solid-state structure; an ORTEP diagram is shown in Fig. 1, while metrical parameters are given in Table 1, and atomic coordinates are given in Table 2. Two coordinate organozinc compounds are typically monomeric with linear geometries (12), and most of those whose structures have been determined bear this out (13). The exception is diphenylzinc (13*a*), which is dimeric in the solid state by virtue of an interaction between an ipso carbon of one σ-bound phenyl group and the zinc center of another $Zn(C_6H_5)_2$ unit. This interaction was rationalized as being akin to an electrophilic attack on the zinc phenyl group by an adjacent Lewis acidic zinc center. This feature is not replicated in the structure of perflouro diphenylzinc, **1**, presumably because the C_6F_5 groups are much less susceptible to electrophilic attack even though the zinc centers must also be more powerful electrophiles.

Thus, in contrast to its perproteo cousin, **1** behaves like most other ZnR_2 derivatives and is monomeric in the solid state with with C(1)-Zn-C(7) approaching ideal linearity at 172.6(2)°. The Zn—C bonds in **1** are typical of ZnR_2 compounds, which range from 1.93–1.95 Å in compounds where R is not sterically bulky. These lengths are slightly shorter than those found in four coordinate $Zn(C_6F_5)_2\cdot L_2$ compounds (cf. Zn—C lengths of 1.999(4) and 2.102(3) Å in $Zn(C_6F_5)_2(THF)_2$) (10). The two C_6F_5 rings in **1** are almost orthogonal to one another, with an angle between the planes of the aromatic rings of 76.7(2)°. This compares to 67.1° for the same parameter in $Zn[2,4,6\text{-}(CF_3)_3C_6H_3]_2$ (13*c*).

In addition to alleviating intramolecular steric interactions between the C_6F_5 rings, the orthogonality of the C_6F_5 rings in **1** allows for intramolecular stacking interactions between rings on adjacent molecules in the crystal structure of the compound. These stacking interactions engender a layered structure in the crystal; Fig. 2 shows a chemical 3-D representation of the molecular arrangement in the crystal looking down on a portion of one layer (*A*) and from the side (*B*). The distances between the centroids of each C_6F_5 ring and its stacking partner are 3.503 and 3.563 Å, similar to the ring separations observed in stacking interactions between phenyl and pentafluorophenyl rings (14). Between the layers, a weak interaction between one of the meta fluorines, F(2), and a Zn center of an adjacent molecule may be present, as judged by the intermolecular separation of 2.849(2) Å. Although this is at the long end of the range (2.532(6)–2.733(6) Å) of previously observed intramolecular C-F···Zn interactions (15), the intermolecular nature of the contact here might be expected to be slightly longer. Furthermore, the distance is within the sum of the van der

Fig. 1. An ORTEP drawing of $Zn(C_6F_5)_2$, **1** (thermal ellipsoid probability = 50%).

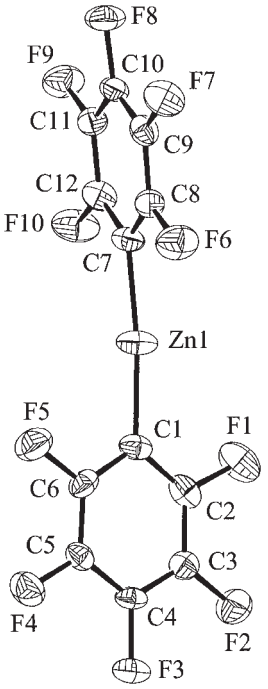

Fig. 2. Two views of the molecular arrangment of $Zn(C_6F_5)_2$ molecules in the crystal structure of **1**. (*A*) View looking down on one of the layers of stacked $Zn(C_6F_5)_2$ molecules. (*B*) Side view of layer shown in *A*.

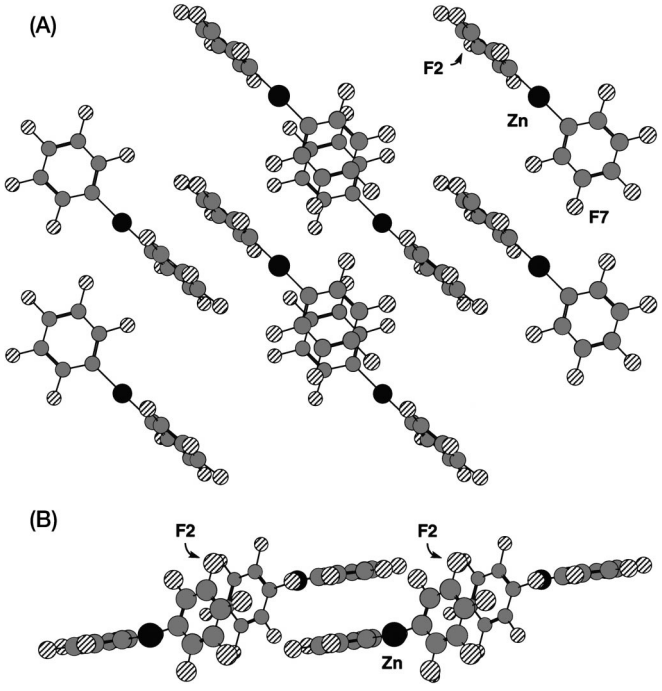

Waals radii(16) for fluorine (1.50–1.60 Å) and zinc (1.40 Å). The fact that the slight bend in the C(1)-Zn-C(7) angle is oriented away from the C(3)-F(2) vector is further evidence in favor of this interaction. The tendency of ZnR_2 complexes to coordinate Lewis bases is thus partially satisfied in the crystal structure of "base free" **1** through this intermolecular contact.[3]

As expected, **1** rapidly reacts with Lewis bases to form $\mathbf{1}\cdot L_2$ adducts in toluene solution. For example, the known adducts of diethyl ether (8, 10) and THF (10) can be generated quantitatively upon treatment with these solvents. Base free, **1** is an efficient C_6F_5 transfer agent, although it does not react selectively with BCl_3 (eq. [5]). Unfortunately, inseparable mixtures of $Cl_2B(C_6F_5)$, $ClB(C_6F_5)_2$, and $B(C_6F_5)_3$ were formed when **1** was reacted with 1 equiv. of BCl_3 under various conditions, a similar situation to that observed in the reaction of C_6F_5Li with BCl_3. Thus, **1** is too reactive to be a suitable reagent for selective formation of $ClB(C_6F_5)_2$; however, it has promise as a C_6F_5 transfer agent to compounds of general formula $RBCl_2$. We will report on its utility in this capacity in due course.

[5] $$\underset{\mathbf{1}}{Zn(C_6F_5)_2} \xrightarrow[-\ ZnCl_2]{BCl_3} \underset{\text{major (≈80\%)}}{Cl_2B(C_6F_5)} + ClB(C_6F_5)_2 + B(C_6F_5)_3$$

[3] The second closest contact between the zinc centers and a fluorine atom is that of meta fluorine F(7) at 3.200(3) Å. This interaction occurs within the layers mentioned in the text; however, due to the rather large separation, caution must be employed in interpreting this interaction as the second incipient zinc/base interaction.

Experimental

General procedures have been presented in detail elsewhere (17). Pentafluorobromobenzene and zinc dichloride were purchased from Aldrich Chemicals. The former was used without further purification, while the latter was rendered completely anhydrous by refluxing in dry dioxane along with zinc dust. The suspension was filtered hot and cooled; the resulting crystalline $ZnCl_2$·dioxane adduct was isolated by filtration and exposed to high vacuum at 110°C for several hours to liberate the coordinated dioxane.

Preparation of 1

A procedure similar to that reported earlier by Sartori and Weidenbruch (8) was employed to generate **1**·$(OEt_2)_2$. (CAUTION! Do not allow solutions of C_6F_5Li to warm above –40°C; spontaneous elimination of LiF is possible above this temperature.) The only modification involved quenching the reaction with a small amount of methanol (≈1–2%) to ensure that no C_6F_5Li remained for the workup procedure. For smaller scale reactions (≈0.5–1.0 g), distillation of **1**·$(OEt_2)_2$ at 140°C and high vacuum was sufficient to completely remove the ether. For larger scale preparations (>2 g), multiple distillations were required to generate pure **1**. This was most conveniently accomplished by repeatedly subliming the material in a long glass tube. Loss of the oily appearance of the sublimate signalled the complete removal of ether. The material thus obtained had essentially identical ^{19}F NMR data as that reported previously for **1** by Weidenbruch et al. (10).

X-ray determination of 1

A suitable crystal was affixed to a glass fiber with epoxy resin and mounted onto a Rigaku AFC6S diffractometer. A summary of data collection, reduction, and refinement parameters are given in Table 3. Measurements were made at 103°C using graphite monochromated Mo-Kα radiation (λ = 0.71069 Å). Omega scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.39° with a take-off angle of 6.0° For data collection, the weak reflections ($I < 10\sigma(I)$) were rescanned, and the counts were accumulated to ensure good counting statistics. No decay correction was required. The data were corrected for Lorentz, polarization, and for absorption correction by ψ scans of a few reflections (18). A correction for secondary extinction was also applied (coefficient = 5.11673×10^{-6}) (19). The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. The function minimized was $\Sigma\, w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F_o) = [\sigma^2_c(F_o) + p^2/4(F_o)^2]^{-1}$ and the p-factor was 0.0200. The final cycle of full-matrix least-squares refinement converged with unweighted ($R = \Sigma\, ||F_o|| - |F_c||/\, \Sigma\, |F_o|$) and weighted ($R_w = [\Sigma\, w(|F_o| - |F_c|)^2/\, \Sigma\, w|F_o|^2)]^{1/2}$] agreement factors of 0.048 and 0.069, respectively. All calculations were performed using the TEXAN[4] crystallographic software package of Molecular Structure Corporation. Anisotropic thermal parameters along with a full listing of torsion angles and nonbonded contacts to 3.60 Å are available as supplementary material.[5]

Cyclic–acyclic equilibrium and selective P—O bond cleavage in 2-hydroxyphenyldiphenylphosphinate, $Ph_2P(O)OC_6H_4OH$

Edward Paul Segstro, Kerry Davie, Xiaoling Huang, and Alexander Frank Janzen

Abstract: The equilibrium in the $Ph_2P(O)OC_6H_4OH$–base system may be shifted by varying the base concentration, where base = imidazole, triethylamine, dimethyl sulfoxide, pyridine, and 1,4-dioxane. This equilibrium was studied by ^{31}P and ^{1}H NMR, and information about the symmetry of phosphorus-containing intermediates is provided by the ^{1}H NMR spectrum of the catecholyl ring, with its *ABCD* spin system. The equilibrium is also affected by trifluoroacetic acid. A mechanism is proposed that involves protonation–deprotonation, cyclic–acyclic equilibria, and selective P—O bond cleavage, with all steps occurring rapidly on the NMR time scale.

Key words: $Ph_2P(O)OC_6H_4OH$–base system, cyclic–acyclic equilibrium, and selective P—O bond cleavage.

Résumé : On peut déplacer la position de l'équilibre du système $Ph_2P(O)OC_6H_4OH$–base en faisant varier la concentration de base (base = imidazole, triéthylamine, diméthylsulfoxyde, pyridine, 1,4-dioxane). On a étudié cet équilibre par RMN du ^{31}P et du ^{1}H et l'information relative à la symétrie des intermédiaires contenant du phosphore découle du spectre RMN du ^{1}H du noyau catécholyle comportant un système de spin *ABCD*. L'équilibre est aussi affecté par l'acide trifluoroacétique. On propose un mécanisme pour cet équilibre qui implique une protonation–déprotonation, un équilibre cyclique–acyclique et la rupture sélective de la liaison P—O; toutes les étapes se produiraient rapidement à l'échelle de temps de la RMN.

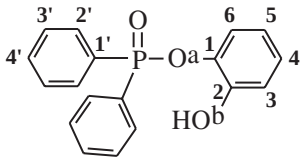
Mots clés : système $Ph_2P(O)OC_6H_4OH$–base, équilibre cyclique–acyclique, rupture sélective de la liaison P—O.

[Traduit par la rédaction]

Introduction

Five-membered rings, cyclic–acyclic equilibria, and protonation–deprotonation are common features of the hydrolysis, and enzymatic hydrolysis, of phosphorus esters (see examples in ref. 1). Previously, we studied the base-initiated cyclic–acyclic equilibrium of a perfluoropinacolyl phosphorus compound (2). The perfluoropinacolyl septets in the ^{19}F NMR spectrum collapsed to a broad peak with increasing base concentration or temperature, which is consistent with the cyclic–acyclic equilibrium of Scheme 1, but line broadening made it impossible to distinguish between trigonal bipyramidal or square pyramidal intermediates; both structural types have been established by X-ray crystallography for phosphorus compounds that contain five-membered rings (3).

In this study, perfluoropinacol was replaced by catechol, and the equilibrium of 2-hydroxyphenyldiphenylphosphinate, $Ph_2P(O)OC_6H_4OH$ **1**, in the presence of base was monitored by ^{31}P and ^{1}H NMR. Analysis of the ^{1}H NMR spectrum of the planar catecholyl ring, with its *ABCD* spin system, was carried out in an attempt to obtain information about the symmetry of phosphorus-containing intermediates.



1

Results and discussion

In a series of experiments, the ^{31}P chemical shift of **1** was measured in CH_2Cl_2 solution as a function of base concentration. As seen in Fig. 1, there is an upfield shift with increasing base concentration, i.e., towards five-coordinate phosphorus (4), and the relative shift is in the order: imidazole ~ Et_3N > DMSO > pyridine > 1,4-dioxane. Only limited data are available for imidazole and triethylamine because these bases bring about decomposition of **1**, but solutions of **1** in excess DMSO, pyridine, or 1,4-dioxane are stable in CH_2Cl_2, as judged by ^{31}P and ^{1}H NMR.

To eliminate the possibility that changes in $\delta^{31}P$ are due to solvent or concentration effects, two compounds were chosen that lack a hydroxyl substituent, namely, $(MeO)_3PO$ and $Ph_2P(O)OC_6H_4OSiMe_3$. Addition of pyridine to these compounds produced only minor changes in $\delta^{31}P$. For example, $\delta^{31}P$ of $(MeO)_3PO$ (0.071 M in CH_2Cl_2 at 27°C) shifts from 1.39 to 1.10 ppm as the pyridine concentration increases from

Scheme 1. Cyclic–acyclic equilibrium in a perfluoropinacolyl phosphorus compound.

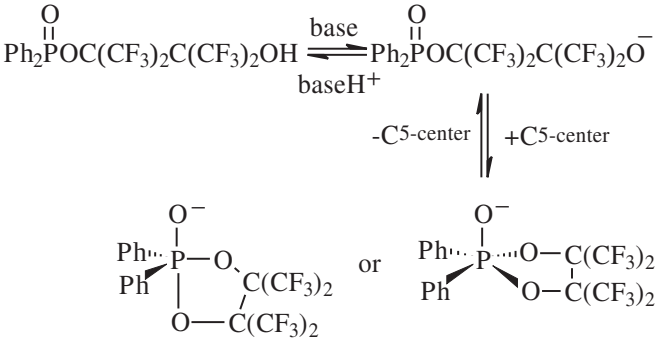

Fig. 1. Plot of $\delta^{31}P$ of $Ph_2P(O)OC_6H_4OH$ **1** as a function of base concentration, and of CF_3COOH concentration. Temperature is 27°C, solvent is CH_2Cl_2, and [**1**] = 0.032 M in all experiments.

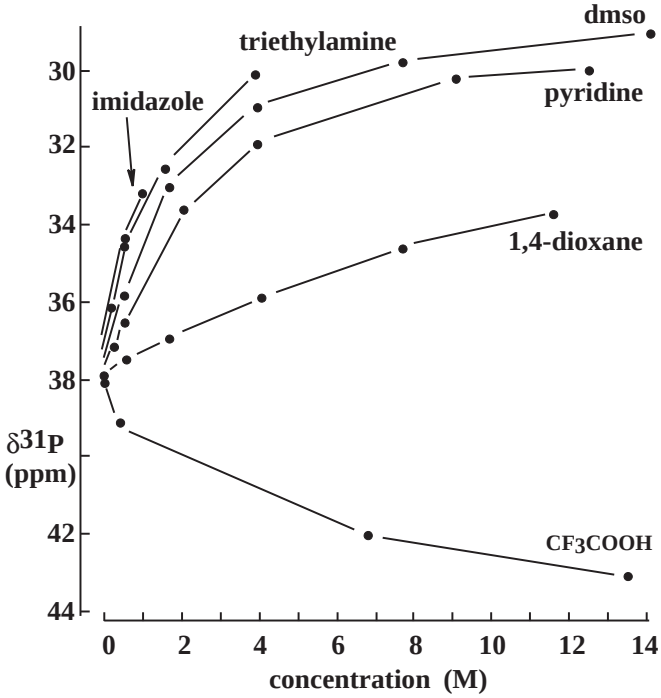
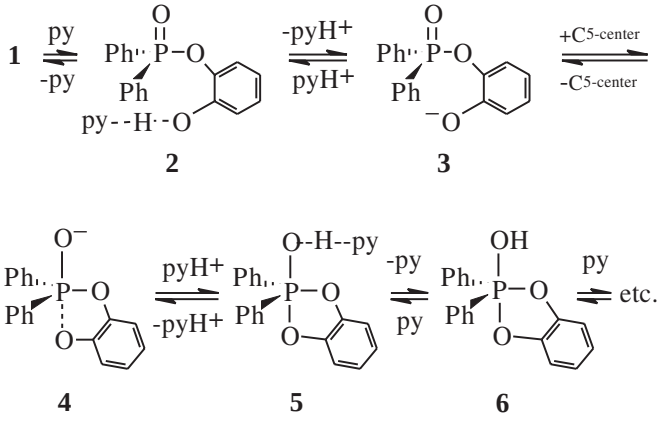


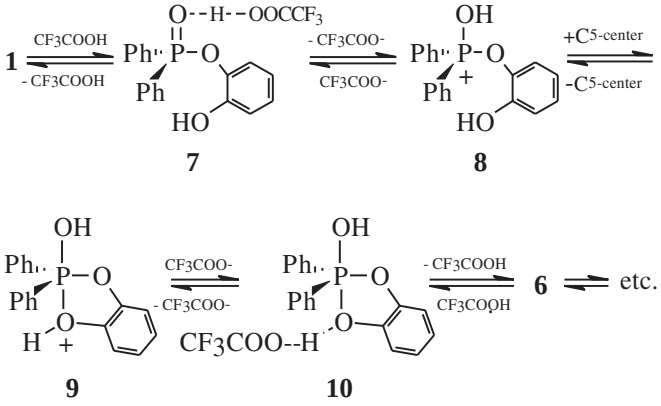
0 to 12.4 M. Similarly, $\delta^{31}P$ of $Ph_2P(O)OC_6H_4OSiMe_3$ in CH_2Cl_2 at 27°C changes from 29.83 to 29.04 ppm as the pyridine concentration increases from 0 to 9.3 M.

A mechanism is proposed in Scheme 2 to account for the behaviour of the **1**-base system. This mechanism is written in sufficient detail so that the connectivity of atoms along the reaction pathway is evident, and ring-opening and rapid ring-closing of five-membered rings is denoted as $-C^{5\text{-center}}$ and $+C^{5\text{-center}}$, respectively (5). The overall shift towards five-coordinate phosphorane is rather modest, for example, $\delta^{31}P$ of **1** (37.80 ppm in CH_2Cl_2) shifts to 29.85 ppm in excess pyridine (Fig. 1). Much greater changes of 63–79 ppm have been found in related compounds as they are converted to authentic five-coordinate phosphoranes (4). If a chemical shift of about –32 ppm is assumed for **6**, i.e., 70 ppm upfield from that of **1**, then an equilibrium constant can be crudely estimated for Scheme 2 by assuming an equilibrium between two species only,

Scheme 2. Proposed protonation–deprotonation and cyclic–acyclic equilibrium in the $Ph_2P(O)OC_6H_4OH$–base system.



Scheme 3. Proposed protonation–deprotonation and cyclic–acyclic equilibrium in the $Ph_2P(O)OC_6H_4OH$–acid system.



namely, **1** and **6**. In that case, from the weighted average of $\delta^{13}P$, and standard equations (6), equilibrium constants are estimated as ~0.09 for imidazole and triethylamine, ~0.04 for DMSO and pyridine, and ~0.01 for 1,4-dioxane. Thus the concentration of five-coordinate phosphorane depends on the nature and concentration of base, but the equilibrium in Scheme 2 favours phosphinate **1** in all experiments.

All samples of **1** and base (Fig. 1) give only single ^{31}P peaks at 27°C, and individual species cannot be observed by NMR at ambient temperature. On lowering the temperature of a sample of **1** (0.031 M) and pyridine (9.31 M) in CH_2Cl_2, $\delta^{31}P$**1** shifts from 31.07 ppm at 27°C to 29.62 ppm at –63°C, in the direction of five-coordinate phosphorane. However, no appreciable line-broadening was evident, confirming that all steps of Scheme 2 are rapid on the NMR time scale, even at –63°C. It follows from this result that only very weak bonds are cleaved, and these are identified in Scheme 2 as bridging

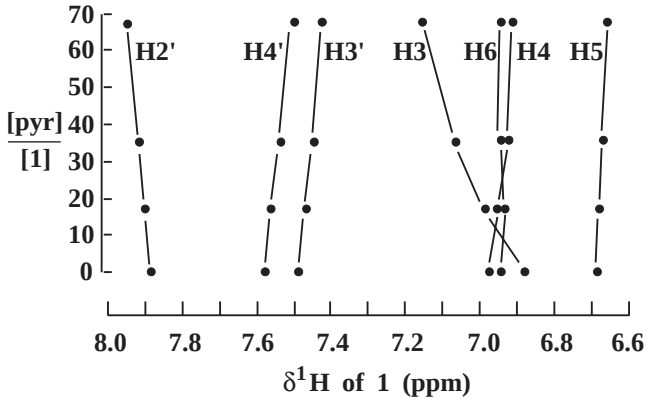
Fig. 2. Plot of δH of catecholyl and phenyl protons of **1** as a function of pyridine concentration, showing retention of an *ABCD* spin system in the catecholyl ring. H3-H6 are catecholyl hydrogens, and H2′-H4′ are phenyl hydrogens.



N--H--O bonds in **2** and **5**, and a P—O^b bond in **4**. The latter bond is *trans* to an oxo substituent, and contributing structures **4a** and **4b** may account for the weakness of the *trans* P—O^b bond.

Trifluoroacetic acid was also added to **1**, and the chemical shift of **1** moves downfield, as seen in Fig. 1, presumably as a result of protonation at the phosphoryl bond. Authentic phosphonium ions have downfield ^{31}P chemical shifts (7), and a mechanism that accounts for the behaviour of **1** in the presence of acid is shown in Scheme 3.

According to the mechanism of Scheme 2, the axial P—O^b bond in **4** is cleaved, but not the equatorial P—O^a bond. Evidence that the P—O^a bond remains intact is based on the ^{1}H NMR spectrum of the catecholyl ring. Its *ABCD* spectrum contains information about the symmetry of the intermediates and the stereospecificity of the overall reaction, and the question is whether this *ABCD* spin system is maintained at all stages of the equilibrium, as required by Scheme 2, or whether it is converted into an A_2B_2 (or *AA′BB′*) spin system.

The ^{1}H NMR spectra of **1** were recorded at 300 MHz, and a complete assignment was carried out for the catecholyl and phenyl regions at various pyridine concentrations. Hydrogens are assigned by comparison with 2-methoxyphenol (8) and related compounds (9). The downfield shift of H3 with increasing pyridine concentration is in agreement with the effect of base on the chemical shift of *ortho* hydrogens in phenol (10), but no argument that depends on the *ABCD* spin pattern is changed if the assignment of hydrogens is interchanged.

The variation in δH as a function of pyridine concentration is shown in Fig. 2, and the corresponding changes in *J*(H,P) and *J*(H,H) are given in Table 1. As seen in Fig. 2 and Table 1, the NMR parameters depend on pyridine concentration, but H3 and H6 never become equivalent, nor H4 and H5, and therefore the *ABCD* spin system is preserved. Selective P—O^b bond cleavage in **4**, and trigonal bipyramidal geometry of **4**–**6**, as postulated in Scheme 2, is entirely compatible with this "*ABCD* criterion."

Our results do not allow us to eliminate square pyramidal intermediate **11** from consideration, however, square pyramidal **12** is incompatible with an *ABCD* spin system, moreover, any polytopal rearrangement such as Berry pseudorotation or turnstile rotation that generates **12** is eliminated. Bond breaking of the P—O^a bond is not allowed by the *ABCD* criterion, nor complete loss of catechol, and there cannot be any pathways that interchange O^a and O^b substituents.

12

Experimental

All solvents were dried and stored over molecular sieve under N_2 in a dry box. Diphenylchlorophosphane, Ph_2PCl, and bis(pentafluorophenyl)chlorophosphane, $(C_6F_5)_2PCl$, were oxidized to $Ph_2P(O)Cl$ and $(C_6F_5)_2P(O)Cl$ by bubbling O_2 through a benzene solution. Elemental analyses were carried out by Galbraith Laboratories, Knoxville, Tenn.

The ^{31}P and phosphorus-decoupled ^{1}H NMR spectra were recorded on a Bruker WH90 spectrometer, and the ^{13}C and ^{1}H NMR spectra were recorded on a Bruker AM300 spectrometer. A complete assignment of ^{1}H NMR spectra was carried out of the catecholyl and phenyl regions of **1** at various pyridine concentrations, with the aid of computer program LAME (11).

2-Hydroxyphenyldiphenylphosphinate 1

The $Ph_2P(O)Cl$ (9.5 g, 40 mmol) in benzene (25 mL) was added dropwise over 30–40 min to a stirred solution of 1,2-benzenediol (catechol) (4.4 g, 40 mmol) and pyridine (3.2 g, 40 mmol) in benzene (30 mL). At the completion of the reaction, solid was filtered off, washed several times with water, dried under vacuum and recrystallized from 1:1 benzene:methanol, and identified as 2-hydroxyphenyldiphenylphosphinate **1**. Anal. calcd. for $C_{18}H_{15}O_3P$: C 69.68, H 4.87; found: C 69.51, H 4.87. The filtrate was concentrated on a

rotary evaporator and solids filtered off and purified as above to give a total yield of **1** of 40%; mp 185°C; MS, *m/z*: 310 $(M)^+$, 233 $(M - C_6H_5)^+$, 232 $(M - C_6H_6)^+$, 201 $(Ph_2PO)^+$.

^1H NMR of **1** is given in Table 1 and Fig. 2. Variable-temperature ^1H NMR of OH in CD_2Cl_2, δ: 9.02 ppm (+40°C), 9.19 ppm (–25°C), 9.35 ppm (–56°C); in DMSO: 8.96 ppm (+39°C), 9.29 ppm (–23°C), 9.57 ppm (–60°C). ^1H NMR of OH as a function of molar ratio of pyridine/**1** in CD_2Cl_2, δ: 9.01 ppm (py/**1** = 0), 9.10 ppm (py/**1** = 1.83), 9.57 ppm (py/**1** = 14.9), 10.52 ppm (py/**1** = 125.4). $\delta^{31}P$ of **1** (0.032 M) in various solvents: (CH_2Cl_2) δ 37.80, ($CDCl_3$) δ 38.04, (1,4-dioxane) δ 33.75, (pyridine) δ 29.85, (DMSO) δ 29.07, (CF_3COOH) δ 43.16.

^{13}C NMR of **1** (CD_2Cl_2): C1 δ 139.6, ^2J(PC) = 9.50 Hz; C2 δ 148.6, ^3J(PC) = 3.15 Hz; C3 δ 119.9, ^4J(PC) = 1.23 Hz; C4 δ 126.8, ^5J(PC) = 1.27 Hz; C5 δ 120.8, ^4J(PC) = 0.68 Hz; C6 δ 122.9, ^3J(PC) = 4.56 Hz; C1′ δ 129.2, ^1J(PC) = 137.1 Hz; C2′ δ 132.2, ^2J(PC) = 10.62 Hz; C3′ δ 129.2, ^3J(PC) = 13.58 Hz; C4′ δ 133.6, ^4J(PC) = 2.89 Hz.

A similar reaction of 1,2-benzenediol and $(C_6F_5)_2P(O)Cl$ gave 2-$HOC_6H_4OP(O)(C_6F_5)_2$; MS, *m/z*: 490$(M)^+$.

2-$Me_3SiOC_6H_4OP(O)Ph_2$ and 2-$MeOC_6H_4OP(O)Ph_2$

$Ph_2P(O)OC_6H_4OH$ **1** (0.11 g, 0.35 mmol) and Me_3SiCl (0.038 g, 0.35 mmol) and 2 drops of Et_3N in CH_2Cl_2 (2 mL) were refluxed for 2 h. The solvent was removed by rotary evaporator and a white solid remained, which was washed with 1:1 benzene:methanol and identified by mass spectrometry as $Ph_2P(O)OC_6H_4OSiMe_3$; MS, *m/z*: 382 $(M)^+$, 367 $(M - CH_3)^+$. This product was also formed if **1** was treated with $(Me_3Si)_2NH$ or with a mixture of $(Me_3Si)_2NH$, Me_3SiCl, and pyridine, but a red solid was formed in the reaction of **1** with Et_2NSiMe_3.

Reaction of 2-$MeOC_6H_4OH$ (1.4 g, 11 mmol) and $Ph_2P(O)Cl$ (2.37 g, 10 mmol) in pyridine (13 mL) gave 2-$MeOC_6H_4OP(O)Ph_2$; MS, *m/z*: 324 $(M)^+$, 306 $(M - 18)^+$, 293 $(M - OMe)^+$. The NMR spectra of these compounds, as well as of 2-methoxyphenol (8), and others (9), were helpful in assigning the ^1H NMR spectrum of **1**.

***cis*-3-Diphenylphosphinatotetrahydro-3,4-furandiol**

$Ph_2P(O)Cl$ (8.5 g, 36 mmol) in benzene was added dropwise to a stirred solution of *cis*-tetrahydro-3,4-furandiol (3.70 g, 36 mmol) and pyridine (2.82 g, 36 mmol) in CH_2Cl_2 (30 mL) over 30 min. The mixture was stirred for 24 h, then *n*-hexane added and the precipitate washed with water, dried under vacuum, and recrystallized from 1:1 benzene:methanol to give *cis*-3-diphenylphosphinatotetrahydro-3,4-furandiol (37%). Anal. calcd. for $C_{16}H_{17}O_4P$: C 63.16, H 5.63; found: C 63.35, H 5.47. MS, *m/z*: 304 $(M)^+$, 286 $(M - H_2O)^+$. ^{31}P NMR ($CDCl_3$), δ: 32.3 ppm. ^1H NMR ($CDCl_3$), δ: 3.72–4.78 (aliphatic), 7.33–7.96 (phenyl), 5.80 (OH). Its complex ^1H NMR spectrum made this compound less suitable for NMR study than **1**.

Bisthiosemicarbazones of 2,4-pentanedione are pyrazolines

Duncan H. Hunter, Chantelle McRoberts, and Jagadese J. Vittal

Abstract: Attempts to prepare 2,4-bisthiosemicarbamoylpentanediones **1** via literature precedent from 2,4-pentanedione and three different thiosemicarbazides resulted instead in the formation of cyclic pyrazolines **5**. The preparation was attempted with thiosemicarbazide, 4-methylthiosemicarbazide, and 4-ethylthiosemicarbazide, respectively. A single-crystal X-ray structure study of the product from 4-methylthiosemicarbazide confirmed the pyrazoline structure. This observation serves to correct earlier misassignments of structure.

Key words: pentanedione, bisthiosemicarbazone, pyrazoline, ethylenediamine.

Résumé : Les efforts déployés en vue de préparer les 2,4-bisthiosemicarbamoylpentanediones, **1**, par le biais de méthodes décrites dans la littérature à partir de la pentane-2,4-dione et de trois thiosemicarbazides différentes ont tous conduit plutôt à la formation de pyrazolines cycliques, **5**. On a tenté les préparations à l'aide de la thiosemicarbazide, de la 4-méthylthiosemicarbazide et de la 4-éthylthiosemicarbazide respectivement. Une étude de structure par diffraction des rayons X sur un cristal unique du produit obtenu à partir de la 4-méthylthiosemicarbazide a permis de confirmer la structure pyrazoline. Cette observation permet de corriger de mauvaises attributions de structures proposées antérieurement.

Mots clés : pentanedione, bisthiosemicarbazone, pyrazoline, éthylènediamine.

[Traduit par la rédaction]

Metal complexes of bisthiosemicarbazones have long been known for anticarcinogenic, antibacterial, and antifungal properties (1). The N_2S_2 chelation system of bisthiosemicarbazones has been used with a variety of metals, including Ni(II), Cu(II), Zn(II), Hg(II) (2), as well as ^{99m}Tc (3). Technetium chelates present many interesting possibilities for nuclear medicine applications. As part of a project on the preparation of N_2S_2 ^{99m}Tc chelates for diagnostic imaging, bisthiosemicarbazones of 2,4-pentanedione **1** were targeted. This molecule, after substitution at the 3-position of the dione, would provide a simple and versatile chelation system for ^{99m}Tc nuclear imaging agents **2** (Fig. 1).

Typically, bisthiosemicarbazones have been synthesized directly from a 2:1 ratio of thiosemicarbazide and dicarbonyl compound (4). However, there is confusion in the literature regarding the specific case of 2,4-pentanedione. In 1967, it was reported that the bisthiosemicarbazones of 2,4-pentanedione could not be prepared by the direct reaction of 2,4-pentanedione and various thiosemicarbazides (5). Instead, a method involving the use of ethylenediamine was devised, resulting in the reported preparation of bisthiosemicarbazones of 2,4-pentanedione **1** with R = H, methyl, ethyl, cyclohexyl, and phenyl (Fig. 1). However, in 1986, the direct reaction was reported to be successful with 4-phenylthiosemicarbazide and 2,4-pentanedione (6). Independent of this paper, the structure assigned to the bisthiosemicarbazones of 2,4-pentanedione **1** in the original 1967 report was questioned on the basis of the ^{1}H NMR spectra of two adducts, prepared from thiosemicarbazide and 4-methylthiosemicarbazide. A pyrazoline structure **5** (Fig. 3) was suggested instead (7).

In 1990, a modified ethylenediamine route was employed to synthesize the bis(4-methylthiosemicarbazone) of 2,4-pentanedione (8), which was assigned structure **1** based on the ^{1}H NMR spectrum. This material was then used to prepare a technetium-99m chelate and biodistribution studies were carried out. Surprisingly, labelling with technetium-99m resulted in two radioactive species as observed by HPLC analysis of a hexane extract. This observation led the authors to a further study in which 3,3-dimethyl-2,4-pentanedione was prepared and reacted with 4-methylthiosemicarbazone by the same procedure (9). Again, the product was characterized by the ^{1}H NMR spectrum and assigned a structure similar to **1**. Radiolabelling of this material with technetium-99m resulted in just one radioactive species being observed by HPLC analysis of a chloroform extract.

Results

Because we were interested in preparing similar bisthiosemicarbazones as technetium-99m bioconjugates, the reaction of three thiosemicarbazides with 2,4-pentanedione was repeated. In our hands, the direct reaction of thiosemicarbazides with 2,4-pentanedione failed. Specifically, reaction of 2,4-pentanedione with thiosemicarbazide, 4-methylthiosemicarbazide, and 4-ethylthiosemicarbazide in 20% acetic acid solution resulted in recovery of starting materials. This finding is consistent with the report of 1967 (5) but not the 1986 report (6).

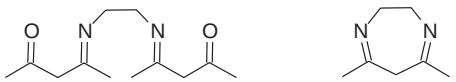
Fig. 2. Ethylenediamine intermediates of 2,4-pentanedione.



3 **4**

In contrast, the modified ethylenediamine preparation of 1990 led to products with the same melting point and mass spectra as those originally published (5).

The 1967 route (5) through compounds **3** and **4** (Fig 2.), adducts of dione and diamine, was repeated. A 2:1 adduct of dione to diamine, 1,2-bis(1-methyl-3-oxobutylideneamino)ethane **3**, was prepared in 70% yield. The proton NMR spectrum indicated the product to be an enol (10), mp 110–113°C; ^{1}H NMR ($CDCl_3$), ppm: 1.85 (3H, s, CH_3), 1.88 (3H, s, CH_3), 3.38 (1H,m, CH_2), 4.9 (1H,s, CH), 10.9 (1H,s, OH); MS, *m*/*z* calcd. for $C_{12}H_{20}N_2O_2$: 224.1524; found: 224.1516.

This 2:1 dione:diamine adduct was converted to 1:1 adduct **4** in 20% acetic acid over 24 h at room temperature. An ^{1}H NMR spectrum indicated only the 1:1 adduct as judged by the dione methyl equivalency at 1.9 ppm in the crude spectrum ($CDCl_3$). Adduct **4** was reacted with thiosemicarbazide, 4-methylthiosemicarbazide, and 4-ethylthiosemicarbazide in a 50% methanolic solution at reflux, yielding crystalline material in each case. Specifically for the 4-methylthiosemicarbazide example, colourless, block-like crystals were isolated in 40% purified yield. MS, *m*/*z* calcd. for $C_9H_{18}N_6S_2$: 274.1034; found: 274.1032. On the basis of the melting point (mp 174–176°C), this product and that previously reported in 1967 (5) are the same compound.

The 1990 modification of the dione–ethylenediamine route (7) was repeated successfully for 2,4-pentanedione and 4-methylthiosemicarbazide with addition of ethylenediamine. This modified route was not repeated for the thiosemicarbazide and 4-ethylthiosemicarbazide examples. Small, colourless needles precipitated in 24% crude yield and were found to be identical to the material produced above (melting point and mixture melting point). The melting point of this product was also in agreement with the 1990 report.

However, ^{1}H and ^{13}C NMR spectra were more complicated than anticipated symmetrical product **1** would suggest and are consistent with pyrazoline **5** (R = CH_3). In particular, the ^{1}H NMR spectrum in $CDCl_3$ showed 10 sets of signals rather than the anticipated 5. ^{1}H NMR ($CDCl_3$), ppm: 1.8 (3H, s, CH_3), 1.98 (3H, s, CH_3), 2.59 and 2.97 (2H, CH_AH_B, J_{AB} = 18 Hz), 3.07 (3H, d, CH_3), 3.15(3H, d, CH_3), 6.63 (1H, s, NH), 6.85 (1H, s, NH), 7.25(1H, brq, $NHCH_3$), and 7.38 (1H, brq, $NHCH_3$). Similarly, the ^{13}C NMR spectrum showed nine separate signals instead of the anticipated five: ^{13}C NMR ($CDCl_3$), ppm: 183.7, 175.5 (C═S); 153.5 (C═N); 85.0 (C6); 47.2 (C5); 30.9, 30.2 ($NHCH_3$); 23.5, 16.2 (CH_3). The products of the thiosemicarbazide and 4-ethylthiosemicarbazide reactions with adduct **4** showed analogous NMR patterns. Because of the confusion already present in the literature, we obtained a single-crystal X-ray structural determination of the product of the 4-methylthiosemicarbazide reaction. The results of the crystallographic analysis shown in Fig. 4 confirm the 1986 proposal of a pyrazoline **5**.

Conclusions

In conclusion, in our hands, reaction of 2,4-pentanedione with thiosemicarbazide, 4-methylthiosemicarbazide, and 4-ethylthiosemicarbazide proceeded only with the involvement of ethylenediamine as initially reported in 1967 and as modified in 1990. The products obtained are not the desired **1** but instead pyrazoline **5**, as confirmed by X-ray crystallographic analysis for the 4-methylthiosemicarbazide reaction. It should be noted that the material prepared in 1990 and used to form technetium-99m chelates was actually a pyrazoline that had been misidentified on the basis of its ^{1}H NMR spectrum. This might be a consequence of the dramatic solvent dependence of the ^{1}H NMR spectrum of the pyrazoline in $CDCl_3$ versus DMSO-d_6. The bisthiosemicarbazone **1** reported in the literature was misidentified, possibly due to the lack of an obvious AB pattern for the dione methylene protons and the coincidental methyl amine protons of the thiosemicarbazide in the ^{1}H NMR when analysed in DMSO-d_6 versus $CDCl_3$. Thus, the report of technetium-99m chelates of bisthiosemicarbazones of pentanedione (8) should be regarded with suspicion.

A subsequent article (9) by the same researchers in 1991 attempts to explain why a supposed symmetrical molecule would lead to two isomers upon radiolabelling. On the basis of the misidentification of the bis(4-methylthiosemicarbazone) of pentanedione, this 1991 report should be viewed with some suspicion as well. Although we did not repeat the 1991 preparation with 3,3-dimethyl-2,4-pentanedione and 4-methylthiosemicarbazide, the reported ^{1}H NMR spectrum seems more consistent with a pyrazoline, similar to structure **5**, than the proposed bisthiosemicarbazone.

Rate enhancement of organic reactions by microwaves at atmospheric pressure

R.N. Gedye and J.B. Wei

Abstract: Several different reactions have been studied to determine whether they occur more rapidly than conventionally heated reactions at atmospheric pressure. Small rate enhancements have been observed for some reactions carried out under microwave reflux in a modified domestic microwave oven. The Knoevenagel reaction of acetophenone with ethyl cyanoacetate was shown to have a rate enhancement of 2.5 times. However this reaction showed no rate increase over conventional heating, at the same temperature, in a variable-frequency microwave oven. It is therefore probable that the small rate enhancements observed in these experiments, using microwave heating, were due to hot spots or superheating of the solvent rather than to nonthermal effects.

Key words: microwave, nonthermal effects, superheating, hot spots.

Résumé : On a étudié plusieurs réactions différentes pour déterminer si elles se produisent plus rapidement que les réactions chauffées normalement, à la pression ambiante. On a observé de légères augmentations de vitesse pour quelques réactions effectuées sous reflux à microondes, dans un four à microondes domestique modifié. Il a été démontré que la vitesse de la réaction de Knoevenagel de l'acétophénone avec le cyanoacétate d'éthyle est multipliée par 2,5. Toutefois, lorsqu'on utilise un four à microonde à fréquence variable, cette réaction ne présente aucune augmentation de vitesse par rapport à un chauffage conventionnel, à la même température. Il donc probable que les faibles augmentations de vitesse observées au cours de ces expériences, par chauffage à microondes, seraient le résultat de points chauds ou de surchauffe du solvant plutôt que d'effets non thermiques.

Mots clés : microonde, effets non thermiques, surchauffe, points chauds.

Introduction

Substantial rate enhancements are frequently observed when chemical reactions are carried out under microwave irradiation in sealed vessels (1–4). These rate enhancements are generally attributed to superheating of the solvent due to the increased pressures generated when reactions are carried out in this manner (3, 5). However, there have been a number of reports that claim that significant rate increases occur in some reactions under microwave irradiation in open vessels (6–14), suggesting a specific or nonthermal microwave effect. Some of these reactions have been reexamined, however, and shown to occur at similar rates under microwave and conventional heating at the same temperature (15–17).

Berlan et al. (6) reported that certain Diels–Alder reactions occur more rapidly under microwave heating than under conventional heating at the same temperature. In a subsequent paper (18), however, he cast doubt on the existence of nonthermal effects, attributing the rate increases to localized "hot spots" in the reaction mixture or to superheating of the solvent above its boiling point. He emphasized the difficulty in measuring the temperature accurately in microwave cavities. In fact, kinetic studies by Raner et al. (15) on the Diels–Alder reaction of anthracene with diethyl maleate, previously reported by Berlan et al. (6) to show a microwave effect, showed no microwave enhancement compared with conventional heating at the same temperature.

Jahngen and co-workers (7) reported that the rate of hydrolysis of the biomolecule ATP was 25 times greater during microwave heating than conventional heating at comparable temperatures. However Jahngen et al. (16) later showed that, with more accurate temperature control, no such effect could be observed.

Bose et al. (8) suggested that the rapid reaction rates achieved in the synthesis of a variety of heterocycles in microwave ovens, at low power levels in open vessels, were not only due to thermolysis. This implied specific activation by microwaves. However, Westaway and Gedye (17) have shown that the rates of two of these syntheses were not accelerated appreciably by microwave heating compared with conventional heating at similar temperatures.

There have also been reports (9, 10) that racemization of amino acids occurs more rapidly on microwave heating than conventional heating at similar temperatures. This could have important negative consequences in nutrition, since proteins and peptides in food are hydrolyzed to amino acids (10). Again no real evidence for a nonthermal effect was found in a study of the racemization of L-proline under microwave and conventional reflux in aqueous solution (17). The increase in

racemization rate was found to be very small, and could be attributed to localized hot spots or superheating of the solvent.

It should be noted that Baghurst and Mingos (19) have reported recently that some solvents superheat under microwave heating at atmospheric pressure and that this could account for any small rate enhancements observed. Furthermore, Mingos (20) suggests that rate enhancements should only be attributed to nonthermal effects if they are substantial (100 times or more).

A number of other reactions have been shown to occur at the same rate under microwave and conventional heating at the same temperature These include the esterification of carboxylic acids with alcohols (3, 5), the acid-catalyzed isomerization of carvone (15), and ene reactions involving carbonyl enophiles (18).

On the other hand kinetic studies by Lewis et al. (21) showed that microwave irradiation enhanced the rate of imidization of a polymer (BTDA–DDS polyamic acid) and that the apparent activation energy was reduced from 105 kJ/mol (conventional heating) to 55 kJ/mol. It was suggested, however, that this enhancement was due to nonuniform temperature on a molecular scale rather than a nonthermal effect. Wei et al. (22) have reported that the cross-linking of epoxies using the curing agents diaminodiphenyl sulfone (DDS) and *m*-phenylenediamine (*m*-PDA) occurred more rapidly using microwave heating than conventional heating at similar temperatures and resulted in higher Tg (glass transition temperature) values. Higher rate enhancements and Tg values were observed for the higher lossy curing agent, DDS, than the lower lossy *m*-PDA. The higher Tg values for the microwave-cured samples was regarded as evidence for a nonthermal effect.

Recently Shibata et al. (23) reported a reduction in activation energy in the microwave assisted decomposition of sodium bicarbonate in water, attributing their results to a nonthermal effect. It should be noted, however, that the reaction was carried out using a 20% suspension of sodium bicarbonate, i.e., under heterogeneous conditions. Thus it is possible that selective superheating of the solid $NaHCO_3$ might have caused the rate increase.

This paper describes the study of a number of reactions, including reactions previously claimed to show a microwave effect at atmospheric pressure, in order to determine whether they occur more rapidly under microwave irradiation than under conventional heating at the same temperature.

Results & discussion

Srikrishna and Nagaraju (11) reported that microwave irradiation accelerated the *ortho* ester Claisen rearrangement of allylic alcohols in DMF in open vessels. For example, alcohol **1** gave an 83% yield of product **2** in 10 min, using a commercial microwave oven (eq. [1]).

[1] 
1 **2**

A similar reaction, heated conventionally in a sealed tube at 180°C took 48 h. It is not clear, however, whether DMF was used in this experiment. In the present study the rearrangement of geraniol (**3**) to compound **4** was investigated (eq. [2]).

[2] 
3 **4**

This reaction had been reported (11) to give an 87% yield of **4** in 12 min in a microwave oven. Identical reaction mixtures (i.e., geraniol, TEOA, propanoic acid in DMF) were heated at the boiling point (153°C) of DMF conventionally (heating mantle) and in a microwave oven for 10 min in an open vessel. The yield of **4** (52%) in the microwave reaction was not significantly higher, however, than that of **4** (47%) obtained by conventional heating.

Recently, Gupta et al. (12) have reported considerable rate enhancements in the synthesis of chalcones by Crossed–Aldol condensations in a microwave oven at atmospheric pressure. The reaction times and yields were compared with those reported earlier using conventional conditions, and it was claimed that reaction times were reduced from hours to minutes using microwave heating. For example, the chalcone **5** was synthesized from cyclohexanone and benzaldehyde in ethanol in the presence of one or two pellets of NaOH (catalyst) in 1 min in a 90% yield, compared with a "standard time" of 2 h, giving a 72% yield (eq. [3]).

The same reaction was carried out under microwave and conventional heating in an open vessel, with the same proportions of reactants, catalyst, and solvent used by Gupta. Initial experiments showed a two- to five-fold rate increase in the microwave heated reactions. A more careful investigation showed, however, that substantial evaporation of ethanol occurred in the microwave-heated reactions, whereas the conventionally heated reactions lost less solvent. Thus the microwave-heated reactions would have been expected to give higher yields in the same time period because of a more concentrated solution and a higher reaction temperature. It was also considered possible that, since the NaOH pellets did not dissolve appreciably under the reaction conditions, the rate enhancement could be caused by selective heating of the solid catalyst. To test this hypothesis, the reactions were also carried out using a solution of KOH in ethanol, but the rate enhancements were comparable to those observed in the reactions carried out with pellets of solid NaOH.

To prevent evaporation of the solvent, the reaction was carried out in a microwave oven modified to enable the reaction vessel to be connected to a reflux condenser outside the microwave oven (24). The reaction was carried out under reflux in the microwave oven and compared with a similar reaction carried out under conventional reflux. The results are shown in Table 1.

However, it can be seen (Table 1) that only slightly higher yields were obtained in the microwave reactions than in the conventionally heated reactions, in the same time period, when either solid NaOH (heterogeneous catalyst) or alcoholic KOH (homogeneous catalyst) were used. The rate enhancement using solid NaOH was only 1.5 times, and this could be attributed to superheating of the solvent or to hot spots in the reaction mixture in the microwave reactions rather than to a nonthermal effect (18, 19).

Adamek and Hajek (13) have reported that the addition of CCl_4 and CCl_3CO_2Et to styrene in the presence of a homogeneous Cu(I)-amine catalyst in CH_3CN occurs more rapidly under microwave heating than conventional heating at the same temperature (eq. [4]). Rate enhancements of 21 times were observed for the CCl_3CO_2Et addition and 7 times for the CCl_4 addition to styrene. The present investigation, in which the rates of the reaction using microwave reflux and conventional reflux were compared, showed a rate enhancement of only 1.5 times for the addition of CCl_3CO_2Et and no rate increase for the addition of CCl_4.

[4] 
Higher rate enhancements were observed, however, when the reactions were done in the presence of a small amount of solid CuCl (heterogeneous conditions). The rate enhancements for the additions of CCl_3CO_2Et and CCl_4 to styrene were 11 and 3 times, respectively. The results of these experiments are summarized in Tables 2 and 3 and Fig. 1.

The larger rate enhancements observed under heterogeneous conditions can be accounted for by the increased temperature

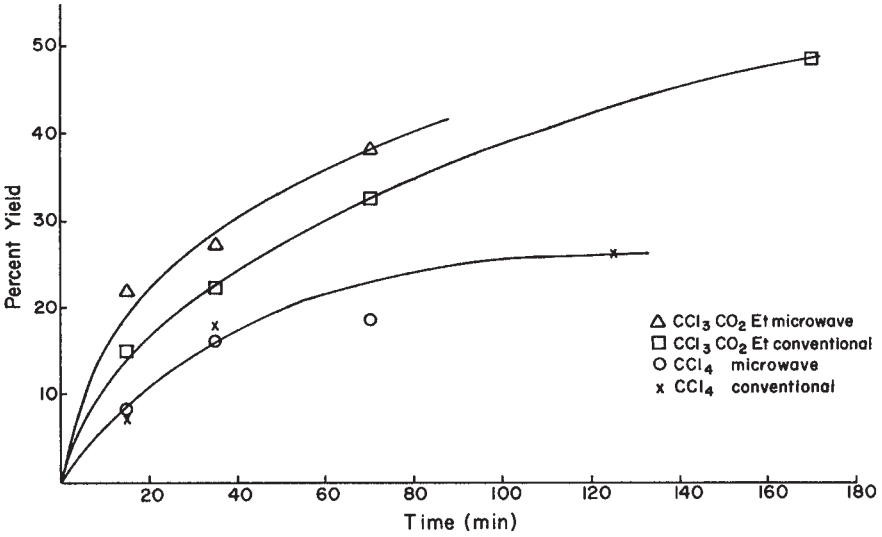
Fig. 1. The effect of microwave heating on the rate of the reaction of styrene with carbon tetrachloride and ethyl trichloroacetate in the presence of a Cu(I) catalyst in refluxing acetonitrile.



of the solid CuCl in the microwave reaction. It has been reported that CuCl is a strong absorber of microwaves and heats very rapidly (20°C/s) in a 2.45 GHz microwave cavity (25).

Soufaioui and co-workers (14) synthesized a series of 1,5-aryldiazepin-2-ones in high yield by the condensation of *o*-β-arylenediamines with β-ketoesters in xylene under microwave heating in open vessels. The reaction time was only 10 min with a final reaction temperature of 136–139°C. They reported, however, that no reaction occurred when similar reactions were heated classically under the same conditions of time and temperature. This would suggest a very dramatic rate increase under microwave heating at atmospheric pressure, and these results were taken as evidence for a specific microwave effect (14).

The reaction of *o*-phenylenediamine with ethyl acetoacetate was repeated using the same quantities of reagents and solvent used by Soufaioui. Care was taken to carry out the microwave- and conventionally heated reactions in the same vessels and at, as close as possible, the same temperature. Initially an attempt was made to carry out the reactions under microwave and classical reflux, respectively. Unfortunately it was found that insufficient microwave energy was absorbed in the low-polarity solvent *o*-xylene for the reaction to reach reflux temperature in 10 min. Even when a solution of *o*-phenylendiamine in *o*-xylene was preheated to reflux temperature (143°C) and the ethyl acetoacetate then added followed immediately by heating at 720 W in the microwave oven, the temperature slowly dropped and was only 105°C at the end of 10 min of microwave heating. In this experiment, the product failed to crystallize on cooling overnight although GC analysis indicated about 50% conversion to the expected product. Under classical reflux (oil bath heating), refluxing was maintained throughout the 10 min heating period, but the temperature dropped from 143 to 122°C due to containment of the ethanol liberated in the reaction. The product crystallized on cooling, giving a 37% yield.

Since the reflux conditions were unsatisfactory the reactions were then carried out in open Erlenmeyer flasks. The results obtained in the conventionally heated experiments were very different from these reported by Soufiaoui, and showed that there was virtually no difference in the rate of the microwave and conventionally heated reactions (Table 4). The temperature of the microwave-heated reaction, carried out at 720 W, was initially 143°C (after preheating), and fell to 105–115°C in different runs. The temperature profiles were simulated as far as possible in the conventionally heated (oil bath) experiments, giving comparable yields of the crystalline product (Table 4). In each case the product was shown, by GC – mass spectrometry and NMR to be the expected 2-methyl-1,5-phenyldiazepin-2-one **6** (eq. [5]).

[5] 
6

It can also be seen from Table 4 that the yields were affected by reaction temperature but not by the heating method (microwave or classical). For example, the microwave-heated reaction, with a temperature range 143–115°C gave a yield of 53%, and a comparable yield of 46% was obtained in the conventionally heated reaction with a similar temperature range

(143–110°C). A higher yield (75%) was obtained by conventional heating for 10 min at the boiling point of xylene (143–140°C). Hence, there was no evidence for specific microwave effects.

Bose et al. (8) reported the rapid synthesis of a variety of heterocyclic compounds in microwave ovens using open vessels. Among these reactions, the Knoevenagel reaction between sacilylaldehyde and ethyl malonate in the presence of piperidine (eq. [6]) was reported to give an 82% yield of 3-carbethoxycoumarin **7** in 3 min in a microwave oven.

[6] 
7

Initial studies on this reaction by Westaway and Gedye (17) showed slightly increased rates both in the presence of ethanol and in the absence of a solvent, when microwave heating was used at approximately the same temperature as the conventionally heated reactions. However, it was difficult to measure the temperature accurately in the microwave reaction without solvent, and in the presence of ethanol, evaporation of the solvent proved to be a problem. In the present study, the reaction in ethanol was carried out using a reflux condenser as described earlier, and it was found that the rate enhancement of the microwave reaction was approximately 2.5 times, since the yield of the product **7** was found to be 73% in 8 min using microwave heating compared with a yield of 71% in 20 min using conventional heating under reflux.

A similar rate enhancement (2.5 times) was observed in the much slower Knoevenagel reaction of acetophenone with ethyl cyanoacetate in ethanol in the presence of piperidine (eq. [7]).

[7] 
8 **9**

The results are shown in Table 5 and Fig. 2. It can been seen that the same yield (17%) of the isomer mixture **8** and **9** was obtained after refluxing for 120 min in the microwave oven and 320 min of conventional reflux. The isomer ratio *E*:*Z* was not affected by the heating method, and it was concluded that microwave irradiation did not effect the stereochemical outcome of this reaction.

The question that remained was whether these rate increases were due to a nonthermal microwave effect. To investigate this, the reaction was carried out using a variable-frequency (Variwave) microwave system. This instrument includes temperature measurement and provides very uniform heating, minimizing the possibility of hot spots. Ethanol was not suitable as a solvent because it would evaporate in the Variwave system. For this reason both microwave and conventional reactions were carried out at 80°C in the absence of solvent. The results are shown in Table 6 and Fig. 3. It can be seen that there is no significant difference in the rate of the microwave and conventional reactions. The microwave (Variwave) and conventional reactions were also carried out in anisole as a solvent at 100°C. Again the microwave and conventional reactions occurred at virtually the same rate (Table 7, Fig. 4).

These results suggest that the rate enhancement (2.5 times)

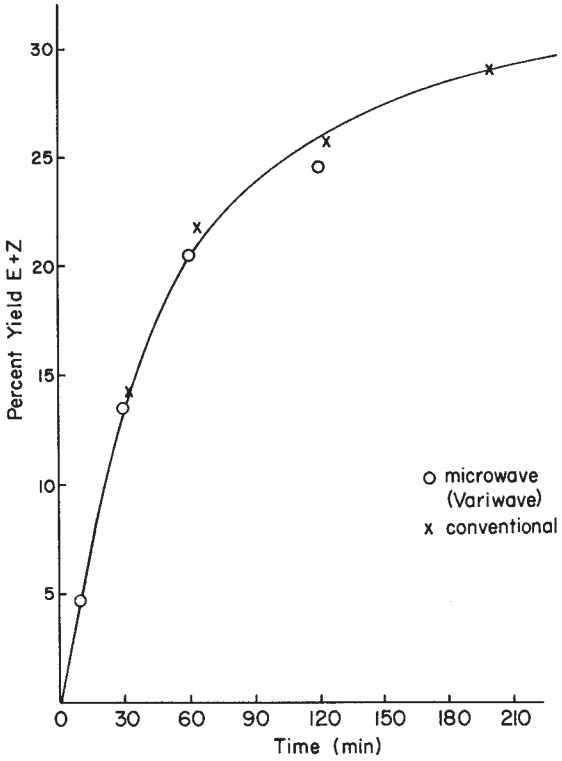
of the same reaction carried out under reflux in the microwave oven was due to hot spots or to general superheating of the solvent (ethanol) rather than to a nonthermal effect.

Conclusions

Several reactions, previously reported to show substantial rate enhancements using microwave heating at atmospheric pressure, were shown to occur at the same rate or only slightly faster than under conventional heating at the same temperature. The largest rate enhancement found in this study under homogeneous conditions, was 2.5 times in the Knoevenagel reaction of acetophenone with ethyl cyanoacetate. However, when this reaction was carried out in a variable-frequency microwave oven, it showed no rate enhancement compared with a conventionally heated reaction at the same temperature. It is therefore probable that the small rate enhancements observed in some reactions at atmospheric pressure are due to hot spots or to general superheating of the solvent under microwave heating.

Higher rate enhancements may be observed for reactions carried out under heterogeneous conditions, for example, in the presence of a solid catalyst that absorbs microwave energy.

Fig. 3. The effect of microwave heating on the rate of the reaction of acetophenone with ethyl cyanoacetate in the presence of piperidine at 80% (no solvent).



This can be attributed to localized heating of the catalyst to a temperature higher than that of the reaction mixture.

Experimental

Apparatus

The microwave ovens used in this study were the following:

(*i*) A Kenmore model 88560 microwave oven with 10 power settings, maximum output 900 W, modified to allow reactions to be carried out under reflux. A 7/8 in. (1 in. = 25.4 mm) hole was punched in the centre of the top of the oven to permit insertion of a B-14 air condenser surrounded by a 3/4 in. internal diameter copper tube, 4 in. long. A B-14 water-cooled condenser was inserted in the air condenser above the microwave oven.

(*ii*) A Toshiba model ER-8000 BTC microwave oven with a maximum output of 720 W.

(*iii*) A variable-frequency (Variwave) microwave furnace, Model 1500 manufactured by Lambda Technologies, Raleigh, North Carolina, U.S.A.

Product analysis

Reaction products were identified by their melting and boiling points (uncorrected), by GC – mass spectrometry and by NMR spectroscopy. GC–MS analysis was carried out using a Varian 3400 gas chromatograph, fitted with a 30 m × 0.25 nm PTE-5 silica column coupled to a Saturn II mass spectrometer operated in the electron impact mode. Proton NMR spectra were recorded with a Varian Gemini 200 MHz FT–NMR spectrometer. Reactions were monitored by GC using a Varian

Temperature measurement

In the microwave experiments carried out in the Variwave microwave oven, temperatures were measured using a fibre-optic probe manufactured by Luxtron.

Temperatures quoted in other microwave experiments were estimated either pointing a Williamson 600 infrared sensor at the reaction mixture or by inserting a standard thermometer into the reaction mixture immediately after heating was completed. It was recognized that the temperatures observed using the former method were not very accurate (± 5°C) and using the latter method were a few degrees lower than the actual final temperature.

General procedure

Each experiment was carried out both by conventional heating and by microwave heating using the same quantities of reagents and solvent. Most of the experiments were carried out under reflux (conventional and microwave) and the reactions monitored by withdrawing samples at regular time intervals and analyzing them by GC. In reactions that required catalysts, the mixture of reactants and solvent was heated until refluxing commenced, and the catalyst was then added. The reaction time was the reflux time after the addition of the catalyst. This procedure eliminated the problem caused by the fact that the conventionally heated reactions took longer to reach the boiling point than the microwave heated reactions.

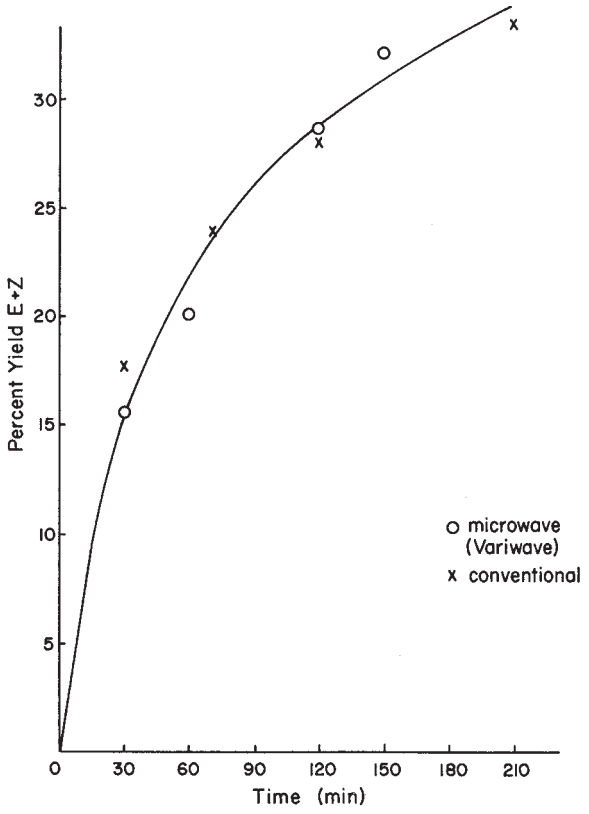
Reaction rates of the Knoevenagel reaction of acetophenone with ethyl cyanoacetate using the variable-frequency (Variwave) microwave oven were compared with the conventional reactions at the same temperature. The temperature of the Variwave reactions was monitored and held constant, and the conventional reactions were heated at the same temperature in a constant-temperature oil bath. Again the catalyst was added after the temperature had equilibrated to the required value, and the reaction time measured from this point.

The individual microwave heated reactions are described in the following section.

Ortho ester Claisen rearrangement

A mixture of geraniol (230 mg, 1.5 mmol), triethyl orthoacetate (1.3 g, 8.2 mmol), and propanoic acid (5 drops) in dry

Fig. 4. The effect of microwave heating on the rate of the reaction of acetophenone with ethyl cyanoacetate in the presence of piperidine in anisole at 100°C.



DMF (5 mL) was placed in an open Erlenmeyer flask and heated in the Toshiba microwave oven for 10 min at 640 W.

Crossed–Aldol condensation

A mixture of cyclohexanone (0.98 g, 10 mmol), benzaldehyde (2.12 g, 20 mmol), and anhydrous ethanol (20 mL) was heated to reflux in the Kenmore microwave oven. Two pellets of solid NaOH were then added, and the mixture refluxed in the microwave oven at 180 W for the specified time. The yield was estimated by GC and also by isolating the product. The product was cooled for 15 min in an ice bath, the pale yellow crystalline solid filtered, washed repeatedly with water, and dried in a dessicator.

Addition of CCl_3X to styrene

A mixture of styrene (2.1 g, 20 mmol), carbon tetrachloride (6.2 g, 40 mmol), copper(I) chloride (0.020 g, 0.2 mmol), *n*-butylamine (0.030 g, 0.4 mmol), and acetonitrile (5 mL) was refluxed in the Kenmore microwave oven at 180 W for the specified time.

The reaction was repeated using ethyl trichloroacetate (7.7 g, 40 mmol) and the above amounts of the other reagents.

Reaction of *o*-phenylenediamine with ethyl acetoacetate

(*i*) A mixture of *o*-phenylenediamine (1.08 g, 10 mmol) and *o*-xylene (20 mL) was heated to reflux (143°C) on a hot plate, forming a homogeneous solution. Ethyl acetoacetate (1.95 g, 15 mmol) was added and the mixture heated briefly (about 30 s) to reflux. The resulting mixture was immediately placed

© 1998 NRC Canada

in the Kenmore microwave oven (boileezers added) and heated with a reflux condenser attached for 10 min at 720 W. It was observed that the mixture ceased boiling after about 2 min. At the end of the heating period the temperature was measured and found to be approximately 105°C. An aliquot was analyzed by GC. The mixture was left to stand overnight in the refrigerator but failed to crystallize.

(*ii*) The above experiment was repeated except that the preheated mixture, in an open 125 mL Erlenmeyer flask, was heated in the Toshiba microwave oven at 720 W for 10 min. The temperature of the mixture fell to 105–115°C (in different experiments) by the end of the heating period. The crystalline product (yellow needles) was filtered off and washed with two 5 mL portions of ether.

Knoevenagel reaction of salicylaldehyde and diethyl malonate

A mixture of salicylaldehyde (3.0 g, 25 mmol), diethyl malonate (4.4 g, 27.5 mmol), acetic acid (40 μL), and anhydrous ethanol (10 mL) was heated to reflux in the Kenmore microwave oven. Piperidine (0.25 mL) was then added and the mixture refluxed for the specified time. The yield of the product was estimated by GC and by isolation after cooling and recrystallization from aqueous ethanol.

Knoevenagel reaction of acetophenone with ethyl cyanoacetate in the presence of piperidine

(i) In refluxing ethanol

A mixture of acetophenone (3.0 g, 25 mmol), ethyl cyanoacetate (2.9 g, 25 mmol), acetic acid (40 μL), and ethanol (10 mL) was heated to reflux in the Kenmore microwave oven. Piperidine (250 mL) was then added, and the mixture refluxed in the microwave oven at 180 W. Heating was interrupted at regular time intervals and samples withdrawn for GC analysis.

(ii) In the absence of solvent in the Variwave microwave oven at 80°C

The same amounts of reagents were used as in (*i*) except that no ethanol was used. The temperature of the Variwave was set at 80°C with a microwave central frequency of 8.1 GHz, a bandwidth of 0.30 GHz and a scan rate of 0.10 s. Initially a power of 80 W was used to preheat the mixture to 80°C. Piperidine was then added and the mixture maintained at 80°C using a power of 15 W. The heating was interrupted at regular time intervals and aliquots taken for GC analysis.

(iii) Using anisole as a solvent in the Variwave microwave oven at 100°C

The above reaction was repeated except that 5 mL of anisole was used as the solvent. The temperature was set at 100°C and maintained at that temperature with a power of 22 W. The central frequency was 12.2 GHz, bandwidth 0.40 GHz, and scan rate 0.5 s.

Structure bifurcation in containerless low-temperature syntheses of solid state niobium chloride compounds from lanthanoid atoms: an X-ray absorption and ab initio EXAFS analysis

C. Den Auwer, M.P. Andrews, V. Briois, C. Cartier dit Moulin, and H. Dexpert

Abstract : A new method of preparing solid state chlorometallates by reductive dechlorination of solvated niobium pentachloride with the vapour of nominally free atoms of erbium and samarium is described. Products were prepared in a model of a rotatable Pyrex cryostat by evaporating Sm or Er into a turbulently mixed solution of $NbCl_5$ in toluene at 130 K. Since no single crystal had been isolated, local order around the Nb atom was probed by far-IR, XPS, and EXAFS spectroscopy. Depending on the vaporized rare earth, two structurally distinct products were found. Combining information gathered by EXAFS results and ab initio EXAFS calculations on clusters to model the growing solid state compound using the FEFF6 code, two different condensation patterns were proposed: chlorine edge-shared aggregation was preferred for Er vaporization, face-shared condensation patterns emerged from Sm vaporization.

Key words: X-ray absorption spectroscopy, niobium, metal vapour synthesis, XPS.

Résumé : Ce travail décrit une nouvelle méthode de synthèse de composés chlorométalliques par abstraction réductrice des atomes de chlore à partir de pentachlorure de niobium solvaté et de vapeur d'atomes libres d'erbium et de samarium. Les produits ont été préparés dans un cryostat rotatif par évaporation de Sm et Er sur la solution de $NbCl_5$ dans le toluène, agitée et refroidie à 130 K. Aucun monocristal n'ayant pu être isolé, l'ordre local autour du Nb a été sondé par spectroscopie IR, XPS et EXAFS. Deux structures différentes dépendantes de la terre rare vaporisée ont été identifiées. Additionnant les informations EXAFS aux calculs ab initio d'EXAFS par FEFF6 et simulant la croissance des clusters formés, deux modes de condensation ont été proposés : condensation via les chlores des arêtes de l'octaèdre pour la vaporisation d'Er et condensation via les chlores des faces de l'octaèdre pour la vaporisation de Sm.

Mots clés : spectroscopie d'absorption des rayons X, niobium, synthèse à l'aide de métaux à l'état vapeur, spectroscopie photoélectronique des rayons X, « XPS ».

Introduction

It is surprising how little is known about reactions that take molecular compounds to infinite solids. This is due in part to a traditional reliance on high-temperature reactions in sealed containers to carry out syntheses that involve complex equilibria and heterogeneous reactions among components at solid, liquid, and gas interfaces. Among the low-temperature methods for making solid state materials from molecular precursors, those based on the so-called "chimie douce" approaches offer the potential of access to mechanistic details of growth by chemical or spectroscopic interception and interrogation. More generally, molecular building block approaches to solid state materials at reduced temperatures may provide control over molecular assembly, and thus allow systematic amplification of physical properties by chemical tuning at the molecular level. This kind of approach converges to the limit of the so-called "top down" methods of microfabrication technologies, while carrying with it all the advantages of "bottom up" molecular-scale chemistry. Synthetic tactics have included decomposition of precursor transition metal mononuclear and cluster chalcogenides (1–3), reactions of molecules in low-temperature molten salts (3), combinations of transition metal halides and carbonyls with soluble polychalcogenide anions, excision of cluster fragments from solid state lattices (4), and Rieke-type reductive condensations (5–7). These methods offer the advantage of access to significant quantities of metastable products, therefore giving considerable impetus to the study of new compounds not accessible under more forcing conditions. Our interest in this subject is twofold: (*i*) to develop so called "containerless," low-temperature syntheses of new solid state compounds using atoms and molecules as starting

materials and building blocks; and (*ii*) to identify structural intermediates, or proto-forms, of bulk solids in order to understand more about how structure–property relationships develop as molecules are elaborated into extended solids. This is undertaken in the present study by introducing a method to elaborate $NbCl_5$ into chains by reaction with vaporized atoms of samarium and erbium.

$NbCl_5$ was selected for our study in part because of the prominent role it has played as an entry into a large number of early transition metal halide solids in groundbreaking studies that have linked electronic properties with the extraordinary structures and patterns of their ramifying substructural motifs (8–10). More recently, $NbCl_5$ has served as a material source for a new series of mixed ternary rare earth $RENb_6Cl_{18}$ and quaternary $MRENb_6Cl_{18}$ (RE = rare earth, M = group 1 element) compounds showing the trademark Nb_6 octahedral cluster motif (10). Erbium and samarium were selected as reducing agents based on their ease of vaporization and their well-known trivalent (Er, Sm) and bivalent (Sm) oxidation-state chemistry. The lanthanoids are attractive because they offer a range of ionic radii (0.86–1.03 Å) depending on the choice of element, tunable redox properties, and a host of magnetic properties related to *f*-orbital occupancy. Sm^{3+} and Er^{3+}, respectively, are valence state $4f^6$ and $4f^{12}$ ions. Differences in the radii of these ions show up in solid state quaternary niobium halides where unit cell volumes are observed to increase on changing from Er^{3+} to Sm^{3+} (11). In their own right, lanthanoid halides show interesting structural variations (12). Additional points of contact of our work can be found in the literature on synthesis of chloroniobates or chlorotantalates (13). The preparation of colloids of samarium by freezing Sm vapor with alkane at liquid nitrogen temperature was described. Colloid slurries were active in Rieke-like reductions of large excesses of Nb_2Cl_{10} and Ta_2Cl_{10}.

Synthesis with atoms and molecules has much in common with so called *chimie douce*. Our method is "containerless" in the following sense: we replace the high-temperature container and the metal powder reducing agent with a vapour of erbium or samarium. The target molecule is dissolved in an organic solvent whose purpose is to maximize the "surface area" of the $NbCl_5$, and to provide a kind of dilution factor so that atom–atom encounters that would favor lanthanoid atom repolymerization are diminished. Timms and Turney (14) have described a high-temperature variation of the approach, in which atoms have been deposited into molten eutectic salt mixtures, with product work-up in the laboratory. Our method differs in that atoms are deposited into low-temperature solutions of dissolved inorganic molecules: atoms of erbium and samarium are used in the reductive condensation of $NbCl_5$ and its elaboration into the extended solid state compound.

A drawback to the *chimie douce* approaches is that products are not usually obtained in single-crystal form, so that elaborate techniques of structure refinement must be brought to bear on the materials. X-ray Absorption Spectroscopy (XAS) figures prominently among the characterization tools. A major challenge to using Extended X-ray Absorption Fine Structure spectroscopy (EXAFS) in this manner to extract quantitative structural information is that accurately known experimental reference standards must be applied against each intermediate composition. Since each EXAFS wave implies two sets of highly correlated variables: ($F(\theta,k)$, σ, N) and ($\Phi(k)$, r), (*i*) the amplitude function $F(\theta,k)$ must be well known to obtain reliable coordination numbers (N) and Debye–Waller factors (σ); (*ii*) bond distances (r) must be determined from accurate phase functions ($\Phi(k)$) (15). This is clearly a formidable problem when studying sequences of reactions like those described in the present work. Our atom reactions generate samples of unknown structure or samples that exhibit subtle variations in structural parameters. The problem is certainly exacerbated in the kind of problem undertaken in our studies because suitable standards are simply lacking. This makes ab initio theoretical standards essential. But until recently, ab initio methods have been less successful than experimental standards because of the approximations and ad hoc parameters required by the models.

Most widely used among the theoretical phase and amplitude functions are the tabulations of Teo and Lee (16) or of McKale et al. (17). Their approaches either ignore curved-wave effects (Teo) (16) known to be important, or neglect inelastic losses (McKale) (17). To overcome these limitations and provide a flexible framework for XAS analysis, we use the recently developed ab initio multiple-scattering curved-wave XAFS method, FEFF6, introduced by Rehr and co-workers (18). The method offers theoretical standards that can be tailored to a particular chemical environment. The theory has the added advantage that multiple-scattering effects are taken into account.

The first part of this paper is devoted to spectroscopic results. Far-IR, XPS, and EXAFS spectroscopy are used to follow an unusual low-temperature assembly process. We identify a surprising dependence of the final cluster structure on the choice of rare earth atom. We then discuss, in the second part, two possible condensation routes. Ab initio calculations are compared with experimental EXAFS spectra and conclusions are drawn regarding dependence of the condensation route on the identity of rare earth atom.

Experimental section

Materials and atom syntheses

Manipulations of all air-sensitive compounds and starting materials were carried out under argon in a dry box. All solvents were dried and distilled under argon prior to use. $NbCl_5$ (Alfa) was purified by sublimation. Lanthanides (Alfa) were evaporated from fragments of the bulk solid elements after removal of the oxide layer on the surface by mechanical abrasion. Boron nitride crucibles suspended from dual-strand tungsten wire baskets were used as containers (19, 20).

Reactions were conducted at low temperature (~170 K) by resistive vaporization of Sm or Er under vacuum into deoxygenated red-orange liquid toluene solutions saturated with $NbCl_5$. Atom reactions were carried out in a 5 L rotatable cyostat. The rotatable cryostat – atom reactor has been described elsewhere (20, 21). The solution was metered into the Pyrex reaction vessel through connecting valves and cannulae, and then spun into a thin liquid film on the inner surface of the rotating vessel. Current to the crucible was set to obtain a constant atom vaporization flux of about 4 mg Er/min and 6 mg Sm/min. The difference between these two rates is due to the difference between the vaporization enthalpy of Er and Sm (65 kcal/mol and 46 kcal/mol, respectively). Metal atoms

© 1998 NRC Canada

impinging on the film reacted with dissolved $NbCl_5$ and deposited a fine brown-black solid in liquid. When erbium was vaporized initially at a constant rate of 3.6 mg/min, the deep red-orange solution characteristic of $NbCl_5$ in toluene rapidly turned red-brown. After approximately 15 min the solution was distinctly brown, consisting of a suspension of fine, brown particles. Electronic absorption spectroscopy was carried out on anaerobic samples of the supernatant liquid acquired after increasing amounts of Er were deposited. The absorption band intensity located at 370 nm and characteristic of $NbCl_5$ in toluene systematically decreased as the starting material was consumed. Similarly, samples of precipitate were extracted at intervals from the reaction vessel so that changes in spectral features of the products could be evaluated. Color change from deep red-orange solution for $NbCl_5$ in toluene to brown-black powder was observed upon samarium vaporization.

Typically, 2 g of $NbCl_5$ was dissolved in 150 mL of degassed toluene. Er vaporizations were sampled at intervals of time during the reaction. The products are identified in the text under the name ErNb5, ErNb30, and ErNb45, indicating 5-, 30-, and 45-min vaporizations during one reaction. These correspond to about 20, 120, and 180 mg of Er vaporized, respectively. Elemental analysis gave the following stoechiometry: $NbCl_{4.30}Er_{0.10}$, $NbCl_{4.98}Er_{0.15}$, and $NbCl_{3.28}Er_{0.20}$ for ErNb5, ErNb30, and ErNb45, respectively. The non-proportionality between the vaporization time and the Er stoechiometry is believed to be mainly related to vaporization rate fluctuations. Because small changes in current to the electrodes led to dramatic changes in the Sm vaporization rate, we chose to fix the current to complete sets of experiments for Sm atom reactions. Samarium atom evaporations were conducted for 15, 30, and 50 min (SmNb15, SmNb30, SmNb50), corresponding to about 90, 180, and 300 mg of Sm in sequence. After vaporization, insoluble reaction products were filtered from unreacted solution and washed three times with dry, oxygen-free toluene to remove unreacted $NbCl_5$. Other side products of the reactions (as oxides) are minor since both reaction medium and all starting materials were carefully manipulated under argon. The filtrate was then dried under vacuum to give red-brown (Er) or brown-black (Sm) powders.

Infrared spectroscopy

Far-IR spectra were recorded on a Bruker IFS 88 FT spectrometer. Samples were prepared under argon in a dry box as Nujol mulls between two sealed CsI windows.

X-ray photoelectron spectroscopy (XPS)

XPS spectra of solid products were recorded on a VG Instrument ESCALAB MKII unit, using a Mg twin anode source (1253.6 eV). Samples were transported to UHV via an anaerobic transfer device adapted to the preparation chamber of the ESCALAB unit. Rigorous exclusion of air during sample transport and manipulation was achieved in this way. Spectra were energy calibrated versus the carbon binding energy peak at –285 eV. Cl 2*p* XPS spectra for the products have been adjusted with the same parameters as those used to fit the $NbCl_5$ XPS spectrum. Considering a spin-orbit coupling ζ_{2p} = 1.6 eV, we performed a deconvolution of each spin orbit component with two Gaussian functions representative of two types of chlorine bridging and terminal ligands (Full Width at Half Maximum FWHM = 1.45 eV).

$NbCl_5$ $NbCl_4$

X-ray absorption spectroscopy

Data measurement

All samples were prepared in an argon-filled dry box. Quantities of materials were chosen to ensure an absorption jump $\Delta\mu$ close to 1. Ground powders were placed between two sheets of parafilm in a copper sample holder, which was then attached to a liquid nitrogen cryostat tip and enclosed in an evacuable cryostat shroud before data acquisition at 77 K.

Data were collected on beam-line D42 of the DCI 1.800 GeV synchrotron light source (LURE, Orsay, France) at the Nb K edge (18 986 eV). A channel cut Si 331 monochromator was used. Calibration of the monochromator was achieved by measuring the absorption K edge of a Zr metal foil at 17 998 eV. Spectra were taken in transmission mode using argon ionization chamber detectors coupled with Keithley pico-ampermeters (energy range from 18 850 to 19 850 eV with energy steps of 2 eV and 2 s acquisition time per point). Energy resolution at 19 000 eV was 9.7 eV.

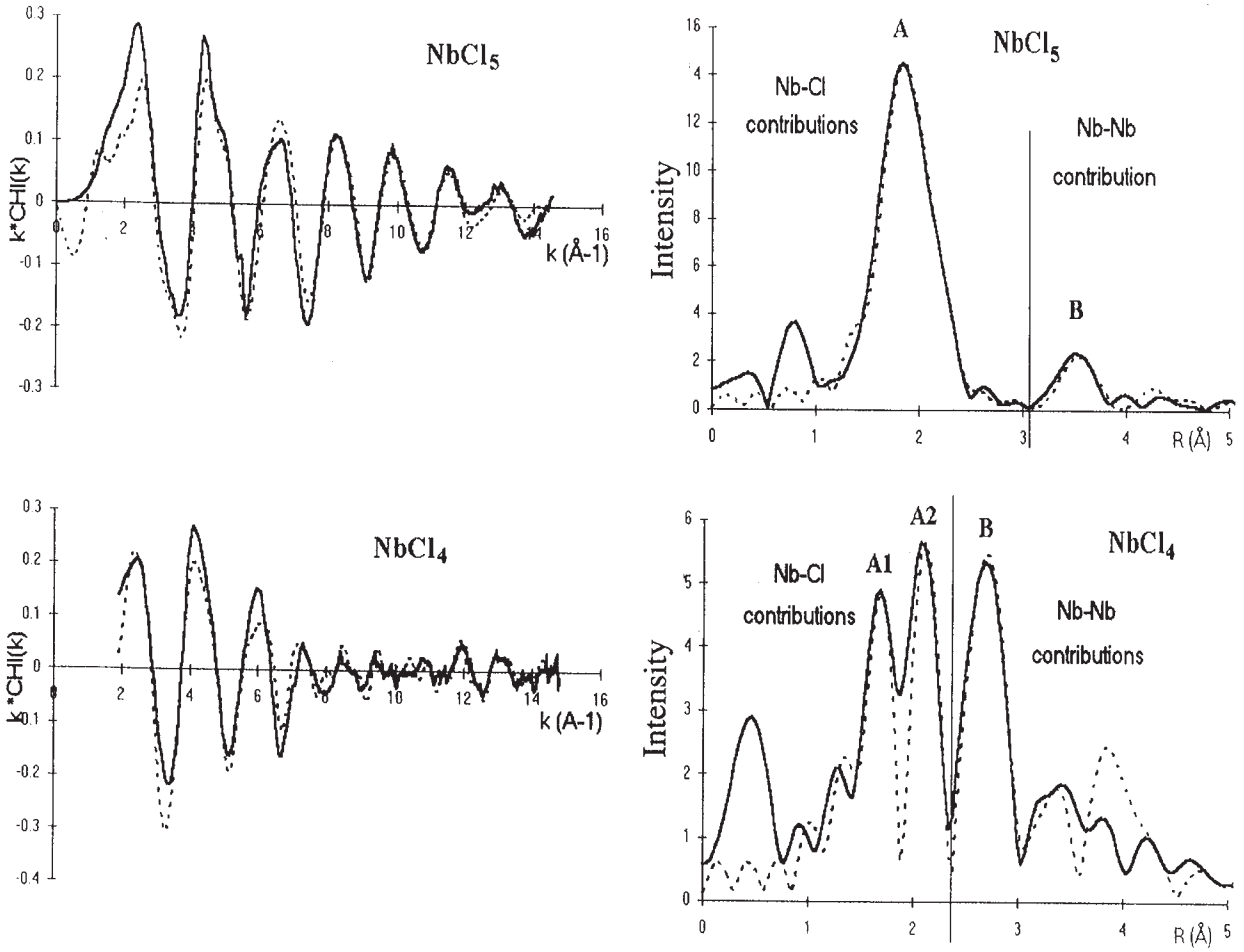
Data treatment

EXAFS analysis was performed with a set of locally written programs called "EXAFS pour le Mac" that have been fully described elsewhere (22, 23). A straight-line approximation was used to remove background absorption. Heitler–Eisenberger normalization after 4th degree polynomial removal of the atomic absorption gave EXAFS oscillations in *k*-space. Fourier transformation of the EXAFS signal was achieved between 3.0 and 13.5 $Å^{-1}$ using a Kaiser window with τ = 1.5. Filtering of the main peak (Nb-Cl contribution) of the FT was done by back-Fourier transformation between 1.5 and 2.4 Å. Theoretical phase and amplitude functions used in adjustments of the Nb–Cl contributions were obtained by using the code FEFF6 (24). An effective curved-wave scattering amplitude plays a central role in this computation. The code is equipped with efficient filtering algorithms to enumerate scattering paths that contribute meaningfully to the EXAFS signal. It was first calibrated by comparison of the simulations with experimental spectra of reference compounds $NbCl_5$ and $NbCl_4$, which are schematically represented in Fig. 1 (25, 26). In the repeating dimer motif of $NbCl_5$ there is no Nb—Nb chemical bond, given the large 3.97 Å Nb–Nb separation. In $NbCl_4$, one recognizes alternating short (3.03 Å) and long (3.79 Å) Nb–Nb distances due to the presence of one bonding electron on each niobium atom.

The main lines of the FEFF6 used to reproduce the references are summarized below. Solid state $NbCl_5$ was simulated by a cluster of 12 atoms, namely Nb_2Cl_{10}. Plane waves were first used to accelerate the computation by determining normalized contributions to each path (18). In subsequent steps

© 1998 NRC Canada

Fig. 2. Experimental (—) and calculated (FEFF6) (– – –) EXAFS spectra of reference compounds $NbCl_5$ and $NbCl_4$. Both EXAFS oscillations in *k*-space and Fourier transform in *R*-space (not phase-shift corrected) are shown.



the curved-wave formalism was invoked to eliminate those paths that contributed intensity less than the threshold value of 2.5%. A second round of calculations, again within the curved-wave approximation, enabled us to delete those paths with relative intensity less than 4%. The EXAFS signal was then computed as the sum of contributions of all surviving paths. For $NbCl_5$ the maximum effective paths were determined to be no longer than 6 Å. Paths corresponding to scattering between Nb–Cl centers were the most intense. The contribution of the neighboring Nb atom itself was shown to be rather weak (13%). This is as expected because of the long metal–metal distance. The agreement between experimental results and ab initio calculations is shown in Fig. 2 in *k* space and in *R* space. Peak A is due to chlorine contribution whereas peak B is related mainly to niobium–niobium single scattering contribution. In fact, we found that multiple scattering paths less than fifth order also contribute to peak B and, in particular, paths including bonds that make an angle close to 180° with respect to each other. Overall, multiple scattering effects were found to reinforce the major single scattering contribution beyond 3 Å, so that multiple scattering needs to be included to fully rationalize this region of the FT.

In a similar manner, $NbCl_4$ was simulated for an aggregate of 27 atoms, where 3 chemically distinct chlorine centers can be identified. The comparison between experimental and ab initio calculations is presented in Fig. 2. As for $NbCl_5$, peak A, which is now split into two components A1 and A2, is due to chlorine contributions whereas peak B is related to Nb–Nb contribution. Contributions A1,2 and B were well reproduced by the calculation in the single scattering approximation. Amplitude enhancement due to the so-called focusing effect was clearly evident for the short Nb—Nb bond in $NbCl_4$. This effect accounts for the large intensity of peak B in the FT of $NbCl_4$. Multiple scattering corrections to the spectrum gave only minor cosmetic improvements, not because there were no such events of significant amplitude, but because the imaginary parts of the scattering contributions of order 3 and 4 were shown to be completely out of phase from 2 to 5 Å.

According to the structure of $NbCl_5$, three phases and amplitudes obtained in the curved-wave formalism can be extracted from the FEFF6 calculation: one for equatorial Cl_{eq} at 2.25 Å, one for apical Cl_{ap} at 2.29 Å, and one for bridging Cl_{br} at 2.57 Å. These theoretical functions, introduced in the "EXAFS pour le Mac" codes, were checked in the simulation of the Nb–Cl contributions of $NbCl_5$ in order to determine unknown electronic parameters like G, related to the mean free path λ of the photoelectron ($\lambda = k/\Gamma$) and the ionization threshold, $E_0 + \Delta E_0$, used to convert from energy to wave vector. The electronic parameters used in the fit of the Nb–Cl contribution of the reaction products were: $\Gamma = 1.2$ Å^{-2} for the three chlorine

© 1998 NRC Canada

layers and $E_0 + \Delta E_0 = 19\,000 - 0.2$ eV for equatorial chlorine, 19 000 – 1.0 eV for apical chlorine, and 19 000 + 6.2 eV for bridging chlorine. Accurate structural parameters are then determined on the Er and Sm reaction products by keeping the Γ and ΔE_0 parameters to these values and by using phases and amplitude functions extracted from the above ab initio simulation of $NbCl_5$.

The residual of the fit of the experimental spectra is given by the function (22):

$$[1] \qquad \rho = \frac{\sum_k [\chi^{exp}(k) - \chi^{fit}(k,\pi)]^2}{\sum_k [\chi^{exp}(k)]^2}$$

where $\chi^{exp}(k)$ is the extracted experimental EXAFS signal and $\chi^{fit}(k,\pi)$ is the fitted signal with π parameters.

Results and discussion

Part I: Chlorine environment probed by IR, XPS, and EXAFS spectroscopies

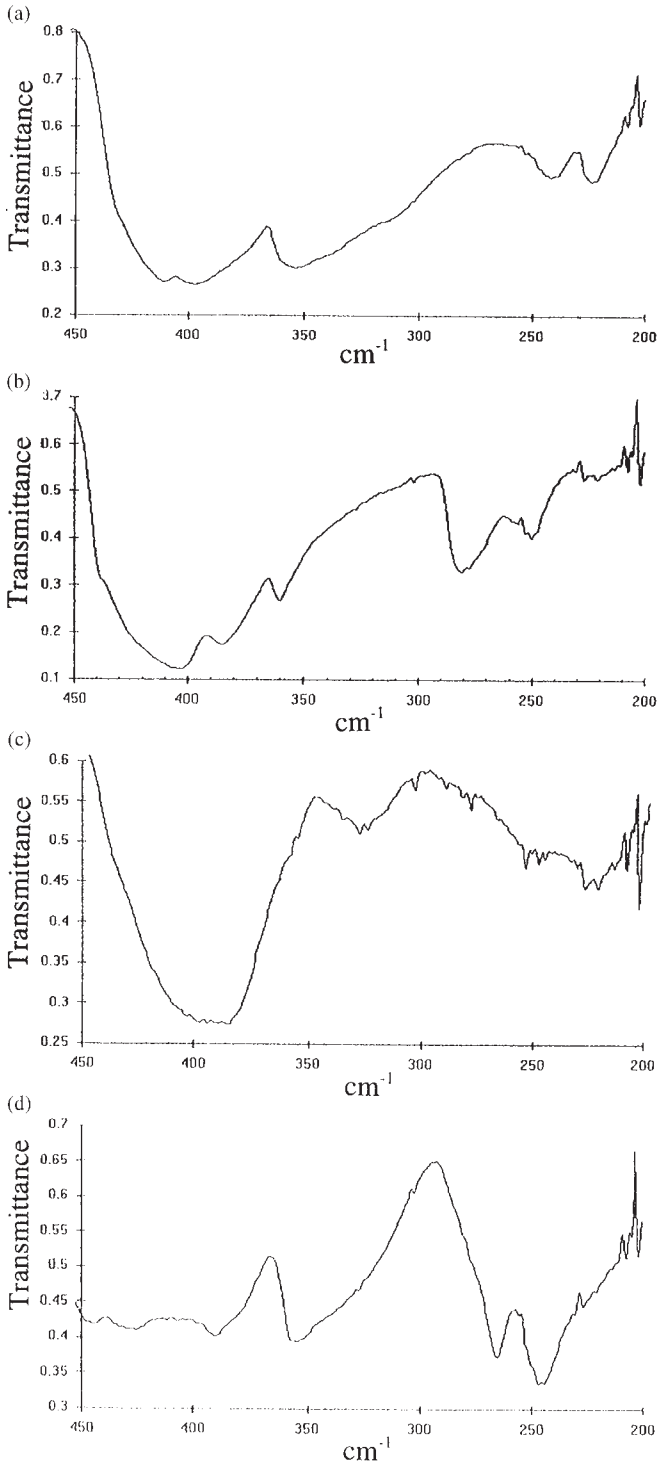
The X-ray diffraction patterns of the solid products show, exclusively, the broadened diffraction peaks that account for the presence of microcrystalline materials and which made further quantitative analysis impossible. Attempts to produce single crystals for X-ray diffraction structure determination, by either heat treatment or reaction-blocking units (such as phosphine groups), have failed. We then investigated the chlorine environment of the solid products with infrared and X-ray photoelectron spectroscopies. Both probes suggest that new products are formed when Er or Sm react with $NbCl_5$.

It is convenient to view the starting $NbCl_5$ dimer (Nb_2Cl_{10} in the solid state) and the $NbCl_4$ infinite chain (representing an infinite condensation of the $NbCl_5$ units) as material boundary conditions for the chlorometallate reductive condensation process and consequently compare systematically the products of reactions with these references. Higher condensation processes leading to Nb oxidation states lower than (III) were a priori considered as very unlikely (and confirmed by further EXAFS measurements, *see after*). In fact, infinite chain Nb_3Cl_8 or well-known Nb_6 clusters such as $RENb_6Cl_{18}$ (RE = rare earth metal) are obtained under different reductive conditions with a large excess of Nb metal (10, 27).

Infrared analysis

Figure 3 shows far-IR spectra of $NbCl_5$ and $NbCl_4$ compared with two reaction products (ErNb45 and SmNb50, respectively). We recall here the nomenclature used: the number after the product's name represents the vaporization time, here 45 and 50 min vaporization, respectively). Bond vibrations corresponding to Nb–Cl stretches in the solid are located in the region between 100 and 500 cm^{-1}. Despite the apparent simplicity of the $NbCl_5$ dimer, a definitive asignment of the vibrational spectrum is still unavailable (28). The most complete treatment belongs to Beattie et al., and so we have chosen to follow their assignments (29, 30). One can distinguish two regions in the vibrational spectra of $NbCl_5$. The first is located between 200 and 300 cm^{-1} and is due to Nb–Cl_{br} vibrational modes. These are not pure modes, but the vibrations are sufficiently characteristic that this region can be distinguished

Fig. 3. Far-infrared spectra of solid state (*a*) $NbCl_5$ and (*d*) $NbCl_4$ compared with those of (*b*) ErNb45 and (*c*) SmNb50.



neatly from the second one falling between 300 and 450 cm^{-1}. The latter arises from modes that are terminal Nb–Cl_{term} stretches. It is interesting to contrast these data with data obtained in a study of Nb–Cl vibrations derived from Cl associated with the octahedral core of Nb_6 in the compound $MRENb_6Cl_{18}$ (M is a group 1 element and RE is a rare earth atom) (31). In this study, the higher frequency vibration at

© 1998 NRC Canada

340 cm^{-1} has been assigned to bridging Cl, whereas the lower frequency modes at 280 and 230 cm^{-1} have been attributed to terminal Cl ligands. To our knowledge, only Pisarev and coworkers (32) have reported the IR spectrum of $NbCl_4$, and with only a qualitative interpretation. Bands that we detect at 425, 390, 354, 265, and 244 cm^{-1} correspond to those given by Pisarev (32). Below 550 cm^{-1} we have also located bands maximizing at 530, 490, and 440 cm^{-1}. For comparison, we assign the doublet at 265 and 244 cm^{-1} in $NbCl_4$ to vibrations of the bridging chlorine atoms. The shift to higher frequency compared with the corresponding doublet exhibited by $NbCl_5$ is a consequence of stronger in-plane bonding associated with the decrease in oxidation state of Nb in the tetrachloride. Given that $NbCl_4$ corresponds roughly to a one-electron reduction and infinite condensation of $NbCl_5$ units, one might anticipate that reductive polycondensation of $NbCl_5$ by rare earth atoms might be accompanied by a similar shift to higher energy of the modes related to bridging chlorine, were the product to bear some structural congruity with $NbCl_4$.

The infrared spectra of the products of reaction of $NbCl_5$ with samarium or erbium vapors were found to be rather insensitive to the quantity of deposited atoms, for a reason that is still not clear. However, we are not sure that IR bands are very sensitive to whether or not trimers, tetramers,... are involved. Vaporizing the rare earth atoms modifies the electronic configuration of the cluster and this accounts for the evolutions between $NbCl_5$ and our products. We therefore present only two spectra for Er and Sm vaporizations in Fig. 3. The first important result of the IR study is the shift to higher energy of the Nb–Cl_{br} bands (ErNb45, the doublet 250, 280 cm^{-1} in Fig. 3*b*) observed for compounds derived from Er atom reactions, relative to both $NbCl_4$ and $NbCl_5$. Moreover, we detect relative intensity changes, the higher energy component of the doublet being the more intense of the two bands. Interestingly, the 350–500 cm^{-1} region of the spectrum of sample ErNb45 shows a band profile similar to that of $NbCl_5$. The second important point of this study lies in the significant differences between the spectra for SmNb50 (Fig. 3*c*) and ErNb45 over the 200–500 cm^{-1} region. This is evidence that reactions with Er atoms yield products that differ from those of Sm. The doublet feature at lower energy (225 and 250 cm^{-1}) is still retained in SmNb50, but is clearly shifted to lower wave number. An intense broad band centered near 380 cm^{-1} now replaces the articulated band located near this position for ErNb45. SmNb50 also manifests a new absorption at 330 cm^{-1} that has no correspondence in either $NbCl_5$ or $NbCl_4$.

X-ray photolectron spectroscopy

The binding energy of 210.7 eV for the Nb $3d_{3/2}$ level in $NbCl_5$ agrees well with the literature value (33). Shifts in the binding energy of Nb for products of Er or Sm atom reactions differed little from those of the parent $NbCl_5$ compound: binding energies for Er-containg products were consistently 0.1–0.3 eV lower than in $NbCl_5$, whereas those of the Sm products were 0.1–0.2 eV higher. In fact, data relative to the Nb $3d_{3/2}$ binding energy are not very informative about the condensation process involved during the vaporization, and interesting results come from the chlorine 2*p* XPS spectra since the presence of bridging and terminal chlorine atoms has been again evidenced. Table 1 gives the binding energy of the Cl $2p_{1/2}$ contribution for terminal and bridging chlorines of $NbCl_5$, and of the products of the atom reactions. Figure 4 represents the analysis of the Cl 2*p* binding energy peak for $NbCl_5$, ErNb45, and SmNb50. The fit with two types of chlorine ligands for $NbCl_5$ gave an area ratio R^{XPS} = (terminal chlorine peak area / bridging chlorine peak area) of 3.8. This corresponds satisfactorily to the ratio of the number of terminal to the number of bridging Cl atoms in this compound. The value carries an error of 5% compared with the expected value of 4.0 for the D_{2h} dimer. R^{XPS} extracted from the fits are on the order of 1.5 for Er products and 0.5 for Sm products. These values are strikingly smaller than those of $NbCl_5$ and support the idea of some kind of condensation of the target molecule (i.e., a decrease in the number of terminal chlorine atoms compared with the number of bridging atoms). The different R^{XPS} ratios for Er and Sm products also point to structural differences between them, as suggested by the IR studies.

Table 1. Cl 2*p* binding energy (eV) of the solid products. R^{XPS} is defined as the ratio of terminal Cl peak area to the bridging Cl peak area, as explained in the text.

Compound	Cl $2p_{1/2}$ term.	Cl $2p_{1/2}$ br.	R^{XPS}
$NbCl_5$	–200.8	–200.1	3.8
ErNb5	–200.7	–200	1.5
ErNb30	–200.8	–200.1	1.45
ErNb45	–200.8	–200.7	0.42
SmNb30	–201.5	–200.7	0.54
SmNb50	–201.6	–200.7	0.54

EXAFS

The local niobium environment was probed by EXAFS measurements at the Nb K edge for both Er and Sm atom reaction products.

These experiments confirmed the structural differences anticipated from the IR and XPS spectra. The moduli of the Fourier transformed EXAFS spectra of the atom reaction products are compared to the $NbCl_5$ and $NbCl_4$ reference compounds in Figs. 5*a* and 5*b*. As for the references, peaks in *R* ranging between 1.3 and 2.4 Å are related to chlorine contributions. This contribution, labeled A, is structured in the vaporization products into two components. Regarding the Er products, contribution A splits into peak A1 and a shoulder A2 on the right side of A1. The main peak A1 is shifted towards shorter distances on going from sample ErNb5 to sample ErNb45 in Fig. 5*a*, i.e., for increasing erbium content. Simultaneously, the shoulder identified as A2 becomes better resolved as the amount of lanthanoid in the reaction medium increases. This compares well with the features of contribution A in infinite chain $NbCl_4$. The Sm atom reaction products show different trends in Fig. 5*b*. Contribution A splits into a peak A2′ and shoulder A1′ on the left side of A2′. Main peak A2′ is shifted towards larger distances on going from SmNb15 to SmNb50. These differences between the main contribution of the Fourier transform reflect structural differences as suggested by XPS and IR. This is also confirmed in Figs. 5*c* and 5*d* by comparing the filtered EXAFS oscillations of Er and Sm compounds for the chlorine contribution. On one hand, the filtered EXAFS oscillations of Er reaction products present a "beating" between 6 and 10 $Å^{-1}$ (weak around 7 $Å^{-1}$ for ErNb5)

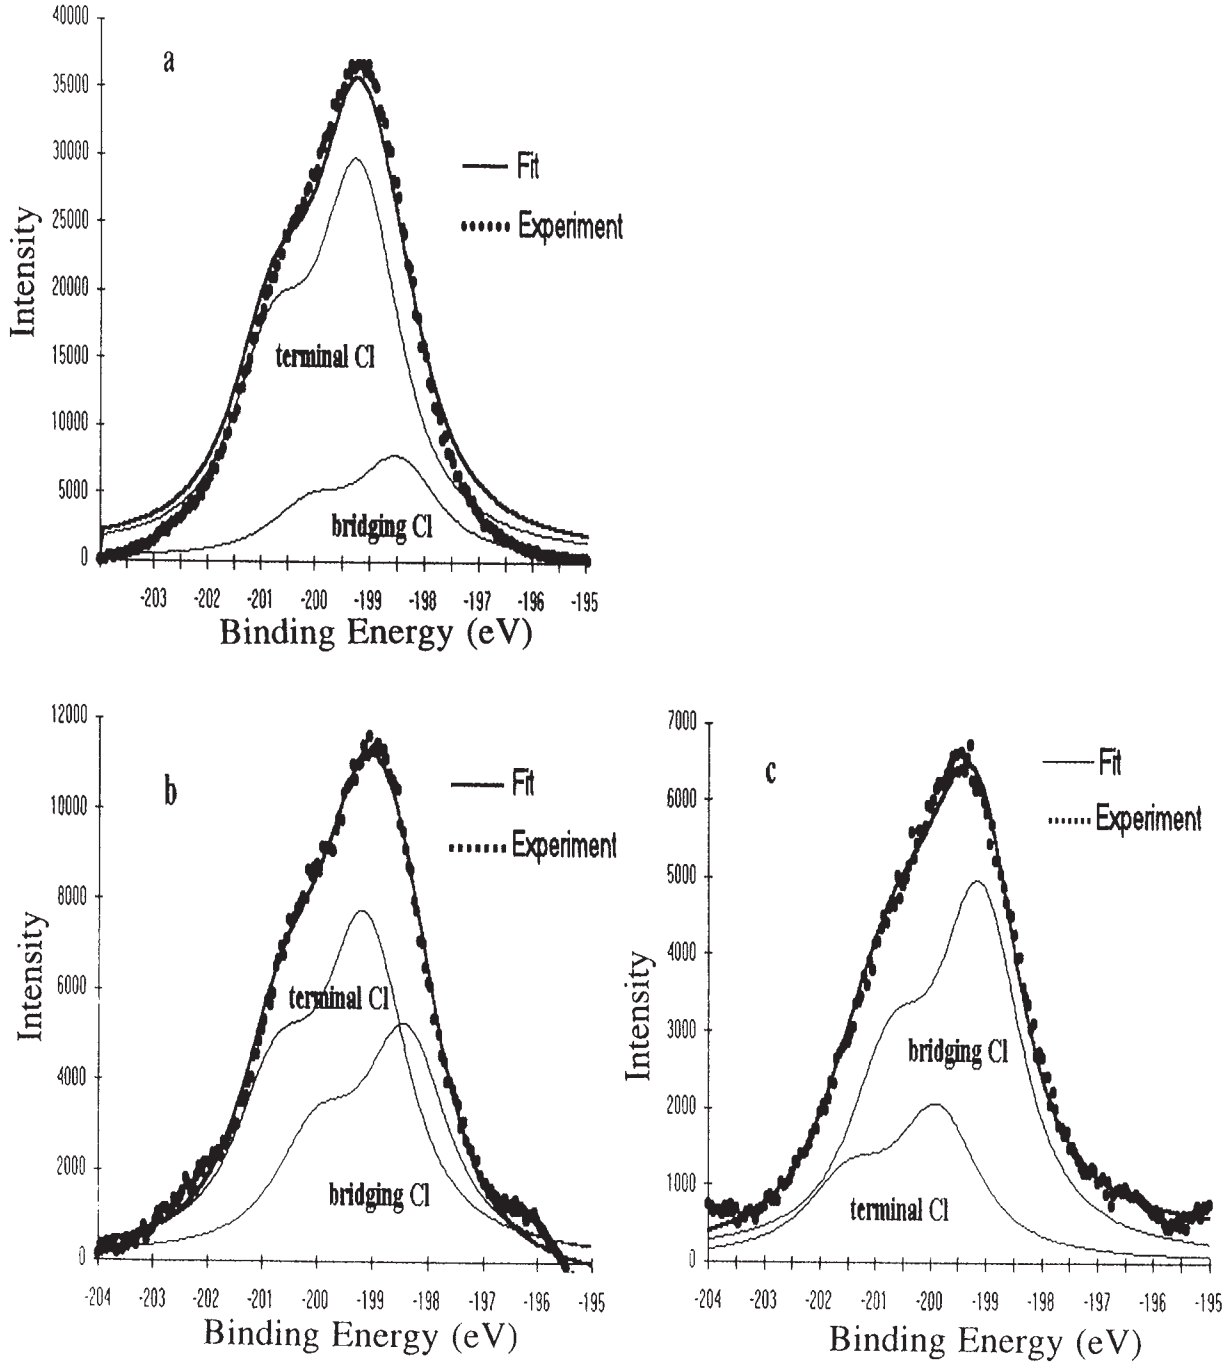
Fig. 4. Deconvolution of the Cl 2*p* binding energy contributions of (*a*) $NbCl_5$; (*b*) ErNb45; and (*c*) SmNb50.



(Fig. 5*c*). Beating is caused by interference between scattered waves emerging from two or more chlorine shells around the niobium atom. The effect becomes correspondingly pronounced as the amount of deposited Er increases. On the other hand, Fig. 5*d* shows that there is no beating in any of the spectra of the Sm atom products. This is evidence again that the chlorine contributions for both Er and Sm atom reaction products are not the same.

The Nb contribution (contribution B in $NbCl_5$) is too weak to be analyzed. However, the weak intensity of this contribution and its position confirm that the condensation involved during the vaporization does not lead to the formation of more reduced Nb species as, for instance, Nb_6Cl_{14} units or even $Nb^{(0)}$: the FT of the EXAFS spectrum that we recorded on $LuNb_6Cl_{18}$ compound exhibits a very strong Nb–Nb contribution because each Nb atom has four Nb neigbhours at 2.91 Å (34), which is not the case for the samples.

Part II: Ab initio EXAFS simulations to distinguish condensation patterns

According to IR, XPS, and EXAFS analyses, Er and Sm atom reactions with $NbCl_5$ give different reaction products that are evolving as a function of the rare earth content. It is very likely that a mixture of phases is present during the reaction.

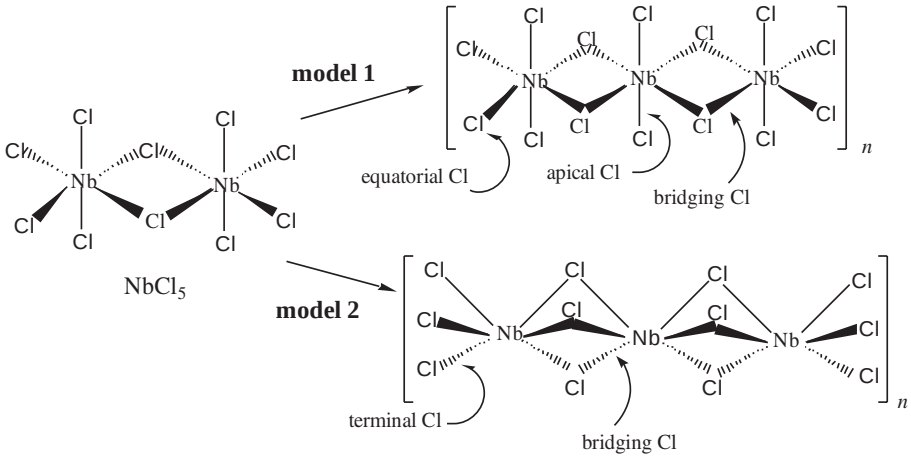
Fig. 6. Proposed condensation patterns to account for the assembly of dimer $NbCl_5$.

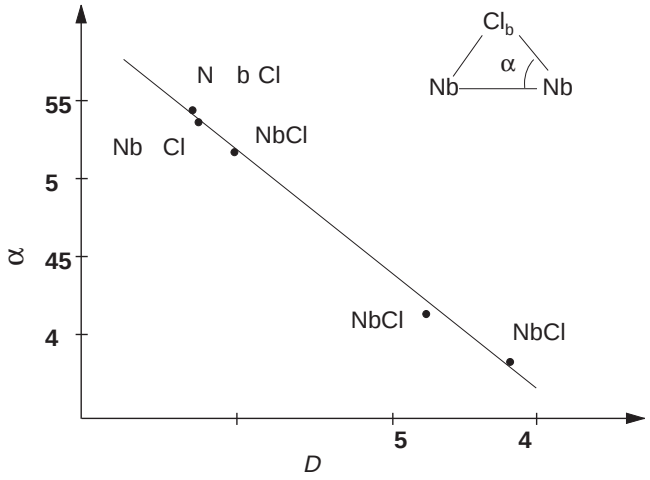


However, here, we first intend to fit the observed evolutions, using simple models of ideal reaction products. IR and XPS data together suggest that the product phases may contain bridging and terminal chlorine atoms. After considering a number of possible models for the products, we converged on two pathways that involve linear condensation. These condensations incorporate the starting $NbCl_5$ units in a manner that preserves the sixfold coordination of chlorine substituents about niobium. Accordingly, we offer two assembly routes as shown in Fig. 6. One route involves an edge-sharing condensation process, whereas the other is based on a face-sharing condensation mechanism. Both Nb environnements will be referred to in the text as edge-sharing octaedra and face-sharing octaedra for purposes of clarity. However, distortion of the Nb coordination sphere toward a trigonal prism geometry cannot be precluded.

The models are closely related since both contain bridging chlorine substituents. This is why the use of an ab initio code such as FEFF (with which absorption spectra are directly calculated from atomic coordinates of the cluster) is of particular interest in this case.

Confident that the ab initio method based on the use of the FEFF code functioned well to reproduce all features of the EXAFS of the model compounds $NbCl_5$ and $NbCl_4$, we chose to explore the proposed condensation patterns of models 1 and 2. Calculations were carried out on trimer, tetramer, and pentamer molecular fragments. Reduction of the Nb oxidation state due to polycondensation was simulated by contracting Nb–Nb and Nb–Cl_{br} (br = bridging) intracluster distances in the following way: bond angles and distances were estimated from the Nb–Nb distance *D* and the Nb-Nb-Cl_{br} bond angle α correlations from structures of known Nb_xCl_y compounds (25–27), as shown in Fig. 7. In general, polycondensation of niobium chloride fragments to give clusters of increasing size is accompanied by shortening of the Nb–Cl_{br} distances. Decreasing the Nb–Nb distance *D* implies an increase in the Nb-Nb-Cl_{br} bond angle. Simulations were required to account then for both the effect of increasing degree of polymerization of molecular subunits and the effect of shortening of the Nb–Cl_{br} distance. These two features of the process are closely related, but in a way that is not known in detail. We simplify the problem by separating it into two distinct studies: (*i*) the influence of bond contraction (i.e., decrease of distance *D*) on trimer units (Fig. 8*a*), and (*ii*) the influence of increasing cluster nuclearity, *n*, on trimers, tetramers, and pentamers, with fixed *D* (Fig. 8*b*). Finally, coordinates of the terminal Cl atoms were deduced from those of the $NbCl_5$ fragment.

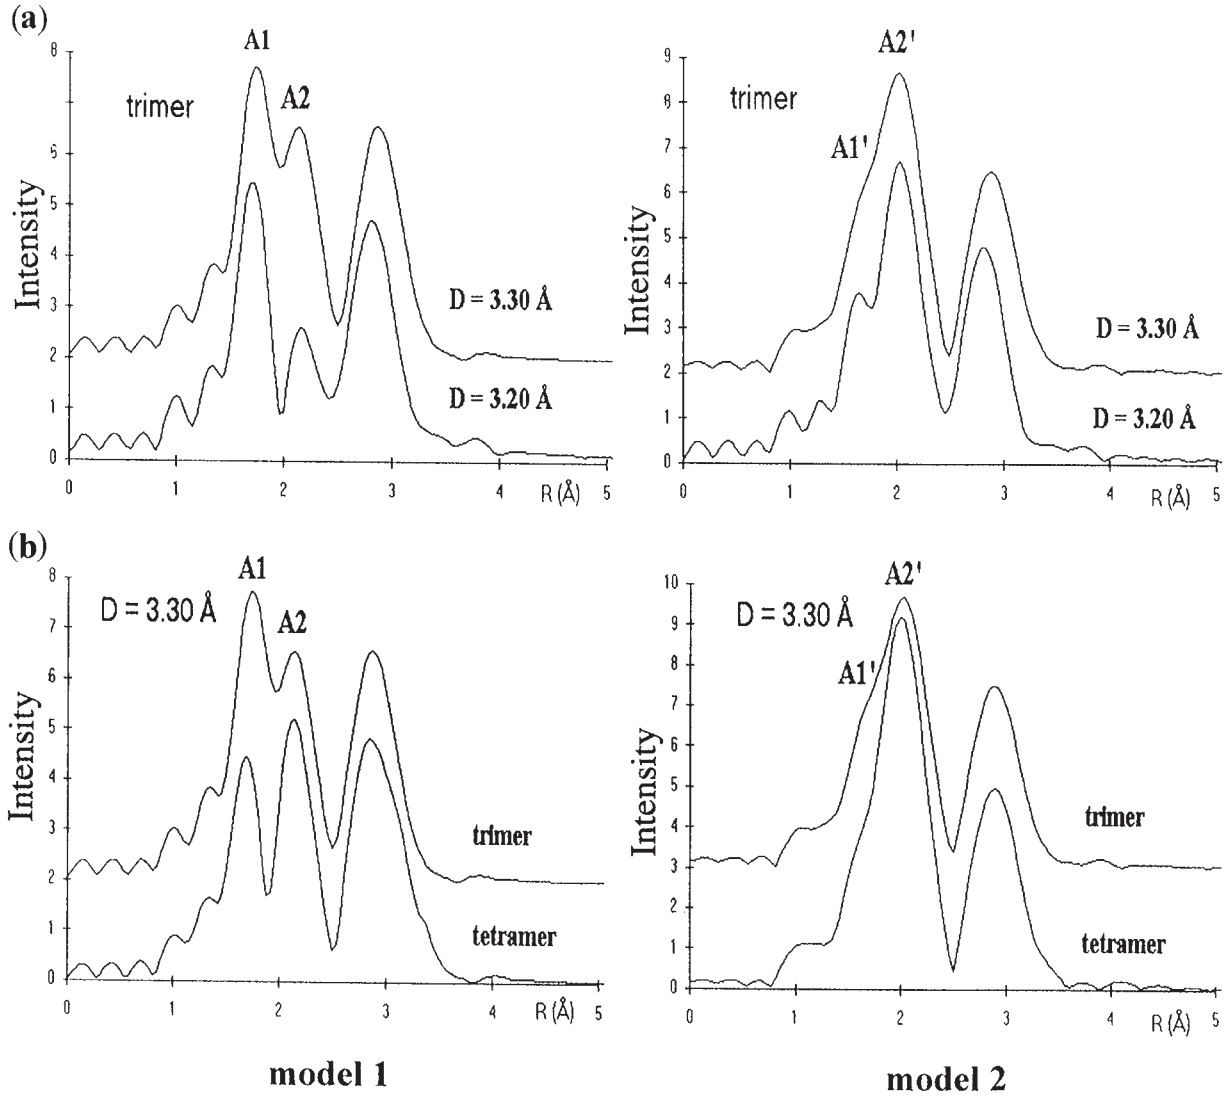
Fig. 7. Bond angle α as a function of the Nb–Nb distance *D* for several niobium halide clusters.



In Fig. 8, the intense peak around 3 Å is due to the overestimation of the Nb–Nb contribution by FEFF. This is not significant for the following discussion, which is based on the Nb–Cl contributions. In the case of constant nuclearity (trimers), the moduli of the EXAFS (Fig. 8*a*) exhibit the same gross features as those derived from experiment. Regarding more precisely model 1, our ab initio simulations indeed show that contribution A splits into a peak A1 at 1.7 Å, and peak A2 at 2.1 Å, which dominates A1. This formation of a shoulder A2 is what is observed in the FT derived from atom experiments with Er and also expressed by $NbCl_4$ (Fig. 5*a*). The similarity of our simulations to the FT of $NbCl_4$ is perhaps not surprising since $NbCl_4$ is an infinite chain model that rather closely resembles the structure postulated for the product derived from Er. For model 2, a shoulder A1′ is formed on the left of peak A2′, as observed experimentally in the case of Sm vaporization. Again, this shoulder becomes more resolved as the polycondensation is simulated to increase. In the case of

© 1998 NRC Canada

Fig. 8. Moduli of the simulated (FEFF6) EXAFS spectra pf clusters derived from models 1 and 2.



constant Nb–Nb distance and increasing nuclearity from trimer to tetramer (Fig. 8*b*), the features observed for trimers (formation of a shoulder A2 for model 1 and a shoulder A1′ for model 2) are not significantly evolving. In fact, a more realistic simulation of the polycondensation would involve both variations in the same time (*n* and *D*). Figure 9 shows the simulated EXAFS oscillations of the Nb–Cl contribution of trimers for Nb—Nb bond distances of 3.30 Å and 3.20 Å. It is striking that simulations of model 1 show a beating between 6 and 10 $Å^{-1}$ in the filtered EXAFS oscillations, whereas simulations of model 2 show no beating under any circumstances. Furthermore, beating is displaced towards higher *k*-values as the inter-niobium bond distance *D* diminishes for model 1, reflecting the trend in the experimental spectra for the erbium atom reaction products.

In light of these results and comparing findings of the previous section (Fig. 5), we propose that model 1 corresponds to the outcome of Er vaporization and model 2 to Sm vaporization. This also suggests an evolution of the cluster structures according to the amount of metal deposited, as demonstrated by comparison of the experimental EXAFS spectra with FEFF6 simulation of tetramer and pentamer clusters. Quantitative EXAFS analysis and XPS as discussed here would seem to support these assignments. Accordingly, the filtered EXAFS oscillations of chlorine contribution of Er atom/$NbCl_5$ reaction products were fitted using model 1 (i.e., three Nb–Cl layers: equatorial, apical, and bridging). The filtered EXAFS oscillations of Sm atom reaction products were fitted to model 2 (i.e., two Nb–Cl layers: terminal and bridging). Fits of ErNb45 and SmNb50 in real space are given as examples in Fig. 10. The fitting parameters in Table 2 illustrate, in the case of Er vaporization, a reduction of $Nb–Cl_{br}$ distances from 2.55 Å after 5 min Er vaporization, to 2.50 Å after 45 min of vaporization. A ratio, R^{EXAFS}, corresponding to the number of terminal to bridging chlorine atoms, was extracted from these fits. We have calculated R^{EXAFS} for each model as a function of the cluster nuclearity, *n*. For model 1, $R_1^{EXAFS} = (n + 2)/2(n - 1)$. For model 2, $R_2^{EXAFS} = 1/(n - 1)$. These ratios are bounded for minimum condensation ($n = 3$) and infinite condensation ($n = \infty$): model 1 gives $0.5 < R_1^{EXAFS} < 1.25$, whereas model 2 gives $0.0 < R_2^{EXAFS} < 0.5$. The value of 1.1 for R^{EXAFS} extracted from fits of ErNb5, ErNb30, and ErNb45 displayed in

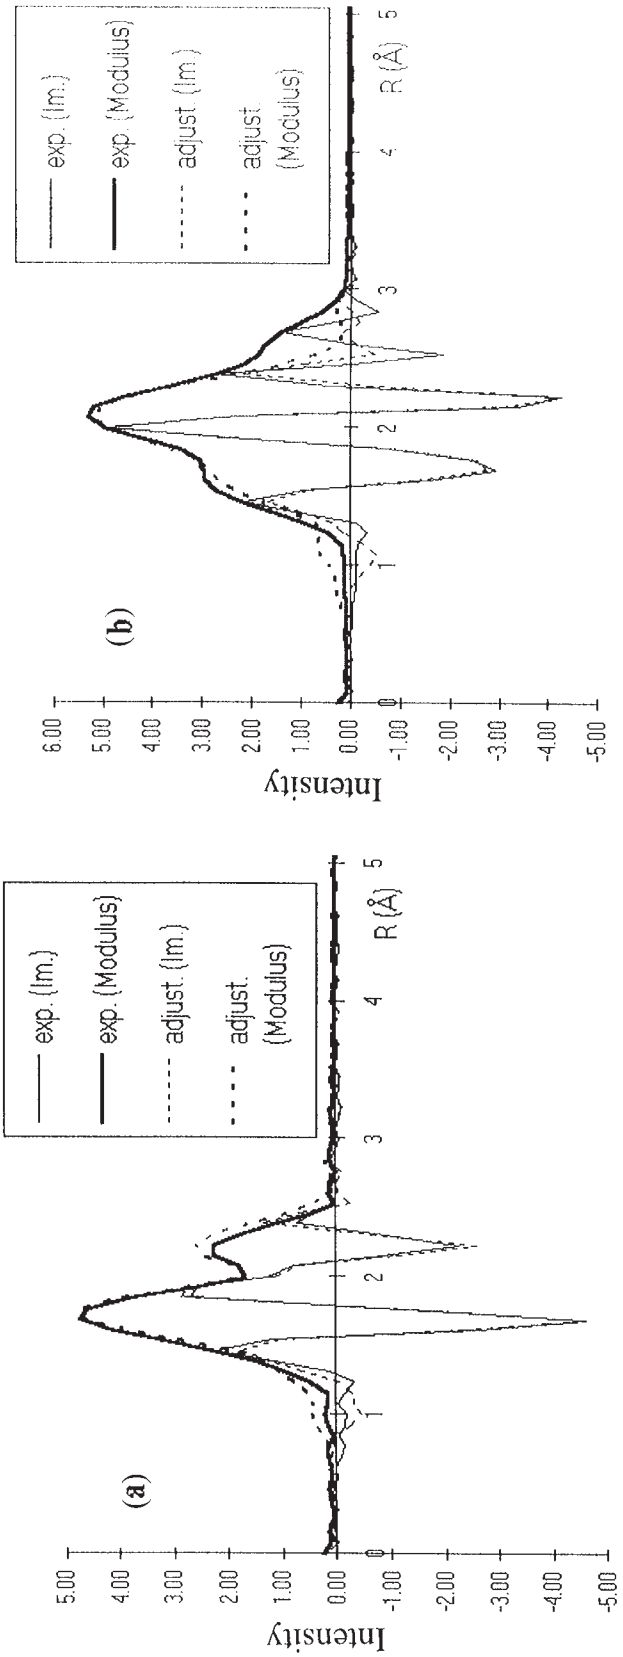

Fig. 10. Fits in *R*-space (not phase-shift corrected) of (*a*) ErNb45 and (*b*) SmNb50.

Table 2. EXAFS best-fit parameters of the Nb–Cl contributions.

Compound	*N*	σ (Å)	*r* (Å)	Cl type	R^{EXAFS}	Residual
	2.0[a]	0.04	2.25[a]	Equatorial		
$NbCl_5$	2.0[a]	0.04	2.29[a]	Apical	2	1.9%
	2.0[a]	0.09	2.57[a]	Bridging		
	1.2	0.1	2.28	Equatorial		
ErNb5	2	0.06	2.3	Apical	1.14	2.1%
	2.8	0.1	2.55	Bridging		
	1.2	0.05	2.28	Equatorial		
			2.35			
ErNb30	2	0.08		Apical	1.14	2.5%
	2.8	0.09	2.52	Bridging		
	1.1	0.04	2.26	Equatorial		
ErNb45	2	0.07	2.35	Apical	1.07	3.1%
	2.9	0.08	2.5	Bridging		
SmNb15	2	0.06	2.37	Terminal	0.5	4.2%
	4	0.06	2.5	Bridging		
SmNb30	2	0.1	2.36	Terminal	0.5	2.7%
	4	0.1	2.49	Bridging		
SmNb50	2	0.08	2.3	Terminal	0.5	3.5%
	4	0.07	2.48	Bridging		

[a] These values are fixed to the crystallographic data (25, 26).

N: number of neighbours; s: Debye–Waller factor. R^{EXAFS} is defined by the number of terminal Cl over the number of bridging Cl, as defined in the text.

Table 2 falls within the range of R_1^{EXAFS}. The R^{EXAFS} value of 0.5 extracted from fits of SmNb15, SmNb30, and SmNb50 is within the range of R_2^{EXAFS} values. The fact that the value of R^{EXAFS} does not seem to depend on the quantity of lanthanoid vaporized is simply due to insensitivity of these ratios to small changes in nuclearity. This is also the reason why these ratios are not used for the cluster nuclearity determination.

Our assignments find further support from the XPS spectra. As shown in Table 1, R^{XPS} values extracted from fits of the Cl 2*p* electron binding energy differ for Er and Sm vaporizations. Theoretical limits to R^{XPS} can be also calculated according to models 1 and 2 as a function of *n*. For model 1, $R_1^{XPS} = (n + 2)/(n - 1)$, and for model 2, $R_2^{XPS} = 2/(n - 1)$. These ratios give the following bounds for *n* ranging from 3 to ∞ : $1.00 < R_1^{XPS} < 2.50$ and $0.0 < R_2^{XPS} < 1.0$. Experimental ratios are of the order of 1.5 for Er products and 0.5 for Sm products. This confirms unambiguously the condensation patterns attribution for each rare earth vaporization.

Our results should be compared with studies of Ginsberg and Wayda (13) who produced niobium halide trimers by reacting Rieke-type colloidal samarium with $NbCl_5$. Their analysis was consistent with the formulation $Sm^{3+}[Nb_3Cl_{14}]^{3-}$, but the authors were unable to distinguish between face- or edge-sharing structural models. In a qualitative manner, formation of a shoulder on the right of main contribution Nb–Cl for $Sm^{3+}[Nb_3Cl_{14}]^{3-}$ would suggest, according to our study, a model 1 condensation pattern. This differs from our conclusions with Sm vaporization. However, the use of colloidal samarium instead of vaporized samarium atoms accounts, to our mind, for the structural differences. Why the condensation patterns observed in our studies exhibit structural bifurcation is not yet completely understood. It is well known that rare earth trichlorides crystallize in different crystal systems: hexagonal UCl_3 type (*P*63/*m*) from La to Gd; monoclinic YCl_3 type (*C*2/*m*) from Dy to Yb (11, 35). The change in size of the radii

© 1998 NRC Canada

in the 3+ lanthanides may account for these structural differences in the solid state. A possible 2+ oxidation state for the Sm atom may also explain the differences. Further support is given by Templeton and Dauben (11), who calculated the rare earth radii, based primarily on the cubic oxides. With a radius (coordination number = 6) of 0.958 Å (1.19 Å for Sm^{2+}), Sm^{3+} differs significantly from Er^{3+} (R = 0.890 Å) (36).

To confirm the role of (*i*) the increasing quantity of metal atoms that are condensed and (*ii*) the role of the rare earth, we intended to first look at the early stages of the cluster formation and to study the rare earth local order. In the first case, small metal quantities are deposited into $NbCl_5$/toluene molecules on a cryogenic matrix isolation quartz window. Reaction is followed in situ by EXAFS spectroscopy. First results with Sm vaporization already confirm our interpretation of a condensation route based on model 2. In the second case, post-mortem compounds from both Er and Sm vaporization are studied by EXAFS at the rare earth L_{III} edge to examine RE–Cl interactions. We shall discuss the results in detail in upcoming papers.

Conclusions

We have demonstrated in this study the usefulness of metal atom vaporization techniques to achieve controlled new solid state structures. The obtention of non-crystallized materials led us to the use of EXAFS, XPS, and IR spectroscopy to study the structural evolutions of $NbCl_5$ upon Er and Sm vaporization. EXAFS Nb *K* edge spectra of the products suggested different condensation patterns depending on the metal atom deposited. XPS and IR measurements confirmed that Sm and Er vaporization do not yield the same condensation route: edge-sharing octahedra for Er vaporization and face-sharing octahedra for Sm vaporization. Furthermore, we observed the effect of vaporization time upon evolution of the cluster structures. An in situ matrix isolation study by EXAFS spectroscopy has been undertaken and has already confirmed these findings (37).

Synthesis of the first [*n*]paracyclophane with an annulene as the aromatic, a necklace-like molecule; NMR, X-ray, and MMX structural comparisons

Reginald H. Mitchell, Danny Y.K. Lau, Thomas C.W. Mak, Bo-mu Wu, and Clemens Anklin

Abstract: The [18]paracyclo[14]annulene, **6**, a *trans*-10b,10c-dimethyldihydropyrene bridged by an 18 atom chain at the 2,7-positions, was prepared in 33% yield from 1,14-tetradecanedioyl dichloride and 2,7-bis(hydroxymethyl)-10b,10c-dimethyldihydropyrene (**7**). Molecular mechanics calculations were carried out to correlate the lowest energy conformers of **6** with the experimental X-ray structure. High field NMR spectra of **6** were fully assigned and correlated with the lower energy conformers, which in solution equilibrate such that the annulene ring can freely spin. The molecule, which is necklace shaped, has the protons H(9/6), and not those at the centre of the chain of the necklace [H(8/7)], closest to the centre of the annulene ring, and most shielded by the ring current. Shielding of various protons of the chain approximately correlates with the distances of their appropriate carbons, averaged over the 10 lowest energy conformers, from the centre of the ring current.

Key words: paracyclophane, bridged annulene, molecular mechanics, ring current.

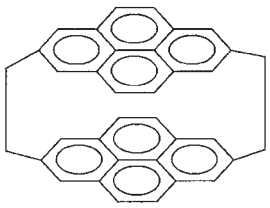
Résumé : Utilisant le dichlorure de 1,14-tétradécanedioyle et le 2,7-bis(hydroxyméthyl)-10b,10c-diméthyldihydropyrène (**7**) comme produits de départ, on a préparé (rendement de 33%) le [18]paracyclo[14]annulène (**6**), un *trans*-10b,10c- diméthyl-dihydropyrène portant une chaîne de 18 atomes qui relient les positions 2 et 7. On a effectué des calculs de mécanique moléculaire pour établir une corrélation entre les conformères de basse énergie du composé **6** et la structure déterminée par diffraction des rayons X. Les spectres RMN de haut champ du composé **6** ont permis de faire une attribution complète et d'établir une corrélation avec les conformères de basse énergie qui, en solution, s'équilibrent d'une façon telle que le noyau annulène peut tourner librement. Dans la molécule en forme de collier, ce sont les protons H(9/6) et non pas ceux au centre de la chaîne du collier [H(8/7)] qui sont le plus près du centre du noyau annulène et, par conséquent, les plus blindés par le courant du cycle. Il existe une corrélation approximative entre le blindage des divers protons de la chaîne et les distances de leurs carbones, établies comme moyenne des 10 conformères de plus basse énergie, du centre du courant de cycle.

Mots clés : paracyclophane, annulène ponté, mécanique moléculaire, courant de cycle.

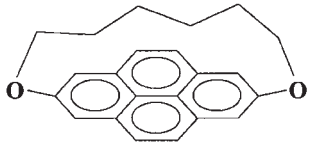
[Traduit par la rédaction]

Introduction

Despite the huge interest in cyclophanes (1), examples in which the aromatic residues are the more highly condensed aromatics rather than benzene, naphthalene, anthracene, or phenanthrene derivatives are sparse. For example, even though three groups (2) reported the pyrenophane **1** in the mid 1970s, only recently has Bodwell et al. (3) reported the [8]paracyclopyrenophane **2**, and Siegel and co-workers (4) a paracyclocorrannulene. Examples in which the aromatic is a higher annulene are even rarer, despite the fact that Ito (5) has pointed out that non-benzenoid phanes should have interesting properties, because they can be distorted more easily. To our knowledge, only three cyclophanes, **3**–**5**, containing 10π or larger annulenes have been reported (6, 7).



1



2

We now report the first singly bridged higher annulene, **6**, an [18]paracyclo[14]annulene.

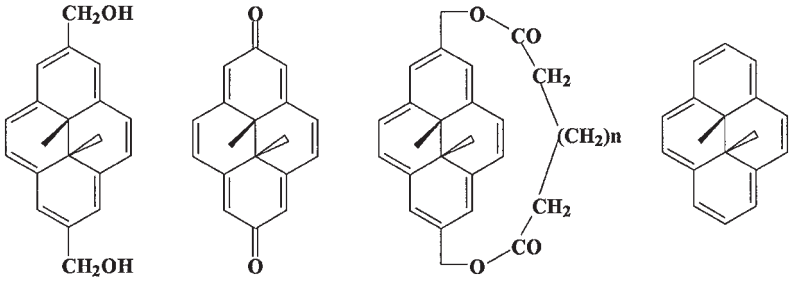
Results and discussion

Synthesis of cyclophane 6

The lack of cyclophanes containing higher annulenes is probably partly due to the problems encountered in synthesis, either difficulty in obtaining the annulene or difficulty because of its reactivity. Annulenes are generally highly electron-rich species and so often decompose on attempted alkylation. In the synthesis of **5** (7), we avoided this problem by proceeding through the dialcohol **7**, which was obtained not by direct alkylation, but rather by reacting the quinone **8** with the Corey reagent $(CH_3)_2S{=}CH_2$, and then reduction of the products to **7** (7). Not surprisingly reaction of **7** with 1,6-hexanedioyl chloride yielded only cyclic dimer **5** and none of the monomer **9**, a [10]paracylo[14]annulene. However, reaction of **7** with the longer 1,14-tetradecanedioyl dichloride in the presence of enough pyridine to complex any HCl formed, did yield 33% of the singly bridged cyclophane **6**, and to our surprise only minute amounts (that we could detect by mass spectrometry) of the cyclic dimer. The dark green crystals of **6** obtained, showed mp 124–126°C. Both a high-resolution mass spectrum, (MH^+ calcd. for $C_{34}H_{43}O_4$: 515.3161; found: 515.3135) and a single-crystal X-ray structure proved the identity of 6 as the monomer.



7 8 6: n = 10 9: n = 2 10

X-ray structure of 6

Suitable crystals of **6** could be obtained by crystallization from acetonitrile; small crystals appear yellow–green, while bulk quantities appear darker green. A yellow–green crystal, 0.15 × 0.25 × 0.60 mm, was mounted on a glass fibre to obtain the data summarized in Table 1. Full data containing molecular structures, crystal data, data collection, solution and refinement, sample experimental information, atomic coordinates, isotropic displacement coefficients, bond lengths and angles, anisotropic displacement coefficients, and H-atom coordinates have been deposited.[3]

An ORTEP drawing of cyclophane **6** is shown in Fig. 1. The molecule exhibits two-fold disorder associated with two alternate arrangements of its internal bridge system (see Fig. 1). Some important bond lengths are given in Table 2.

The C—C bond lengths around the periphery of the annulene are 1.37–1.41 Å, consistent with those (8) in the parent dimethyldihydropyrene **10**, and indicate that the annulene is fully delocalized. The C—C bond lengths of the long chain are mostly normal at 1.51–1.52 Å, but the C(6)—C(7) bond seems shorter, 1.41 Å, and the C(6)—C(5) bond longer, 1.59 Å, than would be expected. Interestingly, in the calculations described

below, one of the hydrogen atoms on C(6) is calculated to have the closest interaction with the C(32) methyl group, at 2.60 Å.

The ORTEP view shown in Fig. 1 is a little deceptive. Better perceptiveness of the molecule can be obtained by examination of Fig. 2.

From Fig. 2, it can be seen that the chain does not form vertically above the plane of the dihydropyrene, as in a basket, but goes off to one side, at least in the crystalline state. From the distances involved, one would expect in solution there to be many contributing conformations, with even the dihydropyrene ring being able to freely rotate. This aspect is discussed below.

Molecular mechanics calculations

The program[4] GMMX was used to search conformational space to determine the lowest energy conformers of **6**. This program uses an MM2 + PI calculation to search out unique conformers. It found 423 conformers within 3.5 kcal/mol energy of the most stable conformer. In fact the lowest energy calculated structure was not the X-ray structure, but the one almost identical, with the two carbonyl groups pointed to the same side of the molecule and not to opposite sides as in the X-ray structure, which it calculated had higher energy by about 0.3 kcal/mol. The fifth lowest energy conformer in fact corresponds most closely to the X-ray structure. Views of conformers **1** and **5** and the X-ray structure are compared in Fig. 3.

Clearly the molecular mechanics calculations do a reasonably good job in predicting the structure of **6**, especially since this is an annulene for which calculations can be a problem (9). To meaningfully discuss the NMR spectra of **6** (below), we need to have reasonable estimates of the distances between the chain atoms and those of the annulene ring. In the NMR spectrum, because the annulene ring can spin, the chain carbons and hydrogens average, thus C(13) and C(2) are equivalent,

C(31)—C(33)	1.576(16)	C(1)—O(2)	1.193(5)

C(12) and C(3) are equivalent, and so on. We therefore calculated average distances of each type of chain carbon from the closest methyl group, C(32), for comparison between the various structures. This data is presented in Table 3.

It can be seen that except for C(13/2), in terms of distances from the chain carbons to C(32), the X-ray structure is in fact closest to the lowest energy conformer **1** rather than conformer **5**. However in both conformers **1** and **5**, and in the X-ray structure the order of distance from C(32) is

9/6 < 11/4 < 10/5 < 8/7 < 12/3 < 13/2

Only when conformers **6**–**10** are included in the average does the order significantly change:

9/6 < 8/7 < 11/4 < 10/5 < 12/3 < 13/2

and the pair 8/7 moves closer to C(32), however pair 9/6 still

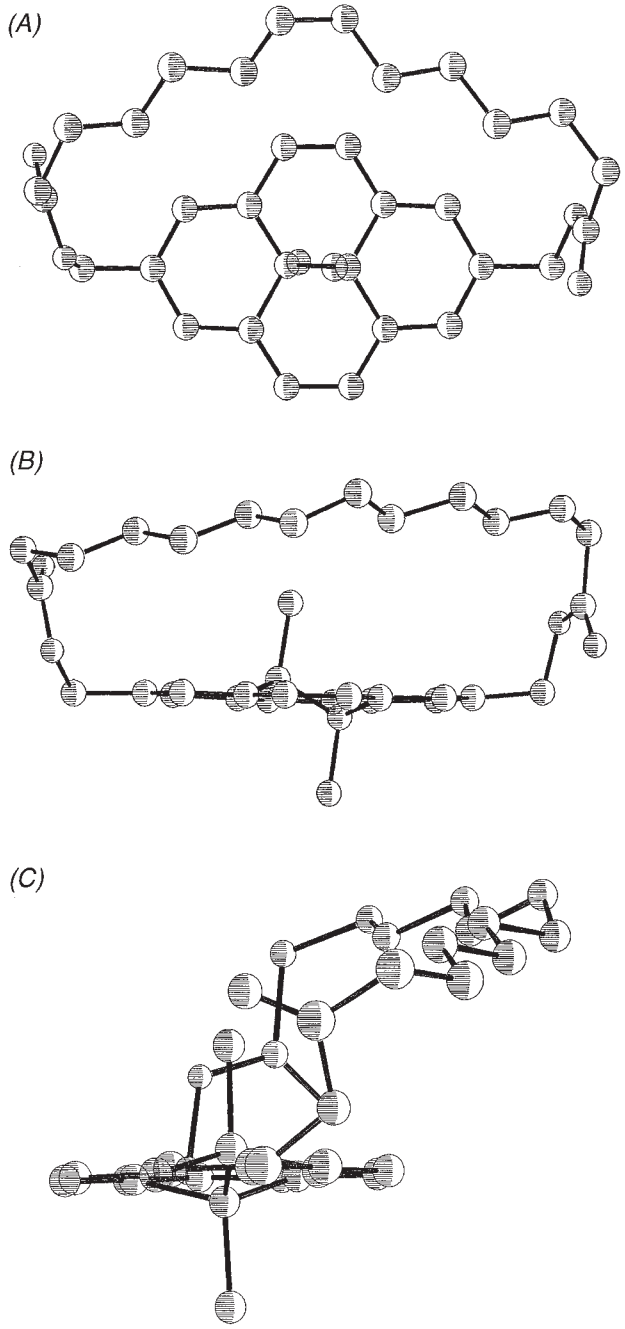
Fig. 2. Alternative views of the cyclophane **6**. View *A*: from above the dihydropyrene, which is in the plane of the paper. View *B*: from the edge of the plane containing the dihydropyrene. View *C*: from the end of the plane containing the dihydropyrene.



remains closest to the internal methyl carbon. This will have ramifications for the proton spectra (below).

NMR spectra of 6

The ^{1}H and ^{13}C NMR spectra of **6** were run at 600.13 and 150.91 MHz, respectively. The chemical shifts are given in Table 4.

The fact that the singlets at δ –4.07, 5.85, and 8.62 remained so even at –100°C suggests that in solution, the molecule has the annulene ring freely rotating.

The assignments were made as follows: the protons on C(13/2) are known unambiguously because of their chemical shift at δ 2.39. A 2-D phase-sensitive, double quantum filtered COSY spectrum, Fig. 4, indicated that these were coupled to the protons at δ 1.53, which must therefore be H(12/3); likewise these were coupled to those at δ 0.75, H(11/4), which

were coupled to those at δ 0.88, H(10/5), which were coupled to those at δ 0.46, H(9/6), which finally were coupled to those at δ 0.68, H(8/7). Additionally, H(17) could be distinguished from H(19) by the very weak cross peak from the former to the benzyl protons, H(15). With the protons fully assigned, their corresponding carbons were assigned using 2-D HMQC and HSQC 1H/13C correlation spectra. The quaternary carbons were assigned using 2-D HMBC 1H/13C long-range correlation spectra: specifically the methyl protons at δ –4.07 correlated to C(30) at δ 30.26 and C(18) at δ 137.2, while the benzylic protons at δ 5.83 correlated to C(16) at δ 131.9.

A series of 1-D GOESY gradient Overhauser spectra were run: irradiation of the internal methyl protons indicated interactions decreasing in intensity in the order H(9/6), H(8/7), H(11/4), and H(10/5) (see Fig. 5), which is exactly the order obtained above in the calculation of the chain carbon distances to the methyl carbons, averaged over the 10 lowest energy conformers. For the X-ray structure, the minimum and average H—H distances were calculated for the C(32) methyl and the hydrogens on the chain. These are given in Table 5.

The Me–H interactions nicely follow the calculated H—H distances, except that the interaction with H(8/7) is stronger than would be expected on the basis of the X-ray conformer, but as explained above, when the other conformers are mixed in, these hydrogens average closer to the methyl groups.

Table 5 also shows the minimum ring—H distances.

δ (**11**)	2.15	1.48	1.14	1.14	1.14	1.14
Δδ	–0.24	–0.05	0.39	0.26	0.68	0.48
C—C[a]	6.42	6.34	5.18	5.49	4.73	4.94

[a] Å, from Table 3.

Irradiation of the ring hydrogens at δ 8.62 indicates interaction with H(9/6) and H(11/4) most strongly, consistent with the closest approach distances in Table 5, and then weaker interactions with the other chain hydrogens.

Thus overall, the annulene ring can spin freely about the chain, and although the chain is obviously averaging many conformations, the Overhauser experiments indicate that on average the internal methyl protons come closest to H(9/6) and H(8/7) in the centre of the chain of the necklace, while the ring hydrogens approach closest on average H(9/6) and H(11/4) during the rotation.

The chemical-shift shielding of the chain hydrogens depends upon the distance from the centre of the dihydropyrene ring, where the ring-current effect is strongest. The observed order of chemical-shift shielding, which can be obtained by subtracting the chemical shift of the appropriate hydrogens in the free acid (Table 6) is H(9/6) > H(8/7) > H(11/4) > H(10/5) > H(12/3).

This is exactly the order observed above for the increasing chain C — methyl C distances averaged for the 10 lowest energy conformers. We have carried out the comparison between both the minimum and average "chain H to centre of ring" distance and the "C—C" distances given in Table 3 for the X-ray conformer and found an exact correspondence of order. Thus using the C—C distances averaged over the 10 lowest energy conformers to correlate with the ring-current shielding is a reasonable approximation. Both DuVernet and Boekelheide (10) and Lai and Zhou (11) have attempted to correlate ring-current shielding of the internal substituents in dihydropyrenes to distance from the plane of the ring. Unless a frozen conformer is available, this has some difficulty. In the case of our necklace **6**, correlation would need to include both the out-of-plane and in-plane distances from the centre of the ring and then would best be done in a fixed conformer. Our approximation, which uses the C—C distances averaged over the 10 lowest energy conformers, gives surprisingly good results, but correlation with a more precise Johnson–Bovey model (12) will have to wait until we are able to synthesize a necklace with a shorter chain that is unable to move very much. This we will attempt.

Conclusions

We have synthesised the first "paracyclo" dihydropyrene, **6**, a molecule shaped like a necklace. The pendant, the dihydropyrene ring, can freely spin in solution at room temperature. The dihydropyrene ring appears unstrained on the basis of the X-ray structure and by comparison of the proton spectrum and UV spectrum to those of the parent **10** and its 2,7-dimethyl derivative (13). Molecular mechanics calculations were carried out to obtain the lowest energy conformers of **6**, and these were compared to the X-ray conformer, and calculations based on these gave good correlation with NMR chemical-shift data.

Experimental

Melting points were determined on a Reichert 7905 melting point apparatus integrated to a chrome–alumel thermocouple. Infrared spectra, major peaks only, calibrated with polystyrene, were recorded on a Bruker IFS25 FT–IR spectrometer as KBr disks. Ultraviolet-visible spectra were recorded on a Cary 5 or a Perkin–Elmer Lambda-4B spectrometer in chloroform. Proton NMR spectra were recorded at 360 MHz on a Bruker AMX 360 or at 600MHz on a Bruker DRX600 using $CDCl_3$ as solvent. Carbon NMR spectra were recorded at 90.6 MHz or 151 MHz in $CDCl_3$, using the solvent peak at 77.0 ppm for calibration. Exact mass measurements used a Kratos Concept-H instrument with perfluorokerosene as calibrant. Elemental analyses were carried out by Canadian Microanalytical Services Ltd, Vancouver, B.C. All evaporations were carried out under reduced pressure on a rotary evaporator, and all organic

extracts were washed with water and dried over anhydrous $MgSO_4$. SiGel refers to Merck Silica Gel, 70–230 mesh.

2,7-Bis(hydroxymethyl)-*trans*-10b,10c-dimethyl-10b,10c-dihydropyrene (7)

NaH (1.0 g, 20 mmol, 52% dispersion in mineral oil) was washed thrice with dry hexane (5 mL), and then heated at 60°C for 45 min with dry DMSO (20 mL) under N_2. The resulting grey solution was diluted with dry THF (50 mL) and cooled to –20°C, and then a solution of trimethylsulfonium iodide (4.08 g, 20 mmol) in dry DMF (40 mL) was added and the mixture stirred for 15 min. It was then cooled to –78°C, and with good stirring a solution of the quinone **8** (7) (0.524 g, 2.0 mmol) in dry THF (20 mL) was added dropwise. After further stirring at –78°C for 30 min, the reaction was warmed to room temperature over 2 h, and then the reaction mixture was poured into water and dichloromethane. The aqueous layers were further extracted with dichloromethane, and the extracts were washed, dried, and evaporated. The resulting purple coloured residue was dissolved in THF (50 mL) and $NaBH_4$ (80 mg, 2 mmol) was added, and then the reaction mixture stirred for 14 h at 20°C. The resulting green solution was treated with dichloromethane (at least 100 mL) and water. Any remaining green dialcohol **7** was extracted from the aqueous layer with dichloromethane, and then the combined extracts were washed, dried, and evaporated. The residue was dissolved in dichloromethane and chromatographed on 10% water deactivated SiGel using N_2 degassed dichloromethane–diethyl ether (8:2) as eluant to give 430 mg (73%) of dialcohol **7**, as green needles from methanol–hexane, mp 192–193°C. ^{1}H NMR (360 MHz, d_6-acetone) δ: 8.58 (s, 4H), 8.56 (s, 4H), 5.31 (d, J = 5.8 Hz, 4H), 4.68 (t, 2H, -OH), –4.11 (s, 6H); ^{13}C NMR δ: 138.1, 137.4, 123.9, 122.7, 66.2, 31.0, 14.6; IR 3280 (vb) cm^{-1}; UV (CH_2Cl_2) λ_{max} nm (ϵ_{max}): 343 (79 000), 361 sh (37 000), 381 (31 000), 457 (6400), 480 (8600), 650 (~400); MS (CI) *m*/*z*: 293 MH$^+$. Anal. calcd. for $C_{20}H_{20}O_2$: C 82.15, H 6.90; found: C 81.97; H, 6.80.

Cyclophane 6

Dry pyridine (0.35 mL, 4.4 mmol) was added to a solution of dialcohol **7** (511 mg, 1.75 mmol) in dry dichloromethane (500 mL) and was stirred for 15 min. Then a solution of 1,14-tetradecanedioyl dichloride (516 mg, 1.75 mmol) in dry dichloromethane (120 mL) was added fast in one portion with vigorous stirring under argon protection. The reaction mixture was further stirred for 4 h, and then was concentrated to about 5 mL and was loaded onto a neutral alumina column (deactivated with 5% water). The green band eluted with dichloromethane was collected and evaporated to yield 300 mg (33%) of the cyclophane **7**. Recrystallization from benzene yielded dark green crystals, mp 124–126°C. NMR: see text, Table 4. The multiplets referred to in Table 4 appeared at the following chemical-shift ranges: 2.41–2.37, 1.57–1.49, 0.94–0.84, 0.78–0.71, 0.71–0.65, 0.49–0.42 ppm. IR 1732, 1446, 1377, 1341, 1263, 1216, 1158, 1101, 882, 756, 664 cm^{-1}; UV λ_{max} nm (ϵ_{max}): 344 (78 400), 359 (17 400), 384 (31 100), 446 (7600), 483 (13 200), 590 (380), 637 (440), 646 (430). MS (CI) *m*/*z*: 515 MH$^+$; HRMS (LSIMS) calcd. for $C_{34}H_{43}O_4$: 515.3161; found: 515.3135.

Solubility prediction of *n*-fatty alcohols and sterols in complexing and non-complexing solvents according to the mobile order theory

Paul Ruelle and Ulrich W. Kesselring

Abstract: The volume fraction solubilities of a number of solid *n*-fatty alcohols and sterols are predicted in neat organic nonpolar, polar, and hydrogen-bonded solvents including water. In the frame of the mobile order thermodynamics, the predictions are based on the knowledge (*a*) of the melting properties of the alcohols, which affect the fluidization process, (*b*) of their molar size, which mainly rules the exchange entropy and the hydrophobic effect, and (*c*) of the group interaction stability constants, which are responsible for the balance between the competing self-association and strong intermolecular interactions of the alcohols in solution. Owing to its ability to deal properly with these various elementary processes, the proposed thermodynamic solubility model derived from the mobile order theory in H-bonded liquids represents an advance towards reliable and comprehensive estimates of the solubilizing capacity of common solvents for nonideal complexing systems, i.e., the solid alcohols.

Key words: solubility prediction, solution thermodynamics, mobile order theory, *n*-fatty alcohols, sterols.

Résumé : On prédit les fractions volumiques de solubilité d'un certain nombre d'alcools gras et de stérols dans des solvants organiques non polaires, polaires et à liaisons hydrogènes, y compris dans l'eau. Dans le cadre de la thermodynamique de l'ordre mobile, on base les prédictions sur la connaissance (*a*) des propriétés de fusion des alcools affectés au cours du processus de fluidisation, (*b*) de la taille molaire qui détermine principalement l'entropie d'échange et l'effet hydrophobe (*c*) ainsi que des constantes de stabilité des interactions entre groupes qui sont responsables de la balance entre les interactions d'autoassociation et les fortes interactions intermoléculaires des alcools en solution. À cause de sa capacité à traiter ces divers processus élémentaires, le modèle thermodynamique de solubilité proposé — qui dérive de la théorie de l'ordre mobile dans des liquides à liaisons hydrogènes — représente une amélioration vers des évaluations plus fiables et plus complètes de la capacité des solvants ordinaires à solubiliser des substances formant des complexes non idéaux, comme les alcools solides.

Mots clés : prédiction de la solubilité, thermodynamique des solutions, théorie de l'ordre mobile, alcools gras, stérols.

