The kinetics of the formation of the α-CD pseudorotaxanes of the $[Me_3N(CH_2)_nNMe_3]^{2+}$ (n = 8–12) and $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$ threads at 25°C were determined by ^{1}H NMR spectra taken at timed intervals following the addition of an excess of α-CD, as described previously (10). The rate constants for the formation of the α-CD pseudorotaxane with the $[Me_3P(CH_2)_{10}PMe_3]^{2+}$ guest were determined, in the presence of an excess of α-CD (50–150 mM), at 75, 80, and 85°C by ^{31}P NMR, as described above. The extent of pseudorotaxane formation after 24 h was also determined at five degree temperature intervals between 50 and 70°C in the presence of 150 mM α-CD.

The kinetics of the dissociation of the α-CD pseudorotaxanes into their cyclic and linear components were studied in the case of the $[Me_3N(CH_2)_nNMe_3]^{2+}$ (n = 9–12) and $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$ guests by the addition of 1,12-bis(4,4′-bipyridinium)dodecane dibromide ($[bpy(CH_2)_{12}bpy]Br_2$, 10 mM) to the pseudorotaxane (1 mM) solution, monitoring the rate of formation of the $\{bpy(CH_2)_{12}bpy\cdot\alpha\text{-CD}\}^{2+}$ pseudorotaxane as described previously (10, 12*d*).

The mass spectra were obtained on a VG Quattro quadrupole mass spectrometer, with an atmospheric-pressure electrospray source. Samples of the pseudorotaxanes, as solutions in distilled water with excess α-cyclodextrin, were introduced into the source at a flow rate of 5 mL min^{-1}. Elemental analyses were performed by Canadian Microanalytical Services Ltd (Delta, B.C.).

Results

The additions of excess α-cyclodextrin to aqueous solutions of the $[Me_3N(CH_2)_nNMe_3]^{2+}$ (n = 8–12) and the $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$ dications result in the room-temperature formations of [2]pseudorotaxanes. Attempts to assemble the corresponding [2]pseudorotaxanes with the more sterically demanding $[Et_2MeN(CH_2)_{10}NMeEt_2]^{2+}$ and $[Et_3N(CH_2)_{10}NEt_3]^{2+}$ dications were unsuccessful, even upon heating the solutions at 70°C for prolonged periods (up to one week).

The symmetry-related proton resonances of the dicationic threads of the pseudorotaxanes are split into pairs of resonances upon the threading of the asymmetic α-CD cavity (Fig. 2). From 2-D ROESY spectra of α-CD pseudorotaxanes with related threads (A.P. Lyon and D.H. Macartney; A.C. Smith and D.H. Macartney),[2] we have determined that the upfield peak of the pairs of resonances for each of the aliphatic thread protons is located near the narrower end of the cyclodextrin. The chemical-shift differences (on a 400 MHz instrument) between the two methyl singlets decrease as the polymethylene chain length is increased (34 Hz (n = 8), 25 Hz (n = 9), 19 Hz (n = 10), 14 Hz (n = 11), and 10 Hz (n = 12)), and the trimethylammonium end groups are located further from the rims of the α-CD cavity. The proton resonances of the α-cyclodextrin also exhibit chemical-shift changes upon inclusion of the threads (Fig. 2). In the ^{13}C NMR spectrum of the pseudorotaxane with the $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ thread the polymethylene resonances are split into pairs of peaks, while no splitting is observed in the methyl carbon resonance.

At higher concentrations of α-cyclodextrin (in excess of that needed for pseudorotaxane formation) there are no noticeable changes in the chemical shifts of the pairs of methyl proton resonances, which might be associated with inclusion of the methyl groups by additional α-CD hosts in solution. Such 1:1 and 2:1 α-CD adducts of the [2]pseudorotaxanes may be detected, however, in the gas phase by electrospray mass spectrometry. The $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ dication in the presence of excess α-CD gives rise to peaks at m/z = 614.5 ($\{L(CH_2)_{10}L\cdot\alpha\text{-CD}\}^{2+}$ 100%), 1101.6 ($\{L(CH_2)_{10}L\cdot 2\alpha\text{-CD}\}^{2+}$ 30%), 1588.0 ($\{L(CH_2)_{10}L\cdot 3\alpha\text{-CD}\}^{2+}$ 7%).

The stability constants for the pseudorotaxanes (K_1) containing the $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ (n = 8–12) dications were determined by a ^{1}H NMR titration of the threads with α-cyclodextrin at 25°C in D_2O (I = 0.10 M NaCl) and are presented in Table 1. The approaches to equilibrium for the pseudorotaxanes

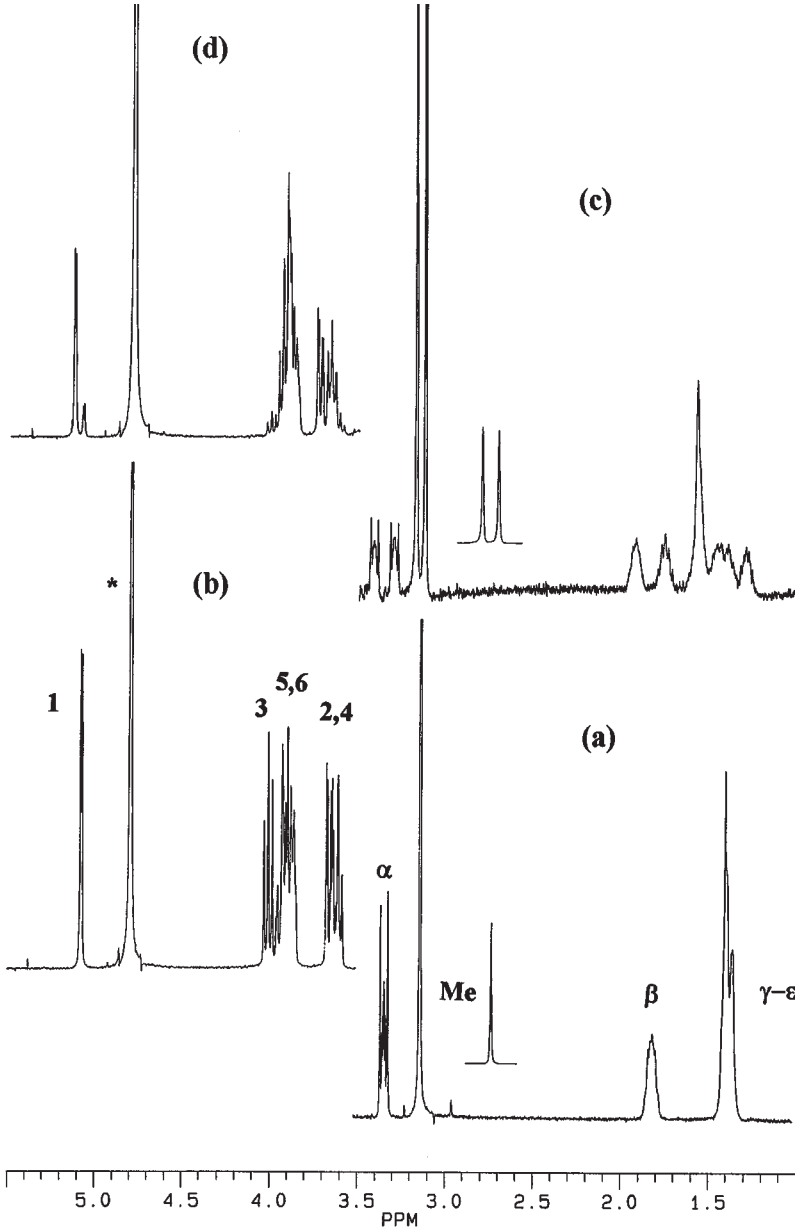
The ^{1}H NMR spectra of (*a*) $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ (5 mM), (*b*) α-CD (5 mM), (*c*) $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ (5 mM) in the presence of α-CD (50 mM), and (*d*) α-CD (5 mM) in the presence of $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ (50 mM) in D_2O. The polymethylene protons of the thread (spectrum (*a*)) are labelled α-ε according to their positions with respect to the quaternized N atoms, while the α-CD protons (spectrum (*b*)) are labelled as in Fig. 1. The resonance denoted by the asterisk is for the solvent HDO proton.



containing the $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$ and $[Me_3P(CH_2)_{10}PMe_3]^{2+}$ threads are too slow at 25°C to permit accurate determinations of K_1 by this titration method.

The kinetics of the formation of the [2]pseudorotaxanes from α-CD and the $[Me_3N(CH_2)_nNMe_3]^{2+}$ (n = 9–12) and $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$ dications were determined at 25°C in D_2O (I = 0.10 M NaCl) by monitoring the methyl proton resonances of the threads in the ^{1}H NMR spectra (Fig. 3).

$$[1] \quad [L(CH_2)_nL]^{2+} + \alpha\text{-CD} \xrightarrow{k_1} \{L(CH_2)_nL{\cdot}\alpha\text{-CD}\}^{2+}$$

The observed pseudo-first-order rate constants exhibited a first-order dependence on the concentration of α-CD (10–50 mmol) present in excess of the thread (1–2 mmol), as illustrated in Fig. 4.

The second-order rate constants k_1 are presented in Table 1. Activation parameters associated with k_1 were determined for the $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ and $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$ dications and are also presented in Table 1, along with the rate and activation parameters for the $[tbp(CH_2)_{10}tbp]^{2+}$ (tbp = 4-*tert*-butylpyridinium) dication, determined in a previous study (10). It was not possible to accurately determine the formation rate constant for the pseudorotaxane with the $[Me_3N(CH_2)_8NMe_3]^{2+}$ thread by ^{1}H NMR, due to the low stability constant (K_1 = 44 M^{-1}) and the rapid approach to

equilibrium (k_1[α-CD] + k_{-1}) at higher concentrations of α-CD. The rate constant for the formation of the pseudorotaxane with the $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ thread at 25°C was observed to decrease with an increase in the ionic strength: k_1 = 0.215 M^{-1} s^{-1} (I = 0.003 M (no added NaCl), 0.164 M^{-1} s^{-1} (0.10 M), and 0.138 M^{-1} s^{-1} (1.0 M).

The kinetics of the dissociation of the [2]pseudorotaxanes were determined by ^{1}H NMR, following the addition of an excess of $[bpy(CH_2)_{12}bpy]^{2+}$ to the assembled pseudorotaxane. Upon pseudorotaxane dissociation, the $[bpy(CH_2)_{12}bpy]^{2+}$ dication rapidly traps the released α-CD, forming a stable pseudorotaxane (K_1 = 3700 M^{-1} at 25°C (12*b*)).

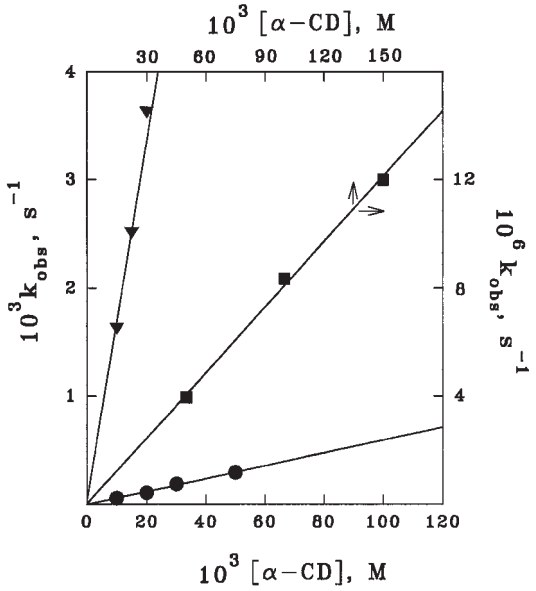
Fig. 4. The dependencies of the observed rate constants on [α-CD] for the formations of the [2]pseudorotaxanes with (●) $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$ (25°C), (■) $[Me_3P(CH_2)_{10}PMe_3]^{2+}$ (75°C), and (▼) $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ (25°C).



conveniently monitored by using $^{31}P\{^1H\}$ NMR, as the free guest exhibits a singlet at 26.45 ppm. The addition of dibromide salt of the dication (5 mM) to a large excess of α-CD (150 mM) in aqueous solution (20% D_2O, 80% H_2O, 0.10 M NaCl) at 25°C does not result in the formation of a pseudorotaxane, even after one week. At elevated temperatures, however, slow formation of the pseudorotaxane is indicated by the appearance of a pair of singlet resonances (26.79 and 26.50 ppm) and the disappearance of the free-guest resonance (Fig. 5). Similar splittings of the proton and carbon resonances of the methyl groups are observed in the ^1H and ^{13}C spectra of the pseudorotaxane, with proton doublets centred at 1.94 and 1.89 ppm (J_{PH} = 14 Hz) and carbon doublets centred at 7.22 and 7.21 ppm (J_{PC} = 52 Hz). The percent inclusion of the guest dication after 24 h in the presence of 150 mM α-CD was determined at five degree intervals over the temperature range of 50–70°C: 9% (50°C), 16% (55°C), 27% (60°C), 35% (65°C), 51% (70°C). A study of the formation rate constant as a function of α-CD concentration at 75°C (Fig. 4) revealed a first-order dependence on [α-CD] and a second-order rate constant of (7.9 ± 0.6) × 10^{-5} M^{-1} s^{-1}. The enthalpy and entropy of

activation for the formation of the [2]pseudorotaxane were determined to be 96 ± 10 kJ mol^{-1} and –50 ± 30 J K^{-1} mol^{-1}, respectively. The electrospray mass spectrum of this pseudorotaxane in the presence of excess α-CD exhibits peaks at *m*/*z* = 632.3 ($\{L(CH_2)_{10}L\cdot\alpha\text{-CD}\}^{2+}$ 100%), 1118.5 ($\{L(CH_2)_{10}L\cdot2\alpha\text{-CD}\}^{2+}$ 43%), and 1605.0 ($\{L(CH_2)_{10}L\cdot3\alpha\text{-CD}\}^{2+}$ 5%), corresponding to the [2]pseudorotaxane and its 1:1 and 2:1 adducts, respectively, in the gas phase.

Discussion

The rate constants and activation parameters for the formation (k_1) and dissociation (k_{-1}) of α-cyclodextrin [2]pseudorotaxanes have been determined for series of dicationic threads $[Me_2RX(CH_2)_nXRMe_2]^{2+}$, varying the polymethylene chain length (n = 8–12), the quaternized atom X (N or P), and the

© 1998 NRC Canada

alkyl substituent R (Me or Et). The kinetic data obtained in this study indicated that the rate constants for the formation of the [2]pseudorotaxanes are very dependent on the size of the end group, but are relatively independent of the polymethylene chain length.

The results of this study indicate that α-CD is able to effectively discriminate between end groups on the basis of their size and shape as demonstrated by the slow formation of the pseudorotaxane with $[Me_2EtN(CH_2)_{10}NEtMe_2]^{2+}$, as compared to the inability to form pseudorotaxanes with threads containing the more sterically demanding diethylmethyl- and triethylammonium head groups. Extrapolation of the rate constant for the formation of the [2]pseudorotaxane with the $[Me_3N(CH_2)_{10}NMe_3]^{2+}$ dication to 75°C gives a value of 200 M^{-1} s^{-1}, which is 2.5×10^6 times greater than the rate constant for the $[Me_3P(CH_2)_{10}PMe_3]^{2+}$ dication. Using crystallographic data determined for $[(CH_3)_4N]I$ (19) and $[(CH_3)_4P][Cu_2Cl_5]$ (20), the diameter of the trimethylphosphonium end group is estimated to be 0.54 Å larger than the trimethylammonium end group. Therefore, the threading of the larger trimethylphosphonium end group must occur by the slippage mechanism at elevated temperatures.

In a separate study using dicationic threads bearing 4-(α-alkyl-α-methylmethanol)pyridinium (L) end groups, $[L(CH_2)_{12}L]^{2+}$, similar dependences of the pseudorotaxane formation constants on the steric bulk of the head groups were observed (A.C. Smith and D.H. Macartney)[2]. With these dications, however, the threading is preceded by inclusion of the end groups in the α-CD cavities. In the present study, there is no evidence, other than in the electrospray mass spectrum, of significant inclusion of the trialkylammonium or -phosphonium groups by the cyclodextrin. ^{1}H NMR studies of the proton chemical shifts of the tetramethylammonium and trimethylethylammonium ions in the presence of α-CD indicate that there is negligible inclusion of these cations. For this reason, the tetramethylammonium ion has been proposed as an internal reference for NMR titrations with cyclodextrins (21).

The rate constants for the dissociation of the [2]pseudorotaxanes into their cyclic and linear components indicate a dependence on both the size of the head group and the length of the polymethylene chain. The effects of the steric bulk of the head group have been discussed above, and the length of the polymethylene chain is related to its hydrophobicity and the degree of hydrophobic interactions with the cyclodextrin interior cavity. As a result, the stability constants for the pseudorotaxanes with the $[Me_3N(CH_2)_nNMe_3]^{2+}$ threads increase with the polymethylene chain length and are similar in magnitude to the corresponding values for other $[L(CH_2)_nL]^{2+}$ threads with *N*-heterocyclic head groups (8, 12). The stability constants were also calculated from the ratio of the formation and dissociation rate constants ($K_1 = k_1/k_{-1}$, Table 2) and are in reasonable agreement with the values determined by the ^{1}H NMR titrations. We have observed similar degrees of agreement in stability constants between kinetic and NMR measurements in previous studies (12).

The enthalpies of activation for the formation of these α-cyclodextrin [2]pseudorotaxanes are in the range of 95–120 kJ mol^{-1} and are likely associated the distortions required in the α-CD and the end group upon threading, along with desolvation of the end group. The entropies of activation are comprised of an unfavourable term associated with the combining of the cyclic and linear components and a favourable contribution from the release of water molecules solvating the quaternized atom. The $\Delta S^{\ddagger}_1$ values (and the values of $\Delta H^{\ddagger}_1$ to a lesser extent) determined in this study (Tables 1 and 2) tend to decrease with an increase in the bulk and hydrophobicity of the end groups. Upon replacing N by P as the quaternized atom, or replacing one methyl group by an ethyl, the hydrophobicity of the cationic end group is increased and the group is less strongly solvated, leading to decreases in both the entropy and enthalpy of activation associated with end group desolvation. The rate constants for pseudorotaxane formation (with $[Me_3N(CH_2)_{10}NMe_3]^{2+}$) were also found to decrease with increasing ionic strength, as ion pairing between the quaternized nitrogen and the chloride ion inhibited the threading of the α-CD by the end group. We have also recently observed that the rate constants for α-CD pseudorotaxane formation with these and other cationic threads are significantly increased in basic solution as a result of α-CD hydroxyl deprotonation. We are continuing to investigate this and other medium effects on the kinetics and mechanisms of pseudorotaxane self-assembly.

On the possibility of conversion of strained bridgehead alkenes into carbenes via 1,2 hydrogen and 1,2 carbon migrations. A theoretical study of the rearrangements in the adamantene and protoadamantene systems

Gennady V. Shustov and Michael T.H. Liu

Abstract: Rearrangements of 2-adamantene **3**, adamantylidene **4**, and 4-protoadamantylidene **5** have been studied theoretically using high level ab initio computations. Adamantene **3** and adamantylidene **4** have singlet ground states. The conversion of **3** into **4** via 1,2 hydrogen migration ($\Delta G^{\neq}$ = 69.1 kcal mol^{-1}) cannot compete with 1,2 carbon migration of **3** to **5** (30.3 kcal mol^{-1}). The singlet carbene **5** rearranges to 2,4-dehydroadamantane **6** and 4,5-protoadamantene **9** via 1,3H and 1,2H shifts, respectively, with identical activation barriers of 8.8 kcal mol^{-1}. The 1,2 migration of the bridge hydrogen in **5** leading to 3,4 protoadamantene **8** has a higher activation barrier (37.2 kcal mol^{-1}). A retro Diels–Alder cycloaddition of **3** to 5-allyl-3-methylenecyclohex-1-ene **7** is the main channel of the unimolecular conversion of **3** ($\Delta G^{\neq}$ = 20.5 kcal mol^{-1}). A predicted ratio of **7** > > **6** ≈ **9** of the products of thermolysis of **3** is in agreement with experimental data. The rearrangement of **4** into **6** via the 1,3H shift ($\Delta G^{\neq}$ = 11.8 kcal mol^{-1}) dominates over the 1,2C shift of **4** to **8** (13.5 kcal mol^{-1}), also in accord with experiment.

Key words: adamantene, protoadamantenes, carbenes, rearrangements, ab initio, computation.

Résumé : Faisant appel à des calculs ab initio à des niveaux élevés, on a étudié d'une façon théorique les réarrangements des adamant-2-ène (**3**), adamantylidène (**4**) et 4-protoadamantylidène (**5**). Les adamant-2-ène (**3**) et adamantylidène (**4**) possèdent des états fondamentaux singulets. La conversion de **3** en **4** par le biais d'une migration 1,2 d'hydrogène ($\Delta G^{\neq}$ = 69,1 kcal/mol) ne peut pas faire compétition à la migration 1,2 de carbone de **3** à **5** (30,3 kcal/mol). Le carbène singulet **5** se réarrange en 2,4-déhydroadamantane (**6**) et en 4,5-protoadamantène (**9**) par le biais de déplacements 1,3 et 1,2 d'hydrogène respectivement; les barrières initiales d'activation sont toutes les deux égales à 8,8 kcal/mol. La barrière d'activation pour la migration 1,2 de l'hydrogène de pont du composé **5** conduisant au 3,4-protoadamantène (**8**) est plus élevée (37,2 kcal/mol). Une rétrocycloaddition de Diels–Alder du composé **3** en 5-allyl-3-méthylènecyclohex-1-ène (**7**) correspond à la voie principale de la conversion unimoléculaire de **3** ($\Delta G^{\neq}$ = 20,5 kcal/mol). Un rapport prévu de **7** > > **6** ≈ **9** pour les produits de thermolyse de **3** est en bon accord avec les données expérimentales. Le réarrangement de **4** en **6** par le biais d'un déplacement 1,3 d'hydrogène ($\Delta G^{\neq}$ = 11,8 kcal/mol) est plus important que le déplacement 1,2 de carbone de **4** à **8** (13,5 kcal/mol); ces prédictions sont aussi en accord avec les données expérimentales.

Mots clés : adamantène, protoadamantènes, carbènes, réarrangements, ab initio, calculs théoriques.

[Traduit par la rédaction]

Introduction

Conversions of strained bridgehead alkenes (anti-Bredt alkenes) into the corresponding carbenes have been known for two decades (1–12). A "bridgehead alkene–carbene" isomerization has been thoroughly studied in the case of the homocubene system **1/2** (6–12) (Scheme 1).

The strain in anti-Bredt alkenes is one of the factors promoting their isomerization to carbenes because, owing to this strain, energy of the alkene energy approaches that of the carbene, or even exceeds it (6, 12). From the formation of "carbene products" under conditions of generation of the bridgehead alkenes, one can make judgements about the "alkene–carbene" conversion process (4–14).

As a rule, the isomerization process of anti-Bredt alkenes into the corresponding carbenes is described as a 1,2 carbon migration (4–11, 14). However, for adamantene **3**, Bian and Jones (13) proposed the possibility of its isomerization into adamantylidene **4** via a 1,2 hydrogen shift. They explained the

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

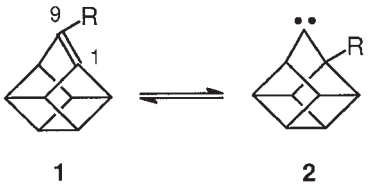
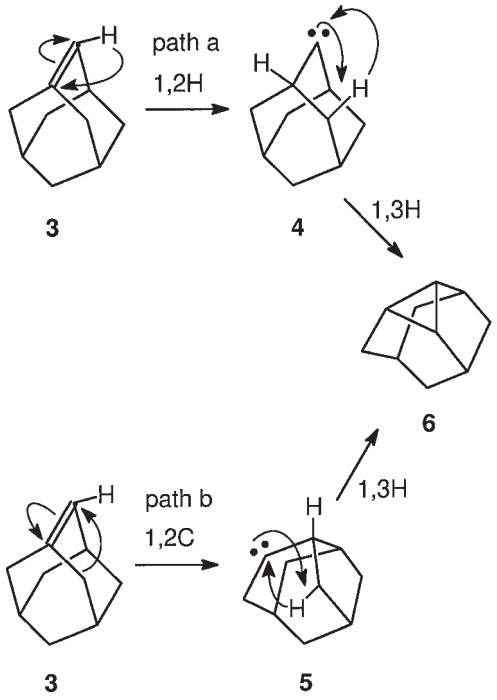


Scheme 2.



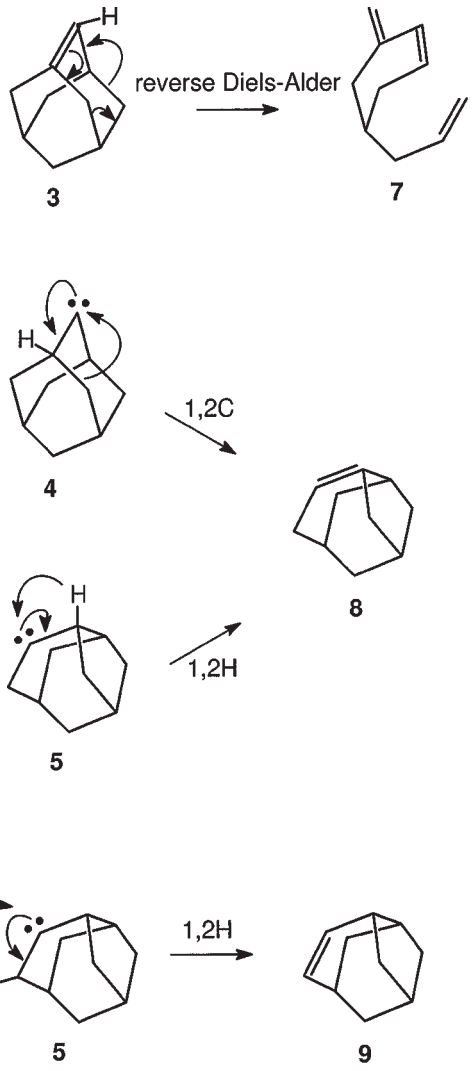
formation of 2,4-dehydroadamantane **6** under the conditions of the generation of adamantene **3** (vacuum flash pyrolysis of 1-noradamantyldiazomethane at 500°C) by consecutive rearrangements involving a 1,2H shift in **3** and a 1,3H shift in **4** (Scheme 2, path a).

It was shown earlier that dehydroadamantane **6** is the main product of vacuum pyrolysis of 2-diazoadamantane (15) and adamantane-2-spiro-3′-diazirine (16): the precursors of carbene **4**. Formation of **6** was also observed in photolysis of adamantane-2-spiro-3′-diazirine in β-cyclodextrin (17) and argon matrixes (18) and inside a zeolite (19). The possibility of 1,2 hydrogen migration in the pair **3/4** has been considered (17, 18), but no experimental proof for this process at low temperatures was found.

On the other hand, the formation of dehydroadamantane **6** under the conditions of the generation of adamantene **3** can be explained by a 1,2 carbon migration followed by a 1,3H shift in the intermediate protoadamantylidene **5** (Scheme 2, path b). This path was demonstrated in the rearrangement of 2-(1-adamantyl)-adamantene into 2-(1-adamantyl)-2,4-dehydroadamantane (14).

Thus, it is of interest to estimate quantitatively the possibility of rearrangement of adamantene **3** via 1,2 hydrogen and 1,2 carbon migrations. In the present work, we have undertaken a theoretical study of the paths a and b (Scheme 2), including

Scheme 3.



the corresponding transition states. In previous ab initio theoretical studies (12, 18) of the "anti-Bredt alkene–carbene" isomerization, transition structures connecting anti-Bredt alkenes with the corresponding carbenes were not considered.

For comparison with the experimental data (13–19), we have also studied a reverse Diels–Alder reaction, the 1,2C shift in **4**, and the 1,2H shifts in **5** (Scheme 3) as competitive conversion paths for adamantene **3**.

It is worthy of note that rearrangements of bi- and tricyclic carbenes, like **4** and **5,** themselves are a field of much current interest (20).

Computational methods

All ab initio calculations presented here were performed with the Gaussian 94 system of programs (21) on a Silicon Graphics Power Challenge computer with 18 R8000 processors. The geometry optimizations and frequency calculations were carried out at the RHF/6-31G(d) and B3LYP/6-31+G(d) (UB3LYP/6-31+G(d) for the triplets **3**, **4**) theoretical levels using procedures implemented in the Gaussian molecular orbital package. The (U)B3LYP/6-31+G(d) optimized structures

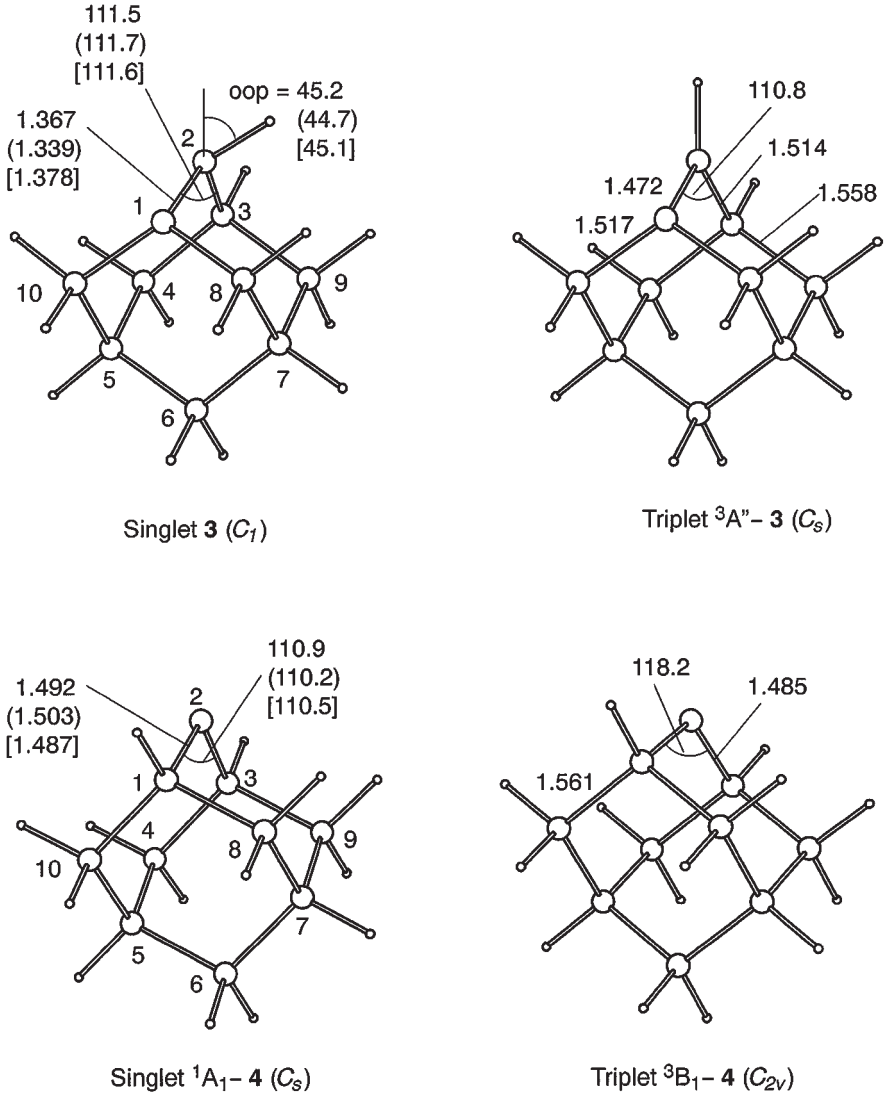
Fig. 1. (U)B3LYP/6-31+G(d), HF/6-31G(d) (in parentheses), and MP2(fc)/6-31G(d) (in square brackets) optimized structures of the singlet and triplet states of adamantene **3** and adamantylidene **4**; oop = out-of-plane angle. Bond lengths in angstroms, angles in degrees.



of $C_{10}H_{14}$ are drawn in Figs. 1–4 using a program written by Professor Arvi Rauk. The harmonic frequency analysis verified the nature of the stationary points as minima (all real frequencies) or as transition structures (one imaginary frequency) and was used to provide an estimate of the zero-point vibrational energies (ZPVE). Zero-point corrections (ΔZPVE) were scaled by a 0.91 factor for the RHF/6-31G(d) level and by a 0.98 factor for the (U)B3LYP/6-31+G(d) level (22). Final energies were obtained at the (U)B3LYP/6-311++G(3df, 2pd)//(U)B3LYP/6-31+G(d) level of theory (hereinafter referred to B3LYP). Geometries of the singlet species **3**, **4**, and **TS(3/4)** were also optimized at the MP2/6-31G(d) level with the frozen-core approximation. Table 1 shows total energies of $C_{10}H_{14}$ stationary structures along with ZPVEs. Schematic presentations of the relative energies of the $C_{10}H_{14}$ isomers are drawn in Figs. 5–7.

Heat capacities and entropy corrections were made using scaled (0.98) B3LYP/6-31+G(d) frequencies and standard statistical procedures within the rigid rotator – harmonic oscillator model (23) to determine enthalpies and free energies at 25 and 500°C (1 atm). Half-lives ($t_{1/2}$) of the reactions **3**→**4** and **3**→**5** were estimated ($t_{1/2}$ = (ln 2)/$k(T)$) using values of the first-order rate constants ($k(T)$). These constants were computed assuming that the transmission coefficient is equal to 1, as expressed by the following relation

$$k(T) = (kT/h)\exp(-\Delta G^{\neq}/RT)$$

which provides a direct relationship between the rate constant for an elementary reaction and its free energy of activation, $\Delta G^{\neq}$. In this equation, k and h are the Boltzmann and Planck constants, respectively.

It should be noted that density functional theory methods proved to be quite reliable for computing carbenes (20, 24), strained alkenes (24), "strained alkene-carbene" isomerizations (25- 29), and cycloaddition reactions (30).

Results and discussion

Relative energies and the singlet–triplet separations of 3 and 4

As in the case of the earlier studied pair of 1(9)-homocubene **1**

and 9-homocubylidene **2** (12) (Scheme 1), the ground states of the singlet adamantene **3** and adamantylidene $^1A_1$-**4** belong to the C_1 and C_s symmetries, respectively (Fig. 1).

The pyramidal configuration of the C2 atom in alkene **3** (out-of-plane angle for the hydrogen at C4 is 45.2°) provides a small but significant overlapping of the *p* atomic orbitals of the formally double C1—C2 bond, since these AOs are orthogonal in the planar configuration of the C2 atom (12). However, in the same time, pyramidalization of the C1 and C2 atoms decreases the *p* character of the lobes participating in the "π" bonding. Therefore, the pyramidalization of the bridgehead C1 atom, unlike the pyramidalization of the C2 atom, reduces double bonding between these atoms and has to be a destabilizing factor. The latter must bear on the relative energies of a strained alkene and the corresponding carbene. Evidently, the pyramidality of the bridgehead C1 atom in adamantene **3** is smaller than the pyramidality in homocubene **1**. According to GVB-PP(1)/6-31G(d) calculations (12), **1** is less stable than the isomeric singlet carbene **2**. For the pair **3/4**, the HF method predicts a small preference for carbene $^1A_1$-**4** (Fig. 5). However, taking into account the effects of electron correlation in the MP2 method leads to a substantial stabilization (24.2 kcal mol^{-1}) of adamantene **3** relative to the singlet adamantylidene **4**. A B3LYP energy difference between **3** and $^1A_1$-**4** is 17.4 kcal mol^{-1} in favor of **3** and is closer to the difference (ca. 12 kcal mol^{-1}) calculated earlier for this pair at the CASSCF/6-31G(d) level (18).

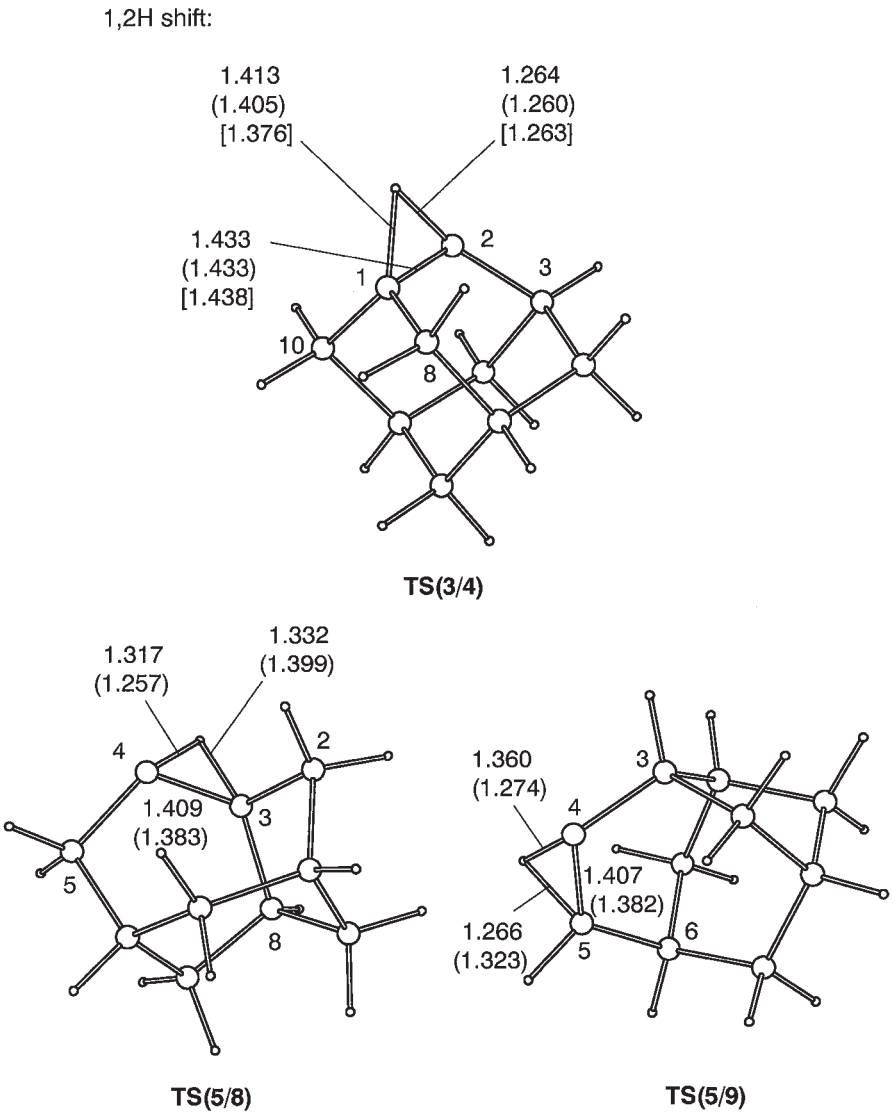
We also estimated the singlet–triplet separations for anti-Bredt alkene **3** and carbene **4** at the B3LYP level (Table 1, Fig. 5). The triplet states of **3** and **4** were optimized under C_s and C_{2v} symmetry constraints, respectively (Fig. 1), and were minima.

The triplet adamantene $^3A''$-**3** is characterized by a longer C1—C2 bond (1.472 Å) (1 Å = 0.1 nm) in comparison with the C1—C2 bond in the singlet **3,** and by the planar configuration of the C2 atom. A calculated destabilization of triplet **3** with respect to singlet **3** is 11.4 kcal mol^{-1} (ΔG°_{298} = 10.3 kcal mol^{-1}, ΔS°_{298} = 7.0 cal mol^{-1} K^{-1}).

The rigidity of the adamantane skeleton in the triplet $^3B_1$-**4** does not allow the valence angle at the carbene atom C2 to adopt the value (ca. 130°), which is typical for triplet carbenes (24, 31–33). Narrowing of the valence angle C1-C2-C3 to

© 1998 NRC Canada

Fig. 3. B3LYP/6-31+G(d), HF/6-31G(d) (in parentheses), and MP2(fc)/6-31G(d) (in square brackets) optimized structures of the transition states for 1,2 hydrogen migrations. Bond lengths in angstroms.



118.2° increases the *s* character in the nonbonding σ^1 orbital of the triplet, and reportedly leads to destabilization of this state (31). The B3LYP energy difference between $^3B_1$-**4** and $^1A_1$-**4** is 3.1 kcal mol^{-1} ($\Delta G°_{298}$ = 3.2 kcal mol^{-1}, $\Delta S°_{298}$ = –1.2 cal mol^{-1} K^{-1}) in favor of the latter. This value is close to an experimental estimate of the singlet–triplet gap in carbene **4** (–4.8 kcal mol^{-1}) (18, 34). Acyclic dialkyl carbenes are characterized by a smaller singlet–triplet splitting (–0.2/–1.6 kcal mol^{-1}) (24, 32, 33). The angle dependencies of singlet–triplet gaps in other strained carbenes and alkenes have recently been dealt with in detail by Bettinger et al. (27, 29) and Xie et al. (28).

Supposedly, the large singlet–triplet gap in **4** is also caused by the stabilizing effects of hybridization of the carbene atom C2 and hyperconjugation between the empty carbene *p* orbital and the σ orbitals of the proximal C—C bonds in $^1A_1$-**4** (Fig. 8*a*). Indeed, the valence angle at the carbene atom in $^1A_1$-**4** (110.9°) is smaller than it is in acyclic dialkyl carbenes (ca. 113°) (24, 32, 33), and the occupied σ^2 carbene orbital in $^1A_1$-**4** must have a larger *s* character. One can deduce there is enhanced σ–*p* hyperconjugation in $^1A_1$-**4** from the decrease of the C2-C1-C8 and C2-C3-C9 valence angles (103.7°), compared with the C2-C1-C10 and C2-C3-C4 angles (115.3°), as well as from the lengthening of the C1—C8 and C3—C9 bonds (1.567 Å) in comparison with the C1—C10 and C3—C4 bonds (1.555 Å) at the B3LYP level (for numbering see Figs. 1–4).

Owing to the substantial destabilization of the triplet states of adamantene **3** and adamantylidene **4**, we have limited our theoretical investigation of the rearrangements of these compounds to the singlet $C_{10}H_{14}$ potential energy surface.

1,2 Hydrogen migration

The HF and MP2 methods predict almost identical high relative energies for the transition state **TS(3/4)** of 1,2H migration in adamantene **3** (Table 1, Fig. 5). The B3LYP method gives a rather smaller relative energy for **TS(3/4)**, although the calculated activation barrier ($\Delta G^{\neq}_{773}$ = 69.1 kcal mol^{-1}, $\Delta S^{\neq}_{773}$ = 0.9

© 1998 NRC Canada

cal mol^{-1} K^{-1}) is predicted to be prohibitively high even at 500°C, the temperature at which the generation of adamantene **3** was carried out (13). The half-life of **3** with respect to 1,2 hydrogen migration is 402 h at 500°C, based on the B3LYP activation barrier.

It should be noted that the B3LYP relative energy of transition state **TS(3/4)** for the 1,2H shift in adamantene **3** (69.6 kcal mol^{-1}) is almost the same as for the less strained alkenes **8** and **9** –68.8 (**TS(5/8)**) and 69.5 kcal mol^{-1} (**TS(5/9)**), respectively (Fig. 6), although these barriers have different origins.In the case of planar alkenes like **9**, the migrating C—H bond is orthogonal to the *p* part of the π* orbital of the C═C bond. A high barrier for the 1,2H shift results from the necessity of breaking the double bond at turning the migrating C—H bond to an angle close to 90° from the initial plane of the C═C bond. In particular, this angle is 82° in the transition state **TS(5/9)** (Scheme 4). The other bonds of the alkene fragment in the transition state must remain close to the initial plane.

In the anti-Bredt alkene **3**, the migrating C—H bond is nonorthogonal to the corresponding lobe of the "π" orbital, i.e., the double bond itself has been broken in the ground state of **3**. However, the rigidity of the molecular skeleton does not allow the bridgehead C1 atom to be planar and retains the C2—C3 bond at almost bisector orientation with respect to the

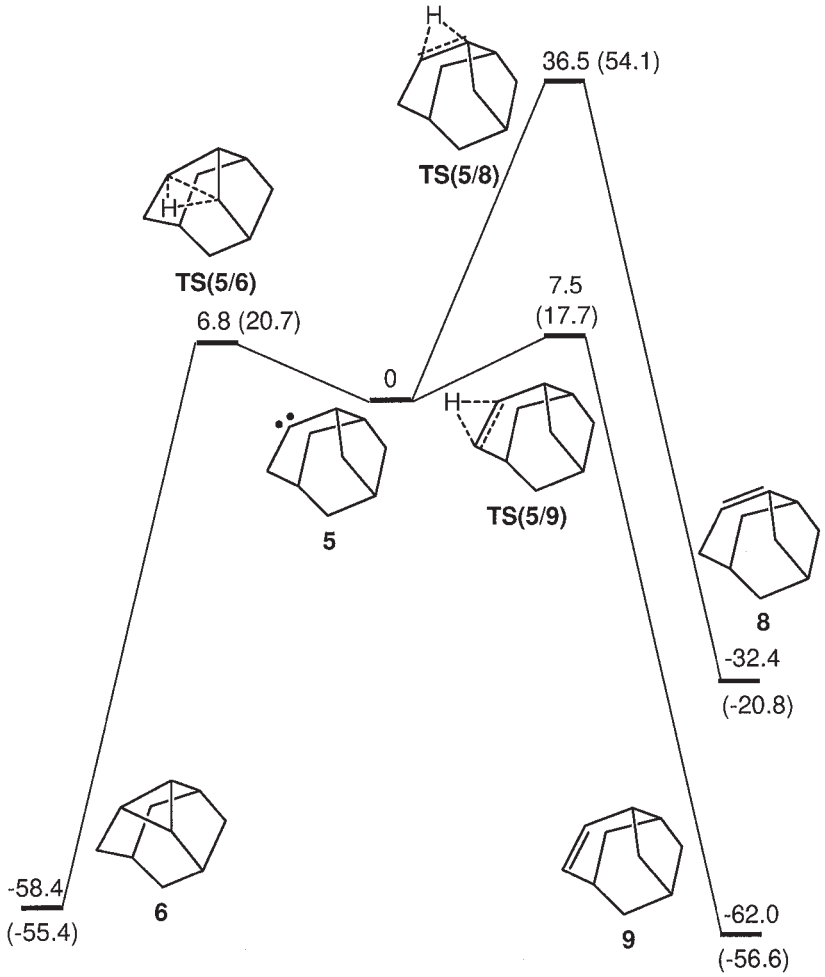
Fig. 6. Schematic presentation of the relative energies of the $C_{10}H_{14}$ isomers participating in rearrangements of singlet adamantylidene **5** at B3LYP/6-311++G(3df,2pd)//B3LYP/6-31+G(d) + 0.98 × ΔZPVE and HF/6-31G(d) + 0.91 × ΔZPVE (in parentheses) in kcal mol^{-1}.



C8-C1-C10 angle (Scheme 4). Such a geometry provides a considerable strain in transition state **TS(3/4)**. The 1,2 H shift in the bridgehead, but less strained, alkene **8** (Scheme 4) can be considered as an intermediate case in which both factors (energy of breaking the C═C bond and the strain of the transition state) play their role.

If we consider the 1,2 hydrogen migration from the side of the singlet carbenes **4**, **5**, a different picture emerges. Substantial differences are seen in the free enthalpies of activation for the migration of the bridge hydrogens in **4** and **5** ($\Delta G^{\neq}_{773}$ = 53.5 and 37.2 kcal mol^{-1}, respectively) and of a nonbridge hydrogen at C4 in **5** ($\Delta G^{\neq}_{773}$ = 8.8 kcal mol^{-1}). This barrier ratio is caused entirely by the difference in the strain of the transition states **TS(3/4) > TS(5/8) > TS(5/9)**.

1,2 Carbon migration and other rearrangements

Examination of the ground-state orbital alignment in adamantene **3** implies that the lobes of the "π" and "π*" orbitals of the formally double C1—C2 bond overlap better with the σ orbitals of the proximal C—C bonds than with each other. Such "π"–σ* and σ–"π*" interactions (Fig. 8*b*) are revealed in the noticeable lengthening of the C3—C9 (1.593 Å) and C7—C8 (1.607 Å) bonds and in the shortening of the C1—C8 (1.509 Å) and C7—C9 (1.555 Å) bonds in comparison with the corresponding relatively unperturbed C3—C4 (1.536 Å), C5—C10 (1.542 Å), C1—C10 (1.518 Å), and C4—C5 (1.547 Å) bonds (Fig. 1, B3LYP level). The C2-C1-C8 (110.2°) and C2-C3-C9 (96.4°) valence angles are also substantially smaller than the C2-C1-C10 (119.1°) and C2-C3-C4 (115.2°) valence angles. Thus, in the ground state of adamantene **3**, an especially favorable stereoelectronic situation for breaking the C3—C9 and C7—C8 bonds, i.e., for a reverse Diels–Alder cycloaddition, has been created. The interaction of the C2 lobe of the "π*" orbital with the σ orbital of the C1—C8 bond, which promotes the 1,2 carbon migration, also should be pointed out in **3** (Fig. 8*c*). However, unlike the C3—C9 bond, the C1—C8 bond looks unperturbed because a stretching of this bond, as a result of the σ–"π*" interaction, is compensated for by its shortening, owing to the interaction of the C1 lobe with the C8—C7 bond (Fig. 8*b*).

The B3LYP method gives more realistic activation energies for the 1,2C shift and retro Diels–Alder reaction in adamantene **3** than does the HF method (Fig. 5). A B3LYP activation barrier of the 1,2 carbon migration ($\Delta G^{\neq}_{773}$ = 30.3 kcal mol^{-1}, $\Delta S^{\neq}_{773}$ = –0.9 cal mol^{-1} K^{-1}) is more than twice as low as the barrier of the 1,2 hydrogen migration. The calculated half-life of adamantene **3** for the 1,2C shift is 1.6 × 10^{-5} s at 500°C. The product of the 1,2 carbon migration, the singlet

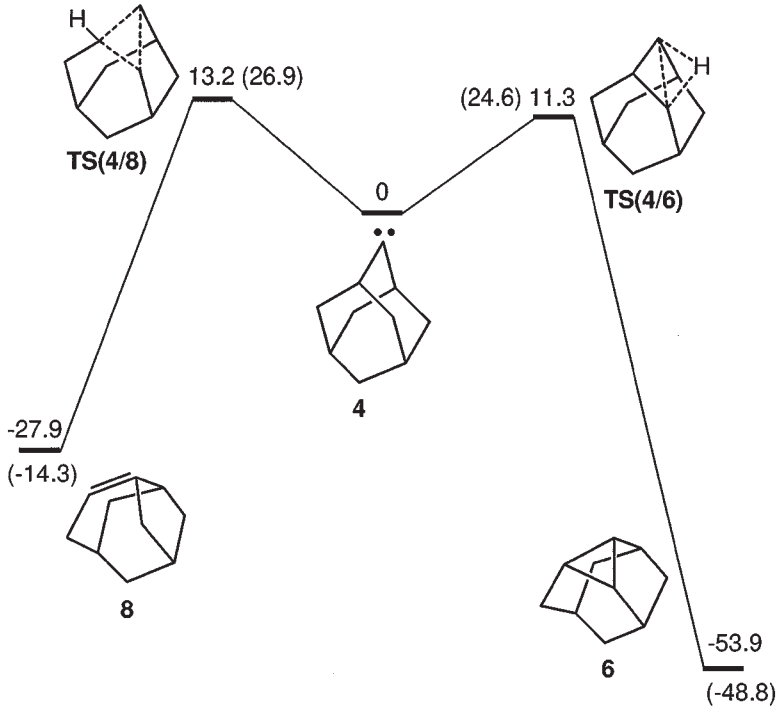
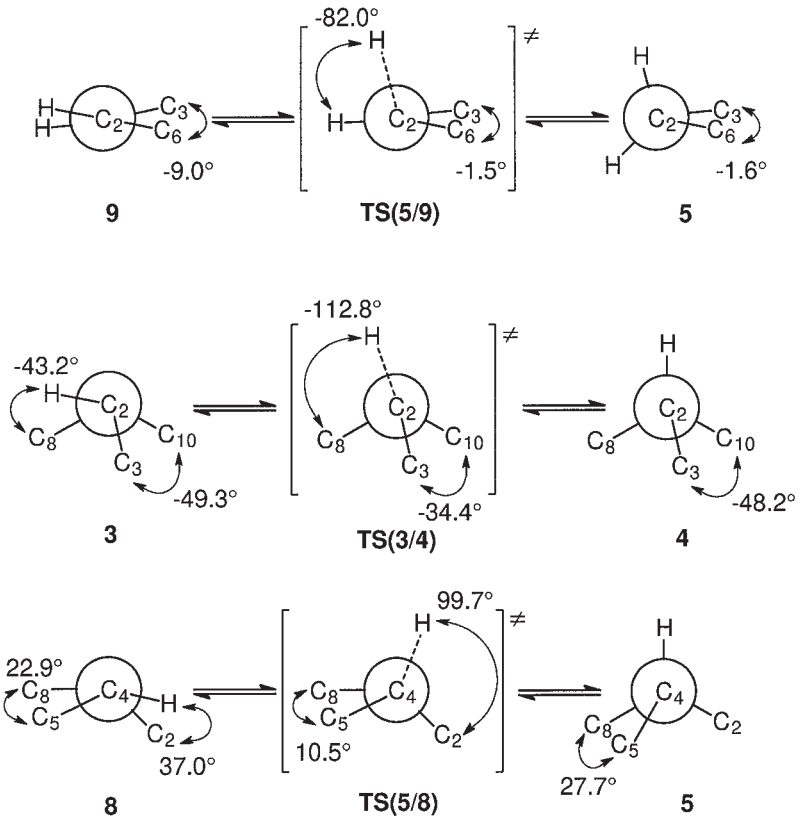
Fig. 7. Schematic presentation of the relative energies of the $C_{10}H_{14}$ isomers participating in rearrangements of singlet adamantylidene **4** at B3LYP/6-311++G(3df,2pd)//B3LYP/6-31+G(d) + 0.98 × ΔZPVE and HF/6-31G(d) + 0.91 × ΔZPVE (in parentheses) in kcal mol^{-1}.



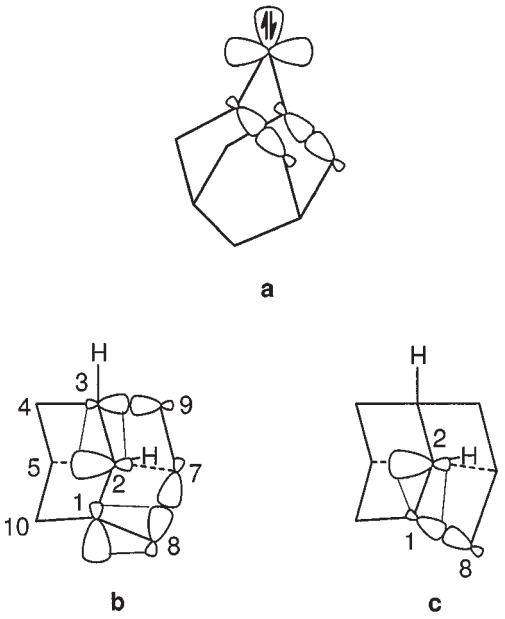
Scheme 4.



4-protoadamantylidene **5**, in its turn can rearrange in at least three ways: a 1,3 hydrogen migration with the formation of 2,4-dehydroadamantene **6**, and two 1,2H shifts, which lead to protoadamantenes **8**, **9** (Fig. 6). For the reason discussed above, the activation barrier ($\Delta G^{\neq}_{773}$ = 37.2 kcal mol^{-1}, $\Delta S^{\neq}_{773}$ = –1.6 cal mol^{-1} K^{-1}) for the bridge 1,2H migration is four

© 1998 NRC Canada

Fig. 8. Ground-state orbital alignments in the singlet adamantylidene **4** (*a*) and adamantene **3** (*b*, *c*).



times higher than the barrier ($\Delta G^{\neq}_{773}$ = 8.8 kcal mol^{-1}, $\Delta S^{\neq}_{773}$ = –3.2 cal mol^{-1} K^{-1}) for migration of the nonbridge hydrogen at C4, which is identical to the barrier ($\Delta G^{\neq}_{773}$ = 8.8 kcal mol^{-1}, $\Delta S^{\neq}_{773}$ = –4.4 cal mol^{-1} K^{-1}) for the 1,3 hydrogen shift. Therefore, the bridge 1,2H shift in carbene **5** cannot compete with the two other rearrangements of this carbene. The products of these rearrangements (protoadamantene **9** and dehydroadamantane **6**) must be formed with almost identical yields.

According to the B3LYP calculations, the retro Diels–Alder reaction in adamantene **3** has a lower activation barrier ($\Delta G^{\neq}_{773}$ = 20.5 kcal mol^{-1}, $\Delta S^{\neq}_{773}$ = 5.3 cal mol^{-1} K^{-1}) than the 1,2 carbon migration. Therefore, this reaction is predicted to be the main channel of the gas-phase unimolecular conversion of adamantene **3**. It is feasible to assume 5-allyl-3-methylenecyclohexene **7** to be the major product of the vacuum flash thermolysis of **3**, and dehydroadamantane **6** and protoadamantene **9** — minor ones. The theoretical distribution of the products (**7** > > **6** ≈ **9**) is in good agreement with the experimental data (13).

The B3LYP activation energy for 1,2 hydrogen migration in singlet adamantylidene **4** ($\Delta G^{\neq}_{298}$ = 52.7 kcal mol^{-1}, $\Delta S^{\neq}_{298}$ = –1.7 cal mol^{-1} K^{-1}) is too high for this process to be considered as a real path of conversion of this carbene. For two other probable rearrangements of **4** (Fig. 7), low activation barriers were found: $\Delta G^{\neq}_{298}$ = 11.8 kcal mol^{-1}, $\Delta S^{\neq}_{298}$ = –3.2 cal mol^{-1} K^{-1} for the 1,3H shift (**TS(4/6)**), and $\Delta G^{\neq}_{298}$ = 3.2 kcal mol^{-1}, $\Delta S^{\neq}_{298}$ = –1.2 cal mol^{-1} K^{-1} for the 1,2C shift (**TS(4/8)**). The predicted domination of the 1,3 hydrogen migration in **4** is in accord with the experimental data (15–19).

The transition state **TS(4/8)** for the 1,2C shift in adamantylidene **4** lies only 0.2 kcal mol^{-1} lower than the transition state **TS(3/5)** for the 1,2C shift in adamantene **3**, whereas the activation barrier for the 1,2C shift in **4** is 16.8 kcal mol^{-1} lower than the barrier in **3**. Apparently, this difference in the barriers is due to destabilization of adamantylidene **4** with respect to adamantene **3**.

A similar situation is observed in the case of the 1,3 hydrogen migration in the singlet carbenes **4**, **5**. The energies of transition states **TS(4/6)** and **TS(5/6)** also differ by 0.2 kcal mol^{-1} at the B3LYP level (Figs. 6, 7). However, stabilization of carbene **4** with respect to **5** by the effects of hybridization and σ–π hyperconjugation results in the higher activation energy for the 1,3H shift in the former.

Conclusions

According to the B3LYP study of the singlet $C_{10}H_{14}$ potential energy surface, 2-adamantene **3** is more stable than the corresponding carbene, adamantylidene **4**. The activation barrier for conversion of **3** into **4** via the 1,2 hydrogen migration is prohibitively high even at 500°C ($\Delta G^{\neq}_{773}$ = 69.1 kcal mol^{-1}) and is almost identical to the barrier for the 1,2H shift in a planar alkene, 4,5-protoadamantene **9** ($\Delta G^{\neq}_{773}$ = 69.7 kcal mol^{-1}). The barrier in the latter is caused mainly by the necessity of breaking the C═C double bond, whereas in the anti-Bredt alkene **3** the origin of the barrier is connected with the strain of the transition state **TS(3/4)**. This is so because of the impossibility of forming a planar arrangement of the C—C bonds around the rearranging fragment. Anti-Bredt alkenes with a more rigid skeleton and a more pyramidal bridgehead carbon atom must have a higher barrier for 1,2 hydrogen migration.

The C1 and C2 lobes of the "π" and "π*" orbitals of the formally double C1—C2 bond in adamantene **3** overlap better with the σ orbitals of the proximal C—C bonds than with each other. Such a stereoelectronic situation favors the 1,2 carbon migration ($\Delta G^{\neq}_{773}$ = 30.3 kcal mol^{-1}) and especially the reverse Diels–Alder cycloaddition ($\Delta G^{\neq}_{773}$ = 20.5 kcal mol^{-1}), which leads to 5-allyl-3-methylenecyclohexene **7**. The products of the 1,2C shift, singlet 4-protoadamantylidene **5**, in its turn quickly rearranges into 2,4-dehydroadamantane **6** and 4,5-protoadamantene **9** via 1,3 and 1,2 hydrogen migrations with identical activation barriers ($\Delta G^{\neq}_{773}$ = 8.8 kcal mol^{-1}). The theoretical yield distribution of the products (**7** > > **6** ≈ **9**) is in accord with the experimental data (13). Thus, the calculations support the formation of 2,4-dehydroadamantane **6** through path b, shown in Scheme 2. The activation energy of the 1,2 carbon migration has to be lower in more strained bridgehead alkenes because of increased reactivity of the formally double bond and the better electron-donating ability of the more strained proximal C—C bonds.

The B3LYP calculations also properly predict the preference of the rearrangement of adamantylidene **4** into 2,4-dehydroadamantane **6** via 1,3 hydrogen migration ($\Delta G^{\neq}_{298}$ = 11.8 kcal mol^{-1}), as well as the greater stability of the singlet state of **4** with respect to the triplet state (ΔG°_{298} = 3.2 kcal mol^{-1}, ΔS°_{298} = –1.2 cal mol^{-1} K^{-1}).

The mechanism of solvolysis of 2-adamantyl azoxytosylate: isotopic labelling, medium effect, and attempted deoxygenation studies

John K. Conner, Johanna Haider, M.N. Stuart Hill, Howard Maskill, and Monique Pestman

Abstract: Rates of solvolysis of 2-adamantyl azoxytosylate (**1**) have been measured over a range of temperatures in ethanoic acid, methanoic acid, 50:50 (v/v) trifluoroethanol:water, 80:20 (v/v) trifluoroethanol:water, 97:3 (w/w) trifluoroethanol:water, and 70:30 (v/v) ethanol:water. For comparison, rates of solvolysis of 2-adamantyl tosylate (**2**) have also been measured in 50:50, 80:20, and 90:10 (v/v) trifluoroethanol:water, and for both compounds, activation parameters have been determined. These and results published earlier allow a correlation of the two reactions and indicate that the *m* value for 2-adamantyl azoxytosylate solvolysis is only 0.46. This is one of the lowest *m* values for a reaction that is unambiguously an S_N1 solvolysis. We have also recorded the ^{17}O NMR spectrum of the 2-adamantyl tosylate formed from ^{17}O-labelled 2-adamantyl azoxytosylate in deuteriochloroform, and the millimeter-wave spectrum of the nitrous oxide evolved in the hydrolysis of ^{18}O-labelled 2-adamantyl azoxytosylate. These labelling studies have provided more detailed knowledge of the S_N1 fragmentation mechanism of **1** and exclude a mechanism of reaction via rearrangement to *N*-nitroso,*N*-(2-adamantyl),*O*-(*p*-toluenesulfonyl)hydroxylamine (**5**). Attempted deoxygenation of **1** to give 2-adamantyl diazotosylate (**8**) and a subsequent fragmentation proved unsuccessful.

Key words: nitrous oxide, carbenium ion, isotopic labelling, solvolysis, *m* value.

Résumé : On a mesuré les vitesses de solvolyse de azoxytosylate d'adamant-2-yle (**1**) à diverses températures, dans l'acide éthanoïque, l'acide méthanoïque, le trifluoroéthanol:eau (50:50, v/v), le trifluoroéthanol:eau (80:20, v/v), le trifluoroéthanol:eau (97:3, p/p) et l'éthanol:eau (70:30, v/v). Pour fins de comparaison, on a aussi mesuré les vitesses de solvolyse du tosylate d'adamant-2-yle (**2**) dans des mélanges (50:50, 80:20 et 90:10, v/v) de trifluoroéthanol:eau et, dans les cas des deux composés, on a déterminé les paramètres d'activation. Ces résultats couplés à d'autres publiés antérieurement permettent d'établir une corrélation entre les deux réactions et ils indiquent que la valeur *m* pour la solvolyse de l'azoxytosylate d'adamant-2-yle n'est que 0,46. Ceci correspond à l'une des valeurs de *m* les plus faibles pour une réaction qui est sans ambiguïté S_N1. On a aussi déterminé le spectre RMN du ^{17}O du tosylate d'adamant-2-yle formé à partir de l'azoxytosylate d'adamant-2-yle marqué au ^{18}O lors d'une réaction dans le chloroforme deutéré ainsi que le spectre d'onde à un millimètre de l'oxyde nitreux qui se dégage lors de l'hydrolyse de l'azoxytosylate d'adamant-2-yle marqué au ^{17}O. Ces études de marquage ont fourni des connaissances plus détaillées du mécanisme de fragmentation S_N1 du composé **1** et elles ont permis d'exclure un mécanisme réactionnel impliquant un réarrangement en *N*-nitroso-*N*-(adamant-2-yl)-*O*-(*p*-toluènesulfonyl)hydroxylamine (**5**). Il a été impossible de provoquer une désoxygénation du composé **1** pour donner du diazotosylate d'adamant-2-yle (**8**) et provoquer une fragmentation subséquente.

Mots clés : oxyde nitreux, ion carbénium, marquage isotopique, solvolyse, valeur *m*.

[Traduit par la rédaction]

Introduction

Mechanisms of reactions involving intermediate carbenium ions are amongst the earliest to have been investigated, and early proposals that some of the most deep seated of molecular rearrangements (e.g., amongst terpenoids) occur via such intermediates were some of the boldest (1). These proposals were accepted only after fierce debate and overwhelming evidence, and much of current organic chemistry reaction mechanisms vernacular originates from that Olympian period earlier this century. However, even though the principal features of substitution and elimination reactions that involve carbenium ions are well known, some details of the natures of these intermediates have been inferred from only indirect evidence or still remain obscure.

According to a frequently encountered model for S_N1 reactions (2*a*), the carbenium ion is generated in an initial rate-limiting step, then is captured by a nucleophile (which could be a

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

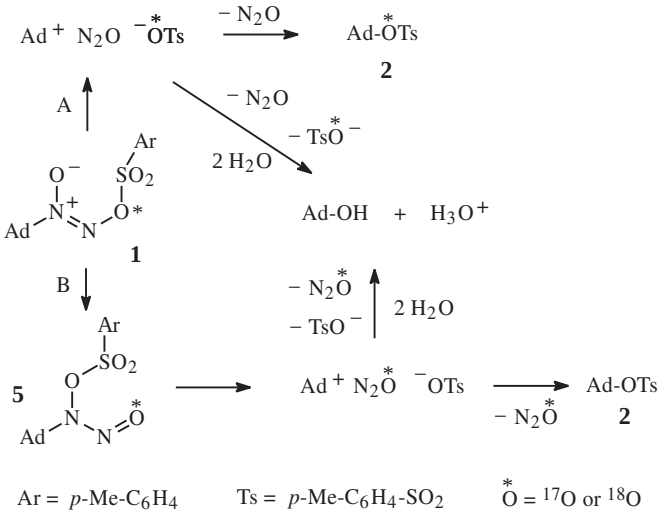
Scheme 1.



solvent molecule) in a subsequent product-forming step. In this simple model, the transition structure in the first step involves vestigial bonding between the developing trigonal electrophilic carbon and the nucleofuge. According to the more complete Winstein–Shiner ion-pair model (2*b*, 3), the rate-limiting step in the solvolysis of 2-adamantyl tosylate, for example, is not the initial ionization but the separation of the first-formed contact (or intimate) ion pair to give the solvent-separated ion pair. Clearly, this model requires that the contact ion pair undergoes internal return in competition with, but faster than, progression to the solvent-separated ion pair. In this model, the transition structure in the rate-limiting step of the solvolytic process involves a fully developed positive charge in the electrophilic fragment, and the solvent-separated ion pair is the main product-forming intermediate from 2-adamantyl tosylate.

Comparison of the effect of solvents upon the rate of solvolysis of a compound with the effect upon the rate of solvolysis of a standard compound may be quantified using the Winstein–Grunwald equation (4) (or an extended (5) or modified (6) version). An *m* value, the gradient of the $\log(k_{compound})$ versus $\log(k_{standard})$ correlation, close to unity means that the solvent effect for the solvolysis of the compound in question is the same as for the standard compound, and this is usually interpreted as evidence for very closely similar S_N1 solvolytic mechanisms. The original standard compound was *tert*-butyl chloride but 2-adamantyl tosylate is now regarded as more appropriate for substrates with arenesulfonate nucleofuges (7, 8). An *m* value appreciably lower than unity is usually interpreted as indicating that the reaction involves a low degree of charge separation in the transition structure (assuming there are other reasons for believing that the reaction is still an S_N1), or that the mechanism is not an S_N1 at all.

Recently, there has been an expansion in our knowledge of carbenium ion chemistry partly through developments in fast reaction methods pioneered by McClelland et al. (9), partly through new experimental techniques developed, for example, by Olah et al. (10) and Mayr and Patz (11) for preparing carbenium ions under nonnucleophilic conditions, partly through improved theoretical procedures for studying isolated carbenium ions themselves, for example, by Schleyer and co-workers (12), and partly due to better conceptual models for solvolytic and related reactions offered by Jencks and Richard (13). It is within this last context that the present project had its origins. Some years ago (14), we introduced the solvolysis of alkyl azoxyarenesulfonates as a heterolytic reaction, which is unambiguously unimolecular and allows the study of the S_N1 mechanism uncomplicated by competitive bimolecular substitution. The carbenium ions so formed are the same as when produced by other means, but their initial environment is different. We proposed a mechanism that is a link between the solvolysis of alkyl arenesulfonates on the one hand and nitrous acid induced deamination of primary alkylamines (and related reactions) on the other (14, 15). We also presented evidence that the initial fragmentation to give an ion pair and nitrous oxide is rate-determining (i.e., there is no internal

return) and concerted (14, 16). In nonnucleophilic, weakly ionizing solvents such as chloroform or toluene, the initially formed ion pair collapses to give the covalent alkyl arenesulfonate whereas in ionizing nucleophilic media such as water, the carbocation is captured by a solvent molecule to give a solvolytic substitution product (17). These possibilities are illustrated for 2-adamantyl azoxytosylate (**1**) in Scheme 1, path A. An alternative mechanism for the decomposition of **1** is included in Scheme 1 path B, which is based (in part, see later) upon the probable mechanism for the isomerization of *N*-alkyl,*N*-nitrosoamides into alkyl diazocarboxylates prior to fragmentation in the nitrosoamide method of deamination and related reactions, Scheme 2 (18). In this route, there is an initial rearrangement of the substrate to give *N*-nitroso,*N*-(2-adamantyl),*O*-(*p*-toluenesulfonyl)hydroxylamine (**5**), possibly but not necessarily through a concerted cyclic mechanism, followed by the fragmentation step.

We now report a comparison of the decompositions in a range of solvents of 2-adamantyl azoxytosylate (**1**) and 2-adamantyl tosylate (**2**), the latter long having been regarded as an archetypal S_N1 substrate (19); we also compare the solvolyses of **1** and pinacolyl brosylate (3,3-dimethyl-2-butyl *p*-bromobenzenesulfonate, **6**) (19, 20), an S_N1 substrate that reacts with rate-limiting ionization, i.e., with no internal return, and 1-adamantyl chloroformate (**7**), an S_N1 substrate that also solvolyzes with liberation of a gas molecule (21). Additionally, we present oxygen isotope labelling results, which allow us to refine our earlier mechanistic proposal for the solvolysis of **1**. Finally, attempts to remove the pendant oxygen from **1**, which would lead to the previously unknown but presumably more unstable 2-adamantyl diazotosylate (**8**), are described. Compound **8**, which is analogous to the alkyl diazocarboxylate in Scheme 2 should, if formed, fragment to give a nitrogen-separated ion pair and thence either 2-adamantyl tosylate or solvent-derived products.

Results

The two substrates **1** and **2** were made by literature methods, see Scheme 3 for **1**, and all solvolytic media were prepared in conventional ways. Rate constants were already known for 2-adamantyl tosylate in many solvents, but to allow comparison with all our results for 2-adamantyl azoxytosylate, some new values were required. Rates of reaction of both substrates in all solvolytic media were investigated by our normal UV spectrophotometric methods (see experimental section) and activation parameters were calculated using the Eyring equation from rate constants measured over a temperature range of at least 30°C. Our results are shown in Table 1; Fig. 1 is a correlation of the rate results for the solvolyses of **1** and **2** in 11 solvents (gradient = 0.46, $R = 0.96$), and Fig. 2 is a correlation of the rate results for the solvolyses of **1** and pinacolyl brosylate (**6**) in just six solvents (gradient = 0.53, $R = 0.96$).

We also prepared samples of 2-adamantyl azoxytosylate specifically enriched with ^{17}O and with ^{18}O in the oxygen marked with an asterisk in Scheme 3 by reaction of tosyl chloride (22) with a specifically labelled sample of *N*-(2-adamantyl)hydroxydiazenium oxide (**3**), which in turn had been prepared by nitrosation of *N*-(2-adamantyl)hydroxylamine by a method based upon earlier work by Dahn and Ung-Truong (23). The ^{17}O NMR spectrum of the 2-adamantyl tosylate from the reaction of the labelled 2-adamantyl azoxytosylate in deuteriochloroform after more than 10 half-lives at 65°C unambiguously showed enhancement of the signal at δ_O 158.4 ppm

	80TFE	1.95[c]	1.83	96	–32
	90TFE	1.9[c]	1.63	94	–41

[a] Rate constants at 25°C are by extrapolation from results at other temperatures, which in turn are means of several determinations and estimated to be reliable to 5%. The uncertainties in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are estimated to be 5 kJ mol^{-1} and 8 J K^{-1} mol^{-1}.

[b] Reference 8.

[c] Estimated from ref. 8.

[d] Less reliable results of $\Delta H^{\ddagger}$ = 89 kJ mol^{-1} and $\Delta S^{\ddagger}$ = –35 J K^{-1} mol^{-1} were reported earlier in ref. 14*b*.

[e] A result of 3.35×10^{-6} s^{-1} is reported in ref. 8.

Fig. 1. Graph of log k/s^{-1} for solvolysis of 2-adamantyl azoxytosylate **1** plotted against log k for solvolysis of 2-adamantyl tosylate **2**.

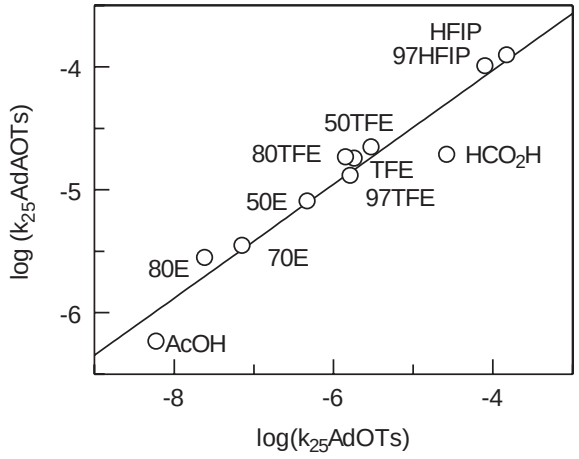

Fig. 2. Graph of log k/s^{-1} for solvolysis of 2-adamantyl azoxytosylate **1** plotted against log k for solvolysis of pinacolyl brosylate **6**.

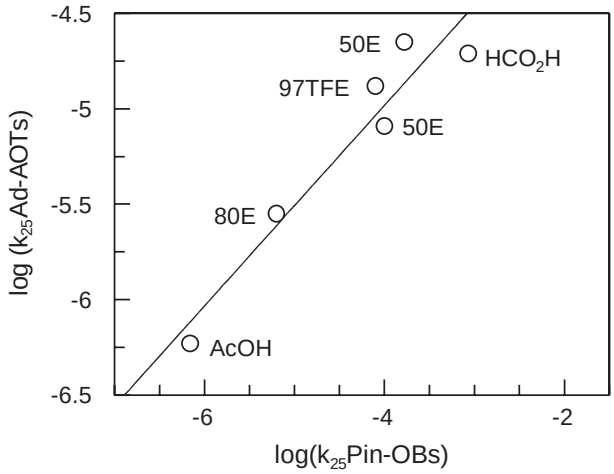


due to the sulfonyl oxygens; this compares with the signal at δ_O 157.5 ppm due to the sulfonyl bonded oxygens in the starting material. The millimeter-wave spectrum of the gas produced from the hydrolysis of the ^{18}O-labelled substrate was also recorded (24), which identified it unambiguously as nitrous oxide by the J 4←3 band at 96 512 MHz due to $N_2{}^{16}O$; there was no trace of the J 3←2 band at 71 155 MHz previously identified in the spectrum of N_2O containing the ^{18}O isotope (25).

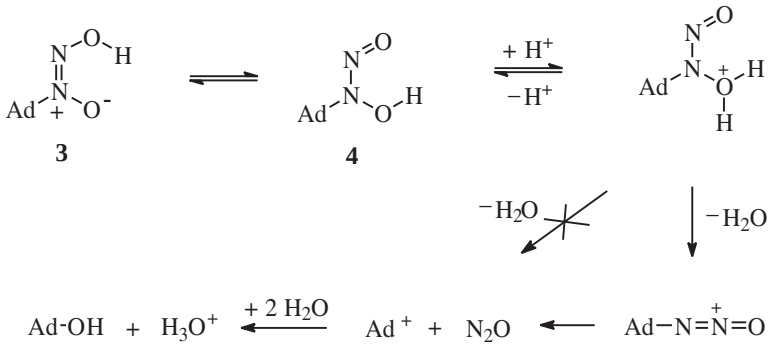
Using a variety of reaction conditions and established deoxygenating agents (acetyl bromide (26), triethyl phosphite (27, 28), thionyl chloride (26), phosphorus trichloride (26, 29), triphenylphosphine (28), tri(*n*-butyl)phosphine (28*b*), and lithium metal (30)), we found no unambiguous evidence for the formation of 2-adamantyl tosylate from 2-adamantyl azoxytosylate under nonnucleophilic conditions.

Discussion

Isomerization of **3**, the product of nitrosation of *N*-(2-adamantyl)hydroxylamine, into **4** prior to the fragmentation in Scheme 4 has been identified as the first step in the mechanism of reaction of **3**; it involves a proton transfer either intermolecularly by protonation/deprotonation under the acidic conditions, or intramolecularly along a trajectory beginning in a strong hydrogen bond within **3** (25). In the next acid-catalysed step of this mechanism, the fragmentation is not concerted but stepwise via the oxodiazonium ion. In view of this preferred reaction of **3** via the *N*-nitroso tautomer, an intramolecular rearrangement of 2-adamantyl azoxytosylate (**1**) into the isomeric *N*-nitroso,*N*-(2-adamantyl),*O*-(*p*-toluenesulfonyl)hydroxylamine (**5**) via a cyclic transition structure is included as a preliminary to a credible alternative solvolytic mechanism for **1** in Scheme 1, path B. To distinguish between paths A and B in Scheme 1, we prepared 2-adamantyl azoxytosylate specifically labelled separately with ^{17}O and ^{18}O in the tosylated oxygen marked with an asterisk in Scheme 1. Clearly, if the mechanism follows path A, the labelled oxygen will end up in the 2-adamantyl tosylate in a nonnucleophilic medium whereas if the mechanism follows path B it will be lost as nitrous oxide. We have already shown that nitrous oxide

© 1998 NRC Canada

Scheme 4.



enriched with ^{18}O can be readily identified by observation of the J 3←2 rotational band at 71 155 MHz (25); its absence in the sample isolated in the present case established that the label is not in the nitrous oxide. To corroborate this negative evidence and now using ^{17}O enriched starting material **1** (25) we recorded an enhanced ^{17}O NMR signal at δ_O 158.4 ppm in the 2-adamantyl tosylate product (**2**). Clearly, the oxygen marked with an asterisk in 2-adamantyl azoxytosylate (**1**) in Scheme 1 ends up in the 2-adamantyl tosylate product (**2**), and not in the nitrous oxide, so path B via rearrangement to *N*-nitroso,*N*-(2-adamantyl),*O*-(*p*-toluenesulfonyl)hydroxylamine (**5**) in Scheme 1 may now be ruled out.

The logarithmic correlation of solvolytic rate constants at 25°C for 2-adamantyl azoxytosylate (**1**) and 2-adamantyl tosylate (**2**) is shown in Fig. 1. The nine points for aqueous alcoholic media constitute an excellent linear plot ($R > 0.99$), and the points for the two carboxylic acid solvents are noticeably off; omitting these two points has a negligible effect upon the gradient. Since 2-adamantyl tosylate is the standard compound for defining the solvent parameter Y(OTs), the gradient of this plot is the m value for 2-adamantyl azoxytosylate (**1**); the actual plot for **1** of log k/s^{-1} against Y(OTs) with the two carboxylic acid solvents omitted gives $m = 0.46$ ($R > 0.99$). Confidence in our earlier proposal that solvolysis of **1** involves rate-limiting fragmentation with formation of an ion pair separated by a molecule of nitrous oxide (14) is strengthened by our now having excluded the alternative mechanism for reaction of **1** via rearrangement through **5** (see above). Consequently, this very low m value for a reaction that is unambiguously an S_N1 indicates that the transition structure for this fragmentation has only a modest degree of dipolarity spread over four atoms, structure **9**. This is in accord with our conclusion from a double Hammett investigation of solvolyses of substituted benzyl azoxyarenesulfonates, i.e., that the bonds from the carbon to one nitrogen and from the other nitrogen to oxygen are about half broken in the transition structure (16). In contrast, the rate-limiting step in the solvolysis of **2** involves conversion of one type of ion pair into another (17, 31), i.e., ionization occurs in a prior (reversible) step, and the higher dipolarity in this transition structure arises from fully developed charges even though they are at only a small interionic separation. Our m value for **1** establishes that such a low result alone cannot be taken as a reliable indicator that a reaction of a simple secondary alkyl system is not an S_N1.

The deviations for the two carboxylic acids in the correlation of Fig. 1 indicate that the reactions of 2-adamantyl tosylate (**2**) in these solvents are faster than anticipated on the basis of their reactivity in aqueous alcohols. The most credible explanation on the basis of existing mechanistic understanding is that the bidentate carboxylic acid molecules are more effective than the aqueous alcohols at preventing internal return in the solvolysis of **2**. Internal return is also absent in the solvolysis of pinacolyl brosylate (**6**) but for a reason different to that for **1**. In the solvolysis of **6**, rearrangement is either concerted with the ionization or follows on so rapidly that internal return cannot compete (20). Consequently, in the correlation of pinacolyl brosylate with 2-adamantyl tosylate, points for carboxylic acids are also not on the line defined by reactions in aqueous ethanol (19). Low extents of internal return in the acetolysis and formolysis of 2-propyl brosylate (compared with trifluoroethanolysis) have been reported earlier (20). A fair correlation is obtained between the log k values for solvolyses of **1** and **6**, neither of which undergoes internal return, as shown in Fig. 2; the gradient (0.53) corresponds to an appreciably higher solvent effect for **6** than for **1**. This indicates a transition structure for the ionization of **6** with a higher degree of dipolarity than that in the ionization of **1**.

Another model for the reaction of **1** is 1-adamantyl chloroformate (**7**), although it is tertiary rather than secondary. A low m value determined over a wide range of solvents and appreciably positive $\Delta S^{\ddagger}$ values were reported by Kevill and colleagues (21); their solvolytic mechanism for **7** involves ionization to give the 1-adamantyl cation, carbon dixide, and chloride. Clearly, fragmentation in this system also cannot be followed by internal return to give covalent **7**, although the ions of the carbon dioxide separated ion pair can collapse to give 1-adamantyl chloride.

The newly determined activation parameters for the solvolysis of **1** shown in Table 1 are unexceptional except that they provide further supportive evidence that the reactions are S_N1 solvolyses, i.e., the enthalpies of activation are relatively high, and the entropies of activation are small (close to zero). In general terms, these and earlier results (14) show that the $\Delta S^{\ddagger}$ values are somewhat less negative than the corresponding results for **2**. We attribute this to a positive contribution to the overall entropy of activation arising from the nascent N_2O molecule in the reaction of **1** not found in the reaction of **2**. However, even this does not compensate in all cases for the substantial negative contribution to $\Delta S^{\ddagger}$ from the enhanced solvation that occurs due to the increased dipolarity in the transition state from **1**.

The original isolation of alkyl azoxyarenesulfonates as

stable compounds was initially surprising in view of the instability of analogous compounds prepared by White et al. (18, 32), which fragment at low temperatures into cation, stable molecule, and anion. We reasoned that abstraction of the pendant oxygen atom of azoxytosylates such as **1** would give the corresponding diazotosylate (**8**) and that fragmentation of **8** would now liberate nitrogen (rather than nitrous oxide), and consequently be an easier reaction. We anticipated that **8**, if formed, would be too unstable to isolate under the deoxygenation reaction conditions and sought its expected decomposition product under non nucleophilic conditions, i.e., 2-adamantyl tosylate (17). Using a range of deoxygenating reagents, we found no firm evidence by TLC or NMR for the formation of **2** and conclude that **1** does not undergo an easy deoxygenation.

Experimental

Ethanoic acid was heated under reflux for 12 h with ethanoic anhydride, then fractionally distilled; trifluoroethanol was either stirred over molecular sieves for several days, then fractionally distilled, or heated under reflux over calcium hydride for 2 h, then fractionally distilled; spectroscopic grade absolute ethanol was used as supplied; methanoic acid was purified by standing over boric anhydride (B_2O_3) for several days followed by successive distillation from fresh B_2O_3 under reduced pressure until the separation of the OH and the CH signals in the ^{1}H NMR spectrum of the neat distillate became constant at ca. 3.158 ppm. Aqueous solvolytic media were prepared by mixing appropriate volumes of glass distilled water with either ethanol or trifluoroethanol except 97TFE, which was prepared by weight; the ethanoic acid was buffered with 0.15 mol dm^{-3} anhydrous sodium ethanoate, but all other solvents were unbuffered. Isotopically enriched water was purchased from Goss (10% enriched with ^{17}O) and from Aldrich (10% enriched with ^{18}O).

2-Adamantyl azoxytosylate (1) and 2-adamantyl tosylate (2)

2-Adamantyl azoxytosylate (**1**) (mp 111–112°C, lit. (14) 111–113°C) and 2-adamantyl tosylate (**2**) (mp 82–83°C, lit. (33) 82.7–83.7°C; δ_O 159.3 ppm (S═O, natural abundance)) were prepared as described previously (14*b*).

Isotopically labelled *N*-(2-adamantyl)hydroxydiazenium oxide (3) and the corresponding azoxytosylates

An ice-cold solution of sodium nitrite (0.20 g) in water (10% enriched with ^{18}O, 0.5 cm^3) was added dropwise over about 10 min to an ice-cold stirred solution of conc. hydrochloric acid (37%, 0.20 cm^3), *N*-(2-adamantyl)hydroxylammonium chloride (170 mg), and water (10% enriched with ^{18}O, 0.5 cm^3) in ethanol (3 cm^3). After about 20 min, the white crystalline product was filtered at the pump, washed with cold water, and dried under vacuum (143 mg; mp 134–135°C, lit. (14*b*) (unlabelled material) 137–139°C; δ_H 1.60–2.10 (m, 14H), 4.29 (s, 1H), 12.1 (br, 1H)). The ^{17}O-labelled analogue (148 mg, mp 135–136°C) was made in the same way from *N*-(2-adamantyl)hydroxylammonium chloride (167 mg) using 10% ^{17}O-enriched water and had an identical ^{1}H NMR spectrum.

Specifically labelled 2-adamantyl azoxytosylate (**1**)-^{17}O (δ_O 157.5 (S═O), 291.6 (N-O-S), 452.4 ppm (N-O)) and (**1**)-^{18}O were then made by our usual Tipson (14*b*, 22) method from **3**-^{17}O and **3**-^{18}O; both had melting points and ^{1}H NMR spectra identical with the unlabelled compound.

Decomposition of ^{17}O-labelled 2-adamantyl azoxytosylate

A sample (85 mg) of ^{17}O-labelled 2-adamantyl azoxytosylate (δ_O 157.5 (S═O)) was dissolved in a 1:4 mixture of chloroform:deuteriochloroform (4 cm^3) in an NMR tube and maintained at ca. 50°C in an oil bath for 10 h. The ^{1}H NMR spectrum indicated only about 10% conversion, so the temperature of the oil bath was raised to about 60°C, and the reaction was continued for a further 15 h by which time the conversion was about 40% by ^{1}H NMR, and the ^{17}O NMR spectrum showed a single strong but broad band centred at 158 ppm. After 4 days at this temperature, the ^{1}H NMR spectrum showed complete conversion to 2-adamantyl tosylate; there was no trace of the starting material, and the product showed a strong ^{17}O NMR signal at δ_O 158.4 ppm (S═O).

Decomposition of ^{18}O-labelled 2-adamantyl azoxytosylate

A gentle flow of nitrogen was passed through a stirred solution made up from aqueous perchloric acid (70%, 6.1 cm^3), water (24 cm^3), and ^{18}O-labelled 2-adamantyl azoxytosylate (85 mg, 0.25 mmol) in a flask fitted with a reflux condenser. The reaction was maintained at 69°C for 6 h, then for another 30 min as the reaction mixture cooled down; the gas flow passed through a KOH drying tower and a gas trap immersed in liquid nitrogen. The contents of the gas trap were then transferred at room temperature to a millimeter-wave spectrometer using standard vacuum line procedures, and predetermined regions of the spectrum were scanned. An intense absorption was recorded at 96 512 MHz due to the J 4←3 transition of $N_2{}^{16}O$; no absorption was detected in the region of 71 155 MHz previously identified as due to the J 3←2 transition of $N_2{}^{18}O$ (25).

Kinetics

Rates of solvolytic reactions were measured using either a Pye–Unicam SP8-300 spectrophotometer connected to an Apple microcomputer with in-house software for data collection (34) or a Cecil CE 5502 spectrophotometer connected to an Elonex PC using commercial data collection software. In the former case, rate constants were calculated also using in-house software (34); in the latter case, GraFit version 3.0 (Erithacus Software Ltd.) was used. In both cases, cell holders for up to four cells were thermostatted by circulating water, the cell-holder block temperature being measured with a fitted platinum resistance thermometer, and the system was programmed to record absorbance data automatically at predetermined time intervals. Rate constants were calculated from absorbance–time data collected over about three or four half-lives using standard computational techniques.

Attempted deoxygenations

(*i*) Four drops of triethyl phosphite (27, 28) were added to a solution of compound **1** (10 mg) in toluene (0.5 cm^3), and the reaction was monitored by TLC for 24 h. The temperature was then raised to 40°C but TLC showed only starting material after several days.

(*ii*) A solution of **1** (26 mg) in phosphorus trichloride (26, 29) (2 cm^3) was stirred at room temperature under nitrogen and protected from atmospheric moisture (SiO_2 tube). No change

© 1998 NRC Canada

was detected by TLC after 24 h whereupon the reaction was worked up, and the isolated crystalline product was shown to be starting material by ^{1}H NMR and TLC. Further reactions with acetyl bromide (26) thionyl chloride (26), triphenylphosphine (28), tri(*n*-butyl)phosphine (28), and lithium wire (30), were also attempted but gave negative or ambiguous results.

Acknowledgement

We thank Dr. J.G. Smith for help with the millimeter-wave spectroscopy, the ERASMUS Bureau for grants to J.H. and M.P., the EPSRC for a grant to J.K.C., and Drs. J.S. Roberts (Stirling University) and C.I.F Watt (Manchester University) for helpful discussions.

Are mesoionic compounds aromatic?

Alfredo Mayall Simas, Joseph Miller, and Petrônio Filgueiras de Athayde Filho

Abstract: We have evaluated the experimental evidence relevant to the structure and character of mesoionic compounds, accumulated for more than 100 years and including X-ray diffraction studies. We have also evaluated relevant theoretical studies. All these, including our own extensive work, lead us to conclude that mesoionic compounds are not aromatic. According to our recent definition "mesoionic compounds are planar five-membered heterocyclic betaines with at least one side chain whose α-atom is also in the ring plane and with dipole moments of the order of 5 D. Electrons are delocalized over two regions separated by what are essentially single bonds. One region, which includes the α-atom of the side chain is associated with the HOMO and negative π-charge whereas the other is associated with the LUMO and positive π-charge."

Key words: mesoionic compounds, betaines, aromaticity.

Résumé : On a évalué les données expérimentales accumulées au cours des cent dernières années, y compris les études de diffraction des rayons X, relatives à la structure et au caractère des composés mésoioniques. On a aussi évalué les études théoriques appropriées. Toutes ces données ainsi que nos propres travaux permettent de conclure que les composés mésoioniques ne sont pas aromatiques. Selon notre définition récente, « les composés mésoioniques sont des bétaïnes planaires d'hétérocycles à cinq chaînons portant au moins une chaîne latérale dont l'atome α est aussi dans le plan du noyau et dont les moments dipolaires sont de l'ordre de 5 D. Les électrons sont délocalisés sur deux régions séparées par ce qui essentiellement des liaisons simples. L'une des régions, qui comprend l'atome α de la chaîne latérale, est associée avec l'orbitale moléculaire HO et la charge π négative alors que l'autre est associée avec l'orbitale moléculaire BV et la charge π positive. »

Mots clés : composés mésoioniques, bétaïnes, aromaticité.

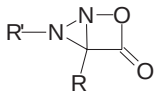
[Traduit par la rédaction]

Introduction

Compounds now classified as mesoionic have been known for more than 100 years (1, 2): many others have since been prepared. By 1976 several comprehensive reviews had appeared (3–10) and were followed soon afterwards by the extensive review of Ramsden et al. (11).

Their unusual character was indirectly illuminated by the improbable classical structures put forward in early studies. Later, recourse was made to both covalent and polar structures to represent mesoionic compounds.

The sydnones (vide infra) are perhaps the best known group of mesoionic compounds. They were first prepared in 1935 by Earl and Mackney (12), working in Sydney, hence the trivial name. They suggested the improbable bicyclic aza-β-lactone structure (**I**).



I

An important contribution was made by Schönberg in 1938. In his paper (13) he suggested that mesoionic compounds should be represented by resonance and charge hybrid structures. The designation mesoionic was launched by Baker et al. in 1949 (14): from "mesomeric" and "ionic." They also put forward the first definition, refined in 1976 by Ollis and Ramsden (15): "A compound may appropriately be called mesoionic if it is a five-membered heterocycle which cannot be satisfactorily represented by any one covalent or ionic structure and possesses a sextet of electrons in association with the five atoms comprising the ring."

While the word satisfactorily leaves a margin for uncertainty, there has in fact been little doubt as to which compounds should be called mesoionic.

The main general structures used at the time, are shown as **II**–**V**. Structure **V** clearly suggests that mesoionic compounds are aromatic.

It is important to note that there were dissenting voices. In 1955, Katritzky (15) wrote on "the representation of the

© 1998 NRC Canada

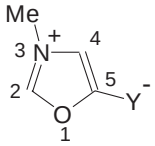
so-called mesoionic compounds." He suggested that the ± representation should be discontinued as should the term mesoionic, to be substituted by mesomeric betaine.

While not directly relevant to the question of aromaticity, it is worth intercalating that Ollis and Ramsden (16) divided mesoionic compounds into two broad subclasses (so-called Type A and Type B) according to the degree to which each ring atom contributes to the total of eight π-electrons (ring plus α-atom with formal negative charge): most mesoionic compounds belong to Type A. It is worth adding further that Type B mesoionic compounds are 1,3-dipoles, and Type A mesoionic compounds are "masked" 1,3-dipoles. In any event 1,3-dipolar additions are common and important reactions of mesoionic compounds.

In 1978 Potts (16) suggested that "the term mesoionic should be restricted to five-membered heterocycles that cannot be satisfactorily represented by normal covalent structures but are better represented as a hybrid of all possible charged forms."

He added that this implies the presence of some degree of aromatic character ($(4n+2)\pi$ electrons) in the positively charged ring system, which is counterbalanced by a negatively charged atom.

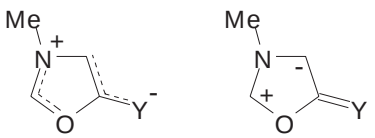
A highly relevant contribution was made by Dewar and Turchi (17) in 1975 in their theoretical studies by the MINDO/3 molecular orbital method inter alia the 3-*N*-methyl-1,3-oxazolium-5-Y$^-$ system (**VI**). They also referred to a series of relevant earlier studies (18–23) of the sydnones (1,2,3-oxadiazolium-5-olates); as well as two more recent studies (24, 25) using CNDO/2, ab initio, and INDO molecular orbital methods (assumed geometries).



VI

They added that the results were in qualitative agreement with (*i*) X-ray crystallography data for 4,4′-dichloro-3,3′-ethylene-disydnone (24) and (*ii*) a ^{13}C NMR study of 3-methylsydnone (25).

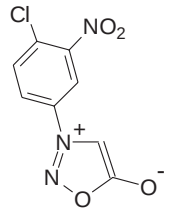
Dewar and Turchi emphasized the large positive charge at C-2 and the large negative charge at C-4. This led them to suggest the nonaromatic structures **VII** and **VIII**.



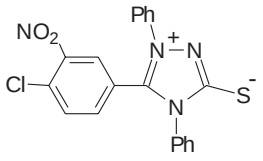
VII VIII

It is noteworthy that the authors of the crystallographic study (24) referred to "the unusually long endocyclic C—O bond," i.e., having little or no π-character.

The group of Miller and Simas have contributed an extensive sequence of experimental and theoretical studies (the latter more recent) following the pioneering study by Chan et al. (26) in 1964. These authors made a comparative kinetic study of the S_NAr reactions of 3-(4-chloro-3-nitrophenyl)-1,2,3-oxadiazolium-5-olate (**IX**) and of 1-chloro-2,4-dinitrobenzene with methanethiolate in methanol. This study was amplified much later by Braz et al. (27). By that time Echevarria and Miller (28) and Echevarria (29) had made kinetic studies of the S_NAr reactions of 5-(4-choro-3-nitrophenyl)-1,3-diphenyl-1,3,4-triazólium-2-thiolate (**X**) with a range of anionic and neutral nucleophiles in methanol comparing their data with those for 1-chloro-2,4-dinitrobenzene in the same solvent.



IX



X

It is of special interest that in both cases the mesoionic ring as an activating substituent for S_NAr reactions in a benzenoid ring has an equivalent σ^- value (Hammett substituent constant appropriate for S_NAr reactions) ca. 0.7; recalling that in one case the benzene ring suffering nucleophilic attack was attached to the formally positively charged 3-nitrogen atom of the 1,2,3-oxadiazolium moiety and in the other case attached to the formally neutral 2-carbon atom of the 1,3,4-triazolium moiety.

An analysis of the enthalpies and entropies of activation for the reactions of 5-(4-chloro-3-nitrophenyl)-1,3,4-triazólium-2-thiolate with the wide range of nucleophiles used led Echevarria and Miller to conclude that in the mesoionic substrate the positive and negative regions were so well separated that it behaved as a *pair of ions* with respect to solvation.

Echevarria and Miller (28), having demonstrated that the positively charged region of the 1,3,4-triazolium-2-thiolate system served as an activating group for S_NAr reactions (vide supra), then showed that the negative region acted as a nucleophile (29), and that nucleophilic character was not confined to the formally negative thiolate function but was shared by the 3-nitrogen atom. They formed both mono- and dimethyl salts. Still more importantly, their study indicated that the *first* methyl group was linked to the 3-nitrogen atom.

It is relevant that early studies of the sydnones (3, 5, 9) showed that they react with electrophiles at the 4-carbon atom giving, e.g., a bromo derivative.

In contrast, protonation (30) occurs on the exocyclic olate oxygen. The similarity to the behaviour of enolate ions is noteworthy.

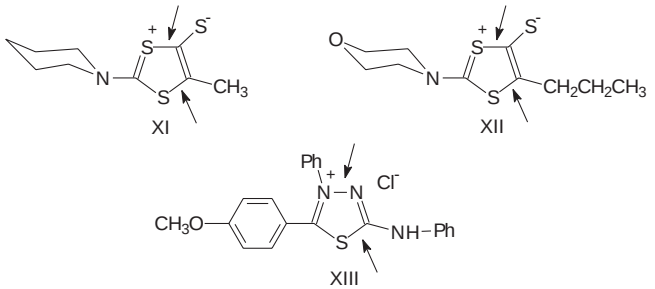
Very recently, the group of de Athayde Filho, Miller, and Simas (31) reported (*i*) the condensation of 1,4-diphenyl-5-(4-chloro-3-nitrophenyl)-1,3,4-triazolium-2-thiolate, acting as a nucleophile, with its hydrochloride acting as an electrophile; (*ii*) the cross-condensation of four different 1,4-diphenyl-5-aryl-1,3,4-triazolium-2-thiolates, acting as nucleophiles, with the hydrochloride of 1,4-diphenyl-5-(4-chloro-3-nitrophenyl)-1,3,4-triazolium-2-thiolate acting as an electrophile; (*iii*) the self-condensation of 1,4-diphenyl-5-(4-chloro-3-nitrophenyl)-1,3,4-triazolium-2-thiolate, acting as both nucleophile and electrophile, forming an oligomer.

We are currently studying systems in which the positive region of mesoionic compound acts directly as an electrophilic centre.

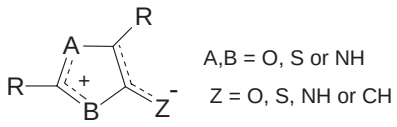
© 1998 NRC Canada

The combination of the synthetic and kinetic studies indicates clearly that the mesoionic systems studied have well-separated positive and negative regions able to act *independently* as electron-deficient and electron-rich functions. This is tantamount to indicating that mesoionic compounds should *not* be considered aromatic.

This conclusion has been further reinforced by our X-ray diffraction studies (32, 33). These indicated clearly the existence of two regions in each of which bond distances correspond to the existence of electron and charge delocalization and that *these two regions are separated by what are essentially single bonds*. In particular, we studied 2-*N*-piperidino-5-methyl-1,3-dithiolium-4-thiolate (**XI**), 2-*N*-morpholino-5-*n*-propyl-1,3-dithiolium-4-thiolate (**XII**), and the hydrochloride of 4-phenyl-5-(4-methoxyphenyl)-1,3,4-thiadiazolium-2-phenylaminide (**XIII**).

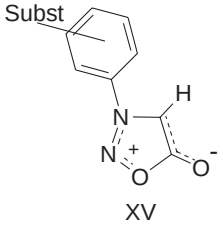


In these structures the single annular bonds are indicated by arrows. These studies clearly indicate that mesoionic compounds are not aromatic. Moura and Simas (34) carried out theoretical studies of 36 mesoionic systems with two heteroatoms in the five-membered ring. The structures were optimized by the semiempirical AM1 molecular orbital method, codified in the MOPAC 93 programme. Their results are fully coherent with X-ray and other studies. The positive and negative regions are separated by what are essentially single bonds; whereas the other annular bonds and that linking the five-membered ring to the α-atom, bearing a formal negative charge, have bond order between single and double bonds. This is illustrated in structure **XIV**.



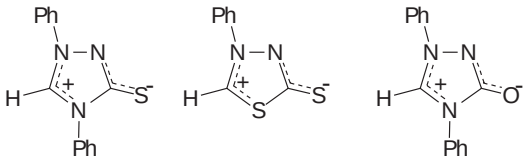
The existence of separate electron-rich and electron-deficient regions is well illustrated by ^{1}H NMR data.

In a series of 4-*N*-arylsydnones (**XV**) (35) the chemical shifts of the hydrogen atom attached to C-3, i.e., in the negative region, lie between 6.3–6.8 ppm, at higher field than otherwise similar five-membered aromatic heterocycles.

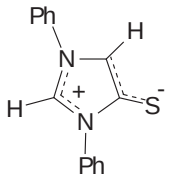


Calculations (36) indicate a fractional negative charge on the 3-carbon atom a clear contribution to diamagnetic protection.

In contrast, in mesoionic compounds of the classes 1,3,4-triazolium-2-thiolate, 1,3,4-thiadiazolium-2-thiolate, and 1,3,4-triazolium-2-olate, the hydrogen atoms linked to C-5 in each case have chemical shifts of 10.40 and 10.10 ppm, at lower field than otherwise similar five-membered aromatic heterocycles. Calculations (37, 38) indicate a fractional positive charge on the five-carbon atom, a clear contribution to diamagnetic deprotection (see structures **XVI**, **XVII**, and **XVIII**).



It is especially convenient at this point to refer to 1.4-diphenyl-1,4-diazolium-2-thiolate **XIX** (39). This has a hydrogen atom atached to the three-carbon atom in the negative region and another to the five-carbon atom in the positive region.



The hydrogen atom attached to C-3 has a chemical shift of 6.82 ppm, whereas that attached to C-5 has a chemical shift of 8.36 ppm.

Jaz´win´ski et al. (40) have published an extensive review of the structures and NMR parameters of mesoionic compounds.

They used ^{1}H, ^{13}C, ^{14}N, ^{15}N, ^{17}O, and ^{77}Se NMR; while the the systems they studied all have three or four hetero-atoms in the five-membered ring. However they simply assumed aromatic character and did not use their data to clarify this or otherwise; though they affirmed that the positive charge is delocalized over the ring atoms, while the negative charge is situated on the exocyclic atom.

It is convenient to present here the definition of mesoionic compounds by the group of Miller and Simas (41): "Mesoionic compounds are planar five-membered heterocyclic betaines with at least one side chain whose α-atom is also in the ring plane and with dipole moments of the order of 5 D. Electrons are delocalized over two regions separated by what are essentially single bonds. One region, which includes the α-atom of the side chain, is associated with the HOMO and negative π-charge whereas the other is associated with the LUMO and positive π-charge."

We add, finally, a quotation from Gilchrist's text on heterocyclic chemistry (42), revised in 1992. He states, "It does not therefore seem useful or appropriate to classify sydnones and

© 1998 NRC Canada

other mesoionic compounds as aromatic, despite the existence of a cyclic array of *p*-orbitals."

Conclusion

On the basis of the available evidence, accumulated for more than 100 years and summarized in this paper, we conclude that mesoionic compounds are not aromatic though well-stabilized in two separate regions by electron and charge delocalization.

Regioselectivity and stereoelectronic effects in the reactions of the dinitroaniline herbicides trifluralin and benefin with nucleophiles

Michael T. Annandale, Gary W. vanLoon, and Erwin Buncel

Abstract: The reactions of two members of the dinitroaniline class of herbicides, *N*,*N*-di-*n*-propyl-2,6-dinitro-4-(trifluoromethyl)aniline (trifluralin; **1**) and *N*-ethyl-*N*-*n*-butyl-2,6-dinitro-4-(trifluoromethyl)aniline (benefin; **2**), along with their analogue, *N*-phenyl-2,6-dinitro-4-(trifluoromethyl)aniline (**3**), with the nucleophiles, OD^- and SO_3^{2-}, have been investigated using 400 MHz ^1H NMR spectroscopy. The reactions of both **1** and **2** with OD^- result in formation of Meisenheimer anionic σ-complexes according to a K3T1 (*kinetic* preference for formation of the C-3 adduct with *thermodynamic* preference for formation of the C-1 adduct) reaction sequence while the reaction of **3** with OD^- and that of **1** with SO_3^{2-} follow a K3T3 (*kinetic* and *thermodynamic* preference for formation of the C-3 adduct) sequence. There was no observation of the C-1 adducts of **1** and **2** with OD^-, but the products of S_NAr displacement at C-1 were observed as the final thermodynamic products. Geometry optimization calculations support our hypothesis of $n \rightarrow \sigma^*$ stabilization of the C-1 adduct leading to S_NAr displacement. In the reaction of **3** with OD^-, initial N-deprotonation to form the anion, **3a**, is followed by σ-complex formation. The final thermodynamic product observed in this system is 3,5-dinitro-4-(*N*-phenylamino)benzoic acid formed through hydrolysis of the trifluoromethyl group on the anion, **3a**. Aryl H–D exchange has been found for the systems of **1** and **2** with OD^-, but not for the SO_3^{2-} system and neither for the reaction of **3** with OD^-. Since dimethylpicramide showed significantly slower H–D exchange under identical conditions, it is argued that this discrepancy has as origin the ability of the amino N lone electron pair to interact with the π-system of the ring. With both **1** and **2** the larger size of the amino alkyl chains prevent the amino N lone pair from aligning with the π-system of the ring, thus hindering electron density donation to the electron-deficient ring carbons.

Key words: trifluralin, benefin, herbicides, Meisenheimer complexes, stereoelectronic effects.

Résumé : Faisant appel à la spectroscopie RMN du ^1H à 400 MHz, on a étudié les réactions de deux herbicides membres de la classe des dinitroanilines, soit la *N,N*-dipropyl-2,4-dinitro-4-(trifluorométhyl)aniline (trifluraline; **1**) et la *N*-éthyl-*N*-butyl-2,6-dinitro-4-(trifluorométhyl)aniline (bénéfine, **2**), et de leur analogue, la *N*-phényl-2,6-dinitro-4-(trifluorométhyl)aniline (**3**), avec les nucléophiles OD^- et SO_3^{2-}. Les réactions des composés **1** et **2** avec OD^- conduisent à la formation de complexes σ anioniques de Meisenheimer suivant une séquence réactionnelle K3T1 (préférence *cinétique* pour la formation de l'adduit C-3 avec préférence *thermodynamique* pour la formation de l'adduit C-1); par ailleurs, la réaction de **3** avec OD^- ainsi que celle de **1** avec SO_3^{2-} d'après une séquence K3T3 (préférences *cinétique* et *thermodynamique* pour la formation de l'adduit C-3). On n'a pas observé de formation d'adduits C-1 entre **1** et **2** et OD^-, mais les produits de substitution S_NAr en C-1 ont été observés comme produits thermodynamiques finals. Des calculs avec optimisation de la géométrie supportent notre hypothèse d'une stabilisation $n \rightarrow \sigma^*$ de l'adduit C-1 conduisant à une substitution S_NAr. Dans la réaction de **3** avec OD^-, la N-déprotonation initiale conduisant à la formation de l'anion **3a** est suivie de la formation d'un complexe σ. Le produit thermodynamique final observé dans ce système est l'acide 3,5-dinitro-4-(*N*-phenylamino)benzoïque formé par hydrolyse du groupe trifluorométhyle de l'anion **3a**. On a observé un échange H–D des protons aromatiques pour les systèmes de **1** et de **2** avec le OD^- ; on ne l'a toutefois pas observé ni pour le système avec SO_3^{2-} ni pour la réaction de **3** avec OD^-. Puisque l'échange H–D de la diméthylpicramide est beaucoup plus lent dans des conditions identiques, il a été suggéré que cette différence provient de l'habilité de la paire d'électrons non partagée de l'azote à interagir avec le système π du noyau. Avec les composés **1** et **2**, la taille plus grande des chaînes alkyles du groupe aminé empêche la paire d'électrons non partagée de l'azote de l'amine de s'aligner avec le système π du noyau et ceci empêche d'accroître la densité électronique sur les carbones électrodéficients du noyau.

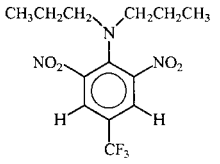
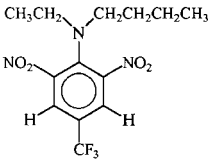
Introduction

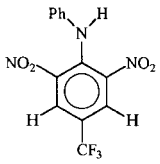
Trifluralin (*N*,*N*-di-*n*-propyl-2,6-dinitro-4-(trifluoromethyl)-aniline; **1**) and benefin (*N*-ethyl-*N*-*n*-butyl-2,6-dinitro-4-(trifluoromethyl)aniline; **2**) are members of the dinitroaniline family of herbicides, widely used for the control of most grasses and broad-leafed weeds. They are selective pre-emergence soil-herbicides used on a variety of crops, including beans, carrots, tomatoes, potatoes, and strawberries. They are also used for the control of annual grasses and broad-leafed weeds in grain and cereal crops as well as in orchards and vineyards (1).



Trifluralin (1)



Benefin (2)



3

The mode of action of these herbicides is not fully understood at present. However, since dinitroanilines possess an electron-deficient aromatic ring, it has been postulated that the biological activity may arise from their ability to form stable covalent anionic adducts (Meisenheimer complexes) with nucleophiles (e.g., -NH_2 of lysine protein residues, -SH of cysteine residues, etc.) in plant cells (2–4).

The present study focuses on the reaction pathways of herbicides **1** and **2**, and their aryl analogue, *N*-phenyl-2,6-dinitro-4-(trifluoromethyl)aniline, **3**, with hydroxide and sulfite ions. The reactions were followed by ^{1}H NMR spectroscopy in order to eludicate the degradation products formed, and to identify any Meisenheimer complex intermediates that may lie along the reaction path.

^{1}H nuclear magnetic resonance (NMR) spectroscopy has proved to be the most useful tool in the determination of the structures of σ-complexes in solution (5–11). For example, in the reaction of 1,3,5-trinitrobenzene (TNB) with nucleophiles, the ring carbon (C-2) to which the nucleophile becomes attached, undergoes a change in hybridization from sp^2 to sp^3, which affects the shielding felt by the attached proton. The resonances of the C-4 and C-6 protons are also shifted upfield relative to uncomplexed TNB, but to a lesser extent than the C-2 proton, due to loss of aromaticity (reduction of ring current) in the trinitrocyclohexadienate moiety and the increased negative charge on the ring in the complex.

[a] Measurements obtained using a Bruker AM-400 spectrophotometer (^{1}H: 400.1 MHz). Residual DMSO-d_5H was used as a reference.
[b] 80% DMSO-d_6–20% D_2O (v/v) solvent.

Results

The proton chemical shifts of the observed Meisenheimer complexes, intermediates, and products for the reactions of the three dinitroaniline compounds (**1–3**) with deuteroxide nucleophile and for the reaction of **1** with sulfite ion are given in Table 1. Proton-labelled structures are shown in Chart 1.

Reaction of trifluralin (1) and benefin (2) with OD^-

Upon addition of the OD^- solution to the substrate solutions of **1** and **2** in DMSO-d_6 (final DMSO concentration 80% v/v), there was an immediate disappearance of the peak at 8.39 ppm (**1**) or 8.42 ppm (**2**) and, concurrently, the appearance of downfield peaks at 5.77 and 7.43 ppm (**1a**) and 5.74 and 7.43 ppm (**2a**) characteristic of formation of Meisenheimer adducts through addition of OD^- at C-3. Due to the asymmetry of **1a**, the *N*-propyl resonances appear to be in a pseudo-$ABMNX_3$ spin system, similar to the ABX_3 spin system described by Servis (12) for the C-3 σ-adduct of *N,N*-diethyl-2,4,6-trinitroaniline with MeO^-. The AB and MN methylene groups arise from the asymmetric environment induced by the OD^- group in a preferred conformation as shown in Fig. 1, where AB and MN represent the two protons on the N-bound methylene group and the two protons on the C-bound methylene group, respectively. The methylene protons of **1a**, H_a and H_d, are found at 3.35 (2H) and 2.64 (2H) ppm; H_b and H_e at 1.55 (2H) and 1.36 (2H) ppm; and the methyl protons, H_c and H_f, at 0.76 (6H) ppm (Fig. 2).

Homonuclear decoupling (13) experiments, leading to more specific assignments of the individual peaks, were performed. The decoupling results indicated that each of the four methylene protons on the individual propyl groups have significant chemical shift differences from one another, but have chemical shifts similar to the corresponding proton on the other propyl group. Therefore, one can assign the four multiplets to the following four pairs of protons: $H_{1,4}$, $H_{2,3}$, $H_{5,8}$, and $H_{6,7}$ (using the numbering scheme portrayed in Fig. 1). Specific assignments identifying the separate N-bound methylene proton multiplets or the C-bound methylene proton multiplets cannot be made at this time.

The initial formation of the C-3 Meisenheimer adduct (**1a**, **2a**) is followed by the appearance of aryloxide, **4**, and the amines, **6** and **7** (**6** from **1**; **7** from **2**). In time, **4** becomes hydrolyzed to **5** in the basic medium. Adducts **1c** and **2c** become observable as the concentration of **6** and **7** increases in their respective systems. However, as the reaction proceeds and the available substrate concentration decreases, the peaks assigned to **1c** and **2c** also decrease. The C-1 adducts (**1b** and **2b**) were not detected.

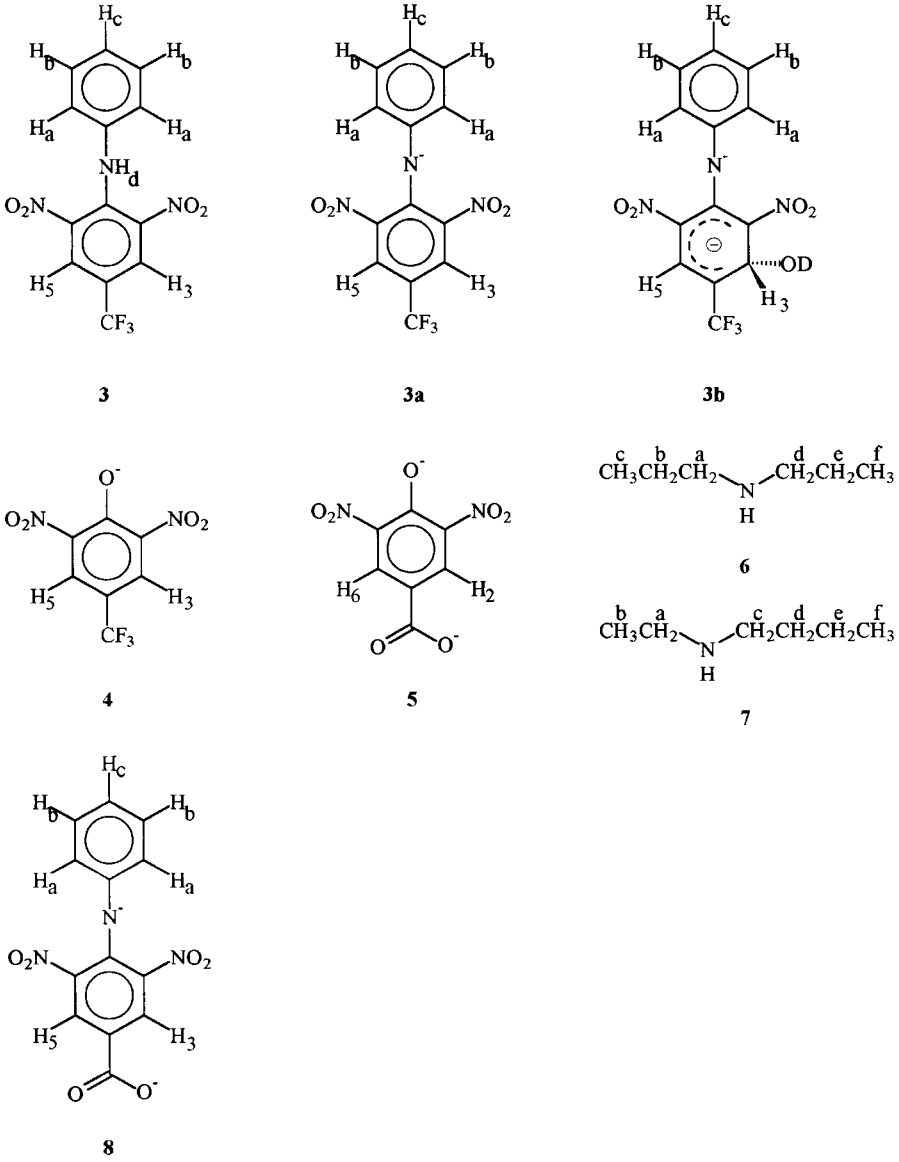
Reaction of both **1** and **2** with OD^- was accompanied by a notable decrease in the aromatic proton signals of **1** and **1a** (**2** and **2a**) as a result of H–D exchange, which was confirmed through product isolation and MS analysis.

Reaction of trifluralin (1) with SO_3^{2-}

Addition of the nucleophile (Na_2SO_3–D_2O) to **1** in DMSO-d_6 (final DMSO concentration 80% v/v) resulted in the immediate reduction of the peak at 8.39 ppm (**1**). This was accompanied by formation of the C-3 adduct (**1d**) with characteristic ring proton resonances at 5.50 and 7.28 ppm; however, no C-1 adduct or S_NAr displacement products were detected. With time, new peaks assignable to the *cis* and *trans* diadducts of **1e**

© 1998 NRC Canada

Chart 1.



were observed at 5.01, 7.15, and 7.68 ppm. No aromatic proton exchange was observed for this system.

Reaction of *N*-phenyl-2,6-dinitro-4-(trifluoromethyl)-aniline (3) with OD^-

Upon the addition of the base (KOH–D_2O) to the solution of **3** in DMSO-d_6 (final DMSO concentration 85% v/v), there was an immediate distinct colour change from orange to deep purple. Concurrently the peak at 8.53 ppm (**3**) disappeared and was replaced by a singlet at 7.74 ppm assigned to the anion, **3a**. This deprotonation was followed by the appearance of a singlet at 8.06 ppm assignable to **8**, a hydrolysis product of **3a**. At low base:substrate ratios (ca. < 4:1 molar ratio) no σ-adduct formation was observed. Only with a large excess of base, specifically, 10:1 molar equivalents of OD^-:**3**, formation of the C-3 adduct (**3b**) was detected by the appearance of small peaks at 5.56 and 6.91 ppm. No aromatic proton exchange was observed for this system.

Discussion

Regioselectivity and stereoelectronic factors in reaction of trifluralin (1) and benefin (2) with OD^-

The reaction pathways for the reactions of trifluralin (**1**) and benefin (**2**) with OD^- are shown in Scheme 1. The reactions of both **1** and **2** with OD^- appear to follow a K3T1 sequence, i.e., *kinetic* preference for formation of the C-3 adduct with *thermodynamic* preference for formation of the C-1 adduct. This kind of behaviour has been observed with a number of oxygen nucleophiles (14). General qualitative free energy diagrams for common reaction sequences, including the K3T1 sequence, are shown in Fig. 3.

Although the products of nucleophilic aromatic substitution (S_NAr) at C-1 are predicted to be the final thermodynamic products, the C-1 adduct was not spectroscopically observed in the present system. Thus our assumption, that the C-1 adduct is thermodynamically more stable than the C-3 adduct and that

once formed the C-1 adduct rapidly decomposes with loss of a secondary amine (**6** from **1**, **7** from **2**) to yield the phenoxide **4**, is supported by past findings that C-1 OH^- adducts have not been observed in any system where the C-1 position is also substituted by an acceptable leaving group (15).

Since there is no direct observation of the C-1 adduct in the present system, one needs to consider the possibility that the C-3 adduct is actually more stable than the C-1 adduct. It has been documented in 1,3,5-trinitrobenzene (TNB) and other polynitroaromatics (16, 17), that the nitro group *para* to the site of attack plays an important role in stabilizing adduct formation through resonance. Since the adducts derived from **1** and **2** have a CF_3 group rather than NO_2 in the *para*-position, this kind of stabilization is reduced. However, there remains the possibility of stereoelectronic stabilization of the C-1 adduct (14, 18, 19) with lone pair electron density donated from

Scheme 1.

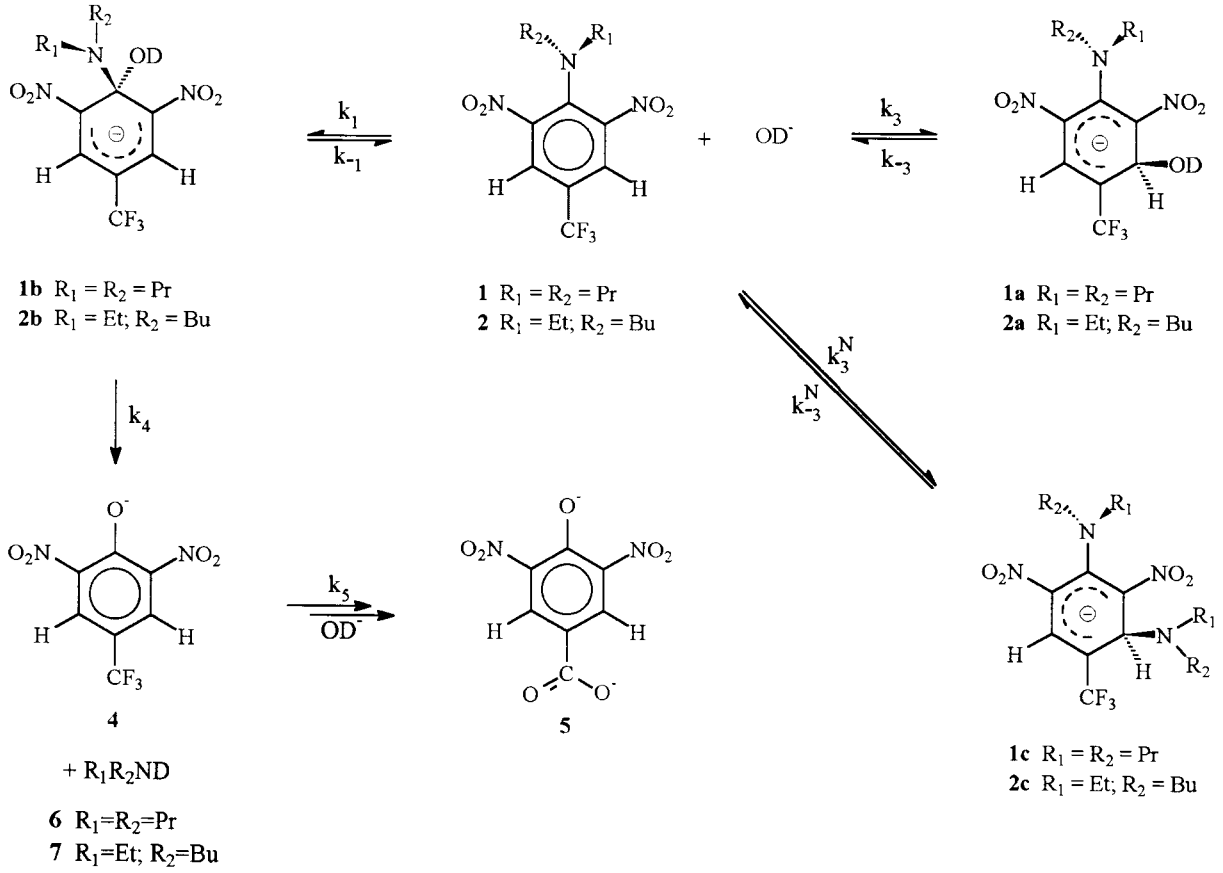

Fig. 3. Qualitative comparative energy – reaction coordinate profiles for the four general patterns of regioselectivity. Barrier heights and relative stabilities are exaggerated for clarity. K3T1 describes those systems in which formation of the C-3 adduct is the product of kinetic control, while the the C-1 adduct is the thermodynamic product. In the K1T1 profile the C-1 adduct is favoured by both kinetics and thermodynamics. Conversely, K3T3 represents the situation where the C-3 adduct is doubly preferred: by kinetics and thermodynamics. The K1T3 profile describes the inverse behaviour of that indicated by K3T1; now, the C-1 adduct is favoured kinetically, but the C-3 adduct is the most stable product (14).

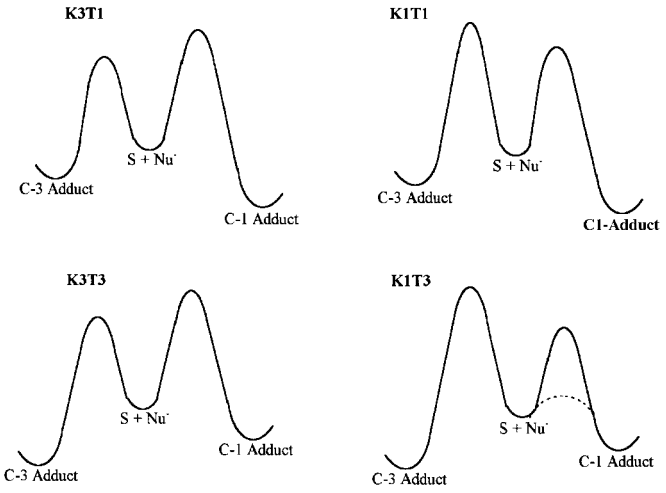

the oxygen of the OD moiety into the antibonding orbital of the C-1—NR_2 bond, and vice versa. Such $n \rightarrow \sigma^*$ interactions (20, 21) have previously been shown to be important in stabilizing structurally similar C-1 adducts (14, 18, 19, 22). The calculated (geometry optimized, PM3) structure supports the supposition of $n \rightarrow \sigma^*$ stabilization for the C-1 adduct **1b** (vide infra).

A further complexity in the reactions of **1** and **2** with OD^- results from the displacement of secondary amines (**6** from **1**; **7** from **2**); once liberated, these amines can act as nucleophiles and compete with OD^- for reaction with the substrates. From separate experiments in which **1** was reacted with **6** in the presence of OD^-, it was noted that **6** formed the C-3 adduct, **1c**, but no adduct resulting from attack at C-1 was seen, in accord with a K3T3 sequence. However, an important note of caution has been raised (14), namely, that if the rate constants are of vastly different magnitudes and the kinetic conditions $k_1 > k_3$ but $k_{-1} > > k_{-3}$ both apply (shown by the dotted lines in Fig. 3, K1T3 profile), then it may not be possible to observe the C-1 adduct owing to the time scale of the reaction. In the present system, it is unlikely that the C-1 adduct would be kinetically favoured because of the greater steric interactions associated with attack at the C-1 position (F-strain) (11, 18, 23–25).

Geometry optimization calculations on **1**, **1a,** and **1b** yield conformations that concur with the aforementioned hypotheses. The geometry-optimized structure of **1** (Fig. 4) has both nitro groups aligned perpendicular to the plane of the ring

© 1998 NRC Canada

Fig. 4. Geometry-optimized structure using SPARTAN for trifluralin (**1**) showing the alignment of the *N,N*-di-*n*-propyl groups such that the amine nitrogen lone electron pair is parallel with the plane of the ring and cannot interact with the ring π-system. The ChemWindow3 structure is shown in the centre.

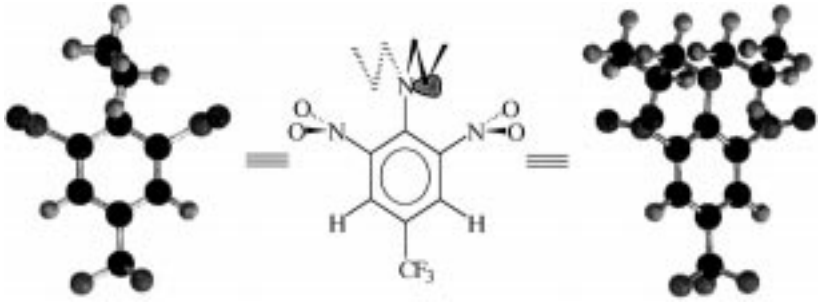

Fig. 5. Geometry-optimized structure using SPARTAN for *N,N*-dimethylpicramide (DMP) showing the alignment of the *N,N*-dimethyl groups such that the amine nitrogen lone electron pair is perpendicular to the plane of the ring and has maximum interaction with the ring π-system. The ChemWindow3 structure is shown in the centre.

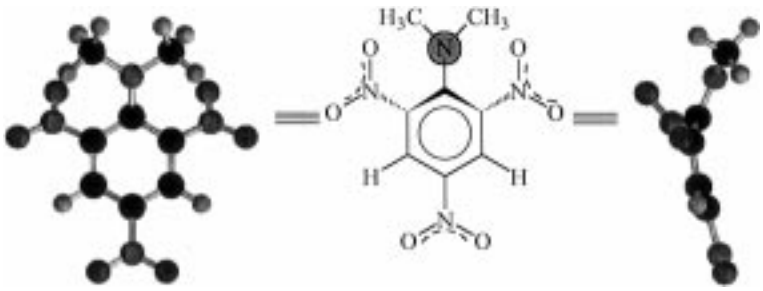

Fig. 6. Geometry-optimized structure using SPARTAN for **1a** showing the alignment of the nitro group *para* to the site of nucleophilic attack such that its π-system can interact with the π-system of the ring, allowing for greater charge stabilization of the anionic Meisenheimer adduct. The ChemWindow3 structure is shown in the centre.

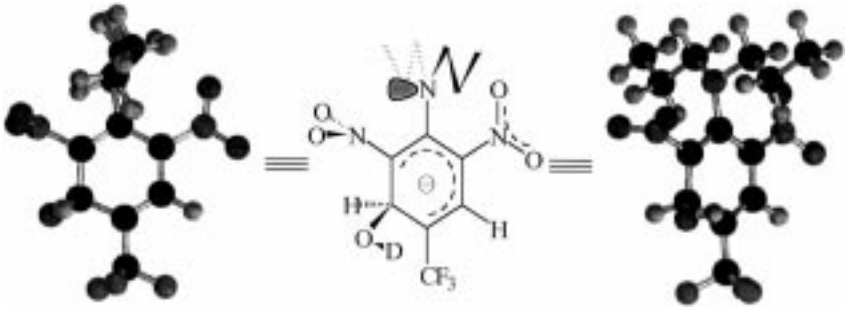

along with the two *N*-*n*-propyl groups. The orientation of the nitro groups perpendicular to the plane of the ring probably results from steric interactions with the two *N*-*n*-propyl groups. This may be expected since the optimized geometry for *N,N*-dimethylpicramide (DMP; Fig. 5) suggests significant ring strain (indicated by the displacement of C-1 from the plane of the ring) due to interaction between the *N*-methyl and the nitro groups.

The importance of the nitro group *para* to the sp^3 hybridized carbon (C-3) in **1a** can be seen in the geometry-optimized structure shown in Fig. 6; the *para*-NO_2 has become aligned with the ring for maximum π–π interaction while the *ortho*-NO_2 remains perpendicular to the plane of the ring. This conformation allows for greater delocalization of negative charge onto the *para*-NO_2 group, and such stabilization is unavailable to the C-1 adduct of **1**. However, the geometry-optimized structure for **1b** (Fig. 7) shows the -OH substituent aligned such that one of the oxygen lone pairs is approximately antiperiplanar to the C-1—NR_2 bond. This orientation is optimal for $n \rightarrow \sigma^*$ interactions where electron density is donated from the oxygen lone electron pair into the antibonding orbital of the C-1—NR_2 bond.

The $n \rightarrow \sigma^*$ stabilization indicated above provides support for the assumption that the C-1 adduct is more thermodynamically stable than the C-3 adduct in the reactions of both **1** and **2** with OD^-. This stereoelectronic stabilization does not appear to occur from the amine-N lone pair to the C-1—OH bond since the amine-N lone electron pair is not in an antiperiplanar alignment to the C-1—OH bond.

Aryl H–D exchange in trifluralin (1) and benefin (2)

It was noted in the Results that in the reaction of **1** and **2** with OD^- there is a significant decrease in the intensity of the resonances due to H_3 and H_5 on **1** and **1a**, as well as on **2** and **2a**,

relative to their aliphatic signals, arising from aryl ring hydrogen–deuterium exchange. Exchange of polynitroaromatic ring hydrogen by deuterium is well known to compete with σ-complex formation (26–31). It has been documented that σ-complexes do not themselves undergo exchange (24, 26, 32), and neither do polynitroaryloxides (26, 33). Thus H–D exchange occurs in the uncomplexed trifluralin and benefin molecules.

Although exchange of aryl hydrogen is well documented, its observation in this system is unexpected for a number of reasons. First, aryl ring H–D exchange generally occurs preferentially at a position *ortho* to **two** nitro groups (26–31, 34), whereas with **1** and **2** the aryl hydrogens are *ortho* to one nitro group and a trifluoromethyl group. Equally important is the slower rate of aryl H–D exchange in *N,N*-dimethylpicramide (DMP) under identical conditions. Preliminary observations indicate that 100% H–D exchange of trifluralin aryl protons has occurred within 24 h whereas with DMP under the same conditions only ca. 50% H–D exchange was observed over a 48 h period. It is suggested that this reduced rate of exchange has as origin the electron-donating properties of the C-1 N substituent. The ability of the lone pair of electrons on the amine-nitrogen in DMP to donate electron density by aligning with the π-orbital system of the ring (π–π overlap) (21) will lead to an increase in the electron density of the ring carbons. In trifluralin and benefin, however, the increased steric interactions associated with the larger *N*-alkyl groups prevent the alignment of the amine-N lone electron pair for effective π–π overlap and, therefore, aryl proton abstraction leading to H–D exchange is facilitated.

Geometry optimization calculations (semi-empirical; AM1) support this hypothesis. The optimized configuration for **1** and **1a** with the *N*-propyl groups aligned perpendicular

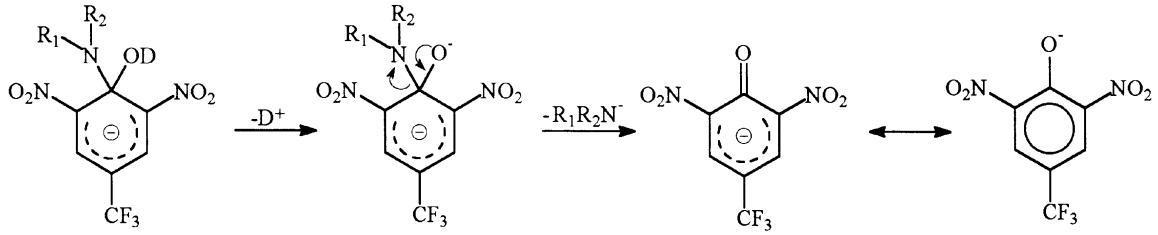
Scheme 3.



to the plane of the ring are displayed in Figs. 4 and 6, respectively. The same geometry optimization calculation performed for DMP (Fig. 5) yielded an optimized configuration with the *N*-methyl groups aligned with the plane of the ring, allowing for maximum interaction of the amine-N lone pair of electrons with the ring π-electron system. A comparison of partial atomic charges (semi-empirical; AM1; Mulliken population analysis) shows that the amine nitrogen of DMP is more positively charged than the amine nitrogen of **1**. This supports our arguement that there is significant overlap between the C-1 nitrogen lone pair of DMP with the ring π-system that is hindered in the sterically constrained molecules of trifluralin (**1**) and benefin (**2**).

Regioselectivity in reaction of trifluralin (1) with SO_3^{2-}

As shown in Scheme 2, reaction of SO_3^{2-} with **1** initially results in formation of the C-3 adduct. By analogy with the SO_3^{2-} adducts of picramides (5, 6, 9, 35–37), bonding to sulfite nucleophile is presumed to occur through the *S*-center. The C-1 adduct is not observed in the present system, presumably due to steric hindrance (F-strain) arising from the bulky *N,N*-di-*n*-propylamine substituent at the C-1 position. Nevertheless, further attack on **1d** by SO_3^{2-} occurs at the C-1 position, forming the *cis* and *trans* isomers of diadduct **1e**. Formation of the diadduct, **1e**, is thought to be stabilized by $n \rightarrow \sigma^*$ stabilization from the NR_2 lone electron pairs and the forming C-1—SO_3^{2-} bond. Due to the alignment of the NR_2 group in **1**, this stereoelectronic interaction is not present to help stabilize the formation of the C-1 monoadduct with SO_3^{2-}. Interestingly, a diadduct of **1** with the two -SO_3^{2-} groups at the C-3 and C-5 positions was not observed, even though such diadducts are seen with related picramides (35–37). This is probably due to the presence of the C-4 -CF_3 group in **1**, whereas in picramides with a -NO_2 substituent at C-4 negative charge can be delocalized onto the -NO_2 group. Since no C-1 monoadduct is observed in this system, we conclude that this reaction follows a K3T3 sequence.

The fact that there is no overall nucleophilic displacement of the dialkylamino group by sulfite, in contrast to the hydroxide reaction, is worthy of comment. One factor is the ease of formation and the stability of adduct **1d**, attack at the 3-position of **1** being favored over the 1-position for steric reasons as discussed above. Moreover, there is clearly no expulsion of the dialkylamino group from the *cis* and *trans* diadducts **1e**, i.e., in Scheme 2, **1e** may eject SO_3^{2-} but not R_2N^-. The much greater nucleofugality of sulfite relative to the dialkylamino group is readily evident on the basis of pK_a values but, as shown in Scheme 1, expulsion of the dialkylamino group does occur from **1b** and **2b** despite an unfavorable pK_a situation (though clearly not as unfavorable as in the sulfite case). However, another pathway is available for expulsion of R_2N^- in the case of **1b** and **2b**, namely, a prior ionization of the deuteroxide adduct followed by expulsion of R_2N^-, as shown in Scheme 3.

Proton abstraction versus σ-complex formation in the reaction of *N*-phenyl-2,6-dinitro-4-(trifluoromethyl)aniline (3) with OD^-

Since *N*-phenyl-2,6-dinitro-4-(trifluoromethyl)aniline (**3**) has only one substituent on the C-1 nitrogen, the interaction with base can, in principle, lead to N-deprotonation as well as σ-complex formation. Such behaviour has been reported for the reaction of *N*-methylpicramide (NMP) with MeO^- in DMSO–MeOH solutions, which was reported to undergo initial N-deprotonation upon the addition of 1 molar equivalent of MeO^-, with further reaction to the C-3 adduct upon addition of excess base (38). In fact this behaviour has also been found in the present study.

Scheme 4 shows the reaction pathway for the reaction of **3** with OD^-. It was found that, initially, reaction results in N-deprotonation to form the anion, **3a.** This is followed by the further reaction of **3a** with OD^- to form the C-3 adduct, **3b**, but only when a large excess of base is present. Of notable significance is the fact that with the NMP–MeO^- system, σ-complexation was reported for solutions containing 1.1 molar equivalents of MeO^- to NMP (38). However, in the present system σ-complexation required ca. 10 molar equivalents of OD^-. The origin of this contrasting behaviour is not clear at present, although a possible explanation is the decreased electron deficiency of **3** relative to the NMP system.

As in the reaction of **1** with SO_3^{2-}, there was no observation of a C-1 monoadduct, in accord with a K3T3 sequence. The final thermodynamic product of this reaction is the hydrolysis product of **3a**, 3,5-dinitro-4-(*N*-phenylamino)benzoic acid, **8**.

Experimental

N,N-Di-*n*-propyl-2,6-dinitro-4-(trifluoromethyl)aniline (trifluralin; **1**) was available from Chem Service, Inc. with a reported purity of 99.0% and was used without further purification. *N*-Ethyl-*N*-*n*-butyl-2,6-dinitro-4-(trifluoromethyl)-aniline (benefin; **2**) was prepared via a variation of method II reported by Marshall et al. (39) by adding ca. 4 molar equivalents of *N*-ethyl-*n*-butylamine to a solution of 2,6-dinitro-4-(trifluoromethyl)chlorobenzene in diethyl ether and acidifying the resulting solution with HCl (ca. 1 M). After removal of the colourless aqueous layer, the clear orange-yellow diethyl ether solution was washed with H_2O and dried over $MgSO_4$ followed by evaporation of the ether under reduced pressure. The resulting solid was further purified using flash chromatography

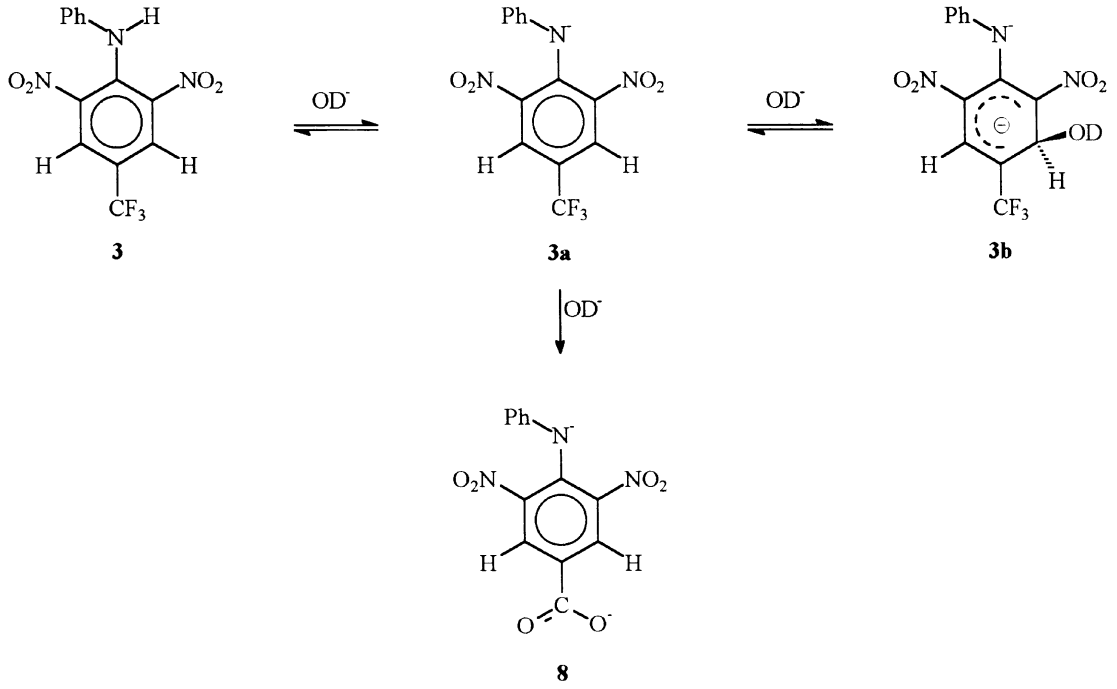
Scheme 4.



($CHCl_3$ eluent), yielding bright yellow crystals, mp 66–67°C (lit. (40) mp 67–68°C). *N*-Phenyl-2,6-dinitro-4-(trifluoromethyl)aniline (**3**) was prepared using the same procedure as described for **2** with the addition of aniline in place of *N*-ethyl-*n*-butylamine, yielding bright yellow crystals, mp 123°C (lit. (41) mp 119–121°C).

N,N-Di-*n*-propyl-2,6-dinitro-4-(trifluoromethyl)aniline-d_2 (trifluralin-d_2) was isolated by adding ca. 2 molar equivalents of NaOD (D_2O) to a solution of **1** in DMSO-d_6. The solution was let stand for ca. 24 h at which time ca. 3 molar equivalents of trifluoroacetic acid were added to quench the reaction. The reaction mixture was then added to H_2O and orange crystals were collected via vacuum filtration and dried under reduced pressure (< 0.1 Torr; 1 Torr = 133.3 Pa); mp = 48–49°C. ^{1}H NMR (DMSO-d_6) δ: 2.93 (4H, t, J_{H-H} = 7.3, $H_{c,c'}$), 1.50 (4H, tq, J_{H-H} = 7.3, $H_{b,b'}$), 0.80 (6H, t, J_{H-H} = 7.3, $H_{a,a'}$). ^{13}C NMR (DMSO-d_6) δ: 145.5 (1C, C_1), 140.3 (2C, $C_{2,6}$), 126.9 (2C, t, J_{C-D} = 23, $C_{3,5}$), 122.4 (1C, q, J_{C-F} = 270, C_7), 121.0 (1C, q, J_{C-F} = 36, C_4), 53.2 (2C, $C_{8,11}$), 20.4 (2C, $C_{9,12}$);,10.8 (6C, $C_{10,13}$). EI-MS: M = 337 m/z (calcd. for $C_{13}H_{14}D_2F_3N_3O_4$: 337.0 g/mol).

Sodium deuteroxide solutions were prepared by adding freshly cut sodium metal to D_2O (99.9% D) under a stream of N_2. Potassium deuteroxide solutions were prepared from a weighed amount of potassium hydroxide (AnalaR by BDH, Inc.), which was added to D_2O under N_2. The alkaline solutions were standardized against 0.108 M potassium hydrogen phthalate (KHP). Sodium sulfite solutions were prepared by dissolving a calculated amount of Na_2SO_3 (Aldrich Chemical Company, Inc.) in D_2O under N_2.

Stock solutions of substrate were prepared in DMSO-d_6 while stock solutions of nucleophile were prepared in D_2O. Solutions used in the reaction studies were prepared in clean dry NMR tubes by adding appropriate volumes of the stock solutions to a known volume of DMSO-d_6–D_2O such that the final concentration of DMSO-d_6 was 80% v/v. The reactions were then monitored at various intervals by ^{1}H NMR until completion. Nuclear magnetic resonance (NMR) measurements were obtained using a Bruker AM-400 spectrophotometer (^{1}H: 400.1 MHz) with DMSO-d_5H acting as reference (^{1}H: 2.50 ppm).

Phenanthroimidazole dimers: structure and free radical reactivity; piezochromism, thermochromism, and photochromism

Yuehui Zhou, W.E. Baker, P.M. Kazmaier, and E. Buncel

Abstract: A series of 2-phenyl phenanthroimidazole dimers was synthesized by means of a two-phase preparative method, which allowed their isolation in pure form. Definitive proof of structure was obtained by means of ^{1}H and ^{13}C NMR spectroscopy; five of the six possible structural isomers of the dimer could thus be eliminated. The dimers exhibited thermochromic and piezochromic behavior, but not photochromic. The colored species were shown to be free radicals formed on dissociation of the dimers; this was confirmed through ESR measurements. The electronic absorption spectra of the radicals were influenced by substituents on the phenyl ring. The UV–VIS measurements allowed the evaluation of the dimer–radical equilibrium constants, which were also found to be dependent on substituents on the phenyl ring.

Key words: phenanthroimidazole dimers, free radical equilibrium, piezochromism, thermochromism, photochromism.

Résumé : Faisant appel à une méthode de synthèse en deux phases qui permet d'isoler les produits à l'état pur, on a synthétisé une série de dimères de la 2-phénylphénanthroimidazole. On a obtenu des preuves irréfutables de structure grâce à la spectroscopie RMN du ^{1}H et du ^{13}C; on a ainsi pu éliminer cinq des six structures isomères possibles du dimère. Les dimères présentent un comportement thermochromique et piézochromique, mais pas photochromique. Il a été démontré que les espèces colorées proviennent de radicaux libres formés lors de la dissociation des dimères; cette conclusion a été confirmée par des mesures RPE. Les spectres d'absorption électronique des radicaux sont influencés par les substituants présents sur les noyaux phényles. Les mesures UV–VIS ont permis d'évaluer les constantes d'équilibre dimère–radical; on a trouvé que celles-ci dépendent des substituants présents sur le noyau phényle.

Mots clés : dimères de la phénanthroimidazole, équilibre de radicaux libres, piézochromie, thermochromie, photochromie.

Introduction

Nitrogen-containing heterocyclic compounds play an important role in many biological systems (1). It is known that certain dimeric nitrogen-containing heterocyclic compounds such as dimeric NAD (*N*-benzyldihydronicotinamide) are involved in some biological redox processes (2). On the other hand, triphenylimidazole dimers have also attracted attention because of the sensitivity of these compounds to light and heat, as well as to pressure. Hayashi and Maeda (3) observed that, upon oxidation with potassium ferricyanide in ethanolic solution, triphenylimidazole (**1**) gave rise to a violet color; the color then disappeared rapidly. The oxidation product was obtained as a pale violet-colored powder, which turned deep violet in solution under UV irradiation. The authors suggested (3) that the colored species was a free radical, and soon afterwards EPR evidence for the existence of the radical was presented (4).

It is now known that the oxidation product is a piezochromic dimer, which transforms to the photochromic dimer on dissolution in a solvent. In solution the photochromic dimer exists in a photostationary equilibrium with its radical form.

Radical stability in these systems has been investigated by a number of workers with respect to the influence of substituents (5). It was found that an electron-donating group on the phenyl ring will shift the photostationary state to the radical form. Interestingly, on replacing 1,4,5-triphenylimidazole by phenanthro[9,10-*d*]imidazole, so that the conjugation system is extended, the characteristics of the dimer changed dramatically. The electronic absorption of the radical form of the phenanthroimidazole dimers is shifted to longer wavelength (~600 nm) so that the solution appears blue or green, whereas the triphenylimidazole dimer solution is violet. Moreover, the dissociation of the phenanthroimidazole dimers becomes a thermal process and irradiation is no longer necessary. Various papers and patents have described the application of triphenylimidazole dimers in silver-free photographic processes (6); their application as initiators in polymerization has also been investigated (7). However, relatively few papers have elucidated problems inherent in the synthesis and characterization of the phenanthroimidazole dimer system (8). We

Received January 8, 1998.

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

report here our results concerning the synthesis and characterization of phenanthroimidazole dimers **2a–i**, using the oxidative synthesis method shown in Scheme 1. Compounds **2c**, **2d**, **2f**, **2g**, and **2i** have not been reported previously. Some comparisons are also made with corresponding dimer systems derived from triphenylimidazole (lophine), **1**. The original purpose of this work was to devise pressure- and sheer-sensitive dye molecules that could be used as sensors in polymer processing (9*a–d*)]; this is an extension of our studies on thermochromic and photochromic dye molecules and other photoactive pigments (9*e–r*).

Results and discussion

Synthesis

The synthesis of phenanthroimidazole dimers by the literature method used in the synthesis of triphenylimidazole dimers (10, 11), i.e., addition of an aqueous solution of potassium ferricyanide to a cold solution of the imidazole in ethanolic potassium hydroxide, proved to be unsuitable in the present work because of precipitation of reactants and isolation of impure products due to decomposition. In our experience, only dimer **2a** could be synthesized in pure form by the method used in the synthesis of triphenylimidazole dimers, probably because of its lower solubility in organic solvents, thus retarding decomposition. Coincidentally, this compound was the only one whose structure was fully elucidated by Sakaino et al. (8*a*).

Oxidation with potassium ferricyanide is of common use in organic synthesis, especially in oxidative coupling of phenols (12) and of amines (13), but, importantly, in both cases two-phase reaction conditions were used: inorganic reactant dissolved in water and the organic reactant in methylene chloride. A two-phase system (water–benzene) was used previously by Cescon et al. (5*a*) in the synthesis of triarylimidazole dimers and has been successfully applied to the synthesis of phenanthroimidazole dimers in the present work. The dimer product could be obtained in crystalline form from the organic phase after most of the solvent was evaporated; these products gave unambiguous NMR spectra. Dimer **2e** is an exception, since this gave the correct molecular peak corresponding to the dimer in the mass spectrum but failed to give a definitive NMR

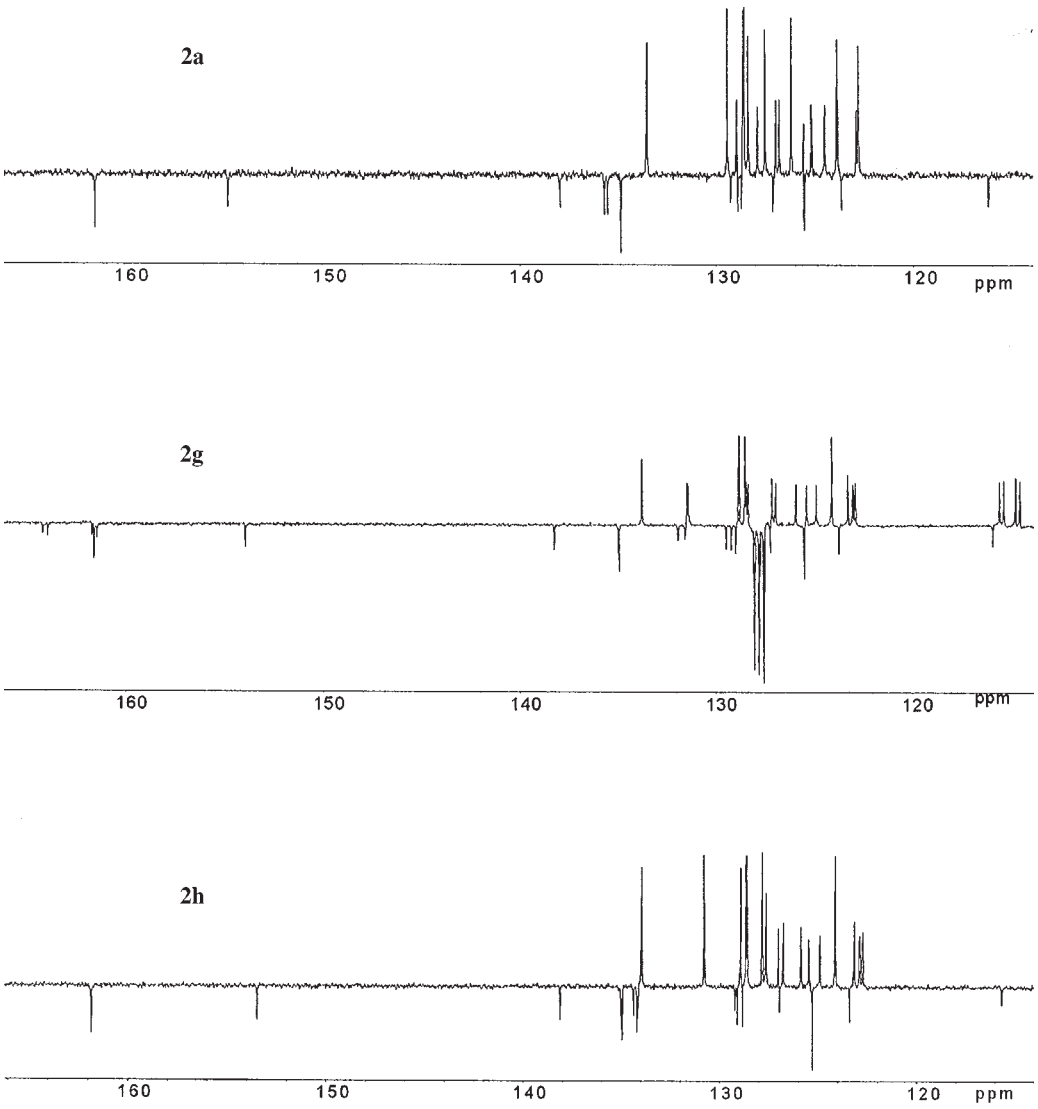
Fig. 1. ^{13}C NMR spectra of representative phenanthroimidazole dimers **2a**, **2g**, and **2h**.



spectrum, probably because of decomposition, as indicated by the color change of the $CDCl_3$ solution. The other dimers were relatively more stable in $CDCl_3$ and allowed definitive characterization by NMR.

Structure elucidation by NMR

Triarylimidazole dimers can, in principle, exist in six structurally different isomeric forms (11). Since our work entailed a modified literature method, the structure suggested by Sakaino et al. (8*a*) for the phenanthroimidazole dimers in their work cannot be taken for granted in the case of dimers **2a–i**. Structure elucidation in the present work was based mainly on the use of NMR spectroscopy. Structures **5** and **6** can readily be excluded because of their symmetry, which would lead to a smaller number of signals of aromatic carbons than actually observed in the ^{13}C NMR spectra. Structures **7** and **8** could also be excluded, for the opposite reason, i.e., lower symmetry, which should give rise to more signals of aromatic carbons than actually observed in the ^{13}C NMR spectra. Only structures **3** and **4** satisfy the requirement of the observed number of ^{13}C NMR signals: 16 for the protonated aromatic carbons and 15 for nonprotonated aromatic carbons in the case of *para*-substituted dimers **2b–d**, **2h**, and **2i**. For the unsubstituted dimer **2a** the number of signals for protonated aromatic carbons is 18 and for nonprotonated aromatic carbons 13. However, due to overlap only 17 distinct signals were observed. In the case of the *p*-fluoro-substituted dimer **2g**, due to coupling between ^{19}F and ^{13}C (J_{CF} = 249.1 Hz, 247.7 Hz; $^1J_{CF}$ = 22.0 Hz, 21.9 Hz; $^2J_{CF}$ = 8.5 Hz, 8.3 Hz; $^3J_{CF}$ = 3.1 Hz, 3.0 Hz) the number of signals for protonated aromatic carbons increased to 20 and for nonprotonated aromatic carbons to 19 (Fig. 1). For **2f**, on the other hand, the three fluorines of the trifluoromethyl group split the signals of the vicinal carbons of the phenyl ring to a quartet ($^1J_{CF}$ = 32.5 Hz, 32.3 Hz), increasing the signal number of nonprotonated ring carbons to 21. Again, due to overlap only 15 protonated and 20 nonprotonated carbon signals were observed. The other eight signals corresponding to two quartets (J_{CF} = 272.3 Hz, 272.3 Hz) in the aromatic chemical shift region stem from the two trifluoromethyl carbons due to the deshielding and coupling with the three fluorines (Table 1).

To distinguish between structures **3** and **4**, we have made use of the reference compounds **9**–**14** reported in the literature (8*a*, 14), which are good representatives of the half-dimer subunits. The ^{1}H NMR chemical shifts (in ppm) for the 2,6-protons on the 2-phenyl ring are as follows: <8.0 in **9**, **10**; 8.47, 8.18 in **11**; 7.50 in **12**; 7.85 in **13**; and 8.45 for **14**.

The reference compounds **9**–**14** fall into two structurally similar sets: the triaryl imidazole series **9**–**11** and the phenanthroimidazole series **12**–**14**. These structural parallels are reflected in parallel trends in the ^1H NMR chemical shifts of the 2-phenyl 2,6-protons. The COSY and ^1H NMR spectra of the synthesized dimers indicate that the resonance of the 2-phenyl 2,6-protons was lower than 8.00 ppm, the chemical shift values being <8.00 (**2a**); 7.31, 7.0 1(**2b**); 7.34, 7.05 (**2c**); 7.51, 7.19 (**2d**); 7.41, 7.25 (**2f**); 7.35, 7.06 (**2g**); 7.35, 7.05 (**2h**); and 7.28, 7.15 (**2i**), respectively (Table 2). This shows that the dimer structure must be made of two moieties that resemble the reference compounds **12** and **13**. Hence generic structure **3** is assigned to the synthesized dimers, which is consistent with the conclusions of the earlier work (8*a*). Moreover, by analysis of the COSY spectra on the dimers and the NOE results, we could make unambiguous assignment of the ^1H NMR spectra of the dimers (in the case of **2a**, only assignment for the phenanthryl rings was made) as shown in Table 2.

The assignment is made on the following basis: (*i*) the chemical shift values of protons in ring A bonded to the imidazole ring via an sp^2 carbon will be higher (further downfield) than those in the ring B bonded to the imidazole ring via an sp^3 carbon, because of more facile transmission of electronic effects in the former case. (*ii*) The protons on the asymmetric phenanthroimidazole ring at positions 4 and 11 have the same splitting pattern and integral values, but the higher chemical shift is assigned to position 11 since molecular models have shown that the proton at this position is the more "crowded."

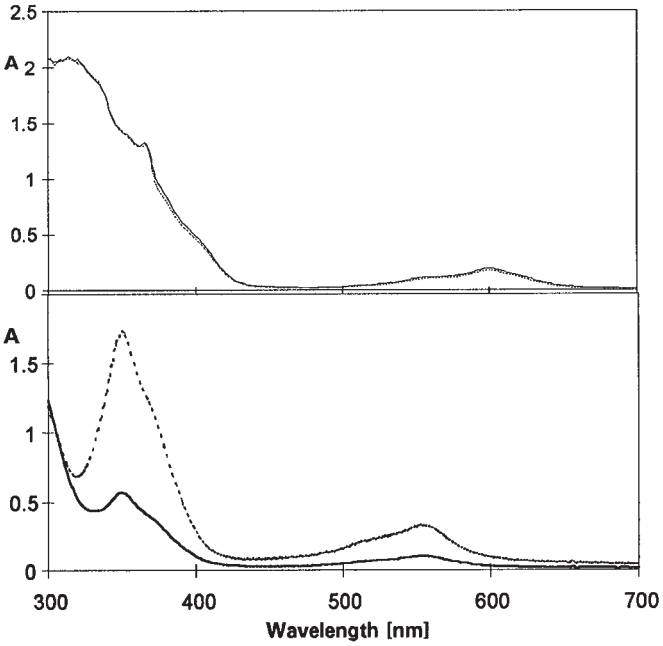
Fig. 2. (*a*) Spectra of dimer **2h** in benzene (8.55×10^{-5} M) after UV irradiation for 20 s at 25°C, solid line: before irradiation; dotted line: after irradiation. (*b*) Spectra of lophine dimer in benzene (9.15×10^{-5} M) after UV irradiation for 20 s at 25°C, solid line: before irradiation; dotted line, after irradiation.



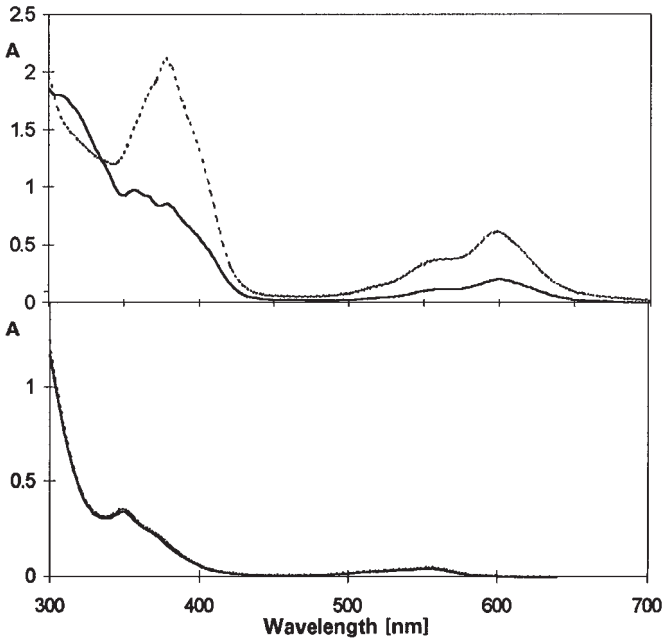
This crowding is also found in the optimized structure of dimer **2e** by the AM1 computational method.[2] Other cases have been recorded in the literature where "crowded" protons in aromatic compounds were found to have abnormally high chemical shifts (15). (*iii*) The protons at positions 4′(11′) and 7′(8′) on the symmetric phenanthroimidazole ring have the same splitting pattern and integral value, and the higher chemical shift value is assigned to position 4′(11′) due to proximity of the nitrogen in the imidazole ring. (4). Other assignments are based on results of COSY experiments with each dimer.

Features (*i*) and (*ii*) have been confirmed by means of an NOE experiment with dimer **2b**, the results of which show a strong Overhauser effect between protons having chemical shifts 9.38 and 7.01. These two values have been assigned to the protons at positions 11 and 6‴(2‴). The results of the AM1 optimization on dimer **2b** also reveal that the spatial distance between positions 11 and 6‴(2‴) is 2.81 Å,[2] which falls in the effective range of Overhauser effects (16). In the work of Sakaino et al. (8*a*), a chemical shift of 9.3 was also assigned to the proton at position 11 of dimer **2a**, though definitive proof for the assignment was not given.[3]

[2] S. Chen, Y. Zhou, and E. Buncel. Unpublished results.

[3] It has been pointed out by a referee that one can distinguish between structures **3** and **4** on the basis of symmetry. Structure **4** has a stereogenic centre at the dimer linkage to the top imidazole ring. Hence the lower phenanthroimidazole ring system does not have symmetry and will have the same carbon count in the ^{13}C NMR as the lower ring in **7**, which leaves the generic structure **3** as the only possible one. We thank the referee for this observation, which complements the structural assignment made on the basis of the experimental NMR evidence.

Fig. 3. (*a*) Spectra of dimer **2h** in benzene (8.67×10^{-5} M) on heating from 25°C (solid line) to 60°C (dotted line). (*b*) Spectra of lophine dimer in benzene (9.15×10^{-5} M) on heating from 25°C (solid line) to 60°C (dotted line).



Photochromism

The synthesized phenanthroimidazole dimers are not photosensitive at room temperature. Thus the absorbance of the dimer solution in benzene remains constant under irradiation (Fig. 2*a*); in contrast the absorbance of the solution of lophine dimer in benzene increased 2–3 fold under identical irradiation conditions (Fig. 2*b*). Figure 2*a* shows the constant absorbance of the solution of dimer **2h** in benzene at 25°C after UV irradiation for 20 s. All other synthesized phenanthroimidazole dimers behave similarly to dimer **2h** toward UV irradiation.

Thermochromism

In contrast to the lack of an effect of UV irradiation on spectra in the phenanthroimidazole dimer series, the absorbance of the dimer solutions in benzene increased 2–3 fold when the temperature of the solutions was raised from 25°C to 60°C (Fig. 3*a*); on cooling the color faded again. The process of color development on heating and the subsequent fading of color on cooling could be repeated a number of times. However, a gradual decomposition took place on standing at a given temperature. This color fading followed a first-order process, but it was not possible to identify the products of decomposition. The triphenylimidazole dimers, in contrast, show little or no change in their UV–VIS spectra on heating (Fig. 3*b*), even though literature reports claim these compounds to also be thermochromic (10, 17).

Piezochromism

We have found that all synthesized phenanthroimidazole dimers are pressure sensitive: the originally brown or yellow crystals turned green or bluish green upon grinding. The colored ground dimers could be pressed to a transparent disc with potassium bromide and the absorption in the visible range

recorded (Fig. 4). After several days the color formed through grinding and pressurization faded. Interestingly, it was found that spectra recorded in this way displayed a bathochromic shift with electron-donating substituents such as OCH_3 and CH_3, similar to the observation with the benzene solutions of these dimers (Table 3).

It seems plausible that the observed color development on grinding and pressurization is due to dissociation of the dimers to free radicals, although it is not clear whether the dissociation is brought about by crystal deformation or rupture through external pressure, or as a result of a thermal effect from mechanical grinding. Both factors have been reported to cause color change through structural changes (18). In general, one expects formation of two radicals from a dimer to be accompanied by an increase in molecular volume, but in the present system the reverse situation may obtain since the radicals will be essentially planar and capable of stacking, which is clearly not the case with the dimer as shown by molecular models and AM1 calculations. The experiments described below prove conclusively that the colored species formed from the dimers are indeed free radicals.

Dimer–radical equilibrium

It was possible to investigate the dimer–radical thermal equilibrium for the phenanthroimidazole dimers and to determine the molar extinction coefficient as well as the equilibrium constant for formation of the radical species by means of the following derivations.

Consider the dissociation of the dimer to its radical form:

Table 4. Equilibrium constants and molar extinction coefficients calculated from the slope and intercept of A versus $[D]_o/A$ plots of dimer solutions in benzene at 25°C, and the fraction of dissociation, $\alpha = K^{1/2}$.

	$-\log K$	$10^{-3}\varepsilon$	$10^{3}\alpha$

2d (CN)	0.66	552	[a]

[a] K values too small to be measured accurately.

$$D \rightleftharpoons R + R$$

where D stands for the dimer and R for the radical formed from the dimer on dissociation. The equilibrium constant is given by

$$K = \frac{[R]^2}{4[D]} = \frac{[R]^2}{4[D]_0 - 2[R]}$$

where [D] and [R] refer to the equilibrium concentrations while $[D]_0$ is the initial dimer concentration. If the Lambert–Beer law is valid and the radical species is responsible for the color formation, then $[R] = A/\varepsilon l$, where A is absorbance, ε the molar extinction coefficient, and l, the light pathlength, equals 1. Hence

$$K = \frac{(A/\varepsilon)^2}{4[D]_0 - 2(A/\varepsilon)}$$

$$A = 4K\varepsilon^2 \frac{[D]_0}{A} - 2K\varepsilon = a\frac{[D]_0}{A} - b$$

It follows that a plot of A against $[D]_0/A$ will be linear with slope $a(= 4K\varepsilon^2)$ and intercept $b(= 2K\varepsilon)$. The molar extinction coefficient ε and equilibrium constant K can then be obtained: $\varepsilon = a/2b$ and $K = b^2/a$. The degree of dissociation is given by $\alpha = K^{1/2}$ (where $\alpha << 1$).

In Fig. 5 is shown the relevant plot of A vs. $[D]_o/A$ for the various substituted dimers and it is seen that satisfactory linearity is obtained. The resulting values of K, ε, and α are given in Table 4. Importantly, the results show that the fraction of dissociation of the phenanthroimidazole dimers to radical is of the order of 10^{-3}. This is consistent with the fact that the NMR spectra of the dimers appear to be free of paramagnetic

interference. In that regard, it is interesting that Maeda and Hayashi (10) reported a degree of dissociation, $\alpha = 0.3$, for triphenylimidazole dimers, although one might have expected α to be smaller for triphenylimidazole dimers than for phenanthroimidazole dimers.

The results in Table 5 indicate that the dimer–radical equilibrium constants increase as the *para* substituents on the 2-phenyl ring of the dimers become more electron donating (Table 5). This is consistent with the trend that electron-donating substituents stabilize the radicals, as was also found for dissociation of triphenylimidazole dimers (5). The halogenated phenanthroimidazole dimers do not show a clear trend, given the experimental error in measurement of K, though the λ_{max} values exhibit a reverse trend relative to the electron-donating substituents. The strong electron-withdrawing trifluoromethyl and cyano substituents both exhibit a hypsochromic effect on λ_{max} and decreased dissociation constants, which were in fact too small to be measured accurately.

ESR spectra

Several studies have reported on the ESR hyperfine structure of the free radical derived from the lophine dimer (20, 21) and the radical anion derived from lophine (22). It was found that the free radical of the lophine dimer has spin density distributed in all three phenyl rings even though these are twisted out of the plane of the imidazole ring and also with respect to one another (21). One would expect that in the free radical derived from the phenanthroimidazole dimer the spin density would be more delocalized because of the extended conjugation, leading to more complex ESR hyperfine structure. We have, indeed, obtained a much more complex ESR hyperfine structure from dimer **2b** than from the corresponding 2-*p*-methylphenyl-4,5-diphenyl imidazole dimer (Fig. 6).

While the ESR signal of the lophine dimer in benzene is enhanced following UV irradiation (Fig. 7), the ESR signal of dimer **2b** in benzene becomes stronger on heating (Fig. 8). It is interesting to note that the ESR signal of dimer **2b** in the solid state is also enhanced on grinding (Fig. 9). These experiments confirm that the colored species obtained on UV

irradiation of the triphenylimidazole dimers, and also on heating the solutions of the phenanthroimidazole dimers or on grinding the phenanthroimidazole dimer, are free radical species. These qualitative observations on solutions of phenanthroimidazole dimers further validate the measurement of the molar extinction coefficient of the colored species as described above.

Experimental

The starting phenanthroimidazole compounds were synthesized according to the modification by Davidson et al. (23) of Radziszewski's imidazole synthesis (24). The dimers were synthesized by means of a two-phase reaction as described below.

To a solution of 1 g of the imidazole derivative in 250–350 mL methylene chloride was added a solution of potassium ferricyanide (5 g) and sodium hydroxide (5 g) in 100 mL water while cooling to 0°C and with vigorous stirring. The blue- or green-colored solution was stirred for 5 min at 0°C. The aqueous phase was separated and the organic phase was dried over sodium sulfate, and evaporated under reduced pressure to ca. 3 mL. After addition of ca. 3 mL ethyl acetate, the solution was placed in a refrigerator until crystals formed; these were filtered and washed with diethyl ether, yield over 90%. The MS data of the synthesized dimers are summarized in Table 6.

The UV–VIS spectroscopic measurements on the dimer solution in benzene were carried out by dissolution of ca. 20 mg of a dimer in 50 mL of benzene (BDH) freshly distilled from calcium hydride, followed by repetitive dilution to half concentration. UV–VIS spectra were recorded on an HP 8452A diode array spectrophotometer supported by HP89531A MS-DOS – UV–VIS operating software.The temperature of solutions in the cuvette (1 cm) was equilibrated to ± 0.1°C by means of a thermostatted water bath, RTE-210 (Neslab Instruments. Inc., Newington, NH 03801 U.S.A.). The UV light source for the irradiation was Spectroline, CX-Series (Spectronics Corporation, Westbury, New York).

NMR spectra were taken on a Bruker AM-400 NMR spectrometer operating at 400.134 MHz for ^{1}H and at 100.614 MHz for ^{13}C. The NMR solvents were purchased from CDN. The ESR spectra were recorded on a Varian E 104 ESR spectrometer and the UV light source for ESR measurement was a 1000-W Xe/Hg arc lamp. Sharp melting points could not be obtained; instead the sample in the capillary turned to a straw-colored resin-like material when the temperature was raised slowly (10°C/min). On raising the temperature quickly (>20°C/min) a transient blue or green color characteristic of the radical was observed; then the compound changed to the resin-like material. Purity was judged by the ^{1}H NMR spectra, which showed the absence of any extraneous peaks except for solvent (CH_2Cl_2 or EtOAc) of crystallization, which was difficult or impossible to remove, rendering

elemental analysis a poor criterion of purity. A typical ^{1}H NMR spectrum is shown in Fig. 10.

Acknowledgments

This research was supported by a grant from the Ontario Center for Materials Research. The authors are also grateful to Dr. L. Johnston, Dr. J. Lusztyk, and Dr. D. Shukla (National Research Council of Canada, Steacie Institute for Molecular Science) for assistance with the ESR measurements. We thank Prof. B.K. Hunter and Ms. S. Blake for helpful discussion on NMR data analysis.

Mechanism of the benzidine disproportionation of (arylhydrazo)pyridines. The reactions of 4-(4-chlorophenylazo)pyridine and -hydrazo)pyridine in acid media

Robin A. Cox, Kap-Soo Cheon, Sam-Rok Keum, and Erwin Buncel

Abstract: A kinetic and product analysis study of the reactions of 4-(4-chlorophenylhydrazo)pyridine (**1**) and 4-(4-chlorophenylazo)pyridine (**2**) in acid media is reported. The disproportionation of two moles of **1** in aqueous sulfuric acid gives one mole of the oxidized product **2**, and one mole each of the reduced products 4-chloroaniline and 4-aminopyridine. The azo compound **2**, a product of the reaction of **1**, undergoes a slower hydroxylation reaction in acid media, and this process was also investigated. The first-formed product in the reaction of **2** is probably 4-(4-hydroxyphenylazo)pyridine, the 4-chlorine being displaced. At the low substrate concentrations used for the kinetic measurements both reactions are straightforward, but at the much higher concentrations used for product isolation studies a complex product mixture results, one of the products being a dimer. The complexity is increased because **1** had to be used as its hydrochloride salt for reasons of stability, and the chloride ion can also react with the diprotonated substrates; chloride ion also accumulates in the system as it is displaced from **2** during the hydroxylation. Thus chloride ion competes with bisulfate ion (present in large excess) for the diprotonated substrates. Nevertheless, complete mechanistic schemes accounting for all of the observed products, including the dimer, could be derived and are presented. Values of $pK_{BH_2^{2+}}$ for **2** and two of the azo products, needed for the kinetic analysis, were measured using the excess acidity equilibrium method. The nucleophile reacting with protonated **2** in the rate-determining step of the hydroxylation was positively identified as being bisulfate ion by an excess acidity analysis. A comparison of the reaction of **1** with the equivalent reactions of two previously studied 4-(arylhydrazo)pyridines, **9** and **10**, reveals that the benzidine disproportionation of these molecules is an A1 process with the second protonation being a pre-equilibrium; $pK_{BH_2^{2+}}$ values for the hydrazo compounds could not be measured as they react too quickly, but they could be determined from the kinetic data, using the excess acidity method. The rate-determining step is a thermally allowed 10-electron electrocyclic process of the diprotonated substrate, giving rise to an intermediate that undergoes fast reaction with a molecule of protonated substrate in a thermally allowed 14-electron electrocyclic process to give the observed products.

Key words: azopyridines, benzidine, disproportionation, excess acidity, hydrazopyridines, hydroxylation, mechanism.

Résumé : On a réalisé une étude cinétique ainsi qu'une analyse des produits des réactions des 4-(4-chlorophénylhydrazo)pyridine (**1**) et 4-(4-chlorophénylazo)pyridine (**2**) en milieu acide. La dismutation de deux molécules de **1** dans de l'acide sulfurique conduit à une mole du produit oxydé **2** et à une mole chacun des produits réduits, 4-chloroaniline et 4-aminopyridine. En milieu acide, le composé azo **2**, un produit de la réaction de **1**, subit une réaction d'hydroxylation plus lente; on a aussi examiné ce processus. Le premier produit formé dans la réaction de **2** est probablement la 4-(4-hydroxyphénylhydrazo)pyridine (**1**) provenant d'un remplacement du chlore en position 4. Aux faibles concentrations utilisées dans les mesures cinétiques, les deux réactions sont simples; toutefois, aux concentrations plus élevées utilisées pour les études en vue d'isoler les produits, il y a formation d'un mélange complexe de produits comprenant un dimère. La complexité est accrue à cause du fait qu'il a été nécessaire, pour des raisons de stabilité, d'utiliser le chlorhydrate du composé **1** et que l'ion chlorure peut aussi réagir avec les substrats diprotonés; de plus, l'ion chlorure s'accumule aussi dans le système lorsqu'il est déplacé du composé **2** par hydroxylation. L'ion chlorure est donc en compétition avec l'ion bisulfate (présent en très grand excès) pour les substrats diprotonés. Malgré tout, on peut présenter des schémas mécanistiques complets permettant d'expliquer tous les produits observés, y compris le dimère. Utilisant la méthode d'équilibre d'acidité en excès, on a mesuré les valeurs de $pK_{BH_2^{2+}}$ du composé **2** et de deux produits azo nécessaires pour l'analyse cinétique. Faisant appel à l'analyse de

l'acidité en excès, il a été possible d'identifier sans ambiguïté que l'ion bisulfate est le nucléophile qui réagit avec la forme protonée de **2** dans l'étape cinétiquement limitante de l'hydroxylation. Une comparaison de la réaction de **1** avec les réactions équivalentes de deux 4-(arylhydrazo)pyridines (**9** et **10**) étudiées antérieurement révèle que la dismutation de la benzidine de ces molécules est un processus A1 dans lequel la deuxième protonation est un prééquilibre; il n'a pas été possible de mesuré les valeurs des $pK_{BH_2^{2+}}$ de ces composés hydrazo à cause de leur trop grande vitesse de réaction, mais il a été possible de les déterminer à partir de données cinétiques faisant appel à la méthode d'acidité en excès. L'étape cinétiquement limitante est un processus électrocyclique thermique permis, à 10 électrons, du substrat diprotoné qui conduit à un intermédiaire qui réagit rapidement avec une molécule de substrat protoné par le biais d'un processus électrocyclique thermique permis, à 14 électrons, conduisant aux produits observés.

Mots clés : azopyridines, benzidine, dismutation, acidité en excès, hydrazopyridines, hydroxylation, mécanisme.

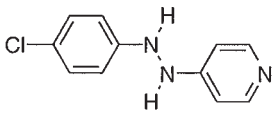
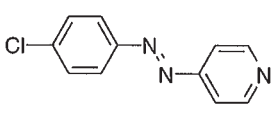
Introduction

Studies of azo and azoxy compounds have revealed a remarkable diversity of structure–reactivity relationships, and some challenging problems in mechanism. Our work in this area was originally concerned with the mechanism of the acid-catalyzed Wallach rearrangement of azoxyarenes (1–7). This has developed in recent years to encompass a variety of photoactive molecules and processes, including the synthesis (8) and electronic spectral characteristics (9) of novel azo merocyanine dyes, and their solvatochromism (9, 10), which led to the establishment of the π^*_{azo} solvent polarity scale (10). The photochemical and thermal interconversion of merocyanines and their spiro precursors (11–15) has led most recently to studies of the chiroptical properties of spiro molecules, with a view to developing a ferroelectric liquid crystal optical switch based on the principle of photoresolution (16, 17).

The present series of studies is an extension of the Wallach rearrangement studies of phenyl and naphthyl substrates (2–6) to the heteroaromatic series, with the observed $>10^4$ reactivity difference between the isomeric α- and β-phenylazoxypyridines involving di-and tri-protonation processes in the 95–100 wt.% H_2SO_4 acidity region (7). This led to the discovery of the remarkably facile hydrolysis of the aryl azo ethers in acid media, with protonation on nitrogen, oxygen or carbon centers occurring as fast equilibria or as the rate-determining step (18, 19). In the course of these studies it was discovered that phenylazopyridine is itself unstable in strong acid media, undergoing hydroxylation and disproportionation (20). Since this was reminiscent of the classical benzidine rearrangement (21–23), kinetic studies were extended to the surmised intermediate, 4-(4-hydroxyphenylhydrazo)pyridine (24). However, an excess acidity treatment of the results (25) led to uncertainties in the postulated reaction mechanism. This was unsatisfactory, since the excess acidity method (25) has proven to be very useful in the determination of the mechanisms of reactions that take place in strong acid media. For instance, lactam (26), alkylnitramine (27), *N*-nitro amide (28), and acylimidazole (29) hydrolyses, as well as imidazoline cyclizations (30), alkene hydrations (31), aromatic hydrogen exchange processes (32), and ether (19, 33) and thioacetal (34) hydrolyses have been studied using this approach.



1

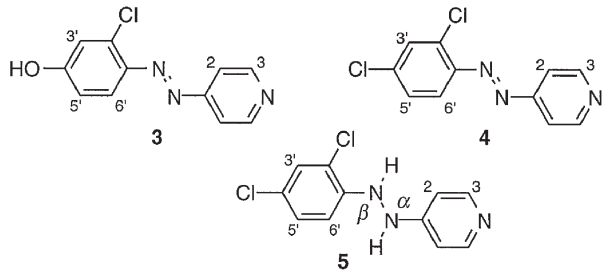


2

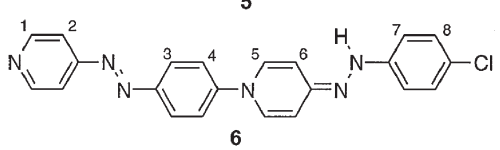
Thus, in our quest to resolve the mechanistic ambiguity in the benzidine-type disproportionations of the 4-(arylhydrazo)pyridines (24), we have extended these studies to include 4-(4-chlorophenylhydrazo)pyridine **1**. We also examined the azo analog **2**, the results for which can be compared with those previously obtained for other (arylazo)pyridines (20). These substrates form the subject of the present paper; it will be shown that while the results obtained using **1** and **2** are more complex in terms of reaction products, the kinetic data obtained do, in fact, allow the definitive resolution of the mechanism of this benzidine rearrangement-like process.

Experimental

The hydrochloride salt of 4-(4-chlorophenylhydrazo)pyridine **1** was obtained in 33.8% yield when 4-phenylazopyridine was simultaneously chlorinated and reduced (35), mp 241–242°C (lit. (35) mp 243°C). This compound was used as its hydrochloride salt rather than in the free base form, since the former proved to be much more air-stable. 4-(4-Chlorophenylazo)pyridine **2** resulted in 22.3% yield when **1** was oxidized (35), mp 97–98°C (lit. (35) mp 99–100°C). The synthesized compounds were characterized as before (20).



3 **4** **5**



6

Substrates and isolated products were purified by several techniques, recrystallization, and column and thin-layer chromatography using silica gel 60 F_{254} plates (BDH) in various eluting solvent systems. The products of the reactions of **1** and **2** in 65 wt.% aqueous H_2SO_4 were identified by UV–vis, NMR, and GC–MS analysis following direct isolation as previously described (20); some of the isolated products, **3**–**6**, are shown above. The MS results were particularly useful for

[a] Since two aniline products result from one substrate molecule, their yields have to be averaged in calculating the overall yield, which is why the numbers in this column are not the simple sum of those in the previous column.

identifying the chlorine-containing products; for instance, the mass spectrum of **4** with its two chlorine atoms showed a characteristic intensity pattern of 100:65.3:10.6, in which each peak is separated by two mass units due to the natural abundance of the two chlorine isotopes, ^{35}Cl:^{37}Cl being 100:32.5. The structural identification of the products was achieved using ^1H NMR spectroscopy and MS. For **3**: δ_H (DMSO-d_6): 12.82 (OH), 8.79 (H^3), 7.83 (H^2), 7.68 ($H^{6'}$), 7.17 ($H^{3'}$), 6.98 ($H^{5'}$); *m/z*: 233.0 (M). For **4**: δ_H (DMSO-d_6): 8.86 (H^3), 7.96 ($H^{3'}$), 7.77 (H^2), 7.73 ($H^{6'}$), 7.60 ($H^{5'}$); *m/z*: 251.0 (M). For **5**: δ_H (DMSO-d_6): 8.90 (NH^{α}), 8.14 (H^3), 8.08 (NH^{β}), 7.48 ($H^{3'}$), 7.20 ($H^{5'}$), 6.74 ($H^{6'}$), 6.67 (H^2); *m/z*: 235.1 (M). For the dimer **6**: δ_H (DMSO-d_6): 9.98 (NH), 8.72 (H^1), 8.14 (H^5), 7.86 (H^3), 7.65 (H^2), 7.42 ($H^{7,8}$), 7.16 (H^4), 6.60 (H^6); *m/z*: 401.2 (M+1).

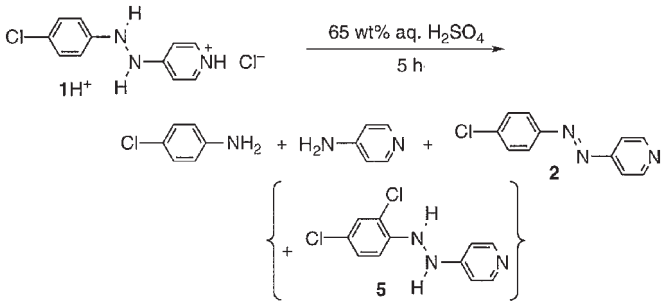
The $pK_{BH_2^{2+}}$ values of the azo substrate **2** and the azo products **3** and **4** were determined from the variation of the UV–vis spectra with sulfuric acid concentration as previously described (20); the acid concentration and extinction data are given here as supplementary information, Tables S1–S3.[3] The kinetic techniques used were similar to those used before (20).

Results

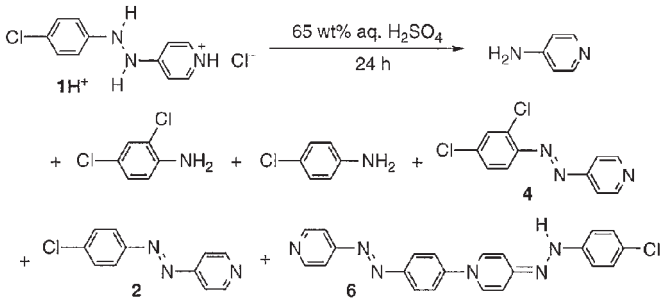
Products

The products formed when 4-(4-chlorophenylhydrazo)pyridine **1** is allowed to react in 65 wt.% H_2SO_4 for 5 h at a substrate concentration of 0.05 M are given in Table 1, and illustrated in Scheme 1. Under these conditions, and at the much lower substrate concentrations used for the kinetic runs (as determined from the UV–vis spectra after the kinetic runs), the reaction gives the three products shown, 4-(4-chlorophenylazo)pyridine **2**, 4-chloroaniline, and 4-aminopyridine. Trace amounts of 4-(2,4-dichlorophenylhydrazo)pyridine **5** were also present in the mixture analyzed.

Scheme 1.



Scheme 2.



If the reaction of **1** is allowed to continue for longer periods the number of products increases, as shown in Table 1 and illustrated in Scheme 2. The products still include **2**, 4-chloroaniline, and 4-aminopyridine, but 4-(2,4-dichlorophenylazo)pyridine **4** and 2,4-dichloroaniline are also present, with trace amounts of the dimeric product **6**. There is no evidence for the presence of **5**, leading to the inference that at least some of the new products may have been formed from it. The presence of extra Cl^- (**1** had to be used as its hydrochloride salt)

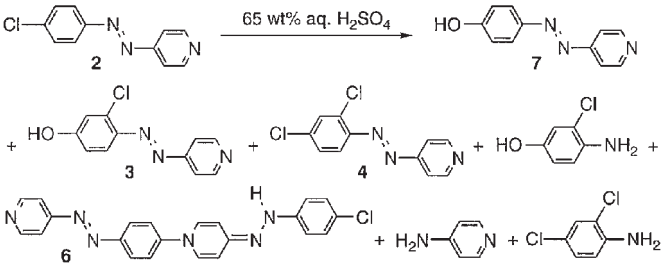
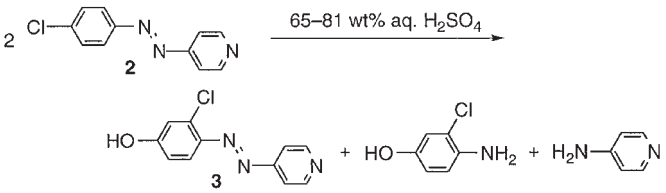
Scheme 3.



Scheme 4.



also complicates the situation. The product recovery in Table 1 is less than 100%, probably due to losses incurred during the TLC technique used for product separation (20).

The first-formed product **2** also reacts in aqueous H_2SO_4, albeit more slowly than does **1**, and the products of the reaction of **2** at 0.05 M substrate concentration were also investigated, see Table 1. A complex mixture of **4**, 4-(2-chloro-4-hydroxyphenylazo)pyridine **3**, 4-(4-hydroxyphenylazo)pyridine **7**, 2-chloro-4-hydroxyaniline, 2,4-dichloroaniline, 4-aminopyridine, and the dimeric product **6** was found, as shown in Scheme 3.

However, at the substrate concentrations typically used for the kinetic runs, ~8×10^{-5} M, the situation for **2** is much simpler, as shown in Scheme 4. The primary product is **3**, which could be identified by its UV–vis spectrum; the concentration of this product was shown not to depend on the medium acidity, averaging (46.8 ± 4.0)% over the 65–81 wt.% H_2SO_4 concentration range, as determined from the known extinction coefficients and the observed absorbances after 10 half-lives. The two aniline products also formed could not be directly identified, but undoubtedly form in equivalent amounts (20). Evidently the reaction is uncomplicated; according to Table 1 two moles of **2** give one mole of oxidized products (total 30% azo compounds) and one mole of reduced products with the N—N bond broken (total 24% anilines, 26% 4-aminopyridine).

$pK_{BH_2^{2+}}$ values

The azo compounds **2**–**4** are all protonated on the pyridine nitrogen in the pH range (8), so the protonation of interest in this work is the second protonation at the azo group. The $pK_{BH_2^{2+}}$ values were measured as described before (20). Extinction differences ($\delta\varepsilon = \varepsilon_{BH^+} - \varepsilon_{BH_2^{2+}}$) were obtained from UV–vis spectra measured in different sulfuric acid solutions at wavelengths appropriate for the peak maxima of the protonated and diprotonated forms; this is the Davis–Geissman method (36), preferred because errors due to small differences between the individual samples tend to cancel out when the difference is taken (these may cause irregular isosbestic point behaviour, for instance), and spectra of both forms contribute to the resulting $pK_{BH_2^{2+}}$ values. The data were treated according to the excess acidity method; for equilibria the relevant equation is $\log I - \log C_{H^+} = pK_{BH_2^{2+}} + m^*X$ (37), where C_{H^+} is the proton concentration in the sulfuric acid solution and X is the excess acidity, both obtained from published sources (37). The ionization ratio I is given in terms of $\delta\varepsilon$ by $I = (\delta\varepsilon_{BH^+} - \delta\varepsilon)/(\delta\varepsilon - \delta\varepsilon_{BH_2^{2+}})$ (38), where $\delta\varepsilon_{BH^+}$ and $\delta\varepsilon_{BH_2^{2+}}$ apply to the pure monoprotonated form and the pure diprotonated form, respectively. This expression was substituted in the excess acidity equation and the result recast in terms of $\delta\varepsilon$ and curve-fitted directly, as before (38); previous experience (39) shows that this method gives reliable protonation constants. The slope parameter m^* is characteristic of the substrate, having values of 1.0 for primary nitroanilines, 0.6 for amides and so on (37). The parameters given by the curve fit are $\delta\varepsilon_{H^+}$, $\delta\varepsilon_{BH_2^{2+}}$, $pK_{BH_2^{2+}}$, and m^*; the latter two are listed for **2**–**4** in Table 2. Also listed in Table 2 are the $pK_{BH_2^{2+}}$ and m^* values for 4-(4-hydroxyphenylazo)pyridine **7** and the parent compound **8**, already available (20), for comparison. The experimental data obtained and the values of X and $\log C_{H^+}$ used for **2**–**4** are given as supplementary material in Tables S1–S3,[3] together with the calculated $\delta\varepsilon_{BH^+}$ and $\delta\varepsilon_{BH_2^{2+}}$ values.

Kinetics

The kinetics of the reaction of 4-(4-chlorophenylazo)pyridine **2** (see Scheme 4) were monitored spectrophotometrically by following the disappearance of the reactant, in either its monoprotonated SH^+ form at 354 nm (up to 72 wt.% H_2SO_4), or its diprotonated SH_2^{2+} form at 444 nm (at the higher acidities). The observed pseudo-first-order rate constants as a function of acidity, k_ψ, and other parameters relevant to the kinetic analysis, are given in Table 3. All the kinetic plots showed excellent first-order linearity over the three half-lives for which the reaction was typically followed.

$$[1] \quad \log k_\psi - \log (C_{SH_2^{2+}} / (C_{SH^+} + C_{SH_2^{2+}})) - \log a_{Nu^-} = \log k_0 + (m^{\ddagger} - 1)m^* X$$

Previously it was found that eq. [1] describes the kinetic behaviour of 4-(phenylazo)pyridine (**8**) (and that of 2-(phenylazo)pyridine) at these acidities (20), and the behaviour of **2** was found to be very similar. Protonation of the substrate is a pre-equilibrium process (20), and so the $pK_{BH_2^{2+}}$ and m^* values given in Table 2 were used with the equilibrium excess acidity equation to calculate protonation correction terms (PCT) on the basis of full substrate protonation, $\log (C_{SH_2^{2+}} / (C_{SH^+} + C_{SH_2^{2+}}))$, or $\log (I/(1 + I))$ after division by C_{SH^+} (since the ionization ratio $I = C_{BH_2^{2+}} / C_{BH^+}$), which correct

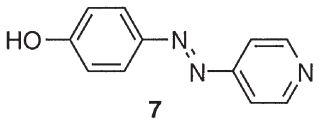
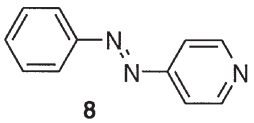
[c] Protonation Correction Term; log ($C_{SH_2^{2+}}$ / (C_{SH^+} + $C_{SH_2^{2+}}$)). Calculated using p$K_{BH_2^{2+}}$ = –6.47 and m^* = 0.991 from Table 2.

for less than full substrate protonation at the acidity under investigation. The nucleophile involved at these acidities is bisulfate ion, and log bisulfate ion concentrations were used for log a_{Nu^-} as before (20). Log k_0 refers to the rate constant for the reaction in the hypothetical ideal 1 M acid solution which is the standard state (37), and $m^\ddagger$ refers to the transition state, having values of >1 for an A1 reaction, <1 for an A-S_E2 reaction, and probably ~1 for an A2 reaction with water (25). Plots according to eq. [1] are given in Fig. 1 for **2**, with that for the parent compound **8** for comparison (20). For the reaction of **8** with bisulfate, log $k_0 = 0.36 \pm 0.11$ and $m^*(m^\ddagger - 1) = -0.645 \pm 0.018$, i.e. $m^\ddagger = 0.201 \pm 0.050$ (20). In this work we find, for the reaction of **2** with bisulfate, log $k_0 = -1.60 \pm 0.13$ and $m^*(m^\ddagger - 1) = -0.612 \pm 0.024$, i.e. $m^\ddagger = 0.383 \pm 0.031$.

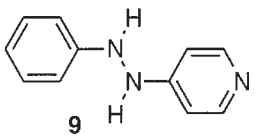


7



8

The kinetics of the disproportionation of **1** could be conveniently followed spectrophotometrically over the 60–86 wt.% H_2SO_4 range, by monitoring the formation of the azo product, 4-(4-chlorophenylazo)pyridine **2** (see Scheme 1) at either 354 nm (up to 72 wt.% H_2SO_4, monoprotonated form) or at 444 nm (at the higher acidities, diprotonated form). Reactions were generally followed over three half-lives, and all showed excellent first-order behaviour over this range. The observed pseudo-first-order rate constants, k_ψ, are given in Table 4, together with other pertinent information.



9

[c] Protonation Correction Term; log ($C_{BH_2^{2+}}$ / (C_{BH^+} + $C_{BH_2^{2+}}$)). Calculated using the p$K_{BH_2^{2+}}$ value of –4.806 (m^* = 1) given in Table 5.

These rate data were also treated according to the excess acidity method (25). To this end plots of log k_ψ – log C_{H^+} vs. X for **1**, together with the previously published equivalent plots for the parent 4-(phenylhydrazo)pyridine **9** and 4-(4-hydroxyphenylhydrazo)pyridine **10** for comparison (24), are shown here as Fig. 2. The observed downward curvature in Fig. 2 indicates (*a*) that the reaction is not an A-S_E2 process, as otherwise these plots would be straight, and (*b*) that the data go through a pK_a value (substrate titration) in an A1 reaction, which means that a protonation correction term has to be applied (25). Reaction with water in an A2 process would also

[a] Errors listed are standard deviations.

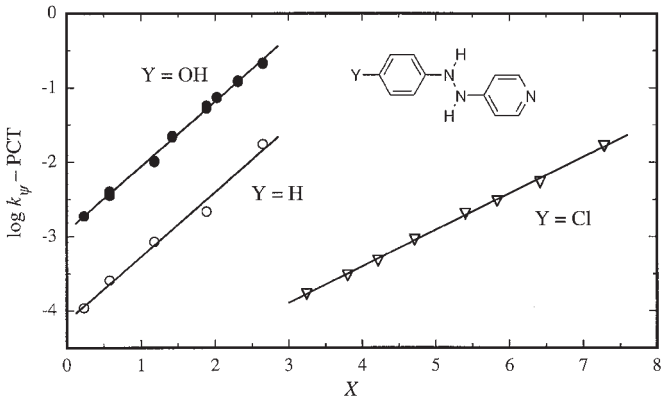
cause downward curvature in these plots (20, 27), but if that were the case here the curvature would be different for the different substrates, with much stronger curvature for **2** than for **10**, since the water activity decreases with acidity much faster at the higher acidities (4). The observed (Fig. 2) very similar curvature for **2** and **10** is much more likely to be due to a substrate titration; indeed, the Fig. 2 plots straighten out, as expected for a substrate protonation, rather than show the increasing curvature that would be expected for a reaction with water. This mechanistic distinction can now be made, with the addition of the data for **2**, whereas it could not without it (24).

The protonation involved is again the second one, undoubtedly on the hydrazo group, because these compounds are all already protonated on the pyridine ring, this process occurring in the pH range (8). The $pK_{BH_2^{2+}}$ values for these compounds are not known, and reaction is too fast to allow them to be measured, but $pK_{BH_2^{2+}}$ values can be estimated from the curvature of the kinetic plots in Fig. 2. It has recently been shown that quite precise values can be obtained in this way (29). The modified excess acidity equation for an A1 reaction that applies here, accounting for the changing state of protonation with acidity, is eq. [2] (25):

$$[2] \quad \log k_\psi - \log C_{H^+} - \log (C_{BH^+}/(C_{BH^+} + C_{BH_2^{2+}})) = \log (k_0/K_{BH_2^{2+}}) + m^\ddagger m^* X$$

where k_0 is the standard-state rate constant for the reaction. The protonation correction term in eq. [2], log $(C_{BH^+}/(C_{BH^+} + C_{BH_2^{2+}}))$, becomes log $(1/(1 + I))$ upon division by C_{BH^+}, and we can put $m^* = 1$ in the excess acidity equation

Fig. 3. Excess acidity plots of log k_ψ – log $(C_{BH_2^{2+}}/(C_{BH^+} + C_{BH_2^{2+}}))$ (PCT) vs. X for the reactions of **1** (open triangles), **9** (open circles), and **10** (closed circles) in aqueous sulfuric acid.



for equilibria (log $I = pK_{BH_2^{2+}} + m^*X + \log C_{H^+}$), because these hydrazo compounds are very similar to the H_0 primary aniline indicators, for which m^* is known to have the value 1.0 (37). Using eq. [2] means that we have three unknowns to calculate for each compound, slope ($m^\ddagger m^*$), intercept (log $(k_0/K_{BH_2^{2+}})$) and $pK_{BH_2^{2+}}$. A standard curve-fitting computer program was used (40), and the resulting, reasonably precise, $pK_{BH_2^{2+}}$ values are given in Table 5. These were then used to calculate protonation correction terms in the form log $(C_{BH_2^{2+}}/(C_{BH^+} + C_{BH_2^{2+}}))$. Subtraction of the latter from log k_ψ results in the very good straight lines in Fig. 3. This figure is drawn on the basis of full substrate protonation, which more accurately reflects the true situation at these acidities. The slope is $(m^\ddagger - 1)m^*$ and the intercept is log k_0 (25). These and the observed $m^\ddagger$ values, with their errors, are also given in Table 5. The $m^\ddagger$ values, all >1, are only consistent with an A1 mechanism (25). The Table 5 values were used to calculate the theoretical curves in Fig. 2.

Discussion

Reaction pathways

The products of the reactions of **1** and **2** in acid media, given in Table 1 and in Schemes 1–4, are quite complex. Although under kinetic conditions Schemes 1 and 4 prevail, it is nevertheless most convenient to begin with the elements that are common to several schemes. We have established previously (24) that 4-(phenylhydrazo)pyridines undergo a disproportionation in sulfuric acid media, for example, see Scheme 1, very similar to the processes undergone by other hydrazo compounds that have both 4-positions blocked (21, 41). Two substrate molecules give an azo compound (oxidized product) and two anilines (reduced products), as shown in Scheme 5. This disproportionation is much faster than any reaction undergone by the 4-(phenylazo)pyridine products (24); for the reactions of **1** and **2** this is readily apparent from a comparison of the rate constants in Tables 3 and 4. It is also very likely to be irreversible, since the reverse would be a termolecular process.

Deferring consideration of the mechanism until later, it is apparent that as soon as a hydrazo compound is formed it will react according to Scheme 5. The other products, apart from the dimer, can then be accounted for as shown in Scheme 6.

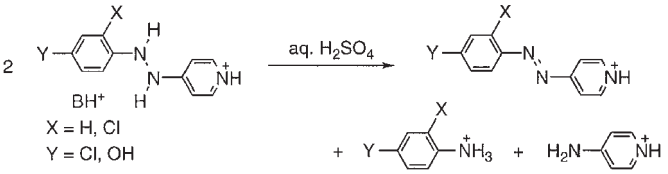
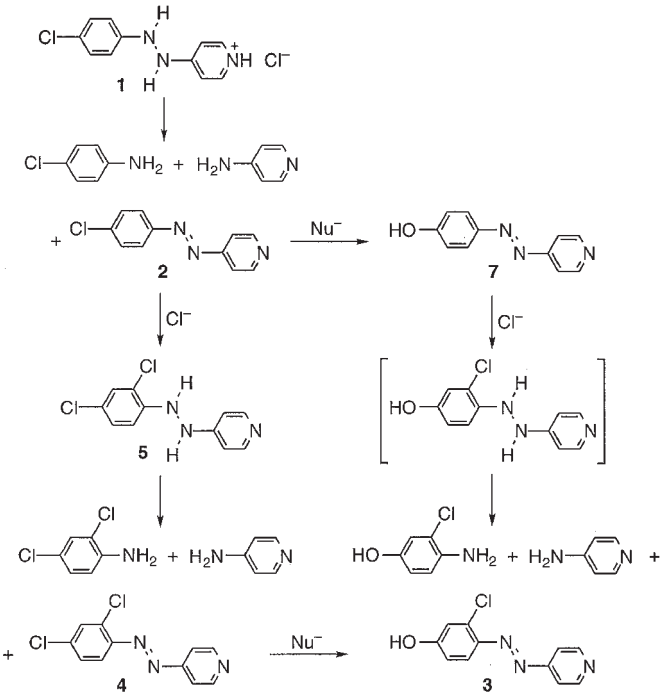
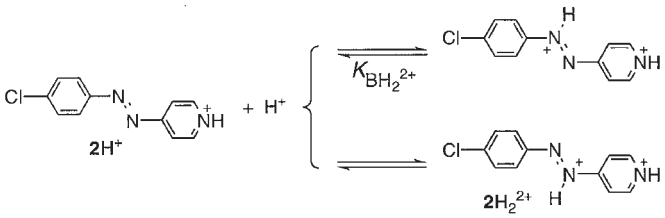
Scheme 5.



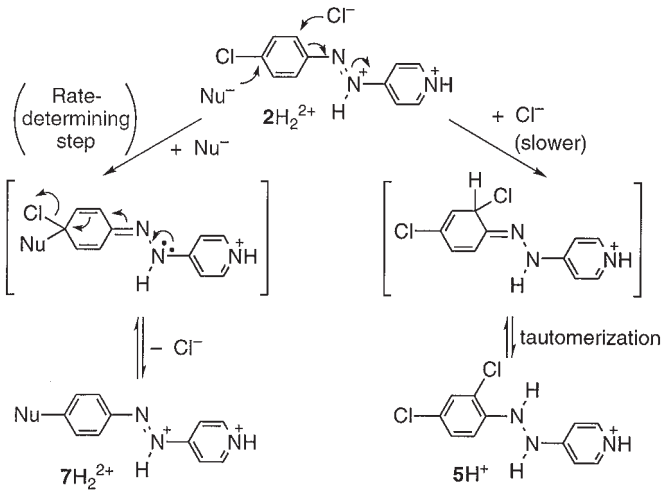
Scheme 6.



Scheme 7.



Scheme 8.



Starting with **1**, which has an equimolar amount of chloride ion present, product formation takes place from top to bottom on the left-hand side only, with no displacement by hydroxide occurring; products on the right are not observed if the starting material is **1**. On the other hand, if the starting material is **2** there is no free chloride ion present initially and the first reaction is **2** → **7**, with subsequent product formation taking place down both sides of Scheme 6, chloride ion accumulating as it is displaced. The hydrazo product in brackets is the only one we did not observe, presumably because it is too reactive.

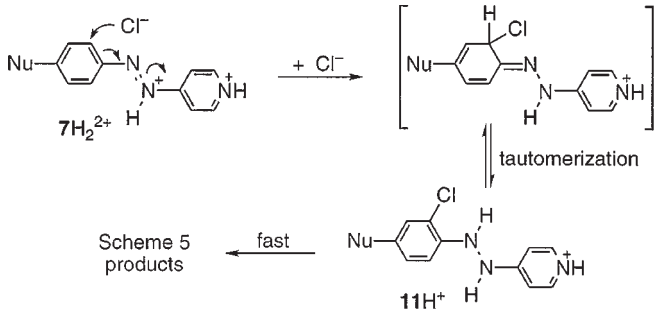
The reaction of **2**H$^+$ begins with a second protonation (the reaction is acid catalyzed), undoubtedly on the azo group. There are two nitrogens that can be protonated, as shown in Scheme 7. It does not particularly matter which azo nitrogen bears the proton, since the nitrogen lone pairs do not form part of the π system, but it seems reasonable to place it on the nitrogen furthest from the pyridinium positive charge, and the p$K_{BH_2^{2+}}$ values quoted in Table 2 probably refer to this. However, it is easier to draw the mechanistic schemes for subsequent reactions with the proton on the other nitrogen, **2**H_2^{2+} in Scheme 7.

Two different mechanistic possibilities for **2**H_2^{2+} are given in Scheme 8. (In Scheme 8 and subsequently the attacking nucleophile is identified as either Cl^- or as Nu^-; the latter is actually HSO_4^- in these media, as shown by the kinetic analysis (see Fig. 1), but in the identified products it appears as OH, since these sulfate ester products hydrolyze very rapidly to phenols in more dilute acid, as we have shown previously (42), and this will occur during the product work-up.) Chloride ion is present during the reaction of **2** when it derives from **1**, since **1** had to be used as its hydrochloride salt, and it accumulates as Nu^- displaces it from **2**; it is the best nucleophile in the system, and can react at the 2-position of the phenyl group in **2**H_2^{2+} as shown on the right-hand side of Scheme 8. Tautomerization leads to the hydrazo compound **5**H$^+$, most of which will react according to Scheme 5, giving the observed product **4** (Schemes 2 and 3). However, in the initial reaction of **2** itself the chloride concentration is zero, and thus the rate-determining step involves diprotonated **2** and bisulfate ion, as shown by the kinetic analysis; this is the left-hand pathway in Scheme 8. Loss of chloride ion (a good leaving group) as shown gives **7**H_2^{2+}. With free chloride ion now present, the right-hand side of Scheme 8 can come into play, and **7**H_2^{2+} can also react further, as shown in Scheme 9. Presumably the better nucleophile Cl^- can react at the more crowded *ortho* site (Schemes 8 and 9), whereas the far worse (and much bigger) nucleophile HSO_4^- is limited to *para* attack.

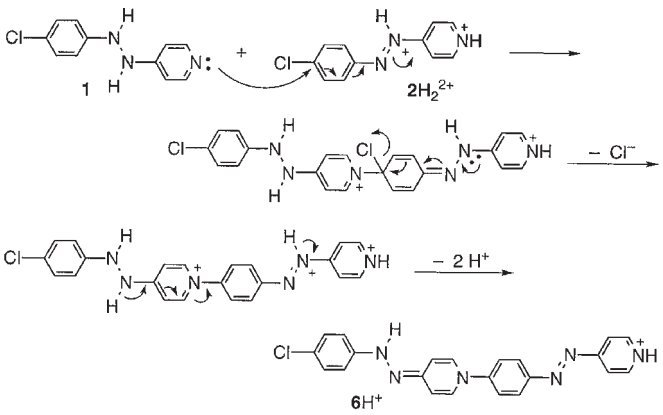
The chlorination of **7**H_2^{2+}, shown in Scheme 9, will be faster than the chlorination of **2**H_2^{2+}, shown at the right of Scheme 8, because of the presence of the inductively electron-withdrawing oxygen in the Nu group encouraging nucleophilic attack. Again, fast tautomerization leads to a hydrazo compound, **11**H$^+$, which will immediately react via Scheme 5 to give the observed product **3** (Schemes 3 and 4); in fact this is the first-formed major product in the reaction of **2**, according to the kinetics and Scheme 4. There are other possibilities; for

© 1998 NRC Canada

Scheme 9.



Scheme 10.

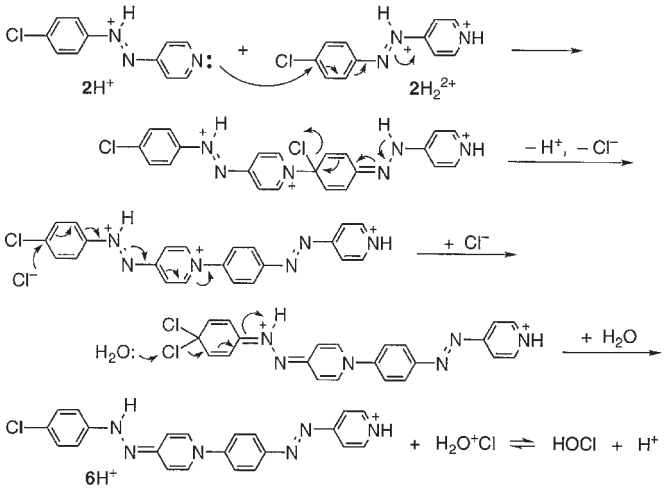


instance, it seems reasonable that $\mathbf{4}H_2^{2+}$ could undergo a chlorine displacement as in Scheme 8 to give $\mathbf{3}H_2^{2+}$ (and hence the isolated products should contain more **3** than **4**, see Table 1), and any two hydrazo compounds can take part in the disproportionation of Scheme 5. It is also possible (although probably less likely) that the 4-chloro- and 4-hydroxyanilinium ion products formed can be chlorinated at the 2-position by the free chloride ion (the presence of the $^+NH_3$ group increasing susceptibility to nucleophilic attack), perhaps giving rise to some of the observed 2,4-dichloro- and 2-chloro-4-hydroxyanilinium products.

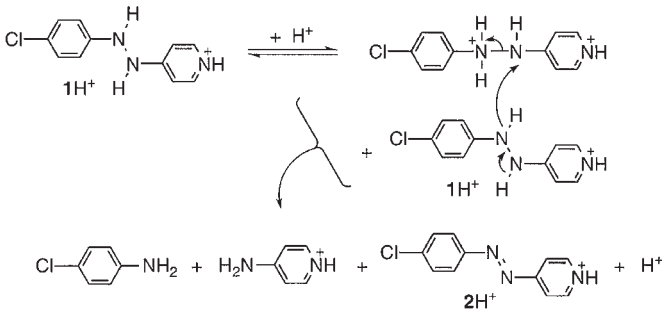
The only remaining major product to be accounted for is the dimer **6**. It has been mentioned that chloride ion is the best nucleophile in the system, but if any starting material that is not protonated on the pyridine nitrogen is present, this will be quite nucleophilic as well. The simplest dimerization possibility is a nucleophilic attack by **1** on $\mathbf{2}H_2^{2+}$, as shown in Scheme 10. (It is likely that **1** will be protonated somewhere on the hydrazo group; for simplicity it is shown as being unprotonated in Scheme 10.) Loss of chloride ion from the resulting intermediate is straightforward, and simple loss of two more protons gives the observed dimer product **6**.

Another possibility results from an attack of $\mathbf{2}H^+$ on $\mathbf{2}H_2^{2+}$, as shown in Scheme 11. Essentially, chlorine has to be lost as Cl^+ in this scheme, but this has precedence in reactions of this type; Rhee and Shine have observed a similar Cl^+ loss during the benzidine rearrangement and disproportionation of 4,4′-dichlorohydrazobenzene (43). Whatever the dimerization mechanism may be, presumably dimerization will diminish in importance as the acidity increases, since the probability of

Scheme 11.



Scheme 12.



having an unprotonated pyridine nitrogen present decreases with increasing acidity, and, being bimolecular, the reaction will only occur at all at the high substrate concentrations used for the product analysis.

pK_a relationships

The $pK_{BH_{2^+}}$ values for the various 4-(arylphenylazo)pyridines listed in Table 2 seem reasonable, with compounds having electron-donating OH groups being easier to protonate on the azo group, and those with electron-withdrawing Cl being more difficult. There are insufficient data for a good linear free energy relationship (some of the substituents are *ortho* in any case), but a ρ^+ value of -2.9 ± 0.6 can be estimated. The m^* slopes show considerable variation, averaging 0.86 ± 0.09. The reactions undergone by **2** and **8** are not quite the same, that of **2** being an *ipso* substitution at a carbon already bearing a substituent but, as Fig. 1 shows, the kinetic behaviour is very similar, and reaction of the deactivated chloro compound is slower, by a factor of ~100 in the standard state according to the intercept difference.

The $m^‡$ values for both **2** and **8** are <0.5. At the moment

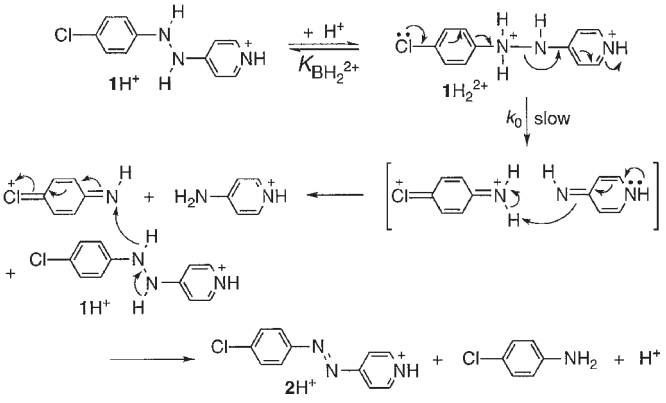
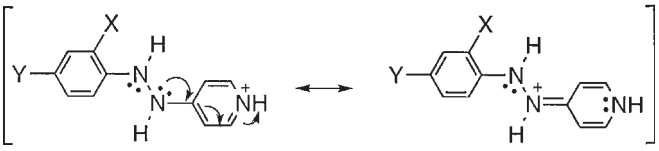
Scheme 13.



there are very few data for comparison, and so it is difficult to predict $m^{\ddagger}$ values for reaction with bisulfate. In the case of protonated benzamide a value of 1.1 was found for nucleophilic attack of bisulfate at the carbonyl group (44) (but this number is subject to revision (26)), and for several substituted alkylnitramines values of $m^{*}m^{\ddagger}$ between 0.9 and 1.2 were found for S_N2 displacement by bisulfate (27), the value of m^{*} unfortunately not being known. Neither case corresponds very well to the situation in the reaction under discussion here, nucleophilic attack on a benzene ring.

Benzidine disproportionation mechanism

Proposed mechanisms for the benzidine disproportionation of **1** (and the other 4-(phenylhydrazo)pyridines involved in this work) have to account for the observed kinetic behaviour, which is that the rate-determining step of these disproportionations is an A1 process involving the diprotonated substrate, as well as the reaction products. The second protonation is written as occurring on the hydrazo nitrogen away from the pyridinium ring. There are two reasons for this: apart from simple electrostatic repulsion of the two positive charges, the lone pair on the other nitrogen is occupied to some extent in resonance interaction with the pyridinium centre, as shown, and so is less available for protonation.

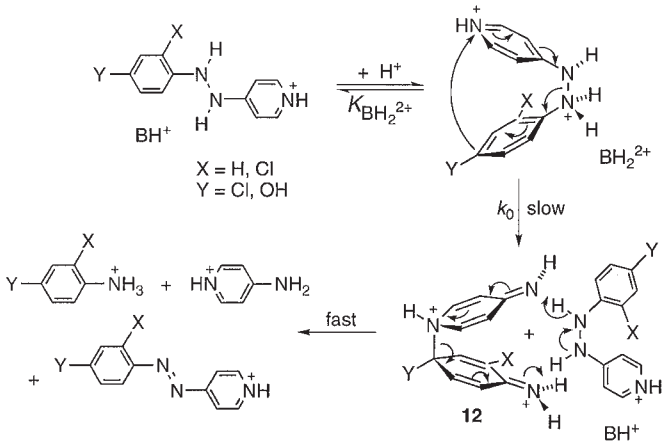


Processes such as the one shown in Scheme 12, although it gives the correct products, can be ruled out as Scheme 12 would result in second-order kinetics, and all of the observed kinetics were accurately first order, for **1** and also for **9** and **10** (24).