[Traduit par la rédaction]

1. Introduction

Over the years, a large number of studies have been carried out to find a general solubility model enabling a priori predictions. An important step towards solubility predictions was achieved around 1930 with the development by Hildebrand and Scott of the *regular* solution theory (1, 2). Expressions such as "*polar solutes dissolve in polar solvents*," "*like dissolves like,*" or "*similia similibus solvuntur*" are based on this theory. Although this treatment originally was strictly intended for systems involving dispersion forces, its use has largely been extended to include highly polar solvents and solutes, and still constitutes the background of practically all theoretical approaches of solubility prediction found in the literature (3–9). These predictive models rely on the premise that the solubility of a solute in a particular solvent is simply related to the bulk properties of the pure components. However, whenever hydrogen bonds are involved in the solution process, solubilities may no longer be described in terms of bulk properties of the components such as their solubility parameters, and may not be obtained either by the regular solution theory or by any of its further expanded developments. The regular solution theory and the Scatchard–Hildebrand expression are mainly based on two fundamental assumptions: (*a*) the rule of the geometric mean, i.e., the adhesive energy of a pair of unlike molecules is the geometric mean of the cohesive energies of the two equivalent like pairs; and (*b*) the interactions between molecules in solution occur "at random," i.e., there are no preferential contacts in solution and the randomness of ideal mixtures is preserved. A direct consequence of the geometric mean rule is that regular solutions always give positive deviations from Raoult's law and positive enthalpies of mixing. This implies that adhesive forces are always inferior to cohesive forces. Consequently, the regular solution theory is a reasonable approximation for relatively nonpolar systems, in which attraction forces essentially result from dispersion, but it no longer holds for solutions in which specific interaction forces or hydrogen bonds occur, because hydrogen bonds do not obey the

rule of the geometric mean and do not lead to random contacts. In contrast, one of the most important characteristics of H-bonding in the liquid phase is the establishment of "*highly preferential contacts*" between the proton-donor and proton-acceptor sites of the various molecules. These contacts in turn confer to H-bonded liquids a higher degree of "order" and a kind of structure. The structuration produced by H-bonding is, however, intermittent and labile. The fundamental difference with the crystalline state lies in the "mobility" of the H-bonds in the liquid phase: the disorder or the order in an associated liquid is dynamic. Both the temporary order introduced in the liquid by the formation of hydrogen bonds (preferential contacts) as well as the labile nature and the perpetually moving character of these bonds (their mobility) constitute the basic foundations of the "mobile order" theory developed by Huyskens et al. (10–12). The mobile order theory is at the origin of the nonergodic thermodynamic treatment of the H-bonded liquids, which is based not on static configurations but on movements and time fractions. In effect, the thermodynamics of the mobile order (13–16) consider equilibrium between the fractions of the time during which an amphiphilic proton follows the electron-donor site of one or another molecule in its walk through the liquid, rather than equilibria between concentrations of the various H-bonded (dimers, trimers, tetramers,...) or non-H-bonded (monomers) entities present in solution. The quantitative development of the mobile order theory then led to a universal predictive equation for solubility (17, 18) accounting for all the contributions to the free energy change implied when a solute is dissolved in a solvent.

Up to now, the mobile-order-derived solubility model has been sucessfully applied to predict the solubilities of low-polarity substances in one- and two-components solvent systems (19–33), the mutual solubilities of water and hydrocarbons (34, 35), the solubilities of proton-acceptor mono- and polyfunctional substances in aprotic and protic solvents (36–41), and the aqueous solubility of aliphatic alcohols (42). The mobile order theory has furthermore been used to make reliable estimates of the *n*-octanol–water partition coefficient of various hydrophobic compounds (43), and to explain the peculiarities of the conductance of LiCl solutions as well as the paradoxical effects of the addition of LiCl on both the conductivity of Polystyryl$^-$Li$^+$ solutions and the kinetics of the anionic polymerization (44). The apparent success obtained in these different studies already tends to demonstrate the high potential of the mobile order thermodynamics for predicting solubility in real systems, and confirms that this model may also be of great help in providing explanations of various solution phenomena (45–49). The mobile order theory undoubtedly constitutes an advancement in particular over the regular solution thermodynamic approaches against which the present model has been tested in the past (50). Contrary to the "solubility parameters"-based models (issued from the regular solution theory), which do not explicitly consider preferential contacts and entropy effects, the present approach is based, for H-bonds, on stability constants and on concentrations of the interacting sites that permit taking into account the important entropy effects accompanying the formation of the specific interactions.

The aim of the present paper then is twofold: (*i*) to further apply the mobile order thermodynamic model to predict the solubility of amphiprotic substances capable not only of self-association in solution — no matter the nature of the solvent — but also of interacting by hydrogen bond with proton-donor and proton-acceptor solvents; (*ii*) to determine the stability constants characterizing the various solute–solvent hydrogen bonds. For that purpose, five primary *n*-fatty alcohols, i.e., 1-dodecanol, 1-tetradecanol, 1-hexadecanol, 1-octadecanol, and 1-eicosanol, and two sterols, i.e., cholesterol and β-sitosterol, have been considered. Their solubilities are predicted in a wide range of both complexing and noncomplexing organic solvents. In the case of solid *n*-fatty alcohols, the knowledge of their solubility characteristics is of relevance to fat, cosmetic, and oil technology, whereas the knowledge of the solubility behavior of the sterols is of importance for understanding their pathophysiological role, as in gallstone disease and atherosclerosis. From the comparison of the relative importance of the different contributions involved in the solubility calculation, the origin of the solubility of the alcohols is analyzed, leading to a thorough understanding of the solution process of these substances.

2. Theoretical section

The ability to estimate solubility in real solutions certainly depends on the proper knowledge of the physical phenomena implied in the solubility process as well as of the forces that operate between molecules in solution, but also on the possibility of describing these phenomena correctly by thermodynamic expressions. Considering both the enthalpy and entropy changes accompanying the fusion and solvation processes, different thermodynamic expressions (17, 18) were previously derived in the frame of the mobile order theory to account for the influence of the solvent–solvent, solute–solute, and solute–solvent interactions on the chemical potential of the solute. According to these developments, the volume fraction solubility, Φ_B, of the solid alcohols in pure organic solvents may be considered to arise from the sum of maximum five contributions.

$$[1] \qquad \ln \Phi_B = A + B + D + F + \mathrm{OH}$$

Representing a particular physical phenomenon of the whole solubility process, each contribution reported hereafter has a thermodynamically well-defined expression, and plays either in favor or against solubility. (The interested reader will find, for each appropriate solubility contribution given hereafter, the appropriate references concerning the origin and derivation of its thermodynamic expression.)

"*A*" represents the fluidization (the ideal solubility) of the crystalline substance. This contribution corresponds to the suppression of the collective forces that bind the alcohol molecules within their crystalline state. Being in general an endothermic process, the fluidization is independent of the solvent and affects solubility unfavorably. At first approximation, the ideal solubility (51) is calculated from the knowledge of the enthalpy of melting, $\Delta_m H$, of the pure crystalline substance and from the difference between the melting point, T_m, and the absolute temperature, T, of interest.

$$[2] \qquad A = -\frac{\Delta_m H}{R}\left(\frac{1}{T} - \frac{1}{T_m}\right)$$

The fluidization is, however, not always a simple mathematical transformation of the Gibbs energy of melting, because it

© 1998 NRC Canada

may contain additional terms if some solid–solid or solid–liquid crystal transitions occur between the temperature of interest and the melting point temperature (52–54). This is especially the case for the long-chain 1-alkanols and for cholesterol, for which polymorphism is now well established as a characteristic feature.

"*B*" represents the correction factor for the entropy of mixing and is related to the difference between the sizes of the solvent (S) and alcohol (B) molecules in solution. This term essentially depends on the ratio, V_B/V_S, between the molar volumes, and contributes positively to the solubility as long as V_B is greater than V_S. Remember that, in the mobile order theory, the entropy of mixing in liquids is calculated by a hybrid expression (10, 18) taking into account both the nominal exchanges of place between unlike molecules, and the expansion of the individual domains available for the motions within the solution.

$$[3] \qquad B = 0.5\Phi_S\left(\frac{V_B}{V_S} - 1\right) + 0.5\ln\left(\Phi_B + \Phi_S\frac{V_B}{V_S}\right)$$

"*D*" accounts for the effect of the difference in the solute–solute, solvent–solvent, and solvent–solute nonspecific cohesion forces in the liquid phase. This effect brings about a reduction of the solubility that may, as a first approximation, be estimated from an expression of the usual Scatchard–Hildebrand type (55) using nonspecific solubility parameters δ' instead of the Hildebrand solubility parameters, δ. This equation, which is essentially based on the assumption of random contacts in solution, is, however, no longer valid when H-bonds are formed between the solute and solvent molecules, because these interactions modify the random distribution of the molecules. The effect of the new mode of distribution on the solubility is then accounted for by multiplying the Scatchard–Hildebrand expression by the fraction of the time during which the solute is not bound to the solvent, i.e., during which the distribution between the solvent and unbound solute molecules can still be considered to occur at random. As previously demonstrated (56), the new expression for *D* is then given by eq. [4]:

$$[4] \qquad D = -\frac{1}{(1.0 + K_{OH}\frac{\Phi_S}{V_S})}\frac{\Phi_S^2 V_B}{RT}\left(\delta'_B - \delta'_S\right)^2$$

where K_{OH} denotes the stability constant governing the solute–solvent H-bonds. Note that this equation assumes that the nonspecific interactions involving the bound solute are negligible.

"*F*" accounts for the reduction in the solubility of the alcohol in amphiphilic solvents that results from the solvent–solvent self-association, i.e., the hydrophobic effect. The hydrophobic effect has been properly defined and quantified in the frame of the mobile order theory (17, 18, 42). This contribution is composed of three parts (eq. [5]): the first term describes the loss of the mobile order entropy of the self-associated solvent molecules related to the hindrance of these molecules to dispose of a larger domain consecutive to the addition of the solute. For solutes involving amphiprotic groups (42), such as alcohols, this loss of entropy is, however, partially reduced by the insertion of these proton-donor groups in the solvent H-bond chains, which reduces the fraction of the time during which the solvent molecules are free from H-bonding. This reduction of the loss of entropy is expressed by the second part of eq. [5]. In the particular case of water, the effect on solubility of the strengthening of the water hydrogen bonding network by the formation of stronger mixed water–alcohol H-bonds from homogeneous chains is accounted for by the last term of eq. [5]

$$[5] \qquad F = -r_S\,\Phi_S\frac{V_B}{V_S} + \Phi_S r_S + \Phi_S b$$

In this equation, r_S represents the "structuration factor" of the solvent, and *b* is a constant accounting for the degree of branching of the alcohol, amounting to 1.2, 2.0, and 2.9 for primary, secondary, and tertiary alcohols, respectively (42). At room temperature, the value of r_S is equal to zero for non-associated solvents (aliphatic and aromatic hydrocarbons, esters, ethers, ketones, nitriles); r_S is approximately 1 for strongly associated solvents forming single H-bonded chains (alcohols), and amounts to 2 for water and diols whose molecules are involved in double hydrogen-bonded chains.

"OH" describes the effect of the amphiphilic OH group of the alcohol on its solubility (with the exception of the reduction of the hydrophobic effect considered in eq. [5]). The way that these groups affect the solubility is twofold: (*a*) the insertion of the alcohol molecules in their own hydrogen-bonded chains in solution (self-association) tends to decrease the solubility; (*b*) with proton-acceptor and amphiphilic solvents, either the formation of single solute–solvent H-bonds or the solute insertion in mixed solute–solvent hydrogen-bonded chains promotes the solubility. The OH chemical contribution depends upon the relative strengths of these various molecular interactions, and is expressed by eq. [6] (18, 42).

$$[6] \qquad OH = \ln\left(1 + K_{OH}\frac{\Phi_S}{V_S} + K_{BB}\frac{\Phi_B}{V_B}\right) - \ln\left(1 + \frac{K_{BB}}{V_B}\right)$$

In this expresion, the constants K_{BB} and K_{OH} represent the stability constants that govern, respectively, the alcohol self-association and the alcohol–solvent complexation in solution.

The complete universal solubility equation (18) derived from the mobile order theory would still contain an additional term called the "O term" to account for the positive effect of the H-bond formation between proton-acceptor sites on the solute and proton-donor solvents. In the present study, this contribution vanishes since the fatty alcohols and sterols of interest do not display such proton-acceptor groups.

3. Results and discussion

From the foregoing, the solubility of the *n*-fatty alcohols and sterols can be estimated on the basis of a limited number of properties characterizing both the alcohol and solvent molecules and their interactions in solution. Considering the fatty alcohols and sterols, all the physico-chemical parameters needed to estimate their solubility are collected in Table 1. Remember that for the compounds of interest, which are solid at room temperature, the molar volume, V_B, to be considered is not that of the crystalline compound, but the volume of the dissolved substance, which is, in general, larger by a few percentage points. Practically, these molar volumes are estimated from the addition of the volume contributions for the various

© 1998 NRC Canada

groups constituting the molecule (18, 39). The modified nonspecific cohesion parameter, δ_B', of all 1-alcohols and sterols has been set to 16.30 $MPa^{1/2}$, as the lowest limit of the decreasing cohesion parameter values with respect to the number of carbon atoms in the homologous 1-alcohol series. As for the fluidization constants, *A*, of the fatty alcohols and sterols, their values were not calculated from their melting and transition properties, but were directly estimated to fit the experimental solubilities in hydrocarbons. This procedure allows us to avoid the discrepancies observed between the existing data concerning the phase transformation enthalpies and temperatures. It is well known (59–69) that solid–solid transitions of the long-chain 1-alcohols and cholesterol are affected by the presence of minute amounts of impurities, as well as by variations in the measurement technique and by variations in the thermal histories of the materials. It is also noted that the solid–solid transition points of these materials, as well as the types and sequences of the solid phases, vary with the solvent, as a result of solute–solvent intermolecular interactions (70–80).

Concerning the solvents, their molar volumes and their modified nonspecific cohesion parameters are reported in Table 2. Numerical values were obtained from our previous published compilations (21, 36), or were calculated either according to the correlations reported by Huyskens et al. (40), or from the Hansen's dispersive, d_d, and polar, d_p, partial cohesion parameter values (81), or were simply estimated on the analogy of similar organic solvents with known modified nonspecific cohesion parameters.

Finally, predictions of solubility in complexing solvents still require the knowledge of the stability constants, K_{OH}, characteristic of the interactions between the OH group of the solute and the functional group of the solvent. Assuming that a given type of interaction, such as alcohol–ketone, has always the same strength regardless of its chemical environment, one therefore uses for each type of intermolecular interaction a "standard" stability constant whose values were deduced to fit the experimental solubilities (Table 3). Notice that the insertion constant of alcohol molecules in the hydrogen-bonded chains of such amphiphilic solvents as alcohols and water is considered to be identical to the alcohol–alcohol self-association constant in solution, i.e., $K_{BB} \cong 5000$ cm^3 mol^{-1}.

On the basis of the aforementioned physico-chemical data, the solubilities of five *n*-fatty alcohol (1-dodecanol, 1-tetradecanol, 1-hexadecanol, 1-octadecanol, 1-eicosanol) and of two sterols (cholesterol, β-sitosterol) have been calculated in a wide range of complexing and non-complexing solvents at 25°C and (or) 37°C according to eq. [1]. The results as well as the corresponding experimental data are given in Table 4 together with the contributions of the different terms involved in the solubility calculations. The agreement between observed and predicted solubilities is illustrated in Fig. 1, whereas the predictive ability of the model is furthermore characterized by the calculated vs. experimental volume fraction solubility ratios, $\Phi_B^{calc}/\Phi_B^{exp}$, given in the fifth column of Table 4. Apart from a few exceptions, most predictions, i.e., 98% of the 210 solubilities, show a solubility ratio between 0.1 and 10.0, whereas 70% of the predicted values are even less than twice higher or lower than the experimental values. Several reasons may be invoked to explain the small disagreement observed between calculated and experimental results. From the theoretical point of view, different errors could stem (*a*) from the uncertainties concerning both the molar volumes and the modified nonspecific cohesion parameters of the sterols and *n*-fatty alcohols in solution, (*b*) from the assignment of a common value, K_{BB}, to characterize the self-association of all the hydroxy compounds, and (*c*) from the use of standard solute–solvent stability constants instead of using particular values depending on the chemical environment of the interacting functional groups. Moreover, the values of all these parameters have not been modified for the predictions at 37°C. From the experimental point of view, variations in solid state factors such as hydration state, polymorphism, crystallinity, crystal inhomogeneity, and impurities may affect the solubility determination. The largest deviation between calculated and experimental solubilities is observed for cholesterol in water. Although we actually are unable to explain so large a discrepancy, it is important to mention that, for sparingly soluble compounds, like cholesterol, in water, accurate measurements of solubility are particularly difficult, and solubility values may vary considerably. Notwithstanding, the results on the whole clearly confirm the ability of the mobile-order-derived solubility model to provide reliable estimates of solubility of the solid long-chain *n*-alcohols and sterols in a wide range of organic solvents.

β-Sitosterol (37°C) [c]	–2.620	428.5	16.3	2.0

[a] The self-association constant K_{BB} for all *n*-alcohols and sterols is equal to 5000 cm^3 mol^{-1}.

[b] The molar volume of cholesterol corresponds to the infinite partial molar volume determined in toluene, carbon tetrachloride, chlorobenzene, and nitrobenzene (ref. 57).

[c] In the absence of available solubilities in hydrocarbons, the solute crystallinity contribution, *A*, is calculated according to Yalkowsky's equation (58): $A = -0.023\ (T_m - 298.15)$.

The solubility behavior of the hydroxy compounds appears as a complex phenomenon subject to the balance of enthalpic and entropic contributions, depending in particular on the relative importance of the competing self-association and strong intermolecular interactions. Such information can be learned from the present thermodynamic solubility model, which, beyond its satisfactory predictive ability, also enables us to assess the factors that affect solubility differences between the hydroxy compounds, and the parameters that are responsible for the solubility changes from one solvent to another. A comprehensive understanding can be obtained either by comparing the relative importance of the terms involved in the solubility calculation or by considering their evolution with respect to the solvent or solute properties.

Irrespective of the nature of the solvent, the fluidization constant (term *A*), i.e, the removal of the alcohol molecule from its crystal lattice, always represents a barrier, the height of which is inversely related to the solubility. Practically, in a

given solvent, both experimental and predicted solubilities decrease as one moves forward through the series of the higher 1-alcohols. There is even an almost direct linear relationship between the lowering of the logarithm of the volume fraction solubility and the increase of the fluidization constant (*A* term) as a result of the addition of a methylene group in the hydrocarbon chain on going to higher homologues. Given a particular solvent, more than 90% of the solubility dependence on the length of the paraffin chain is dictated by the melting and transition properties of the pure solid alcohols. Such an evolution means that all parameters other than the crystal properties of the fatty alcohols of interest exert nearly the same influence, or cancel each other to produce the same influence, in determining the solubility in a fixed solvent. In contrast, the solubility of a particular *n*-alcohol or sterol is favorably or unfavorably affected according to whether the solvent is of complexing or non-complexing, polar or nonpolar, nature. Once the melting has occurred, the solute forms a homogeneous solution with the solvent following the solvation process whose enthalpic and entropic contributions determine the overall noncrystalline solubility. At this stage, it is interesting to observe that solvents can be sorted roughly into four groups with respect to their solubilizing capacity for the hydroxy compounds (Fig. 2): the *n*-fatty alcohols and sterols are very insoluble in very polar associated solvents with strong hydrophobic

propensity, such as water or diols, but have appreciable solubility either in associated solvents with moderate hydrophic propensity, like alcohols, or in nonpolar solvents like the aliphatic hydrocarbons. The highest solubilities are observed in proton-acceptor aprotic solvents with partial polarity, such as aromatics, ethers, esters, and ketones. A more in-depth analysis of the various contributions encoded in the overall solubility value can then reveal, for each class of solvents, which physical elementary processes are responsible for the alcohol noncrystalline solubility.

1. In aprotic noncomplexing solvents, the sum of the *B*, *D*, and OH terms is negative or close to zero. Because of the closeness of the modified nonspecific cohesion parameters between these solvents and the hydroxy compounds, the *D* component generally remains very low, and the noncrystalline solubility of the higher 1-alcohols and sterols thus results essentially from the balance between the *B* and OH terms. In such solvents, the solute–solute self-association in solution, not being counterbalanced by the formation of strong intermolecular interactions, disfavors the solubility process (OH term

Fig. 1. Predicted vs. experimental volume fraction solubility of the *n*-fatty alcohols and sterols.

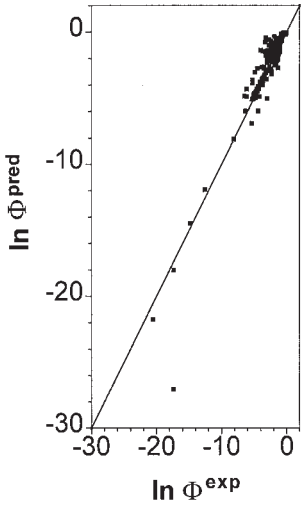

Fig. 2. Neperian logarithm of the experimental volume fraction solubility of the *n*-fatty alcohols and sterols versus the *B*+*D*+OH noncrystalline solubility contribution.

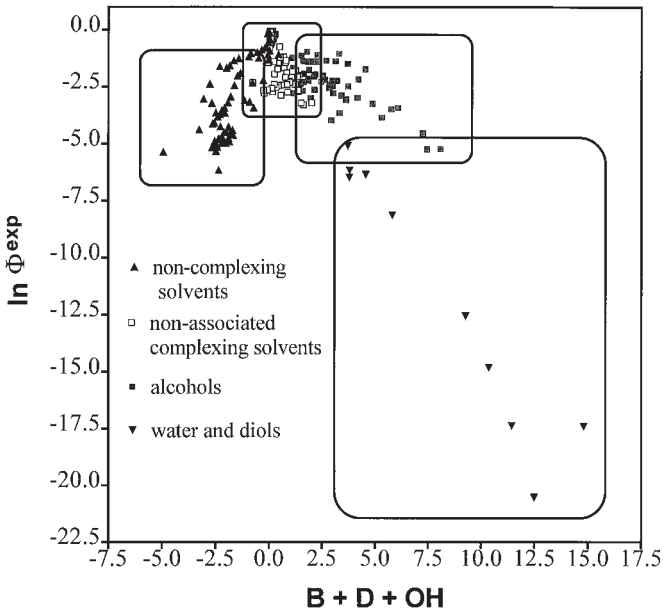

is negative). This explains why the hydroxy compounds are generally less soluble in aprotic noncomplexing solvents than in aprotic but complexing solvents of similar volume. For instance, the volume fraction solubilities of all *n*-fatty alcohols are always lower in *n*-hexane than in *n*-butyl acetate. Furthermore, the continuous lowering of the alcohol solubility with increasing alkyl chain length of the hydrocarbons used as solvents (Fig. 3) can also be explained from a consideration of the *B* and OH terms. Given a solute, any increase of the solvent size by addition of a methylene group in the homologous alkane series acts against solubility by simultaneously reducing the positive *B* term and increasing the unfavorable OH term.

2. In aprotic complexing solvents (aromatic hydrocarbons, halogenated hydrocarbons, ethers, esters, ketones), the addition of the *B*, *D,* and OH contributions is in most cases positive. As the *D* values remain generally low, the noncrystalline solubility of the 1-alcohols and sterols in these solvents is still governed by the balance between the *B* and OH terms. However, if the hydroxy compounds appear to be more soluble in the present class of solvents than in the previous one, this does not result from an increase of the positive *B* term, but rather stems from the less negative OH contribution. The solubility in polar non-associated complexing solvents is in fact enhanced by the formation of specific molecular interactions between the proton-donor hydroxyl group of the solute and the various proton-acceptor sites of the solvents. These intermolecular H-bonds sometimes counterbalance, but overcome in most cases the alcohol–alcohol self-association as demonstrated by the existence of slightly negative and positive values of the OH term, which expresses the net result of the two opposite effects. In the present class of solvents, as in the previous one, any increase in the molar volume of the solvent in a chemical homologous series leads to both the decrease in the *B* term and the increase in the OH term, resulting in a lowering of the solubility. Indeed, although more irregular, the solubility profile of cholesterol versus the carbon chain length of the ethyl carboxylate derivatives at 37°C (Fig. 4) presents the same trend as that given by the sum of the *B* and OH solubility components.

3. In the third group of solvents, namely, the alkanols, the sum of the *B* and *D* terms favors the solubility, and the OH term is even more positive than in the previous classes. Although, in these solvents, the insertion of the fatty alcohol molecules into the molecular hydrogen bond chains of the solvent contributes more efficiently to promoting the solubility process, the solubility values remain generally lower than those observed in ketones, ethers, or esters, but are rather comparable to those observed in the aliphatic hydrocarbons of similar volume. The reason for such behavior is that, in amphiphilic solvents and in alkanols in particular, the noncrystalline part of the solubility is not only determined by the sum of the *B* and OH components (*D* term ≈ 0), but is also ruled by an additional component, i.e., the hydrophobic effect (*F* term), which acts against solubility. Practically, this effect related to the solvent–solvent self-association reduces the solubility by a factor depending on the solute/solvent molar volume ratio. According to whether or not the *F* term predominates over the other solubility components, one can expect that the solubility will either increase (19), decrease, or pass through a maximum with increasing alkyl chain length of the alkanol solvent molecules. Actually, the hydrophobic propensity of the alkanols towards the *n*-fatty alcohols and sterols remains relatively small because of the possible insertion of the solute molecules into the solvent H-bond chains, and two types of solubility pattern are experimentally observed (Fig. 5). On the one hand, for the lower solid *n*-fatty alcohols, i.e., 1-dodecanol and 1-tetradecanol, the plots of the experimental solubility versus the carbon chain length of the alkanol are similar to those previously observed for *n*-fatty alcohol solubility in the alkane or

Fig. 3. Comparison between the experimental solubility profile and the variation of the non-crystalline solubility components (*B*+OH) of 1-tetradecanol and 1-octadecanol in the *n*-alkane series (C_6–C_{16}).

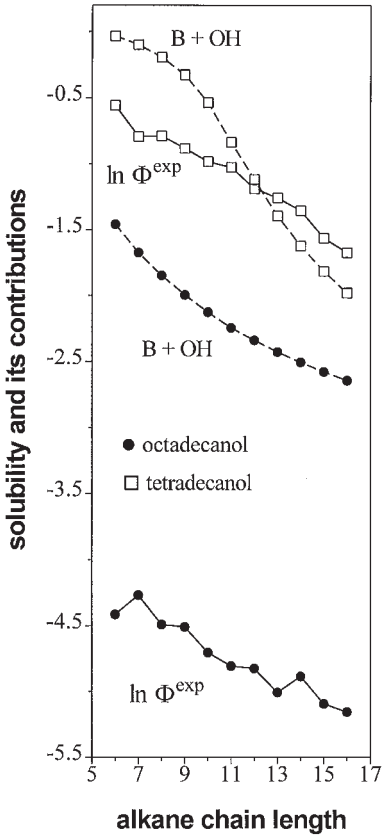

Fig. 4. Comparison between the experimental solubility profile and the variation of the non-crystalline solubility components (*B*+OH) of cholesterol in the homologous ethyl carboxylate series at 37°C.

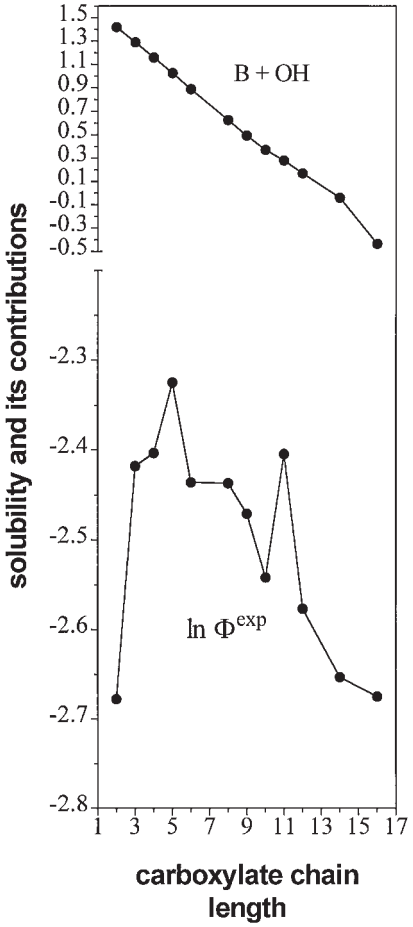

ethyl carboxylate series: the solubility decreases with the increasing length of the alkyl chain of the alkanol. On the other hand, for the upper *n*-fatty alcohols and for the sterols, a maximum of the solubility is observed in the curves presenting the experimental solubility versus the alkanol carbon chain length: the solubility first sharply increases up to a maximum (the position of which varies from one solute to another between a length of six and seven carbon atoms), and then slowly decreases with further lengthening in the alkanol chain length. It is remarkable that both types of behavior are correctly accounted for by the sum of the *B*, *F*, and OH components involved in the solubility estimation. The present thermodynamic solubility model is thus also able to account for subtle changes concerning the dependence of the solubility on the molar size of the solvent.

4. The fourth category of solvents is represented by water and diols. In these solvents, the solubilities of the *n*-fatty alcohols and sterols are the lowest observed, notwithstanding the fact that the positive *B* and OH contributions are larger than in the other groups of solvents, and that the negative *D* contributions remain close to zero. In fact, in water and diols, the solubilities are predominantly governed by the hydrophobic effect (*F* term). The very large hydrophobic propensity of these solvents towards the alcohol substances is due either to the exceptional smallness of the water molar volume with respect to that of the fatty alcohol and sterol molecules ($V_B >> V_S$), or to the fact that the water and diol molecules are involved in double hydrogen bond chains ($r_s = 2$). Practically, the solubility is reduced by a factor of $2V_B/V_S$. In these solvents, the extremely important loss of the mobile order entropy of the H-bonded solvent molecules following the addition of the solute cannot be counterbalanced by the exothermic energy gained by the various solute–solvent specific interactions. A direct consequence of the hydrophobic effect is that any increase of the molar volume of the solute, which normally promotes its noncrystalline solubility in non-associated solvents via the *B* term of the solubility equation, will lessen it in water and diols because of the *F* contribution.

The foregoing analysis thus provides better understanding of the factors that govern the solubility of the *n*-fatty alcohols as well as some practical rules that might help in choosing a suitable solvent system for a substance involving a hydroxyl amphiphilic group.

4. Conclusion

Based on the knowledge of a limited number of physicochemical parameters characterizing both the high molecular weight alcohols and solvent molecules and their specific interactions in solution, the mobile-order-derived solubility equation permits reliable predictions of the solubilities of solid *n*-fatty alcohols and sterols in common organic solvents including

water. The model provides better understanding of their solution process by assessing the factors that determine their solubility behavior. By considering the relative importance of the noncrystalline solubility components involved in the solubility calculation, four groups of solvents can be differentiated with respect to their solubilizing capacity: the aliphatic hydrocarbons, the non-associated polar solvents, the alkanols, and water and diols. Furthermore, the detailed analysis of the solubility components provides both the grounds for the *n*-fatty alcohol and sterol solubility dependence on the solvent carbon chain length for different homologous chemical series of solvents, and the interpretation of the solubility differences between the *n*-fatty alcohols in a particular solvent. At the present time, the solubility theory has a sound theoretical basis, and a priori prediction of solubility in a number of systems has become a reality.

Ab initio conformational analysis of the model tripeptide *N*-formyl-L-alanyl-L-alanine amide

Michael Ramek, Ching-Hsing Yu, and Lothar Schäfer

Abstract: The ab initio conformational energy minima of the model tripeptide *N*-formyl-L-alanyl-L-alanine amide (ALA-ALA) were determined by ab initio RHF/4-21G and RHF/6-31G* gradient geometry refinement. For the current investigation, 11 664 RHF/4-21G structures were optimized, representing grid points in the four-dimensional (ϕ_1, ψ_1, ϕ_2, ψ_2) conformational space, which were constructed in 40° increments along the outer torsions ϕ_1 and ψ_2 and in 30° increments along the inner torsions ψ_1 and ϕ_2 of ALA-ALA. Two new energy minima, previously not reported, are described. The positions of the RHF/6-31G* energy minima in ϕ,ψ-space can differ significantly from the corresponding RHF/4-21G locations, and both sets are not clustered in the centers but on the fringes of the most populated regions of ϕ,ψ-space in protein crystal structures. Thus, the torsion angles of the ab initio energy minima are not those of the typical substructures of proteins: the most stable helices are not α_R, and the torsion angles of the most stable bend forms are not those most frequently encountered in protein bends. Limitations of the dipeptide approximation are explored, illustrating how the conformational energies of an amino acid residue depend on the state of its neighbor.

Key words: alanyl alanine amide, dipeptide approximation, model tripeptide, peptide models, structure of peptides.

Résumé : On a effectué des calculs ab initio, RHF/4-21G et RHF/6-31G* avec affinement de gradient de la géométrie, de minimums d'énergie conformationnelle du tripeptide modèle *N*-formyl-L-alanyl-L-alanine amide (ALA-ALA). Pour la présente étude, on a optimisé 11 664 structures RHF/4-21G qui représentent des points de la grille de l'espace conformationnel en quatre dimensions (ϕ_1, ψ_1, ϕ_2, ψ_2) construits avec des augmentations de 40° autour des torsions externes, ψ_1 et ϕ_2, et des augmentations de 30° le long des torsions internes, ψ_1 et ϕ_2, de ALA-ALA. On décrit deux nouveaux minimums qui n'avaient pas été rapportés antérieurement. Les positions des minimums d'énergie RHF/6-31G* dans l'espace ϕ,ψ peuvent être assez différents des locations correspondantes de RHF/4-21G; les deux ensembles ne sont toutefois pas groupés dans les centres, mais plutôt sur les bordures des régions les plus populeuses de l'espace ϕ,ψ des structures cristallines de la protéine. Ainsi, les angles de torsion des minimums d'énergie ab initio ne correspondent pas à ceux des sous-structures types des protéines: les hélices les plus stables ne sont pas α_R et les angles de torsion des formes courbées les plus stables ne sont pas celles que l'on rencontre le plus fréquemment dans les courbures des protéines. On a exploré les limitations de l'approximation du dipeptide qui montrent comment les énergies conformationnelles d'un résidu d'acide aminé dépend de l'état de son voisin.

Mots clés : alanyl alanine amide, approximation du dipeptide, tripeptide modèle, modèles de peptide, structure de peptides.

[Traduit par la rédaction]

Introduction

Model tripeptides, such as the *N*-formyl or *N*-acetyl derivatives of diamino acid amides, are of great interest in computational chemistry because they allow for the computer modeling of structural aspects of relevance for larger systems, such as oligopeptides and proteins (1–21), which are not readily amenable to study by advanced computational techniques. In the recent past there has been considerable interest in ab initio conformational analyses of such model compounds (22–30) and, specifically, in *N*-acetyl-L-alanyl-L-alanine-*N*′-methyl amide (31–33) and the title compound *N*-formyl-L-alanyl-L-alanine amide (ALA-ALA, henceforth; Fig. 1) (33–39).

In attempts to find a working basis for dealing with the considerable complexity of the conformational properties of proteins, the *dipeptide approximation* has frequently been applied (40–48). In this approximation it is assumed that the conformational properties of the *i*th residue of a peptide chain, particularly the values of the torsional angles ϕ_i and ψ_i (Fig. 1), depend mainly on the nature of the residue R_i and are largely independent of the neighboring pairs, ϕ_{i-1},ψ_{i-1} and ϕ_{i+1},ψ_{i+1}. More specifically (48), "the interactions associated with rotations of a ϕ_i,ψ_i pair are largely independent of the angles assumed by the neighbouring pairs ϕ_{i-1},ψ_{i-1} and ϕ_{i+1},ψ_{i+1}." Since short-range interactions are highly important in the folding of polypeptide chains, the dipeptide model has been rather effective, in spite of the fact that it neglects cooperative phenomena and long-range interactions in polymer chains.

Investigations of systems like ALA-ALA allow one to step beyond the limits of the dipeptide approximation. For this

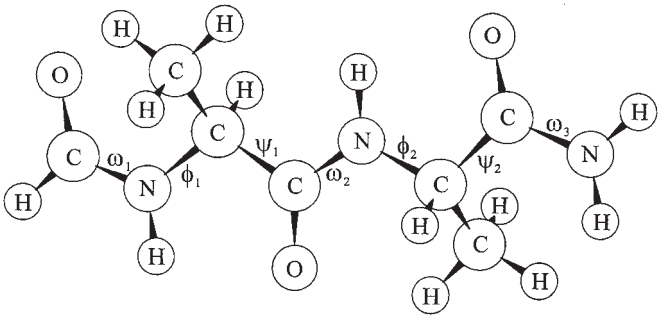
Fig. 1. *N*-Formyl alanyl alanine amide. Notation for backbone torsional angles.



reason we have optimized the geometries of this compound at grid points in its four-dimensional (ϕ_1, ψ_1, ϕ_2, ψ_2) conformational space (Fig. 1) defined by 40° increments along the outer torsions ϕ_1 and ψ_2, and by 30° increments along the inner torsions ψ_1 and ϕ_2. The smaller stepsize for the latter was chosen because the properties of the central peptide bond are of particular interest to us. At each of the $9 \times 12 \times 12 \times 9 = 11\,664$ grid points geometry optimizations were performed via RHF/4-21G (49) calculations, in which the torsions ϕ_1, ψ_1, ϕ_2, and ψ_2 were kept constant while all other structural parameters were relaxed without any constraints. The orientation of the torsions ω_1 (i.e., H-C-N-C) and ω_2 was *trans* in all cases.

Previous ab initio geometry optimizations of ALA-ALA involved the all-extended and $C_7^{eq} - C_7^{eq}$ conformations (36), followed by studies of bend and helical forms (37–39). On the basis of these studies it was concluded that the latter are stable in ALA-ALA, in contrast to model dipeptides, such as the *N*-acetyl-*N*′-methyl derivatives of amino acids, where bends and helices are not energy minima (50–54). It was a further characteristic (38) of ALA-ALA that its stable helical form is displaced from the standard right-handed α_R-helical region to that of the 3/10 helix. This result is important in view of the experimental finding (55) that 3/10 helices, rather than α_R, are preferred by short alanine-based peptides in aqueous solution.

Perczel et al. (37, 39) have reported a particularly extensive study of ALA-ALA in an ambitious attempt to present a complete set of minimum energy conformations. The current investigation will add two more energy minima not found previously.

The current paper is focused on the conformational energies of ALA-ALA. The structures of all RHF/4-21G energy minima found by our analysis were also optimized at the RHF/6-31G* level of theory because the latter will yield better estimates of the locations of minima in ϕ,ψ-space. Apart from the concerns of the current paper, this data base is intended for use in developing improved parameters for computer simulations of organic compounds adsorbing to clay mineral surfaces (56).

Computational procedures

The RHF optimizations were carried out with Pulay's original 4-21G basis set (49) using the program GAMESS (57) on a variety of different machines until the maximum gradient was less than 10^{-4} H/Bohr, and the root mean square gradient was below 3.33×10^{-5} H/Bohr. The nature of all local minima reported here was confirmed by calculating the eigenvalues of the Hessian matrix.

Cubic spline functions were used to generate an analytical approximation of the potential-energy surface (PES) from the 11 664 grid points. Subsequently the local minima of this analytical approximation were determined and their positions in the four-dimensional space (ϕ_1, ψ_1, ϕ_2, ψ_2) were used as starting points for unrestricted geometry optimizations with the 4-21G basis set. The 4-21G energy minima were then reoptimized with the 6-31G* (58, 59) basis set.

On the basis of some recent analyses (60–62), the following error estimates can be given for the 4-21G results of this study: in calculations of glycine and *N*-formyl alanine amide (60, 61), HF/4-21G energies were found closer to MP2 energies or experimental values than results obtained with larger basis sets, with maximum inaccuracies of 1.5 kcal/mol for HF/4-21G (60, 61). This result shows that the 4-21G basis set is well balanced for compounds like ALA-ALA. Similarly, essential geometry trends, differences between comparable bond distances and angles in different conformations, are well determined at the 4-21G level (60–62), but the exact minima of torsional angles were found (60) inaccurate by up to 15°. On the basis of the previous comparisons (60, 61) we expect that the ϕ,ψ-torsions of the RHF/6-31G* optimized energy minima are within ~5° of comparable MP2-optimized geometries.

Results and discussion

The results of our analysis are given in Tables 1–4. The ϕ,ψ-torsional angles, conformational energies, and notation used to characterize the RHF/4-21G and RHF/6-31G* optimized minimum energy structures of ALA-ALA are given in Table 1. Some selected conformational energies and their transitions are presented in Tables 2 and 3. The RHF/3-21G data of two previously not reported energy minima are listed in Table 4.

The notation adopted for this study makes use of a convention generally accepted for characteristic regions of peptide ϕ,ψ-space in protein crystallography (63) (Fig. 2). The nomenclature introduced by Perczel et al. (64) is also included in Table 1, but merely for the sake of comparing the current and previous (39) data sets. We do not wish otherwise to adhere to it because it uses the same symbol, $\alpha_L\alpha_L$, for both type I and type III bends, which are usually (65, 66) considered as different types; furthermore, the same symbol, $(\alpha_L)_n$, is used to denote both standard α-helices and helices in model tripeptides (39), omitting the important detail that the latter are 3/10 helices and not α_R (36, 38, 55). Moreover, characterizing regions of ϕ,ψ-space in accordance with frequently populated regions in protein crystal structures, rather than with the energy minima of model dipeptides, helps to clarify an important result of the current study. That is (see below) that the torsional angles of the ab initio energy minima of ALA-ALA are not typical of the most populated regions of ϕ,ψ-space in protein crystal structures and, furthermore, cannot be extrapolated from the corresponding model dipeptide in all cases.

In addition to the crystallographic regions specified in Fig. 2, the results of the geometry optimizations of ALA-ALA require the definition of a provisional region, denoted as "p" in Table 1, whose approximate boundaries are given by $\phi > 150°$ or $\phi < -150°$ and $-90° < \psi < 0°$. Some of the calculated

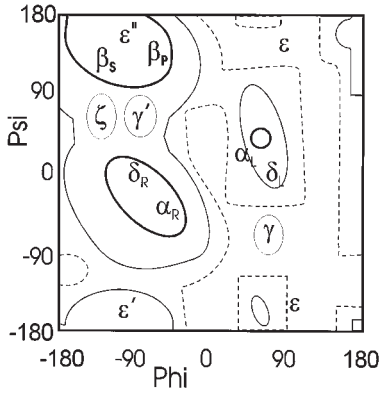
Fig. 2. Notation for characteristic regions of peptide ϕ,ψ-space taken from Karplus (63). The frequencies of observed peptide conformations in protein crystal structures are also indicated. They decrease from areas enclosed by heavy solid lines to regions enclosed by plain solid lines and broken lines. The outlines are an approximate rendering of the exact contours given by Karplus (63).



energy minima (Table 1) are situated in this part of ϕ,ψ-space, even though it is seldom populated in protein crystal structures.

Comparisons with previous ab initio studies

Even though a search for stationary points on the potential-energy surface (PES) of ALA-ALA was not the purpose of our geometry optimizations, it is a relatively easy by-product: once the energies at all grid points are determined, effective functions can be fitted to give a mathematical representation of the PES, which can then be used to search for minima and saddle points. The set by Perczel et al. (39) seemed to be a good test for the quality of the PES engendered by our approach. Indeed, most of the local minima encountered on the 4-21G PES are a good match with the RHF/3-21G optimized structures reported by Perczel et al., with deviations in backbone torsions of less than 1°. Several of the local minima reported in ref. 39, however, did not match and were therefore reoptimized with the 3-21G basis set. The resulting structures indicate that the data of ref. 39 contain a number of typographical errors[2] that are relevant to point out for this important molecule.

We cannot be sure that the 4-21G grid search of ALA-ALA has led to the discovery of all the local energy minima of ALA-ALA, but it has revealed two additional minima not listed in ref. 39. Reoptimization of these structures with the 3-21G basis set followed by calculations of the vibrational frequencies showed that these conformers are true minima in the RHF/3-21G space. Their 3-21G optimized energies and backbone torsional angles are given in Table 4. The two new conformers, $\beta_P\alpha_L$ and $\gamma\delta_R$, are relatively close to other energy minima reported by Perczel et al. (39), namely to $\gamma'\alpha_L$ and $\gamma\zeta$ ($\gamma_L\alpha_D$ and $\gamma_D\delta_L$ in the notation of ref. 39), but they are separated from them by distinct saddle points. Both of the conformers identified in Table 4 are characterized by two intramolecular C═O···H—N hydrogen bonds, one between the formyl group and the central peptide bond (1←3) and the other between the two terminal groups (1←4). The bond orders (67), which are also listed in Table 4, indicate that the latter is stronger than the former.

In further deviation from the results reported in ref. 39, we note that the RHF/3-21G $\varepsilon_D\delta_D$ conformer is not a local minimum in either the RHF/4-21G or the RHF/6-31G* calculations. Geometry optimizations starting with that conformation yield γp (labeled $\gamma_D\delta_D$ in ref. 39) in the former and $\varepsilon\delta_R$ ($\varepsilon_D\delta_L$) in the latter.

The previously noted (38) type of the helical form of ALA-ALA, i.e., 3/10 rather than α_R, was confirmed by the present investigation and, most importantly (see conformation $\delta_R\delta_R$ in Table 1), this finding was not changed by optimizing the structure of $\delta_R\delta_R$ at the RHF/6-31G* level of theory. When α_R-helical forms of *N*-formyl-pentaglycine amide and pentaalanine

[a] Symbols for conformational regions (CONF) were taken from Fig. 2. The ϕ,ψ-torsional angles are in degrees and identified in Fig. 1. Energies (ENG) are in kcal/mol relative to the β,β conformation.

[2] In Table 6 of ref. 39 the values of the ϕ_1 torsions of $\delta_L\delta_D$, $\delta_L\varepsilon_D$, $\delta_L\gamma_D$, and $\delta_L\gamma_L$, in Table 9 the value of ϕ_1 for $\gamma_D\beta_L$, and in Table 5 the value of ψ_1 for $\varepsilon_D\beta_L$ should have the opposite sign. Also in Table 5, the correct value of ψ_2 for $\varepsilon_D\gamma_D$ should be –58.1°. The last two misprints also appear in Figs. 2 and 3 (39). Also in Table 5 (39), the optimized value of ψ_1 should be –60.9° for conformer $\varepsilon_D\alpha_D$; in the nomenclature used by Perczel et al. this will require to change the label of $\varepsilon_D\alpha_D$ to $\gamma_D\alpha_D$. As it is, the paper (39) contains an inconsistency, because on p. 2055 $\varepsilon_D\alpha_D$ is listed as an unstable conformation, but in Table 5 it is an energy minimum. The correction suggested here, changing $\varepsilon_D\alpha_D$ to $\gamma_D\alpha_D$, will remove this inconsistency. The same change should also be considered in Scheme 7 (39) and in the footnote to Table 5 (39) regarding conformational shifts. It also vitiates the first part of footnote (a) in Table 9 (39). Finally, in Table 4, the notation of $\beta_L\alpha_L$ is not in agreement with scheme 2 (39). Similarly, Table VI of ref. 37 should be corrected for the ψ_2 value (–58.1°) of conformer $\varepsilon_D\gamma_D$.

[b] The last row presents RHF/4-21G energy differences (100) for the model dipeptide, *N*-formyl alanine amide.

amide were optimized at the HF/4-21G level (36), the same result was obtained.

Comparison of RHF/6-31G* and RHF/4-21G energy minima

Previous investigations of basis-set effects on the structures of amino acids and peptides (60, 61) have shown that backbone torsional angles in glycine and *N*-formyl alanine amide can vary by up to ~15° when the same structures are optimized at the RHF/4-21G, RHF/6-311G**, and MP2/6-311G** levels of theory. The largest parts of these changes were encountered (60, 61) in going from RHF/4-21G to RHF/6-311G*, with the latter yielding backbone torsional angles in close proximity, within 4°, of the MP2/6-311G** optimized geometries. Similar variations can be noted in the case of ALA-ALA, which cause a change in the conformer symbol in several cases. The most significant variations are found for $\gamma'\beta_S$ (4-21G) for which ψ_1 shifts more than 20° (Table 1), and the conformers $\beta_P\alpha_L/\beta_P\delta_L$ ($\Delta\psi_1 > 30°$), γε ($\Delta\psi_2 > 40°$),γβ_P, β_Sε, pε, and εε ($\Delta\psi_2 > 20°$). Similar differences were found by Möhle et al. (32) in the case of Ac-Ala-Ala-NHMe. Uncertainties of that order in backbone torsional angles are highly significant when they are propagated along a polypeptide chain. We expect the 6-31G* structures to yield more realistic estimates of the positions of minima on the φ,ψ-PES than their 4-21G counterparts. Several RHF/4-21G energy minima are no local minima in the RHF/6-31G* PES, as indicated in Table 1.

In Fig. 2 a φ,ψ-map is presented that illustrates the frequencies of observed peptide conformations in protein crystal structures as found by Karplus (63) on the basis of a critical analysis of protein crystal data. Figure 3 summarizes the positions of the ab initio energy minima of ALA-ALA in φ,ψ-space. Comparison of Figs. 2 and 3 reveals that the energy minima of the model tripeptide are not clustered in the centers but on the fringes of the most populated regions of φ,ψ-space in proteins. Möhle et al. (32) noted the same deviation for the special case of β-turns; the present comparison seems to show that this is a general feature. Thus it is true that examples for the substructures of the ab initio energy minima of ALA-ALA can be found in the X-ray data of proteins (39) but, at the same time, these substructures are not typical for proteins. It is seen from Fig. 4 that the same result is obtained when only ala-ala sequences

in protein structures are included in this comparison. It follows that, like dipeptides (50–54, 64, 68–100) whose global energy minimum (C_7^{eq}) is rarely populated in proteins and whose PES does not contain a minimum for one of the most frequently populated conformations (α_R) of proteins, tripeptides, too, are not sufficient to model the exact positions of energy minima of polypeptide chains in the solid state.

Limitations of the dipeptide approximation

In the dipeptide approximation the conformations A and B of two amino acid residues linked in a chain are considered independent of one another. In contrast, the peptide sequence AB, as a rule, is noncommutative and AB ≠ BA. The current study provides some quantitative estimates as to what extent the conformational energy of an amino acid residue in a peptide sequence depends on the state of its neighbor.

Fig. 4. Values of the ϕ,ψ-torsional angles of alanine residues in ala-ala sequences in protein crystal structures, according to the protein data file by Karplus (63).

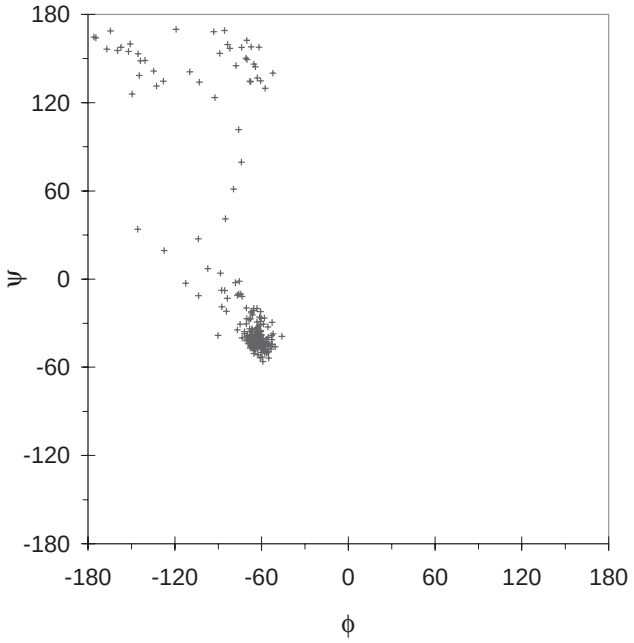

Fig. 5. The conformational energy surface (kcal/mol) PES_2 of residue 2 of *N*-formyl alanyl alanine amide as a function of ϕ_2 and ψ_2 calculated with residue 1 being held fixed at $f = -165°$ and $y = +165°$. The upper graph shows a projection of the three-dimensional rendering of PES_2. The lower graph shows a linearized version, plotting average energies on PES_2 as a function of region numbers in ϕ,ψ-space. Each region is a segment of a 15° grid in ϕ,ψ-space. Region numbering was started with segment $-180° \le \phi < -165°$ and $-180° \le \psi < -165°$ and proceeded from –180° to 180°, moving along the ψ-axis first. In each segment energy values were calculated at 5° intervals and averaged.

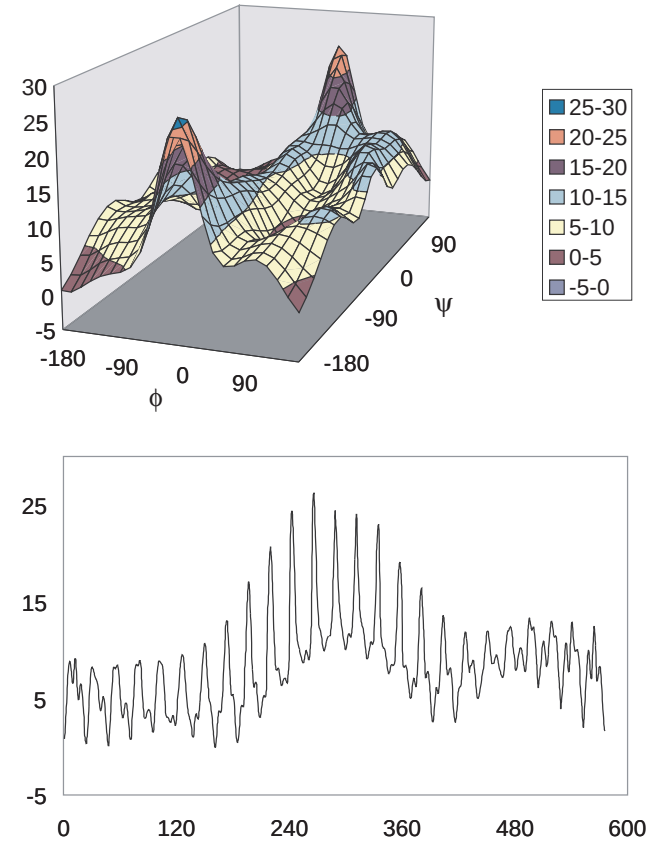

Figure 5 presents the conformational energy surface, PES_2, of residue 2 of ALA-ALA as a function of ϕ_2 and ψ_2, which was calculated with residue 1 being held constant on its own PES (i.e., PES_1) in the β-region at $\phi_1 = -165°$ and $\psi_1 = +165°$. In a qualitative way PES_2 is similar to the RHF/4-21G ϕ,ψ-PES of the model dipeptide *N*-formyl alanine amide (ALA) (100) shown in Fig. 6. Both surfaces have regions of high and low energy at approximately the same locations in ϕ,ψ-space, and in general they display similar topologies. However, quantitatively the energy surfaces of ALA-ALA are not identical with those of ALA, because PES_i in the former varies with PES_j (Fig. 6).

To simplify the comparisons described below, we shall concentrate on four characteristic and frequently populated regions in protein ϕ,ψ-space, that is α_L, α_R, β, and the bridge region, δ_R (Fig. 2). Due to limitations of the graphics software, the latinicized symbols "al," "ar," "bt," and "br," respectively, were used in our graphs to denote these regions, associating with them fixed points at the ϕ,ψ-values of –75°, –45° for ar; +55°, +55° for al; –90°, 0° for br; and –165°, +165° for bt. As a further shorthand convention we mean by xx.1 the PES_1 calculated when residue 2 is being held constant on PES_2 in conformation xx, where xx is either ar, al, bt, or br, as defined above. Similarly, xx.2 is PES_2 calculated when residue 1 is being held fixed at xx equal to either ar, al, bt, or br. To display differences between comparable PES, it is advantageous to transform the three-dimensional surface to two-dimensional line drawings. This was done in Figs. 5–7 by forming a 15° grid in ϕ,ψ-space, numbering the grid regions as described in Fig. 5 and presenting energies as functions of region numbers. Figure 5 shows both the three-dimensional surface and the corresponding line drawing that results when bt.2 (i.e., PES_2 calculated with residue 1 fixed at bt) is transformed in this way.

The asymmetry AB ≠ BA is apparent when the conformational properties of commutated pairs, AB and BA, are compared. It can be seen from Table 1 that ϕ,ψ-torsions and energies can differ significantly for pairs of energy minima such as $\beta_S\gamma'$ and $\gamma'\beta_S$; γ'p and pγ'; $\gamma'\varepsilon$ and $\varepsilon\gamma'$; and others. In some of these cases, the ϕ,ψ-torsions in same-name conformations of a given pair differ by only a few degrees. In others, for example $\gamma'\varepsilon$, they differ almost 10°. Similarly, the conformational energies of the members of a pair may differ by less than 0.5 kcal/mol, or by more than 2.5 kcal/mol, as in the case of $\beta_S\gamma'$.

Further illustrations of inter-residue conformation transmission effects are provided by Fig. 7, which shows differences of type xx.*i* minus yy.*i*; that is, between different PES_i, which were calculated with residue *j* being held constant in different regions, xx or yy, of PES_j, where $i \neq j = 1$ or 2. Furthermore, differences xx.1 minus xx.2 are shown in Fig. 7; that is, differences $PES_1 - PES_2$, which were calculated with residue 2 or 1, respectively, being held fixed at identical points in ϕ,ψ-space. From all these data it is seen that the conformational energy of a residue in ALA-ALA can be significantly affected by the state of its neighbor. These results further

Fig. 6. The conformational energy surface (kcal/mol) of *N*-formyl alanine amide (100) (top) plotted relative to the energy at $\phi = -165°$ and $\psi = +165°$. The lower graph is the difference curve (energy differences as a function of the region numbers defined in Fig. 5) between PES_2 of *N*-formyl-alanyl alanine amide (Fig. 5) and the PES of *N*-formyl alanine amide (top).

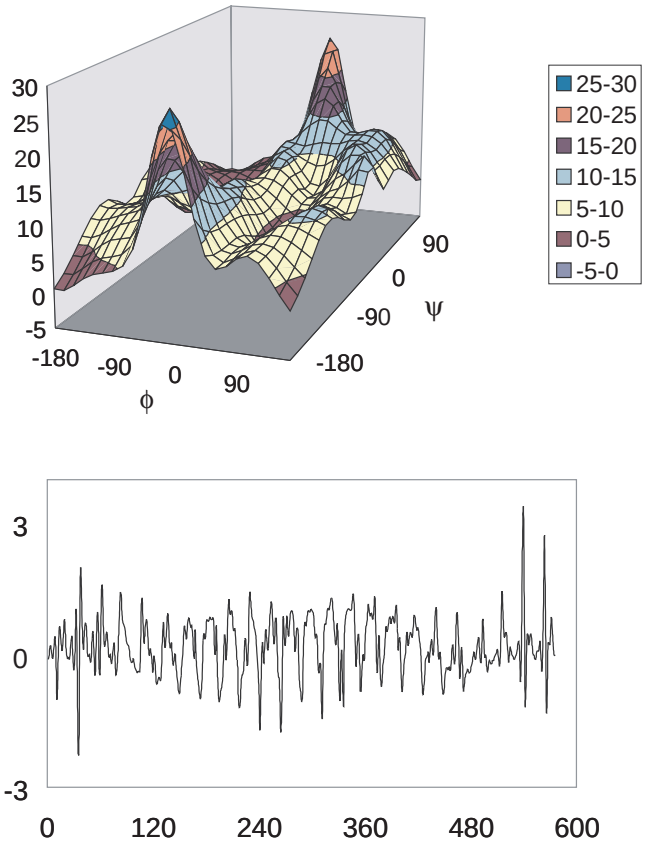

Fig. 7. Energy differences (kcal/mol) for *N*-formyl alanyl alanine amide. The sequence of curves from top to bottom is the same as that of the curve identifiers in the legends. Notation used for the identifiers is "al" for α_L; "ar" for α_R; "bt" for β; and "br" (bridge region) for δ_R. The symbol xx.*i* denotes PES_i (that is, the PES for residue *i* of *N*-formyl alanyl alanine amide as a function of ϕ_i and ψ_i) calculated when residue *j* is being held fixed at α_L, α_R, β, or δ_R on PES_j, where $i \neq j = 1$ or 2. To avoid overlap, some curves have been offset by constant energy amounts (kcal/mol) as indicated at the end of each identifier.

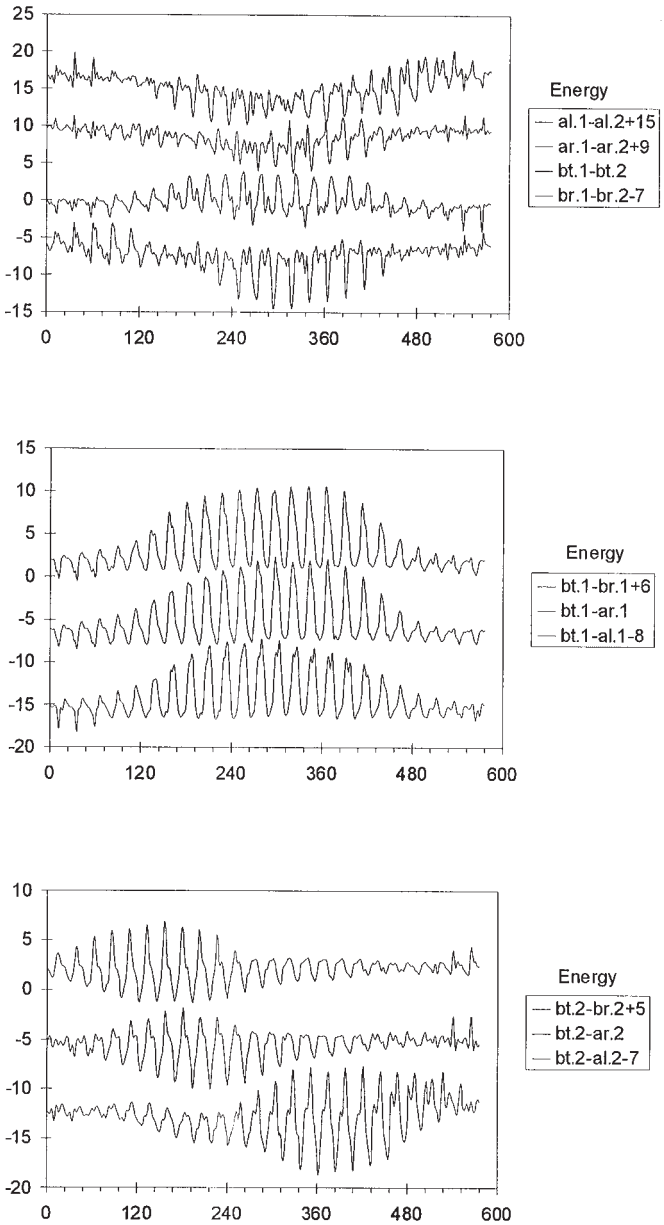


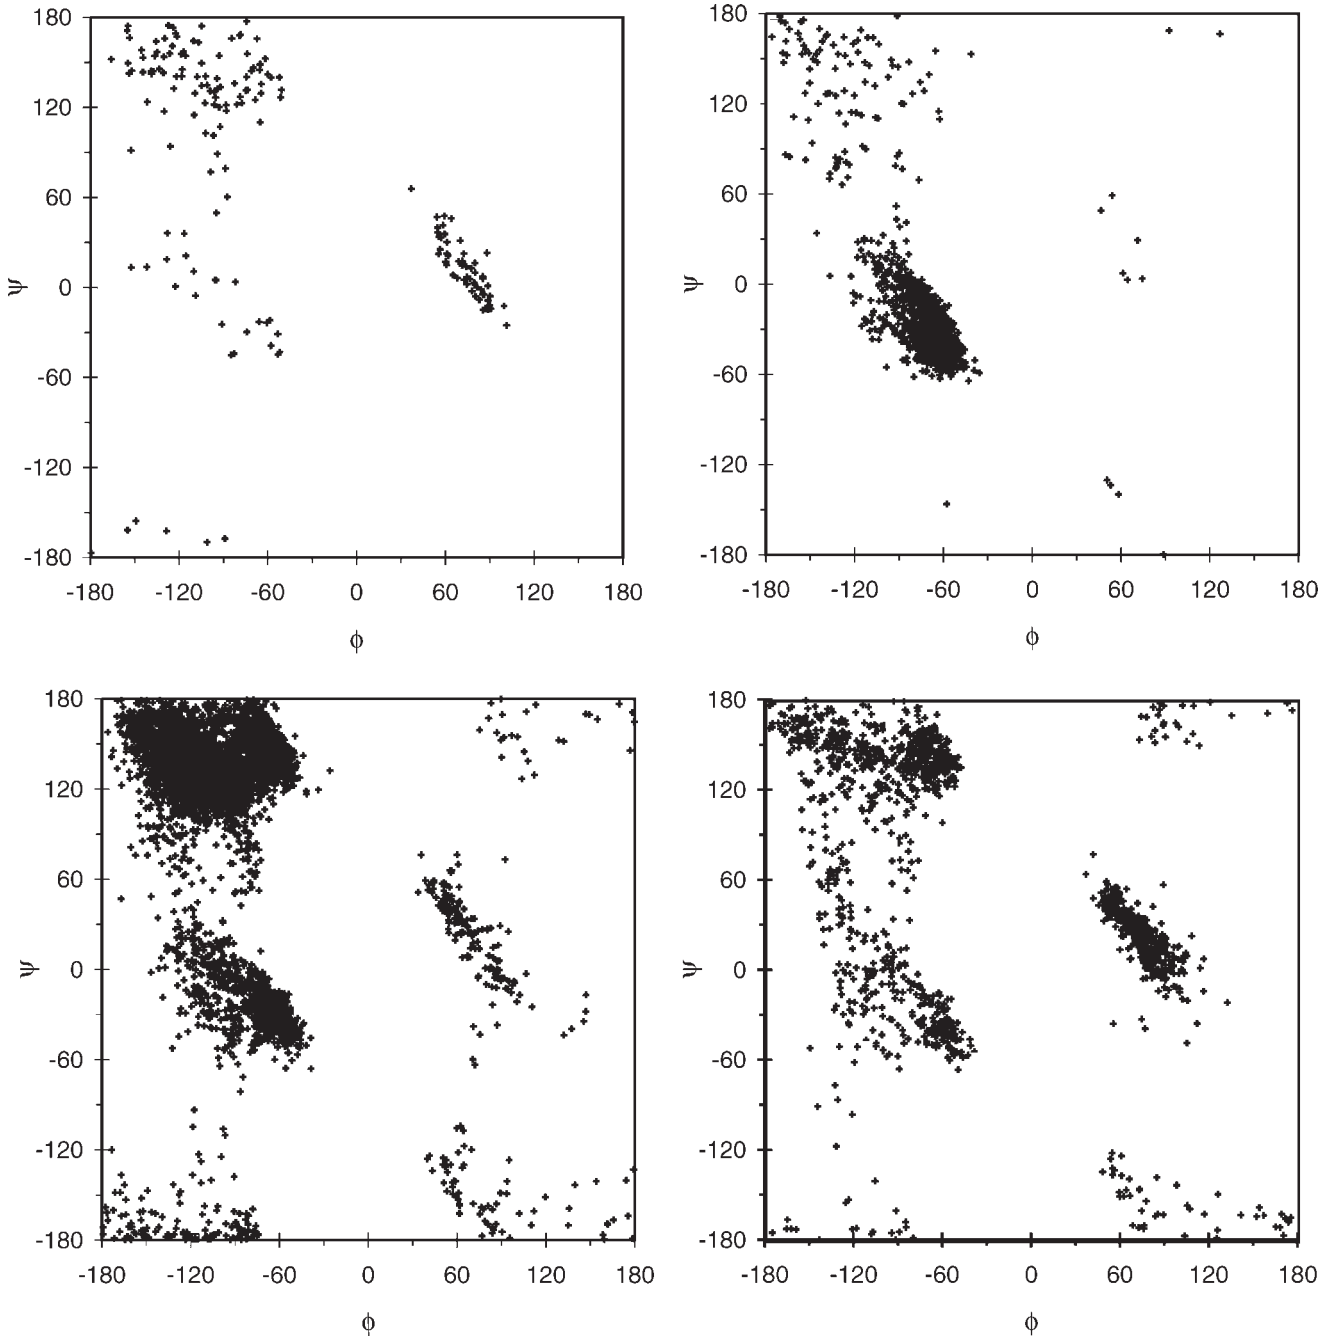
illustrate the asymmetry of the case. For example (Fig. 7), differences of type xx.1 – yy.1 are entirely different from xx.2 – yy.2.

In Tables 2 and 3 relative energies of specific points in the ϕ,ψ-space of ALA-ALA are listed, including the region γ', which is rarely populated in protein crystal structures but of low energy in ALA-ALA. Tables 2 and 3 show that, regardless of what the nature of the first residue is, preference is always for the second residue to be added in the γ'- or β-conformations. Table 3 also shows the importance of cooperative phenomena in the structures of ALA-ALA. That is, energy differences between the same conformational regions in the dipeptide and tripeptide are not the same. In addition it can be seen that transitions between the same conformations of residue 2 depend on the state of residue 1.

These results also show that the conformational energies of small model peptides such as ALA-ALA cannot be used to predict the conformational frequencies of peptide units in proteins. If the population frequencies of residues R_i in protein crystal structures (63) are investigated as a function of the conformational state of the preceding residue R_{i-1}, then the results of Fig. 8 are obtained. Restricting the analysis to the most common cases, i.e., to residues following a preceding neighbor in either the α_R, α_L, β, or δ_R state, Fig. 8 is in agreement with the general expectation of finding β-sheets, α-helices, turns of type (α_L,α_L), (α_L,β), (β,δ_R), (β,α_L), etc., in peptide chains, but the relative frequencies are not in accordance with the energy pattern of ALA-ALA shown in Table 3. The comparison is, of course, not perfect because residues of any kind, not only alanine, were included in Fig. 8, and much of the driving force of conformational selection is by the nature of the side chain. If the analysis underlying Fig. 8 is restricted

© 1998 NRC Canada

Fig. 8. Values of the ϕ,ψ-torsional angles of amino acid residues, R_i, in protein crystal structures, which are found when the preceding residue, R_{i-1}, is in the α_L (top left), α_R (top right), β (lower left), or δ_R-conformation (lower right). The protein data file by Karplus (63) was used. The following simplified boundaries were used (in degrees): $-165 \le \phi \le -60$ and $105 \le \psi \le 180$ for β; $-75 \le \phi \le -30$ and $-75 \le \psi \le -30$ for α_R; $45 \le \phi \le 70$ and $30 \le \psi \le 60$ for α_L; $-120 \le \phi \le -75$ and $-30 \le \psi \le 20$ for δ_R.



to two alanine residues in sequence, only a small number of cases is found. They indicate preference mainly for α_R to follow α_R and β to follow β, again not in accordance with the conformational energy pattern of Table 3.

Conclusions

In the current study we present, in the 6-31G* geometries of the energy minima of *N*-formyl alanyl alanine amide summarized in Table 1, a data base from which improved parameters can be refined for empirical molecular modeling procedures of organic compounds with functional groups of the kind exhibited by ALA-ALA.

From the ab initio conformational energies of ALA-ALA quantitative estimates can be made of the extent to which the conformational energies of individual residues in peptide chains are affected by the states of neighboring peptide units. The concomitant limitations of the dipeptide approximation (40–48) are more extensive in the ab initio results than previously estimated (101) on the basis of empirical modeling

© 1998 NRC Canada

calculations. Nishikawa et al. (101) found significant departure from additivity of single-residue energies mainly for minimum-energy bends. Figure 7 indicates that significant departures from additivity are found in many regions of ϕ,ψ-space.

Small peptides contain a great deal of information that is relevant for understanding structural trends, specifically those involving bond angles of larger systems such as oligopeptides and proteins (100, 102). However, as far as the exact positions of conformations in ϕ,ψ-space are concerned, small peptides seem to be much less informative. In the case of ALA-ALA, specifically, the torsion angles of the ab initio energy minima are not those of the typical substructures of proteins: the most stable helices are not α_R, and the torsion angles of the most stable bend forms deviate from those most frequently encountered in protein bends.

Determination of the acid dissociation constants for some mycotoxins of the *Alternaria alternata* genus

Patricia Gabriela Molina, María Alicia Zón, and Héctor Fernández

Abstract: The acid dissociation constants for alternariol monomethyl ether (AME), altertoxin-I (ATX-I), and alternariol (AOH), three of the *Alternaria alternata* genus mycotoxins, are estimated through conventional UV–VIS spectroscopic studies at different pH values. Experimental variations of absorbance as a function of pH at a given wavelength were fitted by using the exact equations that describe the systems studied. Good agreement between the experimental absorbance vs. pH plots and the curves generated by the fitting process was found. A comparison between the acidic constants for the first step of dissociation of these mycotoxins and the value for the acidic constant of phenol is discussed by assuming that phenolic structures are responsible for the acidity of these mycotoxins.

Key words: mycotoxins, alternariol monomethyl ether, altertoxin-I, alternariol, acidic constants.

Résumé : En se basant sur des études spectroscopiques UV–VIS conventionnelles réalisées à diverses valeurs de pH, on a évalué les constantes de dissociation acide de l'éther monométhylique de l'alternariol (EMA), de l'altertoxine-1 (ATX-1) et de l'alternariol (AOH), trois mycotoxines du genre *Alternaria alternata*. On a ajusté les variations expérimentales d'absorption en fonction du pH à une longueur d'onde donnée à l'aide d'équations exactes qui décrivent les systèmes étudiés. On a observé de bons accords entre l'absorption expérimentale en fonction des courbes de pH et celles générées par le procédé d'ajustement. Pour discuter de la comparaison entre les constantes d'acidité de la première étape de dissociation de ces mycotoxines et la valeur de la constante d'acidité du phénol, on fait l'hypothèse que les structures phénoliques sont responsables de l'acidité de ces mycotoxines.

Mots clés : mycotoxines, éther monométhylique de l'alternariol, altertoxine-1, alternariol.

[Traduit par la rédaction]

Introduction

Alternaria species are common in many foods and feed crops. In grain or seeds, *Alternaria* infection usually occurs before harvest when the seed moisture content is still high. The infection becomes extensive enough to produce secondary metabolites only when drying in the field is delayed by rainfall and high humidity. Post-harvest infection by *Alternaria* is more likely to occur in fruits and vegetables that remain high in moisture content after harvest, resulting in economic loss to growers and commercial marketers (1–7).

Alternariol monomethyl ether (AME), alternariol (AOH), and alternuene (ALT), which are benzopyrone derivatives; altertoxin-I (ATX-I) and altertoxin-II (ATX-II), which are perylene derivatives; and tenuazonic acid (TA), a tetramic acid derivative, are considered to be the most important *Alternaria* mycotoxins (see Fig. 1) (1). They are toxic in many biological systems, including animal and mammalian cells (8–13).

Given the fact that these secondary metabolites have multibasic sites, it is expected that more than one acid–base pair will be under equilibrium conditions depending on the pH of the medium. The knowledge of the acid dissociation constants is of utmost importance both for understanding their reaction mechanisms and for firmly grounding their toxicological properties.

In this paper, we estimate the acidity constants for AME, ATX-I, and AOH through conventional UV–VIS spectrophotometric studies at different pH values as part of a general program for the study of the properties of mycotoxins recently started by our group.

Experimental

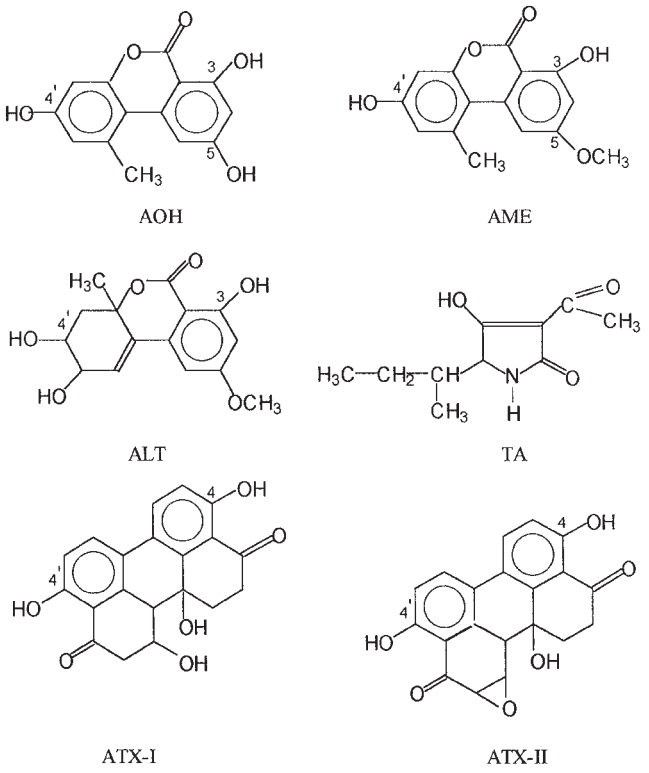
Reagents

AME, ATX-I, and AOH were obtained from Sigma Chemical Company and were used as received. Acetonitrile (ACN), methanol (MeOH), and acetone (Ac) were Sintorgan, HPLC grade. They were dried over 3 Å molecular sieves for 48 h prior to use and were then employed without further purification. Water was obtained from the Labconco WaterPro Mobile system model 90901–01 (HPLC grade water).

Working solutions of mycotoxin were prepared daily at concentrations in the $(0.3–3) \times 10^{-5}$ M range from stock solutions of AME, ATX-I, and AOH (prepared in ACN, Ac, and MeOH, respectively). The pH region 0–1 was covered using 1 and 0.1 mol dm^{-3} HCl and pH 12–13 by 0.01 and 0.1

© 1998 NRC Canada

Fig. 1. Chemical structures of some *Alternaria alternata* genus mycotoxins.



mol dm^{-3} NaOH. The pH range 2–12 was covered by the appropriate buffer with the pH adjusted by the addition of various volumes of 1 mol dm^{-3} HCl or NaOH. Twenty percent of ACN in the medium studied was necessary to allow the complete solubilization of mycotoxins.

Apparatus and methods

UV-VIS spectra were recorded immediately after the preparation of solutions by using a Hewlett–Packard model 8452A spectrophotometer equipped with a temperature controller. Absorbances at three selected wavelengths for each toxin were obtained from the spectra recorded against the corresponding blanks. Silica cells were of 1 cm pathlength.

pH Measurements were performed by using an Orion model 720A pH meter that was calibrated daily with three commercial buffers (manufactured according to the National Institute for Standards and Technology recommendations). The pH meter was used with an Orion 8104 Ross (pH 0–14) combination electrode. All measurements were performed at 25 ± 0.5°C.

Manipulation of all the experimental laboratory material was done by using thin plastic gloves for security.

In our calculations, the unknown parameters were the acid dissociation constants (K_i) and extinction coefficients (ε); nevertheless, the ε value for some species in solution at a given pH could always be experimentally determined for each one of the toxins. This provides a way of checking the accuracy of our data and calculations by comparing the experimental and calculated values. Treatment of experimental data was by the nonlinear least-squares fitting procedure (14, 15). The nonlinear regression method is based on the Levenberg–Marquardt algorithm. The two necessary building blocks of any fitting procedure are: (*i*) data that represent the results of certain measurements in which one or several independent variables ($X_1, X_2, X_3,....$) was varied over a certain range in a controllable manner to produce the measured dependent variable(s) Y_1, Y_2, Y_3, and (*ii*) mathematical expressions in the form:

$$[1] \quad Y_1 = f_1\,(X_1, X_2, X_3,....; p_1, p_2, p_3,....)$$

$$[2] \quad Y_2 = f_2\,(X_1, X_2, X_3,....; p_1, p_2, p_3,....)$$

$$[3] \quad Y_3 = f_3\,(X_1, X_2, X_3,....; p_1, p_2, p_3,....)$$

which represent the theoretical model believed to explain the process that produced the experimental data. The model usually depends on one or more parameters. The search for the values of the parameters that best describe the experimental data was performed by minimization of the Chi-square function (χ^2), being the sum of the squares of the differences between the absorbances calculated according to the model and the corresponding experimental absorbances for a range of independent variables. For the case where there is only one independent and one dependent variable the function simplifies to

$$[4] \quad \chi^2\,(p_1, p_2, p_3,....) = (1/d) \sum w_i\,[Y_i - f\,(x_i; p_1, p_2,...)]^2$$

where Y_i are the measured values of the dependent variable for the values of the independent variable x_i; d is the number of degrees of freedom defined as $d = n^{\text{eff}} - p$, where n^{eff} is the total number of experimental points and p the total number of adjustable parameters used in the fitting. The quantities w_i represent the weight of each experimental point. In this work w_i was taken as equal to 1.

The presence of intramolecular hydrogen bonds in mycotoxin structures was inferred from calculations performed by using the HyperChem software package (Autodesk, Inc.). Mycotoxin molecular geometries were optimized by using the MM+ molecular mechanics force field and hydrogen bonds were recomputed. HyperChem creates a hydrogen bond if the distance between the donor hydrogen and acceptor atom is less than 3.2 Å and the angle made by covalent bonds to the donor and acceptor atoms is greater than 150°.

Results and discussion

The equilibria involved in aqueous solutions containing AME or ATX-I (diprotic acids) can be represented in the usual way by the following equations (16):

$$[5] \quad AH_2 \Leftrightarrow AH^- + H^+ \qquad K_1 = [AH^-]\,[H^+] / [AH_2]$$

$$[6] \quad AH^- \Leftrightarrow A^{2-} + H^+ \qquad K_2 = [A^{2-}]\,[H^+] / [AH^-]$$

while those corresponding to AOH (triprotic acid) aqueous solutions must be represented by the following sequence:

$$[7] \quad AH_3 \Leftrightarrow AH_2^- + H^+ \qquad K_1 = [AH_2^-]\,[H^+] / [AH_3]$$

$$[8] \quad AH_2^- \Leftrightarrow AH^{2-} + H^+ \qquad K_2 = [AH^{2-}]\,[H^+] / [AH_2^-]$$

$$[9] \quad AH^{2-} \Leftrightarrow A^{3-} + H^+ \qquad K_3 = [A^{3-}]\,[H^+] / [AH^{2-}]$$

where K_1, K_2, and K_3 are, by definition, the acid dissociation constants for the first, the second, and the third ionization steps, respectively. The brackets represent the equilibrium molar concentrations of the corresponding species. They are

© 1998 NRC Canada

related to the analytical concentration, C_A, through either of the following mass balance equations:

[10] $C_A = [AH_2] + [AH^-] + [A^{2-}]$

or

[11] $C_A = [AH_3] + [AH_2^-] + [AH^{2-}] + [A^{3-}]$

depending upon whether the different equilibria are represented by eqs. [5] and [6] or [7]–[9], respectively.

On the other hand, by assuming that Beer's law holds under the experimental conditions used, the absorbance at a given wavelength, A^λ, can be expressed either as (17)

[12] $A^\lambda = \varepsilon^\lambda_{AH_2}\, b\, [AH_2] + \varepsilon^\lambda_{AH^-}\, b\, [AH^-] + \varepsilon^\lambda_{A^{2-}}\, b\, [A^{2-}]$

or

[13] $A^\lambda = \varepsilon^\lambda_{AH_3}\, b\, [AH_3] + \varepsilon^\lambda_{AH_2^-}\, b\, [AH_2^-] + \varepsilon^\lambda_{AH^{2-}}\, b\, [AH^{2-}] + \varepsilon^\lambda_{A^{3-}}\, b\, [A^{3-}]$

for the di- and triprotic acids, respectively; b represents the pathlength of light and ε^λ are the extinction coefficients of the corresponding species for a given wavelength.

The exact analytical solutions for eqs. [12] and [13] are obtained by expressing the concentration of each species in equilibrium as a function of the acid dissociation constants and of the analytical concentration of the corresponding species. Then, the rearranged forms for eqs. [12] and [13] are

[14] $A^\lambda = C_A\, b\, \{[A(10^{-x})^2 + B\, 10^{-x} + C] / [(10^{-x})^2 + D\, 10^{-x} + E]\}$

and

[15] $A^\lambda = C_A\, b\, \{[F(10^{-x})^3 + G(10^{-x})^2 + H\, 10^{-x} + I] / [(10^{-x})^3 + J(10^{-x})^2 + L\, 10^{-x} + M]\}$

respectively, with x = pH; $A = \varepsilon^\lambda_{AH_2}$; $B = \varepsilon^\lambda_{AH^-} K_1$; $C = \varepsilon^\lambda_{A^{2-}} K_1K_2$; $D = K_1$; $E = K_1K_2$; $F = \varepsilon^\lambda_{AH_3}$; $G = \varepsilon^\lambda_{AH_2^-} K_1$; $H = \varepsilon^\lambda_{AH^{2-}} K_1K_2$; $I = \varepsilon^\lambda_{A^{3-}} K_1K_2K_3$; $J = K_1$; $L = K_1K_2$; and $M = K_1K_2K_3$.

UV–VIS spectra recorded at different pH values for AME, ATX-I, and AOH are shown in Figs. 2(*a*)–(*c*), respectively. They show changes with pH, mainly above pH 8. The absence of an isosbestic point in the pH range was, at first sight, an argument in favor of the occurrence of more than one equilibrium.

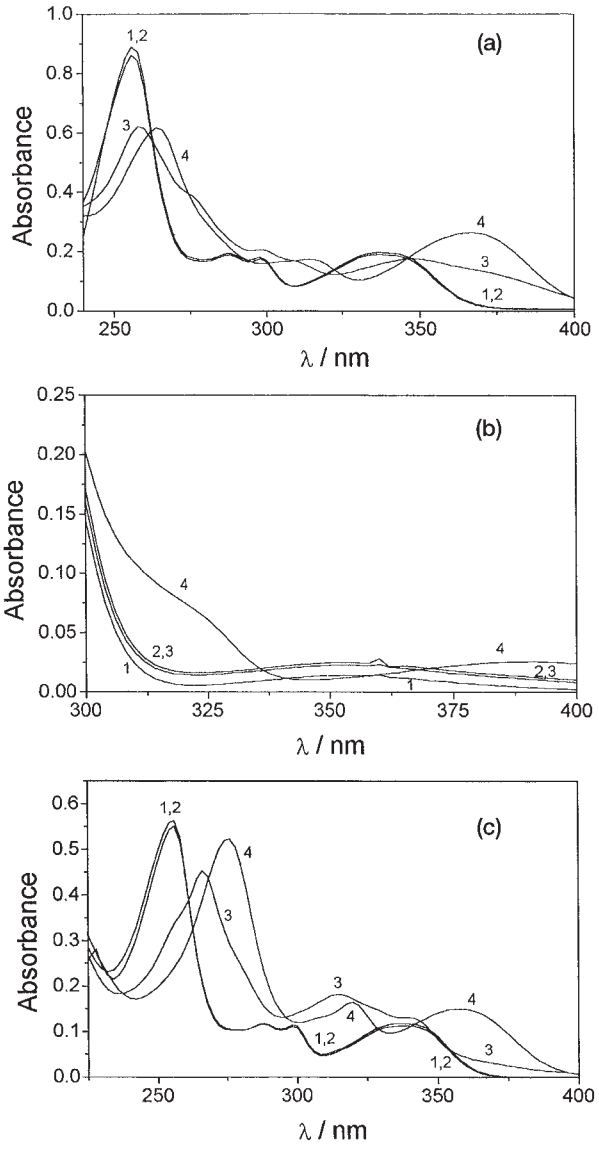
The unknown parameters for each system were estimated by fitting the variation of experimental absorbance with the pH at selected wavelengths (see experimental section).

The theoretical functions chosen to start the fitting were selected as those given by eqs. [14] and [15] for di- and triprotic compounds, respectively. Before starting the fitting procedure the experimental data of A^λ vs. pH were interpolated by a polynomial regression or a sigmoidal curve in order to generate a greater number of points on the select dataset for fitting (experimental curve). At the end of the procedure the fitted parameter values were listed with the corresponding estimated standard errors (σ_i).

A detailed discussion about the choice of the best parameters for each system studied is described as follows.

For AME and ATX-I, values reported for the D and E parameters corresponded to the best fit (the lowest χ^2) for the three wavelengths chosen by considering that those parameters must be independent of the wavelength ($D = K_1$ and $E = K_1K_2$).

Fig. 2. Absorption spectra at different pH for: (*a*) AME (pH = 1.463, 4.616, 8.900, and 12.050 from 1 to 4, respectively), [AME] = 2.35×10^{-5} M; (*b*) ATX-I (pH = 1.066, 4.492, 8.664, and 12.595 from 1 to 4, respectively), [ATX-I] = 2.83×10^{-6} M; and (*c*) AOH (pH = 1.060, 4.360, 8.620, and 13.380 from 1 to 4, respectively), [AOH] = 7.74×10^{-6} M.



Then, they were used as constants for the determination of A, B, and C at the three wavelengths. In the same way, for AOH, the J, L, and M parameters were chosen from the best fit (the lowest χ^2) following the same criteria as explained above. They were then kept constant for the determination of the F, G, H, and I parameters at the three wavelengths chosen ($J = K_1$, $L = K_1K_2$, and $M = K_1K_2K_3$).

AME

Fitting results as well as the extinction coefficients calculated for the different species from the fitting parameters obtained at three wavelengths (λ = 256, 330, and 374 nm) are gathered in Table 1. In Table 1 is also included an estimate of the $\varepsilon^{exp}_{AH_2}$ value at a given wavelength, reached from the experimental

absorbance in the pH range of 1–2 by considering that the species should be the only one in solution in an acidic pH range (see below). A reasonably good agreement between the experimental data and the curve generated with the fitting results was found, as can be seen in Fig. 3(I). On the other hand, the low relative percent error, $\Delta\varepsilon_{AH_2}\%$ (Table 1) shows good agreement between experimental and calculated extinction coefficients.

A distribution of AME acid species as a function of pH was calculated with the parameters determined from the fitting procedure. The results are shown in Fig. 4(*a*). It can be seen that below pH ≈ 7 the only species present is AH_2. This is in agreement with the fact that no change in absorption spectra is observed up to a pH of ≈7. Above this pH, two species are present in an appreciable amount up to about pH ≈10.5 where AH^{-} should be the only predominant species. This can be taken as an additional proof of the quality of the fitting. The experimental ε values at a given wavelength calculated at pH = 10.31 ($\varepsilon^{256}_{exp} = 1.9 \times 10^4$ M^{-1} cm^{-1}; $\varepsilon^{330}_{exp} = 4.4 \times 10^3$ M^{-1} cm^{-1}; and $\varepsilon^{374}_{exp} = 9.0 \times 10^4$ M^{-1} cm^{-1}) are in good agreement with those obtained from the ratio between the *B* and *D* fitting parameters ($\varepsilon_{AH^-} = B/D$) shown in Table 1.

The estimated values of K_1 and K_2 for AME are also gathered in Table 1. A value of $K_1 = 3.34 \times 10^{-9}$ is reasonable when comparing it with the acidity constant value of phenol ($K_a = 1.3 \times 10^{-10}$ (17)) by assuming that two phenolic structures can be found in the AME structure (see Fig. 1). On the other hand, it may be argued that the hydroxyl group in C(3) for AME (see Fig. 1) should be responsible for the first stage of dissociation for this mycotoxin by considering that a K_1 value rather higher than the K_a of phenol was found. This might be explained by assuming that the phenoxide ion generated should be stabilized by resonance in an extension greater than that of the corresponding ion in phenol as a consequence of AME having an electron-withdrawing group (C═O) close to the hydroxyl group in C(3) (see Fig. 1), leading AME to be more acidic than phenol itself. In this way, the second ionization step should correspond to the loss of hydrogen atom bonded to the hydroxyl group in C(4′) (see Fig. 1). Besides, the absence of an intramolecular hydrogen bond between the hydroxyl group in C(3) and the δ-lactone carbonyl group could be verified by theoretical MM+ calculations as indicated in the Experimental.

On the other hand, no change in the absorption spectra recorded at different times during a period of 40 min was observed either at pH = 1.224 (acidic medium) or pH = 10.825 and 12.865 (basic media). This indicates that if a basic hydrolysis of the six-membered ring of the δ-lactone occurs in the AME structure, its kinetics should be very slow, at least up to pH 12.865. This behavior might be understood by assuming that the reaction hydrolysis would take place through a typical nucleophilic acyl substitution pathway in which the hydroxide ion is added to the lactone carbonyl group, giving a tetrahedral intermediate. This could be sterically hindered in AME as a consequence of the bulky substituents involved in that structure. As well, when the solution composed of AME – basic medium was acidified it spontaneously recovered the characteristic form of the absorption spectra for this mycotoxin in an acidic medium. This appears as powerful evidence that true acid–base equilibria exist in solution.

ATX-I

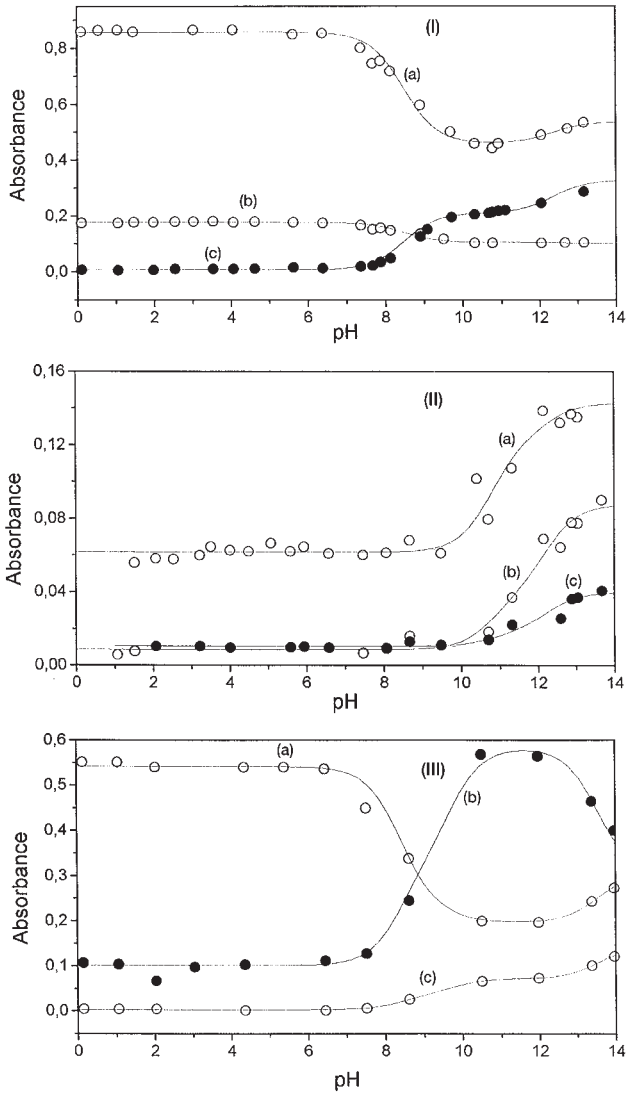
Fig. 3. Comparison between the experimental and theoretical variation of absorbance as a function of pH for: (I) AME: (*a*) = 256 nm, (*b*) = 330 nm, and (*c*) = 374 nm, [AME] = 2.35×10^{-5} M; (II) ATX-I: (*a*) = 306 nm, (*b*) = 324 nm, and (*c*) = 390 nm, [ATX-I] = 2.83×10^{-6} M; and (III) AOH: (*a*) = 256 nm, (*b*) = 280 nm, and (*c*) = 374 nm, [AOH] = 7.74×10^{-6} M. The open and closed circles are the experimental points; the solid lines represent the theoretical curves obtained by the fitting process.



were recorded in the ACN – 1 M $HClO_4$ medium. An absorption maximum was observed at $\lambda = 264$ nm. A plot of A^{264} vs. [ATX-I] was linear, with a correlation coefficient $r = 0.9905$ and a standard deviation sd = 0.05. From the slope of this plot the ε value ($\varepsilon^{264}_{ATX-I} = 3.4 \times 10^4$ M^{-1} cm^{-1}) was calculated.

On the other hand, absorption spectra did not show any change when they were recorded at different times in an acidic medium (pH = 1.224). However, spectral changes with time were observed in basic media (pH = 9.502 and 12.865), showing a solution decomposition. The origin of these spectral changes was not analyzed. However, they were insignificant for time periods below 1 min from the beginning of the solution preparation. Therefore, when absorption spectra for ATX-I solutions as a function of pH were measured, the whole

process (mixing of solutions and recording) did not exceed 1 min (these spectra at different pH values are shown in Fig. 2*b*).

The experimental curves of A^{λ} vs. pH were fitted by the procedure previously described. Results of the fitting process at three wavelengths (λ = 306, 324, and 390 nm) are gathered in Table 1.

A previous estimate of the quality of *A* values can be drawn from the comparison with the $\varepsilon^{exp}_{AH_2}$ by assuming that AH_2 is the only species in solution in an acidic pH range. Thus, the relative percent errors, $\Delta\varepsilon_{AH_2}\%$, are about 10% or lower for the

three wavelengths chosen (Table 1). However, a reasonably good agreement was found between the experimental A^{λ} vs. pH plots and the calculated curves by using the fitting results at the three wavelengths studied (see Fig. 3(II)).

Values of K_1 and K_2 for ATX-I determined from the fitting process are also collected in Table 1. A K_1 value rather lower than the value of the acidity constant of phenol was estimated. A tentative explanation for this behavior might be given by considering that carbonyl groups near the hydroxyl groups in C(4) or C(4′) in the ATX-I structure (see Fig. 1) can be in solution in a keto–enol tautomeric equilibrium. The probable formation of an intramolecular hydrogen bond between the hydroxyl groups in C(4) or C(4′) and those of the corresponding enol tautomers could be responsible for an ATX-I acidity weaker than that of phenol. Theoretical calculations were used to confirm the probable existence of the intramolecular hydrogen bonds between the above-mentioned hydroxyl groups. Furthermore, it should be noticed that a marked structural difference can be found between the ATX-I structure and those corresponding to AME and AOH. When comparing the structures of ATX-I, AME, and AOH, a greater flexibility for ATX-I could be suspected by considering that three aliphatic six-membered rings are found in ATX-I. Besides, it is more difficult to decide which of the two phenolic hydroxyl groups in ATX-I is involved in the first ionization step. A distribution of species as a function of pH for this mycotoxin is shown in Fig. 4(*b*). As can be seen, AH_2 is the only species present in solution below a pH of ≈9. The contribution of AH^- and A^{2-} begins to be appreciable above that pH value.

AOH

AOH absorption spectra in ACN – 1 M $HClO_4$ were very similar to those recorded for AME in the same reaction medium. This can be explained by assuming that there is a similarity between the molecular structures of both compounds (see Fig. 1). These spectra showed an absorption maximum at λ = 256 nm. A plot of A^{256} as a function of the bulk concentration of AOH was linear in the concentration range from 7×10^{-6} to 2×10^{-5} M. From the slope of this plot, ε for AOH ($\varepsilon^{256}_{AOH} = 7.5 \times 10^4$ M^{-1} cm^{-1}) was calculated.

Absorption spectra of AOH did not show any change with time when recorded either at pH = 1.224 (acidic medium) or at pH = 10.825 and 12.825 (basic media) as was previously observed for AME. Also, the acidification of AOH – basic medium solutions allowed recovery of the characteristic form of the AOH absorption spectra obtained in acidic medium. This is evidence that the opening of the δ-lactone ring in the AOH structure in a basic medium should be sufficiently slow to be detected in the time period analyzed (40 min), at least up to pH 13.

The fitting was performed at three wavelengths (256, 280, and 374 nm) in a manner similar to that previously explained for other mycotoxins. Characteristic fitting parameters as well as calculated and experimental ($\varepsilon_{AH^{2-}}$) extinction coefficients with their relative percent errors are collected in Table 2. Good agreement was found between the experimental variation of A^{λ} as a function of pH and the curves calculated for a given wavelength by using the fitting results (see Fig. 3(III)).

Values of K_1, K_2, and K_3 determined from the fitting process are also collected in Table 2. The K_1 value ($K_1 = 4.1 \times 10^{-9}$) is very similar to that previously obtained for AME ($K_1 = 3.34 \times 10^{-9}$). This can be explained by assuming that the molecules are structurally related to one another (see Fig. 1). On the other hand, the fact that K_1 values calculated for AME and AOH are greater than the K_a value of phenol should allow us to infer that the formation of an intramolecular hydrogen bond between the hydroxyl group in C(3) of both AME and AOH and the carbonyl group of the corresponding δ-lactone rings should be absent. This hypothesis was later verified through the MM+ theoretical calculation. A similar conclusion was also reached by other authors (18) who performed a study about solvent effects on these mycotoxins by using both UV–VIS spectroscopic measurements as well as the retention times in normal-phase HPLC. They found that the changes in both spectroscopic and chromatographic properties could be explained by applying Taft's solvatochromic comparison

© 1998 NRC Canada

method (19). Only the Taft β-parameter, which measures the hydrogen-bond acceptor capacity of the solvent, had statistical significance in the correlation. It was also observed that the sensitivity of AOH to that parameter was greater than that of AME. They explained this behavior by assuming that AOH has one more free hydroxyl group than AME (18) (see Fig. 1).

A distribution of AOH species is shown in Fig. 4(*c*). AH_3 is the only species present in solution below pH 7. An appreciable contribution of AH_3, AH_2^-, and AH^{2-} is found from pH 7 to pH 12. $AH^{2-}$and A^{3-} are practically the only species present in solution above pH 12.

By assuming that AH^{2-} should be the only species present in solution close to pH = 12 (see Fig. 4(*c*)), additional proof concerning the quality of the fitting process for this mycotoxin can be reached by comparing the $\varepsilon_{AH^{2-}}$ value determined at pH = 11.98 and the $\varepsilon^{\lambda}_{AH^{2-}}$ value calculated from the fitting results ($\varepsilon^{\lambda}_{AH^{2-}} = H / L$). As can be observed in Table 2, good agreement was found between the $\varepsilon_{AH^{2-}}$ values obtained at that pH value and the $\varepsilon^{\lambda}_{AH^{2-}}$ values obtained from the ratio between the *H* and *L* parameters.

Crystal chemistry of tetraradial species. Part 9. The versatile BPh_4^- anion, or how organoammonium H(N) atoms compete for hydrogen bonding[1]

Katherine N. Robertson, Pradip K. Bakshi, Susanne D. Lantos, T. Stanley Cameron, and Osvald Knop

Abstract: In organoammonium cations containing two or more N atoms, the H(N) atom introduced by the protonation may engage in an N—H(N)···Y bond to an external acceptor (anion or solvent molecule); in an *intra*-cation (intra-annular) N—H(N)···N′ bond; or in a branched N—H(N)···N′,Y bond(s), simultaneously intra-cation and to one or more external acceptors. The outcome of the competition for these bond types is determined by various factors, e.g., the size of the ring to be closed by insertion of the H(N) atom, steric accessibility of H(N), and the H-bond-forming strength of Y. Some of these are discussed in considerable detail and are exemplified by the hitherto unreported crystal structures of the tetraphenylborates (solvated or unsolvated) of the 2,2′:6′,2″-terpyridinium (**1**), 2,3-bis(2-pyridyl)pyrazinium (**2**), 2,2′-dipyridylammonium (**3**), 6,7-dihydro[*b*,*j*][1,10]phenanthrolinium (**9**), 2,4,7-triamino-6-pteridinium (triamterenium, **10**), proton-sponge (1-Me_2N-8-Me_2NH-naphthalene, **11**, **12**), and 9-amino-1,2,3,4-tetrahydroacridinium (tacrinium, **13**) cations. The crystal structures of the comparison compounds 2,3-bis(2-pyridyl)pyrazine (**4**) and its mono- (**2A**) and diprotonated (**3**) chlorides, and of 2-phenylpyridinium (**6**) and 7,8-benzoquinolinium (**7**, **8**) tetraphenylborates, have also been determined. The many interesting features of these crystal structures, such as the X—H(X)...phenyl bonding (X = N, O, C), are commented upon and crystallographic comparisons with numerous literature compounds are offered. Included in the discussion are the monoprotonated intrabridgehead cations of the bicyclic diamines of Alder et al., the N-H(N)-N′ angle of which has been shown, analytically, to be dominated by the size of the smallest of the rings in these tricyclic systems.

Key words: crystal structures, hydrogen bonding, intrabridgehead cations, proton sponges, tetraphenylborates.

Résumé : Dans les cations organoammonium contenant deux ou plusieurs atomes d'azote, l'atome H(N) introduit par la protonation peut donner lieu à une liaison N—H(N)···Y avec un accepteur externe (anion ou molécule de solvant); à une liaison N—H(N)···N′ intra-annulaire à l'intérieur du cation; ou à une (ou plusieurs) liaison(s) ramifiée(s), N—H(N)···N′,Y qui sont simultanément intra-cation et à l'un ou plusieurs accepteurs externes. Le résultat de la compétition pour ces types de liaisons est déterminé par divers facteurs, comme la grandeur du cycle à fermer par l'insertion de l'atome H(N), l'accessibilité stérique du H(N) et par la force de la liaison hydrogène qui se forme avec Y. On discute en détail de quelques-uns de ces facteurs et on en donne des exemples à l'aide de structures cristallines de tétraphénylborates (solvatés et non solvatés) des ions 2,2′:6′,2″-terpyridinium (**1**), 2,3-bis(2-pyridyl)pyridinium (**2**), 2,2′-dipyridylammonium (**3**), 6,7-dihydro[*b*,*j*][1,10]phénanthrolinium (**9**), 2,4,7-triamino-6-ptéridinium (triamtérénium, **10**), de l'éponge à proton (1-Me_2N-8-Me_2NH-naphtalène, **11**, **12**) et 9-amino-1,2,3,4-tétrahydroacridinium (tacrinium, **13**) qui n'avaient pas été rapportées jusqu'à maintenant. On a aussi déterminé les structures cristallines des composés de référence suivants : 2,3-bis(2-pyridyl)-pyrazine (**4**) et de ses chlorures mono- (**2A**) et diprotonés (**3**) et tétraphénylborates de 2-phénylpyridinium (**6**) et 7,8-benzoquinolinium (**7**, **8**). On commente plusieurs caractéristiques intéressantes de ces structures cristallines, telles les liaisons X—H(X)···phényle (X = N, O, C) et on présente des comparaisons cristallographiques avec de nombreux composés de la littérature. La discussion comporte les cations monoprotonés entre les têtes de pont de diamines bicycliques d'Alder et al., l'angle N-H(N)-N′ pour lequel il a été démontré d'une façon analytique qu'il est déterminé en grande partie par la grandeur du plus petit des cycles de ces systèmes tricycliques.

Mots clés : structures cristallines, liaison hydrogène, cations entre les têtes de pont, éponges de protons, tétraphénylborate.

The existence of N—H···phenyl hydrogen bonds in tetraphenylborates (TB) of organoammonium cations is by now well documented (1–3). As might be expected, these H-bonds are ordinarily of the *inter*-ion type. The H(N)···phenyl bond has only moderate or weak strength, and the size and shape of the TB anion are such that under favourable circumstances the H(N) may participate in bonds to other acceptors, viz. in an *intra*-cation N—H···N′ bond, in a normal N—H···Y bond to an external (neutral) acceptor Y, or in a branched N—H···phenyl,N′ or N—H···phenyl,Y bond. Such competition for bonding to the H(N) atom(s) will occur when the free-base molecule contains two or more N atoms, some or all protonable, or when the TB crystal contains solvent molecules with good H-bonding properties (H_2O, MeCN, Me_2CO, etc.), or when both conditions exist. Examples of various combinations of these bonds have been reported previously (1–3). In this paper we focus on providing conditions that are conducive to the formation of *intra*-cation N—H···N′ bonds in tetraphenylborates, sometimes to the exclusion of N—H···phenyl or even any other kind of H(N)-bonding in the crystal.

The cations selected for this investigation (Table 1) contain two or more rings that either form a planar system to begin with (fused-ring systems, **9**–**13**) or are converted to a planar ring system on protonation (*syn* rotamers; **1**, **2**, **5**). The two single-nitrogen cations, in **6** and **7**, have been included for comparison with their two-nitrogen counterparts, the previously (1) investigated cations in **15** and **17** that were found to be singly protonated. In the case of 7,8-benzoquinolinium TB, the crystal structures of both the unsolvated (**7**) and the solvated (**8**) forms have been determined. Also investigated were two solvates of the classical proton-sponge TB, the Me_2CO (**11**) and the $MeCN{\cdot}H_2O$ (**12**) forms. Included for comparison are 2,3-bis(2-pyridyl)pyrazine (**4**) and its mono- and dihydrochlorides (**2A**, **3**).

The two more exotic-sounding cations of **10** and **13**, triamterenium(1+) and tacrinium(1+), were chosen for investigation primarily because of the expected engagement of their several ring and exocyclic nitrogens in N—H···phenyl bonds. However, both are important also for their therapeutically noteworthy activity (18, 29). Triamterene, which contains a rigid pteridine ring system, is a "valuable potassium-sparing diuretic and also a modest inhibitor of dihydrofolate reductase" (17). Tacrine contains a 1,2,3,4-tetrahydroacridine ring system and has found application as an apparently effective acetylcholinesterase inhibitor in the treatment of Alzheimer disease (29).

We also report on our examination of the N—H···N′ bond geometry in the inside-protonated, intrabridgehead bicyclic diamines **44**–**50** investigated by Alder and co-workers (Table 1). These cations afford interesting comparisons with the above aromatic planar-ring cations.

Housekeeping

Crystal data of compounds **1**–**13** are listed in Table 2. The atom numbering adopted for **1**–**13** is a compromise between the IUPAC system and the desire for consistency when comparing corresponding structural features of the ring skeleton systems. The conformations shown in Fig. 1 anticipate those actually found in the crystal structures determined.

Phenyl rings in a TB anion are numbered R1–R4. Aromatic and other rings in a cation are numbered c1, c2, etc.; cat designates the skeleton of the whole cation, and c2/c1, etc. represents the angle between the best planes through the ring skeletons cl and c2, etc. In discussions involving H-bonding to phenyl rings, $\bar{d}$(X···R3), etc. is the mean of the X···C distances to the carbon atoms in ring R3, etc.; Δ(X···C) = $d(X{\cdots}C)_{max} - d(X{\cdots}C)_{min}$ for the same phenyl ring; π_c(R3), etc. refers to the centre of the phenyl ring R3, etc. skeleton.

Unless stated otherwise, the bond lengths and angles have not been corrected for the effects of thermal motion. Corrections, where made, are based on the rigid-body-motion (RBM) model. Crystallographic esd's are quoted in parentheses. No esd's are quoted for bond lengths and angles involving placed and not refined hydrogen atoms. Standard deviations of means of bond lengths and angles are quoted in square brackets. The means were computed with unit weights and their standard deviations do not take account of the esd's of the individual component values.

In discussing N—H bond lengths in N—H···N* bonds, use will be made of the expression

$$[1] \qquad d^* = d_o - b\ \ln\{1 - \exp[(d_0 - d)/b]\}$$

proposed by Steiner (30) for correlating d = N—proton and d = proton···N* distances. For moderately strong, essentially straight N—H···N* bonds (cf. also ref. 31), on introducing $D = d(N{\cdots}N^*) - d + d^*$ and setting $d_0 = 0.996$ Å and $b = 0.381$ Å from ref. 30, eq. [1] can be recast as

$$[2] \qquad d^* = D - 0.996 + 0.381\ \ln\{1 - \exp[(0.996 - d^*)/0.381]\}$$

Since in X-ray diffraction D is always determined with greater accuracy than d or d^*, eq. [2] makes it possible to estimate d and d^* from the N···N* separation alone, thus circumventing the uncertainty in the location of the H(N) atom.

The following tables and figures have been deposited:[5]

A. Positional parameters of the nonhydrogen atoms.
B. Positional parameters and isotropic temperature factors of the H atoms.
C. Anisotropic thermal parameters of the nonhydrogen atoms.
D. Geometry of the tetraphenylborate anions.
E. Planarity of the phenyl rings in the tetraphenylborate anions.
F. X···C and H(X)···C distances in the X—H(X)···phenyl bonds.
G. XOH_2 distances in TPTBw.
Fig. A. 2PyPzTB: difference map in the N(2)-N(2′)-C(2) plane.
Fig. B. 2PyPzCl: difference map in the N(2′)-C(2′2)-C(2′6) plane.

Results and discussion

Intra-cation N—B···N′ ring closure: general considerations

The skeleton topology, the suitability of the local cation

distances in the pertinent (completed) hexagonal cell: *ortho* (*o*) for the two N atoms in a cell edge, at a nominal distance in the template plane of ~1.4 Å (but see below), *meta* (*m*) and *para* (*p*) across the hexagon, at ~2.4 and ~2.8 Å, respectively.[6]

The planar template cell containing the two N atoms cannot be completed, i.e., the ring cannot be closed by an intra-annular N—H(N)···N′ bond, without distortion of the cation geometry. Insertion of a H(N) atom into the free-base molecule will result, on closure, in a 7-membered ring for the *o* type, a 6-membered ring for the *m* type, and a 5-membered ring for the *p* type; the template geometry for a 4-membered ring is unfavourable for closure (Fig. 2). Because the N—H(N) bond (nominally 1 Å) is shorter than the mean cell edge, the H(N) atom will not fall on any cell apex in the template.

It is immediately obvious that in the *o* case the H(N) atom introduced by the protonation cannot be accommodated between the two N atoms ~1.4 Å apart without a significant departure from planarity if reasonable skeleton bond angles are to be maintained. There will also be some "hydrophobic" shielding of the H(N) proton from involvement in *external* H-bonding by the H(C) atoms on the neighbouring exposed ring carbons.[8] In the *m* and *p* cases an appreciable departure from planarity on ring closure would not be expected, but some in-plane distortion should result, partly because of the H(N)···N′ interaction and partly because of the expansion of the endocyclic *ipso* angle at the N atom on protonation. The

[6] Genuinely three-dimensional situations (e.g., **57**) would require a three-dimensional template, less likely to be useful than the planar template of Fig. 1. For the special case of the inside-protonated, intrabridgehead cations of bicyclic diamines (34–46; see also footnote 7), see a later section.

situations obtained are illustrated, in terms of the template geometry, in Fig. 2. The N-H(N)-N′ angle, which decreases with the decreasing ring size, is favourable for the formation of a bifurcated H(N)···N′,Y bond to an external acceptor Y in both the *m* and *p* systems, until exclusive formation of unbranched H-bonds to external acceptors is-expected for 3-membered N-C-N′ groups.

Intra-cation ring closure: present results

Tables 3 and 4 provide synoptic presentations of the N—H···N′ ring-closure situations in our structures as well as in the comparison structures of Table 1.[9] The results, without exception, agree with the expectations outlined in the preceding section.

[9] For details and for other aspects of the structures the reader is referred to the descriptions of the individual crystal structures below.

In the ortho case, analysis of our example, 2PyPzTB (**2**), substantiates two points: (*i*) protonation, of only one of the pyridine nitrogens, does result in ring closure, and (*ii*) the expected nonplanarity of the pyridine rings is confirmed, c2′/c2 = 14.3°. The first point is not trivial. Ring closure very similar to that in **2** is observed in the counterparts of **2**, the analogous TBs of the 2,3,5,6-tetra(2-pyridyl)pyrazinium(2+) (**22**) and 2,3-bis(2-pyridyl)quinoxalinium(1+) cations (S.D. Lantos, T.S. Cameron, and O. Knop, to be published). In **22** the centrosymmetric diprotonated (two protons per four pyridine nitrogens) cation has ring closure on both sides of the pyrazine ring, with a c2′/c2 angle between the two ipsolateral pyridine rings of ~37°. The relevant geometry of the 2,3-bis(2-pyridyl)-quinoxalinium(1+) cation is practically the same as that of the cation in **2**. The free bases of the cations in these last two TBs are known to occur with both the *syn* and the *anti* conformations (**19** and **20**, **23** and **24**). If the ground-state conformation

Fig. 1. Idealized (flattened) ring systems of cations in Table 1; all can be embedded in the heavily outlined portion (**a**–**g**) of the honeycomb template. Large black circles, N atoms; small black circles, H(N) atoms introduced by protonation; small open circles, H(N) atoms present before protonation. The conformations shown correspond to those actually found. The atom and ring numbering in **6** and **7** matches that in **15** and **17**, respectively (1). The Me groups on N(1) and N(8) of **11** and **12** are not shown.

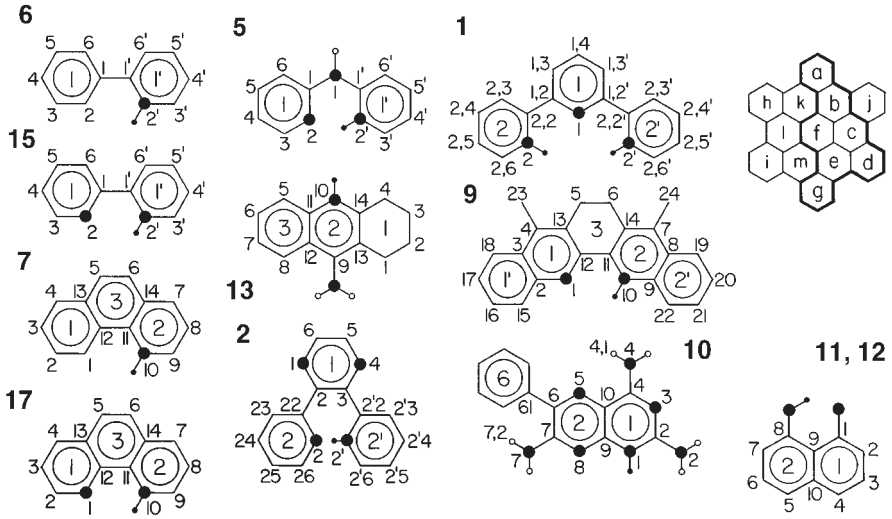

Fig. 2. Possible formation of intra-cation H-bonds through intra-annular N—H···N′ ring c1osure resulting in 6-, 5-, and 4-membered rings. The approximate distances and angles shown are for undistorted planar ring systems of Fig. 1 and for N—H bond lengths of nominally 1 Å. H(N) atoms in the 6- and 5-membered rings are likely to form bifurcated H(N)···N′,Y bonds to external Y acceptors, while those in the putative 4-membered ring are likely to form normal, possibly somewhat bent H(N)···Y bonds (see text).

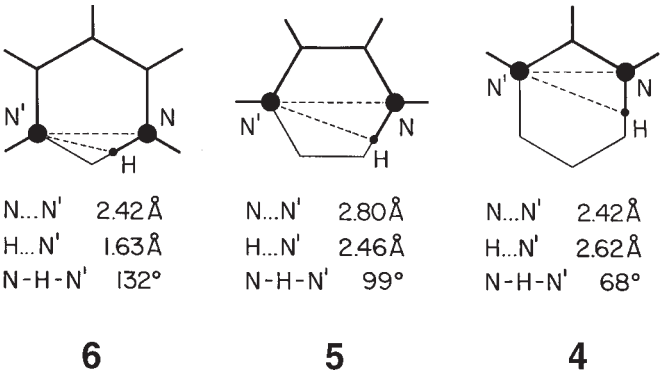

of the free base is *syn* and is maintained in the crystal, the ring closure on formation of the TB will merely correspond to a natural, minimum-energy conformational adjustment. If, however, the ground-state conformation is *anti*, the existence of a crystalline *syn* form of the free base must be due to crystal forces. The existence, then, of a protonated *syn* conformation in the TB crystal means that the energy of the ring closure must be sufficient to overcome the *anti–syn* conversion barrier, with or without assistance from crystal forces. If the ground-state conformation of the free base is *anti*, the *syn* conformation in the TB is then the result of a positive tendency of the proton to effect ring closure. Adequate conformation-energy calculations or, better still, experimental evidence of the conformational preference in the free base would be required to resolve this problem. For the free base of **2** only the *syn* form (**4**) has been reported, but it seems possible that the situation here parallels that of the two preceding cations and that an *anti* form may eventually be found.[10]

The ring closures in the TBs **2** and **22** correspond to short normal (i.e., unbranched) N—H(N)···N′ bonds (Table 4). There is no effective H-bonding interaction between H(N) and the anion. In **2** the three shortest H(N)···C(phenyl) distances are H(2′)···C(132) = 3.66(4) Å (N(2′)···C(132) = 3.656(4) Å, N(2′)-H(2′)-C(132) = 80(2)°); H(2′)···C(142) = 3.87(4) Å (N(2′)···C(142) = 4.225(4) Å, N(2′)-H(2′)-C(142) = 100(4)°); and H(2′)···C(133) = 3.90(4) Å (N(2′)···C(133) = 3.493(4) Å, N(2′)-H(2′)-C(133) = 61(2)°); all the other H(N)···C(phenyl) distances are longer than 4.0 Å (Tables 5 and F). In **22** the two shortest H(N)···C(phenyl) distances are ~3.15 Å (N···C = 3.54 Å, N-H(N)-C ~ 98°) and ~3.43 Å (N···C = 3.65 Å, N-H(N)-C ~ 90°), both to the same phenyl ring; all the other H(N)···C(phenyl) distances are ≥ 3.6 Å, with the corresponding N-H(N)-C angles between 61° and 99°.

In the corresponding *chlorides* **2A** and **21**, both with the pyridine nitrogens *syn* to each other, closure of the 6-membered ring through proton insertion is precluded by the large c2′/c2 angle, 55.5° and 60.0°, respectively, the consequence of a competing strong inter-ion N—H(N)···Cl bond (Fig. 3). In **3**, in which *both* pyridine nitrogens are protonated, closure of the

[10] The pyridinium nitrogens are *syn* also in **41** and **43**. In **41** the angles between the pyridine and pyrazine rings are ~43° and ~24°, respectively. Protonation of **41** is reported to result, in the tetrafluoroborate **42**, in ring c1osure but with the proton in two locations with, respectively, 0.8 and 0.2 occupancy factors and N—H and H···N′ distances of 0.79(4) and 1.80(4) Å, and 1.08(11) and 1.49(10) Å. The occurrence of alternative locations may be associated with the disorder of the BF_4^- anion, although in the analogous case of the perchlorate **27** (Table 4) only one proton location is mentioned. For the stated N···N′ distance of 2.574(4) Å in **42**, eq. [2] yields *d*(N···H) of ~1.14 Å and ~1.43 Å if the stated N-H-N′ angles of 169(4)° and 172(4)°, respectively, are taken as sufficiently c1ose to 180°.

[a] Other examples will be found in Tables 3 and 4 of ref. 1. *o*,*o*, *m*,*m*, *p*,*p*: *two* pairs of eligible N atoms.

[b] Intra, N—H(N)···N′ intra-cation bond; inter, external N—H(N)···Y bond to an anion, to an adjacent molecule, or to a solvent molecule, involving the H(N) atom of the N—H(N)···N' intra-cation bond. H(N)···N',Y bonds are bifurcated.

[c] H(N) partially shielded from possible external acceptors by vicinal H(C) atoms.

[d] Free base (**19**, **20**) and dihydrochloride (**21**) colourless; **22** yellow both in crystal and in solution (MeCN + MeOH).

[e] See text.

[f] Also N(1)—H(1)···O and O—H(O)···phenyl interactions.

[g] Also H(C)···phenyl interactions.

[h] H_2O molecules disordered.

[i] Both N atoms protonated. The H(1)-N(1)-C(12)-C(11)-N(10)-H(10) group is closed by the O atom of a H_2O molecule to yield a 7-membered ring.

[j] The pertinent H(N) atom(s) is present before protonation.

[k] N atom of a neighbouring molecule.

[m] Also O—H(O)···phenyl interactions.

[n] N(10)—H(10)···MeCN, N(9)—H(9A/B)···phenyl.

[p] N(10)···H(10)···H_2O, N(9)—H(9A/B)···Cl.

6-membered ring is prevented by the change in the orientation of ring c2 from *syn* to *anti* relative to c2′. This change is associated with the formation of a *second* H(N)C1 bond and results in the closure of the *4-membered* ring between c2 and cl, i.e., between N(2) and the pyrazine nitrogen N(1). This closure, with a strong inter-ion component, belongs to the *p* class (Table 4).

In the meta case, conversion of the free base into the cation of **5** brings the two pyridine rings into a *syn* conformation and results in the closure of the N(2)-C(l)-N(l)-C(l′)-N(l′) group and thus in the formation of a relatively unstrained 6-membered ring (Fig. 1). An analogous N(l)-C(l)-C(9)-C(8)-N(8)-H(8) ring is formed when the classical, rigid-skeleton proton sponge 1,8-$(Me_2N)_2$-naphthalene is protonated to the cation of **11** and **12** (Fig. 1); an example of the corresponding *two-sided* proton-sponge cation is provided in **28**. The N-H(N)-N′ angles in these cations are more or less in the expected range of 130°–140°.[11] The eligible acceptors of H(N) are a phenyl group in **5**, the acetone oxygen in **11**, the MeCN nitrogen in **12**, and a Br^- anion in **28**. The H(N)···Y distances to these acceptors (Tables 4 and 5) are considerably longer than would be expected for unbranched H-bonds, but the orientations of the acceptors with respect to the cation are such as to support the existence of weak H-bonding interactions, cf. the N-H(N)-Y angles, all in the same general range of 100°–120°. The question of whether such H(N)···Y distances represent H-bonds will have to await detailed deformation electron density studies.

In the para case, the N-H(N)-N′ angles (Table 4) are, as expected, significantly smaller, in the range of 85°–110°. The estimated shortest H(N)···C(phenyl) distances range from ~2.35 to ~2.9 Å. The distances from H(N) to other acceptors appear to qualify for weak or very weak H-bonds, but in several cases the geometries are not clear-cut, since the acceptor atom is involved in positional disorder. The N-H(N)-Y angles form a reasonably homogeneous set, with an approximate mean value of 135[15]°. On the whole, ring closure in the *p* groupings can be said to result in the formation of bifurcated N—H(N)···N′,Y bonds to phenyl as well as other acceptors.

An interesting *p* case is **18**, which contains a *doubly*-protonated 1,10-phenanthrolinium(2+) cation. Since both N atoms of the rigid ring system are protonated, closure of the six-atom H(1)-N(1)-C(12)-C(11)-N(10)-H(10) group can only take place by co-option of an external acceptor capable of simultaneous bonding to both H(1) and H(10). This atom is the oxygen of an H_2O molecule. The structure of **18** contains two nonequivalent cations and two nonequivalent water molecules; the bond lengths and angles averaged over the two cations can be compared with the corresponding mean values in the monoprotonated 1,10-phenanthrolinium(l+) cation (Tables 3 and G of ref. 1):

[11] The mean of the N-H(N)-N′ angles in the c1assical proton-sponge cations in Table 4 of ref. 1 is 155[5]°.

[a] Distances (Å) involving H(N) atoms are estimated to be accurate to within ±0.05 Å, angle to within ±5°. For N···Y distances see Table 8. O_w, oxygen atom of an H_2O molecule. Entries in square brackets refer to H(N)···Y bonds that are at best marginal.

[b] See text.

[c] No external bond. Oxygens of the ClO_4^- anion are disordered; the values quoted here refer to one O set only.

[d] Disordered BF_4^- anion (see footnote 10 in text).

[e] N(2')—H(N2′)···Cl(1); potentially *o* type but no intra-cation ring closure.

[f] N(2)—H(N2)···N(1),Cl(2); intra-cation ring closure to pyrazine N(1) atom.

[g] The shortest N···C(R2) and H(N)···C(R2) distances in **5**.

[h] The shortest N···C(R1) and H(N)···C(R1) distances in **9**.

[i] The shortest N···C(R2A) and H(N)···C(R2A) distances in **15**.

[j] Trifurcated H(N)···N',R3,R1 bond, see ref. 1.

[k] These are the averages of the distances in the two nonequivalent *diprotonated* cations in **18**, in which an O_w atom closes the H(1)-N(1)-C(12)-C(11)-N(10)-H(10) group to form a 7-membered ring. Each H(N) atom may be regarded as involved in a weakly bifurcated N—H(N)···N',O_w bond with H(N)···O_w as the principal component (see text).

[m] N atom of an adjacent molecule.

[n] H(N) disordered.

	Dication	Monocation
C(11)—C(12)	1.421[7] Å	1.431[3] Å
N(1)···N(10)	2.873[4] Å	2.722[9] Å
H(1)···H(10)	1.94 Å	—
N(1)—C(12) } N(10)—C(11) }	1.366[6] Å	{ 1.356[1] Å, 1.358[6] Å }
H(N)···N′	2.56[4] Å	2.38[3] Å
N-H(N)-N′	97[3]°	102[3]°
N···O	2.757[24] Å	—
H(N)···O	1.76[2] Å	—
N-H(N)-O	169[12]°	—

The differences for N(1)···N(10) and H(N)···N′ are statistically highly significant, whereas the difference for N-H(N)-N′ is not significant (*t* test for two means). Thus while the protonation at N(1) has little if any effect on the C(11)—C(12) bond length, the significant expansion of the N(1)···N(10) distance and the attendant changes in the bond angles (cf. Fig. 8 of ref. 1) are such as to separate H(1) and H(10) by ~1.94 Å. This separation apparently is sufficient, on closure by the O atom, to maintain planarity of the resulting 7-membered ring;[12] the N···O ~ 2.76 Å

[12] The skeleton of cation 1 is planar to 0.01[1] Å and that of cation 2 to 0.02[1] Å; the deviation of the pertinent O atom from the cation plane is 0.07 Å for cation 1 and 0.00 Å for cation 2.

Fig. 3. Conformations in the crystal structures of 2-pyridyl-substituted pyrazines (**4**, **19**, **20**) and quinoxalines (**23**, **24**), and H-bonding in their chlorides (**2A**, **3**, **21**) and tetraphenylborates (**2**, **22**). The angle between the pyrazine (or quinoxaline) and the pyridine planes is indicated next to the pyridine ring, and that between the planes of the two ipsolateral pyridine rings (the acute angle) at the bottom of each figure. Large black circles, N atoms; small black circles, H(N) atoms; large open circles, Cl atoms; broken-line hexagons, anion phenyl rings potentially eligible for N—H(N)···phenyl bonding. The orientations of the ring systems match those of Fig. 1. Note the similarity of the pyridine/pyridine angles in the free bases.

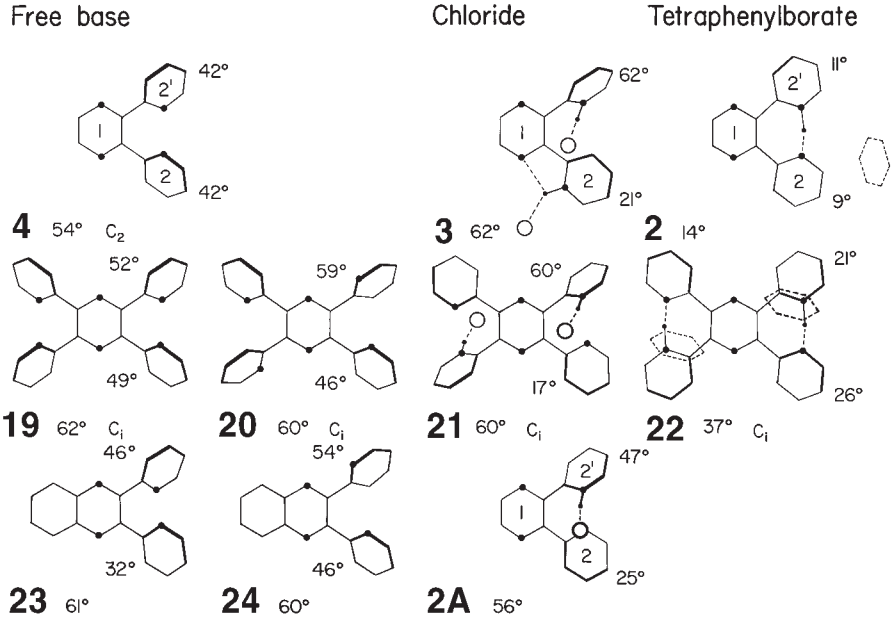

Fig. 4. N-H-N′ angle vs. *d*(N···N′) in the inside-protonated cations **44**–**50**. Large circles, experimental values (with N-H-N′ esd bars); small circles, values obtained from eq. [3]. The results of a regression of N-H-N′ on *w* and *d*(N···N′) alone are indicated by broken lines.

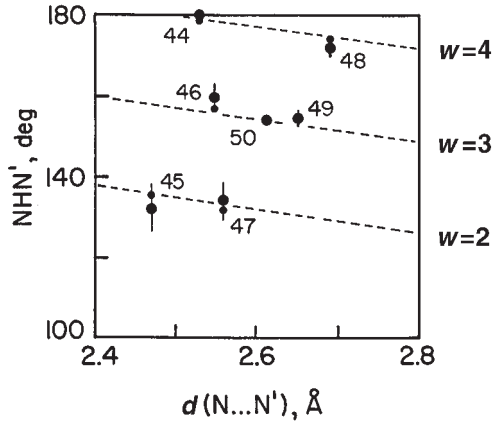
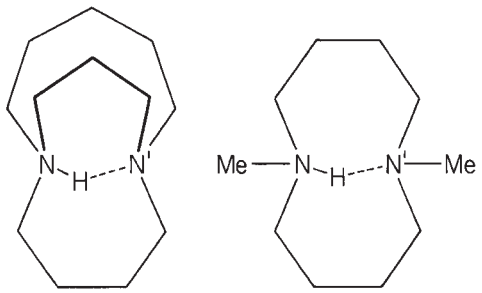


distance and the N-H(N)-O ~ 169° angle are in the normal range for weak to moderately strong N—H···O bonds.

It is interesting to note that the N-H(N)-N′ angles in **18** are much the same as the corresponding angles in the monocation, i.e., the intra-cation N-H(N)-N′ closure angle appears to be unaffected by the presence of the second H(N) atom.

Intra-cation N—H···N′ ring closure: intrabridgehead cations

In saturated, nonplanar ring systems, ring closure on protonation leads to less predictable results. Nevertheless, circumstances exist in which the cation system may possess sufficient rigidity to permit the N—H···N′ geometry to be rationalized. A case in point that merits examination in this context are the bicyclic diamines extensively investigated by Alder and coworkers (34–46, and footnote 7). Protonation of these molecules may result in the formation of inside-protonated intrabridgehead cations. When it does, insertion of the proton effects simultaneous closure of *three* saturated rings (**44**–**50**) with little or no opportunity for bifurcation to external acceptors:



46 [5.4.3] [4.4.Me_2]

Of particular interest here is the wide variation of the N-H-N′ angle, which is reported to range from ~132° to ~180°.

Inspection of the pertinent geometric parameters of **44**–**50** (Table 6) suggests that these parameters are interrelated and that the dominant correlation occurs between the N-H-N′ angle ϕ and the size of the smallest, (*w*+3)-membered cation ring, with possible secondary association with *d*(N···N′). The sample is too small for a more elaborate statistical treatment, but even the simplest model, a linear regression of ϕ on *d*(N···N′)

	10	N(3)	2.01	—	—	—	—	170°	

[a] Distances in Å; for d(X—H) see Experimental. $d_{min} = d[X\cdots C(R)]_{min}$ or $d[H(X)\cdots C(R)]_{min}$, i.e., the shortest X···C(R) or H(X)···C(R) distance, respectively; $d(\pi_c) = d[X\cdots\pi_c(R)]$ or $d[H(X)\cdots\pi_c(R)]$. X-H-C_{min} is the X-H(X)-C angle corresponding to $d[H(X)\cdots C(R)]_{min}$; when the shortest X···C distance is to a different carbon of R than the shortest H(X) distance, the mean of the X-H-C′ and the X-H-C″ angles is given. X-H/R = angle formed by the X–H(X) vector with the R plane. For distances to individual C atoms see Table F.

[b] In the absence of another indication, X = N, H(X) = H(N).

[c] $\pi_c(c2)...\pi_c(R2) = 4.87$ Å.

[d] A: x, ½ – y, ½ + z.

[e] A: ½ + x, ½ – y, ½ + z; B: (3/2) – x, y – ½, (3/2) – z.

[f] N atom of MeCN.

[g] Bifurcated intra-cation N(4)—H(4,1)···N(5), R(1A) bond; N(4)-H(4,1)-N(5) - 84°.

[h] A: x, y, z + 1.

[i] A: x, y – 1, z.

[j] A: 1 – x, 1 – y, 1 – z.

(which is better determined than d(N—H)) and the numbers u, v, and w of the carbon atoms in the three rings ($u \geq v \geq w$),

[3] $\phi = 145.3 + 0.19u - 1.72v + 22.39w - 19.72d(N\cdots N')$

confirms that ϕ is indeed strongly correlated with w but only weakly with d(N···N′) and shows that changes in w and d(N···N′) work in opposite directions: $r^2 = 0.986$, with the residual standard error of the regression $\sigma = 3.6° \sim 7.5\%$ of range and with the pairwise correlation coefficients

	u	v	w	d(N...N′)
ϕ	–0.36	–0.09	0.99	0.41
d(N···N′)	0.52	0.45	0.50	1

The other correlations, while not negligible, have an even smaller effect on ϕ than d(N···N′); in fact, regressing ϕ on w and d(N···N′) alone gives a fit not significantly different from that of eq. [3]. The distance d(N···N′) correlates very weakly but about equally with the other four variables.[13]

While approximating ϕ by a *linear* function is not unassailable, it is clear that w will dominate ϕ far more strongly than any of the other parameters no matter what the representation (Fig. 4). This undoubtedly reflects the limits on conformational adjustment that are narrowest for the smallest ring and thus determine the relative orientations of the N–H vector and of the axis of the lone pair at N′.[14] This finding may not come as a surprise, but eq. [3] puts it in proper perspective.

Since no structures of *simple* cations of this type other than **44**–**50** appear to have been reported, the extent of the usefulness of eq. [3] remains to be seen. However, the applicability of the correlation may well extend to more varied systems. Thus the ϕ angle calculated from eq. [3] for the inside-monoprotonated [5.5.3] cation in **51** is 154° compared to the ~158° estimated from the crystal-structure determination. For the [5.5.4] cation in **52** the agreement between the calculated ϕ of 173° and the experimental value of ~167° is less satisfactory. In the inside-monoprotonated cation of the macrocyclic amine in **53** the acidic H(N) atom is inside a pseudo-C_2 tetrahedron

[13] When d(N···N′) is regressed on the ring-size parameters only (thus exc1uding the uncertainties in the H(N) location), the result is $d(N\cdots N') = 1.838 + 0.073u + 0.040v + 0.065w$ ($r^2 = 0.81$, σ = 0.048 Å ~ 22% of range), i.e., the increase in d(N···N′) with each of u, v, and w is of the same order but the correlation is weak.

[14] The problem of which N—H···N′ geometry in these cations corresponds to a single-well, a symmetric double-well, or an asymmetric double-well potential does not appear to have been completely solved as yet (44). For ir and nmr spectra of the intrabridgehead cations in solution, see ref. 36.

50	6.5.3	2.610 (5)	1.19 (3)	154 (3)°	153.5°	–0.5°
44	4.4.4[c]	2.526 (3)	1.278 (2)	180°	178.9°	–1.1°
48	5.5.4	2.690 (4)	1.096 (33)	171.7 (17)°	174.2°	2.5°

[a] Parameter values from refs. 35 and 38–43; distances in Å; $u \geq v \geq w$, numbers of C atoms in the respective (—$(CH_2)_n$N—H···N′-) rings of the cation. NHN'_{calcd} from eq. [3].
[b] Neutron diffraction at 130 K.[7]
[c] Neutron diffraction at 20 K[7].

of the *endo* atoms N(1)–N(4), with the in-plane bridgehead atoms N(2) and N(4) at 2.636(7) Å and the off-plane atoms N(1) and N(3) at 3.081 Å; the N···H(N) distances are 1.35(9) Å to N(4), 1.38(9) Å to N(2), 2.13(9) Å to N(3), and 2.29(9) Å to N(1). The intrabridgehead bond is thus essentially N(2)—H(N)···N(4), with an N(2)-H(N)-N(4) angle of ~150°. The cation may therefore be regarded as an inside-protonated three-ring [5.5.3] system, with N(2) and N(4) as the bridgehead atoms, one 3C ring, two 2C + N + 2C rings, and a 3C bridge between N(1) and N(3). Setting $u = v = 5$, $w = 3$, *d*(N···N′) = 2.636 Å, the ϕ angle obtained from eq. [3] is 153°, in agreement with the experimental value if the uncertainty in the location of H(N) is taken into account. The distance between a bridgehead and a nonbridgehead N atom ranges from ~2.75 to ~2.85 Å and is thus not appreciably longer than N(2)···N(4), but the ϕ angle spanning it is only about 100° and must correspond to a substantially weaker H-bonding interaction.[15]

Equation [3] also accommodates the unbridged two-ring *cis*-1,6-Me_2-1,6-diazacyclodecanium(1+) cation (= [4.4.Me_2] (44, 45); see line drawing). Substitution of the experimental values ϕ = 169(2)° and *d*(N···N′) = 2.60 Å into eq. [3] yields $w = 3.6$. This cation thus fits between the [4.4.3] and [4.4.4] systems, which seems reasonable since the two *N*-Me carbons, although not in a ring and thus not constrained, may be regarded as parts of a virtual, uncompleted low-strain 5- or 6-membered third ring.

The ϕ angle in **44**–**50** for a given *w* is larger than the ϕ angle in a ring of corresponding size in the quasi-planar cations discussed in the preceding section (Fig. 2): $\phi(w)_{intrabr.} = 76.5 + 0.58\ \phi(w)_{planar}$. The conditions for the formation of an N—H···N′ bond are thus more favourable in the former, in spite of the conformational constraints imposed by the three-dimensional aliphatic three-ring system on protonation.

Geometry of the H(X)···phenyl interactions

The relevant numerical parameters are assembled in Table 5; the corresponding structural details will be found under the individual crystal structures below. As shown in ref. 3, such a body of information can be examined in various ways and treated statistically depending on the specific purpose. Here we limit ourselves to consideration of the two perhaps most important parameters, $d[X\cdots C(phenyl)]_{min}$ and $d[H(X)\cdots C(phenyl)]_{min}$. For X = N and N-H(N)-$C_{min} \geq 90°$, the means of the 14 values are 3.37[17] Å ($\gamma_1 = -0.34$, $\gamma_2 = 4.03$) for $d[N\cdots C(phenyl)]_{min}$ and 2.64[22] Å ($\gamma_1 = 0.45$, $\gamma_2 = 2.18$) for $d[H(N)\cdots C(phenyl)]_{min}$.[16] This compares with the means 3.37[12] Å ($\gamma_1 = 0.76$, $\gamma_2 = 3.23$) and 2.60[20] Å ($\gamma_1 = 0.67$, $\gamma_2 = 3.07$) for the 47 TB structures in Table 7 of ref. 3.[17] The corresponding means for the two X = O cases in **5** are 3.34[2] Å and 2.49[2] Å, respectively,[18] and for the nine X = C bonds in the two proton-sponge TBs **11** and **12**, 3.69[14] Å ($\gamma_1 = 0.95$, $\gamma_2 = 3.19$) and 3.06[14] Å ($\gamma_1 = 1.44$, $\gamma_2 = 4.18$).

Based on these statistics, the expectation values of the minimum X···C(phenyl) and H(X)···C(phenyl) distances to the associated-ring carbons in TB structures would appear to be 3.4[2] Å and 2.6[3] Å for X = N, O, and 3.7[2] Å and 3.1[2] Å for X = C. Thus with some exceptions (e.g., BQTBs, PSTBs, PSTBw), in organoammonium TBs the anion always provides an opportunity for an H(N)···phenyl separation in a range acceptable for an effective H-bonding interaction. In BQTBs, the introduction of MeCN results in a winning competition for H-bonding in favour of the strongly polar solvent molecule; in **11** and **12** the combination of overall packing requirements, closure of the 6-membered ring, and the presence of polar solvent molecules supervenes, with the result that a priori conceivable H(N)···phenyl interactions are replaced by H(C)···phenyl interactions (cf. below).

Noteworthy also is the variability of the angle of inclination X-H(X)/R of the X-H(X) vector to the phenyl plane, and of the related quantity Δ, which indicates the displacement of X or H(X) from the perpendicular through the centre π_c of the phenyl ring (cf. Housekeeping and ref. 3). For the 30 H(X)···phenyl bonds of Table 5 the means of Δ(X···C) and Δ[H(X)···C] are 0.76[57] Å ($\gamma_1 = 0.79$, $\gamma_2 = 2.67$) and 0.95[57] Å ($\gamma_1 = 0.51$, $\gamma_2 = 2.35$), respectively, with both distributions skewed toward zero. This means that only rarely would X or H(X) be above π_c. Information concerning X-H(X)/R and Δ acquires special relevance when deformation electron density and bond-path topology in X—H(X)···phenyl

[15] If the H(N) atom is regarded as located between a bridgehead and a nonbridgehead N atom, and the cation as a [6.6.2] three-ring system with an extra bridge between two N atoms, the ϕ angle from eq. [3], for *d*(N···N′) = 2.80 Å, is 125°.

[16] $\gamma_1 = m_3/m_2^{3/2}$, moment coefficient of skewness; $\gamma_2 = m_4/m_2^2$, moment coefficient of kurtosis. For a normal distribution, $\gamma_1 = 0$, $\gamma_2 = 3$.

[17] Bond lengths in ref. 3 calculated assuming N—H = 1.02 Å, O—H = 1.00 Å.

[18] 3.41[5] Å ($\gamma_1 = -0.05$, $\gamma_2 = 2.15$) and 2.62[17] Å ($\gamma_1 = 1.28$, $\gamma_2 = 2.94$) for the ten X = O cases in Table 7 of ref. 3.

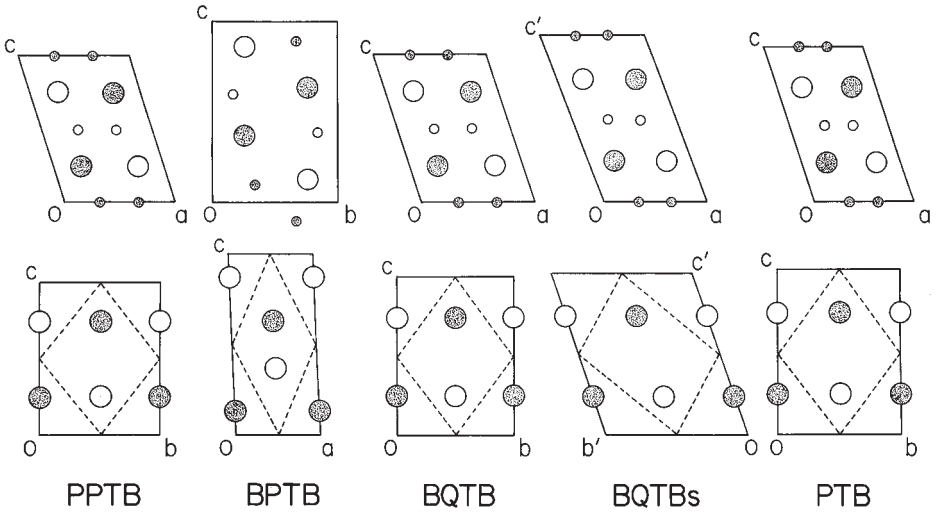
Fig. 5. Matching projections of the unit cells and of the B atom and cation centroid $\bar{c}$ positions designed to display similarity of ion packing in PPTB, BQTB, and PTB ($P2_1/c$), BQTBs ($P\bar{1}$, see text), and BPTB ($P2_1/n$). *Bottom*: Large circles, B atoms at $x \sim$ ¼ (open) and $x \sim$ ¾ (stippled). The symmetry centres, at x = ½, relating the $\bar{c}$ in closest cation pairs define the corners of CdI_2-type cells (broken lines). *Top*: Large circles, B atoms at $y \sim 0$ (open) and $y \sim$ ½ (stippled). Small circles, cations centroids $\bar{c}$ at $y \sim 0$ (open) and $y \sim$ ½ (stippled). Note that for BPTB x and y are reversed.



bonds are investigated (W. Kwiatkowski, K.N. Robertson, T.S. Cameron, and O. Knop, work in progress).

PPTB, BQTB, and BQTBs: comparison with BPTB and PTB

The unsolvated PPTB (**6**) and BQTB (**7**) investigated in this work form chemically matched pairs with the TBs BPTB (**15**) and PTB (17) reported previously (1). The introduction of a second ring nitrogen into the cation skeletons of PPTB and BQTB opens up the possibility of formation of an intra-cation N—H···N′ bond that is absent in the single-nitrogen cations. This provides an opportunity for examining the effect of the intra-cation bond on the geometry of the cation and on the ion packing.

PPTB, BQTB, and PTB crystallize in the same space group, $P2_1/c$, and their cell dimensions and axial ratios are similar; the monoclinic angle β is almost constant, $\bar{\beta}$ = 107.65[26]° (Table 7). The packing of the *ions* cannot be related directly in a natural manner to any of the simple 1:1 packing types. However, the cations in each of the three structures occur in centrosymmetric pairs in which the minimum separation $\bar{c}\cdots\bar{c}$ of the cation centroids is of the order of 4 Å.[19] When the three structures are juxtaposed, after appropriate shifts of origin to match up the atom positions with those tabulated for

[19] The smallest $\bar{c}\cdots\bar{c}$ separations in PPTB, BQTB, and PTB are 4.30, 4.13, and 4.61 Å, respectively; in BPTB, 6.29 Å.

© 1998 NRC Canada

PTB in ref. 1 (Fig. 5),[20] the symmetry centres relating the cations in each pair are seen to be located at equipoints 2(*d*) of $P2_1/c$, i.e., at points of a lattice complex *A*2/*m*. The B atoms of the anions, which are close to the anion centroids, occupy, in the standardized $P2_1/c$ cells, positions that differ only slightly from (¼, 0, ¾) etc. The packing of the cation-pair centres and the anion centroids can thus be regarded as a monoclinically distorted packing of the CdI_2 type. This is illustrated in the projections of the three structures on (100) in Fig. 5. However, the inclination to (100) of the cation planes in the pairs varies considerably, as does the shortest $\bar{c}\cdots\bar{c}$ distance, so that the actual ion packing has a different appearance in each of the projections. The characteristic orientation of the phenyl rings of the anion (in a conformation of approximate C_s symmetry) is one in which one of the rings is in the quasi *m* plane approximately ||*a*, another approximately perpendicular to that plane, and the remaining two more or less symmetrically disposed about the quasi *m* plane.

The similarity of ion packing is seen to extend even to the solvated BQTBs if the triclinic $P\bar{1}$ cell is transformed into an *A*-centred double cell by $(a'/b'/c') = (1,0,0/0,1,1/0,1,-1)(a/b/c)$ and the atom coordinates by $(x'/y'/z') = (1,0,0/0,½,½/0,½,-½)(x/y/z)$ (Fig. 5).[21] The minimum $\bar{c}\cdots\bar{c}$ distance in BQTBs is 3.88 Å.

The effect of the second ring nitrogen on the cation bond lengths and angles in the BPTB/PPTB and PTB/BQTB pairs is discussed under the structures of **6** and **7** below.

Conclusions

In heterocyclic amines that contain N—$C_1\cdots C_{n-2}$—N′ atom groups G_n in pro-closure configurations, intra-cation ring closure can be accomplished through insertion of the H atom introduced by the protonation of one of the nitrogens, i.e., through formation of an intra-annular N—H···N′ bond contained in an (*n*+1)-membered ring. In the present work, the skeleton of the aromatic free-base molecule either is planar or becomes so on protonation, i.e., the tendency to form an intra-cation H-bond is at the very least a cofactor in bringing about a *syn* conformation of N and N′. On geometric evidence, intra-cation ring closure is present in the TBs **1**, **2**, **5**, **9**, **11**, **12**, **15**, **17**, **22**; in **3**, **28**, and **33**; and almost certainly also in **25** and **26**. In **10** it is present independently of protonation, between an H atom of an exocyclic amino group and a ring nitrogen.

The magnitude of the N-H-N′ angle depends primarily on *n* (Fig. 2, Table 4). For G_6, where there is steric crowding and where ring closure requires departure from planarity, the angle tends to be large, >160°. For G_5 the closed 6-membered ring is relatively strain-free, with N-H-N′ > 120°; values as high as ~158° are seen. For G_4 the mean N-H-N′ angle expected from molecular geometry is ~100°, and this is observed.

Whether or not the H(N) atom is involved in a secondary H-bonding interaction with an external acceptor Y will depend on *n* and on the nature of the counter anion and the extent of solvation. Conversely, the two last-named factors may codetermine the occurrence of a ring closure and influence the N-H-N′ angle. In the unsolvated G_4 TBs **9**, **15**, and **17**, Y = phenyl, and H(N) forms a bifurcated H(N)···phenyl bond, whereas in the G_6 TBs **2** and **22** the bifurcation is tenuous at best and in **2** probably absent owing to unfavourable packing geometry.

In the *solvated* G_5 TBs **5** and **10**–**12** the acceptor Y is either a phenyl (**5**, **10**) or a solvent molecule (**11**, **12**), but while the *orientation* of Y with respect to the N–H(N) vector is favourable, the H(N)···Y distances are longer and the N-H-Y angles smaller than would be thought acceptable for H-bonds of conventional types. In the G_4 TB **1** there is an unmistakable H(N)···N′,H_2O bifurcation, but the oxygen atom of the H_2O molecule is positionally disordered (probably dynamically), the result of a compromise involving several simultaneous H-bonding interactions (Figs. 6 and 7).

In none of the TBs does the H-bond to the anion or the solvent molecule prevent ring closure. However, this is not necessarily so when the anion is Cl or Br. In the unsolvated G_6 chlorides **2A** and **21** the H-bonding is dominated by the N—H(N)···Cl interaction, which directs the N-H(N) vector away from the potential N′ acceptor and which is associated with a large inclination of the protonated pyridine ring to the pyrazine ring (Fig. 3). A similar absence of ring closure is observed for one of the pyridine H(N) atoms in the doubly protonated chloride **3**; the second pyridine H(N) atom is involved in a bond to the second Cl atom, but in this case it also closes a G_4 ring containing a pyrazine nitrogen and forms a bifurcated N—H(N)···Cl,N(pyrazine) bond. By contrast, in **25**, **26**, **28**, and **33** the G_4 group is closed in spite of the presence of a halide anion, and there appears to be bifurcation from H(N) to N′ and Br^- (**28**) or to H_2O.[22]

In sum, for the amines under discussion, intra-cation ring closure will result on protonation except where there is disruptive competition from a strongly H-bonding anion (Cl^-, Br^-). Where ring closure does occur, the H(N) atom may be involved in a branched H(N)···N′,Y bond to an external acceptor. This appears to be always the case for G_4 cations but less so for G_5 cations (weaker H(N)···Y interaction) and even less so for G_6 cations.

The cations in BPTB (**15**) and PTB (**17**) each contain two ring nitrogens in pro-closure configurations, whereas the corresponding, matching cations in PPTB (**6**) and BQTB (**7**) each contain one ring nitrogen only. Intra-annular N—H···N′ bonding therefore occurs in the former two but not in the latter two, the cation geometry otherwise being similar. The effect of the ring closure on ion packing and on H(N) bonding in the PPTB/BPTB and BQTB/PTB pairs can thus be examined. While the effect in the rigid-cation BQTB/PTB pair is minor and BQTB and PTB are practically isostructural and not dramatically different from PPTB, the packing in BPTB is significantly different and not for reasons that are immediately apparent.

While in the above aromatic ammonium cations the N-H-N′ angle is largely determined by the size of the pro-closure grouping G_n, in the analogous inside-protonated intrabridge-

[20] For PPTB this requires a transformation $(x, y, z) \rightarrow (x - ½, y, z + ½)$ and for BQTB, $(x, y, z) \rightarrow (x, y, z + ½)$, where (x, y, z) are the tabulated coordinates (Table A). The transformed coordinates match the tabulated PTB(x, y, z) coordinates (1).