Scheme 13, involving rate-determining breakup of diprotonated $\mathbf{1}H_2^{2+}$, is a more plausible mechanism. Deriving an excess acidity rate equation based on Scheme 13 is straightforward (25). On the basis of full substrate diprotonation, the observed rate constants k_{ψ} can be equated with k_0 and the activities of the species present in the activated complex according to eq. [3].

$$[3] \quad k_{\psi}\,(C_{BH^+} + C_{BH_2^{2+}}) = k_0 a_{BH_2^{2+}}/f_{\ddagger}$$

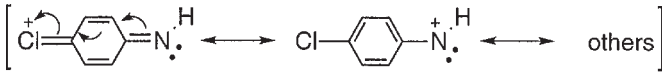
Scheme 14.



$$[4] \quad \log k_{\psi} - \log\,(C_{BH_2^{2+}}/(C_{BH^+} + C_{BH_2^{2+}})) = \log k_0 + (m^{\ddagger} - 1)m^{*}X$$

Upon replacing activity by concentration and activity coefficient, taking logs and rearranging, eq. [3] becomes eq. [4], since the log activity coefficient ratio term here is equal to $(m^{\ddagger} - 1)m^{*}$ (25), where the slope parameters m^{*} (= 1 in this case) and $m^{\ddagger}$ are defined above. This is the rate equation that gives the good straight lines in Fig. 3.

Although Scheme 13 explains the products and the kinetics, there is a problem with it. The proposed chloronium intermediate is actually a nitrenium ion:



and these are highly reactive, with very short lifetimes (45). They have carbene-like properties, and would be expected to react almost instantly with the water present, probably on the aromatic ring (46). So Scheme 13 can be ruled out on the grounds that this nitrenium ion would not exist long enough for the suggested hydride transfer from another $\mathbf{1}H^+$ molecule to be possible.

Thus the most likely mechanism for the reaction of **1**, **9**, and **10**, and the other hydrazo compounds suggested as intermediates in this work, is the benzidine-type disproportionation mechanism shown in Scheme 14 for the general structure BH^+, as proposed previously (24). This would give the same kinetic behaviour as does Scheme 13, i.e., eq. [4] is followed. The rate-determining step is a thermally allowed 10-electron electrocyclic reaction involving the diprotonated substrate BH_2^{2+}, giving rise to intermediate **12**. This is now firmly established as being the key step in the rearrangement mechanism for hydrazobenzene and many other hydrazo aromatics, primarily by the application of heavy-atom isotope effect studies to these processes (21, 23). Also, for hydrazobenzene itself, an intermediate equivalent to **12** has been experimentally observed under stable-ion conditions (47). Regular hydrazo compounds can form benzidines by rearomatization of intermediates like **12**, but this cannot happen here because the pyridine nitrogen would have to acquire a permanent positive charge, and

© 1998 NRC Canada

because of the presence of the substituents. So disproportionation occurs instead, and reaction with another BH^+ molecule is proposed by analogy with a similar proposal made for the disproportionation of 4,4′-diiodohydrazobenzene (21, 41). This is likely to be quite a fast reaction, because (*a*) it is a highly favourable, thermally allowed 14-electron electrocyclic reaction, (*b*) it is energetically downhill because the aromatic protonated products formed are all much more stable than is **12** in the reaction medium, and (*c*) formation of three molecules from two counteracts the entropy factor involved in orienting **12** and BH^+ for reaction.

The benzidine rearrangement of hydrazobenzenes is a fast reaction (1). Our reactions are quite fast, but rate comparisons are difficult because most other kinetic studies have been performed in dilute acid media containing a cosolvent, and the acid used is usually HCl or $HClO_4$ rather than H_2SO_4 (1). The most recent study is that of Bunton and Rubin (48), who studied hydrazobenzene (i.e., 1,2-diphenylhydrazine) and two substituted hydrazobenzenes in pure aqueous HCl and $HClO_4$ to concentrations of about 1 M; their substrates were diprotonated (on both hydrazo nitrogens), and their reaction rates were much faster than ours, in the stopped-flow range.

Depending on the substrate, the hydrazo group may be diprotonated, monoprotonated, or even unprotonated during the rearrangement step, but the process is fastest for diprotonated substrates and slowest for unprotonated ones (1, 21, 48). Our substrates are diprotonated but one of the protons is on the pyridine nitrogen; because of this, protonation on the other hydrazo nitrogen (to give a triprotonated species) is expected to be very difficult, only occurring at acidities much higher than those used here. Diprotonation in hydrazobenzenes is assumed to speed reaction by encouraging N—N bond cleavage and the subsequent charge separation (1). Hydrazo group protonation presumably does that here too, but since the two positive charges are further apart in our case the reaction will not be accelerated nearly so much, which probably accounts for our rates being slower than those of Bunton and Rubin.

Mechanisms are sometimes suggested for the benzidine rearrangement in which the second proton transfer is part of the rate-determining step (A-S_E2 mechanism). For instance, rate-limiting ring carbon protonation followed by fast N—N bond cleavage (47) was a popular mechanism at one time (1), as was rate-determining formation of the $-\overset{+}{N}H_2 - \overset{+}{N}H_2-$ species with its subsequent rearrangement being a fast process (48). More recent heavy-atom isotope effect results (49) have rendered these mechanisms unlikely, however (21). For the disproportionations in this paper we have good evidence that the second protonation is a pre-equilibrium process (A1 mechanism) and not part of the rate-determining step: the excellent linearity of the Fig. 3 plots, and the fact that the $m^‡$ values (Table 5) are all much greater than one (25).

The log k_0 values in Table 5 fall in the expected order, electron-donor OH fastest, then H, with the electron-withdrawing Cl slowest. The observed $pK_{BH_2^{2+}}$ values (Table 5) are indicative of only inductive interaction with the positive charge on the hydrazo group; both OH and Cl are inductively electron withdrawing, and both **1** and **10** are more basic than **9**. Any attempted mesomeric interaction of the lone pairs on oxygen with the positive charge on the hydrazo nitrogen leads to cleavage of the N—N bond as shown at the top of Scheme 13, and this was not observed.

The $m^‡$ values in Table 5 are all quite large, 1.5–1.9, values that are only compatible with an A1 reaction mechanism (25), as discussed. However, they are not all the same; the value for **1**, with a *p*-Cl substituent, is smaller than the others. Variation of $m^‡$ with substituent is not unusual; for instance, a gradual increase with σ^* was observed in *N*-nitro amine decompositions in aqueous H_2SO_4 (27), a slow decrease with σ^+ was seen in some phenylpropiolic acid hydrations in these media (50), and slow increases or decreases with σ or σ^+ were found for some acylal and thioacylal hydrolyses (51), and some thiol- and thion-benzoate ester hydrolyses, in aqueous H_2SO_4 (52). What, if anything, these trends mean is not clear at present, although as data accumulate it may become possible to use them for mechanistic diagnosis. It is interesting that Marziano, Tomasin, and Tortato have commented upon similar trends in m^* value in a variety of aqueous acid systems (53), although it is not certain with the data available at present that the adduced variations are real.

Hydroxylation of the (arylazo)pyridines is an unusual reaction. Normal azobenzenes are stable in strong acid solution, indeed, acidity functions based on their protonation behaviour have been defined (54). Presumably the strongly electron-withdrawing pyridinium substituent in these molecules strongly activates the other ring to nucleophilic attack. The benzidine rearrangement and related processes have always fascinated chemists, and interest in them continues to be high (1, 21–24). For instance, an 18-electron thermally allowed electrocyclic reaction in a benzidine rearrangement has been described very recently (55), which complements the 10- and 14-electron processes discussed in this work. To our knowledge, the work in this paper is the first definitive delineation of the mechanism of the acid-catalyzed benzidine disproportionation reaction as an A1 process.

On the role of copper and iron in DNA cleavage by ochratoxin A. Structure–activity relationships in metal binding and copper-mediated DNA cleavage

Jason A. Ardus, Ivan G. Gillman, and Richard A. Manderville

Abstract: Ochratoxin A (OTA, **1**: X = Cl) is a fungal carcinogen that facilitates single-strand DNA cleavage and DNA adduction when metabolically activated. To determine if redox-active transition metals induce OTA-mediated DNA damage, we have examined the toxin's ability to bind Cu(II) and Fe(III) in aqueous media and facilitate DNA cleavage in their presence using agarose gel electrophoresis and supercoiled plasmid DNA. Using fluorescence spectroscopy, **1** was found to bind Cu(II) readily at physiological pH, while acidic conditions (pH 2.6) were employed to study Fe(III) binding due to the formation of Fe-oxide precipitates at higher pH values. Structure–activity relationships employing synthetic derivatives of **1** implied that **1** binds both Cu(II) and Fe(III) by its phenolic oxygen, while the carboxylic acid of its phenylalanine moiety binds Cu(II), but does not appear to play a role in Fe(III) coordination at pH 2.6. In terms of metal-mediated DNA cleavage, no role for **1** could be detected in Fe-induced DNA strand scission. With Cu(II), DNA cleavage by the 1:1 copper-bound complex of **1** could only be initiated by addition of a suitable reducing agent (sodium ascorbate). However, **1** was found to facilitate DNA cleavage by the Cu(II) complex of 1,10-phenanthroline ($Cu(OP)_2$); a prototypical Cu-mediated nuclease system that cleaves DNA upon activation by an external reducing agent. Structure–activity relationships employing analogs lacking the chlorine atom, ochratoxin B (**2**: X = H), and the lactone (**12**), indicated that the chlorine atom is essential for activity of the OTA in potentiating DNA cleavage by $Cu(OP)_2$. The implications of our findings to the genotoxic properties of **1** are discussed.

Key words: ochratoxin, DNA cleavage, copper, iron, 1,10-phenanthroline.

Résumé : L'ochratoxine A (OTA, **1**; X = Cl) est un cancérigène de champignon qui, lorsqu'il est métaboliquement activé, facilite le clivage de l'ADN monobrin et l'adduction de l'ADN. Dans le but de déterminer si les métaux de transition actifs en oxydoréduction induisent des dommages à l'ADN sous l'influence de l'OTA, on a utilisé l'électrophorèse sur gel d'agarose et un plasmide d'ADN surtorsadé pour examiner l'habilité de la toxine à se lier au Cu(II) et au Fe(III) en milieu aqueux et à faciliter le clivage de l'ADN en leur présence. En utilisant la spectroscopie de fluorescence, on a trouvé que **1** se lie facilement au Cu(II) à pH physiologique alors que, à cause de la formation de précipités d'oxyde de Fe à des valeurs de pH plus élevées, des conditions acides sont nécessaires pour étudier la liaison avec le Fe(III). Des relations structure–activité développées à l'aide de dérivés synthétiques de **1** impliquent que **1** se lie au Cu(II) ainsi qu'au Fe(III) par son oxygène phénolique; par ailleurs, l'acide carboxylique de sa partie phénylalanine se lie au Cu(II), mais ne semble pas jouer de rôle dans la coordination du Fe(III) à un pH de 2,6. En termes de clivage de l'ADN sous l'influence des métaux, on n'a détecté aucun rôle pour **1** dans la scission de l'ADN catalysé par le Fe(III). Avec le Cu(II), le clivage de l'ADN par le complexe 1:1 de cuivre lié à **1** ne peut être initié que par l'addition d'un agent réducteur approprié (ascorbate de sodium). Toutefois, on a trouvé que **1** facilite le clivage de l'ADN par le complexe du Cu(II) avec la 1,10-phénanthroline, ($Cu(OP)_2$), un prototype de système de nucléase catalysée par le Cu qui clive l'ADN lors d'une activation par un agent réducteur externe. Les relations structure–activité utilisant des analogues ne comportant pas d'atome de chlore, ochratoxine B (**2**, X = H) et la lactone (**12**), indiquent que l'atome de chlore est essentiel pour l'activité de l'OTA pour potentialiser le clivage de l'ADN par le $Cu(OP)_2$. On discute des implications de nos observations en relation avec les propriétés génotoxiques de **1**.

Mots clés : ochratoxine, clivage d'ADN, cuivre, fer, 1,10-phénanthroline.

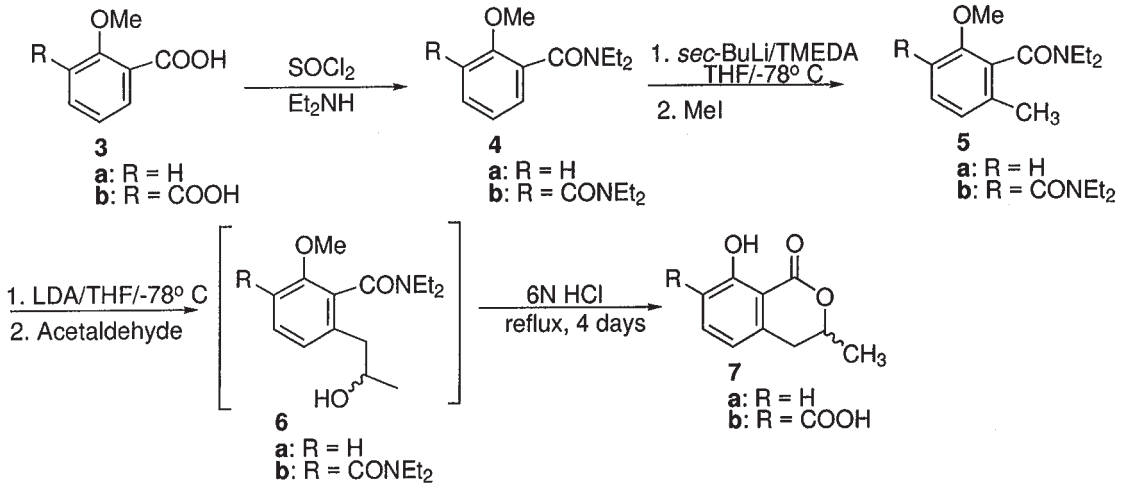
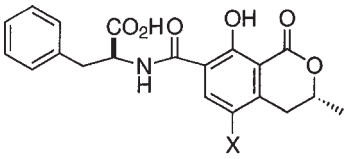
Scheme 1. Synthetic route used for the preparation of the dihydroisocoumarine.



Ochratoxin A (OTA, **1**: X = Cl) is a fungal carcinogen produced by species of *Aspergillus* and *Penicillium* (1). Its occurrence in feed is widespread (2) and ingestion has been linked to the disease Balkan endemic nephropathy in which patients suffer from urinary tract tumors (3). The toxin consists of a phenolic dihydroisocoumarin, amide linked to L-phenylalanine, and has been shown to promote DNA adduction (4) and single-strand DNA cleavage (5); properties that establish a basis for its genotoxic action.



OTA, **1**: X = Cl
OTB, **2**: X = H

Although the mechanisms underlying the genotoxicity of OTA are uncertain, in vivo studies have established that the chlorine atom (6) and lactone (7) are essential and that activation may be mediated by cytochrome P-450 (8) with subsequent formation of activated oxygen species, such as superoxide (9) and (or) hydroxyl radicals (10, 11). The ability of **1** to bind Fe(III) has also been implicated as a possible source of reactive oxygen species that promote lipid peroxidation (12), and may facilitate DNA cleavage (10). Reports by Hecht et al. (13) and Li and Trush (14) that certain phenols and hydroquinones damage DNA by a copper-redox mechanism implies that Cu(II) ions may also play a role in OTA carcinogenicity.

Since OTA activation appears to be oxidative (3–11) and may involve participation of redox-active transition metals (9–14), we examined the toxin's ability to bind Cu(II) and Fe(III) in aqueous solutions and facilitate DNA cleavage in their presence using supercoiled plasmid DNA and agarose gel electrophoresis.

In the present article, we report that, although no role for **1** in Fe-mediated DNA cleavage could be detected, the toxin was found to bind Cu(II) to form a stable 1:1 complex that initiates DNA strand scission upon activation by a suitable reducing agent (sodium ascorbate). However, more importantly to the possible mechanism of OTA genotoxicity, the toxin was found to facilitate DNA cleavage by the Cu(II) complex of 1,10-phenanthroline ($Cu(OP)_2$), a well-known footprinting reagent (15) that requires an external reducing agent to convert Cu(II) → Cu(I). Structure–activity relationships employing synthetic derivatives of **1** that lack the chlorine atom, OTB (**2**, X = H), and the lactone functionality indicated that these components (especially the chlorine atom) facilitate the ability of **1** to potentiate DNA cleavage by $Cu(OP)_2$. This contrasting behavior for **1** in Cu-mediated DNA cleavage is discussed through consideration of the toxin's chelating versus redox properties.

Results

Synthesis of structural analogs

To derive structure–activity relationships for metal binding and DNA cleavage by ochratoxin A (OTA, **1**: X = Cl), we prepared analogs that lack the following: the chlorine atom, OTB, **2**: X = H; the dihydroisocoumarine (lactone), (**12**); and the phenylalanine moiety, (±)-mellein (**7a**) (16). Derivatives of **2** containing an altered phenylalanine side-chain, i.e., the methyl ester (**9a**) and the amide (**9b**), were also prepared.

Compounds containing the lactone ring system of **1** were synthesized according to methods outlined in Scheme 1. Using procedures described by Snieckus and co-workers (17), *o*-anisic acid (2-methoxybenzoic acid, **3a**) was converted into (±)-mellein (**7a**) (16), while 2-methoxyisophthalic acid (**3b**) yielded the carboxylic acid derivative **7b** (17).

To attach the L-β-phenylalanine side-chain moiety, the phenolic groups were initially protected as the acetate and then reacted with the requisite phenylalanine using a dicyclohexylcarbodiimide (DCC)/1-hydroxybenzotriazole (HOBT) peptide coupling procedure (18), as outlined in Scheme 2. The coupled products, **9a**, **9b**, and **11**, were isolated as the free phenols as the acetate protecting groups were lost in the work-up. Hydrolysis of the methyl ester derivatives (**9a** and **11**) into the corresponding free acids (**2** and **12**) was carried out under basic conditions. These strategies provided mixtures of stereoisomers for **2**, **9a**, and **9b** that were not separated.

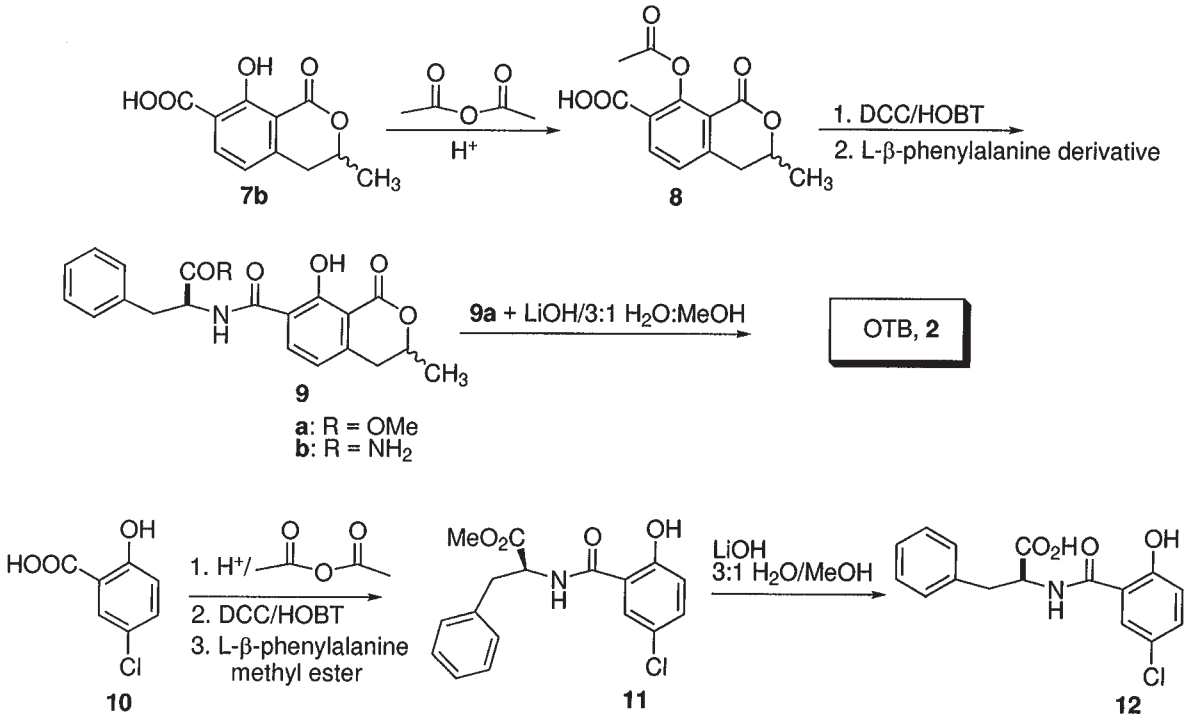

Fig. 1. The UV–absorption spectrum of **1** in ethanol (0.175 mM) in the absence (bold trace) and presence of 1 equiv. of $Cu(OAc)_2$. Inset: spectrum of Cu(II)·OTA complex at 1.75 mM highlighting the absorbance at 608 nm.

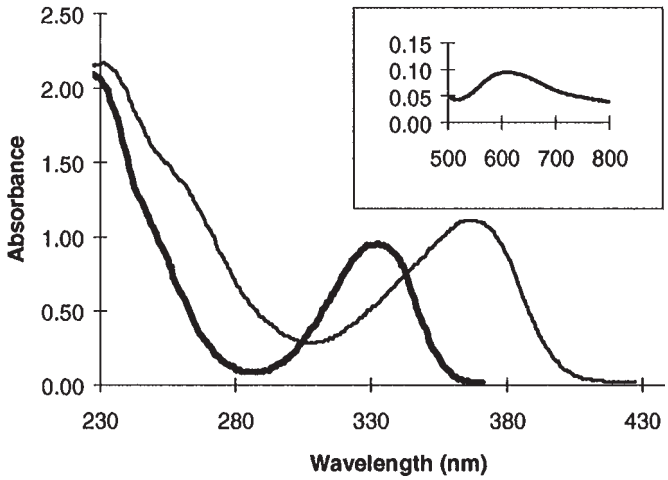

Copper and iron binding affinity

In ethanol, **1** exhibits an absorption spectrum with λ_{max} at 215 (ε = 28 000 M^{-1} cm^{-1}) and 333 nm (ε = 5500 M^{-1} cm^{-1}) (19). Addition of 1 equiv. of $Cu(OAc)_2$ yielded a pale green solution with λ_{max} at 222 (ε = 20 911 M^{-1} cm^{-1}), 258 (sh), 367 (ε = 6420), and 608 nm (ε = 55) (Fig. 1). Figure 2 shows the electrospray mass spectrum of the 1:1 mixture (in methanol) using negative ionization (ES^-). The copper complex was found to have $[M - H]^-$ = 463, which corresponds to a complex with molecular formula $CuC_{20}H_{16}NO_6Cl$ and suggests that complexation between **1** (*m*/*z* 403) and Cu(II) (*m*/*z* 63) leads to the loss of two protons. This observation strongly implies that the ligands bearing the two acidic groups of **1** (COOH and phenolic oxygen) participate in copper coordination. The OTA also forms a 1:1 complex with $FeCl_3$ that is pink in alcoholic solution (10). Generation of the complex in methanol followed by analysis by ES^- showed the presence of a single iron complex with $[M - H]^-$ = 563. This mass corresponds to a complex with molecular formula $FeC_{20}H_{18}NO_6Cl_4$ and indicates that $FeCl_3$ (*m*/*z* = 161) binding in methanol does not lead to deprotonation of **1**. Table 1 contains UV–absorption data in ethanol for the protonated and deprotonated forms of **1**, **2**, and **12**, along with their corresponding 1:1 Cu(II) and Fe(III) complexes.

The ability of **1** to bind Cu(II) and Fe(III) was determined in aqueous buffer at 25°C using fluorescence spectroscopy. Addition of Cu(II) and Fe(III) quenched the fluorescence of the toxin (10), which permitted determination of apparent equilibrium binding constants (log *K**). That the observed fluorescence quenching was due to metal binding was confirmed by performing the metal titration in the presence of excess EDTA. This metal chelator inhibited the fluorescence quenching if added prior to addition of the metal, and restored the fluorescence of OTA if added after the titration.

Figure 3*a* shows fluorescence quenching of the emission spectrum (λ_{em} = 441 nm) of **1** by $Cu(OAc)_2$ in 4-morpholineethanesulfonic acid (MES) buffer (pH 6.0), while the accompanying Scatchard analysis (20) is shown in Fig. 3*b*. From the negative slope in Fig. 3*b*, an apparent equilibrium binding constant of log *K** = 5.35 M^{-1} for formation of the 1:1 Cu(II)·OTA complex was determined. For Fe(III) binding by **1** (log *K** = 3.34 M^{-1}), aqueous HCl·KCl buffer (pH 2.6) was utilized due to the formation of Fe-oxide precipitates at higher pH values.

Apparent equilibrium binding constants (log K^*) for formation of 1:1 Cu(II) and Fe(III) complexes of **1** and our synthesized derivatives are listed in Table 2. Values in parentheses for Cu(II) binding represent the copper binding affinity of the anionic forms of the various derivatives (log $K_{1:1}$). For comparison to our synthesized sample of **2**, metal binding by the natural stereoisomer of **2** (purchased from Sigma) was determined, and as anticipated, the binding constants of the purchased **2** and our synthesized sample were nearly identical. The binding affinity of **1** for Zn(II) in 4-morpholinepropanesulfonic acid (MOPS) buffer (pH 7.4) was also measured to provide insight into Cu(I) binding, as both Zn(II) and Cu(I) are diamagnetic d^{10}-electron metals that favor a tetrahedral binding arrangement (21). Also presented are pK_a values for **1**, **2**, **7a**, and **12**. Values for **1** (7, 22) and **2** (7, 23) are from the literature, while pK_as for **7a** and **12** were measured at 25°C in 0.1 M aqueous buffer solutions using the recommended spectrophotometric procedure (24).

DNA cleavage

The ability of **1** to effect DNA cleavage in the presence of Fe and Cu was determined using supercoiled plasmid DNA and agarose gel electrophoresis. In our initial experiments, attempts were made to establish the toxin's ability to facilitate DNA cleavage in the presence of Fe. However, utilizing both Fe(III) and Fe(II) in the presence of excess **1** under various conditions (sodium ascorbate and HOOH as additives), no definitive role for **1** was determined, as control lanes in the gels for free Fe were equally efficient in promoting single-strand DNA cleavage (data not shown).

For DNA cleavage by Cu(II) ($Cu(OAc)_2$, 20 μM) admixture of **1** had very little effect on the extent of single-strand DNA cleavage (over a 15 h incubation period at 37°C in MOPS buffer, pH 7.4). Thus, the ability of the Cu(II)·OTA complex to facilitate DNA cleavage in the presence of sodium ascorbate was examined. For these experiments, 20 μM Cu(II) was premixed with 60 μM **1** prior to addition of plasmid DNA

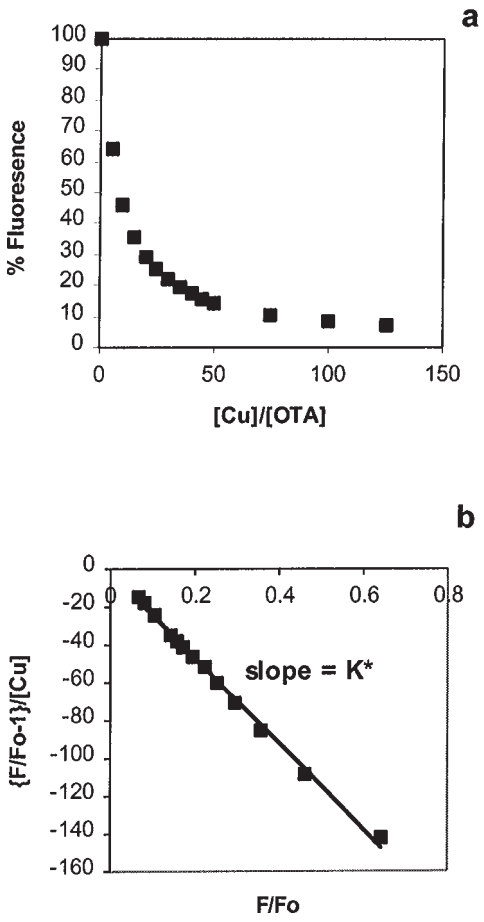
Fig. 3. (*a*) Emission spectrum (λ_{ex} = 380 nm, λ_{em} = 440 nm) of fluorescence quenching of **1** (10 μM) at increasing $Cu(II)(OAc)_2$ concentrations in 10 mM MES (pH 6.0) and 100 mM $NaClO_4$ buffer solution at 25°C, and (*b*) Scatchard plot of the fluorescence quenching of part *a*.



and sodium ascorbate. Under these conditions, approximately 99% of Cu(II) is bound by the toxin, determined from log *K** = 6.26 M^{-1} for formation of the 1:1 Cu(II)·OTA complex at pH 7.4. Figure 4 shows a representative gel highlighting that the Cu(II)·OTA complex is capable of redox cycling and thus inducing DNA cleavage in the presence of sodium ascorbate. Additional experiments showed the cleavage to be completely inhibited by the enzyme catalase (1000 units/mL) and sodium azide (100 mM), while the hydroxyl radical scavengers, dimethyl sulfoxide (1 M) and *tert*-butanol (1 M), provided only partial protection (data not shown). These results indicate a requirement for HOOH and favor the involvement of a copper-oxo species over a freely diffusible hydroxyl radical (15).

To further explore Cu-mediated DNA cleavage by **1**, its ability to induce DNA cleavage by Cu(II) prebound to 2 equiv. of 1,10-phenanthroline (OP) was examined. The OP ligand binds Cu(II) to form a $Cu(OP)_2$ complex that is a prototypical copper nuclease system and facilitates DNA cleavage in the presence of an external reducing agent (15). As reported by Sigman (15), reduction of $Cu(II)(OP)_2$ to $Cu(I)(OP)_2$ followed by HOOH oxidation produces a copper-oxo species that cleaves DNA through H1′-atom abstraction of the deoxyribose sugar. The utility of $Cu(OP)_2$ here was to test if **1** could facilitate the production of $Cu(I)(OP)_2$, the species necessary for DNA cleavage (15). Figure 5 shows that DNA cleavage by $Cu(OP)_2$ was potentiated by OTA in a concentration dependent fashion. Additional experiments showed that the reaction was completely inhibited by the enzyme catalase, which mimicked the findings observed by Sigman and co-workers (15) for $Cu(OP)_2$ cleavage in the presence of thiol. However, unlike thiol-potentiation, the cleavage reaction was also partially inhibited by superoxide dismutase (SOD) (ca. 70%, data not shown), which suggests that the reduction of $Cu(II)(OP)_2$ is also mediated by O_2^- (15).

Since in vivo studies on OTA genotoxicity suggest a role for the chlorine atom and lactone (6, 7, 11), we also examined $Cu(OP)_2$-mediated DNA cleavage in the presence of **2** and **12** (Scheme 2). Figure 6 shows that under conditions where **1** effectively potentiates DNA cleavage by $Cu(OP)_2$ (lane 4), the derivative **12** (lane 5) was only slightly less efficient, while **2** (lane 6) failed to induce DNA cleavage above background (lane 2). To test if differences in the phenolic pK_as for these species (Table 2) could account for these results, the experiment was repeated in 2-(cyclohexylamino)-ethanesulfonic acid (CHES) buffer at pH 8.6. Interestingly, no change in the extent of cleavage was detected for all species (data not shown), indicating that the presence of the phenoxy anion does not explain the differences noted in the gel.

The ability of **1** to induce DNA cleavage in the presence of Fe(III) prebound to the metal chelator EDTA (25) was also examined. At 20 μM Fe(III)·EDTA, additions of **1** up to 250 μM, followed by 30 min incubation time at 37°C, failed to induce DNA cleavage (data not shown). This result was contrasted by our findings with $Cu(OP)_2$ and by the reaction of Fe(III)·EDTA (20 μM) with sodium ascorbate (50 μM), which almost facilitated the complete conversion of Form I into Form II DNA after the 30 min incubation time.

Discussion

One of the major goals in the field of toxicology is to elucidate the mechanisms by which xenobiotics produce detrimental biological responses in an organism (26). This knowledge can be used to identify chemical structures that predispose a molecule to a sequence of events that leads to toxicity. In the present study, we have evaluated the role played by Fe(III) and Cu(II) ions in DNA cleavage by the fungal carcinogen ochratoxin A (OTA, **1**). Since it had been shown that an Fe(III) complex of **1** produces hydroxyl radicals to an extent greater than free iron (10), it was anticipated that **1** would facilitate Fe-mediated DNA cleavage. That **1** possesses a *para*-chlorophenolic group also suggested that copper ions may promote OTA-induced DNA damage, based on analogy to Cu-mediated DNA cleavage by hydroquinones (13, 14).

Initial studies focused on the ability of the toxin and several structural analogs (Schemes 1 and 2) to bind Fe(III) and Cu(II) using fluorescence spectroscopy (Table 2). Both metals were found to quench the fluorescence of the toxin, which permitted determination of apparent equilibrium binding constants (log *K**) for formation of the 1:1 complexes. Of particular relevance to the biological properties of these compounds was the ability to monitor Cu(II) binding at physiological pH, while acidic conditions (pH 2.6) were employed for Fe(III) binding due to the formation of Fe-oxide precipitates at higher

pH values. This finding indicates that **1** would be more efficient at binding Cu(II) than Fe(III) ions in biological systems.

Although we have not unequivocally determined the exact Cu(II) binding mode for **1**, that formation of the Cu(II)·OTA complex in methanol (Fig. 2) was accompanied by the loss of two protons suggests strongly that the two acidic groups of **1** (COOH and phenol) participate in Cu(II) coordination. Support for participation of the phenolic group stems from the fact that at pH 6, log $K^* = 5.35$ M^{-1} for **1**, while for **2** log $K^* = 4.42$ M^{-1} (Table 2). Clearly the binding affinity is sensitive to ionization of the phenolic group. Participation of the COOH group was supported by the finding that the OTB derivatives **9a** and **9b** (Scheme 2), which possess the methyl ester and amide

As demonstrated by Bredenkamp et al. (27), **1** adopts a β phenylalanine group respectively, showed diminished Cu(II) binding affinity when compared to the free acid **2**. The results presented in Table 2 also indicate that the dihydroisocoumarin moiety (lactone) of **1** is not important for formation of the 1:1 Cu·OTA complex. This hypothesis stems for the fact that the derivative **12**, which lacks the lactone moiety, has a greater affinity for Cu(II) than **1** (compare log $K_{1:1}$ values in Table 2).

For both the phenolic oxygen and the carboxylic acid of the phenylalanine moiety of **1** to participate in Cu(II) binding, it also appears that the amide nitrogen coordinates Cu(II). This hypothesis was derived from inspection of molecular models and from consideration of the conformation of the free toxin derived from single-crystal X-ray structural studies (27).

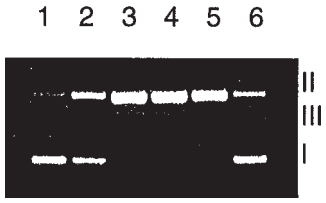
Fig. 6. Structure–activity relationships in OTA–potentiation of Form I DNA cleavage by $Cu(II)(OP)_2$. Cleavage was carried out at 37°C for 30 min in 10 mM MOPS (pH 7.4), 50 mM NaCl buffer solution. Lane 1: DNA alone; lane 2: 20 μM $Cu(II)(OP)_2$; lane 3: 20 μM $Cu(II)(OP)_2$ + 10 μM sodium ascorbate; lane 4: 20 μM $Cu(II)(OP)_2$ + 50 μM OTA; lane 5: 20 μM $Cu(II)(OP)_2$ + 50 μM **12**; lane 6: 20 μM $Cu(II)(OP)_2$ + 50 μM **2**.



maximizes hydrogen bonding interactions between the amide, phenolic group, and lactone carbonyl. The alternative α form was not detected. Although the fully protonated form of **1** is not important for Cu(II) coordination, the orientation of the phenylalanine moiety in the β form appears to facilitate coordination to Cu(II) by the phenolic oxygen and carboxylic acid of the phenylalanine. This conformation also predicts that the amide nitrogen participates in Cu(II) binding, which is consistent with previous studies on Cu(II) binding by the amide group of peptides (28), and Cu(II)·phenylalanine complexes (29).

For Fe(III) binding the data in Table 2 indicates that all derivatives possess similar binding affinity at pH 2.6. These results are consistent with the mass spectral data obtained in methanol, which indicated that $FeCl_3$ binding by **1** is not accompanied by proton removal from the toxin. This suggests that $FeCl_3$ forms a coordinate bond with the phenolic oxygen. Consistent with this hypothesis, **7a**, which lacks both the electron-withdrawing chlorine atom and amide group ($pK_a = 10.4$), possesses the greatest affinity for $FeCl_3$ at pH 2.6 (Table 2). In contrast to Cu(II) binding, the derivatives **9a** and **9b** do not show significant differences in binding from **2**. This result appears to indicate that the carboxylic acid does not participate in Fe(III) binding at pH 2.6 and may suggest that these compounds bind Fe(III) by the phenolic oxygen (7, 10) and an *ortho*-carbonyl, either from the lactone (10) or the amide group (7, 30).

To define the role played by Fe(III) and Cu(II) in OTA-induced DNA cleavage, we examined the ability of **1** to facilitate DNA strand-scission in the presence of free iron and copper ions. Utilizing both Fe(III) and Fe(II) ions, no definitive role for the toxin could be identified. This result was surprising, given reports that **1** coordinates Fe(III), facilitates lipid peroxidation (12), and produces the hydroxyl radical via the Fenton reaction (10). However, results by Marquardt and co-workers (11*b*) on production of the hydroxyl radical in a microsomal-NADPH preparation, showed conclusively that addition of **1** and Fe(III) produces the hydroxyl radical in a lower yield than NADPH and Fe(III) alone. Our in vitro results are in accord with this finding and reaffirm that coordination of **1** to Fe(III) is not responsible for OTA genotoxicity.

For Cu-mediated DNA cleavage, **1** was found to form a 1:1 Cu(II)·OTA complex that induced DNA strand-scission only upon activation by a suitable reducing agent (Fig. 4). This result is in sharp contrast to the reports by Hecht and co-workers (13) and Li and Trush (14) on the ability of hydroquinones to induce copper-mediated DNA cleavage. They found that 30 min incubation time at 37°C was more than sufficient to cleave the DNA through reduction of Cu(II) to Cu(I) with concomitant oxidation of the hydroquinone to the respective benzoquinone (13, 14). The inability of **1** to induce Cu-mediated DNA cleavage in the absence of a reducing agent, however, can be rationalized by consideration of the toxin's chelating properties. Unlike *ortho*- or *para*-hydroquinone, which are not expected to coordinate Cu(II) with high binding affinity, **1** binds Cu(II) very efficiently (Table 2). If binding affinity of the OTA for Zn(II) ($\log K = 3.92\ M^{-1}$ at pH 7.4) is representative of the toxin's affinity for Cu(I) (both are d^{10}-electron metals that favor a tetrahedral binding arrangement (21)) then the Cu(II) complex is significantly more stable than the putative Cu(I) complex ($\log (K_{Cu}/K_{Zn})$ at pH 7.4 = 6.26/3.92 = 1.6). This finding would explain the inability of **1** to facilitate Cu-mediated DNA damage in the absence of a reducing agent, and is consistent with the fact that Cu(II) is much less efficient in reduction when it is bound to protein ligands than when it is free in solution (31). Studies by Marquardt and co-workers (11*a*) on hydroxyl radical production by **1** in bacteria also show that additions of divalent cations such as Fe(II) and Cu(II) ions fail to enhance hydroxyl radical production, which appears consistent with the findings presented here on the inability of **1** to cleave DNA in the presence of these metal ions free in solution. Furthermore, Cu(II)·OTA mediated DNA cleavage in the presence of sodium ascorbate is probably irrelevant to OTA genotoxicity, since antioxidants inhibit the toxicity of **1** (9).

To explore the role played by Cu(II) ions in OTA-induced DNA cleavage in more detail, we also examined the ability of **1** to potentiate DNA cleavage by the Cu(II) complex of 1,10-phenanthroline ($Cu(OP)_2$). As described by Sigman (15), the nuclease activity of $Cu(OP)_2$ proceeds by an obligatory, ordered mechanism, whereby the cupric complex $Cu(II)(OP)_2$ is reduced to the cuprous complex, $Cu(I)(OP)_2$, which is then oxidized by HOOH to generate the copper-oxo species directly responsible for strand-scission. Since the reaction is independent of the reductant used to potentiate it (15), we used the $Cu(OP)_2$ nuclease system to gain insight into redox properties of the OTA in DNA cleavage. Interestingly, **1** was found to potentiate DNA cleavage by $Cu(OP)_2$ (Fig. 5), presumably by reducing $Cu(II)(OP)_2 \rightarrow Cu(I)(OP)_2$ with the concomitant oxidation of **1**. Although the exact nature of OTA oxidation is uncertain, it is informative that the nonchlorinated derivative **2** failed to induce DNA cleavage by $Cu(OP)_2$. The derivative **12**, which lacks the lactone of **1**, showed only slightly diminished activity (Fig. 6), which indicates that the chlorine atom is more important than the lactone for OTA potentiation of $Cu(OP)_2$-mediated DNA cleavage.

To provide a rationale for the ability of **1** to induce DNA cleavage by $Cu(OP)_2$, it is informative to consider oxidation of phenols, where the oxidation takes place according to the routes presented in Scheme 3 (32). Under aprotic conditions, oxidation of phenol (**I**) produces the cation radical (**II**), which deprotonates to the neutral radical (**III**). For solutions containing the phenolate ion (**V**), oxidation to the phenoxyl radical (**III**) proceeds readily and the resulting phenoxyl radical (**III**) may be further oxidized to the phenoxonium ion (**IV**), or couple to yield a variety of products (32).

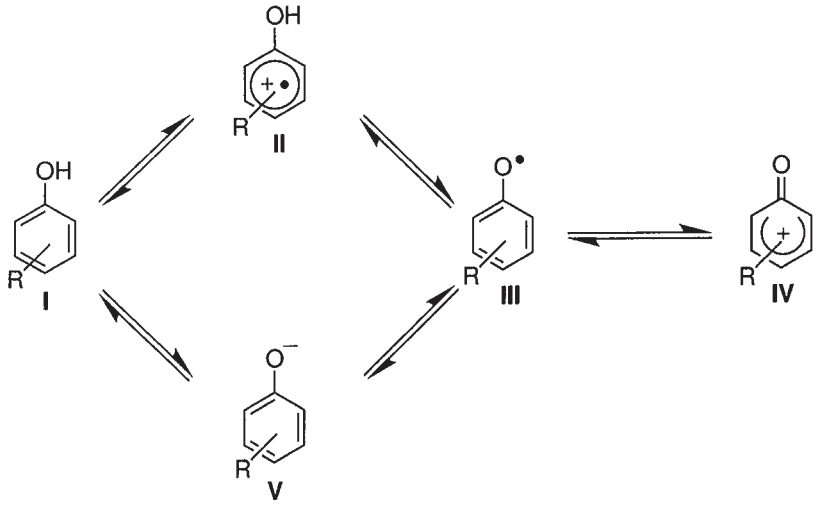
Scheme 3. Oxidation pathway for common phenols.



Insight from Scheme 3 suggests that single electron transfer from **1** to $Cu(II)(OP)_2$ would yield the OTA phenoxyl radical ($OTA^{\cdot}$) and $Cu(I)(OP)_2$ (eq. [1*a*]). For $Cu(I)(OP)_2$ to initiate DNA strand-scission, it must combine with hydrogen peroxide (HOOH) to generate a copper-oxo species (15). The finding that SOD inhibits the reaction (70%) suggests that the reduction of $Cu(II)(OP)_2$ is also mediated by $O_2^{\cdot-}$. Although oxidation of $Cu(I)(OP)_2$ by O_2 can yield $O_2^{\cdot-}$ (15), another possible source of superoxide is the oxidation of $OTA^{\cdot}$ by O_2 to yield the phenoxonium ion of OTA (OTA^+), eq. [1*b*]. The liberated $O_2^{\cdot-}$ could assist OTA in the reduction of $Cu(II)(OP)_2$ (eq. [1*c*]) and yield HOOH after disproportionation (eq. [1*d*]). Oxidation of $Cu(I)(OP)_2$ by HOOH would yield a copper-oxo species (eq. [1*e*]), that initiates DNA cleavage (eq. [1*f*]).

[1*a*] $OTA + Cu(II)(OP)_2 \rightarrow OTA^{\cdot} + Cu(I)(OP)_2$

[1*b*] $OTA^{\cdot} + O_2 \rightarrow OTA^+ + O_2^{\cdot-}$

[1*c*] $Cu(II)(OP)_2 + O_2^{\cdot-} \rightarrow Cu(I)(OP)_2 + O_2$

[1*d*] $2O_2^{\cdot-} + 2H^+ \rightarrow HOOH + O_2$

[1*e*] $Cu(I)(OP)_2 + HOOH \rightarrow$ copper-oxo species

[1*f*] Copper-oxo species + DNA $\rightarrow$ DNA cleavage

While we have yet to identify the products resulting from OTA oxidation, it is informative that the intermediacy of the OTA phenoxyl radical in the in vivo genotoxicity of **1** has been proposed by Malaveille et al. (6). Oxidation to the putative phenoxonium ion (OTA^+) may also provide a rationale for the toxin's ability to facilitate DNA adduction (4). A DNA-derived nucleophile could react directly with OTA^+, or reaction of OTA^+ with H_2O to furnish a quinone intermediate after loss of HCl could precede DNA adduction. In this regard, chlorinated phenols have been converted to the respective *para*-quinones with $CuCl_2$ and O_2 (33) and by enzymatic oxidative pathways (34), and quinones are Michael acceptors that have been implicated in DNA adduct formation (35).

Conclusions

The present study implies that the genotoxic properties of **1** may be attributable to the toxin's redox properties, instead of its ability to bind redox-active transition metals. The toxin does not facilitate DNA cleavage in the presence of free Fe, or Fe(III) bound to EDTA. With Cu(II), **1** forms a stable 1:1 Cu(II)·OTA complex that facilitates DNA cleavage upon activation by sodium ascorbate. However, since OTA toxicity is inhibited by antioxidants, this pathway is unlikely to play a role in the mechanism(s) of OTA genotoxicity. A more significant finding was the demonstrated ability of **1** to initiate DNA cleavage by $Cu(II)(OP)_2$. Here, **1** provides the reducing equivalents to convert $Cu(II)(OP)_2 \rightarrow Cu(I)(OP)_2$. The chlorine atom was found to be critical for this activity, which is consistent with in vivo studies on OTA genotoxicity (6). Currently, we are studying oxidation of **1** by electrochemical and chemical means in an effort to determine the nature of the oxidized OTA species and the potential of such a species to induce DNA adduction.

Experimental section

Materials

Ochratoxin A (OTA, **1**: X = Cl) was purchased from Dr. Ronald Marquardt, Department of Animal Sciences, University of Manitoba, and was used without further purification. Supercoiled plasmid (Form I) DNA was a gift from Dr. Fred W. Perrino, Department of Biochemistry, Bowman Gray School of Medicine, Wake Forest University. The plasmid was a derivative of pOXO4 (36) containing the dnaQ gene. The following enzymes and reagents were obtained commercially and used without further purification: 1,10-phenanthroline (OP), copper acetate ($Cu(OAc)_2$), ferric chloride ($FeCl_3$), sodium perchlorate ($NaClO_4$), 4-morpholinepropanesulfonic acid (MOPS), 4-morpholineethanesulfonic acid (MES), 2-(cyclohexylamino)ethanesulfonic acid (CHES), ethylenediaminetetraacetic acid (EDTA), 1,3-dicyclohexylcarbo-diimide (DCC), 1-hydroxybenzotriazole hydrate (HOBT), L-phenylalanine methyl ester hydrochloride, 5-chlorosalicylic acid, *sec*-butyllithium (*sec*-BuLi), *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA), methyl iodide (MeI), lithium diisopropyamide (LDA), acetaldehyde, and acetic anhydride

(Aldrich); ochratoxin B (**2**: X = H), catalase, superoxide dismutase (SOD), and L-β-phenylalanine amide (Sigma).

Methods

Elemental analyses were carried out by Atlantic Microlab, Inc. High-resolution mass spectral analyses were carried out by the Nebraska Center for Mass Spectrometry. Melting points were taken on a Mel-Temp apparatus and are not corrected. NMR spectra were recorded on a Varian VXR-200 spectrometer (^{1}H, 200 MHz; ^{13}C, 50 MHz). Chemical shifts are given in parts per million (ppm) relative to tetramethylsilane (TMS), and coupling constants (*J*) are reported in hertz (Hz). The following abbreviations are used: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad. Absorption measurements were made on a Hitachi U-2001 UV-vis spectrophotometer, and fluorescence spectra were acquired with a Hitachi F-2000; both instruments were equipped with a thermostated cell compartment. Distilled, deionized water from a Milli-Q system was used for all aqueous solutions and manipulations. Other solvents were purified and dried according to standard procedures. Agarose gel electrophoresis was carried out in 40 mM Tris-acetate buffer (pH 8.0), containing 5 mM EDTA. Agarose gel loading buffer: 40 mM Tris-OAc (pH 8.0), 5 mM EDTA, 40% glycerol, 0.3% bromophenol blue.

Mass spectra were acquired using a Micromass Quattro II operating in the negative ion spray mode (ES^-). The system acquired signal over a *m*/*z* range of 200–1000 at 8 s/scan with a 0.06 step. Samples of **1** and Cu(II)·OTA (0.1mg/mL) were prepared in methanol and injected via syringe into a fixed loop injector port (100 μL volume) interfaced to the ion spray source. The Cu(II)·OTA sample was also prepared in 10 mM NH_4OAc (pH 7.0) buffer and subjected to reverse-phase high-pressure liquid chromatography (HPLC, Hewlett Packard (HP) 1100 series with photodiode array detection, 190–600 nm, using a gradient of MeOH in 2 mM ammonium acetate, pH 7.0), prior to analysis by ESI/MS. The sample of Fe(III)·OTA (0.1mg/mL) was prepared in methanol and was analyzed by ESI/MS without prior separation by HPLC.

N,N-Diethyl-2-methoxybenzamide (4a)

To prepare **4a** (37), 2-methoxybenzoic acid (1.00 g, 6.57 mmol) was reacted with excess thionyl chloride ($SOCl_2$) and diethylamine using standard conditions. After purification by silica-gel chromatography (1:1 EtOAc–hexane), **4a** was obtained as a colorless oil: yield 1.21 g (89%); ^{1}H NMR ($CDCl_3$), δ: 7.29 (m, 1H), 7.18 (m, 1H), 6.93 (m, 1H), 3.79 (s, 3H), 3.59–3.54 (m, 2H), 3.14 (q, 2H, *J* = 7.02), 1.24 (t, 3H, *J* = 7.02), 1.02 (t, 3H, *J* = 7.02); ^{13}C NMR ($CDCl_3$), δ: 168.3, 154.7, 129.5, 126.9, 126.5, 120.3, 110.5, 55.0, 42.4, 38.4, 13.6, 12.5.

N,N-Diethyl-2-methoxy-6-methylbenzamide (5a)

Using the procedure described by Snieckus and co-workers (17*a*), **5a** was obtained as a colorless oil: yield 0.191 g (80%); ^{1}H NMR ($CDCl_3$), δ: 7.13–6.66 (m, 3H), 3.78–3.68 (m, 1H), 3.72 (s, 3H), 3.39–3.29 (m, 1H), 3.05 (q, 2H, *J* = 7.19), 2.17 (s, 3H), 1.18 (t, 3H, *J* = 7.33), 0.95 (t, 3H, *J* = 7.19); ^{13}C NMR ($CDCl_3$), δ: 168.2, 155.1, 135.4, 128.9, 126.2, 122.3, 107.9, 55.3, 42.2, 38.3, 18.5, 13.6, 12.6.

8-Hydroxy-3-methyl-3,4-dihydroisocoumarin (Mellein) (7a)

To a stirred solution of **5a** (0.193 g, 0.873 mmol) in dry THF (75 mL) at –78°C under argon was added lithium diisopropylamide (LDA, 0.655 mL, 1.31 mmol, from 2.0 M solution in heptane–THF–ethylbenzene). After stirring for 1 h at –78°C, the resulting burgundy red mixture was quenched with acetaldehyde. The mixture was allowed to warm to room temperature, stirred for an additional 12 h, and then washed with 1 N HCl (50 mL) and extracted with EtOAc. The organic layer was dried over $MgSO_4$, filtered, and the solvent removed under reduced pressure. The resultant crude residue was then refluxed in 6 N aqueous 6 N HCl (50 mL) for 4 days. The mixture was filtered, washed with water, and dried under vacuum to afford **7a** as a light yellow solid. Recrystallization from acetone gave **7a** as a white solid: yield 0.080 g (52%); mp 38.0°C (lit. (17*b*) 38°C); ^{1}H NMR ($CDCl_3$), δ: 11.0 (s, 1H), 7.38 (m, 1H), 6.86 (m, 1H), 6.66 (m, 1H), 4.71 (m, 1H), 2.91 (m, 2H), 1.51 (d, 3H, *J* = 6.3 Hz); ^{13}C NMR ($CDCl_3$), δ: 162.9, 161.3, 142.1, 134.6, 119.3, 111.0, 74.2, 56.3, 36.2, 20.8.

N,N-Diethyl-2-methoxy-3-(diethylcarbamoyl)benzamide (4b)

The benzamide **4b** (17*c*) was prepared from 2-methoxyisophthalic acid (0.850 g, 4.33 mmol), excess $SOCl_2$ and diethylamine using standard conditions. After purification by silica-gel chromatography (elution with EtOAc), **4b** was obtained as a white solid: yield 1.13 g (85%); mp 82°C from Et_2O–hexane (lit. (17*c*) 82°C); ^{1}H NMR ($CDCl_3$), δ: 7.27 (m, 3H), 3.86 (s, 3H), 3.80–3.20 (br, 8H), 1.27 (t, 6H, *J* = 7.18 Hz), 1.06 (t, 6H, *J* = 7.14 Hz); ^{13}C NMR ($CDCl_3$), δ: 166.8, 150.6, 127.0, 42.0, 37.9, 12.8, 11.7.

N,N-Diethyl-2-methoxy-3-(diethylcarbamoyl)-6-methylbenzamide (5b)

To a stirred mixture of **4b** (0.304 g, 0.993 mmol) in dry THF (75 mL) at –78°C under argon, was added via syringe *sec*-BuLi (1.25 mL, 1.19 mmol, from 0.950 M in cyclohexanes) and TMEDA (0.138 g, 1.19 mmol). The resulting yellow solution was allowed to stir for 1 h at –78°C, and dry methyl iodide (0.423 g, 2.98 mmol) was added. The stirred mixture was allowed to warm to room temperature and stirred for an additional 12 h. The solution was then washed with 1 N HCl (100 mL) and extracted with EtOAc. The organic layer was separated, washed with three 20 mL portions of brine, then dried over $MgSO_4$. The solution was concentrated under reduced pressure to afford a crude product that was purified by silica-gel chromatography. Elution with ether (containing 1% triethylamine) afforded **5b** as a light yellow oil: yield 0.27 g (85%); ^{1}H NMR ($CDCl_3$), δ: 7.13 (d, 1H, *J* = 7.6), 7.00 (d, 1H, *J* = 7.6), 3.84 (s, 3H), 3.80–3.20 (br, 8H), 2.27 (s, 3H), 1.27 (m, 6H), 1.06 (t, 6H, *J* = 7.06 Hz); ^{13}C NMR ($CDCl_3$), δ: 167.9, 167.1, 151.3, 136.2, 127.2, 42.6, 42.3, 18.3, 13.5, 13.4, 12.3; mass spectrum (HREI), *m*/*z*: 320.209 ($C_{18}H_{28}N_2O_3$ requires 320.210).

3-Methyl-7-carboxy-8-hydroxy-2,3-dihydroisocoumarin (7b)

To a stirred solution of **5b** (1.20 g, 3.75 mmol) in dry THF (75 mL) at –78°C under argon was added LDA (2.25 mL, 4.50 mmol, from 2.0 M in heptane–THF–ethylbenzene). After

© 1998 NRC Canada

stirring for 1 h at –78°C, the resultant burgundy red solution was quenched with acetaldehyde. The mixture was allowed to warm to room temperature, stirred for an additional 12 h, washed with 1 N HCl (100 mL) and then extracted with EtOAc. The organic layer was separated, dried over $MgSO_4$, and then concentrated under reduced pressure. The crude residue was then refluxed in 6 N HCl for 4 days. The mixture was filtered, washed with water, and dried under vacuum, producing **7b** as a white solid: yield 0.528 g (63%); mp 233–235°C from acetone (lit. (17*c*) 234–236°C); ^{1}H NMR (DMSO-d_6), δ: 7.96 (d, 1H, J = 7.9), 6.88 (d, 1H, J = 7.9), 4.70 (br, 1H), 3.00 (m, 2H), 1.39 (d, 3H, J = 6.27); ^{13}C NMR (DMSO-d_6), δ: 168.9, 165.4, 161.9, 146.9, 136.6, 117.9, 115.7, 110.9, 74.8, 34.5, 20.2.

3-Methyl-7-carboxy-8-acetate-2,3-dihydroisocoumarin (8)
To a suspension of **7b** (0.200 g, 0.901 mmol) in acetic anhydride (10 mL) was added phosphoric acid (0.10 mL). The resulting solution was stirred for 24 h at 50°C. Concentration under reduced pressure, followed by purification by silica-gel chromatography (EtOAc) afforded **8** as a white solid: yield 0.233 g (98%); mp 136–137°C; ^{1}H NMR ($CDCl_3$), δ: 10.4 (br, 1H), 8.22 (d, 1H, J = 8.01), 7.24 (d, 2H, J = 8.01), 4.63 (m, 1H), 2.99 (m, 2H), 2.21 (s, 3H), 1.50 (d, 3H, J = 6.4); ^{13}C NMR ($CDCl_3$), δ: 169.3, 168.6, 161.0, 146.8, 136.7, 125.1, 123.3, 119.4, 77.2, 74.3, 35.8, 21.0, 20.6. Anal. calcd. for $C_{13}H_{12}O_6$: C 59.09; H 4.58; found: C 59.03; H 4.62.

Methyl ester of ochratoxin B (9a)
To a stirred solution of **8** (0.250 g, 0.87 mmol) in dry acetonitrile–DMF (10:3, 65 mL) at 0°C under argon was added DCC (0.217 g, 1.05 mmol) and HOBT (0.141 g, 1.05 mmol). The mixture was allowed to warm to room temperature and then stirred for an additional 1.5 h. L-Phenylalanine methyl ester (0.157 g, 0.87 mmol) in pyridine (2 mL) was then added in a dropwise fashion. After stirring for 12 h, the solvent was removed under reduced pressure. The resulting residue was redissolved in EtOAc (25 mL), washed with three 20 mL portions of brine, dried over $MgSO_4$, and concentrated under diminished pressure to yield a crude product. Purification by silica-gel column chromatography (elution with EtOAc–hexane, 80:20) afforded **9a** as a colorless residue: yield 0.276 g (83%); ^{1}H NMR ($CDCl_3$), δ: 12.7 (s, 1H), 8.53 (d, 1H, J = 6.4), 8.36 (d, 1H, J = 7.9), 7.27 (br, 5H), 6.84 (d, 1H, J = 7.9), 5.06 (m, 1H), 4.77 (m, 1H), 3.74(s, 3H), 3.24 (m, 2H), 2.99 (m, 2H), 1.56 (d, 3H, J = 6.4); ^{13}C NMR ($CDCl_3$), δ: 172.0, 170.3, 163.6, 160.5, 143.6, 139.0, 136.1, 129.3, 128.6, 127.1, 119.3, 118.4, 114.0, 108.7, 54.2, 52.3, 38.0, 34.6, 20.6; mass spectrum (HREI), *m*/*z*: 383.136 ($C_{21}H_{21}NO_6$ requires 383.137).

Ochratoxin B (2)
The hydrolysis of the methyl ester **9a** (0.383 g, 1.00 mmol) into the free acid, OTB (**2**), was achieved by reaction in a 3% LiOH solution in 3:1 H_2O–MeOH. Recrystallization from benzene afforded **2** as a white solid: yield 0.243 g (66%); mp 205–208°C (lit. (19) 220°C); ^{1}H NMR (DMSO-d_6), δ: 8.50 (d, 1H, J = 7.4), 8.06 (d, 1H, J = 7.9), 7.24 (m, 5H), 6.95 (d, 1H, J = 7.9), 4.81 (m, 2H), 3.16 (m, 2H), 1.41 (d, 3H, J = 6.1); ^{13}C NMR (DMSO-d_6), δ: 172.6, 169.1, 163.7, 159.6, 144.8, 137.0, 136.9, 129.3, 128.3, 126.7, 118.5, 118.3, 109.4, 76.1, 53.9, 36.7, 33.7, 20.2.

Amide of ochratoxin B (9b)
To a stirred solution of **8** (0.264 g, 0.379 mmol) in dry acetonitrile–DMF (8:1, 45 mL) at 0°C under argon was added DCC (0.094 g, 0.455 mmol) and *N*-hydroxysuccinimide (0.52 g, 0.455 mmol). The resulting mixture was allowed to warm to room temperature and then stirred for an additional 1.5 h under argon. L-Phenylalanineamide (0.062 g, 0.379 mmol) in pyridine (2 mL) was then added in a dropwise fashion. The mixture was stirred for an additional 12 h, then concentrated under reduced pressure to leave a residue that was resuspended in EtOAc (25 mL). The resulting solution was washed with three 20 mL portions of brine, dried over $MgSO_4$, then concentrated under diminished pressure to afford a crude product that was purified by silica-gel chromatography. Elution with 80/20 EtOAc–hexanes produced **9b** as a white residue: yield 0.027 g (20%); ^{1}H NMR ($CDCl_3$), δ: 12.4 (br, 1H), 8.53 (d, 1H, J = 7.1), 8.29 (d, 1H, J = 8.1), 7.24 (m, 5H), 6.82 (d, 1H, J = 8.1), 6.32 (s, 1H), 5.82 (s, 1H), 4.89 (m, 1H), 4.78 (m, 1H), 3.20 (m, 2H), 2.96 (m, 2H), 1.55 (d, 3H, J = 6.2); ^{13}C NMR ($CDCl_3$), δ: 173.3, 170.2, 164.0, 160.3, 143.7, 138.7, 136.6, 129.3, 128.6, 126.9, 118.9, 118.5, 108.7, 54.9, 37.8, 34.5, 20.6; mass spectrum (HREI), *m*/*z*: 368.13734 ($C_{20}H_{20}N_2O_5$ requires 368.1372).

5-Chloro-2-hydroxy-*N*-L-phenylalaninebenzamide methyl ester (11)
To a stirred solution of the acetate of 5-chloro-2-hydroxybenzoic acid (1.00 g, 4.66 mmol) in dry acetonitrile–DMF (5:1, 55 mL) at 0°C under argon was added DCC (1.15 g, 5.59 mmol) and HOBT (0.755 g, 5.59 mmol). The mixture was allowed to warm to room temperature, stirred for an additional 1.5 h, and then L-phenylalanine methyl ester (1.55 g, 4.66 mmol) in dry pyridine (3 mL) was added in a dropwise fashion. The resulting mixture was stirred for an additional 12 h and then concentrated under diminished pressure. The resulting residue was resuspended in EtOAc (25 mL), filtered, and then washed with three 20 mL portions of brine. The organic layer was collected, dried over $MgSO_4$, and concentrated under reduced pressure to afford a crude product that was purified by silica-gel chromatography. Elution with 40/60 EtOAc–hexanes afforded **11** as a white solid: yield 0.9 g (60%); mp 83–85°C. ^{1}H NMR ($CDCl_3$), δ: 11.9 (s, 1H), 7.40–6.60 (m, 9 H), 5.07 (m, 1H), 3.80 (s, 3H), 3.26 (m, 2H); ^{13}C NMR ($CDCl_3$), δ: 171.7, 168.4, 160.1, 135.3, 134.5, 129.2, 128.8, 127.5, 125.2, 123.5, 120.1, 114.7, 114.0, 53.3, 52.7, 37.8. Anal. calcd. for $C_{17}H_{16}ClNO_4$: C 61.18; H 4.83; N 4.20; found: C 61.07; H 4.87; N 4.16.

5-Chloro-2-hydroxy-*N*-L-phenylalaninebenzamide (12)
The hydrolysis of the methyl ester **11** (1.00 g, 3.00 mmol) into the free acid **12** was achieved by reaction in a 3% LiOH solution in 3:1 H_2O–MeOH (33). Recrystallization from MeOH–H_2O afforded **12** as a white solid: yield 0.67 g (70%); mp 172–173°C. ^{1}H NMR (acetone-d_6), δ: 12.3 (br, 1H), 8.62 (d, 1H, J = 7.9), 7.92 (m, 1H), 7.54–7.10 (m, 6H), 6.94 (d, 1H, J = 8.9), 5.01 (m, 1H), 3.4–3.1 (m, 2H); ^{13}C NMR (acetone-d_6), δ: 173.0, 169.2, 160.6, 138.3, 134.6, 130.0, 129.2, 127.7, 127.5, 123.7, 120.3, 116.7, 55.0, 37.7. Anal. calcd. for $C_{16}H_{14}ClNO_4$: C 60.10; H 4.41; N 4.38; found: C 60.02; H 4.47; N 4.39.

Metal binding

The ability of **1** and our synthesized derivatives to bind Fe(III) and Cu(II) was studied by fluorescence spectroscopy at 25°C. Stock solutions of the toxin samples were prepared in 1,4-dioxane. Concentrations were determined by UV-vis in ethanol using extinction coefficients for the phenolic absorptions, ca. 330 nm. For Cu(II) binding, a solution (2 mL) containing 10 mM MES (pH 6.0), 100 mM $NaClO_4$ buffer, or 10 mM MOPS (pH 7.4), 100 mM $NaClO_4$ buffer was utilized. Studies on Fe(III) binding were performed in buffer solutions (2 mL) containing 10 mM HCl·KCl (pH 2.6), 100 mM $NaClO_4$. In each case, 2 μL of the toxin dioxane stock solution was added for a final concentration of 10 μM. For determination of the metal binding constants, quenching of the toxin's emission spectrum (emission ca. 440 nm, excitation ca. 330–380 nm) was measured 5 min after each addition of $Cu(II)(OAc)_2$ or $Fe(III)Cl_3$ to allow binding equilibration. Scatchard analysis (20) of the quenching was performed using the following equation: $(F/F_o) - 1)/[L] = (k_{11}/k_s)K_{11} - K_{11}(F/F_o)$ where F_o is the fluorescence intensity of free toxin, [L] is the ligand concentration, and k_{11}/k_s are proportionality constants (20). From a plot of $(F/F_o) - 1/[L]$ versus F/F_o, an association constant was derived from the negative slope. For $Zn(OAc)_2$ binding at pH 7.4 (10 mM MOPS, 100 mM $NaClO_4$), emission spectra were recorded at 400 nm, and the data was analyzed by the Benesi–Hildebrand equation (20*b*, 38). Double-reciprocal plots of $1/\Delta A$ (change in emission) versus 1/[Zn] afforded straight lines from which the association constant (K_{11}) was determined from K_{11} = (*y*-intercept)/(slope) (20*b*).

pK_a determination

The pH measurements were obtained on a Fisher Scientific Accumet pH meter 910 using standard glass electrodes. Calibration was done using commercial buffers (BDH, pH 4.00, 7.00, and 10.00, all ± 0.01). The pK_a of **12** (Scheme 2) was determined using 0.1 M phosphate buffers, which were prepared by dilution of a stock (1 M K_2HPO_4) solution with deionized water. For (±)-mellein (**7a**), 0.1 M $NaHCO_3$–Na_2CO_3 buffer solutions were utilized. All UV-vis spectra were acquired at 25°C using a standard matched pair of 1 cm quartz cells. In the case of **12**, the sample and reference were filled with 1.00 mL of buffer solution, and to the sample cell was added 2 μL of a stock solution of **12** in 1,4-dioxane. For **7a**, 1 mL of carbonate buffer containing 20 vol.% 1,4-dioxane was used, and to the sample cell was added 2 μL of the stock solution of **7a** in 1,4-dioxane. The UV-visible spectra were recorded by the overlay method in the wavelength range of 250–500 nm.

Relaxation of supercoiled DNA by Fe and Cu in the presence of ochratoxin A

Reaction mixtures (20 μL total volume) contained 400 ng of Form I DNA, 10 mM MOPS (pH 7.4), 50 mM NaCl, and 20 μM each of OTA (**1**) and metal ion. The metal salts employed were $Cu(OAc)_2$, $Fe(Cl)_3$, and $Fe(NH_4)_2(SO_4)_2$. For reactions with iron, external reducing agents (200 μM sodium ascorbate) and oxidants (200 μM HOOH) were also employed. Reaction mixtures were incubated at 37°C for varying lengths of time, then quenched by the addition of 4 μL of loading buffer. Samples were loaded onto a 1% agarose gel containing ethidium bromide (1 ug/mL). The gel was run at 110 V for 2 h and visualized by UV illumination.

Densitometric quantitation was performed using a Microtek Scanmaker E_6 equipped with PhotoImpact and UTHSCSA Image Tool software. Supercoiled plasmid DNA values were corrected by a factor of 1.3, based on average literature estimates of lowering binding of ethidium to this structure (39).

Relaxation of supercoiled DNA by Cu(II)·ochratoxin A

Reaction mixtures (20 μL total volume) contained 400 ng of Form I DNA, 10 mM MOPS (pH 7.4), 50 mM NaCl, 20 μM $Cu(OAc)_2$, and 60 μM OTA. The OTA and $Cu(OAc)_2$ were premixed prior to addition of Form I DNA. Addition of sodium ascorbate 10–250 μM initiated the reaction, and mixtures were incubated at 37°C for 30 min, then quenched by the addition of 4 μL loading buffer. Samples were loaded onto a 1% agarose gel containing ethidium bromide (1 μg/mL). The gel was run at 110 V for 2 h and visualized by UV illumination. In a separate experiment, the quenching effect of catalase (1000 units/mL), sodium azide (100 mM), DMSO (1 M), and *tert*-butanol (1M) was examined.

Relaxation of supercoiled DNA by $Cu(OP)_2$ in the presence of ochratoxin A

Reaction mixtures (20 μL total volume) contained 400 ng of Form I DNA, 10 mM MOPS (pH 7.4), 50 mM NaCl, 20 μM $Cu(OAc)_2$, 40 μM OP, and either 10 μM sodium ascorbate or 50–250 μM OTA (**1**). Reaction mixtures were incubated at 37°C for 30 min, then quenched by the addition of 4 μL loading buffer. Samples were loaded onto a 1% agarose gel containing ethidium bromide (1 μg/mL). The gel was run at 110 V for 2 h and visualized by UV illumination. In a separate experiment, the quenching effect of catalase (1000 units/mL) and SOD (1000 units/mL) on the ability of 50 μM OTA to potentiate DNA cleavage by $Cu(II)(OP)_2$ was examined.

Relaxation of supercoiled DNA by $Cu(OP)_2$ in the presence of OTA, OTB, and 12

Reaction mixtures (20 μL total volume) contained 400 ng of Form I DNA, 10 mM MOPS (pH 7.4), 50 mM NaCl, 20 μM $Cu(OAc)_2$, 40 μM OP, and 50 μM OTA (**1**), OTB (**2**), or **12**. Reaction mixtures were incubated at 37°C for 30 min, then quenched by the addition of 4 μL loading buffer. Samples were loaded onto a 1% agarose gel containing ethidium bromide (1 μg/mL). The gel was run at 110 V for 2 h and visualized by UV illumination. In a separate experiment, the reactions described above were repeated, but in 10 mM CHES buffer, pH 8.6.

Relaxation of supercoiled DNA by Fe^{III}·EDTA in the presence of OTA

Reaction mixtures (20 μL total volume) contained 400 ng Form I DNA, 10 mM MOPS (pH 7.4), 50 mM NaCl, 20 μM $FeCl_3$, 20 μM EDTA, and either 50 μM sodium ascorbate or 50–250 μM OTA. Reaction mixtures were treated as described in the previous experiments.

Mechanisms for the oxidation of secondary alcohols by dioxoruthenium(VI) complexes

Zhao Wang, W. David Chandler, and Donald G. Lee

Abstract: Possible mechanisms for the oxidation of alcohols by dioxoruthenium(VI) complexes are critically evaluated. Rate constants for the reduction of *trans*-$[(TMC)Ru^{VI}(O)_2]^{++}$ (TMC = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) by substituted benzhydrols are correlated more satisfactorily with Hammett σ substituent constants ($\rho = -1.44 \pm 0.08$, $r^2 = 0.98$) than with σ^+ substituent constants ($\rho = -0.72 \pm 0.11$, $r^2 = 0.83$). Similar observations for the oxidation of substituted benzyl alcohols have recently been reported, confirming that the transition state for these reactions is not carbocation-like. Primary deuterium isotope effects indicate that cleavage of the α-C–H bond is rate-limiting. The lack of an observable O-D isotope effect and the ease of oxidation of ethers indicates that the presence of a hydroxyl is not essential. The previously reported observation that cyclobutanol is quantitatively converted into cyclobutanone by dioxoruthenium(VI) complexes eliminates free-radical intermediates from consideration as part of the mechanism, and negative entropies of activation ($-\Delta S^{\ddagger} = 96$–$137$ J mol^{-1} K^{-1}) suggest a structured transition state. Only two of eight possible reaction mechanisms considered were found to be consistent with the available data. A critical analysis of the available data indicates that a 2 + 2 (C—H + Ru═O) addition and a reaction initiated by ligand formation through the interaction of the reductant's HOMO with the oxidant's LUMO are the most likely reaction mechanisms.

Key words: oxidation, alcohols, ruthenium(VI), mechanism, substituent effects.

Résumé : On évalue d'une façon critique divers mécanismes possibles pour l'oxydation des alcools par des complexes de dioxoruthénium(VI). La corrélation entre les constantes de vitesse de réduction du *trans*-$[(TMC)Ru^{VI}(O)_2]^{++}$ (TMC = 1,4,8,11-tétraméthyl-1,4,8,11-tétraazacyclotétradécane) par des benzhydrols substitués est meilleure avec des constantes de substituants σ^+ de Hammett ($\rho = -1{,}44 \pm 0{,}08$; $r^2 = 0{,}98$) qu'avec des constantes de substituants σ^+ ($\rho = -0{,}72 \pm 0{,}11$; $r^2 = 0{,}83$). Des observations semblables ont été rapportées récemment pour l'oxydation d'alcools benzyliques substitués; elles confirment que l'état de transition de ces réactions ne ressemble pas à un carbocation. Les effets isotopiques primaires du deutérium indiquent que le clivage de la liaison C-H en α limite la vitesse. Le fait que l'on n'observe pas d'effet isotopique O-D et la facilité d'oxydation des éthers indiquent que la présence d'un groupe hydroxyle n'est pas essentielle. L'observation rapportée antérieurement à l'effet que le cyclobutanol peut être transformé quantitativement en cyclobutanone par les complexes de dioxoruthénium(VI) élimine la possibilité d'un mécanisme impliquant des intermédiaires radicalaires; par ailleurs, les entropies d'activation négatives ($-\Delta S^{\ddagger} = 96$ à 137 J mol^{-1} K^{-1}) suggèrent la présence d'un état de transition structuré. On a trouvé que seulement deux des huit mécanismes réactionnels possibles sont en accord avec les données disponibles. Une analyse critique des données disponibles indique qu'une addition 2 + 2 (C-H + Ru═O) et une réaction initiée par la formation de ligand par interaction des OMHO du réducteur avec les OMBV de l'oxydant sont les mécanismes réactionnels les plus probables.

Mots clés : oxydation, alcools, ruthénium(VI), mécanisme, effets de substituants.

[Traduit par la rédaction]

Introduction

A knowledge of the redox properties of dioxoruthenium(VI) complexes, $[LRu(O)_2]^{++}$, where L is a neutral macrocyclic ligand, is important because of their potential use as stoichiometric or catalytic oxidants. The chemical and physical properties of these complexes, which can exist as either *cis* or *trans* isomers, have been studied in several laboratories including those of Che (1), Meyer (2), Drago (3), James (4), Groves (5), Morishima (6), Hirobe (7), and Jorgensen (8).

It has been observed in these studies that dioxoruthenium(VI) complexes can be used as oxidants for alcohols, alkenes, arenes, sulfides, amines, and phosphines. The products obtained from the oxidation of primary and secondary alcohols are aldehydes (7, 9–13) and ketones (9–14) respectively; from alkanes the products are alcohols (3, 10, 12) or ketones (10, 12); from alkenes the products are α,β-unsaturated ketones (10–13, 15), epoxides (5, 7, 10–13, 16), or products derived from the oxidative cleavage of the double bond (10, 11, 16); from arenes the products are α-phenyl alcohols (10, 12, 13, 16), aldehydes (11, 16, 17), ketones (10, 12, 16), or carboxylic acids (10), depending on the nature of the side

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

Scheme 1.

Single-electron transfer:

$$R_2CHOH + [LRu^{VI}(O)_2]^{++} \longrightarrow R_2C\dot{O}H^{+} + [LRu^{V}(O)_2]^{+}$$

Hydrogen atom transfers:

$$R_2CHOH + [LRu^{VI}(O)_2]^{++} \longrightarrow R_2C\dot{O} + [LRu^{V}(OH)O]^{++}$$

$$R_2CHOH + [LRu^{VI}(O)_2]^{++} \longrightarrow R_2\dot{C}OH + [LRu^{V}(OH)O]^{++}$$

Hydride transfers:

$$R_2CHOH + [LRu^{VI}(O)_2]^{++} \longrightarrow R_2CHO^{+} + [LRu^{IV}(OH)O]^{+}$$

$$R_2CHOH + [LRu^{VI}(O)_2]^{++} \longrightarrow R_2\overset{+}{C}OH + [LRu^{IV}(OH)O]^{+}$$

2+2 (C-H + Ru=O) addition:

$$R_2CHOH + [LRu^{VI}(O)_2]^{++} \longrightarrow [L(R_2\overset{HO}{\overset{|}{C}})Ru^{VI}(OH)O]^{++}$$

2+2 (O-H + Ru=O) addition:

$$R_2CHOH + [LRu^{VI}(O)_2]^{++} \longrightarrow [L(R_2CHO)Ru^{VI}(OH)O]^{++}$$

Ligand Formation:

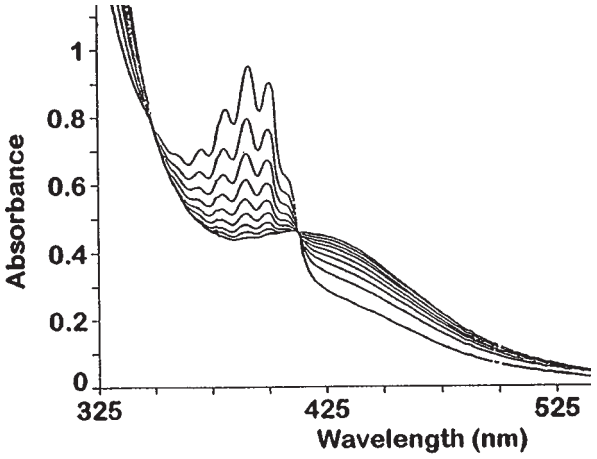
$$R_2CHOH + [LRu^{VI}(O)_2]^{++} \longrightarrow [L(R_2C\overset{+}{\underset{H}{\underset{|}{O}}})Ru^{VI}(O)_2]^{+}$$

chain; from cyclic ethers the products are lactones (10); from sulfides the products are the corresponding sulfoxides (6, 7) or sulfones (7); from amines, dehydrogenated products (primarily nitriles and imines) are obtained (18); and from phosphines the products are the corresponding phosphine oxides (2, 6, 19, 20).

This paper reports the results obtained from a variety of experiments designed to provide a better understanding of the mechanism of the reaction between secondary alcohols and a typical dioxoruthenium(VI) complex, *trans*-$[(TMC)Ru^{VI}(O)_2]^{++}$ (TMC = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane). Eight theoretically possible reaction mechanisms have been considered: direct single-electron transfer from the alcohol to the oxidant, hydrogen atom or hydride ion transfer from either oxygen or carbon, 2 + 2 addition of a ruthenium oxo (Ru═O) to either the O—H or the α-C—H bond of the alcohol and ligand formation followed by a cyclic transfer of hydrogen. These possibilities, derived from the discussion by March (21*a*) and the theoretical work of Deng and Ziegler (22), Mayer and co-workers (23), and Rappe and Goddard (24) on the reactions of high valent transition metal compounds, have been summarized in Scheme 1.

Each of the mechanistic possibilities outlined in Scheme 1 has been examined in light of the rather large amount of experimental evidence currently available with respect to the reactions of dioxoruthenium(VI) complexes and alcohols. From such an analysis it is possible to eliminate several potential processes and to arrive at the "most likely" mechanisms.

Fig. 1. Sequential scans for the oxidation of benzhydrol (0.485 M) by *trans*-$[(TMC)Ru(O)_2]^{++}$ (1.68×10^{-3} M) at 40.0 ± 0.1°C. Scans were taken at intervals of 5500 s.



Experimental section

Materials

Benzhydrol (α-phenylbenzenemethanol), 4-methylbenzhydrol, 4-chlorobenzhydrol, and 4,4′-dichlorobenzhydrol were obtained commercially (Aldrich) and purified by repeated crystallizations from a mixture of diethyl ether and hexane until sharp melting points in agreement with literature values were obtained. 2-Propanol was purified by distillation from calcium oxide. A middle fraction (bp 80.5–81.0°C) was collected and analyzed by use of GLC. The results indicated a purity of at least 99.9%.

4-Bromobenzhydrol, 4,4′-dimethylbenzhydrol, 4-fluorobenzhydrol, and 4-methoxybenzhydrol were prepared by reduction of the corresponding benzophenones with lithium aluminum hydride (25). The benzophenones were obtained from Aldrich. In a typical procedure, a flame-dried 300 mL three-necked flask, fitted with a magnetic stirrer and a dropping funnel, was charged with 0.3 g (8 mmol) of lithium aluminum hydride (J.T. Baker) and 100 mL of anhydrous ether. A solution of benzophenone (24 mmol) in anhydrous ether (50 mL) was added dropwise. The mixture was stirred under gentle reflux until the reaction was complete. The solution was then treated with 50 mL of ice water while cooling the reaction flask in an ice bath. The organic layer was separated and the aqueous layer extracted with ether (2 × 30 mL). The combined organic layers were dried over $CaCl_2$, filtered, and evaporated to give the corresponding benzhydrol in 85–93% yield. The products were repeatedly recrystallized from a solution of diethyl ether and hexane until sharp melting points were obtained and then identified from physical and spectral data. 4-Bromobenzhydrol, mp 62–63°C, lit. (26) 63–65°C; ^{1}H NMR ($CDCl_3$), δ: 2.12 (d, 1H), 5.74 (d, 1H), 7.36 (m, 9H); ^{13}C NMR ($CDCl_3$), δ: 75.6, 121.4, 126.6, 127.9, 128.3, 128.7, 131.6, 142.8, 143.4. 4,4′-Dimethylbenzhydrol, mp 68.5–69.0°C, lit. (26) 69°C; ^{1}H NMR ($CDCl_3$), δ: 2.22 (d, 1H), 2.36 (s, 6H), 5.72 (s, 1H), 7.38 (M, 8H); ^{13}C NMR ($CDCl_3$), δ: 21.2, 76.0, 126.5, 129.2, 137.2, 141.2. 4-Fluorobenzhydrol, mp 47–48°C; ^{1}H NMR ($CDCl_3$), δ: 2.41 (d, 1H), 5.78 (d, 1H), 6.99 (t, 2H), 7.28 (m, 7H); ^{13}C NMR ($CDCl_3$), δ: 75.6, 115.5, 126.5, 127.8,

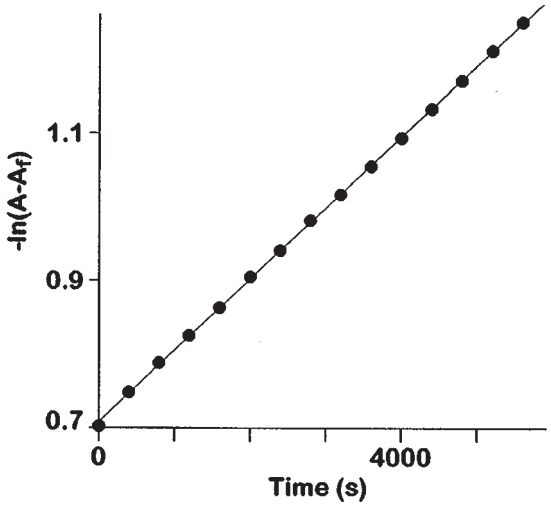
Fig. 2. Typical pseudo first-order plot for the oxidation of benzhydrol (0.670 M) by *trans*-[(TMC)Ru(O)$_2$]$^{++}$. Slope = 9.67 × 10^{-5} s^{-1}, r^2 = 0.999.



128.2, 128.3, 128.6, 139.5, 143.0. 4-Methoxybenzhydrol, mp 65–66°C; ^{1}H NMR ($CDCl_3$), δ: 2.65 (d, 1H), 3.81 (s, 3H), 5.74 (d, 1H), 6.88 (d, 2H), 7.33 (M, 7H); ^{13}C NMR ($CDCl_3$), δ: 55.3, 75.8, 113.9, 126.5, 128.0, 128.5, 136.0, 144.5, 159.5.

Benzhydrol-α-*d* and 2-propanol-α-*d* were prepared by the reduction of benzophenone and acetone with lithium aluminium deuteride (Aldrich). Benzhydrol-α-*d*, mp 67.5–68.0°C, was identified by use of NMR: ^{1}H NMR ($CDCl_3$), δ: 2.39 (s, 1H), 7.38 (m, 10H); ^{13}C NMR ($CDCl_3$), δ: 126.6, 127.6, 128.5, 144.5. 2-Propanol-α-*d* was purified by distillation from calcium oxide, bp 80.0–80.5°C, and identified by NMR: ^{1}H NMR ($CDCl_3$), δ: 1.11 (s, 6H), 2.66 (br, 1H). Only one peak was detected in a GLC analysis indicating at least 99.9% purity. From the NMR integrals, the incorporation of deuterium was calculated to be 98%. 2-Propanol-*O*-*d* was prepared by repeatedly treating 2-propanol with D_2O. The product was identified by NMR; the ^{1}H NMR integrals indicated 96.7% incorporation of deuterium.

The oxidant was prepared in two forms, [(TMC)-$Ru^{VI}(O)_2](ClO_4)_2$ and [(TMC)$Ru^{VI}(O)_2](BF_4)_2$ using procedures previously described in the literature (27). Both salts reacted with alcohols at the same rate under any particular set of conditions, indicating that the identity of the anion has little influence on the reaction rate. The initial work was done with the perchlorate salt; however, on two occasions small explosions occurred when it was being transferred as a dry solid from the reaction flask in which it had been prepared to a storage vial. The explosions were sufficiently violent to shatter glassware and cause minor cuts to the hand of one of us (Z.W.). The fluoroborate salt proved to be much safer to work with.

Both salts were prepared starting from $K_2[Ru^{III}(Cl)_5H_2O]$, obtained from either Johnson Matthey or Strem Chemicals. Initially, 1.056 g (2.82 mmol) of $K_2[Ru^{III}(Cl)_5(H_2O)]$ was suspended in 150 mL of absolute ethanol and heated under reflux with vigorous stirring for 15 min. 1,4,8,11-Tetramethyl-1,4,8,11-tetraazacyclotetradecane, TMC (Aldrich, 0.92 g, 3.59 mmol), dissolved in 280 mL of ethanol was added dropwise to the refluxing suspension over a period of 6 h. After refluxing for an additional 12 h (overnight), the solution was filtered hot, and the yellow filtrate evaporated to dryness. This product was redissolved in a minimum of hot 3 M HCl. Yellow crystals of *trans*-[(TMC)$Ru^{III}(Cl)_2$]Cl formed when the solution was allowed to slowly cool. After filtration and washing with cold 3 M HCl, a yellow crystalline product (0.70 g, 1.64 mmol, 58%) was obtained; λ_{max} = 370 nm, with a shoulder at 315 nm when dissolved in acetonitrile. A portion of this product (0.43 g, 0.95 mmol) and silver *p*-toluenesulfonate (0.77 g, 2.77 mmol) were heated at 60°C for 0.5 h in 35 mL of distilled water. A grey–white precipitate (AgCl), which formed immediately, was removed by filtration, and 50% H_2O_2 (9 mL) was added dropwise to the remaining yellow solution at 60°C. After 30 min the solution was cooled in an ice–water bath and an excess of $NaClO_4$ added. The compound *trans*-[(TMC)$Ru^{VI}(O)_2](ClO_4)_2$, which slowly precipitated, was collected and recrystallized from hot (60°C) 0.1 M $HClO_4$. Crystalline product (0.23 g, 43%) was obtained. The spectrum of this product dissolved in acetonitrile was similar to that reported in the literature for other dioxoruthenium(VI) complexes: λ_{max} = 228, 257, and 388 nm; lit. (13, 27) 223, 255, and 388 nm.

The compound *trans*-[(TMC)$Ru^{VI}(O)_2](BF_4)_2$ was prepared by first treating *trans*-[(TMC)$Ru^{III}(Cl)_2$]Cl (0.43 g, 0.95 mmol) with silver *p*-toluenesulfonate (0.77 g, 2.77 mmol) dissolved in 35 mL of distilled water and heating the mixture at 60°C for 0.5 h. The solution was filtered to remove AgCl, and 50% H_2O_2 (9 mL) was added dropwise to the yellow filtrate at 60°C. This solution was concentrated to two thirds of its volume and cooled in an ice-water bath. When an excess of saturated $NaBF_4$ solution was added, a precipitate formed slowly over several hours. Collection of the precipitate and recrystallization from hot (60°C) 0.1 M HBF_4 yielded *trans*-[(TMC)$Ru^{VI}(O)_2](BF_4)_2$ (0.12 g, 34%).

Plots of the concentration of this product in acetonitrile solutions vs. absorbance at 388 nm were precisely linear, as required by Beer's Law, with a slope of ε = 539 ± 5.

The solvent, acetonitrile, used in these experiments was purified by stirring with $KMnO_4$ overnight and simple distillation. The distillate was then carefully redistilled over CaH_2 in a nitrogen atmosphere.

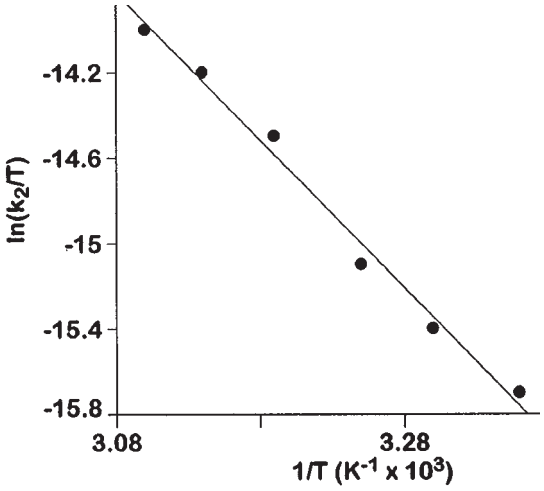
Fig. 5. Eyring plot for the oxidation of benzhydrol (0.504 M) by $[(TMC)Ru(O)_2]^{++}$. Slope = –6920 ± 370 K, intercept = 7.5 ± 1.2, $r^2 = 0.989$.



approximately 1×10^{-3} M $[(TMC)Ru^{VI}(O)_2]^{++}$ in acetonitrile was placed in the thermostated cell compartment of a Hewlett Packard 8450A diode array spectrophotometer and held there until thermal equilibrium had been established. An excess of the alcohol, also dissolved in acetonitrile and thermostated at the same temperature, was added from a microliter syringe and, after thorough mixing, spectra recorded at equal time intervals. Sequential scans exhibited sharp isosbestic points at 334 nm and 404 nm (Fig. 1). The final spectrum was identical to that reported for $[(TMC)Ru^{IV}O(CH_3CN)]^{++}$ (13).

Results

Rate law

Plots of ln(absorbance – final absorbance) at 388 nm were linear (Fig. 2), indicating that the reaction is first order in oxidant. Second-order rate constants, calculated by division of the pseudo first-order rate constants by alcohol concentration (Table 1), were observed to be constant, indicating that the reaction is also first order with respect to the reductant. The rate law is therefore given by eq. [1].

$$[1] \quad -d[Ru^{VI}]/dt = k_2[Ru^{VI}][alcohol]$$

Isotope effects

Kinetic isotope effects, determined for the oxidation of 2-propanol-2-*d*, 2-propanol-*O*-*d* and benzhydrol-α-*d* are summarized in Table 2. The results reported from other laboratories for the oxidation of isotopically substituted alcohols by dioxoruthenium(VI) complexes have also been included in Table 2 for comparison purposes.

Substituent effects

The second-order rate constants for the oxidation of substituted benzhydrols by $[(TMC)Ru^{VI}(O)_2]^{++}$ were found to correlate well with Hammett σ values (Fig. 3), but not with the corresponding σ^+ values (Fig. 4). The negative ρ value (–1.44) indicates that the electron density on the α-carbon has decreased in the transition state; however, the lack of correlation with σ^+ values, observed in this and other studies, indicates that the transition state is not carbocation-like. Table 3 contains a comparison of the Hammett correlations for similar reactions of dioxoruthenium(VI) complexes that have been reported from other laboratories.

[b] L is 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (TMC). L′ is *N*,*N*,*N*′,*N*′-tetramethyl-3,6-dimethyl-3,6-diazaoctane-1,8-diamine. L″ is *N*,*N*′-dimethyl-6,7,8,9,10,11,17,18-octahydro-5*H*-dibenzao[en][1,4,8,112] dioxadiazacyclopentadecane. L‴ is 5,5-dimethyl-2,2′-bipyridine.

Activation parameters

The enthalpies and entropies of activation for the oxidation of 2-propanol and benzhydrol were determined from a study of the reaction rates at different temperatures. A typical Eyring plot has been reproduced in Fig. 5. The activation parameters that have been reported for other similar reactions are included in Table 4 for comparison purposes.

Discussion

There are at least two reasons why chemists wish to have a good understanding of reaction mechanisms: (*i*) a knowledge of the mechanism of a reaction provides an indication of the conditions that should be used to maximize the yield and rate of formation of a specific reaction product, and (*ii*) insights into the details of a particular reaction mechanism are often transferable to other reactions; i.e., there is a likelihood that all chemistry will ultimately be understandable in terms of a finite number of fundamental principles.

The reactions between high valent transition metal compounds (oxidants) and organic reductants are examples of important, often used processes for which the chemistry is not particularly well understood, despite a voluminous literature. The products obtained, in common with most redox reactions, could be produced via several possible mechanisms (21*a*), as summarized in Scheme 1 for the reaction under consideration. With such a multiplicity of viable mechanistic options available, it will likely be very difficult to "prove" that a particular mechanism is correct; the best that can be expected at this time is a critical evaluation of each possible mechanism in light of the available experimental evidence and the most current theoretical calculations. Using this approach several possibilities can be eliminated and the "most likely" mechanisms proposed. Ultimately, it is reasonable to expect that it may be possible to arrive at a unified mechanistic consensus that is applicable to a large number of redox reactions (28).

The observation made by Che and co-workers (12, 29), that

© 1998 NRC Canada

the only product obtained from the oxidation of cyclobutanol by dioxoruthenium(VI) complexes is cyclobutanone, indicates that free-radical intermediates are not involved. As discussed in detail elsewhere (16, 30–36), it is known that the internal strain of the cyclobutyl system causes it to open if free radical intermediates are formed. For example, acyclic products are obtained when cyclobutanol is oxidized by typical one-electron oxidants such as vanadium(V) (30, 31), manganese(III) (31), chromium(IV) (32), cerium(IV) (33), and ruthenium(VII) (34, 36), while cyclobutanone is obtained from typical two-electron oxidants such as ruthenium tetroxide (35), ruthenium(VI) (35, 36), chromium(VI) (32), and chromium(V) (32). The expected products from oxidations involving single-electron or hydrogen atom transfers would therefore be acyclic compounds (Scheme 2), while two-electron transfer reactions would result in the formation of cyclobutanone (Scheme 3).

Reaction mechanisms that involve cleavage of the O—H bond in the rate-limiting step are also eliminated from further consideration by the observation that there is no measurable kinetic deuterium isotope effect when the hydroxyl hydrogen is replaced by deuterium (Table 2). This would include both hydrogen atom and hydride ion transfers from oxygen, as well as 2 + 2 (O-H + Ru=O) additions. The report that ethers, such as tetrahydrofuran, are readily oxidized by dioxoruthenium(VI) complexes (10, 29, 37) indicates that the presence of O-H groups in the structure of the reductant is not essential, in contrast to chromic acid oxidations (for example see ref. 38).

A mechanism involving direct transfer of a hydride ion from the α-carbon would be in agreement with the observed isotope effects, but not with the Hammett studies reported here and elsewhere. The rate constants for such reactions (eq. [2]) should correlate better with σ^+ values (39), contrary to the experimental observations summarized in Table 3. In fact, any reaction in which the α-carbon is carbonyl-like (sp^2 hybridized) in the transition state should correlate better with σ^+ values. The correlation reported herein and those found in the literature are consistently better when σ values are used, the clear implication being that direct hydride transfer is not a likely mechanism.

[2] $$Ar_2CHOH + [(TMC)Ru^{VI}(O)_2]^{++} \longrightarrow Ar_2\overset{+}{C}OH + [(TMCRu^{IV}(OH)O]^{+}$$

A mechanism in which the reaction is initiated by a 2 + 2 addition of a ruthenium oxo to the α-C—H bond, as has been proposed for several other oxidation reactions (40–42), is in agreement with the isotope effects reported in Table 2 and the Hammett studies summarized in Table 3. In this reaction (eq. [3]) the α-carbon remains sp^3 hybridized, eliminating the possibility of a direct resonance contribution from the substituents and therefore a lack of correlation with σ^+ values.

[3] 
1

The observation (37) that the oxidation of tetrahydrofuran by dioxoruthenium(VI) complexes exhibits a primary isotope effect and activation parameters ($k_H/k_D = 20 \pm 2$, $\Delta H^{\ddagger} = 59 \pm 4$ kJ mol^{-1}, $\Delta S^{\ddagger} = -117 \pm 13$ J mol^{-1} K^{-1}) similar to those for the corresponding alcohol reactions (Tables 2 and 4) is also consistent with a possible 2 + 2 (C—H + Ru=O) addition mechanism. The α-hydrogens of ethers and alcohols are electronically similar and would therefore be expected to respond similarly to oxidants that cause C—H bond cleavage in the rate-limiting step.

It is also possible to consider a mechanism for conversion of the organometallic intermediate, **1**, into products. Two possibilities exist: (*i*) homolytic cleavage of the Ru—C bond would give a ruthenium(V) complex and a free radical that could subsequently undergo a hydrogen atom transfer as in eqs. [4] and [5], or (*ii*) heterolytic cleavage of the Ru—C bond to give a ruthenium(IV) complex and a cation that could transfer a proton to give the observed products as in eqs. [6] and [7].

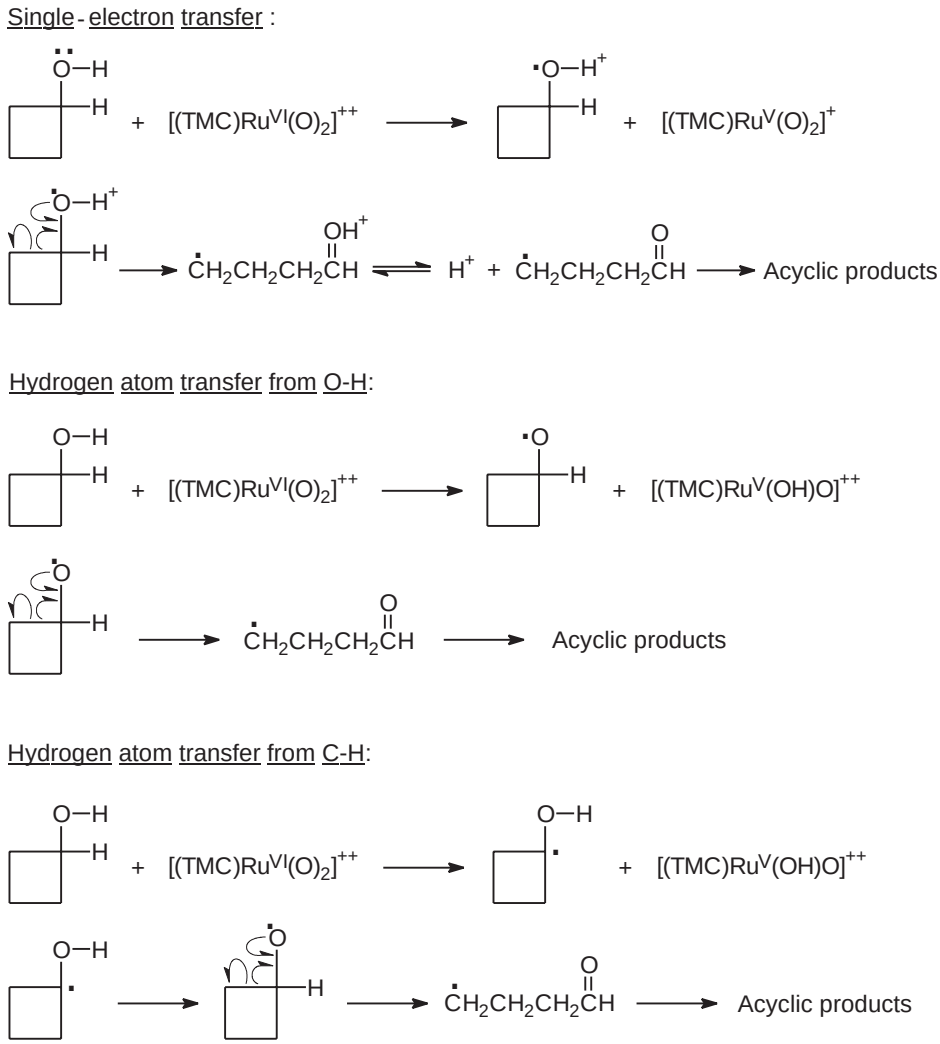
[4] 
[5] $$Ar_2\dot{C}OH + [(TMC)Ru^{V}(OH)O]^{++} \longrightarrow Ar_2CO + [(TMC)Ru^{IV}(OH)_2]^{++}$$

[6] 
[7] $$Ar_2\overset{+}{C}OH \rightleftharpoons A_2CO + H^{+}$$

The reaction sequence in eqs. [4] and [5] involves formation of free-radical intermediates, which are considered to be unlikely because of the previously described observation that oxidation of cyclobutanol does not result in ring opening. It is,

© 1998 NRC Canada

Scheme 2.



however, possible that the transfer of the hydrogen atom (eq. [5]) could occur more rapidly than ring opening, thereby precluding the formation of acyclic products. In such an event, the hydrogen atom transfer would have to take place rapidly before the free radical could diffuse out of the solvent cage enclosing it and the ruthenium(V) complex; diffusion out of the solvent cage would provide more than sufficient time for ring opening to occur.

A mechanism consisting of reaction [3], followed by either [4] and [5] or [6] and [7], is consistent with the observed rate law, the products from the oxidation of cyclobutanol, the isotope effects, and the Hammett study. It is also consistent with the observed activation parameters (Table 4). A 2 + 2 addition (eq. [3]) would be expected to exhibit a negative entropy of activation in common with most combination reactions that require an organized transition state and result in the loss of one translational degree of freedom. The low enthalpy of activation is also consistent with a 2 + 2 addition of a ruthenium oxo bond to a C—H bond because the energy required for bond cleavage would be partly compensated for by the concurrent formation of new O—H and Ru—C bonds.

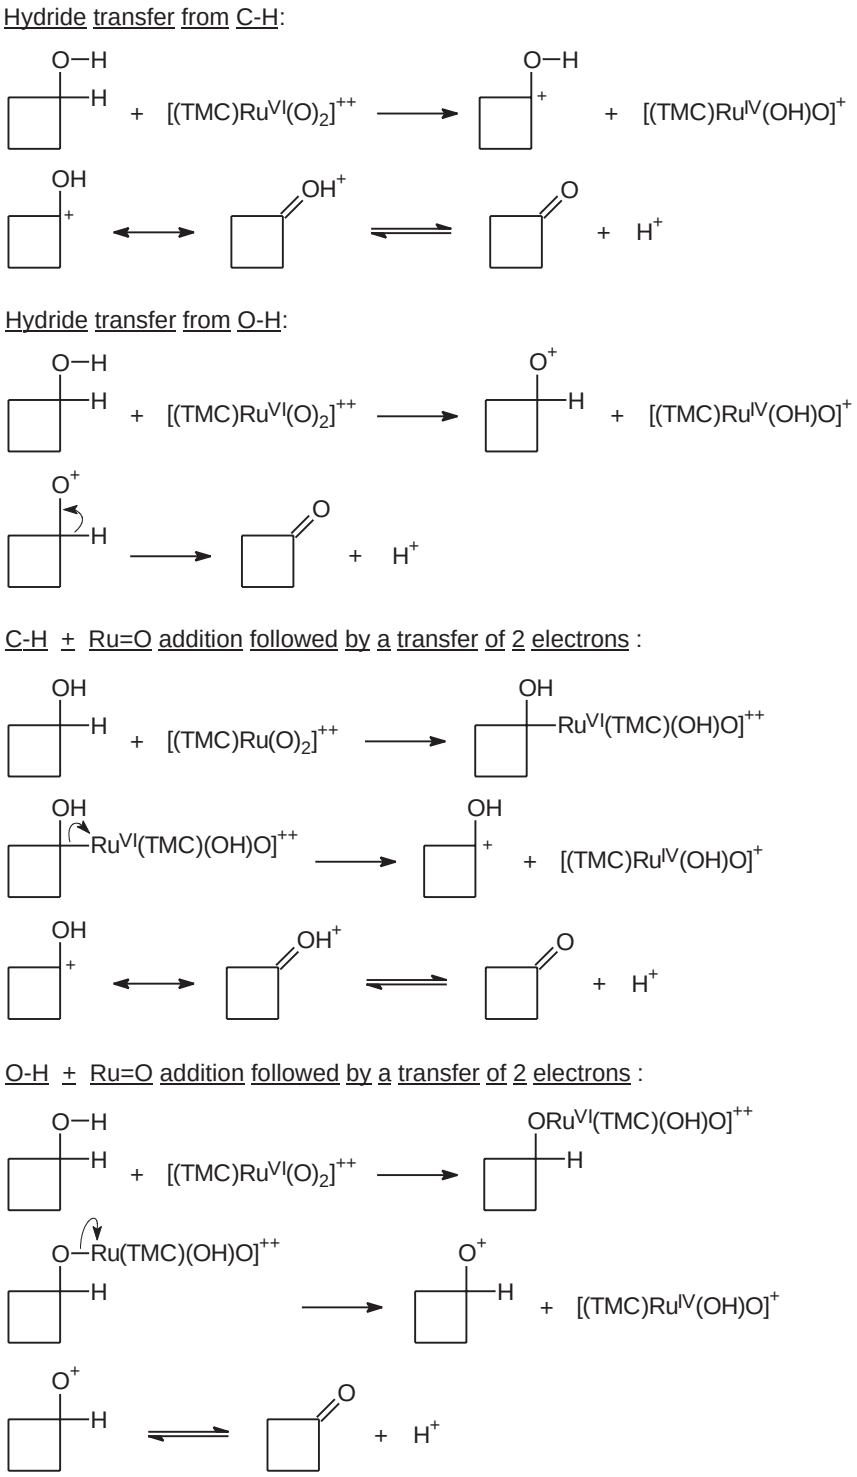
There is, however, a theoretical difficulty associated with the 2 + 2 (C—H + Ru=O) mechanism. Frontier molecular orbital theory suggests that oxidation reactions of this type should involve an initial interaction between the reductant's HOMO and the oxidant's LUMO. The oxidant's LUMO in this case would be an Ru=O π^* antibonding orbital (28), while the reductant's HOMO would be an oxygen 2*p*-nonbonding orbital. Since the LUMO would be centered primarily on the metal, it is predicted on the basis of this theory that the initial reaction would involve ligand formation as in eq. [8].

[8] $Ar_2CHOH + [(TMC)Ru(O)_2]^{++} \longrightarrow (TMC)Ru(O)(O)-OCHAr_2 \rightleftharpoons (TMC)Ru(O)(OH)-OCHAr_2$

3 **4**

© 1998 NRC Canada

Scheme 3.

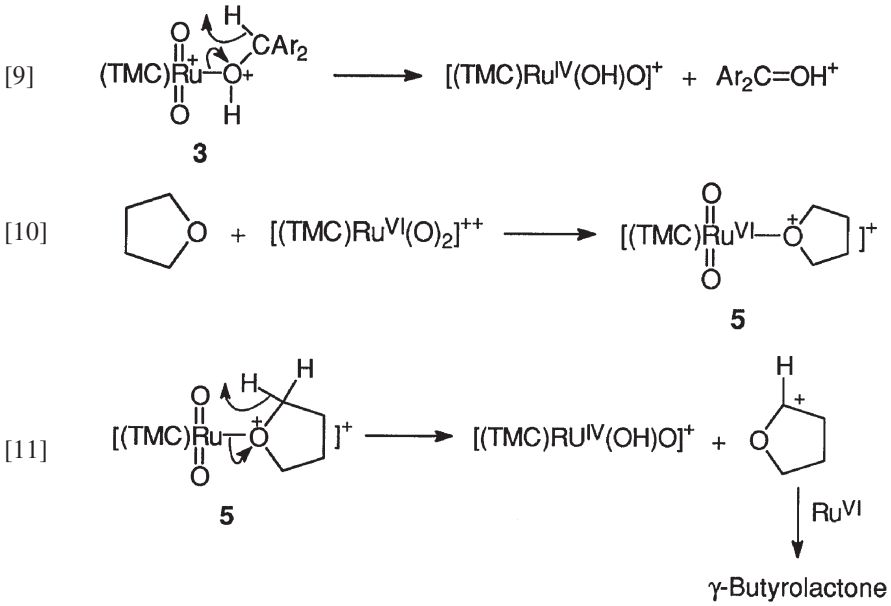


Ligand formation would be followed by proton transfer as in eq. [8] to give **4**, which is formally the 2 + 2 (O—H + Ru═O) addition product. The amounts of **3** and **4** present would be controlled by the relative pK_{BH^+} values for the two compounds. However, the lack of an observable O-D isotope effect (Table 2) suggests that **4** may not be part of the reaction sequence leading to product formation. The aforementioned fact that tetrahydrofuran is readily oxidized by dioxoruthenium(VI) complexes also indicates that a proton transfer would not be an essential part of the reaction if this is the correct mechanism.

The intermediates **3** and **5** for alcohol and ether oxidation, respectively, would decompose to yield oxidized products by a cyclic transfer of hydrogen as depicted in eqs. [9] or [10] and [11]. This mechanism is similar to one recently proposed by Espenson and co-workers (43) for the oxidation of alcohols by $[Cr = O]^{++}$. It is also in general agreement with the theoretical

© 1998 NRC Canada

description of the reaction between methanol and oxidants containing chromium or ruthenium oxos recently published by Deng and Ziegler (22).



The electron flow in these reactions has been indicated as if it involved hydride transfer; however, for cyclic redox mechanisms it is not possible to specify the direction of electron flow, nor whether it occurs by single- or double-electron shifts. The assumption that the oxygen bears a positive charge in the transition state is consistent with the negative Hammett ρ value and with the observation that electronic substituent effects correlate with σ rather than σ^+ values. Since the positive charge is not located adjacent to the aromatic ring in intermediate **3**, direct resonance interactions are not possible.

In common with the 2 + 2 (C—H + Ru═O) reaction mechanism discussed previously, the mechanism defined by eqs. [8] and [9] would be consistent with the unfavorable entropies of activation and the low enthalpies of activation summarized in Table 4. The cyclic, well-organized transition state would be expected to result in an unfavorable entropy of activation and the simultaneous bond making and breaking would be consistent with a low enthalpy of activation. The significant C-D isotope effect and the lack of an observable O-D isotope effect are also consistent with this mechanism.

Both the 2 + 2 (C—H + Ru═O) addition mechanism (eq. [3]) and the ligand association mechanism (eq. [8]) require the introduction of a new ruthenium ligand into the octahedral complex, $[(TMC)Ru^{VI}(O)_2]^{++}$. In eq. [3] the new ligand is attached through carbon to give an organometallic intermediate, while in eq. [8] the new ligand is attached through oxygen giving a ruthenate ester intermediate. Whether these new ligands would be introduced by associative or dissociative mechanisms (44) cannot be determined conclusively on the basis of the experimental evidence currently available. However, the observation made by Che et al. (9) that complexes with more flexible acyclic tetraaza ligands react faster by several orders of magnitude than the corresponding cyclic tetraaza ligands suggests that a dissociative mechanism with loss of an *N*-donor ligand may be most likely (45).

Conclusions

The experimental and theoretical information available with respect to the oxidation of alcohols by dioxoruthenium(VI) complexes is not compatible with several possible redox mechanisms including a single-electron transfer and direct hydrogen atom or hydride ion transfers from either carbon or oxygen. The available information is consistent with both a 2 + 2 (C—H + Ru═O) mechanism (eqs. [3]–[7]) or attachment of the alcohol as a ligand on Ru, followed by a cyclic transfer of hydrogen from the reductant to the oxidant as in eqs. [8] and [9]. Currently available information does not permit a choice between these two possibilities; however, the latter appears to be more consistent with theoretical considerations.

Thermodynamics of methanesulfonic acid, methanesulfonyl chloride, and methyl methanesulfonate

J. Peter Guthrie, Allan R. Stein, and Anthony P. Huntington

Abstract: The heat of formation of liquid methanesulfonic acid, –178.09 ± 1.48, was determined by measuring the heat of reaction of methyl thiolacetate with aqueous hypochlorite solution to give aqueous methanesulfonate and acetate. The heats of formation of liquid methanesulfonyl chloride, –126.91 ± 1.54, and methyl methanesulfonate, –164.34 ± 1.58, were determined by measuring the heats of reaction of methanesulfonyl chloride with water or methanol in the presence of a suitable basic catalyst. Heats of vaporization (based on vapor-pressure data), entropies (based on ab initio molecular orbital calculations), and free energies of transfer from gas phase to aqueous solution were calculated leading to values for the free energies of formation in aqueous solution. The free energies of formation so determined were methanesulfonic acid, –151.72 ± 2.68, methanesulfonyl chloride, –101.29 ± 1.96, and methyl methanesulfonate, –127.28 ± 2.08. From these values the free energies of hydrolysis (leading to unionized methanesulfonic acid) are methanesulfonyl chloride, –25.11 ± 3.04, and methyl methanesulfonate, –9.90 ± 2.48.

Key words: sulfonic acids, heat of formation, free energy of formation, hydrolysis.

Résumé : On a déterminé la chaleur de formation de l'acide méthanesulfonique liquide (–178,09 ± 1,48) en mesurant la chaleur de réaction du thiolacétate de méthyle avec une solution aqueuse d'hypochlorite qui conduit à la formation de méthanesulfonate et d'acétate aqueux. Les chaleurs de formation du chlorure de méthanesulfonyle liquide (–126,91 ± 1,54) et du méthanesulfonate de méthyle (–164,34 ± 1,58) ont aussi été déterminées en mesurant les chaleurs de réaction du chlorure de méthanesulfonyle avec l'eau ou le méthanol en présence d'un catalyseur basique approprié. On a calculé les chaleurs de vaporisation (en se basant sur des données de tension de vapeur), les entropies (en se basant sur des calculs d'orbitales moléculaires ab initio) et les énergies libres de transfert de la phase gazeuse à une solution aqueuse et on en a déduit les valeurs pour les énergies libres de formation en solution aqueuse. Les énergies libres de formation ainsi déterminées sont acide méthanesulfonique, –151,72 ± 2,68, chlorure de méthanesulfonyle, –101,29 ± 1,96, et méthanesulfonate de méthyle, –127,28 ± 2,08. À partir de ces valeurs, les énergies libres d'hydrolyse (conduisant à de l'acide méthanesulfonique non ionisé) sont: chlorure de méthanesulfonyle, –25,11 ± 3,04 et méthanesulfonate de méthyle, –9,90 ± 2,48.

Mots clés : acides sulfoniques, chaleur de formation, énergie libre de formation, hydrolyse.

[Traduit par la rédaction]

Introduction

Although sulfonic esters have been extensively studied as substrates for nucleophilic substitution reactions (1), and are frequently used either as activating or protecting groups in synthesis (2), there has been no direct information about the thermochemistry of these important compounds (3). Values for the thermodynamics of sulfonate ester hydrolysis have been estimated (4), and recently an indirect evaluation of the heats of formation of methanesulfonyl chloride and benzene sulfonyl chloride has been reported (3, 5).

We wish to report calorimetric determinations of the heats of formation of methanesulfonic acid, methanesulfonyl chloride, and methyl methanesulfonate. These are the first determinations of heats of formation of sulfonic acid derivatives based on calorimetric heats of reaction for conversion of a thiol derivative to the corresponding sulfonic acid derivative. Although less direct than a heat of combustion measurement, it is much less indirect than all previous attempts to determine such heats of formation. Although the values are in the same general range as previous estimates, there are substantial differences. We will show that our thermochemical data lead by way of values of the free energies of formation of the ester and acid to a free energy of hydrolysis close to the previous estimate of the free energy of hydrolysis from this laboratory (4). The new value differs by slightly more than the sum of the standard deviations from the old value.

The approach we have used could be applied to many other sulfonic acids and their derivatives so that thermochemical

information about this large and important class of compounds should at last become available.

Results

S-Methyl thiolacetate was used as a (relatively) nonvolatile nonodoriferous equivalent of methanethiol. It reacted rapidly and quantitatively with aqueous sodium hypochlorite solution to give sodium acetate and sodium methanesulfonate. NMR analysis confirmed that no other products were observed and that the signals from acetate and methanesulfonate were in a 1:1 ratio. The observed heat of reaction corresponds to

[1] $$CH_3SCOCH_3(l) + 3NaOCl(soln) + H_2O(soln) \rightleftharpoons CH_3SO_3H(soln) + CH_3COOH(soln) + 3NaCl(soln)$$

By measuring heats of solution for the organic products we were able to derive the heat of reaction for the more convenient hypothetical process:

[2] $$CH_3SCOCH_3(l) + 3NaOCl(soln) + H_2O(soln) \rightleftharpoons CH_3SO_3H(l) + CH_3COOH(l) + 3NaCl(soln)$$

The relevant heats of reaction and solution are found in Table 1. Then from the heats of formation of all reactants and products except methanesulfonic acid we could calculate the heat of formation of methanesulfonic acid. In the case of the starting material, *S*-methyl thiolacetate, we had to estimate the heat of formation of both the gaseous and liquid forms, starting from the accurately known heat of formation of *S*-ethyl thiolacetate. The heat of formation of *S*-methyl thiolacetate could be calculated from that of *S*-ethyl thiolacetate by subtraction of the group contribution for $[CH_2(C)(S)]$. The heat of vaporization of *S*-methyl thiolacetate was estimated from the boiling point, using the correlation that we have reported (6). These literature data are summarized in Table 2, as is our value for the heat of formation of methanesulfonic acid.

The reaction of methanesulfonyl chloride with water required a basic catalyst in order to get sufficiently rapid reaction for calorimetry to be practical. With sodium hydroxide solution, however, the reaction was so rapid and exothermic that spattering of the solution and liquid acid chloride occurred when the ampoule broke, leading to scatter in the measured heat of reaction. Reaction in carbonate buffer, pH 10.2, led to a convenient rate of reaction. The observed heat of reaction refers to the process:

[e] This work.

[3] $CH_3SO_2Cl(l) + H_2O(soln) \rightleftharpoons CH_3SO_3H(soln) + HCl(soln)$

In this process HCl(soln) will actually be sodium bicarbonate, because carbonate buffer will be partially neutralized by the reaction. To bypass the problems of defining the heat of solution of HCl from some known state to the product solution, we used the analogous reaction of acetyl chloride for which the standard heat of formation is known.

[4] $CH_3COCl(l) + H_2O(soln) \rightleftharpoons CH_3CO_2H(soln) + HCl(soln)$

By combining these two reactions, and measuring heats of solution for the organic products, we obtain the convenient, if somewhat artificial process:

[5] $CH_3SO_2Cl(l) + CH_3CO_2H(l) \rightleftharpoons CH_3SO_3H(l) + CH_3COCl(l)$

where the only unknown heat of formation is that of $CH_3SO_2Cl(l)$.

The heat of reaction of methanesulfonyl chloride with methanol also required base catalysis in order to get an adequate rate of reaction. In this case we employed 1% tributylamine in methanol. The observed heat of reaction refers to the process:

[6] $CH_3SO_2Cl(l) + CH_3OH(soln) \rightleftharpoons CH_3SO_3CH_3(soln) + HCl(soln)$

Once again we bypass the problem of determining the heat of solution of HCl by measuring the heat of reaction for the process:

[7] $CH_3COCl(l) + CH_3OH(soln) \rightleftharpoons CH_3CO_2CH_3(soln) + HCl(soln)$

By combining reactions [6] and [7] and measuring heats of solution for the organic products we obtain the convenient process:

[8] $$CH_3SO_2Cl(l) + CH_3CO_2CH_3(l) \rightleftharpoons CH_3SO_3CH_3(l) + CH_3COCl(l)$$

where the only unknown heat of formation is that of $CH_3SO_3CH_3$(l).

For further thermodynamic calculations we wished to have the heats of vaporization for these compounds. For methane sulfonic acid we calculated the heat of vaporization from the Clausius–Clapeyron equation, which fits data including the vapor pressure at 25°C (7). This is based very heavily on one point, the value at 25°C. If we were to use the relationship between heat of vaporization at 25°C and the boiling point and pressure (6) (which is not really applicable, because it is based on non-hydrogen bonding liquids) we obtain an average value of 20 kcal/mol. We have used the Clausius–Clapeyron value of 18 kcal/mol, but assign an error of 2 kcal/mol. For methanesulfonyl chloride and methyl methanesulfonate we calculated the heats of vaporization from literature vapor-pressure data, using the correlation that we have reported (6). These data, and the derived heats of vaporization, are found in Table 3.

Given the heats of vaporization we can calculate the heats of formation of the gaseous compounds; these values are found in Table 4. Entropies were estimated by statistical mechanics, using vibrational frequencies from molecular orbital calculations using Gaussian 92 (8). We used the 6–31 G** Hamiltonian and the default scaling factors for vibrational frequencies from Gaussian 92. This procedure is approximately the E1 method of East and Radom (9). The experimental barrier to torsional rotation of the methyl in methanesulfonyl chloride is 2.1 kcal (10), safely over the 0.84 kcal which East and Radom suggest as the cutoff for using the harmonic oscillator approximation. Since we have not used the full E1 method of East and Radom we make a more pessimistic estimate of uncertainty, i.e., 2 cal deg^{-1} mol^{-1} in $S°$. With estimates in hand we could calculate the free energies of formation of the gaseous molecules: see Table 4.

We are most interested in free energies of formation in aqueous solution. Here the problem is to determine the free energies of transfer, which except in the case of methane sulfonic acid comes down to determining the solubilities.

We begin with methyl methanesulfonate for which the solubility in aqueous solution, 3.16 M, was determined in this work. The vapor pressure can be estimated as 0.331 ± 0.095 Torr (1 Torr = 133.3 Pa) (6) from the vapor pressure at 101°C (11), the heat of vaporization, 13.96 ± 0.70 kcal/mol, estimated as described (6), and the heat capacity of vaporization, –35.24 ± 1.5 cal deg^{-1} mol^{-1}, estimated as described (12). These values lead to a free energy of transfer for methyl methanesulfonate of –5.27 ± 0.18 kcal/mol, and a free energy of formation in aqueous solution of –127.28 ± 2.08.

To estimate the free energy of transfer for methanesulfonic acid, we first examined the relationship between the difference in free energies of transfer of acids and their methyl esters, and the pK_a of the acids. Our expectation was that the difference in free energy of transfer would be dominated by hydrogen bonding effects, which would be related to the pK_a. The available data, found in Table 5, led to the correlation equation $\Delta\Delta G_t = -(6.06 \pm 0.66) + (0.732 \pm 0.20)\ pK_a$, and a predicted value for methanesulfonic acid of $\Delta G_t = -12.73 \pm 0.79$ kcal/mol.

Alternatively we interpolate between dimethyl sulfone and

© 1998 NRC Canada

sulfuric acid. The vapor pressure of dimethyl sulfone can be estimated as 0.0100 ± 0.0024 Torr (6) from the boiling point at 1 atm (1 atm = 101.325 kPa) (13), the heat of vaporization, 15.10 ± 0.30 kcal/mol (14), the heat capacity of vaporization, –28.06 ± 1.5 cal deg^{-1} mol^{-1}, estimated as described (12), the heat of sublimation, 18.40 ± 0.67 kcal/mol (14), and the heat capacity of sublimation, –6.06 ± 1.5, calculated from the heat capacity of the gas estimated by Benson's additivity method (15), and the heat capacity of the solid estimated by Kopps law (16). The hypothetical ideal solubility of the supercooled liquid can be estimated as log s = 2.78 ± 0.04 (M) from the partition constant, log P = –1.34 (17), and the relation between log P and log s (18). Then using the heat of fusion, 3.3 ± 0.6 kcal/mol (14), we can calculate the hypothetical ideal solubility of the solid as log s = 2.25 ± 0.56. With these values in hand the free energy of transfer can be calculated as –9.74 ± 0.78 kcal/mol. The free energy of transfer for H_2SO_4 can be calculated from the free energy of formation in the gas, –156.20 ± 2.01 (19), and in aqueous solution, –176.84 ± 0.69, as –20.65 ± 2.13. By interpolation, which assumes simple group additivity, we obtain ΔG_t = –15.20, with an uncertainty of several kilocalories because the assumption of simple group additivity is unlikely to be exact. The two values seem to be in agreement. A similar estimation of the value (calculated above) for ΔG_t of methyl methanesulfonate can be made by interpolation between the value for dimethyl sulfate (–3.2 kcal/mol (4)) and that for dimethyl sulfone. The value so obtained is –6.47, again with an uncertainty of several kilocalories because the assumption of simple group additivity is unlikely to be exact. The agreement here is better.

We hoped to determine the solubility of methanesulfonyl chloride, despite its rapid hydrolysis, by determining the pseudo-zero order rate of reaction for a saturated solution (20), but the process proved to be too rapid to follow titrimetrically. Instead we determined the free energy of transfer of propanesulfonyl chloride and estimated that of methanesulfonyl chloride by group additivity. For propanesulfonyl chloride the zero order rate of hydrolysis, at a pH of approximately 2.7, was 2.57×10^{-5} M s^{-1}, while the rate constant for uncatalyzed hydrolysis is 3.93×10^{-4} s^{-1} (21). These values lead to a solubility of 0.065 M. From vapor-pressure data in Beilstein we could calculate (6) the heat of vaporization as 12.88 ± 0.09 kcal/mol. The heat capacity of vaporization was estimated from that of dimethyl sulfone by atomic additivity (12), as –30.67 cal deg^{-1} mol^{-1}. The vapor pressure can then be estimated (6) as 0.67 Torr. From the solubility and vapor pressure we obtain ΔG_t for propanesulfonyl chloride as –2.55 ± 0.23.

The free energy of transfer for methanesulfonyl chloride could be estimated from that for propanesulfonyl chloride by means of the group contribution for a CH_2 group (22); in this way we obtained ΔG_t = –2.97 ± 0.27.

Now we can calculate the free energy of formation of aqueous methanesulfonic acid as –151.72 ± 2.68, of aqueous methyl methanesulfonate as –127.28 ± 2.08, and of aqueous methanesulfonyl chloride as –101.29 ± 1.96.

With free energies of formation in hand we can calculate the free energy of hydrolysis for methyl mesylate:

$$CH_3SO_3CH_3(aq) + H_2O(l) \rightleftharpoons CH_3SO_3H(aq) + CH_3OH(aq)$$

as –9.90 ± 2.48 kcal/mol (4). We have previously estimated this quantity as –5.4 ± 1.6 kcal/mol. The agreement is not as good as might be desired, but the difference is only just outside the sum of the standard deviations.

Table 5. Difference in free energy of transfer between acids and methyl esters as a function of acid pK_a.[a]

Acid	pK_a	ΔG_t acid	ΔG_t ester	$\Delta\Delta G_t$
H_2SO_4	–2.8[b]	–19.96[b]	–3.2[b]	–8.38[c]
HNO_3	–1.3[b]	–6.79[b]	1.09[b]	–7.88
CH_3COOH	4.76[d]	–4.80[e]	–1.42[e]	–3.38
CF_3COOH	–0.78[f]	–4.88[g]	0.80[g]	–5.68
HCOOH	3.77[d]	–4.94[e]	–0.88[e]	–4.06
PhCOOH	4.17[d]	–5.80[e]	–1.88[e]	–3.92

[a] Free energies of transfer have units of kcal/mol for transfer from ideal gas at 1 atm to ideal 1 M aqueous solution with an infinitely dilute reference state.
[b] Reference 4.
[c] Corrected for the number of OH groups by dividing by two.
[d] Reference 44.
[e] Reference 42.
[f] References 45 and 46.
[g] Reference 47; both values involved some estimated quantities.

Similarly we can calculate the free-energy change for the hydrolysis of methanesulfonyl chloride:

$$CH_3SO_2Cl(aq) + H_2O(l) \rightleftharpoons CH_3SO_3H(aq) + HCl(aq)$$

as –25.11 ± 3.05 kcal/mol (calculated for undissociated methanesulfonic acid, but dissociated HCl).

Discussion

Liebman (3), in a thorough review of the literature on thermochemistry of sulfonic acid derivatives, estimated the heat of formation of liquid methanesulfonic acid as –147 kcal/mol, that of the liquid methyl ester as –135, and that of the liquid mesyl chloride as –101 kcal/mol. The corresponding values from this work are –178.09 ± 1.48, –164.34 ± 1.58, and –126.91 ± 1.54. Liebman's values ultimately all depend on the heat of reaction for the chlorosulfonation of *n*-dodecane to a mixture of primary and secondary dodecanesulfonyl chlorides (3*b*) from which he deduced the heat of formation of *n*-dodecanesulfonyl chloride and *n*-dodecanesulfonic acid, and then scaled to methanesulfonic acid and its chloride by a form of group additivity. It should be noted that the differences in heat of formation are in better agreement: ΔH_f(l) acid – ΔH_f(l) ester = 12 (ref. 3) or 15 (this work); ΔH_f(l) acid – ΔH_f(l) chloride = 46 (ref. 3), 51 (this work).

Chatgilialoglu et al. (5) derived, from photoacoustic calorimetry experiments, a bond dissociation energy for CH_3SO_2-Cl that leads to a heat of formation of gaseous methanesulfonyl chloride of –101.1, where our value is –115.37 ± 1.73. It should be noted that Chatgilialoglu et al. did not report a heat of formation for methanesulfonyl chloride, but they did calculate a heat of formation for benzenesulfonyl chloride; the only additional number needed to calculate a heat of formation of gaseous methanesulfonyl chloride was a heat of formation for methanesulfonyl radical for which a value is available in the literature (23). The difficulty may lie in the necessarily indirect determination of the heat of formation for methanesulfonyl radical. Thus our new values deviate significantly from the

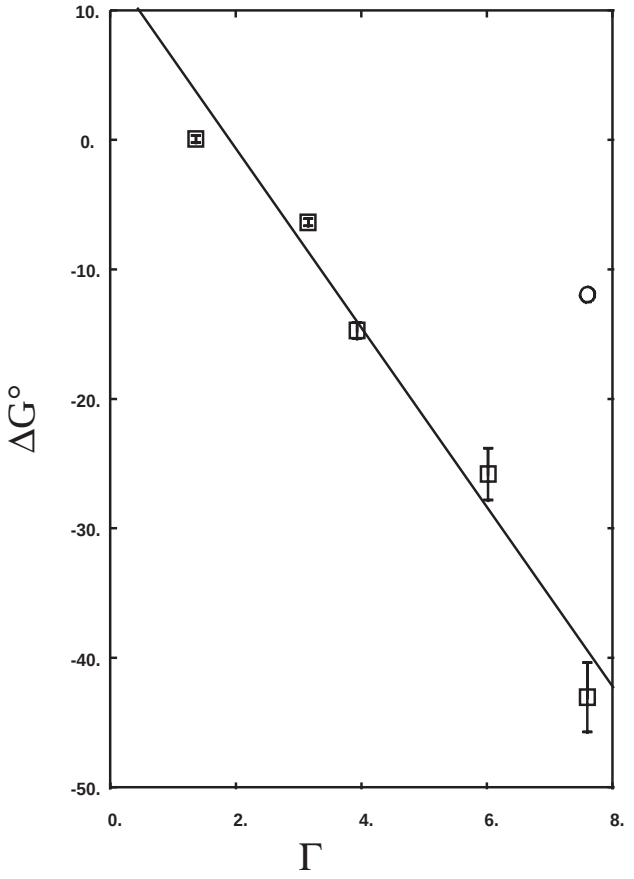
Fig. 1. Free-energy change (kcal/mol) for reaction [9] as a function of Γ for the nucleophile. The line was determined by least squares to the points $\Delta G° = -(12.3 \pm 1.7) - (6.85 \pm 0.69)\Gamma$. The points (□) represent (from left to right) the reactions of CH_3OH, $(CH_3)_2NH$, CH_3CH_2SH, HCN, and HSO_3^- with CH_3OH. The error bars correspond to the estimated standard deviations; 95% confidence limits would be twice as large. The point (○) represents the reaction of HSO_3^- based on the heat of formation in ref. 3.



best previous estimates, which unavoidably involved extended arguments.

We believe that the new calorimetric technique reported in this paper will provide a convenient method for determining the heats of formation of sulfonic acids, for which there has been a surprising dearth in the literature (3). Further applications of this approach from this lab will be reported in due course. The principal limitations on the approach are as follows. (*i*) The heat of reaction is large so that even with a small relative error, 0.59% in this case, the absolute uncertainty in the heat of reaction is 1.4 kcal/mol. It will be difficult to improve this. (*ii*) The compound OCl^- is a powerful oxidant, which limits the other functional groups that can be present in the initial thiol or thiol equivalent. (*iii*) The heat of formation of the thiol (or thiol equivalent) used as starting material must be available. Since heats of formation for many of the simple thiols are available this is not a severe restriction.

Once the heat of formation of a sulfonic acid has been determined, heats of formation of other derivatives at the sulfonate level of oxidation can be determined by measurement of heats of reaction of the corresponding sulfonyl chloride, as we have demonstrated here.

Table 6. Free-energy changes for reaction [9].[a]

Nucleophile	Γ	$\Delta G°$
CH_3OH	1.36	0.07 ± 0.28
$(CH_3)_2NH$	3.15[b]	–6.36 ± 0.28
CH_3CH_2SH	3.93[c]	–11.65 ± 0.63
HCN	6.02	–25.81 ± 2.00
HSO_3^-	7.60	–43.03 ± 2.68[d]
		–11.93[e]

[a] In water at 25°C; free energies in kcal/mol; Γ values calculated from γ values from ref. 25 except as noted; $\Delta G°$ values calculated from data in Table 4.

[b] The value for morpholine (25) was used; morpholine, piperidine, and piperazine have very similar γ values (25).

[c] The value for β-mercaptoethanol (25) was used; β-mercaptoethanol, methoxyethanethiol, and ethanethiol have very similar equilibrium constants for addition to acetaldehyde or isobutyraldehyde (48).

[d] The equilibrium gives methanesulfonate anion; the free-energy change was calculated using the pK_a of methanesulfonic acid (49).

[e] Calculated using the value for $\Delta H°_f(l)$ for methanesulfonic acid from ref. 3.

As a further test of the consistency of our value for the free energy of formation of methanesulfonic acid, we have examined the (hypothetical) equlibrium processes

[9] $$CH_3OH + H\text{-}Nu \rightleftharpoons CH_3\text{-}Nu + H\text{-}OH$$

The free-energy change for such reactions can be calculated from the free energies of the four species involved. This free energy is expected to be linear in Γ (24) (where Γ is related to the Sander and Jencks γ values (25); $\Gamma = \gamma_{HNu} - \gamma_{H_2O}$) by analogy with carbonyl reactions, which can be expressed (24) as

$$R_1R_2C(OH)_2 + H\text{-}Nu \rightleftharpoons R_1R_2C(OH)(Nu) + H\text{-}OH$$

Data are available for five such reactions; the data are found in Table 6. Figure 1 shows that there is indeed an approximate relationship of the form expected; this suggests that the new thermodynamic data in this paper are indeed consistent with the body of existing information, and suggests a novel way to make approximate estimates of the free energy of formation in solution of other alkanesulfonate ions. The line in Fig. 1 was calculated by an unweighted least-squares fit to the points. One ought to use weighted least squares, but in this case the two points with the smallest calculated uncertainty are both at one end of the plot, and would essentially determine the slope. Because of the uncertainties in the points at high Γ this test is less rigorous than one would like, but it clearly shows that our value for methanesulfonate is in much better agreement with other thermodynamic data from the literature than the best previous estimate (3).

Experimental

Materials

S-Methyl thiolacetate, methanesulfonic acid, methanesulfonyl chloride, propanesulfonyl chloride, methyl methanesulfonate, acetyl chloride, and tributylamine were purchased as reagent grade; purity was checked and materials were redistilled as necessary. Sodium hypochlorite was purchased as a 5% analytical reagent solution (Malinckrodt). The sodium hypo-

© 1998 NRC Canada

chlorite solution used for calorimetry was made up by diluting 35 mL of 5% sodium hypochlorite to 100 mL with distilled water. Methanolic tributylamine was made up with a molar ratio of 100:1. Carbonate buffer for the hydrolysis of methanesulfonyl chloride was made by dissolving 22.35 g $NaHCO_3$ and 4.70 g NaOH in a total volume of 500 mL using CO_2-free distilled water.

Methods

Boiling points at reduced pressures were determined as previously described (26). Calorimetric measurements were carried out using a Tronac Model 458 isoperibol calorimeter. Data were captured by computer and analyzed using software from Tronac, as has been described (27).

The solubility of propanesulfonyl chloride was determined indirectly (20) by titrimetric kinetic measurements. Water (25 mL) was charged to a jacketed reaction vessel maintained at 25 ± 0.1°C by a circulating water bath. This was allowed to equilibrate for 10 min before initiation of the experiment by injection of 400 mL of propanesulfonyl chloride. The contents of the reaction vessel were stirred rapidly to ensure complete dispersion of the excess propanesulfonyl chloride throughout the solvent. The stirring rate was kept constant between replicate runs to ensure uniformity of the experimental conditions. The pH of the aqueous solution was monitored throughout the experiment using a Fisher Scientific Accumet pH meter and was allowed to fall uncontrolled for the first 2 min to allow the solution to reach saturation. After this time the pH was held constant at a convenient value (i.e., one where only water-catalyzed hydrolysis would take place) by titration with aqueous sodium hydroxide (0.297 M). The uptake of sodium hydroxide was measured as a function of time. Since the propanesulfonyl chloride was always in excess the concentration of the substrate dissolved in water is constant throughout the experiment. The uptake of sodium hydroxide is therefore a pseudo-zero order rate process. A plot of concentration of base versus time gave a straight line of slope $2k_0$. Each mole of hydrolyzed sulfonyl chloride produces two moles of acid. Therefore, the rate of uptake of base is twice the rate of hydrolysis. The solubility could then be calculated from the known rate constant for uncatalyzed hydrolysis (21).

The aqueous solubility of methyl methane sulfonate was determined by NMR analysis. A standard solution of sodium 3-trimethylsilylpropanesulfonate (DSS) (125.06 mg) in water (5 mL) was prepared. Four 5 mL volumetric flasks were filled with distilled water, which had been adjusted to pH = 5.67 with dilute HCl (to prevent hydrolysis of the ester). An excess of methyl methane sulfonate was then added to each of these flasks and the flasks shaken vigorously. They were then placed in a water bath maintained at 25 ± 0.1°C and allowed to stand, with periodic shaking, for 1 h. Four NMR tubes were then filled with 300 mL of the standard solution and 300 mL of the aqueous methyl methane sulfonate, which was carefully withdrawn from the top of each volumetric flask after they had been allowed to settle for a further 10 min. A sealed capillary tube containing D_2O was then placed inside each NMR tube (to provide a lock signal). The ^1H NMR was then run for each of the samples. The NMR spectra taken after 24 h confirmed that no hydrolysis had taken place. Integration of the signals from the methyl groups of methyl methanesulfonate and DSS were used to determine the solubility: the value so determined was 3.16 ± 0.25 M.

Carbon–carbon coupling of 4,6-dinitrobenzofuroxan with 3-aminothiophenes: a kinetic and structural study

François Terrier, Marie-José Pouet, Khalid Gzouli, Jean-Claude Hallé, Francis Outurquin, and Claude Paulmier

Abstract: Potentiometric measurements carried out in a 50–50 (v/v) H_2O–Me_2SO mixture together with ^1H and ^{13}C NMR studies carried out in pure Me_2SO-d_6 reveal that 3-aminothiophene (**4a**), 3-*N*-(methylamino)thiophene (**4b**), and 3-*N*,*N*-dimethylaminothiophene (**4c**) undergo protonation exclusively at the amino groups in dilute acid solutions. The pK_a values of **4a**, **4b**, and **4c** are equal to 3.38, 3.65, and 3.53, respectively, at 25°C, comparing well with those for related anilines in the same aqueous Me_2SO mixtures. However, despite this similarity of the nitrogen basicities, compounds **4a**, **4b,** and **4c** are found to behave differently from anilines upon treatment with super-electrophilic 4,6-dinitrobenzofuroxan (DNBF). While anilines react to give first an N-bonded σ-adduct that subsequently decomposes to afford the thermodynamically more stable C-bonded adduct, the 3-aminothiophenes react only as carbon nucleophiles, giving rise directly to the corresponding C-adducts. Based on ^1H and ^{13}C NMR data as well as measurements of the rate constants (k_1^{DNBF}) for DNBF addition to **4a**, **4b,** and **4c**, it is demonstrated that 3-aminothiophenes possess such high negative charge density at C-2 that they can be regarded as strongly enaminic in nature. Estimates of the pK_a values for protonation at C-2 of **4a**, **4b**, and **4c** could be made: $pK_a^{\mathbf{4a}} \approx -0.4$; $pK_a^{\mathbf{4b}} \approx 0.2$; $pK_a^{\mathbf{4c}} \approx 0.8$. Thus, these compounds are more susceptible to electrophilic addition at this position than most of the five-membered ring heterocycles studied so far. Altogether, the results demonstrate the importance of the hyper-*ortho* relationship in the thiophene systems, accounting for the ease of both electrophilic and nucleophilic reactivity of 3-X-thiophenes in σ-complex formation processes.

Key words: aminothiophenes, enamines, superelectrophiles, dinitrobenzofuroxan, hyper-*ortho* relationship.

Résumé : Des mesures potentiométriques effectuées dans un mélange 50/50 (v/v) de H_2O/Me_2SO et des études de RMN du ^1H et du ^{13}C effectuées dans du Me_2SO-d_6 révèlent que, en solutions diluées d'acide, les 3-aminothiophène (**4a**), 3-*N*-méthylaminothiophène (**4b**) et 3-*N,N*-diméthylaminothiophène (**4c**) se protonent exclusivement au niveau des groupes aminés. À 25°C, les valeurs de pK_a des composés **4a**, **4b** et **4c** sont respectivement égales à 3,38, 3,65 et 3,53 et elles se comparent avantageusement à celles des anilines correspondantes dans les mêmes mélanges aqueux de Me_2SO. Toutefois, malgré cette similarité dans les basicités, on a observé que les composés **4a**, **4b** et **4c** ont des comportements différents de ceux des anilines lors de leur traitement par le 4,6-dinitrobenzofuroxane (DNBF) superélectrophile. Alors que les anilines réagissent pour donner en premier lieu un adduit-σ lié à l'azote qui se décompose ultérieurement pour conduire à l'adduit lié au carbone qui est thermodynamiquement plus stable, les 3-aminothiophènes ne réagissent que comme des nucléophiles carbonés conduisant directement aux adduits-C correspondants. Sur la base de données de RMN du ^1H et du ^{13}C ainsi que de mesures de constantes de vitesse (k_1^{DNBF}) pour l'addition de DNBF sur les composés **4a**, **4b** et **4c**, on peut démontrer que les 3-aminothiophènes portent une densité de charge négative tellement élevée en C-2 que l'on peut considérer qu'ils ressemblent fortement aux énamines. On a pu évaluer que les valeurs de pK_a pour la protonation en C-2 des composés **4a**, **4b** et **4c** sont respectivement –0,4, 0,2 et 0,8. Ces composés sont donc plus susceptibles à une réaction d'addition électrophile dans cette position que la plupart des composés hétérocycliques à cinq chaînons qui ont été étudiés jusqu'à maintenant. Dans l'ensemble, les résultats démontrent l'importance de la relation hyper-*ortho* dans les systèmes du thiophène; elle explique la réactivité tant électrophile que nucléophile des 3-X-thiophènes dans les processus de formation de complexes σ.

Mots clés : aminothiophènes, énamines, superélectrophiles, dinitrobenzofuroxane, relation hyper-*ortho*.

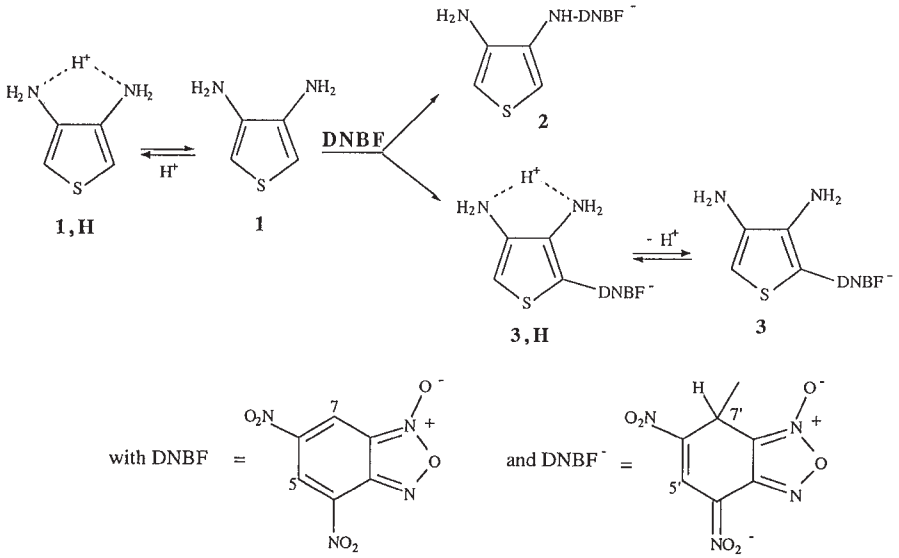
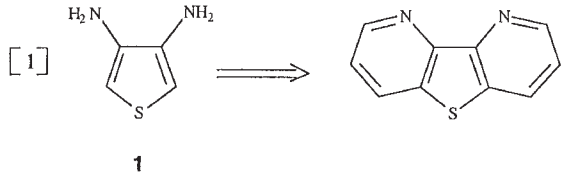
Scheme 1.



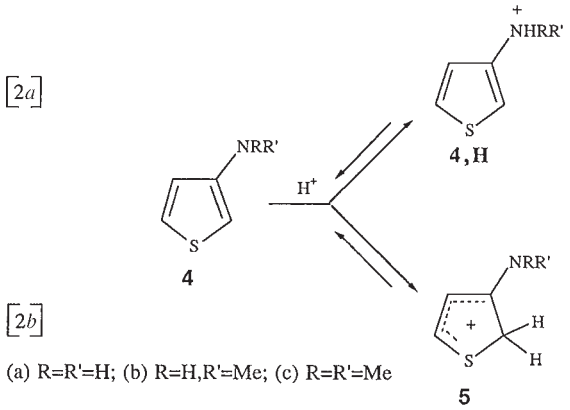
Various synthetic procedures have been described that have afforded facile access to a number of 3-amino and 3,4-diaminothiophene derivatives (1–3). A remarkable feature of these compounds is their ability to act as nitrogen as well as carbon nucleophiles towards a number of electrophiles (2, 4, 5). This ambident behaviour has proven to be especially useful for building certain fused ring systems; a prototype example is shown in eq. [1] (2).



The increasing interest in the chemistry of aminothiophenes called for better understanding of the factors governing their reactivity (6–11). In this context, we have recently undertaken a potentiometric and NMR study of the protonation of 3,4-diaminothiophene **1** in water–Me_2SO mixtures and have investigated the kinetics of the reaction of this compound with 4,6-dinitrobenzofuroxan (DNBF), a super-electrophilic compound known to be a good probe for assessing the carbon nucleophilicity of very weak carbon bases (12–18). The results obtained have provided clear evidence that the proton affinity of the amino groups to give the cation **1,H** is considerably greater than that of the α-carbon but that the electrophilic coupling of DNBF at C-2 of **1** to give the carbon-bonded adduct **3,H** is both kinetically and thermodynamically favored compared to the coupling at the amino groups to give the N-adduct **2** (Scheme 1). On these grounds, we concluded that this behaviour of **1** must be the reflection of an appreciable enaminic character (12).

In the course of our NMR investigation of the reactivity of **1** towards H^+ and DNBF, we made the interesting observation that the resonances of the H_2 and C_2 atoms of **1** appear at considerably higher field than analogous resonances for common thiophene derivatives (19). Surprisingly, little attention was paid previously to this feature, and so we decided to

Scheme 2.



extend our measurements to a number of 3-aminothiophenes. In this paper, we report a detailed structural, thermodynamic, and kinetic investigation of the protonation (Scheme 2) and substitution by DNBF (Scheme 3) of the three monoamino compounds **4a–c** in 50:50 (v/v) H_2O–Me_2SO and (or) pure Me_2SO. As will be seen, our collected data support the idea that 3-aminothiophene derivatives exhibit a strong enaminic behaviour. Moreover, our results emphasize the extent to which the hyper-*ortho* relationship governs the reactivity of the 3-X-thiophene systems, especially in electrophilic and nucleophilic processes.

Results

Protonation of 4a–c

The protonation behaviour of **4a–c** was first studied by ^1H and ^{13}C NMR. Addition of increasing amounts of a strong acid, namely methanesulfonic acid, to a solution of **4a**, **4b,** or **4c** in Me_2SO-d_6 results in a progressive and significant deshielding of the AMX system representative of the H_2, H_4, and H_5 resonances of these compounds. This deshielding is essentially complete after addition of 1 equiv. CH_3SO_3H (Table 1), which

supports the quantitative formation of the cations **4a–c,H** (eq. [2*a*] in Scheme 2). No evidence for the appearance of new absorption patterns consistent with the occurrence of a protonation process at C-2 to give the C-adducts **5a–c** according to eq. [2*b*] could be found in the ^{1}H NMR spectra. Similar conclusions could be formulated on the basis of the chemical shift variations observed in the ^{13}C NMR spectra (Table 2). Clearly, the very large downfield shifts engendered by the C-2 carbons upon protonation of **4a–c** can only be accounted for in terms of the formation of the nitrogen cations **4a–c,H**.

Because of the poor solubility of **4a–c** in aqueous solution, we have measured the pK_a values associated with the equilibrium [2*a*] in Scheme 2 in a 50:50 (v/v) H_2O–Me_2SO mixture, using a standard potentiometric procedure (see Experimental section). The results obtained at 25°C (I = 0.1 M, KCl) are given in Table 3, together with those for nitrogen protonation of 3,4-diaminothiophene **1** and the corresponding anilines **8a–d** under equal or rather similar experimental conditions (12, 20).

4b, or **4c** at room temperature resulted in the immediate and quantitative formation of the zwitterionic C-bonded adducts **6a–c,H** (cf. Scheme 3). In addition to the presence of the AB systems expected for the H4 and H5 protons of the thiophenic ring, the ^1H NMR spectra showed the presence of AX systems typical of the negatively charged DNBF moieties of related carbon-bonded σ-complexes (H5′,H7′) (12, 13, 15–17, 21), e.g., $\delta_{H4} = 7.57$, $\delta_{H5} = 7.74$, $J_{H4-H5} = 5.6$, $\delta_{H5'} = 8.68$, $\delta_{H7'} = 6.36$ for the *N,N*-dimethyl adduct **6c,H**. A most noteworthy feature, however, derives from the ^{13}C NMR data, which reveal that substitution of **4a-c** by DNBF results in a significant downfield shift of the C-2 carbon of the thiophene ring ($\Delta\delta \approx 35$ ppm). Such a $\Delta\delta$ value is actually typical of formation of the zwitterionic structure **6,H**, being the reflection of two effects: (*i*) the fact that a negatively charged DNBF moiety still exerts a considerable *–I* effect (13, 14, 21); (*ii*) the presence of the positive charge at the amino group. Interestingly, lower values of the order of 12.5–13 ppm, consistent with those generally observed at the sites of substitution of aromatic or heteroaromatic positions by DNBF (e.g., $\Delta\delta \approx 10$ ppm for formation of the indole adducts **9** (21*a*)) are obtained when comparing δC_2 between **6a–c,H** and the related protonated thiophenes **4,H**. On the other hand, we have observed that use of an excess of the aminothiophene reagent over DNBF leads partially to the conversion of **6a–c,H** to the conjugate anionic bases **6a–c**. Complete conversion of **6b,H** to **6b** could be effected by adding 3 equiv. of triethylamine to a solution resulting on mixing equimolar amounts of DNBF and **4b**. As can be seen in Tables 1 and 2, the process is accompanied by significant upfield shifts of the proton and carbon resonances of the thiophenic ring but, because of the *–I* effect of the DNBF moiety, the C-2 resonance of **6b** still appears at lower field than in the parent thiophene. However, the observed shift ($\Delta\delta \approx 17$ ppm) is now reduced, comparing well with that found on formation of the 3-methoxythiophene σ-adduct **11** from the parent thiophene **10** ($\Delta\delta \approx 18$ ppm) (21*c*). As will be emphasized in our discussion, this finding of a greater value when comparing **4** and **6** rather than **4,H** and **6,H**,reflects the fact that the C-2 position of **4**, as well as that of 3-methoxythiophene, is markedly

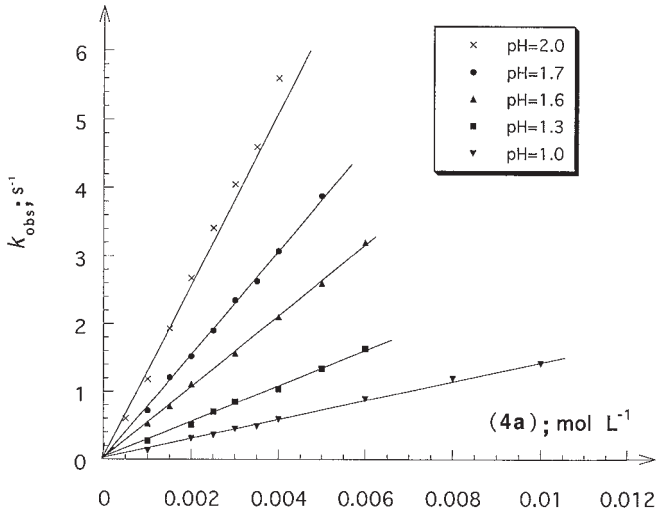
Fig. 1. Influence of the concentration of 3-aminothiophene **4a** and pH on the observed first-order rate constant k_{obs} for addition of DNBF in 50:50 (v/v) H_2O–Me_2SO at $T = 25°C$.



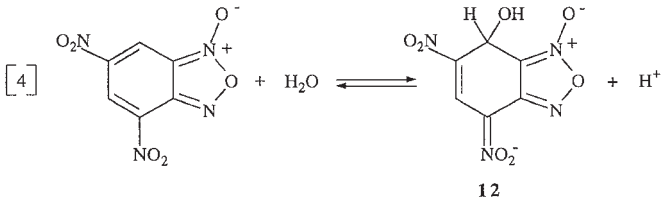
shielded as compared with that of other 3-X thiophenes, due to an especially strong +M effect of the NR_2 and OMe groups (structures **4,E** and **10,E**).

The three zwitterionic adducts **6a–c,H** could be isolated as crystalline solids from experiments carried out at –60°C in THF (see Experimental section). Dissolution of these compounds in Me_2SO-d_6 gave NMR spectra identical to those recorded in the in situ experiments. In any of the above NMR experiments, signals ascribable to the isomeric N-adducts **7,H** or **7** (Scheme 3) could be detected in the recorded spectra. The structures of **6a–c,H** were confirmed by mass spectral experiments. In addition, the visible spectra of **6a–c,H** recorded in 50:50 (v/v) H_2O–Me_2SO were typical of C-bonded σ-adducts of DNBF: $\lambda_{max} = 481$ nm for **6a,H** and **6b,H** and 479 nm for **6c,H** (12, 14–16, 21).

For purposes of comparison, Tables 1 and 2 contain the ^1H and ^{13}C NMR data for the **4a–c** – DNBF systems as well as those for the previously studied 3-methoxythiophene– and 3,4-diaminothiophene–DNBF systems (12, 21*c*).

Kinetic studies

The kinetics of reactions of **4a–c** with DNBF were studied at 25°C under pseudo-first-order conditions with respect to the thiophene reagents as the excess components in 50:50 (v/v) H_2O-Me_2SO. Experiments were carried out by mixing various HCl solutions of DNBF (3×10^{-5} M) with equal volumes of solutions of **4a–c** (10^{-3}–10^{-2} M) in a stopped-flow apparatus. The HCl concentrations of the DNBF solutions were chosen so as to afford, after mixing, H^+ concentrations in the range 0.01–0.1 M ($I = 0.1$ M KCl). Under these experimental conditions, the three aminothiophenes **4a–c** were present essentially in their protonated forms. Only one relaxation time corresponding to the quantitative formation of the C-adducts **6a–c,H** was observed in all cases. In particular, no interference between the formation of these adducts and that of the hydroxy adduct **12** according to eq. [4] was detected (17*a*, 22).



The most reasonable mechanism for the complexation process is described in eq. [3*b*] of Scheme 3, which involves the attack of DNBF by equilibrium concentrations of **4a–c**. The general expression for the observed first-order rate constants, k_{obs}, for the formation of the adducts **6,H**, as derived under the assumption that the "Wheland–Meisenheimer" zwitterion $ZH^{\pm}$ is a low concentration ("steady-state") intermediate, is given by

$$[5] \quad k_{obs} = \frac{k_1^{DNBF} k_2}{k_{-1} + k_2} \frac{K_a}{K_a + [H^+]} [\mathbf{4a–c}]_0$$

which reduces to

$$[6] \quad k_{obs} = \frac{k_1^{DNBF} k_2}{k_{-1} + k_2} \frac{K_a}{[H^+]} [\mathbf{4a–c}]_0 = k [\mathbf{4a–c}]_0$$

at the different pH's studied ($[H^+] >> K_a$).

In accord with eq.[6], excellent linear plots of k_{obs} vs. the total concentration of the aminothiophene reagent ($[\mathbf{4a–c}]_0 = [\mathbf{4a–c}] + [\mathbf{4a–c,H}]$) were obtained at each pH studied (Fig. 1). Table 4 summarizes the values of the second-order rate constants k, which were readily determined from the slopes of

these plots in the three DNBF–aminothiophene systems studied.

Also given in Table 4 are the *k* values corresponding to a series of experiments carried out with the 2-deuteriated-3-aminothiophenes. As can be seen, the results do not reveal a significant influence of the nature of the isotopic substitution at C-2 on the rates of formation of **6a–c,H**; the measured k_H/k_D ratios are 1.1 ± 0.1. This absence of a significant isotope effect shows that proton removal from the zwitterionic intermediate $ZH^{\pm}$ is rapid and that the rate-determining step of the complexation is the nucleophilic addition step, i.e., $k_2 >> k_{-1}$ in Scheme 3 (12,14, 21*a*, 21*c*). Accordingly, the expression of the second-order rate constant *k* takes on the simplified form of eq. [7]:

$$[7] \qquad k = \frac{k_1^{DNBF} K_a}{[H^+]}$$

from which values of the second-order rate constant k_1^{DNBF} for the addition of **4a–c** to DNBF could be readily calculated at each pH (Table 4). The average values of k_1^{DNBF} obtained for the three systems in 50:50 (v/v) H_2O–Me_2SO are compared in Table 5 with similar data previously reported for DNBF addition to 3,4-diaminothiophene **1**, 3-methoxythiophene **10**, and a number of 5-X substituted indoles (**9a–f**) as well as a few pyrrole derivatives (**13a–d**).

Discussion

Nitrogen vs. carbon basicity of 4a–c

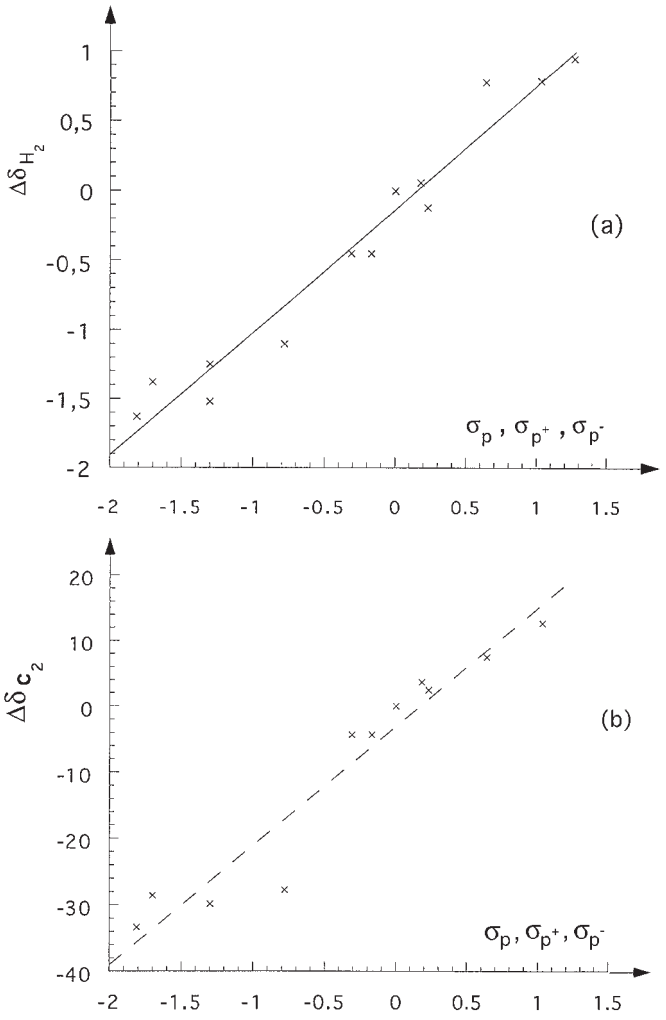
As seen from the results in Table 3, the pK_a values associated with protonation of the three monoaminothiophenes **4a–c** in 50% H_2O–Me_2SO are very similar to those for the related 3,4-diamino compound **1** and the anilines **8a–d**. These results agree well with the NMR experiments carried out in pure Me_2SO, which show unambiguously that protonation of **4a–c**, as well as that of **1**, occurs exclusively on nitrogen in the presence of a strong acid such as methanesulfonic acid (Scheme 2). However, important information for understanding the reactivity of **4a–c** derives from comparison of the H_2 and C_2 chemical shifts of these compounds with those previously reported for a number of 3-X-substituted thiophenes (19, 23). These chemical shifts are collected in Table 6.

The first noteworthy feature in Table 6 is that introduction of an amino group at C-3 of the thiophene ring induces, as does that of a methoxy group, a large upfield shift of the H_2 and C_2 resonances, e.g., $\Delta\delta H_2$ = –1.52 ppm; $\Delta\delta C_2$ = –29.8 ppm for X = NH_2; $\Delta\delta H_2$ = –1.10 ppm, $\Delta\delta C_2$ = –27.7 ppm for X = OMe. For comparison, the $\Delta\delta H_2$ and $\Delta\delta C_2$ values are only –0.45 and –4.3 ppm, respectively, for X = Me. Obviously, such chemical shift variations favor the idea that the enaminic resonance contributor **4,E** is very important in determining the structure of the 3-aminothiophenes **4a–c**. In a similar way, Gronowitz and Hoffman (19) as well as Takahashi et al. (23) previously suggested that the vinyl ether structure **10,E** contributes significantly to the representation of **10**.

As previously emphasized by Spinelli and co-workers, the electron density at C-2 of a thiophene ring is greatly dependent on the nature of the X substituent at C-3 (24–26). This phenomenon, known as the hyper-*ortho* relationship, is commonly expressed through Hammett relationships based on use of the σ_{para} substituent constants defined in the benzene series (24–26). Although all available data do not refer to the same solvent, it can be seen in Fig. 2 that an approximately linear relationship is obtained on plotting the $\Delta\delta C_2$ ($= \delta C_{2(X)} - \delta C_{2(H)}$) value, measuring the shielding or deshielding effects exerted

© 1998 NRC Canada

Fig. 2. Effect of a 3-X substituent on (*a*) the H2 and (*b*) the C2 chemical shifts of a thiophene ring. See Table 6 for the data used to draw these plots.



by the 3-X substituent, against σ_p (27). A similar correlation is obtained when considering the related $\Delta\delta H_2$ values, including that for 3-nitrothiophene. Interestingly, the above Hammett-type relationships require the use of the σ_{p+} and σ_{p-} values for substituents exhibiting strong +M or –M effects. Hence it is clear that the resonance structures **14** and **15** must primarily govern the reactivity of 3-X-thiophenes at the two extremes of the substituent spectrum. This conclusion fits well the experimental observation that **4a–c** and **1** are highly susceptible to electrophilic substitution at C-2 while 3-nitrothiophenes are highly prone to nucleophilic addition or substitution processes at this position.

14 (= **4,E** if X = NRR') **15**

A comparison of the rate constants k_1^{DNBF} for formation of the adducts **6a-c,H** and **3H** with those previously measured for the 3-methoxythiophene adduct **11** as well as the various indole and pyrrole adducts **9** and **13**, is useful both to assess the carbon nucleophilicity of **4a–c** and **1** and to estimate indirectly the basicities of these derivatives (14, 21*a*, 21*c*). As can be seen in Table 5, the k_1^{DNBF} values for C-2 substitution of **4a–c** and **1** by DNBF are by far the highest in the series of heterocycles studied, reaching 3×10^5 M^{-1} s^{-1} for 3-(methylamino)thiophene **4b** and nearly 10^6 M^{-1} s^{-1} for **1**. Even though a few faster carbon–carbon bond-forming reactions of this type have been reported, these k_1^{DNBF} values rank among the highest ever measured for σ-complexation processes by carbon nucleophiles (28, 29).

In the case of indoles **9** and pyrroles **13**, a roughly linear Brönsted-type relationship was found to describe the observed increase in k_1^{DNBF} with increasing carbon basicity of these derivatives (21*a*). If one assumes as a first approximation that this correlation will also fit the nucleophilic behaviour of related five-membered heterocycles, the pK_a^{CH} values for C-protonation of thiophene derivatives can be estimated. In fact, we have recently applied this treatment to the DNBF–3-methoxythiophene system and estimated a pK_a^{CH} value for **10** of –6.5, which compares well with an independent determination of ≈–7 (21*c*). In the case of **4a–c**, one thus obtains: $pK_a^{CH} \approx -0.4$ for **4a**; $pK_a^{CH} \approx +0.8$ for **4b**; $pK_a^{CH} \approx +0.2$ for **4c**, as compared with a pK_a^{CH} value ≈ +1.5 for **1** and a pK_a^{CH} value of –0.49 for the most basic nitrogen heterocycle in Table 5, namely 1,2,5-trimethylpyrrole.

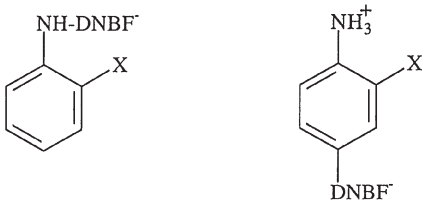
In considering the carbon basicities of **1** and **4a–c**, it is first noteworthy that they are all lower by 2.5–3 p*K* units than the basicities of the related amino groups. This accounts very well for the acid–base behaviour observed in dilute HCl solutions in 50% H_2O – 50% Me_2SO or CH_3SO_3H solutions in Me_2SO. Recalling, however, that thiophene compounds are the five-membered ring heterocycles that are by far the least prone to electrophilic addition or substitution processes (30, 31), the above pK_a^{CH} values are in themselves convincing evidence that the C-2 position of **1** and **4a–c** bears an especially high electron density, further supporting the predominance of the enaminic representation **4,E** in the structure of **1** and **4a–c**. To be noted are the much higher k_1^{DNBF} and pK_a^{CH} values for the 3-aminothiophenes than for 3-methoxythiophene, a result that is perhaps unexpected in view of the similar shielding effects exerted by the NRR′ and OMe groups at C-2 of a thiophene ring.

DNBF–aniline systems vs. DNBF–aminothiophene systems

In view of the high k_1^{DNBF} values measured for reaction [3*b*] in Scheme 3, it seems reasonable to suggest that initial formation of the N-bonded adducts **7** is not observed because this is both kinetically and thermodynamically disfavored compared to the C-adducts **6,H**. The situation is therefore in marked contrast to that observed in the DNBF–aniline system (15, 16). In this case, Buncel et al. as well as Spear et al. have reported that the reaction involves first the reversible formation of the N-adduct **16a** under kinetic control. In a second and much slower step, similar to the one depicted in eq. [3*b*] for the aminothiophene systems, the formation of the zwitterionic C-adduct **17a,H** occurs irreversibly; hence **17a,H** was obtained quantitatively as

© 1998 NRC Canada

the thermodynamically favored product (15, 16). Similarly, the reaction of DNBF with 1,2-diaminobenzene **8d** afforded initially the N-adduct **16b** but it is the C-adduct **17b,H** which formed eventually as the stable product (21*a*).



16 (a) X=H, (b) X=NH_2 **17,H**

The similarity of the nitrogen basicities of aminothiophenes and anilines implies that donation of the nitrogen lone pair to the respective aromatic or heteroaromatic ring is rather similar. On the other hand, formation of N-bonded adducts like **7** or **16** does not require major geometrical or electronic changes in these rings. Thus, it is difficult to understand why anilines should be intrinsically more efficient nucleophiles in forming the adducts **16** than aminothiophenes in forming the adducts **7**. Accordingly, we suggest that the initial formation of **16** in the aniline–DNBF system is made possible only because formation of the related C-adduct **17,H** is kinetically less favored than that of **6,H** in the thiophene system. In the formation of C-adducts such as **6,H** and **17,H**, the first step involves not only σ-complexation of the carbocyclic ring of DNBF but also that of the benzene or thiophene ring. In this regard, it is well known that σ-complex formation is a more favored process in the thiophene than in the benzene series (32, 33). According to Illuminati and co-workers (32, 34), two main factors would account for this behaviour: (*i*) a somewhat lower aromaticity of the heterocyclic ring system as compared with the benzene system; (*ii*) the fact that the σ-complexation process does not involve as much change in geometry in the five- as in the six-membered ring systems. The bond angle at the site of addition of a benzene derivative is almost 120° while the analogous angle at the reactive C_α center in a thiophene substrate is 111.5° (35). Since tetrahedral geometry must be achieved at the reaction site in all σ-complexes, it is clear that the complexation process must involve much greater bond strain in the benzene than in the five-membered ring system (34, 36, 37). It is this factor which would reduce the rate of formation of **17,H**, as compared to that of **6,H**, thus allowing the formation of **16** under kinetic control. Clearly, an additional factor will also be present, namely, that in the thiophene system delocalization of the nitrogen lone pair occurs solely at C-2 whereas in the aniline system dispersion of charge density occurs in part at the *ortho* position though predominantly at the *para* reaction center.

In conclusion, the enaminic character of 3-aminothiophenes is a feature of considerable importance in understanding the chemistry of these compounds, which are attractive synthons for the preparation of biologically active compounds (10). Interestingly, our finding that **4a**, **4b,** and **4c**, as well as the 3,4-diamino derivative **1**, act exclusively as carbon nucleophiles towards DNBF is also consistent with recent reports of a similar behaviour of these thiophenes in reactions with other types of electrophiles (11). Thus, alkylation of the thiophene ring occurs exclusively at C-2 upon treatment of 3-aminothiophenes with carbonyl derivatives in the presence of an acid catalyst and of selenophenol used as a reducing agent.

Experimental section

Materials

4,6-Dinitrobenzofuroxan (DNBF) was prepared according to the procedure of Drost: mp 172°C (lit. (12, 14–16, 38) mp 172–174.5°C). 3-Aminothiophene (**4a**), 3-*N*-(methylamino)thiophene (**4b**), and 3-*N,N*-dimethylaminothiophene (**4c**), were prepared as described previously (2, 4): Me_2SO was stirred with calcium hydride and distilled under vacuum. Me_2SO-d_6 was dried by storing over molecular sieves.

Deuteriation of **4a**, **4b,** or **4c** at C-2 to give 2-deuterio-3-*N,N*-dideuteriothiophene (**4a-*d*$_3$**), 2-deuterio-3-*N*-deuterio-*N*-methylthiophene **(4b-d$_2$)**, and 2-deuterio 3-*N,N*-dimethylaminothiophene (**4c-*d***) was effected according to the efficient H^+-catalyzed exchange process described by Paulmier and coworkers (4). Dissolution of **4a-*d*$_3$** or **4b-*d*$_2$** in 50% H_2O – 50% Me_2SO was found by NMR to restore only the signals assigned to the amino protons in a few minutes, as expected from the known ability of these hydrogen atoms. For this reason, the kinetic experiments carried out to measure the effect of isotopic substitution at C-2 on the rates of complexation of **4a**, **4b,** or **4c** by DNBF have been described in the Results as referring to reactions involving the 2-deuteriothiophenes **4a-*d***, **4b-*d,*** and **4c-*d*** as the starting deuteriated substrates. In fact, similar rates were obtained whether isolated samples of **4a-*d*** or **4a-*d*$_3$**, **4b-*d*** or **4b-*d*$_2$** were used as starting materials.

The zwitterionic DNBF σ-adducts of **4a**, **4b,** and **4c**, i.e., **6a,H**, **6b,H**, and **6c,H,** were prepared as follows: a solution of 0.2 mmol of a freshly prepared sample of the appropriate 3-aminothiophene compound in 2 cm^3 of dry THF was prepared in a small reactor equipped with a septum and cooled at –60°C with an acetone–CO_2 bath. To this solution was added dropwise by means of a syringe a solution of 45 mg DNBF (0.2 mmol) in 2 cm^3 of THF, which had previously been cooled at –60°C. A red-orange solution was thus obtained in each case, and was allowed to warm up slowly. At about –30°C, dark-orange solids began to precipitate, and were collected by filtration at room temperature. After washing with copious amounts of dry diethyl ether, the crystals were dried under vacuum and stored at –20°C under argon and in the dark; yields of 50–60% were obtained. As with most DNBF adducts studied so far, attempts to obtain satisfactory elemental analyses of the collected solids failed, but mass spectra experiments performed with the FAB technique left no doubt that we have isolated the expected zwitterions **6,H**. Thus, we have $m/z = 324$ for **6a,H**, m/z = 338 for **6b,H,** and m/z = 352 for **6c,H**. In addition, dissolution of the crystals in Me_2SO-d_6 gave NMR spectra identical to those recorded in the in situ generation of **6a,H**, **6b,H**, and **6c,H** in this solvent. Also, the strong maxima at λ_{max} = 480 nm observed in 50% H_2O – 50% Me_2SO were typical of the formation of C-bonded adducts of DNBF (12,16).

pK_a measurements

The pK_a values for protonation of the amino groups of **4a**, **4b,** and **4c** in 50% H_2O – 50% Me_2SO (v/v) were obtained from

© 1998 NRC Canada

potentiometric measurements carried out by using buffer solutions of these aminothiophenes with [**4**]/[**4,H**] ratios equal to 1:2, 1:1, and 2:1. These solutions were prepared so that the molarity of the cationic species, i.e., **4,H**, was always equal to 0.01 M. Under these experimental conditions, the pK_a values at $I = 0.01$ M (Table 3) were thus deduced from the measured pH values of the buffers by means of eq. [8]. The details of the cell and experimental procedure used were as described previously (12).

$$[8] \qquad pK = pH - \log \frac{[\mathbf{4}]}{[\mathbf{4,H}]}$$

Kinetic measurements

Stopped-flow determinations were performed on either a Durrum or a Tritech spectrophotometer, the cell compartments of which were maintained at 25 ± 0.3°C. All kinetic runs were carried out in triplicate under pseudo-first-order conditions with a DNBF concentration of ca. 3×10^{-5} M and aminothiophene concentrations in the range 5×10^{-4} to 0.01 M. In a given experiment, the rates were found to be very reproducible (to ± 2–3%) and to be similar whether the process was followed by monitoring the increase in absorbance at $\lambda_{max} = 480$ nm of the adduct **6,H** or the decrease in absorbance at $\lambda_{max} = 425$ nm of the parent DNBF substrate as a function of time.

Spectroscopy

The NMR, UV–visible, and mass spectrometers used in this study were as described in our previous work of σ-complexation of DNBF by indoles, pyrroles, and thiophenes. The FAB experiments were performed in triplicate with negative ion detection.

Dephosphorylation and aromatic nucleophilic substitution in nonionic micelles. The importance of substrate location

Clifford A. Bunton, Houshang J. Foroudian, Nicholas D. Gillitt, and Christy R. Whiddon

Abstract: Reactions of OH^- and F^- with *p*-nitrophenyl diphenyl phosphate (pNPDPP) are inhibited by very dilute dodecyl (10) and (23) polyoxyethylene glycol ($C_{12}E_{10}$ and $C_{12}E_{23}$, respectively), but rate constants become independent of surfactant concentrations at concentrations above the critical micelle concentration. Low charge density anions, e.g., ClO_4^-, inhibit and low charge density cations, e.g., $(n\text{-}C_7H_{15})_4N^+$, accelerate reactions, probably by controlling concentrations of nucleophiles in the palisade layer. Diphenyl phosphorofluoridate, generated by attack of F^-, is not detected but is rapidly hydrolyzed to phenyl phosphorofluoridate or diphenyl phosphate ion with loss of phenol or F^-. The products are different in DMSO containing modest amounts (<15 vol%) of water and no surfactant and are phenyl phosphorofluoridate and difluorophosphate ions generated by attack of F^- on the initial phosphorofluoridate. These differences are consistent with the micellar palisade layer being water-rich. Although the nonionic surfactants do not intervene nucleophilically in reactions of pNPDPP, considerable amounts of ether are formed in the reaction of 2,4-dinitrochlorobenzene (DNCB), in $C_{12}E_{10}$ and $C_{12}E_{23}$ at high pH by attack of alkoxide ion with the relatively hydrophilic DNCB located close to the micellar surface. The differences in the chemistries of reactions of pNPDPP and DNCB appear to be associated largely with differences in locations of these substrates in the nonionic micelles.

Key words: fluoridates, *p*-nitrophenyl diphenyl phosphate, 2,4-dinitrochlorobenzene, nonionic micelles, palisade layer.

Résumé : Les réactions des ions OH^- et F^- avec le phosphate de *p*-nitrophényle et de diphényle (PpNPDP) est inhibée par des solutions très diluées de dodécyl (10) et (23) polyoxyéthylèneglycol (respectivement $C_{12}E_{10}$ et $C_{12}E_{23}$), mais les constantes de vitesse deviennent indépendantes de la concentration de l'agent tensioactif à des concentrations supérieures à la concentration micellaire critique. Les réactions sont inhibées par les anions de faible densité de charge, comme le ClO_4^-, et accélérées par les cations de faible densité de charge, comme le $(n\text{-}C_7H_{15})_4N^+$; ces effets sont probablement dus à un contrôle des concentrations de nucléophiles dans la couche palissade. On ne peut détecter la présence de phosphorofluoridate de diphényle, généré par une attaque du F^-; il est rapidement hydrolysé en phosphorofluoridate de phényle ou en ion phosphate de diphényle avec perte de phénol ou de F^-. Les produits sont différents dans le DMSO contenant de faibles quantités (<15% par volume) d'eau et aucun agent tensioactif; il s'agit de phosphorofluoridate de phényle et de l'ion difluorophosphate généré par l'attaque du F^- sur le phosphorofluoridate initial. Ces différences sont en accord avec une couche micellaire palissade riche en eau. Même si les agents tensioactifs non ioniques n'interviennent pas d'une façon nucléophile dans les réactions du PpNPDP, il se forme de grandes quantités d'éther lors de la réaction du 2,4-dinitrochlorobenzène (DNCB), dans $C_{12}E_{10}$ et $C_{12}E_{23}$, à pH élevé; elles proviennent d'une attaque de l'ion alcoolate sur le DNCB relativement hydrophile qui se trouve près de la surface micellaire. Les différences dans les chimies des réactions du PpNPDP et du DNCB semblent associées à des différences dans la situation de ces substrats dans les micelles non ioniques.

Mots clés : fluoridates, phosphate de *p*-nitrophényle et de diphényle, 2,4-dinitrochlorobenzène, micelles non ioniques, couche palissade.

[Traduit par la rédaction]

Phosphate esters with nitrophenoxy groups are often used in simulating detoxification of phosphonofluoridates, e.g., Sarin, GB, by nucleophilic attack (1), because formation of nitrophenoxide ion is readily followed spectrophotometrically. Many nucleophiles have been examined (1), especially such α-effect nucleophiles as HO_2^-, oximate and hydroxamate ions (2), metal complexes (3–6), and iodosobenzoate ion and its derivatives (7). Reactions are often carried out in micelles or microemulsions, which solubilize reactants and may accelerate reaction by concentrating reactants in the small volume of the association colloid. If this concentration effect is taken into account, second-order rate constants in the interfacial region of the association colloid are generally similar to those in water (5, 8, 9). Much of the work with anionic nucleophiles has involved

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

cationic micelles that concentrate anions, but nonionic micelles provide useful media for dephosphorylation by amphiphilic metal complexes (3, 6), and nonionic are better solubilizing agents than ionic micelles (10).

In his pioneering work Hartley (11) showed that nonionic micelles have little effect on acid–base equilibria, although they are sensitive to charges on ionic micelles. Subsequently rate constants of reactions of hydrophilic ions with polar, nonionic substrates were found to be generally similar to those in water, even though substrates were micellar-bound. These observations are summarized in monographs (12).

Many nonionic surfactants have apolar groups attached to polyoxyethylene chains, as in the Brij$^{(R)}$ family,

$$CH_3(CH_2)_{m-1}O(CH_2CH_2O)_{n-1}CH_2CH_2OH$$

designated C_mE_n. In aqueous micelles the ethylene oxide, palisade layer is extensively hydrated (13–16), although estimated hydration numbers depend upon structures of the apolar and hydrophilic groups, and probably also upon the method of determination. Evidence on hydration is summarized (16). Therefore hydrophilic ions should be able to penetrate the palisade layer, although there should be no coulombic micelle–ion interactions, as in ionic micelles. Depending upon values of *m* and *n* the volume of the palisade layer may be much greater than that of the apolar core, unlike the situation with ionic micelles (8, 9, 12). In addition, many nonionic surfactants, e.g., Brij$^{(R)}$35, $C_{12}E_{23}$, are of high molecular weight (ca. 10^3), and even at low molarities their micelles occupy a significant volume of the solution.

The similarity between rate constants in water and in nonionic micelles indicates that many substrates reside in an interfacial micellar region, where they are exposed to ionic reagents (9, 12). However, reactions of OH^- and F^- with *p*-nitrophenyl diphenyl phosphate (pNPDPP) are significantly inhibited by dilute Igepal (17), a nonyl phenol condensed with ca. 24 ethylene oxide residues (12). First-order rate constants, k_{obs},

$$(PhO)_2PO{\cdot}OC_6H_4NO_2(p) \xrightarrow{Nu^-} (PhO)_2PO{\cdot}Nu + O^-C_6H_4NO_2, \quad Nu = OH, F$$

(pNPDPP)

decrease sharply at Igepal concentration below the critical micelle concentration, cmc, and then become independent of the Igepal concentration (17). Physical evidence shows that pNPDPP is bound strongly to Igepal, even at low concentration, and it probably goes sufficiently deep into the micelle to be partially protected from OH^- or F^-. This behavior is different from that seen for reaction in an anionic micelle of sodium dodecyl sulfate, SDS, where there is little inhibition until micelles form and then k_{obs} decreases monotonically with increasing SDS concentration to very low, but non-zero, values (17, 18).

At high pH alkoxide ions generated by deprotonation of hydroxyl groups in micelles or microemulsions can be effective nucleophiles (19, 20). For example, 1-butoxide ion in microemulsions with 1-butanol as co-surfactant reacts with pNPDPP (20). The terminal OH of a nonionic surfactant should have an acidity similar to that of ethane diol ($pK_a = 14.8$ (21)), and its alkoxide residue should be an effective nucleophile. This reaction was considered, but excluded, for reaction of pNPDPP in $C_{12}E_{23}$ (3). However, this intervention may be feasible with a shorter polyoxyethylene residue, as in $C_{12}E_{10}$, or with a less hydrophobic substrate. So far as we know the only kinetic test of intervention is that with pNPDPP in $C_{12}E_{23}$ (3), although a very short-lived aryl cation generated by decomposition of an amphiphilic diazonium ion in micelles of $C_{12}E_6$ is trapped, albeitly weakly, by the terminal OH group (16).

Alkoxide ions compete with OH^- in reactions of 2,4-dinitrochlorobenzene (DNCB) in cationic micelles and microemulsions (19). This relatively hydrophilic substrate may bind at the surface of a nonionic micelle and react with an alkoxide ion generated by deprotonation of the terminal OH^-. The reaction with OH^-, followed by formation of 2,4-dinitrophenoxide appeared to be slightly faster in Igepal than in water (22), but intervention of the alkoxide ion was not examined, and we have now examined the products of this reaction in $C_{12}E_{10}$ and $C_{12}E_{23}$.

Reaction of F^- with pNPDPP probably involves initial formation of a fluoridate **1**, which should react further.

$$(PhO)_2PO{\cdot}OC_6H_4NO_2 \xrightarrow{F^-} (PhO)_2PO{\cdot}F + O^-C_6H_4NO_2$$

1

Attack of OH^- upon pNPDPP displaces *p*-nitrophenoxide ion, but there is a minor displacement of phenoxide ion (3, 20). We expected this minor reaction to be less important when the nucleophile is F^-, but so far as we know this possibility has not been tested.

The interfacial regions of ionic micelles have polarities, based largely on spectrophotometric probes, slightly lower than that of water (12), but the recent application of linear solvation free-energy relationships to solute–micelle interactions shows that micellar charge and head group structure are important (23). However, the kinetic implications of these treatments have not been explored extensively, nor have the effects of differences between volumes of the interfacial regions of ionic and nonionic micelles relative to total micellar volumes (8, 9, 12).

Experimental

Materials

The surfactants, $C_{12}E_{10}$ (Sigma) and $C_{12}E_{23}$ (Brij$^{(R)}$35) (Aldrich), were used as received but samples, purchased in both 1996 and 1997, gave similar rate data. Diphenyl phosphorochloridate (Aldrich) was redistilled, tetrabutylammonium fluoride (ACROS), sodium fluoride (Fisher), and ammonium fluoride (Aldrich) were used as received, and pNPDPP and DNCB had been used earlier (5, 22). Reactions were carried out in redistilled, CO_2-free deionized water or in DMSO or DMSO–H_2O without surfactants.

Kinetics

Reactions were followed spectrophotometrically in Beckman or HP 8450 spectrophotometers at 25.0°C as described (5, 17). Substrate was added in MeCN to give 2×10^{-5} M pNPDPP and 0.2 vol% MeCN in the kinetic solution. Solutions of the more concentrated surfactants were viscous, and then substrate was mixed by using a square plunger with small holes. Provided that the plunger did not break the surface we could mix reagents without introducing air bubbles. Freshly made up solutions

were always used. For reactions of NaF in nonionic micelles we added 0.01 M sodium borate to prevent build up of acidity (17).

NMR spectroscopy

Products of reactions at ca. 21.5°C were identified by their ^1H, ^{19}F, and ^{31}P NMR spectra, generally on a Varian Unity (Inova) instrument, 400 M Hz for ^1H. The ^{31}P chemical shifts were referred to external 85% H_3PO_4, ^1H chemical shifts were referred to TMS, TSP, or DMSO at 2.50 ppm as convenient, and ^{19}F chemical shifts were referred to CF_3Cl by using external CF_3CO_2H, $\delta_F = -76.55$ ppm.

We typically used 10^{-2} M substrate, except for $C_{12}E_{10}$ where we used 5×10^{-3} M pNPDPP. We generally used $d1$ = 1 s for ^1H and ^{19}F but increasing it to 5 s did not change the signals, and we used $d1 = 3$ s for ^{31}P, but increasing it to 20 s had no effect on the signals.

Most reactions went to completion, but in some experiments with pNPDPP and KOD in surfactants we stopped the reaction after about one half-life with DCl, and saw only signals of pNPDPP and the final products. There was considerable overlap of some ^1H signals in the aromatic region, and in some cases we used the COSY spectrum to identify products. Chemical shifts are medium dependent, but not so much so as to complicate product identification.

Chemical shifts of pNPDPP are δ_P –18.19 and –18.15 ppm in 0.1 M $C_{12}E_{10}$ and $C_{12}E_{23}$, respectively, and in 0.1 M $C_{12}E_{23}$ ^1H chemical shifts are phenyl group, *o*-H, 7.26 (d); *m*-H, ca. 7.48 (m); *p*-H, 7.35 (t), and for the nitrophenyl group are *o*-H, ca. 7.48 (m); *m*-H, 8.31 (d) ppm. For DNCB in $C_{12}E_{10}$ and $C_{12}E_{23}$ ^1H chemical shifts are δ (ppm): H-3, 8.75 (d), J = 2.7 Hz; H-5, 8.60 (dd), J = 2.8, 9.0 Hz; H-6, 8.11 (d), J = 8.8 Hz. There is a large, broad surfactant signal at ca. 3.7 ppm with shoulders to the main peak. Some of the ^1H signals of $C_{12}E_{10}$ in D_2O were identified. For the dodecyl group they are CH_2(1), 3.44; CH_2(2), 1.55; CH_2(3–11), 1.31; ω-CH_3, 0.89 ppm, numbering from the junction with the polyoxyethylene group. The ^1H NMR spectrum of $C_{12}E_{23}$ is similar to that of $C_{12}E_{10}$ except that the broad signal at ca. 3.7 ppm is much larger.

[b] With 0.1 M CsF, 10^3 $k_{obs} = 0.87$ s^{-1}.
[c] In 0.05 M $C_{12}E_{10}$, 10^3 $k_{obs} = 0.31$ s^{-1}.

Results

Kinetics of dephosphorylation

Values of k_{obs}, monitored by formation of *p*-nitrophenoxide ion (Table 1) decrease sharply in very dilute surfactant and then level off, as found earlier for reactions in Igepal (17), and rate–surfactant profiles are similar for the three surfactants, when allowance is made for differences in concentrations of the nucleophiles. There is inhibition by Igepal well below its cmc, and we see significant inhibition near the cmc of the surfactants (ca. 10^{-4} M for $C_{12}E_{10}$ and 6×10^{-5} M for $C_{12}E_{23}$) (24), and values of k_{obs} for reaction of F^- with old and new samples agreed within ± 5%. Added inorganic salts inhibit the reactions (Table 2), and as with cationic micelles, inhibition increased with decreasing charge density of the anion (9), but tetra *n*-heptyl ammonium bromide increased k_{obs}. In agreement with earlier results (17) k_{obs} is greater by about one order of magnitude for OH^- relative to F^-.

Products of dephosphorylation by OD^-

In agreement with earlier work in $C_{12}E_{23}$ (3) and in microemulsions

[b] Extensive overlap with signals of $(PhO)_2PO_2^-$.

with 1-butanol with co-surfactant (20) the major reaction at 21.5°C is loss of *p*-nitrophenoxide ion with minor loss of phenoxide ion (11 and 14 mol% in DMSO, 15 vol% D_2O and $C_{12}E_{10}$ or $C_{12}E_{23}$, respectively) and formation of the corresponding diarylphosphate ion (Table 3). There is some overlap of the ^1H NMR signals, but based on these and the ^{31}P NMR signals, there is no product of dephosphorylation by the alkoxide residue of $C_{12}E_{10}$ or $C_{12}E_{23}$ (cf. ref. 3). Trisubstituted phosphates react readily with OH^-, but if a phosphorylated derivative had been formed it would decompose with loss of phenoxide ion, and we would have seen additional NMR signals. These conclusions were confirmed by stopping reaction with DCl at about one half-life and by examining the ^1H NMR spectrum, which except for signals of unreacted pNPDPP was similar to that observed at complete reaction. Reaction of the terminal group of the surfactants is unimportant, consistent with the similar values of k_{obs} for reactions in $C_{12}E_{10}$ and $C_{12}E_{23}$ (Table 1).

Products of dephosphorylation by F^-

The products of reaction depend upon the reaction medium, and although phenol is formed (Table 4 and Scheme 1) we do not believe that it comes from the initial attack of F^-. A number of possible phosphorofluoridates were synthesized and their ^{19}F and ^{31}P NMR signals characterized by Reddy and Schmutzler (25) whose compilation was very useful in the identification, or exclusion, of intermediates and products.

Reaction in $C_{12}E_{10}$ and $C_{12}E_{23}$ (Scheme 1) gave phenol and *p*-nitrophenoxide ion, identified by their ^1H NMR signals, diphenyl phosphate ion, **2**, identified by its ^{31}P signal, and phenylphosphorofluoridate, **3**, identified largely by its ^{19}F and ^{31}P signals (Table 4). Addition of KOD at the end of reaction did not affect the NMR spectra, except by generating phenoxide ion from phenol. Reactions of the anions **2** and **3** with OD^- are slow, and NMR signals changed only slowly with time.

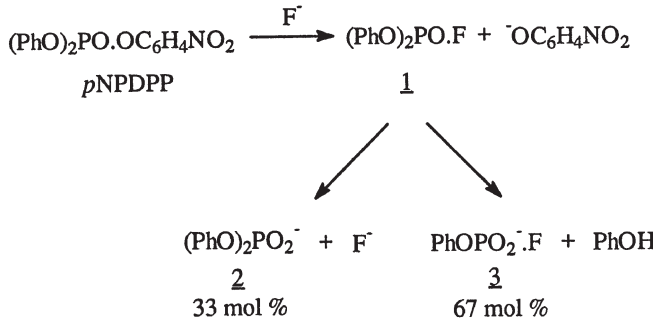
We saw no signals of diphenyl phosphorofluoridate, **1**, which has $\delta_P = -21.8$ ppm, d; $\delta_F = -78.4$ ppm, d; $J_{PF} = 1001$ Hz (25). A sample prepared by the original method (reaction of the chloridate with NH_4F in refluxing toluene (25)), but without purification, had $\delta_F = -77.9$ ppm, $J_{PF} = 999$ Hz in DMSO-d_6, the differences in the NMR data are due to the original values being obtained with the pure liquid (25).

The reactions and yields are shown in Scheme 1, and **1** is hydrolyzed with loss of either phenol or F^-. There were no products that could be ascribed to reaction of F^- with pNPDPP and direct displacement of phenol.

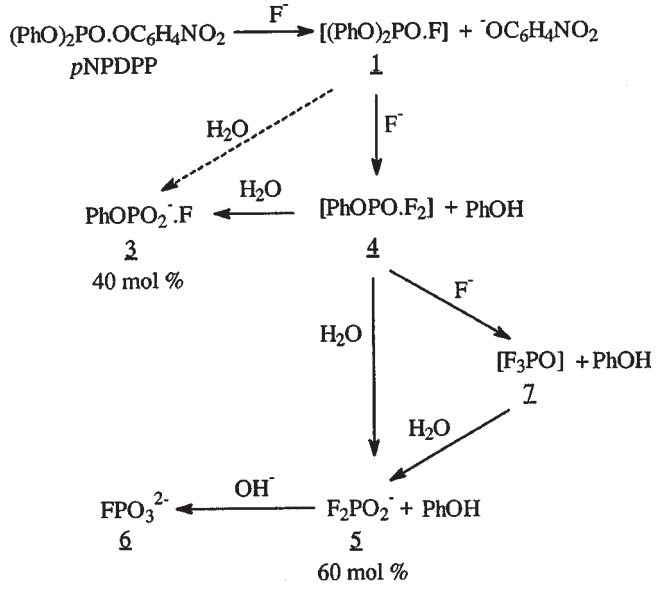
The products of the very rapid reaction in DMSO with or without added D_2O differ from those in water, probably because the increased nucleophilicity of F^- (26) allows it to attack the first-formed diphenyl phosphorofluoridate, **1** (Scheme 2). This reaction gives the difluoridate, **4**, which can

© 1998 NRC Canada

Scheme 1.



Scheme 2.



be hydrolyzed with loss of either phenol or F^-, giving **5** and **3**, respectively. Alternatively, displacement of phenol from **1** by water could give **3**, but we think that this reaction is improbable because in aqueous nonionic micelles it competes with displacement of F^-, giving diphenyl phosphate ion, **2** (Scheme 1), and we do not obtain **2** in DMSO. Both **3** and difluorophosphate ion, **5**, are relatively stable in the reaction conditions, but the latter is slowly converted into fluorophosphate dianion, **6**, on addition of KOD-D_2O, and **6** is hydrolyzed only in aqueous acid (27). Conversion of the difluoridate, **4**, into difluorophosphate ion, **5**, could occur via formation of trifluorophosphate, **7**, which should be very reactive in our conditions, and this alternate reaction path is also shown in Scheme 2. The NMR parameters are given in Table 4, and the differences from literature chemical shifts (25) are due to the use of pure liquids or concentrated solutions in the earlier work.

There are minor ^{19}F and ^{31}P signals (ca. 25% of the major signals) in the products of reaction in nominally dry DMSO-d_6 at δ_F = 54.85 ppm (d), J = 828 Hz and δ_P = –75.7 ppm (t), J = 828 Hz. The ^{31}P signal is not much above the noise level, and there are no corresponding ^1H signals in the aromatic region. We did not see these signals in DMSO-d_6:D_2O 85:15 v/v, and they disappear slowly (over a few hours at 21.5°C) due to reaction with small amounts of water in the DMSO and immediately on addition of D_2O to the reaction mixture. Our speculation is that they are formed by reaction of DMSO, acting as a nucleophile (28), towards a fluorophosphate, e.g., **7** (Scheme 2). These signals also appear in the products of reaction of tris(*p*-nitrophenyl) phosphate with Bu_4NF in DMSO-d_6; they also disappear on addition of D_2O, and there are no corresponding ^1H signals in the aromatic region. We carried out the reaction in 80% DMSO – 20% DMSO-d_6 in the hope of seeing new ^1H signals in the aromatic region, but without success. However, ^1H signals of a phosphorylated DMSO could have been obscured by those of Bu_4NF or DMSO. Formation of the pyrophosphate, $(F_2PO)_2O$, would explain the multiplicity of the signals, but this compound has δ_F = –85.7 ppm, δ_P = –22.1 ppm. J_{PF} = 980 Hz (25).

We see no signals of diphenyl phosphorofluoridate, **1**, even in DMSO-d_6, but the signals of **3** and **5** appear within the time required for running the NMR spectrum in DMSO.

Reaction of DNCB in nonionic micelles

The terminal OH group of a polyoxyethylene surfactant should be partially deprotonated at high pH, and based on examples of alkoxide ion reactions in micelles and microemulsions (19, 20, 29), there should be a reaction with DNCB if it is bound close to the micellar surface.

Reaction of 0.02 M DNCB and 0.15 M DNCB in 0.1 M $C_{12}E_{10}$ initially gives signals of an ether, **8a**, and weak signals of 2,4-dinitrophenoxide ion, **9** (Table 5). With time, signals of **8a** decrease and those of the phenoxide ion increase. Approximate half-lives for appearance of **8a** and its disappearance are 0.9 and 25 h, respectively, from inspection of the data in Table 5. There are also methylene signals of **8a** at 3.97 and 4.52 ppm whose areas are twice those of the aromatic ^1H signals. A third signal at 3.75 ppm appears to have a similar area to the first two, but it is too close to the large signal at ca. 3.7 ppm for estimation of its area.

The reactions shown in Scheme 3 are confirmed by taking the absorbance spectra of the NMR reaction mixture after 200-fold dilution (Fig. 1). Some plots are omitted for clarity but formation and subsequent reaction of **8a** are evident.

Some dinitrophenoxide ion may be formed by direct reaction with OH^- in the micelle, or in water, because DNCB is probably not fully micellar bound. Association constants with respect to micellized surfactant are 88, 75, and 44 M^{-1} in Igepal, CTABr, and SDS, respectively (22), and is probably similar in $C_{12}E_{10}$ and $C_{12}E_{23}$, indicating that ca. 10% DNCB will be in the water.

The reaction was carried out as above in 0.01 M DNCB with added 0.01 M 2,4-dinitrophenol, but there were no additional ^1H NMR signals, so we exclude formation of bis(2,4-dinitrophenyl) ether as an intermediate.

An ether, **8b**, is formed in the reaction in 0.1 M $C_{12}E_{23}$, and its ^1H NMR spectrum in the aromatic and aliphatic regions is very similar to that of **8a** (Table 5). However, formation and disappearance of this ether are not as well separated as in $C_{12}E_{10}$, and we did not examine this system in detail. The different behaviors could be due to differences in the contributions of a direct reaction with OD^- in water, or differences in relative rates of formation and reaction of the ethers in the two micellized surfactants. However, it has been known for many years that rates of aromatic nucleophilic substitutions are

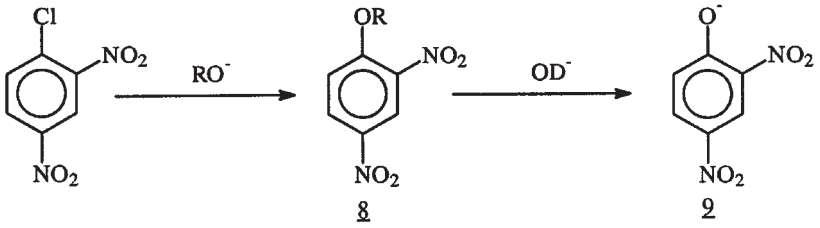
[c] δ (ppm) for aromatic H; H-5, 8.03 (d); H-6, 6.72 (d) ppm.

Scheme 3.



$R = C_{12}H_{25}O(CH_2CH_2O)_{n-1}\ CH_2CH_2$

typically not very sensitive to the nature of the leaving group (30) (fluoride is a major exception to this generalization).

There are overlaps in some of the ^{1}H NMR signals (Table 5), but chemical shifts of the ethers were determined from spectra taken after DNCB had disappeared. We did not see signals of H-3 due to H–D exchange in the reaction conditions (31).

Discussion

The fate of the putative phosphorofluoridate, **1** (Schemes 1 and 2), does not affect values of k_{obs} calculated from the rate of formation of *p*-nitrophenoxide ion, and they are insensitive to structures of the nonionic surfactants (Tables 1 and 2). The relative reactivities of OH^- and F^- are as expected (17, 32). Reactions are approximately first-order in nucleophile concentration, unlike kinetics in ionic micelles (9), indicating that transfer of ions into the micelles does not significantly deplete them in the aqueous pseudophase. The initial sharp decrease of k_{obs} in dilute surfactant at concentration close to the cmc (Table 1) is indicative of inhibition by monomeric surfactant or premicelles (9).

Inhibition of bimolecular reactions in ionic micelles by inert counterions is explained in terms of ionic competition at the micellar surface, which, in this respect, behaves like an ion-exchange resin (9, 33). The interactions are not solely coulombic, but depend on the charge densities of the ions, and the source of this ion specificity has been discussed (9, 33, 34). The salt order for inhibitions of dephosphorylation in nonionic micelles is that for reactions mediated by cationic (9, 33) (and sulfobetaine (35)) micelles, but effects are smaller, probably because there are no coulombic ion–micelle interactions. Cation effects are small, except that the bulky tetra-*n*-heptylammonium ion increases the reactivity of F^- (Table 2). Incorporation of ClO_4^- or $(C_7H_{15})_4N^+$ in the palisade layer generates charges that affect ionic transfer from water into this region. This subject will be covered in more detail elsewhere.

Based on the binding constant of pNPDPP to micellized Igepal, estimated by solubility (17), we assume that pNPDPP will be fully micellar-bound at 2×10^{-3} M surfactant. The constancy of k_{obs} over a range of $[C_{12}E_{10}]$ and $[C_{12}E_{23}]$ indicates that concentrations of OH^- and F^- in the palisade layer do not decrease with increasing surfactant concentration, as in ionic micelles (9, 33). We do not know the extent to which concentrations of OH^- and F^- in the "water-rich" palisade layer depend upon the length of the polyoxyethylene group, but the similarities of values of k_{obs} in micelles of $C_{12}E_{10}$ and $C_{12}E_{23}$ (Table 1) indicate that there is little effect.

If the acidity of the terminal OH group is similar to that of ethane diol (21), alkoxide ion should be generated at the micellar surface in dilute OH^-, but it does not react with pNPDPP, probably because eclipsing strains make it difficult for the terminal groups to reach the micellar interior, but see ref. 16 for different observations on $C_{12}E_6$. Therefore terminal alkoxide residues cannot compete with OH^- in reacting with pNPDPP, although in other situations alkoxide ions are effective dephosphorylating agents (19, 20, 36, 37).

Reactions of pNPDPP with anionic nucleophiles are inhibited by initial addition of organic solvents to water (38), due to a decrease in the activity coefficient of the substrate, although rate constants increase in the drier solvents due to decreased anion solvation (39). Therefore the inhibitions by nonionic micelles could be merely kinetic medium effects. We cannot exclude this possibility, but polyethylene glycol (PEG, MW 10^4) does not strongly inhibit the reaction of F^- with *p*-nitrophenyl diphenyl phosphinate,[2] and based on this surrogate for the micellar palisade layer, we conclude that the micellar inhibition of reactions of pNPDPP is due largely to depletion of OH^- and F^- in the palisade layer relative to water. This explanation is consistent with the kinetic salt effects (Table 2).

There is no simple and rigorous way of comparing ionic concentrations in aqueous and micellar pseudophases (9).

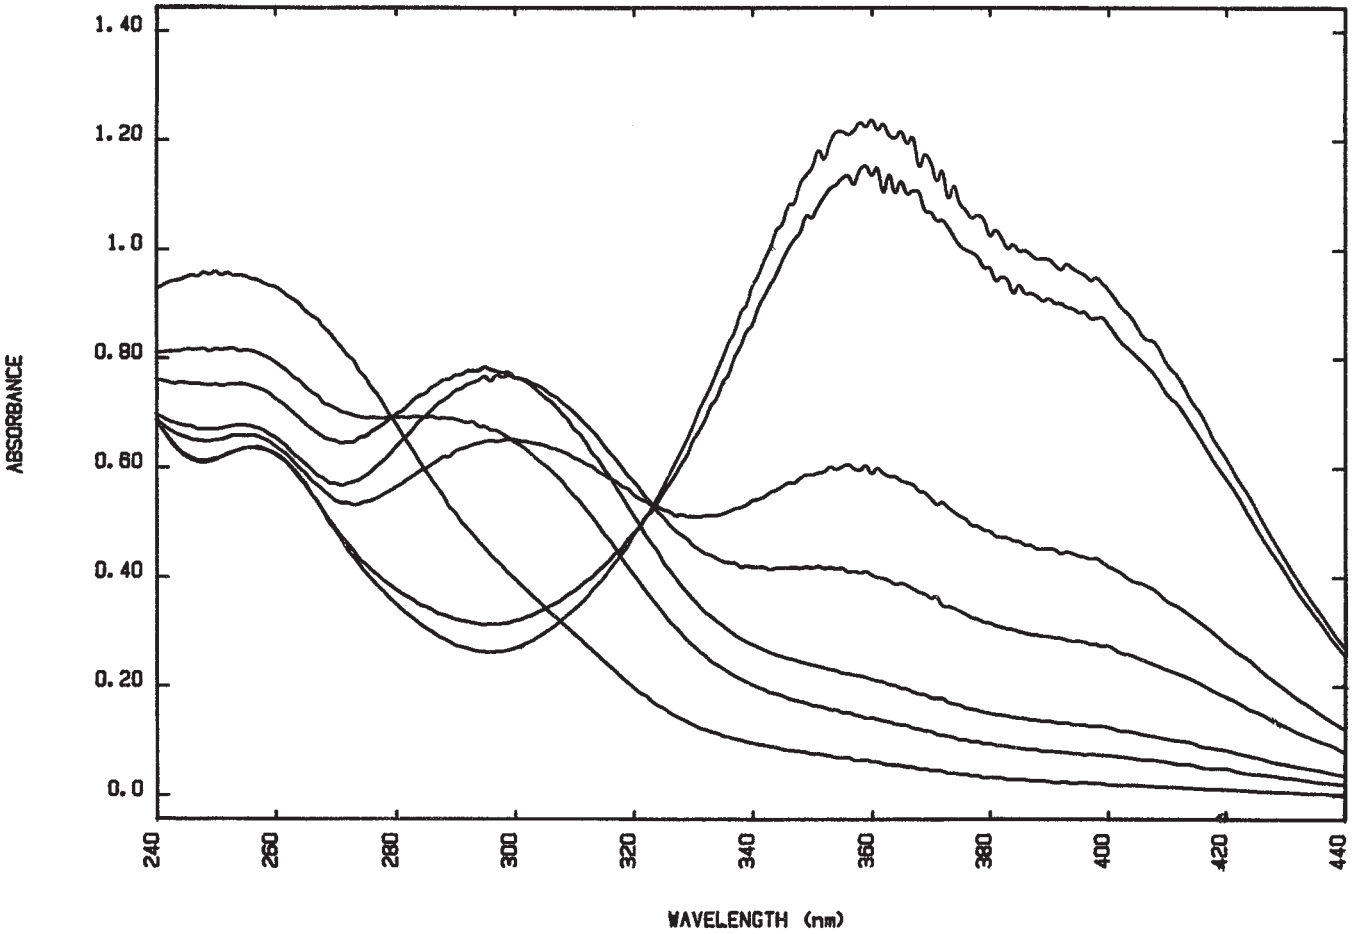
Fig. 1. Time dependence of the absorbance spectrum of the reaction mixture of DNCB in $C_{12}E_{10}$: 0.08, 0.45, 1.00, 4.25, 19.8, 92.5, and 141 h in order of increasing absorbance at $\lambda > 340$ nm. For conditions see text and Table 5.



Concentrations in ionic micelles can be written in terms of the relative numbers of head groups and counterions in the interfacial region, but this measure of concentration is not readily comparable with concentration in a bulk solvent, written as molarity. There are various approaches for estimating local ionic molarities in the interfacial regions of association colloids (9), but they all depend on unverified assumptions. However, dediazonization is an experimental method for determining local molarities (40), and these values are similar to some values estimated theoretically for anions in cationic micelles (41). So far as we know, this method has not been applied to anionic nucleophiles in nonionic micelles. The volume of the palisade layer can be estimated from simple geometry for a spherical micelle, and if we assume a hydration number of three for each ethylene oxide residue (14–16) and the usual densities of water and alcohols or ethers, water will occupy approximately half the volume of the palisade layer.

Micellar reactivity and substrate location

Most kinetic work with aqueous association colloids has involved ionic surfactants, and it is generally accepted that both counterions and polar nonionic substrates bind largely in the interfacial region that encompasses the head groups (9, 12). This region is often identified with the micellar Stern layer. Most, but not all, quantitative treatments of rate effects involve the assumption that reactant composition is uniform in this region, although the dimensions of many substrates are greater than the thickness of this interfacial region, which is taken to be 2–5 Å. Despite the weaknesses of these assumptions the quantitative treatments indicate that for many bimolecular reactions second-order rate constants are similar in water and the association colloids (8, 9, 33). Minor failures of this generalization are understandable on the assumption that the concept of uniform location is merely a crude first approximation, and the few major deviations are understandable in terms of the dependence of kinetic medium effects on reaction mechanism (42).

These simplifying assumptions regarding reactant location are expected to be less useful for reactions in nonionic micelles where the interfacial region is the palisade layer, and its volume is usually very much larger than those of the Stern layers in ionic micelles. Nonetheless, local second-order rate constants of dephosphorylation of pNPDPP and tris(*p*-nitrophenyl) phosphate by amphiphilic metal complexes in nonionic micelles of $C_{12}E_{23}$(3) and Triton X-100 (6) are similar to those of monomeric complexes in water, on the assumption that the molar volume of the reaction region is somewhat larger than those of ionic micelles, viz. 0.5 M^{-1}.[3] However,

[3] We are indebted to Prof. P. Scrimin for his insight into this question of the source of rate enhancements by amphiphilic metal complexes in nonionic micelles.

© 1998 NRC Canada

these conclusions apply to reactions of relatively hydrophobic substrates with amphiphilic nucleophiles, which probably occur deeply in the palisade layer, close to the apolar core and may not apply when one reactant is hydrophobic and the other hydrophilic.

A referee made the interesting comment that transition-state geometries are different for aromatic nucleophilic substitution and dephosphorylation, which may affect the discrimination between reactions of hydroxide and alkoxide ion. However, in cationic and zwitterionic micelles with a functional alkoxide residue its reactions are dominant for both aromatic nucleophilic substitution and dephosphorylation (9, 29, 37).

The concentration of OH^- should be similar at the surface of a nonionic micelle to that in water, because there are no ion–micelle interactions. If we assume that the pK_a of the terminal OH group is 14.8, as for ethane diol (21), the mole fraction of alkoxide ion is 0.024 in 0.15 M OH^-, and the local molarity is $0.024/V_M$, where V_M is the molar volume of the reaction region at the micellar surface (9). We do not know the value of V_M, but values of 0.14–0.37 M^{-1} have been used in fitting rate data (8, 9, 33). The lower value gives the local molarity of alkoxide ion at the micellar surface as ca. 0.17 M, and in view of the higher nucleophilicities of alkoxide ions as compared with OH^- (36, 43) it is understandable that the dominant reaction at the micellar surface involves attack of the alkoxide ion. These estimates of local molarity apply to reactions in H_2O, but should be reasonable approximations to our systems in D_2O.

It appears that nonionic micelles can behave as functional micelles at high pH, provided that the substrate is bound at or near the micellar surface. This behavior will not be seen in reactions of very hydrophilic substrates that occur largely in the aqueous pseudophase, or of very hydrophobic substrates that bind deeply in the micelle.

It is difficult to give other than an approximate concentration of alkoxide ion in the micellar reaction region, because we do not know either the value of V_M or the precise location of DNCB in the micelle. Alkoxide ions compete effectively with OH^- in dephosphorylation and aromatic nucleophilic substitution in cationic micelles and microemulsions (19, 20, 29), because reactions occur in the compact interfacial region at the surface of the association colloid, regardless of substrate hydrophobicity. This simplifying generalization does not apply to nonionic micelles with very large palisade layers, which allow a very hydrophobic substrate, e.g., pNPDPP, to locate deeply in the micelle, while a less hydrophobic substrate, e.g., DNCB, stays closer to the surface. The kinetic significance of these differences in location depends also upon the nucleophile and its ability to reach various regions of the micelle or other association colloid.

Solute location may be concentration dependent if solutes are very hydrophobic; for example, distribution of a hydrophobic, bulky porphyrin between the apolar core and the palisade layer of a Triton micelle is concentration dependent (44).

Conclusions

Reactions of OH^- and F^- with pNPDPP in nonionic micelles occur in a region of the micelle from which nucleophilic ions are partially excluded, but which is not accessible to a terminal alkoxide residue of the surfactant. The initial reaction with F^- generates labile diphenyl phosphorofluoridate, which in the micelles is hydrolyzed with loss of either phenol or F^-. In DMSO with up to 15 vol% D_2O the first-formed fluoridate is converted into the relatively unreactive phenyl phosphorofluoridate ion and difluorophosphate ion by reactions with F^-. These differences in products indicate that the micellar reaction region is not behaving like a mixed solvent of low water content.

Reaction of DNCB with OH^- in $C_{12}E_{10}$ and $C_{12}E_{23}$ gives considerable amounts of the ether formed by attack of alkoxide ion on DNCB. This ether gradually forms 2,4-dinitrophenoxide ion by reaction with OH^-. Consideration of the probable pK_a of the terminal OH group indicates that the local concentration of alkoxide ion at the micellar surface will be higher than that given by deprotonation of a monomeric 1,2-diol monoether at the same stoichiometric $[OH^-]$ in water.

Catalysis by topologically anchored metal complexes. Liquid-phase hydroxylation of benzene by H_2O_2 in the presence of zeolite-supported Fe(II) phthalocyanine

Nikolai S. Zefirov and Alexandre N. Zakharov

Abstract: Fe(II) phthalocyanine topologically anchored on NaA zeolite has been prepared. The catalytic activity of zeolite-supported Fe(II) phthalocyanine has been studied in the liquid-phase hydroxylation of benzene by H_2O_2. The main product of the reaction at room temperature is phenol. By refluxing, the reaction proceeds to give the products of subsequent oxidation, i.e., hydroquinone and *p*-benzoquinone, in low yields.

Key words: topologically anchored Fe(II) phthalocyanine, catalysis, oxidation, benzene, phenol.

Résumé : On a preparé le phthalocyanine du Fe(II) ancré topologiquement sur le zeolite du NaA. On a étudié l'activité catalytique du phthalocyanine du Fe(II) supporté sur le zeolite dans l'hydroxylation du benzène par le H_2O_2 dans la phase liquide. Le phénol est le produit principal de la réaction à température ordinaire. La réaction dans les conditions refluées conduit à des produits consécutives de l'oxydation, i.e., l'hydroquinone et le *p*-benzoquinone, avec un rendement négligeable.

Mots clés : phthalocyanine du Fe(II) ancré topologiquement, catalyse, oxydation, benzène, phénol.

Introduction

The metal complexes of phthalocyanine are known to be active catalysts for a number of reactions. These compounds, however, are practically insoluble in most organic solvents, which restricts their application in homogeneous processes. Earlier (1–5), the synthesis of metal phthalocyanines in zeolites to produce supported heterogeneous catalysts was reported. Elsewhere (6) was suggested an alternative way of supporting these complexes via their incorporation into a system of crystallizing zeolite to get higher dispersion throughout the bulk of the porous material. However, the "inner" catalyst molecules hidden deep in a grain of crystallite were found (7, 8) to be inaccessible to the substrates as a result of a sieve effect and thus are excluded from the catalytic process even for small molecules such as CO, NO, NH_3, etc. Because of the above considerations these systems cannot be accepted as really advanced systems for catalysis, especially for sterically hindered organic substrates and products.

The external-surface catalyst molecules are species that really operate in heterogeneous processes. We have suggested withdrawing the metal complexes from the zeolite crystal structure without, however, losing any topologic linkage with the zeolite matrix (9). While that idea was first illustrated for metalloorganic compounds, the topologic bond with the support can also be realized for a number of organic molecules.

This work presents the results obtained by supporting Fe(II) phthalocyanine on the NaA zeolite via topologic anchoring of a backside fragment of the ligand, and the studies of the catalytic properties of the samples obtained in the liquid-phase hydroxylation of benzene by H_2O_2.

Experimental

The kinetics of the oxidation of benzene in the presence of Fe(II) phthalocyanine topologically anchored on NaA zeolite ($FePc^*$/NaA) were studied under liquid-phase conditions in the temperature range 20–80°C. In a typical experiment, a glass reactor was loaded with benzene, a sample of $FePc^*$/NaA containing 0.25 mg of iron per 1 g of calcined NaA, and an aqueous solution of 50% H_2O_2. Stirring of the mixture was carried out intensively with a magnetic stirring rod to provide the kinetic conditions. The oxidation of benzene by H_2O_2 proceeds neither in the absence of Fe(II) phthalocyanine derivative topologically anchored on the NaA zeolite nor in the presence of the calcined NaA at operating temperatures.

The reaction kinetics were monitored spectrophotometrically with a Specord UV–VIS spectrometer and verified chromatographically on a Chrom-5 instrument (Separon, 1.5 m × 3 mm). All solutions were prepared using reagent grade materials.

The NaA zeolite was dehydrated by calcination in air at 500°C for 5 h. The sample of $FePc^*$/NaA was prepared according to ref. 9, from (1-acetyl)phthalocyanine of Fe(II), zeolite containing diethyl ketone, and hexamethylene diamine, by refluxing in benzene under anaerobic conditions. The colored solid was extracted by warm benzene and characterized by

diffuse reflectance spectra, SEM technique, IR spectroscopy, and elemental analysis.

Results and discussion

The **zeolite-encapsulated** metal phthalocyanines are localized in supercages of the solid, which results in an increase in diffusion resistance for any substance penetrating the crystalline framework. Thus it is reasonable to expect a decrease in the adsorption capacity of the samples containing the guest molecules (3, 7, 8). The rate of the reaction in the presence of the intracrystalline metal complexes was found to be proportional to the covering only at low concentration of the catalyst (7, 8). There is a critical concentration of the zeolite-encapsulated metal complexes at which the "inner" active centers become inaccessible to the substrates. The values of the critical concentration for a stochastic distribution of the catalyst molecules usually depends on a number of factors, the main one being the size of reactants. The rate of the reaction is shown to become independent of the metal complex concentration at higher coverings. The absence of the concentration dependence of the reaction rate suggests that some of the active centers seem to be screened by the crystal framework of the support and so to be excluded from the catalytic process. **Thus, in the case of the zeolite-encapsulated metal complexes, the increase in covering does not result in an adequate enhancement of the corresponding rate of the reaction**. In fact, increasing the metal complex concentration in the zeolite further worsens the diffusion conditions, which makes this factor ineffective especially for reactions of organic molecules.

On the other hand, the above considerations show that the active molecules on the **external surface** are the only ones that work as operating catalysts. Taking this into account, we recently developed (9) a means of supporting metal complexes on porous materials. The main thrust of the new approach consists in the application of the zeolite or other porous material as a support only for that part of the molecular complex which is located far away from the center of the catalysis. This part may be a side fragment of the ligand that does not affect dramatically the donor–acceptor properties of the coordinated atoms.

The side fragment of the ligand is connected by some available means with an "anchor," a molecule topologically entrapped by the zeolite. The scheme of the anchoring is depicted in Fig. 1.

The anchor fragment **A** may either be synthesized inside a large cavity of the zeolite according to the usual scheme for topologically encapsulated metal complexes or remain as the starting molecule having lost one degree of the freedom for movement within the supercage of the zeolite. In this work, we suceeded in anchoring the Fe(II) phthalocyanine derivative by means of diethyl ketone, the carbon-chain precursor that played the role of anchor fragment **A**. Although the effective diameter of the entrance into the supercage of the zeolite crystal lattice is somewhat greater than the linear size of this compound, it is the asymmetric shape of diethyl ketone that permits it to penetrate the large cavities of the NaA zeolite. Thus, the anchoring is possible if a starting material is a linear compound and bears a function group in the middle of the chain. Diethyl ketone is shown to satisfy all of these requirements.

The above scheme demonstrates the anchoring via a linear molecule **A** as precursor. Normally, the linear compound is reversibly adsorbed in the large cavity of the NaA zeolite. This means that desorption occurs in the same manner, i.e., the precursor can abandon the supercage along the axis of the chain, while, on the contrary, the removal of the adsorbate in the direction perpendicular to the axis of the chain is impossible. So if the molecule possesses only one possibility for removal from the supercage of the NaA zeolite it becomes sterically retained. It is this mode of retention that we applied to the supporting of the Fe(II) complex of (1-acetyl)phthalocyanine on the NaA zeolite. The resulting sample, $FePc^{*}$/NaA, containing a zeolite-supported complex of Fe(II) is shown in Scheme 1.

The treatment of the sample $FePc^{*}$/NaA (Scheme 1) containing the Fe(II) phthalocyanine derivative topologically anchored via a diethyl ketone fragment with organic solvents results in no extraction of the metal complexes. Thus, the retention of the catalyst on the support indicates that there are certain restrictions for the motion of the anchor inside the large cavity of the NaA zeolite. Such behavior of the supported catalyst confirms the conclusion that the Fe(II) phthalocyanine derivative is linked to the anchor fragment, which in turn, after formation of the bond with the ligand, becomes sterically hindered.

Characterization of the sample

The effective diameter of the starting complex of Fe(II) is greater than the size required for entering the supercage of the

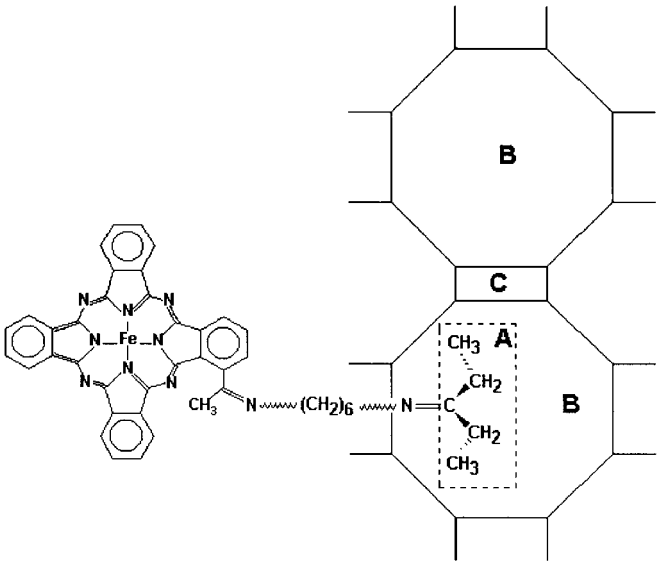
Scheme 1.

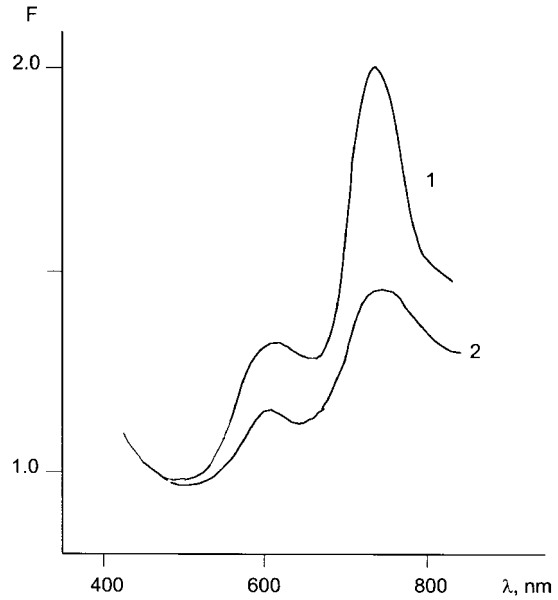


NaA zeolite so that it cannot penetrate the crystal structure. On the other hand, the anchor fragment also is shown to be sterically entrapped by the supercage of the NaA zeolite as it could not be dragged out of the framework by the same route followed on adsorption, i.e., along the main axis of the carbon chain. The sample of FePc*/NaA obtained did not lose the metal complex by multiple extraction with DMF, which is known to dissolve metal phthalocyanines. At the same time, the diffuse reflectance spectrum of FePc*/NaA revealed a band at 660–780 nm (Fig. 2), which is consistent with the data obtained for the initial complex and for Fe(II) phthalocyanine supported on the zeolite (2, 5). This result provides evidence that the introduction of the anchor fragment into the backside of the phthalocyanine ligand does not appreciably disturb the electron configuration of the compound.

IR spectroscopy is known to provide no information on the samples of Fe(II) phthalocyanine embedded in the zeolite except for the regions of 1500–1300 and 800–700 cm^{-1} (10). In these regions the zeolite absorption is practically absent; however, bands appear at 1290, 1340, 1390, 1420, 1460, 1500, and 732 cm^{-1} (10) that are characteristic of stretching and deformation vibrations in the phthalocyanine ligand. Opposite to the absorption of the zeolite, the sample FePc*/NaA exhibits an asymmetric doublet at 700–800 cm^{-1} consistent with the intensive band at 740–730 cm^{-1} assigned to the stretching vibrations of benzopyrrole CH fragments of the ligand. As we found previously for the zeolite-encapsulated Fe(II) phthalocyanine (10), most of these bands also appear in the IR spectrum of the FePc*/NaA sample.

According to the SEM data obtained for FePc*/NaA, the sample contains 0.24 mg of Fe per 1 g of NaA, which is consistent with an elemental analysis within 3–5%. This result indicates that the metal complexes are quantitatively deposited on the external surface of the zeolite crystals.

Fig. 2. Diffuse reflectance spectra for FePc*/NaA (1) and the mixture of the initial complex and zeolite (2).



Catalytic properties of FePc*/NaA

No reaction between benzene and H_2O_2 occurs in the absence of topologically anchored Fe(II) (1-acetyl)phthalocyanine. As mentioned, free Fe(II) phthalocyanine is of low solubility in benzene (less than 10^{-7}–10^{-8} mol/L), which makes its use in homogeneous processes impractical. The acylated derivative, Fe(II) (1-acetyl)phthalocyanine, also is practically insoluble in benzene and exhibits no catalytic activity on being suspended in the benzene – 50% H_2O_2 heterogeneous mixture either at room temperature or upon refluxing. On the contrary, the topologically anchored FePc* complex shows remarkable catalytic activity in reaction [1].

[1] 
The hydroxylation of benzene by H_2O_2 in the presence of FePc*/NaA occurred even at room temperature. Under these conditions, the substrate gave quantitatively the only product of the reaction, which is phenol. As the process at 20°C was sluggish, it needed some days for the reaction to be complete. At small conversions, the initial rate of the hydroxylation of benzene was constant with time. A plot of the concentration of phenol vs. time is shown in Fig. 3.

The rate of the hydroxylation of benzene by H_2O_2 proved to be dependent on the amount of the sample of the catalyst used. As the mass of the sample was proportional to the concentration of the active molecules within a statistical deviation, the above-mentioned dependence reflects the influence of the Fe(II) (1-acetyl)phthalocyanine derivative on the observed rate of the reaction. A similar result was obtained with respect to the proportionality between the observed rate of the hydroxylation of benzene and the amount of H_2O_2. These data are presented in Fig. 4.

Thus, according to these facts, the observed rate of the reaction, r_{obs}, is as follows:

© 1998 NRC Canada

Fig. 3. A plot of phenol concentration vs. time for the hydroxylation of benzene by H_2O_2 (mole ratio is 100:1) at 20°C in the presence of FePc*/NaA: 0.45 (1), 0.80 (2), and 1.0 (3) g.

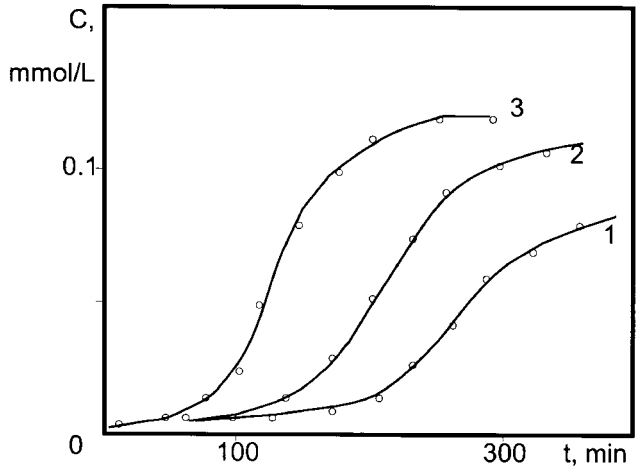


Fig. 4. A plot of phenol concentration vs. time for the hydroxylation of benzene at 20°C in the presence of 0.5 g of FePc*/NaA and varying amounts of H_2O_2: 0.6 (1), 1.1 (2), and 1.8 (3) mmol/L. The arrows indicate when the additional amount of H_2O_2 was introduced into the system.

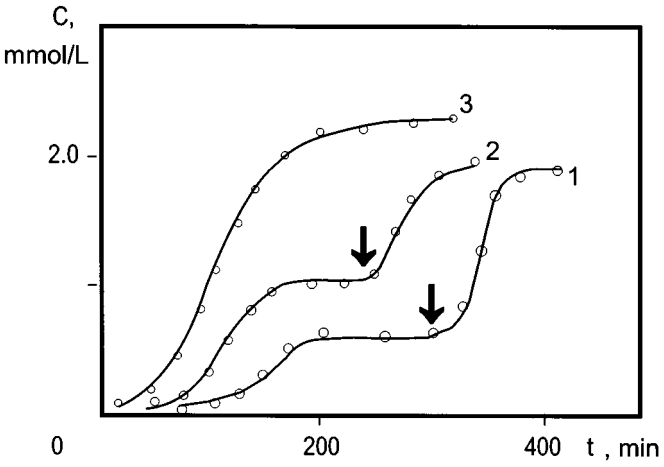
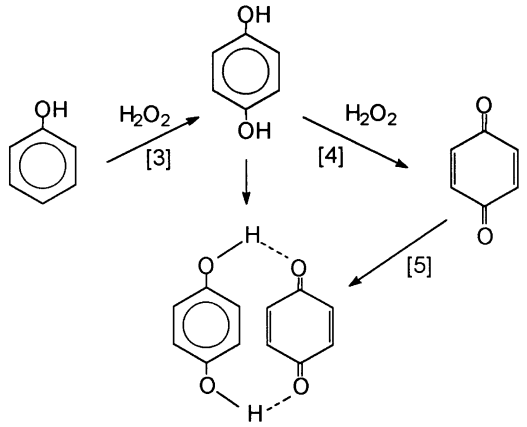


[2] $r_{obs} = k_{eff}[H_2O_2][Cat]$

where k_{eff} is the effective rate constant, and $[H_2O_2]$, and [Cat] are the current concentration of hydroperoxide and the total concentration of the catalyst, respectively.

In fact, eq. [2] also remains operative at elevated temperatures. However, during reflux of the heterogeneous mixture, the side processes become noticeable. It was found that the excess of H_2O_2 on refluxing of benzene in the presence of the topologically supported phthalocyanine derivative of Fe(II) gives the products of further hydroxylation and oxidation of the phenol formed. Semi-quinone and *p*-benzoquinone were detected chromatographically. The former obviously appears as a by-product of the interaction of hydroquinone and *p*-benzoquinone (Scheme 2, reaction [5]), which in turn are formed by the side reactions [3] and [4], respectively.

Scheme 2.



However, it should be noted that semi-quinone and *p*-benzoquinone are also formed on reflux with low yields (no more than 2 and 5%, respectively).

The variation in effective rate constants with temperature between 20 and 80°C calculated according to eq. [2] is presented graphically in Fig. 5. The effective activation energy for the formation of phenol determined from these data using the Arrhenius equation is 12.6 (0.5) kJ/mol, a value that is too small for molecular or ionic reactions.

Also, the reaction stops when a certain amount of radical traps (e.g., $HNPh_2$ and others) is introduced into the system This result is consistent with a radical chain mechanism, which is typical of oxidation by H_2O_2 in the presence of Fe(II) complexes of chelating ligands and phthalocyanine.

Thus, according to refs. 11 and 12, the proposed mechanism for the hydroxylation of benzene by H_2O_2 in the presence of topologically anchored Fe(II) (1-acetyl)phthalocyanine may be as follows:

$$FePc + H_2O_2 = (HO)FePc + HO^{\bullet}$$

$$(HO)FePc + C_6H_6 = FePc + C_6H_5^{\bullet} + H_2O$$

$$HO^{\bullet} + C_6H_6 = H_2O + C_6H_5^{\bullet}$$

$$(HO)FePc + C_6H_5^{\bullet} = FePc + C_6H_5OH$$

$$H_2O_2 + C_6H_5^{\bullet} = C_6H_5OH + HO^{\bullet}$$

$$HO^{\bullet} + C_6H_5^{\bullet} = C_6H_5OH$$

$$HO^{\bullet} + HO^{\bullet} = H_2O_2$$

Therefore the homolytic cleavage of H_2O_2 within the coordination sphere of Fe(II) is considered to produce free radicals, giving rise to a chain process in the liquid phase.

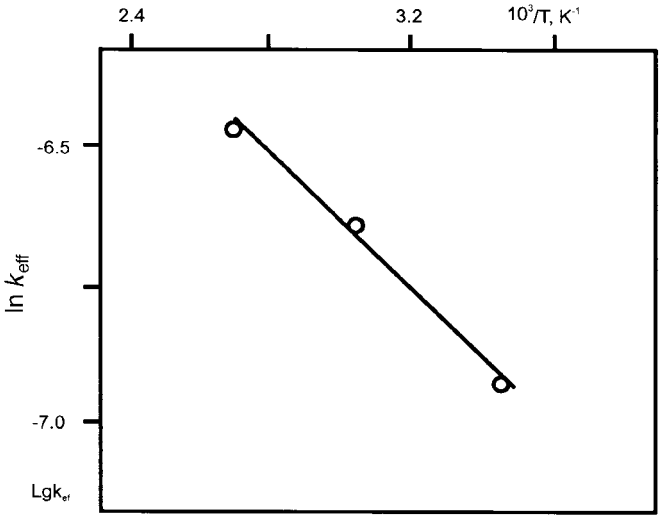
Conclusions

The topologic anchoring of the Fe(II) phthalocyanine derivative on the NaA zeolite provides for a more effective application of chelate–metal complexes to heterogeneous catalysis. The topologically anchored metal complexes differ from zeolite-encapsulated chelates, which are known to become nonoperative as catalysts for sterically hindered substrates.

There have also been some difficulties for the intracrystalline synthesis of metal complexes using ligands or precursors unable to penetrate the cavities of the solids. In that sense,

© 1998 NRC Canada

Fig. 5. A plot of ln k_{eff} against $1/T$ for the hydroxylation of benzene by H_2O_2 in the presence of zeolite-anchored FePc*/NaA.



the topologic anchoring by the side fragment of the ligand is shown to be applicable to the supporting of coordination compounds of any dimension and shape.

The high affinity of the NaA zeolite for water obviously results in an increase in the efficiency of the anchoring. Indeed, the water, after the process of anchoring (9), fills up the free space of the large cavities. This additionally hinders the moving of the anchor in the supercage of the zeolite and makes negligible any extraction of the entrapped fragment of the ligand by the liquid reaction medium.

Thus, the example of the liquid-phase hydroxylation of benzene by H_2O_2 in the presence of the topologically anchored derivative of Fe(II) (1-acetyl)phthalocyanine shows higher catalytic efficiency of the samples obtained in comparison with the patterns containing the intracrystalline complexes. This confirms that, in any case, it is unreasonable to attempt to obtain more effective molecular dispersion of the catalytically active species throughout the bulk of the support.

Kinetic effects induced by cellulose on water-catalyzed reactions. Hydrolysis of 2,4-dinitrophenyl cellulose xanthate and some sugar xanthate ester analogues

Eduardo Humeres, Luiz Fernando Sequinel, Mauricéa Nunes, Célia M.S. Oliveira, and Patrick J. Barrie

Abstract: The hydrolysis of 2,4-dinitrophenyl cellulose xanthate (CelXDNP) was studied in 10% v/v aqueous ethanol at 25°C and $\mu = 0.1$ (KCl). The water-catalyzed hydrolysis showed that, as for *p*-nitrobenzyl cellulose xanthate, it occurs through two parallel reactions with rate constants $k'_{H2O} = 4.40 \times 10^{-3}$ s^{-1} for the fast hydrolysis, and $k''_{H2O} = 6.90 \times 10^{-5}$ s^{-1} for the slow hydrolysis. The entropy of activation of the fast hydrolysis was 0.7 ± 1.8 cal K^{-1} mol^{-1}. External nucleophiles such as hydroxide and simple amines show simple first-order kinetics. The spontaneous hydrolysis of CelXDNP in acetone–water mixtures indicates that the fast reaction does not occur through water polymers and that for water molarity higher than 30 M there are no acetone molecules (or very few) in the highly ordered cybotactic region of cellulose. The spontaneous hydrolysis of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside 3-(*S*-*p*-nitrobenzyl-xanthate) although is faster than the 6-isomer, it is slower than the fast hydrolysis of *p*-nitrobenzyl cellulose xanthate (CelXNB). Also $\Delta S^{\neq}$ is highly negative (–41.0 cal K^{-1} mol^{-1}), as it is for alkyl and sugar analogues. Only for the fast hydrolyses of CelXDNP and CelXNB is the entropy of activation almost zero. It is concluded that there is no neighbouring OH effect on the fast hydrolysis of cellulose xanthate esters.

Key words: hydrolysis, water catalysis, cellulose xanthate esters, methyl glucose, xanthate esters, neighbouring OH effect.

Résumé : On a étudié l'hydrolyse du xanthate de 2,4-dinitrophénylcellulose (CelXDNP) en opérant à 25°C, en solutions aqueuses d'éthanol à 10% v/v et à $\mu = 0,1$ (KCl). L'hydrolyse catalysée par l'eau montre que, comme dans le cas du xanthate de *p*-nitrobenzylcellulose, celle-ci se produit par le biais de deux réactions parallèles avec des constantes de vitesse de $k'_{H2O} = 4,40 \times 10^{-3}$ s^{-1} pour l'hydrolyse rapide et de $k''_{H2O} = 6,90 \times 10^{-5}$ s^{-1} pour l'hydrolyse lente. L'entropie d'activation de l'hydrolyse rapide est égale à $0,7 \pm 1,8$ cal K^{-1} M^{-1}. Les nucléophiles externes, tels l'hydroxyde et les amines simples, réagissent avec une cinétique du premier ordre simple. L'hydrolyse spontanée du CelXDNP dans des mélanges eau–acétone indique que la réaction rapide ne se produit pas avec des polymères-eau et que, à des molarités d'eau supérieures à 30 M, il n'y a pas (ou très peu) de molécules d'acétone dans la région cybotactique bien organisée de la cellulose. L'hydrolyse spontanée du 3-(*S*-*p*-nitrobenzylxanthate) de 4,6-*O*-benzylidène-α-D-glucopyranoside de méthyle, même si elle est plus rapide que celle de son isomère en position 6, est plus lente que l'hydrolyse rapide du xanthate de la *p*-nitrobenzylcellulose (CelXNB). Les $\Delta S^{\neq}$ est très négatif (–41,0 cal K^{-1} mol^{-1}), comme c'est le cas avec les analogues alkylés ou avec les sucres. Ce n'est que dans le cas des hydrolyses rapides des CelXDNP et CelXNB que l'entropie d'activation est pratiquement égale à zéro. On en conclut qu'il n'y a pas d'effet avoisinant de OH sur l'hydrolyse rapide des esters xanthiques de la cellulose.

Mots clés : hydrolyse, catalyse par l'eau, esters xanthiques de la cellulose, esters xanthiques de glucosides de méthyle, effet avoisinant de OH.

Introduction

The nonbonding interactions of carbohydrates with water depend on their stereochemistry and have been the subject of numerous studies (1). Kinetic medium effects induced by carbohydrates give some insight into the specificity of the stereochemical interaction with water (2) and are important to the understanding of their role in the sugar–protein recognition involved in carbohydrate transport (3).

The study of the reactivity of a moiety covalently bound to a polysaccharide system showed that the reaction of water was much faster compared to small analogue molecules (4). The water-catalyzed hydrolysis of *p*-nitrobenzyl cellulose xanthate

© 1998 NRC Canada

(CelXNB) occurred through a fast reaction and a slower parallel reaction. The faster hydrolysis was ascribed to the reaction of the C-2 + C-3 isomers and the slower hydrolysis to the C-6 isomer. The acceleration observed in the fast hydrolysis was attributed to an entropic effect due to a well-oriented water molecule, catalyzed by a second water molecule that acts as a general base as shown by proton inventory. However, it was also recognized that instead of a second water molecule, a neighbouring OH was able to act as a general base. External nucleophiles such as hydroxide ions and amines do not discriminate between the isomers and react like small analogue molecules (5).

This paper deals with the hydrolysis of 2,4-dinitrophenyl cellulose xanthate (CelXDNP), a cellulose ester with a good leaving group, in order to characterize the spontaneous reaction in comparison to CelXNB (eq. [1]).

[1] 
The hydrolysis of the 3- and 2,3-*p*-nitrobenzyl methyl glucose xanthate esters was studied to determine if there was a neighbouring OH group involved in the rate acceleration observed in the spontaneous hydrolysis of CelXNB.

Experimental

All chemicals and solvents were of analytical grade and were used as received, except the amines, which were previously distilled.

The solid-state ^{13}C NMR measurements were obtained using cross polarization (CP), magic angle spinning (MAS), and total sideband suppression (TOSS), and were performed using a Bruker MSL-300 spectrometer. The NMR spectra in solution were obtained with Bruker AC-200, WM-250, and AMX-400 equipment.

2,4-Dinitrophenyl cellulose xanthate (CelXDNP)

Commercial cotton tissue (2.2 g) was washed with 1 M HCl for 1 h and then several times with water. The sample was mechanically shaken in 100 mL of 2 M NaOH for 1 h. Half of the basic solution was taken away, a solution of 30 mL of CS_2 in 20 mL of *p*-dioxane was added, and the suspension was shaken for 2 h. The cellulose xanthate was filtered and treated with 0.1 M phosphate buffered solution at pH 8.0, then washed with dried acetone, and allowed to react with a solution of 3 g of 2,4-dinitro-1-fluorobenzene dissolved in 100 mL of dried acetone for 72 h with mechanical shaking. The cellulose xanthate ester was filtered, washed rapidly with 0.1 M HCl, then with acetone and finally with diethyl ether, and dried under vacuum for 10 h at room temperature over P_2O_5. The degree of substitution (DS, number of xanthate ester groups per 100 glucoanhydropyranose units) was 4.6 determined as described previously (4), measuring the number of moles of 2,4-dinitrothiophenol liberated in the ethylaminolysis, observed at 410 nm, using the extinction coefficient of 1.38×10^4 (6).

The CelXDNP was characterized from the ^{13}C NMR spectra with 12 h acquisition time, 2 ms contact time, 4 s recycle delay between scans, using CP/MAS TOSS (Table 1).

The thiocarbonyl signal of CelXDNP appears at 195 ppm, about 19 ppm at higher field than for the *p*-nitrobenzyl cellulose xanthate (CelXNB) where there is a methylene bridge between the xanthate group and the phenyl ring. All the signals

[c] From noncrystalline components (refs. 7 and 8). Values in parentheses are calculated (ref. 9).

for the 2,4-dinitrophenyl ring in the 120–150 ppm region agreed with the calculated values (9). Considering the area of the signals due to the 2,4-dinitrophenyl ring with respect to that of C-1, the DS was 5.1, reasonably close to that calculated by ethylaminolysis.

After *n*-butylaminolysis of CelXDNP, the NMR spectrum of *n*-butyl cellulose thioncarbamate showed that the signal at 195 ppm disappeared, producing a signal at 189.6 ppm assigned to the thioncarbamate group [O-C(S)-N] and the calculated signals for the *n*-butyl group at 45.1, 30.6, 20.6, and 14.5 ppm. This spectrum was identical to that obtained from CelXNB after *n*-butylaminolysis.

Methyl-D-glucopyranoside 6-(*S*-*p*-nitrobenzyl xanthate) (MGX-6)

In a solution of 20 g of methyl-α-D-glucopyranoside in 20 mL of water, 4.5 g of sodium hydroxide was slowly added, and when it was completely dissolved, 3.1 mL of carbon disulfide was mixed dropwise with constant stirring for 3 h at room temperature. The mixture was then neutralized with cooled acetic acid. A solution of 11.02 g of *p*-nitrobenzyl bromide in methylene chloride (20 mL) was added slowly while stirring, and the mixture was allowed to react for 2 h. The solution was concentrated under vacuum. The solid product was dissolved in 90% v/v aqueous ethanol and allowed to crystallize. Upon recrystallization in the same solvent, the white crystals were dried under vacuum over phosphorus pentoxide. The product gave positive test of carbohydrate, showing only one spot of TLC on alumina with ethyl acetate (R_f 0.75); mp 70–71°C; λ_{max} 283 nm; $[\alpha]_D^{25}$ +72.3 (*c* 0.41, chloroform). Anal. calcd. for $C_{15}H_{19}NO_8S_2$: C 44.4, N 3.4, H 4.7, S 15.8; found: C 43.1, N 3.4, H 4.8, S 15.5.

^{13}C NMR (Table 2); ^1H NMR (400 MHz, CD_2Cl_2), δ: 8.13 (d, *J* = 6.7 Hz, 2H, C_e-H), 7.54 (d, *J* = 6.7 Hz, 2H, C_d-H), 5.08 (s, 1H, OH), 4.85 (dd, *J* = 11.7, 2.0 Hz, 1H, C_6-H), 4.73 (d, *J* = 3.6 Hz, 1H, C_1-H, dd, *J* = 11.7, 6.0, 1H, C_6-H′), 4.46 (s, 3H, C_b-H2, H_2O?), 4.1 (d, *J* = 7.2, 1H, OH), 3.89 (ddd, *J* = 9.7, 5.8, 1.9, 1H, C_5-H), 3.73 (t, *J* = 9.2, 1H, C_3-H), 3.52 (m, 1H, C_2-H), 3.43 (ddd, *J* = 9.5, 9.5, 7.0, 1H, C_4-H), 3.37 (s, 3H, OMe). Couplings between C_6-H and C_5-H are not equal (2.0 and 6.0 Hz), showing that the side chain is in a preferred conformation.

Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside 3- and 2,3-(*S*-*p*-nitrobenzyl-xanthate) (MGX-3 and MGX-2,3)

Twenty five milliliters of CS_2 and 10 mL of 5 N NaOH were added to a solution of 10 g of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside in 25 mL of *p*-dioxane, and the reaction mixture was stirred for 30 min at room temperature. Then it was neutralized with acetic acid at 5°C. *p*-Nitrobenzyl bromide (7.6 g) was slowly added, and the mixture was stirred for 5 h. The layers were separated, and the organic layer was concentrated under vacuum to a solid that was extracted with diethyl ether. After evaporation, the solid was recrystallized several times with dried 2-propanol, giving white crystals of MGX-3: TLC, alumina, 2-propanol, R_f 0.74; mp 176°C; λ_{max} 283; $[\alpha]_D^{22}$ + 51.9 (*c* 0.03, chloroform). For MGX-3 the C_2-OH proton couples to the C_2-H proton, which is also coupled to the anomeric proton. This coupling can only be due to a *trans*-CH-OH conformation. Thus, the hydroxyl is not hydrogen-bonding to either of the neighbouring methoxy or xanthate groups. The IR spectrum confirmed this, showing a sharp OH band. The other proton couplings are consistent with a rigid chair–chair conformation.

For the MGX-2,3, the assignment fits with the chair–chair conformation.

Kinetics

The hydrolysis of CelXDNP was studied in a continous-flow system, with mechanical stirring, under inert atmosphere, using deoxygenated water as described previously (5), following the appearance of 2,4-dinitrothiophenol at 410 nm. The basic hydrolysis was pseudo-first order. The spontaneous hydrolysis of CelXDNP showed a biphasic plot of ln Δ*A* vs. time similar to that observed for CelXNB, due to two parallel reactions with rate constants k'_{H2O} (fast) and k''_{H2O} (slow) (5).

In the range of pH 4–12 all the hydrolyses were carried out at three different buffer concentrations, and the rate constants were extrapolated to zero buffer concentration.

Hydrolyses of the methylglucose xanthates were followed by the disappearance of the xanthate at 283 nm. The spontaneous hydrolysis of MGX-2,3 showed also a biphasic plot as a consequence of the consecutive hydrolyses of the two xanthate groups with rate constants k_1 and k_2.

Activation parameters were calculated from the Eyring equations at four temperatures.

Results

Hydrolysis of sugar xanthates

The spontaneous hydrolysis of CelXDNP occurs through two parallel reactions with rate constants k'_{H2O} for the fast hydrolysis and k''_{H2O} for the slow hydrolysis. At high pH where the hydroxide catalyzed reaction predominates, kinetics become simple first-order.

The pH–rate profile of the fast spontaneuos hydrolysis of CelXDNP is shown in Fig. 1. It is similar to other xanthate esters and can be represented by eq. [2], where k_{obs} is the rate constant extrapolated to zero buffer concentration; k'_{H2O} and k_{OH} are

$$[2] \quad k_{obs} = k'_{H2O} + k_{OH}[OH^-]$$

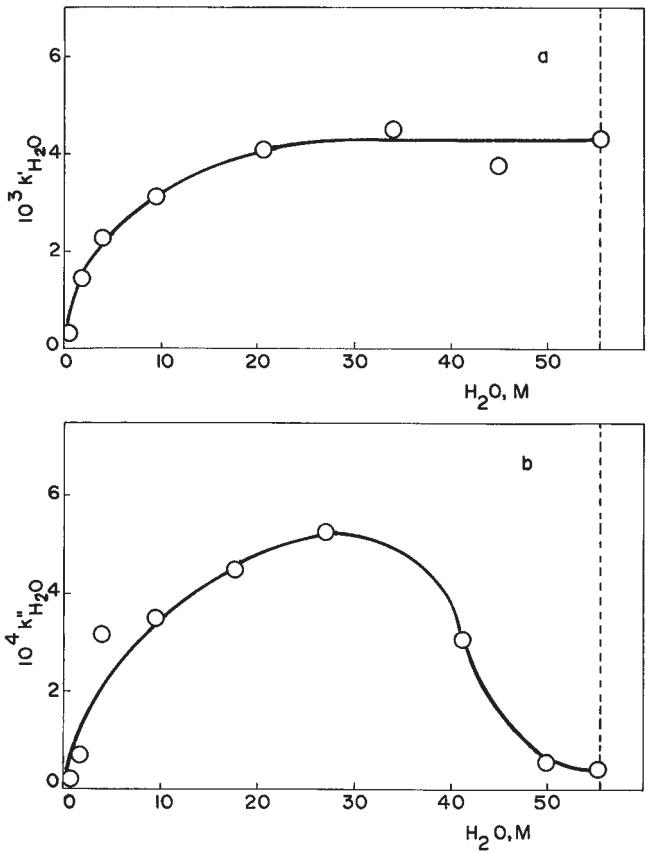
Fig. 2. Hydrolysis of CelXDNP in aqueous acetone at 25°C; (*a*) fast hydrolysis (k'_{H2O}); (*b*) slow hydrolysis (k''_{H2O}).



the rate constants for the water-catalyzed fast reaction and hydroxide-catalyzed reaction, respectively. In Table 3 are shown k'_{H2O}, k''_{H2O}, and k_{OH} for CelXDNP and some sugar xanthates. The rate constants for the ethylxanthate ester analogues are also included for comparison. All sugar xanthates, except the 6-substituted methylglucose xanthates (MGXB and MG-6), hydrolyze faster than the ethyl analogues. The rate constant k_2 for MG-2,3 is the same as that for MG-3.

Hydrolysis in aqueous acetone

To observe if the active species involved in the spontaneous hydrolysis were water polymers, the reaction of CelXDNP in acetone with increasing molarity of water was studied. The rate constants showed a downward curve for both the fast and slow spontaneous hydrolysis (Fig. 2), which is the reverse of the type of the curve expected when water polymers are involved in the transition state of the spontaneous hydrolysis (12). Both rate constants k'_{H2O} and k''_{H2O} increase with water molarity, following the change of dielectric constant of the medium, up to ca. 30 M water, whereas k'_{H2O} remains approximately constant with further increase while k''_{H2O} decreases rapidly in pure water.

Activation parameters

The activation parameters for the hydrolysis of sugar xanthates are shown in Table 4. The average value of $\Delta G^{\neq}$ was obtained from four temperatures, and $\Delta H^{\neq}$ was obtained from the least-squares fit of ln(k/T) vs. 1/T. It is important to note that only

Table 4. Activation parameters for the hydrolysis of sugar xanthates in 10% v/v aqueous ethanol, μ = 1.0 (KCl).

Ester	Nucleophile	$\Delta G^{\neq}$, kcal mol^{-1}	$\Delta H^{\neq}$, kcal mol^{-1}	$\Delta S^{\neq}$, cal K^{-1} mol^{-1}[a]
CelXDNP	H_2O (fast)[b]	20.68 ± 0.22	20.87 ± 0.43	0.7 ± 1.8
	OH-	18.56 ± 0.18	7.50 ± 0.23	–37.1 ± 0.8
CelXNB	H_2O (fast)[c]	21.67 ± 0.03	22.68 ± 0.20	3.3 ± 0.8
	OH-	21.17 ± 0.06	11.20 ± 0.30	–33.4 ± 0.8

[c] μ = 0.6 (KCl), ref. 5.

for the spontaneous hydrolysis of the cellulose esters is the entropy of activation near zero. For the other sugar xanthates, MGX-3 and MGX-2,3 (k_1 and k_2), the values of $\Delta S^{\neq}$ are highly negative, as they also are for all the hydroxide ion-catalyzed reactions.

Discussion

The spontaneous hydrolysis of cellulose esters is faster than it is for ethyl xanthates. For CelXDNP, k'_{H2O} is more than 1000 times the rate constant of 2,4-dinitrophenyl ethylxanthate (EXDNP), and the ratio k'_{H2O}/ k''_{H2O} is about 60. Therefore the kinetic behaviour of the spontaneous hydrolysis CelXDNP is similar to that of CelXNB. For CelXNB it was found that the water molecule acting as a nucleophile is general-base catalyzed by a second water molecule (5). The fast hydrolysis has been attributed to the reaction of isomers C-2 + C-3. The reaction of CelXDNP in aqueous acetone showed that k'_{H2O} is insensitive to the increase of the molarity of water higher than 30 M (Fig. 2), suggesting that the cybotactic region is tight enough to expulse the cosolvent. The slow hydrolysis (k''_{H2O}) due to C-6 isomer is more sensitive to the composition of the medium because C-6 might be in a looser region.

We then addressed the question as to whether the observed acceleration of the fast hydrolysis of cellulose esters, such as CelXNB, could be a consequence of the

neighbouring effect of the OH in the C-2 or C-3 positions. The effect was expected to be the same for the 2- or 3-substituted ester. The spontaneous hydrolysis of the 3-isomer is indeed about 200 times faster than the 6-isomer (Table 3). However, it is still slower than the fast hydrolysis of CelXNB. The ratios of the rate constants for CelXNB (k'_{H2O}):MGX-3:EXNB are 603:14:1, and for CelXNB (k''_{H2O}):MGX-6:EXNB they are 10:0.1:1. The fast hydrolysis of CelXNB is much faster than expected from the 3-isomer. In addition, the acceleration of the spontaneous hydrolysis is due not only to the sugar moiety, because the 6-isomer is slower than EXNB. The ratio k'_{H2O}/k''_{H2O} for CelXNB is 64, also very different to the ratio MGX-3:MG-6 of 185.

The main argument against the anchimeric assistance of the hydroxyl group comes from the activation parameters. In Table 4 is shown that only for the fast hydrolyses of CelXDNP and CelXNB is the entropy of activation almost zero. For the other water- and hydroxide ion-catalyzed hydrolyses, $\Delta S^{\neq}$ is

© 1998 NRC Canada

highly negative, supporting the theory that the rate acceleration observed for the cellulose esters is due to the ordered water around the cellulose matrix.

The spontaneous hydrolysis of the first xanthate group of MG-2,3 might be faster than the second due to steric compression that is relieved in that step. The hydrolysis of MGX-2,3 raises the possibility that k'_{H2O} and k''_{H2O} correspond to the rate constants of the hydrolysis of dixanthated anhydroglucopyranose rings in CelXNB. The ratios k'_{H2O}/k_1 and k''_{H2O}/k_2 for the rate constants of CelXNB and the hydrolysis of MGX-2,3 are 2,5 and 0.7, respectively. However, there are two pieces of evidence against this alternative. In the first place, the C-6 isomer should predominate over the C-2 + C-3 isomers, because the xanthation of methylglucose in alkaline solution produces mainly the C-6 isomer (13, 14). Therefore, if k'_{H2O} and k''_{H2O} correspond to the hydrolysis of di- and monoxanthated rings, the reactivity of the C-6 isomer should be the same as the C-2 or C-3 isomer, when actually it is about 100 times slower than MGX-3 (Table 3). The second piece of evidence comes again from the negative entropies of activation of the water catalyzed hydrolysis of MG-2,3 (Table 4).

As for the CelXNB, the hydroxide ion-catalyzed hydrolysis of CelXDNP follows simple first-order kinetics, and this reaction is slower than that of the ethylxanthate analogue, as can be observed in Table 3. The slower rates might be due to a diffusion effect of the bulky hydrated OH- through the cybotactic region of cellulose.

Acknowledgements

The solid-state NMR spectra were obtained through the ULIRS Solid State NMR Service at University College London. The NMR spectra of the sugar xanthates were obtained from the Chemistry Department of the University of Liverpool. We are grateful to Prof. Raymond J. Abraham for advice in the assignments and comments.

COMMUNICATION

Effects of superoxide anion generated from aromatic radical anions produced in nucleophilic aromatic photosubstitution reactions

Maria Cervera and Jordi Marquet

Abstract: Superoxide anion is generated from aromatic radical anions produced in nucleophilic aromatic photosubstitutions when the reactions are carried out in non-deoxygenated solutions of polar aprotic solvents. Superoxide anion thus generated displaces cyanide anion from acetonitrile and benzyl cyanide, ethoxide anion from ethyl acetate, and methanesulfenate anion from dimethyl sulfoxide. Hence, non-deoxygenated polar aprotic solvents should be avoided in nucleophilic aromatic photosubstitution reactions.

Key words: superoxide, fluoride, nucleophilic aromatic photosubstitution.

Résumé : Lorsqu'on effectue des photosubstitutions aromatiques nucléophiliques dans des solutions non désoxygénées de solvants aromatiques polaires, on génère l'anion superoxyde à partir des anions radicaux aromatiques alors produits. L'anion superoxyde ainsi produit déplace l'anion cyanure de l'acétonitrile et du cyanure de benzyle, l'anion éthylate de l'acétate d'éthyle et l'anion méthanesulfonate du diméthylsulfoxyde. Lorsqu'on effectue des réactions de photosubstitution aromatiques nucléophiles, on doit donc éviter les solvants aprotiques polaires non désoxygénés.

Mots clés : superoxyde, fluorure, photosubstitution aromatique nucléophilique.

[Traduit par la rédaction]

Nucleophilic aromatic photosubstitutions have been the object of intense research since their discovery in 1956 (1). A mechanistic borderline between polar S_N2Ar^* (2) and S_N2Ar^*-SET (reactions that take place through single electron transfer from the nucleophile to the excited nitroaromatic substrate) has been well established (3, 4). These photoreactions are normally carried out in protic solvents (water is the more common) and without any precautions with regard to the presence of oxygen since its effect on the photoreaction is generally negligible. This has been attributed to the very short lifetime of the nitroaromatic excited states (5) and to the fact that the S_N2Ar^*-SET reactions involve a collapse of radicals in the solvent cage (6).

Fluorinated aromatics nowadays constitute an important class of compounds because of their wide applications, especially in medicinal chemistry (7). The most common way of introducing a fluorine atom into an aromatic nucleus is based on the use of nucleophilic fluoride anion through nucleophilic aromatic substitution reactions (known as the "Halex method") (8). The efficiency of this method has been much improved by the use of tetralkylammonium fluorides (9). Fluoride anion is strongly solvated in protic solvents, its reactivity being very reduced in these media. Therefore, reactions with fluoride anion are normally carried out in anhydrous polar aprotic solvents where fluoride behaves as a very strong base and nucleophile (10).

Nucleophilic aromatic photosubstitutions show in many cases a different regioselectivity when compared with the corresponding ground state reaction. Moreover, inefficient leaving groups in thermal reactions, such as alkoxy groups, are operative in the photochemical version. Therefore, we decided to explore the nucleophilic aromatic photosubstitution of 4-nitroveratrole (NVT), a typical nitrophenyl ether for which the regioselectivity of the photoreaction can be established, with fluoride anion in non-deoxygenated polar aprotic solvents such as acetonitrile (ACN). However, no fluorinated products were obtained. In Scheme 1 the results of the photoreactions carried out in acetonitrile are described. There is no precedent in the literature for the reaction reported in the Scheme 1.

Received December 15, 1997.

This paper is dedicated to Professor Erwin Buncel in recognition of his contributions to Canadian chemistry.

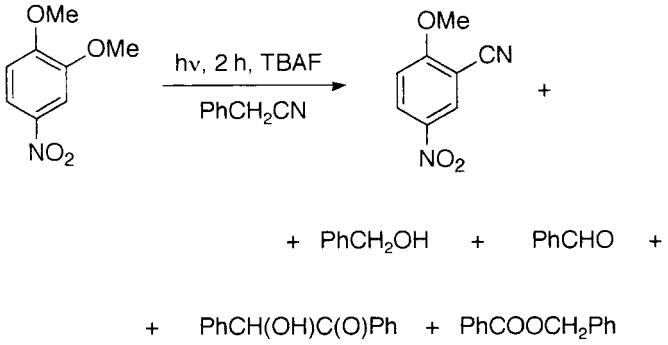
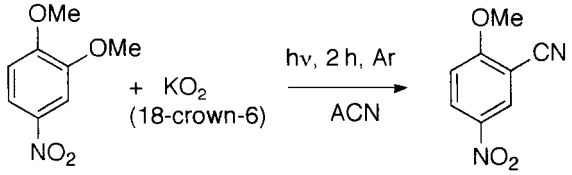
Scheme 2.

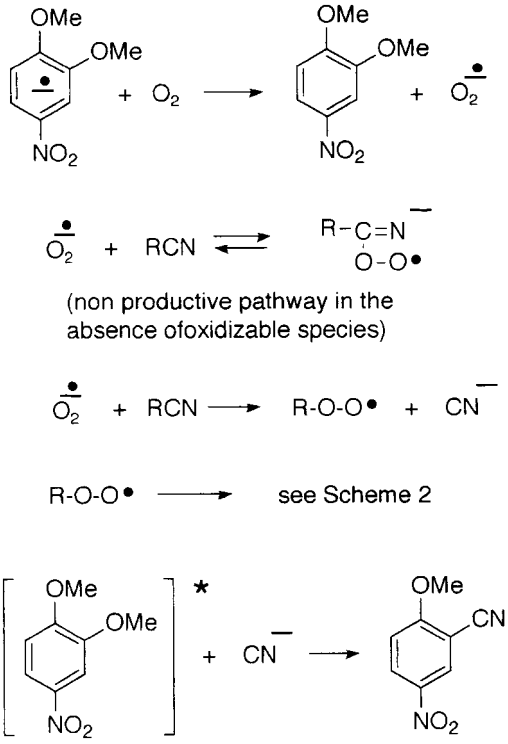


Scheme 3.



For the sake of comparison, we carried out the photoreaction of NVT with sodium cyanide in ACN–H_2O (1 h), obtaining the same photosubstitution product, 2-cyano-4-nitroanisole (46% yield), as the only cyanide substitution product, indicating complete *meta* regioselectivity. Therefore, it seems that the photoreaction described in Scheme 1 involves the fragmentation of the solvent. However, the only related cases described in the literature refer to reductive cleavage of tertiary or secondary alkylnitriles (11) promoted either electrochemically or by solvated electrons, and to photoinduced reductive cleavage of benzylnitriles (12). In these cases the resulting free radical would be stabilized by conjugative or hyperconjugative effects. No such effects are present in the methyl radical and, in addition, our photoreactions proved to be very sensitive to the presence of oxygen. Thus, the photoreaction in non-deoxygenated ACN led to 17% yield of photosubstitution product, but this yield was increased to 67% by bubbling air into the solution. The photoreaction in the absence of oxygen led to

Scheme 4.



complete recovery of the starting material. These results rule out the hypothesis of a reductive cleavage in the mechanism for the photoreactions described in Scheme 1.

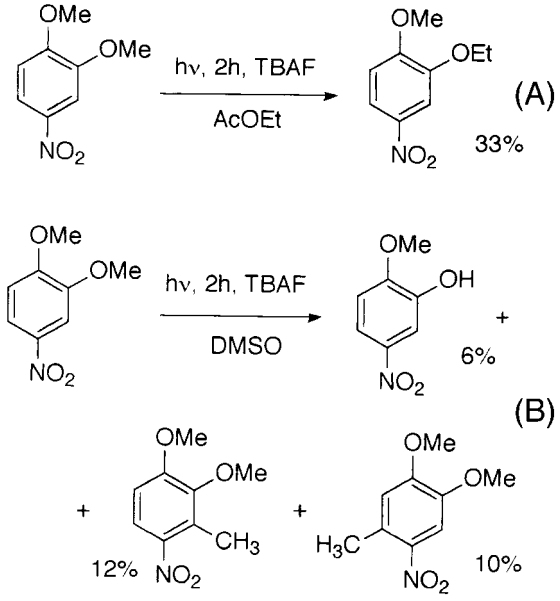
To investigate the evolution of the alkyl fragment, the photoreaction was carried out in benzyl cyanide (instead of ACN) and with air bubbling. The reaction crude was directly analyzed by GC–MS and the products detected are described in the Scheme 2.

From the results reported in Scheme 2 it was clear that the photofragmentation of alkylnitriles is a general process under our conditions, and that the agent responsible for it is an oxidizing species with nucleophilic properties. All products derived from the benzyl moiety are easily justified by considering the radical $PhCH_2OO^{\bullet}$ as a key intermediate (13). These results led us to the hypothesis that the "oxidizing species with nucleophilic properties" was the superoxide anion ($O2^{-\bullet}$) (14). The excellent nucleophilic properties of superoxide anion in polar aprotic solvents are well documented (it reacts with alkyl halides (15) or carbonylic compounds (16)); however, as far as we know no displacement of cyanide from nitriles has been reported (Sawyer and co-workers (18) describe the action of superoxide as a base with acetonitrile, obtaining condensation products). On the contrary, acetonitrile has been used as a solvent in fundamental studies on the reactivity of superoxide anion and its derivatives (18); however, it has been noted that the reactivity of $O2^{-\bullet}$ in acetonitrile is different from that in other solvents (for example, ref. 19), the lifetime of $O2^{-\bullet}$ being typically 10 times shorter in the nitrile.

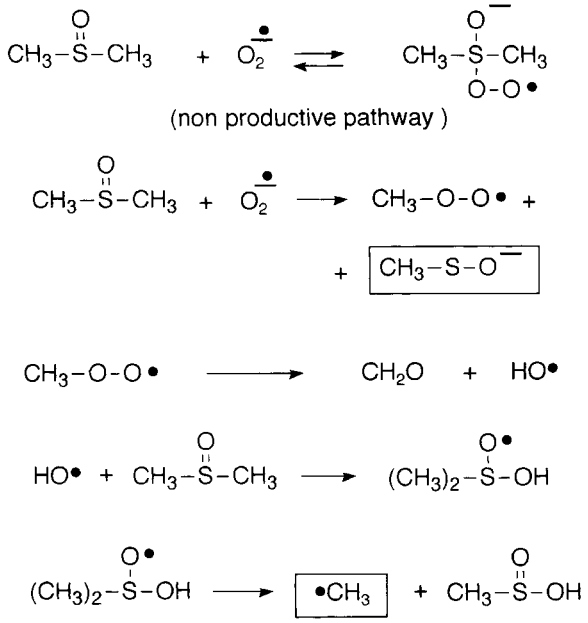
Sawaki and Ogaka (20) reported the reaction between superoxide and acetonitrile in the presence of an easily oxidizable species such as dimethyl sulfoxide as leading to acetamide and dimethylsulfone through the attack of superoxide on the nitrile. However, when the reaction was carried out

© 1998 NRC Canada

Scheme 5.



Scheme 6.



in the absence of the oxidizable species, these authors described the disappearance of the superoxide anion. No explanation was advanced for this behavior.

We have confirmed the role played by the superoxide anion in our reactions by carrying out the photoreaction of NVT with potassium superoxide in acetonitrile and in inert atmosphere, in the presence of the 18-crown-6 (Scheme 3). Direct analysis of the reaction crude by GC showed only the presence of starting NVT and 2-cyano-4-nitroanisole. The displacement of cyanide from acetonitrile in the presence of superoxide anion seems to be a ground state reaction, and this was shown by the detection of cyanide anion (Prussian blue test) in a solution of potassium superoxide and 18-crown-6 in acetonitrile.

After the identification of the agent responsible for our photoreactions an immediate question arises: how is the superoxide anion produced? A still unsolved paradox in ground state aromatic chemistry is the fact that when an electronically poor aromatic (e.g., polynitrobenzenes) substrate is placed in the presence of not easily oxidizable anions such as alkoxy or cyanide, not only the Meisenheimer complexes, but also the corresponding radical anions, can be detected (21). It is known that the concentration of radical anions depends on the concentration and nature of the nucleophile, and on the concentration of Meisenheimer complexes present in the solution (normally very low in ground state chemistry) (22). Therefore, the simplest hypothesis is that production of significant amounts of superoxide anion in our photochemical reactions originates by interaction of dioxygen with the radical anion of the aromatic substrate (NVT), and that this radical anion is present in a significant concentration under our photochemical conditions due to the enhanced reactivity of the nucleophile (fluoride) versus the excited state of the aromatic substrate (NVT is not a very electronically poor substrate), affording a sufficiently large concentration of Meisenheimer complexes. The dependence of the photoreaction upon the nature of the nucleophile and on the concentration of Meisenheimer complexes is demonstrated by the fact that the reactions of Scheme 1 fail when attempted with bromide (a weaker nucleophile in anhydrous acetonitrile) instead of fluoride. In addition, the radical anion of NVT (23) was detected by UV–vis spectroscopy when NVT was irradiated in the presence of TBAF in acetonitrile, under inert atmosphere, but this radical anion could not be detected when bromide was used. These results strongly support our hypothesis. In Scheme 4 a simplified mechanistic proposal is described.

As expected, this behavior was not restricted to nitriles. The photoreaction of NVT in the presence of TBAF·$3H_2O$ in ethyl acetate gave rise to 2-ethoxy-4-nitroanisole (Scheme 5*A*), whereas in dimethyl sulfoxide (DMSO), 1,2-dimethoxy-3-methyl-4-nitrobenzene, 1,2-dimethoxy-4-methyl-5-nitrobenzene, and 2-methoxy-5-nitrophenol were obtained (Scheme 5*B*). These results support our previous conclusions and can also be justified by considering the superoxide anion as responsible. Thus, and for the case of ethyl acetate, it is well known that superoxide anion reacts with esters producing alkoxy anions (17). Here, the ethoxy anion would act as a nucleophile towards NVT in a nucleophilic aromatic photosubstitution reaction (last step of Scheme 4, RO^- instead of CN^-). In the case of the photoreaction carried out in DMSO, the main photoreaction corresponds to the methylation of the aromatic ring. This result suggests the operation of methyl radicals as reaction intermediates. It is known (24) that hydroxyl radicals (•OH) add to DMSO producing methyl radicals through decomposition of intermediate species such as $Me_2S(O^•)OH$. The presence of hydroxyl radicals can be justified by assuming that superoxide anion behaves towards DMSO in a similar way as towards ACN (Scheme 6), through nucleophilic displacement of, in this case, methanesulfenate anion. The methanesulfenate anion thus produced would be responsible for the observed 2-methoxy-5-nitrophenol through a nucleophilic attack upon the excited state of NVT and subsequent hydrolysis, probably at work-up, since no phenol was observed in the photoreactions carried out in ACN, either in ethyl acetate or in a blank irradiation in the absence of fluoride anion.

COMMUNICATION

Formation of *cis*-[R_f(CO)Re(CO)$_4$Hal]Na complexes as an evidence of halogen–metal exchange between [Re(CO)$_5$]Na and polyfluorinated aryl and vinyl halides

Galina A. Artamkina, Petr K. Sazonov, Vasily A. Ivushkin, and Irina P. Beletskaya

Abstract: Halo(acyl)rhenate complexes *cis*-[R_f(CO)Re(CO)$_4$Hal]Na (Hal = Cl, Br; R_f = C_6F_5, *trans*-$(CF_3)_3$CCF═CF) are the primary products of the reactions of [Re(CO)$_5$]Na with the corresponding aryl or vinyl halides R_fHal.

Key words: pentacarbonylrhenate anion, carbonylmetallates, halogen–metal exchange, nucleophilic aromatic substitution, nucleophilic vinylic substitution.

Résumé : Les complexes d'halo(acyl)rhénate du type *cis*-[R_f(CO)Re(CO)$_4$Hal]Na (Hal = Cl, Br; R_f = C_6F_5, *trans*-$(CF_3)_3$CCF═CF) sont les produits primaires des réactions du [Re(CO)$_5$]Na avec les halogénures d'aryle ou de vinyle correspondants, R_fHal.

Mots clés : anion pentacarbonylrhénate, carbonylmétallates, échange halogène–métal, substitution aromatique nucléophile, substitution vinylique nucléophile.

[Traduit par la rédaction]

Nucleophilic aromatic and vinylic substitution with metal carbonyl anions in perfluorinated arenes and alkenes is a well-established synthetic approach to σ-aryl– and σ-vinyl–metal complexes (1, 2). Polyfluorinated aryl and vinyl halides bearing heavier halogens (Cl, Br, I) were shown to be much more reactive than their totally fluorinated analogues in the few cases that have been examined (2–4). It was even possible to likewise obtain the substitution products with the metal carbonyl anions that were unreactive towards the corresponding perfluoroarene or alkene (5). Up until now the reactions of carbonylmetallates with halopolyfluoroarenes and alkenes were treated as ordinary nucleophilic substitution in the framework of the classic addition–elimination mechanism, even though the yields of substitution products often were poor (2–4). We show in this paper that halogen–metal exchange can be the actual reaction pathway in the case of substrates containing the heavier halogens. The reactions of [Re(CO)$_5$]Na with C_6F_5Hal and $(CF_3)_3$CCF═CFHal (Hal = Cl, Br) taken as a model in our study do not yield the nucleophilic substitution products at all; instead the *cis*-[R_f(CO)Re(CO)$_4$Hal]Na complexes are observed, the first example of halo(acyl)carbonylmetallate formed in the reaction of metal carbonyl anion with organic halide.

The reaction of [Re(CO)$_5$]Na with C_6F_5Cl and C_6F_5Br in THF at room temperature occurs within the time of mixing of the reactants. The ^{19}F NMR spectrum of the resulting light yellow solution shows that in both cases only one reaction product is formed quantitatively. The chemical shifts of three resonances belonging to these products are typical of a C_6F_5 group bound to a carbonyl in transition metal – acyl complexes (6). The metal-coordinated acyl group is also evidenced by a band in the IR spectrum at ≈1610 cm^{-1} (7, 8) and a ^{13}C NMR resonance observed at 256–258 ppm (9). The IR spectrum in the metal–carbonyl stretching region shows a characteristic pattern of three bands, and the ^{13}C NMR spectrum displays three resonances due to metal carbonyls with the expected 1:2:1 intensity ratio,[2] both spectra being similar to that of the known *cis*-[R(CO)Re(CO)$_4$X]M complexes (7–9). The structure of *cis*-[C_6F_5(CO)Re(CO)$_4$Cl]Na was also confirmed by the FAB-MS spectrum.[3]

Various (acyl)carbonylmetallates, known as precursors to neutral metal carbene complexes, can be readily obtained via

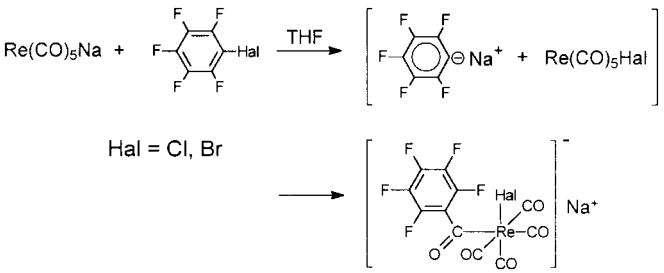
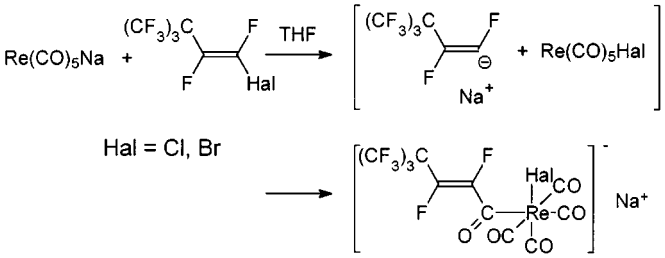


Scheme 2.



nucleophilic addition of carbanionic species such as organolithiums to the carbonyl coordinated to transition metal (10). It was reported that methyllithium does not displace halogen in $Re(CO)_5Hal$ but attacks the carbonyl ligand, producing the corresponding halo(acyl)rhenate (7). In the reaction studied the products are apparently formed by a similar pathway, which seems to have no reasonable alternatives. Any mechanistic hypothesis involving migratory insertion of C═O should be rejected, since with perfluorinated organic ligands the migratory insertion reactions are considered infeasible (11). Moreover, lithium bromide failed to induce CO insertion even in $Re(CO)_5Me$ (7) and, further still, in our case NaCl is almost insoluble in THF. In the proposed mechanism, halogen transfer between $[Re(CO)_5]Na$ and C_6F_5Hal is required to produce $Re(CO)_5Hal$ and C_6F_5Na intermediates (Scheme 1). Thus the formation of such a product as halo(acyl)rhenate may be considered as "autotrapping" of these intermediates, and is a strong argument for the halogen–metal exchange being the primary process in the reaction of metal carbonyl anion and halopolyfluoroarene.

The complexes obtained are unstable; C_6F_5H builds up in solution after several hours at room temperature (yield 4%) as a result of their decomposition.

Analogous products are observed in the reaction of $[Re(CO)_5]Na$ with *trans*-1-chloroundecafluoro-2-*tert*-butylethylene and the corresponding bromide (Scheme 2). Their structure was assigned on the basis of IR and ^{19}F and ^{13}C NMR spectra, which are very similar to the spectra of corresponding aryl complexes.[4] Also formed in these reactions are $Re_2(CO)_{10}$ (20–30%) with chloroalkene and a small amount of $Re(CO)_5Br$ (≈10%) with bromoalkene. Halopolyfluoroalkenes turned out to be less reactive than the aryl halides C_6F_5Hal; the reaction of $[Re(CO)_5]Na$ is completed within 1 h with the chloroalkene and in less than 4 min with the corresponding bromide, indicating that the reactivity of organic halide increases in the same order (Br > Cl) as in the halophilic reactions (12).

The formation of halo(acyl)rhenate complexes demonstrates that $[Re(CO)_5]Na$ attacks halogen rather than the carbon atom in both polyfluorinated aryl and vinyl halides studied. In the reactions of other metal carbonyl anions such as $[CpFe(CO)_2]^-$ with C_6F_5Cl, the halo(acyl)metallate complexes are not observed among the final products; nevertheless in that case other products including $C_6F_5Fe(CO)_2Cp$ are formed via the halogen–metal exchange mechanism (13).

[3] Spectral properties of *cis*-$[C_6F_5(CO)Re(CO)_4Cl]Na$ are IR (THF), ν cm^{-1}: 1927 (vs), 1998 (vs), 2101 (m) (C≡O); 1607 (m) (acyl); ^{19}F NMR (376.3 MHz, THF-d_8) δ: –150.24 (m, 2F, *ortho*), –161.88 (m, 2F, *meta*), –160.06 (t, 1F, *para*); ^{13}C NMR (100.58 MHz, THF-d_8): 185.45 (1C), 187.65 (2C), 188.18 (1C) (C≡O), 256 (C═O); FAB MS (*m*-nitrobenzyl alcohol, NBA, matrix, beam of Xe atoms at 8 kV and 4 mA) m/z^+: 761 (M + 2Na, +NBA), 728 (M + Na, +NBA), 633 (M + 2Na, +NaCl), 625 (M + H, +THF), 575 (M + Na).

[4] Spectral properties of *cis*-[*trans*-$(CF_3)_3CCF^{\alpha}$═CF^{β}(CO)-$Re(CO)_4Br]Na$; IR (THF), ν cm^{-1}: 1937 (vs), 1997 (vs), 2100 (m) (C≡O); 1593 (m) (acyl); ^{19}F NMR (376.3 MHz, THF-d_8) δ: –62.00 (dd, J = 12.5 Hz, J = 17 Hz, 9F, CF_3),–128.62 (d of m, $J_d(F^{\alpha},F^{\beta})$ = 135 Hz, 1F, CF═), –166.09 (d of m, 1F, CF═); ^{13}C NMR (100.58 MHz, THF-d_8): 187.09 (d, J ≈ 5 Hz), 189.45 (d, J ≈ 3.5 Hz), 189.52 (s) (C≡O).

1997 Polanyi Award Lecture
Why are there atoms in chemistry?[1]

R.F.W. Bader

Abstract: Dalton made a bold assumption in his atomic hypothesis by stating that atoms retained their mass and their identity in chemical combination. Its vindication had to await Rutherford's nuclear model of the atom. The continuing evolution of chemistry led to the realization that atoms exhibit not only a unique mass but also characteristic additive properties, thereby making it possible to recognize their presence in a molecule and to predict the molecule's static and reactive properties. The theoretical vindication of the model of a functional group as the carrier of chemical information had to await the work of Feynman and Schwinger. Their generalization of physics leads to a unique definition of an atom as an open quantum system and makes possible the renormalization that is required to account for the short-range nature of the forces that enable one to identify a given group in any environment. The lecture will demonstrate that the proper open systems predicted by the quantum action principle define the atom and that this definition accounts for the retention of an atom's chemical identity by enabling one to replace the quantum mechanical observables for force and energy with dressed, real space density distributions whose forms parallel the transferable topology of the electron density distribution.

Key words: atom, action principle, atoms in molecules, functional groups.

Résumé : Dalton, dans son hypothèse atomique, a posé un postulat audacieux lorsqu'il a affirmé que les atomes gardent leur masse et leur identité dans les combinaisons chimiques. Il a fallu attendre le développement du modèle de l'atome de Rutherford pour le justifier. L'évolution continuelle de la chimie a permis de réaliser que les atomes ne présentent pas uniquement une masse qui est spécifique, mais aussi des propriétés additives caractéristiques qui permettent de reconnaître leur présence dans une molécule et de prédire les propriétés statiques et réactives de la molécule. La justification théorique du modèle d'après lequel le groupe fonctionnel est porteur de l'information chimique a dû attendre les travaux de Feynman et Schwinger. Leur généralisation de la physique a conduit à une définition unique d'un atome d'après laquelle il s'agit d'un système quantique ouvert et elle permet la renormalisation requise pour tenir compte de la nature à courte portée des forces qui permettent d'identifier un groupe donné dans tous les environnements. Dans cette conférence, on démontrera que les systèmes ouverts appropriés prédits par le principe de l'action quantique permettent de définir l'atome et que cette définition permet de tenir compte de la rétention de l'identité chimique d'un atome en permettant de remplacer les données observables de la mécanique quantique pour la force et l'énergie par des distributions de densité d'espace réel dont les formes sont parallèles à la topologie transférable de la distribution de la densité électronique.

Mots clés : atome, principe d'action, atomes dans les molécules, groupes fonctionnels.

[Traduit par la Rédaction]

How to define an atom in a molecule

It is almost 200 years since Dalton put forth his atomic hypothesis and we are approaching the centennial of Rutherford's experimental vindication of Dalton's hypothesis regarding the constancy of the atomic mass and identity throughout chemical combination in terms of the nuclear model. Not only does the nuclear model account for the conservation of the atomic mass, but it also stamps each atom with its own chemical identity. The force of attraction between the positive charge concentrated at the nucleus and the diffuse distribution of electronic charge is the single most dominant force operative in an atom, molecule, or solid. This force determines the atom's fundamental form and endows it with a set of characteristic and measurable properties, properties that underlie the cornerstone of chemical thinking, the concept of a functional group. We shall show in this lecture that because of an atom's fundamental form, all of the molecular structure hypotheses, that is, all of the concepts of chemistry, follow from physics.

In the past there have been many failed attempts to define an atom in a molecule and its contributions, or those of a functional group, to the properties of the molecule. There was and, for some, there remains a prevailing belief that a unique definition is not possible. Consider for example the following statement that appeared in the Journal of the

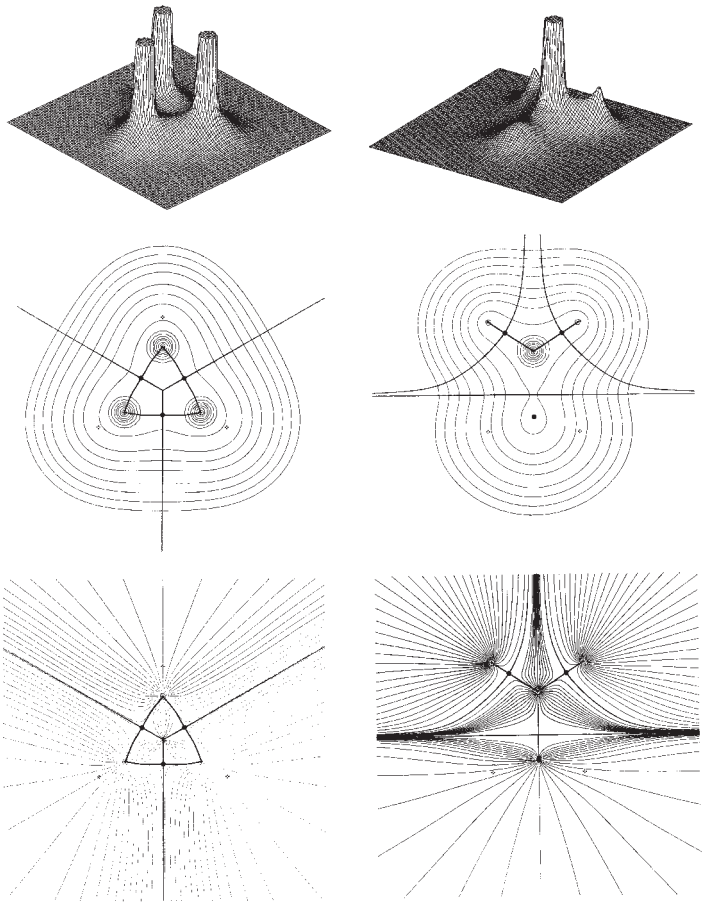
PROOF/ÉPREUVE

Fig. 1. The electron density for the cyclopropane molecule in the form of a relief map and a contour plot together with a display of its gradient vector field in two planes: LHS in plane of carbon nuclei, RHS in symmetry plane containing one carbon nucleus and two attached protons. The density is a local maximum at each nucleus with the result that space is partitioned into atomic basins, each basin being defined by the set of trajectories traced out by $\nabla\rho(\boldsymbol{r})$, the gradient vectors of the density, that terminate at a given nucleus. Shown in bold are the pairs of trajectories in each indicated plane that terminate at the positions of (3,–1) or bond critical points (bcps). These cps, whose positions are denoted by dots, are found only between certain pairs of nuclei. Each such pair of trajectories is part of a set of trajectories defining a two-dimensional manifold embedded in three-dimensional space, which terminate at each bcp and define an interatomic surface. The set of trajectories defining the C | C interatomic surface between two out-of-plane carbon nuclei, for example, is represented by the trajectories that terminate at the bcp in the lower portion of the gradient map on the RHS. The interatomic surfaces defined in this manner are not crossed by any trajectories of the gradient vector field of the density — they are "zero-flux surfaces." Unique pairs of trajectories, also shown in bold, originate at each bcp, and define a bond path — a line of maximum electron density linking the neighboring nuclei. Trajectories originate at the ring or (3,+1) cp in the bottom LH diagram and a pair of trajectories originate at this point in the RH diagram. The outer contour has the value 0.001 au and the remaining contours increase in value in the order 2×10^n, 4×10^n, and 8×10^n with n beginning at –3 and increasing in steps of unity. The same contours are used in all density diagrams.



American Chemical Society in 1994: "The atom (or functional group) in a molecule is not easily defined. There are always subjective factors for any definition, or strict partition of the molecule. What model one chooses is subject to one's particular needs." The remark that how one defines an atom is a matter of expediency is at variance with the practice of science wherein one's attempts at definition and understanding are necessarily guided by observation and by theory. Any definition that does not recover the essential observations that are associated with the concept of an atom in a molecule serves no useful purpose. Any definition that does not ultimately allow for the quantum definition of the atom's properties cannot be a physically admissible one. We shall, in turn, consider the chemical and theoretical constraints on the definition of an atom.

Chemical constraints

There are three essential requirements imposed upon the definition of an atom in a molecule by the observations of chemistry. (*i*) The first stems from the necessity that two identical pieces of matter exhibit identical properties. Since the form of matter is determined by the distribution of charge throughout real space, two objects are identical only if they possess identical charge distributions. This parallelism of properties with form exists not only at the macroscopic level but, in accordance with Dalton's assumption that atoms of a given element are alike in all respects, is assumed to exist at the atomic level as well. It demands that an atom be a function of its form in real space, requiring that it be defined in terms of the charge distribution. It follows that if an atom exhibits the same form in the real space of two

© 1998 NRC Canada

PROOF/ÉPREUVE

systems, or at two different sites within a crystal, it must contribute identical amounts to the total value of every property in each case. (*ii*) This requirement of property following form as described in (*i*) demands in turn that the atomic contributions sum to yield the total value for the system. That is, that the atomic contributions to some property must sum to yield the value of the property for the molecule. Only atoms meeting these two requirements can account for the existence of so-called additivity schemes wherein the atomic properties appear to be transferable as well as additive. (*iii*) Finally, the boundary defining an atom or functional group must be such as to maximally preserve its form and thereby maximize the transfer of chemical information from one system to another.

Quantum constraints

The only subjectivity one can exercise in "a strict partition of a molecule" is to decide whether or not to adhere to the constraints imposed by physics or to ignore them, thereby abandoning physics as "subject to one's particular needs." The constraints imposed by quantum mechanics on the definition of an atom are best stated in the form of two questions: (*a*) Does the state function, the function that contains all of the information that can be known about a system, predict a unique partitioning of the molecule into atoms? and (*b*) Does quantum mechanics provide a complete description of the atoms so defined? Affirmative answers to these two questions in effect require that quantum mechanics be extended to properly bounded open systems, that is, that one define the physics of a piece of a total system.

The extension of quantum mechanics to obtain the definition of a class of open systems with such a unique set of properties is indeed possible. It is based on the reformulation of quantum physics provided by the work of Feynman (1) and Schwinger (2). Their approach is based on the Lagrangian as opposed to the Hamiltonian formalism of quantum mechanics and makes possible the asking and answering of questions not possible within the traditional Hamiltonian framework. Indeed, Schwinger's generalization of the action principle provides a unifying description of quantum and classical physics. That the answers to chemistry would be found within the physics formulated to "provide a framework capable of admitting fundamentally new physical ideas" into the general theory of quantum field dynamics (2) is not something that was or is immediately obvious, certainly not to someone like myself, trained as an experimental chemist. It is the purpose of this paper to trace out the path of the research that led to this conclusion, and to emphasize in particular how it evolved from a search for the conceptual basis of chemistry in terms of the observable properties of a system.

Observational basis for the definition of an atom

Through a collaboration with the Mulliken–Roothaan laboratory in the 1960s, my group had access to near Hartree–Fock quality wave functions, before their publication (3), for nearly 300 diatomic molecules, in both ground and excited states, and these were used to study the properties of the electron density, $\rho(\boldsymbol{r})$. I consider these studies (4) to be "theoretical" experiments in the study of $\rho(\boldsymbol{r})$. The general properties we found for the density in these diatomic molecules could now be observed in the densities obtained experimentally for solids (5, 6), but at that time the experimental techniques and methods had not been perfected to the degree needed to obtain reliable electron density distributions.

These studies led to the realization that the topology of $\rho(\boldsymbol{r})$ provided a unique partitioning of the space of a molecule or a crystal into mononuclear regions that I shall refer to as atoms (7). Equally important, it soon became apparent that the resulting regions were transferable to varying extents between molecules. Indeed, if one insisted that the pieces transferred had to exhaust the system, they had the property of maximizing any transferability that was present.

This atomic form imposed on the structure of matter is a consequence of the principal topological form exhibited by the charge density — that, in general, it exhibits maxima only at the positions of the nuclei (7, 8). In a manner now well documented in terms of the topology of the electron density, as revealed by its associated gradient vector field (9) and illustrated in Fig. 1, this property results in an exhaustive partitioning of real space into a set of non-overlapping atomic domains Ω, each of which is bounded by a surface $S(\Omega,\boldsymbol{r})$ characterized by a local zero-flux in the gradient vector field of the electron density, eq. [1],

$$[1] \qquad \nabla\rho(\boldsymbol{r}) \cdot \boldsymbol{n}(\boldsymbol{r}) = 0 \ \forall \ \boldsymbol{r} \in \boldsymbol{S}(\Omega, \boldsymbol{r})$$

where $\rho(\boldsymbol{r})$ for a system of N electrons is defined as

$$[2] \qquad \rho(\boldsymbol{r}) = N \int d\tau' \psi^* \psi$$

The manner of integration implied by the symbol $\int d\tau'$ occurs throughout the theory and denotes a sum over all spins and an integration over the spatial coordinates of all electrons but the one whose position vector is denoted by $\boldsymbol{r}$. Examples of atoms bounded by a surface defined by eq. [1] whose density distributions changed little upon substitution of the neighboring atom are provided by the Li atoms in the set of diatomic molecules illustrated in Fig. 2 (7). One must regard the observed similarity in form of the Li atoms so defined as no less than remarkable when one considers the very different natures of its bonded neighbors in the three systems. The electron populations of the Li atom are obtained by integration of $\rho(\boldsymbol{r})$ over its basin and yield similar net charges of +0.94, +0.93, and +0.91 e for LiF, LiO, and LiH, respectively (7).

In addition to $\rho(\boldsymbol{r})$, we were also studying the properties of the electronic kinetic energy density (10). An important point of this parallel study is that the zero-flux defining condition stated in eq. [1] ensures that the average electronic kinetic energy of the atom is uniquely determined (7). One may define the kinetic energy density using the usual Schrödinger or Laplacian form for the operator as

$$[3] \qquad K(\boldsymbol{r}) = (-\hbar^2/4m)N \int d\tau'\{\psi^* \nabla^2\psi + (\nabla^2\psi^*)\psi\}$$

or in its eminently real form as

$$[4] \qquad G(\boldsymbol{r}) = (\hbar^2/2m)\, N \int d\tau' \nabla\psi^* \cdot \nabla\psi$$

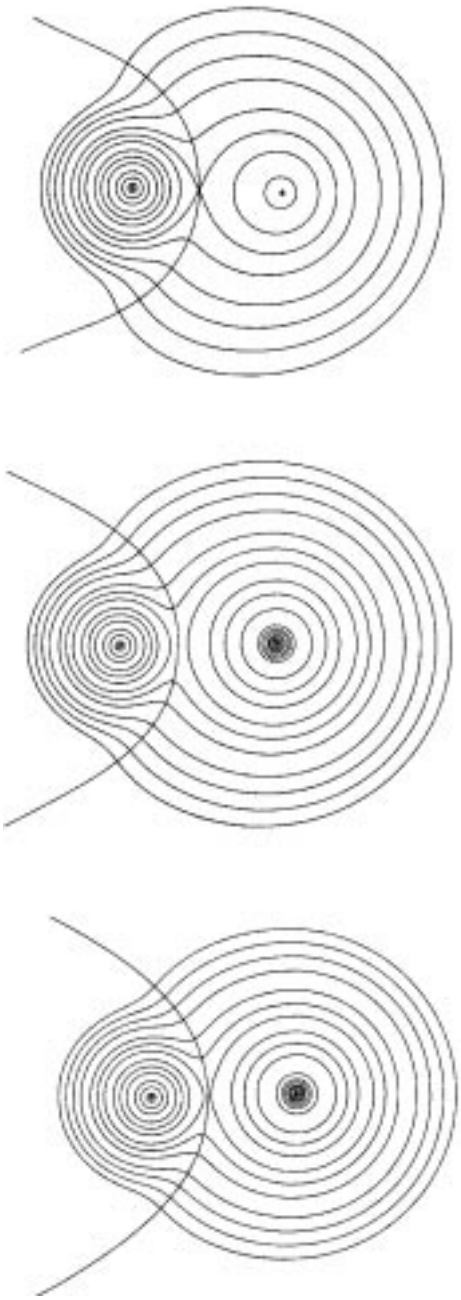
PROOF/ÉPREUVE

Fig. 2. Contour plots of the ground state electron density distributions in the plane of the nuclei for LiH ($^1\Sigma^+$), LiO ($^2\Pi$), and LiF ($^1\Sigma^+$) in descending order in the diagram. The intersections with this plane of the zero-flux interatomic surfaces defining the Li atom and its bonded neighbor are also indicated. The reader is asked to note the high degree of similarity in the distribution of the density over the basins of the Li atom defined in this manner and to contrast this with the very different distributions of the density found within the basins of its neighbors, differences that extend up to the interatomic surface. Any other choice of surface would either include a portion of the neighboring density, which changes radically in each case, or assign to the neighbor a portion of the density that is similar for the Li atom in all three molecules. These results are for Hartree–Fock calculations (7).



Since operators are not necessarily Hermitian over a subsystem, one must always consider a quantity plus its complex conjugate to ensure a real quantity in taking an average, as is done in eq. [3]. These two kinetic energy densities differ by a function of the electron density, its Laplacian, as given by eq. [5]:

$$[5] \qquad K(r) - G(r) = (-\hbar^2/4m)\nabla^2\rho(r)$$

Thus the two forms for the kinetic energy density differ locally, as will their average values when the densities are integrated over an arbitrary region of space Ω. Their integrated values are related by

$$[6] \qquad K(\Omega) - G(\Omega) = (-\hbar^2/4m)\int_{\Omega} d\boldsymbol{r}\nabla\cdot\nabla\rho(\boldsymbol{r}) = (-\hbar^2/4m)\oint dS(\Omega, \boldsymbol{r})\nabla\rho(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r})$$

Gauss' theorem enables one to rewrite the volume integral of $\nabla^2\rho = \nabla\cdot\nabla\rho$ in eq. [6] as an integral of the flux in $\nabla\rho$ through the surface of Ω. Clearly this integral vanishes for an atom, as it does for the total system, because of the defining condition given in eq. [1]. Thus, as indicated below in eq. [7], the average electronic kinetic energy of an atom in a molecule, $T(\Omega)$, is well defined,

$$[7] \qquad T(\Omega) = K(\Omega) = G(\Omega)$$

One notes that the average electronic kinetic energy defined in this manner is necessarily additive to yield the total value T over any set of disjoint regions such as the atoms that exhaust the space of the system

$$[8] \qquad T = \sum_{\Omega} T(\Omega)$$

The paralleling behavior of the electron and kinetic energy densities

These studies of the kinetic energy density resulted in a most important observation — that both $K(\boldsymbol{r})$ and $G(\boldsymbol{r})$ exhibit the same degree of transferability over the basin of an atom up to its zero-flux surface as does the electron density $\rho(\boldsymbol{r})$. Thus the conservation in the form of $\rho(\boldsymbol{r})$ and, consequently in its integrated electron population on transfer, was paralleled by a conservation in the electronic kinetic energy density and its atomic average. The average kinetic energies of the Li atoms in the three molecules fall within 8 kcal/mol (7). The paralleling transferability of $\rho(\boldsymbol{r})$ and $G(\boldsymbol{r})$ is further illustrated in Fig. 3 for the methylene group adjacent to a methyl group in butane in one case and pentane in the other. This paralleling behavior is the crucial observation that leads to the theory of atoms in molecules, as deduced from the following chain of reasoning.

The virial theorem for a system with Coulombic forces states that the total energy of a set of particles equals the negative of their average kinetic energy, $E = -T$. In our case, it states that the total electronic energy equals the negative of the average electronic kinetic energy. If one could show that there is a virial theorem for an atom in a molecule — that is, for a region of space bounded by a zero-flux surface — then one could use this theorem to define the energy of atom in a molecule $E(\Omega)$ in terms of its electronic kinetic energy $T(\Omega)$, as shown in eq. [9],

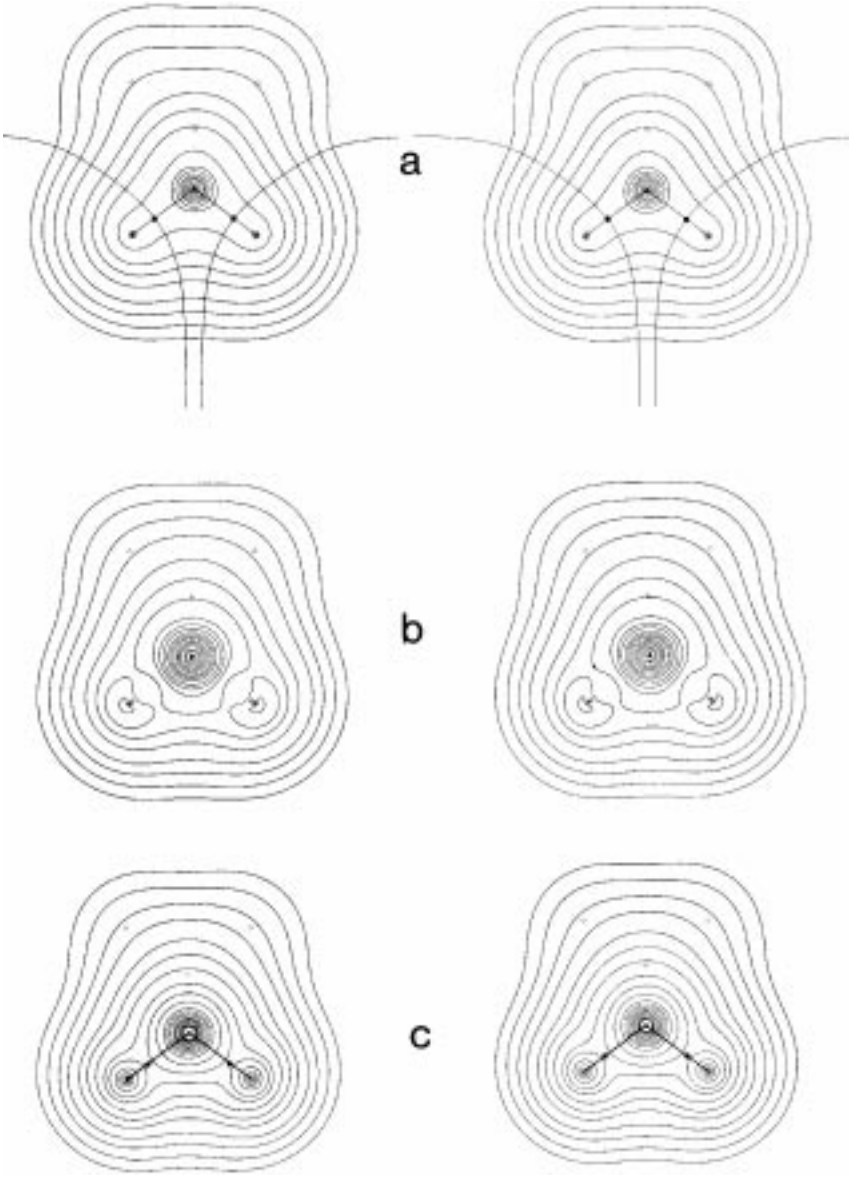
PROOF/ÉPREUVE

Fig. 3. Contour plots for the methylene group adjacent to a methyl group in butane (LHS) and in pentane (RHS): (*a*) the electron density $\rho(\boldsymbol{r})$, eq. [2]; (*b*) the kinetic energy density $G(\boldsymbol{r})$, eq. [4]; and (*c*) the virial field or potential energy density $\mathcal{V}(\boldsymbol{r})$, eq. [67]. The plane shown is the symmetry plane containing the carbon nucleus and two protons. Also shown in the electron density maps are the intersections of the C–H interatomic surfaces and the C—H bond paths, which intersect at a bcp, denoted by a dot. The virial paths, the lines of maximally negative potential energy density, are also indicated on the maps of the virial field. Every bond path is mirrored by such a virial path. The results are from MP2/6-311++G(2d,2p) calculations. Each map is superimposable on its counterpart for the two molecules. All three fields are equally transferable between the normal hydrocarbons, but only the electron density and the virial field are homeomorphic (33).



[9] $$T(\Omega) = -E(\Omega)$$

Since $T(\Omega)$ is additive, this definition of the energy of an atom would necessarily be additive as well, and the total electronic energy of a molecule would be the sum of its atomic contributions $E(\Omega)$,

[10] $$E = \sum_{\Omega} E(\Omega)$$

Most important, because of the paralleling behavior of $\rho(\boldsymbol{r})$ and $G(\boldsymbol{r})$, one would know that when the form of the atom in real space remains unchanged on transfer between systems, so does its contribution to the total energy. That is, by observation, the energy of an atom would be transferable to the same extent as is its distribution of charge. Thus the topological atoms, those defined by eq. [1], meet the very observational requirements of additivity and transferability that, as discussed above, are essential for the definition of an atom in a molecule.

A spatial partitioning of the total energy is not a trivial problem, because it requires a partitioning of the potential energy contributions. How does one spatially partition the

© 1998 NRC Canada

PROOF/ÉPREUVE

energy of repulsion between the nuclei and between the electrons or partition the energy of attraction of each nucleus for all of the electrons? We shall return to this in detail later, but the underlying physics is readily understood. The answer is provided by the virial theorem, which identifies the potential energy as the virial of the forces exerted on the electrons. One can write down the operator that determines the force exerted on one electron at a given point in space by all of the remaining particles in the system. This is the Ehrenfest force (11). Knowing the force exerted on an electron, and hence on the electron density at a point in space, enables one to determine the potential energy of that element of density by taking the virial of the force, that is, by forming the scalar product of the force with the position vector of the point. Integration of the resulting potential energy density or virial field $\mathcal{V}(\boldsymbol{r})$ over the basin of the atom yields its average potential energy, $\mathcal{V}(\Omega)$. The energy $E(\Omega)$ of the atom can, by the virial theorem, be alternatively expressed as the sum of $T(\Omega)$ and $\mathcal{V}(\Omega)$. Furthermore, Fig. 3 shows that this virial field is as transferable for the methylene groups in butane and pentane as are the electron and kinetic energy densities. Thus the total energy defined as the sum of $T(\Omega)$ and $\mathcal{V}(\Omega)$ would be as transferable as is $\rho(\boldsymbol{r})$. The average numbers of electrons in the two methylene groups obtained by integration of $\rho(\boldsymbol{r})$ differ by 0.0005 e, and their total energies, obtained by integration of $G(\boldsymbol{r})$, by less than one kcal/mol.

Thus with these observations we have reformulated the question of "how does one define an atom in a molecule?" into "can one show that the virial theorem applies to a spatial region bounded by a zero flux surface?." It is clear that if the virial theorem applies to such a region then all the theorems of quantum mechanics should apply, and one is, therefore, asking whether regions bounded by zero-flux surfaces and their properties are defined by quantum mechanics. To answer this question we initially turned to Schrödinger and his original derivation of "wave mechanics" (12). In retracing Schrödinger's steps to extend quantum mechanics to an open system bounded by a surface of zero flux (13) one is led to a statement of Schwinger's principle of stationary action for a time-independent system, a principle that completely determines the physics of a system in a stationary or time-dependent state (2).

From Schrödinger to atoms in molecules

Derivation of the hypervirial theorem for an open system

Before giving the derivation of Schwinger's principle for a stationary state, we introduce ourselves to the quantum mechanics of an open system and the manner in which it differs from the quantum mechanics for the total system. This difference is a result of operators no longer necessarily being Hermitian when averaged over an open system. This has the important result of introducing fluxes in property currents through the surface of the open system when deriving the Heisenberg equation of motion for an observable $\hat{\boldsymbol{A}}$. In the Schrödinger representation this most important equation determines the time rate-of-change of the average value of the observable

$$\mathrm{d}\langle\hat{A}\rangle/\mathrm{d}t = (i/\hbar)\langle\Psi[\hat{H},\hat{A}]\Psi\rangle$$

For each choice of the operator $\hat{A}$, one obtains a corresponding theorem. For example, the virial theorem is obtained by setting $\hat{A} = \boldsymbol{r}\cdot\boldsymbol{p}$, the product of the position and momentum coordinates of an electron. In the case of a stationary state the equation is referred to as the hypervirial theorem, and is of the form

$$[11] \quad \langle\psi,[\hat{H},\hat{A}]\psi\rangle = 0$$

This result is easily proved independently of setting the time derivative of $\langle\hat{A}\rangle$ equal to zero by (*a*) expanding the commutator, (*b*) making use of the fact that $\hat{H}$ is Hermitian, that is, one makes use of the identity

$$[12] \quad \langle\psi,\hat{H}\hat{A}\psi\rangle = \langle\hat{H}\psi,\hat{A}\psi\rangle$$

and (*c*) recognizing that ψ is a solution to the stationary state equation $\hat{H}\psi = E\psi$.

We shall, without any loss in generality, consider a single-electron case in deriving the theorem for an open system Ω. To ensure a real quantity, one must consider the sum of $\langle\psi,[\hat{H},\hat{A}]\psi\rangle_\Omega$ and its complex conjugate (cc). In addition, one can no longer assume that $\langle\psi,\hat{H}\hat{A}\psi\rangle_\Omega = \langle\hat{H}\psi,\hat{A}\psi\rangle_\Omega$, as is done in eq. [12]. We shall detail the derivation for just the term $\langle\psi,[\hat{H},\hat{A}]\psi\rangle_\Omega$. One adds and subtracts the term $\langle\hat{H}\psi,\hat{A}\psi\rangle_\Omega$ to the terms obtained by averaging the expanded commutator over the open system to obtain

$$[13] \quad \langle\psi,[\hat{H},\hat{A}]\psi\rangle_\Omega = \langle\psi,\hat{H}\hat{A}\psi\rangle_\Omega - \langle\hat{H}\psi,\hat{A}\psi\rangle_\Omega + \langle\hat{H}\psi,\hat{A}\psi\rangle_\Omega - \langle\psi,\hat{A}\hat{H}\psi\rangle_\Omega$$

Making use of Schrödinger's equation $\hat{H}\psi = E\psi$ results in cancellation of the last two terms on the RHS. The terms $\hat{V}\psi^*\psi$ cancel in taking the difference between the two remaining terms, where $\hat{V}$ is the potential energy operator in $\hat{H}$. Writing out the explicit form for an open system average denoted by $\langle\ \rangle_\Omega$ for the difference between the two remaining terms yields

$$[14] \quad \langle\psi,[\hat{H},\hat{A}]\psi\rangle_\Omega = (\hbar^2/2m)\int_\Omega \mathrm{d}\boldsymbol{r}\{(\nabla^2\psi^*)\hat{A}\psi - \psi^*\nabla^2(\hat{A}\psi)\}$$

$$[15] \quad \langle\psi,[\hat{H},\hat{A}]\psi\rangle_\Omega = (\hbar^2/2m) \times \int_\Omega \mathrm{d}\boldsymbol{r}\nabla\cdot\{(\nabla\psi^*)\hat{A}\psi - \psi^*\nabla(\hat{A}\psi)\}$$

Making use of Gauss' theorem for transforming the volume integral of a divergence into a surface integral, one has

$$[16] \quad \langle\psi,[\hat{H},\hat{A}]\psi\rangle_\Omega = (\hbar^2/2m) \times \oint \mathrm{d}S(\Omega,r)\{(\nabla\psi^*)\hat{A}\psi - \psi^*\nabla(\hat{A}\psi)\}$$

The surface term represents the flux in vector current density for the observable $\hat{A}(\boldsymbol{r})$ through the surface of the open system, as can be seen by comparing the bracketed term in the surface integral with the expression for the current density of property A given in eq. [17]:

$$[17] \quad \boldsymbol{j}_A(\boldsymbol{r}) = (\hbar/2mi)\{\psi^*\nabla(\hat{A}\psi) - (\nabla\psi^*)\hat{A}\psi\}$$

© 1998 NRC Canada

PROOF/ÉPREUVE

Thus unlike the total system, the average of the commutator $[\hat{H},\hat{A}]$ does not vanish for an open system but is given by the flux in the property density of A through the surface of the subsystem,

$$[18] \quad (1/2)\{(i/\hbar)\langle\psi,[\hat{H},\hat{A}]\psi\rangle_\Omega + \text{cc}\} = (1/2)\oint dS(\Omega,\boldsymbol{r})\,\boldsymbol{j}_A\cdot\boldsymbol{n}(\boldsymbol{r}) + \text{cc}$$

The presence of the flux term is essential to describe the properties of an open system. When $\hat{H}$ and $\hat{A}$ do not commute, there is a property flux across the surface bounding the atom, a contribution that is necessarily equal and opposite to the average of the corresponding commutator for an open system in a stationary state. In the time-dependent case, the difference between the two terms in eq. [18] determines the time rate of change of the average value of the property A for an open system.

The surface term in eq. [18] determines the net outflow of the property A in terms of the flux in the property's current density through surface bounding the open system. Thus the quantum description of a property and its time rate of change are determined only for bounded regions of space including the total system that is bounded at infinity. An essential part of this description for an open system is provided by the surface flux of the associated current density. An important consequence of this result is that one must forego all definitions of an atom based on the orbital model or on partitionings of the basis set used in its construction, as these definitions assume the atom to be without boundaries and to extend over all space.

The generalization of the result in eq. [18] to the many-electron case is straightforward, as one simply modifies all of the integrals by inserting the symbol $N\int d\tau'$ denoting a summation over all spins and an integration over all coordinates save those denoted by the vector $\boldsymbol{r}$, the coordinate of the electron whose integration is restricted to the open system Ω followed by multiplication by N, the number of electrons. Thus for example, the general definition of the current density for property A for the many-electron case obtained from eq. [17] becomes

$$[19] \quad \boldsymbol{j}_A(\boldsymbol{r}) = (\hbar/2mi)N\int d\tau'\{\psi^*\nabla(\hat{A}(\boldsymbol{r})\psi) - (\psi^*\nabla)\hat{A}(\boldsymbol{r})\psi\}$$

where the gradient operator ∇ is a function of the coordinate $\boldsymbol{r}$, as is explicitly indicated for the operator $\hat{A}(\boldsymbol{r})$. When $\hat{A}(\boldsymbol{r})$ equals the unit operator, one obtains the definition for the current $\boldsymbol{j}(\boldsymbol{r})$ that describes the flow of the electron density through space:

$$[20] \quad \boldsymbol{j}(\boldsymbol{r}) = (\hbar/2mi)N\int d\tau'\{\psi^*\nabla\psi - (\psi^*\nabla)\psi\}$$

This is the same mode of integration used to define the electron density, eq. [2], and through its use one obtains a spatial and current density for any property. The mode of integration denoted by $N\int d\tau'$ is not arbitrary but, as demonstrated later, follows directly from the field theoretic derivation of the principle of stationary action wherein every operator $\hat{A}(\boldsymbol{r})$ is identified with a generator that acts on a single field point.

In what follows we shall consider a one-electron system with the understanding that the many-electron case is trivially obtained from it by the insertion of $N\int d\tau'$. Or alternatively, one can consider what follows to be in the language of field theory with $\psi \equiv \hat{\Psi}(\boldsymbol{r})$ and $\psi^* \equiv \hat{\Psi}^+(\boldsymbol{r})^*$ describing the Schrödinger matter field, an interpretation underscored by a quotation from Schwinger (14): "The essence of field theory is to provide a conceptually simpler and more fundamental description by depending on the particle as the basic entity."

We have used Schrödinger's equation to derive the hypervirial theorem for an open system without placing any restrictions on its form other than that it be bounded. The question remaining is whether any and all regions Ω have physical significance, or whether there is a special class of open systems, special in the sense that they and their properties would be defined and determined by the same physics that determines the properties of the total system of which they are a part?

Schrödinger revisited

In his first paper, Schrödinger (12) demonstrated that making the energy functional $\mathcal{J}[\psi]$ stationary with respect to first-order variations in the wave function ψ, where

$$[21] \quad \mathcal{J}[\psi] = \int d\tau\{(\hbar^2/2m)\nabla\psi^*\cdot\nabla\psi + V\psi^*\psi\}$$

and subject to the constraint that ψ remain normalized, yields $\hat{H}\psi = E\psi$ as the Euler equation. The constant E is introduced as the Lagrange multiplier required for the normalization constraint on ψ. The functional $\mathcal{J}[\psi]$, which he termed the "Hamilton integral,"is the total energy expressed in a manifestly real form, with the kinetic energy expressed as $(1/2m)\,\langle\hat{\boldsymbol{p}}\psi,\hat{\boldsymbol{p}}\psi\rangle$, see eq. [4]. Thus the function ψ, which makes the energy stationary (and a minimum) through the condition $\delta\mathcal{J}[\psi] = 0$, is the same function that satisfies Schrödinger's equation. In his first paper Schrödinger considered the hydrogen atom and showed that the solutions to his equation yielded quantization of the energy and angular momentum, as opposed to previous work in which such quantization was imposed in the form of "quantum conditions." The manner in which the variation of eq. [21] is carried out is outlined in the next section for those unfamiliar with the calculus of variations. The actual procedure is quite simple. Someone interested in more detail can refer to my book (15) or to one particular Feynman lecture (16).

Schrödinger's energy functional for an open system Ω, $\mathcal{G}[\psi,\Omega]$, is defined as (13)

$$[22] \quad \mathcal{G}[\psi,\Omega] = \int_\Omega d\tau\{(\hbar^2/2m)\nabla\psi^*\cdot\nabla\psi + (\hat{V}-E)\psi^*\psi\}$$

where the undetermined multiplier for normalization is incorporated into the expression and identified with $-E$, the negative of the total energy. The variation of $\mathcal{G}[\psi,\Omega]$ must include a variation of the surface bounding Ω if one is to obtain a non-arbitrary definition of Ω and its properties. Using the usual recipe for the variation of some functional, as described in my book (15), one obtains the result given in eq. [23]. The integrand of the functional $\mathcal{G}[\psi,\Omega]$, denoted by f, depends upon ψ and $\nabla\psi$ (and their complex conjugates; ψ

© 1998 NRC Canada

PROOF/ÉPREUVE

is treated independently of ψ^* in the variation) and the variation of $\mathcal{G}[\psi,\Omega]$, including a variation of its surface, assumes the form

$$[23]\quad \delta\mathcal{G}[\psi,\Omega] = \int_\Omega d\tau\{(\partial f/\partial\psi)\delta\psi + (\partial f/\partial\nabla\psi)\partial\nabla\psi\} + \oint dS(\Omega,\boldsymbol{r}) f(\psi,\nabla\psi)\delta S(\Omega,\boldsymbol{r}) + cc$$

where $\delta\psi$ and $\delta\nabla\psi$ denote variations (infinitesimal changes) in ψ and its gradient. The surface bounding the open system is denoted by $S(\Omega,\boldsymbol{r})$, a function of the coordinate $\boldsymbol{r}$, and δS denotes a variation of S through its dependence on ψ. Carrying out the steps indicated above one obtains

$$[24]\quad \delta\mathcal{G}[\psi,\Omega] = \int_\Omega d\tau\{\hat{H}\psi^* - E\psi^*\}\delta\psi + \oint dS(\Omega,\boldsymbol{r})\{(\hbar^2/2m)\nabla\psi^*\cdot\boldsymbol{n}(\boldsymbol{r})\delta\psi + \delta S(\Omega,\boldsymbol{r}) f(\psi,\nabla\psi)\} + cc$$

where the Hamiltonian appearing in eq. [24] is

$$[25]\quad \hat{H} = -(\hbar^2/2m)\nabla^2 + \hat{V}$$

An integration by parts is used to obtain eq. [24] by ridding the original expression of variations in $\nabla\psi$ that arise from the second term on the RHS of eq. [23]. The identity in eq. [26]

$$[26]\quad \nabla\cdot(\nabla\psi^*\delta\psi) = (\nabla^2\psi^*)\delta\psi + \nabla\psi^*\cdot(\delta\nabla\psi)$$

enables one to replace the resulting troublesome term $\nabla\psi^*\cdot(\delta\nabla\psi)$ with the term $-(\nabla^2\psi^*)\delta\psi$, the kinetic energy operator as it appears in $\hat{H}$ together with the divergence term appearing on the LHS. The integral of this latter term is replaced with the first of the surface terms appearing in eq. [24] using Gauss' theorem.

When Ω refers to the total system, the surface $S(\boldsymbol{r})$ then occurs infinitely remote from the attractors of the system and the surface terms vanish either by demanding that $\delta\psi = 0$ when any $\boldsymbol{r} = \infty$ or by imposing the so-called natural boundary condition, that

$$[27]\quad \nabla\psi\cdot\boldsymbol{n}(\boldsymbol{r}) = 0 \text{ and } \nabla\psi^*\cdot\boldsymbol{n}(\boldsymbol{r}) = 0 \qquad \forall\boldsymbol{r} = \infty$$

In this case, the variation in eq. [24] becomes the variation in $\mathcal{G}[\psi]$, the functional used by Schrödinger, see eq. [21], and eq. [24] reduces to eq. [28]

$$[28]\quad \delta\mathcal{G}[\psi] = \int d\tau\{\hat{H}\psi^* - E\psi^*\}\delta\psi + cc = 0$$

The variation $\delta\mathcal{G}[\psi]$ is equated to zero, making the functional stationary with respect to arbitrary variations in ψ, as postulated by Schrödinger (12). The condition that $\delta\mathcal{G}[\psi]$ be stationary for *any* and *all* arbitrary variations $\delta\psi$ or $\delta\psi^*$ (which are considered to be independent), can be satisfied only if the quantity multiplied by the variation $\delta\psi$ or $\delta\psi^*$ in eq. [28] vanishes. This yields the so-called Euler equations of the variation, which in this case is Schrödinger's equation and its complex conjugate,

$$[29]\quad \hat{H}\psi^* - E\psi^* = 0 \text{ and } \hat{H}\psi - E\psi = 0$$

If eq. [24] for the variation in $\mathcal{G}[\psi,\Omega]$ is to be obtained for all variations and for all regions, then it necessarily holds for the case $\Omega = \boldsymbol{R}^3$, which, as demonstrated above, yields Schrödinger's equations as the Euler equations. Thus at the point of variation, Schrödinger's equations apply and the variation of Schrödinger's energy functional generalized to any open system reduces, at the point of variation, to

$$[30]\quad \delta\mathcal{G}[\psi,\Omega] = \oint dS(\Omega,\boldsymbol{r})\{(\hbar^2/2m)\nabla\psi^*\cdot\boldsymbol{n}(\boldsymbol{r})\delta\psi + \delta S(\Omega,\boldsymbol{r}) f(\psi,\nabla\psi)\} + cc$$

Thus, unlike the case for the total system where $\delta\mathcal{G}[\psi] = 0$, the variation in $\mathcal{G}[\psi,\Omega]$ does not vanish but rather equals a sum of two surface terms. One is proportional to the variation of ψ on the boundary, the other to the variation of the boundary itself. It is clear that the surface term proportional to $\delta\psi$ does not vanish, for the boundary of Ω involves finite values of $\boldsymbol{r}$ where the natural boundary condition does not apply and the variations of ψ on such a boundary must remain arbitrary and cannot be set equal to zero.

As we were later to discover, this generalization of the variation principle that we obtained by retaining the variations in ψ on the boundary of the system and of varying the boundary itself, a procedure followed out of necessity in the variation of $\mathcal{G}[\psi,\Omega]$, is precisely the step that Schwinger purposely introduces in his generalization of the variation of the action integral to obtain the principle of stationary action (2).

Equation [30] is not an operational result because of the appearance of the variation of the surface $S(\Omega,\boldsymbol{r})$, which prevents one from relating the result to the physics governing the system. Further progress is possible only through the replacement of this term. It is this step which limits the final result to a particular class of open systems. One first notes that when Schrödinger's equations apply, the integrand of $\mathcal{G}[\psi]$ or $\mathcal{G}[\psi,\Omega]$ reduces in the manner shown in eq. [31]:

$$[31]\quad f(\psi,\nabla\psi) = (\hbar^2/4m)\nabla^2(\psi^*\psi) = (\hbar^2/4m)\nabla^2\rho(\boldsymbol{r})$$

This result, and an identical one for the complex conjugate, is obtained using the identity relating the alternative expressions for the kinetic energy densities as previously discussed in eq. [5]. Equation [31] is a remarkable result. It states that Schrödinger's energy functional reduces to a term proportional to the Laplacian of the electron density at the point of variation, that is, when $\hat{H}\psi = E\psi$. This same reduction occurs in the many-electron case for both stationary and time-dependent states. In the latter case, the functional becomes the many-particle Lagrangian density, including that appropriate to the presence of an electromagnetic field. For this reason there is a parallel in the development given here for a stationary state and that for the generalized variation of the action integral. By Gauss' theorem, the integral of $\nabla^2\rho$ over Ω reduces to the flux in $\nabla\rho$ through its surface, eq. [6], a term that vanishes for an atom because of the zero-flux condition, eq. [1]. Thus the atomic average of the energy functional $\mathcal{G}[\psi,\Omega]$, of the Lagrangian and of the action integral vanish, as they do for the total system.

Using the result given in eq. [31], the variation of $\mathcal{G}[\psi,\Omega]$ as given in eq. [30] reduces to

© 1998 NRC Canada

PROOF/ÉPREUVE

[32] $$\delta\mathcal{G}[\psi,\Omega] = \oint dS(\Omega,\boldsymbol{r})(\hbar^2/4m)\{2\nabla\psi^*\cdot\boldsymbol{n}(\boldsymbol{r})\delta\psi + \delta S(\Omega,\boldsymbol{r})\nabla^2\rho(\boldsymbol{r})\} + cc$$

an expression that makes possible the elimination of the surface variation term by the imposition of a constraint on the form of the open system. One considers the entire variation to be carried out using a trial function Φ, which, at the point of variation, reduces to the state function ψ. One imposes, at all stages of the variational procedure, the constraint that the region $\Omega(\Phi)$, defined in terms of the trial function Φ, be bounded by a "zero-flux surface," one such that

[33] $$\nabla\rho_\Phi(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r}) = 0 \quad \forall\boldsymbol{r}\in S(\Omega,\boldsymbol{r})$$

where ρ_Φ is the trial density. The region $\Omega(\Phi)$ represents the open system in the varied total system described by the trial function Φ just as $\Omega(\psi)$ represents the open system in the state described by ψ. Requiring the fulfillment of eq. [33] amounts to imposing the variational constraint that the divergence of $\nabla\rho_\Phi = \nabla\cdot\nabla\rho_\Phi$ integrates to zero at all stages of the variation, i.e.,

[34] $$\int_\Omega \nabla^2\rho_\Phi(\boldsymbol{r})\,d\tau = 0$$

for all admissible Φ, which in turn implies that

[35] $$\delta\{\int_\Omega \nabla^2\rho(\boldsymbol{r})\,d\tau\} = 0$$

The variation denoted in eq. [35] requires a variation of the surface as well as a variation of the integrand, as in eq. [23]. Since the sum of these two terms must vanish as a result of the constraint, one is able to equate the integral of the variation in the surface to the negative of the variation of the integrand to obtain

[36] $$(\hbar^2/4m)\oint dS(\Omega,\boldsymbol{r})\delta S(\Omega,\boldsymbol{r})\nabla^2\rho(\boldsymbol{r}) = -(\hbar^2/4m)\int_\Omega \delta\{\nabla^2\rho(\boldsymbol{r})\}\,d\tau$$

and the RHS of this constraint equation can be substituted for the term involving the variation of the surface appearing in eq. [32]. The RHS is easily evaluated to yield

[37] $$\int_\Omega \delta\{\nabla^2\rho(\boldsymbol{r})\}d\tau = \int_\Omega d\tau\nabla\cdot\{\nabla\psi^*\delta\psi + \psi^*\nabla\delta\psi\} = \int_\Omega dS(\Omega,\boldsymbol{r})\{\nabla\psi^*\delta\psi + \psi^*\nabla\delta\psi\}\cdot\boldsymbol{n}(\boldsymbol{r})$$

where the final step uses Gauss' theorem to replace the volume integral of a divergence with a surface integral. This is a most important step for, because of it, the imposition of the variational constraint yields only surface terms and thus Schrödinger's equations are still obtained as the Euler equations from the volume variations. Using eqs. [36] and [37], the expression for the constrained variation obtained from eq. [32] is

[38] $$\delta\mathcal{G}[\psi,\Omega] = (\hbar^2/4m)\times\oint dS(\Omega,\boldsymbol{r})\{\nabla\psi^*\delta\psi - \psi^*\delta\nabla\psi\}\cdot\boldsymbol{n}(\boldsymbol{r})$$

Equation [38] is a physical result because, as is now demonstrated, it expresses the variation of the energy functional for an open system in terms of the flux in the infinitesimal change in the vector current density through its surface. The single-particle vector current density is defined in eq. [20] and the infinitesimal change in $\boldsymbol{j}(\boldsymbol{r})$ caused by a variation in ψ is

[39] $$\delta\boldsymbol{j}(\boldsymbol{r}) = (\hbar/2mi)\{\psi^*\delta(\nabla\psi) - (\nabla\psi^*)\delta\psi\}$$

The expression for the variation of the open system energy functional constrained to a region bounded a zero-flux surface in the gradient vector field of the electron density can thus be expressed as (13)

[40] $$\delta\mathcal{G}[\psi,\Omega] = -(i\hbar/2)\oint dS(\Omega,\boldsymbol{r})\delta\boldsymbol{j}(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r}) + cc$$

Equation [40] is obtained as a result of taking two distinct steps: (*a*) generalizing the variation so as to retain the variation in ψ on the system's boundary together with a variation of the boundary, and (*b*) restricting the system to one bounded by a zero-flux surface in $\nabla\rho$. It provides the basis for the formulation of the principle of stationary action for an open system in a stationary state. This is accomplished by identifying the variations in ψ appearing in the surface term of eq. [40] with the generators of infinitesimal unitary transformations, the procedure introduced by Schwinger (2).

The transformations of quantum mechanics are unitary transformations and Schwinger makes use of the fact that *infinitesimal unitary transformations, acting separately on the state function or observables, can be used to generate any and all possible changes in the dynamical variables of a quantum system*. The transformations are introduced into the theory by identifying them with the variations of the state function obtained in the generalized variation of Schrödinger's energy functional.

The operator for an infinitesimal unitary transformation and its inverse, its Hermitian conjugate, are given by

[41] $$\hat{U} = \hat{\imath} - (i\varepsilon/\hbar)\hat{G} \text{ and } \hat{U}^{-1} = \hat{\imath} + (i\varepsilon/\hbar)\hat{G}$$

where ε denotes an infinitesimal and $\hat{G}$, referred to as the generator of the transformation, is any linear Hermitian operator, i.e., any observable. The first-order changes in ψ and ψ^* are equated to the action of the generator $\hat{G}$ on ψ and ψ^* according to

[42] $$\delta\psi = -(i\varepsilon/\hbar)\hat{G}\psi \text{ and } \delta\psi^* = (i\varepsilon/\hbar)\hat{G}\psi^*$$

The generator of an infinitesimal temporal change is $-\hat{H}\,\delta\boldsymbol{t}$ while the generators of all possible spatial changes are functions of the coordinate and (or) momentum operators. A generator $\hat{G}$ that is a function only of the position operator $\hat{\mathbf{r}}$ will generate a gauge transformation while one which is linear in the momentum $\hat{\boldsymbol{p}}$ will generate a coordinate translation.

Replacing the variations $\delta\psi$ and $\delta\psi^*$ in eq. [40], as they appear in the expression for the variation of the current in eq. [39], by the action of infinitesimal generators defined in eq. [42] yields

[43] $$\delta\mathcal{G}[\psi,\Omega] = -(\varepsilon/2)\{\oint dS(\Omega,\boldsymbol{r})\boldsymbol{j}_G(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r}) + cc\}$$

© 1998 NRC Canada

PROOF/ÉPREUVE

using the definition of a property current density given in eq. [19]. Thus the variation in Schrödinger's energy functional for an open system bounded by a zero-flux surface is proportional to the surface flux of the current density of the infinitesimal generator causing the change in the system. An alternative and final form for the variation of the functional is obtained by using the statement of the hypervirial theorem for an open system, eq. [18], to substitute for the surface terms. This yields (13)

$$[44] \quad \delta\mathcal{G}[\psi,\Omega] = -(\varepsilon/2)\{(i/\hbar)\langle\psi\,|\,[\hat{H},\hat{G}]\,|\,\psi\rangle_{\Omega} + \text{cc}\}$$

It will be demonstrated below that eq. [44] is a statement of the principle of stationary action for a system in a stationary a state. It determines the physics of an atom in a molecule. It applies only to a region of real space Ω bounded by a surface of zero flux in the gradient vector field of the electron density, eq. [1], a condition fulfilled by the total system as well. *Thus a single principle provides the quantum mechanical description of the total system and of its constituent atoms*. Open systems defined by the principle of stationary action are called *proper open systems.*

The derivation of the theorems that govern the behavior of atoms in molecules using eq. [44], the atomic virial theorem for example, is preceded with a condensed account of how Dirac's work laid the groundwork for the ideas of Schwinger and Feynman and of how and why Schwinger's principle of stationary action reduces to eq. [44] for a proper open system in a stationary state.

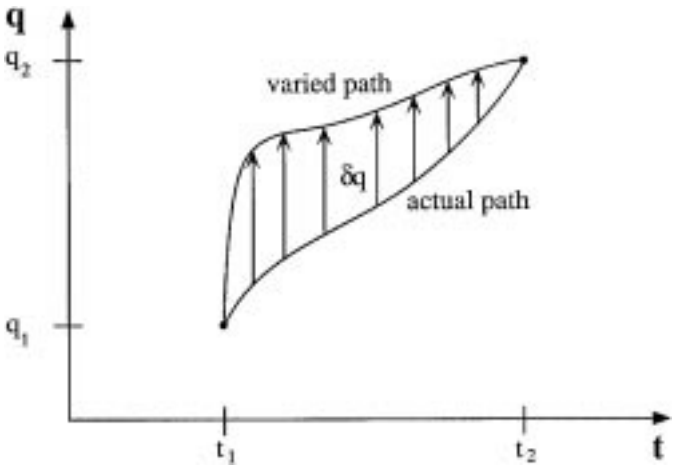
From Dirac to Schwinger

Dirac's work set the stage for the work of Feynman and Schwinger. First and foremost, he introduced transformation theory into quantum mechanics (17). This is the underlying mathematical formalism of this new physics, which consists of the general mathematical scheme of linear operators and state vectors with its associated probability interpretation. In doing so, he stressed how the theory of infinitesimal unitary transformations in quantum mechanics parallels the infinitesimal canonical transformations of classical theory, as is made clear in the quotation given in the endnote.[3]

In particular, in 1933 these arguments led Dirac to write what was to be a paper of singular importance (18). In it he posed the question of what would correspond to the limiting classical expression for the quantum probability amplitude for the passage of a system with a set of coordinates denoted collectively by q at time t to another state with coordinates q' at t', a quantity denoted by the transformation amplitude $\langle q,t\,|\,q',t'\rangle$. In effect, Dirac was asking for the correspondence of quantum mechanics with the Lagrangian method of classical mechanics, a formulation he considered to be more fundamental than the one based on Hamiltonian theory.

In the Lagrangian approach, the equation of motion (Lagrange's or Newton's) that determines how a system proceeds from one classical state (q,t) to another (q',t') is

Fig. 4. A diagram illustrating the correct space-time trajectory linking an initial position q_1 at time t_1 to the final position q_2 at t_2 and a second possible trajectory obtained from it by a variation of the position q at each time t along the path. The correct path is the one that minimizes the action integral W_{tt}'. Note that the variations in q are set to zero at each time end point, a limitation that is removed in Schwinger's generalization of the variation of the action integral.



obtained from the principle of least action. In this principle the space-time trajectory connecting the two classical states, as illustrated in Fig. 4, is the one that minimizes a quantity called the action, the time integral of the system's Lagrangian and denoted by $W_{tt'}$. The Lagrangian has the dimensions of energy, and the action, of energy multiplied by time. The classical Lagrangian is a function of the coordinates, their velocities, and the time, $L(q,\dot{q},t)$, and is expressed as the difference between the kinetic and potential energies. The action is expressed as a double integral of the Lagrangian: once over the space interval q to q' and again over the time interval t to t', as shown in eq. [45]:

$$[45] \quad W_{tt'} = \int \mathrm{d}t \int \mathrm{d}q\; L(q,\dot{q},t)$$

Minimizing the action integral through a variation of the coordinates defining the path followed by the system through time, that is, setting the variation in $W_{tt'}$ equal to zero, yields the classical equation of motion as the Euler equation in the same manner that the variation of the wave function in Schrödinger's functional $\mathcal{G}[\psi]$ yielded Schrödinger's equation by setting $\delta\mathcal{G}[\psi] = 0$, eq. [28]. The particular form for the Lagrangian is chosen so as to yield the correct equation of motion in the minimization of the action, as described above. Taking the Lagrangian as given, whether it be classical, quantal, or relativistic, enables one to derive the corresponding equation of motion using this "principle of least action."

The limiting classical expression for the quantum probability amplitude proposed by Dirac is

[3] "The variation with time of the Heisenberg dynamical variables may thus be looked upon as the continuous unfolding of a unitary transformation. In classical mechanics the dynamical variables at time $t + \mathrm{d}t$ are connected with their values at time t by an infinitesimal contact transformation and the whole motion may be looked upon as a continuous unfolding of a contact transformation. We have here the mathematical foundation of the analogy between the classical and quantum equations of motion, and can develop it to bring out the quantum analogue of all the main features of the classical theory of dynamics." Dirac, see ref. 17, p. 125.

PROOF/ÉPREUVE

[46] $\langle q,t \mid q',t'\rangle = \exp\,(i\,W_{tt'}/\hbar)$

where $W_{tt'}$ is the classical action evaluated along the unique path the causes it to assume its minimum value, that is, the path that causes $\delta W_{tt'} = 0$. Equation [46] set the stage for the reformulation of quantum mechanics by Feynman and Schwinger.

The classical concept of a system following a uniquely defined trajectory must be abandoned in a quantum description. Thus Feynman, in 1948, replaced the expression given by Dirac for the single classically allowed path, by a corresponding sum over all possible paths $q(t)$ connecting the two space-time points to obtain the path integral expression for the quantum probability amplitude $\langle q,t \mid q',t'\rangle$ (1). (The sum is replaced by an integral in eq. [47] in the limit of a continuum of possible paths $\delta q(t)$, and N is a normalizing factor.)

[47] $\langle q,t \mid q',t'\rangle = (1/N)\int \exp\,(i\,W/\hbar)\delta q(t)$

Each contributing path has the same modulus, but its phase is proportional to the classical action along the path, as given in Dirac's expression. Feynman went on to show that the path integral expression yields Schrödinger's equation and the commutation relations (1).

Schwinger, in a related but separate derivation given in 1951, showed how one can obtain all the laws of physics by combining the action principle with Dirac's transformation theory (2). Schwinger realized that infinitesimal unitary transformations can be used to provide a differential characterization of a transformation function such as $\langle q,t \mid q',t'\rangle$ and this led him to postulate his new dynamical principle, eq. [48], that is in effect a differential form of Feynman's expression

[48] $\delta\langle q,t \mid q',t'\rangle = (i/\hbar)\langle q,t \mid \delta\hat{W}_{tt'} \mid q',t'\rangle$

The corresponding expression for $\delta\langle q,t \mid q',t'\rangle$ obtained from Dirac's transformation theory in terms of infinitesimal generators $\hat{G}(t)$ acting at the two time end points is given by (the infinitesimal ε is absorbed in the symbol for the generator in eqs. [49] and [50])

[49] $\delta\langle q,t \mid q',t'\rangle = (i/\hbar)\langle q,t \mid \hat{G}(t) - \hat{G}(t') \mid q',t'\rangle$

A comparison of these two expressions leads to the principle of stationary action, eq. [50],

[50] $\delta\hat{W}_{tt'} = \hat{G}(t) - \hat{G}(t')$

that is, the variation of the action integral does not vanish, as it does in the principle of least action, but instead equals the difference in the values of the generators acting at the two time end points. This principle, like Feynman's, yields Schrödinger's equation and the commutation relations (2).

What Schwinger has done is to identify the variations in the state vectors at the two time end points with generators of infinitesimal unitary transformations. The time evolution of an open system will sweep out a space-time volume and, in the general formulation of his principle, Schwinger allows for the generators to act not only at the time end points, but also on the spatial boundaries of an open system by retaining the variations both on and of its surface at each time. Thus in Schwinger's general formulation, one retains the variations at the time-like surface that is created by the temporal evolution of the spatial boundary, as well as at the space-like surfaces that represent the system at the two time end points, and identifies them with the generators of infinitesimal unitary transformations.

In our generalization of the variation of Schrödinger's energy functional to an open system to obtain eq. [44] we necessarily retained the variations in ψ on its spatial boundary, but for just a single time, and then identified them with the action of infinitesimal generators. Schwinger on the other hand recognized that, by making such an identification at both the time-like and space-like surfaces bounding the space-time volume swept out by the action integral, he could incorporate all of physics into a single dynamical principle, the principle of stationary action. Clearly, if one desires a fundamental definition of an atom based on the action principle, its motion through time must sweep out a piece of space-time and its boundaries must therefore, be defined in real space, the same conclusion arrived at earlier using the equation of motion for an observable.

Having realized that eq. [44] was a stationary state embodiment of the ideas used by Schwinger in his principle of stationary action, we were faced with the challenge of deriving the corresponding expression for the time-dependent case through a variation of the action integral for an open system (19, 20). While Schwinger's paper gives the general expression for the variation of both the time-like and space-like surfaces of the action integral, he limits his use of this result to variations at the two time endpoints of a total system, to obtain the result given in eq. [50].

The generalization of eq. [50] to a proper open system through a variation of the action integral follows, step for step, the variation of Schrödinger's energy functional for an open system in a stationary state. To show this correspondence we shall reproduce two important steps in the derivation and, to make them particularly clear, state them in the form of a variation for an infinitesimal time interval, that is, as variations of the Lagrange integral rather than of the action integral (21). Equation [51] comes at the point corresponding to that of eq. [30] in the stationary state case,

[51] $$\delta\hat{\mathscr{L}}[\hat{\Psi},\Omega] = (\varepsilon/2)\int_{\Omega} d\boldsymbol{r}\partial\{\hat{\Psi}^{+}(\hat{G}\hat{\Psi}) + \text{cc}\}/\partial t + \oint dS(\Omega,\boldsymbol{r})\cdot\{(-\hbar^2/2m)(\nabla\hat{\Psi}^{+}\delta\Psi + \text{cc} + \boldsymbol{n}\hat{\boldsymbol{L}}\delta S(\Omega,\boldsymbol{r}))\}$$

At this point, the appropriate Schrödinger equation has been obtained from the variation of the action over the space-time volume corresponding to the variation of $\mathscr{G}[\psi,\Omega]$ over the interior of the system in the stationary state case, leaving variations on the boundaries in both cases. For $\delta\mathscr{G}[\psi,\Omega]$ this yields only the surface integral, but eq. [51] contains a time-dependent term resulting from the variation of $\hat{\Psi}$, as represented by the action of a generator, over the open system Ω at each time end point, that is, over the space-like surfaces of the open system. The surface integrals in eqs. [30] and [51] are identical in form and content and one proceeds, from this point on, in an identical manner. The troublesome term involving the variation of the surface is treated as before, by recognizing that at the point of variation, the Lagrange

PROOF/ÉPREUVE

density $\hat{L}(\hat{\Psi},\nabla\hat{\Psi},t)$ in eq. [51] reduces to $-(\hbar^2/4m)\nabla^2\,\hat{\rho}$. Aside from a sign change, this is the same property exhibited by Schrödinger's functional $f(\Psi,\nabla\Psi)$, eq. [31]. Because of this property of $\hat{L}(\hat{\Psi},\nabla\hat{\Psi},t)$ one may impose the variational constraint on the boundary of the open system given in eq. [35] and thereby replace the term $\boldsymbol{n}\cdot\hat{L}\delta\boldsymbol{S}(\boldsymbol{r}_s)$ with one proportional to the variation of $\nabla\rho\cdot\boldsymbol{n}$, as done in eqs. [36] and [37]. Combining this result with the first of the surface terms in eq. [51] and replacing the variations in $\hat{\Psi}$ with the action of infinitesimal generators, transforms the surface integral into an integral of the flux in the current of the generator though the surface of the open system, eq. [52],

$$[52]\qquad \delta\hat{\mathscr{L}}[\hat{\Psi},\Omega] = (\varepsilon/2)\int_{\Omega} d\boldsymbol{r}\partial\{\hat{\Psi}^{+}(\hat{G}\hat{\Psi}) + cc\}/\partial t + (\varepsilon/2)\oint dS(\Omega,\boldsymbol{r})\cdot\{\boldsymbol{J}_G(\boldsymbol{r}) + cc\}$$

the identical surface term to that obtained in the generalization of Schrödinger's variation principle, eq. [43]. Indeed, eq. [52] reduces to eq. [43] when applied to a stationary state. Finally, through the use of the Heisenberg equation of motion for a generator $\hat{G}$, eq. [52] is transformed into eq. [53] (19–21):

$$[53]\qquad \delta\hat{\mathscr{L}}[\hat{\Psi},\Omega] = (\varepsilon/2)\{(i/\hbar)\langle\hat{\Psi}\,|[\hat{H},\hat{G}(\boldsymbol{r})]\,|\,\hat{\Psi}\rangle_{\Omega} + cc\}$$

Thus the form of the principle of stationary action obtained from a variation of the action integral operator is in complete correspondence with the expression obtained for a stationary state, eq. [44]. Like eq. [44], eq. [53] applies only to systems bounded by a surface satisfying eq. [1], that is, to the total system and its proper open systems. This principle, in addition to yielding Schrödinger's equation, defines the observables, their equations of motion, and their expectation values. These are the properties that must be established and defined for an open system if one wishes to obtain a quantum description of an atom in a molecule.

The physics of an atom in a molecule

The atomic theorems are obtained by setting the generator $\hat{G}$ in eq. [53] equal to the observable of interest, as done for a number of important cases to obtain the theorems listed in Table 1 (22). Each term on the LHS in Table 1 is the time-rate-of change of $\rho_G(\boldsymbol{r})$, the density of property G. This term and the surface term on the RHS are obtained from eq. [52], giving the variation of $\hat{\mathscr{L}}[\hat{\Psi},\Omega]$ as caused by the generator $\hat{G}(\boldsymbol{r})$ for a proper open system. The first term on the RHS is the atomic average of the commutator in eq. [53]. For a total system, the surface integral in each theorem vanishes and one obtains the usual Heisenberg equation of motion for $\hat{G}(\boldsymbol{r})$. For a total system in a stationary state, one obtains the hypervirial theorem wherein the commutator average is equated to zero. For an open system in a stationary state, the commutator average is equated to and balanced by the negative of the flux of the corresponding current through the surface of the open system.

The commutator average is obtained in the manner previously described by the notation $N\int d\tau'$ and illustrated in the definition of the electron density, eq. [2], and its current, eq. [20]. As pointed out in the latter case, this mode of integration follows directly from the field theoretic derivation of eq. [53], as consequence of each generator $\hat{G}(\boldsymbol{r})$ acting at a single field point. It is this feature of the theory that yields a spatial density $\rho_G(\boldsymbol{r})$ and a current $\boldsymbol{j}_G(\boldsymbol{r})$ describing its flow for every property G and leads to the renormalization of the mechanics underlying chemistry referred to in the Abstract. The resulting densities and currents account for the short-range nature of the forces that enable one to identify a given atom or group in any environment. This transformation from field theory, which "depends on the particle as the basic entity" (14), to the Schrödinger representation employed in Table 1 is indicated in eq. [54]

$$[54]\qquad \{(i/\hbar)\langle\hat{\Psi}\,|[\hat{H},\hat{G}(\boldsymbol{r})]\,|\,\hat{\Psi}\rangle_{\Omega} + cc\} \Rightarrow \{(i/\hbar)N\int_{\Omega} d\boldsymbol{r}\int d\tau'\{\psi^*[\hat{H},\hat{G}(\boldsymbol{r})]\psi\} + cc\}$$

Atomic force theorem

To illustrate the use of the atomic principle of stationary action, we derive the atomic force theorem, obtained when $\hat{G}(\boldsymbol{r})$ is set equal to $\hat{\boldsymbol{p}}\,(\boldsymbol{r}) = -i\hbar\nabla$, the momentum operator for an electron. The time-rate-of change of $\hat{\boldsymbol{p}}(\boldsymbol{r})$ is force and the commutator yields, the force acting on the electron. Since $(i/\hbar)[\hat{\boldsymbol{H}},\hat{\boldsymbol{p}}(\boldsymbol{r})] = -\nabla\hat{\boldsymbol{V}}$ where $\hat{\boldsymbol{V}}$ is the total potential energy operator, the commutator determines the force exerted on the electron at $\boldsymbol{r}$ by all of the remaining particles in the system and the averaging of this operator over the coordinates of the remaining electrons yields a force density $\boldsymbol{F}(\boldsymbol{r})$

$$[55]\qquad \boldsymbol{F}(\boldsymbol{r}) = N\int d\tau'\{\psi^*(-\nabla\hat{\boldsymbol{V}})\psi\}$$

While the operator $-\nabla\hat{\boldsymbol{V}}$ determines the force acting on the electron at the point $\boldsymbol{r}$ for one configuration of the system, the averaging denoted in eq. [55] yields the force acting on the electron at $\boldsymbol{r}$ for all possible configurations of the remaining electrons. The result is a "dressed particle," one whose density is determined by its interactions with the remainder of the system. Note that the definition of the force density differs from the definition of the electron density in eq. [2] only by the inclusion of the force operator between the state functions. In this manner, any property, even one involving many-particle interactions, is reduced to a corresponding real space density and this is how physics recovers real space chemistry. The integration of $\boldsymbol{F}(\boldsymbol{r})$ over the atomic basin then yields $\boldsymbol{F}(\Omega)$, the force acting on the electron density within the atomic basin,

$$[56]\qquad \boldsymbol{F}(\Omega) = \int_{\Omega} d\boldsymbol{r}\boldsymbol{F}(\boldsymbol{r}) = \int_{\Omega} N d\boldsymbol{r}\int d\tau'\{\psi^*(-\nabla\hat{\boldsymbol{V}})\psi\}$$

The current for $\hat{G}(\boldsymbol{r}) = \hat{\boldsymbol{p}}(\boldsymbol{r})$ appearing in eq. [52] is of particular importance. Its real part defines the quantum stress tensor $\boldsymbol{\sigma}(\boldsymbol{r})$,

$$[57]\qquad \boldsymbol{\sigma}(\boldsymbol{r}) = (N\hbar^2/4m)\int d\tau'\{(\nabla\nabla\psi^*)\psi - \nabla\psi^*\nabla\psi - \nabla\psi\nabla\psi^* + \psi^*\nabla\nabla\psi\} = -\mathrm{Re}\{\boldsymbol{j}_p(\boldsymbol{r})\}$$

$$m\int_{\Omega} d\boldsymbol{r}\; \boldsymbol{r}\cdot\partial \boldsymbol{j}(\boldsymbol{r})/\partial t = 2T(\Omega) + \int_{\Omega} d\boldsymbol{r}\int d\tau'\, \Psi^*(-\boldsymbol{r}\cdot\nabla\hat{V})\Psi + \oint dS(\boldsymbol{r})\, \boldsymbol{r}\cdot\boldsymbol{\sigma}(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r})$$

Atomic torque theorem $\hat{G} = \hat{\boldsymbol{r}}\times\hat{\boldsymbol{p}}$

$$m\int_{\Omega} d\boldsymbol{r}\; \boldsymbol{r}\times\partial \boldsymbol{j}(\boldsymbol{r})/\partial t = \int_{\Omega} d\boldsymbol{r}\int d\tau'\, \Psi^*(-\boldsymbol{r}\times\nabla\hat{V})\Psi - \oint dS\; \boldsymbol{\sigma}(\boldsymbol{r})\times\boldsymbol{r}\cdot\boldsymbol{n}$$

Atomic current theorem $\hat{G} = \hat{\boldsymbol{r}}$

$$\int_{\Omega} d\boldsymbol{r}\; \boldsymbol{r}\, \partial\rho(\boldsymbol{r})/\partial t = \int_{\Omega} d\boldsymbol{r}\;\; \boldsymbol{j}(\boldsymbol{r}) - \oint dS\; \boldsymbol{n}(\boldsymbol{r})\cdot\; \boldsymbol{j}(\boldsymbol{r})\boldsymbol{r}$$

Atomic continuity theorem $\hat{G} = \hat{N}$

$$\int_{\Omega} d\boldsymbol{r}\, \partial\rho(\boldsymbol{r})/\partial t = -\oint dS\;\; \boldsymbol{j}(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r})$$

Atomic power theorem $\hat{G} = \hat{\boldsymbol{p}}^2/2m$, written without $1/2\; m$

$$\int_{\Omega} d\boldsymbol{r}\, \partial\rho_{\mathrm{p}^2}(\boldsymbol{r})/\partial t = \int_{\Omega} d\boldsymbol{r}\int d\tau'\,(\hbar/i)\{\Psi\nabla\Psi^* - \Psi^*\nabla\Psi)\cdot\nabla\hat{V}\} + \oint d\boldsymbol{S}\mathrm{Re}\{\boldsymbol{j}_{\mathrm{P}^2}(\boldsymbol{r})\}$$

Quantum stress tensor density

$$\boldsymbol{\sigma}(\boldsymbol{r}) = (\hbar^2/4m)\int d\tau'\,\{(\nabla\nabla\Psi^*)\Psi - \nabla\Psi^*\nabla\Psi - \nabla\Psi\nabla\Psi^* + \Psi^*\nabla\nabla\Psi\}$$

Quantum vector current density

$$\boldsymbol{j}(\boldsymbol{r}) = (\hbar/2mi)\int d\tau'\,\{\Psi^*\nabla\Psi - \Psi\nabla\Psi^*\}$$

which is expressible in terms of the one-electron density matrix. Thus the surface term in eq. [52], like the commutator, yields a density, the stress tensor having the dimensions of an energy density or pressure, force per unit area. For an open system in a stationary state, the atomic force theorem, eq. [58], equates the force acting over the basin of the atom to the momentum flux through its surface, that is, to the pressure acting on each of its surface elements $d\boldsymbol{S}$,

$$[58]\qquad \boldsymbol{F}(\Omega) = N\int_{\Omega} d\boldsymbol{r}\int d\tau'\,\{\psi^*(-\nabla\hat{V})\psi\} = -\oint dS(\Omega,\boldsymbol{r})\boldsymbol{\sigma}(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r})$$

Equation [58] states that the force acting on the electron density in an atomic basin is completely determined by the momentum flux through its surface, and is otherwise independent of the nature of the remainder of the system. That is, no knowledge of the remainder of the system is required over and above the pressure it exerts on the surface of the atom. The interdependence of basin and surface properties for an open system in a stationary state is a general result and is a consequence of the variational principle stated in eq. [40] (23). For example, if the two amidic surfaces of zero flux bounding an amino acid residue remain unchanged on its transfer from one polypeptide environment to another, then the residue and all of its properties remain unaffected by the transfer. When this behavior is found, one can construct polypeptides from amino acid residues defined as the central residue in tripepetides (23, 24).

Atomic virial theorem

The virial operator $\hat{\boldsymbol{r}}\cdot\hat{\boldsymbol{p}}$ has the dimensions of action and its time derivative is energy. Setting the generator equal to $\hat{\boldsymbol{r}}\cdot\hat{\boldsymbol{p}}$ yields the atomic statement of the virial theorem (13, 20). The commutator average yields twice the average electronic kinetic energy and the basin virial

$$[59]\qquad (1/2)\{(i/\hbar)\langle\psi|[\hat{H},\hat{\boldsymbol{r}}\cdot\hat{\boldsymbol{p}}]|\psi\rangle_{\Omega} + \mathrm{cc}\} = 2\boldsymbol{T}(\Omega) + \mathscr{V}_{\mathrm{b}}(\Omega)$$

The basin virial is the virial of the Ehrenfest forces acting over the basin of the atom (compare eq. [58])

$$[60]\qquad \mathscr{V}_{\mathrm{b}}(\Omega) = N\int_{\Omega} d\boldsymbol{r}\int d\tau'\,\psi^*(-\boldsymbol{r}\cdot\nabla\hat{V})\psi = -\int_{\Omega} d\boldsymbol{r}\;\boldsymbol{r}\cdot\nabla\cdot\boldsymbol{\sigma}$$

The surface term is determined by $\mathrm{Re}\{\boldsymbol{j}_{\mathrm{r}\cdot\mathrm{p}}\}$ and yields the contribution $-\mathscr{V}_{\mathrm{s}}(\Omega)$, the virial of the forces exerted on the surface of the atom (compare with the surface term in eq. [58])

PROOF/ÉPREUVE

$$[61]\quad (1/2)\oint dS(\Omega, \boldsymbol{r})\{\boldsymbol{j}_{r\cdot p}(\boldsymbol{r}) \cdot \boldsymbol{n}(\boldsymbol{r}) + cc\} = -\mathcal{V}_s(\Omega) - (\hbar^2/4m)\oint dS \nabla\rho(\boldsymbol{r}) \cdot \boldsymbol{n}(\boldsymbol{r})$$

where

$$[62]\quad \mathcal{V}_s(\Omega) = \oint dS(\Omega, \boldsymbol{r})\boldsymbol{r} \cdot \boldsymbol{\sigma}(\boldsymbol{r}) \cdot \boldsymbol{n}(\boldsymbol{r})$$

The final surface integral in eq. [61] vanishes because of the zero-flux boundary condition, eq. [1]. The surface integral $\mathcal{V}_s(\Omega)$ has been shown to be proportional to the pressure volume product for the atom Ω and it enables one to determine the pressure acting on an atom in any environment (25).

Equating the commutator and surface integrals for a stationary state followed by some rearrangement, yields the atomic statement of the virial theorem

$$[63]\quad -2T(\Omega) = \mathcal{V}_b(\Omega) + \mathcal{V}_s(\Omega) = \mathcal{V}(\Omega)$$

where the atomic virial $\mathcal{V}(\Omega)$ is the sum of the basin and surface contributions. By equating the electronic potential energy to the virial, the electronic energy of an atom in a molecule $E(\Omega)$ is defined as

$$[64]\quad E(\Omega) = T(\Omega) + \mathcal{V}(\Omega) = -T(\Omega)$$

where the final identity comes from the use of eq. [63]. This is precisely the form of the virial theorem that was postulated to hold for an atom in a molecule based on the studies of the charge and kinetic energy densities in 1972 (7). When there are no external (Hellmann–Feynman) forces acting on the nuclei, the virial $\mathcal{V}$ equals the average potential energy of the molecule and $E = T + \mathcal{V}$ then equals the total energy of the molecule. Equation [64] is as remarkable as it is unique. It uses a theorem of quantum mechanics to spatially partition all of the interactions in a molecule, electron–nuclear, electron–electron, and nuclear–nuclear, into a sum of atomic contributions, and the total energy of the molecule, as are all molecular properties, is given by a sum of atomic contributions as previously surmised in eq. [10].

Remarkable as this definition of the energy of an atom in a molecule is, it would be of no practical use if it did not exhibit the same degree of transferability from one molecule to another as does the atom itself, as previously illustrated for the methylene group in Fig. 3. As stated in the section listing the chemical constraints on the definition of an atom, if the atom appears the same in two different systems, that is, if its distribution of charge remains unchanged on transfer, then all its properties must exhibit the same invariance, the property exhibited by the methyl and methylene groups both experimentally and theoretically, when defined as proper open systems.

Atomic properties

The atomic theorems make possible the definition of all properties of an atom in a molecule and in every case, the sum of the atomic contributions $\boldsymbol{A}(\Omega)$ to property A equals the molecular value

$$[65]\quad \langle\hat{\boldsymbol{A}}\rangle = \sum_{\Omega} \boldsymbol{A}(\Omega)$$

The atomic current theorem, for example, enables one to define the atomic contributions to magnetically induced properties such as the magnetic susceptibility (26) and NMR shielding constants (27). As a consequence of the atomic statement of the principle of stationary action, the properties of an atom are determined by its distribution of charge, changing only in response to changes to its form in real space, and because of the zero-flux boundary condition, atoms are consequently the most transferable pieces that can be defined in an exhaustive partitioning of real space. Thus atoms maximize the transfer of chemical information from one system to another. In those limiting cases where an atom can be transferred from one molecule to another without apparent change to its charge distribution, the atom contributes the same amount to every property in both systems and the result, experimentally, is a so-called additivity scheme. The theory of atoms in molecules recovers the experimentally observed additivity of volume (28), of heats of formation (29), of moments and of polarizability (30), and of magnetic susceptibility (26). The theory recovers all nuances of the experimental additivity schemes, including the measured change in the energy of the transferable methylene group found in small ring systems, the so-called strain energy, and the exaltation in the magnetic susceptibility of a carbon atom when in an aromatic ring.

Chemistry and the short-sighted nature of the one-matrix

With the atomic theorems at hand, we are in a position to understand the presence of functional groups in chemistry — linked groupings of atoms in molecules or crystals that exhibit characteristic and measurable sets of properties. All of the atomic theorems have corresponding local expressions that integrate term for term to give the atomic expressions. The local statement of the virial theorem (31) given in eq. [66]

$$[66]\quad -2G(\boldsymbol{r}) = \mathcal{V}(\boldsymbol{r}) - (\hbar^2/4m)\nabla^2\rho(\boldsymbol{r})$$

defines the virial field $\mathcal{V}(\boldsymbol{r})$ in terms of the stress tensor in two equivalent ways:

$$[67]\quad \mathcal{V}(\boldsymbol{r}) = \{-\boldsymbol{r} \cdot \nabla\boldsymbol{\sigma}(\boldsymbol{r}) + \nabla \cdot (\boldsymbol{r} \cdot \boldsymbol{\sigma}(\boldsymbol{r}))\} = \text{Trace } \boldsymbol{\sigma}(r)$$

The virial field $\mathcal{V}(\boldsymbol{r})$ is the potential energy density of an electron at $\boldsymbol{r}$ (7, 15, 20). For a system with no net forces exerted on the nuclei as denoted by the symbol $\mathcal{V}_{eq}$, it integrates to the total potential energy of a system, including the nuclear–nuclear repulsions V_{nn},

$$[68]\quad \mathcal{V}_{eq} = \int \mathcal{V}(\boldsymbol{r})d\boldsymbol{r} = V_{ne} + V_{ee} + V_{nn}$$

Like the other property densities defined within the theory, it is a "dressed" density, one that determines the effective potential field experienced by a single electron in a many-particle system. All of the complex interactions between the electrons and the nuclei that are determined by the many-electron wave function are representable in real three-dimensional space by the density of the virial field. It provides the most short-range possible description of the interactions experienced by an element of the density (32). This is a consequence of the electronic virial containing the contribution from the nuclear–nuclear forces of repulsion that are described locally as the virial of the Hellmann–Feynman forces exerted on the electron density by the nuclei. Not

PROOF/ÉPREUVE

only does $\mathcal{V}(\boldsymbol{r})$ mimic the transferable nature of $\rho(\boldsymbol{r})$, as first noted in the 1972 paper that established the observational basis for the theory, $-\mathcal{V}(\boldsymbol{r})$ is found to be structurally homeomorphic with $\rho(\boldsymbol{r})$, exhibiting the same number and type of critical points and yielding the same structures (33). Thus a density, which has the appearance of a scaled version of $\rho(\boldsymbol{r})$, has the property of integrating to twice the total energy of the system. The homeomorphism has the important consequence of mirroring each bond path, the line of maximum electron density linking neighbouring nuclei, with a virial path, a line of maximally negative potential energy linking the same nuclei (33).

When an atom is transferred between molecules, the individual contributions to $\mathcal{V}(\boldsymbol{r})$, since they are individually long-range interactions, will in general exhibit large changes, of the order of thousands of kcal/mol when integrated over the atom, even in those cases where the integrated value of $\mathcal{V}(\boldsymbol{r})$ changes by only a few kcal/mol. The exchange and correlation energy densities of density functional theory also exhibit long-range behavior (34). The virial field, on the other hand, exhibits only the resultant change, one that reflects the corresponding chemical changes in the form of the atom, as reflected in the behavior of $\rho(\boldsymbol{r})$. It is not generally appreciated how small these changes can be. It is an experimental observation that, throughout most of chemistry, a group changes by amounts small enough so as to stamp it with a set of characteristic properties. These changes in $\rho(\boldsymbol{r})$, as now demonstrated in many cases, frequently translate into relatively small energy changes and can approach zero, as exhibited by the examples given in Fig. 3. The transferable nature of functional groups defined as proper open systems is currently being exploited through the determination of transferable amino acid residues that are to be used as building blocks in the construction of polypeptides or portions thereof (23, 24). These groups are prepared by sandwiching the residue between two glycyl groups in a tripeptide.

The stress tensor, even though it contains all of the two-electron information required for the determination of the electronic force and energy, is completely determined by just the one-electron density matrix. The one-matrix determines the kinetic energy density and its diagonal elements determine $\rho(\boldsymbol{r})$. Thus chemistry is a consequence of the shortsighted nature of the one-matrix as reflected in the paralleling shortsighted behavior of $\rho(\boldsymbol{r})$, $G(\boldsymbol{r})$, and $\mathcal{V}(\boldsymbol{r})$ exemplified in Fig. 3 (15, 32). Density functional theory demonstrates that the ground state energy is a unique functional of the electron density and does so by establishing the existence of a one-to-one correspondence between the density and the external potential (35). Thus, this theory does not account for the underlying observation of the theory of atoms in molecules: that what are apparently identical distributions of charge can be observed for a group in systems with differing external potentials, leaving one unprepared for the fundamental observation of chemistry — the existence of functional groups that exhibit characteristic properties in spite of changes in their environment. The two methylene groups whose properties are displayed in Fig. 3, for example, are from molecules that have very different external potentials and should, by the basic tenet of the theorem of Hohenberg and Kohn (35), have different distributions of charge. While differences necessarily do exist (36), they appear in this case to be vanishingly small.

The observations of chemistry, as interpreted by the theory of atoms in molecules, require the existence of a local relationship between the electron density and the virial field (7) while in density functional theory one searches for the functional relating the density to the total energy. The above comments on density functional theory are offered not as a criticism but rather to illustrate how the differing relationships between the density and the energy demanded by the two theories complement one another, a complementarity that could aid in the search for the complete understanding of the relationship between the energy and the density.

Conclusions

This account has focused on how the mapping of chemical concepts onto the observed topology of the electron density leads to the development of the statement of the principle of stationary action for a proper open system, the quantum mechanics underlying the definition of an atom in a molecule. In addition to defining the quantum boundary condition for the atom, eq. [1], the topology of this real, measurable field (5, 6) also provides the basis for a theory of molecular structure and structural stability (9, 15). Since both the quantum and structural aspects of the theory are determined by the topology of a common field, the two components of the theory are intimately coupled and provide the basis for a unified theory of molecular structure, one that demonstrates that chemistry follows from physics.

The description of a system provided by physics is unique. When alternative formulations are provided, such as the Heisenberg and Schrödinger representations of quantum mechanics, they are found to be equivalent. Thus there are no other definitions of a group that will yield the energies and other properties that are defined by quantum mechanics for a proper open system. It is these values that are found to be in agreement with the experimentally measured group properties, measurements that are possible in those cases where the properties of a group are found to be transferable, as well as additive. The definition of functional groups as quantum mechanical proper open systems is unique and no other definition can recover their observed properties.

Synthesis, conformational studies, and inclusion properties of tris[(2-pyridylmethyl)oxy]hexahomotrioxacalix[3]arenes

Takehiko Yamato, Mitsuteru Haraguchi, Jun-Ichi Nishikawa, Seiji Ide, and Hirohisa Tsuzuki

Abstract: *O*-Alkylation of the flexible macrocycle **1** with 2-(chloromethyl)pyridine in the presence of Cs_2CO_3 resulted in the preferential formation of partial-cone-**2**. The cone-to-partial-cone ratio of **2** increased in the presence of K_2CO_3, and led to almost equal in the presence of NaH. The template effect of the alkali metal cations plays an important role in this *O*-alkylation reaction. The structural characterization of these products is also discussed. The two-phase solvent extraction data indicated that tris[(2-pyridylmethyl)oxy]hexahomotrioxacalix[3]arenes **2** show moderate extractability for *n*-butylammonium ion and high extractability for Ag^+. The ^1H NMR titration of cone-**2** with $AgSO_3CF_3$ clearly demonstrates that a 1:1 complex is formed, which is stable on the NMR time scale. Thus, the synergism of cyclophane moiety and two or three lower-rim side chains with pyridyl groups play a significant role on the complexation of tris[(2-pyridylmethyl)oxy] derivatives cone-**2** and partial-cone-**2** with Ag^+ ion and *n*-butylammonium ion.

Key words: macrocycles, calixarenes, *O*-alkylation, ionophores, cation–N interaction.

Résumé : La *O*-alkylation du macrocycle flexible **1** par de la 2-(chlorométhyl)pyridine en présence de Cs_2CO_3 conduit à la formation préférentielle du cône-partiel **2**. Le rapport de cône à cône-partiel augmente en présence de K_2CO_3 et, en présence de NaH, les quantités sont pratiquement égales. L'effet de gabarit des cations des métaux alcalins joue un rôle important dans cette réaction de *O*-alkylation. On discute de la caractérisation des structures de ces produits. Des données d'extractions par deux phases de solvants indiquent que les tris[(2-pyridylméthyl)oxy]hexahomotrioxacalix-[3]arènes, **2**, peuvent être extraits relativement facilement par l'ion butylammonium et très facilement par Ag^+. Un titrage par RMN du ^1H du cône-**2** par du $AgSO_3CF_3$ démontre sans ambiguïté qu'il se forme un complexe 1:1 qui est stable à l'échelle de temps de la RMN. La synergie entre la portion cyclophane et deux ou trois des chaînes latérales de la portion inférieure portant des groupes pyridyles joue un rôle important dans la complexation des dérivés tris[(2-pyridylméthyl)oxy] cône-**2** et cône-partiel-**2** avec l'ion Ag^+ et l'ion *n*-butylammonium.

Mots clés : macrocyles, calixarènes, *O*-alkylation, ionophores, interaction N–cation.

[Traduit par la Rédaction]

Introduction

Calixarene and related macrocycles have received considerable attention for their host–guest chemistry as ionophoric receptors (1–4; for a comprehensive review of all aspects of calixarene chemistry see ref. 1) and potential enzyme mimics in biology (5). Chemical modification of calixarene represents an effective and versatile way of producing receptors with high selective cation binding properties (6–10). Even minor changes in the regioselective functionalization (11) or conformation (12) of the chemically modified calixarene can be associated with drastic changes in the complexation properties.

Recently, Shinkai and co-workers (13, 14) have reported the complexation of alkali metals with the *O*-alkylated hexahomotrioxacalix[3]arene derivatives, e.g., tris[(ethoxycarbonyl)methoxy]hexahomotrioxacalix[3]arene and tris-[(N,N-diethylaminocarbonyl)methoxy]hexahomotrioxacalix-[3]arene. However, satisfied high selectivities for alkali metal ions or alkyl ammonium ions have not been established so far. On the other hand, Pappalardo et al. (15) reported on the synthesis of calix[4]arenes bearing pedant pyridine groups at the lower rim as potential ligands for transition metals. Thus, hexahomotrioxacalix[3]arene derivatives bearing 2-picolyl groups on the phenolic oxygens are also supposed to selectively bind with soft metal ions, such as transition metal ions, Ag^+, or alkyl ammonium ions and should exhibit some superior to ester or amide derivatives because of a high stability in a wide pH range (16, 17).

			Distribution (%)[a,b]	
Run	Base	Solvent	Cone	Partial-cone
1	NaH[c]	THF–DMF	25 [10]	30 [21]
2	K_2CO_3[d]	Acetone	24 [20]	71 [50]
3	Cs_2CO_3	Acetone	12 [8]	88 [62]

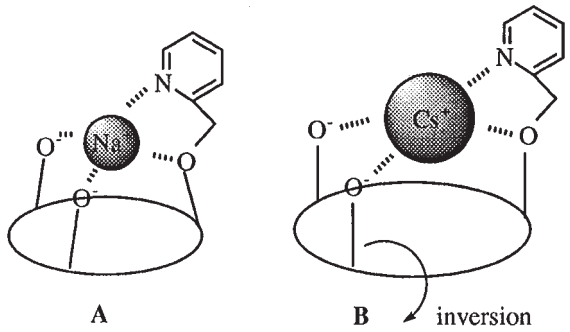
[a] Relative yields determined by ^{1}H NMR spectra.
[b] Isolated yields are shown in square brackets.
[c] Starting compound **1** was recovered in 45% yield.
[d] Starting compound **1** was recovered in 5% yield.

In this paper, we describe the synthesis, structures, and metal and ammonium ion complexation properties of tris[(2-pyridylmethyl)oxy]hexahomotrioxacalix[3]arenes with cone and partial-cone conformations, which are supposed to have encapsuled ionophilic cavities. Crystallographic data, structural report, bond distances and angles, and data collection have been deposited.[2]

Results and discussion

Hexahomotrioxacalix[3]arene **1** (18–20) was *O*-alkylated with 2-(chloromethyl)pyridine in the presence of Cs_2CO_3 to yield a mixture of two conformers of tri-*O*-alkylated product **2** in a ratio of 12:88 (cone-**2**:partial-cone-**2**) in 70% yield. The cone-to-partial-cone ratio of **2** increased in the presence of K_2CO_3 to 24:71 (cone-**2**:partial-cone-**2**), and led to almost equal in the presence of NaH in the *O*-substitution of triol **1**. However, Na_2CO_3 is employed, only the starting compound **1** was recovered in quantitative yield. (See Scheme 1 and Table 1.)

Fig. 1. Ring inversion of *O*-alkylation intermediate of triol **1** and immobilization by metal template.



The ratio of the products cone-**2** and partial-cone-**2** is governed by the nature of alkali metal carbonates or NaH used as a base. Thus, when Cs_2CO_3 is used in this reaction, partial-cone-**2** was obtained as a major product in 62% yield. On the other hand, when K_2CO_3 or NaH is employed, the increased formation of cone conformer was observed. Although the much larger contribution of Cs^+ to the template effect than Na^+, as reported by Harrowfield et al. (21), can be expected; the larger Cs^+ might enlarge the cyclophane ring (e.g., the intermediate **B**) to form a sufficient space for ring inversion to afford thermodynamically stable partial-cone conformer. In contrast, the smaller Na^+ or K^+ might increase the contribution of the metal template effect, which can hold the 2-pyridylmethyl group(s) and the oxide group(s) on the same side of the hexahomotrioxacalix[3]arene through the cation–O and cation–N interactions (Fig. 1(*a*)).

The ^{1}H NMR spectrum of cone-**2** shows a singlet for the *tert*-butyl protons at δ 1.12 and a singlet for ArO*CH*$_2$Py and the aromatic protons at δ 4.73 and 7.05, respectively,

Table 2. Chemical shifts of pyridine protons in cone-**2** and reference compound **4**.[a]

	Chemical shifts, δ (ppm)			
Compd.	H_6	H_5	H_4	H_3
Cone-**2**	8.49	7.09[c]	7.33	7.50
4	8.58	7.20	7.74	7.74
$\Delta\delta$[b]	+0.09	–0.11	–0.41	–0.24

[a] $\Delta\delta$ value is the difference of the chemical shift between cone-**2** and reference compound **4** in $CDC1_3$ at 27°C.
[b] A plus sign (+) denotes a shift to lower magnetic field, whereas a negative sign (–) denotes a shift to higher magnetic field.
[c] The midpoint value of multiplet.

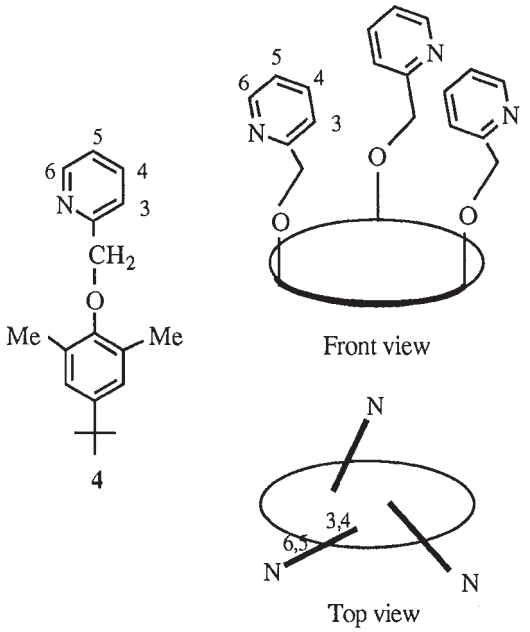
indicating a C_3 symmmetric structure of cone-**2**. Interestingly, the heteroaromatic protons of the pyridine rings of cone-**2** are exposed to the ring current shielding effect (22, 23) operated by the opposing pyridine ring among the dibenzyl ether linkage, and resonate at higher fields with respect to those of the reference compound **4**, which was prepared by *O*-alkylation of 4-*tert*-butyl-2,6-dimethylphenol with 2-(chloromethyl)pyridine in the presence of NaH. Table 2 shows that the magnitude of this shielding, computed as the difference between pertinent pyridine protons of cone-**2** and reference compound **4**, increases significantly on H_3 and H_4 protons. The remarkable shielding effect experienced by H_4 (–0.41 ppm) and H_3 (–0.24 ppm) protons of the pyridine suggests that these protons are located in much closer environment toward the opposing pyridine ring than H_5 and H_6 protons due to the repulsion among the nitrogen atoms in the pyridine rings between the dibenzyl ether linkage. Thus, nitrogens in all of the pyridine rings were oriented outwards the cyclophane cavity as shown in Fig. 2.

In contrast, the ^{1}H NMR spectrum of partial-cone-**2** shows two singlets for the *tert*-butyl protons at δ 0.99, 1.14 (relative intensity 2:1), a singlet and a pair of doublets at δ 7.37 and 7.17, 7.24 for the aromatic protons. Furthermore, the resonance for the ArOCH_2Py methylene protons appeared as a singlet at δ 4.12 and a pair of doublets at δ 4.65, 4.74 (J_{AB} = 12.7 Hz). Upfield shifts for the inverted pyridine ring protons were observed, especially at δ 6.45 for $H_{3'}$ proton. These signals correspond to C_s symmetric structure. On the basis of the ^{1}H NMR studies and the consideration of CPK model of partial-cone-**2**, two 2-pyridylmethyl groups in the compound point upwards and the another one folded into the π-cavity formed by two benzene rings and are thus shifted stronger upfield. Furthermore, two *tert*-butyl groups are located on the pyridine ring of the inverted 2-pyridylmethyl group in spite of the sterically crowded enviroment. This finding might be attributed to the C-H-π interaction (24) between methyl groups of the *tert*-butyl group and the pyridine ring.

It was also found that ring inversion by oxygen-through-the-annulus rotation is inhibited for tris[(2-pyridylmethyl)oxy] derivatives cone-**2** and partial-cone-**2** because of the observation of no change of spectrum pattern for the ArCH_2OCH_2Ar methylene protons below 150°C in DMSO-d_6.

Although cone- (cone-**2**) and partial-cone-tris[(2-pyridylmethyl)oxy]hexahomotrioxacalix[3]arene (partial-cone-**2**) both

Fig. 2. Reference compound **4** and orientation of the pyridine N atoms in cone-**2**.



hardly extracted alkali metal cations in the present experimental system (2, 3, 9, 25–27), moderate extractability for *n*-butylammonium ion and high extractability for Ag^+ was observed (Table 3). The presently developed ionophores exhibit not only more superior extractabilities for Ag^+ (% extraction: 84% for cone-**2** and 80% for partial-cone-**2**) but also high selectivities for Ag^+ and *n*-butylammonium ion than those of commercially available dibenzopyridino-18-crown-6 (% extraction: 65%) (28) or other Ag^+ ionophores.

To obtain quantitative insights into the metal affinity of tris[(2-pyridylmethyl)oxy]hexahomotrioxacalix[3]arene **2** and to compare it with that of the partial confomer of tris(benzyloxy)hexahomotrioxacalix[3]arene **3**, which was prepared by *O*-benzylation of triol **1** in the presence of Cs_2CO_3 in 95% yield (Scheme 2), we have determined the association constants by absorption spectroscopy.

Interestingly, tris[(2-pyridylmethyl)oxy] derivatives cone- and partial-cone-**2** show higher association constants K ($\times 10^3$) for both Ag^+ ion and *n*-butylammonium ion as 29.4–42.4, respectively, than those for tris(benzyloxy) derivative partial-cone-**3**, i.e., the association constants for Ag^+ ion and *n*-butylammonium ion are 2.6 and 12.5, respectively (Table 4). Therefore, the synergism of cyclophane moiety and two or three lower-rim side chains having pyridyl groups play a significant role on the complexation of tris[(2-pyridylmethyl)oxy] derivatives cone-**2** and partial-cone-**2** with Ag^+ ion and *n*-butylammonium ion. Although cone-**2** with C_3 symmetry might serve as an efficient receptor for alkylammonium ions (14, 29), the significant increase of the association constants by the introduction of pyridyl groups was observed in complexation of partial-cone-**2** with *n*-butylammonium ion. This finding might be attributable to not only the contribution of the inverted pyridyl group but also to the much larger ionophilic cavity in partial-cone conformer than that in cone conformer from the consideration of molecular model.

Table 3. Extraction (%) of metal picrates in CH_2C1_2.[a]

	Ionophore	
Cation	Cone-**2**	Partial-cone-**2**
Li^+	0.6	1.1
Na^+	8.4	1.8
K^+	4.0	5.0
Cs^+	0	0
n-$BuNH_3^+$	23.4	13.5
Ag^+	84.4	80.0

[a] Extraction (%) of alkali metal picrates by ionophores **2** in CH_2C1_2. Extraction conditions: 2.5×10^{-4} M of ionophore in CH_2C1_2; 2.5×10^{-4} M of picric acid in 0.1 M of alkaline hydroxide at 25°C. Ionophore solution (5.0 mL) was shaken for 2 h with picrate solution (5.0 mL) and % extraction was measured by the absorbance of picrate in CH_2C1_2. Experimental error was ±2%.

Recently, Shinkai and co-workers (30) reported that the 1,3-alternate conformer of calix[4]arene tetraester can form both a 1:1 and a 2:1 metal–calixarene complex, and the two metal-binding sites display negative allostericity by ^{1}H NMR titration experiment. In the present systems, due to the existence of three metal-binding sites of pyridine moiety there are several possibilities for metal complexation mode. Thus, a 1:1 and a 2:1 metal complexation of cone-**2** might be possible. As shown in Fig. 3, the percent extractions reach maximum at 0.5 mol fraction for this cation. This fact clearly indicates that Ag^+ forms 1:1 complex with cone-**2**. Thus we could prove the synergism of the cyclophane moiety and three pyridine arms at the complexation.

To prove the synergism between cyclophane moiety and three lower-rim side chains with pyridyl groups in more detail, we examined the ^{1}H NMR chemical-shift differences between those before and after the addition of an equimolar $AgSO_3CF_3$, and the composition of the ion–ionophore complex. In fact, the chemical shifts of the aromatic protons of cone-**2** were altered by titration with $AgSO_3CF_3$ in $CDCl_3/CD_3OD$ (1:1 v/v): i.e., 1:1 mixture of cone-**2** and $AgSO_3CF_3$ showed a completely different ^{1}H NMR spectrum, with sharp lines becoming evident for these protons. The methylene proton peak ArO*CH*$_2$Py resonates at lower field at δ 5.07 (Δδ = +0.40 ppm) in comparison to that in the metal-free spectrum. Particularly, as shown Fig. 4, the pyridine moieties show considerable shifts lower field (Δδ = +0.52 ppm for H_4, +0.38 ppm for H_5, and +0.50 ppm for H_6), just as the reported one composed by two pyridine arms, one crown ether ring, and one Ag^+ ion (28*b*). In contrast to these observations, the signals for the aromatic protons and *tert*-butyl protons did not appear separately (Δδ = –0.10 and +0.01 ppm, respectively).

More detailed examination of the chemical-shift change suggests that Ag^+ should be bound to the lower rim of the cavity, which is composed of three phenolic oxygens and three nitrogens of pyridine rings, because the large downfield shifts were observed for H_4, H_5, and H_6 protons on a pyridine ring due to the inductive effect arising from the N---Ag^+ interaction present around this cavity. The similar downfield shift of methylene protons of ArO*CH*$_2$Py was also observed (Δδ = +0.40 ppm) due to the interaction of the

Scheme 2.

[a] K = [M^+Pic^-, ionophore]/[M^+Pic^-][ionophore].

oxygen atoms in these phenyl units with Ag^+. Another interesting feature is the upfield shift observed for the Ar*CH*$_2$O*CH*$_2$Ar methylene protons (Δδ from –0.11 to –0.35 ppm). In calix[4]arenes, the Ar*CH*$_2$Ar methylene protons serve as a measure of the "flattening" of each phenyl unit: $\Delta\delta_H$ is generally 0.9 ppm for a system in the regular cone conformation, and in the "flattened" conformation $\Delta\delta_H$ is significantly decreased (1). In the absence of Ag^+ $\Delta\delta_H$ is 0.09 ppm, whereas in the presence of Ag^+ $\Delta\delta_H$ becomes 0.32 ppm. Provided that the concept established in calix[4]arenes is also applicable to the hexahomotrioxacalix[3]arenes, it follows that the phenyl groups in cone-**2** are more flattened than those in cone-calix[4]arenes and stand up when Ag^+ enters into the ionophoric cavity. This finding is also supported by the upfield shift observed for the aromatic protons attributable to the ring current shielding effect (22, 23) operated by the opposing benzene rings (Δδ = –0.10 ppm). Thus the conformational changes of the cyclophane moiety of *cone*-**2** also exists after Ag^+ ion complexation in the present system. Consequently, these results are explicable only by the "interaction" of Ag^+ with the pyridine rings: that is, Ag^+ is trapped in a cavity composed of three phenolic oxygens and three nitrogens of pyridine rings, by both metal–oxygen electrostatic interactions and metal–nitrogen interactions.

In partial-cone-**2**–Ag^+ complex, the ArO*CH*$_2$Py methylene protons and the pyridine ring protons (H_4, H_5, H_6) in the ordinary phenyl units shift to lower magnetic field (by +0.15 and from +0.35 to +0.38 ppm), whereas those in the one inverted phenyl unit shift to higher magnetic field (by –0.06 and from –0.03 to –0.14 ppm). This fact suggests that Ag^+ ion is mainly bound to the phenolic oxygens and nirogens of pyridine rings in the two ordinary phenyl units, and the picolyl group in the inverted phenyl unit rotates into the cavity. Probably, this rotation is induced by steric repulsion between bound Ag^+ ion and the *tert*-butyl group in the inverted phenyl unit. In this complex the splitting pattern for the Ar*CH*$_2$O*CH*$_2$Ar methylene protons is very complicated.

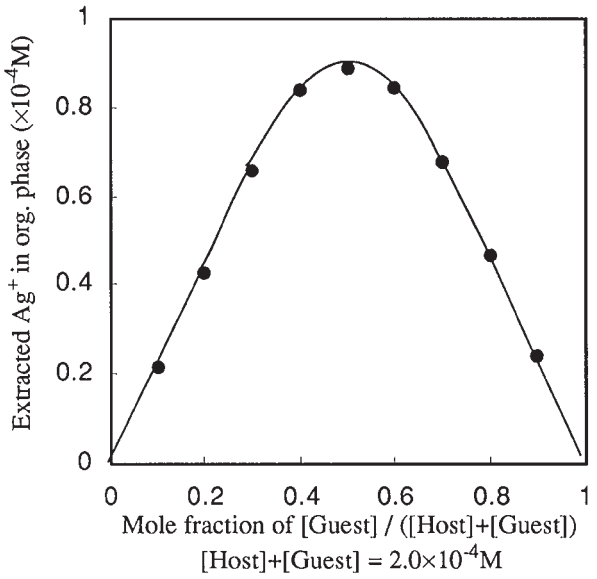
Fig. 3. Job plots of the extractions of Ag^+ with host cone-**2**.



Hence, it is difficult to obtain useful information from the δ values for the propane bridged protons.

The conformational changes of pyridine moiety from the original outward orientation of the ring nitrogen to the inside orientation toward the cyclophane cavity was observed in the process of Ag^+ complexation. This result strongly suggests that the original C_3 and C_s symmetry might remain after the complete metal-cation complexation. Further experiments on these metal complexations are currently in progress in our laboratory.

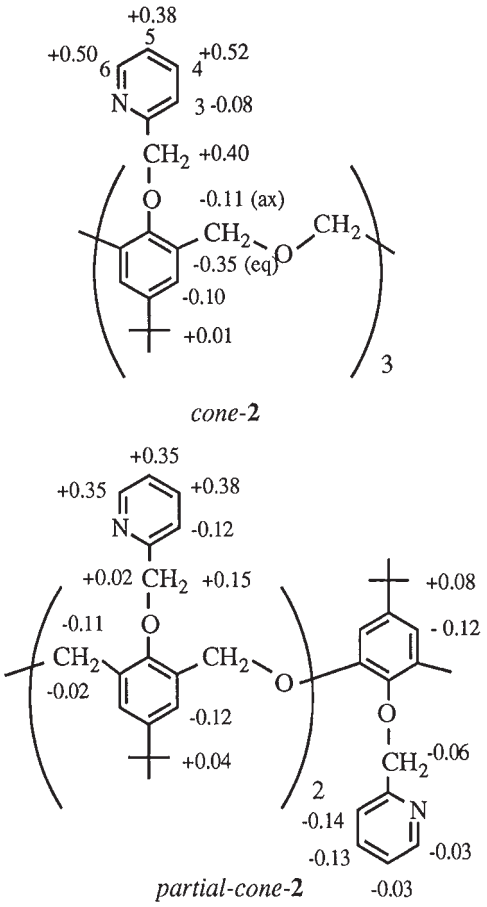
Conclusions

An interesting result was obtained by introduction of 2-picolyl groups into the hydroxy groups of triol **1**. We have demonstrated for the first time that *O*-alkylation of the flexible macrocycle **1** with 2-(chloromethyl)pyridine gave tri-*O*-alkylated products with cone or partial-cone conformation. The alkali metal cation can play an important role for the confomer distribution based on the template effect. The two-phase solvent extraction data indicated that tris[(2-pyridylmethyl)oxy]hexahomotrioxacalix[3]arenes **2** show strong Ag^+ ion and *n*-butylammonium ion affinity. The ^1H NMR titration of cone- and partial-cone-**2** with $AgSO_3CF_3$ clearly demonstrates that a 1:1 complex is formed with retention of the original symmetry. The conformational changes of pyridine moiety from the original outward orientation of the ring nitrogen to the inside orientation toward the cyclophane cavity was observed in the process of Ag^+ complexation.

Experimental

All melting points (Yanagimoto MP-S1) were uncorrected. Proton nuclear magnetic resonance (^1H NMR) spectra were recorded on a Nippon Denshi JEOL FT-270 spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Mass spectra were obtained on a Nippon Denshi JMS-01SA-2 mass spectrometer at an ionization energy of 70 eV; *m*/*z* values reported include the parent ion peak. Infrared (ir) spectra were obtained on a Nippon Denshi JIR-AQ2OM spectrophotometer as KBr disks. Elemental analyses were performed by Yanaco MT-5. The GLC analyses were performed by Shimadzu gas chromatograph, GC-14A; Silicone OV-1, 2 m; programmed temperature rise, 12°C/min; carrier gas nitrogen, 25 cm^3/min.

Fig. 4. Chemical-shift changes of cone-**2** and partial-cone-**2** induced in the presence of $AgSO_3CF_3$; a plus sign (+) denotes the downfield, and a negative sign (–) denotes the upfield shift.



Materials

7,15,23-Tri-*tert*-butyl-25,26,27-trihydroxy-2,3,10,11,18,19-hexahomo-3,11,19-trioxacalix[3]arene **1** was prepared according to the literature (18).

Alkylation of 1 with 2-(chloromethyl)pyridine in the presence of NaH

A mixture of **1** (600 mg, 1.04 mmol) and NaH (400 mg, 10.0 mmol, 60%) in dry tetrahydrofuran (THF) (12 mL) was heated at reflux for 1 h under N_2. Then a solution of 2-(chloromethyl)pyridine (10.4 mmol)(prepared by neutralization of 2-(chloromethyl)pyridine hydrochloride (1.71 g, 10.4 mmol) in DMF (10 mL) with a solution of triethylamine (1.45 mL, 10.4 mmol) in THF (20 mL) at room temperature) was added and the mixture heated at reflux for an additional 17 h. After cooling the reaction mixture to room

© 1998 NRC Canada

temperature, it was acidified with 1 M HCl (10 mL) and extracted with CH_2Cl_2 (100 mL × 2). The combined extracts were washed with water (50 mL × 2), dried (Na_2SO_4), and condensed under reduced pressure to give a yellow oil. The yellow precipitate was obtained by adding Et_2O (5 mL), which was recrystallized from methanol to give partial-cone-**2** (184 mg, 21%). The ethereal filtrate was condensed in vacuo to leave a residue, which was chromatographed on silica gel with methanol as an eluent to give cone-**2** (88 mg, 10%).

Partial-cone-7,15,23-tri-*tert*-butyl-25,26,27-tris[(2-pyridylmethyl)oxy]-2,3,10,11,18,19-hexahomo-3,11,19-trioxacalix[3]arene (partial-cone-2)

Colorless prisms [MeOH/$CHCl_3$ (3:1)]; mp 172–173°C; ^{1}H NMR ($CDCl_3$): 0.99 (18 H, s), 1.14 (9 H, s), 4.12 (2 H, s, O*CH*$_2$Py), 4.14 (2 H, d, *J* 11.2), 4.22 (d, 2 H, *J* 12.2), 4.27 (d, 2 H, *J* 10.7), 4.53 (d, 2 H, *J* 10.7), 4.65 (d, 2 H, *J* 12.7, O*CH*$_2$Py), 4.74 (d, 2 H, *J* 12.7, O*CH*$_2$Py), 4.83 (d, 2 H, *J* 12.2), 4.97 (d, 2 H, *J* 11.2), 6.45 (d, 1 H, *J* 7.8, $H_{3'}$), 6.96 (m, 2 H, H_5), 7.00 (d, 2 H, *J* 7.8, H_3), 7.06 (m, 1 H, $H_{5'}$), 7.17 (d, 2 H, *J* 2.4), 7.24 (d, 2 H, *J* 2.4), 7.34 (ddd, 2 H, *J* 2.0, 7.3, 7.8, H_4), 7.37 (s, 2 H), 7.56 (ddd, 1 H, *J* 2.0, 7.3, 7.8, $H_{4'}$), 8.31 (d, 1 H, *J* 4.9, $H_{6'}$), 7.34 (d, 2 H, *J* 4.9, H_6); MS, *m/z*: M^+ 850. Anal. calcd. for $C_{54}H_{63}N_3O_6$: C 76.3, H 7.47, N 4.94; found: C 75.95, H 7.28, N 4.86.

The splitting pattern in ^{1}H NMR shows that the isolated compound is partial-cone-**2**.

Cone-7,15,23-tri-*tert*-butyl-25,26,27-tris[(2-pyridylmethyl)oxy]-2,3,10,11,18,19-hexahomo-3,11,19-trioxacalix[3]arene (cone-2)

Colorless prisms (MeOH/$CHCl_3$ (3:1)); mp 166–168°C; ^{1}H NMR ($CDCl_3$): 1.12 (s, 27 H), 4.63 (d, 6 H, *J* 13.2, *CH*$_2$O*CH*$_2$, eq), 4.65 (d, 6 H, *J* 13.2, *CH*$_2$O*CH*$_2$, ax), 4.73 (s, 6 H, O*CH*$_2$Py), 7.05 (s, 6 H, ArH), 7.09 (m, 3 H, H_5), 7.33 (ddd, 3 H, *J* 2.0, 7.3, 7.8, H_4), 7.50 (d, 3 H, *J* 7.8, H_3), 8.49 (d, 3 H, *J* 4.9, H_6); MS, *m/z*: M^+ 850. Anal. calcd. for $C_{54}H_{63}N_3O_6$: C 76.3, H 7.47, N 4.94; found: C 76.13, H 7.29, N 4.80.

The splitting pattern in ^{1}H NMR shows that the isolated compound is cone-**2**.

Alkylation of 1 with 2-(chloromethyl)pyridine in the presence of Cs_2CO_3

A mixture of **1** (600 mg, 1.04 mmol) and Cs_2CO_3 (3.39 g, 10.4 mmol) in dry THF (12 mL) was heated at reflux for 2 h under N_2. Then a solution of 2-(chloromethyl)pyridine (10.4 mmol) (prepared by neutralization of 2-(chloromethyl)pyridine hydrochloride (1.71 g, 10.4 mmol) in DMF (10 mL) with a solution of triethylamine (1.45 mL, 10.4 mmol) in THF (20 mL) at room temperature) was added and the mixture heated at reflux for an additional 17 h. After cooling the reaction mixture to room temperature, it was filtered. The filtrate was concentrated, and the residue was extracted with CH_2Cl_2 (2 × 100 mL) and washed with water (2 × 50 mL), dried (Na_2SO_4), and condensed under reduced pressure. The ^{1}H NMR analyses of the residue was in accord with its being a mixture of cone-**2** and partial-cone-**2** in the ratio of 12:88. The yellow precipitate was obtained by adding Et_2O (10 mL), which was recrystallized from methanol to give partial-cone-**2** (552 mg, 62%). The ethereal filtrate was condensed in vacuo to leave a residue, which was chromatographed on silica gel with methanol as an eluent to give cone-**2** (70 mg, 8%).

Benzylation of 1 with benzyl bromide in the presence of Cs_2CO_3

A mixture of **1** (100 mg, 0.174 mmol) and Cs_2CO_3 (567 mg, 1.74 mmol) in acetone (10 mL) was heated at reflux for 1 h. Then benzyl bromide (0.21 mL, 1.74 mmol) was added and the mixture heated at reflux for 17 h. After cooling the reaction mixture to room temperature, it was filtered. The filtrate was concentrated, and the residue was extracted with CH_2Cl_2 (2 × 100 mL) and washed with water (2 × 50 mL), dried (Na_2SO_4), and condensed under reduced pressure. The residue was washed with methanol to give the crude partial-cone-**3** (139 mg, 95%) as a colorless solid. Recrystallization from methanol/$CHCl_3$ (3:1) gave partial-cone-7,15,23-tri-*tert*-butyl-25,26,27-tris(benzyloxy)-2,3,10,11,18,19-hexahomo-3,11,19-trioxacalix[3]arene (partial-cone-**3**) as colorless prisms (MeOH/$CHCl_3$ (3:1)); mp 180–185°C; ^{1}H NMR ($CDCl_3$): 0.93 (s, 18 H), 1.20 (s, 9 H,), 3.40 (s, 2 H, O*CH*$_2$Ph), 4.07 (d, 2 H, *J* 12.7), 4.15 (d, 2 H, *J* 12.2, O*CH*$_2$Ph), 4.19 (d, 2 H, *J* 12.2, O*CH*$_2$Ph), 4.27 (d, 2 H, *J* 9.3), 4.28 (d, 2 H, *J* 12.7), 4.46 (d, 2 H, *J* 12.7), 4.53 (d, 2 H, *J* 12.7), 4.54 (d, 2 H, *J* 9.3), 6.72–6.78 (m, 2 H), 7.01–7.14 (m, 17 H), 7.29 (s, 2 H); MS, *m/z*: M^+ 846. Anal. calcd. for $C_{57}H_{66}O_6$: C 80.82, H 7.85; found: C 80.53, H 7.73.

The splitting pattern in ^{1}H NMR shows that the isolated compound is partial-cone-**3**.

Preparation of 4-*tert*-butyl-2,6-dimethyl[(2-pyridylmethyl)oxy]benzene 4

A mixture of 4-*tert*-butyl-2,6-dimethylphenol (400 mg, 2.25 mmol) and NaH (580 mg, 14.5 mmol, 60%) in dry THF (20 mL) was heated at reflux for 1 h under N_2. Then a solution of 2-(chloromethyl)pyridine (14.5 mmol) (prepared by neutralization of 2-(chloromethyl)pyridine hydrochloride (2.38 g, 14.5 mmol) in DMF (15 mL) with a solution of triethylamine (2.02 mL, 14.52 mmol) in THF (25 mL) at room temperature) was added and the mixture heated at reflux for an additional 17 h. After cooling the reaction mixture to room temperature, it was acidified with 1 M HCl (10 mL) and extracted with CH_2Cl_2 (100 mL × 2). The combined extracts were washed with water (50 mL × 2), dried (Na_2SO_4), and condensed under reduced pressure to give a yellow oil. The residue was chromatographed on silica gel with methanol as an eluent to give the title compound **4** (380 mg, 63%) as a colorless oil; ^{1}H NMR ($CDCl_3$): 1.30 (s, 9 H), 2.31 (s, 6 H), 4.95 (s, 2 H), 7.05 (s, 2 H), 7.20 (m, 1 H, H_5), 7.74 (m, 2 H, H_3 and H_4), 8.58 (dd, 1 H, *J* 0.9, 4.9, H_6); MS, *m/z*: M^+ 269. Anal. calcd. for $C_{18}H_{23}NO$: C 80.26, H 8.61, N 5.2; found: C 80.55, H 8.49, N 4.98.

Picrate extraction measurements

Alkali metal picrates (2.5×10^{-4} M) were prepared in situ by dissolving the alkali metal hydroxide in 2.5×10^{-4} M picric acid; triply distilled water was used for all aqueous solutions. Similarly, silver picrate was prepared in situ by

© 1998 NRC Canada

dissolving silver nitrate in 2.5×10^{-4} M picric acid. Two-phase solvent extraction was carried out between water (5 mL, alkali picrate conc. = 2.5×10^{-4} M) and CH_2Cl_2 (5 mL, ionophore conc. = 2.5×10^{-4} M). The two-phase mixture was shaken in a stoppered flask for 2 h at 25°C. We confirmed that this period is sufficient to attain the distribution equilibrium. This was repeated three times, and the solutions were left standing until phase separation was complete. The extractability was determined spectrophotochemically from the decrease in the absorbance of the picrate ion in the aqueous phase as described by Pedersen (31).

^{1}H NMR complexation experiment

To a $CDCl_3$ solution (5×10^{-4} M) of cone-**2** in the NMR tube was added a [D_4]methanol solution (5×10^{-4} M) of $AgSO_3CF_3$. The spectrum was registered after addition and the temperature of NMR probe kept constant at 27°C.

Cone-7,15,23-tri-*tert*-butyl-25,26,27-tris[(2-pyridylmethyl)oxy]-2,3,10,11,18,19-hexahomo-3,11,19-trioxacalix[3]arene (cone-2)

^{1}H NMR ($CDCl_3$:[D_4]methanol, 1:1 v/v): 1.08 (s, 27 H), 4.51 (d, 6 H, *J* 13.2, CH_2OCH_2, eq), 4.60 (d, 6 H, *J* 13.2, CH_2OCH_2, ax), 4.67 (s, 6 H, OCH_2Py), 6.95 (s, 6 H, ArH), 7.03 (m, 3 H, H_5), 7.29 (ddd, 3 H, *J* 2.0,7.3,7.8, H_4), 7.45 (d, 3 H, *J* 7.8, H_3), 8.43 (d, 3 H, *J* 4.9, H_6).

ipso-Nitration of *tert*-butyl[*n*.2]metacyclophanes; through-space electronic interactions between two benzene rings

Takehiko Yamato, Hideo Kamimura, and Hirohisa Tsuzuki

Abstract: The selective introduction of one or two nitro groups by direct replacement of *tert*-butyl groups via the *ipso* aromatic nitration of the meta-bridged aromatic compounds having two arene rings is described. The *ipso*-nitration at the *tert*-butyl groups of *syn*- and *anti*-di-*tert*-butyl-dimethoxy[*n*.2]metacyclophanes **1** is attributed to the highly activated character of the aryl ring and the increased stabilization of a σ-complex intermediate arising from the dienone-type σ-complex intermediate possible in the case of an internally methoxy substituent. However, only one *tert*-butyl group is *ipso*-nitrated in the mild reaction conditions such as copper(II) nitrate in an acetic anhydride solution because of deactivation of the second aromatic ring by the introduced nitro group. A first σ-complex intermediate would be stabilized by two types of the through-space electronic interaction, i.e., face-to-face overlapping and intra-annular interaction with the opposing benzene ring, thus accelerating the reaction. The higher yields of mononitrated product are obtained in syn-conformer than in anti-conformer. Therefore, face-to-face overlapping might be much more favourable to stabilize the first σ-complex intermediate than the intra-annular interaction. On the other hand, nitration of **1** with fuming nitric acid afforded the two-fold *ipso*-nitration product **3** in quantitative yield. Thus, the number of *ipso*-nitration at the *tert*-butyl groups of **1** was strongly affected by the reactivity of the nitration reagent.

Key words: cyclophanes, electrophilic aromatic substitutions, *ipso*-nitration, σ-complex intermediates, through-space electronic interactions.

Résumé : On décrit l'introduction sélective d'un ou de deux groupes nitro par le remplacement direct de groupes *tert*-butyles par le biais d'une nitration aromatique *ipso* de composés aromatiques comportant deux noyaux arènes portant des ponts en méta. La nitration *ipso* au niveau des groupes *tert*-butyles des *syn*- et *anti*-di-*tert*-butyl-diméthoxy-[*n*.2]métacyclophanes, **1**, est attribuée au caractère hautement activé du noyau aryle et à une stabilisation accrue d'un complexe-σ intermédiaire découlant d'un complexe-σ intermédiaire de type diénone qui serait possible dans le cas d'un substituant méthoxy interne. Toutefois, dans des conditions douces comme celles rencontrées avec du nitrate de cuivre(II), un seul des groupes *tert*-butyles donne lieu à une nitration *ipso* à cause de la désactivation du deuxième noyau aromatique par le groupe nitro qui a été introduit. Un premier complexe-σ intermédiaire serait stabilisé par deux types d'interactions électroniques à travers l'espace, à savoir un recouvrement face à face et une interaction intraannullaire avec le noyau benzénique opposé, et conduirait à une accélération de la réaction. On obtient de meilleurs rendements de produit mononitré avec le conformère syn qu'avec le conformère anti. Le recouvrement face à face semble donc plus favorable que l'interaction intraannullaire pour stabiliser le premier complexe-σ intermédiaire. Par ailleurs, la nitration du produit **1** à l'aide d'acide nitrique fumant conduit au produit **3**, découlant d'une double nitration *ipso*, avec un rendement quantitatif. Le nombre de nitrations *ipso* au niveau de groupes *tert*-butyles du composé **1** est donc fortement affecté par la réactivité du réactif de nitration.

Mots clés : cyclophanes, substitutions aromatiques électrophiles, nitration *ipso*, complexe-σ intermédiaire, interactions électroniques à travers l'espace.

[Traduit par la Rédaction]

Introduction

Although the replacement of a *tert*-butyl group by a nitro group in electrophilic aromatic substitutions has frequently been described in the literature (1, 2), generally the yields are mostly modest because of the accompanying side reactions (3). Only in activated compounds are better yields obtained. However, there have been only a few investigations on the *ipso*-electrophilic aromatic substitution of *tert*-butylarenes having more than two benzene rings (4, 5). Recently, we have reported (6) that *ipso* aromatic nitration of 1,n-bis(5-*tert*-butyl-2-methoxyphenyl)alkanes leads to the direct introduction of one or two nitro groups, depending on

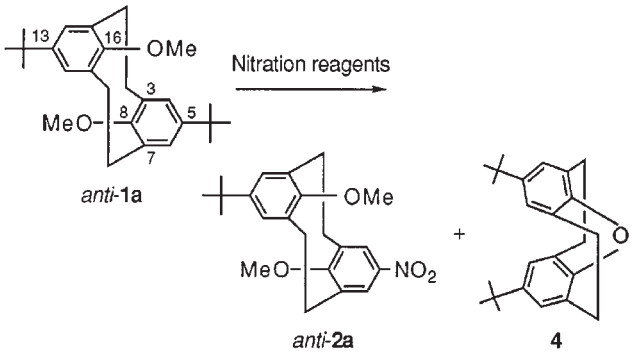
Scheme 1.



the nitration reagents. However, the mechanistic aspects of *ipso*-attack in electrophilic aromatic substitutions having more than two aromatic rings are still not clear because of the possibility of through-space electronic interactions occurring among the other benzene rings.

Subsequently, we reported (7) that nitration of 5,13-di-*tert*-butyl-8,16-dimethoxy[2.2]MCP (MCP = metacyclophane) *anti*-**1a** with various nitrating reagents led to *ipso*-nitration at the *tert*-butyl group to give 5-*tert*-butyl-8,16-dimethoxy-13-nitro[2.2]MCP *anti*-**2a** as well as the corresponding 8,16-epoxy[2.2]MCP **4** arising from intramolecular condensation reaction via *anti*-*syn*-ring inversion of the nitration intermediate. The latter novel product was found to be obtained, owing to the release of the strain in these systems (Scheme 1).

In contrast, nitration of 5,13-di-*tert*-butyl-8,16-dimethyl-[2.2]MCP with fuming HNO_3 afforded a different type of product, 2,7-di-*tert*-butyl-4,9-dinitro-*trans*-10b,10c-dimethyl-10b,10c-dihydropyrene (8). This novel transannular reaction might be attributed to the electronic interaction between two benzene rings, the proximity of 8,16-positions and the release of the considerable strain energy to form the more stable annulene π-electron system, 10b,10c-dihydropyrene. Thus there is substantial interest in systematically investigating the effect of substituents on the *ipso*-attack and the relationship between neighbouring benzene rings in electrophilic aromatic substitutions of larger ring-sized *tert*-butyl-[*n*.2]MCPs, which might only afford the *ipso*-nitration product at the *tert*-butyl group because of not only the formation of the intramolecular condensation product via *anti*-*syn*-ring inversion of the nitration intermediate but also the formation of 14π dihydropyrene derivatives being impossible.

In this paper we describe the selective introduction of one or two nitro groups by direct replacement of *tert*-butyl groups via the *ipso* aromatic nitration of the meta-bridged aromatic compounds having two arene rings to investigate the through-space electronic interactions occurring among other benzene rings.

Results and discussion

Attempted nitration of *anti*-6,14-di-*tert*-butyl-9,17-dimethoxy[3.2]MCP *anti*-**1b** (9) with copper(II) nitrate at room temperature for 24 h gave *anti*-6-*tert*-butyl-9,17-dimethoxy-14-nitro[3.2]MCP *anti*-**2b** in 56% yield as a major product along with *anti*-9,17-dimethoxy-6,14-dinitro[3.2]MCP

[b]Isolated yields are shown.
[c]Starting compounds, *anti*-**ld**, *anti*-**le**, and *anti*-**lf**, were recovered in 75, 53, and 55% yields, respectively.

anti-**3b** in 25% yield. No formation of the corresponding 9,17-epoxy[3.2]MCP arising from intramolecular condensation reaction via *anti*-*syn*-ring inversion like 8,16-dimethoxy[2.2]MCP *anti*-**1a** was observed. While in the nitration of *anti*-[4.2]MCP *anti*-**1c**, mono *ipso*-nitrated product *anti*-**2c** was also obtained in 58% yield; two other different dinitrated products *anti*-**5c** and *anti*-**6c** were obtained in 10 and 15% yields, respectively. The formation of a two-fold *ipso*-nitration product, i.e., *anti*-10,18-dimethoxy-7,15-dinitro[4.2]MCP *anti*-**3c**, was not observed under the reaction conditions used (Scheme 2, Table 1).

In fact, nitration of mono *ipso*-nitrated product *anti*-**2c** carried out under the same conditions afforded almost same ratio of dinitrated products *anti*-**5c** and *anti*-**6c** along with recovery of starting compound. This result strongly suggests

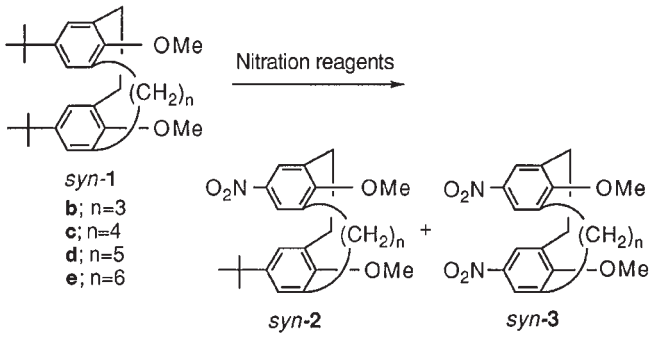
Scheme 3.



that in the first step the *ipso*-nitration at the *tert*-butyl group must occur. In the second step, the different regioselectivity was then observed exclusively to complete nitration at positions 6 or 8 *ortho* to the *tert*-butyl group, because of deactivation of the second aromatic ring by the nitro group. It was also found that nitration of *anti*-**5c** and *anti*-**6c** with copper(II) nitrate resulted in only the recovery of the starting compound. Thus, an attempted nitration with fuming HNO_3 of *anti*-**5c** and *anti*-**6c** also failed. Only the starting compound was recovered in quantitative yield. Formation of a two-fold *ipso*-nitration product, i.e., *anti*-10,18-dimethoxy-7,15-dinitro[4.2]MCP *anti*-**3c**, was not observed under the reaction conditions. These results suggest that *anti*-**5c** and *anti*-**6c** are not the intermediates for the formation of two-fold *ipso*-nitration product *anti*-**3c**, as discussed later.The structures of *anti*-**5c** and *anti*-**6c** were assigned on the basis of elemental analyses and spectral data. The ^{1}H NMR spectrum of *anti*-**5c** in $CDCl_3$ shows three singlets at δ 1.38 for *tert*-butyl protons, at δ 3.23 and 3.34 for methoxy protons, respectively, and a set of doublets (J = 2.9 Hz) at δ 7.76 and 8.02 for aromatic protons in a strongly deshielded region due to the nitro group. It was also found that one of the ethano-bridge protons has been observed in a deshielded region (δ 3.30–3.34) due to the nitro group at position 8. As a result *anti*-**5c** has been assigned to 7-*tert*-butyl-10,18-dimethoxy-8,15-dinitro[4.2]MCP. Similar spectrum was observed in *anti*-**6c** and assigned to 7-*tert*-butyl-10,18-dimethoxy-6,15-dinitro[4.2]MCP.

We have reported (8) that nitration of *anti*-8,16-dimethyl[2.2]MCP exclusively afforded mononitrated product because of deactivation of the second aromatic ring by nitro group introduced. Thus, one *tert*-butyl group is *ipso*-nitrated because of deactivation of the second aromatic ring by nitro group by a through-space electronic interaction through the intra-annular 8,16 positions. However, this effect is much as a tendency to decrease as a number of bridged methylene group increases. Interestingly, in the case of higher methylene bridged *anti*-[*n*.2]MCPs, only mononitrated products were obtained along with recovery of the starting compounds. In the MCP system a first σ-complex intermediate would be stabilized by a through-space electronic interaction with the opposing benzene ring, thus accelerating the reaction. The order of reactivity of *anti*-[*n*.2]MCPs for nitration is estimated from the above results to be [3.2] > [4.2] > [5.2]MCP, and almost same reactivites are observed in [6.2] and [10.2]MCPs similar to those for 1,n-bis(5-*tert*-butyl-2-methoxyphenyl)alkanes (6). This finding

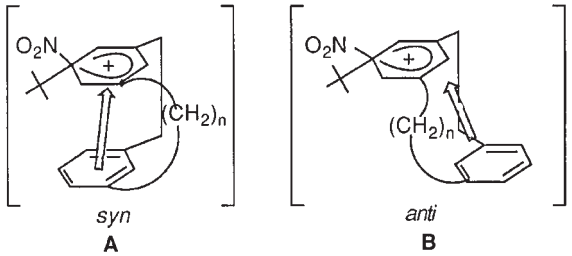
suggests that the stability of the cation intermediate, which may be due to a through-space electronic interaction with the opposing benzene ring through the intra-annular positions, decreases as the size of the polymethylene bridge increases.

Cram et al. (10) reported that the rate of the acetolysis of [2.2]paracyclophane tosylates was accelerated by the through-space electronic interactions with the opposite aromatic ring. This phenomenon was explained by the stability of the cationic intermediates, which should arise from the through-space electronic interaction with the benzene ring located on the opposite side. The rate increases as the degree of the overlapping with benzene ring increases. In the present [*n*.2]MCPs there are two possible conformers, anti- and syn-conformer. The through-space electronic interaction could be performed through the intra-annular positions in the former conformer, but through face-to-face overlapping among the two benzene rings in the latter conformer. Therefore, there is substantial interest to investigate the different behaviour on the nitration of *anti*- and *syn*-[*n*.2]MCPs and which conformer contributes more strongly to the through-space electronic interaction (Scheme 3, Table 2).

Nitration of *syn*-6,14-di-*tert*-butyl-9,17-dimethoxy-[3.2]MCP *syn*-**1b** (9) with copper(II) nitrate at room temperature for 24 h gave only a complex mixture of nonvolatile materials. But formation of the desired nitro compound *syn*-**2b** was not detected. This result might be attributable to a highly strained structure of *syn*-[3.2]MCP. In contrast, nitration of *syn*-[4.2]MCP *syn*-**1c** afforded mononitrated product *syn*-**2c** in 65% yield as a major product along with *syn*-10,18-dimethoxy-7,15-dinitro[4.2]MCP *syn*-**3c** in 20% yield. The same result was obtained in the nitration of *syn*-[5.2]MCP (*syn*-**1d**) and *syn*-[6.2]MCP (*syn*-**1e**) to afford a mixture of mononitrated product *syn*-**2d** and *syn*-**2e** in 81 and 73% yields along with the dinitrated product *syn*-**3d** and *syn*-**3e**. The higher yields of mononitrated product are obtained in syn-conformer than in anti-conformer. A first σ-complex intermediate would be stabilized by the through-space electronic interaction through face-to-face overlapping with the opposing benzene ring (**A**), thus accelerating the reaction. Therefore, face-to-face overlapping might be much

© 1998 NRC Canada

Fig. 1. Two possible through-space electronic interactions of [*n*.2]metacyclophanes.



more favourable to stabilize the first σ-complex intermediate than the intra-annular interaction (**B**) (Fig. 1).

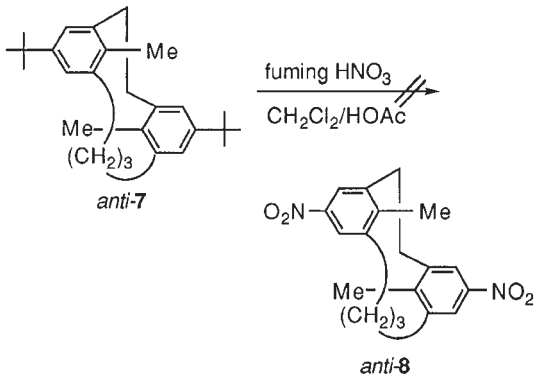
Interestingly, with varying reactivity of the nitrating reagents the ratio of the product arising from mono *ipso*-nitration **2** to the product arising from two-fold *ipso*-nitration at the *tert*-butyl groups **3** changed. When the nitration reagent was changed from copper(II) nitrate or 61% HNO_3 to the more reactive fuming HNO_3 the yield of di-*ipso*-nitrated products **3** increased from 5 to 35% to quantitative yields. Thus, the number of *ipso*-nitration at the *tert*-butyl groups of **1** was strongly affected by the reactivity of the nitration reagent, as has been reported for nitration in normal aromatic systems (11).

It should be noted that the present *ipso*-nitration of **1** is quite different from the results of the nitration of the corresponding internally methyl substituted *anti*-di-*tert*-butyl-[*n*.2]MCPs. For example, *anti*-6,14-di-*tert*-butyl-9,17-dimethyl[3.2]MCP *anti*-**7** (12) with fuming HNO_3 did not afford the desired *anti*-dinitro[3.2]MCPs *anti*-**8**, instead only intractable mixture was obtained. This result seems to indicate that the methoxy group in **1** plays an important role in the present *ipso*-nitration reaction. The *ipso*-nitration of **1** is attributed to the highly activated character of the aryl ring and the increased stabilization of the σ-complex intermediate arising from a dienone-type σ-complex intermediate, which is possible in the case of a methoxy substituent (Scheme 4).

Recently, we have reported (7) that similar treatment of 4-*tert*-butyl-2,6-dimethylanisole **9** with excess copper(II) nitrate in an acetic anhydride solution at room temperature only gave a quantitative recovery of starting compound. Raising the reaction temperature to 50°C afforded 2,6-dimethyl-4-nitroanisole **10** from *ipso*-nitration at the *tert*-butyl group in 40% yield, along with the starting compound **9**.

In contrast, as mentioned previously, nitration of [*n*.2]MCPs **1** with excess copper(II) nitrate in an acetic anhydride solution led to *ipso*-nitration at only one of the *tert*-butyl groups to give **2** in moderate yields along with dinitrated product **3**, thus differing from the nitration of **9** under the same conditions, which afforded only the starting compound. Recently, Cacace et al. (13) reported an intramolecular proton shift, namely, a ring-to-ring proton migration, in (β-phenylethyl)arenium ions during the cationic alkylation of 1,2-diphenylethanes, which occurs at a faster rate than the same reaction conducted with toluene in the gas phase. In the present system, an initial σ-complex intermediate would be stabilized by a through-space electronic interaction with the opposing benzene ring, therefore

Scheme 4.



accelerating the reaction, as in the formylation of *tert*-butyl[*n*.2]MCPs (4*c*).

We previously reported the crystal structure of *anti*-[6.2]MCP *anti*-**1e** (9). Although the two benzene rings are located on different sides, but a longer distance was estimated in *anti*-**1d** than that for *anti*-[3.2]MCP *anti*-**1b** (14). Thus when the rings are *anti*, an increased bridge length increases the ring separation and decreases the ring–ring electronic interaction. In contrast, from consideration of the crystal structure of *syn*-[5.2]MCP *syn*-**3d** as shown in Fig. 2, in the *syn* series the through-space electronic interaction through face-to-face overlapping with the opposing benzene ring can still be large, even the larger bridge length. Therefore, the initial σ-complex intermediate could be much more stabilized by a through-space electronic interaction with other benzene rings through the face-to-face overlapping, and thus higher reactivity for syn-conformer than that for anti-conformer in the present *ipso*-nitration was observed.

Interestingly, the bridged methylene protons for $CH_2CH_2\mathit{CH_2}CH_2CH_2$ in the compound *syn*-**3d** are located in different spaces, with one of them folded into the π-cavity formed by two benzene rings. Thus, a higher field signal at δ –0.90–0.10 ppm was observed. The individual peaks of the methylene protons for middle $\mathit{CH_2}$ in the pentane bridge do not coalesce below 140°C in DMSO-d_6, and the energy barrier to conformational wobbling is above 25 kcal/mol.

The presently developed procedure was further applied to the direct removal of a *tert*-butyl group of *O*-(ethoxycarbonyl)methoxy derivative. Thus, nitration of *syn*-16,24-bis[(ethoxycarbonyl)methoxy]-13,21-di-*tert*-butyl[10.2]MCP *syn*-**12**, which was prepared by di-*O*-alkylation of 13,21-di-*tert*-butyl-16,24-dihydroxy[10.2]MCP **11** (15) with ethyl bromoacetate in the presence of NaH (16), with fuming HNO_3, afforded the desired 16,24-bis[(ethoxycarbonyl)-methoxy]-13,21-dinitro[10.2]MCP *syn*-**13** in 91% yield. No cleavage of the ester groups of *syn*-**12** was observed under the condition used as previously observed in the *ipso*-nitration of tetrakis[(ethoxycarbonyl)methoxy]-*tert*-butylcalix-[4]arene (5*c*) (Scheme 5).

We conclude that the selective *ipso*-nitration of *syn*- and *anti*-di-*tert*-buty[*n*.2]MCPs **1** led to the direct introduction of one or two nitro group(s) due to a through-space electronic interaction with the opposing benzene ring, similar to the electrophilic aromatic substitution of MCPs. The number of *ipso*-nitration of **1** has been controlled by the reactivity of the nitration reagent. Especially, the present two-fold

ipso-nitration with fuming HNO_3 provides excellent yields and easy isolation of the products. Further studies on *ipso*-nitration are currently in progress in our laboratory.

Experimental

All melting points (Yanagimoto MP-S1) were uncorrected. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on a Nippon Denshi JEOL FT-270 spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Mass spectra were obtained on a Nippon Denshi JMS-01SA-2 mass spectrometer at an ionization energy of 70 eV; *m/z* values reported include the parent ion peak. Infrared (ir) spectra were obtained on a Nippon Denshi JIR-AQ2OM spectrophotometer as KBr disks. Elemental analyses were performed by Yanaco MT-5. The GLC analyses were performed by Shimadzu gas chromatograph, GC-14A; Silicone OV-1, 2 m; programmed temperature rise, 12°C/min; carrier gas nitrogen, 25 cm^3/min.

Materials

The preparations of *anti*-dimethoxy[*n*.2]MCPs *anti*-**1b**–**f** (9), *syn*-dimethoxy[*n*.2]MCPs *syn*-**1b**–**e** (9), 13,21-di-*tert*-butyl-16,24-dihydroxy[10.2]MCP **11** (15*a*), and *anti*-6,14-di-*tert*-butyl-9,17-dimethyl[3.2]MCP *anti*-**7** (12) were previously described.

Nitration of 1 with copper(II) nitrate in acetic anhydride. Typical procedure

To a solution of 7,15-di-*tert*-butyl-10,18-dimethoxy-[4.2]metacyclophane (*anti*-**1c**) (118.1 mg, 0.289 mmol) in a mixture of CH_2Cl_2 (2.5 mL) and acetic anhydride (50 mL) was added $Cu(NO_3)_2{\cdot}3H_2O$ (150 mg, 0.62 mmol) at 0°C. After the mixture had been stirred at room temperature for 24 h, the reaction mixture was poured into ice-water and then extracted with CH_2Cl_2, washed with water and 10% aqueous sodium hydrogen carbonate. The extract was dried over anhydrous sodium sulfate and concentrated. The GLC analyses of the residue was accord with its being a mixture of *anti*-**2c**, *anti*-**5c**, and *anti*-**6c** in the ratio of 65:14:21. The residue was subjected to silica-gel (Wako, C-300; 100 g) column chromatography using as eluent hexane/benzene (2:1), hexane/benzene (1:1), and benzene to give 7-*tert*-butyl-10,18-dimethoxy-6,15-dinitro[4.2]metacyclophane (*anti*-**6c**) (19.2 mg, 15%), 7-*tert*-butyl-10,18-dimethoxy-15-nitro[4.2]metacyclophane (*anti*-**2c**) (66.7 mg, 58%), and 7-*tert*-butyl-10,18-dimethoxy-8,15-dinitro[4.2]metacyclophane (*anti*-**5c**) (13.0 mg, 10%), respectively.

Alkylation of 11 with bromoethylacetate in the presence of NaH to afford *syn*-13,21-di-*tert*-butyl-16,24-bis[(ethoxycarbonyl)methoxy][10.2]metacyclophane (*syn*-12)

A mixture of **11** (81 mg, 0.175 mmol) and NaH (28.0 mg, 0.700 mmol, about 60% in oil) in dry tetrahydrofuran (9 mL) was heated at reflux for 1 h under N_2. Then ethyl bromoacetate (0.1 mL, 0.902 mmol) was added and the mixture heated at reflux for an additional 3 h. After cooling the reaction mixture to room temperature, it was filtered. The filtrate was concentrated to give a yellow oil, which was then distilled under the reduced pressure to remove the excess unreacted ethyl bromoacetate using a kugelrohr apparatus. The residue was recrystallized from hexane/benzene (1:1) affording the *title compound syn*-**12** (101 mg, 91%) as colorless prisms; mp 38–40°C; ir (KBr): 2931, 2860, 1741 (C=O), 1480, 1461, 1371, 1284, 1195, 1142, 1059, 1039, 949, 863, 777, 745, 667 cm^{-1}; ^1H nmr ($CDCl_3$): 0.81–0.92 (m, 8 H), 1.16 (s, 18 H), 1.21–1.30 (m, 2 H), 1.27–1.35 (m, 6 H), 1.38–1.47 (m, 4 H), 2.17–2.29 (m, 2 H), 2.62–2.74 (m, 2 H), 2.77–2.89 (m, 2 H), 3.32–3.44 (m, 2 H), 4.19–4.31 (m, 4 H), 4.38 (s, 4 H), 6.73 (d, 2 H, *J* 2.4), 6.89 (d, 2 H, *J* 2.4); MS, *m/z*: M^+ 636. Anal. calcd. for $C_{40}H_{60}O_6$: C 75.43, H 9.5; found: C 75.26, H 9.59.

Nitration of *syn*-12 with fuming HNO_3

To a solution of *syn*-**12** (38.0 mg, 0.06 mmol) in a mixture of CH_2Cl_2 (1.0 mL) and glacial acetic acid (1.0 mL) was added fuming HNO_3 (0.25 mL) at 0°C. After the mixture had been stirred at room temperature for 30 min, it was poured into ice-water, extracted with CH_2Cl_2, washed with water and 10% aqueous sodium hydrogen carbonate. The extract was dried over anhydrous sodium sulfate and concentrated. The residue was subjected to silica-gel (Wako, C-300; 100 g) column chromatography using as eluent chloroform to give *syn*-16,24-bis[(ethoxycarbonyl)methoxy]13,21-dinitro[10.2]metacyclophane (*syn*-**13**) (33 mg, 91%) as pale-yellow prisms (hexane/benzene (1:1)); mp 72–74°C; ir (KBr): 2933, 2854, 1765, 1728 (C=O), 1619, 1448, 1371, 1342, 1310, 1283, 1265, 1198, 1184, 1105, 1086, 1056, 1042, 1030, 944, 920, 886, 865, 746 cm^{-1}; ^1H nmr ($CDCl_3$): 0.79–0.92 (m, 8 H), 1.15–1.55 (m, 8 H), 1.30 (t, 6 H, *J* 7.3), 2.29–2.43 (m, 2 H), 2.69–2.83 (m, 2 H), 2.86–2.98 (m, 2 H), 3.52–3.67 (m, 2 H), 4.26 (q, 4 H, *J* 7.3), 4.44 (s, 4 H), 7.57 (d, 2 H, *J* 2.9), 7.88 (d, 2 H, *J* 2.9). – MS (75 eV); MS, *m/z*: M^+ 614. Anal. calcd. for $C_{32}H_{42}N_2O_{10}$: C 62.53, H 6.89, N 4.56; found: C 62.35, H 6.68, N 4.36.

Crystallographic data for *syn*-11,19-dimethoxy-8,16-dinitro[5.2]metacyclophane (*syn*-3d)

Crystal data: $C_{21}H_{24}N_2O_6$; M = 400.44; triclinic; a = 996.28 (8), b = 1200.77 (6), c = 875.12 (5) pm; α = 102.604 (5), β = 94.445 (6), γ = 83.340 (6)°; V (m^3) = 1745.5 (4) × 10^{-30} (by least-squares refinement on diffractometer angles for 25 automatically centered reflections); λ (Å) = 1.54184; space group P-1 (no. 2); Z = 2; D_x (g/cm^3) = 1.312; pale-yellow prism; crystal size (mm) 0.3 × 0.25 × 0.2; μ(Cu-K_α) (cm^{-1}) = 7.65.

Data correction and procedure

Enraf–Nonius CAD4 FR586 diffractometer, $\omega/2\theta$ mode with ω scan width of 0.8 + 0.140 tan θ, scan speed 1.0–7.0 deg min^{-1}, graphite-monochromated Cu-K_α radiation; 4250 reflections were measured ($2.31 \leq \theta \leq 64.92$, $-h$, k, l); 3702 unique (merging R = 0.0260, no absorption correction); linear and approx. isotopic crystal decay, ca. –3.8% corrected during procedure.

Structure analysis and refinement

The structure was solved by direct method (SIR88 (17)). Full-matrix least-squares refinement on F with all non-hydrogen atoms anisotropic and hydrogens isotropic fixed at B_{eq} 4.0 Å^2. The weighting scheme is $\omega = 4F_o^2/[(\sigma I_o)^2 + 0.0016F_o^4]$. Final R and Rw values are 0.083 and 0.121 (refined on F). All calculations were performed on a Micro VAX3100 using MolEN (18).

The non-hydrogen atoms were refined anisotropically, but it was considered that C2A and C4A were disordered with their counterparts C2B and C4B in a ratio of 0.64:0.36 and 0.57:0.43, respectively. The 14 independent hydrogen atoms except for C(2A), C(2B), C(3), C(4A), and C(4B) were located in the calculated positions at thermally fixed B_{iso} 5.0 Å^2 and included in the refinement, but restrained to ride on the atoms to which they are bonded.

The refined non-hydrogen atomic coordinates are listed in Table 3, whilst the hydrogen coordinates, temperature factors (anisotropic for carbon atoms), scale factor, secondary estimation coefficient, bond distances and angles, and crystal data have been deposited.[2]

A comparative theoretical study of the electronic structure of some nickel(II) azides, thiocyanates, and isothiocyanates

R.H. Abu-Eittah, M. El-Esawy, N. Ghoneim, and A.T. Aly

Abstract: The electronic structure, conformation, and molecular orbitals of some nickel(II) azides, thiocyanates, and isothiocyanates have been studied. Three different basis sets: split valence (SV), split valence with six *d*-Gaussians (SV6D), and double zeta (DZ) sets, were used to find the best ground state for nickel. It has been found that the combination, DZ-^3F, gives results closest to the experimental values. The electronic structures of the nickel azides studied were completely different from those of the nickel thiocyanates. On the other hand, the electronic structures of the nickel thiocyanates studied were highly comparable to those of the corresponding nickel isothiocyanates. Molecular orbitals were computed for the complexes studied and the types of electronic transitions expected were identified and discussed.

Key words: Ni(II) azides, thiocyanates, and isothiocyanates: ab initio SCF calculations; MO calculations on some Ni(II) complexes; theoretical treatment of some Ni(II) ions and salts; geometry and energetics of some nickel(II) azides, thiocyanates, and isothiocyanates.

Résumé : On a étudié la structure électronique, la conformation et les orbitales moléculaires de quelques azotures, thiocyanates et isothiocyanates de nickel(II). On a utilisé trois ensembles de base (ensembles de valence scindée (VS), de valence scindée avec six gaussiennes-*d* (VS6G) et de double zêta (DZ)) pour déterminer le meilleur état fondamental du nickel. On a trouvé que la combinaison DZ-^3F conduit aux résultats qui se rapprochent le plus des valeurs expérimentales. Les structures électroniques des azotures de nickel étudiés sont complètement différentes de celles des thiocyanates de nickel. Par ailleurs, les structures électroniques des thiocyanates étudiés se comparent avantageusement avec celles des isothiocyanates de nickel correspondants. On a calculé les orbitales moléculaires des complexes étudiés, on a identifié et on discute des types de transitions électroniques attendues.

Mots clés : azotures de nickel(II), thiocyanates et isothiocyanates : calculs ab initio autocohérents, calculs d'OM, géométrie, énergies.

[Traduit par la Rédaction]

1. Introduction

Theoretical calculations on the compounds of third-row and higher elements are still scarce in the literature due both to the problems faced with parameterization of these elements in semiempirical calculations and to the need for fast computers for ab initio calculations. A theoretical study of transition metals and their compounds is important. There have been several studies on the role of transition metals in catalytic dehydrogenation and their mode of interaction with hydrocarbons. Rappe and Goddard (1) studied the electronic states of $NiCH_2$ and $NiCH_3$ using effective core potentials(ECPs) instead of all-electron calculations. The results obtained for the ^3F and ^3D states were very illustrative.

Kitaura et al. (2) used ab initio MO calculations on the complexes of nickel with phosphines whereas Lin and Hall (3) investigated the stability of hydrides. Simpson and Hall (4) studied the carbonyls and discussed the possibilities of bridging as well as metal–metal bonding.

The complexes of nickel with azide ion and different phosphines have been studied (5). Sensie et al. (6) used polarographic and potentiometric methods in their study of nickel azide. The formation of azido nickel complexes was studied by Egghart (7) while a study in nonaqueous media was carried out by Gutmann and Bardy (8). The formation of Ni(II) and Co(II) azides as well as the electronic absorption spectra of the complexes formed have been studied (9, 10).

The thiocyanate ion, having S and N atoms on its ends, has the ability to bond through either of them, thus producing the so-called thiocyanates and isothiocyanates. The bonding of thiocyanate ion through the nitrogen atom has been widely reported (11–15) and bond lengths were determined from single-crystal X-ray measurements.

2. Computational methods

2.i. Electronic state of Ni

Computations throughout this work were carried out using the GAMESS program (16) distributed free of charge by Mike Schmidt. Smaller programs were developed for fine

© 1998 NRC Canada

analysis of the outputs without incorporation into the original GAMESS code.

When dealing with a system of $2n$ electrons occupying n double-occupied molecular orbitals, the restricted Hartree–Fock state function is a product of the antisymmetrized spin orbitals

$$[1] \qquad \Psi^{\mathrm{RHF}} = \left|\phi_1 \ldots \bar{\phi}_1 \phi_n \bar{\phi}_n\right|$$

The LCAO approximation involves expanding ϕ_i as a finite series of simpler basis functions (which roughly correspond to atomic orbitals), i.e.,

$$[2] \qquad \phi_i = \sum_{p=1}^{m} C_{ip} \chi_p$$

Roothaan's equations (17) give

$$[3] \qquad \sum_{p=1}^{m} C_{ip} \left\langle \chi_p \left| \hat{H}^{\mathrm{HF}} \right| \chi_p \right\rangle = \sum_{p=1}^{m} \varepsilon_i C_{ip} \left\langle \chi_q \middle| \chi_p \right\rangle$$

or

$$[4] \qquad \sum_{p} C_{iq} (h_{pq}^{\mathrm{HF}} - \varepsilon_i S_{pq}) = 0$$

For a given basis set, the Hartree–Fock operator is

$$[5] \qquad h_{pq}^{\mathrm{HF}} = \left\langle \chi_p(1) \left| -\frac{\nabla^2}{2} \right| \chi_q(1) \right\rangle + \left\langle \chi_p(1) \left| -\frac{Z_j}{r_{ij}} \right| \chi_q(1) \right\rangle + \sum_j \sum_r \sum_s C_{jr} C_{js} \left[\left\langle \chi_p(1)\chi_q(1) \left| \frac{1}{r_{12}} \right| \chi_r(2)\chi_s(2) \right\rangle + \left\langle \chi_p(1)\chi_r(1) \left| \frac{1}{r_{12}} \right| \chi_q(2)\chi_s(2) \right\rangle \right]$$

which is written as

$$[6] \qquad h_{pq}^{\mathrm{HF}} = h_{pq}^{\mathrm{N}} + \sum_r \sum_s D_{rs} (2\langle pq | rs \rangle - \langle pr | qs \rangle)$$

where

$$[7] \qquad D_{rs} = \sum_j C_{jr} C_{js}$$

With an open-shell system, two treatments will be used. The first is that proposed by Roothaan (18) and is called restricted open-shell Hartree–Fock (ROHF) where the wave function is partitioned into a closed-shell part describing the doubly occupied MOs and an open-shell part for the rest of the occupied MOs. Thus, for a doublet system with $2n + 1$ electrons the ROHF wave function is

$$[8] \qquad \Psi^{\mathrm{RHF}} = \left|\phi_1 \bar{\phi} \ldots \phi_n \bar{\phi}_n \phi_{n+1}\right|$$

The second treatment is that proposed by Pople and Nebest (19) and is called the unrestricted Hartree–Fock (UHF) method. It is based on the fact that, since the number of electrons of spin *a* differs from the number of electrons of spin *b* and the repulsion between electrons depends on their spin, the state function for $2n + 1$ electrons is

$$[9] \qquad \Psi^{\mathrm{UHF}} = |a_1(1) \ldots a_n(n) a_{n+1}(n+1) b_1(1) \ldots b_n(2n+1)|$$

where the a_i and b_i are the α and β spin orbitals. The energy of this system is given by

$$[10] \qquad E = \sum_{i}^{\alpha+\beta} h_i^{\mathrm{N}} + \frac{1}{2} \sum_{i}^{\alpha+\beta} \sum_{j}^{\alpha+\beta} J_{ij} - \frac{1}{2} \left[\sum_{i}^{\alpha} \sum_{j}^{\alpha} + \sum_{i}^{\beta} \sum_{j}^{\beta} \right] K_{ij}$$

where J_{ij} and K_{ij} are the conventional Coulomb and exchange integrals. The Ψ^{UHF} is not an eigen function of the spin operator $\hat{s}^2$ and the resulting states are spin contaminated and are difficult to interpret.