[21] To match the tabulated positions of the B atom and of the cation centroid $\bar{c}$ in PTB, approximately (¼, 0, ¾) and $(x, \sim0, \sim½)$, respectively, the atom coordinates in BQTBs (Table A) are transformed by $(x, y, z) \rightarrow [x - ½, ½(1 - y - z), ½(1 - y + z)]$.

[22] Location of some of the acceptors may not be adequately characterized because of disorder.

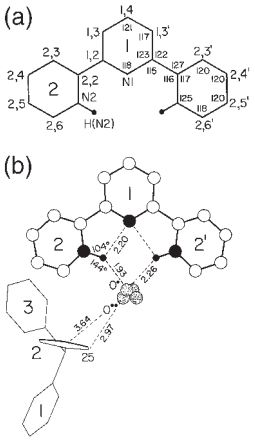
Fig. 6. (*a*) Atom numbering and bond angles (deg) in TPTBw. (*b*) H-bond system, cation and H_2O oxygen in the page. Large filled circles, N atoms; small filled circles, H(N) atoms; stippled circles, O atoms (resolved disorder, partial occupancy; see text). Ring R4 and H(C) atoms omitted for c1arity. H-bonds shown in broken lines.



head cations reported to date (**44**–**50**) the N—H···N′ group is intra-annular simultaneously to *three* (aliphatic) rings. The N-H-N′ angle, which ranges from ~132° to ~180°, would then be expected to be codetermined by the sizes of all three rings. Our analysis shows that the angle is in fact determined almost entirely by the size of the *smallest* of the three rings and that the N···N′ separation plays a relatively minor role.

N—H···phenyl interaction is a common (though not universal, as already noted) feature of the present as well as of previously reported (1–3) TB structures. The geometry of this interaction is noteworthy for its variability (Table 5). Particularly striking is the range of positions and orientations the N–H(N) vector can assume with respect to the associated phenyl ring, and the angle between this vector and the ring plane. The fundamental questions of (*i*) how to account for the observed variability, and (*ii*) whether the H···phenyl interaction is in fact a *bond* in the chemical sense (with nonvanishing electron density at the bond critical point and a demonstrable bond path), are currently being investigated on selected TB structures.

In addition to the H(N)···phenyl interactions, some of the structures of Table 1 contain evidence of H(O)···phenyl and H(C)···phenyl interactions. The former involve solvent molecules, the latter come to prominence in the two solvated proton-sponge TBs **11** and **12**, where they appear to compensate for the absence of H(N)···phenyl bonds.

Individual crystal structures

Crystallographic information for **1**–**13** and details of the structure determinations are presented in Table 2 (cf. also Experimental). Information concerning cation geometry will be found in Tables 8 and 9, and that for H-bonding in Table 5. Relevant X···C and H(X)···C distances in the X—H(X)···phenyl bonds are listed in Table F.

The average geometry of the TB anion in **1**, **2**, and **5**–**13** (Tables D and E) is virtually the same as that reported previously (3): $\bar{d}$(B—C) for the 28 more accurate bond lengths (not corrected for thermal motion) is 1.646[10] Å (γ_1 = –0.82, γ_2 = 3.69) compared to 1.646[18] Å (n = 88, γ_1 = 0.81, γ_2 = 4.49) in ref. 3; the mean deviation δ(C) of the C atoms from their respective best planes is 0.006[4] Å (44 phenyl rings, γ_1 = 1.68, γ_2 = 5.79) for the present structures compared to 0.007[4] Å for the 60 rings in ref. 3.

TPTBw (1)

The geometry of the TP^{2+} cation (Figs. 6 and 7) is related to that of the 2,2′-bipyridinium(1+) and 1,10-phenanthrolinium(1+) cations (1).[23] The cation, of symmetry C_2, is not completely planar: c2/c1 = 13.5°, c2′/c2 = 21.5° (Table 9). Noteworthy are the small exocyclic angles at carbons C(1,2) and C(1,2′), 115.1°, and at C(2,2) and C(2,2′), 115.7°, and the corresponding large exocyclic angles at C(2,2) and C(2,2′), 127.4°. The departures of all three angles from 120° are in directions that make the cation bend in its approximate molecular plane, i.e., so as to decrease the N(2)···N(1) and N(2′)···N(1′) separations, consistent with the presence of N(2)—H(N2)···N(1) and N(2′)—H(N2′)···N(1) intra-cation H-bonds (Fig. 6*b*). In this, $TP2^+$ strongly resembles the 2,2′-bipyridinium(1+) cation: the mean N(2)···N(2′), C(1)···C(1′), and C(6)···C(6′) distances in the latter (Table F of ref. 1; cf. also **15**) are statistically indistinguishable from the corresponding distances in **1**.

The cation is approximately perpendicular to R2 of the associated anions, c2/R2 = 92.6° (Figs. 6*b*, 7). The ring centres π_c(c2) and π_c(R2) are 4.87 Å apart. The mean distances to R2 carbons of the cation atoms nearest to R2, C(2,6) and H(2,6), are 3.81[2] and 2.90[3] Å, respectively, the minimum distances being C(2,6)···C(23) = 3.52 Å and H(2,6)···C(24) ~ 2.57 Å; the C(2,6)···π_c(R2) and H(2,6)···π_c(R2) distances are 3.55 and 2.56 Å, respectively. The spatial relationship of c2 and R2 thus qualifies for a T-shape π–π interaction.[24] However, unlike the 1,10-phenanthrolinium(1+) (**17**) and paraquat(1+) (PQTB) TBs (discussed in ref. 1), in which *both* cofacial and T-shape geometries are present, the aromatic-ring relationship found in TPTBw represents a clear-cut case of a

[23] The unprotonated TP^0 molecule may be regarded as one half of the sexipyridine **14** molecule.

[24] These interactions may manifest themselves also in the pale lemon-yellow colour of freshly prepared TPTBw; on dissolution of the solid in acetone the colour disappears.

		N(3)-C(31)-C(32)	177.9(9)

T-shape only π–π interaction (alternatively, a perpendicular C(2,6)—H(2,6)···R2 H-bonding interaction).

In the intra-cation N(2)—H(N2)···N(1) and N(2′)—H(N2′)···N(1) bonds, N(2)···N(1) = 2.637(5) Å, H(N2)···N(1) ~ 2.20 Å, and N(2)-H(N2)-N(1) ~ 104° (assuming N(2)—H(N2) = 1.02 Å). This geometry again is very similar to the corresponding intra-cation H-bond geometry in the 2,2′-bipyridinium(1+) cation, in which the mean distance analogous to H(N2)···N(1) is 2.23[8] Å and the mean angle analogous to N(2)-H(N2)-N(1) is 106[5]° (Table 3 of ref. 1). The H(N2)···H(N2′) ~ 2.65 Å separation in TPTBw may be co-responsible for the nonplanarity of the cation, although the H(1,3)···H(2,3) repulsion, at ~2.23 Å, is probably the principal factor.

The location of the H_2O molecule suggests H-bonding interactions with N(2) and possibly with R2 or R4 or both (Figs. 6*b*, 7). The refined coordinates of the O atom, on the cation C_2 axis, were (0, 0.5040(5), ¾), with U_{11} = 0.121(6), U_{22} = 0.058(4), U_{33} = 0.45(1), U_{12} = U_{23} = 0, and U_{13} = 0.118(7) Å^2. The very large U_{33} (perpendicular to the cation plane) and the interatomic distances from the oxygen (which were compatible with the suspected interactions) pointed to disorder of the H_2O molecule. An attempt was therefore made to resolve the disorder by placing the O atom at partial occupancy between two pairs of C_2-related but otherwise unconstrained sites O* and O**. The oxygen positions that resulted from the ensuing refinement are shown in Fig. 7, with 74% of the oxygen occupying positions O* and 26% positions O**. Although the refinement was unconstrained (i.e., unbiased), the resulting location at O* is such that it improves the geometry of the N(2)—H(N2)···O bond (Table G), and the location at O** is in the natural direction for the formation of an O**···R2 hydrogen bond given a favourable (dynamic?) orientation of the H_2O hydrogens, as also shown by the reasonable O**···R2 interatomic distances. The O*···R4 and O**···R4 separations are too long for effective O—H···π bonding, but it should be noted that the U_{22} of the R4 carbons C(43), C(44), and C(45) are large, 0.13–0.17 Å^2 (Table C), so that a dynamic O···R4 interaction cannot be entirely excluded. The U_{ij} of the cation-skeleton atoms could not be satisfactorily accounted for on an RBM model.

The H-bonding at N(2) can then be described as a bifurcated N(2)—H(N2)···N(1),O* bond with H(N2)···N(1) ~ 2.20 Å, H(N2)···O* ~ 1.93 Å, N(2)-H(N2)-N(1) ~ 104°, N(2)-H(N2)-O* ~ 144°, and N(1)-H(N2)-O* ~ 108° (Fig. 6*b*). The H_2O molecule is loosely H-bonded to N(2) and N(2′) as well as to R2 and R2′. The H-bonding at room temperature has a strong dynamic component, not easily described in detail.

2PyPzTB (2)

The anions in the large tetragonal cell (origin at $\bar{1}$) of **2** are arranged in tightly wound helices with 4_1 as axes. The B atoms, at z ~ 0, ± ¼, ½, tesselate the structure into a stack ⊥(001) of four successive layers of cuboids. In each layer, cuboids containing a cation pair alternate with "empty" cuboids, and the orientations of the cation pairs in this square tiling again alternate in an *antiferro* manner. The near-planar (see below) cations in a pair are related by a $C_2 \subset S_4$ rotation; the cation planes are perpendicular to (001) and their perpendicular separation in a pair is ~3.7 Å. The 2PyPzTB structure may then be regarded as a three-dimensional *antiferro* mosaic of alternating $[cat_2an]^+$ and $[0,an]^-$ CsCl-like cells.

The pyrazine ring c1 is less planar than the two pyridine rings (Table 9). The c1 plane forms angles ~10° with the pyridine rings, while the c2′/c2 angle between the two pyridine planes is ~14°; the mean deviation of the nonhydrogen atoms from the best plane through the cation is ~0.1 Å.

The H(2′) atom effecting the intra-cation ring closure was clearly seen in an otherwise flat difference map (Fig. A) and was refined isotropically. The cation geometry and that of the N(2′)—H(2′)···N(2) bond are described in Tables 5, 8, 9, and Fig. 3. The shortest H(2′)···C(phenyl) distance is to C(132), 3.66(4) Å (N(2′)···C(132) = 3.656(4) Å, N(2′)-H(2′)-C(132) = 80(2)°), followed by H(2′)···C(142) = 3.87(4) Å (N(2′)···C(142) = 4.225(4) Å, N(2′)-H(2′)-C(142) = 100(2)°) and H(2′)···C(133) = 3.90(4) Å (N(2′)···C(133) = 3.493(4) Å, N(2′)-H(2′)-C(133) = 61(2)°). All the other H(2′)···C(phenyl) distances are longer than 4 Å. The intra-cation N(2′)—H(2′)···N(2) bond, N(2′)-H(2′)-N(2) = 168(3)°, cannot thus be said to be bifurcated, i.e., there is no significant H-bonding interaction with the anion.

Comparison of **2** with the analogous **22** (Fig. 3) shows that with respect to H-bonding the situations in these two structures are not completely similar. Although the N—H(N)···N′ geometry in the double-sided, centrosymmetric cation of **22** closely resembles that in the cation of **2** (Table 4), in the latter the two pyridine rings are significantly more coplanar than the corresponding ipsolateral rings in **22**. Furthermore, the opportunity for H(N)···phenyl bonding is somewhat more favourable in **22**, even though effective interaction would be difficult to claim. The shortest N···C(phenyl) and H(N)···C(phenyl) distances in **22** are 3.54 and 3.15 Å, N-H(N)-C ~ 98°. All the other H(N)···C(phenyl) distances are ≥ 3.4 Å, with N-H(N)-C angles of 61°–99°.

2PyPzCl (2A)

The H-bonding in **2A** is completely dominated by the Cl^- anion: N(2′)···Cl = 2.92 Å, H(N2′)···Cl ~ 1.77 Å, N(2′)-H(N2′)-Cl ~ 171°. The essentially straight, strong N—H···Cl bond minimizes the opportunity for intra-cation ring closure to an extent that renders the N—H···N′ interaction structurally ineffective even though the pyridine nitrogens are *syn* to each other: H(N2′)···N(2) ~ 2.96 Å, N(2′)-H(N2′)-N(2) ~ 75°.[25] The

[25] The location of H(N2′) in a difference map was very well defined (Fig. B).

[a] $\bar{\delta}$(C,N), mean deviation of the C atoms in carbocyclic or of the C and N atoms in heterocyclic cation rings from the fitted ring plane; δ(X), deviation of the exocyclic atom X (in brackets, of the endocyclic atom X) from the fitted ring plane; cat, the complete cation ring system.

[b] 0.006 and 0.008 Å in TT, 0.007 Å in TTsw.

[c] 0.040 and 0.027 Å in TT, 0.022 Å in TTsw.

H-bonding in **2A** resembles that in **21** except for the somewhat smaller deviations of the cation rings from coplanarity (Fig. 3, Table 4). The shortness of the N(2′)—H(N2′)···Cl bond and the lack of interactive neighbours of the Cl atom other than H(N2′) permit the structure of **2A** to be viewed as composed of neutral [cat$^+$Cl$^-$] units.

2PyPz2Cl (3)

In the divalent (one Cl per pyridine) cation of **3** the protonation is on both pyridine nitrogens and both *N*-hydrogens are involved in N—H···Cl bonds (Fig. 3). While the N(2′)—H(N2′)···Cl(1) bond (N(2′)···Cl(1) = 2.988(3) Å, H(N2′)···Cl(1) ~ 1.83 Å, N(2′)-H(N2′)-Cl(1) ~ 176°) is analogous to the N(2′)—H(N2′)···Cl bond in **2A** and to the corresponding bond in **21**, formation of the second N—H···Cl bond changes the conformation of the two pyridine rings from *syn* to *anti* and results in an intra-cation ring closure between N(2) and the *pyrazine* nitrogen N(1). The H(N2) atom (N(2)—H(N2) ~ 1.09 Å) engages Cl(2) at ~2.07 Å, N(2)-H(N2)-Cl(2) ~ 142°, and N(1) at ~2.25 Å, N(2)-H(N2)-N(1) ~ 99°, to form a bifurcated N(2)—H(N2)···Cl(2),N(l) bond.[26] The distances from H(N2′) to N(4) and N(2), ~3.60 and ~3.90 Å, respectively, are too long and the corresponding N(2′)-H(N2′)-N angles too small, ~69° and ~112°, respectively, to qualify even for a bifurcated H-bonding interaction.

The cations are arranged in layers approximately ∥(001). The pyrazine rings are stacked face-to-face along *c*; neighbouring rings form centrosymmetric pairs with minimum vertical C—C and C—H separations of ~3.7 Å, too long for an effective facial π–π overlap. Similar to **2A**, the structure of **3** may be viewed as composed of neutral [cat^{2+}·2Cl$^-$] units.

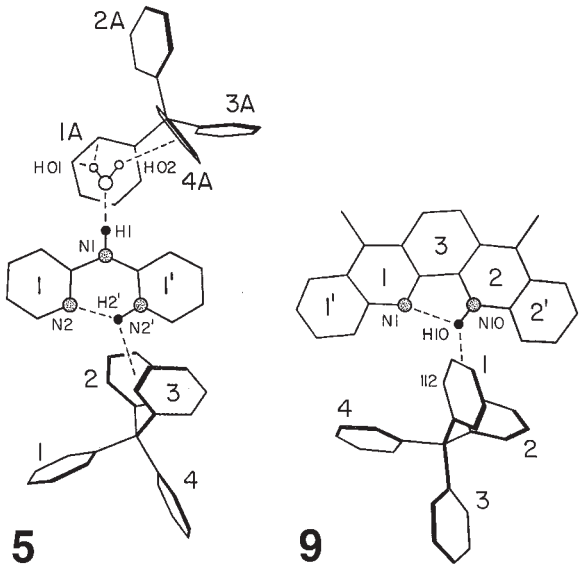
2PyPz (4)

The crystal structure of **4** determined here from Cu *K*α data agrees very well with a previous determination (7) based on

[26] The N(1)-C(22)-C(2)-N(2) group is planar to 0.070[27] Å and N(1)-C(22)-C(2)-N(2)-H(N2) to 0.081[33] Å. The H(N2) atom is 0.20 Å out of the first plane; the Cl(2) atom is 0.43 Å out of the first and 0.16 Å out of the second plane.

© 1998 NRC Canada

Fig. 8. Hydrogen bonding in **5** and **9**. Projection on the plane of the cation ring 1′ or 2. Stippled circles, N atoms; black circles, H(N) atoms; large open circle, O atom; small open circles, H(O) atoms. Atom numbering as in Tables 8 and A.



Mo *K*α data. The differences between corresponding bond lengths (11 pairs, Table 8) and bond angles (13 pairs) in the two determinations are all within three times the pooled esd's (9 of the bond lengths and 11 of the bond angles are within twice the pooled esd's).[27] The c2′/c2 angles are the same, 54°, and c2/cl differs by only 0.3° (41.9° against 42.2° in ref. 7).

The molecules, of C_2 symmetry (Fig. 3), are arranged in slightly puckered sheets ||(001).

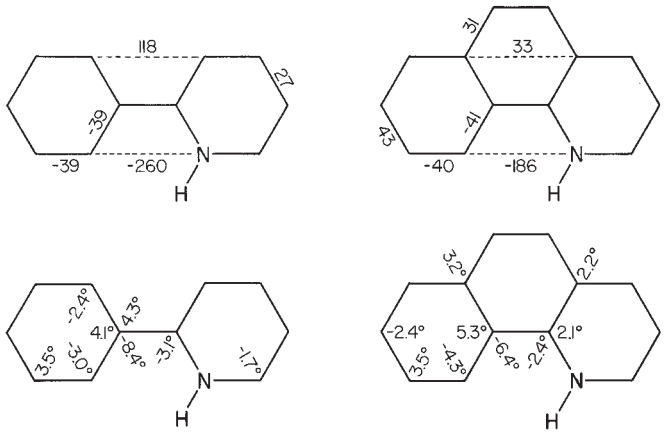
DPATBw (5)

The cation in **5** is almost planar, cl′/cl = 3.9°, with the pyridine nitrogens *syn* to each other and C(1)-N(1)-C(1′) = 127.7(5)°. Direct comparison with the three related structures from the literature cannot be made, as the conformations in both the chloride **56** and the two forms of the free base (**54**, **55**) are *anti*. However, in none of these three structures are the two pyridine rings anywhere near coplanar: in **56** the interplanar angle is 50°, in **54** it is 23°, and in the two nonequivalent molecules in **55** the angles are 8° and 30°; the corresponding C-N-C angles at the amino nitrogen are 124.2(2)° (**56**), 131.4(4)° (**54**), and 129.9(2)° and 132.1(2)° (**55**), respectively. It is thus clear that, in the absence of a strong competition for an external H-bond, the ring closure in **5** on protonation is effective in producing a nearly planar *syn* conformation of the pyridine rings.

The ring closure results in the formation of a bifurcated N(2′)—H(N2′)···N(2),R2 bond (Fig. 8, Tables 4, 5, 8). The amino hydrogen H(N1) is involved in an almost straight bond to the oxygen of the H_2O molecule: N(1)-H(N1)-O ~ 173°. The H_2O molecule in turn is H-bonded to rings 1 and 4 of an adjacent anion (Fig. 8).

[27] Paired *t* statistic testing for equality of sample means gave t_{10} = 2.71 ($t_{0.01,\,10}$ = 3.17) for the bond lengths and t_{12} = 0.46 ($t_{0.01,\,12}$ = 3.06) for the bond angles.

Fig. 9. Effect of the second ring nitrogen on the cation bond lengths *d* (×10³, Å) and angles ε in the pairs BPTB/PPTB and PTB/BQTB. *Top left*: *d*(BPTB) – *d*(PPTB); *top right*: *d*(PTB) – *d*(BQTB); *bottom left*: ε(BPTB) – ε(PPTB); *bottom right*: ε(PTB) – ε(BQTB). The differences shown are equal to or exceed three pooled esd's of the respective *d* or ε values. c1′/c1(BPTB) – c1′/c1(PPTB) = –10.1°.



PPTB (6), BQTB (7), and BQTBs (8)

The bond lengths and angles in the cations of PPTB and BPTB (**15**), and in the cations of BQTB and PTB(**17**), are compared in Fig. 9, which displays differences exceeding three times the pooled esd's in respective pairs of corresponding bond lengths and angles. In the PPTB/BPTB pair, apart from the expected changes in ring c1, the effect of converting the phenyl ring into a pyridine ring on the geometry of ring c1′ is minor. However, the contraction of the X(2)···N(2′) (X = C, N) distance and the expansion of the C(6)···C(6′) distance on going from PPTB to BPTB are significant They and the simultaneous decrease in the dihedral c1′/c1 angle from 15.3° in PPTB to 5.2° in BPTB are associated with the appearance of the intra-cation N(2′)—H(N2′)···N(2) bond, which cannot exist in PPTB. Similarly, in the BQTB/PTB pair the effect of the introduction of N(1) on the geometry of ring 2 is minor. However, since the planarity of the cation skeleton remains practically the same

	$\bar{\delta}$(C,N)	c2/c1	c3/c1	c3/c2
BQTB	0.025[19] Å	3.4°	1.1°	2.3°
PTB	0.029[17] Å	3.7°	1.2°	2.6°

(Table 9; $\bar{\delta}$(C,N) = mean deviation of the C and N atoms from the fitted cation plane), comparisons of the compensatory changes in the bond lengths and angles in the BQTB/PTB and PPTB/BPTB pairs are not completely straightforward. Nevertheless, the change in the endocyclic angle at the X atom of ring 1 appears, on substituting N for C, to be larger in the BQTB/PTB pair, –4.3° as against –3.0° in the PPTB/BPTB pair. (For unprotonated 7,8-benzoquinoline and 1,10-phenanthroline see **16** and ref. 58, respectively.)

The similarities of the ion packing in the three $P2_1/c$ structures PPTB, BQTB, and PTB discussed above are reflected in the similarities of the H(N)···phenyl bond geometry, which are particularly conspicuous in the PPTB/BQTB pair (Fig. 5). The N···B and H(N)···B distances are much the same, as is the

N···B, Å	4.21	4.20	4.28
H(N)···B, Å	3.37	3.75	3.69

the N···B and H(N)···B distances in BPTB and BQTBs differ considerably from the above (6.60 and 7.47 Å, respectively, in the former, and 4.72 and 4.60 Å, respectively, in the latter), and the H-bonded phenyl ring in BPTB is oriented differently. In BQTBs the H-bond is exclusively to MeCN (cf. below), so the phenyl involvement is irrelevant.

The main difference between the solvated BQTBs and the unsolvated BQTB arises from the manner in which the H(N) atom is engaged in H-bonding. In BQTB it forms an unbranched N—H(N)···phenyl bond, whereas in BQTBs the H-bond is exclusively to the N atom of the MeCN molecule: N(10)···N(50A) = 2.85(1) Å, H(10)···N(50A) ~ 1.99 Å, N(10)-H(10)-N(50A) ~ 147°, C(51A)-N(50A)-H(10) ~ 163° (A: $x + 1, y, z$). The shortest distance of H(10) to a phenyl carbon is to C(2,6), 3.55 Å; the distance of H(10) from the cation hydrogen H(1) is ~2.00 Å.

Within the accuracy of the structure determination the bond lengths and angles in BQTBs are the same as those in BQTB and are thus not included in Table 8. The cation rings in BQTBs appear to be slightly less coplanar than those in BQTB and PTB: in this order, c2/c1 = 6.1°, 3.4°, 3.7°; c3/c1 = 2.5°, 1.1°, 1.2°; c3/c2 3.6°, 2.2°, 2.6° (Table 9).

The external H(N)···phenyl bonding and the intra-cation ring closure would be expected to manifest themselves in the ir spectra of the four unsolvated compounds, primarily in the value of the ν(NH) stretching frequency and in the temperature coefficient $\delta\nu(NH)/\delta T$. Tracing the effect of the two bonding factors on ν(NH) is, however, difficult. The spectra are complex (Fig. 10; cf. also Fig. 12 of ref. 1) and contain a variety of features that seem to arise from coupling, Fermi resonance, or both, of vibrations involving the H(N) atom.[28] The principal ν(NH) adsorptions were identified by deuteration at N(2′) or N(10): over the observed ν(NH) range, ~3300 to ~3100 cm^{-1}, the corresponding ν(NH) and ν(ND) values show a linear correlation (Table 10, Fig. 11), with ν(NH)/ν(ND) ratios between 1.337 and 1.333. The ν(NH) shift with temperature is practically zero for BPTB and BQTB; in PPTB, ν(NH) decreases on cooling by a few wave numbers, while in PTB (1) it increases somewhat. This lack of pronounced temperature dependence over almost 300 K is consistent with weak or diffuse H-bonding. In addition, in PPTB $\delta\nu/\delta T > 0$ is indicative of an unbranched H-bond, whereas in PTB $\delta\nu/\delta T < 0$ points to branched H-bonds (cf. ref. 54), which indeed is what is observed (Fig. 12), even though the type of H-bond may not be the only factor responsible for this temperature dependence, given the smallness of the change in ν(NH) over such a substantial temperature range.

The relative lowering of ν(NH) in the sequence PTB, PPTB~BQTB (no ring closure), BPTB (Fig. 11) indicates that the decrease is the consequence of H-bonding both to a phenyl and to the unprotonated N atom. The present set of four compounds is too small for a meaningful statistical analysis. Nevertheless, exploratory regressions of averaged ν(NH) and ν(ND) frequencies on $d(\pi_c)$ (or $d[H(N)\cdots C(phenyl)]_{min}$) and $d[H(N)\cdots N']$, taking the latter in PPTB and BQTB arbitrarily as 10–50 Å, seem to show that the effect of the bonding to the phenyl on the stretching frequency by far exceeds that of the ring closure.

DDPTB (9)

The aromatic rings c1, c2, c1′, and c2′ are reasonably planar (Table 9), but the large B_{eq} of C(5) and C(6) and the significantly

[28] For further details of the BPTB and PTB spectra see ref. 1.

lower nominal planarity of c3 compared to cl and c2 indicate that these two atoms are positionally disordered. Since the volume of data was barely sufficient for an isotropic refinement of the structure, resolution of the disorder was not attempted (cf. Experimental).

The H-bond resulting from the intra-cation ring closure has the expected geometry. but the N(10)–H(l0)···phenyl distances, to the nearest phenyl R1, are long (Fig. 9, Tables 4, 5). Although some of the features of the structure appear to suggest the existence of π–π interactions, the pertinent distances and angles seem unfavourable for such interactions to be effective: the angle c2′/R2 is only 76°, at π_c(c2′)···π_c(R2) ~ 4.9 Å, and the shortest (perpendicular) separations in the centrosymmetric cation pairs are N(1)···C(14)* = N(1)*···C(14) ~ 3.63 Å.

The pattern generated by the projections of the cations and anions along *a* on (011) is essentially that found for a projection of a hexagonal NiAs-type structure on (0001):[29] the cation projections form almost equilateral triangles inside which are located the anion projections.

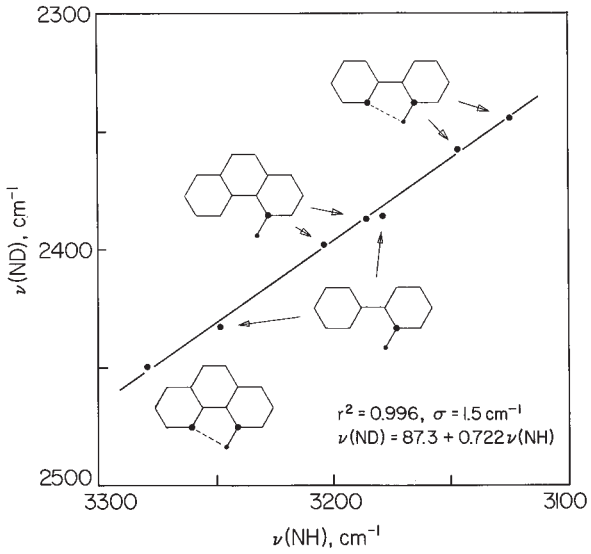
TTTBs (10)

The pteridine skeleton is essentially planar (Table 9). The phenyl ring c6 forms an angle of 48.4° with the best plane through the cation skeleton. This angle is almost the same as that in the neutral solvated TTsw (**30**), 47.1°, but larger than in the neutral unsolvated TT (**29**), 31.6° and 34.7°.

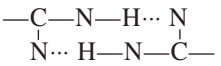
The cation is protonated at the N(1) ring atom, as in **33**. Corresponding bond lengths and angles in the skeleton ring system in the two structures are statistically indistinguishable within three, and in most cases two or fewer, stated esd's. To estimate the effect of the protonation on the geometry of the pteridine skeleton, corresponding mean bond lengths and angles in the two cations were compared with those in the unprotonated pteridine skeletons in **29**–**32**. Comparison of the means for the two groups (*t* test for two means and analysis of variance, both at the 0.01 significance level) shows that the only angles significantly affected are the angle C(9)-N(1)-C(2), which as expected is increased (119.7[3]° against 115.0[5]°), and the two flanking endocyclic angles N(l)-C(9)-C(10) and N(1)-C(2)-N(3) (119.1[2]° against 122.1[8]°, and 123.3[6]° against 127.8[8]°, respectively); the decrease in the latter two is a compensatory response to the increase in the angle at N(1). Also increased on protonation is the exocyclic angle N(3)-C(2)-N(2), 118.4[1]° against 115.7[5]°, whereas the exocyclic N(1)-C(2)-N(2) angle apparently remains unchanged, 118.1[8]° against 116.9[9]°. The sum of these five mean angles before protonation is 598.6°, and after protonation is 597.5°, i.e., the changes are compensatory and localized around N(1).

[29] *b*/*c* = 1.32 compared with the ideal $\sqrt{3}$ ~ 1.73 for the true orthohexagonal geometry.

Fig. 11. Correlation of the principal ν(NH) and ν(ND) absorption frequencies in PPTB, BQTB, BPTB, and PTB (FT-ir spectra at 298 K, see text). In the structural formulae the large dots represent N and the small dots H(N) atoms.



The H-bonding in TTTBs is illustrated in Fig. 13, with details of the relevant bond lengths and angles in Tables 3, 8, and F. All the H(N) atoms are engaged in H-bonds to phenyl groups of the neighbouring anions except H(2,2), which is bonded to the N atom of the MeCN molecule, and H(7,2), which interacts with phenyl c6 of its own cation. The three anions and the MeCN molecule coordinate the cation in such a way that there is no H-bonding between adjacent cations. Specifically, there is no pairing of cations across a centre (or pseudo centre) of symmetry to form cyclic



dimers. Such pairing of molecules (N···N ~ 3.00–3.09 Å)[30] occurs not only in anhydrous TT, but also in the solvated TTsw crystal and in **32**, and even between *cations* in the hydrated salt **33**, in all of which there is competition for H-bonds from the solvent molecules, and in the chloride **33** also from the Cl^- anion.[31] The disruption of the pairing and the absence of other cation–cation H-bonding interactions in TTTBs are attributable to the shape and size of the coordinating TB anions, which isolate the cations from one another; to the ample opportunity to form N—H···phenyl bonds provided by the acceptor-rich

[30] The N–proton distance estimated for N···N = 3.00 from eq. [3] is 1.027 Å, that for N···N = 3.09 Å is 1.020 Å.

[31] As pointed out in ref. 21, such paired N—H···N* bonds have been observed in almost every crystalline dihydrofolate reductase inhibitor investigated to that date.

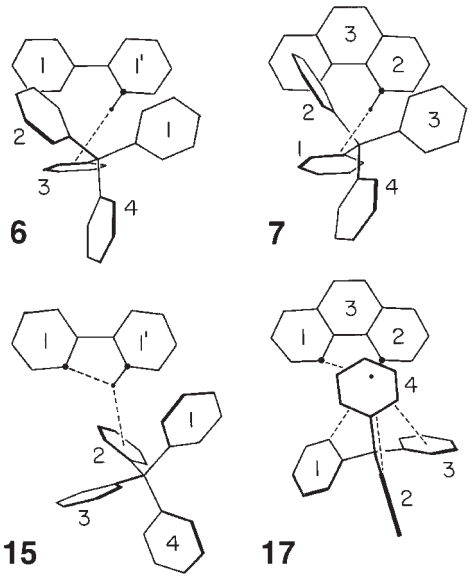
Fig. 12. Competition of the H(N) atom in **6** and **15**, and in **7** and **17**, for hydrogen bonding. Projection on the c1′ or c2 plane. Large circles, N atoms; small circles, H(N) atoms; broken lines, H(N)···phenyl or H(N)···N′ bonds. Anion rings numbered as in Tables A, D, and E. Note the similarity of the anion orientations in the isostructural TBs **6** and **7**.



counter anion; and to the non-negligible strength of the H···phenyl interaction.

The H(1), H(4,2), and H(7,1) atoms are involved in unbranched N—H(N)···phenyl bonds to anion rings R3. R4A, and R2B, respectively; H(4,1) forms a bifurcated N(4)—H(4,1)···R1A,N(5) bond that effects a *p*-type intra-cation ring closure (Fig. 13, Tables 4, 5). The H(2,1) hydrogen forms an asymmetrically bifurcated bond to R2 and R3, while H(2,2) is bonded, at the unfavourable angle of only 114°, to the N(9) atom of the MeCN molecule: N(2)···N(9A) = 3.041(8) Å, H(2,2)···N(9A) ~ 2.53 Å. Oddly, this unexpectedly small angle is associated with an equally small H(2,2)-N(9A)-C(9A) angle, 107°, at the MeCN nitrogen. Examination of the immediate environment of H(2,2) and N(9A) reveals that the only other neighbour within a distance possibly eligible for H-bonding is R3C (C, 1 – *x*, –*y*, 2 – *z*): N(9A)···H(33C) ~ 3.06 Å, N(9A)-H(33C)-C(33C) ~ 120°, C(9A)-N(9A)-H(33C) ~ 144°. It is uncertain whether or not this geometry qualifies as corresponding to marginal —C≡N···N—C(phenyl) bonding (cf. ref. 55).

The minimum N···C distances in the bonds to the phenyl rings range from 2.96 to 3.72 Å and the minimum H(N)···C distances from ~2.48 to ~3.05 Å. The approach of an N–H(N) vector to the associated ring plane can be very oblique, cf. the (N-H)/R angle, which varies considerably (Table 5). With the exception of R2, which is the acceptor of H(2,1) and H(7,1) from two different cations, a phenyl ring is H-bonded from one side only.

An interesting feature of the cation geometry is the proximity of the NH_2 group on C(7) to the phenyl ring c6 of its own cation. As noted above, this ring forms a substantial angle with the pteridine skeleton not only in TTTBs but also in the neutral unsolvated as well as solvated triamterene, and the corresponding relevant N(7)···c6 distances are similar (Table 5):

Fig. 13. Hydrogen bonding in TTTBs. Open circles, N atoms; stippled circles, C atoms; filled circles, H(N) atoms. H(C) atoms omitted for clarity. H-bonds are indicated by broken lines. For atom numbering see Table A and Fig. 1.

	TTTBs	TT (mean)	Ttsw
d(N···C)$_{min}$, Å	2.960(8)	2.998[10]	2.946
d(N···C), Å	4.10[86]	4.15[89]	4.05
$d(\pi_c)$, Å	3.96	4.13	3.92
Δ, Å	2.17	2.20	2.15

The shortest N···c6 distance, between N(7) and C(61), is shorter than any of the other N···C(phenyl) separations in TTTBs (Table 5). This distance and the corresponding N(7,2)···C(62) distance of 2.44 Å clearly point to the existence of an *intra*-cation N(7)—H(7,2)···c6 hydrogen bond. However, the very large Δ values, 2.17 Å for N(7)···C(c6) and 2.30 Å for H(7,2)···C(c6), indicate that the attitude of the N(7)-H(7,2) vector to the ring plane is very oblique, the [N(7)-H(7,2)]/c6 angle being only 13°. The H-bonding situations at the corresponding phenyl ring in TT and TTsw are similar.[32] Thus while the steric interaction with the NH_2 group at C(7) causes c6 to twist out of the pteridine plane, it simultaneously results in the observed distorted H-bonding geometry (cf. also refs. 56 and 57).

TLS analysis accounted only moderately well for the U_{ij} of the skeleton atoms: $R(U_{ij})$ = 10.1%, $R_w(U_{ij})$ = 9.7%, rms(U_{ij}) = 0.0035 Å, rms[esd(U_{ij})] = 0.0040[8] Å^2; the mean bond-length correction based on this model amounted to ≤ 0.003 Å, and that to the bond angles to ≤ | 0.04 |°. Comparison of the $\bar{U}_{ii}$ for the skeleton ring atoms with the $\bar{U}_{ii}$ for the exocyclic nonhydrogen atoms in TTTBs and **29**, **30**, **32**, and **33** resulted in $\bar{U}_{ii}$(exocyclic) = 1.43$\bar{U}_{ii}$(skeleton) (r^2 = 0.98), i.e., in these structures at room temperature there is substantial thermal activity of the substituent atoms.

PsTBs (11) and PsTBw (12)

The main difference between the structures of these two proton-sponge TBs is in the nature of their solvation: in the monoclinic **11** the solvent molecule is Me_2CO, whereas in the triclinic **12** it is MeCN and H_2O. This would suggest that the two structures are organized in a similar manner. Indeed,

[32] The shortness of this distance in TT is noted in ref. 17, but it is not interpreted there as arising from the intra-molecular N(7)—H(7)···c6 H-bond.

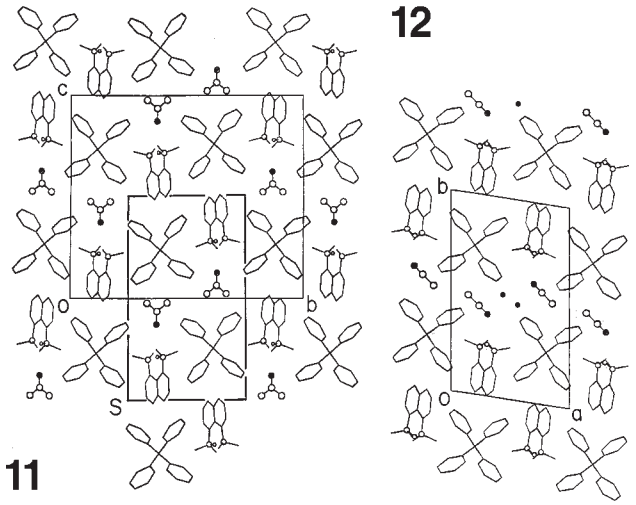
Fig. 14. Packing relationship between the monoc1inic **11** and the tric1inic **12**. The heavily-outlined subcell *S* of **11** corresponds to the unit cell of **12**. The *S* bands ||*c* alternate with bands of similar subcells roughly antiparallel to the *S* bands, with pseudo anticentres of inversion $\bar{1}'$ (at the corners of *S*) relating cations to the Me_2CO molecules. Black circles, O or N atoms of the solvent molecules.



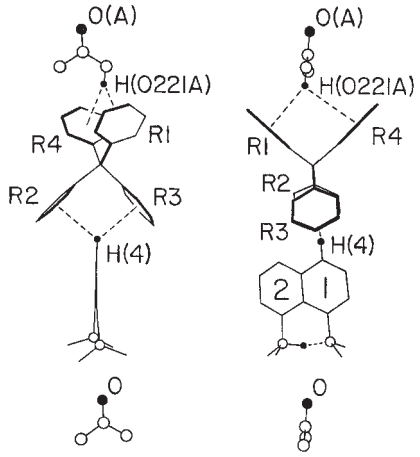
V_1(**11**) – V_1(**12**) = 871 – 861 ~ 10 Å, which is in the right direction of the difference for nominal space filling by C + H and N. Furthermore, the unit cells of **11** and **12** can be transformed with reasonable fidelity into each other: $(a, b, c)_{\mathbf{11}}$ = (0,0,1/2,0,0/0,1,0)$(a, b, c)_{\mathbf{12}}$ or $(a, b, c)_{\mathbf{12}}$ = (0,½,0/0,0,l/l,0,0) $(a, b, c)_{\mathbf{11}}$; a(**11**)/c(**12**) = 0.991, b(**11**)/2a(**12**) = 0.979, c(**11**)/b(**12**) = 1.022. The relationship of the two structures is represented in Fig. 14.

In **11**, the components of the structure are arranged in $[\cdots Me_2CO\cdots an\cdots cat\cdots]_\infty$ columns ||*c*, with the cation planes ⊥(001). Projections of these columns on (001) define the lattice points of a distorted rhombic tiling with rhombs of ~7.2 Å on the side.[33] The space in the channels between the columns is occupied by H(C) atoms of both the anions and the cations. The N(1)-C(1)-C(9)-C(8)-N(8) group of the cation is closed by H(N8) to form a 6-membered ring in which the nonhydrogen atoms are coplanar to 0.044[22] Å, with H(N8) 0.16 Å off their plane; the N(1)···N(8) distance, 2.552(9) Å, is ~1.4% longer than d[C(l)···C(8)] = 2.516(9) Å. The N(8)-H(N8)-N(1) angle of ~163° (N(8)—H(N8) ~ 1.18 Å, H(N8)···N(1) ~ 1.40 Å; H(N8) seen in the difference map) offers a poor opportunity for H-bond bifurcation at H(N8): the unique external acceptor atom is the acetone oxygen at ~3.00 Å from H(N8), which is too far for an effective H-bonding, and the relative orientations of the cation and the anion exclude any possibility of H(N8)···phenyl interaction. Nonetheless, the Me_2CO molecule is oriented in the right direction for an H(N8)···O bond (Fig. 15), and the two angles N(8)-H(N8)-O and N(1)-H(N8)-O, though small, are practically the same, ~97° and ~95°, respectively, and not inconsistent with the existence of a branched H-bond, however weak.[34] In this context it is of interest to recall the above observation that all three components of the structure are located on parallel strings in the sequence

[33] The tiling may also be regarded as corresponding to a distorted hexagonal honeycomb packing of the infinite columns.

[34] The O atom is 0.26 Å out of the N(1)-C(1)-C(9)-C(8)-N(8) plane.

Fig. 15. PSTBs: intra-cation and putative H(C)···phenyl hydrogen bonds (see text). Only those H atoms that participate in H-bonding are shown (small black circles). Large black circles, O atoms; large open circles, C atoms; small open circles, N atoms (A: x, y, 1 + z, cf. Table A). H-bonds in broken lines.



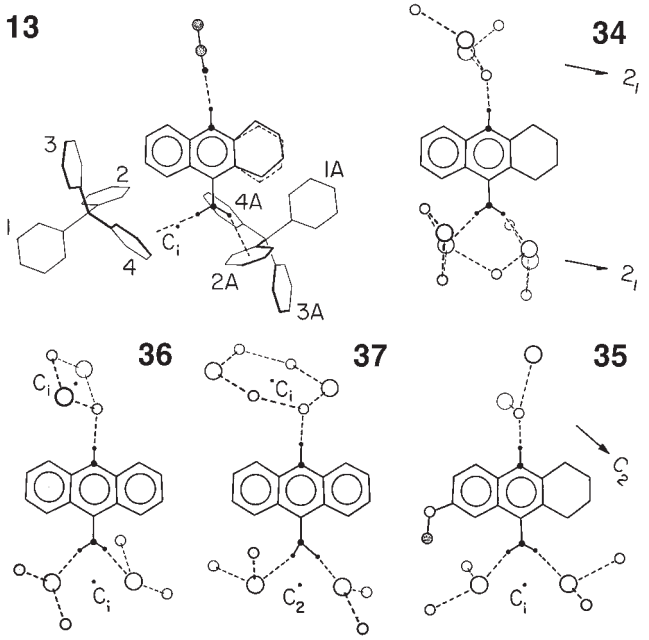
···[Me_2CO···an···cat]···. This arrangement permits a close approach of the neighbours on the string; notably, the cation plane, which is parallel to the string axis, fits almost symmetrically in the wedge-shaped space formed by the pair of anion phenyl rings closest to the cation, thus providing an opportunity for an H(C) atom(s) of the cation to interact with these phenyl groups (Fig. 15). Similarly, the Me groups of the solvent molecule fit between the other pair of phenyl rings of the flanking anion. Examination of the shortest H(C)···phenyl distances shows that H(4) of the cation is ~3.02 Å from C(26) and ~3.09 Å from C(32), the corresponding H(4)···π_c (R2) and H(4)···π_c (R3) distances being ~2.76 and ~2.83 Å, respectively. Similarly, the distance of the acetone hydrogen H(O221A) (A: x, y, 1 + z) from C(16) is ~3.17 Å, with H(O221A)···π_c (R1) ~ 2.95 Å, and from C(41), ~3.41 Å, with H(O221A)···π_c (R4) ~ 3.31 Å. The H(4) atom is thus engaged in a putative bifurcated C(4)—H(4)···R2,R3 bond (C(4)-H(4)-π_c (R2) ~ 133°, C(4)-H(4)-π_c (R3) ~ 129°) to one side of the anion, while the other side of the anion is involved in an asymmetric bifurcated C(O22A)—H(O221A)···R1,R4 bond, C(022A)-H(0221A)-π_c(R1) ~ 139°, C(022A)-H(O221A)-π_c(R4) ~ 122°; the cation and acetone planes are approximately mutually perpendicular. This arrangement is reminiscent of the ···cat···an··· strings ||*c* in the tetragonal alkali and ammonium TBs, in which the wedge-shaped spaces between the phenyl rings on each side of the S_4 anion are occupied by like cations (cf. ref. 3).

The C—H bond lengths used to place the H(C) atoms in the refinement of **11** were 0.95 Å. If allowance is made for this assumed thermal foreshortening, the H(C)···C and H(C)···π_c distances quoted here compare with those found in the terminal alkynes of ref. 55 and considered to correspond to weak —C≡C—H···phenyl bonds. A case can thus be made for the existence of similar, *bifurcated* weak H(C)···phenyl hydrogen bonds in **11**.

The overall features of the structure of **12** are quite similar to those of **11**. However, the solvent content of the reported structure is rendered somewhat ambiguous because of the ~30% decrease in the intensities of the standard reflections

© 1998 NRC Canada

Fig. 16. Hydrogen bonding in the 9-aminoacridine derivatives **13** and **34**–**37**. Only one conformation of ring c1 is shown for **34** and **35**. Black circles (decreasing size), C, N. and H atoms. Large open circles, Cl atoms; small open circles, O atoms. H-bonds are shown as broken lines. Projections of symmetry elements ($\bar{1}$, 2, 2_1) on the cation planes are indicated by dots or arrows.



over the course of data collection. This decrease is taken to be the effect of a partial loss of solvent. Although an empirical correction was applied to the intensities (cf. Experimental), the degree of solvation remains uncertain, more so for H_2O than for MeCN on the evidence from the refined structure.

The components of the structure form [···MeCN···cat···an···]$_\infty$ strings ||*b* (Fig. 14). The distance of the MeCN nitrogen atom N(5) from H(N8) is ~2.84 Å, at an N(8)-H(N8)-N(5) angle of ~117°, both unfavourable for H-bonding. However, the C(51)-N(5)-H(N8) angle of ~135° indicates that N(5) may be involved in a weak bifurcated bond to the H_2O molecule. The O atom of the latter appears to be positionally disordered across a centre of symmetry, the O···O* distance being ~1.85 Å; the N(5)···O distance to the O position more likely to be engaged is ~3.44 Å. Thus here again the solvent molecule (MeCN) has a reasonable orientation for H-bonding to H(N8), but the interatomic distances are much longer than conventionally accepted for effective H-bonding. The H_2O molecule is almost certainly bonded to MeCN, but details of the bonding could not be ascertained.

Putative interaction can be claimed between the cation H(C) hydrogen H(5) and the phenyls R1 and R2 (H(5)···π_c(R1) ~ 2.82 Å, C(5)-H(5)-π_c(R1) ~ 131°, $\bar{d}$[H(5)···C(R1)] = 3.14(10) Å, mean C(5)-H(5)-C(R1) angle = 129[13]°; H(5)···π_c(R2) ~ 3.19 Å, C(5)-H(5)-π_c(R2) ~ 128°, $\bar{d}$[H(5)···C(R2)] = 3.46[30] Å), and between H(4) and R2 (H(4)···π_c(R2) ~ 3.17 Å, C(4)-H(4)-π_c(R2) ~ 129°, $\bar{d}$[H(4)···C(R2)] = 3.44[38] Å).[35] Furthermore, the H(521) atom of the MeCN molecule is situated appropriately for a bifurcated H(521)···R3,R4 bond (H(521)···π_c(R3) ~ 2.87 Å, C(52)-H(521)-π_cC(R3) ~ 125°; H(521)···π_c(R4) ~ 3.04 Å, C(52)-H(52)-π_c(R4) ~ 117°), so that the anion appears to be H-bonded from opposite sides. The nearly symmetric bifurcation at H(521) may well account for the seemingly unfavourable orientation of the MeCN molecule with respect to the H(N8) atom of the cation and probably represents a compromise between simultaneous weak interactions involving MeCN, the cation, two of the phenyl rings, and the H_2O molecule (Fig. 15).

It should be noted that in both **11** and **12** the solvent molecule engaged in the putative H(C)···phenyl interaction has an appreciable dipole moment (2.83 D for Me_2CO, 3.44 D for MeCN, both in benzene), and that the polar axis of the Me_2CO molecule in **11** is aligned with the column axis (Fig. 15), thus ensuring maximum dipolar interaction of Me_2CO with its neighbours in the column.

TcTBs (13)

The cation geometry is practically the same as that found for the monohydrated hydrochlorides **34** and **35**. The skeletons of the aromatic rings c2 and c3 are planar to 0.020[8] and 0.004[3] Å, respectively, and c3/c2 = 3.2° (Table 9). As in the hydrochlorides, atoms in the saturated portion of c1 are positionally disordered. The coordinates of atoms C(1)–C(4) listed in Table A are the result of modelling the disorder as a 1:1 superposition of two c1 conformations, A and B, with C(13) and C(14) stationary (cf. Experimental). The protonated atom is, as in **34** and **35**, the ring nitrogen N(10), C(11)-N(10)-C(14) = 122.5(6)°. It is weakly bonded to the N(3) atom of the MeCN molecule, N(10)···N(3) = 3.018(7) Å, H(10)···N(3) ~ 2.01 Å, N(10)-H(10)-N(3) ~ 172°. These distances agree well with the estimated obtained for N···N = 3.018 Å from eq. [2], N—H = 1.03 Å, H···N′ ~ 1.99 Å.

The interaction of the amino group with its anion neighbours is very asymmetric (Tables 5, F): the shortest H(9a)···C(phenyl) distance is to R2A, ~2.76 Å (H(9a)···π_c(R2A) ~ 2.60 Å), and the shortest H(9b)···C(phenyl) distance is to R4, ~3.27 Å (H(9b)···π_c(R4) ~ 3.84 Å). The former corresponds to only a weak H(N)···phenyl interaction, while the latter is much too long to qualify for any such significant interaction.[36] Moreover, the geometric H···phenyl parameters involving either amino hydrogen fit only poorly in the correlation plots of ref. 3 for H···phenyl bonds, indicating the absence of an ion-charge reinforcement at the amino group. Nevertheless, the *orientation* of the N(9)–H(9b) vector is favourable for potential H(N)···phenyl bonding.

The gross structure of TcTBs may be regarded as consisting of centrosymmetric [···(cat + MeCN)···an···]$_2$ ring dimers in which H(9a) is bonded to R2 (from one side only), N(9)—H(9b) points in the direction of R4, and rings R1 and R3 remain unengaged (Fig. 16). The dimer groups are thus discrete, i.e., there is no H-bonding interaction between them. In this, TcTBs differs from the structures of **34** and **35** as well as from the mutagenic hydrochloride hydrates **36** and **37**, in all of which the Cl^- anion is 4-coordinated by two amino and

[35] For further details see Table F.

[36] This H-bond engagement is reminiscent of 4-aminopyridine (38), in which only one of the amino hydrogens is involved in an H-bond: N···N′ = 3.01 Å, H···N′ ~ 2.13 Å, N-H-N′ ~ 169° (N, amino nitrogen; N′, ring nitrogen of a neighbouring molecule).

© 1998 NRC Canada

two water hydrogens, so that the anion and the water molecule are able to propagate the H-bonding three-dimensionally throughout the crystal (Fig. 16). Viewed along *b*, the centroids of the cations and anions project into a honeycomb array of irregular centrosymmetric hexagons with *b* as the column axis and with the MeCN molecules forming 2_1-helices about this axis.

In contrast to protonated 4-aminopyridine (**39**, **40**), the py_2H^+-type cation with mutually perpendicular pyridine rings and a short N···N′ separation (N···N′ ~ 2.70 Å, N—H ~ 1.17 Å, H···N′ ~ 1.52 Å. N-H-N′ ~ 177°) is not present in the structures of the 9-aminoacridine derivatives of Fig. 16. The reason for this might be the inefficient space filling that would result if the two three-ring acridine systems were mutually perpendicular. In fact, even the formation of an essentially coplanar biacridine cation appears to be stereochemically unfavourable (H(C) repulsions!).

It is noteworthy that the compounds discussed in this section, all of which contain a 4-aminopyridine core, have properties injurious to human biology (high toxicity, strong mutagenic activity, undesirable enzyme inhibitions.

Experimental

The TBs were prepared by precipitation from aqueous solutions of $NaBPh_4$ and the appropriate organoammonium halide, usually the chloride. After washing with water the precipitate was recrystallized from MeCN, or it was dissolved in acetone and water was added until a precipitate reappeared. Sufficient acetone was then added to restore the clear solution, and the resulting solution was allowed to crystallize by slow evaporation at room temperature. For X-ray work the crystals were sealed in glass capillaries.

The crystallographic information is summarized in Table 2. All intensities were corrected for Lorentz, polarization, absorption (ψ-scans), secondary extinction, and, where appropriate, for time-decay effects. We wish to reiterate that, in general, organoammonium TB crystals are weak and fickle scatterers. As pointed out previously (1–3), significant reflections are seldom observed above a (sin θ)/λ limit of 0.48 $Å^{-1}$ (θ_{Mo} ~ 20°, θ_{Cu} ~ 48°). Since in this laboratory X-ray data collection routinely extends to (sin θ)/λ ~ 0.55 $Å^{-1}$ (θ_{Mo} ~ 25°, θ_{Cu} ~ 60°), the ratio of observed reflections to total measured unique reflections never exceeds 50%. In several cases there was an observable decline in the intensities of the standard reflections over the course of data collection (see below). A linear correction was applied to take account of the decline unless stated otherwise.

The structures were solved by direct methods (59) and refined using the TEXSAN-TEXRAY software package (60) or SHELXL-93 (61) or both. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$. The anisotropic temperature factor is defined as $\exp[-2\pi^2(U_{11}h^2a^{*2} + ... + 2\ U_{12}\ hka^*b^* + ...)]$; U_{iso} (H) = $1.2U_{eq}$(X) of the attached X atom. The H(C) atoms, though seen in the difference maps, were in the final refinement placed geometrically and not refined. The positions of the H(N) atoms were obtained from the difference maps; in favourable cases they were well defined (e.g., in Figs. A and B) and were kept fixed at the observed values during the final refinement, as noted. Otherwise the H(N) atoms were placed geometrically and not refined.[37] In addition to Table 2 the following experimental details are noted:

1: pale lemon yellow.[24] **2**: yellow crystals; H(N) refined isotropically, N—H, 1.17(4) Å. **2A**: crystal cut from a light-yellow needle; ~5% intensity decline. **3**: colourless needle; <1% decline. **4**: yellow needle, ~1% decline. **5**: colourless needle; ~6% decline. **6**: N—H. 1.18 Å. **7**: crystal cut from a faint yellow plate. **8**: in contrast to the unsolvated **7** obtained from aqueous acetone, the crystals obtained from MeCN were solvated. Although the colourless block crystal was in a sealed glass capillary, it appeared to lose solvent. To compensate for the ~70% intensity decline, a fourth-order polynomial correction was applied. ORTEP drawings before the last refinement showed that the thermal ellipsoids on the B and cation C(11)–C(14) atoms were essentially spherical; these atoms were therefore refined only isotropically. **9**: orange needle. **10**: colourless needle. **11**: colourless block; N—H. 1.18 Å, C—H = O—H = 0.95 Å. **12**: colourless prism; ~30% decline; N—H. 1.17 Å, C—H = O—H = 0.95 Å. In the final refinement the N(1) and N(8) atoms were treated isotropically, as their thermal ellipsoids in the preceding refinement were nearly spherical and the d/p ratio was not high. **13**: the quality of the yellow needles obtained from MeCN was rather poor; ~6% decline. To model the disorder in ring c1 the structure was refined by full-matrix least squares on F^2 using SHELXL-93, with the C—C bond lengths and angles involving carbons C(1)–C(4) loosely constrained. This treatment differs from that of **20** and **34** (22, 23), where only carbons C(2) and C(3) were assumed disordered. The anion was refined as a rigid body, and the nonhydrogen atoms of the MeCN molecule were refined isotropically. The H(N) atoms, though seen in the difference map, were placed geometrically (N—H. 1.02 Å) and not refined. The exocyclic NH_2 group was treated as an extension of the planar system of rings c2 + c3.

Acknowledgments

We thank Dr M. Falk and Mr Ping Seto for obtaining the FT-ir spectra, and Dr R.W. Alder for providing us with unpublished experimental data on the inside-protonated cations. This investigation was supported by grants from the Natural Sciences and Engineering Research Council of Canada to O.K. and T.S.C.

[37] The structures of the 14 compounds were determined over a period of time and by different hands. This and the varying quality of the primary data accounts for a certain nonuniformity in the treatment of the H-atoms. The earlier refinements were based on assumed C—H, N—H, and O—H bond lengths of 1.08, 1.02, and 1.00 Å, respectively. In the more recent determinations the H-atoms were placed at C—H = 0.96 Å, N—H = O—H = 0.95 Å, or as mentioned under the individual structures.

Coupling P-31 NMR with the Mannich reaction for the quantitative analysis of lignin

Zhi-Hua Jiang and Dimitris S. Argyropoulos

Abstract: The reactivity of lignin model compounds under Mannich conditions with piperidine and formaldehyde was studied. The piperidinomethyl group was confirmed to be introduced quantitatively at sterically unhindered positions *ortho* to a phenolic hydroxyl when the substrate was allowed to react under ambient conditions. The sequential application of the Mannich reaction followed by quantitative ^{31}P NMR on a variety of lignin samples allowed the amounts of various aromatic groups bearing free phenolic hydroxyls to be determined. More specifically, the technique allowed the quantification of *para*-hydroxyl phenols, catechols, guaiacols, and phenols bearing C_5 or C_6 substituents. The quantitative reliability of the technique was also examined with a series of dissolved kraft lignins, isolated at various degrees of delignification. The data were found to favourably compare to those obtained by permanganate oxidation.

Key words: lignin, lignin model compounds, Mannich reaction, nuclear magnetic resonance (NMR), phenols, phosphorus, piperidine, quantitative analysis.

Résumé : On a étudié la réactivité de composés modèles de la lignine dans la réaction de Mannich avec de la pipéridine et du formaldéhyde. Il a été confirmé que, lorsque le substrat réagit dans des conditions ambiantes, le groupe pipéridinométhyle s'introduit quantitativement dans les positions stériquement non empêchées en *ortho* de l'hydroxyle phénolique. L'application séquentielle de la réaction de Mannich sur divers échantillons de lignine, suivie d'une étude quantitative RMN du ^{31}P, permet de déterminer les quantités de divers groupes aromatiques portant des hydroxyles phénoliques. D'une façon plus spécifique, la technique permet de quantifier les *para*-hydroxyphénols, les catéchols, les guaïacols et les phénols portant des substituants en C_5 et en C_6. On a aussi évalué la fiabilité quantitative de la technique avec une série de lignines kraft dissoutes, isolées à divers degrés de délignification. On a trouvé que les données se comparent favorablement à celles obtenues par oxydation avec le permanganate.

Mots clés : lignine, composés modèles de la lignine, réaction de Mannich, résonance magnétique nucléaire (RMN), phénols, phosphore, pipéridine, analyse quantitative.

[Traduit par la rédaction]

1. Introduction

Softwood lignin contains, amongst others, a variety of phenolic units that may be classified (1, 2), based on their substitution patterns, as shown in Fig. 1. The relative frequencies of these moieties have been determined by a variety of degradative techniques, i.e., oxidative degradation (3–5) and thioacidolysis–desulfuration (6). Amongst the nondegradative methods of analysis, advanced ^{13}C NMR spectroscopy may offer a quantitative estimate for some of these units (7). Its execution, however, requires acetylation, independent methoxyl analyses, and lengthy acquisition protocols. Therefore, at present, there is no facile, nondegradative means to determine these units.

The potential and unique features of 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane as an additional phosphitylation reagent used in quantitative ^{31}P NMR analysis of lignin have been demonstrated by Jiang et al. (8) and Granata and Argyropoulos (9). This reagent offers some distinct advantages compared to 2-chloro-1,3,2-dioxaphospholane, i.e., better resolution of the various phenolic moieties (8, 9), permitting the accurate calculation of ^{31}P chemical shifts for various phenolic compounds (8), and better stability of the phosphitylated moieties (9).

However, the spectral resolution obtained using 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane as the phosphitylation reagent is still not adequate for quantifying all types of phenolic structures. The ^{31}P NMR signals belonging to types (B), (C), and (D) phenolic units overlap in the region of 138.3–140.2 ppm as observed by Granata and Argyropoulos (9). The information about the amount of each type of phenolic units (B), (C), and (D) cannot therefore be determined using quantitative ^{31}P NMR alone. Data reported elsewhere by Jiang et al. (8) demonstrated that *ortho* substitution onto the aromatic ring of phenols has a considerably higher effect on the magnitude of the ^{31}P NMR chemical shifts than that of *para* and *meta* substitution patterns. As such it became of interest to investigate the potential of coupling quantitative ^{31}P NMR with the Mannich reaction, aimed at obtaining further structural information for lignin.

The Mannich reaction on phenols is a classic organic reaction. The essential feature of the reaction is the replacement of

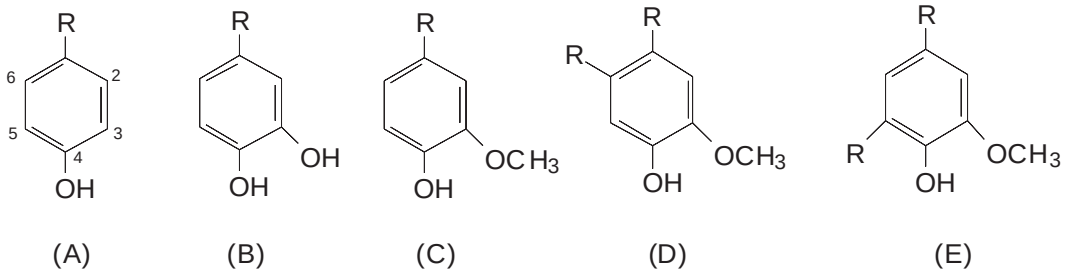
Fig. 1. The major types of phenolic units in softwood lignin, where R represents a lignin interunit [1,2].



the active hydrogen atoms in phenols, especially active hydrogen atoms in positions *ortho* and *para* to phenolic hydroxyl groups, by aminomethyl or substituted aminomethyl groups (10–15).

The reactivity of various lignin model phenols toward the Mannich reaction with dimethylamine and (or) piperidine was first investigated by Mikawa et al. (17). They demonstrated that a dimethylaminomethyl or piperidinomethyl group was introduced quantitatively to free C_5 positions of lignin-related phenolic units (17). The application of the Mannich reaction to lignin, followed by nitrogen analysis, allowed Mikawa et al. (17) to quantify the phenolic units with free C_5 positions in lignin. Their data showed that about 25–40% of the phenolic hydroxyl groups in a dissolved softwood kraft lignin belong to this type of phenolic unit. The Mannich reaction has also been applied in the preparation of lignin derivatives with ion-exchange properties by Brezny et al. (18) and Rusina et al. (19).

This study examines the potential of coupling the Mannich reaction with quantitative ^{31}P NMR, to provide further fine structural information of lignin. Initially, the course and conditions of the Mannich reaction with piperidine were examined on 4-hydroxy-3-methoxybenzoic acid, and then the Mannich reaction with piperidine was carried on a variety of lignin model compounds. Finally the Mannich reaction was coupled with quantitative ^{31}P NMR for quantifying various types of phenolic units in lignin. The determined values were compared to those reported in the literature for similar samples.

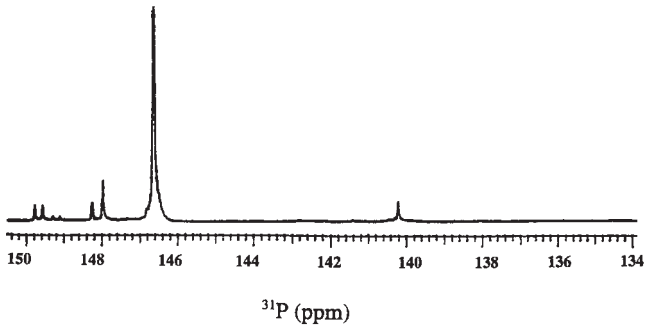
2. Results and discussion

2.1 Studies on lignin model compounds

Although dimethylamine is the most frequently reported secondary amine for use in the Mannich reaction of phenols, piperidine was chosen in this study since the former also causes substitution at available methylol groups (17). Piperidine is more selective in this respect (unreactive with methylol groups) (17), yet of comparable reactivity to dimethylamine (15).

The work of Mikawa et al. (17), using either dimethylamine or piperidine as bases, has shown that type (C) lignin model compounds (see Fig. 1) give, without exception, C_5 substituted Mannich bases at very high yields. When the C_1 position of type (C) is a carboxyl group, it forms the Mannich base with simultaneous decarboxylation and substitution at the C_5 and C_1 positions. Other C_1 groups remain intact when piperidine is used. Mikawa et al. (17) also confirmed that type (E) moieties do not react, and also the Mannich reaction does not occur in all cases, when the phenolic hydroxyl group is etherified. These conclusions offered the basis for interpreting the ^{31}P NMR spectra obtained with the following lignin model compounds, using 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane as a phosphitylation reagent. Since the ^{31}P chemical shifts of phenolic hydroxyls with various substitution patterns strongly depend on the nature of the substituents, they can be calculated using the parameters developed by Jiang et al. (8). All lignin-related phenols with *ortho*-mono substituents have ^{31}P chemical shifts within the range 138.3–140.5 ppm. These signals are completely separated from those of *ortho*-disubstituted phenols, including phenols with a substitution of a piperidinomethyl group at C_5 positions, which are located in the range 141.1–144.5 ppm (8).

Fig. 2. The ^{31}P NMR spectrum, phosphitylated with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane, of blank Mannich reaction medium, a mixture of equivalent amounts of piperidine and formaldehyde with 3.3 equiv. of ethanol.



Furthermore, in the early phases of this study, it was found that the ^{31}P NMR technique could be applied to identify the Mannich reaction products even if the reaction products are not completely pure. A ^{31}P NMR spectrum of the Mannich reaction medium used in this work (a mixture of equivalent amounts of piperidine and formaldehyde with 3.3 equiv. of ethanol) is shown in Fig. 2. The major signals of the reaction medium are located in the downfield (146–150 ppm) and are well separated from those signals of phenols and carboxylic acids (8, 9).

The course and conditions of the Mannich reaction with piperidine were first reexamined on 4-hydroxy-3-methoxybenzoic acid **1** (see Fig. 3) as a lignin model compound. Figure 4 shows the ^{31}P NMR spectra of 4-hydroxy-3-methoxybenzoic acid under Mannich conditions as a function of time. The following progressive changes can be visualized from these spectra: (*i*) reduction of signal intensity at 139.1 and 135.1 due to the ^{31}P derivatives of the phenolic hydroxyl and the carboxylic acid of 4-hydroxy-3-methoxybenzoic acid respectively; (*ii*) increase of signal intensity at 143.7, which is assigned to the ^{31}P derivative of the phenolic hydroxyl of the Mannich

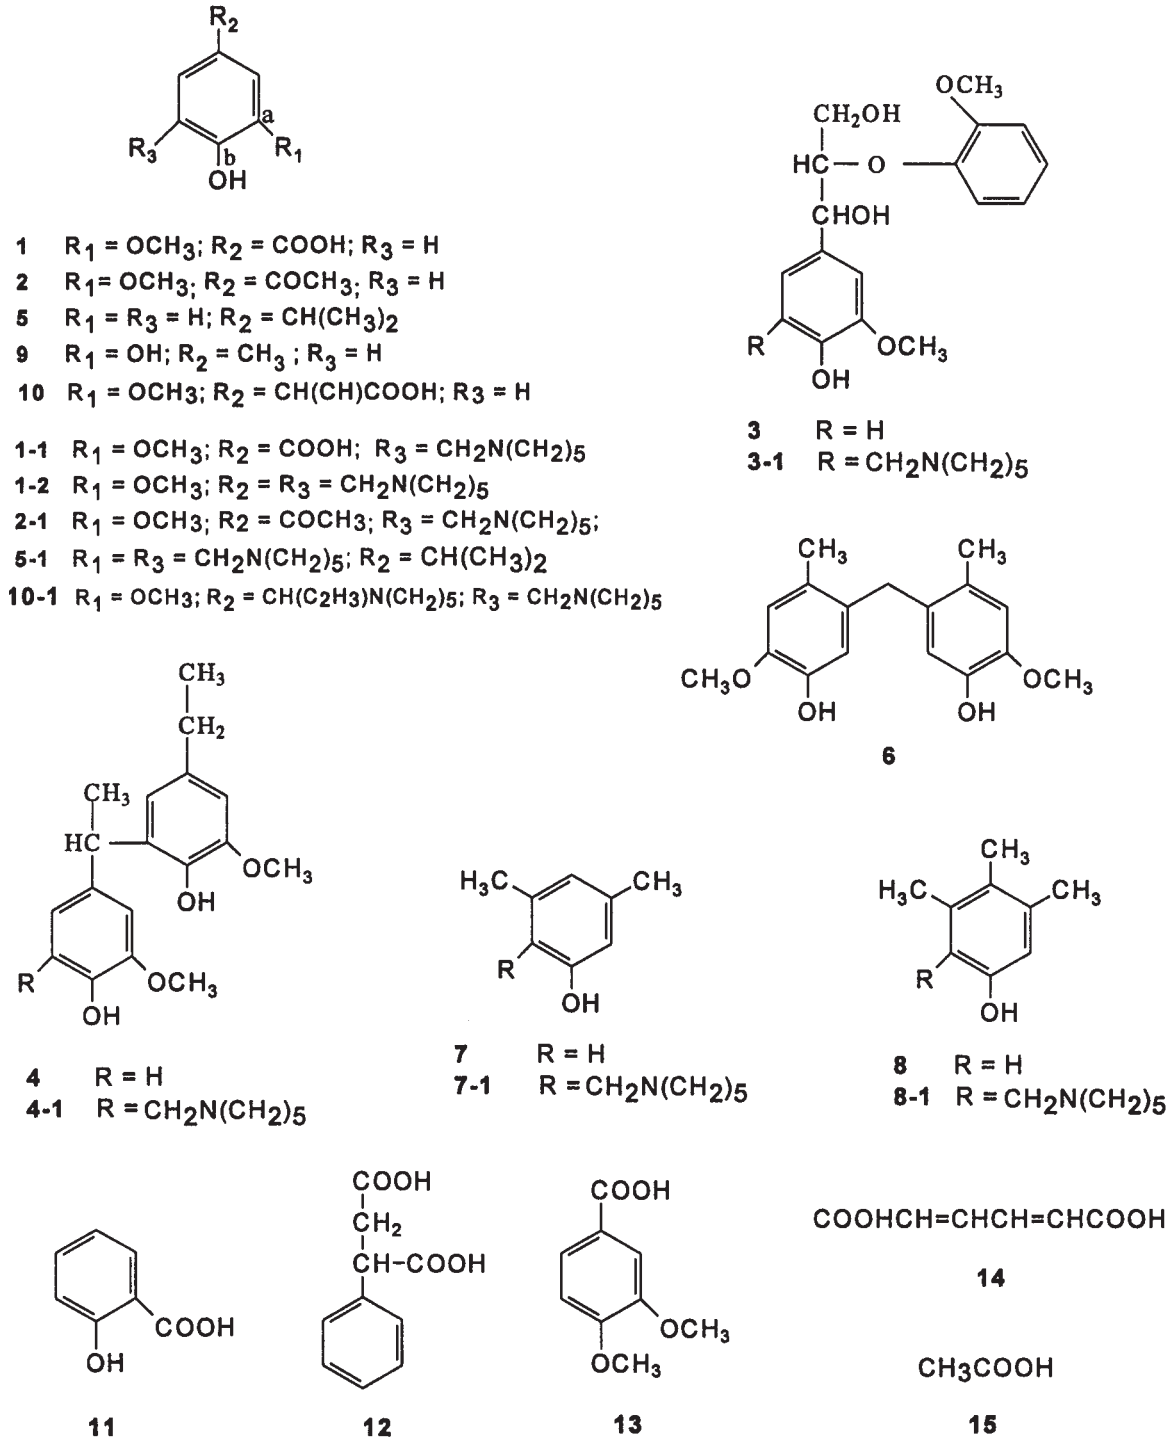
Fig. 3. The structure of model compounds examined in this work and their Mannich reaction products with piperidine and formaldehyde.



base, 2,4-dipiperidinomethyl-6-methoxyphenol **1-2** (see Fig. 3); (*iii*) increase over the first day and reduction thereafter of signal intensity at 143.4, which is assigned to the ^{31}P derivative of the phenolic hydroxyl of the Mannich base, 5-piperidinomethyl-4-hydroxy-3-methoxybenzoic acid **1-1** (see Fig. 3). Figure 5 shows further the results of this kinetic investigation.

As anticipated, the active hydrogen position *ortho* to the phenolic hydroxyl in 4-hydroxy-3-methoxybenzoic acid **1** was completely substituted to form the Mannich base **1-1** within 24 h. However, the displacement of the carboxyl group, which results in product **1-2**, was considerably slower as evidenced from quantitative ^{31}P NMR studies, which showed that the carboxyl groups reacted completely only after a 5-day reaction period. When the temperature was increased to 45°C, more than 50% of the carboxyl groups in model **1** were substituted within 2 h and about 85% of them were reacted after 6 h. Besides, the reaction of model **1** was found to be considerably

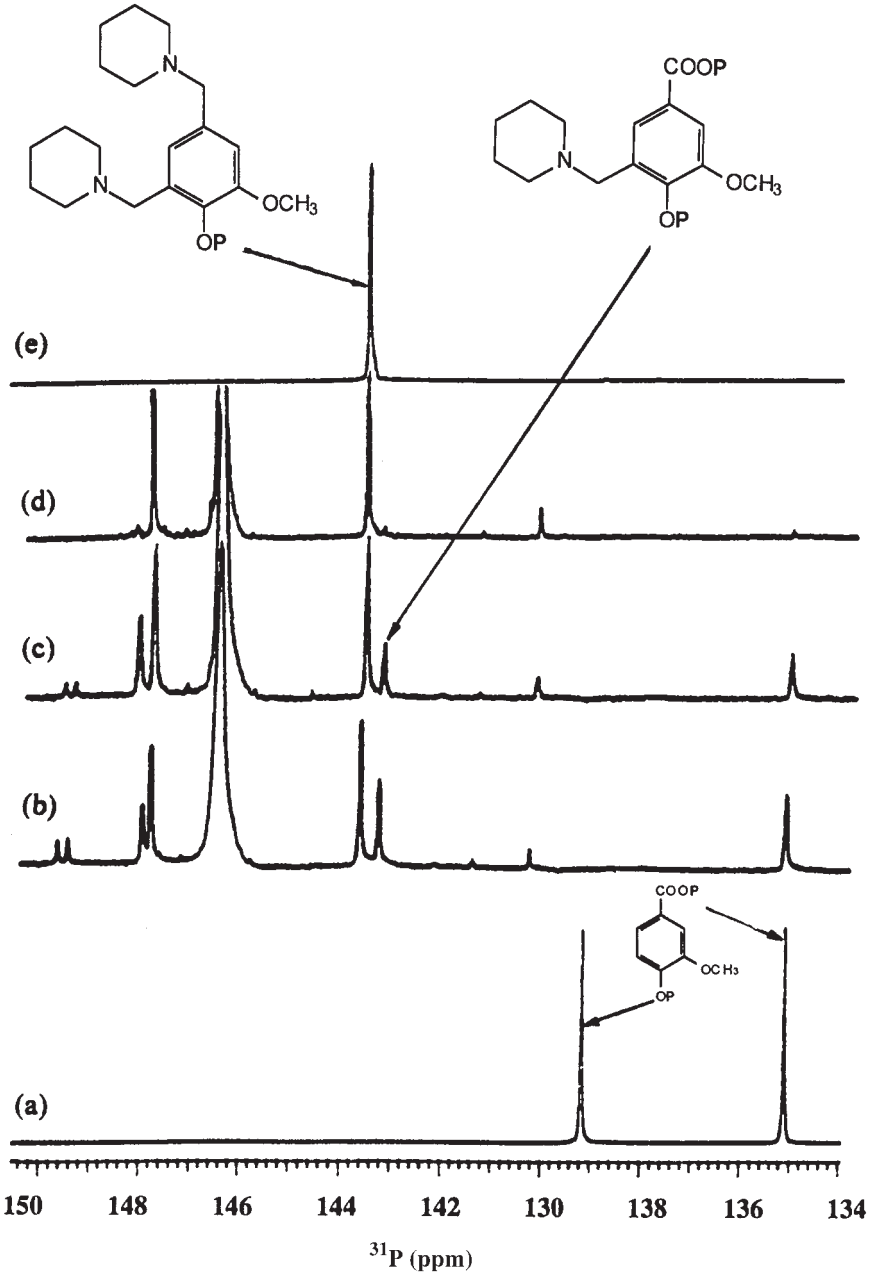
Fig. 4. The ^{31}P NMR spectra, phosphitylated with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane (shown as P), of 4-hydroxy-3-methoxybenzoic acid under the Mannich reaction conditions as a function of time: (*a*) before reaction; (*b*), (*c*), and (*d*) after reaction for 1, 3, and 5 day(s), respectively; (*e*) after reaction for 5 days followed by purification. The unassigned signals belong to the Mannich reaction medium (see Fig. 2).



slower under acidic conditions. At pH 4–5 and after 3 days of reaction, only about 38% of the carboxylic groups and 92% of the active hydrogen position *ortho* to the phenolic hydroxyl were replaced. At the same pH and at 45°C, 11.5% of the carboxylic groups and 23.5% of the active hydrogen position *ortho* to the phenolic hydroxyl were replaced after 3 h.

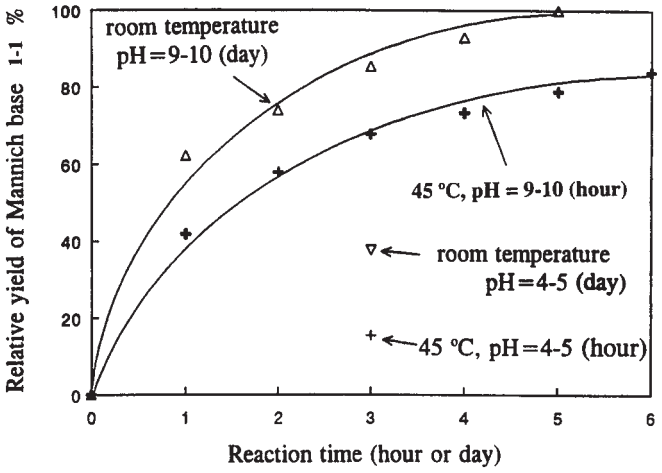
The Mannich reaction was then carried out at room temperature on a variety of lignin-related model phenols. These model compounds were such chosen so as to represent all types of phenolic units in softwood lignin as shown in Fig. 1. The structure of these model compounds and their Mannich reaction products are shown in Fig. 3.

Acetovanillone **2** and lignin model dimer **3** over a period of 5 days gave the Mannich bases **2**-**1** and **3**-**1**, respectively. The active hydrogen positions *ortho* to the phenolic hydroxyl were substituted, however, the side chains of models **2** and **3** remained intact, in agreement with Mikawa et al. (17). Lignin model dimers **4**, over a period of 24 h, gave the Mannich base **4**-**1** with a 5-piperdinomethyl substituent at the C_5 position as expected.

p-Isopropylphenol **5**, which represents type (A) phenolic units, containing two active hydrogen positions *ortho* to the phenolic hydroxyl, was found to yield the Mannich base **5**-**1** within 5 days. Similar observations have also been reported

© 1998 NRC Canada

Fig. 5. The course of the Mannich reaction with piperidine on 4-hydroxy-3-methoxybenzoic acid under various conditions.



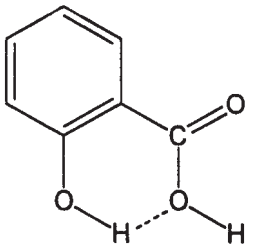
when unhindered phenols were allowed to react with dimethylamine and morpholine (15). No changes in terms of ^{31}P NMR chemical shifts were observed for model **6**, after the Mannich reaction was carried out for 5 days at room temperature. This seems to indicate that both unsubstituted positions *ortho* to the phenolic hydroxyls were unreactive because the substitution of the piperidinomethyl group at one of these positions is expected (8, 20) to result in a very significant change in the ^{31}P NMR chemical shift (downfield shift of about 4 ppm).

After the Mannich reaction, the ^{31}P NMR chemical shifts of both models **7** and **8** were found to shift downfield by about 0.7 ppm. For a similar reason as described above, these data seem to indicate that the reaction products were Mannich bases bearing a substituent *ortho* to the phenolic hydroxyl.

Although this information seems to be adequate as far as the main objective of this study is concerned, these products were further purified and identified. It was found that only one unsubstituted position *ortho* to the phenolic hydroxyl reacted. This is very likely due to steric effects exerted by the peri positions, inhibiting Mannich disubstitution. Steric factors are known to significantly affect the course of the Mannich reaction (15). For example, hydroquinone treated with 3 equiv. each of dimethylamine and formaldehyde gave 2,5-dimethylhydroquinone not tri-(dimethylaminomethyl)-hydroquinone (21). Also, 5,7-bis(piperidinomethyl)-8-quinolinol could not be prepared by means of the Mannich reaction with 8-quinolinol under usual conditions, since only monosubstituted Mannich base (7-piperidinomethyl-8-quinolinol) was formed (16).

When the Mannich reaction was carried out on model **9** (*m*-methylcatechol), using 3 equiv. of piperidine, a mixture of several Mannich bases was obtained. No attempts were made to identify these products. However ^{31}P NMR analyses of the products seem to indicate that the positions *ortho* to the phenolic hydroxyl (C_2 and C_5) were not simultaneously substituted, and one of them was substitued by the piperidinomethyl group, as evidenced by quantitative ^{31}P NMR analysis of the mixtures of the Mannich base products, which showed that the signal intensity in the range of 138.4–139.0 ppm is the same compared to those in the range of 143.0–144.4 ppm. The signals at around 138.4–139.0 and 143.0–144.4 ppm are known to be due to the phenolic hydroxyl groups with *ortho*-mono and *ortho*-disubstitutents, respectively (8).

Fig. 6. A possible six-membered ring in salicylic acid formed through hydrogen bonding.



Similar to model **3**, 4-hydroxy-3-methoxycinnamic acid **10** gave Mannich base **10-1** with simultaneous decarboxylation. However, such decarboxylation reactions were not observed when the Mannich reaction was carried out, under similar conditions, on model acid compounds salicylic acid **11**, phenylsuccinic acid **12**, 3,4-dimethoxybenzoic acid **13**, muconic acid **14**, and acetic acid **15**, as evidenced by ^{31}P NMR analyses, which showed that the ^{31}P NMR signals of acid groups in these models did not change in terms of position and intensity. These observations seem to indicate that the decarboxylation reaction, during the Mannich reaction, may occur only to the carboxyl groups that link (i.e., model **1**) or are conjugated with (i.e., model **10**) aromatic units bearing a *para* hydroxyl substituent.

The Mannich reaction did not seem to occur on the positions *ortho* and *para* to the phenolic hydroxy of salicylic acid **11** because the ^{31}P NMR signal position due to the phenolic hydroxy group did not change after the Mannich reaction. Similar results were reported previously by Regnier et al. (22). A possible explanation for this phenomenon is that intramolecular interactions cause the formation of a six-membered ring and may consequently reduce the acidity of the phenol and prevent Mannich substitution as shown in Fig. 6.

2.2 Summary of studies on lignin model compounds

The results of the model compound studies described above confirmed and complemented the results reported by Mikawa et al. (17). These results showed that: (*i*) model compounds of type (A) gave Mannich bases with the substituents at both the C_3 and C_5 positions; (*ii*) a type (B) model compound gave a mixture of the Mannich bases with the substituent at the C_2 or C_5 position; (*iii*) model compounds of type (C) gave Mannich bases with the substituent at the C_5 position; (*iv*) those of type (D) and (E) do not react; (*v*) carboxyl groups that link or are conjugated with aromatic units bearing a phenolic hydroxyl group in the *para*-position gave Mannich bases with simultaneous decarboxylation; however, all other carboxyl groups do not react; (*vi*) all other groups attached to phenolic aromatic units at C_1 positions including methylol and methyl groups remain intact.

2.3 Summary of ^{31}P NMR chemical shifts of Mannich base products

A methodology for accurate prediction of the ^{31}P chemical shifts of lignin-related phenolic compounds was developed in our previous effort as a result of correlation analysis using the Hammett principles (8). This methodology has recently been

[d] For all these compounds, no changes in terms of signal positions were observed after the Mannich reaction.

successfully applied for calculating or assigning the ^{31}P chemical shifts of phenolic units in lignin (9, 20, 23). In the present study the methodology was also applied to calculate the changes of the ^{31}P chemical shifts occurring on model phenols before and after the Mannich reaction (Table 1). These changes were further generalized as shown in Table 2, using the parameters previously developed (8, 20) and taking the changes of the lignin structure after the Mannich reaction into account.

2.4 The Mannich reaction on lignin

2.4.1 Kinetics of the Mannich reaction with piperidine on lignin

Prior to embarking at an extensive investigation of the Mannich reaction on lignin, a kinetic study was carried out on a dissolved softwood kraft lignin isolated at a degree of delignification of 92.9%. When this lignin sample was treated with formaldehyde and piperidine, the nitrogen content of the lignin sample was found to increase as the reaction time was prolonged (Table 3). The increase was most pronounced during the first 2 days, which seems to reflect the rapid replacement of the active hydrogens in phenolic units by the piperidinomethyl group. This increase is unlikely to be attributed to piperidine contamination because the excess piperidine seems to be effectively removed by the work-up procedure applied (see relevant experimental section for more details). The nitrogen content was found to remain constant after 3 days. Very similar results were also reported by Mikawa et al. (17) with dimethylamine. The Mannich reaction on lignin was therefore carried out at room temperature for 5 days.

2.4.2 The determination of the various phenolic moieties in kraft lignin

A series of dissolved and well characterized (24) softwood kraft lignins, isolated at various degrees of delignification, were subjected to the Mannich reaction with piperidine at room temperature for 5 days. Quantitative ^{31}P NMR analyses prior to and after the Mannich reaction quantified the various phenolic units in the lignin samples. Figure 7 shows typical quantitative ^{31}P NMR spectra of such a lignin sample and its Mannich reaction product.

By integrating the region between 144.4–140.3 ppm and 138.2–137.3 ppm in the spectrum before the Mannich reaction (Fig. 7*a*), the amounts of type (E) and type (A) phenolic nuclei can be quantified. Integration of the region 140.2–138.3 ppm in the same spectrum allows the determination of the sum of phenolic types (B), (C), and (D) to be made. Furthermore, integration over from 144.4 to 137.3 ppm allows the determination of the amount of all phenolic moieties. These integration ranges applied are based on previous model compound (see Table 2 for details) and lignin studies by Granata and Argyropoulos (9). Such integration ranges have recently been adopted by Sun and Argyropoulos (25, 26), Froass et al. (27), and Senior et al. (28).

On the other hand, the ^{31}P NMR signals at 139.1–138.0, 140.4–139.1, and 144.8–138.0 ppm, in the spectrum after the Mannich reaction (Fig. 7*b*), could be assigned to the corresponding Mannich base products of phenolic (B), (D), and the sum of all types of phenolic units, respectively. These integration ranges are based on the results of early calculations (Table 2). Integrating the ranges between 139.1–138.0 and 140.0–139.1 ppm and dividing these integrals to the integral obtained by integrating the region 144.8–138.0, respectively, gives rise to the relative frequencies of type (B) and (D) phenolic units, expressed in terms of their percentages in the total phenolic hydroxyls. These relative frequencies should remain unchanged prior to and after the Mannich reaction. The absolute amounts of type (B) and (D) phenolic units in a given sample can therefore be obtained by multiplying their relative frequencies with the absolute amount of all phenolic hydroxyls obtained by integrating the region 144.4–137.3 ppm in the spectrum (*a*) of Fig. 7. By subtracting the absolute amounts of type (B) and (D) phenolic units from the sum of (B), (D), and (C), obtained by integrating the region 140.2–138.3 ppm in the spectrum (*a*) of Fig. 7, the amount of type (C) phenolic units in a given sample was calculated.

Using the method described above, the absolute amounts of all types of phenolic units shown in Fig. 1 could be quantified. This method when applied to a series of softwood dissolved kraft lignin samples revealed the data of Table 4. These data can now be compared to those reported in the literature with similar samples. The relative frequencies of individual phenolic units (A)–(E) were calculated and expressed as a percentage of the total phenolic hydroxyl content. The major phenolic units were then compared to those obtained by Gellerstedt and Gustafsson (29) using permanganate degradation analysis (Fig. 8). The agreement shown between the two sets of data is apparent, bearing in mind that different wood species and techniques were used to detect these moieties. In addition, a

comparison of the sum of types (A), (B), (C), and (D) phenolic units can also be made for a sample of softwood milled wood lignin. When these moieties are expressed per methoxyl group, Alder and Lundquist (30) obtained values of 0.15–0.18 using Fremy's salt oxidation, while the methodology of this work showed a value of 0.16.

2.4.3 The reproducibility of the Mannich – ^{31}P NMR analysis

Quantitative ^{31}P NMR analysis of lignin using 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane as the phosphitylation reagent was found to have a high reproducibility by Sun and Argyropoulos (25). For all functional groups, the maximum error obtained between duplicate acquisitions was found to be below 1% (25). This is probably due to the better stability of the moieties phosphitylated with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane than with 2-chloro-1,3,2-dioxaphospholane moieties (9).

In an effort to examine the reproducibility of the Mannich – ^{31}P NMR technique, the dissolved softwood lignin with a degree of delignification of 92.9% was subjected to three Mannich – ^{31}P NMR analyses (Table 5). The relative standard derivation obtained for the major types of phenolic units (types (C) and (E)) was found to be less than 6.0%.

3. Experimental

3.1 ^{31}P NMR spectroscopy

The lignin sample (about 40 mg), predried overnight in a vacuum oven set at 40°C, was dissolved with 800 μL of solvent (pyridine – deuterated chloroform 1.6:1 v/v) at room temperature in a 5 mL flask with magnetic stirring. Internal standard cyclohexanol (about 1.3 mg) and relaxation reagent chromium acetylacetonate (about 0.4 mg) were added as 200 μL in the same solvent mixture, and the solution was stirred until the lignin was fully dissolved. The phosphitylation reagent

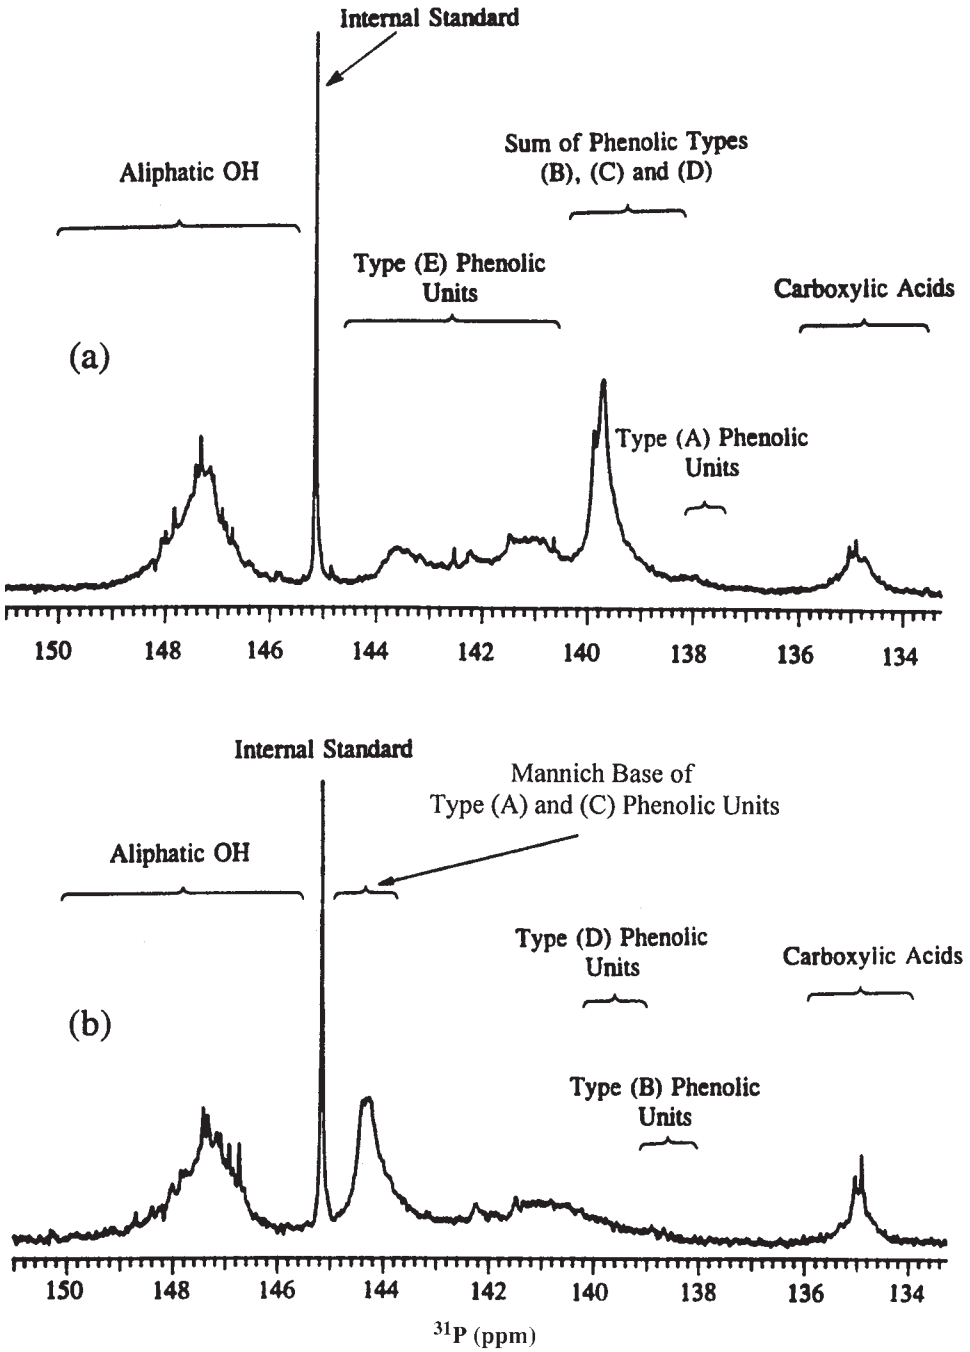
Fig. 7. Quantitative ^{31}P NMR spectra, phosphitylated with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane, and signal assignment of (*a*) a softwood kraft dissolved lignin sample and (*b*) its Mannich reaction product with piperidine. The chemical shifts of type (E) phenolic units do not change after the Mannich reaction.



2-chloro-4,4,-5,5-tetramethyl-1,3,2-dioxaphosphalane (about 100 μL), was then added and the flask was sealed, stirred to ensure thorough mixing, and this slightly exothermic reaction was complete in about 20 min.

Quantitative ^{31}P NMR analysis was obtained in 5 mm sample tubes on a Varian XL-300 spectrometer at 125.5 MHz following the procedures described by Granata and Argyropoulos (9).

3.2 ^{1}H NMR spectroscopy

The ^{1}H NMR spectra were obtained in 5 mm sample tubes on a Varian XL-200 or Varian XL-300 NMR spectrometers, operating at 200.1 and 299.9 MHz, respectively. Deuterated chloroform was used as solvent and tetramethylsilane was used as internal reference. No relaxation delay was used during acquisition.

3.3 Gas chromatography – mass spectroscopy

The GC–MS analyses were carried out on a Hewlett–Packard 5792 mass spectrometer interfaced to a Hewlett–Packard 5890A gas chromatography with a 30 m × 0.25 mm packed silica capillary column DB-5. The injection port temperature was 280°C, and the oven temperature was varied from 100 to

250°C, with a gradient of 10°C/min. Samples were analyzed after silylation with chlorotrimethylsilane.

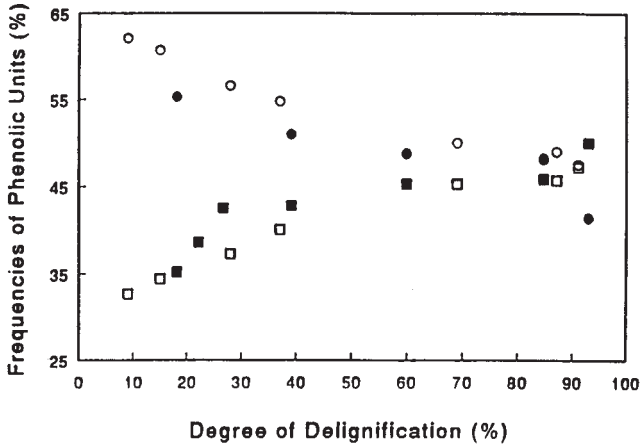
3.4 Elemental analyses

Elemental analyses were carried out by the Schwarzkopf microanalytical laboratories, Woodside, N.Y., in a Perkin–Elmer 2400 carbon, hydrogen, and nitrogen analyzer.

3.5 Mannich reaction with piperidine on 4-hydroxy-3-methoxybenzoic acid

4-Hydroxy-3-methoxybenzoic acid **1** (20 mmol) was dissolved in a mixture of 99% piperidine (60 mmol), aqueous formaldehyde (37%) (60 mmol), and absolute ethanol (20 mL). The reaction mixture was kept at a preset temperature for the required time with occasional shaking. When necessary, the solution was acidified to pH 4–5 with acetic acid prior to the onset of the reaction. After the reaction, a few drops of the solution were used for the ^{31}P NMR analyses without purification. The work-up prior to obtaining the spectrum of Fig. 1(*d*) was as follows: the solution was concentrated repeatedly in order to expel residual Mannich reagents by adding distilled water and freeze-dried. The solid product obtained was subjected to ^{31}P NMR and GC–MS. ^{31}P NMR δ (ppm): 143.7; MS *m/z*: 390 (M^+, 6), 375 (11), 307 (48), 232 (9), 222 (100), 207 (32), 191 (64), 149 (9), 98 (23), 73 (65), 55 (8). ^{1}H NMR (200 MHz, TMS, $CDCl_3$) δ (ppm): 1.30–1.80 (m, 12H), 2.25–2.90 (m, 8H), 3.75 (s, 4H), 3.86 (s, 3H), 6.68 (s, 1H), 6.94 (s, 1H).

Fig. 8. A comparison of the relative frequencies of type (C), circles, and type (E) phenolic units, squares, as obtained by this work, closed symbols, and those reported by Gellerstedt and Gustafsson (29), open symbols.



3.6 Mannich reaction with piperidine on other model compounds

*Acetonevanillone **2***

Acetonevanillone **2** (10 mmol), 99% piperidine (20 mmol), aqueous formaldehyde (37%) (20 mmol), and absolute ethanol (10 mL) were mixed and allowed to stand at room temperature for 5 days. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water and freeze-dried to give the Mannich base product 5-piperidinomethyl-acetonevanillone **2-1** in a quantitative yield based on ^{31}P NMR analysis. ^{31}P NMR δ (ppm): 143.5; ^{1}H NMR (200 MHZ, TMS, $CDCl_3$) δ (ppm): 1.50–1.75 (m, 6H), 2.40–2.80 (m, 7H), 3.76 (s, 2H), 3.92 (s, 3H), 7.28 (s, 1H), 7.43 (s, 1H). MS *m/z*: 335 (M^+, 22), 320 (15), 292 (11), 252 (42), 221 (57), 194 (19), 179 (8), 144 (11), 98 (39), 84 (100), 73 (66), 55 (8). For crystallization, 5-piperidinomethyl-acetonevanillone (6 mmol) was dissolved in absolute ethanol (5 mL), and concentrated hydrochloric acid (6.2 mmol) was added. The product precipitated as crystals when the mixture was cooled in a fridge. It was finally recrystallized from absolute ethanol, yield 59%. No correct elemental analysis results were obtained.

*1-(4-Hydroxy-3-methoxyphenyl)-2-(2-hydroxy-3-methoxyphenol)-1,3-propanediol **3***

To 1-(4-hydroxy-3-methoxyphenyl)-2-(2-hydroxy-3-methoxyphenol)-1,3-propanediol **3** (5 mmol) was added 99% piperidine (10 mmol), aqueous formaldehyde (37%) (10 mmol), absolute ethanol (5 mL). The reaction mixture was stirred and allowed to stand at room temperature for 5 days. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water and freeze-dried to give the Mannich base 1-(5-piperidinomethyl-4-hydroxy-3-methoxyphenyl)-2-(2-hydroxy-3-methoxyphenol)-1,3-propanediol **3-1** in a quantitative yield based on ^{31}P NMR analysis. ^{31}P NMR δ (ppm): 148.2 (1OH, OH_γ), 147.4 (1OH, OH_α), 144.2 (1OH, phenolic OH). MS *m/z*:

*1-(4-Hydroxy-3-methoxybenzyl)-1′-(4-ethyl-3-methoxy-2-phenyl)-ethane **4***

To 1-(4-hydroxy-3-methoxybenzyl)-1′-(4-ethyl-3-methoxy-2-phenyl)-ethane **4** was added 99% piperidine (10 mmol), aqueous formaldehyde (37%) (10 mmol), absolute ethanol (5 mL). The reaction mixture was stirred and allowed to stand at room temperature for 1 day. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water and freeze-dried to give the Mannich base 1-(5-piperidinomethyl-4-hydroxy-3-methoxybenzyl)-1′-(4-ethyl-3-methoxy-2-phenyl)-ethane **4**-**1** in a quantitative yield based on ^{31}P NMR analysis. ^{31}P NMR δ (ppm): 143.9 (1OH^a), 144.4 (1OH^b). MS *m*/*z*: 543 (M^+, 5), 528 (7), 460 (34), 429 (11), 399 (7), 251 (100), 220 (31), 205 (11), 84 (13), 73 (94).

p-*Isopropylphenol **5***

To *p*-isopropylphenol **5** (10 mmol) was added 99% piperidine (30 mmol), aqueous formaldehyde (37%) (30 mmol), and absolute ethanol (10 mL). The reaction mixture was stirred and kept at room temperature for 5 days. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water and freeze-dried to give the Mannich base 2,6-dipiperidinomethyl-4-isopropylphenol **5**-**1** in a quantitative yield based on ^{31}P NMR analysis. ^{31}P NMR δ (ppm): 144.3. ^{1}H NMR (200 MHz, TMS, $CDCl_3$) δ (ppm): 1.00–1.24 (m, 6H), 1.30–1.80 (m, 12H), 2.20–2.90 (m, 9H), 3.61 (s, 4H), 6.60–6.84 (m, 1H), 6.90–7.00 (m, 1H). MS *m*/*z*: 402 (M^+, 5), 387 (11), 319 (83), 276 (34), 235 (55), 219 (53), 161 (24), 98 (42), 73 (100), 55 (15).

*3.3′-(6,6′-Dimethoxy-4,4′-dimethyl)-diphenylmethane **6***

To 3.3′-(6,6′-dimethoxy-4,4′-dimethyl)-diphenylmethane **6** (5 mmol) was added 99% piperidine (15 mmol), aqueous formaldehyde (37%) (15 mmol), and absolute ethanol (5 mL). The reaction mixture was stirred and kept at room temperature for 1 day. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water and freeze-dried. The product, obtained in a quantitative yield based on ^{31}P NMR analysis, has an identical structure as starting material 3.3′-(6,6′-dimethoxy-4,4′-dimethyl)-diphenylmethane **6**. ^{31}P NMR δ (ppm): 139.8; MS *m*/*z*: 432 (M^+, 84), 402 (47), 372 (12), 329 (12), 193 (13), 73 (100), 45 (17); ^{1}H NMR (200 MHz, TMS, $CDCl_3$) δ (ppm): 2.20 (s, 6H), 3.90 (s, 6H), 6.50 (s, 2H), 6.53 (s, 2H). The crystallization of the product was carried out from absolute ethanol, yield 48%. Anal. calc. for $C_{17}H_{20}O_4$: C 70.8, H 6.99; found: C 71.0, H 6.77.

*3.5-Dimethylphenol **7***

To 3,5-dimethylphenol **7** (10 mmol) was added 99% piperidine (20 mmol), aqueous formaldehyde (37%) (20 mmol), and absolute ethanol (10 mL). The reaction mixture was stirred and kept at room temperature for 1 day. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water and freeze-dried to give the Mannich base 2-piperidinomethyl-3,5-dimethylphenol **7**-**1** in a quantitative yield based on ^{31}P NMR analysis. ^{31}P NMR δ (ppm): 138.5; ^{1}H NMR (200 MHz, TMS, $CDCl_3$) δ (ppm): 1.40–1.75 (m, 6H), 2.19 (s, 3H), 2.23 (s, 3H), 2.40–2.70 (m, 4H), 3.65 (s, 2H), 6.46 (s, 1H), 6.51 (s, 1H). MS *m*/*z*: 291 (M^+, 11), 217 (21), 206 (79), 191 (20), 135 (27), 84 (100), 73 (27). The crystallization of 2-piperidinomethyl-3,5-dimethylphenol was carried out from absolute ethanol, yield 48%. Anal. calcd. for $C_{14}H_{20}ON$: C 77.1, H 9.24, N 6.42; found: C 76.6, H 9.40, N 6.58.

*3.4,5-Trimethylphenol **8***

To 3,4,5-dimethylphenol **8** (10 mmol) was added 99% piperidine (20 mmol), aqueous formaldehyde (37%) (20 mmol), and absolute ethanol (10 mL). The reaction mixture was stirred and kept at room temperature for 1 day. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water, diluted with distilled water, and freeze-dried to give the Mannich base 2-piperidinomethyl-3,4,5-trimethylphenol **8**-**1** in a quantitative yield based on ^{31}P NMR analysis. ^{31}P NMR δ (ppm): 138.8 (s); ^{1}H NMR (200 MHz, TMS, $CDCl_3$) δ (ppm): 1.40–1.70 (m, 6H), 2.12(s, 3H), 2.17 (s, 3H), 2.24 (s, 3H), 2.40–2.70 (m, 4H), 3.72 (s, 2H), 6.55 (s, 1H). MS *m*/*z*: 305 (M^+, 18), 290 (6), 220 (100), 205 (27), 191 (6), 149 (6), 105 (6), 73 (22).

m-*Methylcatechol **9***

To 3-methylcatechol **9** (10 mmol) was added 99% piperidine (30 mmol), aqueous formaldehyde (37%) (30 mmol), and absolute ethanol (10 mL). The reaction mixture was stirred and kept at room temperature for 5 days. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water and freeze-dried to give a mixture of Mannich bases. ^{31}P NMR δ (ppm): 138.4–139.0 (d, 1OH), 143.0–144.4 (d, 1OH).

*4-Hydroxy-3-methoxylcinnamic acid **10***

4-Hydroxy-3-methoxycinnamic acid **10** (10 mmol) 99% piperidine (20 mmol), aqueous formaldehyde (37%) (20 mmol), and absolute ethanol (10 mL) were mixed and allowed to stand at room temperature for 1 day. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water and freeze-dried to give the Mannich bases 3,5-dimethoxyl-4-hydroxycinnamic acid and 5-piperidinomethyl-4-hydroxy-3-methoxycinnamic acid **10**-**1** in a quantitative yield based on ^{31}P NMR analysis. ^{31}P NMR δ (ppm): 143.8 (1OH). MS *m*/*z*: 416 (M^+, 5), 401 (8), 333 (94), 248 (92), 233 (26), 217 (63), 110 (63), 98 (47), 73 (100).

*Mannich reaction on model carboxylic acids **11**–**15***

Individual model carboxylic acids (5 mmol) 99% piperidine (10 mol), aqueous formaldehyde (37%) (10 mol), and absolute ethanol (5 mL) were mixed and kept for 5 days at room temperature with stirring. After the reaction, the solution was concentrated under reduced pressure at room temperature and freeze-dried. The solid products were subjected to ^{31}P NMR analysis with 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane as the phosphitylation reagent. In all cases, the spectra obtained for the products were identical with corresponding starting materials.

3.7 Mannich reaction with piperidine on lignin

The procedures used by Mikawa et al. (17) were essentially followed. Approximately 200 mg of lignin was dissolved in 2 mL of a mixture solution composed of 99% piperidine, aqueous formaldehyde (37%), and absolute ethanol in the following

© 1998 NRC Canada

molar proportions of 1.00:1.05:3.30. It was then kept at room temperature for 5 days with stirring or occasional shaking. After the reaction, the reaction mixture was concentrated repeatedly by adding distilled water and freeze-dried. The solid lignin was washed with diethyl ether three times, centrifuged, and dried in a vacuum oven at room temperature.

4. Conclusions

The absolute amounts of various phenolic nuclei such as, *para*-hydroxylphenyls, catechols, guaiacols, and phenols bearing C_5 or C_6 substituents in lignin, can be determined by using the combination of the Mannich reaction and quantitative ^{31}P NMR. The Mannich – ^{31}P NMR analysis is a facile and nondestructive technique that may provide detailed structural information of lignin samples, with minimum experimental complexity.

Escherichia coli β-galactosidase is heterogeneous with respect to the activity of individual molecules

Douglas B. Craig and Norman J. Dovichi

Abstract: *Escherichia coli* β-galactosidase molecules were incubated with fluorogenic substrate in a capillary. Upon flushing the reactor contents past the detector, individual randomly distributed peaks of product were observed, each representing the activity of an individual enzyme molecule. Individual molecules were found to differ with respect to their activities. Molecules showed a 23-fold distribution of activities with the majority of molecules within a 4-fold distribution.

Key words: single-molecule chemistry, β-galactosidase, capillary electrophoresis, laser-induced fluorescence, enzyme assay.

Résumé : On a incubé des molécules de β-galactosidase de l'*E. coli* avec un substrat fluorogénique dans un capillaire. Après avoir fait passé le contenu du réacteur hors du champ du détecteur, on a observé des pics individuels de produits distribués d'une façon aléatoire; chacun correspond à l'activité d'une molécule individuelle d'enzyme. On a trouvé que les activités des molécules individuelles diffèrent. Les molécules présentent une distribution d'activité de 23 alors que la majorité des molécules se trouve dans une distribution de 4.

Mots clés : chimie des molécules individuelles, β-galactosidase, électrophorèse capillaire, fluorescence induite par un laser, essai enzymatique.

[Traduit par la rédaction]

Introduction

Until recently, enzymology, and chemistry in general, has relied on measurements taken on large ensembles of molecules, with data representing average values for many individual molecules. Any differences between individual molecules is obscured by this averaging. To determine whether individual enzyme molecules are homogeneous or heterogeneous with respect to a particular characteristic, it is necessary to assay molecules one at a time.

Activities of individual molecules using a capillary reactor and laser-induced fluorescence detection have been determined on the enzymes lactate dehydrogenase (1) and bovine (2) and *E. coli*[3] alkaline phosphatase. These enzymes have been found to be heterogeneous with respect to individual molecule activities.

High-sensitivity assays of ensembles of β-galactosidase enzyme molecules have shown mass limits of detection close to single molecule (3). This study was undertaken to modify such methods to allow for the detection of the activities of individual molecules of β-galactosidase.

Experimental

Reagents

Sodium resorufin and resorufin β-D-galactopyranoside were obtained from Molecular Probes (Eugene, Oreg.). *Escherichia coli* β-galactosidase (E.C. 3.2.1.23) and *o*-nitrophenyl β-D-galactoside were purchased from Sigma (St. Louis, Mo.). Polymer 6 was from Applied Biosystems (Mississauga, Ont.).

Instrumentation

The injection end of a fused silica capillary (10 μm i.d., 145 μm o.d., 72.5 cm long, Polymicro Technologies, Phoenix, Ariz.) was immersed into sample or running buffer along with a platinum wire connected to a high-voltage power supply (CZE1000R, Spellman, Plainview, N.Y.). The polyimide coating from the detection end of the capillary was removed with a gentle flame and the capillary end was placed inside a 250 × 250 μm inner bore sheath flow cuvette. Molecules exiting the capillary were hydrodynamically focused post-capillary into a cone by sheath buffer flowing within the cuvette. Eluting species were excited by a 543.5 nm line from a 1 mW helium neon laser (Melles Griot, Nepean, Ont.) focused 20 μm below the capillary end by a 6.3×, 0.20 NA microscope objective (Melles Griot). Fluorescence was collected at right angle from the direction of excitation by a 60×, 0.70 NA microscope objective (model 60x-LWD, Universe Kogaku, Japan) and selectively passed through a slit and a 580DF40 bandpass filter (Omega Optical, Brattleboro, Vt.) to an R1477 photomultiplier tube (PMT) (Hamamatsu, Middlesex, N.J.). The analog PMT output was dropped across a 1 MΩ resistor and conditioned with a simple RC filter ($t_c = 0.022$ s). The resulting voltage was digitized at 10 Hz by a MacIntosh IIsi via an NB-MIO-16XH-

18 I/O board (National Instruments, Austin, Tex.). The same board controls the CE power supply. Sheath and running buffers were 50 mM HEPES (pH 7.3) containing a 1/100 dilution of the proprietary sieving matrix Polymer 6 marketed by Applied Biosystems.

Standards

Resorufin standards were used to determine the sensitivity of the detector. Dye at a concentration of 1 nM was injected for 5 s at 209 V/cm and swept past the detector at 400 V/cm.

Standard assay

The concentration of active enzyme was determined by monitoring the change in absorbance at 410 nm of a solution of 93 mM phosphate (pH 7.3) containing 2.3 mM *o*-nitrophenyl β-D-galactoside, 1 mM $MgCl_2$, 112 mM 2-mercaptoethanol, and 0.02–0.1 unit β-galactosidase at 37°C. One unit is defined as the amount of enzyme that will hydrolyze 1.0 μmol *o*-nitrophenyl β-D-galactoside under these conditions in 1 min. The millimolar extinction coefficient for *o*-nitrophenol is 3.5 at 410 nm. To convert activity to concentration, a specific activity of 1200 units/mg and a mass of 540 kDa was used.

Capillary coating

The capillary was flushed using a syringe with 100 mM NaOH for 30 min followed by a 1/10 dilution of Polymer 6 in 50 mM HEPES (pH 7.3) for 3 h. The capillary was then flushed with a 1/100 dilution of Polymer 6 in 50 mM HEPES (pH 7.3). This treatment resulted in the dynamic coating of the inner capillary wall with a layer of polymer. To maintain this coating buffers contained a 1/100 dilution of Polymer 6.

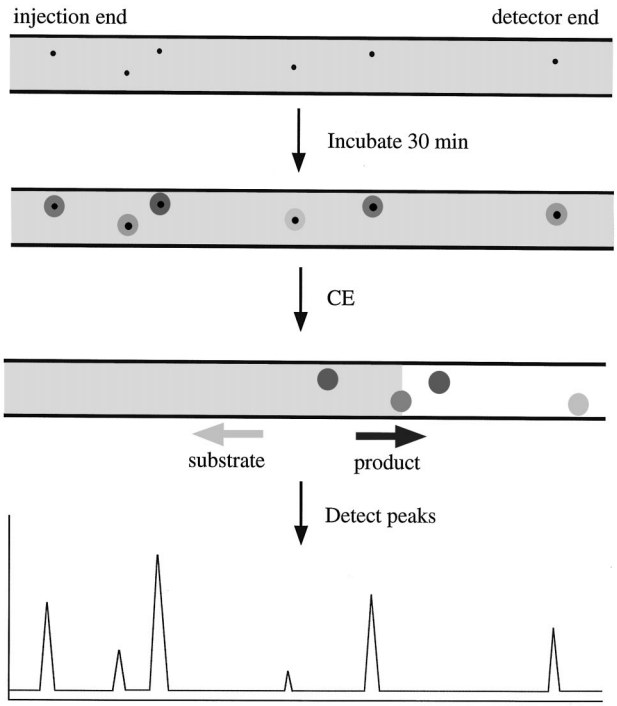
Single-molecule assay

The commercial suspension of enzyme was diluted by 10 orders of magnitude into a solution of final concentration of 50 mM HEPES (pH 7.3) containing 200 μM resorufin galactoside and a 1/100 dilution of Polymer 6. The sample was continuously injected with a syringe into the capillary for 10 min, filling the capillary, and was allowed to sit in the capillary for a 30 min incubation period. After incubation, the capillary contents were swept past the detector at an electric field of 400 V/cm, injection end negative, using 50 mM HEPES (pH 7.3) containing a 1/100 dilution of Polymer 6 as running buffer. Data were collected with a MacIntosh IIsi and converted to PC format to analyze peak areas using PeakFit (Jandel Scientific Software, San Rafael, Calif.) on a Pentium computer. Blanks contained no enzyme.

Results and discussion

In this assay, substrate concentration is approximately 12 orders of magnitude greater than that of the enzyme. Substrate concentration does not significantly drop over the course of the 30 min incubation period. A minute fraction of the resorufin galactoside is converted to the highly fluorescent product resorufin by the action of β-galactosidase. Resorufin galactosidase is itself mildly fluorescent. The sensitivity of the detector is such that the 200 μM residual substrate will saturate the detector, making it impossible to detect product. Fortunately, the relative electrophoretic mobilities of the substrate and product allow us to detect only the product, even in the presence of a huge excess of substrate. We coat the capillary with Polymer 6, which has the effect of reducing electroosmotic flow such that it is less than the electrophoretic mobility of the product resorufin. At pH 7.3, resorufin is negatively charged while resorufin galactosidase is neutral. When the injection end of the capillary is negative relative to the detection end, the residual electroosmotic flow is towards the injector.

Fig. 1. Assay protocol. A capillary was filled with a solution of substrate (shaded) containing a few enzyme molecules (black dots). The sample was incubated for 30 min, resulting in the accumulation of product in the vicinity of the enzyme molecules. An electric field was placed across the length of the capillary. The product migrated towards the detector, producing peaks observed on the electropherogram. The substrate migrated towards the injection end of the capillary and was not detected.



The capillary is filled with substrate and very dilute enzyme and incubated (Fig. 1). The concentration of enzyme is such that only a few of the molecules will be present and randomly spread along the 72.5 cm capillary. During the incubation period, the enzyme converts the substrate into product. Product molecules diffuse only a small distance from the enzyme molecule that produced them. After the incubation period, an electric field of 400 V/cm is placed across the capillary length. Residual electroosmotic flow directs the unreacted substrate towards the injection end of the capillary and away from the detector. The product has an electrophoretic mobility directed towards the detector. The product exits the capillary at the detector end and results in a set of peaks, each peak produced by the localized pool of product formed by a single enzyme molecule. If the reaction product from individual enzyme molecules is indeed being detected, the number of peaks detected should be similar to that expected by the product of the putative enzyme concentration and the capillary volume, the

Fig. 2. Single-molecule β-galactosidase assay. The capillary was filled with 200 μM resorufin galactoside in 50 mM HEPES (pH 7.3) containing 1/100 dilution of Polymer 6. The sample was incubated 30 min and electrophoretically flushed past the detector. A plateau was detected due to non-enzymatic hydrolysis of the substrate (bottom). Addition of putative 87 aM β-galactosidase to the reaction mixture resulted in the detection of five peaks atop this plateau, indicating the capture of five enzyme molecules within the capillary.

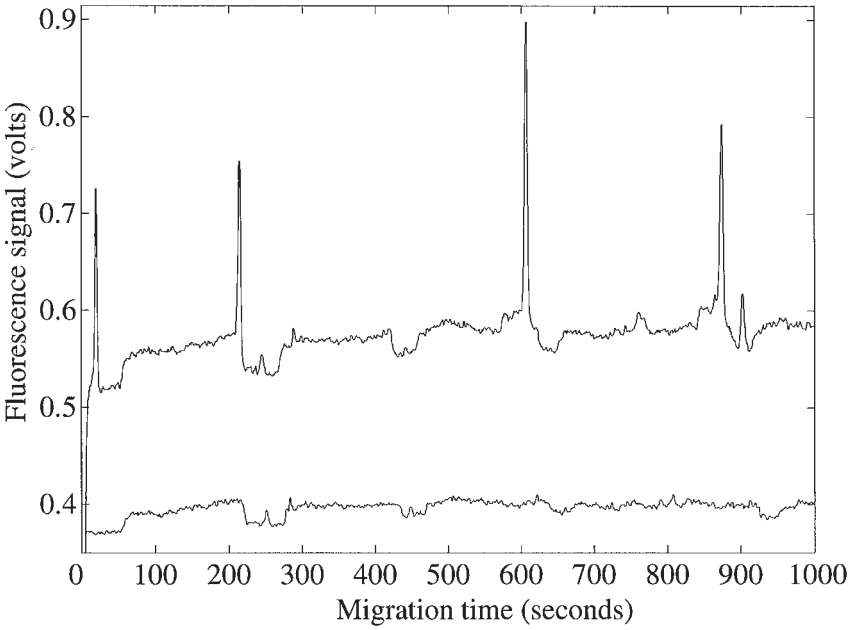

Fig. 3. Distribution of activities. The number of molecules with an activity within the given range is shown.

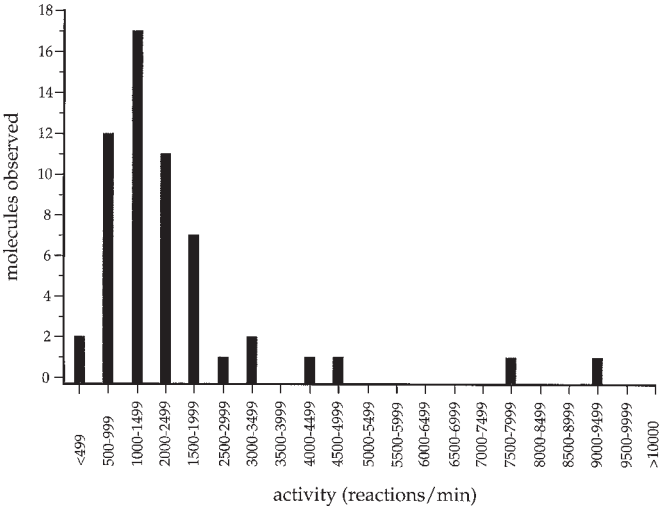

enzyme molecules should be randomly distributed along the capillary length, and the number of molecules observed per run should be dominated by Poisson statistics.

Resorufin galactoside contains a small amount of resorufin as an impurity. At the pH used for electrophoresis, resorufin is charged. However, near pH 5, the weak acid is protonated and neutral. To remove trace amounts of resorufin, the substrate, resorufin galactoside, was dissolved in 5 mM HEPES (pH 5) and extracted 3 times with an equal volume of $CHCl_3$ at the beginning of the day and once more immediately prior to use, and was diluted to give a final concentration of 200 μM in 50 mM HEPES (pH 7.3) containing 1/100 dilution Polymer 6 and enzyme. The neutral resorufin was extracted into the organic layer and removed from the substrate.

In the absence of enzyme, resorufin galactosidase hydrolyzes slowly to produce resorufin. This hydrolysis results in an increased background signal present in all runs. Enzyme product peaks will be present atop this background signal.

Figure 2 shows an electropherogram resulting from the 30 min incubation of $1/10^{10}$ dilution of enzyme in 200 μM resorufin galactosidase and a blank containing substrate but no enzyme. A plateau due to the non-enzymatic hydrolysis of substrate is observed in the blank. In the presence of enzyme, individual peaks are seen sitting atop this plateau. From the stock solution enzyme concentration determined by standard assay and the dilution factor, the enzyme concentration is estimated as 87 aM (1 aM = 10^{-18} M). With a capillary volume of 59 nL, we expect 5.1 ymol (1 ymol = 10^{-24} mol) or approximately three molecules. Experimentally, 5.1 ± 3.3 peaks were observed per run (N = 11) with no peaks observed in any of the blanks (N = 5). Exact enzyme concentrations are difficult to calculate due to the poor accuracy for the specific activity. Peak numbers were dominated by Poisson statistics and the peaks were randomly distributed along the length of the capillary.

A total of 56 molecules were detected. Converting the peak areas into product molecules was done by comparison to resorufin standards. Turnover numbers were calculated by dividing the number of product molecules formed by the incubation time. The average turnover was 1800 ± 1500 reactions/min. Figure 3 shows the distribution of activities of individual molecules. The majority of molecules (47/56) showed activities of between 500 and 2000 reactions/min. The total spread of activity detected was 23-fold, from 400 to 9200 reactions/min.

The range in activity appears to reflect differences in the

© 1998 NRC Canada

molecules. Experimental sources of noise would include shot noise in the number of product molecules generated during the incubation; this noise source would produce about 0.4% relative standard deviation in turnover numbers. Similarly, the shot noise in the photon flux can be calculated from the known charge generated per photon from this photomultiplier tube (4); this noise source contributes less than 2% relative standard deviation to the distribution in activity. Instead, we believe that the distribution in turnover number reflects differences in the structure of these enzyme molecules.

Conclusions

Single-enzyme molecule assays have previously been performed on lactate dehydrogenase (1) and bovine (2) and *E. coli*[3] alkaline phosphatases. All these enzymes were shown to be heterogeneous with respect to activity. Here we report on the activities of individual molecules of *E. coli* β-galactosidase. We find individual molecules to range 23-fold in turnover numbers with the majority of individuals varying by 4-fold. It is noteworthy that all the enzymes studied to date at the single-molecule level have shown microheterogeneity, leading one to speculate that such heterogeneity may be a common phenomenon amongst enzymes in general.

The central paradigm of chemistry states that structure affects function. Differences in function must arise from some differences in structure. There are two possible causes of structural differences. In the simplest case, all enzyme molecules would consist of the same atoms arranged in the same order. Differences in chemical behavior would arise from differences in the higher order structures into which the molecule has folded. This argument is a particularly attractive explanation for the behavior of enzymes such as lactate dehydrogenase that generate a single band in gel electrophoresis but individual molecules generate a broad distribution of activities (1).

As a second case, there is a vast menagerie of post-translational modifications found in nature. In this case, molecules have differences in activity because they have differences in primary structure. Proteins are usually decorated with sugars, lipids, phosphates, and other functional groups. A protease often forms the protein from a larger apoprotein, which is the original translation product from mRNA; different cutting sites lead to different product molecules. All of these post-translational modifications are generated in a somewhat haphazard fashion, leading to a population of product molecules that contain a range of different modifications. Further complication occurs for enzymes that are formed from two or more monomer peptides. Differences in each monomer could combine to form a huge number of different assembled products.

Kinetic studies of σ-adduct formation and nucleophilic substitution in the reactions of ethyl 2,4,6-trinitrophenyl ether, some phenyl 2,4,6-trinitrophenyl ethers, and phenyl 2,4-dinitronaphthyl ether with aniline in dimethyl sulfoxide

Michael R. Crampton and Ian A. Robotham

Abstract: The reaction of ethyl 2,4,6-trinitrophenyl ether with aniline in dimethyl sulfoxide containing Dabco occurs in two stages. The first gives **5**, the σ-adduct intermediate on the substitution pathway, which has been identified spectroscopically. The second yields 2,4,6-trinitrodiphenylamine, the substitution product. Kinetic studies show that proton transfer is rate limiting both in the formation of the intermediate and in its subsequent acid-catalysed decomposition. Phenoxide is a considerably better leaving group than ethoxide and the substitution reactions of phenyl 2,4,6-trinitrophenyl ethers and phenyl 2,4-dinitronaphthyl ether with aniline in DMSO occur without the accumulation of intermediates. The kinetics indicate both uncatalysed and base-catalysed pathways. The kinetic and equilibrium data for reaction of the ethyl and phenyl ethers are compared with data for σ-adduct formation from 1,3,5-trinitrobenzene and aniline.

Key words: nucleophilic substitution, proton transfer, base catalysis, σ-adducts.

Résumé : La réaction de l'oxyde d'éthyle et de 2,4,6-trinitrophényle avec l'aniline, dans le diméthylsulfoxyde contenant du DABCO, se produit en deux étapes. La première fournit le produit **5**, l'adduit-σ intermédiaire sur la voie de la substitution, que l'on a identifié par spectroscopie. La deuxième conduit à la 2,4,6-trinitrodiphénylamine, le produit de substitution. Des études cinétiques ont permis de montrer que le transfert de proton est l'étape cinétiquement limitante tant pour la formation de l'intermédiaire que pour sa décomposition acidocatalysée subséquente. L'ion phénolate est un bien meilleur groupe partant que l'éthanolate; les réactions de substitutions des oxydes de phényle et de 2,4,6-trinitrophényle, et de l'oxyde de phényle et de 2,4-dinitronaphtyle, avec l'aniline dans le DMSO se produisent sans accumulation d'intermédiaires. Les données cinétiques indiquent la présence de voies réactionnelles non catalysées et d'autres catalysées par les bases. On a comparé les données cinétiques et d'équilibre pour les réactions des oxydes d'éthyle et de phényle avec celles relatives à la formation de l'adduit-σ à partir du 1,3,5-trinitrobenzène et de l'aniline.

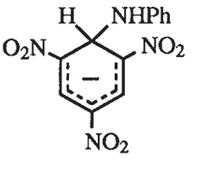
Mots clés : substitution nucléophile, transfert de proton, catalyse par les bases, adduits-σ.

[Traduit par la rédaction]

Introduction

Whereas the reaction of 1,3,5-trinitrobenzene, TNB, with primary and secondary aliphatic amines in dimethyl sulfoxide, DMSO, spontaneously produces σ-adducts (1–3), reaction with aromatic amines requires the presence of a strong base. Buncel and co-workers showed, by use of ^{1}H NMR spectroscopy, that reaction of the TNB–methoxide σ-adduct with aniline (4), or with ring-substituted anilines (5), resulted in the formation of TNB–anilide adducts, such as **1**.

Interestingly, kinetic studies (6, 7) showed that this conversion involved a dissociative mechanism rather than an S_N2



1

displacement on the σ-adduct. It was later found that **1** may be formed directly from TNB and aniline in DMSO (8), or in acetonitrile (9), in the presence of a tertiary amine, B, such as Dabco or triethylamine, to act as a proton acceptor. The

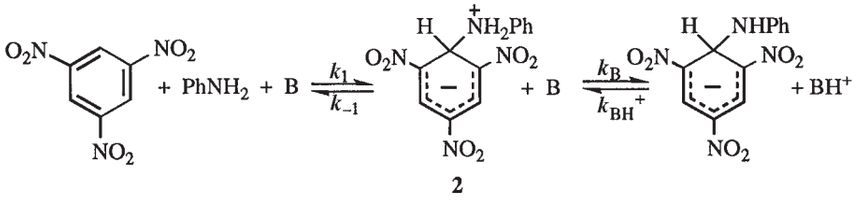

Fig. 1. Visible spectra of **3** (4×10^{-5} mol dm^{-3}) in DMSO containing aniline (0.1 mol dm^{-3}), Dabco (0.05 mol dm^{-3}), and Dabco hydrochloride (0.01 mol dm^{-3}) taken after (*a*) 1 min, (*b*) 5 min, and (*c*) 3 h. The spectra show the rapid formation of **5** followed by the slower conversion to **6**.

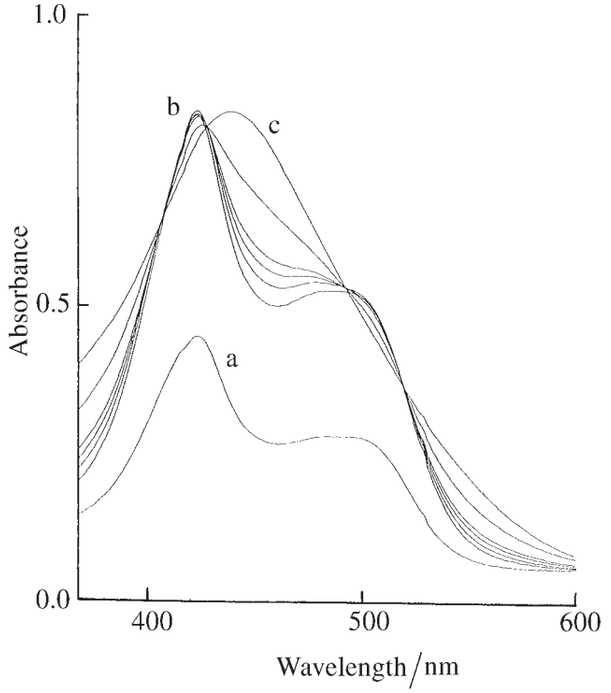

reaction involves two steps, as shown in Scheme 1. The first step is thermodynamically unfavourable due to the weak basicity of aniline. However, the presence of a strong base renders the proton transfer step sufficiently favourable to allow formation of the anionic adduct. Nevertheless, kinetic studies (10, 11) showed that the proton transfer from the zwitterion, **2**, is rate limiting, corresponding to the condition $k_{-1} > k_B[B]$. When Dabco was used as the added base, a specific salt effect involving association of protonated Dabco with chloride ions was observed (12). There is also clear kinetic evidence for rate-limiting proton transfer in the reactions of TNB with aliphatic amines (13–15).

We have previously examined the kinetics of the reaction of ethyl 2,4,6-trinitrophenyl ether (16), **3**, and some ring-activated phenyl aryl ethers (17) with aliphatic amines in DMSO. In agreement with the classic work of Orvik and Bunnett (18), the results for **3** indicated that substitution involves the specific base – general acid catalysis mechanism, SB–GA, in which leaving-group expulsion is the overall rate-limiting step. However, the observation of base catalysis in reactions of the phenyl aryl ethers was best explained in terms of rate-limiting proton transfer from a zwitterionic intermediate to base (17). Previous studies of nucleophilic substitution using aniline as the nucleophile have shown that in reaction with methyl 2,4,6-trinitrophenyl ether there is competition between attack at the ring carbon atom to give a diphenylamine derivative, and at the side-chain carbon to give picric acid (19). Reactions of aniline with phenyl 2,4,6-trinitrophenyl ether yield the diphenylamine derivative and are subject to base catalysis in methanol, acetonitrile, tetrahydrofuran, ethyl acetate, and benzene (20). However, there was little evidence for catalysis in DMSO (19, 21).

Here we examine the kinetics of the reactions of **3**, and of some ring-activated phenyl aryl ethers with aniline in DMSO. Our results show that in these substitution reactions, as in the reaction of aniline with TNB, proton transfer may be the rate-limiting step.

Results and discussion

Kinetic and equilibrium measurements of the reactions with aniline were generally made in the presence of Dabco and Dabco hydrochloride. The pK_a values (22) in DMSO of the protonated forms of the bases are, for aniline, 3.82, and for Dabco, 9.06. Hence the value of the equilibrium constant, K_a', for eq. [1] is 5.8×10^{-6}.

[1] aniline + DabcoH$^+$ ⇌ aniline H$^+$ + Dabco

$$K_a' = \frac{K_a(\text{DabcoH}^+)}{K_a(\text{AnilineH}^+)} = 5.8 \times 10^{-6}$$

Thus the concentrations of the reagents in the reaction mixture will be very similar to the stoichiometric concentrations; relatively little protonation of aniline will occur.

Reactions of ethyl 2,4,6-trinitrophenyl ether, 3

Ultraviolet–visible spectra of **3** in DMSO containing aniline (0.1 mol dm^{-3}) indicated no reaction during 90 min. When the reaction was repeated with the addition of Dabco and DabcoH$^+$ a biphasic reaction was observed. The spectra in Fig. 1 show that, in the first stage, a species with λ_{max} 430 nm and 500 nm is produced. The spectrum is typical of that for σ-adducts (2, 3) and ^{1}H NMR experiments confirm the formation of **5**, the intermediate on the substitution pathway. A second, much slower, reaction gave a species with λ_{max} 445 whose spectrum is identical to that of 2,4,6-trinitrodiphenylamine, **6**, in the reaction medium. Since the pK_a value (22) of **6** is 8.01, this species will be present largely in its deprotonated form, **7**.

[b] Calculated as $\frac{\text{Abs.[DabcoH}^+]}{(1.05 - \text{Abs})[\text{An}][\text{Dabco}]}$.

[c] Calculated from eq. [6] with $K_1k_{Dabco} = 1.17$ dm^6 mol^{-2} s^{-1}, $k_{DabcoH^+} = 0.2$ dm^3 mol^{-1} s^{-1}, and $k_{An}/k_{Dabco} = 0.46$.

δ 9.09 (ring hydrogens), 4.26 (q, J = 7 Hz, OCH_2), and 1.35 (t, CH_3). In the presence of aniline (1 equiv.) and Dabco (1 equiv.), bands due to **5** are observed at δ 8.62 (ring), 3.14 (q, J = 7 Hz, OCH_2), and 1.08 (t, CH_3). It is interesting (4, 5) that the anilide group of **5** shows a singlet at δ 5.98 attributed to the amino hydrogen together with spin-coupled, J = 8 Hz, bands due to ring hydrogens at δ 6.93(t), 6.52(t), and 6.35(d). Over a period of 1 h the bands due to **5** decrease in intensity while bands attributable to the substitution products, **7** and ethanol, increase in intensity. A small band at δ 8.58 is also observed, indicating the formation of some picric acid.

UV–visible measurements show that, in solutions containing Dabco but without aniline, **3** is very slowly converted to picric acid, λ_{max} = 380 nm. This reaction could be inhibited by the presence of Dabco hydrochloride. The latter observation indicates that picric acid formation is likely to be due to attack of hydroxide, formed from adventitious water in the solvent, at the 1-position rather than attack by Dabco at the side-chain ethyl group. All quantitative measurements involving aniline were made in buffered solutions, Dabco with Dabco hydrochloride, to suppress picric acid formation.

Our kinetic and equilibrium results are interpreted in terms of Scheme 2, in which the zwitterion, **4**, is expected to be an intermediate present in low concentrations. The first stage of the reaction, representing the equilibration of **3** and **5**, was monitored at 430 nm. With concentrations of aniline (An), Dabco, and Dabco hydrochloride in large excess of the concentration of **3**, first-order kinetics were observed. Rate constants, k_{fast}, and absorbances at completion of the equilibration are given in Table 1. All measurements were made in the presence of DabcoH$^+$, 0.01 mol dm^{-3}, to maintain constant ionic strength.

An equilibrium constant for formation of **5** may be defined in terms of the Dabco concentration by eq. [2]. The absorbance values in Table 1 lead to a value for K_1K_{Dabco} of 7 ± 1 dm^3 mol^{-1}.

$$[2] \qquad K_1K_{Dabco} = \frac{k_1\,k_{Dabco}}{k_{-1}\,k_{DabcoH^+}} = \frac{[\mathbf{5}]}{[\mathbf{3}]} \times \frac{[\text{DabcoH}^+]}{[\text{An}]\,[\text{Dabco}]}$$

© 1998 NRC Canada

Alternatively, the equilibrium constant may be defined in terms of the aniline concentration in eq. [3]:

$$[3] \quad K_1K_{An} = \frac{k_1}{k_{-1}} \times \frac{k_{An}}{k_{AnH^+}} = \frac{[\mathbf{5}]}{[\mathbf{3}]} \times \frac{[AnH^+]}{[An]^2}$$

Use of eq. [1] leads to eq. [4], showing that the value of K_1K_{An} will be many orders of magnitude lower than the value of K_1K_{Dabco}, and explaining why adduct formation is not observed in the absence of Dabco.

$$[4] \quad K_1K_{An} = K_1K_{Dabco}\, K_a'$$

The variation of k_{fast} with values of the Dabco and aniline concentrations is compatible only with proton transfer being rate determining in the formation of **5**. Using the condition $k_{-1} > k_B[B]$ and treating **4** as a steady-state intermediate leads to the rate expression given in eq. [5]:

$$[5] \quad k_{fast} = \frac{k_1}{k_{-1}}[An](k_{An}[An] + k_{Dabco}[Dabco]) + k_{DabcoH^+}[DabcoH^+] + k_{AnH^+}[AnH^+]$$

Here k_{Dabco} and k_{An} represent k_B when reaction involves Dabco and aniline, respectively, while k_{DabcoH^+} and k_{AnH^+} represent k_{BH^+} for reactions with the appropriate conjugate acids.

Since K_{An}/K_{Dabco} has a constant value (eq. [4]) it is possible to reduce the number of variables in eq. [5] to give eq. [6]:

$$[6] \quad k_{fast} = K_1k_{Dabco}[An]\left([Dabco] + \frac{k_{An}}{k_{Dabco}}[An]\right) + k_{DabcoH^+}[DabcoH^+]\left(1 + \frac{k_{An}}{k_{Dabco}}\frac{[An]}{[Dabco]}\right)$$

Excellent agreement between the calculated and observed values of k_{fast} was obtained with K_1k_{Dabco} 1.17 ± 0.10 dm^6 mol^{-2} s^{-1}, k_{DabcoH^+} 0.20 ± 0.05 dm^3 mol^{-1} s^{-1}, and k_{An}/k_{Dabco} 0.46 ± 0.10. The latter value indicates that aniline competes effectively with the much stronger base Dabco in the proton transfer step, **4** ⇌ **5**. This point is discussed later. It was not possible to obtain an acceptable fit between calculated and observed values of k_{fast} with lower values of the ratio k_{An}/k_{Dabco}. Combination of the values of K_1k_{Dabco} and k_{DabcoH}+ leads to a value of K_1K_{Dabco} of 5.9 dm^3 mol^{-1}, in acceptable agreement with that obtained independently from absorbance measurements at equilibrium.

The slow product-forming reaction was measured at 445 nm. Values of the first-order rate constants, k_{slow}, are reported in Table 2. Making the assumption that **3** and **5** are in rapid equilibrium during this stage of the reaction leads to the rate expression of eq. [7].

$$[7] \quad k_{slow} = \left(k_{sub,DabcoH^+}[DabcoH]^+ + k_{sub,AnH^+}[AnH^+]\right)\left(\frac{K_1K_{Dabco}[Dabco][An]}{K_1K_{Dabco}[Dabco][An] + [DabcoH^+]}\right)$$

Here $k_{sub,DabcoH^+}$ and k_{sub,AnH^+} are, respectively, the rate constants for the substitution reactions involving protonated Dabco and aniline. Use of eq. [1] results in eq. [8]:

$$[8] \quad k_{slow} = \left(k_{sub,DabcoH^+} + k_{sub,AnH^+}.\frac{[Dabco]}{[An]}\right)\left(\frac{K_1K_{Dabco}[Dabco][An][DabcoH^+]}{K_1K_{Dabco}[Dabco][An] + [DabcoH^+]}\right)$$

Analysis of the results using the known value for K_1K_{Dabco} of 7 dm^3 mol^{-1} showed that most of the reaction flux involved the protonated Dabco. Agreement between observed and calculated values of k_{slow} was optimized with values of 0.06 ± 0.01 dm^3 mol^{-1} s^{-1} for $k_{sub,DabcoH^+}$ and 0.005 ± 0.002 dm^3 mol^{-1} s^{-1} for $k_{sub,AnH^+}.K_a'$. Using the known value of K_a' leads to a value for k_{sub,AnH^+} of 860 dm^3 mol^{-1} s^{-1}.

Reactions of phenyl 2,4,6-trinitrophenyl ethers, 8

Reactions of **8a–c** with aniline in DMSO proceeded in a single stage. UV–visible spectra, and NMR spectra (in more concentrated solutions), at completion of reaction were identical to those of **6**, the expected substitution product, in the reaction medium.

Kinetic measurements were made with aniline and with solutions containing aniline, Dabco, and Dabco hydrochloride. With these concentrations in large excess of the substrate concentration, first-order kinetics were observed. Data obtained with aniline alone are shown in Fig. 2. Plots of the second-order rate constant, k_{obs}/[aniline], versus aniline concentration were linear with positive intercepts. At a constant aniline concentration, values of the first-order rate constant, k_{obs}, increased linearly with Dabco concentration, as shown in Fig. 3. These results are interpreted in terms of the process shown in Scheme 3. It is known (17, 23) that phenoxide is a considerably better leaving group than ethoxide, by a factor of ca. 10^6. Our failure to observe **10**, the intermediate on the substitution pathway, may be attributed to its rapid decomposition by loss of phenoxide. The assumption that **9** may be treated as a steady-state intermediate leads to the rate expression of eq. [9], where k_{An} and k_{Dabco} represent k_B for the respective bases.

$$[9] \quad k_{obs} = \frac{k_1[An]\,(k_2 + k_{An}[An] + k_{Dabco}[Dabco])}{k_{-1} + k_2 + k_{An}[An] + k_{Dabco}[Dabco]}$$

Our results, which provide evidence for base catalysis, indicate that the condition $k_{-1} >> k_2 + k_{An}[An] + k_{Dabco}[Dabco]$ applies so that eq. [9] reduces to eq. [10].

$$[10] \quad k_{obs} = K_1[An](k_2 + k_{An}[An] + k_{Dabco}[Dabco])$$

Values obtained for K_1k_2, K_1k_{An}, and K_1k_{Dabco} can be found in Table 3.

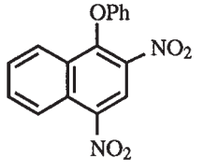
[a] Calculated from eq. [8] with $k_{sub,DabcoH^+}$ 0.060 dm^3 mol^{-1} s^{-1}, $k_{sub,AnH^+} \cdot K_a'$ 0.005 dm^3 mol^{-1} s^{-1}, and K_1K_{Dabco} 7.0 dm^3 mol^{-1}.
[b] Ionic strength was maintained at 0.01 mol dm^{-3} using tetrabutylammonium chloride.

Reactions of phenyl 2,4-dinitronaphthyl ether, 11

UV–visible and ^{1}H NMR studies showed that in the presence of aniline, or aniline with Dabco, **11** was smoothly converted into *N*-phenyl-2,4-dinitronaphthylamine. Kinetic measurements at 440 nm showed a single first-order process. Values of the rate constant, k_{obs}, are given in Table 4. Data are interpreted in a manner similar to that given for **8** so that Scheme 3 is applicable and eq. [10] will apply. Values calculated with K_1k_2 2.0×10^{-4} dm^3 mol^{-1} s^{-1}, K_1k_{An} 1.1×10^{-2} dm^6 mol^{-2} s^{-1}, and K_1k_{Dabco} 0.24 dm^6 mol^{-2} s^{-1} give excellent agreement with values of k_{obs}.



11

Comparisons

Data for reactions of **3**, **8,** and **11** are collected in Table 3, where they are compared with values for the formation of **1** from TNB. The value of K_1K_{Dabco}, the overall equilibrium constant for formation of the adduct **5** from **3**, is ca. 20 times larger than that for formation of **1** by reaction at an unsubstituted ring position of TNB. The major effect is likely to be an increase in K_1 due to relief of steric strain present in the parent (16, 24) when the ethoxy group is twisted from the ring plane. Stereoelectronic stabilization of **5** relative to **1** may also contribute, as described in related systems by Buncel et al. (25). The polar effect of the ethoxy group will be expected to result in an increase in the value of K_1 and may also give rise to a small increase in K_{Dabco}. For comparison (16), the equilibrium constant for formation of **12** from **3** and *n*-butylamine has a value 50 times larger than that for the corresponding formation of **13**. We have not observed an adduct formed by attack of

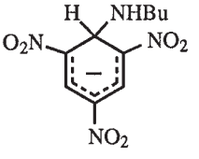
12



13

aniline at the unsubstituted 3-position of **3**. This may be explained by the much lower thermodynamic stability expected for this adduct compared with its isomer **5** or with the adduct **1** formed from TNB. Attack at the 3-position of **3** will not relieve the steric strain present in the parent, and work with aliphatic amines (16) suggests that the adduct so formed would have a stability ca. 100 times lower than that of the adduct **1** from TNB.

Buncel et al. (10, 11) showed that, in the formation of **1** from TNB and aniline, the proton transfer step is rate limiting. Similarly in the formation of **5** our results indicate rate-limiting proton transfer. From eqs. [1] and [4], K_{An}/K_{Dabco} has the value 5.8×10^{-6}, showing that the equilibrium constant for the proton-transfer step is very much smaller when the reaction involves aniline than when it involves Dabco. Nevertheless the ratio of 0.46 obtained for k_{An}/k_{Dabco} shows that *kinetically* aniline may compete effectively with Dabco, a much stronger base, in the proton-transfer step. This may seem surprising; however, it should be remembered that the proton-transfer step, **4** ⇌ **5**, in Scheme 2 will be thermodynamically favourable even when the reaction involves aniline as B and the anilinium ion as BH^+. Thus it is known (5, 26) that the trinitrocyclohexadienate group, even though negatively charged, is electron withdrawing relative to hydrogen. Hence **4** will be more acidic than the anilinium ion. Values of k_{An} and k_{Dabco} will be

© 1998 NRC Canada

affected by steric factors rather than the relative basicities of the amines. It is likely that the proton to be transferred from **4** will be hydrogen bonded to a DMSO molecule in the solvent (13, 27, 28) and this, together with steric hindrance to the approach of the reagents, will reduce values of rate constants below the diffusion limit.

It is interesting to speculate on values of rate constants for the proton-transfer step. It has previously been estimated (15, 16) that the presence of the trinitrocyclohexadienate ring in zwitterions such as **4** will acidify the adjacent ammonium protons by a factor of ca. 500, as indicated in eq. [11]:

[11] $K_a(\mathbf{4})/K_a(AnH^+) = 500$

Use of eq. [1] allows the comparison of the relative acidities of **4** and protonated Dabco as shown in eq. [12]:

[12] $$K_a(\mathbf{4})/K_a(DabcoH^+) = \frac{500}{5.8 \times 10^{-6}} = 8.6 \times 10^7$$

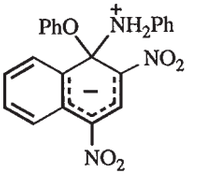
The ratio obtained corresponds to k_{Dabco} / k_{DabcoH^+} and since k_{DabcoH^+} has been found experimentally to be 0.2 $dm^3\ mol^{-1}\ s^{-1}$ we obtain a value for k_{Dabco} of 1.7×10^7 $dm^3\ mol^{-1}\ s^{-1}$. This allows the calculation of values for k_{An} of 8×10^6 $dm^3\ mol^{-1}\ s^{-1}$ and for K_1 of 7×10^{-8} $dm^3\ mol^{-1}$. Since the ratio given in eq. [11] is not known precisely, the values calculated using it should be regarded only as estimates.

The data in Table 3 indicate that values of rate constants for proton transfer are larger in the formation of **1** from TNB, than in the formation of **5**. Here reaction occurs at an unsubstituted ring position so that there is less steric congestion at the reaction centre. A calculation analogous to that given above leads here to a value for k_{Dabco} in excess of 10^9 $dm^3\ mol^{-1}\ s^{-1}$.

The formation of **6** from **5** involves general acid-catalysed expulsion of the ethoxy group. Values of the rate constants for reaction with the anilinium ion, 860 $dm^3\ mol^{-1}\ s^{-1}$, and DabcoH$^+$, 0.06 $dm^3\ mol^{-1}\ s^{-1}$, may be used in conjunction with eq. [1] to calculate a Brønsted α value of 0.80.

Phenoxide is known to be a considerably better leaving group than ethoxide (17, 23), and we did not observe intermediates in the substitution reactions of the phenyl ethers **8a**–**c**. We interpret the increases in the rate constant shown in Figs. 2 and 3 as base catalysis. Previous work (19, 21), at lower base concentrations, did not find evidence for base catalysis. The effects we have observed are not particularly large. However, values calculated for K_1k_{An} and K_1k_{Dabco} for reactions of **8a**–**c** are similar to those found for reaction of **3**, where there is genuine base catalysis. These similarities are to be expected if proton transfer from zwitterion, **9** or **4**, to base is rate limiting. The presence of a phenoxy group rather than an ethoxy group at the 1-position is not expected to drastically affect the value of K_1 for formation of the zwitterion (29). Nor will this change be expected to greatly alter the values of k_{An} or k_{Dabco} for the proton-transfer step. A major difference between the phenyl ethers, **8**, and the ethyl ether, **4**, is that in the former case much of the reaction flux involves the direct uncatalysed decomposition of the zwitterions, **9**, by the k_2 step. This step is likely to involve intramolecular proton transfer from nitrogen to oxygen coupled with carbon–oxygen bond cleavage. Leaving-group expulsion is part of the rate-limiting step here, so that reaction of the 4-nitrophenoxy derivative, **8c**, is six times faster than that of the phenoxy derivative, **8b** (Table 3).

Comparison of data for reaction of phenyl 2,4-dinitronaphthyl ether, **11**, with that for phenyl 2,4,6-trinitrophenyl ether, **8b**, shows decreases in K_1k_2, K_1k_{An}, and K_1k_{Dabco} by factors of 250, 24, and 7, respectively. These changes may be attributed (2, 3) to two main factors: the decrease in ring activation in **11** compared to **8b**, and the reduction in steric crowding at the reaction centre in the zwitterionic



14

intermediate **14** compared to that in the corresponding intermediate, **9b**. The first factor will result in a decrease in the value of K_1 and hence in the value of K_1k_2. That the decreases observed for K_1k_{An} and K_1k_{Dabco} are smaller than that observed for K_1k_2 may be attributed to the second factor. A reduction in steric crowding in **14** compared to **9b** may allow the easier approach of a base molecule to accept a proton from the zwitterionic intermediate. Hence values of k_{An} and k_{Dabco} may be larger in the 2,4-dinitronaphthyl system. The k_{An}/k_{Dabco} ratio is somewhat decreased in the dinitronaphthyl system and this may indicate that the situation is being approached in which the reduction in the electron-withdrawing ability of the ring system renders the proton transfer from **14** to aniline thermodynamically unfavourable.

Experimental

Ethyl 2,4,6-trinitrophenyl ether (16), **3**, phenyl 2,4,6-trinitrophenyl ether (17), **8b**, and phenyl 2,4-dinitronaphthyl ether (17), **11**, were available from previous work. The 4-substituted phenyl 2,4,6-trinitrophenyl ethers **8a** and **8c** were prepared by reaction at 45°C for 3 h of picryl chloride (1 equiv.) with sodium hydroxide (1 equiv.) in an excess of the appropriate 4-substituted phenol containing a little water. On completion, water was added to remove any picric acid produced and recrystallization from ethanol yielded **8a**, mp 100°C (lit. (30) mp 103°C) and **8c**, mp 163°C (lit. (30) mp 157°C). 2,4,6-Trinitrodiphenylamine, **6**, and *N*-phenyl-2,4-dinitronaphthylamine were available from previous work (22). Solvent, amines, and amine salts were prepared and (or) purified as described previously (22).

^{1}H NMR spectra were recorded using Varian-200 XL or VXR-400 spectrometers. UV–visible spectra and kinetic measurements were made with Beckman Lambda 2 or Applied Photophysics SX.17 MV stopped-flow spectrophotometers at 25°C. Reported rate constants are the means of several determinations and are precise to ±5%.