Most molecular calculations begin with the choice of a basis set. The success of the calculations is dependent on the use of an adequate basis set. In the LCAO method each molecular orbital is expressed as a finite sum of Slater-type orbitals (STOs) or Gaussian-type functions (GTFs). Instead of using individual Gaussian functions as basis functions, contracted Gaussian-type functions are used. The latter consist of a linear combination of a small number of primitive Gaussians, which are Cartesian Gaussians centered on the same atom but have different orbital exponents.

Transition metals are hard to deal with because of their peculiar electronic structure. The partially filled and closely spaced *d*-orbitals allow the transition metal to have more than one ground state with little energy difference (20).

Several trials have been attempted to obtain a consistent theoretical description of the electronic states that arise from the s^2d^n, $s\ d^{n+1}$, and d^{n+2} configurations of the transition metal atoms (21–23). It has been generally accepted that for the first-row transition metal atoms the ground state is s^2d^n; experimentally this was not always true. The Hartree–Fock calculations give inadequate results, since a difference of up to 1.3 eV is found between the experimental results and the Hartree–Fock calculations.

Botch et al. (24) considered the differential correlation effects within the lowest-lying states arising from s^2d^n, $s\ d^{n+1}$, and d^{n+2} of the first-row transition metal atoms using multiconfiguration SCF and non-relativistic procedures. For nickel, the experimental results indicate that the ^3F ($4s^23d^8$) state lies 0.03 eV above the ^3D ($4s3d^9$) state (24). The numerical HF calculations result in a ^3F state that is of 1.3 eV lower energy than the ^3D state. Theoretical attempts could not predict this order; for example, the excitation energy $^3F \rightarrow {}^3D$ calculated by Botch et al. was 0.42 eV using Wachters' basis set. It turned out that a ^3F state is not a good ground state (lowest energy) for $Ni(CO)_4$ whereas a ^1S ($3d^{10}$) is a good one. On the other hand, a ^3D state is a good ground state for nickel atom in NiH and Ni_2 (25).

2.ii. Basis sets

The split valence 3-21G (26) basis set was used for carbon, nitrogen, and hydrogen atoms. For sulphur atom an extra *d*-function was added to the 3-21G basis set.

Several attempts have been applied to building basis sets for transition metals. Wachters (27) and Viellard (28) used fairly large basis sets (14*s*9*p*5*d*). Basch et al. (29) introduced a 15*s* 8*p* 5*d* basis set whereas Roos et al. (30) introduced a smaller basis set (12*s*6*p*4*d*). In an attempt to improve the description of the different ground state configurations of the

Ref. 42		2.11			

[a] Experimental bond length = 2.06 Å (43, 44).

transition metals, Hay (31) modified the representation of the 3*d* atomic orbitals and used diffuse functions for more extension of the basis sets. Many other attempts have been made (32–34).

Recently, Schaefer et al. (35) published a collection of reoptimized basis sets. For the nickel atom, a collection of basis sets of different sizes: split valence (SV), split valence with six *d*-Gaussian functions (SV6D), and double zeta (DZ) were reported. Each basis set was optimized for three possible ground states for the Ni atom, namely, the ^3F, ^3D, and ^1S states. In this work these sets were tested and the best was adopted for use throughout. The size of each basis set differs according to the electronic state under consideration. For the singlet *S*-state, $^1S = 3d^{10}$, the split valence basis set is SV = (12s8*p* 5*d)* contracted to [2*p* 2*d* 3s] = {633/53/41} whereas for the ^3D state, the basis set is SV = (14*s* 8*p* 5*d*) contracted to [5*s* 2*p* 2*d*] = {633 11/53/41}. For the ^3F state the basis set is the same as that of the ^3D state. The split valence with six *d*-functions basis set for the ^1S state of nickel is SV6D = (12*s* 8*p* 6*d*) contracted to [3*s* 2*p* 2*d*] = {633 /53/51}; for the ^3D state it is SV6D = (14*s* 8*p* 6*d*) contracted to [5*s* 2*p* 2*d*] = {633 11/53/51} and is also used for the ^3F state. The double zeta basis set for the nickel ^1S state is denoted by DZ = (12*s* 9*p* 5*d*) contracted to [6*s* 5*p* 3*d*] = {62 1111/33 111/3 11} whereas that used for the ^3D state is (14*s* 9*p* 5*d*) contracted to [8*s* 5*p* 2*d*] = {62 111111/33 111/41}; the ^3F DZ basis set is (14*s* 9*p* 5*d*) contracted to [8*s* 5*p* 2*d*] = {62 111111/33 111/3 11}.

2.iii. Testing the basis sets on $Ni(H_2O)_6^{2+}$

Three basis sets were used for MO calculations on the $Ni(H_2O)_6^{2+}$ ion. Geometry optimization was performed using gradient methods assuming a T_h symmetry. The Ni—O bond was considered as the judging parameter since it was found that the energy dependence on the O—H bond is insignificant; results are given in Table 1. The observation of Antolovic and Davidson (36) that the SCF geometry overestimates the ligand bond lengths and underestimates the metal–ligand bond length is confirmed in this work; the results show that the Ni—O bond length of the ^3F state was closer to the experimental value with SV and SV6D basis sets, whereas the ^3D state gave closer agreement with the DZ basis set.

The results for the total energy are given in Table 1. The ^3F ground state has the lowest energy, especially with the DZ basis sets.

It is worthwhile to investigate other parameters such as Mulliken overlap population and transition energies. In this work the numerical value of atomic overlap population is taken as a criterion for the type of bonding between atoms. The calculated overlap populations between Ni and O atoms in $Ni(H_2O)_6^{2+}$ using the different basis sets are given in Table 1. The highest overlap population is obtained for the ^3F ground state using both the DZ and SV basis sets. However, using the SV6D sets, where the *d*-orbitals are represented by a large number of basis functions, the highest population was obtained for a ^1S ground state. Atomic population is represented by the net charge on the atom, Table 1; the smaller sets give a high accumulation of positive charge on the Ni atom.

The UV–VIS spectrum (37) of aqueous Ni^{2+} ions shows a band at 8500 cm^{-1} and at about 13800 cm^{-1}. Configuration interaction calculations (38), CIS, were carried out on $Ni(H_2O)_6^{2+}$ using the different basis sets. The results of DZ-^3F calculations were closest to the experimental (Table 1). The above results indicate that the ground state for nickel in $Ni(H_2O)_6^{2+}$ is the ^3F state and the best basis set is the DZ. This combination, DZ-^3F, is used in all subsequent calculations.

3. Results and discussion

3.i. Monoazidonickel (II) ion; $[Ni(N_3)]^+$

Azide ion is a linear ion, it remains so when attached to metal ions and most probably when attached to an organic moiety such as CH_3N_3 or phenyl azide (38–40). An extensive structural study of transition-metal-ion azides is not found in the literature. In this work ab initio procedures were applied to Ni(II) mono- and diazides. The singlet states were calculated at the RHF-SCF level whereas the triplets were calculated at the ROHF and UHF-SCF levels. During geometry optimization, the azide ion was allowed to bend by imposing C_1 symmetry but the resulting optimum geometry was linear.

The optimized geometry of monoazidonickel(II) is given in Table 2. The linear molecule follows the $C_{\infty v}$ point group; a reduced symmetry C_{4v} was adopted throughout the MO calculations, but the reduction in symmetry had no effect on the energetics of the ion.

Nickel(II) ion, d^8 configuration, exists in a high-spin triplet state when placed in an O_h field, while it exists in a low-

© 1998 NRC Canada

spin singlet state if placed in a D_{4h} field. The energetics and geometry of $Ni(N_3)^+$ have been calculated for both singlet and triplet states. The RHF-SCF procedures were used for singlet calculations, which resulted in a total energy of –1668.701 19 au with a binding energy of –0.609 681 au (–392 kcal mol^{-1}). As can be seen, $Ni(N_3)^+$ is significantly stable; the distribution of charge density is given in Table 3.

Table 2. Optimized geometry of nickel(II)-azides, thiocyanates, and isothiocyanates ions.

Ion	Bond length, Å		
Nickel azides	Ni—N_1	N_1—N_2	N_2—N_3
Ni N_3^+	1.724	1.196	1.112
Ni $(N_3)_2$	1.799	1.185	1.126
Nickel thiocyanates	Ni—S	S—C	C—N
$Ni(SCN)^+$	2.019	1.630	1.150
$Ni(SCN)_2$	2.064	1.647	1.147
Nickel isothiocyanates	Ni—N	N—C	C—S
$Ni(NCS)^+$	1.743	1.573	1.176
$Ni(NCS)_2$	1.775	1.173	1.598

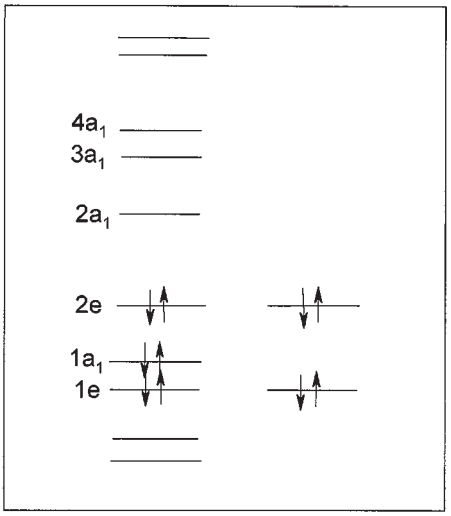
In this work, Mulliken overlap population is taken as an indication of bonding between atoms. The calculated Mulliken overlap population is 0.2418 between nickel atom and the adjacent nitrogen and is analyzed to 0.3092 for σ overlap and –0.0674 for π overlap. The overlap between N_1 and N_2 is 0.9058 whereas that between N_2 and N_3 is 0.4196; the σ overlap between Ni and N_1 is of the same order of magnitude as that between N_2 and N_3 in the $Ni(N_3)^+$ ion. This result indicates the existence of an apparent covalent bonding between Ni^{2+} and N_3^- and shows the absence of π-bonding between Ni^{2+} and azide ion.

The singlet ground state of $Ni(N_3)^+$ has the electronic configuration $\ldots 1e^4 1a_1^2 2e^4 2a_1^0 3a_1^0 4a_1^0 3e^0$. A molecular orbital energy level diagram is shown in Fig. 1 and an analysis of the molecular orbitals is given in Table 4. The four highest occupied MOs are localized on the azide ion whereas the three lowest unoccupied MOs are metal ion orbitals. These results mean that the electronic transitions of $Ni(N_3)^+$ must be very intense and result from azide → nickel (ligand → metal) charge transfer transitions.

The electronic population of nickel in $Ni(N_3)^+$ is found to be $\ldots 3d^{7.98}4s^{0.32}4p^{0.02}$, which is evidence for covalent bonding between nickel and azide in $Ni(N_3)^+$.

The triplet ground state of $Ni(N_3)^+$ was calculated using the UHF-SCF procedures with 25 α-spin electrons and 23 β-spin electrons. The total energy is –1668.707 316 au, giving a –0.616 148 au (–386 kcal mol^{-1}) binding energy. It is more stable than the singlet state by 4 kcal mol^{-1}. The charge distribution has changed significantly (Table 3) from that in the singlet state. A buildup of electron density on nickel in the triplet state of $Ni(N_3)^+$ is indicated by the results of the electronic configuration, which is $\ldots 3d^{8.70}4s^{0.26}4p^{0.004}$. Thus in the triplet state, back-donation of electrons from N_3^- to Ni^{2+} is more pronounced than in the singlet state. Consequently, covalent bonding between Ni^{2+} and N_3^- in $Ni(N_3)^+$ is more pronounced in the triplet than in the singlet state. Analysis of the MO energy level diagram of the triplet state of $Ni(N_3)^+$ indicated that the lowest electronic transition is a *d*–*d* transition, a result that was not obtained in the singlet state.

Fig. 1. A MOED for the ground singlet state of $Ni(N_3)^+$.



3.ii. Diazidonickel(II) ion; $Ni(N_3)_2$

Geometry optimization has shown that the molecule is linear; D_{4h} symmetry was imposed on the molecule. The singlet ground state energy gave a binding energy of –615 kcal mol^{-1}, which reflects an extra stability of the molecule relative to its components. The charge density on nickel is lower in $Ni(N_3)_2$ than it is in $Ni(N_3)^+$, Table 3.

The total atomic overlap population between Ni and the nearest N atom in $Ni(N_3)_2$ is 0.2244, which is analyzed to give 0.254 for σ overlap and –0.0296 for π overlap, i.e., the aabsence of π-bonding between nickel and azide in $Ni(N_3)_2$. This result is confirmed by the calculated electronic configuration of Ni in $Ni(N_3)_2$, which is $\ldots 3d^{8.00}4s^{0.41}4p^{0.03}$; back-donation to the 4*s*-orbital results in σ- and not π-bonding. It is found that covalent bonding between nickel and azide is stronger in $Ni(N_3)^+$ than it is in $Ni(N_3)_2$.

The electronic configuration of the singlet ground state of $Ni(N_3)_2$ is $\ldots a_u^2 1e_u^4 1e_g^4 1a_g^0 2a_g^0 2e_u^0 2e_g^0$. A MO energy level diagram is shown in Fig. 2 and a MO analysis is given in Table 4. One observes a large energy separation between the occupied and vacant MOs compared to the situation in $Ni(N_3)^+$, in addition to the fact that the lowest electronic transitions in $Ni(N_3)_2$ are charge transfer and not *d*–*d* transitions.

The ground triplet state of $Ni(N_3)_2$ was investigated using ROHF-SCF procedures. The binding energy is –637 kcal mol^{-1} compared to –615 kcal mol^{-1} for the singlet state. The charge distribution is shown in Table 3 where one can observe a lower charge density on the different atoms than is the case for the singlet state. Mulliken population analysis for nickel in the triplet ground state of $Ni(N_3)_2$ gives the population $3d^{7.87}4s^{0.62}4p^{0.02}$. The *s*-orbital becomes populated and σ-bonding predominates between the 4*s* atomic orbital of nickel and the appropriate orbital of the nitrogen atom.

A MO energy level diagram is shown in Fig. 3 and an analysis is given in Table 4. Here, the highest occupied and lowest vacant MOs are mainly metal orbitals. The lowest transition, $d_g \rightarrow s_g$, is both Laporte and angular momentum forbidden. On the other hand, a strong symmetry-allowed

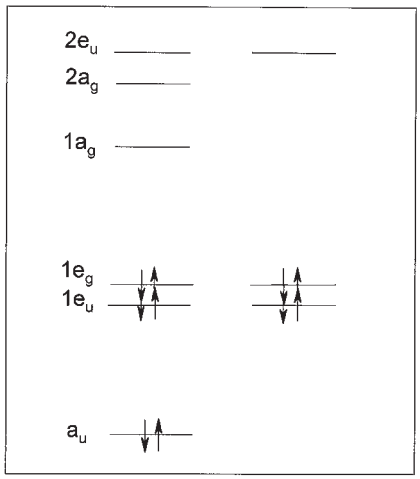

Fig. 3. A MOED for the ground triplet state of $Ni(N_3)_2$.

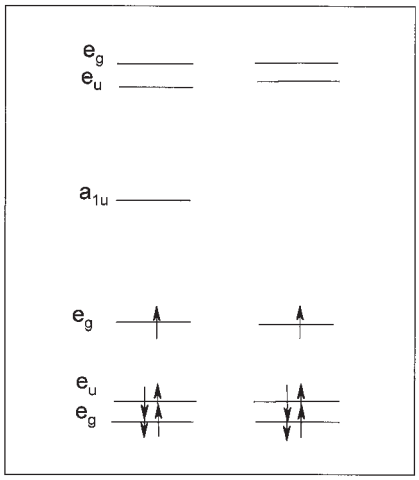

metal-to-azide charge transfer, $e_g \rightarrow e_u$, is expected to predominate.

The overlap population between the different atoms of $Ni(N_3)_2$ in the ground triplet state gives

$Ni–N_1 = 0.2674$, $N_1–N_2 = 0.7412$, and $N_2–N_3 = 0.4494$

One observes a larger overlap between the metal ion and the azide ion in the triplet than in the singlet state.

Computations on the triplet state of $Ni(N_3)_2$ using the UHF procedures led to results that are less favourable than those obtained with the ROHF procedures. Lower binding

energy and lower overlap population were obtained with UHF procedures.

3.iii. Monothiocyanatonickel(II) ion, $Ni(SCN)^+$

Ab initio MO calculations adopting full geometry optimization were performed and results showed the linearity of the $Ni(SCN)^+$ ion. Further computations adopted the C_{4v} point group instead of the $C_{\infty v}$ point group. The optimized geometry is given in Table 2. The binding energy (heat of formation) is –56 kcal mol^{-1} compared to –392 kcal mol^{-1} for $Ni(N_3)^+$. The population of nickel in $Ni(SCN)^+$ is $\ldots 3d^{8.81}4s^{0.22}4p^{0.01}$ whereby a unit of charge has been transferred from the SCN^- ion to the Ni^{2+} ion. The distribution of charge density is given in Table 5.

The Mulliken overlap population gives

N–S: 0.1514; S–C: 0.4594, and C–N: 1.4376

The existence of a covalent bond between nickel and sulphur is quite evident. Analysis of Mulliken overlap gives 0.0844 for σ overlap and 0.2358 for π overlap. Thus, the character of Ni—S π-bonding is more than twice that of the σ-bonding. Comparing these results with the corresponding overlap in $Ni(N_3)^+$, one finds a value of 0.3090 for σ overlap between Ni and N atoms and a value of –0.0673 for π overlap. In other words, no π overlap exists between Ni and N in $Ni(N_3)^+$ in contrast to the situation between Ni and S in $Ni(SCN)^+$.

A comparison of the electron population of the nickel atom in the ground singlet states of the two ions gives

$Ni(SCN)^+$:$\ldots 3d^{8.81}4s^{0.22}4p^{0.01}$

$Ni(N_3)^+$:$\ldots . 3d^{7.89}4s^{0.32}4p^{0.02}$

The SCN^- ion is a stronger electron donor than is the $(N_3)^-$ ion.

A MO energy level diagram for the ground singlet state of $Ni(SCN)^+$ is shown in Fig. 4 and an analysis of these MOs is given in Table 4. A pronounced mixing between the orbitals of metal and thiocyanate ion is observed. The four highest occupied MOs and the lowest three vacant MOs span the whole ion $Ni(SCN)^+$ and none of the low-energy transitions can be assigned to metal → metal, ligand → ligand, metal → ligand, or ligand → metal transitions. At least the lowest five electronic transitions are between MOs extending over the whole $Ni(SCN)^+$ ion. Consequently one expects to observe intense electronic transition and the weak $d \rightarrow d$ transitions would not be observed.

Computations on the ground triplet state of $Ni(SCN)^+$ were performed using UHF procedures. The binding energy of such a state is –272 kcal mol^{-1} compared to –56 kcal mol^{-1} for the singlet state. The charge density distribution varies more in the triplet state than in the singlet as shown in Table 5 whereby a buildup of positive charge is encountered on nickel and a buildup of negative charge is encountered on the S and N atoms. Analysis of atomic overlap population indicated an extensive π-bonding between Ni and S atoms and the following configuration is obtained for Ni in the triplet ground state of $NiSCN^+$: $3d^{8.07}4s^{0.27}4p^{0.02}$. In the triplet state, the highest occupied MOs are ligand (SCN^-) orbitals whereas the lowest vacant MOs are almost metal-ion orbitals. The lowest electronic transition should be ligand → metal charge transfer transitions. Mixing between metal and ligand orbitals is highly decreased as compared to the case in $Ni(N_3)^+$ or in the triplet state in $NiSCN^+$.

3.iv. Dithiocyanatonickel(II): $Ni(SCN)_2$

Geometry optimization proved that the molecule is linear. D_{4h} symmetry was imposed on the structure of the molecule. The optimized geometry is given in Table 2. The binding energy of the singlet ground state is –212 kcal mol^{-1}, which is much less negative than the binding energy of $Ni(N_3)_2$, –615 kcal mol^{-1}. The charge distribution is given in Table 5 and the configuration of the nickel atom is $3d^{8.73}4s^{0.40}4p^{0.01}$. Both the population and charge density on the nickel atom are different in $Ni(SCN)_2$ than in $Ni(N_3)_2$. In the latter, the positive charge on nickel is higher than in $Ni(SCN)_2$. Hence, electron back-donation (metal → ligand) is stronger when the ligand is the azide than when it is the thiocyanate ion. One can say that the π* molecular orbitals on the $(N_3)^-$ ion are of lower energy and act as electron acceptors.

The singlet ground state configuration of $Ni(SCN)_2$ is $\ldots 1a_g^2 1e_g^4 1e_u^4 2e_g^2 2a_{1g}^0 3a_{1g}^0 2e_u^0$. A MO energy level diagram is shown, Fig. 5, and an analysis of the MOs is given in Table 4. The lowest electronic transition, $1e_u \rightarrow 2e_g$, possesses a large contribution from an L → M charge transfer configuration.

The binding energy of the ground triplet state of $Ni(SCN)_2$ is –440 kcal mol^{-1}. The distribution of charge density is given in Table 5 and is different than is observed in the singlet state. One observes a buildup of positive charge density on the metal atom, indicating an electron back-donation from metal atom (ion) to the ligand, SCN^- ion. The electronic population of nickel in the ground triplet state of $Ni(SCN)_2$ is $\ldots 3d^{7.97}4s^{0.45}4p^{0.03}$. The Mulliken overlap population indicates the existence of σ as well as π overlap between the Ni and S atoms. The MO energy level diagram is given in Fig. 6 and the analysis of MOs is given in Table 6. The lowest-lying electronic transitions are L → M charge transfer transitions.

The above results indicate the following conclusions: the ground state of $Ni(SCN)_2$ is the triplet state; mixing between metal and ligand orbitals is not pronounced, and covalency between Ni^{2+} and SCN^- is more apparent than is the case for $Ni(SCN)^+$.

3.v. Monoisothiocyanatonickel(II) ion: $Ni(NCS)^+$

Computations showed that $Ni(NSC)^+$ is linear; the optimized geometry is shown in Table 2. The binding energy is

© 1998 NRC Canada

Fig. 4. A MOED for the ground singlet state of $Ni(SCN)^+$.

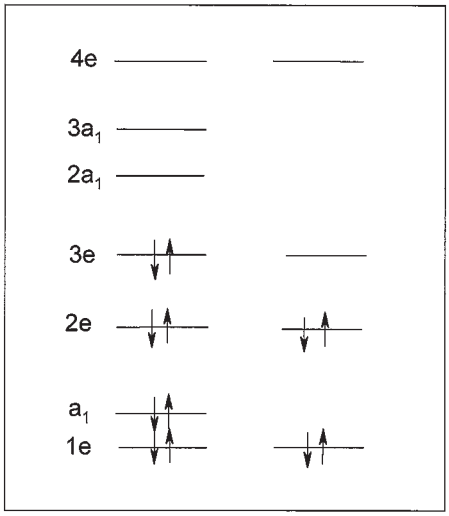

Fig. 5. A MOED for the ground singlet state of $Ni(SCN)_2$.

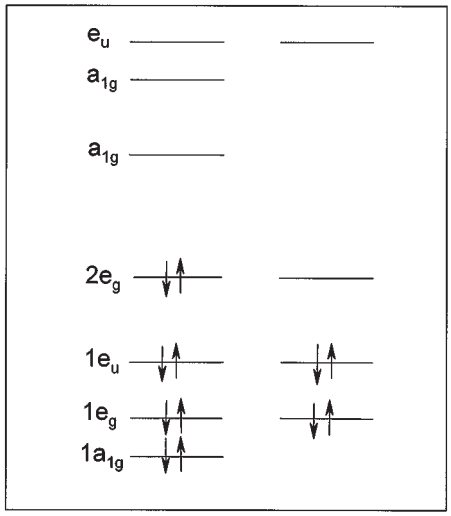


–90 kcal mol^{-1}, which is more negative than that of $Ni(SCN)^+$ but is much higher than that of $Ni(N_3)^+$, –392 kcal mol^{-1}. The distribution of charge is given in Table 5 whereas the electronic population of nickel is $3d^{8.58}4s^{0.36}4p^{0.01}$, which is significantly different from the population in $Ni(SCN)^+$.

It is important to compare bonding between the metal and SCN^- with that between the metal and NCS^-. Mulliken overlap population analysis for the ground singlet state of $Ni(NCS)^+$ gives

Ni–N = 0.1844; Ni–C = 1.0944; and C–S = 0.6224

Analysis of the Ni–N overlap gives –0.0518 for σ overlap (no σ bond) and 0.2362 for π overlap. The same behaviour was observed with $Ni(SCN)^+$.

The electronic configuration of the ground singlet state of $Ni(NCS)^+$ is $\ldots 1b_1^2 1b_2^2 1a_1^2 1e^2 2e^0 2a_1^0 3a_1^0$. A molecular orbital energy level diagram is shown, Fig. 7, and the weight percent of atomic orbitals in the different MOs is given in Table 4. The following observations are noted:

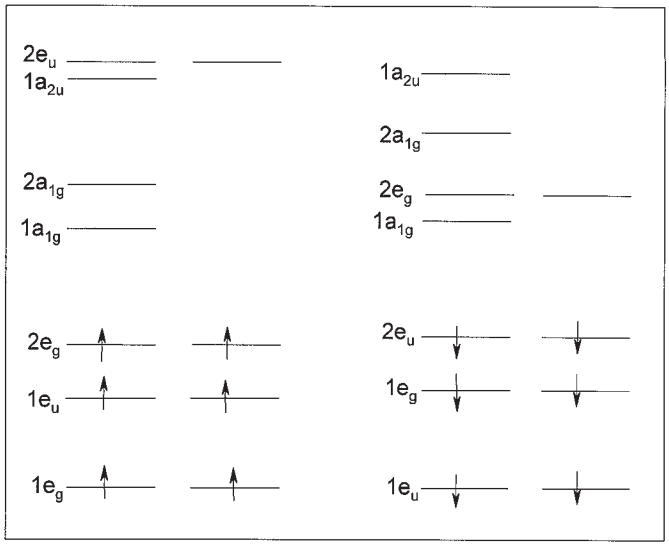
1. The energy of HOMO is –0.4071 au compared to –0.4342 au for N $(SCN)^+$.
2. The lowest electronic transition: $2e \rightarrow 3e$, is neither a *d–d* transition, localized on the metal ion, nor an L–L transition localized on the NCS^- ligand, nor a charge transfer transition.
3. The four HOMOs and the two LUMOs are delocalized over the whole ion, $Ni(NCS)^+$, which indicates a good mixing between the orbitals of the metal and the NCS^- ions.
4. The HOMO, $1e^2$, should result in a high-spin state.

Mulliken population analysis gives the following configurations for metal ion in $Ni(NCS)^+$: $\ldots 3d^{7.91}4s^{0.42}4p^{0.01}$ compared to $\ldots 3d^{8.08}4s^{0.27}4p^{0.02}$ for the metal ion in $Ni(SCN)^+$. The overlap population between Ni and N atoms in the triplet ground state of $Ni(NCS)^+$ is mainly π overlap, although the σ overlap is not zero.

3.vi. Diisothiocyanatonickel(II): $Ni(NCS)_2$

The ground singlet state of $Ni(NCS)_2$ has a binding energy of –278 kcal mol^{-1} and the optimum geometry is given in Table 2. The electronic configuration of the singlet

Fig. 6. A MOED for the ground triplet state of $Ni(SCN)_2$.



ground state of $Ni(NCS)_2$ is $\ldots 1e_g^4 1e_u^4 2e_g^2 a_{1g}^0 2e_u^0 3e_g^0$. A molecular orbital energy level diagram is shown in Fig. 8 and the analyses of the wave function of the MOs are given in Table 4, which indicates the following:

$1e_g$: MO spanning metal and ligand atoms; $1e_u$: pure ligand orbitals; $1a_{1g}$: pure metal ion orbitals;

$2e_g$: MO spanning metal and ligand atoms and $2e_u$: pure ligand orbitals.

The lowest electronic transition, $1e_u \rightarrow 2e_g$, has a contribution of charge transfer configuration and must be intense.

The Mulliken population of nickel in $Ni(NCS)_2$ is $3d^{8.31}4s^{0.67}4p^{0.02}$ compared to $3d^{8.73}4s^{0.4}4p^{0.01}$ in $Ni(SCN)_2$. The atomic overlap populations give

Ni–N = 0.2730; N–C = 1.2604; and C–S = 0.5306

Analysing the overlap to σ and π overlaps yields results that are very comparable to the situation in $Ni(SCN)_2$. The triplet state of $Ni(SCN)_2$ is of much lower energy than the singlet state. The population of nickel atomic orbitals and the extent and type of overlap between the AOs were very comparable

to their values in $Ni(SCN)_2$. One concludes that the electronic structures are similar in the two molecules, $Ni(SCN)_2$ and $Ni(NCS)_2$. However, the latter has a binding energy of 278 kcal mol^{-1}, whereas the former has a binding energy of 212 kcal mol^{-1}.

Conclusions

A controversy exists between experimental values and the theoretical predictions for the ground state of the nickel atom. Experimentally, the ^3F state lies 0.03 eV above the ^3D state, whereas HF calculations indicate that the ^3F state is not a good ground state for $Ni(CO)_4$ but that the ^1S state is a good one. In this work three different basis sets, namely, split valence (SV), split valence with six *d*-Gaussian functions (SV6D), and double zeta (DZ) basis sets, were used to predict the ground state of nickel in $Ni(H_2O)_6^{2}$. Geometry optimization was performed assuming a T_h symmetry. The three basis sets were applied to the three possible ground states: ^3F, ^3D, and ^1S; the calculations showed that the combination DZ-^3F gave results closest to the experimental values. Using the combination DZ-^3F, calculations were performed on $Ni(N_3)^+$, $Ni(N_3)_2$, $Ni(SCN)^+$, $Ni(SCN)_2$, Ni(NCS), and $Ni(NCS)_2$.

Table 7. A comparison between the binding energies of the compounds studied.

	Binding energy (kcal mol^{-1})	
Compound	Singlet state	Triplet state
$Ni(N_3)^+$	–392	–386
$Ni(N_3)_2$	–615	–637
$Ni(SCN)^+$	–56	–272
$Ni(SCN)_2$	–212	–440
$Ni(NCS)^+$	–90	–310
$Ni(NCS)_2$	–278	–229

The ion $Ni(N_3)^+$ is of significant stability with a binding energy of –392 kcal mol^{-1}. Bonding between nickel and azide ions has an apparent covalent character. The lowest electronic transitions are of charge transfer character. Computations on diazidonickel(II) showed that the molecule is linear, as is the case in $Ni(N_3)^+$, and is of significant stability (bonding energy is –615 kcal mol^{-1} for the ground singlet state). The character of covalent bonding in $Ni(N_3)_2$ is less than it is in $Ni(N_3)^+$.

The binding energy of $Ni(SCN)^+$, –56 kcal mol^{-1}, is much less than that of $Ni(N_3)^+$, –392 kcal mol^{-1}. Also, the

© 1998 NRC Canada

electronic population of nickel in $Ni(SCN)^+$ is $\ldots 3d^{8.81}4s^{0.22}4p^{0.01}$, which is totally different than in $Ni(N_3)^+$, $\ldots 3d^{7.98}4s^{0.32}4p0.02$, a result indicating that the SCN^- ion is a stronger electron donor than N_3^- ion. Another important and significant difference between the electronic structure of $Ni(N_3)^+$ and $Ni(SCN)^+$ is the existence of pronounced mixing of AOs to build the MOs in the latter ion. In addition, more extensive π-bonding is found between nickel and thiocyanate in $Ni(SCN)^+$ than between nickel and azide in $Ni(N_3)^+$. The Mulliken overlap population between atoms in $Ni(SCN)^+$ differs significantly from that between the corresponding atoms in $Ni(N_3)^+$. The covalent bonding between nickel and sulfur in $Ni(SCN)^+$ is of significant π character, whereas that between nickel and nitrogen in $Ni(N_3)^+$ is of significant σ character. A comparison between the binding energies of the different compounds studied is given in Table 7.

The binding energy of $Ni(SCN)_2$ is –212 kcal mol^{-1}, which is less negative than that of $Ni(N_3)_2$, –615 kcal mol^{-1}. The charge distribution as well as the atomic overlap population is different in the two compounds. Electron back-donation, metal → ligand, is stronger when the ligand is azide ion than when it is thiocyanate ion.

Computations on nickel isothiocyanates showed that their electronic structure is highly comparable to the structure of the corresponding thiocyanate complexes.

Ion channels based on bis-macrocyclic bolaamphiphiles: effects of hydrophobic substitutions

T.M. Fyles, D. Loock, and X. Zhou

Abstract: Four new bis-macrocyclic bolaamphiphiles were prepared to explore the effects of hydrophobic substitutions on ion transport. In bilayer vesicles the new compounds were remarkably similar to more hydrophilic derivatives prepared previously. Planar bilayer conductance experiments showed the new compounds induced an unique current–time signal consisting of a rapid rise time, followed by a slower decay time. Signal shape was cation dependent and was related to a modest selectivity between cations. Cation–anion selectivity was very high, approaching an ideal cation selectivity. One compound also showed voltage dependence of the signal shape and duration. Qualitative changes in signal shape, duration, and voltage dependence were provoked by variation in the electrolyte pH and by masking the head-group electrostatic interactions with low levels of barium ions. A model for the signal shape is proposed, involving a rapid current rise due to aggregate restructuring, followed by slower decay due to development of the local Donnan potential that results from the high cation–anion selectivity.

Key words: ion channel, synthesis, bilayer membrane, bilayer clamp, mechanism.

Résumé : On a préparé quatre nouveaux bolaamphiphiles bis-macrocycliques dans le but d'examiner les effets des substituants hydrophobes sur le transport ionique. Dans les vésicules à doubles couches, le comportement des nouveaux composés est remarquablement semblable à celui de dérivés plus hydrophobes préparés antérieurement. Des expériences de conductance de doubles couches planaires ont permis de montrer que les nouveaux produits induisent un signal unique de courant–temps qui consiste en un temps rapide d'augmentation du temps, suivie d'un temps de décroissante plus lent. La forme du signal dépend du cation et elle est reliée à une modeste sélectivité entre les cations. La sélectivité cation–anion est très élevée; elle approche une sélectivité idéale pour les cations. Pour un composé la forme et la durée du signal dépendent aussi du voltage. Une variation du pH de l'électrolyte provoque aussi des changements qualitatifs dans la forme du signal, sa durée et sa dépendance sur le voltage; ces mêmes effets sont aussi obtenus en masquant les interactions électrostatiques du groupe de tête par de faibles quantités d'ions baryum. On propose un modèle pour la forme du signal qui implique une augmentation rapide du courant résultant d'une restructuration de l'agrégat, suivie d'une décroissance plus lente provoquée par le développement du potentiel de Donnan qui résulte de la grande sélectivité cation–anion.

Mots clés : canal ionique, synthèse, membrane à double couche, champ de double couche, mécanisme.

[Traduit par la Rédaction]

Synthetic and naturally occurring peptides provide some of the best small-molecule models of ion channel proteins, yet even with relatively low molecular weights and precise sequence information, the structural and functional details of the models themselves remain complex (1, 2). "Channel engineering," or the site-specific modification of individual amino acid residues of active peptide ion channels, has emerged as a productive strategy for exploring structure–function relationships and for generating new channel behaviors (3). It is increasingly evident that non-peptide compounds can also mimic both natural channels and peptides, that specific activities can be as high as natural examples, and that a large range of structural types can promote ion translocation across bilayer membranes (4, 5). Relatively few non-peptide systems have been the object of channel engineering, either as a probe of mechanism, or to optimize activity. A notable exception is the extensive work of Gokel and co-workers on a very active tris-macrocyclic channel, which shows that structural variations at the core and at the head-group region can critically control activity (4*b*, 6).

Our own efforts with bis-macrocyclic bolaamphiphiles have shown that specific activity is related to the core regions of the molecule (7*a*), while ion selectivity (7*a*, 7*b*) and, ultimately, voltage switching (7*c*) are controlled by the polar head groups. As for ion stabilization during transit and the role of the channel walls, neither the Gokel system nor our bis-macrocyclic bolaamphiphiles is dramatically improved by additional donor atoms in these locations, as assessed by vesicle techniques for determining transport. The Gokel system activity actually *decreases* tenfold on substitution

of a polymethylene segment by an oligoethylene oxide segment (6*a*). A similar type of substitution in our system makes only a small difference, albeit in the expected sense of increased activity (7*a*).

The channel "walls" must interact in some way with the ions as they pass through the channel, and the counter-intuitive results from vesicle experiments require resolution. We report here a new suite of compounds related to the active bis-macrocycle **1** and show, via a combination of vesicle and planar bilayer techniques, that minor hydrophobic substitutions provoke substantial mechanistic changes and give unique ion conduction behaviors.

Relative to the "parent" compound **1**, compounds **2**–**5** offer three significant structural variations. The first is the substitution of oxygen donor atoms in the macrocycle by methylene groups (Y = O to Y = CH_2). This will reduce the number of direct donor interactions with a cation in transit. As a secondary consequence, compound **2** will be more hydrophobic than **1**.[2] A similar effect due to hydrophobicity differences is expected for the substitution of ester by thioether as in the comparison of **1** or **2** and **4**. A second major structural variation is the effect of overall length; **3** is three atoms longer than **2** measured from the terminal carboxyl groups, while **4** is one atom shorter. More significant than the length difference between **2** and **4** is the marked difference in conformation expected for a thioether compared to an ester. Exploration of this problem by molecular mechanics (gas phase) showed a very large number of low-energy conformers for **1–5.**[3] Despite numerous small differences, compounds **1–3** adopted extended conformations with distances between the terminal carboxyl groups of about 3.1 nm for **1** and **2** and about 3.3 nm for **3**. Conversely, both **4** and **5** adopted a family of "U-shaped" conformations with a through-space carboxyl separation of about 1.9 nm. This reveals a third structural variation in the series, namely, shape. Previous work from Regen's group (9), confirmed by our subsequent explorations (10), has established that U-shaped conformations can lead to membrane disruption.

Results and discussion

Synthesis

The syntheses are based on routes described previously (7, 11), as outlined in Schemes 1 (**2** and **3**) and 2 (**4** and **5**). The starting material in both cases is the diene tetraester **6**, available from maleic anhydride and 1,8-octanediol in good yield (11). Michael addition of two equivalents of mercapto acetic acid gave the diacid **7a** in quantitative yield. One equivalent of the previously reported mesylate **8** (11) and one equivalent of the tetramethyl ammonium salt of **7a** were then coupled in DMF. Preparative gel permeation chromatography of the product mixture gave fractions enriched in the expected product **9a**, but successive separation steps consistently failed to produce high-purity samples. The NMR spectra were equivocal, but a relatively broad peak by analytical gel permeation analysis and a persistent ion at 1253 *m*/*z* in the negative LSIMS spectra eventually convinced us that we had an inseparable mixture of **9a** and **2**. This was confirmed by conversion of the mixture to **2** with mercapto acetic acid. The target **2** was fully characterized by NMR, showed a sharp analytical gel permeation peak, and a strong molecular ion by negative LSIMS at 1253 *m*/*e*.

The formation of **2** in the coupling of **7a** and **8** suggests that base-catalysed retro-Michael reaction of **7a** has occurred, leading to free mercapto acetate, which indiscriminately adds to available maleate diesters, including **9a**. It is possible to sketch an intramolecular elimination via a cyclic transition state in which the carboxylate abstracts the proton β to the sulfur. If this were occurring to a significant extent, we would expect that the longer homologue **7b** (from **6** and mercapto propionic acid) would undergo significantly less of this undesirable side reaction. In the event, **7b** and **8** again produced **9b** mixed with **3**, suggesting that intermolecular decomposition (not intra-) is the major source of the retro-Michael process. The proportion of contaminating **3** in **9b** was somewhat less than the corresponding **2** in **9a**. As previously, the **9b** mixture was treated with mercapto propionic

[2] Each substitution of O to CH_2 corresponds to an increase in log P_{ow} of approximately 1.1, thus log P_{ow} **(1)** + 4.4 = log P_{ow} (**2**), etc. (ref. 8).

[3] Energies of macrocycles were minimized using molecular mechanics from four initial nonplanar geometries. Thereafter, each minimized structure was subjected to molecular dynamics annealing to generate additional candidate geometries. A set of 10–20 geometries lying within 10 kJ of the lowest minimum found were examined and two "typical" examples were selected. Bis-macrocycles were then built from these two "typical" macrocycles, and the process of mechanics–dynamics–selection was repeated for the bolaamphiphiles; CAChe Ver 3.7, CAChe Scientific Inc.

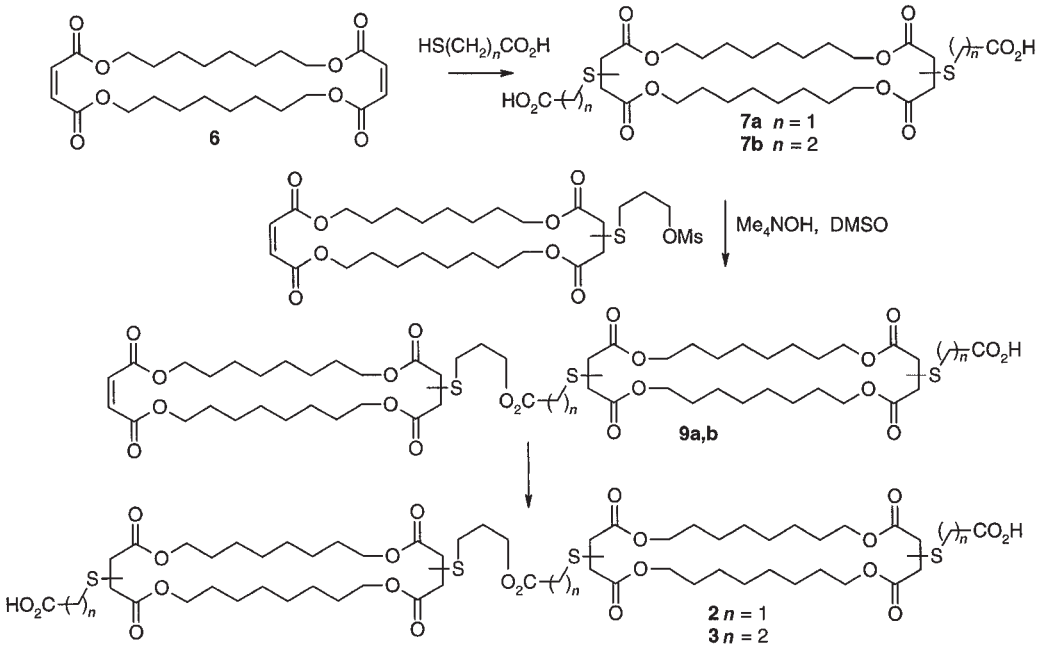
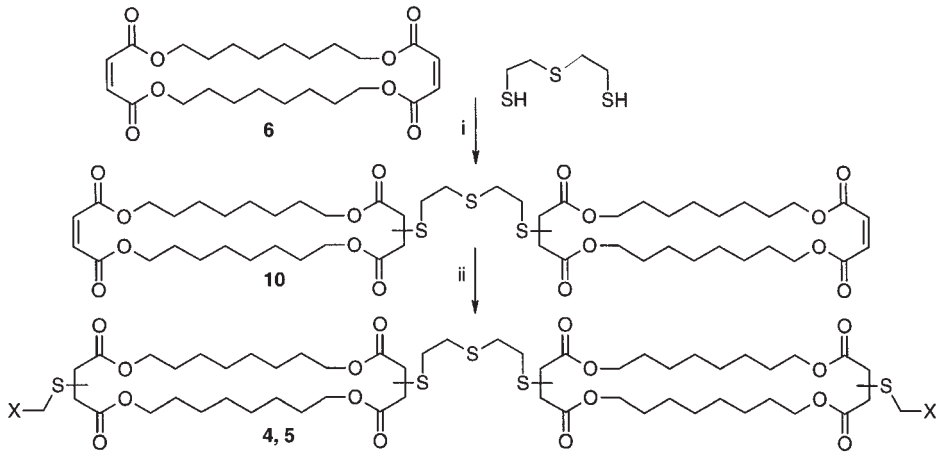
Scheme 1.



Scheme 2.



acid to produce a pure sample of **3** with the expected spectroscopic properties.

The synthesis of **4** and **5** used a common diene precursor **10** (Scheme 2), a strategy we reported previously (7*b*) Thus equivalent amounts of the macrocycle **6** and 2-mercaptoethyl sulfide were reacted, and the product mixture was repeatedly chromatographed on a preparative gel permeation column. Each fraction was inspected by analytical gel permeation and mass spectroscopy to ensure that a homogeneous sample of the expected mass was isolated. The main impurities are unreacted **6**, a product of mono-reaction of **6** and the sulfide, and higher oligomers. The latter were very obvious in the analytical gel permeation traces and give clear molecular ions in negative LSIMS. The addition of carboxylic acid and amino head groups proceeded as in previous cases (7, 11), and pure samples of **4** and **5** were isolated and characterized.

Vesicle experiments

The activities of compounds **2**–**5** were surveyed using the pH-stat vesicle assay used previously (7, 12). Vesicles containing an entrapped buffer at pH 6.6 were suspended in unbuffered medium held at pH 7.6 by automatic addition of base under pH-stat control. Addition of alkali metal sulfates to the solution created an additional cation concentration gradient, but no transport occurred until solutions of **2**–**5** in methanol were added. In each case, a rapid burst of activity immediately followed addition of the compound. We previously ascribed this to vesicle lysis due to high local concentrations of bolaamphiphile. After 1–2 min, the proton efflux occurred in a steady manner that could be fit using a first-order analysis to derive a rate. As previously, the transport rate depended on initial transporter concentration and an apparent kinetic order in transporter was determined. The results are given in Table 1, together with previously reported data for **1**.

Fig. 1. Current–time recordings showing typical "shark-fin" signals: (*a*) 75 nmol **2,** 38 min after first addition, data acquired at 2 kHz, and filtered at 500 Hz; (*b*) 78 nmol **3**, 30 min after first addition, data acquired at 10 kHz and filtered at 100 Hz. Both experiments used 1 M KCl electrolyte, diphytanoyl phosphatidyl choline membrane, +120 mV applied potential.

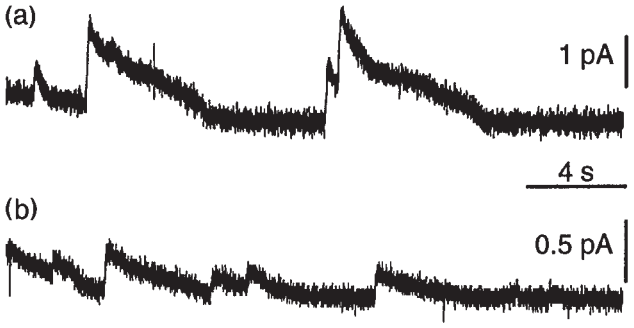

Fig. 2. Cation dependence of "shark-fin" signal for **2**: 1 M electrolyte, other conditions as in Fig. 1(*a*).

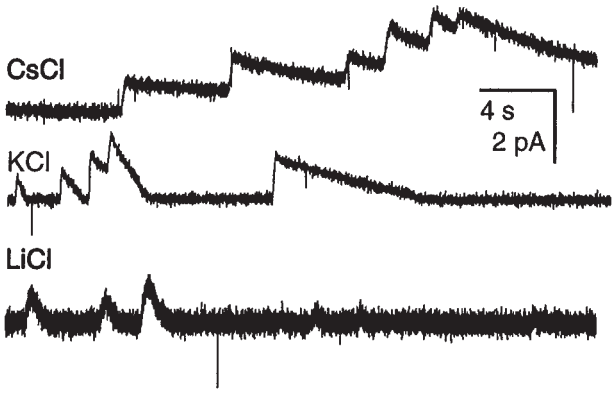


Apart from some modest differences in ion selectivity, the substitution of four oxygens in **1** by four methylenes in **2** has remarkably little influence on the transport of the alkali metal cations. Other structural variables, such as overall length (compare **2** and **3**) and shape (compare **2** with **4** or **5**) apparently play a much larger role in controlling the transport. Similar conclusions were previously drawn both for bolaamphiphiles and for more complex crown ether channels bearing similar macrocycles (12). The most significant difference between compounds **2–5** and **1** is in the apparent kinetic order: the former are all close to one, while the latter is nearly two. This suggests that the initiation of transport involves some unimolecular process rather than the slow formation of dimers or aggregates as suggested by previous work. We return to this issue below.

Bilayer clamp experiments

The ionic conductance behavior of channels formed by **2–5** in bilayer membranes was examined in a bilayer clamp experiment (time dependence of current carried at an applied potential). The presence of an ion channel is typically revealed as a series of "square-topped" peaks in the current–time record due to the abrupt shift from the "off" to the "on" state of the channel (13). As previously, bilayers were formed by painting a lipid solution in decane over a small hole in a polystyrene barrier between two aqueous electrolytes (7*a*). Transmembrane potential was imposed across the bilayer via two Ag/AgCl electrodes directly immersed in the separated electrolytes. The liquid junction potential of the cell was "backed-off" to zero prior to membrane formation. Each bilayer used was monitored at a range of applied potentials over 30–60 min to ensure stability and low conductance in the absence of added transporter. Bilayers showing "leaky" or "erratic" events at any point in this monitoring period were rejected.

The typical conductance behaviour of **2** and **3** in bilayer membranes is illustrated in Fig. 1. The odd-shaped conductance events were observed throughout the current–time records for six independent replicates, and subsequently through the records of experiments to be described below. The odd-shaped conductance events persisted throughout experiments lasting up to 2 h, without sign of diminishing in frequency. To ensure that the unusual signal shape was not due to some impurity or decomposition product, an independent sample of **2** was prepared and found to show the same behaviour. Given the reproducibility of the signals over long periods of time, in a variety of experiments, it is unlikely that they are due to transient experimental artefacts. They are the "normal" behaviour of this system. About twice the amount of compounds **2** or **3**, compared to **1,** is required to induce conductance events, contrary to the expectation of increased partition to the lipid. It is evident that **2** and **3** act in a fundamentally different fashion to **1**.

The characteristic conductance events consist of a relatively rapid increase in current flow, followed by a slower decay over a few seconds. The rise amplitudes vary between 1 and 6 pA and vary within a single experiment. The rise times, typically tens of milliseconds, are at least three orders of magnitude slower than the step-conductance changes

© 1998 NRC Canada

observed for **1** (microseconds or less). Occasionally a second rise occurred, superimposed on a preceding decay, suggesting more than one active species. Each conductance event for **2** apparently carries more current than does the comparable event for **3** even though the characteristic signal shapes are similar. Reversal of the applied potential reversed the sign of the current flow but did not alter the rise amplitudes or the decay times of the conductance events. As the experiments progress in time, the current amplitudes and decay durations of the conductance events increase, but retain the characteristic signal shape. To distinguish these conductance events from typical "square-topped" step conductance changes typically observed for channels, with **1** as an example, we refer to the characteristic signal shape illustrated in Fig. 1 as a "shark-fin" conductance event.

The shark-fin behaviour is cation dependent as illustrated in Fig. 2 for compound **2** and three electrolytes. The opening rise time and amplitudes are independent of the cation, but the decay times are progressively shorter for K^+ and Li^+ relative to Cs^+. Typical durations were 4–10 s for CsCl, 2–6 s for KCl, and 1–2 s for LiCl. The differences between electrolytes is less marked with **3**, consistent with the lower cation selectivity observed in the vesicle experiments.

The charge selectivities of channels are typically determined from the reversal potential for two ions in competition. The reversal potential is the applied potential at which there is no net ion flux with different electrolyte solutions on either side of the membrane. If the channel is permeable to multiple ionic species then the system is not at a thermodynamic equilibrium but at a steady state. The Goldmann–Hodgkin–Katz equation (13) applies to the steady state, and is given in eq. [1] for mixed cesium and sodium chlorides:

$$[1] \qquad V_{\text{rev}} = \frac{RT}{F} 1\text{n}\left(\frac{P_{\text{Na}}\gamma_{\text{Na}}[\text{Na}^+]_{trans} + P_{\text{Cs}}\gamma_{\text{Cs}}[\text{Cs}^+]_{trans} + P_{Cl}\gamma_{Cl}[\text{Cl}^-]_{cis}}{P_{\text{Na}}\gamma_{Na}[\text{Na}^+]_{cis} + P_{\text{Cs}}\gamma_{\text{Cs}}[\text{Cs}^+]_{cis} + P_{Cl}\gamma_{Cl}[\text{Cl}^-]_{trans}} \right)$$

where V_{rev} is the reversal potential, P_x and γ_x are the permeability and activity coefficients of the species x, respectively, R is the gas constant, T the absolute temperature, and F is the Faraday constant. Other cations can be substituted and the cation–anion selectivity can be obtained from the dilution potential for single electrolyte at two concentrations across the membrane (13).

The reversal potentials were determined manually by changing the holding potential and monitoring currents over periods up to one minute per potential. The initial liquid junction potential was "backed-off" to zero before the membrane was formed. A reversal potential of –50 mV was obtained for **2** with a gradient of 0.5 M KCl_{cis} : 0.1 M KCl_{trans}, and a potential of –56 mV was obtained for the same gradient of LiCl solutions. In a similar experiment a reversal potential of –36 mV was obtained for **3** under a gradient of 0.5 M KCl_{cis} : 0.1 M KCl_{trans}. These values can be compared to the equilibrium potentials for the cations of –37.6 mV for KCl and –39.9 mV for LiCl. The observed values are more negative than these limiting values, giving unrealistic negative values of $P_{\text{M:}}P_{\text{Cl}}$. These experiments were additionally complicated by a varying junction potential: although initially set to zero, small amounts of transport will alter the electrolyte compositions and the initial zeroing process will be inadequate to correct for these changes. If we assume a linear correlation between the change in junction potential, then the corrected reversal potentials approach the theoretical values for a perfectly cation-selective channel. An additional factor is a variable reference potential due to direct insertion of the reference electrodes into the electrolyte. Neither of these effects previously interfered with determination of the selectivities of **1** and related compounds (7), or with the determination of cation selectivity for these compounds (below). We conclude that the problems we encountered with our experimental procedure are a result of a very high cation–anion selectivity of **3**. The selectivity of two cations in competition was not complicated by junction potential problems, and a value of –20 mV for the reversal potential was observed for 1 M $CsCl_{cis}$: 1 M KCl_{trans}, which corresponds to P_{K}:P_{Cs} = 2.2. Similar results were obtained for the CsCl : LiCl system, indicating a weak selectivity among the cations.

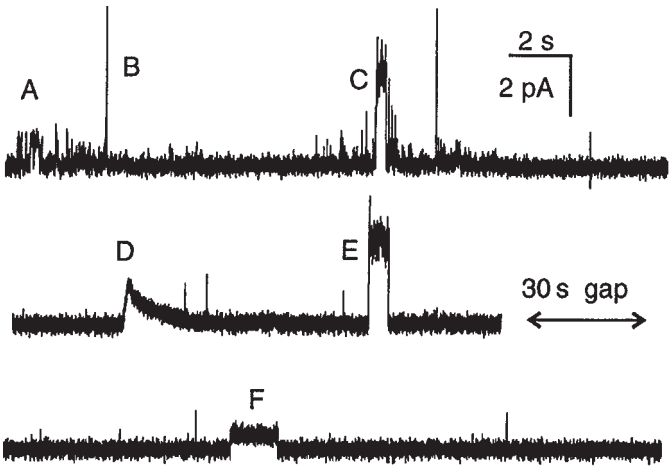
The relatively slow opening process suggests that several molecules are involved. We consider some mechanistic alternatives below, but our working hypothesis is that several bolaamphiphiles are involved in the formation of an active aggregate. A number of additional observations are consistent with this hypothesis. Firstly, the activity of **2** depends markedly on the ionic strength. More compound is required at lower ionic strength, the currents carried per opening are smaller, and the decay times are faster. Ionic strength will affect partitioning of the amphiphile into the bilayer, and will assist in masking head-group electrostatic repulsions leading to aggregate stabilization. More direct control of head-group repulsion is available through partial protonation of the head groups by lowering the electrolyte pH. Figure 3 shows the effect of lowering the pH to 4.75, where approximately 50% of the head-groups will be protonated.[4] These two segments of an experiment show the typical features that extend over much longer periods (tens of minutes). "Shark-fin" events such as D are occasionally observed, and in some cases have very long decay times (up to 50 s). More interesting are the "square-top" openings, evident at C and E with amplitudes of about 2.7 pA, and at F with an amplitude of 0.6 pA. Some erratic or very short-lived square-top openings are also observed throughout the record, including a cluster of events at A, which consist of numerous short openings of about 0.8 pA amplitude. Short high-amplitude openings, such as the truncated one at B, occur occasionally.

The main conclusion from Fig. 3 is that the active transporter species formed from **2** are very sensitive to the external conditions. Although less active, compound **3** behaves in

[4] Assuming the pK_a is similar to acetic acid (4.75).

© 1998 NRC Canada

Fig. 3. Current–time recording for **2** at pH 4.75: 80 nmol of **2**, 1 M KCl, diPhyPC bilayer, +120 mV, data acquired at 20 kHz and filtered at 2 kHz.

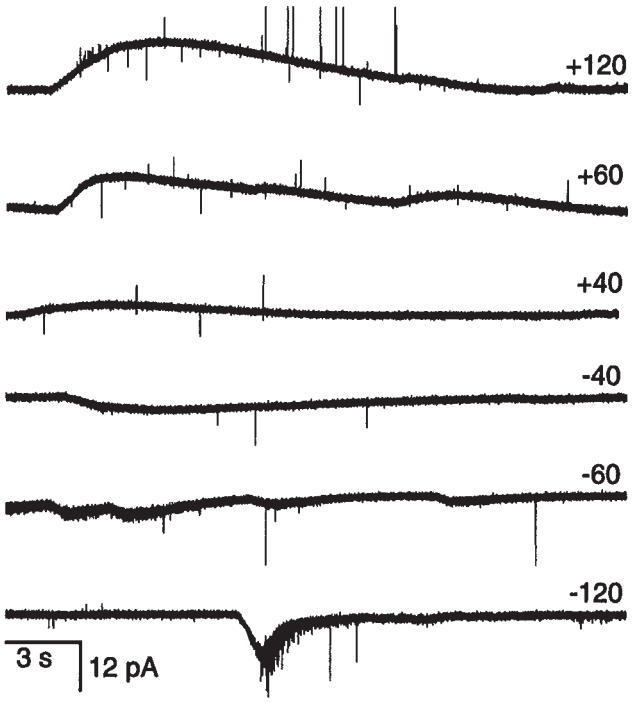


a similar fashion. The results are consistent with our hypothesis of some type of aggregate structure. The aggregates of **1** responsible for its square top conductance behaviour were previously assigned to a fixed stoichiometry, probably a dimer (7*a*). If aggregates are implicated here, they must be larger as the rise times are significantly longer. Large aggregates would be consistent with the different levels observed, corresponding to aggregates with different numbers of monomers, or different organizations of the same number of monomers.

What is the origin of the "shark-fin" signal? The different time scales of the opening and closing processes indicate different underlying physical processes. They are too long for conformational changes (picoseconds) or lateral diffusion processes (nano- to micro-seconds) (14). Whatever the opening process, transport via highly cation-selective channels will develop a Donnan potential, due to excluded anions, which opposes the applied transmembrane potential (13). In the absence of anion translocation, this opposing potential will build until it is locally equal to the applied potential and no net current flow would be observed. Development of the Donnan potential will depend on the probability that transported cations remain near the aggregate after transport, and this could lead to the cation dependence observed. Before developing these mechanistic ideas more fully, the behaviour of **4** and **5** must be considered.

Compounds **4** and **5** proved to be difficult to study. Compound **5** is inactive below a threshold of about 90 nmol added (1.8 μM concentration in the aqueous phase), and above this threshold inevitably provokes bilayer breakage (2–4 replicates for each of 1 M NaCl, KCl, RbCl electrolytes). Typically, a few current spikes of 1–3 ms duration and amplitudes greater than 10 pA were observed in the 60–90 s preceding breakage. The threshold concentration dependence might implicate aqueous phase aggregates as the membrane-disrupting species. Compound **4** also provokes bilayer breakage above a threshold of 70 nmol for 1.0 M NaCl and CsCl electrolytes. In KCl electrolyte, however, **4** resembled **2** and **3** in its ability to produce "shark-fin" conductance events. Figure 4 shows data at a range of applied

Fig. 4. Voltage-dependent "shark-fin" behaviour of **4**: 77 nmol **4**, other conditions as in Fig. 1(*a*).



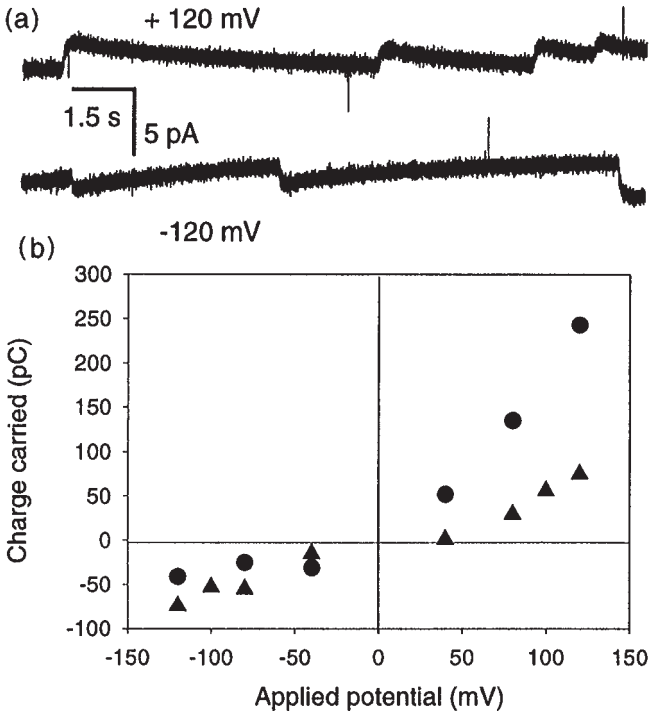
potentials. The "shark-fins" produced by **4** have current amplitudes of up to 15 pA, substantially larger than were observed with **2** under similar conditions (Fig. 1). The "shark-fin" amplitudes vary throughout the experiment, implying aggregates of variable stoichiometry or structure. In addition to the dominating "shark-fin" signals, brief (2–5 ms) openings of varying amplitude (10–1000 pA) were observed in all records. These brief events occurred with other compounds, but are much more frequent with **4** (compare Figs. 1, 2, and 4).

The remarkable feature of Fig. 4 is that the "shark-fin" shape was voltage dependent. Not only did the total duration of each event became progressively shorter as the potential was changed from positive to negative, the opening rise time of the signal decreased. The illustrated events are representative of at least 10 events at each potential, and the effect was replicated in three independent experiments. An additional feature of the replicate experiments is that the maximum amplitude varied between experiments from a low of 4 pA to the high of 15 pA illustrated in Fig. 4. Within a single experiment the amplitude varied only a few pA for a given potential.

As discussed above, our working hypothesis for the "shark-fin" signal is based upon aggregates formed by **4**. The propensity for membrane disruption except under limited conditions suggests that U-shaped monomers are present (9, 10) Combining these two ideas suggests an aggregate involving U-shaped molecules. If the hypothesis is correct, the local Donnan potential must develop more rapidly and decay more quickly at *cis*-negative potentials than at *cis*-positive potentials in order to result in the observed voltage dependence. The transporter **4** has no marked asymmetry, hence the voltage dependence must arise from some asymmetry in the aggregate itself. Suppose that **4** has a propensity

© 1998 NRC Canada

Fig. 5. (*a*) Current–time record for **4** in the presence of added barium: 100 nmol **4** added, 1 M KCl plus 1.6 mM $BaCl_2$ electrolyte, other conditions as in Fig. 1(*a*); (*b*) charge carried by **4** during a 2 min period as a function of applied potential: in the presence of barium (triangles), and the absence of barium (circles).



for a U-shaped conformation that limits its ability to flip-flop across the membrane. In this case fewer molecules of **4** would be available on the side of the bilayer opposite to the side of the addition, and an aggregate containing U-shaped conformations would form with fewer molecules on the *trans* side of the bilayer. The aggregate would therefore contain an asymmetric distribution of anionic head groups and this would offer the possibility of asymmetric interactions with the applied electric field. The decay of the signal was related to the stability of the aggregate in the case of **2** (above), so the prediction would be that asymmetric aggregates should be stabilized to a greater extent at *cis*-positive potentials. Fundamentally, the transmembrane potential directs the cation flow (cations flow from *cis* to *trans* at *cis* positive potentials). A larger number of monomers in the aggregate at the *cis* face of the bilayer than at the *trans* face would imply that head-group repulsions would be more important on the *cis* face. The flow of cations under positive potentials could thus stabilize the aggregate by masking head-group repulsions. The longer decay times at positive potentials would be consistent with this analysis. The voltage dependence of the rise times could also be related to the cation flux through the aggregate. The slow buildup of the opposing Donnan potential at *cis*-positive potentials would allow for more extensive restructuring of the aggregate during the rise period. Conversely, less restructuring of the aggregate would occur in the shorter-lived aggregates formed at *cis*-negative potentials.

If the working hypothesis discussed above is correct, then the voltage-dependent behaviour should be eliminated by factors that reduce the energy barrier to flip-flop of **4**. Addition of divalent cations could potentially produce a formally neutral U-shaped salt. This would accelerate flip-flop, lead to formally neutral divalent cation–transporter complexes equally distributed across the membrane, and the local Donnan potential would develop at the same rate for either sign of the applied potential. Alternatively, neutralized head groups would experience smaller repulsive interactions, larger aggregates would be expected, and the differences between the two faces of the bilayer would be reduced. Thus, for addition of a divalent cation such as barium, the working hypothesis predicts that the "shark-fin" signal should persist, but the voltage dependence should vanish. The result of this experiment is illustrated in Fig. 5. Part (*a*) shows that the prediction is qualitatively supported: at either potential the rise times and decay times are similar. The current carried was integrated over a 2 min period at several applied potentials to determine the total charge carried, and the results are displayed in part (*b*) of Fig. 5. In the absence of barium, substantially more charge is carried at positive applied potentials, due to the prolonged decay times under these conditions. In the presence of barium, the charge carried is significantly reduced at positive potentials, leading to a nearly symmetric dependence on applied potential in accord with the prediction.

Partial protonation of the head groups by lowering the pH would be predicted to achieve a similar attenuation in the voltage-dependent behaviour of **4**. At pH 4.75, typical "shark-fin" signals were observed at all potentials examined and no "square-top" step conductance changes were observed. Parts of the current–time traces were similar at both positive and negative potentials, but the negative potential records included examples of rapid rise, and of short- duration "shark-fins" as well. This could be due to a mixed population of symmetric and asymmetric aggregates as a result of incomplete equilibration of monomers across the membrane.

Mechanism

The "shark-fin" signal shape for an ion channel is unprecedented. It is unlikely that the signals are just experimental artefacts given the level of reproducibility over the range of experimental conditions explored. The slow time course of signal evolution would be consistent with some slower diffusional process such as a carrier of some type. We think a carrier mechanism of any type is unlikely since freely diffusing species would simply increase the "zero conductance" level over time, not periodically reverse direction as is observed. A referee sees parallels between the signal shapes reported here and the distorted single-channel currents observed with vesicles attached to a patch-clamp pipette immediately following removal of the membrane patch from the cell (13*a*).[5] The signal shape in these examples is due to the modulating effect of the membrane capacitance of the attached vesicle on the single-channel currents. Any vesicle attachment should also perturb the signal shape of the capacitance test function routinely used to monitor the

[5] For examples see Figs. 10 A–D and 11 A,B of ref. 13*a*, pp. 490–491.

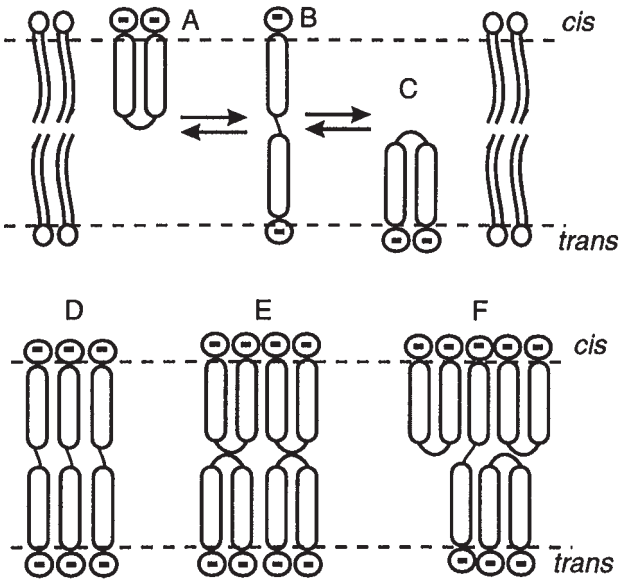
Fig. 6. Schematic mechanism: upper section shows membrane-bound monomers; lower sections shows candidate aggregates. See text.



membrane; no such changes were seen. Also, the effect of the vesicle attached to a patch-clamp pipette diminishes over a few minutes. Attached vesicles, if formed in our system, would need to be constant over periods of a few hours. It is difficult to see how the "shark-fin" signal and the "square-topped" signal could follow one another as illustrated in Fig. 3 if the former were due to a long-lived vesicle.

We conclude that the "shark-fin" signal must be related to some type of channel opening and closing process. Some aspects of the working hypothesis were discussed above. Overall, the mechanism needs to account for the "shark-fin" signal shape and its voltage dependence with **4**, the origin of the high cation selectivity, the structural effects of length and shape, and the apparent discrepancy between the aggregates invoked by the working hypothesis and the rate-limiting unimolecular process of the vesicle experiments. It should also bear close resemblance to the well-supported mechanism derived for **1** and other compounds containing ether oxygen in the macrocyclic units (*7a*) and should explain the differences between **1** and **2–5**.

To assist discussion of the alternatives, Fig. 6 sketches some structures of bolaamphiphile aggregates in a bilayer. We assume, as previously, that the bolaamphiphile diffuses to the membrane and inserts in a stepwise process involving both U-shaped (A) and spanning (B) conformations. A flip-flop process would generate a second U-shaped conformation on the *trans* side of the bilayer (C). These states were previously assumed to be in rapid equilibrium, and must be electrically silent. Thereafter, the monomer states (A–C) can aggregate to form a variety of structures. For example, several spanning molecules could cluster to form a bundle (D), several U-shaped molecules in states A and C could associate (E), or mixed aggregates involving A–C could form (F).

The structures of **2–5** are devoid of specific complementary sites for intermolecular interactions and the head groups are charged at the pH of the experiments. So what drives the aggregation? Aggregates D–F are akin to phase separation within the bilayer. Overall lipid ordering will tend to push transporter molecules to defect areas where they eventually form the aggregates envisaged. Depending on the external conditions of concentration, electrolyte, and pH, the aggregates will vary both in the number and the packing of the monomers. The aggregates are "leaky" relative to the bulk bilayer phase, but still offer some control over the transport of ions.

We view hydration differences as the central difference between channels formed by **1** and related oxygenated bolaamphiphiles, and compounds **2–5**. The former can support a predominantly aqueous channel due to association of water with the walls of the channel, while the latter cannot. One consequence is the high cation–anion selectivity observed. Typically, anions are much more highly solvated than cations; the free energy of hydration of K^+ is –306 kJ mol^{-1} while it is –356 kJ mol^{-1} for Cl^- (15). Hydrated chloride ion is also somewhat larger than hydrated potassium (16), and partial dehydration of potassium ion in the gas-phase is more endothermic than for chloride for all extents of dehydration (17). As a result, the migration of a partially desolvated ion, or of an ion that requires additional solvation from the channel, will be more difficult for an anion than for a cation.

The high cation–anion selectivity is the root cause of the "shark-fin" signal shape, since the initial flow of cations in response to the transmembrane potential is not accompanied by a neutralizing flow of anions. Compound **1** is already cation-selective (P_K:P_{Cl} = 25 ± 4) (7), and the enhancement of this selectivity in **2–5** poses severe restrictions on charge balance during transport. The result is a Donnan potential, which opposes the transmembrane electric field gradient. The driving force for cation translocation is diminished and the ionic flux eventually falls off to zero. This accounts for the decay of the signal over periods of seconds and for its cation dependence. The relatively slow rise time of the "shark-fin" signal could be due to reorganization processes within the aggregate in response to the flow of cations and their associated waters of hydration. Suppose that nonconducting aggregates form. As a result of thermal motions, a transient aqueous defect could form in the aggregate. Once this "seed" defect forms, it could be stabilized by reorientations to eventually produce an efficient channel. During the reorganization time, the current observed would rise. Subsequently, the retarding effect of the Donnan potential would predominate and the current would fall off as discussed above.

The molecular structures of **2–5** control the type of aggregates formed. The small increase in the length of the bolaamphiphile (from **2** to **3**) is destabilizing, and the channels formed by **3** are less efficient than those formed by **2**. This suggests that the aggregates of **2** and **3** are of similar type. The absence of voltage dependence in these cases implies the aggregate is symmetrical, hence a cluster of spanning molecules is likely, such as illustrated in Fig. 6 D. Substitution in the central linker as in **4** and **5** results in a greater proportion of U-shaped states (A and C), so the aggregates formed are more likely to be as sketched in Fig. 6 E and F. An asymmetric structure involving a greater head-group charge on the *cis* face of the bilayer is required to rationalize the voltage-dependent behaviour of **4** as discussed

© 1998 NRC Canada

above. Compound **5** apparently does not form stable aggregates of any of the types sketched in Fig. 6. Aggregates of U-shaped monomers have been previously implicated as essential for membrane disruption by a mechanism involving aggregation in only the *cis* leaflet of the bilayer (9, 10). If the proportion of the molecules in state A (Fig. 6) was high for compound **5**, then disruption would proceed in preference to the subsequent aggregation steps illustrated.

The mechanism of Fig. 6 is inconsistent with the apparent kinetic order of approximately one, determined in the vesicle experiment. Another puzzling feature of the vesicle experiments is the apparent lack of membrane-disrupting activity by **4,** and especially **5,** for a range of cations. There are a number of possible ways to deal with these discrepancies. One is simply to refute the mechanism presented above (at least for vesicles) and assert that only monomeric species are involved. We think this is unlikely due to the very slow time scales involved. The molecular events of conformational change and diffusion have characteristic times that are many orders of magnitude faster than the "shark-fin" signal evolution (14). A more appealing rationalization is that the vesicle experiment probes a particular subset of the proposed mechanism, which in fact involves a unimolecular slow step. The central difference between the vesicle and planar bilayers is the curvature of the former. The lipid packing densities in the two leaflets of the bilayer differ and there is greater free volume in the outer leaflet (18). The symmetrical processes illustrated for states A–C in Fig. 6 will be biased by this curvature, with state C particularly disfavoured. Suppose that mixed aggregates such as state F are the dominant active species in vesicles. Consider a simple case of a trimer of two state B molecules and a state C molecule. If the transition from state B to C were slow, then the formation of the active aggregate would be controlled by a unimolecular step and would appear in the overall kinetics as a first-order process. The processes discussed here are strongly influenced by environmental factors. The shift of the rate-limiting step is just another example, this time involving membrane curvature. Curvature also accounts for the differences in membrane-disrupting ability. The outer leaflet of a vesicle can accommodate a certain proportion of U-shaped molecules due to the available free volume. The *cis* leaflet of a planar bilayer cannot. Compounds **4** and **5** lie close to the tolerance level for vesicles and they largely exceed the tolerance of planar bilayers.

Experimental section

^{1}H NMR spectra were recorded with 300 MHz spectrometers in $CDCl_3$ as solvent referenced to the residual $CHCl_3$ line (7.24 ppm relative to TMS). ^{13}C NMR spectra were recorded with 75.47 MHz spectrometers in $CDCl_3$ as solvent referenced to the central solvent line (77.0 ppm relative to TMS). Complete ^{1}H and ^{13}C NMR spectra of all new compounds (**2**, **3**, **4**, **5**, **7a**, **7b**, and **10**) have been deposited as supplementary material.[6] LSIMS spectra and Exact Mass were recorded with a sector mass spectrometer in *meta*-nitrobenzyl alcohol as matrix. In addition to the data reported, all samples ran as single sharp peaks on an analytical gel permeation column (mixed polydivinylbenzene, 10 mm i.d. × 25 cm) with $CHCl_3$ as eluent. The gel permeation column can resolve products differing by >50 g mol^{-1}. THF was dried by refluxing over, then distilling from, potassium metal under a dry nitrogen atmosphere.

Bis[3- or 4-, 17- or 18-(2-carboxy-1-thiaethyl)]-1,6,15,20-tetraoxa-2,5,16,19-tetraoxocyclooctacosane (7a)

Macrocycle **6** (2.00 g, 4.42 mmol) and 2-mercaptoacetic acid (2.04 g, 22.1 mmol, 5 equiv.) were dissolved in THF (150 mL). 2,2,6,6-Tetramethylpiperidine (6 mL) was added and the mixture was stirred at 64°C under nitrogen for 26 h. The THF was removed under reduced pressure. The pale yellow mixture was dissolved in dichloromethane (200 mL), and washed with 1 M hydrochloric acid (4 × 100 mL). After drying with sodium sulfate and removal of dichloromethane, the compound **7a** was collected as a pale yellow oil (2.81 g, quantitative).

^{1}H NMR 300 MHz (δ, $CDCl_3$): 9.14 (br s, 2H), 4.16–3.96 (m, 8H), 3.79 (dd, J_1 = 10.7 Hz, J_2 = 3.2 Hz), 3.47 (dd, J_1 = 56.6 Hz, J_2 = 16.2 Hz), 2.94, 2.70 (dd, J_1 = 16.9 Hz, J_2 = 11.0 Hz, J_1' = 16.9 Hz, J_2' = 4.4 Hz, 4H), 1.60–1.56 (m, 8H), 1.27 (br s, 16H). ^{13}C NMR 75.47 MHz (δ, $CDCl_3$): 174.9, 174.8, 174.7, 170.9, 170.1, 65.7, 65.2, 41.8, 41.7, 41.6, 36.1, 33.0, 29.0, 28.9, 28.4, 25.6. MS (–LSIMS, mNBA): 635.2 $(M - H)^-$ 100%. Exact Mass calcd. for $(M - H)^-$, $C_{28}H_{43}O_{12}S_2$, *m/e:* 635.2196; found: 635.2188.

3- or 4-[8′-[17″- or 18″-(2‴-Carboxy-1‴-thiaethyl)-1″,6″,15″,20″-tetraoxa-2″,5″,16″,19″-tetraoxocyclooctacos-3″- or 4″-yl]-6′-oxo-5′,1′,8′-oxadithiaoctyl]-17- or 18-(2-carboxy-1-thiaethyl)-1,6,15,20-tetraoxa-2,5,16,19-tetraoxocyclooctacosane (2)

Tetramethylammonium hydroxide pentahydrate (0.29 g, 1.60 mmol) was dissolved in dimethyl sulfoxide (2 mL) at 55°C under nitrogen, and mixed with **7a** (1.02 g, 1.60 mmol, 1 equiv.) in dimethyl sulfoxide (4 mL). Compound **8** (1.00 g, 1.61 mmol, 1 equiv.) in dimethyl sulfoxide (6 mL) was added dropwise and the solution was stirred at 50°C under nitrogen for 7.5 h. The dimethyl sulfoxide was removed under reduced pressure. The yellow mixture was dissolved in dichloromethane (200 mL), and washed with 1 M hydrochloric acid (3 × 100 mL). It was dried over magnesium sulfate and the solvent was removed. The yellow oil was chromatographed on a gel permeation column (LH-20, 3 × 60 cm) eluted with a mixed solvent of 2-propanol:chloroform (3:4). The desired compound **9a** was obtained in the middle fractions, and the product-containing fractions were evaporated to give compound **9a** as a light yellow oil (0.10 g, 0.086 mmol, 5.4%). The –LSIMS indicated **9a** was contaminated by compound **2** due to the retro-Michael addition discussed in the text.

A mixture of **9a** and **2** (0.101 g, 0.087mmol) and 2-mercaptoacetic acid (0.079 g, 0.86 mmol, 9.9 equiv.) were dissolved in THF (10 mL). 2,2,6,6-Tetramethylpiperidine (1.5 mL) was added and the solution was stirred for 39 h at 60°C under nitrogen. The THF was removed under reduced

pressure. The light yellow mixture was dissolved in dichloromethane (150 mL), and washed with 1 M hydrochloric acid (4 × 100 mL) and distilled water (3 × 70 mL). It was dried over magnesium sulfate and the solvent was removed to give a light yellow oil. The crude product was chromatographed on a gel permeation column (LH-20, 3 × 20 cm) eluted with a solvent of 2-propanol:chloroform (3:4). The middle fractions contained the expected product **2**, and the early and later fractions contained unidentified by-products. The product-containing fractions were evaporated to give **2** as a light yellow oil (0.037 g, 0.030 mmol, 34%). ^{1}H NMR 300 MHz (δ, $CDCl_3$): 9.05 (br s, 2H), 4.19–3.93 (m, 18H), 3.84–3.31 (m, 10H), 2.98–2.59 (m, 10H), 1.94–1.87 (m, 2H), 1.59–1.56 (m, 16H), 1.27 (br s, 32H). ^{13}C NMR 75.47 MHz (δ, $CDCl_3$): 174.3, 171.3, 170.8, 170.4, 170.1, 170.0, 169.5, 65.6, 65.5, 65.1, 63.9, 41.7, 41.5, 36.5, 36.2, 36.1, 33.1, 33.0, 29.1, 29.0, 28.4, 28.0, 27.8, 25.7, 25.6. MS (–LSIMS, mNBA): 1253.5 $(M - H)^-$ 100%, 1275.5 $(M + Na - 2H)^-$ 4.0%. Exact Mass calcd. for $(M - H)^-$, $C_{57}H_{89}O_{22}S_4$, *m*/*e*: 1253.4728; found: 1253.4706.

Bis[3- or 4-, 17- or 18-(3-carboxy-1-thiapropyl)]-1,6,15,20-tetraoxa-2,5,16,19-tetraoxocyclooctacosane (7b)

Macrocycle **6** (1.00 g, 2.21 mmol) and 3-mercaptopropionic acid (1.17 g, 11.0 mmol, 5 equiv.) were dissolved in THF (40 mL). 2,2,6,6-Tetramethylpiperidine (3 mL) then was added to the solution, and it was kept to reflux for 47 h under nitrogen. The THF was removed under reduced pressure, and the residual oil was dissolved in dichloromethane (200 mL) and washed with 1 M hydrochloric acid (6 × 100 mL). The solution was dried over magnesium sulfate, and solvent was removed to give a acidic mixture. It was chromatographed with a silica column (50 g silica) and eluted by the following solvent gradient: 30% ethyl acetate – hexanes (300 mL), 50% ethyl acetate – hexanes (200 mL), and 100% ethyl acetate (200 mL). The early fractions were unreacted **6**, the middle fractions were the mono adduct, and the later fractions were the desired double adduct **7b**. Product-containing fractions were combined to give **7b** as an oily solid (0.44 g, 0.66 mmol, 30%); by-product, mono adduct, as an oily solid (0.20 g, 0.36 mmol, 16%); and recovered **6** as a white solid (0.28 g, 0.62 mmol, 28%). ^{1}H NMR 300 MHz (δ, $CDCl_3$): 9.91 (br s, 2H),; 4.14–3.94 (m, 8H), 3.40 (d d, J_1 = 11.0 Hz, J_2 = 4.4 Hz, 2H), 2.98–2.60 (m, 12H), 1.60–1.57 (m, 8H), 1.28 (br s, 16H). ^{13}C NMR 75.47 MHz (δ, $CDCl_3$): 177.3, 171.3, 171.2, 170.2, 65.5, 65.0, 41.7, 36.5, 34.1, 29.1, 29.0, 28.4, 26.1, 25.7, 25.6. MS (–LSIMS, mNBA): 485.2 $(M - CH_2CH_2CO_2H)^-$ 9.3%, 663.2 $(M - H)^-$ 100%. Exact Mass calcd. for $(M - H)^-$, $C_{30}H_{47}O_{12}S_2$, *m*/*e* 663.2509; found: 663.2522.

3- or 4-[9′-[17″- or 18″-(3‴-Carboxy-1‴-thiapropyl)-1″,6″,15″,20″-tetraoxa-2″,5″,16″,19″-tetraoxocyclooctacos-3″- or 4″-yl]-6′-oxo-5′,1′,9′-oxadithianonyl]-17- or 18-(3-carboxy-1-thiapropyl)-1,6,15,20-tetraoxa-2,5,16,19-tetraoxocyclooctacosane (3)

Tetramethylammonium hydroxide pentahydrate (0.072 g, 0.40 mmol) was dissolved in DMSO (2 mL) at 60°C under nitrogen, and mixed with compound **7b** (0.24 g, 0.39 mmol, 1 equiv.) in DMSO (4 mL). Compound **8** (0.26 g, 0.39 mmol, 1 equiv.) in DMSO (6 mL) was added dropwise and the solution was stirred for 22 h at 62–65°C under nitrogen protection. After DMSO was removed under reduced pressure, the yellowish mixture was dissolved in dichloromethane (200 mL) and washed with 1 M hydrochloric acid (4 × 100 mL). The organic layer was dried over sodium sulfate and the dichloromethane was removed. The crude oil was chromatographed on a gel permeation column (LH-20, 3 × 60 cm) and eluted with a mixed solvent of 2-propanol:chloroform (3:4). The desired compound **9b** was obtained in the middle fractions, and the product-containing fractions were evaporated to give the compound **9b** as a pale yellow oil (0.14 g, 0.12 mmol, 31%). The negative LSIMS indicated **9b** was contaminated by compound **3** due to the retro-Michael addition discussed in the text.

A mixture of **7b** and **3** (0.12 g, 0.10 mmol) and 3-mercaptopropionic acid were dissolved in THF (10 mL). 2,2,6,6-Tetramethylpiperidine (0.7 mL) was added to the solution, and it was refluxed for 18 h under nitrogen protection. After THF was removed under reduced pressure, the yellowish solution was dissolved in dichloromethane (150 mL), and washed with 1 M hydrochloric acid (3 × 100 mL). The organic layer was dried over sodium sulfate and dichloromethane was removed. The crude oil was chromatographed on a gel permeation column (LH-20, 3 × 60 cm) and eluted with a mixed solvent, 2-propanol:chloroform (3:4). The desired compound **3** was in the middle fractions, and the product-containing fractions were evaporated to give the compound **3** as a pale yellow oil (0.080 g, 0.062 mmol, 62%). ^{1}H NMR 300 MHz (δ, $CDCl_3$): 8.38 (br s, 2H), 4.14–3.97 (m, 18H), 3.66–3.57 (m, 4H), 2.98–2.60 (m, 22H), 1.89 (m, 2H), 1.58–1.56 (m, 16H), 1.27 (br s, 32H). ^{13}C NMR 75.47 MHz (δ, $CDCl_3$): 176.6, 171.4, 171.2, 170.3, 170.2, 170.1, 65.5, 65.0, 63.1, 41.7, 41.5, 36.5, 34.2, 34.0, 29.6, 29.0, 28.4, 28.1, 27.9, 26.4, 26.1, 25.7. MS (–LSIMS, mNBA): 1295.4 $(M - H)^-$ 100%, 1334.7 $(M + K - H)^-$ 4.3%. Exact Mass calcd. for $(M - H)^-$, $C_{60}H_{95}O_{22}S_4$, *m*/*e* 1295.5198; found: 1295.5187.

3- or 4-[7′-(1″,6″,15″,20″-tetraoxa-2″,5″,16″,19″-tetraoxocyclooctacos-17-enyl-3″- or 4″-yl)]-1′,4′,7′-trithiahepta]-1,6,15,20-tetraoxa-2,5,16,19-tetraoxocyclooctacosa -17-ene (10)

Macrocycle **6** (3.53 g, 7.8 mmol) and 2,2,6,6-tetramethylpiperidine (8 drops) were dissolved in THF (15 mL). 2-Mercaptoethyl sulfide (0.30 g, 1.95 mmol, 0.25 equiv.) in THF (7 mL) was added dropwise for 1 h and 45 min at 63–68°C under nitrogen. The solution was then kept at reflux for 23 h. After removal of THF under reduced pressure, the crude product was added to a column of silica gel (50 g) prepared in 20% ethyl acetate – hexanes as a slurry. A solvent gradient was used to elute the column: 20% ethyl acetate – hexanes (400 mL), 35% ethyl acetate – hexanes (250 mL), 50% ethyl acetate – hexanes (400 mL), 100% ethyl acetate – hexanes (200 mL). Two cycles of separation were applied following the same procedures, and the unreacted **6** was eventually separated from the mixture. The rest of the mixture was put on a Lipophilic Sephadex gel permeation column (LH-20, 3 × 60 cm), and eluted with 2-propanol: chloroform (3:4). After two cycles of purification, the expected compound **10** came out in the middle fractions. The analytical gel permeation column indicated it was a

© 1998 NRC Canada

single sharp peak. The combined product-containing fractions were evaporated to give compound **10** as colorless oil (0.50 g, 0.47 mmol, 24%). ^{1}H NMR 300 MHz (δ, $CDCl_3$): 6.76, 6.17 (s, 4H), 4.16–3.90 (m, 16H), 3.65–3.60 (m, 2H), 2.95–2.58 (m, 12H), 1.60–1.56 (m, 16H), 1.27 (br s, 32H). ^{13}C NMR 75.47 MHz (δ, $CDCl_3$): 171.0, 170.0, 165.2, 165.1, 133.4, 129.6, 129.4, 65.4, 65.2, 64.9, 41.5, 36.5, 31.5, 29.1, 29.0, 28.8, 28.4, 28.3, 25.7, 25.6. MS (–LSIMS, mNBA): 1058.4 $(M - H)^-$ 70.0%. Exact Mass calcd. for $(M - H)^-$, $C_{52}H_{81}O_{16}S_3$, *m/e*: 1057.4687; found: 1057.4737.

3- or 4-[7′-[17″- or 18″-(2‴-Carboxy-1‴-thiaethyl)-1″,6″,15″,20″-tetraoxa-2″,5″,16″,19″-tetraoxocyclooctacos-3″- or 4″-yl]-1′,4′,7′-trithiahepta]-17- or 18-(2-carboxy-1-thiaethyl)-1,6,15,20-tetraoxa-2,5,16,19-tetraoxocyclooctacosane (4)

Compound **10** (0.20 g, 0.19 mmol) and 2-mercaptoacetic acid were dissolved in THF (15 mL), and 2,2,6,6-tetramethylpiperidine (0.5 mL) was added to the solution. The mixture was refluxed for 36 h under nitrogen. After evaporation of THF under reduced pressure, the crude product was dissolved in dichloromethane (150 mL) and washed with 1 M hydrochloric acid (5 × 100 mL). Drying with magnesium sulfate and evaporation gave a colorless oil. Gel permeation (LH-20, 3 × 60 cm) of the product eluted with 2-propanol:chloroform (3:4) gave the desired product **4** in the middle fractions. The combined product-containing fractions were evaporated to give compound **4** as a colorless oil (0.15 g, 0.12 mmol, 63%).^{1}H NMR 300 MHz (δ, $CDCl_3$): 7.61 (br s, 2H), 4.12–3.93 (m, 16H), 3.81, 3.65 (dd, $J_1 = J_1' = 4.4$ Hz, $J_2 = J_2' = 11.1$ Hz, 4H), 3.46 (dd, $J_1 = 16.2$ Hz, $J_2 = 56.6$ Hz), 2.97–2.60 (m, 16H), 1.57 (br s, 16H), 1.27 (br s, 32H). ^{13}C NMR 75.47 MHz (δ, $CDCl_3$): 174.1, 171.2, 170.8, 170.3, 170.0, 65.6, 65.5, 65.1, 41.7, 41.5, 36.5, 36.1, 33.0, 31.6, 31.5, 29.1, 29.0, 28.4, 25.7, 25.6. 3- or 4-[7′-[17″- or 18″-(*N*,*N*-Dimethyl-3‴,1‴-azathiapropyl)-1′,6″,15″,20″-tetraoxa-2″,5″,16″,19″-tetraoxocyclooctacos-3″- or 4″-yl]-1′,4′,7′-trithiahepta]-17- or 18-(*N*,*N*-dimethyl-3,1-azathiapropyl)-1,6,15,20-tetraoxa-2,5,16,19-tetraoxocyclooctacosane (5)

Compound **10** (0.20 g, 0.19 mmol) and 2-dimethylaminoethanethiol (0.11 g, 0.78 mmol, 4.1 equiv.) were dissolved in 2-propanol (15 mL), and 2,2,6,6-tetramethylpiperidine (0.5 mL) was added. The solution was refluxed for 4 h under nitrogen. After solvent evaporation, the crude product was dissolved in chloroform (150 mL), washed with 1 M hydrochloric acid (5 × 100 mL), and dried over magnesium sulfate. Following evaporation of chloroform, the crude product was chromatographed by a gel permeation column (LH-20, 3 ×60 cm) eluted with 2-propanol:chloroform (3:4). The desired compound **5** was in the middle fractions. The combined product-containing fractions were evaporated to give compound **5** as a colorless oil (0.18 g, 0.14 mmol, 74%). ^{1}H NMR 300 MHz (δ, $CDCl_3$): 4.01–3.83 (m, 16H), 3.61–3.53 (m, 4H), 2.91–2.52 (m, 36H), 1.48 (br s, 16H), 1.18 (br s, 32H). ^{13}C NMR 75.47 MHz (δ, $CDCl_3$): 170.8, 170.7, 169.8, 65.4, 65.2, 64.8, 64.7, 57.1, 43.4, 41.5, 41.3, 36.3, 36.1, 31.4, 31.3, 28.9, 28.8, 28.2, 28.7, 26.6, 25.5, 25.4. MS (+LSIMS, mNBA): 1269.4 $(M + H)^+$ 100%. Exact Mass calcd. for $(M - H)^-$, $C_{60}H_{103}O_{16}N_2S_4$, *m/e:* 1267.5911; found: 1267.6014.

Vesicle experiments

The general procedures for vesicle preparation and pH-stat titration have previously been reported (7, 12) Compounds **2–5** were dissolved in methanol (5.0 mM) and were directly added to the vesicle suspension to initiate transport. All experiments gave good (r^2 >0.98) fits to a first-order expression for consumption of titrant as a function of time for the period of the experiment where the pH-stat controlled the pH.

Bilayer clamp experiments

All electrolytes were analytical grade or better. The apparatus and general procedures for single-channel recording and analysis have been reported (7*a*). In experiments with two cations in competition, 1 M chloride salts of the ions in question were employed. The dilution potentials were determined from 0.1 M and 0.5 M salts. Liquid junction potentials were "backed-off" to zero before the membrane was formed. In cases of moderate selectivity, the junction potential after membrane rupture was still at the zero set point. High-selectivity cases are discussed in the text; the change in junction potential over an experiment was less than 20 mV in all cases. Enough transporter was added to ensure macroscopic (nA) currents across the bilayer to avoid artifacts from periods of low channel activity. Usually a potential of ±100 mV was applied initially until channel activity was established. The reversal potential was then manually approached from both directions. Following this estimation, a voltage ramp crossing the region of interest, typically with a rate of 2–13 mV s^{-1}, was applied using the Clampex data acquisition program. A current–voltage diagram was constructed as an average of 10–20 cycles and the reversal potential was determined from the voltage intercept. The manual and averaged values generally agreed within ±2 mV.

Effect of the hydrogen bond network in carbonic anhydrase II zinc binding site. A theoretical study

Silvia Álvarez-Santos, Àngels González-Lafont, and José M. Lluch

Abstract: The hydrogen bond network influence on the carbonic anhydrase II (CAII) zinc binding site has been studied theoretically by using the semiempirical AM1 method. To this aim, quantum mechanical reduced models of wild-type CAII and several CAII variants have been constructed. We have shown that, when a direct metal ligand donates a hydrogen bond to an indirect metal ligand, the first-shell residues enhance their electrostatic interaction with the zinc cation. Thus, the hydrogen-bond network is able to modulate the zinc binding affinity and the zinc–water pK_a.

Key words: hydrogen bond network, carbonic anhydrase II, Zn^{2+} metalloenzyme ligands.

Résumé : Faisant appel à la méthode semi-empirique AM1, on a effectué une étude théorique de l'influence du réseau de liaisons hydrogènes sur le site de fixation du zinc de l'anhydrase carbonique (ACII). À cet effet, on a construit plusieurs modèles (de mécanique quantique) réduits de l'ACII de type sauvage et de ses variantes. On a montré que, lorsqu'un ligand métallique direct donne une liaison hydrogène à un ligand métallique indirect, les résidus de la première couche augmentent leur interaction électrostatique avec le cation zinc. Il en résulte donc que le réseau de liaisons hydrogènes peut moduler l'affinité de fixation du zinc et le pK_a du complexe zinc–eau.

Mots clés : réseau de liaisons hydrogènes, anhydrase carbonique II, ligands métalloenzyme du Zn^{2+}.

Introduction

The design of proteins with predictable structure and function is one of the objectives of protein engineering. Knowledge of the ligand geometry and stereochemistry of many metalloenzymes, which are well characterized structurally, has been used to redesign some metal sites with different protein scaffoldings (1–4). However, these sites cannot reproduce the catalytic activity and the avid metal binding of natural metalloenzymes (5).

An important point that has to be considered is that the side chains that ligate the metal ion in metalloenzymes are nested in a hydrogen-bonding network with other protein residues. Hydrogen bonding interactions with metal ligands are proposed to orient the ligands for optimal metal coordination, enhancing the electrostatic interaction between the ligands and the metal ion (6). These hydrogen bond networks with metal ligands could be important for the structure and function of metalloenzymes.

Zinc metalloenzymes, such as carbonic anhydrase II (CAII) (7), carboxypeptidase A (CPA) (8), or termolysin (TLN) (9), generally have a water molecule (solvent) bound to the zinc ion. Hydrogen-bonding networks with zinc ligands could also modulate the pK_a and reactivity of the zinc-bound water molecule (10, 11), which is implicated in the catalytic mechanism of the enzyme. The residues that establish hydrogen-bonding interactions with direct metal ligands (first-shell residues) are referred to as "indirect metal ligands" and build a second shell of residues surrounding protein–metal binding sites.

Recently, carbonic anhydrase II (CAII) has been used as the most appropriate zinc enzyme paradigm to analyze the structural and functional roles of hydrogen-bond networks between "indirect ligands" and direct metal ligands (12, 13). In CAII, the zinc ion is coordinated to three histidine residues (94, 96, and 119) and a water molecule. Those direct ligands interact through a hydrogen-bond network with a second shell of residues of the enzyme as shown schematically in Fig. 1.

To investigate the functional role of these hydrogen bonds, Kiefer et al. (12) have determined experimentally the effects of varying the structure of the side chain of indirect ligands on zinc binding and catalysis. The authors conclude that weakening the hydrogen bonds to the zinc ligands should increase the mobility of the histidine residues and decrease the metal ion affinity due to the increased entropic cost of metal binding. Removing two indirect ligands has an additive effect on zinc affinity, leading to a decrease in zinc binding energy of 2.2 kcal/mol. It seems that the role of indirect ligands is to preorganize the direct ligands for optimal metal coordination, and increase the electrostatic interaction between the ligands and metal ion, so enhancing metal affinity. Moreover, the authors suggest that the indirect ligand interacting with His-119 plays an essential role in slow zinc dissociation.

The zinc–water pK_a is also perturbed when the indirect ligands are altered in carbonic anhydrase II (12). Altering

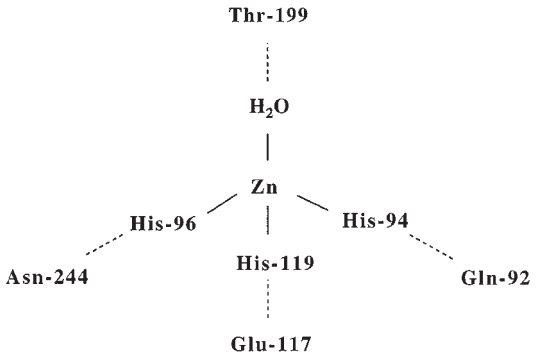
Fig. 1. Scheme of the active site of wild-type CAII.



the hydrogen-bonding interactions with zinc ligands provokes changes in the electrostatic environment of zinc. Then the ability of zinc to polarize its bound water molecule is modified, which confirms that the indirect ligands do modulate the catalytic efficiency of zinc in CAII, beginning with alterations to the pK_a of the zinc–water ligand.

X-ray crystallographic studies on several recombinant CAIIs (13) confirm the importance of indirect ligands modulating the pK_a of zinc-bound water and the zinc binding affinity, which leads us to conclude that in the structure-assisted design of protein–metal binding sites, not only direct ligands, but also the indirect ligands involved in the hydrogen-bond network, must be included.

The purpose of the present paper is to theoretically analyze the hydrogen-bond network influence on the zinc binding affinity and the zinc–water pK_a in carbonic anhydrase II. To this end we will use a quantum mechanical reduced model of that enzyme.

Method of calculation

The reduced quantum mechanical model of wild-type CAII, which we designed in order to reproduce the hydrogen-bond networks on the active site of the enzyme, consisted of the following key elements: a zinc ion coordinated to its four direct ligands (a water molecule and three histidines) and the second shell of residues that hydrogen bond to those zinc ligands (glutamine, glutamate, threonine, and asparagine) (see Fig. 1). The protonated nitrogen atom in the imidazole ring of His-94 donates a hydrogen bond to the carboxamide side chain of Gln-92, His-119 donates a hydrogen bond to the carboxylate side chain of Glu-117, zinc-bound water donates a hydrogen bond to the hydroxyl side chain of Thr-199, and His-96 donates a hydrogen bond to the backbone carbonyl oxygen of Asn-244.

Unlike proline, all the amino acids commonly found in proteins contain a primary amino group (-NH_2) on the α-carbon atom (the one attached to the carboxyl group). The rest of the molecule, the side chain, is also bonded to the α-carbon atom and characterizes the different amino acids. In this paper, we are interested in second-shell hydrogen bonds between residues that ligate zinc and the side chains of indirect ligands. To reduce computational requirements, histidines were modeled by imidazole rings. In modeling the three indirect ligands that are hydrogen bonded to the first-shell residues through their side chains, the substituents bonded to the α-carbon atom were simplified by substituting the $NH_2C^{\alpha}HCOOH$ terminal group by a CH_3 group, but the chemical structure of the side chains was maintained in the quantum mechanical model. As for the fourth indirect ligand, the backbone fragment corresponding to Asn-244 has been modeled by a propanamide. A three-dimensional picture of the model compound that we have used in our calculations for the wild-type CAII is displayed in Fig. 2. We have also modeled some enzymatic variants of CAII by replacing wild-type CAII indirect ligands with other amino acid side chains. Those new indirect ligands have also been simplified in our

quantum mechanical model by substituting the $NH_2C^{\alpha}HCOOH$ terminal group by a CH_3 group but maintaining the chemical structure of their side chains. A three-dimensional picture of the model compounds used in our calculations to represent the new residues (alanine, leucine, and aspartate) is shown in Fig. 3.

In spite of those reductions, the calculations carried out in this work involved systems containing up to 85 atoms. Due to the size of those systems, the use of ab initio or DFT methods is quite beyond our computational capabilities. Thus, calculations were performed using the standard AM1 (14) semiempirical procedure, as implemented in the AMPAC (15) package of computer programs. It must be noted that the AM1 semiempirical method has provided good theoretical results in several recent Zn^{2+} metalloenzyme simulations (16–18) although it does not reproduce the geometry of hydrogen bonds properly (19). Geometry minima on the semiempirical hypersurface were located by minimizing the energy with respect to all geometrical variables using the Davidon–Fletcher–Powell (DFP) method (20, 21). In any event, it must be kept in mind that the full geometry optimization of our reduced model can move some groups away from the position that they occupy in the real entire enzyme. In some cases (indicated below), several internal coordinates were kept frozen in the optimization run. The stationary points (that is, when no constraint is introduced) found on the complete hypersurface were characterized as minima by diagonalizing their Hessian (force constant) matrices and looking for all positive eigenvalues.

Results and discussion

First, we present our results concerning the influence of the CAII hydrogen-bond network on the zinc binding affinity, between zinc first-shell and second-shell residues. Secondly, the effect of the hydrogen-bond network on the pK_a of the zinc–water ligand is analyzed.

To theoretically estimate the zinc binding affinity in CAII, several complexation enthalpies within our quantum mechanical model have been calculated. Those enthalpy values are presented in Table 1. In this work, complexation enthalpies are defined as enthalpy differences between each fully optimized complex (zinc plus residues) and a set of different fragments of that complex. We have distinguished between two main kinds of complexation enthalpies. The first will be called the fragment complexation enthalpy (first column in Table 1) and it comes from putting together five different fragments. These five fragments are, on the one hand, zinc ion and, on the other hand, each one of its four direct ligands, which are hydrogen bonded to a second-shell ligand depending on whether the indirect ligand is present in the final complex. In these enthalpy calculations, each fragment and the complete complex were fully optimized. The second complexation enthalpy that we have calculated will be called zinc complexation enthalpy (second column in Table 1). These zinc complexation enthalpies correspond to enthalpy differences between each optimized complex and two different fragments: zinc ion, on the one hand, and, on the other hand, the whole set of ligands present in the final complex. In the calculation of these zinc complexation enthalpies the set of residues are held fixed at their optimized disposition in the final system, that is, when binding to zinc ion. The first row in Table 1 gives fragment and zinc complexation enthalpy values when only the first-shell ligands are present in the final complex. In the rest of the rows, the corresponding complexation enthalpies are given for those systems formed when the different indirect ligands are successively included at the locations indicated in Fig. 1. In this paper, amino acids will be designated using either the well-known three-letter or the one-letter abbreviations. That is: His or H, Thr or T, Asn or N, Glu or E, Gln or Q, Ala or A, Leu or L, and Asp or D. Here, Glu and Asp refer to negatively charged glutamate and aspartate species, respectively.

Table 1. Complexation enthalpies. From top to bottom the different indirect ligands are successively introduced in going from the first shell up to the wild-type model (TNEQ).

Model	Fragment complexation (kcal/mol)	Zn complexation (kcal/mol)
First shell	–395.2	–411.1
T	–404.6	–421.4
TN	–416.7	–438.5
TNE	–534.5	–570.9
TNEQ	–540.4	–582.9

The calculated fragment complexation enthalpies presented in Table 1 (first column) become more negative as the complex size increases, as a result of progressively including the indirect ligands, until completing the second shell of residues. A more significant stabilization is observed when the indirect ligand being added is Glu-117 or E117, in good agreement with previous experimental results where the carboxylate–histidine–zinc triad was classified as stronger than, for instance, the carboxamide–histidine–zinc triad (10, 11). Zinc complexation enthalpies (second column of Table 1) show the same above-mentioned trends with increasing number of hydrogen bonds, but this magnitude compares better with the experimental measurement of zinc binding affinity in CAII, because the experimental process only consists of zinc dissociation, without dismantling the rest of the structure of the enzyme. The difference between the values in the two columns of Table 1 comes from the destabilization energy that results from the approach of the four fragments different from zinc from infinity to their final location in the complex. As can be seen, this destabilization effect becomes more significant as the number of indirect ligands increases.

The role of indirect ligands in the enhancement of metal affinity in metalloenzymes has been attributed to two different factors: the capability of indirect ligands to orient first-shell ligands for optimal metal coordination, and the increase of electrostatic interaction between direct ligands and the metal ion due to the presence of second-shell residues. In our quantum-mechanical calculations only the electrostatic effect is introduced because we have included in our model just two shells of amino acids. This electrostatic effect is due to both the through-space charge interactions and the formation of the hydrogen bond. As for the contribution of the hydrogen bond, when a first-shell residue donates a hydrogen bond to a second-shell residue, the net effect is equivalent to

E117A/Q92A	–418.5	–438.6	160 ± 35

[a] From ref. 12.

a negative charge transfer in the reverse direction, that is, from the second to the first shell, which enhances its electrostatic interaction with the metal cation. As already noted, this electrostatic contribution to metal binding affinity is particularly important when Glu-117 (with a negatively charged side chain) is added in the second shell. Experimentally it has been shown that about 1.4 kcal/mol of zinc binding energy is conferred per hydrogen bond for up to 5 kcal/mol increase in zinc affinity for four hydrogen bonds (12). Our calculations in vacuo show the qualitative trends although they are quantitatively exaggerated because Zn^{2+} becomes free when dissociated in our quantum-mechanical model. As a matter of fact, Weinhold (22) has recently shown that a simple ab initio gas-phase cluster model is able to qualitatively reproduce the H-bond network of an enzyme active site. It could be expected that adding solvent molecules would decrease zinc binding energy per hydrogen bond, progressively approaching the corresponding experimental value in solution.

The experimental conclusions on the function of the hydrogen bond network of CAII in zinc binding affinity have been assessed from the study of several CAII variants (12, 13). We have also modeled those enzymatic variants by replacing hydrogen bond acceptors with other amino acid side chains. The criteria for choosing CAII variants have been the following: (*a*) removal of the entire side chain functionality that forms a hydrogen bond with the first-shell ligands by substituting the hydrogen bond acceptor amino acid with Ala or Leu; (*b*) the change of size or charge of the hydrogen-bonded second-shell residues. In addition, several double variants have been considered in order to study combined effects. The different CAII variants that we have modeled theoretically are listed in the first column of Table 2 using one-letter abbreviations. The first one-letter symbol (followed by the location numbering) indicates the wild-type hydrogen acceptor residue while the second one-letter abbreviation refers to the amino acid used for substitution in the enzyme variant. Double substitution variants are individually specified in the same way and separated by a slash. For each of the modeled CAII variants, fragment complexation enthalpies of the entire system (i.e.,with the second shell of residues completed) were calculated relative to the five fragments: zinc ion, on the one hand, and, on the other hand, the four pairs of direct–indirect ligands. Zinc complexation enthalpies have also been calculated for each variant relative to zinc ion, on the one hand, and, on the other hand, relative to the whole set of ligands frozen at their optimized location in the final complex. The results are presented in Table 2 along with the corresponding wild-type values for the sake of comparison. Fragment and zinc complexation enthalpies present very similar trends along the series of CAII variants. For that reason, in this section we will comment only on zinc complexation enthalpy values, which are, in addition, more comparable to experimental data as we have previously observed.

The series of CAII variants that we modeled can be classified in three different groups. In the first group, Q92 was changed by four different residues. In the Q92A and the Q92L variants, the existing hydrogen bond with His-94 is eliminated in both cases, although those two new residues maintain a weak interaction with the imidazole ring of the first shell. Our calculations show that in both the Q92A and the Q92L variants, the system is destabilized relative to wild-type CAII in agreement with the electrostatic effect explained in the previous paragraphs. It has to be noted at this point that additional geometry constraints were needed in the calculations for optimizing the Q92A variant. Concretely, the hydrogen forming the hydrogen bond between His-119 and Glu-117 was fixed in such a way that both the hydrogen-acceptor atom and the hydrogen-donor atom distances were kept frozen. In the absence of this constraint, a proton transfer from His-119 to E117 occurs in our model, which has nothing to do with the elimination of the hydrogen bond in the system.

Zinc avidity is not very sensitive to the length of the side chain of the acceptor residue as long as the potential for forming a hydrogen bond is maintained. This can be seen by the insignificant change in the complexation enthalpy when going from wild-type CAII to the Q92N variant, in which a methylene group of the side chain of the acceptor residue has been eliminated. On the contrary, when a net negative charge is introduced at the 92 location in the Q92E variant, the complexation enthalpy decreases nearly 100 kcal/mol, confirming the important role played by carboxylate–histidine–zinc triads (10).

In the second group of CAII variants that we modeled, Glu-117 was substituted by Asp in the wild-type enzyme and, as well, in the four CAII variants described in the previous paragraph. Altering the length of the acceptor residue in the E117D variant does not modify metal affinity for its ligands, as we had already inferred from substitution at location 92. The series of double substitution variants modeled by changing Gln-92 for Ala, Leu, Asn, and Glu in the E117D variant show trends similar to our first group of variants. The only difference worth noting concerns Q92A substitution. In the E117D variant, when a hydrogen bond is eliminated by introducing Ala at location 92, there is no proton transfer from H119 to D117 and the destabilization effect of removing a hydrogen bond can be observed.

The third group of variants were modeled to analyze the energetic effects of removing the hydrogen bond network at

© 1998 NRC Canada

position 117. The great increase in the complexation enthalpy obtained for the E117A and E117A/Q92A variants indicates that the indirect ligand at position 117 anchors the zinc ion more tightly than any other indirect ligand, in particular, the Gln at position 92. In other words, our calculations confirm again that the carboxylate–histidine–zinc triad is stronger than the carboxamide–histidine–zinc triad.

Kiefer et al. (12) assessed the effects of altering the indirect ligands on metal binding by measuring zinc dissociation constants at pH 7 for the different CAII variants. Those dissociation constants were obtained by establishing the relationship between unbound zinc concentration (metal ion outside the active site) and the concentration of bound zinc (metal ion inside the active site) in an equilibrium dialysis experiment. In Table 2 (third column) the experimental dissociation constants values are given. When Ala or Leu is used for substitution either at position 92 or at position 117, larger zinc K_D values are experimentally measured, indicating that in those variants zinc affinity has decreased relative to wild-type CAII. This increase is particularly important in the E117A variant and in E117A/Q92A CAII, where the effect is found to be additive. In any case, these zinc K_D values are somewhat underestimated because, even in those variants where the hydrophobicity of the indirect ligand was changed to disrupt the hydrogen-bond network, a hydrogen bond is always experimentally maintained by the unexpected recruitment of new hydrogen-bond partners from the protein or from the solvent. In two variants, Q92A and E117A, a compensatory hydrogen bond is experimentally formed between the histidine zinc ligand and either an inserted water molecule or a chloride ion. In the Q92L variant an alternative amino acid side chain moves to form a poorly oriented hydrogen bond with H94. Our theoretical complexation enthalpies qualitatively agree with the trends observed for the zinc K_D dissociation constants. That is, when the zinc dissociation constant increases, the zinc complexation enthalpy relative to wild-type CAII is less negative. In particular, our theoretical results reproduce the high destabilization of the E117A and E117A/Q92A variants, which experimentally present 10-fold and 40-fold larger zinc K_D dissociation constants than wild-type CAII. Moreover, the greater effect on weakening protein–zinc affinity at position 117 than at position 92 can be seen from a comparison of the zinc complexation enthalpies in the E117A and Q92A variants. Kiefer et al. (12) also indicate that shortening the side chain of the acceptor residue has no major effect on the zinc dissociation constants, in agreement with the calculated values for the corresponding (Q92N and E117D) zinc complexation enthalpies that do not significantly differ from wild-type CAII. Taking all this into account, the large experimental zinc K_D value in the E117D variant appears rather surprising. In the Q92E variant another disagreement is found between experimental and theoretical results. Altering the charge of the hydrogen-bond acceptor does not significantly modify the experimentally determined zinc dissociation constant, leading the authors to conclude that the charge of the indirect ligand at position 92 is not a primary determinant of metal affinity. In contrast, our calculations show a particular stabilization of the system when neutral glutamine is substituted by negatively charged glutamate at position 92. This theoretical result agrees better with the changes in the zinc electrostatic environment in the Q92E variant compared to the wild-type CAII that we have already described, because a negatively charged acceptor side chain increases the electrostatic interaction between the ligands and the metal ion. This discrepancy in the experimental results may be attributed to the influence of certain factors in the experimental measurements that have not been included in the quantum mechanical model. In any case, the experimental value for the zinc dissociation constant in Q92E CAII is rather surprising and contradicts the result of the rate dissociation constant for the same system given by the authors, which decreases 6-fold relative to wild-type CAII (12). Thus, the experimental half-time for dissociation ($t_{1/2}$) of zinc from CAII appears to be 31.7 days for Q92E whereas it is 5.2 days for wild-type CAII. In addition, the reported value for $t_{1/2}$ in the Q92N variant is only 1.1 days while, according to the experimental results, the Q92N and Q92E variants present identical dissociation rate constants.

Table 3. Deprotonation enthalpy differences relative to the wild-type CAII and experimental zinc–water pK_a values.

Model	$\Delta\Delta H^0$ (cal/mol)	pK_a [a]
First shell	–425.1	—
Wild type	0	6.8
Q92A	55.8	6.8
Q92L	–47.9	6.4
Q92N	36.5	6.9
Q92E	683.1	7.7

[a] From ref. 12.

As for the second subject under consideration in this paper, the pK_a of zinc-bound water affords a convenient means of quantifying the electrostatic contributions, including hydrogen bonding to the metal ligands, with respect to the ability of zinc to polarize its bound water molecule. In other words, changes in the electrostatic environment of the zinc in CAII should be reflected in the pK_a of the zinc–water ligand since this measures the ability of zinc to stabilize a negatively charged hydroxide ion. We have studied theoretically the acid–base equilibrium of removing a proton from the zinc-bound water by calculating the corresponding standard deprotonation enthalpy in some of our quantum mechanical models of the CAII active site. The differences in those reaction enthalpies with respect to wild-type CAII ($\Delta\Delta H^0$) are listed in Table 3 along with the experimental pK_a's reported by Kiefer et al. (12). The hydrogen-bond network between zinc first-shell and second-shell residues contributes to diminishing the effective positive charge of the zinc ion and thereby one would expect an increase in the water-bound pK_a. In agreement, the $\Delta\Delta H^0$ value for the first-shell model (with no indirect ligand included) is negative. This is indicative of the more acidic character of the water-bound molecule in the model where none of the metal direct ligands is hydrogen bonded to indirect ligands. With only first-shell residues, the zinc ion supports more positive charge and it is able to better stabilize a negatively charged hydroxide ion. The opposite effect is observed in Q92E CAII: the substitution of neutral glutamine with negatively charged glutamate at position 92 increases the electron density on zinc and, consequently, its water ligand is less

© 1998 NRC Canada

polarized and has significantly less acidic character. This accounts for the positive $\Delta\Delta H^0$ value listed in Table 3. In good agreement, the experimental pK_a increases by almost one pH unit. When, instead, a hydrogen bond to a histidine zinc ligand in wild-type CAII is eliminated, the pK_a of zinc-bound water should decrease. In Q92L CAII, the aliphatic side chain of Leu cannot accept a hydrogen bond from H94, although, as we have already explained, a compensatory hydrogen bond is formed in the experimental system between an alternative amino acid side chain and H94. In any case, that new hydrogen bond is not well oriented and, consequently, the effective positive charge on zinc increases. This explains the experimental decrease by 0.4 pK_a units of the wild-type pK_a. In the theoretical model, no alternative hydrogen bond is formed and we obtain a negative $\Delta\Delta H^0$ value. At first glance, it could seem surprising that the experimental pK_a's in wild-type CAII and in the Q92A variant are identical. Kiefer et al. (12) explain that in this substitution there is no net change in the electrostatic environment of zinc because the void created on the active site of Q92A CAII allows for the entrance of a water molecule, which forms a compensatory hydrogen bond with the histidine zinc ligand. The theoretical $\Delta\Delta H^0$ value is slightly positive. However, this theoretical value cannot be used for comparison because of the above-mentioned constraint used to avoid the proton transfer between His-119 and E117. The perturbation of this constraint is much too strong in the scale of cal/mol of the computed $\Delta\Delta H^0$. Finally, the effect of shortening the side chain of the acceptor residue in the Q92N variant leads to a slight increase of the experimental pK_a and, in agreement, of a positive theoretical $\Delta\Delta H^0$ value.

To summarize, in this paper we have shown theoretically that the hydrogen bond network, in which the direct zinc ligands are nested in CAII, modulates the zinc binding affinity and the zinc–water pK_a. These results, which confirm previous experimental findings, prove the importance of hydrogen bonds in determining the structure and reactivity of metalloenzymes. As a matter of fact, the role of these hydrogen bonds between direct and indirect ligands of the metal ion is to create a hydrogen-bonding network of residues on the active site. The energetic stabilization achieved once the hydrogen-bond network is formed comes from several contributions: those arising from the hydrogen bond itself and those due to electrostatic interactions at longer distances.

Finally we have to note again that the calculations presented in this paper correspond to in vacuo supermolecules, whereas the experimental quantities were obtained in solution. Although no quantitative comparison can be made between both sets of results, our theoretical gas-phase model is able to qualitatively reproduce the main trends of the different ligands in a real hydrogen-bond network.

Heteroleptic gold complexes with 4,5-diselenolate-1,3-dithiole-2-thione ($C_3S_3Se_2^{2-}$, dsit)

Elena Cerrada and Mariano Laguna

Abstract: The reaction of $(NBu_4)_2[Zn(dsit)_2]$ (dsit = 4,5-diselenolate-1,3-dithiole-2-thione) with AuClL in a 1:4 ratio leads to $[Au_2(dsit)L_2]$ (L = PPh_3 (**1**), PPh_2Me (**2**)), transferring the diselenolate group. Complex **2** reacts further with equimolar amounts of $[Au(OClO_3)L]$, affording the trinuclear complex $[Au_3(dsit)(PPh_2Me)_3]ClO_4$ (**3**). When the reaction of $(NBu_4)_2[Zn(dsit)_2]$ with $[Au_2Cl_2(P\text{-}P)]$ was carried out in a 1:2 ratio, complexes $[Au_2(dsit)(P\text{-}P)]_n$ (P-P = dppe (1,2-bis(diphenylphosphine)ethane), n = 1 (**4**); P-P = dppm (bis(diphenylphosphine)methane), n = 2 (**5**)) are obtained. Anionic derivatives such as $(NBu_4)[Au(dsit)_2]$ (**6**) could be obtained by reaction of the zinc complex with $(NBu_4)[AuBr_4]$ in a 1:1 ratio while other gold complexes require a tin complex as ligand transfer. So $[Sn(dsit)Me_2]$ (**7**), obtained from the zinc complex and $[SnCl_2Me_2]$, reacts with $PPN[Au(C_6F_5)Cl]$ (PPN = bis(triphenylphosphine)iminium) or $[AuBr_2(S_2CNR_2)]$ affording $[Au(dsit)(S_2CNR_2)]$ (R = Me (**8**); R = Bz (**9**)) or $(PPN)_2[Au_2(dsit)(C_6F_5)_2]$ (**10**), respectively. Electrochemical oxidation of **6** gives $(NBu_4)_{0.4}[Au(dsit)_2]$ (**11**) and the reaction with $(TTF)_3(BF_4)_2$ (TTF = tetrathiafulvalene) affords $(TTF)[Au(dsit)_2]$ (**12**). Electrical conductivities of these complexes at room temperature in compacted pellets are 3×10^{-8} (**11**) and 5×10^{-3} (**12**) S cm^{-1}.

Key words: diselenolate, dsit, gold complexes, tin complexes.

Résumé : La réaction du $(NBu_4)_2[Zn(dsit)_2]$ (dsit = 4,5-disélénaloate-1,3-dithiole-2-thione) avec le AuClL dans un rapport de 1 : 4 conduit au $[Au_2(dsit)L_2]$ (L = PPh_3 (**1**), PPh_2Me (**2**)) avec transfert du groupe disélénolate. Le complexe **2** réagit ultérieurement avec des quantités équimolaires de $[Au(OClO_3)L]$ pour conduire au complexe trinucléaire $[Au_3(dsit)(PPh_2Me)_3]ClO_4$ (**3**). Lorsqu'on fait réagir le $(NBu_4)_2[Zn(dsit)_2]$ avec du $[Au_2Cl_2(P\text{-}P)]$ dans un rapport de 1 : 2, on obtient des complexes $[Au_2(dsit)(P\text{-}P)]_n$ (P-P = dppe [1,2-bis(diphénylphosphine)éthane], n = 1 (**4**); P-P = dppm [bis(diphénylphosphine)méthane], n = 2 (**5**)). On peut obtenir des dérivés anioniques, tel que le $(NBu_4)[Au(dsit)_2]$ (**6**), en faisant réagir le complexe de zinc avec du $(NBu_4)[AuBr_4]$ dans un rapport de 1 : 1; pour la préparation d'autres complexes de l'or, il est nécessaire d'utiliser un complexe d'étain comme ligand de transfert. Ainsi, le complexe $[Sn(dsit)Me_2]$ (**7**), obtenu à partir du complexe de zinc et du $[SnCl_2Me_2]$, réagit avec le $PPN[Au(C_6F_5)Cl]$ (PPN = bis(triphénylphosphine)iminium) ou le $[AuBr_2(S_2CNR_2)]$ pour conduire respectivement au $[Au(dsit)(S_2CNR_2)]$ (R = Me (**8**); R = Bz (**9**)) et au $(PPN)_2[Au_2(dsit)(C_6F_5)_2]$ (**10**). L'oxydation électrochimique du composé **6** conduit au $(NBu_4)_{0,4}[Au(dsit)_2]$ (**11**) alors que sa réaction avec le $(TTF)_3(BF_4)_2$ (TTF = tétrathiafulvalène) mène au $(TTF)[Au(dsit)_2]$ (**12**). Les conductivités électriques de ces complexes, à la température ambiante, sous la forme de pastilles, sont 3×10^{-8} (**11**) et 5×10^{-3} (**12**) S cm^{-1}.

Mots clés : disélénolate, dsit, complexes d'or, complexes d'étain.

[Traduit par la Rédaction]

Introduction

Metal complexes containing 4,5-dithiolate-1,3-dithiole-2-thione ($C_3S_5^{2-}$, dmit) have been investigated because of the high conductivity reported in certain of them (1, 2). Since the discovery in 1986 of the first formally inorganic molecular superconductor (3) $(TTF)[Ni(dmit)_2]_2$ (TTF = tetrathiafulvalene), a great number of $(cation)_x[M(dmit)_2]$ (M = Ni, Pd, and Pt; cation = TTF or NMe_4 and $0 \leq x \leq 2$) have been synthesized (4–10), including the recently reported α-EDT-TTF$[Ni(dmit)_2]$, which is superconducting at ambient pressure (4). The dmit ligand acts in all these complexes as a bidentate chelate but the coordination chemistry of this ligand is very rich, at least in gold chemistry, where coordination as μ_2 (11–13) and μ_3 (12) bridging modes in di-, tri-, and tetra-nuclear complexes have been described.

Substituting selenium atoms for sulphur atoms in dmit has led to a number of new ligands such as dsit ($C_3S_3Se_2$), dsise (C_3S_4Se), dmise ($C_3S_2Se_3$), and dsis (C_3Se_5) (14–17) (Fig. 1). They have been investigated because they are expected to enable more effective molecular interaction through the selenium–selenium contacts due to the more diffuse and spatially extended *p* and *d* orbitals of the selenium atom as compared with sulphur. However, to date only a few complexes of these ligands have been reported and those with metallic behaviour are scarce, namely, $[NHMe_3][Ni(dmise)_2]_2$ (18), $[NMe_4][Ni(dmise)_2]_2$ (19), and $[NMe_4][Pd(dsise)_2]_2$ (20).

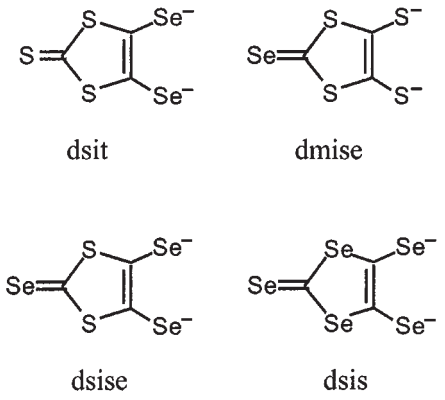
Fig. 1.



This paper reports a systematic study of the coordination properties of dsit as a ligand in gold(I) and gold(III) chemistry, giving rise to novel bridging coordination modes, through the useful transfer of dsit from zinc and tin complexes, such as $[NBu_4]_2[Zn(dsit)_2]$ and $[Sn(dsit)Me_2]$. Gold complexes with the dsit acting as μ_2 (e.g., $[Au_2(dsit)(PPh_2Me)_2]$) or μ_3 (e.g., $[Au_3(dsit)(PPh_2Me)_3]ClO_4$) bridging ligand are reported among others, with the dsit acting in a chelate form (e.g., $[Au(dsit)(S_2CNMe_2)]$). Complex $[Bu_4N][Au(dsit)_2]$ undergoes oxidation to give fractional oxidation state complexes $[NBu_4]_{0.4}[Au(dsit)_2]$ or reacts with $(TTF)_3(BF_4)_2$ affording $[TTF][Au(dsit)_2]$ (TTF = tetrathiafulvalene). Both gold complexes show low electrical conductivity in compacted pellets, 3×10^{-8} and 5×10^{-3} S cm^{-1}, respectively.

Experimental

$Q_2[Zn(dsit)_2]$ (Q = NBu_4, NEt_4) (21), $[AuCl(PPh_3)]$ (22), $[AuCl(PPh_2Me)]$ (22), $[Au_2(\mu\text{-dppe})Cl_2]$ (dppe = 1,2-bis(diphenylphosphine)ethane) (23), $[Au_2(\mu\text{-dppm})Cl_2]$ (dppm = bis(diphenylphosphine)methane) (23), $PPN[Au(C_6F_5)Cl]$ (PPN = bis(triphenylphosphine)iminium) (24), $[AuBr_2(S_2CNR_2)]$ (25), and $(TTF)_3(BF_4)_2$ (26) were prepared by literature procedures. $[Au(OClO_3)(PPh_2Me)]$ was synthesized from $[AuCl(PPh_2Me)]$ with $AgClO_4$ in dichloromethane. All other reagents were commercially available.

IR spectra were recorded on a Perkin–Elmer 559 or 883 spectrophotometer, over the range 4000–250 cm^{-1}, using Nujol mulls between polyethylene sheets, and Raman spectra were recorded using a Dilor XY spectrometer with a multichannel diode array detector and λ (Ar^+) = 514.5 nm. NMR spectra were recorded on a Varian Unity 300 spectrometer in $CDCl_3$ solutions (^1H (300 MHz), $^{31}P\{^1H\}$ (121.4 MHz), and ^{19}F (282.2 MHz)) using tetramethylsilane, H_3PO_4 (85%, external), and $CFCl_3$ as references. Mass spectra were recorded with the VG Autospec LSIMS technique using 3-nitrobenzylalcohol as matrix and a cesium gun. The C, H, N, and S analyses were performed with a Perkin–Elmer 2400 microanalyser; Au was determined by ashing the samples with an aqueous solution of hydrazine. Conductivities were measured in acetone with a Philips PW 9509 apparatus. Electrical conductivities were measured in compacted pressed pellets at room temperature.

$[Au_2(dsit)L_2]$ (L = PPh_3 (1), PPh_2Me (2)), $[Au_2(dsit)(P\text{-}P)]_n$ (P-P = dppe, n = 1 (4); P-P = dppm, n = 2 (5)), $(NBu_4)[Au(dsit)_2]$ (6), $[Sn(C_3S_3Se_2)Me_2]$ (7)

To an acetone (20 mL) solution of $(NBu_4)_2[Zn(dsit)_2]$ (56 mg, 0.05 mmol) under a dinitrogen atmosphere was added $[AuCl(PPh_3)]$ (98 mg, 0.2 mmol), $[AuCl(Ph_2Me)]$ (86 mg, 0.2 mmol), $[Au_2(\mu\text{-dppe})Cl_2]$ (86 mg, 0.1 mmol), or $[Au_2(\mu\text{-dppm})Cl_2]$ (85 mg, 0.1 mmol). Orange solids precipitated immediately in the case of **4** and **5**; these were filtered off, washed with acetone, and dried under vacuum. In the other cases orange solutions were obtained. After stirring for 1 h, the solutions were concentrated to 1 mL. Addition of diethyl ether (15 mL) gave a pale solid, which was filtered off. The resulting solution was concentrated to 5 mL. Addition of *n*-hexane (10 mL) led to precipitation of **1** and **2** as yellow solids The solids were filtered off, washed with water, and recrystallized with diethyl ether – hexane. Formation of **7** was accomplished similarly, but starting from $(NEt_4)_2[Zn(dsit)_2]$ (45 mg, 0.05 mmol) and $SnCl_2Me_2$ (22 mg, 0.1 mmol).

Complex **6** was formed similarly but starting from $NBu_4[AuBr_4]$ (38 mg, 0.05 mmol) and $(NBu_4)_2[Zn(dsit)_2]$ (56 mg, 0.05 mmol) and using diethyl ether to precipitate a garnet solid, which was filtered off, washed with water, and recrystallized from dichloromethane – diethyl ether.

$[Au_3(dsit)(PPh_2Me)_3]ClO_4$ (3)

To a dichloromethane (20 mL) solution of $[AuCl(PPh_2Me)]$ (43 mg, 0.1 mmol) was added $AgClO_4$ (21 mg, 0.1 mmol). After 1 h of stirring the suspension was filtered through a 1 cm layer of Celite. $[Au_2(dsit)(PPh_2Me)_2]$ (110 mg, 0.1 mmol) was added to the resulting solution. After being stirred for 2 h, the solution was concentrated to 2 mL. Addition of *n*-hexane led to precipitation of an orange solid. Λ_M in acetone (5×10^{-4} M) 107 Ω^{-1} cm^2 mol^{-1}.

$[Au(dsit)(S_2CNR_2)]$ (R = Me (8), CH_2Ph (Bz) (9)), $(PPN)_2[Au_2(dsit)(C_6F_5)_2]$ (10)

To an acetone (20 mL) solution of $[Sn(dsit)Me_2]$ (39 mg, 0.1 mmol) under a dinitrogen atmosphere was added $[AuBr_2(S_2CNMe_2)]$ (47 mg, 0.1 mmol), $[AuBr_2(S_2CNBz_2)]$ (63 mg, 0.1 mmol), or $PPN[Au(C_6F_5)Cl]$ (180 mg, 0.2 mmol). Dark brown (**8**) and green (**9**) solids inmediately appeared and were filtered off and dried under vacuum. In the other case, the solution was concentrated to 1 mL. Addition of *n*-hexane (15 mL) gave a brown solid (**10**), which was filtered off.

$(NBu_4)_{0.4}[Au(dsit)_2]$ (11)

An acetonitrile solution (10 mL) containing $(NBu_4)[Au(dsit)_2]$ (24 mg, 24 mmol) and NBu_4ClO_4 (27 mg, 80 mmol) was subjected to controlled-current (1.2 μA) electrolysis for 15 days in an H-type glass cell consisting of platinum wires (27). Black microcrystals (7 mg) of complex **11** produced on the anode were collected and washed with acetonitrile.

$(TTF)[Au(dsit)_2]$ (12)

To an acetonitrile (20 mL) solution of $NBu_4[Au(dsit)_2]$ (101 mg, 0.1 mmol) was added $(TTF)_3(BF_4)_2$ (102 mg,

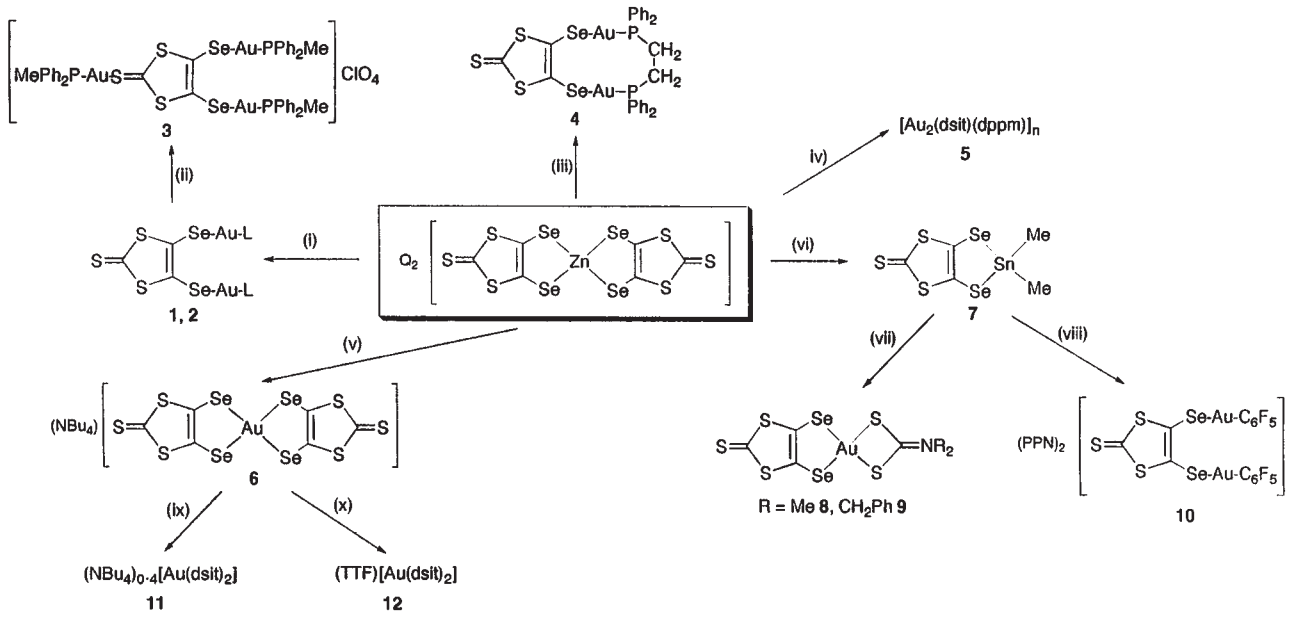
Scheme 1.



0.13 mmol). A dark garnet solid precipitated immediately and was filtered off and dried under vacuum.

Results and discussion

The syntheses of dmit and dsit complexes reported to date have been carried out mainly from the COPh protected derivatives, $C_3S_5(COPh)_2$ and $C_3S_3Se_2(COPh)_2$, respectively. The reaction of these stable derivatives with ethanol solutions of EtONa yields fresh solutions of $C_3S_5Na_2$ or $C_3S_3Se_2Na_2$, which further react with the corresponding halo–metal complexes (17, 28, 29). This method does not yield good results with the dsit and gold(I) complexes [AuClL] (L = PPh_3, PPh_2Me). The preparation of $[Au_2(dsit)L_2]$ (L = PPh_3, **1**; PPh_2Me, **2**) can be achieved through the use of the zinc derivative $(NBu_4)_2[Zn(dsit)_2]$ with the corresponding [AuClL] complexes in a 1:4 ratio in acetone solutions (reaction (i), Scheme 1) in a similar way to those reported for dmit derivatives (30). The reaction works in very mild conditions such as 1 h reaction time at room temperature. The lack of solubility of the by-product $(NBu_4)_2[ZnCl_4]$ in diethyl ether permits the separation of complexes **1** and **2** in good yields (Table 1).

The spectroscopic properties of these complexes are in agreement with their formulation, showing one singlet in the $^{31}P\{^1H\}$ NMR spectrum, displaced slightly low field with respect to the $[Au_2(dmit)L_2]$ derivatives (31). The mass spectra (LSIMS +) are very informative, showing the parent peak M^+ at *m/z* (%) 1210 (15), **1,** and 1086 (12), **2**, with the expected isotopic distributions, which in this case are illustrative because of the presence of six isotopes of selenium. It is noteworthy that, as happened in the dithiolate mass spectra (30, 31), there are signals assignable to $[M + Au\ L]^+$ at *m/z* (%): 1669 (9), **1**, and 1483 (8), **2**. The trinuclear gold(I) complex $[Au_3(dsit)(PPh_2Me)_3](ClO_4)$ (**3**) can be obtained by reaction of complex **2** with a fresh solution of $[Au(OClO_3)(PPh_2Me)]$. The corresponding PPh_3 derivative is not obtained in a pure form. Complex **3** shows conductivity in acetone solution (5×10^{-4} M) corresponding to a 1:1 electrolyte, in agreement with its formulation (32). The mass spectrum shows the parent ion peak with the lack of the ClO_4 anion at *m/z* 1483 (17%). The ^1H NMR spectrum shows a CH_3 doublet at 2.4 ppm ($^2J_{P-H}$ = 7.8 Hz) and the $^{31}P\{^1H\}$ NMR spectrum consists of a broad singlet at room temperature, which is resolved into two singlets with a 2:1 intensity ratio at –80°C, as did the dmit complex $[Au_3(dmit)(PPh_2Me)_3](ClO_4)$ (31). In accordance with all these data we believe that complexes **1–3** have similar structures as those reported for the dmit derivatives with the dsit acting as μ_2 and μ_3 bridging ligands as represented in Scheme 1.

The zinc derivative $(NBu_4)_2[Zn(dsit)_2]$ reacts with $[Au_2Cl_2(P\text{-}P)_2]$ (P-P = dppm, dppe) in a 1:2 ratio with the transfer of a diselenolate group. New complexes $[Au_2(dsit)(P\text{-}P)]_n$ (P-P = dppe, n = 1, **4** ; P-P = dppm, n = 2, **5**) appear as insoluble yellow solids in the reaction solvent, acetone. The $^{31}P\{^1H\}$ NMR spectra show a single resonance at δ 33.7 ppm for **4** and an AA′XX′ system for **5**: δ_A = 36.7 ppm, δ_X = 27.1 ppm, $^2J_{AA}$ = 112 Hz, $^2J_{AX} = {}^2J_{A'X}$ = 46 Hz. All these values are very close to those reported for the dmit derivatives (12, 13) and are displaced slightly low field with respect to them with the exception of δ_A. It is noteworthy that although the differences are small (one CH_2 group) between the diphosphines used, dppm and dppe, the spectroscopic properties of complexes **4** and **5** are very different. Similar $^{31}P\{^1H\}$ NMR spectral patterns have been

observed in the dmit derivatives and in fact their structures [Au_2(dmit)(dppe)] (13) and [Au_2(dmit)(dppm)]$_2$ (12) are very different. The spectroscopic properties indicate a similar structure for the dmit and dsit derivatives, dinuclear for **4** and tetranuclear for **5**, although other polynuclear structures are not ruled out (Scheme 1). The mass spectra of these complexes are not helpful because only Au(dsit) and Au(P-P) fragments appear.

The use of the zinc derivative as the diselenolate transferring group can be extended to the preparation of gold(III) complexes, but in this case only the reaction with (NBu_4)[$AuBr_4$] works in a clean way to give the previously described (NBu_4)[Au(dsit)$_2$] (**6**) (33) in a very good yield. Because of the square planar coordination of gold(III), the dsit ligand acts as a bidentate chelate ligand in this complex. The preparation of anionic gold(I) complexes or gold(III) derivatives requires other transferring metal complexes. For this reason we tested the preparation of the dsit–tin derivative, which can be obtained from the reaction of (NBu_4)$_2$[Zn(dsit)$_2$] with [$SnCl_2Me_2$] (reaction (vi)). The resulting tin [Sn(dsit)Me_2] **7** and the zinc by-product (NBu_4)$_2$[$ZnCl_4$] complexes can be easily separated because of their different solubilities in diethyl ether. The ^{1}H NMR spectrum of **7** shows a singlet for methyl groups bonded to tin flanked by a broad pair of satellite peaks ($^2J_{Sn–H}$ = 60.0 Hz). Although there are two active tin isotopes, ^{117}Sn and ^{119}Sn, the different coupling constants are not resolved in this case.

Complex **7** is a suitable reagent for transferring the dsit to different dithiocarbamate gold(III) complexes [$AuBr_2$(S_2CNR_2)] or to the anionic gold(I) derivative (PPN)[Au(C_6F_5)Cl] (PPN = $Ph_3P{=}N{=}PPh_3$), affording the mononuclear [Au(dsit)(S_2CNR_2)] (R = Me, **8**; CH_2Ph (Bz), **9**) or the dinuclear gold(I) complex (PPN)$_2$[Au_2(dsit)(C_6F_5)$_2$] (**10**). In both cases the reaction by-product [$SnCl_2Me_2$] can be separated from the reaction mixture because of its solubility in acetone or hexane, respectively. Due to the insolubility of complexes **8** and **9**, data from measurements in solution were not available. Complex **10** shows three signals in the ^{19}F NMR spectrum: –115.4 (m, F_o), –163.3 (t, F_p), –164.6 (m, F_m) in accordance with two equivalent C_6F_5 groups. Complex **10** shows in the mass spectrum (LSIMS–) a signal corresponding to the anion at *m/z* 821 (3%). The coordination of dsit ligand in compounds **6**, **8**, and **9** should be as bidentate chelate because of the preferred square planar arrangement of the gold(III) center, whereas the prefered linear array at gold(I) centers induces a coordination of dsit as μ_2- or μ_3-bridge as proposed for compounds **1–5** and **10**.Unfortunately, all attempts to obtain crystals of good quality for X-ray studies of the new complexes were unsuccessful and do not permit us to confirm the proposed coordination properties of the dsit ligand in gold chemistry.

The preparation of fractional charge complexes has usually been achieved by starting from anionic complexes. In our case neither gold(I) anionic **10**, nor neutral derivatives, **1** and **2,** give non-integral derivatives. On the contrary, the electrochemical oxidation of an acetonitrile solution of (NBu_4)[Au(dsit)$_2$] **6** in the presence of NBu_4ClO_4 affords black microcrystals of complex: (NBu_4)$_{0.4}$[Au(dsit)$_2$] **11**,

© 1998 NRC Canada

which has been characterized by elemental analyses and the electrical conductivities measured from compacted pellets of 3×10^{-8} S cm^{-1} at room temperature.

The reaction of complex **6** with $(TTF)_3(BF_4)_2$ gives complex (TTF)[Au(dsit)$_2$] (**12**) in which no oxidation has taken place. Complex **12** shows IR (KBr pellets) absorption at 1050 and 1025 cm^{-1} corresponding to the ν(C=S) band and a Raman spectrum with a band at 1415 cm^{-1} due to the C=C of the TTF molecule in accordance with a formulation as TTF^+ (34), so the metal atom remains as gold(III) in the complex. The solid shows a conductivity in a compacted pellet of 5×10^{-3} S cm^{-1} at room temperature.

Conclusions

In conclusion, the complexes $(NBu_4)_2[Zn(dsit)_2]$ and [Sn(dsit)Me$_2$] are able to transfer the dsit group to gold centers under very mild conditions, allowing the synthesis of dsit gold compounds that cannot be obtained using fresh solutions of $C_3S_3Se_2Na_2$. Remarkably, the NMR spectra of the new complexes show similar patterns to those of the dmit gold compounds; therefore the structures of the dsit derivatives should be similar to those reported on dmit analogues. We are interested in the study of the generality of this synthetic strategy to transfer the dsit and related selenium ligands to other metal centers, because the mild conditions should permit a more effective control of the final products.

Studies with polyfunctionally substituted heteroaromatics: synthesis of new heterocyclic aromatic amines as potential intermediates for preparation of dyes for thermal diffusion printing

Ayman Wahba Erian, Ebtisam Abdul Aziz Hafez, Elham Sayed Darwish, and Mohamed Hilmy Elnagdi

Abstract: Several new dibenzopyrans as well as novel thiadiazaacenaphthenes are obtained via 4 + 2 addition of the thienocoumarins (1) and thienopyridazines (2) to electron-poor olefins.

Key words : pyridazines, thienopyridazines, phthalazines, coumarines, thiadiazaacenaphthenes.

Résumé : L'addition 4 + 2 de thiénocoumarines (1) et de thiénopyridazines (2) sur des oléfines pauvres en électron permet d'obtenir plusieurs dibenzopyranes et thiadiazaacénaphtènes nouveaux.

Mots clés : pyridazines, thiénopyridazines, phtalazines, coumarines, thiadiazaacénaphtènes.

[Traduit par la Rédaction]

Introduction

Heterocyclic aromatic amines are interesting compounds because of considerable utility as intermediates in both the pharmaceutical and dye industries (1–6). In the last years we were involved in a program to develop new polyfunctional substituted heterocyclic amines for use as agrochemicals and as intermediates in the dye industry (7–9). During this phase of our research we have developed a synthesis of benzo-fused azines via addition of electron-poor olefins and acetylenes to aminothienoazines. It is well documented that thiophene and its derivatives are reluctant partners in [4+2] cycloadditions with dienophiles containing a double bond in general and with dimethyl fumarate in particular. For instance, Gaertner and Tonkyn (10) failed to add maleic anhydride to tetramethylthiophene even when the reaction was carried out in boiling nitrobenzene (bp 211°C). A similar failure was also reported by Clapp (11), who attempted to induce tetraphenylthiophene to react with maleic anhydride. Similarly, thiophene fails to undergo [4+2] cycloaddition with dienophiles (12) such as dimethyl maleate, dimethyl fumarate, methyl acrylate, acrylonitrile, or acrylaldehyde, even under high pressure. A Diels–Alder adduct was obtained, however, with maleic anhydride (100°C, 15 kbar, 3 h) (1 bar = 100 kPa) (12). However, it should be noted that at atmospheric pressure diene reactivity towards compounds containing a double bond has been observed with 2,5-dimethoxythiophene (13), 2,4-bis-(*N*-isopropyl-*N*-phenylamino)thiophene (14), and 2,3,4,5-di(naphthalene-1,8-diyl)thiophene (15). However, aminothienopyridazines, being both electron-rich and strained molecules, add readily to electron-poor olefins to yield aminophthalazines via [4+2] cycloaddition reaction followed by ring opening and aromatization through loss of hydrogen sulfide or elimination of hydrogen depending on the nature of the reagent and applied reaction condition (15, 16). To our knowledge this was the first reported addition of an electron-rich strained thiophene to an electron-poor olefin. Recently Dopp and coworkers (17) have reported the addition of dimethyl fumarate and dimethyl acetylenedicarboxylate to 3-amino-4-imino-4H-thieno[3,4-*c*]-benzopyran. Although the reaction of dimethyl fumarate afforded dibenzopyran via a reaction sequence similar to that observed earlier by us (15), the cycloadduct from reaction with dimethyl acetylene dicarboxylate underwent a novel type of rearrangement that afforded benzopyrano-thiepine (17). In conjunction of this work we reported here synthesis of 3-aminothieno[3,4-*c*]coumarin (1) and thieno[3,4-*d*]pyridazin-1-carboxylates (2) and their reactivity toward electron-poor olefins.

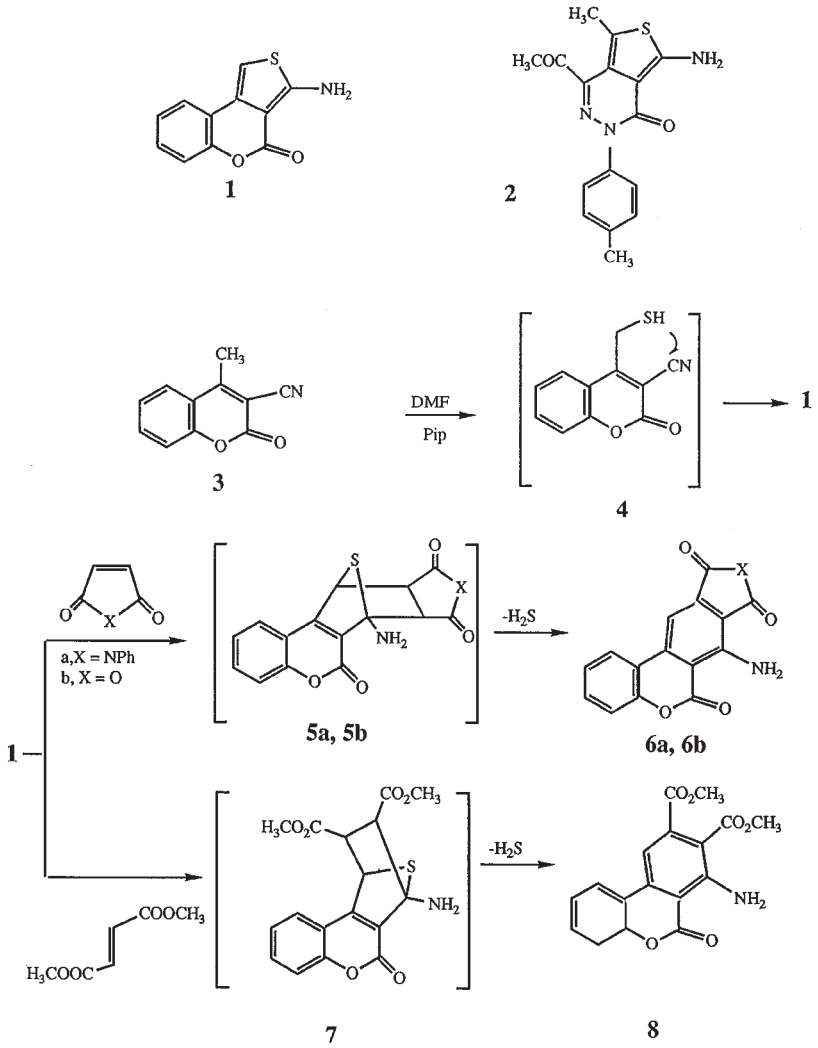
Results and discussion

Thus, we have found that 4-methylcoumarin-3-carbonitrile (3) reacts readily with sulfur in refluxing dimethylformamide in the presence of ethanolic piperidine to yield the thienobenzopyran derivative **1** via the intermediate **4**. This compound readily added *N*-phenylmaleimide and

© 1998 NRC Canada



maleic anhydride to yield the condensed dibenzopyran **6a**,**b**. Formation of **6** is assumed to proceed via initial [4+2] cycloaddition of the olefinic double bond to diene system of **1**, yielding intermediate cycloadducts **5a** and **5b** that then loses hydrogen sulfide to yield the final isolable product. This is similar to the recently reported (17) behaviour of 3-amino-4-imino-4H-thieno[3,4-*c*][1]benzopyran toward dimethyl fumarate. Similar to this, it has also found that **1** reacts with dimethyl fumarate to yield the dibenzopyrane derivative **8,** most likely via the intermediate of the cycloadduct **7**.

Compound **2** reacted with methyl acrylate when refluxed in dioxane containing few drops of acetic acid to yield products of addition and methanol elimination. These are assigned structure **11** and are assumed to be formed via rearrangement of the initially formed cycloadduct **9** to **10** in presence of acid medium. The latter cyclized via loss of methanol to give **11**. If **10** would lose hydrogen sulphide to yield a phthalazine, the methyl and ester function in this product would experience large steric interactions. The structure proposed for compound **11** was established with ^{13}C NMR. Furthermore ^{1}H NMR showed an AB multiplet near δ 3.00 ppm for CH_2 protons at position C-8. Similarly, the reaction of maleic anhydride with **2** afforded **12**. It is believed that the methanol eliminated during formation of **12** effects ring opening of the anhydride ring.

Compound **2** reacted with benzoyl isothiocyanate to yield a 1:1 adduct. The ^{1}H NMR of this adduct revealed the presence of two lower field D_2O exchangeable hydrogen atoms at δ 12.10 and 15.20 ppm. The absence of any amino hydrogens excludes the possibility that the cycloadduct **14** was formed. It is most likely that this product is the benzoyl thiourea derivative **13**. This assumption is further supported by ^{13}C NMR data, which did not show any signals for sp^3 hybridized besides carbons those of the methyl and methoxy group (further detail cf. experimentat section).

Experimental

All melting points are uncorrected, IR spectra were obtained on a Pye Unicam SP 1000 spectrophotometer using KBr discs. The ^{1}H NMR were recorded on a varian EM 390-90 MHz, and Bruker WM 300 MHz using TMS as internal reference. The chemical shifts were expressed as a δ ppm GCMS-QP 1000-EX Shimadzu, Japan. Analytical data were obtained from the microanalytical data unit at Cairo University.

3-Aminothieno[3,4-*c*]coumarin (1)

To a solution of **3** (1.8 g, 0.01 mol) in DMF (15 mL) containing few drops of piperidine was added elemental sulfur (0.32 g, 0.01 mol). The reaction mixture was heated under reflux for 5 h, then left to cool. The resulting solution was poured on ice water and acidified with few drops of hydrochloric acid. The resulting precipitate was collected by filtration and crystallized from ethanol to give yellow plates (1.9 g, 87%), mp 195°C. IR, ν (KBr): 3400–3300 (NH_2) and 1680 cm^{-1} (C=O). ^1H NMR (DMSO), δ: 3.45 (br, 2H, NH_2), 6.9–8.15 ppm (M, 5H, Ar-H, and thiophene H). Anal. calcd. for $C_{11}H_7NO_2S$ (217): C 60.8, H 3.2, N 6.4, S 14.7; found: C 60.7, H 3.1, N 6.2, S 14.5.

4-Methylcoumarin-3-carbonitrile (3)

In a flask fitted with a Dean–Stark trap, a solution of *o*-hydroxy-acetophenone (1.36 g, 0.01 mol) in a mixture of acetic acid (10 mL) and toluene (10 mL), ammonium acetate (2 g), and malononitrile (0.66 g, 0.01 mol) was refluxed for 6 h. The solvents were evaporated in vacuo, and the remaining solid was collected and crystallized from acetic acid to give yellow needles, mp 184°C.

9-(*N*-Phenyl)-8,10-dioxoisoindolo[5,6-*c*]coumarin-7-amine (6a)

A solution of **1** (2.17 g, 0.01 mol) in a mixture of acetic acid (10 mL) and dioxane (10 mL) was treated with *N*-phenylmaleimide (1.7 g, 0.01 mol) and refluxed for 8 h. After evaporation of the solvents the solid product was collected by filtration and crystallized from dioxane to give yellow needles (3.3 g, 94%), mp > 300°C. IR, ν (KBr): 3440–3322 (NH_2), 3043 (CH aromatic), 1760–1709 (3 C=O), and 1630 cm^{-1} (C=C). ^1H NMR (DMSO), δ: 7.74–7.39 (m, 9H, Ar-H), 8.06 (s, 1H, H-11), and 8.60 ppm (br, 2H, NH_2). Anal. calcd. for $C_{21}H_{12}N_2O_4$ (356): C 70.7, H 3.3, N 7.8; found: C 70.7, H 3.2, N 7.5. Mass, *m*/*z*: 356 (M^+).

8,10-Dioxoisobenzofuro[5,6-*c*]coumarin-7-amine (6b)

A solution of **1** (2.17 g, 0.01 mol) in a mixture of acetic acid (10 mL) was treated with maleic anhydride (0.98 g, 0.01 mol) and refluxed for 3 h. The solvents were evaporated, and the solid product was washed with ethanol, collected by filtration, and crystallized from ethanol to give yellow needles (2.2 g, 78%), mp 194°C. IR, ν (KBr): 3433–3340 (NH_2), 3084 (CH aromatic), 1835–1763(3 C=O), and

© 1998 NRC Canada

1630 cm^{-1} (C=C). ^1H NMR (DMSO), δ: 7.20–7.82 (m, 4H, Ar-H), 8.00 (s, 1H, H-11), and 8.50 ppm (br, 2H, NH_2). Anal. calcd. for $C_{15}H_7NO_5$ (281): C 64.0, H 2.4, N 4.9; found: C 63.9, H 2.3, N 4.7. Mass, *m*/*z*: 281 (M^+).

Dimethyl 4-aminobenzo[c]coumarin-2,3-dicarboxylate (8)

A mixture of **1** (2.17 g, 0.01 mol) and dimethyl fumarate (1.44 g, 0.01 mol) was heated in an oil bath at 170°C for 4 h. The reaction mixture was cooled, then triturated with ethanol. The solid product, so formed, was collected by filtration and crystallized from dioxane as brown needles, (2.5 g, 76%), mp > 300°C. IR, ν (KBr): 3464–3351 (NH_2), 3095 (CH aromatic), and 1721–1608 cm^{-1} (3 C=O). ^1H NMR (300 MHz, $CDCl_3$), δ: 3.68 (3 H, s, CO_2Me), 3.74 (3H, s, CO_2Me), 6.69–7.06 (1H, dd, *J* = 8.19 and 1.15, 7-H), 7.02 (1H, s, 1-H), 7.05–7.15 (1H, ddd, *J* = 7.91, 7.69, and 1.18, 9-H), 7.27–7.36 (1H, ddd, *J* = 8.16, 7.75, and 1.47, 8-H), 7.74–7.78 (1H, dd, *J* = 8.11 and 1.41, 10-H), 9.05 (2H, br s, NH_2). Anal. calcd. for $C_{17}H_{13}NO_6$ (327): C 62.3, H 3.9, N 4.2; found: C 62.2, H 3.8, N 4.1. Mass, *m*/*z*: 327 (M^+).

Methyl 6-amino-8,8a-dihydro-2,5-dioxo-8a-methyl-4-(*p*-tolyl)-1,3,4-thiadiazaacenaphthene-7-carboxylate (11)

A solution of **2** (3.2 g, 0.01 mol) in dioxane (20 mL) and few drops of acetic acid was treated with methyl acrylate (0.86 g, 0.01 mol). The reaction mixture was refluxed for 10 h, then evaporated in vacuo. The remaining product was triturated with water, and the resulting solid product was collected by filtration and crystallized from dioxane as red needles (3 g, 79%), mp 201°C. IR, ν (KBr): 3402–3292 (NH_2), 2987 (CH_3), 1711 (C=O), 1676 (ring CO), 1675 (CO), and 1620 cm^{-1} (C=C). ^1H NMR (300 MHz, DMSO), δ: 1.82 (s, 3H, CH_3), 2.40 (s, 3H, CH_3), 2.95 and 3.16 (AB system, 2H, CH_2, JAB = 15.7 Hz), 3.70 (s, 3H, OCH_3), 7.31–7.68 (m, 4H, aromatic protons), and 8.10 ppm (br, 2H, NH_2); ^{13}C NMR, δ: 194.20 (C-2), 171.35 (C=O ester), 163.29 (C-5), 153.07 (C-2a), 146.01 (C-6), 144.22, 133.11, 131.20, 129.42 (aromatic ring), 124.35 (C-5a), 104.0 (C-7), 80.56 (C-8a), 50.91 (C-8), 54.82 (CH_3), 15.48 (CH_3). Anal. calcd. for $C_{19}H_{17}N_3O_4S$ (383): C 59.5, H 4.4, N 10.9, S 8.3; found: C 59.3, H 4.2, N 10.8, S 8.2. Mass, *m*/*z*: 383 (M^+).

Methyl 6-amino-8,8a-dihydro-2,5-dioxo-8a-methyl-4-(*p*-tolyl)-1,3,4-thiadiazaacenaphthene-7-carboxy-8-carboxylate (12)

A solution of **2** (3.2 g, 0.01 mol) in a mixture of acetic acid (10 mL) and dioxane (10 mL) was treated with maleic anhydride (0.98 g, 0.01 mol). The reaction mixture was refluxed for 10 h. The reaction mixture was evaporated, then washed with ethanol. The solid product, so formed, was collected by filtration and crystallized from ethanol–dioxane as orange needles (3 g, 71%), mp 280°C. IR, ν (KBr): 3446–3251 (NH_2), 3035 (CH aromatic), 2953 (CH_3), 1830–1731–1673 (4 C=O), and 1637 cm^{-1} (C=C). ^1H NMR (DMSO), δ: 2.40 (s, 3H, CH_3), 2.79 (s, 3H, CH_3), 3.40 (s, 3H, OCH_3), 3.98 (s, 1H, C-8), 7.3–7.7 (m, 4H, Ar-H), 8.88 (br, protons of NH_2), and 11.70 ppm (s, 1H, COOH) (the downfield shift of the amino group due to the effect of the amino acid moiety). Anal. calcd. for $C_{20}H_{17}N_3O_6S$ (427): C 56.2, H 3.9, N 9.8, S 7.4; found: C 56.0, H 3.6, N 9.5, S 7.1. Mass, *m*/*z*: 427 (M^+).

1-Benzyl-5-[7-methyl-3,4-dihydro-7-methyl-3-(*p*-tolyl)-4-oxo-thieno[3,4-*d*]pyridazin-1-carboxylate]-3-ylthiourea (13)

To a suspension of ammonium thiocyanate (0.76 g, 0.01 mol) in dry acetone (20 mL), benzoyl chloride (1.4 g, 0.01 mol) was added. The reaction mixture was refluxed for 5 min then treated with **2** (3.2 g, 0.01 mol). The reaction mixture was refluxed for 3 h, then left to cool. The resulting solution was poured onto ice water. The solid product, so formed, was collected by filtration and crystallized from dioxane as yellow needles (4.8 g, 97%), mp 270°C. IR, ν (KBr): 3350–3220 (2 NH), 2948 (CH_3), 1732 (ester CO), 1675 (2 C=O), and 1641 cm^{-1} (C=C). ^1H NMR (DMSO), δ: 2.40 (s, 3H, CH_3), 3.30 (s, 3H, CH_3), 3.98 (s, 3H, OCH_3), 7.3–7.7 (m, 9H, Ar-H), 12.10 (br, 1H, NH), and 15.20 ppm (br, 1H, NH). ^{13}C NMR, δ: 177.08 (C=O), 174.32 (C=O), 169.26 (C=S), 165.71 (ring C=O), 159.12 (C-1), 147.95 (C-5), 139.31–125.65 (phenyl ring), 121.96 (C-7), 117.38 (C-7a), 106.42 (C-4a), 54.65 (CH_3), 22.26 (CH_3), 14.92 (CH_3). On the influence of secondary structure on the α-C—H bond dissociation energy of proline residues in proteins: a theoretical study

D.A. Block, D. Yu, D.A. Armstrong, and A. Rauk

Abstract: Ab initio computations (B3LYP/6-31G(D), coupled with isodesmic reactions) were used to predict $^{\alpha}$C—H bond dissociation energies (BDEs) for proline as a residue in a model peptide, intended to mimic the environment in proteins. The environment was further constrained to mimic common proline positions in β turns of different types. The BDEs were found to be very dependent on the structural constraints imposed by the β turn type, implying different structure-mediated susceptibilities to free radical damage to proline residues. Unnatural repair of proline (inversion of chirality) was found to be thermodynamically unfavourable. The predicted BDEs for the proline $^{\alpha}$C—H bond, in kJ mol^{-1}, to an estimated accuracy of ±10 kJ mol^{-1} are as follows: fully optimized *trans* rotamer, 368.6; fully optimized *cis* rotamer, 357.7; β turn type I, 380.7; β turn type II, 397.8; β turn type II′, 385.4; β turn type VIa, 374.0; β turn type VIb, 355.0.

Key words: proline, β-turns, free radical, bond dissociation energy, molecular structure, oxidative damage.

Résumé : On a utilisé des calculs ab initio (B3LYP/6-31G(D) couplés à des réactions isodesmiques) pour prédire les énergies de dissociations des liaisons (EDL) $^{\alpha}$C—H de la proline comme résidu d'un modèle de proline qui devrait servir de modèle pour l'environnement des protéines. On a restreint encore plus l'environnement de façon à reproduire les positions habituelles de la proline dans divers types d'orientations β. On a trouvé que les EDL dépendent fortement des contraintes structurales imposées par le type d'orientation β; ceci implique que, suivant leur structure, les résidus prolines ont des susceptibilités différentes aux dommages causés par les radicaux libres. On a trouvé que les réparations non naturelles de la proline (inversion de chiralité) sont thermodynamiquement défavorisées. Les EDL de la liaison $^{\alpha}$C—H de la proline (en kJ mol^{-1}, à une précision évaluée à ±10 kJ mol^{-1}) sont les suivantes : rotamère *trans* complètement optimisé, 368,6; rotamère *cis* complètement optimisé, 357,7; orientation β de type I, 380,7; orientation β de type II, 397,8; orientation β de type II', 385,4; orientation β de type VIa, 374,0; orientation β de type VIb, 355,0.

Mots clés : proline, orientations β, énergie de dissociation des liaisons, structure moléculaire, dommage oxidatif.

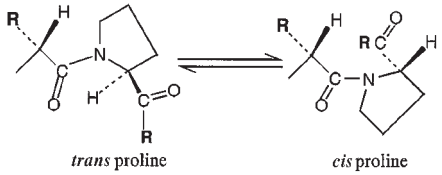
[Traduit par la Rédaction]

Introduction

Oxidative damage to proteins is an everyday event, and inadequate cellular response to oxidative stress can lead to disease states. Proteins damaged by oxidation are normally marked for degradation, but buildup of such proteins has been shown to be a mark of aging (1). Oxidative damage to proteins has also been implicated in various disorders, including inflammatory diseases, atherosclerosis, ischemia–reperfusion tissue damage, and various neurologic disorders (1, 2). The damage to proteins is a poorly understood process, both in its mechanism and in its selectivity. It often occurs on the side chains of amino acids in the protein, but it can also occur by the removal of the hydrogen on the α-carbon of amino acids. The strength of the $^{\alpha}$C—H bond will be influenced by the chemical nature of the side chains of the amino acids.

Proline (**1**) is a unique amino acid because it contains a five-membered ring on the peptide backbone (see Fig. 1). The presence of the ring creates a tertiary amide as opposed to the secondary amides in the other amino acids. This means that there is no proton on the amide nitrogen to form hydrogen bonds. It constrains the Ramachandran Φ dihedral angle in proline peptides to around 60°, where in other amino acids there is much more flexibility. Whereas the peptide linkage of all other amino acid residues has the *trans* relationship between the $^{\alpha}$C centres (3), the proline ring allows the *cis* rotamer to exist as perhaps 10% of the population of proline residues in nature (see eq. [1]).

[1]



The above properties lead to proline's unique role in protein structure. Proline is the preferred residue at the second of

four positions in β turns of type I, II, and III (4). It is also the preferred residue at the third of four positions in a β turn of type II′ (5). The *cis* rotamer is the third of four residues by definition in type VI turns (5). Proline is also common on the first turn of an α-helix, and is also seen just following the end of the helix. It is commonly found on the outside edge of β sheets, and is the cause of β bulges in the interior of β sheets (5). It is a crucial structural member of collagen, in which it is on the outside of a unique triple helical structure.

These properties make proline, although a hydrophobic residue, usually the most exposed residue in proteins (3). Its position in β turns, on the edge of sheets, at the beginning of helices, and just following both helices and sheets, leaves it exposed to solvent and the environment. β turns, in particular, have been postulated to be important in molecular recognition because they are almost exclusively on the exterior of globular proteins, and they are highly conserved (3, 6).

Proline has been found to be sensitive to oxidation, both by radiolysis (7) and in metal- catalyzed systems (8). The hydroxyl radical can produce hydroxyproline, or it can abstract the $^{\alpha}$C hydrogen, leaving a neutral radical. This radical can spontaneously cleave the peptide backbone (see Scheme 1*a*) (7), or it can be further attacked by O_2, also resulting in peptide cleavage (Scheme 1*b*) (9). Radiolysis can result in the cleavage of the C—N bond, leading to unnatural flexibility in the peptide backbone, and possibly further radical damage within the protein (Scheme 1*c*) (9). All of these results are expected to occur in vivo.

The combination of a crucial role in protein structure, general exposure of proline to the environment, and a C—H bond that is easily oxidized leads to the importance of this study. We continue the work done earlier on the bond dissociation energies (BDEs) of the $^{\alpha}$C—H bond of peptide models of the amino acids (10–14). The BDE of the $^{\alpha}$C—H bond of a proline peptide model, $D_{\alpha CH}$ (pro), has been calculated, as well as the equivalent BDEs for a number of constrained systems, simulating the constraints placed on the proline residue in various secondary structural environments.

Computation

The minimum energy structure and constrained minima were calculated at the 6-31G(D) level of theory, using the B3LYP hybrid HF-DFT procedure as implemented in the Gaussian 94 suite of programs (15), with the keyword INT = FINEGRID. Preliminary minimizations were performed at the AM1 semiempirical level using the Spartan (16) program.

The $^{\alpha}$C—H bond dissociation energies (BDEs), $D_{\alpha CH}$, are defined as the heat of reaction [2], $\Delta H^{\circ}_{(2)}$:

[2] 
where **PH**(res) represents a mid-chain amino acid residue of a polypeptide chain, and $^{\alpha}$**P**$^{\bullet}$(res) the corresponding α-carbon centred radical.

In the present case, as a means of reducing residual errors due to basis set and correlation effects, they were derived from the heats of isodesmic reactions (10). These reactions can be represented by eq. [3]:

[3] $^{\alpha}\mathbf{P}^{\bullet}(\text{res}) + \text{AH} \leftrightarrow \mathbf{PH}(\text{res}) + \text{A}^{\bullet}$

AH is a reference molecule for which the BDE, D_{CH}(AH), is known accurately. For each **PH**(res) the heat of reaction (3), $\Delta H^{\circ}_{(3)}$, was evaluated from the energies obtained in the ab initio calculations at the B3LYP/6-31G(D) level, which was shown to give reliable results for the glycine model peptides (11). In the context of BDEs, D_{CH}(**PH**) is then given by

[4] $$D_{CH}(\mathbf{PH}) = D_{CH}(\text{AH}) - \Delta H^{\circ}_{(3)}$$

To obtain the most effective cancellation of residual errors, the structures of the reference molecule and radical used in reaction [3] should be related as closely as possible to those of **PH**(res) and $^{\alpha}$**P**$^{\bullet}$(res), respectively. Ideally AH should have both an adjacent amino group and a carbonyl group so that the special feature of the captodative effect can be taken into account. Previous studies have shown (11, 17) that H_2NCH_2COOH (glycine) is the most suitable reference molecule to give reliable values of $D_{\alpha CH}$. The magnitude of $D_{\alpha CH}$ for glycine itself (331.0 kJ mol^{-1}) (12), was not directly available from experiment. However, it has been derived from a number of isodesmic reactions with heats of reaction based on G2(MP2) calculations (12).

Frequency calculations were not undertaken in this study, as the presence of constraints in nearly every structure leads to imaginary frequencies and difficulty in calculating the zero point energy. Fortuitously, the zero point energies and thermal corrections ($H^{\circ}_{298} - H^{\circ}_{0}$) approximately cancel each other out, as seen in this group's previous work (10). The error introduced by not adding the zero point energy and the thermal correction is estimated to be less than 2 kJ mol^{-1}, whereas the estimated error in the BDEs calculated by the isodesmic reaction procedure is approximately ±10 kJ mol^{-1}. This cancellation, and the approximations involved in doing frequency analysis of constrained systems, led us to decide

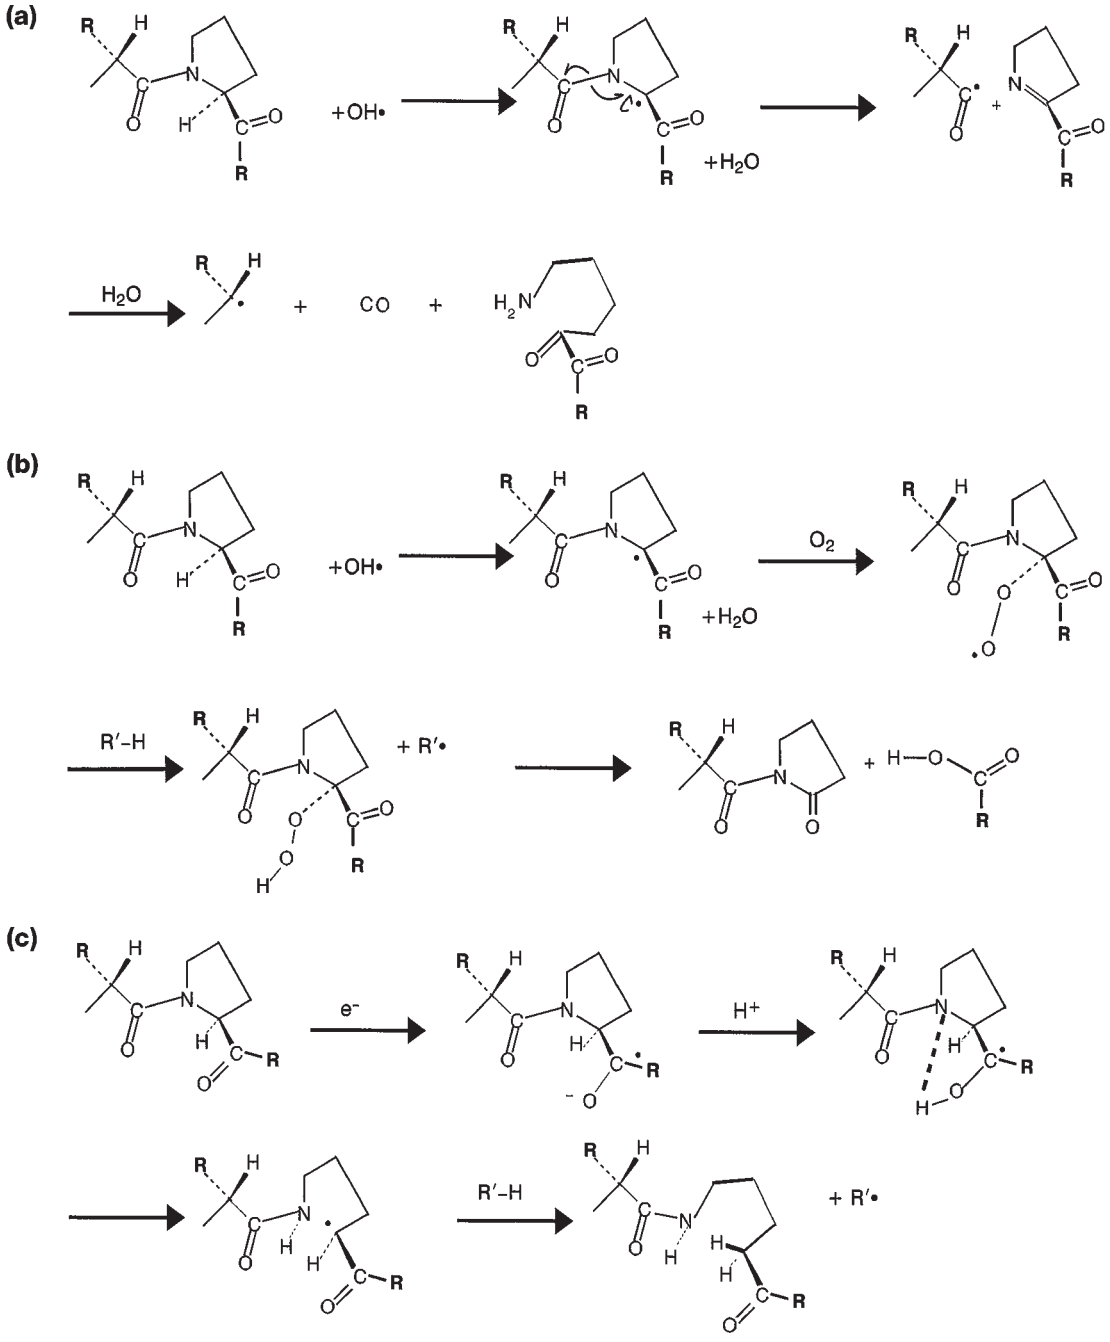
Scheme 1.



that frequency calculations were not justified. The structures presented are all converged geometries according to the default convergence criteria of Gaussian 94 (15).

In previous studies of $^{\alpha}$C—H BDEs, an *N*-formyl amino acid amide was adopted as the model of the mid-chain residue (10, 11). In this model, the next $^{\alpha}$C site is replaced by the formyl hydrogen atom. It was shown that use of *N*-acetyl glycine amine rather than the *N*-formyl analogue resulted in only a 3 kJ mol^{-1} difference in the calculated $^{\alpha}$C—H BDE (11). However, the higher steric requirements imposed by the five-membered ring of proline, particularly for the *cis* rotamer, dictated the use of the larger *N*-acetyl proline amide (**2, 3)** (see Fig. 2) as the peptide model for the present work since the steric requirements of the next $^{\alpha}$C site are better modelled by a methyl group than by a hydrogen atom. The *N*-formyl proline amide model **(4)** will be briefly touched upon in the discussion.

Constrained geometries

It has been estimated that one third of amino acid residues in globular proteins are involved in turns (5). As noted earlier, proline is frequently found in turns, the most common of which is the β turn (**5**), which allows the reversal of direction of the peptide chain within four residues (see Fig. 3). The convention is to number the residues relative to the first one, calling the first *i*, the second *i*+1, etc. The β turns have

been classified in terms of the Φ and Ψ angles of the *i*+1 and *i*+2 residues. The major types are summarized, with asterisks indicating common proline positions, in Table 1 (4).

Type I and II turns contain proline most often in the *i*+1 position. It can be noted that type III turns are identical to type I turns at the *i*+1 position (5), where proline is the most common residue (4). Proline is the most common residue at the *i*+2 position of type II′ β turns (5), where the prime indicates a mirror image of the unprimed β turn types in terms of the Ramachandran dihedral angles Φ and Ψ of the peptides in the *i*+1 and *i*+2 positions. Both types VIa and VIb are defined as having a *cis* proline residue in the *i*+2 position (5).

Proline residues in the first turn of an α-helix will have structural constraints very similar to type II′ β turns (3). Prolines are proportionately rare in β sheets due to their lack of an N-H for hydrogen bonding (3); typical Ψ values in β sheets are not favorable for the five-membered ring of proline.

Collagens form the most common protein type by mass in the vertebrate body. They are made up primarily of repeats of the three peptides (Gly-X-Y) where X and Y are predominantly proline or lysine. The proline and lysine residues may or may not be oxidatively modified by the addition of a hydroxyl group to one of the side-chain carbons. The rigidity of proline (and hydroxyproline) is crucial in stabilizing the unique left-handed helical structure of collagen. Because three strands wind together, the small glycine unit is needed in the middle of the braid. This forces proline in collagen to be exposed to the solvent (18).

Proline's conformation in collagen is very similar to proline in residue *i*+1 in a type II β turn, with Φ and Ψ angles of about –60° and +160°, respectively (19), as compared with –60° and +120° for a type II turn. The energetics of radical damage to collagen at the proline α-centre is modelled adequately by our β turn type II model. Damage to

[a]Data from ref. 11.

proline at this site can be expected to lead to cleavage of the peptide bond (7) (see Scheme 1*b*).

In this study, proline was constrained in geometries corresponding to β turns of type I, II, II′, VIa, and VIb (Table 2). Proline was assumed to be the $i+1$ residue for turn types I and II, and the $i+2$ residue for types II′, VIa, and VIb. In types VIa and VIb, the proline model was constrained to be a *cis* residue.

For each natural constraint the minimum energy geometry was calculated. The α-radical was created by removing the hydrogen attached to the α-carbon. This structure was then optimized as well, maintaining the existing constraints on the Ramachandran angles. The radical $^{\alpha}$C centre thus created was nearly planar and sp^2-hybridized. A hydrogen atom was then added to the opposite side of the α-carbon to create the unnatural *R* isomer of proline. This was also optimized, while maintaining the constraints on the system. This procedure allows the examination of the thermodynamics of unnatural repair of an amino acid radical in the peptide backbone.

Results

The results of our calculations are shown in Table 3. The corresponding structures of the natural (*S*) isomers, the unnatural (*R*) isomers, and the radicals are shown in Fig. 4. All represent minimum energy geometries subject only to secondary structural constraints (on Φ and Ψ). All Φ and Ψ angle measurements are indicated. The bond dissociation energies were calculated using the isodesmic reaction described above, with glycine and the glycine α-radical as the known components of the reaction, and the value of glycine's BDE taken as 331.0 kJ mol^{-1} (10).

Discussion

Stabilizing β turns is the most significant role for proline in protein secondary structure. Damage to the proline α-carbon can result in peptide bond scission, modification into glutamic acid, or formation of other carbonyl-containing derivatives. Any of these results could lead to the loss of local secondary structure about the proline residue, and perhaps loss of tertiary structure as well. The oxidation of proline would thus initiate a cascade of events that may lead to pathological processes (7, 8, 20). The most common pathway for the oxidation of amino acids generally is the abstraction of the hydrogen from the α-carbon by a hydroxy radical (9). Understanding the impact of the structural environment on the strength of the $^{\alpha}$C—H bond is important in order to predict the likelihood of oxidative damage to proline.

$^{\alpha}$C—H bonds

The BDE of the $^{\alpha}$C—H bond in fully optimized *trans*- and *cis*-proline residues (**2**, 368.6 kJ mol^{-1}, and **3**, 357.7 kJ mol^{-1}, respectively, Fig. 4*a* and Table 3, column four) are higher than the corresponding bonds of glycine (348 kJ mol^{-1}), alanine (344 kJ mol^{-1}), serine (348 kJ mol^{-1}), threonine (356 kJ mol^{-1}) (10), or any of the other residues studied thus far (21). This is because structural requirements of the five-membered ring result in increased steric repulsion from the groups of neighbouring residues and the $^{\alpha}$C-centered radical cannot achieve the planar geometry required for maximum captodative stabilization. That this is the case is dramatically illustrated in the *N*-formyl model (**4**) in which the next α-carbon is replaced by a hydrogen atom. There the $^{\alpha}$C-centered radical is able to achieve a planar geometry and the BDE is calculated to be 321 kJ mol^{-1}. The additional

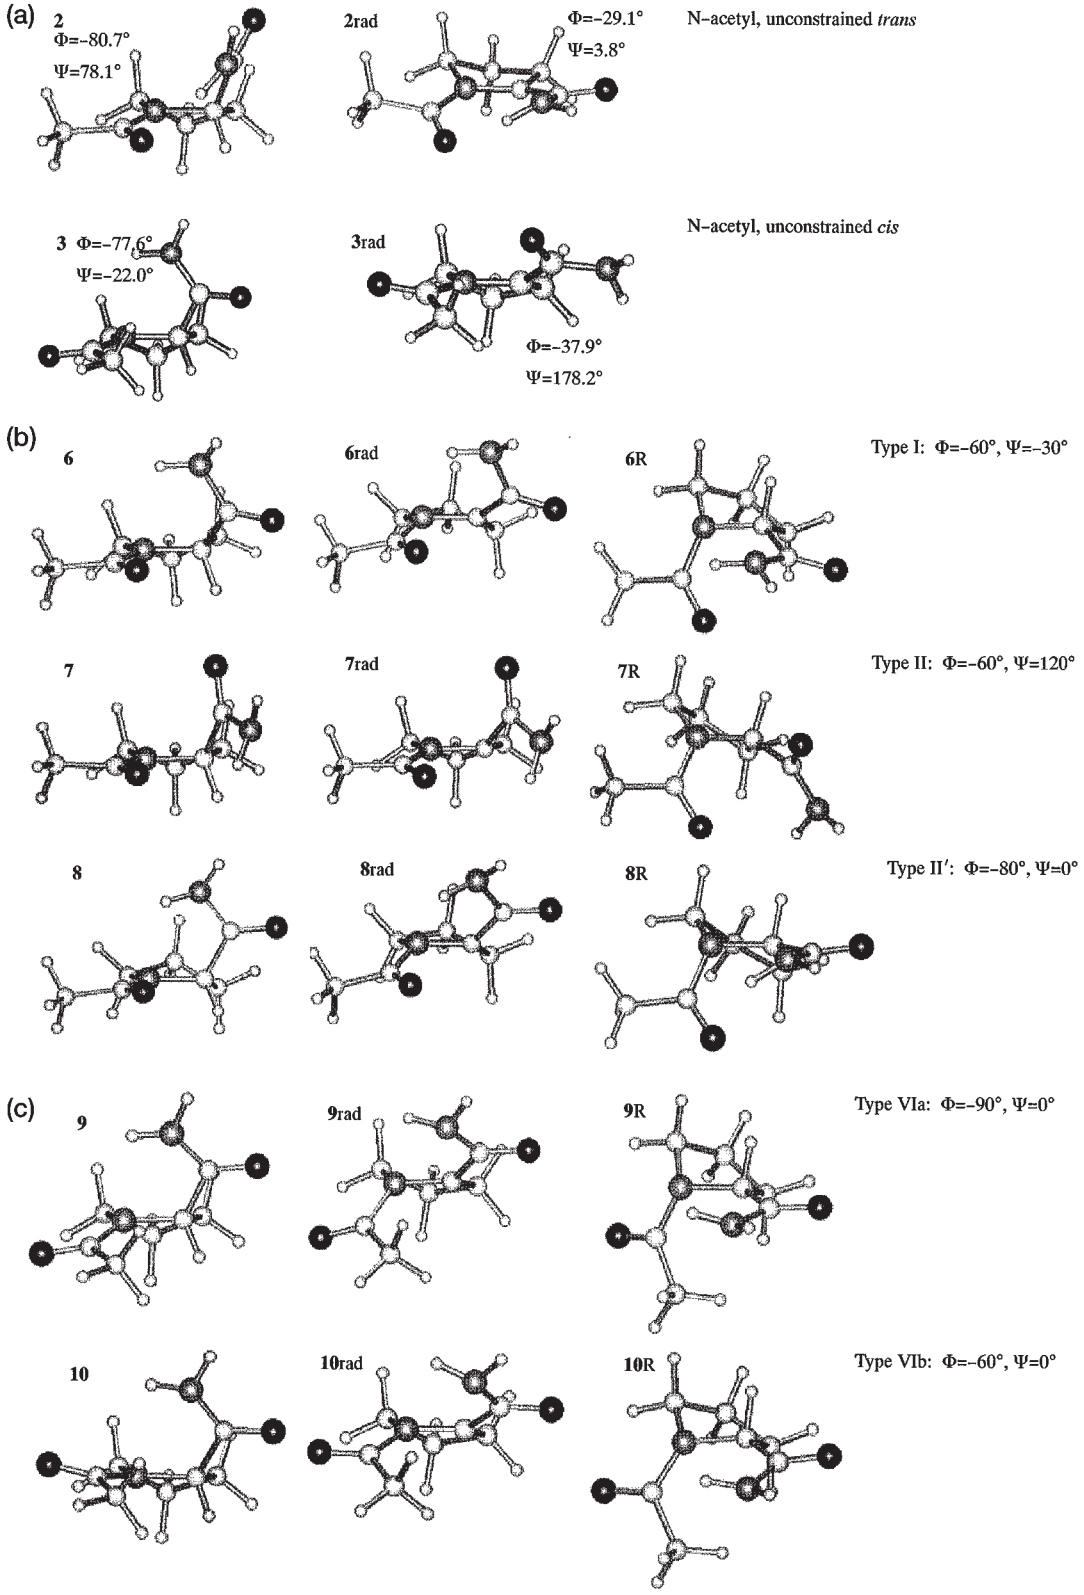
Fig. 4. B3LYP/6-31G(D)-optimized structures of the parent molecule, the $^{\alpha}$C-radical, and the unnatural (R) isomer of the proline conformers in Table 3. The view selected is edge-on to the proline's five-membered ring, which allows one to see the variations in the orientations of the backbone amide groups with respect to changes in the $^{\alpha}$C—H bond. Also shown is the *N*-formyl *cis* unconstrained conformer and its $^{\alpha}$C-radical.



© 1998 NRC Canada

steric hindrance manifests itself primarily in the parent system — the optimized *trans* conformer **2** is 18.9 kJ mol^{-1} more stable than the *cis* conformer **3**, while the difference in the respective radicals is 8.0 kJ mol^{-1}.

The high $^{\alpha}$C—H BDEs are significant because they are close to the BDE of an alkyl sulfhydryl bond, 370 kJ mol^{-1}, as occurs in cysteine, cysteine residues (22), or glutathione (GSH) (23). $^{\alpha}$C—H bonds that are weaker than 370 kJ mol^{-1} are liable to be damaged by thiyl radicals, such as GS$^{\bullet}$, or conversely, the corresponding $^{\alpha}$C-centered radicals would not be repairable by, for example, GSH.

The constraints imposed by secondary structure on this system prevent any of the α-carbon radicals from achieving planarity, and cause a concomitant rise in BDE. Other than β turn type VIb (**10**), all of the constrained systems have BDEs higher than 370 kJ mol^{-1}. This indicates that the sulfur radical of glutathione, GS$^{\bullet}$, is not able to abstract hydrogens from the α-carbon of proline, and glutathione would be able to repair damage at this site. Given proline's position at the "hinge" of turns, the loss of a proline residue's $^{\alpha}$C—H bond may be expected to result in the destruction of the protein's tertiary structure and therefore its function. The high $^{\alpha}$C—H BDEs confer some protection against weaker oxidizing species such as thiyl radicals, ROO$^{\bullet}$, or superoxide ($O_2^{\bullet-}$).

The $^{\alpha}$C—H BDE of proline residues in the type II β turn (**7**) is higher than the corresponding BDE of proline in type I turns (**6**). The natural type II conformation is lower in energy, and the type II radical higher in energy, than the type I equivalents. The difference is in the rotation of the C-terminal amide group: the type II conformation does not allow the α-carbon radical to link its π orbitals with those of the amide system, which are perpendicular to it. The type I system allows some limited mixing of the π systems, which accounts for the lower BDE.

The BDE of proline residues in type II′ turns (**8**) is similar to that of residues in type I turns. This is to be expected, as their structures differ by only 20° and 30° at the Φ and Ψ angles, respectively. The molecule's attempt at planarity is blocked by the angle constraints, but the α-carbon and the nitrogen are each individually almost planar. Because proline residues in the first turn of an α-helix will have similar structural constraints, these results can be also applied to proline in that environment. Proline residues in an α-helix are thus protected against GS$^{\bullet}$ attack.

Turn types VIa (**9**) and VIb (**10**) are similar, and have similar BDEs for proline residues. Type VIb (**10**) has, as mentioned previously, the weakest $^{\alpha}$C—H bond among the constrained systems. It appears that the α-carbon is able to achieve planarity in these systems, at the expense of the planarity of the neighbouring nitrogen. This means that the amide system including the proline nitrogen is unable to delocalize electrons, but the amide system on the other side is able to delocalize electrons all the way to the radical centre. This strategy appears to be the most successful in stabilizing the radical.

It is evident from Table 3 that the BDEs of the unnatural *(R)* isomers are much lower than those of the natural *(S)* isomers. Loss of the hydrogen from the *(S)* isomer does not induce much change in conformation outside of the α-carbon. Addition of a hydrogen to the radical on the pro-*R* face of the α-carbon forces the proline ring to pucker the opposite way, leading to a higher energy conformation. Thermodynamics will thus favor formation of the natural (*S*) isomers, when prolyl radical residues are repaired by hydrogen transfer agents such as glutathione.

C—H bonds of the proline ring

We have not explicitly examined the BDEs of the remaining six C—H bonds of the proline ring. The two C—H bonds that are adjacent to the N atom will have BDEs similar to the corresponding bonds in pyrrolidone, 377 kJ mol^{-1} (24). The remaining four C—H bonds should have BDEs similar to those of cyclopentane, 398 ± 5 kJ mol^{-1} (25). Thus C—H BDEs of the methylene groups of proline are higher than the $^{\alpha}$C—H BDE of unconstrained proline, similar to the highest $^{\alpha}$C—H BDEs among the proline β-turn conformations, and substantially higher than the parent BDEs of the weaker oxidizing radicals, ROO$^{\bullet}$ and RS$^{\bullet}$.

Enzyme-controlled oxidation of the 3- and 4-carbon of the five-membered ring occurs only in collagen and collagen-like proteins. Prolyl 4-hydroxylase selectively and stereospecifically hydroxylates the inactivated carbon β to the nitrogen on the pyrrole ring. The peptide must contain an X-Pro-Gly triplet for the hydroxylation to proceed. The reaction consumes one O_2 and one 2-oxoglutarate, and occurs at an active site containing an Fe^{2+} atom. Prolyl 3-hydroxylase uses a similar active site and set of cosubstrates, but requires a Pro-4-hydroxyproline-Gly triplet. The purpose of 3-hydroxyproline is unknown, but the hydroxyl group of 4-hydroxyproline is important in hydrogen-bonding to other peptide residues in the formation of the unique collagen triple helix (26).

Ascorbate is required to regenerate the Fe^{2+} after an uncoupled decarboxylation of the 2-oxoglutarate. Without ascorbic acid (Vitamin C), the enzyme will decarboxylate a 2-oxoglutarate molecule and be deactivated, leading to collagen without hydroxyproline. This reduces the strength of the collagen helices, leading to scurvy (the breakdown of the body's connective tissues) (26).

Significance for oxidative damage

The most striking result from the present work is that the $^{\alpha}$C—H BDEs of all the natural proline residues in Table 3 are appreciably larger than those of glycine and the residues of the other common amino acids thus far examined. While they are much lower than the O—H BDE of water (499 ± 1 kJ mol^{-1} (25)), and thus still susceptible to oxidative damage by the exothermic hydrogen abstraction reaction, eq. [5],

$$[5] \qquad \mathbf{PH}(\text{res}) + OH^{\bullet} \leftrightarrows {}^{\alpha}\mathbf{P}^{\bullet}(\text{res}) + H_2O$$

the proline $^{\alpha}$C-centres will not be preferred sites of attack by OH$^{\bullet}$; they are less exposed than the C—H bonds on the ring. Nor will they be susceptible to oxidative damage by the weaker oxidants like peroxy (ROO$^{\bullet}$) and thiyl (RS$^{\bullet}$) radicals, which may be present in cellular systems and whose parent precursors have BDEs near 370 kJ mol^{-1} (23, 27). At the same time, the repair reaction, eq. [6],

$$[6] \qquad {}^{\alpha}\mathbf{P}^{\bullet}(\text{res}) + GSH \leftrightarrows \mathbf{PH}(\text{res}) + GS^{\bullet}$$

© 1998 NRC Canada

would be exothermic and they should be repairable by the natural protector glutathione, GSH, which has a BDE of ~370 kJ mol^{-1} (23). As noted above, this repair will give preference to the natural isomer. The only radical potentially not repairable by GSH is the proline β turn type VIb, **10**, which has a relatively low BDE (355 kJ mol^{-1}) near to that of the glycine residue.

Inspection of the β-turn conformation (Fig. 3) indicates that the ring carbons are more exposed to solvent than the α-carbon. The comparable C—H BDEs of the ring carbons indicate that accidental oxidation of these C—H bonds is perhaps more likely than attack at the $^{\alpha}$C—H bond, given the structural constraints of the protein environment. Accidental oxidation of these bonds will create a C-centred radical that could abstract a hydrogen from a nearby carbon, propagating damage into the peptide backbone or onto another amino acid side chain. However, oxidation of the ring carbon is itself not likely to be damaging to a protein's secondary or tertiary structure, or its function.

Conclusions

Proline is vulnerable to oxidative damage at the $^{\alpha}$C—H bond when it is unconstrained; rigid constraints, such as would exist in nature, serve to protect the bond from damage. The degree of planarity at the radical centre seems to be a good visual indicator of the stabilization of the radical; better stabilization indicates a lower BDE and a weaker $^{\alpha}$C—H bond. Proline residues in β turns of type VIb are expected to have sufficiently weak $^{\alpha}$C—H bonds to allow attack by weaker oxidizing agents, like $ROO^{\bullet}$ and thiyl radicals, whereas other turn types should protect the $^{\alpha}$C—H bond from all but the strongest oxidizers.

Damage to the $^{\alpha}$C—H bond of proline may be expected to lead to the degradation of the parent protein. This is a common event for many proteins, but may lead to pathological states if the damaged protein is not removed and replaced quickly. Thus pathology will result if damage occurs in structural proteins such as collagen, which have a high proline content. This long-lasting damage can be seen, for example, in the breakdown of the vitreous humour of the eye during aging (28).

This work extends our investigation of the BDEs of the amino acids in proteins (10–12), both unconstrained and in specific secondary structural environments. These calculations support earlier experimental work (7, 8, 20, 29) and will be crucial in the goal of predicting the site specificity of oxidative damage to proteins.

The preparation, X-ray crystal structure, and spectroscopic characterization of pentafluorophenyl-bis(pentafluorophenylthio)sulfonium hexafluoroarsenate, $[(C_6F_5S)_2SC_6F_5][AsF_6]$

Scott Brownridge, T. Stanley Cameron, Jack Passmore, Gabriele Schatte, and George W. Sutherland

Abstract: Pentafluorophenyl-bis(pentafluorophenylthio)sulfonium hexafluoroarsenate, $[(C_6F_5S)_2SC_6F_5][AsF_6]$, was prepared by the reaction of $(C_6F_5)_2S_2$ and AsF_5 in liquid SO_2 at room temperature. The compound has been characterized by single-crystal X-ray and powder diffraction, and IR and FT-Raman spectroscopy. Crystals of $[(C_6F_5S)_2SC_6F_5][AsF_6]$ are orthorhombic, space group $P2_12_12_1$ (cell dimensions measured at room temperature in brackets): a = 13.132(3) [13.157(2)] Å, b = 21.477(4) [21.575(3)] Å, c = 8.770(2) [8.775(1)] Å, α = ß = γ = 90.00°; V = 2473.3(9) Å^3, Z = 4, temperature = 181 ± 1 K. The structure consists of $[AsF_6]^-$ anions and $[(C_6F_5S)_2SC_6F_5]^+$ cations that have a different structure than the related $[X_2MMMX]^+$ cations (M = S, Se; X = Cl, Br), which contain a trichalcogen chain with a pronounced chalcogen–chalcogen bond alternation. Ab initio calculations suggest the observed $[(C_6F_5S)_2SC_6F_5]^+$ geometry is due to steric and solid state effects. Comparison of the Raman spectra of $[(C_6F_5)S_2SC_6F_5][AsF_6]$, $[Cl_2SSSCl][AsF_6]$, and $[(CH_3)_2ClS_3]^+$ implies that $[(CH_3)_2ClS_3]^+$ has a structure with equal sulfur–sulfur distances, and therefore the structure is likely $[(CH_3S)_2SCl]^+$ and probably not the previously reported $[(CH_3)_2SSSCl]^+$.

Key words: $[R_3X_3]^+$ cations, X-ray crystal structure, FT-Raman spectroscopy, $[(C_6F_5S)_2SC_6F_5]^+$, pentafluorophenyl-bis(pentafluorophenylthio)sulfonium cation, hexafluoroarsenate.

Résumé : On a préparé l'hexafluoroarsénate de pentafluorométhyl-bis(pentafluorophénylthio)sulfonium $[(C_6F_5S)_2SC_6F_5][AsF_6]$ en faisant réagir le $(C_6F_5)_2S$ avec du AsF_5, dans du SO_2 liquide, à la température ambiante. On a caractérisé le composé par son spectre de diffraction des rayons X de poudre et de cristal unique ainsi que par spectroscopies IR et Raman à transformée de Fournier. Les cristaux de $[(C_6F_5S)_2SC_6F_5][AsF_6]$ sont orthorhombiques, groupe d'espace $P2_12_12_1$ (les dimensions cellulaires mesurées à la température ambiante apparaissent entre parenthèses carrées) : a = 13,132(3) [13,157(2)], b = 21,477(4) [21,575(3)] et c = 8,770(2) [8,775(1)] Å, α = β = γ = 90,00°, V = 2473,3(9) Å^3, Z = 4, à une température de 181 ± 1 K. La structure est formée d'anions $[AsF_6]^-$ et de cations $[(C_6F_5S)_2C_6F_5]^+$ dont la structure est différente de celle des cations apparentés $[X_2MMMX]^+$ (M = S, Se; X = Cl, Br) qui contiennent une chaîne de trichalcogène avec une forte alternance de liaison chalcogène–chalcogène. Des calculs ab initio suggèrent que la géométrie observée pour le cation $[(C_6F_5S)_2C_6F_5]^+$ résulte d'effets stériques et d'état solide. Une comparaison des spectres Raman des composés $[(C_6F_5S)_2C_6F_5][AsF_6]$, $[Cl_2SSSCl][AsF_6]$ et $[(CH_3)_2ClS_3]^+$ implique que, dans ce dernier, les distances soufre–soufre sont égales et que, en conséquence, la structure correspond à $[(CH_3S)_2SCl]^+$ plutôt qu'à la structure $[(CH_3)_2ClS_3]^+$ proposée antérieurement.

Mots clés : cations $[R_3X_3]^+$, structure cristalline par diffusion des rayons X, spectroscopie Raman à TF, $[(C_6F_5S)_2C_6F_5]^+$, cation pentafluorométhyl-bis[pentafluorophénylthio]sulfonium, hexafluoroarsénate.

[Traduit par la Rédaction]

Introduction

The $[(MeS)_2SMe]^+$ (Me = CH_3) (1, 2) and $[(PhS)_2SPh]^+$ (3) cations ($[SbCl_6]^-$ or $[BF_4]^-$ salts) are useful electrophilic reagents in organic and pharmaceutical chemistry (4). Their structures, and those of related species, are of interest in the context of sulfur–sulfur bonding, both in simple polysulfur-containing molecules, e.g., neutral sulfur oxides

S_nO (5*a*), sulfur homopolyatomic cations (5*b*), and polysulfur halogen cations (5*c*). The X-ray crystal structures of $[(MeS)_2SMe][A]$ (A = $[SbCl_6^-]$ (1), $[AsF_6]^-$ (2)) show the cations to adopt the configuration **1** with equal S—S bond distances. In contrast, the structures (X-ray) of $[M_3X_3][AsF_6]$ (M = S, Se; X = Cl, Br) contain isomeric $[X_2MMMX]^+$ cations **2** with alternating chalcogen–chalcogen bonds (5*d*–5*g*). In an attempt to understand the factors governing the difference in the geometries of these $[S_3X_3]^+$ cations (X = univalent group) we prepared and determined the X-ray structure of $[(Ph_FS)_2SPh_F][AsF_6]$($Ph_F = C_6H_5$) (with cation geometry **3**), containing the C_6F_5 substituent, which has an electronegativity between those of chlorine and bromine (5*h*) and also has back-bonding capability. The preparation of $[(Ph_FS)_2SPh_F][AsF_6]$ by the reaction of Ph_FSSPh_F and arsenic pentafluoride, the IR and FT-Raman spectra and X-ray crystal structure, and theoretical ab initio (RHF/6-31G*) calculations on isomers of $[S_3H_3]^+$ are reported below.

Experimental

General aspects

General techniques and apparatus are described in ref. 6. All reactions were carried out in a carefully dried one-piece apparatus consisting of two thick-walled round-bottom flasks (V = 25 mL) linked by a glass tube (o.d. 10 mm) incorporating a sintered glass filter disk (medium porosity). Both bulbs were fitted with Pyrex glass valves with PTFE pistons (J. Young, London, U.K.). All apparatus were carefully dried prior to use. Moisture-sensitive materials, crystals suitable for X-ray analysis, and all solid products were manipulated in a Vacuum Atmospheres Dri-Lab using dry nitrogen and equipped with a Dri-Train (HE-493) and an internal circulating drying unit containing 1 kg of 3 Å molecular sieves. Sulfur dioxide (Matheson) was vacuum distilled onto and stored over CaH_2. SO_2ClF (Ozark–Mahoning) was vacuum distilled onto and stored over molecular sieves. AsF_5 (Ozark–Mahoning) was used as received. Sulfur (precipitated; Fisher Scientific) was vacuum dried prior to use. The compound Ph_FSSPh_F was a gift from Dr. M. Peach and was characterized by FT-Raman[3] and IR (7) spectroscopy. Elemental analyses were carried out by Beller Mikroanalytisches Laboratorium, Göttingen, Germany.

Infrared and FT-Raman spectroscopy

Infrared spectra of Nujol mulls of $[(Ph_FS)_2SPh_F][AsF_6]$ between CsI plates were recorded using a Perkin–Elmer model 683 grating spectrometer in the range 4200–200 cm^{-1}. FT-Raman spectra were obtained from neat samples, sealed under nitrogen atmosphere in melting point tubes, using an FT-IR spectrometer (Bruker IFS66) equipped with an FT-Raman accessory (Bruker FRA 106) using a Nd-YAG laser (emission wavelength: 1064 nm; maximum laser power: 300 mW). The data were collected in the backscattering mode (180° excitation; resolution: 4 cm^{-1}) at room temperature in the range 4200–70 cm^{-1}.

Preparation of $[(Ph_FS)_2SPh_F][AsF_6]$ from Ph_FSSPh_F and arsenic pentafluoride (eq. [1])

Sulfur dioxide (7.2 g) and AsF_5 (0.500 g, 2.9 mmol) were successively condensed onto Ph_FSSPh_F (1.33 g, 3.34 mmol) placed into one bulb of a two-bulb reaction vessel. A pale green homogeneous solution was observed immediately on warming the reaction mixture to room temperature. Slow removal of 2/3 of the solvent into the second bulb cooled to 15°C (ΔT = 5°C), filtration of the last portion (ca. 2 mL) of solution, and removal of the volatiles by brief evacuation resulted in large plate-like yellow-orange crystals and small amounts of a noncrystalline green product from the soluble fraction that likely contained the slight excess (0.43 mmol) of Ph_FSSPh_F. The total weight of product was 1.73 g. The estimated weight of product according to eq. [1] with limiting reagent AsF_5, and unreacted Ph_FSSPh_F: 1.70 g. In another experiment, an excess of AsF_5 (1.015 g, 5.97 mmol) was reacted with Ph_FSSPh_F (0.771g, 1.93 mmol) in AsF_3 (10.9275 g) to give $[(Ph_FS)_2SPh_F][AsF_6]$ (Raman) (1.628 g, 2.04 mmol, 105% yield based on eq. [1]) containing some AsF_3 (Raman).

The FT-Raman spectra of crystalline $[(Ph_FS)_2SPh_F][AsF_6]$ and Ph_FSSPh_F[3] are shown in Fig. 1. FT-Raman of $[(Ph_FS)_2SPh_F][AsF_6]$, ν cm^{-1} (peak height): 1644 (100), 1593 (4), 1584 (4), 1526 (4), 1517 (4), 1430 (6), 1421 (53), 1403 (86), 1309 (10), 1298 (42), 1279 (8), 1263 (3), 1162 (3), 1109 (sh, 5), 1099 (8), 869 (77), 861 (58), 680 (21) $[AsF_6]^-$, 640 (6), 639 (sh, 2), 590 (43), 577 (3) $[AsF_6]^-$, 521 (34), 471 (87), 442 (29), 416 (93), 388 (42), 369 (26) $[AsF_6]^-$, 334 (15), 316 (15), 277 (18), 231 (sh, 12), 208 (br, 42), 177 (26), 149 (8), 120 (44), 103 (54). IR of $[(Ph_FS)_2SPh_F][AsF_6]$, ν cm^{-1} : 1638 m, 1513 vs, 1488 vs, 1413 m, 1403 s, 1312 m, 1298 s, 1279 m, 1263 m, 1163 m, 1099 sh, 1095 vs, 1043 w, 1020 m, 980 vs, 865 m, 854 m, 720 s, 695 s $[AsF_6]^-$, 635 sh, 629 m, 590 w, 573 w $[AsF_6]^-$, 518 m, 473 w, 395 m $[AsF_6]^-$, 310 m. The actual spectra have been deposited.[4] Crystals suitable for single-crystal X-ray diffraction were obtained by recrystallization of the yellow-orange crystals (0.68 g) in SO_2–SO_2ClF solution (molar ratio 5:1; 5.36 g SO_2–SO_2ClF). Elemental analysis (found (calcd.) for $[(Ph_FS)_2SPh_F][AsF_6]$): C 27.97 (27.50); S 12.69 (12.23); As 9.30 (9.53); F 49.70 (50.74)}.

X-ray analysis

Crystals of $[(Ph_FS)_2SPh_F][AsF_6]$ were examined, in a Dri-Lab filled with very dry nitrogen, using a Wild M3 microscope of long focal length mounted outside the dry box. A number of crystals were inserted into rigorously dried

hand-drawn Pyrex glass capillaries under dry nitrogen atmosphere and then flame sealed.

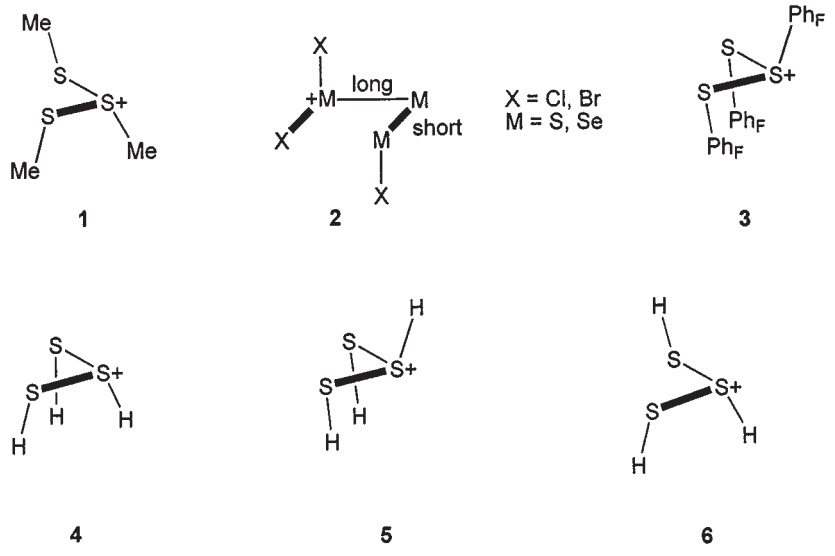
Space group and cell dimensions

The yellow-orange crystals of $[(Ph_FS)_2SPh_F][AsF_6]$ were orthorhombic, space group $P2_12_12_1$ (cell dimensions measured at room temperature in brackets): a = 13.132(3) [13.157(2)] Å, b = 21.477(4) [21.575(3)] Å, c = 8.770(2) [8.775(1)] Å, $\alpha = \beta = \gamma = 90.00°$; V = 2473.3(9) Å^3, Z = 4, and D_{calc} = 2.111 g cm^{-3}. Temperature: 181 ± 1 K. Crystal size: 0.10 × 0.17 × 0.40 mm. Empirical formula: $AsC_{18}F_{21}S_3$. FW = 786.27. $\lambda(MoK_\alpha)$ = 0.71069 Å. $\mu(MoK_\alpha)$ = 17.96 cm^{-1}.

Data collection, structure solution, and refinement

The data for $[(Ph_FS)_2SPh_F][AsF_6]$ were collected on a Rigaku AFC5R diffractometer with graphite monochromated Mo-K_α radiation at a temperature of 181 ± 1 K using ω–2θ scans ($2\theta_{max}$ of 50°). The ω scan width was (0.84 + 0.35 tan θ)° and the ω scan speed was 4° min^{-1}. The weak reflections ($I < 15\sigma(I)$) were rescanned up to a maximum of six scans and the counts were accumulated. Stationary background counts were recorded on each side of the reflection with a peak/background counting time ratio of 2:1.

Cell constants and an orientation matrix for the data collection were obtained from a least-squares refinement using the setting angles of 21 carefully centred reflections in the range 22.13° < 2θ < 30.61°. All of the 2513 reflections collected were unique. The structure was determined by direct methods (8) and the data were corrected for Lorentz and polarization effects and for absorption using the program ψ-scan corrections, which resulted in absorption coefficients ranging from 0.9055 to 1.0000. Over the course of data collection the standards increased by 1.1%; a linear correction factor was applied to the data to account for this phenomenon. The $[AsF_6]^-$ group was disordered, and was refined with all the fluorine atoms having isotropic thermal parameters. Initially these fluorine atoms were restrained to have reasonable As—F distances and F-As-F interbond angles and were subsequently refined, riding on the As position. This $[AsF_6]^-$ was badly disordered and, unless extraordinarily fierce restraints are applied to the As–F distances, they spread over the range 1.68–1.80 Å. It is not clear whether this is an artifact of the disorder or a consequence of the F···F interactions. The three SC_6F_5 were also originally restrained to give a reasonable geometry to the C_6F_5 groups, and they were subsequently refined with the group riding on the sulfur position. The final cycle of full-matrix least-squares refinement was based on 1221 observed reflections ($I > 3\sigma(I)$)



© 1998 NRC Canada

and 257 variable parameters and resulted in the final residuals $R = \Sigma\Delta F^2/\Sigma|F|^2 = 0.058$ and $R_w = \Sigma(w\Delta F)^2/\Sigma w^2|F|^2 = 0.063$. The standard deviation of an observation of unit weight (goodness-of-fit factor) was 1.93. The weighting scheme was based on counting statistics and included a factor ($p = 0.0266$) to downweight the intense reflections. A correction for secondary extinction was not applied. The maximum and minimum peaks in the final difference Fourier map correspond to 0.74 and –0.63 $e^- Å^{-3}$, respectively. All calculations were performed using the teXsan crystallographic software package of Molecular Structure Corporation.[5] Scattering factors for the structure determinations were taken from ref. 9 and effects of anomalous dispersion were included in F_{calc} (10); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (11).

The final atomic coordinates are listed in Table 1. Available as supplementary material are a complete listing of thermal parameters, distances, angles, and the X-ray powder diffraction data.[4]

Theoretical methods

A series of RHF/6–31G* geometry optimizations were carried out on isomers of $[(HS)_2SH]^+$ (**4–6**) using the GAUSSIAN 92/DFT suite of programs (12), with **4** having all H atoms arranged *cis* to each other, and **5** and **6** having the starting geometries of $[(Ph_FS)_2SPh_F]^+$ and $[(MeS)_2SMe]^+$, respectively.

Discussion

Preparation

The yellow salt $[(Ph_FS)_2SPh_F][AsF_6]$ was prepared quantitatively from Ph_FSSPh_F and AsF_5 (in slight deficit or large excess) according to eq. [1].

$$[1] \quad 3\,Ph_FSSPh_F + 3\,AsF_5 \xrightarrow{SO_2(l)} 2[(Ph_FS)_2SPh_F][AsF_6] + AsF_3$$

The identity of $[(Ph_FS)_2SPh_F][AsF_6]$ was supported by elemental analyses of all elements and vibrational spectra (Raman spectra shown in Fig. 1, IR spectra deposited), and confirmed by single-crystal X-ray analysis. The bulk material was shown to be the same as the single crystal by the similarity of the intensities of the observed reflections given in an X-ray powder diffraction photograph with intensities calculated from the single-crystal data (details included in the supplementary material).

The $SbCl_6^-$ salts of related hydrocarbon derivatives have been prepared according to eq. [2]. $[(MeS)_2SMe][AsF_6]$ was obtained in a more complex synthesis (eq. [3]) from $[MeSCl_2][AsF_6]$, which was prepared from MeSCl, Cl_2, and AsF_5 (2).

$$[2] \quad 3\,(RS)_2 + 3\,SbCl_5 \xrightarrow[0\,^\circ C \text{ or } -60\,^\circ C]{CH_2Cl_2 \text{ or } SO_2} [(RS)_2SR][SbCl_6] + SbCl_3$$

(R = Me, Ph, 4-MeC_6H_4, 4-ClC_6H_4, 2,4,6-$Me_3C_6H_2$)

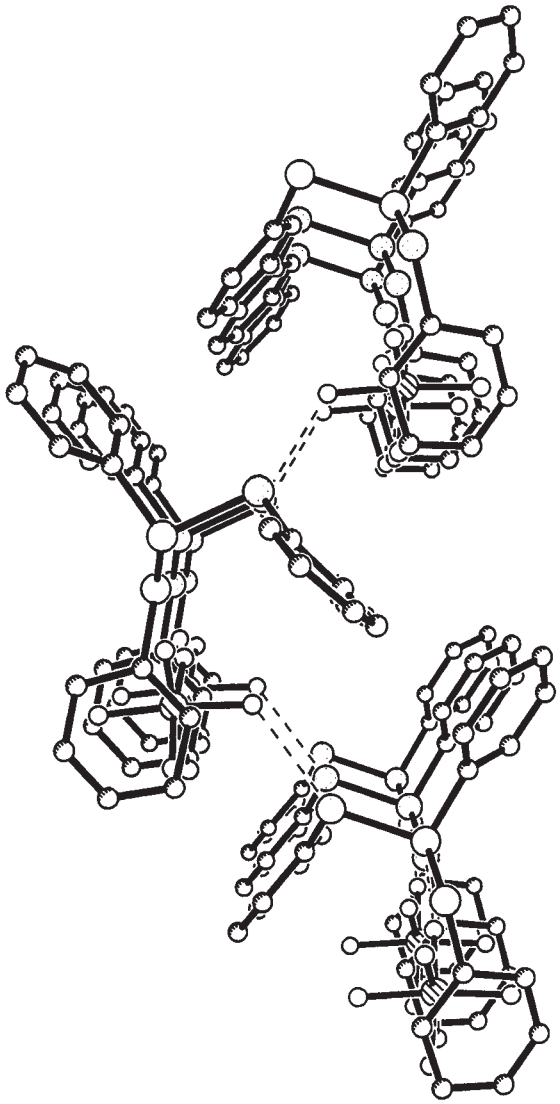
Fig. 2. A PLUTO view of the structure $[(Ph_FS)_2SPh_F][AsF_6]$ including nine $[(Ph_FS)_2SPh_F]^+$ and six $[AsF_6]^-$ (only F(1)–F(6) included). Fluorine atoms attached to carbons have been omitted for clarity.

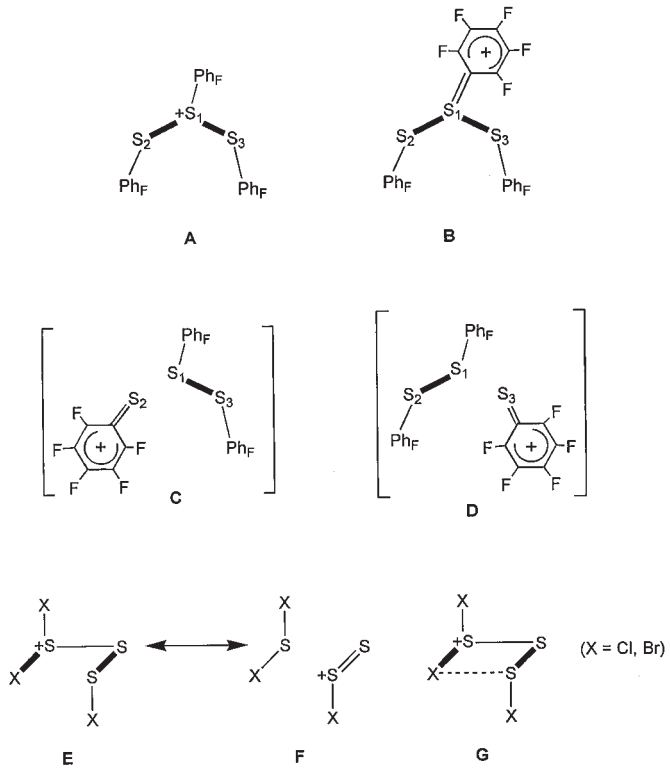


[3] $[MeSCl_2][A] + 2\ (MeS)_2 \xrightarrow[-65°C]{CH_2Cl_2} [(MeS)_2SMe][A] + 2\ MeSCl$

$(A = [AsF_6]^-, [SbCl_6]^-)$

The X-ray crystal structure of $[(Ph_FS)_2SPh_F][AsF_6]$

Figure 2 includes a portion of the crystal structure illustrating the packing and the presence of discrete $[(Ph_FS)_2SPh_F]^+$ cations with stacking of perfluorophenyl rings, $[AsF_6]^-$ anions, and some weak cation–anion contacts (broken lines). The cation and the disordered $[AsF_6]^-$ are illustrated in Fig. 3. Table 2 lists intercation–anion and intracation contacts, and related intraionic angles are given in Table 3. The minor set of four fluorine atoms used to model the observed $[AsF_6]^-$ electron density has not been included in Fig. 2 for clarity.



The bond distances, corresponding bond orders, and angles in the cations $[(Ph_FS)_2SPh_F]^+$ and $[(MeS)_2SMe]^+$, and Ph_FSSPh_F (13) are compared in Table 4, and the geometries of $[(Ph_FS)_2SPh_F]^+$ and $[(MeS)_2SMe]^+$ compared in Fig. 4. The C—F and C—C distances and angles are very similar in all three C_6F_5 rings in $[(Ph_FS)_2SPh_F]^+$, and similar to those in Ph_FSSPh_F (13). To a first-order approximation, the structure of $[(Ph_FS)_2SPh_F]^+$ may be represented by valence bond structure **A**. The S—S bond orders (Table 5) are less than one and longer than in $[(MeS)_2SMe]^+$ and Ph_FSSPh_F, whereas the C—S bond orders are shorter and slighty greater than one. This can be accounted for by some contribution of the resonance structures **B, C,** and **D** as well as **A**, with positive charge delocalization into the C_6F_5 ring. Consistently, there are several weak C···F interionic contacts that are less than the sum of the anisotropic van der Waals radii[6] (see Table 2). Alternatively, polarization of positive charge from tricoordinate S(1) to dicoordinate S(2) and S(3), rendering all sulfur atoms positively charged, and delocalization of electron density from the C_6F_5 ring into the S—S antibonding orbitals leads to the observed C—S bond strengthening and S—S bond weakening. Interestingly, there is only one S···F interionic contact to S(1) (see Table 2) which is formally positively charged, (S(1)···F(1*a*), 3.29(2) Å (0.06 v.u.)), whereas there are stronger contacts to formally neutral S(2) and S(3): (S(2)···F(6*b*), 2.92(3) Å (0.09 v.u.); S(2)···F(20*d*), 3.19(2) Å (0.06 v.u.); S(2)···F(24*a*), 3.26(3) Å (0.06 v.u.); S(3)···F(4*c*), 2.99(2) Å (0.08 v.u.)).

[6] Sum of the van der Waals radii: C···F, 3.17 Å; S···F, 3.27 Å (see ref. 14).

C(5)···F(2)	3.05(3)	C(10)···F(10*b*)	3.07(3)	C(18)···F(5*c*)	3.11(3)
C(5)···F(22)	2.85(4)	C(10)···F(25*b*)	3.15(4)	C(18)···F(24*b*)	3.04(4)

[a] Includes all interionic contacts less than the sum of the isotropic van der Waals radii for S···F ≤ 3.27 Å and C···F ≤ 3.17 Å; van der Waals radii: C, 1.70 Å; F, 1.47 Å; S, 1.80 Å (14).

[b] The letters *a*, *b*, *c*, and *d* indicate symmetry equivalent atoms: *a*, 1.5 – *x*, 1.0 – *y*, –0.5 + *z*; *b*, 1.5 – *x*, 1.0 – *y*, 0.5 – *z*; *c*, 1.0 – *x*, –0.5 + *y*, 0.5 – *z*; *d*, *x*, *y*, –1 + *z*.

Intracationic S—F contacts are similar to all three sulfur atoms. The relative strength of these contacts supports the view that all three sulfur atoms are positively charged. The cation–anion contacts are slightly stronger than those in monoclinic $[(MeS)_2SMe][AsF_6]$ (S(1)···F(6*i*), 3.137 Å (0.07 v.u.); S(2)···F(6*c*), 3.244 Å (0.06 v.u.); S(3)···F(1*j*), 3.061 Å (0.07 v.u.); see ref. 2).[7]

The average As—F distance (1.68 Å) in the $[AsF_6]^-$ anions of the $[(Ph_FS)_2SPh_F][AsF_6]$ salt is slightly shorter than the one in $KAsF_6$ (1.719(3) Å (16)), likely reflecting greater cation–anion contacts in the potassium salt.

A comparison of the geometries of $[(Ph_FS)_2SPh_F]^+$ and $[(MeS)_2SMe]^+$

The geometries of $[(Ph_FS)_2SPh_F]^+$ and $[(MeS)_2SMe]^+$ are not identical and are compared in Fig. 4. The

[7] It has been shown that the strength of the S(IV)···F contacts can be assessed by the relative magnitude of the bond valences (*S*) in valency units (v.u.) and is directly correlated to the localization of positive charge. An increase of positive charge on an atom leads to an increase in the sum of bond valences around the atom and this is accompanied by the formation of additional bonds and contacts (interionic and (or) intracationic) equal to the charge on the atom. The bond valence *S* in valence units (v.u.) is given by: $S = (R/R_0)^{-N}$, where *R* is the observed bond distance (Å), R_0 = 1.55 Å, and N = 3.8 (see ref. 15).

[a] Bond orders were estimated using a variation of Pauling's bond distance – bond order relationship (22*a*), $D(n') = D_1 - b \log n'$, where n' is the bond order, $D(n')$ is the observed bond length, D_1 is the single bond distance, and b is a constant. Carbon–sulfur bond orders were estimated using the relationship $D(n') = D_1 - 0.71 \log n'$, where $D_1 = 1.82$ Å is the length of a C—S single bond with an sp^3 hybridized carbon, and $D_1 = 1.78$ Å for an sp^2 hybridized carbon (22*b*). Similarly, sulfur–hydrogen bond orders were estimated using the relationship $D(n') = 1.34 - 0.71 \log n'$, where 1.34 Å is the length of a S—H single bond (22*b*). Sulfur–sulfur bond orders were estimated using the relationship $D(n') = 2.05 - 0.526 \log n'$, given in ref. 23.

[c] Atom labelling is for $[(Ph_FS)_2SPh_F][AsF_6]$.

orientation of perfluorophenyl groups to S(1)—S(2) and S(1)—S(3) are *trans* and face to face with an angle of 60.1° (best planes through the carbon atoms of each ring attached to S(2) and S(3)), whereas those of the methyl groups are *cis* to S(1)—S(3) and *trans* to S(1)—S(2). There are three possible isomers (**4–6**) for $[(HS)_2SH]^+$ with $3p^2$ lone pairs on the terminal dicoordinate sulfur atoms approximately in the S(3)S(1)S(2) plane, with **5** having the structure of $[(Ph_FS)_2SPh_F]^+$ and **6** the structure of $[(MeS)_2SMe]^+$. The $3p^2$ lone pairs perpendicular to the S(3)S(1)S(2) plane will have high repulsion with the S(1)—X substituent (17) as well as any S(1) sp^3 lone pair if it has any existence, therefore isomers including them have been omitted. The optimized geometries and electronic energies of **4–6** (**5** and **6** included in Table 4) were calculated by ab initio methods using the GAUSSIAN 92/DFT suite of programs at the

[a] See footnote *a* of Table 4 for definition of bond order.
[b] As $[AsF_6]^-$ salt.
[c] The C–S stretching vibration is hidden underneath the stretching vibration of the $[AsF_6]^-$ anion in $[(MeS)_2SMe][AsF_6]$, so the values for the $SbCl_6^-$ salt are given. The frequencies for the S–S stretching vibration are observed at 501 and 455 cm^{-1} for the $[AsF_6]^-$ salt (see ref. 2*a*.

RHF/6–31G* level (12). In each case, the optimization led to a stationary point geometry. The energies of all isomers were similar (**6** and **4** were 2.1 and 9.3 kJ/mol higher in energy than **5**, respectively), suggesting steric and solid state effects (e.g., inter- and intraionic contacts, maximization of dipolar and van der Waals interactions, and the electrostatic[8] and repulsion components of the lattice energies) determine the relative energies of the isomers of $[(Ph_FS)_2SPh_F]^+$ and $[(MeS)_2SMe]^+$.

[8] The geometry of the dithionite anion was similarly shown to be very dependent on the electrostatic environment (18).

The structure of $[(Ph_FS)_2SPh_F]^+$ as an aid to an understanding of the structure of the $[X_2MMMX]^+$ cations (refs. 5*d*–5*g*)

The overall geometry of $[(Ph_FS)_2SPh_F]^+$ is symmetrical with essentially equal sulfur–sulfur bond distances, similar to that of $[(MeS)_2SMe]^+$ and dissimilar to the $[X_2MMMX]^+$ cations (M = S, Se; X = Cl, Br) (5*d*–5*g*). We have proposed that the $[X_2MMMX]^+$ cations (M = S, Se; X = Cl, Br) and related cations (5*b*, 5*c*) are stabilized by M—M bond alternation and charge delocalization (as shown for the $[X_2MMMX]^+$ cations in **E** and **F**), as well as intracationic and intercationic M···X contacts (**G**). Replacement of X (X = Cl, Br) by C_6F_5, with a similar electronegativity to Cl and Br (5*h*), allows the stabilization of the cation by bond alternation (i.e., **E** and **F**) and back-donation accompanied by further positive charge delocalization, but inter- and intracationic X···M contacts would not be possible (e.g., as in **G**). This supports the view that inter- and intracation X···M contacts are an important factor in determining the geometry of the $[X_2MMMX]^+$ (M = S, Se; X = Cl, Br) and related cations (5*b*, 5*c*, 19) in the solid state (5g).

The vibrational spectrum of $[(Ph_FS)_2SPh_F][AsF_6]$, and implications of the Raman spectra of $[(Ph_FS)_2SPh_F]^+$ and related cations for the structure of $[Me_2ClS_3]^+$ (ref. 20)

The IR and FT-Raman spectra of $[(Ph_FS)_2SPh_F][AsF_6]$ (see Fig. 1) contain bands attributable to the $[AsF_6]^-$ anion as well as to the Ph_FS group and the S_3 chain of the cation. The bands at 471 and 416 cm^{-1} in the FT-Raman spectrum were assigned to the asymmetric and symmetric SS stretching vibrations by comparison with the stretching vibrations for related species and those calculated for **5** and **6** (see Table 5). Similarly, the bands at 869 and 861 cm^{-1} were assigned to the asymmetric and symmetric CS vibrations (Table 5). The wide range of observed CS vibrations is attributed to the electronic effects of different substituents (21).

The Raman spectrum of $[Me_2ClS_3][SbF_6]$ has been reported (20) but not the X-ray structure. The S–S stretching vibrations are reported at 456(29) and 435(100) cm^{-1}. These frequencies are similar to those of the S–S stretches found for $[(MeS)_2SMe][AsF_6]$, $[(Ph_FS)_2SPh_F][AsF_6]$, and other related symmetrical S_3-containing cations (Table 5), but very different from the S–S stretches (223(100), 614(7, br) cm^{-1}) observed (5*e*, 5*g*) in the asymmetric $[Cl_2SSSCl]^+$. This implies that $[Me_2ClS_3]^+$ has a structure with equal sulfur–sulfur distances, and therefore the structure is likely $[(MeS)_2SCl]^+$ and probably not $[Me_2SSSCl]^+$ as previously suggested (20).

Crystal structure of the spirophosphorane $(OCMe_2C(O)O)_2PH$

Craig D. Montgomery, Steven J. Rettig, and Bryn Shurmer

Abstract: The crystal structure of the spirobicyclic phosphorane $(OCMe_2C(O)O)_2PH$, **1**, has been determined. Crystals of $C_8H_{13}O_6P$, **1**, are orthorhombic, a = 10.515(2), b = 10.623(2), c = 20.552(2) Å, Z = 8, space group $Pca2_1$. The structure was solved by direct methods and refined by full-matrix least-squares procedures to R = 0.037 (R_w = 0.033) for 1616 reflections with $I > 3\sigma(I)$. The structure consists of two independent molecules each displaying a distorted trigonal bipyramidal geometry; the distortion follows closely the Berry pseudorotation coordinate.

Key words: crystal structure, phosphorane, Berry pseudorotation, trigonal bipyramid.

Résumé : On a déterminé la structure cristalline du phosphorane spirobicyclique $(OCMe_2C(O)O)_2PH$, **1**. Les cristaux de $C_8H_{13}O_6P$, **1**, sont orthorhombiques, groupe d'espace $Pca2_1$, avec a = 10,515(2), b = 10,623(2) et c = 20,552(2) Å et Z = 8. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,037 (R_w = 0,033) pour 1616 réflexions avec $I > 3\sigma(I)$. La structure est formée de deux molécules indépendantes que présentent chacune une géométrie trigonale bipyramidale déformée; la déformation suit d'assez près la coordonnée de pseudorotation de Berry.

Mots clés : structure cristalline, phosphorane, pseudorotation de Berry, bipyramide trigonale.

[Traduit par la rédaction]

Introduction

Koenig et al. (1) have shown that a number of spirobicyclic hydrophosphoranes, including $(OCMe_2C(O)O)_2PH$, **1**, could be prepared by reaction of PCl_3 with the appropriate α-hydroxycarboxylic acid in the presence of NEt_3, eq. [1].

[1] 
1

We have chosen compound **1** as a starting material in the synthesis of metallophosphoranes $L_nM\text{-}PR_5$, as shown in eq. [2] (2). In this study, we report the X-ray crystal structure of the starting material **1**.

[2] 
1

In addition, interest has been shown recently in the application of phosphoranes in the Wittig reaction (3, 4); compound **1** may be useful as an entry point into this chemistry. For this reason also, knowledge of the stereochemistry of **1** is desirable.

Experimental

General

All manipulations were performed under prepurified nitrogen in a Vacuum Atmospheres HE 553–2 glovebox equipped with a MO-40 2H purifier or in standard Schlenk type glassware.

Solvents were dried by refluxing first over calcium hydride and then over sodium benzophenone followed by distillation under Ar. Deuterated benzene was purchased from Aldrich Chemicals and dried over 4 Å molecular sieves and vacuum-transferred prior to use.

The compound $(OCMe_2C(O)O)_2PH$, **1**, was prepared by literature method (1).

The ^1H NMR spectra were recorded on a Bruker WH-400 (400 MHz). The $^{31}P\{^1H\}$ NMR were recorded on a Varian XL-300 (121.42 MHz) and were referenced to external $P(OMe)_3$, set to +141.0 ppm relative to 85% H_3PO_4.

X-ray crystal structure determination of 1

Crystals suitable for X-ray crystallography were obtained by recrystallization in toluene. Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 35.0–62.8°. The intensities of three standard reflections, measured every 200 reflections throughout the data collection, showed only small random fluctuations. The data were processed (5), corrected for Lorentz and polarization effects, and absorption (based on azimuthal scans).

The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. The asymmetric unit contains two independent molecules, related by a pseudo-inversion centre. As a result, the *E*-statistics are centrosymmetric. The structure cannot be refined in the centrosymmetric space group *Pbcm* because the pseudocentre in $Pca2_1$ is not correctly located in the *xy* plane for conversion to the higher symmetry space group. All non-hydrogen atoms were refined with anisotropic thermal parameters. The P-H hydrogen atoms were refined

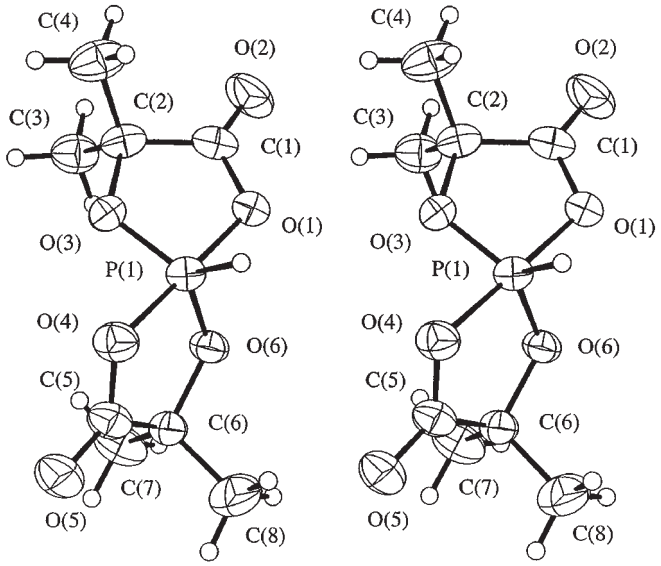
isotropically, and the remaining hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and B_H = 1.2 $B_{\text{bonded atom}}$. A correction for secondary extinction was applied (Zachariasen type, isotropic, Gaussian), the final value of the extinction coefficient being 2.04(6) × 10^{-6}. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (6). A parallel refinement of the opposite polarity gave slightly higher residuals, the R and R_w factor ratios being 1.017 and 1.010, respectively. Refinement of the Flack parameter (final value 0.046(6)) indicates that the polarity is correct, and the crystal is not a racemic twin. Final atomic coordinates and equivalent isotropic thermal parameters, selected bond lengths, and selected bond angles appear in Tables 2–4, respectively. Other tabulated data have been deposited.[2]

Results and discussion

In this study, **1** was first characterized by ^{1}H and ^{31}P{^{1}H} NMR. The ^{31}P{^{1}H} NMR spectrum is identical to that reported by Koenig et al. (1) with one singlet appearing at –53.4 ppm. In addition we report that the ^{1}H NMR spectrum displays a doublet at 6.85 ppm (^1J(H,P) = 915 Hz), which is comparable to that reported by Koenig et al. (7). However Koenig et al. reported a singlet at 1.2 ppm due to the methyl protons whereas we found two closely spaced singlets at 1.07 and 1.08 ppm. This observation is consistent with the different chemical environments of the methyl groups.

Bond lengths and angles for the two crystallographically independent molecules of **1** (one of which is shown in Fig. 1) are not significantly different. The two independent molecules have opposite chiralities, and the mirror images of both are also present in the crystal lattice as a result of the glide planes. The chiral nature of **1** enhances its value as a ligand.

Fig. 1. Stereoview of one of the two crystallographically independent molecules of **1**; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.



Both molecules display a distorted trigonal bipyramidal geometry (TBP) about the phosphorus atoms with the more strongly electron-withdrawing acyloxy groups occupying the axial positions. The distortion from an idealized TBP towards a rectangular pyramid (RP), as measured by the method of Holmes & Deiters (8) is l8.6% for molecule 1 (with P1) and 26.2% for molecule 2 (with P2). However this decreases to 7.3% and 4.3%, respectively, when unit bond lengths are used, suggesting that there is little angular distortion. This is true in spite of the presence of three of the five factors that Holmes has listed as favouring distortion towards a rectangular pyramid in cyclic phosphoranes: the presence of two rings as opposed to one, the presence of like atoms bonded to the phosphorus in any one ring and an

[2] Supplementary materials include a complete table of crystallographic data, complete tables of bond distances and bond angles, tables of hydrogen atom parameters, anisotropic thermal parameters, bond lengths involving hydrogen atoms, bond angles involving hydrogen atoms, torsion angles, intermolecular contacts, and least-squares planes. Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2. With the exception of anisotropic parameters, torsion angles, and least-squares planes, these data have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

acyclic, electropositive, sterically demanding fifth substituent in a spirobicyclic compound, all of which are present in **1**. However Holmes also stresses the importance of steric bulk in this last factor before it becomes operative and this is confirmed by the structure of **1**.

That the nature of the distortion is via the Berry pseudorotation mechanism is confirmed by the fact that the percentage distortions from an RP towards a TBP (when unit bond lengths are used) are 98.2% and 97.4%, respectively. Thus when the percentage distortions of **1** in each direction are added together, the sum is close to 100% (105.5% and 101.7%, respectively). Furthermore the equatorial O-P-O angles are greater than 120° (121.4(3)° and 121.2(3)°, respectively).

While crystal structures are known for a number of other hydrophosphoranes (see ref. 9 for examples), $(C_6H_4O_2)_2PH$ is the only one which, like **1**, is a tetraoxohydrophosphorane (10). Like **1**, $(C_6H_4O_2)_2PH$ also exhibits a near ideal TBP geometry with the hydrogen in an equatorial position. The work reported here on compound **1** further extends this class of structures.

Conclusions

The crystal structure of $(OCMe_2C(O)O)_2PH$ displays a distorted trigonal bipyramidal geometry with the acyloxy groups in the axial positions. The small amount of distortion from an idealized TBP structure follows the Berry pseudorotation coordinate towards a rectangular pyramidal geometry.

Decomposition of peracetic acid catalyzed by cobalt(II) and vanadium(V)

X.-Z. Zhang, R.C. Francis, D.B. Dutton, and R.T. Hill

Abstract: Peracetic acid (Pa) is now being used for totally chlorine-free delignification and bleaching of wood pulps. During the process, metals desorb from the pulp fibers into the aqueous solution. Of the relevant metals in bleaching systems, cobalt(II) and vanadium(V) are the most potent in wastefully decomposing Pa to O_2. In the present study, radical scavenging by *N*,*N*′-(5-nitro-1,3-phenylene)-bisglutaramide (GAMID) indicates that free-radical mechanisms are operative. Kinetic data support a free-radical decomposition mechanism previously described for Co(II). A similar type of mechanism, involving $VO(OH)_{2(aq)}$ and $VO(OH)_{3(aq)}$, is postulated to partially explain catalysis by vanadium.

Key words: peracetic acid, peroxymonosulfuric acid, transition metals, free radicals, acetoxy radical, peracetoxy radical.

Résumé : L'acide peracétique (aP) est maintenant utilisé pour la délignification et le blanchiment de pulpes de bois en absence totale de chlore. Durant ce processus, les métaux se désorbent des fibres de la pulpe et se retrouvent dans la solution aqueuse. De tous les métaux les plus importants pour les systèmes de blanchiment, le cobalt(II) et le vanadium(V) sont les plus puissants pour la décomposition inutile de l'aP en O_2. Dans le présent travail, des piégeages de radicaux à l'aide de *N*,*N*′-(5-nitro-1,3-phénylène)-bisglutaramide (GAMID) indiquent que des mécanismes radicalaires sont impliqués. Les données cinétiques sont en accord avec le mécanisme de décomposition radicalaire décrit antérieurement pour le Co(II). Pour expliquer la catalyse par le vanadium, on suggère un mécanisme semblable impliquant du $VO(OH)_{2(aq)}$ et $VO(OH)_{3(aq)}$.

Mots clés : acide peracétique, acide peroxymonosulfurique, métaux de transition, radicaux libres, radical acétoxy, radical peracétoxy.

[Traduit par la rédaction]

Introduction

The pulp and paper industry is under great pressure to delignify and bleach kraft pulps without using chlorine-containing chemicals. Peracids, peroxymonosulfuric acid (H_2SO_5), and peracetic acid (CH_3CO_3H) are being investigated as replacement oxidants. European mills are now using peracetic acid in TCF (totally chlorine-free) production runs (1).

The effects of transition metal ions on the decomposition of both peracids have been previously investigated (2–10). The metals that are most relevant to pulp delignification are Mn, Fe, Cu, V, and Co (8, 9). These metals are present in wood that is converted to pulp by high temperature, alkaline extraction of approximately 90% of the original lignin. Delignification and bleaching (whitening) involve the degradation and solubilization of the residual lignin in the fibers. Oxidation of phenolic and alcoholic groups to carboxylic groups followed by alkaline extraction is the usual approach. Peracid delignification is generally conducted in an aqueous slurry (1 kg pulp fibers in 9 L of solution) at an initial pH in the range of 2.0–6.0. Some of the transition metals desorb from the pulp under the mildly acidic conditions.

Under pulp bleaching conditions, cobalt(II) is the only reported active catalyst for HSO_5^- (8), while both cobalt(II) and vanadium(V) are potent catalysts for peracetic acid (Pa) (9). The free-radical mechanism by which Co(II) decomposes H_2SO_5 or HSO_5^- is well established (4–6). However, its role in Pa decomposition has not been fully elucidated (2, 3, 11). As for V species and Pa, the only reference found was one showing VO_3^- to be a highly catalytic anion but no reaction mechanism was postulated (12).

The objective of this research was to investigate the free-radical reactions associated with cobalt(II) and vanadium(V) catalysis of Pa decomposition. Free-radical reactions are particularly important because, in addition to giving rise to wasteful decomposition of Pa to O_2 (which is unreactive in the pH 2–6 range), free radicals cause random chain scission of the cellulose leading to a weaker fiber and ultimately to paper products having lower strength properties.

Fig. 1. First-order plots for peracetic acid decomposition at pH 4.8. Conditions: $[Pa]_0$ = 33 mM, $[Co(II)]_0$ = 3. 4 × 10^{-6} M, $[V(IV)]_0 = [V(V)]_0$ = 2.0 × 10^{-5} M, 60°C.

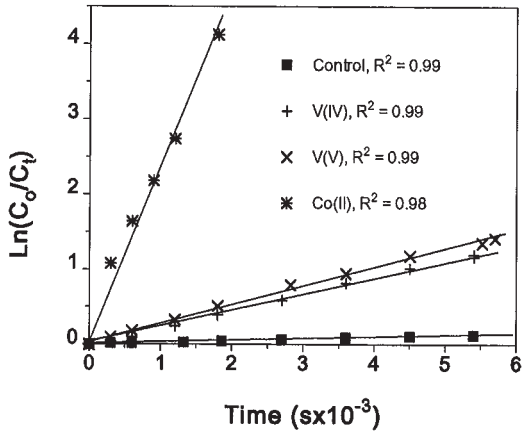

Fig. 2. First-order plots for peracetic acid decomposition at pH 2.4. See Fig. 1 caption for conditions.

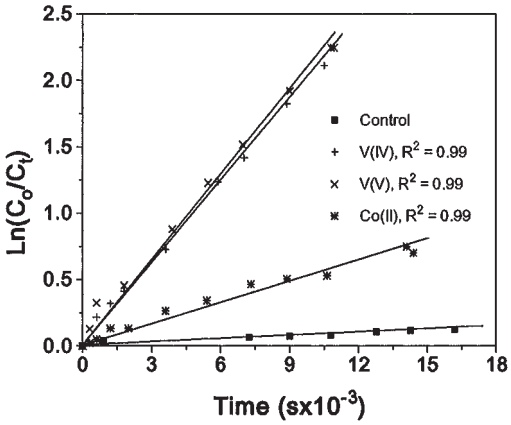

Fig. 3. *N*,*N*′-(5-Nitro-1,3-phenylene)-bisglutaramide, an effective scavenger for hydroxyl and other free radicals.

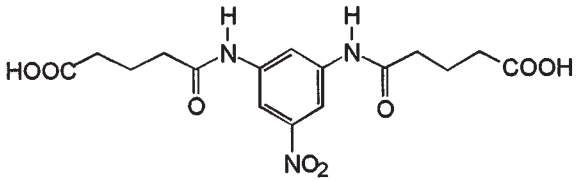

Dilute solutions of the cations were standardized by ICP spectroscopy. Ultrapure NaOH was obtained from Alfa Chemicals. *N*,*N*′-(5-Nitro-1,3-phenylene)-bisglutaramide was synthesized as described by Singh and Hider (13). Equilibrium peracetic acid, that is, peracetic acid formed in the equilibrium reaction shown in eq. [1], was obtained from Aldrich; distilled peracetic acid was obtained following treatment of acetic acid with H_2O_2 (both at ~20 wt.%) in dilute H_2SO_4 solution at ~40°C and ~60 torr (1 torr = 133.3 Pa). Peracetic acid and water are the most volatile products and are distilled off in an apparatus specially designed to avoid peracetic acid concentrations >40 wt.%.

Peracetic acid decomposition

The cations were preheated in acid-washed polyethylene bottles. An aliquot of concentrated Pa was added and a zero-time sample taken after pH adjustment. The pH was continuously monitored and controlled to ±0.1 unit by the addition of one or two drops of concentrated NaOH. When GAMID was used, crystals were added to give an initial concentration of 10 mM just prior to Pa addition. Residual Pa was determined by iodometric titration; while ceric sulfate titration was used to determine H_2O_2. Solutions containing hydroxylated GAMID were made alkaline and diluted 10-fold. Their UV-vis spectra were measured against a solution 1 mM in GAMID and 30 mM in Pa. The water used for all experiments had no transition-metal concentrations higher than 10 ppb.

Gas analysis

The Pa decomposition gases were collected in a Tedlar gas sampling bag. A sample was injected into a GC fitted with two columns in series and equipped with a thermal conductivity detector. The first column was packed with 80–100 mesh Columpak ^{TM}PQ and the second with 60–80 mesh Molecular Sieve 13X. Helium was the carrier gas.

Results and discussion

Peracetic acid is generated by the reaction in eq. [1]. An equilibrium product mixture or a distilled product mixture can be obtained. The latter is used in the paper industry and was used in all of the previous research (9) and in most of the present research.

$$[1] \qquad CH_3COOH + H_2O_2 \xleftrightarrow{H^+} CH_3COOOH + H_2O$$

In the preparation of distilled Pa, dilute solutions of CH_3COOH and H_2O_2 are allowed to react. Water and Pa are the most volatile components and are distilled from the reaction mixture. Equilibrium Pa can be prepared by treating concentrated solutions of CH_3COOH with H_2O_2. A product mixture containing ~34 wt.% Pa and ~5 wt.% H_2O_2 is normally obtained. Experiments conducted with equilibrium Pa are identified.

Catalysis by Co(II)

Research was initiated with Co(II) because free-radical mechanisms were already postulated to explain its catalytic effect (2, 3). Also, this ion catalyzed the depolymerization of cellulose more severely than V species (9). The secondary alcohols in cellulose can be oxidized to carbonyl groups by successive abstraction of hydrogen atoms (14). During alkaline extraction of depolymerized and oxidized lignin, the ketols in the cellulose undergo alkali-induced β-alkoxy elimination reactions causing cleavage of the glycosidic linkages (15).

Koubek and Edwards (2) investigated the decomposition of distilled Pa catalyzed by low concentrations of Co(II) at pH 5.4. They observed that the rate equation was first order in both Pa and Co(II) concentrations and postulated a free-radical mechanism involving acetoxy (AcO·) and peracetoxy (AcOO·) radicals. We observed that at pH 4.8 the rate equation was first order in Pa and approximately first order in Co(II) (an order of 1.1 was actually obtained, results are not included). The precision of the first-order fits (in terms of Pa concentration) is summarized in Figs. 1 and 2 for pH 4.8 and 2.4 with no added catalyst (control), and

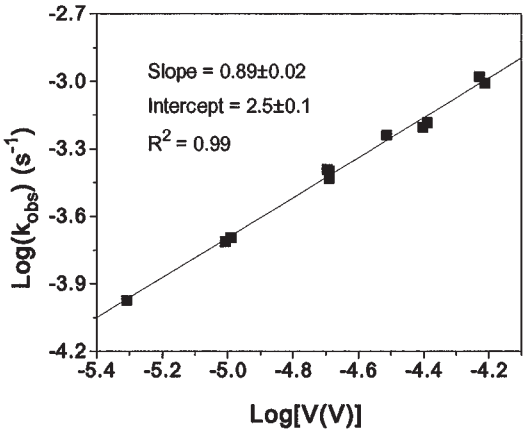
Fig. 4. Log of observed first-order rate constant for Pa decomposition as a function of the log of vanadium(V) concentration. Conditions: $[Pa]_0$ = 33 mM, pH 2.4, 60°C.



with 3.4 × 10^{-6} M Co(II) and 2.0 × 10^{-5} M V(IV) or V(V) solutions. The R^2 value consistenctly exceeded 0.985.

N,*N*′-(5-Nitro-1,3-phenylene)-bisglutaramide (GAMID) (see Fig. 3) was used to test for free radicals. This molecule was specifically designed to scavenge ·OH by ring hydroxylation (13). The resulting phenols are unreactive, and their phenolates can be quantified by UV-vis spectroscopy. We have observed that for a wide range of reaction conditions, GAMID is not degraded by H_2O_2, H_2SO_5, or Pa. It has also been observed that, when it scavenges ·OH, GAMID disrupts the free-radical mechanism with the result that peroxide decomposition is retarded (8, 16). GAMID was chosen because it is effective in scavenging the sulfate radical anion ($SO_4^{\cdot-}$) generated during HSO_5^- decomposition (hydroxylated products are not formed). It has been conclusively demonstrated (4–6) that $SO_4^{\cdot-}$ is generated by HSO_5^- decomposition catalyzed by Co(II) in the pH range 1.0–2.0. When GAMID was added to HSO_5^-–Co(II) reaction systems at a concentration of 1 mM, decomposition rates decreased by ~90% (8). When GAMID was added to the Co(II)–Pa system at 10 mM concentration, the decomposition rate decreased by ~70%, and there was no significant hydroxylation, indicating that ·OH was not involved. The possibility that hydroxylation occurred but that the resulting phenols were then oxidized by Pa was examined. Peracetic acid was added to the HSO_5^-–Cu(II) system, which is known to cause significant hydroxylation of GAMID (16). The result was a slight increase in hydroxylated products as compared to HSO_5^-–Cu(II).

We accepted the conclusion of Edwards (2, 6) and co-workers that eqs. [2] and [3] were key to the generation of free radicals and discontinued research with Co(II).

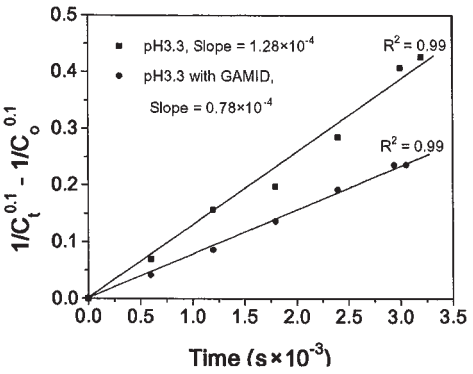
[2] $\quad Co(II) + AcOOH \rightarrow Co(III) + AcO\cdot + OH^-$

[3] $\quad Co(III) + AcOOH \rightarrow Co(II) + AcOO\cdot + H^+$

Catalysis by vandium species

The first experiments with V(IV) and V(V) were conducted at pH 4.8 and 2.4 with the results shown in Figs. 1 and 2. If a free-radical mechanism involving V(IV) and V(V) was operative, it is likely that the rate equation would

Fig. 5. Effect of radical scavenger on the decomposition of peracetic acid catalyzed by V(V). Plotted in accordance with 1.1 order in peracetic acid. Conditions: $[Pa]_0$ = 33 mM, $[V(V)]_0$ = 1.0 × 10^{-5} M, 60°C.



be first order in both [V(V)] and [Pa] (6). The [V(V)] concentration was varied at pH 2.4, and the results reported in Fig. 4 were obtained. The order for [V(V)] was 0.9. For mechanistic purposes the rate equation was assumed to be first order in both [V(V)] and [Pa] (eq. [4]).

$$[4] \qquad -\frac{d[Pa]}{dt} = k[V(V)][Pa]$$

Vanadium species caused less depolymerization of cellulose than Co(II) (9). Therefore, GAMID was used to determine if catalysis by V species was dominated by free-radical reactions. The first-order rate constant (in terms of [Pa], $k_{obs} = k[V(V)]$) was determined with and without GAMID addition at pH 4.8 and in the pH range of 3.0–3.5 ($[V(V)] = 2.0 \times 10^{-5}$ M). Multiple experiments were performed in the pH 3.0–3.5 range because it was difficult to maintain the pH to ±0.1. The decomposition rate was very sensitive to pH, particularly in this range. The control of pH was less tedious at values <2.5 and >4.0. The radical scavenger decreased the rate constant by 30–50% in the pH range of 3.0–3.5 and by ~10% at pH 4.8. It appears that a free-radical mechanism was operative but was not as dominant as in Co(II) catalysis.

The rate of Pa decomposition was found to be proportional to $[V(V)]^{0.9}$. It would then be expected that the reaction order in [Pa] should be slightly more than 1.0, i.e., about 1.1. In some experiments the R^2 values were slightly better for the 1.1 order fit as compared to 1.0. Such was the case for the results in Fig. 5 where the effect of GAMID on vanadium-induced decomposition is demonstrated. It can be seen that the radical scavenger decreased the rate constant (slope) by 39%.

The pH range of 3.0–3.5 was used instead of pH 2.4 to provide increased GAMID solubility. One interesting observation is that the decomposition rate increased in going from pH 4.8 to pH 3.0–3.5 but decreased when the pH was lowered from 3.0–3.5 to 2.4 ($[V(V)] = 2.0 \times 10^{-5}$ M, no GAMID). Several other pH levels were investigated in the 2.0–6.0 range. Also, literature on the variation of vanadium(V) species with pH was reviewed. Vanadium(IV) is known to be rapidly oxidized to V(V) by HSO_5^- (7). It is assumed that the case is similar for Pa solutions and that only V(V) is present at a detectable concentration. Other than the

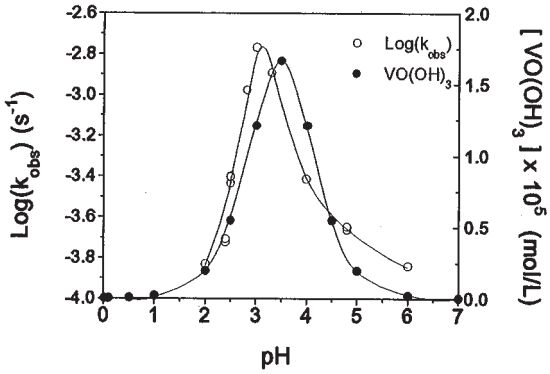
Fig. 6. Variation of $[VO(OH)_3]$ at 25°C and log of observed first-order rate constant for Pa decomposition (60°C) with pH (total $[V(V)] = 2.0 \times 10^{-5}$ M).



experiments in Fig. 4, the highest [V(V)] used was 2.0×10^{-5} M. At these low concentrations, only mononuclear V(V) species are present in solution (17). If the equilibrium relationship in eqs. [5] and [6] (17) are used to calculate the concentrations of VO_2^+, $VO(OH)_{3(aq)}$, and $VO_2(OH)_2^-$ at different pHs, the variation of $[VO(OH)_3]$ is as shown in Fig. 6 (concentration of total V species = 2.0×10^{-5} M). This hydroxide is soluble up to a concentration of 6.3×10^{-5} M (17). The variation of Pa decomposition rate with pH is also shown in Fig. 6. The similarity in the shape of the two curves suggests that $VO(OH)_3$ is the active vanadium(V) species.

[5] $VO_2^+ + 2H_2O \leftrightarrow VO(OH)_{3(aq)} + H^+, \quad \log K = -3.2$

[6] $VO_2^+ + 2H_2O \leftrightarrow VO_2(OH)_2^- + 2H^+, \quad \log K = 7.0$

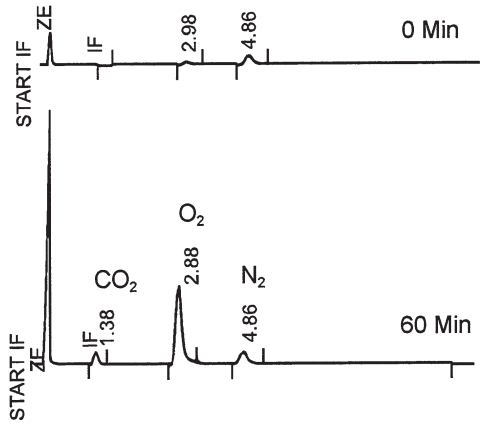
Gas analysis

In alkali- or metal-induced H_2O_2 decomposition, 1 mol of O_2 is generated from every 2 mol of peroxide decomposed. For a wide range of decomposition mechanisms it appears that nearly 1.0 mol of O_2 is generated from 2 mol of HSO_5^- (6). These two peroxides have very few side reactions, and eq. [7] is obeyed. On the other hand, many side reactions have been reported for Pa decomposition catalyzed by Co(II) (2, 3). In one study, the evolution of CO_2 was found equal to that of O_2 (2), and a substantial amount of CH_4 was detected in the other (3). Both publications discussed the possible side reactions (2, 3). Interestingly, the above results conflict with each other and with earlier results showing O_2 to be the only gas generated by Co(II) catalysis (11). However, pH was not controlled in this earlier study (11).

[7] $2ROOH \rightarrow 2ROH + O_2$

It appears that reaction conditions, particularly pH, have a great influence on these side reactions. In a recent investigation on Pa decomposition catalyzed by Mn(II), the gas evolved at pH 8.2 was primarily O_2, and only a negligible amount of CO_2 was detected. However, a significant amount of CO_2 was generated at pH 5 (10). The aim of the present research was not to clarify the situation for Co(II) and Mn(II) but to collect data for V(V) so that a more detailed reaction mechanism could be postulated.

Fig. 7. Gas chromatograms for the analysis of gases from Pa decomposition: 0 min (top) and 60 min (bottom).



An equilibrium Pa solution was used for this experiment. Unconverted acetic acid (eq. [1]) does not affect the rate of V-induced decomposition. Distilled Pa solutions contain only a small amount of acetic acid (~4 wt.%), and when a 1:1, 2:1, or 4:1 mole ratio of acetic acid to Pa was used, the rate of Pa decomposition catalyzed by V(V) was unaffected. The small amount of H_2O_2 in distilled Pa solutions was rapidly decomposed by V species (9). An equilibrium Pa solution containing 49 mM Pa, 17 mM H_2O_2, and 2.0×10^{-5} M V(V) was allowed to decompose at pH 2.5 and 60°C for 40 min. The residual peroxide concentrations were 19 mM Pa and 0.5 mM H_2O_2. The solution was cooled, adjusted to pH 3.0, and poured into a gas bag that was then sealed. The bag was flushed with He at atmospheric pressure without it being inflated. The bag was then placed in a 60°C water bath and the gases analyzed after a given retention time. The bag was appropriately sized so that the final pressure was approximately atmospheric. The experiment was done twice (different degrees of Pa decomposition), and for every 2 mol of Pa decomposed, an average of 0.96 mol of O_2 was detected. The chromatograms corresponding to one of the gas mixtures at 0 and 60 min are shown in Fig. 7. Only a small amount of CO_2 was generated, and CH_4, whose retention time was ~7.2 min, was not detected.

Proposed free-radical mechanism

The following mechanism consists of likely reactions and is consistent with all of the data obtained in the pH 3 range. The rate equation for Pa decomposition was first order in [Pa] and approximately first order (0.9) in [V(V)] at pH 2.4. Based on Pa decomposition catalyzed by 1.0×10^{-5} M and 2.0×10^{-5} M V(V), it was concluded that the rate equation did not change in going from pH 2.4 to ~3.0. Reactions similar to those in eqs. [8]–[10] are frequently observed in peroxide decomposition chemistry (6), and eqs. [11] and [12] are found in the literature for metal-catalyzed decomposition of Pa (2, 3). Equations that support this data have been deposited.[2]

[8] $VO(OH)_{3(aq)} + AcOOH \xrightarrow{k_{1a}} VO(OH)_{2(aq)} + AcOO\cdot + H_2O$

[9] $VO(OH)_{2(aq)} + AcOOH \xrightarrow{k_{1b}} VO(OH)_{3(aq)} + AcO\cdot$

[10] $AcO\cdot + AcOOH \xrightarrow{k_{2a}} AcOH + AcOO\cdot$

[11] $AcOO\cdot + AcOOH \xrightarrow{k_{2b}} AcOH + AcO\cdot + O_2$

[12] $2\ AcOO\cdot \xrightarrow{k_3} O_2 + \text{other products}$

The first reaction (eq. [8]) is the rate-determining step. Using the steady-state approximation for the concentrations of $VO(OH)_2$, AcOO·, and AcO·, the rate law (eq. [24]) for the reaction scheme can be derived as follows.

[13] $$\frac{d[AcOOH]}{dt} = -k_{1a}[VO(OH)_3][AcOOH] - k_{1b}[VO(OH)_2][AcOOH] - k_{2a}[AcO\cdot][AcOOH] - k_{2b}[AcOO\cdot][AcOOH]$$

[14] $$\frac{d[VO(OH)_2]}{dt} = 0 = k_{1a}[VO(OH)_3][AcOOH] - k_{1b}[VO(OH)_2][AcOOH]$$

[15] $$k_{1b}[VO(OH)_2] = k_{1a}[VO(OH)_3]$$

[16] $$\frac{d[AcO\cdot]}{dt} = 0 = k_{1b}[VO(OH)_2][AcOOH] + k_{2b}[AcOO\cdot][AcOOH] - k_{2a}[AcO\cdot][AcOOH]$$

Substitute eq. [15] into eq. [16]:

[17] $$[AcO\cdot] = \frac{k_{1a}[VO(OH)_3] + k_{2b}[AcOO\cdot]}{k_{2a}}$$

[18] $$\frac{d[AcOO\cdot]}{dt} = 0 = k_{1a}[VO(OH)_3][AcOOH] + k_{2a}[AcO\cdot][AcOOH] - k_{2b}[AcOO\cdot][AcOOH] - k_3[AcOO\cdot]^2$$

Substitute eq. [17] into eq. [18]:

[19] $$\frac{d[AcOO\cdot]}{dt} = 0 = k_{1a}[VO(OH)_3][AcOOH] + \frac{k_{2a}}{k_{2a}}(k_{1a}[VO(OH)_3] + k_{2b}[ACOO\cdot])[AcOOH] - k_{2b}[AcOO\cdot][AcOOH] - k_3[AcOO\cdot]^2$$

[20] $$\frac{d[AcOO\cdot]}{dt} = 0 = 2k_{1a}[VO(OH)_3][AcOOH] - k_3[AcOO\cdot]^2$$

[21] $$[AcOO\cdot] = \left(\frac{2k_{1a}}{k_3}[VO(OH)_3][AcOOH]\right)^{1/2}$$

Substitute eq. [21] into eq. [17]:

[22] $$[AcO\cdot] = \frac{k_{1a}}{k_{2a}}[VO(OH)_3] + \frac{k_{2b}}{k_{2a}}\left(\frac{2k_{1a}}{k_3}[VO(OH)_3][AcOOH]\right)^{1/2}$$

Substitute eqs. [15], [21], and [22] into eq. [13]:

[23] $$\frac{d[AcOOH]}{dt} = -k_{1a}[VO(OH)_3][AcOOH] - k_{1a}[VO(OH)_3][AcOOH] - \frac{k_{2a}}{k_{2a}}[k_{1a}[VO(OH)_3][AcOOH]] - \frac{k_{2a}k_{2b}}{k_{2a}}\left(\frac{2k_{1a}}{k_3}[VO(OH)_3][AcOOH]\right)^{1/2}[AcOOH] - k_{2b}\left(\frac{2k_{1a}}{k_3}[VO(OH)_3][AcOOH]\right)^{1/2}[AcOOH]$$

Equation [23] simplifies to:

[24] $$\frac{d[AcOOH]}{dt} = -3k_{1a}[VO(OH)_3][AcOOH] - 2k_{2b}\left(\frac{2k_{1a}}{k_3}[VO(OH)_3]\right)^{1/2}[AcOOH]^{3/2}$$

The second term on the right-hand side (RHS) of eq. [24] is likely to be much less than the first term. Therefore, the theoretical rate law is approximately first order in both [V(V)] and [Pa]. The second term on the RHS of eq. [24] can be approximated at pH 3.3 where the free-radical mechanism is most significant. At a $[VO(OH)_3]$ of ~1.5×10^{-5} M, the first-order rate constant, k_{obs}, is ~1×10^{-3} s^{-1} (Fig. 6). The second-order rate constant, k', for eq. [25] would equal to 5×10^{-4} s^{-1} (one-half of the total rate) divided by 1.5×10^{-5} M or 33.3 M^{-1} s^{-1}. If the second term on the RHS of eq. [24] is assumed to be much less than the first term then $k' = 3k_{1a}$. The rate constant k_3 is reported to be ~1×10^8 M^{-1} s^{-1} (18) so that the term $(2k_{1a}/k_3[VO(OH)_3])^{1/2}$ is equal to ~1.82×10^{-6} $M^{0.5}$. At [AcOOH] of 0.03 M, the term $(2k_{1a}/k_3[VO(OH)_3])^{1/2}[AcOOH]^{1/2}$ would be equal to ~3.15×10^{-7} M, which is lower than $1.5 \times 10^{-5}([VO(OH)_3])$ by a factor of 48. Therefore, the second term on the RHS is significant only if $2k_{2b} > > 3k_{1a}$. Allen and Aguilo (3) proposed eq. [11] only because a similar reaction is known in H_2O_2 chemistry. However, the rate constant for that reaction ($HOO\cdot/H_2O_2$) is <1.0 M^{-1} s^{-1} (19). Acylperoxy radicals are known to be more reactive than HOO· (18), but even if 50 M^{-1} s^{-1} is assumed for k_{2b}, the second term on the RHS would be lower than the first term by a factor of ~16.

[25] $$-\frac{d[AcOOH]}{dt} = k'[VO(OH)_3][AcOOH]$$

If it is assumed that GAMID is efficient at scavenging AcO· and (or) AcOO· then approximately 50% of the decomposition of Pa can be explained by the mechanism

© 1998 NRC Canada

above. Ionic mechanisms have been postulated for H_2O_2 decomposition catalyzed by V(V) (20, 21) and may be responsible for additional decomposition of Pa. Since the rate laws for the proposed free-radical mechanism and total decomposition (eq. [4]) are both first order in [V(V)] and [Pa], it would be expected that the rate law for heterolytic decomposition is similar.

Conclusions

Peracetic acid (Pa) is now being used for totally chlorine-free delignification and bleaching of wood pulps. The Pa stage is normally conducted in the pH range of 2.0–6.0, and some transition metals desorb from the pulp fibers to the aqueous phase.

Of the metals likely to be present in bleaching systems, Co(II) and V(V) are the most potent catalysts for the wasteful decomposition of Pa to O_2. Radical scavenging by *N*,*N*′-(5-nitro-1,3-phenylene)-bisglutaramide (GAMID) indicated that free-radical mechanisms were operative. Kinetic data supported a free-radical mechanism previously published for Co(II). A similar type mechanism, involving $VO(OH)_{2(aq)}$ and $VO(OH)_{3(aq)}$, was postulated to partially explain catalysis by vanadium. The variation of $VO(OH)_3$ concentration with pH (total [V(V)] = 2.0×10^{-5} M) was obtained from the literature (17). The shape of the curve was very similar to that for decomposition rate with pH.

Highly diastereoselective synthesis of 1,2-amino alcohols via nucleophilic addition of organocerium reagents to 4- and 5-oxazolidinonecarbaldehydes

Andrew G.H. Wee and Fuxing Tang

Abstract: The reaction of chiral, non-racemic 4- and 5-oxazolidinonecarbaldehydes, **6** and **13**, with organocerium reagents proceeds efficiently with good to excellent diastereoselectivity to give *syn* and *anti* alcohols, respectively. A model to explain the observed diastereoselectivity of the reaction of **6** and **13** is provided. The utility of this method for the synthesis of amino alcohols is exemplified by the synthesis of C-18-D-*ribo*-phytosphingosine from the *anti* alcohol **14f**.

Key words: oxazolidinonecarbaldehydes, organocerium, diastereoselective, amino alcohols, C-18-*ribo*-phytospingosine.

Résumé : La réaction de réactifs organiques du cérium avec les 4- et 5-oxazolidinonecarbaldéhydes chiraux et non racémiques, **6** et **13**, s'effectuent d'une façon efficace, avec des diastéréosélectivités allant de bonnes à excellentes, et elles conduisent aux alcools *syn* et *anti* respectivement. On propose un modèle pour expliquer la diastéréosélectivité de la réaction des produits **6** et **13**. Comme exemple pour démontrer l'utilité de cette méthode pour la synthèse d'aminoalcools, on propose la synthèse de la C-18-D-*ribo*-phytosphingosine à partir de l'alcool *anti*, **14f**.

Mots clés : oxazolidinonecarbaldéhydes, organocérium, diastéréosélectif, aminoalcools, C-18-*ribo*-phytosphingosine.

[Traduit par la Rédaction]

Introduction

The 1,2-amino alcohol moiety is a common subunit that is found in many naturally occurring and medicinally important compounds such as sphingolipids (1*a*), hydroxylated alkaloids (1*b*, 1*c*), amino acids (1*d*, 1*e*), HIV-enzyme inhibitors (1*f*, 1*g*), and amino sugars (1*h*). As well, chiral auxiliaries (2*a*) and ligands (2*b*) that are widely employed in asymmetric synthesis possess the 1,2-amino alcohol unit as a key structural feature. Much effort has, therefore, been devoted towards developing new strategies (for reviews, see ref. 3) for the synthesis of 1,2-amino alcohols. The most widely used method involves the nucleophilic addition of C-centred nucleophiles to α-amino aldehydes (3*a*, 3*c)* However, some limitations of the method have been noted; for example, the α-amino aldehyde is prone to racemization under the reaction conditions (3*a*, 4). As well, the diastereoselectivity of the nucleophilic addition reaction is usually not as high as expected although, recently, methods (3*c*) have been devised to overcome this problem.

In comparison, the use of 2-oxazolidinones for the synthesis of 1,2-amino alcohols has not been extensively investigated (5). Two aspects that make them attractive synthetic intermediates are (*a*) the 2-oxazolidinone moiety can be considered as a protected amino alcohol synthon, which can be subsequently unmasked to reveal the 1,2-amino alcohol unit, and (*b*) the reactions carried out on oxazolidinone derivatives are usually highly stereoselective (5).

Herein, we report our studies on the nucleophilic addition of organocerium reagents to chiral, non-racemic 4- and 5-oxazolidinonecarbaldehydes (**6** and **13**, respectively) (for a preliminary communication, see ref. 6). The addition was found to proceed with good to excellent diastereoselectivity to give *syn* or *anti* alcohol products in moderate to good chemical yields. We also developed a procedure for the generation and in situ reaction of 4-oxazolidinonecarbaldehyde **6** with organocerium reagents.

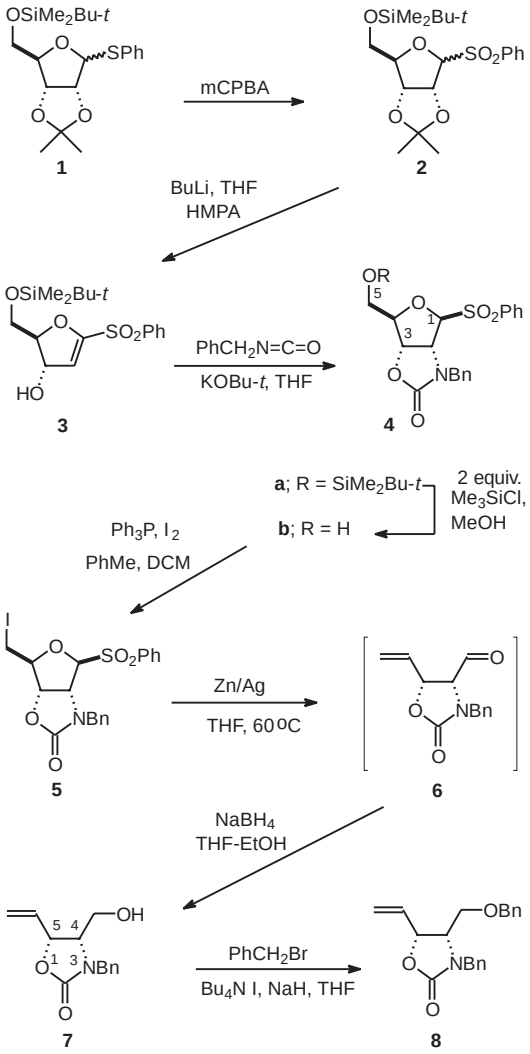
Results and discussion

Preparation of iodophenylsulfone (5) and benzylether (8)

The iodo phenylsulfone **5** serves as a convenient and shelf-stable precursor of the aldehyde **6**. The preparation of **5** is summarized in Scheme 1 and began with the oxidation of the known phenylsulfide **1** (7*a*) (α:β ratio 8.5:1.5 based on integration of H-1) with mCPBA to give a separable mixture of α,β-anomers (8:2)[2,3] of **2**. The slightly light-sensitive **2** were then treated with *n*-butyllithium in the presence of HMPA as a cosolvent to effect 1,2-elimination of a molecule of acetone to give the ene alcohol **3** (for the use of

 © 1998 NRC Canada

Scheme 1.



organosulfones in synthesis, see ref. 8). We found it unnecessary to treat α-**2** and β-**2** separately in this elimination reaction since both anomers lead to the same ene alcohol with no loss in yield. Compound **3** was found to be unstable during storage (~ 3 d) and was utilized immediately in the carbamation step. Base-catalyzed reaction of **3** with benzylisocyanate afforded *cis*-bicycle **4a** as a single diastereomer in good yield.

It was found that the use of KOBu-*t* is essential for efficient carbamation. With NaH as the base only a low yield of the **4a** was obtained; the uncyclized urethane, which had resulted from the nucleophilic addition of only the alcohol unit to the benzylisocyanate, was the major product. A likely explanation for the lack of intramolecular Michael addition is that, with NaH, the phenylsulfonyl-stabilized carbanion (8*b*) intermediate is prone to undergo a retro-Michael reaction. This pathway is absent in the *tert*-butoxide-catalyzed reaction because the phenylsulfone-stabilized carbanion is protonated by the *tert*-butyl alcohol that is present.

Desilylation of **4a** to the primary alcohol **4b** was accomplished using Me_3SiCl in MeOH and was followed by reaction of **4b** with $Ph_3P–I_2$ (9) to give the iodo phenylsulfone **5**.

We were not able to ascertain from the ^{1}H NMR spectra of **4a,b** whether the stereochemistry of the 1-phenylsulfonyl group is α or β because of the overlap of the H-1, H-2, and PhCHN resonances. However, the ^{1}H NMR of **5** was better resolved and showed H-1 as a doublet centred at δ 4.82 with a vicinal coupling constant, $J_{1,2}$, of 1.8 Hz. This small *J* value[3] suggests that the 1-phenylsulfonyl group has the β-configuration. This outcome is unexpected when the conversion of **3** to **4a** is considered and it suggests that the phenylsulfone-stabilized carbanion intermediate that is generated during the intramolecular carbamation reaction is protonated from the more hindered, concave side of the bicycle to give **4a**. It should be noted that protonation from the less hindered, convex side of the bicycle should, in principle, be more favoured; however, this would lead to a sterically congested product wherein the α-phenylsulfonyl moiety is engaged in severe nonbonded interactions with the *syn* oxazolidinone moiety.

The next step was the Zn–Ag[4] (10) mediated reductive elimination of **5** in dry THF at 60°C to afford the olefinic aldehyde **6**. Subsequent reduction of **6** with $NaBH_4$ proceeded uneventfully to give crystalline primary alcohol **7** ($[\alpha]_D^{23}$ –15.2 (*c* 0.98, $CHCl_3$))[5] in high yield. Alcohol **7** was then benzylated to give **8**, which served as the precursor for the 5-oxazolidinonecarbaldehyde **13**.

The formation of **6** deserves some comments. The ^{1}H and ^{13}C NMR spectra of the primary alcohol **7** that is derived from **6** are in accord with the assigned structure. The salient feature in the ^{1}H NMR spectrum is the pseudo triplet due to H-5 that was centred at δ 4.92. It has a $J_{4,5}$ of 7.4 Hz[6] that is characteristic of a *cis* stereochemistry (11). This indicates that no epimerization of the aldehyde to the *trans* diastereomer had occurred under the reaction conditions used in the reductive elimination step.

Formation and reaction of 4-oxazolidinonecarbaldehyde (6) with $RCeCl_2$

It is well documented (3*a*, 4) that amino aldehydes (except for a serine-derived aldehyde (12)) are, in general, unstable and are not amenable to isolation. To avoid potential difficulties associated with the isolation of **6**, we decided to investigate its generation and in situ reaction with the preformed organocerium reagent (13*a*, 13*b*) (hereafter referred to as $RCeCl_2$; the exact speciation of the organocerium reagent is not known. See ref. 13*c*) as depicted in eq. [1]. The

[2] Ratio is based on isolated yields. Decoupling of the H-3 multiplet (δ 4.72–4.81) in α-2 simplified the H-1,H-2 multiplet at δ 5.02–5.10; H-2 collapsed to a singlet at δ 5.9. H-1 was observed as a doublet centred at δ 5.7 and has a $J_{1,2}$ of 3.8 Hz.

[3] Typically, H-1 in the α-anomer shows a $J_{1,2}$ in the range 3.8–4.4 Hz, and in the β-anomer $J_{1,2}$ is in the range of 1.8–2.0 Hz (7).

[4] We have also examined other Zn-based methods such as Zn dust, EtOH; Zn/Cu, THF; and $ZnCl_2–C_8K$, THF. These methods either gave low yields of 6 and a substantial amount of the reduced product or decomposition products.

[5] We have prepared ent-**7** from D-mannose and it has $[\alpha]_D^{23}$ = +14.8 (c 1.01, $CHCl_3$).

[6] Decoupling of the alkene methine multiplet at δ 5.99–6.19 collapsed the H-5 "triplet" to a broad doublet centred at δ 4.92. Typically, J_{trans} = 3.3–4.5 Hz and J_{cis} = 6.2–7.5 Hz (11).

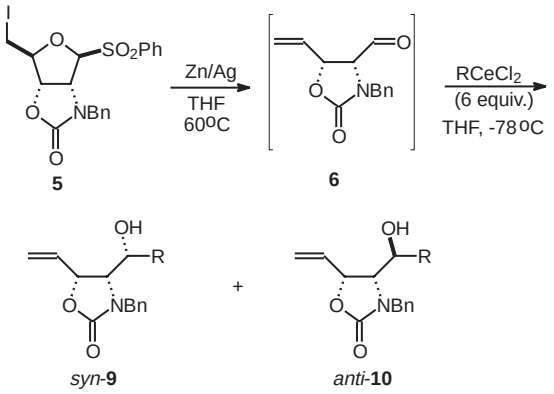
use of dry THF for the reductive elimination step was essential for the success of this procedure.

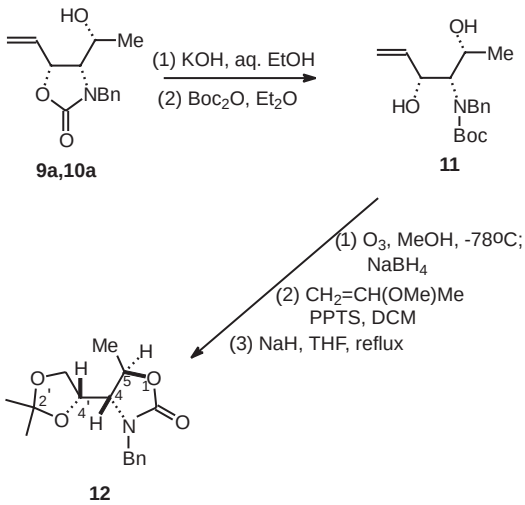
[1]



As shown in Table 1, Grignard-derived and organolithium-derived organocerium reagents reacted well with **6**. The nucleophilic addition reaction produced a crystalline, diastereomeric mixture of alcohols *syn*-**9** and *anti*-**10** in which the former was present as the predominant or exclusive product. For reactions in which Grignard-derived $RCeCl_2$ reagents were used, it was advantageous to warm the reaction mixture to 0°C and to maintain the reaction at 0°C for at least 1 h. Thus, quenching the $PhCeCl_2$ reaction after 5 h at –78°C yielded 29% of a mixture of **9f** and **10f** (entry 9). However, a 52% yield of **9f**, **10f** was obtained when the mixture was warmed to and maintained at 0°C for 1 h (entry 8). For the CH_2=$CHCeCl_2$ reaction, the reaction mixture must be conducted at –78°C because the organocerium reagent is unstable at 0°C (13*b*, 14). The use of Grignard and organolithium reagents alone resulted in lower diastereoselectivity and poorer chemical yields of products (compare entries 1, 2 and 3, 4).

The relative stereochemistry of the hydroxyl group and the benzylamino moiety of the oxazolidinone unit in **9** was assigned as *syn* on the basis of the data obtained from proton decoupling and NOE experiments performed on **12**. Compound **12** was synthesized from **9a,10a** using standard functional group manipulations as summarized in eq. [2]. Decoupling of the C-5 methyl doublet (δ 1.25) in **12** collapsed the H-5 quintet (br, δ 4.42) to a doublet, $J_{5,4}$ = 4.4 Hz. Similarly, irradiation of the H-4′ multiplet (δ 4.00–4.18) simplified the H-4 triplet (δ 3.11) to a doublet, $J_{4,5}$ = 4.4 Hz. Based on this small vicinal coupling constant (11) the relative stereochemistry of the methyl and dioxalanyl groups was, therefore, assigned as *trans*. This result was confirmed by the observation of a strong NOE enhancement (6.7%) for the H-4 proton upon irradiation of the C-5 methyl doublet.

[2]



Formation and reaction of 5-oxazolidinonecarbaldehyde (13) with $RCeCl_2$

Aldehyde **13** was prepared by ozonolysis of the benzyl ether **8** in DCM followed by replacement of the DCM with dry THF. The THF solution of crude **13** was then added to $RCeCl_2$ (4 equiv.) at –78°C (eq. [3]). Again, we found that it

[a]Reaction was performed in the absence of $CeCl_3$.
[b]Isolated yields.

was advantageous to warm the reactions involving Grignard-derived $RCeCl_2$ to 0°C before being quenched (Table 2, entries 8 and 9). In all cases, the alcohol product **14** was obtained as an oil, and in moderate to good overall yields. Only one diastereomer was produced as evidenced by ^1H and ^{13}C NMR analysis of the crude product: the other epimer was not detected.

The use of $CeCl_3$ is essential for the success of the reaction. For example, the use of MeLi only resulted in the complete decomposition of **13** (Table 2, compare entries 1 and 2) and the use of only CH_2=CHMgBr gave a lower yield of **14** (compare entries 3 and 4). The relative stereochemistry between the hydroxyl and the oxygen atom of the oxazolidinone unit was assigned as *anti* on the basis of the conversion of compound **14f** to C-18-D-*ribo*-phytosphingosine **18** (see later).

It was also of interest to examine the diastereoselectivity of nucleophilic addition reaction of **6** and **13** with $MeTi(OPr\text{-}i)_3$. It is well documented (15) that this nucleophilic reagent reacts with α-alkoxy aldehydes in a non-chelation controlled pathway because of the reduced Lewis acidity of the titanium centre. Unfortunately, the reaction of $MeTi(OPr\text{-}i)_3$ with **6** (using the same procedure developed for the conversion of **5** → **9**, **10**) resulted only in decomposition products. On the other hand, the reaction of $MeTi(OPr\text{-}i)_3$ with **13** (eq. [4]) gave a good yield (72%) of the addition product **15**. The ^1H NMR spectrum of **15** was very similar to that of *anti*-**14a**. We therefore prepared the

[4]

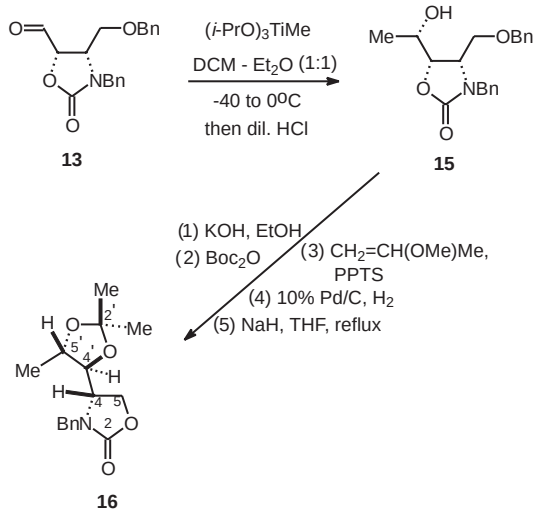

Chart 1.

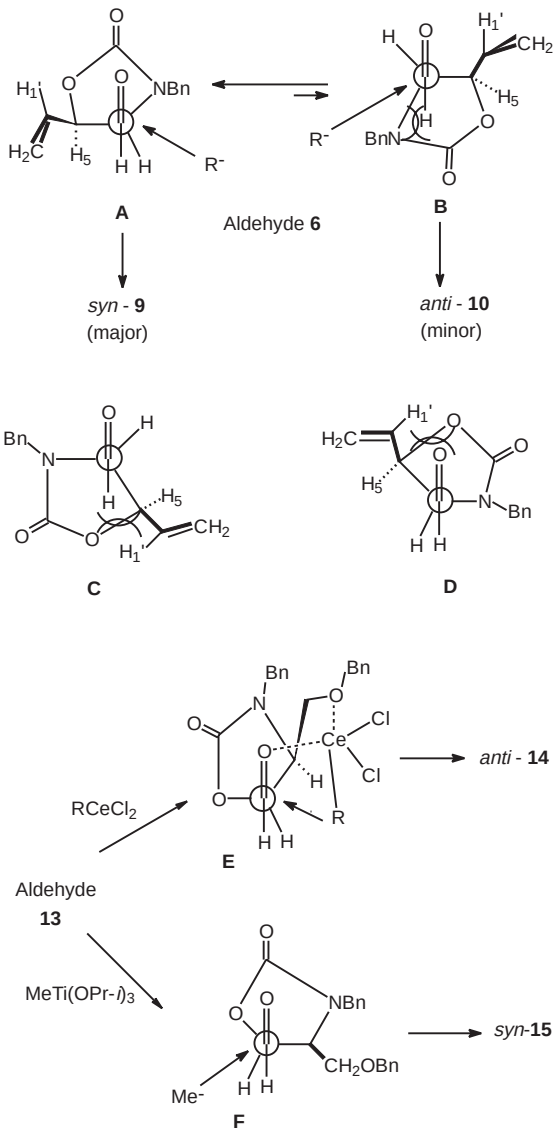
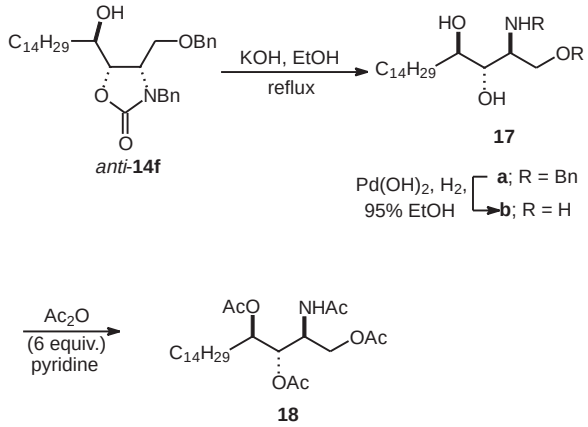


oxazolidinone derivative **16** (eq. [4]), which was subjected to NOE analysis. In particular, irradiation of the C-5′ methyl doublet centred at δ 1.05 resulted in a 3% enhancement of the H-4′ double doublet centred at δ 4.44. On the basis of this result, the configuration of the newly created carbinol

© 1998 NRC Canada

Scheme 2.



centre was assigned as *S*. That is, the addition reaction has proceeded with *syn* diastereoselectivity.

Reaction pathway

The diastereoselectivity observed in the reaction of aldehyde **6** can be understood if we consider the two reactive conformers **A** and **B** (Chart 1). In each of the conformers, the preferred orientation of the C-5-vinyl substituent with respect to the rigid, planar oxazolidinone unit is the one in which the vinyl H-1′ hydrogen is aligned antiperiplanar to the oxazolidinone H-5 hydrogen. This arrangement is adopted in order to relieve $A^{1,3}$ strain (16). Conformer **A** (17*a*) is more stable than **B** because in the latter a destabilizing interaction is present. Preferential nucleophilic attack via the sterically less hindered side in **A** leads to the major *syn* diastereomer **9** whereas attack via the sterically encumbered side in **B** results in the minor *anti* diastereomer **10**. The conformers **C** and **D** correspond to the Felkin–Anh-type model (17) but are considered less stable than **A** and **B** because of the presence of destabilizing steric interactions. **C** is destabilized by the steric interaction between the aldehydic hydrogen and the *cis*-vinyl group and especially H-1′. Similarly, steric interaction between the *cis*-vinyl group/H-1′ and the oxygen of the carbonyl function in **D** results in its destabilization.

The involvement of a five-membered chelate intermediate resulting from coordination of the carbonyl oxygen and the nitrogen atom of the NBn moiety to Lewis acidic Ce(III) (13*a*) is not likely because of the reduced basicity of the nitrogen atom resulting from conjugation of the nitrogen lone pair of electrons with the π-bond of the carbonyl group of the oxazolidinone unit.

In the case of **13**, a possible explanation for the unexpectedly high diastereoselectivity is the involvement of a seven-membered Ce(III) chelate **E** (Chart 1) (for the involvement of 7-membered chelates, see ref. 18). Its formation is entropically favoured because of the *cis* relationship of the aldehyde and $BnOCH_2$ moieties. Also, it is well documented that the oxygen atom in benzyl ethers shows a propensity to coordinate to Lewis acids (15*a*). The chelate can also accommodate a Felkin–Anh (17) arrangement. Thus, both chelation control and stereoelectronic effects reinforce one another in controlling the diastereoselectivity of the reaction. Intramolecular or intermolecular delivery of R′ will occur from the less hindered side of the carbonyl function, leading to *anti*-**14**. This line of reasoning is further supported by the result from the reaction of **13** with $MeTi(OPr\text{-}i)_3$. In the absence of any chelation to the titanium centre in the reagent, nucleophilic addition would proceed via **F** to give the *syn* diastereomer **15**.

Synthesis of C-18-D-*ribo*-phytosphingosine.

The oxazolidinone alcohol *anti*-**14f** ($[\alpha]_D^{22}$ +35.0 (*c* 1.50, $CHCl_3$)) was hydrolyzed in alcoholic 2 M aqueous KOH to provide **17a** in 83% yield (Scheme 2). Hydrogenolysis of the N,O-benzyl protecting groups in **17a** using Pearlman's catalyst afforded phytosphingosine **17b** as a powdery solid, which was subsequently peracetylated to give the crystalline tetraacetate derivative **18**. The spectroscopic data and specific rotations of **17b** and **18** are in excellent agreement with those reported (19).

Conclusions

The reactions of oxazolidinonecarbaldehydes **6** and **13** with organocerium reagents were found to proceed efficiently and with good to excellent diastereoselectivity to afford the corresponding secondary alcohol products. Compounds **6** reacted to give *syn* alcohols **9** as the major or exclusive products. With compounds **13**, the *anti* alcohols **14** were formed as the exclusive products. The results suggest that oxazolidinonecarbaldehyde **6** reacted with $RCeCl_2$ in a non-chelation pathway but with **13** a cerium chelate is involved. The method was applied to the synthesis of naturally occurring amino alcohol C18-D-*ribo*-phytosphingosine. Further application of this method and use of chiral, non-racemic 2-oxazolidinonecarbaldehydes in synthesis are in progress.

Experimental

General

Melting points are uncorrected and were measured on a Kofler hot-stage melting point apparatus. Infrared spectra were recorded using a Perkin Elmer 1600FT spectrophotometer: only diagnostic absorptions in the infrared spectrum are reported. ^1H (200 MHz) and ^{13}C (50.3 MHz) NMR spectra were recorded in $CDCl_3$ (unless otherwise stated), using a Bruker 200QNP spectrometer. Tetramethylsilane (δ_H = 0.00) and the $CDCl_3$ resonance (δ_C = 77.0) were used as references. Multiplicities "t", "q", and "quintet" represent pseudo triplet, quartet, and quintet, respectively, and are quoted as they appear in the ^1H NMR spectra. Where applicable, the signals of minor diastereomers are given within square brackets. Proton assignments were made using double irradiation experiments and, where necessary, 2D-COSY-45 experiments. Numberings in compounds **2–5** follow sugar numberings and, in compounds **6** onwards, numberings follow 2-oxazolidinone numberings. Elemental analyses and high-resolution electron impact (70 eV) and chemical ionization mass spectral analyses were performed at the Chemistry Department, University of Saskatchewan. Optical rotations were measured using an Optical Activity AA-5 polarimeter.

Reaction progress was monitored by thin-layer chromatography on Merck silica gel $60F_{254}$ precoated (0.25 mm) on aluminum backed sheets. Air- and moisture-sensitive reactions were conducted under a static pressure of argon. All organic extracts were dried over anhydrous Na_2SO_4. Flash chromatography (20) was performed on Merck silica gel 60 (230–400 mesh). Unless stated otherwise, the eluent is a mixture of petroleum ether:EtOAc in v/v ratio as follows: solvent A, 1:1; solvent B, 2:1; solvent C, 3:1; solvent D, 4:1; solvent E, 5:1. Abbreviations of solvents used: petroleum ether (PE, bp 35–60°C), ethyl acetate (EtOAc), diethyl ether (Et_2O), tetrahydrofuran (THF), and dichloromethane (DCM). THF and Et_2O were distilled from sodium-benzophenone, and DCM was distilled from CaH_2.

Organometallic reagents

Simple Grignard and organolithium reagents were purchased from Aldrich. Tetradecylmagnesium bromide was prepared from tetradecylbromide and magnesium metal as a 0.5 M solution in THF. Lithium phenylacetylide (21*a*), 2-lithiofuran (21*b*), and $CH_2 = C(OBu\text{-}t)O^- Li^+$ (21*c*) were prepared according to literature procedures. Organometallic reagents were standardized before use by titration using either 1,3-diphenylacetone *p*-tosylhydrazone (22*a*) (RLi) or pyreneacetic acid (22*b*) (RMgBr) as indicators.

Phenyl 5-*O*-(*tert*-butyldimethylsilyl)-2,3-*O*-isopropylidene-α,β-D-ribofuranosyl sulfone (2)

The phenylthio furanoside (7 g, 18 mmol) was dissolved in DCM (100 mL) and saturated aqueous $NaHCO_3$ (200 mL) was added. The biphasic mixture was cooled to 0°C in an ice-bath and mCPBA (11 g, 39 mmol, 60% tech.) was added portionwise. Then the mixture was stirred at room temperature (rt) for 20 h. The mixture was recooled to 0°C and 10% aqueous $NaHSO_3$ was added to destroy unreacted mCPBA. The mixture was stirred at rt for 1 h, and the aqueous phase was separated and back-extracted with DCM (50 mL). The combined organic phases were washed with saturated $NaHCO_3$ (2 × 50 mL), dried, filtered, and evaporated. The crude oil was chromatographed (solvent E) to give the desired sulfone (6.2 g, 85%) as a thick, viscous oil. β-**2**: ^{1}H NMR, δ: 0.00 (s, 6H, $SiMe_2$), 0.80 (s, 9H, *t*-Bu), 1.28 (s, 3H, Me), 1.40 (s, 3H, Me), 3.66 (dd, 1H, *J* = 10.3, 7.6 Hz, H-5), 3.76 (dd, 1H, *J* = 10.3, 6.5 Hz, H-5′), 4.23 (dt, 1H, *J* = 6.5, 2.1 Hz, H-4), 4.65 (dd, 1H, *J* = 6.5, 2.1 Hz, H-3), 4.82 (d, 1H, *J* = 2.1 Hz, H-1), 5.24 (dd, 1H, *J* = 6.5, 2.1 Hz, H-2), 7.40–7.62 (m, 3H, PhH), 7.76–7.87 (m, 2H, PhH). α-**2**: ^{1}H NMR, δ: –0.06 (s, 3H, SiMe), –0.02 (s, 3H, SiMe), 0.70 (s, 9H, *t*-Bu), 1.15 (s, 3H, Me), 1.26 (s, 3H, Me), 3.63 (dd, 1H, *J* = 11.4, 2.2 Hz, H-5), 3.75 (dd, 1H, *J* = 11.4, 2.2 H, H-5′), 4.27–4.32 (m, 1H, H-4), 4.72–4.81 (m, 1H, H-3), 5.02–5.13 (m, 2H, H-1, H-2), 7.42–7.62 (m, 3H, PhH), 7.94 (d, 2H, J = 7.5 Hz, PhH). ^{13}C NMR, δ: –5.4, 17.9, 24.2, 25.1, 25.7, 65.0, 81.0, 82.1, 86.1, 96.3, 114.3, 128.5, 129.4, 133.4, 139.1. Anal. calcd. for $C_{20}H_{32}O_6SSi \cdot ¼H_2O$: C 55.46, H 7.57; found: C 55.41, H 7.52.

Phenyl 2-benzylamino-5-*O*-(*tert*-butyldimethylsilyl)-2-deoxy-α-D-ribofuranosyl sulfone (4a)

The phenylsulfone **2** (6.2 g, 14.5 mmol) was dissolved in a mixture of dry THF (77 mL) containing dry HMPA (3.2 mL) under Ar. The solution was cooled to –78°C and *n*-BuLi (10.8 mL, 21.7 mmol, 2.1 M in hexanes) was added dropwise via syringe to the mixture. A deep yellow-orange solution resulted, which was stirred at –78°C for 1 h and then the cooling bath was removed. The mixture was allowed to warm slowly to rt, stirred at rt for 2 h, and then recooled to 0°C. Saturated aqueous NH_4Cl (15 mL) was added, followed by EtOAc (50 mL). The organic layer was removed and the aqueous phase was reextracted with EtOAc (2 × 50 mL). The combined organic phases were washed with saturated aqueous NaCl (70 mL), dried, filtered, and evaporated. The residual yellow oil was chromatographed (solvent C) to give **3** as a pale yellow oil (3.8 g, 71%) that slowly crystallized on standing. The product was found to be unstable and is best kept in the freezer for prolonged storage. IR, ν_{max}: 3575–3275 cm^{-1}. ^{1}H NMR, δ: –0.02 (s, 3H, SiMe), –0.05 (s, 3H, SiMe), 0.78 (s, 9H, *t*-Bu), 2.08–2.20 (br hump, 1H, OH), 3.57 (dd, 1H, *J* = 11.5, 4.8 Hz, H-5), 3.69 (dd, 1H, *J* = 11.5, 4.8 Hz, H-5′), 4.50 (q, 1H, *J* = 4.9 Hz, H-4), 4.92–5.2 (m, 1H, H-3), 5.98 (d, 1H, *J* = 2.6 Hz, H-2), 7.46–7.71 (m, 3H, PhH), 7.92–8.01 (m, 2H, PhH). ^{13}C NMR, δ: –5.4, 18.2, 25.7, 62.5, 74.9, 92.7, 109.6, 128.7, 129.2, 134.3, 137.9, 157.9.

The above ene alcohol (3.8 g, 10.3 mmol) was dissolved in dry THF (37 mL), under Ar. Benzyl isocyanate (1.4 mL, 11.4 mmol) was added and the reaction mixture was cooled to 0°C. Potassium *tert*-butoxide (0.24 g, 2.2 mmol) was added in one portion and the brown reaction mixture was stirred at 0°C for 1 h and at rt for 20 h. Then saturated NH_4Cl (20 mL) and EtOAc (20 mL) were added. The organic phase was separated and the aqueous phase was reextracted with EtOAc (3 × 30 mL). The combined organic extracts were washed with brine (50 mL), dried, filtered, and evaporated. The crude product was chromatographed (solvent E) to give the bicyclic oxazolidinone **4a** (4.6 g, 89%) as a pale yellow, viscous oil. IR, ν_{max}: 1766, 1585 cm^{-1}. ^{1}H NMR, δ: 0.30 (s, 6H, SiMe), 1.10 (s, 9H, *t*-Bu), 4.02 (dd, 1H, *J* = 10.9, 7.7 Hz, H-5), 4.08 (dd, 1H, *J* = 10.9, 6.0 Hz, H-5′), 4.55–4.65 (m, 1H, H-4), 4.57 (d, 1H, *J* = 14.6 Hz, PhCHN), 4.95 (d, 1H, *J* = 14.6 Hz, PhCHN), 4.98–5.05 (m, 2H, H-1, H-2), 5.09–5.18 (m, 1H, H-3), 7.50–8.10 (m, 10H, PhH). ^{13}C NMR, δ: –5.5, 18.1, 25.7, 47.2, 60.3, 62.0, 78.0, 89.1, 97.5, 128.3, 128.9, 129.2, 134.6, 135.0, 135.5, 156.6. Anal. calcd. for $C_{25}H_{33}NO_6SSi$: C 59.62, H 6.60, N 2.78; found: C 59.71, H 6.77, N 2.81.

Phenyl 2-benzylamino-2*N*,3*O*-carbamoyl-2-deoxy-α-D-ribofuranosyl sulfone (4b)

Compound **4a** (6.7 g, 13.4 mmol) was dissolved in dry MeOH (100 mL) under Ar, and the solution was cooled to 0°C. Freshly distilled Me_3SiCl (3.4 mL, 27 mmol) was added dropwise, via syringe, and the mixture was stirred at 0°C for 1 h. During this time, the white, fluffy, alcohol product precipitated out of solution. The solid product was filtered off and the filtrate was concentrated. The residue was triturated with solvent D and the resulting white, fluffy, product was filtered off. The filtrate was concentrated and chromatographed (solvent A) to obtain more product. The combined yield of **4b** was 4.5 g (88%); mp 172–174°C. IR,

ν_{max}: 3565–3307, 1754 cm^{-1}. ^1H NMR, δ: 3.30–3.40 (m, 1H, OH), 3.66–3.84 (m, 1H, H-5′), 3.86–3.99 (m, 1H, H-5), 4.36 (d, 1H, *J* = 14.4 Hz, PhCHN), 4.57–4.63 (m, 1H, H-4), 4.73 (d, 1H, *J* = 14.4 Hz, PhCHN), 4.77–4.87 (m, 2H, H-1, H-2), 5.03–5.12 (m, 1H, H-3), 7.30–7.85 (m, 10H, PhH). ^{13}C NMR, δ: 47.1, 61.2, 62.8, 78.6, 89.9, 98.5, 128.3, 128.7, 128.9, 128.9, 129.4, 134.8, 135.2, 135.5, 156.2. Anal. calcd. for $C_{19}H_{19}NO_6S$: C 58.60, H 4.92, N 3.60; found: C 58.53, H 5.13. N 3.67.

Phenyl 2-benzylamino-2*N*,3*O*-carbamoyl-2,5-dideoxy-5-iodo-α-D-ribofuranosyl sulfone (5)

The alcohol **4b** (2.9 g, 7.5 mmol) was dissolved in a mixture of dry toluene (60 mL), dry DCM (28 mL), and dry pyridine (1.8 mL, 26 mmol), under Ar. In a separate flask, Ph_3P (2.5 g, 9.4 mmol) was dissolved in dry toluene (30 mL) and iodine (2 g, 7.9 mmol) was added. The mixture was heated at 60°C for 30 min and then the temperature was raised to 80°C. The solution of the alcohol was added dropwise, via cannula, to the $Ph_3P–I_2$ mixture. After addition was complete, the mixture was heated at 80°C (oil bath) for 4 h, during which time the reddish brown precipitate was consumed and a white precipitate was formed. The reaction mixture was cooled to rt, filtered through a Florisil pad, and the solid residue was washed with EtOAc (2 × 30 mL). The combined filtrates were evaporated to leave a thick oil. Chromatographic purification (30:1 DCM:acetone) gave the desired iodide **5** (3.6 g, 95%) as a white solid; mp 188–190°C. IR, ν_{max}: 1747, 1584 cm^{-1}. ^1H NMR, δ : 3.43 (dd, 1H, *J* = 10.1, 6.3 Hz, H-5), 3.52 (dd, 1H, *J* = 10.1, 8.2 Hz, H-5′), 4.37 (d, 1H, *J* = 14.6 Hz, PhCH), 4.64 (dq, 1H, *J* = 8.5, 6.1, 2.2 Hz, H-4), 4.71 (d, 1H, *J* = 14.6 Hz, PhCH), 4.82 (d, 1H, *J* = 1.8 Hz, H-1), 4.89 (dd, 1H, *J* = 8.4, 1.8 Hz, H-2), 4.96 (dd, 1H, *J* = 8.4, 2.2 Hz, H-3), 7.30–7.40 (m, 5H, PhH), 7.50–7.80 (m, 3H, PhH), 7.80–7.90 (m, 2H, PhH). ^{13}C NMR, δ: 2.9, 47.5, 60.9, 79.9, 89.4, 97.8, 128.5, 128.9, 129.0, 129.4, 134.7 134.8, 135.1, 155.9. Anal. calcd. for $C_{19}H_{18}INO_5S$: C 45.70, H 3.63, N 2.81; found: C 45.70, H 3.59, N 2.82.

(4*S*,5*R*)-3-Benzyl-4-(hydroxymethyl)-5-vinyl-2-oxazolidinone (7)

Activated Zn dust (0.73g, 0.011 g atoms) was added to a solution of AgOAc (0.29 g, 1.77 mmol) in glacial AcOH (87 mL) at 110°C (oil bath). The mixture was stirred at 110°C for

35–40 s and then was allowed to cool slightly. Glacial AcOH was decanted off and the Zn/Ag couple was washed thoroughly with dry THF (4 × 10 mL) and then was covered with dry THF (10 mL). The slurry of the Zn/Ag couple in dry THF was heated to 60°C and a solution of the iodosulfone **5** (0.250 g, 0.50 mmol) was added dropwise via cannula to the Zn/Ag couple. The reaction mixture was heated at 60°C for 1 h, allowed to cool to rt, and the THF supernatant containing the aldehyde **6** was filtered through glass wool plug into a clean flask. The reaction flask was rinsed with THF (2 × 5 mL) and the washings filtered into the flask. The THF filtrate was cooled to 0°C and 95% ethanol (10 mL) was added, at which time the reaction mixture turned cloudy. Sodium borohydride (0.19 g, 5 mmol) was added, portionwise, to the mixture and the reaction mixture was stirred at 0°C for 2 h and then at rt overnight. The reaction mixture was recooled to 0°C and glacial AcOH (0.5 mL) was carefully added to destroy excess $NaBH_4$. After effervescence had subsided, the reaction mixture was evaporated and the residual oil was taken into EtOAc (15 mL). The organic phase was washed with water (10 mL), saturated aqueous $NaHCO_3$ (3 × 10 mL), and brine and then dried. The filtered solution was evaporated to give the crude crystalline primary alcohol. Chromatographic purification of the alcohol **7** (40:1 DCM:acetone) yielded white, fine needles (106 mg, 90%); mp 138–140°C. IR ν_{max}: 3518–3330, 1724, 1713 cm^{-1}. ^1H NMR, δ ($CDCl_3$-CD_3CN): 2.87 (t, 1H, *J* = 5.1 Hz, OH), 3.50–3.76 (m, 3H, H-4, CH_2O), 4.20 (d, 1H, *J* = 14.4 Hz, PhCH), 4.80 (d, 1H, *J* = 14.4 Hz, PhCH), 4.95 (“t”, 1H, *J* = 8.2 Hz, H-5), 5.32–5.51 (m, 2H, CH_2=), 5.99–6.19 (m, 1H, =CH). ^{13}C NMR, δ ($CDCl_3$-CD_3CN): 45.7, 57.8, 58.1, 77.1, 116.5, 119.8, 127.1, 127.3, 128.1, 131.1, 135.9, 157.9. Anal. calcd. for $C_{13}H_{15}NO_3$: C 66.94, H 6.48, N 6.00; found: C 66.70, H 6.68, N 5.89.

(4*S*,5*R*,)-3-Benzyl-4-(benzyloxymethyl)-5-vinyl-2-oxazolidinone (8)

The primary alcohol **7** (106 mg, 0.455 mmol) was dissolved in dry THF (5 mL), under Ar. The solution was added to a suspension of NaH (66 mg, 50% dispersion in mineral oil) in dry THF (10 mL) containing benzyl bromide (70 µL, 0.59 mmol) at 0°C. The mixture was stirred at 0°C to rt overnight (20 h). Then saturated NH_4Cl (5 mL), followed by saturated NaCl (5 mL) and EtOAc (10 mL), was added. The aqueous phase was separated and reextracted with EtOAc (5 mL). The combined organic phases were washed with water (10 mL), saturated NaCl (10 mL), dried, filtered, and evaporated. The crude oil was chromatographed (solvent C) to give the benzyl ether **8** as a pale yellow oil (127 mg, 86%). $[\alpha]_D^{21}$ –8.8 (*c* 1.70, $CHCl_3$). IR, ν_{max}: 3086, 3063, 3031, 1760 cm^{-1}. ^1H NMR, δ: 3.43 (dd, 1H, *J* = 14.7, 5.3 Hz, CHOBn), 3.51 (dd, 1H, *J* = 14.7, 3.5 Hz, CHOBn), 3.75 (“quintet”, 1H, *J* = 4.4 Hz, H-4), 4.12 (d, 1H, *J* = 14.3 Hz, PhCHN), 4.39 (d, 1H, *J* = 14.1 Hz, PhCHO), 4.47 (d, 1H, *J* = 14.1 Hz, PhCHO), 4.81 (d, 1H, *J* = 14.3 Hz, PhCHN), 4.93 (“t”, 1H, *J* = 8.5 Hz, H-5), 5.30–5.53 (m, 2H, $=CH_2$), 5.87–6.06 (m, 1H, =CH), 7.15–7.45 (m, 10H, PhH). ^{13}C NMR, δ: 46.6, 57.1, 66.6, 73.2, 77.1, 120.3, 127.7, 127.8, 128.0, 126.4, 128.6, 131.1, 136.2, 137.2, 157.9. HRMS, calcd. for $C_{20}H_{21}NO_3(M^+)$: 323.1521; found: 323.1525. Anal. calcd. for $C_{20}H_{21}NO_3$: C 74.28, H 6.55 N 4.33; found: C 73.99, H 6.43, N 4.35.

General procedure for the preparation of $RCeCl_2$ and reaction with oxazolidinonecarbaldehydes (6) and (13)

Anhydrous $CeCl_3$ (see also ref. 23)

Powdered $CeCl_3 \cdot 7H_2O$ (3 g) was placed in a 100 mL round-bottom flask containing a stir bar. The flask was fitted with an outlet tap and then connected to a high-vacuum pump (0.01–0.015 Torr; 1 Torr = 133.3 Pa). The flask was carefully evacuated, during which time a small amount of water was removed, and the salt had a whitish appearance. The flask was immersed in an oil bath that was heated at between 60 and 70°C and the salt was vigorously stirred. The

© 1998 NRC Canada

salt was heated at 60–70°C for 6 h and then the temperature of the bath was raised to 80–90° C and heating was continued for 2 h. After this period, the temperature was raised slowly, over a period of 1 h, to 140°C and the salt was stirred at this temperature for 18 h. The salt was cooled slowly to rt and then stored under Ar. The salt has an off-white appearance.

Method A: Dry THF (5 mL, at rt) was added to anhydrous $CeCl_3$ (1.2 mmol) under Ar and the mixture was stirred briefly. Then the suspension was sonicated for 1 h and allowed to stir at rt for 18 h. The white suspension was cooled to –78°C and RLi or RMgBr reagent (1.2 mmol) was added slowly. After addition was complete, the mixture assumed a light yellow or yellow-orange colour. The organometallic reagent was allowed to stir at –78°C for 1.5 h before use. The aldehyde **6** was generated from iodosulfone **5** (0.2 mmol) using a Zn/Ag couple (prepared using 292 mg Zn dust and 119 mg AgOAc) in dry THF (5 mL) according to the procedure used in the preparation of **7**. The THF supernatant was filtered (5 mL THF rinse) under Ar into a clean flask. This solution of **6** was transferred via cannula to the $RCeCl_2$ and the mixture was stirred at –78°C for the specified time (see Table 1). Then the mixture was quenched by addition of saturated NH_4Cl (5 mL) and stirred at rt for 20 min. The mixture was filtered through Florisil, and the residue washed with THF (2 × 10 mL). The combined filtrates were concentrated and the aqueous mixture was extracted with EtOAc (3 × 10 mL). The combined organic extracts were washed with brine, dried, filtered, and evaporated. The residual product was purified by chromatography.

Method B: The organocerium reagent was prepared as described in Method A except that 4 mol- equiv. of $RCeCl_2$ (0.62 mmol dry $CeCl_3$ and 0.62 mmol RLi or RMgBr) was used. The aldehyde **13** was generated by ozonolysis of olefin **8** (0.16 mmol) in dry DCM (5 mL) at –78°C. Ph_3P (0.19 mmol) was added and the mixture was slowly warmed to rt, under Ar, and stirred at rt for 18 h. The DCM was removed at rt under high vacuum and dry THF (5 mL) was added under Ar. The THF solution of **13** was added to the organocerium reagent and the mixture was stirred at –78°C for the specified time (see Table 2). The reaction mixture was processed as described in Method A.

(4*S*,5*R*)-3-Benzyl-4-[(1*RS*)-1-(hydroxyethyl)]-5-vinyl-2-oxazolidinone (9a,10a)

Method A: Solvent B: Yield, 85%; mp 95–97°C. IR, ν_{max}: 3600–3250, 1731 cm^{-1}. ^1H NMR, δ: 1.22 (d, *J* = 6.6 Hz, Me) and [1.48, d, *J* = 6.6 Hz, Me](3H), 2.46 (d, 1H, *J* = 5.6 Hz, OH), 3.52 (dd, *J* = 8, 4.8 Hz, H-4) and [3.71, dd, *J* = 8, 2.1 Hz, H-4](1H), 3.85–4.05 (m, 1H, CHOH), 4.41 (d, 1H, *J* = 15.2 Hz, PhCH), 4.85 ("t", 1H, *J* = 7.5 Hz, H-5), 4.93 (d, 1H, *J* = 15.2 Hz, PhCH), 5.36–5.54 (m, 2H, $=CH_2$), 5.90–6.12 (m, 1H, =CH), 7.24–7.42 (m, 5H, PhH). ^{13}C NMR, δ: 21.1, 48.4, 62.3, 66.6, 78.4, 121.0, 127.8, 128.0, 128.9, 131.4, 136.6, 159.3. LRMS-CI, NH_3 (*m*/*z*, rel. intensity): 265 (M + 18, 7.4), 248 (M + 1, 100), 202 (M – MeCHOH, 32), 91 ($PhCH_2^+$, 57). HRMS, calcd. for $C_{14}H_{17}NO_3$ (M^+): 247.1208; found: 247.1207.

(4*S*,5*R*)-3-Benzyl-4-[(1*R*)-1-(hydroxy-2-propenyl)]-5-vinyl-2-oxazolidinone (9b)

Method A: Solvent B: Yield, 85%; mp 157–159°C. IR, ν_{max}: 3471–3213, 1715, 1704 cm^{-1}. ^1H NMR, δ: 2.08 (d, 1H, *J* = 7.7 Hz, OH), 3.70 (dd, 1H, *J* = 8.5, 2.5 Hz, H-4), 4.25 (d, 1H, *J* = 15.4 Hz, PhCHN), 4.27–4.35 (m, 1H, CHOH), 4.90 ("t", 1H, *J* = 8.5 Hz, H-5), 4.95 (d, 1H, *J* = 15.4 Hz, PhCHN), 5.24–5.58 (m, 4H, 2× $=CH_2$), 5.81–6.00 (m, 1H, =CH), 6.08–6.23 (m, 1H, =CH), 7.16–7.40 (m, 5H, PhH). ^{13}C NMR, δ: 47.2, 60.7, 70.5, 78.3, 116.6, 121.1, 127.9, 128.0, 128.8, 131.6, 136.2, 137.9, 158.7. LRMS-CI, NH_3 (*m*/*z*, rel. intensity): 277 (M + 18, 8.4), 260 (M + 1, 100), 202 (M – CH_2=CHCHOH, 45), 91 ($PhCH_2^+$, 70). HRMS, calcd. for $C_{15}H_{18}NO_3$ (M + 1): 260.1286; found: 260.1275.

(4*S*,5*R*)-3-Benzyl-4-[(1*R*,*S*)-2-(*tert*-butyloxycarbonyl)-1-(hydroxyethyl)]-5-vinyl-2-oxazolidinone (9c,10c)

Method A: Solvent C: Yield, 92%; mp: 97–99°C. IR, ν_{max}: 3618–3131, 1726 cm^{-1}. ^1H NMR, δ: 1.40 (s, *t*-Bu) and [1.43, s, *t*-Bu](9H), 2.31 (dd, *J* = 15.4, 3.8 Hz) and 2.40–2.58 (m)(2H, CH_2CO), 3.14 (d, *J* = 5.1 Hz, OH) and [3.49, d, *J* = 5.1 Hz, OH](1H), 3.60 (dd, *J* = 7.7, 5.1 Hz, H-4) and [3.76, dd, *J* = 7.7, 2.3 Hz, H-4], 4.08–4.21 (m, 1H, CHOH), 4.31 (d, *J* = 14.9 Hz, PhCHN) and [4.33, d, *J* = 14.9 Hz, PhCHN](1H), 4.85 ("t", 1H, *J* = 7.7 Hz, H-5), 4.91 (d, 1H, *J* = 14.9 Hz, PhCHN), 5.34–5.55 (m, 2H, $=CH_2$), [5.80–5.97, m, =CH] and 5.98–6.17 (m, =CH)(1H), 7.20–7.35 (m, 5H, PhH). ^{13}C NMR, δ: 28.0, [30.0], [37.0], 39.1, [47.3], 48.0, 60.0, [60.6], 67.0, [68.1], 77.9, [81.2], 82.2, [85.2], [120.6], 120.8, 127.8, 128.0, [128.4], 128.7, 128.8, [128.9], [129.3], [130.6], 131.6, [134.6], 136.2, [157.5], 158.8, 171.5, [172.0]. Anal. calcd. for $C_{19}H_{25}NO_5$: C 65.69, H 7.25, N 4.03; found: C 65.59, H 7.38, N 3.95.

(4*S*,5*R*)-3-Benzyl-4-[(1*R*)-1-hydroxy-(3-phenyl-2-propynyl)]-5-vinyl-2-oxazolidinone (9d)

Method A: Solvent C: Yield, 94%; mp 119–121°C. IR, ν_{max}: 3550–3125, 2212, 1743, 1725, 1595, 1500 cm^{-1}. ^1H NMR, δ: 2.90–3.20 (br hump, 1H, OH), 3.90 (dd, 1H, *J* = 8.2, 3.3 Hz, H-4), 4.60 (d, 1H, *J* = 15.2 Hz, PhCHN), 4.75 (d, 1H, *J* = 3.1 Hz, CHOH), 4.94 ("t", 1H, *J* = 8 Hz, H-5), 5.02 (d, 1H, *J* = 15.2 Hz, PhCHN), 5.38–5.56 (m, 2H, $=CH_2$), 6.10–6.33 (m, 1H, =CH), 7.23–7.44 (m, 10H, PhH). ^{13}C NMR, δ: 47.4, 61.0, 61.2, 78.2, 87.3, 121.8, 128.0, 128.2, 128.5, 128.8, 129.0, 131.2, 131.6, 136.4, 158.4. LRMS-CI, NH_3 (*m*/*z*, rel. intensity): 351 (M + 18, 12), 334 (M + 1, 100), 202 (M – PhCCHOH, 52), 91 ($PhCH_2^+$, 66). HRMS, calcd. for $C_{21}H_{20}NO_3$(M + 1): 334.1443; found: 334.1426.

(4*S*,5*R*)-3-Benzyl-4-[(1*S*)-1-(2-furanyl)-1-(hydroxymethyl)]-5-vinyl-2-oxazolidinone (9e)

Method A: Solvent C: Yield, 85%; mp 137–139°C. IR ν_{max}: 3500–3150, 1715, 1703 cm^{-1}. ^1H NMR, δ (CD_3CN): 3.75 (d, 1H, *J* = 15 Hz, PhCHN), 3.93 (d, 1H, *J* = 6 Hz, OH), 4.08 (dd, 1H, *J* = 7.2, 3.6 Hz, H-4), 4.73 (d, 1H, *J* = 15 Hz, PhCHN), 4.75–4.85 (m, 1H, CHOH), 4.95 ("t", 1H, *J* = 7.2 Hz, H-5), 5.30–5.46 (m, 2H, $=CH_2$), 5.95–6.18 (m, 1H, =CH), 6.28–6.45 (m, 2H, furan-H), 7.05 (dd, 1H, *J* = 6.6,

(4*S*,5*R*)-3-Benzyl-4-[(1*R*,*S*)-1-hydroxy-1-phenylmethyl]-5-vinyl-2-oxazolidinone (9f,10f)

Method A: Solvent B: Yield, 52%; mp 142–144°C. IR ν_{max}: 3600–3283, 3075, 3025, 1751 cm^{-1}. ^{1}H NMR, δ: [2.28, d, *J* = 4.4 Hz, OH] and 2.47 (d, *J* = 4.4 Hz, OH)(1H), 3.56 (d, 1H, *J* = 15.4 Hz, PhCHN), 3.90 (dd, 1H, *J* = 8, 2.2 Hz, H-4), 4.80 (d, 1H, *J* = 15.2 Hz, PhCHN), 4.85–5.00 (m, 2H, CHOH, H-5), 5.30–5.70 (m, 2H, $=CH_2$), 6.00–6.27 (m, 1H, =CH), 7.12–7.50 (m, 10H, PhH). ^{13}C NMR, δ: 47.7, [48.1], 60.7, 62.6, 71.3, 78.1, 118.7, 121.3, 125.7, [126.9], 127.8, 128.1, 128.5, 128.6, [128.7], 131.2, 136.2, 140.7, 158.2. LRMS-CI, NH_3 (*m/z*, rel. intensity): 310 (M + 1, 100), 232 (M – Ph, 10), 202 (M – PhCHOH, 30), 91 ($PhCH_2^+$, 90). HRMS, calcd. for $C_{19}H_{20}NO_3$ (M + 1): 310.1443; found: 310.1453.

(4*R*,5*R*)-3-Benzyl-5-methyl-4-[(4*S*)-4-(2,2-dimethyl-1,3-dioxolanyl)]-2-oxazolidinone (12)

Compound **9a,10a** (111 mg. 0.45 mmol) was hydrolyzed using 2 M aqueous KOH (2.6 mL) in 95% EtOH (6.4 mL) at reflux for 20 h. The cooled reaction mixture was evaporated to dryness and distilled water (1 mL) was added followed by DCM (2 mL). The mixture was cooled to 0°C and Boc_2O (108 mg, 0.49 mmol) was added and the mixture was stirred under Ar for 20 h. The DCM layer was separated and saturated aqueous NaCl and solid NaCl were added to the aqueous layer. The mixture was stirred for 1 h and extracted with DCM (2 × 5 mL). The combined organic phases were dried, filtered, and evaporated to give the crude diol as a thick oil. Chromatographic separation (solvent B) gave 81 mg (59%) of diol **11.** IR ν_{max}: 3680–3113, 1690, 1660 cm^{-1}. ^{1}H NMR, δ: 0.80 (d, 3H, *J* = 7 Hz, Me), 1.50 (s, 9H, *t*-Bu), 2.90–3.10 (m, 1H), 3.25–3.42 (m, 1H), 3.95–4.25 (m, 1H), 4.65 (d, 1H, *J* = 12.6 Hz, PhCHN), 4.65–4.78 (m, 1H), 4.95–5.30 (m, 3H), 5.67–5.90 (m, 1H, =CH), 7.15–7.35 (m, 5H, PhH).

The diol **11** (40 mg) was dissolved in dry MeOH (3 mL) and was ozonized at –78°C until the blue color of ozone is visible. Argon was bubbled into the cold mixture and then $NaBH_4$ (25 mg, 0.65 mmol) was added. The mixture was allowed to stir at –78°C for 15 min and then warmed slowly to rt and stirred at rt for 20 h. Glacial AcOH (4 drops) was added to destroy unreacted $NaBH_4$. The mixture was concentrated and saturated aqueous $NaHCO_3$ (5 mL) was added. The mixture was thoroughly extracted with DCM (2 × 10 mL), the combined organic phases were dried, filtered, and evaporated to furnish crude triol (40 mg). Without further purification, the triol was treated with 2,2-dimethoxypropane (20 µL, 0.16 mmol) in dry DCM (2 mL) in the presence of *p*-$TSO_3H\cdot H_2O$ (1 crystal). After reaction was complete, dry Et_3N was added, the mixture was evaporated, and the residue was chromatographed (solvent C) to give the ketal (26 mg, 55%) as an oil. IR, ν_{max}: 3577–3224, 1691, 1675 cm^{-1}. ^{1}H NMR, δ: 1.08 (d, 3H, *J* = 7.1 Hz, Me), 1.25 and [1.32] (s, 3H, Me), 1.35 and [1.42] (s, 3H, Me), 1.49 (s, 9H, *t*-Bu), 3.42–3.95 (m, 3H), 4.05–5.85 (m, 5H), 7.18–7.40 (m, 5H, PhH).

The ketal (26 mg, 0.071 mmol) was dissolved in dry THF (2 mL) and was transferred, via cannula, to a suspension of NaH (2.5 mg, 0.11 mmol, 50% dispersion in mineral oil) in dry THF (2 mL). The mixture was refluxed under Ar for 2 h and then cooled to rt. Saturated NH_4Cl (4 drops) was added and the mixture was concentrated in vacuo. EtOAc (5 mL) and saturated NaCl (4 mL) were added and the organic layer was separated. The aqueous layer was reextracted with EtOAc (3 mL) and the combined organic extracts were dried, filtered, and evaporated to crude ketal oxazolidinone. Chromatographic purification (solvent C) furnished crystalline 2-oxazolidinone **12** (16 mg, 77%); mp 88–90°C. IR, ν_{max}: 1745 cm^{-1}. ^{1}H NMR, δ: 1.25 (s, 3H, Me), 1.27 (d, 3H, *J* = 7.0 Hz, Me), 1.35 (s, 3H, Me), 3.11 (t, 1H, *J* = 4.2 Hz, H-4), 3.51 (dd, 1H, *J* = 7.9, 5.5 Hz, H-4′), 3.90 (br "t", 1H, *J* = 7.9 Hz, H-5′), 4.07 (d, 1H, *J* = 14.3 Hz, PhCHN), 4.06–4.16 (m, 1H, H-5′), 4.42 (br "quintet", 1H, *J* = 4.2 Hz, H-5), 4.82 (d, 1H, *J* = 14.3 Hz, PhCHN), 7.10–7.40 (m, 5H, PhH). (4*S*,5*S*)-3-Benzyl-4-(benzyloxymethyl)-5-[(1*R*)-1-(hydroxytetradecyl)]-2-oxazolidinone (14f)

Method B: Solvent D: Yield, 69%. IR, ν_{max}: 3600–3150, 1737, 1500 cm^{-1}. ^{1}H NMR, δ: 0.90 (t, 3H, *J* = 6.5 Hz, Me), 1.12–1.55 (m, 25H, CH_2), 1.65–1.85 (m, 1H, CH), 3.23 (d, 1H, *J* = 3.6 Hz, OH), 3.52 (dd, 1H, *J* = 9.7, 3.4 Hz, CHOBn), 3.60 ("t", 1H, *J* = 9.7 Hz, CHOBn), 3.70–3.85 (m, 2H, H-4, CHO), 3.99 (d, 1H, *J* = 15.4 Hz, PhCHN), 4.17 (dd, 1H, *J* = 9.5, 6.8 Hz, H-5), 4.46 (d, 1H, *J* = 12 Hz, PhCHO), 4.55 (d, 1H, *J* = 12 Hz, PhCHO), 4.75 (d, 1H, *J* = 15.4 Hz, PhCHN), 7.15–7.40 (m, 10H, PhH). ^{13}C NMR, δ: 14.1, 22.6, 24.8, 29.3, 29.6, 29.6, 31.9, 33.5, 46.4, 56.0, 64.5, 68.1, 73.8, 79.1, 127.6, 127.9, 128.0, 128.1, 128.4, 128.7, 128.8, 135.9, 136.1, 157.4. Anal. calcd. for $C_{33}H_{49}NO_4$: C 75.60, H 9.44, N 2.68; found: C 75.68, H 9.59, N 2.94.

(4*S*,5*S*)-3-Benzyl-4-(benzyloxymethyl)-5-[(1*S*)-1-(hydroxyethyl)]-2-oxazolidinone (15)

The MeTi(OPr-i)$_3$ reagent was prepared by treatment of ClTi(OPr-i)$_3$ (0.22 mL, 0.90 mmol) with MeLi (0.90 mL, 0.90 mmol) in dry ether (5 mL) at –40°C. Then the mixture was warmed slowly to rt and stirred at rt for 1.5 h. The mixture turned cloudy and a yellow precipitate was formed. In a separate flask the olefin **8** was dissolved in dry DCM (5 mL) and then oxidized (O_3; Pah_3) as described in Method B to provide **13**. The solution of **13** was added to the ethereal solution of MeTi(OPr-i)$_3$ at –40°C and the mixture was stirred at –40°C for 1 h. After this time, the reaction mixture was warmed slowly to rt and stirred at rt for 1.5 h. The reaction mixture was quenched by addition of aqueous 1 M HCl (10 mL) followed by DCM (10 mL). The aqueous phase was separated and reextracted with DCM (10 mL). The combined organic extracts were washed with brine, dried, filtered, and evaporated. Chromatographic purification (solvent B) of the residual oil gave **15** (57 mg, 74%). IR, ν_{max}: 3450–3050, 1735 cm^{-1}. ^{1}H NMR, δ: 1.29 (d, 3H, *J* = 5.7 Hz, Me), 3.34 (d, 1H, *J* = 8.5, 3.6 Hz, CHOBn), 3.62 (t, 1H, *J* = 8.5 Hz, CHOBn), 3.78 (td, *J* = 8.5, 8.5, 3.6 Hz, H-4), 3.92–4.06 (m, 1H, CHOH), 3.99 (d, 1H, *J* = 15.4 Hz, PhCHN), 4.14 (dd, 1H, *J* = 8.5, 6.8 Hz, H-5), 4.50 (s, 2H, OCH_2Ph), 4.76 (d, 1H, *J* = 15.4 Hz, PhCHN), 7.10–7.48 (m, 10H, PhH). ^{13}C NMR, δ: 20.1, 46.4, 55.9, 64.5, 64.6, 73.8, 80.5, 127.9, 127.9, 128.0, 128.4, 128.7, 128.8, 135.8, 136.1, 157.4. Anal. calcd. for $C_{20}H_{23}NO_4$: C 70.36, H 6.79, N 4.10; found: C 70.17, H 7.00, N 3.90.

(4*R*)-3-Benzyl-4-[(4*S*,5*R*)-4-(2,2,5-trimethyl-1,3-dioxolanyl)]-2-oxazolidinone (16)

2-Oxazolidinone **15** (33 mg, 0.097 mmol) was dissolved in a mixture of 95% EtOH (5 mL) and 2 M aqueous KOH (2 mL). The mixture was refluxed under Ar for 20 h. The cooled reaction mixture was evaporated to dryness and distilled water (2 mL) was added. Then Et_2O (4 mL) and Boc_2O (25 mg, 0.12 mmol) were added and the mixture stirred at rt, under Ar, for 4 h. The aqueous phase was removed and solid NaCl (1 g) was added. The mixture was stirred for 1 h; the aqueous phase was removed and then back-extracted with Et_2O (3 × 5 mL). The combined ether extracts were dried, filtered, and evaporated to leave crude diol as an oil (34 mg). Without further purification, the diol (34 mg) was dissolved in dry DCM (3 mL), and PPTS (11 mg) and 2-methoxypropene (0.2 mL) were added. The mixture was stirred under Ar for 3 h and then dry Et_3N (0.5 mL) was added. The mixture was evaporated to dryness and the crude residue was chromatographed (PE:EtOAc, 10:1) to give the ketal (30 mg).

The ketal (30 mg) was dissolved in dry MeOH (2 mL) and was hydrogenated (H_2, 1 atm (101.3 kPa), balloon) over 10% Pd/C (15 mg) for 4 h. The mixture was filtered through a Celite pad, the residue washed with dry MeOH (4 mL), and the combined filtrate was evaporated to leave an oil. The crude oil was dried under high vacuum for 2 h and then dissolved in dry THF (2 mL). The solution was added to a suspension of hexane-washed NaH (7 mg, 50% dispersion in mineral oil) in dry THF (2 mL). The mixture was refluxed for 45 min, cooled, and saturated NH_4Cl (4 drops) was added. The mixture was evaporated, and EtOAc (5 mL) and

© 1998 NRC Canada

saturated aqueous NaCl were added. The aqueous phase was separated and reextracted with EtOAc (4 mL). The combined organic phases were dried, filtered, and evaporated to give crude **16**. Chromatographic purification (solvent C) gave crystalline **16** (17 mg, 89%); mp 134–135°C. IR, ν_{max}: 1748 cm^{-1}. ^1H NMR, δ: 1.05 (d, 3H, *J* = 6.3 Hz, Me), 1.34 (s, 3H, Me), 1.50 (s, 3H, Me), 3.57 (dq, 1H, *J* = 8.9, 5.6, 2.1 Hz, H-4), 4.13 (d, 1H, *J* = 15.9 Hz, PhCHN), 4.25 ("t", 1H, *J* = 8.2 Hz, H-5), 4.27 (dd, 1H, *J* = 8.2, 2.1 Hz, H-5), 4.37 ("q", 1H, *J* = 6.3 Hz, H-5′), 4.44 (dd, 1H, *J* = 8.9, 5.2 Hz, H-4′), 4.93 (d, 1H, *J* = 15.9 Hz, PhCHN), 7.25–7.50 (m, 5H, PhH). ^{13}C NMR, δ: 15.2, 24.48, 26.4, 45.7, 54.8, 63.0, 71.6, 73.3, 108.4, 127.8, 127.9, 128.9, 135.7, 158.5. Anal. calcd. for $C_{16}H_{21}NO_4$: C 65.96, H 7.27, N 4.81; found: C 65.97, H 7.40, N 4.60.

(2*S*,3*S*,4*R*)-2-Benzylamino-1,3,4-dihydroxyoctadecane (17a)

The 2-oxazolidinone **14f** (270 mg, 0.528 mmol) was dissolved in 95% EtOH (10 mL) and aqueous 2 M KOH (4 mL) was added. The mixture was refluxed under Ar for 20 h, then cooled to rt, at which time a fluffy white precipitate was formed. The reaction mixture was concentrated and saturated NaCl (10 mL) was added. The mixture was thoroughly extracted with DCM (3 × 10 mL), the combined organic extracts were dried, filtered, and evaporated. The crude solid was chromatographed (DCM:MeOH, 190:2) to give crystalline **17a** (256 mg, 83%); mp 75–77°C. $[\alpha]_D^{23}$ +21.4 (*c* 1.75, $CHCl_3$). IR, ν_{max}: 3154–3448 cm^{-1}. ^1H NMR, δ: 0.90 (t, 3H, *J* = 6.5 Hz, Me), 1.15–1.75 (m, 26H, CH_2), 2.92 (dt, 1H, *J* = 6.8, 4 Hz), 3.10–3.30 (br hump, 3H), 3.47 ("t", 1H, *J* = 6.8 Hz), 3.55–3.85 (m, 5H), 4.49 (d, 1H, *J* = 13 Hz, PhCHO), 4.56 (d, 1H, *J* = 13 Hz, PhCHO), 7.20–7.42 (m, 10H, PhH). ^{13}C NMR, δ: 14.1, 22.7, 25.3, 29.3, 29.7, 29.8, 31.9, 33.9, 51.3, 60.3, 67.1, 72.1, 73.3, 74.4, 76.4, 77.0, 77.6, 127.3, 127.8, 127.9, 128.2, 128.5, 137.7, 139.1. HRMS, calcd. for $C_{32}H_{51}NO_3$ (M^+): 497.3869; found: 497.3868.

Synthetic (2*S*,3*S*,4*R*)-2-Amino-1,2,3-trihydroxyoctadecane (phytosphingosine) (17b)

The amino alcohol **17a** (256 mg) was dissolved in 95% EtOH (15 mL) and $Pd(OH)_2$ (281 mg) was added. The mixture was hydrogenated (H_2 at 50 psi (1 psi = 6.9 kPa)) for 16 h using a Parr apparatus. The mixture was filtered through Celite and the residue washed with 95% EtOH (3 × 2 mL). The combined filtrate was concentrated to about 8 mL, distilled water was added until the mixture was slightly turbid, and the mixture was placed in the freezer. The white powdery solid was filtered off and dried. Yield of **17b** was 130 mg (80%); mp 99–100°C (lit. (19*b*) mp 98–100°C; (19*c*) mp 103°C). $[\alpha]_D^{21}$ +8.3 (*c* 1.2, pyridine) (lit. (19*a*) $[\alpha]_D^{24}$ +8.7 (*c* 0.80, pyridine); (19*c*) $[\alpha]_D^{20}$ +7.9 (*c* 1.0, pyridine)). ^1H NMR, δ (DMSO-d_6): 0.85 (t, 3H, *J* = 6.5 Hz, Me), 1.15–1.35 (m, 24H, CH_2), 1.40–1.65 (m, 2H, CH_2), 2.60–2.75 (m, 1H, CHO), 3.05 (t, 1H, *J* = 6.7 Hz, CHO), 3.20–3.40 (m, 5H), 3.52 (dd, 1H, *J* = 9.6, 3.6 Hz), 4.40–4.60 (m, 1H).

Synthetic phytosphingosine tetraacetate (18)

Phytosphingosine **17b** (84 mg, 0.27 mmol) was dissolved in dry pyridine (2 mL) containing DMAP (30 mg), and Ac_2O (150 μL, 1.60 mmol) was added. The mixture was kept at rt for 18 h and then diluted with EtOAc (15 mL). The organic layer was washed twice with aqueous 1 N H_2SO_4 (10 mL), water (10 mL), and saturated $NaHCO_3$, then dried, filtered, and evaporated. The crude product was chromatographed (solvent B) to give **18** (126 mg, 98%); mp 46–48°C (lit. (19*c*) mp 48°C; (19*a*) mp 34–37°C).$[\alpha]_D^{21}$ +28.9 (*c* 0.95, $CHCl_3$), $[\alpha]_D^{21}$ +4 (*c* 1.25, DMF) (lit. (19*a*) $[\alpha]_D^{24}$ +28 (*c*, 1.30, $CHCl_3$); (19*b*) $[\alpha]_D^{30}$ +4.4 (*c* 1.12, DMF)). IR, ν_{max}: 3236–3342, 1746, 1660 cm^{-1}. ^1H NMR, δ: 0.87 (t, 3H, *J* = 6.8 Hz, Me), 1.18–1.33 (m, 24H, CH_2), 1.55–1.75 (m, 2H, CH_2), 2.20 (s, 3H, OAc), 2.50 (s, 6H, OAc), 2.80 (s, 3H, OAc), 4.00 (dd, 1H, *J* = 10.9, 2.8 Hz, CHOAc), 4.29 (dd, 1H, *J* = 10.9, 4.2 Hz, CHOAc), 4.40–4.55 (m, 1H), 4.94 (dt, 1H, *J* = 8.3, 3.4 Hz), 5.11 (dd, 1H, *J* = 8.0, 3.1 Hz), 6.05 (d, 1H, *J* = 8.3 Hz). ^{13}C NMR, δ: 14.1, 20.6, 20.7, 21.0, 22.6, 23.2, 25.5, 28.1, 29.2, 29.3, 29.4, 29.5, 29.6, 29.6, 31.9, 47.5, 62.8, 71.9, 72.9, 76.4, 76.9, 77.6, 169.7, 170.0, 170.8, 171.1. HRMS, calcd. for $C_{23}H_{42}NO_5$ (M – CH_2OAc): 412.3063; found: 412.3056.

C-(2-Hydroxyaryl)-*N*-(2-hydroxyphenylmethyl)nitrones as regioselective bidentate ligands in boron chelate formation. Crystal and molecular structures of a diphenylboron complex and its parent ligand[1]

Wolfgang Kliegel, Jörg Metge, Steven J. Rettig, and James Trotter

Abstract: The *C*-(2-hydroxyaryl)-*N*-(2-hydroxyphenylmethyl)nitrones **5** are synthesized by the condensation of variously substituted salicylaldehydes with *N*-(2-hydroxyphenylmethyl)-hydroxylamine. These nitrones react with diphenylborinic acid anhydride to form seven-membered diphenylboron chelates **6**. Crystals of *C*-(4-diethylamino-2-hydroxyphenyl)-*N*-(2-hydroxyphenylmethyl)nitrone, **5***d*, are monoclinic, a = 6.911(2), b = 10.663(2), c = 22.951(1) Å, β = 97.33(1)°, Z = 4, space group $P2_1/n$, and those of 4-dimethylamino-8-(2-hydroxyphenylmethyl)-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocyclohepten e–ethanol, **6***d*·EtOH, are monoclinic, a = 9.069(2), b = 29.881(1), c = 11.1883(6) Å, β = 109.426(9)°, Z = 4, space group $P2_1/n$. The structures were solved by direct methods and refined by full-matrix least-squares procedures to R = 0.032 and 0.039 (R_w = 0.031 and 0.036) for 2510 and 4162 reflections with $I > 3\sigma(I)$, respectively.

Key words: *C*-(2-hydroxyaryl)-*N*-(2-hydroxyphenylmethyl)nitrones, organoboron compounds, crystal structures.

Résumé : La condensation de divers salicylaldéhydes substitués avec de la *N*-(2-hydroxyphénylméthyl)hydroxylamine conduit aux *C*-(2-hydroxyaryl)-*N*-(2-hydroxyphénylméthyl)nitrones (**5**). Ces nitrones réagissent avec l'anhydride de l'acide diphénylborinique pour former les chélates à sept chaînons du diphénylbore (**6**). Les cristaux de la *C*-(4-diéthylamino-2-hydroxyphényl)-*N*-(2-hydroxyphénylméthyl)nitrone (**5***d*) sont monocliniques, groupe d'espace $P2_1/n$, avec a = 6,911(2), b = 10,663(2) et c = 22,951(1) Å, β = 97,33(1)° et Z = 4 alors que ceux du 4-dimethylamino-8-(2-hydroxyphénylméthyl)-6,6-diphényl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocycloheptèn e–éthanol, **6***d*·EtOH, sont monocliniques, groupe d'espace $P2_1/n$, avec a = 9,069(2), b = 29,881(1) et c = 11,1883(6) Å, β = 109,426(9)° et Z = 4. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R = 0,032 et 0,039 (R_w = 0,031 et 0,036) pour respectivement 2510 et 4162 réflexions avec $I > 3\sigma(I)$.

Mots clés : *C*-(2-hydroxyaryl)-*N*-(2-hydroxyphénylméthyl)nitrones, composés organiques du bore, structures cristallines.

[Traduit par la Rédaction]

Introduction

Various boron chelates of *N*-alkyl or *N*-aryl salicylaldehyde nitrones **1** (1) provide relatively rare examples of seven-membered chelate complexes. An X-ray crystallographic analysis of the diphenylboron chelate **2** (R = Me) established the seven-membered ring structure (2). Chelates of the same ring size could also be obtained from aromatic aldonitrones of *N*-(2-hydroxyphenylmethyl)hydroxylamine **3**, provided that the nitrone basicity was enhanced by electron-donating substituents on the aromatic aldehyde moiety. The structure of the diphenylboron chelate **4** (Ar = 4-$Me_2NC_6H_4$) was also determined by an X-ray analysis (3). Continuing this investigation we have now synthesized a new class of nitrones, which offer both of the bidentate ligand systems **1** and **3**, combined in the same molecule, **5**, for the purpose of determining which of the two competing ligand moieties would be involved in the boron chelate formation. Based on the above-mentioned results it could generally be expected that chelates of type **6** should possess a greater stability compared to the (also) seven-membered chelates of type **7**. In the case of the *para*-dialkylamino substituted salicylaldehyde nitrone **5***d* ($R^2 = Et_2N$), however, the formation of both type **6** and (or) type **7** chelates had to be considered.

Experimental

General procedures

All preparations and reactions were carried out under normal conditions, without protective gas atmosphere. Commercial solvents and reagents were used as supplied. Oxybis(diphenylborane) was prepared according to literature methods (4). Melting points were measured on a Linström SPA-1 apparatus and are uncorrected. Elemental analyses: (C, H, N) Carlo Erba elemental analyzer 1106; (B) oxidative disintegration (Schöninger), and potentiometric titration. Infrared spectra: Phillips PU 9800 FT-IR spectrometer, V 3.00, and Mattson Genesis Series FTIR Rev. I (ATI Unicam). ^{1}H nmr: Varian EM 390. ^{11}B nmr: Bruker AC 200. Mass spectra: Finnigan MAT 8430.

C-(2-Hydroxyphenyl)-*N*-(2-hydroxyphenylmethyl)nitrone, 5*a*[3]

According to the general procedure for the synthesis of *C*-aryl-*N*-(2-hydroxyphenylmethyl)nitrones **3** from *N*-(2-hydroxyphenylmethyl)hydroxylamine (3) **5***a* is obtained using salicylaldehyde (3.36 g, 30.0 mmol) as the aromatic aldehyde component. Yield: 5.0 g (69%) of orange-yellow crystals; mp 140°C (from ethanol). Infrared (KBr, cm^{-1}): 3000–1800 ("curtain" O-H), 1661 (C=N), 1609, (C=N), 1586 (C=C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.75 (s, broad, exchangeable, 65% of 1H, N-OH or $^+$NH-O$^-$), 3.2–4.9 (m, 65% of 3H, CH_2, and N-CH-O), 5.10 (s, 35% of 2H, CH_2), 6.60–7.86 (m, 8 aromatic H), 7.73 (s, 35% of 1H, N=CH), 9.83 (s, broad, exchangeable, 35% of 1H, phenolic OH), 11.83 (s, exchangeable, 35% of 1H, phenolic OH). Anal. calcd. for $C_{14}H_{13}NO_3$: C 69.13, H 5.39, N 5.76; found: C 69.14, H 5.13, N 5.78. The reaction of **5***a* in ethanolic solution with triphenyltetrazolium chloride (TTC) spontaneously gives a deep red color upon addition of 2 N NaOH solution, indicating the reductive potency (5) of an *N*-hydroxylamine grouping present in one of the possible tautomers of **5***a*.

C-(5-Chloro-2-hydroxyphenyl)-*N*-(2-hydroxyphenylmethyl)nitrone, 5*b*[4]

The compound is prepared as described for **5***a*, using 5-chloro-2-hydroxybenzaldehyde (4.70 g, 30.0 mmol). Yield: 6.3 g (75%) of a yellow powder; mp 177°C (from ethanol). Infrared (KBr, cm^{-1}): 3000–1800 (curtain O-H), 1602 (C=N), 1577 (C=C); ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 5.12 (s, CH_2), 6.73–7.46 (m, 6 aromatic H), 8.08 (d, ^4J = 3 Hz, 1 aromatic H), 8.16 (s, N=CH), 10.08 (s, broad, exchangeable, phenolic OH), 11.88 (s, broad, exchangeable, phenolic OH). Anal. calcd. for $C_{14}H_{12}ClNO_3$: C 60.55, H 4.36, Cl 12.77, N 5.04; found: C 60.80, H 4.43, Cl 12.03, N 4.96. The TTC test, carried out as with 5a, gives no red coloring of the solution.

C-(2-Hydroxy-5-nitrophenyl)-*N*-(2-hydroxyphenylmethyl)nitrone, 5*c*[5]

The compound is prepared as described for **5***a*, using 2-hydroxy-5-nitrobenzaldehyde (5.01 g, 30.0 mmol). Yield: 6.0 g (69%) of yellow crystals; mp 213°C (from ethanol). Infrared (KBr, cm^{-1}): 3421 (O-H), 3000–2000 (curtain O-H), 1602 (C=N), 1579 (C=C); ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 5.20 (s, CH_2), 6.76–7.53 (m, 5 aromatic H), 8.23 (dd, ^3J = 9 Hz, ^4J = 3 Hz, 1 aromatic H), 8.36 (s, N=CH), 9.23 (d, ^4J = 3 Hz, 1 aromatic H), 10.06 (s, broad, exchangeable, phenolic OH), 13.33 (s, broad, exchangeable, phenolic OH). Anal. calcd. for $C_{14}H_{12}N_2O_5$: C 58.33, H 4.20, N 9.72; found: C 58.32, H 4.25, N 9.57. The TTC test, carried out as with **5***a*, gives no red coloring of the solution.

C-(4-Diethylamino-2-hydroxyphenyl)-*N*-(2-hydroxyphenylmethyl)nitrone, 5*d*[6]

The compound is prepared as described for **5***a*, using 4-diethylamino-2-hydroxybenzaldehyde (5.80 g, 30.0 mmol). Yield: 4.7 g (50%) of pale-yellow crystals; mp 143°C (from ethanol). Infrared (KBr, cm^{-1}): 3100–1800 (curtain O-H), 1624 (C=N), 1600 (C=C); ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.10 (t, J = 7 Hz, 2 CH_3), 3.35 (q, J = 7 Hz, $N(CH_2)_2$), 5.00 (s, CH_2), 5.98 (d, ^4J = 3 Hz, 1 aromatic H), 6.21 (dd, ^3J = 9 Hz, ^4J = 3 Hz, 1 aromatic H), 6.73–7.43 (m, 5 aromatic H), 7.86 (s, N=CH), 10.30 (s, exchangeable, phenolic OH), 13.83 (s, exchangeable, phenolic OH); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.15 (t, J = 7 Hz, 2 CH_3), 3.33 (q, J = 7 Hz, $N(CH_2)_2$), 4.93 (s, CH_2), 6.00–7.43 (m, 7 aromatic H), 7.33 (s, N=CH), 10.63 (s, broad, exchangeable, phenolic OH), 13.23 (s, exchangeable, phenolic OH). Anal. calcd. for $C_{18}H_{22}N_2O_3$: C 68.77, H 7.05, N 8.91; found: C 68.82, H 7.48, N 8.94. The TTC test, carried out as with **5***a*, gives no red coloring of the solution. Crystals suitable for X-ray analysis were obtained by slow cooling of a solution of **5***d* in absolute ethanol. A stereoview of **5***d* is shown in Fig. 1.

2-Chloro-8-(2-hydroxyphenylmethyl)-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocycloheptene, 6*b*[7]

The compounds **5***b* (0.28 g, 1.0 mmol) and oxybis(diphenylborane) (0.17 g, 0.5 mmol) are dissolved separately, each in 20 mL of ethanol, with slight warming if necessary. After mixing the two solutions crystallization commences rapidly and gives an analytically pure product in most instances. Yield: 0.33 g (68%) of pale-yellow needles; mp 164°C (from ethanol). Infrared (KBr, cm^{-1}): 3430 (O-H), 1636 (C=N), 1615 (C=C); ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 1.06 (t, J = 6 Hz, CH_3), 3.45 (q, J = 6 Hz, OCH_2), 3.6 (s, broad, exchangeable, associated OH), 5.26 (s, NCH_2), 6.76–7.70 (m, 17 aromatic H), 8.53 (s, N=CH), 10.03 (s, exchangeable, phenolic OH); ^{11}B nmr (64 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 8.0 (broad, very

weak signal due to poor solubility). Anal. calcd. for $C_{26}H_{21}BClNO_3 \cdot C_2H_5OH$ ($C_{28}H_{27}BClNO_4$): C 68.95, H 5.58, B 2.22, Cl 7.27, N 2.87; found: C 69.20, H 5.67, B 2.33, Cl 7.04, N 2.79. The product gives a blue-colored solution in ethanol upon addition of diphenylcarbazone, indicating the presence of the chelated diphenylborenium (Ph_2B^+) ion (6).

8-(2-Hydroxyphenylmethyl)-2-nitro-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocycloheptene, 6*c*

The compound **5***c* (0.29 g, 1.0 mmol) is reacted with oxybis(diphenylborane) (0.17 g, 0.5 mmol) as described for **6***b*. Yield: 0.25 g (55%) of a pale-yellow powder; mp (dec.) 295°C; very poor solubility in the usual solvents (alkanols, alkanes, $CHCl_3$, CH_2Cl_2, Me_2SO, benzene, toluene, and water). Infrared (KBr, cm^{-1}): 3460 (O-H), 1651 (C=N), 1615 (C=C); mass spectrum (EI, 170°C, 70 eV), *m*/*z* (%): 452 (0.8) [M^+], 357 (100) [$M^+ - H_2O - C_6H_5$], 311 (22) [$M^+ - H_2O - C_6H_5 - NO_2$]; (CI, 170°C, NH_3, pos), *m*/*z* (%): 452 (58) [M^+], 435 (100) [M^+ – OH], 357 (56) [$M^+ - H_2O - C_6H_5$], 311 (5) [$M^+ - H_2O - C_6H_5 - NO_2$], 271 (24) [$M^+ - (C_6H_5)_2BO$]; (CI, 170°C, NH_3, neg), *m*/*z* (%): 434 (100) [$M^+ - H_2O$]. Anal. calcd. for $C_{26}H_{21}BN_2O_5$: C 69.05, H 4.86, B 2.39, N 6.19; found: C 69.09, H 4.73, B 2.33, N 6.10. The product gives a blue-color reaction with diphenylcarbazone, as described for **6***b*.

4-Diethylamino-8-(2-hydroxyphenylmethyl)-6,6-diphenyl-5,7-dioxa-8-azonia-6-borata-6,7-dihydro-5*H*-benzocycloheptene, 6*d*[7]

The compound **5***d* (0.31 g, 1.0 mmol) is reacted with oxybis(diphenylborane) (0.17 g, 0.5 mmol) as described for **6***b*. Yield: 0.40 g (76%) of yellow crystals; mp 118°C (from ethanol). Infrared (KBr, cm^{-1}): 3400 (O-H), 1605 (C=N/C=C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 1.18 (t, J = 6 Hz, 2 CH_3), 1.20 (t, J = 6 Hz, CH_3), 1.73 (s, broad, exchangeable, OH), 3.35 (q, J = 6 Hz, $N(CH_2)_2$), 3.65 (q, J = 6 Hz, OCH_2), 4.86 (s, NCH_2), 6.00–7.60 (m, 17 aromatic H and possibly phenolic OH), 7.48 (s, N=CH); ^{11}B nmr (64 MHz, $CDCl_3$–Et_2OBF_3), δ (ppm): 7.4 ($W_{1/2}$ = 430 Hz) and 45.4 ($W_{1/2}$ = 340 Hz), ratio of peak areas: 20:1. Anal. calcd. for $C_{30}H_{31}BN_2O_3 \cdot C_2H_5OH$ ($C_{32}H_{37}BN_2O_4$): C 73.28, H 7.11, B 2.06, N 5.34; found: C 72.96, H 7.27, B

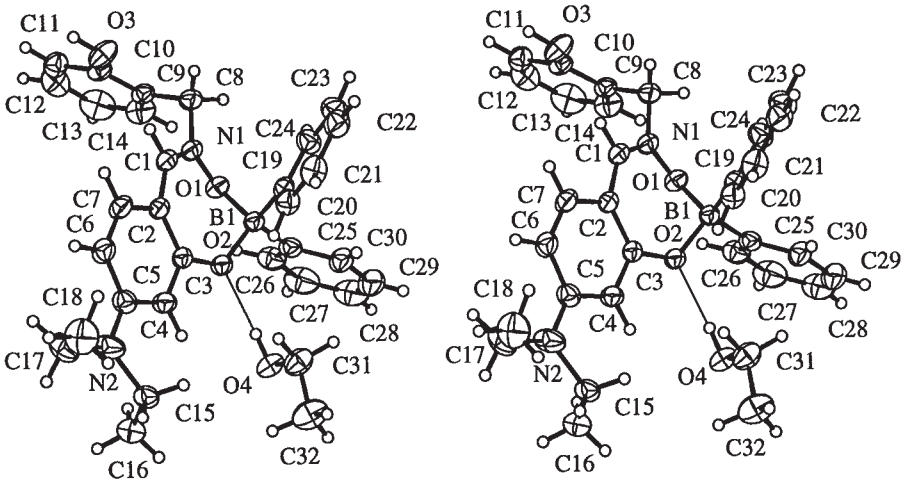
Fig. 2. Stereoview of **6***d*; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.



1.93, N 5.25. The product gives a blue-color reaction with diphenylcarbazone as described for **6***b*. Crystals suitable for X-ray analysis were obtained by slow cooling of a solution of **6***d* in absolute ethanol. A stereoview of **6***d* is shown in Fig. 2.

2-(2-Hydroxyphenyl)-4*H*-1,3-benzoxazine, 10*a*

The compound **5***a* (0.24 g, 1.0 mmol) is refluxed for 30 min in 30 mL of benzene using a Dean–Stark trap for continuous removal of water. After evaporation in vacuo the residue is recrystallized from ethanol. Yield: 0.21 g (93%) of colorless crystals; mp 155°C (from ethanol). Infrared (KBr, cm^{-1}): 3000–2000 (curtain O-H), 1661 (C=N), 1607 (C=C); ^{1}H nmr (90 MHz, $CDCl_3$–TMS), δ (ppm): 4.80 (s, CH_2), 6.80–7.50 (m, 7 aromatic H), 7.86–8.00 (m, 1 aromatic H), 13.13 (s, exchangeable, OH). Anal. calcd. for $C_{14}H_{11}NO_2$: C 74.65, H 4.92, N 6.22; found: C 74.63, H 4.86, N 6.11. The TTC test, carried out as with **5***a*, gives no red coloring of the solution.

6,6-Diphenyl-5,12-dioxa-6a-azonia-6-borata-5,6,7,12-tetrahydrobenz[a]anthracene, 11*a*[8]

The compound **5***a* (0.24 g, 1.0 mmol) is reacted with oxybis(diphenylborane) as described for the synthesis of **6***b*. Yield: 0.28 g (72%) of colorless crystals, mp 234°C (from ethanol). Infrared (KBr, cm^{-1}): 1651 (C=N), 1604 and 1591 (C=C); ^{1}H nmr (90 MHz, DMSO-d_6–TMS), δ (ppm): 4.38 (s, CH_2), 6.80–8.03 (m, 18 aromatic H); ^{1}H nmr (400 MHz, $CDCl_3$–TMS), δ (ppm): 4.33 (s, CH_2), 6.00 (dt, ^3J = 7 Hz, ^4J = 1 Hz, 1 aromatic H), 7.01 (s, 1 aromatic H), 7.03 (s, 1 aromatic H), 7.20–7.28 (m, 8 aromatic H), 7.33–7.37 (m, 1 aromatic H), 7.41–7.49 (m, 5 aromatic H), 7.79 (dd, ^3J = 8 Hz, ^4J = 1.5 Hz, 1 aromatic H); mass spectrum (EI, 125°C, 70 eV), *m*/*z* (%): 312 (100) [$M^+ - C_6H_5$]; (CI, 150°C, NH_3, neg), *m*/*z* (%): 389 (100) [M^+]. The product gives a blue-color reaction with diphenylcarbazone as described for **6***b*.

The compound **11***a* is also obtained in quantitative yield by the reaction of **10***a* (0.23 g, 1.0 mmol) with oxybis(diphenylborane) (0.17 g, 0.5 mmol) in ethanol. The spontaneously crystallizing substance is identical (by mp and IR) with **11***a* obtained from the reaction of **5***a* with oxybis(diphenylborane).

X-ray crystallographic analyses of 5*d* and 6*d*

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 93.8–107.8° for **5***d* and 76.5–90.7° for **6***d*. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random fluctuations for both compounds. The data were processed,[9] corrected for Lorentz and polarization effects, and absorption (based on azimuthal scans).

The structures were both solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. A two-fold disordering of one of the NEt groups of **6***d* was modeled by split-atom refinement. A constrained group occupancy factor was refined. All non-hydrogen atoms were refined with anisotropic thermal parameters. For **6***d* the hydrogen atoms associated with the disordered ethyl group were fixed in calculated positions with C-H = 0.98 Å and $B_H = 1.2B_{\text{bonded atom}}$, and all remaining hydrogen atoms for both structures were refined with isotropic thermal parameters. Corrections for secondary extinction were applied (Zachariasen type, isotropic, Gaussian), the final values of the extinction coefficients being $6.88(6) \times 10^{-6}$ for **5***d* and $3.18(13) \times 10^{-6}$ for **6***d*. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (7). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and intra-annular torsion angles appear in Tables 2–5, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles,

[8] Alternative nomenclature: 2-(2-diphenylboryloxyphenyl)-4*H*-1,3-benzoxazine (*N*→*B*).

Values given for *R*, R_w, and gof are based on those reflections with $I > 3\sigma(I)$.

intermolecular contacts, and least-squares planes are included as supplementary material.[10]

Results and discussion

The nitrones 5 are synthesized by the condensation of variously substituted salicylaldehydes with *N*-(2-hydroxyphenylmethyl)hydroxylamine. The infrared and ^{1}H nmr spectra generally confirm the supposed nitrone structure via C=N absorption frequencies between 1602 and 1624 cm^{-1} and broad O-H "association" bands between 1800 and 3100 cm^{-1} or the ^{1}H nmr signals of the N=CH methine protons between δ = 7.73 and 8.36 ppm, respectively. Moreover, two OH signals of two different phenolic groups are found in the ^{1}H nmr spectra, one around 10 ppm, and the other between 11.8 and 13.8 ppm. Comparable shift data have been reported for δ (N=CH) and δ (OH) of the *N*-*tert*-butylsalicylaldonitrone **1** (R = *t*-C_4H_9) (8): 7.72 and 12.37 ppm, respectively.

Only compound **5***a* displays additional bands in the infrared and additional signals in the ^{1}H nmr spectrum. The infrared spectrum of **5***a* shows a distinct second band in the C=N absorption region at 1661 cm^{-1} in addition to the expected nitrone C=N band at 1609 cm^{-1}. A probable explanation for the higher frequency band might be the formation of a dehydration product, **10***a*, during the preparation of the KBr pellet (high pressure and vacuum). The dehydration pathway via the cyclotautomeric forms **8** and (or) **8′** is suggested by the discovery of additional signals indicating the cyclotautomers **8***a* or **8′***a* in the ^{1}H nmr spectrum of **5***a* in $CDCl_3$ solution. The presence of a cyclic form like **8′***a* in the solid state cannot be excluded, considering that a nitrone of type **3** (Ar = 4-$MeOC_6H_4$) has been shown by X-ray analysis to

exist as its cycloisomer **3′** in the crystalline state (9). If **5***a*/**8′***a* is refluxed in benzene with continuous removal of water by a Dean–Stark trap, compound **10***a*, a hitherto (apparently) unknown 4*H*-1,3-benzoxazine derivative, is obtained in nearly quantitative yield. Furthermore, of all type **5** nitrones only **5***a* reacts spontaneously with triphenyltetrazolium chloride in alkaline solution, indicating the oxidizable N-OH function of the cyclic form **8′***a*, as demonstrated for other *N*-hydroxyl amines (6). This strongly supports the facile formation of the cycloisomer in solution, and also its probable existence in the solid state. The other type **5** nitrones, however, seem to be stable enough in their open-chain nitrone form and display no observable tendency to isomerize.

The X-ray analysis of **5***d* establishes the nitrone structure **5** for the crystalline state. Molecules of **5***d* feature an intramolecular hydrogen bond from the phenol group of the salicylaldehyde moiety to the nitrone *N*-oxide oxygen atom. This O(2)-H···O(1) bond is another example of a very strong intramolecular hydrogen bridge within a seven-membered "proton chelate" and has metrical parameters similar to those found in a similar salicylaldonitrone, **1** (R = *t*-C_4H_9) (8). The second phenol group, originating from the *N*-(2-hydroxyphenyl)hydroxylamine moiety, does not form an intramolecular hydrogen bond to the nitrone *N*-oxide group but rather links to the nitrone group of a neighboring molecule via intermolecular hydrogen bonding, thus forming infinite chains of **5***d* molecules about the two-fold screw axis. As a consequence, the nitrone oxygen atom serves as the nucleophilic center for bifurcated intra- and intermolecular hydrogen bonding to both of the phenol groups of **5***d*. In the nitrone **3** (Ar = 4-$Me_2NC_6H_4$) (3) the phenol group of the hydroxylamine moiety is engaged in a metrically similar intramolecular hydrogen bond to the *N*-oxide group, the O···O distance lying between those for the "chelate" and "chain" types found in **5***d*. Hydrogen-bonding parameters (O···O, O···H, H—O (Å), O···H-O (°)) are as follows: 2.473(4), 1.53(5), 0.96(5), 171(4) for **1**; 2.496(2), 1.53(2), 0.97(2), 170(2) for **5***d* (intramolecular H^+-chelate); 2.673(2), 1.75(2), 0.93(2), 172(2) for **5***d* (intermolecular "chain associate"); and 2.521(3), 1.40(3), 1.13(3), 174(2) for **3** (Ar = 4-$Me_2NC_6H_4$).

The N(1)—O(1) bond in **5***d* (1.343(2) Å) is significantly longer than the corresponding N—O bonds in **3** (Ar = 4-$Me_2NC_6H_4$) (1.324(2) Å) and related nitrones (3). One reason for this might be the two-fold demand on the nitrone oxygen atom by both intra- and intermolecular hydrogen bonds. In the nitrone **3** there is only a weak intramolecular C-H···O interaction in addition to the intramolecular O-H···O proton chelate bridge. The C=N bond of **5***d* (1.296(2) Å) does not differ significantly from the C=N double bond lengths of other nitrones (3).

An approximate coplanarity is seen, as in other *p*-dialkylaminosalicylaldehyde nitrone derivatives (3, 9), between the planes of the salicylaldehyde moiety, the dialkylaminophenyl moiety, and the nitrone function. The nature of the mesomeric resonance system is evinced by shortened bonds within the conjugated double-bond arrangement: N(2)—C(5) = 1.364(2) Å, C(3)—C(4) = 1.378(2) Å, C(6)—C(7) = 1.362(2) Å, and C(1)—C(2) = 1.429(2) Å.

Reaction of the nitrones **5** with diphenylborinic acid anhydride gives crystalline compounds containing an intact diphenylboron moiety shown by the blue-color reaction with diphenylcarbazone, which indicates the presence of the diphenylborenium (Ph_2B^+) moiety (5). The infrared, ^{1}H nmr, and ^{11}B nmr spectra, as well as the elemental analyses point to the alternative structures **6** and **7**. In the unique case of **5***a* the diphenylboron chelate has an elemental composition consistent with the elimination of one water molecule. Considering the missing O-H bands in the infrared spectrum, the missing phenolic proton, and the observed N=CH methine proton in the ^{1}H nmr spectrum; the chelate structure **11** seems most probable for this reaction product of **5***a*, especially since the above mentioned dehydration product of **5***a*, compound **10***a*, is easily formed. A simple confirmation comes from the reaction of **10***a* with diphenylborinic acid that results in **11***a*, an apparently new type of boron chelate.[11]

The diphenylboron chelates deriving from **5***b–d*, however, possess the spectroscopic properties of a seven-membered chelate of type **6** or **7**. The ^{1}H nmr spectra of **6***b* and **6***d* (the solubility of **6***c* was too low to record spectra) both display signals for the N=CH methine proton of the nitrone group and a phenolic OH proton. This precludes, at least for **6***b* and **6***d*, the isomeric structure **9** representing the

[11] Several boron chelates deriving from 2-(2-hydroxyphenyl)benzoxazole and other heteroanalogs of the benzazole series have been described in the literature (10) and are structurally similar to the diphenylboron chelate **11***a*.

diphenylboron chelate of the ring-isomeric form **8**. A compound of type **9** should display an acetalic O-CH-N proton in the ^{1}H nmr spectrum instead of the N=CH proton. No such signal is found. There still remains the problem of the assignment to one of the chelate structures **6** or **7**. As mentioned in the introduction, the seven-membered chelate **6** (employing the phenol group of the salicylaldehyde moiety) might be expected to be more stable; but, particularly in the case of the *p*-diethylamino substituted salicylaldehyde nitrone, the isomeric seven-membered chelate **7** could have formed. This ring system has already been established for the diphenylboron chelate **4** derived from a *p*-dimethylamino substituted benzaldehyde nitrone (3). For unambiguous proof of the molecular structure, an X-ray crystallographic analysis of the diphenylboron chelate of **5***d* was carried out. The diphenylboron chelates of both **5***b* and **5***d* crystallize as 1:1 ethanol solvates.

The X-ray analysis establishes the molecular structure **6***d* and thus shows that the chelate ring system of type **2** is favored, although the *p*-diethylamino substituent ($R^2 = NEt_2$) would allow the formation of a type **4** chelate ring, leading to the molecular structure **7***d*. It is reasonable to conclude that the structures of **6***b* and **6***c* are analogous to that of **6***d*, especially in view of the fact that there are no

p-dialkylamino substituents present in the aldehyde moieties of the ligands (**5***b* and **5***c*) increasing the basicities of the respective nitrone groups. Due to the poor solubility of **6***c* it was not possible obtain an ^{1}H nmr spectrum, thus confirmation of the nitrone structure by the presence of the N=CH methine proton signal is lacking. The mass spectra of **6***c* give different fragmentation patterns depending on the method. In the EI mode only a very weak molecular ion peak (0.8%) is found, and the most prominent peak corresponds to a ($M^+ - H_2O - C_6H_5$) fragment showing the formation of the above-mentioned 1,3-benzoxazine derivative via the elimination of water and dephenylation. The CI mass spectrum gives a ($M^+ - H_2O$) parent peak in the negative mode and a ($M^+ - OH$) parent peak in the positive mode, which could be identical to (**11***c*)$^+$ and (**11***c* + H)$^+$, respectively. The latter dephenylates to the ($M^+ - H_2O - C_6H_5$) fragment, as in the EI mass spectrum, identical to (**11***c* – C_6H_5)$^+$. The loss of NO_2 is also observed in both the EI and CI mass spectra. The molecular ion peak is observed at 58% in the CI (positive mode) spectrum. It might be concluded from the mass spectra that the cyclized isomer **9***c* is the educt, or perhaps an intermediate in the fragmentation of **6***c*. It would be premature at this point to present a definitive decomposition pathway, since we were not able to produce crystals of the educt (**6***c* or **9***c*) suitable for X-ray crystallographic analysis. The occurrence of **11***c* and its dephenylation product in the mass spectra is in accordance with the above-mentioned facile dehydration reactions and the formation of the 1,3-benzoxazine derivative and its diphenylboron chelate **11***a*.

In the crystal lattice of **6***d*·EtOH the ethanol connects two of the **6***d* molecules via hydrogen bonds. The ethanolic hydroxyl group associates with the phenolic oxygen atom O(2) in the boron chelate ring of **6***d*, and the ethanol oxygen atom donates electrons to the phenol group O(3)-H(2) of a neighboring molecule. Hydrogen-bonding parameters (O···O, O···H, H—O (Å), O-H···O(°)) are as follows: 2.852(2), 1.97(2), 0.90(2), 166(2) for O(2)···H(1)-O(4); and 2.689(2), 1.82(2), 0.90(2), 161(2) for O(4)(x, y, 1 + z)···H(2)-O(3).

The seven-membered ring in **6***d* has a somewhat distorted "envelope" (or "sofa") conformation with the boron atom on the "flap," displaced 1.00 Å from the mean plane of the O(1)-N(1)-C(1)-C(2)-C(3)-O(2) ring segment (see Table 5). One of the *B*-phenyl groups is oriented above the mean plane of the coplanar fused-ring system, and closely resembles the chelate ring system of compound **2** (R = Me) in its overall geometry (2). The difference between the two O—B bonds in **6***d* (0.024 Å), however, is smaller than the corresponding value of 0.054 Å in **2** (R = Me) (2). This is primarily a result of the relatively short (N)O—B bond in **6***d*, reflecting the enhanced basicity of the *N*-oxide group via the inductive and (or) mesomeric influence of the dialkylamino substituent *para* to the nitrone group. The mean O—B (1.516 Å) and C—B distances (1.607 Å) are both slightly shorter than the corresponding mean bond lengths in **2** (1.528 and 1.610 Å, respectively) (2), and the mean C—B/mean O—B bond length ratio of 1.060 is slightly larger than the value of 1.054 for **2** (R = Me) (2). This might point to a slightly increased overall binding strength (11) of the ligand with respect to the Ph_2B^+ nucleus in **6***d* relative to that in **2**, but there should be additional stabilizing factors in effect because the overall binding strength in the Ph_2BO_2 moiety of the seven-membered chelate system of **4** (Ar = 4-$Me_2NC_6H_4$) is roughly the same, if not slightly greater (mean C—B/mean O—B bond length ratio = 1.063) (3). Thus the preference of the seven-membered chelate ring type **6** to the isomeric type **7** cannot be rationalized in terms of ligand–BPh_2 binding strength alone. It is possible that steric factors, or even differences in solubility between **6** and **7**, may cause the preferential formation–precipitation of **6** out of an equilibrium mixture of the possible chelate forms **6** and **7**.

The C=N and N—O bond lengths of the nitrone group in **6***d* (1.299(2) and 1.360(2) Å) are very similar to those reported for the chelate **2** (R = Me) (1.286(4)[12] and 1.360(3) Å), and the phenolate C—O distances in these two compounds are equal within experimental error (C(3)—O(2) = 1.342(2) Å for **6***d* and 1.334(7) Å for **2**). The most conspicuous difference can be seen at the bond between the nitrone carbonyl carbon atom and the aryl residue of the salicylaldehyde moiety: in **6***d* the C(1)—C(2) bond (1.419(2) Å) is distinctly shorter than the corresponding (N)C—C(aryl) bond (1.466(4) Å) in compound **2** (2). This can be easily explained by a +M effect of the *para*-diethylamino group in **6***d*, which increases the double-bond character of the C(1)—C(2) bond. This is further supported by the approximate coplanarity (within ±0.06 Å) of the dialkylaminoaryl system. Relative to the free ligand **5***d*, both the C(1)—C(2) and N(2)—C(5) bonds show increased double-bond character in the boron chelate **6***d* with decreases in the bond lengths of about 0.01 Å, pointing to an influence of the electron-withdrawing effect of the Lewis-acid diphenylborenium (Ph_2B^+) nucleus over the entire resonance system.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada and the Fonds der Chemischen Industrie, Frankfurt am Main, for financial support. We are grateful to the spectroscopy laboratory of the Chemische Institute der Technischen Universität, Braunschweig, for running the ^{11}B nmr and mass spectra.

[12]All values reported for **2** (R = Me) correspond to average uncorrected values for the two independent molecules. The esd given is the individual value standard deviation or the rms deviation from the mean, whichever is larger.

Conformational isomers of 1,2,5,6-tetrathiocins and the photoisomerization of a 1,2,5,6-tetrathiocin into a 1,2,3,6-tetrathiocin: X-ray structures of $(C_6X_4S_2)_2$ (X = F, Cl) and $C_6F_4SSSC_6F_4S$

Tristram Chivers, Masood Parvez, Ignacio Vargas-Baca, and Gabriele Schatte

Abstract: The 1,2,5,6-tetrathiocins $(C_6X_4S_2)_2$ (**3a**, X = F; **3b**, X = Cl) are obtained in high yields by the oxidation of the dithiols 1,2-$C_6X_4(SH)_2$ (X = F, Cl) with I_2 or SO_2Cl_2, respectively. In the solid state **3a** has the C_{2h} (chair) conformation and crystallizes in two different phases: α-$(C_6F_4S_2)_2$, monoclinic, $P2_1/a$, a = 9.351(2), b = 6.465(2), and c = 11.546(2) Å, β = 95.60(1)°, V = 694.6(2) Å^3, Z = 2; and β-$(C_6F_4S_2)_2$, monoclinic, $P2_1/c$, a = 4.825(2), b = 11.302(2), and c = 12.453(2) Å, β = 91.45(3)°, V = 678.8(3) Å^3, Z = 2. By contrast, **3b** displays a D_2 (twist-boat) structure and crystallizes in the $C2/c$ space group with a = 15.243(3), b = 8.703(2), and c = 27.010(14) Å, β = 92.81(4)°, V = 3578(1) Å^3, and Z = 8. The derivative **3a** exists as an equilibrium mixture of two conformational isomers in toluene solution. The VT ^{19}F NMR data afford the thermodynamic parameters $\Delta H°$ = 9.9 ± 0.4 kJ mol^{-1} and $\Delta S°$ = 14 ± 1 J K^{-1} mol^{-1}. Density functional theory calculations for **3a** indicate that the D_2 conformation is lower in energy than the C_{2h} isomer by 4.6 kJ mol^{-1}. The photolysis of **3a** in benzene promotes a transannular sulfur migration to give the 1,2,3,6-tetrathiocin, $C_6F_4SSSC_6F_4S$ (**6**), which exists in a chair conformation with respect to antipodal sulfur atoms. Crystal structure of **6**: orthorhombic, space group *Pnma*, a = 8.652(6), b = 19.084(4), and c = 8.301(6) Å, V = 1370.6(14) Å^3, and Z = 4. The isomers **3a** and **6** were also characterized by EI mass spectrometry, ^{19}F NMR, FTIR, and Raman spectroscopies.

Key words: tetrathiocins, conformational isomers, photoisomerization.

Résumé : Les oxydations des dithiols 1,2-$C_6X_4(SH)_2$ (X = F, Cl) par I_2 ou SO_2Cl_2 conduisent aux 1,2,5,6-tétrathiocines $(C_6X_4S_2)_2$ (**3a**, X = F; **3b**, X = Cl) avec des rendements élevés. À l'état solide, le composé **3a** adopte la conformation C_{2h} (chaise) et cristallise dans deux phases différentes: α-$(C_6F_4S_2)_2$, monoclinique, $P2_1/a$, a = 9,351(2), b = 6,465(2) et c = 11,546(2) Å, β = 95,60(1)°, V = 694,6(2) Å^3, Z = 2 et β-$(C_6F_4S_2)_2$, monoclinique, $P2_1/c$, a = 4,825(2), b = 11,302(2) et c = 12,453(2) Å, β = 91,45(3)°, V = 678,8(3) Å^3, Z = 2. Par opposition, le composé **3b** existe sous la forme D_2 (bateau-croisé) et cristallise dans le groupe d'espace $C2/c$ avec a = 15,243(3), b = 8,703(2) et c = 27,010(14) Å, β = 92,81(4)°, V = 3578(1) Å^3, Z = 8. En solution dans le toluène, le dérivé **3a** existe sous la forme d'un mélange à l'équilibre de deux isomères conformationnels. Des données de RMN du ^{19}F à TV permettent de déterminer les paramètres thermodynamiques suivants: ΔH^0 = 9,9 ± 0,4 kJ mol^{-1} et ΔS^0 = 14 ± 1 J K^{-1} mol^{-1}. Des calculs de densité fonctionnelle sur le composé **3a** indiquent que l'énergie de la conformation D_2 est 4,6 kJ mol^{-1} plus faible que celle de l'isomère C_{2h}. La photolyse du composé **3a** dans le benzène provoque une migration transannulaire du soufre conduisant à la formation de la 1,2,3,6-tétrathiocine, $C_6F_4SSSC_6F_4S$ (**6**), qui existe dans une conformation chaise par rapport aux atomes de soufre antipodaux. Structure cristalline du composé **6**: orthorhombique, groupe d'espace *Pnma*, a = 8,652(6), b = 19,084(4) et c = 8,301(6) Å, V = 1370,6(14) Å^3, Z = 4. Les isomères **3a** et **6** ont aussi été caractérisés par spectrométrie de masse sous IE, par RMN du ^{19}F et par spectroscopies FTIR et Raman.

Mots clés : tétrathiocines, isomères conformationnels, photoisomérisation.

[Traduit par la Rédaction]

Introduction

A sulfur atom (-S-) and a -CH_2- group can be viewed as isoelectronic with the important difference that, in a ring system, the exocyclic electron pairs are nonbonding for -S- but bonding for -CH_2-. Consequently, the effect that the replacement of some of the -CH_2- groups by -S- linkages has

Received February 2, 1998.

on the structures and conformational barriers of organic ring systems is of interest. This substitution generally facilitates the observation of interconversion by increasing the magnitude of the inversion barriers (1). Since the number of degrees of freedom and the complexity of the system increase with the number of atoms in the ring, the majority of conformational investigations has been concerned with six-membered heterocycles (2).

The study of larger rings is simplified when some atoms are constrained to remain in a plane, e.g., 1,2,5,6-tetrathiocin **1**.[2] Although 3,4,7,8-tetrakis(trifluoromethyl)-1,2,5,6-tetrathiocin has been known since 1960 (3), it has not been structurally characterized. The parent ring system **1** was synthesized for the first time in 1996 (4). As in the case of cycloocta-1,5-diene (5), 1,2,5,6-tetrathiocin (**1**) should exhibit several conformers. Recent ab initio molecular orbital calculations predict that a (*Z*,*Z*) twist form of **1** (approximately D_2 symmetry) represents a global minimum (6) and that structure has been found in the solid state by an X-ray crystallographic analysis (Scheme 1) (4). By contrast the twist-boat form (C_2 symmetry) was calculated to be the global minimum for cycloocta-1,5-diene (5). The calculations also predict that the chair (*Z*,*Z*) conformation of **1** (C_{2h} symmetry) (Scheme 1) is only 22.2 kJ mol^{-1} higher in energy than the D_2 isomer (6), and consequently, this alternative geometry should be readily accessible. Indeed the chair conformation of the C_4S_4 ring has been established for C_6S_{10} (**2a**) (7) and the related derivative (**2b**) (8).

In this article we describe the synthesis and X-ray structures of the octahalogenated derivatives **3a** and **3b**. The fluoro derivative **3a** exists as an equilibrium mixture of two conformational isomers in solution. The thermodynamic parameters for this interconversion process, obtained from variable temperature ^{19}F NMR data, are compared with the values calculated by density functional theory (DFT) calculations. In view of the photochemical sensitivity of the parent system **1** (4), the photolysis of **3a** was also investigated.

Experimental section

Reagents and general procedures

All solvents were dried by treatment with the appropriate drying agent and freshly distilled before use. 1,2,3,4-Tetrafluorobenzene, C_6Cl_6, *n*-BuLi (2.5 M solution in hexanes), $Na_2S\cdot 9H_2O$, and I_2 were commercial reagents used as received. The SO_2Cl_2 was distilled under an N_2 atmosphere before use. Sulfur was recrystallized from CS_2. Tetrafluorobenzene-1,2-dithiol, C_6F_4-1,2-$(SH)_2$ (bp 50°C, 5 × 10^{-2} Torr (1 Torr = 133.3 Pa); ^{1}H NMR ($CDCl_3$), δ: 3.82; ^{19}F NMR ($CDCl_3$): –131.7 (m) and –158.5 (m)) was obtained in 70% yield by the literature method (9). The C_6Cl_4-1,2-$(SH)_2$ was prepared by a modification (vide infra) of the literature method (10). The $(C_6F_4S)_2$ was also synthesized by a known procedure (11).

Instrumentation

The ^{1}H NMR spectra were obtained on a Bruker ACE 200 MHz spectrometer, and chemical shifts are reported in ppm relative to Me_4Si. The ^{19}F NMR spectra were recorded on a Bruker AMX 300 spectrometer; chemical shifts are reported relative to $CFCl_3$ and were measured with an external standard of C_6F_6 (δ –162.9 ppm). Electron impact mass spectra were obtained by using a VG Micromass spectrometer (VG 7070) set at 70 eV. The FTIR spectra were recorded as Nujol mulls (KBr plates) on a Mattson 4030 FTIR spectrometer in the range 4000–300 cm^{-1} (resolution: 4 cm^{-1}; number of scans: 128). Raman spectra were recorded using a Jarrell–Ash model 25-100 monochromator interfaced to a microcomputer. A Coherent Radiation Model 540 argon laser fitted with an Innova 70 plasma tube was used as the exciting source (emission wavelength: 514.5 nm; laser power: 100 mW; laser current: 30 A). Scattered radiation was collected at 90° to the incident light. The Raman spectra were obtained from neat samples sealed in melting point tubes and measured in the range 2500–100 cm^{-1} at room temperature. The frequencies are believed accurate to ±2 cm^{-1}. Elemental analyses were performed by Canadian Microanalytical Service Ltd., Vancouver, B.C., and by Galbraith Laboratories Inc., Knoxville, Tennessee.

Preparation of C_6Cl_4-1,2-$(SH)_2$

In a typical preparation C_6Cl_6 (32.7 g, 0.11 mol), Fe powder (6.2 g, 0.11 mol) and $Na_2S\cdot 9H_2O$ (54 g, 0.22 mol) were heated at reflux in DMF (1 L) for 48 h. **Caution**: a wide-necked condenser and vigorous reflux are necessary to prevent sublimed C_6Cl_6 from plugging the condenser and

causing a pressure build-up. The mixture was allowed to cool to 23°C and then 2 L of NaOH (0.75 M) were added with vigorous stirring. The mixture was allowed to settle (48 h) and then centrifuged to separate the solid, which was dissolved in 300 mL of MeOH and refluxed for 3 h with ZnO (8 g) and NaOH (150 mL, 0.75 M). The hot slurry was filtered, and the solution was acidified to a neutral pH with H_2SO_4. A pale-yellow precipitate was filtered and dried with an air stream in the filtration funnel. This product was extracted (Soxhlet apparatus) with Et_2O to remove a dark-green insoluble material. The solvent was evaporated from the solution to leave 11.3 g of a yellow solid. This crude product was shown by EIMS to consist of a mixture of C_6Cl_5SH and C_6Cl_4-1,2-$(SH)_2$ (yield ~36%). Recrystallization from toluene and subsequent sublimation (140°C, 5×10^{-2} torr) produced C_6Cl_4-1,2-$(SH)_2$ containing only traces of C_6Cl_5SH.

Preparation of $(C_6F_4S_2)_2$ (3a)

A solution of C_6F_4-1,2-$(SH)_2$ (1.66 g, 7.70 mmol) in methanol (50 mL) was treated with a solution of I_2 (1.97 g, 7.70 mmol) in methanol (50 mL). A pale-yellow, microcrystalline product was formed. The crude product was filtered, rinsed with cold methanol, and recrystallized from Et_2O to give $(C_6F_4S_2)_2$ (**3a**) (1.42 g, 3.32 mmol, 86%); mp 193°C. Anal. calcd. for $C_6F_4S_2$: C 33.96, F 35.82, S 30.23; found: C 33.81, F 33.85, S 30.55.[3]

EIMS (*m*/*z*, %): 424, 40 (M^+), 328, 15 ($C_{12}F_8S^+$), 212, 100 ($C_6F_4S_2^+$), 168, 38 ($C_5F_4S^+$). ^{19}F NMR ($CDCl_3$, δ): two sets of resonances at –130.1 (m), –154.4 (m) and –122.1 (m), –147.4 (m) with approximate relative intensities 1:4. IR (Nujol, cm^{-1}): 1594 m, 1307 s, 1237 s, 1038 s, 973 m, 872 s, 818 s, 724 s, 483 w, 414 s.

Preparation of $(C_6Cl_4S_2)_2$ (3b)

A solution of SO_2Cl_2 (0.67 g, 5.0 mmol) in benzene (10 mL) was added to a solution of C_6Cl_4-1,2-$(SH)_2$ (1.33 g, 4.75 mmol) in benzene (50 mL). After 1 h the solvent was decanted by cannula to leave a yellow solid, which was rinsed with pentane (2 × 10 mL) to give $(C_6Cl_4S_2)_2$ (**3b**) (1.18 g, 2.12 mmol, 90%); mp 290°C (dec.). Anal. calcd. for $C_6Cl_4S_2$: C 25.92, Cl 51.01, S 23.07; found: C 26.30, Cl 48.88, S 23.27.[3] EIMS (*m*/*z*): 556 (M^+). IR (Nujol, cm^{-1}): 1377 s, 1335 m, 1303 s, 1095 m, 869 m.

Photoisomerization of 3a

A solution of **3a** (0.60 g, 1.41 mmol) in benzene (50 mL) in a Pyrex vessel at 23°C was irradiated with a Hg lamp. The progress of the reaction was monitored by ^{19}F NMR spectroscopy. After 7 h, solvent was removed under vacuum and the pale-yellow product was recrystallized from CH_2Cl_2–hexane to give $C_6F_4SSSC_6F_4S$ (**6**) (0.35 g) contaminated with **3a** (^{19}F NMR). A pure sample of **6** was obtained as a white solid by vacuum sublimation at 90°C and 10^{-3} Torr; mp 116–117°C. Anal. calcd. for $C_6F_4S_2$: C 33.96, S 30.23; found: C 33.53, S 32.10.[3] EIMS (*m*/*z* %): 424, 30 (M^+), 392, 26 ($C_{12}F_8S_3^+$), 360, 40 ($C_{12}F_8S_2^+$), 328, 100 ($C_{12}F_8S^+$), 244, 20 ($C_6F_4S_3^+$), 212, 100 ($C_6F_4S_2^+$), 180, 37 ($C_6F_4S^+$), 168, 40 ($C_5F_4S^+$); ^{19}F NMR ($CDCl_3$, δ): –117.3 (m), –122.9 (m), –147.5 (m), –147.8 (m). IR (Nujol, cm^{-1}): 1600 (s), 1487 (vs), 1305 (s), 1237 (s), 1163 (s), 1115 (s), 1042 (vs), 970 (m), 951 (m, sh), 866 (s), 817 (s), 771 (m), 724 (s), 491 (m), 446 (m).

X-ray diffraction studies

All measurements were made on a Rigaku AFC6S diffractometer using graphite monochromated Mo-K_α radiation. Crystallographic data for α-**3a**, β-**3a**, **3b**, and **6** are given in Table 1.[4]

α-3a

A yellow hexagonal-plate crystal of α-$(C_6F_4S_2)_2$ was mounted on a glass fibre. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 17 carefully centred reflections in the range $30.00 < 2\theta < 50.00°$, corresponded to a primitive monoclinic cell. The data were corrected for Lorentz, polarization, and empirical absorption effects (12). The structure was solved by direct methods (13) and expanded using Fourier techniques (14). All non-hydrogen atoms were refined anisotropically. All calculations were performed using the teXsan crystallographic software package (15).

β-3a

A yellow prismatic crystal of β-$(C_6F_4S_2)_2$ was mounted on a glass fibre. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 13 carefully centred reflections in the range $40.00 < 2\theta < 50.00°$, corresponded to a primitive monoclinic cell. The structure was solved by direct methods (16) and expanded using Fourier techniques (14). The rest of the calculations involving data processing and structure refinement followed the same procedures as described for α-**3a**.

3b

An orange prismatic crystal of $(C_6Cl_4S_2)_2$ was mounted on a glass fibre. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 25 carefully centred reflections in the range $15.00 < 2\theta < 30.00°$, corresponded to a C-centred monoclinic cell. Based on the systematic absences *hkl*, $h + k \neq 2n$ and *h*0l, $l \neq 2n$, packing considerations, a statistical analysis of intensity distribution, and the successful solution and refinement of the structure, the space group was deter-

[3] Consistently low analyses for halogens were obtained for both **3a** and **3b** by two different commercial analysts. Low analyses for fluorine were also obtained for **6**.

[4] Crystal data, tables of atomic coordinates and displacement parameters, complete listings of bond lengths and angles, and other refinement data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2. Crystal data, atomic coordinates, and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

mined to be *C*2/*c* (no. 15). The data processing, structure solution, and refinement followed the same procedures as described for α-**3a**.

6

A colourless, plate-like crystal of $\overline{C_6F_4SSSC_6F_4S}$ was mounted on a glass fibre. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 25 carefully centred reflections in the range $18.21 < 2\theta < 21.43°$, corresponded to a primitive orthorhombic cell. Based on the systematic absences of 0*kl*, $k + 1 = 2n + 1$ and *hk*0, $h = 2n + 1$, packing considerations, a statistical analysis of intensity distribution, and the successful solution and refinement of the structure, the space group was determined to be *Pnma* (no. 62). The structure was solved by direct methods (16) and expanded using Fourier techniques (14). The structure was refined with the aid of SHELX93 (17). Other details of the structure refinement were similar to those described for β-**3a**.

Computational details

Details of the methods used for the DFT calculations can be found in ref. 18.

Results and discussion

Synthesis and X-ray structures of dibenzotetrathiocins 3a and 3b

The tetrathiocins $(C_6F_4S_2)_2$ (**3a**) and $(C_6Cl_4S_2)_2$ (**3b**) were prepared by the oxidation of the corresponding dithiols with I_2 or SO_2Cl_2, respectively, in >85% yields. Compounds **3a** and **3b** are air stable, pale-yellow solids with high thermal stability. They are also stable in polar solvents, e.g., acetonitrile or chloroform. For comparison, the parent tetrathiocin (**1**), which is obtained in only 14% yield by the oxidation of *cis*-disodium ethene-1,2-dithiolate, is converted to the tetramer $(-CH{=}CH-S-S-)_4$ in acetonitrile at room temperature (4).

Single crystals of **3a** were grown from a diethyl ether solution. Two different crystalline phases, which could be separated manually, were apparent. The most abundant (α-**3a**) consists of hexagonal plates, while the other phase (β-**3a**) forms rectangular prisms. X-ray diffraction analysis reveals that the chair conformer (C_{2h}) of the 1,2,5,6-tetrathiocin ring pertains in both types of crystals (see Fig. 1). The difference between the α and β phases is caused by distinctive packing arrangements (see Figs. 2 and 3). A chair conformation for the 1,2,5,6-tetrathiocin ring has also been observed for **2a** (7) and **2b** (8). By contrast, crystals of **3b**, obtained by slow evaporation of a very dilute THF solution, provided an

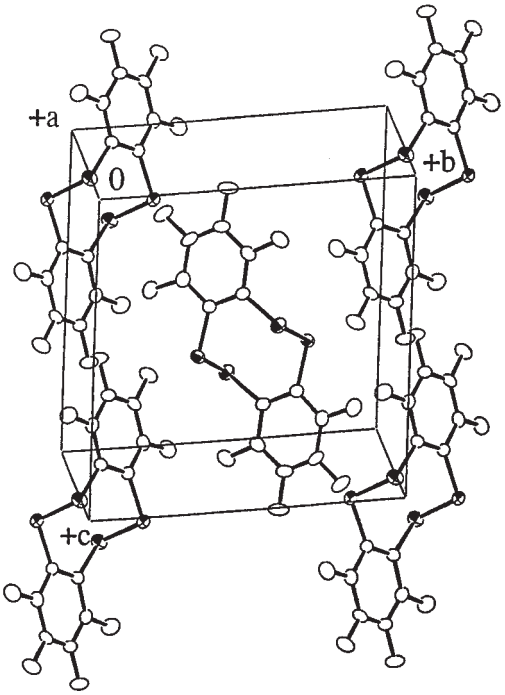
X-ray structure corresponding to the known twist-boat conformation (D_2) of the tetrathiocin ring **1** (4)) (see Fig. 4).

Relevant molecular dimensions for **3a** and **3b** are summarized in Tables 2 and 3. The mean bond distances and bond angles in the two dibenzotetrathiocins are very similar (|*d*(C—C)| = 1.40 Å, *d*|(C—S)| = 1.77 Å, *d*|(S—S)| = 2.05 Å, |angle CCS| = 124.3°, |angle CSS| = 103.8°). For comparison, the corresponding values for the parent compound **1** are 1.33 Å, 1.75 Å, 2.06 Å, 129.0°, and 104.8°(4). The benzo-dithiolato units in **3a** and **3b** are nearly planar, with S-C-C-S and S-C-C-C torsion angles close to 0° and 180°,

Fig. 3. Packing diagram for the β crystalline phase of $(C_6F_4S_2)_2$ (**3a**).



respectively. The C-S-S-C torsion angles are ca. 111° for **3a** and 115.3(4)° and 118.2(4)° for **3b**. The major disparity resulting from the different ring conformations of **3a** and **3b** is in the S-S-C-C torsion angles, which are 79.9° for **3a** and 42.3-52.2° for **3b**.

Conformational isomers of 3a

The ^{19}F NMR spectrum of **3a** in toluene solution at 300 K displays four resonances. These can be separated into two pairs, on the basis of their relative intensities. The less intense pair of AA′XX′ multiplets is centred at δ –130.7 and –154.7 ppm, while the more intense pair appears at δ –123.3 and –148.3 ppm. These observations suggest that **3a** exists as a mixture of the C_{2h} and D_2 conformers in solution (see Table 4). The interconversion of these two conformational isomers in toluene solution was investigated by variable temperature ^{19}F NMR spectroscopy. The relative intensity of the two pairs of resonances changes reversibly within the temperature range 300–380 K, as a result of the equilibrium between the two conformers. However, no significant line broadening or chemical-shift changes were observed, indicating that the fluxional process is too slow to be observed on the NMR time scale. The equilibrium constants at different temperatures were obtained from the intensity ratios for the two pairs of resonance (see Table 5) and a plot of ln *K* vs. T^{-1} (see Fig. 5) was used to determine $\Delta H°$ and $\Delta S°$ for this process. The experimental value of $\Delta H°$ is 9.9 ± kJ mol^{-1}. The $\Delta S°$ value of 14 ± 1 J K^{-1} can be attributed primarily to changes in solvation.

In view of the apparent inversion of the order of stability of the C_{2h} and D_2 conformers for **3a** compared to that calculated for **1** (6), the energies of these two conformers were determined by density functional theory calculations. The structure of **3a** was fully optimised for both C_{2h} and D_2 sym-

metries. The molecular dimensions were in agreement with the experimental values for **3a** and **3b** to within 0.01 Å for bond distances, 1° for bond angles, and 5° for torsional angles. The calculations indicate that the D_2 conformer should be the most stable in this case, but the difference of total energies of the two conformers is only 4.6 kJ mol^{-1}, significantly less than the value of 22.2 kJ mol^{-1} estimated for **1** (6).

produced the bicyclic product **4** in 62% yield, suggesting the intermediate formation of the thioaldehyde **5**.

In view of these observations it was of interest to determine the influence of the rigid benzo substituents in **3a** on the outcome of the photochemical transformation. A solution of **3a** in benzene in a Pyrex vessel was irradiated with a medium-pressure mercury lamp through a Pyrex filter. The reaction was monitored by ^{19}F NMR, which revealed the formation of an intermediate with resonances at δ –121.8, –123.3, –146.7, and –147.1. The final product was identified as octafluorodibenzo-1,2,3,6-tetrathiocin (**6**) by elemental analysis, EIMS, ^{19}F NMR, IR, and Raman spectra, and by an X-ray structure (vide infra).

The photoisomerized product **6** is readily distinguished from the isomers of **3a** by the ^{19}F NMR spectrum, which exhibits an AMXY pattern (Table 4). The multiplets attributed to the inequivalent *ortho*-fluorine atoms have significantly different chemical shifts whereas those assigned to the other pair of inequivalent fluorine atoms differ by only 0.3 ppm. The mass spectra of **3a** and **6** show major differences. Both compounds exhibit the molecular ion $C_{12}F_8S_4^+$ with similar intensities. However, the mass spectrum of **6** also exhibits increasingly high abundances of the ions $[C_{12}F_8S_3]^+$ and $[C_{12}F_8S_2]^+$, suggesting that loss of sulfur (from the S_3 chain) is the dominant fragmentation process, which leads to the parent ion $[C_{12}F_8S^+]$. By contrast, the parent ion for **3a** is the monomeric fragment $C_6F_4S_2^+$, indicating that cleavage of *both* disulfide bonds occurs predominantly in this case.

Raman spectroscopy is a diagnostic technique for the identification of SS vibrations, which are normally observed in the 450–550 cm^{-1} region (19). In the present work, the photoisomerized product **6** should be readily distinguished by the presence of both asymmetric and symmetric stretching vibrations for the trisulfide (S_3) unit, whereas the precursor **3a** will exhibit only ν_s(SS). Consistently, the Raman spectrum of **6** shows bands at 492 and 469 cm^{-1}. On the basis of its stronger intensity, the former is attributed to ν_s(SSS) (cf. HSSSH (20)). The Raman spectrum of **3a** exhibits only one band in the 450–550 cm^{-1} region at 497 cm^{-1}, which is assigned to ν_s(SS) (cf. 489 cm^{-1} for $C_6F_5SSC_6F_5$ (21)).

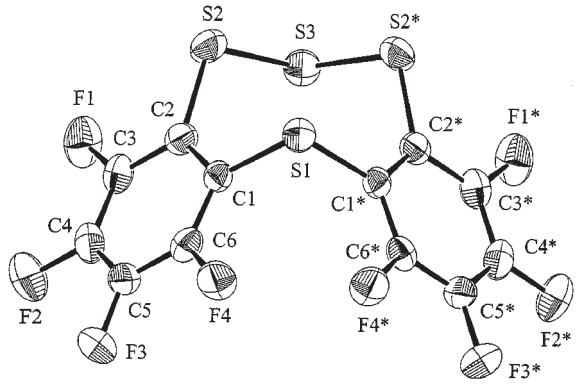
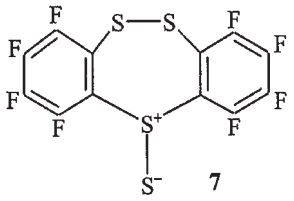
Fig. 6. The ORTEP diagram for $\overline{C_6F_4SSSC_6F_4S}$ (**6**).



The photochemical transformation of **3a** into **6** (eq. [1]) formally involves a transannular migration of a sulfur atom. In view of the similarity of the ^{19}F NMR spectra of **6** and the intermediate observed in this process (vide supra), it is suggested that this intermediate is a conformational isomer of **6**. A similar isomerization of a C_4S_4 ring has been reported for C_6S_{10} (**2a**) but, in that example, the transformation from a 1,2,5,6- to a 1,2,3,6-tetrathiocin involves a Hg^{2+}-promoted hydrolysis to give $C_6S_8O_2$ (22*a*). A mechanism involving a thiosulfoxide intermediate has been proposed for the sulfur transfer process (22*b*). Although organic



7

thiosulfoxides R_2SS have not characterized, the SS double bond is known to be stabilized by electronegative groups (23). For example, the cyclic thiosulfite ROS(=S)OR (R = cyclohexylidene) is stable at 20°C (24). In the case of the transformation represented by eq. [1], the proposed intermediate **7** may be stabilized by the electronegative perfluoroaryl groups attached to sulfur. Finally, we note that **6** is unstable in solution in polar solvents and slowly reverts to **3a**.

X-ray structure of octafluorodibenzo-1,2,3,6-tetrathiocin (6)

The structure of **6** was established by X-ray crystallography. An ORTEP diagram is represented in Fig. 6, and relevant structural parameters are given in Table 6. The S—S bond length of 2.047(1) Å is, as expected, a typical single-bond value. The bond angle S-S-S = 107.2(1)° is close to the mean value of 107.9° reported for *cyclo*-octasulfur (21). However, the mean bond distance, *d*|(C—S)| = 1.79 Å, and mean bond angles, |angle CCS| = 122.6°, |angle CSS| = 103.1°, show small, but significant, differences from the corresponding values for **3a** and **3b**, possibly owing to slightly greater ring strain in **6**. The small bond angle C(1)-S(1)-S(1)* of 102.81(1)° is perhaps indicative of some ring strain. The C_4S_4 ring in **6** adopts a chair conformation with respect to the sulfur atoms S(1) and S(3). The value of

[a] Starred atoms are related to the unstarred atoms by symmetry operation: *x*, 1/2 – *y*, *z*.

93.8(1)° for the torsion angle C-S-S-S in **6** is significantly smaller than the corresponding values for the torsion angles involving a central disulfide linkage in **3a** or **3b**, which are in the range 111–118°. We tentatively suggest that the intermediate detected by ^{19}F NMR in the photochemical transformation of **3a** into **6** is the corresponding boat conformer of **6**.

Conclusions

The 1,2,5,6-tetrathiocins $(C_6F_4S_2)_2$ (**3a**) and $(C_6Cl_4S_2)_2$ (**3b**) adopt chair (C_{2h}) and twist-boat (D_2) conformations of the C_4S_4 ring, respectively. The difference in the energies of the two conformers for **3a** is very small (<5 kJ mol^{-1}), and this derivative undergoes a slow conformational isomerization in solution. The photolysis of **3a** promotes a reversible, transannular sulfur migration to give the 1,2,3,6-isomer (**6**).

A new one-dimensional thiocyanato-bridged bimetallic compound $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$. Synthesis, crystal structure, and magnetic properties

Hui-Zhong Kou, Dai-Zheng Liao, Peng Cheng, Zong-Hui Jiang, Shi-Ping Yan, Geng-Lin Wang, Xin-Kan Yao, and Hong-Gen Wang

Abstract: A bimetallic compound $[Cu(en)_2Mn(NCS)_4(H2O)_2]_n$ (en = ethylenediamine) has been prepared and its structure determined. It crystallizes in space group $P\bar{1}$, with a = 7.432(1), b = 7.492(1), c = 9.751(2) Å, α = 91.00(3)°, β = 99.14(3)°, γ = 112.51(3)°, and Z = 1. The structure consists of one-dimensional chains in which alternating Mn(II) and Cu(II) ions are bridged by NCS ligands. The coordination environment is octahedral for Mn(II) and elongated octahedral for Cu(II). From magnetic susceptibility measurements the compound was found to exhibit a ground state of low-spin multiplicity. Comparison between theory and experimental has been made using 1-D model and taking into account the zero-field splitting effect. The decrease in $\chi_m T$ observed at low temperature for the compound is attributed to a dominant zero-field splitting of the single Mn(II) ions with a weak antiferromagnetic interaction superimposed between the Mn(II) ions via the NCS-Cu-SCN pathway within each chain.

Key words: crystal structure, copper(II) complexes, manganese(II) complexes, thiocyanate bridges, bimetallic complexes.

Résumé : On a préparé un composé bimétallique $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$ (en = éthylènediamine) et on a déterminé sa structure. Il cristallise dans le groupe d'espace $P\bar{1}$, avec a = 7,432(1), b = 7,492(1) et c = 9,751(2) Å, α = 91,00(3), β = 99,14(3) et γ = 112,51(3)° et Z = 1. La structure comporte des chaînes unidimensionnelles dans lesquelles les ions Mn(II) et Cu(II) qui alternent sont reliés par des ponts de ligands NCS. L'environnement de coordination est octaédrique pour le Mn(II) et octaédrique allongé pour le Cu(II). Sur la base de mesures de susceptibilité magnétique, on a trouvé que l'état fondamental du composé présente une multiplicité à faible spin. On a effectué une comparaison entre les résultats expérimentaux et les valeurs théoriques obtenues à l'aide d'un modèle 1-D, en tenant compte de l'effet de couplage à champ nul. La diminution dans la valeur de $\chi_m T$ observée pour le composé à basse température est attribuée à un couplage à champ nul dominant des ions Mn(II) individuels avec une faible interaction antiferromagnétique superposée entre les ions Mn(II) par le biais d'une voie NCS-Cu-SCN dans chaque chaîne.

Mots clés : structure cristalline, complexes du Cu(II), complexes du Mn(II), ponts thiocyanates, complexes bimétalliques.

[Traduit par la rédaction]

Introduction

The first molecular-based magnet emerged a decade ago (1), and during the last period a number of new compounds of this type have been reported (2–8). To obtain molecular-based ferromagnets, several means have been used (9–11). Among them, the exchange couplings of low-dimensional bimetallic Cu(S = 1/2)-Mn(S = 5/2) compounds have been paid much attention (12–15). Kahn and co-workers (3, 13) have suggested that such compounds may exhibit ferrimagnetic behavior at low temperatures. The Kahn concept is based on the following assumptions. In theory, provided that the Mn(II) and Cu(II) ions are antiferromagnetically coupled in all cases, an ordered alternation of the Mn and Cu ions is required throughout the crystal lattice. If so, below certain transition temperature the intrinsic antiferromagnetic interactions between the adjacent metal ions make the S_{Mn} and S_{Cu} antiparallel, and the material retains a net spin ($S = S_{Mn} - S_{Cu} = 2$) because the two sublattices are not equivalent (15).

However, it should be noted that some Cu(II)-Mn(II) compounds assume different magnetic properties. Very recently, Chiari et al. (16) reported that a bimetallic chain compound $Cu(en)_2MnCl_4$, exhibiting a ground state of low-spin multiplicity, does not conform to the above expectation.

N(1)-C(1)-S(1)	178.3(6)

The unexpected cancellation of the spins has been attributed to the presence of either a dominant Mn(II)···(Mn(II) antiferromagnetic interaction within the chain or, alternately, cooperative intrachain and interchain Mn···Cu interactions of opposite signs. Some other compounds of this type show similar magnetic behaviours; however, the zero-field splitting effects were introduced to interpret the phenomenon (17, 18). Obviously, more such examples are needed in order to determine the relationship between the magnetic properties and molecular structures.

In this paper, we report a new compound, $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$ (en = ethylenediamine). The compound has bimetallic chains with alternating copper(II) and manganese(II) ions within each chain, and shows magnetic properties quite different from those expected but similar to those of $Cu(en)_2MnCl_4$ (16).

Experimental

Synthesis of $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$

To an aqueous solution of $MnSO_4 \cdot H_2O$ was added KSCN dissolved in water in a Mn:SCN molar ratio of 1:4. To the resulting solution was added ethanol (95%), then filtered. The filtrate was evaporated in a water bath giving rise to light pink microcrystals of $K_2[Mn(NCS)_4(H_2O)_2]$.

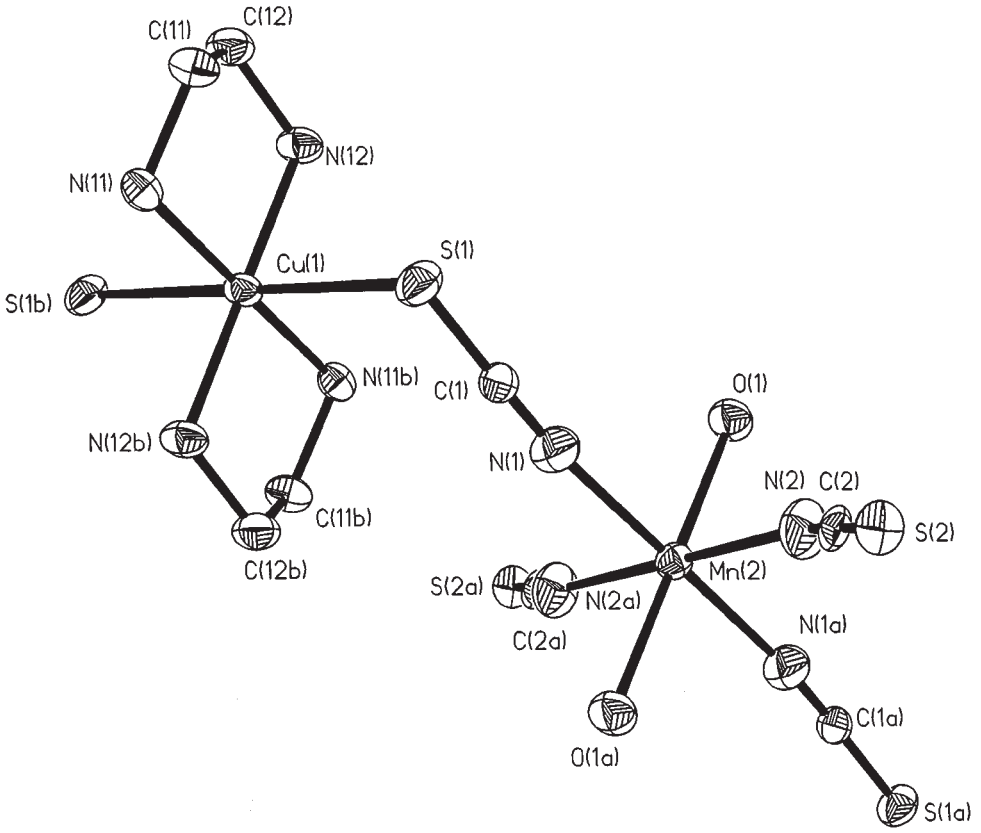
Equimolar amounts of $K_2[Mn(NCS)_4(H_2O)_2]$ and $Cu(en)_2Cl_2$ were mixed in aqueous solution to give rise to blue microcrystals. Crystals of large size for X-ray analysis and magnetic studies were obtained by recrystallization of the material from water. The yield is almost quantitative; mp 162–163°C. Anal. calcd for $C_8H_{20}N_8O_2S_4CuMn$: C 18.95, H 3.9, N 22.1; found: C 19.3, H 3.8, N 22.0%.

Physical measurements

Elemental analyses of carbon, hydrogen, and nitrogen were carried out with a Perkin–Elmer analyzer model 240. The electronic spectrum was measured with a Perkin–Elmer Hitachi-240 spectrophotometer. The infrared spectroscopy using a KBr pellet was performed on a Nicolet 5DX FT-IR spectrophotometer in the 4000–400 cm^{-1} region. Using the flotation method (carbontetrachloride and 1,3-dibromopropane), the density of the compound was determined. Magnetic susceptibility measurement of a crystalline sample was

© 1998 NRC Canada

Fig. 1. The ORTEP (35) drawing of $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$, showing thermal ellipsoids drawn at the 30% probability level.



carried out in the temperature range 1.5–296 K on a vibrating sample magnetometer, model CF-1. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal's tables).

Crystallographic data collection and structure determination

A blue prismatic crystal with dimensions 0.2 × 0.3 × 0.4 mm^3 was mounted on a computer-controlled Enraf–Nonius CAD4 diffractometer equipped with a graphite-monochromatized $M_oK\alpha$ radiation. Cell parameters were determined by least-squares calculations based on the setting angles and 25 reflections with 2θ angles ranging from 15 to 27° at 299(1) K. Cell dimensions and additional crystal data are listed in Table 1. The intensities of the ±*hkl* reflections were measured up to θ_{max} = 23°; the ω-2θ scan technique was employed, the ω-scan width equal to (0.65 + 0.35 tan θ)°, and the scan speed 0.92–5.49° min^{-1}. A total of 1313 independent reflections was measured giving 1121 observed reflections ($I > 3\sigma(I)$) used in the refinement. Three standard reflections monitored every 60 min showed no intensity variation during the data collection. No absorption correction was made during processing.

The structure was solved by direct method (MULTAN 82) using SDP-PLUS program (19). Atomic scattering factors were taken from ref. 20. The hydrogen atoms attached to the oxygen atoms were found in the Δ*F* map, and the other hydrogen atoms were added theoretically. All hydrogen atoms were refined with riding model and fixed isotropic thermal parameters.

Final atomic coordinates and equivalent isotropic displacement parameters are given in Table 2 and selected bond distances and angles appear in Table 3. Crystal data, data collection, solution and refinement, anisotropic displacement coefficients, bond lengths and angles, and atomic coordinates have been deposited.[2]

Results and discussion

Crystal structure

The structure has an inversion center and consists of chains in which alternating $Cu(en)_2^{2+}$ and $Mn(NCS)_4(H_2O)_2^{2-}$ entities are bridged by thiocyanate ligands. The molecular arrangement with an atom numbering scheme is shown in Fig. 1. The chains are generated by unit cell translation of the $Cu(en)_2Mn(NCS)_4(H_2O)_2$ unit as shown in Fig. 1.

The Mn coordination environment can be considered as a slightly distorted octahedral, with two oxygen atoms occupying the axial positions (Mn(2) – O(1) = 2.242(4) Å) and four nitrogen atoms from two bridging NCS groups (Mn(2) – N(1) = 2.166(7) Å) and two terminal ones (Mn(2) – N(2) = 2.190(9) Å) forming the basal plane. The NCS groups are

[2] Supplementary material may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2. With the exception of the anisotropic displacement coefficients, these have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

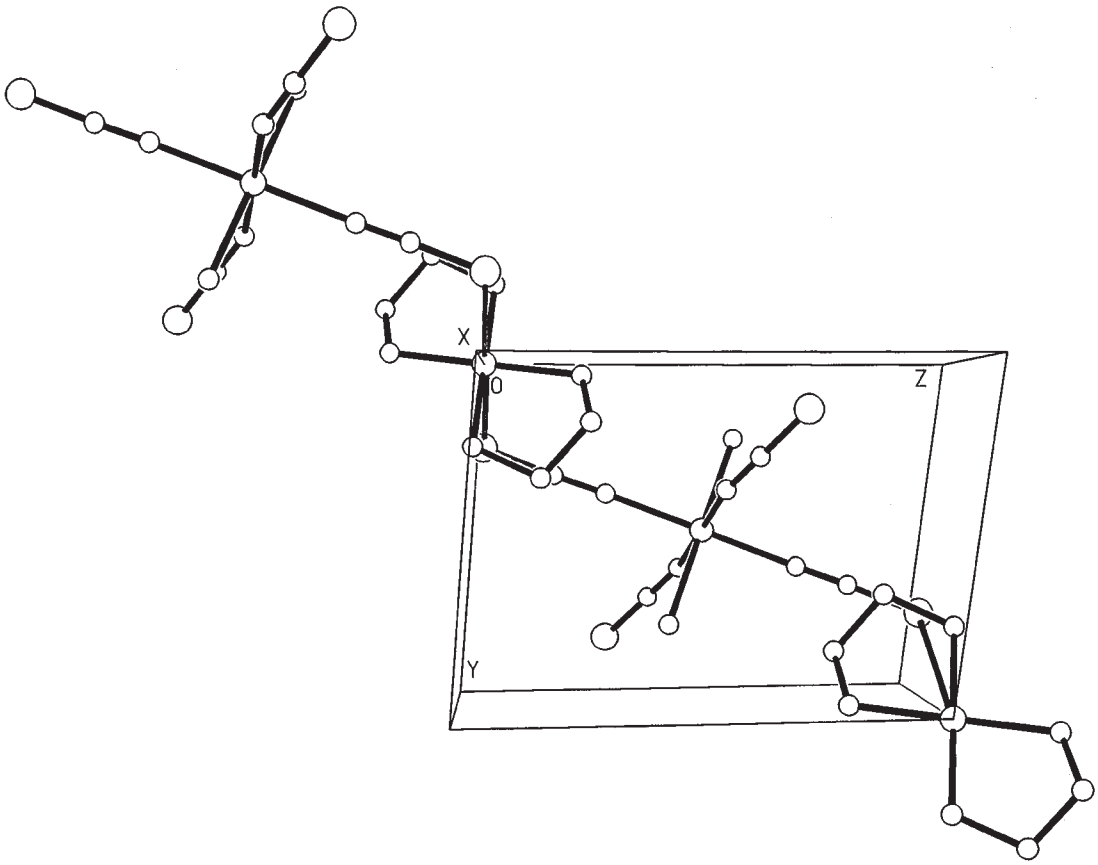
Fig. 2. View of the crystal cell of $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$.



almost linear with the bond angles of 179.5(7)° for N(2)-C(2)-S(2) and 178.3(7)° for N(1)-C(1)-S(1). Also, the bond distances of C≡N (average value: 1.157 Å) and C—S (average value: 1.606 Å) fall within the normal ranges. The Mn-N-C linkages are bent with angles ranging from 149.5(7)° for Mn(2)-N(2)-C(2) to 172.9(7)° for Mn(2)-N(1)-C(1).

The copper ion has elongated octahedral surroundings: the equatorial positions are occupied by the four nitrogen atoms from two en ligands with the Cu—N distances of 1.995(5) Å to 2.008(5) Å and the axial positions by the sulfur atoms from the bridging NCS ligands. The bond distances of Cu—S, 3.065(10) Å, are shorter than the sum of van der Waals radii of Cu and S atom, 3.4 Å (21), and similar to the values reported for related axially S-thiocyanate copper(II) compounds (22–27). The adjacent Cu···Mn intrachain separations are 6.096 Å. It is worth mentioning that as far as the copper coordination environment is concerned, it is similar to that of a monomeric compound, $Cu(en)_2(SCN)_2$, whose molecular structure was determined three decades ago (27). The significant difference lies in the Cu—S bond length, considering that $Cu(en)_2(SCN)_2$ possesses a Cu—S distance of 3.27(1) Å, much longer than that of the present compound (3.065(10) Å).

The chain arrangement within the lattice cell is shown in Fig. 2. The shortest interchain metal–metal separations are Cu···Mn = 6.200 Å and Cu···Cu = Mn···Mn = 7.432 Å and 7.492 Å along the *a* and *c* directions, respectively. The interchain intermolecular contacts of S and O are 3.261, and 3.269 Å, slightly shorter than the sum of van der Waals radii of S and O atoms, 3.30 Å (21).

Spectroscopic properties

The interest in the IR spectrum of the compound lies mainly in the bands due to the NCS groups. A sharp and strong band at 2092 cm^{-1} and a shoulder at 2100 cm^{-1} are attributed to the asymmetric stretching vibration ν(CN). The weak band corresponding to ν(CS) vibration appears at 771 cm^{-1}, and the δ(NCS) bending mode is observed at 480 cm^{-1} as a shoulder.

The reflectance electronic spectrum on a crystalline sample exhibits a broad band centred at 543 nm, which can be assigned to the copper *d-d* transitions. This value is greater than that of $Cu(en)_2(SCN)_2$ (525 nm) with analogous CuN_4S_2 chromophores (28, 29). As stated by Lever et al. (29), the crystal field strengths of the coordinating axial ligands remarkably influence the value of ΔDq (the difference in in-plane and out-of-plane field strengths); in other words, the more strongly the axial ligands coordinate, the smaller ΔDq is. This gives rise to a red shift of *d-d* bands. Comparing with $Cu(en)_2(SCN)_2$, $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$ has a much shorter Cu—S bond (3.066(10) Å) that can be considered a stronger one to afford a smaller ΔDq value. Therefore, a greater λ_{max} value compared with $Cu(en)_2(SCN)_2$ is obtained.

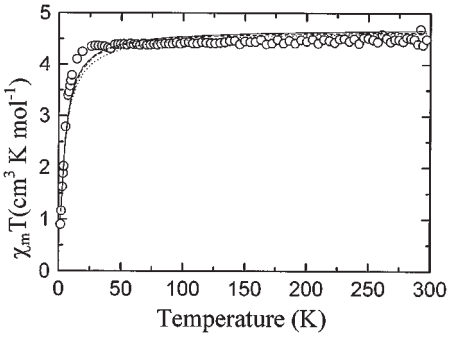
The electronic spectrum of the compound in an aqueous solution affords the same band at 543 nm, which suggests that no dissociation takes place upon dissolution.

Magnetic properties

The magnetic behaviour of the compound is represented in Fig. 3, in the form of $\chi_m T$ vs. *T*. At room temperature, the

© 1998 NRC Canada

Fig. 3. Plots of the product $\chi_m T$ vs. temperature for $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$. The dotted, dashed, and solid lines represent the theoretical values based on the eqs. [2], [3], and [4], respectively.



$\chi_m T$ value is 4.40 cm^3 K mol^{-1}, close to expected for isolated $S = 5/2$ and $S = 1/2$ spins (4.75 cm^3 K mol^{-1} for $g_{Mn} = g_{Cu} = 2$). When the temperature is lowered, $\chi_m T$ remains constant until 20 K and then decreases sharply to 1.14 cm^3 K mol^{-1} at 1.5 K.

According to Kahn's theory, in an antiferromagnetic exchange ($J < 0$) within an alternating Mn(II)-Cu(II) chain, the net spins ($S = S_{Mn} - S_{Cu} = 2$) are parallel to each other in the ground state, and $\chi_m T$ should diverge below a critical temperature. Two different results may be obtained (Fig. 4): first, the antiferromagnetic interchain interaction between the nearest manganese and copper ions gives rise to a ferrimagnetic behaviour (Fig. 4*a*); second, on the contrary, a cancellation of the spins (Fig. 4*b*) occurs (30–32). Although the crystal structure of $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$ shows that the arrangements of Cu and Mn ions meet the former case, the fact that the spin density in an *xy*-like orbital delocalized from the copper ion to the sulphur atoms situated at the axial positions in the copper coordination sphere is negligibly small prevents us from drawing the above conclusion.

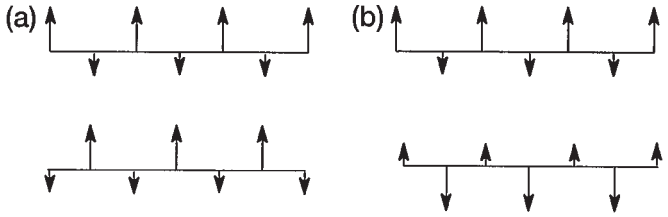
Under the circumstances, the Mn···Mn (ca. 11.7 Å) superexchange within the chain propagated by the filled d_{z^2} -like orbital of the NCS-Cu-SCN pathway may prevail over the Mn···Cu and, certainly, Cu···Cu interactions. A similar situation has been found in $Cu(en)_2MnCl_4$ (16). On the basis of the above hypothesis, the magnetic susceptibility of the chain χ_{chain} was calculated by eq. [1], where the first term describes an infinite Mn(II) chain according to the polynomial expression of Hiller et al. (18), and the second term is a temperature independent contribution from Cu(II).

$$[1] \qquad \chi_{chain} = \frac{Ng_{Mn}{}^2\beta^2}{KT}[A + Bx^2][1 + Cx + Dx^3] + \frac{Ng_{Cu}{}^2\beta^2}{3KT} S_{Cu}(S_{Cu} + 1) + TIP$$

where $x = |J|/KT$, $A = 2.9167$, $B = 208.04$, $C = 15.543$, and $D = 2707.2$, J is the exchange coupling constant, and TIP is the temperature-independent paramagnetism (60×10^{-6} cm^3 mol^{-1}).

Taking into account the 2-D interactions, we modified the molar magnetic susceptibility χ_m employing eq. [2], where J' is the interchain coupling constant and $z = 2$, the number of nearest Mn(II) neighbors. Other symbols have the usual meanings.

Fig. 4. Schematic representation of two modes of interchain metal–metal magnetic interactions: (*a*) antiferromagnetic interchain interaction between the nearest manganese and copper ions, giving rise to a ferrimagnetic behaviour; and (*b*) on the contrary, a cancellation of the spins.



$$[2] \qquad \chi_m = \chi_{chain}/[1 - \chi_{chain}(2zJ'/Ng^2\beta^2)]$$

The least-squares fit from eq. [2] to the data was found with $J = -0.22(1)$ cm^{-1}, $g_{Mn} = g_{Cu} = 1.98$ and $zJ' = -0.004$ cm^{-1}, and the agreement factor, defined as $F = \Sigma_i(\chi_i{}^{obs} - \chi_i{}^{calcd})^2/\chi_i{}^{obs}$, was 1.95×10^{-3} for all of the 94 observations. On the basis of the above results, it can be concluded that a small antiferromagnetic intrachain interaction (J) between the nearest Mn(II) ions and a smaller antiferromagnetic interchain interaction (J') are present.

Alternatively, we attempted to interpret the phenomenon employing the zero-field splitting effect within the $S = 5/2$ local ground states of the Mn(II) ions. The theoretical expression of χ_{zfs} (33) is then

$$[3] \qquad \chi_{zfs} = \frac{Ng_{Mn}{}^2\beta^2}{4KT}\left[\frac{1 + 9\exp(2D/KT) + 25\exp(6D/KT)}{1 + \exp(2D/KT) + \exp(6D/KT)}\right]$$

$$\chi_m = \chi_{zfs} + \frac{Ng_{Cu}{}^2\beta^2}{3KT} S_{Cu}(S_{Cu} + 1) + TIP$$

where D is the axial zero-field splitting parameter for Mn(II). Least-squares fitting gave rise to $g_{Mn} = 1.99$, $g_{Cu} = 1.99$, and $D = 1.16$ cm^{-1}. The agreement factor F is equal to 2.5×10^{-3}.

Both analyses seem satisfactory, considering, however, the fact is that both situations usually concur in the case of Mn(II) and Mn(III) compounds. Therefore, the magnetic susceptibility expressed as a combination of the Mn···Mn interaction and the zero-field splitting may be more reasonable. The expression of Hiller (12) then was modified by replacing the $NS(S+1)g_{Mn}^2\beta^2/3KT$ term with χ_{zfs}, which is represented by eq. [3] (34). The final expression is as follows:

$$[4] \qquad \chi_{chain} = \frac{12}{35}\chi_{zfs}[A + Bx^2][1 + Cx + Dx^3] + \frac{Ng_{Cu}{}^2\beta^2}{3KT} S_{Cu}(S_{Cu} + 1) + TIP$$

$$\chi_m = \chi_{chain}/[1 - \chi_{chain}(2zJ'/Ng^2\beta^2)]$$

This led to the parameters $g_{Cu} = g_{Mn} = 1.99$, $J = -0.062$ cm^{-1}, $D = 0.73$ cm^{-1} and $zJ' = -0.005$ cm^{-1}. The agreement factor F is equal to 1.3×10^{-3}. The result that the D value is much larger than the absolute J value indicates

© 1998 NRC Canada

the presence of a very weak antiferromagnetic interaction between the Mn(II) ions within the chain and a dominant zero-field splitting within the $S = 5/2$ local ground states of the Mn(II) ions.

Conclusions

A new 1-D thiocyanate-bridged bimetallic compound $[Cu(en)_2Mn(NCS)_4(H_2O)_2]_n$ has been synthesized and structurally and magnetically characterized. The theoretical models presented fit the experimental data quantitatively, based on a vanishingly small interaction between the adjacent Cu(II) and Mn(II) ions, which leads to a weak intrachain AF coupling of manganese ions and a dominant zero-field splitting of the single Mn(II) ions. Apparently, similar examples or variations of such Cu-Mn compounds would help confirm and clarify the magnetic exchanges. The studies along this end are in progress.

Abstract: The PEGA resin, a beaded polyethylene glycol dimethylacrylamide copolymer, was evaluated as an affinity support for the purification of carbohydrate-binding macromolecules, namely, the cation-independent mannosyl phosphate receptor (CI-MPR) and a polyclonal antibody directed against a *Streptococcus* Group A oligosaccharide. Two polyethylene glycol (PEG) derivatives, a di-acryloylated PEG_{1900} derivative or a longer di-acryloylated PEG_{4000} derivative, were used as cross-linkers. The longer cross-linker was synthesized in four steps from polyethylene glycol 4000. The mannosyl 6-phosphate (M6P)-containing immunoaffinity columns were prepared through the inverse suspension radical copolymerization of the corresponding allyl glycoside with acrylamide and the PEG cross-linker. The resin with the shorter cross-linker (PEG_{1900} derivative) had a 6.3% molar cross-linking while that with the longer cross-linker (PEG_{4000} derivative) had a 3.8% molar cross-linking. For the *Streptococcus* Group A trisaccharide-containing immunoaffinity columns, three PEGA affinity supports bearing free amino groups were prepared and subsequently substituted with a trisaccharide activated as its squarate adduct. While one resin contained the shorter cross-linker PEG_{1900} and had a 3% molar cross-linking, the other two resins contained the longer cross-linker PEG_{4000} with a molar cross-linking of 5% and 3%, respectively. In affinity chromatographic studies, the M6P-containing columns were ineffective in retaining the cation-independent mannosyl phosphate receptor (CI-MPR, ~ 215 kDa), whereas antibody (~ 150 kDa) retention was observed with two of the three *Streptococcus* Group A trisaccharide-containing immunoaffinity columns.

Key words: PEGA resins, immunoaffinity supports, carbohydrate ligands, antibody purification.

Résumé : On a évalué la résine PEGA, un copolymère en perle de polyéthylèneglycol et de diméthylacrylamide, comme support d'affinité pour la purification de macromolécules se liant aux carbohydrates, à savoir, le récepteur phosphate de mannosyle indépendant du cation («CI-MPR») et un anticorps polyclonal orienté vers un oligosaccharide d'un *Streptococcus* du groupe A. Pour la réticulation, on a utilisé deux dérivés du polyéthylèneglycol (PEG), un dérivé diacryloylé du PEG_{1900} ou un dérivé diacryloylé du PEG_{4000}. On a synthétisé le dérivé le plus long en quatre étapes à partir du polyéthylèneglycol 4000. On a préparé les colonnes d'immunoaffinité contenant du 6-phosphate de mannosyle (6PM) par le biais d'une copolymérisation radicalaire en suspension inverse du glucoside d'allyle correspondant avec de l'acrylamide et l'agent de réticulation du PEG. Dans le cas de la résine incorporant l'agent de réticulation le plus court (dérivé du PEG_{1900}), le niveau de réticulation est de 6,3 mol%; il est de 3,8 mol% dans le cas de l'agent de réticulation le plus long. Pour les colonnes d'immunoaffinité contenant le trisaccharide du *Streptococcus* du Groupe A, on a préparé trois supports d'affinité PEGA portant des groupes aminés libres qui ont été ultérieurement substitués par un trisaccharide activé sous la forme d'adduit. Alors qu'une résine contenait l'agent de réticulation le plus court, PEG_{1900}, et un taux de réticulation de 3 mol%, les deux autres contenaient l'agent plus long, PEG_{4000}, avec des taux de réticulations respectifs de 5 et 3 mol%. Lors des études de chromatographie d'affinité, les colonnes contenant du 6PM n'ont pas été efficaces pour retenir le récepteur phosphate de mannosyle cation indépendant (CI-MPR, ~215 kDa) alors que l'on a observé une rétention de l'anticorps (~ 150 kDa) avec deux des trois colonnes d'immunoaffinité contenant du trisaccharide de *Streptococcus* du Groupe A.

Mots clés : résines de PEGA, supports d'immunoaffinité, ligands carbohydrates, purification d'anticorps.

Introduction

Affinity chromatography is a method of choice to purify enzymes, antibodies, lectins, and other macromolecules by binding selectively to a well-defined ligand. Methods to prepare affinity columns using carbohydrate-bearing adsorbents have been reviewed (1). The materials used for the preparation of affinity adsorbents are carbohydrate polymers such as agarose or cellulose (1, 2), polyacrylamide polymers (2–5), or porous glass beads (1). An ideal support material should have good permeability to and be compatible with biological molecules; it should be stable to chemical reagents and resistant to microbial and enzymic degradation. The PEGA resin, a beaded polyethylene glycol dimethylacrylamide copolymer (6–8), has been developed for solid phase peptide synthesis and has shown a very high permeability to chemicals. It has also been used in biochemical assays in which a protease (9) and a glycosyltransferase enzyme (10) have been tested for their ability to enter the polymer network. While this highly cross-linked resin (25% molar cross-linking) was shown to be permeable to the 27 kDa protease, the 50 kDa glycosyltransferase was not able to enter the resin network. However, an analogous PEGA resin, in which acrylamide replaced dimethylacrylamide and which had a lower degree of cross-linking (5%), was highly permeable to the glycosyltransferase (10) as well as to globular proteins of up to 66 kDa (8). The compatibility and permeability of the PEGA resins to biological macromolecules prompted us to evaluate the resins as affinity supports for the purification of carbohydrate-binding macromolecules such as the cation-independent mannosyl phosphate receptors (CI-MPRs) and the *Streptococcus* Group A-specific anti-carbohydrate polyclonal antibodies.

Results and discussion

The CI-MPRs are membrane glycoproteins with an apparent molecular weight of 215 kDa and whose binding to lysosomal enzymes bearing terminal mannosyl 6-phosphate residues (M6P) is partly reponsible for intracellular transport and binding of the enzyme to the cell surface (11–17). To attempt the purification of CI-MPRs using a PEGA-based immunoaffinity column, we prepared an M6P derivative containing a reactive double bond that allowed its copolymerization with the other constituents of the resin. Allyl α-D-mannopyranoside (18, 19) was trimethylsilylated to give the persilylated derivative **1**, which was then selectively hydrolyzed (20, 21) to give the alcohol **2**. Phosphorylation of **2** with phosphorus oxychloride followed by hydrolysis gave the phosphate **3**. To introduce a spacer-arm between the oligosaccharide and the solid support, the phosphate **3** was converted directly to the corresponding cysteamine adduct **4** by addition of cysteamine hydrochloride to the allyl group (22). The aminated derivative **4** was obtained in 73% yield after RP-HPLC purification and it was subsequently acryloylated to give the monomer **5**. The acryloylation of **4** using acryloyl chloride as the acylating agent gave only low yields of the desired acryloylated derivative **5**, together with side products resulting from the acryloylation of the phosphate group. Thus, the less reactive 3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-yl acrylate **6**, prepared in situ from the reaction of 3,4-dihydro-4-oxo-1,2,3-benzotriazine (DhbtOH) with acryloyl chloride in the presence of *N*-ethylmorpholine, was reacted with the phosphate

4. The acryloylated monomer **5** was obtained in 77% yield and was used for the preparation of the immunoaffinity columns **15** and **16** (see Fig. 1). Since it was shown that the permeability of the PEGA resins depended on the degree of molar cross-linking as well as the length of the cross-linker (8), we prepared two affinity columns in which the cross-linker was either the di-acryloylated PEG_{1900} derivative **7** (8) or the longer di-acryloylated PEG_{4000} derivative **13**. The latter cross-linker was synthesized in four steps from polyethylene glycol 4000 **9** (PEG_{4000}). Thus, treatment of **9** with

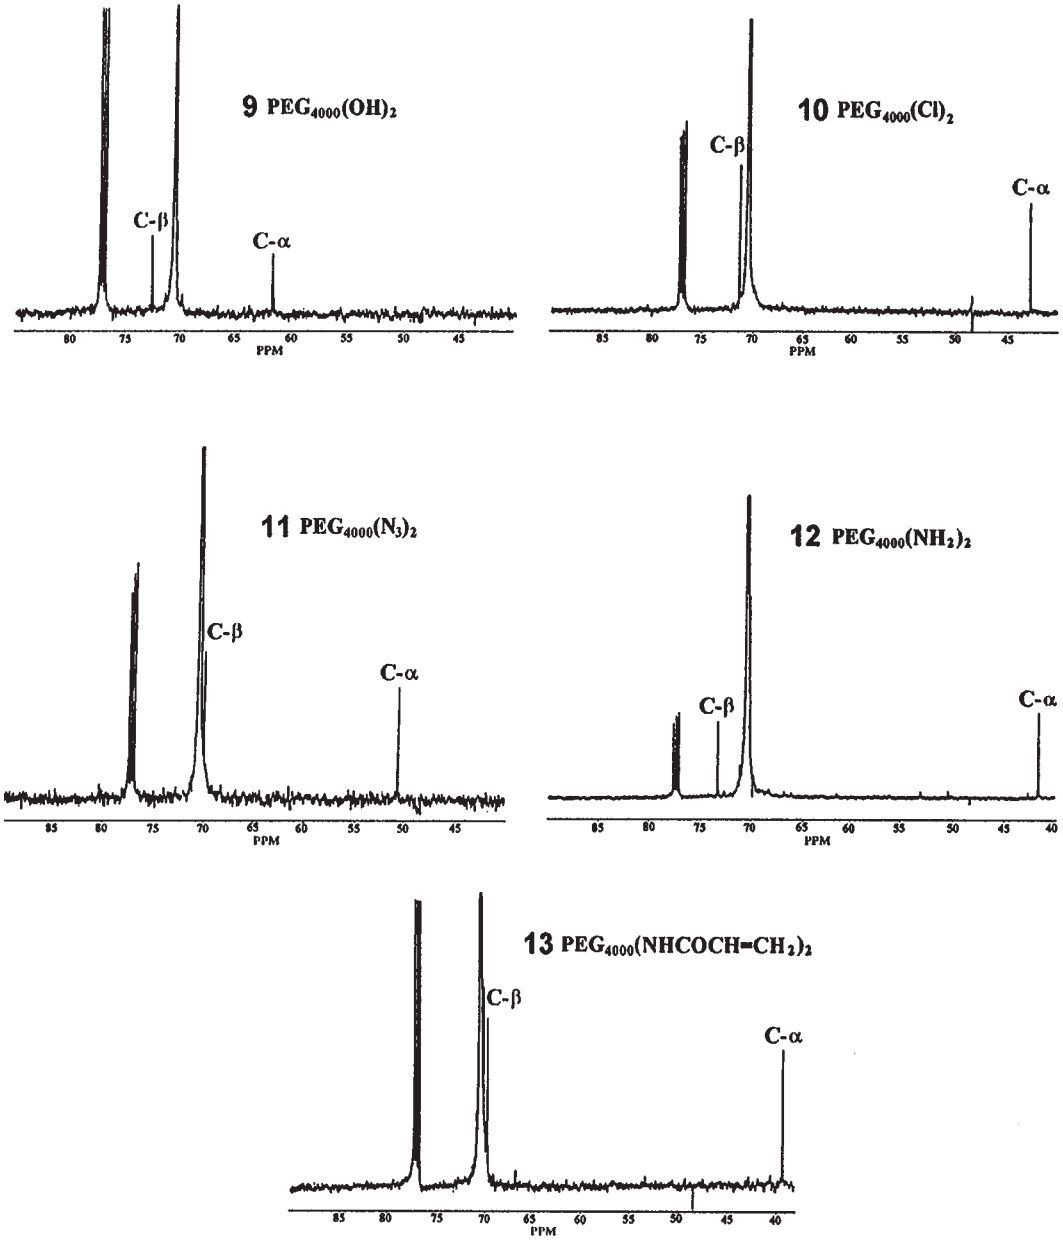
Fig. 2. ^{13}C NMR spectra of PEG derivatives **9–13**.



thionyl chloride gave the corresponding dichloride **10**, which was converted into the diazide **11** with sodium azide. The diazide **11** was, in turn, submitted to high-pressure hydrogenation in the presence of palladium-on-carbon catalyst to give the diamine **12**, which was acryloylated to yield the cross-linker **13**. Since separation of these PEG derivatives was not possible by common purification means, the reactions were monitored by ^{13}C NMR spectroscopy and driven to completion. Figure 2 shows that the signals corresponding to the α and β carbons of the PEG chains could be easily identified for each of compounds **9–13** and appear at very different chemical shifts depending on the subtitution of C-α. Therefore, the purity and integrity of these derivatives were assessed by ^{13}C NMR spectroscopy. Copolymerization of the M6P derivative **5** with acrylamide and the cross-linkers **7** or **13** was performed, as previously described (8), by inverse suspension radical polymerization (23), using sorbitan monolaurate as a droplet stabilizer, ammonium persulfate as the initiator, and *N*,*N*,*N*′,*N*′-tetramethylethylene diamine (TMEDA) as a promoter. The resin **15**, which used the shorter cross-linker **7**, was prepared to have a 6.3% molar cross-linking while the resin **16**, which used the longer cross-linker **13**, was designed to have a 3.8% molar cross-linking. These differences resulted in very different swelling abilities of the resins **15** and **16**, which were 13 mL and 22 mL per gram of resin, respectively. The incorporation of the sugar into resins **15** and **16** was confirmed by the ^{13}C NMR spectra in which the anomeric carbon atom gave a signal at 102 ppm (see Fig. 3 for resin **15**).