Acknowledgements

We thank the Engineering and Physical Sciences Research Council (EPSRC) for a studentship and for a research grant to purchase the stopped-flow spectrophotometers. Mrs. J. Say is thanked for assistance with the NMR measurements.

Novel syntheses of 4-alkyl-2(*5H*)-thiophenones and 8-phenylimino-1,2,4-triazolo[5,1-*c*]-1,4-thiazines

Alan R. Katritzky, Daming Feng, Hengyuan Lang, Ming Qi, and Peter J. Steel

Abstract: 1,2,4-Triazole stabilized allene anions are intermediates for the synthesis of 4-alkyl-2(5*H*)-thiophenones and 8-phenylimino-1,2,4-triazolo[5,1-*c*]-1,4-thiazines. Structures are confirmed by X-ray crystallography.

Key words: allene anion, 4-alkyl-2(5*H*)-thiophenones, 8-phenylimino-1,2,4-triazolo[5,1-*c*]-1,4-thiazines, X-ray crystallography.

Résumé : Les anions alléniques stabilisés par un 1,2,4-triazole sont des intermédiaires dans la synthèse de 4-alkyl-(5*H*)-thiophén-2-ones et de 8-phénylimino-1,2,4-triazolo[5,1-*c*]-1,4-thiazines. Les structures ont été confirmées par diffraction des rayons-X.

Mots clés : anion allénique, 4-alkyl-(5*H*)-thiophén-2-ones, 8-phénylimino-1,2,4-triazolo[5,1-*c*]-1,4-thiazines, diffraction des rayons-X.

Introduction

We recently reported convenient syntheses of α,β-unsaturated esters, α,β-unsaturated γ-lactones, and alkoxypyrroles (1) by reactions of triazole-stabilized allene–triazole dianions (formed from 1-(1,2,4-triazol-1-yl)-3-phenylpropargyl ethyl ether) with alkyl halide, aldehyde, ketone, and imine electrophiles. In these syntheses, treatment of **1** with two equivalents of BuLi at –78°C for a few minutes, followed by reactions with electrophiles, led to exclusive attack at the γ-carbon of **2** ⇌ **3** to form allene intermediate **4** (Scheme 1), which then underwent acidic hydrolysis. We now report further novel reactions of dianions **3** with carbon disulfide and phenyl isothiocyanate, which lead to synthetically useful preparations of a variety of compounds.

Results and discussion

Reactions of 1-(1,2,4-triazol-1-yl)propargyl ethyl ethers 1 and 5 with carbon disulfide

Treatment of **1** with two equivalents of BuLi at –90°C for a few minutes, followed by reaction with CS_2 (2 equiv.), unexpectedly formed the disulfide **8a** (Scheme 2). Acidic hydrolysis of **8a** and corresponding treatment of **5**, without isolation of the disulfide, produced the 4-alkyl-2-thiophenones **9a**,**b**. These reactions may proceed through intermediates **6**, which cyclize to the substituted thiophene derivatives **7**. Compounds **7** then oxidatively dimerize. The structures of bis(5-ethoxy-3-phenyl-2-thienyl) disulfide **8a** and the substituted thiophenones **9a**,**b** were supported by ^{1}H and ^{13}C NMR spectra and microanalysis and were confirmed by X-ray crystallography, as shown in Figs. 1 and 2.

The disulfide **8a** crystallizes in the monoclinic space group $P2_1/n$, with a complete molecule in the asymmetric unit. One of the two ethoxy substituents has the methyl group disordered over two sites (Fig. 1). Although the two halves of the molecule have similar bond lengths and angles (see Experimental), they differ in the relative orientations of the phenyl rings, which are inclined to the planes of their attached thiophene rings at angles of 39.9(9)° and 48.5(9)°. There are no unusually short intermolecular interactions in the solid state. The 2-thiophenone **9a** also crystallizes in the monoclinic space group $P2_1/n$, with a full molecule in the asymmetric unit (Fig. 2). As well as confirming the structure, the X-ray analysis unambiguously showed that this compound exists as the conjugated 5*H* tautomer, in accord with well-established rules for the tautomerism of thiophenones (2). The geometry of the thiophenone ring in **9a** differs somewhat from that reported in the only other X-ray structure determination of a monosubstituted 2-thiophenone (3), which, as a 4-alkylamino-substituted 2-thiophenone, exhibited the greater polarization, expected for a vinylogous amide. Surprisingly, the two rings in **9a** are almost coplanar (angle between mean planes = 5.5(2)°), which is undoubtedly associated with the molecular packing. The molecules pack in sheets approximately perpendicular to the *a* axis, with adjacent molecules exhibiting π–π stacking between phenyl and thiophene rings separated by approximately 3.6 Å.

Several previous methods exist for the synthesis of 4-alkyl-2-thiophenones of type **9**: (*i*) reaction of bismetallated thioacids with α-chloroacetophenone followed by dehydration (4); (*ii*) basic hydrolysis of 2-amino-4-phenyl-3-thenoic esters (5); (*iii*) two-step conversion of 4-(chloromethyl)-4-methyl-azetidin-2-one with sodium hydrosulfide (6). Kagabu and Kaku recently reported a novel route for the synthesis of 4-aryl-2-thiolenones via treatment of 2-substituted 3-ethoxycarbonyl-2-propenylisothiuronium salts with alkali in a two-phase system (7).

Reactions of 1-(1,2,4-triazol-1-yl)propargyl ethyl ethers 1 and 10 with phenyl isothiocyanate

When the allenic dianion **3** was treated with two equivalents of phenyl isothiocyanate, compound **12a** was isolated in 64% yield (Scheme 3). The structure of novel compound **12a** was determined by X-ray crystallography (Fig. 3), and its NMR spectra and microanalysis match this structure.

Crystals of **12a** suitable for X-ray structure determination were obtained only by recrystallization from acetone. At room temperature these underwent spontaneous decomposition, through loss of solvate upon removal from the mother liquor, but were stable at –110°C. This compound crystallizes in the monoclinic space group $P2_1/c$, with two molecules of **12a** and one acetone solvate molecule in the asymmetric unit. The two independent molecules of **12a**, one of which is shown (Fig. 3), have very similar bond lengths and angles (see Experimental) but differ in the relative orientations of the conformationally

free phenyl and ethoxy substituents. The molecular packing is controlled by intermolecular hydrogen bonds between the thioamide NH and a nitrogen (N3 or N4) of an adjacent symmetry-related molecule. This represents the first X-ray structure of this heterocyclic ring system.

As indicated in Scheme 3, we believe that the thioamide anion at the 5-position of the triazole ring in **11** cyclizes to form the second ring. After hydrolysis, intermediate **11** is converted into 8-phenylimino-1,2,4-triazolo[5,1-*c*]-1,4-thiazine **12a**. This is different from the reaction between **3** and carbon disulfide, in which the triazole group was displaced by the dithiocarboxylate anion attached to the side chain (Scheme 2). Alkyl-substituted heterocycle **12b** was prepared in 70% yield in a manner similar to that for **12a**.

Only a few examples of 8*H*-1,2,4-triazolo[5,1-*c*]-1,4-thiazines have previously been recorded in the literature (8–11). They were prepared by the formation of the thiazine ring (8, 9) or the triazole ring (10, 11). No 8-phenylimino-1,2,4-triazolo[5,1-*c*]-1,4-thiazines have previously been known.

In conclusion, we have demonstrated that 1,2,4-triazole stabilized allenic anions, which can be easily prepared from available starting materials, have significant synthetic utility for the synthesis of a variety of polyfunctionalized heterocycles, as shown in the previous (1) and present papers. Many of these syntheses show advantages over previous literature methods.

Experimental

Melting points were measured on a hot-stage microscope and are uncorrected. ^{1}H and ^{13}C NMR data were collected on a 300 NMR spectrometer (300 MHz and 75 MHz, respectively) in $CDCl_3$, except where stated, with TMS or $CDCl_3$, respectively, as internal reference. Column chromatography was carried out using 230-400 mesh silica.

Crystallographic analyses

The crystal data, data collection, and refinement parameters for the three structures are listed in Table 1. All measurements were made with a Nicolet P4s diffractometer using graphite monochromatized Mo Kα (λ = 0.710 73 Å) radiation. Cell parameters were determined by least-squares refinement on diffractometer angles for at least 25 accurately centered reflections with 2 θ > 20°. Throughout data collection (ω scan mode) the intensities of three standard reflections were monitored at regular intervals and in no case showed variations of >5%. Intensities were corrected for Lorentz and polarization effects and for absorption using a technique based on azimuthal ψ scans.

The structures were solved by direct methods using SHELXS (12), and refined on F^2, using all data, by full-matrix least-squares procedures with SHELXL-96 (13). All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in calculated positions with isotropic displacement parameters 1.3 times the isotropic equivalent of their carrier atoms. The functions minimized were $w(F_o^2 - F_c^2)$, with $w = [\sigma^2(F_o^2) + aP^2]^{-1}$, where $P = [\max(F_o)^2 + 2F_c^2]/3$. Final non-hydrogen atom coordinates are listed in Tables 2–4. Tables 5–7 list bond lengths and angles for **8**, **9a**, and **12a**, respectively. Tables of hydrogen atom coordinates and anisotropic displacement parameters are available as supplementary data.[2]

1-(1,2,4-Triazol-1-yl)-3-phenylpropargyl ethyl ether (**1**)

[2] Copies of the supplementary data (Tables S1–S6) can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The tables of hydrogen atom coordinates have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

5, or **10** (5 mmol) in THF (70 mL) at –90°C was added *n*-butyllithium (2.5 M in cyclohexane, 4 mL, 10 mmol). The solution was stirred at this temperature for 5 min and the appropriate electrophile (carbon disulfide or phenyl isocyanate, 10 mmol) was then added. After the reaction mixture was stirred for an additional 10 min, it was quenched at this temperature with water (50 mL). HCl (5 N, 5 mL) was added to the above solution, which was then stirred at room temperature for 2 h. The resulting solution was extracted with ether (3 × 100 mL), and the organic extractant was dried over anhydrous $MgSO_4$. Evaporation of the solvent gave a residue that was purified by column chromatography on silica gel (eluent: hexane–EtOAc).

*Bis(5-ethoxy-3-phenyl-2-thienyl) disulfide (***8a***)*: yellow microcrystals, mp 93–94°C; ^{1}H NMR: 1.45 (6H, t, J = 7.1 Hz), 4.08 (4H, q, J = 7.1 Hz), 6.20 (2H, s), 7.22–7.32 (10H, m); ^{13}C NMR: 14.7, 69.0, 107.9, 127.3, 127.9, 129.1, 135.4, 148.5, 168.5. Anal. calcd. for $C_{24}H_{22}O_2S_4$: C 61.24, H 4.71; found: C 61.46, H 4.61.

*5-Ethoxy-6-[1-phenyl-1-(phenylaminothiocarbamoyl)methyl]-8-phenylimino-1,2,4-triazolo[5,1-c]-1,4-thiazine (***12a***)*: yellow microcrystals, mp 212–214°C; ^{1}H NMR (DMSO-d_6): 1.44 (3H, t, J = 7.1 Hz), 4.22–4.42 (2H, m), 6.03 (1H, s), 6.91 (2H, d, J = 7.7 Hz), 7.15 (1H, t, J = 7.4 Hz), 7.24–7.54 (10H, m), 7.71 (2H, d, J = 7.7 Hz), 8.57 (1H, s), 11.98 (1H, s); ^{13}C NMR (DMSO-d_6): 14.9, 57.2, 70.9, 110.0, 118.9, 123.7, 125.0, 126.5, 127.8, 128.4, 128.6, 128.7, 129.6, 137.2, 138.9, 139.1, 145.3, 146.7, 148.6, 152.8, 199.6. Anal. calcd. for $C_{27}H_{23}N_5OS_2$: C 65.17, H 4.66, N 14.07; found: C 65.57, H 4.78, N 13.92.

*5-Ethoxy-6-[1-(phenylaminothiocarbamoyl)heptanyl]-8-phenylimino-1,2,4-triazolo[5,1-c]-1,4-thiazine (***12b***)*: yellow microcrystals, mp 82–85°C; ^{1}H NMR: 0.86 (3H, t, J = 6.6 Hz), 1.10–1.45 (8H, m), 1.55 (3H, t, J = 7.2 Hz), 1.74–1.94 (1H, m), 2.04–2.23 (1H, m), 4.24–4.38 (2H, m), 4.46–4.59 (1H, m), 7.02 (2H, d, J = 7.2 Hz), 7.09–7.29 (2H, m), 7.30–7.40 (4H, m), 7.60 (2H, d, J = 7.8 Hz), 8.20 (1H, s), 9.40 (1H, s); ^{13}C NMR: 13.9, 15.2, 22.4, 27.3, 28.8, 31.4, 32.7, 54.2, 72.1, 110.2, 119.4, 123.5, 125.5, 126.9, 128.8, 129.5, 138.4, 138.6, 144.1, 147.3, 148.5, 152.5, 200.9. Anal. calcd. for $C_{27}H_{31}N_5OS_2$: C 64.13, H 6.18, N 13.85; found: C 64.09, H 5.82, N 13.58.

General procedure for the preparation of 2-thiophenones 9 by acidic hydrolysis

Disulfide **8** (3 mmol) was hydrolyzed in a mixture of ethanol (25 mL), water (25 mL), and concentrated HCl (2 mL) under reflux for 2 days. After the usual extraction work-up, the crude product was purified by column chromatography on silica gel (eluent: hexane–EtOAc).

*4-Phenyl-2-thiophenone (***9a***)*: yellow solid, mp 133–135°C (lit. (4) mp 134–136°C); ^{1}H NMR: 4.44 (2H, s), 6.69 (1H, t, J = 1.6 Hz), 7.46–7.62 (5H, m); ^{13}C NMR: 37.5, 111.1, 126.3, 126.8, 129.1, 131.1, 133.3, 165.2. Anal. calcd. for $C_{10}H_8OS$: C 68.15,H 4.58; found: C 68.32, H 4.46.

*4-Pentyl-2-thiophenone (***9b***)*: This compound was obtained directly from **5**, without isolation of the intermediate disulfide, as a brown oil; ^{1}H NMR: 0.91 (3H, t, J = 6.6 Hz), 1.25–1.35 (4H, m), 1.61 (2H, t, J = 7.3 Hz), 2.47 (2H, t, J = 7.7 Hz), 3.97 (2H, s), 6.09 (1H, s); ^{13}C NMR: 13.8, 22.2, 27.5, 31.2, 33.1, 39.7, 116.2, 128.1, 172.2; HRMS (EI) calcd. for $C_9H_{14}OS$: 170.0765; found: 170.0782.

On the relationship between the rate constants for racemization and isotopic exchange

John M.W. Scott and Danny Summers

Abstract: The relationship between the rate constants that describe the halide ion catalysis of the racemization (k_r) of optically alkyl halides and the related isotopic halide exchange reaction (k_e) is shown to be valid in two distinct cases. The first is when the racemization and exchange mechanisms follow the classical and conventional S_N2 path characterized by a symmetrical trigonal (sp^2) transition state. The second envisages the trigonal species characteristic of the S_N2 reaction as an intermediate instead of a transition state. The latter mechanism is also shown to be characterized by the relationship $k_r = 2k_e$, and hence this diagnostic test is seen to be a necessary but not a sufficient condition for invoking the S_N2 mechanism.

Key words: racemization, isotopic exchange, kinetics, bimolecular substitution, inversion.

Résumé : On montre que la relation entre les constantes de vitesse, qui décrit la racémisation (k_r) des halogénures d'alkyle optiquement actifs catalysée par un ion halogénure et la réaction apparentée d'échange isotopique d'halogénure (k_e), est valide dans deux cas distincts. Le premier cas est celui où la racémisation et le mécanisme d'échange suivent le chemin classique et conventionnel d'une réaction S_N2 caractérisée par un état de transition trigonal (sp^2). Le second cas met en jeu une espèce trigonale caractéristique d'une réaction S_N2 comme intermédiaire plutôt que comme état de transition. On montre également que le mécanisme, dans le deuxième cas, est caractérisé par la relation $k_r = 2k_e$, et par conséquent ce test caractéristique semble être une condition nécessaire mais pas suffisante pour invoquer le mécanisme S_N2.

Mots clés : racémisation, échange isotopique, cinétique, substitution bimoléculaire, inversion.

Introduction

The racemizations of optically active alkyl halides catalysed by halide ions

$$[1] \qquad (\pm)\mathrm{RX} + \mathrm{X} \underset{k_\alpha}{\overset{k_\alpha}{\leftrightarrows}} (\mp)\mathrm{RX} + \mathrm{X}$$

and the related isotopic exchange reactions summarized

$$[2] \qquad \mathrm{RX} + \mathrm{X}^* \underset{k_\gamma}{\overset{k_\alpha}{\leftrightarrows}} \mathrm{RX}^* + \mathrm{X}$$

form an important part of the substance and theory of nucleophilic displacement reactions (1, 2). Some specific examples generally described by eqs. [1] and [2] are the following:
(*a*) RX = 2-octyl iodide with X = iodide ion (NaI in acetone);
(*b*) RX = 1-phenylethyl bromide with X = bromide ion (LiBr in acetone);
(*c*) RX = 1-bromopropionic acid with X = bromide ion (LiBr in acetone).

The kinetics of the process represented by eq. [1] are described by a pseudo-first-order rate constant k_α, which is related to a second-order rate constant k_1 and the concentration of the halide ion:

$$[3] \qquad k_\alpha = k_1[\mathrm{X}]$$

Similar rate constants k_β and k_γ, related respectively to the concentration of the alkyl halide and the halide ion, characterize the exchange process:

$$[4] \qquad k_\beta = k_1[\mathrm{RX}]$$

$$[5] \qquad k_\gamma = k_1[\mathrm{X}]$$

The rates of the processes described by eqs. [1] and [2] differ because the same potential energy surface is being probed in two distinct ways. The assumption that the two kinetic processes are underpinned by a single potential energy surface is limited only by departures from the Born–Oppenheimer Principle (BOP). For heavy atoms such as bromine and iodine, departures from the BOP are negligible.

Clearly, both the racemization and exchange processes for a given substrate at a fixed temperature relate to a common second-order rate constant k_1, which becomes a component of the pseudo-first-order rate constants k_α, k_β, and k_γ when the kinetics of any given experimental system are treated formally. Thus, eqs. [3], [4], and [5] merely emphasize the second-order character of the basic processes without, for instance, determining the condition of the ionic substances dissolved in acetone. The calculation of the true second-order rate constants

[a] k_1C/k(calc.)

from experimental data that may relate to either kinetically free ions or saline ion pairs is not a trivial matter. Nevertheless, such problems are of marginal concern here; rather the first-order character of eqs. [3], [4], and [5] with respect to the saline nucleophiles serves to highlight the bimolecular nature of the transition state, which is conventionally regarded as a symmetrical bipyramidal sp^2 structure. The overall mechanism represents a classical example of the S_N2 displacement reaction; indeed, the distinct relationships between racemization ($k_r = 2k_1$) and exchange ($k_e = k_1$) are central to the hypothesis that the activated complex is symmetric. For instance, Ingold (1) states categorically that this particular observation "requires that ***every*** (C.K.I's emphasis) individual act of bimolecular substitution inverts configuration" and thus "passes through" a trigonal bipyramidal transition state. Hammett (2) is characteristically more circumspect and suggests that "the data do not exclude the possibility of a detailed mechanism involving further intermediates," but concludes that "there seems to be no reason to take the uncertainty very seriously."

Notwithstanding the comments of Ingold and Hammett, the question arises as to the relative rates of racemization and exchange for more complex barriers. The purpose of the present paper is to examine this question for a reaction described by a symmetrical barrier with a single symmetrical intermediate, i.e., in the more complicated regime the structure of the intermediate is identical to that of the S_N2 transition state. The racemizations are now described by the reaction

$$[6] \qquad (+)\mathrm{A} + \mathrm{X} \underset{k_2}{\overset{k_\alpha}{\rightleftarrows}} \mathrm{I} \underset{k_\alpha}{\overset{k_2}{\rightleftarrows}} (-)\mathrm{A} + \mathrm{X}$$

where k_α is defined again by eq. [3] and I is the symmetrical intermediate. The related exchange reaction is analogously represented by

$$[7] \qquad \mathrm{RX} + \mathrm{X}^* \underset{k_2}{\overset{k_\beta}{\rightleftarrows}} \mathrm{I} \underset{k_\gamma}{\overset{k_2}{\rightleftarrows}} \mathrm{RX}^* + \mathrm{X}$$

where k_β and k_γ are as previously defined by eqs. [4] and [5].

It is useful to repeat the derivations of the kinetic equations for the S_N2 racemization and exchange reactions described by eqs. [1] and [2] using mathematical techniques that can be readily extended to more complex barriers. The methodology adopted here is similar to that described briefly by Ritchie (3), and some aspects are also covered in a translated Russian monograph (4). In summary, the mathematical solutions of the appropriate differential equations are derived via an auxiliary polynomial equation, the roots of which are always negative. These negative roots, *with their sign changed*, define the dynamic constants (necessarily positive), that describe the time evolution of the chemical systems of interest. For complex systems the dynamic constants are functions of the primitive component rate constants (for extensive details see ref. 4). In general, the symbols of chemical species *without square brackets* (but italicized to indicate that they possess numerical value) will be used to denote concentrations since the inclusion of such brackets would render the more involved expressions too cumbersome.

The kinetic expressions that relate to the simple S_N2 racemizations and isotopic exchanges are derived in Appendices A and B, respectively. The related kinetic formulae for the cases when an intermediate is present (eqs. [6] and [7]) are derived in Appendices C and D. Several calculations using synthetic composition–time data are examined in the

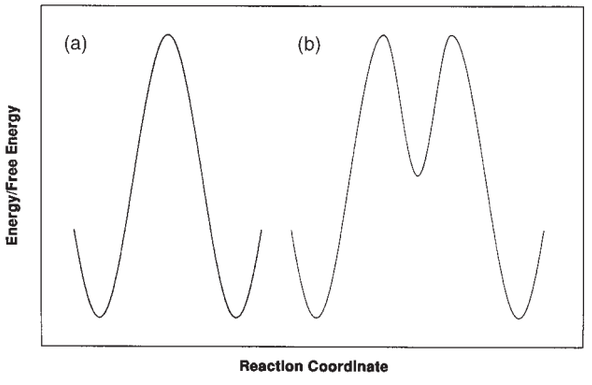
Fig. 1. Schematic energy (or free energy) versus reaction coordinate diagram for (*a*) a simple symmetrical S_N2 displacement (LHS) and (*b*) a symmetrical displacement involving an intermediate (RHS).



following section to verify numerically the formal conclusions established in Appendix D.

Calculations

The numerical tests were carried out using the analysis presented in Appendix D. Thus a range of synthetic data was calculated using eq. [23D] after solving the quadratic part of eq. [6D] to generate the dynamic constants γ_1 and γ_2. The concentrations of RX and X were arbitrarily fixed at 1.00×10^{-1} M L^{-1} and the tagged atom X^* concentration was set at 1.00×10^{-4} M L^{-1}, i.e., $0.001 \times$ [X]. The rate constant k_1 was set at 1×10^{-4} L M^{-1} s^{-1}, with 21 values of k_2 in the range $1.00 \times 10^{-3} < k_2 < 1.00 \times 10^3$. For each of the 21 pairs of k_1 and k_2, 100 values of X^*_n (n = 1–100) were calculated at equal intervals over a period estimated to be four half-lives ($4t_{1/2}$). Thus the time interval between each calculated value of X^*_n is approximately $t_{1/2}/25$. The half-life was estimated from the smaller dynamic constant of the pair γ_1 and γ_2. The values of X^*_n so calculated were then processed using the Guggenheim algorithm (5) and in the present context this approach is best considered in terms of eq. [7D].

Consider two sets of the quantities X^*_n; the first set is defined for n = 1–30 and the second set for n = 60–90. For the first set eq. [7D] gives

$$[8] \quad X^*_n\,(n = 1\text{–}30) = a_{11} + a_{12}\exp(-\gamma_1 t) + a_{13}\exp(-\gamma_2 t)$$

and, for the second set,

$$[9] \quad X^*_{n\tau}\,(n = 60\text{–}90) = a_{11} + a_{12}\exp\{-\gamma_1\,(t+\tau)\} + a_{13}\exp\{-\gamma_2(t+\tau)\}$$

where $\tau \approx 60t_{1/2}/25$. Subtracting eq. [9] from eq. [8], on the assumption that $\gamma_1 < \gamma_2$ and that $a_{12} > a_{13}$, gives

$$[10] \quad X^*_n - X^*_{n\tau} \approx a_{12}\{1 - \exp(-\gamma_1\,\tau)\}exp(-\gamma_1 t)$$

which in logarithmic form becomes an equation suitable for linear regression

$$[11] \quad \ln\{X^*_n - X^*_{n\tau}\} \approx \ln[a_{12}\{1 - \exp(-\gamma_1\,\tau)\}] - \gamma_1 t$$

A correlation with t as the "x" variable and $\ln\{X^*_n - X^*_{n\,\tau}\}$ as the "y" variable gives $-\gamma_1$ as the slope, which is equal to $-k$(calc.) and should, if the previous analysis is correct, be equal to $k_1C/2$. This requirement is amply confirmed by the data shown in Tables 1 and 2. In Table 2 the values of X, X*, and RX are the same as in Table 1, but k_2 is fixed at 10 s^{-1} and k_1 varies from 1×10^{-4} to 1×10^{-1} L M^{-1} s^{-1}. In all the cases numerically examined the ratio k_1C/k(calc.) = 2.

Conclusions

The diagnostic test for the S_N2 mechanism, which requires $k_r = 2k_e$, is necessary but not sufficient evidence for the operation of the S_N2 mechanism.

Appendix A

Racemization for the simple S_N2 case

The standard derivations for the racemization and exchange reactions are reported by Stein (6) and Espenson (7). For the racemization reaction, the experimental observables are the optical rotation (α) and time (t). For a given initial concentration of (+)RX represented by the symbol $(+)A_o$ the observed optical rotation at any time depends on the concentration of the two optical isomers present at that time, represented by the symbols (+)A and (–)A, hence

$$[1A] \quad \alpha = (+)\,\alpha_M\{(+)A + (-)\alpha_M\{(-)A\}$$

By definition

$$[2A] \quad (+)\alpha_M = -(-)\alpha_M = |\alpha_M|$$

Hence

$$[3A] \quad \alpha = \alpha_M\{(+)A - (-)A\}$$

At $t = 0$, if only one optical isomer is present the optical rotation (α_o) is given by

$$[4A] \quad \alpha_o = \alpha_M(+)A_o$$

The differential equations that describe reaction [1] are

$$[5A] \quad -\frac{d(+)A}{dt} = k_\alpha(+)A - k_\alpha(-)A$$

© 1998 NRC Canada

$$[6A] \quad -\frac{d(-)A}{dt} = -k_\alpha(+)A + k_\alpha(-)A$$

The auxiliary equation related to eqs. [5A] and [6A] is readily obtained from the determinant related to the matrix formulation of these equations:

$$[7A] \quad \begin{bmatrix} D + k_\alpha & -k_\alpha \\ -k_\alpha & D + k_\alpha \end{bmatrix} \begin{bmatrix} (+)A \\ (-)A \end{bmatrix} = 0$$

where D is the differential operator d/dt. The determinant is

$$[8A] \quad \begin{vmatrix} \lambda + k_\alpha & -k_\alpha \\ -k_\alpha & \lambda + k_\alpha \end{vmatrix} = 0$$

and the related auxiliary equation is

$$[9A] \quad \lambda(\lambda + 2k_\alpha) = 0$$

Equation [9A] has roots $\lambda = 0$ and $\lambda = -2k_\alpha$ and hence solutions of $(+)A$ and $(-)A$ as functions of time are of the form

$$[10A] \quad (+)A = a_{11} + a_{12}\exp(-2k_\alpha t)$$

and

$$[11A] \quad (-)A = a_{22} + a_{21}\exp(-2k_\alpha t)$$

where the quantities a_{nr} are constants evaluated from the boundary conditions, namely, $(+)A = (+)A_o$ at $t = 0$; $(+)A = (+)A/2$ at $t = \infty$; $(-)A = 0$ at $t = 0$; $(-)A = (+)A/2$ at $t = \infty$. These conditions yield the solutions

$$[12A] (+)A = \{(+)A_o/2\}\{1 + \exp(-2k_\alpha t)\}$$

$$[13A] (-)A = \{(+)A_o/2\}\{1 - \exp(-2k_\alpha t)\}$$

The observed optical rotation at any time (α) for the reacting system is related to the quantity $\{(+)A - (-)A\}$, which can be generated by subtracting eq. [13A] from eq. [12A]. Multiplication of both sides of the resulting equation by α_M gives

$$\alpha_M\{(+)A - (-)A\} = \alpha_M(+)A_o\exp(-2k_\alpha t)$$

or

$$[14A] \quad \alpha = \alpha_o\exp(-2k_\alpha t)$$

Equation [14A] is the usual form given for the change of optical activity with time for a labile optically active system (6).

Appendix B

Isotopic exchange for the simple S_N2 case

The kinetic equations for the isotopic exchange process are based on eq. [2]

$$[1B] \quad RX + X^* \underset{k_\gamma}{\overset{k_\beta}{\leftrightarrows}} RX^* + X$$

with the assumptions that the concentration of X^* is much less than the concentrations of X and RX, which are assumed to be comparable. The pseudo-first-order rate constants are those defined in eqs. [4] and [5]. The differential equations that describe the exchange process are

$$[2B] \quad -\frac{dX^*}{dt} = k_\beta X^* - k_\gamma RX^*$$

$$[3B] \quad -\frac{dRX^*}{dt} = -k_\beta X^* + k_\gamma RX^*$$

and their equivalent matrix form is

$$[4B] \quad \begin{bmatrix} D + k_\beta & -k_\gamma \\ -k_\beta & D + k_\gamma \end{bmatrix} \begin{bmatrix} X^* \\ RX^* \end{bmatrix} = 0$$

The related determinant

$$[5B] \quad \begin{vmatrix} \lambda + k_\beta & -k_\gamma \\ -k_\beta & \lambda + k_\gamma \end{vmatrix} = 0$$

gives the auxiliary equation

$$[6B] \quad \lambda(\lambda + k_\beta + k_\gamma) = 0$$

The roots of eq. [6B] are $\lambda = 0$ and $\lambda = -(k_\beta + k_\gamma)$, and the equation for X^* as a function of time is of the form (cf. eqs. [12A] and [13A])

$$[7B] \quad X^* = a_{11} + a_{12}\exp(-(k\beta + k_\gamma)t)$$

At $t = 0$, $X^* = X^*_o$, and at $t = \infty$, $X^* = X^*_\infty$. These conditions produce the result

$$[8B] \quad X^* - X^*_\infty = (X^*_o - X^*_\infty)\exp(-(k_\beta + k_\gamma)t)$$

Mass balance at all times requires that

$$[9B] \quad X^*_o = X^* + RX^*$$

and at $t = \infty$,

$$[10B] \quad X^*_o = X^*_\infty + RX^*_\infty$$

Eliminating X^*_o between eqs. [9B] and [10B] gives

$$[11B] \quad X^* - X^*_\infty = RX^*_\infty - RX^*$$

From eq. [9B],

$$[12B] \quad X^*_o - X^*_\infty = RX^*_\infty$$

Combining eqs. [11B] and [12B] with eq. [8B] gives

$$[13B] \quad RX^*_\infty - RX^* = RX^*_\infty\exp(-(k_\beta + k_\gamma)t)$$

or, in the more conventional form (7):

$$[14B] \quad \ln\{1 - (RX^*/RX^*_\infty)\} = -(k_\beta + k_\gamma)t$$

Combining eq. [14B] with eqs. [4] and [5] gives

$$[15B] \quad \ln\{1 - (RX^*/RX^*_\infty)\} = -k_1(RX + X)t$$

Note that the racemization rate constant is $k_r = 2k_1$ whereas the isotopic exchange rate constant is $k_e = k_1$. We now demonstrate in Appendices C and D that the same ratio, $k_r/k_e = 2$, characterizes racemization and exchange when an intermediate structurally identical to the S_N2 transition state is present in the reacting system.

Appendix C

Racemization with an intermediate present

The chemical equation for the racemization with an intervening intermediate is given by

$$[1C] \quad (+)A + X \underset{k_2}{\overset{k_\alpha}{\leftrightarrows}} I \underset{k_\alpha}{\overset{k_2}{\leftrightarrows}} (-)A + X$$

© 1998 NRC Canada

where k_α is defined in eq. [3].
The differential equations that describe this reaction are

$$[2C] \quad -\frac{d(+)A}{dt} = k_\alpha(+)A - k_2 I$$

$$[3C] \quad -\frac{dI}{dt} = -k_\alpha(+)A + 2k_2 I - k_\alpha(-)A$$

$$[4C] \quad -\frac{d(-)A}{dt} = -k_2 I + k_\alpha(-)A$$

The equivalent matrix form is

$$[5C] \quad \begin{bmatrix} (D + k_\alpha) & -k_2 & \\ -k_\alpha & (D + 2k_2) & -k_\alpha \\ & -k_2 & (D + k_\alpha) \end{bmatrix} \begin{bmatrix} (+)A \\ I \\ (-)A \end{bmatrix} = 0$$

and the related determinant gives the auxiliary equation

$$[6C] \quad \lambda(\lambda + k_\alpha)(\lambda + k_\alpha + 2k_2) = 0$$

for which the roots are $\lambda = 0$, $\lambda = -k_\alpha$, and $\lambda = -(k_\alpha + 2k_2)$. Hence the solutions of eq. [5C] are

$$[7C] \quad X_n = a_{1n} + a_{2n} \exp(-k_\alpha t) + a_{3n} \exp(-(k_\alpha + 2k_2)t)$$

where for $n = 1$, $X_n = (+)A$; for $n = 2$, $X_n = I$; and for $n = 3$, $X_n = (-)A$.

Standard methods give the following expressions for $(+)A$, $(-)A$, and I as functions of time

$$[8C] \quad (+)A = (+)A_o \left\{ \frac{k_2}{(k_\alpha + 2k_2)} + \frac{\exp(-k_\alpha t)}{2} + \frac{k_\alpha \exp(-(k_\alpha + 2k_2)t)}{2(k_\alpha + 2k_2)} \right\}$$

$$[9C] \quad I = \frac{(+)A_o k_\alpha}{k_\alpha + 2k_2} \{1 - \exp(-(k_\alpha + 2k_2)t)\}$$

$$[10C] \quad (-)A = (-)A_o \left\{ \frac{k_2}{(k_\alpha + 2k_2)} - \frac{\exp(-k_\alpha t)}{2} + \frac{k_\alpha \exp(-(k_\alpha + 2k_2)t)}{2(k_\alpha + 2k_2)} \right\}$$

Because the intermediate I is symmetrical, it makes no contribution to the optical activity of the system, which, as before, is defined (cf. eqs. [12A]–[14A]) by the difference $\{(+)A - (-)A\}$. This quantity can be generated in the present case by subtracting eq. [10C] from eq. [8C], yielding the result,

$$[11C] \quad (+)A - (-)A = (+)A_o \exp(-k_\alpha t)$$

Equation [11C] is analogous to eq. [14A] with the important exception that k_r is now equal to k_1 rather than $2k_1$. We now consider the exchange reaction when an intermediate is present.

Appendix D

Isotopic exchange with an intermediate present

Section I(D)
The reaction for the isotopic exchange process is now described by the equation

$$[1D] \quad RX + X^* \underset{k_2}{\overset{k_\beta}{\rightleftarrows}} I \underset{k_\gamma}{\overset{k_2}{\rightleftarrows}} RX^* + X$$

where the quantities k_β and k_γ have the same meaning as in eqs. [4] and [5]. The differential equations that describe this version of the isotopic exchange are

$$[2D] \quad -\frac{dX^*}{dt} = k_\beta X^* - k_2 I$$

$$[3D] \quad -\frac{dI}{dt} = -k_\beta X^* + 2k_2 I - k_\gamma RX^*$$

$$[4D] \quad -\frac{dRX^*}{dt} = -k_2 I + k_\gamma RX^*$$

The matrix form corresponding to eqs. [2D], [3D], and [4D] is

$$[5D] \quad \begin{bmatrix} (D + k_\beta) & -k_2 & \\ -k_\beta & (D + 2k_2) & -k_\gamma \\ & -k_2 & (D + k_\gamma) \end{bmatrix} \begin{bmatrix} X^* \\ I \\ RX^* \end{bmatrix} = 0$$

which yields, via the related determinant, the auxiliary equation

$$[6D] \quad \lambda\{\lambda^2 + k_\beta + k_\gamma + 2k_2)\,\lambda + k_2(k_\beta + k_\gamma) + k_\beta k_\gamma\} = 0$$

At this point there are several ways of comparing the present system with that described in Appendix B. This comparative analysis is presented with varying degrees of approximation and rigour below.

Section II(D)
Equation [6D] has three roots, $\lambda = 0$, $\lambda = \lambda_1$, and $\lambda = \lambda_2$. The time evolution of the system represented by eq. [5D] is characterized by three amplitude factors, a_{11}, a_{12}, and a_{13}, and two dynamic constants, γ_1 and γ_2, that correspond to the two nonzero roots of the quadratic part of eq. [6D] with the signs of the roots reversed (cf. eq. [6C] where the roots are $-(k_\alpha + 2k_2)$ and $-k_\alpha$ but the dynamic constants are $(k_\alpha + 2k_2)$ and k_α). Thus, in particular, we have

$$[7D] \quad X^* = a_{11} + a_{12}\exp(-\gamma_1 t) + a_{13}\exp(-\gamma_2 t)$$

Generally, the smaller of the dynamic constants (say γ_1) will dominate the time evolution of the system because the amplitude factors are inversely correlated with γ_1 and γ_2. If the intermediate I is labile, then the rate constant k_2, which characterizes the paths of its destruction, must be such that $k_2 > k_\beta = k_1 RX$. With these approximations, the quadratic part of eq. [6D] becomes

$$[8D] \quad \lambda^2 + 2k_2\lambda + k_2(k_\beta + k_\gamma) = 0$$

If $\lambda << 1$ then $\lambda^2 << \lambda$, and hence eq. [8D] can be linearized to the form

$$2k_2\lambda = -k_2(k_\beta + k_\gamma)$$

or

$$[9D] \quad \lambda \approx -(k_\beta + k_\gamma)/2 = -k_1(RX + X)/2 = -k_1 C/2 \text{ or } \gamma_1 = k_1 C/2$$

where C represents the concentration term related to RX and X in eq. [9D]. Thus, the approximate root of eq. [6D] leads to the same relationship between k_r and k_e as is observed in the classical S_N2 reaction, namely, $k_r = 2k_e$. If λ is large, then the

© 1998 NRC Canada

constant term in eq. [8D] is negligible, and the larger approximate dynamic constant is given by

[10D] $\lambda^2 = -2k_2\lambda$ or $\gamma_2 = 2k_2$

These approximate roots can be improved by solving eq. [8D] in the usual way, and then using the binomial theorem to expand the square-root term, giving the following expressions for the dynamic constants γ_1 and γ_2:

[11D] $\gamma_1 = \{2k_2 - (4k_2^2 - 4k_1k_2C)^{1/2}\}/2 \approx k_1C$

[12D] $\gamma_2 = \{2k_2 + (4k_2^2 - 4k_1k_2C)^{1/2}\}/2 \approx 2k_2 - k_1C/2$

The values of γ_1 and γ_2 established in eqs. [11D] and [12D] confirm the previous estimates of these quantities.

Section III(D)

In the present section the amplitude factors are calculated for eq. [7D] so that synthetic data for X^* as a function of time can be established. The synthetic data are then processed in the same manner as experimental data to recover the input rate constant k_1. Setting $t = 0$ and $X^* = X^*_o$ in eq. [7D] gives

[13D] $X^*_o = a_{11} + a_{12} + a_{13}$

Similarly, setting $X^* = X^*_\infty$ at $t = \infty$ in eq. [7D] gives

[14D] $X^*_\infty = a_{11}$

Using the condition that $I = 0$ at $t = 0$ gives $\left.\frac{dX^*}{dt}\right|_{t=0} = k_\beta X^*_o$

Hence

[15D] $k_\beta X^*_o = \lambda_1 a_{12} + \lambda_2 a_{13}$

Combining eqs. [13D] and [14*D*] gives

[16D] $X^*_o - X^*_\infty = a_{12} + a_{13}$

Solving eqs. [15D] and [16D] simultaneously gives

[17D] $a_{12} = \dfrac{\lambda_2(X^*_o - X^*_\infty) - k_\beta X^*_o}{(\lambda_2 - \lambda_1)}$

[18D] $a_{13} = \dfrac{\lambda_1(X^*_o - X^*_\infty) - k_\beta X^*_o}{(\lambda_1 - \lambda_2)}$

At $t = \infty$, mass balance requires

[19D] $X^*_o = X^*_\infty + I_\infty + RX^*_\infty$

with the further equilibrium condition that

[20D] $k_\beta X^*_\infty = k_2 I_\infty = k_\gamma RX^*_\infty$

Using the relationships between I_∞, RX^*_∞, and X^*_∞ given in eq. [20D] to eliminate the quantities I_∞ and RX^*_∞ in eq. [19D] gives

[21D] $X^*_o = X^*_\infty + (k_\beta/k_2)X^*_\infty + (k_\beta/k_\gamma)X^*_\infty$

which, after further manipulations, gives

$$X^*_o = X^*_\infty + (k_1RX/k_2)X^*_\infty + (RX/X)X^*_\infty$$

or

[22D] $X^*_\infty = \dfrac{k_2XX^*_o}{k_2X + k_1XRX + k_2RX}$

Equation [13D] combined with eqs. [17D], [18D], and [22D] gives

[23D] $X^* = \dfrac{k_2XX^*_o}{k_2X + k_1XRX + k_2RX} + \dfrac{\lambda_2(X^*_o - X^*_\infty) - k_\beta X^*_o}{(\lambda_2 - \lambda_1)}\exp(-\lambda_1 t) + \dfrac{\lambda_1(X^*_o - X^*_\infty) - k_\beta X^*_o}{(\lambda_1 - \lambda_2)}\exp(-\lambda_2 t)$

Lactams in sulfuric acid. The mechanism of amide hydrolysis in weak to moderately strong aqueous mineral acid media

Robin A. Cox

Abstract: Reaction rate constants obtained in moderately concentrated sulfuric acid for the hydrolysis of simple lactams of ring sizes five, six, seven, and eight as a function of acidity and temperature have been analyzed using the excess acidity kinetic method. The basicity constants for these substrates have been recalculated; the ^{13}C NMR spectra used to obtain these values are very sensitive to medium effects. It was found that the basicities of the lactams at 0.003–0.1 M lactam concentration were over half a p*K* unit more basic than they were at 0.5 M lactam, presumably because of the medium effect. Apart from this, the rate constant results obtained at different times by different groups using different techniques for monitoring the kinetics are in adequate agreement. The excess acidity analysis showed that the kinetics could be fitted according to the "three-water-molecule followed by one-water-molecule" mechanistic scenario previously found, or could just as well be fitted by a "one-water-molecule followed by unknown mechanism" scenario, with the mechanistic change taking place at 50 wt.% sulfuric acid for all the substrates. Other evidence makes the latter seem the more likely possibility of the two, and activation parameters based upon the "one-water-molecule" process were determined. Sufficient data points to enable the unknown mechanism to be established were not present; possible mechanisms applicable in media more concentrated than 50 wt.% sulfuric acid are discussed. Previously obtained values of the parameter *r*, the number of water molecules involved with the substrate in A2 processes, are now questionable.

Key words: amides, lactams, excess acidity, hydrolysis, mechanism.

Résumé : Faisant appel à la méthode cinétique d'excès d'acidité, on a analysé les constantes de vitesse d'hydrolyse de lactames simples, de cycles à cinq, six, sept et huit chaînons, obtenues en solution dans de l'acide sulfurique modérément concentré, en fonction de l'acidité et de la température. Les constantes de basicité de ces substrats ont été recalculées; les spectres RMN du ^{13}C utilisés pour obtenir ces valeurs sont très sensibles aux effets du milieu. À des concentrations de lactames allant de 0,003 à 0,1 M, on a trouvé que les basicités des lactames sont 0,5 unité de p*K* plus basique qu'à 0,5 M, probablement à cause d'un effet de milieu. À part cette différence, il existe un bon accord entre les constantes de vitesse obtenues à différents moments, par différents groupes utilisant des techniques de mesures cinétiques différentes. L'analyse d'excès d'acidité a montré que la cinétique peut tout aussi bien être accommodée par le scénario mécanistique de "trois molécules d'eau suivies par une molécule d'eau" proposé antérieurement que par le scénario d'"une molécule d'eau suivie d'un mécanisme inconnu;" le changement de mécanisme se produit pour tous les substrats à 50% en poids d'acide sulfurique. D'autres données laissent croire que la deuxième possibilité est la plus plausible des deux; on a déterminé les paramètres d'activation basés sur le scénario d'"une molécule d'eau." On ne disposait pas d'assez de données pour déterminer le mécanisme inconnu; on discute de divers mécanismes qui pourraient être appliqués dans des milieux plus concentrés que 50% en poids d'acide sulfurique. Les valeurs obtenues antérieurement pour le paramètre *r*, le nombre de molécules d'eau impliquées avec le substrat dans un processus A2, sont remises en question.

Mots clés : amides, lactames, excès d'acidité, hydrolyse, mécanisme.

[Traduit par la rédaction]

Introduction

The mechanism of the hydrolysis of amides in acidic media is now thought to be reasonably well established. Although nitrogen protonation has been advocated (1), it is now generally agreed that the reaction begins with protonation on the amide oxygen, followed by rate-determining attack of water at the carbonyl carbon and subsequent processes, as shown in Scheme 1 (2).

However, in moderately concentrated mineral acid media, the Yates *r*-parameter treatment (3) (which is an update of Bunnett's original proposal (4) that log rate constant minus H_0 for reactions like this should be linear in the log water activity, slope *w*, which becomes slope *r* if the H_A amide acidity function is used instead of H_0) showed that three water molecules rather than one were involved in the rate-determining step (3, 5). In consequence it is very tempting to write the N-protonated tetrahedral intermediate as being formed in the rate-determining

Received 1 October 1997.

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

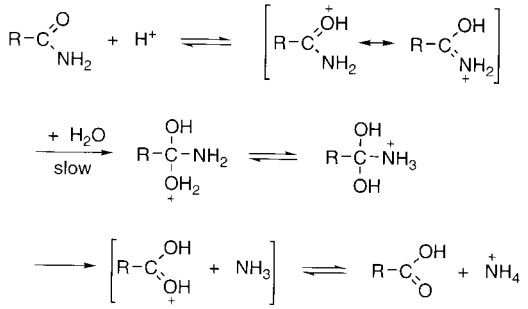
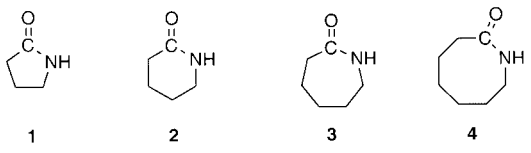
© 1998 NRC Canada

Scheme 1.



step directly, via a proton switch in a five-membered ring, as shown in eq. [1], since this involves no charge transfer (the positive charge merely becoming concentrated on the nitrogen) (6). This would also account quite well for the small amount of of ^{18}O exchange observed in amide hydrolysis (7), as compared to the considerable amounts found in ester hydrolysis (8), for instance, since the breakup of the N-protonated tetrahedral intermediate would be expected to be essentially irreversible.

[1] 
This proposal was made following an application of the excess acidity kinetic method (9) to rate data for the hydrolysis of a number of benzamides, benzimidates, and lactams (6). The analysis resulted in a two-mechanism scenario, with eq. [1] being followed at low acidities (high water activities), and the regular Scheme 1 process (one water molecule) taking over as the acidity increased and the water activity decreased, which seemed eminently reasonable (6). However, more recent work is not consistent with this. Small but measurable amounts of ^{18}O exchange accompanying hydrolysis have been reported for acetanilide (10), *N*-cyclohexylacetamide (10), and *N*,2,4-trimethylacetanilide (11) in reasonably concentrated aqueous HCl media. For *N*,2,4-trimethylacetanilide the solvent deuterium isotope effect was found to be close to one (11), which is a long way from what would be expected on the basis of eq. [1], which has three protons in flight at the transition state (11). For acetanilide and *N*-cyclohexylacetamide the amount of ^{18}O exchange was observed to decrease as the acidity increased (10), which is the reverse of what would be expected if only the high-acidity mechanism led to exchange, although later this was found not to be the case for acetanilide (11), the rate profiles for exchange and hydrolysis being parallel.



In view of this it was decided to reexamine the data for lactam hydrolysis in dilute to moderately concentrated sulfuric acid media. Subsequent to the publication of our previous paper (6), which included lactam hydrolysis data obtained by ^1H NMR spectroscopy for **1**, **2**, and **3** (12), an extensive new examination of lactam hydrolysis in aqueous sulfuric acid as a function of medium and temperature was published by Vinnik and Moiseev (13) for **1**–**4**, using UV-vis spectroscopy. Using both sets of data, together with that obtained by titration for **3** by Mhala and Jagdale (14) in the same medium, it should be possible to answer the nagging question as to whether amide hydrolysis data obtained by different kinetic methods are in fact comparable, as well as to shed some light on the mechanistic issues raised above. Again the excess acidity kinetic method was used (9); this has enabled mechanistic insights to be made into such diverse processes as ether cleavage (15), the benzidine rearrangement (16), aryl ring hydroxylation (17), acylimidazole hydrolysis (18), the reactions of *N*-nitro amides (19), *N*-nitroamine decomposition (20), alkene hydration (21), and imidazoline cyclization (22), to cite only the most recent examples.

Results

Since amides and lactams change their state of protonation over the acidity range covering most hydrolysis rate measurements, being unprotonated at low acid concentrations and protonated at high ones, it is necessary to know the pK_{BH^+} values of the substrates. These are determined from the variation of the spectrum of the substrate with acid concentration. Lactam (and amide) spectra, ^{13}C NMR, ^1H NMR, and UV-vis, are all very sensitive to medium effects. A method for accurately dealing with these has been devised (23), using the excess acidity method (24). This consists of determining slopes and intercepts of eq. [2]:

$$[2] \quad \log I - \log C_{H^+} = pK_{BH^+} + m^*X$$

where I is the ionization ratio, C_{BH^+}/C_B, obtained from the spectra, X is the excess acidity (essentially an activity coefficient ratio, $\log(f_{B^*}f_{H^+}/f_{B^*H^+})$ for a standard base B*), available for this medium along with log proton concentrations, $\log C_{H^+}$ (24), and m^* is a parameter characteristic of the substrate, having values of 1.0 for primary aromatic amines, 1.3 for tertiary amines, 0.6 for most carbonyl compounds, and so on (24). In simple cases where medium effects are negligible, the equation $I = (D_B - D)/(D - D_{BH^+})$ applies, where D is UV-vis optical density or NMR chemical shift, and D_B and D_{BH^+} refer to the pure unprotonated and protonated forms, respectively (23). This equation is then substituted into eq. [2] and the result curve-fitted in its entirety, giving D_B, D_{BH^+}, m^*, and pK_{BH^+} as coefficients (23).

With medium effects present, D_B or D_{BH^+} (or both) also become functions of the medium. For lactams the excess acidity treatment gives the medium dependence of D_{BH^+} as eq. [3]:

$$[3] \quad D_{BH^+} = D_{Aaq} + \delta D_A I'_A, \text{ where } I'_A = \Delta m^*_A X$$

Here D_{Aaq} is what the optical density (or chemical shift) of the acid form (A) (i.e., D_{BH^+}) would be in the standard state (water), δD_A is a constant, and I'_A is a medium variable controlled by the excess acidity X (24); Δm^*_A is another constant, with values typically around 0.1 (23). Substitution of eq. [3] into eq. [2] leads to two new coefficients that have to be calculated by the curve-fitting program, δD_A and Δm^*_A, giving six

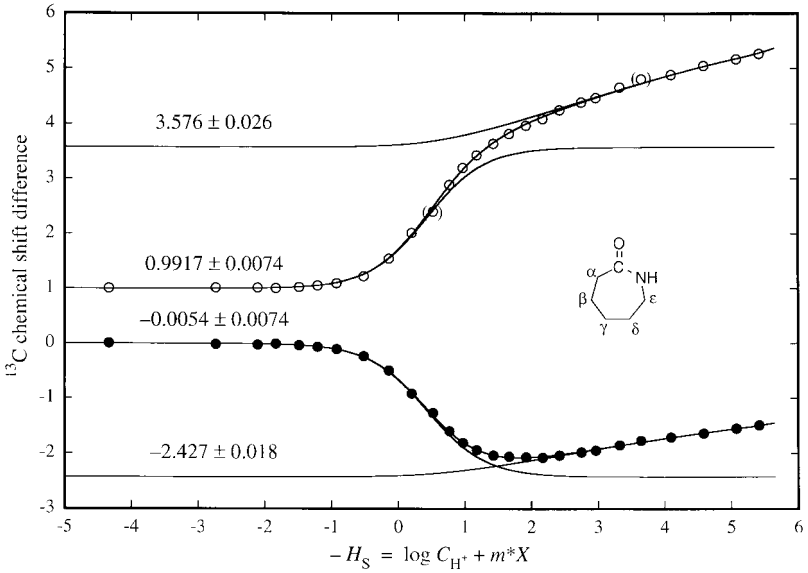
Fig. 1. Plot of ^{13}C chemical shift differences for ε-caprolactam **3** against the substrate acidity function specifically applicable to it, $-H_S$. Open circles, $\delta_\varepsilon - \delta_\gamma$, plotted as differences from the value in water taken as being 1.0000; closed circles, $\delta_\alpha - \delta_\gamma$, plotted as differences from the value in water taken as being 0.0000. The points are experimental and the curves theoretical (see text). The numbers quoted are the fitted shift difference values for pure unprotonated **3** (values at center) and for pure protonated **3** (upper and lower values). The δD_A values were 2.350 ± 0.083 (upper curve) and 1.281 ± 0.062 (lower curve).



coefficients in all, which means that plenty of good data is required for the analysis to work.

Much good ^{13}C NMR chemical shift data is available for all of these lactams (25). As an example, a plot of two chemical shift differences for ε-caprolactam **3** as a function of the acidity function specifically applicable to it (24) is given as Fig. 1. As can be clearly seen, the chemical shift differences of the protonated form are strongly medium dependent, despite the fact that chemical shift differences are used rather than the chemical shifts themselves, which is supposed to minimize medium effects (26). The curve fitting to eqs. [2] and [3] is very good, as the excellent agreement with the theoretical curves in Fig. 1 and the very low errors on the parameters in Fig. 1 and Table 1 show; for **3** Δm^*_A was 0.1076 ± 0.0063. Precise ^{13}C NMR chemical shift measurements as a function of sulfuric acid concentration are available for all of the substrates, at a lactam concentration of 0.5 M (25). For this study I reworked these data, taking into account dilution of the acid solutions by the substrate and the NMR probe temperature of 33°C, but the resulting values were, within experimental error, identical with those already given (25). The reworked values are given here in Table 1; these values can be regarded as quite reliable, with the proviso that the lactam concentration is fairly high at 0.5 M. A standard curve-fitting program (27) was used throughout.

The pK_{BH^+} values are used to calculate protonation correction terms for the observed reaction rate constants as a function of acid concentration. These have the form $\log(C_{SH^+}/(C_S + C_{SH^+}))$ for amides and lactams (S for substrate) (6), and are easily calculated using eq. [2] and the data in Table 1. One complication is that they have to be calculated at the reaction temperature rather than at 25°C; we have found previously that this is best done by converting pK_{BH^+} to $\Delta G°$ and assuming that $\Delta S° = 0$ in the absence of any information regarding the variation of pK_{BH^+} with temperature (6, 28, 29).

Table 1. Basicities of the lactam substrates at 25°C.

Substrate	pK_{BH^+} (NMR)[a]	pK_{BH^+} (UV)[b]	m^*
1	–0.632 ± 0.014	–0.099	0.766 ± 0.047
2	–0.160 ± 0.016	0.373	0.934 ± 0.073
3	–0.439 ± 0.010	0.094	0.586 ± 0.028
4	–0.345 ± 0.011	0.188	0.715 ± 0.052

[a] Substrate concentration 0.5 M.
[b] Substrate concentration 0.003–0.1 M.

Values of log C_{H^+} and X were corrected to temperature as previously described; if this is done the m^* values are temperature-independent (28, 29).

Excess acidity kinetic expressions that apply to Scheme 1 and (or) eq. [1] are easily derived. Writing the number of water molecules involved in the mechanism as r and the substrate concentration as the sum of protonated and unprotonated forms, absolute rate theory requires that eq. [4] holds, where the observed rate constants are k_ψ.

$$[4] \qquad k_\psi(C_S + C_{SH^+}) = k_0 a_{SH^+} a_{H_2O}{}^r \frac{1}{f_\ddagger} = k_0 C_{SH^+} a_{H_2O}{}^r \frac{f_{SH^+}}{f_\ddagger}$$

Here k_0 is the standard-state rate constant and a_{H_2O} the water activity, and including the activity coefficient of the transition state $f_\ddagger$ enables equation of concentrations and activities. Rearranging and taking logs gives the relevant rate equation, eq. [5].

$$[5] \qquad \log k_\psi - \log \frac{C_{SH^+}}{C_S + C_{SH^+}} - r \log a_{H_2O} = \log k_0 + \log \frac{f_{SH^+}}{f_\ddagger} = \log k_0 + (m^\ddagger - 1) m^* X$$

In eq. [5] the activity coefficient ratio is linear in X as shown, with the value of $m^\ddagger$ being characteristic of the transition state,

>1 for A1 reactions, <1 for A-S$_E$2 processes, and ~1 for A2 mechanisms (but see below) such as the ones under discussion here (9).

In calculating the protonation correction term (PCT) in eq. [5], it was found that the same pK_{BH^+} value could not be used for both the NMR kinetic data (12) and the UV-vis kinetic data (13). The PCT values calculated using the NMR entries in Table 1, obtained at a substrate concentration of 0.5 M, applied well to the rate data obtained by NMR spectroscopy, also at a substrate concentration of 0.5 M (12), and gave the same curve fits to the 3H$_2$O and 1H$_2$O mechanisms already described (6). However, using the same value with the UV-vis data, obtained at substrate concentrations of 0.003–0.1 M (13), did not lead to agreement with the NMR data. Consequently, the curve-fitting program was allowed to calculate a ΔG° value applicable to the UV-vis data, assuming that the same $\Delta H^{\ddagger}_{25^\circ}$, $\Delta S^{\ddagger}_{25^\circ}$, and m^* and $(m^*-1)m^*$ slope values applied to both data sets, and that the ΔG° value derived from the Table 1 NMR pK_{BH^+} values applied to the NMR data. For simplicity only rate data obtained in the more dilute acid media were used, where only one mechanism applies, but this still included a large majority of the data points. Within experimental error the difference between the NMR ΔG° and UV-vis ΔG° values obtained in this way was the same for all four substrates, +0.727 ± 0.072 kcal mol^{-1}, or +0.533 pK units at 25°C. Adding this to the NMR values gives the UV values in Table 1.

The availability of rate data at several different temperatures T was accommodated by replacing log k_0 in eq. [5] according to eq. [6] (6, 28), based upon the formulation given by Clarke and Glew (30), where the standard temperature θ is 25°C (298.15 K):

$$[6]\quad \log k_0 = 10.3188 + \log T - \frac{\Delta G^{\ddagger}_{25^\circ}}{R\theta \ln 10} - \left(\frac{\Delta H^{\ddagger}_{25^\circ}}{R\theta \ln 10}\right)\left(\frac{T-\theta}{T}\right)$$

Subsequently $\Delta S^{\ddagger}_{25^\circ}$ is calculated from $\Delta G^{\ddagger}_{25^\circ}$ and $\Delta H^{\ddagger}_{25^\circ}$.

Provided that the protonation correction terms were calculated using the correct pK_{BH^+} value, all of the rate constant data, NMR and UV-vis, could be fitted to the same "3H$_2$O mechanism followed by 1H$_2$O mechanism" scenario used before (6). The enthalpies and entropies of activation, etc., obtained according to this fit are not given here because they are not significantly different from the values already quoted (6). In view of the mechanistic situation noted in the introduction, however, other possible data fits were tested. It was soon found that all of the experimental data for all of the substrates obtained in sulfuric acid media more dilute than 50 wt.% acid were fitted by eq. [5] (including eq. [6]) with $r = 1$. A standard multiple linear regression program was used for this (31), curve fitting not being necessary. The resulting parameters are given in Table 2, and the fit for all four substrates is illustrated in Figs. 2–5.

These are difficult experimental data to obtain, and much scatter is evident in Figs. 2–5. Nevertheless the large amount of data available compensates for this to some extent, over 90 points in most cases, and the computer programs I use reject points which, to 95% confidence, do not form part of the same data set as the rest (32). As a result the experimental errors on the parameters obtained, quoted as standard deviations in Table 2, are acceptably low. The scatter on the points in Figs. 2–5 is mainly random; any remaining systematic deviations from linearity are probably due to the real variation of pK_{BH^+} with temperature being slightly different from the one assumed. The data for ε-caprolactam **3** includes that obtained by Mhala and Jagdale (14) at 97°C by titration; since the substrate concentration used was 0.1 M, the UV-vis pK_{BH^+} value was used to calculate the PCT. As is apparent from Fig. 4, most of these data are in agreement with the rest, but some are not and were rejected by the program.

Only data obtained at acidities below 50 wt.% H_2SO_4 were used to obtain the Table 2 parameters, so the fitted lines in Figs. 2–5 stop there; rate constants obtained in stronger acids all fall above the extrapolated lines, indicating that another mechanism is taking over at this point. However, all attempts to discover what this second mechanism is were inconclusive. The experimental scatter is too bad to enable a decision to be made between an A1 mechanism, a one-bisulfate-ion mechanism or another one-water-molecule mechanism, based upon a multiple linear regression using only the points obtained at acidities above 50 wt.% acid; there are too few points and the scatter is too bad. This is unrealistic anyway, since both mechanisms must contribute to the overall process at acidities well above and below 50 wt.%. All attempts to fit the entire data set as a sum of two mechanisms, by curve fitting, failed. This is probably because the multitude of data describing the first mechanism swamps the few data points describing the second, and the high random scatter on the points does not help. Undoubtedly many more data points at acidities greater than 50 wt.% acid would be needed for this approach to work.

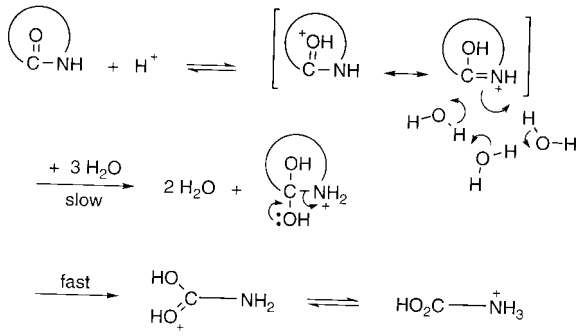
Discussion

With regard to the question raised in the introduction as to whether hydrolysis data obtained by different kinetic methods are in fact comparable, the best answer that this work can provide is "probably." Certainly the results obtained by three different sets of workers at different times by different

© 1998 NRC Canada

Scheme 2.

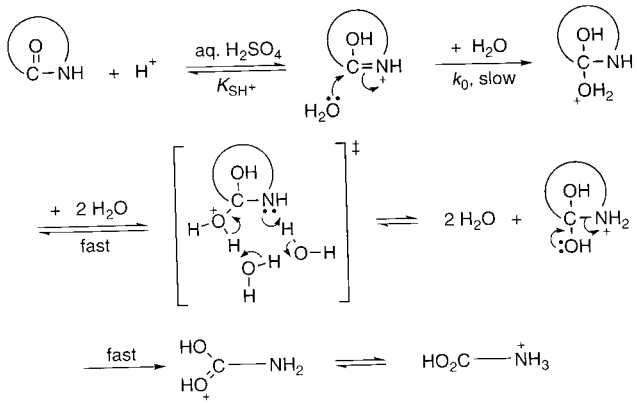


techniques, illustrated in Figs. 2–5, are highly comparable, considering the scatter present. However, to obtain the protonation correction terms used in these plots, different pK_{BH^+} values have to be used for the different data sets, NMR data obtained at a substrate concentration of 0.5 M (12) and UV-vis data obtained at a substrate concentration of 0.003–0.1 M (13). These are different media, with the organic content in one case being at least five times larger than that in the other case, and considering the high sensitivity of amide and lactam protonations to medium effects (25), illustrated in Fig. 1, it is perhaps not too surprising that this causes a difference of half a pK unit. In cases where comparison is possible amide pK_{BH^+} values obtained by NMR seem to be consistently more negative than those obtained by UV. For instance, for acetamide values between –0.48 and +0.37 are reported, using a variety of techniques including UV spectroscopy (33). An NMR value of –0.9 has been obtained (34), and our own value, obtained after accounting for the medium effect, was –0.73 (25). (The "best" value, obtained by conductance measurements, is probably –0.62 ± 0.07 (33).) For *N*-ethyl- and *N*,*N*-diethyl-acetamide our values of –0.49 and –0.33 (25) are both somewhat more negative than the conductance values of –0.42 ± 0.03 and –0.28 ± 0.03 reported for the *N*-methyl and *N*,*N*-dimethyl derivatives (33).

The three-water-molecule mechanism for the lactams is given in Scheme 2; this, in combination with a one-water-molecule process taking over in the stronger acids, is the mechanism given before for these substrates (6). Previously only the NMR data were available (12); adding in the UV-vis data (13) and the titration data for **3** (14) does not change anything, beyond having to use different substrate basicities as already noted. All of the data are fitted quite well according to this scheme. However, in this work it is found that a one-water-molecule mechanism, with another unidentified mechanism taking over above 50 wt.% H_2SO_4, fits the data equally well (the root-mean-square errors of the fit for the two mechanistic schemes being comparable, with no statistically significant differences between them evident for any of the substrates). A likely one-water-molecule mechanism is given in Scheme 3.

The difference between Schemes 2 and 3 boils down to: synchronous nucleophilic addition of a water molecule and a proton switch to the nitrogen (Scheme 2); and nucleophilic attack by a water molecule taking place *before* the proton switch to the nitrogen (Scheme 3). Guthrie's latest work (34) indicates that these processes are commonly stepwise rather than concerted, that charge separation can take place within

Scheme 3.



the ring of water molecules (typically two or three) involved in a proton switch, and that there is an intrinsic barrier for proton transfer reactions along a preformed hydrogen bond. Such theoretical calculational evidence as exists at present (36) does not enable an easy distinction between concerted and stepwise processes to be made, although better calculations are on the way.[2]

Since it is not possible from the kinetic evidence to statistically distinguish between the three-water-molecule followed by one-water-molecule mechanistic scheme given before (6) and the equally applicable one-water-molecule followed by unknown mechanism scenario under discussion here, additional information must be used. The only piece of compelling evidence in favour of the latter case is the lack of solvent isotope effect found in the case of *N*,2,4-trimethylacetanilide (11), since a large one would be expected if three protons were in flight at the transition state of Scheme 2. One could wish there were more evidence, but until this materializes I am forced to conclude that the one-water-molecule plus unknown mechanism scenario is in fact closer to the truth.

If this is the case, several questions present themselves. Because the one-water-molecule mechanism only applies up to 50 wt.% H_2SO_4, and all attempts to fit the lactam hydrolysis rate constants obtained at higher acidities failed, the first one to ask is "what is the nature of the second mechanism?" There is good evidence for a second A1 process in the stronger acid region for a number of acetanilides (37), for instance a rate increase at higher acidities being observed following on from the downside of the bell-shaped rate profile usually found for amide hydrolyses (38), and also for some benzamides (39) and ureas (40). This is shown for the lactams in Scheme 4; it is really only possible to visualize an A1 mechanism from the N-protonated lactam. This is not the most probable protonation site for a typical amide, but reaction from the N-protonated form is quite possible if this form is much more reactive than is the O-protonated form. In fact this mechanism is the one accepted for β-lactam hydrolysis (6, 12).

Another possibility is reaction with bisulfate ion as a nucleophile, as shown in Scheme 5. We have actually seen this before with benzamide (6); the problem is that 50 wt.% H_2SO_4 is rather dilute acid for bisulfate to take over from water, 80 wt.% being more typical (6, 20).

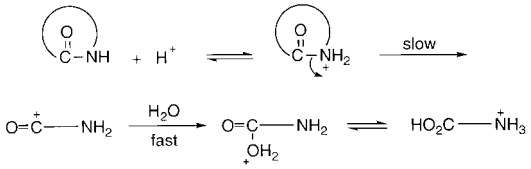
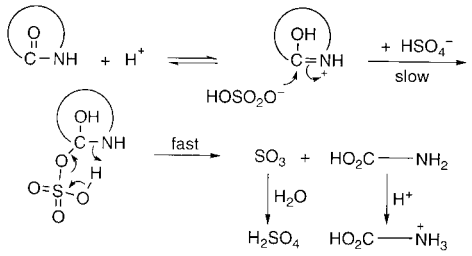
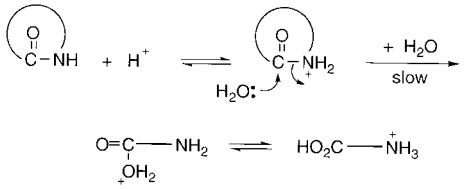
Scheme 4.



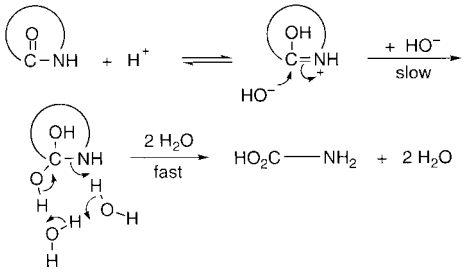
Scheme 5.



Scheme 6.



Scheme 7.



The only other one-water-molecule mechanism that seems possible is an A2 reaction with the N-protonated lactam, shown in Scheme 6. Although looking reasonable on the face of it, there is no evidence for a mechanism like this in the hydrolysis of simple amides. Also possible is bisulfate reacting with the N-protonated form, but this seems less likely still. At present there is not enough evidence to enable a decision to be made between Schemes 4, 5, and 6; this will have to await further experimental work at higher acid concentrations. This will be difficult as the reaction rates become quite slow in the stronger acids (12, 13).

While dealing with possible mechanistic schemes, it is interesting to note that there is no evidence for any reaction between protonated amide or lactam and hydroxide ion; this possibility is shown in Scheme 7. Evidence for Scheme 7 would be a zero slope in a plot of log rate constant against pH or log acid concentration, whereas it is found experimentally that plots of this type have good unit slopes for several amides in dilute HCl (10, 11). Recently several examples of the reaction of hydroxide ion with nitroamine and nitroamide substrates in acid media have been observed (18, 19); perhaps the clearest example of this is found in the hydrolysis of nitrourea in dilute H_2SO_4 (19). In 0.1 M HCl the hydroxide concentration would be 10^{-13} M, and if the lactam concentration was also 0.1 M then according to Table 1 the protonated lactam concentration should be about 10^{-2} M. If the two react with a diffusion-controlled rate constant of 10^{10}, we would obtain an observed rate constant of 10^{-5} s^{-1} at 25°C, and most amide hydrolyses, including those in this work, are carried out at higher temperatures. Stewart's proton activating factor analysis (41) indicates that protonated amide should react much faster with hydroxide than does unprotonated amide; however, the fact that no reaction is observed must mean that the reaction has a considerable activation energy.

If it is true that only one water molecule is involved in the reaction, then $m^{\ddagger}$ values other than one (9) will have to be accepted as normal for A2 reactions. The values for the lactams in Table 2 range from 0.8 to 0.1 and, interestingly, show a fairly steady decrease with increasing lactam ring size. What if anything this means is at yet unclear, since little attention has been paid to the magnitudes of these quantities for A2 processes, but it is suggestive of the possibility of their becoming valuable mechanistically. We have found systematic variation of $m^{\ddagger}m^{*}$ with substituent before, for instance in acylal and thioacylal hydrolyses (42), but in this and several other cases the m^{*} values were not known. However, variation due to changing substituent seems more likely than variation due to changing m^{*}, within a series of closely similar substrates.

The basicities and rate data in Tables 1 and 2 are interesting with respect to the effect of lactam ring size upon reactivity; see the discussion in ref. 12. The six-ring lactam **2** is unusually basic compared to the others, and has an unusually high m^{*} value for an amide, 0.6 being typical (24). It also has the fastest hydrolysis rate, the lowest activation energy, and the highest entropy of activation, followed by the seven-ring lactam **3**, the five-ring lactam **1**, and the eight-ring lactam **4**. It has been found that a six-ring lactam will rearrange to a five-ring lactam under suitable conditions (43), so it must be inherently less stable. The hydrolysis reaction is primarily enthalpy-controlled, with the enthalpy contributing about two-thirds of the overall free energy of activation; the entropies of activation for all four substrates are much the same as one another, quite negative at -32 ± 4 cal mol^{-1} K^{-1}. With the number of different bond angle changes, eclipsing interactions, and other ring strain effects possible in these systems, which will be different in the protonated and unprotonated forms, it is difficult to isolate any one factor as being the most important contributor to the relative basicities and reactivities, however.

If the r values of 3 associated with amide hydrolysis in fact turn out to be spurious, as the work in this paper would seem to indicate, then all reported r values other than 1 must be called into question too. For instance r values of 2 are commonly associated with the A2 ester hydrolysis mechanism (44). The excess acidity method has not been applied to many ester hydrolyses, but r values of 2 have been found for methyl benzoate and its *o*- and *p*-methyl derivatives (28), and to ethyl benzoate and various ethyl thiol- and thion-benzoates (45). (Values of $m^{\ddagger}$ for these substrates ranged from 0.74 to 1.30 (28, 45).) However, since the A2 ester hydrolysis mechanism

© 1998 NRC Canada

applies over a wide acidity range (typically 0–80 wt.% H_2SO_4), and the change in water activity with X is considerable over this range, allowing easy separation of variation due to one from variation due to the other, I think it likely that $r = 2$ for ester hydrolyses will hold up. Nevertheless, this will have to be checked.

What is needed to distinguish the mechanistic possibilities implied by Schemes 4–6 is an excess acidity analysis of much more amide hydrolysis data, preferably obtained at higher acidities. Fortunately there is quite a lot of this in the literature, and I hope to report further on this topic in future pages of this journal, probably starting with the benzamide and benzimidate results analyzed previously (6). More solvent isotope effect results would be useful too.

The acid dissociation constant of triphenylethenethiol, a simple thioenol, and that of its oxygen-enol analog

Yvonne Chiang, A. Jerry Kresge, Norman P. Schepp, Vladimir V. Popik, Zvi Rappoport, and Tzvia Selzer

Abstract: The acidity constant, $pQ_a^E = 8.49$, for the stable thioenol, triphenylethenethiol, was determined by spectrophotometric titration, and that, $pQ_a^E = 11.37$, for its unstable oxygen analog, triphenylethenol, was determined by analysis of its ketonization rate using enol generated flash photolytically from triphenylvinyl bromide. (These acidity constants are *concentration* quotients applicable at 0.10 M ionic strength in 50 vol.% aqueous methanol.) This appears to be the first determination of the acid strength of a simple thioenol. Triphenylethenethiol was unreactive in dilute acid or base, but in concentrated perchloric acid solutions it was slowly transformed into diphenylacetophenone and 2,3-diphenylbenzo[*b*]thiophene; the mechanisms of these reactions are believed to involve rapid equilibrium protonation of the enol on the β-carbon followed by rate-determining capture of the cation so formed, either externally by solvent or internally by one of the β-phenyl groups of the ion.

Key words: enol ketonization, thioenol, flash photolysis, vinyl halide.

Résumé : Utilisant un titrage spectrophotométrique, on a déterminé la constante d'acidité, pQ_a^E, du thioénol stable, triphényléthènethiol, alors que l'on a déterminé celle, pQ_a^E, de son analogue oxygéné instable, le triphényléthénol, par analyse de sa vitesse de cétonisation en utilisant l'énol généré par photolyse éclair à partir du bromure de triphénylvinyle. (Ces constantes d'acidité sont les quotients de *concentration* applicables à une force ionique de 0,10 M, dans une solution aqueuse de méthanol à 50% en volume.) Il semble que ce travail corresponde à la première détermination de la force acide d'un thioénol simple. Le triphényléthènethiol ne réagit pas en milieux acide ou base faibles; toutefois, en solutions concentrées d'acide perchlorique, il se transforme lentement en diphénylacétophénone et en 2,3-diphénylbenzo[*b*]thiophène. On croit que les mécanismes de ces réactions impliquent une protonation à équilibre rapide de l'énol sur le carbone-β, suivie d'une capture cinétiquement limitante du cation ainsi formé, d'une façon externe par le solvant ou externe par l'un des groupes β-phényles de l'ion.

Mots clés : cétonisation des énols, thioénol, photolyse éclair, halogénure de vinyle.

[Traduit par la rédaction]

Introduction

Simple enols are generally much less stable than their aldehyde or ketone tautomers (1). The same, however, is not true of simple thioenols: in the sulfur systems, enol and keto isomers usually exist in comparable amounts, and the enol is sometimes even the dominant tautomer (2). A recently examined example of the latter situation is provided by triphenylethenethiol, **1**, which could not be converted to its keto isomer, diphenylthioacetophenone, **2**, eq. [1], under conditions much more drastic than usually required to equilibrate oxygen keto–enol systems (3). This predominance of the enol isomer in the system of eq. [1] is consistent with the estimate $pK_E = 2.7$ for the oxygen system[2] and the suggestion that the

[1] 
ratio of the keto–enol equilibrium constant of a sulfur system to that of its oxygen analog, $K_E(S)/K_E(O)$, will generally be equal to or greater than 10^6 (3).

We have taken advantage of this stability of triphenylethenethiol to measure the equilibrium constant for its ionization as an acid, eq. [2], using a conventional spectroscopic method based upon the difference in uv absorbance of

[2] 
the enol (λ_{max} = 285 nm) and its enolate ion, **3** (λ_{max} = 315 nm). This, to the best of our knowledge, is the first determination of the acidity constant of a simple thioenol.

To assess the effect on enol acidity of replacing oxygen with sulfur, we also determined the equilibrium constant for the ionization of triphenylethenol, **4**, eq. [3]. This enol, however, is not stable with respect to its keto isomer, and it reverts to the latter too rapidly to allow measurements by the method we employed for the thio analog. We therefore used a flash

[3] 
photolytic technique instead: we generated the enol by photoionization of triphenylvinyl bromide, **5**, and subsequent hydration of the ensuing vinyl cation, **6**, eq. [4], and then determined the acidity constant of the enol, **4**, from the dependence of its rate of ketonization to diphenylacetophenone, **7**, upon the acidity of the medium.

Because some of the substrates used were insufficiently soluble in a purely aqueous solvent, this work was done in 50 vol.% aqueous methanol.

[4] 
Experimental section

Materials

Triphenylethenethiol was a sample that had been prepared before (3), and 2,3-diphenylbenzo[*b*]thiophene was kindly provided by Dr. T. Kitamura (7). All other materials were best available commercial grades.

Spectrophotometric pK_a determination

The acid dissociation constant of triphenylethenethiol was determined by monitoring the absorbance of this substance in solutions of different acidity. The solvent was 50 vol.% aqueous methanol, and its acidity was controlled by using either perchloric acid or sodium hydroxide, or acetic acid, biphosphate ion, tris(hydroxymethyl)methylamine, or ammonia buffers; the ionic strength of these solutions was maintained at 0.10 M by adding sodium perchlorate as required.

Measurements were made at λ = 340 nm, the wavelength at which the difference in absorption between triphenylethenethiol and its thiolate anion is greatest. A Cary 2200 spectrometer, with cell compartment thermostatted at 25.0 ± 0.05°C, was used. The absorbance of the acid, base, or buffer solution without substrate was first recorded, a fixed amount of an acetonitrile stock solution of substrate (0.02 M) was then added (10.0 μL to 3.00 mL or 5.00 μL to 1.00 mL), and the absorbance was recorded again. The difference, Δ*A*, between such pairs of absorbance readings was then calculated, and the relationship between Δ*A* and the hydrogen ion concentration of the solutions was analyzed by least-squares fitting of eq. [5]; here A_B and A_A are the limiting absorbances of the basic and acidic forms of the substrate and *Q* is its acidity constant.[3]

$$[5] \qquad \Delta A = \frac{A_B Q_a^E + A_A[H^+]}{Q_a^E + [H^+]}$$

Hydrogen ion concentrations of the solutions in which the absorbances were recorded were determined by measuring their pH using a Beckman Research pH meter, in conjunction with a ROSS combination electrode model no. 81–02 (Orion Research Inc.), and then converting that reading into [H^+] with the aid of eq. [6] (8*a*).

$$[6] \qquad -\log[H^+] = pH_{meas} + \log \gamma_{H^+} - \delta = pH_{meas} - 0.205$$

In this equation, γ_{H^+} is the activity coefficient of H^+, which was calculated using the Debye–Hückel equation (8*b*) with parameters appropriate to the medium employed, and δ is an empirical parameter (8*a*). The validity of this method was checked by measuring the pH of five perchloric acid solutions of known concentration in the range 0.02–0.10 M. The results obtained gave an average value of ($-\log[H^+] - pH_{meas}$) = –0.2049 ± 0.0061, in excellent agreement with eq. [6].

Flash photolysis

Flash photolytic rate determinations were made using a conventional flash-lamp system with cell compartment thermostatted at 25.0 ± 0.05°C that has already been described (5). Measurements were carried out in perchloric acid and sodium hydroxide solutions whose ionic strength was maintained at 0.10 M; substrate (triphenylvinyl bromide) concentrations were (2–3) × 10^{-5} M. The lifetimes of the transient species observed in basic solution were short enough to be analyzed by the flash photolysis monitoring system, but those observed in acidic solution were too long-lived (*t* = 15–40 min). For rate measurements in acidic solutions, therefore, transients were generated by a single flash in the flash system, and the reacting solutions were then transferred to a Cary 118 spectrometer, with cell compartment thermostatted at 25.0 ± 0.05°C, for rate measurement there. Decay of the transients observed in both kinds of experiment obeyed the first-order rate law accurately, and observed first-order rate constants were calculated by least-squares fitting of an exponential function.

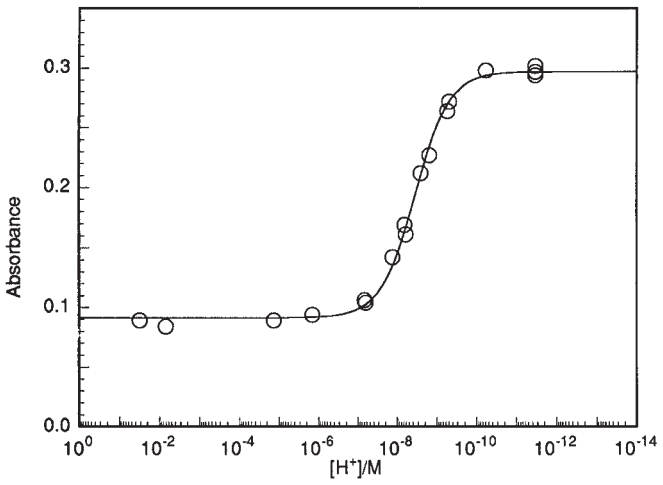
The equilibrium constant for ionization of triphenylethenethiol

[3] This is a *concentration* dissociation constant, applicable at ionic strength = 0.10 M.

© 1998 NRC Canada

Fig. 1. Spectrophotometric titration curve for the acid ionization of triphenylethenethiol in 50 vol.% aqueous methanol at 25°C.



as an acid, eq. [2], was determined by measuring the absorbance of this substance dissolved in 50 vol.% aqueous methanol solutions of different acidity. Two series of experiments were carried out, one at a fixed total concentration of substrate of 7×10^{-5} M and another at 1×10^{-4} M. The data so obtained are summarized in Table S1.[4]

As Fig. 1 illustrates, these data describe the expected titration curve, eq. [5], well. Least-squares analysis gave the results $Q_a^E = (3.48 \pm 0.22) \times 10^{-9}$ M, $pQ_a^E = 8.46 \pm 0.03$, and $Q_a^E = (3.07 \pm 0.21) \times 10^{-9}$ M, $pQ_a^E = 8.51 \pm 0.03$. The weighted average of these gives $Q_a^E = (3.27 \pm 0.15) \times 10^{-9}$ M, $pQ_a^E = 8.49 \pm 0.02$, as the best value of this acidity constant.

Reaction of triphenylethenethiol in strong acid

Except for the acid ionization described above, triphenylethenethiol proved to be unreactive in dilute 50 vol.% aqueous methanol solutions of acid or base. In concentrated perchloric acid, however, its uv absorbance did decrease slowly in an acid-catalyzed process, and some rate measurements were made by monitoring this decay at $\lambda = 300$ nm. The rate constants so obtained are summarized in Table S2.[4] These data were extrapolated down to dilute solution by the Cox–Yates method (9) using the X_0 acidity function (10) on the assumption that values of X_0 in 50 vol.% aqueous methanol are the same as those in wholly aqueous solutions of the same acid concentration. This gave $k_{H^+} = (2.72 \pm 0.41) \times 10^{-8}$ M^{-1} s^{-1} as the dilute solution rate constant.

A product study was performed by allowing 0.0025 M triphenylethenethiol dissolved in 4 M perchloric acid in 2:1 methanol:water (vol/vol) to react for 36 h, and then subjecting the resulting solution to HPLC analysis. This showed that two products were formed in comparable amounts, and spiking with authentic samples showed them to be diphenylacetophenone, **7**, and 2,3-diphenylbenzo[*b*]thiophene, **8**.

Flash photolysis

Flash photolysis of vinyl halides is known to produce vinyl cations (11), which, in the presence of water, are hydrated to enols; the enols then ketonize to their carbonyl isomers (11*b*,*c*). Evidence that this is the sequence of reactions that occurred in the present study upon flash photolysis of triphenylvinyl bromide, as depicted in eq. [4], is provided by the uv spectral changes that took place. The uv spectrum of triphenylvinyl bromide in 50 vol.% aqueous methanol consists of a strong absorption band with $\lambda_{max} = 290$ nm. Upon flashing, this band immediately increased in intensity in a process that was complete within the duration of the flash (50 ms). Such a change in intensity without the appearance of any new absorption bands is to be expected for the conversion of a vinyl halide to a vinyl alcohol with no change in the other double-bond substituents; the lifetime of vinyl cations in aqueous media, moreover, is known to be much shorter than 50 ms (11*c*), and formation of the enol would be expected to be immediate on the time scale of the present experiment. This increase in absorbance at $\lambda = 290$ nm was followed by a decrease whose velocity was catalyzed by both hydronium and hydroxide ions, with saturation of the hydroxide ion catalysis at high basicities. Such behavior is characteristic of the ketonization of simple enols, where saturation of hydroxide ion catalysis represents conversion of enol to enolate ion (12). The absorbance decrease at $\lambda = 290$ was also accompanied by an increase occurring at the same rate at $\lambda = 250$ nm, where diphenylacetophenone, the expected product of the present ketonization reaction, has an absorption maximum. It appears safe to conclude, therefore, that the process monitored here was ketonization of triphenylethenol to diphenylacetophenone.

Rates of this ketonization reaction were measured in

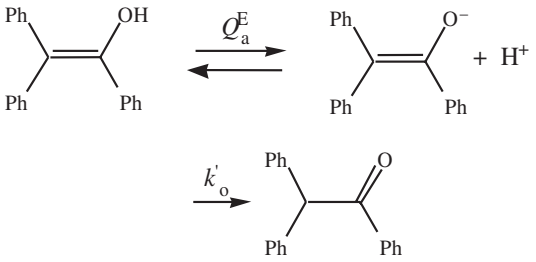
© 1998 NRC Canada

0.02–0.10 M perchloric acid solutions. The data are summarized in Table S3.[4] Observed rate constants proved to be accurately proportional to acid concentration, and the data were therefore analyzed by least-squares fitting of eq. [7]. This produced the result $k_{H^+} = (1.05 \pm 0.04) \times 10^{-2}$ M^{-1} s^{-1} for the acid-catalyzed reaction and $k_{uc} = (2.11 \pm 0.30) \times 10^{-4}$ s^{-1} for an "uncatalyzed" process.

[7] $$k_{obs} = k_{uc} + k_{H^+}[H^+]$$

Rates of ketonization of triphenylethenol were also measured in sodium hydroxide solutions over the concentration range 0.002–0.10 M. These data are summarized in Table S4.[4] As Fig. 2 shows, observed first-order rate constants increased with increasing basicity at low hydroxide ion concentrations, but at higher basicity the effect diminished, and rate constants finally reached a constant value independent of hydroxide ion concentration. Such behavior is commonly found in enol ketonization. It is known to be caused by a shift in the initial state of the reaction from enol to enolate ion, plus the facts that ketonization occurs by rate-determining protonation of the substrate on the β-carbon and that enolate ions are much more susceptible to such electrophilic attack than are enols (12). In weakly basic solutions, therefore, where the substrate exists mainly as un-ionized enol, ketonization will occur as shown in eq. [8]: rapid equilibrium ionization of the enol will be followed by rate-determining reaction of the more labile enolate ion by proton transfer from the only available proton donor, the hydroxylic solvent. Since hydrogen ions are produced in the pre-equilibrium step but are not used up in the rate-determining step, the overall reaction rate will show an inverse dependence on hydrogen ion concentration or a direct dependence on hydroxide ion concentration. This apparent hydroxide ion catalysis, however, will diminish as the hydroxide ion concentration increases and the position of the pre-equilibrium step

[8]



shifts toward enolate ion, and that will produce the saturation behavior shown in Fig. 2.

The rate law that applies to the reaction scheme of eq. [8] is shown in eq. [9]. Least-squares fitting of the data using this equation gave $k'_o = 63.1 \pm 0.07$ s^{-1} and $Q_a^E = (4.28 \pm 0.22) \times 10^{-12}$ M, $pQ_a^E = 11.37 \pm 0.02$.[3] Hydrogen ion concentrations needed for this purpose were obtained from pH meter readings with the aid of eq. [6].

[9] $$k_{obs} = \frac{k'_o Q_a^E}{[H^+] + Q_a^E}$$

Discussion

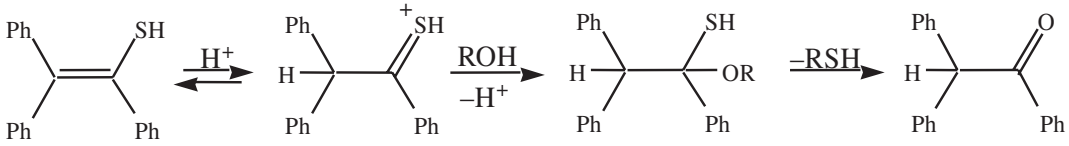
9 **10**

Comparison of the rate constants obtained here for the acid-catalyzed ketonization of triphenylethenol and the disappearance of triphenylethenethiol in concentrated perchloric acid solutions shows that the oxygen enol is 3.8×10^5 times as reactive as the thioenol. This is an unusually large oxygen-to-sulfur rate ratio for rate-determining protonation of a carbon–carbon double bond activated by these atoms; for example, the acid-catalyzed hydrolysis of ethyl vinyl ether, **9**, and ethyl vinyl sulfide, **10**, both of which occur by rate-determining protonation of the substrate on its β-carbon atom, give an oxygen-to-sulfur rate ratio of only 37 (13), some 10 000 times smaller than the present value.

This striking difference suggests that the disappearance of triphenylethenethiol in concentrated perchloric acid does not represent rate-determining protonation of this substance on its β-carbon atom, but rather that such protonation occurs rapidly and reversibly and is then followed by some other, much slower, reaction step. This hypothesis is consistent with the conclusion reached before (3) that the enol in this system is more stable than the thioketone, for the ketone, once formed, would then revert to the enol. It is also consistent with our observation that the oxygen ketone and a thiophene derivative, rather than the thioketone, are the products of the concentrated acid reaction. It is likely that the oxygen ketone is formed by occasional capture, by water or methanol, of the cation produced by reversible carbon protonation of the thioenol, followed by decomposition of that adduct, as shown in eq. [10], and that the thiophene product is formed by intramolecular capture of this cation by one of its β-phenyl groups, in an electrophilic aromatic substitution reaction, followed by aromatization of the thiophene ring, as shown in eq. [11]; a similar cyclization to a benzofuran has been observed in an analogous stable oxygen-enol system (14).

These observations reinforce the conclusion reached before (3) that the enol is the more stable tautomer in the diphenylthioacetophenone keto–enol system. Additional evidence that this is so is provided by the fact that we were able to determine the acidity constant of this thioenol by a conventional slow method. The limiting rate constant for ketonization of the corresponding oxygen enol, triphenylethenol, determined by our flash photolysis experiments, is 63 s^{-1}. Applying a sulfur-to-oxygen rate ratio of ca. 10^{-2} to this, as expected, for example, on the basis of the rates of reaction of ethyl vinyl

[10]



© 1998 NRC Canada

[11] 
ether and ethyl vinyl sulfide discussed above, puts the lifetime of triphenylethenethiol at about 1 s; this short lifetime would have made our conventional measurements impossible if the enol were not the stable isomer.

We are aware of no previous determination of the acidity constant of a simple thioenol, and we consequently cannot compare the value we have obtained with other results. It is interesting, however, that our value makes triphenylethenethiol, with $pQ_a^E = 8.49$, a considerably stronger acid than its oxygen analog, triphenylethenol, with pQ_a^E = 11.37, for this is consistent with the fact that simple thiols are considerably stronger acids than simple oxygen alcohols (15). A quantitative comparison might be more appropriately based upon phenols rather than alcohols, for phenols, like enols, have their acidic groups attached to carbon–carbon double bonds, and enol pK_a's are in fact quite similar to phenol pK_a's (12). It is significant, therefore, that the difference in acid strength between the oxygen and sulfur enols examined here, ΔpQ_a^E = 2.88, is not unlike the difference in acidity between phenol (pK_a = 10.00 (16)) and thiophenol (pK_a = 6.49 (17)), ΔpK_a = 3.51.

Carbon versus oxygen nucleophilic selectivity in the reaction of the aryloxide ions, 2,6- and 3,5-di-*tert*-butylphenoxide, with the 2-[(nitro)$_x$aryl]-4,6-dinitrobenzotriazole 1-oxide series of super-electrophiles. Stereoelectronic factors on C-7 Meisenheimer complex formation versus C-1′ S_NAr displacement

Julian M. Dust and Richard A. Manderville

Abstract: The 2-[(nitro)$_x$aryl]-4,6-dinitrobenzotriazole 1-oxides (**1**, Pi-DNBT ($x = 3$); **2**, DNP-DNBT ($x = 2$); **3**, NP-DNBT ($x = 1$)) are electron-deficient nitro-substituted heteroaromatic substrates that possess two sites for nucleophilic attachment: C-7 and C-1′. Generally, attack at the super-electrophilic C-7 site yields spectroscopically observable anionic σ-bonded adducts, whereas attack at C-1′ leads to displacement products in an overall process of nucleophilic aromatic substitution (S_NAr). To gain an understanding of the factors affecting C-1′ versus C-7 attack by potentially ambident aryloxide (C- and O-)nucleophiles, we have monitored the reactions of **1**–**3** with 2,6-di-*tert*-butylphenoxide (2,6-ArO$^-$) and 3,5-di-*tert*-butylphenoxide (3,5-ArO$^-$) using 400 MHz ^{1}H NMR spectroscopy (deuterated dimethyl sulfoxide solvent at ambient temperature). The results indicate that 2,6-ArO$^-$ acts only as a C-nucleophile with O-attack precluded, presumably by the sterically demanding *tert*-butyl groups flanking the O-nucleophilic centre. Although 2,6-ArO$^-$ reacts preferentially at C-7 of **1–3**, the biphenyl derivative that arises from C-1′ attack is also observed with **1**, the first time that C-nucleophilic attack has been seen at this electrophilic site. In contrast, 3,5-ArO$^-$ acts only as an O-nucleophile, also as a consequence of the steric hindrance to the C-4 position; this aryloxide reacts entirely at C-1′ of Pi-DNBT but also exclusively at C-7 of **3**. However, with DNP-DNBT, **2**, both the C-7 O-adduct and C-1′ displacement products are noted; attack at C-1′ is dominant. The selectivity (C-7 versus C-1′) found in these reactions is discussed with emphasis given to stereoelectronic factors that may stabilize the putative C-1′ O-adducts.

Key words: aryloxides, super-electrophiles, Meisenheimer complexes, 2-[(nitro)$_x$aryl]-4,6-dinitrobenzotriazole 1-oxides.

Résumé : Les 1-oxydes de 2-[(nitro)$_x$aryl]-4,6-dinitrobenzotriazole (**1**, Pi-DNBT ($x = 3$); **2**, DNP-DNBT ($x = 2$); **3**, NP-DNBT ($x = 1$)) sont des substrats hétéroaromatiques électrodéficients porteurs de groupes nitro qui possèdent deux sites, C-7 et C-1′, permettant d'effectuer des substitutions nucléophiles. En général, l'attaque du site superélectrophile C-7 conduit à la formation d'adduits anioniques à liaisons-σ qui peuvent être observés par spectroscopie alors que l'attaque en C-1′ conduit à des produits de déplacement résultant d'un processus global de substitution aromatique nucléophile (S_NAr). Afin de mieux comprendre les facteurs pouvant affecter les attaques en C-1′ et en C-7 par des nucléophiles aryloxydes ambidents (C- et O-), on a suivi les réactions des composés **1–3** avec le 2,6-di-*tert*-butylphénolate (2,6-ArO$^-$) et le 3,5-di-*tert*-butylphénolate (3,5-ArO$^-$) en faisant appel à la spectroscopie de résonance magnétique nucléaire du ^{1}H, à 400 MHz (diméthylsulfoxyde deutéré comme solvant, à la température ambiante). Les résultats indiquent que le 2,6-ArO$^-$ n'agit que comme nucléophile pour le C alors que l'attaque en O est empêchée, probablement à cause des contraintes stériques imposées par les groupes *tert*-butyles voisins du centre nucléophile O. Même si le 2,6-ArO$^-$ réagit préférentiellement en position C-7 des composés **1–3**, on a aussi observé, dans le cas du composé **1**, la formation du dérivé biphényle qui provient de l'attaque en C-1′; c'est la première fois que l'on observe une attaque nucléophilique C pour ce site électrophile. Par ailleurs, le 3,5-ArO$^-$ ne réagit que comme nucléophile O; ceci résultat de l'empêchement stérique en position C-4; cet aryloxyde ne réagit qu'en position C-1′ du

Pi-DNBT, mais il réagit aussi en position C-7 avec le composé **3**. Toutefois, avec le DNP-DNBT, **2**, on observe la formation de l'adduit O en C-7 ainsi que des produits de substitution en C-1′; l'attaque en C-1′ est prédominante. On discute de la sélectivité (C-7 versus C-1′) observée dans ces réactions en insistant sur les facteurs stéréoélectroniques qui peuvent stabiliser les adduits O en C-1′.

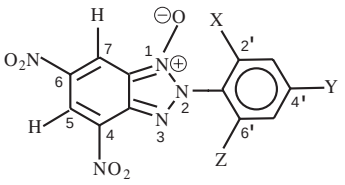
[Traduit par la rédaction]

Introduction

The 2-[(nitro)$_x$aryl]-4,6-dinitrobenzotriazole 1-oxides (**1**–**3**, 2-Ar(NO$_2$)$_x$-DNBT) are novel electrophiles that yield anionic σ-bonded adducts, as well as displacement products, as a result of nucleophilic reaction (1). This series of compounds is related structurally to the super-electrophile, 4,6-dinitrobenzofuroxan (**4**, DNBF). As a neutral 10 π-electron heteroaromatic,

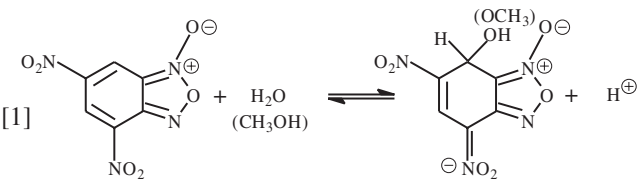


X = Y = Z = NO$_2$; **1**, Pi-DNBT

X = Y = NO$_2$, Z = H ; **2**, DNP-DNBT

X = Z = H, Y = NO$_2$; **3**, NP-DNBT

4, has been assessed to be a more powerful electron-pair or bond acceptor than such powerful electrophiles as the proton and the 4-nitrobenzenediazonium ion (2). Consequently, even weakly nucleophilic solvents such as water and methanol react with DNBF to yield the C-7 hydroxide and methoxide anionic σ-bonded (Meisenheimer) complexes, as shown (eq. [1]).



[1]

4

These adducts are more stable than the corresponding adducts formed by 1,3,5-trinitrobenzene (TNB), by a factor of 10^{10} (3–6). As implied by this comparison the TNB·OH$^-$ and TNB·OCH$_3^-$ Meisenheimer complexes are not formed unless the anionic nucleophiles, hydroxide and methoxide, are used. Further evidence for the super-electrophilicity of DNBF is provided by the observation that **4** reacts *quantitatively* with such weak carbon nucleophiles as aniline (7) and 1,3,5-trimethoxybenzene (8, 9), as well as pyrroles, indoles, thiophenes, and furans (10–12), to give Meisenheimer C-bonded adducts that are formally products of electrophilic aromatic substitution of the respective nucleophilic benzene rings (13). In general, DNBF is a very strong electrophile, notably towards weak oxygen or nitrogen bases and weakly nucleophilic double bonds (14, 15).

Two factors differentiate the 2-nitroaryl-4,6-dinitrobenzotriazole 1-oxide series, **1**–**3**, from its structural analog, **4**. First, each member of the series possesses two main electrophilic sites for nucleophilic attack: C-7 and C-1′. Second, the C-7 site appears to be less electrophilic than the corresponding position in DNBF.

With regard to the first factor, attack of alkoxide nucleophiles at C-7 generally leads to formation of relatively persistent C-7 σ-bonded anionic adducts. In contrast, attack at C-1′ results in formation of unobserved metastable Meisenheimer adducts that yield products of an overall S_NAr displacement (16). The C-7 site is super-electrophilic, whereas the C-1′ site is of normal electrophilicity, perhaps comparable to C-1 in picryl halides. In the strictest sense the two sites are not insulated from one another, but to a first approximation we may treat them as though they were, and consequently, we have an internal comparison of super-electrophilic and normal electrophilic centres built into the same molecule.

While prevailing evidence supports the view that the C-7 site is super-electrophilic, it also appears to be less electrophilic than the corresponding position in DNBF. Thus, the C-7 site in **1** (2-picryl-4,6-dinitrobenzotriazole 1-oxide, Pi-DNBT) has been assessed to be intermediate in electrophilicity: more electrophilic than the standard electrophile used in Meisenheimer complexation studies, TNB, but less electrophilic than DNBF, on the basis of the reactivity of the three electrophiles towards ethanethiol (7*b*). The C-7 sites of **2** and **3** also exhibit enhanced electrophilicity as compared to the C-1 site of TNB, on the basis of their reactivity with phenoxide ion, as a carbon-centred nucleophile (1*a*–*c*).

Recently we have examined the reactions of various aryloxide nucleophiles with DNBF (17) and with picryl halides (18). In the case of DNBF, the O-centred C-7 adduct of phenoxide could be observed at –40°C (400 MHz NMR) in the novel acetonitrile–dimethoxyethane (MeCN-d_6:DME-d_6 1:1 v/v) medium but *not at ambient temperature* in deuterated dimethyl sulfoxide (DMSO-d_6). Similar behaviour has been reported in the TNB–PhO$^-$ reaction system (19). Consequently, it is not surprising that the related O-adduct of phenoxide of Pi-DNBT was similarly not detected in the room temperature DMSO-d_6 system (1*e*); in accord with the intermediate C-7 electrophilicity assigned to Pi-DNBT as compared to TNB and DNBF. However, attack by PhO$^-$ as an O-nucleophile at C-1′ of **1** leads to facile displacement of the 4,6-dinitrobenzotriazole 1-oxyanion (DNBT$^-$) (1*e*, 20) similar to the reactivity observed with picryl chloride and picryl fluoride, where clean formation of the same phenoxy-2,4,6-trinitrobenzene product occurred (17). On the other hand, the phenoxide C-7 carbon-bonded adducts (*ortho* and *para*) of DNP-DNBT, **2**, and NP-DNBT, **3**, form promptly at room temperature; C-1′ displacement occurs via O-attack and is a relatively slow process (1*c*). Thus, reaction of aryloxides at C-7, whether as C- or O-nucleophiles, could only be observed on the time scale of these NMR experiments when the barrier to attack at C-1′ had

been raised, in this case by the successive removal of groups from the 2-nitroaryl ring.

In the current study we have examined the reaction of two aryloxides with the 2-nitroaryl-4,6-dinitrobenzotriazole 1-oxide series, **1–3**. The aryloxides used are 2,6-di-*tert*-butylphenoxide (2,6-ArO$^-$) and 3,5-di-*tert*-butylphenoxide (3,5-ArO$^-$). Although, in principle, both may act as O- and (or) C-nucleophiles in attack at either position of the electrophiles **1–3**, previous work suggests that the latter will function only as an O-nucleophile while the former is effectively restricted from acting other than as a C-nucleophile (17, 18). The significance of using such hindered aryloxides derives from the sensitivity to steric factors that has been found for C-1′ displacement as compared to C-7 complexation with these substrates (1*a*, *b*). In essence, the choice of nucleophiles was made with a view to observing C-7 adducts, particularly oxygen-bonded ones, and consequently, assessing the selectivity of the two electrophilic sites to aryloxide O- versus C-attack.

We have had a long-term interest in the ambident reactivity of aryloxides (1, 19, 21, 22) and enolates (23) and in the regioselectivity found in nucleophilic attack on electron-deficient systems (17, 18, 22, 24). The current study is, therefore, a further foray into this field.

Results

1. Overview

The reactions of the aryloxide ions, 2,6- and 3,5-di-*tert*-butylphenoxides, with Pi-, DNP-, and NP-DNBT electrophiles, were studied by ^{1}H NMR (400 MHz) in deuterated dimethyl sulfoxide (DMSO-d_6) solvent at ambient (ca. 23°C) temperatures. Chemical shifts are reported in parts per million (ppm) relative to residual DMSO-d_5**H** in the solvent (δ 2.50 ppm), and coupling constants are given in Hertz (Hz). Initial spectra of the substrates **1–3** in the absence of added nucleophile demonstrated the purity of the starting materials; no signals for hydroxide adducts, formed by reaction of the substrates with traces of water in the solvent, were seen in these spectra. The ^{1}H NMR spectroscopic characteristics of the pertinent C-7 O-bonded adducts are given in Table 1, while the characteristics of the C-7 C-bonded adducts are listed in Table 2, along with NMR parameters for comparable C-7 methoxide O-adducts of **1–3** and aryloxide C-7 adducts of **4**. In these tables and throughout this report adducts are designated thus: for example, **1a**·3,5-OAr$^-$ denotes the C-7 O-adduct formed by substrate **1** and the aryloxide, 3,5-di-*tert*-butylphenoxide, while **3a**·2,6-ArO$^-$ indicates the C-7 C-adduct formed by **3** and 2,6-di-*tert*-butylphenoxide ion. Assignments partly rest on the chemical shift comparisons derived from Tables 1 and 2. The percentages of each adduct (or product derived from an adduct), determined from the earliest spectrum acquired (i.e., typically 3–4 min of mixing of the reagents), are listed in Table 3.

The salient features of the reactions, undertaken with equimolar aryloxide (i.e., under selective conditions) are as follows. First, neither O- nor C-adduct formation with 3,5-ArO$^-$ was observed at the C-7 site of Pi-DNBT, but **1** both forms a C-7 C-bonded adduct with 2,6-ArO$^-$ and shows significant C-1′ attack of 2,6-ArO$^-$ *as a C-nucleophile.* In contrast, DNP-DNBT, in reaction with 3,5-ArO$^-$ yields products of O-attack at both C-7 and C-1′, whereas reaction with the isomeric 2,6-ArO$^-$ gives only the C-7 C-bonded Meisenheimer complex of **2,** and C-1′ displacement is not observed over the period of

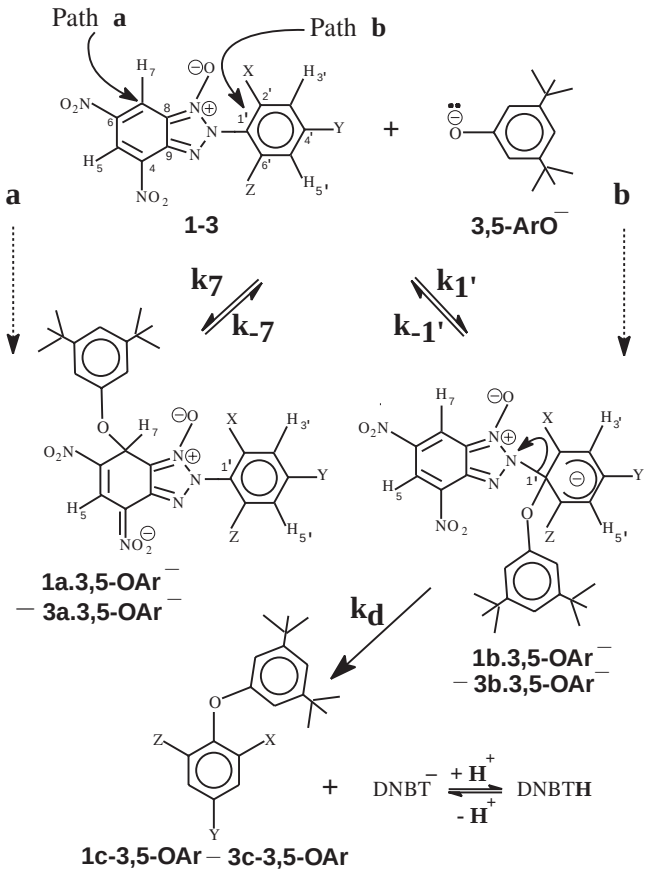
observation. Finally, NP-DNBT, **3**, reacts with 3,5-ArO⁻ *or with* 2,6-ArO⁻ to yield the products of addition at the C-7 position, **3a**·3,5-OAr⁻ and **3a**·2,6-ArO⁻, respectively; products of N-2:C-1′ bond scission are not observed. In the following sections details of these sequences will be given.

2. Reaction of the 2-[(nitro)$_x$aryl]-4,6-dinitrobenzotriazole 1-oxide series, 1–3, with 3,5-di-*tert*-butylphenoxide ion, 3,5-ArO⁻, in DMSO-d_6

The ^{1}H NMR spectrum recorded immediately after injection of 1 equiv. of 3,5-ArO⁻ (as the potassium salt in DMSO-d_6) into a DMSO-d_6 solution of Pi-DNBT, **1** (final concentrations of both reactants: 0.03 M), contains diminished signals for the substrate (refer to ref. 1*b* for substrate ^{1}H NMR data), accompanied by the appearance of signals that can be attributed to products of attack at C-1′. Therefore, the resonances of the 3,5-di-*tert*-butylphenyl picryl ether, **1c**-OAr (Scheme 1) are observed at 9.21 (s, H-3′,5′ picryl ring), 7.18 (t, J = 1.5, H-*para* aryl ether), 6.84 (d, J = 1.5, H-*ortho* aryl ether), and 1.25 (s, *meta*-di-*tert*-butyls). The spectrum of **1c** found in the reaction medium is in good agreement with the signals found for an authentic sample of the ether prepared by reaction of 3,5-ArO⁻ with picryl chloride (18). At the same time a pair of broad singlets can be seen at 8.77 and 8.73; these signals correspond to the 4,6-dinitrobenzotriazole 1-oxyanion, DNBT⁻, the other displacement product.

Even in this initial spectrum no signals could be noted that would correspond to a C-7 O-bonded adduct of 3,5-ArO⁻ with **1**. Comparison of the chemical shifts found for the diagnostic proton attached to the site of nucleophile attack (i.e., the proton bonded to the sp^3 hybridized carbon of the adduct) shows that aryloxide O-adducts have signals located in a very different place from that found for the structurally related alkoxide O-adducts (1, 17, 19*c*, 21). Thus, the C-7 proton (i.e., H-7) in aryloxide O-bonded complexes appears ca. 0.6–0.9 ppm downfield of H-7 in alkoxide O-adducts (cf. Table 1). (Conversely, in C-bonded aryloxide adducts H-7 appear ca. 0.6 ppm upfield of H-7 for the alkoxide O-adducts.) On this basis, the H-7 peak for a C-7 aryloxide O-adduct would be expected to be found in the 6.6–6.9 ppm region of the NMR spectrum. Close inspection of this region shows no such H-7 signal, nor are the peaks assigned to **1c**-OAr distorted (as would occur if the H-7 signal were hidden by an overlapping resonance of **1c**-OAr).

Scheme 1.



In short, *the reaction of* **1** *with the aryloxide at C-1′ is complete at the moment that the first spectrum could be recorded.*

In a separate control experiment, the reaction mixture was acidified with trifluoroacetic acid (TFA, 5 μL) immediately after the initial spectrum was recorded. Under these acidic conditions the peaks attributed to the 4,6-dinitrobenzotriazole 1-oxyanion leaving group are found to shift downfield to 9.12

© 1998 NRC Canada

and 8.89; these peaks now appear as well-resolved doublets for the ring protons ($J = 1.9$). These observations are consistent with protonation of DNBT$^-$to give DNBT**H**, the conjugate acid of the nucleofuge (1*a–c*). The peaks due to **1c**-OAr remain unchanged, as would be expected. However, small extraneous peaks are also apparent in the aromatic region (6.5–8.5 ppm). These peaks are as yet unidentified.[2]

Addition of one equiv. of the 3,5-ArO$^-$ nucleophile to the NMR tube containing DNP-DNBT, **2**, dissolved in DMSO-d_6 (final concentration: 0.06 M) results in an initial spectrum that includes small peaks ascribed to the C-7 O-bonded DNP-DNBT·3,5-OAr$^-$ adduct, **2a**·3,5-OAr$^-$. These peaks are located at 8.91 (d, $J = 2.4$, H-3′), 8.78 (d,d, $J = 8.8, 2.4$, H-5′), 8.68 (s, H-5), 8.12 (d, $J = 8.8$, H-6′), 6.98 (br s, H-*para* aryloxyl ring), 6.74 (br s, H-*ortho* aryloxyl ring), 6.71 (s, H-7), and 1.18 (s, *meta*-di-*tert*-butyls). Note the similarity in chemical shift of the sp^3-bound H-7 proton in this aryloxide O-adduct and that of H-7 of the C-7 DNBF·3,5-OAr$^-$ adduct (Table 1).

As expected for an O-bonded aryloxide adduct, the signals of **2a**·3,5-OAr$^-$ disappear from the spectrum upon acidification of the solution (5 μL TFA), and the original peaks of **2** are reinstated in the spectrum. Similar behaviour has been noted before with these types of O-bonded Meisenheimer complexes and, generally, serves to distinguish them from carbon-bonded aryloxide adducts that are not acid labile (1, 3, 17, 18, 22).

However, even in the initial (not acidified) spectrum the peaks due to **2a**·3,5-OAr$^-$ constitute a minority of the signals present. Broadened signals for starting material are present. The dominant peaks are ascribable to the products of N-2:C-1′ bond rupture and, importantly, these peaks indicate that such displacement proceeds exclusively through O-attack at C-1′. Peaks of 3,5-di-*tert*-butylphenyl 2′,4′-dinitrophenyl ether, **2c**-OAr (Scheme 1), appear at 8.87 (d, $J = 2.8$, H-3′), 8.44 (d,d, $J = 9.4, 2.8$, H-5′), 7.38 (t, $J = 1.6$, H-*para* aryl ether), 7.10 (d, $J = 1.6$, H-*ortho* aryl ether), and 1.29 (s, *meta*-di-*tert*-butyls). Under these conditions the signals of DNBT**H** (8.71, 8.69, d, $J = 1.9$) are also observed.

Thus, for the first time in these systems (**1**–**3** with aryloxide nucleophiles) *O-attack at both C-7 and C-1′ has been observed.* In the case of the reaction of **2** with phenoxide ion the C-7 adducts were formed via attack of the *ortho* and *para* carbons of phenoxide, while displacement at C-1′ occurred exclusively via the nucleophilic oxygen centre (1*c*).

When the reaction is not quenched by adding an excess of acid the C-7 O-bonded complex, **2a**·3,5-OAr$^-$, decomposes and is not present at the detection level of the method after 30 min. However, peaks that correspond to the C-7 DNP-DNBT·OH$^-$ adduct (cf. ref. 1*b*) can be noted. This adduct presumably arises from general base equilibration of adventitious water within the DMSO-d_6 solvent that generates low levels of OH$^-$, which attacks preferentially at the super-electrophilic site, C-7. The intervention of this adduct has been noted previously in the reactions of DNP-DNBT with various nucleophiles (1, 20), and comparable adducts are formed competitively in related electron-deficient aromatic–nucleophile systems (18, 22, 24) under conditions similar to those used in the present NMR study.

The reaction is complete within 1 h, at which time the only signals present are those of unchanged **2** and 3,5-di-*tert*-butylphenol, along with the anionic nucleofuge, DNBT$^-$, and **2c**-OAr, the ether formed as a result of C-1′ O-attack of the aryloxide.

A deep red solution is formed immediately upon reaction of equimolar 3,5-ArO$^-$ with NP-DNBT, **3**. The initial spectrum was acquired within 4 min of mixing; it includes the C-7 O-adduct, **3a**·3,5-OAr$^-$, with resonances recorded at 8.72 (d, $J = 0.8$, H-5), 8.46, and 8.34 (A_2X_2 d, $J = 9.3$), 6.95 (br s, H-*para* aryloxyl ring), 6.84 (d, $J = 0.8$, H-7), 6.72 (d, $J = 1.3$, H-*ortho* aryloxyl ring), and 1.16 (s, *meta*-di-*tert*-butyls). These are the dominant signals found in this first spectrum.

As observed in the other reaction systems, injection of TFA results in disappearance of the signals assigned to the C-**7** **3a**·3,5-OAr$^-$ adduct. Upon acidification the peaks of NP-DNBT are restored to close to their original intensity and 3,5-di-*tert*-butylphenol, also noted in the spectrum.

When the NP-DNBT–3,5-ArO$^-$ system is monitored without interruption, the signals of the **3a**·3,5-OAr$^-$ adduct decline below detection limits within 30 min. A number of unidentified signals are present in the spectrum, some of which may arise from reaction **3** with adventitious OH$^-$ or from NO_2 group displacement from the 2-nitroaryl ring.[2] However, resonances that could be attributed to the products of N-2:C-1′ bond cleavage (i.e., DNBT$^-$and the 3,5-di-*tert*-butylphenyl 4-nitrophenyl ether, **3c**-OAr) are not identified.

Therefore, only O-attack at the C-7 position can be unambiguously assigned in the NP-DNBT–3,5-ArO$^-$ reaction system.

3. Reaction of the 2-[(nitro)$_x$aryl]-4,6-dinitrobenzotriazole 1-oxide series, 1–3, with 2,6-di-*tert*-butylphenoxide ion, 2,6-ArO$^-$, in DMSO-d_6.

Equimolar 2,6-ArO$^-$ solution was injected into the NMR tube that contained Pi-DNBT, **1**, in DMSO-d_6 (final concentration: 0.03 M). The first spectrum was recorded within 4 min of mixing of the reagents. Among the signals found in the complex spectrum include those consistent with formation of the C-7 C-bonded **1a**·2,6-ArO$^-$ adduct (Table 2), the biphenyl product, **1c**-2,6-ArOH (Scheme 2), and DNBT$^-$/DNBT**H**, from C-1′ attack of the nucleophile. Hence, the peaks that represent the C-**7** **1a**·2,6-ArOH$^-$ adduct are found at 9.22 (s, H-3′,5′ picryl), 8.68 (s, H-5), 7.00 (s, H-*ortho* of C-7 aryl moiety), 6.86 (s, O**H** aryl), 5.37 (s, H-7), and 1.31 (s, *meta*-di-*tert*-butyls of aryl moiety).

The assignment is supported by the observation (vide supra) that the characteristic sp^3-bound proton (H-7) of aryl C-bonded adducts is found ca. 0.6 ppm upfield of the corresponding peak in alkoxide adducts, i.e., at about 5.4 ppm (cf. Tables 1 and 2). In separate experiments it was shown that the σ-adduct is stable to acid (5 μL TFA) and that the peak at δ 6.86 is exchangeable with D_2O. The former result supports the assignment of the signals to a C-7 C-adduct, since such aryloxide C-adducts have been found to be acid stable, while their O-bonded counterparts are acid labile. The latter result confirms the identity of the aryloxyl OH. Interestingly, this signal (6.86 ppm) is seen in the present system, whereas it could not be detected in the spectra of the *ortho* and *para* C-7 C-bonded adducts formed by phenoxide with **2** (1*a*).

[2] The current limited spectroscopic data supports assignment of the peaks to 3,5-di-*tert*-butylphenyl ethers arising from nitro group displacement from the substrate picryl ring or from similar displacement from **1c**, although full characterization awaits further work. Similar NO_2 displacement has been observed previously in these systems (1*b*).

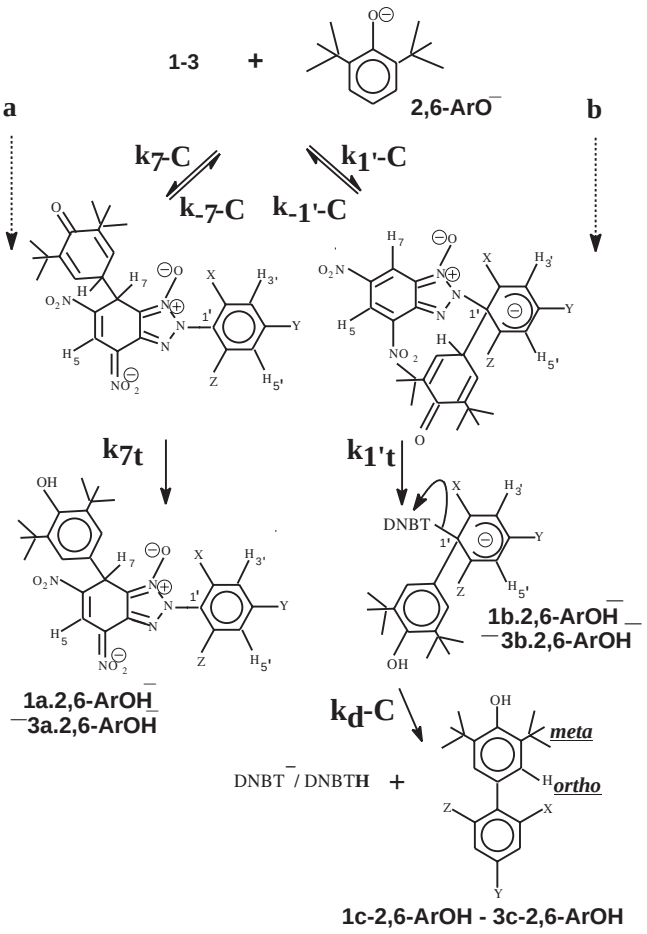
Scheme 2.



Attack at C-1′ via the *para* C-position of the 2,6-di-*tert*-butylphenoxide results in cleavage of the N-2:C-1′ bond and formation of the displacement products: 2,6-di-*tert*-butyl-4-(2′,4′,6′-trinitrophenyl)phenol, **1c**-2,6-ArOH (Scheme 2), and DNBT⁻/DNBTH. The signals for this biphenyl derivative are found at 9.12 (s, H- 3′,5′ picryl), 7.63 (br s, O**H**), 7.04 (s, H-3,5 phenolic moiety), and 1.35 (s, 2,6-di-*tert*-butyls). These peaks were previously observed in our study of the displacement reactions of 2,6-ArO⁻ with picryl chloride (17) and are in good agreement with the spectroscopic characteristics of authentic picryl 2,6-di-*tert*-butylphenol prepared separately (see Experimental). Interestingly, in our previous study the reaction medium was apparently basic enough to deprotonate the phenolic OH, whereas here this signal is observed and is seen to undergo exchange with D_2O.

Also apparent in the spectrum were resonances due to a small amount of PicO⁻, picrate anion, at 8.59 (s, H-3,5) and those assigned to 2,6-di-*tert*-butylphenol at 7.07 (d, J = 7.8, H-3,5), 6.89 (s, O**H**), 6.76 (t, J = 7.8, H-4), and 1.37 (s, 2,6-di-*tert*-butyl). These peaks also matched those recorded for the authentic materials. As would be expected, this initial spectrum remained unchanged over the period of observation (ca. 5 h).

Thus, for the first time in our examination of this series of electrophiles, **1**–**3***, C-attack at both the C-7 and C-1′ positions has been observed.*

The substrate DNP-DNBT, **2**, reacts with equimolar 2,6-ArO⁻ (as the potassium salt in DMSO-d_6; final concentration: 0.06 M) to yield a red-coloured mixture. In the spectrum acquired within 4 min of mixing, peaks attributable to the C-7 C-bonded adduct, **2a**·2,6-ArOH⁻, are seen at 8.83 (d, J = 2.5, H-3′), 8.76 (s, H-5), 8.71 (d,d, J = 8.8, 2,5, H-5′), 8.10 (d, J = 8.8, H-6′), 7.03 (s, H-*ortho* phenolic moiety), 6.86 (s, O**H**), 5.39 (s, H-7), and 1.31 (s, *meta*-di-*tert*-butyl). The σ-adduct meets the usual test for a C-bonded aryloxide adduct: the signals are stable to acid (5 μL TFA). The phenolic OH peak disappears when D_2O is added to the NMR tube, the tube is shaken, and then a new spectrum is recorded.

Unlike the Pi-DNBT–2,6-ArO⁻ reaction system, no signals are noted that could be assigned to the products of N-2:C-1′ bond scission; neither DNBT⁻/DNBT**H** nor 2,5-di-*tert*-butyl-4-(2′,4′-dinitrophenyl)phenol are formed. Again, the reaction is essentially complete at the time that the initial spectrum is recorded.

Here, only C-7 C-adduct formation is observed.

Consistent with its behaviour with the other aryloxide, NP-DNBT, **3**, reacts with 2,6-di-*tert*-butylphenoxide to give rise to the C-7 C-bonded adduct as the only product. Thus, when one equiv. of the 2,6-ArO⁻ solution (as the potassium salt in DMSO-d_6) is injected into the NMR tube that contains **3** (final concentration: 0.06 M), the first spectrum recorded consists of much diminished and broadened peaks for the starting material and dominant signals for the **3a**·2,6-ArOH⁻ σ-adduct. The characteristic resonances of this C-7 Meisenheimer complex are located at 8.79 (s, H-5), 8.39 (d), and 8.29 (d) (A_2X_2 system, J = 9.3), 7.07 (s, H-*meta* phenolic moiety), 6.89 (s, O**H**, D_2O-exchangeable), 5.38 (s, H-7), and 1.31 (s, *meta*-di-*tert*-butyl). The separate acidification experiment confirms the acid stability of this aryloxide C-adduct.

Attack at C-7 of **3** *by 2,6-ArO⁻ yields the C-7 C-bonded adduct and is complete within the time of mixing.*

Discussion

1. Reaction pathways: C-7 complexation versus C-1′ S_NAr displacement.

Although the aryloxides studied show a range of selectivity for the C-7 and C-1′ positions, a selectivity that is modulated for each substrate in turn, the basic pathways for reaction are shown by all the nucleophiles and all of the ambident electrophiles, **1**–**3.** However, the two nucleophiles show their own individual behaviours. Thus, 3,5-di-*tert*-butylphenoxide has been shown to act strictly as an O-nucleophile, and the pathways for its reaction with the substrates **1**–**3** are shown in Scheme 1. On the other hand, reactions with 2,6-di-*tert*-butylphenoxide proceed via attack of the *para*-carbon of the nucleophile; the *ortho* positions are blocked by the bulky *tert*-butyl groups, and this hindrance is also apparently large enough to effectively preclude attack of the aryloxide as an O-nucleophile. The pathways involving this aryloxide are detailed in Scheme 2.

As shown in Scheme 1, 3,5-ArO⁻ may attack at C-7 of any of the substrates to give rise to a σ-adduct via Path a. With Pi-DNBT, no C-7 adduct (e.g., **1a**·3,5-OAr⁻) was seen at the time of earliest observation. Instead, the only reaction noted was formation of the products of N-2:C-1′ bond scission via

© 1998 NRC Canada

Path b: the ether, **1c**·3,5-OAr, and the charge delocalized nucleofuge, DNBT⁻–DNBT**H**. Attack at C-1′ of 3,5-di-*tert*-butylphenoxide, as a "constrained phenoxide O-nucleophile," plausibly proceeds through a transient C-1′ adduct (or transition state modelled on such a C-1′ Meisenheimer complex), labelled **1b**·3,5-OAr⁻ in Scheme 1. The apparent preference for attack at this site is consistent with previous examinations of the Pi-DNBT–phenoxide and Pi-DNBT–mesitoxide reaction systems; in both cases reaction proceeded exclusively via C-1′ to give the corresponding ether products (or Meisenheimer adducts derived immediately from these ethers) (1, 20). (Stereoelectronic factors that may favour C-1′ attack have not previously been discussed for these types of systems (1) and will be discussed further in section 2). On the other hand, it should be recognized that the method of monitoring these reactions is a relatively slow one, and a rapidly formed C-7 O-adduct that also rapidly reverts to starting material may not be seen.

The rapid decomposition of adducts such as **1b**·3,5-OAr⁻ to the displacement products, **1c**·3,5-OAr and DNBT⁻, partly reflects the high nucleofugality of DNBT⁻, as a charge delocalized anion, and partly the relief of steric congestion that attends N-2:C-1′ bond rupture in **1b**·3,5-OAr⁻. As a result, C-1′ Meisenheimer adducts such as **1b** (or **2b** or **3b**) have not been observed in this or related studies (1, 7, 20).

Previous studies of the reactivity of DNP-DNBT, **2**, has shown that the removal of an *ortho* NO_2 group (in going from Pi-DNBT to DNP-DNBT) raises the barrier to attack at C-1′ more than it influences reaction at C-7. In the current study, then, reaction of 3,5-ArO⁻ as an O-nucleophile with **2** follows both Paths a and b, as outlined in Scheme 1. Here, a C-7 O-adduct, **2a**·3,5-OAr⁻, is observed along with the products of C-1′ displacement, via the putative **2b**·3,5-OAr⁻ adduct. This constitutes the first observation of an O-bonded C-7 aryloxide σ-adduct and illustrates the fine balance of C-7 stability (i.e., larger $K_7 = k_7/k_{-7}$, Scheme 1) and C-1′ barrier height (i.e., higher barrier = smaller $k_{1'}$) required to observe these adducts. Nonetheless, the C-7 adduct is present only as a minority product and within 30 min is no longer observed, presumably having decomposed back to **2** and the 3,5-ArO⁻; these rapidly recombine at C-1′ to yield the final S_NAr displacement products.

A further increase in the C-1′ kinetic barrier is associated with NP-DNBT, **3**, as substrate, as compared to **2**. In fact, the reduction in electrophilicity at the C-1′ position is now apparently significant enough to strongly bias the system towards C-7 adduct formation. Now the C-7 O-bonded adduct, **3a**·3,5-OAr⁻, is the only Meisenheimer complex formed in the system, and it persists over the period of observation. Note, however, that the overall percentage of O-adducts (C-7 plus C-1′) formed with **3** is lower than that found with **2** (Table 3 for 3,5-ArO⁻ as nucleophile, 70% vs. 88%), indicative of the reduction of overall electrophilicity that attends successive removal of electron-withdrawing groups from the 2-[(nitro)$_x$aryl] ring. (The comparison with 2,6-ArO⁻ as a nucleophile is not as straightforward and likely also reflects the generally higher barriers to attack via the C-centre.)

For 2,6-di-*tert*-butylphenoxide, reaction at the *ortho* carbon positions is prevented, and reaction via the oxygen centre is sterically demanding, to such an extent that no adducts (or products) have been observed to form in the present reaction systems or with either picryl chloride or fluoride (17). Rather, reaction proceeds via the *para*-carbon. With Pi-DNBT**, 1**, attack at C-7 according to Path a (Scheme 2) is the dominant process (Table 3). The comparison between the Pi-DNBT–2,6-ArO⁻ and Pi-DNBT–3,5-ArO⁻ reaction systems is striking. In the former, C-7 C-attack of the aryloxide is preferred over C-1′ C-attack and displacement, whereas in the latter system, only Path b attack can be observed via the oxygen-centre of the aryloxide. When the electrophilicity of the C-1′ site is reduced, as in **2** and even more so in **3**, reaction proceeds exclusively by Path a; the C-7 C-adducts, **2a**·2,6-ArOH⁻ and **3a**·2,6-ArOH⁻, are both persistent σ-complexes.

The selectivity towards C-7 complex formation found in these systems will now be considered in light of stereoelectronic factors.

2. Stereoelectronic factors: $n\rightarrow\sigma^*$ stabilization in C-1′ adducts.

In the course of our investigation of the regioselectivity shown in picryl ethers, and related electron-deficient aromatic–nucleophile systems (18, 22, 24, 25), we have found stereoelectronic stabilization of σ-adducts to be an important factor in determining the behaviour. In brief, C-1 dialkoxy adducts formed by alkoxides with 2,4,6-trinitroanisole (TNA), for example, can be viewed as acetals (26, 27). In such systems electron density from a lone pair of one OR group may be donated into the antibonding σ* orbital of the C(1)—OR bond, and vice versa, particularly when each OR group is aligned antiperiplanar to the relevant C—OR bond (22, 28–30). These $n\rightarrow\sigma^*$ interactions stabilize the C-1 methoxide adduct of TNA relative to the kinetically preferred C-3 Meisenheimer complex; the C-1 TNA·OCH_3^- adduct is the product of thermodynamic control (22, 31). In Buncel's nomenclature, this pattern of regioselectivity is termed K3T1 (kinetic preference for C-3 adduct formation, but the C-1 adduct is the thermodynamic product) (22). Where kinetic factors, such as F-strain to attack, are favourable an adduct that is stereoelectronically stabilized may be formed as the product of both kinetic and thermodynamic control. This is the case for the phenoxide O-adducts of TNA (22) and phenyl picryl ether (20); these systems are labelled K1T1. Note, however, that stereoelectronic stabilization is also generally considered to be less significant when it involves "unsymmetrical geminal disubstitution," that is, the stabilization is greatest when both acceptor fragment σ* orbitals are of equal energy, as would be expected for the methoxide C-1 adduct of TNA but as would not be expected for the O-centred phenoxide C-1 adduct of TNA (28). When stereoelectronic stabilization is diminished or precluded, for instance, because antiperiplanar rotameric forms of the geminally disubstituted adduct may not be populated as a result of steric congestion, an initially formed C-1 adduct may give way to its C-3 counterpart, as occurs in the case of 2,4,6-trimethylphenoxide (mesitoxide) reacting with TNA (32). In this case, the regioselectivity is denoted as K1T3. The preference of aryloxides, acting as O-nucleophiles, for C-1 of picryl chloride and fluoride was also partly attributed to $n\rightarrow\sigma^*$ stabilization of the C-1 adducts; no C-3 O-adducts were noted in these reaction systems (17).

In the context of the current study it should be recognized that Pi-DNBT, for example, can be viewed as "a 2-N substituted 4,6-dinitrobenzotriazole 1-oxide" or just as correctly be

[a] Spectra were recorded at 100.0 MHz using the J-mod pulse sequence (37). The numbering of the carbons follows that shown in Schemes 1 and 2 for the substrates **1**–**3**.

[b] Given in ref. 38.

[c] Given in ref. 17.

considered "a C-1 substituted 2,4,6-trinitrobenzene." The first description of the dinitrobenzotriazole 1-oxide series is the one that we have usually invoked in our comparison of the selectivity of nucleophilic attack on these substrates, **1**–**3**. In this case the C-7 site is super-electrophilic and should be expected to be the site of preferred attack. According to the second description, however, nucleophiles such as methoxide and phenoxide (as an O-nucleophile) could derive stabilization from $n\rightarrow\sigma^*$ interactions involving the oxygen lone pairs of the erstwhile nucleophiles and the N-2:C-1′ bond. While such an interaction is formally possible with the 2-nitrogen lone pair and the C-1′:OR (or :OAr) bond, donation of this pair of electrons would result in loss of aromaticity for the dinitrobenzotriazole 1-oxide fragment and is, therefore, likely unfavourable. Furthermore, stereoelectronic stabilization in these systems would be of the unsymmetrical kind and also energetically less rewarding, as a result.

However, when the possibility of $n\rightarrow\sigma^*$ stabilization is considered it should be conceded that the real comparison in selectivity lies between the C-7 site and the C-3′ site (at least in Pi-DNBT). Here, where the stereoelectronic stabilization is absent at both sites, an unbiased comparison should be possible. In this regard, note that in no system studied thus far has attack at C-3′ (or comparable unsubstituted centres on the 2-[(nitro)$_x$aryl] rings) been observed. Methoxide reacts with TNA to initially form the C-3 adduct that gives way to the more stable C-1 geminal dialkoxy adduct (K3T1 behaviour), but methoxide reacts preferentially at C-7 of **1** followed by C-1′ attack and displacement (K7T1′ pattern), without any apparent formation of a C-3′ adduct (1*c*, 22). This is an indirect confirmation of the super-electrophilicity of the C-7 position in **1**–**3**.

With this understanding we will now consider the selectivity data compiled in Table 3. The table gives the selectivity (*S*) as the ratio of the ratios of C-7 versus C-1′ adducts (i.e., displacement products) formed at the earliest point of observation. Properly, *S* should be defined only on the basis of the forward rate constants for formation of these adducts, that is, $S = k_7/k_{1'}$ or k_7-C/$k_{-1'}$-C (Schemes 1 and 2). In fact, the selectivities given in Table 3 reflect both the stability of the C-7 adduct (i.e., K_7) as well as the kinetic barrier to formation of it and its C-1′ analogue. In this sense, *S* here is a guide to the actual selectivity, though it has proved to be a useful construct for describing the behaviour in related systems (1). In considering the full series of substrates, we can see that the selectivity for C-7 attack increases from one end of the spectrum to the other as we proceed from **1** to **3**. Thus, 3,5-ArO$^-$ reacts entirely at C-1′ of **1**, as an O-nucleophile, shows a strong selectivity for C-1′ in **2** (i.e., the selectivity, $S = 0.1 = \%$ C-7/% C-1′, where % C-1′ = % DNBT$^-$ or % **1c**; Table 3, Scheme 1) but is specific in its reaction at C-7 for **3**. A somewhat similar situation is found for the reaction of 2,6-ArO$^-$ with the series, in that the preference for C-7 reaction increases in going from **1** to **3**. However, a preference for C-attack at C-7 over C-1′ exists even with **1** ($S = 2.2$), while with **2** and **3** C-7 regiospecificity of attack is found.

Further interesting comparisons arise from considering the aryloxide pairs with a given substrate. Therefore, in examining the reaction systems that involve Pi-DNBT, 2,6-di-*tert*-butylphenoxide ion shows significantly higher selectivity for C-7 than its isomer, the 3,5-di-*tert*-butylphenoxide ion; $S = 0$ for the former system and 2.2 for the latter. This is consistent with the reactivity–selectivity principle (33, 34[3]) in the sense that reaction via the *para*-C of 2,6-ArO$^-$ requires initial loss of aromaticity in formation of the quinoidal C-adduct ($k_{1'}$-C and k_7-C steps in Scheme 2). This adduct presumably tautomerizes rapidly ($k_{1't}$ and k_{7t}, Scheme 2) to give the observable C-7 adduct (**1c**·2,6-ArOH$^-$ in the case of Pi-DNBT) or the biphenyl product (**1c**-2,6-ArOH) of decomposition of the rearomatized C-1′ adduct (**1b**·2,6-ArOH$^-$). The loss of aromaticity that is required in C-attack as compared to O-attack would presumably raise the barrier for this step for 2,6-ArO$^-$ as a C-nucleophile as compared to 2,6-ArO$^-$ as a hypothetical O-nucleophile or 3,5-ArO$^-$ as an actual O-nucleophile. Thus, 2,6-ArO$^-$ is expected to be intrinsically less reactive than 3,5-ArO$^-$, and hence the 2,6-isomer is the most selective. That appears to be the case here, and the situation is confirmed in the DNP-DNBT systems where, again, the 2,6-ArO$^-$ ion favours C-7 attack more than the isomeric 3,5-ArO$^-$ ion does.

Reaction of either aryloxide with NP-DNBT gives the respective C-7 adducts, exclusively. This reflects the much lower electrophilicity of C-1′ as a site on an aryl ring that contains only a single electron-withdrawing NO_2 group.

These selectivity results support the notion that stereoelectronic stabilization plays a significant role in these systems. The 2,6-di-*tert*-butylphenoxide ion cannot act as an oxygen nucleophile, owing to the high steric congestion about the nucleophilic oxygen, and has been shown to react only via

[3] This is an issue devoted to articles about the RSP.

© 1998 NRC Canada

carbon, while the 3,5-di-*tert*-butyl isomeric ion is limited to reaction via oxygen. Neither the C-7 adduct nor the C-1′ adduct formed by 2,6-ArO^-, then, could derive stabilization via $n\rightarrow\sigma^*$ interactions, since the *para*-C fragment cannot be an *n* electron donor and, in the C-1′ adduct, it is unlikely that the N centre would be an *n* donor either. Conversely, the C-1′ adducts of 3,5-ArO^- could achieve a significant measure of such stereoelectronic stabilization.

The preferences for sites of attack parallel the possible stereoelectronic stabilization. Lacking any possibility of such stabilization, 2,6-ArO^- shows selectivity for C-7 of **1** whereas 3,5-ArO^- reacts entirely via the (presumably) stereoelectronically stabilized C-1′ O-adduct. From examination of models (Darling or Dreiding) it appears unlikely that any of the oxygen-centred C-1′ adducts would be able to take up the optimal orientations for full $n\rightarrow\sigma^*$ stabilization, as a result of steric hindrance. Nonetheless, the greater propensity for C-1′ attack shown by the 3,5-ArO^- nucleophile towards **2** also likely indicates some degree of stereoelectronic stabilization of the C-1′ adduct, a stabilization that the C-7 adduct does not share. That the **2a**·3,5-OAr^- adduct is observable under these conditions provides further support for our contention that C-7 is super-electrophilic. In the case of NP-DNBT the low electrophilicity of C-1′, linked largely to the diminished ability to conjugatively delocalize negative charge in the putative C-1′ adduct, is such that stereoelectronic stabilization cannot compete with C-7 electrophilicity: only C-7 adducts are formed by both nucleophiles.

It is interesting to compare the result of the reaction of 3,5-ArO^- with **3** and the reaction of phenoxide, as an O-nucleophile, with DNBF, **4**. Although phenoxide anionic σ-adducts of all common electron-deficient aromatic and heteroaromatic compounds have shown themselves to be elusive species (19, 35, 36) the DNBF.OPh^- adduct was recently observed at low temperature (17). In some senses, DNBF can be viewed as a truncated member of the current series of electrophiles. Unlike **1** and **2**, competition between complex formation and S_NAr displacement is not possible for **4**. This is similar to the situation with **3**, where the electrophilicity of C-1′ is no longer competitive with that of C-7, and the C-1′ adduct would clearly be less stable than its C-7 counterpart. In both cases, clean C-7 O-adduct formation can now be observed. With **3**, however, C-7 C-adduct formation with PhO^- is still preferred over O-adduct formation (1*c*), and only by barring C-adduct formation can the C-7 O-adduct be observed with 3,5-ArO^-, at room temperature in DMSO-d_6.

In conclusion, we have seen that selectivity for the C-7 complexation (defined as the ratio of the percentages of C-7 adduct to C-1′ adduct formed at the point of earliest observation) increases in going from **1** to **3** for either aryloxide. For the first time complexation via an aryloxide carbon has been observed along with attack of a ring carbon on C-1′. Thus, 2,6-di-*tert*-butylphenoxide ion, which cannot act as an O-nucleophile, reacts preferentially at C-7 ($S = 2.2$) of Pi-DNBT, but the biphenyl derivative that arises from C-1′ attack is also observed.

The preference for reaction at C-1′ of **1** that has been shown by phenoxide and mesitoxide (20) is also displayed by 3,5-di-*tert*-butylphenoxide. This is partly attributed to stereoelectronic stabilization of the C-1′ adduct.

Future work will focus on selectivity with less sterically demanding nucleophiles.

Experimental

Materials

Preparation of the 2-nitroaryl-4,6-dinitrobenzotriazole 1-oxide substrates, **1**–**3**, has been described previously (1). The ^{13}C NMR spectra of the substrates (**1**–**3**) have not previously been reported. These spectra were acquired using the J-modulated (JMOD) pulse sequence (37), which aided in assignment (38) of these spectra (Table 4). The DMSO-d_6 (CDN or Merck), used for the NMR studies, was dried by treatment with 4 or 3 Å molecular sieves prior to use, as advocated by Burfield and Smithers (39). The method of Kornblum and Laurie (40) was used for the preparation of the potassium aryloxide salts; the ^1H NMR spectroscopic characteristics of these salts have been reported previously (17, 18). For purposes of comparison the biphenyl derivatives (i.e., 2,6-di-*tert*-butyl-4-(2′,4′,6′-trinitrophenyl)phenol, **1c**·2,6-ArOH, and 2,6-di-*tert*-butyl-4-(2′,4′-dinitrophenyl)phenol, **2c**·2,6-ArOH) were prepared by reaction of potassium 2,6-di-*tert*-butylphenoxide with picryl chloride and fluoro-2,4-dinitrobenzene, respectively, as previously described (17, 41). Similarly, the ethers (namely, 3,5-di-*tert*-butylphenyl 2′,4′,6′-trinitrophenyl ether, **1c**·3,5-OAr, and 3,5-di-*tert*-butylphenyl 2′,4′-dinitrophenyl ether, **2c**·3,5-OAr), were prepared from potassium 3,5-di-*tert*-butylphenoxide with picryl chloride and fluoro-2,4-dinitrobenzene, respectively, again as reported previously (20*a*).

Methods

NMR experiments

The NMR spectra were recorded at Queen's University (Kingston) on a Bruker AM-400 spectrometer operating at 400.1 MHz (^1H) and 100.0 MHz (^{13}C). The spectrometer was typically tuned, as reported previously (22). Wilmad PP-507 NMR tubes were used in all experiments. Potassium aryloxide solutions were prepared in volumetric flasks (1 mL), from weighed quantities of the salts and dry DMSO-d_6 in a nitrogen dry-box; the flasks were capped with rubber septa before removal from the dry box.

Typically, an NMR tube that contained ca. 400 μL of dry DMSO-d_6 was septum-capped and swept out with nitrogen. Appropriate amounts of substrate, dissolved in DMSO-d_6, and 1,4-dibromobenzene (integration standard) in the same solvent were injected into the tube. An initial spectrum was acquired to demonstrate the purity of the starting material. Reaction was initiated by injection of the nucleophile solution, in an amount such that the final concentrations of substrate and nucleophile were equal (usually 0.03–0.06 M for each). The first spectrum was acquired as soon as possible (ca. 3 min), using 16 scans to obtain the FID. After the initial spectrum was obtained the system was monitored at varying intervals until the reaction was deemed complete.

Acknowledgments

Support of this research in the form of a grant from the Principal's Research Fund of Sir Wilfred Grenfell College (J.M.D.) and from the American Cancer Society (R.A.M.) is gratefully

A calculational and ultraviolet photoelectron spectroscopic study of distorted amides

N.H. Werstiuk, H.M. Muchall, C.D. Roy, J. Ma, and R.S. Brown

Abstract: Distorted amides 3,4-dihydro-2-oxo-1,4-ethanoquinoline (**1a**), 3,4-dihydro-2-oxo-1,4-propanoquinoline (**1b**), 3,3,4,5-tetrahydro-2-oxo-1,5-ethanobenzazepine (**1c**), and 3,3,4,5-tetrahydro-2-oxo-1,5-propanobenzazepine (**1d**) and the model compounds 2,*N*-dimethyl-acetanilide (**2a**), 2,*N*,*N*-trimethylaniline (**3**), and benzoquinuclidine (**4**) have been studied calculationally and with He(I) ultraviolet photoelectron spectroscopy. We find good agreement between experimentally obtained ionization energies for **1b**, **1c**, **1d**, **2a**, **3**, and **4** and values calculated with HAM/3 using the equilibrium geometries obtained at the HF/6-31G** level of theory. An excellent correlation between experimental ionization energies and orbital energies from Becke3LYP/6-31+G* calculations led to the characterization of the highest occupied molecular orbitals for these compounds and for **1a,** whose photoelectron spectrum could not be obtained due to its reactivity in the solid state.

Key words: distorted amides, He(I) photoelectron spectroscopy, Becke3LYP, molecular orbitals.

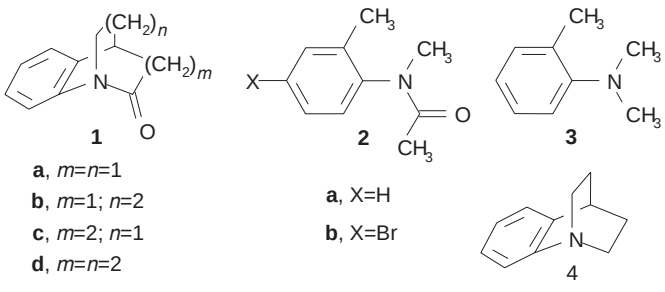
Résumé : Faisant appel à des calculs et à la spectroscopie photoélectronique ultraviolette He(I), on a étudié des amides déformés 3,4-dihydro-2-oxo-1,4-éthanoquinoléine (**1a**), 3,4-dihydro-2-oxo-1,4-propanoquinoléine (**1b**), 3,3,4,5-tétrahydro-2-oxo-1,5-éthanobenzazépine (**1c**) et 3,3,4,5-tétrahydro-2-oxo-1,5-propanobenzazépine (**1d**) ainsi que des composés modèles 2,*N*-diméthylacétanilide (**2a**), 2*N,N*-triméthylaniline (**3**) et benzoquinuclidine (**4**). On a observé un bon accord entre les énergies d'ionisation obtenues expérimentalement pour les composés **1b, 1c, 1d, 2a, 3a** et **4** et les valeurs calculées par la méthode HAM/3 en utilisant les géométries d'équilibre obtenues au niveau HF/6-31G** de la théorie. Une excellente corrélation entre les énergies d'ionisation expérimentales et les énergies d'orbitales obtenues à l'aide de calculs Becke3LYP/6-31+G* conduit à la caractérisation des orbitales moléculaires hautes occupées de ces composés et du produit **1a** dont on n'a pas pu obtenir le spectre photoélectronique à cause de sa réactivité à l'état solide.

Mots clés : amides déformés, spectroscopie photoélectronique He(I), Becke3LYP, orbitales moléculaires.

[Traduit par la rédaction]

Introduction

By studying a group of benzo-substituted bicyclic amides, Brown and co-workers showed that distorting the amide linkage away from planarity leads to a dramatic change in the basicity of the amides and their reactivities in H_2O (1, 2). The kinetics of hydrolysis of distorted amides 3,4-dihydro-2-oxo-1,4-ethanoquinoline (**1a**), 3,4-dihydro-2-oxo-1,4-propanoquinoline (**1b**), 3,3,4,5-tetrahydro-2-oxo-1,5-ethanobenzazepine (**1c**), and 3,3,4,5-tetrahydro-2-oxo-1,5-propanobenzazepine (**1d**) were studied as a function of pH and it was suggested that on going from **1d** to **1a** the site of protonation changes from oxygen to nitrogen, giving rise to N-protonated amides as reactive intermediates in the case of **1a**, **1b,** and **1c**. Because He(I) photoelectron spectroscopy provides a way of ordering the molecular orbitals (MOs) while quantum chemical calculations can be used to calculate orbital energies and MO coefficients, the availability of these distorted amides and the model compounds 2,*N*-dimethylacetanilide (**2a**), 2,*N*,*N*-trimethylaniline (**3**), and benzoquinuclidine (**4**) provided us with a unique opportunity to determine the impact of pyramidalizing the bridgehead nitrogen, twisting the amide linkage, and changing the ring size on the nature of the highest occupied molecular orbitals of the amides. This paper documents the results of our study.



Received September 30, 1997.

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

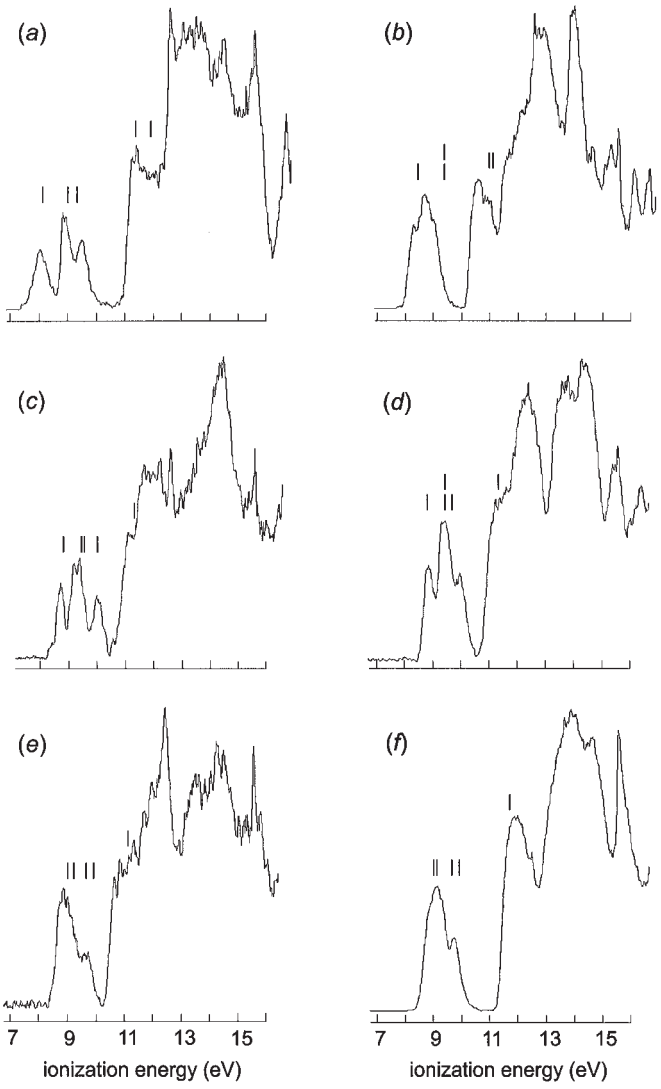
HAM/3 ionization energies are shown as vertical bars.



locally built spectrometer (3) designed to facilitate the handling of solids. Samples of the amides were placed in a 3 mm o.d. Pyrex tube — closed at one end — and inserted into the tip of a probe that could be electrically heated or cooled with circulating water. The tip of the sample tube was positioned 1 cm from the point of intersection with a He(I) photoionizing photon beam and the PE spectra were obtained by averaging 15–25 scans. During the acquisition of the spectra, the probe temperature was adjusted to maintain an acceptable signal level. The spectra were calibrated with N_2 (15.6 eV) and H_2O (12.6 eV), and linearity of the scale was ensured through calibrations with N_2 and acetone (9.7 eV) performed prior to the experiments. The spectra of **1b**, **1c**, **1d**, **2a**, **3,** and **4** are displayed in Fig. 1. Attempts to obtain the spectrum of **1a** failed because it rapidly polymerized when handled in the solid state. The vertical ionization energies (IEs) given in Table 1 were estimated from the maxima of the bands lying between 8 and 12 eV; shoulders are indicated (sh).