Purification of the receptor, CI-MPR, on these affinity columns was then attempted, as described previously (24); however, the receptor was not retained on either resin. Since

Table 1. Characteristics of PEGA resins **17–19** and immunoaffinity columns **22–24**.

PEGA resin	**17**	**18**	**19**
$[NH_2]$ mmol/g	0.15	0.08	0.09
Cross-linker	PEG_{1900}	PEG_{4000}	PEG_{4000}
Molar cross-linking (%)	3	6	3.5
Swelling in water (mL/g)	34	35	35
Immunoaffinity column	**22**	**23**	**24**
Yield of sugar coupling (%)	59	52	57
Sugar content (μmol)	4.45	2.1	2.8
Sugar loading (μmol/mL)	2.5	1.1	1.5
Weight of protein retained (μg)	71.2	0	90.1
Ratio of protein retained (%)	3	0	6

purification of the CI-MPR had been achieved by Sahagian et al. (25), using the M6P derivative **4** coupled to cyanogen bromide activated Sepharose, we concluded that the M6P unit was inaccessible to the binding site of the CI-MPR either because the spacer-arm was too short or because the receptor was too big (~ 215 kDa) to enter the resin beads of either **15** or **16**. To investigate the latter hypothesis we then attempted the purification of a smaller protein: a polyclonal IgG antibody (~ 150 kDa), using a similar solid support.

The β-hemolytic *Streptococcus* Group A is a common infective agent in humans, causing streptococcal pharyngitis, some forms of pneumonia, and toxic shock-like syndrome (26, 27). It can also act as a trigger of acute rheumatic fever, heart valve diseases, or glomerulonephritis (26, 28) resulting from an autoimmune reaction in which antibodies directed against streptococcal antigens lead an attack against the host tissues (29–33). To characterize these autoimmune responses, mono- and polyclonal antibodies have been raised against oligosaccharide portions of the *Streptococcus* Group A polysaccharide and it has been shown that the branched trisaccharide α-L-Rha*p*-(1→2)-[β-D-GlcNAc*p*-(1→3)]-α-L-Rha*p* was the smallest oligosaccharide recognized distinctly by the antibodies (34, 35). Since this trisaccharide **20** had been prepared previously (5, 36), we decided to prepare three PEGA affinity supports bearing free amino groups and to subsequently couple the activated trisaccharide to these supports. As described previously (8), the molar cross-linking of such resins as well as the amount of free amino groups incorporated in the network depends on both the degree of acryloylation of the PEG monomer used in the copolymerization and the ratio of the monomer to diluent used. Thus, we prepared resins **17–19** using the partially acryloylated monomers **8** and **14**. While resin **17** contained the shorter cross-linker PEG_{1900} and had a 3% molar cross-linking, resins **18** and **19** contained the longer cross-linker PEG_{4000} with a molar cross-linking of 5% and 3%, respectively. The swelling abilities of these copolymers in water were shown to be very similar (~ 35 mL/g). The number of free amino groups per gram of resin was measured for resins **17–19** by the bromophenol blue method (8) and the results are reported in Table 1. The trisaccharide **20** was coupled to the PEGA copolymers **17–19** using the method recently developed by Hindsgaul and co-workers (37) to give the immunoaffinity columns **22–24**, respectively. Thus, aliquots of the aminated oligosaccharide **20** were reacted with one equivalent of 3,4-diethoxy-3-cyclobutene-1,2-dione (diethyl squarate) and the reactions were followed by TLC, which

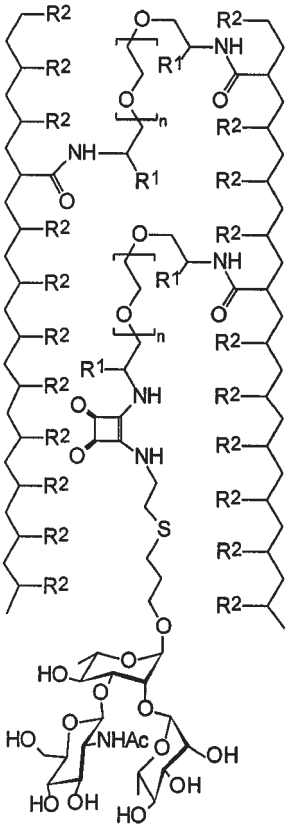
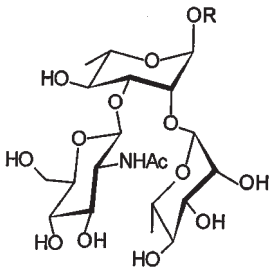
Fig. 4. Schematic representation of immunoaffinity columns **22–24**.



22 $R^1 = CH_3$, $R^2 = CONH_2$, n = 43-45
23, **24** $R^1 = H$, $R^2 = CONH_2$, n = 77-100

showed the complete disappearance of the starting material and the appearance of a less polar, UV-absorbent compound that was assumed to be the oligosaccharide–squarate adduct **21**. The reaction mixtures were concentrated to dryness and the crude adducts were coupled directly to the PEGA supports in a pH 10 buffer. After draining, the columns were washed until no more unreacted sugar could be detected (38) in the eluent. The amount of unreacted sugar was measured for each column using the method of Dubois et al. (38) and, by difference, the amount of trisaccharide incorporated into each column was calculated. Whether the trisaccharide was used in excess or not, the yield of the coupling reaction was greater than 50% (Table 1). The remaining free amino groups were capped by acetylation, thus giving the three immunoaffinity columns **22–24** (Fig. 4), which had the same swelling abilities as the copolymers from which they were obtained. Since resin **17** contained a higher number of free amino groups than resins **18** or **19**, the immunoaffinity column **22** presented the highest sugar loading (Table 1).



20 $R = (CH_2)_3S(CH_2)_2NH_2$
21 $R = (CH_2)_3S(CH_2)_2NH$ OEt

The availability of the immobilized trisaccharide **20** to antibodies (Abs) was investigated by using the immunoaffinity reagents **22** and **24** to purify the trisaccharide **20**-reactive Abs from polyclonal Abs raised against a pentasaccharide portion of the *Streptococcus* Group A polysaccharide (35). Trisaccharide **20**-reactive Abs are present in the polyclonal Abs since the latter were shown to react with the trisaccharide **20** (35).

For affinity reagent **23**, none of the fractions eluted with GlcNAc exhibited an absorbance at 280 nm. Moreover, the amount of protein collected during the initial TBS wash was equal to the total amount of protein added to the column. Therefore, no Ab was bound. However, fractions eluted with GlcNAc from affinity reagents **22** and **24** did contain 70 mg and 90 mg of protein, respectively, corresponding to 3% and 6%, respectively, of the total protein added to the columns. The columns could be reused without loss of binding, suggesting that all bound protein had been eluted. Thus, PEGA **18**, which was used to make affinity reagents **23**, does not appear to be permeable to Abs. Presumably, the higher degree of molar cross-linking found in PEGA **18** results in a pore opening that is too small to allow the passage of Abs. In contrast, the lower degree of molar cross-linking in PEGAs **17** and **19** results in a resin that is permeable to Abs.

The Abs that were eluted with GlcNAc from the affinity reagents **22** and **24** were compared to the Abs purified by caprylic acid precipitation alone or those obtained by sequential purification on protein A and BSA affinity columns (35). The binding of the different Ab preparations to a linear trisaccharide–BSA conjugate (Lin Tri-BSA) (35), the trisaccharide **20**–BSA conjugate, a pentasaccharide–BSA conjugate, and *Streptococcus* Group A bacteria was determined by ELISA and the data are shown in Table 2 (the cross-reaction of the different oligosaccharides with the polyclonal antibody against the pentasaccharide conjugate was demonstrated previously (35)). While purification with the affinity reagents **22** and **24** does decrease the background binding to BSA as compared to caprylic acid precipitation alone, the binding to BSA is still above the signal for binding to *Streptococcus* Group A and Lin Tri-BSA; however, signals for binding to trisaccharide **20** and the pentasaccharide could be detected. By way of comparison, purification with a pentasaccharide-UltraLinkTM reagent (5) yields a greater reduction in background binding to BSA as compared to the PEGA reagents, and gives signals above background for all antigens tested (data not shown). Abs purified with protein A and BSA affinity columns still have lower background binding to BSA. Thus, while the trisaccharide **20** immobilized on affinity reagents **22** and **24** was available for Ab binding, it appears that purification on protein A and BSA affinity columns is a more efficient

method for preparing polyclonal Abs with low binding to BSA.

The ratio of eluted protein to total immobilized carbohydrate can be used to compare the different affinity reagents. This ratio is 16 µg protein per µmol of immobilized carbohydrate for reagent **22** and 33 µg protein per µmol of immobilized carbohydrate for the reagent **24**. Thus, PEGA resins with 3% molar cross-linking are permeable to Abs. Moreover, the affinity reagent **24**, made from the PEGA containing the longer linker arm PEG_{4000}, provided the best access to immobilized carbohydrate.

Experimental section

General procedures

TLC was performed on Merck Silica Gel 60 F_{254} aluminum sheets with detection by charring with sulfuric acid, and by UV light. Vacuum liquid chromatography (VLC) (39) was performed on Merck Silica Gel 60 H (0.040–0.060 mm), and VLC under dry conditions was performed on dried silica gel (120°C; >24 h) with solvents dried over molecular sieves. Solvents were distilled and dried according to standard procedures (40). Concentrations were performed under reduced pressure at temperatures <40°C. Commercially available zinc was "activated" by washing with 1 M HCl and water and drying at 120°C overnight. Hydrogenation was performed in a Parr 4842 apparatus. Preparative HPLC reverse-phase separations were performed on a Waters HPLC system using a Delta PAK C-18 column (300 Å, 25 mm × 200 mm) with a flow rate of 10 cm^3 min^{-1} and detection at 215 nm with a photodiode array detector (Waters M 991); solvent system A: 0.1% TFA; B: 0.1% TFA in 90% acetonitrile – 10% water. Gel filtrations were performed on Sephadex G-10 (Pharmacia) with a flow rate of 1 mL/min and detection at 230 nm. ^{1}H NMR spectra were recorded on a Bruker AM500 spectrometer operating at 500.13 MHz. ^{13}C NMR spectra were recorded on DRX 250 or AM 500 Bruker spectrometers operating at 62.90 and 125.76 MHz, respectively. Chemical shifts are given in ppm and referenced to internal $SiMe_4$ (δ_H, δ_C 0.00) for solutions in $CDCl_3$ at 300 K, and to external dioxane (δ_H 3.76, δ_C 67.40) for solutions in D_2O at 300 K. For the assignment of signals, proton–proton and carbon–proton shift correlation spectroscopy were used. Optical rotations were recorded on a Perkin–Elmer 241 polarimeter. Elemental analysis was carried out at LEO Pharmaceutical Products, Denmark. Electrospray mass spectrometry was performed in the negative mode for deprotected carbohydrates on a VG Fisions Quattro instrument. Polymerizations were performed, as described previously (8), in a 250 mL or 850 mL laboratory-scale suspension polymerization apparatus (23) equipped with a four-blade stirrer.

Measurement of swelling

A weighed amount of dry resin was placed in a syringe equipped with a sintered Teflon filter and was allowed to swell in water. The excess solvent was drained, and the bed volume was measured and related to the sample weight to obtain the swelling ability.

Allyl 2,3,4,6-tetra-*O*-(trimethylsilyl)-α-D-mannopyranoside (1)

Chlorotrimethylsilane (35 mL, 279.3 mmol) was added dropwise over a period of 30 min to a solution of allyl α-D-mannopyranoside (19) (12.3 g, 55.8 mmol) in pyridine (50 mL). The mixture was stirred for 1 h, diluted with CH_2Cl_2 (50 mL), and left overnight at room temperature. The solids were removed by filtration, washed with toluene, and the combined filtrate and washings were concentrated. The residue was diluted with toluene (100 mL), filtered, and concentrated to give **1** (25.2 g, 89%), $[\alpha]_D^{25}$ +55° (*c* 3, CH_2Cl_2). Anal. calcd. for $C_{21}H_{48}O_6Si_4$: C 49.56, H 9.50; found: C 49.37, H 9.27.

Allyl 2,3,4-tri-*O*-(trimethylsilyl)-α-D-mannopyranoside (2)

Compound **1** (18.4 g, 36.2 mmol) was dissolved in methanol (100 mL) and a saturated solution of potassium carbonate in anhydrous methanol (1 mL) was added. The mixture was stirred for 1 h at room temperature, toluene (100 mL) was added, and the mixture was concentrated. Purification by VLC (light petroleum) and crystallization from acetonitrile yielded the *title compound* **2** (9.55 g, 60%); $[\alpha]_D^{25}$ +55° (*c* 1.3, CH_2Cl_2); mp 66–67°C. ^{1}H and ^{13}C NMR data are presented in Table 3. Anal. calcd. for $C_{18}H_{40}O_6Si_3$: C 49.50, H 9.23; found: C 49.27, H 9.25.

3-(2-Aminoethylthio)propyl α-D-mannopyranoside 6-phosphate (4)

$POCl_3$ (1.07 cm^3, 11.5 mmol) was added to a solution of the alcohol **2** (5 g, 11.4 mmol) and *N*-ethylmorpholine (1.6 mL, 12.65 mmol) in dry CH_2Cl_2 (25 mL), and the mixture was stirred overnight at room temperature. After concentration to half volume the mixture was diluted with hexane (13 mL) and stirred for 10 min at 0°C. Solids were removed by filtration and the filtrate was concentrated. The residue was dissolved in CH_2Cl_2 (25 mL) and washed with an ice-water HCl solution (0.4%, 30 mL) and with water. The organic phase was concentrated, and the resulting crude chlorophosphate ester was hydrolyzed by concentration with water (3 × 100 mL) at 40°C to give the phosphate **3** (3.0 g, 88%), which was characterized by ^{1}H and ^{13}C NMR (Table 3) and used directly in the next step. The crude allyl glycoside **3** (3.0 g, 10.0 mmol) was dissolved in degassed water (25 mL), cysteamine hydrochloride (12.6 g, 10.9 mmol) was added, and the solution, kept under Ar atmosphere, was irradiated with UV light for 4 h and then left standing at room temperature for 2 days. The cysteamine adduct **4** was purified by preparative RP-HPLC using solvent A (t_r 45 min) to yield the *title compound* **4** (2.76 g, 73%) as a hygroscopic syrup. $[\alpha]_D^{25}$ +36° (*c* 2.2, water). ^{1}H and ^{13}C NMR data are presented in Table 3. MS, *m/z*, M calcd. for $C_{11}H_{24}NO_9PS$: 377.09; found (M – H^+): 376.3.

3-[(2-Acrylamido)ethylthio]propyl α-D-mannopyranoside 6-phosphate (5)

Dhbt-OH (0.82 g, 5 mmol) and *N*-ethylmorpholine (640 µL, 5 mmol) were dissolved in DMF (5 mL) and acryloyl chloride (450 µL, 5.5 mmol) was added. After 30 min, 2 mL of this mixture was added to a solution of compound **4** (0.51 g, 1.4 mmol) in water (2 mL, degassed)

For personal use only.

and DMF (3 mL). *N*-Ethylmorpholine (0.17 mL, 1.4 mmol) was then added in small portions. After 3.5 h, water (10 mL) was added to the reaction mixture, which was then cooled to 0°C (10 min) and filtered. The water was evaporated and the mixture was directly purified by preparative RP-HPLC using, first, solvent A (100%) for 60 min, then the linear gradient 0–100% solvent B for 100 min (t_r 92 min) to yield the *title compound* **5** (0.45 g, 77%) as a hygroscopic syrup. $[\alpha]_D^{25}$ +46° (*c* 1.7, water). ^{1}H and ^{13}C NMR data are presented in Table 3. MS, *m/z*, M calcd. for $C_{14}H_{26}NO_{10}PS$: 431.40; found ($M - H^+$): 430.4.

Bis-chloro-polyethylene glycol 4000 (10)

PEG_{4000} **9** (50 g, ~12.5 mmol) was melted by heating in an oil bath. Thionyl chloride (3.65 cm^3, 50 mmol) was added with stirring at 100°C over a period of 30 min. The mixture was stirred at 100°C overnight, and then slowly poured into cold (0°C) stirred diethyl ether (200 mL). The resulting white powder was filtered off, washed three times with diethyl ether, and dried to yield the *title compound* **10** (47.1 g, 93%). ^{13}C NMR (125.76 MHz, $CDCl_3$) δ_C: 42.59 (Cl-*C*H_2-CH_2-), 71.33 (Cl-CH_2-*C*H_2-). For compound **9** δ_C: 61.73 (HO-*C*H_2-CH_2-), 72.54 (HO-CH_2-*C*H_2-).

Bis-azido-polyethylene glycol 4000 (11)

Compound **10** (46.07 g, ~11.4 mmol) was suspended in DMF (75 mL), and sodium azide (1.63 g, 25.1 mmol) was added. The suspension was slowly heated to 50°C, tetradecyl trimethylammonium bromide (150 mg) was added, and the mixture was heated to 110°C. After 4 h, the reaction mixture was cooled to room temperature, filtered, and concentrated. The residue was dried under high vacuum for 2 days to give **11** (46.2 g, 100%). ^{13}C NMR (125.76 MHz, $CDCl_3$) δ_C: 50.62 (N_3-*C*H_2-CH_2-), 69.91 (N_3-CH_2-*C*H_2-).

Bis-amino-polyethylene glycol 4000 (12)

Compound **11** (45.7 g, ~11.3 mmol) was dissolved in DMF (25 mL), and the solution was transferred to a Parr apparatus. Palladium-on-charcoal (10%, 200 mg) was added and the mixture was hydrogenated overnight at 80 bar (1 bar = 100 kPa). The suspension was diluted with CH_2Cl_2, filtered through Celite, and concentrated. The residue was taken up in water, the remaining Pd/C was precipitated by centrifugation at 13 000 rpm for 10 min, and the supernatant was filtered through Celite. The filtrate was lyophilized to give compound **12** (36.6 g, 81%) as a colorless syrup. ^{13}C NMR (125.76 MHz, $CDCl_3$) δ_C: 41.65 (H_2N-*C*H_2-CH_2-), 73.23 (H_2N-CH_2-*C*H_2-).

Bis-acrylamido-polyethylene glycol 4000 (13)

Compound **12** (36.2 g, ~9.1 mmol) was dissolved in CH_2Cl_2 (20 mL), the solution was cooled to 0°C, and triethylamine (2.5 mL, 18.2 mmol) was added, followed by acryloyl chloride (1.48 mL, 18.2 mmol). The reaction mixture was stirred at 0°C for 2 h, filtered, and concentrated. The residue was dissolved in CH_2Cl_2, filtered, concentrated, and dried under high vacuum to give **13** (35.0 g, 94%). ^{13}C NMR (125.76 MHz, $CDCl_3$) δ_C: 39.28 (($CH_2CHCONH)_2$-*C*H_2-CH_2-), 69.75 (($CH_2CHCONH)_2$-CH_2-*C*H_2-), 126.05 (CH_2=), 131.07 (=CH-).

Partially acryloylated bis-amino-polyethylene glycol 4000 (14)

A solution of acryloyl chloride (275 µL, 3.38 mmol) in anhydrous CH_2Cl_2 (10 mL) was added dropwise to a solution of the diaminated PEG_{4000} **12** (17 g, 4.25 mmol) in anhydrous CH_2Cl_2 (12 mL) stirred at 0°C. The mixture was stirred at room temperature for 30 min, concentrated, and dried under high vacuum to give crude $PEG_{4000}(Acr)_{0.8}$ **14** (17.5 g), which was used directly in the preparation of resin **18**. A second portion of **12** (17 g, 4.25 mmol) was acryloylated under the same conditions as described above and the resulting partially acryloylated monomer **14** was used in the preparation of resin **19**.

Preparation of the immunoaffinity column (15)

A mixture of *n*-heptane–CCl_4 (6:4, v/v, 140 mL) was purged with argon for 30 min in the 250 mL polymerization flask. The solution was warmed to 70°C and the stirring speed adjusted to 650 rpm. A mixture of the monomers **7** (9.8 g, 4.64 mmol) (8), **5** (100 mg, 0.23 mmol), and acrylamide (4.9 g, 69 mmol) in water (27 mL) was purged with argon for 30 min. Solutions of sorbitan monolaurate (166 mg) in DMF (750 mL) and ammonium persulfate (205 mg) in water (750 mL) were added to the monomer mixture that was, in turn, quickly poured into the polymerization flask. After 4 min, tetramethylethylenediamine (TMEDA, 600 mL) was added and the sticky point was reached within 30 s. The reaction was allowed to proceed for 4 h at 650 rpm and 70°C and the mixture was cooled to room temperature. The resin was filtered off, washed with ethanol and water, and sieved through a steel net (1 mm^2 holes). It was transferred back to the filter, washed with ethanol, and dried successively under low vacuum (water pump), then high vacuum (freeze-dryer) for 2 days to give 11.3 g of resin **15** (76%). Molar cross-linking: 6.5%. Swelling ability in water: 13 mL/g. ^{13}C NMR is shown in Fig. 3.

Preparation of the immunoaffinity column (16)

Copolymerization of compound **5** (500 mg, 1.16 mmol), bis-2-acrylamido-PEG_{4000} **13** (9.3 g, 2.25 mmol), and acrylamide (4.0 g, 56.3 mmol) was performed as described for the preparation of the resin **15**, and gave 10.4 g of resin **16** (75%). Molar cross-linking: 4%. Swelling ability in water: 22 mL/g.

Preparation of the PEGA resin (17)

Copolymerization of partially acryloylated PEG_{1900} **8** (8) (60 g, 29 mmol) and acrylamide (10 g, 140 mmol) was performed in the 850 mL polymerization flask essentially as described for the preparation of resin **15**. The volumes and weights of the reagents and solvents were as follows: 470 mL of *n*-heptane–CCl_4 (6:4, v/v), 90 mL of water to dissolve the monomers, 1 g of sorbitan monolaurate in 2.5 mL of DMF, 700 mg of ammonium persulfate in 2.5 mL of water, 2 mL of TMEDA. The polymerization was performed with stirring at 1800 rpm and gave 27.4 g of the resin **17** (91%). Loading, as measured by the bromophenol blue test (8), [NH_2, HCl] = 0.15 mmol/g. Molar cross-linking: 3.5%. Swelling ability in water: 34 mL/g.

Preparation of the PEGA resin (18)

Copolymerization of partially acryloylated PEG_{4000} **14** (4.25 mmol) and acrylamide (1.43 g, 20.1 mmol) was performed in the 250 mL polymerization flask essentially as described for the preparation of resin **15**. The volumes and weights of the reagents and solvents were as follows: 138 mL of *n*-heptane–CCl_4 (6:4, v/v), 28 mL of water to dissolve the monomers, 350 g of sorbitan monolaurate in 730 µL of DMF, 250 mg of ammonium persulfate in 730 µL of water, 700 µL of TMEDA. The polymerization was performed with stirring at 1800 rpm and gave 7.9 g of the resin **18** (79%). Loading as measured by the bromophenol blue test (8), [NH_2, HCl] = 0.08 mmol/g. Molar cross-linking: 6%. Swelling ability in water: 35 mL/g.

Preparation of the PEGA resin (19)

Copolymerization of partially acryloylated PEG_{4000} **14** (4.25 mmol) and acrylamide (2.21 g, 31.1 mmol) was performed in the 250 mL polymerization flask essentially as described for the preparation of the resin **15**. The volumes and weights of the reagents and solvents used as well as the stirring speed were identical to those used in the preparation of the resin **18**. The polymerization gave 8.9 g of the resin **19** (79%). Loading, as measured by the bromophenol blue test (8), [NH_2, HCl] = 0.09 mmol/g. Molar cross-linking: 3.5%. Swelling ability in water: 35 mL/g.

3-[2-*N*-(3,4-Dione-2-ethoxycyclobutene)aminoethylthio]propyl 3-*O*-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-2-*O*-(α-L-rhamnopyranosyl)-α-L-rhamnopyranoside (21)

The trisaccharide **20** (36) (4.7 mg, 7.45 µmol) was dissolved in freshly distilled MeOH (500 µL) and a solution (10 µL/mL, 110 µL, 7.45 µmol) of 3,4-diethoxy-3-cyclobutene-1,2-dione (diethyl squarate) in freshly distilled methanol was added. The reaction mixture was left standing at room temperature for 3 h, after which time TLC (EtOAc–MeOH–H_2O, 6:3:1) showed that the starting amine had been quantitatively converted to one homogeneous spot that was assumed to be the trisaccharide **21** ($R_f = 0 \rightarrow 0.61$). The reaction mixture was concentrated to dryness and the trisaccharide **21** was used without further purification in the conjugation to the PEGA columns **17** to give the immunoaffinity column **22**. Aliquots of the trisaccharide **20** (5.95 µmol and 6.66 µmol) were treated with diethyl squarate under the same conditions as described above and the resulting squarate adducts were used for coupling to the PEGA resins **18**, **19** to give the immunoaffinity columns **23**, **24**, respectively.

Preparation of the immunoaffinity column (22)

The crude squarate adduct **21** (7.45 µmol) was dissolved in a 0.1 M carbonate buffer pH 10 (1 mL) and added to the PEGA resin **17** (52.7 mg, 7.8 µmol of NH_2 groups); the flask that contained **21** was rinsed with more buffer (2 × 500 µL) and the washings were added to the reaction mixture. After 7 days at room temperature, the slurry (2 mL) was transferred to a syringe equipped with a sintered Teflon filter, the solvent was drained, and the resin was washed with water. The eluate was collected in a volumetric flask that was made up to a volume of 10 mL with the washings. Further washings with water were collected in a second volumetric flask (5 mL). These solutions were saved for quantitative analyses of the non-incorporated sugar. The column was subsequently washed with MeOH (10 mL), anhydrous MeOH (10 mL), 10% Ac_2O in MeOH (3 mL), and the resin was treated for 1 h with 5 mL 10% Ac_2O in MeOH. The solution was drained and the resin washed with EtOH (20 mL), 20% aqueous EtOH (20 mL), capped, and stored at 4°C until use for immunoaffinity purifications. Quantitation of non-incorporated sugar, fully recovered in the eluate and first washings, was accomplished using the method of Dubois et al. (38) and gave, by difference, the level of sugar incorporation. The immunoaffinity column **22** contained 4.45 µmol of trisaccharide (84 µmol/g or ≈2.5 µmol/mL of gel), corresponding to a 59% yield of incorporation of the trisaccharide.

Preparation of the immunoaffinity column (23)

Coupling of the squarate adduct **21** (4 µmol) to the PEGA resin **18** (54 mg, ~4.3 µmol of NH_2 groups), followed by acetylation of the unreacted amino groups, was performed under the same conditions as described for the preparation of column **22**. Quantitation of the non-incorporated trisaccharide (38) showed, by difference, that the immunoaffinity column **23** contained 2.1 µmol of sugar incorporated (39 µmol/g or ~1.1 µmol/mL of gel), corresponding to a 52% yield of incorporation of the trisaccharide.

Preparation of the immunoaffinity column (24)

Coupling of the squarate adduct **21** (6.66 µmol) to the PEGA resin **19** (54 mg, ~ 4.9 µmol of NH_2 groups), followed by acetylation of the unreacted amino groups, was performed under the same conditions as described for the preparation of column **22**. Quantitation of the non-incorporated trisaccharide (38) showed, by difference, that the immunoaffinity column **24** contained 2.8 µmol of sugar incorporated (52 µmol/g or ≈1.5 µmol/mL of gel), corresponding to a 57% yield for the coupling reaction.

Caprylic acid precipitation of IgG's

Four parts of sodium acetate (60 mM, pH 4) were added to one part of serum (35). The pH was adjusted to 4.5 with sodium hydroxide (5 N) and caprylic acid was slowly added with vigorous stirring until 2.5% (volume/volume) had been added. The mixture was stirred for 30 min at room temperature and then centrifuged (10 000 × *g*) for 30 min at less than 10°C. The supernatant was carefully collected and filtered through a 45 µm filter. One part of 10× phosphate buffered saline was added to 10 parts of filtered supernatant and the pH was adjusted to 7.4 with sodium hydroxide. The supernatant was cooled to 4°C and ammonium sulfate (saturated) was added until 45% saturation. The mixture was stirred for 30 min at 4°C and then centrifuged (7000 × *g*) for 15 min at 4°C. The pellet was collected and resuspended in the original volume of phosphate-buffered saline (PBS). The solution was dialyzed against PBS at 4°C overnight. The dialzylate was heated at 50°C for 20 min and cent

ELISA

Microwells were coated with the BSA glycoconjugates (1 µg/well, diluted in TBS, 40 µL/well), or *Streptococcus* Group A (4×10^7 bacteria/well, diluted in TBS, 40 µL/well),

© 1998 NRC Canada

BSA (2% in TBS) or blotto (5% milk powder in TBS) and incubated overnight at 4°C. The wells were washed three times with TBS and were blocked with blotto (200 µL) for 2 h at room temperature. After three washes with TBS, caprylic acid precipitated polyclonal Abs were added (approximately 0.5 µg in 35 mL of TBS with 0.2% BSA) and incubated for 4 h at room temperature. The wells were washed six times with TBS and bound Abs were detected with a secondary Ab conjugated to horseradish peroxidase (Pierce, Rockford, Ill.). Optical densities are reported as $(A_{405} - A_{490}) \times 1000$.

Affinity purification of polyclonal antibodies

Caprylic acid purified polyclonal Abs (2.3 mg, 1.1 mg, or 1.4 mg) were added to columns containing affinity reagents **22**, **23**, or **24**, respectively. After washing away unbound protein, bound Abs were eluted with 1 M GlcNAc in Tris buffered saline (TBS). The protein content was assessed by absorbance readings at 280 nm.

Aqueous nonelectrolyte solutions. Part XV. The deuterium sulfide – deuterium oxide system and the deuterium sulfide D-hydrate

Colin W. Clarke and David N. Glew

Abstract: The univariant (l_1l_2g) saturation vapor pressure of liquid deuterium oxide (phase l_1) with liquid deuterium sulfide (phase l_2) in equilibrium with a gas phase (g) has been measured in a stirred titanium reaction vessel at 19 temperatures from 33.003 to 18.905°C and at total pressures from 2.4500 to 1.7428 MPa. The univariant (hl_1g) saturation vapor pressure of deuterium sulfide D-hydrate (phase h) in equilibrium with liquid deuterium oxide and a gas phase has been measured at 58 temperatures from 30.666 to 2.798°C and at pressures from 2.2959 to 0.11629 MPa. The maximum temperature for deuterium sulfide D-hydrate with a gas phase, the invariant quadruple point $Q(hl_1l_2g)$, has been determined from the cut of the (hl_1g) and the (l_1l_2g) curves at temperature 30.770°C with standard error 0.0043°C and at pressure 2.3263 MPa with standard error 0.00018 MPa. The univariant (s_1l_1g) equilibrium of D-ice (phase s_1) with liquid deuterium oxide and a gas phase containing deuterium sulfide has been measured at 11 temperatures from 3.8061 to 3.4540°C and at pressures between 0.00242 and 0.10542 MPa. The lowest temperature for stability of deuterium sulfide D-hydrate with liquid deuterium oxide, the invariant quadruple point $Q(hs_1l_1g)$, has been determined directly at 3.3917°C with standard error 0.0009°C and at pressure 0.12364 MPa with standard error 0.000011 MPa. This quadruple point $Q(hs_1l_1g)$ has also been defined by the cut of the (hl_1g) and the (s_1l_1g) curves at temperature 3.3912°C with standard error 0.0006°C and at pressure 0.12363 MPa with standard error 0.000002 MPa. The deuterium sulfide – deuterium oxide gas mixture, represented by a Redlich–Kwong equation of state, has been used to evaluate the fugacities and compositions of the gaseous and liquid deuterium oxide phases for all equilibria. Raoult's law using fugacities has been used to evaluate the saturation mole fraction of deuterium oxide in liquid deuterium sulfide and the Henry's law constant for deuterium oxide solubility in liquid deuterium sulfide between 33.003 and 18.905°C. Data for the (l_1l_2g) and (s_1l_1g) equilibria have been accurately represented by simple two-parameter equations. Data for the (hl_1g) equilibrium have required a model with seven significant parameters for proper representation betweem 30.666 and 2.798°C.

Key words: deuterium sulfide – deuterium oxide system, clathrate D-hydrate of deuterium sulfide, deuterium sulfide D-hydrate stability, freezing of deuterium oxide – deuterium sulfide, phase equilibria of deuterium sulfide – deuterium oxide.

Résumé : Opérant dans une cuve réactionnelle de titane sous agitation, à 19 températures allant de 33,003 à 18,905°C et à des pressions totales allant de 2,4500 à 1,7428 MPa, on a mesuré la tension de vapeur de saturation à une variable (1_11_2g) de l'oxyde de deutérium liquide (phase 1_1) avec du sulfure de deutérium liquide (phase 1_2) en équilibre avec une phase gazeuse (g). Opérant à 58 températures allant de 30,666 à 2,798°C et à des pressions allant de 2,2959 à 0,11629 MPa, on a aussi mesuré la tension de vapeur de saturation à une variable ($h1_1g$) du D-hydrate de sulfure de deutérium (phase h) en équilibre avec de l'oxyde de deutérium liquide et une phase gazeuse. En se basant sur le point de jonction des courbes ($h1_1g$) et (1_11_2g) à une température de 30,770°C avec une erreur-type de 0,0043°C et à une pression de 2,3263 MPa avec une erreur-type de 0,00018 MPa, on a déterminé la température maximale du D-hydrate du sulfure de deutérium, le point quadruple invariant $Q(h1_11_2g)$. Opérant à 11 températures allant de 3,8061 à 3,4540°C et à des pressions allant de 0,00242 à 0,10542 MPa, on a mesure l'équilibre à une variable (s_11_1g) de la glace-D (phase s_1) avec de l'oxyde de deutérium liquide et une phase gazeuse contenant du sulfure de deutérium. Opérant à 3,3917°C avec une erreur-type de 0,0009°C et à une pression de 0,12364 MPa avec une erreur-type de 0,000011 MPa, on a déterminé directement la température minimale pour la stabilité du D-hydrate de sulfure de deutérium avec de l'oxyde deutérium liquide, le point quadruple invariant $Q(hs_11_1g)$. Ce point quadruple, $Q(hs_11_1g)$, a aussi été défini par le point de rencontre des courbes ($h1_1g$) et (s_11_1g) à la température de 3,3912°C avec une erreur-type de 0,0006°C et à une pression de 0,12363 MPa avec une erreur type de 0,000002 MPa. On a utilisé le mélange gazeux sulfure de deutérium – oxyde de deutérium représenté par l'équation d'état de Redlich–Kwong pour évaluer les fugacités et les compositions des phases gazeuses et liquides de l'oxyde de deutérium de tous les équilibres. On a fait appel à la loi de Raoult utilisant des fugacités pour évaluer la fraction molaire de saturation de l'oxyde deutérium dans

le sulfure de deutérium liquide et on a utilisé la constante de la loi de Henry pour évaluer la solubilité de l'oxyde de deutérium dans le sulfure de deutérium liquide entre 33,003 et 18,905°C. On peut donner une représentation graphique correcte des données des équilibres ($1_1 1_2 g$) et ($s_1 1_1 g$) en faisant appel à des équations simples à deux paramètres. Pour donner une représentation adéquate des données pour l'équilibre ($h1_1 g$) entre 30,666 et 2,798°C, on doit faire appel à un modèle à sept paramètres significatifs.

Mots clés : système sulfure de deutérium – oxyde de deutérium, clathrate du D-hydrate de sulfure de deutérium, stabilité du D-hydrate du sulfure de deutérium, congélation de l'oxyde de deutérium – sulfure de deutérium, équilibre de phase du sulfure de deutérium – oxyde de deutérium.

[Traduit par la Rédaction]

Introduction

As part of a continuing study (1, 2) of the structural and thermodynamic properties of aqueous nonelectrolyte solutions and of their solid clathrate hydrate solutions, it became of interest to compare the thermodynamic properties of nonelectrolyte solutions in deuterium oxide with their solid clathrate D-hydrate solutions. The properties of aqueous hydrogen sulfide solutions (3, 4) and of the hydrogen sulfide gas hydrate (5–7) were well known, but the properties of deuterium sulfide solutions in deuterium oxide and of the deuterium sulfide D-hydrate had not been reported in the literature. Due to the importance in Canada of the hydrogen sulfide – water dual temperature exchange process (8, 9) for the initial extraction of deuterium oxide from water, it was desirable to know the equilibrium properties of deuterium sulfide with deuterium oxide and of deuterium sulfide D-hydrate.

The present experimental study, performed between 1963 and 1966, defines part of the deuterium sulfide – deuterium oxide system up to 33°C and the conditions for formation of deuterium sulfide D-hydrate with liquid deuterium oxide.

Experimental

Materials

Deuterium oxide was 99.75% pure with 0.25 wt.% protium oxide as supplied by Atomic Energy of Canada Limited: a complete isotopic analysis of this deuterium oxide has been reported earlier (10). Deuterium sulfide was prepared by the reaction of deuterium oxide with CP grade aluminum sulfide as described previously (11, 12).

Apparatus

The deuterium oxide – deuterium sulfide system was studied in a continuously stirred titanium pressure vessel, which was suspended in an enclosed and insulated water thermostat bath. The vessel was constructed of titanium to resist corrosion and was stirred continuously by an impellor operated by magnetic induction. All metal fittings, valves, and tubing used to connect the titanium vessel to the pressure gauge and to the vacuum filling system were of type-316 stainless steel, which was completely resistant to corrosion by wet deuterium sulfide.

Titanium pressure vessel

The titanium pressure vessel, shown in Fig. 1, was axially symmetric and 360 mm high, and was constructed from three machined titanium bodies, which were aligned vertically on top of each other by two pairs of flanges F1 and F2. The upper motor body was 90 mm high with a lower flange F1, the middle shaft body was 170 mm high with an upper flange F1 and a lower flange F2, and the lower impellor body was 100 mm high with an upper flange F2. Each pair of flanges was drawn together by six hexagonal nuts on 9.5 mm lug-bolts and was sealed by compression of an enclosed 1.6 mm thick gasket of polytetrafluoroethylene.

The central stirrer shaft, 336 mm long, 6.35 mm o.d., was of type-316 stainless steel and carried the rotor of the induction motor at its upper end and a two-blade titanium impellor at its lower end. The bearing at the bottom of the stirrer shaft was polytetrafluoroethylene and at the top a nylon sleeve. The induction rotor, 51 mm high × 32 mm o.d., was protected from corrosion by an epoxy resin coating that had been baked to enhance its chemical resistance. The upper motor body was 41.5 mm o.d. and carried the external stator of the induction motor (not shown) and enclosed the internal rotor with a clearance of 1.6 mm. The underside of the upper flange pair F1 was supported 14 mm above the insulated top cover of the thermostat tank (not shown) and was about 36 mm above the level of the thermostat water. The lower 220 mm of the titanium vessel, comprised of the shaft body, the lower flange pair F2, and the impellor body, was immersed in the thermostat water. The shaft body was 15.9 mm o.d. and enclosed the drive shaft with a radial clearance of 1.6 mm.

The lower impellor body was 63.5 mm o.d. and enclosed a stirred internal cell space, 80 mm high × 50.8 mm i.d., this provided a maximum cell volume of ~158 cm^3 of which 90 cm^3 was occupied by deuterium oxide. A titanium thermowell, 6.35 mm o.d., containing a 10-junction copper-constantan thermocouple, was located 5 mm from the cell wall and extended 64 mm from the top of the cell to 16 mm above the bottom. The lower end of the drive shaft was reduced to 4.76 mm o.d. and was threaded enabling two nuts to fix the position of the upper collar, 14 mm high × 9.5 mm o.d., 4.77 mm i.d., of the impellor. The titanium impellor was composed of two vertically aligned, symmetrically opposed blades, 42 mm × 6 mm × 1.6 mm, welded along the upper collar. The impellor was located centrally within the cell and its blades swept out a cylinder, >30 mm high × 16 mm o.d., within the stirred liquid sample.

Temperature measurement

The original experimental temperatures were measured on the International Practical Temperature Scale of 1948 (IPTS-48), and these have been converted to the International Temperature Scale of 1990 (ITS-90), using the approximate differences given in Table 4 of Goldberg and Weir (13). This

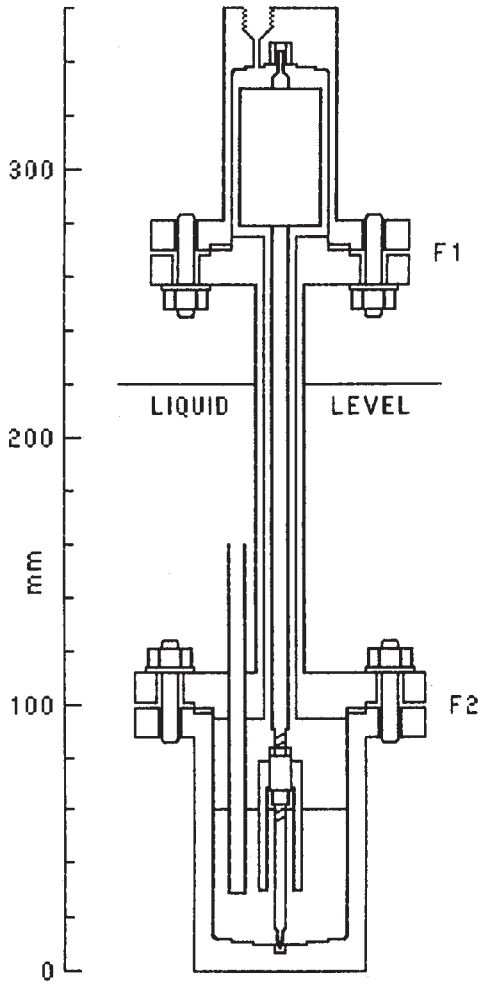
Fig. 1. Titanium pressure vessel.



conversion has a root mean squared bias of less than 0.0003°C in the range zero to 40°C, of slightly smaller magnitude than the accuracy of our most precise measurements. All temperatures and equations are based on the units degree Celsius (ITS-90), with (t°C + 273.15) = T K.

Temperatures were measured on the (IPTS-48) scale using a standardized 25 ohm platinum resistance thermometer with a Leeds and Northrup G-2 Mueller bridge, nanovolt amplifier, and galvonometer (11). Resistances were measured to within 1×10^{-5} ohm, corresponding to about 0.0001°C. The resistance at the triple point of water was checked regularly using Jarrett triple-point cells, by Trans-Sonics Incorporated, maintained in an insulated ice-packed chest (14). The thermostat temperature was controlled to within 0.001°C and was measured with the platinum resistance thermometer mounted in a cavity in a submerged stainless-steel block located within the rapidly recirculating water of the thermostat bath. The temperature difference between the titanium thermowell and the stainless-steel block was measured by a 10-junction copper-constantan thermocouple with the off-balance signal detected by a nanovolt amplifier and galvonometer. With this arrangement the temperature of the stirred liquid sample within the reaction cell could be readily determined with a precision of 0.0005°C.

Pressure measurement

The top of the motor body of the titanium vessel was connected via Swagelok fittings to small-bore high-pressure tubing, 1.6 mm i.d., 6.35 mm o.d., and high-pressure bonnet bar stock valves to (*i*) the quartz pressure gauge, (*ii*) the deuterium sulfide storage cylinder, and (*iii*) the high-vacuum system. For pressure measurements with the titanium vessel above 25°C the high-pressure tubing was heated electrically to about 40°C using a thermally and electrically insulated external winding of a flat, 3.2 mm in width nichrome heating ribbon: the motor body and the high-pressure valves were heated by infra-red lamps.

Pressure was measured using fused quartz spiral precision Bourdon gauges manufactured by Texas Instruments Incorporated, which were completely resistant to corrosion. The temperature of the compartment containing the capsule of the quartz spiral was controlled at 35°C, and the gauge was capable of measuring absolute pressure with an accuracy of 0.020% at low pressure and 0.030% at high pressures (11): the precision of pressure measurement was better by a factor of two. An electrical output from the quartz gauge was recorded continuously to follow the attainment of equilibrium. All pressures have been corrected to the standard acceleration due to gravity, 9.80665 m s^{-2}.

Over the wide range of pressure exhibited by the deuterium sulfide D-hydrate, pressure was measured using three different capsules containing quartz spirals of different sensitivity: (*i*) the 16 psi capsule was used for pressures between 0.1163 and 0.1980 MPa, (*ii*) the 200 psi capsule between 0.1323 and 1.4449 MPa, and (*iii*) the 500 psi capsule between 1.1510 and 2.2959 MPa. The saturation pressure of the binary mixture of liquid deuterium sulfide and liquid deuterium oxide was measured using the 500 psi capsule. The pressure of the deuterium sulfide solutions in deuterium oxide with D-ice was measured using the 16 psi capsule.

Experimental method

Late in 1963 the 200 psi gauge was used for our initial measurements of the pressure. Approximately 90 cm^3 deuterium oxide liquid (l_1) was placed in the titanium cell and, with continuous stirring, was thoroughly degassed using the vacuum system. The thermostat was set at about 5°C, and deuterium sulfide from its storage cylinder was admitted to give a gas (g) pressure of about 100 psig in the cell. Rapid formation of solid deuterium sulfide D-hydrate (h) ensued as shown by a steady drop in pressure. After about 16 h, when it was evident that the three-phase (hl_1g) equilibrium had been attained, data sets of 14–37 pairs of pressure–temperature measurements were made over periods of 2–5 days: the determinations reported are the means of these data sets. The thermostat temperature was then raised by about 1°C and the measurement procedure repeated. In 1965, when the pressure exceeded 1.4449 MPa the 200 psi gauge was replaced by the 500 psi gauge. Temperature was increased incrementally, with further additions of deuterium sulfide to maintain the D-hydrate phase at higher pressures, up to the temperature of the quadruple point $Q(hl_1l_2g)$, about 30.77°C, above which the solid deuterium sulfide D-hydrate (h) became unstable and decomposed into its two liquid

components, liquid deuterium oxide (l_1) and liquid deuterium sulfide (l_2).

At higher temperatures, where the three-phase (l_1l_2g) system was stable, total equilibrium pressures were determined for the stirred, mutually saturated, partially miscible liquids. Measurements began at highest temperatures ~33°C, and data sets of exactly 18 equilibrium pressure–temperature measurements were collected for each temperature at intervals of 2–3 days. The temperature was decreased and the process repeated. In this manner the equilibrium pressure was most rapidly attained by the removal of super-saturation from the two liquid phases: attainment of equilibrium from lower temperatures and from undersaturated conditions required up to 7 days. The (l_1l_2g) equilibrium was also measured with continuous stirring below the quadruple point in the metastable region down to 18.9°C: below this temperature the stirred, two-liquid system spontaneously reformed the stable deuterium sulfide D-hydrate. Three high temperatures were finally remeasured for the (l_1l_2g) system to check the hysteresis and reproducibility of the 500 psi gauge. Equilibrium total pressures for the mutually saturated deuterium oxide and deuterium sulfide liquids are listed in Table 1.

In 1966, to define the (hl_1g) system at lower temperatures with better accuracy, the 16 psi gauge was used (11), the stirred reactor temperature was reduced to 7.961°C, and some deuterium sulfide was removed so that excess solid D-hydrate did not impede the stirrer. Again data sets of exactly 18 equilibrium pressure–temperature measurements were collected at each temperature over periods of 3–4 days: the mean values are reported. The temperature was decreased and the process repeated down to 2.798°C. The seven measurements listed between 3.383 and 2.798°C are metastable relative to freezing of D-ice. Table 2 lists the equilibrium pressures for deuterium sulfide D-hydrate.

The pressure and temperature of the invariant lower quadruple point $Q(hs_1l_1g)$ were determined directly from equilibrium measurements of the (hs_1l_1g) system with the thermostat temperature controlled so that (*i*) the stirred D-hydrate (h) was neither forming nor decomposing, as shown by a constant observed pressure and (*ii*) the stirred D-ice (s_1) was neither freezing nor melting, as shown by a zero signal from the 10-junction thermocouple. To confirm equilibrium conditions the impressed thermostat temperature was bracketed, with decreasing temperature differences, slightly above and slightly below the temperature of the stirred reactor at the quadruple point for a period of 15 days.

In our final study in 1966 the (s_1l_1g) system was measured at preselected total pressures of deuterium sulfide. The equilibrium temperature for the (s_1l_1g) system was measured directly for a period of 2 days, by bracketing the thermostat temperature to equal the thermowell temperature, so that the D-ice (s_1) was in equilibrium (neither freezing nor melting) with the stirred deuterium oxide (l_1) saturated with deuterium sulfide (g) at the pre-defined total pressure. Table 3 lists the total pressures and temperatures found for the (s_1l_1g) equilibrium.

All pressures and temperatures listed as determinations for the various equilibria are the mean values of the sets of repeated single measurements. All regression equations have been evaluated using the method of least squares (15). Standard error, abbreviated to SE, is to be understood to mean the statistical estimate of the standard error.

Results and discussion

Equation of state

Following our earlier work (11, 12) gas-phase imperfections have been represented by the Redlich–Kwong equation of state (16), using the extension to mixtures by Spear et al. (17). The a_{22} and b_{22} parameters used for deuterium sulfide vapor are those derived from the high temperature (h.t.) measurements from –30 to +30°C (11): the a_{11} and b_{11} for

deuterium oxide vapor are those derived for the solubility measurements (12).

Method of evaluating compositions of aqueous and gaseous phases

The iterative process used to evaluate the intensive properties of the liquid deuterium oxide solution and of the binary gaseous phase at equilibrium with deuterium sulfide is similar in principle but different in method from that briefly outlined for the solubility (12). Modern values (*i*) for $p_1°$, the saturation vapor pressure of deuterium oxide, are from Hill and MacMillan (18) and (*ii*) for V_1^{l1}, the molar volume of liquid deuterium oxide, are from Kell (19), evaluated with proper allowance for the difference of the IPTS-48 and the IPTS-68 scales of temperature.

Consider the equilibrium evaporation at a total pressure P and temperature T of 1 g molar mass of deuterium oxide from its liquid solution with mole fraction x_1^{l1} deuterium oxide into its binary gas phase with mole fraction y_1 deuterium oxide as formally represented by the reaction equation:

$$[1] \qquad \begin{array}{ccc} D_2O(l_1) & \rightleftharpoons & D_2O(g) \\ P, x_1^{l1} & & P, y_1 \\ G_1^{l1}(P, x_1^{l1}) & & G_1^{g}(P, y_1) \end{array}$$

The molar Gibbs energy for deuterium oxide in the liquid and in the gas phases are defined as $G_1^{l1}(P, x_1^{l1})$ and $G_1^{g}(P, y_1)$, respectively. For the system in thermodynamic equilibrium at constant T and P the molar Gibbs energy of deuterium oxide is the same in both the liquid and the gas phases so that

$$[2] \qquad G_1^{l1}(P, x_1^{l1}) = G_1^{g}(P, y_1)$$

For the equilibrium evaporation of pure deuterium oxide with $x_1^{l1} = 1$, $y_1 = 1$, and $P = p_1°$, eq. [2] yields the relations:

$$[3] \qquad G_1^{l1}(p_1°, 1) = G_1^{*l1} = G_1^{g}(p_1°, 1) = G_1^{°g} + RT \ln f_1°$$

where G_1^{*l1} is the molar Gibbs energy of pure liquid deuterium oxide at its saturation vapor pressure $p_1°$, and where $f_1°$ is its saturation fugacity, and $G_1^{°g}$ is the standard molar Gibbs energy of gaseous deuterium oxide at unit pressure.

For pure liquid deuterium oxide at a total pressure $P(>p_1°)$ the molar Gibbs energy $G_1^{l1}(P, 1)$ is

$$[4] \qquad G_1^{l1}(P, 1) = G_1^{*l1} + (P - p_1°)V_1^{l1} = G_1^{*l1} + RT \ln f_1(\text{Poynting})$$

where $f_1(\text{Poynting}) = \exp((P - p_1°)V_1^{l1}/RT)$ is the Poynting pressure coefficient, and V_1^{l1} is the molar volume of the liquid.

For dilute solutions of deuterium sulfide in deuterium oxide with mole fraction x_1^{l1} of deuterium oxide at pressure P the molar Gibbs energy for deuterium oxide is taken as

$$[5] \qquad G_1^{l1}(P, x_1^{l1}) = G_1^{l1}(P, 1) + RT \ln x_1^{l1}$$

where the liquid is assumed to obey Raoult's law.

The sum of eqs. [3]–[5] gives

$$[6a] \qquad G_1^{l1}(P, x_1^{l1}) = G_1^{og} + RT \ln f_1° + RT \ln f_1(\text{Poynting}) + RT \ln x_1^{l1}$$

$$[6b] \qquad G_1^{l1}(P, x_1^{l1}) = G_1^{og} + RT \ln [f_1° \cdot f_1(\text{Poynting}) \cdot x_1^{l1}]$$

expressing the molar Gibbs energy of deuterium oxide $G_1^{l1}(P, x_1^{l1})$ at P and x_1^{l1} in eq. [6*a*] in terms of the molar Gibbs energy for the pure liquid at its saturation vapor pressure with fugacity $f_1°$, plus the Poynting molar Gibbs energy change with activity coefficient $f_1(\text{Poynting})$, plus the Raoult-law molar Gibbs energy change with activity coefficient x_1^{l1}. Alternately eq. [6*b*] expresses the same molar Gibbs energy in terms of the fugacity product within the square brackets.

The Redlich–Kwong equation of state for gas mixtures (12, 16, 17) provides an independent expression for the fugacity f_1 of deuterium oxide at mole fraction y_1 in a gas mixture with deuterium sulfide at total pressure P. Under

these conditions the molar Gibbs energy for deuterium oxide in the gas phase $G_1^g(P, y_1)$ is given by

$$[7] \qquad G_1^{\,g}(P, y_1) = G_1^{\,og} + RT \ln f_1$$

Returning to the equilibrium of the binary aqueous phase with the binary gaseous phase, eqs. [6*b*] and [7] are substituted into eq. [2] to obtain the equilibrium relationship

$$[8] \qquad f_1 = [f_1° \cdot f_1(\text{Poynting}) \cdot x_1^{\,l1}]$$

where the fugacity f_1 of deuterium oxide from the Redlich–Kwong equation is equal to the saturation fugacity $f_1°$ of the pure liquid corrected for the effects of pressure and of solution mole fraction. The equilibrium values for f_1 and x_1^{l1} are obtained by successive approximations to evaluate eq. [8] as follows.

As a first approximation the gas-phase mole fraction of deuterium oxide y_1' at total pressure P is taken as

$$[9] \qquad y_1' = p_1°/P$$

with $p_1°$ evaluated from the equation of Hill and MacMillan (18). This y_1' is used at P and T in the Redlich–Kwong (R–K) equation for gas mixtures (12, 16, 17) to obtain V' the molar volume of the gas mixture, and thence to evaluate the first approximations f_1' and f_2' for the R–K fugacities of deuterium oxide and of deuterium sulfide, respectively. This f_2' is used with the Henry's law solubility constant (12) and its Poynting correction to evaluate $x_2^{l1\prime}$, the mole fraction of undissociated deuterium sulfide dissolved in deuterium oxide.

The Poynting correction for the deuterium sulfide solute is $f_2(\text{Poynting}) = \exp((P - p_1°)V_2^{l1}/RT)$, where V_2^{l1} is the partial molar volume of deuterium sulfide in deuterium oxide. Values of V_2^{l1} for deuterium sulfide are estimated from the measurements for hydrogen sulfide in water by Barbero et al. (20).

The $x_2^{l1\prime}$ is used with the ionization constant for deuterium sulfide in deuterium oxide (12) to evaluate $x_3^{l1\prime}$, the dissolved mole fraction of the deuterium sulfide anion. In the first approximation $x_1^{l1\prime}$, the solution mole fraction of deuterium oxide, is given by $(1 - x_2^{l1\prime} - 2x_3^{l1\prime}) = x_1^{l1\prime}$.

The fugacity of deuterium oxide evaluated for the compressed solution using eq. [6*b*] is $[f_1° \cdot f_1(\text{Poynting}) \cdot x_1^{l1\prime}]$, which is greater than the fugacity f_1' evaluated from the Redlich–Kwong equation using y_1'. The reason that the R–K fugacity f_1' is too small is because our first approximation of y_1', using partial pressures, is too small: thus, in our second approximation we multiply y_1' by a converging factor greater than unity.

In the second approximation the gas-phase mole fraction of deuterium oxide y_1'' at total pressure P is taken as

$$[10] \qquad y_1'' = y_1'[f_1° \cdot f_1(\text{Poynting}) \cdot x_1^{\,l1\prime}] / f_1'$$

giving the second sequence of approximations, $y_1'' \rightarrow V'' \rightarrow f_1'', f_2'' \rightarrow x_2^{\,l1\prime\prime}, x_3^{\,l1\prime\prime} \rightarrow x_1^{\,l1\prime\prime} \rightarrow y_1''[f_1° \cdot f_1(\text{Poynting}) \cdot x_1^{\,l1\prime\prime}]/f_1'' = y_1$ (3rd approximation), and so on. The approximations converge rapidly to give equilibrium values after six cycles of iteration, satisfying eq. [8] within the limits of single precision arithmetic.

Liquid D_2O – liquid D_2S – gas (l_1l_2g) equilibrium

Table 1 presents 19 determinations of $P(l_1l_2g)$, the saturation vapor pressure of the partially miscible liquids deuterium oxide and deuterium sulfide between 33.003 and 18.905°C, together with calculated values from the best (21) representative equation

$$[11] \qquad \ln P(l_1l_2g) = 7.95368 - 2160.7 / T$$

with $P(l_1l_2g)$ in MPa and absolute temperature T in Kelvin. The percentage differences between observed and calculated pressures, shown in the fourth column, indicate a SE of 0.025% on a single determination: this precision properly

3.7160	0.02762	0.00066	23.4	0.908	0.44
3.6741	0.04067	0.00065	16.0	1.338	0.54
3.6291	0.05306	0.00065	12.3	1.748	0.61
3.5866	0.06544	0.00065	10.0	2.159	0.68
3.5285	0.08204	0.00065	7.98	2.711	0.76
3.5264	0.08270	0.00065	7.92	2.733	0.76
3.4953	0.09158	0.00064	7.16	3.030	0.80
3.4540	0.10363	0.00064	6.33	3.432	0.86
3.3917	0.12142	0.00064	5.41	4.029	0.93

corresponds with the 0.030% accuracy of the 500 psi gauge (11). The parameter –2160.7 has SE 1.2 K. The fifth column shows the SE on the pressure calculated from eq. [11].

The vapor pressure of the mixed liquids, $P(l_1l_2g)$, is less than that of pure deuterium sulfide (11), $p_2°$, and the ratio of pressures in this temperature range is best represented by

$$[12] \quad \ln [P(l_1l_2g) / p_2°] = -0.09553 + 25.7 / T$$

where $p_2°$ has been evaluated using eq. [2] from ref. 11 and has a SE of 0.027%. The combined SE on an observed single ratio of pressure is 0.037%, and the parameter 25.7 has SE 1.7 K.

At 25°C the computed ratio of $P(l_1l_2g)/p_2°$ is 0.99074 with SE 0.000088 and 17 degrees of freedom; this gives the deviation (1 – 0.99074), a student t ratio of 106, which confirms that $P(l_1l_2g)/p_2°$ is significantly less than unity at a very high level of probability.

Table 4 presents values for the intensive properties of the equilibrium (l_1l_2g) phases under the conditions of Table 1. Values in columns three to seven are, respectively, for the fugacities f_2 of deuterium sulfide and f_1 of deuterium oxide, for the gas-phase mole fraction y_1 of deuterium oxide, for the mole fractions x_2^{l1} of undissociated deuterium sulfide and x_3^{l1} of deuterium sulfide anion in the liquid deuterium oxide phase l_1. In column eight the saturation mole fraction x_1^{l2} of deuterium oxide in the liquid deuterium sulfide phase l_2 has been evaluated as $(1 - (f_2/f_2°))$, using fugacities assuming the deuterium sulfide solvent obeys Raoult's law. Column two provides the required Redlich–Kwong fugacity $f_2°$ for pure deuterium sulfide at its saturation vapor pressure $p_2°$ (11).

The saturation solubility x_1^{l2} of deuterium oxide in liquid deuterium sulfide l_2 is best discussed in terms of the Henry's law constant, $H_1^{l2} = f_1/x_1^{l2}$ MPa, for transfer of deuterium oxide from phase l_2 into the gas phase. Comparison of our 19 estimates of f_1/x_1^{l2} for deuterium oxide in liquid deuterium sulfide with 27 similar estimates of f_1/x_1^{l2} for water in liquid hydrogen sulfide, derived from the vapor pressure data of Scheffer (6), shows that f_1/x_1^{l2} for deuterium oxide in deuterium sulfide and for water in hydrogen sulfide are equal within experimental error at the same temperature between 33 and 19°C.

Combination of our 19 estimates of f_1/x_1^{l2} for deuterium oxide in deuterium sulfide with five estimates of f_1/x_1^{l2} for water in hydrogen sulfide, derived from the direct phase analyses of x_1^{l2} between 40 and 105°C by Carroll (22), gives the best representative equation

$$[13] \quad \ln [f_1/x_1^{l2}] = 9.0634 - 3102/T$$

for the Henry's law constant of deuterium oxide in liquid deuterium sulfide with SE of 3.6% on a single determination between 33 and 19°C: the parameter –3102 has SE 67 K. At 25°C the Henry's law constant H_1^{l2} for deuterium oxide in deuterium sulfide is 0.261 with SE 0.0022 MPa, that evaluated from ref. 6 for water in hydrogen sulfide is 0.261 with SE 0.0073 MPa.

The temperature dependence of x_1^{l2}, the saturation mole fraction of deuterium oxide in liquid deuterium sulfide between 33 and 19°C, is best represented by

$$[14] \quad \ln x_1^{l2} = 2.7474 - 2182/T$$

with SE of 4.6% on a single determination: the parameter –2182 has SE 70 K. At 25°C x_1^{l2} for deuterium oxide in deuterium sulfide is 0.0103 with SE 0.00011, that evaluated from (6) for water in hydrogen sulfide is 0.0119 with SE 0.00034: the difference 0.0016 of x_1^{l2} is significant.

D_2S D-hydrate – liquid D_2O – gas (hl_1g) equilibrium

Table 2 presents 58 equilibrium determinations of $P(hl_1g)$, the saturation vapor pressure of deuterium sulfide D-hydrate in contact with liquid deuterium oxide between 30.666 and 2.798°C. The seven determinations below 3.392°C are in metastable equilibrium.

The second column denotes the pressure gauge used, data marked 500, 200, and 16 used the 500 psi, 200 psi, and 16 psi gauges, respectively. The third column gives the square root of the weights used to combine the data from the various gauges into a properly weighted least-squares regression of the logarithm of pressure as a function of temperature.

The fourth column lists the observed $P(hl_1g)$, the fifth gives $P(hl_1g)$ calculated from the best model of the form (21)

© 1998 NRC Canada

$$[15a] \quad \ln P(\mathrm{hl_1g}) = b0 + b1{\cdot}u1 + b2{\cdot}u2 + b3{\cdot}u3 + b4{\cdot}u4 + b5{\cdot}u5 + b6{\cdot}u6$$

which is mathematically equivalent to

$$[15b] \quad \ln P(\mathrm{hl_1g}) = A + B/T + C \ln T + DT + ET^2 + FT^3 + GT^4$$

and which required seven parameters for a proper representation of the 58 data. The percentage differences between observed and calculated pressures, shown in the sixth column, yield an overall SE of 0.013% for a single determination of unit weight with 51 degrees of freedom. The seventh column shows the percentage error on the pressure estimated from the weighted regression model.

The 14 residuals using the 16 psi gauge indicate a SE of 0.013%, the 19 residuals at highest pressure using the 200 psi gauge indicate a SE of 0.018%, and the 14 residuals at highest pressure using the 500 psi gauge indicate a SE of 0.039%. Comparison of these SE estimates with the gauge accuracies (11) shows that (*i*) the data at low pressure are properly represented with SE 0.013% and a 0.020% accuracy of 16 psi gauge calibration, (*ii*) the data at intermediate pressure with SE 0.018% are somewhat more precise than the 0.030% accuracy of 200 psi gauge calibration, and (*iii*) the high-pressure data with SE 0.039% are slightly more variable than the 0.030% accuracy of 500 psi gauge calibration.

The six temperature variables $u1$–$u6$ in eq. [15*a*] are defined in ref. 21 with $x = (T - 298.15)/298.15$, and the parameters $b0$–$b6$ with their (SEs) are $b0$ = 0.157129 (0.000090), $b1$ = 33.0126 (0.010), $b2$ = 232.179 (1.2), $b3$ = 5590.55 (84), $b4$ = 121 174 (5900), $b5$ = 1 619 360 (130 000), and $b6$ = 8 860 000 (890 000). We note that the deuterium sulfide D-hydrate pressures properly define six temperature parameters $b1$–$b6$ at 25°C, that all parameters are positive with no alternation of sign, and that the value of the least significant parameter $b6$ could arise by pure chance at a probability level of less than one in 10^{15} times.

Regression of the 58 data, each assumed equally probable with unit weight, (*i*) gave an unrealistic poor fit of the 14 most accurate determinations at low pressure by the 16 psi gauge and (*ii*) indicated an unrealistic high SE estimate of 0.057% for a single determination, but (*iii*) still required a seven-parameter model (21) with $b1$–$b6$ all positive and highly significant.

The requirement of a seven-parameter model together with the unusually large positive values of $b1$–$b3$ show that the $P(\mathrm{hl_1g})$ data contain information of significant composition change with temperature for deuterium sulfide D-hydrate between 2.8 and 30.7°C.

Table 5 presents values for the intensive properties of the equilibrium $\mathrm{l_1}$ and g phases under the conditions of Table 2. The values listed under f_2, f_1, y_1, x_2^{l1}, and x_3^{l1} have the same meaning as in Table 4.

The saturation vapor pressure $P(\mathrm{hl_1g})$ of deuterium sulfide D-hydrate is about 88% of that for hydrogen sulfide hydrate (6, 7) at the same temperature. This ratio of $P(\mathrm{hl_1g})$ is similar to the ratio of 81% exhibited by the Structure I cyclopropane D-hydrate relative to its cyclopropane hydrate (23) at the same temperature between 6 and 16°C.

D-Ice – liquid D_2O – gas ($\mathrm{s_1l_1g}$) equilibrium

Table 3 presents 11 determinations of $t(\mathrm{s_1l_1g})$, the equilibrium temperature of D-ice with a deuterium oxide solution saturated with deuterium sulfide at total pressure $P(\mathrm{s_1l_1g})$ between 0.00242 and 0.10542 MPa. The final row presents the temperature $t(\mathrm{hs_1l_1g})$ determined at the total pressure $P(\mathrm{hs_1l_1g})$ 0.12364 MPa. The third column shows calculated temperatures from the representative equation

$$[16] \quad t(\mathrm{s_1l_1g}) = \underset{(0.00047)}{3.81473} - \underset{(0.0067)}{3.4258}\, P(\mathrm{s_1l_1g})$$

with $t(\mathrm{s_1l_1g})$ in °C and $P(\mathrm{s_1l_1g})$ in MPa: the SEs are shown in parenthesis below the parameters. Differences between observed and calculated temperatures, shown in the fourth column, indicate a SE of 0.00090°C on a single temperature determination, with 10 degrees of freedom. The fifth column shows the SE estimate on the temperature evaluated from eq. [16].

The first row of Table 3 shows an estimated triple-point temperature of 3.8125 with SE 0.00047°C: this disagrees significantly with our first direct measurement of the triple-point at 3.800 with SE 0.0005°C in a preliminary experiment in 1963. We suggest in that first experiment, where we were unaware of the need to bracket the thermostat temperature both above and below the stirred reactor temperature, we unwittingly had applied a "too large" cooling differential to the stirred reactor, and that had caused the negative bias –0.0125°C on the observed temperature. We note that the 12 determinations presented in Table 3 were made at the end of our study in 1966, with more experience and with temperature bracketing, and therefore probably with less bias.

Table 6 presents values for the intensive properties of the equilibrium $\mathrm{l_1}$ and g phases under the conditions of Table 3.

Upper quadruple point $Q(\mathrm{hl_1l_2g})$

The upper quadruple point $Q(\mathrm{hl_1l_2g})$ is the invariant four-phase point at the highest temperature where the D-hydrate can coexist in equilibrium with a gas phase: it is located at the cut of the two univariant three-phase curves $(\mathrm{hl_1g})$ and $(\mathrm{l_1l_2g})$. The $(\mathrm{hl_1g})$ curve has been defined by the upper 14 determinations using the 500 psi gauge between 25.000 and 30.666°C and indicated a SE of 0.042% on a single pressure determination with 10 degrees of freedom. The $(\mathrm{l_1l_2g})$ curve has been defined by eq. [11]. The quadruple-point temperature $t(\mathrm{hl_1l_2g})$ is 30.770 with SE 0.0043°C and the quadruple-point pressure $P(\mathrm{hl_1l_2g})$ is 2.3263 with SE 0.00018 MPa.

Comparison of $Q(\mathrm{hl_1l_2g})$ for deuterium sulfide D-hydrate with that for hydrogen sulfide hydrate, reported by Scheffer (6) at 29.5°C and at 2.24 MPa, shows a difference of temperature of 1.27°C and a difference of pressure of 0.09 MPa.

Lower quadruple point $Q(\mathrm{hs_1l_1g})$

The lower quadruple point $Q(\mathrm{hs_1l_1g})$ is the invariant four-phase point at the lowest temperature where the D-hydrate coexists in stable equilibrium with a liquid deuterium oxide phase: it is located at the cut of the two univariant three-phase curves $(\mathrm{hl_1g})$ and $(\mathrm{s_1l_1g})$. The $(\mathrm{hl_1g})$ curve has been defined by the lower 10 determinations using the 16 psi gauge between 3.987 and 2.798°C and indicated a SE of 0.0072% on a single pressure determination with 8 degrees

© 1998 NRC Canada

of freedom. The (s_1l_1g) curve has been defined by eq. [16]. The lower quadruple-point temperature $t(hs_1l_1g)$ has been evaluated at 3.3912 with SE 0.00057°C and the quadruple-point pressure $P(hs_1l_1g)$ at 0.12363 with SE 0.000002 MPa.

The lower quadruple point, determined directly, has given the temperature $t(hs_1l_1g)$ at 3.3917 with SE 0.00090°C and the pressure $P(hs_1l_1g)$ at 0.12364 with SE 0.000011 MPa.

Comparison of $Q(hs_1l_1g)$ for deuterium sulfide D-hydrate with that for hydrogen sulfide hydrate evaluated by Scheffer and Meyer (7) at –0.4°C and at about 0.094 MPa, indicates a difference of temperature of 3.79°C and of pressure of about 0.030 MPa. The ratio of $P(hs_1l_1g)$ for deuterium sulfide D-hydrate relative to hydrogen sulfide hydrate at their quadruple points is equal to that 1.31 ratio exhibited by Structure I cyclopropane D-hydrate (23) relative to cyclopropane hydrate at their quadruple points.

Acknowledgments

We wish to thank Dr. Howard K. Rae of Atomic Energy of Canada Limited for his assistance in obtaining isotope analysis for our deuterium oxide sample. This work was supported in part by grants under the National Research Council of Canada, Industrial Research Assistance Program, for 1963–1966.

Transition metal azolates from metallocenes. Part 3: Polymeric manganese(II) and nickel(II) pyrazolates; synthesis, characterization, and magnetochemistry

Alan Storr, David A. Summers, and Robert C. Thompson

Abstract: Direct reactions of nickelocene and manganocene with molten pyrazoles in an inert atmosphere or under vacuum have led to the isolation of the following metal pyrazolate compounds: $[Ni(4\text{-}Xpz)_2]_x$ (where X = H, Cl and pz = pyrazolate); $[M(4\text{-}Xdmpz)_2]_x$ (where X = H, CH_3, Cl, Br and M = Ni, Mn and dmpz = 3,5-dimethylpyazolate); and $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ (where X = Cl, Br and pzH = pyrazole). On the basis of indirect evidence all compounds are considered to have extended chain structures with metal ions linked in chains by double bridging pyrazolates. The two $[Ni(4\text{-}Xpz)_2]_x$ compounds are diamagnetic while all others are paramagnetic. Variable temperature magnetic susceptibility studies on the paramagnetic compounds reveal antiferromagnetic coupling between neighbouring metal ions. Analysis of the magnetic data (Hamiltonian of the form $H = -2J \Sigma S_i \cdot S_j$) yields values of the exchange coupling constant J of -14 to -17 cm^{-1} for the $[Ni(4\text{-}Xdmpz)_2]_x$ compounds, –1.2 to –2.1 cm^{-1} for the $[Mn(4\text{-}Xdmpz)_2]_x$ compounds, and –0.41 cm^{-1} for the $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ compounds.

Key words: nickel, manganese, manganocene, nickelocene, pyrazolates, antiferromagnetic exchange.

Résumé : Par réactions directes du nickelocène et du manganocène avec des pyrazoles fondus, dans une atmosphère inerte ou sous vide, on a isolé les pyrazolates de métal suivants: $[Ni(4\text{-}Xpz)_2]_x$ (dans lesquels X = H, Cl et pz = pyrazolate); $[M(4\text{-}XpzH)]_x$ (dans lesquels X = H, CH_3, Cl, Br et M = Ni, Mn et dpmz = 3,5-diméthylpyrazolate) et $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ (dans lesquels X = Cl, Br et pzH = pyrazole). Sur la base de données indirectes, on considère que tous les composés comportent des structures en chaînes étendues avec des ions métalliques liés aux chaînes par des pyrazolates agissant comme doubles ponts. Les deux composés $[Ni(4\text{-}Xpz)_2]_x$ sont diamagnétiques alors que tous les autres sont paramagnétiques. Des études de susceptibilité magnétique à température variable sur les composés paramagnétiques mettent en évidence la présence d'un couplage antiferromagnétique entre les ions métalliques voisins. L'analyse de données magnétiques (hamiltonien de la forme $H = -2J \Sigma S_i \cdot S_j$) conduit à des constantes de couplage d'échange, J, qui vont de –14 à –17 cm^{-1} pour les composés $[Ni(4\text{-}Xdmpz)_2]_x$, de –1,2 à –2,1 cm^{-1} pour les composés $[Mn(4\text{-}Xdmpz)_2]_x$ et de –0,41 cm^{-1} pour les composés $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$.

Mots clés : nickel, manganèse, manganocène, nickelocène, pyrazolates, échange antiferromagnétique.

Introduction

Pyrazole and pyrazolate containing transition metal coordination complexes have been extensively investigated and several review papers have been devoted to the topic (1–4). Our interest in pyrazolate ligands stems from their tendency (*i*) to bind metal ions in an exobidentate fashion and hence to form oligo- and poly-metallic compounds and (*ii*) to act as efficient mediators of magnetic exchange interactions. In previous studies we have synthesized several transition metal azolate complexes and investigated their magnetic properties (5–11). The main objectives in this research have been to gain a better understanding of the factors that influence the nature and magnitude of magnetic exchange between the transition metal centers in these materials. To achieve this and explore both electronic and steric effects it is necessary to study a variety of systems involving different C-substituted pyrazolates and different metals. To date our research has involved investigations on copper(II) and cobalt(II) systems (7–11) and the work described here complements these earlier studies.

Several synthetic approaches to generate linear chain transition metal pyrazolate polymers have been reported. Seel and Sperber described the preparation of $[Fe(pz)_2]_x$ and $[Fe(pz)_3]_x$ (where pz = pyrazolate) from a variety of iron derivatives such as $Fe(CO)_5$ or $[CpFe(CO)_2]_2$ (12). Bagley et al. prepared $[Co(dmpz)_2]_x$ (where dmpz = 3,5-dimethylpyrazolate) from Co(II) acetylacetonate and hydrazine in

isopropanol (13) and synthesized several other cobalt(II) C-substituted pyrazolate analogues by reacting cobalt(II) salts with the appropriate pyrazole in basic solutions. Trofimenko reported, as unpublished results, the preparation of nickel(II) and copper(II) pyrazolates by pyrolysis of the appropriate $M(pzH)_4(OAc)_2$ (OAc = acetate) complexes or by reacting pyrazole with metal salts in basic solutions (1). The preparation of $[Co(dmpz)_2]_x$, and $[Ni(dmpz)_2 \cdot 2H_2O]_x$, by the reaction of the appropriate bis-acetylacetonato metal(II) complex with hydrazine, was described by Singh et al. (14). A series of reports by Vos and Groeneveld described the synthesis and characterization of metal pyrazolate complexes of Mn, Co, Ni, Cu, Zn, and Cd with 4-Xpz and 4-Xdmpz (X = H, CH_3, Cl, Br, I, NO_2) (15, 16). The materials were prepared by reacting aqueous solutions of metal salts with basic aqueous solutions of pyrazoles. It should be noted that in many cases the reported purity of the materials described in this latter work was based on metal analysis alone, and attempts in this laboratory to reproduce much of this work led, at best, to the formation of impure products. The synthesis of $[Fe(pz)_2]_x$ from $FeCl_2$ and lithium pyrazolate in toluene has been described by Strahle et al. (17) and recently Vecchio-Sadus described an electrochemical synthesis route to a series of transition metal pyrazolates (18).

A novel synthetic approach, detailed in our previous reports, involving the reaction between metal shot (Cu or Co) and molten pyrazoles under a dioxygen atmosphere led not only to transition metal pyrazolates of high purity but also, in some cases, afforded crystalline materials (8*a*, 8*d*). In addition, three $[Cu(4\text{-}Xdmpz)_2]_x$ complexes (X = Cl, Br, CH_3) were prepared by reacting the corresponding trimetallic copper(I) complex, $[Cu(4\text{-}Xdmpz)]_3$, again with the appropriate molten pyrazole under an atmosphere of dioxygen (9*a*). Another method of producing binary metal pyrazolates, $[M(pz^*)_2]_x$ (M = Zn, Pt, Pd and pz^* = substituted pyrazolates), involves removing thermally the neutral coordinated pz^*H from complexes of formulation $[M(pz^*)_2(pz^*H)]_2$ (8*c*, 19–21).

Our attempts to prepare pyrazolate complexes of nickel(II) by the metal – molten azole method yielded pure samples only for $[Ni(pz)_2]_x$. In an earlier report we described an alternative synthetic approach involving nickelocene that led to the preparation of diamagnetic oligometallic nickel(II) pyrazolate complexes (6). The present report details the use of metallocenes to obtain several paramagnetic linear chain polymers containing either nickel(II) or manganese(II). The idea to synthesize pyrazolates via this pathway came from a 1977 article by Blake et al. in which two diamagnetic nickel(II) pyrazolate polymers, prepared by reacting nickelocene with the appropriate azole in benzene solvent, were reported (22). In the current work, eight paramagnetic complexes of composition $[M(4\text{-}Xdmpz)_2]_x$ (where M = Ni(II), Mn(II) and X = H, Cl, Br, CH_3), two paramagnetic complexes of composition $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ (where X = Br, Cl), and two diamagnetic complexes of composition $[Ni(4\text{-}Xpz)_2]_x$ (where X = H, Cl) were obtained. We report here variable temperature (2–300 K) magnetic susceptibilities and other studies on these systems. The materials prepared in the present work were not obtained in a form suitable for single crystal X-ray diffraction studies; however, on the basis of indirect spectroscopic and other evidence they are proposed to have structures involving extended chains of metal ions doubly bridged by pyrazolate ligands. The polymeric copper(II) and cobalt(II) pyrazolates, previously studied, have been shown to exhibit this structural motif, with the structures of three of the copper compounds having been determined by single crystal X-ray diffraction studies (8*a*, 8*d*).

Experimental

Syntheses

Nickelocene and manganocene were prepared using the method of R.B. King (23). $Ni(Cp)_2$ was prepared from nickel powder, bromine, and cyclopentadiene while $Mn(Cp)_2$ was prepared from manganese powder, bromine, and sodium cyclopentadienide. Pyrazoles were used as supplied (Aldrich) or prepared as described previously (8*d*, 24). Solvents used were reagent grade and were dried and distilled under an atmosphere of dry dinitrogen before use.

$[Ni(4\text{-}Hpz)_2]_x$

$[Ni(4\text{-}Hpz)_2]_x$ was prepared using two different synthetic approaches. The complex was first produced by heating (110°C) nickel powder (0.24 g, 4.1 mmol) with an excess of molten pyrazole (1.25 g, 18 mmol) under normal atmosphere conditions for 48 h. The mixture was allowed to cool and the excess pyrazole was removed by washing with dichloromethane. The pure product was isolated as an insoluble orange powder by physical separation, using a magnet to remove the unreacted nickel powder. Anal. calcd. for $NiC_6H_6N_4$: C 37.4, H 3.1, N 29.1; found: C 37.4, H 3.4, N 28.9.

$[Ni(4\text{-}Hpz)_2]_x$ was also prepared by reacting a mixture of freshly sublimed nickelocene (0.5 g, 2.6 mmol) with an excess of molten pyrazole (4.5 g, 65 mmol) at 100°C under a dry nitrogen atmosphere for 24 h. After cooling, the excess pyrazole was dissolved in dichloromethane and the insoluble orange powder was isolated by vacuum filtration. TGA: 61% weight loss between 400°C and 515°C. Anal. calcd. for $NiC_6H_6N_4$: C 37.4, H 3.1, N 29.1; found: C 37.2, H 3.2, N 29.2.

$[Ni(4\text{-}CIpz)_2]_x$

This compound was prepared in a manner analogous to the latter method described above for the preparation of $[Ni(4\text{-}Hpz)_2]_x$. TGA: 70% weight loss between 360°C and 545°C. Anal. calcd. for $NiC_6H_4N_4Cl_2$: C 27.5, H 1.5, N 21.4; found: C 27.8, H 1.4, N 21.2.

$[Ni(4\text{-}Hdmpz)_2]_x$

The synthesis of $[Ni(4\text{-}Hdmpz)_2]_x$ was attempted, without success, using the nickel metal in molten pyrazole reaction that was employed in the $[Ni(4\text{-}Hpz)_2]_x$ preparation described above. The target compound was successfully prepared, however, using nickelocene and 3,5-dimethylpyrazole under inert atmosphere conditions. Freshly sublimed $Ni(Cp)_2$ (0.25 g, 1.3 mmol) was mixed intimately with an excess of 3,5-dimethylpyrazole (1.34 g, 19 mmol) and placed in a dry and oxygen-free glass Carius tube. The tube was flame-sealed under vacuum and placed in an oven (140°C) for 48 h. Following the initial melting of the 3,5-dimethylpyrazole a green solution, presumably of

© 1998 NRC Canada

nickelocene dissolved in the molten pyrazole, was observed. After approximately 10 min the colour of the solution had changed to a deep red and a few hours later a puce powder had begun to precipitate out. After 48 h the amount of puce solid had increased considerably and the intensity of the colour in the solution had diminished. At this point the tube was allowed to cool and the insoluble product (0.31 g, 94.3%) was purified by removal of the excess 3,5-dimethylpyrazole by dissolution in dry and oxygen-free THF. TGA: 70% weight loss between 380°C and 520°C. Anal. calcd. for $NiC_{10}H_{14}N_4$: C 48.2, H 5.7, N 22.5; found: C 48.1, H 5.7, N 22.3.

$[Ni(4\text{-}Xdmpz)_2]_x$ (where X = Br, Cl, or CH_3)

These polymers were prepared from nickelocene and an excess of the appropriate pyrazole as described above for the synthesis of $[Ni(4\text{-}Hdmpz)_2]_x$. $[Ni(4\text{-}Brdmpz)_2]_x$; TGA: 82% weight loss between 315°C and 595°C. Anal. calcd. for $NiC_{10}H_{l2}N_4Br_2$: C 29.5, H 3.0, N 13.8; found: C 29.9, H 3.0, N 14.1. $[Ni(4\text{-}Cldmpz)_2]_x$; TGA: 76% weight loss between 300°C and 495°C. Anal. calcd. for $NiC_{10}H_{12}N_4Cl_2$: C 37.8, H 3.8, N 17.6; found: C 38.1, H 3.9, N 17.5. $[Ni(4\text{-}CH_3dmpz)_2]_x$; TGA: 73% weight loss between 335°C and 480°C. Anal. calcd. for $NiC_{12}H_{18}N_4$: C 52.0, H 6.6, N 20.2; found: C 52.3, H 6.4, N 20.1.

$[Mn(4\text{-}Hdmpz)_2]_x$

Manganocene (1.1 g, 5.9 mmol) and 3,5-dimethylpyrazole (5.19 g, 54 mmol) were intimately mixed and placed in a Carius tube. The tube was flame-sealed under vacuum and placed in an oven (150°C). The 4-HdmpzH melted after a few minutes resulting in a mixture of molten ligand and solid manganocene. It was not possible to determine the extent of the reaction by visual means as both the manganocene and desired product appear as beige solids in the colourless and clear molten 4-HdmpzH. After 2 weeks the tube was allowed to cool, and the excess ligand to solidify, prior to the tube being opened under a dinitrogen atmosphere. The beige solid product was isolated by dissolving the excess 3,5-dimethylpyrazole in THF, benzene, and hexanes. The slurry was vacuum filtered and the $[Mn(4\text{-}Hdmpz)_2]_x$ collected on the filter. The product was dried, and any remaining volatile starting materials removed, under vacuum for 48 h, yielding 0.74 g (52%) of $[Mn(4\text{-}Hdmpz)_2]_x$ as a beige powder. Anal. calcd. for $C_{10}H_{14}N_4Mn$: C 49.0, H 5.8, N 22.9; found: C 49.0, H 5.7, N 23.0.

$[Mn(4\text{-}Xdmpz)_2]_x$ (where X = Br, Cl, or CH_3) and $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ (where X = Br or Cl)

These polymers were prepared from manganocene and an excess of the appropriate pyrazole as described above for the synthesis of $[Mn(4\text{-}Hdmpz)_2]_x$. $[Mn(4\text{-}Brdmpz)_2]_x$; TGA: 76% weight loss between 265°C and 660°C. Anal. calcd. for $C_{10}H_{12}N_4Br_2Mn$: C 29.8, H 3.0, N 13.9; found: C 30.0, H 3.0, N 14.0. $[Mn(4\text{-}Cldmpz)_2]_x$; TGA: 75% weight loss between 250°C and 480°C. Anal. calcd. for $C_{10}H_{12}N_4Cl_2Mn$: C 38.2, H 3.9, N 17.8; found: C 38.5, H 3.8, N 17.7. $[Mn(4\text{-}CH_3dmpz)_2]_x$; TGA: 65% weight loss between 250°C and 505°C. Anal. calcd. for $C_{12}H_{18}N_4Mn$: C 52.8, H 6.6, N 20.5; found: C 52.7, H 6.6, N 20.3. $[Mn(4\text{-}Brpz)_2(4\text{-}BrpzH)]_x$; Anal. calcd. for $C_9H_7N_6Br_3Mn$: C 21.9, H 1.4, N 17.1; found: C 21.6, H 1.2, N 16.8. $[Mn(4\text{-}Clpz)_2(4\text{-}ClpzH)]_x$; TGA: 78% weight loss between 250°C and 700°C. Anal. calcd. for $C_9H_7N_6Cl_3Mn$: C 30.0, H 2.0, N 23.3; found: C 29.5, H 2.0, N 23.0.

Physical characterization

All compounds characterized here were found to be insoluble in common solvents and to decompose upon dissolution in acid. Differential scanning calorimetry (DSC; 35–600°C) and thermal gravimetric analysis (TGA; 35–800°C) measurements were made using a TA Instruments DSC 910S cell and a TA Instruments TGA 51 unit, respectively.

Electronic spectra (200–3000 nm) were obtained at room temperature on Nujol mulls pressed between quartz plates using a Varian Cary 5 UV–Vis-NIR spectrophotometer. Infrared spectra (4000–400 cm^{-1}) were recorded at room temperature on a Bomen FTIR spectrophotometer. Samples were prepared by compressing a powdered mixture of compound and KBr between portions of pure powdered KBr.

Magnetic susceptibilities were measured over the temperature range 2–300 K using a Quantum Design (MPMS) SQUID magnetometer (applied field = 10 000 G). A specially designed sample holder, as described previously (8*f*), was used to minimize the background signal. Magnetic susceptibilities were corrected for diamagnetism: nickel, –11; manganese, –14; $C_3H_3N_2$, –40; $C_3H_2N_2Br$, –72; $C_3H_2N_2Cl$, –61; $C_3H_3N_2Br$, –75; $C_3H_3N_2Cl$, –64; $C_5H_7N_2$, –62; $C_5H_6N_2Br$, –90; $C_5H_6N_2Cl$, –79; $C_6H_9N_2$, –74 (values in 10^{-6} cm^3 mol^{-1}). Data reported here are on a per mole of metal center basis.

Molecular modeling

Molecular models of $[Ni(4\text{-}Xdmpz)_2]_x$ in which the nickel(II) ions are present in either a square planar or tetrahedral NiN_4 chromophore geometry were generated by utilizing single crystal X-ray diffraction data from the related trimetallic complex $[CpNi(4\text{-}Cldmpz)_2]_2Ni$ (6). The crystallographic data of this trimetallic complex were manipulated to produce two different linear chain structures: one in which all of the nickel(II) centers are present in square planar NiN_4 chromophore geometries and the other in which the nickel ions are present in ideal tetrahedral geometries. To generate these models the internal bond lengths and angles in the pyrazolate rings were assumed to be identical to those found in the trimetallic system. In addition, the nickel to nitrogen bond lengths determined in $[CpNi(4\text{-}Cldmpz)_2]_2Ni$ were used in both of the modeled structures.

Results and discussion

Syntheses and stabilities

Following largely unsuccessful attempts to prepare manganese(II) and nickel(II) binary metal pyrazolates by reacting pure metal with molten pyrazoles, a synthetic method employed with success in the preparation of many copper(II) and cobalt(II) derivatives, an alternate approach was developed. This approach, involving the direct reaction of a metallocene with an excess of the appropriate pyrazole in an inert atmosphere or under vacuum gave, in the case of nickelocene, either oligometallic cyclopentadienyl nickel(II) pyrazolates (6) or, depending on conditions, binary nickel(II)

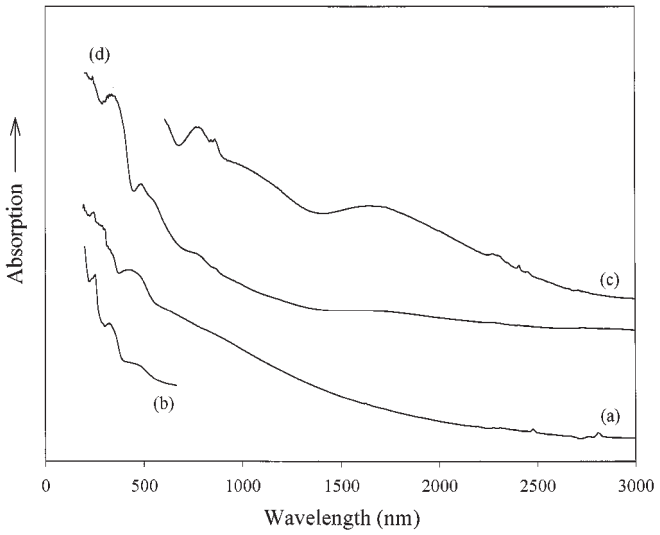
Fig. 1. Electronic spectra: (*a*) and (b), $[Ni(4\text{-}Hpz)_2]_x$ at high and low mull concentrations respectively; (*c*) and (d), $[Ni(4\text{-}Hdmpz)_2]_x$ at high and low mull concentrations respectively.



pyrazolates of composition $[Ni(4\text{-}Xpz)_2]_x$ (X = H or Cl) and $[Ni(4\text{-}Xdmpz)_2]_x$ (X = H, CH_3, Cl, or Br). The corresponding reactions with manganocene yielded manganese(II) pyrazolates of composition $[Mn(4\text{-}Xdmpz)_2]_x$ (X = H, CH_3, Cl, or Br) and $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ (X = Cl, Br).

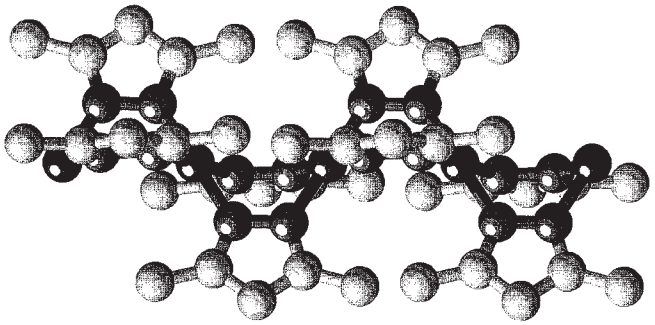
The six nickel(II) compounds reported here were all characterized as being air stable and thermally robust. TGA experiments showed decomposition at temperatures above 300°C. That decomposition occurs without melting was shown by DSC measurements that revealed no thermal events at temperatures below the onset of thermal decomposition. In addition to being thermally robust, all six of the nickel complexes were found to be insoluble in both polar and nonpolar solvents.

The manganese(II) complexes were also found to be thermally robust. TGA and DSC experiments on four of these compounds ($[Mn(4\text{-}Xdmpz)_2]_x$, (X = CH_3, Cl, Br) and $[Mn(4\text{-}Clpz)_2(4\text{-}ClpzH)]_x$) show them to decompose without melting at temperatures above 250°C. All six manganese compounds were also found to be insoluble in polar and nonpolar solvents: however, unlike the nickel compounds, the manganese derivatives decompose on exposure to air. The sensitivity to air is somewhat variable, with the four $[Mn(4\text{-}Xdmpz)_2]_x$ complexes being more sensitive than the two $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ compounds. The presence of the additional neutral pyrazole appears to be responsible for the added stability of the latter complexes.

Electronic spectra

The nickel compounds can be divided into two groups, the four $[Ni(4\text{-}Xdmpz)_2]_x$ derivatives in the first and the two $[Ni(4\text{-}Xpz)_2]_x$ forming the second. Electronic spectra of powdered (mulled) samples revealed distinct spectral characteristics for each group. The electronic spectra of the X = H derivatives of the two groups are shown in Fig. 1. The $[Ni(4\text{-}Xpz)_2]_x$ spectra comprise a single strong band attributed to a *d–d* transition at 440 nm, consistent with square planar NiN_4 chromophores (25). Two higher energy bands, centered at 250 and 350 nm, are clearly visible in the spectra

Fig. 2. Modeled polymer segment for $[Ni(4\text{-}Hdmpz)_2]_x$ in which the metal centers are present in a square planar geometry.



of samples run at lower mulled concentrations (Fig. 1(*b*) and 1(*d*)) and are likely charge transfer in origin. The $[Ni(4\text{-}Xdmpz)_2]_x$ compounds have spectra with three observable spin-allowed *d–d* transitions as is expected for tetrahedral Ni(II), and one observable spin-forbidden *d–d* transition. The three spin-allowed transitions, ν_1: $^3T_1(F) \rightarrow {}^3T_2(F)$, ν_2: $^3T_1(F) \rightarrow {}^3A_2(F)$, and ν_3: $^3T_1(F) \rightarrow {}^3T_1(P)$ are observed in the ranges of 1670–1700 nm, 770–780 nm, and 520–530 nm, respectively. The remaining observed transition has been assigned as $^3T_1(F) \rightarrow {}^1D$ and lies in the range 860–870 nm. Employing ν_1 and ν_2 values of 6000 and 13 000 cm^{-1} and the appropriate energy level expressions (26), ligand field parameter Dq, and *B* values of 700 and 970 cm^{-1}, respectively, were obtained. Employing these parameter values, ν_3 is calculated to be at 19 600 cm^{-1} (510 nm), in good agreement with experiment. Spectra obtained on highly concentrated mulls showed a broad feature in the 1000 nm region. It seems unlikely that a single feature of this nature is due to an additional nickel(II) chromophore. It is possibly part of the strong background signal that arises due to light scattering from mulled samples.

We were unable to obtain electronic spectra of solid samples of the manganese compounds. These are high-spin d^5 complexes and the resulting low-intensity spin-forbidden electronic transitions could not be observed on our mulled samples.

Structural considerations

The high thermal stabilities and low solubilities of the binary nickel(II) pyrazolates are properties consistent with polymeric structures for these materials. Moreover, extended-chain double pyrazolate-bridged structures are supported by the stoichiometry, the evidence from electronic spectroscopy that the metals are four coordinate, and by the fact that pyrazolate ligands tend to bind to metal centers in an exobidentate rather than endobidentate fashion (1–3). We note, though, that large ring structures as described, for example, by Ardizzoia et al. (27), cannot be ruled out.

Further support for a tetrahedral NiN_4 chromophore in the case of $[Ni(4\text{-}Hdmpz)_2]_x$ came from X-ray powder diffraction studies. These showed the compound to be isomorphous with the cobalt analogue $[Co(4\text{-}Hdmpz)_2]_x$ (28) for which strong evidence in favour of a linear chain polymer with tetrahedral metal centers has been presented (9*b*).

Magnetic studies on the nickel compounds, to be described in detail below, provide further evidence in support

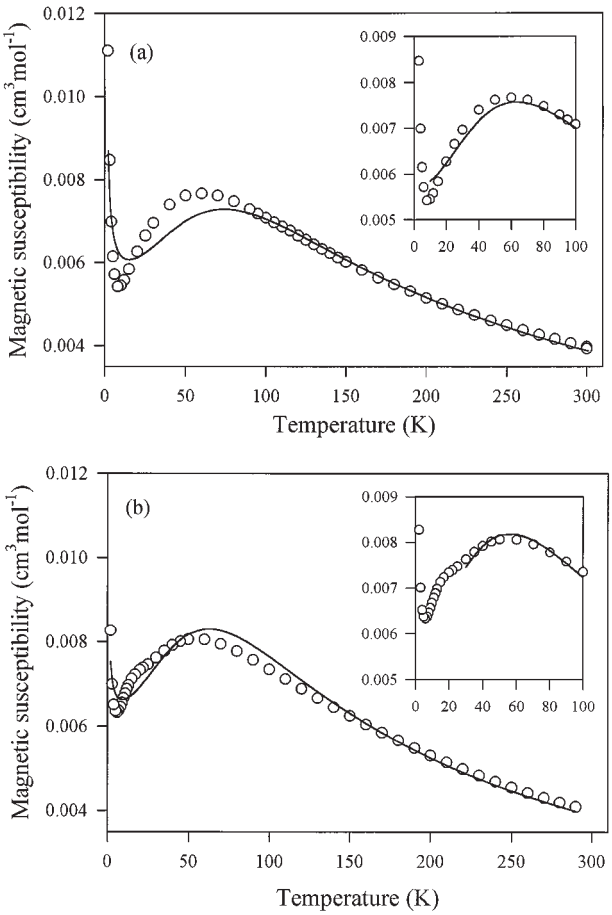

Fig. 4. Magnetic susceptibility versus temperature plots: (*a*) for $[Mn(4\text{-}Hdmpz)_2]_x$ and (*b*) for $[Mn(4\text{-}Clpz)_2(4\text{-}ClpzH)]_x$. Circles are experimental data and lines are calculated from theory as described in the text.

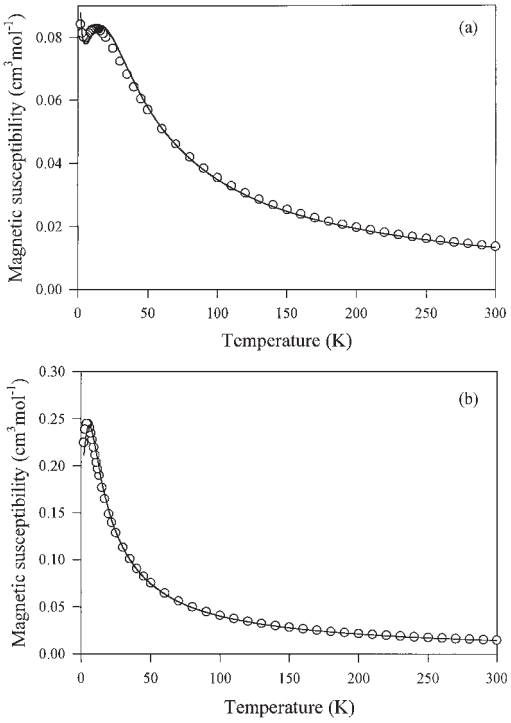

of the NiN_4 chromophore geometries proposed above. As expected, the complexes proposed to have square planar nickel ions are diamagnetic while those with tetrahedral geometry are paramagnetic. It thus appears that while both groups of nickel(II) polymers have similar extended-chain double pyrazolate-bridged structures, each group has a distinctive NiN_4 chromophore. For the polymers incorporating the 4-Xpz ligands the nickel is able to obtain the coordination geometry preferred for four-coordinate Ni(II), namely, square planar. However, in polymers incorporating the relatively bulky 4-Xdmpz ligands, it appears the nickel is forced into a distorted tetrahedral geometry due to steric interactions.

The geometry-related steric interaction, with nickel(II) in a square planar environment, is illustrated in Fig. 2. This diagram, which models a portion of the chain, was generated using X-ray crystallographic data from the related trimetallic compound $[CpNi(4\text{-}Cldmpz)_2]_2Ni$ (6). Steric crowding between the methyl groups in the 3 and 5 positions on neighbouring, translationally equivalent, pyrazolates is evident in the figure. The $C(CH_3)\cdots C(CH_3)$ distances in this structure are calculated to be 1.24 Å. Allowing the chromophores to become regular tetrahedral while keeping N—N and Ni—N distances the same as in the model structure generates a less sterically crowded structure and a calculated $C(CH_3)\cdots C(CH_3)$ distance of 1.88 Å. Hence, with methyl substituents in the 3,5 positions, the less sterically crowded tetrahedral geometry is obtained while in the absence of the two methyl substituents this steric interaction is eliminated and electronic effects control the nickel geometry, generating square planar nickel(II) centers.

Interestingly, no linear chain polymeric materials have been successfully prepared involving any of the metals Cu, Co, Mn, or Ni with the even bulkier 3,5-bis(trifluoromethyl)-pyrazolate ligand (7). This suggests that the additional steric bulkiness of the CF_3 groups is sufficient to prevent polymer formation.

The thermal stabilities and solubility properties of the manganese compounds studied here are similar to those of the nickel compounds and it seems likely that they also have linear- chain double pyrazolate-bridged structures. In the absence of definitive spectral or magnetic criteria to identify the geometry about the metal centers in the manganese systems, however, it is not possible to determine the nature of the MnN_x (x = 4,5) chromophore. Nonetheless, it is evident from the stoichiometry that, depending on the nature of the bridging ligands, there are at least two distinct manganese chromophore geometries. In the $[Mn(4\text{-}Xdmpz)_2]_x$ materials the metal centers are likely present in a tetrahedral geometry due to similar steric requirements to the ones discussed above. The $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ materials, on the other hand, likely possess either 5-coordinate Mn(II) ions or an equal mixture of 4-coordinate and 6-coordinate metal centers with neutral 4-Xpyrazole ligands occupying the additional sites. The presence of neutral pyrazole molecules is

[a] Interdependencies of the three parameters prevented estimation of individual errors in this instance.

evident from both the stoichiometry and from IR spectroscopy. Unlike the $[Mn(4\text{-}Xdmpz)_2]_x$ materials or the nickel(II) polymers, the $[Mn(4\text{-}Xpz)_2(4XpzH)]_x$ complexes exhibit a strong and sharp IR band at ~3340 cm^{-1}, consistent with an N–H stretch. Evidence supporting coordinated neutral pyrazole, rather than lattice pyrazole, comes from the thermal studies performed on $[Mn(4\text{-}Clpz)_2(4\text{-}ClpzH)]_x$. This compound is thermally stable to 250°C, a temperature above the melting temperature of the neutral pyrazole (76°C).

Magnetic properties

All four $[Ni(4\text{-}Xdmpz)_2]_x$ complexes exhibit strong antiferromagnetic exchange, as evidenced by susceptibility maxima at T = 55 K for X = Br and at T = 60 K for the other three. Representative plots are shown in Fig. 3. Each compound shows an increase in susceptibility as temperature is decreased at very low temperatures, indicating the presence of small amounts of paramagnetic impurity. There is an observable discontinuity at 30 K in the data for $[Ni(4\text{-}CH_3\text{-}dmpz)_2]_x$ (Fig. 3*b*), suggesting a structural phase change for this polymer. Similar discontinuities were observed previously in related copper systems (8*d*).

The magnetic susceptibility data for the nickel complexes were modeled based on the linear chain structures proposed for these materials. This was accomplished using the isotropic Heisenberg model ($H = -2J \Sigma S_i \cdot S_j$) for exchange-coupled linear chains of S = 1 metal centers developed by Weng (29) and Hiller et al. (30). The model incorporates two parameters: J, the exchange coupling constant, and g, the Landé splitting factor. The theoretical expression was modified, in the manner described recently (31), to incorporate a third parameter P, the fraction of paramagnetic impurity present in the sample. The calculated susceptibilities were obtained by treating J, g, and P as variable parameters and minimizing the fitting function F, where:

$$F = \left[\frac{1}{n} \sum_{j=1}^{n} \left[\frac{\chi^i_{calc} - \chi^i_{obs}}{\chi^i_{obs}} \right]^2 \right]^{1/2}$$

The parameters J, g, P, and the values of F for the best fits are shown in Table 1. It is obvious from the plots comparing the experimental and calculated magnetic susceptibilities (Fig. 3), as well as by considering the values of F (Table 1), that the agreement between the observed and calculated data is not good. The primary difficulty in modeling these systems involves the orbitally degenerate ground state of the tetrahedral nickel(II) centers. There have been no models developed for extended chain systems that can simultaneously predict the effects (on magnetic properties) of spin-orbit coupling in orbitally degenerate ground term configurations and magnetic exchange coupling between metal centers as a function of temperature. For this reason, the magnetic data have also been analyzed employing data restricted to the region of the susceptibility maxima. As is evident from the fits (Fig. 3 (insets)) and from the F values listed in Table 1, this gives better agreement between the experimental and calculated data.

Table 2. Magnetic parameters for the $[Mn(4\text{-}Xdmpz)_2]_x$ and $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ polymers.

Compound	J (cm^{-1})	P	F
$[Mn(4\text{-}Hdmpz)_2]_x$	–1.206(8)	0.0097(8)	0.023
$[Mn(4\text{-}CH_3\text{-}dmpz)_2]_x$	–2.12(2)	0.0051(5)	0.028
$[Mn(4\text{-}Cldmpz)_2]_x$	–1.53(3)	0.090(3)	0.045
$[Mn(4\text{-}Brdmpz)_2]_x$	–1.64(1)	0 (fixed)	0.031
$[Mn(4\text{-}Brpz)_2(4\text{-}BrpzH)]_x$	–0.412(4)	0 (fixed)	0.028
$[Mn(4\text{-}Clpz)_2(4\text{-}ClpzH)]_x$	–0.408(4)	0 (fixed)	0.030

The observed room temperature magnetic moments for the six manganese complexes show the presence of high-spin Mn(II) and the decrease in moment with decreasing temperature, in all cases, indicates antiferromagnetic exchange. Plots of χ_m versus temperature reveal susceptibility maxima at 5 K for $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ (X = Cl, Br) and at 13 K, 20 K, and 25 K for the $[Mn(4\text{-}Xdmpz)_2]_x$ complexes (X = H, Br, CH_3, respectively). The maximum in the χ_m versus T plot for $[Mn(4\text{-}Cldmpz)_2]_x$ is less obvious due to the presence of a relatively large amount of paramagnetic impurity. For this compound, only an inflection point is seen at approximately 20 K. The abnormally large amount of impurity in this sample suggests the average chain length may be relatively small. Representative plots are given for $[Mn(4\text{-}Hdmpz)_2]_x$ and $[Mn(4\text{-}Clpz)_2(4\text{-}ClpzH)]_x$ in Fig. 4.

The magnetic data were modeled as described above using the equation for exchange-coupled linear chains of S = 5/2 metal centers developed by Weng (29) and Hiller et al. (30). Calculated magnetic susceptibilities were obtained by fixing g at 2.00, treating J and P as variable parameters, and minimizing the value of F. The resulting best-fit parameters with corresponding values of F are listed in Table 2.

Table 3. $|J|$ and $|4\ JS^2|$ ranges for polymeric transition metal (Ni(II), Cu(II), Co(II), Mn(II)) C-substituted pyrazolates.

Metal	Bridge type	S	$\|J\|$ values (cm^{-1})	$\|4\ JS^2\|$ values (cm^{-1})
Ni(II)	4-Xpz	0	–	–
	4-Xdmpz	1	14–16	56–64
Mn(II)	4-Xpz	5/2	0.4	10
	4-Xdmpz	5/2	1–2	25–50
Cu(II)	4-Xpz	½	81–105[a]	81–105
	4-Xdmpz	½	58–67[b]	58–67
Co(II)	4-Xpz	3/2	4–6[c]	36–54
	4-Xdmpz	3/2	2[c]	18

[a] References 8*a*, 8*d*.
[b] Reference 9*a*.
[c] Reference 9*b*.

An examination of J values obtained for the eight $[M(4\text{-}Xdmpz)_2]_x$ complexes shows very little dependence of the magnitude of exchange on electronic contributions from the 4-X substituents. In the case of the nickel complexes, the more highly electron-withdrawing Cl and Br substituents do not produce significantly different J values from those obtained for the X = H or CH_3 compounds (Table 1). For the manganese compounds, the J values for the X = Cl and Br derivatives are intermediate between those obtained for the other two (Table 2). The exchange coupling in the two $[Mn(4\text{-}Xpz)_2(4\text{-}XpzH)]_x$ materials is significantly weaker than in the corresponding $[Mn(4\text{-}Xdmpz)_2]_x$ compounds (Table 2). The presence of coordinated non-bridging pyrazole ligands in the former compounds presumably weakens the metal to bridging ligand interactions, resulting in a decrease in the magnitude of the magnetic exchange.

It is now possible to compare the magnitude of exchange in pyrazolate-bridged polymeric systems of four different metals, Ni(II) and Mn(II) studied here and Cu(II) and Co(II) studied in earlier work (9*a*, 9*b*). To compare the magnitude of exchange coupling in systems with different total spin, S, it is appropriate to compare $|4JS^2|$ values (32) instead of simply comparing values of J. Therefore, the range of $|J|$ and $|4JS^2|$ values for the four metal systems have been tabulated (Table 3). For both Co (II) and Cu(II) the exchange coupling is stronger for the 4-Xpz complexes than for the 4-Xdmpz complexes. This may be a consequence of steric interactions involving the methyl substituents in the 3,5 positions leading to weaker bridge bonding and hence weaker exchange. Similar comparisons cannot be made for the Ni(II) and Mn(II) systems since, as described earlier, the $Ni(4\text{-}Xpz)_2]_x$ complexes are diamagnetic due to the presence of a square planar NiN_4 chromophore, while in the case of manganese the 4-Xpz complexes are not simple binary pyrazolates. The best comparison among the four metals involves the 4-Xdmpz derivatives. In all of these a tetrahedral or distorted tetrahedral MN_4 chromophore is assumed. Based on the $|4JS^2|$ values, the strength of the exchange coupling is very similar for the Cu(II) and Ni(II) complexes and greater than that seen in either of the Mn(II) or Co(II) systems. Assuming tetrahedrally coordinated metal centers, the magnetic orbitals for all four metal systems are of t_2 symmetry (also of e symmetry for manganese). Interestingly, increasing the number of unpaired electrons in these orbitals does not lead to stronger exchange. Instead it appears that the coupling strength is more closely related to the total number of electrons, suggesting that the covalent character of the bridging ligand – metal ion bond is an important factor.

Noble gas catalysed 1,2-migrations in N_2H^+ and $N_2CH_3^+$

Alwin Cunje, Christopher F. Rodriquez, Diethard K. Bohme, and Alan C. Hopkinson

Abstract: Molecular orbital calculations are reported for N_2H^+ and $N_2CH_3^+$ and for the transition structures for the rearrangement of these ions by 1,2-shifts of H and CH_3. All reaction profiles were also calculated with one atom of noble gas, M, present (M = Ne, Ar, Kr). Structure optimizations were performed at B3LYP/6-311++G(d,p) and, in the case of $N_2H^+\cdots M$, single point calculations were also performed at QCISD(T)(full)/6-311++G(2df,p). For N_2H^+, inclusion of one noble gas atom reduces the barrier to rearrangement from 46.6 kcal mol^{-1} for the uncatalysed reaction to 42.6 kcal mol^{-1} (by Ne), to 21.4 kcal mol^{-1} (by Ar), and to 11.0 kcal mol^{-1} (by Kr). For $N_2CH_3^+$, the barrier of 36.4 kcal mol^{-1} is reduced to 35.1 kcal mol^{-1} by Ne, to 27.4 kcal mol^{-1} by Ar, and to 18.4 kcal mol^{-1} by Kr.

Key words: catalysis, molecular orbital theory, argon, krypton.

Résumé : On a effectué des calculs d'orbitales moléculaires pour N_2H^+ et $N_2CH_3^+$ et pour les structures de transition des réarrangements de ces ions par des déplacements 1,2 de H et de CH_3. On a aussi calculé tous les profils de réactions avec un atome de gaz rare, M (M = Ne, Ar, Kr). On a réalisé les optimisations de structure au niveau B3LYP/6-311++G(d,p) et, dans le cas de $N_2H^+\cdots M$, on a aussi effectué des calculs au niveau QCISD(T)(full)/6-311++G(2df,p). Dans le cas de N_2H^+, l'inclusion d'un atome de gaz rare réduit la barrière au réarrangement de 46,6 kcal mol^{-1} pour la réaction non catalysée à 42,6 kcal mol^{-1} (par le Ne), à 21,4 kcal mol^{-1} (par le Ar) et à 11,0 kcal mol^{-1} (par le Kr). Dans le cas de $N_2CH_3^+$, la barrière de 36,4 kcal mol^{-1} est réduite à 35,1 kcal mol^{-1} (par le Ne), à 27,4 kcal mol^{-1} (par le Ar) et à 18,4 kcal mol^{-1} (par le Kr).

Mots clés : catalyse, théorie des orbitales moléculaires, argon, krypton.

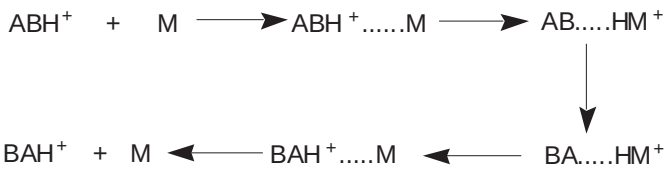
[Traduit par la Rédaction]

Introduction

Protonated dinitrogen, N_2H^+, has been observed in the gas phase (1) and has also been detected in interstellar clouds (2). The methyl analogue, $N_2CH_3^+$, has also been observed in the gas phase and this ion has been used as the primary standard in the construction of a methyl cation affinity scale (3, 4).

There have been several high-level theoretical studies of N_2H^+ and $N_2CH_3^+$, with emphasis on structure determination and on calculating proton affinities and methyl cation affinities (4–16). Recently, detailed calculations on N_2H^+ using the CCSD(T) method with a large basis set have been used to provide a potential energy surface for an intramolecular dynamics and density of states study (17). Both H^+ and CH_3^+ add end-on to one nitrogen atom, i.e., N_2H^+ is linear and $N_2CH_3^+$ has C_{3v} symmetry. Bending at the central N is a high-energy process and the barrier to a 1,2-proton shift in N_2H^+ is calculated to be 47.1 kcal mol^{-1} at MP2(full)/6-31G(d,p) (11). The barrier to 1,2-methyl migration in $N_2CH_3^+$ is lower and has been calculated to be 36.8 kcal mol^{-1} at MP4(SDTQ)/6-311G(d,p)//MP2(full)/6-31G(d) (13).

In solution, barriers to proton migration are often reduced by the solvent. The mechanism involves proton transfer to a solvent molecule followed by reprotonation at a different site on the substrate. A similar proton-switching mechanism has been proposed for gas-phase reactions. Here diatomic molecule AB can, in principle, protonate at either A or B and conversion of the higher energy isomer ABH^+ into the lower energy isomer BAH^+ can be achieved in a collision with a molecule, M, that has a proton affinity intermediate between those of atoms A and B in molecule AB. The overall reaction can be described as follows (18):



Here the proton is transferred from atom B to M and then in the third step the fragment AB in the hydrogen-bonded complex $AB\cdots HM^+$ rotates and subsequently the proton is transferred back to A. This "forth and back" mechanism, first proposed by Ferguson (19) to explain how $HNNO^+$

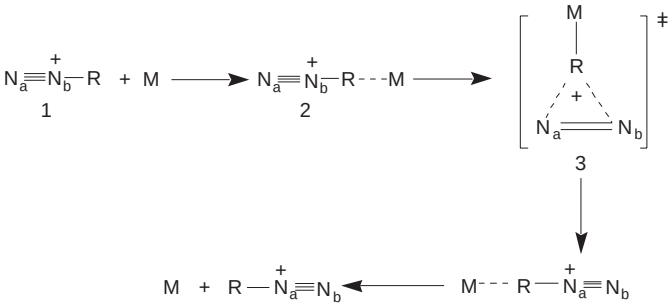
reacts with NO in a charge transfer reaction to give NO^+, N_2, and OH, has also been invoked to explain the isomerization reactions of COH^+ catalysed by H_2 (20) and of HCN^+.catalysed by CO and CO_2 (21). By contrast, rearrangement of $HSiO^+$ to the lower energy isomer $SiOH^+$ is not catalysed by H_2 and this has been attributed to the high energy of the intermediate complex $OSi\cdots H_3^+$ (18, 22).

The barriers to 1,2-methyl migration in cations can also be high and recently inert gases Xe and N_2 have been shown to catalyse the conversion of ion $CH_3NO_2^+$ into the lower energy isomer, $ONOCH_3^+$, prior to dissociation into CH_3O and NO^+ (23). Molecular orbital calculations have also shown that the barrier to rearrangement of COH^+ to HCO^+ can be reduced substantially by the presence of one molecule of catalyst (24, 25).

These observations encouraged us to examine the effect of inert gases on the barrier to 1,2-proton and methyl shifts. For simplicity we have chosen here a system in which there are large barriers and where both the reactant and product are identical, namely, the migration of R from one nitrogen atom to the other in N_2R^+. In the presence of a potential catalyst, M, the overall barrier is given by the energy difference between the separated reactants N_2R^+ plus M and the complexed transition state, **3**.



The choice of a diatomic with identical basicity sites means that any molecule M that has a larger R^+ affinity than N_2 will simply remove R^+. Only molecules with R^+ affinities *less* than that of N_2 can act as a catalyst to assist in transporting R^+ from one nitrogen atom to the other. In the current study we examine the noble gas atoms Ne, Ar, and Kr as catalysts for the rearrangements of ions N_2H^+ and $N_2CH_3^+$.

Computational methods

All molecular orbital calculations were performed using Gaussian 94 (26). Structure optimizations were carried out using the CALCALL routine along with molecular orbital calculations employing Density Functional Theory (DFT) at the B3LYP level (27, 28). The 6-311++G(d,p) basis set (29–33) was used for all structure optimizations and then for the N_2H^+ and $N_2H^+\cdots M$ systems these geometries were used for single-point calculations at QCISD(T)(full)/6-311++G(2df,p) (34, 35). For each transition state, Intrinsic Reaction Coordinate (IRC) calculations (36) were performed to establish that the structure was indeed for the migration of R^+ from one N atom to the other and not for transferring R^+ from N_2 to the catalyst. For all structures at critical points the calculations were corrected to 298 K by inclusion of zero-point and thermal energies.

[a]B3LYP/6-311++G(d,p).
[b]QCISD(T)(full)/6-311++G(2df,p).

The overall conclusions on the relative energies of reactants and transition states from the two different levels of theory for $N_2H^+\cdots M$ were very similar and consequently we decided that it was unnecessary to perform QCI calculations on the larger $N_2CH_3^+\cdots M$ ions. All the computed energies are given in Table 1 and the optimized structures are given in Figs. 1 and 2.

Results and discussion

(a) Structures

(i) Ions $N_2H^+\cdots M$ (where M = Ne, Ar, and Kr)

The B3LYP/6-311++G(d,p) level calculations gave N_2H^+ to be linear with N—N and N—H distances of 1.090 and 1.040 Å, respectively. These compare with experimental equilibrium values of 1.093 and 1.033 Å (37). Protonation of N_2 is calculated to result in a slight shortening of the N—N distance from 1.096 to 1.090 Å. In the transition state for the 1,2-rearrangement the N—N distance is lengthened to 1.120 Å and the N—H distances are considerably longer than in the structure at the minimum (1.295 Å compared with 1.040 Å).

Noble gas atoms interact with N_2H^+ by attachment to the hydrogen atom along the N-N-H axis. Neon has little effect on the structure of N_2H^+, producing an increase in the N—H distance of only 0.001 Å, and the Ne—H distance in the complexed ion is 1.777 Å compared with a distance of 1.006 Å in the isolated NeH^+ ion. This interaction between Ne and N_2H^+ is calculated to be stabilizing by only 1.8 kcal mol^{-1} at B3LYP/6-311++G(d,p) and by only 2.1 kcal mol^{-1} at QCISD(T)(full)/6-311++G(2df,p). Interactions with argon and with krypton result in elongations of the N—H bond to

Fig. 1. Geometric parameters for $N_2H^+\cdots M$ ions. Bond lengths are in Ångstroms and angles are in degrees.

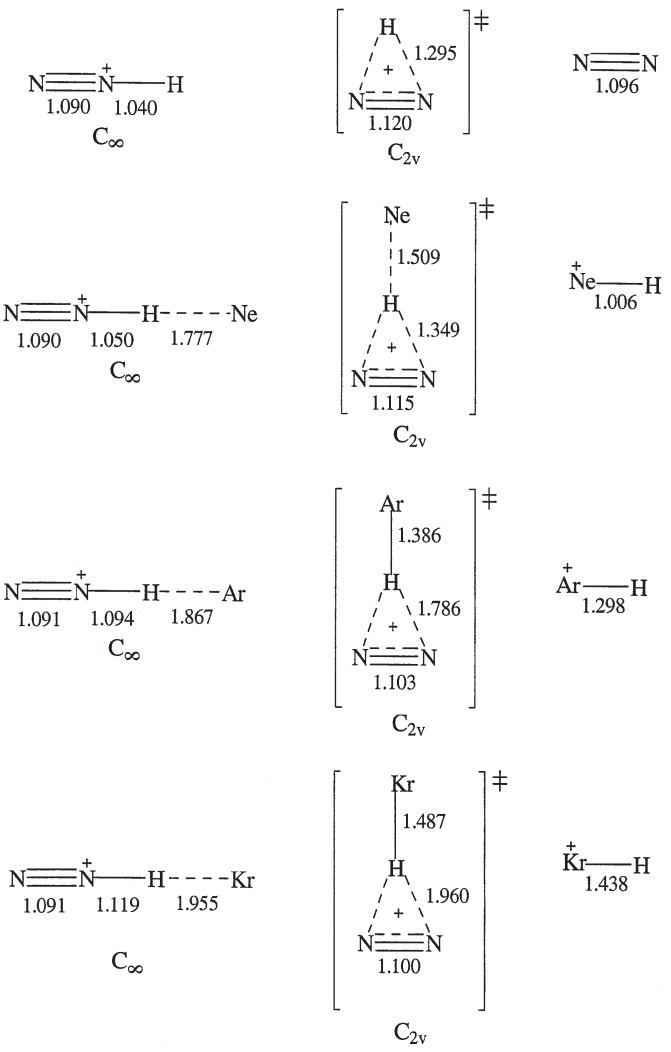

Fig. 2. Geometric parameters for $N_2CH_3^+\cdots M$ ions. Bond lengths are in Ångstroms and angles are in degrees.

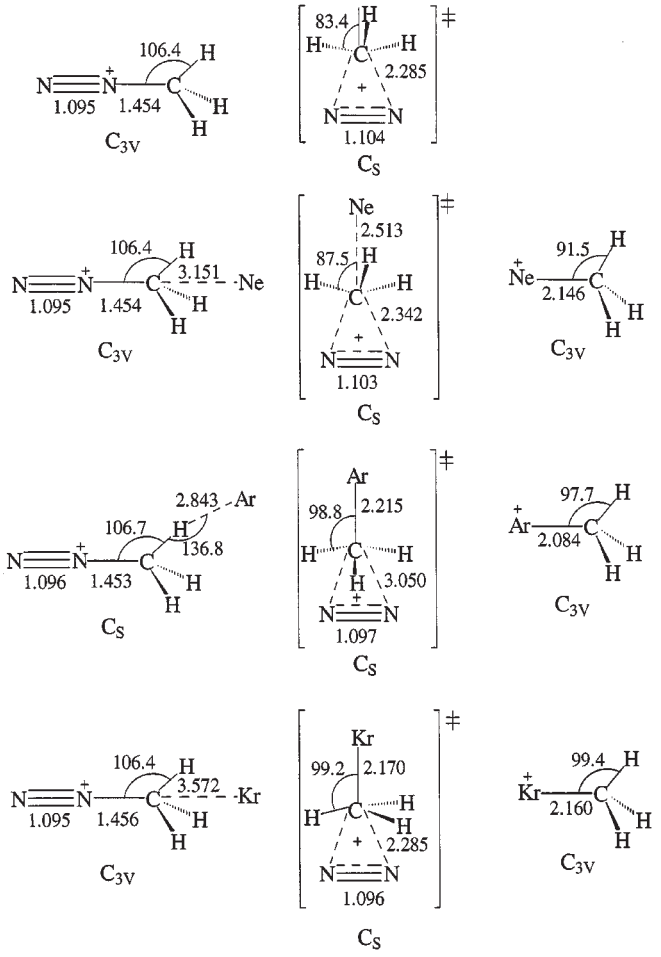

1.094 and 1.119 Å, respectively (from 1.004 Å), and, while the H—Ar and H—Kr distances of 1.867 and 1.955 Å are both more than 0.5 Å longer than in the isolated ArH^+ and KrH^+ ions, there is considerable interaction with the noble gases as shown by stabilization energies of 7.3 and 7.5 kcal mol^{-1} for Ar at the two levels of theory, and of 11.6 and 10.5 kcal mol^{-1} for Kr. Counterpoise calculations (38) on the fragments of dissociation, N_2H^+ and Kr, at the geometry of the complex $N_2H^+\cdots Kr$, gave a correction factor of only 0.2 kcal mol^{-1} for the basis set superposition error at B3LYP/6-311++G(d,p). In this complex the combination of a large basis set and the long distance between the two fragments in the complex that dissociate both contribute to a small counterpoise correction.

The geometric parameters for the transition structure for the 1,2-proton shift are heavily dependent upon which noble gas atom is present. The smallest structural changes are again produced by interaction with neon. Here the N—H distance of 1.349 Å is 0.054 Å longer than that in the transition state for the uncatalysed reaction and the Ne—H^+ distance of 1.509 Å is much longer than that in NeH^+ (1.006 Å), i.e., Ne interacts more strongly with the transition structure than with the structure at the minimum, but even in the the transition structure the proton is still firmly attached to N_2. This is most easily demonstrated by the stabilization resulting from interaction between Ne and N_2H^+. For the linear N_2H^+, i.e., the structure at the minimum, the interaction energy is calculated to be 3.1 and 3.4 kcal mol^{-1} at B3LYP/6-311++G(d,p) and QCISD(T)(full)/6-311++G(2df,p), respectively, while for the transition structure the interaction energies are 5.3 and 4.9 kcal mol^{-1}, respectively. Furthermore, dissociation of the transition structure into N_2 and NeH^+ is endothermic by approximately 30 kcal mol^{-1} at both levels of theory.

Interaction with argon produces a dramatic change in the transition structure. The N—N distance is decreased to 1.103 Å and the N—H increased to 1.786 Å. The Ar—H distance of 1.386 Å is only 0.088 Å longer than that in the isolated ArH^+ ion and this structure is best described as being ArH^+ solvated by attachment of the proton to the -bond of N_2. Interaction of the N_2H^+ transition structure with krypton results in an even larger N—H distance (1.960 Å) and the Kr—H distance of 1.487 Å is only 0.049 Å longer than that in KrH^+. Both the N_2HM^+ transition structures (where M = Ar and Kr) have energies just below those of the

dissociation products MH^+ and N_2 (6.6 kcal mol^{-1} for Ar and 3.5 kcal mol^{-1} for Kr, where both calculations are at B3LYP/6-311++G(d,p)). Here again the basis set superposition errors are small and counterpoise calculations reduced the dissociation energy of the Kr-containing transition structure by 0.3 kcal mol^{-1} to 3.2 kcal mol^{-1}.

(ii) Ions $N_2CH_3^+\cdots M$ (where M = Ne, Ar, and Kr)

For the structure at the minimum for $N_2CH_3^+$, addition of an atom of Ne, Ar, or Kr produces essentially no geometric changes in the $N_2CH_3^+$ fragment and the noble gas atom is approximately 3 Å away from the methyl group. The exothermicities for formation of these weak association complexes, uncorrected for BSSE effects, are 0.1 kcal mol^{-1} for Ne, 0.3 kcal mol^{-1} for Ar, and 0.9 kcal mol^{-1} for Kr.

The transition structure for the 1,2-methyl migration in $N_2CH_3^+$ is characterized by long N—C distances and, as with the $N_2H^+\cdots$Ne transition structure, attaching a neon atom elongates the N—R distance slightly but overall there is little geometric change. The CH_3 group remains slightly pyramidal with the carbon atom pointing towards the N_2.

Attachment of argon and krypton both have a more profound effect on the geometry of the transition structure. The N—C distances of over 3 Å are much larger than those in the transition structure for the uncatalysed process (2.285 Å), the M—C distances are close to those in isolated $ArCH_3^+$ and $KrCH_3^+$ ions, and the methyl group has inverted so that the carbon atom is directed towards M and the hydrogen atoms are directed towards N_2. These geometric parameters are consistent with the transition structure being best described as MCH_3^+ stabilized by the -bond of N_2. Here there are close similarities with the $N_2H^+\cdots M$ transition structures. Despite the structural similarities to MR^+ plus N_2, however, it is important to realize that on both the N_2HM^+ and $N_2CH_3M^+$ (M = Ar or Kr) energy hypersurfaces the transition structures are indeed for the 1,2-migration of either the proton or the methyl cation. On both surfaces this was confirmed by Intrinsic Reaction Coordinate calculations.

(*b*) Barriers to rearrangement

(i) Proton migration

There is a substantial barrier to the migration of a proton from one nitrogen atom to the other in N_2H^+. At 298 K the barrier to this rearrangement is 45.4 kcal mol^{-1} at B3LYP/6-311++G(d,p) and 46.6 kcal mol^{-1} at QCISD(T)(full)/6-311++G(2df,p). When N_2H^+ is complexed by an inert gas atom M, then both the reactant and the transition structure are stabilized. As indicated by the change in structural parameters, the effect is much larger for the transition structure and the result is a pronounced lowering of the barrier to the 1,2-migration. Neon, the noble gas that is the least effective at "solvating" N_2H^+, has the smallest effect and reduces the barrier by only 2.5 and 1.9 kcal mol^{-1} at B3LYP/6-311++G(d,p) and QCISD(T)(full)/6-311++G(2df,p), respectively. At the same levels of theory, argon produces lowerings of 16.3 and 17.7 kcal mol^{-1} to give barriers of 29.1 and 28.9 kcal mol^{-1}, and krypton produces a lowering

© 1998 NRC Canada

of 22.3 and 25.1 kcal mol^{-1} to give values of 23.1 and 21.5 kcal mol^{-1} (see Table 2).

The barriers discussed in the preceding paragraph are for the rearrangement of an ion stabilized by attachment to one noble gas atom. Only one complexing or "solvating" molecule is considered in this treatment, but as the proton in the transition structure is essentially transferred to the "solvent" when M = Ar and Kr, inclusion of this one molecule is likely to be the major factor in reducing the barrier in solution. These calculations then give a crude upper estimate of the barrier height in solvent M. In the gas phase, when N_2H^+ collides with M, then the resulting complex rearranges via the same "solvated" transition structure and, as the energy of the reactants is that of the separated N_2H^+ and M, then the barrier to rearrangement is reduced even further. Thus the barrier to the krypton-catalysed rearrangement of N_2H^+, which is 23.1 and 21.5 kcal mol^{-1} respectively, at B3LYP/6-311++G(d,p) and QCISD(T)(full)/6-311++G(2df,p) starting from the "solvated" ion, is reduced further by 11.5 and 10.5 kcal mol^{-1} when starting from the unsolvated ion (see Fig. 3). For the purely gas-phase process, then, the barrier for the 1,2-proton migration in N_2H^+ is 46.6 kcal mol^{-1} in the absence of a catalyst and this is reduced to 42.6 kcal mol^{-1} by neon, to 21.4 kcal mol^{-1} by argon, and to 11.0 kcal mol^{-1} by krypton (all calculations at QCISD(T)(full)/6-311++G(2df,p)).

(ii) Methyl cation migration

Comparison of geometric parameters on the transition structures for the uncatalysed reactions revealed that the migrating CH_3^+ ion in $N_2CH_3^+$ is less firmly attached to N_2 than is the migrating H^+ in N_2H^+. This is a consequence of the greater ability of the CH_3 group to carry a substantial amount of the charge in cations. A population study on the structure at the minimum for $N_2CH_3^+$ using Bader's atoms in molecules method (39) showed that the methyl group carries the majority of the positive charge (+0.83 at MP2(full)/6-31G(d)) (13). In the present study a Mulliken population analysis (40) at B3LYP/6-311++G(d,p) showed that in the structure at the minimum on the $N_2CH_3^+$ surface the CH_3 group has a charge of +0.525 and that in the transition structure it is increased to +0.703. This enhanced ability of the migrating group to carry the positive charge results in the barrier to CH_3^+ shift being lower than that for proton migration in N_2H^+ by 9.0 kcal mol^{-1} at B3LYP/6-311++G(d,p) and by 9.5 kcal mol^{-1} at QCISD(T)(full)/6-311++G(2df,p).

More effective delocalization of the charge in $N_2CH_3^+$, as compared to that in N_2H^+, is expected to result in "solvation" by noble gases playing a smaller role in the rearrangement reaction. For the reactant ion at its equilibrium configuration there is little or no interaction with noble gas atoms and, in the presence of Ne, Ar, and Kr, both the complexed and uncomplexed ions have essentially the same barriers to rearrangement. "Solvation" of the transition structure then provides the major difference in the reaction profiles for the different noble gas atoms. At B3LYP/6-311++G(d,p), in the absence of catalyst, the barrier to migration in $N_2CH_3^+$ is 36.4 kcal mol^{-1} and this is reduced to 35.1 kcal mol^{-1} by neon, to 27.4 kcal mol^{-1} by argon, and to 19.3 kcal mol^{-1} by krypton.

Conclusions

The barriers to 1,2-migration in N_2R^+ (R = H, CH_3) are substantial, but are reduced considerably by inclusion of a single noble gas atom. Of the three noble gases studied, neon has the lowest affinity for R^+ and it displays only a small catalytic effect, reducing the barrier to rearrangement by approximately 4.0 kcal mol^{-1} in N_2H^+ and by only 1.3 kcal mol^{-1} in $N_2CH_3^+$. By contrast, both argon and krypton essentially form M—R bonds in the transition structure and the resulting stabilization leads to large reductions in the barriers. The largest catalytic effect is for the Kr-assisted migration of H^+ where the barrier is reduced from 46.6 to 11.0 kcal mol^{-1}.

The symmetric rearrangement that we have chosen here to illustrate the catalytic effect of noble gases establishes that preferential stabilization of the transition structure leads in some examples to a substantial reduction in the barriers to 1,2-migration. This discovery has important implications for rearrangements in cations formed from molecules that have two different sites for addition of R^+. Noble gas atoms are frequently used to thermalize the products of ion–molecule reactions. If the product ion has a lower energy isomer, then our calculations suggest that the noble gas atom may catalyse the rearrangement of the ion rather than simply thermalize the products. We are currently using theory to examine the rearrangements of several such ions.

Direct optimization of self-modeling curve resolution: application to the kinetics of the permanganate – oxalic acid reaction

Peter D. Wentzell, Ji-Hong Wang, Leon F. Loucks, and Kelli M. Miller

Abstract: A new procedure to extract spectral and concentration information for unknown components in a series of mixture spectra is described. The algorithm, a form of self-modeling curve resolution (SMCR), requires no assumptions about the mixture data except for linear additivity and non-negativity of component spectra, and non-negativity of concentrations. It provides permissible bands for the spectra and concentration profiles of individual components in the mixtures and is applicable to problems in chromatography, equilibrium studies, and kinetics, among others. The new method employs a nonlinear optimization procedure and is substantially more efficient than similar methods that have been previously reported. The SMCR algorithm is demonstrated by applying it to the autocatalytic oxidation of oxalic acid by permanganate in the presence of sulfuric acid. The reaction was monitored spectroscopically between 200 and 1000 nm under four different reaction conditions. Results verified the presence of two reaction intermediates previously proposed in the literature and confirmed their spectral properties. Concentration profiles for the intermediates are described.

Key words: curve resolution, kinetics, chemometrics, permanganate, oxalic acid.

Résumé : On décrit une nouvelle procédure pour extraire des informations relatives aux spectres et à la concentration de composants inconnus présents dans une série de spectres de mélanges. L'algorithme, une forme de résolution de courbes automodélisante (RCAM), ne nécessite aucune hypothèse concernant les données des mélanges si ce n'est que les concentrations ne sont pas négatives et que les composantes spectrales donnent une additivité linéaire et non négative. Il conduit aux bandes permises des spectres et aux profils de concentration de composants individuels dans les mélanges et il est applicable, entre autres, aux problèmes de chromatographie, d'études d'équilibre et de cinétique. La nouvelle méthode fait appel à une procédure d'optimisation non linéaire et elle est sensiblement plus efficace que les méthodes similaires proposées antérieurement. On a démontré l'utilité de l'algorithme RCAM en l'appliquant à l'oxydation autocatalytique de l'acide oxalique par le permanganate en présence d'acide sulfurique. On a suivi la réaction spectroscopiquement entre 200 et 1000 nm dans quatre conditions réactionnelles différentes. Les résultats ont permis de vérifier la présence de deux intermédiaires réactionnels proposés antérieurement dans la littérature et de confirmer leurs propriétés spectrales. On décrit les profils de concentration des intermédiaires.

Mots clés : résolution de courbe, cinétique, chimimétrie, permanganate, acide oxalique.

Introduction

The use of multichannel detectors to study chemical phenomena has become commonplace in recent years. Such detectors are known as *first-order* detectors in the vernacular of chemometrics and the most common examples are multiwavelength absorption or emission spectrometers and mass spectrometers. When coupled with an experiment that presents a time series of mixtures varying in composition, such as in chromatographic or kinetics studies, a first-order detector produces a sequence of vectors that can be combined to form a matrix, or *second-order* data set. Even if the detector is not completely selective for each chemical species of interest, such a data matrix can significantly enhance the quality of information available to the investigator over that obtained with a single-channel detector.

The most common model assumed for a data matrix of this type is second-order bilinear, represented mathematically as

$$[1] \qquad \mathbf{D} = \mathbf{C}\mathbf{S}^{T} + \mathbf{E}$$

Here **D** is the $m \times n$ matrix of responses measured at n detector channels for the m samples in the time series (i.e., each row of **D** is a vector of responses for a single mixture). The $m \times p$ matrix **C** is the matrix of concentrations of each of p observable components in the m mixtures, and the $n \times p$ matrix **S** consists of the sensitivities of each of the components

Table 1. Glossary of symbols used.

Symbol	Description
$\mathbf{C}$	True or estimated $m \times p$ matrix of component concentration profiles
$\tilde{\mathbf{C}}$	Estimate of $\mathbf{C}$ with negative values set to zero
$\mathbf{D}$	$m \times n$ data matrix of mixture spectra as a function of time
$\hat{\mathbf{D}}$	Truncated PCA estimate of $\mathbf{D}$
$\tilde{\mathbf{D}}$	Estimate of $\mathbf{D}$ from $\tilde{\mathbf{C}}$ and $\tilde{\mathbf{S}}$
$\mathbf{E}$	$m \times n$ residual error matrix for $\mathbf{D}$
H	Inverse Heaviside (step) function to penalize negative values
m	Number of mixture spectra in the time series
n	Number of wavelength channels for the spectra
P	Penalty function used in Sasaki algorithm
P', P'', P'''	Objective/penalty functions for new algorithm
p	Number of observable components in mixtures; pseudorank of $\mathbf{D}$
q	Number of factors retained in PCA/SVD truncation
$\mathbf{R}$, $\hat{\mathbf{R}}$	Scores matrix from PCA ("^" indicates truncation)
$\mathbf{S}$	True or estimated $n \times p$ matrix of pure component spectra
$\tilde{\mathbf{S}}$	Estimated matrix $\mathbf{S}$ with negative values set to zero
$\mathbf{s}_i$	Estimated or true $n \times 1$ spectrum for component i
$\mathbf{s}_i^0, \mathbf{s}_i'', \mathbf{s}_i'''$	Initial estimate and boundary estimates of spectrum for component i
s_{ik}	An element of the spectrum for component k at channel j
$\mathbf{T}$	$p \times p$ transformation matrix for converting eigenvectors ($\mathbf{V}$) to pure component spectra
$\mathbf{T}^\circ$	Initial estimate of $\mathbf{T}$
$\mathbf{t}_i$	$p \times 1$ transformation vector to estimate spectrum of component i
Δt	Step size for simplex optimization
$\mathbf{U}$, $\hat{\mathbf{U}}$	Left singular matrix from SVD ("^" indicates truncation)
$U_{jk}^{(+)}, U_{jk}^{(-)}$	Objective functions used in Sasaki algorithm
$\mathbf{V}$, $\hat{\mathbf{V}}$	Right singular matrix (eigenvectors) from SVD ("^" indicates truncation)
w	Weighting factor used in penalty function
γ	Scale factor for penalty functions
Λ, $\hat{\Lambda}$	Diagonal matrix of eigenvalues from PCA ("^" indicates truncation)
λ_i	Diagonal element i of $\mathbf{L}$ (eigenvalue i)
σ_1	Root-mean-square difference between $\mathbf{D}$ and $\hat{\mathbf{D}}$
σ_2	Root-mean-square difference between and $\tilde{\mathbf{D}}$

at each of the n detector channels (i.e., the columns of $\mathbf{S}$ represent the "spectra" of individual components at unit concentration). The superscript "T" indicates the transpose of the matrix. Finally, $\mathbf{E}$ is the $m \times n$ matrix of residuals (errors) for the measurements. (A complete list of symbols used is given in Table 1.)

Given a multivariate data set of this type, it is generally the objective of the chemist to extract the matrices $\mathbf{C}$ and $\mathbf{S}$ from the matrix $\mathbf{D}$, thereby obtaining the concentration profiles and spectra of the species of interest. Such information can be extremely valuable, for example, in the identification of unknown species or the elucidation of a reaction mechanism. If either $\mathbf{C}$ or $\mathbf{S}$ is completely known, computation of the companion matrix is straightforward, but more often this information is incomplete. This is the case, for example, in a kinetics experiment where one or more unidentified intermediates may be present, or in chromatography where component peaks may be unresolved, or in equilibrium studies where several unknown species may coexist. In some of these cases, it may be possible to extract spectra and concentration profiles for the individual components if there are regions of the data (spectral channels or samples) that are uniquely associated with particular components, but in many instances this will not be true. In these cases, it is usually impossible to obtain unique solutions for the profiles of interest. However, by imposing some simple general constraints, it is often possible to define upper and lower boundaries for the component spectra (and concentration profiles) in the mixtures, thereby providing some information about what is happening in the mixtures. This procedure is known as self-modeling curve resolution (SMCR).

The principles of SMCR were introduced in 1971 by Lawton and Sylvestre (1), who applied the method to two-component mixtures. There are only three basic constraints applied in the original method: (*i*) pure component spectra cannot be negative, (*ii*) component concentrations cannot be negative, and (*iii*) pure component spectra (and concentration profiles) must lie in the p-dimensional subspace defined by the mixture spectra, where p is the number of mixture components. Since the original work, many applications and extensions of the method have appeared, with a substantial amount of effort directed to devising algorithms applicable to more than two components. Unfortunately, SMCR becomes more difficult as the number of components becomes large, and these methods have had mixed success.

This paper describes a new approach to SMCR for mixtures of more than two components. The new method is

© 1998 NRC Canada

illustrated through its application to an interesting autocatalytic reaction, the oxidation of oxalic acid by permanganate. Like virtually all SMCR methods, this new approach is based on principal component analysis, which will be introduced first.

Principal component analysis

The first step in applying SMCR to a second-order bilinear data set is usually the determination of the number of observable components present (note that the term "observable" is used here to indicate that a chemical species must have a measurable response and have concentration and spectral profiles that are sufficiently different from other species in the mixture). This determination is typically carried out using principal component analysis (PCA) (2), normally implemented through singular value decomposition (SVD):

$$[2] \qquad \mathbf{D} = \mathbf{U}\Lambda^{1/2}\mathbf{V}^{\mathrm{T}} = \mathbf{R}\mathbf{V}^{\mathrm{T}}$$

If $\mathbf{D}$ is $m \times n$ and $m \leq n$, then $\mathbf{U}$ and $\mathbf{R}$ are $m \times m$, Λ is $m \times m$ diagonal matrix of eigenvalues ($\Lambda^{1/2}$ is called the matrix of singular values), and $\mathbf{V}$ is $n \times m$. The matrix $\mathbf{R}$ ($= \mathbf{U}\,\Lambda^{1/2}$) is sometimes called the scores matrix and the columns of $\mathbf{V}$ are called the eigenvectors or loadings. The columns of $\mathbf{U}$ and $\mathbf{V}$ are orthonormal. If the measurements in $\mathbf{D}$ were error-free, then the rank of $\mathbf{D}$ would be equal to p, the number of independently observable components in the linear system, and the last $(m - p)$ eigenvalues would be zero. In practice, the presence of experimental errors means that the numerical rank of $\mathbf{D}$ is normally full ($min(m,n)$), so an estimate of the "pseudorank" (also called the chemical rank) of the data matrix is needed in order to determine the number of components. To do this, the SVD results are truncated to the first q principal components and then used to reconstruct the data matrix:

$$[3] \qquad \hat{\mathbf{D}} = \hat{\mathbf{U}}\hat{\Lambda}^{1/2}\hat{\mathbf{V}}^{\mathrm{T}} = \hat{\mathbf{R}}\hat{\mathbf{V}}^{\mathrm{T}}$$

In this equation, $\hat{\mathbf{U}}$ and $\hat{\mathbf{R}}$ are $m \times q$, $\hat{\Lambda}$ is $q \times q$, and $\mathbf{V}$ is $n \times q$. Although there are a variety of methods to estimate the pseudorank of $\mathbf{D}$, most are typically based on increasing q from unity until $\mathbf{D}$ reproduces $\mathbf{D}$ within experimental error (2). At this point, q is taken to be equal to p, the pseudorank of the data matrix.

Two-component mixtures

Although PCA is useful for estimating the number of components in a series of mixtures, it does not generally provide the concentration or spectral profiles of those components. In the context of eq. [1], the p columns of $\mathbf{V}$ are sometimes called "abstract spectra" and will define the p-dimensional subspace of the n-dimensional spectral space containing the pure component spectra. However, the abstract spectra are orthonormal, whereas the real spectra usually are not, and therefore the p-dimensional subspace can theoretically be defined by an infinite number of combinations of p vectors. The same arguments hold for the relationship between $\hat{\mathbf{U}}$ (or $\hat{\mathbf{R}}$) and the concentration profiles of each component.

A solution to this dilemma was provided by Lawton and Sylvestre (1) who proposed SMCR for two-component mixtures. In addition to the restrictions imposed by the SVD, these authors reasoned that most linearly additive spectroscopic methods were bound by two additional constraints: non-negative concentration and spectral profiles for the pure components. Although these constraints do not generally specify unique solutions, they do define boundaries for spectra and concentration profiles that are useful in certain circumstances. By normalizing pure component spectra to unit area, Lawton and Sylvestre were able to describe a simple mathematical procedure to identify the high and low limits of pure component spectra.

One unavoidable problem with this approach, and others like it, is that the absolute scales of the spectra and concentration profiles have no meaning. This "ambiguity of scale" is a consequence of the fact that a spectral response is a product of concentration and sensitivity, and a change in scale for one can be offset by a reciprocal change in scale for the other. Nevertheless, the shape of a spectrum or concentration profile for a given component is consistent for that component and these can be very useful for identifying unknown mixture components or modeling their behaviour. Some applications of this approach have been reviewed by Hamilton and Gemperline (3).

More than two components

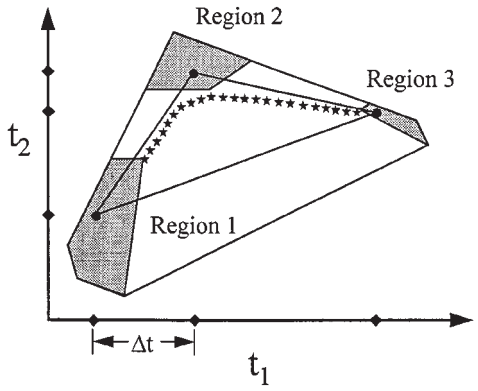
Although the SMCR method of Lawton and Sylvestre has been widely used, it does not easily extend itself to more than two components. The principles of the method are quite general and it is essentially a problem in linear programming, but the practical difficulties of encoding the constraints become difficult to manage as the number of components increases (4, 5). For this reason, several alternative strategies to the problem have been adopted. These have been reviewed by Hamilton and Gemperline (3) and will be treated only briefly here.

One of the problems in extending SMCR to more than two components is that the technique must define a region of feasible solutions for each component, and this is not as straightforward as in the two-component case, since a higher dimensional space means more boundaries to define. One approach to the problem has been to attempt to define unique solutions by adding additional constraints. These constraints may be based on physical requirements, such as the existence of pure component responses (6, 7) or the presence of the component in a spectral library (8), or may be more general, such as requirements for maximum dissimilarity among spectra (9) or maximum spectral simplicity (10).

One of the most popular methods of generating "unique" solutions by curve resolution is iterative target-transformation factor analysis (ITTFA) (11, 12), which is also known as alternating least squares (ALS). With this method, the spectral or concentration profiles of one of the components is first estimated using some independent method. This estimation can be as simple as choosing a delta function to represent a chromatographic peak (11), or may involve a technique such as varimax rotation (12) or evolving factor analysis (13). The estimate is then projected into the SVD subspace and iteratively refined with its companion

© 1998 NRC Canada

Fig. 1. Visual representation of optimization problem for a three-component system and the step size (Δt) used in simplex optimization.



profile by setting negative values to zero until the process converges on positive solutions. The principle advantages of ITTFA are its speed and simplicity. Among its drawbacks, however, is a sensitivity to the initial estimate of the concentration profile or spectrum and a susceptibility to poorly defined convergence (14). Furthermore, the ITTFA procedure produces a single solution, ignoring the fact that there are usually a range of solutions.

True SMCR methods will generate a range of feasible solutions for component spectra and concentration profiles where no unique solutions exist. A direct extension of the original two-component approach can be used (4, 5), but solutions can become complex, especially if there are no additional constraints or the number of components is greater than three. Ohta (15) developed a Monte Carlo method to search for feasible solutions for the spectra that should be generally applicable, but is also likely to be slow. Nonlinear optimization has also been used to address the problem (16, 17) and this is the strategy used in this work. Since the method presented in this paper is derived from the work of Sasaki et al. (16), a brief description of this approach will be given.

The first step in this procedure developed by Sasaki et al. is decomposition of the data matrix **D** by SVD followed by truncation of the solution to rank *p*. Since the pure component spectra must lie in the subspace defined by the eigenvectors, each of these spectra can be represented as a linear combination of eigenvectors, that is:

$$\mathbf{S} = \mathbf{VT} \quad [4]$$

or,

$$\mathbf{s}_i = \mathbf{V}\,\mathbf{t}_i \quad [5]$$

Here **V** is the $n\times p$ matrix of eigenvectors (although this is the truncated matrix, the "^" has been removed for notational convenience), **S** is the $n\times p$ matrix of pure component spectral vectors, and $\mathbf{s}_i$ is the $n\times 1$ spectral vector for component *i* ($\mathbf{S} = [\mathbf{s}_1\ \mathbf{s}_2\ \cdots \mathbf{s}_p]$). The $p\times p$ matrix **T** (or alternatively the $p\times 1$ vectors **t**) describes the linear combinations of the eigenvectors in **V** needed to give the pure component spectra. Of course, the elements of **T** are unknown and are the parameters sought by the optimization. As was the case with two-component methods, the pure component spectra are normalized to unit area, i.e.,

$$\sum_{i=1}^{n} s_{ij} = 1 \quad [6]$$

This places a consequential restriction on **T** such that, for the *k*th component,

$$t_{pk} = \frac{1 - \sum_{i=1}^{p-1}\left(t_{ik}\sum_{j=1}^{n} v_{ji}\right)}{\sum_{j=1}^{n} v_{jp}} \quad [7]$$

In other words, the last row of **T** is defined by the first ($p-1$) rows and only $p\times(p-1)$ parameters need to be optimized.

With the Sasaki method (16), the optimization proceeds as follows for each component and each spectral channel. First, a set of t_{ij}'s is selected to define **T** and, therefore, the pure component spectra in accordance with eq. [4]. The matrix **S** is then used to estimate the concentration profile according to

$$\mathbf{C} = \mathbf{DS}(\mathbf{S}^{\mathrm{T}}\mathbf{S})^{-1} = \mathbf{DV}(\mathbf{T}^{-1})^{\mathrm{T}} \quad [8]$$

Note that this calculation can only be performed if **T** is non-singular, ensuring that the spectral profiles are not linear combinations of one another.

Once the spectral and concentration profiles have been calculated, the Sasaki algorithm minimizes the following functions with respect to the t_{ij}'s:

$$U_{jk}^{(+)} = +s_{jk} + P \quad [9]$$

$$U_{jk}^{(-)} = -s_{jk} + P \quad [10]$$

where the penalty function, *P*, is given by:

$$P(\mathbf{T}) = \gamma\left[\sum_{j=1}^{n}\sum_{k=1}^{p} H(s_{jk})s_{jk}^2 + \sum_{i=1}^{m}\sum_{k=1}^{p} H(c_{ik})c_{ik}^2\right] \quad [11]$$

and,

$$H(y) = \begin{cases} 0 & (y \geq 0) \\ 1 & (y < 0) \end{cases} \quad [12]$$

The functions $U_{jk}^{(+)}$ and $U_{jk}^{(-)}$, which are optimized separately for each component and spectral channel, represent the optimization functions for the upper and lower boundaries. The penalty function, *P*, ensures that no negative spectral or concentration values are tolerated if the scaling factor, γ, is set to a very large value. This function will be zero for non-negative solutions, allowing eqs. [9] and [10] to seek the highest and lowest allowed values for the spectral profiles.

It is useful to provide a visual interpretation of the Sasaki algorithm for a three-component system. In this case, the acceptable solutions can be regarded as being confined (by the unit area constraint) to three regions of the t_1–t_2 plane as shown in Fig. 1. (The diagram is not intended to represent an actual mixture problem, but is included for pedagogical

© 1998 NRC Canada

purposes.) The shaded regions indicate those cases which give $P = 0$ (i.e., they satisfy the non-negativity constraints) and therefore represent candidate spectra for the three components. The stars represent spectra obtained for the mixtures and in this case are shown as a smoothly varying sequence such as that which might be observed in a kinetics experiment or a chromatography run. Note that a selected combination of pure component spectra, such as that indicated by the points connected by the triangle, must encompass all of the mixture spectra. Because of this, it is not possible to simply choose a spectrum from each region arbitrarily, and the three spectra are mathematically interdependent, as suggested by the triangle. For each spectral channel, the Sasaki method seeks to find the points in each component region that give the highest and lowest response values. For more components, the process is essentially the same, except that the feasible regions become volumes and hyper-volumes instead of surfaces.

The Sasaki method is a useful, general approach to the problem of SMCR with more than two components, but it has some drawbacks as well. Some of these are listed below.

1. The discontinuous nature of the penalty function can make the optimization difficult and inhibits the use of gradient techniques.
2. The optimization is done twice for each spectral channel and each component, requiring $2np$ repetitions of the process. To further compound this problem, the original work (16) suggests an iterative procedure in which the value of the scaling factor, γ, is increased by a factor of 10 at the end of each run. Thus, the proposed procedure can be very computationally demanding, and becomes more so as the number of components is increased.
3. The search strategy needs to be able to locate local optima. The optimization is carried out one component at a time, with the intention of locating a pair of points within each region corresponding to the spectral boundaries for that component. However, it is possible for the search to "jump" to a different region and locate the optima for a different component. This problem can lead to redundant solutions and becomes more serious as the regions in Fig. 1 move closer together and, in some circumstances, overlap. Therefore, any optimization procedure used must be able to locate local optima associated with each component.
4. In some instances, there is no region in which the penalty function, P, is equal to zero. With experimental data, measurement errors can lead to negative values for some responses, which in turn may create a situation that forces either the concentration or spectral profiles to have negative values. If this is the case, the penalty function dominates the optimization and generates a single solution (i.e., no upper and lower bands) for each component. Furthermore, the nature of the solution depends on the scale of the measurements. This is because the spectra in eq. [11] are scaled to unit area, whereas the magnitude of the concentration values will depend on the magnitude of the measurements. The relative magnitudes of the concentration and spectral values will determine which is more likely to be forced to negative values during the course of the optimization, and therefore the shape of the extracted profile.
5. Because each spectral channel is separately optimized, the final bands produced to define the spectral boundaries do not necessarily represent contiguous spectra. In other words, the maximum value found for component 1 at wavelength 1 is not necessarily derived from the same spectrum as the maximum found at wavelength 2. Because of this, the resulting bands may show the limits, but do not themselves represent a spectrum. This may cause problems. For example, the resulting spectra will not necessarily have unit area.

In this work, the algorithm originally proposed by Sasaki et al. has been refined in an attempt to overcome some of these weaknesses.

A new approach

The procedure developed in this paper for treating mixtures of more than two components by SMCR is substantially faster than the Sasaki algorithm discussed in the previous section and, furthermore, helps minimize the influence of negative observations. The first step in the new algorithm is the same as for the Sasaki algorithm: decomposition of the original data matrix by SVD and estimation of the number of components present. Following this, the residual variance is calculated from

$$[13] \qquad \sigma_1^2 = \frac{\sum_{i=1}^{m}\sum_{j=1}^{n}(d_{ij} - \hat{d}_{ij})^2}{(m-p)(n-p)} = \frac{\sum_{i=p+1}^{min(m,n)}\lambda_i}{(m-p)(n-p)}$$

In this equation, d_{ij} and $\hat{d}_{ij}$ are elements of the original and reconstructed data matrices, λ represents an eigenvalue, p is the number of components, and m and n are the number of rows and columns in the data matrix. In this work, the residual variance is used as an estimate of the measurement variance.

The second stage of the modified algorithm involves the optimization of a function similar to eq. [11] that was used in the Sasaki algorithm. In this work, the objective function has been modified to

$$[14] \qquad P'(\mathbf{T}) = \sum_{j=1}^{n}\sum_{k=1}^{p} H(s_{jk}) s_{jk}^2 + \frac{1}{w^2}\sum_{i=1}^{m}\sum_{k=1}^{p} H(c_{ik}) c_{ik}^2$$

where the weighting factor, w, is given by

$$[15] \qquad w = \frac{max_{i=1,\ldots,m}(|u_{i1}|)\lambda_1^{1/2}\left(\sum_{i=1}^{n} v_{i1}\right)^2}{max_{i=1,\ldots,n}(|v_{i1}|)}$$

The purpose of the weighting factor in eq. [14] is to compensate for scale differences between the spectra and concentration profiles. Because the spectra are normalized to unit area, elements of the concentration vectors can be much larger or much smaller than the elements of the spectral vectors, depending on the magnitude of the observations. Although this will not be a problem when it is possible for all of the elements of **S** and **C** to be positive, some data sets will require negative elements and the disproportionate weighting of the two terms can cause difficulties (i.e., the

© 1998 NRC Canada

contribution of negative values is not equally balanced between the two parts). The weighting factor is calculated assuming that the first eigenvector is a reasonably good approximation for the "average" spectrum ($= \mathbf{v}_1/\Sigma v_{i1}$) and the first scores vector estimates the "average" concentration profile ($= \mathbf{u}_1\lambda_1^{1/2}\Sigma\ v_{i1}$). An approximate normalization factor is obtained from the ratio of the maxima of these two profiles.

The optimization of eq. [14] with respect to the elements of **T** is carried out using a simplex procedure because of the discontinuities in the objective function. In cases where there are feasible non-negative solutions for **S** and **C**, there is no unique solution for **T**, but this is not important. The purpose of this step is to locate the general region of potential solutions so that local optimization procedures can be used. The optimization of P' results in a solution that will be designated as **T**°, and this serves as an initial guess for the local optimization procedures.

The third stage of the algorithm uses **T**° as a starting point and attempts to locate one of the boundary solutions for each of the components in turn. Again, simplex optimization is used, but care must be taken to ensure that the search for one component does not stray into the local minimum corresponding to another component (see Fig. 1) or else redundant solutions will result. To reduce the chances of this happening, **T**° is used to gauge the distance between the component regions in "t"-space and set the step size for the simplex optimization. This could be done in a variety of ways (for example, taking the average distance between the components), but we have found it useful to set the step size to the largest value of the smallest differences among coordinate pairs, i.e.,

$$[16] \quad \Delta t = max_{i=1,\ldots,p}\{min_{j,k=1,\ldots,p:\, j\neq k}(|t_{ij} - t_{ik}|)\}$$

Because this equation is somewhat confusing, a visual example is presented in Fig. 1, although only the two dimensions t_1 and t_2 are considered, since the t_3 axis is not shown. Imagining the points shown to represent **T**°, it is clear that the smallest separation on the t_1 axis is between components 1 and 2, i.e., $(t_{12} - t_{11})$, and the minimum separation on the t_2 axis is between components 2 and 3, i.e., $(t_{22} - t_{23})$. Since the former of these two minimum distances is larger, it is chosen as the step size for the simplex optimization, Δt, as shown in Fig. 1 (again, this ignores the t_3 axis simply for purposes of illustration). The rationale for this defintion is that this is the largest step size that is still likely to confine the search to a particular region. The value of this step size is not critical, however, as long as it sufficiently restricts the search space.

For each of the components present, the initial guess for the simplex optimization is provided by **T**° and this is adjusted to find an optimum **T** by the following procedure. First, the spectra are calculated from the trial solution using eq. [4] (subject to the constraints in eqs. [6] and [7]. Any negative values in the calculated spectra are then set to zero:

$$[17] \quad \tilde{s}_{ij} = max(s_{ij},0)$$

Here s_{ij} is an element of the calculated matrix of spectra and $\tilde{s}_{ij}$ is an element of the adjusted spectra. The adjusted spectra are normalized to unit area as before and then used to calculate the concentration profiles according to:

$$[18] \quad \mathbf{C} = \mathbf{D}\tilde{\mathbf{S}}(\tilde{\mathbf{S}}^T\tilde{\mathbf{S}})^{-1}$$

As with the spectra, negative concentration values are set to zero, giving the new matrix, $\tilde{\mathbf{C}}$. The result is then used to calculate a new estimate for the data matrix:

$$[19] \quad \tilde{\mathbf{D}} = \tilde{\mathbf{C}}\tilde{\mathbf{S}}^T$$

The purpose of this procedure is to ensure that negative values are removed from the concentration and spectral profiles. Obviously, if negative values are present, the space spanned by $\tilde{\mathbf{C}}$ and $\tilde{\mathbf{S}}$ will not be the same as the original described by **U** and **V**, which could result in a poor reconstruction by eq. [19]. However, if the negative values are small, resulting only from measurement errors, the perturbations introduced should also be small and may result in an acceptable solution. Following the reconstruction, a new residual variance is calculated from the difference between the spectra reconstructed from eq. [19] ($\tilde{\mathbf{D}}$) and the PCA reproduced spectra ($\hat{\mathbf{D}}$):

$$[20] \quad \sigma_2^2 = \frac{\sum_{i=1}^{m}\sum_{j=1}^{n}(\tilde{d}_{ij} - \hat{d}_{ij})^2}{mn}$$

The quantity σ_2 is analogous to what Malinowski refers to as "imbedded" error, giving the difference between the proposed "pure" data and the PCA reconstructed data. If there were no negative values in the calculated spectra or concentration profiles, $\tilde{\mathbf{D}}$ should equal $\hat{\mathbf{D}}$ and therefore σ_2 will be zero. If adjustments for negative values were made, $\tilde{\mathbf{D}}$ and $\hat{\mathbf{D}}$ will not be equal and the question is whether $\tilde{\mathbf{D}}$ is an acceptable estimate of **D**. To answer this question, we simply examine the ratio

$$[21] \quad \alpha = \sigma_2^2/\sigma_1^2$$

In Malinowski's treatment of errors in PCA (2), the imbedded error should always be less than the real error (estimated by σ_1), so the solution is considered feasible if α is less than unity. Because the imbedded error for the correct solution is usually significantly smaller than the real error, this criterion is likely to provide slightly wider boundaries than should be the case, but in practice the boundaries predicted are not particularly sensitive to the critical value of α.

At this stage of the procedure, the actual objective function minimized is

$$[22] \quad P''(\mathbf{T}) = -\|\mathbf{s}_i - \mathbf{s}_i^{\circ}\| + \gamma\, H(\sigma_1^2 - \sigma_2^2)$$

where $\mathbf{s}_i$ is the trial spectrum for component i, $\mathbf{s}_i^{\circ}$ is the spectrum for component i computed from **T**°, and γ is a large constant. The second term of this expression ensures that only solutions that produce reasonable estimates of the original data are accepted. The first term attempts to maximize the difference between the trial spectrum and $\mathbf{s}_i^{\circ}$, thereby pushing the solution towards one of the boundaries of the acceptable range. This procedure is carried out for each component, in each case resulting in a solution which will be designated as $\mathbf{s}_i'$.

The final stage of the procedure is similar to the one just described except that the function minimized in this case is

Table 2. Conditions used for permanganate/oxalic acid reaction.

Run	$[H_2SO_4]$ (M)	$[H_2C_2O_4]$ (M)	$[KMnO_4]$ (M)	Time interval (s)	Delay + run time (s)
1	0.27	0.200	0.00050	10	30+600
2	0.27	0.025	0.00050	8	25+480
3	0.27	0.0013	0.00050	4	20+180
4	0.09	0.0013	0.00050	6	20+360

[23] $$P'''(\mathbf{T}) = -\| \mathbf{s}_i - \mathbf{s}_i' \| + \gamma H(\sigma_1^2 - \sigma_2^2)$$

This will seek an acceptable solution that is as far as possible from the first solution, thereby defining the other boundary for spectrum *i*. This solution will be designated as $\mathbf{s}_i''\}$, and the pairs $\mathbf{s}_i'$ and $\mathbf{s}_i''$ define the boundaries of the spectrum for component *i*.

It should be noted that the procedure described here differs from many other approaches to SMCR in one important respect — it allows the component spectral and concentration vectors to exist outside the subspace determined by PCA. This is a particularly useful feature when dealing with real data that have measurement errors since it allows some flexibility in adapting to negative values.

Although the procedure described here appears more complex than the original algorithm described by Sasaki et al. (16), we have found it to be less prone to numerical problems and much more efficient. Because it follows the initial optimization with more localized search procedures, it is less likely to generate redundant solutions. The new method is also more tolerant of negative values that arise from measurement error. Furthermore, there is a substantial reduction in computation time resulting from the fact that only $2p + 1$ optimizations are required as opposed to $2pn$ in the original work. This can save a significant amount of time as the number of channels becomes large. Finally, the boundaries determined by this method define mathematically feasible spectra, which is not necessarily the case for the Sasaki algorithm, since it does a separate calculation for each wavelength rather than considering each spectrum as a single entity.

Experimental

Data sets

Five sets of data were used to test the new algorithm in this work. The first was that originally given by Lawton and Sylvestre in their initial description of SMCR (1). These data consist of spectra measured for 5 mixtures of 2 dyes at 30 wavelength channels and were used to compare the new algorithm to the original procedure for two-component mixtures. The remaining four data sets were recorded for the autocatalytic reaction between permanganate and oxalic acid in a sulfuric acid medium. The conditions for these reactions were intended to duplicate those used by Pimienta et al. (18) in an earlier study. Further experimental details on the procedures used in obtaining these data are given below.

Procedure

All chemicals used were ACS Reagent Grade or better and solutions were prepared in deionized water. Solutions of oxalate were prepared from the disodium salt (Fisher, primary standard) and were acidified by adding the required amount of 1.000 M sulfuric acid (Caledon). Volumetric transfers were carried out using Class A glassware and Eppendorf pipettes (10–100 µL and 1–10 mL).

The permanganate – oxalic acid reaction was carried out by first adding 2.50 mL of a solution containing sodium oxalate and sulfuric acid to a standard 1 cm quartz cuvette (Hellma). To initiate the reaction, a 60.6 µL aliquot of potassium permanganate solution (0.02113 M) was added to the cuvette to give a starting concentration of 5.00×10^{-4} M for all of the reaction mixtures. Following this addition, timing was initiated and the solution was mixed by inverting it twice before placing it in the optical path of an HP8453 diode array spectrophotometer (Hewlett-Packard, Palo Alto, Calif.). Spectra were recorded at 1 nm intervals between 200 and 1000 nm with an integration time of 0.5 s and the shutter closed between measurements. The initial reagent concentrations, interval between measurements, and total run time for each of the four data sets are given in Table 2. A blank consisting of 5.00×10^{-4} M sulfuric acid was recorded prior to each kinetic run. All solutions were brought to 25°C prior to initiating the runs and the thermostatted cell holder of the spectrometer was maintained at 25.0°C. No stirring was done during the run.

Computational aspects

All calculations were carried out using programs written in Matlab 5.0 (The MathWorks, Natick, Mass.) on a Sun Microsystems SparcServer 1000 with 230 MB of memory and four 50 MHz SuperSPARC CPUs.

Results and discussion

Two-component data

The algorithm developed in this work was initially applied to the two-component data of Lawton and Sylvestre (1). Although the two-component case is easily solved analytically, these data were included here to validate the new method. Figure 2 shows the spectral boundaries obtained by the Lawton and Sylvestre (LS) method and the new method for both components in the mixture. From the figure, it is clear that there is excellent agreement between the two methods at the crossover points and the shapes of the spectral profiles are very similar, but the boundaries obtained by the new method are somewhat outside of those found by the LS technique. This is as expected, since the new SMCR method assumes a certain level of experimental error and therefore permits a wider range of solutions. In fact, it should be noted that the LS boundaries, so often employed for two-component SMCR problems, are actually too

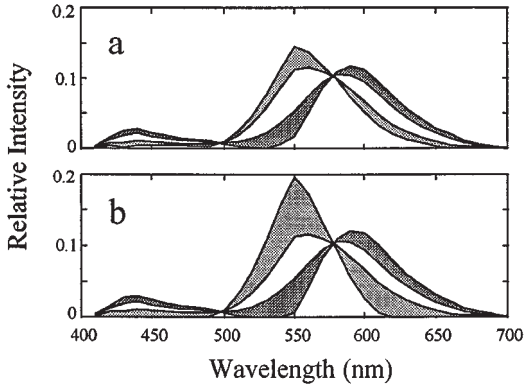
Fig. 2. Comparison of spectral boundaries of a two-component system determined by (*a*) the Lawton–Sylvestre method, and (*b*) the new SMCR method.



narrow. We were able to generate, with relatively little effort, realistic cases of simulated chromatographic/spectroscopic data in which the true spectra were outside of the LS boundaries, but inside the boundaries found by the new algorithm. This suggests that the results provided by the new algorithm may be more reliable than those based solely on a linear programming approach.

Permanganate – oxalic acid reaction

Figure 3 shows a three-dimensional mesh plot typical of the kinetic data obtained in this work. The example chosen is run number 3, the same as that shown in the earlier work of Pimienta et al. (18), and this figure exhibits virtually identical features. Characteristic of this reaction are the accelerating decay of the permanganate peak between 450 and 650 nm due to the autocatalytic reduction of permanganate by oxalic acid to form Mn(II), and the transient absorbance between 300 and 400 nm, which rises to a maximum before finally decaying to zero. This latter feature is attributed to the presence of one or more intermediates. Pimienta et al. (18) have proposed two intermediates, the first a well-recognized Mn(III) species (bis(oxalato)manganate (III), $[Mn(C_2O_4)_2]^-$), and the second a soluble Mn(IV) species. The aim of the present work was to use this autocatalytic reaction system to test the new SMCR algorithm and, if possible, confirm the presence of the two intermediates with the spectral characteristics reported by Pimienta.

The kinetics of this system are characterized by several isosbestic points that occur in the early to middle part of the reaction and then disappear. Some of these are evident in Fig. 4, which shows superimposed spectra for run number 3. Pimienta et al. (18) reported and used the isosbestic point around 450 nm, and its presence was confirmed in this work, along with similar isosbestic points around 335 nm and 390 nm. All of these points shift somewhat with reaction conditions. In addition, measurements made above 700 nm in this work established an additional early isosbestic point around 730 nm (710–740 nm, depending on reaction conditions). This is shown in the enlarged portion of Fig. 4. The isosbestic points arise at wavelengths where permanganate and the intermediate complexes of Mn(III) and Mn(IV) switch roles as the strongest absorbers. Permanganate is the stronger absorber between 335 and 390 nm and between 450 and 730 nm; the complexes are the stronger absorbers below 335 nm, between 390 and 450 nm, and above 730 nm. The shift in isosbestic points has been used to suggest the presence of more than one intermediate.

The analysis of the kinetic data began by removing measurements at wavelengths below 320 nm. This was done for two reasons. First, it eliminated possible absorbance by oxalic acid in the UV region, thereby reducing the number of components by one and simplifying the problem. Second, the absorbances at shorter wavelengths tended to be high, introducing problems with nonlinear response and larger noise levels, both of which complicated the mathematical analysis. Although component spectra generated by including wavelengths below 320 nm were of the same general shape as those generated when these wavelengths were excluded, the spectral boundaries were wider and sometimes truncated to zero due to excursions to negative values. Because of this, they were regarded as less reliable.

The next step in preparing for SMCR was to build one large "augmented" array from the four kinetic runs available. This was done by first appending the data matrix from the second run (61 time channels × 680 wavelength channels) to the bottom of the matrix from the first run (same dimensions). Runs 3 and 4 were then appended to this in the same way. This is a common practice (see, for example, ref. 13) that can be used whenever all data sets have the same wavelength channels. Although each of the four data matrices were also treated independently by SMCR, there are certain advantages to using the augmented matrix. First, the number of measurements is increased, providing more reliable results from PCA. Second, because several systems (encompassing different conditions) are analyzed simultaneously, the restrictions of non-negativity constrained solutions to narrower (and probably more reliable) regions than when single runs were analyzed. Finally, the use of the augmented data set results in one set of spectral boundaries, whereas four separate runs produce four sets of spectral boundaries for each component. Although these should be consistent with one another, they are likely to have broader limits and differ somewhat from run to run, making their interpretation more difficult. Of course, the use of an augmented array makes the implicit assumption that the spectra are independent of the kinetic run, which does not seem unreasonable in this study.

The SMCR analysis of the augmented data matrix was carried out assuming that there were four components present. Although only permanganate and two intermediates were expected, the assumption of four components allowed for the possibility of an additional intermediate, which, if not present, would result in a meaningless spectrum. The spectral boundaries for each of the four components extracted by SMCR are shown in Fig. 5. As noted earlier, SMCR produces an ambiguity of scale, so all of the spectra are normalized to unit area and there is no significance to the absolute scale of the *y* axis. The first spectrum is clearly that of the permanganate ion and the upper and lower bounds are so close together as to be indistinguishable, indicating very little ambiguity in the shape of this spectrum. The second spectrum, labeled "Intermediate 1," corresponds very closely to the spectrum of the Mn(III) complex

Fig. 3. Mesh plot of absorbance data from permanganate – oxalic acid reaction (run number 3).

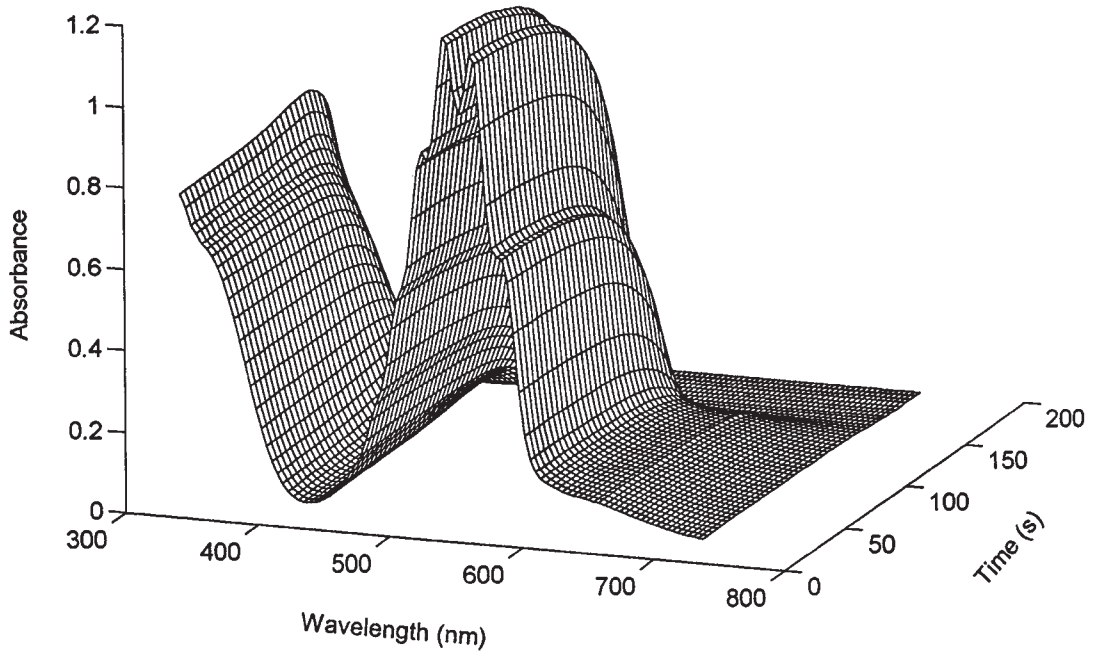

Fig. 4. Time series of spectra from the permanganate – oxalic acid reaction (run number 3). The region above 700 nm has been enlarged and offset to show the detail.

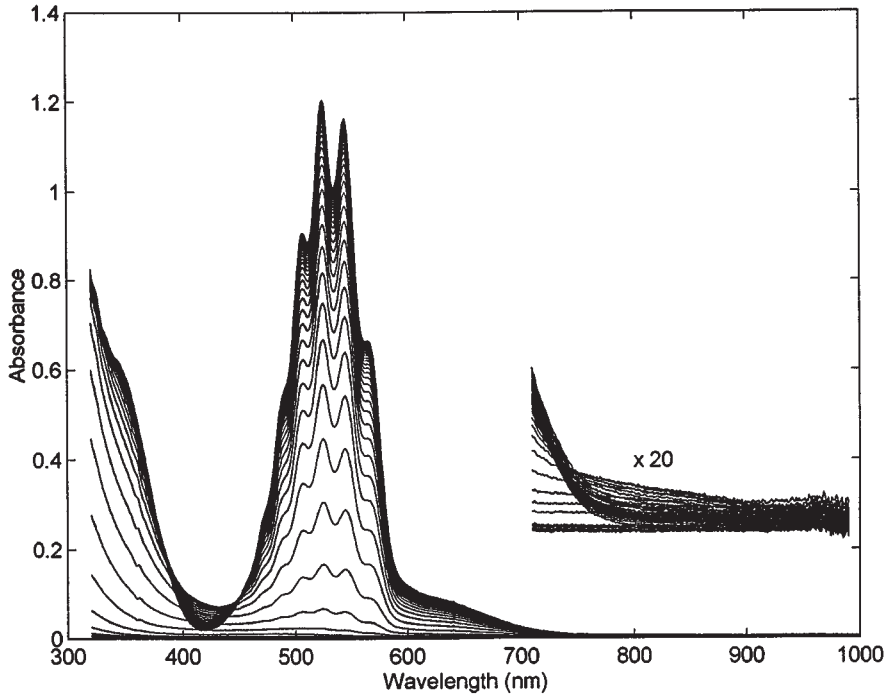
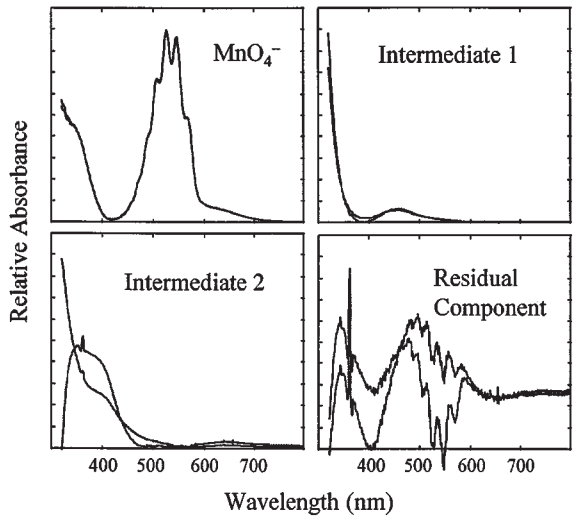


reported by Pimienta et al. (18) and has fairly tight boundaries as well. This is consistent with the fact that this species is a well-recognized intermediate. The third spectrum represents the second intermediate, which has been attributed to a soluble Mn(IV) species. Again, this spectrum is in good agreement with the spectrum reported in the literature (18), although the spectral bands are substantially wider than for the Mn(III) species, particularly at shorter wavelengths. This indicates that there is a fair amount of difficulty determining the spectrum of this species, probably because its contribution is dominated by other absorbing species (although it is also possible that the spectrum is sensitive to reaction conditions). The fourth spectrum in the series, although it exhibits some systematic features, is not considered to support the presence of an additional intermediate. Ideally, this spectrum should appear completely random in the absence of another component, but the features observed, which occur mainly in high-absorbance regions, are likely compensating for

© 1998 NRC Canada

Fig. 5. Spectral boundaries of four components extracted by SMCR.



small amounts of nonlinearity in the response. In PCA it is not unusual to see this type of behaviour when the nonideal characteristics of the instrument are compensated for by additional eigenvectors. Similar structure in the residual spectra was observed when the system was modeled with five components, consistent with non-chemical artifacts.

To facilitate a better comparison between the spectral boundaries obtained for the intermediates and those reported by Pimienta et al. (18), the latter results were digitized and the two sets of spectra were scaled to a common area. The results are compared in Fig. 6. It is clear that there is excellent agreement between the two sets of results, with the spectra reported by Pimienta (indicated by the open circles) closely matching one of the spectral boundaries (solid lines) in both cases. Since the results of Pimienta et al. were obtained through an alternative approach, assuming the presence of only two intermediates and making use of isosbestic point data, this serves as validation of the SMCR results. The difference is that the latter results were obtained without any assumptions other than the non-negativity of spectral and concentration profiles.

Also shown in the figure are spectral boundaries obtained by the Sasaki algorithm (dotted lines). For both species, the upper and lower boundaries extracted by the Sasaki algorithm are completely overlapped and so appear as a single line. This demonstrates one of the weaknesses of this algorithm when even small negative values remain in the data after PCA. Because the penalty function in the Sasaki algorithm is essentially absolute in its rejection of negative values, the optimization routine ignores the spectral contribution to the objective functions in eqs. [9] and [10] and simply minimizes the penalty, giving the same result for both boundaries. In other words, whenever negative spectral and concentration contributions cannot be removed, regardless of how small they are, a single solution results. In this case, the Sasaki solutions match one of the boundaries from our algorithm for both species, but it is clear that there is a discrepancy with Pimienta's reults for the first intermediate.

The concentration profiles extracted by SMCR for each of the three species are shown in Fig. 7. As with the spectra, the concentration profiles extracted by SMCR normally have an ambiguity of scale, so while comparisons can be made for the same species in different runs, interspecies comparisons are not generally possible. In this case, however, the spectra reported by Pimienta et al. (18) were used to bring the concentration profiles for the intermediates to an approximately comparable scale. This means that the relative magnitudes of the concentration profiles in the last two columns of Fig. 7 can be compared directly. The concentration profiles for MnO_4^- are on a separate scale, however, and can only be compared within the column.

As in the case of the spectral profiles, the concentration profiles for MnO_4^- show very tight boundaries, to the point of being indistinguishable. These show a very clear picture of the autocatalytic reduction under different reaction conditions. The concentration profiles for the intermediates show generally wider bands and exhibit differing contributions from each species under different reaction conditions. In an attempt to quantify the relative contribution of each species for each run, Pimienta et al. (18) reported the percentage of intermediate 2 (Mn(IV)) to the total intermediate contribution in each run. This assumed a constant ratio of the intermediates, which is probably approximately valid for a significant portion of the reaction. They reported values of 9, 31, 60, and 68% Mn(IV) in runs 1 through 4, respectively. By integrating the mean concentration profiles for our results, we obtained values of 7, 29, 50, and 54%. Given the approximate nature of both calculations, this agreement is quite good. More importantly, however, the results presented in Fig. 7 give a picture of what is happening to species in solution, allowing a better visualization of reaction dynamics.

Conclusions

The principal objective of this work has been to introduce and demonstrate a modified SMCR procedure based on nonlinear optimization. The new procedure is substantially faster than the former procedure on which it is based, requiring many fewer steps in the optimization. In addition, the new method handles experimental measurement error in a more logical way and, unlike other SMCR methods, allows small departures of the solutions from the PCA subspace if these are warranted by measurement uncertainty. The new method requires no pure component regions or constraints other than non-negativity. Application of the method to the two-component data of Lawton and Sylvestre (1) led to results consistent with the analytical solution, but with broader boundaries, as expected when accounting for experimental error. Furthermore, the new method works in certain cases where the analytical solution fails because of the presence of measurement uncertainty. The new method was also applied to kinetic data for the permanganate oxidation of oxalic acid. This was an excellent case study, since (*i*) there were no clear pure component regions, (*ii*) there were a wide range of signal amplitudes, and (*iii*) results from an alternative approach were available for comparison. Results confirmed the presence of the two intermediates proposed by Pimienta et al. (18) and the spectra extracted by SMCR were in excellent agreement with those reported earlier. This clearly indicates the potential for SMCR in kinetic studies. In addition,

Fig. 6. Comparison of spectra of intermediates reported by Pimienta et al. (18) (open circles) with spectral boundaries extracted by the SMCR method in the present work (solid lines) and that used by Sasaki et al. (16) (dotted lines): (*a*) intermediate 1 (proposed Mn(III) species), (*b*) intermediate 2 (proposed Mn(IV) species).

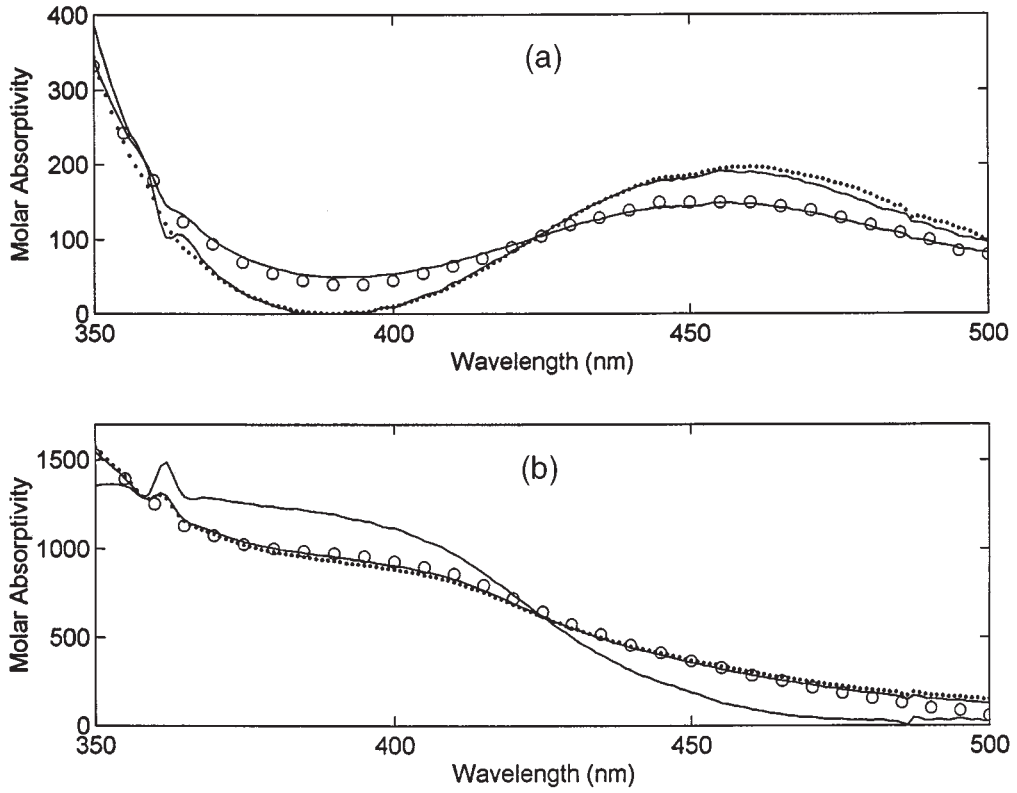

Fig. 7. SMCR-extracted concentration boundaries for permanganate and two intermediates for each of the four reaction conditions used. The horizontal axis runs from 0 to 700 s in all cases. Vertical scales are relative only. Permanganate profiles are on comparable scales, as are the profiles for all of the intermediates.

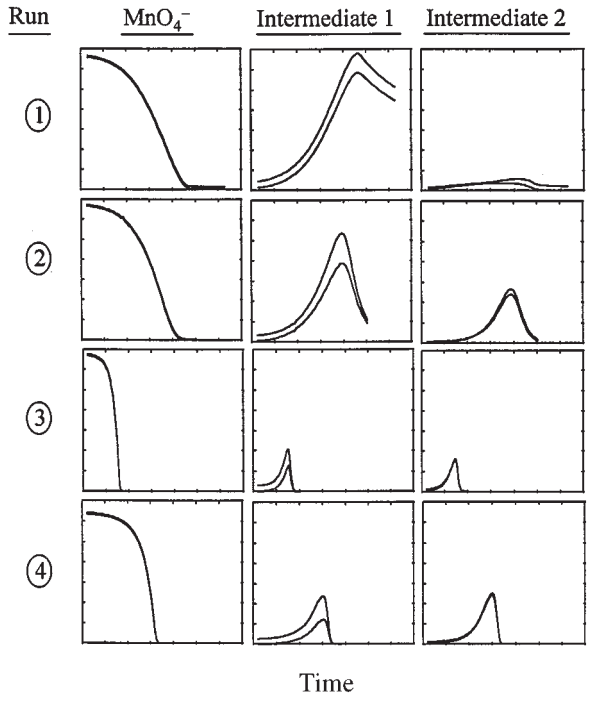

our laboratory has applied this algorithm to chromatography with multiwavelength fluorescence detection and to environmental receptor modeling. Given the wide range of studies now producing second-order data, tools such as this are likely to become more important in the future.

Electrochemical behaviour of silver in aqueous chromate solutions

Sayed S. Abd El Rehim, Magdy A.M. Ibrahim, Hamdy H. Hassan, and Mohammed A. Amin

Abstract: The electrochemical behaviour of silver was studied under cyclic voltammetry and chronoamperometry conditions in aqueous K_2CrO_4 solutions. The forward cyclic voltammograms exhibited one oxidation peak, A_1, due to the formation of Ag_2CrO_4. The height of the anodic peak, A_1, increases with increasing chromate concentration, temperature, and scan rate. The solid films formed on the anode surface have been examined by X-ray diffractometry. The reverse voltammograms exhibited two reduction peaks, C_1 and C_2, indicating the formation of two distinct surface layers of Ag_2CrO_4, an inner compact layer reduced in peak C_1 and an outer powdery layer reduced in peak C_2.

Key words: silver electrode, cyclic voltammetry, K_2CrO_4 solutions.

Résumé : Faisant appel à la voltampérométrie cyclique et à la chronoampérométrie, on a étudié le comportement électrochimique de l'argent en solutions aqueuses de K_2CrO_4. Les voltampérogrammes cycliques de la réaction directe présentent un pic d'oxydation, A_1, dû à la formation de Ag_2CrO_4. La hauteur du pic anodique A_1 augmente avec une augmentation de la concentration du chromate, de la température et de la vitesse de balayage. Faisant appel à la diffraction des rayons X, on a examiné les films solides qui se forment à la surface anodique. Les voltampérogrammes inverses présentent deux pics de réduction, C_1 et C_2, qui indiquent qu'il y a formation de deux couches superficielles de Ag_2CrO_4 distinctes, une couche compacte intérieure réduite dans le pic C_1 et une couche extérieure en poudre qui est réduite dans le pic C_2.

Mots clés: électrode d'argent, voltampérométrie cyclique, solutions de K_2CrO_4.

[Traduit par la Rédaction]

Introduction

Very little work has been reported on the electrochemical behaviour of Ag in aqueous chromate solutions. However, the reduction of Ag_2CrO_4 was investigated in a number of nonaqueous electrolytes because Ag_2CrO_4 was used as a cathode in various lithium batteries (1–3). The system $Ag(s)–Ag_2CrO_4(s)–CrO_4^{2-}(aq)$ is a second kind of electrode, which is common and easy to use as a reference electrode (4). Druskovich et al. (4) studied the electrochemical behaviour of Ag in a solution containing sodium perchlorate and sodium chromate. In the absence of any chromate, only silver dissolution and deposition are observed. In the presence of low chromate ion concentrations ($<10^{-2}$ M), a film of silver chromate was observed. This Ag_2CrO_4 film did not suppress the silver dissolution reaction. However, the dissolution of silver was suppressed when the film of Ag_2CrO_4 was formed in more concentrated chromate solutions.

In the present work, an attempt is made to throw more light on the electrochemical behaviour of Ag in chromate solutions and the effect of chromate concentration, scan rate, temperature, repetitive cycling, and current transients on the voltammetric response of Ag electrode.

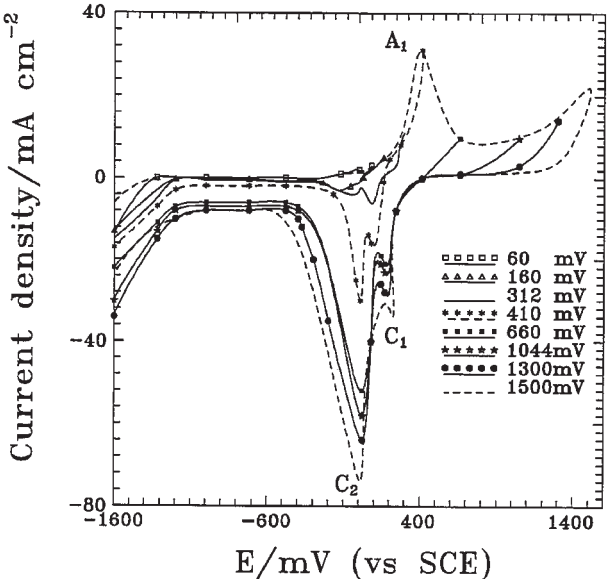
Experimental

The working electrode employed in the present study was made of pure polycrystalline silver (99.99%, Koch light laboratories, Colnbrook Bucks England) axially embedded in an Araldite holder to offer an active flat disc-shaped surface of area 0.1256 cm^2. Prior to each experiment, the working electrode was mechanically polished with different grade emery papers, i.e., 600, 800, 1000, and finally 1200, and then the polished metal surface was rinsed with acetone, distilled water, and finally dipped in a conventional three-electrode cell. A platinum wire was used as the counter electrode. All potentials were measured against the saturated **c**alomel electrode (vs. SCE). To avoid contamination, the reference electrode was connected to the working electrode through a bridge with a Luggin capillary filled with the test solution. The capillary tip was put very close to the electrode surface to minimize the ohmic drop of the solution. All solutions were freshly made using doubly distilled water and analytical grade chemicals. All measurements were conducted at constant temperature ±1°C with the help of an air thermostat.

Electrochemical measurements were performed using a Potentiostat–Galvanostat Model 273 EG & G. The *E*/*i* curves were recorded using an X-Y recorder (series 2000, Omnigraphic).

 © 1998 NRC Canada

Fig. 1. Cyclic voltammograms for polycrystalline Ag electrode in 0.5 M K_2CrO_4 at 25°C and at a scan rate of 100 mV s^{-1} starting from $E_{s,c}$ = –1600 mV and reversed at various anodic potentials.



The current–time transients (constant anodic step potential limits, $E_{s,a}$) were recorded in the following way. The silver electrode was first held at the starting potential $E_{s,c}$ = –1600 mV for 60 s to attain a reproducible reduced silver surface, and then, the electrode was scanned potentiodynamically from –1600 mV in the positive direction with a constant scan rate of 100 mV s^{-1} to a potential limit $E_{s,a}$ at which the current–time transients were recorded for 100 s.

The composition and structure of the passive film formed on the silver electrode surface was examined by X-ray diffraction analysis. The X-ray diffraction system used for this analysis was a Philips P.W. model no. 1730 with a Cu-K_α radiation and nickel filter. The scanning speed was 1°/min. The X-ray diffraction measurements were performed on the electrode surface potentiodynamically polarized from –1600 mV up to 500 mV (with scan rate of 100 mV s^{-1}) and then held for 10 min at the potential 500 mV before withdrawing the electrode from the solution.

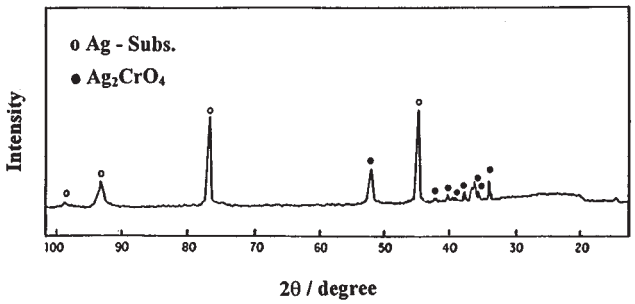
Results and discussion

Cyclic voltammetry

In Fig. 1, the dotted curve represents a typical cyclic voltammogram recorded in 0.5 M K_2CrO_4 at 25°C between the hydrogen and oxygen evolution reactions at a scan rate of 100 mV s^{-1}. The anodic response exhibits a well-defined anodic peak, A_1, followed by a passive region prior to oxygen evolution. This anodic peak is due to the formation of Ag_2CrO_4, since its potential range covers the potentials of the formation of Ag_2CrO_4 ($E°$ = 0.446 V for $Ag–Ag_2CrO_4–CrO_4^{2-}$) (4). The formation of solid phase Ag_2CrO_4 on the surface can be explained as follows:

$$2Ag + CrO_4^{2-} = Ag_2CrO_4 + 2e$$

Fig. 2. X-ray diffraction pattern for Ag anode potentiodynamically polarized from –1600 mV up to 500 mV (within the potential range of peak A_1) in 0.5 M K_2CrO_4 at a scan rate of 100 mV s^{-1}.



When the concentration of Ag_2CrO_4 at the anode surface exceeds its solubility product, precipitation of solid Ag_2CrO_4 occurs on the electrode surface, suggesting that the formation of solid Ag_2CrO_4 takes place via a dissolution–precipitation mechanism (4). When the surface is entirely covered with Ag_2CrO_4 passive film, the anodic current density falls sharply to a low value, i_{pass}, indicating the onset of passivation, which extends up to the oxygen evolution potential. The films formed were subsequently analyzed by X-ray diffraction. The diffraction analysis detected only Ag_2CrO_4, as shown in Fig. 2.

The cathodic response exhibits two distinct reduction peaks, C_1 and C_2, prior to hydrogen evolution. The existence of two reduction peaks suggests that two distinct films or phases are formed on silver surface during the anodic potential scan. Druskovich et al. (4) reported that the passivity of the silver anode in chromate solutions is due to the formation of compact layer of Ag_2CrO_4 containing a number of paths or flaws. However, in the passive region, the passive current density is involved in the formation and growth of a powdery layer of Ag_2CrO_4 on top of the inner compact layer. The authors proposed that, the formation of the powdery layer can be achieved by Ag^+ ions traveling rapidly along the paths and flaws of the compact layer to the chromate–solution interface. Therefore, it can be concluded that the peak, C_1, is assigned to the reduction of the compact layer, while the cathodic peak, C_2, is related to the reduction of the powdery layer. It seems that the difference in reduction potential between peaks C_1 and C_2 is due to the difference in morphology, which might exist between the silver formed during the reduction of the two solid layers (4). It is probable that the compact layer reduces more easily than the powdery layer because it is in good electrical contact with the underlying metal.

The solid curves of Fig. 1 show a series of voltammograms reversed at various anodic limits, $E_{s,a}$. The data reveal that, if the anodic potential is reversed at 60 mV, the reversing scan retraces itself and does not display any cathodic peaks, indicating the absence of any solid product. When $E_{s,a}$ is 160 mV, the reverse scan retraces part of the forward scan and then yields the reduction peak, C_1, corresponding to the reduction of the compact layer. When $E_{s,a}$ is 312 mV, the reverse scan shows hysteresis between the forward and the return scan and then yields two reduction peaks, C_1 and C_2, indicating that the two layers are formed

Fig. 3. Cathodic stripping voltammograms recorded for polycrystalline Ag electrode in 0.5 M K_2CrO_4 at 25°C and at a scan rate of 100 mV s^{-1} after potentiostatic oxidation at 840 mV for various times.

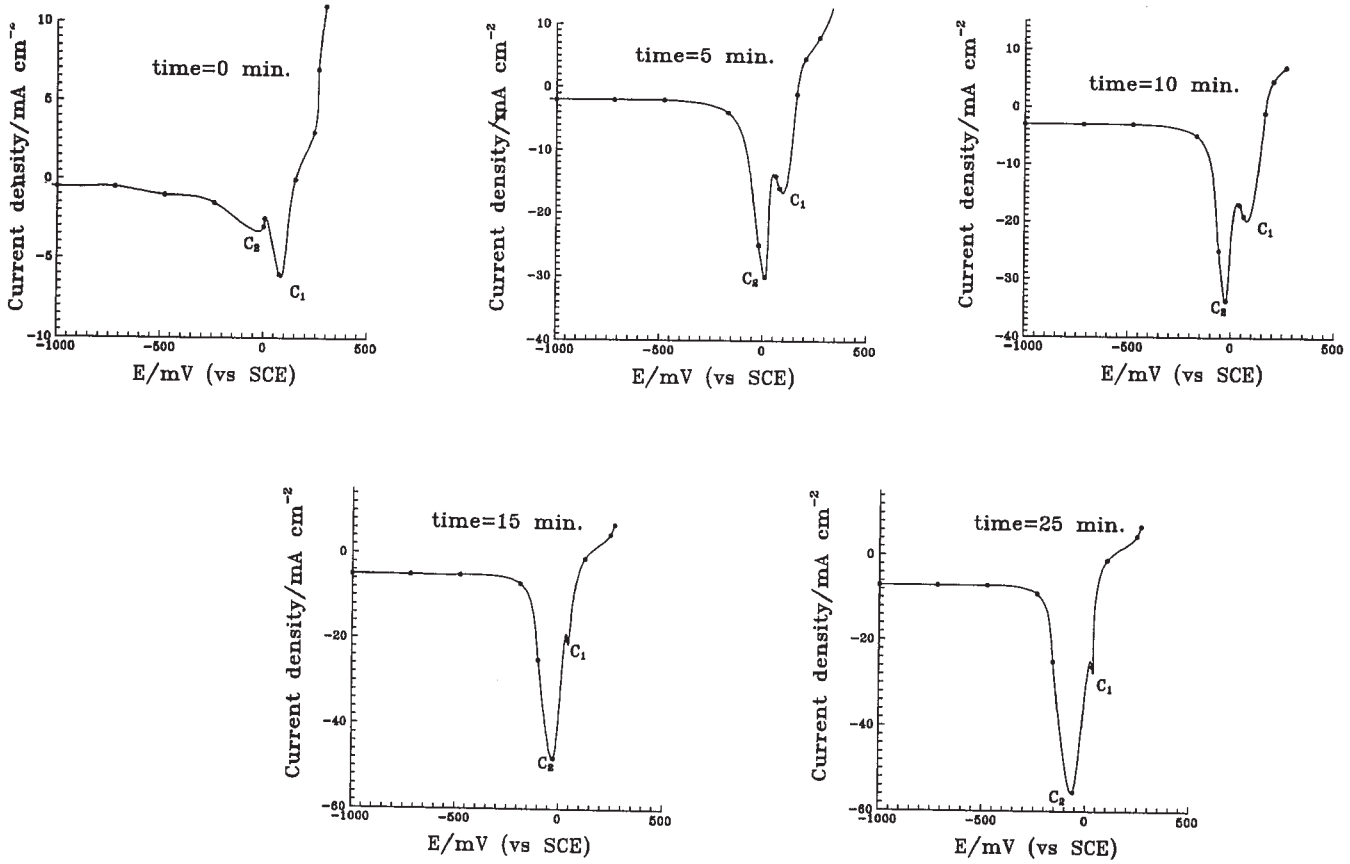

Fig. 4. Cyclic voltammograms for polycrystalline Ag electrode in 0.50 M K_2CrO_4 solution between $E_{s,c}$ = –1600 mV and $E_{s,a}$ = 1500 mV at 25°C and at different scan rates.

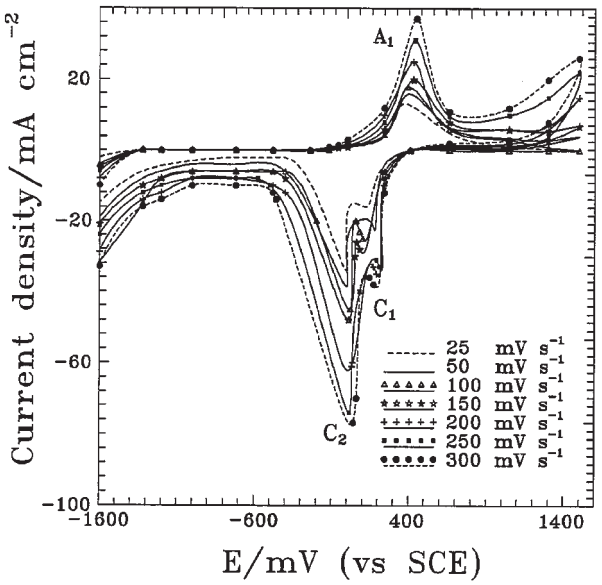

on the cathodic side of the anodic peak. It is seen that the cathodic peak height (i_{PC2}) is highly affected by increasing the anodic limit, while that of C_1 (i.e., i_{PC1}) increases slightly with increasing $E_{s,a}$, indicating that the thickness of the Ag_2CrO_4 powdery layer increases, while that of the compact layer remains nearly constant, as the scan progresses to more positive potentials.

It is interesting to note that i_{PC2} increases, not only by increasing $E_{s,a}$ within the passive region, but also by holding $E_{s,a}$ constant for some time before reversing the scan, as shown in Fig. 3. This figure shows a series of cathodic stripping voltammograms recorded after scanning the potentials up to $E_{s,a}$ = 840 mV and then holding $E_{s,a}$ constant for various periods of time before reversing the scan. The data reveal that the areas of both reduction peaks increase with increasing holding time as a result of increasing thickness of the two layers, but peak C_2 increases more significantly than peak C_1.

In Fig. 4 are presented cyclic voltammograms obtained at various sweep rates. It is seen that, current densities i_{PA1} (peak current for the process A_1), i_{pass} (current for the passivation process), i_{PC1} (peak current for the process C_1), and i_{PC2} (peak current for the process C_2) increase with increasing scan rate, ν. It is seen from Fig. 4 that the sweep rate is more effective on the powdery layer, than on the compact layer, indicating the formation of greater number of flaws and paths in the compact layer. The plots of i_{PA1}, i_{PC1}, and i_{PC2} against the square root of ν were straight lines with ordinates at their origins, as shown in Fig. 5. This is in accordance with the following equation (5):

$$i_p = abz^{1/2}CD^{1/2}\nu^{1/2}$$

© 1998 NRC Canada

Fig. 5. Dependence of the peak current density, i_p, on the square root of the potential scan rate $\nu^{1/2}$ for Ag electrode in 0.50 M K_2CrO_4 solution at 25°C.

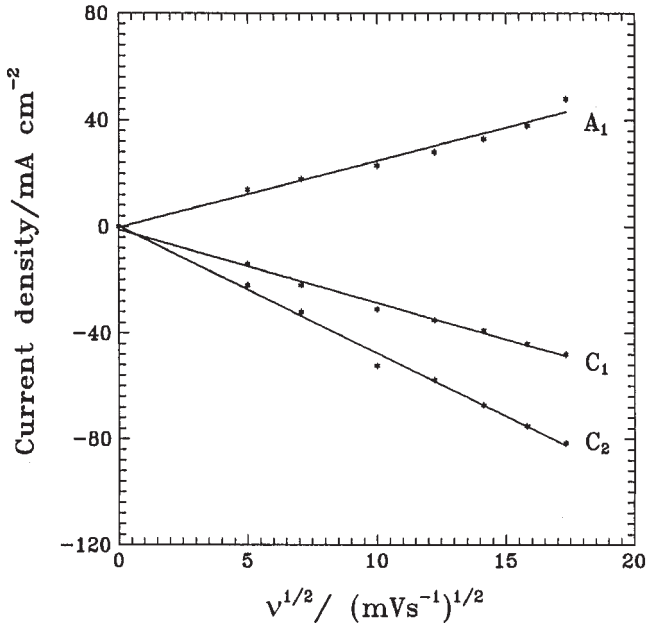

Fig. 6. Cyclic voltammograms for polycrystalline Ag electrode in K_2CrO_4 solutions of various concentrations (0.10–1.25 M) between $E_{s,c}$ = –1600 mV and $E_{s,a}$ = 1500 mV at 25°C and at a scan rate of 100 mV s^{-1}.

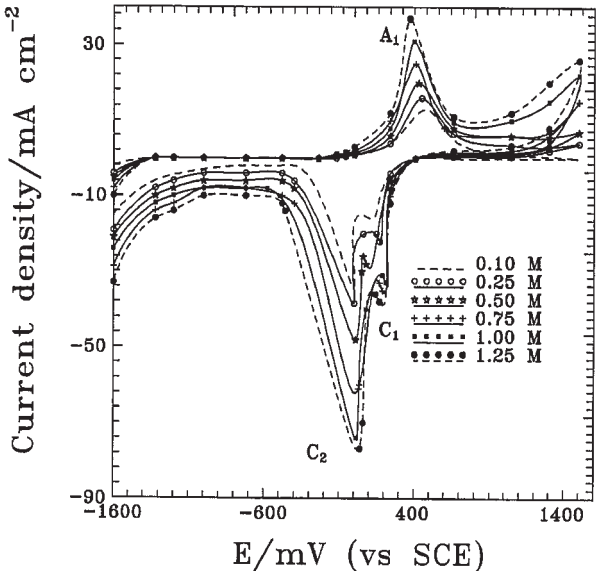

where a and b are constants, z is the number of exchanged electrons, C is the concentration, and D is the diffusion coefficients of the diffusing species. These results suggest that the formation of Ag_2CrO_4 passive layers and their subsequent reduction are under diffusion control.

Figure 6 shows the effect of chromate concentration on the cyclic voltammogram curves obtained at the silver electrode. The data reveal that the charges involved in the formation of both compact and powdery Ag_2CrO_4 layers increase with an increase in CrO_4^{2-} concentration. The peak

Fig. 7. Cyclic voltammograms for polycrystalline Ag electrode in 0.50 M K_2CrO_4 solution between $E_{s,c}$ = –1680 mV and $E_{s,a}$ = 1500 mV at different temperatures (10–60°C) and at a scan rate of 100 mV s^{-1}.

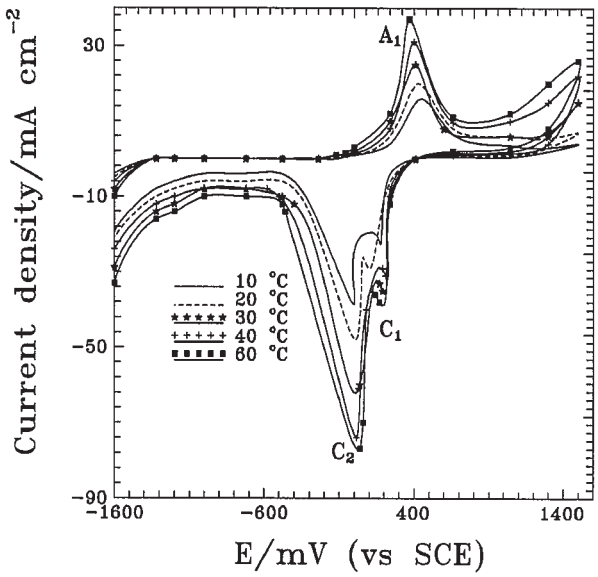

Fig. 8. Dependence of log i_p on $1/T$ (K) for Ag electrode in 0.5 M K_2CrO_4 solution at a scan rate of 100 mV s^{-1}.

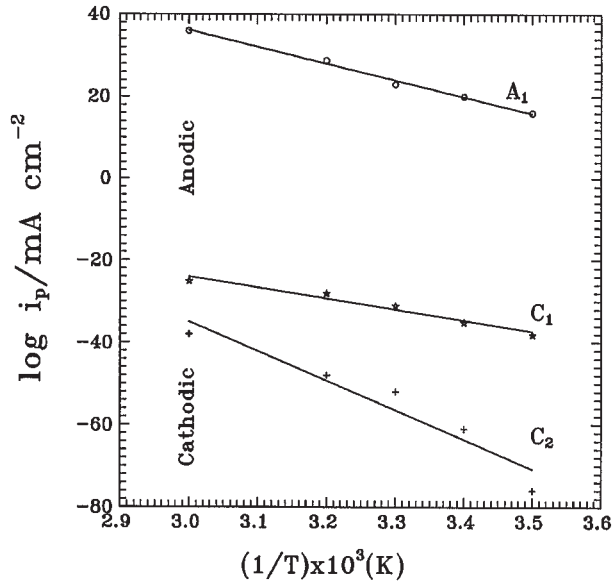

potential of the anodic peak, A_1, shifts to more negative potentials, while those of both C_1 and C_2 shift positively with increasing chromate concentration. The dissolution acceleration effect of CrO_4^{2-} ion may be due to its direct participation in the elementary act of Ag ionization and also to the increase of the rate of its transport through the flaws and paths of the compact layer.

Figure 7 shows the influence of solution temperature on the cyclic voltammograms obtained at the Ag electrode in 0.5 M K_2CrO_4 with a scan rate of 100 mV s^{-1}. The heights of the A_1, C_1, and C_2 peaks increase with rising temperature. The peak potential of peak A_1 shifts in the negative

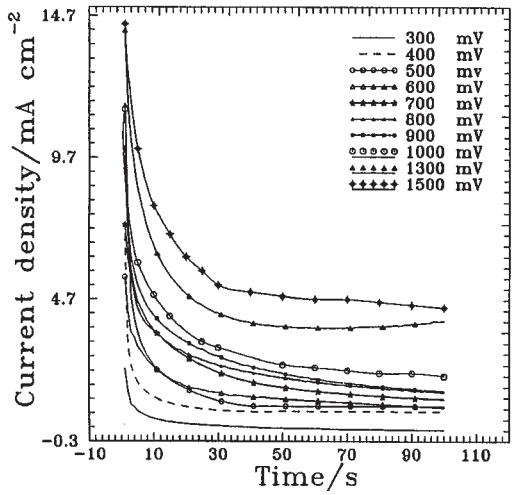
Fig. 9. Current transients at constant step potential, $E_{s,a}$, recorded for a polycrystalline Ag electrode in 1.0 M K_2CrO_4 at 25°C after applying to the electrode the pretreatments mentioned before. $E_{s,a}$ = 300, 400, 500, 600, 700, 800, 900, 1000, 1300, and 1500 mV.



direction, while those of the two reduction peaks, C_1 and C_2, shift towards more positive potentials. The value log i_p of the A_1, C_1, and C_2 peaks for various temperatures was plotted as a function of $1/T$ (K) in Fig. 8. The apparent activation energies, E^*, for the formation of the compact powdery layers and their reduction were calculated from the slopes of the Arrhenuis plots, according to the equation:

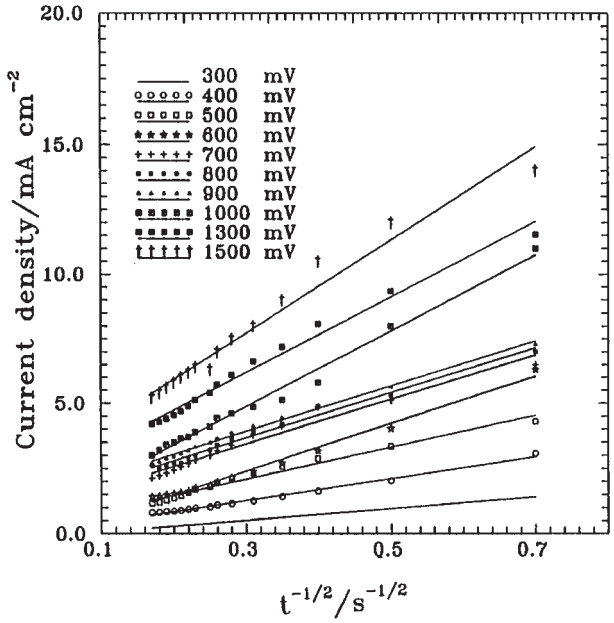
$$i_p = A \exp(-E^*/RT)$$

and they are 6.4, 4.1, and 8.3 kJ mol^{-1} for peaks A_1, C_1, and C_2, respectively. The stimulation effect of temperature for the formation of Ag_2CrO_4 may be attributed to an increase in the solubility of the silver salt with temperature. In addition, an increase in temperature accelerates the diffusion rate of the diffusing species.

Current transient

A series of current–time transients at constant anodic step potentials, $E_{s,a}$, in the potential range $300 \le E_{s,a} \le 1500$ mV for a Ag electrode in 0.5 M K_2CrO_4 at 25°C were recorded after a two-step procedure. The Ag electrode was first held at $E_{s,c}$ = –1680 mV for 60 s to attain a reproducible reduced Ag surface, and then the electrode was potentiodynamically polarized in the positive direction with a scan rate of 100 mV s^{-1} to a potential limit $E_{s,a}$ at which the current transient was recorded. Figure 9 shows the current–time relationship for different anodic step potentials, $E_{s,a}$. The transient current decreases monotonically with time to reach a steady-state value. As $E_{s,a}$ is made more positive, the values of the instantaneous and steady-state currents increase, indicating an increase in the thickness of the anodically formed Ag_2CrO_4 layers. No peak is observed in the current transients, indicating that a phase nucleation and growth process is not involved. The continuously falling current was linear versus $t^{-1/2}$, as shown in Fig. 10. The slope of these lines depends on the value of $E_{s,a}$. This type of linear relationship suggests that the growth of the Ag_2CrO_4 layers is a

Fig. 10. Dependence of the current density on $t^{-1/2}$ for the descending portions of the current transients for Ag electrode in 0.5 M K_2CrO_4 at 25°C recorded in the potential range (300 mV $\le E_{s,a} \le$ 1500 mV) at a scan rate of 100 mV s^{-1}.



diffusion-controlled process and obeys the following equation (6):

$$i = P/t^{1/2}$$

where $P = zCD^{1/2}/\pi^{1/2}$ and z is the number of exchanged electrons, C is the concentration, and D is the diffusion coefficient of the diffusing species.

Conclusion

The electrochemical behaviour of silver in aqueous K_2CrO_4 solutions was studied using both cyclic voltammetry and chronoamperometry techniques. The cyclic voltammograms showed one oxidation peak, A_1 (due to the formation of solid Ag_2CrO_4 on the electrode surface), and two reduction peaks, C_1 and C_2. The presence of these two reduction peaks is an indication of two distinct layers of Ag_2CrO_4, an inner compact layer (peak C_1) and an outer powdery layer (peak C_2). The powdery layer is formed via the transport of Ag^+ ions through flaws and paths in the compact layer to the chromate–solution interface. The relative thickness of the powdery layer increases markedly with increasing applied potential, the holding time at a given potential, electrolyte concentration, scan rate, and temperature. On the other hand, the relative thickness of the compact layer is only slightly affected by these parameters. Current–time transients showed that the values of the instantaneous and steady-state currents increase with increasing anodic potential limit, $E_{s,a}$, indicating an increase in the thickness of the anodically formed Ag_2CrO_4 layers.

A study of the vacuum pyrolysis of *para*-substituted diazoacetophenones with He(I) ultraviolet photoelectron spectroscopy

Nick H. Werstiuk, Heidi M. Muchall, Jiagong Ma, and Michael T.H. Liu

Abstract: An ultraviolet photoelectron (PE) spectrometer apparatus that utilizes a tuneable 50 W CW CO_2 laser as a directed heat source was used to study the vacuum pyrolysis of diazoacetophenone (**1a**) and its *p*-methyl, *p*-methoxy, *p*-chloro, and *p*-nitro analogues **1b**, **1c**, **1d**, and **1e**. Analysis of the pyrolysate with He(I) ultraviolet PE spectroscopy shows that at a laser power level of 26 W (500 ± 50°C) **1a**, **1b**, **1c**, and **1d**, cleanly yield the corresponding phenylketenes **2a**, **2b**, **2c**, and **2d**, respectively, the products of the Wolff rearrangement of the incipient ketocarbenes. Of this group of highly reactive ketenes, which cannot be isolated in the condensed phase at ambient temperature, only **2a** has been the subject of a previous PE spectroscopic study. But our work indicates that the sample of **2a** prepared in the earlier study was impure. The low volatility of *p*-nitrodiazoacetophenone (**1e**) thwarted our attempts to generate **2e** and obtain its spectrum. Calculations at semiempirical (AM1) and ab inito (HF/6-31G(d)) levels of theory established that the diazoacetophenones prefer to adopt twisted *syn* conformations. That the calculated ionization potentials (HAM/3 and Becke3LYP/6-31+G(d)//HF/6-31G(d)) of **1a**–**1d** and the synthesized PE spectra of **1a**, **1b**, and **1c** correlate well with the PE spectroscopic data supports this finding. Shifts observed in the three low-energy ionizations of ketenes **2b, 2c**, and **2d** induced by the *para*-substitution can be related to the character of the corresponding occupied molecular orbitals of phenylketene (**2a**).

Key words: diazoacetophenones, phenylketenes, He(I) photoelectron spectroscopy, thermolysis, quantum chemical calculations.

Résumé : On a fait appel à un spectromètre photoélectronique (PE) ultraviolet, qui utilise comme source de chaleur un laser à CO_2 de 50 W ajustable et à VC, pour étudier la pyrolyse sous vide de la diazoacétophénone (**1a**) et de ses analogues *p*-méthyl-, *p*-méthoxy-, *p*-chloro- et *p*-nitro- (**1b, 1c, 1d** et **1e**). L'analyse des pyrolysats par spectroscopie PE ultraviolette à He(I) montre que, à une puissance de laser de 26 W (500 ± 50°C), les composés **1a, 1b, 1c** et **1d** conduisent proprement aux phénylcétènes correspondants, soit les produits **2a, 2b, 2c** et **2d** respectivement, qui correspondent aux produits de réarrangement de Wolff des cétocarbènes qui se forment. De ce groupe de cétènes hautement réactifs qui ne peuvent pas être isolés sous forme condensée à la température ambiante, seul le composé **2a** avait fait l'objet d'une étude antérieure par spectroscopie PE. Les résultats obtenus au cours de ce travail indiquent toutefois que le composé **2a** préparé antérieurement n'était pas pur. La faible volatilité de la *p*-nitrodiazoacétophénone (**1e**) nous a empêché de générer le produit **2e** et d'en obtenir un spectre. Des calculs théories aux niveaux semiempirique (AM1) et ab initio (HF/6-31G(d)) ont permis de déterminer que les diazoacétophénones adoptent préférentiellement les conformations *syn* déformées. Le fait que les potentiels d'ionisation calculés (HAM/3 et Becke3LYP/6-31+G(d)//HF/6-31G(d)) pour les composés **1a–1d** et que les spectres PE synthétisés des produits **1a**, **1b** et **1c** donnent une excellente corrélation avec les données de spectroscopie PE est en accord avec cette conclusion. Les déplacements observés dans les trois ionisations de faible énergie des cétènes **2b, 2c** et **2d** sont induits par les substituants en *para* et on peut les relier au caractère des orbitales molécules occupées correspondantes du phénylcétène (**2a**).

Introduction

To facilitate the preparation and detection of highly reactive transients in the gas phase, we developed a He(I) ultraviolet photoelectron (PE) spectrometer-CW CO_2 laser apparatus and used it successfully to study the vacuum pyrolysis of 6,6-dihalobicyclo[3.1.0]hexanes (1), 1,2,3-benzotriazines (2), 4-diazoisochroman-3-one (3), and 4-diazoisothiochroman-3-one (4), 11-oxatricyclo[6.2.1.$0^{2,7}$]-undeca-2,9-diene (5), and 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (6). To widen our research in this field, we undertook a study of the vacuum pyrolysis of diazoacetophenone (**1a**), *p*-methyldiazoacetophenone (**1b**), *p*-methoxydiazoacetophenone (**1c**), *p*-chlorodiazoacetophenone (**1d**), and *p*-nitrodiazoacetophenone (**1e**) that are potential precursors of ketocarbenes and the corresponding *para*-substituted phenylketenes, which are the Wolff rearrangement products (7). Only a limited number of ketenes which cannot be isolated in the condensed phase at ambient temperature have been studied in the gas phase with PE spectroscopy (5, 8–13), and there is comparatively little experimental data available on the vacuum pyrolysis of α-diazocarbonyl compounds (see, for example, ref.14) in contrast to the large body of work that has been accumulated on the photochemistry of this class of compounds (14–21). Given that a wide variety of diazocarbonyl compounds can be synthesized (14) and, as our studies have shown, easily pyrolyzed in the gas phase, we expected PE spectroscopic and calculational studies to provide fundamental information on aspects of the electronic structure and reactivity of this group of compounds and the products derived from the incipient ketocarbenes (4, 5). We undertook a study of **1a**, **1b**, **1c**, **1d**, and **1e** specifically (*i*) to gain information about the nature of the frontier molecular orbitals (MOs), (*ii*) to study the conformational properties of these compounds in the gas phase, (*iii*) to establish whether our instrument is generally useful for preparing and studying ketenes in the gas phase (five new *para*-substituted phenylketenes were to be prepared), and (*iv*) to determine the effect of the *para*-substituents on the ionization potentials of **2a** with the goal of characterizing its highest occupied molecular orbitals. This paper documents the results of a PE spectroscopic study of the pyrolysis of diazoacetophenones **1a**, **1b**, **1c**, and **1d** and a computational study of the conformational properties and molecular orbitals of this group of compounds, the nitro analogue **1e**, and the corresponding ketenes (Scheme 1).

Experimental

Calculations

Calculations at the semiempirical level of theory were carried out with AM1 of HyperChem 4.0 (22), AMPAC 2.0 (23), or MOPAC 6.0 (24), with the latter two programs running on IBM RS/6000 model 320H, 350, and 530 computers. An RMS gradient of 0.02 was used to obtain optimized geometries with HyperChem 4.0, and the keyword PRECISE was used in the case of AMPAC and MOPAC calculations to tighten the convergence criteria. Ab initio HF (25) and Becke3LYP (26) calculations were carried out with GAUSSIAN 94 (27) running on IBM RS/6000 model 350, 530, 39H, and SP2 and SGI R10000 Impact computers. Optimized geometries were shown to be minima by frequency calculations; total energies are uncorrected for zero-point energies. The semiempirical method HAM/3 (28) was used to compute the ionization potentials. The acronyms HAM/3//AM1 and HAM/3//HF/6-31G(d) indicate that HAM/3 calculations were carried out on AM1 and HF/6-31G(d) optimized equilibrium geometries, respectively. Synthetic spectra were calculated from the MO results with a FORTRAN program PESPEC (29). Spectra were synthesized from the 10 lowest IPs (HAM/3), with a Gaussian convolution of 0.4 and the temperature set at 300 K. Graphical representations of the computationally determined eigenvectors (AM1//HF/6-31G(d)) were plotted from HyperChem 4.0.

PE spectroscopic studies

The locally built PE spectrometer-CW CO_2 infrared laser apparatus (the laser is used as a directed heat source) employed in this study is described in our earlier publications (1–5). To obtain the PE spectra of the diazoacetophenones (**1a**, mp 51–52; **1b**, mp 57–58; **1c**, mp 87–88; **1d**, mp 115–116; **1e**, mp 116–117°C), which were prepared by established methods (30), a 20 mg sample was placed in a bottle-shaped quartz reaction vessel that was inserted into the tip of a heated probe. The temperature was slowly ramped up (a

maximum temperature of 80°C was used) until a suitable source pressure in the region of (3×10^{-3})–(8×10^{-3}) Torr (1 Torr = 133.3 Pa) was obtained. In the case of **1b**, **1c**, and **1d**, which exhibited low volatilities, N_2 was used as a pressure make-up gas to improve the signal to noise.[2] Consequently, vertical expansions of the spectra were required in the region of 8–15 eV.

Spectra were obtained by averaging 20–35 scans and calibrated with the 15.6 eV band of N_2. Linearity of the scale was ensured through calibrations with methyl iodide (9.54 and 10.16 eV) and O_2 (12.30 eV) performed prior to the experiments. Vertical ionization potentials are accurate to ± 0.05 eV. Pyrolyses of the diazoacetophenones were carried out in a hot zone 1–2 mm in length obtained by focusing the laser beam (power levels of 26, 42, and 47 W were used) on the tip (2–3 mm inner diameter) of the bottle-shaped quartz sample vessel. Due to the very low volatility of **1e** we were not able to obtain its spectrum and study its pyrolysis even in the presence of the pressure make-up gas. Hatched bands in the PE spectra are due to traces of H_2O (12.6 eV) and a shadow peak (13.6 eV) of N_2.

Results and discussion

Calculations

1. Conformational properties of diazoacetophenones and phenylketenes

Figure 1(*a*) shows the AM1 optimized geometrical structures of the *syn* forms of **1a**–**1e**. The gas-phase torsional potential energy surfaces of **1a**, **1b**, and **1c** were calculated with AM1 by varying the N=C—C=O and phenyl—C=O dihedral angles from 0° to 180° in 15° increments. At the AM1 level, **1a** prefers a twisted *syn* rather than an *anti* conformation of the N=C—C=O group, and the conformer with the N=C—C=O and phenyl—C=O dihedral angles fixed at 90° is the highest energy species. Because the potential energy surfaces of **1a**–**1c** exhibit very similar topologies we report only the surface obtained for diazoacetophenone (**1a**) as Fig. 2. That the surfaces of **1b** and **1c** (not shown) are virtually identical to the surface of **1a** indicates that **1a**, **1b**, and **1c** have similar conformational properties in the gas phase. That twisted *syn* conformers are

[2] Although He(I) PE spectra of **1a**, **1b**, and **1d** already have been reported by Modelli et al. (31) they are presented again for two reasons: (*i*) the spectra reported earlier contain bands of nitrogen — and along with these, bands of further products — due to decomposition of the compounds, and (*ii*) the different analyzer transmission functions of the spectrometers used in the previous and in this study lead to PE spectra that differ in intensities of the bands. As we planned to record pyrolyses spectra, knowledge of the actual appearance of the spectra of the starting compounds taken with our instrument was essential.

the low-energy structures in the cases of **1d** and **1e** as well indicates that the diazoacetophenones which are the subject of this study prefer to adopt twisted *syn* conformations in the gas phase.

At the AM1 level, the twisted *syn* isomers of **1a**–**1e** (the N=C—C=O twist angles are 4.1, 4.1, 4.3, 2.9, and 2.4°; the phenyl—C=O dihedral angles are 31.6, 30.0, 31.3, 35.9, and 38.1°, respectively) are 11.08–12.38 kJ mol^{-1} lower in energy than the twisted *anti* isomers (Table 1). The *syn* and *anti* isomers of **1a**, **1b**, and **1c** were also studied at the HF/6-31G(d) level of theory. Selected geometrical parameters are collected in Table 2, and the optimized equilibrium geometries of the *syn* isomers of **1a**–**1d** are displayed in Fig. 1(*b*). At the HF/6-31G(d) level, we find that the twisted *syn* isomers of **1a**, **1b**, and **1c** are 16.88, 17.05, and 18.02 kJ mol^{-1} lower in energy than the twisted *anti* isomers, and the N=C—C=O and phenyl—C=O twist angles are

Fig. 3. The He(I) PE spectra of (*a*) **1a**, (*b*) the pyrolysate of **1a** obtained at a laser power level of 26 W, and (*c*) the pyrolysate of **1a** obtained at a laser power level of 42 W. approximately one-half the values calculated with AM1 (Table 2). This is most likely a result of the fact that the ab initio calculations more accurately recover the stabilizing phenyl—C=O–π interaction, which would act to decrease the twist angle. When the geometries of the *syn* and *anti* isomers of **1a** were reoptimized — the geometries obtained with the default convergence limits were used as input — at the HF/6-31G(d) level of theory with the keyword TIGHT to tighten the convergence criteria, the total energies (E_Ts) obtained were identical within 10^{-6} hartree to E_Ts calculated with the default convergence limits, and the geometries differed little from the input geometries (Table 2). These results are in accord with published experimental data: 1,4-bisdiazo-2,3-butanedione adopts a bis-*syn* conformation in the solid state (32), and variable-temperature solution ^1H NMR studies in the temperature range of +30 to –40°C showed that diazoketones of the type $RCOCHN_2$ (R=H, CH_3, C_2H_5, *t*-C_4H_9, $C_6H_5CH_2$, CH_3O, and C_2H_5O) adopt *syn* and *anti* conformations with the *syn* forms being preferred (33). In the case of **1a**, **1c**, and **1e**, single stereoisomers identified as the *syn* forms were detected down to –40°C, but

N=C—C=O and phenyl—C=O twist angles were not determined (33).

Phenylketenes **2a**–**2e** are found to adopt planar conformations with AM1, in accordance with previous findings for **2a** (13). This also holds at the ab initio level, **2a**–**2e** are planar with HF/6-31G(d). The AM1 heats of formation and ab initio total energies of **2a**–**2e** are listed in Table 1. According to AM1, the 90° conformation of **2a** is destabilized by 9.04 kJ mol^{-1}.

2. Ionization potentials

We have repeatedly demonstrated that the use of calculated ionization potentials (IPs) instead of orbital energies for the interpretation of PE spectra leads to excellent correlations between theory and experiment (2–4, 6, 34). This is especially important where a good agreement between absolute energy values is needed, as is the case for highly reactive or transient species which are generated in the PE spectrometer itself. The semiempirical HAM/3 method gives IPs directly, and both semiempirical and ab initio optimized geometries can be employed. The HAM/3//AM1 and HAM/3//HF/6-31G(d) results for diazoacetophenones **1a**–**1c** are given in Table 3. Although AM1 and HF/6-31G(d) geometries for **1a**–**1c** are distinctly different, IP values from the two levels of theory differ little. We therefore report HAM/3//AM1 results only for phenylketenes **2a**–**2c**. Because HAM/3 is not parameterized for chlorine, we also use the routine we developed in previous publications (6, 34): orbital energies calculated with the hybrid HF/DFT Becke3LYP method[3] are shifted uniformly so that the

[3] The successful application of the Koopmans' theory-like (35) interpretation of orbital energies obtained at the DFT level of theory in PE spectroscopic studies of numerous compounds has been shown and commented on (6, 34, 36–38).

HOMO energy equals that of the calculated first vertical ionization potential IP_v. The IP_v is determined from the energy difference between the neutral (N electrons) and its radical cation (N – 1 electrons, geometry of the neutral) obtained using Becke3LYP/6-31+G(d)//HF/6-31G(d) (Table 4). Orbital energies and ionization potentials derived from the shift are reported in Table 3 for **1a**–**1d** and **2a**–**2d**. This level of theory is sufficient as could be concluded from virtually identical IP_vs and orbital energies of **2a**–**2d** obtained with Becke3LYP/6-31+G(d)//Becke3LYP/6-31+G(d) (not given).

Photoelectron spectroscopic studies

1. Experimental PE spectra

The spectrum of **1a** (20 mg; source pressure 2.2×10^{-3} Torr) displayed as Fig. 3(*a*) was obtained at a probe temperature of 50°C. The vertical solid lines and vertical broken lines on the spectrum correspond to the 10 lowest HAM/3//AM1 and HAM/3//HF/6-31G(d) IPs (values in Table 3), respectively, and show that the experimental spectrum of this diazoacetophenone can be reproduced nicely with HAM/3. Figure 3(*b*) is a display of the spectrum of the pyrolysate of **1a** obtained at a laser power of 26 W (~500 ± 50°C). Based on the 1:1:1 relative intensities of the bands at 8.2, 9.3, and 10.4 eV and excellent correlation between the experimental vertical IPs and the IPs of phenylketene (**2a**) calculated with HAM/3//AM1 (vertical solid lines), the conversion of **1a** to **2a** is complete at a laser power level of 26 W. The IPs for **1a** and **2a** calculated with Becke3LYP/6-31+G(d)//HF/6-31G(d) (Table 3, compare to experimental IPs in Table 5) give an equally good representation of both spectra and therefore support this. That there was no significant change in the spectrum of the pyrolysate (Fig. 3(*c*)) and no CO (it exhibits a sharp band at 14.01 eV (39)) was formed when the laser power was increased from 26 W to 42 W (~850 ± 50°C) indicates that the loss of CO from **2a** is subject to a high activation energy.[4] This observation is in keeping with the results of our previous calculational study (5). The spectrum of **2a** obtained in this study differs to

[4] A comprehensive computational study of the decomposition of **1a**, **1c**, and **1e** (loss of nitrogen) and **2a**, **2c**, and **2e** (loss of CO) as well as the rearrangement of the ketocarbenes derived from **1a**, **1c**, **1d**, and **1e** will be the subject of a following publication. As shown in Scheme 1, the pyrolyses of the diazoacetophenones are expected to proceed via the respective intermediate ketocarbenes, even though thermolysis spectra provide no evidence for this. Alternatively, extrusion of nitrogen and rearrangement could be a concerted process.

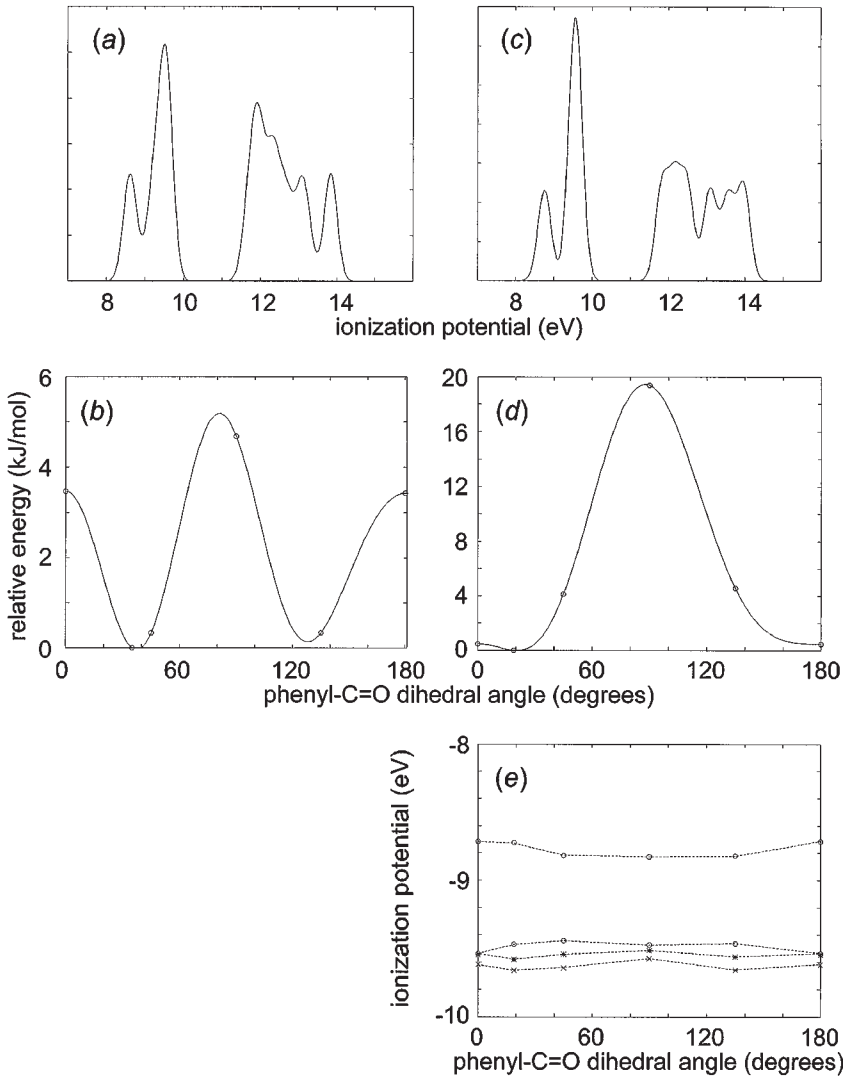
Fig. 8. (*a*) Synthetic partial PE spectrum (HAM/3//AM1), (*b*) surface for the torsion of the phenyl—C=O dihedral angle (AM1), (*c*) synthetic spectrum (HAM/3//HF/6-31G(d)), (*d*) torsional potential (HF/6-31G(d)), and (*e*) angular dependences of the four lowest HAM/3//HF/6-31G(d) IPs of **1a**.



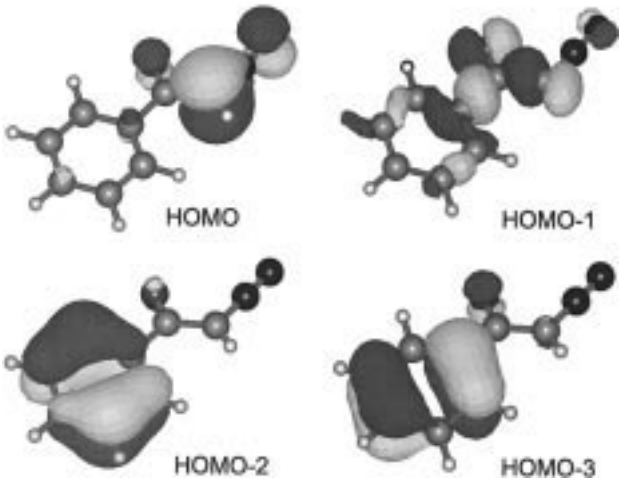
some degree from the published spectrum of phenylketene that was prepared by the zinc-induced dechlorination of 2-chloro-2-phenylacetyl chloride (13). While we find the relative areas of the first three bands to be 1:1:1 (Fig. 3(*b*)) in line with HAM/3//AM1 and Becke3LYP/6-31+G(d)//HF/6-31G(d) (Table 3) results, the relative areas of the first three bands of the previously published spectrum are approximately 1:2:1, an indication that phenylketene was not the sole product of the dechlorination reaction.

The spectrum of **1b** (20 mg; probe temperature 65°C), obtained with nitrogen added as a make-up gas to maintain the total pressure in the source at 3×10^{-3} Torr, is displayed along with the HAM/3//AM1 and HAM/3//HF/6-31G(d) IPs as Fig. 4(*a*). Again, HAM/3 values mirror experimental IPs. Figure 4(*b*) is a display of the spectrum of the pyrolysate of **1b** obtained at a laser power of 26 W and the calculated IPs of ketene **2b**. As in the case of the unsubstituted ketene **2a**, the experimental IPs in this spectrum are accurately reproduced by the computed values for **2b**, which shows that **1b** cleanly yields *p*-methylphenylketene (**2b**). The IPs for **1b** and **2b** calculated using Becke3LYP (Table 3) agree with this finding. Figure 4(*c*) displays the PE spectrum of the pyrolysate of **1b** obtained at a laser power of 47 W (>900°C). That spectra in Figs. 4(*b*) and 4(*c*) are virtually identical and no CO is formed indicates that the activation energy for decarbonylating ketene **2b**, as in the case of **2a**, is significantly higher than the activation energy for loss of nitrogen from the respective diazoacetophenones.

Figure 5(*a*) displays the PE spectrum of **1c** obtained at a probe temperature of 76°C along with its HAM/3//AM1 and HAM/3//HF/6-31G(d) IPs. As in the case of **1b**, N_2 was used as a make-up gas to maintain the source pressure at 3×10^{-3} Torr. HAM/3 once more correctly predicts the experimental spectrum. The spectra displayed as Figs. 5(*b*) and (*c*) were obtained when **1c** was pyrolyzed at laser power levels of 26 and 42 W, respectively. These spectra show that **1c** cleanly affords *p*-methoxyphenylketene (**2c**), which does not undergo pyrolysis at a nozzle-tip temperature in the region

© 1998 NRC Canada

Fig. 9. The four highest occupied molecular orbitals of **1a**.



of 850 ± 50°C. Again, HAM/3 and Becke3LYP IPs for **1c** and **2c** do not differ much, which shows the validity of our Becke3LYP approach.

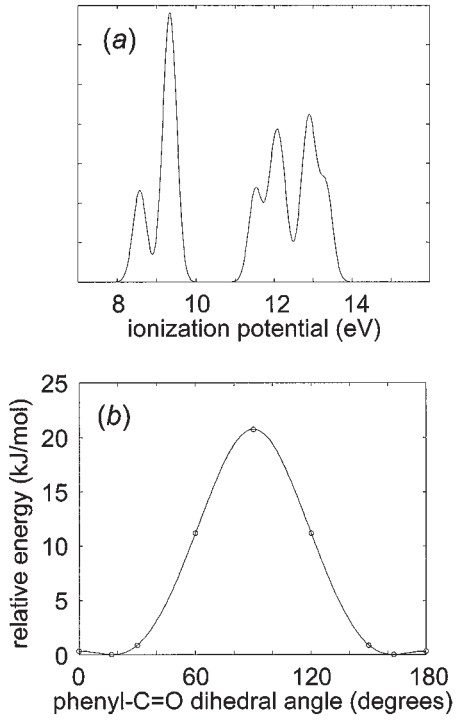
Figure 6(*a*) displays the PE spectrum of **1d** obtained at a probe temperature of 55°C with N_2 added as a make-up gas to maintain the source pressure at 3×10^{-3} Torr. Figures 6(*b*) and (*c*) display spectra of the pyrolysate of **1d** obtained at laser power levels of 26 and 42 W, respectively. As HAM/3 is not parameterized for chlorine, Figs. 6(*a*) and (*b*) include the 10 lowest ionization potentials of **1d** and **2d** as calculated with Becke3LYP/6-31+G(d)//HF/6-31G(d) and described above. As expected from the encouraging results of the pyrolyses of **1a**–**1c** with respect to this approach, the correlation between predicted spectra (vertical bars) and experimental spectra is excellent. These spectra show that **1d** yields *p*-chlorophenylketene (**2d**), which also appears to be stable at a nozzle-tip temperature in the region of 850 ± 50°C. The spectrum in Fig. 6(*c*) also exhibits a feature at 7.8 eV. A calculational study on *p*-chlorophenyloxirene, which is a second rearrangement product from the ketocarbene derived from **1d**, at the Becke3LYP/6-31+G(d)//HF/6-31G(d) level of theory established that the five lowest IPs of this compound should be 7.5, 9.6, 9.9, 11.0, and 11.7 eV. While the calculated first IP for *p*-chlorophenyloxirene is close to the first IP in the pyrolysis spectrum, at this point we cannot say with certainty whether it actually is a pyrolysis product of **1d**.[5]

The low volatility of **1e** thwarted our attempts to obtain its spectrum and study its pyrolysis. Even heating a relatively large sample (40 mg) of **1e** at 94°C near its melting point of 116°C in a 4 mm outer diameter tube inserted into the probe did not yield an acceptable spectrum. Selected experimental vertical ionization potentials of the diazoacetophenones **1a**–**1d** and the corresponding ketenes are collected in Table 5.

2. Synthesis of PE spectra

We have already demonstrated in several previous studies that PE spectra synthesized from torsional potential energy surfaces and the angle dependence of ab initio or semiempirical orbital energies as well as IPs calculated with HAM/3 using PESPEC correlate well with experimental spectra and can be used to obtain information about the conformational properties of molecules in the gas phase (29, 40–42). Additional support for this finding is seen in the excellent correlation between the experimental spectrum of phenylketene (**2a**) given in Figs. 3(*b*) and (*c*) and the synthesized spectrum displayed as Fig. 7(*a*). The synthetic spectrum of **2a** (with a Gaussian convolution of 0.4, temperature is 300 K) was obtained from the AM1 potential energy surface for the rotation of the ketene group given in Fig. 7(*b*) and the angle dependence of the 10 lowest HAM/3//AM1 ionization potentials (not shown).

Fig. 10. (*a*) Synthetic partial PE spectrum (HAM/3//HF/6-31G(d)) and (*b*) surface for the torsion of the phenyl—C=O dihedral angle (HF/6-31G(d)) of **1b**.



While Modelli et al. (31) do not offer an interpretation of the spectra of **1a**, **1b**, and **1d** with respect to orbital interactions or conformational considerations, for **1a** Vorob'ev et al. (43) report only weak π–π interactions both in the heterobutadiene group due to a large energy gap between interacting MOs and between diazo group and phenyl ring because of inefficient spatial overlap. Figure 8(*a*) is the PE spectrum of diazoacetophenone (**1a**) synthesized from the angle dependence of the HAM/3//AM1 IPs (not shown) and the AM1 potential energy surface displayed as Fig. 8(*b*) that corresponds to the 0–180° trajectory (the N=C—C=O dihedral angle is fixed at 0°) of Fig. 2. The synthetic spectrum recovers the general features of the experimental spectrum. Figure 8(*c*) is the synthetic spectrum of **1a** obtained from the

[5] While from the first IP *p*-chlorophenyloxirene is a likely candidate, it will only be present in the pyrolysis gas mixture if there is a reasonable barrier to the reverse reaction, the ring opening of the three-membered ring to give the ketocarbene. Calculations for the rearrangement of ketocarbenes derived from diazoacetophenones **1a**, **1c**, and **1e** to the corresponding oxirenes have shown no significant barrier.[4]

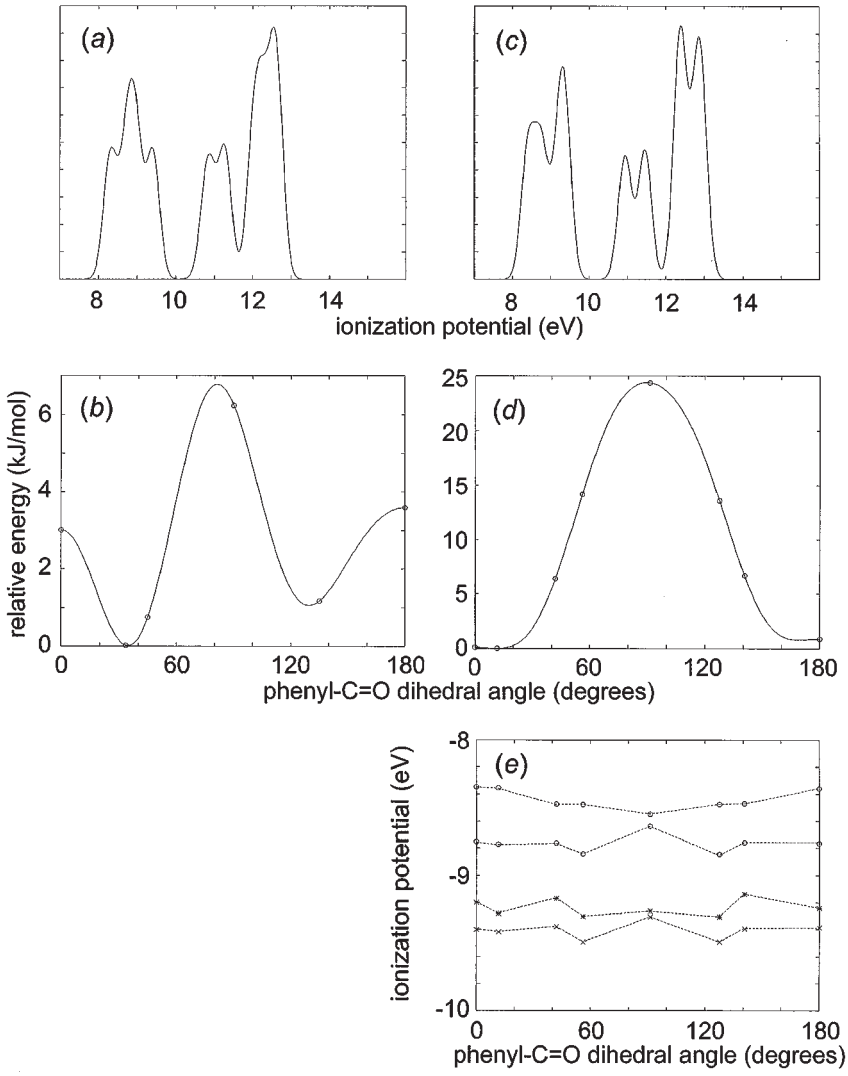
Fig. 11. (*a*) Synthetic partial PE spectrum (HAM/3//AM1), (*b*) surface for the torsion of the phenyl—C=O dihedral angle (AM1), (*c*) synthetic spectrum (HAM/3//HF/6-31G(d)), (*d*) torsional potential (HF/6-31G(d)), and (*e*) angular dependences of the four lowest HAM/3//HF/6-31G(d) IPs of **1c**.



HF/6-31G(d) torsional potential (Fig. 8(*d*)) and the angular dependence of 10 HAM/3//HF/6-31G(d) IPs of which four are displayed in Fig. 8(*e*). Even though the rotational barrier at this level of theory is substantially higher than the AM1 barrier and the twisted *syn* conformer is only marginally lower in energy than the planar structure, the synthetic spectrum closely resembles the one obtained from the AM1 potential energy surface. This result derives from the fact that the low-energy IPs show a low sensitivity to the twist angle in both cases, as can be seen in Fig. 8(*e*). An explanation for this is given by the corresponding molecular orbitals (Fig. 9), which show that phenyl and diazoketo groups are present as separate units that do not interact at this energy level, a fact that was hinted at by Vorob'ev et al. (43). According to Becke3LYP/6-31+G(d)//HF/6-31G(d),[6] the HOMO is a π-type orbital with coefficients mainly on the diazo group ($\pi_{C=N}$), HOMO – 1 is a σ-type orbital, which represents an oxygen lone pair (n_O), and HOMO – 2 and HOMO – 3 are mostly phenyl π-type MOs (π) with small coefficients on the oxygen atom. This orbital sequence is in accord with the one given by Modelli et al. (31), while Vorob'ev et al. (43) give $\pi_{C=N} > \pi > n_O > \pi$ from MNDO calculations. Thus in **1a**, which can be considered to be the parent of this class of compounds, the low lying occupied MOs of the carbonyl group effectively function as an insulator for phenyl and diazo moieties.

Figure 10(*a*) displays the synthetic spectrum of **1b** obtained from the torsional potential obtained at the HF/6-

[6] Even though there is "no physical relevance" to Kohn–Sham orbitals, we have found eigenvectors obtained at the Becke3LYP/6-31+G(d)//HF/6-31G(d) level of theory to be similar to those computed with HF/6-31G(d)//HF/6-31G(d) or AM1//HF/6-31G(d). Yet for a number of diazoketones and diazo acyl esters containing an aromatic ring the predicted orbital sequence differs at the above-mentioned levels of theory. In a following paper (44) we will show that in these cases the orbital sequence as determined with the Becke3LYP method should be taken. For this reason, the orbitals displayed in Fig. 9 are arranged according to the Becke3LYP/6-31+G(d)//HF/6-31G(d) calculated sequence.

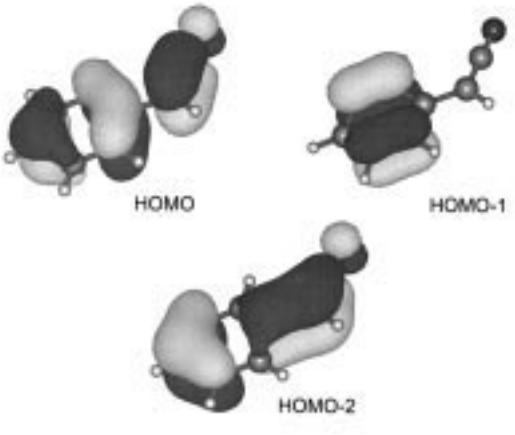
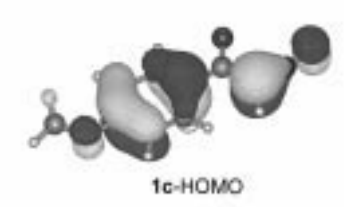
Fig. 12. The three highest occupied molecular orbitals of **2a**.



31G(d) level (Fig. 10(*b*)) and the HAM/3//HF/6-31G(d) IPs (not shown). The torsional dependence of the IPs as well as the corresponding molecular orbitals are similar to what we found for **1a**. On the whole, the general features of the experimental spectrum are reproduced in the synthethic spectrum with reasonable accuracy even though there is baseline separation of one band from three overlapping bands. Figure 11(*a*) is the synthetic spectrum of **1c** obtained from the AM1 potential energy surface shown as Fig. 11(*b*). While the general features of band structure correlate with the PE spectrum, the relative intensities of the peaks of the low-IP band are at variance with the experimental data. On the other hand, the synthetic spectrum of **1c (**Fig. 11(*c*)) obtained from the HF/6-31G(d) torsional potential (Fig. 11(*d*)) and the angular dependence of 10 HAM/3//HF/6-31G(d) ionization potentials of which four are displayed in Fig. 11(*e*) closely resembles the experimental spectrum. In contrast to **1a** and **1b**, the HOMO of **1c** is a phenyl π-type orbital that is raised in energy above the $\pi_{C=N}$ because of a substantial coefficent on the methoxy oxygen atom. This antibonding combination (π^-) is followed by $\pi_{C=N}$, n_O, π, and the corresponding bonding combination (π^+). As a consequence of this change in orbital sequence a phenyl π-type orbital (π^-) and the $\pi_{C=N}$ are closer in energy in **1c** than the respective orbitals in **1a**, which results in electron density on the diazo group being mixed into the HOMO of **1c**. Despite the presence of electron density on diazo group and aromatic ring, it is clear from Fig. 11(*e*) that the rotation of the ring does not affect the HOMO energy significantly, which again shows the insulating effect of the low-lying carbonyl orbitals. Our study shows that when compared to spectra synthesized on the basis of torsional potentials obtained at the HF/6-31G(d) level, experimental PE spectra provide support that diazoacetophenones **1a**–**1d** prefer twisted *syn* conformations in the gas phase.



Substituent effects on ionization potentials of phenylketenes

Figure 12 displays the HOMO, HOMO – 1, and HOMO – 2 of phenylketene (**2a**) obtained at the AM1//HF/6-31G(d) level. The HOMO is a π-type MO characterized by substantial antibonding mixing of the ketene and phenyl π systems, with the latter exhibiting a large p_z coefficient at C-4. The HOMO – 1 is a pure phenyl π-type MO, which does not mix with the ketene π system and which has no p_z component at C-4. The HOMO – 2 is the bonding π-type MO that, like the HOMO, has contributions from the ketene and phenyl groups. Nevertheless, it has a larger p_z coefficient at C-4 than the HOMO. The nature of these frontier MOs indicates that the HOMO and HOMO – 2 should be affected more strongly than HOMO – 1 by *para*-substituents, which interact with the phenyl ring via π conjugation. That this is the case is seen in the PE spectra of **2a** (Figs. 3(*b*) and (*c*)), **2b** (Figs. 4(*b*) and (*c*)), and **2c** (Figs. 5(*b*) and (*c*)), and the data in Table 5, which clearly show that HOMO and HOMO – 2 are destabilized by the introduction of π donors at C-4. That HOMO – 2 appears to be more sensitive to substitution at C-4 is a consequence of the size of the p_z component at C-4 and its proximity in energy to the other filled orbitals of lower energy with which it interacts.

Conclusions

The gas-phase thermolysis of diazoacetophenones **1a**–**1d** at a laser power level of 26 W (500 ± 50°C) gave the corresponding phenylketenes **2a**–**2d**, which do not decompose at higher laser power levels. A comparison of our PE spectrum of **2a** with the one published earlier indicates that the sample prepared in the previous study was impure. The low volatility of **1e** made the recording of its PE spectrum and the generation of **2e** impossible. According to AM1 and HF/6-31G(d) calculations, diazoacetophenones prefer twisted *syn* conformations in the gas phase. This is supported by excellent correlations between calculated ionization potentials of **1a**–**1d** at the HAM/3 and Becke3LYP/6-31+G(d)//HF/6-31G(d) levels of theory as well as simulated PE spectra of **1a**–**1c** and experimental spectra.

A new diaza heteroaromatic crown of 3,5-disubstituted 1*H*-pyrazole which forms solid dinuclear complexes with lipophilic phenethylamines

Ana M. Sanz, Pilar Navarro, Fernando Gomez-Contreras, Mercedes Pardo, Gèrard Pèpe, and André Samat

Abstract: The cyclic stannoxane obtained from *N*-methyldiethanolamine and dibutyltin oxide reacts with 1*H*-pyrazole-3,5-dicarbonyl dichloride to afford the new 26-membered diaza tetraester crown **3**. In neutral medium, the above crown forms 1:2 solid dinuclear complexes with phenethylamine (**3a**) and homoveratrylamine (**3b**), which, after crystallization from acetonitrile, were isolated in high yield (90% and 85%, respectively). The **3**, **3a**, and **3b** structures were identified from their analytical and spectroscopic (^{1}H, ^{13}C NMR, and MS (FAB)) data. The spectroscopic properties of **3a** and **3b** are demonstrating that, in each complexation centre, simultaneously to the strong participation of the four pyrazole nitrogens, an additional weaker interaction between the aliphatic nitrogen of the side chain and the amine is involved. Comparison of the total interaction energies calculated (GenMol software) for phenethylamine-derived complex (**3a**) and homoveratrylamine-derived one (**3b**) suggests that the *o*-dimethoxy substitution of the guest aromatic ring could be improving the stability of **3b** in relation to **3a**.

Key words: diazacrown, 1*H*-pyrazole, dinuclear, complexes, phenethylamines.

Résumé : Le stannoxane cyclique obtenu à partir du *N*-méthyldiéthanolamine et de l'oxyde de dibutylétain réagit avec le dichlorure de 1*H*-pyrazole-3,5-dicarbonyle pour conduire à un nouvel éther diazacouronne tétraester à 26 chaînons (**3**). En milieu neutre, cette couronne forme des complexes dinucléaires solide 1:2 avec la phénéthylamine (**3a**) et l'homovératrylamine (**3b**) qui ont été isolés avec d'excellents rendements (90 et 85% respectivement) après cristallisation dans l'acétonitrile. On a identifié les structures **3**, **3a** et **3b** à partir de leurs données analytiques et spectroscopiques (RMN du ^{1}H et du ^{13}C et SM (FAB)). Les propriétés spectroscopiques des composés **3a** et **3b** démontrent que, pour chaque centre de complexation, en plus de la forte participation des quatre azotes des pyrazoles, il existe une faible interaction entre l'azote aliphatique de la chaîne latérale et celui de l'amine. Une comparaison des énergies totales d'interaction (calculées à l'aide du programme GenMol) des complexes dérivés de la phénéthylamine (**3a**) et de l'homovératrylamine (**3b**) suggère que le substituant *o*-diméthoxy du noyau aromatique de l'invité améliore la stabilité du composé **3b** par rapport à **3a**.

Mots clés : diazacouronne, 1*H*-pyrazole, dinucléaire, complexes, phénéthylamines.

[Traduit par la Rédaction]

Introduction

One of the two main categories of psychedelic drugs that produce perceptual distortions (hallucinations, illusions, and disorders of thinking such as paranoia) are hallucinogen phenethylamines methoxy and (or) methylenedioxy substituted at the aromatic ring (1).

The selective complexation of such hallucinogen substrates by adequately arranged synthetic receptors, in relation to neurotransmitter catecholamines, is an important but difficult target due to the similarity of their structures. Thus, dopamine and norepinephrine, involved in the normal emotional and autonomic control of humans, have in common a hydrophilic 3,4-dihydroxyphenethylamine nucleus, while its 3,4-dimethoxy substituted analogue (homoveratrylamine) of higher lipophilic character shows hallucinogen effects (2).

It is well known that synthetic oxaaza and polyaza macrocycles containing a trigonal symmetrical arrangement of NH binding sites are able to selectively complex ammonium and catecholammonium ions (3). In this way, we have previously synthesized and studied the transport properties of different series of synthetic heteroaromatic receptors

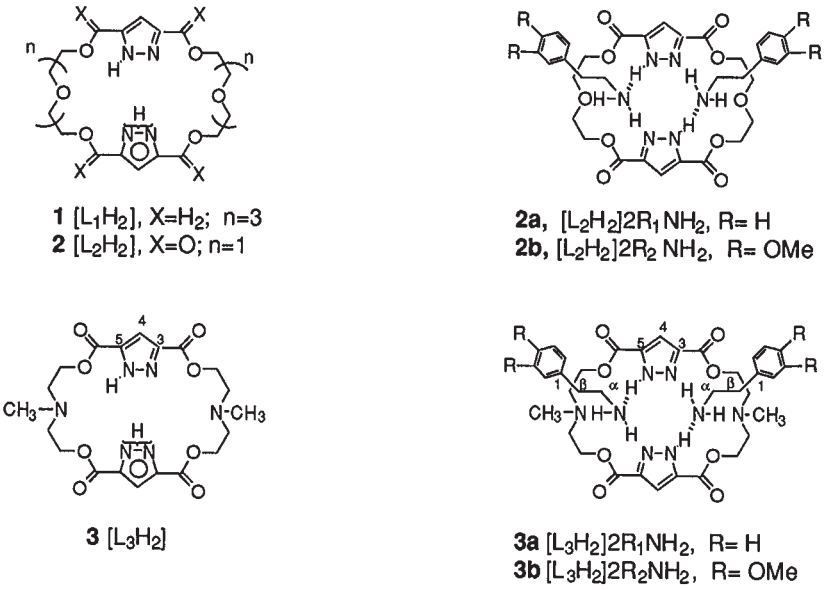
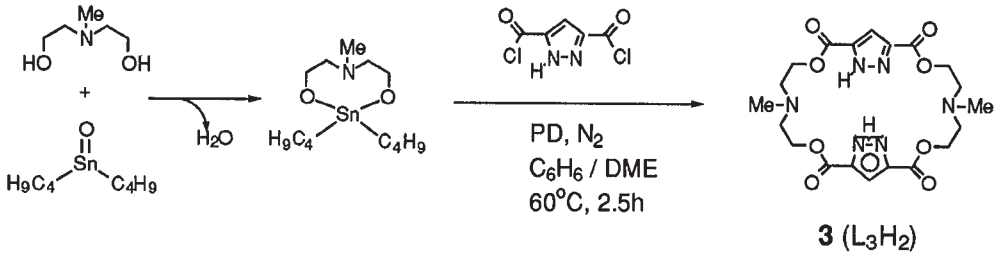
Fig. 1.



Scheme 1.



containing one to three 1,3,5- or 3,5-substituted pyrazole units (4). As the result of the above studies, we discovered a dinuclear receptor of 1*H*- pyrazole of similar size to that of valinomycin (36-membered) **1** [L_1H_2] (X = H_2; *n* = 3) (Fig. 1), which behaves as an effective and selective carrier of NH_4^+ (5). Furthermore, it has been recently discovered that such crown is able to form dinuclear complexes with lipophilic phenethylamine R-NH_3^+ ions of higher stability than those formed with those of hydrophilic phenethylamines.[2]

On the other side, we have also synthesized an analogous dinuclear receptor of 1*H*- pyrazole **2** [L_2H_2] of smaller size (26-membered), which strongly interacts with neutral lipophilic R-NH_2 phenethylamines, affording dinuclear complexes **2a** R = H; phenethylamine) and **2b** R = OMe;

homoveratrylamine), which were isolated in the solid state (6). Besides, the theoretical calculations (GenMol software) together with a careful ^{1}H and ^{13}C NMR study has recently demonstrated that in both complexes, the two sp^2 pyrazole nitrogens and the two N*H* pyrazole protons are involved in the complexation of the two guest amine molecules, affording a molecular association mainly stabilized by symmetrical hydrogen bonds (7), while other hydrogen bonds with ether oxygens belonging to the receptor side chains were discarded.

Considering the strong insoluble character of the above dioxa substituted coronand **2**, and taking into account that N···HN hydrogen bonds are more effective than O···HN ones, in this paper we have synthesized a more convenient diazatetraester crown of 1*H*-pyrazole **3**, [L_3H_2], which is soluble in common lipophilic organic solvents. This new diazacoronand is containing a double trigonal symmetrical arrangement of NH binding sites in which the two basic nitrogens incorporated to the side chains are improving the complexing properties of **3** toward phenethylamine and homoveratrylamine.

Results and discussion

The synthesis of the **3** has been achieved as depicted in Scheme 1.

N-Methyldiethanolamine was heated to reflux in benzene with dibutyltin oxide to give the corresponding cyclic stannoxane (8), which was reacted with 1*H*-pyrazole-3,5-dicarbonyl dichloride to afford crown **3** (mp 190–192°C; $C_{20}H_{26}N_6O_8 \cdot 2H_2O$; MH^+ 479) in a 10% overall yield.

In the FAB mass spectrum of the diaza tetraester crown **3**, the expected molecular ion MH^+ corresponds to the base peak (*m/z* 479, 100%). From MH^+, the fragmentation is mainly governed by usual ruptures of amine and ester bonds,

responsible for sequential losses of a = C_3H_7N (57) and b = C_5H_9N (83) fragments belonging to the host flexible chain, as well as c = $C_5H_2N_2O_2$ (122) and d = $C_5H_2N_2O_3$ (138) fragments corresponding to the losses of one of the two diceto pyrazolo moieties. Furthermore, as usually occurs with tetraester and polyether crowns of dimmer structure (5), from M^+ other important decompositions give rise to the characteristic $(M/2 + H)^+$ species (m/z 240, 7%).

The complexing ability of crown **3** [L_3H_2] was tested by stirring for 15 min with phenethylamine or homoveratrylamine in a 1:2 molar ratio using chloroform as solvent. In both cases, after concentration, the diaza substituted complexes were isolated as white solids and crystallized from acetonitrile. Their analytical and spectroscopic data were consistent with neutral dinuclear complexes **3a** (mp 140–142°C; $C_{36}H_{48}N_8O_8 \cdot 3H_2O$; $MH^+ - C_3H_7N$ 664) and **3b** (mp 170–172°C; $C_{40}H_{56}N_8O_{12} \cdot H_2O$; $MH^+ - C_3H_7N$ 684), which were obtained in 90% and 85% yield, respectively (Fig. 1).

The FAB mass spectra of both dinuclear complexes are clearly demonstrating the strong interaction of the two amino groups with both pyrazole rings. The phenethylamine complex **3a** shows a pattern in which two a = C_3H_7N (57), b = C_4H_9N (71), or c = $C_5H_{11}N$ (85) fragments belonging to the host flexible side chain, as well as two d = C_6H_5 (77) aromatic fragments belonging to the amine guest, are simultaneously lost giving up a series of peaks of m/z: 606 ($M^+ - 2(C_3H_7N)$) (0.1); 578 ($M^+ - 2(C_4H_9N)$) (1.9); 567 ($MH^+ - 2(C_6H_5)$) (0.6); 551 ($MH^+ - 2(C_5H_{11}N)$) (11.0); 550 ($M^+ - 2(C_5H_{11}N)$) (26.3). In a similar way, the homoveratrylamine complex **3b** show a pattern in which one or two host flexible side chain fragments (a = C_3H_7N (57); b = C_4H_9N (71); c = $C_5H_{10}N$ (84); and d = $C_5H_{11}NO_2$ (117)) and one or two homoveratrylamine fragments (e = $C_8H_9O_2$ (137) and f = $C_8H_9O_2$ (138)) are successively or simultaneously lost from the $MH^+(H_2O)$, $M^+(H_2O)$, MH^+, and M^+ molecular ions, affording different series of peaks of m/z: 801 ($M^+(H_2O) - C_3H_7N$) (0.2); 744 ($M^+(H_2O) - 2(C_3H_7N)$) (0.2); 788 ($MH^+(H_2O) - C_4H_9N$) (0.2); 716 ($MH^+(H_2O) - 2(C_4H_9N)$) (0.1); 703 ($M^+ - C_8H_9O_2$) (0.5); 566 ($M^+ - 2(C_8H_9O_2)$) (0.5); 606 ($M^+ - 2(C_5H_{11}NO_2)$) (0.1); 565 ($M^+ - (C_8H_9O_2) - (C_8H_{10}O_2)$) (0.46); 373 ($MH^+ - 2\ (C_5H_{10}N) - 2(C_9H_{10}O_2)$) (11.0).

As could be expected in the formation of strong NH···N hydrogen bonds (9), in the ^1H NMR spectra of **3a** and **3b** registered in Cl_3CD, the complexation strongly affects the amine RNH···N= signals, which are deshielded by 3.55 and 3.07 ppm in relation to the free phenethylamine and homoveratrylamine respectively.

Comparison of the ^{13}C NMR spectral data of these complexes with those corresponding to the free guests and host (Table 1) affords some relevant structural information. The two methylene carbons closer to the complexation centre, as well as the *ipso* aromatic carbons of the guest amines experience considerable upfield shifts, which are larger for the β than for the α and C_1-Ar carbons (Table 1*a*). This behaviour agree with a reduction of electronic density at the sp^3 nitrogen, which takes place when the complex is formed (10). Furthermore, it may be noted that shieldings measured are much higher for homoveratrylamine (Δδ **3b**-Ho) than for phenethylamine (Δδ **3a**-Ph).

On the other hand, the comparison of the ^{13}C NMR data of **3a** and **3b** and those of the free host **3** (Table 1*b*) shows that the signals belonging to the pyrazole ring undergo in both complexes chemical shifts to downfield carbons C(3,5) and highfield carbons C(4), which are much more smaller but of identical sign to those previously observed in the formation of dipyrazolate anions by deprotonation of 26-membered dinuclear 1*H*-pyrazole macrocycles (6*b*). Furthermore, the pyrazole carbons C(3,5), which in **3** appear as a broad signal due to the pyrazole prototropic equilibrium, collapse after complexation to a sharp singlet. As it was previously observed from dioxa tetraester crown-derived complexes(7), the above behaviour confirms that in complexes **3a** and **3b**, the NH pyrazole protons are not ambigously located but fastened to the guest amines. The above situation agrees with a molecular association mainly stabilized by symmetric RN·HN(Pz) and RNH···N=(Pz) hydrogen bonds. On the other hand, taking as reference the basic nitrogens located in middle of the host flexible side chains, it can be observed that after complexation, the β methylene carbons (CH_2O) as well as the a methyl ones (MeN) experience in both complexes upfield shifts, which suggest an additional interaction between the sp^3 nitrogens and the guest amines.

Theoretical approach of the stability of diaza tetraester crown-derived complexes 3a and 3b

The stability of the complexes has been evaluated using molecular modelling GenMol software (11). This program based on molecular mechanics calculations is designed to build molecules and to find their preferred conformations (12). It also allows to model molecular interactions and to find the minimum energy of complex molecular systems (13).

We have previously shown that, for dinuclear complexes obtained from the dioxa tetraester crown **2** [L_2H_2] with phenethylamine (**2a**) and homoveratrylamine (**2b**), *syn*- conformations (both amines on the same face of the crown) were more stable than the *anti*-conformations (amines on the opposite faces of the crown) (7).

Now, starting from the *syn*-conformation of the diaza tetraester crown **3** [L_3H_2], we have calculated the interaction energy between the host (crown) and the guest (both

© 1998 NRC Canada

Table 2. Relative stability of dinuclear cyclic complexes **3a** and **3b** modelled from diaza substituted coronand **3**. (E_I, E_H, E_{vdw}, E_C are, respectively, the interaction, hydrogen bond, van der Waals, and coulombic energies (kcal mol^{-1}).)

Compound	E_I	E_H	E_{vdw}	E_C
3a (Ph)	–18.4	–5.3	–13.2	–0.01
3b (Ho)	–22.1	–5.8	–16.2	–0.12

molecules of amine), which is directly connected to the association constants.

In Table 2 are reported the interaction energies (E_I, kcal mol^{-1}) and the hydrogen bond energies (E_H, kcal mol^{-1}) corresponding to the new dinuclear complexes obtained from the diaza substituted receptor **3** [L_3H_2] with phenethylamine (**3a**) and homoveratrylamine (**3b**).

The value E_I is the sum of classic nonbond interactions occurring between the crown and the amines:

$$E_I = E_{vdw} + E_C + E_H$$

in which E_{vdw}, E_c, and E_H are, respectively, van der Waals, coulombic, and hydrogen bond energies. The more E_I is negative, the more the complex is stable.

Regarding the geometries of the most stable complexes obtained for **3a** and **3b** it seems that hydrogen bonds exist really between the guest amine nitrogen atoms and the host pyrazole nitrogen ones (the distance is close to 2.9 Å), while the distances with nitrogen atoms of the NMe groups (3.2 Å) may correspond to weaker hydrogen bonds.

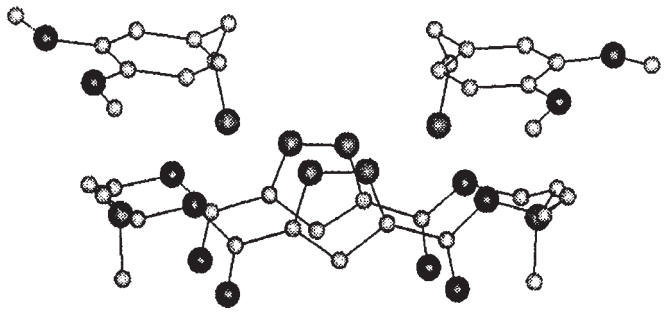
Comparison of the total interaction energies suggest that the theoretical stability of the homoveratrylamine complex **3b** is higher than that of the phenethylamine **3a**. Detail of the interaction energies (Table 2) shows that this increase is due at once to hydrogen bonding and van der Waals type interactions.

The more stable conformations of the diaza tetraester crown-derived homoveratrylamine complex **3b** is shown in Fig. 2.

Conclusions

(*i*) The synthesis of a new proton ionizable ester crown **3** (mp 190–92°C) has been performed in 10% yield by direct cyclization of 1*H*-pyrazole-3,5 dicarbonyl dichloride and 2,2-dibutyl-6-methyl-6-aza-1,3-dioxa-2-stannocyclooctane. (*ii*) Using chloroform as solvent, the reaction of crown **3** with phenethylamine and homoveratrylamine (molar ratio 1:2) affords solid dinuclear complexes, which after being crystallized from acetonitrile were obtained in high yield (**3a**, mp 140–142°C, 90%; **3b**, mp 170–72°C, 85%). (*iii*) The structure of the new compounds **3**, **3a**, and **3b** have been identified from their analytical and spectroscopic (FAB MS, IR, ^{1}H, and ^{13}C NMR) data. (*iv*) The ^{13}C NMR study is demonstrating that, in the new diaza substituted complexes **3a** and **3b**, simultaneously to a strong molecular association through NH···N=(Pz) and N·HN(Pz) hydrogen bonds, an additional weaker interaction between the host sp^3 nitrogens and the guest amines is contributing to the formation of these new solid complexes. (*v*) Comparison of the total interaction energies calculated for phenethylamine-derived

Fig. 2.



complexes (**3a**) and homoveratrylamine-derived ones (**3b**) is suggesting that the *o*-dimethoxy substitution of the guest aromatic ring could be improving the stability of **3b** in relation to **3a**. Now, work is in progress in order to evaluate the experimental stability constants of phenethylamine and homoveratrylamine dinuclear complexes **2a**, **2b** and **3a**, **3b**, as well as those formed from mescaline, amphetamine, and neurotransmitter catecholamines (dopamine and norepinephrine).

Experimental section

The IR spectra were recorded in KBr, and the NMR spectra in $CDCl_3$ solution, taking Me_4Si as internal reference. Analytical TLC and flash column chromatography were performed using silica gel 60 PF254 (Merck) and silica gel (Merck), 200–400 mesh, respectively. All reagents were of commercial quality from freshly opened containers. Thionyl chloride (Scharlau) was freshly purified prior to use as follows: distilled from quinoline (to remove acid impurities) followed by distillation from boiled linseed oil under argon. Pyrazole-3,5-dicarboxylic acid monohydrate (Aldrich), *N*-methyldiethanolamine (Aldrich), dibutyltin oxide (Merck), homoveratrylamine (Aldrich), phenethylamine (Aldrich), and reagent quality solvents were used without further purification.

1*H*-Pyrazole-3,5-dicarbonyl dichloride

Thionyl chloride freshly purified (350 mL) was slowly added to 1*H*-pyrazole-3,5-dicarboxylic acid monohydrate (2 g, 11.49 mmol) by stirring and heating until all the acid was completely dissolved. Then, the temperature was allowed to 140°C over 2 h. The hot reaction mixture was filtered, and the resulting solution evaporated to dryness to give the title compound (2 g, 10.3 mmol) as a white solid (mp 72–74°C) in 93% yield.

2,2-Dibutyl-6-methyl-6-aza-1,3-dioxa-2-stannocyclooctane (8)

To a solution of *N*-methyl diethanolamine (1.36 g, 11.46 mmol) in benzene (200 mL), solid dibutyltin oxide (2.85 g, 11.49 mmol) was slowly added. The reaction mixture was refluxed for 2 h, and the water formed in the cyclocondensation was removed by azeotropic distillation. The resulting suspension was diluted into dry toluene (260 mL) and collected to be used in the following step.

© 1998 NRC Canada

6,18-Dimethyl-25(26),27(28)-*H*,*H*-3,9,15,21-tetraoxa-6,18,25,26,27,28-hexaazatricycle[21.2.1.2^{11,13}]-octacosa-1(26),13(28),11,23-tetraen-2,10,14,22-tetraone 3

The suspension obtained above was heated to 60°C under nitrogen, and a solution of pyrazole-3,5-dicarbonyl chloride (21 g, 11.46 mmol) in dry dimethoxyethane (80 mL) was added dropwise. The reaction mixture was kept at 60°C under nitrogen for 24 h. After that, the solvent was removed in vacuo to give a syrup that was purified by flash column chromatography, eluting with an ethyl acetate – ethanol – ammonium hydroxide (5:1:0.15 v/v) mixture. From the fraction of R_f = 0.36, compound **3** was isolated as a pure solid compound (mp 190–92°C) in 10% yield. IR (KBr, cm^{-1}): 3360, 2950, 1725, 1750, 1600, 1250, 1000, 760. ^{1}H NMR (300 MHz, Cl_3CD (after treated with D_2O)), δ (ppm): 7.36 (s, 2H, Pz-H), 4.48 (t, 8H, $COOCH_2$), 2.79 (t, 8H, C*H*$_2$-NMe), 2.42 (s, 6H, MeN). MS (FAB): 479 (MH^+) (100), 435 ($MH^+ - C_2H_4O$) (1.0), 422 ($MH^+ - C_3H_7N$) (3.0), 396 ($MH^+ - C_5H_9N$) (5.2), 359 ($MH^+ - C_5H_2N_2O_2$) (2.0), 341($MH^+ - C_5H_2N_2O_3$) (8.0), 240 ($M^+/2 + 1$) (7.0), 139 $(C_5H_3N_2O_3)^+$ (5.4), 122 $(C_5H_3N_2O_2)^+$ (5.4). Anal. calcd. for $C_{20}H_{26}N_6O_8\cdot 2H_2O$: C 46.69, H 5.83, N 16.34; found: C 46.36, H 5.42, N 16.69.

Cyclic dinuclear complex 3a

Crown **3** (18 mg, 0.037 mmol) was dissolved at rt in chloroform (5 mL), and a solution of phenethylamine (9.11 mg, 0.075 mmol) in chloroform (2 mL) was added dropwise under stirring. After that, the solvent was removed in vacuo to give a residue, which was crystallized from acetonitrile, affording the pure dinuclear complex **3a** as a white solid (mp 140–142°C) in 90% yield. IR (KBr, cm^{-1}): 3400–3100, 1720, 1630, 1265, 1220, 1035, 795, 760. ^{1}H NMR (300 MHz, Cl_3CD), δ (ppm): 7.31 (s, 2H, Pz-H), 4.40 (m, 8H, $COOCH_2$), 2.70 (m, 8H, C*H*$_2$-NMe), 2.31 (s, 6H, MeN), 4.70 (brs, 6H, NH), 3.00 (t, 4H, C*H*$_2$-NH_2), 2.80 (t, 4H, C*H*$_2$-C_6H_5), 7.18 (m, 10H, C_6H_5). MS (FAB): 664 ($MH^+ - C_3H_7N$) (0.1), 663 ($M^+ - C_3H_7N$) (0.2), 606 ($M^+ - 2(C_3H_7N)$) (0.1), 600 ($MH^+ - C_8H_{11}N$) (0.8), 578 ($M^+ - 2(C_4H_9N)$) (1.9), 567 ($MH^+ - 2(C_6H_5)$) (0.6), 551 ($MH^+ - 2(C_5H_{11}N)$) (11.0), 550 ($M^+ - 2(C_5H_{11}N)$) (26.3), 479 ($MH^+ - 2(C_8H_{11}N)$) (63.0), 122 $(C_5H_2N_2O_2)^+$ (100), 121 $(C_8H_{11}N)^+$ (14.0), 77 $(C_6H_5)^+$ (31.0), 85 $(C_5H_{11}N)^+$ (8.0), 71 $(C_4H_9N)^+$ (14.0), 57 $(C_3H_7N)^+$ (31.0). Anal. calcd. for $C_{36}H_{48}N_8O_8\cdot 3H_2O$: C 55.81, H 7.02, N 14.47; found: C 56.12, H 6.62, N 14.32.

Free phenethylamine; ^{1}H NMR (300 MHz, Cl_3CD), δ (ppm): 1.13 (brs, 2H, NH), 2.94 (t, 2H, C*H*$_2$$NH_2$), 2.72 (t, 2H, C*H*$_2$$C_6H_5$), 7.15 (m, 5H, C_6H_5).

Cyclic dinuclear complex 3b

Crown **3** (18 mg, 0.037 mmol) was dissolved at rt in chloroform (5 mL), and a solution of homoveratrylamine (13.63 mg, 0.075 mmol) in chloroform (2 mL) was added dropwise under stirring. After that, the solvent was removed in vacuo to give a residue, which was crystallized from acetonitrile, affording the pure complex **3b** in 85% yield as a white solid (mp 170–172°C). IR (KBr, cm^{-1}): 3480–3200, 2920, 1720, 1635, 1260, 1235, 1035, 785, 760. ^{1}H NMR (300 MHz, Cl_3CD), δ (ppm): 7.37 (s, 2H, Pz-H), 4.47 (m, 8H, $COOCH_2$), 2.78 (m, 8H, C*H*$_2$-NMe), 2.38 (s, 6H, MeN), 6.78 (brs, 6H, NH), 3.04 (t, 4H, C*H*$_2$-NH_2), 2.80 (t, 4H, C*H*$_2$-$C_6H_3(OMe)_2$), 6.76 (m, 6H, $C_6H_3(OMe)_2$), 3.87 (s, 6H, MeO), 3.85 (s, 6H, MeO). MS (FAB): 801 ($M^+(H_2O) - C_3H_7N$)) (0.2); 788 ($MH^+(H_2O) - (C_4H_9N)$) (0.2), 684 ($MH^+ - (C_3H_7N)$) (0.1), 744 ($M^+(H_2O) - 2(C_3H_7N)$) (0.2), 716 ($M^+(H_2O) - 2(C_4H_9N)$) (0.1), 703 ($M^+ - (C_8H_9O_2)$) (0.5), 702 ($M^+ - (C_8H_{10}O_2)$) (1.0), 660 ($MH^+ - (C_{10}H_{15}NO_2)$) (0.3), 606 ($M^+ - 2(C_5H_{11}NO_2)$) (0.1), 566 ($M^+ - 2(C_8H_9O_2)$) (0.5); 565 ($M^+ - (C_8H_9O_2) - (C_8H_{10}O_2)$) (0.5), 551 ($M^+ - (C_8H_{10}O_2) - (C_9H_{11}O_2)$) (8.0), 550 ($M^+ - (C_8H_{10}O_2) - (C_9H_{11}O_2)$) (18.0), 479 ($MH^+ - 2(C_{10}H_{15}NO_2)$) (39.0), 373 ($MH^+ - 2(C_9H_{10}O_2) - 2(C_5H_{10}N)$) (11.0), 181 $(C_{10}H_{15}NO_2)^+$ (9.0), 165 $(C_{10}H_{13}O_2)^+$ (66.0), 164 $(C_{10}H_{12}O_2)^+$ (31.0), 150 $(C_9H_{10}O_2)^+$ (11.0), 151 $(C_9H_{11}O_2)^+$ (21.0), 138 $(C_8H_{10}O_2)^+$ (17.0), 137 $(C_8H_9O_2)^+$ (31.0), 117 $(C_5H_{11}NO_2)^+$ (9.0), 73 $(C_4H_{11}N)^+$ (100%), 71 $(C_4H_9N)^+$ (36.0), 57 $(C_3H_7N)^+$ (70.0). Anal. calcd. for $C_{40}H_{56}N_8O_{12}\cdot H_2O$: C 55.94, H 6.75, N 13.05; found: C 56.33, H 6.49, N 12.94.

Free homoveratrylamine; ^{1}H NMR (300 MHz, Cl_3CD), δ (ppm): 1.38 (brs, 2H, NH), 2.92 (t, 2H, C*H*$_2$$NH_2$), 2.66 (t, 2H, C*H*$_2$$C_6H_3(OMe)_2$), 6.75 (m, 3H, $C_6H_3(OMe)_2$), 3.85 (s, 3H, OMe), 3.83, (s, 3H, OMe).

Molecular modelling

GenMol (11) is a molecular mechanics software including some specificities, able to treat atomic and molecular systems till 10^5 atoms of 96 types: (*i*) The program uses local stretching and bending parameters, which depend not only on the chemical neighbourhood (nature of the bonded atoms, which is the case in all molecular mechanic programs), but also of the geometrical neighbourhood. This concept allows to win an order of magnitude in the geometry accuracy if compared to X-ray data. (*ii*) An original algorithm deforming the molecule by rotation around the bonds, and based on empirical rules deduced from X-ray observations, allow to very quickly find the most probable conformation of a molecule. (*iii*) The π systems are taken into account. The program calculates the atomic charges.

For the design of the complex, different packing of molecules were tested, and the most stable corresponding to the minimum of the nonbonded energy (van der Waals, coulombic, and hydrogen bond) was considered. Then in a first step, a calculation imposing all the possible hydrogen bonds was performed, and in a second step these constraints were removed in order to find the true hydrogen bonds and the more stable assemblage of the molecules.

Preparation, properties, and reductive alkylation of arylhydrazides

Giancarlo Verardo, Nicoletta Toniutti, and Angelo G. Giumanini

Abstract: 1-Acyl-2-arylhydrazines (**1**), readily obtained in high yield from the condensation of arylhydrazines and the appropriate liquid carboxylic acid (**2**), underwent reductive alkylation with the same or different liquid carboxylic acids (**2**) and $NaBH_4$ to give 1-acyl-2-alkyl-2-arylhydrazines (**3**) in good to moderate yields. The carboxylic acid has both the role of supplying the entering alkyl group and of acting as solvent. Most likely, it also modifies the BH_4^- anion to an active reducing agent under those conditions. The ^1H NMR criteria for identifying the location of acylation of hydrazines and *E* and *Z* isomers are given. The MS spectra of the prepared hydrazides were analyzed in order to identify relevant structural features leading to specific fragmentations.

Key words: 1-acyl-2-arylhydrazine, 1-acyl-2-alkyl-2-arylhydrazine, reductive alkylation, sodium tetrahydroborate, carboxylic acid.

Résumé : La condensation d'arylhydrazines et d'acides carboxyliques liquides appropriés (**2**) conduit facilement aux 1-acyl-2-arylhydrazines (**1**) avec d'excellents rendements; celles-ci, par alkylation réductrice avec les mêmes (ou d'autres) acides carboxyliques (**2**) liquides et du $NaBH_4$, conduisent aux 1-acyl-2-alkyl-2-arylhydrazines (**3**) avec des rendements qui vont de bons à moyens. L'acide carboxylique joue à la fois le rôle de source du groupe méthyle qui entre et de solvant. Il est probable qu'il modifie aussi l'anion BH_4^- afin qu'il devienne un agent réducteur actif dans ces conditions. On présente les critères de RMN du ^1H permettant d'identifier la position de l'acylation des hydrazines et les isomères *E* et *Z*. On a analysé les SM des hydrazides préparés dans le but d'identifier les caractéristiques structurales pertinentes aux fragmentations spécifiques.

Mots clés : 1-acyl-2-arylhydrazine, 1-acyl-2-alkyl-2-arylhydrazine, alkylation réductrice, tétrahydroborate de sodium, acide carboxylique.

[Traduit par la Rédaction]

Introduction

The use of carboxylic acids in combination with $NaBH_4$ was found to effect *N*-alkylation of aliphatic as well as aromatic amines (1), nevertheless, the synthetic utility of this method was never developed to date on hydrazines and derivatives. The direct reductive alkylation of phenylhydrazine with carboxylic acid and $NaBH_4$ gave a mixture of products resulting from different multiple alkylations as well as acylation of the hydrazine.[2] In fact, it is well established that alkylation of alkyl- or arylhydrazines occurs preferentially on the substituted nitrogen atom (2), however, this reaction usually requires the use of protecting groups to limit or avoid multiple alkylations. For this reason, it has been performed on hydrazones or acylhydrazines. The resulting alkyl derivatives could be either hydrolyzed to remove the protecting group and give 1,1-disubstituted hydrazines or reduced to yield trisubstituted hydrazines (3). Herein, we focused our attention on arylhydrazides as better substrates for selective alkylation.

Hydrazides are an important class of compounds not only in organic synthesis, but also for industrial applications. Arylhydrazides (**1**) and 1-acyl-2-alkyl-2-arylhydrazines (**3**) were used in the preparation of herbicides (4), antiinflammatory indoles (5), derivatives with antimicrobial (6) or antimycotic activity (7, 8).

We now report the preparation and full characterization of some arylhydrazides (**1**) and their reductive alkylation with carboxylic acids and $NaBH_4$ combination as the method of choice for preparation of 1-acyl-2-alkyl-2-arylhydrazines (**3**). This simple, inexpensive, high-yielding method is also proposed as a one-pot procedure in which the carboxylic acid acts as acylating as well as alkylating agent. The MS and NMR spectra of these hydrazides were carefully discussed because literature data were sparse and scattered.

Results and discussion

1-Acyl-2-arylhydrazines (**1a**–**f**) were readily obtained by heating the corresponding carboxylic acid and arylhydrazines without any condensing agent (9). This direct approach seems scarcely known and even less attended (10, 11). In producing 1-acyl-2-arylhydrazine instead of its isomer 1-acyl-1-arylhydrazine, the carboxylic acid here behaves in the same way as other acylating agents, frequently

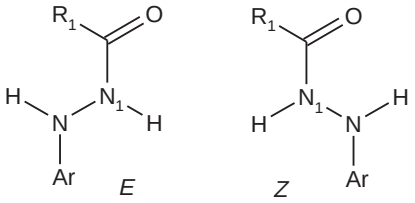
used for hydrazines, such as esters, anhydrides, and acyl chlorides (12).

All the starting hydrazides **1a–f** were characterized and their properties compared with literature data (Tables 1 and 2). The correct structural identification of the arylhydrazides **1a–f** was essentially based on their ^{1}H NMR features. Upon accurate examination of the available literature data, we made the following observation. Although 1-acyl-1-substituted-hydrazines usually exhibit the *E*/*Z* amide isomerism (Fig. 1), which doubles all the hydrogen resonances, their primary amino group hydrogens appear as singlets at ca. 3.8–4.8 ppm in $CDCl_3$ and 4.2–5.3 ppm in DMSO-d_6 (13).

Completely different NMR features are recognized when the acyl and the aryl (or alkyl) groups are located on different nitrogens (that is, for 1-acyl-2-substituted derivatives). The hydrogen belonging to the amide function shows up as two unequal resonances with a separation of ca. 0.3–0.7 ppm both in $CDCl_3$ (at ca. 7.4 ppm) and in DMSO-d_6 (at ca. 9.0 ppm) (13). Interestingly, the amino proton also reflects

Fig 1.

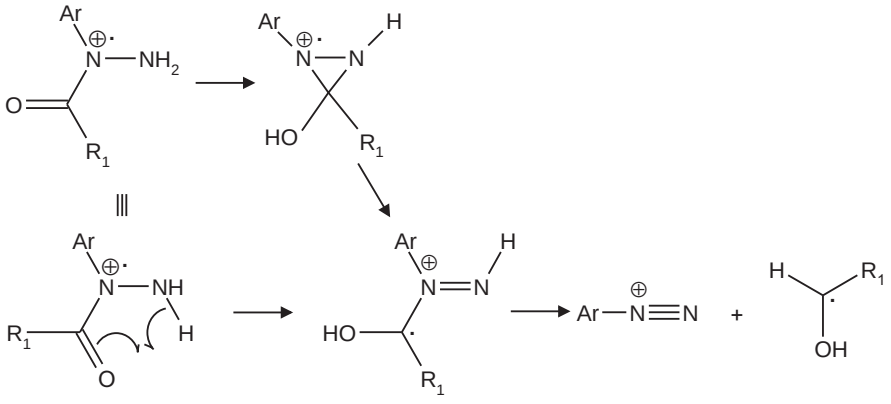


the different environment by showing two peaks at ca. 6.0 ppm in $CDCl_3$ and ca. 8.0 in DMSO-d_6 (13). After comparing these data with the spectra of our 1-acyl-2-arylhydrazines (1) (see Table 2), we confirmed their identification.

Of all the hydrazides **1a–f**, only 1-acetyl-2-(4-nitrophenyl)hydrazine (**1e)** did not show the *E*/*Z* isomerism in the NMR. The H-decoupled ^{13}C-NMR spectra of **1a–f** showed extensive doubling of the several peaks, but again **1e** did not exhibit this feature, a good indication that it was present in a single conformation.

The mass spectra of **1a–f** and of their 1,1-isomers **1a′–f′** differed in a number of features (Table 2 and experimental part). The latter showed weaker parent ions, which underwent extensive fragmentations to the RCO^+ acyl ions and the R^+ ions (likely in a rearranged form, whenever possible). Intense peaks at *m*/*z* 77 and 78 (corresponding to peaks at *m*/*z* 122, 123 for **1e′** and 91, 92 for **1f′** deriving from the substituted phenyl group) were detected. But their most impressive feature was the production of an outstanding peak at *m*/*z* 105 for PhN_2^+ (or the corresponding charged fragment from **1e′** and **1f′**), always accompanied by a weak peak at *m*/*z* 108 for the formula of phenylhydrazine (or the corresponding substituted phenylhydrazine from the parent ions **1e′** and **1f′**). A possible mechanism for the formation of ArN_2^+ involves a few rearrangements before cleavage of the parent ion of **1a′–f′**, eq. [1].

[1]



The 1,2-isomers **1b–f** also yielded all these ions, with the relevant difference that the ion at *m*/*z* 105 (or the corresponding charged fragment from **1e** and **1f**) was hardly discernible and that the ion at *m*/*z* 108 (or the corresponding peak for the formula of substituted phenylhydrazine from the parent ions **1e** and **1f**), due to the loss of ketene from the parent ion, was the base peak. The mass spectrum of **1a** is quite different from **1b–f** as the first most intense peak was the molecular ion (*m*/*z* 136), and the second one was the peak at *m*/*z* 107 ($PhN_2H_2^+$). On the contrary, the ion at *m*/*z* 108 was scarcely present.

[a]Solvent:$CDCl_3$.
[b]Solvent: DMSO-d_6.

The GC–MS analysis of the intact reaction mixtures, after removal of excess acid, showed that the 1,1-isomer was usually present in small concentrations (<5%). In the course of the GC analyses we observed that 1-acyl-2-arylhydrazines (**1**) isomerized extensively to the 1,1-isomer when they were injected using CH_2Cl_2 as solvent. We assumed that this was the result of the formation of HCl in the injector, kept at 250°C, which catalyzed the 1,2-migration of the acyl group.

We submitted the 1-acyl-2-arylhydrazines **1b–f** to reductive alkylation using an excess of either the same (R_1 = R_2, eq. [2]), or different ($R_1 \neq R_2$, eq. [2]) carboxylic acids and $NaBH_4$.

[d]Literature (8) 94°C.
[e]Recrystallized at –20°C.
[f]Literature (11) 144°C.

In the former case the reaction can be easily carried out in a stepwise, one-pot procedure. The synthetic route reported herein promised to be an easy way to obtain monoalkylated arylhydrazides compared to previously described methods, mostly affording fair yields of impure products (14–18). Most of the alkylated products (**3**), prepared and characterized herein, were never synthesized before. The results are summarized in Table 3, and the spectroscopic and MS properties are collected in Table 4.

The structural identification of products **3a**–**i** were based both on chemical degradation and spectroscopic investigations. It was reported that treatment of azo compounds with Zn in aqueous HCl effected the reductive cleavage of the NN double bond (19). It is reasonable to conclude that the conversion went through the intermediacy of hydrazines. We applied this treatment to **3b** and **3d** and obtained *N*-ethyl and *N*-butylaniline, respectively, as the only aromatic amines, as determined by GC–MS analysis. The ^{1}H NMR spectra of **3b** and **3d** showed two relatively sharp singlets each at 7.66, 8.32 ppm and 7.50, 8.10 ppm, respectively, in $CDCl_3$ for the *E* and *Z* amide hydrogens. This assignment turned out to be correct upon comparison with the range for this proton in the spectra of **1a**–**f** (7.03–7.46 ppm and 7.50–8.26 ppm in $CDCl_3$). The ^{13}C NMR spectra were consistent with the data obtained from the proton spectra. As expected, the IR spectra for **3b** and **3d** showed single NH bands. The common features in the mass spectra of **3b** and **3d** are illustrated in Scheme 1. The outlined patterns of fragmentations were found in all other *N*-alkyl arylhydrazides **3a**, **c**, **e**–**i**. Analogously, the ^{1}H and ^{13}C NMR spectra of these compounds repeated quite consistently the features outlined above for **3b** and **3d**.

A likely mechanism of the reductive alkylation of 1-acyl-2-arylhydrazines **1** with the carboxylic acids **2** implies the reduction of **2** to aldehydes **4** by the action of some borohydride species formed in solution (20) and subsequent condensation of aldehydes with **1** to an easily reducible iminium ion **5** (Scheme 2). This rationale is consistent with the formation of traces of ethanal-phenylhydrazone from the reaction of phenylhydrazine with acetic acid and $NaBH_4$ (see footnote 2) as detected by GC–MS and confirmed the observation made by Gribble et al. (1). The proposed mechanism turned out to be correct when we tested the reaction between 1-acyl-2-phenylhydrazine (**1b**) and butanal in the presence of $NaBH_4$ (21) (see experimental part). The reaction afforded 1-acyl-2-butyl-2-phenylhydrazine (**3d**) in 50% yield together with some unreacted 1-acyl-2-phenylhydrazine.

The reductive alkylation of 1-aryl-2-acylhydrazines with carboxylic acids and $NaBH_4$ is a valid alternative method to the usual reductive alkylation with carbonyl compounds due to the high yields and easy procedure. The reaction implied the use of few and readily available reagents. The carboxylic acid plays the role of solvent, acylating agent, source of entering alkyl group, modifier of $NaBH_4$ reactivity, and acid catalyst.

When we applied our procedure of reductive alkylation with carboxylic acids and $NaBH_4$ to phenylhydrazine hydrochloride, after neutralization with the minimum amount of 10% aqueous NaOH, we observed the formation of the corresponding 1-acyl-2-phenylhydrazine only, but no formation of the alkylated product. This result was consistent with decomposition of acyloxyborohydride species in the presence of water as reported in literature (22).

Moreover, $NaBH_4$ is a mild and selective reagent. The GC–MS analysis revealed that neither any amide was reduced nor N—N bond was cleaved by $NaBH_4$. Even in 6 M H_2SO_4 at 80°C, sodium borohydride left 1-acetyl-2-butyl-2-phenylhydrazine (**3d**) unchanged; only some 2-butyl-2-phenylhydrazine was detected as the usual hydrolysis product obtainable under acidic conditions.

While the reductive alkylation of *N*-acyl-*N*′-arylhydrazines was applicable to **1b**–**f**, the only exception was **1a**, which resisted *N*′-ethylation by acetic acid – $NaBH_4$ under the standard condition.

Experimental

Phenylhydrazine hydrochloride, (4-methylphenyl)hydrazine hydrochloride, phenylhydrazine, (4-nitrophenyl)hydrazine, and $NaBH_4$ pellets were purchased from Aldrich, Italy, Milan. Solvents were used as received. The GC–MS analyses were performed with a Fisons Trio 2000 mass spectrometer, working in the positive ion 70 eV electron impact mode. Spectra were recorded in the range 35–500 u. Injector temperature was kept at 250°C, and the column (Supelco SPB^{TM}-5, 30 m long, 0.32 mm i.d.) temperature was programmed from 60 to 300°C with a gradient of 10°C/min. The GC analyses performed, keeping the injector at 250°C on pure 1-acyl-2-arylhydrazines (**1**), showed, at times, the formation of isomeric 1-acyl-1-arylhydrazines; the reaction was relevant when very dilute CH_2Cl_2 solutions were used, but did not occur with other solvents. The IR spectra were obtained with a Nicolet FT-IR Magna 550 spectrophotometer using KBr technique for solids in the range 4000–400 cm^{-1}. The ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ or DMSO-d_6 at room temperature on a Bruker AC-F 200 spectrometer at 200 and 50 MHz, respectively. The NMR peak locations are reported as δ-values from TMS (^{1}H NMR) and the central peak of $CDCl_3$ or DMSO-d_6 (^{13}C NMR). Some ^{1}H multiplets are characterized by the term app (apparent): this refers only to their

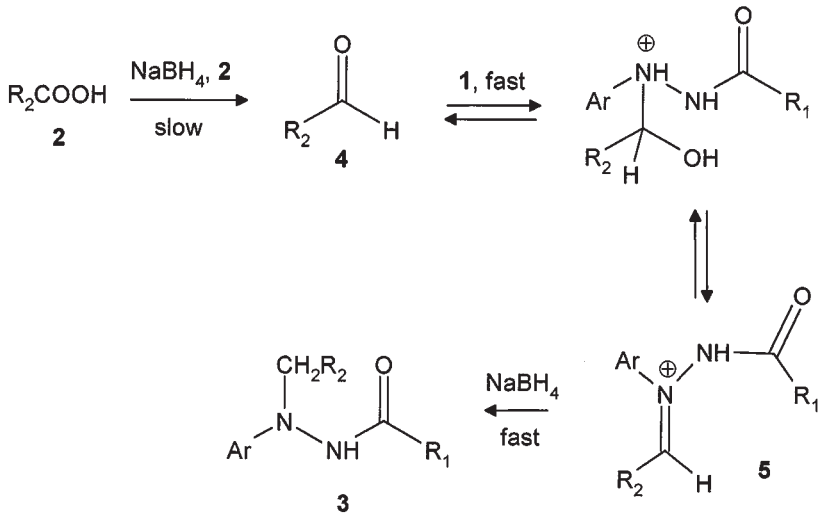
appearance and may be an oversimplification. Elemental analysis were performed with a Carlo Erba Mod. 1106 elemental analyzer.

Preparation of 1-formyl-2-phenylhydrazine (1a)

1-Formyl-2-phenylhydrazine (**1a**) was prepared as described procedure (9) by heating a mixture of

© 1998 NRC Canada

Scheme 2.



phenylhydrazine (5 mL, 46 mmol) and 50% HCOOH (18 mL, 240 mmol) at 120°C for 15 min. After the mixture was allowed to stand at rt, crystals of product precipitated; the resulting solid was recrystallized from EtOH and hexane.

Preparation of 1-acyl-2-arylhydrazines (1b–e)

The arylhydrazine (30 mmol) was added at rt to the appropriate carboxylic acid (**2**, 750 mmol), and the resulting mixture was stirred at 80°C for 1.5 h. Most of the acid was distilled off; the warm residue was treated with Et_2O or hexane and the crystals of the desired products **1b**–**e** precipitated. The products were further purified by recrystallization from hexane and the minimum amount of EtOH. Their physical and spectroscopic data are collected in Tables 1 and 2.

Procedure A

*Preparation of 1-acyl-2-alkyl-2-arylhydrazines (**3b**–**d**, **3f**–**i**)*

Sodium borohydride (pellets, 1.5 g, 40 mmol) was added portionwise to a mixture of 1-acyl-2-phenylhydrazine (**1**, 13 mmol) in carboxylic acid (**2**, 200 mmol) at ca. 60°C under vigorous stirring. The reaction usually required about 1 h for completion and could be considered completed soon after the sodium borohydride pellets were completely dissolved. The solvent was then partly distilled off under reduced pressure and, after neutralization of the residue with $NaOH–Na_2CO_3$ solution at ca. 0°C, the product was extracted with CH_2Cl_2 (20 mL × 5). Whenever after addition of $NaBH_4$ a too dense mixture resulted, distillation of the solvent was avoided and only a treatment with $NaOH–Na_2CO_3$ solution followed by CH_2Cl_2 extraction was performed. After the combined organic extracts were dried (Na_2SO_4) and the solvent was removed under reduced pressure, the product was crystallized from hexane by the addition of the minimum amount of EtOH. The physical and spectroscopic data of **3** are shown in Tables 3 and 4.

*Preparation of 1-acyl-2-methyl-2-phenylhydrazine (**3a**, **3e**)*

Procedure A was followed except that warming was prevented, keeping the temperature at 0–5°C, and that the amounts of reagents used were 13 mmol of 1-acyl-2-phenylhydrazine (**3**), 400 mmol of HCOOH, and 70 mmol of $NaBH_4$ (pellets). In the case of **3a**, twice crystallization from hot Et_2O was necessary to purify the desired product impure of 1-acetyl-2-formyl-2-phenylhydrazine.

In the case of **3e**, the reaction mixture containing 30% of unreacted reagent, was isolated in neutral form as explained in Procedure A and treated again with HCOOH and $NaBH_4$. At the end of reaction GC–MS analysis revealed the presence of product **3e** and a trace of unreacted **1c**. The reaction mixture was treated as in Procedure A. The physical and spectroscopic data of **3a** and **3e** are reported in Tables 3 and 4.

Procedure B

*One-pot preparation of 1-acetyl-2-ethyl-2-(4-methylphenyl)hydrazine (**3i**). Preparation of 1-acetyl-2-(4-methylphenyl)hydrazine (**1f**)*

(4-Methylphenyl)hydrazine hydrochloride (2.1 g, 13 mmol) was heated at 80°C for 15 h in acetic acid (20 mL, 320 mmol) with sodium acetate (1.1 g, 14 mmol) to allow the formation of 1-acetyl-2-(4-methylphenyl)hydrazine (**1f**), as revealed by GC–MS. The temperature was allowed to decrease to 60°C when $NaBH_4$ pellets (2.2 g, 58 mmol) were added portionwise. After all pellets were dissolved, GC–MS analysis revealed 1-acetyl-2-ethyl-2-(4-methylphenyl)-hydrazine (**3i**) as the sole volatile product. The reaction mixture was treated as described in Procedure A. Procedure B was repeated, obviously without the addition of $NaBH_4$, in order to obtain 1-acetyl-2-(4-methylphenyl)hydrazine (**1f**); it was recrystallized from EtOH and hexane. The physical and spectroscopic data of **1f** are reported in Tables 1 and 2 and **3i** in Tables 3 and 4.

*Reductive alkylation of 1-acyl-2-phenylhydrazine (**1b**) with butanal and $NaBH_4$*

A solution of aqueous 3 M H_2SO_4 (1.4 mL, 0.46 mmol) and butanal (0.18 mL, 2 mmol) in THF (3 mL) was slowly added to an open vessel containing a solution of 1-acetyl-2-phenylhydrazine (**1b**, 0.2 g, 1.33 mmol) in THF (10 mL) and MeOH (1.3 mL), while $NaBH_4$ pellets (0.17 g, 4.5 mmol) were added portionwise at 0°C (±5°C) under magnetic

© 1998 NRC Canada

stirring. The mixture was stirred for an additional hour at rt, diluted with H_2O, made strongly alkaline with NaOH (cooling), and extracted with CH_2Cl_2. After solvents were distilled off, 1-acetyl-2-butyl-2-phenylhydrazine (**3d**, 40% yield) and 1-acetyl-2-phenylhydrazine (**1b**, 43% yield) were separated by crystallization from Et_2O.

*Reductive cleavage of 1-acetyl-2-ethyl-2-phenylhydrazine (**3b**) and of 1-acetyl-2-butyl-2-phenylhydrazine (**3d**)*

Treatment of 0.22 mmol of either 1-acetyl-2-ethyl-2-phenylhydrazine (**3b**) or of 1-acetyl-2-butyl-2-phenylhydrazine (**3d**) in 37% HCl (3 mL) with Zn dust (0.6 g, 9.2 mmol) at 70°C for ca. 16 h gave *N*-ethylaniline and *N*-butylaniline, respectively, as the sole GC–MS products. The original products were completely transformed.

Importance de la présence de magnésie dans le stockage de la chaux : carbonatation de l'oxyde et de l'hydroxyde de magnésium

Rose-Marie Dheilly, Yahya Sebaibi, Joseph Tudo et Michèle Queneudec

Résumé : L'influence de l'humidité relative de l'air, de la température et de la concentration en CO_2 sur la carbonatation de MgO et $Mg(OH)_2$ a été examinée dans des domaines compatibles avec des conditions climatiques courantes. L'oxyde et l'hydroxyde de magnésium purs utilisés pour cette étude originale étaient à l'état pulvérulent. Les espèces apparaissant au cours du processus de carbonatation ont été mises en évidence et la forme la plus stable dans les conditions usuelles de stockage a été identifiée. De plus l'étude des différents facteurs climatiques a montré que la carbonatation n'est jamais totale même après une exposition prolongée.

Mots clés : carbonatation, oxyde de magnésium, hydroxyde de magnésium, stockage, conditions climatiques.

Abstract: The influence of relative air moisture, temperature, and concentration of carbon dioxide on the carbonation of magnesium oxide and hydroxide have been studied in normal climatic conditions. The MgO and $Mg(OH)_2$ used for this original work are pure granular materials. The different species that appear during the process of carbonation and the most stable form in usual conditions of storage were identified. Moreover, the study of the different climatic factors showed that the carbonation is never complete even after a prolonged exposure.

Key words: carbonation, magnesium oxide, magnesium hydroxide, storage, climatic conditions.

1. Introduction

Dans des travaux publiés antérieurement (1) nous avons montré l'influence des conditions climatiques sur la carbonatation de l'oxyde de calcium et l'hydroxyde de calcium pulvérulents. Toutefois les roches calcaires utilisées pour la préparation de la chaux contiennent parfois du carbonate de magnésium. La cuisson à une température supérieure à 900°C conduit alors à un mélange de MgO et CaO : chaux magnésienne ou dolomitique. Le mécanisme de la carbonatation de CaO à l'état pulvérulent a déjà été élucidé (1). L'étude du stockage des chaux magnésiennes nécessite donc une seconde étape qui est l'étude du comportement de MgO dans différentes conditions atmosphériques et hygrothermiques.

La carbonatation de MgO a déjà fait l'objet de nombreux travaux. En particulier Evans et Saint Claire (2), Horiguchi et Yoshikazu (3) et Kataev et Kulikov (4) ont étudié la réaction avec le dioxyde de carbone de MgO en solution dans de l'eau afin de déterminer les conditions optimales d'obtention d'une solution saturée en hydrogénocarbonate. Smithson et Bakshi (5) ainsi que Xiangting et al. (6) ont étudié la préparation de $MgCO_3 \cdot 3H_2O$ à partir des pâtes de MgO en vue de la production de $MgCO_3 \cdot KHCO_3 \cdot 4H_2O$. Medvinskii et al. (7) ont relié le mécanisme de la carbonatation à la surface spécifique de l'hydroxyde $Mg(OH)_2$. Afin de réduire les émissions de dioxyde de carbone dans l'atmosphère Lackner et al. (8) se sont intéressé à la réaction de CO_2 avec des minéraux contenant de l'oxyde de magnésium. Ils ont travaillé sur la possibilité de fixer chimiquement CO_2 dans une forme carbonatée stable, en utilisant deux procédés différents de carbonatation : directe à haute température ou en solution aqueuse. Butt et al. (9) ont étudié les cinétiques des réactions simultanées de déshydroxylation et de carbonatation de $Mg(OH)_2$ pulvérulent à haute température. De nombreux carbonates de magnésium neutres ou basiques ont été identifiés mais souvent leurs compositions chimiques ont été contestées. Citons en particulier la nesquehonite $MgCO_3 \cdot 3H_2O$ (10–15), l'hydromagnésite $Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$ (15, 16) et la giorgiosite $Mg_5(CO_3)_4(OH)_2 \cdot 5H_2O$ (17). En ce qui concerne les carbonates basiques il semblerait qu'il soit possible de préparer toute une gamme de formule générale $a\mathrm{MgO} \cdot b\mathrm{CO_2} \cdot c\mathrm{H_2O}$ avec a = 5,4 ou 3, b = 4,3 ou 2 et c = 4–11. Pour l'hydromagnésite deux compositions sont le plus souvent formulées : $Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$ ($5MgO \cdot 4CO_2 \cdot 5H_2O$) et $Mg_4(CO_3)_3(OH)_2 \cdot 3H_2O$ ($4MgO \cdot 3CO_2 \cdot 4H_2O$). Les travaux les plus récents (15) confirmeraient la première formule. Par ailleurs Langmuir (18) présente les domaines de stabilité de ces différents carbonates en étudiant les équilibres dans le système CO_2–H_2O–$MgCO_3$ en fonction de la température (0–100°C) et de la pression de CO_2 (0–100 atm (1 atm = 101,3 kPa)).

Enfin, depuis les 10 dernières années, l'interaction de MgO avec le dioxyde de carbone a fait l'objet d'un intérêt grandissant dans le domaine de la catalyse hétérogène. Ces travaux se sont particulièrement intéressés aux phénomènes d'adsorption–désorption de molécules de gaz en surface de l'oxyde (19–25). Les essais sont essentiellement réalisés à basse température (T voisine de 100 K) sur le plan (100) du cristal isolé de MgO. Seuls Beruto et al. (26) et Yanagisawa et al. (27) ont étudié l'adsorption–désorption de CO_2 sur MgO à haute température (entre 400 et 1000 K).

Toutefois aucun de ces auteurs ne s'est intéressé à l'oxyde de magnésium pulvérulent à des températures voisines de 20°C et sous pression atmosphérique. Le présent travail s'intéresse donc à l'étude de l'influence des trois facteurs : température, humidité relative et concentration en CO_2 de l'atmosphère sur les réactions d'hydratation et de carbonatation de MgO et $Mg(OH)_2$ pulvérulents à des températures voisines de 20°C et sous pression atmosphérique.

2. Matériaux et techniques expérimentales

L'oxyde et l'hydroxyde de magnésium sont des produits du commerce purs «pour analyse». Sur les images en électrons secondaires faites au microscope électronique à balayage, l'oxyde de magnésium apparaît comme un amas sphérique de fines plaquettes de 1 à 2 × 10^3 nm de long, dont l'enchevêtrement ne permet pas de définir la forme exacte (fig. 1). L'hydroxyde de magnésium se présente sous la forme d'amas de plaquettes hexagonales de 200 à 300 nm d'épaisseur et de 0.5 à 1 × 10^3 nm de long (fig. 2).

Le dispositif expérimental utilisé pour la carbonatation est donné en fig. 3. La première enceinte thermostatée (1), régulée électroniquement, permet de maintenir l'ensemble de la chambre atmosphérique (2) et du système de saturation (3) à la température voulue. Ceci permet d'éviter tout point froid susceptible de modifier la pression de H_2O recherchée. L'atmosphère dans la chambre atmosphérique (2) est maintenue aux caractéristiques désirées par une circulation des gaz provenant du système de saturation (3). L'humidité relative souhaitée, 30 ou 60%, est obtenue grâce à des mélanges, toujours renouvelés, d'eau et d'acide sulfurique (17,82 M), dans les concentrations respectives suivantes : 775 et 495 g d'acide par litre de solution. Dans tous les cas les débits d'air et de gaz carbonique sont contrôlés par des débitmètres de façon à maintenir des conditions expérimentales constantes. Compte tenu de la forme de la nacelle dans laquelle est déposé l'échantillon, pour avoir une couche très fine de matériau pulvérulent le nombre de moles initial est fixé à 8,93 × 10^{-3} soit en masse 357 mg d'oxyde de magnésium ou 518 mg d'hydroxyde de magnésium.

Au cours de chaque expérience, les échantillons sont suivis par : (*i*) analyse gravimétrique : l'échantillon est pesé, en général, toutes les douze heures et replacé rapidement dans la chambre atmosphérique; (*ii*) analyse par diffraction des rayons X, effectuée sur un deuxième échantillon identique à celui pesé, placé dans les mêmes conditions. Le générateur utilisé est un Siemens Kristalloflex 700.

Pour déterminer rapidement le pourcentage de MgO, $Mg(OH)_2$ et d'espèce carbonatée présente dans l'échantillon nous avons défini un protocole de dosage par analyse thermogravimétrique, menée sur une microthermobalance Setaram 92, sous oxygène sec à la vitesse de chauffage de 40° par heure. Les différents constituants qui peuvent entrer dans la composition d'un échantillon sont repérés et dosés grâce aux étapes observées lors de la dégradation thermique de l'échantillon :

(*i*) L'hydroxyde de magnésium perd son eau pour donner MgO entre 270 et 370°C.

(*ii*) La nesquéhonite ($MgCO_3 \cdot 3H_2O$) se dégrade à partir de 80°C avec une perte de deux molécules d'eau pour donner à 280°C un composé qu'il faut globalement écrire

Fig. 2. Image en électrons secondaires (microscopie électronique à balayage) de l'hydroxyde de magnésium (G = 7500).

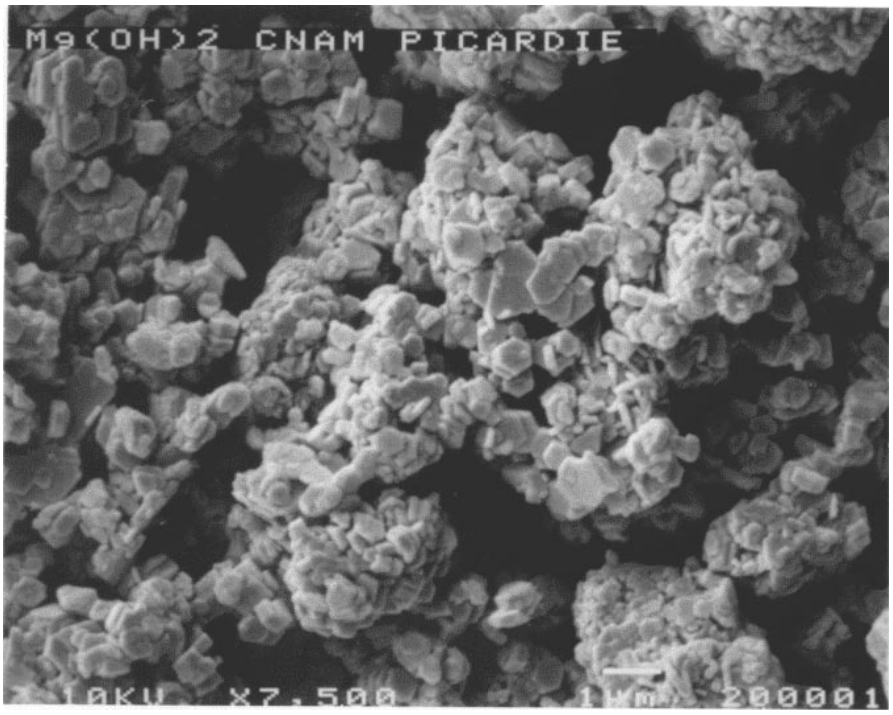

Fig. 3. Dispositif expérimental.

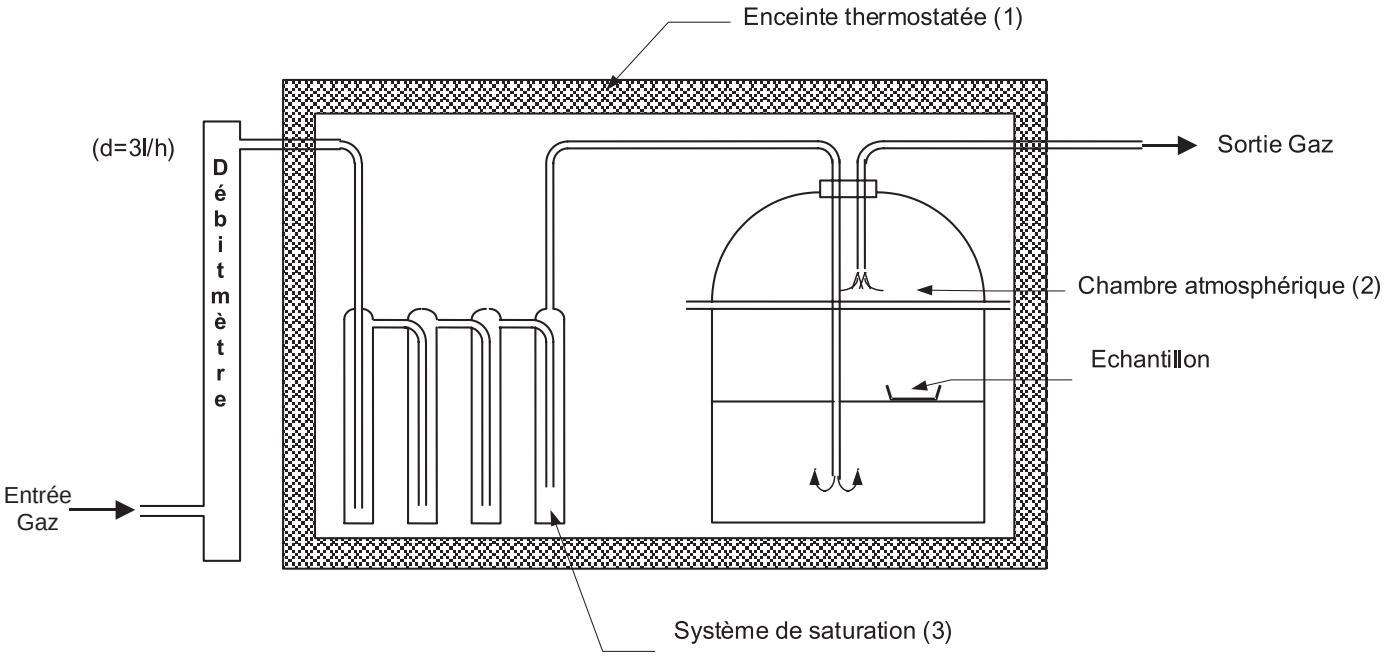

$MgCO_3 \cdot H_2O$. Entre 340 et 415°C celui-ci donne MgO avec départ simultané d'une molécule de H_2O et d'une molécule de CO_2.

(*iii*) L'hydromagnésite ($Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$) se dégrade à partir de 160°C pour donner à 295°C un palier, qui en masse correspondrait au produit anhydre $Mg_5(CO_3)_4(OH)_2$ amorphe aux rayons X. La dégradation se poursuit à partir de 335°C pour obtenir MgO à 420°C.

(*iv*) Quant à la giorgiosite ($Mg_5(CO_3)_4(OH)_2 \cdot 5\ H_2O$), nous ne l'avons jamais isolée pure mais toujours mélangée avec de l'hydromagnésite et de la brucite ($Mg(OH)_2$). Sa dégradation thermique est très voisine de celle de l'hydromagnésite.

(*v*) La présence de perte de masse à des températures inférieures à 100°C montre que les échantillons possèdent de l'eau « libre » ou faiblement liée.

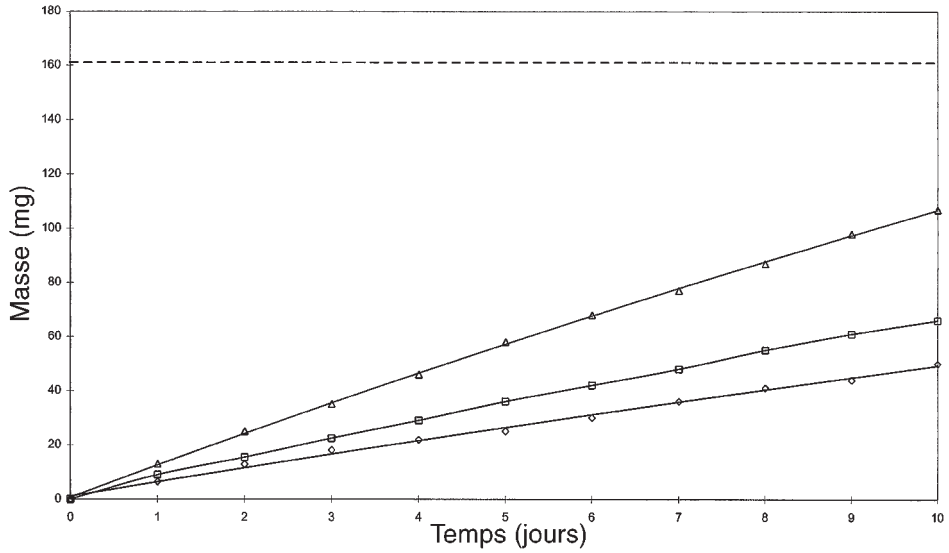
Fig. 4. Analyse gravimétrique d'échantillons de MgO placés pendant 10 jours sous atmosphère pauvre en CO_2 avec HR = 60%. (◇) T = 10°C; (□) T = 20°C; (△) T = 40°C; (---) $Mg(OH)_2$ théorique.



Il faut cependant reconnaître que si l'identification des espèces par analyse thermogravimétrique est aisée dans le cas des échantillons composés de mélanges $Mg(OH)_2$–$MgCO_3{\cdot}3H_2O$ ou $Mg(OH)_2$–$Mg_5(CO_3)_4(OH)_2{\cdot}4H_2O$, elle est plus difficile lorsque l'échantillon est un mélange des trois composés précédents ou des deux phases hydromagnésite et giorgiosite, même si les spectres obtenus par diffraction des rayons X sont différents.

3. Résultats expérimentaux et analyse

L'influence de la température et de l'hygrométrie a été étudiée pour des concentrations « extrêmes » en CO_2. La teneur minimum correspond à un air peu pollué soit 0.03% de CO_2, et la teneur maximum à une atmosphère carbonique. Les températures choisies sont des températures types d'un climat tempéré. L'humidité relative de 60% est une moyenne typique de ce type de climat. Les humidités de 30 et 100% correspondent à des états extrêmes qu'on peut rapprocher respectivement des conditions de stockage en silo et de périodes humides.

Sur les figures représentatives de cette étude nous avons indiqué la masse théorique de l'échantillon totalement transformé en $Mg(OH)_2$ et $MgCO_3{\cdot}3H_2O$.

L'étude des paramètres : température, hygrométrie, teneur en dioxyde de carbone de l'atmosphère, a permis les observations suivantes :

(*i*) Pour une humidité relative égale à 30%, quelles que soient la température d'étude et l'atmosphère sous laquelle est conservé l'échantillon, l'oxyde et l'hydroxyde de magnésium n'évoluent pas. La masse de l'échantillon ne varie pas et l'analyse par diffraction des rayons X décèle uniquement la présence de l'espèce initiale.

(*ii*) Lorsque l'humidité relative est de 60%, quel que soit le pourcentage de CO_2 de l'atmosphère, MgO se transforme lentement en $Mg(OH)_2$. L'examen en microscopie électronique et l'analyse thermogravimétrique montrent qu'il n'y a pas d'évolution vers le carbonate mais une fixation d'eau (fig. 4), la réaction étant plus rapide à 40°C.

(*iii*) Quel que soit le pourcentage de CO_2 de l'atmosphère, pour une humidité relative supérieure (HR = 100%) on remarque aussi que la variation de masse de MgO ou de $Mg(OH)_2$, est d'autant plus importante que la température est plus élevée (figs. 5 et 7).

En première lecture des courbes de la fig. 5*a*, sous atmosphère pauvre en CO_2 avec HR = 100% la transformation de l'oxyde en hydroxyde semble totale, quelle que soit la température. Les résultats des analyses radiocristallographique et thermogravimétrique confirment bien la formation de $Mg(OH)_2$, mais elles indiquent toujours la présence de magnésie. L'importance du gain de masse, enregistré pour 10 jours, s'explique différemment suivant la valeur de la température. À 40°C les analyses révèlent la présence dans l'échantillon des espèces carbonatées : hydromagnésite et giorgiosite en plus de celles de MgO et $Mg(OH)_2$. Alors que lorsque la température est inférieure ou égale à 20°C, l'analyse thermogravimétrique de l'échantillon met en évidence la présence d'eau « libre » en plus de celles de l'oxyde et l'hydroxyde de magnésium (fig. 6).

Le gain de masse de l'hydroxyde, sous atmosphère humide pauvre en CO_2 et pendant 10 jours (fig 7*a*), est aussi dû uniquement à un apport d'eau libre : $Mg(OH)_2$ s'humidifie, mais n'évolue pas en carbonate.

Sous atmosphère carbonique humide, que ce soit pour l'oxyde ou l'hydroxyde de magnésium, le gain de masse est plus grand que celui observé sous atmosphère pauvre en CO_2. Ce qui a été observé sous atmosphère pauvre en CO_2 est toujours valable : MgO évolue en $Mg(OH)_2$, qui fixe des molécules d'eau par adsorption. Mais sous atmosphère carbonique, l'analyse thermogravimétrique des produits obtenus enregistre aussi des pertes qu'il faut attribuer à l'existence d'une phase carbonatée dans l'échantillon en plus de la présence de MgO et $Mg(OH)_2$. La nature du carbonate qui se forme dépend de la température.

Pour une humidité relative de 100%, nous avons pu mettre en évidence, en maintenant l'échantillon plus

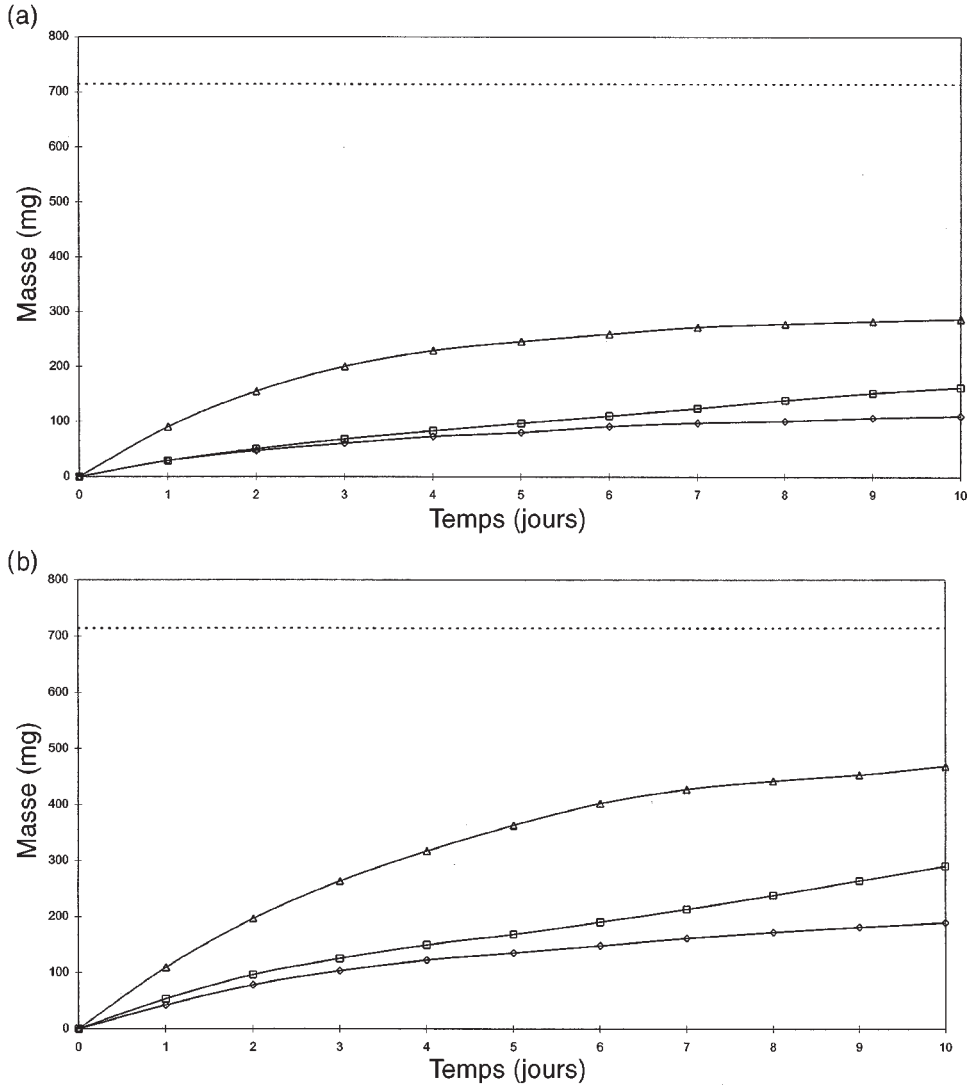
Fig. 7. Analyses gravimétriques d'échantillons de $Mg(OH)_2$ placés 10 jours sous une humidité relative égale à 100% : (*a*) atmosphère pauvre en CO_2; (*b*) atmosphère carbonique. (◇) T = 10°C; (□) T = 20°C; (△) T = 40°C; (—) $MgCO_3 \cdot 3H_2O$ théorique.



longtemps sous cette humidité, que le processus de carbonatation dépendait de la température et de la pression de CO_2.

Trois réactions ont pu être proposées suivant les conditions hygrothermiques et atmosphériques :

$$MgO \quad Mg(OH)_2 \quad MgCO_3 \quad 3H_2O$$
(Nesquéhonite)

si l'atmosphère est riche en CO_2 et la température inférieure ou égale à 20°C (conditions 1).

$$MgO \quad Mg(OH)_2 \quad Mg_5(CO_3)_4(OH)_2 \quad 4H_2O$$
(Hydromagnésite)

$$+ MgCO_3 \quad 3H_2O + Mg_5(CO_3)_4(OH)_2, 5H_2O$$
(Nesquéhonite) (Giorgiosite)

si l'atmosphère est riche en CO_2 et la température égale à 40°C (conditions 2).

$$MgO \quad Mg(OH)_2 \quad Mg_5(CO_3)_4(OH)_2 \quad 4H_2O$$
(Hydromagnésite)

$$+ Mg_5(CO_3)_4(OH)_2 \quad 5H_2O$$
(Giorgiosite)

si l'atmosphère est pauvre en CO_2, quelle que soit la température (conditions 3).

Il faut remarquer que le carbonate de magnésium $MgCO_3$ ne se forme pas.

Ces résultats ne sont pas en contradiction avec ceux de Langmuir (16). Pour lui, pour p_{CO_2} 1 atm, la nesquéhonite est la forme stable entre 10 et 50°C. Dans nos expériences il semble effectivement que 40°C soit la température limite, car un essai rapide à 50°C nous a montré que $MgCO_3 \cdot 3H_2O$ ne se formait pas. Dans le même diagramme sous atmosphère pauvre en CO_2 la phase hydromagnésite est la seule signalée au dessus de 5–10°C.

Nos travaux nous permettent aussi de noter que, quels que soient la température et le pourcentage de CO_2 contenu dans l'atmosphère, la conversion de l'oxyde, ou de l'hydroxyde,

en espèce carbonatée n'est pas totale même après 80 jours d'expérimentation. Les analyses le confirment et, en particulier, l'analyse radiocristallographique qui révèle, à côté de la forme carbonatée formée, la présence dans l'échantillon de l'espèce $Mg(OH)_2$ sous atmosphère humide pauvre en CO_2 ou des espèces MgO et $Mg(OH)_2$ sous atmosphère

Fig. 10. Image en électrons secondaires (microscopie électronique à balayage) de l'oxyde de magnésium conservé 80 jours sous atmosphère carbonique avec HR = 100% et T = 40°C (G = 3500).

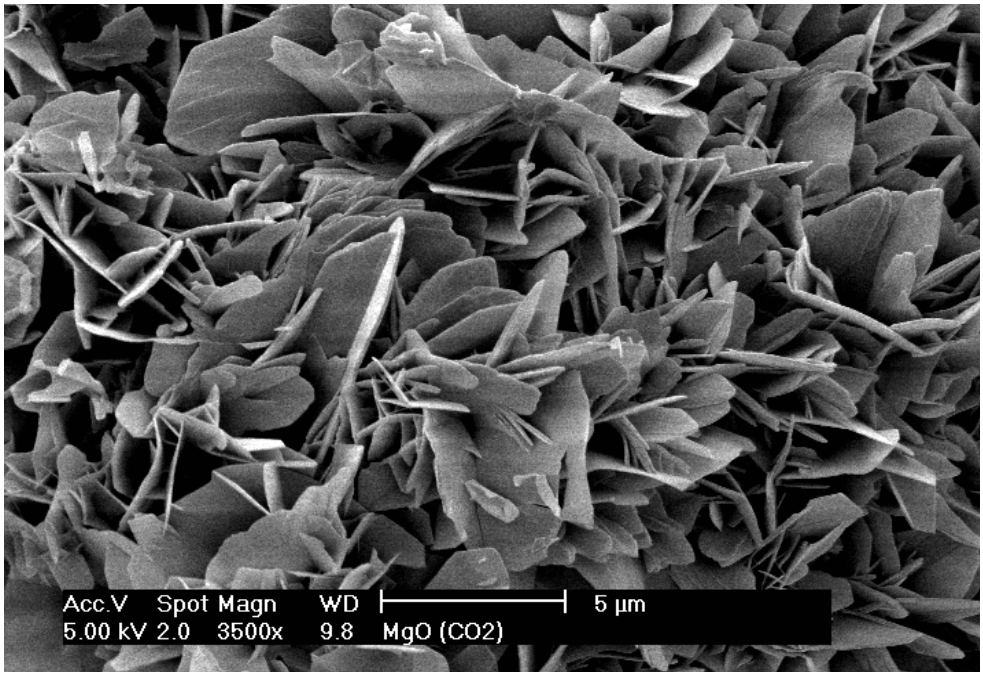

Tableau 1. Surfaces spécifiques BET mesurées après 80 jours de traitement et exprimées en m^2/g.

	Espèces chimiques de départ	
Conditions de conservation	MgO	$Mg(OH)_2$
Sans traitement	39,04	6,31
Sous CO_2, T 20°C HR = 100%	12,27	4,77
Sous CO_2, T = 40°C HR = 100%	6,51	3,79
Sous air, quelle que soit T HR = 100%	35,15	5,38

carbonique. La diffusion de H_2O et de CO_2 est probablement freinée par la formation des espèces carbonatées, quelle que soit leur nature.

Ces différentes espèces carbonatées obtenues présentent cependant des structures différentes. En effet lorsque l'oxyde de magnésium est placé pendant 80 jours sous atmosphère carbonique avec HR = 100% et T = 20°C l'échantillon conserve sa forme pulvérulente, mais l'image en électrons secondaires (fig. 8) montre qu'une couche de carbonate $MgCO_3 \cdot 3H_2O$ se forme sur la surface de l'oxyde de magnésium. Butt et al. (9) ont observé le même phénomène lors de leur étude de la carbonatation de $Mg(OH)_2$ sous CO_2 sec à haute température : un film de $MgCO_3$ se formait à la surface des cristaux de $Mg(OH)_2$ et, selon eux, freinait la diffusion interne de CO_2.

Nous avons précédemment montré qu'en atmosphère saturée en humidité la carbonatation présente une étape intermédiaire correspondant à la formation de l'hydroxyde $Mg(OH)_2$. L'évolution structurelle de l'échantillon après maintien pendant 80 jours dans les conditions 2 et 3 a donc été étudiée pour MgO et $Mg(OH)_2$. Dans les deux cas l'aspect pulvérulent disparaît. L'échantillon apparaît à l'œil nu comme une couche solide cohérente. L'analyse par microscopie électronique à balayage montre (figs. 9 et 10) la formation de touffes de fines plaquettes enchevêtrées qui peuvent être identifiées comme du $Mg_5(CO_3)_4(OH)_2$ cristallisé avec quatre molécules d'eau (15), soit un rapport CO_2 / MgO égal à 4/5 et inférieur à celui de la nesquéhonite (CO_2 / MgO = 1) obtenu dans les conditions 1.

Cette limitation dans la carbonatation peut s'expliquer, étant donnée l'évolution structurelle, par un blocage de la diffusion du dioxyde de carbone au sein de l'échantillon. Cette hypothèse a pu être confortée par la détermination de la surface spécifique BET.

On peut constater dans le tableau 1 que la surface spécifique évolue de façon considérable avec les conditions du traitement de MgO. Dans le cas de $Mg(OH)_2$ la surface spécifique de l'hydrate non traité est faible par rapport à celle de MgO et l'évolution est moins importante.

Cette diminution de la surface spécifique de l'oxyde, ou de l'hydroxyde, de magnésium semble être la cause du blocage de la diffusion de CO_2 au sein de l'échantillon, qui se traduit, quels que soient la température et le pourcentage de CO_2 contenu dans l'atmosphère, par une conversion non totale de l'oxyde, ou de l'hydroxyde, en espèce carbonatée.

4. Conclusion

L'objectif de ce travail était de déterminer l'influence des conditions climatiques sur la carbonatation de MgO et $Mg(OH)_2$. L'étude des différents facteurs : humidité relative et teneur en dioxyde de carbone de l'ambiance, a permis de montrer que quelles que soient les conditions expérimentales la transformation en espèce carbonatée n'est pas totale même après 80 jours. De plus, la forme la plus stable dans les conditions usuelles de stockage serait l'hydromagnésite.

© 1998 NRC Canada

Ce travail avait pour but de préparer l'étude du stockage des chaux magnésiennes ou dolomitiques dans lesquelles la quantité de magnésie peut atteindre des proportions relativement importantes. Toutefois la présence simultanée de composés calciques et magnésiens ne permet pas d'éloigner l'hypothèse d'un processus de carbonatation préférentiel pour l'une des espèces. C'est pourquoi actuellement une étude s'intéressant à la carbonatation de mélanges des espèces précédentes dans des proportions variables est en cours.

Remerciements

Que la Société LHOIST Europe trouve ici l'expression de nos sincères remerciements pour sa contribution technique et professionnelle et pour l'intérêt qu'elle porte à nos travaux.

Method for the differentiation of leaf litter extracts and study of their interaction with Cu(II) by molecular fluorescence

Joaquim C.G. Esteves da Silva, Adélio A.S.C. Machado, Miguel A. Ferreira, and Francisco Rey

Abstract: Six leaf litter extracts (LLE) (eucalyptus (*Eucaliptus globulus*), fern (*Pteridium aquilinium*), oak (*Quercus robur*), chestnut (*Castanea sátiva*), laurel (*Laurus nobilis*), and ulex (*Ulex europoeus*) canopies) were isolated following an extraction procedure similar to that used for fulvic acids (FA) and were characterized by elemental analysis and UV–Vis, FT-IR, and synchronous molecular fluorescence (SyF) spectroscopies. Moreover, information about their interaction with the Cu(II) ion in aqueous solution (100 mg/L of LLE in 0.1 M KNO_3 at pH = 6) was obtained from the measurement of SyF spectra at increasing concentrations of Cu(II). These spectral sets were treated by a self-modeling mixture analysis method (SIMPLISMA) to obtain improved quenching profiles to be used in the estimation by the method of Ryan and Weber of the conditional stability constants (K_c), concentration of binding sites, and percentage of fluorescent binding sites accessible for complexation. For comparison purposes, two samples of FA extracted from two horizons of an oak forest soil (0–5 cm and 5–15 cm) were also studied. The spectroscopic data obtained for LLE and FA were different. The results suggest that LLE are characterized by relatively high concentrations of individualized simple molecules and include reactive structures (alkene and protein residues). The ratio of aliphatic/aromatic structures was higher in LLE than for FA. Both LLE and soil FA form stable complexes with Cu(II), but the logarithm of the conditional stability constant of the 1:1 complexes is larger for LLE (about 5) than for the soil FA (about 4.5).

Key words: leaf litter extracts, soil fulvic acids, synchronous fluorescence, Cu(II) complexation, SIMPLISMA, spectral pattern recognition.

Résumé : On a isolé les extraits de six litières feuillues (ELF) (couvertes d'eucalyptus (*Eucaliptus golbulus*), fougère (*Pteridum aquilinium*), chêne (*Quercus robur*), châtaignier (*Castanea sâtiva*), laurier (*Laurus nobilis*) et ajonc (*Ulex europoeus*)) par une méthode d'extraction semblable à celle utilisée pour les acides fulviques (AF) et on les a caractérisés par analyse élémentaire et par spectroscopies UV–Vis, FT-IR et de fluorescence moléculaire synchrone (FSy). De plus, faisant appel à des mesures de spectre de FSy à des concentrations de plus en plus élevées de Cu(II), on a obtenu des informations relatives à leur interaction avec des solutions aqueuses d'ion Cu(II) (100 mg/L d'ELF dans 0,1 M KNO_3, à un pH = 6). Ces ensembles de spectres ont été traités par une méthode d'analyse de mélanges automodelante (SIMPLISMA) pour d'obtenir des profils améliorés d'extinction pouvant être utilisés dans l'évaluation par la méthode de Ryan et Weber des constantes de stabilité conditionnelles (K_c), de la concentration des sites de fixation et du pourcentage de sites de liaison fluorescents accessibles à la complexation. Pour fins de comparaison, on a aussi étudié deux échantillons d'AF extraits de deux horizons de sol d'une forêt de chêne (0–5 et 5–15 cm). Les données spectroscopiques obtenues pour l'ELF et l'AF sont différentes. Les données suggèrent que les ELF sont caractérisés par des concentrations relativement élevées de molécules simples individualisées et qu'elles contiennent des structures réactives (résidus d'alcène et de protéine). Le rapport des structures aliphatique/aromatique est plus élevé dans les ELF que dans les AF. Les ELF et les AF forment des complexes stables avec le Cu(II); toutefois, le logarithme de la constante de stabilité conditionnelle des complexes 1 : 1 est plus élevé pour les ELF (environ 5) que pour les AF des sols (environ 4,5).

Mots clés : extraits de litières feuillues, acides fulviques de sols, fluorescence synchrone, complexation du Cu(II), SIMPLISMA, reconnaissance du patron de spectre.

Introduction

Soil organic matter (SOM) plays an important role in the capacity of soils to retain metal ions (1, 2). One of the most important fractions of SOM, of concern to the chemistry of soils, is humic substances (HS), and particularly its most soluble material, the fulvic acids (FA). These play an important part in the movement of metals down into the soil because of their strong complexing properties. As well as HS embedded in soils, there exists at the soil surface another SOM fraction, constituted by the leaf litter (LL), which can be considered as a precursor to HS. Aqueous extracts of LL have been shown to complex metal ions (3–7) and therefore must also have a role in their movement into the soil.

Aqueous extracts of LL are a mixture of simpler and easily assimilated compounds and other, more stable, chemical and biochemical complex molecules. To obtain further information about this less reactive fraction of LL, extracts can be isolated by an extraction procedure similar to that usually used for the extraction of soil FA (8–12), instead of the aqueous extracts studied previously. One of the properties of FA, employed in their extraction from soils, is the ability of FA to be adsorbed in a hydrophobic resin when they are in the acid form and to be desorbed when they are in the ionized (base neutralized) form (13). This property allows their isolation from other soluble soil constituents and their subsequent extraction. LL extracted by this procedure (LLE) are expected to present structural affinities to FA and have been shown to complex metal ions, but further information about them remains limited (9–12). Therefore, it was decided to continue our previous studies on FA with research addressed to this type of extracts.

The characterization of HS and like substances is a quite difficult problem because classical analytical techniques, such as elemental and spectroscopic analysis (UV–Vis and FT-IR, for example), show little variability and, consequently, are not suitable for exploratory studies and (or) classification of this type of substance. Recently, synchronous molecular fluorescence (SyF) spectroscopy has been found to give a large amount of information about FA and LLE, opening new perspectives for their study (14–18). Besides fingerprinting, further information can be generated, for example, about the complexation properties of the samples, by monitoring the SyF spectra as a function of metal ion concentration. If the metal ion (e.g., Cu(II)) provokes quenching of the fluorescence, it is possible to obtain quantitative equilibrium parameters for the complexation reaction (17–20). However, useful information can be extracted from these sets of SyF spectra if suitable chemometric techniques are employed for data reduction. This data treatment requires two levels of implementation: (*i*) the raw spectral data are reduced to the number of components, their spectra, and SyF fluorescent intensity profiles, by self-modeling mixture analysis, such as SIMPLISMA (21, 22); and (*ii*) when several samples are studied simultaneously, the comparison and classification of their spectra is best accomplished by pattern recognition techniques (23, 24).

The main objective of the present work was to develop a method for the differentiation of FA and similar substances based on the use of SyF spectra quenching initiated by Cu(II). As multiwavelength data sets are analyzed, chemometric methods for multidimensional reduction are necessary and three types of techniques are used: (*i*) SIMPLISMA, to detect different components in SyF spectral data sets collected at increasing concentrations of Cu(II) ion, and to obtain their spectra and SyF intensity profiles; (*ii*) pattern recognition methods, namely, cluster analysis and multidimensional scaling, to compare the previously calculated spectra for the samples under analysis; and (*iii*) least-squares adjustment by SIMPLEX of the SyF quenching profiles detected by SIMPLISMA, to determine the conditional equilibrium parameters for the Cu(II) complexation by the method of Ryan and Weber (19, 20). A secondary objective of this work was to obtain information about LLE samples. In addition, well-known methods of HS characterization, namely, elemental analysis and UV–Vis and FT-IR spectroscopy, were also used for comparative proposes.

The procedures described above were tested in the discrimination of six LLE obtained from the following canopies: eucalyptus (*Eucaliptus globulus*), designated feu; fern (*Pteridium aquilinium*) — fer; oak (*Quercus robur*) — foa; chestnut (*Castanea sátiva*) — fch; laurel (*Laurus nobilis*) — fla; and ulex (*Ulex europoeus*) — ful. For comparison purposes, two samples of FA extracted from the soil of an oak forest (0–5 cm, fuao1, and 5–15 cm, fuao2) were also obtained and characterized.

Methodology

Reagents

Materials were extracted from LL collected in Pontevedra (Galicia, Spain) (feu, fer, and foa), Forcarey (Galicia, Spain) (fch), Mugardos (La Corunã, Spain) (fla), and Guitiriz (Lugo, Spain) (ful), and from an oak forest soil collected in Salvatierra de Miño (Galicia, Spain) (fuao1 and fuao2). Solid samples were isolated by the procedure recommended by the IHSS (19). This, briefly, involves mixing the powdered LL or soil with hydrogen chloride (until pH = 1) followed by adsorption of the materials to be extracted on an XAD-8 resin (Fluka AG, Bucks, Switzerland). The extract is then recovered using sodium hydroxide, followed by acidification with a cation exchanger (Amberlite IR-120, Fluka AG, Bucks, Switzerland) in the acid form and freeze-drying.

Solutions (100 mg/L FA) were prepared in 0.1 M potassium nitrate. For adjusting the titrated solutions to constant pH = 6.0 (± 0.1 pH units), a 0.05 M decarbonated potassium hydroxide solution was used. A standard $Cu(NO_3)_2$ was used as titrant and the range of Cu(II) concentration covered in the titrated solutions was always between 0 and about 0.3 mM.

Equipment

The UV–Vis spectra of 20 mg/L of the samples in sodium hydrogen carbonate (0.05 M) were recorded between 250 and 800 nm, with a Hewlett-Packard 8452A spectrometer (0.5 s accumulation time and 2 nm resolution) using 1 cm quartz cells and with a background of 0.05 M sodium hydrogen carbonate.

The FT-IR spectra of solid FA samples (5% in KBr) were recorded between 500 and 4000 cm^{-1} with a Nicolet Magna 550 FT-IR spectrophotometer (200 scans and 2 cm^{-1}

fuao2	Oak(5–15 cm)	0.75	44.55	3.95	1.02	0.014

resolution), using a microsampling diffuse reflectance (DRIFT) accessory (Baseline Nicolet).

Potentiometric and SyF measurements were made as previously described (16–18). SyF spectra were acquired between 250 and 550 nm excitation wavelength using a 20 nm wavelength interval between excitation and emission monochromators (each with 7.5 nm slit). The raw SyF spectra were reduced to the 270–500 nm wavelength range with a 5 nm resolution between points (47 points per spectrum) to be used in the data analysis.

Self-modeling mixture analysis

SIMPLISMA (21, 22) is a three-step self-modeling mixture analysis method. After analysis of the SyF spectra collected as a function of the Cu(II) concentration, the first step allows the calculation of the number of components that show linearly independent SyF quenching with an increase in Cu(II) concentration. In the second and third steps, the spectra and improved quenching profiles of the detected components, respectively, are calculated. The SIMPLISMA procedure used in this work is similar to that previously reported (17).

Spectral pattern recognition

Analysis of the spectral similarity was done using cluster analysis and multidimensional scaling. These methods are part of the statistical package SPSS for Windows 5.0 (SPSS Inc., Chicago). In these analyses each spectrum represents a point in the hyperspace of 47 dimensions (wavelengths).

Estimation of equilibrium parameters

If the interaction of Cu(II) with a FA (L) follows a 1:1 stoichiometry for complex formation, it can be schematically represented by

$$[1] \qquad L + Cu(II) \Leftrightarrow CuL$$

and the respective conditional stability constant (K_c), at fixed pH value, is defined by

$$[2] \qquad K_c = [CuL]/([Cu(II)][L])$$

where [CuL] is the concentration of the complex, [Cu(II)] is that of the total uncomplexed metal ion, and [L] is the total concentration of the uncomplexed FA (charges are omitted for sake of simplicity).

To obtain the complexation parameters from fluorescence intensity measurements, a procedure similar to that previously reported (17, 18) was used. The procedure involves several variables: experimental fluorescence intensity (I); fluorescence intensity due to the free FA (I_L); residual fluorescence intensity due to the bound ligand or fluorescent structure not accessible for complexation (I_{CuL}); conditional stability constant (K_c); total ligand concentration (C_L); and total metal concentration (C_{Cu}). The fraction of the total FA bound (= [CuL]/C_L) is given by (19, 20)

$$[3] \qquad [CuL]/C_L = (I_L - I)/(I_L - I_{CuL})$$

and, after setting I_L = 100, the relationship between the calculated SyF intensity profiles I, K_c, I_{CuL}, C_L, and C_M is given by

$$[4] \qquad I = [I_{CuL} - 100/(2K_cC_L)]\{(K_cC_L + K_cC_{Cu} + 1) - [(K_cC_L + K_cC_{Cu} + 1)^2 - 4K_c^2C_LC_{Cu}]^{1/2}\} + 100$$

This equation can be solved for K_c, C_L, and I_{CuL} by nonlinear regression analysis using the quenching profiles previously detected and calculated with SIMPLISMA by a SIMPLEX method previously described (17). The quality of the fitting of this equation to the experimental data can be assessed by the average deviation (ΔE) and sum of the squares of the residuals (SSR) functions.

Results and discussion

Characterization

Elemental analysis

The elemental composition (N, C, and H) and the atomic ratios H/C and N/C of the LLE and FA samples are shown in Table 1. These percentages are within the ranges expected for HS (25) but not for nitrogen, where somewhat lower values were obtained. Although the carbon and nitrogen mass percentages show some variation, respectively, between about 44–54% and 0.06–1.27%, the atomic ratios are almost invariant. Indeed, the H/C ratio is 1.00 ± 0.04 for all

Table 2. UV–Vis spectral characteristics of the LLE and FA samples.[a]

Sample	E_4/E_6	ε_{280nm}
feu	4.04	401
fer	6.04	716
foa	8.53	616
fch	5.43	590
fla	8.83	323
ful	3.89	344
fuao1	10.12	491
fuao2	7.40	609

samples except ful (1.13) and fuao1 (1.09). The N/C ratio is less than or equal to 0.010 for the LLE samples but shows higher values for the two FA samples.

Comparison of the N/C ratio for the two soil FA samples shows that nitrogen is lost by mineralization in the upper layer of the soil, the N/C ratio of fuao1 (0–5 cm) being nearly double that for fuao2 (5–15 cm). A similar trend in the N/C ratio was previously observed for FA samples extracted from a pinewood soil (11).

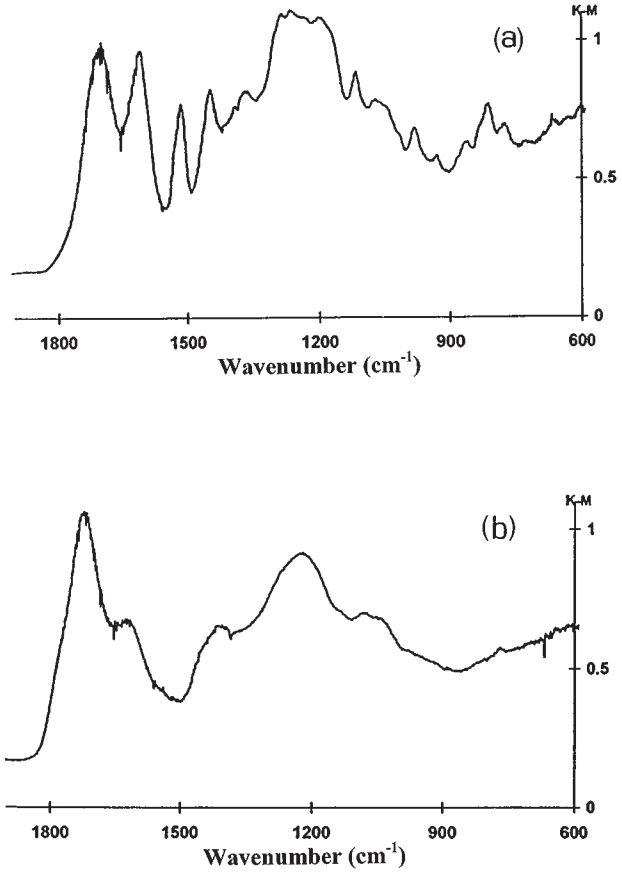
UV–Vis spectra

All the UV–Vis spectra of the LLE samples (Fig. 1*a* shows that of fch) have a particular feature when compared to those of soil FA samples (Fig. 1*b* shows that of fuao1), i.e., a more or less well-defined band at about 280 nm. Moreover, some LLE samples show further fine details, namely, a narrow shoulder at about 260 nm (feu and fch samples) and a wider shoulder at about 350 nm (feu, fch, and ful samples). The band at about 280 nm may be due to π–π* electronic transitions for phenolic substances and benzoic-type acids (26), suggesting that a relatively high concentration of these structures is present in the LLE. These simple compounds undergo chemical transformation and are incorporated into the FA macromolecules during humification and therefore FA show no characteristic bands of the π–π* electronic transitions due to them in the LLE.

Table 2 presents semiquantitative information obtained from the UV–Vis spectra, namely, the E_4/E_6 ratio (an indicator of humification) and the molar absorptivity at 280 nm (26). The E_4/E_6 ratio for the LLE has the following sequence: 3.89 (ful) < 4.04 (feu) < 5.43 (fch) < 6.04 (fer) < 8.53 (foa) < 8.83 (fla), which may be related to a decrease of the molecular weight or particle size of the extracts (27). The E_4/E_6 ratios for the FA samples (fuao1, 10.12, and fuao2, 7.40) are in the same range as, or above, the highest values found for the LLE and are similar to those for other FA samples (28). The smaller E_4/E_6 ratios of the LLE samples (within 3–5) fall in the range of those usually found for the humic acids (28).

The molar absorptivity at 280 nm for the LLE and FA samples varied from about 300 to about 700 L (mol of carbon)$^{-1}$ cm^{-1}, within the range of values found for other HS samples (26).

Fig. 2. Typical diffuse reflectance FT-IR spectra (1900–600 cm^{-1}) of (*a*) fer and (*b*) fuao1 samples.



FT-IR spectra

Although infrared spectra are very powerful for the classification of organic materials, in the case of HS this type of spectra is characterized by a remarkably low dependence on sample origin, which limits the use of this technique for classification proposes (29–31). Nevertheless, some information can be obtained from these spectra. Two spectral regions, 4000–2500 cm^{-1} and 1900–600 cm^{-1}, can be considered separately.

The 4000–2500 cm^{-1} range of the FT-IR spectra shows little difference for all samples and is characterized by two bands: a broad band centered at about 3300 cm^{-1}, which is attributed to the O–H stretch; and a narrower band centered at about 2950 cm^{-1}, attributed to the C–H stretch. As these bands are always present in the FT-IR spectra of HS, they are useless for the classification of samples from different origins.

In contrast, the 1900–600 cm^{-1} FT-IR spectra show differences between the six LLE and the two FA samples, as exemplified by Fig. 2, where the spectra for fer (Fig. 2*a*) and fuao1 (Fig. 2*b*) are included. Table 3 indicates the position of the bands detected in this range of the FT-IR spectra, with some assignments based on literature information (29–31).

Comparison of the two spectral types (Fig. 2) shows that the spectra of LLE (Fig. 2*a*) are characterized by a much larger number of well-defined bands than those of the FA (Fig. 2*b*), as expected from the smaller extent of

humification. Particularly well-defined bands observed in the spectra of the LLE (Fig. 2*b*) are those at 1716, 1614, 1518, and 1450 cm^{-1}. The following information can be obtained from these bands:

(*i*) The first two bands, 1716 and 1614 cm^{-1}, which are due to the C=O stretch (mainly carboxyl groups, esters, ketones, and aldehydes) and C=C stretch, respectively, are also present in the FT-IR spectra of the FA, although in different relative proportions. Indeed, while in the spectra of the FA the 1614 cm^{-1} band is very weak, in those of the LLE the intensity of this band is similar to that at 1716 cm^{-1}. This result shows that the LLE have a larger proportion of alkene structures and a smaller proportion of carbonyl compounds than the soil FA.

(*ii*) The 1518 cm^{-1} band, which occurs only in the spectra of the LLE, is assigned to protein residues (29). The presence of these molecular fragments confirms that decaying biological material is still present in these substances. This type of structure is not found in the FA, because protein fragments are transformed almost completely and mixed with other complex structures in the following stages of the humification process.

(*iii*) The 1450 cm^{-1} band, due to the bending of CH_2 and CH_3 structures, is only detected in the LLE. The presence of this well-defined band, together with those assigned to C–H bending (1366 and 1280 cm^{-1}), shows that these samples contain a relatively high proportion of aliphatic branches.

Besides these marked differences between the two types of spectra, analysis of Table 3 shows the existence of common bands in the C–O stretch and O–H bend spectral ranges, suggesting the existence of qualitatively similar structures in LLE and FA.

In conclusion, the FT-IR spectra allowed the identification of particularly reactive structures in the LLE, namely, alkene groups and protein fragments, that were not detected in the FA. These reactive structures play an important role in the decaying process of biomass in soil and in the humification process.

SyF spectra

The SyF spectra of the LLE and FA samples as a function of the Cu(II) concentration are shown in Fig. 3. These spectral sets show a major difference between LLE and FA. Indeed, while the SyF spectra of the LLE (Fig. 3*a–f*) are characterized by a strong and well-defined band around 280 nm, for FA (Fig. 3*g–h*) this band does not appear in the fuao1 spectra (extracted from the upper horizon (0–5 cm)) and is relatively weak in the fuao2 (from the lowest horizon (5–15 cm)). Monoaromatic phenolic structures and (or)

© 1998 NRC Canada

some fluorescent protein residues (tryptophan, tyrosine, and phenylalanine amino acid residuals) may be responsible for the 280 nm band (32) and the present results confirm the UV–Vis results and suggest that these types of structures are destroyed in the humification process of the LLE. Moreover, the shape of the SyF spectra of the LLE is simpler than for FA, i.e., the SyF bands are better defined in these spectra (Fig. 3*a*–*f*) than in those for FA (Fig. 3*g*–*h*), which show a high degree of overlapping.

The effect of Cu(II) on the SyF properties of the eight samples is different and the eight spectral sets can be classified into three classes according to the observed variations (quenching of fluorescence): (*i*) little variation is observed for ful and foa (Fig. 3*c*, *f*); (*ii*) marked quenching is observed in only one band of the spectra for feu, fer, fch, and fla (Fig. 3*a*, *b*, *d*, *e*); and (*iii*) marked quenching is observed in several bands or over a wide range of wavelengths for the FA samples (Fig. 3*g*, *h*). This shows that only some of the fluorescent structures that exist in the samples interact with Cu(II) at pH = 6, i.e., those that show quenching.

Further information about the LLE and FA can be obtained from the spectra shown in Fig. 3 as discussed in the following section.

[a]Component number.

Interaction with the Cu(II) ion

Self-modeling mixture analysis

The bands of each spectral data show different sensitivity towards the Cu(II) ion, owing to different complexation properties of the corresponding fluorescent structures. Any attempted detailed visual analysis of the observed spectral variations is useless, because of the large number of samples and different types of variations in the spectra. To overcome this difficulty, the three-dimensional spectral sets were analyzed by SIMPLISMA to reduce the information to a small number of components, each one characterized by a spectrum and a quenching profile (17, 21, 22). The quenching profile of the component (resulting from complex formation) that corresponds to the largest variation in each case permits an estimation of the respective equilibrium parameters (conditional stability constant and binding site concentration).

For all samples except ful, the SIMPLISMA analysis of the spectral sets, using criteria similar to those described previously (17), showed the existence of two components with linearly independent variations as the concentration of Cu(II) is increased. For ful, only one component was detected. The first of the two components is associated with the quenching provoked by the Cu(II) ion and the second to a non-varying (or showing a small variation) SyF spectrum. The first component is due to the binding structures that form stable complexes with Cu(II), while the second refers to structures that are not involved in the complexation, i.e., not accessible to the metal ion, or that form weak complexes with it.

The calculated spectra of the components for the eight samples are shown in Fig. 4 and, as examples, the concentration profiles for the feu and fuao2 samples are presented in Fig. 5. Table 4 shows the main bands of the SyF spectra of Fig. 4.

Inspection of Fig. 4 and Table 4 shows the following: (*i*) the main band of the first component, located at 350–355 nm, is observed in the feu, foa, fch, and fla samples; (*ii*) the main band of the second component, located at 280–285 nm, is observed in all the LLE samples and in fuao1; a second band, located at 390–395 nm, is present in the feu, foa, fch, and fuao1 samples. This result shows the existence of similarities both in the intrinsic SyF properties of the samples under analysis and in the variations imposed on those properties by the Cu(II) ion. Although the variations observed in the SyF spectra for each sample upon Cu(II) addition are now explained by a small number of spectra instead of the original set, this number is still too high to allow a detailed overall visual comparison. Therefore multidimensional pattern recognition techniques were applied to detect the similarities between them, as discussed below.

Figure 5*a* shows typical quenching profiles, i.e., the quenching of fluorescence as a function of the Cu(II) concentration, calculated for the two components of the feu sample. The curve corresponding to the first component shows the characteristic quenching, provoked by the Cu(II) ion, on the fluorescence of a binding site (17–20), while that for the second component shows little variation, indicating that the corresponding fluorescent structures are not involved in complexation reactions. The same observations can be made for the concentration profiles of the FA (Fig. 5*b* shows the profile for the fuao1 sample), but the curve for the second component is characterized by a larger quenching than for the LLE. This suggests that some of the structures that correspond to the second component of the soil FA samples compete with those of the first component for the complexation of Cu(II) ion.

Similarity analysis of the spectra of the detected components

the wavelengths) and Fig. 7 the nonlinear map resulting from their multidimensional scaling (24).

The shape of the dendrograms (Fig. 6) indicates that several well-defined clusters of spectra occur, because quite a number of agglomerations are observed in the high similarity zone. Using the similarity slit for cluster identification included in the dendrogram obtained when the average linkage (between groups) method was used (Fig. 6*a*), which is less than 1/5 of the total similarity scale, seven clusters are detected, named from I to VII. The composition of these seven classes is presented in Table 5. Using the same approach for the analysis of the dendrogram obtained by the Ward method, shown in Fig. 6*b* (now with a similarity slit of about 1/10 of the total similarity scale), the same seven clusters are detected.

Figure 7 shows the nonlinear map obtained from the multidimensional scaling of the calculated spectra of the components and includes schematic borders to indicate the previously detected classes. The goodness-of-fit of this scaling, given by the stress value, is 0.063. The distribution observed in Fig. 7 is compatible with the results of the cluster analysis and confirms that the elements within clusters I–IV are very similar, particularly those of clusters I and III. The analysis of Fig. 7 also shows that the one-element clusters V–VII are very dissimilar from all the others.

By considering the similarity of the clusters and their composition (Table 5), the following conclusions can be drawn: (*i*) the nature of the fluorescent structures and that of the qualitative composition of the binding site are very similar in the feu, fer, foa, and fla LLE but quite different from all the others; (*ii*) the same situation is observed for the soil FA samples, fuao1 and fuao2; (*iii*) the fch and ful LLE have unique fluorescent structures and qualitative compositions of the binding site. The dissimilarity of the ful sample agrees with the differences detected in its elemental analysis (relatively high H/C and N/C ratios).

Table 5. Composition of the classes detected in the cluster analysis.

Class	Classification	Elements
I	LLE	feu(2); fer(2); foa(2); fla(2)
II	FA	fuao2(1); fuao1(1)
III	LLE	feu(1); fer(1); foa(1); fla(1)
IV	FA	fuao2(2); fuao1(2)
V		fch(1)
VI		fch(2)
VII		ful(1)

Calculation of the equilibrium parameters

Table 6 presents the results of the nonlinear fitting to eq. [4] above of the observed quenching profiles for the component of each sample that shows larger quenching. The values of the parameters ΔE and SSR indicate that the quality of the fitting is quite good for all cases. Indeed, these

Table 6. Equilibrium parameters for the complexation of Cu(II) by LLE and FA. [a]

Sample	log K_c	Conc	I_{CuL}	N_p	ΔE	SSR	ΔCu
feu	5.35(1)	0.11(2)	35(4)	13	0.30	2.1	0.008–0.1
fer	5.8(2)	0.057(9)	20(3)	9	0.30	1.6	0.007–0.09
foa	4.5(1)	0.13(2)	20(6)	17	0.36	3.2	0.01–0.1
fch	5.05(7)	0.13(1)	22(4)	12	0.45	4.1	0.008–0.2
fla	5.0(2)	0.04(1)	9(3)	13	0.36	2.9	0.005–0.1
ful	4.1(1)	[b]	77(2)	18	0.22	1.4	0.03–0.3
fuao1	4.43(7)	0.03(2)	1(1)	21	0.41	5.1	0.005–0.3
fuao2	4.6(2)	0.04(1)	4(2)	21	0.22	1.8	0.004–0.3

[a]log K_c: logarithm of the conditional stability constant; Conc.: concentration of the ligand (mM); I_{CuL}: fluorescence intensity value at the end of the titration; N_p: number of points used in calculations; ΔE: average deviation of the estimates; SSR: sum of squares of residuals; ΔCu: Cu(II) concentration range used in calculations (mM). Average and average deviations of three independent experiments in parentheses for log K_c, Conc., and I_{CuL} and typical values for the other parameters.
[b]No convergence within reasonable values was observed.

parameters are always relatively small (SSR < 6 and ΔE < 0.5), particularly ΔE, because the experimental error of the SyF measurement is about one fluorescence intensity unit.

I_{CuL} is the lower limit of fluorescence achieved when all the corresponding binding sites are bounded to Cu(II) and, because the complex is usually nonfluorescent (17, 18), corresponds to the percentage of fluorescent structures not accessible for complexation. Data in Table 6 show that this parameter depends on the sample and ranges from zero (fuao2) to 77 (ful). Four of the LL samples (feu, fer, foa, and fch) have values ranging between ca. 20 and 30 units, while the fla and ful samples have, respectively, a relatively lower (I_{CuL} = 9) and a much higher (I_{CuL} = 77) value. The soil FA samples have values of I_{CuL} near zero. This and the existence of other SyF bands with quite small quenching show that the LLE have a relatively higher percentage than soil FA of fluorescent material that does not interact with Cu(II).

Comparison of the conditional stability constants shows that most of the LLE samples have higher values (log K_c > 5), but two (foa and ful) have log K_c close to those of soil FA (log K_c around 4.5). The log K_c values for fuao1 and fuao2 are similar to those of other samples of the same type found in the literature (17–19).

Although the methodology used for equilibrium parameter estimation provides only rough estimates of the concentration of binding sites (17–20), the values of C_L in Table 6 provide semiquantitative information about the number of binding sites for Cu(II) present in the samples. While feu, foa, and fch have a higher concentration of binding sites (C_L > 0.1 mM) than the soil FA samples (C_L around 0.04 mM), fer and fla have lower. No value for C_L could be obtained for the ful sample, probably because it is much smaller than the remainder.

The differences in the complexation properties (K_c and C_L) and in the percentage of fluorescent structures not accessible for complexation (I_{CuL}) observed between LLE and FA are related to structural differences in the two materials. LLE include a wide range of aliphatic and aromatic, amine, carboxylic, and hydroxylic molecules with low molecular weight. The carboxylic acid structures, probably together with hydroxylic groups, form relatively stable complexes with Cu(II), contributing to relatively high stability constants and C_L values. Fluorescent structures without Cu(II) binding capacity remain uncomplexed, contributing to relatively high I_{CuL} values, i.e., the percentage of fluorescent structures not accessible for complexation is relatively high. Conversely, the FA are constituted by relatively high molecular weight molecules containing "humified" conjugates with carbonyl, ester, and hydroxyl groups having a lower binding constant (K_c), but if these groups are more evenly distributed, a larger fraction would be available for quenching (providing relatively lower I_{CuL} values).

The global analysis of the equilibrium parameters shown in Table 6 shows that these are compatible with the clusters found in the similarity analysis of the SyF spectra, with two exceptions: (*i*) the stability constant of the foa sample is somewhat smaller than those for the other members of clusters I and III (feu, fer, and fla); and (*ii*) the equilibrium parameters obtained for the fch sample are similar to those of the other LLE, but no similarity was observed in the analysis of the SyF spectra of the components.

Conclusion

The methodology for the study of FA and like substances presented in this paper proved to be useful for the classification of this type of substance and permits the detection of fine details.

With reference to the characterization of the LLE, this study provided comparative information on structural features and quantitative data about the complexation of Cu(II) by these substances. From a qualitative point of view, different materials originate in similar LLE (feu, fer, foa, and fla), which proved to be different from the soil FA. Spectroscopic results (FT-IR and SyF) suggest a higher ratio of aliphatic/aromatic structures for the LLE than for soil FA. Because LLE contain such reactive structures as alkene and protein residues, they are expected to undergo chemical transformations to HS in a relatively short time. Moreover, the binding sites for Cu(II) that exist in LLE are mainly composed of one type of structure, while those in soil FA show a higher degree of mixture.

The LLE (with the exception of ful) show an overall larger complexation capacity for Cu(II) than soil FA samples. This result confirms that these substances may play an important role in the retention of metal ions in the superficial soil horizons and may be active participants in their transport into the soil.

Solubilité de la β-cyclodextrine dans les mélanges eau – nitrate d'éthylammonium à 25°C

Stéphane Duvivier, Mireille Turmine et Pierre Letellier

Résumé : Les solubilités de la β-cyclodextrine ont été déterminées dans les mélanges eau – nitrate d'éthylammonium (NEA) à 25°C. Le NEA est un sel fondu à la température ambiante (θ_f = 14°C) miscible à l'eau en toutes proportions. Contrairement aux solvants moléculaires, l'ajout du NEA à l'eau a pour effet de diminuer la solubilité de la β-cyclodextrine. Pour les milieux riches en sel, cette solubilité augmente à nouveau pour atteindre dans le sel fondu pur, environ 20 fois celle de l'eau. Le comportement de la β-cyclodextrine dans les mélanges eau–NEA peut être décrit simplement dès lors que l'on suppose la présence en solution d'un ion complexe associant deux molécules de β-cyclodextrine à un ion éthylammonium, susceptible de précipiter avec l'ion nitrate. La solubilité de la β-cyclodextrine dans les mélanges eau–NEA a été comparée à celle d'autres composés moléculaires (la 3-nitroaniline et la 2,4-dinitrodiphénylamine) et au comportement d'un composé ionique (le bromure de dodécyltriméthylammonium).

Mots clés : nitrate d'éthylammonium, β-cyclodextrine, solubilité, produit de solubilité, complexe d'inclusion.

Abstract : β-Cyclodextrin solubilities were determined in water – ethylammonium nitrate (EAN) mixtures at 25°C. EAN is a molten salt at room temperature (θ_f = 14°C). It is miscible with water in the whole range of mixtures. Unlike molecular solvents, addition of EAN to water involves a decrease of β-cyclodextrin solubility. In mixtures rich in salt, this solubility increases anew. β-Cyclodextrin solubility in pure salt is about 20 times the value in pure water. β-Cyclodextrin behavior in water–EAN mixtures can be easily described by assuming the presence in solution of a complex ion linking two molecules of β-cyclodextrin to one ethylammonium ion, which precipitates with nitrate ion.

Key words: ethylammonium nitrate, β-cyclodextrin, solubility, solubility product, inclusion compounds.

Introduction

Le nitrate d'éthylammonium (NEA) est un sel fondu à température ambiante (température de fusion θ_f = 14°C), miscible en toutes proportions à l'eau (1–3) et à d'autres solvants comme le méthanol (4), ou l'acétonitrile (5). Il démixte partiellement avec le *n*-octanol (6, 7). Les mélanges eau–NEA peuvent être utilisés comme milieux réactionnels. Ils possèdent un produit d'autoprotolyse élevé de l'ordre de 10 qui permet de fixer l'acidité de ces milieux au moyen de solutions tampons (8). Les propriétés redox dans le sel pur ont été également explorées. Le domaine très large d'électroactivité du sel (supérieur à 2 V), et sa conductivité importante, permettent d'envisager son utilisation comme solvant pour la synthèse électrochimique (9). Evans et al. ont montré que le sel pur possédait curieusement des propriétés physicochimiques très comparables à celles de l'eau (10). Ainsi, les amphiphiles ioniques peuvent former des édifices micellaires à des concentrations critiques 5–10 fois supérieures à celles observées en milieu aqueux (11, 12). D'autres types de structures organisées, telles que des bicouches phospholipidiques ou des cristaux liquides (13) ont pu être mises en évidence dans ce milieu salin. L'activité enzymatique de la phosphatase alcaline se conserve dans les mélanges eau–NEA jusqu'à plus de 60% en volume de sel (14). Cette ressemblance de comportement entre l'eau et le sel pur a été attribuée à la capacité de celui-ci de former des structures tridimensionnelles, entre le cation en configuration tétraédrique avec ses trois atomes d'hydrogène donneurs et l'anion plan et ses trois sites accepteurs. Cette structure est différente de celle, également tridimensionnelle, de l'eau qui ne fait intervenir que deux sites d'interaction donneur–accepteur de liaison hydrogène par molécule. Le passage de l'eau au NEA s'accompagne ainsi d'une modification de la structure du milieu. Les variations des grandeurs thermodynamiques (activités, volumes molaires partiels...) entre l'eau et le NEA pur traduisent cette évolution. Il a été ainsi montré que le nitrate d'éthylammonium se comportait comme un «briseur de structure» envers l'eau (5). Par ailleurs, les mélanges eau–NEA se caractérisent par un pouvoir solubilisant important envers les composés moléculaires. Ainsi, les solubilités de la 3-nitroaniline et de la 2,4-dinitrodiphénylamine dans le NEA pur sont de l'ordre de celles que l'on détermine dans un solvant hydro-organique à 70% en masse de méthanol ou encore à 45% en masse de dioxanne (8). Le NEA pur possède, sur ce plan, des propriétés qui le font ressembler à un solvant organique. Ce comportement ambivalent se traduit par la modification des propriétés physicochimiques d'un certain nombre de systèmes lorsqu'on les met en présence de NEA. Il en est ainsi des concentrations micellaires critiques des

tensioactifs cationiques qui diminuent tout d'abord lors de l'ajout de sel à l'eau (effet de sel sur les micelles en milieu aqueux), puis qui augmentent fortement pour les milieux les plus riches en sel (stabilisation de l'amphiphile par le milieu).

Un autre exemple, qui fait l'objet de cet article, peut être trouvé avec les variations de la solubilité de la β-cyclodextrine (CD) dans les milieux eau–NEA à 298 K. La β-cyclodextrine est un oligosaccharide cyclique susceptible de fixer, dans l'eau (15–18) et dans les solvants mixtes (19), un certain nombre de composés dans sa cavité interne hydrophobe. Cette propriété est mise à profit dans de nombreux domaines de l'industrie pharmaceutique et cosmétique (20). Malgré la présence à la surface de cette molécule, de groupements hydroxyles susceptibles d'interagir avec le milieu environnant, la solubilité de la β-cyclodextrine est anormalement basse dans l'eau ($C_{sat.}$ = $1{,}6 \times 10^{-2}$ mol L^{-1}) (21). Ce comportement est attribué à l'auto-agrégation par liaisons hydrogènes des molécules de β-cyclodextrine. La méthylation de la cyclodextrine a pour effet d'augmenter la solubilité de ce composé sans pour cela modifier ses propriétés de complexation (22). L'ajout à l'eau d'additifs qui la destructurent, comme le propanol, le DMSO (23), l'urée (24) ou différents sels (25) comme $Ca(NO_3)_2$ et $CaCl_2$, se traduit également par une augmentation de la solubilité de la β-cyclodextrine. Il apparaît ainsi que la solubilité de la β-cyclodextrine est un paramètre directement lié à la structure de l'eau dans le milieu réactionnel. Il était intéressant d'étudier cette grandeur dans les mélanges eau–NEA.

I. Partie expérimentale

I.1. Matériel

Le nitrate d'éthylammonium a été préparé selon une procédure décrite dans une publication antérieure (2). La β-cyclodextrine est un produit commercial de la société Ringdex, Orsan (France). Sa masse molaire est égale à 1135 g mol^{-1}. Le bromure de dodécyltriméthylammonium est un produit Aldrich.

I.2. Procédures

Les mélanges eau–NEA ont été préparés volumétriquement dans des fioles jaugées de 50 mL et versés dans des flacons bouchés. Une quantité suffisante de β-cyclodextrine est introduite dans chaque flacon contenant les mélanges et le NEA pur, de manière à ce que la limite de solubilité soit largement dépassée (100–200 mg de phase solide restent présents dans le milieu). Les solutions sont portées à 40°C, puis mises à agiter en thermostat pendant 48 h à 25°C. De la β-cyclodextrine solide est éventuellement ajoutée à la solution lorsque la quantité initiale s'avère insuffisante. La concentration de β-cyclodextrine saturée est déterminée par dosage potentiométrique en prenant le bromure de dodécyltriméthylammonium comme réactif selon une procédure très générale de dosage par ajout, utilisée par ailleurs pour le dosage des tensioactifs neutres (26) ou l'établissement d'isothermes d'adsorption (27). L'électrode indicatrice de l'ion amphiphile est préparée au laboratoire selon une technique précédemment exposée (20). Les opérations de dosage sont réalisées directement dans le milieu lui-même. La précision du dosage est de l'ordre de 5%.

II. Résultats expérimentaux

Les valeurs des solubilités de la β-cyclodextrine obtenues dans les mélanges eau–NEA sont reportées dans le tableau 1. On constate que la solubilité de la β-cyclodextrine décroît très fortement dès les premiers ajouts de sel. Elle passe par un minimum pour une concentration en NEA de l'ordre de 7 mol L^{-1}, puis augmente à nouveau très fortement. Dans le sel pur, la solubilité de la β-cyclodextrine est environ 20 fois celle de l'eau. Ce comportement de la cyclodextrine diffère également de celui observé dans la plupart des autres solvants (28) dans lesquels la solubilité de la β-cyclodextrine croît dès l'addition du co-solvant.

Le comportement de la β-cyclodextrine diffère également, pour les mélanges eau–NEA, de celui observé pour la plupart des autres molécules. Pour la 3-nitroaniline et la 2,4-dinitrodiphénylamine, la solubilité moléculaire croît dès l'addition du NEA, comme on peut le constater sur le tableau 2 qui regroupe des résultats antérieurs (8) obtenus dans les mêmes milieux. Ce type de variation est caractéristique de la non-spécificité des interactions entre le solvant et les composés moléculaires. Afin de comparer les amplitudes de ces variations nous avons reporté sur la figure 1 les enthalpies libres standard de transfert entre l'eau (E) et la solution saline (S) de la β-cyclodextrine et des deux anilines subtituées. On rappelle que, pour le composé *i*, lorsque sa concentration est suffisamment faible pour identifier les valeurs des concentrations à celles des activités, l'enthalpie libre standard de transfert entre l'eau et le solvant S s'écrit :

$$[1] \qquad \Delta_t G^o_{E\to S}(i) = {}^S\mu_i^\theta - {}^E\mu_i^\theta = RT \ln \frac{{}^E C_{sat}(i)}{{}^S C_{sat}(i)}$$

${}^S\mu_i^\theta$ et ${}^E\mu_i^\theta$ étant les potentiels chimiques standard de *i* en prenant comme référence l'état infiniment dilué.

Nous avons également illustré sur la figure 1, le comportement du bromure de dodécyltriméthylammonium (M^+) (12) en reportant la quantité

$$[2] \qquad Y = \Delta_t G^o_{E\to S}(M^+_{mic.}) - \Delta_t G^o_{E\to S}(M^+_{mono.}) = RT \ln \frac{{}^E cmc}{{}^S cmc}$$

correspondant à la différence des enthalpies libres standard de transfert du cation sous ses formes micellisée et monomère en fonction de la fraction molaire en sel du milieu. La cmc du tensioactif diminue fortement dès l'ajout du NEA à la solution, ce qui correspond au maximum de *Y*. Puis la cmc augmente à nouveau pour les fortes concentrations en sel, ce qui se traduit par une diminution continue de *Y*.

III. Interprétation des résultats

Les mesures de grandeurs d'excès (volume, enthalpies libres) sur les mélanges eau–NEA montrent que, pour des concentrations en sel inférieures à 2 mol L^{-1}, le NEA se comporte essentiellement comme un sel dissocié (2). Ce

domaine correspond à celui de la très forte diminution de la solubilité de la cyclodextrine. Coleman et al. (28) suggèrent que les additifs qui déstructurent l'eau augmentent la solubilité de la β-cyclodextrine par destruction des agrégats. Si l'on adoptait cette seule hypothèse, pour interpréter les présents résultats, il faudrait en conclure que le NEA renforce la structure de l'eau jusqu'à une fraction molaire x = 0,2 en NEA. Cette affirmation serait en contradiction avec les résultats de Perron et al. (5) qui démontrent qu'au contraire le NEA possède un caractère destructurant affirmé (5, 29).

Le comportement de la β-cyclodextrine s'apparente à celui des tensioactifs ioniques dont la concentration micellaire critique passe par un minimum lorsque l'on ajoute le NEA dans l'eau (voir tableau 2 et figure 1). La diminution de cmc correspond à une stabilisation de l'agrégat micellaire par diminution des interactions électrostatiques entre les têtes polaires de même signe lors de l'augmentation de la densité de charges dans la solution. La relation de Corrin–Harkins (30) rend compte de ces variations. Ceci suggère l'intervention d'une ou plusieurs espèces chargées dans l'équilibre de solubilisation de la β-cyclodextrine. La possibilité pour la β-cyclodextrine d'interagir avec des ions minéraux, comme NO_3^-, ClO_4^- a été évoquée dans plusieurs travaux (31, 32).

Supposons que la β-cyclodextrine (CD) forme, en solution, un complexe d'inclusion (C = $CD(EtA)_n$) avec n ions éthylammonium (E),

$$CD + nE \rightleftharpoons C$$

La constante de cet équilibre fait intervenir les activités des différentes espèces, référées à la solution infiniment diluée dans l'eau pour la β-cyclodextrine et le complexe, et au NEA pur pour l'ion éthylammonium.

$$[3] \qquad K = \frac{a_{CD}\cdot a_E^n}{a_C}$$

Supposons que le complexe intervienne dans un équilibre de solubilité (P = $CD(EtA)_n(NO_3)_n$) avec les ions nitrate (N) du milieu, selon

$$P \rightleftharpoons C + nN$$

Cette écriture suppose que le cation précipité possède une même stoechiométrie que l'ion complexe. Le produit de solubilité s'écrit :

$$[4] \qquad K_S = a_C a_N^n$$

L'activité de l'ion nitrate est également référée au sel pur.

La solubilité de la cyclodextrine, s, s'exprime en fonction des concentrations de CD et C :

$$s = [CD] + [C]$$

On peut considérer que pour les milieux les plus proches de l'eau, la solubilité est suffisamment faible pour que les valeurs des concentrations des cyclodextrines moléculaire et complexée s'identifient à leur activité et que les valeurs des potentiels chimiques standard de ces espèces sont encore peu affectées par la présence de sel (faible effet de solubilisation ou de relargage).

On peut alors écrire :

$$[5] \qquad s = [C]\left(1 + \frac{K}{a_E^n}\right)$$

x_{NEA}	ln γ_{NEA}	ln a_{NEA}	ln $s_{exp.}$	ln $s_{calc.}$
0,019	–1,106	–5,07	–6,38	–6,51
0,042	–0,820	–3,99	–7,08	–7,05
0,1	–0,520	–2,82	–7,60	–7,64

soit

$$[6] \qquad K_s = s\left(\frac{a_N^n}{1+\frac{K}{a_E^n}}\right)$$

soit

$$[7] \qquad s = \frac{K_s(a_E^n + K)}{(a_E a_N)^n} = \frac{K_s(a_E^n + K)}{(a_{NEA})^n}$$

l'activité du NEA étant liée à celle de ses ions par la relation :

$$[8] \qquad a_{NEA} = a_E a_N = \gamma_{NEA} X$$

Les valeurs du coefficient d'activité du NEA pur peuvent être calculées au moyen de la relation suivante (3) :

$$[9] \qquad \ln \gamma_{NEA} = -\frac{\Delta_d G_E^\theta}{RT}(\ln x + 1 - x)$$

où $\Delta_d G_E^\theta$ ($\Delta_d G_E^\theta = -919$ J mol^{-1}) est l'enthalpie libre standard de dilution de l'eau pure à dilution infinie dans le sel.

Les valeurs de l'activité du NEA ont été déterminées pour les milieux les plus dilués en sel et reportées dans le tableau 3.

La relation [7] admet plusieurs cas limites selon l'importance de la complexation de l'ion éthylammonium par la β-cyclodextrine dans la solution. Dans le cas particulier où l'on considère un complexe en solution très peu formé, le précipté $CD(EtA)_n(NO_3)_n$ est en équilibre avec la β-cyclodextrine et le nitrate d'éthylammonium selon :

$$CD(EtA)_n\,(NO_3)_n \rightleftharpoons CD + n\,NEA$$

La relation [7] devient alors

$$[10] \qquad s = \frac{K\,K_s}{(a_E\,a_N)^n} = \frac{K}{(a_E\,a_N)^n}$$

K est le produit du complexe de la β-cyclodextrine et du NEA dans le milieu considéré. La relation [10] peut encore être écrite

$$[11] \qquad \ln s = \ln K\,K_s - n \ln a_{NEA}$$

Le tracé de la courbe représentative de ln *s* en fonction de ln a_{NEA} conduit à une droite d'équation :

$$\ln s = -9{,}05 - 0{,}5 \ln a_{NEA}$$

On a reporté dans le tableau 3 les solubilités calculées par cette équation. Elles sont en excellent accord avec les valeurs expérimentales.

Il apparaît ainsi, que le comportement de la β-cyclodextrine dans les mélanges eau–NEA peut être convenablement décrit en supposant qu'il se forme un édifice insoluble associant deux molécules de β-cyclodextrine pour une molécule de NEA en équilibre avec de la β-cyclodextrine en solution et du nitrate d'éthylammonium.

© 1998 NRC Canada

Can. J. Chem. Downloaded from www.nrcresearchpress.com by China University of Science and Technology on 09/05/12
For personal use only.

Le produit des deux constantes est alors égal à :

$$P = KK_s = 1{,}2 \times 10^{-4}$$

Cette valeur relativement petite montre que les associations entre la cyclodextrine et le NEA sont relativement faibles et que la précipitation ne survient que parce que le sel est en forte concentration en solution. Nous avons pu vérifier, au cours des procédures de dosage que la β-cyclodextrine conservait ses propriétés complexantes, même dans le sel pur, envers l'ion dodécyltriméthylammonium. La diminution de la solubilité de la β-cyclodextrine avec l'ajout de nitrate d'éthylammonium à l'eau relève donc d'un effet de sel sur la solubilité et non pas d'un effet de solvant.

Pour les fortes concentrations en sel, le nitrate d'éthylammonium se comporte comme un solvant moléculaire. Celui-ci stabilise la β-cyclodextrine dont la solubilité croît à nouveau malgré l'enrichissement de la solution en ions nitrate. Le phénomène est patent près du sel pur.

Contrairement aux additifs moléculaires, la modification de la structure du milieu ne semble pas jouer un rôle déterminant dans le cas présent sur la solubilité de la β-cyclodextrine.

Conclusions

Contrairement à l'ensemble des solvants moléculaires étudiés par Coleman et al. (28) l'ajout du nitrate d'éthylammonium à l'eau a pour effet de diminuer la solubilité de la β-cyclodextrine. Cette solubilité passe par un minimum puis augmente lorsque le milieu s'enrichit en sel fondu. La solubilité dans le sel fondu pur est importante et comparable à celle déterminée dans des solvants organiques comme le diméthylformamide (28). Les variations de la solubilité de la β-cyclodextrine dans les mélanges eau–NEA peuvent être interprétées simplement dès lors que l'on suppose la formation d'un cation complexe associant deux molécules de β-cyclodextrine à une d'éthylammonium, susceptible de précipiter sous la forme d'un nitrate.

Pour les faibles concentrations en sel, la diminution de la solubilité s'explique alors par un simple effet de sel. Ce cas particulier est complémentaire de celui étudié par Sanemasa et al. (18) qui ont examiné les solubilités de la β-cyclodextrine en présence d'additifs moléculaires. Lorsque le milieu s'enrichit en NEA, le solvant obtenu possède un comportement qui le rapproche des milieux hydro-organiques. Son pouvoir solubilisant augmente par rapport aux espèces moléculaires comme la 3-nitroaniline et la 2,4-dinitrodiphénylamine. La β-cyclodextrine est stabilisée. La valeur de sa solubilité augmente alors continûment jusqu'au sel pur.

vic-Diacrylic ester porphyrins as starting materials for monobenzoporphyrin and *opp*-dibenzoporphyrin syntheses

Arezki Boudif, Sandrine Gimenez, Bernard Loock, and Michel Momenteau

Abstract : Synthesis of a bis(*vic*-diacrylic ester) porphyrin using the "3+1" methodology is described. A two-step procedure is used to convert the *vic*-diacrylic ester porphyrin and the bis(*vic*-diacrylic ester) porphyrin to the monobenzoporphyrin and the *opp*-dibenzoporphyrin, respectively. Characterization of the compounds by ^{1}H NMR and UV–visible spectroscopies is also discussed.

Key words: tripyrrane, diformylpyrrole, *vic*-diacrylic ester porphyrin, "3+1" synthesis methodology, monobenzoporphyrin, *opp*-dibenzoporphyrin, photosensitizer.

Résumé : Nous décrivons la synthèse de la tétra (acrylate d'éthyle) porphyrine, également appelée bis(*vic*-diacrylate de diéthyle) porphyrine, en utilisant la méthode « 3+1 » de synthèse des porphyrines. Une séquence réactionnelle comportant deux étapes est ensuite utilisée pour convertir les groupes acryliques de la *vic*-(acrylate d'éthyle) porphyrine et de la bis(*vic*-diacrylate de diéthyle) porphyrine, et obtenir une monobenzoporphyrine et une dibenzoporphyrine, respectivement. La caractérisation des composés, par RMN du proton et par spectroscopie UV–visible, est rapportée et discutée.

Mots clés : tripyrrane, diformylpyrrole, *vic*-di(acrylate d'éthyle) porphyrine, méthode de synthèse « 3+1 », monobenzoporphyrine, dibenzoporphyrine, photosensibilisateur.

Introduction

Benzoporphyrins, especially the lower analog mono- and dibenzoporphyrins, are interesting chromophores that may find application as photosensitizers in photodynamic therapies (PDT). Indeed, a new generation of photosensitizers is needed to accompany the development of this new therapy. In this regard, criteria for an efficient photosensitizer have been established (1, 2): (*i*) a well-defined structure with large absorption coefficients in the red region; (*ii*) a high yield in the energy transfer process leading to $^1O_2$ and (or) $(O_2)^-$ reactive species; (*iii*) no toxicity in the absence of light; (*iv*) a preferential retention in tumor tissues and rapid evacuation from normal tissues.

Our objective in this work is to design porphyrins with expanded aromatic systems and bearing substitutents that could be easily converted to permit water solubility. Herein is reported the development of a short route for the synthesis of a monobenzoporphyrin **1** and an *opp*-dibenzoporphyrin **2**, in which the benzene isocycles are substituted by two ester groups. The starting material for the synthesis of **1** (Scheme 1) is the *vic*-diacrylic ester porphyrin **3**, whereas **2** (Scheme 2) was obtained from the bis(*vic*-diacrylic ester) porphyrin **4**.

Work on monobenzoporphyrins was initially motivated by the desire to determine a common structure (and to confirm some structural assumptions) of a series of petroporphyrins showing a rhodo-type electronic absorption spectrum. In pursuit of this aim, Clezy et al. (3) reported the preparation of monobenzoporphyrins using two different routes (Scheme 3, routes a and b). In the first approach, the starting material was a free-base porphyrin bearing a six-membered ring as a precursor of the isocycle (Scheme 3, route a). The second approach involved the formation of the benzene isocycle on a preformed zinc porphyrin. This was achieved through a Dieckmann cyclization on a pyrrole subunit conveniently substituted by propionic and acetic side chains (Scheme 3, route b). Investigating the ring-closure process, Chaudhry and Clezy (4) reported unsuccessful attempts to cyclize divinyl porphyrins in order to obtain monobenzoporphyrins. In contrast, di-(2-chloroethyl)porphyrins undergo a cyclization process to lead to a very low yield (about 1%) of monobenzoporphyrin. However, the aromatization of a cyclohexenylporphyrin isolated as a minor product (about 5%) in the basic treatment of the *vic*-divinylporphyrin afforded the desired monobenzoporphyrin.

Extension of the macrocycle π-system is one of the approaches to increase absorption in the red. Thus Bonnett and McManus (5) reported the synthesis of *opp*-dibenzoporphyrins by self-condensation of benzopyrromethene hydrobromides and later Smith and co-workers (6) also reported synthesis of an *opp*-dibenzoporhyrin in which the two benzo isocycles had been generated by aromatization of cyclohexyl moieties. In addition to purpurins in which a

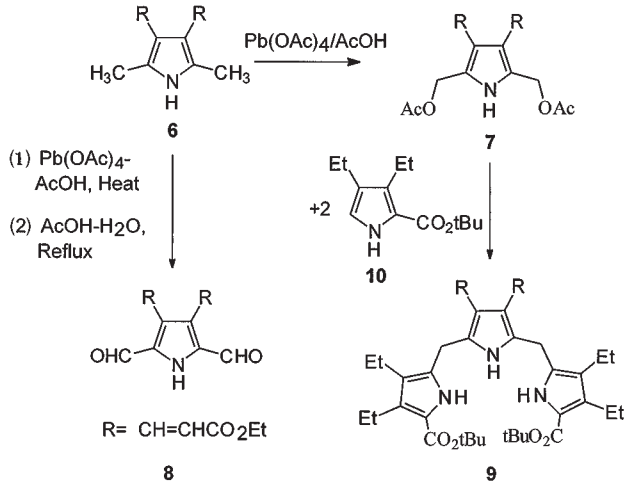
fused conjugated five-membered isocycle provides an interesting absorption feature (7), synthesis and evaluation of other types of photosensitizers have been reported in the literature. Among these are benzochlorins (8–10), which combine the extension of the π-system of the macrocycle and the absorption pattern of chlorins for a promising approach.

Results and discussion

In previous reports, we have described the preparation of vicinal diacrylic ester porphyrins using the "3+1" methodology, including the porphyrin **3** (Scheme 1) (11, 12). The same strategy was applied to the synthesis of the tetra acrylic ester porphyrin **4** (Scheme 2), also designated as the bis(*vic*-diacrylic ester) porphyrin. Starting from the 3,4-di(ethoxycarbonylvinyl)-2,5-dimethylpyrrole **6** (Scheme 4), the α- and α′-methyl groups have been oxidized either to obtain the 2,5-diacetoxymethylpyrrole **7** or the 2,5-diformylpyrrole **8**. We have described the preparation of these two compounds in a previous publication (12). However, in order to improve the yield of the reaction leading to the diformylpyrrole **8**, we have undertaken a modification of the procedure. Indeed, when the dimethyl derivative **6** was heated in the presence of 4 equivalents of $Pb(OAc)_4$ in glacial acetic acid, followed by the hydrolysis of the intermediate (probably the dihemiacetal pyrrole), the diformyl pyrrole

© 1998 NRC Canada

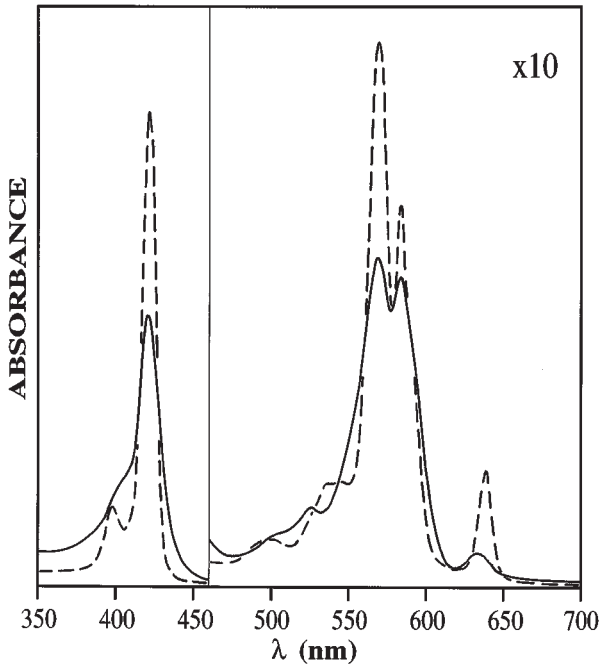
Scheme 4.



8 was isolated in 30% yield. Synthesis of the tripyrrane **9** (Scheme 4) was achieved by condensation of 2 equivalents of the α-free position pyrrole **10** with the 2,5-diacetoxymethylpyrrole **7**, catalyzed by an acidic clay (Montmorillonite K 10). The pyrrole **10** was prepared according to the procedure reported by Zard, Barton, and co-workers (13). Protection of the 1- and 14-positions of the tripyrrane **9** by *tert*-butyl esters, instead of benzyl esters, allowed us to remove these moieties without reducing the acrylic double bonds. Tripyrrane **9** was then treated with TFA and stirred for 4 h at room temperature before adding the diformylpyrrole **8** in dry methylene chloride. This mixture was then stirred for 16 h in the dark. Addition of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) completed the oxidation of the resulting porphyrinogen and the bis(*vic*-diacrylic ester) porphyrin **4** was isolated in 40% yield. When the porphyrin **3** in acetic acid solution was heated at reflux under argon, the ring closure occurred to afford quantitatively the cyclohexenylporphyrin **5** (Scheme 1). However, it is unlikely that acetic acid could protonate the acrylic double bonds under these conditions. Therefore, the formation of the cyclohexenyl ring could result from a thermal intramolecular Diels–Alder reaction followed by a rearrangement of the π-system. Porphyrin **5** was then refluxed in toluene, in the presence of 4 equivalents of DDQ. The oxidation–aromatization process led to the monobenzoporphyrin **1** (Scheme 1) in 64% yield.

A second product of this reaction was identified as the diacrylic ester porphyrin **3** resulting from a retro Diels–Alder process. The same procedure as described above was applied to convert the porphyrin **4** into a bis(cyclohexenyl) porphyrin. As expected, this reaction gave a mixture of intermediate isomers that was used in the following step without further purification. During the oxidation–aromatization step, triethylamine was added to minimize the six-membered ring opening, as mentioned in the case of **5**. The *opp*-dibenzoporphyrin **2** was then isolated in 40% yield (Scheme 2). Identification of porphyrins **1**, **2**, **4**, and **5** was achieved by ^{1}H NMR in $CDCl_3$. In the case of the cyclohexenylporphyrin **5**, the *meso* protons are magnetically nonequivalent since they give four singlets near 10 ppm. One can note the disappearance of the doublets at 9.28 and

Fig. 1. UV–visible absorption spectra of **1** (——) and **2** (——) in CH_2Cl_2.



7.05 ppm, corresponding to acrylic protons of compound **3**. These were replaced by weakly coupled doublets at 5.03 and 5.12 ppm attributable to protons borne by the 5′-asymmetric carbon. Protons at the 6′-position appear as a multiplet at 5.48 ppm. The proton NMR spectrum of porphyrin **1** showed two singlets at 10.2 and 10.3 ppm for the *meso* protons and a singlet at 9.62 ppm for the 3′- and 6′-protons of the isocycle, suggesting the presence of a plane of symmetry and thus confirming the aromatization of the six-membered isocycle. NMR spectra of **2** and **4** were even simpler because of the presence of two planes of symmetry. Indeed, *meso* proton signals for each of these porphyrins were seen as singlets at 9.66 and 9.84 ppm, respectively. One should note the striking influence of the substituted benzene groups on the NH resonances, resulting in an upfield shift (–5.93 ppm in $CDCl_3$), in comparison to the shifts of the same groups in the 7,8,17,18-dibenzo-2,3,12,13-tetraethylporphyrin (δ, –2.65 ppm) reported by Smith and co-workers (5).

UV–visible electronic spectra (Fig. 1) of compounds **1** and **5** in dichloromethane show oxorhodo-type spectra. This spectral type is generally obtained when substituents in appropriate relative positions exercise a strong electron-withdrawing effect on the porphyrin macrocycle. Although monobenzoporphyrins reported by Clezy et al. (3) show a rhodo-type spectrum, the absorption feature shown by **1** seems to be consistent with the proposed structure since the electronic effect exercised by the two carboxyl groups is still evident due to the extension of the conjugated system. The same general absorption feature was observed in the case of the dibenzoporphyrin **2**.

From the synthetic point of view, this reaction sequence is an advantageous route allowing conversion of two peripheral acrylic groups, at the vicinal β-pyrrolic positions on porphyrins, into a six-membered conjugated isocycle. The route

will be of interest to chemists wishing to develop a new generation of chromophores as potent photosensitizers for photodynamic therapies.

Experimental section

3,4-Di(ethoxycarbonyl vinyl)-2,5-diformyl pyrrole 8

A suspension of lead tetraacetate (9.75 g, 22 mmol) and the 3,4-di(ethoxycarbonyl vinyl)-2,5-dimethyl pyrrole (1.45 g, 5 mmol) in glacial acetic acid (75 mL) was heated at 80–90°C for 2 h. Afterwards, the resulting solution was concentrated under vacuum, diluted with CH_2Cl_2, washed with water, neutralized with aqueous $NaHCO_3$ solution, and washed again with water. The organic layer was ultimately dried over Na_2SO_4 and the solvent was evaporated. The purpose of this first work-up was to remove lead salts. The solid was dissolved again in acetic acid (50 mL). An equal volume of H_2O was added and the mixture was heated at 80°C, for an hour. The solvent was evaporated under vacuum and the residue was dissolved in dichloromethane. This organic phase was treated with an aqueous solution of $NaHCO_3$, washed with water, and dried over Na_2SO_4. The drying agent was removed by filtration and the concentrated solution of the crude product was chromatographed on a silica gel column eluting with CH_2Cl_2/Et_2O (10/1, v/v), then (10/2, v/v). After evaporation of the solvent, the diformylpyrrole **8** (0.48 g, 30%) was obtained as a white solid. ^{1}H NMR ($CDCl_3$, 200 MHz), δ, ppm: 10.62 (1H, br, NH), 9.96 (2H, s, CHO), 7.85 (2H, d, $J_{HH\ trans}$ = 16 Hz, CH=), 6.28 (2H, d, $J_{HH\ trans}$ = 16 Hz, =CH), 4.25 (4H, q, CH_2CH_3), 1.3 (6H, t, CH_2CH_3). Anal. calcd. for $C_{16}H_{17}NO_6$: C 60.18%, H 5.33%, N 4.38%; found: C 59.22%, H 5.78%, N 3.91%.

1,4-Di(*tert*-butoxycarbonyl)-7,8-diethoxycarbonylvinyl-2,3,12,13-tetraethyl tripyrrane 9

Montmorillonite K-10 clay (1 g) was added to a solution of pyrroles **7** (0.5 g, 1.2 mmol) and **10** (0.630 g, 2 equiv.) in CH_2Cl_2 and the mixture was stirred at room temperature for 6 h. The reaction was monitored by TLC. The clay was removed by filtration and the organic phase was neutralized with aqueous $NaHCO_3$ solution, washed with water, and dried over Na_2SO_4. The crude product was chromatographed over a silica gel column with elution by mixtures of CH_2Cl_2/Et_2O (100/3, v/v) then (100/5, v/v). The desired tripyrrane **9** (0.566 g, 63%) was collected. ^{1}H NMR ($CDCl_3$, 200 MHz), δ, ppm: 8.39 (2H, br, 15- and 17-NH), 7.78 (2H, d, $J_{HH\ trans}$ = 16 Hz, CH=), 7.55 (1H, br, 16-NH), 5.99 (2H, d, $J_{HH\ trans}$ = 16 Hz, =CH), 4.25 (4H, q, OCH_2CH_3), 3.91 (4H, s, bridge CH_2), 2.6 and 2.25 (8H, q, CH_2CH_3), 1.5 (18H, s, $C(CH_3)_3$), 1.3 (6H, t, OCH_2CH_3), 1.1 and 0.85 (6H, t, CH_2CH_3). Anal. calcd. for $C_{46}H_{51}N_3O_8$: C 71.41%, H 6.59%, N 5.43%; found: C 71.31%, H 6.71%, N 5.18%.

[2,3]-(4′,5′-Diethoxycarbonyl cyclohex-3′-enyl)-12,13-di(ethoxycarbonyl ethyl)-7,8,17,18-tetraethyl porphyrin 5

Porphyrin **3** (50 mg, 0.06 mmol) was dissolved in glacial acetic acid (20 mL) and refluxed under nitrogen for 10 h. After the solvent was evaporated under reduced pressure, the crude product was dissolved in CH_2Cl_2 and the organic phase was neutralized, washed with H_2O, and dried over Na_2SO_4. Evaporation of the solvent led to the porphyrin **2** in quantitative yield after recrystallization from methanol. UV–visible (in CH_2Cl_2), λ_{max} (nm)(ε 10^{-3} M^{-1} cm^{-1}): 414 (198.9), 513 (10.1), 555 (27.8), 574 (15.6), 641 (2.5). ^{1}H NMR ($CDCl_3$, 200 MHz), δ, ppm: 10.09, 10.05, 10.02, 10.0(4H, 4s, *meso* H), 9.28 (1H, s, 2′-CH=), 5.1 (1H, dd, J_{HH} = 17.5 Hz, 4′-H), 4.6 (2H, m, 5′-CH_2), 4.41 (4H, t, $CH_2CH_2CO_2$), 4.20 (16H, m, CH_2CH_3 and 4 OCH_2CH_3), 1.93, 1.55, 1.18 (24H, 3m, 4 OCH_2CH_3 and 4 CH_2CH_3), –3.69 (2H, s, NH). Anal. calcd. for $C_{48}H_{58}N_4O_8 \cdot CH_3OH$: C 69.15%, H 7.34%, N 6.58%; found: C 69.41%, H 7.08%, N 6.71%.

[2,3]-(4′,5′-Diethoxycarbonyl benzo)-12,13-di(ethoxycarbonyl ethyl)-7,8,17,18-tetraethyl porphyrin 1

The cyclohexenylporphyrin **5** (50 mg, 0.06 mmol) in dry toluene (20 mL) was refluxed under nitrogen, for 24 h, in the presence of DDQ (55 mg, 4 equiv.). The solution was allowed to cool to room temperature and was washed several times with water to remove the oxidizing agent. The organic layer was then dried over Na_2SO_4. TLC analysis revealed the presence of two compounds with very close polarities. Nevertheless, the two porphyrins could be separated on preparative silica gel plates, after several elutions with CH_2Cl_2/Et_2O (10/2, v/v). The more polar band was the diacrylic porphyrin **3**. The slightly less polar band weighing 32 mg (64%) was found to be the monobenzoporphyrin **1.** It was recrystallized from methanol. UV–visible (in CH_2Cl_2), λ_{max} (nm)(ε 10^{-3} M^{-1} cm^{-1}): 421 (276.4), 498 (shoulder), 531 (7.8), 567 (33.4), 580 (31.4), 632 (2.8). ^{1}H NMR ($CDCl_3$, 200 MHz), δ, ppm: 10.29, 10.19 (4H, 2s, *meso* H), 9.62 (2H, s, benzo-H), 4.6 and 4.2 (16H, 2m, 4 OCH_2CH_3 and 4 CH_2CH_3), 4.54 (4H, t, $CH_2CH_2CO_2$), 3.26 (4H, t, $CH_2CH_2CO_2$), 1.9, 1.5, and 1.3 (24H, 3m, CH_2CH_3 and OCH_2CH_3), –3.76 (2H, s, NH). Anal. calcd. for $C_{48}H_{58}N_4O_8.CH_3OH$: C 69.33%, H 7.07%, N 6.60%; found: C 69.47%, H 6.61%, N 6.73%.

2,3,12,13-Tetraethoxycarbonyl vinyl-7,8,17,18-tetraethyl porphyrin 4

Tripyrrane **9** (88 mg, 0.12 mmol) was treated with trifluoroacetic acid (1 mL) and stirred under argon for 4 h. Dry methylene chloride (7 mL) was added followed by a solution of 2,5-diformyl pyrrole **8** (38 mg, 0.12 mmol) in CH_2Cl_2. The reaction mixture was stirred at room temperature, in the dark, for 16 h and the reaction progress was monitored by UV–visible spectroscopy. The solution was cooled with an ice-water bath during neutralization by addition of 2.5 mL of triethylamine. Oxidation of the porphyrinogen intermediate was completed by addition of DDQ (55 mg, 0.24 mmol) as a solution in THF (1.5 mL) with subsequent reflux of the mixture for 1 h. After being diluted with 30 mL of CH_2Cl_2, the solution was treated with dilute aqueous sodium hydroxide and then washed with water to neutral pH. After drying over Na_2SO_4 the organic layer was filtered and the solvent was evaporated. The crude product was chromatographed on a silica gel column with elution by mixtures of CH_2Cl_2–Et_2O with increasing ratios of diethyl ether from 100/1 to 100/3 (v/v). Recrystallization

© 1998 NRC Canada

from CH_2Cl_2–MeOH gave 39 mg, 40% of the desired porphyrin **4**. UV–visible (in CH_2Cl_2), λ_{max} (nm) (ε 10^{-3} M^{-1} cm^{-1}): 407 (shoulder), 431 (205), 536 (5), 591 (31.4), 614 (38.5). ^1H NMR ($CDCl_3$, 200 MHz), δ, ppm: 9.84 (4H, s, *meso* H), 9.07 (4H, d, J_{HH} = 16 Hz, CH=), 6.95 (4H, d, J_{HH} = 16 Hz, =CH), 4.59 (8H, q, OCH_2CH_3), 4.00 (8H, q, CH_2CH_3), 1.84 (12H, t, CH_2CH_3), 1.58 (12H, t, OCH_2CH_3), -4.57 (2H, s, NH). Anal. calcd. for $C_{48}H_{54}N_4O_8$: C 70.74%, H 6.68%, N 6.87%; found: C 69.85%, H 6.64%, N 6.76%.

***opp*-Di [4′,5′-(diethoxycarbonyl) benzo]-2,3,12,13-tetraethyl porphyrin 2**

Porphyrin **4** (82 mg, 0.1 mmol) was dissolved in glacial acetic acid (30 mL) and refluxed under inert atmosphere for 10 h. The solvent was then evaporated and the product of the reaction was redissolved in CH_2Cl_2. The solution was neutralized with an aqueous solution of $NaHCO_3$, washed with water, and dried over Na_2SO_4. The drying agent was removed by filtration and the solvent was evaporated. Recrystallization from methanol afforded 80 mg (98%) of the dicyclohexenylporphyrin isomeric mixture. This latter compound (40 mg, 0.05 mmol), along with DDQ (45 mg, 4 equiv.) and triethylamine (28 ml, 4 equiv.), was dissolved in toluene (15 mL) and refluxed for 24 h. The reaction was cooled to room temperature, washed once with H_2O, and then with a 10% aqueous NaOH solution. The organic phase was then dried over Na_2SO_4 and the drying agent was removed by filtration. The solution was concentrated and chromatographed over a silica gel column with elution by mixtures of CH_2Cl_2/Et_2O 100/2 (v/v) and 100/5 (v/v). Recrystallization from methanol afforded the dibenzoporphyrin **2** (20 mg, 45%) as purple crystals. UV–visible (in CH_2Cl_2), λ_{max} (nm)(ε 10^{-3} M^{-1} cm^{-1}): 398 (79), 421 (487), 498 (shoulder), 544 (10.6), 569 (55.8), 582 (39.1), 638 (11.8). ^1H NMR ($CDCl_3$, 200 MHz), δ, ppm: 9.66 (4H, s, *meso* H), 9.43 (4H, s, benzo-H), 4.8 (8H, q, OCH_2CH_3), 3.9 (8H, q, CH_2CH_3), 1.6 and 1.3 (24H, m, OCH_2CH_3 and CH_2CH_3), –5.93(2H, s, NH). Anal. calcd. for $C_{46}H_{51}N_4O_8$: C 71.09%, H 6.21%, N 6.91%; found: C 69.78%, H 6.17%, N 6.79%.

Acknowledgments

We would like to thank Prof. Harold Goff (University of Iowa, Department of Chemistry, Iowa City) for useful discussions and for his assistance with the revision of this paper. We would like also to express our gratitude to Dr. Philippe Maillard (UMR 176 du CNRS, Institut Curie-Recherche, Université Paris-Sud, Orsay, France) for his constant encouragement and helpful suggestions.

Abstract: The compound $[SNS]^+$ ($[SNS][AsF_6]$) reacts with benzene in liquid sulfur dioxide to give orange-, blue-, and then purple-colored solutions. The assignment of the orange color to a molecule–ion charge-transfer complex $[C_6H_6{\cdot}SNS]^+$ is supported by the linear dependence of the ionization potential of the arenes (C_6H_6, C_6H_5Me, $C_6H_5Bu^t$, C_6HMe_5) and the energy of the charge-transfer absorption of freshly prepared arene–$[SNS][AsF_6]$ mixtures in liquid SO_2 solution. Variable-temperature multinuclear NMR studies of the reactions of $[SNS][AsF_6]$ and $[SNS][Sb_2F_{11}]$ with benzene are consistent with the blue color being due to a sulfur protonated substitution product $[C_6H_5(S_2N)H]^+$, providing the first example of a CH electrophilic substitution reaction of SNS^+. The geometries calculated at the RHF/6-31G* level for $[C_6H_5(SNS)H]^+$, the isomeric $[C_6H_5NSSH]^+$, and $[C_6H_5N(S)SH]^+$, together with NMR data, support $[C_6H_5(SNS)H]^+$ (i.e., suggest S, not N, is attached to the ring) as the structure of the cation. The electrophilic aromatic substitution reaction of $[SNS]^+$ and benzene is also supported by NMR studies of $[SNS][AsF_6]$ and other arenes (e.g., C_6HMe_5) in SO_2 solution. The UV-visible spectrum of $[SNS]^+$ ($[SNS][AsF_6]$) in liquid SO_2 is reported, and the absorption (λ = 406 nm, ϵ = 80) responsible for the yellow color is assigned to the $[SNS]^+$ HOMO–LUMO transition. Evidence is also presented for the formation of a molecule–ion charge-transfer complex between 5-methyl-1,3,2,4-dithiadiazolium and hexamethylbenzene in liquid SO_2, the first dithiadiazolium charge-transfer complex.

Key words: UV-visible, charge transfer, dithionitronium, benzene, electrophilic substitution.

Résumé : Le $[SNS]^+$ ($[SNS][AsF_6]$) réagit avec le benzène dans le dioxyde de soufre liquide pour donner des solutions colorées successivement en orange, bleu et finalement violet. L'attribution de la couleur orange à un complexe de transfert de charge molécule–ion $[C_6H_6{\cdot}SNS]^+$ découle de la dépendance linéaire du potentiel d'ionisation des arènes (C_6H_6, C_6H_5Me, *t*-BuC_6H_5, C_6HMe_5) et l'énergie de l'absorption de transfert de charge de mélanges fraîchement préparés d'arène–$[SNS][AsF_6]$ en solution dans le SO_2 liquide. Des études RMN multinucléaires à températures variables des réactions du $[SNS][AsF_6]$ et du $[SNS][Sb_2F_{11}]$ avec le benzène seraient en accord avec le fait que la couleur bleue est due à un produit de substitution protoné du soufre $[C_6H_5(S_2N)H]^+$; ceci constituerait le premier exemple de réaction de substitution électrophile de SNS^+ par un CH. Les géométries calculées au niveau RHF/6-31G* pour le $[C_6H_5(SNS)H]^+$ et les formes isomères $[C_6H_5(NSSH]^+$ et $[C_6H_5N(S)SH]^+$ considérées avec les données de la RMN sont en accord avec une structure $[C_6H_5(SNS)H]^+$ (c'est-à-dire que le S, et non pas le N, est attaché au noyau) pour le cation. La réaction de substitution aromatique électrophile du $[SNS]^+$ et du benzène est aussi appuyée par des études RMN du $[SNS][AsF_6]$ et d'autres arènes (comme le C_6HMe_5) en solution dans le SO_2 liquide. On a mesuré le spectre UV-visible du $[SNS]^+$ ($[SNS][AsF_6]$) dans le SO_2 liquide et l'absorption (λ = 406 nm, ϵ = 80) responsable de la couleur jaune est attribuée à la transition des OM HO et BV du $[SNS]^+$. On présente aussi des données relatives à la formation d'un complexe de transfert de charge molécule–ion entre le 5-méthyl-1,3,2,4-dithiadiazolium et l'hexaméthylbenzène dans le SO_2 liquide; il s'agirait du premier complexe de charge du dithiadiazolium.

Mots clés : UV-visible, transfert de charge, dithionitronium, benzene, substitution électrophile.

[Traduit par la rédaction]

Introduction

Aromatic nitration has been of interest in organic chemistry for many years (1). It was shown by Ingold and co-workers (2) in 1946 that nitronium $[ONO]^+$ was the reactive intermediate in the nitration of benzene by a mixture of sulfuric and nitric acids. Since then many reactions of salts of $[ONO]^+$ with arenes have been investigated. Spectroscopic and other evidence indicate that nitration of arenes proceeds in essentially two steps: first the formation of a charge-transfer complex (eq. [1]), followed by the formation of the Wheland complex **1** as shown in eq. [2] (1, 3).

[1] $$C_6H_6 + [ONO]^+ \rightarrow [C_6H_6{\cdot}NO_2]^+$$

[2] $$[C_6H_6{\cdot}NO_2]^+ \rightarrow \mathbf{1} \rightarrow C_6H_5NO_2 + \text{“}H^+\text{”}$$

The sulfur analog of nitric acid HNS_3 is unknown. However, dithionitronium $[SNS]^+$, the analog of $[ONO]^+$, can be

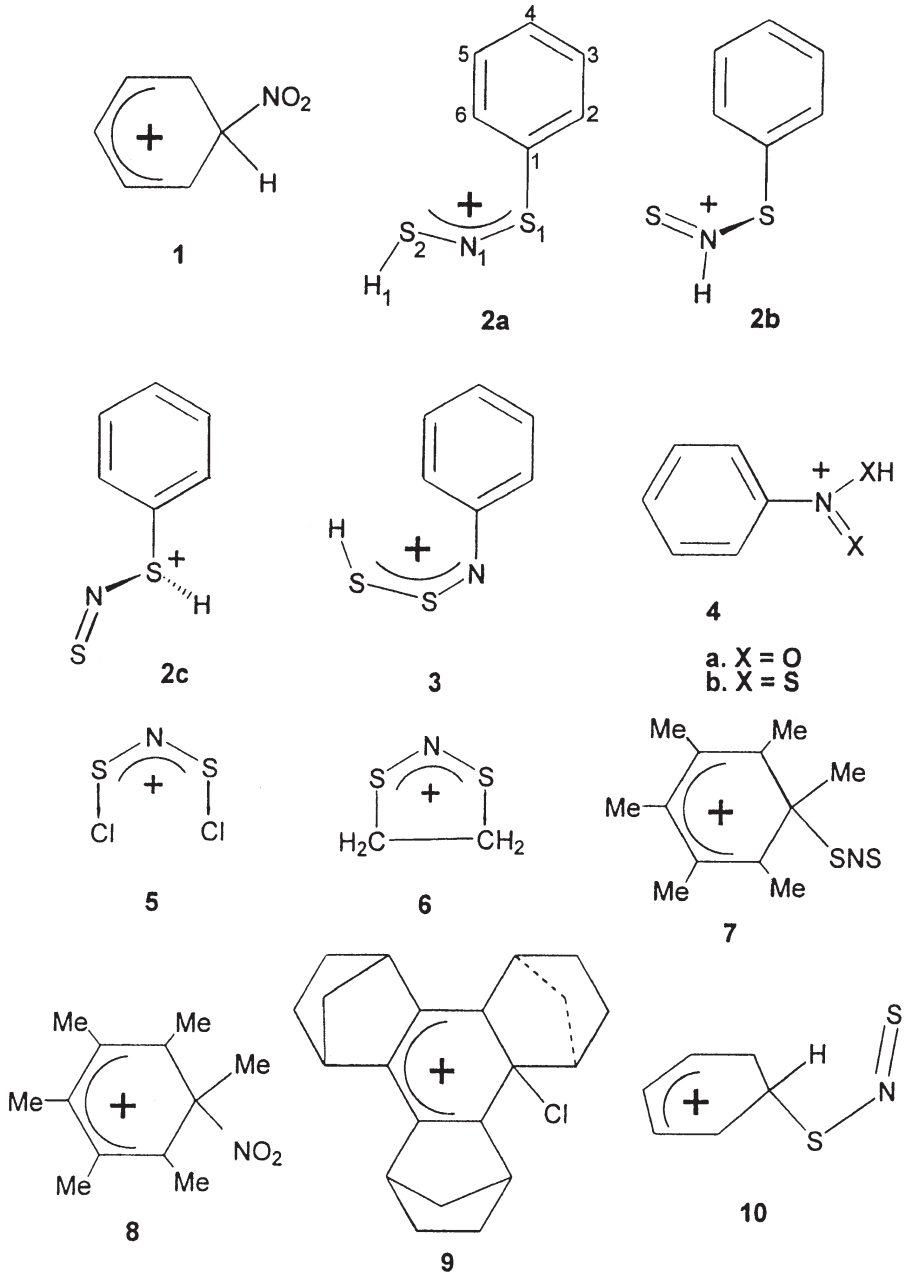
For personal use only.



readily synthesized as the hexafluoroarsenate $[AsF_6]^-$ salt (4). We have shown (5) that $[SNS]^+$ (as $[SNS][AsF_6]$ in liquid sulfur dioxide) has an extensive symmetry allowed concerted cycloaddition chemistry with a wide range of multiple bonds including C≡N (5*a–e*), C≡C (5*a–e*), C=C (5*d–g*), C≡P (5*h*), and S≡N (5*i*). Analogous reactions of $[ONO]^+$ generally lead to nitration (1). Therefore it was of interest to investigate the reactions of $[SNS]^+$ with benzene and related arenes.

Preliminary experiments showed that $[SNS]^+$ reacted with benzene in liquid sulfur dioxide to give an orange solution, which changed to blue then purple with time (5*d*). In this work we present evidence that the color of the orange solution is due to a π–π^* molecular (more formally a molecule–ion) charge-transfer complex $[C_6H_6 \cdot SNS]^+$, and that the blue species is the sulfur protonated substitution product $[Ph(S_2N)H]^+$ (Ph = C_6H_5) (i.e., **2**, **3**, or **4b**). A preliminary account of this work has been reported (6).

Experimental

Benzene and C_6H_5Me were purchased from Anachemia, $C_6H_5Bu^t$ from Aldrich, and were dried over CaH_2. The C_6HMe_5 and C_6Me_6 were purchased from Anachemia and were used as received. Sulfur dioxide was obtained from Matheson and dried over CaH_2. The preparation of $[SNS][AsF_6]$ and general techniques were as previously described (4). The $[SNS][AsF_6]$ often contained a very small amount of brown impurities, and further purification was carried out for the spectroscopic studies. The UV-visible spectra were recorded using a Hewlett–Packard 8452A spectrophotometer. The acquisition of FT–Raman (5*c*, *f*) and NMR (^1H, ^{13}C, ^{14}N) (5*g*) spectra are described elsewhere.

The preparation of high-purity $[SNS][AsF_6]$

The SO_2 (2.90 g) was condensed at –196°C onto yellow

Fig. 1. The UV-visible spectrum of $[SNS][AsF_6]$ in liquid SO_2.

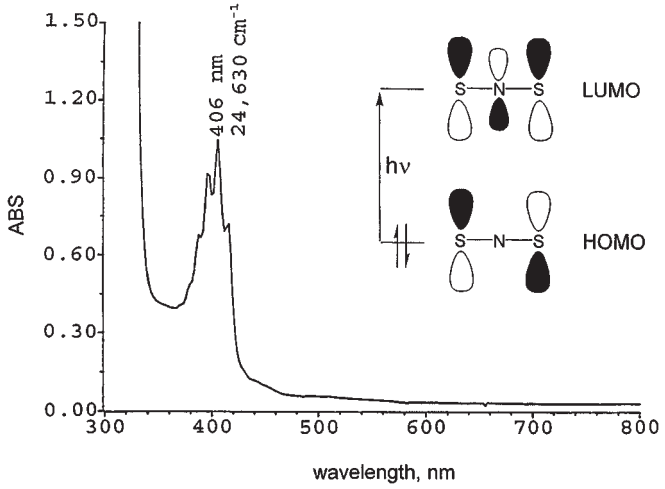

Fig. 2. The UV-visible spectra of the initial mixtures of arenes and $[SNS][AsF_6]$ in liquid SO_2, showing the absorption of the charge-transfer complex $[C_6H_6 \cdot SNS]^+$.

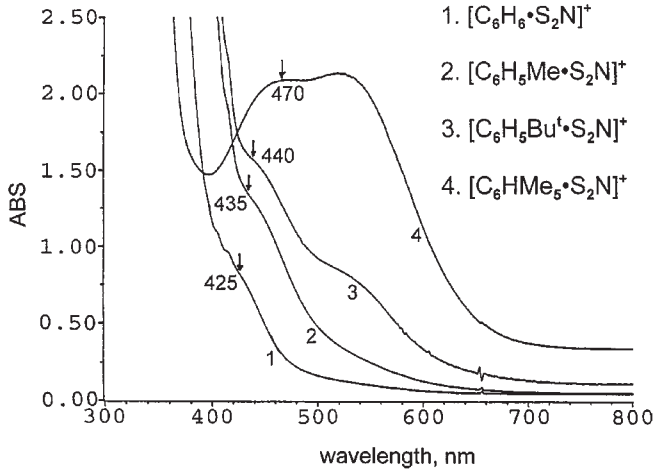

crystalline $[SNS][AsF_6]$ (2.90 g, 10.9 mmol) placed in a two-bulb vessel (7). The contents were warmed to room temperature, giving a very light brown solution over a yellow solid. The solution and solid were swirled, and all the solubles were then poured through a glass frit into the second bulb. The solid was washed again with an aliquot of SO_2 and all the resulting solution again poured into the second bulb. Part of the SO_2 was then condensed onto the yellow solid, giving a clean yellow solution, indicating the brown impurities had been extracted. All the SO_2 was then removed by evacuation, giving very yellow $[SNS][AsF_6]$ (1.83 g, 6.85 mmol) in 63% recovered yield. This product was used for all UV-visible spectroscopic measurements.

The preparation of $[SNS][Sb_2F_{11}]$

The $[SNS][Sb_2F_{11}]$ was prepared by reacting $[SNS][AsF_6]$ with SbF_5 (Ozark–Mahoning, triple distilled (7)) in a one-bulb vessel. The SO_2 (5.25 g) and SbF_5 (2.536 g, 11.7 mmol) were condensed successively onto $[SNS][AsF_6]$ (1.407 g, 5.27 mmol) at –196°C. The contents were warmed to room temperature, giving a homogeneous light brown solution, which was then stirred for 20 h. The volatiles were removed by evacuation, giving a brown tarry product. The product was heated with a heat-gun under dynamic vacuum until no further weight loss was observed. The final weight of the product $[SNS][Sb_2F_{11}]$ was 2.93 g (expected 2.80 g, 5.27 mmol). FT–Raman: 699.9 (s, $[SNS]^+$), 678.7 (s), 657 (m, sh), 646.5 (s), 599.4 (m), 576.3 (w), 299.0 (w), and 293.9 (w) cm^{-1}. The vibrations other than that at 699.9 cm^{-1} are attributable to $[Sb_2F_{11}]^-$.

The measurements of UV-visible spectra of $[SNS][AsF_6]$ and of $[SNS][AsF_6]$ with arenes (C_6H_6, C_6H_5Me, $C_6H_5Bu^t$, and C_6HMe_5)

The samples were prepared in a vessel constructed with a glass bulb (10 cm^3), incorporating a medium porosity sintered glass frit and a UV-vis cell (0.1 cm, Hellma). The SO_2 (0.89 g) was condensed onto high-purity $[SNS][AsF_6]$ (0.020 g, 0.15 mmol) in the bulb at –196°C. The contents were warmed to room temperature, giving a yellow solution (0.13 M). Part of the solution was poured into the UV cell, and a UV-visible spectrum was recorded at room temperature between 200 and 800 nm (Fig. 1).

For the measurements of mixtures of $[SNS][AsF_6]$ with arenes (C_6H_6, C_6H_5Me, $C_6H_5Bu^t$, and C_6HMe_5), preweighed SO_2 and the arenes were successively condensed onto preweighed high-purity $[SNS][AsF_6]$ (ca. 0.1 M) in the bulb at –196°C. The mixtures were quickly warmed to room temperature, giving orange solutions for C_6H_6 and C_6H_5Me, and reddish solutions for $C_6H_5Bu^t$ and C_6HMe_5 mixtures. The UV-visible spectra (Fig. 2) were recorded after 5 min. Another mixture of $[SNS][AsF_6]$ (0.042 g, 0.16 mmol) and C_6H_6 (0.05 g, 0.64 mmol) in liquid SO_2 (2.08 g) was examined by UV-visible spectroscopy as a function of time (Fig. 3), showing the disappearance of the band at 425 nm and the emergence of a new band at 500 nm, the center of which shifted to lower energies over time. Similarly for the $[SNS]^+$–$C_6H_5Bu^t$ mixture, the initial band at 440 nm disappeared after 30 min and a new band emerged at 520 nm. The strong absorption below 340 nm in all the spectra originated from the absorption of the SO_2 solvent.

The NMR (^1H, ^{13}C, ^{14}N) spectroscopic studies of the reaction of $[SNS][AsF_6]$ with C_6H_6

^1H spectra

The SO_2 (0.775 g) and excess of C_6H_6 (0.0159 g, 0.204 mmol) were condensed onto $[SNS][AsF_6]$ (0.0416 g, 0.156 mmol) in a 5 mm NMR tube at –196°C, and the tube was then flame sealed. The reactants were quickly warmed to room temperature, and the color of the solution turned to orange immediately, then gradually turned to blue after 30 min. Some colorless crystalline needles of $[NH_4][AsF_6]$ (see footnote 2) formed after a few hours; nevertheless, the

[2] The colorless crystalline by-product was identified to be $[NH_4][AsF_6]$ by ^1H NMR (6.0 ppm, 1:1:1 triplet, $^1J(^1H\text{-}^{14}N)$ = 54 Hz, attributable to the resonance of $[NH_4]^+$) and IR (695 s, br, and 398 s cm^{-1}, attributable to vibrations of $[AsF_6]^-$). Crystallographic parameters: rhombohedral, $a = b = c = 5.019(2)$, $\alpha = \beta = \gamma = 96.72(3)°$ (8).