Calculational studies

Ab initio HF (4) and Becke3LYP (5) calculations were carried out on IBM RS/6000 model 39H, 350, and 530 computers with GAUSSIAN 92 (6) and GAUSSIAN 94 (7). The optimized equilibrium geometries of **1b**–**1d** and **2a** (geometrical structures not shown) correlated closely with the molecular structures of **1b**–**1d** and **2b** obtained with X-ray diffraction (1, 8, 9): the seven-membered ring of **1b** and **1c** adopts a chair conformation, the trimethylene bridge is oriented *syn* to the aromatic ring; the eight-membered ring of **1d** adopts a crown conformation; the planar amide group of acetanilide **2a** is nearly perpendicular to the plane of the phenyl ring. Table 2 lists calculated (HF/6-31G** and Becke3LYP/6-31+G*) and experimental N—C(O) and C═O bond lengths. HF/6-31G** optimized geometrical structures obtained with GAUSSIAN 92 were used in the semiempirical HAM/3 (10) calculations of the IEs (Table 1). PERGRA (11) was used to obtain displays of the Becke3LYP/6-31+G* MOs (which were found to compare well to HF/6-31G** eigenvectors).[3]

Results and discussion

The data in Table 2 show that calculations on **1b**–**1d** at both the HF/6-31G** and Becke3LYP/6-31+G* level of theory yield N—C(O) and C═O bond lengths that correlate well with the parameters obtained with X-ray diffraction. There is a progressive decrease in the calculated N—C(O) bond lengths on going from **1a** to **2a**, yet the C═O bonds lengthen only marginally, in keeping with the results of a calculational study on formamide reported by Wiberg and Breneman (13). The results are in accord with the expectation that the interaction of the nitrogen lone pair with the carbonyl group increases through the series **1a**–**1d** and **2b**. That the N—C(O) bond of **1d** is longer than the N—C(O) bond of **2b** (we expect that the experimental N—C(O) and C═O bond lengths of **2b** and **2a** are virtually identical) suggests that the interaction of the nitrogen lone pair with the carbonyl group of **1d** does not occur to the same extent in this case as in **2a** and **2b** even though **1d** has two 3-carbon bridges that allow the bridgehead nitrogen to become planar, a requirement for a maximal n_N–$\pi_{C=O}$ interaction in an amide. It is interesting to note that the calculated N—C(O) bond length of **1a** is substantially longer than the one calculated for **1b**. Because the N—C(O) and C═O bond lengths of **1b**, **1c**, and **1d** are reproduced with good accuracy by the calculations, we expect that the calculated N—C(O) and

[3] A rationale for the successful application of the Koopmans' Theory-like interpretation of the orbital energies obtained at the DFT level of theory in a PE spectroscopic study of a series of carbenes has recently been provided by Arduengo and co-workers (12). It is clear that applying a uniform shift, based on the difference in calculated HOMO energy and experimental first vertical IP, to orbital energies obtained with the hybrid HF/DFT Becke3LYP method nicely reproduces the PE spectra of compounds presented here (which are vastly different from the carbenes studied by Arduengo).

[a]Reference 2.
[b]The X-ray crystal structure was not determined due to the reactivity of **1a**.
[c]One of two molecules with slightly different structural parameters in the unit cell.
[d]The X-ray crystal structure was not determined.
[e]Not studied calculationally.

C═O bond lengths of **1a** are close to the experimental values, which have not yet been determined.

The computed four highest occupied MOs of amides **1b**–**1d** and **2a** comprise the electron lone pairs on nitrogen (n_N) and oxygen (n_O) as well as the two highest occupied MOs of the aromatic ring (π_3 and π_2). Ionizations from these four orbitals are expected in the low-energy region of the PE spectrum and, as seen in Figs. 1*c*–1*f*, bands arising from four ionizations are well separated from the main group of σ ionizations. On going from **1b** to **1d** and **2a**, the spectra exhibit increasing overlap of the respective bands: while for **1b** (Fig. 1*c*) all four ionizations can be assigned to individual peaks, for **2a** (Fig. 1*f*) only two maxima can be given (Table 1). This is due to a shift of the first band towards higher values, which eventually leads to a complete overlap with the former second band. PE spectra of amines **3** and **4** (Figs. 1*a* and 1*b*), which correspond well to those published earlier (14), possess one ionization less in this region due to the missing oxygen atom.

As seen from the data in Table 1 and the spectra displayed in Fig. 1, there is good agreement between the five lowest experimental vertical ionization energies of **1b**–**1d**, **2a**, **3,** and **4** and their IEs calculated with HAM/3 (shown as vertical bars in Fig. 1). Yet HAM/3 does not reproduce the gradual shift of the first ionization band towards higher energies in the amide series. As this seemed to be an important point, we performed ab initio calculations for amides **1a**–**1d** and **2a** and included amine **4** in the study. While orbital energies taken from HF/6-31G** calculations (not given) correspond only poorly to the experimental data, the correlation is excellent using Becke3LYP/6-31+G* orbital energies and applying Koopmans' Theorem (15).[3] For **1b**–**1d**, **2a**, and **4**, all relative orbital energy differences — for the single molecules as well as those between different molecules — are represented correctly (the rather large differences in absolute values are common with Becke3LYP and are not relevant to this analysis). Calculated Becke3LYP/6-31+G* orbital energies and assignments taken from the eigenvectors are given in Table 3.[3]

[a]n_N–n_O mixing.
[b]n_N–n_O–π mixing.

Graphical representations of the highest occupied molecular orbitals of amine **4** and amides **1a**–**1d** and **2a** determined with Becke3LYP/6-31+G* (these were checked against HAM/3//HF/6-31G** orbitals and found to compare well) are given in Figs. 2–7, respectively. The HOMO of **4** (Fig. 2) is of n_N character with σ electron density on the bridge C—C bonds. HOMO-1 and HOMO-2 are benzene-type π orbitals (π_3 and π_2). Introduction of the carbonyl group into the system leads to a loss of σ–π separation: n_N, which is in the plane of the aromatic ring in amine **4** and therefore does not interact with benzene π MOs, is twisted out of this plane in amides **1a**–**1d**. The HOMO of **1a** (Fig. 3) is essentially n_N with a small contribution from n_O (the torsional angle between these lone pairs estimated from the PERGRA plots is close to 0°)[4] and electron density on the C—C(O) bond; the nitrogen lone pair shows a pronounced tilt towards the benzene ring.

[4] In a detailed theoretical study of the topology of the charge densities of **1a**–**1d** and **2a** with the quantum theory of atoms in molecules (16) (the results will be documented in a following paper) we have characterized the outer and inner nonbonded charge concentrations (nbcc's) of the nitrogen atoms. The torsional angles between the outer (3, –3) critical points and the C—O linkages of **1a**, **1b**, **1c,** and **1d** are 4.2° ($\nabla^2\rho = -3.531$), 45.2° ($\nabla^2\rho = -3.225$), 50.3° ($\nabla^2\rho = -3.148$), and 72.8 ($\nabla^2\rho = -2.806$), respectively. In the case of **2a**, the nbcc's of the nitrogen atom exhibit two similar $\nabla^2\rho$ values of –2.553 (torsional angle 92.8°) and –2.168 (87.6°).

Fig. 2. HOMO to HOMO-2 of amine **4**.

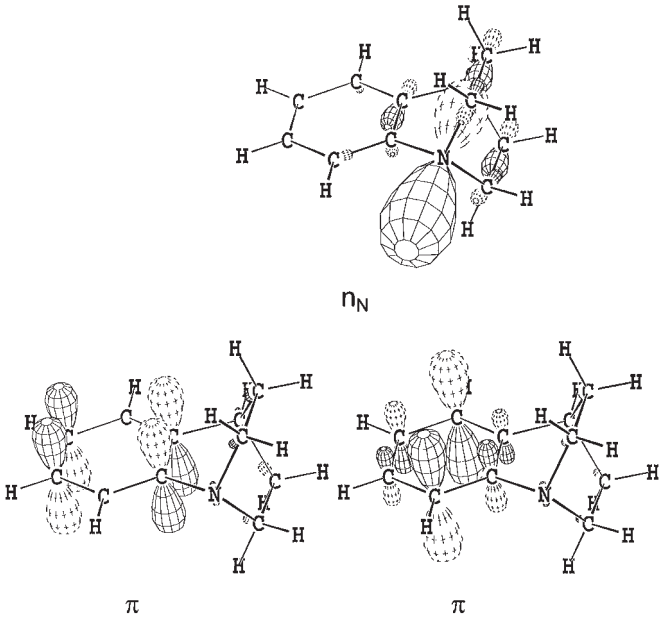

Fig. 3. HOMO to HOMO-3 of amide **1a**.

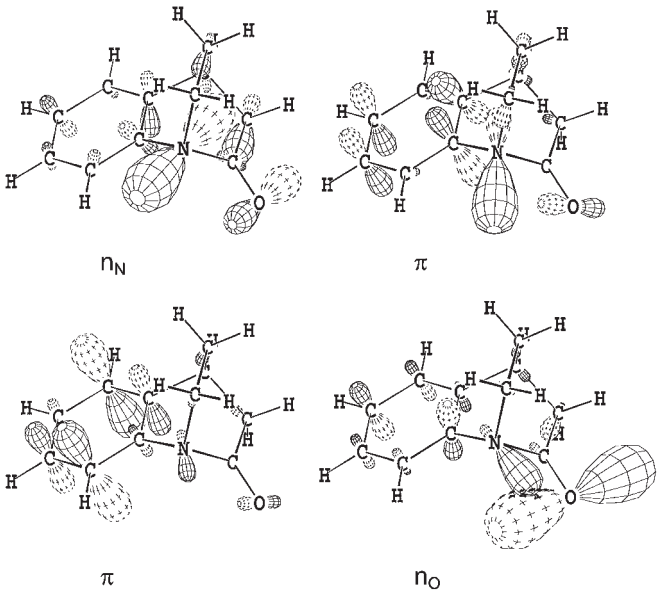

HOMO-1 and HOMO-2 have mainly π character on the benzene ring, with some n_N and n_O mixing. HOMO-3 is essentially n_O (with contributions on N—C(O) and C—C(O) bonds). As was found for **1a**, the HOMO of **1b** is n_N with n_O mixing, with a considerable additional amount of π mixing (Fig. 4). The torsional angle between the lone pairs is about 40°.[4] HOMO-1 is n_O, as described for **1a**. HOMO-2 is a benzene-type π MO while HOMO-3 shows π mixing with n_N and n_O, as was found for the HOMO: HOMO and HOMO-3 of **1b** seem to be two combinations of n_N and benzene π (n_O, which is always mixed with n_N, is found in different amounts according to individual interactions). For **1c**, HOMO and HOMO-1 are two combinations of nearly equal amounts of n_N and n_O

Fig. 4. HOMO to HOMO-3 of amide **1b**.

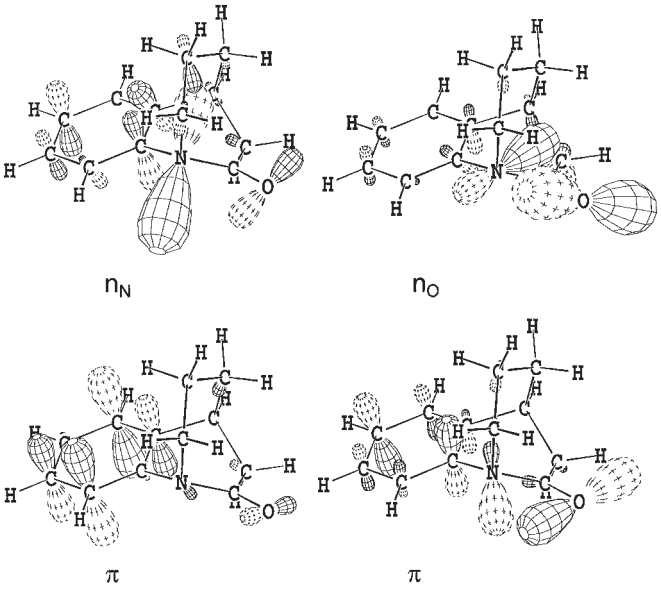

Fig. 5. HOMO to HOMO-3 of amide **1c**.

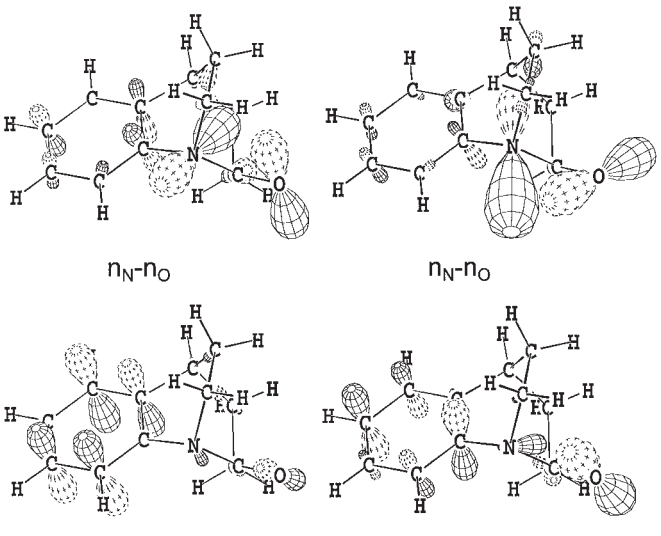

(Fig. 5). The torsional angle between n_N and n_O in the HOMO is comparable to that in the HOMO of **1b** (40°).[4] As in **1b**, HOMO-2 is of π character; HOMO-3 shows π–n_O mixing. For amides **1d** and **2a** (Figs. 6 and 7, respectively), the HOMO is n_O with pronounced coefficients along the N—C(O) and C—C(O) bonds. HOMO-1 is n_N with a large contribution from n_O (the torsional angle is greater than 60°);[4] HOMO-2 and HOMO-3 are benzene-type π orbitals. As for **1c**, HOMO-3 shows π–n_O mixing. It is apparent from inspection of the coefficients making up the various orbitals in Figs. 2–7 that the extensive mixing of the n_N, n_O, and π components does not fit with our simplistic notions of an isolated amide π system and C═O lone pair, even in the case of **2a** where such amidic resonance is allowed by the planarity of the amide unit.

The experimental (compare the spectra displayed in Fig. 1) and computational results, which are presented graphically in

Fig. 6. HOMO to HOMO-3 of amide **1d**.

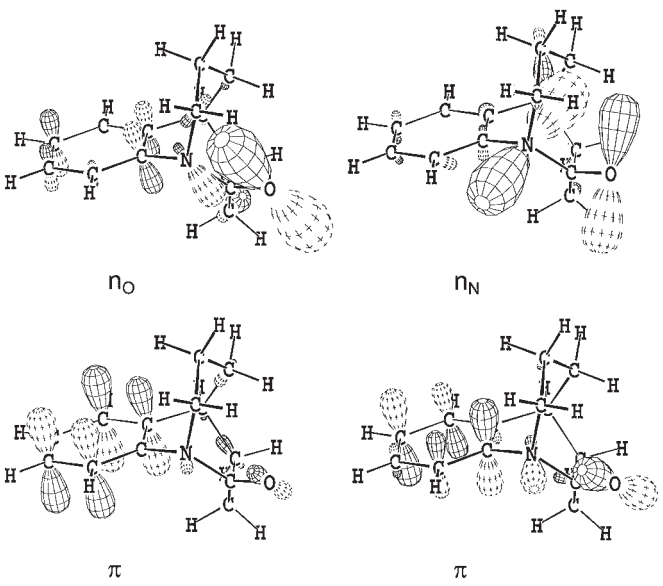

Fig. 7. HOMO to HOMO-3 of amide **2a**.

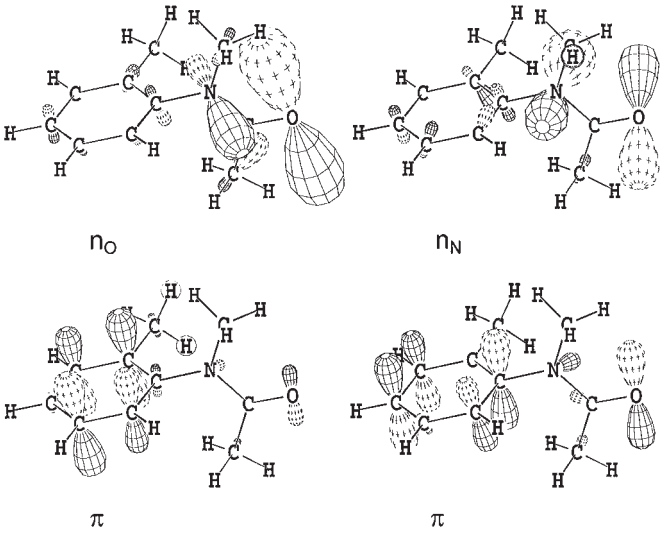

Fig. 8, show remarkable agreement. The high quality of the Becke3LYP calculations even allows for a prediction of the partial PE spectrum of **1a** (from orbital energies given in Fig. 8).[3] The first ionization should be close in energy to that of **2a** with the first three bands possibly overlapping.

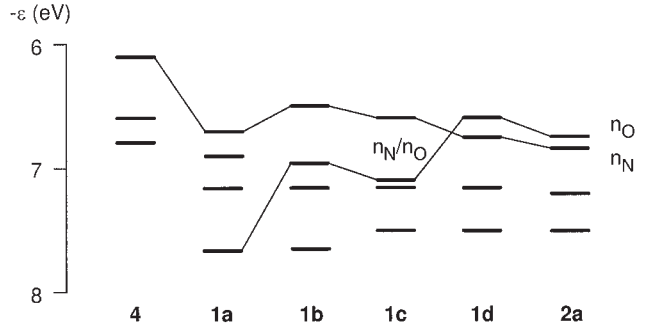
Figure 8 shows that, in going from amine **4** to orthogonal amide **1a**, the n_N HOMO is stabilized by an inductive effect of the carbonyl group. The most striking feature obvious from Fig. 8 is the change of character of the HOMO: starting out as n_N in amine **4**, it is increasingly mixed with n_O in amides **1a**–**1c** and finally changes to n_O in **1d** and **2a**. This is nicely in accordance with findings on the site of protonation in these amides (2). While n_N is more or less energetically constant in the bicyclic amide series **1a**–**1d**, the energy of n_O changes dramatically. On going from **1a** to **1b**, n_O is destabilized by 0.71 eV. There is little change in n_O energy from **1b** to **1c** and, again, a destabilization from **1c** to **1d**. This can be correlated with the size of the amide ring in six-membered **1a**,

Fig. 8. Progression of orbital energies ε (Becke3LYP/6-31+G*) for amides **1a**–**1d** and **2a** as well as amine **4**. Unassigned orbitals are of aromatic π-character.



seven-membered **1b** and **1c,** and eight-membered **1d**. Such a correlation (shift of n_O due to ring expansion) in cyclic — undistorted — amides was shown before (17) and was explained by recognizing that n_O contains a significant coefficient at the carbon atom in the position α to the carbonyl group and is therefore strongly influenced by changes in ring size. There is no such contribution in the n_N of undistorted amides, which accordingly changes little in energy upon expansion or contraction of the ring. This explanation, modified, can also be applied to the ordering of n_N and n_O in distorted bicyclic amides **1a**–**1d**. It has to be modified for **1a** because of the coefficient at the carbon atom in the position α to the carbonyl group in the n_N HOMO, which explains why this orbital is destabilized on going from **1a** to **1c**. Thus a more or less constant energy n_N and a gradually destabilized n_O give rise to the computed and observed changes in orbital sequence. The conspicuously high HOMO energy of **1b** (which is confirmed by the low first IP of this amide, see Table 1) is due to an extraordinary amount of *n*–π mixing.

Conclusions

By combining PE spectroscopy with calculations at HAM/3 and Becke3LYP levels of theory, we gained detailed information about the highest occupied molecular orbitals of amides **1b**–**1d** and **2a**. This allowed the corresponding MOs of **1a** and its PE spectrum, which could not be obtained experimentally due to the extreme reactivity of **1a** in the solid state, to be predicted with certainty. Amide **1b** exhibits an unusually large degree of *n*–π mixing with the benzene ring. While the HOMO of **1a** is essentially n_N, destabilization of the n_O orbital as the ring size increases leads to a HOMO of n_O character in the case of **1d**.

α-Effect nucleophiles and azide ion: effective charge studies of displacement reactions at esters

Matthew J. Colthurst, Angeline J.S.S. Kanagasooriam, Michael S.O. Wong, Christian Contini, and Andrew Williams

Abstract: The bimolecular reactions of azide, 2-iodosobenzoate, and acetohydroxamate ions and methoxyamine nucleophiles with substituted phenyl acetates possess Yukawa–Tsuno type correlations with substantial resonance interaction. The rate constants for hydroperoxide ion and the oxyanion of *N*,*N*-diethylhydroxylamine obey simple Hammett equations. The reactivities of azide, acetohydroxamate, hydroperoxide, and 2-iodosobenzoate ion nucleophiles exhibit modest α-effects when the reactivity in substitution at 4-nitrophenyl acetate is compared with that of phenoxide ions of similar pK_a values. The *N*,*N*-diethylhydroxylamine oxyanion is less reactive than its phenoxide ion analogue due to steric requirements, and the reactivities of the anionic nucleophiles exhibit changes in effective charge on the leaving oxygen similar to those for regular nucleophiles of similar pK_a. Methoxyamine possesses only a small enhancement compared with the reactivity of a normal primary amine of similar pK_a.

Values of the Leffler parameters for the bond fission process in the reactions of α-nucleophiles with phenyl acetates do not exhibit any special differences apart from those due to the pK_a of the nucleophile. The causes of the α-effect are considered to be due to steric and solvation requirements of the reactions.

Key words: α-effect, nucleophile, Yukawa–Tsuno, Leffler, Hammett, phenyl ester, effective charge, Brønsted.

Résumé : Les réactions bimoléculaires des acétates de phényles substitués avec les ions azoture, 2-iodosobenzoate et acétohydroxymate et la méthoxyamine, qui sont tous nucléophiles, présentent des corrélations du type Yukawa–Tsuno comportant une interaction de résonance importante. Les constantes de vitesse pour les réactions de l'ion hydroperoxyde et de l'oxyanion de la *N*,*N*-diéthylhydroxylamine obéissent à des équations de Hammett simples. Les réactions des ions nucléophiles iodure, acétohydroxamate, hydroperoxyde et 2-iodosobenzoate présentent de faibles effets σ lorsqu'on compare la réactivité de leurs réactions de substitution avec l'acétate 4-nitrophényle avec celle des ions phénolates de pK_a semblables. L'oxyanion *N*,*N*-diéthylhydroxylamine est moins réactif que l'ion phénolate correspondant à cause d'effets stériques et les réactivités des nucléophiles anioniques présentent des changements dans la charge effective présente sur l'oxygène partant qui sont semblables à ceux observés avec les nucléophiles réguliers de pK_a semblables. La méthoxyamine ne présente qu'une faible augmentation de réactivité par comparaison avec celle d'une amine primaire normale de pK_a semblable.

Les valeurs des paramètres de Leffler pour le processus de bris de liaison dans les réactions de nucléophiles α avec les acétates de phényle ne présentent pas de différences spéciales, à l'exception de celles dues au pK_a du nucléophile. On considère que l'effet α est causé par des effets stériques et des exigences imposées aux réactions par le solvant.

Mots clés : effet α, nucléophile, Yukawa–Tsuno, Leffler, Hammett, ester de phényle, charge effective, Brønsted.

[Traduit par la rédaction]

Introduction

A nucleophile with a lone pair of electrons on the atom adjacent to the nucleophilic atom often exhibits enhanced reactivity compared with that of a nucleophile of comparable Brønsted basicity (1, 2), which does not possess this structural feature. The phenomenon is called the α-effect, and it occurs to different degrees in reactions with many substrates. The α-effect phenomenon has been reviewed (3, 4), and several explanations have been advanced, none of which provides a universal explanation. Four major causes have been suggested for the α-effect and are ground-state destabilization of the nucleophile, transition-state stabilization, differences in solvation, and stabilization of the reaction products (3). Among other factors that may contribute to the above are hydrogen bonding in the transition state (5), intra-molecular general base catalysis (6), and cyclization in the transition state (7). The contribution of ground-state stabilization towards the α-effect via the repulsion of adjacent lone pairs (8) has been questioned

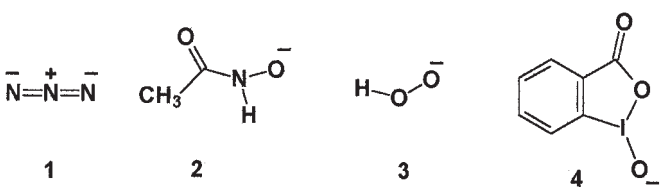
(3, 9) on the grounds that enhancement of nucleophilicity should also lead to an increase in the Brønsted basicity except where transition state stabilization is involved.

Recent literature suggests that stabilization of the transition state is a major factor (10–12) in the manifestation of the α-effect, and a contribution from solvation has been reported (12*b*). The reaction of 4-nitrophenyl acetate with various nucleophiles, such as oximate anions (12*b*, 13), has often been used in such experimental studies, although other reactions, such as that of phosphorylated pyridine monoanions with hydrogen peroxide, acetohydroxamate, and fluoride ions, have been investigated (10).

This work is to study the extent of fission in the C—OAr bond of reactions with substituted phenyl acetates as a function of the α-nucleophile structure and azide ion (**1**–**6**). Change in effective charge is a useful measure of bond formation or fission (14*a*), and there is a substantial body of data that can be used as a standard so that the charge distribution in reactions of nucleophiles with enhanced reactivity can be compared with



1 **2** **3** **4**

5 **6**

that of normal amines and oxyanions. The aim of this paper is to determine if there is a significant electronic difference between reactions of α-nucleophiles with substituted phenyl acetates compared with that of normal nucleophiles of similar pK_a.

Experimental

Materials

The nucleophiles (except hydrogen peroxide) were redistilled or recrystallized from bench-grade materials, and the substituted phenyl acetates were from a previous study or prepared by the method of Chattaway (14*b*). The 3-nitro-phenyl acetate, 4-formyl-phenyl, and 4-acetyl-phenyl acetates were donated by Dr. A.B. Maude. Hydrogen peroxide was of analytical reagent grade and was standardized by titration with $KMnO_4$.

Methods

All solutions were prepared with water double distilled from glass and degassed. Buffer materials were either of A.R. grade or purified before use. A series of buffered solutions for studies of rates at different nucleophile concentrations were prepared by dilution of a stock solution containing the nucleophile with a solution (identical in respect of buffer component concentration, pH, and ionic strength) but without nucleophile. Acetonitrile was added (to give 10% v/v) to counter solubility problems of the ester substrates; footnote *a* in Tables 1–6 gives the identities of the buffer components.

Reactions were initiated by the addition of an aliquot (0.01–0.05 mL) of a solution of the substrate (in acetonitrile) on the tip of a glass rod to 2.5 mL of buffered solution, contained in a 1 cm path-length silica cuvette in the thermostatted cell compartment of either a Pye Unicam SP 800 or a Perkin–Elmer Lambda 5 UV/visible spectrophotometer. A few vertical strokes of the glass rod effected mixing, and the

reaction was followed by monitoring the change in absorbance with time at the optimal wavelength for analysis of the product. The pH values of the solutions were measured before and after each kinetic run using a Radiometer PHM62 meter with a Russell CMAWL combined electrode, calibrated with BDH buffers; data for experiments where the pH changed by more than 0.1 units were discarded.

Pseudo-first-order rate constants were obtained from linear plots of $\log(A_\infty - A_t)$ vs. time where A_t is the absorbance of the solution at the given wavelength at time t. Rate constants were also obtained by fitting the value of A_t (which increases with time in these cases) to the equation $A_t = A_\infty - (A_\infty - A_o)\exp(-kt)$. Ester concentrations employed in the kinetics were between 50 to 100 μM; some of the esters exhibited solubility problems, and for these esters concentrations near the lower limit were employed.

Values of pK_a for the nucleophilic species were determined by pH titration of solutions of the species with standard KOH solutions.

Data were fit to theoretical equations by use of programs operating on an Opus IV or V PC or by use of "grid-search" programs written in BASIC and employing a BBC Master 128 computer.

Results

The reactions of substituted phenyl acetates with the nucleophiles displayed good first-order kinetics for over 90% of the total reaction. The pseudo-first-order rate constants k_{obs} fitted eqn. [1] for all the nucleophiles studied here, and selected examples of the fit are illustrated in Fig. 1.

$$[1] \quad k_{obs} = k_{intercept} + k_2'[\text{total nucleophile}]$$

No buffer effect was observed, as deduced from the linearity of the rate–concentration plots. This was confirmed in the case of the reaction of acetohydroxamate ion with 4-chlorophenyl acetates by observing the effect on the pseudo-first-order rate constant (Fig. 2) of different concentrations of added buffer

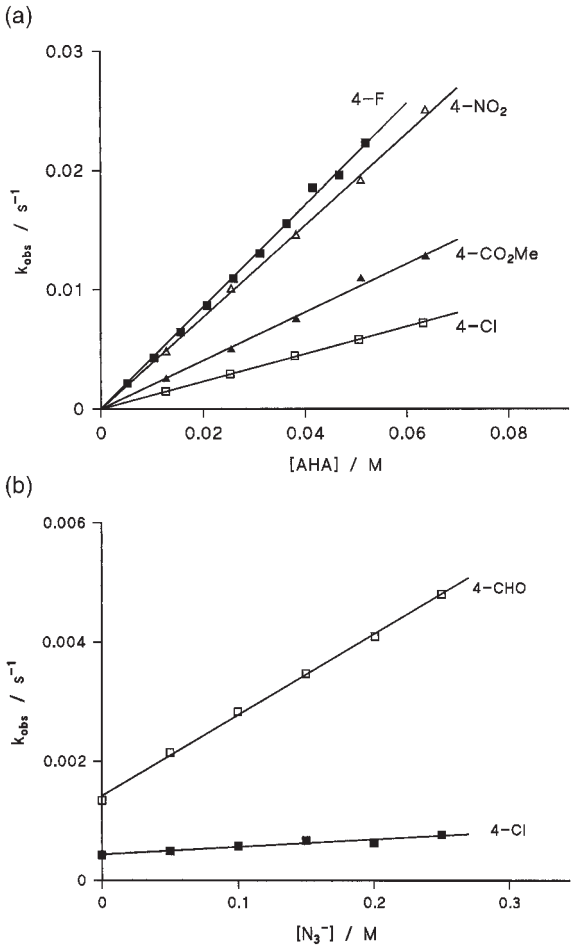
Fig. 1. (*a*) Dependence of k_{obs} on the concentration of aceto-hydroxamic acid for reaction with substituted phenyl acetates. Conditions as in Table 2. (*b*) Dependence of k_{obs} on the concentration of azide ion for reaction with substituted phenyl acetates. Conditions as in Table 1.



species. The second-order rate constants (k_2) were obtained by dividing the slope (k_2') of the rate-concentration plots by the fraction of base (FB) present at the pH of the reaction.

The values of k_2 are collected in Tables 1–6 together with experimental conditions, which include the ranges of nucleophile concentrations and the ranges of observed pseudo-first-order rate constants. The second-order rate constants for the nucleophiles with the 4-nitrophenyl ester agree with the literature values where these are known (1, 2, 8, 15–17).

The reactions of phenolate ions and amines with phenyl acetates involve nucleophilic attack (18). Since the nucleophiles studied here have reactivity close to or greater than that of the corresponding amine or phenolate ion of the same pK_a, it is reasonable that nucleophilic attack rather than general base catalysis of hydrolysis is occurring. Reaction of azide ion with phenyl cinnamates (19) has been demonstrated to be nucleophilic and acetohydroxamate ion has been shown to react as a nucleophile with 4-nitrophenyl acetate (20). The hydroxylamine species react via their oxyanions at the pH values studied here by analogy with the results for the parent hydroxylamine (21).

Fig. 2. The linear correlation of k_{obs} and acetohydroxamate ion-concentration at different HEPES buffer concentrations (○, 100 mM; ■, 50 mM; □, 25 mM) for the attack of the ion upon 4-chlorophenyl acetate. Conditions in Table 2.

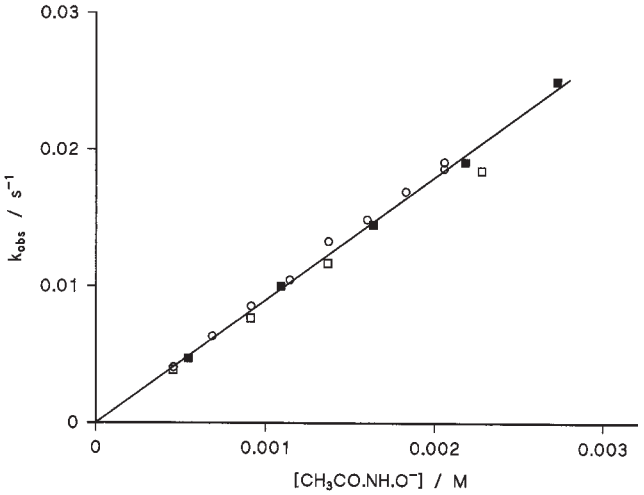


Fig. 3. The Hammett σ and σ⁻ correlations for the attack of the acetohydroxamate ion on substituted phenyl acetates. The conditions of measurement are listed in Table 2. The line is calculated from parameters in Table 7. ■, ▲, calculated from $\sigma + \rho r(\sigma^- - \sigma)$; ▲, resonating substituents; △, Hammett σ⁻ for resonating substituents; ○, Hammett σ value of resonating substituents.

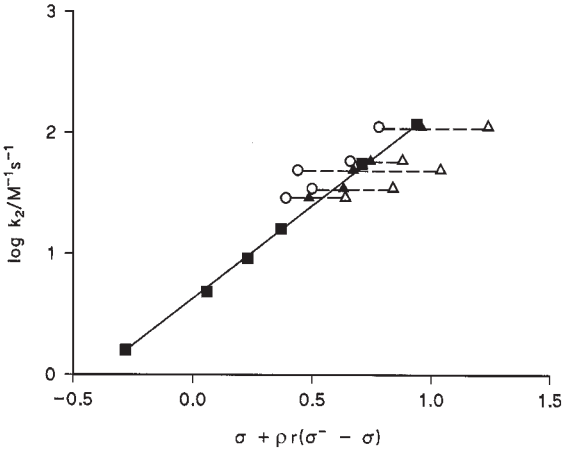

The second-order rate constants were fit to the Hammett eqn. [2], as modified by the Yukawa–Tsuno procedure for assessing resonance effects (22*a*).

[2] $$\log k_{nuc} = \rho\sigma + \rho r(\sigma^- - \sigma) + C$$

An example of the fit to the Yukawa–Tsuno type plot is illustrated in Fig. 3 for reaction of acetohydroxamate ion with phenyl acetates; the resonating substituents in the illustration (Fig. 3) are given sigma constants derived from the equation, sigma = $\sigma + r(\sigma^- - \sigma)$, which reduces to σ for all the non-resonating substituents. The parameters of the equations for each of the reactions in Tables 1–6 are recorded in Table 7.

The Leffler parameters, α_{lg} (Table 7), are obtained by division of the Hammett ρ_{lg} value for the reaction by the ρ_{eq} value

for the equilibrium transfer of the acetyl group from the phenyl ester (3.79) obtained by multiplying the β_{eq} 1.7 (14*a*) by 2.23 (23), the r value for ionization of phenols. The values of the α-effect (see Table 7 for the definition) for the anionic nucleophiles are computed from the rate constants for the reaction of the nucleophiles with 4-nitrophenyl acetates (Tables 1–6), and the rate constants for reaction of 4-nitrophenyl acetate with phenolate ion of the same pK_a are calculated according to the equation: $\log k_{normal} = 0.75pK_a^{ArOH} - 7.28$ (18*a*). The α-effect of the methoxyamine is calculated using the rate constant for reaction of 4-nitrophenyl acetate with a primary amine of the same pK_a determined from the equation calculated from literature data (15):

$$\log k_{normal} = 0.82pK_a^{RNH3} - 7.59$$

Discussion

Reactions of substituted phenyl acetates with azide, acetohydroxamate, iodosobenzoate ions, and methoxyamine fit the Yukawa–Tsuno type equation (eqn. [2]), consistent with a substantial component of bond fission in the transition state (26). Although the general requirements for concerted displacement mechanisms at the acyl centre are known (25*b*) it is not possible to predict concerted or stepwise mechanisms with certainty, although reactions of phenyl esters with anionic nucleophiles are most likely to be concerted (25*b*). The more weakly basic anions (**1**, **2**, and **4**) would be expected to possess more bond fission in the transition state than more basic ones thus giving rise to resonance interaction. Hydrogen peroxide and diethylhydroxylamine oxyanions are more basic, and the transition state of the process would be expected to involve little bond fission and the absence of significant resonance interaction in these cases.

The reactions of **1**, **2**, **3**, **4**, and **6** with 4-nitrophenyl acetate exhibit enhanced reactivity compared with that of analogous "normal" nucleophiles (Table 7). The diminished reactivity of the *N*,*N*-diethylhydroxylamine ion (**5**) is simply ascribed to steric hindrance afforded by the ethyl groups even though the anion is an "α-nucleophile."

The Leffler parameter, α_{lg}, measures the change in effective charge on the leaving atom of the bond undergoing fission normalized by the change in effective charge for complete bond fission. The question of timing of bond fission and formation in the displacement reaction does not alter the conclusions to be obtained from knowledge of α_{lg} concerning bond fission. Molecular orbital theory predicts that the α-effect is dependent on the extent of bond formation between nucleophile and electrophilic centre (8). The theory was originally tested for amine (25*a*) and oxyanion nucleophiles (25*c*), but the data are equivocal. The observation in the case of aminolyses is based on a diverse series of reactions including ester aminolysis, aromatic substitution, alkyl substitution, phosphorolysis, and sulphation. In both amine and oxyanion nucleophiles the extent of bond formation was measured using β_{nuc} values and normalization by use of β_{eq} (14*a*) yields Leffler α_{nuc} values, which indicate a smaller value for bond formation than that expressed by the unnormalized β_{nuc} value.

The values of α_{lg} displayed in Table 7 may be compared with those from the literature for reaction of other nucleophiles with substituted phenyl esters. The α_{lg} values for amino nucleophiles show no correlation or trend and the α-effect of neutral nitrogen nucleophiles have α_{lg} values within the range observed for the regular amines (Fig. 4*a*). In the anion series there is an overall trend in α_{lg} to lower values as pK_a^{nuc} increases (Fig. 4*b*). Within the structurally related phenoxide ion series there is a good correlation between α_{lg} and pK_a (27). The azide ion is included in the oxyanion series simply because of its negative charge. The value of α_{lg} does not appear to be dependent on whether or not the nucleophile has a lone pair on its α-atom.

The role of solvation with regard to the α-effect remains a subject of controversy (3, 9). The range of α-effect enhancements, from 1 to 60 for amines (25*a*), is scarcely at levels to be regarded as energetically significant, and the deviations are within the range that might be expected for solvation effects. Similar arguments may be recruited for reactions of oxyanion α-nucleophiles, which exhibit enhancements corresponding to

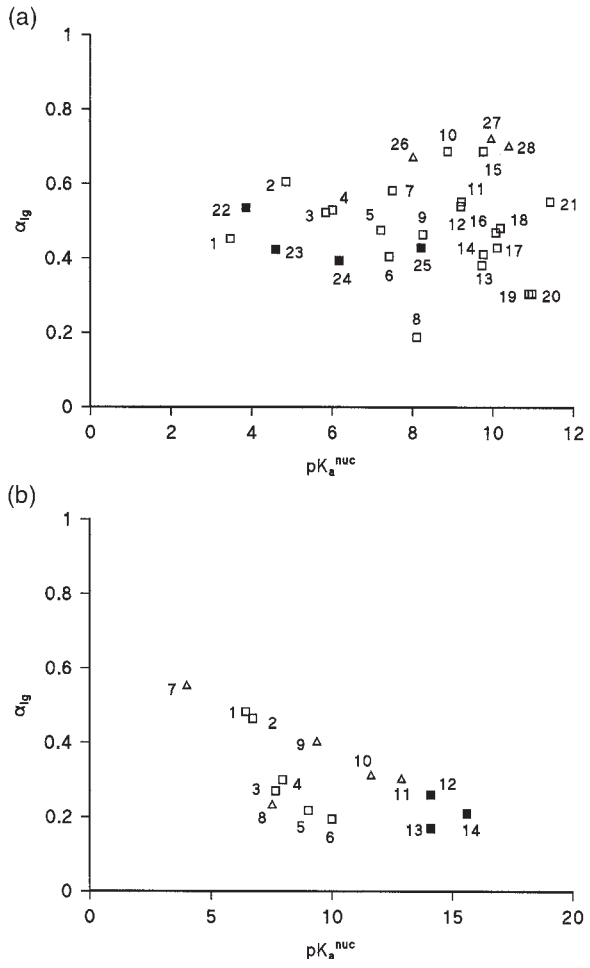
Data is taken from Table 7 and calculated from data from refs. 15, 17, 30, and 33. ■, α-effect nitrogen; △, small ring nitrogen; □, primary, secondary, and tertiary amines. (*b*) Leffler's α_{lg} for attack of oxyanions on substituted phenyl acetates. Identities of the ions are as follows: 1, 2,3,5-trichlorophenolate; 2, 2,4,5-trichlorophenolate; 3, 4-formylphenolate; 4, 4-cyanophenolate; 5, 3-chlorophenolate; 6, phenolate; 7, azide; 8, 2-iodosobenzoate; 9, acetohydroxamate; 10, hydroperoxide; 11, *N*,*N*-diethylamino-oxy; 12, pentaerythritol (oxyanion); 13, tris(hydroxymethyl)aminomethane (oxyanion); 14, hydroxide. Data is taken from Table 7 and calculated from data from refs. 27 and 34. △, α-effect anions; □, phenolate ions; ■, alkoxide and hydroxide ions.



small energy differences. The α-effect is not manifest in a gas-phase reaction (22*b*) and is, therefore, caused by solvation, but it has also been suggested that the α-effect is less significant for low values of β_{nuc}; since a gas-phase reaction would be expected to have a low β_{nuc}, the absence of the α-effect is not surprising (3). Recent studies by Um and co-workers (22*c*) have shown that an α-effect is not apparent in the reaction of nitrophenyl acetates with α-nucleophiles in the presence of cetyltrimethylammonium bromide (CTAB), but is present in acetonitrile containing solutions (12*b*). It was concluded that solvation has a role in the manifestation of the α-effect. A desolvation effect was proposed by Terrier and co-workers (13) to account for the small Brønsted β_{nuc} obtained in the reaction of 4-nitrophenyl acetate and oximate anions of high pK_a. The reaction was considered to involve a rate-limiting desolvation of the nucleophile followed by a fast addition step. This explanation could, in part, explain the low α-effect of *N*,*N*-diethylhydroxylamine.

Deviations of nucleophiles from Brønsted and Hammett correlations have been discussed for many reactions, and these can have values of the same order as those ascribed to the α-effect (15, 28–31) while not possessing the structural requirements of the "α-nucleophile." When the rigorous test of hypernucleophilicity, discussed by Hoz and Buncel (3), is applied to many α-nucleophiles the enhancements are not substantial enough in our view to warrant a unique name, especially since nucleophiles without a lone pair on the α-atom can also exhibit similar enhancements of reactivity. The lower limit of rate enhancement commonly accepted as significant is about 50-fold (24), and this is larger than many α-effects in the amine series (25*a*). Prior to Hoz and Buncel's paper (3) the reactivity of the hydroxide ion nucleophile was employed as a standard, and it is now accepted that due to a solvation effect this nucleophile has a lower reactivity than its Brønsted basicity would predict. The enhanced reactivity of hydroperoxide ion over hydroxide ion is of significant practical importance, but a large component of the explanation must be due to the depressed activity of the latter ion due to solvation. It must be remembered that an α-effect (Table 7) remains for the hydroperoxide ion when a phenoxide ion is employed as the normal nucleophile in the α-effect calculation.

The acetate ion has two formal lone pairs of electrons on the oxygen atom β to the nucleophilic oxygen, and these could interact to cause an enhanced reactivity, as discussed for other similar nucleophiles (32). However, the nucleophilic reactivity of acetate ion towards 4-nitrophenyl acetate is only 0.016 of that of a phenolate of similar pK_a, even before it is statistically corrected for two possible centres. The most probable cause of the difference in reactivity is a solvation effect on the acetate ion, causing it to have substantial steric requirements compared with that of phenoxide ions.

We propose that the case for a special electronic explanation of the α-effect is not proven in view of the relatively small α-effects observed and the lack of any substantial difference between Leffler's α-parameter and those for normal nucleophiles of similar pK_a. Since the stability of the nucleophile component is independent of that of the electrophile in the ground state, it is clear that any effects on reactivity of hypernucleophiles relative to those of "regular" ones must be a result of differences in stability induced in the transition state where electrophile and nucleophile interact with each other.

Abstract: Syntheses and negative solvatochromism of two new lipophilic pentaphenyl pyridinium *N*-phenolate betaine dyes, substituted with seven *tert*-butyl groups (**9**) or with three *tert*-butyl and two 1-adamantyl groups (**13**) in the peripheral phenyl rings, are described in order to get zwitterionic dyes that are more soluble in nonpolar solvents such as the standard betaine dye, **1**, which has been used for the construction of an empirical scale of solvent polarity, called the E_T(**30**) scale.

Key words: betaine dyes, E_T(**30**) values, lipophilic dyes, pyridinium *N*-phenolate betaine dyes, solvatochromism, solvent polarity.

Résumé : On décrit les synthèses et la solvatochromie négative de deux colorants bétaïnes lipophiles, le *N*-phénolate de pentaphényl pyridinium, dans lesquels les noyaux benzéniques périphériques sont respectivement substitués par sept groupes *t*-butyles (**9**) et trois groupes *t*-butyles ainsi que deux groupes 1-adamantyles (**13**). Ces produits ont été préparés dans le but d'obtenir des colorants zwitterioniques plus solubles dans les solvants non polaires que le colorant bétaïne standard, **1**, et ils ont été utilisés pour élaborer une échelle empirique de polarité de solvant appelée échelle E_T(**30**).

Mots clés : colorants bétaïnes, valeurs E_T(**30**), colorants lipophiles, colorants bétaïnes *N*-phénolate de pyridinium, solvatochromie, polarité de solvant.

[Traduit par la rédaction]

Introduction

Solutions of pyridinium *N*-phenolate betaine dyes such as **1** and **2** (Scheme 1) exhibit the phenomena of solvatochromism, thermochromism, piezochromism, and halochromism.[3] That means the longest wavelength, intramolecular charge-transfer (CT) absorption band of their UV-vis absorption spectra depends on solvent polarity, solution temperature, external pressure, and on the nature and concentration of added salts. The extraordinarily large negative solvatochromism of the standard pyridinium *N*-phenolate betaine dye **1** has been used to establish UV-vis spectroscopically derived empirical parameters of solvent polarity, called E_T(**30**) values (3).[4] The E_T(**30**) values are simply defined as the molar electronic transition energies (in kcal/mol) of the standard betaine dye **1**, measured in solvents of different polarity at room temperature (25°C) and normal pressure (1 bar) (1 bar = 100 kPa), according to eq. [1].

$$[1] \quad E_T(\mathbf{30})\ (\text{kcal/mol}) = hc\nu_{max}N_A = 2.8591(10^{-3})\nu_{max}\ (\text{cm}^{-1}) = 28\,591/\lambda_{max}\ (\text{nm})$$

where ν_{max} is the frequency and λ_{max} the wavelength of the maximum of the longest wavelength, intramolecular CT

absorption band of betaine dye **1**. In the first publication (3*a*), the betaine dye **1** had, by chance, the formula number **30**. Therefore, the number (**30**) was later added in order to avoid confusion with E_T, which has been often used as an abbreviation for triplet energy in photochemistry. High E_T(**30**) values correspond to high solvent polarity (here defined as the overall solvation capability of a solvent[5]) and vice versa. The E_T(**30**) values are known for more than 360 solvents and for numerous binary solvent mixtures (4*d*, 6).[4] These and other empirical parameters of solvent polarity have been successfully used in the correlation analysis of solvent effects on chemical equilibria, reaction rates, and spectral absorptions (6).

The E_T(**30**) scale ranges from 63.1 kcal/mol for water, as the most polar solvent, to 30.7 kcal/mol for tetramethylsilane (TMS), as the least polar solvent. That means, a solvent change from water to TMS reduces the electronic excitation energy of the dissolved indicator dye **1** by 32.4 kcal/mol, caused by the differential solvation of the strongly dipolar ground state and the considerably less dipolar excited state of **1**. To avoid the non-SI unit kcal/mol, in 1983 the normalized E_T^N scale was introduced and defined according to eq. [2] (7).

$$[2] \quad E_T^N = \frac{E_T(\text{solvent}) - E_T(\text{TMS})}{E_T(\text{water}) - E_T(\text{TMS})} = \frac{E_T(\text{solvent}) - 30.7}{32.4}$$

The dimensionless E_T^N scale ranges now from 1.000 for water to 0.000 for TMS and is easier to handle, particularly in multiparameter equations (4*d*).[4]

The prerequisite to the measurement of E_T(**30**) and the resp. E_T^N values was the synthesis of the more lipophilic penta-*tert*-butyl-substituted betaine dye **2**, which is, in contrast to **1**, sufficiently soluble in nonpolar solvents such as aliphatic hydrocarbons and TMS. The excellent linear correlation between the E_T values of **1** and **2** for solvents in which both dyes are soluble allows the calculation of E_T(**30**) values, according to eq. [3] for nonpolar solvents in which the primary indicator dye **1** is not soluble enough. In eq. [3],

$$[3] \quad E_T(\mathbf{30}) \text{ (kcal/mol)} = (28\,591/\lambda'_{max}\text{ (nm)} - 1.808)/0.9424$$

λ'_{max} corresponds to the wavelength of the visible absorption maximum of the secondary indicator dye **2** (7).

[5] For a recent pragmatic definition of the term "solvent polarity" see ref. 5.

Nevertheless, the solubility of the penta-*tert*-butyl-substituted betaine dye **2** in nonpolar solvents is rather small, and the corresponding UV-vis spectroscopical measurements are sometimes cumbersome (see, for examples, ref. 1 and footnote 6). In perfluorohydrocarbons, **2** is completely unsoluble. Therefore, we have tried to obtain new, suitably substituted, solvatochromic betaine dyes, which are more lipophilic and hopefully more soluble in nonpolar solvents. In this paper, we describe the syntheses and UV-vis spectroscopic properties of two new negatively solvatochromic pyridinium *N*-phenolate betaine dyes, **9**, with seven *tert*-butyl groups, and **13**, with three *tert*-butyl and two 1-adamantyl groups in the peripheral phenyl groups of **1** (8). The increase in the number of lipophilic alkyl groups, corresponding to an increase in dispersion interactions with the solvent, and the introduction of bulky alkyl groups, distorting the crystal lattice of the betaine dyes, should lead to a better solubility of **9** and **13** in nonpolar solvents. The introduction of such lipophilic bulky substituents into the peripheral aryl groups of the already heavily twisted chromophore of **1** (9)[7] should not disturb its long-wavelength solvatochromic CT absorption.

Results and discussion

Syntheses of the substituted betaine dyes 9 and 13

The synthesis of betaine dye **9** is outlined in Scheme 2. The chalcone **5**, prepared from 3,5-di(*tert*-butyl)acetophenone **3** (10) and 4-(*tert*-butyl)benzaldehyde **4** (11)[8] by a base-catalyzed Aldol condensation reaction, undergoes in perchloric acid-containing solution an acid-catalyzed Michael addition with **3**, forming an intermediate nonisolated 1,5-diketone, which closes the ring to the new pyrylium salt **6** (12, 13). Condensation of **6** with 4-amino-2,6-bis[4-(*tert*-butyl)phenyl]phenol **7** (7) leads to the *N*-(4-hydroxyphenyl)pyridinium salt **8**, which, on deprotonation with sodium methanolate in methanol, gives the desired betaine dye **9** in good yield as black–green crystals, which contain some water of crystallization.

The preparation of the betaine dye **13** is shown in Scheme 3. 4-(Adamantane-1-yl)acetophenone **10** is synthesized from 1-phenyladamantane by Friedel–Crafts acylation with $CH_3COCl/AlCl_3$ (14). The latter is obtained by Friedel–Crafts alkylation of benzene with 1-bromoadamantane (14), which is prepared by bromination of adamantane (15). Synthesis of the pyrylium salt **11** analogous to **6** (cf. Scheme 2) from the corresponding chalcone (from **10** and **4**) and **10** leads to **11** with a yield of ca. 15% only (8). Therefore, another method first described by Dorofeenko and Krivun (16) was employed: condensation of two moles of **10** with one mole of **4** (11)[8] with aqueous perchloric acid (70% w/w) in Ac_2O/AcOH gives immediately the pyrylium salt **11** with a yield of 55% after recrystallization. Further condensation of **11** with the 4-aminophenol 7 (7) leads analogously to the *N*-(4-hydro-

Solvatochromic properties of the betaine dyes 9 and 13

The positions of the solvatochromic long-wavelength intramolecular CT absorption band of dyes **9** and **13** in various solvents of different polarity (as measured by the E_T(**30**) values (4*d*)[4]) are compiled in Table 1, together with the corresponding electronic transition energies E_T(**9**) and E_T(**13**) in kcal/mol. In analogy to the prior standard betaine dyes **1** and **2**, both new dyes **9** and **13** exhibit also an extraordinary negative solvatochromism: the intramolecular CT absorption band of **9** and **13** is hypsochromically shifted by $\Delta\lambda \approx 400$ nm (!) in changing the solvent from polar 1,2-ethanediol to nonpolar cyclohexane. This corresponds to an increase of their molar transition energies E_T of about 24 kcal/mol (or ca. 1 eV). With increasing solvent polarity, the highly dipolar ground state of these betaine dyes is increasingly stabilized by differential solvation, relative to the less dipolar CT excited state, with the observed hypsochromic band shift as consequence.

The completely analogous solvent-dependent behaviour of the new betaine dyes **9** and **13** with respect to standard dye **1**, necessary for their use as further standard betaines, is demonstrated by the good linear correlation between the E_T(**30**) values of **1** and the E_T values of **9** and **13** (Table 1), as exemplarily shown for the hepta-*tert*-butyl-substituted betaine dye **9** in Fig. 1. The correlation line of Fig. 1 follows eq. [4]:

[4] E_T(**9**) (kcal/mol) = 0.9084E_T(**30**) (kcal/mol) + 2.670

where pairs of values $n = 28$, correlation coefficient $r = 0.9961$, standard deviation of the estimate $s = 0.6886$. The analogous linear correlation between the E_T(**30**) and E_T(**13**) values is given by eq. [5]:

[5] E_T(**13**) (kcal/mol) = 0.9312E_T(**30**) (kcal/mol) + 2.438

where $n = 28$, $r = 0.9988$, $s = 0.3927$.

By means of these two equations, it is easily possible to calculate the empirical parameter of solvent polarity E_T(**30**) for those nonpolar solvents in which the standard betaines **1** and **2** are not sufficiently soluble. The excellent linear correlations between E_T(**30**) and the E_T values of both new betaine dyes **9** and **13** allow such calculations with great accuracy. The slope of the correlation lines as described by eqs. [4] and [5] is only a little smaller than unity, thus demonstrating that the

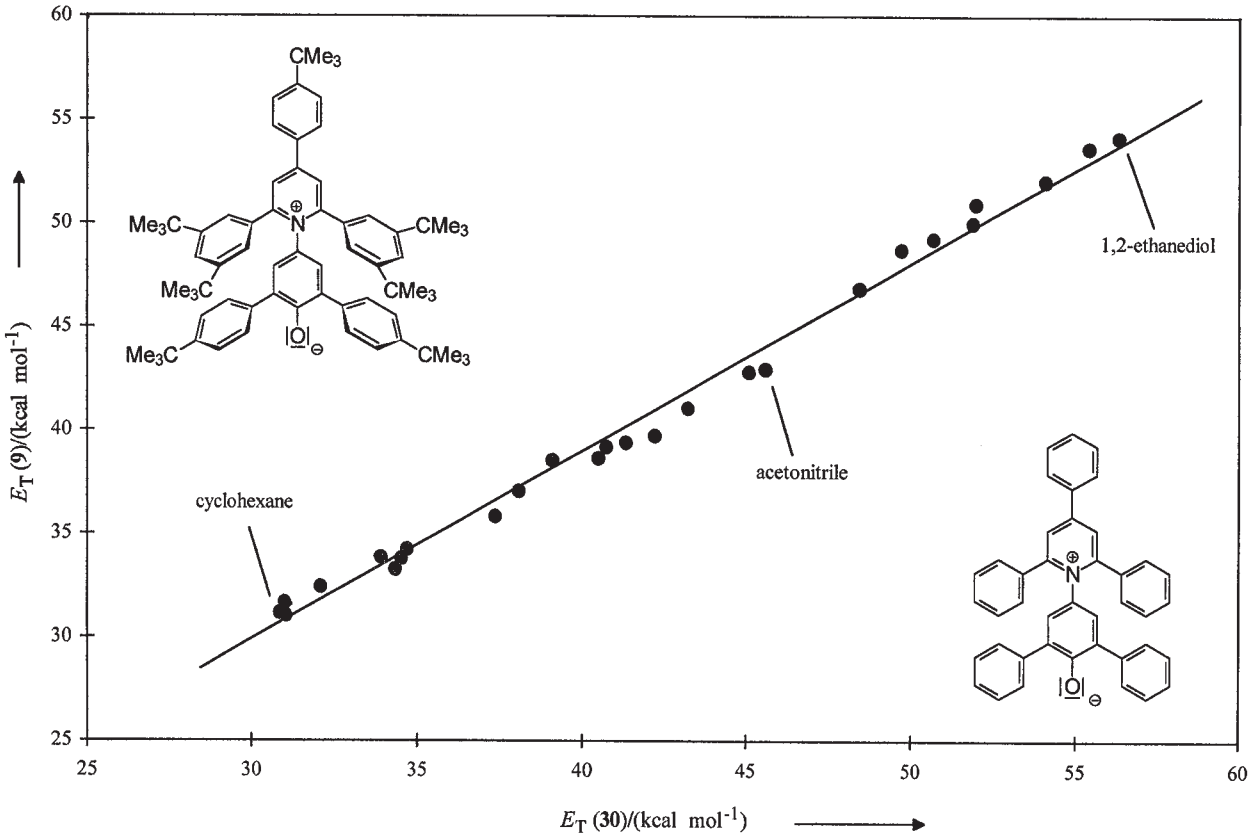
Fig. 1. Linear correlation between the E_T(**30**) values of standard betaine dye **1** and the E_T(**9**) values of the hepta-*tert*-butyl-substituted betaine dye **9** (cf. eq. [4]).



susceptibility of the light absorption of dyes **9** and **13** against a solvent change is nearly the same as for the standard dye **1**.

The introduction of more lipophilic and bulky alkyl substituents into the basic betaine chromophore **1** increases indeed the solubility of **9** and **13** in nonpolar solvents such as the hydrocarbons (e.g., *n*-hexane, *n*-pentane, cyclohexane, etc.), particularly for **9**. Therefore, the use of dyes **9** and **13** can be recommended for UV-vis spectroscopic studies of the polarity of such nonpolar solvents and their mixtures. More recently, dyes **2** and **9** have been used for the determination of the solvation capability of supercritical carbon dioxide (sc-CO_2) at various pressures and temperatures (1).[6] According to these measurements, the E_T(**30**) values of sc-CO_2 are comparable with the values for hydrocarbons such as *i*-octane (1).[6] However, to our disappointment, both new dyes are not soluble in perfluorohydrocarbons (also called perfluorocarbons, PFCs), the least polar solvents, which recently gain more and more interest as inert media for organic reactions and spectroscopic measurements (17). The introduction of a third 1-adamantyl group into the *para*-position of the 4-phenylpyridinium ring of dye **13** failed because we could not repeat the synthesis of the necessary 4-(adamantan-1-yl)benzaldehyde (18).

Conclusion and further considerations

Two new negatively solvatochromic betaine dyes **9** and **13** were prepared in good yield in four-step syntheses from easily available starting materials. Introduction of seven *tert*-butyl groups (**9**) or three *tert*-butyl and two 1-adamantyl groups (**13**) into the basic pentaphenyl pyridinium *N*-phenolate chromophore of **1** led to the desired increased solubility of these zwitterionic dyes in nonpolar solvents (except perfluorohydrocarbons). This and the excellent linear correlation between the molar electronic transition energies E_T of **9** and **13** with the E_T(**30**) values of the standard dye **1** make these new dyes potentially useful for the UV-vis spectroscopic determination of the empirical solvent polarity parameter E_T(**30**) for nonpolar solvents and solvent mixtures.

The particular structure of the betaine dyes **1**, **2**, **9**, and **13** (i.e., high permanent dipole moment, large polarizable π-electron system, strong electron-pair donor center Ar-O^s) enables them to interact with surrounding solvent molecules by means of nonspecific dipole–dipole, dipole – induced dipole, and dispersion interactions as well as specific hydrogen-bonding and electron-pair donor (EPD) – electron-pair acceptor (EPA) interactions. Therefore, the dissolved betaine dyes experience a rather complex combination of solute–solvent interactions, and the corresponding E_T values measure preferably the dipolarity and polarizability, the hydrogen-bond donating (HBD) capacity, and the Lewis acidity of solvents. An analysis of the E_T(**30**) values by means of the "master" eq. [6] for the empirical treatment of solute–solvent interactions, introduced by Kamlet and Taft (19*a*) in 1976, leads to eq. [7], as has been recently shown by Marcus (20).

$$[6] \quad XYZ = (XYZ)_0 + s\pi^* + a\alpha + b\beta + m\delta_H^2$$

$$[7] \quad E_T(\mathbf{30}) = 31.2 + 11.5\pi^* + 15.2\alpha$$

where n = 166 solvents, r = 0.979, $s[E_T(\mathbf{30})]$ = 2.1 kcal/mol

© 1998 NRC Canada

The XYZ value resp. $(XYZ)_0$ is the solvent-dependent physicochemical solute property under investigation in a given solvent and in the gas phase (or in an inert solvent). The π^*, α, and β values are UV-vis spectroscopically derived solvatochromic parameters measuring the dipolarity and polarizability of the solvent, its HBD capacity, and its hydrogen-bond accepting (HBA) capability, respectively. The value δ_H is Hildebrand's solubility parameter, accounting for the intermolecular solvent–solvent interactions, which must be overcome in producing a cavity in the solvent in order to accommodate the solute molecules. Since electronic transitions are not accompanied by a change in molar volume of the absorbing solute on excitation, the δ_H term drops out in application of eq. [6] to the correlation of solvent effects on spectra.

According to eq. [7] (20), the mutual interaction between the solvatochromic probe molecule **1** and solvent molecules is mainly determined by a blend of nonspecific dipolarity and polarizability interactions (as measured by π^*) as well as specific solute – HBD solvent interactions (as measured by α). The solute – HBA solvent interaction term, β, drops out in going from eq. [6] to [7]; that is, the HBA properties and the Lewis basicity of the solvents are not measured by the probe molecule **1**. The positive charge of the pyridinium moiety of **1** is delocalized and shielded by the peripheral phenyl groups, and a specific interaction with EPD solvent molecules is not possible. Hence, the betaine probe molecule **1** (as well as **2**, **9**, and **13**) measures in HBD solvents mainly the HBD acidity and Lewis acidity of the solvents: the ratio of regression coefficients of α and π^* in eq. [7] is $\alpha/\pi^* = 1.32$. In non-HBD solvents with $\alpha = 0$, the E_T(**30**) values are mainly determined by the nonspecific dipolarity and polarizability interactions. A recent thermodynamic analysis of the E_T(**30**) polarity scale comes to analogous conclusions (21). The unexpected success of the E_T(**30**) scale in correlating solvent effects of all kinds of organic solvent-dependent processes (cf. ref. 6)[3,4] stems from the fact that the composition of intermolecular solute–solvent interactions is for these processes often similar to that as described by eq. [7].

If in addition to the Lewis acidity the Lewis basicity of the solvents comes into the solvation play, then a two-parameter equation such as eq. [8], introduced by Krygowski and Fawcett (22) in 1975, should be used in the correlation of solvent effects.

$$[8] \quad XYZ = (XYZ)_0 + aE_T(\mathbf{30}) + b\mathrm{DN}$$

where DN is Gutmann's donor number, obtained by measuring the heat of reaction of the solvent with the strong Lewis acid $SbCl_5$ dissolved in 1,2-dichloroethane. Other Lewis basicity parameters can also be used; a critical compilation of solvent Lewis basicity parameters has been recently given by Gritzner (23). A linear correlation of solvent-dependent physicochemical solute properties with E_T(**30**) alone can only be expected if in eq. [8] $b = 0$. The E_T(**30**) values describe empirically the solvation capability (which is equal to solvent polarity)[5] of solvents as representatively experienced by the dissolved betaine dye **1** (as well as **2**, **9**, and **13**), representative for a large number of other solvent-dependent processes.

Experimental

General

The betaine dyes **1** and **2** were prepared according to the procedures described in refs. 3*a* and 24 (**1**) and 7 (**2**). Dye **1** is also commercially available (see advertisements in ref. 25).[9] For UV-vis and NIR measurements, the double-beam spectrophotometers U-3410 (Hitachi) and Omega 20 (Bruins Instruments) with 1 cm quartz cells SUPRASIL (Hellma) were used. Solvents were used as commercially supplied in the highest available quality (analytical or spectroscopic grade) and were additionally dried and purified by means of molecular sieves and, if necessary, by filtration through a column of basic alumina, activity grade I, in order to remove traces of acids. For the solvatochromic measurements, the solvents must be acid-free. Otherwise, the betaine dyes are (reversibly) protonated at the phenolate oxygen atom, and the long-wavelength solvatochromic CT absorption band disappears. Infrared spectra were obtained with the Interferometer IFS 88 (Bruker) with KBr discs. The ^1H and ^{13}C nuclear magnetic resonance spectra were performed on the spectrometer AC-300 (Bruker) in $CDCl_3$ or CD_3CN, with tetramethylsilane as an internal standard. Mass spectra were determined with the spectrometers MAT CH-7A (Varian) with electron impact (EI) and MAT 711 (Varian) with field desorption (FD) technique. Melting points were measured with a Kofler–Mikroheiztisch (Reichert) and are corrected. Elemental analyses were determined with the CHN-Rapid (Heraeus) by the Analytik-Servicelabor of the Department of Chemistry, Marburg.

Synthesis of the hepta-*tert*-butyl-substituted betaine dye 9

*3,5-Di(*tert*-butyl)acetophenone,* ***3***

In a three-necked, round-bottom 500 mL flask with dropping funnel, stirrer, and a reflux condenser with drying tube, magnesium ethanolate was prepared from magnesium turnings (4.62 g, 0.19 mol), dry ethanol (4.50 mL), and dry tetrachloromethane (0.45 mL). After addition of dry diethyl ether (70 mL) with stirring, a mixture of dry diethyl malonate (30.4 g, 29 mL, 0.19 mol), dry ethanol (18 mL), and dry diethyl ether (23 mL) was added, and the whole was heated under reflux for 3 h to give the ethoxymagnesium derivative of diethyl malonate. A solution of 3,5-di(*tert*-butyl)benzoyl chloride (50.6 g, 0.20 mol; prepared from 3,5-di(*tert*-butyl)benzoic acid and thionyl chloride) in diethyl ether (50 mL) was then added and heating under reflux was continued for 50 min. After cooling to room temperature, the mixture was made acidic by diluted sulfuric acid, and the two phases formed were separated. In the organic phase, some crystals of the intermediate acyl diethyl malonate were already formed; they were isolated by filtration and dissolved in diethyl ether. The aqueous phase was several times extracted with diethyl ether. The volume of the combined ethereal solutions of 3,5-di(*tert*-butyl)benzoyl diethyl malonate was reduced in a rotary evaporator until a suspension was obtained. This suspension was added to a mixture of acetic acid (54 mL), concentrated sulfuric acid (7 mL), and water (36 mL), and the whole was heated under reflux for 5 h until the hydrolysis and decarboxylation was finished. After cooling with an ice bath, the solution was made alkaline by addition of an aqueous NaOH solution (20% w/w), and the two phases formed were separated. The aqueous phase was

[9] Sigma–Aldrich Chemical Co., Milwaukee, Wisconsin, U.S.A. Order no. 27244–2; Fluka Chemie AG, Buchs/Switzerland. Order no. 43358.

© 1998 NRC Canada

extracted with diethyl ether. The combined ethereal phases were dried with Na_2SO_4 and filtered, the ether was distilled off in a rotary evaporator, and the oily residue was subjected to fractional distillation under reduced pressure (oil pump) to give **3** (10.10 g, 22%) as colorless crystals with mp 38°C (ref. 10*a,* 38.6–39.0°C).

*1-[3,5-Di(*tert-*butyl)phenyl]-3-[4-(*tert-*butyl)phenyl]-prop-2-en-1-one,* ***5***

A mixture of **3** (2.32 g, 10 mmol), 4-(*tert*-butyl)benzaldehyde **4** (11)[8] (1.62 g, 10 mmol), and sodium methanolate in methanol (10% w/w, 15 mL) was stirred at room temperature until stirring was impossible due to crystallization of the product. The reaction mixture was washed with water until the washing water was neutral. Recrystallization from methanol–water (3:1) gives **5** (3.19 g, 85%) as light yellow needles with mp 74°C. IR (KBr): 1651 cm^{-1} (C═O); ^1H NMR ($CDCl_3$) δ: 1.34 and 1.38 (27H, two close s, all CMe_3), 7.43–7.60 (6H, m, *p*-H of 1-phenyl, *o*- and *m*-H of 3-phenyl, β-CH), 7.66 (1H, d, ^3J = 15.7 Hz, α-CH), 7.81 (2H, d, ^4J = 6.9 Hz, *o*-H of 1-phenyl); ^{13}C NMR ($CDCl_3$) δ: 31.1 [*p*-C($\underline{C}H_3)_3$], 31.4 [*m*-C($\underline{C}H_3)_3$], 34.9 (*p*-$\underline{C}Me_3$), 35.0 (*m*-$\underline{C}Me_3$), 122.3 (*o*-C of 1-phenyl), 122.7 (α-CH), 125.9, 126.8, and 128.2 (aromatic C), 132.4 (ipso-C of 1-phenyl), 138.1 (ipso-C of 3-phenyl), 144.4 (β-CH), 151.2 (*m*-$\underline{C}$-CMe_3), 154.0 (*p*-$\underline{C}$-CMe_3), 191.8 (C═O); MS (EI, 70 eV) *m/z* (%): 376 (100) [M^+]; $C_{27}H_{36}O$ (376.6) calcd.: C 86.12, H 9.64; found: C 85.37, H 9.45.

*2,6-Bis[3,5-di(*tert-*butyl)phenyl]-4-[4-(*tert-*butyl)phenyl]-pyrylium perchlorate,* ***6***

A solution of ketone **3** (0.32 g, 1.36 mmol) and chalcone **5** (0.96 g, 2.55 mmol) in 1,2-dichloroethane (3.5 mL) in a three-necked, round-bottom 100 mL flask, equipped with stirrer, dropping funnel, and reflux condenser, was warmed to 70–75°C, and then aqueous perchloric acid (70% w/w; ca. 0.3 mL) was added dropwise during 30 min. First, the mixture became orange; subsequently the colour changed to brownish yellow. After the addition was completed, the mixture was heated under reflux for 1 h. Then, the solvent was distilled off in a rotary evaporator, and the solid residue was dissolved in diethyl ether (50 mL). This solution was added dropwise to *n*-pentane (400 mL), the yellow precipitate was filtered off, dried, recrystallized from ethanol–water (2:1), and dried with P_4O_{10} to give **6** (0.37 g, 39% related to **3**) as yellow microcrystalline powder with mp 312°C. ^1H NMR ($CDCl_3$) δ: 1.37 and 1.45 (45H, two close s, all CMe_3), 7.74–8.27 (10H, m, aromatic H), 8.49 (2H, s, 3/5-H of pyrylium ring); ^{13}C NMR ($CDCl_3$) δ: 30.9 [*p*-C($\underline{C}H_3)_3$], 31.3 [*m*-C($\underline{C}H_3)_3$], 35.3 (all $\underline{C}Me_3$), 114.5 (C-3/5 of pyrylium ring), 122.7 (*o*-CH of 2,6-phenyl), 126.6 (*m*-CH of 4-phenyl), 126.8 (*p*-CH of 2,6-phenyl), 128.5 (*o*-CH of 4-phenyl), 129.7 (ipso-C of 2,6-phenyl), 130.0 (ipso-C of 4-phenyl), 153.3 ($\underline{C}$-CMe_3 of 2,6-phenyl), 160.0 ($\underline{C}$-CMe_3 of 4-phenyl), 167.5 (C-4 of pyrylium ring), 171.1 (C-2/6 of pyrylium ring); MS (FD) *m/z* (%): 589 (100) [$M^+ - ClO_4$]; $C_{43}H_{57}C1O_5$ (689.3) calcd.: C 74.92, H 8.33; found: C 74.19, H 8.10.

*4-[4-(*tert-*Butyl)phenyl]-2,6-bis[3,5-di(*tert-*butyl)phenyl]-1-{4-hydroxy-3,5-bis[4-(*tert-*butyl)phenyl]phenyl}pyridinium perchlorate,* ***8***

A solution of pyrylium salt **6** (0.30 g, 0.43 mmol), 4-amino-2,6-bis[4-(*tert*-butyl)phenyl]phenol **7** (7) (0.19 g, 0.51 mmol), and water-free sodium acetate (0.29 g, 3.50 mmol) in dry ethanol (15 mL) was heated under reflux for 2.5 h in a three-necked, round-bottom 50 mL flask with stirrer, reflux condenser, and dropping funnel. To the still warm solution, aqueous perchloric acid (70% w/w, 0.70 mL, 8.2 mmol) was added with stirring. Then, the solvent was distilled off in a rotary evaporator, and the brown oily residue was dissolved in 1,2-dichloroethane (ca. 3 mL). This solution was added slowly to petroleum ether (bp 40–60°C, 300 mL). The yellow precipitate formed was filtered off. The crude product was recrystallized from methanol–water (2:1) and dried with P_4O_{10} at 80°C in vacuo (ca. 10^{-3} Torr) (1 Torr = 133.3 Pa) to give **8** (0.24 g, 54%) as light yellow microcrystalline powder with mp 345°C. IR (KBr): 3500 cm^{-1} (OH); UV-vis (CH_3CN) λ_{max} (log ε): 240 (4.092), 323 nm (4.024); ^1H NMR ($CDCl_3$) δ: 1.21, 1.31, and 1.42 (63 H, three close s, all CMe_3), 5.50 (1H, s, OH), 6.89–7.87 (16H, m, aromatic H and 3/5-H of phenol ring), 7.87–8.58 (4H, m, AA′BB′ system, aromatic H of 4-phenyl ring), 8.19 (2H, s, 3/5-H of pyridinium ring); ^{13}C NMR ($CDCl_3$) δ: 31.1 and 31.2 (all C($\underline{C}H_3)_3$), 35.0 and 35.2 (all $\underline{C}Me_3$), 123.8, 124.7, 125.5, 125.8, 126.7, and 128.3 (aromatic CH), 128.4 (C-3/5 of phenol ring), 128.9, 129.4, and 130.2 (quaternary aromatic C), 132.1 (C-3/5 of pyridinium ring), 132.3 (C-4 of pyridinium ring), 132.9 (C-2/6 of phenol ring), 149.5 (C-4 of phenol ring), 151.1, 151.5, and 155.7 (quaternary aromatic $\underline{C}$-CMe_3), 157.3 (C-2/6 of pyridinium ring), 157.4 (C-OH); MS (FD) *m/z* (%): 945 (100) [$M^+ - ClO_4$]; $C_{69}H_{86}ClNO_5$ (1044.9) calcd.: C 79.31, H 8.30, N 1.34; found: C 79.14, H 8.35, N 1.23.

*4-{4-[4-(*tert-*Butyl)phenyl]-2,6-bis[3,5-di(*tert-*butyl)phenyl]-1-pyridinio}-2,6-bis[4-(*tert-*butyl)phenyl]phenolate,* ***9***

To a stirred solution of perchlorate **8** (0.22 g, 0.21 mmol) in dry methanol (50 mL) a methanolic sodium methanolate solution (10% w/w, 1.3 mL) was added at room temperature, during which the solution changed from yellow to a dark colour. After heating under reflux for 3 min., cooling to room temperature, and filtration, the dark solution was poured into aqueous NaOH (10% w/w, 300 mL). After standing for ca. 12 h in a refrigerator, the precipitate formed was filtered off and dried with P_4O_{10} in vacuo. Purification by multiple hot extraction with 200 mL of boiling methanol–water (2:1) gave, after drying with P_4O_{10} at 70°C and 10^{-3} Torr in a drying pistol, betaine **9** (0.20 g, 95%) as black–green crystals with mp 239–240°C, which still contain ca. four moles water of crystallization. IR (KBr): 3550 cm^{-1} (OH from water); UV-vis (CH_3OH) λ_{max} (log ε): 321 (4.300), 327 (4.297), and 533 nm (3.106); UV-vis (CH_3CN): 317 (4.262), 379 (3.611), and 667 nm (3.251); ^1H NMR ($CDCl_3$) δ: 1.26, 1.29, and 1.39 (63H, three close s, all CMe_3), 2.96 (ca. 2H, broad s, H_2O), 6.67 (2H, s, 3/5-H of phenolate ring), 6.93–7.28 (14H, m, aromatic H), 7.52–7.91 (4H, m, AA′BB′ system, aromatic H of 4-phenyl ring), 8.17 (2H, s, 3/5-H of pyridinium ring), ^{13}C NMR ($CDCl_3$) δ: 31.1 and 31.2 (all C($\underline{C}H_3)_3$), 34.5 and 35.0 (all $\underline{C}Me_3$), 123.8, 124.7, 125.6, 125.7, 126.8, and 128.4 (aromatic CH), 128.5 (C-3/5 of phenolate ring), 128.8, 129.5, and 130.2 (quaternary aromatic C), 132.1 (C-3/5 of pyridinium ring), 132.2 (C-4 of pyridinium ring), 132.9 (C-2/6 of phenolate ring), 149.5 (C-4 of phenolate ring), 151.1, 151.6, and 155.7 (quaternary aromatic $\underline{C}$-CMe_3), 157.3 (C-2/6 of pyridinium ring), 157.4 (C-O^-); MS (FD) *m/z*

Synthesis of the bis(adamantan-1-yl)-substituted betaine dye 13

4-(Adamantane-1-yl)acetophenone, ***10***

To a stirred solution of water-free aluminium trichloride (10.67 g, 0.08 mol) in dry trichloromethane (40 mL) acetylchloride (6.28 g, 0.08 mol) was added dropwise at 0–10°C. To this suspension was then dropwise added with stirring at –10°C a solution of 1-phenyladamantane (12.74 g, 0.06 mol) (prepared from 1-bromoadamantane (26)[10] and benzene, according to ref. 15) in dry trichloromethane (40 mL). After standing at room temperature for ca. 12 h, the mixture was carefully poured into ice water (200 mL). The precipitate of aluminium trihydroxide was dissolved by adding a small amount of concentrated HCl, and the two phases formed were separated. The aqueous phase was extracted twice with trichloromethane. The combined organic phases were washed with water, aqueous NaOH (2% w/w), again with water, and dried with K_2CO_3. The trichloromethane was distilled off and the residue was recrystallized from petroleum ether (bp 40–60°C) to give **10** (5.02 g, 33%) as colourless crystals with mp 106°C (ref. 14, 105–107°C).

*2,6-Bis[4-(adamantane-1-yl)phenyl]-4-[4-(*tert*-butyl)phenyl]-pyrylium perchlorate,* ***11***

To a solution of **10** (1.40 g, 5.50 mmol) and 4-(*tert*-butyl)benzaldehyde **4** (0.45 g, 2.75 mmol) (11)[8] in acetic acid (5.0 mL) and acetic anhydride (0.30 mL) was added aqueous perchloric acid (0.3 mL, 70% w/w), and the mixture was heated under reflux for 90 min. After cooling to room temperature, the dark brown solution was dropwise poured into diethyl ether (250 mL). The yellow precipitate was filtered off, recrystallized from methanol–water (3:1), and dried to give **11** (1.10 g, 55%) as yellow microcrystalline powder with mp 263°C. ^{1}H NMR ($CDCl_3$) δ: 1.40 (9H, s, CMe_3), 1.82–2.12 (30H, m, adamantyl-H), 7.70–7.78 (12H, m, aromatic H), 8.31 (2H, s, 3/5-H of pyrylium ring); ^{13}C NMR ($CDCl_3$) δ: 29.6 (CH_2 of adamantyl groups), 31.1 [$C(\underline{C}H_3)_3$], 37.0 ($\underline{C}Me_3$), 43.1 (CH of adamantyl groups), 115.1 (C-3/5 of pyrylium ring), 125.5, 127.4, 127.9, and 129.4 (aromatic CH), 130.5 (ipso-C of 2/6-phenyl rings), 130.8 (ipso-C of 4-phenyl ring and C-1 of adamantyl groups), 160.5 ($\underline{C}$-CMe_3), 160.6 (aromatic $\underline{C}$-adamantyl), 165.7 (C-4 of pyrylium ring), 170.8 (C-2/6 of pyrylium ring); MS (FD) *m/z* (%): 633 (100) [M^+ – $C1O_4$]; $C_{47}H_{53}C1O_5$ (733.4) calcd.: C 76.97, H 7.28; found: C 77.84, H 7.28.

*2,6-Bis[4-(adamantane-1-yl)phenyl]-4-[4-(*tert*-butyl)phenyl]-1-{4-hydroxy-3,5-bis[4-(*tert*-butyl)phenyl]phenyl}pyridinium perchlorate,* ***12***

A solution of pyrylium salt **11** (1.17 g, 1.60 mmol), 4-amino-2,6-bis[4-(*tert*-butyl)phenyl]phenol **7** (7) (0.70 g, 1.87 mmol), and water-free sodium acetate (0.29 g, 3.50 mmol) in dry ethanol (15 mL) was heated under reflux for 2.5 h in a three-necked, round-bottom 50 mL flask with stirrer, reflux condenser, and dropping funnel. To the still warm solution, aqueous perchloric acid (70% w/w, 0.70 mL, 8.2 mmol) was added with stirring. Then, the solvent was distilled off in a rotary evaporator, and the residue was dissolved in acetone (50 mL). This solution was added slowly to petroleum ether (bp 40–60°C, 300 mL). The yellow precipitate was filtered off. The crude product (1.50 g) was recrystallized from methanol–water (4:1) and dried with P_4O_{10} at 80°C in vacuo (ca. 10^{-3} Torr) to give **12** (1.40 g, 80%) as light yellow microcrystalline powder with mp 297–299°C. IR(KBr): 3526 cm^{-1} (OH); UV-vis (CH_3CN) λ_{max} (log ε): 237 (3.553), 324 nm (3.503); ^{1}H NMR ($CDCl_3$) δ: 1.35 and 1.42 (27 H, two s, all CMe_3), 1.53–2.10 (30H, m, adamantyl-H), 5.60 (1H, s, OH), 6.94 (2H, s, 3/5-H of phenol ring), 6.97–7.43 (16 H, m, aromatic H), 7.54–7.86 (4H, m, AA′BB′ system, aromatic H of 4-phenyl ring), 8.10 (2H, s, 3/5-H of pyridinium ring); ^{13}C NMR ($CDCl_3$) δ: 28.8 (CH_2 of adamantyl groups), 31.1 (all $C(\underline{C}H_3)_3$), 36.4 (all $\underline{C}Me_3$), 42.9 (CH of adamantyl groups), 121.3, 125.2, 125.9, and 126.0 (aromatic CH), 126.7 (CH_2 of adamantyl groups), 128.3 (ipso-C of 2/6-phenyl rings at the pyridinium ring), 128.7 (aromatic CH), 128.9 (C-3/5 of phenol ring), 129.4 (ipso-C of 4-phenyl ring at the pyridinium ring), 129.9 (C-1 of adamantyl groups), 130.8 (ipso-C of 2,6-phenyl rings at the phenol ring), 131.6 (C-3/5 of pyridinium ring), 131.9 (C-4 of pyridinium ring), 132.3 (C-2/6 of phenol ring), 149.8 (C-4 of phenol ring), 151.4 ($\underline{C}$-CMe_3 of 4-phenyl ring), 153.7 ($\underline{C}$-CMe_3 of 2/6-phenyl rings at the phenol ring), 155.8 (aromatic $\underline{C}$-adamantyl), 156.7 (C-2/6 of pyridinium ring), 157.2 (C-OH); MS (FD) *m/z* (%): 989 (100) [M^+ – ClO_4]; $C_{73}H_{82}ClNO_5$ (1088.9) calcd.: C 80.52, H 7.59, N 1.29; found: C 79.95, H 7.49, N 1.10.

*4-{2,6-Bis[4-(adamantane-1-yl)phenyl]-4[4-(*tert*-butyl)phenyl]-1-pyridinio}-2,6-bis[4-(*tert*-butyl)phenyl]phenolate,* ***13***

To a stirred solution of perchlorate **12** (1.09 g, 1.00 mmol) in dry methanol (100 mL) a methanolic sodium methanolate solution (10% w/w, 2.6 mL) was added at room temperature, during which the solution changed from yellow to a dark colour. After heating under reflux for 3 min., cooling to room temperature, and filtration, the dark solution was poured into aqueous NaOH (10% w/w, 300 mL). After standing for ca. 12 h in a refrigerator, the precipitate formed was filtered off and dried with P_4O_{10} in vacuo. Purification by multiple hot extraction with 200 mL of boiling methanol–water (2:1) gave, after drying with P_4O_{10} at 70°C and 10^{-3} Torr in a drying pistol, betaine **13** (0.97 g, 95%) as black–green crystals with mp 265–267°C, which still contain ca. 1.5 moles water of crystallization. IR (KBr): 3500 cm^{-1} (OH from water); UV-vis (methanol) λ_{max} (log ε): 326 (4.283) and 528 nm (3.211); UV-vis (CH_3CN): 379 (4.280) and 641 nm (3.977); ^{1}H NMR ($CDCl_3$) δ: 1.30 and 1.38 (27H, two s, all CMe_3), 1.72–2.10 (30H, m, adamantyl-H), 6.46 (2H, s, 3/5-H of phenolate ring), 7.12–7.47 (16H, aromatic H), 7.59–7.77 (4H, m, AA′BB′ system, aromatic H of 4-phenyl ring at the pyridinium ring), 8.02 (2H, s, 3/5-H of pyridinium ring); ^{13}C NMR ($CDCl_3$) δ: 28.8 (CH_2 of adamantyl groups), 31.4 (all $C(\underline{C}H_3)_3$), 36.6 (all $\underline{C}Me_3$), 42.9 (CH of adamantyl groups), 118.4, 124.0, 125.0, and 125.6 (aromatic CH), 126.9 (CH_2 of adamantyl groups), 127.3 (ipso-C of 2/6-phenyl rings at the pyridinium ring), 127.6 (aromatic CH), 128.9 (C-3/5 of phenolate ring), 129.1 (ipso-C of 4-phenyl ring at the pyridinium ring), 130.4 (C-3/5

[10] 1-Bromoadamantane is meanwhile also commercially available (Acros, Aldrich, Fluka, Lancaster).

Primary and secondary 5-(alkyloxy)thianthrenium perchlorates. Characterization with ^{1}H NMR spectroscopy, reactions with iodide and bromide ion, and thermal decomposition in solution

Wenyi Zhao and Henry J. Shine

Abstract: A series of 5-(alkyloxy)thianthrenium perchlorates has been made in which the alkyl group is primary (**1a**–**1p**) and secondary (**2a**–**2g**). Preparations were carried out by reaction of the corresponding alkanol with thianthrene cation radical perchlorate in CH_2Cl_2 solution followed by precipitation of the perchlorate salt with dry ether. ^{1}H NMR spectroscopy reveals that the presence of a stereogenic center in the alkyl group causes inequivalence in the ordinarily paired protons (e.g., H-4, H-6) of the thianthrenium ring. Reaction of iodide and bromide ion with primary alkyl-group compounds (e.g., methyl, ethyl, propyl, butyl) gave the alkyl halide in very good yield and by a second-order kinetic displacement. The second product was thianthrene 5-oxide (ThO). Rate constants for some of these reactions are reported. Reaction of secondary alkyl group compounds (e.g., 2-propyl, 2-pentyl, 2-hexyl, and 3-hexyl) with iodide ion gave good yields of alkyl iodide but also increasing evidence for a side reaction at the sulfonium sulfur, leading to I_2, thianthrene, and secondary alkanol. Decomposition of some compounds at 100°C in solution (acetonitrile or 1,2-dichloroethane) was studied and gave alkene(s) and ThO.

Key words: thianthrene cation radical, 5-(alkyloxy)thianthrenium perchlorates.

Résumé : On a préparé une série de perchlorates de 5-(alkyloxy)thianthrénium portant des groupes alkyles primaires (**1a–1p**) et secondaires (**2a–2g**). On a réalisé ces préparations en faisant réagir les alcanols correspondants avec le chlorate du cation radical thianthrène en solution dans du CH_2Cl_2 et en faisant ensuite précipiter le sel de perchlorate dans de l'éther anhydre. La spectroscopie RMN du ^{1}H révèle que la présence d'un centre stéréogène dans le groupe alkyle provoque une inéquivalence dans les protons généralement pairés (par exemple, H-4 et H-6) du noyau thianthrénium. Par un déplacement cinétique du premier ordre, la réaction des ions iodure et bromure avec les composés incorporant des groupes alkyles primaires (par exemple, méthyle, éthyle, propyle ou butyle) conduit à l'halogénure d'alkyle avec un très bon rendement alors que le deuxième produit est le 5-oxyde de thianthrène (ThO). On rapporte les constantes de vitesse d'un certain nombre de ces réactions. La réaction de l'ion iodure avec les composés comportant un groupe alkyle secondaire (par exemple, prop-2-yle, pent-2-yle, hex-2-yle et hex-3-yle) donne de bons rendements d'iodure d'alkyle; toutefois, on observe une augmentation d'une réaction secondaire au niveau de l'atome de sulfonium qui conduit à la formation de I_2, de thianthrène et d'alcanol secondaire. On a étudié la décomposition de certains de ces composés à 100°C, en solution (acétonitrile ou 1,2-dichloroéthane); elles conduisent à des alcènes et à du ThO.

Mots clés : cation radical du thianthrène, chlorhydrates de 5-(alkyloxy)thianthrénium.

[Traduit par la rédaction]

Introduction

The reactions of thianthrene cation radical ($Th^{\bullet+}$) with a diverse number of nucleophiles have been well documented during the last 20 or more years. Reaction occurs mainly at a sulfur atom and occasionally at a ring position (1–3). The reaction with water has been particularly well studied and it

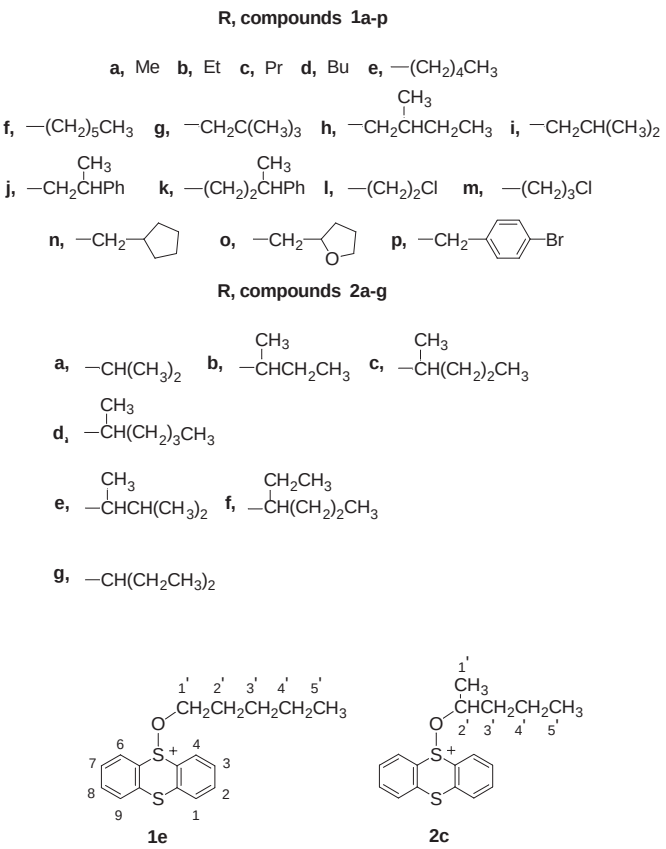
Scheme 1.



served as a model of the kinetics and mechanism of such reactions (1–4). In contrast, little was known until recently (5, 6) of the reaction of alcohols with $Th^{\bullet+}$. We have shown that thianthrene cation radical perchlorate ($Th^{\bullet+}ClO_4^-$) reacts readily with primary and secondary alcohols to form 5-(alkyloxy)thianthrenium perchlorates (eq. [1]).

When reaction was carried out in CH_2Cl_2 solution, the perchlorate salt could be precipitated easily by addition of ether. We have, in this way, reported the isolation, structure, and thermal decomposition of some 5-(cyclohexyloxy)thianthrenium perchlorates (5, 6). It was shown in these studies that when the cyclohexyl ring was stereogenic at its 1-position, inequivalence in ^1H and ^{13}C chemical shifts of the remote thianthrenium ring positions resulted.

We have now studied the reaction with alcohols in more depth and report here the isolation of a series of 5-(alkyloxy)thianthrenium perchlorates in which the alkyl group is primary (**1a**–**1p**) and a series in which it is secondary (**2a**–**2g**), Scheme 1. Inequivalence of aromatic ring protons where the alkyl group is stereogenic at its attachment to the oxygen atom is again recorded in the ^1H NMR spectra of **2a**–**2g**. In the spectra of some of compounds **1**, a similar effect is caused by stereogenicity at an even more remote position in the alkyl group. Reaction of compounds **1** having linear alkyl groups R with I^- and Br^- was essentially quantitative so that rates of formation of RI and RBr could be measured. Reaction of compounds **2a, 2c, 2d,** and **2f** with I^- also gave high yields of the alkyl iodides but small amounts of alkene were formed as well. Thermal decomposition of compounds **2** in solution was reasonably straightforward and is reported here. In contrast, we have been unable to quantify satisfactorily products of the thermal decomposition of several examples of **1** and further investigation of those reactions is in progress. Only decomposition of **1h** is reported.

^1H NMR spectra

Chemical shifts (δ) and coupling constants (*J*) are listed for convenience in Tables 1 and 2 (primary R) and Tables 3 and 4 (secondary R). Characteristics in δ for the thianthrenium protons are similar to some that have been noted recently (2). That is, where R is astereogenic, signals from four sets of equivalent protons are obtained, and the overall ^1H NMR spectrum is similar in most respects to that of thianthrene 5-oxide (ThO) but with shifts that are relatively further downfield (2). The presence of a stereogenic center in **2b–2f** can be seen in unequal shifts for H-4 and H-6 (**2b, 2e**), within each of sets H-4, -6 and H-2, -8 (**2c**), and H-4, -6, H-2, -8, and H-3, -7 (**2f**). Inequivalence in H-4 and H-6 resulted in two sets of doublet of doublets (dd) signals, while inequivalence in H-2 and H-8 and in H-3 and H-7 resulted in two groups of overlapping triplet of doublets (td) signals. The absence of inequivalence in the spectrum of **2a** with its small astereogenic isopropyl group, and of **2g** with its larger 3-pentyl group, is evident. Remarkably, the stereogenic center in **1j, 1k,** and **1o**, even more remote from the thianthrenium ring than in **2b**–**2f**, caused inequivalence in the H-4, -6 thianthrenium protons (**1j, 1k,**and **1o**) and H-3, -7 protons (**1o**) (Table 1). Inequivalence in more distant pairs H-2, -8, and H-1, -9 was, however, not found in **1j, 1k,** and **1o**. The effect of the stereogenic center in **1k** on nearby diastereotopic protons H-1′ and H-2′ was also seen. With **1h** only H-1′, and not H-4, -6, was affected by the stereogenic center.

In one respect, the NMR spectra of many of the compounds **1** differ from those of compounds **2** and the compounds of our earlier report (2). Coupling of H-3 with H-1, H-2, and H-4, i.e., H-3(2,4), 3(1), no longer led to a td, but to two sets of dd, namely, H-3(2), H-3(1) (equivalent to H-7(8), H-7(9)), and H-3(4), H-3(1) (equivalent to H-7(6), H-7(9)). This was the case with **1a, 1c**–**1f**, **1h, 1i**, and **1l**–**1o**. The expected td were observed in **1b** and **1g**.

As found earlier as well (2), δ for the -OC*H*$_2$ protons in compounds **1** and the –OC*H* proton in **2** were approximately 1 ppm downfield from the analogous proton in the corresponding alcohol. In the footnotes of Table 1 and Table 3 are listed the characteristics of signals from the alkyl-group protons.

Reactions with I^- and Br^-

Reactions with I^- were carried out in an acetonitrile solution of KI. Because KBr is itself not readily soluble in acetonitrile, it was used in conjunction with 18-crown-6. As a second source of Br^-, the more soluble Bu_4NBr was used.

[a]Protons are listed in order of decreasing δ. For example, H-4 (before H-6) coupling with H-3, a doublet; and H-2 (before H-8) coupling with H-1 and H-3, a triplet.

[b]In Hz; coupling constants are averages when more than one value was measured. For example, the coupling pattern for H-4 in **1a** was a dd, so that coupling with H-2 gave two doublets with averaged J = 1.13 Hz.

[c]Overlapping peaks obscured coupling.

[d]In **1b**, for example, H-3 coupling equally with H-2 and H-4, and H-7 coupling equally with H-6 and H-8, leading to a triplet of doublets, δ = 7.770 ppm. In contrast, in **1c**, for example, coupling of H-3 with H-2 was not the same as coupling with H-4. Similarly, coupling of H-7 with H-6 was not the same as coupling with H-8, leading therefore to two sets of doublet of doublets, δ = 7.768 ppm.

[e]H-3 coupled equally with H-2 and H-4, leading to a triplet of doublets, δ = 7.757 ppm.

[f]Coupling of H-7 with H-6 was not the same as coupling with H-8, leading therefore to two sets of doublet of doublets, δ = 7.736ppm.

conversion in rate measurements. Some of the latter are reported in Tables 5 and 6 (e.g., runs 5 and 12 of Table 5), and in those cases we assayed also the alcohol (ROH) that was formed by reaction of the remaining **1** with the aqueous quench solution. Reaction of compounds **2** with I^- also gave good yields of alkyl iodide but not as close to quantitative as those

[a]Protons are in order of decreasing δ. For example, H-4 (before H-6) coupling with H-3; and H-2 (before H-8) coupling with H-1 and H-3, a triplet.

[b]In Hz; coupling constants are averages when more than one value was measured. For example (**2c**), the coupling pattern for H-4 was a dd so that coupling with H-2 gave two doublets with averaged *J* = 1.28 Hz.

[c]Average of *J* = 0.99 and 1.35.

[d]Resolution too poor to measure *J*.

of compounds **1**. Instead, small amounts of alkene were formed by a competitive bimolecular elimination, frequently designated as E_2C for eliminations by weakly basic nucleophiles (7, 8). Elimination, like substitution, gave ThO as the accompanying product, shown schematically in eq. [3], so that ThO is reported in the tables. Table 5 lists small amounts of I_2 and thianthrene (Th). These arose from reaction of I^- at sulfonium sulfur in compounds **1** and **2**, shown schematically in eq. [4]. Iodine was assayed by conventional iodometry after

[2]

[3] 
[4] 
quenching the reaction solution with aqueous K_2CO_3. Table 6 lists, analogously, small amounts of Th and Br_2. We were unable, however, to assay Br_2 directly. Instead, it was converted into I_2 by addition of KI to the dry acetonitrile solution after reaction of **1** with Br^- was completed. I_2 was then assayed in the usual way, but is expressed as Br_2 in Table 6. In principle, the sum of amounts of alkyl halide and alkene (where formed) should be equal to the amount of ThO. Also, the amounts of Th and X_2 should be the same. For the most part these equalities are borne out by the data in the tables.

Rates of reaction (Table 7) were measured by quenching aliquots of the reaction solution with aqueous K_2CO_3 and assaying the amount of alkyl halide by GC. Good second-order rate plots were obtained, and led to the second-order rate constants listed in Table 7. These show the typical ordering expected of S_N2 displacements, namely Me > Et > Pr > Bu, pentyl, hexyl > isoPr (9). Rate constants of reactions with Br^- are somewhat larger than those of reactions with I^-. This can be attributed to our measuring rates in an aprotic solvent (10) or may have been caused by differences in counterion (11). The significance of the data of Tables 5–7 is in the demonstration of clean S_N2 displacements with **1** and **2**, the driving force being the departure of a good leaving group, ThO.

In accordance with S_N2 principles, displacement of the

neopentyl group from 5-(neopentyloxy)thianthrenium perchlorate (**1g**) by iodide ion did not occur. Instead, iodide ion reacted slowly at the sulfonium sulfur atom with the formation of Th, I_2, and neopentyl alcohol, eq. [4]. Details in the experimental section show that solutions containing **1g** and I^- decomposed to neopentyl iodide when injected onto the GC column, but that the only solution-reaction products were as shown in eq. [4].

Thermal decompositions

Compounds **1** and **2** are stable to storage as solids and in dry solution. They decompose when heated in solution, forming alkenes and ThO. We report here (Table 8) the decomposition of **1h**, **2d,** and **2f** in 1,2-dichloroethane (DCE) and of **2e** in MeCN. Solvent MeCN was avoided for the most part because amides were formed in it along with the major alkene products, and the amides had broad, poorly shaped GC peaks that were not suited to reliable assay. The formation of amides was diagnostic of carbonium ion intermediates, and that diagnosis is also made from rearrangement alkenes in some of the examples reported here. The solutions were heated in sealed ampules at 100°C and, after cooling, aliquots were taken for GC analysis both before and after quenching with a small amount of aqueous K_2CO_3 solution. The data in Table 8 are from solutions that had been quenched. Heated solutions contained a small excess of 2,6-di-*tert*-butyl-4-methylpyridine (DTBMP) over the amount of substrate to prevent acid-catalyzed decompositions, and appropriate GC standards. In principle, only alkene and ThO in equal amounts should be formed in thermal decomposition. Thianthrene (Th) should not be formed, and the origin of the small amounts in Table 8 is unknown.

© 1998 NRC Canada

The only primary-alkyl-group compound in Table 8 is **1h**. From this, both 2-methyl-1- (40%) and 2-methyl-2-butene (51%) were obtained, the latter arising from rearrangement during decomposition. Rearrangement is also indicated in the formation of 2-methyl-1-butene (19%) from **2e**. From **2d** only *cis*- (28%) and *trans*-2-hexene (70%) were obtained, that is, unaccompanied by evidence of rearrangement. No 1-hexene was found. Isomeric **2f** gave both 2- and 3-hexenes. In that case, we could not distinguish by GC among *cis*- and *trans*-3-hexene and *trans*-2-hexene. We obtained 17% of *cis*-2-hexene and, if we assume that the same ratio of *cis*- and *trans*-2-hexenes was formed from **2f** as from **2d**, the mixture of inseparable hexenes from **2f** should have contained about 43% of *trans*-2-hexene. The addition of aqueous K_2CO_3 as a quench was to destroy any **1h** or **2d**–**2f** that was not decomposed in the heated solution. Undecomposed substrate would have decomposed to alkene in an uncontrolled way when injected onto the column. Reaction with aqueous K_2CO_3 converts **1** and **2** into ThO and the corresponding alcohol. Our assays (Table 8) did not show the presence of an alcohol in any quenched thermal reaction solution, attesting to the completeness of the thermal reaction.

Experimental section

Acetonitrile (MeCN, Eastman HPLC grade) was dried by distillation from CaH_2 and, again, from P_2O_5, each under N_2. 1,2-Dichloroethane (DCE) was from Baker Chemical Co, and was distilled from P_2O_5. Dichloromethane (CH_2Cl_2) was distilled from P_2O_5. All alcohols were from commercial sources, as were most of the authentic alkyl bromides and iodides. Neopentyl-, 2-pentyl-, and 2- and 3-hexyl iodides were prepared by reaction of the alcohols with iodotrimethylsilane, and had acceptable ^{1}H NMR spectra. All authentic alkenes, except 2-methyl-1-butene from Phillips Petroleum Co., were from Wiley Organics (now ChemSamp Co.), and were obtained as individual geometric isomers (where appropriate). Quantitative gas chromatographic (GC) assays were made with a Varian Associates model 3700 instrument attached to a Spectra Physics model 4290 recorder-integrator. Five columns were used, each of 1/8 in. (0.3175 cm) stainless steel: A, 10% OV-101 on 80–100 mesh Chrom-WHP, 4 ft (1.22 m); B, 10% Carbowax 20M on Chrom-WHP, 6 ft (1.83 m); C, 10% OV-17 on 80–100 mesh Chrom-Q11, 6 ft; D, 20% BEEA on 60–80 mesh Chrom PAW, 6 ft; E, 20% BEEA, on 60–80 mesh Chrom PAW, 8 ft (2.44 m). The conditions of usage of the columns were as follows: for A and C, injector at 250°C, detector at 300°C, oven at 50°C for 2 min and then ramped at 12°/min to 250°C; for B and D, initially similar settings but ramped only to 100°C; for E, ramping was omitted and the column was kept at 50°C. GC assays were made with the use of predetermined concentration factors for authentic compounds and internal standards: naphthalene for A and C; 2-butanone, acetone, or butyl methyl ether, as appropriate, for B; 2-butanone for D; and acetone for E.

Preparation of compounds 1 and 2

An example is given with **1a**.$Th^{\bullet+}ClO_4^-$ (253 mg, 0.80 mmol), *warning about explosiveness* (12), was weighed into a 50 mL flask containing a magnetic stirrer, and to this was added 15 mL of CH_2Cl_2. The flask was capped with a septum through which was added by syringe, after 5 min of stirring, an excess (2.1 mmol) of methanol in 5 mL of CH_2Cl_2. Stirring was continued at room temperature until the color of $Th^{\bullet+}$ had disappeared, about 15 h. The yellow solution was concentrated to about 5 mL on a rotary evaporator and was diluted with 25 mL of dry ether. The white precipitate of **1a** was filtered, washed three times with dry ether, and dried in air. Preparation of all other compounds was carried out in the same way except that higher concentrations of reactants were used and that, for **1p,** all procedures were conducted in an ice bath prior to concentration and dilution with ether. Compounds **1j**, **1k,** and **1m** were oils; they were reprecipitated from CH_2Cl_2 with ether and dried by pumping over P_2O_5. The times of stirring the reactants (h), % yield, and mp (dec.) °C of products were: **1a**, 15, 61, 93–96; **1b,** 2, 76, 91–107; **1c**, 2.5, 76, 70–90; **1d**, 1.5, 79, 87–90; **1e**, 1.5, 70, 85–86; **1f**, 1.0, 63, 64–65; **1g**, 7.5, 79, 105–123; **1h**, 1.0, 92, 88–90; **1i**, 1.5, 94, 91–94; **1j**, 3, 94, oil; **1k**, 1, 79, oil; **1i**, 72, 66, 69–71; **1m**, 26, 97, oil; **1n**, 1, 76, 89–91; **1o**, 5, 79, 82–84; **1p**, 7, 42, 71–74; **2a**, 2, 63, 82–84; **2b**, 2, 81, 76–82; **2c**, 3.5, 72, 72–73; **2d**, 2.5, 47, 68–70; **2e**, 2, 52, 75–77; **2f**, 2.5, 76, 84–86; **2g**, 4, 65, 75–80. Each of these compounds had a satisfactory ^{1}H NMR spectrum.

Reactions with iodide ion

An example is given with **1a**. Into a 5 mL volumetric flask containing a magnetic stirrer was weighed 36.4 mg (0.105 mmol) of **1a**. Measured amounts of internal GC standards naphthalene and acetone were added, followed by filling to the mark with a stock solution of KI in dry MeCN so as to provide 0.394 mmol of KI. The flask was capped with a septum and the solution was stirred at room temperature for 75 min, when 0.60 mL of 2 M aqueous K_2CO_3 was injected through the septum. Aliquots for GC assay were taken on column A for Th and ThO and on column B for MeI, giving 0.00192 mmol (1.8%) of Th, 0.104 mmol (99%) of ThO, and 0.104 (99%) of MeI. The solution was then titrated with aqueous sodium thiosulfate, giving 0.00152 mmol (1.5%) of I_2. This reaction was replicated three times. The averaged results are given in Table 5. Similar experiments were carried out with other 5-(alkyloxy)thianthrenium perchlorates (Table 5). All assays of Th and ThO were on column A. Assays of ethyl-, propyl-, and 2-propyl iodide, ethanol, 2-propanol, and propene were on column B, while assays of all other alkyl iodides were on column A.

Reaction of 5-(neopentyloxy)thianthrenium perchlorate (1g) with KI

A stirred solution of 47.9 mg (0.119 mmol) of **1g** and 166 mg (1.00 mmol) of KI in 5 mL of MeCN containing naphthalene and 2-butanone as GC standards was sampled for GC assay at 40, 160, and 350 min. 2-Methyl-1-butene (14.9, 12.2, 10.9%), 2-methyl-2-butene (19.9, 16.5, 15.5%), neopentyl iodide (35.3, 45.4, 31.5%), Th (31.1, 35.3, 37.0%), and ThO (68.1, 67.2, 58.0%) were obtained. After the solution had been stirred for 25 h, 0.30 mL of 2 M K_2CO_3 was added and stirring was continued for 7 h. GC assay gave 2-methyl-1-butene (0.21%), 2-methyl-2-butene (0.57%), Th (31.9%), and ThO (65.9%). No neopentyliodide was found. Neopentyl alcohol was formed but its GC peak overlapped that of the solvent, and assay was not possible. I_2 was titrated in the usual way, and gave 0.036 mmol (30.3%).

A second experiment gave, after 315 min of reaction and

© 1998 NRC Canada

stirring with K_2CO_3 for 30 min, 0.33% and 0.89% of the alkenes, 0.34% of neopentyliodide, 22% of Th, 72% of ThO, and 21% of I_2. The formation of the small amounts of alkenes and neopentyl iodide is assumed to stem from decomposition on the column of some residual **1g**.

Reactions with tetrabutylammonium bromide (TBAB)

An example is given with **1b** (run 3, Table 6). Into a 5 mL volumetric flask containing a magnetic stirrer were weighed measured amounts of naphthalene and **1b**. To this was added 5 mL of a 0.0716 M solution of TBAB in MeCN. The flask was capped with a septum and, after 10 min of stirring, a measured amount of GC standard acetone was injected. Aliquots were taken for GC assay. The solution was stirred for 2.5 h and 0.5 g of KI was added. The liberated I_2 was titrated as described.

Reactions with KBr/18-crown-6

A procedure similar to that with TBAB was followed with a solution of MeCN that was 0.0716 M in KBr and 0.132 M in 18-crown-6. Assays were conducted in the same way.

For GC assays of products of bromide ion reactions, column C rather than A was used for Th and ThO, because TBAB overlapped with Th on column A. Column B was used for assaying alkyl bromides except for bromopentane, which was assayed on column C. All results are listed in Table 6.

Measurement of rates of reaction

A, with KI

An example is given with **1a**. Into a 25 mL flask containing a magnetic stirrer were placed 358 mg (0.103 mmol) of **1a**, 27.8 mg (0.217 mmol) of naphthalene, and 0.02 mL (0.272 mmol) of acetone. The flask was made up to volume with a 5.18×10^{-3} M solution of KI in MeCN, and then was capped with a septum. The solutes dissolved rapidly. Aliquots of 4 mL were taken at 45, 75, 135, 195, and 315 s. Each aliquot was discharged into a screw-cap vial containing a magnetic stirrer and 0.1 mL of 2 M K_2CO_3, designed to hydrolyse any **1a** remaining in solution. GC assays for iodomethane were carried out after 35, 60, 90, 120, and 150 min of stirring the quenched aliquot, respectively. The amount of iodomethane (x_t) that was assayed at each time interval was assumed to be equated to the decrease in the initial amounts of **1a** (a_0) and KI (b_0). Consequently second-order rate plots $kt = \ln[b_0/a_0 \cdot a/b]/(a_0 - b_0)$ were made (by computer program) where $a = (a_0 - x_t)$ and $b = (b_0 - x_t)$.

After 18 min of stirring the reaction solution, it was quenched by adding 0.3 mL of 2 M K_2CO_3 solution and all products were assayed after 5 h of stirring. The results are given in run 3 of Table 5.

Rates of reaction of **1b**–**1f** and **2a** were measured similarly except that higher concentrations of reactants in a smaller volume (5 mL) were used for the slower reactions. The rate data are listed in Table 7.

B, with TBAB and KBr/18-crown-6

The procedure was analogous to that used in the KI reactions. The solution of TBAB was 0.0717 M, and the solution containing KBr /18-crown-6 was 0.0717 M in KBr and 0.132 M in 18-crown-6. Assays of alkyl bromides were made as described earlier. Second-order rate constants are listed in Table 7.

Thermal decompositions

An example is given with **2d**. A solution of 49.6 mg (0.119 mmol) of **2d** and 36.8 mg (0.179 mmol) of DTBMP in 5 mL of DCE, containing naphthalene and acetone as GC standards, was sealed in an ampule. The solution was heated at 100°C for 30 min and, after cooling and opening the ampule, was transferred to a 5 mL volumetric flask that was capped with a septum. The solution was then sampled for GC assay on columns A and E, giving 0.084 mmol (71%) of *trans*- and 0.033 mmol (28%) of *cis*-2-hexene (column E), 0.172 mmol (96%) of DTBMP, 0.00203 mmol (1.7%) of Th, and 0.118 mmol (99%) of ThO (column A). To verify that none of the **2d** had survived heating (and thus had decomposed to 2-hexene on the GC column), 0.30 mL of 2 M K_2CO_3 was injected through the septum after GC assays were complete, the solution was stirred for 120 min, and again sampled for GC assay, to give 70% of *trans*- and 28% of *cis*-2-hexene, 100% of DTBMP, 0.85% of Th, and 97% of ThO; these data are given in Table 8. Had **2d** survived heating to be hydrolysed by the K_2CO_3, the yields of 2-hexene would have been lower and 2-hexanol would have been found in the GC analysis.

Similar experiments were carried out with **1h**, **2e**, and **2f**. Results are listed in Table 8.

The solubility of gases and vapours in ethanol — the connection between gaseous solubility and water–solvent partition

Michael H. Abraham, Gary S. Whiting, Wendel J. Shuely, and Ruth M. Doherty

Abstract: Ostwald solubility coefficients, as log L, for solutes in water and ethanol have been combined to give log P^{EtOH} for partition between the two pure solvents. Sixty-four such values have been correlated through our solvation equation, the coefficients of which lead to the conclusion that ethanol and water solvents are equally strong hydrogen-bond bases, but that ethanol is much weaker as a hydrogen-bond acid. A slightly different solvation equation has been used to correlate 68 values of log L^{EtOH}; the coefficients in this equation yield the same conclusions as to the hydrogen-bond acidity and basicity of bulk ethanol. In addition, an analysis of the various terms in the log L^{EtOH} correlation equation allows the elucidation of the various chemical factors that govern the solubility of gaseous solutes in ethanol solvent at 298 K.

Key words: solubility, partition, hydrogen-bonding, ethanol, water.

Résumé : On a combiné des coefficients de solubilité d'Ostwald (exprimés sous la forme de log L) de solutés dans l'eau et dans l'éthanol pour en tirer les valeurs de log P^{EtOH} exprimant le partage entre les deux solvants purs. On a établi une corrélation entre 64 de ces valeurs par le biais de notre équation de solvatation dont les coefficients conduisent à la conclusion que l'éthanol et l'eau sont deux solvants basiques avec de fortes liaisons hydrogènes; toutefois, l'éthanol est beaucoup plus faible comme acide de liaison hydrogène. On a utilisé une équation de solvatation légèrement différente pour établir une corrélation entre 68 valeurs de log L^{EtOH}; les coefficients de cette équation conduisent aux même conclusions relativement à l'acidité et à la basicité de l'éthanol dans les liaisons hydrogènes. De plus, une analyse des divers termes de l'équation de corrélation des log L^{EtOH} permet d'élucider les divers facteurs chimiques qui gouvernent la solubilité des solutés gazeux dans l'éthanol comme solvant, à 298 K.

Mots clés : solubilité, partage, liaison hydrogène, éthanol, eau.

[Traduit par la rédaction]

Introduction

The Gibbs energy of partition of a solute between two solvents, for example, water (W) and an organic solvent (S), is given by the difference between the Gibbs energies of solvation of the gaseous solute in the two solvents. In terms of equilibrium constants, the partition coefficient, as log P^S, is given by eq. [1]:

[1] $\log P^S = \log L^S - \log L^W$

L is the Ostwald solubility coefficient, or gas–liquid partition coefficient, defined as

[2] L = [conc. of solute in solution]/[conc. of solute in gas]

If the concentration units in eq. [2] are the same in each phase, for example mol dm^{-3}, then P^S, L^S, and L^W are all dimensionless. Equation [1] can be applied not only to two pure solvents, but also to solvents that are partially miscible, but then L^S and L^W must refer to the mutually saturated solvents.

Because there is such a clear connection between partitioning and gaseous solubility, it is evident that the solute properties that influence log L values must also influence log P values. However, this is not always the case as regards correlative and predictive methods. There are a number of empirical schemes that relate the solubility of gases in water (1, 2) and water–octanol partition coefficients (3, 4) to solute fragments, but without any connection between the two processes. Other methods for gaseous solubility are often characterized by individualistic approaches. Thus Jurs and co-workers (5) analyse gas chromatographic (GC) data of solutes on OV-101 and Carbowax 20M phases using solute descriptors such as the sum of the products of the partial negatively charged surface areas, a molecular connectivity parameter, the ratio of the first and second moments of inertia, etc., whilst Jalali-Heravi and Garkani-Nejad (6) discuss GC data on an Apiezon phase in terms of a zero-order valence term, the number of methyl groups, the solute volume, and dipole moment. One of the few investigations that considers the general problem of solvation is that of Cramer and co-workers (7–9) who set up a

semiempirical quantum mechanical solvation model that can be used to correlate and predict log L values in water, hexadecane, and other solvents. Then, through eq. [1], they were able to calculate the corresponding log P^S values.

Our interest in the problem of partition and gaseous solubility arises through the use of the general solvation equation, eq. [3], for the characterization of water–solvent partitioning systems (10–13).

$$[3]\quad \log SP = c + rR_2 + s\pi_2^H + a\sum \alpha_2^H + b \sum \beta_2^H + vV_x$$

Here, log SP is a series of log P values for solutes in a given water–solvent system, and the independent variables are solute descriptors as set out before (10). These are, as follows: R_2, an excess molar refraction; π_2^H, the dipolarity/polarizability; $\sum\alpha_2^H$, the overall hydrogen-bond acidity; $\sum\beta_2^H$, the overall hydrogen-bond basicity; and V_X, the characteristic volume of McGowan (14). The coefficients in eq. [3] are found by the method of multiple linear regression analysis. They are not just fitting constants, but contain information on the properties of the system under investigation; in particular, they encode differences in chemical properties between the solvent phase and water. The r-coefficient reflects the differential interaction with solute π- and σ-lone pairs, the s-coefficient gives the difference in dipolarity/polarizability of the solvent and water, the a-coefficient the difference in hydrogen-bond basicity, and the b-coefficient the difference in hydrogen-bond acidity. The v-coefficient is a measure of the relative hydrophobicity of the solvent and water. Equation [3] has now been applied to numerous water–solvent partitions (11–13).

In the present work we extend the scope of eq. [3] to the water–ethanol system. There are two main reasons for the choice of ethanol as the solvent. Firstly, log P^{EtOH} values for the formal distribution between water and ethanol can only be obtained through eq. [1], and so the water–ethanol partition is a good example of the use of this equation. Secondly, there is considerable controversy over the hydrogen-bond basicity of water and alcohol (12): the solvatochromic comparison method of Kamlet, Taft, and co-workers (15) indicates that octanol and other alcohols are stronger hydrogen-bond bases than water (12), but studies (11) using eq. [3], as well as those using similar equations (16, 17) lead to the conclusion that water and (wet) octanol have the same hydrogen-bond basicity. Thus Abraham et al. (11) applied eq. [3] to 613 water–octanol partition coefficients, and obtained the regression:

$$[4]\quad \log P^{oct} = 0.09 + 0.56\,R_2 - 1.05\,\pi_2^H + 0.03 \sum \alpha_2^H - 3.46\,\Sigma\,\beta_2^H + 3.81\,V_x$$

The $s\pi_2^H$ and $b\sum\beta_2^H$ terms show that water is more polarizable/ dipolar and is a stronger hydrogen-bond acid than is wet octanol, but the negligible $a\sum\alpha_2^H$ term strongly suggests that water and wet octanol have the same hydrogen-bond basicity. Whether this similarity in basicity arises because wet octanol contains a considerable quantity of water, or whether octanol itself is as basic as water cannot be deduced from this particular data set. An analysis of log P^{EtOH} values will allow us to obtain the relative hydrogen-bond basicity of water and (dry) ethanol, and hence to address the problem of basicity of alcohols.

Values of log L^{EtOH} are required in order to calculate log P^{EtOH} through eq. [1]. Thus, it seems as though a straightforward application of eq. [3] to the log L^{EtOH} values would yield a direct measure of the hydrogen-bond basicity, and other properties of ethanol. However, we already know (18) that although eq. [3] correlates log P values very well, it is inferior to our second solvation equation, eq. [5], for the correlation of log L values in all nonaqueous solvents. The last descriptor in eq. [3], V_X, is replaced in eq. [5] by the descriptor log L^{16}, where L^{16} is the Ostwald solubility coefficient of solutes on hexadecane at 298 K (19).

$$[5]\quad \log L = c + rR_2 + s\,\pi_2^H + a \sum \alpha_2^H + b \sum \beta_2^H + l \log L^{16}$$

We can still explore solvent properties through eq. [5]. Indeed, the analysis is simpler than that through eq. [3], because the coefficients in eq. [5] are now directly related to the solvent phase properties. Although eqs. [3] and [5] are not identical, they have been constructed using the same chemical principles, and they include four out of five descriptors in common. Hence we can reasonably claim that the same general procedure is used to analyse both water–solvent partition and gas solubility. Another reason for analysis of log L^{EtOH} values is that a good correlative equation would be useful in the prediction of further values.

Our aims are thus to calculate log P^{EtOH} using eq. [1], to apply eq. [3] to these values, and to deduce properties of the solvent ethanol as compared to water; similarly, to apply eq. [5] to log L^{EtOH} values, and again to deduce properties of ethanol solvent.

Data collection

We have used various literature data to assemble log L^{EtOH} values from sources employing dry ethanol as the solvent. For the solution of permanent gases, directly determined log L^{EtOH} values have been recorded by Bo et al. (20), Pollack et al. (21), and Wilhelm and Battino (22). Other direct methods include that of Park et al. (23), who used a headspace analysis method. A useful indirect method involves combination of the infinite dilution activity coefficients of a solute in ethanol with the saturated vapour pressure of the solute, usually with the approximation that gas imperfections can be ignored. In addition, we have calculated log L^{EtOH} for some sparingly soluble aromatic hydrocarbons from their solubility in ethanol and their gaseous concentrations at 298 K (obtained from the saturated vapour pressures). This method can only be used, however, if the solute does not form any solvates with ethanol solvent; details are in Table 1. The gaseous concentrations, C^G, in mol dm^{-3}, are averages from various sources (24–26), and the solubilities of the solids in ethanol are also averages of the recorded values (27). Water solubilities, C^W, in mol dm^{-3} are included in Table 1 (25, 28–30) as they are needed for the calculation of log L^W values.

The final set of 68 values of log L^{EtOH} is in Table 2. There are four fewer log P^{EtOH} values, because the log L^W values for the long-chain alkanes are anomalous (31) and cannot be used to calculate log P^{EtOH}. The required descriptors in eqs. [3] and [5] have been listed before (10, 13, 26).

Analysis of the log P^{EtOH} data

Application of eq. [3] to the 64 log P^{EtOH} values yields the linear free energy relationship (LFER):

$$[6]\quad \log P^{EtOH} = 0.208 + 0.409\,R_2 - 0.959\,\pi_2^H + 0.186\sum \alpha_2^H - 3.645\sum \beta_2^H + 3.928\,V_x$$

where $n = 64$, sd = 0.17, $r^2 = 0.9904$, and $F = 1205$.

The number of solutes is *n*, the correlation standard deviation is sd, the correlation coefficient is *r*, and *F* is the *F*-statistic. Considering that log P^{EtOH} is the difference between two log *L* values, the statistics of eq. [6] are very good. The term in $\sum\alpha_2^H$ is significant at only the 70% level, and so could be omitted if required.

To interpret the coefficients in eq. [6] it is helpful to list the corresponding coefficients for regressions of log *P* values of solutes from water to other solvents; these are in Table 3. Note that decanol, octanol, and isobutanol are listed as "wet" because in equilibrium with water they contain appreciable quantities of water. The main coefficients are s, *a*, *b*, and *v*, which can be interpreted as follows.

The negative *s*-coefficients arise because water is much more dipolar than the organic solvents. The increased polarizability of organic solvents such as benzene or chloroform over that of water leads to rather less negative *s*-coefficients, and a combination of dipolarity and polarizability of nitrobenzene actually negates the dipolarity of water. Ethanol, itself, and the various wet alcohols appear to have rather low polarizability/ dipolarity.

The very negative *a*-coefficients are due to the pronounced hydrogen-bond basicity of water. Solvents such as hexadecane and cyclohexane have no hydrogen-bond basicity, and so the *a*-coefficient in any water–solvent equation cannot be more negative than around –3.8 units. Solvents with some basicity, such as nitrobenzene, give rise to less negative *a*-coefficients, as expected. An extraordinary feature of Table 3, however, is the almost-zero value of the *a*-coefficient for dry ethanol and the wet alcohols. This must indicate that the wet alcohols and dry ethanol have almost exactly the same hydrogen-bond basicity as water. Because dry ethanol has the same basicity as water, the basicity of the wet alcohols is unlikely to be due to just the presence of water; our findings suggest that dry alcohols are as hydrogen-bond basic as water. This is quite contrary to findings from the solvatochromic methods of Kamlet and Taft (32). Published lists of the Kamlet–Taft solvent hydrogen-bond basicity parameter, β, invariably show that dry alcohols, such as ethanol, have appreciably larger β-values than water (15, 33, 34).

In a similar vein, negative *b*-coefficients arise because water is so strong as a hydrogen-bond acid. The *b*-coefficients for the completely non-acidic solvents, hexadecane and cyclohexane, suggest that in eq. [3] for water-to-solvent partitions, this parameter cannot be more negative than around –4.9 units. The less negative the *b*-coefficient, the more acidic is the solvent, so that wet isobutanol is the most acidic solvent listed in Table 3. Dry ethanol, according to the coefficients in Table 3, is about as acidic as wet octanol or wet decanol and, perhaps surprisingly, no more acidic than bulk chloroform (35). Considering that a *b*-coefficient of –4.9 arises because the solvent has no acidity at all, a *b*-coefficient of –3.64 suggests that ethanol is markedly less hydrogen-bond acidic than is water. This is in line with solvatochromic measurements, because Marcus (33) lists the Kamlet–Taft hydrogen-bond solvent acidity, α, as 1.17 for water and 0.86 for dry ethanol. Goncalves et al. (34) give similar values, 1.16 for water and 0.88 for dry ethanol.

As mentioned above, the *v*-coefficient can be interpreted as a measure of the solvent hydrophobicity. Not surprisingly, alkanes and cycloalkanes have very large *v*-coefficients, and the wet alcohols somewhat lower coefficients. The value of 3.93 for dry ethanol seems unexceptional.

Analysis of the log L^{EtOH} data

The 68 values of log L^{EtOH} can be analysed through the LFER, eq. [5], to give the correlation:

$$[7]\quad \log L^{EtOH} = 0.012 - 0.206\,R_2 + 0.789\,\pi_2^H + 3.635\sum \alpha_2^H + 1.311\sum \beta_2^H + 0.853\log L^{16}$$

where $n = 68$, sd = 0.14, $r^2 = 0.9966$, $F = 3534$. The statistics of eq. [7] are a little better than those for eq. [6]. This is not surprising because the error in the log P^{EtOH} values will include the error in log L^W as well as the error in log L^{EtOH}. In any event, eq. [7] is good enough to predict further values of log L^{EtOH} to within around 0.2 log units. Once again, interpretation of eq. [7] is aided by comparison of coefficients for other like

[a] Using eq. [5] with the coefficients in Table 4; note that $c = 0.01$ for ethanol and –1.27 for water.

regressions. Coefficients in eq. [5] are given in Table 4 for the solubility of gaseous solutes, as log *L* at 298 K, in a number of solvents.

Since the coefficients in Table 4 refer to transfers from the gas phase, where there are no solute–solvent interactions at all, to bulk solvents, they can be regarded as "absolute" measurements of the various solvent properties. By and large, they compare very well with the solvent properties, now referenced to water, obtained from log *P* values. Thus the rather low *s*-coefficient again indicates that dry ethanol has a low polarizability/dipolarity. Of considerable interest, in view of our comparison of the log *P* coefficients with solvatochromic parameters, are the *a*- and *b*-coefficients for ethanol. The *a*-coefficient shows clearly that ethanol is as strong a hydrogen-bond base as water, exactly as we found from the log *P* coefficients. But even ethanol and water are by no means as strong as dimethyl sulfoxide (DMSO). The *b*-coefficients in Table 4 confirm our above conclusion that ethanol is a much weaker hydrogen-bond acid than is water, and is only as strong as bulk chloroform. Again, this fits exactly with the *b*-coefficients in Table 3, viz: –3.47 for chloroform and –3.63 for ethanol.

Solvatochromic parameters are not the only measures of hydrogen-bond acidity and basicity of solvents. In Table 5 are collected the Kamlet–Taft α- and β-parameters, the $\Delta_{acid}H$ and the $\delta\Delta H$ (basicity) parameter of Catalan et al. (37, 38), and the AN acceptor parameter of Gutmann (39) for a number of solvents. We do not include the donor number, DN, because this is not a solvent property at all. In Table 5 are given the *a*- and *b*-coefficients in the relevant equations, eq. [3] and eq. [5]. The relative hydrogen-bond acidity of water and ethanol seems not in dispute, at least in a qualitative sense. All measures listed in Table 5 rank water as significantly more acidic than ethanol, although the coefficients obtained in this work suggest that water is much the better hydrogen-bond acid. From the *a*-coefficients obtained through eq. [3] or eq. [5], it is evident that water and ethanol behave as though they had almost the same hydrogen-bond basicity. However, the other four measures listed in Table 5 rank water as a much weaker hydrogen-bond base than ethanol. We have no explanation for this very large discrepancy, except to point out that, of the other four measures, three are spectroscopic in nature and one is enthalpy-related, whereas the *a*-coefficient is a Gibbs energy-related measure.

© 1998 NRC Canada

The *l*-coefficients in Table 4 are of some interest, in that for all nonaqueous solvents they are large and positive, but for water the *l*-coefficient is small and negative. As a result, large gaseous solutes will be much more soluble in ethanol than small solutes, but large solutes will be slightly less soluble in water than small solutes.

The factors that influence solubility in water and ethanol can be set out through a term-by-term analysis of eq. [5]. This is done in Table 6 for a few representative solutes. In the case of solubility in ethanol, the $l \log L^{16}$ term dominates, except for solutes that are strong hydrogen-bond acids. But for water, the three "polar" terms $s\pi_2^H$, $a \Sigma \alpha_2^H$, and $b \sum \beta_2^H$ are dominant, and the $l \log L^{16}$ term makes only a minor contribution. Hence solutes that are large will nearly always be more soluble in ethanol than in water; only if a large solute has substantial values of π_2^H and $\sum \beta_2^H$ will it be more soluble in water. Acetic acid is a case in point, where the large dipolarity and hydrogen-bond basicity together result in a very large solubility in water (note that the effect of hydrogen-bond acidity is very nearly the same in ethanol and water). For small solutes, where the $l \log L^{16}$ terms in ethanol and water do not differ so much, compounds that are strongly dipolar/polarizable and are hydrogen-bond bases will be more soluble in water; ammonia is such a case.

Conclusions

Values of log P^{EtOH} for the transfer of compounds from water to ethanol can be obtained from log *L* values in the two solvents, and the log P^{EtOH} values correlated very satisfactorily through eq. [3]. The coefficients in eq. [3] contain information on the relative chemical properties of water and ethanol, and lead to the conclusion that the two solvents have the same hydrogen-bond basicity, but that ethanol is a much weaker hydrogen-bond acid. The log L^{EtOH} values are well correlated through eq. [5], the coefficients of which now encode "absolute" chemical properties of ethanol, for example, properties relative to the gas phase. Once again, ethanol is seen to be a strong hydrogen-bond base, but only a moderate hydrogen-bond acid — no stronger than bulk chloroform. A term-by-term analysis of eq. [5] enables log L^{EtOH} values to be factored into contributions from particular solute–solvent interactions.

Kinetics and mechanism of the aminolysis of ethyl aryl carbonates in acetonitrile

Han Joong Koh, Ji-Won Lee, Hai Whang Lee, and Ikchoon Lee

Abstract: The aminolysis reactions of ethyl aryl carbonates with benzylamines in acetonitrile at 25.0°C are investigated. The base-catalyzed path, k_2, disappears when strong nucleophiles (X = *p*-CH_3O and *p*-CH_3) react with a substrate activated by a strong nucleofuge (Z = *p*-NO_2). The large magnitude of ρ_x (–1.7 to –2.5), ρ_z (3.4 to 4.3), and ρ_{xz} (1.4) values, and relatively large k_H/k_D (1.6 to 1.8) found for the uncatalyzed path (k_1) can be accounted for in terms of a stepwise mechanism with rate-limiting expulsion of the phenoxide leaving group. The catalyzed process (k_2) is characterized by the much smaller magnitude of ρ_x (–1.0 to –1.7), ρ_z (0.4 to 0.7), and ρ_{xz} (0.2), the larger k_H/k_D (2.1 to 2.5) values, and the lower $\Delta H^{\ddagger}$ values (1.8–1.9 kcal mol^{-1}) than those of the uncatalyzed process (k_1) with large negative $\Delta S^{\ddagger}$ values (–65 to –67 cal K^{-1} mol^{-1}). These results are consistent with four- and six-centered transition states for the two processes, k_1 and k_2, respectively.

Key words: ethyl aryl carbonates, aminolysis mechanism, base catalysis, stepwise mechanism, cross-interaction constant.

Résumé : On a étudié les réactions d'aminolyse des carbonates d'éthyle et d'aryle par les benzylamines, dans l'acétonitrile, à 25,0°C. La voie réactionnelle catalysée par les bases, k_2, disparaît lorsque des nucléophiles forts (X = *p*-CH_3O et *p*-CH_3) réagissent avec un substrat activé par un groupe fortement nucléofuge (Z = *p*-NO_2). Pour expliquer la grande amplitude des valeurs de ρ_x (de –1,7 à –2,5), ρ_z (3,4 à 4,3) et de ρ_{xz} (1,4) ainsi que de la valeur relativement importante observée pour k_H/k_D (1,6 à 1,8) observées pour la voie non catalysée, on peut imaginer un mécanisme par étapes impliquant une expulsion cinétiquement limitante du groupe phénolate partant. Le processus catalysé (k_2) est caractérisé par des amplitudes beaucoup plus faibles de ρ_x (de –1,0 à –1,7), ρ_z (0,4 à 0,7) et de ρ_{xz} (0,2), des valeurs beaucoup plus élevées de k_H/k_D (2,1 à 2,5) et des valeurs de $\Delta H^{\ddagger}$ (1,8 à 1,9 kcal mol^{-1}) beaucoup plus faibles que celles observées pour le processus non catalysé (k_1) avec des valeurs de $\Delta S^{\ddagger}$ très négatives (–65 à –67 cal K^{-1} mol^{-1}). Ces résultats sont en accord avec des états de transition à quatre et à six centres respectivement pour les deux processus k_1 et k_2.

Mots clés : carbonates d'éthyle et d'aryle, mécanisme d'aminolyse, catalyse par les bases, mécanisme par étape, constante d'interaction de croisement.

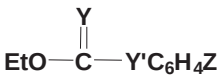
Introduction

Aminolyses of sulfur analogs of ethyl aryl carbonates, **2**–**4** (1–4) have been shown to exhibit interesting mechanistic variations depending on sulfur substitution for oxygen and the reaction medium used. In the aminolysis of thiono compounds, **3** (3), a weaker π-bonding energy of the thio carbonyl (C═S) compared to the carbonyl (C═O) leads to the difficulty in forming the C═S bond to expel the nucleofuge, which results in a lowering of the nucleofugality (k_b in Scheme 1) of ArO^-. The change of O^- by S^- in $\mathbf{T}^{\pm}$ brings about therefore a mechanistic change in aqueous solution to a complex one in which the deprotonation step, k_d, can compete with k_{-a} and k_b (Scheme 1). The increased leaving ability (larger k_b) by introducing nitro groups (**3b**–**3d**) or suppressed proton transfer rate (smaller $k_d[RNH_2]$) by using an aprotic medium (5*a*) can, however, restore the mechanism to a simple rate-limiting breakdown (k_b) of the tetrahedral intermediate, $\mathbf{T}^{\pm}$, which is commonly observed in most of the aminolysis reactions of esters and carbonates (5). On the other hand, in the aminolysis of thiol compounds, **2** (2), the ethoxy group apparently destabilizes $\mathbf{T}^{\pm}$ and is known to enforce a concerted mechanism as a result of the enhanced leaving ability of 2,4-dinitro-, **2c**, and 2,4,6-trinitro-thiophenoxides, **2d** (relative to the corresponding phenoxides). This mechanistic change from a stepwise mechanism for oxyesters and oxycarbonates to a concerted mechanism for the thiol carbonate (**2**) has not been observed with acetates (EtO replaced by Me) (6), methyl aryl carbonates (EtO replaced by MeO) (3*b*), and benzoates (EtO replaced by Ph, in **1**–**4**) (7). The aminolyses of dithio (**4**) derivatives were



1 Y = Y′ = O (**a**) Z = H
2 Y = O, Y′ = S (**b**) Z = 4-NO_2
3 Y = S, Y′ = O (**c**) Z = 2,4-(NO_2)
4 Y = Y′ = S (**d**) Z = 2,4,6-(NO_2)$_3$

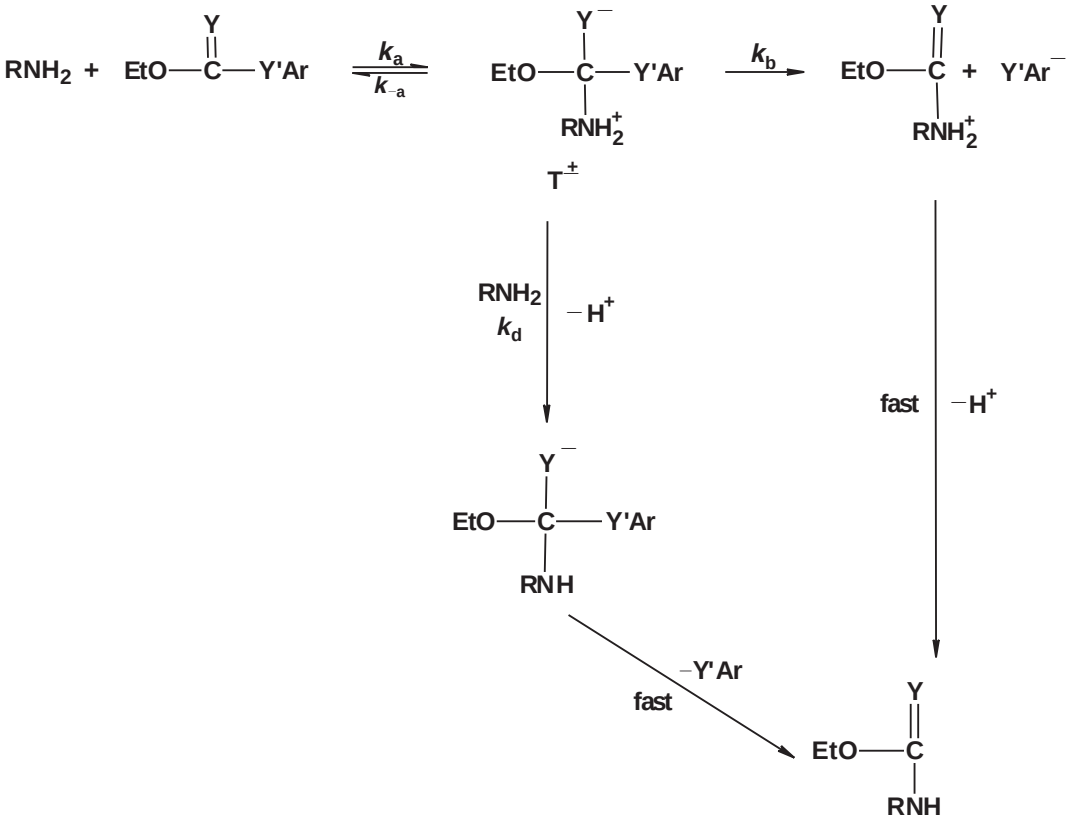
Scheme 1.



found, in general, to proceed by mechanisms similar to those for the thiono (**3**) series (4).

In this work, we carried out kinetic studies of the aminolysis of ethyl aryl carbonates, **1**, with benzylamines (BA, $XC_6H_4CH_2NH_2$) in acetonitrile at 25.0°C. We varied substituents X (X = *p*-CH_3O, *p*-CH_3, H, *p*-Cl, and *m*-Cl) in the nucleophile and Z (Z = *m*-NO_2, *p*-$COCH_3$, *p*-Cl + *m*-NO_2, *p*-CN, and *p*-NO_2) in the nucleofuge to probe the transition state (**TS**) structure through structure–reactivity correlation involving the cross-interaction constant, ρ_{XZ} in eqs. [1] (8). Our previous studies have shown that the sign and magnitude of ρ_{XZ} provide valuable mechanistic information (8).

$$[1a] \quad \log(k_{XZ}/k_{HH}) = \rho_X\sigma_X + \rho_Z\sigma_Z + \rho_{XZ}\sigma_X\sigma_Z$$

$$[1b] \quad \rho_{XZ} = \frac{\partial^2 \log k_{XZ}}{\partial \sigma_X \partial \sigma_Z} = \frac{\partial \rho_Z}{\partial \sigma_X} = \frac{\partial \rho_X}{\partial \sigma_Z}$$

In this work, we aim to test whether or not there is any mechanistic variation found in the aminolysis of thiono (**3**) and (or) thiol (**2**) derivatives, and to characterize the **TS** structure by determining the cross-interaction constant, ρ_{XZ}, and the secondary kinetic isotope effects (SKIEs) involving deuterated nucleophiles ($XC_6H_4CH_2ND_2$) (9).

Results and discussion

For all the carbonates investigated, solvolysis was not observed under the reaction conditions. The rates were measured with amine excesses, [BA] = 0.018–0.430 M and [Substrate] $\cong 1 \times 10^{-4}$ M, and pseudo-first-order rate constants (k_{obs}) were obtained at more than 10 amine concentrations, Figs. 1 and 2. The plots of k_{obs} versus amine concentration, [BA], were linear, eq. [2], for the reactions of substrate with a strong electron acceptor, Z = *p*-NO_2, and nucleophile with a strong electron donor, X = *p*-CH_3O and *p*-CH_3, Fig. 1.

$$[2] \quad k_{obs} = k_1[BA]$$

For all other reactions, the plots were curvilinear, which can be fitted to a second-order equation in benzylamine concentration, eq. [3] and Fig. 2.

$$[3] \quad k_{obs} = k_1[BA] + k_2[BA]^2$$

Because of this second-order term, accurate determinations of the rate constants, k_1 and k_2, required more than 10 k_{obs} data with varied amine concentrations. Plots of k_{obs}/[BA] versus [BA] gave k_1 and k_2 as the intercepts and slopes of the straight line. The k_1 and k_2 values obtained are summarized in Tables 1 and 2. The catalytic rate constants, k_2, are ca. 2 (X = *m*-Cl, Z = *p*-NO_2) to 170 (X = *m*-Cl, Z = *m*-NO_2) times greater than the corresponding uncatalyzed rate constants, k_1; this comparison is unjustified since k_1 and k_2 have different units, but we are making only numerical comparisons with other similar results reported. Similar trends are reported for the reactions of *p*-Cl-phenyl acetates with pyrrolidine (10) and for the reactions of phenyl phenoxyacetates with benzylamines (5*d*) in acetonitrile at 25.0°C. For the aminolysis of *p*-nitrophenyl acetates the k_2 term was absent, but both k_1 and k_2 terms were observed for chloro- and dichloroacetates in acetonitrile (11). This should be an indication that a strong acceptor aryl moiety (the Taft σ* values for CH_3, CH_2Cl, $CHCl_2$, $CH_2OC_6H_5$, and C_2H_5O are

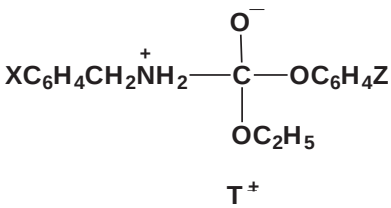
0.0, 1.05, 1.94, ca. 1.0, and 1.68, respectively) (5*d*, 12) requires general base catalysis, especially in aprotic solvents. Moreover, it has been well established that electron withdrawal from the acyl carbon favors amine expulsion relative to the negatively charged phenoxide expulsion from a tetrahedral intermediate, $\mathbf{T}^{\pm}$ (1*c*, 1*d*, 13). The results of the present work also show that the aminolysis of esters and carbonates can proceed without base catalysis even in aprotic solvents if the nucleophile and (or) nucleofuge are strong, i.e., for a strong donor X coupled with a strong acceptor Z. This is evident from the rate ratio (k_2/k_1) changes with the substituents X and Z. The k_2/k_1 ratio becomes smaller as the electron donor ability of X and acceptor power of Z increase: the k_2/k_1 values are 170, 32.4, 6.4, and 2.4 for X = *m*-Cl, Z = *m*-NO_2; X = *p*-Cl, Z = *p*-$COCH_3$; X = *p*-CH_3, Z = *p*-Cl + *m*-NO_2; and X = *p*-CH_3O, Z = *p*-CN, respectively, eventually reaching zero for X = *p*-CH_3O (and *p*-CH_3) with Z = *p*-NO_2. Thus when the aminolysis rate reaches a sufficiently large value by reacting a strong nucleophile with a strong nucleofuge, the base catalysis becomes redundant.

The Hammett ρ and Brönsted β values are listed in Tables 1 and 2. Examination of Table 1 reveals that magnitudes of ρ_X, ρ_Z, β_X, and β_Z values for the uncatalyzed path, k_1, are large and are much greater than the corresponding values for the catalyzed path (k_2). The large magnitudes of ρ_X (β_X) and ρ_Z (β_Z) are indicative of a stepwise mechanism with rate-limiting breakdown of a zwitterionic tetrahedral intermediate, $\mathbf{T}^{\pm}$ (1–5, 13). The importance of expulsion of the leaving group is reflected in the better Hammett correlations with σ_z^- than with σ_Z and in the large magnitude of ρ_Z, which suggests a strong negative charge development in the phenoxide leaving group.

For this mechanism, $k_1 = (k_a/k_{-a}) \times k_b = K \cdot k_b$. Such large ρ_z^- values reflect the importance of leaving group expulsion in the rate-determining step and are commonly found for the stepwise mechanism involving rate-limiting breakdown of $\mathbf{T}^{\pm}$. In acylation, when leaving group departure is kinetically important, substituent changes in leaving groups have a larger effect than do equivalent changes in the remaining group. Although β_X and β_Z values are also listed in Tables 1 and 2, they are less reliable since the pK_a values in water are used in the correlation instead of those in acetonitrile. However, the relative pK_a values ($\Delta pK_a = pK_{CH_3CN} - pK_{H_2O}$) remain constant for various conjugate acids of amines so that the solvent effect on β_X may be small (5*c*). The values of β_Z may be significantly smaller than those reported on the basis of aqueous acidities. We note that both ρ_X and ρ_Z are considerably greater in magnitude than the corresponding values for the reactions reported to proceed



$\mathbf{T}^{\pm}$

by rate-limiting breakdown of $\mathbf{T}^{\pm}$ (2*c*, 3*b*, 4*c*, 4*d*). Another strong support for the proposed mechanism comes from a large positive cross-interaction constant ρ_{XZ} (= 1.35): both the positive sign and the large magnitude of ρ_{XZ} have been shown to be the necessary conditions for the rate-limiting breakdown of $\mathbf{T}^{\pm}$ (8, 9, 13). Since an electron acceptor in the nucleophile, $\delta\sigma_X > 0$ (in the nucleofuge, $\delta\sigma_Z > 0$), leads to an increase in ρ_Z, $\delta\rho_Z >$

[f] Correlation coefficient was better than 0.971.

0 ($\delta\rho_X > 0$), ρ_{XZ} is positive, eq. [1*b*]. Since the rate increase is invariably accompanied by a decrease in the magnitude of ρ (ρ_X or ρ_z^-), the reactivity–selectivity principle (RSP) holds (14). Adherence to the RSP is considered another criterion for the stepwise mechanism with rate-limiting expulsion of the leaving group (phenoxides) (14).

For the third-order process, k_2, the RSP is violated and the ρ_X, ρ_z^-, and ρ_{XZ} values are considerably smaller in magnitude than the corresponding values for the uncatalyzed path (k_1). These can be accommodated with a rate-limiting deprotonation mechanism, $k_2 = (k_a/k_{-a})\cdot k_d[RNH_2]$ in Scheme 1. In this case, deprotonation of $\mathbf{T}^{\pm}$ leads to a decrease in the positive charge on the N atom (decrease in the magnitude of ρ_X) and also to a small increase in the negative charge on the O atom (small positive ρ_z^-) in the intermediate. Since the magnitudes of both ρ_X and ρ_z^- are reduced to much smaller values, the cross-interaction constant ρ_{XZ} also decreases to a smaller value than that for the uncatalyzed process, k_1.

Secondary kinetic isotope effects involving deuterated benzylamine nucleophiles are summarized in Tables 3 and 4. The k_H/k_D values in Table 3 are all greater than 1.0. This is consistent with the stepwise mechanism proposed (5*d*, 7*b*, 15), k_1 =

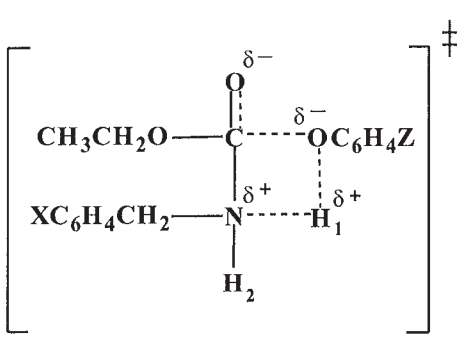
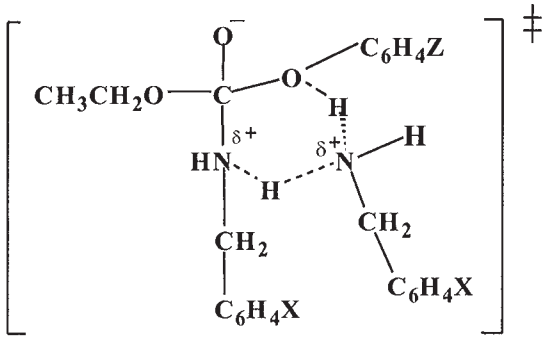
$(k_a/k_{-a})\cdot k_b = K\cdot k_b$. In this mechanism, the H-N-H moiety becomes sterically relieved in the rate-determining step of the leaving-group departure from $\mathbf{T}^{\pm}$. This will cause the decrease in the N–H vibration frequencies and the k_H/k_D values become greater than 1. In the equilibrium step, the effects of k_a and k_{-a} on the N–H vibrational frequencies approximately cancel out, leading to a k_H/k_D value of approximately 1.0 in the complex quantity of $k_1 = K\cdot k_b$ (5*d*, 7*b*, 15). We note, however, that the magnitude of the secondary kinetic isotope effects in Table 3 is somewhat larger with k_H/k_D = 1.6–1.8 than that found (k_H/k_D = 1.0–1.2) in most of the acyl transfer reactions (5*d*, 7*b*, 15) proceeding by a similar mechanism. We therefore suggest that there is weak deprotonation taking place through a four-center type **TS** (16), **5**. The cyclic proton transfer in **5** not only provides charge



5



6

© 1998 NRC Canada

dispersion, but it also assists leaving-group departure (17). This assistance is particularly important in the second-order path, k_1, when the (aprotic) solvent cannot assist by hydrogen bonding (17).

For the catalyzed path, the k_H/k_D values are further increased to 2.0–2.5, reflecting correctly the partial bond cleavage of the N—H(D) bond in the rate-determining step, $k_d[RNH_2]$ in Scheme 1. Among several conceivable **TS** structures for the catalyzed path, the cyclic hydrogen bonded structure, **6**, is considered to be the most likely candidate. The larger k_H/k_D and smaller ρ_z^-, ρ_X, and ρ_{XZ} values for **6** than for **5** can be explained as follows. Two hydrogen bonds are involved so that k_H/k_D should increase, but positive charge on N and negative charge on O should be partially offset by partial deprotonation from N and partial protonation on O. The decrease in the two ρ values, ρ_X and ρ_z^-, should result in a substantial decrease in the intensity of interaction leading to a large decrease in the ρ_{XZ} values (18). The trends of change in the magnitude of k_H/k_D in Tables 3 and 4 are also in line with our proposed **TS** structures, **5** and **6**. In structure **5**, the greater the leaving ability ($\delta\sigma_Z > 0$) of the phenoxide, the greater will be the extent of deprotonation and consequently the larger is the k_H/k_D value (Table 3). However, in **6**, the stronger the electron acceptor in the phenoxide ($\delta\sigma_Z > 0$), the less will be the negative charge on O due to the greater delocalization, and hence the weaker is the hydrogen bond between O and the catalyst amine nitrogen. Thus the k_H/k_D value will decrease as the electron-withdrawing power of Z increases (Table 4). In both structures, an electron acceptor X ($\delta\sigma_X > 0$) should increase the acidity of a substituted benzylammonium cation, i.e., deprotonation becomes more facile, so that k_H/k_D increases.

The proposed mechanism is also supported by the activation parameters (Table 5) determined from rate data at three temperatures, 25.0, 35.0, and 45.0°C. The relatively low positive $\Delta H^{\ddagger}$ and large negative $\Delta S^{\ddagger}$ values are in accord with the stepwise mechanism proposed (11, 19). For the catalyzed path, the $\Delta H^{\ddagger}$ values are lower than those for the uncatalyzed path and the $\Delta S^{\ddagger}$ values are large and negative. This is consistent with a simple proton transfer process involved in **TS 6**, where there is a two-proton bridge that is highly structured but very little energy will be required for the deprotonation.