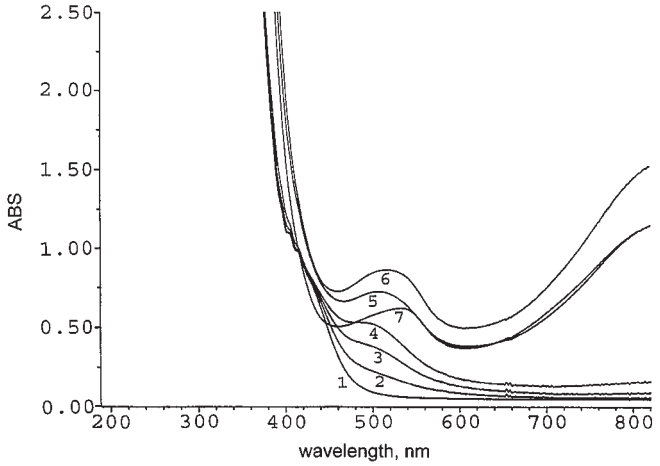
Fig. 3. The UV-visible spectra of the $[SNS][AsF_6]$–C_6H_6 mixture in liquid SO_2 as a function of time. **1**, 5 min; **2**, 41 min; **3**, 78 min; **4**, 108 min; **5**, 258 min; **6**, 380 min; and **7**, 12 h. The color of the solution changed with time: orange (0–40 min), blueish (50–200 min), and purple (after 250 min).

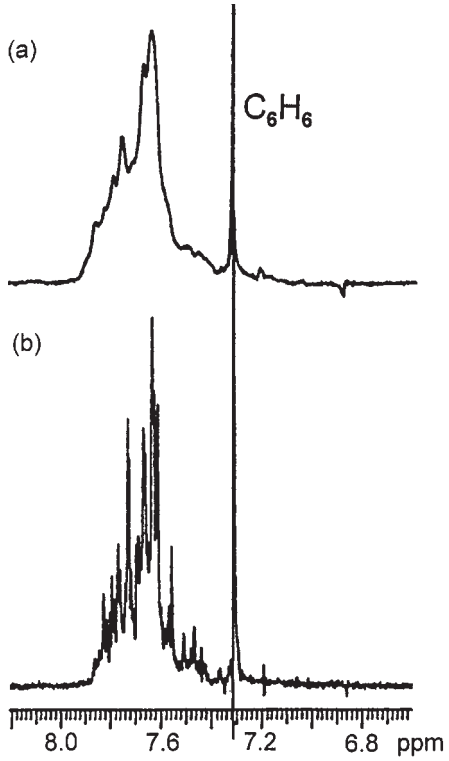


blue color of the solution remained unchanged after one day. The solid was then transferred to the top of the tube, and a ^1H spectrum of the solution was recorded at room temperature (Fig. 4(*a*)). δ (ppm) and assignments: 7.4–7.9 (very broad band, $\Delta\nu_{1/2}$ = 40 Hz, intensity (int) 100%, aromatic H's of $[Ph(S_2N)H]^+$) (**2**, **3**, or **4b**), 7.3 (singlet, int 55%, C_6H_6), and 5.8 (1:1:1 triplet, $^1J(^1H\text{-}^{14}N)$ = 54 Hz, int 3%, $[NH_4]^+$). The ^1H spectrum at –60°C was essentially identical. At both temperatures, resonances attributable to $-(S_2N)\mathbf{H}^+$ were not observed. On the basis of the stoichiometry and NMR integrations, ca. 90% $[SNS]^+$ had reacted at this stage, leading to $[Ph(S_2N)H]^+$. After one week, the color of the solution changed to purple,[3] and a ^1H spectrum was recorded again at room temperature (Fig. 4(*b*)). δ (ppm) and assignments: 7.45–7.88 (multiplet, int 100%, unknown[3]), 7.3 (singlet, int 36%, C_6H_6), and 5.8 (1:1:1 triplet, $^1J(^1H\text{-}^{14}N)$ = 54 Hz, int 2%, $[NH_4]^+$). On the basis of the stoichiometry and NMR integrations, the reaction was complete (100%) after one week. The weak $[NH_4]^+$ resonances are not shown in Fig. 4. A ^1H spectrum of C_6H_6 in liquid SO_2 was recorded (7.3 ppm, singlet) for comparison.

^{13}C and ^{14}N spectra

The SO_2 (3.28 g) and excess C_6H_6 (0.380 g, 4.87 mmol) were condensed onto $[SNS][AsF_6]$ (0.608 g, 2.28 mmol) in a 10 mm NMR tube at –196°C. The reactants were quickly warmed to room temperature, and the observations of the color changes and the formation of the colorless crystals of $[NH_4][AsF_6]$ (see footnote 2) were similar to those observed in the reactions in the 5 mm tube. After one day, the insoluble solid was transferred to the top of the tube, the ^{14}N spectrum was recorded on the solution (blue), and a broad band (–5 ppm, $\Delta\nu_{1/2}$ = 540 Hz, $[Ph(S_2N)H]^+$) was observed. After one week, the color of the solution became purple, and ^{14}N and ^{13}C spectra were recorded.[3] ^{14}N spectral data: δ = –255 ppm, $\Delta\nu_{1/2}$ = 180 Hz. ^{13}C spectral data (δ (ppm) and assignment): 135.5 (C_1), 133.4 (C_4), 132.2 ($C_{3,5}$), 131.3 ($C_{2,6}$), and 129.2 (C_6H_6). In addition, several very weak peaks were also observed in the ^{13}C spectrum at 209, 143,

Fig. 4. The ^1H NMR spectra of the blue product from the reaction of $[SNS][AsF_6]$ with C_6H_6 in liquid SO_2 (*a*) after 1 day and (*b*) after 2 weeks. Benzene was present as the internal standard.



[3] The NMR (^1H, ^{13}C) spectra of the purple species are identical to those of the isolated product formed on an in situ neutralization (with Na_2CO_3) of the blue intermediate $[C_6H_5(S_2N)H]^+$ from the substitution reaction: $[C_6H_5(S_2N)H][AsF_6] + Na_2CO_3 \rightarrow X + NaHCO_3 + Na[AsF_6]$. Without Na_2CO_3 the purple species may be formed as shown by equilibria between **A**, **B**, and **C** (see text). The HF and AsF_5 may then react with the organic material, displacing the equilibrium to **C**. The mass spectrum of X contains peaks attributable to $[C_6H_5]^+$ (77, 20%), $[SNS]^+$ (78, 100%), and a small (4.5%) S_2^+ peak. Other evidence related to the neutral product has been deposited.[4] Several attempted preparations of single crystals were unsuccessful. The nature of X, which is possibly $[C_6H_5(S_2N)]_x$,[5] is as yet undetermined and will be the subject of further investigations.

[4] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2. Interatomic distances and angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[5] Related purple (for some R) RNSS compounds have been isolated and characterized (25, 26), and the crystal structure has been determined for 2,4-di-*tert*-butyl-6-methyl-*N*-thiosulfinylaniline (26*c*). The compound C_6H_5NSS has not been cited in the literature since first reported in 1921 (26*d*), although it has been reported as an intermediate (25).

and 124 ppm. The carbon atoms are numbered in accordance with IUPAC rules (see **2a**). The actual spectra have been deposited with the supplementary material (Figs. S1 and S2).[4] A ^{13}C spectrum of C_6H_6 (129.2 ppm, singlet) and an ^{14}N spectrum of $[SNS][AsF_6]$ (δ = –91 ppm, $\Delta\nu_{1/2}$ = 6 Hz) in liquid SO_2 were recorded for comparison.

The reaction of C_6H_6 with $[SNS][Sb_2F_{11}]$, and ^{1}H (variable temperature) and ^{13}C NMR spectroscopic studies of $[Ph(SNS)H]^+$

The SO_2 (0.81 g) and C_6H_6 (0.0103 g, 0.132 mmol) were condensed successively onto $[SNS][Sb_2F_{11}]$ (0.0424 g, 0.0800 mmol) in a 5 mm NMR tube at –196°C. The contents were warmed to room temperature, and the color changes were observed, which were similar to those described for the reactions with $[SNS][AsF_6]$. After 1 h, the color turned to blue, indicating formation of $[Ph(SNS)H]^+$ (cf. the $[SNS][AsF_6]$ reaction), and this blue color remained unchanged for more than 10 h. The ^{1}H NMR spectra (Fig. 5) were then recorded at various temperatures (+20, +6, –10, –25, –40, –55, and –70°C), showing a multiplet at 7.5–7.9 ppm at all temperatures attributable to the C_6H_5 protons and a broad band at 8.8 ppm attributable to the $–(S_2N)\mathbf{H}^+$ proton, which were confirmed by the ratios of the integrations of the two resonances at various temperatures: 4.8:1 (+20°C), 5.2:1 (+6°C), 4.8:1 (–10°C), 5.0:1 (–25°C), 5.1:1 (–40°C), 5.2:1 (–55°C), and 4.8:1 (–70°C), an average of 5.0:1. A ^{13}C NMR spectrum was recorded at room temperature on a similarly prepared sample by reaction of $[SNS][Sb_2F_{11}]$ (0.101 g, 0.191 mmol) with C_6H_6 (0.0201 g, 0.257 mmol) in liquid SO_2 (0.742 g), leading to $[Ph(S_2N)H]^+$. Spectral data (δ (ppm) and assignment): 135.4 (C_1), 133.2 (C_4), 132.1 ($C_{3,5}$), 131.1 ($C_{2,6}$), and 129.3 (C_6H_6). In addition, several weak unassigned peaks were also observed between 135 and 124 ppm. The actual spectrum is deposited (Fig. S3).[4] The carbon atoms of $[Ph(S_2N)H]^+$ are numbered in accordance with IUPAC rules (see **2a**).

The reaction of the 5-methyl-1,3,2,4-dithiadiazolium cation with hexamethylbenzene

The SO_2 (3.71 g) was condensed onto a mixture of colorless $[MeCNSNS][AsF_6]$ (0.821 g, 2.67 mmol) and C_6Me_6 (0.430 g, 2.65 mmol) in a 10 mm NMR tube at –196°C. The contents were warmed to room temperature, and the color of the solution immediately turned to deep red. The NMR (^{13}C, ^{14}N) spectra were then recorded. The ^{13}C spectral data (δ(ppm)): 207.8, 134.0, 18.1, and 16.4 are almost the same as those for the individual two components, i.e., $[MeCNSNS]^+$ (208 (C_{ring}) and 18 (C_{Me})) (5*b*) and C_6Me_6 (135.6 (C_{ring}) and 18.0 (C_{Me})). The ^{14}N spectral data (δ (ppm), $\Delta\nu_{1/2}$ (Hz)): 21 (1600) and –32 (1070) (cf. ^{14}N spectral data (ppm) for $[MeCN'SN'S]^+$: 126 (550, N′) and –27 (500, N′) (5*b*). The average ^{14}N chemical shift for $[MeCN'SN'S]^+$ (75.5) becomes more shielded in the charge-transfer complex $[MeCN'SN'S]^+ \cdot C_6Me_6$ (–5.5). It is surprising that the ^{14}N′ chemical shift remains the same in the cation and complex, since the LUMO of $[MeCN'SN'S]^+$ is largely based on SN′S (5*a*, *j*).

Theoretical calculations

A series of possible geometries for $[Ph(SNS)H]^+$, **2a–c**, involving variation of the angles within the –(SNS)H group and variation of the dihedral angle between the planes of the benzene ring and the –(SNS)H group, were optimized at the RHF/6-31G* level with the GAUSSIAN 92/DFT suite of programs (9). Similar optimized geometries were also obtained for the isomer $[PhNSSH]^+$ **3**, since there is evidence for the neutral PhNSS as an intermediate,[5] and the isomer $[PhN(S)SH]^+$ **4b**.

Vibrational frequencies for **2a–c** and **3** were calculated at the RHF/6-31G* level from the optimized geometries and were scaled by the usual correction factor of 0.89 (10).

Results and discussion

The UV-visible spectrum of $[SNS]^+$ ($[SNS][AsF_6]$) in liquid sulfur dioxide

The UV-vis spectrum (Fig. 1) of high-purity $[SNS][AsF_6]$ (0.13 M) in liquid SO_2 exhibited an absorption band at 370–430 nm (extinction coefficient at 406 nm (maximum) ca. 80), consistent with its yellow color. The strong absorption below 340 nm was due to the SO_2 solvent. The broad absorption at 370–430 nm can be reasonably assigned to the HOMO (π) – LUMO (π^*) transition (3.05 eV (294 kJ/mol), the absorption maximum 406 nm) of the linear $[SNS]^+$ cation, and the fine structure (poorly resolved) of this band is attributable to the vibrational structure in the excited state of $[SNS]^+$. Previous studies (11) showed that the linear triatomic CO_2 and CS_2 molecules possess a bent lowest

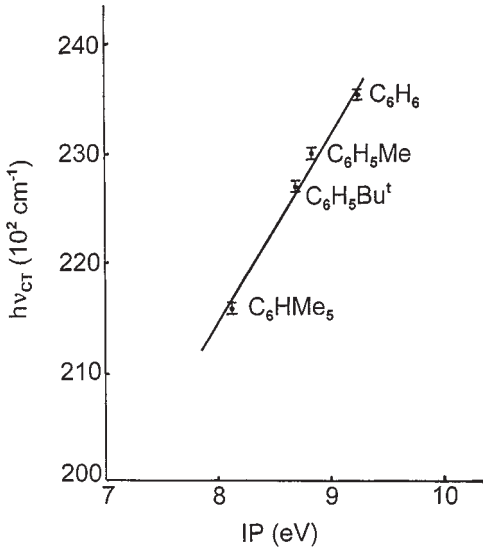
excited state ($^1B_2$ or $^3B_2$ symmetry). By analogy, the triatomic linear $[SNS]^+$ cation is also expected to have a similar bent lowest excited state ($^1B_2$ or $^3B_2$ symmetry). As expected, the observed electronic transition of $[SNS]^+$ has very low extinction coefficient (80), because the geometry change from a linear to a nonlinear configuration decreases the transition moment (11*b*).

The identification of the intermolecular charge-transfer complexes $[ArH{\cdot}SNS]^+$ as the first intermediates in the electrophilic substitution reactions of $[SNS]^+$ with arenes

On mixing C_6H_6 with $[SNS][AsF_6]$ (yellow) in liquid SO_2 at room temperature, the color of the solution immediately changed from yellow ($[SNS]^+$) to orange (425 nm), then gradually to blue (50–200 min) (500 nm), proposed to be $[Ph(S_2N)H]^+$ (i.e., **2**, **3**, or **4b**) (see below), and finally to purple[3] (after 250 min), as monitored visually and by UV-visible spectroscopy (Fig. 3). Previous investigations showed that the first step of aromatic nitration is the formation of a charge-transfer complex (eq. [1]). By analogy, we expected the formation of a charge-transfer complex $[C_6H_6{\cdot}SNS]^+$ in the initial stage of the reaction of $[SNS]^+$ and C_6H_6, which was implied by the orange color.

To obtain further evidence, we studied the reaction of $[SNS]^+$ with a series of arenes. The initial mixtures were characterized by UV-visible spectroscopy (Fig. 2), showing new broad absorption bands at 400–480 nm (maximum 425 nm, extinction coefficient ca. 70) for C_6H_6; 425–500 nm (maximum 435 nm, extinction coefficient ca. 130) for C_6H_5Me; 430–490 nm (maximum 440 nm, extinction coefficient ca. 150) for $C_6H_5Bu^t$; and 420–490 nm (maximum 470 nm, extinction coefficient ca. 210) for C_6HMe_5. All these bands appeared at lower energy regions relative to that of $[SNS]^+$ (370–430 nm, maximum 406 nm), and the original absorption band of $[SNS]^+$ disappeared or only a residual amount was observed (C_6H_6 case). The strong second absorptions observed at lower energies for the $[SNS]^+$–$C_6H_5Bu^t$ (522 nm) and $[SNS]^+$–C_6HMe_5–$[SNS]^+$ (540 nm) mixtures in the initial stages are likely attributable to the electrophilic substitution products related to $[Ph(S_2N)H]^+$ (see below).

Fig. 6. The relationship between charge-transfer energies of $[ArH{\cdot}SNS]^+$ and ionization potentials of the corresponding arenes.



The UV-visible spectroscopic studies showed that the absorption energies of the initial $[SNS]^+$–arene mixtures assigned to the charge-transfer complexes are directly proportional to the ionization potentials of the arenes (Table 1 and Figs. 2 and 6). Kochi has previously shown (3, 12) that for the reactions of arenes (ArH) with various "nitrating agents" NO_2Y (Y = $[OH]^-$, $[OAc]^-$, $[NO_3]^-$, $[Cl]^-$, Py, $[C(NO_2)_3]^-$, etc.) the first step is the formation of a transitory weak intermolecular charge-transfer complex $[ArH{\cdot}NO_2Y]$. For a given NO_2Y, the charge-transfer energy was shown to be directly proportional to the ionization potential of the arene. Thus by analogy, the absorptions at 425, 435, 440, and 470 nm in Fig. 2 reasonably originate from similar molecule–ion charge-transfer complexes $[ArH{\cdot}SNS]^+$ formed between $[SNS]^+$ and the arenes (C_6H_6, C_6H_5Me, $C_6H_5Bu^t$, and C_6HMe_5) through the weak interaction between the arene HOMO (E_{HOMO} = –IP) (donor) and $[SNS]^+$ LUMO (acceptor) in the initial stage of the reactions. Therefore, the greater the ionization potential of an arene, the higher the energy of the charge-transfer absorption, consistent with the observed linear relationship in Fig. 6 and with the observation that the absorptions of all the $[ArH{\cdot}SNS]^+$ appeared at lower energies than that of $[SNS]^+$.[6] Kochi (3) showed that the charge-transfer complexes $[Ar{\cdot}C_7H_7]^+$ formed between arenes and the tropylium $[C_7H_7]^+$ cation exhibit strong absorptions the extinction coefficients of which increased with increase of the number of electron donating groups on the arenes. Similarly, the extinction coefficients of the charge-transfer bands of $[ArH{\cdot}SNS]^+$ (ArH = C_6H_6 (70), C_6H_5Me (130), $C_6H_5Bu^t$ (150), and C_6HMe_5 (210)) become larger with an increase in the electron donating abilities of arenes. The aromatic charge-transfer complexes of $[ONO]^+$ were not directly experimentally observed due to the subsequent very fast electrophilic displacement (i.e., the

[6] The HOMO level of an arene is presumably higher than the HOMO of $[SNS]^+$ because of the positive charge and therefore high ionization potential of the $[SNS]^+$ cation.

formation of **1** in eq. [2] above), followed by formation of nitroarene.[7] The reaction of the heterocyclic 5-methyl-1,3,2,4-dithiadiazolium $[MeCNSNS]^+$ cation (electron acceptor) with hexamethylbenzene C_6Me_6 (electron donor) gave a deep red molecule–cation charge-transfer complex $[MeCNSNS{\cdot}C_6Me_6]^+$. Related charge-transfer complexes have been reported to form between arenes and $[SN]^+$ (13).

Spectroscopic evidence for the formation of the blue protonated $[C_6H_5(S_2N)H]^+$ cation

Olah and co-workers (14) identified the protonated nitrobenzene $[C_6H_5NO_2H]^+$ **4a** in a mixture of $C_6H_5NO_2$ with "magic acid" $FSO_3H\text{–}SbF_5\text{–}SO_3$ by ^{1}H NMR spectroscopy.[8] In this work, the reaction of $[SNS][Sb_2F_{11}]$ and C_6H_6 was performed in liquid SO_2 at room temperature. The ^{1}H NMR spectra of the product at various temperatures (Fig. 5) showed a multiplet centered at 7.7 ppm (lower field than that of C_6H_6 (7.3 ppm)) attributable to the resonance of the C_6H_5 protons, confirmed by the ^{13}C NMR data. In addition, another resonance, although observed at all studied temperatures, was clearly resolved as a broad band at 8.8 ppm below –10°C. Its line width ($\Delta\nu_{1/2}$ = 35 Hz) and chemical shift remained essentially unchanged below –40°C. This band at 8.8 ppm is attributable to the $-(S_2N)\mathbf{H}^+$ proton of a protonated substitution product $[Ph(S_2N)H]^+$. The assignments of the resonances to $C_6\mathbf{H}_5$ and $-(S_2N)\mathbf{H}^+$ protons are consistent with the ratio of their NMR integration (ca. 5:1). The temperature invariance of the proton chemical shift implies that the blue species is not in equilibrium with a dimer (as would likely be the case for **4b**, and possibly for **2c**). The ^{14}N resonance of $[Ph(S_2N)H]^+$ (δ = –5 ppm, $\Delta\nu_{1/2}$ = 540 Hz) is comparable to those of the related **5** (15) (δ = 19 ppm, $\Delta\nu_{1/2}$ = 450 Hz) and **6** (5*f*) (δ = –134 ppm, $\Delta\nu_{1/2}$ = 680 Hz)). The ^{1}H NMR spectrum of the blue reaction product of $[SNS][AsF_6]$ and C_6H_6 in liquid SO_2 showed a broad band at 7.5–7.9 ppm (centered at 7.7 ppm, attributable to the C_6H_5 group) with poorly resolved fine structure (Fig. 4*a*). However, the $-(S_2N)\mathbf{H}^+$ proton was not observable at temperatures down to –60°C, implying a proton exchange between $[Ph(S_2N)H]^+$ and the counterion $[AsF_6]^-$. The $-(S_2N)\mathbf{H}^+$ proton in $[Ph(S_2N)H][AsF_6]$ is more labile than that in $[Ph(S_2N)H][Sb_2F_{11}]$ due to the greater basicity of $[AsF_6]^-$ (16).

The range of ^{1}H and ^{13}C chemical shifts for the C_6H_5 group in $[Ph(S_2N)H]^+$ are more similar to those of neutral sulfur monosubstituted benzenes than those of the related nitrogen monosubstituted aryls (17) (see Table 2). The proton resonances are a complex multiplet, in contrast to those in **4a** (14), which show good resolution of *meta*, *ortho*, and *para* protons at a lower field (8.0–8.8 ppm) than those of $C_6H_5NO_2$ (7.5–8.2 ppm). This implies that there is little charge delocalization into the aryl ring in $[Ph(S_2N)H]^+$. A similar trend is observed in the ^{13}C spectra (Table 2). The structure of $[Ph(S_2N)H]^+$ could be **2a**, which may be represented by resonance structures **A** and **B** in equilibrium with **C**, accounting for the high lability of the $-(S_2N)\mathbf{H}^+$ proton. The presence of positive charge on atoms directly bonded to the aryl ring in isomers **2c** and **4b**, and the extensive charge delocalization into the ring expected for **3** (see resonance structures **D** and **E**) implies that the blue protonated species does not adopt these structures. However we cannot rule out isomer **2b** on these grounds.

We have estimated, based on bond energies and a very simple view of charge redistribution, that the formation of **2**, **3**, and **4b** from $[SNS]^+$ and C_6H_6 is thermodynamically allowed.[9,10] Other less likely possibilities include $[C_6H_5\text{-}N(H)SS]^+$ **3′**[11] and dimers or oligomers of **2**, **3**, and **4b**.[12] Kinetic factors would favor formation of bonds to sulfur in the product as the LUMO of $[SNS]^+$ is sulfur based (5*e*, *j*). So far the products of reactions of $[SNS]^+$ do not include bonds to nitrogen, but are solely formed with sulfur (5*j*).

The reaction of $[SNS][AsF_6]$ and C_6Me_6

The ^{13}C NMR spectrum of the product for the reaction of $[SNS]^+$ with hexamethylbenzene C_6Me_6 in liquid SO_2 at room temperature exhibited complex resonances,[13] indicating the formation of a mixture. Part of the ^{13}C resonances may be tentatively assignable to a stable σ-type complex

[7] The reactions of benzene with $[ONO]^+$ salts are too fast (very fast even at –40°C) to monitor the intermediates. The nitration can be slowed down by combining a base Y (Y = $[OH]^-$, $[OAc]^-$, $[NO_3]^-$, Cl^-, Py, $[C(NO_2)_3]^-$, etc.) to $[ONO]^+$, forming an alternative nitrating agent NO_2Y. These NO_2Y are electron deficient and thus capable of serving as electron acceptors, forming charge-transfer complexes $[ArH{\cdot}NO_2Y]$ with electron-donating aromatics in the first step of the reactions (11).

[8] For the formation of protonated nitrobenzene **4a**, see ref. 14. The ^{1}H NMR data of **4a** were given in the reference as follows: $\delta H_2 = \delta H_6 = 8.76$, $\delta H_3 = \delta H_5 = 7.99$, $\delta H_4 = 8.46$; $J_{23} = J_{56} = 8.00$, $J_{24} = J_{46} = 1.00$; $J_{25} = J_{36} = 0.50$, $J_{26} = J_{35} = 1.00$, $J_{34} = J_{45} = 7.50$. The hydrogen atoms are numbered in accordance with IUPAC rules, i.e., H_2 and H_6 are *ortho* protons; H_3 and H_5 are *meta* protons; and H_4 is a *para* proton.

hexamethylbenzenium cation **7** in the mixture (Fig. 7). A similar σ-complex nitrohexamethylbenzenium cation **8** has been identified from the reaction of $[ONO]^+$ and C_6Me_6 by ^{13}C NMR spectroscopy (22). Concurrent with this work, Kochi and co-workers (23) very recently reported the isolation and structural characterization of a related novel σ-type chloro-arenium cation **9**.

Theoretical calculations

The geometries of the isomers **2a**, **2b**, **2c**, **3**, and **4b** were optimized at the RHF/6-31G* level. Relative energies and selected bond distances, bond angles, and dihedral angles are listed in Table 3. Isomer **4b** is the thio analogue of the known product of the reaction of ONO^+ and benzene, **4a** (14). The structure **4b** is higher in relative energy (428 kJ/mol) than **2a** (51 kJ/mol), **2b** (37 kJ/mol), **2c** (134 kJ/mol), or **3** (0 kJ/mol). This suggests that the isomers **2** and **3** are favored over **4b**. However energies may well not be the same in solution as in the gas phase, and dimers or polymers of the isomers are also possibilities.[12]

Notwithstanding these considerations, **4b** is likely the least favored isomer energetically, both from theoretical calculations and simple bond energy estimates.[9,10] The isomer **2c** is likely less favored than **2a**, **2b**, or **3**.

The calculated geometries are consistent with **2a** represented by resonance structures **A** and **B**, with **3** by resonance structures **D**, **E**, and those related to **E**, and with **2b, 2c**, and **4b** as depicted. The calculated carbon—carbon bond

[9] The standard enthalpy change ($\Delta H°$) of the reaction $C_6H_6 + [S = N = S]^+ \rightarrow C_6H_5\text{-}S\text{-}N = S^+H$ is simply estimated from the energy change in the related bond formation versus bond broken, which is formulated as $\Delta H° = D_{C—H}° + D_{S=N}° - D_{C—S}° - D_{S—N}° - D_{S—H}°$ The bond dissociation energies ($D°$) of C—H, C—S, and S—H bonds are taken as 411, 272, and 363 kJ/mol, respectively (18). The S = N and S—N bond energies were calculated as 335 and 245 kJ/mol, respectively, from the bond lengths (Å) according to the equation $E(SN) = 2143.3 - 1126.4d_{SN}$ (19). Thus, $\Delta H° = -134$ kJ/mol. Similarly, the $\Delta H°$ of the formation of **4b** from C_6H_6 and $[SNS]^+$ is estimated to be –167 kJ/mol by replacing $D_{C—S}°$ (272 kJ/mol) with $D_{C—N}°$ (305 kJ/mol) in the above equation. In this thermodynamic analysis, the following terms are neglected: the energy of charge delocalization in $[SNS]^+$, solvation energy change, entropy change, and charge redistribution from N^+ (in $[SNS]^+$; i.e., of N: 1402 kJ/mol (20)) to S^+ (e.g., in **2a**; i.e., of S: 999 kJ/mol (20)). The inclusion of energy of positive charge redistribution from N^+ to S^+ gives a new ΔH of –537 kJ/mol for **2a**.

[10] Using a similar approach as in footnote 9, the energy difference between **2a** and **3** may be estimated. The structure **3** is favored over **2a** by 14 kJ/mol, with the bond dissociation energies ($D°$) of the C—N, S—S, C—S, and S—N bonds taken as 305, 226, 272, and 245 kJ/mol, respectively (18, 19). Similarly, **3** is favored over **2b** by 394 kJ/mol and over **4b** by 384 kJ/mol, considering the bond dissociation energies of S—H (363 kJ/mol) and N—H (386 kJ/mol) bonds.

[11] The structure **3′**, i.e., $C_6H_5N(H)S^+ = S$, is an isomer of **3**. However, **3′** would contain a sulfur–sulfur double bond in the absence of bulky groups (e.g., 2,4-di-*tert*-butyl-6-methyl-*N*-thiosulfinylaniline (28*c*)). The dimer $(\mathbf{3'})_2$ is also without precendent (21). These and other oligomers containing C_6H_5– are expected to have ^{13}C and ^1H NMR spectra that would be different from that of the blue species **2**, as nitrogen, not sulfur, is attached to the phenyl ring (see text and Table 2).

[12] There are no precedents for dimers or oligomers of **2**, **3**, or **4b** (hydrogen-bonded dimers excluded), e.g., the known $RSNSR^+$ (e.g., **5** (15) and **6** (5*f*)) are monomers (5*j*, 21).

[13] The reaction of $[SNS][AsF_6]$ (0.543 g, 2.03 mmol) and C_6Me_6 (0.345 g, 2.13 mmol) in liquid SO_2 (3.27 g) at room temperature immediately gave a dark red solution, which was characterized by ^{13}C NMR spectroscopy. The ^{13}C resonances (ppm, referenced to TMS in SO_2) are 209, 168.6, 147, 144, 140, 138.5, 135, 126.5, 125, 124.5, 122.7, 54.1, 49.5, 48, 41.8, 24.5, 20.1, 18.1, 16.5.

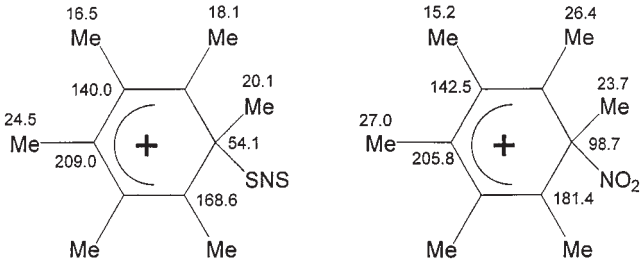
Fig. 7. The ^{13}C chemical shifts (ppm, referenced to TMS in liquid SO_2) of the ring and methyl carbons in $[C_6Me_5{\cdot}SNS]^+$ **7**[13] and $[C_6Me_5{\cdot}NO_2]^+$ **8**.



distances vary for **3** and **4b**, implying significant charge delocalization into the aryl ring in these isomers. In contrast, carbon—carbon distances are all similar in the **2** isomers. The NMR results imply little positive charge delocalization into the aryl ring consistent with the structures of **2**, but not **3** or **4b**.[14] Therefore **4b** is ruled out on thermodynamic grounds, and it does not fit the observed NMR data. The structure **3** is calculated to have the lowest energy of the isomers but does not fit the NMR data and is also kinetically not favored. All **2** isomers fit the NMR data, but **2a** and **2b** are marginally lower in energy than **2c**. The isomer **2a** has a similar structure to the known **5** (15) and **6** (5*f*) and therefore is likely the blue reaction product of benzene and $[SNS]^+$, although we cannot rule out **2b** and we have not calculated the energies of dimers and oligomers (11, 12). The Raman spectra of **2a**, **2b**, **2c**, and **3** were calculated from their stationary point geometries.[15] Unfortunately the spectrum of $[C_6H_5(S_2N)H][Sb_2F_{11}]$ is weak, and we cannot unambiguously distinguish between the isomers **2a–c** and **3**. A complete list of optimized geometries and calculated vibrational frequencies for **2a–c** and **3**, and the observed FT–Raman spectrum of $[C_6H_5(S_2N)H][Sb_2F_{11}]$ have been deposited.[4]

In conclusion the experimental results and the theoretical calculations show that $[SNS]^+$ has undergone an insertion reaction into the C—H bond of benzene to give a product that is different from that of $[ONO]^+$ **4a**, and can be reasonably formulated as $[C_6H_5(SNS)H]^+$ **2**.

The electrophilic aromatic substitution reactions of $[SNS]^+$

The electrophilic aromatic substitution reactions of $[ONO]^+$ have been extensively investigated (1, 3) and are one of the best known and most important studied organic reactions. In this work, the NMR (^1H, ^{13}C, ^{14}N) spectroscopic studies unambiguously show that the $[SNS]^+$ cation, the sulfur analogue of $[ONO]^+$, undergoes a related electrophilic substitution reaction with benzene. This type of electrophilic aromatic substitution is supported by a ^1H NMR spectroscopic study of the reaction of $[SNS]^+$ with C_6HMe_5 (26). Resonances attributable to an aromatic proton were absent in the spectrum, implying that the original aromatic proton (6.8 ppm) of C_6HMe_5 had been substituted by $[SNS]^+$.

The electrophilic reactions of both $[ONO]^+$ and $[SNS]^+$ and benzene can be viewed as proceeding by donation of electron density from the HOMO to the LUMO's of $[ONO]^+$ and $[SNS]^+$. The LUMO of $[ONO]^+$ is lower in energy that of $[SNS]^+$ (5*d*), and consistently the rate of the $[ONO]^+$–benzene reaction is very fast even at –40°C (12), whereas the rate of reaction of $[SNS]^+$ is slow even at room temperature. Consistently, the rate of the reaction of arenes with $[SNS]^+$ increases with decrease of IP of the arene.

A proposed mechanism of the electrophilic substitution of $[SNS]^+$ with benzene

The substitution of C_6H_6 with $[ONO]^+$ (1, 3) proceeds via a transient intermediate charge-transfer complex $[C_6H_6{\cdot}NO_2]^+$ (eq. [1])], which then leads to nitrobenzene via another transient intermediate, the Wheland complex **1** (eq. [2]). We have presented evidence for a relatively stable π–π^* charge-transfer complex $[C_6H_6{\cdot}SNS]^+$ (eq. [3]). We propose that $[C_6H_6{\cdot}SNS]^+$ transforms into a transient σ-type complex **10** (cf. the Wheland complex **1** (eq. [2]), which undergoes an intramolecular hydrogen transfer to give **2** (eq. [4]).

[3] $$C_6H_6 + SNS^+ \rightleftarrows [C_6H_6{\cdot}SNS]^+$$

[4] $$[C_6H_6{\cdot}SNS]^+ \rightarrow \mathbf{10} \rightarrow \mathbf{2}$$

There is evidence that **2** deprotonates to give an unidentified purple neutral species X, which is possibly $[C_6H_5(S_2N)]_x$.[2]

Conclusions

The $[SNS]^+$ cation (cf. $[ONO]^+$) has been previously shown (5) to undergo concerted, symmetry allowed reverse electron demand type cycloaddition reactions with various multiply π-bonded species. This work is the first study of the CH substitution reactions of $[SNS]^+$ opening up a new chapter in the diverse chemistry of this important cationic reagent. Both the cycloaddition and substitution reactions of $[SNS]^+$, as the $[AsF_6]^-$ salt, involve the interactions of the HOMO's of the organic substrates and the LUMO of $[SNS]^+$. The transition between the HOMO and LUMO of $[SNS]^+$ (λ = 406 nm, ϵ = 80, corresponding to 294 kJ/mol) has been observed for the first time in the UV-visible spectrum of $[SNS][AsF_6]$ in liquid SO_2 solution. The initial step of the reaction of $[SNS]^+$ with benzene is the formation of an identified weak molecule–cation charge-transfer complex $[C_6H_6{\cdot}SNS]^+$ (orange). Other arenes also formed charge-transfer complexes with the energy of the absorption of the charge-transfer band in the UV-visible spectrum being

[14]The calculated charges are in agreement with the calculated geometries and valence-bond representations given above, but it is known that charges obtained with this method are unreliable (24).

[15]The FT–Raman frequencies (ν(cm^{-1}), (relative integration, assignment)) were calculated for the lowest energy geometries of **2a** (2979 (12, CH), 2579 (83, SH), 1550 (100, ring CC), 1063 (50, CS), 788 (52, SNS)), **2b** (3264 (41, NH), 1577 (23, ring CC), 1053 (100, SN), 1040 (29, CS)), **2c** (2520 (100, SH), 1543 (49, ring CC), 1132 (29, SNS)), and **3** (3010 (19, CH), 2562 (70, SH), 1554 (100, ring CC), 1252 (35, CN), 960 (29, SN), 450 (5, SS)).

linearly related to the ionization energy of the arene. Thus the charge-transfer complex is formed by interaction of the HOMO of the arene and the LUMO of $[SNS]^+$. The analogous charge-transfer complex in the reaction of $[ONO]^+$ with benzene is a transient intermediate. A subsequent substitution of $[SNS]^+$ to benzene likely occurs on the terminal sulfur, forming a blue species, which we propose is $[C_6H_5(SNS)H]^+$ **2** supported by NMR spectroscopic evidence and theoretical calculations at the RHF/6-31G* level. This is in contrast to the aromatic nitration with $[ONO]^+$, which occurs on the central nitrogen. The difference reasonably relates to both kinetic (FMO's) and thermodynamic (lower IP of S relative to N) factors. The related protonated nitrobenzene **4a**, although identified (14) in a mixture of $C_6H_5NO_2$ with $FSO_3H–SbF_5–SO_3$ (a strong acid system), is not observed in the reaction of benzene with $[ONO]^+$ under similar conditions. The formation of **2** may occur by an intramolecular hydrogen transfer (eq. [5]) via an intermediate σ-complex **10** (cf. **1** for nitrations(1, 3)). The rate of reaction of $[SNS]^+$ with C≡N, C≡C, and other related multiple bonds (5*b*, *c*, *f*, *j*) as well as aryl rings is inversely proportional to the ionization energy of the unsaturated moiety. The $[SNS]^+$ reacts with aryl nitriles and diphenylacetylene to give 99% cycloaddition products on the C≡N and C≡C bonds with small amounts of colored impurities (5*c*, *e*), which are likely derived from attack on the aryl rings. The results imply that $[SNS]^+$ will preferential react with the C≡N and C≡C substituents of an aryl containing molecule with non-electropositive substituents. A purple colored species[2] is formed from the blue **2**, which has yet to be identified.

Evidence is presented for the first example of a dithiadiazolium charge-transfer complex $[MeCNSNS\cdot C_6H_6]^+$.

Acknowledgements

We would like to thank Dr. M.J. Schriver for his initial observations on the color changes during reaction of C_6H_6 with $[SNS]^+$ (5*d*), Dr. F. Grein for discussion on the UV-visible spectrum of $[SNS]^+$, the referees, Dr. A.J. Banister for very helpful comments on the manuscript and possible dimers and oligomers of **2**, and Dr. G. Villemure for use of the Hewlett–Packard UV-visible spectrophotometer. We also thank the Natural Sciences and Engineering Research Council (Canada) for a graduate fellowship (S.B.) and The University of New Brunswick (X.S.) for financial support.

The first reagent-controlled asymmetric halolactonizations. Dihydroquinidine–halogen complexes as chiral sources of positive halogen ion

Robert B. Grossman and Robert J. Trupp

Abstract: The first reagent-controlled asymmetric halolactonizations are described. Complexes of I^+ with *O*-acyl- and *O*-aryldihydroquinidines are used to promote the asymmetric halolactonization of prochiral γ,δ-unsaturated carboxylic acids with low but measurable and reproducible enantioselectivity. Experimental factors affecting the ee's are described.

Key words: halocyclization, halogenation, halonium ions, chiral, stereoselective.

Résumé : On décrit les premières réactions d'halogénolactonisations contrôlées par le réactif. On utilise des complexes de I^+ avec des *O*-acyl- et *O*-aryldihydroquinidines pour favoriser l'halogénolactonisation d'acides carboxyliques γ,δ-insaturés prochiraux avec une énantiosélectivité faible, mais mesurable et reproductible. On décrit les facteurs influençant les ee.

Mots clés : halogénocyclisation, halogénation, ions halogénium, chiral, stéréosélectif.

[Traduit par la Rédaction]

The development of efficient processes for the transformation of achiral starting materials into chiral, enantiopure products continues to be an important goal in organic synthesis (1). Two basic approaches to asymmetric synthesis have been studied. In *substrate-controlled* asymmetric synthesis, an achiral compound is rendered chiral and enantiopure by attachment of a chiral auxiliary, allowing diastereoselective transformations to be executed. The chiral auxiliary is then removed. In *reagent-controlled* asymmetric synthesis, a chiral, enantiopure reagent causes one enantioface or enantiotopic group of a prochiral compound to be selectively transformed. The main disadvantages of substrate-controlled asymmetric synthesis are that the substrate must have a suitable functional group (usually a carboxylic acid) to which the chiral auxiliary can be attached, and that addition and removal of the auxiliary usually requires two extra synthetic steps. Reagent-controlled asymmetric synthesis does not have these problems, but finding reagents with which high enantioselectivities can be achieved is very challenging. The epitome of reagent-controlled asymmetric synthesis is reached when the chiral component can be used in catalytic quantities (2), as in enzyme-mediated organic synthesis (3).

Reactions of alkenes, especially oxidation reactions such as epoxidations and dihydroxylations, have been popular targets for asymmetric modification, and some of the most widely used reagent-controlled catalytic asymmetric transformations have been derived therefrom (4–6). Halogenation reactions (including cohalogenations and halocyclizations) represent another class of widely used alkene oxidation reactions (7–10), but although examples of *substrate-controlled* asymmetric halogenations are abundant in the literature (11–15), there are few or no examples of *reagent-controlled* asymmetric halogenations. The asymmetric addition of Br_2 to cyclohexene in the presence of chiral quaternary ammonium salts has been investigated. Of course the halonium ion derived from cyclohexene is achiral, so the enantiomer-determining step in this reaction is nucleophilic attack of Br^- on the halonium ion (16). A very efficient catalytic asymmetric iodocarbocyclization of unsaturated malonates has also been demonstrated recently: a chiral Ti catalyst reacts with the malonate portion of the substrate, giving a chiral enolate, and a diastereoselective halocyclization ensues (17). The *seleno*cyclization of prochiral unsaturated nucleophiles mediated by chiral, enantiopure diselenides proceeds with very high diastereoselectivities (18, 19). Very good ee's were very recently reported for a Pd-catalyzed hydroxychlorination of alkenes (20), and it should be relatively easy to modify this system to accomplish halocyclization, instead.

We envisioned a reagent-controlled asymmetric cohalogenation reaction in which a *chiral source of* X^+ would be used to deliver X^+ selectively to one enantioface of a prochiral alkene to give a chiral, enantioenriched halonium ion (eq. [1]). Stereospecific nucleophilic attack at one of the

electrophilic carbon atoms would then give a chiral, enantioenriched product.

A reagent-controlled asymmetric cohalogenation requires a chiral source of X^+. Halogen complexes $(amine)_2X^+$ Y^- have seen increasing use in organic synthesis in recent years as mild sources of X^+ (21, 22). Recent work (15, 23) has shown that $(amine)_2X^+$ complexes **1** react with alkenes by dissociation of an amine to give $(amine)X^+$ complex **2** (Scheme 1), association of an alkene with nascent **2** to give the $[(amine)X(alkene)]^+$ complex **3**, and dissociation of the second amine from **3** to give the halonium ion, **4**. Attack of a nucleophile Nu^- on **4** then provides the isolable species, **5**. Loss of the second amine may also be concerted with nucleophilic attack on one of the electrophilic C atoms; in other words, Nu^- may attack **3** directly to give **5**, and intermediate **4** may not have an independent existence at all.

It occurred to us that if a *chiral, enantiopure amine* were used to form the $(amine)_2X^+$ complex, the association of a prochiral alkene with the nascent $(amine)X^+$ complex might proceed with enantiofacial selectivity to provide, after amine dissociation, a *chiral, enantioenriched halonium ion*, which could be captured by a nucleophile to give enantioenriched products. To test the hypothesis, we decided to study the iodolactonization of γ,δ-unsaturated carboxylic acids (**6**) to give δ-iodo-γ-lactones (**7**) using complexes $(amine^*)_2I^+$ BF_4^-, where amine* = *O*-acyl- or *O*-aryldihydroquinidine (**8**) (Scheme 2). This particular reaction was chosen for study for the following reasons.

(*i*) A cyclization reaction was chosen because it involved *intramolecular* nucleophilic capture of the iodonium ion. The rates of racemization processes such as alkene-to-alkene or alkene-to-amine transfer of I^+, which were shown to occur at perceptible rates in other systems (24, 25), were expected to decrease relative to nucleophilic capture if the latter occurred in an intramolecular fashion. The intramolecular reaction was also expected to give fewer regioisomeric complications for unsymmetrically substituted alkenes (7–9).

(*ii*) Iodolactonization was chosen over bromolactonization because the cyclization of an $(alkene)_2I^+$ complex is much faster than the cyclization of a $(alkene)_2Br^+$ complex (24). A longer lifetime for the $(alkene)_2X^+$ complex could lead to enantiomer equilibration and a decrease in the ee of the product.

(*iii*) *O*-Acyl- and *O*-aryldihydroquinidines were chosen as the chiral amine component of $(amine)_2I^+$ BF_4^- because a large number of them were known (6), they were easily prepared, and they had a long and venerable history in asymmetric synthesis (4, 26). Moreover, quinuclidine complexes of I^+ and Br^+ were well-known (27, 28).

(*iv*) The BF_4^- counterion for the $(amine)_2I^+$ complex was chosen because, unlike I^-, this non-nucleophilic counterion was not expected to equilibrate iodonium ion enantiomers by displacing I^+ from the alkene (7–9).

(*v*) Acids **6** were known compounds, and their halocyclizations to give γ-lactones **7** were thoroughly studied (7–9).

We are pleased to report the first reagent-controlled asymmetric halolactonizations of prochiral unsaturated carboxylic acids.

Results and discussion

The cyclizations of four γ,δ-unsaturated carboxylic acids with different substitution patterns around the alkene (terminal (**6a**), *cis*-disubstituted (**6b**) (29), *trans*-disubstituted (**6c**) (29), and geminally disubstituted (**6d**) (30)) were studied. In our initial experiments, the active halogenating agent was prepared in situ by sequential addition of 1.08 equiv. $AgBF_4$ and 1.00 equiv. I_2 to 2.16 equiv. **8a** or **8b** in CH_3CN, respectively (21). The solvent was replaced with CH_2Cl_2, the solution was cooled to –78°C, and 1.08 equiv. unsaturated acid **6** were added. The mixture was maintained at –78°C for 30 min, then allowed to warm to room temperature over 30 min. After filtration through Celite and quenching with aqueous Na_2SO_3, the products were isolated and purified by standard techniques. The reactions proceeded regioselectively in all cases to give only the γ-lactones **7** and no δ-lactones, as shown by the IR spectra of the products. Compounds **6b** and **6c** stereospecifically gave **7b** and **7c**, respectively. Yields of **7** and recoveries of **8** were good to excellent. The ee's of **7** were assessed by capillary GC on a chiral column (Table 1). We were disappointed to find that in most cases racemic **7** was obtained. However, iodolactonization of **6b** mediated by **8b** gave **7b** in 7% ee,

and iodolactonization of **6d** in the presence of the same amine gave **7d** in 3% ee.

We decided to investigate whether the ee of **7b** could be increased by modification of the reaction conditions. If the halonium ion formed with a higher ee initially, one way in which the ee might be degraded was by displacement of I^+ from an iodonium ion by an alkene or an amine, a phenomenon discovered and investigated by Brown and Fraser-Reid and co-workers (24, 25). We hypothesized that dilution of the reaction mixture might increase the ee, and in fact this effect was observed (Table 2). With 54 mM **8b**, the iodolactonization of **6b** gave **7b** in 7% ee. *Halving the concentration doubled the ee to 15%.* Alas, halving the concentration again did not lead to further improvement. A high local concentration of acid at the point of addition of the alkene to the reagent solution may have led to deterioration of the ee, so the **6b** was diluted with CH_2Cl_2 before it was added to the reagent solution. The ee of **7b** remained substantially unchanged at 14%. Further dilution of **6b**, however, degraded the ee to 8%. To decrease the amount of free amine that was present in the solution, one equivalent of AcOH was combined with **7b** prior to its addition to the reaction mixture. Under these conditions the ee was degraded even further, to 7%. (The ee's were reproducible to within 0–2 percentage points, both for each sample and for samples obtained in different runs under identical conditions.) It should be noted that the yield of **7b** and recovery of **8b** remained substantially unchanged by all changes in reaction conditions.

Several other quinidines were investigated for their ability to induce enantioselective cyclization of **6b**. Quinidines **8c** and **8d** were examined in the hope that their greater steric bulk might communicate the asymmetry of the amine better to the approaching alkene, and quinidines **8e** and **8f** were examined to see whether varying the electronic nature of the aroyl group could affect the ee positively. Under the same conditions under which the reagent derived from **8b** gave a 14% ee of **7b**, though, the analogous reagents derived from compounds **8c–8f** gave **7b** with ee's of 3%, 4%, 3%, and 11%, respectively.

The N—Br bond (ca. 2.15 Å) (27) is slightly shorter than the N—I bond (ca. 2.3 Å) (28), so it was hypothesized that an **8b**–Br^+ complex might show higher enantiofacial discrimination toward **6b** than an **8b**–I^+ complex. When Br_2 replaced I_2 in the procedure that gave **7b** in 14% ee, compound **9**, the bromo analog of **7b**, was obtained in only 2% ee. Apparently the longer lifetime of bromonium ions, and the thereby enhanced opportunity to racemize, was more important to the outcome of the reaction than the shorter N—Br bond (24).

Several reasons for the low enantioselectivity can be adduced.

(*i*) The long N—I bond and the linear nature of the (amine)I^+(alkene) complex conspire to diminish the influence of the shape of the amine on the selectivity of approach of the two enantiofaces of the alkene. (The I^+ atom probably coordinates to the more basic of the two N atoms in **8b**, viz. the quinuclidine N, as does OsO_4.)

(*ii*) I^+ transfer to the alkene occurs from the carboxylate, i.e., via an acyl hypoiodite, and not directly from the amine.

(*iii*) The amine **8b** remains associated with the two iodonium ions (**6b**)I^+, either as the (amine)I^+(alkene) complex (**8b**)I^+(**6b**) (23), or as the carboxylate salt **8b**·H^+ (**6b**$^-$)I^+, where **6b**$^-$ is deprotonated **6b**. If this is the case, the two iodonium ions formed upon coordination of one or the other enantioface of **6b** to I^+ are *diastereomers*, not enantiomers. It is therefore possible that the two iodonium ions are in rapid equilibrium with one another, and that the observed enantioselectivities are due to *kinetic resolution* upon cyclization. However, if such a process were occurring, dilution should have a detrimental effect on the ee by retarding the equilibration of the diastereomeric iodonium ions, a prediction that is contrary to our observations.

In conclusion, we have demonstrated for the first time that chiral amines can induce asymmetry in halolactonization reactions. Future work from this laboratory will explore other substrate classes and other chiral amines in a continuing quest for a synthetically useful reagent-controlled asymmetric halolactonization reaction.

Experimental section

General

Acids **6b** and **6c** were prepared by homologation of the corresponding 3-hexen-1-ols, while **6d** was prepared by the literature procedure (29, 30). The latter compound was stored as its Na^+ salt because of its tendency to undergo spontaneous cyclization. Quinidines **8a–8f** were prepared by literature techniques (31–33). The ee's of lactones **7a–7d** and **9** were measured by capillary GC on a 25 m Lipodex E (50% octakis(3-*O*-butyryl-2,6-di-*O*-pentyl)-γ-cyclodextrin) chiral column purchased from Prof. Dr. W.A. König, Universität Hamburg; α values are collected in Table 3. New

compounds **7b**, **7c**, and **9** were prepared in racemic form using standard methods (7–9) and were characterized fully.

Best procedure for asymmetric iodolactonization of 6b

Compound **8b** (464 mg, 1.08 mmol) was dissolved in CH_3CN (20 mL), $AgBF_4$ (106 mg, 0.54 mmol) was added, and the solution allowed to stir for 10 min. A color change from yellow to brown was observed. The solvent was removed under reduced pressure to afford a brown solid. The flask was filled with N_2, and the solid was redissolved in freshly distilled CH_2Cl_2 (10 mL). Iodine (127 mg, 0.50 mmol) was dissolved in CH_2Cl_2 (30 mL) and added to the flask by syringe. The precipitation of a light gray solid was observed, and the reaction was allowed to continue for 10 min. The flask was then cooled to –78°C, and a solution of **6b** (73 μL, 0.54 mmol) in dry CH_2Cl_2 (5 mL) was added dropwise by addition funnel. The solution was allowed to stir for 30 min. The flask was allowed to warm to room temperature, with stirring, for an additional 30 min. The reaction was then filtered through Celite® and quenched with saturated aqueous Na_2SO_3. The organic layer was washed three times with 1 M H_2SO_4 and three times with saturated aqueous $NaHCO_3$, dried over anhydrous $MgSO_4$, filtered, and evaporated to afford **7b** (108 mg, 0.43 mmol, 86% yield) as a clear yellow oil, 14% ee, $[\alpha]_D^{22} = -4.09$ (*c* 1.74, CH_2Cl_2), absolute configuration not determined.

The aqueous acidic washes were made basic with 3 M NaOH and extracted with ether. The organic layer was dried over $MgSO_4$, filtered, and evaporated to give recovered **8b** (380 mg, 0.88 mmol, 82% recovery) as a white foam-like solid.

Photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction: methanol, β-myrcene, and 1,4-dicyanobenzene. Intramolecular cyclization of an ene–diene radical cation[1]

Donald R. Arnold and Kimberly A. McManus

Abstract: The photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction of methanol, 7-methyl-3-methylene-1,6-octadiene (β-myrcene, **1**), and 1,4-dicyanobenzene yields five 1:1:1 adducts: *cis*-2-(4-cyanophenyl)-4-(1-methoxy-1-methylethyl)-1-methylenecyclohexane (**15**), *trans*-2-(4-cyanophenyl)-4-(1-methoxy-1-methylethyl)-1-methylenecyclohexane (**16**), 1-(4-cyanophenylmethyl)-4-(1-methoxy-1-methylethyl)cyclohexene (**17**), 4-[4-methoxy-3,3-dimethylcyclohex-(*E*)-1-ylidenyl]methylbenzonitrile (**18**), and 4-(1-vinyl-4-*trans*-methoxy-3,3-dimethylcyclohexyl)benzonitrile (**19**). All of these adducts are cyclic; variation in the product ratio as a function of methanol concentration indicates cyclization is occurring, 1,6-*endo*, with both the initially formed radical cation and with the intermediate β-alkoxyalkyl radicals. Evidence based upon comparison of the ionization and oxidation potential of β-myrcene with model alkenes and with conjugated dienes indicates the initial electron transfer involves the trisubstituted mono alkene moiety; the diene moiety, mono-substituted at a nodal position, has a higher oxidation potential. High-level ab initio molecular orbital calculations (MP2/6-31G*//HF/6-31G*) provide useful information regarding the nature (relative energies and charge and spin distribution) of the intermediate radical cations, which supports the proposed reaction mechanism.

Key words: photoinduced electron transfer, radicals, radical cations, β-myrcene, cyclization.

Résumé : La réaction photochimique de combinaison nucléophile–oléfine avec substitution aromatique (photo-NOCAS) entre le méthanol, le 7-méthyl-3-méthylène-octa-1,6-diène (β-myrcène, **1**) et le 1,4-dicyanobenzène fournit cinq adduits 1:1:1: *cis*-2-(4-cyanophényl)-4-(1-méthoxy-1-méthyléthyl)-1-méthylènecyclohexane (**15**), *trans*-2-(4-cyanophényl)-4-(1-méthoxy-1-méthyléthyl)-1-méthylènecyclohexane (**16**), 1-(4-cyanophénylméthyl)-4-(1-méthoxy-1-méthyléthyl)cyclohexène (**17**), 4-[4-méthoxy-3,3-diméthylcyclohex-(*E*)-1-ylidényl]méthylbenzonitrile (**18**) et le 4-(1-vinyl-4-*trans*-méthoxy-3,3-diméthylcyclohexyl)benzonitrile (**19**). Tous ces produits sont cycliques; les variations dans les rapports de produits en fonction de la concentration de méthanol indiquent que la cyclisation se produit, 1,6-*endo*, tant avec le cation radical formé initialement qu'avec les radicaux β-alkoxyalkyles intermédiaires. Des données obtenues sur la base d'une comparaison des potentiels d'ionisation et d'oxydation du β-myrcène avec ceux d'alcènes et de dienes conjugués indiquent que le transfert initial d'électron implique la portion trisubstituée du monoalcène; le potentiel d'oxydation de la portion diénique monosubstituée en position nodale est supérieur. Des calculs ab initio d'orbitales moléculaires à un niveau élevé (MP2/6-31G*//HF/6-31G*) fournissent des informations utiles relatives à la nature (énergies relatives et distributions de charge et de spin) des cations radicaux intermédiaires qui supportent le mécanisme réactionnel proposé.

Mots clés : transfert d'électron photoinduit, radicaux, cations radicaux, β-myrcène, cyclisation.

[Traduit par la Rédaction]

Introduction

The definition of the scope and limitations of the photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction has received considerable attention (1–3). This reaction has synthetic utility; yields of the nucleophile, olefin, aromatic (1:1:1) adducts can be high. The reaction is general for mono alkenes, and dienes, both conjugated and nonconjugated, and the reaction can incorporate a variety of nucleophiles; e.g., methanol, fluoride anion, cyanide anion, acetonitrile. Our understanding of the mechanism of this reaction has progressed to the point where the

results from a new reaction can now provide useful fundamental information regarding the reactivity of the intermediates, i.e., radical cation, radical anion, and radical. A main objective of this project was to determine the probability and regiochemistry of intramolecular cyclization of the intermediate(s) involved during the reaction of a nonconjugated alkene – conjugated diene, 7-methyl-3-methylene-1,6-octadiene (β-myrcene, **1**).

Relevant examples of this reaction are shown in reactions [1]–[4] (2). The irradiation of an acetonitrile–methanol solution of 1,4-dicyanobenzene (2) and the unsymmetric mono alkene, 2-methyl-2-butene (**3**), yields both regioisomeric 1:1:1 adducts (**4**, **5**) in 70% yield (reaction [1]) (2*a*). The mechanism proposed for formation of the major (6:1) isomer, 3-(4-cyanophenyl)-2-methoxy-3-methylbutane (**4**), involves rapid equilibration of the initially formed distonic radical cation intermediates, followed by irreversible deprotonation, with preferential formation of the more stable β-alkoxyalkyl radical (2*a*, *b*).

Similar irradiation of an acetonitrile–methanol solution of 1,4-dicyanobenzene and 2-methyl-1,3-butadiene (**6**) gave four isomeric 1:1:1 adducts (reaction [2]) (2*c*). The major

(8:1) adducts (**7**, **8**, **9**) result from combination of methanol with the diene radical cation at C-1, which again leads ultimately to the more stable allylic radical (2*b*).

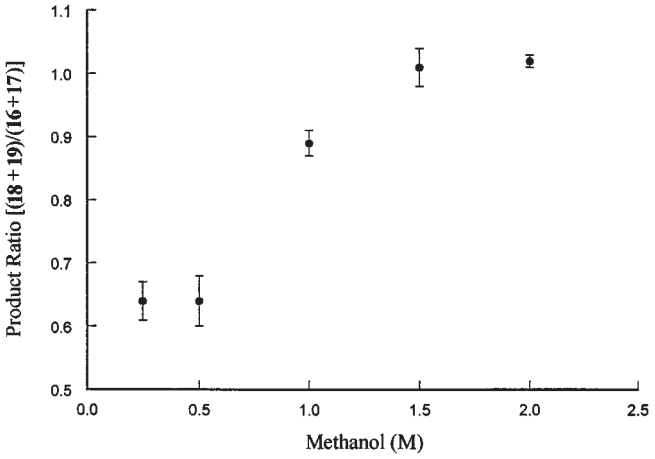
The irradiation of an acetonitrile–methanol solution of 1,4-dicyanobenzene and 2,5-dimethyl-1,5-hexadiene (**11**) provides an example of cyclization of the intermediate radical cation (reaction [3]) (2*d*). The ratio of 1:1:1 adducts is dependent upon the methanol concentration; lowering the concentration of methanol favours radical cation cyclization, increasing the yield of **13**. Cyclization, 1,6-*endo*, *endo*, of the initially formed alkene radical cation yields the more heavily substituted, more stable, 1,4-distonic radical cation intermediate, leading to the formation of **13**.

A particularly interesting example of the photo-NOCAS reaction involves irradiation of an acetonitrile–methanol solution of 1,4-dicyanobenzene and 6,6-dimethyl-2-methylenebicyclo[3.1.1]heptane (β-pinene) (**14**) (reaction [4]) (2*e*). In this case, the initially formed alkene radical cation cleaves an allylic cyclobutyl bond to give the distonic radical cation. The structures of the three 1:1:1 adducts (**15**, **16**, **17**) are consistent with reaction of this intermediate; no other 1:1:1 adducts were obtained. The adducts maintain optical activity, hence, the distonic radical cation does not cleave; cleavage of this distonic radical cation would yield the achiral radical cation of β-myrcene ($\mathbf{1}^{+\cdot}$).

Results

An acetonitrile–methanol (3:1) solution of 1,4-dicyanobenzene (**2**), biphenyl, serving as a codonor, and β-myrcene (1) was irradiated with a medium-pressure mercury vapour lamp through Pyrex. Progress of the reaction was monitored by capillary column gas chromatography with a flame ionization detector (GC–fid). The reaction produced five 1:1:1 (methanol, **1**, **2**) photo-NOCAS adducts (reaction [5]). The yields were based upon complete conversion of 1,4-dicyanobenzene as the limiting reagent (β-myrcene (1) was present in excess) and were calculated from the total weight of the combined products and the ratio of isomers determined by integrated peak (GC–fid) area. The ratio of adducts was not dependent upon the extent of conversion; these ratios remained constant during the irradiation.

Fig. 1. Variation in the product ratio [(**18** + **19**)/(**16** + **17**)] from reaction [5] as a function of the concentration of methanol.



Three of the adducts, *cis*-2-(4-cyanophenyl)-4-(1-methoxy-1-methylethyl)-1-methylenecyclohexane (**15**), *trans*-2-(4-cyanophenyl)-4-(1-methoxy-1-methylethyl)-1-methylenecyclohexane (**16**), and 1-(4-cyanophenylmethyl)-4-(1-methoxy-1-methylethyl)cyclohexene (**17**), were racemic mixtures of the enantiomeric adducts previously characterized from the reaction involving β-pinene (**14**) (reaction [4]) (2*e*). The major adducts were the new compounds: 4-[4-methoxy-3,3-dimethylcyclohex-(*E*)-1-ylidenyl]methylbenzonitrile (**18**) and 4-(1-vinyl-4-*trans*-methoxy-3,3-dimethylcyclohexyl)-benzonitrile (**19**).

The ratio of products [(**18** + **19**)/(**16** + **17**)] was dependent upon the initial concentration of methanol. (The yield of **15** was too low for an accurate measurement.) Irradiations were carried out in Pyrex tubes (5 mm) under conditions similar to those used for the preparative scale reaction described above. The concentration of methanol was varied (0.25–2.0 M). The concentrations of the other reactants were the same as in the preparative scale reaction. The ratio [(**18** + **19**)/(**16** + **17**)] of products was determined from the corresponding integrated peak (GC–fid) areas (Table 1 and Fig. 1). An increase in methanol concentration caused an increase in the yield of **18** and **19** relative to **16** and **17**. At the lower range of methanol concentration (≤ 0.5 M) the ratio of

[5]

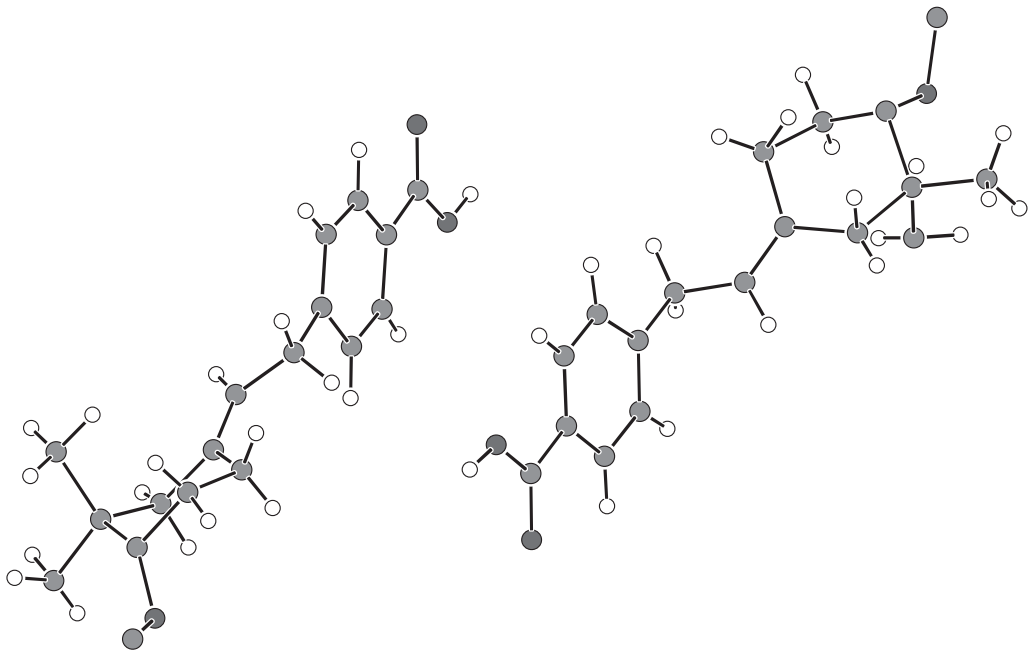
Fig. 2. The X-ray crystal structure of 4-[4-methoxy-3,3-dimethylcyclohex-(*E*)-1-ylidenyl]methylbenzoic acid (**18a**).[3]



products remained constant. The ratios (**18**/**19**) and (**16**/**17**) were independent of methanol concentration.

Structural assignments

Products **15**, **16**, and **17** were shown to have identical gas chromatographic retention times and mass spectra as the previously characterized adducts (2*e*).

Compound **18** was identified as 4-[4-methoxy-3,3-dimethylcyclohex-(*E*)-1-ylidenyl]-methylbenzonitrile. The typical AA′XX′ pattern in the aromatic region of the ^{1}H nmr spectrum is indicative of the 4-cyanophenyl group. The presence of the trisubstituted alkene is supported by a triplet (5.20 ppm), representing a vinyl proton with typical coupling (7.3 Hz) to a geminal methylene, and a doublet (3.43 ppm), representing this geminal methylene, aryl-substituted. The doublet of doublets at 2.93 ppm represents the axial proton of the methoxy-substituted methine ($^3J_{4ax–5ax}$ = 8.5 Hz, $^3J_{4ax–5eq}$ = 3.7 Hz). The ^{1}H nmr also exhibits two singlets at 0.84 and 0.94 ppm indicative of two nonequivalent methyl groups.

The ^{13}C nmr spectrum of **18** exhibits a doublet (85.91 ppm), which indicates a methine group substituted by the methoxy group. There is a lower field triplet (47.93 ppm), which is consistent with an aryl-substituted methylene group (carbons adjacent to the 4-cyanophenyl group tend to occur between 37–55 ppm (1, 2)). The ^{13}C nmr spectrum also exhibits a doublet (120.12 ppm) for the vinyl methine and a singlet (138.77 ppm) for the quaternary vinyl carbon, further supporting the existence of the trisubstituted alkene.

The assigned overall structure and stereochemistry of **18** was substantiated by X-ray crystallography. The nitrile group in compound **18** was converted to a carboxylic acid; 4-[4-methoxy-3,3-dimethylcyclohex-(*E*)-1-ylidenyl]methylbenzoic acid (**18a**). The ^{1}H nmr spectrum of the nitrile (**18**) and this carboxylic acid (**18a**) are almost identical; the X-ray analysis of **18a** (Fig. 2) provides firm evidence for the structure of the initial product (**18**).[3]

Compound **19** was identified as 4-(1-vinyl-4-*trans*-methoxy-3,3-dimethylcyclohexyl)benzonitrile. The typical AA′XX′ pattern in the aromatic region of the ^{1}H nmr spectrum is indicative of the 4-cyanophenyl group. The presence of the terminal alkene is supported by two doublets and a doublet of doublets (4.87, 5.03, and 5.86 ppm) in the vinyl proton region. The distorted four-line multiplet at 2.81 ppm represents the axial proton of the methoxy-substituted methine. Individual coupling constants were not obtained; however, based on the width of the multiplet at half-height (13 Hz), this proton is axial. Typical equatorial–axial and equatorial–equatorial couplings range from 0 to 3 Hz; if this proton were equatorial, the separation of the outer lines of a four-line multiplet would be, at most, 6 Hz. The ^{1}H nmr spectrum also exhibits two singlets at 0.72 and 0.96 ppm indicative of two nonequivalent methyl groups.

A nuclear Overhauser enhancement (NOE) experiment proved the aryl group was *trans* to the methoxy group on the cyclohexyl ring. When the methyl protons at 0.72 ppm were irradiated, a NOE was observed for the proton of the methoxy-substituted methine, the methoxy–methyl protons, and the methyl protons (0.96 ppm). When the methyl protons at 0.96 ppm were irradiated, a NOE was observed for

[3] X-ray crystallographic data for **18a** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2. Details of data collection, structural analysis and refinement, and tables of interatomic distances and bond angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

the methoxy–methyl protons, the vinyl protons, and the methyl protons (0.72 ppm). Based on the evidence that the proton of the methoxy-substituted methine is axial, vide supra, the methoxy group is equatorial, the aryl group is equatorial, i.e., the *trans* configuration.

The ^{13}C nmr spectrum of compound **19** exhibits a doublet (85.58 ppm) indicative of a methine group substituted by the methoxy group. There is a lower field singlet (44.31 ppm), which is consistent with an aryl-substituted quaternary carbon. This spectrum also exhibits a triplet (112.52 ppm) for the vinyl methylene and a doublet (146.73 ppm) for the vinyl methine, thus further supporting the existence of the terminal mono-substituted alkene.

Calculations

Ab initio molecular orbital calculations were carried out, using the GAUSSIAN 94 package of programs (4), to obtain fully optimized structures (HF/6-31G*) of β-myrcene (1) and the radical cations $\mathbf{1}^{+\cdot}$, $\mathbf{1a}^{+\cdot}$, and $\mathbf{1b}^{+\cdot}$. The results of these calculations, optimized structures, and spin and charge density distribution obtained from Mulliken population analysis, are listed in Tables 2 and 3. The total energies, corrected for spin contamination, were obtained from single point calculations with Møller–Plesset perturbation theory (MP2) using the HF/6-31G* optimized structures (5). The results of an extensive stochastic search, using the molecular mechanics program (MM3-94 (6)), identified 24 conformers of β-myrcene (**1**); the more stable conformers are described in Table 4.

Discussion

A mechanism for the formation of **15**, **16**, and **17** involves cyclization of the initially formed radical cation of myrcene ($\mathbf{1}^{+\cdot}$) to the distonic radical cation ($\mathbf{1a}^{+\cdot}$) (Scheme 1). This distonic radical cation is identical to that formed upon cleavage of the β-pinene radical cation ($\mathbf{14}^{+\cdot}$). An alternative mode of cyclization of $\mathbf{1}^{+\cdot}$ yields the distonic radical cation $\mathbf{1b}^{+\cdot}$, which leads to formation of **18** and **19**. The regiochemistry of these adducts requires reaction of these distonic radical cations — tertiary or secondary alkyl cation with methanol and the allylic radical with the radical anion of 1,4-dicyanobenzene ($\mathbf{2}^{-\cdot}$). At lower methanol concentrations (≤0.5 M) cyclization of the radical cation dominates, the product ratio [(**18** + **19**)/(**16** + **17**)] is relatively small (0.64), 1,6-*endo*, *exo* cyclization of $\mathbf{1}^{+\cdot}$ to $\mathbf{1a}^{+\cdot}$ is favoured.

The results from the molecular orbital calculations are consistent with these observations (Table 3). The distonic radical cation $\mathbf{1a}^{+\cdot}$ has most of the positive charge density on the tertiary carbocation (C7, C8, and C9), while the spin density is delocalized over the allylic radical (C2 and C10). Similarly, the distonic radical cation $\mathbf{1b}^{+\cdot}$ has greatest positive charge on C6, and the spin density is delocalized over the allylic radical (C1 and C3). It seems likely that the alternative modes of cyclization of the initially formed β-myrcene radical cation, $\mathbf{1}^{+\cdot}$, are dependent upon conformational factors. The rate of the intermolecular reaction of a diene radical cation with the precursor diene is rapid, 10^8–10^9 M^{-1} s^{-1} (3*a*). Nevertheless, the molecular orbital calculations indicate that the major mode of cyclization of $\mathbf{1}^{+\cdot}$ yields the more stable distonic radical cation $\mathbf{1a}^{+\cdot}$. The calculations also indicate that cyclization is significantly exothermic, –21.6 kcal mol^{-1} for $\mathbf{1}^{+\cdot}$ to $\mathbf{1a}^{+\cdot}$ and –11.3 kcal mol^{-1} for $\mathbf{1}^{+\cdot}$ to $\mathbf{1b}^{+\cdot}$, consistent with the lack of reversibility.

At higher methanol concentrations the product ratio [(**18** + **19**)/(**16** + **17**)] increases; for the preparative runs (6 M methanol) this ratio becomes 1.7. Under these conditions, reaction of the radical cation ($\mathbf{1}^{+\cdot}$) with methanol competes with cyclization; the measured bimolecular rate constant for reaction of diene radical cations with methanol (>10^9 M^{-1} s^{-1}) is consistent (3*a*). Now the product ratio is controlled by the addition of methanol to the radical cation $\mathbf{1}^{+\cdot}$ at the alternative sites, C7 or C6, to yield the β-alkoxyalkyl radicals, $\mathbf{1c}^{\cdot}$ or $\mathbf{1d}^{\cdot}$ (Scheme 2). As expected, based upon the product ratio from reaction (1), addition of methanol to the alkene radical cation at C6, with subsequent formation of the more stable tertiary radical ($\mathbf{1d}^{\cdot}$), is favoured, relative to addition at C7, to give the secondary radical ($\mathbf{1c}^{\cdot}$). Both of these β-alkoxyalkyl radicals then cyclize 1,6-*endo* on the way to the observed products.

Adduct **18** results from cyclization of the radical cation (Scheme 1) or radical (Scheme 2) at C10 of the diene moiety. The *E*-configuration of this adduct (**18**) clearly indicates this diene had the s-*trans* conformation. The result of an extensive stochastic search for conformers of β-myrcene (**1**), using the molecular mechanics program (MM3-94 (6)), is consistent with reaction of this conformation (Table 4). Conformer 3 has close approach between C7 and C10, required for cyclization to $\mathbf{1b}^{+\cdot}$, and the s-*trans* conformation of the diene. Conformers 6 and 8 have close approach between C1 and C6 required for cyclization to $\mathbf{1a}^{+\cdot}$. None of the low-energy conformers have the s-*cis* conformation and close approach of C7-C10 or C1-C6. The fully optimized (ab initio) structures of β-myrcene (1) and of the β-myrcene radical cation ($\mathbf{1}^{+\cdot}$) are similar (Table 4).

Clearly, none of the products from reaction 5 involve initial addition of the nucleophile, methanol, to the conjugated diene moiety. This was, at first, a surprise; however, there is convincing evidence that formation of the trialkyl-substituted mono-ene radical cation (C6, C7) is energetically favoured (1*b*). The oxidation potentials and the ionization potentials of β-myrcene (1) and of the model compounds 2-methyl-2-butene (3) and 2-methyl-1,3-butadiene (**6**) are summarized in Table 5. The radical cation of the trialkyl-substituted mono-ene moiety (C5, C6, C7, C8, C9) is more stable than that at the conjugated diene moiety (C1, C2, C3, C10, C4). The molecular orbital calculations support this conclusion; the charge density of radical cation, $\mathbf{1}^{+\cdot}$, is largely on C6, C7, C8, and C9, while the spin density is on C6 and C7 (Table 3).

Conclusions

Photoinduced electron transfer, from 7-methyl-3-methylene-1,6-octadiene (β-myrcene, **1**) to 1,4-dicyanobenzene, in acetonitrile–methanol, leads to formation of five 1:1:1 (photo-NOCAS) adducts (**15**–**19**). All of these adducts are cyclic; both the initially formed radical cation and the intermediate β-alkoxyalkyl radicals cyclize. The preferred modes of cyclization are for the radical cation $\mathbf{1}^{+\cdot}$, 1,6-*endo*, *exo* and 1,6-*endo*, *endo*, and for the radicals, $\mathbf{1c}^{\cdot}$ and $\mathbf{1d}^{\cdot}$, 1,6-*endo*. The observed products, the measured oxidation and ionization potentials, and the molecular orbital

calculations all indicate the trisubstituted mono alkene moiety is the site of the initially formed radical cation **1**$^{+\cdot}$, not the conjugated diene. Cyclization of this radical cation is significantly exothermic and is irreversible. The observed products and the molecular orbital calculations indicate that on the cyclized, distonic radical cation intermediates, **1a**$^{+\cdot}$ and **1b**$^{+\cdot}$, the positive charge density is largely on the tertiary and secondary alkyl moiety, and the spin density is delocalized on the allylic radical. The addition of methanol to the initially formed radical cation follows the established pattern for alcohol addition to mono alkenes; addition occurs preferentially to ultimately yield the more heavily substituted, more stable, β-alkoxyalkyl radical. Cyclization of these radicals, **1c**$^{\cdot}$ and **1d**$^{\cdot}$, occur 1,6-*endo*.

[a]Spin and charge densities include hydrogens summed into heavy atoms.

Experimental

General information

The ^{1}H and ^{13}C nmr spectra were obtained from a Bruker AC 250 F spectrometer. Spectra were recorded in parts per million and frequencies are relative to tetramethylsilane. Infrared spectra (ir) were recorded on a Nicolet 205 FTIR and are reported in wave numbers (cm^{-1}). Elemental analyses were performed by Canadian Microanalytical Service Ltd., B.C. Exact mass determinations were obtained using a CEC 21-110 mass spectrometer at Dalhousie University, Halifax, NS. Melting points were determined using a Cybron Corporation Thermolyne apparatus with a digital thermocouple and are corrected. Product yields and progress of the reactions were determined using a Hewlett–Packard (HP) 5890 gas chromatograph with a DB-1701 fused silica WCOT column (30 m × 0.25 mm, 0.25 μm film thickness) and a calibrated flame ionization detector (GC–fid) and are based upon 1,4-dicyanobenzene (2) as the limiting reagent. An HP 3392A integrator was interfaced with the GC–fid to obtain peak areas. An HP 5890 gas chromatograph with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33 μm film thickness) interfaced with an HP 5970 mass selective detector (GC–MS) was also used for product analyses. Mass spectra are reported as m/z (relative intensity). Separation of product mixtures was generally carried out using preparative medium-pressure liquid chromatography (mplc) (1*a*). The mplc consists of a 2.5 cm × 1 m column packed with thin-layer chromatography (TLC) grade silica gel (without binder) (Rose Scientific Ltd., cat. 81632) at a pressure of 19 psi using helium (1 psi = 6.9 kPa). Connected to the mplc was a uv spectrophotometer – fraction collector collecting ca. 10 mL fractions.

Materials

Acetonitrile (Fisher ACS grade) was distilled twice, first from sodium hydride and then from phosphorus pentoxide. It was then passed through a column of basic alumina,

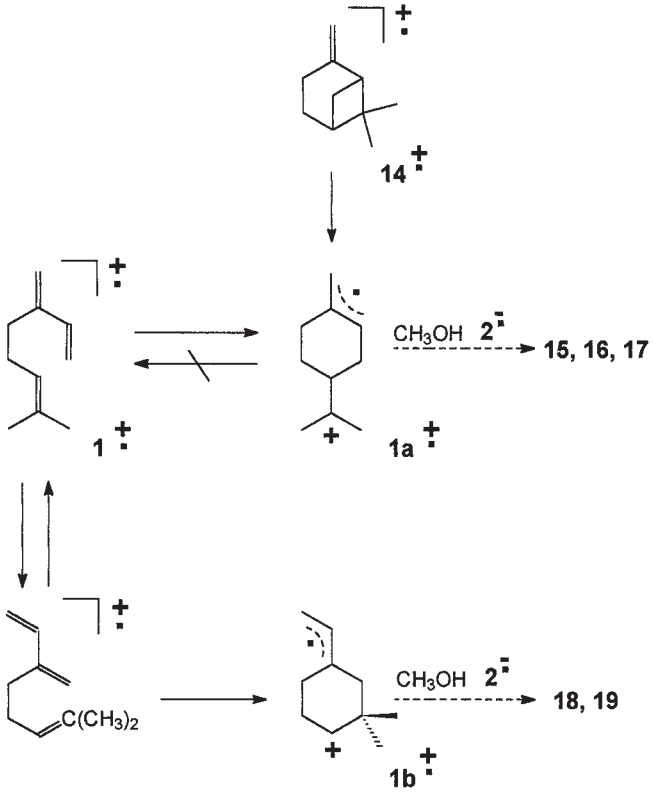
Scheme 1. Cyclization of the initially formed β-myrcene radical cation, to give the distonic radical cation, followed by reaction of the distonic radical cation with nucleophile (methanol) and with the aromatic radical anion.



refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), fractionally distilled (under nitrogen), and stored over molecular sieves (3 Å) (7). Methanol was distilled and then stored over molecular sieves (4 Å). 1,4-Dicyanobenzene (2) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by recrystallization from 95% ethanol. Tetraethylammonium perchlorate (TEAP) (Aldrich) was recrystallized three times from water and then dried in a vacuum oven for 15 h, 70°C, 0.25 Torr (1 Torr = 133.3 Pa). Myrcene (1) (technical grade) was obtained from the Aldrich Chemical Co. and purified by vacuum distillation. Biphenyl (Eastman Kodak Co.) was recrystallized from methanol.

Irradiation

The irradiation was carried out on an acetonitrile–methanol (3:1) solution consisting of myrcene (**1**), 1,4-dicyanobenzene (**2**), and biphenyl. Solutions were irradiated in either 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes, which were degassed by nitrogen ebullition. These samples were irradiated at 10°C using a CGE 1 MW medium-pressure mercury vapour lamp contained in a water-cooled quartz immersion well.

Cyclic voltammetric measurements

Cyclic voltammetry was used to obtain the oxidation potential of myrcene (**1**). The apparatus has been described (8). The working electrode was a platinum sphere (1 mm diameter), and the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (sce), which was connected to the solution (TEAP 0.1 M, acetonitrile) through a Luggin capillary. The alkene concentration was ca. 0.005 M. Since the anodic wave was irreversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (9).

Formation of the methanol, β-myrcene (1), 1,4-dicyanobenzene (2) photo-NOCAS adducts 15, 16, 17, 18, and 19: reaction [5]

A solution of β-myrcene (1) (10.0 mL, 8.0 g, 0.059 mol), 1,4-dicyanobenzene (2) (3.7 g, 0.029 mol), and biphenyl (2.3 g, 0.015 mol) in acetonitrile–methanol (3:1) (240 mL) was degassed by nitrogen ebullition and irradiated for 9 days using a 1 kW lamp at 10°C. The solvent was removed to yield a crude photolysate. The crude photolysate was chromatographed (mplc) using a linear solvent gradient (hexanes – 10% diethyl ether, 90% hexanes). Isolation of the adducts was achieved via further chromatography using mplc and a linear solvent gradient (hexanes – 1% diethyl ether, 99% hexanes). The five 1:1:1 adducts were eluted in

Preparation of 4-[4-methoxy-3,3-dimethylcyclohex-(*E*)-1-ylidenyl]methylbenzoic acid (18a)

4-[4-Methoxy-3,3-dimethylcyclohex-(*E*)-1-ylidenyl]methylbenzonitrile (**18**) (0.041 g, 0.15 mmol) and 4 mL of a 40% sodium hydroxide solution was refluxed for 2 days. This mixture was cooled and extracted with dichloromethane. The aqueous layer was acidified with hydrochloric acid (conc.) and extracted twice with benzene. Evaporation of the solvent left a white solid (0.026 g, 0.090 mmol), which was recrystallized from hexanes.

*4-[4-Methoxy-3,3-dimethylcyclohex-(*E*)-1-ylidenyl]-methylbenzoic acid (**18a**)*

The yield of **18a** was 60%: the melting point was 112–113°C; infrared (Nicolet 205) ν: 2967 (s), 2938 (s), 2900 (m), 2871 (m), 2821 (m), 2674 (w), 2544 (w), 1682 (s), 1608 (m), 1572 (w), 1425 (s), 1318 (m), 1290 (s), 1182 (m), 1101 (s), 951 (w); ^{1}H nmr (250.13 MHz, $CDCl_3$), δ_{TMS}: 0.86 (s, 3H, CH_3), 0.95 (s, 3H, CH_3), 1.39–1.56 (m, 1H, $^3J_{4ax–5ax}$ = 8.6 Hz, $^3J_{5ax–6eq}$ = 5.5 Hz, axial H of methylene group (5ax-H)), 1.80–2.06 (m, 4H, $^2J_{6ax–6eq}$ = 13.7 Hz, $^2J_{2ax–2eq}$ = 13.6 Hz, $^3J_{5eq–6eq}$ = 5.5 Hz, $^3J_{4ax–5eq}$ = 3.7 Hz, H of methylene groups on ring (2ax-, 2eq-, 5eq-, 6ax-H)), 2.49 (m, 1H, $^2J_{6ax–6eq}$ = 13.7 Hz, $^3J_{5ax–6eq}$ = 5.5 Hz, $^3J_{5eq–6eq}$ = 5.5 Hz, equatorial H of methylene group on ring (6eq-H)), 2.94 (dd, 1H, $^3J_{4ax–5ax}$ = 8.6 Hz, $^3J_{4ax–5eq}$ = 3.7 Hz, CH group, methoxy-substituted (4ax-H)), 3.38 (s, 3H, OCH_3), 3.44 (d, 2H, $^3J_{7–8}$ = 7.3 Hz, CH_2 group, aryl-substituted (8-H)), 5.24 (t, 1H, $^3J_{7–8}$ = 7.3 Hz, vinyl H (7-H)), 7.27 (d, 2H, $^3J_{2'–3'}$ = 8.1 Hz, $^3J_{5'–6'}$ = 8.1 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 8.02 (d, 2H, $^3J_{2'–3'}$ = 8.1 Hz, $^3J_{5'–6'}$ = 8.1 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (62.90 MHz, $CDCl_3$), δ: 21.52 (q), 25.06 (t), 25.83 (t), 27.58 (q), 33.90 (t), 37.19 (s), 48.04 (t, CH_2, aryl-substituted), 57.53 (q, OCH_3), 86.14 (d, CH, methoxy-substituted), 120.79 (d, vinyl CH), 126.90 (s, quaternary aryl carbon, COOH-substituted), 128.46 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 130.41 (d, aromatic CH adjacent to COOH-substituted carbon), 138.13 (s), 148.43 (s), 172.13 (s, C=O of COOH); MS, *m*/*z*: 55(26), 77(35), 79(27), 91(36), 93(36), 107(31), 121(78), 128(37), 129(50), 135(30), 141(41), 211(30), 213(50), 256(100). X-ray data: see footnote 3.

Acknowledgement

This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada. We thank Dr. D.L. Hooper, Atlantic Region Magnetic Resonance Centre at Dalhousie University, for help in the preparation of the manuscript, Dr. T.S. Cameron, Dalhousie University, for the X-ray crystal structure of **18a**, and Dr. T.B. Grindley and Dr. M.S.W. Chan, Dalhousie University, for assistance with the molecular mechanics calculations. We also wish to thank Dr. D. Klapstein, St. Francis Xavier University, for the photoelectron spectra of **1**.

Ketone coordination chemistry of the diborane *t*-BuCH=C[B(C_6F_5)$_2$]$_2$

Katrin Köhler and Warren E. Piers

Abstract: Reactions of the bifunctional borane *t*-BuCH=C[B(C_6F_5)$_2$]$_2$, **1**, with simple Lewis bases were investigated to probe its Lewis acidity. Ethereal bases (Et_2O, THF) bind very weakly, if at all, as no adducts were detectable in solution. Certain ketones, however, were observed to bind to **1**. Acetone forms an adduct, **2**, reversibly in solution (K_{eq} at 293 K = 69.1), and the temperature dependence of this equilibrium yield thermodynamic parameters of $\Delta H°$ = –59.5 ± 2.0 kJ mol^{-1}; $\Delta S°$ = –167 ± 4 J K^{-1} mol^{-1}. Low temperature NMR spectroscopy suggests that the acetone binds to the more sterically accessible boron center *trans* to the *t*-Bu group. Ketone binding is strengthened when 2,3-diphenylcyclopropenone is reacted with **1**, irreversibly forming an isolable adduct, **4**, in high yield (95%). The availability of a resonance form incorporating the aromatic cyclopropenyl cation contributes to the added stability of this adduct in comparison to **2**.

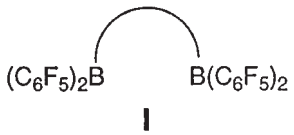
Key words: organoboranes, diboranes, ketone complexes.

Résumé : Afin d'évaluer son acidité de Lewis, on a étudié les réactions du borane bifonctionnel *t*-BuCH=C[B(C_6F_5)$_2$]$_2$, **1**, avec des bases de Lewis simples. Au mieux, les bases éthérées (Et_2O, THF) ne s'y lient que faiblement puisqu'on ne peut détecter la présence d'adduits en solution. Toutefois, on a observé que certaines cétones se lient à **1**. En solution, l'acétone forme d'une façon réversible l'adduit **2** ($K_{éq}$ = 69,1, à 293 K) et la dépendance de cet équilibre sur la température permet de déterminer les paramètres thermodynamiques suivants: $\Delta H°$ = –59,5 ± 2,0 kJ mol^{-1} et $\Delta S°$ = –167 ± 4 J K^{-1} mol^{-1}. Les résultats d'expériences de RMN à basse température suggèrent que l'acétone se lie au bore stériquement le plus accessible, *trans* par rapport au groupe *tert*-butyle. La liaison avec la cétone est plus forte lorsqu'on fait réagir de la 2,3-diphénylcyclopropénone avec **1**; on peut alors isoler l'adduit **4**, formé d'une façon irréversible avec un rendement de 95%. La disponibilité d'une forme de résonance comportant le cation aromatique cyclopropényle contribue à la stabilité accrue de cet adduit par comparaison avec l'adduit **2**.

Mots clés : boranes organiques, diboranes, complexes de cétones.

[Traduit par la Rédaction]

Highly electrophilic pentafluorophenyl boranes and boronic acids have recently been applied as Lewis acids in organic synthesis (1). Much less attention has been given to *bis*-boryl compounds incorporating B(C_6F_5)$_2$ units (**I**) (2), which in principle could offer several advantages over the monofunction boranes in this regard (3).



I

We (4) and others (5) have been interested in the activation of carbonyl functions by pentafluorophenyl substituted boranes. A variety of 1,1-*bis*(pentafluorophenyl)borane substituted alkyl derivatives are available via hydroboration of terminal alkynes with HB(C_6F_5)$_2$ (6). Reactions of the resulting bifunctional boranes with simple Lewis bases such as acetone reveal a problem with these systems, namely the facility of retrohydroboration. Instead of observing adducts, the product mixture shown in Scheme 1 was observed. Although the diborane dominates the equilibrium, ketones such as acetone react preferentially with the small amounts of HB(C_6F_5)$_2$, which are present via retrohydroboration. We judged that in order to study the coordination chemistry of diboranes incorporating the -B(C_6F_5)$_2$ functional group, compounds without β-hydrogens (or at least systems in which elimination of HB(C_6F_5)$_2$ is kinetically and (or) thermodynamically prohibitive) would be required.

To this end, we prepared some 1,1-*bis*-boryl alkenes RCH=C[B(C_6F_5)$_2$]$_2$, which by virtue of the unsaturation in the linker group do not undergo retrohydroboration. These bifunctional Lewis acids were prepared by regioselective hydroboration of boraalkynes with general formula RC≡CB(C_6F_5)$_2$, using HB(C_6F_5)$_2$; their complete characterization, including their molecular structures, have been reported elsewhere (7). Since diborane **1** is sufficiently Lewis acidic to abstract methyl groups from Cp_2ZrMe_2 (7) and generate active olefin polymerization catalysts, we have examined its reactivity with simple Lewis bases to probe its potential for applications in organic synthesis.

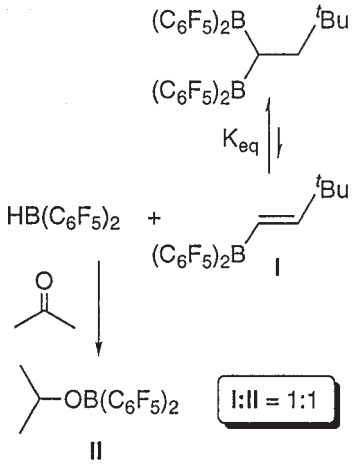
Scheme 1.



Results and discussion

Preliminary experiments were directed at exploring the ability of compound **1** to bind simple ethers, such as Et_2O or THF, since the parent Lewis acid $B(C_6F_5)_3$ strongly binds these solvents. In contrast, bidentate **1** does not form an isolable complex with either of these two bases. Dissolution of **1** in Et_2O or THF, followed by removal of the solvent in vacuo results in complete recovery of base-free **1**. Indeed, ^{1}H NMR experiments suggest that binding of THF in solution is minimal; a 1:1 mixture of THF and **1** in C_6D_6 gives a nearly identical spectrum to that obtained for THF in the absence of **1**, suggesting that the equilibrium does not favor adduct formation. In light of the favorable binding of THF by the related boranes $HB(C_6F_5)_2$ and $CH_3B(C_6F_5)_2$, it is likely that THF coordination to **1** is discouraged by the steric crowding in the molecule (7). Also, the most accessible boron center is the one *trans* to the *t*-Bu group, which is in conjugation with the carbon—carbon double bond (7) and is therefore less Lewis acidic on electronic grounds than, for example, $CH_3B(C_6F_5)_2$.

Sterically less demanding Lewis bases can, however, access the boron centers in **1**. Water reacts rapidly with **1** to liberate Bu-*t*-CH=CH_2 and 2 equiv. of the known boronic acid $HOB(C_6F_5)_2$ (8). Steric differentiation is also observed in ketone binding studies involving benzophenone and acetone (eq. [1]).

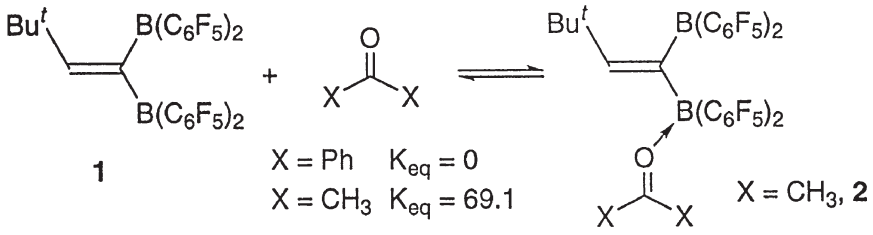
Whereas no binding is observed for benzophenone at room temperature (i.e., $K_{eq} \approx 0$), the smaller and more basic acetone coordinates reversibly to **1** as shown (K_{eq} = 69.1 at 293 K). Attempts to isolate acetone adduct **2** as a solid were unsuccessful; removal of solvent from solutions containing **2** resulted in complete loss of acetone and recovery of uncomplexed **1**.

It was possible, however, to perform detailed spectroscopic studies on adduct **2**. The temperature dependence of the equilibrium involving adduct formation was examined by ^{1}H NMR spectroscopy. Using the signal for the olefinic hydrogen atom as a probe, the equilibrium constant at various temperatures was calculated (9; see also ref. 4*b*) after the requisite chemical shifts for free **1** (7.17 ppm) and fully bound **2** (6.03 ppm)[2] were measured in d_8-toluene. A van't Hoff plot of ln K_{eq} vs. $1/T$ (Fig. 1, Table 1) allowed for extraction of the thermodynamic parameters associated with this equilibrium: $\Delta H° = -59.5 \pm 2.0$ kJ mol^{-1}; $\Delta S° = -167 \pm 4$ J K^{-1} mol^{-1}. Thus, binding is only slightly favored at 298 K ($\Delta G° = -9.7 \pm 2.2$ kJ mol^{-1}) due to a relatively low enthalpic contribution to adduct formation.

At temperatures below ≈–30°C, however, **2** is essentially the only species in solution and can be probed by various multinuclear NMR experiments. Interpretation of the spectra resulting from these experiments is complicated somewhat by the fluxionality observed in **2**, arising from -C_6F_5 ring rotations, which are frozen out at ≈–80°C. In this temperature regime, however, spectral changes can be assumed to be due to the dynamic behavior of **2** and not rapid exchange between free and bound acetone as is observed at higher temperatures.

Since ^{11}B chemical shifts are quite sensitive to the coordination environment about the boron center (10), this technique would seem to be ideal for addressing the question of whether the acetone is bound by one or both of the Lewis acid centers. Unfortunately, ^{11}B NMR spectroscopy gave ambiguous results in this regard. At room temperature, a strong signal centered around 39.0 ppm (fwhh = 650 ± 10 Hz) represents an average of the signals from **1** (7) and **2**. Upon cooling to temperatures at which **2** should dominate in solution (vide supra), this signal broadens considerably into two featureless humps centered around 32 ± 4 and –4 ± 4 ppm. Although this is a pattern that might be expected for a compound with one neutral three-coordinate and one neutral four-coordinate boron center, the rather poor signal-to-noise obtained in this experiment necessitates caution in this interpretation of the data. Attempts to improve the quality of the data were hampered by the fact that these are high molecular weight compounds with poor solubility at low temperature. Since ^{11}B is a quadrupolar nucleus, each boron has

[1]



[2] This was measured at room temperature by adding an excess of acetone in 5 equiv. increments until the chemical shift of the C*H*= resonance did not change upon further addition.

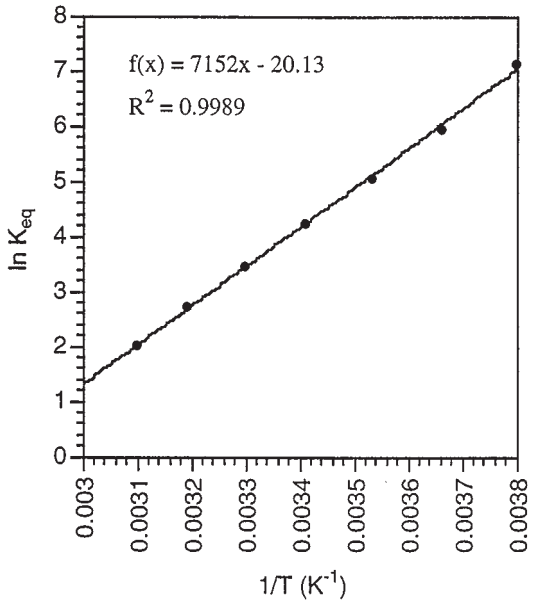
Fig. 1. A van't Hoff plot for the equilibrium between **1** and acetone and the adduct **2**.



a broadening effect on the other; furthermore, the two boron nuclei are chemically inequivalent and therefore coupled to eachother. Together these factors conspire to severely broaden the signals, accounting for the poor quality of the data.

Fluorine-19 NMR spectroscopy was more useful in probing the solution structure of **2**. At room temperature, two sets of signals are observed; as the sample is cooled, these peaks broaden and shift until at –80°C, separate resonances for each of the 20 fluorine atoms present are observed. The resulting spectrum is shown in Fig. 2. To help assign this spectrum, a ^{19}F–^{19}F COSY experiment was performed at –80°C, allowing the signals to be grouped into four sets of resonances arising from each C_6F_5 ring. These assignments are given in Table 2, and the full COSY correlation map is included as supplementary information.[3] Precise assignment of the four different C_6F_5 rings was not possible, but the data indicates that two of the rings are associated with a four-coordinate boron center (**A**, **A′**), while the other two are bonded to tricoordinate boron (**B**, **B′**). The primary evidence for this lies in the observed absolute difference between the chemical shifts of the *para*- and *meta*-fluorines ($\Delta\delta_{m,p}$) in each ring.

Horton et al. (11) has noted the fact that $\Delta\delta_{m,p}$ is sensitive to the coordination environment about boron in pentafluorophenyl substituted borates and boranes. A relatively large $\Delta\delta_{m,p}$ is suggestive of three-coordinate boron, while smaller values of $\Delta\delta_{m,p}$ imply a coordination number of four. In **2**, two of the rings exhibit $\Delta\delta_{m,p}$ values of <10 ppm, while the other two range from 12.5 to 17.1 ppm (Table 2). For comparison, $\Delta\delta_{m,p}$ for free diborane **1**, $B(C_6F_5)_3$ and the acetophenone adduct of $B(C_6F_5)_3$ (*4b*) are also given. These

data suggest, therefore, that only one borane moiety in adduct **2** is engaged in bonding with acetone and that rings **A** and **A′** belong to the ligated four-coordinate boron center. Based on the observation that it is the boron center *trans* to the *t*-Bu group, which abstracts CH_3^- from Cp_2ZrMe_2 (*7*), we presume that it is this more accessible center that is involved in acetone binding. Although this boron center is conjugated with the double bond (note the smaller $\Delta\delta_{m,p}$ for this $B(C_6F_5)_2$ unit compared to the one *cis* to the *t*-Bu group), it is the preferred site of attack for Lewis bases on steric grounds.

A striking feature of the low-temperature ^{19}F NMR spectrum of **2** is the rather large coupling observed between two of the *ortho*-F atoms in the molecule. This coupling is evident also in the ^{19}F–^{19}F COSY spectrum; the *ortho*-F region of this spectrum is shown in Fig. 3. The magnitude (183.5 ± 1.0 Hz)[4] of the coupling, combined with the the fact that the two F atoms in question are on different C_6F_5 rings leads to the conclusion that this is a "through-space" coupling rather than a more common "through-bond" coupling. Indeed, close inspection of the COSY map reveals that there are several inter-ring couplings observable in this complex; the *ortho*-F region of the COSY (Fig. 3) shows three such couplings, and there are others evident in the full spectrum as well (supplementary information[3]).

Ample precident exists for through space coupling between proximal ^{19}F nuclei and, while the phenomenon has been investigated most thoroughly in organic systems (12), instances have recently been observed in organometallic compounds as well (13). The coupling is thought to arise when two ^{19}F nuclei get close enough for the lone pair orbitals to overlap, although couplings between atoms separated by more than the sum of two ^{19}F van der Waals radii have been observed (14). As such, the magnitude of the coupling is directly related to the separation between the two nuclei, with stronger couplings observed between closer contacts. Several quantitative expressions have been developed to relate the coupling constant to the intranuclear distance (15), the most recent and accurate being put forward

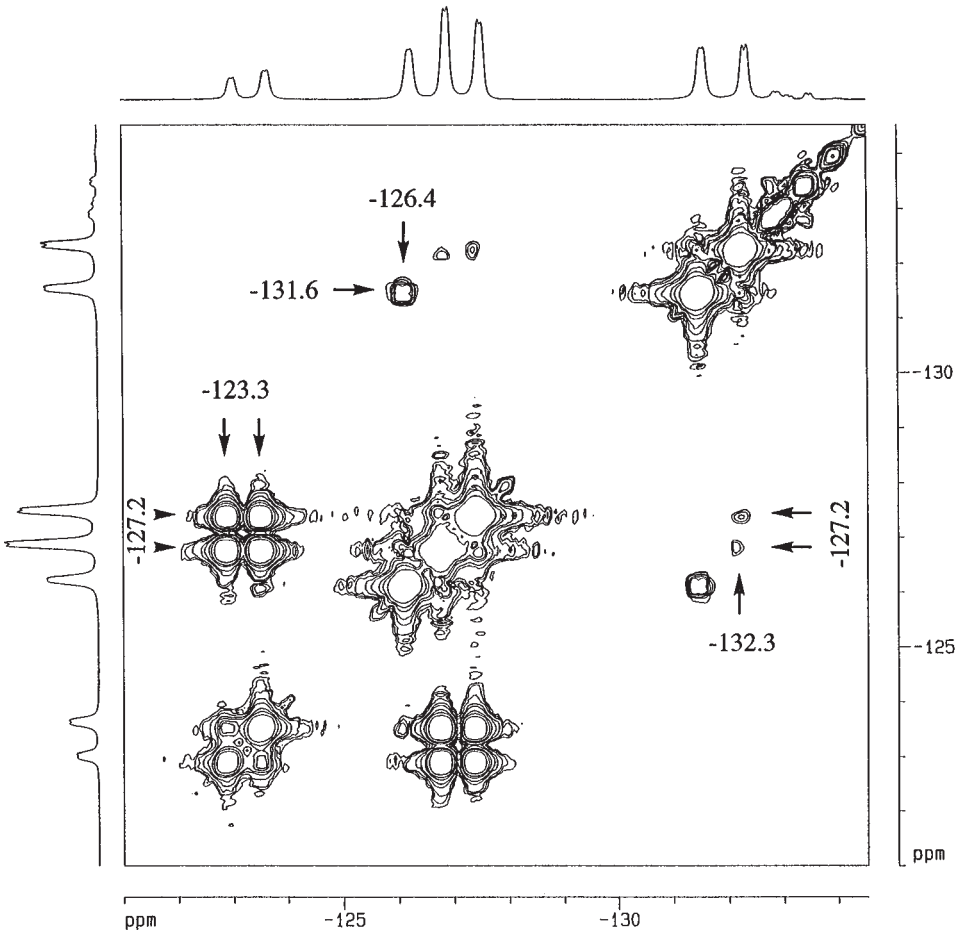
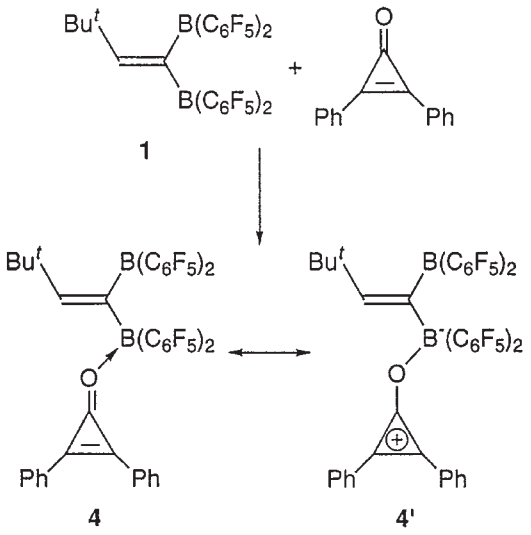


Scheme 2.



by Ernst and Ibrom (16) (J_{FF} = 275 000 $e^{-0.03211d_{FF}}$ (d_{FF} = nonbonding distance)). Using this expression, a distance of 2.28 ± 0.02 Å may be computed for two coupling *ortho*-^{19}F nuclei in **2**, well within the sum of the van der Waals radii of two fluorine atoms (2.70 Å). Molecular models of **2** built and minimized with MacSpartan Plus software (MM2) suggest that the closest contacts between *ortho*-F atoms exist between the "inner" rings (labelled **A′** and **B** in the graphic for Table 2), although none were as close as the coupling constant would indicate. The data does, however, suggest that coordination of a Lewis base (in this case, acetone) to **1**, crowds the molecule further and causes several close contacts between C_6F_5 rings on opposing boron nuclei. A variable temperature ^{19}F NMR study on **1** itself showed some broadening due to the onset of restricted C_6F_5 rotation, but the low-temperature limit was not imminent even at –80°C. It is therefore hard to say to whether similar close F–F contacts exist in free **1**, but the more facile C_6F_5 rotation would argue against this notion. This exacerbation of steric congestion upon Lewis base coordination to **1** accounts for the weak nature of the bonding of acetone to **1** and the apparent lack of bonding by more sterically demanding bases such as THF or Et_2O (vide supra).

In an attempt to strengthen the interaction, the reaction of **1** with 2,3-diphenylcyclopropenone was studied (Scheme 2), the assumption being that a significant contribution from the resonance form depicted as ***4′***, since cyclopropenyl cations are aromatic (17), would help to stabilize the adduct (a similar strategy for encouraging ketone binding to 1,8-naphthalenediylbis(dichloroborane) using 2,6-dimethylpyranone has

© 1998 NRC Canada

been employed; see ref. 18). Indeed, **4** is isolated analytically pure in 95% yield from 1:1 mixtures of the reagents in hexanes. Spectroscopic evidence in favor of the structure as shown in Scheme 2 follows along the same lines as that described above for the acetone adduct of **1**. Again, ^{11}B NMR spectroscopy was ambiguous, giving only one signal 9.4 ppm, implying that the resonance for the three-coordinate boron nucleus is too broad to be readily observed. The $\Delta\delta_{m,p}$ values of 12.6 and 7.1 ppm are consistent with the presence of both three and four coordinate boron nuclei, respectively. Finally, the ^{13}C chemical shifts for the carbon nuclei of the ketone are shifted significantly downfield with respect to the free ketone, consistant with the transfer of electron density from the ketone to the borane upon coordination. For example, the two carbon nuclei associated with the cyclopropenyl ring shift from 154.6 and 149.6 ppm in the free ketone to 158.1 and 157.3 ppm in **4**.

Conclusions

Although diborane **1** is an effective initiator of olefin polymerization reactions (7), it is a relatively poor Lewis acid for activating organic Lewis bases. This can be attributed to the steric properties of the molecule, which renders only one of the borane centers readily accessible to incoming nucleophiles. Although the $B(C_6F_5)_2$ group is quite bulky, the steric problems of the 1,1-alkenyl diboranes would likely be alleviated to a degree by incorporating longer linkers, possibly allowing for more interesting coordination chemistry directly involving both highly electrophilic boron centers. These studies are currently underway.

Experimental section

General

All manipulations of air- and moisture-sensitive materials were undertaken using standard vacuum and Schlenk techniques (19) or in a glove-box under an atmosphere of nitrogen. All solvents were dried and purified by passing through suitable drying agents (alumina and Q5) (20). The NMR spectra were recorded in C_6D_6 at room temperature or in C_7D_8 for low temperature experiments. Data are given in ppm relative to solvent signals for ^{1}H and ^{13}C spectra or relative to external standards for ^{11}B ($BF_3{\cdot}OEt_2$, 0.0 ppm) and ^{19}F ($CFCl_3$ at 0.0 ppm) experiments. Elemental analyses were performed by Mrs. Dorothy Fox in the microanalytical laboratory of the Department of Chemistry at the University of Calgary. Complex **1** was prepared as described previously (7). Acetone was dried over activated molecular sieves and distilled prior to use; ketones benzophenone and 2,3-diphenylcyclopropenone were purchased from Aldrich and used as received.

Reaction of 1 with Et_2O and THF

A small amount of **1** (≈30–40 mg) was dissolved in Et_2O or THF. Upon full dissolution, the solvent was removed in vacuo and the residue subjected to full vacuum for at least 1 h. The resulting solid was then dissolved in C_6D_6 and examined by ^{1}H NMR. Alternatively, **1** (50 mg, 0.064 mmol) was loaded into a 5 mm NMR tube and dissolved in C_6D_6. Dry, degassed THF (5.2 mL, 0.064 mmol) was introduced via syringe and the sample assayed by ^{1}H NMR spectroscopy.

Reaction of 1 with water

Diborane **1** (50 mg, 0.064 mmol) was loaded into a 5 mm NMR tube and dissolved in C_6D_6 (≈0.7 mL). The tube was capped with a rubber septum. Degassed, deionized water (1.2 mL, 0.064 mmol) was added by syringe and the sample assayed by ^{1}H NMR spectroscopy.

Reaction of 1 with benzophenone

Diborane **1** (70 mg, 0.090 mmol) and benzophenone (17 mg, 0.093 mmol) were loaded into a 5 mm NMR, dissolved in C_6D_6 and assayed by ^{1}H NMR spectroscopy.

Equilibrium studies concerning 1, acetone, and 2

Samples for study by a variety of NMR techniques were prepared as follows. Diborane **1**, (45 mg, 0.058 mmol) was dissolved in d_8-toluene (1 mL) and acetone (4.3 mL, 0.058 mmol) was added at 25°C. A portion of this solution ([**1**] = [CH_3COCH_3] = 0.058 M) was loaded into a 5 mm NMR tube and sealed for analysis with a septum wrapped with parafilm. The following data is for room temperature NMR spectra. ^{1}H NMR: 6.61 (s, 1H, *H*C=), 1.49 (s, 6H, OCC*H*$_3$), 0.98 (s, 9H, CC*H*$_3$). ^{13}C{^{1}H} NMR: 215.4 (O*C*CH$_3$), 171.9 (H*C*=), 37.9 (*C*CH$_3$), 29.9 (OC*C*H$_3$), 29.4 (CCH$_3$). ^{11}B NMR: 39.0. ^{19}F NMR: –127.0 (m, 4F, *o*-F), –130.4 (s, br, 4F, *o*-F), –145.6 (t, 2F, *p*-F), –151.2 (t, 2F, *p*-F), –161.5 (m, 4F, *m*-F), –161.8 (m, 4F,*m*-F). See Table 2 and text for low-temperature NMR data on **2**.

Preparation of Bu-*t*-(H)C=C[B(C_6F_5)$_2$]$_2$[OC(CC_6H_5)$_2$], 4

Compound **1**, (150 mg, 0.194 mmol) was dissolved in hexane (20 mL), and a solution of OC(CC_6H_5)$_2$ (40 mg, 0.194 mmol) in hexane (5 mL) was added at –78°C. After stirring for 1 h at –78°C the reaction solution was warmed to 25°C. A white precipitate was formed; a portion of the solvent was removed, the solid was separated by filtration and washed with hexane. Crystallization at –30°C in benzene/hexane (5:1) yielded **4** (180 mg, 95%). ^{1}H NMR: 6.95 (m, 4H, C_6H_5), 6.84 (m, 6H, C_6H_5), 6.16 (s, 1H, *H*C=), 1.08 (s, 9H, Bu-*t*). ^{13}C{^{1}H} NMR: 158.1 (O=*C*); 157.3 (H*C*=); 145.5 (C_{ipso}); 135.8, 132.3, 129.8 (C_6H_5); 120.6 (CC_6H_5); 37.1 (*C*CH$_3$); 30.6 (C*C*H$_3$). ^{11}B NMR: 9.4. ^{19}F NMR: –127.9 (m, 4F, *o*-F), –130.9 (m, 4F, *o*-F), –149.8 (m, 2F, *p*-F), –156.7 (m, 2F, *p*-F), –162.4 (m, 4F, *m*-F), –163.8 (m, 4F, *m*-F). Anal. calcd. for $C_{45}H_{20}B_2F_{20}O$: C 55.25, H 2.06; found: C 55.26, H 1.72.

The ultra high pressure conjugate addition of indoles to electron-deficient olefins

Paul Harrington and Michael A. Kerr

Abstract: The addition of indole and methyl indole at both high and ambient pressures to a series of Michael acceptors under the influence of ytterbium triflate was investigated. Under ambient pressure the more reactive and less sterically hindered electrophiles gave the expected 3-alkylated indoles in good to excellent yields. The more problematic Michael acceptors were subjected to pressures of 13 kbar. In all cases a dramatic reduction in reaction time and a significant improvement in yields was observed. In the cases involving 3-methylcyclohex-2-en-1-one, a by-product was formed and was characterized by single crystal X-ray diffraction. α,β-Unsaturated ketones gave the best yields. Enals tended to polymerize while enoates proved to be much too unreactive. A particularly reactive malonate derived ester and β-nitrostyrene gave good yields at ambient pressures.

Key words: hapalindole, indole, Michael addition, high pressure, ytterbium triflate, Lewis acid.

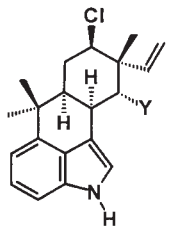
Résumé : On a étudié la réaction d'addition de l'indole et du méthylindole sur une série d'accepteurs de Michael sous l'influence de triflate d'ytterbium et à des pressions tant ambiante qu'élevée. À la pression ambiante, les électrophiles les plus réactifs présentant le moins d'encombrement stérique conduisent, avec des rendements allant de bons à excellents, aux indoles alkylés en position 3 attendus. Les accepteurs de Michael plus problématiques ont été soumis à des pressions de 13 kbar. Dans tous les cas, on a observé une réduction dramatique du temps de réaction et une amélioration significative des rendements. Dans les cas impliquant la 3-méthylcyclohex-2-én-1-one, il se forme un sous-produit qui a été caractérisé par diffraction des rayons X par un cristal unique. Les cétones α,β-insaturées donnent les meilleurs rendements. Les énals tendent à se polymériser alors que les énolates se sont avérés beaucoup moins réactifs. Un malonate particulièrement réactif, obtenu à partir de l'ester et du β-nitrostyrène, donne de bons rendements à des pressions ambiantes.

Mots clés : hapaindole, indole, addition de Michael, pression élevée, triflate d'ytterbium, acide de Lewis.

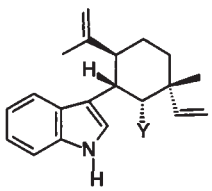
[Traduit par la Rédaction]

Introduction

We have recently been involved in studies directed towards the total synthesis of a class of bioactive indole alkaloids known as the hapalindoles. These cytotoxic compounds are a class of at least 20 members, isolated from the blue-green algae *Hapalosiphon fontinalis* by Moore et (1). The algae were isolated from soil samples collected from the Marshall Islands in 1981 and showed antibacterial, antimycotic, and antialgal activities. Initial reports disclosed the presence of two related compounds, hapalindole A and B (1*a*). Hapalindole A is responsible for the bulk of the biological activity. Three years later, the same group reported the structures of an additional 18 related compounds isolated from the same organism (1*b*). The structures possess either the tetracyclic framework present in hapalindole A and B or a tricyclic skeleton (possibly a biogenetic precursor) represented by hapalindoles C and D. There is large variation in the stereochemistry of the compounds; many have a diastereomeric relationship. This class of compounds provides an excellent opportunity for both stereochemical confirmation of the reported structures by synthesis and for the preparation of certain members for biochemical studies.



1 hapalindole A: Y = NC
2 hapalindole B: Y = NCS



3 hapalindole C: Y = NC
4 hapalindole D: Y = NCS

The study of the chemistry of these compounds (2) as well as activity towards the synthesis of interesting natural products has been steady. There have been several syntheses of a few members of this class of compounds to date (3). Our retrosynthesis of hapalindole C (Scheme 1) centers around the nucleophilic addition of an indole moiety **6** to a suitable terpenoid fragment **7** to produce the key intermediate **5**. Subsequent conversion to the target molecule **3** would involve only the addition of the geminally disposed vinyl

[1]

and methyl substituents and conversion of the ester to an isonitrile. The use of the menthane class of terpenes as starting materials would imply that this approach has the potential to provide homochiral material.

While one could envision the addition of the indole fragment via an organometallic species such as a Grignard reagent or a copper derivative (via the readily available 3-haloindole), we were intrigued by the natural enamine character, which is present in indoles and imparts a relatively high degree of nucleophilicity to the 3-position (4). Because of our interest in the use of hyperbaric conditions to promote useful chemical reactions, we were curious as to whether or not the nucleophilicity of the indole would be sufficient to add to Michael acceptors and whether the nucleophilicity would be enhanced at ultra high pressures.

The addition of indole to electron-deficient olefins is not a new reaction; however, the utility of this process is restricted in that only highly reactive Michael acceptors can be used with acceptable results (5). Recently Kotsuki et al. disclosed their results of a study that investigated the addition of indoles to epoxides at ultra high pressures using catalysts such as ytterbium triflate and silica gel (6). At almost the same time, we reported our preliminary results (7), which showed that indoles add in a 1,4-fashion to α,β-unsaturated ketones under the influence of ytterbium triflate (eq. [1]). In this paper we wish to provide details of the preliminary study as well as report the results of our work involving the ultra high pressure variant of this reaction.

Ytterbium triflate has become, in recent years, a widely used Lewis acid in organic synthesis (8). While researching Lewis acids for use at elevated pressures, a report by Jenner indicated that ytterbium triflate might be a suitable candidate (9). The reaction in eq. [1] may also be considered to be a type of Friedel–Crafts alkylation, a class of reactions that has seen the use of lanthanide triflates (10).

Results and discussion

When investigating the effects of pressure on a reaction it is prudent to run the reaction at ambient pressure in order to isolate and quantify the effects of pressure on the reaction course. During such a reaction it was noticed that indoles added to many of the Michael acceptors under the influence of ytterbium triflate *at ambient pressures*. Table 1 summarizes the results of the addition of indole and 1-methylindole to a series of α,β-unsaturated ketones under ambient pressure. A methyl group was chosen as a simple model for alkyl-derived protecting groups for the nitrogen (i.e., benzyl, methoxymethyl, etc.). The use of an electron-withdrawing substitiuent (i.e., a *p*-toluenesulphonyl group) on the indole nitrogen greatly attenuated the nucleophilic character of the indole and the reactions with the Michael acceptors were suppressed. The 1-triisopropylsilyl derivative underwent the conjugate addition but at a slower rate and with the concomitant loss of the silyl protecting group. The absence of catalyst resulted in low yields of addition with only the most reactive Michael acceptors (methyl vinyl ketone, β-nitrostyrene).

Several trends from Table 1 are worthy of note. As expected, steric hindrance plays an important role in the success or failure of the reaction; an increase in steric bulk on the Michael acceptor generally impedes the reaction. A single β-substituent on the enone does little to slow the reaction (entries 3 and 4) while a second β-substituent greatly reduces the reactivity of the olefin towards the indole (entries 5 and 6 and entry 10). The fact that reactions involving *trans*-3-pentene-2-one (entries 3 and 4) provide improved yields over methyl vinyl ketone (entries 1 and 2) may be due to the fact that the former enone is much less prone to polymerization as a side reaction. Overall, the reactions were quite clean with the only major contaminant being the unreacted starting materials. If this methodology is to be truly useful for the synthesis of the hapalindoles, substrates such as cyclohexenone must work well. Under ambient pressures, the cyclohexenones gave surprisingly low yields with relatively little starting material recovered. An interesting by-product was formed in 6% yield in the reaction of 1-methylindole with 3-methyl-2-cyclohexenone. The ^{1}H and ^{13}C NMR spectra of this by-product were complicated and the structure remained a mystery for some time. The identity of the compound was ultimately found to be the triindolyl cyclohexane **8** using single crystal X-ray diffraction. A complete set of crystallographic data for compound **8** is available as supplementary material.[3] The ORTEP representation is shown in Fig. 1.[4,5] In hindsight, the formation of this material is not surprising. The addition of a single molecule of the indole in a 1,4-fashion would afford a ketone that may undergo what may be considered a vinylogous ketalization reaction.

The fact that a simple ketone can undergo such a reaction under these conditions was confirmed by the fact that when two equivalents of indole were combined with one equivalent of cyclohexanone, **9** was formed as the sole product (eq. [2]). This type of reaction catalyzed by protic acid has

Table 2. $Yb(OTf)_3$ catalyzed alkylations of 1-methylindole with α,β-unsaturated ketones at 13 kbar.

Entry	Enone	Time	Product	Yield
1		2d		72
2		18h		84
3		26h		67
4		2d		56
5		7d		11
6		5d		3

been reported (11). In addition, Wang and co-workers disclosed formally this same observation using a host of lanthanide triflates (12).

Cyclopent-2-en-1-one underwent addition in 95% yield; significantly higher than cyclohex-2-ene-1-one (entry 9). Finally, note that even when the β-substituent on the enone is a rather bulky isopropyl group (entry 7), the yield is still quite high.

The most notable limitation apparent from the results in Table 1 is that in cases where steric hindrance is significant, this methodology fails to produce useful amounts of adducts. In an effort to overcome this difficulty, reactions using these substrates were subjected to hyperbaric conditions (Table 2). In general, the reactions were performed at 13 kbar (1 bar = 100 kPa) using acetonitrile as the solvent.[6] In all cases, there was a notable reduction in reaction time and an increase in the yield of adduct. The most dramatic increase in isolated yield was observed with 4-phenyl-3-buten-2-one as the Michael acceptor (67% compared to 10% under ambient conditions, entry 3). Also of note is the fact that under these conditions, *N*-methyl indole added to cyclohex-2-en-1-one in 56% yield, an improvement from the 37% yield observed under ambient conditions. The same enones bearing an additional β-substituent proved extremely unreactive even under high-pressure conditions; however, small amounts of the expected adducts were isolated and characterized. The fact that high pressure facilitates the addition of indoles to enones is not surprising since formation of the transition state should result in a significant reduction in molar volume. (13). The use of high pressures to promote conjugate additions is not new and has been reported (14).

[6] Although a thorough screening of solvents was not performed, a brief experimental survey revealed that acetonitrile is the solvent of choice for these reactions.

Table 3. $Yb(OTf)_3$ catalyzed alkylations of indoles with other Michael acceptors.

Entry	Indole	Electrophile	Conditions	Product	Yield
1			2d 1 atm		89
2			18h 1 atm		39
3			26h 1 atm		77
4			2d 1 atm		68
5			7d 13 kbar		8

For the sake of exploring the general scope of this reaction, other electrophiles were also subjected to the above conditions and with some success. While many common electron-deficient olefins (phenyl vinyl sulphone, acrylonitrile, ethyl cinnamate, methyl propiolate, crotonaldehyde, and cinnnamaldehyde) failed to give satisfactory results, several reactive Michael acceptors proceeded to give the expected products (Table 3). As expected, β-nitrostyrene (entries 1 and 2) was quite reactive at ambient pressure. The fact that 1-methylindole gave an abnormally low yield is curious and may be due to the formation of a series of by-products that were not characterized. Note that even the reaction with a highly reactive diester such as diethyl benzalmalonate (entries 3 and 4) was sluggish and took several days to go to completion, albeit in good yield. Methyl acrylate was unreactive at ambient pressure but gave an isolable amount of material under hyperbaric conditions.

Finally, it should be noted that when 2-carbomethoxy-2-cyclohexenone was treated with indole in the presence of $Yb(OTf)_3$, a small amount of the desired Michael adduct was formed. The low yield may be attributed to the tendency of these types of compounds to exist, to a large degree, in the enol form.

In summary, we have shown that the use of ytterbium triflate to catalyze the addition of indoles to α,β-unsaturated ketones provides a useful complement to the existing methods available for the 3-alkylation of indole. Of interst to us for the synthesis of hapalindole alkaloids is the fact that cyclohexenones can be made to undergo reaction in acceptable yields under hyperbaric conditions, in contrast to more disappointing results using ambient conditions. Using this methodology, we intend to pursue as targets the interesting class of hapalindole alkaloids. Progress towards this end will be reported in due course.

Experimental section

General

Melting points were determined using a MEL-TEMP II melting point apparatus and are uncorrected. NMR spectra were obtained using a Bruker AM250 spectrometer in $CDCl_3$ as the solvent and are recorded in parts per million downfield from tetramethylsilane. ^1H NMR spectra were recorded at 250 MHz and ^{13}C NMR spectra were recorded at 63 MHz. Infrared spectra were measured on a Perkin–Elmer model 683 infrared spectrophotometer using a thin film of the compound on a sodium chloride plate. Mass spectra were recorded using a CEC model 21-11-B double-focusing mass spectrometer using a heated quartz direct-introduction probe with an 8000 V accelerating voltage. Crystallographic analysis was performed using a Rigaku AAFC5R diffractometer with a 12 MW rotating anode X-ray generator. Thin-layer chromatography was performed on E. Merck precoated TLC plates (Silica gel 60 F-254). Flash column chromatography was performed with EM Science Silica gel 60 (230–400 mesh). High-pressure reactions were performed in a LECO Tem-Pres HPC-200 chemical reactor in heat shrinkable Teflon® tubes. Samples for melting point determination were recrystallized from methylene chloride and hexanes. Commercial reagents and solvents were used as supplied without further purification.

Typical procedure for the ambient pressure reaction of indoles with α,β-unsaturated ketones

To a solution of the indole in acetonitrile was added the enone as a solid or a neat liquid. Ytterbium trifluoromethanesulphonate trihydrate was added and the mixture was stirred in a capped flask for the required amount of time. After thin-layer chromatography indicated the disappearance of starting material or after 1 week, which ever came first, the solvent was removed in vacuo and the residue was taken up in diethyl ether. Filtration of the ether suspension through a pad of Celite® followed by removal of the solvent in vacuo yielded the crude reaction product, which was purified by flash chromatography on a column of silica gel (elution with an appropriate mixture of ethyl acetate and hexanes).

4-(3-Indolyl)-2-butanone (Table 1, entry 1)

Standard procedure: indole (263 mg, 2.24 mmol), methyl vinyl ketone (500 μL, 6.11 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (28 mg, 42 μmol), acetonitrile (2 mL). The mixture was stirred for

© 1998 NRC Canada

4 h after which time an additional 300 μL of methyl vinyl ketone (3.66 mmol) was added. After a total time of 22 h, the mixture was worked up in the usual way. Flash chromatography using gradient elution (20–50% EtOAc – hexanes) afforded 304 mg pure material (72%) as a white solid, mp 95–96°C. R_f = 0.31 (30% EtOAc – hexanes). IR (thin film), ν: 3315, 1700 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 2.14 (s, 3H), 2.84 (t, *J* = 7.3 Hz, 2H), 3.05 (tm, *J* = 7.3 Hz, 2H), 6.98 (dm, *J* = 2.4 Hz, 1H), 7.12 (td, *J* = 7.0, 1.2 Hz, 1H), 7.19 (td, *J* = 7.0, 1.2 Hz, 1H), 7.35 (d, *J* = 7.6 Hz, 1H), 7.59 (d, *J* = 7.0 Hz, 1H), 7.98 (bs, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 19.4, 30.1, 44.1, 111.3, 115.1, 118.7, 119.3, 121.6, 122.1, 127.2, 136.4, 209.0. MS (70 eV), *m*/*e*: 188 (M+1), 187 (M$^+$), 131, 130(100), 117, 115, 42. HRMS (for $C_{12}H_{13}NO$): 187.0997 (calcd.); 187.1008 (found).

4-(3-(1-Methylindolyl))-2-butanone (Table 1, entry 2)

Standard procedure: 1-methylindole (273 mg, 2.08 mmol), methyl vinyl ketone (500 μL, 6.11 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (31 mg, 46 μmol), acetonitrile (2 mL). The mixture was stirred for 7 h and worked up in the usual way. Flash chromatography using gradient elution (10–30% EtOAc – hexanes) afforded 307 mg pure material (73%) as a white solid. R_f = 0.33 (30% EtOAc – hexanes). IR (neat), ν: 3040, 2905, 1700, 1475, 1460, 735 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 2.13 (s, 3H), 2.82 (t, *J* = 7.6 Hz, 2H), 3.03 (tm, *J* = 7.6 Hz, 2H), 3.72 (s, 3H), 6.83 (s, 1H), 7.10 (ddd, *J* = 8.2, 6.7, 1.5 Hz, 1H), 7.22 (td, *J* = 7.9, 6.7, 1.5 Hz, 1H), 7.28 (dm, *J* = 7.9 Hz, 1H), 7.57 (dm, *J* = 7.6 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 19.1, 30.0, 32.5, 44.2, 109.1, 113.5, 118.7 (two carbons), 121.5, 126.3, 127.5, 136.9, 208.9. MS (70 eV), *m/e*: 202(M+1), 201(M$^+$), 158, 145, 144(100), 143, 115. HRMS (for $C_{13}H_{15}NO$): 201.1154 (calcd.); 201.1123 (found).

4-(3-Indolyl)-2-pentanone (Table 1, entry 3)

Standard procedure: indole (258 mg, 2.20 mmol), 3-penten-2-one (500 μL, 5.12 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (33 mg, 49 μmol), acetonitrile (2 mL). The mixture was stirred for 14 h and worked up in the usual way. Flash chromatography using gradient elution (20–50% EtOAc – hexanes) afforded 375 mg pure material (85%) as a white solid. R_f = 0.33 (30% EtOAc – hexanes). IR (neat), ν: 3400, 3045, 2950, 2915, 1705, 1610, 735 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 1.38 (d, *J* = 7.0 Hz, 3H), 2.08 (s, 3H), 2.70 (dd, *J* = 16.2, 8.2 Hz, 1H), 2.93 (dd, *J* = 16.2, 6.1 Hz, 1H), 3.63 (m, 1H), 6.93 (d, *J* = 2.1 Hz, 1H), 7.11 (ddd, *J* = 8.2, 7.3, 1.5 Hz, 1H), 7.18 (ddd, *J* = 8.2, 7.0, 1.5 Hz, 1H), 7.33 (d, *J* = 7.9 Hz, 1H), 7.64 (d, *J* = 7.6 Hz, 1H), 8.02 (bs, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 21.3, 27.1, 30.4, 51.5, 111.4, 119.1, 119.3, 120.2, 121.0, 122.1, 126.3, 136.6, 208.9. MS (70 eV), *m/e*: 201 (M$^+$), 158, 145, 144(100), 143, 42. HRMS (for $C_{13}H_{15}NO$): 201.1154 (calcd.); 201.1190 (found).

4-(3-(1-Methylindolyl))-2-pentanone (Table 1, entry 4)

Standard procedure: 1-methylindole (295 mg, 2.25 mmol), 3-penten-2-one (500 μL, 5.12 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (33 mg, 49 μmol), acetonitrile (2 mL). The mixture was stirred for 10 h and worked up in the usual way. Flash chromatography using gradient elution (5–20% EtOAc – hexanes) afforded 461 mg pure material (95%) as a yellow oil. R_f = 0.41 (30% EtOAc – hexanes). IR (neat), ν: 3040, 2950, 2870, 1700, 1605, 1540, 1475, 1415, 1345, 1320, 1260, 1220, 1145, 1125, 1095, 1005, 755, 735 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 1.36 (d, *J* = 7.0 Hz, 3H), 2.08 (s, 3H), 2.68 (dd, *J* = 16.2, 8.2 Hz, 1H), 2.91 (dd, *J* = 15.9, 6.1 Hz, 1H), 3.61 (m, 1H), 3.70 (s, 3H), 6.81 (s, 1H), 7.09 (tm, *J* = 7.3 Hz, 1H), 7.21 (tm, *J* = 7.5 Hz, 1H), 7.27 (dm, *J* = 7.6 Hz, 1H), 7.62 (dm, *J* = 7.6 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 21.5, 27.0, 30.4, 32.6, 51.6, 109.3, 118.7, 119.2, 119.5, 121.6, 125.0, 126.6, 137.2, 208.6. MS (70 eV), *m/e:* 215(M$^+$), 172, 159, 158(100), 115. HRMS (for $C_{14}H_{17}NO$): 215.1310 (calcd.); 215.1309 (found).

4-(3-Indolyl)-4-methyl-2-pentanone (Table 1, entry 5)

Standard procedure: indole (263 mg, 2.24 mmol), mesityl oxide (500 μL, 4.36 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (32 mg, 47 μmol), acetonitrile (2 mL). The mixture was stirred for 7 d and worked up in the usual way. Flash chromatography using gradient elution (10–20% EtOAc – hexanes) afforded 91 mg pure material (19%) as a yellow oil. R_f = 0.37 (30% EtOAc – hexanes). IR (neat), ν: 3400, 2950, 2915, 1685, 1450, 1410, 1345, 1325, 1235, 1200, 1115, 1100, 1005, 760, 735 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 1.53 (s, 6H), 1.72 (s, 3H), 2.95 (s, 2H), 6.89 (d, *J* = 2.4 Hz, 1H), 7.08–7.21 (m, 2H), 7.34 (dm, *J* = 7.3 Hz, 1H), 7.80 (dm, *J* = 7.9 Hz, 1H), 8.01 (bs, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 28.9, 29.7, 31.8, 34.5, 55.1, 111.7, 119.1, 120.6, 120.7, 121.7, 123.5, 125.5, 137.2, 209.5. MS (70 eV), *m/e*: 216 (M+1), 215(M$^+$), 200, 159, 158(100), 157, 143, 142, 115, 42. HRMS (for $C_{14}H_{17}NO$): 215.1310 (calcd.); 215.1324 (found).

4-(3-(1-Methylindolyl))-4-methyl-2-pentanone (Table 1, entry 6)

Standard procedure: 1-methylindole (290 mg, 2.21 mmol), mesityl oxide (500 μL, 4.36 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (31 mg, 46 μmol), acetonitrile (2 mL). The mixture was stirred for 7 d and worked up in the usual way. Flash chromatography using gradient elution (10–20% ethyl acetate – hexanes) afforded 195 mg pure material (38%) as a yellow oil. R_f = 0.49 (30% EtOAc – hexanes). IR (neat), ν: 3020, 2940, 1700, 1605, 1535, 1475, 1415, 1350, 1230, 1145, 1100, 1010, 980, 760, 730 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 1.53 (s, 6H), 1.73 (s, 3H), 2.94 (s, 2H), 3.73 (s, 3H), 6.79 (s, 1H), 7.11 (ddd, *J* = 8.2, 7.0, 1.2, 1H), 7.22 (ddd, *J* = 7.9, 7.0, 1.2 Hz, 1H), 7.30 (d, *J* = 8.2 Hz, 1H), 7.79 (dd, *J* = 7.9, 1.2 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 29.0, 31.9, 32.7, 34.5, 55.2, 109.7, 118.7, 120.9, 121.3, 122.2, 125.4, 126.0, 137.8, 209.2. MS (70 eV), *m/e*: 230 (M+1), 229 (M$^+$), 173, 172 (100), 130, 115. HRMS (for $C_{15}H_{19}NO$): 229.1467 (calcd.); 229.1473 (found).

4-(3-(1-Methylindolyl))-5-methyl-2-hexanone (Table 1, entry 7)

Standard procedure: 1-methylindole (307 mg, 2.34 mmol), 5-methyl-3-hexen-2-one (500 μL, 3.79 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (30 mg, 44 μmol), acetonitrile (2 mL). The mixture was stirred for 4 d and worked up in the usual way. Flash chromatography using gradient elution (5–20% EtOAc – hexanes) afforded 438 mg pure material (77%) as a low-melting solid. R_f = 0.50 (30% EtOAc – hexanes). IR (neat), ν: 2940, 2915, 2860, 1700, 1475, 1460, 1415, 1360, 1345, 1320, 1250, 1225, 1150, 1125, 1005, 730 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 0.86 (d, *J* = 6.7 Hz, 3H), 0.91 (d, *J* =

6.7 Hz, 3H), 1.96 (s, 3H), 2.05 (m, 1H), 2.78–2.86 (m, 2H), 3.30 (td, *J* = 6.7, 6.4 Hz, 1H), 3.71 (s, 3H), 6.79 (s, 1H), 7.08 (ddd, *J* = 7.5, 6.7, 1.3, 1H), 7.19 (td, *J* = 7.4, 1.0 Hz, 1H), 7.26 (dm, *J* = 7.9 Hz, 1H), 7.63 (dm, *J* = 7.9 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 20.4, 20.6, 30.1, 32.7, 32.8, 39.2, 47.2, 109.2, 115.9, 118.6, 119.5, 121.3, 126.7, 127.7, 136.9, 209.3. MS (70 eV), *m*/*e*: 244 (M+1), 243 (M^+), 201, 200 (100), 186, 158, 157, 143, 69. HRMS (for $C_{16}H_{21}NO$): 243.1623 (calcd.); 243.1626 (found).

3-(3-Indolyl)cyclohexanone (Table 1, entry 8)

Standard procedure: indole (241 mg, 2.06 mmol), 2-cyclohexen-1-one (500 μL, 5.16 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (30 mg, 44 μmol), acetonitrile (2 mL). The mixture was stirred for 2 d and an additional 9 mg (15 μmol) of catalyst was added. The mixture was stirred for an additional 5 d and worked up in the usual way. Flash chromatography using gradient elution (10–30% EtOAc – hexanes) afforded 192 mg pure material (44%) as a pale yellow solid, mp 106–107°C. R_f = 0.26 (30% EtOAc – hexanes). IR (neat), ν: 3270, 2940, 2860, 1695, 1610, 1485, 1440, 1420, 1330, 1255, 1210, 1175, 1100, 1050, 1020, 1000, 870, 800, 755, 730 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 1.78–2.08 (m, 3H), 2.25 (m, 1H), 2.38–2.46 (m, 2H), 2.62 (ddd, *J* = 14.0, 10.5, 1.1 Hz, 1H), 2.79 (ddt, *J* = 14.0, 4.6, 1.5 Hz, 1H), 3.42 (m, 1H), 6.95 (dd, *J* = 2.4, 0.6 Hz, 1H), 7.11 (ddd, *J* = 7.8, 7.0, 1.2 Hz, 1H), 7.19 (ddd, *J* = 7.8, 6.9, 1.5 Hz, 1H), 7.35 (dm, *J* = 7.9 Hz, 1H), 7.61 (dm, *J* = 7.9 Hz, 1H), 8.12 (bs, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 24.9, 31.8, 36.0, 41.6, 48.1, 111.4, 119.0, 119.4, 119.6, 120.5, 122.2, 126.2, 136.5, 212.1. MS (70 eV), *m*/*e*: 214 (M+1), 213 (M^+), 170, 157, 156(100), 144, 143, 130, 128, 117. HRMS (for $C_{14}H_{15}NO$): 213.1154 (calcd.); 213.1166 (found).

3-(3-(1-Methylindolyl))cyclohexanone (Table 1, entry 9)

Standard procedure: 1-methylindole (268 mg, 2.04 mmol), 2-cyclohexen-1-one (500 μL, 5.16 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (34 mg, 50 μmol), acetonitrile (2 mL). The mixture was stirred for 7 d and worked up in the usual way. Flash chromatography using gradient elution (10–30% EtOAc – hexanes) afforded 171 mg pure material (37%) as a yellow oil. R_f = 0.37 (30% EtOAc – hexanes). IR (neat), ν: 3040, 2920, 2855, 1700, 1605, 1540, 1460, 1415, 1365, 1305, 1250, 1210, 1145, 1120, 1045, 1005, 795, 730 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 1.78–2.08 (m, 3H), 2.23 (m, 1H), 2.38–2.46 (m, 2H), 2.60 (ddd, *J* = 14.0, 10.4, 1.2 Hz, 1H), 2.78 (ddt, *J* = 14.0, 4.6, 1.5 Hz, 1H), 3.43 (m, 1H), 3.73 (s, 3H), 6.82 (d, *J* = 0.6 Hz, 1H), 7.10 (ddd, *J* = 7.9, 7.3, 1.2 Hz, 1H), 7.22 (ddd, *J* = 8.2, 7.5, 1.2 Hz, 1H), 7.29 (td, *J* = 8.2, 1.1 Hz, 1H), 7.60 (td, *J* = 7.9, 0.9 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 24.9, 32.0, 32.7, 35.9, 41.6, 48.3, 109.4, 118.2, 118.9, 119.1, 121.8, 125.3, 126.6, 137.2, 211.9. MS (70 eV), *m*/*e*: 228 (M+1), 227 (M^+,100), 184, 170, 157, 144, 115. HRMS (for $C_{15}H_{17}NO$): 227.1311 (calcd.); 227.1302 (found).

3-Methyl-3-(3-(1-methylindolyl))cyclohexanone (Table 1, entry 10)

Standard procedure: 1-methylindole (292 mg, 2.23 mmol), 3-methyl-2-cyclohexen-1-one (400 μL, 3.53 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (37 mg, 55 μmol), acetonitrile (2 mL). The mixture was stirred for 7 d and worked up in the usual way. Flash chromatography using gradient elution (10– 30% EtOAc – hexanes) afforded 16 mg pure material (3%) as a yellow oil. R_f = 0.36 (30% EtOAc – hexanes). IR (neat), ν: 3030, 2920, 1690, 1535, 1475, 1410, 1365, 1320, 1300, 1275, 1235, 1215, 1140, 1130, 1100, 1010, 730 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 1.41–1.59 (m, 1H), 1.53 (s, 3H), 1.76–1.94 (m, 2H), 2.24–2.32 (m, 2H), 2.46 (d, *J* = 14.4 Hz, 1H), 2.58 (m, 1H), 2.89 (dd, *J* = 14.4, 1.5 Hz, 1H), 3.70 (s, 3H), 6.80 (s, 1H), 7.08 (ddd, *J* = 8.3, 7.3, 1.2 Hz, 1H), 7.21 (tm, *J* = 7.3 Hz, 1H), 7.29 (d, *J* = 8.2, Hz, 1H), 7.74 (d, *J* = 7.9 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 22.4, 29.6, 32.7, 36.8, 40.0, 41.0, 54.4, 109.6, 118.5, 120.3, 120.9, 121.5, 125.4, 126.9, 137.8, 212.5. MS (70 eV), *m*/*e*: 242 (M+1), 241 (M^+,100), 226, 198, 184, 171, 131(100), 130, 42. HRMS (for $C_{16}H_{19}NO$): 241.1467 (calcd.); 241.1488 (found).

3-(3-(1-Methylindolyl))cyclopentanone (Table 1, entry 11)

Standard procedure: 1-methylindole (322 mg, 2.45 mmol), 2-cyclopenten-1-one (500 μL, 6.18 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (32 mg, 47 μmol), acetonitrile (2 mL). The mixture was stirred for 4 d and worked up in the usual way. Flash chromatography using gradient elution (20–30% EtOAc – hexanes) afforded 496 mg pure material (95%) as a yellow oil. R_f = 0.38 (30% EtOAc – hexanes). IR (neat), ν: 3040, 2945, 2920, 2870, 1730, 1605, 1475, 1415, 1395, 1365, 1320, 1310, 1235, 1145, 1125, 1005, 730 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 2.03–2.52 (m, 5H), 2.71 (dd, *J* = 18.3, 7.6 Hz, 1H), 3.67 (m, 1H), 3.70 (s, 3H), 6.80 (d, *J* = 0.6 Hz, 1H), 7.11 (ddd, *J* = 7.9, 6.7, 1.5 Hz, 1H), 7.23 (td, *J* = 7.3, 1.2 Hz, 1H), 7.29 (dm, *J* = 8.1 Hz, 1H), 7.59 (td, *J* = 7.9, 0.9 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 30.0, 32.6, 33.6, 38.1, 45.4, 109.4, 116.9, 118.8, 119.1, 121.8, 124.7, 126.9, 137.3, 219.3. MS (70 eV), *m*/*e:* 214 (M+1), 213 (M^+,100), 184, 170, 158 157, 156 144. HRMS (for $C_{15}H_{17}NO$): 213.1154 (calcd.); 213.1167 (found).

4-(3-Indolyl)-4-phenyl-2-butanone (Table 1, entry 12)

Standard procedure: indole (250 mg, 2.13 mmol), benzalacetone (370 mg, 2.53 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (31 mg, 46 μmol), acetonitrile (2 mL). The mixture was stirred for 7 d and worked up in the usual way. Flash chromatography using gradient elution (10–50% EtOAc – hexanes) afforded 89 mg pure material (16%) as a white solid, mp 98–99°C. R_f = 0.27 (30% EtOAc – hexanes). IR (neat), ν: 3400, 3050, 3020, 2910, 1695, 1590, 1485, 1445, 1405, 1345, 1330, 1230, 1215, 1150, 1090, 1000, 735, 695 cm^{-1}. ^{1}H NMR (250 MHz, $CDCl_3$), δ: 2.09 (s, 3H), 3.17 (dd, *J* = 16.2, 7.9 Hz, 1H), 3.27 (dd, *J* = 16.2, 7.3 Hz, 1H), 4.85 (bt, *J* = 7.6 Hz, 1H), 6.98 (dd, *J* = 2.4, 0.6 Hz, 1H), 7.03 (ddd, *J* = 7.9, 7.0, 1.2 Hz, 1H), 7.13–7.35 (m, 7H), 7.44 (dd, *J* = 7.0, 1.2 Hz, 1H), 8.04 (bs, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 30.4, 38.4, 50.4, 111.2, 118.8, 119.4, 121.4, 122.2, 126.4, 126.5, 127.7, 128.5, 136.6, 144.0, 207.8. MS (70 eV), *m*/*e*: 264 (M+1), 263 (M^+,100), 221, 220, 207, 206, 42. HRMS (for $C_{18}H_{17}NO$): 263.1310 (calcd.); 263.1312 (found).

4-(3-(1-Methylindolyl))-4-phenyl-2-butanone (Table 1, entry 13)

Standard procedure: 1-methylindole (290 mg, 2.21 mmol), benzalacetone (386 mg, 2.64 mmol), $Yb(OTf)_3 \cdot 3H_2O$

© 1998 NRC Canada

(34 mg, 50 μmol), acetonitrile (2 mL). The mixture was stirred for 7 d and was worked up in the usual way. Flash chromatography using gradient elution (10–30% EtOAc – hexanes) afforded 63 mg pure material (10%) as a yellow oil. R_f = 0.31 (30% EtOAc – hexanes). IR (neat), ν: 3045, 3015, 2920, 1700, 1590, 1540, 1475, 1410, 1360, 1345, 1320, 1235, 1145, 1070, 1005, 730, 695 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$), δ: 2.07 (s, 3H), 3.14 (dd, *J* = 16.2, 7.9 Hz, 1H), 3.25 (dd, *J* = 16.2, 7.3 Hz, 1H), 3.73 (s, 3H), 4.85 (bt, *J* = 7.6 Hz, 1H), 6.80 (s, 1H), 7.00 (tm, *J* = 7.5 Hz, 1H), 7.11–7.32 (m, 7H), 7.42 (dm, *J* = 7.9 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 30.3, 32.7, 38.3, 50.4, 109.2, 117.3, 118.9, 119.5, 121.7. 126.3, 126.9, 127.7, 128.5, 137.3, 144.1, 207.5. MS (70 eV), *m*/*e*: 278 (M+1), 277 (M^+,100), 221, 220, 218, 204. HRMS (for $C_{19}H_{19}NO$): 277.1467 (calcd.); 277.1464 (found).

3-(3-Indolyl)-3-phenylpropiophenone (Table 1, entry 14)

Standard procedure: indole (253 mg, 2.16 mmol), chalcone (528, 2.54 mmol), $Yb(OTf)_3{\cdot}H_2O$ (34 mg, 50 μmol), acetonitrile (2 mL). The mixture was stirred for 7 d and was worked up in the usual way. Flash chromatography using gradient elution (10–30% EtOAc – hexanes) afforded 366 mg pure material (52%) as a white solid, mp 131–132°C. R_f = 0.36 (30% EtOAc – hexanes). IR (neat), ν: 3410, 3045, 3020, 1670, 1590, 1570, 1485, 1440, 1405, 1325, 1255, 1195, 1090, 1010, 995, 970, 735, 690 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$), δ: 3.71 (dd, *J* = 16.8, 7.6 Hz, 1H), 3.81 (dd, *J* = 16.8, 6.7 Hz, 1H), 5.06 (bt, *J* = 7.3 Hz, 1H), 6.95 (d, *J* = 2.4 Hz, 1H), 7.00 (td, *J* = 7.5. 0.9 Hz, 1H), 7.10–7.55 (m, 12H), 7.92 (dm, *J* = 7.0 Hz, 1H), 7.97 (bs, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 38.2, 45.2, 111.2, 119.3, 119.4, 119.6, 121.5, 122.1, 126.3, 126.6, 127.7, 128.1, 128.5, 128.6, 133.1, 136.6, 137.1, 144.3, 198.6. MS (70 eV), *m*/*e*: 326 (M+1), 325 (M^+), 220, 207, 206 (100), 178, 105, 77. HRMS (for $C_{23}H_{19}NO$): 325.1467 (calcd.); 325.1472 (found).

3-(3-(1-Methylindolyl))-3-phenylpropiophenone (Table 1, entry 15)

Standard procedure: 1-methylindole (287 mg, 2.19 mmol), chalcone (535, 2.57 mmol), $Yb(OTf)_3{\cdot}3H_2O$ (32 mg, 47 μmol), acetonitrile (2 mL). The mixture was stirred for 7 d and was worked up in the usual way. Flash chromatography using gradient elution (5–70% EtOAc – hexanes) afforded 687 mg pure material (93%) as a pale yellow solid, mp 181–182°C. R_f = 0.41 (30% EtOAc – hexanes). IR (neat), ν: 3050, 2910, 1665, 1590, 1560, 1535, 1475, 1440, 1405, 1360, 1325, 1305, 1290, 1235, 1145, 730, 690 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$), δ: 3.69 (s, 3H), 3.74–3.79 (m, 2H), 5.06 (bt, *J* = 7.3 Hz, 1H), 6.83 (s, 1H), 7.00 (td, *J* = 6.7, 1.2 Hz, 1H), 7.14–7.52 (m, 12H), 7.93 (dm, *J* = 7.0 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 37.2, 38.2, 45.4, 109.2, 117.8, 118.9, 119.6, 121.7, 126.3, 127.0, 127.9, 128.1, 128.5, 128.6, 133.0, 137.2, 137.4, 144.4, 198.5. MS (70 eV), *m*/*e:* 340 (M+1), 339 (M^+), 234, 221, 220 (100). HRMS (for $C_{24}H_{21}NO$): 339.1623 (calcd.); 339.1628 (found).

2-(3-Indolyl)-2-phenylnitroethane (Table 3, entry 1)

Standard procedure: Indole (295 mg, 2.52 mmol), β-nitrostyrene (468 mg, 3.14 mmol), $Yb(OTf)_3{\cdot}3H_2O$ (31 mg, 46 μmol), acetonitrile (2 mL). The mixture was stirred for 30 h and was worked up in the usual way. Flash chromatography using gradient elution (10–30% EtOAc – hexanes) afforded 596 mg pure material (89%) as a pale yellow solid, mp 102–103°C. R_f = 0.34 (30% EtOAc – hexanes). IR (neat), ν: 3420, 3050, 3020, 1595, 1545, 1485, 1445, 1415, 1370, 1330, 1255, 1215, 1090, 1000, 965, 740, 695 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$), δ: 4.92 (dd, *J* = 12.4, 8.4 Hz, 1H), 5.04 (dd, *J* = 12.4, 7.5 Hz, 1H), 5.17 (bt, *J* = 7.9 Hz, 1H), 6.98 (d, *J* = 2.8 Hz, 1H), 7.06 (td, *J* = 7.5, 0.9 Hz, 1H), 7.15–7.35 (m, 7H), 7.43 (dm, *J* = 7.9 Hz, 1H), 8.03 (bs, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 41.6, 79.6, 111.4, 119.0, 120.0, 121.7, 122.7, 126.1, 127.6, 127.8, 129.0, 136.5, 139.2. MS (70 eV), *m*/*e*: 267 (M+1), 266 (M^+, 100), 220, 219, 218, 217, 206, 204, 42. HRMS (for $C_{16}H_{14}N_2O_2$): 266.1055 (calcd.); 266.1055 (found).

2-(3-(1-Methyl-indolyl))-2-phenylnitroethane (Table 3, entry 2)

Standard procedure: 1-methylindole (287 mg, 2.19 mmol), β-nitrostyrene (387 mg, 2.59 mmol), $Yb(OTf)_3{\cdot}3H_2O$ (37 mg, 55 μmol), acetonitrile (2 mL). The mixture was stirred for 19 h and was worked up in the usual way. Flash chromatography using gradient elution (10–50% EtOAc – hexanes) afforded 241 mg pure material (39%) as a white solid, mp 94–95°C. R_f = 0.38 (30% EtOAc – hexanes). IR (neat), ν: 3050, 3020, 2910, 1595, 1540, 1465, 1445, 1415, 1370, 1325, 1240, 1150, 1120, 1075, 1005, 735, 695 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$), δ: 3.71 (s, 3H), 4.91 (dd, *J* = 12.5, 8.6 Hz, 1H), 5.03 (dd, *J* = 12.4, 7.5 Hz, 1H), 5.17 (bt, *J* = 7.9 Hz, 1H), 6.84 (d, *J* = 0.6 Hz, 1H), 7.06 (ddd, *J* = 7.9, 6.6, 1.5 Hz, 1H), 7.18–7.33 (m, 7H), 7.44 (td, *J* = 7.9, 0.9 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 32.9, 41.6, 79.6, 109.6, 112.8, 119.0, 119.5, 122.3, 126.4, 126.6, 127.5, 127.8, 128.9, 137.3, 139.4. MS (70 eV), *m*/*e*: 281 (M+1), 280 (M^+, 100), 235, 234, 233, 221, 220, 218, 217, 157, 146, 115, 77, 50. HRMS (for $C_{17}H_{16}N_2O_2$): 280.1212 (calcd.); 280.1204 (found).

Ethyl 2-ethoxycarbonyl-3-(3-indolyl)-3-phenyl propanoate (Table 3, entry 3)

Standard procedure: indole (255 mg, 2.18 mmol), diethyl benzalmalonate (600 mg, 2.68 mmol), $Yb(OTf)_3{\cdot}3H_2O$ (32 mg, 47 μmol), acetonitrile (2 mL). The mixture was stirred for 4 d and was worked up in the usual way. Flash chromatography using gradient elution (20–50% EtOAc – hexanes) afforded 610 mg pure material (77%) as a white solid, mp 164–165°C. R_f = 0.30 (30% EtOAc – hexanes). IR (neat), ν: 3440, 1735, 1705, 1445, 1360, 1310, 1260, 1240, 1180, 1165, 1145, 1085, 740, 695 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$), δ: 0.97 (t, *J* = 7.0 Hz, 3H), 1.00 (t, *J* = 7.0 Hz, 3H), 3.97 (q, *J* = 7.1 Hz, 2H), 4.00 (q, *J* = 7.1 Hz, 2H), 4.29 (d, *J* = 11.9 Hz, 1H), 5.08 (d, *J* = 11.6 Hz, 1H), 7.02 (ddd, *J* = 7.8, 7.0, 0.9 Hz, 1H), 7.09–7.30 (m, 6H), 7.34–7.38 (m, 2H), 7.54 (dd, *J* = 7.9, 0.6 Hz, 1H), 8.05 (bs, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 13.8 (two carbons), 42.9, 58.4, 61.5 (two carbons), 111.0, 116.9, 119.4, 119.5, 129.9, 122.2, 126.8, 128.2, 128.4, 136.2, 141.4, 167.9, 168.1. MS (70 eV), *m*/*e:* 366 (M+1), 365 (M^+), 246, 207, 206 (100). HRMS (for $C_{22}H_{23}NO_4$): 365.1627 (calcd.); 365.1660 (found).

Ethyl 2-ethoxycarbonyl-3-(3-(1-methylindolyl))-3-phenyl propanoate (Table 3, entry 4)

Standard procedure: 1-methylindole (270 mg, 2.06 mmol), diethyl benzalmalonate (600 mg, 2.68 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (35 mg, 52 μmol), acetonitrile (2 mL). The mixture was stirred for 2 d and was worked up in the usual way. Flash chromatography using gradient elution (10–30% EtOAc – hexanes) afforded 530 mg pure material (68%) as a white solid, mp 87–88°C. R_f = 0.37 (30% EtOAc – hexanes). IR (neat), ν: 2925, 2870, 1735, 1695, 1605, 1535, 1460, 1415, 1360, 1020, 860, 735, 695 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$), δ: 0.98 (t, *J* = 7.2 Hz, 3H), 0.99 (t, *J* = 7.0 Hz, 3H), 3.71 (s, 3H), 3.97 (q, *J* = 7.2 Hz, 2H), 3.99 (q, *J* = 7.0 Hz, 2H), 4.27 (d, *J* = 11.6 Hz, 1H), 5.06 (d, *J* = 11.9 Hz, 1H), 7.01 (s, 1H), 7.02 (td, *J* = 7.3, 1.4 Hz, 1H), 7.09–7.25 (m, 6H), 7.36 (dm, *J* = 7.0 Hz, 1H), 7.55 (dt, *J* = 7.9, 0.6 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 13.7 (two carbons), 32.7, 42.8, 58.4, 61.3, 61.4, 109.0, 115.3, 118.9, 119.4, 121.7, 125.6, 126.6, 127.1, 128.1, 129.4, 136.9, 141.6, 167.8, 168.0. MS (70 eV), *m*/*e*: 380 (M+1), 379 (M^+), 233, 221, 200 (100), 218, 217, 206. HRMS (for $C_{23}H_{25}NO_4$): 379.1783 (calcd.); 379.1811 (found).

Typical procedure for the high-pressure reaction of indoles with α,β-unsaturated ketones

The indole and the enone were dissolved in acetonitrile in a length of 1 cm diameter heat- shrinkable Teflon® tubing (about 10 cm in length) that had been clamped at one end using a brass clamp. The catalyst was added and the contents of the tube were mixed. Excess air was squeezed from the reaction vessel and the tube was then sealed with another brass clamp. The vessel was placed in the high-pressure reactor and was subjected to 1.2 GPa (13 kbar) for an appropriate period of time. The solvent was removed in vacuo and the crude residue was purified by flash chromatography on a column of silica gel (elution with an appropriate mixture of ethyl acetate and hexanes).

4-(3-(1-Methylindolyl))-4-methyl-2-pentanone (Table 2, entry 1)

Standard procedure: 1-methylindole (288 mg, 2.20 mmol), mesityl oxide (500 μL, 4.36 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (33 mg, 49 μmol), acetonitrile (2 mL). The mixture was pressurized for 2 d and was worked up in the usual way. Flash chromatography using gradient elution (10–20% EtOAc – hexanes) afforded 360 mg pure material (72%) as a yellow oil. The material was identical in all respects to the compound prepared under ambient pressure (Table 1, entry 6).

4-(3-(1-Methylindolyl))-5-methyl-2-hexanone (Table 2, entry 2)

Standard procedure: 1-methylindole (2.92 mg, 2.23 mmol), 5-methyl-3-hexen-2-one (500 μL, 3.79 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (33 mg, 49 μmol), acetonitrile (2 mL). The mixture was pressurized for 18 h and was worked up in the usual way. Flash chromatography using gradient elution (5–20% EtOAc – hexanes) afforded 455 mg pure material (84%) as a low-melting solid, identical in all respects to the compound prepared under ambient pressure (Table 1, entry 7).

4-(3-(1-Methylindolyl))-4-phenyl-2-butanone (Table 2, entry 3)

Standard procedure: 1-methylindole (295 mg, 2.25 mmol), benzalacetone (547 mg, 3.74 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (33 mg, 49 μmol), acetonitrile (2 mL). The mixture was pressurized for 26 h and was worked up in the usual way. Flash chromatography using gradient elution (20– 30% EtOAc – hexanes) afforded 417 mg pure material (67%) as a yellow oil, identical in all respects to the compound prepared under ambient pressure (Table 1, entry 13).

3-(3-Indolyl)cyclohexanone (Table 2, entry 4)

Standard procedure: indole (276 mg, 2.36 mmol), 2-cyclohexen-1-one (500 μL, 5.16 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (33 mg, 49 μmol), acetonitrile (2 mL). The mixture was pressurized for 2 d and was worked up in the usual way. Flash chromatography using gradient elution (20–30% EtOAc – hexanes) afforded 263 mg pure material (52%) as a pale yellow solid, identical in all respects to the compound prepared under ambient pressure (Table 1, entry 8).

3-Methyl-3-(3-(1-methylindolyl))cyclohexanone (Table 2, entry 5)

Standard procedure: 1-methylindole (292 mg, 2.23 mmol), 3-methyl-2-cyclohexen-1-one (400 μL, 3.53 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (32 mg, 47 μmol), acetonitrile (2 mL). The mixture was pressurized for 7 d and was worked up in the usual way. Flash chromatography using gradient elution (10–30% EtOAc – hexanes) afforded 59 mg pure material (11%) as a yellow oil, identical in all respects to the compound prepared under ambient pressure (Table 1, entry 9).

3-Methyl-3-(3-(1-methylindolyl))cyclopentanone (Table 2, entry 6)

Standard procedure: 1-methylindole (316 mg, 2.41 mmol), 3-methyl-2-cyclopenten-1-one (500 μL, 5.05 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (31 mg, 46 μmol), acetonitrile (2 mL). The mixture was pressurized for 5 d and was worked up in the usual way. Flash chromatography using gradient elution (10–30% EtOAc – hexanes) afforded 17 mg pure material (3%) as a yellow oil. IR (thin film), ν: 2940, 2910, 2860, 1730, 1600, 1475. 1455, 1410, 1390, 1365, 1320, 1230, 1145, 1120, 730 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$), δ: 1.60 (s, 3H), 2.13–2.37 (m, 3H), 2.44 (d, *J* = 17.7 Hz, 1H), 2.58 (m, 1H), 2.80 (d, *J* = 17.7 Hz, 1H), 3.73 (s, 3H), 6.78 (s, 1H), 7.11 (ddd, *J* = 8.1, 6.7, 1.4 Hz, 1H), 7.24 (tm, *J* = 7.5 Hz, 1H), 7.32 (dm, *J* = 7.9 Hz, 1H), 7.71 (dd, *J* = 7.9, 0.9 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 28.0, 32.7, 35.8, 36.9, 39.9, 51.9, 109.7, 118.7, 119.8, 120.6, 121.7, 125.0, 126.5, 135.5, 200.9. MS (70 eV), *m*/*e*: 227 (M^+,100), 212, 198, 184, 172, 171 (100), 156, 144. HRMS (for $C_{15}H_{17}NO$): 227.1311 (calcd.); 227.1315 (found).

Methyl 3-(3-(1-methylindolyl))-propanoate (Table 3, entry 5)

Standard procedure: 1-methylindole (322 mg, 2.45 mmol), methyl acrylate (500 μL, 5.55 mmol), $Yb(OTf)_3 \cdot 3H_2O$ (36 mg, 53 μmol), acetonitrile (2 mL). The mixture was pressurized for 7 d and was worked up in the usual way. Flash chromatography using gradient elution (5–30% EtOAc – hexanes) afforded 40 mg pure material (8%) as a yellow

© 1998 NRC Canada

oil. R_f = 0.49 (30% EtOAc – hexanes). IR (neat), ν: 2935, 2910, 2840, 1730, 1545, 1460, 1425, 1370, 1315, 1180, 1155, 1125, 1110, 1060, 730 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$), δ: 2.73 (t, *J* = 7.6 Hz, 2H), 3.11 (t, *J* = 7.6 Hz, 2H), 3.69 (s, 3H), 3.74 (s, 3H), 6.88 (s, 1H), 7.13 (ddd, *J* = 7.8, 6.7, 1.2 Hz, 1H), 7.25 (td, *J* = 7.3, 1.2 Hz, 1H), 7.31 (dm, *J* = 7.2 Hz, 1H), 7.61 (d, *J* = 7.6 Hz, 1H). ^{13}C NMR (63 MHz, $CDCl_3$), δ: 20.5, 32.6, 35.0, 51.6, 109.2, 113.4, 118.8 (two carbons), 121.6, 126.3, 127.5, 137.0, 173.9. MS (70 eV), *m*/*e*: 217 (M^+), 145, 144 (100), 143, 131, 130, 77. HRMS (for $C_{13}H_{15}NO_2$): 217.1103 (calcd.); 217.1107 (found).

Acknowledgments

This research has been financially supported by the Natural Sciences and Engineering Research Council (NSERC), Sepracor Canada Ltd., and Acadia University. We are grateful to Drs. Don Hooper and Michael Lumsden of the Atlantic Region Magnetic Resonance Centre and Dr. Stuart Grossert of the Dalhousie University mass spectrometry facility for their technical assistance. We thank Drs. Stanley Cameron and Witek Kwiatkowski of Dalhousie University for crystallographic analyses. Paul Harrington thanks NSERC for a summer assistantship.

A nuclear magnetic resonance investigation of the micellar properties of two-headed surfactant systems: the disodium 4-alkyl-3-sulfonatosuccinates. 1. Equilibrium micellar properties

Gregory D. Boucher, Aaron C. MacDonald, Brent E. Hawrylak, and D. Gerrard Marangoni

Abstract: A family of two-headed surfactants, the disodium 4-alkyl-3-sulfonatosuccinates, has been synthesized by the monoesterification of maleic anhydride and the addition of sodium bisulfite to the corresponding monoester. The properties the micelles formed by these compounds in aqueous solution, and the conformations of the chains comprising the micellar interior, have been investigated using a combination of 1-D nmr experiments and homonuclear and heteronuclear 2-D nmr techniques. The critical micelle concentrations (cmc's) and the aggregation numbers determined from the nmr experiments indicate that, in agreement with the earlier literature on other two-headed surfactant systems, these amphiphiles have high cmc's and low aggregation numbers when compared to single-headed surfactants of comparable chain length. All these results are interpreted in terms of the effect of adding a second headgroup to a single-headed, single-tailed surfactant.

Key words: micelles, surfactants, nmr spectroscopy, chemical shifts, aggregation numbers.

Résumé : Procédant à une monoestérification de l'anhydride maléique suivie d'une addition de bisulfite de sodium au monoester correspondant, on a synthétisé une famille d'agents de surface à deux têtes, les 4-alkyl-3-sulfonatosuccinates de disodium. Faisant appel à une combinaison d'expériences de RMN en 1-D et à de techniques RMN homonucléaires et hétéronucléaires en 2-D, on a étudié les propriétés des micelles formées par ces composés en solutions aqueuses ainsi que les conformations des chaînes formant l'intérieur des micelles. Les concentrations micellaires critiques (cmc) et les nombres d'agrégation déterminés par les expériences de RMN indiquent que, en accord avec les données antérieures sur d'autres systèmes d'agents de surface à deux têtes, ces amphiphiles présentent des cmc élevées et des nombres d'agrégation faibles comparés aux valeurs correspondantes d'agents de surface à une seule tête de longueur de chaîne comparable. On interprète tous ces résultats en fonction de l'effet provoqué par l'addition d'une deuxième tête à un agent de surface portant une tête et une queue.

Mots clés : micelles, agents de surface, spectroscopie RMN, déplacements chimiques, nombres d'agrégation.

[Traduit par la Rédaction]

Introduction

The class of compounds known as surfactants (for surface active agents) displays a number of distinct solution properties in water and consist, in their most common form, of a polar or ionic headgroup (e.g., sulfate, carboxylate) and a linear or branched hydrocarbon or fluorocarbon chain. The application of surfactant technology to a number of important industrial and pharmaceutical processes has been intensely investigated in the literature (1).

The unusual properties of aqueous surfactant solutions can be ascribed to the presence of the hydrophilic head group and the hydrophobic chain (or tail) in the molecule. The polar or ionic headgroup usually interacts strongly with its aqueous environment and is solvated via dipole–dipole or ion–dipole interactions, whereas the nonpolar chains interact only very weakly with water, resulting in the formation of ordered water molecules in the vicinity of the nonpolar chain (the hydrophobic effect). Due to the presence of the hydrophobic effect, surfactant molecules (amphiphiles) adsorb at the air–water interface, even at low surfactant concentrations, reducing the surface tension. At a specific amphiphile concentration, the critical micelle concentration, or *cmc*, molecular aggregates known as micelles are formed (2). In fact, a large number of experimental observations can

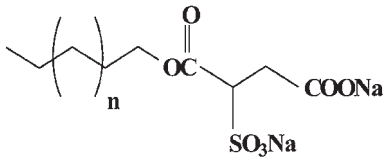
be summed up in a single statement: almost all physicochemical properties vs. concentration plots for a given surfactant–solvent system will show an abrupt change in slope in a narrow concentration range (the cmc).

The most commonly held view of a surfactant micelle at concentrations slightly above the cmc value of the surfactant is not much different than that published by Hartley in 1936 (3). At surfactant concentrations slightly above the cmc, amphiphiles tend to associate into spherical micelles, of about 50–100 monomers, with a radius similar to that of the length of an extended hydrocarbon chain. The micellar interior, being composed essentially of hydrocarbon chains, has properties closely related to the liquid hydrocarbon (4).

Nuclear magnetic resonance (nmr) spectroscopy is well recognized as powerful tool with which the physicochemical properties of micellar systems can be investigated. It is an inherently useful technique for studying micellar solutions, since the transfer of a monomer from the bulk solution to the micellar phase is generally accompanied by changes in a large number of nmr parameters (e.g., chemical shifts and relaxation rates). Nmr studies of surfactant solutions include the following: (*i*) cmc values and conformational changes upon micelle formation from ^{13}C chemical-shift measurements (5–8); (*ii*) counterion binding using counterion relaxation rates, e.g., ^{23}Na and ^{35}Cl (9–11); (*iii*) solubilization, counterion binding, and phase diagrams using the Fourier-transform, pulsed-gradient spin echo (FT-PGSE) method (12–22); (*iv*) the study of micellar structure and the determination of the *p*-value of solubilizates using ^{1}H and (or) ^{13}C paramagnetic relaxation experiments (23–26); (*iv*) reorientation and segmental motions of amphiphiles in lamellar or other ordered phases using ^{13}C, ^{31}P, ^{2}H, and ^{14}N relaxation experiments (27–32). The strength of the nmr technique, in general, lies in its multi-nuclear, multiparameter approach. As such, nmr experiments have been shown to provide important insight into the nature of the micellization process. A number of excellent reviews have been published recently on the application of nmr spectroscopy to the investigation of micellar and mixed micellar systems (33–36).

In view of the increasing and varied number of applications of surfactant technology, it is somewhat surprising that the surfactants usually used are long chain hydrocarbons with typical head groups like sulfate, trimethylammonium, carboxylate, and phosphate. In fact, the bulk of the work in all areas of surfactant technology, including how surfactants aggregate into simple micelles, has been limited to systems similar to those described above. Recently, however, the synthesis of novel surfactants, in particular surfactants possessing multiple or unusual headgroups has been gaining attention in the literature (37–40). As an example, Jobe and Reinsborough (37) have studied the properties of micelles formed by some of the C-6, C-8, and the C-10 members of the disodium 4-alkyl-3-sulfonatosuccinates (i.e., cmc's, aggregation numbers, and degrees of counterions binding) as a function of the alkyl chain length, using conductance, viscosity measurements, and dye solubilization techniques. These authors concluded that the addition of the second polar head group made it more difficult for the surfactant molecules to cluster together to form micelles; hence, these two-headed surfactants have relatively high cmc's and small aggregation numbers. However, the degrees of counterion binding appeared to be in the range most often quoted for single-headed surfactants. Kooreman and Engberts (38) and Beck and co-workers (39) have investigated the synthesis and characterization of the micellar properties of two different families of disulfate surfactants; the results from both groups also indicate that the addition of the second sulfate group affects greatly the properties of the alkanedisulfate micelles (the cmc's, degrees of counterion binding) when compared to the well-known alkanesulfate amphiphiles. In fact, Kooreman and Engberts (38) have demonstrated that two-headed sulfate surfactants are extremely stable towards precipitation by hard water ions (e.g., Ca^{2+}). The purpose of the present paper is to completely characterize the equilibrium properties of the micelles formed by a complete series (C-6 to C-10) of two-headed surfactants, the disodium 4-alkyl-3-sulfonatosuccinates, as a function of the chain length of the surfactant. These surfactants have the following structural formula.

The ^{1}H, ^{13}C, and ^{23}Na chemical shifts will be used to obtain estimates of the cmc values, the surfactant aggregation



number, and examine the environment of the counterion in two-headed surfactant micelles. All these results will be discussed in terms of the change in the equilibrium micellar properties brought about by the addition of the second charged headgroup to a single-headed surfactant monomer.

Experimental

The monoester of maleic anhydride was synthesized by heating together an equimolar amount of maleic anhydride with the appropriate alcohol (1-hexanol-1-decanol, Aldrich Chemical Company, 99% purity, used as received). The monoester was diluted with water, neutralized with 6 M NaOH, and the reaction mixture was refluxed with an aqueous solution of sodium bisulfite (Aldrich Chemical Company, 99% purity) for a period of 24–48 h. The progress of the reaction was monitored by UV spectroscopy; the reflux was stopped when an aliquot of the reaction mixture did not exhibit a peak in the UV spectrum at 300 nm, which is the UV absorption peak for the monoester of maleic anhydride. The mixture was allowed to cool to room temperature, and the solvent was carefully removed under vacuum. The solid surfactants were collected and washed with a cold methanol–water or ethanol–water mixture and two portions of diethyl ether to remove any residual alcohol. The final product was purified via Soxhlet extraction from diethyl ether and (or) ethanol. The overall yield of product was about 65–70%. The purified surfactants were characterized by nmr and FT–IR spectroscopy, and by a two-phase surfactant titration. It was found that the surface tension vs. log (c_{surf}) plots

were free of any minima, indicating that the final product had no surface-active impurities.

The nmr spectra (^1H and proton decoupled ^{13}C) for our sulfosuccinate surfactants were obtained on a Bruker AC-200 at St. F.X. University and a Bruker AC-250 nmr at the Atlantic Region Magnetic Resonance Centre (ARMRC) at Dalhousie University. A typical ^{13}C nmr spectrum for the C_8 sulfosuccinate is presented in Fig. 1. The ^{23}Na chemical shifts were obtained on a Bruker AMX-400 nmr spectrometer at the ARMRC. Homonuclear 2-D nmr spectra (COSY and NOESY) were obtained on both the AC-200 spectrometer at St. F.X. and the AC-250 nmr at Dalhousie University, using the standard pulse programmes from the Bruker software library. The ^{13}C-detected HETCORR experiments were performed on the Bruker AC-200 nmr spectrometer at St. F.X. University. The compound D_2O was used as the solvent for all the nmr experiments. The ^1H spectra were referenced to the HOD peak (δ = 4.81 ppm), while the ^{13}C chemical shifts were referenced to the deuterium lock signal using the method of Söderman (41). The ^{23}Na chemical shifts are reported relative to a 1.00 M solution of NaCl.

Results and discussion

A. The cmc values

The cmc values for the sulfosuccinate surfactants were obtained from the ^{13}C and ^{23}Na chemical-shift measurements as described below. Under the assumption of a two-site model for the surfactant ions and the counterions, i.e., the surfactant and counterions exist as "free" (in the aqueous phase) and "bound" (in the micellar phase), the observed ^{13}C or counterion chemical shifts can be written as follows.

$$[1] \qquad \delta_{s,obs} = p\delta_{s,mic} + (1-p)\delta_{s,aq}$$

where $\delta_{s,obs}$ is the averaged chemical shift of the surfactant or counterion, $\delta_{s,aq}$ is the nmr chemical shift of the surfactant ion or counterion in the aqueous phase, and $\delta_{s,mic}$ is the nmr parameter of the surfactant ion or counterion in the micellar phase. For the surfactant ion, if we define the *p*-value of the surfactant ion as

$$[2] \qquad p = \frac{C_{surf,mic}}{C_{surf,t}}$$

and substituting the definition of the *p*-value into the two-site model, we obtain the following for the ^{13}C chemical shifts.

$$[3] \qquad \delta_{s,obs} = \left(\frac{C_{surf,mic}}{C_{surf,t}}\right)\delta_{surf,mic} + \left(\frac{C_{surf,aq}}{C_{surf,t}}\right)\delta_{surf,aq}$$

where $\delta_{surf,mic}$ and $\delta_{surf,aq}$ are the ^{13}C chemical shifts of the surfactant carbon in the micellar phase and aqueous phase, respectively, and $C_{surf,mic}$, $C_{surf,aq}$ are the concentrations of surfactant in the micellar phase and in the aqueous phase, respectively. A plot of the observed ^{13}C chemical shift vs. the inverse of the total surfactant concentration should yield two linear regions intersecting at the inverse of the cmc value of the surfactant. An example plot of the ^{13}C chemical shifts versus the inverse surfactant concentration is given in Fig. 2 for the methyl carbon of the C_8 sulfosuccinate. The averaged cmc values of the sulfosuccinate surfactants were obtained from the breaks in the ^{13}C δ values vs. the inverse of the surfactant concentration for each of the carbon resonances for the C_7–C_{10} sulfosuccinates. All these values are given in Table 1. As there were no discernible changes in the ^{13}C chemical shifts for the C_6 sulfosuccinate, the cmc

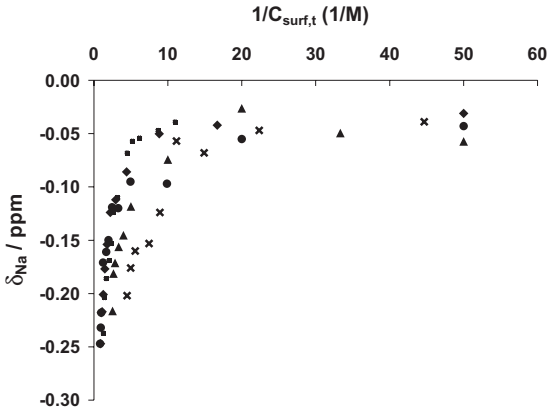
Fig. 3. The ^{23}Na chemical shifts (ppm) vs. the inverse of the surfactant concentration. ●, C_6SS; ◆, C_7SS; ■, C_8SS; ▲, C_9SS; ×, C_{10}SS.



value reported in Table 1 for that surfactant is the cmc value obtained from a plot of the ^{23}Na δ values vs. $1/(C_{Na,t})$. We should point out that the cmc values obtained in this paper are in excellent agreement with the cmc values from a number of different techniques in the work of Jobe and Reinsborough (37) and the work of Wiseman et al. (42).

The degree of counterion binding of a surfactant (the β value) is defined as

$$[4] \qquad \beta = \frac{C_{c,mic}}{C_{surf,mic}}$$

Hence, when the definition of the β value is applied to the two-site model, the counterion nmr chemical shifts can be written as follows.

$$[5] \qquad \delta_{c,obs} = \delta_{c,aq} + \beta(\delta_{c,mic} - \delta_{c,aq})\left(1 - \frac{cmc}{c_{c,t}}\right)$$

A plot of the observed ^{23}Na chemical shifts vs. the inverse of the total counterion concentration should yield two linear regions intersecting at the inverse of the cmc value of the surfactant. With an estimate of the degree of counterion binding (e.g., from conductance measurements), the counterion nmr chemical shift in the micellar phase, $\delta_{c,mic}$, can be estimated from eq. [5]. In all our ^{23}Na spectra for the sulfosuccinates, only a single peak is observed for the counterion, which indicates that fast exchange of the counterion is occurring between the aqueous phase and the micellar phase. The ^{23}Na chemical-shift data for all the sulfosuccinate surfactants are presented in Fig. 3. The slopes and the intercepts of the plots of the counterion chemical shift vs. inverse counterion concentration above the cmc value yield the product of $\beta\delta_{Na,mic}$; these are also reported in Table 1. It appears that from Table 1 that the product $\beta\delta_{Na,mic}$ does not change significantly as the chain length of the carbon atom in the surfactant is increased. This is also the case for single-headed surfactants of comparable chain length. In the work of Gustavsson and Lindman (10, 11), the $\beta\delta_{Na,mic}$ values of alkyl sulfates were observed to be constant (–0.28 ± 0.04) as the chain length of the surfactant increases. Since the counterion binding values of ionic surfactants are not particularly sensitive to the increasing carbon chain length (2, 4), Gustavsson and Lindman (10, 11) estimated the $\delta_{Na,mic}$ values from the observed ^{23}Na chemical-shift plots for a number of different surfactant headgroups using the counterion binding values from tracer self-diffusion measurements. We have calculated our values of $\delta_{Na,mic}$ for the sulfosuccinate micelles using the counterion binding values derived from conductance measurements (37, 42, 46). It is clear from Table 1 that as the chain length of the surfactant increases, the electronic environment of the ^{23}Na counterion does not change significantly, as evidenced by the relatively constant value of the chemical shift of the sodium ion at the micellar surface (–0.70 ± 0.12). This value for the chemical shift of the sodium ion at the surface of a sulfosuccinate micelle is significantly different than the $\delta_{Na,mic}$ values of a sodium ion at the surface of either carboxylate micelles or sulfonate micelles (0.70 ppm and –0.13 ppm, respectively) (10, 11). It is generally assumed that the chemical-shift changes of the counterion are dominated by changes in the paramagnetic shielding term of the ion at infinite dilution. For a hydrated, monatomic counterion, the paramagnetic shielding term is mostly due to the overlap of the outer orbitals of the sodium counterion and the oxygen of the hydrating water molecule (i.e., direct ion–ion interactions are usually unimportant). In the case of the sulfosuccinates, the difference in the electronic environment of the head group must lead to significant differences in the hydration of the sodium counterions at the surface of these micelles than at the surface of either carboxylate or sulfonate micelles. The large, positive $\delta_{Na,mic}$ for the sodium ion bound to the carboxylate micelle indicates that there is a significant amount of polarization of the counterions due to the possibility of H-bonding between the negatively charged O atom in the carboxylate anion and the protons on the water molecules. The oxygen atoms on the sulfonate anion are significantly less polarizing, and the shielding of the Na^+ counterion increases. With the combination of a carboxylate group and a sulfonate group in the headgroup region of the sulfosuccinate micelles, it appears that the headgroup becomes less polarizing. It is clear that there are structural and electronic changes that occur in the headgroup region of the two-headed surfactant micelles, due to the addition of the second charged headgroup, that affect significantly the shielding of the sodium ion at the micellar surface. These effects are largely absent when we examine the ^{23}Na chemical-shift data for single-headed surfactants of Gustavsson and Lindman (11). We will return to the subject of conformational and structural changes when we examine the ^{13}C chemical-shift changes upon micelle formation below.

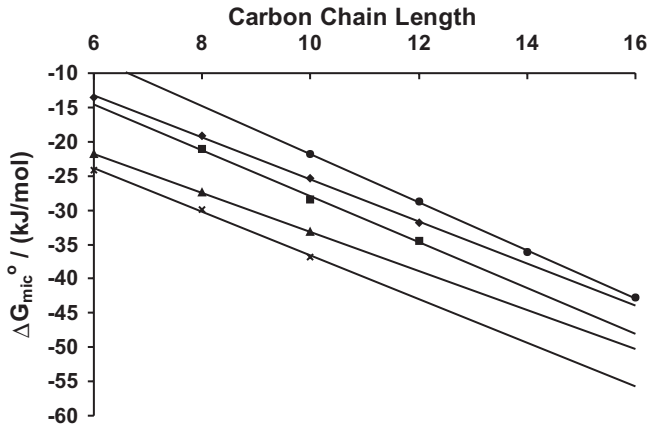
Using the nmr cmc values and the β values of these surfactants from our conductance measurements (42), the Gibbs energy of micellization ($\Delta_{mic}G°$ values) have been calculated using the equations of Zana (43), which for a two-headed surfactant with monovalent counterions is calculated as follows.

$$[6] \qquad \Delta_{mic}G° = RT(1 + 2\beta)\ln X_{cmc} + 2RT\beta\ln 2$$

The $\Delta_{mic}G°$ values for the sulfosuccinate surfactants are plotted in Fig. 4 as a function of the surfactant chain length. The slope of the plot of the $\Delta_{mic}G°$ values vs. surfactant chain length yields an estimate of –3.2 kJ/mol for the Gibbs

© 1998 NRC Canada

Fig. 4. The $\Delta_{mic}G°$ values for some families of one-headed and two-headed surfactant systems. ●, alkanedisulfates; ◆, alkyl carboxylates; ■, alkyl sulfates; ▲, SASA; ×, SASS.



energy of transfer of a CH_2 group from the aqueous phase to the sulfosuccinate micellar phase, in excellent agreement with the literature (2, 43). In Table 2, we have calculated the $\Delta_{mic}G°$ values of the sodium alkylcarboxylates, the sodium alkylsulfates, the sodium alkyl sulfoacetates, and the disodium 1,2-alkanedisulfates (44–46); we have also plotted these Gibbs energies in Fig. 4. The sodium alkyl sulfoacetate surfactants are of interest, since they are structurally related to the sulfosuccinate surfactant family. It is clear that the $\Delta_{mic}G°$ values for the two-headed surfactants are higher than for the single-headed surfactants of comparable chain length, indicating that it is thermodynamically less favourable for the two headed surfactants to form micelles.

B. Surfactant aggregation numbers

The mean aggregation numbers of the surfactants were estimated from the ^{13}C chemical-shift data, using the method outlined by Lang (47) and Gao et al. (48). The N_s values of surfactants can be estimated from the application of the mass-action model of micelle formation to the ^{13}C nmr chemical shifts. Under the assumption of a single aggregation number, the equilibrium between the surfactant monomers (S) in the aqueous phase and the micellar phase (S_{N_s}) can be written as follows.

$$[7] \qquad N_s S \rightleftarrows S_{N_s}$$

The equilibrium constant for the above reaction is written (neglecting activity corrections):

$$[8] \qquad K = \frac{C_{mic}}{C_{surf,aq}^{N_s}}$$

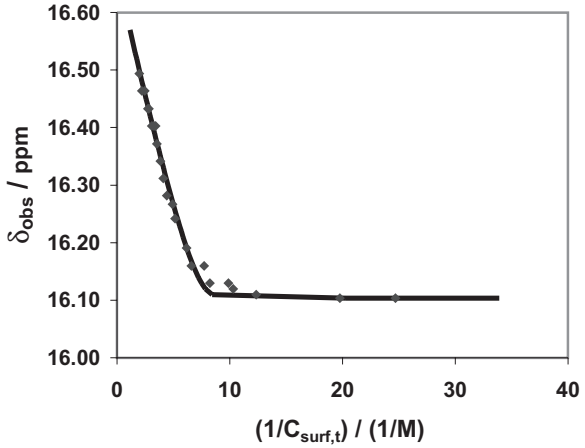
where C_{mic} is the concentration of micelles having an aggregation number N_s (i.e., $C_{mic} = C_{surf,mic}/N_s$), and $C_{surf,aq}$ is the concentration of the free monomer in solution. Since the free-monomer concentration can be written in terms of the total surfactant concentration, $C_{surf,t}$, the equilibrium constant can then be written as

$$[9] \qquad K = \frac{C_{surf,t} - C_{surf,aq}}{N_s C_{surf,aq}^{N_s}}$$

Table 2. The $\Delta_{mic}G°$ values (kJ/mol) for different families of one-headed and two-headed surfactants.

Chain length	Alkyl carboxylates	Alkyl sulfates	SASA	SASS	Disulfates
6	–14.0	—	–21.8	–24.1	—
8	–19.9	–21.1	–27.4	–29.9	—
10	–24.7	–28.4	–33.2	–36.8	–21.8
12	–31.3	–34.5	—	—	–28.8
14	—	—	—	—	–36.1
16	—	—	—	—	–42.8

Fig. 5. Plot of the calculated chemical shifts (from eq. [10]) as a function of the inverse surfactant concentration for the methyl carbon of C_8SS.



The observed chemical shift is written in terms of the total surfactant concentration according to eq. [3]. Hence, substituting for $C_{surf,aq}$ in eq. [8] yields

$$[10] \qquad \frac{1}{C_{surf,t}} = (KN_s)^{\frac{1}{N_s-1}}(\delta_{surf,mic} - \delta_{surf,aq})^{-1} (\delta_{surf,mic} - \delta_{surf,obs})^{\frac{N_s}{N_s-1}}(\delta_{surf,obs} - \delta_{surf,aq})^{\frac{1}{1-N_s}}$$

The aggregation numbers were estimated from fitting the ^{13}C chemical-shift data as a function of surfactant concentration to eq. [10]. A plot of the calculated and experimental chemical shifts as a function of the inverse surfactant concentration is presented in Fig. 5 for the methyl carbon of the C_8SS. The aggregation numbers are also presented in Table 1. The use of ^{13}C nmr chemical shifts to obtain the surfactant aggregation number from the application of the mass action model has been criticized by several authors as yielding low estimates of the surfactants aggregation number for typical anionic surfactants like SDS (41); however, as a function of the carbon chain length, it should at least qualitatively predict the trends in the aggregation number of the carbon chain length. With this in mind, the aggregation numbers range from a value of 13 for the C_7 sulfosuccinate to 42 for the C_{10} sulfosuccinate. These number are in very good agreement with the viscosity and conductivity determination of the aggregation numbers from the work of Jobe and Reinsborough, and for the higher chain lengths, are in

reasonable agreement with the fluorescence quenching data of Hawrylak et al.[2] In Table 3, we compare the cmc values, Gibbs energies of micelle formation, and the aggregation numbers for the structurally related two-headed surfactants vs. the single-headed surfactants. It is quite evident that the addition of the second negatively charged headgroup has an effect on the micellar properties of the two-headed surfactants vs. the single-headed surfactants of the same alkyl chain length. Therefore, in agreement with our earlier paper on the cmc values of the disulfate surfactants (39) and the work of Jobe and Reinsborough (37), these surfactants have relatively high critical micelle concentrations reflecting a shift in the hydrophilic–lipophilic balance. It should be noted that a shift in the HLB of the surfactant also affects a number of other important solution and micellar properties of surfactants (37, 39, 42).

C. Chemical-shift changes upon micelle formation

The ^{13}C chemical-shift changes upon micellization can give qualitative information about conformational changes that surfactant molecules undergo when forming micelles. Generally, a high frequency shift is associated with an increase in the number of *trans* conformers, whereas a low frequency shift is interpreted in terms of an increasing probability of *gauche* configurations (5–8). It should be noted that there are other contributions to the chemical-shift changes upon micelle formation including headgroup interactions and hydration changes (49), but that the conformational arguments appear for the chemical-shift changes upon micelle formation to be supported by other experimental techniques (50, 51). The ^{13}C chemical-shift changes upon micelle formation, $\delta_{surf,mic} - \delta_{surf,aq}$, are plotted in Fig. 6*a–d* and given in Table 4 for the C_7–C_{10} sulfosuccinate. It can be seen from Fig. 6*a–d* that for all the sulfosuccinate surfactants studied, carbons 1, 2, 3, and 5 undergo low frequency shifts on micelle formation, whereas all other carbons undergo high frequency shifts upon the transfer of the monomer from the aqueous phase to the micellar phase. In fact, it appears that for the headgroup region, the magnitude of the shift changes is a function of the carbon chain length. For the headgroup carbons, the ^{13}C chemical-shift differences decrease as the chain length is increased, whereas for the alkyl chains, the shift changes upon micelle formation are essentially constant.

With the assumption that the shift changes upon micelle formation are due to conformational changes and (or) hydration differences only, it appears that the increase in the low frequency shifts indicates a more constrained configuration (i.e., an increase in the number of *gauche* conformers), as the carbon chain length increases. Grant and Cheney (52) have estimated that the ^{13}C chemical shift would change by a maximum of 4.8 ppm for a complete *gauche–trans* isomerization. Hence, in the case of the sulfosuccinate surfactants, the increase in the surfactant chain length decreases the area per headgroup. The packing of the two negatively charged headgroups on the micellar surface becomes more difficult. From the ^{13}C chemical-shift measurements, we propose that, on average, the 1–4 carbons in the headgroup region adopt a predominately *gauche* configuration, and that the carbons bearing the headgroups become significantly more constrained as the surfactant chain length increases.

For the alkyl chains, the $\delta_{surf,mic} - \delta_{surf,aq}$ values are observed to be essentially constant as the alkyl chain length of the surfactant increases. This is interpreted in terms of an increase in the number of *trans* conformers as the sulfosuccinate surfactants form micelles. As has been observed previously in the literature, the maximum $\delta_{surf,mic} - \delta_{surf,aq}$ values are found in the middle of the alkyl chain. This is due to the fact that the methylene groups near the end of the chain and the methyl groups are more able to bend back towards the surface of the micelle. Note that the $\delta_{surf,mic} - \delta_{surf,aq}$ values for the methyl carbons and the final few methylene groups are slightly smaller for the longer chain surfactants, which is likely due to more motional freedom in the micelle. We are currently determining the dynamics of the carbon nuclei inside the micelle via nmr ^{13}C spin – lattice relaxation time measurements. These results will be the subject of a future paper.

Conclusions

The cmc's and aggregation numbers (N_s values) for a series of two-headed surfactants, the sodium sulfosuccinates, have been determined from the nmr chemical-shift data for the appropriate nucleus. The environment of the counterion at the micellar surface has been probed using surfactant counterion chemical-shift measurements. It appears again that the addition of the second charged surfactant headgroup changes significantly the properties of the micelles formed by the two-headed surfactants, when compared to structurally related surfactants (in this case, the sodium sulfoacetates). The chemical-shift changes upon micelle formation have demonstrated that the formation of sulfosuccinate micelles is accompanied by a significant ordering of the headgroup carbons, while the alkyl chains obtain some conformational freedom upon micelle formation.

Regular polyhedral molecules. P_{20} and its inclusion compounds

Lubomír Rulíšek, Zdeněk Havlas, Stanislav Heřmánek, and Jaromír Plešek

Abstract: Based upon the geometrical properties of regular polyhedrons, the possibility of the existence of certain polyhedral molecules composed of only one element is investigated. A very promising candidate — the regular dodecahedron — is selected as the convenient polyhedral structural pattern and phosphorus as the appropriate element. A series of high-level ab initio calculations is performed on the dodecahedral P_{20} molecule, including predictions of its thermodynamic and kinetic stability, natural bond orbital analysis, vibrational analysis, and inclusion of some elements into the molecular skeleton. Due to the potential stabilizing agents that may eventually form stable inclusion compounds and the estimated high kinetic stability, the question of the possible existence of P_{20} is answered in the positive.

Key words: ab initio calculations, inclusion compounds, P_{20}, phosphorus clusters, polyhedra.

Résumé : En se basant sur les propriétés géométriques de polyèdres réguliers, on a évalué la possibilité d'existence de certaines molécules polyédriques formées d'un seul élément. Comme structure polyédrique pratique, on a choisi le dodécaèdre régulier qui possède un grand potentiel et le phosphore comme élément approprié. On a effectué une série de calculs ab initio d'orbitales moléculaires à un niveau élevé sur la molécule dodécaédrique de P_{20} comprenant des prédictions relatives à ses stabilités thermodynamique et cinétique, à l'analyse de l'orbitale de la liaison naturelle, à l'analyse de vibration et à l'inclusion de quelques éléments dans le squelette moléculaire. Compte-tenu des agents stabilisant potentiels qui peuvent éventuellement former des composés d'inclusion et de sa stabilité cinétique évaluée élevée, on prévoit que l'existence du P_{20} est possible.

Mots clés : calculs ab initio, composés d'inclusion, P_{20}, agrégats de phosphore, polyèdres.

Introduction

The fascinating discovery of fullerenes (1) inspired us to investigate the potential existence of polyhedral E_n molecules composed of only one element. To select the most appropriate polyhedron and the most appropriate element, two main factors were considered: (*i*) Due to their high symmetry and equivalency of all vertices, edges, and faces, regular polyhedra could be considered as the favoured geometric shapes. (*ii*) The best candidate among the elements should fit the respective coordination numbers and bond angles of the geometric archetype with the least strain.

Some essential geometric parameters of polyhedral molecules are shown in Table 1.

It is apparent that, primarily, the pentagonal dodecahedron should be considered as the favoured geometric archetype. Each vertex is connected to three neighbours and all the bond angles are uniformly 108°. Such a value of bond angle is often found in compounds of the light main group elements. Moreover, the size of the internal cavity in the dodecahedron (the largest among all regular polyhedra) suggests the possibility of inclusion of some atoms or small molecules that might eventually help stabilize the E_{20} cluster.

The following preliminary and qualitative considerations led us to the selection of the best candidate among elements that might form the dodecahedral skeleton.

The "electron poor" E^{III} elements are excluded from the contest because they prefer triangular polyhedral faces as a consequence of three centre bond requirements (cf. the characteristic deltahedral faces in elemental boron, in a plethora of binary borides, and in the *closo*-$B_nH_n^{2-}$ ions). There are not enough electrons for the population of exohedral orbitals (orbitals perpendicular to the surface of the sphere circumscribed to the dodecahedron and oriented radially out) and that is why elemental boron and almost all binary borides are, instead, polymers composed of deltahedral units (2).

The "electron precise" E^{IV} elements prefer polyhedra with square, pentagonal, or hexagonal faces (3). However, the fourth electron has to either accommodate itself in an exohedral orbital or combine with the nearest neighbour to form a double bond. The latter is quite inconvenient in triangles, squares, or pentagons mainly because of the steric requirements.

Which is why fullerenes begin to be stable enough only if the number of participating carbon atoms is higher than

Table 1. Geometric parameters of regular polyhedral molecules expressed in multiples of the edge length *a* (covalent diameter of the vertex atom).

Polyhedron	*n*	α (°)	d_1	d_2
Tetrahedron	3	60	1.22	0.22
Octahedron	4	60	1.41	0.41
Cube	3	90	1.73	0.73
Icosahedron	5	60	1.90	0.9
Dodecahedron	3	108	2.80	1.8

Note: *n* is the number of neighbouring vertices; α is the endohedral angle between the edges; d_1 is the diameter of the circumscribed sphere; d_2 is the diameter of the inner molecular spherical cavity (distance from the centre of the polyhedron to the covalent surface of the vertex atom under the assumption that the covalent diameter of the vertex atom is equal to the edge length; then it follows that $d_2 = d_1 - 1$).

approximately 48 (14 hexagons). If the fourth electron can participate in a terminal E—X bond, this obstacle vanishes (cubane (4), dodecahedrane (5)).

The "electron rich" E^V elements seem to be very promising candidates. Their lone electron pairs might mimic terminal groups protruding radially out of the polyhedron, whereas the remaining three valence electrons might constitute three covalent single bonds connecting the neighbouring vertices. However, nitrogen with its tendency to prefer multiple bonds will be unstable in the dodecahedral vertex position. On the other hand, phosphorus might fit ideally. The same applies to its heavier homologues — As, Sb, and Bi. But these elements contain occupied orbitals of higher angular momentum (*d* and *f* shells) and may favour a different bond arrangement.

The E^{VI} and E^{VII} elements have more electrons than can be accommodated in three single bonds to their neighbours, and one exohedral orbital. They are not thought to be suitable candidates.

The aforementioned considerations led us to the computational investigation of the stability of the dodecahedral molecule P_{20} and its several inclusion compounds $Y@P_{20}$ (Y stands for an element).

There exists extensive experimental and theoretical material about the clusters of phosphorus. Only those papers pertinent to the present work will be recapitulated here. Jones and Hohl (6) systematically studied small clusters (up to P_8) and found the cuneane-like structure to be the most stable conformation of P_8. Häser et al. (7) extended their study up to P_{26}. They evaluated SCF energies corrected by MP2 contributions of 32 phosphorus clusters and suggested a possible reaction scheme for the polymerization of phosphorus. In their study they mentioned the dodecahedral P_{20} molecule and found it to be unstable with respect to P_4 decomposition. Nevertheless, the MP2 contribution decreased this instability significantly. It corroborates the significant role of correlation energy when studying anisodesmic reactions. The most stable conformations they found were oligomeric structures linked by a single covalent bond. However, their results suggested that P_{20} might be the most stable molecule from the subset of polyhedral clusters. Häser and co-workers (8) extended the above study to many other smaller clusters of phosphorus, polyphosphorus anions, and phosphanes, but the polyhedral clusters of phosphorus were not computed in these papers.

Hu et al. (9) recalculated P_{20} to P_4 and P_{20} to P_2 decompositions at the SCF and MP2 levels using a broad range of basis sets. They answered the question of possible existence in a negative way, concluding that P_{20} is not "special." However, the values of reaction energies (both SCF and MP2) exhibited a very strong basis set dependence (ranging from –165 kcal mol^{-1} at the SCF/DZ level through 23 kcal mol^{-1} calculated at the highest MP2/TZ2P level to 70 kcal mol^{-1} at the SCF/(9*s*6*p*4*d*3*f*) level). The results did not exhibit a systematic convergence.

In our work, we do not attempt to investigate all the families of phosphorus clusters. That was done in a very comprehensive way in the cited papers of Häser and his co-workers. Instead, we would like to focus attention on the possible existence of P_{20} and study this interesting molecule more thoroughly. Starting from the general chemical intuition expressed in the preliminary considerations of this introduction, we have endeavored to utilize more information than can be drawn from a single number representing reaction energy. We analyzed the electronic structure in terms of natural bonding orbitals and their population, carried out the simple thermochemical analysis, estimated the kinetic stability, and looked for "stabilizing agents."

Computational methods

All the calculations reported in this work were performed with the Gaussian 94 program suite (10). DFT calculations were carried out by using a hybrid three-parameter functional developed by Becke (11), which combines the Becke's gradient-corrected exchange functional and the Lee–Yang–Parr and Vosko–Wilk–Nusair correlation functionals (12) with part of the exact Hartree–Fock exchange energy (denoted as B3LYP). The coupled cluster method (13) with singles, doubles, and noniterative triples (CCSD(T)) with frozen core electrons has been used for the reference calculations on several model reactions. The basis sets of 6-311G (14) quality with added polarization and diffuse functions have been used in most of the calculations.

In the case of inclusion compound $Hg@P_{20}$, the Hay–Wadt effective core potential (15) was used for the mercury.

The vibrational analysis, zero point energy corrections, and thermochemical analysis were carried out at the B3LYP/6-31+G(d) (16) level. The B3LYP frequencies were scaled by 0.89 in the thermochemical analysis. We used the Natural Bond Orbital (NBO) method (17) at the HF/6-31+G(d) level.

Results and discussion

Model chemistry

To establish the applicability of the DFT method (B3LYP functional) for phosphorus clusters, we first performed a few tests with P_n molecules.

We studied two simple reactions: $2P \rightarrow P_2$ (formation of P_2) and $2P_2 \rightarrow P_4$. These reactions should provide us with a notion of the accuracy of B3LYP. Both of them are anisodesmic reactions of phosphorus atoms or compounds. The results are summarized in Table 2.

© 1998 NRC Canada

Table 2. $\Delta H°_0$ for the $2P \rightarrow P_2$ and $2P_2 \rightarrow P_4$ reactions. B3LYP/6-311+G(d) optimized geometries were used.

	$2P \rightarrow P_2$	$2P_2 \rightarrow P_4$
Method	$\Delta H°_0$ (kcal mol^{-1})	$\Delta H°_0$ (kcal mol^{-1})
B3LYP/6-311+G(d)	–108.4	–35.7
B3LYP/6-311+G(2df)	–114.6	–46.3
CCSD(T)/6-311+G(d)	–82.2	–46.2
CCSD(T)/6-311+G(2df)	–103.9	–51.6
Experimental value	–115.0 (19*b*)	–54.0 (19*b*)

The computed and experimental enthalpies are in good agreement, especially if a larger basis set is used. Excellent agreement between the computed and experimental equilibrium bond lengths has been achieved. The experimental bond lengths are 1.894 Å for P_2 (18) (calcd. 1.897 Å) and 2.21 Å for P_4 (19*a*) (calcd. 2.219 Å). We conclude that the B3LYP/6-311+G(2df)//B3LYP/6-311+G(d) method is appropriate for the quantitatively correct prediction of the stability of the P_{20} molecule. The more sophisticated and presumably more accurate methods (e.g., MP4(SDQ), CCSD(T), QCISD(T) in polarized triple zeta and higher basis sets) are beyond the present capabilities of computers.

The P_{20} molecule

We have located the minimum on the potential energy surface corresponding to the regular dodecahedral structure of the P_{20} molecule. The equilibrium bond length ($d_{P—P}$ = 2.287 Å) is elongated by 0.07 Å in comparison with the P_4 molecule. The P_{20} molecule is depicted in Fig. 1.

The absence of another minimum close to the regular dodecahedral conformation was tested for by removal of the symmetry imposed on the molecule in the previous calculation. We changed the values of several internal coordinates (0.02 Å in bond lengths and 5° in bond and torsion angles). That resulted in a distorted structure with no symmetry element. The optimization procedure resulted in the same minimum as described above.

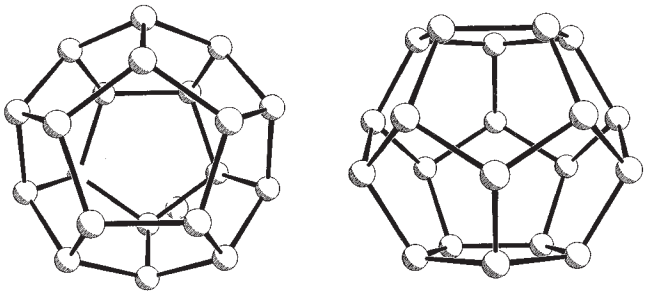
The NBO analyses of the resulting wave functions of P_{20} and P_4 molecules verified the assumptions made in the introductory section. The molecule P_{20} can be described by single P—P covalent bonds with one lone pair protruding radially out from each vertex. The P—P bonds in P_{20} have 16% of *s* character and 84% of *p* character with *d* orbitals participating with less than 1%; the P—P bonds in P_4 have 6% of *s* and 93% of *p* character. Lone pairs on P vertices in P_{20} have 53% of *s* character and 46% of *p* character (82% *s* and 18% *p* character in P_4). The deviations in directionality of natural hybrid orbitals (from the line connecting neighbouring nuclei) are 4° in P_{20} and 24° in P_4. Therefore, the two molecules differ significantly. The bonding in P_{20} is approaching the classical model of sp^3 hybridization whereas the covalent bonds in P_4 are formed mainly by overlap of *p* orbitals of phosphorus ("banana orbitals").

To determine the relative stability of P_{20}, reaction energies and enthalpies of two reactions, $10P_2 \rightarrow P_{20}$ and $5P_4 \rightarrow P_{20}$, were calculated. The results are summarized in Table 3. With respect to the aforementioned test calculations, we estimate the error in the value of the reaction energy (38.5 kcal mol^{-1}) to be about 10%. This value qualitatively agrees with those computed by Häser et al. (7) (64 kcal mol^{-1} at the SCF/TZDP level and 20 kcal mol^{-1} at the MP2/SVP level) and Hu et al. (9) (23 kcal mol^{-1} at the MP2/TZ2P level).

Table 3. The reaction energies and standard enthalpies at 0 K (negative values indicate higher stability of the products and vice versa).

Reaction	ΔE (kcal mol^{-1})	$\Delta H°_0$ (kcal mol^{-1})
$10P_2 \rightarrow P_{20}$	–200.9	–190.3
$5P_4 \rightarrow P_{20}$	38.5	41.0

Fig. 1. P_{20} molecule in two orientations.



The gas phase thermodynamic stability of P_{20} is significantly higher than that of the known P_2 molecule, but lower than that of P_4 molecule. Therefore, it is theoretically possible to prepare P_{20} by increasing the temperature to above approximately 800°C to accomplish the dissociation of the most stable conformation of phosphorus (the P_4 molecule) into the P_2 species (20), and by subsequent cooling of the system under the specified conditions (e.g., presence of a substance to prevent the condensation of P_2 into P_4 molecules or some other energetically stable cluster arrangement) to obtain the P_{20} molecule. The calculation of P_{20} inclusion compounds that may assist in finding the appropriate condensation centres will be presented below.

Thermochemistry of P_{20}

Having computed the vibrational frequencies, we carried out a simple thermochemical analysis to predict the approximate conditions under which the successful synthesis of the P_{20} molecule can be expected. $5\ P_4 \rightarrow P_{20}$ was chosen as the model reaction.

It should be pointed out that the results are only qualitative, based on the assumption of ideal gas behavior of the participating molecules and upon the approximation of rigid rotor and harmonic oscillator. They confirm the expected dependence of Gibbs energy on the pressure and temperature. The introduction of entropy effects reduces the thermodynamic stability of P_{20}. We presume they may be of some importance for experimental chemists.

The results of thermochemical analysis are depicted in Fig. 2.

Kinetic stability

The second factor determining the potential existence of a given molecule is its kinetic stability. It is virtually impossible (and computationally unattainable) to explore all the possible reaction channels, i.e., to locate all the saddle points

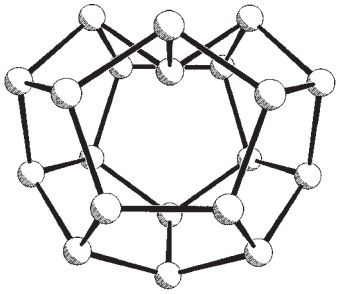
[a] Due to the limitations of the DFT methods within the Gaussian 94 program, the Raman scattering activities reported here were calculated at the HF/6-31+G(d) level.

encompassing the equilibrium geometry of dodecahedral P_{20}. Several attempts were made to employ the transition state optimization methods based upon following the lowest vibration modes (eigenvectors). Since neither of these was successful in locating any transition state close to the dodecahedral conformation, we chose a different approach.

The lowest saddle points usually correspond to only a moderate chemical change (conformational transition, rotation of certain group, etc.) and the saddle points corresponding to chemical reactions (breaking of a covalent bond, decomposition of a molecule, etc.) lie substantially higher.

Initially, we examined the lowest vibrational modes. They are degenerate and could be depicted as pulsing of the dodecahedral skeleton. This agrees with the above consideration, that they may correspond to certain conformational transitions. We conceived such a simple transition for the P_{20} skeleton. In their investigation of phosphorus clusters Häser et al. (7) mentioned another conformer of P_{20}, a dodecahedron with one vertex sunk in the direction of the center of the body (Fig. 3). This transition served us as the model for estimating the depth of the dodecahedral P_{20} minimum. The calculations were carried out at the B3LYP/3-21G level, with both conformers fully optimized at this level, and the transition state was located by QST2 (Synchronous Transit – Guided Quasi-Newton Method (21)) as implemented in the Gaussian 94 program. The distorted P_{20} lies energetically only 1.2 kcal mol^{-1} higher than the dodecahedral molecule. However, the energy barrier is 17 kcal mol^{-1} from the side of dodecahedral P_{20}.

Fig. 3. The conformer of P_{20} with one vertex sunk in the direction of the molecular center.



We consider it a reasonably high barrier. The more severe deformation of the P_{20} cage that must precede its decomposition (such as the disruption of a P_2 edge) must lie energetically higher. It may be concluded that P_{20} is (as far as the calculations show) a kinetically stable molecule, but we must keep in mind that the barrier as computed may not be of an accuracy comparable to the previous calculations and that the considerations are based upon the premise about the nature of the low-lying saddle points.

Vibrational analysis

The IR spectrum of the P_{20} molecule has been predicted using the computed frequencies and intensities (Table 4).

There is only one peak in the IR spectrum with a wavelength of 293 cm^{-1} and absolute intensity of 2.75 km mol^{-1} whose detection may indicate the presence of P_{20}. This peak is absent in both P_2 and P_4 molecules (the calculated frequencies with non-zero intensity are 795 and 461 cm^{-1}, respectively).

Four Raman fundamentals are allowed in the P_{20} spectrum (A_g and all three H_g vibrations).

Inclusion compounds Y@P_{20}

We have considered two classes of appropriate candidates for the condensation centers. The first group contains noble gas atoms (analogy with the known $G\cdots(H_2O)_{20}$ clusters (22)) or ions of noble gas type, such as Li^+. To the second group may belong heavy metal elements that do not form phosphides (e.g., mercury).

The subtle energy changes accompanying weak interactions of atoms with other molecules are very difficult to evaluate precisely and the results should be examined with care. That is why we have run test calculations on a smaller system for each type of interaction studied. It also helped us to estimate errors in the predictions of interaction energies

Table 5. The computed interaction energies of model systems. Negative numbers indicate stabilization of the dimer. The P_2 molecule ($d_{P—P}$ = 1.897 Å) is placed at the position equivalent to the edge in dodecahedral P_{20} and the position of the interacting atom (cation) corresponds to the centre of P_{20} (T-shape structure).

	Interaction energy (kcal mol^{-1})	
System	B3LYP/6-311+G(2df)	CCSD(T)/6-311+G(2df)
He···P_2	1.4	1.5
Ne···P_2	1.9	1.6
Ar···P_2	8.4	7
Li^+···P_2	–14.5	–14.3
Li^+···benzene[a]	–38.4	–38.3 (exp) [b]

[a] The geometry of the system was first optimized at the 6-311+G(d) level with the Li^+ ion lying in the sixfold axis of benzene, equilibrium distance from the benzene ring being 1.84 Å.
[b] Experimental value was taken as the reference (23).

of P_{20} with the atoms or cations. The results of test calculations are summarized in Table 5.

Very good agreement between DFT (B3LYP functional) and CCSD(T) methods (or experiment) was found in all cases and therefore the B3LYP functional was used for further calculations.

The atoms were placed at the center of the dodecahedral P_{20} skeleton. The geometry was optimized at the B3LYP/6-311+G(d,p) level and the energy recalculated at the B3LYP/6-311+G(2df) level. The results are summarized in Table 6.

It can be observed that the noble gas atoms are too large to fit ideally into the P_{20} cage. This is evident both from the interaction energies and equilibrium geometries. Still, they may play an important role in the earlier steps of the synthesis by acting as condensation centers and, in the latter stages, escape from the cluster.

Mercury does not appear to be a very promising inclusion element. But it should be mentioned that we did not test Hay–Wadt pseudopotentials for the Hg···P type of interaction and results may be subject to larger error than in other calculations of inclusion compounds.

On the other hand, the interaction of the Li^+ cation with the P_{20} cage is favourable (as expected for a cation–molecule complex) and the equilibrium P—P bond distance remains almost unchanged. The interaction energy is higher by 0.3 kcal mol^{-1} than in the experimentally studied complex Li^+···benzene (23), which means that the lithium monocation stabilizes P_{20} to an even greater extent. To further ascertain this point, we performed the same calculation for the interaction of Li^+ with P_4. The lithium cation was placed both inside and outside the cage. No minimum was found in the former case. The optimization of the molecular geometry led to disruption of the cage with the lithium cation escaping from the cavity inside P_4. On the other hand, the minimum was found for the system with Li^+ outside the P_4 cage. Lithium is positioned in the threefold rotation axis of P_4 (above one face of the P_4 tetrahedron). The equilibrium distance from the three vertices is 2.58 Å. The calculated interaction energy is –22.3 kcal mol^{-1}. Therefore, the stabilization of P_4 by Li^+ is lower by 16.3 kcal mol^{-1} than in the case of Li^+···P_{20}. It corroborates the hypothesis that the lithium monocation could help in the synthesis of P_{20}.

Table 6. The computed interaction energies of a series of P_{20} inclusion compounds (negative values indicate stabilization and vice versa).

System	$d_{P—P}$	Interaction energy (kcal·mol^{-1})
He···P_{20}	2.288	5.1
Ne···P_{20}	2.292	12.3
Ar···P_{20}	2.320	39.8
Hg···P_{20}[a]	2.296	60.9
Li^+···P_{20}	2.287	–38.6

[a] The Hay–Wadt effective core potential (15) with valence TZ+P basis set has been used for Hg, and the standard 6-311G(d) basis set for all electrons in phosphorus atoms.

It should be noted that all the interaction energies reported in this section represent uncorrected BSSE values. We investigated the BSSE error by the counterpoise method. It turned out to be less than 0.5 kcal·mol^{-1} in the 6-311++G(2df,2pd) basis set.

Another important inclusion compound might be P_{21}^+ with one phosphorus atom inside the dodecahedral cage. This possibility was suggested by Whetten (see ref. 3 of ref. 24), who was studying the formation of phosphorus clusters by laser-based mass spectrometric methods. Our preliminary calculation (CASSCF/3-21G) showed that the accurate evaluation of the interaction energy of P^+ with the P_{20} cage is beyond the capabilities of supercomputers as the ground state cannot be described by a single determinant. Therefore, at least the CASSCF/MP2 method with a large basis set should be used for an accurate calculation. In agreement with our study of the above-mentioned inclusion compounds, we think that the question of whether P_{21}^+ might be "special" remains open.

Conclusions

As presented, our aim is to contribute to the discussion about the existence of polyhedral molecules composed of a single element, motivated by the interest generated by the discovery of the unusual structures of fullerenes. We give a positive answer to the question of the possible existence of the dodecahedral P_{20} molecule, and endeavour to show the conditions under which its successful synthesis can be expected. We have shown the possibility of the existence of Y@P_{20} inclusion compounds (especially with Li^+), but do not dare to predict the properties of such unusual structures. They may belong to a class of high energy density molecular systems. We attempt to demonstrate the close relation between chemical intuition (molecular structural patterns as discussed in the Introduction) and high-level ab initio calculations, and give an example of the general methodology used when predicting the existence of new molecules.

^{31}P chemical shift anisotropies of trimethyl- and triphenylphosphine-substituted Group 6 metal pentacarbonyl complexes

Jordan H. Wosnick, Frederick G. Morin, and Denis F.R. Gilson

Abstract: The ^{31}P chemical shift tensor components and anisotropies of the trimethyl- and triphenylphosphine complexes of the group 6 metal pentacarbonyls, $M(CO)_5PR_3$ (M = Cr, Mo, W and R = Me, Ph), have been measured using solid-state CP-MAS ^{31}P NMR spectroscopy. For the trimethylphosphine derivatives, the chemical shift tensors have near axial symmetry and the shift tensor components are in reasonable agreement with the calculated values for the chromium and molybdenum complexes. In the triphenylphosphine complexes, the tensors are asymmetric due to the different torsion angles of the phenyl rings. The trend to higher shielding of the isotropic ^{31}P chemical shifts on descending group 6 arises from changes in the perpendicular components of the shift tensor. The one-bond coupling constants, $^1J(^{95/97}Mo–^{31}P)$, for the trimethyl- and triphenylphosphine complexes are 129 and 133 Hz, respectively.

Key words: chemical shift anisotropy, phosphines, chromium, molybdenum, tungsten.

Résumé : Faisant appel à la spectroscopie RMN «CP-MAS» à l'état solide du ^{31}P, on a mesuré les composantes du tenseur du déplacement chimique du ^{31}P et les anisotropies des complexes triméthyl- et triphénylphosphines de pentacarbonyles de métaux du groupe 6, $M(CO)_5PR_3$ (M = Cr, Mo, W et R = Me, Ph). Pour les dérivés de la triméthylphosphine, les tenseurs du déplacement chimique présentent une symétrie pratiquement axiale et les composantes du tenseur du déplacement sont en bon accord avec les valeurs calculées pour les complexes du chrome et du molybdène. Pour les dérivés de la triphénylphosphine, les tenseurs sont asymétriques à cause des différents angles de torsion des noyaux phényles. La tendance vers des blindages plus importants des déplacements chimiques isotropes du ^{31}P lorsqu'on descend dans le groupe 6 provient de changements dans les composantes perpendiculaires du tenseur du déplacement. Les constantes de couplage à travers une liaison, $^1J(^{95/97}Mo–^{31}P)$, des complexes triméthyl- et triphénylphosphines sont respectivement 129 et 133 Hz.

Mots clés : anisotropie du déplacement chimique, phosphines, chrome, molybdène, tungstène.