In summary, the aminolysis of ethyl aryl carbonates in acetonitrile proceeds by a stepwise mechanism with rate-limiting expulsion of the phenoxide leaving group from the zwitterionic tetrahedral intermediate, $\mathbf{T}^{\pm}$. Two reaction pathways, catalyzed and uncatalyzed paths, compete in most of the reactions; base catalysis is not required for the reactions involving strong nucleophiles (X = *p*-CH_3O, *p*-CH_3) with a strong nucleofuge (Z = *p*-NO_2). The proposed mechanism is based on (*i*) the large magnitude of ρ_X and especially of ρ_z^-, (*ii*) the relatively large normal kinetic isotope effects ($k_H/k_D > 1.0$) involving a deuterated benzylamine nucleophile, (*iii*) the greater k_H/k_D values for the catalyzed path, and (*iv*) the low $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values for both pathways, but with lower values for the base-catalyzed path than for the uncatalyzed reaction.

Experimental

Materials

Merck GR acetonitrile was used after three distillations. The benzylamine nucleophiles, Aldrich GR, were used without further purification. Preparation of deuterated benzylamines was as described previously (5). The analysis (NMR and GC mass spectroscopy) of the deuterated benzylamines showed more than 99% deuterium content, so that no corrections to kinetic isotope effects for incomplete deuteration were made. Ethyl aryl carbonates were prepared by reacting phenols with ethyl chloroformates. The substrates synthesized were confirmed by IR, NMR, and mass spectral analyses as follows.

*$CH_3CH_2OC(O)OC_6H_4$–*p*-CN:* mp 40–42°C. ν_{max}: 3100 (C-H), 3000 (C-H, aromatic), 2250 (C≡N), 1760 (C═O). $\delta_H(CDCl_3)$: 7.2–7.7 (C_6H_4, 4H, m), 4.3 (CH_2, 2H, q), 1.3 (CH_3, 3H, t). m/z = 119 (M^+).

*$CH_3CH_2OC(O)OC_6H_4$–*p*-$COCH_3$:* mp 44–45°C. ν_{max}: 3100 (C-H), 3000 (C-H, aromatic), 1750 (C═O), 1680 ($COCH_3$). $\delta_H(CDCl_3)$: 7.2–8.0 (C_6H_4, 4H, m), 4.3 (CH_2, 2H, q), 2.6 ($COCH_3$, 3H, s), 1.3 (CH_3, 3H, t). m/z = 208 (M^+).

*$CH_3CH_2OC(O)OC_6H_4$–*m*-NO_2:* mp 50–52°C. ν_{max}: 3100 (C-H), 3000 (C-H, aromatic), 1750 (C═O), 1680 ($COCH_3$). $\delta_H(CDCl_3)$: 7.3–8.1 (C_6H_4, 4H, m), 4.3 (CH_2, 2H, q), 1.2 (CH_3, 3H, t). m/z = 208(M^+).

$CH_3CH_2OC(O)OC_6H_3$–(p-Cl, m-NO_2):* liquid. ν_{max}: 3100 (C-H), 3000 (C-H, aromatic), 1760 (C═O). $\delta_H(CDCl_3)$: 7.2–7.7 (C_6H_3, 3H, m), 4.2–4.4 (CH_2, 2H, q), 1.3 (CH_3, 3H, t). m/z = 245 (M^+).

*$CH_3CH_2OC(O)OC_6H_4$–*p*-NO_2:* mp 60–61°C. ν_{max}: 3100 (C-H), 3000 (C-H, aromatic), 1750 (C═O). $\delta_H(CDCl_3)$: 7.3–8.3 (C_6H_4, 4H, m), 4.2 (CH_2, 2H, q), 1.2 (CH_3, 3H, t). m/z = 211 (M^+).

Kinetic procedures

Rates were measured conductimetrically in acetonitrile. The conductivity bridge used in this work was a homemade computer-automatic A/D converter conductivity bridge. Pseudo-first-order rate constants, k_{obs}, were determined by the Guggenheim (20) method with a large excess of benzylamine. The k_1 and k_2 values were reproducible to ± 5%.

Product analysis

Ethyl *p*-nitrobenzyl carbonate was reacted with excess benzylamine with stirring for more than 15 half-lives at 25.0°C in acetonitrile, and the products were isolated by evaporating the solvent under reduced pressure. The product mixture was treated with column chromatography (silica gel, 20% ethyl acetate – n-hexane). Analysis of the product gave the following results.

$CH_3CH_2OC(O)NHCH_2C_6H_5$: Liquid. ν_{max}: 3300 (N-H), 3000 (C-H, aromatic), 1700 (C═O). $\delta_H(CDCl_3)$: 7.2–7.5 (C_6H_5, 5H, m), 5.2 (NH, 1H, s), 4.2 (CH_2, 2H, q), 4.4 (CH_2, 2H, s), 1.2 CH_3, 3H, t). m/z = 227 (M^+).

Skeletal vibrational circular dichroism of a series of bicyclic dilactones: the fingerprint region?

A. Rauk, J.L. McCann, H. Wieser, P. Bour, Yu.I. El'natanov, and R.G. Kostyanovsky

Abstract: The vibrational circular dichroism (VCD) spectra of 2,5-dioxabicyclo[2.2.1]heptane-3,6-dione **1** (R = H) and the 1,4-dialkyl derivatives, **1** (R = Me) and **1** (R = *t*-Bu), were calculated by the ab initio magnetic field perturbation (MFP) procedure with a B3LYP/6–31G* force field, and the VCD spectra of the dimethyl and di-*t*-butyl derivatives were measured in the region 800–1500 cm^{-1}. While the absolute configurations of **1** (R = Me) and **1** (R = *t*-Bu) could be assigned unambiguously by comparison of the experimental and predicted spectra, there is little obvious correspondence between the spectra of the series of compounds. The VCD spectra are analysed on the basis of operation of a coupled oscillator mechanism involving motions of the polar bonds. In the case of the parent dihydro system, bridgehead C—H bond motions appear to dominate contributions to the VCD of vibrational transitions into which they are mixed.

Key words: vibrational circular dichroism (VCD), 2,5-dioxabicyclo[2.2.1]heptane-3,6-dione, dilactones, optical activity.

Résumé : On a calculé les spectres de dichroïsme circulaire vibrationnel (DCV) de la 2,5-dioxabicyclo[2.2.1]heptane-3,6-dione **1** (R = H) et de ses dérivés 1,4-dialkyles **1** (R = Me ou R = *t*-Bu) grâce à la méthode ab initio de la perturbation du champ magnétique (PCM), en utilisant un champ de force B3LYP/6–31G*; on a aussi mesuré les spectres de DCV des dérivés diméthyle et di-*t*-butyle dans la région allant de 800 à 1500 cm^{-1}. Même si on a pu attribuer les configurations des composés **1** (R = Me) et **1** (R = *t*-Bu) en comparant les spectres expérimentaux à ceux qui avaient été prédits, il n'y a pas de correspondance évidente entre les spectres des séries de composés. On a analysé les spectres de DCV en se basant sur l'opération du mécanisme de l'oscillateur couplé impliquant des mouvements des liaisons polaires. Dans le cas du système dihydro parent, les mouvements de la liaison C–H en tête de pont semblent donner les contributions dominantes aux transitions de vibration du spectre de DCV dans lesquels ils sont mélangés.

Mots clés : dichroïsme circulaire vibrationnel (DCV), 2,5-dioxabicyclo[2.2.1]heptane-3,6-diones, dilactones, activité optique.

[Traduit par la rédaction]

Introduction

As a technique for studying the three-dimensional structures of molecules in solution, particularly in connection with handedness, vibrational circular dichroism (VCD) spectroscopy has matured over the last two decades (1–3). When coupled with ab initio theoretical calculations, it may be used to assign the absolute configuration of small molecules with complete confidence (4, 5). Solution conformation (6) and state of aggregation (7) may also be amenable to analysis by VCD spectroscopy. However, unlike its counterpart, electronic circular dichroism (ECD) spectroscopy, no simple rules of thumb analogous to sector rules like the octant rule in ECD have yet emerged. We examine here the VCD spectra of three structurally related rigid, C_2 symmetric bicyclo[2.2.1]heptane derivatives, **1** (R = H), **1** (R = Me), and **1** (R-*t*-Bu), and compare the theoretically derived spectra with the experimental VCD spectra of two of them. While obvious parallels are not expected in the IR spectra of the three dialkyl derivatives because of congestion in the mid-IR region, it is not immediately apparent that the inherent chirality of the identical rigid skeletons should not be evident in the VCD spectra. The C_2 symmetry permits separation of the vibrational modes into two groups of *A* and *B* symmetry, and the application of the simple coupled oscillator model to the set of molecules.

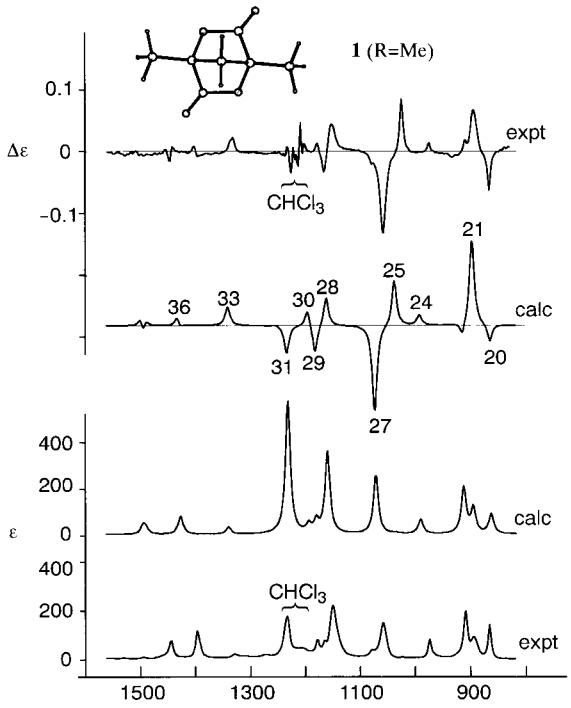
Methods

Theoretical

The structures of compounds **1** (R = H), **1** (R = Me), and **1** (R = *t*-Bu) were optimized at the B3LYP/6–31G* level using

© 1998 NRC Canada

Fig. 1. The experimental and calculated VCD and absorption spectra of (1*R*,4*R*)-**1** (R = Me) in the 800–1600 cm^{-1} spectral region.



procedures implemented in the Gaussian 92 and 94 program packages (8). Harmonic vibrational analysis at the same level was used to determine the quantum mechanical force field. The VCD spectra were calculated using the MFP procedure (9), as implemented in CADPAC (10). The VCD calculation incorporated B3LYP/6–31G* atomic polar tensors and force field (11) and HF/6–31G atomic axial tensors (12–14).[2] For the purpose of the theoretical simulations, the calculated frequencies have been scaled by 0.98, and a constant line width at half height of 10 cm^{-1} has been adopted.

Experimental

The synthesis and resolution of **1** (R = Me)[3] and **1** (R = *t*-Bu) (15) has been described previously. Both enantiomers were obtained: (+)-**1** (R = Me), $[\alpha]_D^{20} = 130$ (*c* 0.3, $CHCl_3$); (–)-**1** (R = Me), $[\alpha]_D^{20} = -131$ (*c* 0.3, $CHCl_3$); (+)-**1** (R = *t*-Bu), $[\alpha]_D^{20} = 86.3$ (*c* 0.93, $CHCl_3$), (+)-CE ($n - \pi^*$) in CD spectrum (λ_{max} 232.5 nm, $\Delta\varepsilon$ + 5.791 (EtOH)); (–)-**1** (R = *t*-Bu), $[\alpha]_D^{20} = -84.5$ (*c* 1.01, $CHCl_3$), (–)-CE ($n - \pi^*$) in CD spectrum (λ_{max} 232.5 nm, $\Delta\varepsilon$ –5.603 (EtOH)). The absolute configuration of **1** (R = *t*-Bu) was assigned previously as (–)-(1*S*,4*S*)-**1** (R = *t*-Bu) on the basis of X-ray diffraction analysis of a diastereomeric intermediate (15).

The VCD spectra were obtained with a Bomem MB100 interferometer described in detail elsewhere (16). The VCD components included a KRS-5 polarizer (Cambridge Physical Sciences), a ZnSe photoelastic modulator operating at 37 kHz (Hinds Instruments), an f/1 ZnSe focussing lens (Infrared Optics), an MCT-A detector, the appropriate electronic filters, and an Ithaca Dynamic 391A Lock-in amplifier. The sample of **1** (R = Me) was contained in a 0.162 M solution in $CHCl_3$ in a 0.15 mm NaCl cell. In total, 5000 ac scans were collected at 4 cm^{-1} in one single block and ratioed against 500 dc scans. The total data accumulation time was about 2 h per spectrum. The raw VCD spectrum was corrected for artefacts by subtracting the VCD spectrum of the enantiomer, and then calibrated in the usual fashion (17). The sample of **1** (R = *t*-Bu), 0.0832 M in $CHCl_3$ was measured under the same conditions. Neither substance was soluble in CCl_4, our preferred solvent. Experimental IR and VCD spectra were analyzed using the Labcalc software (18).

Results and discussion

The measured IR and VCD spectra of (1*R*, 4*R*)-**1** (R = Me) and (1*S*, 4*S*)-**1** (R = *t*-Bu) in the 800–1600 cm^{-1} spectral region are shown in Figs. 1 and 2, respectively, where they are compared with the calculated spectra. Note that the two compounds are homochiral. The experimental data are listed in Tables 1 and 2, respectively, as are the calculated spectra (frequencies scaled by 0.98). Comparison of the theoretical simulations and the measured spectra for both compounds (Figs. 1 and 2) reveals an excellent correspondence. We discuss the assignments in the spectral region below 1500 cm^{-1} of each of the compounds separately.

(1*R*, 4*R*)-1 (R = Me)

The four asymmetric methyl deformation modes and the CH_2 scissoring mode appear as a single unresolved absorption at 1444 cm^{-1}, the latter contributing about 30% to the total absorption. The VCD spectrum in this region is very weak, consisting of a +, –, + pattern that is well-reproduced theoretically (Fig. 1 and Table 1). The remaining two methyl deformation modes, corresponding to umbrella motions, are also not resolved, at 1396 cm^{-1}. The in- and out-of-phase motions are predicted to be separated by only 4 cm^{-1}. The weak +, – pattern of the VCD signal observed experimentally is also reproduced computationally and is explained as due to the *A* symmetry mode (mode 36) with positive VCD, partly cancelled by a weaker negative VCD of the *B* symmetry mode.

Weak absorptions at 1328 and 1271 cm^{-1} originate from C–C stretching modes mixed with methylene twists and wags. An in-phase stretching motion of the bridgehead C—C bonds to the methyls and methylene (mode 33) gives rise to the moderately strong positive VCD signal at 1331 cm^{-1}. The 1271 cm^{-1} absorption is predicted to have only a very weak positive VCD signal. None is apparent in the experimental spectrum. The intensity of the strong absorption at 1233 cm^{-1} (mode 31) is overestimated somewhat by the calculations. It is predicted to arise from an antisymmetric ring deformation composed of C–O bond stretches and to have an intense negative VCD associated with it. Unfortunately, this region of the

[2] The necessity to use HF atomic axial tensors for calculations on large molecules has been circumvented. The use of correlated methods to derive the molecular force field and atomic polar tensors is essential for accurate VCD results, while extension of correlated methods to atomic axial tensors is desirable but less critical (12). Procedures have recently been developed for consistent VCD calculations at CASSCF (13) and B3LYP (14) levels with GIAO (gauge independent atomic orbitals) on molecules of the current size. The use of the GIAO basis removes origin dependence of the rotatory strengths and reduces basis-set dependence of the results.

[e] Obscured by solvent.

VCD spectrum is obscured by solvent absorption. The absorption spectrum has a shoulder at 1207 cm^{-1}, which is attributed to solvent, as no IR band is predicted for this region.

The moderate absorption associated with a weak positive VCD signal at 1177 cm^{-1} (mode 30) is assigned as a wagging motion of the methylene group.

The pattern of the VCD absorptions at 1165 cm^{-1} (mode 29) and 1151 cm^{-1} (mode 28) is that of a highly conservative couplet indicative of a coupled oscillator mechanism (see below). The computed normal modes are complex mixtures of predominantly ring deformation (═C–C and C–O stretches) mixed with CH_2 wagging (*B* symmetry) or methyl rocking (*A* symmetry). The weak shoulder in the absorption spectrum, which appears to be associated with a weak negative VCD, is tentatively assigned as due to a twisting motion of the methylene group. This poorly defined mode is strongly mixed with other modes of *A* symmetry and is calculated to be virtually degenerate with a *B* symmetry ring deformation mode (mode 27). The latter is observed and calculated to have the strongest negative VCD amplitude in the 800–1600 cm^{-1} region. From the appearance of the experimental spectrum, one may infer that it (at 1058 cm^{-1}) is also a part of the bisignate pattern of a coupled pair of oscillators, the other component (mode 25) being the positive VCD absorption at 1024 cm^{-1}. The two modes are of *B* and *A* symmetry, respectively, and can be broadly described as ring deformations. However, the coupling (if it can be described as such) is of the nondegenerate kind, since the 1058 cm^{-1} mode largely involves stretching of the carbon bridgehead C—O bonds, while the 1024 cm^{-1} band is mostly a deformation of the six-membered ring, with carbonyl C–O stretching and C–O–C bending components.

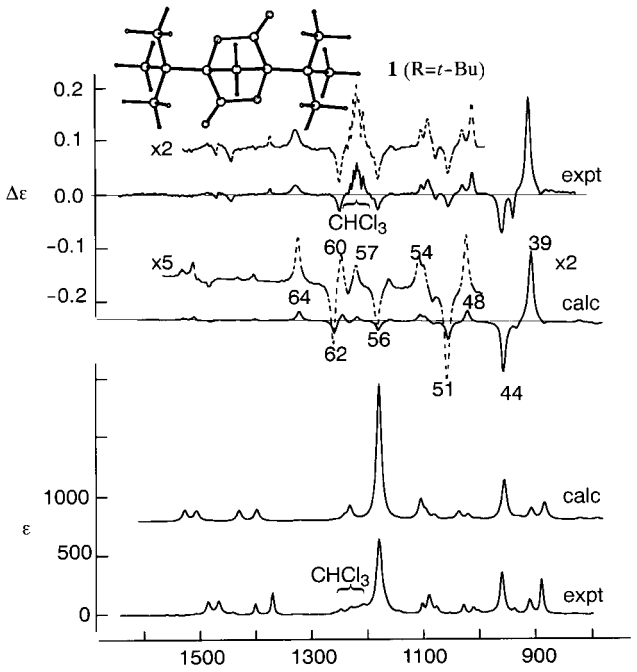
Three of the remaining modes shown in Fig. 1, at 974 cm^{-1} (mode 24), 909 cm^{-1} (mode 23), and 866 cm^{-1} (mode 20), are due to the four methyl rocking modes, two of which are predicted to be within 0.4 cm^{-1} of each other. The fourth band, attributed to another combination (mode 21) involving the methyl rocking and bridgehead C–O stretching gives rise to the large positive VCD signal observed at 894 cm^{-1}. The positive VCD signal observed at 909 cm^{-1} is incorrectly predicted to be negative, while the strength of the negative circular dichroism at 866 cm^{-1} is underestimated. The mistake at 909 cm^{-1} is the only apparent error in sign in the entire mid-IR region.

(1*S*, 4*S*)-1 (R = *t*-Bu)

Although visually not more complex than that of the homochiral dimethyl dilactone, the vibrational spectra of the di-*tert*-butyl dilactone, shown in Fig. 2, are the resultant of many more normal modes, as is apparent from the assignments in Table 2. The calculations indicate that the 12 methyl deformation modes occur in four distinct groups, which correspond to the three unresolved absorption bands at 1485, 1466, and

© 1998 NRC Canada

Fig. 2. The experimental and calculated VCD and absorption spectra of (1*S*,4*S*)-**1** (R = *t*-Bu) in the 800–1600 cm^{-1} spectral region.



1441 cm^{-1}, the last of which also includes the CH_2 scissor mode. The first two groups are predicted to have moderate absorption intensity but negligible VCD. Experimentally, a weak negative VCD band is observed at 1469 cm^{-1} for the second group. The third and fourth groups are predicted to be negligibly weak in both absorption and circular dichroism. The weak signals observed at 1441 cm^{-1} are predicted to arise from the CH_2 scissor mode, which occurs at the same place. The six umbrella modes of the methyl groups also are predicted to separate into two groups, observed at 1401 and 1370 cm^{-1}. No VCD signal is predicted nor observed for the first of these. The second group is predicted and observed to have a net positive VCD band.

The 14 modes predicted for the middle portion of the IR and VCD spectra (1322–1054 cm^{-1}) are complex mixtures of ring deformations, deformations of the heavy atom skeleton of the *tert*-butyl groups, and wags and twists of the methylene group. They are predicted to occur in 12 groups. Ten absorptions are apparent in the IR spectrum and eight bands can be distinguished in the VCD spectrum. The solvent absorption obscures the range 1150–1230 cm^{-1}. The conspicuous positive VCD feature at 1322 cm^{-1} is assigned to a mixed CH_2 wag, C–C stretching combination of *B* symmetry (mode 64). On either side of the solvent-obscured region are two pronounced negative VCD features, at 1249 and 1180 cm^{-1}. The former must be assigned to another combination (mode 62) of the same two CH_2 wag, C–C stretching motions. This is the only mode predicted to have appreciable negative VCD intensity. It is calculated after scaling to be 11 cm^{-1} higher than observed. Under the solvent band are predicted to occur several of the asymmetric C–C stretching combinations of the *tert*-butyl groups (identified as "*t*-Bu def" in Table 2). The moderately intense negative VCD band at 1180 cm^{-1} is associated with the most intense IR absorption in this region and is assigned to a mixed mode of *B* symmetry (mode 56) comprised of some CH_2 wag and a deformation of the six-membered ring involving changes to C—C and C—O bonds terminating at the carbonyl group. This may alternatively be described as in-plane wagging of the C═O bond although in mass-weighted coordinates it is the carbon atom that does most of the moving.

The +, +, – VCD pattern of the bands at 1103, 1090, and 1077 cm^{-1} is nicely reproduced by the calculations, as is the pronounced negative band at 1054 cm^{-1} (assigned to mode 51) for which the absorption can barely be distinguished. All of these originate from various deformations of the bicyclic skeleton.

Nine of the 12 methyl rocking modes are fairly isolated from the bicyclic skeletal modes, and are assigned to the absorption bands observed in the range 940 –1029 cm^{-1}. The exception is the band at 961 cm^{-1}, which has a heavy admixture of, and derives its intensity from, a deformation mode (mode 44) of *B* symmetry of the six-membered ring involving stretching of the bridgehead C—O bonds. The negative VCD feature associated with this absorption is preceded on the high-frequency side by two weaker positive VCD bands, at 1028 cm^{-1} and 1012 cm^{-1}. A methyl rocking combination admixed with the CH_2 wag is predicted to have moderate intensity and is assigned to the 1028 cm^{-1} absorption feature, but its rotatory strength is calculated (two lines predicted) to be very small. The 1012 cm^{-1} feature is readily assigned on the basis of both the absorbance and VCD intensities, as is the weak band at 940 cm^{-1}. In this case, the negative VCD sign is correctly predicted but the intensity is underestimated.

The most intense VCD feature, at 912 cm^{-1} in this region of the spectrum is assigned to a ring deformation of *A* symmetry involving asymmetric stretching of the two C—O bonds to each of the ether oxygen atoms (mode 39). The *B* symmetry combination of the same asymmetric stretch, at 891 cm^{-1}, is correctly predicted to have even greater intensity in absorbance but negligible VCD strength.

Coupled oscillators?

The presence of the C_2 axis of symmetry and of the strongly polar components of the lactone group suggest that an exciton coupling mechanism may provide a simple assignment of absolute configuration and an explanation of features of the VCD spectrum. Electrostatic coupling of the electric dipole transition moments of two chromophores separated in space and chirally oriented relative to each other will give rise to predictable Cotton effects (CEs). If the orientation of the two dipoles has negative handedness ((*M*)-chirality), then the out-of-phase (*B* symmetry) coupling will have a negative CE. The in-phase (*A* symmetry) coupling will have positive rotatory strength. Exactly the reverse is true for a positive-handed ((*P*)-chirality) disposition of the dipoles. If the mechanism of coupling is purely dipole–dipole coupling, then the electrostatic interactions dictate that the out-of-phase combination of the oscillators (*B* symmetry) is lower in energy than the in-phase (*A* symmetry) combination. As a consequence, the pattern of signs, positive–negative or negative–positive, is intrinsically related to the handedness of the spatial arrangement of the chromophoric groups (19). Thus a negative handedness to the orientation of the chromophores ((*M*)-chirality) will be

associated with a +, – pattern of VCD signal in the direction of increasing wavelength and vice versa for positive handedness. However, in their analysis of the VCD spectrum of *trans*-2,3-dideuteriooxirane, Freedman et al. (20), and subsequently Bour and Keiderling (21), showed that mechanical coupling of the oscillators (C—H and C—D bonds, in that case) may lead

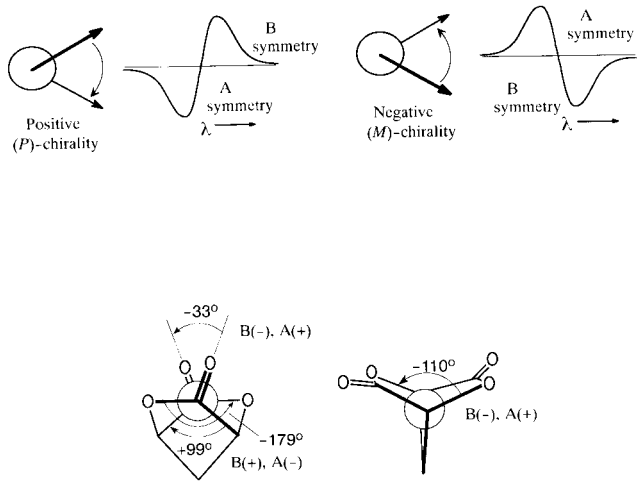
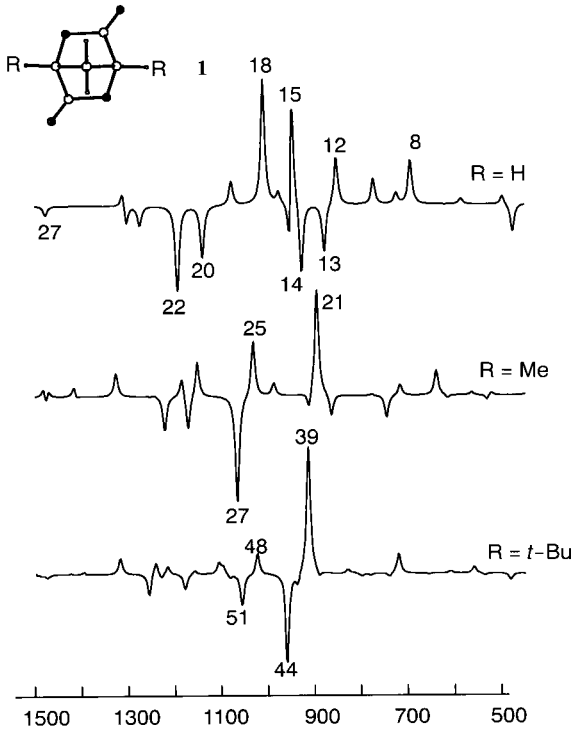
Scheme 1.



to nonconservative coupling patterns, possibly even of opposite sign. The "oscillators" most readily identified in **1** are the stretching vibrations of the polar bonds, C═O (carbonyl), C—O (bridgehead C to ether oxygen), ═C—O (carbonyl C to ether oxygen), and ═C—C (carbonyl C to bridgehead C). In (1*R*, 4*R*)-**1**, the symmetry-related pairs of these bonds have dihedral angles, –33°, –110°, –179°, and +99°, respectively, as shown in Scheme 1. The two C═O stretches form a pair of oscillators, which are most isolated from each other spatially and from other motions by virtue of frequency (no near degeneracies with other oscillators). For these, dipolar coupling should be the dominant mechanism. Indeed, the calculations predict a strong bisignate, conservative VCD pattern consistent with (*M*)-chirality (Tables 1, 2, and 3) in the vicinity of 1870 cm^{-1}. Unfortunately, this region of the VCD spectrum is not accessible to our instrument. The other polar C—O and C—C bonds are strongly coupled to each other as components of the modes identified in the tables as "ring deformations," and they fall in the congested region 900–1100 cm^{-1}. In the methyl and di-*tert*-butyl derivatives, they are also mixed and overlaid by C–C stretches and C-C-H angle deformations. In retrospect, it is not surprising that there are no recognizable coupled oscillator-derived patterns in the spectra of the two 1,4-dialkyl dilactones. Nevertheless, to the extent that one or the other of these degenerate pairs of stretching motions is a component of a particular normal mode, the sign of the CE should be determined by the handedness of the orientation of the bonds. One would not expect to see a VCD contribution from the ═C—O bonds (carbonyl C to ether O), since these are essentially coplanar (the projected dihedral angle is –179°, Scheme 1). However, modes of *A* and *B* symmetry that have a significant contribution from the stretching of the ═C—C bonds (carbonyl C to bridgehead C), which are oriented with positive chirality (+99°), should have negative and positive CEs, respectively. Conversely, the C—O bonds (bridgehead C to ether O) are oriented with negative chirality (–110°), and modes of *A* and *B* symmetry that incorporate the stretches of these bonds should have positive and negative CEs, respectively.

In the VCD spectrum of **1** (R = Me) shown in Fig. 1, a number of the fundamental modes have significant components of one or other of the polar bond stretches. Thus mode

Fig. 3. A comparison of the calculated VCD spectra of (1*R*,4*R*)-**1** (R = H), (1*R*,4*R*)-**1** (R = Me), and (1*S*,4*S*)-**1** (R = *t*-Bu) in the 500–1500 cm^{-1} spectral region.



31 at 1233 cm^{-1} is predicted to arise from a *B* symmetry ring deformation composed of C–O bond stretches and to have an intense negative VCD associated with it, as expected from the (*M*)-chirality. The pattern of the VCD absorptions due to modes 29 and 28 is indicative of a coupled oscillator mechanism. These modes are complex mixtures of ring deformation (═C–C and C–O stretches) mixed with CH_2 wagging (*B* symmetry) or methyl rocking (*A* symmetry). The two polar bonds are disposed as two oppositely handed pairs. The observed and calculated signs are consistent with dominance of the ═C–C stretching mode, i.e., the pair with (*P*)-chirality. Similarly, modes 27 and 25 appear as a nonconservative couplet. The two modes are of *B* and *A* symmetry, respectively. Mode 27 involves stretching of the bridgehead C—O bonds, and the sign of the CE is consistent with the handedness. On the other hand, mode 25 is mostly a deformation of the six-membered ring, with carbonyl ═C–O stretching and ═C–O–C bending components. The ═C—O bonds are nearly coplanar and should not contribute to the CD. The origin of the positive rotatory strength of this band is obscure. Finally, mode 21 involves methyl rocking and bridgehead C–O stretching motions of *A* symmetry. The positive VCD signal is expected to arise from the C–O stretching components of the mode.

In the same vein, the CD signs of two of the fundamental modes of **1** (R = *t*-Bu), can be explained as originating from motions of the chirally disposed polar bonds. The band at 961 cm^{-1}, which is assigned to mode 44 with *B* symmetry, corresponds to a deformation of the six-membered ring involving stretching of the bridgehead C—O bonds. The observed and calculated negative CE is consistent with a coupled

oscillator mechanism for the origin of the CD. Similarly, the most intense VCD feature, at 912 cm^{-1}, is assigned to mode 39, a ring deformation of *A* symmetry involving asymmetric stretching of the two C—O bonds to each of the ether oxygen atoms. Again, because the bonds terminating at the carbonyl C are achirally disposed, the VCD should arise from the bridgehead C–O component and have a positive sign according to the coupled oscillator mechanism.

(1*R*, 4*R*)-1 (R = H)

The parent bicyclic dilactone, **1** (R = H), has not been prepared in optically active form. In Fig. 3 is shown the theoretically predicted VCD spectrum together with the VCD spectra of the dimethyl and di-*tert*-butyl derivatives, which were discussed above. Both the predicted IR and VCD spectroscopic values are listed in Table 3. A cursory inspection of Fig. 3 does not reveal many obvious similarities between the VCD spectra of the three compounds in spite of the fact that they all have the same handedness of the same bicyclo[2.2.1]heptyl dilactone skeleton. We discuss below the assignments of the normal modes of the parent while seeking spectroscopic commonalities among the three compounds.

Lacking methyl groups, the first band of the 500–1500 cm^{-1} region of the spectrum is due to the CH_2 scissor (mode 27) at 1469 cm^{-1}. This mode is predicted to have a weak negative VCD in all three compounds and so is diagnostic of the skeletal chirality. Unfortunately, because of its weakness and the fact that it occurs in the methyl deformation region, it is difficult to identify in the dialkyl derivatives.

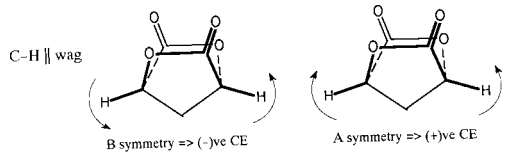
All of the remaining modes of the parent bicyclic dilactone are complex mixtures of C–H and CH_2 wags and twists with various deformations of the bicyclic skeleton. The assignments listed in Table 3 identify what appears to be the dominant contribution based on a visual inspection of the normal modes. We will discuss only the more intense VCD features.

The most intense VCD feature of **1** (R = H) is predicted to be a positive band at 1001 cm^{-1}, originating from a rocking motion of the methylene bridge (*B* symmetry, mode 18). This mode has a minor contribution from stretching of the bridgehead C—O bonds, but the sign is opposite to that expected for the contribution of an (*M*)-chirality bond array to a *B* symmetry mode. Mode 15 of *A* symmetry at 941 cm^{-1}, corresponding to a mixture of CH_2–C and C–O stretches and methine wag parallel to the C_2 axis, is predicted to have a high positive rotatory strength, which is partially cancelled by overlapping negative absorptions due to *B* symmetry modes (modes 14 and 16). The positive CE is consistent with a coupled oscillator mechanism operating for the C–O stretches as is the negative sign for the *B* symmetry mode 14, which also has a significant C–O stretching component.

It is not clear whether the polar bond motions of modes 14 and 15 are responsible for the signs of the CE or merely reinforce a dominant contribution from the methine motions. Mode 16, of *B* symmetry and negative rotatory strength, has a

© 1998 NRC Canada

Scheme 2.



strong contribution of the parallel C–H wag, as do modes 20 and 22, at 1138 and 1190 cm^{-1}, respectively, both of which are also negative and of *B* symmetry. It is of interest that the major part of the ring deformation component of these last two modes appears to be stretching of the =C—C bonds whose (*P*)-chirality would contribute positive rotatory strength to modes of *B* symmetry. Since the observed and calculated signs are negative, the motion of the methine hydrogens must dominate the rotatory strength of the mode, as they apparently did in the case of mode 16. Mode 12, like mode 15, is in part the parallel C–H wag of *A* symmetry and has a positive CE. One may tentatively generalize that the in-phase (*A* symmetry) wag of the C—H bond is associated with a positive CE, and the out-of-phase (*B* symmetry) mode consistently has negative rotatory strength. The situation is summarized in Scheme 2. These contributions from motions of the C—H bonds may overwhelm the effects of other polar bonds in the molecule.

Conclusions

The experimental VCD spectra of 1,4-dimethyl- and 1,4-di-*tert*-butyl-2,5-dioxabicyclo[2.2.1]heptane-3,6-dione were measured in the mid-IR region (800–1500 cm^{-1}) and compared with spectra predicted by the ab initio magnetic field perturbation (MFP) theoretical method in conjunction with a B3LYP/6–31G* force field. The excellent agreement between calculated and experimental spectra permits the assignments not only of the absolute configuration but of all of the fundamental transitions. Although the absolute configuration of **1** (R = Me) was previously inferred from ab initio calculations of the ECD spectrum and comparison with the experimental ECD spectrum of (–)-(1*S*,4*S*)-**1** (R = *t*-Bu) (15), the present work provided an unambiguous confirmation of the assignment as (–)-(1*R*,4*R*)-**1** (R = Me).

The theoretical VCD spectrum of the parent 1,4-dihydro system is also presented and discussed. In spite of the homochirality and structural similarity of the bicyclic skeletons, there is little obvious correspondence among the three VCD spectra. Nevertheless, the analysis of the VCD spectra is greatly enhanced by the presence of the C_2 axis of symmetry. Many of the major VCD features of the two dialkyl compounds can be understood on the basis of the coupled oscillator mechanism where the oscillators are the chirally disposed pairs of equivalent polar bonds. Only the carbonyl stretching modes produce the characteristic bisignate couplet of VCD bands. However, the signs of the contributions to the rotatory strengths of individual fundamental transitions of *A* or *B* symmetry are predictable from the coupled oscillator mechanism if they have stretching of the polar C—O or C—C bonds as components. Surprisingly, VCD contributions due to motions of the C—H bonds in the parent dihydro system may dominate the contributions of the polar bonds. A general rule for the VCD sign of the *A* and *B* symmetry modes, which encompass wagging motions of the bridgehead C—H bonds, is deduced.

Microwave-enhanced metal- and acid-catalysed hydrogen isotope exchange reactions

Jean M. Barthez, Anton V. Filikov, Lottie B. Frederiksen, Marie-Loire Huguet, John R. Jones, and Shui-Yu Lu

Abstract: The benefits of using microwaves to accelerate the rates of hydrogen isotope exchange reactions are illustrated by reference to heterogeneous and homogeneous metal-catalysed reactions as well as to homogeneous acid-catalysed reactions. The results show that good incorporation of deuterium is obtained in very short time intervals, typically <20 min, and that the approach has considerable potential for the labeling of a wide range of compounds with both deuterium and, by implication, tritium.

Key words: microwave enhanced deuteriations, hydrogen isotope exchange.

Résumé : Faisant appel à des réactions hétérogènes et homogènes catalysées par les métaux ainsi qu'à des réactions homogènes catalysées par les acides, on montre les bénéfices de l'utilisation des microondes pour accélérer les vitesses de réaction d'échanges isotopiques de l'hydrogène. Les résultats montrent que l'on obtient une bonne incorporation de deutérium dans des intervalles de temps de réaction très courts, en général <20 min, et que cette approche présente un grand potentiel pour le marquage d'un grand nombre de produits tant avec du deutérium que, par implication, par le tritium.

Mots clés : deutérations facilitées par les microondes, échange isotopique d'hydrogène.

[Traduit par la rédaction]

The focus of our recent labeling studies with both ^{2}H and ^{3}H has been concerned with (*a*) developing one-step catalysed reactions (1–3) and (*b*) the use of polymer-supported acid (4) and base (5) catalysts, the former in order to achieve regiospecific incorporation and the latter in order to simplify the isolation of product, which is particularly important in the case of highly radioactive compounds. In both areas success has been achieved but only by using a combination of high temperatures and prolonged heating times, conditions that many pharmaceuticals find too harsh, leading to decomposition.

Forty years ago Wilzbach (6) reported on an apparently promising radiation-induced method for tritiating organic compounds, which stimulated a great deal of interest in the use of alternative sources of energy, such as microwaves (7), to enhance the attractions of hydrogen isotope exchange labeling procedures. However, it was only in 1986 that the potential of microwaves in organic synthesis (8, 9) was fully appreciated, since when the field has seen considerable expansion (10).

Microwaves have been used to synthesize radiopharmaceuticals containing the short-lived ^{11}C, ^{18}F isotopes (11–13) as well as tritiated peptides (14–17), steroids (18), carcinogens (19), and benzodiazepine-type compounds (20), but the overall picture is one in which relatively few studies have been reported. In the present paper we address this issue by investigating several metal-catalysed hydrogen isotope exchange reactions, both under homogeneous and heterogeneous conditions, as well as a high-temperature dilute acid catalysed exchange procedure that has previously been used with considerable success by Werstiuk (21). The extensive studies of Garnett (22), Garnett and Long (23), and Williams (24) on the use of transition metal catalysed hydrogen isotope exchange reactions show, that like Werstiuk's studies, both high temperatures and long periods of time are required in order to achieve good isotopic incorporation.

Received December 18, 1997.

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

Experimental

Three different microwave instruments (a CEM MDS system, a Scientific and Medical Products unit, and a Matsui M169BT unit) were used for the deuteriation studies of which the first two were of a commercial design and the third of a household kind. It was customary practice when using the commercial instruments to employ a fixed time whilst with the domestic version short pulses, typically of 2 min duration, interspersed by a cooling period, were used.

In the early studies the reagents were contained in a thick-walled glass tube sealed at the top but experience showed that a small conical flask (capacity 25 mL) containing a septum was equally satisfactory. The latter was placed in a beaker containing vermiculite and slowly rotated during the course of the irradiation. The procedure for isolating the labeled product depended on the kind of catalyst employed.

Heterogeneous metal-catalysed hydrogen isotope exchange

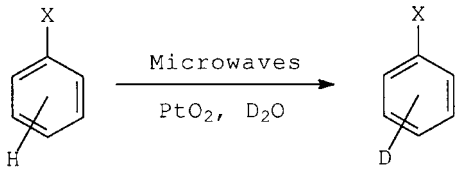
Table 1. Deuteration of selected aromatics under microwave conditions (15 min irradiation at 160 W) using PtO_2 catalyst and D_2O (1 mL).



X	Amount	Catalyst (mg)	Deuteration orientation (relative %)		
CH_3	2 mL	34	*ortho* (29)	*meta* (57)	*para* (14)
COOH	307 mg	124		*meta* (100)	
NH_2	3 mL	130	*ortho* (95)	*meta* (5)	
OH	465 mg	95	*ortho* (54)	*meta* (19)	*para* (27)
$COCH_3$	3 mL	105	acetyl (25)	*meta* (50)	*para* (25)
2,6-Dimethoxy benzoic acid	290 mg	100		*meta* (5)	*para* (95)

isotopic abundance), and substrate were inserted in the reaction flask (Table 1). On completion of the irradiation the flask was allowed to cool, the catalyst filtered off, and the substrate extracted into an organic solvent (usually diethyl ether) and washed with water, before drying over anhydrous Na_2SO_4. The solvent was then removed by rotary evaporation.

Homogeneous metal-catalysed hydrogen isotope exchange

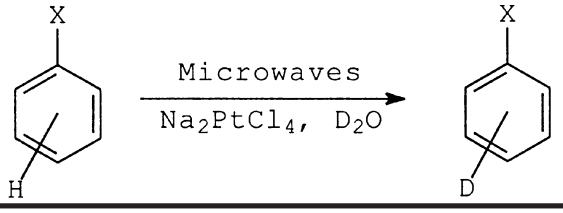
For these studies a 5% aqueous solution of sodium tetrachloroplatinate was used as the catalyst. On completion of the irradiation, solvent extraction, washing with water, and drying over anhydrous Na_2SO_4 were undertaken prior to removal of the solvent.

Homogeneous acid-catalysed hydrogen isotope exchange

Stock *o*-toluidine hydrochloride was prepared by mixing *o*-toluidine (8.57 g), 3 M HCl (27 mL), and activated charcoal (2 g) in a 100 mL flask at 70°C for 15 min. Removal of charcoal using filtration, then removal of water using rotary evaporation, afforded the salt as a grey solid. *o*-Toluidine hydrochloride (0.8 g) was stirred with D_2O (2 mL) at ambient temperature for 4 h and the D_2O was distilled off under vacuum. In each hydrogen isotope exchange reaction, the deuteriated salt (30 mg) was dissolved in fresh D_2O (300 mL) in the conical flask. On completion of the irradiation, the D_2O solution was used directly for NMR analysis. Deuteriated *o*-toluidine in the free amine form was also obtained by neutralizing the reaction mixture with NaOH (3 M), followed by extraction with chloroform, drying over anhydrous $MgSO_4$, and evaporation of the solvent.

In all three kinds of hydrogen isotope exchange the ^1H NMR spectra of a solution of the substrate in a deuteriated solvent were recorded, both before and after deuteriation has taken place; the ^2H NMR (^1H decoupled) spectra were also obtained. For this work a Bruker AC 300 instrument operating at 300 MHz for the ^1H spectra and at 46 MHz for the ^2H spectra was used. For both the heterogeneous and homogeneous metal-catalysed studies it was the orientation effects that were of interest whilst with the acid-catalysed exchange interest focused on the extent of deuteriation; the methyl group hydrogens, which do not undergo exchange, provide a convenient internal standard.

Table 2. Deuteration of selected aromatics under microwave conditions (15 min irradiation at 160 W) using Na_2PtCl_4 catalyst and D_2O (1 mL).



X	Amount	Catalyst[a] (mL)	Deuteration orientation (%)		
COOH	500 mg	0.5		*meta* (100)

Results and discussion

The most remarkable feature of all the results (Tables 1–3) is the very brief time that is necessary to obtain extensive deuteriation. What is achieved in a matter of a few minutes can be compared with what is customarily required under thermal conditions — temperatures in excess of 100°C for prolonged periods, sometimes of several days duration. Furthermore, the short irradiation times ensure that the reactions are cleaner and

© 1998 NRC Canada

lead to less by-product formation, findings that are similar to those reported by others (10).

Pre-reduced PtO_2 has long been considered (24) one of the most active and generally useful heterogeneous metal catalysts for hydrogen isotope exchange studies and the results in Table 1 show that in at least two cases (X = COOH, NH_2) a high degree of regioselectivity is observed. In the case of 2,6-dimethoxy benzoic acid steric hindrance ensures that but little deuterium is inserted in the *meta* positions, neither is deuterium incorporated into the *ortho* positions in acetophenone.

With the homogeneous sodium tetrachloroplatinate catalyst the pattern of labeling is the same as under heterogeneous conditions for benzoic acid but in other cases there are significant differences. Caution is required in interpreting these as there may well be instances, for example, in the case of acetophenone, where base catalysis is in direct competition with metal catalysis. However, the ease and rapidity with which the necessary data can now be obtained, as compared to thermal conditions, greatly increases the attractions of using deuterium orientation as an indicator of possible reaction mechanisms.

Finally the ease with which *o*-toluidine hydrochloride can be deuteriated can be compared with the conditions employed by Werstiuk (21) for deuteriating the structurally similar aniline hydrochloride — heating at 175–250°C for between 12 and 54 h. The hope must be that the present findings can be extended to include more sensitive pharmaceuticals, in which case the hope expressed by Wilzbach in his pioneering paper will have been achieved, albeit with a different kind of radiation. Its extension to the tritiation of organic compounds is currently being explored.

Acknowledgments

We are grateful to NATO and The Royal Society for financial support (A.V.F.) and the European Union for postdoctoral fellowships (J.M.B., L.B.F., and M.-L.H.). We are also grateful to Professor D.M P. Mingos, F.R.S. for useful discussions at the early stages of this work.

An unusual ground-state stabilization effect and origins of the α-effect in aminolyses of Y-substituted phenyl X-substituted benzoates

Ik-Hwan Um, Eun-Kyung Chung, and So-Mi Lee

Abstract: Second-order rate constants have been measured spectrophotometrically for the reactions of X-$C_6H_4CO_2C_6H_4$-Y with a series of primary amines in H_2O containing 20 mol% DMSO at 25.0 ± 0.1°C. The reactivity increases as the substituent (X and Y) becomes a stronger electron-withdrawing group. The σ^+ constants give better Hammett correlation than σ constants for the reactions of 4-nitrophenyl X-substituted benzoates with glycylglycine (glygly) and hydrazine (NH_2NH_2), indicating that the ground-state stabilization effect is unusually significant on the reaction rates. The reactions of X-$C_6H_4CO_2C_6H_4$-Y with glygly and NH_2NH_2 appear to proceed through the same mechanism, but the degree of leaving-group departure and the negative charge developed in the acyl moiety at the rate-determining TS is considered to be more significant for the glygly system than the NH_2NH_2 system based on $ß_{lg}$ and ρ_X values. The magnitude of the α-effect is observed to be not always dependent on the $ß_{nuc}$ value but dependent on the electronic nature of the substituent X and Y, i.e., an electron-donating substituent increases the α-effect, while an electron-withdrawing one decreases the α-effect. The present study has led to the conclusion that the ground-state effect is important for the reaction rates but it is not solely responsible for the α-effect, and the intramolecular H-bonding interactions (**4**) are proposed for the cause of the increasing or decreasing α-effect trends observed in the present system.

Key words: α-effect, intramolecular H-bonding interaction, ground-state stabilization effect.

Résumé : Faisant appel à la spectrophotométrie, on a mesuré les constantes de vitesse du deuxième ordre des réactions de X-$C_6H_4CO_2C_6H_4$-Y avec une série d'amines primaires, dans de l'eau contenant 20 mol% de DMSO, à 25,0 ± 0,1°C. La réactivité augmente lorsque les substituants (X et Y) de plus en plus électroaffinitaires. Pour les réactions des benzoates de 4-nitrophényle substitués par un groupe X avec la glycylglycine (glygly) et avec l'hydrazine (NH_2NH_2), les constantes σ^+ donnent une meilleure corrélation de Hammett que les constantes σ; ces résultats indiquent que l'effet de stabilisation dans l'état fondamental particulièrement important pour les vitesses de réaction. Les réactions des X-$C_6H_4CO_2C_6H_4$-Y avec la glygly et l'hydrazine semblent se produire par le même mécanisme; toutefois, si l'on se base sur les valeurs β_{lg} et ρ_x, il semble que le degré de séparation du groupe partant et le niveau de charge négative développé sur la partie acyle dans l'état de transition (ET) de l'étape cinétiquement limitante soient plus importants pour le système glygly que pour le système de l'hydrazine. On a observé que l'amplitude de l'effet α ne dépend pas toujours de la valeur β_{nuc}, mais qu'elle dépend de la nature électronique des substituants X et Y, c'est-à-dire qu'un substituant électrodonneur augmente l'effet α alors qu'un substituant électroattracteur diminue l'effet α. Le présent travail conduit à la conclusion que l'effet de l'état fondamental influence beaucoup les vitesses de réaction, mais qu'il n'est pas le seul responsable de l'effet α; on suggère que des interactions par liaisons hydrogènes intramoléculaires sont la cause de l'augmentation ou de la diminution des tendances dans les effets α observées dans le présent système.

Mots clés : effet α, interaction par liaison hydrogène intramoléculaire, effet de stabilisation de l'état fondamental.

[Traduit par la rédaction]

Introduction

The basicity of nucleophiles has been most commonly used to predict nucleophilicity (1). However abnormally higher nucleophilic reactivity than would be predicted from the basicity has been often observed in the reaction of nucleophiles containing an atom with one or more nonbonding electron pairs at the α-position of the reaction site, e.g., peroxides, oximates, hydroxamates, hydrazines, hydroxylamine, etc. The term α-effect was given to the abnormally enhanced nucleophilicity shown by these nucleophiles by Edwards and Pearson in 1962 (2). Since then, numerous studies have been performed to investigate the cause of the α-effect (3–10). The explanations suggested for the origin of the α-effect are: ground-state (GS) destabilization due to the repulsion of the nonbonding electrons (2), transition-state (TS) stabilization including intramolecular general acid–base catalysis (5), product stabilization (6), decreased solvation (7), etc. (3).

[c] Rate constant not measured due to extremely slow reaction rate.

We have studied the reaction of 4-nitrophenyl acetate (PNPA) with butane-2,3-dione monoximate (Ox^-) and 4-chlorophenoxide (ArO^-) as an α-effect nucleophile and the corresponding normal nucleophile, respectively, in H_2O – dimethyl sulfoxide (DMSO) mixtures of varying compositions (8). The magnitude of the α-effect has been found to increase as the mol% DMSO increases up to near 50 mol% DMSO and then to decrease upon further additions of DMSO to give a bell-shaped α-effect trend. Such a bell-shaped α-effect trend has been also reported for the reaction of 4-nitrophenyl diphenylphosphinate (PNPDPP) with Ox^- and ArO^- in H_2O–DMSO mixtures (9). However, the reactions of PNPA with Ox^- and benzohydroxamates run in H_2O–acetonitrile (MeCN) mixtures have been observed to exhibit an increasing α-effect as the mol% MeCN increases, indicating that the solvent effect on the α-effect is significant (10).

We have now extended our study to the reactions of Y-substituted phenyl X-substituted benzoates with a series of primary amines including hydrazine and hydroxylamine as shown in Scheme 1. Aminolyses of esters have been intensively studied, and numerous data about the reaction mechanisms are available (11–13). Therefore, our systematic study would be expected to give us important information about the origin of the α-effect.

Results

All the kinetic reactions in the present study obeyed pseudo-first-order kinetics. Pseudo-first-order rate constants (k_{obs}) were measured spectrophotometrically for the aminolyses of X-$C_6H_4CO_2C_6H_4$-Y in H_2O containing 20 mol% DMSO at 25.0 ± 0.1°C, i.e., the k_{obs} value was obtained from the slope of the plot of $\ln(A_\infty - A_t)$ vs. time. Generally five different amine concentrations were used to obtain second-order rate constants from the slope of the linear plot of k_{obs} vs. amine concentration. Correlation coefficient of the plot was usually higher than 0.9995 except for the reactions of 4-chlorophenyl benzoate and 4-ethoxycarbonylphenyl benzoate with hydrazine and glygly, which exhibited an upward curvature as the amine concentration increased. Since the plots of k_{obs}/[amine] vs. [amine] were linear for these reactions, the second-order and third-order rate constants were obtained from the intercept and slope of the linear plots, respectively. It is estimated from replicate runs that the error in any particular measured rate constant is less than ±3%. The kinetic results including the carbonyl stretching bands for the substrates ($\nu_{C=O}$) are summarized in Tables 1–4, and demonstrated graphically in Figs. 1–7.

Discussion

Reaction mechanism

As shown in Table 1, the reactivity increases with increasing the basicity of amines except NH_2NH_2 and NH_2OH. Interestingly, NH_2NH_2 is much more reactive than glycylglycine (glygly), although the basicity of the two amines is comparable. NH_2OH also exhibits higher reactivity than would be expected from its basicity, i.e., NH_2OH is almost as reactive as benzylamine, although the former is about 3.5 pK_a units less basic than the latter. The dependence of reactivity on the basicity of amines is graphically demonstrated in Fig. 1. It is seen from the

figure that the logarithmic apparent second-order rate constant (log k) increases linearly with increasing the pK_a of the amines except NH_2NH_2 and NH_2OH, which exhibit positive deviations from the linear Brönsted-type plots. Since these two amines have been classified into the α-effect nucleophile, the positive deviation shown by them is apparently the α-effect.

To investigate the origin of the α-effect in the present system, it is necessary to understand the reaction mechanism and the structure of the transition state (TS). Aminolyses of carboxylic esters have been generally suggested to proceed via a stepwise mechanism in which the rate-determining step (RDS) is dependent on the basicity of the leaving group and the nucleophilic amine (11–13). A change in the RDS has been reported to accompany a significant decrease in the magnitude of $ß_{nuc}$ value, e.g., from 0.7–0.9 to 0.2–0.3 as the RDS changes from the breakdown of the addition intermediate (the k_2 step in Scheme 1) to the formation of the intermediate (the k_1 step in Scheme 1) (11–13). The $ß_{nuc}$ value for the present system has been calculated to be 0.76 ± 0.2, indicating that the RDS is the k_2 step.

It is interesting that the magnitude of $ß_{nuc}$ values in the present aminolysis appears to be independent on the electronic nature of the acyl substituent X, but remains almost constant within the experimental error. This is an unexpected result based on the reactivity–selectivity principle (RSP) (14). However failures of the RSP have been often reported (14). Lee et al. (15) have observed that the magnitude of $ß_{nuc}$ values increases with increasing electron-withdrawing ability of the acyl substituents for aminolyses of X-substituted benzoyl halides and their related compounds, although the reactivity increases with increasing electron-withdrawing ability of the substituent. We have also observed a larger $ß_{nuc}$ value for a stronger electron-withdrawing substituent in the acyl moiety for the nucleophilic substitution reaction of 4-nitrophenyl X-substituted benzoates with aryloxides in the same reaction condition as in the present system (16). Such anti-RSP behaviors have been often reported for the reactions that proceed via an associative S_N2 mechanism, or for the one in which nucleophilic attack is involved in the RDS (15, 16). Lee et al. (15) have attributed the anti-RSP behavior to more bond formation by the stronger electron-withdrawing substituent. For a stepwise reaction in which the breakdown of the intermediate is the RDS, bond formation between the nucleophile and the carbonyl group of the substrate would be complete at the rate-determining TS. In this case, the acyl substituent would no longer influence the magnitude of $ß_{nuc}$ value. Therefore, the constant $ß_{nuc}$ values also support that the present aminolysis proceeds via a rate-determining breakdown of the addition intermediate.

To get more information about the reaction mechanism and the α-effect, we have performed the reaction of Y-substituted phenyl benzoates with NH_2NH_2 and glygly as an α-effect nucleophile and the corresponding normal nucleophile, respectively. One can see from the kinetic data in Table 2 that NH_2NH_2 is more reactive than glygly for all the substrates studied, and the reactivity of the substrates increases with decreasing the basicity of the leaving aryloxide for both NH_2NH_2 and glygly systems. The dependence of the reactivity on the basicity of the leaving group is demonstrated in Fig. 2. The Brönsted-type plots are not as linear as the ones in Fig. 1. Besides, the points for the weakly basic leaving groups such as 4-chloro-2-nitrophenoxide and 2,4-dinitrophenoxide appear to deviate negatively from linearity for both NH_2NH_2 and glygly systems. Since a break or curvature in Brönsted-type plots has been understood as a change in the RDS or the reaction mechanism (17), one might consider that a change in the RDS occurs as the leaving group becomes weakly basic. However, it has been generally known that a change in the RDS for aminolyses of various carboxylic esters occurs when the nucleophilic amine becomes more basic than the leaving group by ~5 pK_a units (11–13). Although NH_2NH_2 and glygly are more basic than the leaving phenoxide (except 4-chlorophenoxide and 4-ethoxycarbonylphenoxide) in the present system, the basicity of these amines is not larger than that of the leaving aryloxides by ~5 pK_a units even for the least basic leaving group, 2,4-dinitrophenoxide. Therefore, the curvatures obtained in Fig. 2 are not considered to be a result of a change in the RDS.

Curvatures in Brönsted-type plots have been often observed for reactions whose mechanism does not change. Recently, Jencks and co-workers (18) have performed the reactions of 3- and 4-nitrophenyl formates with a series of substituted phenoxides and found nonlinear Brönsted-type plots. Interestingly, the phenoxides having a chlorine atom at the *ortho* position exhibit negative deviations from the linear Brönsted-type plots (18). Accordingly, the steric effect but not a change in mechanism has been suggested to be responsible for the deviations (18). As shown in Fig. 2, the substrates having an *ortho* substituent in the leaving group deviate negatively from the linear Brönsted-type plots. Therefore, one can consider that the present reactions of Y-substituted phenyl benzoates with NH_2NH_2 and glygly proceed through the same mechanism without changing the RDS.

The slopes ($ß_{lg}$) in Fig. 2 have been calculated to be –1.08 and –1.25 for the reaction with NH_2NH_2 and glygly, respectively. Since NH_2NH_2 is more reactive than glygly, the larger $ß_{lg}$ value for the less reactive glygly system appears to be in accordance with the RSP. The magnitude of $ß_{lg}$ has been also used as a measure of the leaving group departure at the rate-determining TS. Accordingly, one can consider that the degree of the leaving-group departure would be slightly more significant for the glygly than the NH_2NH_2 system. However, the shape of the Brönsted-type plots for the reactions of NH_2NH_2

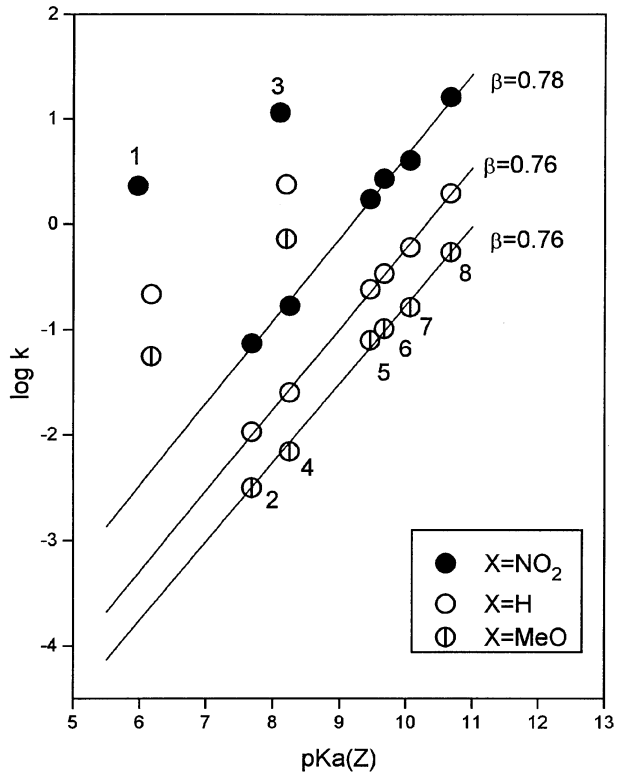
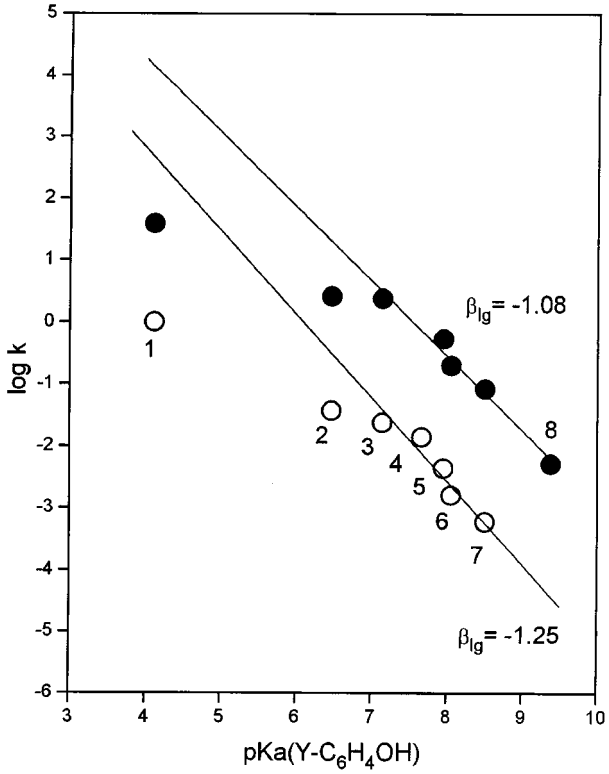
Fig. 1. Brönsted-type plots for the reactions of 4-nitrophenyl X-substituted benzoates (X-$C_6H_4COOC_6H_4$-4-NO_2) with primary amines in water containing 20 mol% DMSO at 25.0 ± 0.1°C. The numbers in the figure refer to the amines in Table 1.



and glygly is similar to each other. Therefore, it is considered that the reaction of Y-substituted phenyl benzoates with NH_2NH_2 and glygly proceeds in a similar mechanism but the leaving group departure at the TS is slightly more advanced for the less reactive glygly system.

Fig. 2. Brönsted-type plots for the reactions of Y-substituted phenyl benzoates ($C_6H_4COOC_6H_4$-Y) with hydrazine (●) and glycylglycine (○) in water containing 20 mol% DMSO at 25.0 ± 0.1°C. The numbers in the figure refer to the substrates in Table 2.



To get further information about the structure of the TS, we have performed the reactions of 4-nitrophenyl X-substituted benzoates with NH_2NH_2 and glygly. The kinetic results are summarized in Table 3. One can see that NH_2NH_2 is more reactive than glygly, and the reactivity of these benzoates increases with increasing electron-withdrawing ability of the acyl substituent (X). The dependence of reactivity on the electronic nature of the substituent is demonstrated in Fig. 3. Excellent linear Hammett plots have been obtained for both NH_2NH_2 and glygly systems, indicating that the variation of the acyl substituent does not cause any change in the mechanism or RDS in the aminolysis reaction.

The ρ_X values have been calculated to be +0.76 and +0.90 for the reaction with NH_2NH_2 and glygly, respectively. It has been known that the sign and the magnitude of the ρ_X value represent the type and the relative degree of the charge development at the acyl moiety at the TS, respectively (19). Therefore, the positive ρ_X value suggests that the negative charge is developing in the acyl moiety at the TS, and the degree is less significant for the NH_2NH_2 system than the glygly system based on the ρ_X values. The magnitude of ρ_X values in the present aminolyses (ρ_X = 0.76, 0.90) has been obtained to be much smaller than the one for the corresponding reactions with anionic nucleophiles, such as HO^- and aryloxides (ρ_X = 2.44–2.96) (20–22). Since the neutral nucleophile would share its electrons less significantly with the acyl moiety of the substrate than the anionic nucleophile, one can expect a smaller ρ_X value for the reaction with amines than for the one with the anionic nucleophiles. Therefore, one might consider the

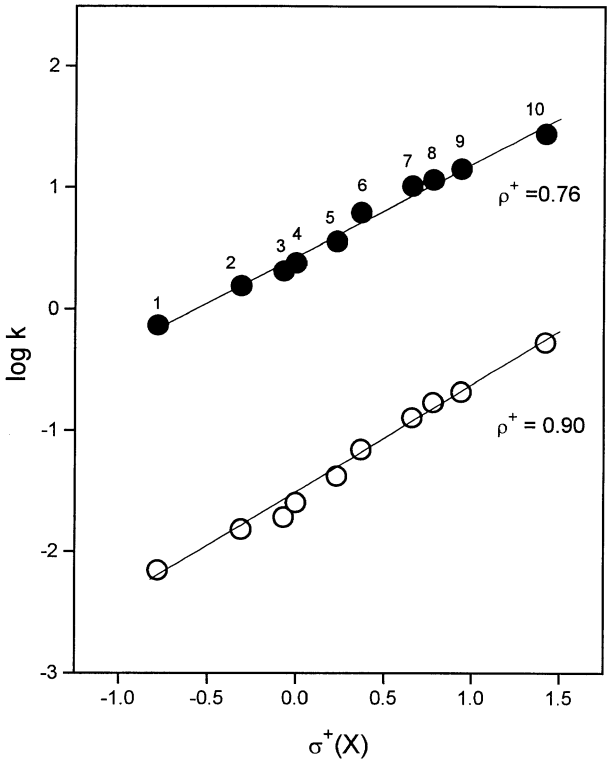
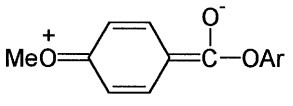
Fig. 3. Hammett plots for the reactions of 4-nitrophenyl X-substituted benzoates (X-$C_6H_4COOC_6H_4$-4-NO_2) with hydrazine (●) and glycylglycine (○) in water containing 20 mol% DMSO at 25.0 ± 0.1°C. The numbers in the figure refer to the substrates in Table 3.



difference in the charge type between the neutral and anionic nucleophiles is responsible for the difference in the magnitude of the ρ_X values. However, the nature of the reaction mechanism is also considered to be responsible for the small ρ_X values in the aminolysis. For a stepwise mechanism (e.g., addition–elimination mechanism), the first step to form an addition intermediate would be accelerated by an electron-withdrawing substituent (EWS) but retarded by an electron-donating substituent (EDS), resulting in a large positive ρ_X value. On the contrary, the second step to break down the addition intermediate would be retarded by an EWS but accelerated by an EDS, yielding a negative ρ_X value. Accordingly, one would expect a small ρ_X value for the reaction that proceeds via a stepwise mechanism with rate-determining breakdown of the intermediate due to the opposite substituent effect. The small ρ_X values for the present aminolysis compared with the ones for the reactions with anionic nucleophiles also support that the aminolysis proceeds via a stepwise mechanism in which the breakdown of the intermediate is the RDS.

Interestingly, as shown in Fig. 3, σ^+ constants give better correlation than σ constants, and the sign of ρ_X is positive. The σ^+ constants have been derived from solvolysis of $ArCMe_2Cl$ in 90% acetone–water at 25°C (23) and used for the reactions in which a positive charge is formed at the reaction centre, which can resonate with an EDS because of the additional resonance transmission for these substituents. Accordingly, negative ρ_X values have been generally obtained. Therefore, the present result (e.g., positive ρ_X values with σ^+ constants) is quite unusual, and one can suggest that the polarization of the C═O bond by resonance (**1**) or by hyperconjugation (**2**) in the ground state (GS) is significantly reflected in the reaction rate for both NH_2NH_2 and glygly systems.



1 **2**

To investigate the contribution of the C═O bond polarization to the reactivity, carbonyl stretching bands of the substrates ($\nu_{C=O}$) have been correlated with log *k*. As shown in Fig. 4, log *k* is linearly correlated with $\nu_{C=O}$ for both NH_2NH_2 and glygly systems, i.e., the substituent that increases $\nu_{C=O}$ accelerates the rate, and the one that decreases $\nu_{C=O}$ retards the rate, whether it is on the acyl moiety (X) or on the leaving group (Y). Good linear correlations of log *k* vs. $\nu_{C=O}$ have been often reported, e.g., aminolyses of 2-furoyl chlorides and their related compounds (24). Therefore, one might consider that the linear correlations observed in Fig. 4 are not so significant. However, such a good linearity is not always available. In fact, we obtained nonlinear correlation for the corresponding reaction with anionic nucleophiles such as substituted phenoxides (25). Therefore, the linearity observed from the plot of log *k* vs. $\nu_{C=O}$ clearly suggests that the effect of the polarization of the C═O bond on rates is significant for both NH_2NH_2 and glygly systems, since $\nu_{C=O}$ is a measure of the force constant and the polarization of the C═O bond. This argument is consistent with the proceeding one based on the positive ρ_X value with σ^+ constant. Therefore, one can conclude that the reactions of $XC_6H_4CO_2C_6H_4Y$ with NH_2NH_2 and glygly proceed in the same mechanism with slightly different TS structures, i.e., the degree of the leaving-group departure and the negative charge developed in the acyl moiety at the rate-determining TS would be slightly more significant for the glygly system than for the NH_2NH_2 system based on the magnitude of $ß_{lg}$ and ρ_X values.

Origin of the α-effect

As shown in Table 2, NH_2NH_2 is more reactive than glygly toward all the Y-substituted phenyl benzoates studied. The ratio of the apparent second-order rate constant for NH_2NH_2 (k^{NH2NH2}) to the one for glygly (k^{glygly}) (the α-effect: k^{NH2NH2}/k^{glygly}) decreases as the leaving group becomes a weaker base. The dependence of the α-effect on the leaving group basicity has been demonstrated graphically in Fig. 5. One can see the magnitude of the α-effect is linearly correlated with the pK_a of the conjugate acid of the leaving group.

Many factors have been suggested to influence the magnitude of the α-effect. Four of them are the basicity of the α-effect nucleophile (26), the kind of solvent (8–10, 27), the type of the hybridization of the electrophilic centre (28), and the magnitude of $ß_{nuc}$ value (29, 30). Recently, Terrier and co-workers (26*a*) have observed that the magnitude of the α-effect becomes smaller as the basicity of the α-effect nucleophile increases for the reactions of 4-nitrophenyl acetate (PNPA) and phosphonate (PNPDPP) with various oximates. A similar result was also reported by Hudson and co-workers (26*b*). On the other hand, significant solvent-dependent α-effects have

Fig. 4. Plots showing dependence of rate constant on $\nu_{C=O}$ for the reactions of Y-substituted phenyl X-substituted benzoates with hydrazine (●, X; ◆, Y) and glycylglycine (○, X; ◇, Y) in water containing 20 mol% DMSO at 25.0 ± 0.1°C.

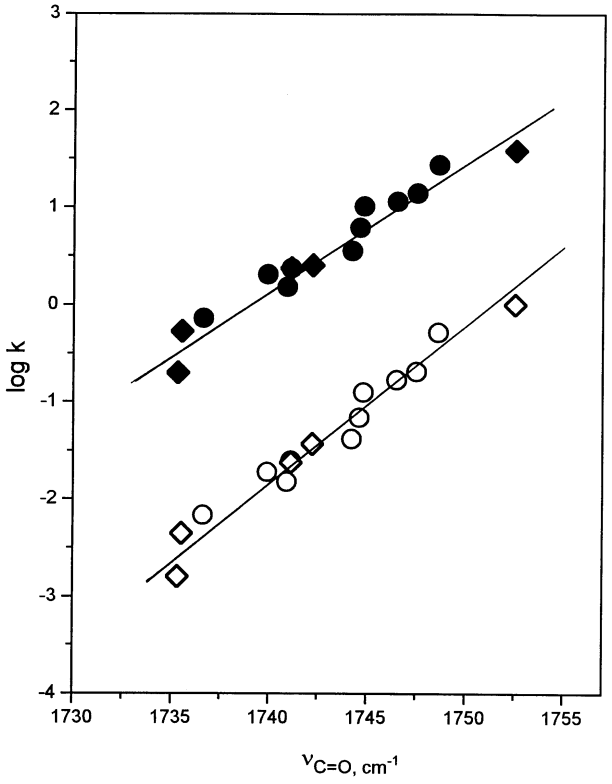

Fig. 5. A plot showing dependence of α-effect (k^{NH2NH2}/k^{glygly}) on the basicity of the leaving group for the reactions of Y-substituted phenyl benzoates ($C_6H_5COOC_6H_4$-Y) with hydrazine and glycylglycine in water containing 20 mol% DMSO at 25.0 ± 0.1°C. The numbers in the figure refer to the substrates in Table 2.

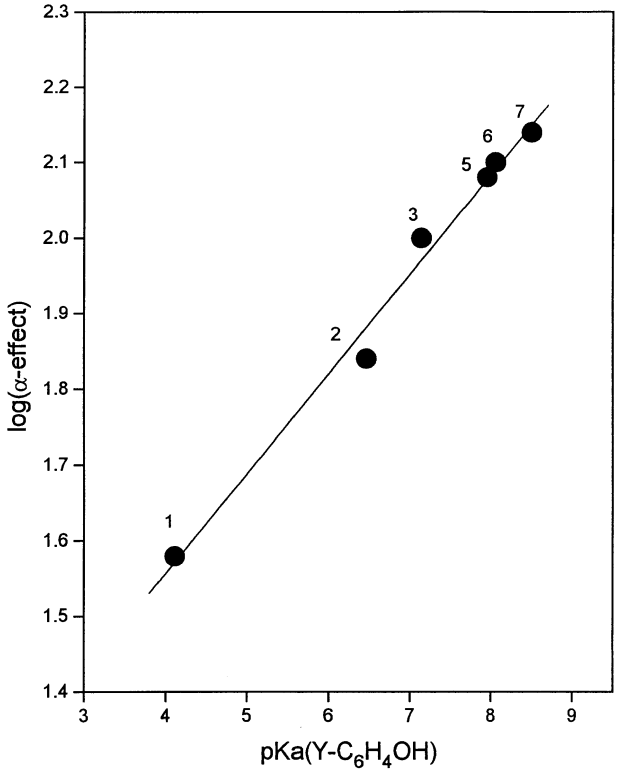

been reported (8–10, 27). Buncel and Um (8) and Tarkka and Buncel (9) have observed bell-shaped α-effect trends for the reactions of PNPA and PNPDPP with butane-2,3-dione monoximate (Ox^-) and 4-chlorophenoxide (ArO^-) in DMSO–H_2O mixtures of varying compositions. On the other hand, Um et al. (10) have reported increasing α-effect trends for the same reactions run in MeCN–H_2O mixtures as the concentration of MeCN increases in the medium. The magnitude of the α-effect has been also suggested to increase with increasing the *s* character of the hybridization of the electrophilic centre (eg., $sp > sp^2 > sp^3$) (28) and with increasing the magnitude of $ß_{nuc}$ value (29, 30). Since the basicity of the nucleophiles, solvent, and the type of the hybridization are kept constant in the present system, these factors are obiously not considered to be responsible for the α-effect trend in Fig. 5.

It has been generally observed that the magnitude of the $ß_{nuc}$ value increases with decreasing the leaving-group ability for the nucleophilic substitution reactions of aryl acetates and benzoates with neutral or anionic nucleophiles. For example, Dixon and Bruice (29) have reported that the magnitude of $ß_{nuc}$ value is 1.05, 0.83, and 0.57 for aminolysis of phenyl, 4-nitrophenyl, and 2,4-dinitrophenyl acetate, respectively. A similar result was reported for reactions of substituted phenyl acetates and benzoates (31). Therefore, one can consider that the α-effect and $ß_{nuc}$ value decrease in the same manner as the leaving group becomes less basic. This argument appears to be consistent with the proposal made by Bruice and Hoz (29, 30) that the magnitude of the α-effect is dependent on the $ß_{nuc}$ value.

In Fig. 6 is demonstrated the relationship of the α-effect with the σ constant for the reaction of 4-nitrophenyl X-substituted benzoates with NH_2NH_2 and glygly. One can see a good linear correlation in the figure, i.e., the magnitude of the α-effect decreases as the σ constant of the acyl substituent X increases. It has been shown from Fig. 1 that the $ß_{nuc}$ value is independent of the electronic nature of the acyl substituents but remains constant ($ß_{nuc}$ = 0.76 ± 0.02) when the leaving group is fixed to 4-nitrophenoxide. Interestingly, the magnitude of the α-effect has been observed to be dependent on the nature of the acyl substituents but $ß_{nuc}$ value is not, i.e., the α-effect is clearly not dependent on the $ß_{nuc}$ value. This is obviously inconsistent with the preceding result, eg., the increasing α-effect trend with increasing $ß_{nuc}$ value. Therefore, the proposal made by Bruice and Hoz appears to not always be true. However, a common feature in Figs. 5 and 6 is that the α-effect decreases as the reactivity of the substrates increases, indicating that the RSP is operative in the present system.

It is clear that the enhanced nucleophilic reactivity shown by the α-effect nucleophile should be determined by decreasing the free energy gap between the GS and the TS of the reaction. Therefore, among the theories suggested to explain the origin of the α-effect, two factors (GS destabilization and TS stabilization) will be considered. One can assume that the GS of the α-effect nucleophiles can be destabilized compared with their corresponding normal nucleophiles either by desolvation, repulsion between the nonbonding electrons, or

Fig. 6. A plot showing dependence of α-effect (k^{NH2NH2}/k^{glygly}) on the electronic nature of acyl substituents for the reactions of 4-nitrophenyl X-substituted benzoates (X-$C_6H_4COOC_6H_4$-4-NO_2) with hydrazine and glycylglycine in water containing 20 mol% DMSO at 25.0 ± 0.1°C.

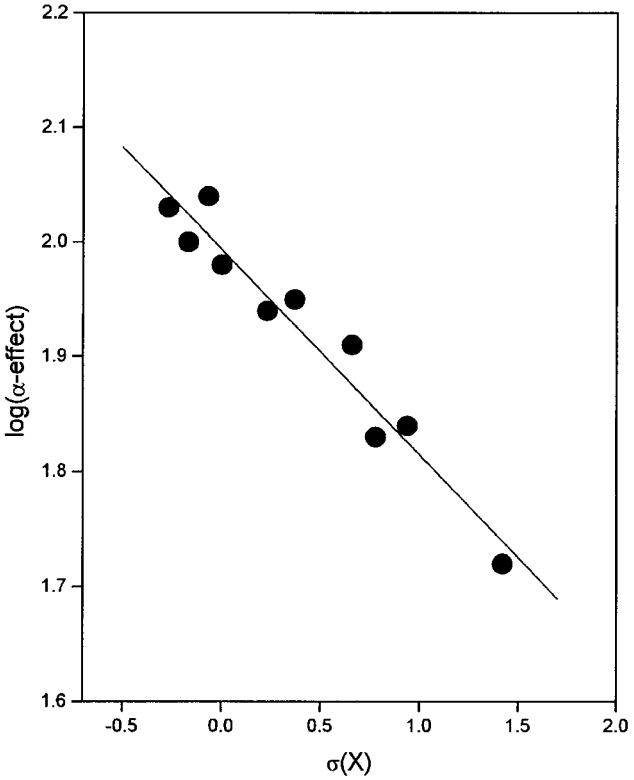

Fig. 7. A plot showing dependence of α-effect (k^{NH2NH2}/k^{glygly}) on $\nu_{C=O}$ for the reactions of Y-substitued phenyl X-substituted benzoates with hydrazine and glycylglycine in water containing 20 mol% DMSO at 25.0 ± 0.1°C (●, X; ○, Y).

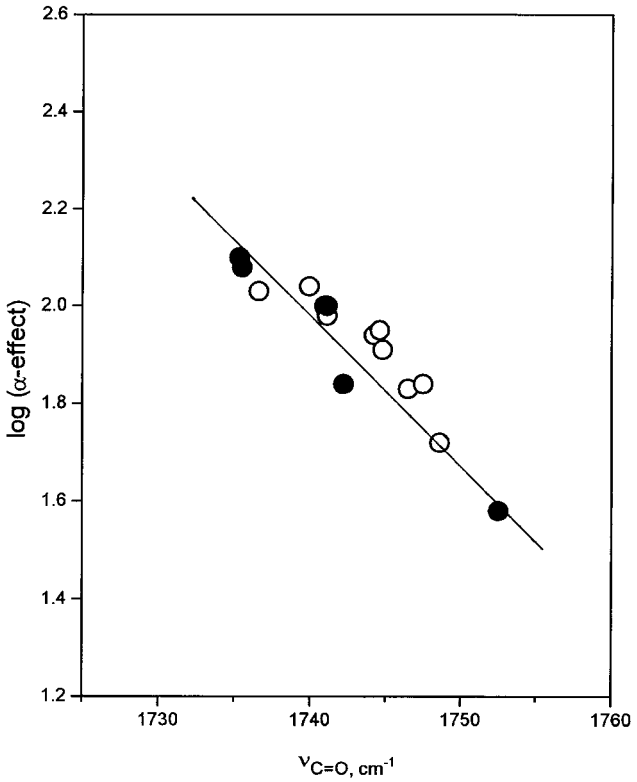


others. However, the difference in the GS energy (ΔE_{GS}) for a given set of nucleophiles (eg., NH_2NH_2/glygly or Ox^-/ArO^-) remains constant although the substrate changes. Therefore, the magnitude of the α-effect should have remained constant for the present aminolyses of X-$C_6H_4CO_2C_6H_4$-Y, if ΔE_{GS} were solely responsible for the α-effect. In fact, the magnitude of the α-effect has been observed to be nearly constant for the corresponding reaction with Ox^- and ArO^- (25), indicating that ΔE_{GS} is significantly responsible for the α-effect observed in the Ox^- system. Therefore, the decreasing or increasing α-effect trends in Figs. 5 and 6 clearly suggest that ΔE_{GS} is not solely responsible for the α-effect in the present NH_2NH_2 system.

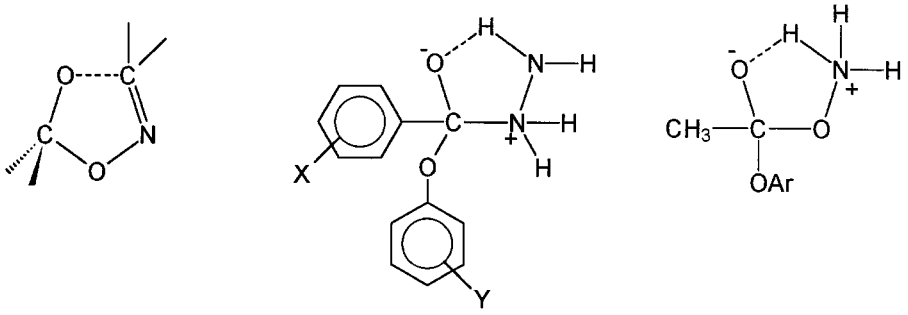
Recently, Terrier et al. (26*a*) have explained the α-effect in terms of the TS stabilization by an intramolecular general base catalysis model (**3**). However, **3** is not possible in the present system. Instead, one can suggest an intramolecular general acid catalysis model (**4**). Such a model was probably one of the first explanations suggested for the α-effect shown by NH_2NH_2, NH_2OH, HOO^-, etc. (3). On the other hand, $MeONH_2$ has often exhibited a large α-effect although it cannot form such an intramolecular H-bonding structure. Therefore, the importance of structure **4** has been neglected. However, the origin of the α-effect shown by NH_2NH_2 and $MeONH_2$ would not necessarily be the same. In fact, Hengge and co-workers (4*i*) have recently suggested an intramolecular H-bonding structure **5** to explain the enhanced nucleophilic reactivity of $HONH_2$, from an intensive study of kinetic isotope effect for acyl-transfer reaction of PNPA with $HONH_2$.

The intramolecular H-bonding interaction as shown in **4** would be dependent on the degree of the polarization of the C═O bond, i.e., an EDS would increase both the H-bonding interaction and C═O bond polarization, while an EWS would decrease them whether the substituent is on the acyl moiety (X) or on the leaving group (Y). It is evident that the H-bonding interaction can stabilize the TS of the NH_2NH_2 system and result in increasing both the rate and the α-effect. In fact, as shown in Figs. 5 and 6, the α-effect increases as the substituent X or Y becomes a stronger EDS, but decreases with increasing electron-withdrawing ability of the substituent X and Y, indicating that the substituent that assists the C═O bond polarization or H-bonding increases the magnitude of the α-effect. Therefore, **4** is considered to be responsible for the α-effect trend obtained in the present system. This argument can be further supported from the linear correlation of the α-effect with $\nu_{C=O}$ as shown in Fig. 7. One can see that the magnitude of the α-effect is inversely correlated with $\nu_{C=O}$. Since $\nu_{C=O}$ represents the force constant of the C═O bond, the degree of polarization of the C═O bond would increase as the $\nu_{C=O}$ decreases. Therefore, the linear dependence of the α-effect on $\nu_{C=O}$ also indicates that the structure **4** plays an important role in the present α-effect trend (e.g., the increasing or decreasing α-effect trend).

Conclusions

The following conclusions have been drawn from the kinetic study for the reaction of X-$C_6H_4CO_2C_6H_4$-Y with a series of

© 1998 NRC Canada



3 4 5

primary amines in H_2O containing 20 mol% DMSO at 25.0 ± 0.1°C. (*i*) The reactions of X-$C_6H_4CO_2C_6H_4$-Y with primary amines including glygly and NH_2NH_2 are considered to proceed through the same mechanism with slightly different TS structures, i.e., the degree of leaving-group departure and the negative charged in the acyl moiety at the rate-determining TS would be slightly more significant for the glygly system than for the NH_2NH_2 system based on the magnitude of β_{lg} and ρ_X values. (*ii*) The magnitude of the α-effect is not always dependent on the β_{nuc} value but dependent on the electronic nature of the substituent, i.e., an EDS increases the α-effect, while an EWS decreases the α-effect whether the substituent is in the acyl moiety (X) or in the leaving group (Y). (*iii*) The difference in the GS energy between NH_2NH_2 and glygly is not considered to be solely responsible for the α-effect. Instead, the intramolecular H-bonding structure **4** is proposed to be responsible for the α-effect, at least for the increasing or decreasing α-effect trends obtained in the present system.

Experimental

Materials

Aryl benzoates (X-$C_6H_4CO_2C_6H_4$-Y) were easily prepared from the reactions of X-substituted benzoyl chloride with Y-substituted phenol in the presence of triethylamine in methylene chloride as reported in literature (33). Their purity was checked by means of melting points and spectral data such as IR and ^1H NMR characteristics. The amines and other chemicals used were of the highest quality available (Aldrich) and recrystallized or distilled before use. Dimethyl sulfoxide (DMSO) was distilled over calcium hydride at a reduced pressure (bp 64–66°C at 6–7 mmHg) (1 mmHg = 133.3 Pa) and stored under nitrogen. Doubly glass distilled water was further boiled and cooled under a nitrogen atmosphere just before use.

Kinetics

The kinetic studies were performed with a Hitachi U-2000 model UV-vis spectrophotometer for slow reactions ($t_{1/2} \geq 10$ s) or with an Applied Photophysics SX 17MV stopped-flow spectrophotometer for fast reactions ($t_{1/2} < 10$ s) equipped with a Neslab RTE-110 model constant temperature circulating bath to keep the temperature of the reaction mixture at 25.0 ± 0.1°C. All the kinetics were performed in H_2O containing 20 mol% DMSO to eliminate a solubility problem. The reactions were followed by monitoring the appearance of the leaving phenoxides (or phenols) at a fixed wavelength corresponding to the maximum absorption (λ_{max}) of Y-$C_6H_4O^-$ (or Y-C_6H_4OH). All the reactions were carried out under pseudo-first-order conditions in which the concentration of amines was at least 20 times greater than that of the substrates. Amine stock solutions of ca. 0.2 M were prepared in a 25.0 mL volumetric flask under a nitrogen atmosphere by adding 2 equiv. of the amine hydrochloride to 1 equiv. of standardized NaOH solution in order to obtain a self-buffered solution. All the solutions were prepared freshly just before use under a nitrogen atmosphere and transferred by Hamiltom gas-tight syringes. Typically, reaction was initiated by adding 5 μL of ca. 0.02 M substrate solution to a 10 mm quartz cuvette containing the self-buffered amine solution. Generally, the concentration of the amines was varied over the range (5–50) × 10^{-3} M. The effect of ionic strength on rate was observed to be negligible in the present reaction condition. Usually, five different amine concentrations were employed and replicate values of k_{obs} were determined to obtain the second-order rate constants from the linear plot of k_{obs} vs. free amine concentration. Other details in kinetic methods were similar to the ones described previously (34).

The rhodium(II)-catalyzed aziridination of olefins with {[(4-nitrophenyl)sulfonyl]imino}phenyl-λ^3-iodane

Paul Müller, Corine Baud, and Yvan Jacquier

Abstract: The aziridination of olefins with {(4-nitrophenylsulfonyl)imino}phenyl-λ^3-iodane, NsN═IPh (**1c**), in the presence of $[Rh_2(OAc)_4]$ proceeds in yields of up to 85% when the olefin is used in large excess. Under optimized conditions, styrene (**4a**) is aziridinated with 1 equiv. of NsN═IPh (**1c**) in 64% yield with 2 mol% of catalyst. The aziridines derived from electron-rich olefins undergo ring-opening under the conditions of the aziridination and afford rearrangement products or pyrrolidines. The aziridination is sterospecific with 1,2-dialkyl- and 1,2-arylalkyl-disubstituted olefins, but nonstereospecific with stilbene.The ρ-value for aziridination of substituted styrenes is –0.61. No ring-opened products are observed upon aziridination of vinylcyclopropanes. In the presence of chiral Rh^{II} catalysts, the aziridination is enantioselective, affording an ee of 73% with *cis*-β-methylstyrene (**4k**) and Pirrungs $[Rh_2\{(R)\text{-}(-)\text{-bnp}\}_4]$ catalyst. The experimental results are consistent with a one-step mechanism for transfer of the nitrenoid moiety from the catalyst to the olefin.

Key words: aziridination, nitrene transfer, rhodium catalysis.

Résumé : Lorsqu'on utilise un grand excès d'oléfine, l'aziridination des oléfines par le {(4-nitrophénylsulfonyl)imino}phényl-λ^3-iodane, NsN═IPh (**1c**), en présence de $[Rh_2(OAc)_4]$, se produit avec des rendements allant jusqu'à 85%. Dans des conditions optimales, le rendement de l'aziridination du styrène (**4a**) par un équivalent de NsN═IPh (**1c**) et 2 mol% de catalyseur est de 64%. Les aziridines obtenues à partir d'oléfines riches en électrons subissent des ouvertures de cycle dans les conditions de l'aziridination et elles conduisent à des produits de réarrangement ou à des pyrrolidines. L'aziridination est stéréospécifique avec les oléfines disubstituées par des groupes alkyle ou arylalkyle en 1,2, mais elle n'est pas stéréospécifique avec le stilbène. La valeur de ρ pour l'aziridination des styrènes substitués est de –0,61. On n'observe pas de produits à cycles ouverts lors de l'aziridination de vinylcyclopropanes. En présence de catalyseurs de Rh^{II} chiraux, l'aziridination est énantiosélective, conduisant à un ee de 73% lors de la réaction du *cis*-β-méthylstyrène (**4k**) en présence du catalyseur de Pirrung $[Rh_2\{(R)\text{-}(-)\text{-bnp}\}_4]$. Les résultats expérimentaux sont en accord avec un mécanisme de transfer en une étape de la portion nitrénoïde du catalyseur à l'oléfine.

Mots clés : aziridination, transfert de nitrène, catalyseur au rhodium.

[Traduit par la rédaction]

1. Introduction

The possibility of generating sulfonylnitrenes from {(organosulfonyl)imino}-λ^3-iodanes has been the subject of different investigations in the past. While thermal reaction in benzene of the phenyliodonium ylid **1a** (MsN═IPh) derived from methane–sulfonamide provided no nitrene-derived decomposition products (1), the tosyl analogue **1b** (TsN═IPh) transferred the sulfonylnitrene moiety to acceptors such as thioanisole (100°C, 49%), triphenylphosphine (100°C, 87%), and dimethylsulfoxide (25°C, 100%) (2). The first reported transition-metal-catalyzed reactions of sulfonylnitrenes, derived from TsN═IPh (**1b**), concerned CH-bond insertions, which occurred in the presence of Mn^{III}- or Fe^{III}-porphyrinate or $[Rh_2(OAc)_4]$ catalysts (3). In connection with model studies on the transfer of oxygen by cytochrome P-450 and model iron or manganese complexes, the group of Mansuy (4) reported the aziridination of olefins with TsN═IPh and Mn^{III}- and Fe^{III}-porphyrinates. These systems were also efficient for formal insertion of sulfonylnitrene into CH bonds (5). The aziridinations and CH-bond insertions exhibited characteristics typical for radical reactions.

The metal-catalyzed nitrene transfer from TsN═IPh (**1b**) to olefins was developed to become an efficient method for aziridination by Evans et al. (6). Cu^{I} and Cu^{II} complexes proved to be the most efficient catalysts. With chiral bis-oxazoline ligands the aziridination became enantioselective, and inductions of up to 97% were reported with cinnamate esters as substrates. With simple olefins such as styrenes the enantiomeric excess was, however, only 63% (7). The aziridination with Jacobsens's (8) Cu-based catalysts having benzylidene derivatives of 1,2-diaminocyclohexane as ligands afforded enantioselectivities near to perfection with 6-cyano-2,2-dimethylchromene, but were less satisfactory with simple olefins (ee's varying from 58–87%). Applications and extensions of the Cu-catalyzed aziridination using TsN = IPh (**1b**) as nitrene

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

[a] Conditions: slow addition of 1.00 mmol of TsNXY (**6**) in 5.0 mL of solvent to 5.0 mmol of styrene (**4a**) and catalyst (0.02–0.35 mmol) in 10.0 mL of solvent.

source have been reported in the literature with achiral (9) as well as chiral ligands (10). Several metal–salen complexes have been tried as catalysts for olefin aziridination with TsN═IPh, using Fe^{III}, Co^{II}, Cr^{III}, Ni^{II}, Mn^{III}, Pd^{II}, and Rh^{II}, but only {Mn(salen)Cl} was effective (11). An efficient chiral salen ligand for aziridination of styrenes with Mn^{III} has, however, been described recently by Katsuki and co-workers (12).

The observation that dimeric rhodium^{II} complexes having chiral carboxamidate ligands are highly efficient for asymmetric cyclopropanations of olefins (13) and cyclopropenations of terminal acetylenes (14) was the starting point of our own investigations on Rh^{II}-catalyzed asymmetric aziridinations. Owing to the formal analogy between TsN═IPh (**1b**) and alkylidene phenyliodonium ylides **2**, which are convenient substitutes for diazo compounds **3** in Rh^{II}-catalyzed carbenoid reactions (15), and the apparent similarity between carbene and nitrene transfer, we speculated that catalysis with chiral Rh^{II} carboxamidates would afford aziridines with enantioselectivities in the range of those reported for cyclopropanations. We therefore initiated a search for an efficient system for Rh^{II}-catalyzed generation and transfer of sulfonylnitrenes. Mechanistic aspects of the reaction were investigated, and a series of chiral Rh^{II}-based catalysts were tested. Some of the results of this investigation using {[(4-nitrophenyl)sulfonyl]imino}phenyl-λ^3-iodane (**1c**) have been reported previously (16).

2. Results and discussion

2.1. Nitrene precursors for aziridination of styrene

The aziridination of styrene (**4a**) was selected as model reaction for several systems, which, on the grounds of literature reports, appeared to have potential as precursors in metal-catalyzed nitrene transfer (17). The decomposition of tosyl azide (**6a**) (18) in the presence of Cu^I or Cu^{II} catalysts and styrene (**4a**) afforded none of the desired aziridine **5b**; however, a poor 3% yield of **5b** was isolated when the reaction was carried out in the presence of copper powder in acetonitrile at 80°C. Similarly, the use of $[PdCl_2(PhCN)_2]$ (19) or $[Rh_2(OAc)_4]$ afforded no **5b**. Exposure of chloramine-T ($TsNCl^-Na^+$) to copper powder in dimethylsulfoxide (DMSO) reportedly affords the corresponding sulfoximine in 80% yield (20), presumably via an intermediate Cu-complexed nitrene. However, application of this and related systems to aziridination of **4a** appears to be limited. In our hands, the best results were obtained with the tetrabutylammonium salt of $TsNCl^-$ (**6b**), which afforded a 36% yield of **5b** with 1 equiv. of Cu^0; [CuCl] (0.1 equiv.) in turn, gave a yield of 29% of **5b**, and the highest yield with $[Rh_2(OAc)_4]$ was 21%. The sulfonamide $TsNH_2$ (**7b**) was the major secondary product in these reactions. See Table 1 and Scheme 2.

2.2. Optimization of aziridination conditions

Selection of catalyst

Recently, Evans et al. (6, 7) reported the metal-catalyzed aziridination of styrene (**4a**) by TsN═IPh (**1b**) with a large variety of catalysts. The Cu^I and Cu^{II} complexes were the most suitable for olefin aziridination, and these catalysts were used later by other groups. $[Rh_2(OAc)_4]$ was also tested, but was found much less suitable than Cu catalysts. In view of the low

[a] Conditions: 1.0 mmol of TsN═IPh (**1b**) suspended in the appropriate solvent (10.0 mL), stirred with 5.0 mmol of styrene (**4a**) and the catalyst at 20°C, unless otherwise indicated.
[b] Activated molecular sieves (6.0 g) added to solvent.

yields in our experiments with **6a**,**b**, we investigated the aziridination of styrene (**4a**) with TsN═IPh (**1b**) with Pd^{II} and Rh^{II} catalysts under a variety of conditions, but success was very limited. In the case of Pd^{II} the highest yield of **5b** (37%) was achieved with $[PdCl_2(PhCN)_2]$ (10%) with a five-fold excess of **4a** (Table 2). With $[Rh_2(OAc)_4]$, reaction in dry dichloromethane at 20°C produced the highest yield (43%) with a five-fold excess of **4a** and 2% of catalyst. When the excess of styrene (**4a**) was increased to 20-fold, the yield of (**5b**) increased to 59%. Other Rh^{II} catalysts, such as $[Rh_2\{(2S)\text{-mepy}\}_4]$ (mepy = methyl pyrrolidone-2-carboxylate) (21) or $[Rh_2(pfb)_4]$ (pfb = perfluorobutyrate) (22) resulted in reduced yields of **5b**.

Optimization of ylide structure

In the next step of the optimization procedure the nature of the sulfonamide group of the iodonium ylides was varied. The ylides **1a**–**g** were synthesized by the standard procedure described for TsN═IPh (**1b**), which consists in the reaction of the appropriate sulfonamide or carboxamide, respectively, **7a**–**g** with diacetoxy iodobenzene, $PhI(OAc)_2$ in MeOH in the presence of KOH (2). They were in general amorphous solids that could not be further purified, but were > 95% pure, except the 4-methoxy derivative **1d**, which was isolated as an unseparable 64:36 mixture of ylide and the starting sulfonamide **7d**. A comparative study was carried out for aziridination of styrene with $[Rh_2(OAc)_4]$ in CH_2Cl_2, (2% of catalyst) and $[Cu(acac)_2]$ in acetonitrile (5–10% of catalyst) and the ylides **1a**–**g** (Table 3, Scheme 3).

Efficient aziridine formation occurred only with the iodonium ylides derived from aromatic sulfonamides, while those derived from methanesulfonamide and trifluoroacetamide were either less effective or failed completely. Among the phenyl derivatives, the 4-nitro-compound (NsN═IPh, **1c**) afforded the highest yield of aziridine with $[Rh_2(OAc)_4]$. Cu catalysis, in turn, was more efficient for TsN═IPh (**1b**). A recent more detailed study revealed, however, that NsN═IPh (**1c**) is also more suitable than TsN═IPh (**1b**) in Cu-catalyzed aziridinations (23). We expected a still higher yield with the 2,4-dinitro derivative **1e**, but this ylide turned out to be significantly less suitable than the mono nitro derivative NsN═IPh (**1c**). The ylide **1f**, derived from pentafluorophenylsulfonamide **7f**, afforded no aziridine with either of the catalysts.

CH_2Cl_2/MeNO2 95:5	25	2 h	37

[a] Conditions: 0.02 mmol of $[Rh_2(OAc)_4]$ stirred in 10 mL of solvent (v/v) containing molecular sieves (6.0 g) with 1.0 mmol of styrene and 1.0 mmol of NsN═IPh (**1c**).
[b] 2.0 equiv. of **1c**.

The reasons for the absence of reactivity of the aliphatic ylides was not further investigated. Nevertheless, a difference in behavior was observed. All the ylides were almost or entirely insoluble in most of the conventional solvents. However, the ylides derived from arenesulfonamides dissolved in CH_2Cl_2 upon exposure to the catalyst and the substrate and produced aziridines or sulfonamides. In contrast, the ylides **1a** and **1f**, derived from methanesulfonamide (**7a**) and pentafluorobenzenesulfonamide (**7f**), respectively, remained suspended in the solvent and were recovered unchanged. The same observation applies to **1g**. The mechanism for formation of the sulfonamide **7** as the main secondary reaction product has yet to be established. In the case of the metallo-porphyrin-catalyzed aziridinations with TsN═IPh (**1c**) it has been proposed that $TsNH_2$ (**7b**) arises from hydrolysis of the intermediate metal nitrene complex; the resulting metal-oxo species, in turn, attacks olefins to afford epoxides. However, no epoxides were ever detected in the aziridinations using iminophenyliodinanes **1** catalyzed with Rh^{II}. In addition, control experiments revealed the absence of epoxide formation when *trans*-stilbene was exposed to iodosylbenzene in the presence of $[Rh_2(OAc)_4]$.

As a precautionary measure, all aziridinations with NsN═IPh (**1c**) were carried out in the presence of activated molecular sieves in order to avoid hydrolysis of NsN═IPh to $NsNH_2$ (**7c**). Despite this, sulfonamide formation could not be suppressed entirely. It became particularly important in the aziridination of electron-deficient or sterically hindered olefins. The reason for this is a catalyst-induced decomposition of NsN═IPh (**1c**), competitive with the aziridination, which ultimately, after work-up, affords $NsNH_2$ (**7c**). However, the nature of this secondary reaction could so far not be established.

Solvent effect

The Rh^{II}-catalyzed aziridination exhibits a peculiar solvent effect. Best results were obtained with chlorinated solvents such CH_2Cl_2. The dipolar nonprotogenic solvents sulfolane or $MeNO_2$, etc., were found inefficient. However, the addition of small quantities of sulfolane or, to a minor degree, $MeNO_2$ to CH_2Cl_2 resulted in an increase of yield of aziridine. Under optimized conditions, with a CH_2Cl_2/sulfolane ratio of 99.5:0.5 the aziridination of styrene (**4a**) with 1.0 equiv. of NsN═IPh (**1c**) proceeded in 64% yield. Smaller, but also larger, amounts of sulfolane resulted in reduced yields, however (see Table 4).

2.3. Scope and limitations of the aziridination

A series of olefins of different structure was examined in order to establish the scope of the reaction. The reaction conditions were optimized for styrene (**4a**) as follows: NsN═IPh (**1c** 1.0 mmol) was suspended in CH_2Cl_2 (20 mL) at room temperature under N_2. After addition of the olefin (20.0 mmol) and

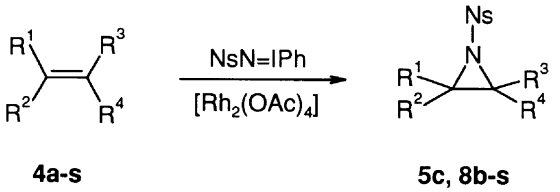
[a] Conditions: 20 mmol of olefin stirred with 1.0 mmol of NsN═IPh (**1c**) and 0.02 mmol of $[Rh_2(OAc)_4]$ in 10 mL of CH_2Cl_2 at room temperature in the presence of molecular sieve (6.0 g).

Scheme 4.



4a-s **5c, 8b-s**

$[Rh_2(OAc)_4]$ (0.02 mmol) the mixture was stirred until all of the ylide was dissolved (see Table 5, Scheme 4).

Inspection of Table 5 reveals that the reactivity of olefins towards NsN═IPh (**1c**) – $[Rh_2(OAc)_4]$ is determined by electronic and steric factors. Electron-deficient olefins such as 3-nitrostyrene (**4g**), 4-methoxycarbonylstyrene (**4e**), or ethyl acrylate (**4o**) afford lower yields of aziridines than the electron-rich substrates. Yields with *cis*-1,2-disubstituted olefins are slightly higher than with the *trans*-isomers (except in the case of stilbene) (16*a*). The low reactivity of 3-methylbut-1-ene (**4i**) and norbornene (**4p**) is best ascribed to steric hindrance. Ethyl sorbate (**4s**) produced no aziridination product with NsN═IPh (**1c**) – $[Rh_2(OAc)_4]$, probably owing to an unfavorable combination of steric and electronic factors, and the same applies to ethyl cinnamate, which is the best substrate in the Cu-catalyzed aziridination of Evans et al. (6). An attempt to extend the aziridination of olefins to acetylenes, a reaction well known in the series of carbenoid additions, failed with hex-1-yne.

Consecutive reactions with electron-rich olefins

With some of the electron-rich olefins complications owing to consecutive reactions of the originally formed aziridines arose. The isolation of rearranged products upon aziridination of 1,1-diphenylethene and *trans*-stilbene has been reported previously (16*a*). Similarly, aziridination of norbornadiene (**4r**) afforded none of the expected aziridine **8r** but a rearranged product **10**, presumably by a mechanism involving **9**, analogous to that proposed for reaction of norbornadiene with phenyl azide (24) (see Scheme 5).

The aziridine derived from 4-methoxystyrene (**4h**) underwent ring-opening under the aziridination conditions, which was followed by cycloaddition of the supposed intermediate dipolar species **11** to a second molecule of olefin to afford a *cis*/*trans* mixture of pyrrolidines **12h**. Analogous products have been isolated upon aziridination of ethyl vinylether (**4m**) and α-methylstyrene (16*a*). The structure of the pyrrolidines was deduced from the mass spectra, which showed the incorporation of a second olefin molecule in the product, and from detailed analysis of the ^1H NMR. Reinspection of the NMR data of the isomers of **12m** revealed that they are *cis*/*trans* isomers and that the previous structural assignement was incorrect (16*a*). The formation of regioisomeric adducts, which would have either C_2 or C_s symmetry, could be ruled out on the grounds of the spectra, but the assignment of relative configurations of the pyrrolidines proved impossible (17). Since no aziridines could be isolated in these reactions, it is not established whether the dipolar intermediate **11** is derived from direct attack of the NsN═IPh (**1c**) to the olefin or via ring-opening of the putative aziridines (see Scheme 6).

Intermolecular CH-bond insertion

The aziridination of olefins having alkyl substituents is usually accompanied by formal products of nitrene insertion into CH bonds. In the case of cyclohexene, the aziridine was formed in only 4% yield, while 70% of the allylic sulfonamide was isolated (16*a*). Subsequent work showed, however, that cyclohexene is an exception. Olefins react usually via aziridination, and CH insertion is only a secondary reaction, although it may occur with other compounds having activated CH bonds, such as arylalkanes and ethers. The reaction proceeds with retention

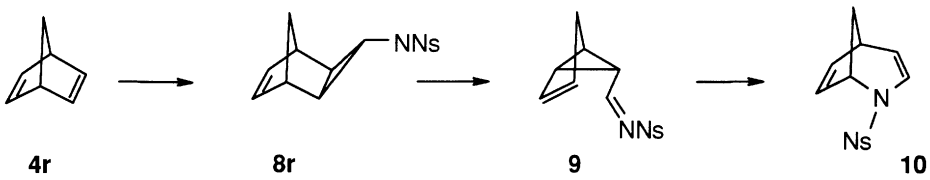
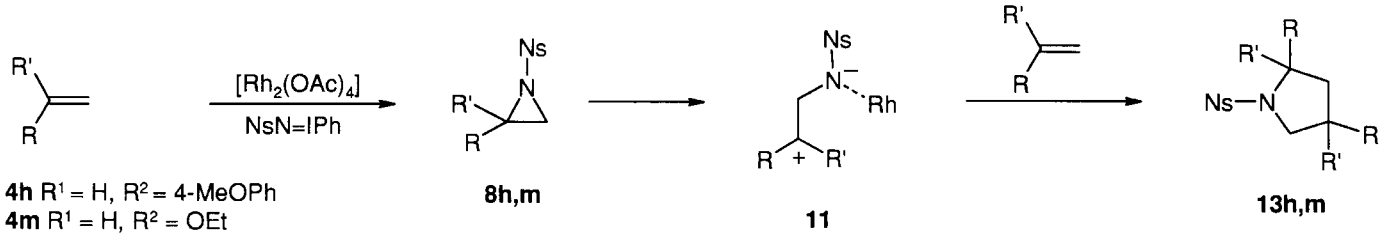
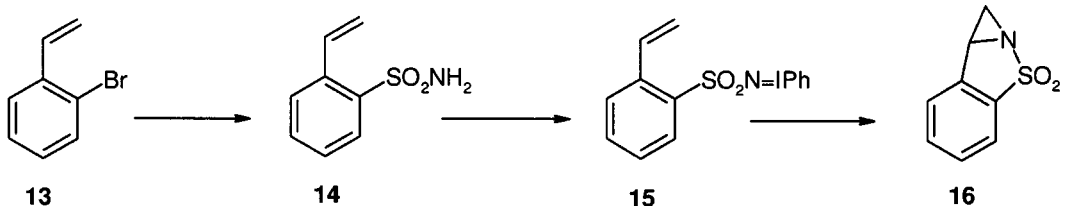
Scheme 5.



Scheme 6.



Scheme 7.



of configuration at the reacting carbon center (25) and most likely proceeds via a one-step mechanism (25).

Intramolecular aziridination

Since the presence of a large excess of olefin is necessary for efficient aziridination, an intramolecular aziridination was carried out in the hope that generation of the reacting species in the immediate vicinity of the double bond would compensate for the reduction of the 20:1 olefin/ylide ratio in the intermolecular reaction to 1:1 ratio in the intramolecular version. Since the preparation of iminophenyliodinanes from unsaturated aliphatic sulfonamides by the conventional methods failed, the aromatic derivative **15** was synthesized via metallation–sulfonation of 2-bromostyrene **13** (26) and treatment of the sulfonamide **14** with diacetoxyiodobenzene. The ylide was contaminated with unreacted **14**, which could not be separated. Treatment of **15** with $[Rh_2(OAc)_4]$ afforded **16** in only 20% yield together with much sulfonamide **12**. Apparently, the eventual advantage of carrying out the reaction intramolecularly is lost owing to a less favorable substitution pattern (absence of nitro substituent) on the aromatic moiety (see Scheme 7).

2.4. Mechanistic investigations

Stereochemistry of aziridination

The stereochemistry of the Rh^{II}-catalyzed aziridination with NsN═IPh (**1c**) was investigated with the *cis*- and *trans*-isomers of hex-2-ene, β-methylstyrene, and stilbene. Hex-2-ene and β-methylstyrene reacted stereospecifically, but *cis*-stilbene afforded a mixture of *cis*- and *trans* aziridines in low yield. In contrast, *trans*-stilbene reacted to a mixture of *trans*-aziridine and a rearranged enamide in 41% and 11% yield, respectively (16*a*).

The observation of stereospecificity upon aziridination of β-methylstyrene contrasts with that observed in the Cu-catalyzed aziridination where, with most ligands, the stereospecificity is lost. The loss of stereospecificity suggests a two-step mechanism for aziridination involving either an intermediate radical **17** or a zwitterionic species **18** in which bond rotation occurs faster than ring closure. The Rh^{II}-catalyzed aziridination, in turn, could be concerted or stepwise, but with the rate of ring closure faster than bond rotation. The loss of stereospecificity observed with *cis*-stilbene appears more consistent with a two-step mechanism, but it is not clear whether stilbene stands at the extreme end of a mechanistic continuum of a general two-step mechanism or whether the general mechanism is concerted and stilbene must be considered an exception (see Scheme 8).

Polar substituent effects

As mentioned above, the two-step mechanism for aziridination could involve either a radical intermediate **17** or a zwitterionic species **18**. To eliminate this latter possibility, the polar substituent effect on the reaction was examined by means of competition experiments using pairs of substituted styrenes **4a**–**g**. Relative reactivities of the styrenes were determined from the product ratios of the aziridines, as analyzed by NMR (Table 6, Figure 1).

The ρ-value for the aziridination with NsN═IPh (**1c**)/$[Rh_2(OAc)_4]$ of –0.61 is close to that measured for the Rh(II)-catalyzed cyclopropanation of styrenes with diazomalonate, and

© 1998 NRC Canada

Scheme 8.

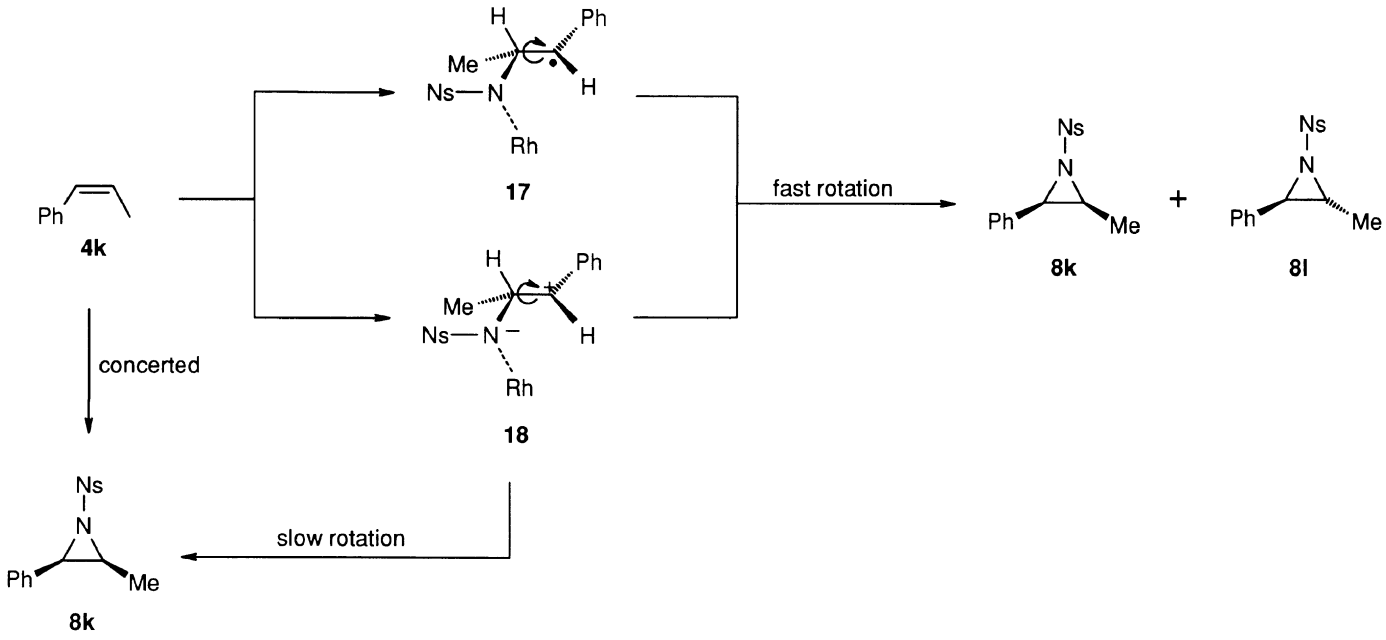


Fig. 1. Hammett plot (vs. σ^+) (27) for aziridination of styrenes with NsN═IPh (**1c**) and $[Rh_2(OAc)_4]$ ($\rho = -0.613$, $r = 0.984$) or $[Cu(acac)_2]$ ($\rho = -0.49$, $r = 0.999$) at 22°C.

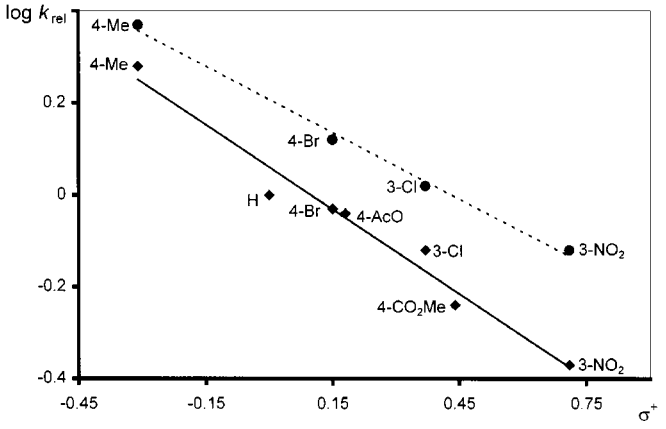

also close to the values reported for dichlorocarbene addition to styrene ($\rho = -0.62$, 80°C) (28) or to α-methylstyrene ($\rho = -0.38$, 0°C) (29). This is clearly too low for a dipolar intermediate with development of a positive charge at the benzylic position in the transition state. On the other hand, it is consistent with a concerted as well as with a radical mechanism. The Hammett ρ-constant for the $[Cu(acac)_2]$-catalyzed reaction is slightly lower (–0.49; $r = 0.991$). The plot of this latter reaction suffers from an anomaly, since it does not pass through the origin. The reasons for this anomaly are not clear, but have not been investigated yet.

Radical clocks in aziridination

The possible intervention of radicals in the aziridination pathway was tested with vinylcyclopropane **19a** and its *cis*-diphenyl-substituted derivative **19b**. The corresponding

4g	3-NO_2	–0.365	–0.123	0.71

[a] Conditions: see Experimental.
[b] Reference 27.

secondary radicals **20a**,**b** ring-open to homoallylic radicals **21a**,**b** with rate constants of $> 2 \times 10^7$ s^{-1} and $> 2 \times 10^{10}$ s^{-1}, respectively (30). The olefins were synthesized via Wittig olefination of the corresponding aldehydes (31) (see Scheme 9).

Aziridination of vinylcyclopropane (**19a**) afforded the aziridine **22a** in ca. 43% yield (partial decomposition during work-up). The diphenyl derivative **19b** reacted only sluggishly to yield the aziridine **22b** in 35% yield. No products derived from ring-opening of an intermediate radical could be detected in the crude reaction mixture. It follows that the aziridination of mono-substituted olefins should proceed via a concerted mechanism or via a radical that undergoes cyclization with a rate constant significantly faster than 10^{12} s^{-1}. While this latter possibility cannot be ruled out, it has no consequences on the actual stereospecificity of the aziridination. On the other hand, the significance of this result with respect to the aziridination mechanism of disubstituted olefins, in particular to stilbene is open to debate.

Asymmetric aziridination

Styrene (**4a**) and *cis*-β-methylstyrene (**4j**) were aziridinated

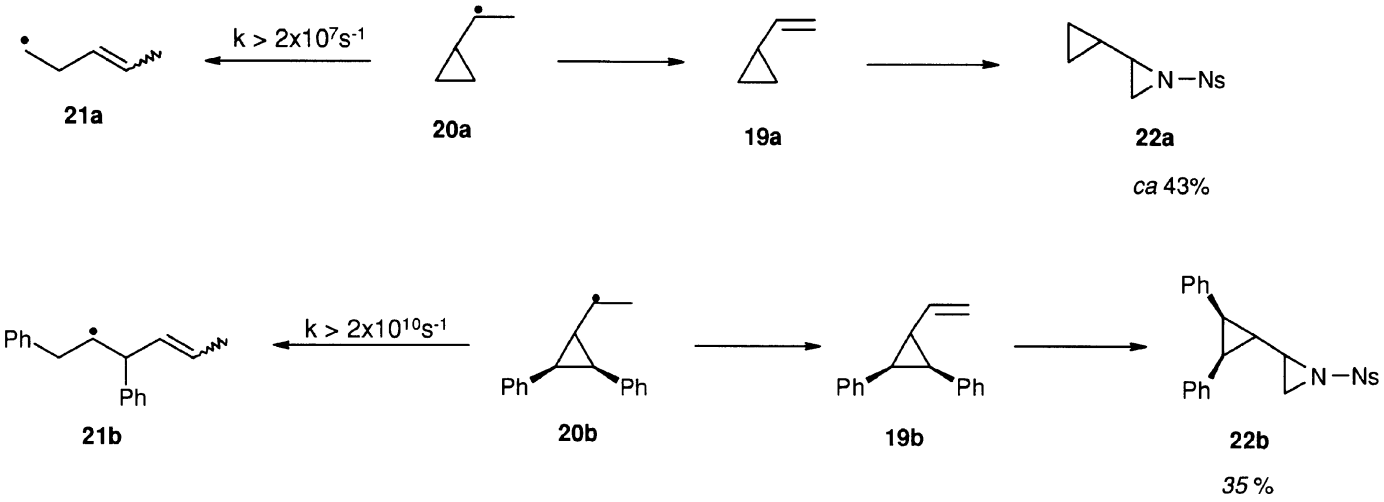
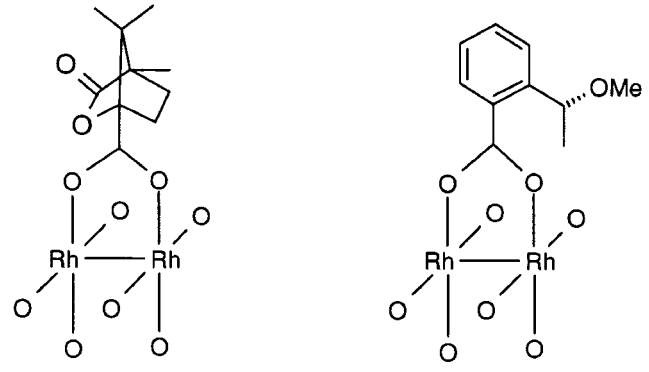
Scheme 9.



Scheme 10.



with NsN═IPh (**1c**) in the presence of the known Rh^{II} catalysts $[Rh_2\{(2S)\text{-mepy}\}_4]$ (22), $[Rh_2\{(4S)\text{-phox}\}_4]$ (32), $[Rh_2\{(2S)\text{-bepy}\}_4]$ (33), $[Rh_2\{(4S)\text{-macim}\}_4]$, $[Rh_2\{(S)\text{-ptpa}\}_4]$ (34), $[Rh_2\{(R)\text{-(–)-bnp}\}_4]$ (35), $[Rh_2\{(S)\text{-psp}\}_4]$ (36), and $[Rh_2\{(–)\text{-mpmt}\}_4]$ (37), which were prepared according to literature procedures. Two new Rh^{II} carboxylate catalysts, $[Rh_2\{(–)\text{-campha}\}_4]$ (**23**) and $[Rh_2\{(R)\text{-meba}\}_4]$ (**24**), were prepared via ligand exchange from $[Rh_2(OAc)_4]$ with camphanic acid, and with 2-(*R*-methoxyethyl)benzoic acid, respectively (38). The results are summarized in Table 6. The chemical yields of the reaction were usually satisfactory, but enantioselectivity has not yet reached levels useful for synthetic applications. Typically, the Rh^{II}-carboxamidate catalysts that have shown exceptional enantioselectivities in carbenoid reactions exhibit only modest selectivity in aziridination. At this time, the best results were obtained with Pirrungs $[Rh_2\{(R)\text{-(–)-bnp}\}_4]$ (bisnaphtholphosphate ligand), which afforded an ee of 55% with styrene (**4a**) and 73% with *cis*-β-methylstyrene (**4j**), respectively. No enantioselectivity was observed in the intramolecular aziridination with **16**.

Although these selectivities are still considerably below the desired level, they show unambiguously that the catalyst is not only involved in the decomposition of the NsN═IPh (**1c**), but that it is intimately associated in the transfer of the nitrene moiety to the olefin (see Scheme 10, Table 7).

Photochemical nitrene generation

Jacobsen (8) has shown that Cu catalysts are highly efficient in trapping 4-toluenesulfonylnitrene, generated by photolysis of the corresponding azide, TsN_3. In the presence of a chiral catalyst, aziridination proceeded with the same enantioselectivity as in the aziridination starting with TsN═IPh (**1b**) and the same catalyst. Analogous experiments have been carried out with the NsN═IPh/$[Rh_2\{(R)\text{-(–)-bnp}\}_4]$ system. The aziridination of styrene (**4a**) proceeds with 74% yield and 55% ee (Table 7). NsN_3 (**25**) is stable towards the catalyst at room temperature. Photolytic decomposition of NsN_3 (20 mmol) in the presence of $[Rh_2(R)\text{-(–)-bnp})_4]$ (1.0 mmol) afforded the aziridine **5c** in 9% yield and 17% ee. Since photolysis of sulfonylazides is known to produce sulfonylnitrenes (39), the observation of enantioselectivity implies that at least part of the reaction must proceed via a metal-complexed nitrene **26**. The trapping efficiency is, however, much lower than that of 100% observed by Jacobsen (8) in the Cu-catalyzed aziridination.

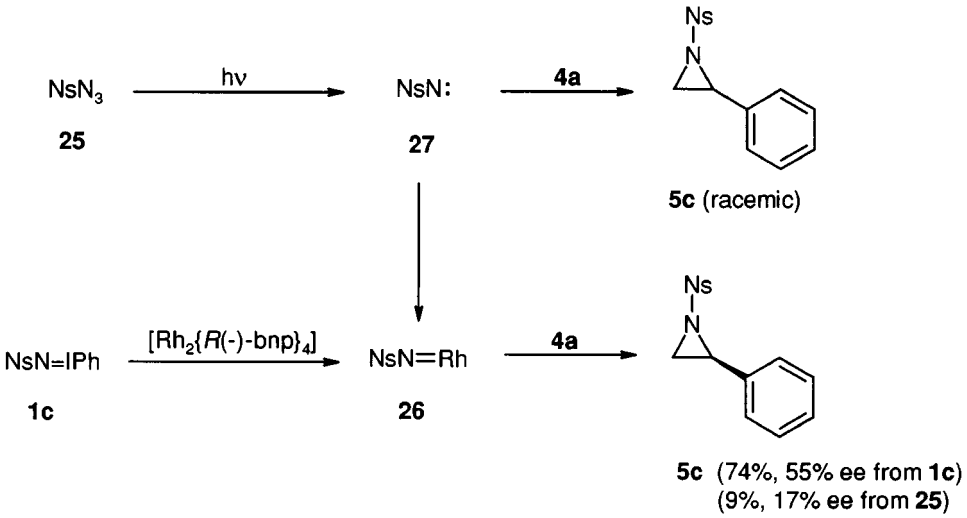
[a] Conditions according to general procedure.
[b] {(2-Ethenylsulfonyl)imino}phenyl-λ^3-iodane (**15**), intramolecular reaction.

Scheme 11.



In our experiments, about two thirds of the reaction proceed directly from attack of the free nitrene **27** to produce racemic aziridine **5c**, and only a minor part is delivered via the metal-complexed species (see Scheme 11).

3. Conclusion

The Rh^{II}-catalyzed aziridination with NsN═IPh (**1c**) exhibits many similarities to the more established Cu^{I}-catalyzed reactions with TsN═IPh (**1b**). In both systems, a metal-complexed nitrene is probably involved. Both are stereospecific with alkyl-substituted olefins, but loss of stereospecificity may occur when the olefin carries one (Cu/TsN═IPh) or two (Rh/NsN═IPh) aryl substituents. Both systems suffer from limited efficiency, which may be overcome by the use of a large amount of catalyst (with Cu) or a large excess of olefin (with Rh). Further work will be directed towards a more efficient system for nitrene transfer and towards improvement of the enantioselectivity, in order to achieve a general method for enantioselective catalytic olefin aziridination.

4. Experimental

General

(See ref. 32.)

Synthesis of iminophenyl-λ^3-iodanes 1a–g

The syntheses of **1a** (1), **1b** (2), and **1g** (4) have been described in the literature.

*Preparation of {(4-nitrophenylsulfonyl)imino}phenyl-λ^3-iodane (**1c**)*

To a solution of *p*-nitrophenylsulfonamide **6c** (10.0 mmol) and KOH (25.0 mmol) in MeOH was added at 0°C diacetoxyiodobenzene (10.0 mmol) at once. The mixture was stirred at 0°C until the color had changed from colorless to pale yellow (25 min). The temperature was allowed to raise to 20°C, and stirring was

Synthesis and characterization of aziridines
The experimental details are summarized in the footnotes of Tables 1–6.

[$Rh_2(OAc)_4$]-catalyzed aziridination of olefins with {[(4-nitrophenyl)sulfonyl]imino}-λ^3*-phenyliodane (**1c**). General procedure*
To [$Rh_2(OAc)_4$] (9.2 mg, 0.02 mmol) in CH_2Cl_2 (10 mL) was added, under N_2, activated molecular sieves 4A (6.0 g) and the olefin (20 mmol), followed by NsN═IPh (**1c**) (404 mg, 1.0 mmol). The suspension was stirred at RT until all of **1c** had dissolved. The mixture was filtered through a plug of celite, which was washed exhaustively with CH_2Cl_2, and the filtrate was evaporated. The excess of olefin was removed by flash distillation under reduced pressure. The crude aziridine was purified by flash *chromatography* with silica gel and a mixture of hexane–ether as eluant, or by recrystallization.

Intramolecular aziridination

*{(2-Ethenylphenylsulfonyl)imino}-phenyl-λ³-iodane (**15**) 2-Ethenylphenylsulfonamide* (***14***)
See ref. 25. The ylide was prepared according to the general procedure and used without purification and characterization.

*1,1a-Dihydro-6-thia-6a-aza-cycloprop[a]inden-6,6-dioxide (**16**)*
The ylide **15** (1.00 mmol) was suspended under N_2 in dry CH_2Cl_2 (10.0 mL) containing [$Rh_2(OAc)_4$] (0.02 mmol) and molecular sieves (6.0 g) and stirred during 2 h. The mixture was filtered through celite, which was washed out with CH_2Cl_2 (100 mL). After evaporation of the solvent, the crude product was purified by flash chromatography on silica gel using hexane – ethyl acetate 2:1 as eluant to afford **16** as an oil. IR ($CHCl_3$): 3155w, 2927w, 1601w, 1552w, 1470w, 1340s, 1178vs, 1052w, 916vs, 738vs. ^{1}H NMR (400 MHz, $CDCl_3$): 7.81–7.54 (m, 4H), 4.14 (m, 1H), 2.88 (dd, J = 1.1, 4.8 Hz, 1H), 2.37 (dd, J = 1.1, 4 Hz, 1H). ^{13}C NMR ($CDCl_3$), 136.9 (s), 133.4 (d), 133.3 (s), 130.4 (d), 125.5 (d), 123.6 (d), 44.2 (t), 43.0 (t). MS: 181 (4, M^+), 167 (13), 117 (93), 103 (11), 90 (100), 76 (29). HR-MS: 167.0022 ($C_7H_5NO_2S^+$; calc. 167.0041).

Relative reactivity of substituted styrenes with respect to NsN═IPh

To a mixture of dry CH_2Cl_2 (10.0 mL), [$Rh_2(OAc)_4$] (0.02 mmol), styrene (**4a**, 5.0 mmol) and substituted styrene (**4b**–**g**, 5.0 mmol), and molecular sieves (6.0 g) was added NsN═IPh (**1c**, 1.00 mmol). The suspension was stirred at room temperature until all of the ylide was dissolved. The solution was filtered through celite, which was washed with CH_2Cl_2 (100 mL). The filtrate was evaporated, and the ratio of the aziridines was determined by ^{1}H NMR by comparison of the integrals of the protons of the aziridines. In the case of 4-methoxycarbonylstyrene (**4e**), 1.0 mmol of **4a** was used with 5.0 mol of **4e** and 0.5 mol of NsN═IPh (**1c**), and with 3-nitrostyrene (**4g**) 10.0 mol were used with 2.0 mol of **4a** and 1.0 mmol of **1c**.

The [Cu(acac)$_2$]-catalyzed reactions were carried out by the same procedure, using 1:1 mixtures of styrenes and 10% of catalyst.

Aziridination of vinylcyclopropanes (radical probes)

*(N-4-Nitrophenylsulfonyl)-2-cyclopropylaziridine (**22a**)*
The reaction was carried out according to the general procedure, using 20 mmol of cyclopropylethene (**19a**) (30*a*), 1.00 mmol of NsN═IPh (**1c**), molecular sieves, and 0.02 mmol of [$Rh_2(OAc)_4$]. After stirring during 10 min. the reaction was worked up as usual; crude yield of aziridine 43%. Part of the product decomposed upon purification (preparative TLC on silica gel, using hexane–ether 2:1 as solvent); colorless oil. IR ($CHCl_3$): 3029vw, 1534s, 1350m, 1166m, 856w. ^{1}H NMR (400 MHz, $CDCl_3$): 8.15 and 8.40 (AA′XX′, app. d, J = 8.6 Hz, 4H), 2.88–2.86 (m, 1H), 2.72 (d, J = 7 Hz, 1H), 2.21 (d, J = 4.8 Hz, 1H), 0.94–0.90 (m, 1H), 0.55–0.42 (m, 2H), 0.25–0.16 (m, 2H). ^{13}C NMR ($CDCl_3$): 151.0(s), 144.0 (s), 129.0 (d), 124.0 (d), 43.0 (d), 34.0 (t), 10.0 (t), 3.0 (t), 2.0 (t). MS: 268 (5, M^+), 186 (4), 82 (80). HR-MS: 268.0512 ($C_{11}H_{12}N_2O_4S^+$; calc. 268.0518).

*(N-4-Nitrophenylsulfonyl)-2-(2-trans-3-trans-diphenylcyclopropyl)aziridine (**22b**)*
Same conditions as above with 20 mmol of 2-*trans*-3-*trans*-diphenylvinylcyclopropane (**19b**) (30*b*). Reaction time three days; yield of aziridine 35% (oil). IR ($CHCl_3$): 3035m, 1604m, 1535vs, 1349s, 1220vs, 1166s, 1092w, 856m. ^{1}H NMR (400 MHz, $CDCl_3$): 8.41 and 8.20 (AA′XX′, app. d, J = 8.8 Hz, 4H), 7.08 (sl, 6H), 6.84–6.80 (m, 4H), 3.30–3.26 (m, 1H), 2.88 (d, J = 7.1, 1H), 2.41 (d, J = 4.9 Hz, 1H), 2.38–2.29 (m, 2H), 1.96–1.92 (m, 1H). ^{13}C NMR ($CDCl_3$): 151.0 (s), 143.9 (s), 136.2 (s), 136.1 (s), 129.3 (d), 128.9 (d), 128.6 (d), 127.9 (d), 126.3 (d), 126.2 (d), 124.4 (d), 41.5 (d), 34.2 (t), 29.6 (d), 27.7 (d), 24.2 (d). Synthesis of Rh^{II} carboxylate catalysts

*[Rh_2{(–)campha}$_4$] (**23**)*
In a flask fitted with a Soxhlet extractor containing ground Na_2CO_3 and sand was heated, under N_2 and with stirring, (–)-camphanic acid (2.19 mmol) and [$Rh_2(OAc)_4$] (0.21 mmol) in chlorobenzene (50 mL) to reflux during three days. The mixture was evaporated to dryness and the residue was purified by flash chromatography on silica gel, using a mixture of ethyl acetate – CH_2Cl2 1:5 containing 1% of MeOH. Yield 97% of amorphous powder. ^{1}H NMR (200 MHz, $CDCl_3$): 2.72–2.50 (d, 1H), 1.90–1.50 (m, 3H), 1.04 (s, 3H), 0.87 (s, 3H), 0.71 (s, 3H). ^{13}C NMR ($CDCl_3$): 186.8 (s), 179.1 (s), 91.5 (s), 54.7 (s), 54.0 (s), 30.7 (t), 28.7 (t), 16.9 (q), 16.8 (q), 9.7 (q). MS (electrospray): 1017.0 (M^+ + Na).

*[Rh_2{(1R)-meba}$_4$] (**24**)*
Same procedure with 2.19 mmol of 2-((1*R*)-methoxyethyl)benzoic acid prepared from 2(1*R*-methoxyethyl)bromobenzene via carbonation of the organomagnesium derivative (92% ee) and 0.21 mmol of [$Rh_2(OAc)_4$]. The crude product was dissolved in CH_2Cl_2 and extracted three times with 10% aq. $NaHCO_3$. The organic layer was dried ($MgSO_4$), filtered, and the filtrate was evaporated to afford the product as amorphous powder in 98%. ^{1}H NMR (400 MHz, $CDCl_3$): 7.49–7.45 (m, 2H), 7.38 (d, J = 7.6 Hz, 1H), 7.26–7.23 (m, 1H), 4.72 (q, J = 6.4 Hz, 1H), 2.81 (s, 2H), 1.15 (d, J = 6.4 Hz, 3H). ^{13}C NMR ($CDCl_3$, 187.9 (s), 143.1 (s), 131.6 (d), 131.4 (s), 128.5 (d), 126.8 (d), 125.4 (d), 75.2 (q), 55.6 (d), 23.8 (q). MS (electrospray): 945 (M^+ + Na). $[\alpha]_D^{22}$ = +21.3 ($CHCl_3$, c = 0.30).

Photochemical nitrene generation

A solution of styrene (**4a**, 20 mmol), [Rh_2{(*R*)-bnp}$_4$] (0.05 mmol), and NsN_3 (**25**, 1.00 mmol) (40) in dry CH_2Cl_2 (15 mL) was irradiated in a Quartz vessel, which was placed in a Rayonet photoreactor (λ_{max} = 254 nm), under N_2 and with stirring during 70 h at room temperature. The reaction mixture was filtered through celite, which was washed with EtOAc. The solvent was evaporated, and excess styrene was removed by flash distillation. The crude product was purified by flash chromatography (silica gel, hexane–ether 3:1) to yield the aziridine **5c** in 9% yield with an ee of 17%.

Correlation of the rates of solvolysis of arylmethyl *p*-toluenesulfonates: application of the aromatic ring parameter and a discussion of similarity models

Dennis N. Kevill, Malcolm J. D'Souza, and Haobo Ren

Abstract: The specific rates of solvolysis of benzyl *p*-toluenesulfonate and nine benzylic-ring-substituted derivatives are satisfactorily correlated using N_T and Y_{OTs} scales within the extended Grunwald–Winstein equation. Addition of a third term, governed by the aromatic ring parameter, shows the additional term to be statistically significant. As one incorporates increasingly more electron-withdrawing substituents, the sensitivities towards changes in solvent nucleophilicity (*l*) increase, and those towards changes in ionizing power and changes in the aromatic ring parameter decrease. The trend of *l* values can be very nicely shown, with very precise correlations, using an internally generated scale of *Y* values. However, it is demonstrated that there is no overall advantage to use of an internally generated scale if one ultimately wishes to make a comparison with sensitivity values generated using an external scale of *Y* values.

Key words: Grunwald–Winstein equation, aromatic ring parameter, solvent nucleophilicity, solvolysis, arylmethyl *p*-toluenesulfonates.

Résumé : Utilisant les échelles N_T et Y_{OTs} dans le domaine d'application de l'équation étendue de Grunwald–Winstein, on peut obtenir une corrélation satisfaisante entre les vitesses spécifiques de solvolyse du *p*-toluènesulfonate de benzyle et de neuf dérivés benzyliques substitués sur le noyau. L'addition d'un troisième terme régit par le paramètre du noyau aromatique permet de montrer que ce terme additionnel est statistiquement important. Lorsqu'on incorpore des substituants de plus en plus électroattracteurs, les sensibilités vis-à-vis les changements dans le caractère nucléophile du solvant (*l*) augmentent et celles relatives au pouvoir ionisant ainsi que les changements dans le paramètre du noyau aromatique diminuent. On peut montrer la tendance des valeurs *l*, avec des corrélations très précises, en utilisant une échelle de valeurs *Y* générée d'une façon interne. Toutefois, on démontre qu'il n'y a pas d'avantage global à utiliser une échelle générée de façon interne si l'on veut éventuellement faire une comparaison avec des valeurs de sensibilité générées en utilisant une échelle externe de valeurs *Y*.

Mots clés : équation de Grunwald–Winstein, paramètre du noyau aromatique, caractère nucléophile du solvant, solvolyse, *p*-toluènesulfonates d'arylméthyles.

[Traduit par la rédaction]

Introduction

In a preliminary communication (1), we presented the analyses in terms of the extended Grunwald–Winstein equation (eq. [1]) of the specific rates of solvolysis of benzyl *p*-toluenesulfonate (tosylate, **1**, X = H) and six substituted derivatives (**1**, X ≠ H) in 11 solvents.

Received December 16, 1997.

This paper is dedicated to Professor Erwin Buncel in recognition of his many contributions to physical-organic chemistry.

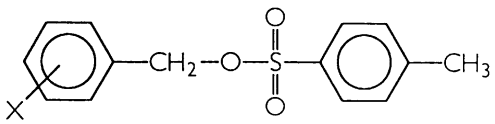
[1] $$\log (k/k_0)_{RX} = lN + mY + c$$



In eq. [1], k and k_0 are the specific rates of solvolysis of RX in a given solvent and in the standard solvent (80% ethanol), respectively; l is the sensitivity towards changes in solvent nucleophilicity (N); m is the sensitivity towards changes in ionizing power (Y); and c is a residual term (zero for ideally behaving solvolyses). Satisfactory analyses were obtained with use of either $N_{Et_3O^+}$ (2) or N_{OTs} (3) solvent nucleophilicity values, in conjunction with Y_{OTs} solvent ionizing power values (3–5); the sensitivities to changes in solvent nucleophilicity (l values) became larger as increasingly electron-withdrawing substituents were introduced.

Subsequently, reports of studies (with analyses in terms of N_{OTs} and Y_{OTs}) of the specific rates of solvolysis in 35–42

© 1998 NRC Canada

solvents of the parent compound (6) and derivatives with X = *m*-methyl (6), *m*-chloro (6), *p*-nitro (7), and 3,5-di(trifluoromethyl) (7) have appeared.

It has been suggested (8, 9) that the N_{OTs} scale is better based on an *m*-value of 0.55, rather than the chosen 0.3, in its derivation (3). The N'_{OTs} values, calculated in this way, are available (9). An even better approach is to use the RX^+-type scale based on the solvolyses of the *S*-methyldibenzothiophenium ion (9, 10). With this type of solvent nucleophilicity scale there is no need to incorporate an *mY* term into its derivation (2*c*, 11). The scale is termed the N_T scale, and the N'_{OTs} values are very similar, giving support to the premise that either of the two scales is giving a valid measure of solvent nucleophilicities. Several secondary N_T values (N''_T) are available (9, 12), based upon the specific rates of solvolysis of the *S*-methylthiophenium ion (13).

When the original N_{OTs} values are used in conjunction with Y_{OTs} values, the *l* value and its standard error and the correlation coefficient will be identical to those obtained using N'_{OTs} values, and the discrepancy will occur within the *m* value obtained, which can be corrected by the addition of 0.25*l* (8, 9). There is, however, no simple way to correct for errors introduced when N_{OTs} scales are used in the presence of leaving groups (X) differing appreciably from the tosylate.

Since the previous reports (1, 6, 7), a new type of scale has been developed for incorporation into the Grunwald–Winstein equations when the solvolyses involve benzylic derivatives (14). This scale is termed the aromatic ring parameter (*I*) and the sensitivity to changes in this value is termed *h*. The full equation is now represented by eq. [2]. The additional term has been found to make a significant contribution to the linear free energy relationship when there is appreciable development of

$$[2] \quad \log (k/k_o)_{RX} = lN_T + mY_X + hI + c$$

carbocationic character on the α-carbon at the transition state for solvolyses of benzylic derivatives (14–16). The *h* value has been found to increase with increase in the number of aromatic rings that can enter into conjugation with the carbocationic center. The origin of the *hI* term is believed (14, 17) to lie in a perturbation of the solvation changes in going to the transition state, relative to the changes observed for solvolyses of the standard adamantyl substrates used in establishment of Y_X scales. These effects may also be reflected in variations in the amounts of hidden internal return to substrate, which will perturb the detailed relationship with the Y_X scale (14).

As an alternative to the use of the *hI* term, numerous similarity models have been developed (18, 19). The use of similarity models has been reviewed (18*f*, 20). For example, the use of solvolyses of neophyl tosylate (Y_{neo}) (21), *p*-methoxyneophyl tosylate (Y_Δ) (21), and α-(*tert*-butyl)benzyl tosylate ($Y_{\alpha\text{-}t\text{-}Bu}$) (18*e*, 22) have been proposed as sources of improved scales for replacement of Y_{OTs}, when benzylic tosylates are being solvolyzed. It has been found, however, that these scales do not adequately correct for the perturbation involved when multiple aromatic rings are capable of entering into conjugation with the carbocationic center and the solvolysis of 2,2-dimethyl-1-(β-naphthyl)propyl tosylate was proposed as a similarity model (23). As a variant, multiple correlation analysis against a linear combination of both Y_Δ and Y_{OTs} terms has been proposed, primarily for ionizations proceeding with 1,2-aryl group migration (24) but also for the solvolyses of benzylic systems (25).

In the present report, we analyze the specific rates of solvolysis of several compounds of structure **1**, with varying identity of substituent X (1, 6, 7), in terms of both simple (eq. [1] without the *lN* term) and extended (eq. [1]) Grunwald–Winstein equations, and we also consider the extent to which the extended correlations are improved when the *hI* term is added (eq. [2]). An indication that it could be helpful to use eq. [2] comes from the study of Westaway and Waszczylo (26). These authors found evidence for appreciable electron deficiency at the α-carbon of benzylic substrates at the transition state, even in the presence of electron-withdrawing substituents and for bimolecular reaction with powerful nucleophiles, such as the thiophenoxide ion. Finally, for the solvolyses of substrates of type **1**, we consider the advantages and disadvantages of replacing the Y_{OTs} scale within eq. [1] by a similarity model scale (Y_{sim}) based on the specific rates of solvolysis of *p*-methylbenzyl *p*-toluenesulfonate (**1**, X = *p*-CH_3).

Results

The specific rates of solvolysis of the seven benzylic tosylates studied are reported in Table 1 for ethanol, methanol, acetic acid, formic acid, two aqueous ethanol compositions, three aqueous 2,2,2-trifluoroethanol (TFE) compositions, 95% acetone, and 60% TFE – 40% ethanol. The reported values (some extrapolated) are for solvolyses at 50.0°C, except for **1** (X = *p*-CH_3), which was studied at 0.0°C. The specific rates for **1** (X = H) were determined in this study only in the TFE–ethanol mixture, in 50% TFE, and in 95% acetone; the other values were available from an earlier publication (27). Also, contained within the footnotes to Table 1 are values determined at other temperatures, which were then extrapolated using the Arrhenius equation to get the corresponding values at 50.0°C.

The data for these substrates have been analyzed in terms of eq. [1], with and without the lN_T term, using the ABSTAT statistical package (Anderson-Bell, Arvada, Colorado, U.S.A.). The results of this analysis are contained within Table 2, together with identical analyses of the five more extensively studied (in terms of number of solvents) substrates, using the data of Fujio, Tsuno, and co-workers (6, 7). When values for solvolyses in acetonitrile–water mixtures are reported (6, 7), the appropriate secondary N''_T values (12) were used, in conjunction with the N_T values available (9, 10) for the other solvents. The Y_{OTs} values were as reported by Bentley and Llewellyn (5), except that those values based on 1-adamantyl tosylate solvolyses were corrected in the manner suggested by Allard and Casadevall (adjusted Y_{OTs} values of –1.75 for EtOH, –0.77 for MeOH, –0.74 for CH_3CO_2H, and –2.53 for 95% acetone, plus an interpolated value of 1.95 for 80% TFE) (4, 28). For the analyses of the literature data (6, 7), a full tabulation of Y_{OTs} values was available (6). For these analyses, several of the N_T values were interpolated values (–1.51 for 30% TFE, –1.68 for 40% TFE, –1.83 for 50% TFE, –2.31 for 80% TFE, and –2.77 for 50% 1,1,1,3,3,3-hexafluoro-2-propanol [HFIP], all mixtures prepared on a volume/volume basis). The N''_T value of –1.07 for 50% acetonitrile was also an interpolated value.

In Table 3, the correlations obtained upon addition of the *hI* term (eq. [2]) are reported. The number of solvents is fewer

than in Table 2 because *I* scale values are not available for HCOOH, CH_3COOH, and the four aqueous acetonitrile mixtures. To allow a direct comparison with an analysis in terms of eq. [1], the eq. [1] analyses of Table 2 have been repeated with omission of these six solvents.

In Table 4 are presented analyses paralleling those of Table 2 but using Y_{sim} values defined as log (k/k_0) for **1** (X = *p*-CH_3) solvolyses in place of Y_{OTs} values.

For the analyses reported in Tables 2–4, the "goodness of fit" is considered in terms of the overall correlation coefficient, the *F*-test values, the probabilities that each individual term is statistically insignificant (reported if greater than 0.005), the standard error of the estimate (reported associated with the *c* value), and the standard errors associated with the calculated *l*, m, and *h* values. If multicollinearity had been a problem, a warning would have been issued to the effect that "the results may be spurious due to a high degree of multicollinearity."

Discussion

Our earlier claim (1), based on treatments in terms of eq. [1] of the seven substrates studied in 10 or 11 solvents, of an S_N1 mechanism involving appreciable nucleophilic solvation for *p*-methylbenzyl tosylate and an S_N2 mechanism (27, 29) with variable transition state structure for the solvolyses of the other six esters has been given very strong support (30) by a detailed correlation analysis of the effect of varying the substituent within a given solvolysis. A Yukawa–Tsuno treatment (31) indicated a gradual change in mechanism from S_N1 for electron-donating substituents, through a borderline region, to S_N2 as the substituents became increasingly electron withdrawing (30).

In Table 2, the earlier (1) treatments of seven of the substrates are now presented in terms of N_T and Y_{OTs} values; as well, the five substrates (three new) studied by Fujio, Tsuno and co-workers in 34–41 solvents (6, 7) are also now treated in terms of N_T and Y_{OTs}. The analyses in terms of the full eq. [1] all show an appreciable sensitivity towards changes in N_T values, even in the presence of an electron-donating methyl substituent. The sensitivities (*l* values) are, however, quite low in the presence of a methyl substituent and the *F*-test value falls slightly on incorporation of the lN_T term into the one-term equation. For **1** (X = *p*-CH_3) the *l* value of 0.34 ± 0.14 is accompanied by a 0.05 probability that the lN_T term is not statistically significant. For the solvolyses of **1** (X = *m*-Me), the study is in 41 solvents, and the *l* value of 0.24 ± 0.06 is associated with a very low probability that the lN_T term is statistically insignificant. The *m* values of 1.07 and 0.80, respectively, indicate appreciable carbocationic character at the transition state.

As one moves onward, in terms of σ^+ values (32), to the unsubstituted ester and then to the four halogenated derivatives (σ^+ of 0.11–0.40), there is a trend of gradually increasing *l* values (0.59–0.80) and gradually decreasing *m* values (0.82–0.67). These substrates appear to be solvolyzing by a mechanism that is S_N2 in character but with the bond breaking running ahead of the bond making, consistent with the picture for S_N2 reactions at benzylic carbon developed by Westaway and Waszczylo (26). The *F*-test values for these five solvolyses are all higher for the two-term treatment, significantly so for the halogenated derivatives.

The analyses for **1** (X = *p*-CF_3; $\sigma^+ = 0.61$), **1** (X = *p*-NO_2; $\sigma^+ = 0.79$), and **1** (X = 3,5-diCF_3; $\sigma^+ = 2 \times 0.52$) all show extremely poor one-term correlation against Y_{OTs}, with very

© 1998 NRC Canada

low correlation coefficients and *F*-test values. The correlations are enormously improved by use of the full eq. [1] and the *l* and *m* values stabilize at 0.94–1.04 and 0.70–0.61, respectively. It is proposed that these values reflect a fairly symmetrical S_N2 transition state, but still with bond breaking running a little ahead of the bond making (26). The values can be compared with those (9) for the typically S_N2 solvolyses of methyl tosylate of 0.96 ± 0.04 for *l* and 0.53 ± 0.04 for m.

The effect of adding an *hI* term to eq. [1], to give eq. [2], is demonstrated in Table 3, where a comparison is made of the applications of the two equations to solvolyses in the same sets of solvents. One cannot draw any firm conclusions from the application of a three-term equation to solvolyses in only nine solvents and, in these cases, the *h* values are associated with large standard errors and very high probabilities that the *hI* term is statistically insignificant; values are included only because the actual values (ignoring the large standard errors) are found to be consistent with those from parallel analyses for the five substrates using 28–35 solvents.

Concentrating on the investigations with 28–35 solvents (6, 7), we find that the *h* values fall as increasingly electron-withdrawing groups are introduced, from 0.79 ± 0.18 for *m*-CH_3, to 0.64 ± 0.18 for the unsubstituted substrate, to 0.50 ± 0.17 for *m*-Cl, to 0.25 ± 0.11 for *p*-NO_2, and to 0.28 ± 0.12 for the 3,5-diCF_3 substituent. Even for the two smallest values, there is only a 0.03 probability that the *hI* term is statistically insignificant. There is an appreciable increase in the correlation coefficient on addition of the *hI* term for the *m*-CH_3, H, and *m*-Cl substituents, but only small increases in the presence of *p*-NO_2 and 3,5-diCF_3 substituents. As regards *F*-test values, incorporation of the *hI* term leads to a slightly higher value for *m*-CH_3 and to slightly lower values for the other four substituents.

It can be concluded that the analyses reported in Table 3 give further support to the concept of carbocationic character for the benzylic carbon at the transition state of these solvolyses (26). The fairly large charge development in the solvolyses of the *m*-CH_3 derivative becomes very much smaller in the presence of the powerfully electron-withdrawing *p*-NO_2 and 3,5-diCF_3 substituents.

An alternative treatment to the incorporation of the *hI* term is to replace the Y_X scale by a similarity model scale, with the same leaving group but with the adamantyl group replaced by a group with a phenyl substituent either at the α-carbon or migrating, at the transition state, from a β-carbon to the α-carbon. In their consideration (6, 7) of benzyl tosylate and four derivatives, Fujio and Tsuno investigated the use within eq. [1] of not only the Y_{OTs} scale but also similarity models termed the $Y_{t\text{-Bu}}$ scale, the Y_{neo} scale, and the Y_Δ scale. It has been shown that the most important aspect of a good similarity model scale is that its h/*m* ratio is very similar to (ideally, identical to) that for the solvolysis under investigation (14, 15). It is instructive to consider the application of these three similarity models in terms of how well their *h*/*m* ratios match those for solvolyses of the five substrates under investigation. The relevant *h*/*m* ratios for the models are 0.82 (15*a*), 0.94 (15*d*), and 1.13 (15*d*), respectively. These values are all quite similar and, as one would expect, the three scales do about equally well when used as the *Y* scale within eq. [1] (6, 7).

Using the data of Table 3, we obtain *h*/*m* ratios of 0.95 with an *m*-Me substituent, 0.80 with no substituent, 0.72 with an *m*-Cl substituent, 0.37 with a *p*-NO_2 substituent, and 0.44 for the 3,5-diCF_3 derivative. The first three *h*/*m* ratios match well with those of the proposed similarity models and, accordingly, it is found (6) that one obtains considerably improved eq. [1] correlations when a similarity model *Y* scale replaces Y_{OTs}.

The finding (7), for each of the two substrates with highly electron-withdrawing substituents, that the Y_{OTs} scale and the three similarity model scales lead to almost identical eq. [1] correlation coefficients is also readily explained in terms of *h*/*m* ratios. The observed *h*/*m* ratios of about 0.4 are roughly half way between the 0.82–1.13 values for the proposed similarity models and the value of zero for solvolyses of 2-adamantyl tosylate. Accordingly, the error resulting from the undercorrection when the Y_{OTs} scale is incorporated is comparable to the error resulting from the overcorrection when one of the similarity models is employed.

For analyses of the specific rates of solvolyses of benzylic derivatives, incorporation of a similarity model scale, based on solvolyses of a substrate with similar structure, will usually lead to better correlations than those obtained using an adamantyl-based Y_X scale. There are several scales that have

[a] Number of solvents (data from Table 1 and refs. 6 and 7; fewer than in Table 2 because of lack of *I* values for CH_3CO_2H, HCO_2H, and CH_3CN–H_2O mixtures).
[b–i] See footnotes to Table 2.

been proposed and, in principle, different scales will be needed for each leaving group.

We have considered above three similarity models that have been used for benzylic tosylates and another one has been proposed (23) for use when two aromatic rings enter into conjugation with the developing positive charge. Further, the high h/*m* ratio of 3.29 observed (15*b*) for the solvolyses of 1-(9-anthranyl)-2,2,2-trifluoroethyl methanesulfonate (33) suggests that yet another scale would be needed in the presence of three aromatic rings.

The concept of similarity models for correlations of specific rates of solvolysis can be considered as one example of the use of internally generated parameters for linear free energy analyses of a grouping of related data. We have recently discussed the advantages and disadvantages of internally generated scales of σ values (34) in a consideration of the importance of cross-interaction coefficients in Hammett treatments of reactions with two (35) or three (36) aromatic sites, each with varying substituents. In terms of evaluating the extent of cross interaction and obtaining calibrated values (37) for the coefficients, this is an excellent approach. The major disadvantage is that, in order to relate the values obtained to values determined using conventional σ scales, it is necessary to introduce the ρ values that are obtained by application of the appropriate conventional σ scale to the experimental data.

In Grunwald–Winstein equation considerations, if one is looking for a trend of relatively small variations in the *lN* term contribution within a series of related compounds, it can be advantageous to use an internally generated similarity model *Y* scale. For the consideration of solvolyses of compounds of type **1**, we have used the solvolyses of **1** (X = *p*-CH_3) to establish a Y_{sim} scale and we then applied the 10 values obtained,

Table 4. Correlation of the specific rates of solvolysis at 50.0°C of ring-substituted benzyl *p*-toluenesulfonates ($XC_6H_4CH_2OTs$) using the simple and extended Grunwald–Winstein equations (eq. [1], with and without the lN_T term) and incorporating Y_{sim} values (log (k/k_o) for *p*-$CH_3C_6H_4CH_2OTs$ solvolysis).

together with N_T values, to the specific rates of solvolysis of the other six compounds of type **1** that were studied in these solvents (Table 1). The results from correlations in terms of eq. [1], with and without the lN_T term, are reported in Table 4. In all cases, a comparison of both the correlation coefficients and *F*-test values shows considerably improved correlations when the lN_T term is included. The correlation coefficients and *F*-test values using the full equation are fairly constant except for **1** (X = *p*-NO_2), where lower values are obtained; this inferior correlation can be rationalized in terms of a much lower *h*/*m* ratio than is obtained in correlation of the Y_{sim} scale and the log (k/k_0) values for the other five substrates of Table 4 (*h* and *m* values from Table 3).

The values in Table 4 show a very clear trend of increasing *l* values as one increases the electron-withdrawing ability of the substituent. It must, however, be emphasized that these values are relative to the extent of nucleophilic participation involved in the solvolyses used to establish the Y_{sim} scale, where there is clear evidence (Tables 2 and 3) for a measure of nucleophilic participation. If one wishes to compare the values of Table 4 with others obtained using the Y_{OTs} scale in conjunction with N_T, it is necessary to know the correlation relationship between the log (k/k_0) values used to establish the Y_{sim} scale and the N_T and Y_{OTs} parameters. Further, not only the sensitivity values but also the associated standard errors will be required and, in particular, even if a sensitivity value should be found to be negligibly small, the associated standard error must still be applied.

If we should wish to compare the data obtained with use of N_T and Y_{sim} with data obtained using N_T and Y_{OTs}, we need the entry for **1** (X = *p*-Me) from Table 2. A general treatment is given below:

[3] $Y_{sim} = \log (k/k_0)_{sim}$ (definition)

[4] $= l_{sim}N_T + m_{sim}Y_{OTs}$

With a substituent X, we can correlate against N_T and Y_{sim}:

[5] $\log (k/k_0)_X = l_X N_T + m_X Y_{sim}$

and, substituting for Y_{sim} from eq. [4], we obtain:

[6] $\log (k/k_0)_X = (l_X + m_X l_{sim})N_T + m_X m_{sim} Y_{OTs}$

This is the same form as the correlation against N_T and Y_{OTs}:

[7] $\log (k/k_0)_X = lN_T + mY_{OTs}$

such that, comparing eqs. [6] and [7]:

[8] $l = l_X + m_X l_{sim}$

and

[9] $m = m_X m_{sim}$

If correlation is done first using internally generated Y_{sim} values and one wishes to compare these results with others obtained using the conventional (external) Y_X values, one must first adjust the l_X and m_X values as indicated. The end result is that the *l* and *m* values and their standard errors are essentially identical to those that would have been obtained by a direct one-step correlation against N_T and Y_X.

We can take, as an example, the correlation of the specific rates of solvolysis of **1** (X = *m*-F). The l_{sim} value is 0.34 ± 0.14 and the m_{sim} value is 1.07 ± 0.11 (from the **1** (X = *p*-Me) entry in Table 2). Using eq. [1] with N_T and Y_{sim} values, one obtains an l_X value of 0.57 ± 0.03 and an m_X value of 0.67 ± 0.03 (Table 4). Therefore, substituting in eqs. [8] and [9], the values corresponding to application of eq. [1] with N_T and Y_{OTs} values are

[10] $l = 0.57 \pm 0.03 + (0.67 \pm 0.03)(0.34 \pm 0.14)$
$= 0.80 \pm 0.10$

and

[11] $m = (0.67 \pm 0.03)(1.07 \pm 0.11) = 0.72 \pm 0.08$

with the values being essentially identical to the 0.80 ± 0.09 and 0.71 ± 0.06 obtained directly (Table 2).

Conclusions

The specific rates of solvolysis of the parent benzyl tosylate and ring-substituted derivatives are correlated with reasonable precision (correlation coefficient 0.930–0.987) using the two-term Grunwald–Winstein equation (eq. [1]), with incorporation of N_T and Y_{OTs} values. As one moves from substituents with negative σ^+ values to substituents with increasingly positive σ^+ values, the *l* values rise from 0.34 for *p*-Me to a value of close to unity for *p*-NO_2 and 3,5-diCF_3 and the *m* values fall from 1.07 to a value of 0.61–0.65. These changes in the values are believed (1) to represent a transition from an ionization mechanism with nucleophilic solvation to an S_N2 mechanism with varying transition state structure that, with strongly electron-withdrawing substituents, attains an *l* value identical to the 0.96 for methyl tosylate solvolysis and an *m* value only slightly higher than the 0.53 for methyl tosylate solvolysis.

For five of the substrates, a sufficiently large number of well-chosen solvents are available to carry out a meaningful investigation of the application of eq. [2], where a term governed by the aromatic ring parameter (*I*) is added to eq. [1]. The sensitivities (*h*) towards this parameter fall in an orderly fashion, from 0.79 ± 0.18 for *m*-Me to 0.25 ± 0.11 for *p*-NO_2. The observation of a meaningful (probability that the *hI* term is statistically insignificant of < 0.03) *h* value throughout the series of substrates, together with an *m* value always somewhat larger than for methyl tosylate solvolysis, is consistent with the previously expressed (26) view that S_N2 reactions of benzyl derivatives have some positive charge development on the α-carbon, even in the presence of powerfully electron-withdrawing ring-substituents.

Application of a similarity model for the *Y* scale, based on the solvolyses of *p*-methylbenzyl tosylate, demonstrates very clearly the well-defined trend of increasing *l* values with increasing σ^+ values, and very good *F*-test values and correlation coefficients (0.992–0.997) are observed. While this type of treatment, using an internally generated *Y* scale, is excellent for examining trends in *l* values within a series of closely related solvolyses, the goodness of fit is considerably diminished when one then applies the calibration factors (and their associated standard errors) needed prior to any comparison with sensitivities determined using N_T values and an external Y_X scale (for a leaving group X). Indeed, using one of the present analyses as an example, it is shown that one arrives at essentially identical sensitivity values and associated standard errors irrespective of whether one proceeds in two steps, use of N_T and Y_{sim} values being followed by adjustment of the *l* and *m* values, or by a one-step application of N_T and Y_{OTs} values.

Experimental

Solvents were purified and kinetic runs carried out as previously described (10).

The parent and six ring-substituted benzyl tosylates were prepared by the silver-salt method (38, 39). All seven substrates had previously been prepared, either by the silver-salt method or by the Schotten–Bauman method, and the melting points observed were in agreement with those initially reported (40–42). The procedure is illustrated for the parent compound as follows: Silver tosylate (Aldrich, 99+%, 3.07 g, 0.011 mol) was dissolved in 25 mL acetonitrile and benzyl bromide (Aldrich, 99%, 1.71 g, 0.010 mol) was added. The mixture was stirred overnight at room temperature and filtered. The filtrate was evaporated under reduced pressure and the residue was recrystallized from petroleum ether to give fine white needles of benzyl tosylate, mp 57.5–59°C (lit. (40) mp 58.5–58.9°C). Anal. calcd for $C_{14}H_{14}O_3S$: C 64.1, H 5.4; found: C 64.2, H 5.3. An identical procedure using commercially available (Aldrich, 95–99%) bromides or chlorides was used for the preparation of the ring-substituted derivatives.

Isotope effects in nucleophilic substitution reactions X. The effect of changing the nucleophilic atom on ion-pairing in an S_N2 reaction

Yao-ren Fang, Zhu-gen Lai, and Kenneth Charles Westaway

Abstract: The effect of ion-pairing in an S_N2 reaction is very different when the nucleophilic atom is changed from sulfur to oxygen, i.e., changing the nucleophile from thiophenoxide ion to phenoxide ion. When the nucleophile is sodium thiophenoxide, ion-pairing markedly alters the secondary α-deuterium kinetic isotope effect (transition state structure) and the substituent effect found by changing the *para* substituent on the nucleophile. When the nucleophile is sodium phenoxide, ion-pairing does not significantly affect the secondary α-deuterium or the chlorine leaving group kinetic isotope effects (transition state structure) or the substituent effects found by changing a *para* substituent on the nucleophile or the substrate. The different effects of ion-pairing may occur because the electron density on the hard oxygen atom of the sodium phenoxide is not affected significantly by ion-pairing.

Key words: nucleophilic substitution, S_N2, kinetic isotope effect, transition state, substituent effects, ion-pair.

Résumé : L'effet de la formation de paires d'ions sur une réaction S_N2 est très différent si l'atome nucléophile est un soufre ou un oxygène, comme lorsque le nucléophile est un ion thiophénolate ou un ion phénolate. Lorsque le nucléophile est le thiophénolate de sodium, la formation de paires d'ions influence l'effet isotopique cinétique secondaire dû aux hydrogènes en α (structure de l'état de transition) ainsi que l'effet de substituant provoqué par le changement de substituants *para* sur le nucléophile. Lorsque le nucléophile est le phénolate de sodium, la formation de paires d'ions n'affecte pas de façon significative l'effet isotopique secondaire dû aux hydrogènes en α ou les effets isotopiques cinétiques du chlore comme groupe partant (structure de l'état de transition) ou les effets de substituants provoqués par le changement de substituants *para* sur le nucléophile ou le substrat. Les effets différents dus à la formation de paires d'ions peuvent être causés par la densité électronique sur l'atome d'oxygène dur du phénolate de sodium qui n'est pas affecté d'une façon significative par la formation de paires d'ions.

Mots clés : substitution nucléophile, S_N2, effet isotopique cinétique, état de transition, effets de substituants, paires d'ions.

[Traduit par la rédaction]

Introduction

Westaway and co-workers have shown that ion-pairing can have a significant effect on the magnitude of the secondary α-deuterium kinetic isotope effect (KIE) and transition state structure of an S_N2 reaction (1–4). For example, in the S_N2 reaction between sodium thiophenoxide and *n*-butyl chloride, eq. [1],

[1] $$C_6H_5\text{-}S^-(Na^+) + CH_3CH_2CH_2CL_2\text{-}Cl \rightarrow CH_3CH_2CH_2CL_2\text{-}S\text{-}C_6H_5 + Na^+ + Cl^-$$
(L = H, D)

in DMSO at 20.000°C, the secondary α-deuterium KIE changes from 1.116 ± 0.002, when the nucleophile reacts as a free ion, to 1.034 ± 0.002, when the nucleophile reacts as a solvent-separated ion-pair complex $[(Na^+)_y(solvent)_x(^-SC_6H_5)_y]$ (1, 2). Since the magnitude of the KIE is related to the nucleophile – leaving group distance in the S_N2 transition state (5, 6), the structure of the transition state for the free ion and the ion-pair reactions must also be different. The secondary α-deuterium KIE (transition state structure) for this reaction also changed, i.e., from 1.131 ± 0.002[2] to 1.07 ± 0.03 when the nucleophile changed from a solvent-separated ion-pair complex to a contact ion-pair in diglyme (3). Another study demonstrated that the substituent effects found by changing a *para* substituent on the nucleophile of an S_N2 reaction is also very different depending on whether the nucleophile is a free ion or a solvent-separated ion-pair complex (4). For example, changing the *para* substituent on the nucleophile from methoxy to

Received December 10, 1997.

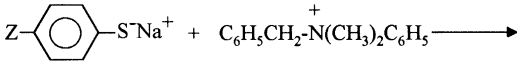
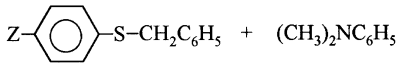
chloro in the S_N2 reaction between *para*-substituted thiophenoxide ions and benzyldimethylphenylammonium ion, eq. [2],



[2]



reduced the secondary α-deuterium KIE by 15%, i.e., from 1.27 to 1.12 when the nucleophile was a free ion but only from 1.22 to 1.15 (by 7%) when the nucleophile was a solvent-separated ion-pair complex. These findings are important because they demonstrate that the transition state and the substituent effects are different when the form of the reacting nucleophile is different. This means one must (*i*) determine the form of the nucleophile and (*ii*) ensure that it remains the same throughout a study where one is measuring the values of mechanistic criteria or substituent effects. The failure to do so could lead to significant errors when interpreting the results.

This study was undertaken to see if changing the nucleophilic atom from sulfur to oxygen affects how ion-pairing alters (*i*) the secondary α-deuterium KIE (transition state structure) and (*ii*) the substituent effects in an S_N2 reaction.

Results and discussion

The secondary α-deuterium KIEs for the S_N2 reactions between *para*-substituted benzyl chlorides and *para*-substituted sodium phenoxides, eq. [3]

[3] 
L = H, D

were measured to determine how ion-pairing (a change in the form of the reacting nucleophile) affects an S_N2 reaction when the nucleophilic atom is oxygen rather than sulfur.

Determining the concentrations where *para*-substituted sodium phenoxides exist as free ions and ion-pairs

Before one could determine how ion-pairing affects S_N2 reactions, it was necessary to determine the concentrations where the *para*-substituted sodium phenoxides exist as free ions and as ion-pairs in the organic solvents used in this study. The onset of ion-pairing in sodium *para*-substituted phenoxide solutions in DMSO, DMF, and methanol was identified by the downward curvature of the conductance versus concentration plot and (or) changes in λ_{max} in the UV spectrum as the concentration of the salt was increased (1). Although the concentration where ion-pairing of the *para*-substituted sodium phenoxides begins was determined by both methods in methanol, it was only determined by conductivity in DMF and DMSO. This was because both DMF and DMSO absorb strongly in the region where the *para*-substituted sodium phenoxide ion-pairs absorb. This is not thought to be a problem because, in those cases where conductivity and UV measurements were possible, the agreement between the two methods is good, Table 1.

Several observations are noteworthy. First, all the *para*-substituted sodium phenoxides exist as ion-pairs at high concentrations in methanol and in DMSO. Second, the substituent on the phenoxide ion does not significantly affect the concentration where ion-pairing occurs, i.e., all the *para*-substituted phenoxide salts begin forming ion-pairs in a very narrow concentration range between 5×10^{-4} and 2×10^{-3} M, Table 1. Third, the results also indicate that sodium phenoxide exists as free ions to a higher concentration than sodium thiophenoxide ions in methanol but forms ion-pairs at lower concentrations than sodium thiophenoxide in DMSO. This different behaviour in the dipolar aprotic and the protic solvents can be rationalized as follows. The higher concentration where ion-pairing begins in methanol is expected because the oxygen of the phenoxide ion has a higher negative charge density (vide infra) and would be more strongly solvated by hydrogen bonding to methanol than the sulfur of the thiophenoxide ion. As a result, the stabilization of the phenoxide ion by ion-pairing in methanol only begins when the concentration of the salt is high. In DMSO, on the other hand, the phenoxide ion forms ion-pairs at lower concentrations than the thiophenoxide ion. This is also reasonable because the negative charge density on the oxygen of the phenoxide ion is much higher than the negative charge density on the sulfur of the thiophenoxide ion. Therefore, phenoxide ion would be more strongly attracted to the sodium ion in these dipolar aprotic solvents, which do not solvate negative ions strongly (7, 8), and ion-pairing will occur at a lower concentration.

Another difference between the sodium phenoxide and sodium thiophenoxide salts is that the change in the form of the phenoxide ion with concentration is less abrupt than that of the thiophenoxide ions, which changed from free ions to a solvent-separated ion-pair complex when the concentration changed by a factor of two.

Finally, the change in the λ_{max} of the UV spectrum on ion-pairing is smaller for sodium phenoxide salt than for sodium thiophenoxide. The shift in the λ_{max} on ion-pairing was 32 nm, i.e., it increased from 235 to 267 nm in methanol when sodium thiophenoxide formed ion-pairs whereas it only increases by 7 nm, i.e., from 272 to 279 nm when sodium phenoxide changes from a free ion to an ion-pair. This indicates that the phenoxide ion chromophore is not altered significantly upon ion-pairing. This is interesting because it suggests that the effect of changing the form of the reacting nucleophile (ion-pairing) might be small when the nucleophile is the phenoxide ion.

The effect of ion-pairing of an oxygen nucleophile on the magnitude of the secondary α-deuterium KIE

The secondary α-deuterium KIE for the S_N2 reaction between sodium phenoxide and benzyl chloride was measured in methanol at 20.000 ± 0.002°C under conditions where (*i*) the

[b] The error in the isotope effect = $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively.

phenoxide ion exists as an ion-pair and (*ii*) in the presence of 15-crown-5 ether where the nucleophile is the free phenoxide ion.[3] The second-order rate constants for the reactions of both the deuterated and undeuterated benzyl chloride and the secondary α-deuterium KIE found using two different methods of analysis[4] are presented in Table 2. The important observation is that the secondary α-deuterium KIEs are identical in these two reactions in spite of the fact that the form of the reacting nucleophile is different. This was surprising because the secondary α-deuterium KIEs were very different when the form of the nucleophile changed (ion-pairing occurred) in the S_N2 reaction when sodium thiophenoxide was the nucleophile; i.e., the KIE changed from 1.13 to 1.03 in DMSO, from 1.13 to 1.085 in DMF, and from 1.13 to 1.10 in methanol when the nucleophile changed from a free ion to a solvent-separated ion-pair complex in the S_N2 reaction between thiophenoxide ion and *n*-butyl chloride (1).

Because it was surprising that ion-pairing did not change the secondary α-deuterium KIE in the phenoxide ion – benzyl chloride reaction in methanol, it was important to learn whether this was a general phenomenon that occurred whenever oxygen nucleophiles were used in an S_N2 reaction. Therefore, the secondary α-deuterium KIEs were measured for two other S_N2 reactions where the form of the sodium phenoxide nucleophile was altered from an ion-pair to a free ion by adding 15-crown-5 ether. The results in Table 3 show that the different behaviour for the thiophenoxide and phenoxide ion nucleophiles is, indeed, real. Identical secondary α-deuterium KIEs were found for the free ion and the ion-pair phenoxide ion reactions with benzyl chloride in DMF and with *n*-butyl chloride in DMSO. It is important to note that these two reaction systems were chosen because the change in the secondary α-deuterium KIE on ion-pairing in the thiophenoxide ion reactions was greatest in DMF and DMSO. (1) However, changing the form of the oxygen nucleophile in two S_N2 reactions in three different solvents did not change the secondary α-deuterium KIE. Clearly, the effect of ion-pairing is very different when the nucleophilic atom in an S_N2 reaction is sulfur and oxygen.

The effect of ion-pairing of an oxygen nucleophile on the substituent effects and the magnitude of the secondary α-deuterium KIE

The different response to ion-pairing by oxygen nucleophiles was tested in another way. The substituent effects observed when the form of the thiophenoxide ion nucleophile changed in the S_N2 reactions between *para*-substituted sodium thiophenoxides and benzyldimethylphenylammonium ion in methanol, eq. [2], were significantly different (4). Changing the *para* substituent on the thiophenoxide ion from methoxy to chloro, when the nucleophile was the free ion, caused the secondary

[3] This method of converting the ion-pair into the free ion was chosen because when the phenoxide ion existed exclusively as a free ion, the phenoxide ion concentration was too low to measure the rate constants needed for the isotope effect accurately.

[4] The second method of analysis was used to ensure that the rate constants and isotope effects were not an artifact of the method.

[a] These isotope effects were taken from ref. 4. The error in the isotope effect equals $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively.

α-deuterium KIE to decrease from 1.27 to 1.12, Table 4. When the *para* substituent on the nucleophile changed from methoxy to chloro and the nucleophile was the solvent-separated ion-pair complex, the secondary α-deuterium KIE decreased from 1.22 to 1.15. In fact, all but one of the secondary α-deuterium KIEs was larger for the free-ion reactions than for the ion-pair reactions. Also, changing the *para* substituent on the free ion changed the secondary α-deuterium KIE by 15% whereas the change in the secondary α-deuterium KIE with substituent was only 7% for the ion-pair reactions. The important observation, however, is that the substituent effects were significantly different when the form of the reacting nucleophile was different and the nucleophilic atom was sulfur.

The substituent effect caused by a change in the form of the reacting nucleophile when the nucleophilic atom is oxygen was determined in two ways. First, the effect of changing the *para* substituent on the nucleophile was determined for both the free ion and the ion-pair nucleophiles by measuring the secondary α-deuterium KIEs for a series of S_N2 reactions between *para*-substituted sodium phenoxides and benzyl chlorides, Table 5. In contrast to the large substituent effects observed when the nucleophilic atom was sulfur, Table 4, the results in Table 5 show that the substituent effect on the secondary α-deuterium KIE is very small (effectively zero) for both the free ion and the ion-pair reactions when the nucleophilic atom is oxygen. Moreover, ion-pairing does not affect the secondary α-deuterium KIE significantly for either the free ion or the ion-paired oxygen nucleophiles.

The substituent effect caused by changing a substituent on the substrate was also determined for both the free ion and ion-pair reactions by measuring the secondary α-deuterium KIEs for the S_N2 reactions between sodium phenoxide and several *para*-substituted benzyl chlorides, Table 6. Again, the substituent effect on the secondary α-deuterium KIE is very small. The effect of ion-pairing is also very small (zero, considering the errors in the KIEs).

The failure to detect a change in the secondary α-deuterium KIE when the form of the reacting nucleophile was changed in the reactions with the phenoxide ion nucleophile is an important discovery because both the substituent effect and the effect of ion-pairing on the KIE were significantly different when the form of the nucleophile was altered in the sodium thiophenoxide S_N2 reactions.

Two explanations are possible for the very different behaviour found with phenoxide ion. One explanation is that ion-pairing does not significantly affect the nucleophilic oxygen atom and, therefore, does not cause a change in transition state structure. In fact, CNDO/2 calculations, Table 7, have shown that ion-pairing affects the electron density on a nucleophilic sulfur and oxygen atom very differently. The change in the negative charge on the nucleophilic atom on forming the contact ion-pair is almost four times greater for the sulfur nucleophiles than for the oxygen nucleophiles. This probably occurs because oxygen is a hard nucleophile (9) and it is more difficult to reduce the electron density on the nucleophilic oxygen atom by bringing the sodium ion near the oxygen. When the nucleophilic atom is sulfur, on the other hand, the nucleophilic atom is soft (polarizable), and bringing the positive sodium ion near the sulfur pulls electron density towards the sodium ion, thereby reducing the electron density available for bond formation (the nucleophilicity) of the sulfur ion. As a result, the sulfur nucleophile is altered significantly when ion-pairing occurs and there is a significant change in the secondary α-deuterium KIE and in transition state structure. When the nucleophile is oxygen, the sodium ion does not significantly alter the tightly held electron density on the nucleophilic atom

and neither the secondary α-deuterium KIE nor the transition state structure changes significantly.

A second explanation for the constant secondary α-deuterium KIEs that are found when a substituent is altered in the nucleophile and in the substrate of the *para*-substituted phenoxide ion – *para*-substituted benzyl chloride reaction series is that the transition states for these reactions are unsymmetrical and product-like. Westaway et al. (10) recently suggested that a change in substituent would not change the secondary α-deuterium KIE in an S_N2 reaction significantly when the transition state is unsymmetrical. They also found that in all the S_N2 reactions with unsymmetrical transition states, the stronger reacting bond is short and the weaker reacting bond is long. In the *para*-substituted phenoxide ion – *para*-substituted benzyl chloride reaction series the O—C_α reacting bond is stronger than the C_α—Cl reacting bond (11). Therefore, if these transition states are unsymmetrical, they should have a short O—C_α bond and a long C_α—Cl bond. A second factor that is important in determining the substituent effects on S_N2 transition state structure is the Bond Strength Hypothesis (11), which predicts that a change in substituent in the nucleophile, the leaving group, or the substrate of an S_N2 reaction will alter the weaker (C_α—Cl) reacting bond but will not affect the stronger (O—C_α) reacting bond significantly. Thus, if the transition states for these reactions are unsymmetrical, they should have a short O—C_α bond that does not change significantly and a long C_α—Cl bond that changes significantly with a change in substituent in the nucleophile or the reactant. Because a change in substituent only changes the long, weak (C_α—Cl) reacting bond in the unsymmetrical (product-like) transition state, the change in transition state structure occurs too far away to affect the C_α–H(D) out-of-plane bending vibrations that determine the magnitude of the secondary α-deuterium KIE, Fig. 1 (10). Therefore, the secondary α-deuterium KIEs will not change with a change in substituent in the nucleophile or the substrate.

There are two possible explanations for the constant secondary α-deuterium KIEs found when the reacting nucleophile changes from a free ion to an ion-pair and when a substituent is altered in the nucleophile and in the substrate of the

[a] Some of these data were taken from ref. 4.

para-substituted phenoxide ion – *para*-substituted benzyl chloride reactions. One is that ion-pairing does not change the structure of the S_N2 transition state. The second is that the transition states are unsymmetrical and product-like and that the transition state changes but that the only significant change is in the long and weak C_α—Cl transition state bond and this change does not affect the magnitude of the secondary α-deuterium KIE. One way to resolve this problem was to measure the chlorine leaving-group KIEs for these reactions. If ion-pairing does not affect the structure of the S_N2 transition state, identical chlorine KIEs should be found for both the free ion and the ion-pair reactions. If the constant secondary α- hydrogen/deuterium KIEs are the result of an unsymmetrical transition state with a short O—C_α bond that does not change significantly with a change in substituent and a long C_α—Cl bond that changes markedly with a change in substituent, the chlorine KIEs should be different for the ion-pair and the free ion reactions.

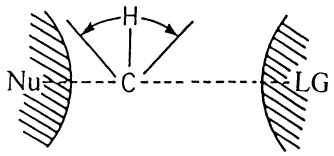
The chlorine (leaving group) KIEs for the free ion and ion-pair reactions between two different *para*-substituted phenoxide ions and benzyl chloride in methanol at 20.000°C and between *n*-butyl chloride and phenoxide ion in DMSO at 20.000°C are presented in Table 8. The obvious conclusion is that ion-pairing does not affect the chlorine KIE in three different S_N2 reactions. This means that ion-pairing does not alter the transition state of an S_N2 reaction when the nucleophilic atom is oxygen. These results are important because they suggest that ion-pairing will not alter transition state structure significantly when a hard nucleophile is used and that one need only worry about the effect of ion-pairing when a soft nucleophile is used.

Experimental

Preparation of reagents

All the *para*-substituted sodium phenoxides were prepared by reacting the appropriate phenol with a sodium methoxide – methanol solution, evaporating the solvent, removing the excess phenol by washing the salt with benzene and hexane, and drying under vacuum at 110°C. A typical synthesis involved preparing a 0.80 M solution of sodium methoxide in anhydrous methanol by adding 5.5 g of freshly cut sodium slowly to 300 mL of anhydrous methanol. Then, a 10% excess (20.6 g, 0.22 mol) of freshly distilled phenol was added to 250 mL of the 0.80 M solution of sodium methoxide. The methanol was evaporated under reduced pressure on a rotary evaporator and the solid was washed three times with 100 mL of dry benzene and finally with 100 mL of hexane under an atmosphere of dry nitrogen (Praxair) in a I^2R glove bag.[5] Finally, the salt was dried under vacuum in a sand bath at 110°C for 12 h. The yield of the purified salt was 15.6 g (67%).

Fig. 1. The unsymmetrical product-like S_N2 transition state where the magnitude of the secondary α-deuterium KIE would be determined by only the changes in the length of the O—C_α transition state bond.



The preparation of the *para*-substituted (1,1-^{2}H) benzyl chlorides and the (1,1-^{2}H) butyl chloride used in this study is described in refs. 12 and 1, respectively. The methanol was ACS reagent grade that was redistilled before use.

A study of ion-pairing for sodium phenoxide in organic solvents

The concentrations at which sodium phenoxide solutions existed as ion-pairs and as free ions were determined by recording the UV spectrum and by determining the conductivity of various sodium phenoxide solutions ranging from 1.433×10^{-5} M to 3.239×10^{-2} M. The procedure used in this study was identical to those used to determine the UV spectrum and the conductivity of sodium thiophenoxide solutions (1).

[5] The 37 in. × 37 in. I^2R glove bags were purchased from Instruments for Research and Industry, I^2R, Inc., P.O. Box 159B, Cheltenham, PA 19012, U.S.A.

[a] The standard deviation of the mean for five different measurements of the isotope effect.

Secondary α-deuterium KIEs

Unless otherwise specified, the rate constants required for calculating the secondary α-deuterium KIEs were determined by titrating the chloride ion produced during the reaction with a standard silver nitrate solution using the electrochemical method described in ref. 1. The only differences between the kinetic procedure described in ref. 1 and that used in this study were that the initial concentrations of the *para*-substituted benzyl chloride, the sodium *para*-substituted phenoxide, and the 15-crown-5 ether were 0.051 M, 0.246 M, and 0.285 M, respectively, and that a 2.5 mL, rather than a 5.00 mL, aliquot from the reaction mixture was titrated.

The rate constants for the benzyl chloride reactions with the free phenoxide ion and the sodium phenoxide ion-pair determined by the HPLC method, Table 2, involved determining the concentration of the unreacted benzyl chloride at various times throughout the reaction with the internal standard method (13). The actual HPLC analysis involved removing a 1.00 mL sample of the reaction mixture at various times throughout the reaction with a Hamilton gas-tight syringe fitted with a 6 in. stainless steel needle. This sample was transferred to a 10 mL volumetric flask containing 1.00 mL of a benzylphenyl sulfide (the internal standard) solution. This mixture was diluted to the mark with methanol and 25 μL of the solution was injected into a Waters 600 HPLC fitted with a Waters 10 cm 5PAH 10 μm column using a 70:30 methanol–water mixture as the eluting solvent. The flow rate was 2 mL/min and the Waters 490 variable wavelength detector was set at 254 nm. The concentration of the unreacted benzyl chloride at different times was determined from a calibration curve and the rate constants for the second-order reaction were calculated in the usual way (14).

Chlorine leaving-group KIEs

The procedure used for measuring the chlorine KIEs has been described elsewhere (15, 16). There were only two differences between the reported procedure and that used in this study. One difference was that the reactions in this study were quenched by adding 100 mL of a 0.09 M nitric acid solution rather than 100 mL of water. The second change was that the unreacted substrate in the benzyl chloride reactions was extracted with two 200 mL portions of toluene and one 100 mL portion of heptane rather than with three 100 mL portions of hexane.

Extended lithium ion pair indicator scale in tetrahydrofuran[1]

Andrew Streitwieser, Daniel Zerong Wang, Manolis Stratakis, Antonio Facchetti, Roustam Gareyev, Alessandro Abbotto, James A. Krom, and Kathleen V. Kilway

Abstract: The lithium p*K* scale has been extended to 25 indicators with a p*K* range of 9.7–24.4. The resulting scale is compared with the cesium ion pair acidities and to ionic p*K*'s in DMSO and aqueous DMSO.

Key words: ion pair acidity, organolithium compounds, indicator, acidity scale.

Résumé : On a étendu l'échelle p*K* du lithium à 25 indicateurs couvrant une plage de p*K* allant de 9,7 à 24,4. On a établi une comparaison entre l'échelle qui en résulte et les acidités des paires d'ion du césium et aux p*K* ioniques dans le DMSO et de DMSO aqueux.

Mots clés : acidité d'une paire d'ion, composés organolithium, indicateur, échelle d'acidité.

Several years ago we proposed a scale of proton transfer indicators in THF based on the solvent separated (SSIP) lithium ion pair salts of hydrocarbons whose UV–vis spectral characteristics are convenient (1). Equilibrium constants for the individual ion pair proton transfer equilibria in eq. [1] were converted to a numerical p*K* scale, eq. [2], by arbitrarily assigning to the lithium SSIP of fluorene its free ion p*K* value in DMSO of 22.90 (per hydrogen) (2).

$$[1] \quad RH + R'^{-}\,Li^{+} \overset{K}{\rightleftharpoons} R^{-}\,Li^{+} + R'H$$

$$[2] \quad pK(RH) = pK(R'H) - \log K$$

The resulting p*K* values were related to a corresponding scale involving the contact ion pairs (CIP) of the cesium salts by conductivity measurements of the dissociation of both the lithium and cesium ion pairs to the free ions in THF (3).

The resulting lithium scale has been used in a number of studies of the ion pair acidities of various substrates in THF, including fluorenes with chelating groups (4), dilithiated carboxylic acids (5), silanes (6), dithianes (7), dilithiated 9,9′-bifluorenyl (8), diphenylamine (9), acetylenes (10), polyhalobenzenes (11), ketones. (12–14), and carbazole (15). In the course of these and other studies we have added a number of new indicators to the lithium scale. The present paper presents a summary of the published and unpublished results in a convenient form.

Received January 5, 1998.

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

Other ion pair scales have been proposed in THF solution. Fraser et al. used NMR measurements of equilibria to determine the effective p*K*'s of a number of types of compounds (16–21). This work required measurements at high concentration and no account was taken of the possible role of ion pair aggregation; such aggregation is known to lower measured p*K* values (22). We have published an extended scale of cesium salts of indicators (23). Buncel and Menon used reactions of 18-crown-6 complexed potassium salts of indicators to determine the ion pair p*K* of dihydrogen in THF (24). Antipin et al. developed a scale of [2.1.1]-cryptated lithium salts of indicators in THF (25–27).

Results and discussion

The most precise measurements of the equilibria in eq. [1] are those of the so-called double-indicator method. In this approach, both lithium salts have conveniently measurable spectra and the concentrations of both are determined directly. Stoichiometry from the known starting amounts of RH and R′H then provides the equilibrium constant without interference from the traces of adventitious water generally present even with careful work. For example, we have found that with the use of Pyrex glassware the water content cannot be reduced below about 5×10^{-5} M because THF extracts water even from carefully dried and baked glassware. Lower water levels are possible with the use of quartz glassware and storage over molecular sieves in a glovebox. In many cases, the lithium salts were generated by adding 9-lithio-9,10,10-trimethyldihydroanthracene (LiTMDA) to the mixture. LiTMDA is a strong base that readily metallates the indicators on this scale.

UV–visible spectroscopic measurements of eq. [1] require that the two lithium salts have significantly different spectra. Moreover, good precision is not possible if *K* is too large or too small. These are the primary reasons for having a number of different indicators.

Table 1 summarizes the lithium indicator scale. Included in this table are the abbreviations for the indicators used in many of our papers, together with the absorption λ_{max} and the extinction

[a] Referred to the equilibrium mixture of the two indene isomers.
[b] References 1 and 3.
[c] Reference 4.
[d] The reference is taken as the Li SSIP salt of fluorene. Since fluorenyllithium in THF at 25°C is about 70% SSIP and 30% CIP the composite p*K*(SSIP+CIP) = 22.75 (3).
[e] CIP p*K* = 28.20, λ_{max} 388 nm (27 500) (7).

coefficient. The p*K* values are statistically corrected to be on a per-hydrogen basis; that is, the uncorrected p*K* of benzanthrene is lower by 0.30 (log 2), 1,3-diphenylindene is higher by 0.30 (the anion has two equivalent positions to which a proton can return), and 9-phenylfluorene is unchanged. The scale ends just below the p*K* value of 25. Above this value the proton transfer equilibria are inconveniently slow. The dithiane shown was measured by a special technique (7). The exchange rates of cesium salts are much higher and this scale goes up to pK's in the high 30s (23).

The indicators were generally compared with more than one reference. Agreement was generally a few parts in the second decimal. Accordingly, the assigned p*K*'s in Table 1 should be accurate to about ± 0.1 units.

The lithium and cesium scales in THF were interrelated by measuring the dissociation constants of several systems (3). The dissociation constants of the SSIP lithium salts of delocalized carbanions are relatively constant at 1×10^{-5} M; the cesium CIP dissociation constants show more variation with structure and are generally in the range $(1–20) \times 10^{-8}$ M. Accordingly, there is generally an excellent correlation between p*K*'s on the two ion pair scales (Fig. 1), but there is some scatter because of the variation in ion pair dissociation constants. Note that both scales are based on fluorene as a standard,

Fig. 1. Comparison of lithium SSIP and cesium CIP acidities in THF at 25°C. The equation of the line shown is p*K*(Li) = –1.984 + 1.080 p*K*(Cs); $R^2 = 0.993$.

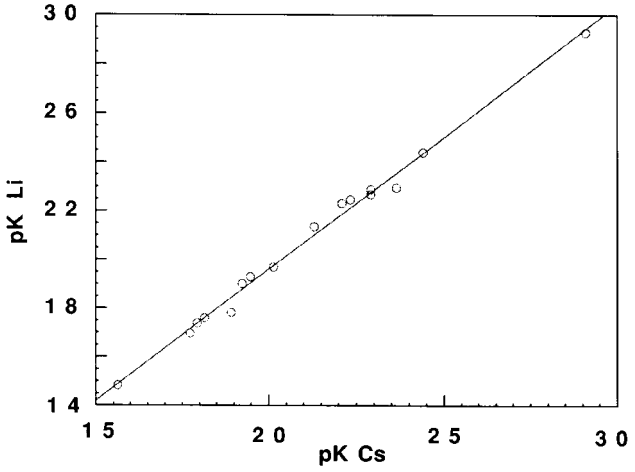

Fig. 2. Comparison of Li ion pair p*K*'s in THF with absolute p*K*'s in DMSO. The line shown is p*K*(Li) = –0.963 + 1.046 p*K*(DMSO); $R^2 = 0.998$.

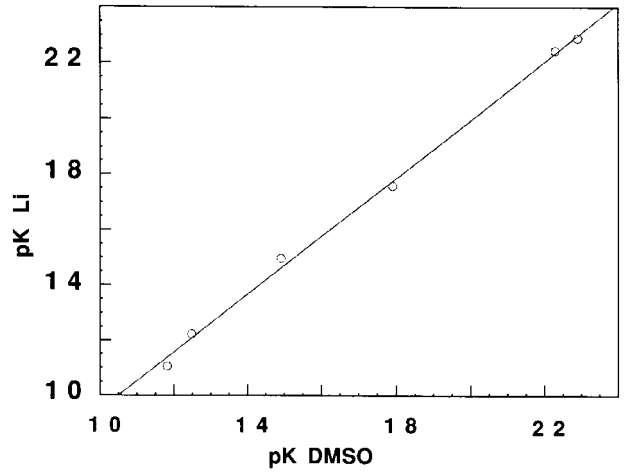

the Li SSIP in one case and the Cs CIP in the other. Because of the relative insensitivity to structural variation of the ion pair dissociation constants of the lithium salts of these delocalized carbanion indicators, the free ion acidities in THF should closely parallel the SSIP acidities. The slope of the correlation in Fig. 1, 1.08, shows that the Cs scale is slightly compressed compared to the Li scale; this result is probably due to the slightly higher electrostatic attraction of the carbanion to a cesium cation, which is effectively smaller than the solvent-separated lithium cation. There is an excellent correlation with the absolute p*K* as in DMSO with a slope close to unity (Fig. 2). This correlation shows that the choice of any other standard than fluorene would result in but little change in the lithium scale. Note that a number of compounds on the Li scale are not on the Cs and DMSO scales.

A number of the same compounds were studied in aqueous DMSO mixtures by the H_ method and should represent the p*K*'s for the dilute aqueous standard state (28). These values are also summarized in Table 2; a comparison with the lithium ion pair values in THF (Fig. 3) shows an excellent correlation but with a slope of only 0.70. The range of p*K*'s of these delocalized carbanions is highly attenuated in the aqueous medium.

Some of the results show features of special interest. The powerful inductive effect of fluorine is shown by comparing PTFl with DPI and TeFPFl with PhFl. The four fluorine substituents increase acidity by 2.6–3.5 p*K* units. Steric hindrance to conjugation can play an important role. A phenyl substituent in the 9-fluorenyl position of 2,3-benzfluorene (11*H*-benzo[*b*]fluorene) and 3,4-benzfluorene (7*H*-benzo[*c*]fluorene) increases acidity by 4.5–5.1 p*K* units, but a similar substitution in 1,2-benzfluorene (7*H*-benzo[*a*]fluorene) has only a 2.3 p*K* unit effect, undoubtedly because of steric interaction between the benzo group and the phenyl ring. In agreement with the DMSO results of Bordwell and Drucker (30), triphenylindene (TPI) is 2.3 p*K* units less acidic than 1,3-diphenylindene (DPI), probably in part because the central phenyl substituent impedes conjugation of the terminal phenyls.

Conclusions

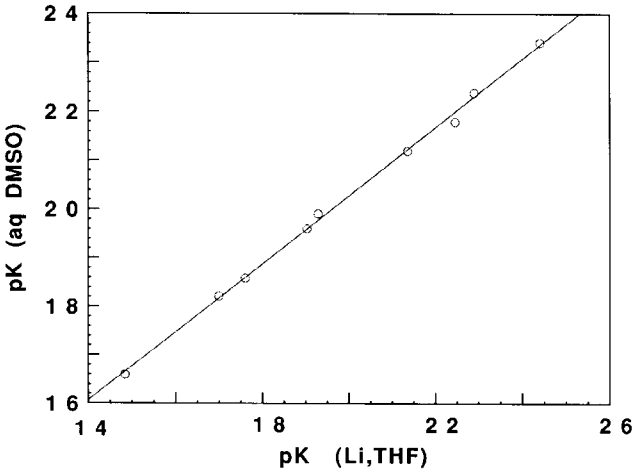
The lithium scale of SSIP indicators in THF has been extended to 25 compounds. This scale should find use in ion pair acidity measurements of lithium salts in THF, particularly in the region of convenient proton transfer rates below p*K* = 25.

Experimental section

The syntheses of many of the indicators have been reported previously (30–35) or were available from our past work or commercially. In general, the aromatic hydrocarbons were recrystallized from hexane or an ethanol–hexane mixture and

© 1998 NRC Canada

Fig. 3. Comparison of aqueous DMSO p*K*'s (H_ method) with lithium ion pair p*K*'s. The correlation line shown is p*K*(aq DMSO) = 6.26 + 0.701 p*K*(Li, THF); $R^2 = 0.998$.



then vacuum sublimed. Purity was assessed by spectroscopic methods, melting point, and (or) elemental analysis as necessary. The details of the procedure of p*K* measurement have been described in previous publications.

1,1,3,3-Bis(biphenylene)propene (BBP)
This compound was prepared following Kuhn et al. (36) and was purified by multiple recrystallizations from benzene–hexane to remove the last traces of fluorene and, finally, from toluene. Sublimation afforded a white powder, mp 215–216°C (lit. (36) mp 205–206°C); ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.33 (d, J = 7.5 Hz, 1H), 7.20–7.85 (m, 15H), 6.51 (d, J = 10 Hz, 1H), 5.87 (d, J = 10 Hz, 1H).

1-Phenyl-3-(2′,3′,5′,6′-tetrafluorophenyl) indene (PTFI)
To a 250 mL flame-dried three-necked flask containing 100 mL of dry THF and 2 g (13.3 mmol) of 1,2,4,5-tetrafluorobenzene was added 5.7 mL of *n*-BuLi (2.1 M in hexanes) dropwise at –78°C. After 20 min, 2.08 g (10 mmol) of 3-phenylindanone was added. The solution was stirred for an additional 1 h at –50°C and then quenched with water. An NMR spectrum of the crude product showed a mixture of the desired carbinol and starting material (probably through enolization of the ketone by the tetrafluorophenyllithium) in a ratio of 60/40. The crude mixture of carbinol and ketone was dissolved in 60 mL of benzene and a few drops of concentrated H_2SO_4 were added. The mixture was refluxed for 5 h until TLC showed no carbinol remaining. The indene was isolated by flash column chromatography using hexane–ether in a ratio of 10/1 as an eluant, recrystallized from methanol, and finally sublimed; mp 104–106°C. ^{1}H NMR: 7.18–7.33 (m, 9H), 7.13 (tt, J_1 = 9.6 Hz, J_2 = 7.3 Hz), 6.81 (d, J = 1.8 Hz), 4.82 (d, J = 1.8 Hz). ^{19}F NMR (H-decoupled): –138.78 (m, 2F), –139.09 (m, 2F) relative to $CFCl_3$.HRMS, calcd.: 340.0882; found: 340.0875.

General procedure for the preparation of the lithium bases
Lithium diisopropylamide (LDA) was freshly prepared, twice sublimed under vacuum, and placed in the glovebox. The neutral indicator, 9,9,10-trimethyldihydroanthracene (5.3 mg, 0.024 mmol), was added to a vacuum-adapted storage flask. To this flask, THF (2 mL) and LDA (2.1 mg, 0.020 mmol) were added, resulting in an orange solution. The deprotonation reaction is slow and it was necessary for reaction to proceed for a minimum of 3 days with occasional stirring. The flask was then taken out of the glovebox and directly attached to a vacuum line. The THF was removed via vacuum and the flask was returned to the glovebox. The resulting red semi-solid was dissolved with an appropriate amount of THF to give a 0.1 M concentration. The resulting base was stored at –10°C and checked periodically for decomposition.

Remarkable efficiency of iron(III) versus manganese(III) tetraphenylporphyrins as catalysts for fast and quantitative oxidation of sulfides into sulfones by hydrogen peroxide

Antonio Marques, Massimo di Matteo, and Marie-Françoise Ruasse

Abstract: The efficiency of various metallo-phtalocyanines (Pht) and -tetraphenylporphyrins (TPP) as catalysts for the H_2O_2 oxidations of dibenzylsulfide, phenylchloroethylsulfide, and thioanisole is investigated in ethanol and acetonitrile, using imidazole as a cocatalyst. Neither $PhtNi^{II}$ nor $TPPCo^{II}$ exhibits any catalytic activity. $PhtMn^{II}$ and $TPPMn^{III}Cl$ accelerate markedly these reactions but do not promote quantitative oxidations, at most 70% of the sulfides being transformed into sulfoxides. In contrast, with $PhtFe^{II}$ sulfoxides are obtained with a 100% yield from sulfides. Finally, the only catalyst able to oxidize sulfides rapidly (<5 min), completely and quantitatively (100% sulfone) is $TPPFe^{III}Cl$ in EtOH. The absence of any by-product, disulfide in particular, suggests that a free sulfenium radical cation is not an active intermediate in these reactions. The marked differences in the behaviour of $TPPMn^{III}Cl$ and $TPPFe^{III}$ Cl are analyzed by comparing the rates of the catalyst decomposition, of the sulfoxide and sulfone formation as a function of the hydrogen peroxide concentration. The results are discussed in terms of a competition between the several oxidative pathways and a possible mechanism for the oxygen transfer to sulfides.

Key words: sulfide, oxidation, H_2O_2, manganese(III) or iron(III) tetraphenylporphyrin.

Résumé : Opérant dans l'éthanol et l'acétonitrile et utilisant l'imidazole comme cocatalyseur, on a étudié l'efficacité de divers métallo-phtalocyanines (Pht) et de -tétraphénylporphyrines (TPP) comme catalyseurs des oxydations par le peroxyde d'hydrogène du sulfure de dibenzyle, du sulfure de chloroéthyle et de phényle et du thioanisole. Ni le $PhtNi^{II}$ ni le $TPPCo^{II}$ ne présente d'activité catalytique. Le $PhtMn^{II}$ et le $TPPMn^{III}Cl$ accélèrent beaucoup ces réactions, mais ils ne conduisent pas à des oxydations quantitatives; au mieux, 70% des sulfures sont transformés en sulfoxydes. Par ailleurs, avec le $PhtFe^{II}$, les sulfures conduisent aux sulfoxydes avec des rendements de 100%. Enfin, le $TPPFe^{III}Cl$ dans l'éthanol est le seul catalyseur à pouvoir oxyder les sulfures rapidement (moins de 5 min), complètement et quantitativement (100% de sulfone). L'absence de sous-produit, en particulier de disulfure, suggère que le cation radicalaire sulfénium libre n'est pas un intermédiaire actif dans ces réactions. On a analysé les différences marquées de comportement du $TPPMn^{III}Cl$ et $TPPFe^{III}Cl$ en procédant à une comparaison des vitesses de décomposition du catalyseur ainsi que les vitesses de formation du sulfoxyde et de la sulfone en fonction de la concentration du peroxyde d'hydrogène. On discute des résultats en fonction d'une compétition entre plusieurs voies d'oxydation et un mécanisme possible pour le transfert d'oxygène aux sulfures.

Mots clés : sulfure, oxydation, peroxyde d'hydrogène, manganèse(III) ou fer(III) tétraphénylporphyrine.

Introduction

Toxic sulfides and, in particular, mustard $(ClCH_2\text{-}CH_2)_2S$, a warfare agent, are markedly detoxified by transforming them into their corresponding oxidized derivatives, sulfoxides, and sulfones (1). Therefore, strong oxidants, hypochlorite, or *N*-chloramines for

$$[1] \quad R_2S \overset{[O]}{\rightarrow} R_2SO \overset{[O]}{\rightarrow} R_2SO_2$$

example, were currently used[2] as decontaminants (1*b*, 2, 3). In contrast, hydrogen peroxide, a cheap, nonpolluting, and not strongly corrosive oxidant, has not been considered[3] until now for this objective (4). This is not surprising, since it is well known that uncatalyzed hydrogen peroxide oxidations[4] of

[2] For synthetic, mechanistic, and other purposes, oxidation of sulfides into sulfoxides but not sulfones by a large variety of oxidants is extensively investigated (3).

[3] In contrast, the reactivity of H_2O_2 under basic conditions towards VX, a toxic organophosphorous thioester, has been investigated (4) using the high nucleophilicity of the perhydroxyl anion.

[4] Sulfide half-lives of several hours for reagent concentrations in the 10 mmol range (5).

© 1998 NRC Canada

sulfides are slow (5) whereas decontamination procedures require very fast chemical transformations. Consequently, hydrogen peroxide can be viewed as an efficient oxidant only if its reaction is markedly catalyzed. Biomimetic catalysts and, in particular, metalloporphyrins have been extensively developed for olefin epoxidations and alkane hydroxylations (6). These catalysts should be efficient also for sulfide oxidations, since these latter are oxidized more readily than unsaturated and saturated hydrocarbons (7). However, with the currently investigated catalysts, strong oxidants (iodosobenzene, peracids, etc.) are generally preferred to hydrogen peroxide, in order to avoid the catalyst destruction by hydroxyl radicals readily released by homolytic H_2O_2 decomposition, itself catalyzed by metal complexes (8). Nevertheless, hydrogen peroxide can be used successfully using specially robust porphyrin ligands (9). More recently, metallo-phtalocyanines were shown to be also powerful catalysts for H_2O_2 oxidation of resistant chlorophenols (10). Moreover, depending on the substrate and on the objectives of the authors, iron or manganese or any other transition metal can be the most efficient for oxygen transfer (11).

With regards to sulfides, much less work has been carried out (3*b* and *c*, 12) and, to the best of our knowledge, there is no data that allows for a reasonable choice of a given catalyst (metal and ligand) for promoting their fast and quantitative oxidation into sulfones. In this paper, we report a preliminary investigation of the efficiency of various commercially available biomimetic catalysts for the hydrogen peroxide oxidation of some alkyl sulfides often used to simulate the reaction of mustard (2).

Results and discussion

In the two last columns of Table 1 are shown the yields in sulfoxide and sulfone obtained by oxidation of dibenzyl ($PhCH_2SCH_2Ph$), (2-chloroethyl)phenyl sulfides ($PhSCH_2CH_2Cl$), and thioanisole ($PhSCH_3$), **1**, **2**, and **3**, respectively, by hydrogen peroxide in ethanol and acetonitrile in the presence of catalysts with phtalocyanine, Pht, and meso-tetrakisphenylporphyrin, TPP, as ligands[5] complexing transition metals in various oxidation states, Co(II), Ni(II), Fe(II), Fe(III), Mn(II), Mn(III).

In all the experiments, the initial concentrations of sulfide and catalyst are 8.5×10^{-2} and 2×10^{-3} M, respectively (these values correspond to a substrate/catalyst molar ratio of 42.5). The catalyst concentration is significantly larger than those currently used to compensate for its decomposition, expected because of the well-known fragility of the ligands in the absence of particular substituents. As usual (6–9, 11–13), imidazol (Im) is employed as a cocatalyst in a [Im]:catalyst conc. ratio of 25. Five sulfide equivalents of hydrogen peroxide (35% in water) are added by small portions (10 μL every 5 min) to minimize dismutation of the oxidant and (or) the destruction of the catalyst by reaction of the active metallic species with H_2O_2. Five minutes after the completion of the addition, an aliquot of the reaction mixture is analyzed by GC. The products are identified by GC–MS analysis and (or) by comparison of their retention times to those of authentic samples that were commercially available. When sulfide is not completely consumed, aliquots of the reaction mixture are analyzed at regular time intervals until the sulfide disappearance does not progress significantly.

[5] On one hand, phtalocyanines, which are important industrial dyes, are very cheap. On the other hand, there is extensive work on metallo-porphyrins as biomimetic catalysts of oxidation (6–9, 11, 12).

Table 1. Sulfide oxidation[a] by hydrogen peroxide in the presence of metallo-phtalocyanines (Phth) and -tetraphenylporphyrins (TPP).[b]

Catalyst	Time (min)[c]	Sulfide	Solvent	%S[d]	%SO[a]	%SO_2[a]
None	2800	$(PhCH_2)_2S$	EtOH	5	95	[f]

$TPPFe^{III}Cl$	5			0	0	99

[a] Sulfoxide, SO, and sulfone, SO_2, are the only products. Product yields are reproducible at ±3%.

[b] Catalyst conc., 2×10^{-3} M; [Im], 5×10^{-2} M; sulfide conc., 8.5×10^{-2} M; $[H_2O_2]_{Tot}$, 0.476 M, added by fraction of 10 μL; room temperature.

[c] Between the last addition of H_2O_2 and the end of the reaction.

[d] Unchanged sulfide.

[e] Catalyst conc., 5×10^{-4} M, because of the poor solubility of the catalyst in EtOH.

[f] This product is not detectable in the corresponding chromatogram.

[g] In this solvent, metallo-phthalocyanines are not soluble at the concentration used in ethanol.

As shown in the three first rows of Table 1, neither $Co^{II}TPP$ nor $Ni^{II}Pht$ catalyzes significantly the oxidation of **1**, since the time required for its almost complete disappearance is similar with and without these catalysts. In contrast, Mn(II) or Fe(II) phtalocyanines exhibit significant catalytic power; 5 min after the complete addition of H_2O_2, most of dibenzylsulfide is transformed into the corresponding sulfoxide. However, Mn(II) is less efficient than Fe(II), since with Mn(II) the reaction stops when 70% of sulfide is oxidized whereas 7% only subsists with Fe(II). The behavior of Mn(II) porphyrin is quite similar to that of the two metallo-phtalocyanines. Compound **1** is significantly oxidized into sulfoxide only. With all these catalysts, no sulfone was obtained. Finally, the only catalyst able to totally oxidize dibenzylsulfide into sulfone is $Fe^{III}TPPCl$. The reaction is very fast under the reaction conditions, sulfide being completely oxidized in less than 5 min. Moreover, oxidation products, other than sulfoxide and sulfone, are never observed.

In Table 1, are also shown results for (2-chloroethyl)phenyl sulfide **2** and thioanisole **3**. Again, $Fe^{III}TPPCl$ is able to promote the complete and quantitative transformation of these sulfides into the corresponding sulfones directly. At variance with dibenzylsulfide, $Mn^{III}TPPCl$ is not very efficient, **2** being oxidized at most 30% with this catalyst.

In these experiments, ethanol is preferred to acetonitrile in order to minimize sulfide oxidation by $OH^{\cdot}$ radicals, formed by metal-mediated homolysis of H_2O_2, which would lead to unwanted oxidation by-products. It is expected that these radicals react with ethanol more rapidly than with sulfide, since

© 1998 NRC Canada

ethanol is an $OH^{\cdot}$ trapping agent more efficient than acetonitrile (13). Nevertheless, when the catalyzed oxidations are carried out in acetonitrile (last rows of Table 1), the product distribution is essentially the same as that observed in ethanol. A reasonable conclusion is, therefore, that free $OH^{\cdot}$ radicals do not play a significant role in these sulfide oxidations under the present reaction conditions.

Another remarkable result of this investigation is the absence of any by-product arising from the cleavage of sulfide radical cations as potential intermediates,[6] namely aldehyde

[2] $R_2S \longrightarrow R_2S^{\bullet+} \longrightarrow R^+ + RS^{\bullet}$ → RS-SR / RCHO

or alcohol and disulfide (eq. [2]). These two latter products are currently obtained in sulfide oxidation by typical electron transfer (ET) oxidants but not when the H_2O_2 oxidation is catalyzed by metal porphyrins or cytochrome P-450 (14). In particular, our results agree fairly well with the conclusions of Baciocchi et al. (14) in their extensive comparison of sulfide oxidation by ET oxidants and by hydrogen peroxide in the presence of biomometic catalyst. Whereas biomometic oxidations give mainly sulfoxide and small amounts of sulfone, these two compounds are very minor products when the oxidant is a $Co^{III}W$ complex (3*c*).

These results are in contrast with previous observations of Oae et al. (12) who obtained some disulfide with an analogous catalytic system. However, disulfides were obtained, only when the starting sulfide ($PhSCH_2CN$ or $PhSCH_2COPh$) presents an α-acidic hydrogen favoring the cleavage of the carbon-sulfur bond and the formation of a phenylthiyl radical.

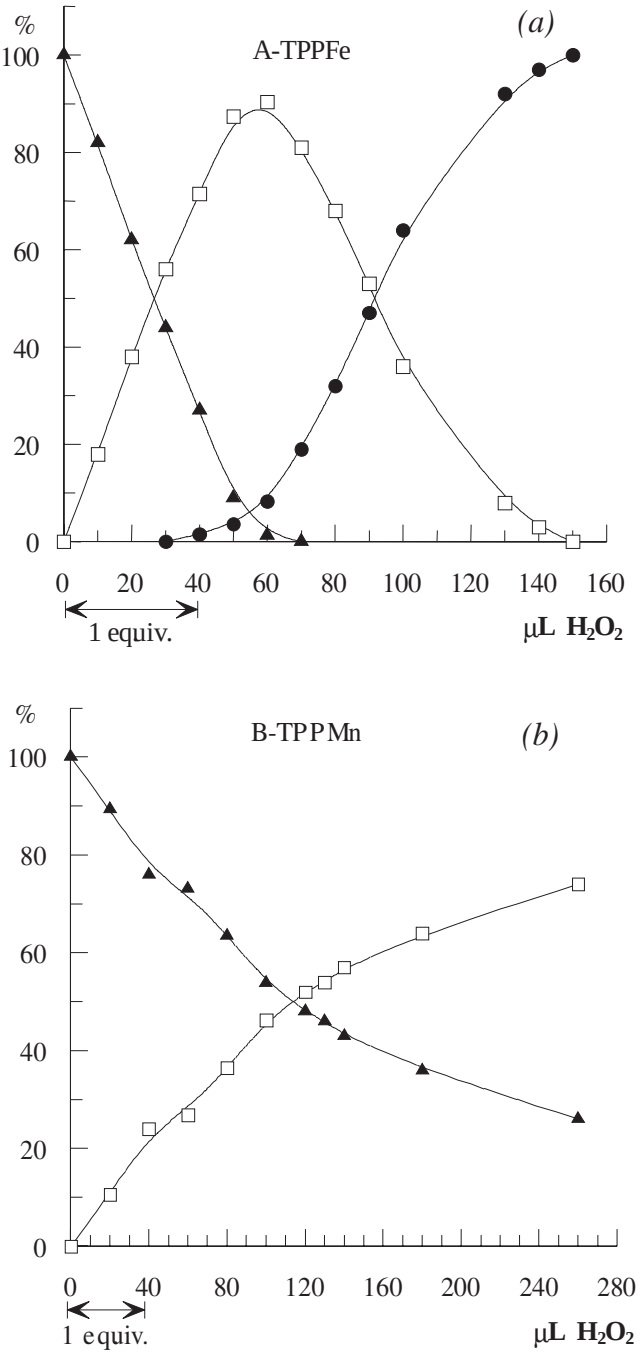
In agreement with Baciocchi results (14), a free sulfur-centered radical cation is not suggested as an active intermediate by our results. Therefore, a mechanism (eq. [3], route *a*) involving a direct oxygen transfer from oxene **4** (6*d*, 8, 15) to sulfide and then to sulfoxide, in a process similar to that for catalyzed epoxidation (9, 11), can be reasonably proposed when the catalyst is Fe^{III}TPPCl. Nevertheless, an oxygen transfer from metal-oxo radical **5** formed by homolysis of the perhydroxymetal species (9) (route *b* of eq. [3]):

[3] Por M → PorM-OOH $\xrightarrow{(a)}$ Por - $\overset{\bullet+}{M}$=O (**4**) $\xrightarrow{+R_2S}$ R_2SO; PorM-OOH $\xrightarrow{-OH^{\bullet}\ (b)}$ PorMO$^{\bullet}$ (**5**) $\xrightarrow{+R_2S}$ R_2SO; R_2SO $\xrightarrow{+\ 4}$ R_2SO_2

cannot be ruled out a priori, in particular when M is Mn(III). However, further results (vide supra) do not support necessarily route *b*.

The markedly different behavior of the Mn(III) and Fe(III) porphyrins is rather surprising, since these two catalysts behave quite similarly in olefin epoxidation (11). In the view of better understanding the origin of this difference, we investigated in more detail the progress of the oxidation of **1** as hydrogen peroxide is added. The results are shown in Figs. 1*a* and *b*. With Fe^{III}TPPCl, the very first additions of H_2O_2 quantitatively transform sulfide into sulfoxide. The further additions are still very efficient, since after the addition of 1 equiv. of H_2O_2, 75% of H_2O_2 is used in sulfide–sulfoxide oxidation, the remaining 25% of sulfide being unchanged. With 1.5 equiv. of H_2O_2, sulfide is totally consumed, the sulfoxide yield reaches

Fig. 1. The progress of the hydrogen peroxide oxidation of dibenzylsulfide with the oxidant addition in the presence of M(III) porphyrins; (*a*) M = Fe; (*b*) M = Mn; △, sulfide; □, sulfoxide; ●, sulfone. (Room temperature. Initial concentrations in ethanol: 0.085 M sulfide; 0.05 M imidazole; 0.002 M $TPPM^{III}$ Cl. 40 μL H_2O_2 (35% in water) corresponds to 1 sulfide conc. equiv.).



[6] However, the formation of this sulfur radical cation by electron transfer from oxene (eq. [3]) and its very fast recombination with **4** cannot be totally excluded.

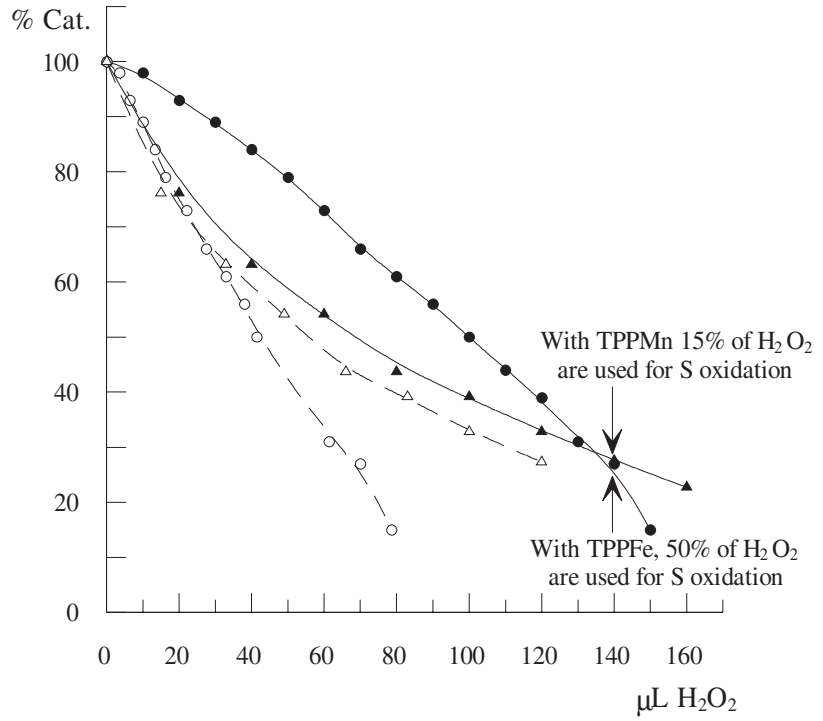
Fig. 2. Catalyst decomposition during dibenzylsulfide oxidation with H_2O_2 addition: ●, TPPFe^{III}Cl; ▲, TPPMn^{III}Cl. The open marks (○ and △) are obtained by correcting the added H_2O_2 from the amount consumed by sulfide oxidation. Reaction conditions are identical to those in Fig. 1.



a maximum at about 95% whereas some sulfone is present. The last additions of H_2O_2 are used for sulfoxide oxidation into sulfone. Finally, after the incorporation of 4 equiv. of H_2O_2, the yield in sulfone is quantitative. There are several conclusions from this experiment. Firstly, oxidation of sulfide into sulfoxide and of sulfoxide into sulfone are consecutive reactions, sulfoxide being an intermediate. This implies that sulfoxide oxidation is slower than that of sulfide, so that sulfone appears only when sulfide is almost completely transformed into sulfoxide. Secondly, at every stage of the reaction progress, the transformation of sulfide and sulfoxide is quantitative, without formation of any other oxidation products. Thirdly, hydrogen peroxide is not quantitatively used for sulfide oxidation, since 4 equiv., as compared to sulfide, are necessary for the complete transformation in sulfone, which requires 2 equiv. only. Clearly, other H_2O_2-consuming processes are involved.

The results with Mn^{III}TPPCl are completely different (Fig. 1*b*). Sulfide is still exclusively transformed into sulfoxide but the efficiency of the oxidant is very small, since after the addition of 1 equiv. of H_2O_2, only 20% of the sulfide is oxidized. After a more and more rapid efficiency decrease, the reaction stops when about 30% of sulfide still subsists.

Therefore, the difference between the two metal porphyrins is that most of hydrogen peroxide is consumed by processes in which sulfide is not involved when Mn^{III}TPPCl is the catalyst whereas with Fe^{III}TPPCl, the H_2O_2 consumption by sulfide is an important route. This difference explains also why no sulfone is obtained with Mn^{III}TPPCl, since sulfoxide oxidation can start only when there is no more sulfide.

To gain some insights on the competing processes that consume hydrogen peroxide, the destruction of the catalysts was monitored spectroscopically at their Soret band (λ_{max} = 466 nm and 415 nm in ethanol for Mn(III) and Fe^{III}TPPCl, respectively), during oxidation of **1** under concentrations identical to those used in the previous experiments. In Fig. 2 is shown the decrease in the concentration of the two catalysts as the reaction progresses. Mn^{III}TPPCl is destroyed rapidly with the first H_2O_2 additions, and then its disappearance is progressively slowed down. Fe^{III}TPPCl is also consumed, although in the first H_2O_2 additions its concentration decreases less rapidly. With 140 μL of H_2O_2 (i.e., 3.5 sulfide equiv.), about 25% of the two catalysts are still preserved, i.e., the catalyst concentration is still 8×10^{-5} M with an initial concentration of 2×10^{-3} M. This remaining amount is enough to promote further substrate oxidation, since sulfide, added at this stage of the reaction, is transformed into sulfoxide. Nevertheless, there is a very large difference between the two catalysts insofar as after the addition of 140 μL H_2O_2, 57% of the added H_2O_2 has been consumed by sulfide, in the presence of Fe^{III}TPPCl, whereas with Mn^{III}TPPPCl, 17% of H_2O_2 has been used for this reaction. Figure 3 shows the disappearance of Fe^{III}TPPCl consecutive to successive additions of H_2O_2 in experiments similar to those of Figs. 1 and 2 but in the absence of sulfide. The comparison of Figs. 2 and 3 exhibits that the catalyst is markedly less consumed when sulfide is present. In other words, it seems that the presence of sulfide exerts some "protection" of the catalyst. However, this conclusion is artificial, since H_2O_2 is used partly in sulfide oxidation. When the amount of added H_2O_2 is corrected for the sulfide uptake, the rates of the ligand destruction by H_2O_2 are not markedly different with Mn(III) and Fe(III).

Therefore, the oxidative destruction of the two catalysts is promoted by hydrogen peroxide via similar processes,

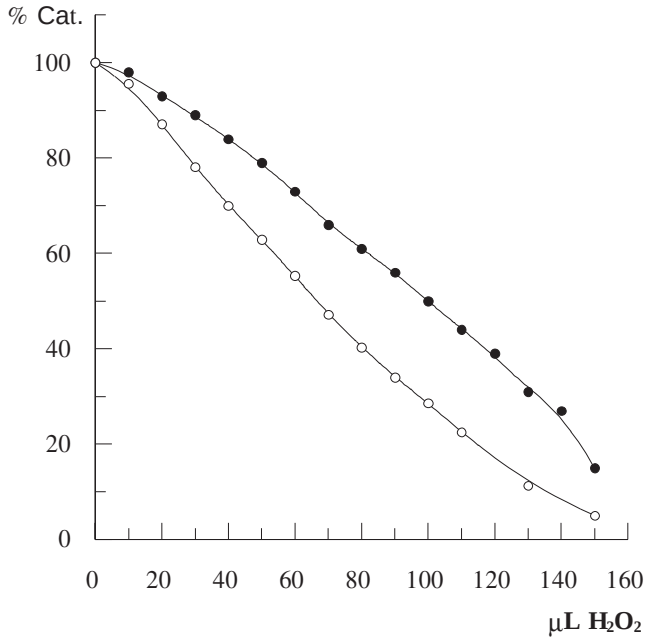
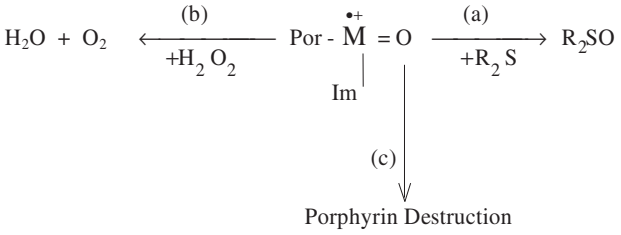
Fig. 3. Comparison of TPPFe^{III}Cl decomposition by hydrogen peroxide in the presence (●) and in the absence (○) of dibenzylsulfide. Reaction conditions are identical to those in Fig. 1.



independently on the catalyzed sulfide oxidation route. Since the efficiencies of the two catalysts are very different, there must be a much more efficient route for the H_2O_2 consumption in the presence of Mn^{III}TPPCl than with Fe^{III}TPPCl. This route is most likely the dismutation of hydrogen peroxide, which is well known to be metal-catalyzed and which would be favoured, particularly by the Mn(III) catalyst. Our results suggest, therefore, that among the various possible fates of the oxene species, which is assumed to be the active form of the catalyst for sulfide oxidation as for alkene epoxydation (9, 11), route *c* (eq. [4]) is of comparable importance when M is Mn(III) or Fe(III).

[4]



In contrast, route *a* is highly favoured as compared to route *b* with iron but not with manganese catalyst. There are two possible interpretations for the observed metal dependence of the competition between these two routes. The H_2O_2 dismutation could be catalyzed by manganese complex more efficiently than by iron complex. This is unlikely in the view of previous data on alkene epoxidation (6*a*), which show that H_2O_2 consumption is similarly fast with the two catalysts in the presence of imidazole, i.e., the rate of route *b* does not markedly depend on the nature of the metal. Since our results suggest that route *a* is favored with iron but not with manganese, a reasonable conclusion is that the oxygen transfer from the high-valent oxo complex to sulfides is probably faster with Fe(III) than with Mn(III) catalyst.

In conclusion, this preliminary work points out that among the investigated biomimetic catalysts, the most efficient catalyst for quantitative and fast oxidation of sulfide into sulfone by hydrogen peroxide is Fe^{III}TPPCl. The efficiency of the analogous Mn(III) complex is markedly smaller. Regarding the selective biomimetic oxidations of sulfide into sulfoxide, Fe(II) phtalocyanine can be used successfully. Therefore, with readily oxidizable sulfides, a significant role of both the metal and its ligand on the oxygen-transfer ability of these catalysts is evidenced. More work, in particular using more robust ligands (16) and aqueous media, is in progress with the objective of designing performant catalytic systems for toxic sulfide oxidation.

Experimental section

Physical measurements

The UV-vis spectra were recorded on a Perkin–Elmer lambda II spectrophotometer. Gas chromatography analysis was carried out on a Delsi–Nermag 200 gas chromatograph equipped with a fid detector and a CP-Sil 5 column. The products were identified by comparison of their retention times with authentic samples or by GC–MS (I.T.D. Finigan 800).

Materials

Acetonitrile and ethanol (HPLC grade, Prolabo) were used as received. Hydrogen peroxide (H_2O_2 35% in water, Acros) was stored at 5°C and titrated every month. Sulfides, sulfoxides, and sulfones were purchased from Aldrich or Acros and used as received. The absence of any oxidation product in the commercial sulfides was checked before use by GC. All the catalysts were commercial (Aldrich) and used without further purification.

Oxidation procedure

To 5 mL of a reaction mixture (0.085 M sulfide, 0.05 M imidazole, and 0.002 M catalyst, in ethanol or in CH_3CN) was added directly the commercial solution of hydrogen peroxide by small amounts with a microsyringe. The oxidant is added 10 μL per 10 μL with a delay of 5 min between each addition, to prevent hydrogen peroxide dismutation. The GC analysis was performed on aliquots withdrawn directly from the reaction mixture. Yields were measured by GC with the internal standard method. All the reactions were carried out at room temperature, without any buffer and under aerobic conditions.

Measurements of the catalyst destruction

The disappearance of the porphyrins were monitored by UV-vis spectrophotometry by the decrease of their Soret band (415 nm for TPPFe^{III}Cl, 466 nm for TPPMn^{III}Cl in ethanol). Eight microliters of the reaction mixture was taken with a microsyringe and diluted directly in the cell containing 2 mL of ethanol. The percentage of remaining catalyst was then calculated.

Theoretical study of O → X (S, Se, Te) coordination in organic compounds

Ruslan M. Minyaev and Vladimir I. Minkin

Abstract: Ab initio (RHF/LanL2DZ, MP2(fc)/LanL2DZ, MP2(fc)/6-31G**, and MP2(fc)/6-311++G**) calculations were performed for a series of β-chalcogenovinylaldehydes, 1,6-dioxa-6a-chalcogenopentalenes, and bimolecular complexes of formaldehyde with chalcogen hydrides and chlorides. The calculations reproduce well the existence and experimentally observed structural peculiarities of the intra- and intermolecular O → chalcogen attractive interactions that stabilize the hypervalent T-shaped bond configuration at a chalcogen atom. These interactions increase in the order S, Se, Te and with the increasing electronegativity of a substituent attached to the chalcogen center. The ab initio calculations performed predict the existence of sufficiently stable bimolecular complexes $H_2CO\cdots XR_1R_2$ (X = S, Se, Te; R_1, R_2 = H, Cl) with a complexation energy comparable to the energy of a strong hydrogen bond.

Key words: ab initio calculations, chalcogen-containing compounds, intramolecular coordination.

Résumé : On a effectué des calculs ab initio (RHF/LanL2DZ, MP2(fc)/LanL2DZ, MP2(fc)/6-31G** et MP2(fc)/6-311++G**) sur une série de β-chalcogénovinylaldéhydes, de 1,6-dioxa-6a-chalcogénopentalènes et de complexes moléculaires du formaldéhyde avec des hydrures et des chlorures de chalcogènes. Les calculs permettent de bien reproduire l'existence et les particularités structurales observées expérimentalement des interactions attractives intra- et intermoléculaires O → chalcogène qui stabilisent la configuration de la liaison hypervalente en forme de T au niveau de l'atome de chalcogène. Ces interactions progressent dans l'ordre S, Se et Te et elles augmentent avec l'électronégativité du substituant attaché au centre chalcogène. Les calculs ab initio effectués permettent de prédire l'existence de complexes bimoléculaires $H_2CO\cdots XR_1R_2$ (X = S, Se, Te; R_1, R_2 = H, Cl) assez stables, avec des énergies de complexation comparables aux énergies de liaisons hydrogènes fortes.

Mots clés : calculs ab initio, composés contenant des chalcogènes, coordination intramoléculaire.

[Traduit par la rédaction]

Introduction

Intra- and intermolecular donor–acceptor interactions play a crucial role in defining the molecular structure of compounds with spatially suitably fitted functionalities, secondary and tertiary structures of biologically important macromolecules, and modes of packing of molecules in a crystal, i.e., solid-state structures as well. The most important types of donor–acceptor interactions involve hydrogen (1–6) and coordination or dative bonds formed by metal centers with ligands donating electrons from lone-pairs or π-orbitals (7–10). During the last two decades a third, less common, type of attractive interaction occurring between two electron-abundant main group 15–17 (VA–VIIA) element centers has become a topic of rapidly growing interest (11–14). Special attention has been given to intramolecular and intermolecular noncovalent attractive interactions existing between di- and tetracoordinated sulfur, selenium, and tellurium atoms from one side and oxygen or nitrogen atoms from another side (11–13, 15–18). When occurring within a molecule, interactions of this kind strongly affect the reactivity and enhance the stability of the chalcogen-containing compounds (13, 19, 20). These interactions are also responsible for the high biological activity of selenium, in particular selenoproteins and nucleoside analogues (21).

A peculiar feature of the chalcogen–oxygen and chalcogen–nitrogen bonds is the strong dependence of their strengths and lengths on the nature of chalcogen, its valence state, and the electronegativity of the attached substituent R (11–13). By varying these factors in a series of compounds with similar geometry it is possible to cover wide ranges of chalcogen–oxygen or chalcogen–nitrogen intramolecular distances, from those approaching values characteristic of covalent bonds to those close to van der Waals contacts. This trend is illustrated by excerpts of X-ray structural data for compounds with five-membered chelate rings formed by the intramolecular O → chalcogen coordination (Fig. 1).

Much effort has been devoted to gaining insight into the origin of the specific attractive forces between the electron-abundant main group centers in type **1–8** molecules. The terms "secondary bonding" (30), "fractional bonds" (31), "specific noncovalent contacts" (32), and "premature hypervalent bonds" (16) have been introduced to describe the tendency in non-metallic compounds to form short intra- and intermolecular contacts between the above centers. The theoretical work

reveals that there exist several principal factors that account for this tendency (16, 18, 31, 33). These include an electrostatic effect, a *d*-orbital participation, and negative hyperconjugation, i.e., donation of an electron pair from the highest π- or *n*-orbitals of one center to the lowest lying σ*-orbital of the neighbouring center. The latter interaction, which corresponds to the n_0–$\sigma^*_{Ch\text{-}X}$ type in compounds **1–8**, has been found to be the principal factor responsible for the formation of additional bonds between the electron-abundant atomic centers associated with expansion of the valence shell of the chalcogen atoms. The degree of this expansion may be characterized by the so-called covalency ratio factor χ introduced by Weinhold and co-workers (34)

$$[1] \qquad \chi = \frac{(R_A + R_B) - d_{AB}}{(R_A + R_B) - (r_A + r_B)}$$

where R_A and R_B stand for van der Waals and r_A and r_B for covalent radii of the interacting centers, d_{AB} being the experimentally determined (or calculated) contact.

[a] 1 au = 627.5095 kcal/mol.
[b] Thermochemistry at temperature 298.15 K and pressure 1 atm (101.3 kPa).

The χ values calculated on the basis of available experimental data for compounds **1–8** are given in Fig. 1. Although seemingly overestimated, these values clearly indicate a rather close similarity of the O $\rightarrow$ chalcogen bonds in compounds **1–8** to corresponding covalent bonds of this type. These values reveal also the trends discussed above of strengthening the O $\rightarrow$ chalcogen bonds (*i*) when passing from sulfur to selenium and tellurium and (*ii*) with increasing electronegativity of a substituent R to the chalcogen atom.

The present work is aimed at further elucidating these trends with the help of ab initio calculations of model compounds **9** and **10** containing intramolecular coordination O $\rightarrow$ chalcogen bonds included in conjugated five-membered rings common to the type **1–8** compounds. Apart from the structural information relevant to the intramolecular coordination O $\rightarrow$ chalcogen bonds, particular attention has been given to the energy of these bonds. The latter values were estimated as the difference between the full energies of the cyclic structures **9** and **10** and their *trans-s-trans* conformers (**11** and **12**) relieved of angle strain.

13

X=S,Se,Te; R_1,R_2=H, Cl

Several important ab initio calculations concerned with the problems addressed by the present work have previously been performed. For a series of β-thiovinylaldehydes **9** (X = S; R = F, OH, NH_2, SH, CH_3), it was found that the stability of the cyclic conformation that results through the intramolecular coordination O → S bond and the characteristic shortening of the O···S contact were well reproduced by calculations even at the moderate RHF/3-21G level of approximation (16). The same type of conclusion was reached by Barton et al. (18) in their MP2 calculations with DZ basis set on two simple selenoiminoquinones that model the compounds **5** (R = H, Cl). By studying

the electron charge distribution around the Se atom with the use of Bader and Mulliken population analyses, the authors (18) qualitatively described the electronic structure of the O → Se-R triad in terms of the VSEPR model and a three-center, four-electron bond. In contrast with this conclusion are the results of the STO-3G* calculations (35) on the dimer formed by two anions of the ammonium trichloro(ethane-1,2-dithiolato-*O*,*O′*)tellurate (IV). The calculations performed at the geometry obtained from the X-ray study that displayed a short O–Te intradimeric distance of 2.764 Å pointed to the donation of a lone pair of an oxygen to the $\sigma^*_{Te\text{-}Cl}$-orbital as the main interaction, but did not reveal three-center orbitals in the O → Te-Cl unit of the dimer.

Methods

All the stationary point optimization calculations in this work were performed by standard RHF/LanL2DZ, MP2(fc)/LanL2DZ, MP2(fc)/6-31G**, and MP2(fc)/6-311++G** methods (36) using the Gaussian-94 (37) and GAMESS (38) packages of ab initio programs. Optimization of molecular geometry at stationary points at all levels of approximation was carried out with a "tight" convergence criterion for the force in the Gaussian program and a 10^{-5} convergence criterion for the RMS gradient in the GAMESS program in order to obtain accurate harmonic vibrational frequencies. Force constants at all levels of approximation were calculated by a numerical method.

No counterpoise corrections were made for the basis set superposition error (BSSE) (39) in calculations concerned with the dimer **13,** accounting for recent findings (40–44) that inclusion of BSSE often enormously decreases thermodynamic stability and binding energy in various multimolecular complexes. For example, the calculations of the alanine dimer give rise to an interaction energy of –19.7 kcal/mol, while including the BSSE affords a value of +14.4 kcal/mol (43).

All the results obtained relate to the gas phase. No attempts were made to take into account solution effects.

We are confident that for heavy elements like Se and Te the influence of relativistic effects on various chemical properties of the compounds under study becomes important. Although no relativistic effects were included in the calculations we expect that the results obtained describe the essential trends in the properties of the compounds under study.

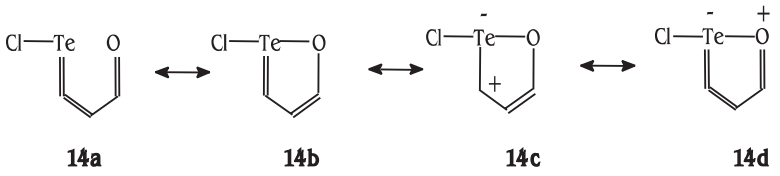
cis-conformation **9** leading to the formation of the intramolecular O → chalcogen bond correspond to minima (the number of the negative Hessian eigenvalues at the corresponding stationary point is zero) on their potential energy surfaces (PES). The values of the total and relative energies of structures **9** and **11** are listed in Table 1. The optimized geometries of the isomers **9** and **11** are featured in Figs. 2–4.

It is worth noting that the results obtained at various levels of approximation are in good agreement with one another. All structures **9** are predicted to be planar with the O···chalcogen distances significantly shortened compared to respective van der Waals contacts (3.30 Å, 3.40 Å, and 3.60 Å for, respectively, O···S, O···Se, and O···Te). In accordance with the experimental data (Fig. 1), the degree of this shortening and, thus, the strength of the intramolecular coordination O → chalcogen bonds were found to be strongly affected by the electronegativity of the substituent R attached to the chalcogen atom. The O···chalcogen distance in **9** decreases by about 0.5 Å when substituent R = H is replaced by R = Cl. In compound **9** (X = Te, R = Cl) the calculated O···Te distance almost approaches the length of a normal covalent O—Te bond, 2.08–2.10 Å, whereas for the sulfur analogue (**9**: X = S, R = Cl) the difference between the calculated O···S contact and the length of a covalent S—O bond is substantially longer and reaches 0.5–0.9 Å depending on the level of approximation. This tendency is also in agreement with the experimental observations.

Not only the geometry calculated for the O···Te-R fragment but also that for the whole five-membered ring of compounds **9** reproduces the experimental data reasonably well. No direct comparisons are possible because no data are available on the compounds bearing no substituents at the carbon centers or containing a hydrogen atom attached to the chalcogen. However, there is good agreement of the corresponding calculated and experimentally determined bond lengths in the following pairs of compounds: **9** (X = Te, R = H) and **6a**, and **9** (X = Te, R = Cl) and **6b** (see Figs 1 and 4). Of special interest is the structure of the compound **9** (X = Te, R = Cl) with a very short O···Te contact and significantly equalized carbon–carbon bonds. A description of such a structure for the compound **6b** was given earlier (15) in terms of the resonance of several forms including those shown as **14a–d**.



14a **14b** **14c** **14d**

A small contribution of the **14c** and **14d** resonance structures is demonstrated by a larger positive charge on the tellurium center in structures **9** as compared with that in its acyclic analogues **11**. For example, the Mulliken charge on the tellurium atom in **9** (X = Te, R = H) is equal to 0.546e and 0.491e, calculated by the RHF/LanL2DZ and MP2(fc)/LanL2DZ methods, respectively, whereas the same charge in the acyclic isomer **11** (X = Te, R = H) is, correspondingly, 0.491e and 0.390e.

conformation **11** is preferable to **9** at all levels of approximation used. An attachment to the sulfur atom of the more electronegative substituent, chlorine, results in inversion of stability of the conformers. For the tellurium analogues, the conformers **9** with the intramolecular O → Te bond are predicted to be more stable than **11,** even for the case of R = H.

Accounting for the electron correlation energy leads to significant enhancement of the X···O hypervalent interactions in **9** and provides for additional delocalization of the electron density. Thus, correlation energy plays an important role in the stabilization of the complexes **9**. The difference between total energies of **9** and **11,** ΔE, can be considered as the energy of the X···O interaction. The value of ΔE for **9** (see Table 1) changes from repulsive for **9** (XR = SH) to slightly attractive for **9** (XR = TeH). At the same time, for the compounds **9** the X···O interaction energy remains strongly attractive, being increased (depending on the calculational method) from about 5 kcal/mol for XR = SCl to 10.5 kcal/mol for XR = SeCl and 16.5 kcal/mol for XR = TeCl. No experimental estimates of energies of the intramolecular O → chalcogen bonds are currently available. Attempts were made to assess the S···N (45) and Se···N (46) dissociation energies on the basis of dynamic NMR studies of the exchange processes that include dissociation of these bonds in one of the steps. Through detecting the energy barriers to mutual exchange of two benzylic protons in a series of 2-selenobenzylamines, **15**, the energies of the intramolecular N → Se bonds were found to lie in the range of 10.8 kcal/mol (R = SPh) to more than 18.8 kcal/mol (R = Cl, Br, OAc). Considering that N → chalcogen bonds are known to be stronger than O → chalcogen ones, the values ΔE and ΔH describing the strength of the O → Se bonds (Table 1) may be regarded as reasonable estimates.

15a **15b**

It appears that the pseudopotential basis set LanL2DZ underestimates the hypervalent bonding effects, as clearly seen from comparison of the geometries of **9** (X = S, R = H, Cl) calculated by the MP2(fc)/LanL2DZ and MP2(fc)/6-311++G(d,p) methods (see Fig. 2). For both structures the MP2(fc)/6-311++G(d,p) method predicts shorter S···O distances and S—H, S—Cl bond lengths than the MP2(fc)/LanL2DZ method. The same trend is revealed in calculations of the Se and Te analogues. This explains a small lengthening of the predicted O···Te distance and the Te—H, Te—Cl bonds (Fig. 4) compared to those experimentally determined for the compounds **6a** and **6b**.

[a] 1 au = 627.5095 kcal/mol.

[b] Experimental data are taken from ref. 52.

O → X bonds when going from sulfur to tellurium is clearly expressed by the values of ΔE. An important structural feature of compounds **10** is further significant shortening of the O···chalcogen contacts, even compared to those occurring in their monocyclic analogues **9** with the electronegative substituents, R = Cl. For the dioxatellurapentalene **10** (X = Te), the length of this contact is almost equal to that of a normal covalent O → Te bond. For the whole set of the compounds **10** (X = S, Se, Te), the calculations in accord with the experimental data available (28, 47) predict equal bond lengths of both the O—X (X = S, Se, Te) bonds and the C_{2v} symmetry of dioxachalcogenopentalenes. Realization of the symmetrical structures in all of the compounds **10** (X = S, Se, Te) may be explained in terms of aromatic stabilization due to their 10π-electron systems. The only exception to this result is found in the RHF/LanL2DZ calculations of dioxathiapentalene **10** (X = S), which is predicted to be a monocyclic C_s structure with T-shaped bond configuration at the chalcogen atom. It should be noted that this result was obtained when using the lowest applied level of approximation and for the compound in the series with the weakest intramolecular O···X interaction.

As for the type **9** compounds, the use of the pseudopotential basis set LanL2DZ leads to underestimation of the hypervalent effects. This is seen in a comparison of the MP2(fc)/LanL2DZ and MP2(fc)/6-311++G(d,p) calculations (Fig. 5). The MP2(fc)/LanL2DZ method predicts all bonds to be longer than those obtained by the MP2(fc)/6-311++G(d,p) method, whose predictions on bond lengths and valence angles are in excellent agreement with the experimental data available on derivatives of dioxathiapentalenes (9, 47). The same tendency may, therefore, be expected for the Se and Te analogues **10** (X = Se, Te) for which the MP2(fc)/LanL2DZ method slightly overestimates bond lengths. As seen from the data of Table 2, accounting for the correlation energy results in additional stabilization of the delocalized structure with the hypervalent chalcogen centers. The difference in energy (ΔE) between total energies of the bicyclic **10** and monocyclic **12** structures, given in Table 2 according to the MP2(fc)/LanL2DZ calculations, are 12.1, 20.0, and 27.7 kcal/mol for X = S, Se, and Te, respectively. These should be considered as the lowest limits of the O → X energies. As follows from the comparison of results obtained by the MP2(fc)/LanL2DZ and MP2(fc)/6-311++G(d,p) methods for **10** (X = S), the former method predicts the S—O bond energy to be nearly 9 kcal/mol lower than the latter. Assuming that the same correction may be applied to the assessment of the O → Se and O → Te energies, these should amount to approximately 30 and 38 kcal/mol, respectively.

The Mulliken X—O bond populations in **10** (X = S, Se, Te)

© 1998 NRC Canada

calculated by the MP2/LanL2DZ method are equal to 0.063, 0.068, and 0.072, respectively. These values are three times larger than the corresponding values for compounds **9**. They reflect much stronger O···X (X = S, Se, Te) bonding in dioxachalcogenopentalenes. The χ values (0.81, 0.88, and 0.94) as well as the Pauling bond orders, n (48) (0.51, 0.65, and 0.81), as calculated by eq. [2]

$$[2] \quad d_{AB} = d(1) - 0.6 \log n$$

where $d(1)$ is the single bond distance, i.e., $(r_A + r_B)$, and d_{AB} is the O—X bond length in **10** (X = S, Se, Te) obtained in the MP2/LanL2DZ calculations, reflect very well the same trend in the strength of these bonds.

Bimolecular complexes with intermolecular O···chalcogen bonds

The tendency of chalcogen atoms towards attractive intermolecular donor–acceptor O → chalcogen interactions is manifested by calculations of molecular structures and energies of the bimolecular complexes **13** (X = S, Se, Te) formed by the parent carbonyl compound with dicoordinated chalcogen hydrides (R_1 = H; R_2 = H, Cl) or chlorides ($R_1 = R_2$ = Cl). According to the ab initio calculations all the dimers **13** correspond to minima on the relevant PES's. The total energies of the bimolecular complexes **13** (X = S, Se, Te) are listed in Table 3. Figure 7 displays the optimized geometrical parameters for the complexes **13** (X = Te).

Predicted geometrical parameters and harmonic frequencies for chalcogen hydrides XHR (R = H, Cl) or chlorides XCl_2 (Table 4 and Fig. 7) are in good agreement with the available experimental data.

The principal trends characteristic of intramolecular O → chalcogen coordination bonds revealed by calculations for compounds **9** and **11** hold true also for the case of the intermolecular interaction. The energy of the donor–acceptor intermolecular interaction increases approximately by 1.5–2 times when the correlation energy is taken into account. The stabilization energy, ΔE, for the complexes with chalcogen hydrides ($R_1 = R_2 = H$) is smaller than that for the complexes **13** in which one or both hydrogen atoms are substituted by the more electronegative chlorine. Worth noting is that the isomers **13** (R_1 = H, R_2 = Cl) with an (approximately) linear arrangement of the O···X-Cl fragment are preferable to their isomers in which the less electronegative hydrogen atom takes an axial position. This effect is particularly noticeable in the case of Te complexes for which the first isomer is about 3 kcal/mol more stable than **13** (X = TeClH) (see Table 3 and Fig. 7). As for the case of the intramolecular O → chalcogen interactions, the complexation energy monotonically increases in the order X = S, Se, Te (Table 3). To the authors' knowledge, no experimental data on the type **13** bimolecular complexes are currently available. However, stabilization of the bimolecular complexes $YF\cdots XH_2$ (Y = F, Cl; X = N, O, S) due to a similar type of weak Y···X interactions has recently been described (49–51). The results of the calculations presented suggest that the stability of the complexes **13** is sufficient for their possible experimental observation.

Conclusions

The ab initio calculations carried out showed that there exists a strong intra- and intermolecular donor–acceptor O → chalcogen interaction that stabilizes the hypervalent T-shaped bond configuration at the chalcogen atom. This interaction in chalcogen-containing compounds increases in the order S, Se, Te and with increasing electronegativity of a substituent attached to the chalcogen center. The ab initio calculations performed predict the existence of rather stable bimolecular complexes $H_2CO\cdots XR_1R_2$ (X = S, Se, Te; R_1, R_2 = H, Cl) with the complexation energy comparable to the energy of strong hydrogen bonds.

The reaction of *S*-nitrosothiols with thiols at high thiol concentration

Andrew P. Dicks, E. Li, Andrew P. Munro, Helen R. Swift, and D. Lyn H. Williams

Abstract: Reactions of *S*-nitrosothiols (RSNO) with their corresponding thiols (RSH) present in a large excess (>20-fold) proceed readily to give the disulfide. Ammonia is formed together with some nitrite anion, and these constitute >90% of the "nitrogen" products. This is in marked contrast with the reaction at low thiol concentration, where nitric oxide is the major initial "nitrogen" product, which is rapidly converted in the presence of oxygen in water to nitrite anion. Also in marked contrast to the "low thiol concentration" reaction, the reaction at high thiol concentration is not affected by added Cu^{2+}, nor by the metal-ion scavenger EDTA. Kinetically all reactions were excellent first-order processes, and the reactions were also strictly first order in thiol concentration. A large range of nitrosothiols were studied and the generality of the reaction established. Some reactions of RSNO with other thiols (R′SH) were examined and the results readily interpreted in terms of a prior rapid equilibrium transnitrosation. The pH dependence for the reaction of *S*-nitrosocysteine with cysteine clearly showed that the reactive species is the cysteine thiolate anion. The results are discussed along with those of two other recent reports of these reactions, in terms of thiolate attack initially at the nitroso nitrogen atom, and subsequently at sulfur atoms, eliminating RSSR and yielding hydroxylamine, which is rapidly reduced by thiolate ion to ammonia. The results are also discussed in connection with the release of NO from nitrosothiols and with the important biological consequences, both for the in vivo reactions of NO and for the potential of nitrosothiols as NO-releasing drugs for medical use.

Key words: *S*-nitrosothiols, thiols, nitric oxide, ammonia, nitrous oxide.

Résumé : Les réactions de *S*-nitrosothiols (RSNO) avec un grand excès (>20 fois) des thiols correspondants (RSH) se produisent facilement et elles conduisent au disulfure. Il y a formation d'ammoniac ainsi que de faibles quantités de l'anion nitrite qui forment tous ensemble plus de 90% des produits «azotés.» Ce résultat est en opposition avec ce qui se passe lors de la réaction à faible concentration de thiol, alors que l'oxyde nitrique, le produit «azoté» principal, se transforme en anion nitrite en présence de l'oxygène présent dans l'eau. Le fait que la réaction à haute concentration de thiol ne soit pas affectée par la présence de Cu^{2+} ou d'EDTA, piège pour les ions métalliques, est une autre différence importante par rapport à la réaction à faible concentration de thiol. On a examiné un large éventail de nitrosothiols et on a démontré la généralité de la réaction. On a aussi examiné quelques réactions de RSNO avec d'autres thiols (R′SH) et on peut facilement interpréter les résultats en fonction d'une réaction d'équilibre rapide de transnitrosation. Le fait que la réaction de la *S*-nitrosocystéine sur la cystéine dépende du pH montre clairement que l'espèce réactive est l'anion thiolate de la cystéine. On discute des résultats, ainsi que ceux de deux rapports récents sur ces réactions, en fonction d'une attaque initiale de l'ion thiolate sur l'atome d'azote du nitroso et d'une attaque ultérieure au niveau des atomes de soufre conduisant à une élimination de RSSR avec formation d'hydroxylamine qui est rapidement réduit par l'ion thiolate en ammoniac. On discute aussi des résultats en relation avec l'élimination de NO à partir des nitrosothiols et de leurs conséquences biologiques importantes qui sont toutes les deux importantes pour les réactions in vivo du NO ainsi que pour le potentiel des nitrosothiols à agir comme médicaments dégageant du NO à des fins médicales.

Mots clés : *S*-nitrosothiols, thiols, oxyde nitrique, ammoniac, oxyde nitreux.

[Traduit par la rédaction]

Introduction

In recent years one of the principal discoveries that has excited biologists and other scientists has been the realisation that we (and other animals) synthesize nitric oxide (NO) in vivo from the amino acid L-arginine, and that NO is principally involved in the control of a number of our bodily functions, including vasodilation (1). These findings have generated a massive research effort worldwide, and there a number of review articles available (2). As part of the findings it was found that the drug widely used to treat angina and other circulatory problems, namely, glyceryl trinitrate (GTN), breaks down in vivo to give NO, which effects vasodilation, and hence gives relief to the patient (3). It is interesting to note that GTN had been used for over a hundred years simply on the basis of observation of the medical patterns of the work force in Nobel's factories, which

Received December 15, 1997.

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

were producing dynamite. GTN is not, however, a totally satisfactory drug, for although it is quick-acting, it is also "short-acting," and in some patients a tolerance to it is generated. Consequently there has been a major research effort directed at the production of an alternative to GTN. One group of compounds being closely looked at in this connection are *S*-nitrosothiols RSNO, i.e., the sulfur analogues of alkyl nitrites. It is known that *S*-nitrosothiols (sometimes called thionitrites) are readily formed from nitrous acid and thiols (4), and decompose thermally (5) and photochemically (6) generating initially NO, eq. [1]. In the presence of oxygen NO can react further.

[1] $2RSNO \rightarrow RSSR + 2NO$ ($h\nu$ or Δ)

We have recently (7) examined the reactions of many RSNO compounds (sometimes generated in situ by thiol nitrosation) in water, mostly at pH 7.4, and have found that reaction is brought about by catalytic amounts of Cu^+, formed by thiolate reduction of Cu^{2+}, present as an impurity (at ~ 10^{-6} M level), or specifically added; see eqs. [2] and [3].Thiolate ion is usually

[2] $2Cu^{2+} + 2RS^- = 2Cu^+ + RSSR$

[3] $RSNO + Cu^+ = RS^- + Cu^{2+} + NO$

[4] $4NO + 4OH^- + O_2 = 4NO_2^- + 2H_2O$

present as a low-level impurity, and also is present from the reversibility of RSNO formation (8). In water in the presence of oxygen at pH 7.4, NO is quantitatively converted to nitrite anion, eq. [4] (9, 10). From a biological point of view it is interesting to note that Cu^+ can also be generated (by thiolate reduction) from Cu^{2+} sources in which the copper is bound to amino acids, peptides, or proteins (11). Further, the copper reduction can also be brought about by other reducing agents, notably ascorbic acid (12). Reaction is virtually halted in the presence of the general metal-ion chelator EDTA or the specific Cu^+ chelator neocuproine, as the thermal reaction is generally very slow at 25°C. Increasing the thiol concentration in some cases promotes reaction by increasing the rate of Cu^+ formation, whilst in other cases (such as with *S*-nitroso penicillamine and added penicillamine) reaction is retarded when the thiol acts as a metal-ion chelator (12).

More recently three reports have shown that a different reaction of *S*-nitrosothiols occurs in the presence of higher concentrations of added thiols (typically in 10–100-fold excess over RSNO). Komiyama and Fujimori (13) reported the kinetics of the reaction of cysteine with *S*-nitroso cysteine under conditions where metal ions were carefully removed, and from initial rate measurements established the rate equation [5]. The first term represents the thermal reaction,

[5] $Rate = k_1[RSNO] + k_2[RSNO]\,[RSH]$

and the value of k_1 confirms the belief that the thermal reaction is negligibly slow at 25 or 37°C. Swift (14) independently found the same rate equation for the reactions of *S*-nitrosoglutathione (GSNO), *S*-nitroso-*N*-acetylcysteine, and *S*-nitrosocaptopril with their corresponding thiols, and showed that the rate constants were independent of added Cu^{2+} and also of added EDTA. In a detailed product study of the reaction of GSNO with glutathione (GSH), Singh et al.(15) showed that, apart from the disulfide, the end products were ammonia, nitrite anion, and nitrous oxide. A scheme was put forward to explain the product distribution, based on the formation of an *N*-hydroxysulfenamide and of radical intermediates.

Because of the intense interest in NO formation from RSNO species, we believed it important to establish details of the "high concentration of thiol" reaction, particularly given that in vivo it is likely that GSNO is likely to encounter intracellularly a large concentration excess of GSH.

Experimental section

Materials

All of the *S*-nitrosothiols (except GSNO) were generated in solution by nitrosation of the corresponding thiols in mildly acidic aqueous solution, immediately before use in the kinetic experiments. All (except GSNO) are too unstable to isolate and characterize in the pure state. Their concentration is taken to be the concentration of the thiol and sodium nitrite used (equimolar). This procedure works well when checked for the stable species GSNO, comparing spectra of solutions made up in this way with those in which the solid is dissolved in the buffer. GSNO was prepared by the literature method described by Hart (16). Thiols, buffer components, and all other materials were of the highest purity grade available, and were used as such. Some of the anaerobic experiments were carried out on N_2-purged solutions, whilst others used the glucose/glucose oxidase method (17). The two methods gave results that were in acceptable agreement. Nitrite anion was determined by the well-known Griess method (18). Ammonia was determined quantitatively with a standard diagnostic kit (Sigma) using the method of van Anken and Shiporst (19), based on the reductive amination of oxoglutarate by the enzymes glutamate dehydrogenase and NADPH. Reaction mixtures were left for ~10 h before the analyses were carried out, to ensure, as nearly as possible, complete decomposition of the *S*-nitrosothiol.

Kinetics

All rate measurements were carried out in water at 25°C mostly in phosphate buffer at pH 7.4. Reactions were followed spectrophotometrically at ~ 340 nm, noting the disappearence of the absorbance due to the RSNO. In all experiments the thiol was in at least a 20-fold excess over the nitrosothiol. Excellent first-order behaviour occurred throughout. The data were collected directly from the spectrophotometer to a PC and a kinetics program used to obtain values of the first-order rate constants k_0. Values of k_0 were reproducible to better than 5%.

Results

Kinetics

Our original work (14) looked at the reactions of GSNO, *S*-nitroso-*N*-acetylcysteine (SNAC), and *S*-nitrosocaptopril with their corresponding thiols. We have now extended the range of RSNO compounds in an attempt to establish the generality of the reaction. In all cases there was excellent first-order behaviour in the individual kinetic experiments when $[RSH]_0 >> [RSNO]_0$, and plots of the first-order rate constants vs. [RSH] were linear with, in many cases, a small positive intercept at [RSH] = 0 representing the thermal reaction. From the slopes of the lines, values of k_2 (eq. [5]) were easily obtained. These are presented in Table 1 for a range of RSNO structures. The

reaction is clearly quite general. Rate constants are independent of both added Cu^{2+} and added EDTA as shown in Tables 2 and 3. Further results (Table 4) were obtained for the reaction of *S*-nitrosocysteine (SNC). The contrast with the effect of metal ions when the reaction is carried out at low thiol concentration is very marked. For example, the addition of EDTA virtually stops reaction under these conditions completely, as shown in Fig. 1, which gives the absorbance–time plots for the decomposition of GSNO (5×10^{-4} M) in the presence of GSH (5×10^{-5} M), (*a*) without added EDTA and (*b*) with added EDTA (1×10^{-4} M). This behaviour is quite general for RSNO decomposition with no added RSH, or at low concentration of added RSH.

Some experiments were carried out using a thiol different from the parent thiol, i.e., for the reaction of RSNO with a large excess of R′SH. Results for two such pairs are given in Table 5.

In one case the effect of pH on reactivity was examined. Figure 2 shows the variation of k_2 for the reaction of SNC with cysteine in the pH range 1–14. The shape of the curve clearly shows that the reacting species is the thiolate anion. In two examples studied, there was no significant difference in the measured second-order rate constants when reaction was carried out anaerobically (see Table 1).

Product analyses

Nitrite anion was determined by the Griess method in the final reaction products of the decomposition of SNC as a function

of added cysteine. The results are in Table 6. Without added cysteine we find 91% nitrite, i.e., almost quantitative formation. This confirms what we and others have observed on a number of occasions, namely that the Cu^+-promoted reaction is dominant, generating NO, which is rapidly converted to NO_2^- in aqueous aerated solution. However, as the concentration of cysteine is increased, the NO_2^- yield drops sharply, approaching 5% at high cysteine concentration.

Following the important and unexpected finding by Singh et al. (15) that ammonia was a major product in the reaction of GSNO with GSH, we analysed the reaction products for ammonia. The results for the reaction of SNC with cysteine are also given in Table 6. It is clear that ammonia is formed at the expense of nitrite ion and that the reaction leading to ammonia is totally dominant when the concentration of cysteine

[a] Standard error less than 3%.

is greater than ~0.05 M. The product total $[NO_2^-]$ + $[NH_3]$ accounts for ~90% of the "nitrogen" product. Similar product distributions were obtained for the reactions of SNAC, and *S*-nitrosothioglycerol with their respective thiols. These analyses were repeated for the reaction of SNC with cysteine under anaerobic conditions. The nitrite analyses were approximately unchanged, within the experimental error, but the ammonia yield was reduced somewhat compared with the results obtained aerobically, rising only to 70% of the theoretical maximum, as compared with 85%.

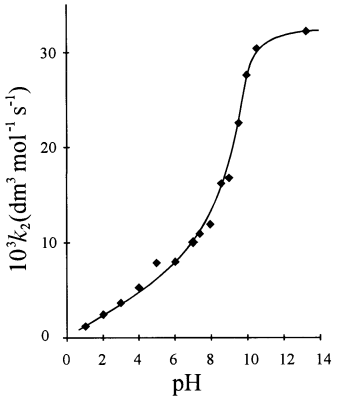
We found that in some cases the disulfide product precipitated from solution at the end of the reaction, and was identified by its nmr or ir spectrum. In other cases (notably with the GSNO reaction) we identified the disulfide by addition of Cu^{2+} at the end of the reaction and observed the characteristic uv spectrum of the Cu^{2+} complex (20). Spectral measurements indicated that reaction was reasonably(>90%) quantitative.

Discussion

We have confirmed the observation by Singh et al. (15) that at reasonably high thiol concentrations there is a reaction between thiols and *S*-nitrosothiols (observed also kinetically by Komiyama and Fujimori (13)), leading to the disulfide formation, which is not catalysed by Cu^+ or any other metal ion, but which is first order in both reactants, and leads principally to the formation of ammonia and **not** nitric oxide. It is now well established that the reaction leading to nitric oxide formation is (in spite of a comment by Singh et al. (15) to the contrary) brought about by Cu^+ (from Cu^{2+} reduction), apart from a component due to the thermal decomposition, which for most *S*-nitrosothiols is very small.

Tables 2–4 show clearly that the reaction rate constants are quite unaffected by the removal of adventitious metal ions and also by the specific addition of Cu^{2+}. This behaviour is in marked contrast with the behaviour at low concentrations of thiol (either added or present in equilibrium concentrations from the preparation of the *S*-nitrosothiols from nitrous acid and thiols), when the addition of EDTA (Fig. 1) or the specific Cu^+ chelator neocuproine (11) completely suppresses reaction (apart from the small component due to the thermal reaction). There are also a large number of examples (e.g., ref. 20) where addition of Cu^{2+}, at low thiol concentrations, results in large rate increases. Again the contrast with the results in Table 2 is marked. The "high concentration of thiol" reaction appears to be quite general from the range of reactants examined (including dinitroso compounds), and rate constants are listed in Table 1. There was no attempt in this range to look for a structure–reactivity relationship; rather the choice reflects the *S*-nitrosothiols that might be of biological interest, including the possibility of their use as NO-releasing drugs. Our value

Fig. 2. Plot of k_2 (eq. [5]) vs. pH for the reaction of SNC with cysteine.



for the reaction of SNC is consistent with that found by Komiyama and Fujimori (13), who carried out their experiments at 37°C. Our duplicate values are also in acceptable agreement.

When a thiol (R′SH) different from that used to generate the *S*-nitrosothiol (RSNO) is taken, reaction still occurs and the results for two such experiments are given in Table 6. The rate constant for the reaction of penicillamine with *S*-nitrosopenicillamine (259×10^{-3} dm^3 mol^{-1} s^{-1}) is much reduced (to 28.5×10^{-3} dm^3 mol^{-1} s^{-1}) when the thiol is changed to thioglycerol, i.e., the value is much closer to that for the reaction of *S*-nitrosothioglycerol with thioglycerol. (However, it is not clear why the value is actually a little *less* than this.) Similarly, when S-nitrosothioglycerol reacts with penicillamine the rate constant is increased compared to the value for its reaction with thioglycerol. Qualitatively these results can be explained if we consider that the transnitrosation reaction, eq. [6], occurs, which then allows a number of reactions to take

[6] $$RSNO + R'SH = RSH + R'SNO$$

place in parallel, and what is measured is some averaged rate constant. Such transnitrosation reactions are well known, and take place by nucleophilic attack of RS^-. The rate then depends on the pK_a of the thiol, but usually takes place quite rapidly at pH 7.4 (21).

We have also confirmed the finding by Singh et al. (15) that ammonia and not nitric oxide is the main "nitrogen" product in RSNO decomposition at high concentration of RSH. Table 6 clearly shows the increasing ammonia yield as the RSH concentration is increased for the reaction of *S*-nitrosocysteine with cysteine. At the same time the nitrite ion (the NO-derived product) yield decreases towards ~5%.

The pattern appears to be general for RSNO species from similar product analyses using other reactants. If our product analyses are correct, then we appear to be "missing" ~10% of our nitrogen product. Singh et al. (15) detected small amounts of nitrous oxide (by mass spectrometry) in the reaction of GSNO with GSH. It is possible that our "missing" 10% is indeed nitrous oxide.

Consideration of the respective rate constants for RSNO reactions with Cu^{2+} and with RSH, e.g., for the reaction of SNC (see the values in Table 7), would suggest that at a Cu^{2+} concentration of 1×10^{-6}, and a thiol concentration of 0.01 mol dm^{-3}, the Cu^{2+} reaction should dominate. However, it is known (22) that at these high thiol concentrations copper

[b] Experiments carried out anaerobically.
[*] These values are not as reliable as the others, since they depend on the oxidation of any NO generated, over many hours, by leakage of oxygen into the solution.

can become complexed (forming either Cu^+ or Cu^{2+} complexes), reducing the rate of the copper reaction to a negligible level. Under these cirumstances there is no need to use EDTA or similar product as a metal-ion scavenger, since the thiol will perform that function.

As to the mechanism of the reaction leading principally to ammonia formation, our pH–rate profile strongly suggests that the thiolate anion is the reactive species. The enhanced reactivity of penicillamine and reduced reactivity of mercaptosuccinic acid (Table 1) can then be rationalized in terms of the inductive effects of the methyl and carboxylic acid groups, respectively, strengthening and weakening the nucleophilic activity of the thiolate anion.

The ammonia-forming reaction is clearly a thiolate-promoted reduction of the nitroso group, of which there are a number of other known examples and where the final product is often an amine (23). A reasonable sequence of reactions, based on the suggestion of Singh et al. and which are compatible with our findings, are given in eqs. [7]–[13]. Presumably the rate-limiting

[7] $RSNO + RS^- = RS(NO^-)SR$

[8] $RS(NO^-)SR + H_2O = RS(NOH)SR + OH^-$

[9] $RS(NOH)SR + RS^- = RSSR + RSN^-OH$

[10] $RSN^-OH + H_2O = RSNHOH + OH^-$

[11] $RSNHOH + RS^- = RSSR + {}^-NHOH$

[12] $^-NHOH + H_2O = NH_2OH + OH^-$

[13] $NH_2OH + RS^- \rightarrow NH_3$

step is the first reaction of RS^- at the nitrogen atom of the *S*-nitrosothiol, eq. [7], which is followed by other reactions of RS^- at the sulfur atom and various proton transfers, leading to the formation of hydroxylamine, which would be expected to undergo thiolate reduction to give ammonia. At the low end of the range of thiolate ion concentrations used in our work, this sequence of reactions is in competition with the copper ion promoted reaction that gives NO (measured in terms of NO_2^-), but as [RS^-] increases (and Cu^{2+} is progressively complexed) the ammonia reaction soon dominates, and at >0.025 mol dm^{-3} cysteine, for example, this pathway accounts for ~80% of the total for the reaction of *S*-nitrosocysteine.

The reaction rate constant is unchanged, within the error of measurement, when reaction is carried out anaerobically. However, the product distribution is somewhat changed, in that the ammonia yield is a little lower, whilst the nitrite level is approximately unchanged (though it is difficult to be precise about the anaerobic nitrite values), when compared with the results of the aerobic experiments. The undetected product (possibly nitrous oxide) yield appears to be higher anaerobically. This suggests that a partitioning of reaction pathways occurs (after the rate-limiting step), and that oxygen plays a part in one of these steps. A detailed mechanism of that part of the reaction awaits further study. Singh et al. (15) have proposed a scheme for nitrous oxide formation involving the radical RS-$\dot{N}$-OH, while Stamler (24) has suggested that earlier reports of nitrous oxide formation (25) can be explained in terms of a heterolytic mechanism involving attack of RS^- at the sulfur atom of RSNO, releasing NO^-, which would lead to nitrous oxide formation. Nitrous oxide has also been detected in the reaction products from sodium nitroprusside and glutathione (26) — a reaction formally similar to RSNO + RSH. We cannot at this time establish whether either of these suggestions is correct.

Table 7. Comparison of the copper-catalysed RSNO decomposition and the thiol–RSNO reaction.

RSNO	Copper reaction [a] k_2/dm^3 mol^{-1} s^{-1}	Thiol reaction [b] k_2/10^{-3} dm^3 mol^{-1} s^{-1}
S-Nitrosocysteine	24 500	10.7
S-Nitrosocysteine – ethyl ester	270 000	8.0

[a] k_2 in rate = k_2 [RSNO] [Cu^{2+}].
[b] k_2 in rate = k_2 [RSNO] [RSH].

The finding that *S*-nitrosothiols generally, in the presence of a large excess of thiol, decompose to give ammonia and not nitric oxide as the principal nitrogen product is, (*a*) surprising, and (*b*) potentially far-reaching, in considering RSNO compounds as possible in vivo NO donors. Hitherto it has been tacitly assumed that RSNO compounds act biologically by first breaking down to give nitric oxide. This is a reasonable assumption given that the biological poperties of RSNO (notably of effecting vasodilation and prevention of platelet aggregation) are much the same as those of nitric oxide itself. Indeed GSNO is currently undergoing clinical trials (*a*) for inhibition of platelet aggregation during coronary angioplasty (27), and (*b*) for the treatment of one form of pre-eclampsia (28), where its role is not so clear. Our results presented here, together with those of Komiyama and Fujimori (13) and of Singh et al. (15), show that in the presence of thiols at reasonably high concentration, the NO-forming reaction is replaced by the NH_3-forming reaction. Given that the the intracellular concentration of glutathione can be as high as 10 mmol dm^{-3} (29), the assumption of RSNO breakdown to NO as a prerequisite to effect the biological action must be reexamined. This is not so much due to the ammonia-forming reaction taking over (in a direct competition in the rate sense), since even at 10 mmol dm^{-3} glutathione concentration the half-life of this reaction is almost 4 h, but rather that under these conditions Cu^{2+} is effectively removed from solution, thus drastically reducing the rate of the NO-forming reaction. Other ways of NO delivery need to be considered, including the direct transfer of the NO group, possibly to an Fe atom in a heme complex, or to another sulfur

© 1998 NRC Canada

site, which could compete effectively with the reaction with the thiolate ion leading to ammonia formation.

Solvent-induced stereospecific isomerization of an allylic alcohol to a homoallylic alcohol catalyzed by a chiral lithium amide

Per I. Arvidsson, Maria Hansson, Agha Zul-Qarnain Khan, and Per Ahlberg

Abstract: Deprotonation of cyclohexene oxide, **1**, by lithium (*S*)-2-(1-pyrrolidinylmethyl)pyrrolidide, **2**-Li, on changing the solvent from tetrahydrofuran (THF) to, for example, 2,5-dimethyltetrahydrofuran (DMTHF) or diethyl ether (DEE) has been shown to yield, besides the lithium alkoxide of 2-cyclohexene-1-ol, **3**-Li, the lithium alkoxide of the homoallylic alcohol 3-cyclohexene-1-ol, **4**-Li. It was shown that compound **4**-Li is formed from **3**-Li. No such rearrangement has been observed in THF. We have now shown that the solvent-induced isomerization of the lithium alkoxide of (*S*)-3-methyl-2-cyclohexene-1-ol, (*S*)-**5**-Li, catalyzed by **2**-Li to the lithium alkoxide of (*S*)-3-methyl-3-cyclohexene-1-ol, (*S*)-**6**-Li, is 100% stereospecific. Furthermore, deuterium-labeling experiments suggest that the rearrangement of the proton is close to 100% intramolecular.

Key words: 1,3-proton transfer, chiral lithium amide, intramolecular, solvent-induced isomerization, stereospecific.

Résumé : On a montré que, lors de la déprotonation de l'oxyde de cyclohexène, **1**, par le (*S*)-2-(1-pyrrolidinylméthyl)pyrrolidure de lithium, **2**-Li, un changement de solvant du tétrahydrofurane (THF) au 2,5-diméthyltétrahydrofurane (DMTHF) ou à l'éthoxyéthane (EE) provoque la formation de l'alcoolate de lithium de l'alcool homoallylique cyclohex-3-én-1-ol, **4**-Li, en plus de celle de l'alcoolate de lithium du cyclohex-2-én-1-ol, **3**-Li, attendu. On n'observe pas ce réarrangement dans le THF. On a maintenant montré que l'isomérisation induite par le solvant de l'alcoolate de lithium du (*S*)-3-méthylcyclohex-2-én-1-ol, (*S*)-**5**-Li, catalysée par le **2**-Li, en alcoolate de lithium du (*S*)-3-méthylcyclohex-3-én-1-ol, (*S*)-**6**-Li, est 100% stéréospécifique. De plus, des expériences de marquage au deutérium suggèrent que le réarrangement du proton est presque 100% intramoléculaire.

Mots clés : transfert de proton-1,3, amide de lithium chiral, intramoléculaire, isomérisation induite par le solvant, stéréospécifique.

[Traduit par la rédaction]

Introduction

Despite the enormous usefulness of lithium organic reagents in synthesis, surprisingly little is known about their reaction mechanisms.

Special attention has been placed on the enantioselective deprotonation of a variety of epoxides to synthesize allylic alcohols in high yields and with high enantiomeric excess (ee) (1–4), for example, deprotonation of cyclohexene oxide, **1**, by lithium (*S*)-2-(1-pyrrolidinylmethyl)pyrrolidide, **2**-Li, in tetrahydrofuran (THF) yields (*S*)-2-cyclohexene-1-ol, (*S*)-**3**, after work-up in 80% enantiomeric excess (ee) (Scheme 1) (5–7). A number of pheromones and drugs may be prepared starting from such optically active alcohols (8–12).

Recently we reported that deprotonation of **1** by **2**-Li, on changing the solvent from THF to, for example, 2,5-dimethyltetrahydrofuran (DMTHF) or diethyl ether (DEE), gives, besides the lithium alkoxide of 2-cyclohexene-1-ol, **3**-Li, the lithium alkoxide of the homoallylic alcohol 3-cyclohexene-1-ol, **4**-Li (Scheme 2) (13).

It was shown that compound **4**-Li is formed from **3**-Li. No such rearrangement was observed in THF. In DMTHF, as in THF, (*S*)-**3**-Li was the enantiomer formed in excess but its ee decreased with time. One of the enantiomers of **4**-Li was also formed in excess but with lower ee than for **3**-Li and its ee decreased even more rapidly with time. The major stereoisomer of **4**-Li was proposed to be (*S*)-**4**-Li. The time dependence of the ee's of (*S*)-**3**-Li and (*S*)-**4**-Li was suggested to be either the result of further 1,3-proton transfers, which take (*S*)-**4**-Li into (*R*)-**4**-Li and (*R*)-**4**-Li into (*R*)-**3**-Li (Scheme 2), i.e., the racemizations may be caused by prototropic rearrangements. Other possibilities not shown in Scheme 2 are that the rearrangement is accompanied by inversion of the configurations of the stereogenic centers in **3**-Li and (or) **4**-Li.

We now wish to report some results on the detailed mechanism of the solvent- induced chiral amide-catalyzed rearrangement using 3-methyl-2-cyclohexene-1-ol, **5**, as substrate (Scheme 3). The results show that the rearrangement is highly stereospecific and that it takes place intramolecularly.

Results and discussion

For the mechanistic studies 3-methyl-2-cyclohexene-1-ol, **5**, a

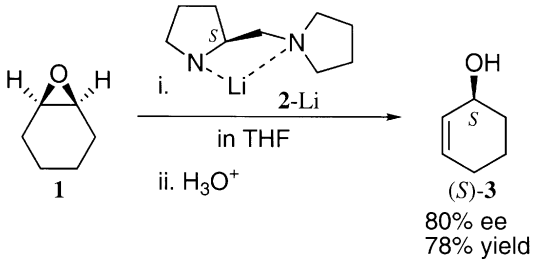
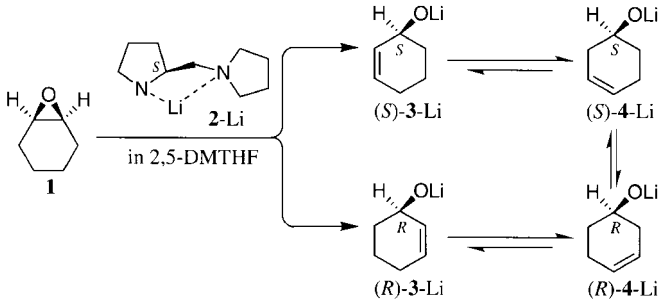


Scheme 2.



compound known as seudenol (a sex pheromone of the Douglas fire beetle), was chosen since the stabilization of **5**-Li and **6**-Li by their methyl groups was expected to make them thermodynamically more stable than their isomers, **7**-Li and **8**-Li (Scheme 3), respectively. As a consequence, further rearrangement to **7**-Li and **8**-Li is expected to be relatively slow, making it possible to study the reversible rearrangement of **5**-Li to **6**-Li without significant interference of further rearrangements.

Racemic **5** is commercially available and can be enzymatically resolved with high selectivity. This procedure was utilized to make a mixture of enantiomers with (*S*)-**5** in 76% ee as measured by chiral gas chromatography (14).

The lithium alkoxide of the enantiomerically enriched allylic alcohol, (*S*)-**5** (76% ee) was reacted with **2**-Li in DMTHF at 30.0°C. Quenching of the reaction and extraction of the mixture of products and remaining reactants followed by chiral gas chromatographic analysis showed that one of the enantiomers of **6** had been formed in 76% ee. The ee was studied as a function of time during the approach of the equilibrium. The equilibrium mixture contained 66% **5** and 34% **6**. The ee of **5** remained constant, within experimental error, at 76% during the whole reaction. That is, no significant racemization of either **5** nor **6** took place during the rearrangement. Obviously the methyl substitution had the predicted result of avoiding racemizations. Thus it is concluded that the rearrangement is 100% stereospecific (15). The results indicate that the racemizations observed upon the rearrangement of **3** into **4** are caused by consecutive 1,3-proton transfer reactions.

Assignment of the absolute configuration of the enantiomer of **6** formed in enantiomeric excess from (*S*)-**5** was investigated in the following way. If (*S*)-**6** is the product formed from (*S*)-**5**, then the chiral chromatogram of the mixture of the enantiomers of **5** and **6** (Fig. 1) shows that the elution order of the enantiomers of **5** and **6** must be unexpectedly different. Therefore, the absolute configuration of the enantiomer of **6** formed in enantiomeric excess was established in the following way. Racemic seudenol, **5**, was rearranged to the homoallylic alcohol **6** by amide **2**-Li in DMTHF. Chiral chromatographic analysis showed to our surprise that compound **5** remained racemic during the rearrangement, i.e., both enantiomers of **5** react with the chiral amide **2**-Li with equal rate constants. As a consequence, the product **6** was also found, within experimental error, to be racemic.

The isolated mixture of racemic **5** and **6** was used in enzymatic resolution of **6** employing the same enzyme that was used to resolve **5** to yield (*S*)-**5** in enantiomeric excess. The enantiomer of compound **6** remaining in excess was by analogy assumed to be (*S*)-**6** (16–19). Chiral chromatography showed that the elution order of the enantiomers of **6** indeed is the reverse of that of the enantiomers of **5**. Thus (*S*)-**5** isomerize exclusively to (*S*)-**6**.

Besides the stereospecificity, i.e., the configuration of the stereogenic carbon center remains intact in the rearrangement, the above results do not give any details of the mechanism of the 1,3-proton transfer reaction: Is the proton transfer intermolecular or intramolecular? Does it take place suprafacially or antarafacially? Is the rearrangement selective with respect to any one of the two protons in the 4-position of **5**? Is the proton delivered to the carbon *syn* or *anti* to the oxygen on the ring? Experiments are in progress to also answer these questions. The first problem has been solved in the following way.

To investigate whether the 1,3-proton transfer takes place intra- or intermolecularly the following experiment was carried out. Compound **5**-Li was isomerized in DMTHF into **6**-Li in the presence of **2**-Li and the N-deuterated amine, **2**-ND (Scheme 4). After ca. 10 half-lives the reaction was quenched and the mixture of the allylic alcohol **5** and product homoallylic alcohol **6** was isolated and analyzed by ^1H and ^2H NMR. Only traces of deuterium were detected in the product and the starting material, respectively. The absence of incorporation of deuterium in the starting material and product during the reaction indicates that the prototropic rearrangement is close to 100% intramolecular (Scheme 4).

In our system the 1,3-proton transfer might take place within a 1:1 complex of lithium alkoxide, e.g., **5**-Li and the lithium amide **2**-Li. Recently we carried out a computational investigation of a model system, i.e., the lithium amide catalyzed rearrangement of lithium allylic alkoxide to lithium homoallylic alkoxide. Pathways have been calculated using semiempirical (PM3), ab initio (HF, MP2), and DFT (B3LYP) methods. The rearrangement takes place in heterodimer complexes in which the two lithiums play different roles in different pathways via intermediates. In the calculated proton-transfer transition states the proton is about half transferred between carbon and nitrogen (20).

Experimental section

General

All glassware used for synthesis was, when needed, dried overnight in a 120°C oven. Glassware and syringes used for isomerization reactions were dried at 50°C in a vacuum oven before transfer into a glove box (Mecaplex GB 80 equipped with a gas purification system that removes oxygen and moisture) containing a nitrogen atmosphere. Typical moisture

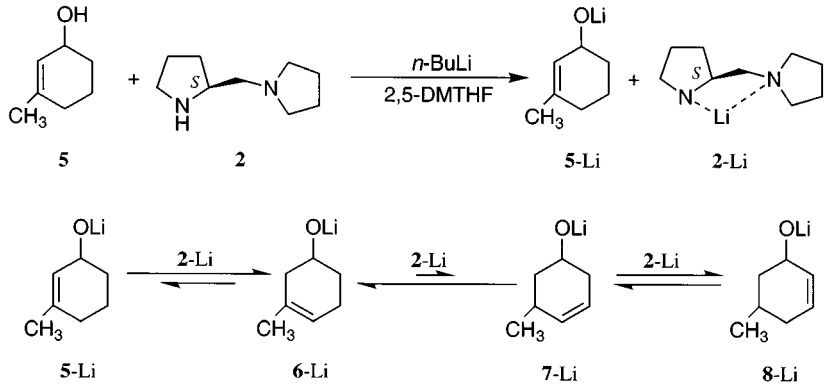
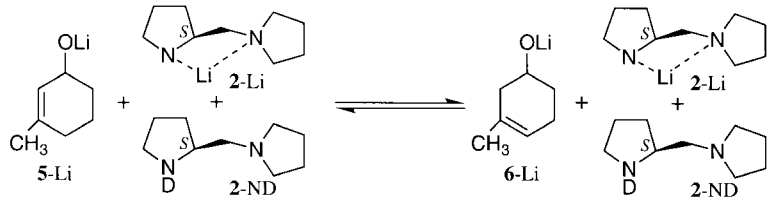
Scheme 3.



Scheme 4.



content was less than 0.5 ppm. All manipulations concerning the isomerization reactions were carried out in the glove box using gas-tight syringes. Etheral solvents, distilled under nitrogen from sodium and benzophenone, were kept over 4 Å molecular sieves in a septum-sealed flask inside the glove box. The concentrations of commercially available butyllithium solutions (*n*-BuLi 1.6 M or 2.5 M solution in hexanes, Aldrich) were determined by titration using biphenylmethanol (21).

Routine 1D ^{1}H and ^{2}H NMR spectra were recorded on a Varian Unity 400 MHz or a Varian Unity 500 MHz machine. Chromatographic analyses were carried out using a Varian Star 3400 CX gas chromatograph and a Varian 9012Q HPLC with Varian 9050 UV detector and Varian 9040 refractive index detector. All GC analyses were run on a chiral stationary-phase column (CP-Chirasil-DEX CB, 25 m, 0.32 mm) from Chrompack. All analyses were done at 95°C (injector 225°C, detector 250°C) using He (2 mL/min) as carrier gas.

Commercially available 3-methyl-2-cyclohexene-1-ol **5** (purity 96%) were obtained from Aldrich. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 5.51 (m, 1 H), 4.18 (m, 1 H), 1.90 (m, 2 H), 1.77 (m, 2 H), 1.69 (s, 3 H), 1.59 (m, 2 H), 1.42 (br s, 1 H); ^{13}C{1H} NMR (100 MHz, $CDCl_3$) δ: 19.2, 23.8, 30.3, 31.9, 66.1, 124.4, 138.9.

(*S*)-2-(1-Pyrrolidinylmethyl)pyrrolidine **2** was synthesized as previously described (13). Commercially available 2,5-dimethyltetrahydrofuran was obtained from Lancaster. After distillation from sodium and benzophenone analysis by GC (J & W Scientific DB-5MS), **2** showed the composition 56% *cis*- and 44% *trans*-DMTHF.

Preparations

*(*S*)-3-Methyl-2-cyclohexene-1-ol ((*S*)-**5**)*

The method of Orrenius et al. (14) was used with some modifications; most importantly, the enzyme preparation was different.

All reagents and the toluene used as solvent were dried over 4 Å molecular sieves for several days prior to use. Racemic **5** (0.5 mL; 4.2 mmol) and vinyl acetate (1.17 mL; 12.6 mmol) were added to a magnetically stirred 50 mL flask containing 1 g of 4 Å molecular sieves and 12 mL of toluene. After a few minutes, the lipase *Candida antarctica* B (100 mg; preparation SP435, immobilized) was added and the flask was capped with a drying tube. The reaction was allowed to proceed for 3 h at room temperature, when gas chromatographic analysis showed that the remaining **5** contained (*S*)-**5** in 76% ee. The reaction mixture was filtered and the solvent evaporated. The remaining alcohol was separated from the ester by dry column flash chromatography using hexane – ethyl acetate (90:10) as eluent, yielding 80 μL (yield 16%) of (*S*)-**5**. Racemization was avoided by not subjecting (*S*)-**5** to acid.

*Racemic 3-methyl-3-cyclohexene-1-ol (**6**)*

Isomerization of racemic **5** into racemic 3-methyl-3-cyclohexene-1-ol, **6**, was performed in up to a half-gram scale according to the general protocol for isomerizations, cited below. For work-up, the organic layer was washed with a solution of NH_4Cl (1 M) followed by brine, prior to drying (Na_2SO_4) and evaporation of the solvent. The alcohol mixture was purified by silica gel flash chromatography (eluent 75/25 hexane/DEE), giving a pure mixture of **5** and **6** in 45% yield as shown by ^{1}H NMR and GC. The isomeric mixture can be separated on analytical and semi-preparative scale using HPLC (Dynamax silica column, solvent: 75/25 cyclohexane/EtOAc (analytical 1.2 mL/min, semipreparative 5.5 mL/min) with refractive index detection.

3-Methyl-3-cyclohexene-1-ol: ^{1}H NMR (500 MHz, $CDCl_3$) δ: 5.39 (m, 1 H), 3.99 (m, 1 H), 2.25 (m, 1 H), 2.16 (m, 1 H), 2.07 (m, 1 H), 1.96 (m, 1 H), 1.75 (m, 1 H), 1.67 (s, 3 H), 1.54 (m 1 H), 1.27 (br s, 1 H); ^{13}C{1H} NMR (100 MHz, $CDCl_3$) δ: 23.3, 23.8, 30.7, 39.3, 67.6, 120.7, 131.5.

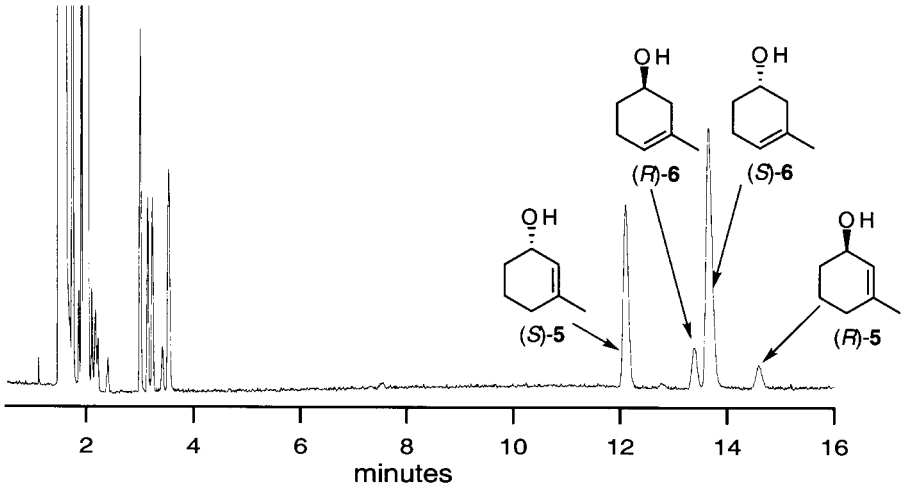
Fig. 1. GC chromatogram (chiral stationary-phase column) of isolated product mixture after 72 h of reaction of (*S*)-**5** (76% ee) with **2**-Li in DMTHF at 30.0°C. The elution order of the enantiomers of **6** is reversed as compared to that of the enantiomers of **5.**



*Mixture of (*S*)-3-methyl-2-cyclohexene-1-ol (*S*)-***5** *and (*S*)-3-methyl-3-cyclohexene-1-ol (*S*)-***6***

An analytical-scale resolution of a mixture of **5** and **6** was performed in order to establish the reverse elution order of the **6** enantiomers, as compared to the **5** enantiomers, respectively, on the chiral column used for gas chromatographic analysis.

To the mixture of **5** and **6** (35/65 **5/6**; 20.0 μL; 0.17 mmol) in toluene (0.50 mL) was added vinyl acetate (47 μL; 0.51 mmol) and 10 mg *Candida antarctica* B (preparation SP435). The resolution was monitored by gas chromatographic analysis during approximately 3 h. Then only the peaks from (*S*)-**5** and (*S*)-**6** remained in the chromatogram.

*Oxygen deuterated 3-methyl-2-cyclohexene-1-ol (***5***-OD)*

3-Methyl-2-cyclohexene-1-ol (1 mL; 8.27 mmol) was dissolved in dry chloroform (4.0 mL). Deuterium oxide (800 μL; 44 mmol) was added and the mixture was stirred for 4 h. Separation of the layers and drying (Na_2SO_4) followed by evaporation of the solvent gave **5** in quantitative yield. The isotopomer fraction of **5**-OD was 66% as measured by ^{1}H NMR.

General protocol for the isomerizations

n-Butyllithium (1.5 M in hexane; 227 μL; 0.34 mmol) was added to a solution of 3-methyl-2-cyclohexene-1-ol **5** (20.0 μL; 0.17 mmol) and (*S*)-2-(1-pyrrolidinylmethyl)pyrrolidine **2** (28.0 μL; 0.17 mmol) in 2,5-dimethyltetrahydrofuran (1.00 mL) maintained at 0°C. The flask was then moved to a thermostat held at 30.0°C. The reaction was monitored by withdrawing 20.0 μL of the reaction mixture using a dry syringe while protecting the reaction mixture by a stream of argon. The sample was transferred to a vial containing diethyl ether (1.0 mL) and saturated NH_4Cl (0.50 mL), and the mixture was shaken. The aqueous layer was removed and the ether layer washed with one portion of brine (0.50 mL) and dried over Na_2SO_4 prior to gas chromatographic analysis. After 72 h the reaction mixture contained **6** and **5** in about a 65/35 ratio.

Intramolecularity of isomerization

(*S*)-2-(1-Pyrrolidinylmethyl)pyrrolidine **2** (584 μL; 3.58 mmol) in 2,5-dimethyltetrahydrofuran (4.0 mL) was cooled to 0°C prior to addition of *n*-butyllithium (1.57 M in hexane; 2280 μL; 3.58 mmol). After 30 min, **5**-OD (300 μL; 2.50 mmol) was added and, after another 10 min, the reaction flask was moved to a thermostat held at 30.0°C. After 192 h (ca. 10 $t_{1/2}$) the reaction was quenched by addition of 1 M NH_4Cl (2.0 mL). The organic layer was washed with 1 M HCl (0.5 mL) and brine (3 × 5 mL) before drying (Na_2SO_4) and evaporation of the solvent. The residue was silica gel flash chromatographed (eluent 75/25 hexane/DEE) giving a mixture of **5** and **6** (120 mg; 43% yield). The deuterium content in the isomers was analyzed by ^{1}H and ^{2}H NMR. Only traces of deuterium were found in position 4 and in the methyl group of **5**, and in the 2- and 5-positions and the methyl group of **6**.

Selective hydroboration of alkenes and alkynes in the presence of aldehydes and ketones

George W. Kabalka, Su Yu, and Nan-Sheng Li

Abstract: The reactions of terminal alkenes in the presence of ketones or aldehydes with a variety of borane reagents have been investigated. It was found that the selective hydroboration of a terminal alkene in the presence of a ketone or an aldehyde is most efficient when dicyclohexylborane is used as the hydroborating agent. The hydroboration of olefinic ketones and olefinic aldehydes with dicyclohexylborane generates the corresponding hydroxyaldehydes and hydroxyketones in good yields after oxidation with sodium perborate. The hydroboration of alkynyl ketones and alkynyl aldehydes with dicyclohexylborane yields the corresponding olefinic carbonyl compounds after protonation, or dicarbonyl compounds after oxidation.

Key words: hydroboration, reduction, dicyclohexylborane, hydroxyaldehyde, hydroxyketone.

Résumé : On a étudié les réactions des alcènes terminaux, en présence de cétones ou d'aldéhydes, avec une variété de boranes comme réactifs. On a trouvé que le dicyclohexylborane est le meilleur agent pour effectuer l'hydroboration sélective d'un alcène terminal en présence d'une cétone ou d'un aldéhyde. L'hydroboration des cétones ou des aldéhydes oléfiniques suivie d'une oxydation avec du perborate de sodium conduit aux hydroxyaldéhydes et aux hydroxycétones correspondants avec de bons rendements. L'hydroboration des alcynylcétones et des alcynylaldéhyes par le dicyclohexylborane conduit aux composés carbonylés oléfiniques correspondants après protonation ou aux composés dicarbonylés après oxydation.

Mots clés : hydroboration, réduction, dicyclohexylborane, hydroxyaldéhyde, hydroxycétone.

[Traduit par la rédaction]

Introduction

Boron hydride reagents have been utilized extensively in organic synthesis. They have proven to be valuable for the selective reduction of carbonyl compounds as well as for the stereoselective hydroboration of alkenes and alkynes (1, 2). Because of the effectiveness of borane reagents in reducing aldehydes and ketones, hydroboration reactions involving substrates containing these functional groups are often carried out by either converting the carbonyl group to a less reactive functionality (3, 4) or modifying the hydroborating agent (5). Otherwise, reduction of the carbonyl moiety might compete with the desired hydroboration reaction. For example, α,β-unsaturated aldehydes and ketones are reduced rapidly and quantitatively to the corresponding allylic alcohols by 9-BBN (6). Similarly, the hydroboration of allyl ketones with diisopinocampheyborane produces enantiomerically enriched 1,4-diols via an intramolecular reduction (7). Diols are also the final products (after oxidation) when olefinic ketones are reduced by either borane or thexylborane (8). These latter reports, and related examples such as one involving a hydroboration with catecholborane in the presence of Wilkinson's catalyst (9), indicate that it might be possible to selectively hydroborate alkenes in the presence of aldehydes and ketones. Recently, we reported the preliminary results of our studies, which focused on the selective hydroboration of alkenes (Fig. 1) and alkynes (Fig. 2) in the presence of ketones and aldehydes (10). We now wish to report the details of these studies.

Results and discussion

Brown and his co-workers (11) have carried out extensive research on the reactions of alkenes and carbonyl compounds with a variety of boron hydrides. Their kinetic data indicates that both the hydroboration of terminal alkenes as well as the reduction of most aldehydes and some ketones by 9-BBN follow first-order kinetics (12). Although they exhibit first-order rate constants when reduced by borane reagents, the aldehydes, ketones, and alkenes exhibit different overall reaction rates. For example, aldehydes are more reactive toward 9-BBN than alkenes but 9-BBN reacts faster with certain alkenes than with ketones. We felt that these reactivity differences might be amplified if more hindered borane reagents were utilized.

As a probe, we allowed a mixture of 1-octene and 2-heptanone to react with a variety of common borane reagents at various temperatures (0, 25, 68°C). The mixtures were then oxidized to the corresponding alcohols using sodium perborate (13); the results of the study are presented in Table 1.

Analysis of the data in Table 1 indicates that the reactivities of a terminal alkene and an acyclic aliphatic ketone toward boron hydrides are quite different; in fact, a terminal alkene

can be successfully hydroborated in the presence of a ketone utilizing essentially all of the common hydroborating agents. As anticipated from earlier studies, 9-BBN is less chemoselective than the more hindered hydroborating reagents (entries 6–11); but dicyclohexylborane is quite effective at hydroborating a terminal alkene in the presence of a ketone. Also noteworthy is the fact that temperature had little effect on the selectivity of the reagents.

Cyclic ketones are present in a number of important naturally occuring molecules. Since cyclic ketones are more reactive toward 9-BBN than acyclic ketones (11), they might compete more effectively with terminal alkenes. As a probe, we allowed 1-octene and cyclopentanone to react with a limited quantity of the various borane reagents. The mixtures were then oxidized with sodium perborate, and the results are presented in Table 2.

As shown in Table 2, cyclopentanone competes more effectively than 2-heptanone for the borane reagents. However, hydroboration is still the major reaction except when 9-BBN is used as the hydroborating reagent. Cyclopentanone is slightly more reactive than 1-octene toward 9-BBN. Dicyclohexylborane is the most effective at hydroborating a terminal alkene in the presence of a cyclic ketone.

We also carried out a competitive study of reactions of alkenes and an aromatic ketone using various borane reagents. The results of the study are presented in Table 3. The data indicate that a terminal alkene can be selectively hydroborated in the presence of an aromatic ketone. Consistent with the earlier studies, 9-BBN is the least chemoselective.

As noted earlier, aldehydes are more reactive than terminal alkenes toward 9-BBN (11). 1-Octene and heptanal were used as model substrates and allowed to react with a limited quantity of the borane reagent. The results are presented in Table 4. The data reveal that hydroboration is the major reaction when hindered borane reagents are utilized, while reduction predominates in reactions using unhindered borane reagents. Dicyclohexylborane is once again the most effective at hydroborating a terminal alkene in the presence of an aldehyde.

We then examined the ability of dicyclohexylborane to selectively hydroborate olefinic aldehydes and ketones (Table 5). The results indicate that hydroxyaldehydes and hydroxyketones can be prepared in good yields after oxidation. Interestingly, no "simple" reduction products (olefinic alcohols) were detectable in any of the reactions except when 11-undecylenic aldehyde was used as the substrate. However,

5	$(c\text{-}C_6H_{11})_2BH$	82:18

[a] Reactions were carried out using 1 equiv. each of hydride, alkene, and ketone.
[b] Ratios obtained by GC analysis after aqueous sodium perborate oxidation.
[c] Overall combined yields ranged from 90 to 100%.
[d] 2-Octanol was also formed in small quantities.

overreduction to the diol product (up to 10%) was observed in some cases.

A variety of unconjugated alkynyl carbonyl compounds were then hydroborated with dicyclohexylborane to probe the ability of dicyclohexylborane to selectively hydroborate alkynes in the presence of both aldehydes and ketones. The results are summarized in Table 6. Both terminal and internal alkynyl carbonyl compounds can be hydroborated in the presence of the carbonyl group. The reaction affords the corresponding olefins in high yields (71–94%) after protonation, or dicarbonyl compounds in good yields (50–76%) after oxidation with sodium perborate.

Experimental section

Alkenyl ketones and alkenyl aldehydes, obtained from Aldrich Chemical Company, were used as received or purified by distillation prior to use. Alkynyl ketones and alkynyl aldehydes were synthesized from the alkynyl alcohols by oxidation with PCC (14). Alkynyl alcohols were either obtained commercially or prepared via Grignard reactions (14). ^{1}H NMR spectra and ^{13}C NMR spectra were run at 250 MHz. Elemental analyses were performed by Atlantic Microlab Inc., Atlanta, Ga.

General procedure for the preparation of hydroxyketones and hydroxyaldehydes

6-Hydroxy-2-hexanone
Borane tetrahydrofuran (5.0 mmol, 5.0 mL of a 1.0 M solution in THF) was placed in a dry, argon-flushed, round-bottomed flask, which was then immersed in an ice-water bath. Cyclohexene (10.0 mmol, 0.82 g, 1.0 mL) was added dropwise and the mixture stirred at 0°C for 1 h. 5-Hexen-2-one (5.0 mmol, 0.49 g, 0.58 mL) was then added to the slurry of dicyclohexylborane in THF. The cooling bath was removed and the mixture stirred for 2 h at room temperature. Oxidation was achieved by adding $NaBO_3$·$4H_2O$ (15 mmol, 2.3 g) and water (5 mL) and stirring the mixture at room temperature for 2 h. The product was extracted into ether (3 × 15 mL), the solvent removed under pressure, and 6-hydroxy-2-hexanone (15) (0.44g, 76% yield) was isolated by flash chromatography. ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 3.62 (t, J = 6.1 Hz, 2H), 2.59 (br s, 1H), 2.49 (t, J = 6.8 Hz, 2H), 2.16 (s, 3H), 1.73–1.50 (m, 4H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 209.38, 61.96, 43.15, 31.87, 19.73, 19.72.

2-Methyl-5-(1-methyl-2-hydroxylethyl)cyclohexanone (16)
Yield: 77%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 3.59–3.44 (m, 2H), 2.49–1.26 (m, 9H), 1.01 (d, J = 6.4 Hz, 2H), 0.94 (d, J = 6.9 Hz), 0.91 (d, J = 6.9 Hz) (total 3H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 213.72, 213.45, 65.45, 65.36, 46.17, 44.83 (44.83), 43.91, 41.57, 41.37, 40.19, 40.00, 34.97 (34.97), 29.71, 27.51, 14.20 (14.20), 13.05, 12.71.

1-Methoxy-2-oxabicyclo[4.4.0]decane (17)
Yield: 70%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 3.72–3.56 (m, 2H), 3.22–3.16 (m, 3H), 1.98–1.12 (m, 13H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 98.34, 60.87, 46.34, 44.44, 31.74, 29.45, 26.36, 25.88, 24.72, 22.67.

6-Hydroxy-5-methyl-2-hexanone
Yield 80%; a cyclic and acyclic mixture (50:50) of 6-hydroxy-5-methyl-2-hexanone was produced. ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 3.55–3.42 (m, 2H), 2.97 (br s, 0.5H) 2.61–2.46 (m, 1.5H), 2.16 (s, 1.5H), 1.81–1.35 (m, 5.5H), 0.91 (d, J = 6.6 Hz, 1.5H), 0.82 (d, J = 6.3 Hz, 1.5H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 209.58, 94.50, 67.18, 60.50, 41.06, 35.15, 34.85, 30.06, 29.94, 29.72, 27.56, 26.65, 17.05, 16.39. HRMS calcd. for $C_7H_{14}O_2$: 130.099; found: 130.096.

4-(2-Propenoxy)-2-hydroxybenzophenone
Yield 78%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 12.66 (s, 1H), 7.61–7.44 (m, 6H), 6.50 (d, J = 2.2 Hz, 1H), 6.38 (dd, J = 8.9, 2.2 Hz, 1H), 4.13 (t, J = 6.0 Hz, 2H), 3.80 (t, J = 6.0 Hz, 2H), 2.66 (s, 1H), 2.02 (p, J = 6.0 Hz, 2H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 199.85, 166.04, 165.40, 138.01, 135.13, 131.32, 128.64, 128.12, 112.93, 107.42, 101.53, 65.32, 59.14, 31.61. Anal. calcd. for $C_{16}H_{16}O_4$: C 70.57, H 5.92; found: C 70.66, H 5.91.

2-Acetyl-5-hydroxynorbornane and 2-acetyl-6-hydroxynorbornane (18)
Yield 68%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 3.85–3.62 (m, 1H), 3.05–1.12 (m, 13H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 209.79, 209.64, 209.28, 73.98, 73.68, 73.38, 69.72, 60.20, 53.39, 52.79, 51.43, 50.13, 47.30, 47.03, 44.65, 43.70, 41.70,

Table 5. The hydroboration of olefinic carbonyl compounds with dicyclohexylborane.

Entry	Substrate	Product[a]	Yield (%)[b]
1[c]			76
2[c]			77
3[d]			70
4			80
5[e]			78
6[c]			68
7[f]			50

[a] Known compounds exhibited physical and spectral characteristics in accord with literature values, and new compounds were characterized by spectral and elemental analysis or HRMS.

[b] Isolated yield.

[c] Up to 10% of the corresponding diols were isolated.

[d] Acetal formed by the reaction of the crude product with methanol in the presence of TsOH.

[e] Two equiv. of dicyclohexylborane were utilized.

[f] A trace of 11-undecylenic alcohol was detected by TLC.

41.21, 39.17, 38.85, 36.27, 34.93, 32.07, 31.63, 31.17, 29.44, 29.23, 28.63, 28.42, 26.76, 25.06.

11-Hydroxyundecanal (19)

Yield 50%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 9.76 (t, J = 1.6 Hz, 1H), 3.61 (t, J = 6.6 Hz, 2H), 2.65 (s, 1H), 2.43 (dt, J = 7.3, 1.6 Hz, 2H), 1.65–1.53 (m, 4H), 1.29 (br s, 12H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 202.71, 62.47, 43.63, 32.51, 29.26, 29.11 (29.11), 28.90, 25.54, 21.82, 13.89.

General procedure for the preparation of alkenyl carbonyl compounds and dicarbonyl compounds

The hydroboration of 11-dodecyn-2-one is representative: BH_3·THF (2.0 mmol, 2.0 mL of a 1.0 M solution in THF) was placed in a dry, argon-flushed flask, which was then immersed in an ice-water bath. Cyclohexene (4.0 mmol, 0.33 g, 0.41 mL) was added dropwise and the mixture stirred at 0°C for 1 h. 11-Dodecyn-2-one (2.0 mmol, 0.36 g) was then added to the slurry of dicyclohexylborane in THF. The cooling bath was removed and the mixture stirred for 1 h at room temperature. Protonation was achieved by adding glacial acetic acid (1.0 mL) and stirring the mixture at room temperature for 1 h. 11-Dodecen-2-one (20) (0.34 g, 94% yield) was isolated after work-up. ^{1}H NMR, δ (ppm): 5.88–5.72 (m, 1H), 5.02–4.90 (m, 2H), 2.41 (t, J = 7.4 Hz, 2H), 2.13 (s, 3H), 2.03 (q, J = 6.8 Hz, 2H), 1.56 (m, 2H), 1.28 (m, 10H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 209.08, 139.05 114.06, 43.70, 33.71, 29.72, 29.25 (29.25), 29.09, 29.00, 28.83, 23.78. Alternatively, oxidation could be achieved by adding of $NaBO_3$·$4H_2O$ (6.0 mmol, 0.92 g) and water (2 mL) and stirring the mixture at room temperature for 2 h. 11-Oxododecanal (21) (0.30 g, 76% yield) was isolated after work-up. ^{1}H NMR, δ (ppm): 9.76

[a] Products exhibited physical and spectral characteristics in accord with literature values or gave acceptable elemental analyses.
[b] Isolated yield.

(t, *J* = 1.9 Hz, 1H), 2.45–2.39 (m, 4H), 2.14 (s, 3H), 1.62–1.56 (m, 4H), 1.29 (m, 10H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 209.07, 202.64, 43.71, 43.58, 29.65, 29.10, 28.95, 23.65, 21.89.

1-Phenyl-(Z)-10-dodecen-1-one
Yield 92%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 7.98–7.94 (m, 2H), 7.58–7.41 (m, 3H), 5.47–5.35 (m, 2H), 2.96 (t, *J* = 7.2 Hz, 2H), 2.04–1.99 (m, 2H), 1.78–1.68 (m, 2H), 1.61–1.58 (m, 3H), 1.43–1.20 (m, 10H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 200.49, 137.07, 132.77, 130.77, 128.47, 127.99, 123.56, 38.55, 29.33 (29.33, 29.33), 29.18 (29.18), 26.77, 24.32, 12.50. Anal. calcd. for $C_{18}H_{26}O$: C 83.67, H 10.14; found: C 83.73, H 10.20.

(Z)-11-Tridecen-2-one
Yield 88%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 5.47–5.32 (m, 2H), 2.41 (t, *J* = 7.4 Hz, 2H), 2.13 (s, 3H), 2.03–1.98 (m, 2H), 1.61–1.54 (m, 5H), 1.28 (br s, 10H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 209.19, 130.72, 123.53, 43.70, 29.72, 29.42, 29.27 (29.27), 29.10 (29.10), 26.72, 23.78, 12.64. HRMS calcd. for $C_{13}H_{24}O$: 196.182; found: 196.182.

(Z)-10-Dodecenal
Yield 71%; ^{1}H NMR, δ (ppm): 9.76 (t, *J* = 1.9 Hz, 1H), 5.43–5.41 (m, 2H), 2.42 (dt, *J* = 7.3, 1.9 Hz, 2H), 2.07–1.98 (m, 2H), 1.78–1.53 (m, 5H), 1.30 (br s, 10H); ^{13}C NMR, δ (ppm): 202.82, 130.76, 123.63, 43.86, 29.45, 29.30 (29.30), 29.16, 26.79, 23.80, 22.06, 12.50. HRMS calcd. for $C_{12}H_{22}O$: 182.167; found: 182.167.

12-Tridecen-3-one (19)
Yield 83%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 5.85–5.72 (m, 1H), 5.03–4.90 (m, 2H), 2.46–2.36 (m, 4H), 2.03 (q, *J* = 6.9 Hz, 2H), 1.62–1.54 (m, 2H), 1.28 (m, 10H), 1.05 (t, *J* = 7.3 Hz, 3H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 211.81, 139.08, 114.06, 42.36, 35.78, 33.72, 29.23 (29.23), 29.00 (29.00), 28.84, 23.87, 7.77.

11-Oxotridecanal (22)
Yield 68%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 9.76 (t, *J* = 1.7 Hz, 1H) 2.46–2.37 (m, 6H), 1.59 (m, 4H), 1.29 (br s, 10H), 1.04 (t, *J* = 7.2 Hz, 3H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 211.52, 202.50, 43.64, 42.12, 35.58, 29.00, 23.66, 21.81, 7.58.

10-Undecenal (23)
Yield 90%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 9.76 (t, *J* = 1.9 Hz, 1H), 5.89–5.73 (m, 1H), 5.03–4.90 (m, 2H), 2.42 (dt, *J* = 7.3, 1.9 Hz, 2H), 2.08–2.00 (m, 2H), 1.66–1.57 (m, 2H), 1.30 (m, 10H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 202.80, 139.08, 114.12, 43.87, 33.73, 29.23 (29.23), 29.11, 29.00, 28.84, 22.03.

1,11-Undecanedial (24)
Yield 50%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 9.76 (t, *J* = 1.6 Hz, 2H), 2.42 (dt, *J* = 7.3, 1.6 Hz, 4H), 1.62 (m, 4H), 1.30 (br s, 10H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 202.74, 43.72, 29.10, 29.01, 28.97, 21.89.

1-Phenyl-5-hexen-1-one (25)
Yield 85%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 7.94 (m, 2H), 7.57–7.41 (m, 3H), 5.90–5.74 (m, 1H), 5.08–4.97 (m, 2H), 2.97 (t, *J* = 7.3 Hz, 2H), 2.15 (q, *J* = 7.3 Hz, 2H), 1.84 (p, *J* = 7.3 Hz, 2H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 200.07, 137.95, 136.98, 132.80, 128.46, 127.92, 115.18, 37.60, 33.10, 23.21.

6-Oxo-6-phenylhexanal (26)
Yield 66%; ^{1}H NMR ($CDCl_3$/TMS), δ (ppm): 9.78 (t, *J* = 1.4 Hz, 1H), 7.96–7.93 (m, 2H), 7.59–7.43 (m, 3H), 3.03 (t, *J* = 6.8 Hz, 2H), 2.53–2.48 (m, 2H), 1.76–1.72 (m, 4H); ^{13}C NMR ($CDCl_3$/TMS), δ (ppm): 202.19, 199.69, 136.77, 132.94, 128.49, 127.89, 43.61, 38.00, 23.50, 21.59.

Kinetics of thermal racemization of (2*S*,3*S*)-1-^{13}C-1,2,3-d_3-cyclopropane followed by vibrational circular dichroism spectroscopy

Teresa B. Freedman, Diane L. Hausch, Steven J. Cianciosi, and John E. Baldwin

Abstract: Vibrational circular dichoism spectra recorded for (2*S*,3*S*)-1-^{13}C-1,2,3-d_3-cyclopropane and for mixtures of it and the three related stereoisomers prepared through gas-phase thermal stereomutation reactions at 407°C lead to the rate constant for racemization: $k_\alpha = (4k_1 + 4k_{12}) = (3.12 \pm 0.04) \times 10^{-5}$ s^{-1}. This and the rate constant measured for geometrical equilibration between the two chiral and the two achiral stereoisomers of 1-^{13}C-1,2,3-d_3-cyclopropane, $k_i = (8k_1 + 4k_{12}) = (4.63 \pm 0.20) \times 10^{-5}$ s^{-1}, give two equations in two unknowns, and allow one to solve for one-center (k_1) and two-center (k_{12}) epimerization rate constants for cyclopropane stereomutations. They are nearly equal, a clear indication of closely competitive reaction pathways.

Key words: cyclopropane stereomutations, thermal epimerizations, chirality through deuterium and carbon-13 labeling, vibrational circular dichroism.

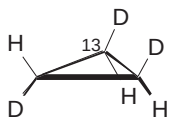
Résumé : On a enregistré les spectres de dichroïsme circulaire vibrationnel du (2*S*,3*S*)-1-^{13}C-1,2,3-d_3-cyclopropane et de son mélange avec les trois stéréoisomères apparentés préparés par stéréomutation thermique en phase gazeuse, à 407°C; ces données permettent de tirer la constante de vitesse de racémisation, $k_\alpha = (4k_1 + 4k_{12}) = (3{,}12 \pm 0{,}04) \times 10^{-5}$ s^{-1}. Cette valeur associée à la constante de vitesse mesurée pour l'équilibre géométrique entre les deux isomères chiraux et les deux isomères achiraux du 1-^{13}C-1,2,3-d_3-cyclopropane, $k_i = (8k_1 + 4k_{12}) = (4{,}63 \pm 0{,}20) \times 10^{-5}$ s^{-1}, fournit deux équations et deux inconnues qui peuvent être résolues pour les constantes de vitesse d'épimérisation à un centre (k_1) et à deux centres (k_{12}) pour les stéréomutations du cyclopropane. Ces valeurs sont presque normales; ceci est une indication claire que les voies réactionnelles compétitives sont très proches.

Mots clés : stéréomutations du cyclopropane, épimérisations thermiques, chiralité due au marquage au deutérium et au ^{13}C, dichroïsme circulaire vibrationnel.

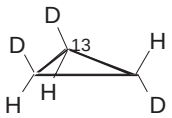
[Traduit par la rédaction]

Vibrational circular dichroism (VCD), the differential interaction of a chiral molecule with left and right circularly polarized infrared radiation during vibrational excitation (1, 2) may be used as a sensitive spectroscopic method for assessing the optical purity of a compound. The method may be readily extended to determine enantiomeric excess (ee) values of a non-racemic compound in the presence of achiral isomers. The VCD spectroscopic method is particularly noteworthy when applied to molecules that cannot be probed for ee by chiral chromatographic techniques or by polarimetry or by chiroptical spectroscopic methods in the ultraviolet or visible regions of the electromagnetic spectrum. There is no other presently available direct method for determining ee values for compounds of this class, such as saturated hydrocarbons chiral only by virtue of isotopic labels.

Both enantiomers of *trans*-1,2-d_2-cyclopropane and both (2*S*,3*S*)-1-^{13}C-1,2,3-d_3-cyclopropane and (2*R*,3*R*)-1-^{13}C-1,2,3-d_3-cyclopropane (**(2*S*,3*S*)-1** and **(2*R*,3*R*)-1**) have been synthesized and have demonstrated the point (3–7). The VCD spectra of the optical antipodes in each case are related as mirror images, with excellent agreement between experimentally determined absolute stereochemistry, observed VCD spectra, and theoretically calculated VCD spectra (6).



(2*S*,3*S*)-**1**



(2*R*,3*R*)-**1**

The first attempt to apply this spectroscopic analytical method to the determination of a rate constant for a thermal racemization reaction was made by Chickos, Annamalai, and Keiderling (8). They followed the loss of relative optical

activity for a chiral *trans*-1,2-d_2-cyclobutane as it underwent reversible thermal stereomutations, forming the enantiomer and the achiral *cis* isomer, and dissociated to ethylene and deuterium-labeled ethylenes.[3]

In a second application of this approach, the thermal stereomutations of (1*R*,2*R*)-1,2-d_2-cyclopropane were followed by VCD, and the rate constant k_α for the first-order loss of optical activity through reversible formation of the *cis* isomer and of the (1*S*,2*S*) isomer at 422.5°C in the gas phase was reported to be 12.3×10^{-5} s^{-1} (10). In hindsight, however, it was recognized that the experimental uncertainties for k_α were too large for it to be of any mechanistically telling significance. The calculated rate constant was based on only three (time, α_{rel}) data points and a two-parameter nonlinear least-squares fit[4] of these three points to an exponential function; the calculated 95% confidence interval for k_α was $(3.9–20.8) \times 10^{-5}$ s^{-1}. This estimation of k_α was inadequate because too few kinetic points were determined and those few points were overinterpreted, not because of some inherent shortcoming in the VCD method itself.

In subsequent work, when the rate of loss of optical activity of **(2*S*,3*S*)-1** was followed by VCD spectroscopy, five well-spaced kinetic points were determined using enantiomerically pure **(2*S*,3*S*)-1** as the reference, and a substantially more precise value for k_α for this system was derived (5). The value of k_α at 407°C reported in a preliminary communication (5) was $(3.10 \pm 0.07) \times 10^{-5}$ s^{-1} (standard deviation) and the 95% confidence interval calculated for k_α was $(2.86–3.33) \times 10^{-5}$ s^{-1}. This k_α value ($k_\alpha = (4k_1 + 4k_{12})$) and the rate constant for geometrical isomerizations of the ^{13}C, d_3-labeled cyclopropanes determined by tunable diode laser spectroscopy (5, 11) ($k_i = (8k_1 + 4k_{12}) = (4.63 \pm 0.20) \times 10^{-5}$ s^{-1}) provided values of $k_1 = (0.38 \pm 0.05) \times 10^{-5}$ s^{-1} and $k_{12} = (0.39 \pm 0.05) \times 10^{-5}$ s^{-1}, thus demonstrating that the thermal stereomutations of isotopically labeled cyclopropanes occur as both one-center and two-center epimerizations and take place with comparable rate constants. This experimental result is now reflected in theoretical calculations and models from several laboratories (12–19).

The rate constants in Scheme 1 are defined so as to include symmetry considerations, for a one-center epimerization at C1 could follow upon cleavage of the C1—C2 bond or the C1—C3 bond. With this convention the rate constants k_1 and k_{12} reflect the competitive situation attendant upon breaking a single C—C bond. By symmetry, neglecting conceivable but surely minuscule carbon-13 kinetic isotope effects, $k_1 = k_2 = k_3$ and $k_{12} = k_{13} = k_{23}$.

The present report presents in full detail the VCD spectroscopic data from which a k_α value for **(2*S*,3*S*)-1** may be derived. While the method and instrumentation used have been detailed in print (4), and the VCD spectra have been available in a dissertation since 1991 (20), this account, prompted by colleagues and a recent renewal of interest in the cyclopropane stereomutation problem (12–23), offers a complete presentation of spectral data and an alternative, independent procedure for data reduction. It provides, in a still more readily accessible form, information necessary for judging the power of VCD spectroscopy applied to problems of this sort. The new derivation of the k_α value for thermal racemization of **(2*S*,3*S*)-1** from the primary spectral data confirms the original kinetic determination (5) and the conclusion that thermal stereomutations of cyclopropane take place with $k_1 \approx k_{12}$.

Experimental

The syntheses and characterizations of **(2*S*,3*S*)-1**, **(2*R*,3*R*)-1**, and of the racemic mixture of both enantiomers, **rac-1**, have been described in detail (7). The gas-phase thermal reactions at 407°C with pentane as a bath gas and the reisolation and purification of labeled cyclopropane samples have been described in a full paper (11). Samples of pure **(2*S*,3*S*)-1** and of preparative-GC purified mixtures of 1-^{13}C-1,2,3-d_3-cyclopropane isomers from thermal reaction mixtures were transferred to a gas infrared spectroscopy cell on a vacuum line, employing a constant volume manifold and a MKS Baritron high-accuracy capacitance manometer pressure-measuring device. The 5 cm path length Pyrex infrared cell, with ~20 mL volume, was equipped with KBr windows, a high-vacuum stopcock, and a cold-finger. The reference sample size was ~5 mg.

The gas-phase VCD spectra were recorded in the CH-stretching region (2900–3200 cm^{-1}) on a dispersive VCD spectrometer (4, 24–26) with a fresh Xenon arc source to maximize throughput, CaF_2 photoelastic modulator, liquid-nitrogen-cooled InSb detector, and computerized data acquisition (interfaced to SpectraCalc, Galactic Industries Corp., Salem, NH 03079). Three scans were recorded for each sample or reference at 8 cm^{-1} resolution and averaged. The noise level was ~1×10^{-6} in absorbance units, whereas the maximum VCD magnitude for the pure sample of **(2*S*,3*S*)-1** was ~2×10^{-5} absorbance units.

For each reaction time, three VCD spectra were measured: one for the kinetic sample from **(2*S*,3*S*)-1**, one for a "baseline" sample obtained from an equal-time thermal reaction of **rac-1**, and one for the pure **(2*S*,3*S*)-1** reference sample; the three VCD spectra were recorded consecutively without modification of instrument settings. Reference and baseline sample pressures (Table 1), which were approximately the same for all the kinetic points, corresponded to maximum sample absorbances below 0.5. Kinetic sample pressures were increased relative to the reference sample pressures to increase the VCD

[3] For recent theoretical work on these reactions and the tetramethylene diradical, see ref. 9.

signal in the partially racemized samples, while maintaining maximum absorbance below 1, for higher absorbances degraded the VCD signal at the absorbance maxima.

The raw VCD spectra for **rac-1**, for **(2*S*,3*S*)-1**, and for **(2*R*,3*R*)-1**, displayed in Fig. 1, were recorded in March 1990; they provided the first experimental confirmation that VCD methods could be applied successfully to saturated hydrocarbons chiral only by virtue of a carbon-13 label.

The spectra of Fig. 1 show a consistent sloping instrumental baseline, an artifact that was readily corrected for spectra observed for the enantiomers or for thermal product mixtures. Subtracting the VCD spectrum recorded for **rac-1** from the VCD spectra for pure **(2*S*,3*S*)-1** and **(2*R*,3*R*)-1** gives nearly mirror image related spectra about $\Delta A = 0$ for the two ^{13}C, d_3 enantiomers (5, 6). Similarly, subtracting VCD spectra for samples obtained from thermolysis of **rac-1** from spectra obtained for the equal-time kinetic samples derived from **(2*S*,3*S*)-1** corrected for the sloping instrumental baseline.

Effects of any slight instrument baseline drift among the three raw spectra for each kinetic point were eliminated by linear offset of the racemic-baseline-corrected kinetic and reference data to zero ΔA (averaged over ~100 consecutive data points) in regions above and below the 3150–2950 cm^{-1} region of sample absorbance. In some cases the linear offset was preceded by a minor two-point baseline slope adjustment. For one sample (960 min) an anomalously large instrumental drift was encountered below 3000 cm^{-1}, a region beyond the data range employed in the ee determination.

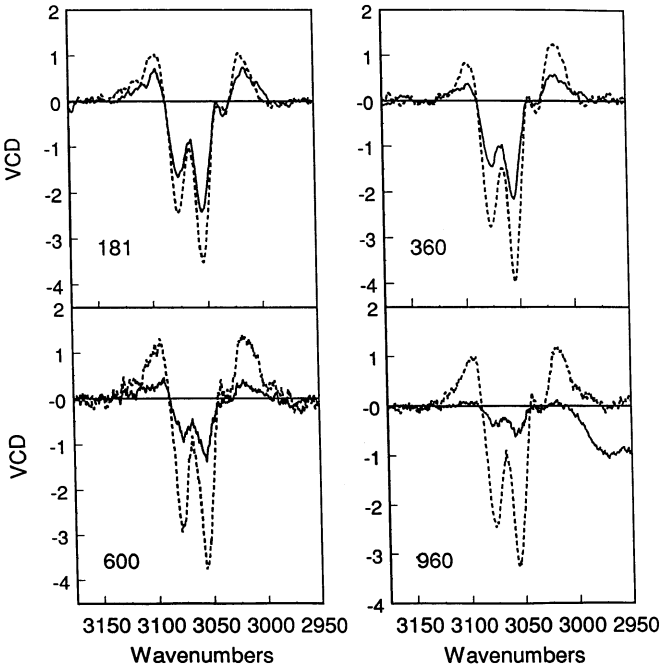
The loss in optical activity of the kinetic samples was determined by first scaling the kinetic point VCD spectra by the pressure ratio (reference (Torr)/sample (Torr)) (1 Torr = 133.3 Pa) to correct for the difference in masses of sample and reference measured. The pressure and baseline corrected VCD spectra for the four pairs of kinetic non-racemic mixtures of isomers and the corresponding reference samples are displayed in Fig. 2.

For each kinetic sample, 30–80 data points in the vicinity of the two VCD maxima at 3077 and 3054 cm^{-1} were selected and the mean and standard deviation of the ratio $\alpha_{rel} = [VCD_{sample} \times (\text{ref. (Torr)/sample (Torr)})/VCD_{reference}]_{mean}$ were determined. These values, compiled in Table 1, were calculated in 1990 (determination 1) and derived independently from the original electronically stored VCD spectral data in 1996 (determination 2). The data for the latter analysis are plotted in Fig. 3.

The data were fit to a function of the form $A*\exp(-b*t)$ by

© 1998 NRC Canada

Fig. 2. Experimental pressure-corrected VCD spectra for thermal stereomutation product mixtures from **(2*S*,3*S*)-1** (——) and reference **(2*S*,3*S*)-1** samples (- - -) with data processing as described in text.



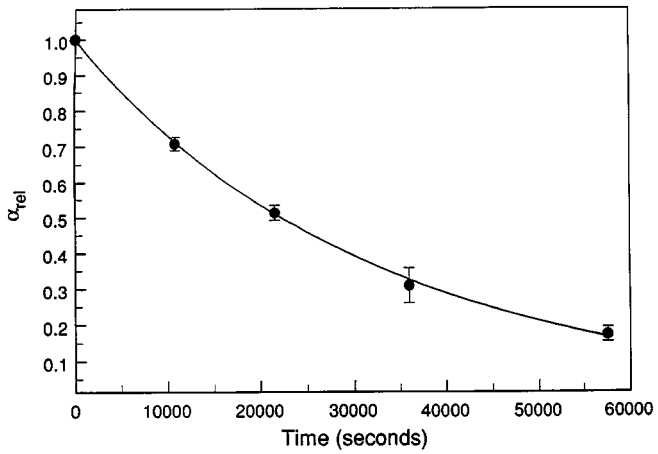
a weighted nonlinear least-squares procedure with the Axum graphics and data analysis software (MathSoft, Inc., Cambridge, MA 02142). Kinetic points were weighted by their inverse standard deviation, with the $t = 0$ point 100 times more heavily weighted. This procedure provides rate constant $k_\alpha = (3.10 \pm 0.06) \times 10^{-5}$ s^{-1} for determination 1, and $k_\alpha = (3.12 \pm 0.04) \times 10^{-5}$ s^{-1} for determination 2, with all five data points used in each calculation. Eliminating the 960 min data point, for which instrumental drift was encountered, does not significantly alter the rate constant ($k_\alpha = (3.15 \pm 0.04) \times 10^{-5}$ s^{-1} for four data points).

Mean values of α_{rel} obtained in determinations 1 and 2 are not significantly different. The newly calculated value of k_α was derived using a different weighting scheme and least-squares program than those originally employed (5), and is only very slightly larger. The redetermined value for $k_\alpha = (3.12 \pm 0.04) \times 10^{-5}$ s^{-1} is well within the originally defined 95% confidence interval, $(2.86–3.33) \times 10^{-5}$ s^{-1}.

Discussion

From $k_\alpha = (4k_1 + 4k_{12}) = (3.12 \pm 0.04) \times 10^{-5}$ s^{-1} and $k_i = (8k_1 + 4k_{12}) = (4.63 \pm 0.20) \times 10^{-5}$ s^{-1} one may calculate $k_1 = (0.38 \pm 0.05) \times 10^{-5}$ s^{-1}, $k_{12} = (0.40 \pm 0.05) \times 10^{-5}$ s^{-1}, $k_{12}:k_1 = 1.05 \pm 0.19$, and $k_i:k_\alpha = 1.48 \pm 0.07$. The determination that k_1 and k_{12} are equal within one-standard-deviation error estimates reinforces the essential experimental finding, $k_1 \approx k_{12}$, reported in the preliminary communication (5). The stereomutations that occur when a C—C bond in cyclopropane is broken are most frequently of the one-center variety, for $2k_1:k_{12}$ is 1.9. Some 66% of the initial stereomutation product mixture formed directly from **(2*S*,3*S*)-1** is ***cis*-1**. Since the ratios of rate

Fig. 3. Exponential kinetic plot for k_α based on determination 2 data in Table 1 and the VCD spectra of Fig. 2.



constants $(k_1 + k_2):k_{12}$ found experimentally for various 1,2-substituted cyclopropanes range from 1.4 to 4 (some 25 examples) (21), the balance between experimentally determined one-center versus two-center epimerization rate constants for 1-^{13}C-1,2,3-d_3-cyclopropanes is unexceptional.

Theoretical models for these stereomutations are still being evolved, and further work will surely be forthcoming. There remain important conceptual and calculational uncertainties to be resolved, especially regarding the detailed topography of the potential energy surface and the role of dynamic effects modeled through trajectory calculations (12–19). The present contribution may aid that ongoing effort and help provide for a measure of agreement between experimental and theoretical assessments of the stereomutations.

The conformational equilibrium of *N*,*N*′-bis[(*S*)-1-phenylethyl]-thiourea and its solvent dependence, studied by NMR and CD spectra and by X-ray crystallography

Knut Rang, Jan Sandström, and Christer Svensson

Abstract: Favoured conformations of *N*,*N*′-bis[(*S*)-1-phenylethyl]thiourea (**1**) have been predicted by empirical force-field calculations, and the corresponding rotational strengths for the important transitions in the near UV region have been calculated. Experimental studies by ^{1}H NMR, IR, UV, and CD spectroscopy have permitted the assignment of a conformation denoted *E*,*Za* to the conformer, which dominates in nonpolar solvents, while hydroxylic solvents were found to favour conformations of *Z*,*Za* type. The *E*,*Za* conformer is also predicted by force-field calculations to be the most stable one.

Key words: circular dichroism, conformation, crystal structure, dynamic NMR spectroscopy, *N*,*N*′-bis[(*S*)-1-phenylethyl]thiourea.

Résumé : Faisant appel à des calculs empiriques de champs de force, on a prédit les conformations privilégiées de la *N*,*N*′-bis[(*S*)-1-phényléthyl]thiourée (**1**) et on a calculé les forces rotationnelles correspondantes des transitions importantes dans la région du proche UV. Des études expérimentales par spectroscopies IR, UV, de DC et RMN du ^{1}H on permis d'attribuer une conformation indiquée par *E*,*Za* au conformère prédominant dans les solvants non polaires; par ailleurs, dans les solvants hydroxyliques, les conformations favorisées sont du type *Z*,*Za*. Les calculs de champs de forces prédisent aussi que le conformère *E*,*Za* devrait être le plus stable.

Mots clés : dichroïsme circulaire, conformation, structure cristalline, spectroscopie RMN dynamique, *N*,*N*′-bis[(*S*)-1-phényléthyl]thiourée.

Introduction

In 1970, Terent'ev and co-workers reported the ultraviolet spectra and the anomalous rotatory dispersion (ORD) curves of *N*,*N*′-bis[(*S*)-1-phenylethyl]-thiourea (**1**) and a number of analogues (1, 2). They observed positive Cotton effects at ca. 300 nm in chloroform and benzene solutions, but negative effects in ethanol. These observations were qualitatively explained by the solvent dependence of the *E*–*Z* equilibrium with respect to the N—C(═S) bonds (2).

Simple *N* -alkylamides (3, 4) and -thioamides (5) prefer the *Z* to the *E* conformation, but simple *N*,*N*′-dialkylthioureas have been shown by ^{1}H NMR (6, 7) and IR (7) spectroscopy to appear as mixtures of *E*,*Z* and *Z*,*Z* forms with the former dominating. The conformational situation becomes more complicated in thioureas substituted by secondary alkyl groups like isopropyl and 1-phenylethyl groups, since these can take up (at least) two different "bisected" orientations with respect to the thioamide plane (8–10). In combination with the *E* and *Z* conformations, this leads to (at least) 10 possible conformations for **1** (Scheme 1).

The early workers were confined by instrumental limitations to use only the ORD technique and to work in the wavelength region above 300 nm, which barely touches the absorption region of these compounds. To examine more closely the detailed conformational behaviour of **1**, we have performed a study of its NMR, IR, UV, and CD spectra in hydrogen bonding and non-hydrogen-bonding solvents. The crystal structure of **1** has also been studied, and the spectral data are interpreted with the aid of CNDO/S calculations and theoretical calculations of CD spectra. The calculations are based on geometries of minimum energy conformations obtained by empirical force-field calculations.

Experimental part

Materials

The synthesis of **1** has been described by Lovén and Ohlsson (11), by Kallenberg (12), and by Terent'ev and co-workers (1). In the present work **1** was prepared in 88% yield by heating an

ethanol solution of (*S*)-1-phenylethylammonium (*S*)-*N*-1-phenylethyldithiocarbamate (13) to reflux; pale yellow crystals, mp 206–207°C (Kofler Heizbank) after recrystallization from 1-propanol. Previous authors have reported melting points of 195.5 (11), 195–197 (12), and 199–200°C (1).

Spectra

^1H *NMR spectra* were recorded with a Bruker ARX 500 NMR spectrometer operating at 500.14 MHz. *IR spectra* in chloroform-*d* solution and in KBr were recorded with a Perkin–Elmer Model 298 infrared spectrophotometer. *UV spectra* were recorded with a Cary Model 2290 spectrophotometer. By using 0.1 cm cells, it was possible to record spectra down to 190 nm. *CD spectra* were recorded with a JASCO Model J-500A spectropolarimeter. The experimental spectra were digitized and simulated by a set of Gaussians, using a least squares approach.[2] In all cases, quite good agreement with the experimental curves were obtained. From the Gaussians, the rotational strengths of the transitions (R_i, in Debye Bohr magnetons) were obtained by eq. [1], where Δ_e is half the band width at $\varepsilon = \Delta\varepsilon_{max}/e$.

[1] $$R_i = 0.4389\Delta\varepsilon_{max}\Delta e/\lambda_{max}$$

X-ray crystallography

Intensity data were collected at room temperature on a Siemens SMART (14) CCD diffractometer using a Rigaku rotating anode generator. The data collection covered, nominally, a hemisphere of reciprocal space, $\Theta_{max} = 46.5°$. Three

sets of exposures were taken, each with a different ϕ setting, and each exposure covered 0.3° in ω. The data reduction was performed by the program SAINT (15).

Space group $P3_2$ was assigned on the basis of the three-dimensional intensity distribution, the systematic extinctions, and the value of the absolute structure parameter. Cell dimensions were refined using the the spot positions determined from the data frames. SHELXTL[3] was used for the full-matrix least-squares structure refinement based on F^2. The final residual electron density was between 0.21 and –0.11 e/Å^3. A summary of the crystal data and structure refinement is given in Table 1.

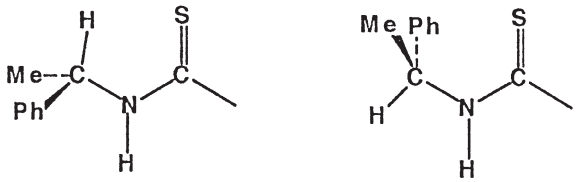
Calculations

The empirical force-field calculations were performed with the MacMimic implementation[4] of the Allinger MM2–91 force field (16).[5] The atomic charges used were obtained by the semiempirical AM1 method (17). Nonstandard force-field parameters related to the thioamide group have been summarized earlier (18), and the small number of new parameters required for the thiourea group are available from the authors on request. The standard length of the C═S bond was changed from 162.6 pm, applicable for simple thioamides, to 169.2 pm as found in the crystal structure of **1** (vide infra).

The minimum energy conformations were found by systematic driving of the 1-phenylethyl groups and by energy minimization starting from a large number of feasible starting geometries, including a variety of torsion angles with respect to the phenyl groups.

CNDO/S calculations were performed with a program based on the original Jaffé formalism but modified for sulfur compounds by Pfister-Guillouzo and co-workers (19). Two-center repulsion integrals were calculated by the Nishimoto–Mataga formalism (20), and configuration interaction was performed with the 20 lowest singly excited states. Inclusion of a larger number of configurations was considered unnecessary, since it has only a moderate effect on the calculated transition energies and oscillator strengths, and it complicates the analysis of the transitions in terms of molecular orbitals.

Scheme 2.



Za *Zb*

Theoretical calculations of the CD spectra were performed with the matrix technique devised by Schellman and co-workers (21–24). This method allows the use of the one-electron (Condon) (25), magnetic–electric coupling ($m\mu$) (26, 27), and coupled oscillator (Kirkwood) (28, 29) mechanisms. The required input is transition energies strengths and directions of electric and magnetic transition dipoles, transition monopoles and quadrupoles, and static charges. The methods for derivation of these data have recently been summarized (30). The input data for the thiourea chromophore are shown in Table 2 and those for the 1-phenylethyl group are taken from ref. 13.

Results and discussion

Conformations, crystal structure, and NMR spectra

A qualitative survey of the 10 conformations of **1** shown in Scheme 1 leads to the conclusion that several of them must be too high in energy to be considered as contributing significantly to observed spectra. No *E*,*E* forms have ever been observed in NMR spectra of *N*,*N*′-dialkylureas or -thioureas, which is explained by the steric repulsion between the alkyl groups. The same effect leads to the considerable nonplanarity found for tetramethylurea and -thiourea (31). Therefore, all *E*,*E* forms are neglected in the forthcoming discussion.

In previous studies of *N*-1-phenylethyl-thioamides (10, 13, 32) it was observed that 1-phenylethyl groups oriented *Z* to the thiocarbonyl group (Scheme 2) prefer the conformation (*Za*) in which the methine hydrogen points in the direction of the C═S group to the conformation (*Zb*) in which the phenyl group approaches the sulfur atom. This preference is not reproduced by force-field calculations in which the electrostatic

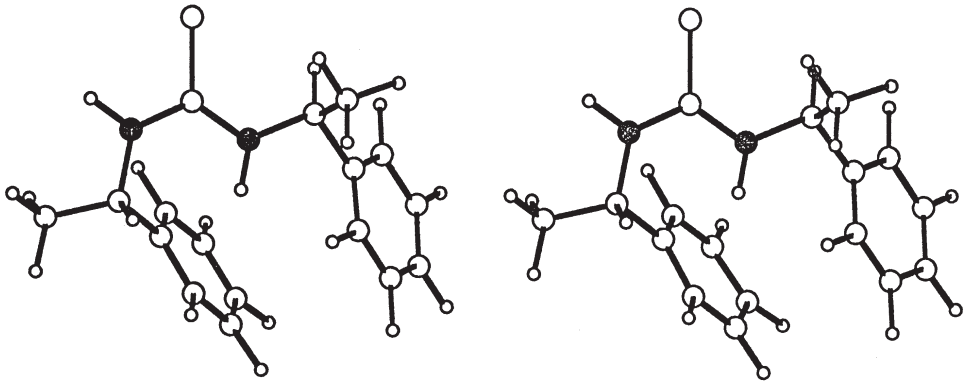

Fig. 2. Stereo picture of the unit cell of **1**.

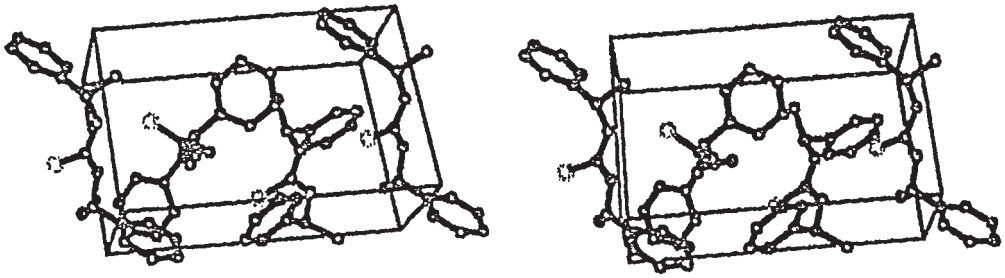

interactions are treated by the dipole model, while use of the point charge model (see ref. 16, p. 195) gives more realistic results (10). In our qualitative survey, this leads to the exclusion of *Z*,*Zb* and *Z*,*Zc* as important conformers. Similarly, the *E*,*Za* and *E*,*Zb* forms have to be considered, while *E*,*Zc* and *E*,*Zd* can be neglected.

As shown in Table 3, these qualitative deductions are corroborated by force-field calculations already by use of the dipole model. With the point charge model, the *Zb* type conformations do not appear as energy minima, but the energy minimization (Table 3) proceeds to *Za* type conformations. According to the calculations, which apply to isolated molecules, the *E*,*Za* and *E*,*Zb* forms are predicted to be much favoured. An analysis of the force-field contributions to the strain energy reveals that the *E*,*Z* forms are favoured in particular by a large number of small attractive van der Waals interactions. The other contributions are very similar for the *E*,*Z* and *Z*,*Z* forms.

The phenyl groups in the *E*,*Za* and *E*,*Zb* forms seem to be attracted by the atoms in the opposite half of the molecule. This leads to short $C_{ipso}\cdots H(\text{-}N)$ distances, *r* in Table 4, down to 219 pm in the *E* part of *E*,*Za*. This attraction leads to rotation of the 1-phenylethyl group out of the ideal bisected conformation (Fig. 1). It should be noted that the *E* phenyl groups approach the thiourea plane from opposite sides in *E*,*Za* and *E*,*Zb*, which has consequences for the predicted signs of the CD bands (vide infra).

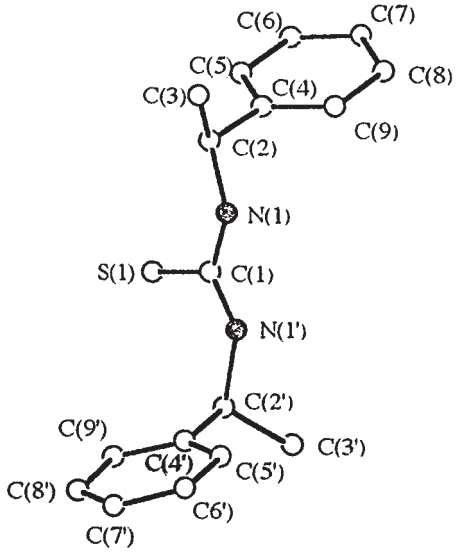
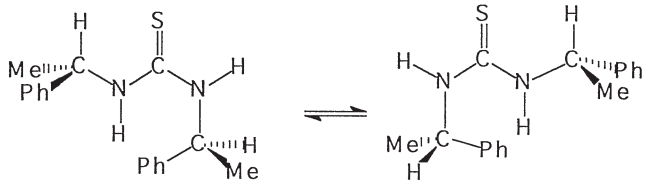
E,*Zb*	–17.7	5.87	225	179.1	8.85	267

[a] The *E* distance is measured from C_{ipso} in the *E* part to (N-)H in the *Z* part, the *Z* distance from C_{ipso} in the *Z* part to (N-)H in the *Z* part.

Scheme 3.



Scheme 4.



The angles called Φ_1 and Φ_2 (see Table 3) have rather high negative values in the *Za* forms (Fig. 1), i.e., the methine protons are rather far from eclipsing the C═S group (Table 4).

However, it was found in a study of *N*-(1-phenylethyl)-thiazoline-2-thiones (32) that the dominant conformer is of *Za* type, but that this corresponds to two conformers with similar energy, one with positive and one with negative Φ_1. A force-field exploration of the *Z*,*Za* region of **1** with positive values for Φ_1 and (or) Φ_2, using the dipole model, reveals further minimum energy conformations, denoted *Z*,Za_1 and *Z*,Za_2 in Table 3. However, these conformations have quite high energies, and when the point charge model is used, they revert to the *Z*,*Za* form.

The energy hypersurface with respect to variations in the *Z* part show several close-lying shallow energy minima with Φ_1

[a] Shoulder.
[b] Negative minimum.

values varying from ca. –20 to ca. –45°, constituting what may be referred to as a *Z*,*Za* "family."

In a protic and (or) basic solvent **1** can be expected to be involved in hydrogen bonding with solvent molecules and with other thiourea molecules both at the C═S and the NH groups, and this may change the populations considerably, but also under such circumstances only the conformations of *Z*,*Za*, *E*,*Za*, and *E*,*Zb* type need to be considered.

The conformation of **1** in the crystal (Scheme 3) was found to be of the *Z*,Za_1 type but without a C_2 axis. The molecules in the crystal form an infinite chain along the *c* axis with bifurcated hydrogen bonds between the sulfur atom in one molecule and the two NH protons in one of the neighbouring molecules (Fig. 2). The corresponding S···N distances are 341.6 and 354.2 pm, quite similar to the S···N distances related to bifurcated hydrogen bonds (335–343 pm) found in a neutron-diffraction study of thiourea (33). Crystal structures for a number of symmetrical *N*,*N*′-disubstituted thioureas have recently been reported. *N*,*N*′-diphenylthiourea (34) was found to have the *Z*,*Z* conformation with bifurcated hydrogen bonds similar to those in **1** but with C_s symmetry, while *N*,*N*′-diethyl- (34), -diisopropyl- (34), bis(2-chlorophenyl)- (35), dibenzyl- (36), and dicyclohexyl-thiourea (36) take up the *E*,*Z* conformation. The preference for this latter conformer in the crystals is ascribed to the formation of hydrogen-bonded cyclic dimers.

The C(1)-N(1)-C(2)-C(3), C(1)-N(1)-C(2)-C(4), C(1)-N(1′)-C(2′)-C(3′), and C(1)-N(1′)-C(2′)-C(4′) dihedral angles in the crystal of **1** are +126.1, –108.4, +143.5, and –91.5°, respectively. (The numbering of the heavy atoms follows from Scheme 3, and the hydrogen atoms are numbered as the attached heavy atoms.) Thus Φ_1 and Φ_2 have approximative values of +9 and +26°, to be compared with the negative dihedral angles predicted by the force-field calculations (Table 3). Pertinent bond lengths and angles are found in Table 5.

The ^{1}H NMR spectrum of **1** in chloroform-*d* solution at ambient temperature displays a doublet for the methyl protons at δ 1.42, a broad resonance for the methine protons at δ 4.95, and a similar resonance for the NH protons at δ 6.02. The aromatic resonance consists of one broad singlet (4H) at δ 7.0 and another (6H) at δ 7.2. When the temperature is lowered, the signals broaden and split. The methyl resonances appear at –40°C as two doublets of equal intensity at δ 1.37 (J = 6.8) and δ 1.48 (J = 6.4 Hz), the methine resonances as two multiplets, nearly quintets, at δ 4.50 (J = 3.0 and 6.4 Hz) and δ 5.39 (J = 6.8 and 8.0 Hz). The NH resonance splits into two doublets, at δ 5.68 (J = 8.0 Hz) and at δ 6.93 (J = 3.0 Hz). The high-field 4H aromatic resonance also splits. Part of it apprears as a doublet (2H) at δ 6.47 (J = 7 Hz), while the remainder is hidden in a 5H multiplet in the range δ 7.30–7.40. Besides, a 3H multiplet appears in the range δ 7.05–7.10.

This NMR spectrum can only be interpreted in terms of the complete dominance of one or more *E*,*Z* conformers, in the latter case rapidly equilibrating. The assignment of the chemical shifts shown in Fig. 4 is based on the following arguments: it has been observed in several studies (37–39) that the resonances of methine protons in *N*-alkylthioamides, which nearly eclipse the thiocarbonyl group, appear at unusually low field. Therefore the methine proton with the low-field shift δ 5.39

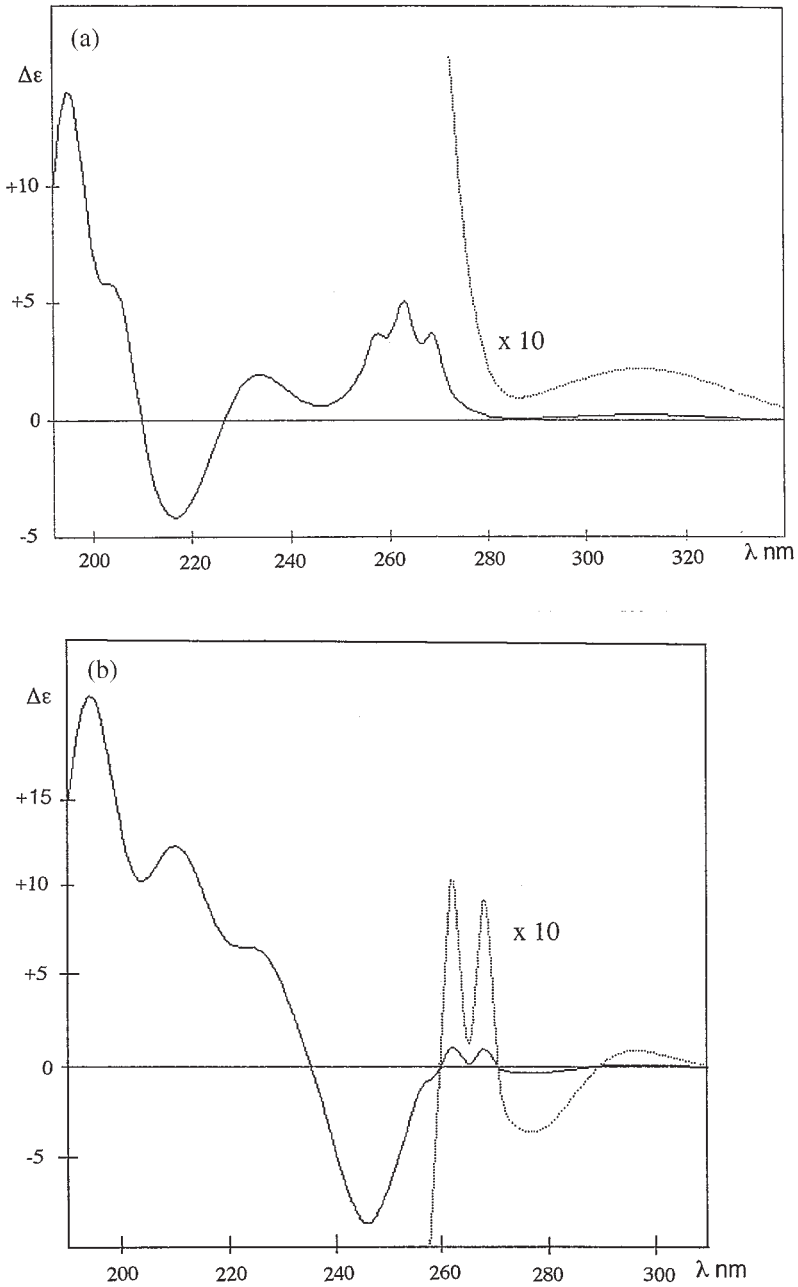
Fig. 5. (*a*) The CD spectrum of **1** in cyclohexane; (*b*) the CD spectrum of **1** in methanol.



must be in a *Za* type 1-phenethyl group and nearly eclipse the thiocarbonyl group, which makes *E*,*Za* and *E*,*Zb* the prime candidates in the detailed conformational analysis. The couplings to this proton identify the corresponding methyl and NH protons. The vicinal HN–CH coupling constant is 8 Hz in the *Z* part and only 3 Hz in the *E* part. This kind of coupling has been much studied in peptides (40–42), and Demarco et al. (42) have proposed a version of the Karplus equation (eq. [2]), which describes ^3J(H-C_α-N-H) as a function of the dihedral angle α for a number of ferrichrome peptides reasonably well. Using this, equation and geometries for the conformers in Table 3,

[2] $$^3J(\alpha) = 5.4 \cos^2 \alpha - 1.3 \cos \alpha + 2.2 \text{ (Hz)}$$

α-values and ^3J values have been found for the relevant conformers (Table 4). The agreement between experimental and calculated ^3J values is much better for *E*,*Za* than for *E*,*Zb*. Consequently, the ^3J(H-C_α-N-H) values support the conclusion that the *E*,*Za* conformer dominates in chloroform and similar solvents.

The resonance of two aromatic protons (*ortho* protons according to the doublet structure with $J = 7$ Hz) falls at an unusually high field (δ 6.47). The *E* phenyl group falls in the shielding region of the thiocarbonyl group (37) both in the *E*,*Za* and the *E*,*Zb* conformation, as follows from the short (N-)H···C_{ipso} distances (Table 4).

The temperature-dependent broadenings observed are in agreement with those expected for an *E*,*Z* –*Z*,*E* exchange (Scheme 4), and complete band-shape analysis (43) of the

methyl resonance at intermediate broadening leads to a free energy barrier to this exchange of 12.8 ± 0.1 kcal mol^{-1}. This agrees well with the barrier found for *N*,*N*′-dimethylthiourea: 12.5 kcal mol^{-1} in CD_3CN (7), 12.7 kcal mol^{-1} in pyridine-d_5 (6). The lower barrier, 11.1 kcal mol^{-1}, found for *N*,*N*′-di-*tert*-butylthiourea (7, 44) can be ascribed to ground-state strain.

The ^{1}H NMR spectrum of **1** in methanol-d_4 solution at ambient temperature shows only one methyl doublet, one broad methine resonance, and a narrow aromatic multiplet. The NH resonance coincides with the water signal, possibly because of fast exchange. On lowering the temperature, broadenings and splittings occur, but because of overlap with the solvent peaks and lack of fine structure, fewer resonances can be observed and identified at slow exchange than in chloroform-*d* solution. The methyl resonance appears as a single broad signal at –38°C, but the methine proton resonance appears split into two equally intense resonances at δ 4.94 and δ 5.59 and a single resonance at δ 5.53.The first two correspond to the *E*,*Z* form observed alone in chloroform-*d* solution, an assignment which is corroborated by NH signals at δ 5.36 and 7.05 and an aromatic 2H resonance at δ 6.63. The single methine resonance at δ 5.53 has a corresponding NH signal at δ 7.00, and these signals must be assigned to a conformer with C_2 symmetry. The low-field position of the methine resonance makes *Z*,*Za* the only likely candidate. The *Z*,*Z*:*E*,*Z* ratio is found to be 1.23:1.

Infrared, ultraviolet, and circular dichroism spectra

The infrared spectrum of **1** in the solid state (KBr tablet) shows NH stretching bands at 3235 and 3254 cm^{-1}, in agreement with the existence of two unequally hydrogen bonded NH groups in the crystal. In 10^{-2} M solution in chloroform-*d* likewise two bands appear, now at 3390 and 3416 cm^{-1}. Walter and Ruess (7, 45) have made an extensive study of the infrared spectra of mono- and symmetrically dialkyl-substituted thioureas, using 10^{-3}–10^{-5} M solutions in carbon tetrachloride. They assign a band at ca. 3450 cm^{-1} to the NH stretching in the *Z* oriented *N*-alkylamino group and another at ca. 3420 cm^{-1} to the *E* counterpart. However, in the spectrum of *N*,*N*′-bis(α,α-dimethylbenzyl)-thiourea, the former band is shifted to 3387 cm^{-1}, which is ascribed to the formation of an intramolecular "hydrogen bond" in the *E*,*Z* conformer (Fig. 5). This interpretation is evidently applicable also to **1** in chloroform-*d* solution for which a dominant *E*,*Za* conformer is inferred from NMR data.

The thioureas discussed above are undoubtedly largely monomeric at the reported measuring concentrations. Dunina et al. (46) report IR bands at 3250, 3400, and 3430 cm^{-1} in the infrared spectrum of **1** in a saturated $CHCl_3$ solution ($C \approx 0.15$ M). The 3250 cm^{-1} band is ascribed to an intermolecularly hydrogen-bonded species, and it disappears at 10-fold dilution. As mentioned below, the CD spectrum of **1** in chloroform and dichloromethane solution is independent of the concentration in the range 10^{-2}–10^{-4} M, which also supports the notion that **1** is largely unassociated in these solvents at concentrations of 10^{-2} M and lower.

Ultraviolet spectra of thiones and in particular of thioamides have been the subject of interest for a long time, among other things because they can be expected to show similarity with the oxygen analogues, albeit with the thione transitions giving rise to absorption bands at longer wavelengths and thus in more accessible spectral regions (47, 48). Thioureas have been studied by among others Janssen (49, 50), Hosoya et al. (51), Gosavi and Rao (52), and Ritchie and Spedding (53). Three bands are observed in the spectra of simple thioureas: a weak band at 280–300 nm, a strong band (ε = 10 000–12 000) at 236–250 nm, and a band of similar intensity at 195–210 nm. We will designate these three bands as due to transitions A, B, and C, respectively. Transition A is assigned to an *n*→π* transition (49, 51, 53). Analysis of transitions B and C by MO theory (51, 53) led to the classification of transition B as a regular π→π* transition, and transition C as a charge transfer transition of π→π* type in which an electron is excited from an MO described as the antisymmetric combination of the nitrogen *p* orbitals to a MO antibonding in the C═S bond. Polarized UV spectra of a thiourea crystal showed that transition B is polarized in the direction of the C_2 axis and transition C perpendicular to this direction and in the molecular plane, in agreement with the MO analysis (51).

Our CNDO/S calculations predict a forbidden *n*→π* transition at 371 nm, a π→π* transition at 271 nm (f = 0.122) polarized along the C═S bond, and another π→π* transition at 172 nm (f = 0.139) polarized perpendicular to the C═S bond. Analysis of the dominant MO:*s* involved in these

© 1998 NRC Canada

transitions shows a complete agreement with the conclusions reached for transitions B and C by the previous authors (51, 53).

The UV spectrum of **1** should be the result of overlap of the A, B, and C transitions with the aromatic ^1L_b, ^1L_a, ^1B_b, and ^1B_a transitions (54). The experimental UV spectrum (Table 5) does not display a $n\rightarrow\pi^*$ band even in cyclohexane solution. The first strong band, assigned to the B transition, appears at 259 nm in cyclohexane, at 251 nm in acetonitrile, and at 245 nm in ethanol. At shorter wavelengths shoulders appear at 215 and 205 nm, less sensitive to the solvent.

The CD spectra of **1** are quite complex and strongly solvent dependent. The spectrum in cyclohexane (Table 6 and Fig. 5*a*) shows a broad, weak positive band at 311 nm assigned to the $n\rightarrow\pi^*$ transition (transition A), followed by a stronger broad and positive band at 262 nm overlapped by three sharp positive bands of lower intensity with separations of 6 nm. The stronger band is assigned to transition B, and the three weaker bands to the aromatic ^1L_b transition. Next follows a positive band at 232 nm, tentatively assigned to the C transition. A negative band appears at 217 nm and a moderately strong positive one at 205 nm, and since model calculations indicate considerable couplings between the transitions in the aromatic rings in some conformations, the two latter bands may be seen as a negative ^1L_a couplet. A stronger positive band at 197 nm is assigned to a ^1B type transition.

Addition of a small amount (5% by volume) of dichloromethane to the cyclohexane solution does not affect the signs of the bands, but the $n\rightarrow\pi^*$ band is shifted to 297 nm and its intensity is increased nearly fourfold. In pure dichloromethane solution this development is further accentuated. In this solvent, the CD spectra at $C = 10^{-2}$ M and $C = 10^{-4}$ M are quite equal, which supports the notion that no dimerization occurs in this concentration range.

In chloroform solution only the $n\rightarrow\pi^*$, the first ^1L_b and the beginning of the B band can be observed. They have the same signs as in cyclohexane and dichloromethane solution, but the $n\rightarrow\pi^*$ band is now still stronger.

In methanol (Fig. 5*b*) and ethanol solutions two bands are observed in the 270–300 nm region, which are resolved into a weak positive band at 295 nm and a stronger negative one at 277 nm, both probably of $n\rightarrow\pi^*$ origin. The ^1L_b bands are unchanged but the stronger band B is now negative and shifted to 246–247 nm, and the following two bands are positive. This means that the ^1L_b and C band have the same signs in cyclohexane–dichloromethane and methanol–ethanol solutions but that the B band has opposite sign. The bands at 210 and 195 nm are both positive, and no couplet is observed in the ^1L_a region. The CD spectrum of **1** in methanol has been described earlier (55), but this spectrum differs in important respects from the one reported here.

The spectrum in acetonitrile is quite similar to those in methanol and ethanol, the main difference being that only one (positive) $n\rightarrow\pi^*$ band is observed and that the ^1L_b bands (positive) are unusually strong.

Dilution of the ethanol solution with water leads to the replacement of the negative $n\rightarrow\pi^*$ band by a positive band at 285 nm, the intensity of which increases with increasing concentration of water. The remainder of the spectrum is less affected by the water.

Rotational strengths for the relevant conformers of **1** (*Z*,*Za* with a selection of Φ_1 and Φ_2 values, *E*,*Za* and *E*,*Zb*) have been calculated using the geometries from the MM2 calculations and are presented in Table 7 together with the experimental data from spectra in cyclohexane and methanol solution, derived by use of eq. [1] (experimental section). The conformer, which dominates in cyclohexane, should give rise to positive A, B, C, and ^1L_b transitions, a negative ^1L_a couplet, and a positive long-wavelength band in the ^1B system. Inspection of Table 7 reveals that these conditions are fulfilled by the *E*,*Za* conformer, but not by any of the others. The predicted magnitudes of the A, B, and ^1L_b rotational strengths are of the same order of magnitude as the experimental ones, whereas the values predicted for the C,^1L_a, and ^1B transitions are vastly exaggerated. This deviation may be qualitatively explained by the low value for the dielectric constant, 1.5, used in these calculations. In any case, the agreement in sign is impressive and lends strong support to the conclusion from NMR spectra that the *E*,*Za* conformer dominates in nonpolar solvents.

The appearance of two bands of $n\rightarrow\pi^*$ type in the CD spectrum of **1** in methanol solution indicates the presence of more than one conformer, in agreement with the NMR results. Of all conformers in Table 7, only *Z*,*Za* with $\Phi_1, \Phi_2 = +17°$ (*Z*,Za_1 type) is predicted to have a negative $n\rightarrow\pi^*$ band. This conformer is similar to the one found in the crystal but idealized to C_2 symmetry, and it may owe its stabilization to favourable hydrogen bonding to solvent molecules. Such bonding evidently involves profound changes in the steric conditions around the NH and C═S groups, and conformers predicted on basis of MM2–91 calculations without solvent must be used with reserve.

The dominant conformer in ethanol should have positive ^1L_b bands and a negative B band, a combination only shown by *Z*,*Za* with $\Phi_1, \Phi_2 = +17°$. It should also have a positive C band, which is predicted for all five conformers. The methanol spectrum displays only one band, positive, in the ^1L_a region, which is not in complete agreement with the predictions for *Z*,*Za*, although the first ^1L_a band is predicted to be positive, as is the first 1B band.

The weak positive $n\rightarrow\pi^*$ band can be assigned to an *E*,*Z* conformer, which was also concluded from the NMR spectrum, but it must not necessarily be *E*,*Za*. The spectrum shows no sign of a positive B transition, which rather speaks for *E*,*Zb* for which a negative B transition is predicted.

The effect of adding water to an ethanol solution, the appearance of a gradually growing positive $n\rightarrow\pi^*$ band, is less readily explained. Replacement of methanol–ethanol by water around the NH and CS groups may change the steric conditions and favour *Z*,*Za* forms with different Φ_1 values. It follows from Table 7 that positive $n\rightarrow\pi^*$ bands are predicted for *Z*,*Za* forms with Φ_1 and Φ_2 equal to –35° and –45°, respectively, but no safe conclusion can be drawn.

Conclusions

Studies of **1** with ^1H NMR, IR, and CD spectroscopy in conjunction with semiempirical calculations of steric energies and rotational strengths show conclusively that the *E*,*Za* conformer dominates in nonpolar solvents. In hydroxylic solvents the equilibrium is shifted towards the *Z*,*Za* "family," and the form(s) dominating in methanol and ethanol may have $\Phi_1, \Phi_2 > 0$. The further changes in the CD spectrum caused by addition

© 1998 NRC Canada

of water to an ethanol solution may be ascribed to changes in Φ_1 within the *Z,Za* "family."

Acknowledgments

We are grateful to the Swedish Natural Science Research Council, the Knut and Alice Wallenberg Foundation, and the Royal Physiographic Society of Lund for for financial support, to Dr. Karl-Erik Bergquist for recording the NMR spectra, to Dr. Ulf Berg for performing the AM1 calculations, and to Dr. Åke Oscarsson for valuable discussions.

Identity-reaction proton transfers from nitrogen acids yielding localized vs. delocalized conjugate bases. An ab initio study

James E. Van Verth, William H. Saunders, Jr., and Thomas W. Kermis

Abstract: Identity-reaction proton transfers from a series of nitrogen acids to the corresponding conjugate bases have been studied by ab initio methods at the MP2/6-31+G*//MP2/6-31+G* level. The acids are NH_4^+, $H_2NNH_3^+$, $CH_3NH_3^+$, CH_2NH_2, $OCNH_2^+$, $OCHNH_3^+$, $H_2NCHNH_2^+$, $HNCHNH_3^+$, NH_3, CH_3NH_2, CH_2NH, OCNH, $OCHNH_2$,and $HNCHNH_2$. Gas-phase acidities were calculated at the G2(MP2) level where experimental values are not available in order to have benchmark values for all acidities. Barriers to proton transfer relative to the separated reactants, ΔH_{TS}, show a straight-line relation to acidity for all of the neutral acids and for all but four of the cationic acids. Three show ΔH_{TS} values well above the line: $HNCHNH_3^+$, $OCNH_2^+$, and $OCHNH_3^+$, in increasing order of positive deviation. One shows a small negative deviation: $H_2NNH_3^+$. The first three acids have localized π systems but can yield delocalized transition structures and conjugate bases. The barriers result from a lag in delocalization relative to proton transfer in the transition structures. All of the other acids give transition structures that can only be localized, or if they can be delocalized they prefer to adopt conformations in which the unshared pair on nitrogen delocalizes rather than the electrons of the N---H bond. The negative deviation for $H_2NNH_3^+$ is attributed to polarizability of the NH_2 group.

Key words: ab initio, nitrogen acids, proton transfer, acidity.

Résumé : Faisant appel à des méthodes ab initio au niveau MP2/6-31+G*//MP2/6-31+G*, on a étudié les réactions d'identité par transfert de proton d'une série d'acides azotés vers les bases conjuguées correspondantes. Les acides étudiés sont le NH_4^+, $H_2NNH_3^+$, $CH_3NH_3^+$, $CH_2NH_2^+$, $OCNH_2^+$, $OCHNH_3^+$, $H_2NCHNH_2^+$, $HNCHNH_3^+$, NH_3, CH_3NH_2, CH_2NH, OCNH, $OCHNH_2$ et $HNCHNH_2$. Dans les cas où les valeurs expérimentales des acidités ne sont pas disponibles, on a calculé les acidités en phase gazeuse au niveau G2(MP2) afin de disposer de valeurs de référence pour toutes les acidités. Les barrières au transfert de proton par rapport aux réactifs séparés, ΔH_{TS}, présentent une relation linéaire avec l'acidité pour tous les acides neutres ainsi que pour tous les acides cationiques à l'exception de quatre. Trois présentent des valeurs de ΔH_{TS} bien au-dessus de la ligne; il s'agit dans l'ordre d'augmentation de la déviation de $HNCHNH_3^+$, $OCHNH_2^+$ et $OCHNH_3^+$. Le $H_2NNH_3^+$ présente une légère déviation négative. Les trois premiers acides possèdent des systèmes π localisés, mais peuvent conduire à des structures de transition délocalisées et à des bases conjuguées. Les barrières résultent d'un retard dans la délocalisation relative au transfert de proton dans les structures de transition. Tous les autres acides conduisent à des structures de transition qui ne peuvent qu'être localisées ou, si elles peuvent être délocalisées, elles préfèrent adopter des conformations dans lesquelles la paire d'électron non partagés de l'azote se délocalise plutôt que les électrons de la liaison N---H. On attribue la déviation négative du $H_2NNH_3^+$ à la polarisabilité du groupe NH_2.

Mots clés : ab initio, acides de l'azote, transfert de proton, acidité.

[Traduit par la rédaction]

Introduction

Proton transfers to or from "normal" or Eigen acids usually occur at a diffusion-controlled (or close to diffusion controlled) rate when the proton transfer is exoergic (1). Slower deprotonation results when the reaction is endoergic, but essentially the only barrier is the endoergicity. Eigen acids are those in which the proton is bound to an electronegative atom such as nitrogen or oxygen. In contrast, carbon acids often deprotonate at much slower rates than Eigen acids of similar acidity. The factors contributing to these barriers have been examined in recent years by means of quantum-chemical calculations as well as experiment.

A clear distinction can be made between carbon acids that yield localized vs. delocalized conjugate bases. Although both, unlike Eigen acids, show significant barriers, the carbon acids yielding delocalized bases deprotonate more slowly than acids of similar acidity yielding localized bases. In general terms the need for heavy-atom reorganization during proton transfer is considered to raise the barrier to the reaction (2, 3). A more

rigorous treatment called the principle of nonperfect synchronization (PNS) has been proposed by Bernasconi (4–6). He argues that charge delocalization lags behind charge transfer from the base, and that the resulting lag in development of resonance stabilization contributes to the intrinsic barrier to proton transfer.

The validity of the PNS can be most easily tested if contributions from solvent reorganization can be eliminated and the intrinsic barrier determined directly by employing identity reactions. It is not easy to accomplish experimentally, but ab initio calculations are ideally suited to this end. Pioneering work by Scheiner and his co-workers on simple systems (7–10) was followed by studies that treated mainly carbon acids yielding delocalized conjugate bases (11–15). From these studies it was clear that, even in the absence of solvent, intrinsic barriers to proton transfers from such carbon acids are higher than expected from their acidity. Furthermore, the charge distributions in the transition structures show that charge delocalization lags well behind proton transfer.

With these results in mind, a natural question to ask is whether the PNS would apply to Eigen acids as well as to carbon acids. Published work provides no guidance on this point. Identity reactions involving a number of neutral and positively charged nitrogen acids have been examined, but none of them has a delocalized conjugate base. The most extensively studied has been the ammonium ion to ammonia proton transfer (16). At the highest levels there is only a small barrier (ca. 1 kcal). The ammonia to amide ion proton transfer has also been studied by several groups (17). Again, the barrier is small (1.2 kcal using the G2+ method (17*b*)). Only a few examples could be found in which other nitrogen acids were used: simple alkylammonium ions to amines (16*e*); CH_2═NH to CH_2═N- (18); and CNH to NC- (19). In these cases the barriers were either small or negligible. There is thus little doubt that nitrogen acids with localized conjugate bases behave as Eigen acids.

Computational procedures

Ab initio calculations utilized the Gaussian 92 (20) and Gaussian 94 (21) programs with the standard basis sets 6-31+G* and 6-31+G** (22). Correlation corrections utilized the Møller–Plesset method (23). The enthalpies (ΔH) in the tables are corrected to constant pressure and, for zero-point-energy differences from MP2/6-31+G*//MP2/6-31+G* calculations, scaled to 0.95 to account for the overestimation of frequencies by Hartree–Fock methods (24). Enthalpies were further corrected to 298 K for the contributions of the translational, rotational, and vibrational partition functions (25). The vibrational correction is not based on scaled frequencies, for it is doubtful that low-lying frequencies (the only ones that contribute significantly to the vibrational partition function) bear a predictable relation to experimental values (26). Although many of the calculations were done up to the MP4SDTQ(frozen core)/6-31+G**//MP2/6-31+G* level, the results did not differ much from the complete set done at MP2/6-31+G*//MP2/6-31+G*, so only the latter are reported in Table 2. Where different stable conformations of a species are possible, the most stable one is listed in the tables. All reasonable conformations of reactants and transition structures were, however, optimized. In nearly all cases, the energy difference between the most stable and the next most stable conformation was large enough that the latter should make no significant contribution. No effort was made to locate all possible conformations of the ion–dipole complexes. Our experience with carbon acids has been that the complexes have several conformations very close in energy and easily interconvertible (11, 14). Since the energies of the complexes in the present context are useful only for establishing the magnitude of the central barrier, they were usually not explored exhaustively.

Z matrices of optimized structures in Cartesian or internal coordinates have been deposited as supplementary material.[2]

Results and discussion

As has been our practice, we compared calculated and experimental (27) gas-phase acidities to test the adequacy of the level of our calculations. The results are given in Table 1. There appear, unfortunately, to be no experimental data for the cationic acids except ammonium ion, where the agreement is excellent at all levels. Calculations by the G2(MP2) method (28) were done where experimental values were not available so as to provide benchmark values for all of the acids. In one case, the symmetrical formamidinium ion, a value was already available in the literature (29). There is only one bad disagreement among the neutral acids, HNCO. The G2(MP2) value is close to the experimental value, however, so the disagreement with values at lower levels is undoubtedly real. Comparison of the results at MP2/6-31+G*//MP2/6-31+G* with the benchmark values shows that the former are usually lower than the latter, but the difference exceeds 5 kcal mol^{-1} in only two cases. The agreement in the case of these nitrogen acids is not as good as for carbon acids (30), but is adequate for the semiquantitative purposes of our proton-transfer calculations.

Stationary points calculated for the identity-reaction proton transfers at MP2/6-31+G*//MP2/6-31+G* are given in Table 2. Enthalpies are relative to the separated reactants except as otherwise noted. Not all ion–dipole complexes were calculated. All of the proton transfers showed potential energy barriers with imaginary frequencies ranging from 600 to 1416i cm^{-1}. The frequencies ran higher for the neutral acids (839–1416i cm^{-1}) than for the cationic acids (600–1193i cm^{-1}). With exceptions to be discussed below, the enthalpic barriers, $\Delta H^{\ddagger}$, were small or even negative relative to the ion–dipole complexes, where these were calculated. The N···H bond lengths in the transition structures were relatively constant, from 1.26 to 1.30 Å for the positively charged acids and 1.25 to 1.31 Å for the neutral acids.

The best way of looking at the transition structure enthalpies is relative to the enthalpies of the corresponding separated reactants, ΔH_{TS}, which avoids complications from specific interactions affecting the enthalpies of the ion–dipole complexes. We have previously shown that for carbon acids yielding localized conjugate bases a plot of ΔH_{TS} vs. ΔH(acid) gives a straight-line relationship (14). An analogous plot in Fig. 1 for the neutral nitrogen acids shows some scatter but no points that are off the line by more than a few kcal in ΔH_{TS}. In fact, the three acids that can yield delocalized conjugate bases,

[c] $H_{TS} - H$reactants.
[d] The ion–dipole complexes were not examined.
[e] A stable low-energy ion–dipole complex could not be found. A spontaneous proton transfer to give $H_2NCHNH_2^+$ occurs. See discussion.

$O{=}CHNH_2$, $HN{=}CHNH_2$, and O=C=NH, show no greater deviations from the line than those that cannot.

The situation is different for the cationic acids. Plots including all of the data points show substantial scatter. Five of the acids, however, define a good straight line, shown in Fig. 2. Three of the remaining acids, $HN{=}CHNH_3^+$, $O{=}CHNH_3^+$, and $O{=}C{=}NH_2^+$, show large positive deviations (6–16 kcal) from the defining line, and one, $H_2NNH_3^+$, shows a smaller negative deviation. The three acids showing positive deviations are precisely those that can yield delocalized conjugate bases. The first two are isoelectronic with acetaldehyde, whose identity-reaction deprotonation also occurs with a substantial barrier (11, 12, 14*a*). In these cases the substrate is localized but the transition structure and product can be delocalized. If delocalization in the transition structure lags behind the proton transfer, as predicted by the PNS, the large barriers can be understood. The situation is a little less obvious with $O{=}C{=}NH_2^+$. Here there can be no interaction between the orthogonal π orbitals of the allene-like system. In the transition structure, however, the electrons of the breaking N---H bond can interact with the π electrons of the C=O group, and the product can be resonance stabilized by an analogous interaction of the unshared pair left behind with the C=O π electrons:

The negative deviation from the line shown by $H_2NNH_3^+$ may arise from the polarizability of the amino-group unshared pair. We have shown previously that the barrier to deprotonation of XCH_3, where X is halogen, is smaller the more polarizable the halogen (14*b*).

Why do the three neutral acids that yield delocalized bases, $O{=}CHNH_2$, $HN{=}CHNH_2$, and O=C=NH, *not* show high barriers to deprotonation like those for the corresponding cationic acids? Part of the answer is that the acids themselves are

Fig. 1. Calculated barriers, ΔH_{TS}, vs. calculated acidity at MP2/6-31+G*//MP2/6-31+G* for neutral acids reacting with their anionic conjugate bases.

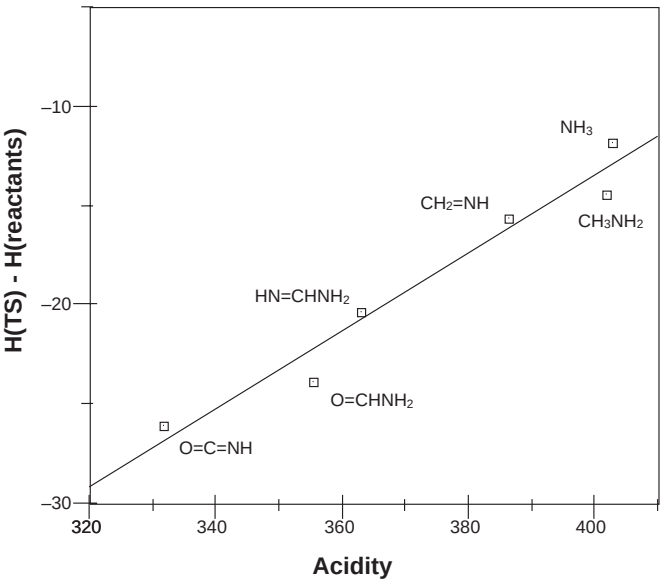

Fig. 2. Calculated barriers, ΔH_{TS}, vs. calculated acidity at MP2/6-31+G*//MP2/6-31+G* for cationic acids reacting with their neutral conjugate bases. Open squares, points included in least-squares fit; closed diamonds, outlying points.

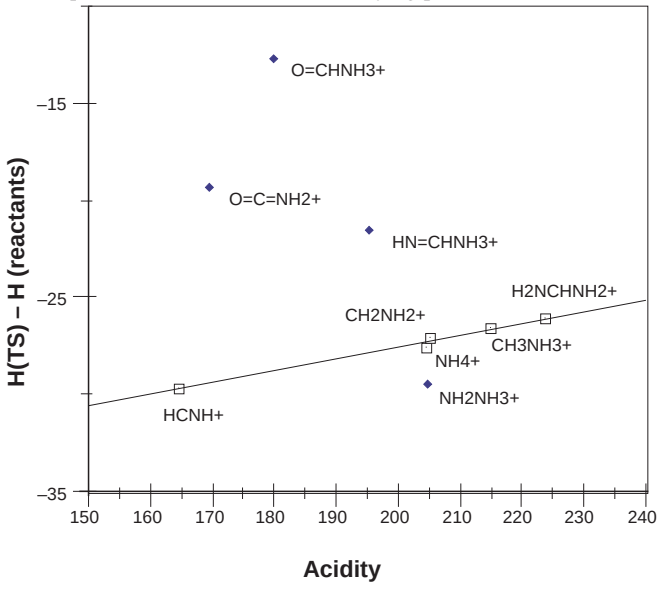

to a considerable degree delocalized. The resonance forms for OCNH are given above; those for the remaining two are

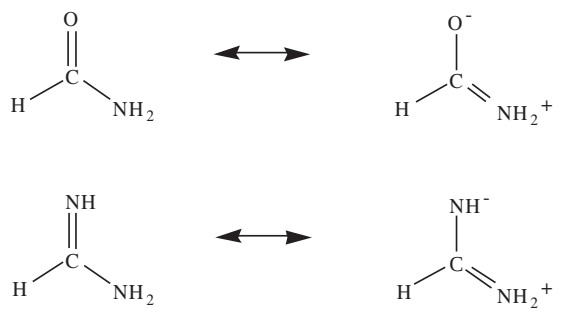

Fig. 3. Transition structures optimized at MP2/6-31+G*//MP2/6-31+G* for $HCONH_3^+$ reacting with $HCONH_2$ (*a*) and $HCONH_2$ reacting with $HCONH^-$ (*b*).

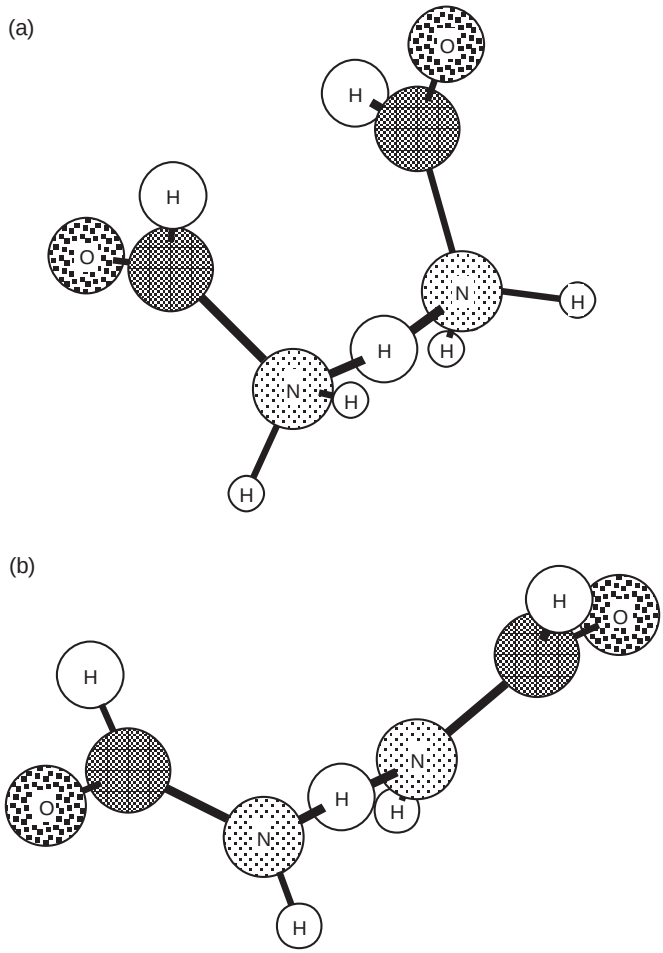

One possible rationalization would be that resonance stabilization is equal in the acid and its conjugate base and thus no delocalization occurs along the reaction coordinate. But there is another, and probably more important, reason for the low barriers shown by these three acids.

Examination of the transition structures shows clear differences between the cationic acids and the neutral acids. Figure 3*a* gives the transition structure for $HCONH_3^+ + HCONH_2$ and Fig. 3*b* the corresponding structure for $HCONH_2$ + $HCONH^-$. The first structure has the atoms aligned so that the N···H bonding electrons can interact with the C═O π orbitals. Thus the system is isoelectronic with and very similar to the transition structure of the $HCOCH_3$ + $HCOCH_2^-$ reaction, which was previously shown to possess a high barrier to deprotonation (11, 12). In contrast, the structure in Fig. 3*b* has the N---H bonding electrons in the N-C═O plane, which makes them orthogonal to and thus unable to interact with the C═O π orbitals. The principle of nonperfect synchronization (4–6) consequently applies to Fig. 3*a* but not to Fig. 3*b*.

Why should Figs. 3*a* and 3*b* be so different? There are two related reasons. In Fig. 3*b* there are unshared electrons on the two nitrogen atoms that can evidently interact more efficiently than the N---H bonding electrons with the C═O π orbitals. In addition, the system can in this way avoid the high-energy path

Fig. 4. Transition structures optimized at MP2/6-31+G*//MP2/6-31+G* for $HCNHNH_3^+$ reacting with $HCNHNH_2$ (*a*) and $HCNHNH_2$ reacting with $HCNHNH^-$ (*b*).

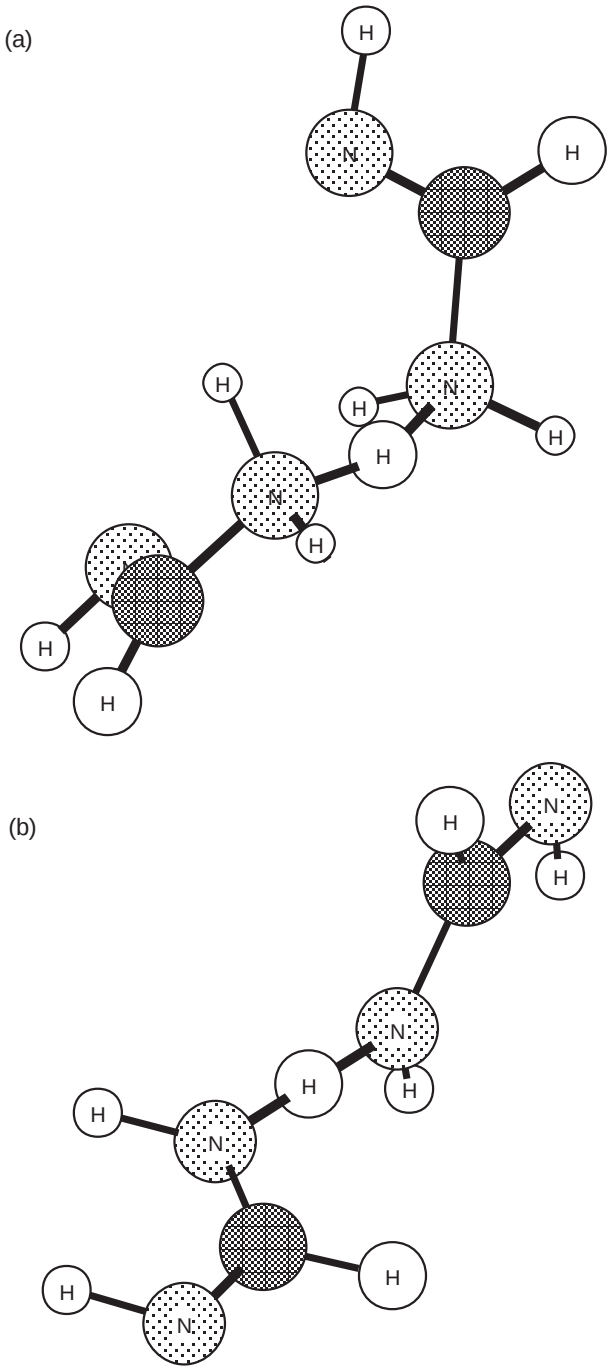

Fig. 5. Transition structures optimized at MP2/6-31+G*//MP2/6-31+G* for $OCNH_2^+$ reacting with OCNH (*a*) and OCNH reacting with OCN^- (*b*).

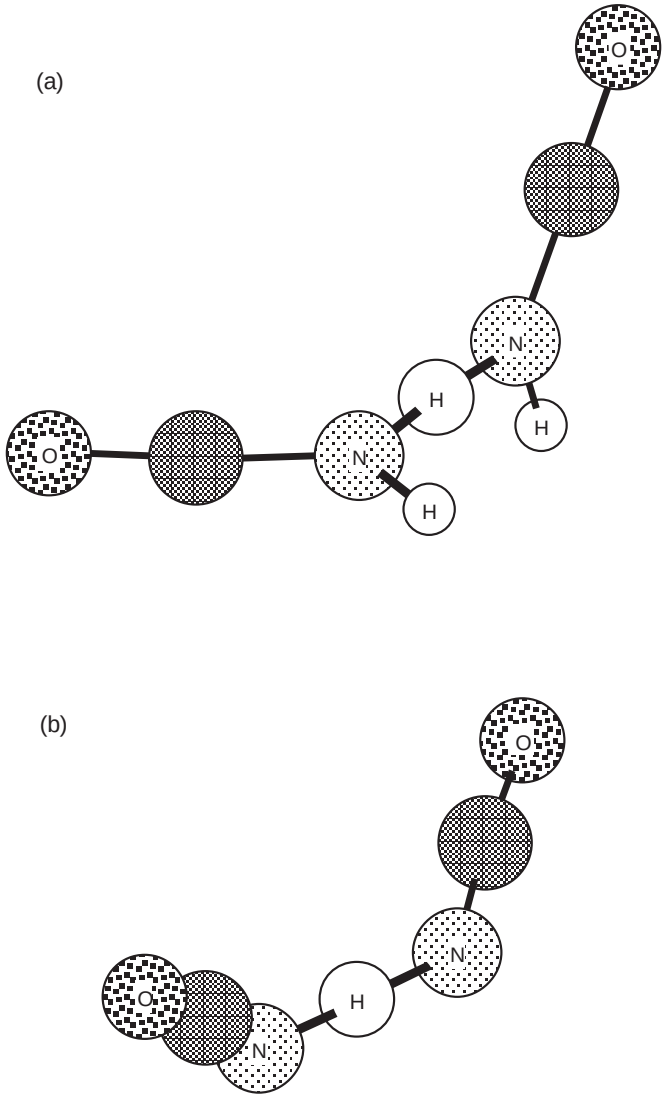

that results in Fig. 3*a* when the N---H electrons of the acid become only partly delocalized as the system proceeds along the reaction coordinate.

Figure 4 reveals an analogous situation in the comparison between the $HCNHNH_3^+$ + $HCNHNH_2$ (Fig. 4*a*) and the $HCNHNH_2$ + $HCNHNH^-$ (Fig. 4*b*) reactions. Again the N---H bonding electrons can interact with the C═N π electrons in Fig. 4*a* but cannot in Fig. 4*b* because the C═N π electrons are now orthogonal to the N---H bonding electrons. The reasons for this difference are clearly the same as in the case of Figs. 3*a* and 3*b*.

The situation is very similar but not completely analogous for the $OCNH_2^+$ + OCNH (Fig. 5*a*) and the OCNH + OCN^- (Fig. 5*b*) reactions. In Fig. 5*a* the N---H bonding electrons are in the H-N═C plane and thus able to interact with the π electrons of the C═O bond. In Fig. 5*b* it appears that the N---H bonding electrons could in principle interact with the C═O π electrons, but so can the unshared pair on nitrogen, and it evidently takes precedence. The structure in Fig. 5*b* shows more *sp* character at the nitrogen by virtue of an H---N═C angle of 146° compared to 123° in Fig. 5*a*. This provides further evidence for substantial delocalization of the unshared pair on nitrogen into the N═C bond in Fig. 5*b*.

The charge distributions in the transition structures also support the idea that the PNS applies to the reactions involving the cationic acids but not the neutral acids. For this purpose NPA (natural population analysis (31)) charges were used for reasons we have discussed previously (14*a*). Since charges are

© 1998 NRC Canada

influenced not only by π electron distributions but also by inductive effects, polarizabilities, and hybridization, an analysis that separates, as far as possible, π electron shifts from shifts due to these other factors is needed. If the PNS did not operate, π electron delocalization in the transition structure of an identity reaction should have proceeded exactly half way. Thus the shift of negative charge into the X of the donor species, XNH_2 or XNH_3^+,should be half completed in the transition structure and fully completed in the product. We therefore compare the change in q_x between the reactant acid and transition structure with the change between transition structure and the product base in Table 3.

Looking first at the reactions of neutral acids with anionic bases, we see that Δq(acid→ TS) and Δq(TS→ base) are close to each other, with a slight preference for the former to be somewhat larger than the latter. These small differences are in the opposite direction from those expected if the PNS were operating, because it predicts that electron shifts within the donor species should lag *behind* the extent of proton transfer. The reactions of cationic acids with neutral bases are definitely in accord with the PNS predictions, for in these cases Δq(acid→ TS) < Δq(TS→ base) for **3*a***, **4*a***, and **5*a*** (Figs. 3*a*, 4*a*, and 5*a*), and the differences are substantial in magnitude. Indeed, if the same factors that cause Δq(acid→ TS) > Δq(TS→ base) with the neutral acids operate, the actual π-electron differences with the cationic acids are even larger.

One would expect greater ionic character to the bonding in nitrogen acids than in carbon acids because nitrogen is more electronegative than carbon. The NPA charges for the cationic acids bear out this expectation. The proton in transit has a charge close to +0.5 in all cases. For the cationic acids this charge differs little (ca. ±0.01) from the charge on the proton in the acid. It does represent a significant increase from the charges on the protons in the neutral acids (+0.36 to +0.46). The neutral acids resemble the neutral carbon acids in this respect, where the charge on the proton goes from ca. +0.25 in the acid to +0.3 for the proton in transit. As an interesting aside, the intuitive picture most chemists have of the ammonium ion as a positive nitrogen surrounded by more or less neutral hydrogens is completely different from the NPA picture of four +0.5 hydrogens around a –1.0 nitrogen.

Of the three reactions that fall above the line in Fig. 2, only the proton transfer from $HCONH_3^+$ to $HCONH_2$ clearly shows a high central barrier, $\Delta H^‡$. A stable ion–dipole complex for $HNCHNH_3^+ + HNCHNH_2$ of lower energy than the transition structure could not be calculated because trial structures on full optimization collapsed to a complex of the products, $(H_2NCHNH_2)^+$ and $HNCHNH_2$, of the non-identity proton transfer, a reaction that can be calculated from the acidities (Table 1) to be nearly 30 kcal exothermic. The intrinsic barrier for this reaction can be estimated from Marcus theory (32) to be approximately the mean of the barriers for each of the corresponding identity reactions. If we assume that a barrier for the identity reaction giving $HNCHNH_3^+$ would be about its height above the line in Fig. 2, and average this with the barrier for the identity reaction giving $(H_2NCHNH_2)^+$ (0.91 kcal from Table 2), the result is a less than 4 kcal intrinsic barrier for the non-identity reaction. From Marcus' quadratic equation relating barrier height to intrinsic barrier and enthalpy of reaction, it becomes readily apparent that there should be no barrier for the actual reaction because $\Delta H^0/4\Delta H^‡ < -1$. Optimization of an ion–dipole complex with a hydrogen bond distance between the components fixed so as to prevent proton transfer did give a "virtual complex" below the transition structure by 7 kcal in potential energy. It was, however, not a stationary state.

Table 3. Group charges (NPA) at MP2/6-31+G*.

TS⁺(**4*a***)	0.2578	–0.1042	–0.1629
CO			
OCNH	0.4339		
TS⁻(**5*b***)	0.1526	–0.2813	–0.2668
OCN^-	–0.1142		
$OCNH_2^+$	0.8501		
TS⁺(**5*a***)	0.7195	–0.1306	–0.2856

The reason for a negligible central enthalpic barrier in the $OCNH_2^+ + OCNH$ reaction is not obvious (there is a potential energy barrier of 1.11 kcal). Consequently, we made an effort here also to determine whether we had missed a more stable ion–dipole complex, because ΔH_{well} for this reaction is considerably less negative than for the other reactions between positive and neutral species. The complex in Table 2 is a head-to-head species. Of the two possible head-to-tail species, only the one with a proton of NH_2^+ hydrogen bonded to the oxygen of the neutral component is stable, and it is actually 0.94 kcal *higher* in enthalpy than the head-to-head species when optimized at MP2/6-31+G*. In any event, other evidence for the operation of the PNS in this reaction is strong, and the apparent absence of a central enthalpic barrier at the higher level serves to underline the importance of using ΔH_{TS} rather than $\Delta H^‡$ in discussing such reactions. It is, of course, ΔH_{TS}, not $\Delta H^‡$, which constitutes the enthalpic contribution to measured efficiencies in experiments on gas-phase proton transfers.

Some speculation is desirable on why these identity-reaction proton transfers choose the paths they do. Evidently the preferred situation is one in which the path can involve little or no change in charge delocalization along the entire reaction coordinate. This is the case for the neutral acids reacting with their conjugate bases, where a transition structure conformation that shuts off delocalization is adopted. It is true that barriers are high when there is a lag in delocalization until after the transition state, but it does not, however, follow that the barrier would be lower if delocalization could become synchronous with progress along the reaction coordinate. The valence bond model pictures the transition structure of such a (hypothetical) synchronous reaction as a hybrid of reactant-like and product-like structures — a 1:1 hybrid for an identity

© 1998 NRC Canada

reaction. In the general case in which the PNS operates, a third contributor with charge localized on the proton donor atom is needed to describe the transition structure (33). For an identity reaction following the PNS, this contributor should also have charge localized on the proton acceptor atom. Admixture of this contributor has the effect of both stabilizing the transition structure and causing the observed lag in charge delocalization. In this view, the lag in delocalization is actually a strategy the system uses to achieve the lowest barrier possible under the circumstances.

The present results point up a problem with the conventional definition of Eigen acids. All of the acids in this study could be considered Eigen acids, but not all of them meet the criterion of a small or negligible barrier unless the proton transfer is endothermic. The proton transfer from $HCONH_3^+$ to $HCONH_2$ more closely resembles that from acetaldehyde to acetaldehyde enolate than it resembles the reactions of most of the other acids in this study. More thought needs to be given to definitions of the categories for classifying acids and their reactions.

1,3-Diphenylsulphonylcyclobutane: an unprecedented case of a higher stability of the *trans* isomer of 1,3-disubstituted cyclobutane

Ariel Sella, Shmuel Cohen, and Shmaryahu Hoz

Abstract: Equilibration of 1,3-diphenylsulphonylcyclobutane in *t*-BuOK/*t*-BuOH shows that the *trans* isomer is more stable than is the *cis* isomer by 2.1 kcal/mol. This is in contradistinction to the general case of 1,3-disubstituted cyclobutanes, where the bulky substituent prefers the *cis* geometry in order to avoid 1,3-diaxial interactions. The effect was found to be enthalpic in nature. Ab initio 3-21G calculations resulted in an energy difference of 2.6 kcal between the two isomers, in favor of the *trans* isomer. The cyclobutane rings were found to be nearly planar. While this may explain the higher stability of the *trans* isomer, it is not clear why the system avoids steric interaction this way, rather than by adopting the puckered conformation with the two bulky substituents at equatorial positions.

Key words: cyclobutanes, 1,3-diaxial interactions, equilibrium constant.

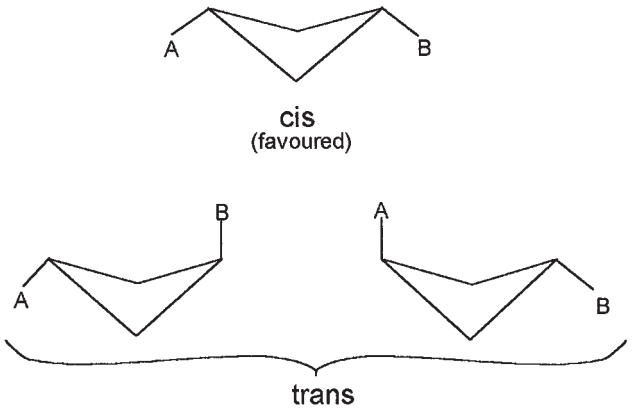
Résumé : L'équilibre du 1,3-diphenylsulfonylcyclobutane dans le *t*-BuOK/*t*-BuOH montre que la différence d'énergie favorisant l'isomère *trans* par rapport l'isomère *cis* est égale à 2,1 kcal/mol. Ce résultat est en contradiction avec le cas général des cyclobutanes 1,3-disubstitués dans lesquels les substituants encombrants se trouvent en général dans une géométrie *cis* de façons à éviter les interactions 1,3-diaxiales. On a trouvé que l'effet est de nature enthalpique. Des calculs ab initio 3-21G indiquent que la différence entre les deux isomères est de 2,6 kcal, en faveur de l'isomère *trans*. On a trouvé que les cyclobutanes sont pratiquement plans. Même si ce fait peut expliquer la stabilité plus grande de l'isomère *trans*, il est difficile d'expliquer pourquoi le système évite l'interaction stérique de cette façon plutôt que d'adopter la conformation plissée avec les deux substituants encombrants en positions équatoriales.

Mots clés : cyclobutanes, interactions 1,3-diaxiales, constante d'équilibre.

[Traduit par la rédaction]

Cyclobutane has been shown by various methods to be puckered (1) with a dihedral angle of 32° (2). Presumably, the relief in the strain, which results from the modest amount of puckering, outweighs the additional bond-angle distortion required by the puckering. As a result, geminal substituents become inequivalent, and axial/equatorial positions may be assumed. In monosubstituted cyclobutane, equatorial positioning of a substituent, such as F, was found (computationally) to be more stable than the planar geometry by 2 kcal/mol and from the axial conformer by 2.5 kcal/mol (3).

In general, in 1,3-disubstituted cyclobutanes, the *cis* isomer is found to be more stable than is the *trans* isomer (4). The explanation offered in the literature (4) is that in the *cis* isomer, the two substituents can simultaneously adopt equatorial positions, whereas in the *trans* isomer, one substituent will always assume an axial position, thus inflicting a destabilizing 1,3-diaxial interaction. To the best of our knowledge, of the many examples studied, the only exception to this rule is the dimethyl-1,3-cyclobutanedicarboxylate **1**. In this case, the *trans*/*cis* isomer ratio at equilibrium is 1.16 at 25°C (5).



The present paper reports the second exception to the above rule, where the *trans*/*cis* ratio of the two isomers sets a record value of 35.5.

Synthesis

The two isomers of the disulfone **2** were synthesized from **3** (6)

Received November 3, 1997.

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

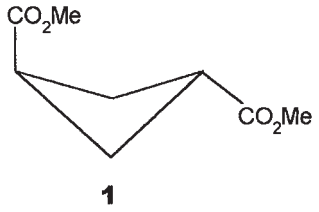
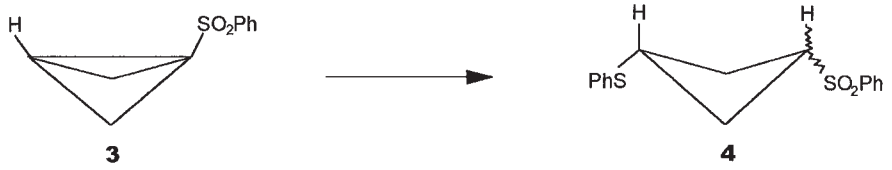
in the following reaction sequence. In the first step, **3** was reacted with PhS^- in MeOH for 2 h. The product **4** was obtained as a mixture of two isomers in a yield of 98% (eq. [1]).

Oxidation of the mixture with metachloroperbenzoic acid in dichloromethane yielded a mixture of the two isomers of **2** in an overall yield of 93% and a *cis*/*trans* (**2**c:**2**t) ratio of 1.16:1 (eq. [2]).



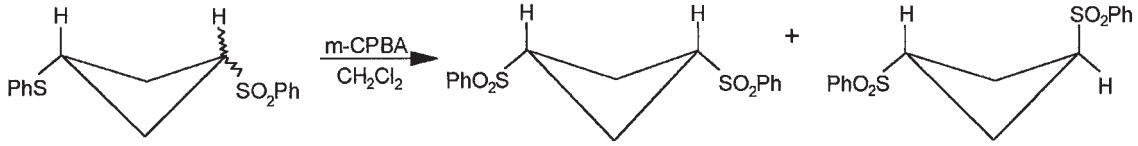
1

[1]



3 **4**

[2]

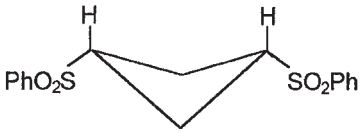


4 **2**c **2**t

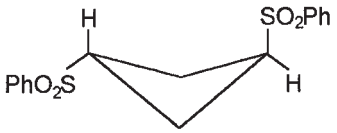
The mixture was separated on a silica column, and the two isomers were obtained in a pure form in an 84% yield. The two isomers could be distinguished from each other by their melting points (**2**c, 236°C and **2**t, 204°C) and by their NMR spectra.

Structural assignment

Structural assignment can be easily made on the basis of two characteristic features of the NMR spectrum. The first one is the absorption of the methine protons on C1 and C3 (7). As a



2c



2t

rule, in a substituted cyclobutane when the substituent is electronegative, the absorption of the protons on the opposing carbon is shifted downfield when *syn* to the electronegative group. Therefore, the absorption of the methine protons in **2**t should be shifted downfield relative to that of **2**c. The second characteristic feature is that the NMR spectrum of the two methylene protons of the *trans* isomer should display a much higher symmetry than that of the *cis* isomer. The high symmetry results from a rapid ring flip, which equilibrates the *endo*- and *exo*-protons in positions 2 and 4 of the ring. The NMR spectra of the two isomers is shown in Fig. 1.

Because of the unexpected results of the equilibration experiment (see below), an X-ray crystallography analysis (Table 1) of **2**t was also made. The results (Fig. 2) show unambiguously that the NMR-based structural assignment is correct.

Equilibration experiments and theoretical analysis

A mixture of the two isomers was equilibrated by 0.154 M *t*-BuO^- in *t*-BuOH, both at room temperature (ca. 25°C) and at 50°C, and the composition of the mixture was analyzed by NMR (Table 2). The estimated error in the NMR determination is 5%. The data show that the **2**t/**2**c ratio is 35.5 ± 1.5 at both temperatures.

Thus, **2** is indeed a unique case, since in contradistinction to current knowledge (with a single exception (5)), the *trans* isomer is, by far, more stable than the *cis* isomer. The absence of a noticeable temperature effect on the equilibrium ratio shows that the difference in stability stems solely from enthalpic effects.

The energies of the two isomers were computed at the 3-21G level (8). The calculations have shown that **the *trans* isomer** (1700.29284 au) **is more stable than the *cis* isomer** (1700.28870 au) by 2.6 kcal, in surprisingly close resemblance to the experimental value of 2.1 kcal. For both isomers, the structure of the cyclobutane was found to be planar with a dihedral angle < 0.17°. The structures of the two isomers are shown in Fig. 3. The fact that similar results were obtained in the liquid phase as well as in the ab initio calculations, which simulate the gas phase, rules out the possibility that the higher stability of the *trans* isomer stems from solvation effect.

To further ensure that the higher stability of the *trans* isomer does not stem from a higher dipole and therefore a better solvation, a series of calculations was carried out at the AM1 level (9). The AM1 was chosen for this purpose because of economic reasons and in spite of the fact that starting at several

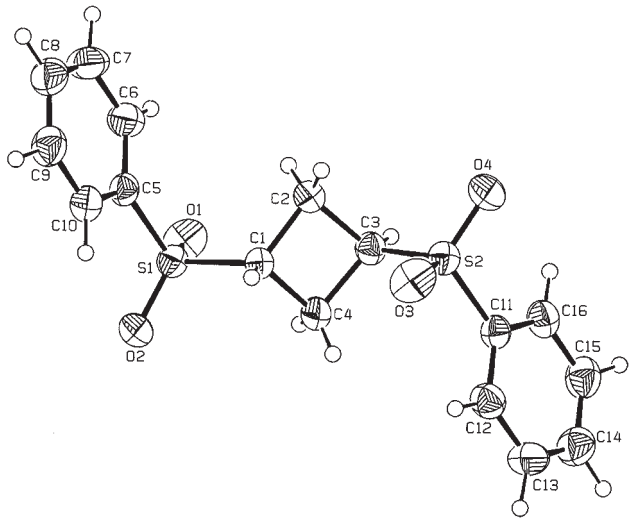
Fig. 2. Structure **2**t, obtained from X-ray analysis.



different initial geometries, **2**c was found to be more stable than **2**t by 0.9 kcal. The dipole moments of 12 different conformations, resulting from rotations around the C1-S and the C3-S bonds by 30° increments, were computed. In 9 conformations out of the 12, the dipole moment of the *cis* isomer was higher than that of the *trans*, by up to 4.4 D. In three conformations, the dipole moment of the *trans* isomer was higher (by only 0.4 D). This clearly rules out the possibility that solvent effects are responsible for the higher solution stability of **2**t. Thus, the sum total of the evidence gathered points to the unexpected higher stability of the *trans* isomer, as an intrinsic property of the isolated molecule.

The cyclobutane ring of the *trans* isomer was found to be nearly planar (X-ray (dihedral angle = 8°) and ab initio calculations (dihedral angle < 0.4°)). Calculations have shown that the cyclobutane is planar also in the *cis* isomer. No doubt, when the cyclobutane ring is planar, the *trans* isomer will be, as observed, more stable than the *cis* isomer. However, we were unable to explain, in classical interaction terms, why the

Experimental

General and instrumentation

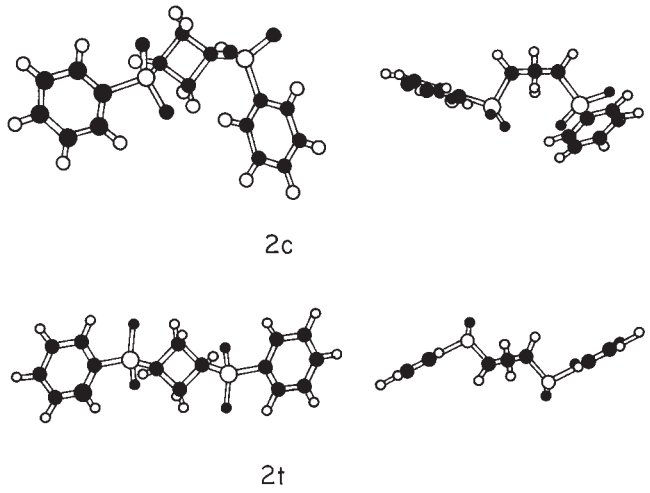
General
The NMR spectra were recorded on a Bruker AC-200 spectrometer and measured in $CDCl_3$ solution. Mass spectra were taken with a VG AutoSpec mass spectrometer.

Syntheses

*3-Thiophenoxycyclobutanephenylsulphone (**4**)*
To a solution of 0.01 g (0.052 mmol) bicyclobutanephenylsulphone (**4**) in 0.5 mL MeOH was added 0.11 mL of PhSNa (0.5 M) solution in MeOH. After 2 h the reaction mixture was quenched with water, extracted by hexane, and dried over $MgSO_4$. The two isomers of **4** were obtained after evaporation of the solvent in 98% yield in a pure form in a ratio *trans*/*cis* of 4.8. **4**c: ^{1}H NMR (200 MHz) δ: 2.60 (4H, t, J = 9 Hz), 3.68 (1H, t, t, J = 10, 8 Hz), 3.67 (1H, t, t, J = 10, 8 Hz), 7.35–7.20 (5H, m), 7.70–7.45 (3H, m), 7.84 (2H, m); ^{13}C NMR δ: 30.22 t, 36.34 d, 54.87 d, 128.28 (o), 129.35 (m), 133.80 (p), 137.88 (ip), 129.86 (o), 129.09 (m), 126.70 (p), ipso AR C 135–130. **4**t: ^{1}H NMR (200 MHz) δ: 2.29 (2H, m), 3.03 (2H, m), 3.93 (1H, t, t, d, J = 10, 8, 1 Hz), 7.70–7.50 (3H, m), 7.88 (2H, m), 7.35–7.20 (5H, m), 4.05 (1H, t, t, d, J = 10, 8, 1 Hz); ^{13}C NMR δ: 36.29 t, 9.48 d, 57.16 d, 128.25 (o), 129.44 (m), 134.00 (p), 137.48 (ip). Anal. calcd. for **4**: C 63.13, H 5.30, S 21.06; found: C 63.27, H 5.41, S 21.18.

*1,3-Diphenylsulphonylcyclobutane (**2**)*
0.08 g (0.0263 mmol) of **4** were dissolved in 3 mL dichloromethane. To the solution, 0.1 g (0.576 mmol) *m*-CPBA were added. The reaction was quenched after 3 h at room temperature. Treating the reaction mixture with water and hexane gave a mixture of **2** and the reagent. Stirring of the mixture with 10% sodium bicarbonate solution for 5 h followed by extraction with dichloromethane gave, after evaporation of the solvent, 0.082 g (93% yield) of the two isomers in a ratio of 1:1.16 in favour of the *cis* isomer. The mixture of the two isomers was separated on a Kieselgel 60 column with dichloromethane as an eluent. The *cis* isomer (**2**c) is eluted first, mp 236°C, and

Fig. 3. Structures **2**c and **2**t, obtained by ab initio calculations (3-21G).



then the *trans* isomer (**2**t) with mp 204°C. **2**c: ^{1}H NMR (200 MHz) δ: 2.36 (2H, m), 2.98 (2H, m), 3.66 (2H, t, t, J = 8, 8 Hz), 7.59 (4H, m), 7.69 (2H, m), and 7.87 (4H, m); ^{13}C NMR δ: 25.10 t, 51.03 d, 128.47 (o), 129.47 (m), 134.14 (p), 137.12 (ip). **2**t: mp 204°C; ^{1}H NMR (200 MHz) δ: 2.80 (4H, t, J = 8 Hz), 3.94 (2H, t, t, J = 8, 8 Hz), 7.59 (4H, m), 7.69 (2H, m), and 7.87 (4H, m); ^{13}C NMR δ: 23.88 t, 53.44 d, 128.28 (o), 129.51 (m), 134.15 (p), 137.19 (ip).

Equilibration experiments
To a solution of ca. 0.02 g (0.06 mmol) **2** in 1.5 mL *t*-BuOH 0.04 g of *t*-BuOK was added. After incubation for the periods of time and temperatures indicated in Table 2, the reaction mixtures were quenched by 2 mL of water and extracted by 3 portions of 3 mL dichloromethane. The solvent was evaporated after drying over $MgSO_4$.

Concerted motion in bicyclobutane

Ariel Sella, Harold Basch, and Shmaryahu Hoz

Abstract: In bicyclobutane, the bridgehead substituents move inward as the bridge bond lengthens, and vice versa. The effect of BH_2, H, F, and OH as bridgehead substituents was investigated using quantum-mechanical calculations. The degree of invertedness of the bridgehead carbon was found to depend on the electronegativity of the substituent. It becomes more pronounced with electropositive substituents which, at the same time, also cause lengthening of the central bond (1.43 Å for F to 1.55 Å for BH_2). The oscillation phenomenon was found to be common to all the substituents regardless of their electronegativity. Substituent effects on the structure, energy, and electronics of the system are discussed.

Key words: bicyclobutanes, oscillation, geometry distortion.

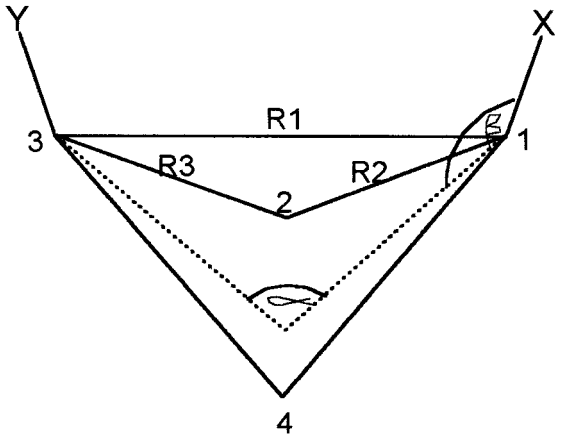
Résumé : Dans le bicyclobutane, les substituants en tête de pont se déplacent vers l'intérieur lorsque la longueur de la liaison augmente et vice versa. Faisant appel à des calculs de mécanique quantique, on a étudié l'effet de BH_2, H, F et OH comme substituants en tête de pont. On a trouvé que le degré d'inversion au niveau du carbone en tête de pont dépend de l'électronégativité du substituant. Il devient plus prononcé avec des substituants électropositifs qui provoquent en même temps une élongation de la liaison centrale (1,43 Å pour le F à 1,55 Å pour le BH_2). On a trouvé que le phénomène d'oscillation est commun à tous les substituants quelle que soit leur électronégativité. On discute des effets de substituant sur la structure, l'énergie et l'électronique du système.

Mots clés : bicyclobutane, oscillation, distorsion de la géométrie.

[Traduit par la rédaction]

Introduction

When all the four valences of a carbon center are contained in a single hemisphere it is said to have an inverted geometry.



This phenomenon, which is rarely encountered in carbon compounds, was first identified in the bridgehead carbon of bicyclobutane (1). While in [1.1.1]-propellane the invertedness at the bridgehead carbons is constrained (2), in bicyclobutane there is no compelling reason why the geometry should be inverted since the hydrogen at either bridgehead is apparently free to move outward to give the "normal" geometry. This unique feature of bicyclobutane is probably also the cause for the equatorial direction being the common course of attack for both nucleophiles and electrophiles (3). Even more surprising is the correlation found between the length of the central bond and the degree of invertedness (4). The latter may be quantified as the inward angle (β) the bridgehead substituent forms with the C2C4C1 plane.

It turns out that as the central bond lengthens, this angle becomes smaller, thus magnifying the degree of invertedness. Likewise, shortening of the central bond results in an outward motion of the bridgehead substituent. In an extreme case, as in tricyclo[2.1.0.$0^{2,5}$] pentane, which has a very short bridge bond, the invertedness is lost (5).

The bond length – bond angle correlation has been demonstrated by X-ray analyses (4, 6) as well as by quantum-mechanical computations (4, 7). Theoretical calculations enable the study of structures in which the length of the bridge bond is varied beyond the constraints of the molecules in their ground state. Thus, (computationally) stretching the bridge bond of bicyclobutane, starting with its optimal geometry, causes the substituents to initially move inward. However, at a certain point the substituents will reverse direction and move outwards to form the final equilibrium geometry around the radical center resulting from homolytic cleavage of the central bond. Similarly, compressing the central bond will result in an outward motion of the substituents. In the case of the radical cation of bicyclobutane, a double oscillation has been observed (8). Namely, as the central bond is stretched, the substituent on the incipient radical center moves first inward and then outward as in the neutral bicyclobutane. However in the

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

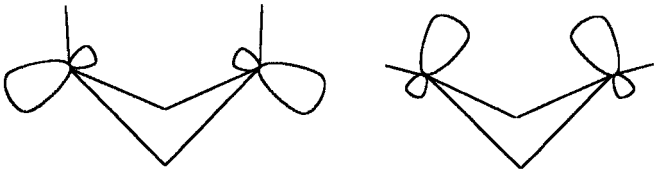
Scheme 1.



course of this outwards motion, the substituent passes by its final equilibrium position, and only at the final stages of the relaxation of the molecule to its open structure the substituent moves back inward. To the best of our knowledge, there is no proven explanation for the oscillation motion. At the intuitive level one can assume that the inward motion of the substituents is aimed at achieving a better alignment of the orbitals forming the central bond at the expense of some squeezing out of the inward lobes of these orbitals, as shown in Scheme 1.

At the point where the gain in energy is not sufficient, the substituents move backward in order to reach the normal geometry around the incipient radical center. In this paper we have examined the effect of various bridgehead substituents (Scheme 2) on the oscillation phenomenon, using quantum-mechanical calculations.

Methods

Ab initio RHF computations were performed with the Gaussian 92 package using the 6-31G* basis set (9) on IBM RS/6000 workstations. The geometries were optimized by gradient methods. After each equilibrium geometry was calculated, the angle α was varied by 10° steps both in the inward and outward direction.

Results and discussion

The various geometrical and electronic parameters are collected in Table 1. Since R1 increases nearly linearly with α (Fig. 1), increasing α (R1) beyond a certain limit could induce a diradicaloid state for which the closed shell method used here is inadequate. We have therefore computed the energy of the triplet and the singlet states (UHF) at α = 30° and 40°. The energies obtained for the triplet state were higher than that for the singlet by 33.7 and 16.1 kcal, respectively, showing that for the values of α used in this study the closed shell method is appropriate.

Geometrical parameters

In the optimum geometry, the degree of invertedness of the bridgehead carbon bearing the substituent depends on the electronegativity of the substituent. Thus, with the boron as a substituent, β decreases and the substituent is tilted more inwards. For BB this angle reaches nearly 160°. For F and O as bridgehead substituents, the invertedness of the carbon practically disappears as β reaches 180° and beyond (Table 1).

It is interesting to note that simultaneously with the lengthening of the central bond, shortening of the side bonds takes place. The sum of the bond lengths remains therefore nearly constant. This is in agreement with the observation made earlier by Eisenstein and Hirshfeld (10) and was confirmed for other systems as well (11, 12). It is correct mainly for the electronegative substituents, whereas for the electropositive ones, H and B, the deviation from a constant sum is as high as 0.1 Å. In addition, it was found that in the length of the central bond is a function of the electronegativity of the substituent. The more electronegative the substituent, the shorter the bond. This demonstrates again the dependence of β on R1 irrespective of the identity of the substituent that causes the variation.

Table 1. Variation of geometrical parameters, energies, and central bond overlap population as a function of α.

Energy and electronic structure

Figure 2 shows that decreasing α (shortening of the bridge bond) leads to a steeper increase in energy than increasing α. This effect, which is in line with the general form of a Morse curve (the RHF method is suitable for at small deviation from equilibrium, see below), is obviously more pronounced as the deviation from the minimum energy structure becomes larger. It is worth pointing out that the substituent differentiating effect is larger on the right-hand side of the diagram than on its left. In the latter, the increase of energy results probably mainly from an increase in the internal repulsion within the bicyclobutane unit, while the increase in energy associated with the motion to the right reflects, most likely, the incipient cleavage of the central bond. As the calculations used the closed shell HF method, it is clear that the differentiating substituent effect does not stem from the ability of the substituent to stabilize the incipient radical center on the bridgehead carbon. The differentiating effect probably reflects more the lowering of the

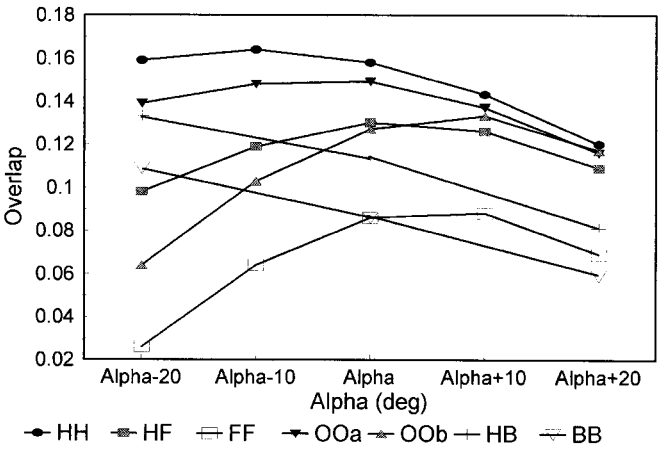
Fig. 4. Variation of the C1—C3 overlap population as a function of α for the various substituted bicyclobutanes.



LUMO of the bicyclobutane moiety and the resulting enhanced interaction with the lone pair(s) on the F or O substituents. In spite of the nonequivalence of the two lone pairs on the oxygen in OOa and OOb, the two conformations have only a moderate effect on the energy rise upon increasing α; the reason being, as we have shown a while ago, that the lone pairs can interact with the LUMO associated with the central bond as well as with the antibonding orbital associated with the combination of the side σ bonds with nearly the same efficiency (13).

We expected that if the simplistic explanation offered in the introductory section for the correlation between the motion of the bridgehead substituents upon varying the central bond length is correct, varying the bridgehead substituents will have a dramatic effect on the phenomenon. However, in spite of the large range of substituents used, the same pattern of behavior is always exhibited. As can be seen from Table 1 and Fig. 3 it is clear that the concerted motion, i.e., coupling between β and α, is independent of the bridgehead substituent. Therefore, we examined the overlap population of the central bond as a function of the substituent. The data displayed in Table 1 and Fig. 4 show, not unexpectedly, a tendency for maximum overlap in the region of α optimum ±10°. It shows also that changing the value of α results in an increase in the overlap for some substituents, whereas for the others the overlap diminishes. Thus, the data at hand, while not allowing a complete rejection of the simplistic model mentioned in the introductory section, clearly does not support it.

Reactions of benzyl methyl substituted-benzyl phosphites with *tert*-butyl hypochlorite: "balanced TS" validating reactivity/selectivity principle

Sung Soo Kim, Yu Zhu, In Seok Oh, and Chang Gyeong Lim

Abstract: Reactions of a series of several benzyl methyl substituted-benzyl phosphites with *tert*-butyl hypochlorite were investigated. The reactions produced phosphates, isobutene, alkyl chlorides, and benzyl chlorides via phosphonium chlorides as intermediates. Furthermore, the phosphates bearing a *tert*-butyl group underwent fragmentation to yield isobutene and another phosphates. Relative rates of formations of substituted benzyl and benzyl chloride (k_Y/k_H) were measured at the temperatures (–20, 0, 20, 40°C). Logarithms of the rates (log k_Y/k_H) were plotted against σ^+ and $1/T$, respectively. The former gave Hammett correlations to suggest a polar transition state (TS). The latter yielded differential activation parameters ($\Delta\Delta H^{\neq}_{Y-H}$ and $\Delta\Delta S^{\neq}_{Y-H}$), which indicate isokinetic relations and enthalpy control of rates. The selectivities (k_Y/k_H) decrease with higher temperatures and thereby follow the reactivity/selectivity principle.

Key words: phosphites, *tert*-butyl hypochlorite, Hammett correlations, differential activation terms, reactivity/selectivity principle.

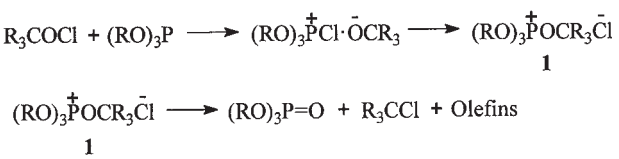
Résumé : On a étudié les réactions de l'hypochlorite de *tert*-butyle avec une série de phosphites de benzyle substitués par des groupes méthyles. Les réactions conduisent à des phosphates, à l'isobutène, à des chlorures d'alkyle et à des chlorures de benzyle par le biais de chlorures de phosphonium comme intermédiaires. De plus, les phosphates portant un groupe *tert*-butyle subissent une fragmentation conduisant à de l'isobutène et à d'autres phosphates. On a mesuré les vitesses relatives de formation des chlorures de benzyle (et benzyle substitué) (k_Y/k_H) à diverses températures (–20, 0, 20 et 40°C). On a tracé les courbes des logarithmes des vitesses (log k_Y/k_H) en fonction respectivement de σ^+ et de $1/T$. La première courbe conduit à des relations de Hammett qui suggèrent un état de transition (ET) polaire. La deuxième fournit les paramètres différentiels d'activation ($\Delta\Delta H^{\neq}_{Y-H}$ et $\Delta\Delta S^{\neq}_{Y-H}$) qui indiquent des relations isocinétiques et un contrôle enthalpique des vitesses. Les sélectivités (k_Y/k_H) diminuent avec une augmentation de la température; elles suivent ainsi le principe de réactivité/sélectivité.

Mots clés : phosphites, hypochlorite de *tert*-butyle, corrélations de Hammett, termes différentiels d'activation, principe réactivité/sélectivité.

[Traduit par la rédaction]

Introduction

Trialkyl phosphites may react with *tert*-alkyl hypochlorites to yield trialkyl phosphates, *tert*-alkyl chlorides, and olefins as major products (1). Tetraalkoxyphosphonium chlorides were assigned as the key intermediates, which decompose to give the products. Previous studies (1) strongly excluded implication of radical intermediates (2, 3). Therefore **1** should undergo heterolytic bond fissions for the reactions to take place. Interestingly, olefins were also produced from the pyrolysis of arylethyl acetates (4). Trialkyl phosphites reacted with *N*-halosuccinimides (5) to give comparable product distributions as with the reactions of *tert*-alkyl hypochlorites (1). We would like to report the mechanism of decomposition of phosphonium chlorides derived from the title reactions.



This paper is dedicated to Professor Erwin Buncel for his outstanding contributions to physical organic chemistry.

intermediate and undergoes heterolytic fragmentation in several pathways (Scheme 2).

Alkyl and benzyl chlorides (**4**, **6**, **7**, and **8**) were identified and quantified. Isobutene **5** has been produced by either eq. [2] or the intramolecular fragmentations of **13**–**15** as shown by Scheme 3. The pyrolysis of the acetates (4) underwent similar fragmentation to give olefins and carboxylic acids via a six-membered TS. Compound **9** with Y = *p*-CH_3 was isolated and identified by comparison with the authentic sample. Formation of **13** could be ignored because eq. [1] is a very minor pathway. Compounds **14** and **15** were not detected in the reaction mixtures. However **10** was isolated and the spectral data showed the consistency with the authentic structure. Table 1 contains yields of the products based on the amount of **2** consumed. According to Schemes 2 and 3, the total quantity of **5** and **6** should be equal to that of **12** undergoing decomposition. The material balances were calculated as (96 ± 3)% or better at the temperatures (40, 20, 0, and –20°C), which strongly supports

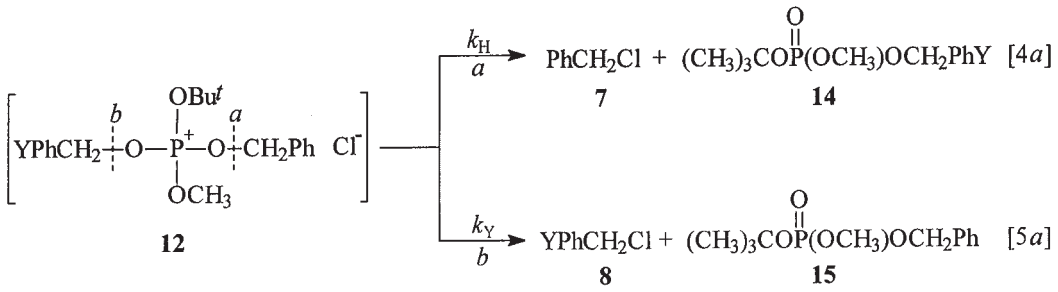
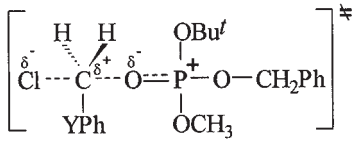
the proposed reaction mechanism. Table 1 shows representative data at 20°C.

Substituent effects and temperature studies

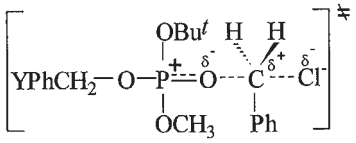
Benzyl chloride **7** and substituted benzyl chloride **8** are products of reactions [4*a*] and [5*a*], respectively. The relative rates (k_Y/k_H) were measured from k_Y/k_H = [**8**]/[**7**] and correlated with Hammett equation using σ^{+} and σ values. Table 2 contains the rate data and Hammett ρ and ρ^{+} values.



Negative sign of ρ^{+} and better correlations with σ^{+} indicate that cleavages of *a* and *b* involve polar TS with the positive charge enjoying conjugation with phenyl ring. Temperature studies employed the Eyring equation (6) and gave differential activation parameters from Fig. 1 (Table 3). Both terms ($\Delta\Delta H^{\neq}_{Y-H}$ and $\Delta\Delta S^{\neq}_{Y-H}$) were plotted against σ^{+} with good linear lines having positive slopes (Figs. 2 and 3).



16



17

The chlorine anion Cl^- in **12** could act as a strong nucleophile in CCl_4 to promote S_N2-type decomposition. Relatively moderate ρ^{+} values (ρ^{+} = –1.17 to –1.58) should then be consistent with TS structures **16** and **17** for reactions [5*a*] and [4*a*], respectively. Accordingly a real carbocation may be developed in neither **16** nor **17**. The differential activation parameters correspond to increment of activation terms perturbed by the substituent effects. When Y is of electron withdrawing, the carbocationic character in **16** becomes destabilized so as to increase magnitude of enthalpy of activation ($\Delta H^{\neq}_{Y}$). The term $\Delta\Delta H^{\neq}_{Y}$ is equivalent to differential substituent effects. Figure 2 shows the systematic perturbation of $\Delta H^{\neq}_{Y}$ caused by substituent constant (σ^{+}). The destabilization by electron-attracting substituents (Y) could also function to reduce extent of the bond cleavage. The lesser bond cleavage could bring about correspondingly the lesser π-bond formation and the smaller charge separation in **16**. The double-bond character restricts the free rotations evolving rotational entropy. Since CCl_4 is nonpolar, the electrostrictions caused by solvent molecules could greatly reduce translational freedom of **16**. Therefore electron-withdrawing substituents could augment the rotational and translational freedoms of **16** so as to increase entropies of activation ($\Delta S^{\neq}_{Y}$) (7).

Figures 2 and 3 are empirical drawings to visualize substituent effects controlling structures of TSs **16** and **17**. The differential terms ($\Delta\Delta H^{\neq}_{Y-H}$ and $\Delta\Delta S^{\neq}_{Y-H}$) realize an excellent isokinetic relation (8) (Fig. 4). The isokinetic behavior (8) may imply that activation process is controlled by a single parameter,

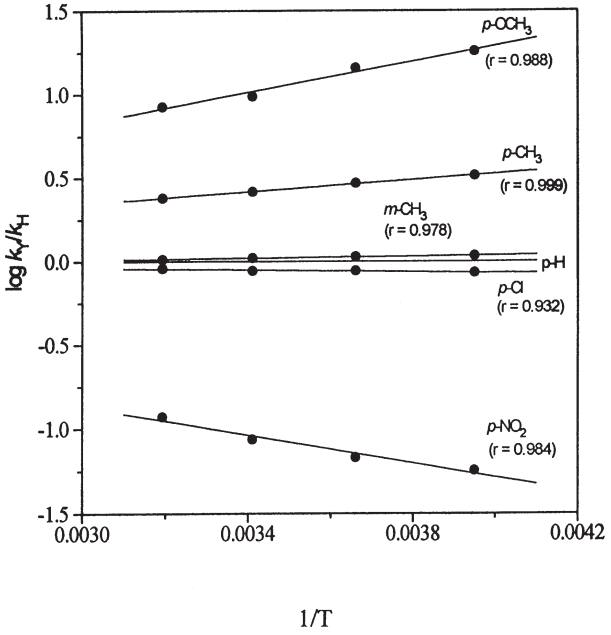

Fig. 2. Plot of $\Delta\Delta H^{\neq}_{Y-H}$ vs. σ^+.

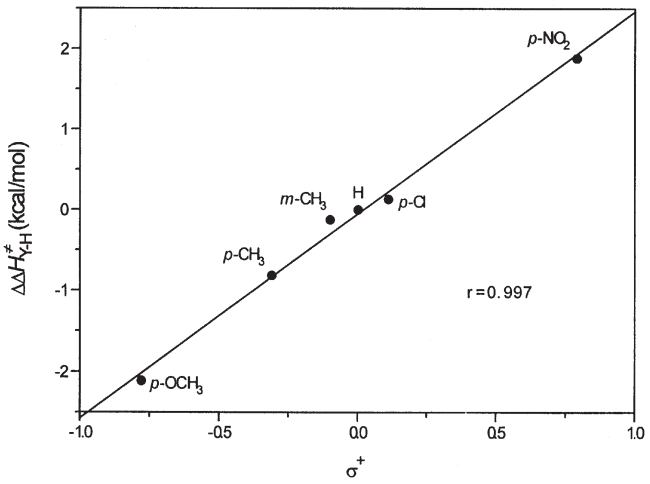

that is, substitutent constant (σ^+). The slope of line of Fig. 4 corresponds to isokinetic point (T_k = 937 K) where the rates become immune to substituent effects. The reaction temperatures are well below 937 K. Such high isokinetic point ($\Delta\Delta H^{\neq}_{Y-H}/\Delta\Delta S^{\neq}_{Y-H}$ = 937 K) indicates that increment of enthalpy term ($\Delta\Delta H^{\neq}_{Y-H}$) provoked by substituents far outweighs corresponding entropy change ($\Delta\Delta S^{\neq}_{Y-H}$). The rates

Fig. 3. Plot of $\Delta\Delta S^{\neq}_{Y-H}$ vs. σ^+.

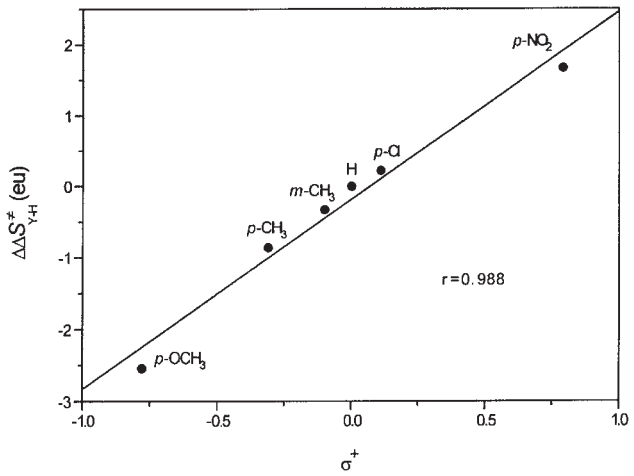

Fig. 4. Isokinetic relationship by the enthalpy–entropy compensation effect.

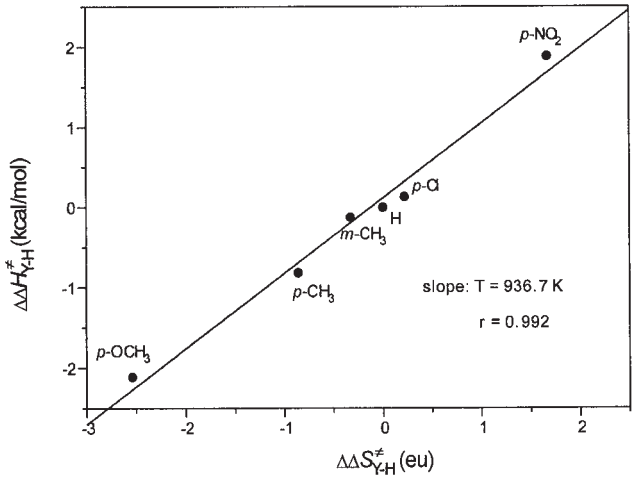
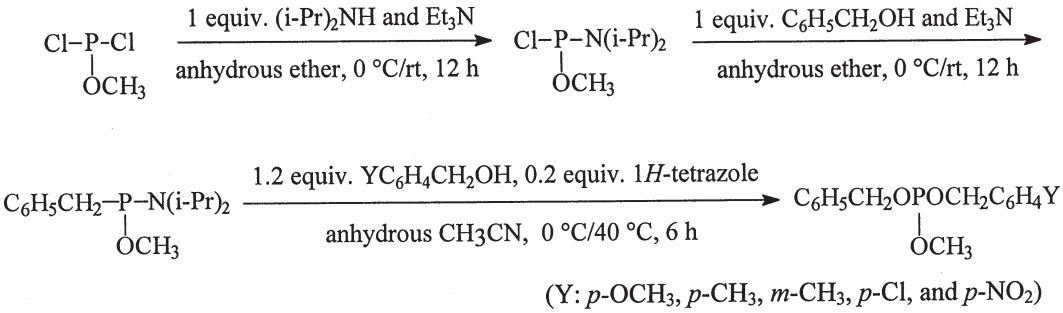


are accordingly determined by contribution of enthalpic term to engender enthalpy control of reactivities. The relative rates (k_Y/k_H) can be taken as selectivities caused by substituent constant (σ^+). The selectivities increase with lower temperatures thus obeying the reactivity/selectivity principle (RSP) (9) (Table 2). The obedience has been featured when rates are parallel with equilibria. The parallelism can be ascribed to a balanced TS such as **16** or **17**, which assumes an intermediate configuration between reactant and product. Polar TS in radical reactions (10, 11) has been however defined as an "imbalanced TS" (12) by us (11). The rates of various radical reactions (10, 11) were fitted to Hammett correlations and controlled by

© 1998 NRC Canada

Scheme 4.



differential entropy term ($\Delta\Delta S^{\neq}_{Y-H}$). Entropy control of reactivities has been also observed very recently in thermal isomerizations of substituted benzyl isocyanides (13). The TS retains cyclic structure that resembles neither reactant (isonitrile) nor product (nitrile). The entropic dominance in a series of reactions (11, 13) confines validity of RSP (9) and Hammond postulate (14).

Selectivity Q can be defined as $Q = \ln(k_Y/k_H)$ and $\ln(k_Y/k_H) = -(\Delta G^{\neq}_Y - \Delta G^{\neq}_H)/RT = -\Delta\Delta G^{\neq}_{Y-H}/RT$. The equation $Q = -\Delta\Delta G^{\neq}_{Y-H}/RT$ can be divided into enthalpy and entropy terms.

[6] $$Q = \Delta\Delta S^{\neq}_{Y-H}/R - \Delta\Delta H^{\neq}_{Y-H}/RT$$

Due to an isokinetic relation (Fig. 4), two differential terms carry the same sign whether positive or negative. Accordingly, Q becomes the difference between the two terms of eq. [6]. Table 3 indicates $|\Delta\Delta H^{\neq}_{Y-H}/RT| > |\Delta\Delta S^{\neq}_{Y-H}/R|$. Therefore increase of temperature must reduce magnitude of Q to decrease selectivities. On the contrary, the radical reactions (11) and the isomerizations of substituted benzyl isocyanides (13) yielded $\Delta\Delta H^{\neq}_{Y-H}$ close to zero. Equation [6] reduces to $Q = \Delta\Delta S^{\neq}_{Y-H}/R$, which is independent of temperature. Constant selectivites (11, 13) were indeed observed against temperature gradient. A number of authors (15) including Professor Buncel (15*d*) have expressed serious concerns about the applicability of RSP to the numerous heterolytic reactions.

Conclusions

The structure of TS controls trend of the selectivities (k_Y/k_H) with variation of temperature. Balanced TS invites enthalpy control of rates to entertain Hammond postulate and reactivity/selectivity principle. The dominance of either term ($\Delta\Delta H^{\neq}_{Y-H}$ or $\Delta\Delta S^{\neq}_{Y-H}$) is due to structural feature of the TS.

Experimental section

Materials and methods

All reagents were purchased from major suppliers. Liquids were distilled with center-cut collection, and solids recrystallized according to the standard procedures (16) when necessary. Varian Vista 4600 gas chromatography, Varian Gemini 2000 NMR, and Fisions VG-Trio-2000 GC–MS spectrometer were used for identifications and analyses of the products.

Chloro diisopropylamino methyl phosphite

To a 2 L three-necked flask equipped with a 250 mL pressure-equalized addition funnel and an efficient magnetic stirrer were added dry ethyl ether (600 mL) and dichloro methyl phosphite (25.0 g, 0.188 mol). The solution was cooled in an ice bath. Ethyl ether solution (200 mL) containing diisopropylamine (19.0 g, 0.188 mol) and triethylamine (19.0 g, 0.188 mol) was added dropwise to the stirred solution over 1 h under nitrogen atmosphere. After completion of the addition, the ice bath was removed and the reaction mixture was allowed to continuously stir for 12 h at room temperature and then filtered. Excess amount of ether was removed by a rotary evaporator. The residue was distilled under reduced pressure to give 17.0 g (46%) of colorless liquid with bp 69–71°C/5 torr (1 torr = 133.3 Pa). ^{1}H NMR ($CDCl_3$, 200 MHz), δ (ppm): 1.24 (d, J = 6 Hz, 12H), 3.58 (d, J = 14 Hz, 3H), 3.83 (m, 2H).

Benzyl diisopropylamino methyl phosphite

To a 250 mL three-necked flask equipped with a 50 mL pressure-equalized addition funnel, an efficient magnetic stirrer, and a condenser were added dry ethyl ether (100 mL) and chloro diisopropylamino methyl phosphite (8.4 g, 0.042 mol) under nitrogen atmosphere. The solution was cooled in an ice bath. Ethyl ether solution (50 mL) containing benzyl alcohol (4.6 g, 0.042 mol) and triethylamine (4.3 g, 0.042 mol) was added dropwise to the stirred solution over 0.5 h under nitrogen atmosphere. After the addition was complete, the ice bath was removed, and the reaction mixture was allowed to continuously stir for 12 h at room temperature and then filtered. The excess amount of ether was removed by evaporation. The product was colorless liquid (9.8 g, 86%). ^{1}H NMR ($CDCl_3$, 200 MHz), δ (ppm): 1.19 (d, J = 2 Hz, 6H), 1.22 (d, J = 2 Hz, 6H), 3.40 (d, J = 13 Hz, 3H), 3.70 (m, 2H), 4.72 (t, J = 8 Hz, 2H), 7.34 (m, 5H).

Benzyl methyl substituted-benzyl phosphite

See Scheme 4 for synthesis of benzyl methyl substituted-benzyl phosphites (17).[3]

Typical run: to a 100 mL three-necked flask equipped with a 50 mL pressure-equalized addition funnel and an efficient magnetic stirrer were added dry acetonitrile (50 mL) and benzyl diisopropylamino methyl phosphite (4.0 g, 0.015 mol). The solution was cooled in an ice bath. Anhydrous acetonitrile solution (15 mL) containing *p*-methylbenzyl alcohol (2.0 g, 0.016 mol) and 1*H*-tetrazole (0.50 g, 0.007 mol) was added dropwise to the stirred solution over 0.5 h under nitrogen atmosphere. After addition was complete, the ice bath was removed, and the reaction mixture was allowed to continuously stir for 12 h at room temperature. The amino salt was formed,

[3] W.G. Bentrude. Private communication.

© 1998 NRC Canada

filtered off, and acetonitrile was removed by evaporation. The residue was separated by flash column chromatography on neutral alumina treated with 5% Et_3N/petroleum. The eluent was 15:1 petroleum ether – ethyl ether. Colorless liquid of benzyl methyl *p*-methylbenzyl phosphite was obtained (3.6 g, 83.5%).

^{1}H NMR ($CDCl_3$, 200 MHz), δ (ppm) data of benzyl methyl substituted-benzyl phosphites. *p*-OCH_3: 3.48 (d, J = 11 Hz, 3H), 4.84 (t, J = 7 Hz, 4H), 6.89 (d, J = 8 Hz, 2H), 7.24 (d, J = 8 Hz, 2H), 7.34 (m, 5H). *p*-CH_3: 2.34 (s, 3H), 3.48 (d, J = 11 Hz, 3H), 4.84 (t, J = 7 Hz, 4H), 7.16 (d, J = 8 Hz, 2H), 7.21 (d, J = 8 Hz, 2H), 7.32 (m, 5H). *m*-CH_3: 2.34 (s, 3H), 3.48 (d, 11 Hz, 3H), 4.84 (t, J = 7 Hz, 4H), 7.14 (m, 4H), 7.32 (m, 5H). *p*-Cl: 3.48 (d, J = 11 Hz, 3H), 4.84 (t, J = 8 Hz, 4H), 7.25 (d, J = 8 Hz, 2H), 7.27 (d, J = 8 Hz, 2H), 7.32 (m, 5H). *p*-NO_2: 3.54 (d, J = 11 Hz, 3H), 4.93 (t, J = 7 Hz, 4H), 7.34 (m, 5H), 7.49 (d, J = 8Hz, 2H), 8.21 (d, J = 8Hz, 2H). *p*-H: 3.49 (d, J = 11 Hz, 3H), 4.85 (d, J = 8 Hz, 4H), 7.33 (m, 9H).

tert-Butyl hypochlorite

Prepared according to a known method (18).

Identifications and isolations of the products

To a jacketed three-necked vessel through which water was circulated from a constant temperature bath operating at 20 ± 0.1°C was placed 2 mL CCl_4 solution containing benzyl methyl *p*-methylbenzyl phosphite (1.5 g, 4.99 mmol). A CCl_4 solution (1 mL) containing *tert*-butyl hypochlorite (0.541 g, 4.99 mmol) was added dropwise to the stirred solution over 3 min under nitrogen atmosphere. Then the reaction mixture was allowed to stir for 30 min. The CCl_4 was removed by evaporation. The residue was separated on neutral alumina (washed with 5% Et_3N/petroleum ether) with petroleum ether – ethyl ether as eluent. *tert*-Butyl chloride **6**, benzyl chloride **7**, *p*-methylbenzyl chloride **8**, and isobutene **5** were identified by comparison of GLC retention time with authentic samples. The molecular ions were also detected by GC–MS. Benzyl methyl *p*-methylbenzyl phosphate **9** was isolated and identified by NMR. Benzyl methyl phosphate **10** was isolated and identified by GC–MS and NMR.

Benzyl methyl *p*-methylbenzyl phosphate (**9**, Y = *p*-CH_3): ^{1}H NMR ($CDCl_3$, 200 MHz), δ (ppm): 2.35 (s, 3H), 3.66 (d, J = 11 Hz, 3H), 5.01 (t, J = 7 Hz, 4H), 7.18 (d, J = 8 Hz, 2H), 7.23 (d, J = 8 Hz, 2H), 7.35 (m, 5H). Dibenzyl methyl phosphate (**9**, Y = H): ^{1}H NMR ($CDCl_3$, 200 MHz), δ (ppm): 3.64 (d, J = 11 Hz, 3H), 5.00 (d, J = 8 Hz, 4H), 7.33 (m, 5H). Benzyl methyl phosphate (**10**): ^{1}H NMR ($CDCl_3$, 200 MHz), δ (ppm): 3.68 (d, J = 11 Hz, 3H), 5.03 (t, J = 10 Hz, 2H), 7.39 (m, 5H), 8.60 (s, 1H). GC–EIMS, *m/z* (rel. intensity): 186 $[M - CH_3 - 1]^+$ (27), 153 $[M - OCH_3 - 1]^+$ (1), 109 $[PhCH_2O]^+$ (100), 91 $[PhCH_2]^+$ (91), 77 $[Ph]^+$ (28).

Reactions of the phosphites with *tert*-butyl hypochlorite

Typical run: the kinetic runs were made using a three-necked jacketed vessel through which water was circulated from a constant temperature bath operating at –20, 0, 20, 40 ± 0.1°C. The CCl_4 solution (1 mL) containing benzyl methyl *p*-methylbenzyl phosphite (0.1449 g, 0.499 mmol) and biphenyl (0.0120 g, 0.0778 mmol, internal standard) was placed in the vessel and stirred to reach the desired temperature. The CCl_4 solution (1 mL) containing *tert*-butyl hypochlorite (0.0541 g, 0.499 mmol) was added dropwise to a stirred solution over 3 min under nitrogen atmosphere. The reaction mixture was allowed to stir for 30 min and was analyzed by GLC.

Analytical procedure

The reaction mixtures were analyzed on a 6 ft × 1/8 in. (1 in. = 25.4 mm) stainless-steel column packed with 10% OV-101 or 10% OV-17 on Chromosorb W with temperature programming from 28 to 250°C. The FID and CDS 401 data system were employed for the analysis.

Acknowledgments

This work has been supported by Non Directed Research Fund administered by the Korea Research Foundation (1994–1995). We are also very grateful to Professor Wesley G. Bentrude for the very careful and kind suggestions for the present investigations. Warm thanks are due to the editor and the reviewers for the kind instructions and comments. The editorial corrections were kindly performed by Professor Bong Rae Cho.

Kinetics of the self-assembly of α-cyclodextrin [2]pseudorotaxanes with polymethylene threads bearing quaternary ammonium and phosphonium end groups

Angela P. Lyon, Nicola J. Banton, and Donal H. Macartney

Abstract: The kinetics and mechanism of the formation and dissociation of a series of [2]pseudorotaxanes, comprised of α-cyclodextrin (α-CD) as the cyclic component and the ($[Me_3N(CH_2)_nNMe_3]^{2+}$ (n = 8–12), $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$, and $[Me_3P(CH_2)_{10}PMe_3]^{2+}$) dications as the threads, were determined by means of ^1H and ^{31}P NMR in aqueous solution. The length of the polymethylene chain (n) of the thread, which has a minor effect on the rate constant for pseudorotaxane formation, is important in the kinetics of the dissociation reactions, with the longer, more hydrophobic chains resulting in slower pseudorotaxane dissociation. The replacement of one methyl substitutent by an ethyl group in each of the end groups on the $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ thread results in a 30-fold decrease in the formation rate constant. Replacements, by ethyls, of two or all of the methyl substitutents prevent the formation of the pseudorotaxane, even after prolonged heating. The pseudorotaxane containing the $\{Me_3P(CH_2)_{10}PMe_3{\cdot}\alpha\text{-CD}\}^{2+}$ thread forms only at elevated temperatures by a slippage mechanism, and the rate constant for its self-assembly at 75°C (8×10^{-5} M^{-1} s^{-1}) is more than 10^6 smaller than the rate constant at 75°C (200 M^{-1} s^{-1}) extrapolated for the corresponding $\{Me_3N(CH_2)_{10}NMe_3{\cdot}\alpha\text{-CD}\}^{2+}$ complex. The enthalpies and entropies of activation for the formation and dissociation of the [2]pseudorotaxanes decrease with an increase in the size and hydrophobicity of the end groups, suggesting a reduced role of desolvation of the quaternized atoms in the threading or dethreading processes.

Key words: pseudorotaxane, α-cyclodextrin, kinetics, self-assembly, slippage, supramolecular.

Résumé : Faisant appel à la RMN du ^1H et du ^{31}P en solutions aqueuses, on a déterminé la cinétique et le mécanisme de formation et de dissociation d'une série de [2]pseudorotaxanes formés d'α-cyclodextrine (α-CD) comme composant cyclique et des dications $[Me_3N(CH_2)_nNMe_3]^{2+}$ (n = 8–12), $[Me_2ETN(CH_2)_{10}NEtMe_2]^{2+}$ et $[Me_3P(CH_2)_{10}PMe_3]^{2+}$ comme fils. La longueur de la chaîne polyméthylénique (n) du fil, qui a un effet mineur sur la constante de vitesse de formation du pseudorotaxane, est importante dans la cinétique des réactions de dissociation; avec de longues chaînes hydrophobes, la dissociation des pseudorotaxane est ralentie. Le remplacement d'un substituant méthyle par un groupe éthyle dans chacun des groupes aux extrémités du fil $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ provoque une diminution de 30 fois de la constante de la vitesse de formation. Les remplacements, par des groupes éthyles, de deux ou de tous les substituants méthyles empêchent la formation des pseudorotaxanes, même après un chauffage prolongé. Le pseudorotaxane contenant le fil $\{Me_3P(CH_2)_{10}PMe_3{\cdot}\alpha\text{-CD}\}^{2+}$ ne se forme qu'à des températures élevées par un mécanisme de glissement et la constante de vitesse pour cette autoassemblée, à 75°C, (8×10^{-5} M^{-1} s^{-1}) est 10^6 fois plus faible que la constante de vitesse, à 75°C (200 M^{-1} s^{-1}), extrapolée pour le complexe correspondant $\{Me_3N(CH_2)_{10}NMe_3{\cdot}\alpha\text{-CD}\}^{2+}$. Les enthalpies et les entropies d'activation pour la formation et la dissociation des [2]pseudorotaxanes diminuent avec une augmentation dans la taille et l'hydrophobicité des groupes terminaux; ceci suggère que la désolvatation des atomes quaternisés joue un rôle réduit dans les processus de formation et de déformation des fils.

Mots clés : pseudorotaxane, α-cyclodextrine, cinétique, autoassemblage, glissement, supramoléculaire.

Introduction

Rotaxanes are supramolecular species in which a cyclic molecular bead is threaded by a linear chain bearing sufficiently bulky end units such that the complex is prevented from dissociating into its cyclic and linear molecular components (1–15). If the end groups are not sufficiently bulky to prevent the dissociation of the complex, the supramolecular species is termed a pseudorotaxane. One of the most frequently used cyclic components in the assembly of rotaxanes and pseudorotaxanes (6–15) is the family of cyclodextrins (CD), a series of cyclic

oligosaccharides normally consisting of six (α-CD), seven (β-CD), or eight (γ-CD) α-(1→4)-linked D-(+)-glucopyranose units (16). The smallest of the cyclodextrins, α-CD (Fig. 1), possesses a hydrophobic interior cavity with a diameter of about 5.5 Å and exhibits a strong affinity for polymethylene chains. A number of [2]pseudorotaxanes (the [2] refers to the total number of cyclic and linear components in the complex) have been prepared with α-CD and threads of the form $[L(CH_2)_nL]^{m+}$ (n = 8–12) in which the end groups (L) may be organic moieties such as amines (11), carboxylates (9), or substituted aromatic *N*-heterocycles (8, 10, 12). Coordination of the end groups to inert transition metal centres such as $[Fe(CN)_5]^{3-}$ (12) or $[Co(NH_3)_5]^{3+}$ (11) results in the formation of kinetically stable [2]rotaxanes.

The self-assembly of cyclodextrin rotaxanes and pseudorotaxanes may occur by one of several mechanisms (2, 3). The threading process for the assembly of rotaxanes involves the attachment of bulky groups to the ends of a pseudorotaxane, which has been formed by threading the cyclodextrin with the linear component. A second method involves the dissociation of a bulky group from one end of a linear chain, allowing threading through the cyclic bead (yielding a semirotaxane), followed by reattachment of the bulky group to yield a rotaxane. We have employed this method to generate a number of [2]rotaxanes with α-CD in which the bulky $[Fe(CN)_5]^{3-}$ ion is coordinated to terminal *N*-heterocycles (L = 4,4′-bipyridine (12*a*–*c*), pyrazine (12*c*), or 4-cyanopyridine (12*d*) on either end of a polymethylene chain ($[(NC)_5Fe\{L(CH_2)_nL{\cdot}\alpha\text{-CD}\}Fe(CN)_5]^{4-}$).

A third method of preparing rotaxanes, termed slippage (13, 14), occurs when the internal diameter of the cavity of the cyclic component and the diameter of the end units on the thread are comparable. In this situation the threading of the cyclic component occurs efficiently only at elevated temperatures. Stoddart and co-workers (15) have employed this method to synthesize a number of rotaxanes with tetracationic cyclophanes as the cyclic component. We have recently reported the very slow self-assembly of a [2]pseudorotaxane of α-cyclodextrin employing the 1,10-bis[4-*tert*-butylpyridinium]-decane dication ($[tbp(CH_2)_{10}tbp]^{2+}$) as the thread (10). The *tert*-butyl group has a similar diameter to that of the α-CD cavity, and the rate constant for the formation of the [2]pseudorotaxane was found to be significantly enhanced at elevated temperatures.

To more fully understand the effects of the nature of the end unit on the rate and activation parameters associated with the cyclodextrin pseudorotaxane self-assembly processes, systematic kinetic investigations, employing several series of linear thread components, have been undertaken. In this paper the results of a ^1H and ^{31}P NMR kinetic study of the self-assembly and dissociation of α-cyclodextrin [2]pseudorotaxanes (Fig. 1) containing the 1,10-bis(trimethylphosphonium)decane dication ($[Me_3P(CH_2)_{10}PMe_3]^{2+}$) and a series of α,ω-bis(trialkylammonium)alkane dications ($[Me_3N(CH_2)_nNMe_3]^{2+}$ (n = 8–12) and $[Et_mMe_{(3-m)}N(CH_2)_{10}NMe_{(3-m)}Et_m]^{2+}$ (m = 1–3) are presented. The rate and activation parameters are discussed in terms of the steric and electronic effects of varying the polymethylene chain length, the nature of the quaternized atom, and nature of the alkyl substituents.

Experimental

Materials

The α-cyclodextrin (Aldrich) was dried at 80°C under reduced pressure for at least 8 h prior to use. The 1,*n*-dibromoalkanes (n = 8–12), 1,12-diiododecane, trimethylphosphine, and decamethonium bromide ($[Me_3N(CH_2)_{10}NMe_3]Br_2$) were purchased from Aldrich and used as received.

The α,ω-bis(trimethylammonium)alkane dibromides ($[Me_3N(CH_2)_nNMe_3]Br_2$, n = 8, 9, 11, 12) were prepared by a modification of the method of Blomquist et al. (17). Trimethylamine hydrochloride (16 mmol) was dissolved in a minimum of methanol and 0.6 mol equiv. of potassium carbonate were added. This solution was stirred for 12 h at which time the appropriate α,ω-dibromoalkane (3.2 mmol) was added slowly to the reaction mixture. After the addition, the reaction mixture was left for approximately 7 days without stirring. The solution was then filtered to remove unreacted potassium carbonate, and the filtrate was reduced in vacuo to obtain the crude product in 41–72% yields. The products were recrystallized from methanol–acetone.

Physical measurements

The ^{1}H, ^{13}C, and ^{31}P NMR spectra were recorded on a Bruker AM-400 instrument in D_2O, utilizing the residual solvent proton signal, external CH_3OH, and external 85% H_3PO_4 as the references, respectively. The stability constants for the α-CD pseudorotaxanes of the $[Me_3N(CH_2)_nNMe_3]^{2+}$ (where n = 8–12) series of threads and of the $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$ thread were determined by ^{1}H NMR titrations by the application of nonlinear least-squares and Simplex optimization programs to the equations for a 1:1 guest–host model, as described previously (12).
